SCALING MATRICES TO PRESCRIBED ROW AND COLUMN MAXIMA*

URIEL G. ROTHBLUM†, HANS SCHNEIDER‡, AND MICHAEL H. SCHNEIDER§

Abstract. A nonnegative symmetric matrix B has row maxima prescribed by a given vector r, if for each index i, the maximum entry in the ith row of B equals r_i. This paper presents necessary and sufficient conditions so that for a given nonnegative symmetric matrix A and positive vector r there exists a positive diagonal matrix D such that $B = DAD$ has row maxima prescribed by r. Further, an algorithm is described that either finds such a matrix D or shows that no such matrix exists. The algorithm requires $O(n \lg n + p)$ comparisons, $O(p)$ multiplications and divisions, and $O(q)$ square root calculations where n is the order of the matrix, p is the number of its nonzero elements, and q is the number of its nonzero diagonal elements. The solvability conditions are compared and contrasted with known solvability conditions for the analogous problem with respect to row sums. The results are applied to solve the problem of determining for a given nonnegative rectangular matrix A positive, diagonal matrices D and E such that DAE has prescribed row and column maxima. The paper presents an equivalent graph formulation of the problem. The results are compared to analogous results for scaling a nonnegative matrix to have prescribed row and column sums and are extended to the problem of determining a matrix whose rows have prescribed l_p norms.

Key words. symmetric matrices, potential, directed graph, weighted graph, scalings, row-maxima

1. Introduction. A matrix B is called a *symmetric scaling* of a nonnegative square matrix A if $B = DAD$ for some positive diagonal matrix D. A matrix B is called an *equivalence scaling* of a nonnegative rectangular matrix A if $B = DAE$ for some positive diagonal matrices D and E. In this paper we give necessary and sufficient conditions that a given symmetric nonnegative matrix A has a symmetric scaling with prescribed row maxima. In particular, we show that for a given pattern (i.e., locations of strictly positive entries) if the class of symmetric nonnegative matrices with that pattern and having the prescribed row maxima is nonempty, then every nonnegative matrix with that pattern can be symmetrically scaled into the class. Thus, our conditions relate the prescribed row maxima to the pattern of the matrix A.

Further, we describe an algorithm that for a given matrix A either determines a symmetric scaling B with prescribed row maxima or shows that no such scaling exists. Using our results for symmetric scalings, we also establish corresponding results for the problem of determining an equivalence scaling of a rectangular nonnegative matrix with prescribed row and column maxima. Our results have natural interpretations in terms of weighted undirected graphs.

We call the problem of finding for a given square nonnegative matrix a symmetric scaling with prescribed row maxima *max symmetric scaling* and the problem of finding for a given rectangular nonnegative matrix an equivalence scaling with prescribed row

and column maxima *max equivalence scaling*. These problems are analogues of corresponding well-studied scaling problems in which row and column sums are prescribed. We refer to the sum versions of these problems as *sum symmetric scaling* and *sum equivalence scaling*. The problem of sum equivalence scaling was described in the engineering literature by Kruithof [10] and was considered by Sinkhorn [17], Brualdi [5], Sinkhorn and Knopp [18], Bregman [1], Menon [12], Menon and Schneider [13], Schneider and Zenios [16], and many other authors. The sum symmetric problem was considered by Brualdi [3], [4] and Marshall and Olkin [11].

One important application of sum equivalence scaling concerns the updating of (dynamic) data that is given in matrix form, e.g., traffic intensity between sources and destinations. When new data is not fully observable, but new marginals consisting of corresponding row sums and column sums are observable, a common technique is to replace the old data given by a matrix A by a scaling DAE whose row sums and column sums equal the observed marginals. Max equivalence scaling arises naturally when observations about the new data concern row and column maxima.

We describe our notation in § 2 and list some solvability results for sum symmetric and sum equivalence scalings in § 3. We consider these problems both for a given pattern and for all subpatterns of a given pattern, and we add some new results in the latter case. In § 4 we give nine equivalent conditions for the existence of a solution of the max symmetric scaling. In § 5 we present an algorithm that, for a given nonnegative matrix A, either symmetrically scales A to have prescribed row maxima or determines that no such scaling can exist. In § 6, we apply the results of § 4 to study max equivalence scaling, and in § 7 we restate our results in terms of weighted undirected graphs. Finally, in § 8 we unify max symmetric scaling and sum symmetric scaling by considering scaling problems in which the l_p norms of the rows of the matrix are prescribed.

2. Notation and definitions. For a positive integer n, we use the notation $\langle n \rangle$ to denote the set of integers $\{1, 2, \ldots, n\}$. For a subset $I \subseteq \langle n \rangle$, we use I^c to denote the set $\langle n \rangle \backslash I$, the *complement of I with respet to* $\langle n \rangle$. The identity of n will always be clear from the context. The cardinality of a finite set S is denoted $|S|$. Also, we use the symbols $\subset$ and $\subseteq$ to denote strict and weak containment, respectively.

Let A be an $m \times n$ nonnegative matrix and let I and J be nonempty subsets of $\langle m \rangle$ and $\langle n \rangle$, respectively. We use the notation A_{IJ} to denote the $|I| \times |J|$ submatrix of A corresponding to the rows and columns of A, indexed by I and J, respectively. We identify an index i and the set $\{i\}$. For example, when $I = \{i\}$, we write A_{iJ} for A_{IJ}. By convention, we write $A_{IJ} = 0$ if either I or J equals the empty set.

For a vector $r = (r_1, \ldots, r_n)^T \in \Re^n$ and subset $I \subseteq \langle n \rangle$, we use the notation r_I to denote the subvector of r whose entries are r_i for $i \in I$, and we use $r(I)$ to denote the element sum of r_I. We follow the standard convention that the summation over the empty set is defined to be 0. Also, the value of $\max_{i \in I} r_i$ in the case of $I = \varnothing$ depends on the underlying group to which the elements r_i belong. Specifically, if we are considering the entries of r as entries of the multiplicative group of nonnegative real numbers, then the maximization over the empty set is defined to be 0, whereas if the entries are viewed as elements of the additive group of real numbers, then the maximization over the empty set is defined to be $-\infty$. The additive case arises in § 7 when we consider graph versions of our results. Also, for $\alpha > 0$, we define the operation $\frac{\alpha}{0} = +\infty$. This operation will occur only in minimization expressions over sets containing an element of finite value.

The $n \times n$ diagonal matrix whose diagonal entries are $d_1, d_2, \ldots, d_n$ is denoted $\operatorname{diag}(d_1, d_2, \ldots, d_n)$. A diagonal matrix $D = \operatorname{diag}(d_1, d_2, \ldots, d_n)$ is called *positive* if $d_i > 0$ for $i \in \langle n \rangle$. For an $n \times n$ nonnegative symmetric matrix A, a matrix B is called

a *symmetric scaling of* A if $B = DAD$ for some positive diagonal matrix D. For an $m \times n$ nonnegative matrix A, a matrix B is called an *equivalence scaling of* A if $B = DAE$ for some positive diagonal matrices D and E.

An $m \times n$ matrix $P = [p_{ij}]$ is called a *pattern* matrix if every entry of P is either 0 or 1. Given two $m \times n$ pattern matrices P and P', the matrix P' is a *subpattern* of P if $P' \leqq P$. Given a $m \times n$ nonnegative matrix $A = [a_{ij}]$, the *pattern of* A is the $m \times n$ pattern matrix P such that for $i \in \langle m \rangle$ and $j \in \langle n \rangle$

$$p_{ij} = \begin{cases} 1 & \text{if } a_{ij} > 0, \quad \text{and} \\ 0 & \text{otherwise.} \end{cases}$$

For an $m \times n$ pattern matrix P, we define the *pattern class of* P, written $\Pi(P)$, to be the set of all $m \times n$ nonnegative matrices whose pattern is P.

3. Existence conditions for sum scaling. We summarize numerous characterizations for the solvability of sum symmetric scaling and sum equivalence scaling.

We call a matrix, or a vector, *positive* if all of its elements are positive. For a positive vector $r = (r_i, \ldots, r_n)^T \in \mathfrak{R}^n$, let $S(r)$ denote the set of all $n \times n$ nonnegative matrices $A = [a_{ij}]$ such that

$$\sum_{j=1}^{n} a_{ij} = r_i \quad \text{for } i \in \langle n \rangle. \tag{1}$$

Conditions (i), (ii), (iii), and (vi) of the following theorem are contained in Brualdi [3], [4]. Conditions (iv) and (v) are, apparently, new.

THEOREM 1. *Let P be an $n \times n$ symmetric pattern matrix, and let $r \in \mathfrak{R}^n$ be strictly positive. Then the following are equivalent*:

(i) *Each symmetric $A \in \Pi(P)$ has a symmetric scaling B in $S(r)$.*

(ii) *Some symmetric $A \in \Pi(P)$ has a symmetric scaling B in $S(r)$.*

(iii) *The set $\Pi(P) \cap S(r)$ is nonempty.*

(iv) *If I and J are subsets of $\langle n \rangle$ such that $P_{IJ} = 0$, then $r(I) \leqq r(J^c)$ with equality holding if and only if $P_{I^cJ^c} = 0$.*

(v) *If I and J are subsets of $\langle n \rangle$ such that $P_{IJ} = 0$, then $r(I \cap J) \leqq r((I \cup J)^c)$ with equality holding if and only if $P_{(I \cap J)^c,(I \cup J)^c} = 0$.*

(vi) *If $\{K, L, M\}$ is any partition of $\langle n \rangle$ such that $P_{K,K \cup L} = 0$, then $r(K) \leqq r(M)$ with equality holding if and only if $P_{L \cup M,M} = 0$.*

Proof. The equivalence of (i), (ii), (iii), and (vi) is given in Brualdi [3], [4]. The implication (iii) $\Rightarrow$ (iv) is found in [13], and the equivalence of (iv) and (v) follows from the observations that $r(I) = r(I \cap J) + r(I \backslash J)$ and $r(J^c) = r((I \cup J)^c) + r(I \backslash J)$. Finally, to see that (v) $\Rightarrow$ (vi), consider a partition $\{K, L, M\}$ of $\langle n \rangle$ such that $P_{K,K \cup L} = 0$. Then apply (v) to the sets K and $K \cup L$. □

For positive vectors $r = (r_1, \ldots, r_m)^T \in \mathfrak{R}^m$ and $c = (c_1, \ldots, c_n)^T \in \mathfrak{R}^n$, let $S(r, c)$ be the set of all $m \times n$ nonnegative matrices $A = [a_{ij}]$ such that

$$\sum_{j=1}^{n} a_{ij} = r_i \quad \text{for } i \in \langle m \rangle \quad \text{and} \quad \sum_{i=1}^{m} a_{ij} = c_i \quad \text{for } j \in \langle n \rangle. \tag{2}$$

The following theorem summarizes results of Menon [12], Brualdi [2], and Menon and Schneider [13].

THEOREM 2. *Let P be an $m \times n$ pattern matrix, and let $r \in \mathfrak{R}^n$ and $c \in \mathfrak{R}^m$ be strictly positive. Then the following are equivalent*:

(i) *Each matrix $A \in \Pi(P)$ has an equivalence scaling B in $S(r, c)$.*

(ii) *Some matrix $A \in \Pi(P)$ has an equivalence scaling B in $S(r, c)$.*

(iii) *The set* $\Pi(P) \cap S(r, c)$ *is nonempty.*

(iv) *If* I *and* J *are subsets of* $\langle m \rangle$ *and* $\langle n \rangle$, *respectively, such that* $P_{IJ} = 0$, *then* $r(I) \leqq c(J^c)$ *with equality holding if and only if* $P_{I^c,J^c} = 0$.

The following two theorems characterize solvability of sum equivalence scaling and sum symmetric scaling for subpatterns of a given pattern matrix P, respectively.

THEOREM 3. *Let* P *be an* $m \times n$ *pattern matrix, and let* $r \in \mathfrak{R}^m$ *and* $c \in \mathfrak{R}^n$ *be strictly positive. Then the following are equivalent*:

(i) *For some subpattern* P' *of* P, *each* $A \in \Pi(P')$ *has an equivalence scaling in* $S(r, c)$.

(ii) *For some subpattern* P' *of* P, *some matrix* $A \in \Pi(P')$ *has an equivalence scaling in* $S(r, c)$.

(iii) *For some subpattern* P' *of* P, *the set* $\Pi(P') \cap S(r, c)$ *is nonempty.*

(iv) *If* I *and* J *are subsets of* $\langle m \rangle$ *and* $\langle n \rangle$, *respectively, such that* $P_{IJ} = 0$, *then* $r(I) \leqq c(J^c)$.

Proof. The equivalence of (i), (ii), and (iii) is immediate from Theorem 2 applied to a corresponding subpattern P' of P. A proof of the equivalence of (iii) and (iv) of Theorem 3, which is simpler than the one given in [14], can be found in [15]. □

THEOREM 4. *Let* P *be an* $n \times n$ *symmetric pattern matrix, and let* $r \in \mathfrak{R}^n$ *be strictly positive. Then the following are equivalent*:

(i) *For some symmetric subpattern* P' *of* P, *each symmetric* $A \in \Pi(P')$ *has a symmetric scaling in* $S(r, c)$.

(ii) *For some symmetric subpattern* P' *of* P, *some symmetric* $A \in \Pi(P')$ *has a symmetric scaling in* $S(r, c)$.

(iii) *For some symmetric subpattern* P' *of* P, *the set* $\Pi(P') \cap S(r)$ *is nonempty.*

(iv) *If* I *and* J *are subsets of* $\langle n \rangle$ *such that* $P_{IJ} = 0$, *then* $r(I) \leqq r(J^c)$.

(v) *If* I *and* J *are subsets of* $\langle n \rangle$ *such that* $P_{IJ} = 0$, *then* $r(I \cap J) \leqq r((I \cup J)^c)$.

(vi) *If* $\{K, L, M\}$ *is any partition of* $\langle n \rangle$ *such that* $P_{K,K\cup L} = 0$, *then* $r(K) \leqq r(M)$.

Proof. The equivalence of (i), (ii), and (iii) follows directly from Theorem 1, applied to a corresponding subpattern P' of P.

(iii) $\Rightarrow$ (iv): If (iii) is satisfied for subpattern P' of P and I, $J \subseteq \langle n \rangle$ with $P_{IJ} = 0$, then $P'_{IJ} = 0$, and it follows from the implication (iii) $\Rightarrow$ (iv) of Theorem 1 that $r(I) \leqq r(J^c)$, and therefore (iv) holds.

(iv) $\Leftrightarrow$ (v) $\Rightarrow$ (vi): These implications follow from the arguments used to show the analogous implications of Theorem 1.

(vi) $\Rightarrow$ (v): Assume that (vi) holds and that I, $J \subseteq \langle n \rangle$ with $P_{IJ} = 0$. Then $P_{I\cap J,J} = 0$, and by the symmetry of P we have $P_{I\cap J,I\setminus J} = [P_{I\setminus J,I\cap J}]^T = 0$; therefore, $P_{I\cap J,I\cup J} = 0$. Applying condition (vi) to the partition $\{K, L, M\}$ with $K = I \cap J$, $L = (I\setminus J) \cup (J\setminus I)$, and $M = (I \cup J)^c$, it follows that $r(I \cap J) = r(K) \leqq r(M) = r((I \cup J)^c)$.

(iv) $\Rightarrow$ (iii): We prove this implication using a modification of the technique used in the proof of Theorem 3.7 in [4]. Suppose that (iv) holds. It follows from the implication (iv) $\Rightarrow$ (iii) of Theorem 3 with $m = n$ and $c = r$ that for some subpattern Q (which need not be symmetric) of P there exists a matrix $C \in \Pi(Q)$ satisfying (2) with $c = r$. Then $B = \frac{1}{2}(C + C^T)$ satisfies (1) and $B \in \Pi(P')$, where $P' = \frac{1}{2}(Q' + Q^T)$ is a symmetric subpattern of P.

We observe that it suffices to prove that for some subpattern P' (which need not be symmetric) of P there exists a matrix $B \in \Pi(P')$ satisfying (2) with $c = r$ (and, consequently, $m = n$). This follows because if B is such a matrix, then $B' = \frac{1}{2}(B + B^T)$ satisfies (1) and $B' \in \Pi(Q)$, where $Q = \frac{1}{2}(P' + (P')^T)$ is a symmetric subpattern of P. Therefore, the implication follows from the implication (iv) $\Rightarrow$ (iii) of Theorem 3. □

4. Problem statement and existence conditions. We present our main result giving eight equivalent conditions characterizing the existence of a solution for max symmetric scaling.

For a positive vector $r = (r_1, \ldots, r_n)^T \in \Re^n$, let $M(r)$ denote the set of all $n \times n$ nonnegative matrices $A = [a_{ij}]$ such that

$$\max_{j \in \langle n \rangle} a_{ij} = r_i \quad \text{for } i \in \langle n \rangle. \tag{3}$$

Also for a vector $r \in \Re^n$ and scalar $\alpha \in \Re$, let the *α-level set of r*, denoted lev (r, α), be the set $\{i \in \langle n \rangle : r_i \geqq \alpha\}$. Finally, if we have that A is an $n \times n$ symmetric matrix and $I = \text{lev}\,(r, \alpha) \neq \phi$, we call A_{II} an *r-upper principal submatrix* of A.

THEOREM 5. *Let P be an $n \times n$ symmetric pattern matrix, and let $r \in \Re^n$ be strictly positive. Then the following are equivalent*:

(i) *Each symmetric $A \in \Pi(P)$ has a symmetric scaling in $M(r)$.*

(ii) *Some symmetric $A \in \Pi(P)$ has a symmetric scaling in $M(r)$.*

(iii) *The set $\Pi(P) \cap M(r)$ is nonempty.*

(iv) *The set $\Pi(P') \cap M(r)$ is nonempty for some pattern matrix P' satisfying $P' \leqq P$.*

(v) *If $P_{IJ} = 0$ for subsets $I, J \subseteq \langle n \rangle$, then*

$$\max_{i \in I} r_i \leqq \max_{j \in J^c} r_j. \tag{4}$$

(vi) *If $P_{IJ} = 0$ for subsets $I, J \subseteq \langle n \rangle$, then*

$$\max_{i \in I \cap J} r_i \leqq \max_{j \in (I \cup J)^c} r_j. \tag{5}$$

(vii) *If $\{K, L, M\}$ is any partition of $\langle n \rangle$ such that $P_{K,K \cup L} = 0$, then*

$$\max_{i \in K} r_i \leqq \max_{i \in M} r_i. \tag{6}$$

(viii) *If $P_{iJ} = 0$ for $J \subseteq \langle n \rangle$ and $i \in J$, then*

$$r_i \leqq \max_{j \in J^c} r_j. \tag{7}$$

(ix) *No upper r-principal submatrix of P has a zero row.*

Proof. The implication (i) $\Rightarrow$ (ii) is trivial because $\Pi(P)$ is nonempty ($P \in \Pi(P)$), and the implication (ii) $\Rightarrow$ (iii) is straightforward because $DAD \in \Pi(P)$ whenever $A \in \Pi(P)$ and D is a positive diagonal matrix. Also, the implication (iii) $\Rightarrow$ (iv) is trivial.

(iv) $\Rightarrow$ (v): Let $A \in \Pi(P') \cap M(r)$ for some pattern matrix $P' \leqq P$, and let I and J be nonempty subsets of $\langle n \rangle$ such that $P_{IJ} = 0$, and therefore $P'_{IJ} = A_{IJ} = 0$. Because r_i is the maximum of the entries in the ith row and A is symmetric, it follows directly that

$$\max_{i \in I} r_i = \max_{i \in I} \max_{j \in \langle n \rangle} a_{ij} = \max_{i \in I} \max_{j \in J^c} a_{ij} = \max_{j \in J^c} \max_{i \in I} a_{ij} \leqq \max_{j \in J^c} r_j.$$

(v) $\Rightarrow$ (vi): Let I and J satisfy the assumptions of condition (vi). Then $P_{I \cap J, I \cup J} = 0$ (see the proof of (vi) $\Rightarrow$ (v) in Theorem 4) and (5) follows by applying (4) to the sets $I \cap J$ and $I \cup J$.

(vi) $\Rightarrow$ (vii): If K, L, and M satisfy the assumptions of condition (vii), (6) follows by applying (5) to the sets $I = K$ and $J = K \cup L$ and observing that $K \cap (K \cup L) = K$ and $[K \cup (K \cup L)]^c = M$.

(vii) $\Rightarrow$ (viii): If i and J satisfy the assumption of condition (vii), then $\{\{i\}, J \backslash \{i\}, J^c\}$ is a partition of $\langle n \rangle$ satisfying the assumptions of condition (viii), and (7) follows by applying (6).

(viii) $\Rightarrow$ (ix): Suppose that for some $\alpha \in \Re$ and $J = \{j \in \langle n \rangle \mid r_j \geqq \alpha\} \neq \varnothing$, the ith row of the upper principal submatrix P_{JJ} is zero. Then, $i \in J \subseteq \langle n \rangle$, $P_{iJ} = 0$, and $r_i \geqq \alpha > r_j$ for $j \in J^c$. This violates condition (viii) for the partition $\{\{i\}, J \setminus \{i\}, J^c\}$ and therefore proves the implication.

(ix) $\Rightarrow$ (i): We prove this implication constructively in § 5 by exhibiting an algorithm that for a given nonnegative symmetric matrix A and positive vector r either finds a symmetric scaling of A in $M(r)$ or finds an upper principal submatrix of A containing a zero row. □

The following observations compare max symmetric scaling and sum symmetric scaling. First, note that feasibility conditions (iii) and (iv) in Theorem 5 are equivalent. By contrast, there is no such equivalence for sum symmetric scaling, and the assertion that for some subpattern P' of P there is a matrix A in $\Pi(P')$ satisfying (1) is not equivalent to condition (iii) of Theorem 1. In fact Rothblum and Schneider [14] provide separate characterizations of each of these two conditions. As a result of the equivalence of conditions (iii) and (iv) of Theorem 5, conditions (v), (vi), and (vii) of Theorem 5 are simpler than the analogous conditions (iv), (v), and (vi) of Theorem 1. For example, for the nonequivalence for sum scaling consider

$$P = \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix} \quad \text{and} \quad r = \begin{pmatrix} 1 \\ 1 \end{pmatrix}.$$

Then $P \in M(r)$, but there is no symmetric scaling of P whose rows sums are $(1, 1)^T$.

Second, as a consequence of properties of the max operation, the *set* conditions (v), (vi), and (vii) of Theorem 5 are equivalent to the simple *point* conditions (vii) and (viii). No analogous simplification is possible for sum symmetric scaling.

Third, a solution for sum symmetric scaling is unique, whereas a solution for max symmetric scaling need not be unique. For example, let

$$A = \begin{pmatrix} 1 & 2 \\ 2 & 1 \end{pmatrix} \quad \text{and} \quad r = \begin{pmatrix} 1 \\ 1 \end{pmatrix}.$$

Then the general symmetric scaling of A that is in $M(r)$ is given by

$$B = \begin{pmatrix} \alpha & 0 \\ 0 & (2\alpha)^{-1} \end{pmatrix} A \begin{pmatrix} \alpha & 0 \\ 0 & (2\alpha)^{-1} \end{pmatrix} = \begin{pmatrix} \alpha^2 & 1 \\ 1 & (4\alpha^2)^{-1} \end{pmatrix},$$

where $\frac{1}{2} \leqq \alpha \leqq 1$.

5. The algorithm. We describe an algorithm for max symmetric scaling. For a given nonnegative symmetric matrix A and strictly positive vector r, our algorithm either finds a symmetric scaling of A in $M(r)$ or certifies that no such scaling exists by showing that condition (ix) of Theorem 5 is violated.

THE MAX SYMMETRIC SCALING ALGORITHM

Input: An $n \times n$ nonnegative symmetric matrix A and a strictly positive vector $r \in \Re^n$.

Output: Either a positive diagonal matrix D such that $DAD \in M(r)$ or a subset $J \subseteq \langle n \rangle$ and an index $i \in J$ such that A_{JJ} is an r-upper principal submatrix of A with zero row A_{iJ}.

Step 0 (Initialization): Let α_i for $i \in \langle m \rangle$ be the distinct values in the vector r listed in decreasing order. That is,

$$\{\alpha_i \mid i \in \langle m \rangle\} = \{r_i \mid i \in \langle n \rangle\} \quad \text{and} \quad \alpha_1 > \alpha_2 > \cdots > \alpha_m.$$

Set $k = 1$, $J = \varnothing$, and $d_i = 1$ for $i = 1, 2, \ldots, n$.

Step 1 (Push down): Set

$$I = \{i \in \langle n \rangle \mid r_i = \alpha_k\} \quad \text{and} \quad J = \{i \in \langle n \rangle \mid r_i \geqq \alpha_k\}. \tag{8}$$

If $A_{iJ} = 0$ for some $i \in I$, output (J, i) and STOP; otherwise, set the values d_i for $i \in I$ so that $d_i \leqq 1$ and

$$d_i a_{ij} d_j \leqq \alpha_k \quad \text{for } i \in I \quad \text{and} \quad j \in J. \tag{9}$$

Step 2 (Pull up): Select any $i \in I$ and set $I = I \backslash i$. Set

$$d_i = \min \left\{ \min_{\substack{j \in J \\ j \neq i}} \left\{ \frac{\alpha_k}{a_{ij} d_j} \right\}, \sqrt{\frac{\alpha_k}{a_{ii}}} \right\}. \tag{10}$$

If $I \neq \varnothing$, repeat Step 2.

Step 3 (Termination): If $k < m$, replace k by $k + 1$ and return to Step 1; if $k = m$, then output $D = \operatorname{diag}(d_1, d_2, \ldots, d_n)$ and STOP.

We observe that whenever the algorithm does not stop in Step 1, then A_{IJ} has no zero row and we can achieve (9) by setting

$$d_i = \min \left\{ \min_{j \in J} \left\{ \frac{\alpha_k}{a_{ij}} \right\}, 1 \right\} \quad \text{for } i \in I. \tag{11}$$

The following lemma is crucial for our analysis.

LEMMA 6. *During the Max Symmetric Scaling Algorithm, after each execution of Step* 2, *we have*

$$d_i a_{ij} d_j \leqq r_i \quad \textit{for } i, j \in J \tag{12}$$

and

$$\max_{j \in J} d_i a_{ij} d_j = r_i \quad \textit{for } i \in J \backslash I. \tag{13}$$

Furthermore, the d's are nondecreasing throughout consecutive executions of Step 2.

Proof. We first show that the d's are nondecreasing and that if (12) and (13) hold at the beginning of an execution of Step 2, then they also hold at the end of that execution. Let s be the element selected out of I for the execution of Step 2, let d' and I' be, respectively, the values of d and I at the beginning of the execution of the current Step 2, and let d'' and I'' be the values of d and I at the end of that execution. Thus, we are assuming that (12) and (13) hold for $d = d'$ and $I = I'$. Now the selection of s and the definition of d''_s ensure that

$$\max_{j \in J} d''_s a_{sj} d''_j = \alpha_k = r_s. \tag{14}$$

As $d''_j = d'_j$ for $j \in J \setminus \{s\}$ and as the specialization of (12) with $d = d'$ to $i = s$ ensures that we have

$$d'_s a_{sj} d'_j \leqq r_s \quad \text{for all } j \in J,$$

we conclude that $d''_s \geqq d'_s$. As the remaining coordinates of d are unchanged, it follows that $d'' \geqq d'$.

We next establish (12) and (13) with $d = d''$ and $I = I''$. First, if $i \in J \setminus \{s\}$ and $j \in J \setminus \{s\}$, then $d''_i a_{ij} d''_j = d'_i a_{ij} d'_j \leqq r_s$. Also, (14) ensures that $d''_s a_{sj} d''_j \leqq r_s$ for all $j \in J$. Next, for $i \in J$ we have from the symmetry of A, from (14), and from the fact that $r_s =$

$\alpha_k = \min\{r_j \mid j \in J\}$ that

$$d_i'' a_{is} d_s'' = d_s'' a_{si} d_i'' \leqq r_s \leqq r_i,$$

completing the proof that (12) holds for $d = d''$. Further, as it is assumed that (13) holds for $d = d'$ and $I = I'$, as $d'' \geqq d'$, and as we have seen that (12) holds for $d = d''$, we conclude that (13) is also valid with $d = d''$ and $I = I'$. This fact combines with (14) to show that

$$\max_{j \in J} d_i'' a_{ij} d_j'' = r_i \quad \text{for } i \in J \backslash I'' = (J \backslash I') \cup \{s\}. \tag{15}$$

That is, (13) holds for $d = d''$ and $I = I''$.

It remains to show that (12) and (13) hold upon each entrance of Step 2 from Step 1. This fact is obvious for the first entrance of Step 2 from Step 1 because then $J = I$; hence, (12) follows from (9) and (13) is vacuous. Next, assume that (12) and (13) hold for the kth entrance of Step 2 from Step 1 and consider the $(k+1)$st entrance, assuming that Step 1 leads to Step 2 rather than to termination. Our earlier arguments show that (12) and (13) will stay valid throughout consecutive iterations of Step 2; hence, they will hold at the $(k+1)$st entrance into Step 1. Let d', J', and $I' = \varnothing$ be the values of d, J, and I upon the $(k+1)$st entrance into Step 1, and let d'', J'', and I'' be the updated values of d, J, and I after the $(k+1)$st execution of Step 1. In particular, $J'' \backslash I'' = J' \backslash I' = J'$, and (12) and (13) hold for $d = d'$, $I = I'$, and $J = J'$. Further, as $d_j'' = d_j'$ for $j \in J'' \backslash I'' = J'$, we have from the validity of (13) for $d = d'$, $J = J'$, and $I = I'$ that for $i \in J'' \backslash I'' = J' \backslash I'$

$$\begin{aligned} \max_{j \in J''} d_i'' a_{ij} d_j'' &= \max\left\{\max_{j \in J'} d_i' a_{ij} d_j', \max_{j \in I''} d_i'' a_{ij} d_j''\right\} \\ &= \max\left\{r_i, \max_{j \in I''} d_i'' a_{ij} d_j''\right\}. \end{aligned} \tag{16}$$

Now, for $j \in I''$, $r_j = \alpha_{k+1} = \min\{r_j \mid j \in J''\}$; hence, the symmetry of A and (9) with $d = d''$, $J = J''$, and $I = I''$ imply that for $j \in I'$

$$d_i'' a_{ij} d_j'' = d_j'' a_{ji} d_i'' \leqq \alpha_{k+1} \leqq \alpha_k = r_i. \tag{17}$$

Combining (16) and (17) we conclude that

$$\max_{j \in J''} d_i'' a_{ij} d_j'' = r_i \quad \text{for all } i \in J'' \backslash I''.$$

That is, (13) holds for $d = d''$, $J = J''$, and $I = I''$. This fact and (9) ensure that (12) holds as well. Thus, both (12) and (13) hold at the end of $(k+1)$st execution of Step 1 and therefore at the entrance to Step 2. □

THEOREM 7. *If the Max Symmetric Scaling Algorithm is executed with input $A \in \mathfrak{R}^{n \times n}$ and $r \in \mathfrak{R}^n$, then either the algorithm terminates in Step 3 with a positive diagonal matrix D such that $DAD \in \Pi(r)$ or the algorithm terminates in Step 1 with $J \subseteq \langle n \rangle$ and $i \in J$ such that A_{JJ} is an r-upper principal submatrix of A with $A_{iJ} = 0$. The algorithm requires $O(n \ln n + p)$ comparisons, $O(p)$ multiplications and divisions, and $O(q)$ square root calculations, where p and q are, respectively, the number of nonzero elements and the number of nonzero diagonal elements of the matrix A.*

Proof. The algorithm must terminate as Step 1 is executed at most m times, and each execution of Step 2 reduces $|I|$. If the algorithm terminates in Step 1, then A_{iJ} is a zero row of the r-upper principal submatrix A_{JJ}. It follows from Lemma 6 that each time Step 3 is executed, we have $(DAD)_{JJ} \in \Pi(r_J)$ because $I = \varnothing$ when Step 3 is exe-

cuted. Therefore, if the algorithm terminates in Step 3, then $J = \langle n \rangle$ and $(DAD)_{JJ} = DAD \in \Pi(r)$.

We finally determine the complexity of the algorithm. With $O(n \ln n)$ comparisons, we can sort the values $\{ r_i \mid i \in \langle n \rangle \}$ as required in Step 0. In total, Step 1 can be performed with p comparisons and p divisions, and Step 2 can be performed with $p - n$ comparisons, $p - q$ multiplications, p divisions, and q square root calculations. □

The following example shows that the square root calculations cannot, in general, be eliminated. Let

$$A = [1] \in \Re^{1 \times 1} \quad \text{and} \quad r = (2) \in \Re^1.$$

Then the only scaling DAD of A that is in $\Pi(r)$ has $D = \sqrt{2}$. If the diagonal elements of A are all zero, then because the square-root operation in (9) can be omitted, the algorithm can be executed over any linearly ordered group (multiplicative) Abelian group with zero, that is, a group G together with an element 0 such that $a0 = 0 = 0a$ for any $a \in G$. In particular, if the underlying matrix is nonnegative, then the output elements will be in any subgroup that contains the input elements. The above example shows that this conclusion need not hold when A has nonzero diagonal elements.

We note that a diagonal element a_{ii} is considered twice in the course of an execution of the algorithm. If $r_i = \alpha_k$, we have $a_{ii} \to a_{ii} d_i^2$ in the kth execution of Step 1, and then in one of the following executions of Step 2, $\sqrt{\alpha_k / a_{ii}} = \sqrt{r_i / a_{ii}}$ is determined and is compared with other numbers to update d_i. Thus, the square rooting can be avoided if each original a_{ii} is the product of r_i and the square of a known number. Consequently, the square rooting can be avoided in the "decision problem" where one determines whether or not there exists a scaling corresponding to a given vector r and matrices in a given pattern P. This is achieved by testing any matrix A in $\Pi(P)$ with $a_{ii} = r_i$ for all i with $P_{ii} \neq 0$.

6. Equivalence scaling. We apply our results for max symmetric scaling to max equivalence scaling.

For strictly positive $r = (r_1, \ldots, r_m)^T \in \Re^m$ and $c = (c_1, \ldots, c_n)^T \in \Re^n$, let $M(r, c)$ denote the set of all $m \times n$ nonnegative matrices $A = [a_{ij}]$ such that

$$\max_{j \in \langle n \rangle} a_{ij} = r_i \quad \text{for } i \in \langle m \rangle \quad \text{and} \quad \max_{i \in \langle m \rangle} a_{ij} = c_j \quad \text{for } j \in \langle n \rangle. \tag{18}$$

In the following theorem we characterize the existence of a solution for the max equivalence scaling by reducing it to max symmetric scaling.

THEOREM 8. *Let P be an $m \times n$ pattern matrix, and let $r \in \Re^m$ and $c \in \Re^n$ be strictly positive. Then the following are equivalent*:

(i) *Some $A \in \Pi(P)$ has an equivalence scaling in $M(r, c)$.*
(ii) *Each $A \in \Pi(P)$ has an equivalence scaling in $M(r, c)$.*
(iii) *The set $\Pi(P) \cap M(r, c)$ is nonempty.*
(iv) *The set $\Pi(P') \cap M(r, c)$ is nonempty for some pattern matrix $P' \leqq P$.*
(v) *The vectors r and c satisfy*

$$\max_{i \in \langle m \rangle} r_i = \max_{j \in \langle n \rangle} c_j; \tag{19}$$

furthermore, if $P_{IJ} = 0$ for subsets $I \subseteq \langle m \rangle$ and $J \subseteq \langle n \rangle$, then

$$\max_{i \in I} r_i \leqq \max_{j \in J^c} c_j \quad \textit{and} \quad \max_{j \in J} c_j \leqq \max_{i \in I^c} r_i. \tag{20}$$

(vi) *The following conditions hold*:

(a) *The vectors r and c satisfy* (19).

(b) *If* $P_{iJ} = 0$ *for* $i \in \langle m \rangle$ *and* $J \subseteq \langle n \rangle$, *then*

$$r_i \leqq \max_{j \in J^c} c_j.$$

(c) *If* $P_{Ij} = 0$ *for* $I \subseteq \langle m \rangle$ *and* $j \in \langle n \rangle$, *then*

$$c_j \leqq \max_{i \in I^c} r_i.$$

(vii) *The vectors r and c satisfy* (19), *and for all* $\alpha \in \Re$ *and subsets* $I = \text{lev}(\alpha, r) \subseteq \langle m \rangle$ *and* $J = \text{lev}(\alpha, c) \subseteq \langle n \rangle$, *if* $I, J \neq \varnothing$, *then the submatrix* P_{IJ} *contains neither a zero row nor a zero column.*

Proof. The implications (i) $\Rightarrow$ (ii) $\Rightarrow$ (iii) $\Rightarrow$ (iv) follow from the arguments used to establish the corresponding implications in Theorem 5.

(iv) $\Rightarrow$ (v): Suppose that $A \in \Pi(P') \cap M(r, c)$ for some pattern matrix $P' \leqq P$. Then

$$\max_{i \in \langle m \rangle} r_i = \max_{i \in \langle m \rangle} \max_{j \in \langle n \rangle} a_{ij} = \max_{j \in \langle n \rangle} \max_{i \in \langle m \rangle} a_{ij} = \max_{j \in \langle n \rangle} c_j.$$

Furthermore, if $P_{IJ} = 0$ for some $I \subseteq \langle m \rangle$ and $J \subseteq \langle n \rangle$, then

$$\max_{i \in I} r_i = \max_{i \in I} \max_{j \in J^c} a_{ij} = \max_{j \in J^c} \max_{i \in I} a_{ij} \leqq \max_{j \in J^c} c_j.$$

A symmetric argument proves the second inequality in (20).

(v) $\Rightarrow$ (vi): This implication is trite because parts (b) and (c) of condition (vi) are the specializations of the second part of condition (v) for the cases of $I = i$ and $J = j$, respectively.

(vi) $\Rightarrow$ (vii): Suppose that for some $\alpha \in \Re$, $I = \text{lev}(\alpha, r) \neq \varnothing$ and $J = \text{lev}(\alpha, c) \neq \varnothing$. It follows that

$$r_i \geqq \alpha > \max_{j \in J^c} c_j \quad \text{for } i \in I$$

and

$$c_j \geqq \alpha > \max_{i \in I^c} r_i \quad \text{for } j \in J.$$

Therefore, if P_{IJ} has a zero row or a zero column, we get a violation of parts (b) or (c), respectively, of condition (vi). The implication (vi) $\Rightarrow$ (vii) now follows because the first assertion of (vii) is the same as part a of (vi).

(vii) $\Rightarrow$ (i): For an $m \times n$ nonnegative matrix A, define the $(m + n) \times (m + n)$ matrix A' and the vector $r' \in \Re^{m+n}$ by

$$A' = \left(\begin{array}{c|c} 0 & A \\ \hline A^T & 0 \end{array}\right) \quad \text{and} \quad r' = \begin{pmatrix} r \\ c \end{pmatrix}. \tag{21}$$

It is straightforward to show that max symmetric scaling with input A' and r' has a solution $D' = \text{diag}(d'_1, d'_2, \ldots, d'_{m+n})$ if and only if max equivalence scaling for A, r, and c has a solution $D = \text{diag}(d'_1, d'_2, \ldots, d'_m)$ and $E = \text{diag}(d'_{m+1}, \ldots, d'_{m+n})$. We conclude that condition (i) of Theorem 8 is equivalent to condition (i) of Theorem 5 applied to A' and r'. It is straightforward to show that condition (vii) of Theorem 8 is

equivalent to condition (vii) of Theorem 5 when applied to A' and r'. Therefore, the equivalence of (i) and (vii) follows from Theorem 5. □

We observe that the reduction of max equivalence scaling to max symmetric scaling in the proof of Theorem 8 shows that max equivalence scaling can be solved by the Max Symmetric Scaling Algorithm. Moreover, the diagonal elements of the matrix A' defined in (21) are all zero. Therefore, it follows from the complexity analysis at the end of § 5 that max equivalence scaling can be solved using $O((n+m)\ln(n+m)+p)$ comparisons and $O(p)$ multiplications and divisions, where p is the number of nonzero elements of the matrix A. Further, we observe that max equivalence scaling can be solved over any linearly ordered Abelian group with zero. The example given in § 5 shows that in general max symmetric scaling does not have this property. Also, sum equivalence scaling does not have this property. For example, let

$$A = \begin{pmatrix} 1 & 2 \\ 1 & 1 \end{pmatrix} \quad \text{and} \quad r = c = \begin{pmatrix} 1 \\ 1 \end{pmatrix}.$$

The only equivalence scaling of A with row and column sums all equality 1 is the matrix

$$B = \begin{pmatrix} \sqrt{2}-1 & 2-\sqrt{2} \\ 2-\sqrt{2} & \sqrt{2}-1 \end{pmatrix} = \begin{pmatrix} 1-2^{-1}\sqrt{2} & 0 \\ 0 & \sqrt{2}-1 \end{pmatrix} A \begin{pmatrix} \sqrt{2} & 0 \\ 0 & 1 \end{pmatrix}.$$

We note that when a solution to max equivalence scaling exists, it need not be unique. For example, let

$$A = \begin{pmatrix} 4 & 1 \\ 2 & 4 \end{pmatrix} \quad \text{and} \quad r = c = \begin{pmatrix} 4 \\ 4 \end{pmatrix}.$$

Then the general equivalence scaling B of A that is in $M(r, c)$ is given by

$$B = \begin{pmatrix} 1 & 0 \\ 0 & \alpha \end{pmatrix} A \begin{pmatrix} 1 & 0 \\ 0 & \alpha^{-1} \end{pmatrix} = \begin{pmatrix} 4 & \alpha^{-1} \\ 2\alpha & 4 \end{pmatrix},$$

where $\frac{1}{4} \leqq \alpha \leqq 2$. By contrast, the corresponding equivalence in sum equivalence scaling is unique.

The results about max equivalence scaling were derived from results about max symmetric scaling. Historically, a reverse logic has been applied in the sum case as results about sum equivalence scaling are used to establish results about sum symmetric scaling (see Brualdi [2] and Csima and Datta [7]). The latter arguments use uniqueness (up to multiplicative scalar) of diagonal matrices D and E for which DAE has prescribed row sum vector r and column sum vector c. Hence, if A is symmetric and $r = c$, the fact that DAE and $EA^TD = EAD$ have the same row and column sums can be used to argue that (with proper normalization) $D = E$. But, as we have seen above, no such uniqueness results are available in the max case.

7. Graphs. We observe that max symmetric scaling and the corresponding solvability theorem have an equivalent undirected graph statement. An (*undirected*) graph is an ordered pair $G = (V, E)$, where V is a finite set of *vertices* and E is a set of *edges* composed of unordered pairs of vertices. Given such a graph $G = (V, E)$ and a vertex $v \in V$, we let $N(v)$ denote the set of neighbors of v, i.e., $N(v) \equiv \{u \in V : \{u, v\} \in E\}$. In particular, we say that v is *isolated* if $N(v) = \phi$. Note that by definition a graph may contain *loops* but may not contain repeated edges. For subsets $S, T \subseteq V$, we use $[S, T]$ to denote the set of edges $\{u, v\} \in E$ with $u \in S$ and $v \in T$ or $u \in T$ and $v \in S$.

A *weight function* for a graph $G = (V, E)$ is a real-valued function f defined on the edges E. For convenience, in this case we write f_{uv} for $f(\{u, v\})$. A *weighted graph* is a triple (V, E, f), where (V, E) is a graph and f is a weight function for G. A *potential* for G is a real-valued function defined on the vertices V. For a nonempty subset W of V, we define the *subgraph induced by* W to be the graph (W, E'), where E' contains all edges of E of the form $e = \{u, v\}$ for vertices $u, v \in W$.

Next, we define a mapping Φ from the set of symmetric nonnegative matrices to the set of weighted graphs. For an $n \times n$ symmetric nonnegative matrix $A = [a_{ij}]$, we define the mapping Φ by

$$A \xrightarrow{\Phi} (V, E, f), \tag{22}$$

where

$$V = \langle n \rangle,$$
$$E = \{\{i, j\} \mid a_{ij} > 0\}, \quad \text{and}$$
$$f_{ij} = \ln a_{ij} \quad \text{for } \{i, j\} \in E.$$

It is easy to see that Φ is a bijection between the set of nonnegative symmetric matrices and the set of weighted graphs.

We state the following lemma without proof.

LEMMA 9. *Let A be an $n \times n$ symmetric nonnegative matrix, and let (V, E, f) be the corresponding weighted graph under the mapping Φ in* (22). *Let $r \in \mathfrak{R}^n$ be strictly positive, and let s be the potential defined by $s_i = \ln r_i$ for $i \in \langle n \rangle$. Then the following are equivalent*:

(i) *There exists a positive diagonal matrix $D = \operatorname{diag}(d_1, d_2, \ldots, d_n)$ such that $DAD \in M(r)$.*

(ii) *There exists a potential p such that*

$$\max_{u \in N(v)} \{p_u + f_{uv} + p_v\} = s_v \quad \text{for } v \in V. \tag{23}$$

Furthermore, D and p are related by $p_u = \ln d_u$ for $u \in \langle n \rangle = V$.

The next theorem follows directly from Theorem 5 and the correspondence between matrices and graphs described in Lemma 9.

THEOREM 10. *Let $G = (V, E)$ be a graph, and let s be a potential for G. Then the following are equivalent*:

(i) *For every weight function f for G there exists a potential p satisfying* (23).

(ii) *For some weight function f for G there exists a potential p satisfying* (23).

(iii) *There exists some weight function f for G such that*

$$\max_{u \in N(v)} f_{uv} = s_v \quad \text{for } v \in V. \tag{24}$$

(iv) *There exists $E' \subseteq E$ and some weight function $f: E' \mapsto \mathfrak{R}$ such that*

$$\max_{u \in N'(v)} f_{uv} = s_v \quad \text{for } v \in V,$$

where $N'(v) = \{u \in V: \{u, v\} \in E'\}$.

(v) *If $[S, T] = \varnothing$ for $S, T \subseteq V$, then*

$$\max_{v \in S} s_v \leqq \max_{v \in T^c} s_v.$$

(vi) *If* $[S, T] = \varnothing$ *for* $S, T \subseteq V$, *then*

$$\max_{v \in S \cap T} s_v \leqq \max_{v \in (S \cup T)^c} s_v.$$

(vii) *If* $\{S, T, U\}$ *is any partition of* V *such that* $[S, S \cup T] = \varnothing$, *then*

$$\max_{v \in S} s_v \leqq \max_{v \in U} s_v.$$

(viii) *Let* $W \subseteq V$. *If* $v \in W$ *is an isolated vertex of the subgraph induced by* W, *then*

$$s_v \leqq \max_{u \in W^c} s_u.$$

(ix) *For every* $\alpha \in \Re$, *the subgraph of* G *induced by the level set* lev (s, α) *has no isolated vertex*.

We observe that Theorem 8 also has an equivalent graph formulation in terms of bipartite graphs. We have omitted the details because they are straightforward.

8. pth power scaling. For $0 \leqq p \leqq \infty$ and $x \in \Re^n$, we define the l_p norm of x by $\|x\|_p$. We consider the problem of determining a symmetric scaling of a given nonnegative symmetric matrix such that the rows of the resulting matrix have prescribed l_p norms. Of course, the cases of $p = 1$ and $p = \infty$ reduce to sum and max symmetric scaling, respectively. Here, we show that the cases of $0 < p < \infty$ can be reduced easily to the case of $p = 1$.

For an $m \times n$ nonnegative matrix A and $0 < p < \infty$, the pth *Hadamard power of* A, written $A^{(p)}$, is the matrix whose ijth entry is $(a_{ij})^p$. Let A_i denote the ith row of the matrix A. For a strictly positive vector $r \in \Re^n$ and $0 < p \leqq \infty$, let $S^p(r)$ denote the set of all $n \times n$ nonnegative symmetric matrices B such that $\|B_i\|_p = r_i$ for each $i \in \langle n \rangle$.

It is easily seen that $B \in S^p(r)$ if and only if $B^{(p)} \in S(r^{(p)})$. Moreover, $B = DAD$ if and only if $B^{(p)} = D^{(p)} A^{(p)} D^{(p)}$. Thus, as an immediate consequence of Theorem 1, we obtain the following theorem.

THEOREM 11 (l_p-symmetric scaling). *Let* P *be an* $n \times n$ *symmetric pattern matrix, let* $r \in \Re^n$ *be strictly positive, and let* $p \in \Re$ *with* $0 < p < \infty$. *Then the following are equivalent*:

(i) *Each symmetric* $A \in \Pi(P)$ *has a symmetric scaling* $B \in S^p(r)$.

(ii) *Some symmetric* $A \in \Pi(P)$ *has a symmetric scaling* $B \in S^p(r)$.

(iii) *The set* $\Pi(P) \cap S^p(r)$ *is nonempty*.

(iv) *If* $P_{IJ} = 0$ *for* $I, J \subseteq \langle n \rangle$, *then* $\|r_I\|_p \leqq \|r_{J^c}\|_p$ *with equality holding if and only if* $P_{I^c J^c} = 0$.

Conditions (v) and (vi) of Theorem 1 can also be extended in the obvious way. Further, analogous results can also be derived for the cases of $-\infty \leqq p < 0$.

A COMPLETED THEORY OF THE UNSYMMETRIC LANCZOS PROCESS AND RELATED ALGORITHMS, PART II*

MARTIN H. GUTKNECHT†

Dedicated to the memory of Heinz Rutishauser (1918–1970).

Abstract. This paper is a continuation of Part I [M. H. Gutknecht, *SIAM J. Matrix Anal. Appl.*, 13 (1992), pp. 594–639], where the theory of the "unsymmetric" Lanczos biorthogonalization (BO) algorithm and the corresponding iterative method BIORES for non-Hermitian linear systems was extended to the nongeneric case. The analogous extension is obtained here for the biconjugate gradient (or BIOMIN) method and for the related BIODIR method. Here, too, the breakdowns of these methods can be cured. As a preparation, mixed recurrence formulas are derived for a pair of sequences of formal orthogonal polynomials belonging to two adjacent diagonals in a nonnormal Padé table, and a matrix interpretation of these recurrences is developed. This matrix interpretation leads directly to a completed formulation of the progressive qd algorithm, valid also in the case of a nonnormal Padé table. Finally, it is shown how the cure for exact breakdown can be extended to near-breakdown in such a way that (in exact arithmetic) the well-conditioned formal orthogonal polynomials and the corresponding Krylov space vectors do not depend on the threshold specifying the near-breakdown.

Introduction. In Part I [13] we derived a number of basic results on sequences of *formal orthogonal polynomials* of the first and second kind (FOP1s and FOP2s, respectively). Given a linear functional $\Phi : \mathcal{P} \to \mathbb{C}$ defined on the space $\mathcal{P}$ of complex polynomials by[1]

$$\Phi_l(z^k) := \phi_{k+l} \quad (k \in \mathbb{N}), \tag{1.1}$$

there is a finite or infinite sequence $\{n_j\}_{j=0}^{J}$ ($J \leq \infty$) of indices with $0 =: n_0 < n_1 < n_2 < \cdots (< n_J \text{ if } J < \infty)$ for which a *regular* (monic) FOP1 $P_{n_j} := P_{l;n_j}$ exists. By definition, these are those values of the index n for which a unique monic polynomial $P_n := P_{l;n}$ of exact degree n satisfying

$$\Phi_l(pP_n) = 0 \quad (\forall p \in \mathcal{P}_{n-1}) \tag{1.2}$$

exists. These indices are also characterized by the nonsingularity of the $n \times n$ moment matrix

$$\mathbf{M}_n := \mathbf{M}_{l;n} := \begin{bmatrix} \phi_l & \phi_{l+1} & \cdots & \phi_{l+n-1} \\ \phi_{l+1} & \phi_{l+2} & \cdots & \phi_{l+n} \\ \vdots & \vdots & & \vdots \\ \phi_{l+n-1} & \phi_{l+n} & \cdots & \phi_{l+2n-2} \end{bmatrix}. \tag{1.7}$$

[1] Equations copied from Part I are numbered as before. Most of those that are explicitly used in this part are recalled in the introduction. Also note that Part I ended with §4 and that Part II, for the sake of continuity, begins its numbering with §5.

Starting from these regular FOP1s P_{n_j} we have obtained a full sequence $\{P_n\}_{n=0}^{\infty} := \{P_{l;n}\}_{n=0}^{\infty}$ of monic FOP1s by setting

$$P_n(z) := W_{n-n_j}(z)P_{n_j}(z) \quad \text{if } n_j \le n < n_{j+1} =: n_j + h_j. \tag{1.28}$$

Here W_{n-n_j} could be an arbitrary monic polynomial of exact degree $n - n_j$, but in view of actual implementations we have primarily considered the case where W_{n-n_j} is the $n - n_j$ element of a fixed sequence $\{W_m\}$ of monic polynomials satisfying a three-term recurrence

$$W_{m+1}(z) = (z - \alpha_m^W)\ W_m(z) - \beta_m^W\ W_{m-1}(z) \quad (m \in \mathbb{N}) \tag{2.10}$$

(with $W_0(z) :\equiv 1$, $W_{-1}(z) :\equiv 0$, $\beta_0^W := 0$).

The FOP1s P_n of (1.28) satisfy the formal orthogonality conditions

$$\Phi_l(pP_n) = 0 \quad (\forall p \in \mathcal{P}_{\hat{n}-1}), \quad \Phi_l(z^{\hat{n}}P_n) \ne 0, \quad \text{where } \hat{n} := n_j + n_{j+1} - n - 1. \tag{2.1}$$

In particular, when P_n is regular, $n = n_j$, then

$$\hat{n} = n_j + h_j - 1 = n_{j+1} - 1. \tag{2.2}$$

Equivalently, assuming $n_i \le n' \le n_{i+1}$ and $n_j \le n \le n_{j+1}$, we can write

$$\Phi_l(P_{n'}P_n) = 0 \quad \begin{array}{l}\text{if } i \ne j \\ \text{or } i = j \quad \text{and} \quad n' + n < n_j + n_{j+1} - 1,\end{array} \tag{2.5}$$

$$\Phi_l(P_{n'}P_n) =: \delta_j \ne 0 \quad \text{if } i = j \quad \text{and} \quad n' + n = n_j + n_{j+1} - 1, \tag{2.6}$$

where δ_j is independent of $n - n_j$ and $n' - n_j$.

The formula (2.10) implies that the nonregular FOP1s P_n ($n_j < n < n_{j+1}$) can be generated according to

$$P_{n+1}(z) = (z - \alpha_{n-n_j}^W)\, P_n(z) - \beta_{n-n_j}^W\, P_{n-1}(z), \qquad n_j \le n \le n_{j+1} - 2. \tag{2.11}$$

(Likewise, any other recurrence for $\{W_m\}$ leads to one for those P_n.) Less trivial is the fact that the orthogonality relation (2.1) allows us to establish for the regular FOP1s a three-term recurrence

$$P_{n_{j+1}}(z) = (W_{h_j}(z) - a_j(z))P_{n_j}(z) - \beta_j P_{n_{j-1}}(z), \quad j = 0, \ldots, J-1, \tag{2.17}$$

with a monic polynomial coefficient $W_{h_j} - a_j \in \mathcal{P}_{h_j}$ (hence, $a_j \in \mathcal{P}_{h_j-1}$) and a scalar coefficient $\beta_j \in \mathbb{C}$. (The initial values are: $P_{n_{-1}}(z) :\equiv 0$, $P_{n_0}(z) :\equiv 1$, $\beta_0 := 0$.) For the coefficient β_j there is an explicit formula and for the coefficients of $a_j(z) = \sum_{s=0}^{h_j-1} \alpha_{s,j} W_s(z)$ we have found a recursive formula based on the solution of a lower triangular system:

$$\beta_j \Phi_l(P_{n_j-1}P_{n_{j-1}}) = \Phi_l(zP_{n_j-1}P_{n_{j+1}-1}), \tag{2.23a}$$

$$\begin{aligned}\Phi_l(a_j P_{n_j+k}P_{n_j}) = {} & \Phi_l(zP_{n_j+k}P_{n_{j+1}-1}) - \alpha_{h_j-1}^W \Phi_l(P_{n_j+k}P_{n_{j+1}-1}) \\ & - \beta_{h_j-1}^W \Phi_l(P_{n_j+k}P_{n_{j+1}-2}), \quad k = 0, \ldots, h_j - 1.\end{aligned} \tag{2.23b}$$

After introducing the infinite row vector $\mathbf{p} := [P_0, P_1, \ldots]$, we can express the recurrences (2.11) and (2.17) as

$$z\mathbf{p}(z) = \mathbf{p}(z)\mathbf{H}, \tag{3.11}$$

where the Gragg matrix $\mathbf{H}$ is an infinite block tridiagonal unit upper Hessenberg matrix

$$\mathbf{H} := \begin{bmatrix} \mathbf{A}_0 & \mathbf{B}_1 & & & \\ \mathbf{C}_0 & \mathbf{A}_1 & \mathbf{B}_2 & & \\ & \mathbf{C}_1 & \mathbf{A}_2 & \ddots & \\ & & \ddots & \ddots & (\mathbf{B}_J) \\ & & & (\mathbf{C}_{J-1}) & (\mathbf{A}_J) \end{bmatrix}. \tag{3.6}$$

Under the assumption (2.10), the diagonal blocks $\mathbf{A}_j$ are $h_j \times h_j$ comrade matrices containing on the diagonal and the first superdiagonal the coefficients α_m^W and β_m^W from (2.10), and in the last column the coefficients $\alpha_{j,i}$ of the polynomial a_j. The off-diagonal blocks $\mathbf{C}_j$ and $\mathbf{B}_j$ are zero except for the element in the upper right corner, which is 1 in $\mathbf{C}_j$ and β_j in $\mathbf{B}_j$. If $J < \infty$, $\mathbf{B}_J$ is the $h_{J-1} \times \infty$ zero matrix, and $\mathbf{A}_J$ is the infinite tridiagonal matrix $\mathbf{T}^W$ representing the recurrence (2.10) in the form $z\mathbf{w}(z) = \mathbf{w}(z)\mathbf{T}^W$ (where $\mathbf{w} := [W_0, W_1, \ldots]$).

By using matrix notation, we can express the orthogonality properties (2.5)–(2.6) in compact form:

$$\Phi_l(\mathbf{p}^T\mathbf{p}) = \mathbf{D}, \tag{3.22}$$

where $\mathbf{D}$ is a block diagonal matrix whose blocks $\mathbf{D}_j$ are $h_j \times h_j$ lower right triangular matrices with all antidiagonal elements equal to δ_j.

The FOP1s P_n and the associated FOP2s Q_n ($n \in \mathbb{N}$) are essentially the denominators and the numerators, respectively, of the proper parts of the Padé approximant lying on the lth diagonal of the Padé table of the formal Laurent series

$$f(z) = \sum_{k=-\infty}^{\infty} \phi_k z^k. \tag{1.25}$$

More exactly, the $(m,n) := (l+n-1, n)$ Padé approximant of f is equal to

$$r_{m,n}(z) := \sum_{k=-\infty}^{m-n} \phi_k z^k + z^{m-n} \frac{Q_n(z^{-1})}{P_n(z^{-1})},$$

cf. (1.21), (1.22), and (1.34). The rational function $r_{m,n}$ is the (m,n) entry of the Padé table.

An important feature of the Padé table is its block structure: Identical entries occur in finite or infinite square blocks, cf. Corollary 1.6. The regular FOP1s belong to entries on the first row or the first column of such a square block. This Block Structure Theorem is important in this second part, where we now consider pairs of sequences of FOP1s, $\{P_n\}_{n=0}^{\infty} := \{P_{l;n}\}_{n=0}^{\infty}$ and $\{P'_n\}_{n=0}^{\infty} := \{P_{l+1;n}\}_{n=0}^{\infty}$, which belong to *two adjacent diagonals* of the Padé table. We mark the quantities corresponding to the second sequence by a prime, writing for example $\mathbf{M}'_n$, $\mathbf{H}'$, $\mathbf{p}'$. We also set $\Phi := \Phi_l$ and $\Phi' := \Phi_{l+1}$. Note that this usage of primes differs from the one in Part I, where they indicated quantities belonging to the FOP2s, the polynomials of the second kind.

In §5 we define a new sequence of regular FOP1s whose elements are alternatively taken from the two above-mentioned sequences and belong to all distinct Padé approximants that lie on the two diagonals. We call the corresponding sequence of

Padé approximants a *block staircase sequence*. In analogy to the three-term recurrence (2.17) for the regular FOP1s that belong to one diagonal, we derive a pair of three-term recurrence formulas (with one polynomial coefficient in each) for the new sequence of FOP1s. Since FOP1s from both diagonals appear in these formulas, we call them *mixed* recurrences. Two equivalent but different matrix formulations for them are given in §6. Actually, these matrix formulations involve all the polynomials from the two sequences $\{P_n\}_{n=0}^{\infty}$ and $\{P_n'\}_{n=0}^{\infty}$ and not just the regular ones.

By eliminating either the first or the second sequence, we rediscover in §7 the matrix formulations of the separate recurrences for the second and the first sequence, respectively, which are both of the type discussed in Part I, i.e., they are determined by Gragg matrices of the form (3.6). It turns out that the Gragg matrix of the second sequence is obtained from the one of the first sequence by executing one step of a *block LR algorithm*, i.e., we have to compute a particular block LU decomposition and then multiply the factors together in reverse order. The factors, which are block bidiagonal (but none of which is chosen with unit block diagonal), are exactly the matrices that describe the mixed recurrences of the block staircase. This block LR algorithm generalizes Rutishauser's LR algorithm for tridiagonal matrices, and hence also his (equivalent) qd algorithm [23]. It is the key to a *nongeneric progressive qd algorithm*, which, in contrast to the classical (generic) progressive qd algorithm, never breaks down in exact arithmetic.

In §4 of Part I we applied the results on (diagonal) sequences of FOP1s to the unsymmetric Lanczos process. Let $\mathbf{A} : \mathcal{H} \to \mathcal{H}$ be a bounded linear operator mapping a separable real or complex Hilbert space into itself. The standard inner product in $\mathcal{H}$ is denoted by $\langle .\,,.\rangle$, but we use instead a formal inner product $\langle .\,,.\rangle_{\mathbf{B}}$ defined by $\langle \mathbf{y}\,,\mathbf{x}\rangle_{\mathbf{B}} := \langle \mathbf{y}\,,\mathbf{B}\mathbf{x}\rangle$, which is induced by another bounded linear operator $\mathbf{B} : \mathcal{H} \to \mathcal{H}$ that commutes with $\mathbf{A}$. (The cases of practical interest are $\mathbf{B} = \mathbf{I}$, $\mathbf{B} = \mathbf{A}$, and $\mathbf{B} = \mathbf{A}^{-1}$.) Orthogonality with respect to this indefinite inner product is referred to as formal orthogonality. Associated with $\mathbf{A}$, $\mathbf{x}_0$, $\mathbf{y}_0$, and this inner product are the *Schwarz constants* or *moments*

$$\phi_k := \langle \mathbf{y}_0, \mathbf{A}^k\mathbf{x}_0\rangle_{\mathbf{B}} := \langle \mathbf{y}_0, \mathbf{B}\mathbf{A}^k\mathbf{x}_0\rangle \quad (k \in \mathbb{N}). \tag{4.1}$$

The link to the above-described theory of FOPs is based on the identification of these moments with the values that the linear functional $\Phi = \Phi_0$ of (1.1) takes on the monomials.

Starting from $\mathbf{A}$, $\mathbf{x}_0$, $\mathbf{y}_0$, the classical (generic) *Lanczos biorthogonalization (BO) algorithm* [19], [15], [11] generates the two sequences $\{\mathbf{x}_n\}_{n=0}^{\nu-1}$ and $\{\mathbf{y}_n\}_{n=0}^{\nu-1}$ such that for $n = 0, 1, \ldots, \nu - 1$

$$\mathbf{x}_n \in \mathcal{K}_{n+1} := \text{span}\,(\mathbf{x}_0, \mathbf{A}\mathbf{x}_0, \mathbf{A}^2\mathbf{x}_0, \ldots, \mathbf{A}^n\mathbf{x}_0), \tag{4.6a}$$

$$\mathbf{y}_n \in \mathcal{L}_{n+1} := \text{span}\,(\mathbf{y}_0, \mathbf{A}^H\mathbf{y}_0, (\mathbf{A}^H)^2\mathbf{y}_0, \ldots, (\mathbf{A}^H)^n\mathbf{y}_0), \tag{4.6b}$$

and

$$\langle \mathbf{y}_m, \mathbf{x}_n\rangle_{\mathbf{B}} \begin{cases} = 0 & \text{if} \quad m \neq n, \\ \neq 0 & \text{if} \quad m = n. \end{cases} \tag{4.7}$$

In view of (4.6), $\mathbf{x}_n$ must be equal to a polynomial in $\mathbf{A}$ times $\mathbf{x}_0$, and $\mathbf{y}_n$ must be equal to a polynomial in $\mathbf{A}^H$ times $\mathbf{y}_0$. From the orthogonality condition (4.7) and the uniqueness of the regular FOPs it follows easily that actually

$$\mathbf{x}_n = P_n(\mathbf{A})\mathbf{x}_0\Gamma_n, \qquad \mathbf{y}_n = \overline{P_n}(\mathbf{A}^H)\mathbf{y}_0\bar{\Gamma}_n, \tag{4.14}$$

where P_n is the monic regular FOP1 of degree n, $\overline{P_n}$ is the polynomial with the complex conjugate coefficients, and Γ_n and $\bar{\Gamma}_n$ are scale factors. As we know, such a regular FOP1 need not exist, and that is when (4.7) no longer holds and the generic BO algorithm breaks down. Our remedy for this breakdown was to use (4.14), with P_n being any FOP1 of degree n (regular or not). The *nongeneric BO algorithm* (Algorithm 1) was then obtained by translating the recurrences for the FOP1s via (4.14) to recurrences for $\mathbf{x}_n$ and $\mathbf{y}_n$. In these recurrences the scale factors Γ_n and $\bar{\Gamma}_n$ are replaced by the relative scale factors

$$\gamma_{n,i} := \Gamma_n/\Gamma_{n-i}\,, \quad \bar{\gamma}_{n,i} := \bar{\Gamma}_n/\bar{\Gamma}_{n-i} \quad (n \in \mathbb{N}, i \in \mathbb{N}). \tag{4.20a}$$

The application of the BO algorithm to solving linear systems of equations $\mathbf{Ax} = \mathbf{b}$ is based on defining a sequence of approximants $\mathbf{z}_n$ in such a way that $\mathbf{x}_n$ is the residual vector for $\mathbf{z}_n$,

$$\mathbf{x}_n = \mathbf{b} - \mathbf{A}\mathbf{z}_n, \quad n = 0, 1, 2, \ldots, \tag{4.61}$$

(*normalized* BIORES *algorithm*) or such that $\mathbf{x}_n$ is the residual of $\mathbf{z}_n$ in a system with scaled right-hand side

$$\mathbf{x}_n = \mathbf{b}\rho_n - \mathbf{A}\mathbf{z}_n, \quad n = 0, 1, 2, \ldots, \tag{4.62}$$

(*unnormalized* BIORES *algorithm*).

The BO algorithm terminates when $\mathbf{x}_n = \mathbf{0}$ or $\mathbf{y}_n = \mathbf{0}$. But while the generic BO algorithm (and thus also BIORES) breaks down seriously whenever $\langle \mathbf{y}_n, \mathbf{x}_n \rangle_{\mathbf{B}} = 0$, our generalization fails only if the inner product vanishes for *all* n beyond some bound n_J. This is then called an incurable breakdown [22], [21]. Unfortunately, in order to detect such an incurable breakdown, we theoretically have to work with exact arithmetic and to iterate until n reaches the rank of $\mathbf{A}$. When the algorithm is applied to solving a linear system, the hope is that in theory $\mathbf{x}_n = \mathbf{0}$ for some n, and that in practice the residual $\mathbf{x}_n$ is sufficiently small even much earlier. There is, however, the additional difficulty that $\mathbf{y}_n = \mathbf{0}$ causes the algorithm to stop, and this requires that we find a nonzero replacement for $\mathbf{y}_n$ that is orthogonal to $\mathcal{K}_n$ and can be used to proceed.

Here, we discuss in §8 three iterative linear system solvers that are closely related to the unnormalized nongeneric BIORES algorithm and have in fact the same breakdown behavior. (For the generic versions this is not true [11].) The first two, *normalized* and *unnormalized nongeneric* BIOMIN, are extensions of the well-known and highly successful *biconjugate gradient (BCG) method* [20], [7], [11]. The third is (*normalized*) *nongeneric* BIODIR, which, independently, has also been developed by Joubert [17], [18]. These three methods generate relevant subsequences of essentially the same sequences of approximants $\mathbf{z}_n$, residuals $\mathbf{x}_n$, and corresponding $\mathbf{B}$-biorthogonal vectors $\mathbf{y}_n$ as nongeneric BIORES; but additionally they produce two $\mathbf{BA}$-biorthogonal sequences $\{\mathbf{u}_n\}$ and $\{\mathbf{v}_n\}$. The elements of the first serve as *direction vectors*, i.e., they specify the direction of the correction for $\mathbf{z}_n$. While the vectors $\mathbf{x}_n$ and $\mathbf{y}_n$ correspond according to (4.14) to a diagonal sequence of FOP1s, the vectors $\mathbf{u}_n$ and $\mathbf{v}_n$ correspond similarly to the FOP1s on the adjacent diagonal. And while nongeneric BIORES is based on the recurrence for the first block diagonal sequence of FOP1s, nongeneric BIOMIN is based on the recursion for the block staircase sequence, and nongeneric BIODIR makes use of the one for the block diagonal sequence on the adjacent diagonal.

Finally, in §§9 and 10, we present a theoretically clean approach to treating near-breakdowns. Of course, such an approach is of great importance in practice, where

the occurrence of exact breakdown is very unlikely, but near-breakdown may cause severe numerical effects. We formulate this theory for polynomials, but the application to the above-mentioned iterative linear solvers is straightforward. (The actual implementation still requires a careful treatment of many nontrivial details. This is the subject of joint work with Roland Freund and Noël Nachtigal [8].)

This treatment of near-breakdown is based on defining appropriate *clusters* or *blocks* of polynomials in such a way that formal orthogonality is maintained between the blocks, but not within the blocks. The first polynomial in each block is still a regular FOP1, and, moreover, it is well conditioned if the blocks are suitably chosen. To construct these polynomials (or the corresponding sequences of Krylov space vectors) we apply a block orthogonalization process, which is just the appropriate generalization of the Gram–Schmidt process.[2] The resulting algorithm, which is described here in terms of polynomials and in [8] in terms of Krylov space vectors, can be considered as a generalization of the nongeneric BO algorithm of §4 and of the similar algorithms proposed by Parlett, Taylor, and Liu [22], [21], [24] and by Boley et al. [1]. Although mainly exact breakdowns were considered in [22], [24], we suggest applying Parlett's adjective *"look-ahead,"* which is by now well established, to the near-breakdown versions of all of the above-mentioned algorithms, while the adjective *"nongeneric"* should be reserved for the versions curing exact breakdown.

In Parlett, Taylor, and Liu [22] the discussion was actually restricted to 2×2 blocks. Several options of block LDU decomposition of the moment matrix were considered for this case, but the resulting generalizations of the Lanczos algorithm differ in detail considerably from the proposals made here, even for exact breakdown. In particular, the left Lanczos vectors are chosen differently; thus, in the relations (4.14) the polynomial $\overline{P_n}$ is there in general *not* the complex conjugate polynomial of P_n. Moreover, as we will see in §9, the above-mentioned "appropriate generalization" of the Gram–Schmidt process for near-breakdowns is not the straightforward one, which would not yield a "block three-term" recurrence. Finally, here we not only treat block diagonal sequences (§9), but also block staircase sequences (§10), which present some additional difficulties.

Upon revision of this paper we learned of nongeneric algorithms developed by Hegedüs [14] for applying conjugate gradients to a particular indefinite problem. From his treatment one must conclude that he was probably also aware of the possibility of developing some of the nongeneric algorithms given here; but he did not specify them.

5. Block staircase sequences and corresponding recurrences. In this section we consider two *adjacent* sequences of FOP1s, $\{P_n\} := \{P_{l;n}\}$ and $\{P'_n\} := \{P_{l+1;n}\}$, and their associated sequences of FOP2s, $\{Q_n\} := \{Q_{l;n}\}$ and $\{Q'_n\} := \{Q_{l+1;n}\}$, and derive a recurrence for a particular sequence formed alternatively from regular elements of $\{P_n\}$ and $\{P'_n\}$. We denote those elements of this sequence that are taken from $\{P_n\}$ by $P_{n_j^\wedge}$, and those taken from $\{P'_n\}$ by $P'_{n_j^\vee}$. The index sequences

$$\{n_j^\wedge\}_{j=0}^{J^\wedge} \quad \text{and} \quad \{n_j^\vee\}_{j=0}^{J^\vee}$$

still indicate the degrees of the corresponding polynomials and are subsequences of the two index sequences $\{n_j\}$ and $\{n'_j\}$, respectively, that belong to the regular FOP1s in

[2] We use the notion "block orthogonal" here, although there is a danger of confusion with the different meaning the word "block" has in "block Lanczos" or "block Gram–Schmidt."

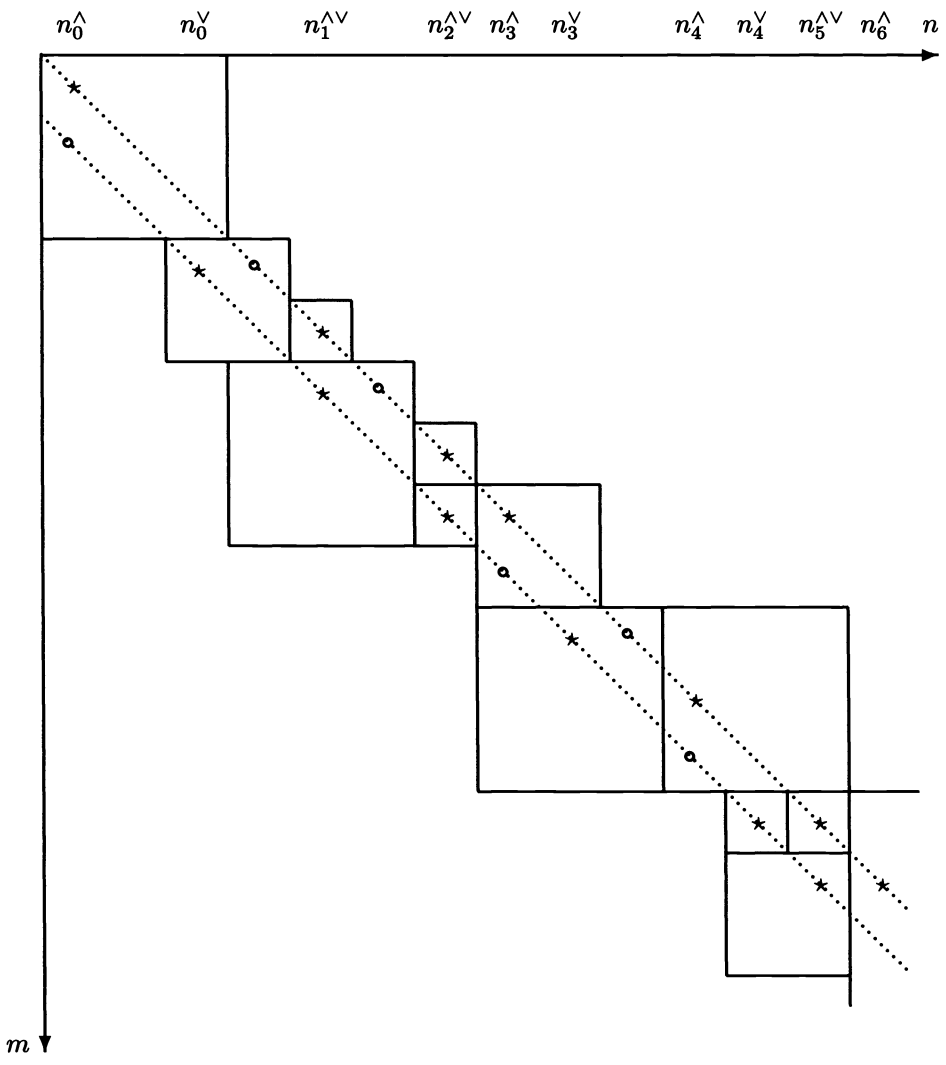

FIG. 3. *A block staircase sequence. The elements of the staircase are marked by* $\star$*, while the other regular elements on the two adjacent diagonals are marked by* $\circ$*. The notation* $n_j^{\wedge\vee}$ *means* $n_j^\wedge = n_j^\vee$.

$\{P_n\}$ and $\{P'_n\}$, respectively. These subsequences are chosen such that $n_0^\wedge := 0$ and

$$n_j^\wedge \le n_j^\vee \ (j = 0, \ldots, J^\vee), \quad n_j^\vee < n_{j+1}^\wedge \ (j = 0, \ldots, J^\wedge - 1), \tag{5.1}$$

and such that they contain as many indices as possible; in the cases where the interlacing condition (5.1) does not determine $n_j^\vee$ or $n_{j+1}^\wedge$ uniquely, we make the last of the choices allowed by (5.1). From the Block Structure Theorem 1.6 for the Padé table, it is seen that such ambiguities occur in connection with blocks that contain elements from both $\{P_n\}$ and $\{P'_n\}$, i.e., which are intersected both by the upper and the lower diagonal (on which $m - n = l$ and $m - n = l + 1$, respectively), cf. Fig. 3. In such cases, either the first column or the first row of the block contains regular elements out of both $\{P_n\}$ and $\{P_{l+1;n}\}$, and then the lower or the right, respectively,

of these elements is dropped, while the other becomes an element of $\{P_{n_j^\wedge}\}$ or $\{P'_{n_j^\vee}\}$, respectively. Note that

$$J^\vee \le J^\wedge \le J^\vee + 1 \le \infty\,, \tag{5.2}$$

i.e., there can be at most one more marked element on the upper diagonal, and the number of elements may be infinite.

Let us also set

$$m_j^\wedge := n_j^\wedge + l - 1\,, \quad m_j^\vee := n_j^\vee + l\,, \tag{5.3}$$

$$h_j^\wedge := n_j^\vee - n_j^\wedge + 1 = m_j^\vee - m_j^\wedge\,, \quad h_j^\vee := n_{j+1}^\wedge - n_j^\vee = m_{j+1}^\wedge - m_j^\vee + 1\,. \tag{5.4}$$

Both $h_j^\wedge$ and $h_j^\vee$ are ≥ 1. If $J^\wedge$, $J^\vee < \infty$, then $h_{J^\wedge}^\wedge := h_{J^\vee}^\vee := n_{J^\wedge}^\vee := n_{J^\vee+1}^\wedge := \infty$.

The index pair sequences $\{(m_j^\wedge, n_j^\wedge)\}_{j=0}^{J^\wedge}$ and $\{(m_j^\vee, n_j^\vee)\}_{j=0}^{J^\vee}$ define the *block staircase sequence* for the two adjacent diagonals of the Padé table. (For the more general situation of the Newton–Padé table, block staircase sequences have been introduced in [12].) Note that the index pairs specify for each block an entry of minimum degrees m and n on one of the two adjacent diagonals, but do not indicate the upper left corner of the block.

The orthogonality result of Theorem 2.1 yields the following lemma for such block staircase sequences.

LEMMA 5.1. *The following formal orthogonality properties hold:*

$$\Phi(pP_{n_j^\wedge}) = 0 \quad (\forall p \in \mathcal{P}_{n_j^\wedge + h_j^\wedge - 2} = \mathcal{P}_{n_j^\vee - 1})\,, \tag{5.5a}$$

$$\delta_j^\wedge := \Phi(z^{n_j^\vee} P_{n_j^\wedge}) \ne 0\,, \tag{5.5b}$$

and

$$\Phi'(pP'_{n_j^\vee}) = 0 \quad (\forall p \in \mathcal{P}_{n_j^\vee + h_j^\vee - 2} = \mathcal{P}_{n_{j+1}^\wedge - 2})\,, \tag{5.6a}$$

$$\delta_j^\vee := \Phi'(z^{n_{j+1}^\wedge - 1} P'_{n_j^\vee}) \ne 0\,. \tag{5.6b}$$

Proof. Apply (2.1) and (2.2) to the current situation and note that the regular elements following $P_{n_j^\wedge}$ and $P'_{n_j^\vee}$ on the same diagonal have the indices

$$n_j^\vee + 1 = n_j^\wedge + h_j^\wedge \quad \text{and} \quad n_{j+1}^\wedge = n_j^\vee + h_j^\vee\,, \tag{5.7}$$

respectively, independently of whether this following regular element is part of the block staircase or not. This is due to the fact that, in case of a dropped element, the index of the next element differs from that of the dropped one only by 1, as can be seen from Fig. 3. □

COROLLARY 5.2. *The following formal orthogonality properties hold:*

$$\Phi'(pP_{n_j^\wedge}) = 0 \quad (\forall p \in \mathcal{P}_{n_j^\wedge + h_j^\wedge - 3} = \mathcal{P}_{n_j^\vee - 2}), \tag{5.8a}$$

$$\delta_j^\wedge = \Phi'(z^{n_j^\vee - 1} P_{n_j^\wedge}) \ne 0, \tag{5.8b}$$

and

$$\Phi_l(zpP'_{n_j^\vee}) = 0 \quad (\forall p \in \mathcal{P}_{n_j^\vee + h_j^\vee - 2} = \mathcal{P}_{n_{j+1}^\wedge - 2})\,, \tag{5.9a}$$

$$\delta_j^\vee = \Phi_l(z^{n_{j+1}^\wedge} P'_{n_j^\vee}) \ne 0\,. \tag{5.9b}$$

Proof. In the same way that (1.2) was written as the homogeneous linear system (1.6), (5.5a) can be written as

$$\sum_{j=0}^{n} \phi_{i+j-n}\pi_{l;j,n} = 0, \quad i = l+n, \dots, l+2n+h-2, \tag{5.10}$$

where $n := n_j^{\wedge}$, $h := h_j^{\wedge}$. When the first equation is deleted, this system represents (5.8a). Both (5.5b) and (5.8b) express that the "next equation after (5.10)," with $i := l+2n+h-1$, is not homogeneous.

Similarly, (5.6a) and (5.9a) are represented by the same homogeneous linear system, and (5.6b) and (5.9b) yield the same strictly inhomogeneous equation. □

Lemma 5.1 and Corollary 5.2 allow us now to establish recurrence formulas for block staircase sequences. By analogy to the derivation of the recurrence formula for diagonal sequences in §2, we start from representations of $P_{n_{j+1}^{\wedge}}$ and $P'_{n_{j+1}^{\vee}}$ in terms of the previous elements of the staircase. Clearly, in view of (5.4), there are polynomials $t_{s,j}^{\wedge} \in \mathcal{P}_{h_s^{\wedge}-1}$ and $t_{s,j}^{\vee} \in \mathcal{P}_{h_s^{\vee}-2}$ $(s = 0, 1, \dots, j)$ such that

$$P_{n_{j+1}^{\wedge}}(z) = zW_{h_j^{\vee}-1}(z)P'_{n_j^{\vee}}(z) - \sum_{s=0}^{j} \left[zt_{s,j}^{\vee}(z)P'_{n_s^{\vee}}(z) + t_{s,j}^{\wedge}(z)P_{n_s^{\wedge}}(z) \right]. \tag{5.11}$$

(If $h_s^{\vee} = 1$, we set $t_{s,j}^{\vee} := 0$.) We multiply this relation with the monomials of degree at most $n_j^{\vee} + h_j^{\vee} - 1 = n_{j+1}^{\wedge} - 1$. Each of these monomials can be written as either $z^{n_i^{\wedge}+k}$ with $0 \le k \le h_i^{\wedge} - 2$, $0 \le i \le j$, or $z^{n_i^{\vee}+k}$ with $0 \le k \le h_i^{\vee} - 1$, $0 \le i \le j$. (Note that the range of k in the first loop is empty if $h_i^{\wedge} = 1$, in which case the multiplier $z^{n_i^{\wedge}+k}$ is not used.) Then, we apply Φ to the resulting $n_{j+1}^{\wedge}$ relations in order to obtain a linear system of $n_{j+1}^{\wedge}$ equations for the polynomials $t_{s,j}^{\wedge}$ and $t_{s,j}^{\vee}$, $s = 0, \dots, j$. In view of (5.4), these polynomials have a total of $n_{j+1}^{\wedge}$ coefficients. In view of (5.8a), all expressions $\Phi(z^{n_i^{\wedge}+k} P_{n_{j+1}^{\wedge}})$ and $\Phi(z^{n_i^{\vee}+k} P_{n_{j+1}^{\wedge}})$ vanish, so that $P_{n_{j+1}^{\wedge}}$ does not appear in the system. In order to verify the structure of this system, we list a number of results following directly from (5.4), (5.5), and (5.9); k is always assumed to lie in the given ranges.

$$\Phi(z^{n_i^{\wedge}+k+1} W_{h_j^{\vee}-1} P'_{n_j^{\vee}}) = 0 \text{ if } i \le j. \tag{5.12a}$$

(Here, for the case $i = j-1$, we have used that $n_{j-1}^{\wedge} + k \le n_{j-1}^{\wedge} + h_{j-1}^{\wedge} - 2 = n_{j-1}^{\vee} - 1 \le n_j^{\wedge} - 2 \le n_j^{\vee} - 2$.)

$$\Phi(z^{n_i^{\vee}+k+1} W_{h_j^{\vee}-1} P'_{n_j^{\vee}}) \begin{cases} = 0 & \text{if } i \le j-1, \\ \neq 0 & \text{if } i = j,\ k = 0. \end{cases} \tag{5.12b}$$

(Here, we have used that $n_{j-1}^{\vee} + h_{j-1}^{\vee} + h_j^{\wedge} - 2 = n_j^{\wedge} + h_j^{\wedge} - 2 = n_j^{\vee} - 1$.)

$$\Phi(z^{n_i^{\wedge}+k+1} t_{s,j}^{\vee} P'_{n_s^{\vee}}) = 0 \text{ if } i \le s; \tag{5.13a}$$

$$\Phi(z^{n_i^{\vee}+k+1} t_{s,j}^{\vee} P'_{n_s^{\vee}}) \begin{cases} = 0 & \text{if } i < s, \\ = 0 & \text{if } i = s,\ k + \partial t_{s,j}^{\vee} < h_s^{\vee} - 1, \\ \neq 0 & \text{if } i = s,\ k + \partial t_{s,j}^{\vee} = h_s^{\vee} - 1; \end{cases} \tag{5.13b}$$

$$\Phi(z^{n_i^\wedge+k}\, t_{s,j}^\wedge\, P_{n_s^\wedge}) \begin{cases} =0 & \text{if } i<s, \\ =0 & \text{if } i=s,\ k+\partial t_{s,j}^\wedge < h_s^\wedge - 1; \\ \neq 0 & \text{if } i=s,\ \partial t_{s,j}^\wedge > 0,\ k+\partial t_{s,j}^\wedge = h_s^\wedge - 1; \end{cases} \tag{5.13c}$$

$$\Phi(z^{n_i^\vee+k}\, t_{s,j}^\wedge\, P_{n_s^\wedge}) \begin{cases} =0 & \text{if } i<s, \\ \neq 0 & \text{if } i=s,\ \partial t_{s,j}^\wedge = 0,\ k=0. \end{cases} \tag{5.13d}$$

By capitalizing on these formulas, the above-mentioned linear system (which was obtained by multiplying (5.11), for $i = 0, 1, \ldots, j$, with $z^{n_i^\wedge+k}$ $(k = 0, \ldots, h_i^\wedge - 2)$ and $z^{n_i^\vee+k}$ $(k = 0, \ldots, h_i^\vee - 1)$, and then applying Φ) reduces to the following set of equations:

$$\sum_{s=0}^{i-1} \Phi(z^{n_i^\wedge+k+1}\, t_{s,j}^\vee\, P'_{n_s^\vee}) + \sum_{s=0}^{i} \Phi(z^{n_i^\wedge+k}\, t_{s,j}^\wedge\, P_{n_s^\wedge}) = 0\,, \qquad k = 0, \ldots, h_i^\wedge - 2;\ i = 0, \ldots, j\,; \tag{5.14a}$$

$$\sum_{s=0}^{i} \Phi(z^{n_i^\vee+k+1}\, t_{s,j}^\vee\, P'_{n_s^\vee}) + \sum_{s=0}^{i} \Phi(z^{n_i^\vee+k}\, t_{s,j}^\wedge\, P_{n_s^\wedge}) = \begin{cases} 0 \text{ if } i \le j-1, \\ \Phi(z^{n_j^\vee+k+1}\, W_{h_j^\vee-1}\, P'_{n_j^\vee}) \neq 0 \text{ if } i=j,\ k=0, \\ \Phi(z^{n_j^\vee+k+1}\, W_{h_j^\vee-1}\, P'_{n_j^\vee}) \text{ if } i=j, \end{cases} \qquad k = 0, \ldots, h_i^\vee - 1;\ i = 0, \ldots, j\,. \tag{5.14b}$$

This system is of triangular structure, like the one for diagonal sequences, which consists of (2.13) and (2.14). Again, except for the last few equations, the system is homogeneous and we can conclude that "most" of the unknown polynomials are zero. In fact, let us assume that $j > 0$ and, at first, that $t_{0,j}^\wedge \neq 0$. Then, if $\partial t_{0,j}^\wedge > 0$, the equation with $i = 0$ and $k = h_0^\wedge - \partial t_{0,j}^\wedge - 1$ in (5.14a), which is homogeneous but contains in view of (5.13c) exactly one nonzero term, yields a contradiction. Likewise, if $\partial t_{0,j}^\wedge = 0$, we let $i = k = 0$ and use (5.14b), (5.13b), and (5.13d) to obtain a contradiction. Next, suppose that $t_{0,j}^\wedge = t_{0,j}^\vee = t_{1,j}^\wedge = \cdots = t_{i-1,j}^\vee = t_{i,j}^\wedge = 0$, but $t_{i,j}^\vee \neq 0$ for some $i \le j-1$. Then, (5.14b) and (5.13b) with $k = h_i^\vee - \partial t_{i,j}^\vee - 1 \in \{1, 2, \ldots, h_i^\vee - 1\}$ lead again to a contradiction; hence $t_{i,j}^\vee = 0$. If $t_{0,j}^\wedge = t_{0,j}^\vee = t_{1,j}^\wedge = \cdots = t_{i-1,j}^\vee = 0$ for some $i \le j-1$, we can likewise conclude from (5.14a) and (5.13c) or from (5.14b), (5.13b), and (5.13d) that $t_{i,j}^\wedge = 0$. In summary, if $j > 0$, there holds

$$t_{0,j}^\wedge = t_{0,j}^\vee = t_{1,j}^\wedge = \cdots = t_{j-2,j}^\vee = t_{j-1,j}^\wedge = t_{j-1,j}^\vee = 0\,. \tag{5.15}$$

By the same arguments we conclude from (5.14a) and (5.13c) that $\partial t_{j,j}^\wedge \le 0$; from (5.14b), (5.13b), and (5.13d), by choosing $i = j$ and $k = 0$, we conclude that

$$t_{j,j}^\wedge(z) \equiv: \varphi_j^\vee \neq 0, \tag{5.16}$$

the constant $\varphi_j^\vee$ being given by

$$\varphi_j^\vee = \delta_j^\vee / \delta_j^\wedge, \quad \text{where } \delta_j^\wedge = \Phi(z^{n_j^\vee}\, P_{n_j^\wedge}),\ \ \delta_j^\vee = \Phi(z^{n_{j+1}^\wedge}\, P'_{n_j^\vee})\,. \tag{5.17a}$$

For $e_j^\vee := t_{j,j}^\vee$ we get from (5.14b) (with $i = j$) the additional $h_j^\vee - 1$ equations

$$\Phi(z^{n_j^\vee+k+1}\, e_j^\vee\, P'_{n_j^\vee}) + \varphi_j^\vee \Phi(z^{n_j^\vee+k}\, P_{n_j^\wedge}) = \Phi(z^{n_j^\vee+k+1}\, W_{h_j^\vee-1}\, P'_{n_j^\vee}), \qquad k = 1, \ldots, h_j^\vee - 1\,. \tag{5.17b}$$

If the polynomial $e_j^\vee$ is expressed in powers of z or in terms of the polynomials W_m, it follows from (5.9b) that the matrix of the resulting linear system for the coefficients is right lower triangular and regular, since its antidiagonal elements are all equal to $\delta_j^\vee \neq 0$. In case of the monomial basis, the matrix is Hankel.

Summarizing, we have shown so far that the general representation (5.11) reduces actually to a mixed three-term recurrence formula

$$P_{n_{j+1}^\wedge}(z) = [zW_{h_j^\vee - 1}(z) - ze_j^\vee(z)]P'_{n_j^\vee}(z) - \varphi_j^\vee P_{n_j^\wedge}(z), \quad j = 0, 1, \ldots, J^\wedge - 1. \tag{5.18}$$

In a completely analogous manner we can derive a mixed three-term recurrence formula for computing $P'_{n_j^\vee}$. We start from the representation

$$P'_{n_j^\vee}(z) = W_{h_j^\wedge - 1}(z)P_{n_j^\wedge}(z) - \sum_{s=0}^{j} t_{s,j}^\wedge(z)P_{n_s^\wedge}(z) - \sum_{s=0}^{j-1} t_{s,j}^\vee(z)P'_{n_s^\vee}(z) \tag{5.19}$$

with *new* polynomials $t_{s,j}^\wedge \in \mathcal{P}_{h_s^\wedge - 2}$ $(s = 0, 1, \ldots, j)$ and $t_{s,j}^\vee \in \mathcal{P}_{h_s^\vee - 1}$ $(s = 0, 1, \ldots, j-1)$. (If $h_s^\wedge = 1$, we set $t_{s,j}^\wedge := 0$.)

This time, we multiply this relation with the monomials $z^{n_i^\wedge + k}$ $(1 \leq k \leq h_i^\wedge - 1,$ $0 \leq i \leq j)$ and $z^{n_i^\vee + k}$ $(1 \leq k \leq h_i^\vee,\ 0 \leq i \leq j-1)$, which together are all the monomials with degrees between 1 and $n_j^\wedge + h_j^\wedge - 1 = n_j^\vee$. Again, we then apply Φ to both sides. Due to (5.9a), $P'_{n_j^\vee}$ does not appear in the resulting linear system of $n_j^\vee$ equations, and in view of (5.4), the total number of coefficients of $t_{s,j}^\wedge$ and $t_{s,j}^\vee$ in (5.19) is also $n_j^\vee$. To simplify the system we need the following formulas, which are analogous to (5.12) and (5.13). (Note that the ranges of k and the maximum degrees of $\partial t_{s,j}^\wedge$ and $\partial t_{s,j}^\vee$ have changed.)

$$\Phi(z^{n_i^\wedge + k} W_{h_j^\wedge - 1} P_{n_j^\wedge}) = 0 \ \text{ if } \ i \leq j - 1; \tag{5.20a}$$

$$\Phi(z^{n_i^\vee + k} W_{h_j^\wedge - 1} P_{n_j^\wedge}) \begin{cases} = 0 & \text{if} \quad i < j - 1, \\ = 0 & \text{if} \quad i = j - 1, \ k \leq h_{j-1}^\vee - 1, \\ \neq 0 & \text{if} \quad i = j - 1, \ k = h_{j-1}^\vee - 1; \end{cases} \tag{5.20b}$$

$$\Phi(z^{n_i^\wedge + k} t_{s,j}^\vee P'_{n_s^\vee}) = 0 \ \text{ if } \ i \leq s; \tag{5.21a}$$

$$\Phi(z^{n_i^\vee + k} t_{s,j}^\vee P'_{n_s^\vee}) \begin{cases} = 0 & \text{if} \quad i < s, \\ = 0 & \text{if} \quad i = s, \ k + \partial t_{s,j}^\vee < h_s^\vee, \\ \neq 0 & \text{if} \quad i = s, \ k + \partial t_{s,j}^\vee = h_s^\vee; \end{cases} \tag{5.21b}$$

$$\Phi(z^{n_i^\wedge + k} t_{s,j}^\wedge P_{n_s^\wedge}) \begin{cases} = 0 & \text{if} \quad i < s, \\ = 0 & \text{if} \quad i = s, \ k + \partial t_{s,j}^\wedge < h_s^\wedge - 1, \\ \neq 0 & \text{if} \quad i = s, \ k + \partial t_{s,j}^\wedge = h_s^\wedge - 1; \end{cases} \tag{5.21c}$$

$$\Phi(z^{n_i^\vee + k} t_{s,j}^\wedge P_{n_s^\wedge}) = 0 \ \text{ if } \ i < s. \tag{5.21d}$$

By applying these formulas, we can rewrite the linear system as

$$\text{(5.22a)}\qquad \sum_{s=0}^{i}\Phi(z^{n_i^\vee+k}\,t_{s,j}^\vee\,P'_{n_s^\vee})+\sum_{s=0}^{i}\Phi(z^{n_i^\vee+k}\,t_{s,j}^\wedge\,P_{n_s^\wedge})$$
$$=\begin{cases}0 \text{ if } i<j-1,\\ 0 \text{ if } i=j-1,\ k\le h_{j-1}^\vee-1,\\ \Phi(z^{n_{j-1}^\vee+k}\,W_{h_j^\wedge-1}\,P_{n_j^\wedge})\neq 0 \text{ if } i=j-1,\ k=h_{j-1}^\vee-1,\end{cases}$$
$$k=1,\dots,h_i^\vee;\ i=0,\dots,j-1;$$

$$\text{(5.22b)}\qquad \sum_{s=0}^{i-1}\Phi(z^{n_i^\wedge+k}\,t_{s,j}^\vee\,P'_{n_s^\vee})+\sum_{s=0}^{i}\Phi(z^{n_i^\wedge+k}\,t_{s,j}^\wedge\,P_{n_s^\wedge})$$
$$=\begin{cases}0 \text{ if } i\le j-1,\\ \Phi(z^{n_j^\wedge+k}\,W_{h_j^\wedge-1}\,P_{n_j^\wedge}) \text{ if } i=j,\end{cases}$$
$$k=1,\dots,h_i^\wedge-1;\ i=0,\dots,j.$$

Again, the system has a triangular structure. For let us assume that $j>0$ and $t_{0,j}^\wedge\neq 0$. Then (5.21c) and (5.22b) with $i=0$ and $k=h_0^\wedge-\partial t_{0,j}^\wedge-1\in\{1,2,\dots,h_0^\wedge-1\}$ yield a contradiction, showing that $t_{0,j}^\wedge=0$. By the same argument, $t_{0,j}^\wedge=t_{0,j}^\vee=\cdots=t_{i-1,j}^\vee=0$ (for some $i\le j-1$) implies that $t_{i,j}^\wedge=0$. On the other hand, assuming $t_{0,j}^\wedge=t_{0,j}^\vee=\cdots=t_{i,j}^\vee=0$, $t_{i,j}^\wedge\neq 0$ (for some $i\le j-1$), we conclude from (5.21b) and (5.22a), by choosing $k=h_i^\vee-\partial t_{i,j}^\vee\in\{1,2,\dots,h_i^\vee\}$ there, that $t_{i,j}^\vee=0$, unless $i=j-1$ and $k=h_{j-1}^\vee$. In the latter case there holds

$$\text{(5.23)}\qquad t_{j-1,j}^\vee(z)\equiv:\varphi_j^\wedge\neq 0,$$

where the constant $\varphi_j^\wedge$ is given by

$$\text{(5.24a)}\qquad \varphi_j^\wedge=\delta_j^\wedge/\delta_{j-1}^\vee,\quad \text{where } \delta_{j-1}^\vee=\Phi(z^{n_j^\wedge}P'_{n_{j-1}^\vee}),\ \ \delta_j^\wedge=\Phi(z^{n_j^\vee-1}P_{n_j^\wedge}).$$

Finally, choosing $i=j$ in (5.22b) yields a linear system of $h_j^\wedge-1$ equations for $e_j^\wedge:=t_{j,j}^\wedge$:

$$\text{(5.24b)}\qquad \Phi(z^{n_j^\wedge+k}\,e_j^\wedge\,P_{n_j^\wedge})+\varphi_j^\wedge\Phi(z^{n_j^\wedge+k}\,P'_{n_{j-1}^\vee})=\Phi(z^{n_j^\wedge+k}\,W_{h_j^\wedge-1}\,P_{n_j^\wedge}),$$
$$k=1,\dots,h_j^\wedge-1.$$

Here also, if $e_j^\wedge$ is expressed in a basis of polynomials with ascending degrees, the coefficient matrix of this system is right lower triangular and regular, with antidiagonal elements $\delta_j^\wedge\neq 0$. If the monomial basis is used, the matrix is again Hankel.

Summarizing, we get the following theorem.

THEOREM 5.3. *The regular* FOP1*s* $P_{n_j^\wedge}$, $j=0,\dots,J^\wedge$, *and* $P'_{n_j^\vee}$, $j=0,\dots,J^\vee$, *of the block staircase sequence starting at* $(0,n_0^\wedge)=(0,l)$ *satisfy a pair of mixed three-term recurrence formulas:*

$$\text{(5.25a)}\quad P'_{n_j^\vee}(z)=[W_{h_j^\wedge-1}(z)-e_j^\wedge(z)]P_{n_j^\wedge}(z)-\varphi_j^\wedge P'_{n_{j-1}^\vee}(z),\quad j=0,1,\dots,J^\vee,$$
$$\text{(5.25b)}\quad P_{n_{j+1}^\wedge}(z)=[zW_{h_j^\vee-1}(z)-ze_j^\vee(z)]P'_{n_j^\vee}(z)-\varphi_j^\vee P_{n_j^\wedge}(z),\quad j=0,1,\dots,J^\wedge-1,$$

with initial values $P'_{n_{-1}^\vee}(z):\equiv 0$, $P_{n_0^\wedge}(z):\equiv 1$, $\varphi_0^\wedge:=0$. $\{W_m\}_{m=0}^\infty$ *is an arbitrary prescribed sequence of monic polynomials of respective degree* m; $\{\varphi_j^\wedge\}_{j=0}^{J^\vee}$ *and* $\{\varphi_j^\vee\}_{j=0}^{J^\wedge-1}$

are sequences of uniquely determined nonzero complex constants, each of which is given by (5.24a) *or* (5.17a), *respectively; and* $\{e_j^\wedge\}_{j=0}^{J^\vee}$ *and* $\{e_j^\vee\}_{j=0}^{J^\wedge-1}$ *are sequences of complex polynomials of respective degree* $\partial e_j^\wedge \le h_j^\wedge - 2$ *and* $\partial e_j^\vee \le h_j^\vee - 2$, *each of which is the unique solution of a linear system* (5.24b) *or* (5.17b), *respectively.* ($e_j^\wedge(z) \equiv 0$ *if* $h_j^\wedge = 1$, *and* $e_j^\vee(z) \equiv 0$ *if* $h_j^\vee = 1$.) *The integers* $h_j^\wedge$ *and* $h_j^\vee$ *are determined by* (5.5) *and* (5.9), *respectively, i.e.,*

$$h_j^\wedge := \min\{k \in \mathbb{N}^+;\ \Phi(z^{n_j^\wedge + k - 1} P_{n_j^\wedge}) \neq 0\} \tag{5.26a}$$
$$= \min\{k \in \mathbb{N}^+;\ \Phi(W_{k-1}(P_{n_j^\wedge})^2) \neq 0\},$$

$$h_j^\vee := \min\{k \in \mathbb{N}^+;\ \Phi(z^{n_j^\vee + k} P'_{n_j^\vee}) \neq 0\} \tag{5.26b}$$
$$= \min\{k \in \mathbb{N}^+;\ \Phi(zW_{k-1}(P'_{n_j^\vee})^2) \neq 0\}.$$

Similar recurrences, which, however, involve all regular FOP1s on both diagonals, have been given by Draux [6, pp. 394–398].

As in §2 we could state as corollaries the special results obtained for the cases where the polynomials W_m satisfy a three-term recurrence and where the polynomials $e_j^\wedge$ and $e_j^\vee$ are expressed as linear combinations of these W_m. At this point, the formulation of these results is left to the reader, but in §6 we will give their matrix formulation.

Theorem 5.3 allows us to construct recursively the sequence $P_{n_0^\wedge}$, $P'_{n_0^\vee}$, $P_{n_1^\wedge}$, $P'_{n_1^\vee}$, $P_{n_2^\wedge}, \ldots$ that contains all essentially distinct regular FOP1s on two adjacent diagonals. However, as is apparent from Fig. 3, each of the sequences $\{P_{n_j^\wedge}\}_{j=0}^{J^\wedge}$ and $\{P'_{n_j^\vee}\}_{j=0}^{J^\vee}$ in general does not contain all regular FOP1s of the corresponding diagonal. If $n_j^\vee > n_j^\wedge$, then $P_{n_j^\wedge}$ is also a regular element of the lower ($^\vee$) diagonal, and if $n_{j+1}^\wedge > n_j^\vee + 1$, then $zP'_{n_j^\vee}$ is also a regular element of the upper ($^\wedge$) diagonal. To obtain two full sequences of FOP1s, we use additionally the definition (1.28):

$$P_n(z) := \begin{cases} W_{n-n_j^\wedge}(z) P_{n_j^\wedge}(z) & \text{if } n_j^\wedge \le n \le n_j^\vee \quad (= n_j^\wedge + h_j^\wedge - 1), \\ zW_{n-n_j^\vee - 1}(z) P'_{n_j^\vee}(z) & \text{if } n_j^\vee < n < n_{j+1}^\wedge \quad (= n_j^\vee + h_j^\vee); \end{cases} \tag{5.27a}$$

$$P'_n(z) := \begin{cases} W_{n-n_j^\wedge}(z) P_{n_j^\wedge}(z) & \text{if } n_j^\wedge \le n < n_j^\vee \quad (= n_j^\wedge + h_j^\wedge - 1), \\ W_{n-n_j^\vee}(z) P'_{n_j^\vee}(z) & \text{if } n_j^\vee \le n < n_{j+1}^\wedge \quad (= n_j^\vee + h_j^\vee). \end{cases} \tag{5.27b}$$

Then, clearly,

$$P'_n(z) = P_n(z) \quad \text{if } n_j^\wedge \le n < n_j^\vee, \tag{5.28a}$$
$$P_n(z) = zP'_{n-1}(z) \quad \text{if } n_j^\vee < n < n_{j+1}^\wedge. \tag{5.28b}$$

Equations (5.27) and (5.28) allow us to modify the recurrences (5.25) in several ways.

If the three-term recurrence (2.10) is assumed to hold, we have moreover

$$P_{n+1}(z) = (z - \alpha^W_{n-n_j^\wedge}) P_n(z) - \beta^W_{n-n_j^\wedge} P_{n-1}(z), \quad n_j^\wedge \le n \le n_j^\vee - 1, \tag{5.29a}$$
$$P'_{n+1}(z) = (z - \alpha^W_{n-n_j^\vee}) P'_n(z) - \beta^W_{n-n_j^\vee} P'_{n-1}(z), \quad n_j^\vee \le n \le n_{j+1}^\wedge - 2. \tag{5.29b}$$

Here, by (5.28), the terms $zP_n(z)$ and $zP'_n(z)$ on the right-hand side can be replaced by $zP'_n(z)$ and $P_{n+1}(z)$, respectively:

$$zP'_n(z) = P_{n+1}(z) + \alpha^W_{n-n_j^\wedge} P_n(z) + \beta^W_{n-n_j^\wedge} P_{n-1}(z), \quad n_j^\wedge \le n \le n_j^\vee - 1, \tag{5.30a}$$
$$P_{n+1}(z) = P'_{n+1}(z) + \alpha^W_{n-n_j^\vee} P'_n(z) + \beta^W_{n-n_j^\vee} P'_{n-1}(z), \quad n_j^\vee \le n \le n_{j+1}^\wedge - 2. \tag{5.30b}$$

It is also worth noting that the terms $e_j^\wedge(z)P_{n_j^\wedge}(z)$ and $ze_j^\vee(z)P'_{n_j^\vee}(z)$, which appear in (5.25) and are only nonzero if $h_j^\wedge > 1$ and $h_j^\vee > 1$, respectively, are, according to (5.28), equal to $e_j^\wedge(z)P'_{n_j^\wedge}(z)$ and $e_j^\vee(z)P_{n_j^\vee+1}(z)$, respectively. In view of the definitions (5.27), the terms $W_{h_j^\wedge-1}(z)P_{n_j^\wedge}(z)$ and $W_{h_j^\vee-1}(z)P'_{n_j^\vee}(z)$ can be written as $P_{n_j^\vee}(z)$ and $P'_{n_{j+1}^\wedge-1}(z)$, so that the recurrences (5.25) become

$$\text{(5.31a)}\quad P'_{n_j^\vee}(z) = P_{n_j^\vee}(z) - e_j^\wedge(z)P_{n_j^\wedge}^{(\prime)}(z) - \varphi_j^\wedge P'_{n_{j-1}}(z), \quad j = 0,1,\dots,J^\vee,$$

$$\text{(5.31b)}\quad P_{n_{j+1}^\wedge}(z) = zP'_{n_{j+1}^\wedge-1}(z) - e_j^\vee(z)P_{n_j^\vee+1}(z) - \varphi_j^\vee P_{n_j^\wedge}(z), \quad j = 0,1,\dots,J^\wedge - 1.$$

The notation $P_n^{(\prime)}$ indicates here and below that one can use either P_n or P'_n.

Finally, in view of the later application to the nongeneric BCG process, we give the analog of Theorem 2.9. By an argument based on the orthogonality relations (5.5) and (5.9), which is analogous to the one for establishing (2.22), and by using (5.27), we obtain:

$$\text{(5.32a)}\quad \varphi_j^\wedge = \delta_j^\wedge/\delta_{j-1}^\vee, \quad \text{where } \delta_{j-1}^\vee = \Phi(zP_{n_j^\wedge-1}^{(\prime)}P'_{n_{j-1}^\vee}),\ \delta_j^\wedge = \Phi(P_{n_j^\vee}P_{n_j^\wedge}),$$

$$\text{(5.32b)}\quad \Phi(e_j^\wedge P_{n_j^\wedge+k}P_{n_j^\wedge}) = \Phi(P_{n_j+k}P_{n_j^\vee}), \quad k = 1,\dots,h_j^\wedge - 1;$$

$$\text{(5.32c)}\quad \varphi_j^\vee = \delta_j^\vee/\delta_j^\wedge, \quad \text{where } \delta_j^\wedge = \Phi(P_{n_j^\vee}^{(\prime)}P_{n_j^\wedge}),\ \delta_j^\vee = \Phi(zP_{n_{j+1}^\wedge-1}^{(\prime)}P'_{n_j^\vee}),$$

$$\text{(5.32d)}\quad \Phi(ze_j^\vee P'_{n_j^\vee+k}P'_{n_j^\vee}) = \Phi(zP'_{n_j^\vee+k}P'_{n_{j+1}^\wedge-1}), \quad k = 1,\dots,h_j^\vee - 1.$$

If (2.10) holds, we may insert $P_{n_j^\vee}$ and $P'_{n_{j+1}^\wedge-1}$ into (5.32b) and (5.32d), according to (5.29). We may also use (5.28b), although, in contrast to the situation in §2, there is no need to do that:

$$\text{(5.32e)}\quad \Phi(e_j^\wedge P_{n_j^\wedge+k}P_{n_j^\wedge}) = \Phi(P_{n_j^\wedge+k}(zP_{n_j^\vee-1} - \alpha_{h_j^\wedge-2}^W P_{n_j^\vee-1} - \beta_{h_j^\wedge-2}^W P_{n_j^\vee-2})), \quad k = 1,\dots,h_j^\wedge - 1,$$

$$\text{(5.32f)}\quad \Phi(e_j^\vee P'_{n_j^\vee+k}P_{n_j^\vee+1}) = \Phi(P'_{n_j^\vee+k}(zP_{n_{j+1}^\wedge-1} - \alpha_{h_j^\vee-2}^W P_{n_{j+1}^\wedge-1} - \beta_{h_j^\vee-2}^W P_{n_{j+1}^\wedge-2})), \quad k = 1,\dots,h_j^\vee - 1.$$

THEOREM 5.4. *The linear systems* (5.24) *and* (5.17) *for computing the polynomials* $e_j^\wedge$, $e_j^\vee$ *and the constants* $\varphi_j^\wedge$, $\varphi_j^\vee$ *can be replaced by the equivalent system* (5.32a)–(5.32d) *consisting of single equations for* $\varphi_j^\wedge$ *and* $\varphi_j^\vee$, *and of a right lower triangular systems for the coefficients of* $e_j^\wedge$ *and* $e_j^\wedge$. *If* (2.10) *holds, we may replace* (5.32b) *by* (5.32e), *and* (5.32d) *by* (5.32f).

6. Matrix interpretations of staircase recurrences. In this section we give a matrix formulation of Theorem 5.3 on the mixed three-term recurrences for block staircase sequences of orthogonal polynomials. It is analogous to the matrix formulation in Theorem 3.1 for the diagonal three-term recurrence (Theorem 2.7 and Corollary 2.8). Whereas a block tridiagonal matrix $\mathbf{H}$ emerged there, we first find here two block diagonal matrices, $\mathbf{E}^\vee$ and $\mathbf{E}^\wedge$, and a lower and an upper block bidiagonal matrix, $\mathbf{F}^\vee$ and $\mathbf{F}^\wedge$, respectively. They give rise to two further block bidiagonal matrices $\mathbf{G}^\vee := \mathbf{F}^\vee(\mathbf{E}^\vee)^{-1}$ and $\mathbf{G}^\wedge := \mathbf{F}^\wedge(\mathbf{E}^\wedge)^{-1}$, which turn out to be block LU factors of $\mathbf{H}$, but also block UL factors of another matrix $\mathbf{H}'$ of the same structure, which belong to the functional Φ' instead of to Φ.

Again, we assume in view of the later application to the BCG method that the polynomial basis $\{W_m\}$ satisfies the three-term recurrence (2.10) whose matrix formulation is given by (3.1)–(3.3). Then Theorem 5.3, the definitions (5.27), and the relations (5.28) and (5.30) easily yield the following theorem.

THEOREM 6.1. *Let $\{P_n\}$ and $\{P'_n\}$ be the sequences of* FOP1s *corresponding to the functionals Φ and Φ', respectively, uniquely specified by* (5.27), *where $\{W_m\}$ is a sequence satisfying the three-term recurrence* (2.10) (*possibly with $\alpha_m^W = \beta_m^W = 0$, $\forall m \in \mathbb{N}$*). *Define the infinite row vectors*

$$\mathbf{p} := [P_0, P_1, \ldots], \quad \mathbf{p}' := [P'_0, P'_1, \ldots], \tag{6.1}$$

and, for finite or infinite value of $J^\wedge$, the infinite matrices

$$\mathbf{E}^\vee := \text{block diag}\,[\mathbf{E}_0^\vee, \mathbf{E}_1^\vee, \ldots, \mathbf{E}_{J^\wedge}^\vee], \quad \mathbf{E}^\wedge := \text{block diag}\,[\mathbf{E}_0^\wedge, \mathbf{E}_1^\wedge, \ldots, \mathbf{E}_{J^\wedge}^\wedge], \tag{6.2}$$

with square blocks $\mathbf{E}_j^\vee$ and $\mathbf{E}_j^\wedge$ of order $h_j^\wedge + h_j^\vee - 1$ that for $j = 0, \ldots, J^\wedge - 1$ are given by

$$\mathbf{E}_j^\vee := \left[\begin{array}{c|c|c} \mathbf{I}_j^\wedge & \mathbf{O} & \mathbf{0} \\ \hline \mathbf{O} & \mathbf{I}_j^\vee & -\mathbf{e}_j^\vee \\ \hline \mathbf{0}^{\mathbf{T}} & \mathbf{0}^{\mathbf{T}} & 1 \end{array}\right], \quad \mathbf{E}_j^\wedge := \left[\begin{array}{c|c|c} \mathbf{I}_j^\wedge & -\mathbf{e}_j^\wedge & \mathbf{O} \\ \hline \mathbf{0}^{\mathbf{T}} & 1 & \mathbf{0}^{\mathbf{T}} \\ \hline \mathbf{O} & \mathbf{0} & \mathbf{I}_j^\vee \end{array}\right]. \tag{6.3}$$

Here, $\mathbf{I}_j^\wedge$ and $\mathbf{I}_j^\vee$ are the unit matrices of order $h_j^\wedge - 1$ and $h_j^\vee - 1$, respectively, and the row vectors

$$\mathbf{e}_j^\vee := [\varepsilon_{0,j}^\vee, \varepsilon_{1,j}^\vee, \ldots, \varepsilon_{h_j^\vee - 2,j}^\vee]^T, \quad \mathbf{e}_j^\wedge := [\varepsilon_{0,j}^\wedge, \varepsilon_{1,j}^\wedge, \ldots, \varepsilon_{h_j^\wedge - 2,j}^\wedge]^T \tag{6.4}$$

contain the coefficients of the polynomials

$$e_j^\vee(z) = \sum_{i=0}^{h_j^\vee - 2} \varepsilon_{i,j}^\vee W_i(z), \quad e_j^\wedge(z) = \sum_{i=0}^{h_j^\wedge - 2} \varepsilon_{i,j}^\wedge W_i(z) \tag{6.5}$$

from Theorem 5.3, *expressed in terms of the basis $\{W_m\}$. If $h_j^\wedge = 1$ or $h_j^\vee = 1$, the rows and columns containing $\mathbf{I}_j^\wedge$ and $\mathbf{I}_j^\vee$, respectively, are missing in $\mathbf{E}_j^\vee$ and $\mathbf{E}_j^\wedge$. If $J^\wedge < \infty$ (and thus $J^\vee < \infty$ also), then $\mathbf{E}_{J^\wedge}^\vee := \mathbf{I}$ (the infinite unit matrix); if $J^\vee = J^\wedge - 1$, $\mathbf{E}_{J^\wedge}^\wedge := \mathbf{I}$ also, while, if $J^\vee = J^\wedge$, then $\mathbf{E}_{J^\wedge}^\wedge$ has the same structure as in* (6.3), *with $\mathbf{I}_{J^\wedge}^\vee := \mathbf{I}$.*

Also define the infinite block bidiagonal matrices

$$\mathbf{F}^\vee := \begin{bmatrix} \mathbf{F}_0^\vee & & & & \\ \mathbf{L}_0^\vee & \mathbf{F}_1^\vee & & & \\ & \mathbf{L}_1^\vee & \mathbf{F}_2^\vee & & \\ & & \ddots & \ddots & \\ & & & \mathbf{L}_{J^\wedge-1}^\vee & \mathbf{F}_{J^\wedge}^\vee \end{bmatrix}, \quad \mathbf{F}^\wedge := \begin{bmatrix} \mathbf{L}_0^\wedge & \mathbf{F}_1^\wedge & & & \\ & \mathbf{L}_1^\wedge & \mathbf{F}_2^\wedge & & \\ & & \mathbf{L}_2^\wedge & \ddots & \\ & & & \ddots & \mathbf{F}_{J^\wedge}^\wedge \\ & & & & \mathbf{L}_{J^\wedge}^\wedge \end{bmatrix}, \tag{6.6}$$

with square blocks $\mathbf{F}_j^\vee$ and $\mathbf{L}_j^\wedge$ of order $h_j^\wedge + h_j^\vee - 1$, whose upper left corner is the $(n_j^\wedge, n_j^\wedge)$-entry[3] *of $\mathbf{F}^\vee$ and $\mathbf{F}^\wedge$, respectively, and which for $j = 0, 1, \ldots, J^\wedge - 1$ are*

[3] The entries in the upper left corner of $\mathbf{F}^\vee$ and $\mathbf{F}^\wedge$ are considered as (0,0)-entries. The entries in the subblocks are in this text identified by their indices in the full matrix, e.g., the $(n_j^\wedge, n_j^\wedge)$ entry of $\mathbf{F}_j^\vee$ is the same as the $(n_j^\wedge, n_j^\wedge)$ entry of $\mathbf{F}^\vee$. Likewise, the $n_j^\wedge$th row (column) of $\mathbf{F}_j^\vee$ is the $n_j^\wedge$th row (column) of $\mathbf{F}^\vee$.

given as follows: If $h_j^\wedge > 1$ *and* $h_j^\vee > 1$,

$$\text{(6.7a)}\qquad \mathbf{F}_j^\vee := \left[\begin{array}{c|c|c} \mathbf{T}_j^\wedge & \mathbf{O} & \mathbf{f}_j^\vee \\ \hline \mathbf{l}_j^{\wedge T} & \mathbf{0}^T & 0 \\ \hline \mathbf{O} & \mathbf{I}_j^\vee & \mathbf{0} \end{array}\right], \quad \mathbf{L}_j^\wedge := \left[\begin{array}{c|c|c} \mathbf{I}_j^\wedge & \mathbf{0} & \mathbf{O} \\ \hline \mathbf{O} & \mathbf{c}_j^\vee & \mathbf{T}_j^\vee \\ \hline \mathbf{0}^T & 0 & \mathbf{l}_j^{\vee T} \end{array}\right];$$

whereas, if $h_j^\wedge = 1$ *and* $h_j^\vee > 1$,

$$\text{(6.7b)}\qquad \mathbf{F}_j^\vee := \left[\begin{array}{c|c} \mathbf{0}^T & \varphi_j^\vee \\ \hline \mathbf{I}_j^\vee & \mathbf{0} \end{array}\right], \quad \mathbf{L}_j^\wedge := \left[\begin{array}{c|c} \mathbf{c}_j^\vee & \mathbf{T}_j^\vee \\ \hline 0 & \mathbf{l}_j^{\vee T} \end{array}\right];$$

and, if $h_j^\wedge > 1$ *and* $h_j^\vee = 1$,

$$\text{(6.7c)}\qquad \mathbf{F}_j^\vee := \left[\begin{array}{c|c} \mathbf{T}_j^\wedge & \mathbf{f}_j^\vee \\ \hline \mathbf{l}_j^{\wedge T} & 0 \end{array}\right], \quad \mathbf{L}_j^\wedge := \left[\begin{array}{c|c} \mathbf{I}_j^\wedge & \mathbf{0} \\ \hline \mathbf{0}^T & 1 \end{array}\right],$$

which reduces even further to

$$\text{(6.7d)}\qquad \mathbf{F}_j^\vee := [\varphi_j^\vee], \quad \mathbf{L}_j^\wedge := [1],$$

if both $h_j^\wedge = 1$ *and* $h_j^\vee = 1$. *If* $\mathbf{T}_m^W$ *denotes the tridiagonal matrix of order* $m+1$ *with entries* β_k^W, α_k^W *and* 1 *in its* $(k+1)$*th column, cf.* (3.2), *then the blocks* $\mathbf{F}_j^\vee$, $\mathbf{F}_j^\wedge$, $\mathbf{L}_j^\vee$, *and* $\mathbf{L}_j^\wedge$ *contain*

$$\text{(6.8a)}\qquad \mathbf{T}_j^\wedge := \mathbf{T}_{h_j^\wedge - 2}^W, \quad \mathbf{T}_j^\vee := \mathbf{T}_{h_j^\vee - 2}^W,$$

$$\text{(6.8b)}\qquad \mathbf{f}_j^\wedge := [\varphi_j^\wedge, 0, \ldots, 0]^T \in \mathbf{C}^{h_j^\vee - 1}, \quad \mathbf{f}_j^\vee := [\varphi_j^\vee, 0, \ldots, 0]^T \in \mathbf{C}^{h_j^\wedge - 1},$$

$$\text{(6.8c)}\qquad \mathbf{c}_j^\wedge := [1, 0, \ldots, 0]^T \in \mathbf{C}^{h_j^\wedge - 1}, \quad \mathbf{c}_j^\vee := [1, 0, \ldots, 0]^T \in \mathbf{C}^{h_j^\vee - 1},$$

$$\text{(6.8d)}\qquad \mathbf{l}_j^{\wedge T} := [0, \ldots, 0, 1] \in \mathbf{C}^{h_j^\wedge - 1}, \quad \mathbf{l}_j^{\vee T} := [0, \ldots, 0, 1] \in \mathbf{C}^{h_j^\vee - 1}.$$

If $J^\vee = J^\wedge - 1 < \infty$,

$$\text{(6.8e)}\qquad \mathbf{F}_{J^\wedge}^\vee := \mathbf{T}^W, \quad \mathbf{L}_{J^\wedge}^\wedge := \mathbf{I},$$

while, if $J^\vee = J^\wedge < \infty$,

$$\text{(6.8f)}\qquad \mathbf{F}_{J^\wedge}^\vee := \left[\begin{array}{c|c} \mathbf{T}_{J^\wedge}^\wedge & \mathbf{O} \\ \mathbf{l}_{J^\wedge}^{\wedge T} & \mathbf{0}^T \\ \mathbf{O} & \mathbf{I} \end{array}\right], \quad \mathbf{L}_{J^\wedge}^\wedge := \left[\begin{array}{c|c|c} \mathbf{I}_{J^\wedge}^\wedge & \mathbf{0} & \mathbf{O} \\ \mathbf{O} & \mathbf{c}_{J^\wedge}^\vee & \mathbf{T}^W \end{array}\right],$$

where $\mathbf{c}_{J^\wedge}^\vee = [1, 0, 0, \ldots]^T$ *has infinitely many components.*

The off-diagonal blocks $\mathbf{F}_j^\wedge$ *and* $\mathbf{L}_j^\vee$ *are rank-one matrices of size* $(h_{j-1}^\wedge + h_{j-1}^\vee - 1) \times (h_j^\wedge + h_j^\vee - 1)$ *and* $(h_{j+1}^\wedge + h_{j+1}^\vee - 1) \times (h_j^\wedge + h_j^\vee - 1)$, *respectively. Each has a single nonzero element, namely, the* $(n_{j-1}^\vee, n_j^\vee)$ *entry* $\varphi_j^\wedge$ *of* $\mathbf{F}^\wedge$ *and the* $(n_{j+1}^\wedge, n_{j+1}^\wedge - 1)$ *entry* 1 *of* $\mathbf{F}^\vee$, *which lies in the upper right corner of* $\mathbf{L}_j^\vee$. *If* $j < J^\wedge$ *and* $h_{j-1}^\wedge, h_{j-1}^\vee, h_j^\wedge, h_j^\vee$, $h_{j+1}^\wedge$, $h_{j+1}^\vee > 1$, *then* $\mathbf{F}_j^\wedge$ *and* $\mathbf{L}_j^\vee$ *have the structure*

$$\text{(6.9)}\qquad \mathbf{F}_j^\wedge := \left[\begin{array}{c|c|c} \mathbf{O} & \mathbf{0} & \mathbf{O} \\ \hline \mathbf{O} & \mathbf{f}_j^\wedge & \mathbf{O} \\ \hline \mathbf{0}^T & 0 & \mathbf{0}^T \end{array}\right], \quad \mathbf{L}_j^\vee := \left[\begin{array}{c|c|c} \mathbf{O} & \mathbf{O} & \mathbf{c}_j^\wedge \\ \hline \mathbf{0}^T & \mathbf{0}^T & 0 \\ \hline \mathbf{O} & \mathbf{O} & \mathbf{0} \end{array}\right],$$

with diagonal blocks of order $(h^{\wedge}_{j-1}-1)\times(h^{\wedge}_{j}-1)$, $(h^{\vee}_{j-1}-1)\times 1$, $1\times(h^{\vee}_{j}-1)$, *and* $(h^{\wedge}_{j+1}-1)\times(h^{\wedge}_{j}-1)$, $1\times(h^{\vee}_{j}-1)$, $(h^{\vee}_{j+1}-1)\times 1$, *respectively. If one or several of these sizes are zero, the structure is again modified, but the nonzero entry of* $\mathbf{L}^{\vee}_{j}$ *is always in the upper right corner; the one of* $\mathbf{F}^{\wedge}_{j}$ *is in the first column if* $h^{\wedge}_{j}=1$, *in the last column if* $h^{\vee}_{j}=1$, *in the first row if* $h^{\wedge}_{j-1}$, *and in the last row if* $h^{\vee}_{j-1}=1$. *If* $J^{\vee}=J^{\wedge}-1<\infty$, $\mathbf{F}^{\wedge}_{J^{\wedge}}=\mathbf{O}$; *and if* $J^{\vee}=J^{\wedge}<\infty$, $\mathbf{F}^{\wedge}_{J^{\wedge}}$ *has the same structure as in* (6.9), *but the last block column is infinitely wide.*

In terms of the above-defined quantities, the mixed recurrences (5.25) *for the sequences* $\{P_{n^{\wedge}_{j}}\}$ *and* $\{P'_{n^{\vee}_{j}}\}$ *can be written as*

$$\mathbf{p}(z)\mathbf{E}^{\wedge}=\mathbf{p}'(z)\mathbf{F}^{\wedge}, \tag{6.10a}$$

$$z\mathbf{p}'(z)\mathbf{E}^{\vee}=\mathbf{p}(z)\mathbf{F}^{\vee}. \tag{6.10b}$$

Likewise, if $\mathbf{E}^{\vee}_{[n]},\mathbf{E}^{\wedge}_{[n]},\mathbf{F}^{\vee}_{[n]},\mathbf{F}^{\wedge}_{[n]}$ *denote the principal submatrices of order* $n+1$ *of* $\mathbf{E}^{\vee},\mathbf{E}^{\wedge},\mathbf{F}^{\vee}$, *and* $\mathbf{F}^{\wedge}$, *respectively, and if*

$$\mathbf{p}_n:=[P_0,P_1,\dots,P_n],\quad \mathbf{p}'_n:=[P'_0,P'_1,\dots,P'_n], \tag{6.11}$$

then we have

$$\mathbf{p}_n(z)\mathbf{E}^{\wedge}_{[n]}=\mathbf{p}'_n(z)\mathbf{F}^{\wedge}_{[n]}, \tag{6.12a}$$

$$z\mathbf{p}'_n(z)\mathbf{E}^{\vee}_{[n]}=\mathbf{p}_n(z)\mathbf{F}^{\vee}_{[n]}+[0,\dots,0,P_{n+1}(z)]\,. \tag{6.12b}$$

Remarks. (i) $\mathbf{E}^{\vee}$ and $\mathbf{E}^{\wedge}$ are unit upper triangular and block diagonal, and the same holds for their inverses, which have the blocks

$$(\mathbf{E}^{\vee}_{j})^{-1}=\left[\begin{array}{c|c|c}\mathbf{I}^{\wedge}_{j} & \mathbf{O} & \mathbf{0}\\ \hline \mathbf{O} & \mathbf{I}^{\vee}_{j} & \mathbf{e}^{\vee}_{j}\\ \hline \mathbf{0}^{T} & \mathbf{0}^{T} & 1\end{array}\right],\quad (\mathbf{E}^{\wedge}_{j})^{-1}=\left[\begin{array}{c|c|c}\mathbf{I}^{\wedge}_{j} & \mathbf{e}^{\wedge}_{j} & \mathbf{O}\\ \hline \mathbf{0}^{T} & 1 & \mathbf{0}^{T}\\ \hline \mathbf{O} & \mathbf{0} & \mathbf{I}^{\vee}_{j}\end{array}\right], \tag{6.13}$$

differing from $\mathbf{E}^{\vee}_{j}$ and $\mathbf{E}^{\wedge}_{j}$ by the missing minus sign in front of $\mathbf{e}^{\vee}_{j}$ and $\mathbf{e}^{\wedge}_{j}$ only.

(ii) $\mathbf{F}^{\vee}$ is unit upper Hessenberg, and $\mathbf{F}^{\wedge}$ is unit upper triangular.

(iii) If $h^{\wedge}_{j}=h^{\vee}_{j}=1$ $(\forall j)$, $\mathbf{E}^{\vee}$ and $\mathbf{E}^{\wedge}$ are the infinite unit matrix, and $\mathbf{F}^{\vee}$ and $\mathbf{F}^{\wedge}$ are lower and upper bidiagonal,

$$\mathbf{F}^{\vee}=\begin{bmatrix}\varphi^{\vee}_{0} & & & \\ 1 & \varphi^{\vee}_{1} & & \\ & 1 & \varphi^{\vee}_{2} & \\ & & \ddots & \ddots\end{bmatrix},\quad \mathbf{F}^{\wedge}=\begin{bmatrix}1 & \varphi^{\wedge}_{1} & & \\ & 1 & \varphi^{\wedge}_{2} & \\ & & 1 & \ddots\\ & & & \ddots\end{bmatrix}. \tag{6.14}$$

By using (6.13), we can readily turn the relations (6.10) into formally explicit formulas for $\mathbf{p}$ and $\mathbf{p}'$, which, however, are used in an implicit way as recurrences for the elements of $\mathbf{p}'$ and $\mathbf{p}$, respectively, appearing on the right-hand side.

COROLLARY 6.2. *Under the assumptions of Theorem* 6.1, *there holds*

$$\mathbf{p}(z)=\mathbf{p}'(z)\,\mathbf{G}^{\wedge} \tag{6.15a}$$

and

$$z\mathbf{p}'(z)=\mathbf{p}(z)\,\mathbf{G}^{\vee}, \tag{6.15b}$$

where

$$\mathbf{G}^{\vee} = \mathbf{F}^{\vee}(\mathbf{E}^{\vee})^{-1} := \begin{bmatrix} \mathbf{G}_0^{\vee} & & & & \\ \mathbf{L}_0^{\vee} & \mathbf{G}_1^{\vee} & & & \\ & \mathbf{L}_1^{\vee} & \mathbf{G}_2^{\vee} & & \\ & & \ddots & \ddots & \\ & & & \mathbf{L}_{J^{\wedge}-1}^{\vee} & \mathbf{G}_{J^{\wedge}}^{\vee} \end{bmatrix} \tag{6.16a}$$

and

$$\mathbf{G}^{\wedge} = \mathbf{F}^{\wedge}(\mathbf{E}^{\wedge})^{-1} := \begin{bmatrix} \mathbf{G}_0^{\wedge} & \mathbf{F}_1^{\wedge} & & & \\ & \mathbf{G}_1^{\wedge} & \mathbf{F}_2^{\wedge} & & \\ & & \mathbf{G}_2^{\wedge} & \ddots & \\ & & & \ddots & \mathbf{F}_{J^{\wedge}}^{\wedge} \\ & & & & \mathbf{G}_{J^{\wedge}}^{\wedge} \end{bmatrix} \tag{6.16b}$$

have the same off-diagonal blocks as $\mathbf{F}^{\vee}$ *and* $\mathbf{F}^{\wedge}$. *The diagonal blocks* $\mathbf{G}_j^{\vee}$ *and* $\mathbf{G}_j^{\wedge}$, $j = 0, 1, \ldots, J^{\wedge} - 1$, *are defined as follows: If* $h_j^{\wedge} > 1$ *and* $h_j^{\vee} > 1$,

$$\mathbf{G}_j^{\vee} := \left[\begin{array}{c|c|c} \mathbf{T}_j^{\wedge} & \mathbf{O} & \mathbf{f}_j^{\vee} \\ \hline \mathbf{l}_j^{\wedge T} & \mathbf{0}^T & 0 \\ \hline \mathbf{O} & \mathbf{I}_j^{\vee} & \mathbf{e}_j^{\vee} \end{array}\right], \quad \mathbf{G}_j^{\wedge} := \left[\begin{array}{c|c|c} \mathbf{I}_j^{\wedge} & \mathbf{e}_j^{\wedge} & \mathbf{O} \\ \hline \mathbf{O} & \mathbf{c}_j^{\vee} & \mathbf{T}_j^{\vee} \\ \hline \mathbf{0}^T & 0 & \mathbf{l}_j^{\vee T} \end{array}\right]; \tag{6.17a}$$

whereas, if $h_j^{\wedge} = 1$ *and* $h_j^{\vee} > 1$,

$$\mathbf{G}_j^{\vee} := \left[\begin{array}{c|c} \mathbf{0}^T & \varphi_j^{\vee} \\ \hline \mathbf{I}_j^{\vee} & \mathbf{e}_j^{\vee} \end{array}\right], \quad \mathbf{G}_j^{\wedge} := \left[\begin{array}{c|c} \mathbf{c}_j^{\vee} & \mathbf{T}_j^{\vee} \\ \hline 0 & \mathbf{l}_j^{\vee T} \end{array}\right] = \mathbf{L}_j^{\wedge}; \tag{6.17b}$$

if $h_j^{\wedge} > 1$ *and* $h_j^{\vee} = 1$,

$$\mathbf{G}_j^{\vee} := \left[\begin{array}{c|c} \mathbf{T}_j^{\wedge} & \mathbf{f}_j^{\vee} \\ \hline \mathbf{l}_j^{\wedge T} & 0 \end{array}\right] = \mathbf{F}_j^{\vee}, \quad \mathbf{G}_j^{\wedge} := \left[\begin{array}{c|c} \mathbf{I}_j^{\wedge} & \mathbf{e}_j^{\wedge} \\ \hline \mathbf{0}^T & 1 \end{array}\right]; \tag{6.17c}$$

and, if both $h_j^{\wedge} = 1$ *and* $h_j^{\vee} = 1$,

$$\mathbf{G}_j^{\vee} := [\varphi_j^{\vee}] = \mathbf{F}_j^{\vee}, \quad \mathbf{G}_j^{\wedge} := [1] = \mathbf{L}_j^{\wedge}. \tag{6.17d}$$

If $J^{\vee} = J^{\wedge} - 1 < \infty$,

$$\mathbf{G}_{J^{\wedge}}^{\vee} := \mathbf{F}_{J^{\wedge}}^{\vee} = \mathbf{T}^W, \quad \mathbf{G}_{J^{\wedge}}^{\wedge} := \mathbf{L}_{J^{\wedge}}^{\wedge} = \mathbf{I}, \tag{6.17e}$$

while, if $J^{\vee} = J^{\wedge} < \infty$,

$$\mathbf{G}_{J^{\wedge}}^{\vee} := \mathbf{F}_{J^{\wedge}}^{\vee} := \left[\begin{array}{c|c} \mathbf{T}_{J^{\wedge}}^{\wedge} & \mathbf{O} \\ \mathbf{l}_{J^{\wedge}}^{\wedge T} & 0^T \\ \mathbf{O} & \mathbf{I} \end{array}\right], \quad \mathbf{G}_{J^{\wedge}}^{\wedge} := \left[\begin{array}{c|c|c} \mathbf{I}_{J^{\wedge}}^{\wedge} & \mathbf{e}_{J^{\wedge}}^{\wedge} & \mathbf{O} \\ \mathbf{O} & \mathbf{c}_{J^{\wedge}}^{\vee} & \mathbf{T}^W \end{array}\right]. \tag{6.17f}$$

Note that the two relations (6.15) are just the recurrences (5.30) and (5.31) expressed in matrix notation.

7. Matrix relations between diagonal and staircase recurrences: The nongeneric qd algorithm. From the two relations (6.15) we can eliminate either $\mathbf{p}$ or $\mathbf{p}'$ to obtain

$$z\mathbf{p}(z) = \mathbf{p}(z)\mathbf{G}^\vee\mathbf{G}^\wedge \tag{7.1a}$$

and

$$z\mathbf{p}'(z) = \mathbf{p}'(z)\mathbf{G}^\wedge\mathbf{G}^\vee. \tag{7.1b}$$

However, these are—in matrix notation—just the recurrences for the FOP1s P_n and those for the FOP1s P'_n. Therefore, they must be identical to (3.11), which describes this recurrence for P_n, and with the corresponding relation for the set $\{P'_n\}$, respectively. This leads to the following result.

THEOREM 7.1. *Under the assumptions of Theorem* 6.1 *let* $\mathbf{H}$ *and* $\mathbf{H}'$ *be the block tridiagonal matrices from* (3.6) *that describe, according to* (3.11), *the recurrences for the* FOP1s $\{P_n\}$ *and* $\{P'_n\}$, *respectively, that correspond to the linear functionals* Φ *and* Φ'. *Then* $\mathbf{H}$ *has the block* LU *factorization*

$$\mathbf{H} = \mathbf{G}^\vee\mathbf{G}^\wedge, \tag{7.2a}$$

and $\mathbf{H}'$ *has the block* UL *factorization*

$$\mathbf{H}' = \mathbf{G}^\wedge\mathbf{G}^\vee, \tag{7.2b}$$

1 *and* 2. *There* n_i *and* n'_i *denote the sequences of the indices of the regular* FOP1*s out of* $\{P_n\}$ *and* $\{P'_n\}$, *respectively; the entries of* $\mathbf{H}'$ *are also distinguished by a prime from those of* $\mathbf{H}$. *The functions* Ω_j *and* Ω'_j *are defined by*

$$\Omega_j(\mathbf{e}_j^\wedge, \varphi) := \mathbf{T}^W_{h_j^\wedge - 1}\left[\begin{array}{c}\mathbf{e}_j^\wedge\\ \hline -1\end{array}\right] + \begin{bmatrix}\varphi\\ 0\\ \vdots\\ 0\end{bmatrix}, \tag{7.3a}$$

$$\Omega'_j(\mathbf{e}_j^\vee, \varphi) := \mathbf{T}^W_{h_j^\vee - 1}\left[\begin{array}{c}\mathbf{e}_j^\vee\\ \hline -1\end{array}\right] + \begin{bmatrix}\varphi\\ 0\\ \vdots\\ 0\end{bmatrix}. \tag{7.3b}$$

Remark. In the case $W_m(z) = z^m$, the definitions (7.3) reduce to

$$\Omega_j(\mathbf{e}_j^\wedge, \varphi) := \left[\frac{\varphi}{\mathbf{e}_j^\wedge}\right], \quad \Omega'_j(\mathbf{e}_j^\vee, \varphi) := \left[\frac{\varphi}{\mathbf{e}_j^\vee}\right]. \tag{7.4}$$

Proof. We have already derived (7.2), so it remains to relate the entries of $\mathbf{H}$ and $\mathbf{H}'$ to those of $\mathbf{G}^\vee$ and $\mathbf{G}^\wedge$. For this we need to compute explicitly the elements of the products $\mathbf{G}^\vee\mathbf{G}^\wedge$ and $\mathbf{G}^\wedge\mathbf{G}^\vee$. The task is complicated by the fact that the structure of the blocks depends on the quantities $h_j^\wedge$ and $h_j^\vee$ being larger than or equal to 1.

Let us start with the off-diagonal blocks of the products. First, the $(j+1, j)$-blocks of $\mathbf{G}^\vee\mathbf{G}^\wedge$ and $\mathbf{G}^\wedge\mathbf{G}^\vee$ are $\mathbf{L}_j^\vee\mathbf{G}_j^\wedge = \mathbf{L}_j^\vee$ and $\mathbf{G}_{j+1}^\wedge\mathbf{L}_j^\vee = \mathbf{L}_j^\vee$, respectively. The

$(j-1,1)$-blocks are $\mathbf{G}^{\vee}_{j-1}\mathbf{F}^{\wedge}_{j}$ and $\mathbf{F}^{\wedge}_{j}\mathbf{G}^{\vee}_{j}$, and their structure depends on the value of $h^{\vee}_{j-1}$ and $h^{\wedge}_{j}$, respectively. Since $\mathbf{F}^{\wedge}_{j}$ has only one nonzero entry, namely, the $(n^{\vee}_{j-1}, n^{\vee}_{j})$ entry $\varphi^{\wedge}_{j}$ of $\mathbf{G}^{\wedge}$, only the $n^{\vee}_{j-1}$th column of $\mathbf{G}^{\vee}_{j-1}$ and the $n^{\vee}_{j}$th row of $\mathbf{G}^{\vee}_{j}$ matter. (Columns and rows of the blocks of $\mathbf{G}^{\vee}$ and $\mathbf{G}^{\wedge}$ are here again numbered according to their indices in the whole matrix.) The $n^{\vee}_{j-1}$th column of $\mathbf{G}^{\vee}_{j-1}$ contains 1 as its $(n^{\vee}_{j-1}+1, n^{\vee}_{j-1})$ entry if $h^{\vee}_{j-1} > 1$, and $\varphi^{\vee}_{j-1}$ as its $(n^{\wedge}_{j-1}, n^{\vee}_{j-1})$ entry if $h^{\vee}_{j-1} = 1$. Consequently,

$$[\mathbf{G}^{\vee}_{j-1}\mathbf{F}^{\wedge}_{j}]_{m,n} = \left\{ \begin{array}{ll} \varphi^{\wedge}_{j} & \text{if } (m,n) = (n^{\vee}_{j-1}+1, n^{\vee}_{j}) \\ 0 & \text{otherwise} \end{array} \right\} \text{ if } h^{\vee}_{j-1} > 1, \tag{7.5a}$$

and

$$[\mathbf{G}^{\vee}_{j-1}\mathbf{F}^{\wedge}_{j}]_{m,n} = \left\{ \begin{array}{ll} \varphi^{\vee}_{j-1}\varphi^{\wedge}_{j} & \text{if } (m,n) = (n^{\wedge}_{j-1}, n^{\vee}_{j}) \\ 0 & \text{otherwise} \end{array} \right\} \text{ if } h^{\vee}_{j-1} = 1. \tag{7.5b}$$

The $n^{\vee}_{j}$th row of $\mathbf{G}^{\vee}_{j}$ contains 1 as its $(n^{\vee}_{j}, n^{\vee}_{j}-1)$ entry if $h^{\wedge}_{j} > 1$, and $\varphi^{\vee}_{j}$ as its $(n^{\wedge}_{j}, n^{\wedge}_{j+1}-1)$ entry if $h^{\wedge}_{j} = 1$, so that

$$[\mathbf{F}^{\wedge}_{j}\mathbf{G}^{\vee}_{j}]_{m,n} = \left\{ \begin{array}{ll} \varphi^{\wedge}_{j} & \text{if } (m,n) = (n^{\vee}_{j-1}, n^{\vee}_{j}-1) \\ 0 & \text{otherwise} \end{array} \right\} \text{ if } h^{\wedge}_{j} > 1, \tag{7.6a}$$

and

$$[\mathbf{F}^{\wedge}_{j}\mathbf{G}^{\vee}_{j}]_{m,n} = \left\{ \begin{array}{ll} \varphi^{\vee}_{j}\varphi^{\wedge}_{j} & \text{if } (m,n) = (n^{\vee}_{j-1}, n^{\wedge}_{j+1}-1) \\ 0 & \text{otherwise} \end{array} \right\} \text{ if } h^{\wedge}_{j} = 1. \tag{7.6b}$$

The diagonal blocks of $\mathbf{G}^{\vee}\mathbf{G}^{\wedge}$ and $\mathbf{G}^{\wedge}\mathbf{G}^{\vee}$ are $\mathbf{G}^{\vee}_{j}\mathbf{G}^{\wedge}_{j} + \mathbf{L}^{\vee}_{j-1}\mathbf{F}^{\wedge}_{j}$ and $\mathbf{G}^{\wedge}_{j}\mathbf{G}^{\vee}_{j} + \mathbf{F}^{\wedge}_{j+1}\mathbf{L}^{\vee}_{j}$. Here we obtain

$$\mathbf{L}^{\vee}_{j-1}\mathbf{F}^{\wedge}_{j} = \mathbf{O} \text{ if } h^{\vee}_{j-1} > 1, \tag{7.7a}$$

$$[\mathbf{L}^{\vee}_{j-1}\mathbf{F}^{\wedge}_{j}]_{m,n} = \left\{ \begin{array}{ll} \varphi^{\wedge}_{j} & \text{if } (m,n) = (n^{\wedge}_{j}, n^{\vee}_{j}) \\ 0 & \text{otherwise} \end{array} \right\} \text{ if } h^{\vee}_{j-1} = 1, \tag{7.7b}$$

$$\mathbf{F}^{\wedge}_{j+1}\mathbf{L}^{\vee}_{j} = \mathbf{O} \text{ if } h^{\wedge}_{j+1} > 1, \tag{7.8a}$$

$$[\mathbf{F}^{\wedge}_{j+1}\mathbf{L}^{\vee}_{j}]_{m,n} = \left\{ \begin{array}{ll} \varphi^{\wedge}_{j+1} & \text{if } (m,n) = (n^{\vee}_{j}, n^{\wedge}_{j+1}-1) \\ 0 & \text{otherwise} \end{array} \right\} \text{ if } h^{\wedge}_{j+1} = 1. \tag{7.8b}$$

Furthermore, if $h^{\wedge}_{j} > 1$ and $h^{\vee}_{j} > 1$,

$$\mathbf{G}^{\vee}_{j}\mathbf{G}^{\wedge}_{j} = \left[\begin{array}{c|c|c} \mathbf{T}^{\wedge}_{j} & \mathbf{T}^{\wedge}_{j}\mathbf{e}^{\wedge}_{j} & \mathbf{f}^{\vee}_{j}\mathbf{l}^{\vee T}_{j} \\ \hline \mathbf{l}^{\wedge T}_{j} & \varepsilon^{\wedge}_{h^{\wedge}_{j}-2,j} & \mathbf{0}^{T} \\ \hline \mathbf{O} & \mathbf{c}^{\vee}_{j} & \mathbf{T}^{\vee}_{j} + \mathbf{e}^{\vee}_{j}\mathbf{l}^{\vee T}_{j} \end{array} \right], \tag{7.9a}$$

$$\mathbf{G}^{\wedge}_{j}\mathbf{G}^{\vee}_{j} = \left[\begin{array}{c|c|c} \mathbf{T}^{\wedge}_{j} + \mathbf{e}^{\wedge}_{j}\mathbf{l}^{\wedge T}_{j} & \mathbf{O} & \mathbf{f}^{\vee}_{j} \\ \hline \mathbf{c}^{\vee}_{j}\mathbf{l}^{\wedge T}_{j} & \mathbf{T}^{\vee}_{j} & \mathbf{T}^{\vee}_{j}\mathbf{e}^{\vee}_{j} \\ \hline \mathbf{0}^{T} & \mathbf{l}^{\vee T}_{j} & \varepsilon^{\vee}_{h^{\vee}_{j}-2,j} \end{array} \right]; \tag{7.9b}$$

if $h_j^\wedge = 1$ and $h_j^\vee > 1$,

$$\text{(7.9b)}\quad \mathbf{G}_j^\vee \mathbf{G}_j^\wedge = \left[\begin{array}{c|c} 0 & \varphi_j^\vee \mathbf{l}_j^{\vee T} \\ \hline \mathbf{c}_j^\vee & \mathbf{T}_j^\vee + \mathbf{e}_j^\vee \mathbf{l}_j^{\vee T} \end{array}\right], \quad \mathbf{G}_j^\wedge \mathbf{G}_j^\vee = \left[\begin{array}{c|c} \mathbf{T}_j^\vee & \mathbf{c}_j^\vee \varphi_j^\vee + \mathbf{T}_j^\vee \mathbf{e}_j^\vee \\ \hline \mathbf{l}_j^{\vee T} & \varepsilon_{h_j^\vee - 2, j}^\vee \end{array}\right];$$

if $h_j^\wedge > 1$ and $h_j^\vee = 1$,

$$\text{(7.9c)}\quad \mathbf{G}_j^\vee \mathbf{G}_j^\wedge = \left[\begin{array}{c|c} \mathbf{T}_j^\wedge & \mathbf{T}_j^\wedge \mathbf{e}_j^\wedge + \mathbf{f}_j^\vee \\ \hline \mathbf{l}_j^{\wedge T} & \varepsilon_{h_j^\wedge - 2, j}^\wedge \end{array}\right], \quad \mathbf{G}_j^\wedge \mathbf{G}_j^\vee = \left[\begin{array}{c|c} \mathbf{T}_j^\wedge + \mathbf{e}_j^\wedge \mathbf{l}_j^{\wedge T} & \mathbf{f}_j^\vee \\ \hline \mathbf{l}_j^{\wedge T} & 0 \end{array}\right];$$

and, if $h_j^\wedge = h_j^\vee = 1$,

$$\text{(7.9d)}\qquad \mathbf{G}_j^\vee \mathbf{G}_j^\wedge = [\varphi_j^\vee], \quad \mathbf{G}_j^\wedge \mathbf{G}_j^\vee = [\varphi_j^\vee].$$

To relate the entries of $\mathbf{H}$ and $\mathbf{H}'$ with those of $\mathbf{G}^\vee\mathbf{G}^\wedge$ and $\mathbf{G}^\wedge\mathbf{G}^\vee$, we need to associate the blocks $\mathbf{A}_i$, $\mathbf{B}_i$, $\mathbf{C}_i$ of $\mathbf{H}$ and the blocks $\mathbf{A}'_i, \mathbf{B}'_i, \mathbf{C}'_i$ of $\mathbf{H}'$ with those of $\mathbf{G}^\vee\mathbf{G}^\wedge$ and $\mathbf{G}^\wedge\mathbf{G}^\vee$, respectively. However, depending on $h_j^\vee$ and $h_j^\wedge$ being equal to or greater than 1, a diagonal block

$$\text{(7.10a)}\qquad \mathbf{H}_j^\wedge := \mathbf{G}_j^\vee \mathbf{G}_j^\wedge + \mathbf{L}_{j-1}^\vee \mathbf{F}_j^\wedge$$

of order $h_j^\wedge + h_j^\vee - 1$ of $\mathbf{G}^\vee\mathbf{G}^\wedge = \mathbf{H}$ and such a block

$$\text{(7.10b)}\qquad \mathbf{H}_j^\vee := \mathbf{G}_j^\wedge \mathbf{G}_j^\vee + \mathbf{F}_{j+1}^\wedge \mathbf{L}_j^\vee$$

of $\mathbf{G}^\wedge\mathbf{G}^\vee = \mathbf{H}'$ corresponds either to a single block $\mathbf{A}_i$ or $\mathbf{A}'_i$ or to a 2×2 block matrix

$$\text{(7.11)}\qquad \begin{bmatrix} \mathbf{A}_i & \mathbf{B}_{i+1} \\ \mathbf{C}_i & \mathbf{A}_{i+1} \end{bmatrix} \quad \text{or} \quad \begin{bmatrix} \mathbf{A}'_{i-1} & \mathbf{B}'_i \\ \mathbf{C}'_{i-1} & \mathbf{A}'_i \end{bmatrix},$$

respectively. Likewise, the off-diagonal blocks may correspond to a $1 \times 1, 1 \times 2, 2 \times 1$, or 2×2 block matrix.

The indices of the regular elements of the sequences $\{P_n\}$ and $\{P'_n\}$ are now denoted by n_i and n'_i, respectively, while $\{n_j^\wedge\} \subseteq \{n_i\}$ and $\{n_j^\vee\} \subseteq \{n'_i\}$ still denote the index subsequences of the regular elements in the generalized staircase. Since the upper left corners of $\mathbf{A}_i$ and $\mathbf{G}_j^\vee\mathbf{G}_j^\wedge$ are at (n_i, n_i) and $(n_j^\wedge, n_j^\wedge)$, the association of the blocks is based on the identification $n_i = n_j^\wedge$. Likewise, the upper left corner of $\mathbf{A}'_i$ at (n'_i, n'_i) corresponds to the $(n_j^\vee, n_j^\vee)$ element of $\mathbf{G}_j^\wedge\mathbf{G}_j^\vee$, hence we have $n'_i = n_j^\vee$. From (7.3)–(7.9) we can then read off the associations listed in Tables 1 and 2. □

Tables 1 and 2 describe the structure and the entries of the products $\mathbf{H} = \mathbf{G}^\vee\mathbf{G}^\wedge$ and $\mathbf{H}' = \mathbf{G}^\wedge\mathbf{G}^\vee$ in terms of the entries of $\mathbf{G}^\vee$ and $\mathbf{G}^\wedge$. Next, we are interested in inverting these two operations, i.e., in computing the lower block bidiagonal matrix $\mathbf{G}^\vee$ and the upper block bidiagonal matrix $\mathbf{G}^\wedge$, either from $\mathbf{H}$ or from $\mathbf{H}'$. Of course, $\mathbf{G}^\vee$ and $\mathbf{G}^\wedge$ are required to have the structure specified by (6.16) and (6.17). While $\mathbf{H} = \mathbf{G}^\vee\mathbf{G}^\wedge$ is a block LU decomposition, $\mathbf{H}' = \mathbf{G}^\wedge\mathbf{G}^\vee$ is a (not so often encountered) block UL decomposition. Theoretically, in view of

$$\text{(7.12)}\qquad (\mathbf{H}')^{-1} = (\mathbf{G}^\vee)^{-1}(\mathbf{G}^\wedge)^{-1},$$

the latter could be obtained via a block LU decomposition of $(\mathbf{H}')^{-1}$ followed by the inversion of the factors, but we can directly determine the block UL decomposition

with ease. From Theorem 7.1 we know that these two block decompositions exist, but it is not yet clear how the sizes of the blocks of $\mathbf{G}^\vee$ and $\mathbf{G}^\wedge$ can be determined from those in $\mathbf{H}$ or from those in $\mathbf{H}'$.

In the jth step of the block LU decomposition, $\mathbf{H} = \mathbf{G}^\vee\mathbf{G}^\wedge$, the block pivot element is obtained by subtracting $\mathbf{L}_{j-1}^\vee\mathbf{F}_j^\wedge$ from a diagonal block $\mathbf{H}_j^\wedge$ of $\mathbf{H}$ of the appropriate size. It must then be split into $\mathbf{G}_j^\vee\mathbf{G}_j^\wedge$:

$$\mathbf{H}_j^\wedge - \mathbf{L}_{j-1}^\vee\mathbf{F}_j^\wedge = \mathbf{G}_j^\vee\mathbf{G}_j^\wedge. \tag{7.13}$$

However, given $\mathbf{H}$ structured according to (3.6)–(3.10), we do not know a priori the sizes of these diagonal blocks, since they may correspond to a single block $\mathbf{A}_i$ or to a 2×2 block matrix given on the left-hand side of (7.11). (This is also the reason for calling these blocks $\mathbf{H}_j^\wedge$ and not $\mathbf{H}_j$; the block sizes are the same as in $\mathbf{G}^\wedge$ and $\mathbf{G}^\vee$.) But any block pivot has to be nonsingular, and from this requirement we can determine the correct size of the block $\mathbf{H}_j^\wedge$. Any tentative 1×1 block pivot is either a 1×1 matrix obtained by updating $[\alpha_{0,i}]$ or a unit upper Hessenberg matrix. The latter is a companion matrix if we assume for the moment that $W_m(z) = z^m$. Hence it is nonsingular if and only if the element in its upper right corner is nonzero. Thus, identifying $n_i = n_j^\wedge$, we then have $\mathbf{H}_j^\wedge := \mathbf{A}_i$ if and only if $\alpha_{0,i}$ minus the $(n_i, n_{i+1}-1)$ element of $\mathbf{L}_{j-1}^\vee\mathbf{F}_j^\wedge$ does not vanish, i.e., in view of (7.7) and $n_j^\vee = n_{i+1} - 1$ (cf. Table 1), if and only if

$$\tilde{\varphi}_j^\vee := \alpha_{0,i} \neq 0 \text{ in case } h_{j-1}^\vee > 1, \tag{7.14a}$$

$$\tilde{\varphi}_j^\vee := \alpha_{0,i} - \varphi_j^\wedge \neq 0 \text{ in case } h_{j-1}^\vee = 1\,. \tag{7.14b}$$

Note that $\varphi_j^\wedge = \beta_i/\varphi_{j-1}^\wedge$ if $h_{j-1}^\vee = 1$ (cf. Table 1), and that this quantity can be computed at this moment. Moreover, in the case of a 1×1 block pivot, i.e., when (7.14) holds, we conclude from Table 1 and (7.4) that $\varphi_j^\vee = \tilde{\varphi}_j^\vee$. Hence, (7.14) means that we test whether the tentative value $\tilde{\varphi}_j^\vee$ of $\varphi_j^\vee$ does not vanish. This value does not depend on the basis $\{W_m\}$ chosen, as long as this basis consists of monic polynomials, since $\varphi_j^\vee$ is the coefficient of a regular FOP1 in one of our mixed three-term recurrence formulas (5.25). Therefore, in the general case, we can replace (7.14) by a test for the nonvanishing of the tentative value of $\varphi_j^\vee$, which can be found by inversion of the function Ω_j, cf. Table 1.

If the test fails, we end up with a 2×2 block pivot,

$$\mathbf{H}_j^\wedge := \begin{bmatrix} \mathbf{A}_i & \mathbf{B}_{i+1} \\ \mathbf{C}_i & \mathbf{A}_{i+1} \end{bmatrix}, \tag{7.15}$$

cf. (7.11), for which the unit Hessenberg matrix $\mathbf{H}_j^\wedge - \mathbf{L}_{j-1}^\vee\mathbf{F}_j^\wedge$ is always nonsingular, since $\beta_{i+1} \neq 0$, while the $(n_i', n_{i+2}' - 1)$-element of $\mathbf{L}_{j-1}^\vee\mathbf{F}_j^\wedge$ is always zero because $n_j^\vee < n_{i+2}' - 1$.

The matrices $\mathbf{G}^\vee$ and $\mathbf{G}^\wedge$ can thus be built up by successive determination of the sizes of the block pivots and simultaneous computation of the entries by using the formulas of Table 1. The result is summarized in the following theorem and in Table 3.

THEOREM 7.2. *Given* $\mathbf{H}$, *one can compute the block* LU *factorization* $\mathbf{H} = \mathbf{G}^\vee\mathbf{G}^\wedge$ *by a Gauss block elimination process. In step* j, *where the upper left corner of the block pivot* $\mathbf{H}_j^\wedge - \mathbf{L}_{j-1}^\vee\mathbf{F}_j^\wedge$ *is at* $(n_j^\wedge, n_j^\wedge) = (n_i, n_i)$, *the block* $\mathbf{H}_j^\wedge$ *of* $\mathbf{H}$ *is defined by identifying it with either the* 1×1 *block* $\mathbf{A}_i$ *or the* 2×2 *block* (7.15) (*hence the size of the block pivot is either* h_i *or* $h_i + h_{i+1}$), *depending on whether the tentative value*

$\tilde{\varphi}_j^\vee$ of $\varphi_j^\vee$ given in Table 3 is nonzero or zero. The relevant entries $\mathbf{e}_j^\vee, \varphi_j^\vee, \mathbf{e}_j^\wedge$, and $\varphi_j^\wedge$ of $\mathbf{G}^\vee$ and $\mathbf{G}^\wedge$ are then obtained according to Table 3. There the functions $\Omega_j^\wedge$ and $\omega_j^\wedge$ are together the inverse of Ω_j defined in (7.3a)*; they are computed as follows: Partition the matrix $\mathbf{T}_{h_j^\wedge-1}^W$ and the vector $\mathbf{a}_i$ according to*

$$\mathbf{T}_{h_j^\wedge-1}^W =: \left[\begin{array}{c|c} \mathbf{s}^T & \tau \\ \hline \mathbf{S} & \mathbf{t} \end{array}\right], \quad \mathbf{a}_i =: \left[\begin{array}{c} \alpha \\ \hline \mathbf{a} \end{array}\right]; \tag{7.16}$$

then set

$$\Omega_j^\wedge(\mathbf{a}_i) := \mathbf{S}^{-1}(\mathbf{a}+\mathbf{t}), \tag{7.17a}$$

$$\omega_j^\wedge(\mathbf{a}_i) := \alpha + \tau - \mathbf{s}^T\Omega_j^\wedge(\mathbf{a}_i)\,. \tag{7.17b}$$

The process starts at $j = i = 0$ with $n_0^\wedge := n_0$, $\varphi_0^\wedge := 0$, $\mathbf{L}_{-1}^\vee\mathbf{F}_0^\wedge := \mathbf{O}$. ($h_{-1}^\vee$ does not matter.)

Remark. In the case where $W_m(z) = z^m$, the definitions (7.17) reduce to

$$\Omega_j^\wedge(\mathbf{a}_i) := \mathbf{a} = \mathbf{J}_{h_j^\wedge-1}\mathbf{a}_i, \tag{7.18a}$$

$$\omega_j^\wedge(\mathbf{a}_i) := \alpha = \alpha_{0,i}\,. \tag{7.18b}$$

For the block UL decomposition $\mathbf{H}' = \mathbf{G}^\wedge\mathbf{G}^\vee$ we must likewise find a diagonal block $\mathbf{H}_j^\vee$ of $\mathbf{H}'$ of appropriate size, so that $\mathbf{H}_j^\vee - \mathbf{F}_{j+1}^\wedge\mathbf{L}_j^\vee$ is nonsingular and can be split into $\mathbf{G}_j^\wedge\mathbf{G}_j^\vee$:

$$\mathbf{H}_j^\vee - \mathbf{F}_{j+1}^\wedge\mathbf{L}_j^\vee = \mathbf{G}_j^\wedge\mathbf{G}_j^\vee\,. \tag{7.19}$$

In the case $W_m(z) = z^m$ any tentative 1×1 block pivot is again either a 1×1 matrix or a companion matrix. The condition for it to be nonsingular is now that $\alpha'_{0,i}$ minus the $(n'_i, n'_{i+1} - 1)$-element of $\mathbf{F}^{\wedge}_{j+1}\mathbf{L}^{\vee}_j$ does not vanish; i.e., in view of (7.8), $n'_i = n^{\vee}_j$ and $n'_{i+1} = n^{\wedge}_{j+1}$ (cf. Table 2) if and only if

$$\alpha'_{0,i} \neq 0 \text{ in case } h^{\wedge}_{j+1} > 1\,, \tag{7.20a}$$

$$\alpha'_{0,i} - \varphi^{\wedge}_{j+1} \neq 0 \text{ in case } h^{\wedge}_{j+1} = 1\,. \tag{7.20b}$$

However, $\varphi^{\wedge}_{j+1}$ is not known at this moment. But we can apply a different argument.

Let $n^{\vee}_j := n'_i$ and assume that the elements of $\mathbf{G}^{\vee}$ and $\mathbf{G}^{\wedge}$ have already been determined up to the $(n^{\vee}_j - 1)$th column. Then $h^{\wedge}_j$, $\mathbf{e}^{\wedge}_j$, and $\varphi^{\wedge}_j$ are known, and $h^{\vee}_j$ is equal to the dimension h'_i of $\mathbf{a}'_i$. From Table 2 we see that $\varphi^{\vee}_j$ is determined by β'_i and $\varphi^{\wedge}_j$. Moreover, by analogy to (7.17) and (7.18) there are functions $\Omega^{\vee}_j$ and $\omega^{\vee}_j$ inverting Ω'_j; the first one yields $\mathbf{e}^{\vee}_j$ if $h^{\vee}_j > 1$.

Next, let us first assume that $h^{\wedge}_j > 1$ and consider

$$\tilde{\varphi}^{\wedge}_{j+1} := \begin{cases} \omega^{\vee}_j(\mathbf{a}'_i) & \text{in case } h^{\vee}_j > 1, \\ \alpha'_{0,i} & \text{in case } h^{\vee}_j = 1 \end{cases} \tag{7.21}$$

as a tentative value for $\varphi^{\wedge}_{j+1}$. If nonvanishing, we let it be the true value of $\varphi^{\wedge}_{j+1}$ and set $h^{\wedge}_{j+1} := 1$ ($\mathbf{e}^{\wedge}_{j+1}$ is then void). Otherwise, $h^{\wedge}_{j+1} > 1$, hence $n^{\vee}_{j+1} := n'_{i+2}$, $\mathbf{e}^{\wedge}_{j+1} := \mathbf{a}'_{i+1}$, $\varphi^{\wedge}_{j+1} := \beta'_{i+1}$.

If $h^{\wedge}_j = 1$, we instead let

$$\tilde{\varphi}^{\wedge}_{j+1} := \begin{cases} \omega^{\vee}_j(\mathbf{a}'_i) - \varphi^{\vee}_j & \text{in case } h^{\vee}_j > 1, \\ \alpha'_{0,i} - \varphi^{\vee}_j & \text{in case } h^{\vee}_j = 1, \end{cases} \tag{7.22}$$

be the tentative value for $\varphi^{\wedge}_{j+1}$. The rest of the step is the same as before.

To complete the definition of the procedure we have to describe its start. At this point we must note that although the functional Φ' is uniquely determined by Φ, the converse is not true, since Φ depends on $\Phi(1) = \phi_l$, while Φ' is independent of ϕ_l. Hence, the set $\{P_n\}$ of FOP1s determined by Φ cannot be uniquely determined by the set $\{P'_n\}$ corresponding to Φ'. Moreover, the value of ϕ_l determines whether the $(l-1, 0)$ and the $(l, 0)$ Padé approximants of $f(z) = \sum \phi_k z^k$ belong to the same block of the table or not. In fact, they do if and only if $\phi_l = 0$. (Recall that these Padé approximants are polynomial interpolants.)

Therefore, given the recurrence formulas for $\{P'_n\}$ (i.e., given the matrix $\mathbf{H}'$), those for $\{P_n\}$ and those for the mixed recurrence (i.e., the matrices $\mathbf{H}$, $\mathbf{G}^{\vee}$ and $\mathbf{G}^{\wedge}$) are only determined after ϕ_l has been specified.

According to (5.17a), $\varphi^{\vee}_0$ satisfies

$$\varphi^{\vee}_0 \Phi(z^{n^{\vee}_0}) = \Phi(z^{n^{\vee}_0 + 1} W_{h^{\vee}_0 - 1} P'_{n^{\vee}_0}). \tag{7.23}$$

In the case $h^{\wedge}_0 = 1$, where $n^{\wedge}_0 := n^{\vee}_0 := n'_0 = 0$ (i.e., $i = j = 0$), $h^{\vee}_0 := h'_0, n^{\wedge}_1 := n'_1$ and where both $\mathbf{e}^{\wedge}_0$ and $\varphi^{\wedge}_0$ are void, we obtain

$$\varphi^{\vee}_0 := \Phi(z W_{n'_1 - 1})/\phi_l, \tag{7.24}$$

which for the monomial basis $W_m(z) = z^m$ reduces to

$$\varphi^{\vee}_0 := \phi_{l+n'_1}/\phi_l. \tag{7.25}$$

In the case $h_0^\wedge > 1$, where $n_0^\wedge := n_0' = 0, n_0^\vee := n_1'$ (i.e., $i = 1, j = 0$), $h_0^\wedge := h_0' + 1, h_0^\vee := h_1'$, we have $\mathbf{e}_0^\wedge := \mathbf{a}_0'$ (cf. (7.9a) and (7.9c) with (3.7)) and, from (7.23),

$$\varphi_0^\vee := \Phi(z^{n_1'+1} W_{h_1'-1} P_{n_1'}')/\phi_{l+n_1'}, \tag{7.26}$$

which for $W_m(z) = z^m$ reduces to

$$\varphi_0^\vee := \phi_{l+n_2'}/\phi_{l+n_1'}\,. \tag{7.27}$$

In both cases $\mathbf{e}_0^\vee, \mathbf{e}_1^\wedge$, and $\varphi_1^\wedge$ are obtained according to the general formulas in Table 4. Altogether we get the following analog of Theorem 7.2.

THEOREM 7.3. *Given* $\mathbf{H}'$ *and either* $\phi_l \neq 0$ *and* $\phi_{l+n_1'}$ *or* $\phi_l = 0$, $\phi_{l+n_1'}$, *and* $\phi_{l+n_2'}$, *we can compute the block* UL *factorization* $\mathbf{H}' = \mathbf{G}^\wedge \mathbf{G}^\vee$ *by the following process. In step* j, *where we compute columns* $n_j^\vee = n_i'$ *through* $n_{j+1}^\vee - 1$ *of* $\mathbf{G}^\vee$ *and* $\mathbf{G}^\wedge$, *the diagonal block* $\mathbf{H}_j^\vee$ *of* $\mathbf{H}'$ (*containing rows and columns* $n_j^\wedge$ *through* $n_{j+1}^\wedge - 1$) *is defined as either the* 1×1 *block* $\mathbf{H}_j^\vee := \mathbf{A}_j'$ *or the* 2×2 *block*

$$\mathbf{H}_j^\vee := \begin{bmatrix} \mathbf{A}_{i-1}' & \mathbf{B}_i' \\ \mathbf{C}_{i-1}' & \mathbf{A}_i' \end{bmatrix}, \tag{7.28}$$

depending on whether the tentative value $\tilde{\varphi}_{j+1}^\wedge$ *of* $\varphi_{j+1}^\wedge$ *given in Table* 4 *is nonzero or zero. The relevant entries* $\mathbf{e}_j^\wedge, \varphi_j^\wedge, \mathbf{e}_{j+1}^\wedge$, *and* $\varphi_{j+1}^\vee$ *of* $\mathbf{G}^\vee$ *and* $\mathbf{G}^\wedge$ *are then obtained according to Table* 4. *There the functions* $\Omega_j^\vee$ *and* $\omega_j^\vee$ *are together the inverse of* Ω_j' *defined in* (7.3b); *they are computed as follows: Partition the matrix* $\mathbf{T}_{h_j^\vee - 1}^W$ *and the vector* $\mathbf{a}_i'$ *according to*

$$\mathbf{T}_{h_j^\vee - 1}^W =: \left[\begin{array}{c|c} \mathbf{s}^T & \tau \\ \hline \mathbf{S} & \mathbf{t} \end{array}\right], \quad \mathbf{a}_i' =: \left[\begin{array}{c} \alpha \\ \hline \mathbf{a} \end{array}\right]; \tag{7.29}$$

then

$$\Omega_j^\vee(\mathbf{a}_i') := \mathbf{S}^{-1}(\mathbf{a} + \mathbf{t}), \tag{7.30a}$$

$$\omega_j^\vee(\mathbf{a}_i') := \alpha + \tau - \mathbf{s}^T \Omega_j^\vee(\mathbf{a}_i')\,. \tag{7.30b}$$

The first step depends on the value $\phi_l = \Phi(1)$ (*on which* $\mathbf{H}'$ *does not depend, while* $\mathbf{H}$ *does*):

If $\phi_l \neq 0$, *then*

$$h_0^\wedge := 1, \quad h_0^\vee := h_0', \tag{7.31a}$$

$$n_0^\wedge := n_0^\vee := n_0' = 0, \quad n_1^\wedge := n_1', \tag{7.31b}$$

$\mathbf{e}_0^\wedge$ *is void, and* $\varphi_0^\vee$ *is given by* (7.24); $\mathbf{e}_0^\vee$, $\mathbf{e}_1^\wedge$, $\varphi_0^\wedge$ *are then obtained from the general formulas in Table* 4, *with* $i = j = 0$.

If $\phi_l = 0$, *then*

$$h_0^\wedge := h_0' + 1, \quad h_0^\vee := h_1', \tag{7.32a}$$

$$n_0^\wedge := n_0' = 0, \quad n_0^\vee := n_1', \quad n_2^\wedge := n_2', \tag{7.32b}$$

$$\mathbf{e}_0^\wedge := \mathbf{a}_0', \tag{7.32c}$$

and $\varphi_0^\vee$ *is given by* (7.26); $\mathbf{e}_0^\vee$, $\mathbf{e}_1^\wedge$, $\varphi_0^\wedge$ *are obtained from Table* 4 *by setting* $i = 1$, $j = 0$.

Starting from the recurrence coefficients for some sequence $\{P_n\}_{n=0}^{\infty}$ of FOP1s, say from $\{P_{n;0}\}_{n=0}^{\infty}$, inductive application of Theorem 7.2 and of the $\mathbf{H}' = \mathbf{G}^{\wedge}\mathbf{G}^{\vee}$ part of Theorem 7.1 allows us to compute the recurrence coefficients of any sequence $\{P_{n;l}\}_{n=0}^{\infty}$, $l = 1, 2, \ldots$. These two theorems therefore define the *progressive qd algorithm*, even for nongeneric situations. In the generic case, for which the algorithm is due to Rutishauser [23], only the formulas for $h_j^{\wedge} = h_j^{\vee} = h_i = h_i' = 1$ $(\forall i, j)$ are used, i.e., only those in the last rows of Tables 2 and 3. In this generic case the *qd table* contains the recurrence coefficients for every diagonal sequence of FOP1s, i.e., our coefficients $\alpha_{0,i}$ $(i = 0, 1, \ldots)$ and β_i $(i = 1, 2, \ldots)$ for every diagonal $(l = 0, 1, \ldots)$. The progressive qd algorithm allows us to build up the qd table from its main diagonal, where $l = 0$. (More generally, one can proceed downwards from any diagonal or row.) Rutishauser had some heuristic rules for dealing with nongeneric situations, namely, rules for filling the then appearing gaps in the qd table with zeros and ∞ symbols. Draux [6] also formulated and established such rules. However, according to the above result, we can define a qd table that is valid in every nongeneric situation and contains as entries on its lth diagonal the nontrivial entries $\mathbf{a}_i$ $(i = 0, 1, \ldots)$ and β_i $(i = 1, 2, \ldots)$ of the matrix $\mathbf{H}$ for this l.

Likewise, starting from the recurrence coefficients of $\{P_{n;0}\}_{n=0}^{\infty}$, inductive application of Theorem 7.3 and of the $\mathbf{H} = \mathbf{G}^{\vee}\mathbf{G}^{\wedge}$ part of Theorem 7.1 allows us to compute those of any sequence $\{P_{n;l}\}_{n=0}^{\infty}$, $l = -1, -2, \ldots$. In each step a new "moment" ϕ_l, $l = -1, -2, \ldots$, has to be provided. Hence, we can proceed from the main (or any other) diagonal upwards and to the right. For the generic case this process is well known. We call this the *backward qd algorithm.*

The progressive qd algorithm enables us in particular to compute the moments

ϕ_l $(l = 0, 1, \ldots)$ from the coefficients $\mathbf{a}_i$ $(i = 0, 1, \ldots)$ and β_i $(i = 1, 2, \ldots)$ of the main diagonal. Conversely, given the moments, the ordinary qd algorithm yields in the generic case the recurrence coefficients on the main diagonal. This process is known to be highly unstable. The same task can be done with the *Chebyshev algorithm*, which is less likely to break down or to be unstable, since it requires only that all FOP1s $P_{0;n}$ on the main diagonal are regular. However, often the problem itself is ill conditioned, and there is no chance for numerically stable computations. It has, therefore, been proposed to replace the moments by modified moments if possible. Golub and Gutknecht [9] have extended the corresponding *modified Chebyshev algorithm* to the nongeneric case. The nongeneric Chebyshev algorithm is included there as a special case.

The progressive and the backward qd algorithms are well known to have interesting convergence properties. Basically, by proceeding downwards in the qd table we obtain the poles of f, and by moving to the right we find its zeros, see, e.g., [3].

8. The nongeneric biconjugate gradient algorithm (BCG or BIOMIN) and nongeneric BIODIR. The biconjugate gradient (BCG) algorithm is closely related to the Lanczos biorthogonalization (BO) method. It can be traced back to Lanczos [20], where it was introduced as "the complete algorithm for minimized iterations." More than 20 years later, Fletcher [7] revived and popularized it. It generates the same biorthogonal vector sequences $\{\mathbf{x}_n\}$, $\{\mathbf{y}_n\}$ characterized by (4.6)–(4.7), and the same iterates $\{\mathbf{z}_n\}$ satisfying (4.61) as the normalized BIORES algorithm [11], but additionally it generates two biconjugate vector sequences $\{\mathbf{u}_n\}$ and $\{\mathbf{v}_n\}$ taken from the same nested sequences of Krylov spaces as $\{\mathbf{x}_n\}$ and $\{\mathbf{y}_n\}$:

$$\mathbf{u}_n \in \mathcal{K}_{n+1} := \text{span}\,(\mathbf{x}_0, \mathbf{A}\mathbf{x}_0, \mathbf{A}^2\mathbf{x}_0, \ldots, \mathbf{A}^n\mathbf{x}_0), \tag{8.1a}$$

$$\mathbf{v}_n \in \mathcal{L}_{n+1} := \text{span}\,(\mathbf{y}_0, \mathbf{A}^H\mathbf{y}_0, (\mathbf{A}^H)^2\mathbf{y}_0, \ldots, (\mathbf{A}^H)^n\mathbf{y}_0) \tag{8.1b}$$

with

$$\langle \mathbf{v}_m, \mathbf{A}\mathbf{u}_n \rangle_{\mathbf{B}} \begin{cases} = 0 & \text{if } m \neq n, \\ \neq 0 & \text{if } m = n. \end{cases} \tag{8.2}$$

This process can break down for various reasons, cf. [11]. From §4 we know already that $\{\mathbf{x}_n\}$ and $\{\mathbf{y}_n\}$ satisfying (4.6) and (4.7) may not exist and that a suitable modification of the process can be based on the theory of formal orthogonal polynomials. An argument analogous to the one given in §4 shows that if (8.1) and (8.2) can be fulfilled for $n = 0, 1, \ldots, \nu - 1$, then they are fulfilled by

$$\mathbf{u}_n = P'_n(\mathbf{A})\mathbf{x}_0\Gamma'_n, \quad \mathbf{v}_n = \overline{P'_n}(\mathbf{A}^H)\mathbf{y}_0\bar{\Gamma}'_n, \tag{8.3}$$

where the scale factors Γ'_n and $\bar{\Gamma}'_n$ are not necessarily the same as the factors Γ_n and $\bar{\Gamma}_n$ in (4.14), and where P'_n is the nth monic FOP1 with respect to the linear functional $\Phi' = \Phi_1$ defined by

$$\Phi'(z^k) := \phi_{k+1} := \langle \mathbf{y}_0, \mathbf{A}^{k+1}\mathbf{x}_0 \rangle_{\mathbf{B}}. \tag{8.4}$$

(Recall that if (8.2) holds for all $m < \nu$ and $n < \nu$, all the polynomials P'_n $(n < \nu)$ in (8.3) are regular FOP1s.)

In case of a breakdown, the formulas (8.3) point again to the correct generalization of the process: $\mathbf{u}_n$ and $\mathbf{v}_n$ must still have the same form, with P'_n being an nth FOP1 for Φ', even if it is not a regular FOP1; hence (8.2) does not hold for this n. The

recurrences of §5 allow us to find a recursive algorithm for computing $\mathbf{u}_n$ and $\mathbf{v}_n$ along with $\mathbf{x}_n$ and $\mathbf{y}_n$, and the relations of §§6 and 7 yield corresponding matrix results.

First we formulate the matrix algorithm that is based on a reinterpretation of Theorems 5.3 and 5.4. Since it yields both a pair of biorthogonal and a pair of biconjugate sequences, we call it, as in [11], the *BOBC algorithm.*

As an extension of (4.20a), for $i, n \in \mathbb{N}$ we let

$$\gamma_{n,i} := \Gamma_n/\Gamma_{n-i}, \quad \bar{\gamma}_{n,i} := \bar{\Gamma}_n/\bar{\Gamma}_{n-i}, \tag{8.5a}$$

$$\gamma'_{n,i} := \Gamma'_n/\Gamma'_{n-i}, \quad \bar{\gamma}'_{n,i} := \bar{\Gamma}'_n/\bar{\Gamma}'_{n-i}, \tag{8.5b}$$

and

$$\gamma^{\wedge}_{n,i} := \Gamma_n/\Gamma'_{n-i}, \quad \bar{\gamma}^{\wedge}_{n,i} := \bar{\Gamma}_n/\bar{\Gamma}'_{n-i}, \tag{8.6a}$$

$$\gamma^{\vee}_{n,i} := \Gamma'_n/\Gamma_{n-i}, \quad \bar{\gamma}^{\vee}_{n,i} := \bar{\Gamma}'_n/\bar{\Gamma}_{n-i}\,. \tag{8.6b}$$

Recall that the mixed three-term recurrence relations (5.25) allow us to generate the two sequences $\{P_{n_j^{\wedge}}\}_{j=0}^{J^{\wedge}}$ and $\{P'_{n_j^{\vee}}\}_{j=0}^{J^{\vee}}$ consisting of regular FOP1s for Φ and Φ', respectively, and that two full sequences of FOP1s for these two functionals are then defined by (5.27). If $h_j^{\wedge} := n_j^{\vee} - n_j^{\wedge} + 1 > 1$ or $h_j^{\vee} := n_{j+1}^{\wedge} - n_j^{\vee} > 1$, some polynomials on the two diagonals coincide or differ only by a factor of z, cf. (5.28); consequently,

$$\mathbf{x}_n = \mathbf{u}_n \gamma^{\wedge}_{n,0}, \quad \mathbf{y}_n = \mathbf{v}_n \bar{\gamma}^{\wedge}_{n,0}, \quad \text{if } n_j^{\wedge} \le n < n_j^{\vee}, \tag{8.7a}$$

$$\mathbf{x}_n = \mathbf{A}\mathbf{u}_{n-1}\gamma^{\wedge}_{n,1}, \quad \mathbf{y}_n = \mathbf{A}^H \mathbf{v}_{n-1}\bar{\gamma}^{\wedge}_{n,1}, \quad \text{if } n_j^{\vee} < n < n_{j+1}^{\wedge}\,. \tag{8.7b}$$

The polynomials W_m in (5.27) are for practicality again assumed to satisfy the three-term recurrence (2.10), so that the recurrences (5.29) hold, which translate into

$$\mathbf{x}_{n+1} = [\mathbf{A}\mathbf{x}_n - \mathbf{x}_n \alpha^W_{n-n_j^{\wedge}}]\gamma_{n+1,1} - \mathbf{x}_{n-1}\beta^W_{n-n_j^{\wedge}}\gamma_{n+1,2}, \quad n_j^{\wedge} \le n \le n_j^{\vee} - 1, \tag{8.8a}$$

$$\mathbf{x}_{n+1} = [\mathbf{A}\mathbf{x}_n - \mathbf{x}_n \alpha^W_{n-n_j^{\vee}+1}]\gamma_{n+1,1} - \mathbf{x}_{n-1}\beta^W_{n-n_j^{\vee}+1}\gamma_{n+1,2}, \quad n_j^{\vee} < n \le n_{j+1}^{\wedge} - 2, \tag{8.8b}$$

$$\mathbf{u}_{n+1} = [\mathbf{A}\mathbf{u}_n - \mathbf{u}_n \alpha^W_{n-n_j^{\wedge}}]\gamma'_{n+1,1} - \mathbf{u}_{n-1}\beta^W_{n-n_j^{\wedge}}\gamma'_{n+1,2}, \quad n_j^{\wedge} \le n \le n_j^{\vee} - 2, \tag{8.8c}$$

$$\mathbf{u}_{n+1} = [\mathbf{A}\mathbf{u}_n - \mathbf{u}_n \alpha^W_{n-n_j^{\vee}}]\gamma'_{n+1,1} - \mathbf{u}_{n-1}\beta^W_{n-n_j^{\vee}}\gamma'_{n+1,2}, \quad n_j^{\vee} \le n \le n_{j+1}^{\wedge} - 2\,. \tag{8.8d}$$

Of course, analogous formulas with the complex conjugate coefficients $\overline{\alpha^W_m}$ and $\overline{\beta^W_m}$, with the scale factors $\bar{\gamma}_{n,i}$ and $\bar{\gamma}'_{n,i}$ of (8.6) and with $\mathbf{A}$ replaced by $\mathbf{A}^H$ hold for $\{\mathbf{y}_n\}$ and $\{\mathbf{v}_n\}$, but from now on we only give those for $\{\mathbf{x}_n\}$ and $\{\mathbf{u}_n\}$. For simplicity we refer to these analogous formulas as the *conjugate* recurrences, although $\bar{\gamma}^{\wedge}_{n,i}$ and $\bar{\gamma}^{\vee}_{n,i}$ need not be complex conjugate to $\gamma^{\wedge}_{n,i}$ and $\gamma^{\vee}_{n,i}$.

If $\varepsilon^{\vee}_{i,j}$ and $\varepsilon^{\wedge}_{i,j}$ denote the coefficients of the polynomials $e_j^{\vee}$ and $e_j^{\wedge}$, respectively, (as is the case in (6.5)), the mixed three-term recurrence formulas (5.25) yield

$$\begin{aligned}\mathbf{u}_{n_j^{\vee}} = {} & \mathbf{x}_{n_j^{\vee}}\gamma^{\vee}_{n_j^{\vee},0} - \mathbf{x}_{n_j^{\vee}-1}\varepsilon^{\wedge}_{h_j^{\wedge}-2,j}\gamma^{\vee}_{n_j^{\vee},1} - \mathbf{x}_{n_j^{\vee}-2}\varepsilon^{\wedge}_{h_j^{\wedge}-3,j}\gamma^{\vee}_{n_j^{\vee},2} - \cdots \\ & - \mathbf{x}_{n_j^{\wedge}}\varepsilon^{\wedge}_{0,j}\gamma^{\vee}_{n_j^{\vee},h_j^{\wedge}-1} - \mathbf{u}_{n_{j-1}^{\vee}}\varphi^{\wedge}_j\gamma'_{n_j^{\vee},h_j^{\wedge}+h_{j-1}^{\vee}-1},\end{aligned} \tag{8.9a}$$

when $h_j^{\wedge} > 1$, cf. (5.27a) and (5.31a). In view of (5.27b), (5.29b), and (5.28b), when $h_j^{\vee} > 1$,

(8.9b)
$$\begin{aligned}\mathbf{x}_{n_{j+1}^{\wedge}} &= \mathbf{A}[\mathbf{u}_{n_{j+1}^{\wedge}-1}\gamma^{\wedge}_{n_{j+1}^{\wedge},1} - \mathbf{u}_{n_{j+1}^{\wedge}-2}\varepsilon^{\vee}_{h_j^{\vee}-2,j}\gamma^{\wedge}_{n_{j+1}^{\wedge},2} - \mathbf{u}_{n_{j+1}^{\wedge}-3}\varepsilon^{\vee}_{h_j^{\vee}-3,j}\gamma^{\wedge}_{n_{j+1}^{\wedge},3} - \cdots \\ &\quad - \mathbf{u}_{n_j^{\vee}}\varepsilon^{\vee}_{0,j}\gamma^{\wedge}_{n_{j+1}^{\wedge},h_j^{\vee}}] - \mathbf{x}_{n_j^{\wedge}}\varphi_j^{\vee}\gamma_{n_{j+1}^{\wedge},h_j^{\vee}+h_j^{\wedge}-1}\end{aligned}$$

(8.9c)
$$\begin{aligned}&= \mathbf{A}\mathbf{u}_{n_{j+1}^{\wedge}-1}\gamma^{\wedge}_{n_{j+1}^{\wedge},1} - \mathbf{x}_{n_{j+1}^{\wedge}-1}\varepsilon^{\vee}_{h_j^{\vee}-2,j}\gamma_{n_{j+1}^{\wedge},1} - \mathbf{x}_{n_{j+1}^{\wedge}-2}\varepsilon^{\vee}_{h_j^{\vee}-3,j}\gamma_{n_{j+1}^{\wedge},2} - \cdots \\ &\quad - \mathbf{x}_{n_j^{\vee}+1}\varepsilon^{\vee}_{0,j}\gamma_{n_{j+1}^{\wedge},h_j^{\vee}-1} - \mathbf{x}_{n_j^{\wedge}}\varphi_j^{\vee}\gamma_{n_{j+1}^{\wedge},h_j^{\vee}+h_j^{\wedge}-1}\end{aligned}$$

(8.9d)
$$\begin{aligned}&= [\mathbf{A}\mathbf{x}_{n_{j+1}^{\wedge}-1} - \mathbf{x}_{n_{j+1}^{\wedge}-1}(\varepsilon^{\vee}_{h_j^{\vee}-2,j} + \alpha^{W}_{h_j^{\vee}-3})]\gamma_{n_{j+1}^{\wedge},1} \\ &\quad - \mathbf{x}_{n_{j+1}^{\wedge}-2}(\varepsilon^{\vee}_{h_j^{\vee}-3,j} + \beta^{W}_{h_j^{\vee}-3})\gamma_{n_{j+1}^{\wedge},2} - \mathbf{x}_{n_{j+1}^{\wedge}-3}\varepsilon^{\vee}_{h_j^{\vee}-4,j}\gamma_{n_{j+1}^{\wedge},3} \\ &\quad - \cdots - \mathbf{x}_{n_j^{\vee}+1}\varepsilon^{\vee}_{0,j}\gamma_{n_{j+1}^{\wedge},h_j^{\vee}-1} - \mathbf{x}_{n_j^{\wedge}}\varphi_j^{\vee}\gamma_{n_{j+1}^{\wedge},h_j^{\vee}+h_j^{\wedge}-1}\end{aligned}$$

(cf. (5.31b)). However, when $h_j^{\wedge} = 1$, i.e., $n_j^{\vee} = n_j^{\wedge}$, then $W_{h_j^{\wedge}-1}(z) \equiv 1$ and $e_j^{\wedge}(z) \equiv 0$, so that instead of (8.9a) we simply obtain

(8.9e)
$$\mathbf{u}_{n_j^{\vee}} = \mathbf{x}_{n_j^{\wedge}}\gamma^{\vee}_{n_j^{\vee},0} - \mathbf{u}_{n_{j-1}^{\vee}}\varphi_j^{\wedge}\gamma'_{n_j^{\vee},h_{j-1}^{\vee}}.$$

Likewise, if $h_j^{\vee} = 1$, i.e., $n_{j+1}^{\wedge} = n_j^{\vee} + 1$, (8.8b)–(8.8d) are replaced by

(8.9f)
$$\mathbf{x}_{n_{j+1}^{\wedge}} = \mathbf{A}\mathbf{u}_{n_j^{\vee}}\gamma^{\wedge}_{n_{j+1}^{\wedge},1} - \mathbf{x}_{n_j^{\wedge}}\varphi_j^{\vee}\gamma_{n_{j+1}^{\wedge},h_j^{\wedge}}.$$

It remains to give formulas for the index sequences $\{n_j^{\wedge}\}$ and $\{n_j^{\vee}\}$ and for the coefficients $\varepsilon^{\vee}_{i,j}$, $\varepsilon^{\wedge}_{i,j}$, $\varphi_j^{\vee}$, and $\varphi_j^{\wedge}$ that appear in (8.9). First, according to (5.26) and (5.27), $h_j^{\wedge} := n_j^{\vee} - n_j^{\wedge} + 1$ and $h_j^{\vee} := n_{j+1}^{\wedge} - n_j^{\vee}$ are given by

(8.10a)
$$h_j^{\wedge} := \min\{k \in \mathbb{N}^+; \langle \mathbf{y}_{n_j^{\wedge}}, \mathbf{x}_{n_j^{\wedge}+k-1}\rangle_{\mathbf{B}} \neq 0\},$$

(8.10b)
$$h_j^{\vee} := \min\{k \in \mathbb{N}^+; \langle \mathbf{v}_{n_j^{\vee}}, \mathbf{A}\mathbf{u}_{n_j^{\vee}+k-1}\rangle_{\mathbf{B}} \neq 0\}.$$

Second, equations for the mentioned coefficients follow from Theorem 5.4; we choose relations (5.32a)–(5.32c) and (5.32f) in order to work without $\mathbf{v}_{n_j^{\vee}+1}, \ldots, \mathbf{v}_{n_{j+1}^{\wedge}-1}$:

(8.11a)
$$\varphi_j^{\wedge}\gamma^{\wedge}_{n_j^{\wedge},h_{j-1}^{\vee}}\overline{\bar{\gamma}_{n_j^{\vee},h_j^{\wedge}}}\langle \mathbf{y}_{n_j^{\wedge}-1}, \mathbf{A}\mathbf{u}_{n_{j-1}^{\vee}}\rangle_{\mathbf{B}} = \langle \mathbf{y}_{n_j^{\vee}}, \mathbf{x}_{n_j^{\wedge}}\rangle_{\mathbf{B}},$$

(8.11b)
$$\sum_{s=1}^{k} \varepsilon^{\wedge}_{h_j^{\wedge}-s-1,j}\gamma_{n_j^{\vee},s}\langle \mathbf{y}_{n_j^{\wedge}+k}, \mathbf{x}_{n_j^{\vee}-s}\rangle_{\mathbf{B}} = \langle \mathbf{y}_{n_j^{\wedge}+k}, \mathbf{x}_{n_j^{\vee}}\rangle_{\mathbf{B}}, \qquad k = 1, \ldots, h_j^{\wedge} - 1,$$

(8.11c)
$$\varphi_j^{\vee}\gamma^{\vee}_{n_j^{\vee},h_j^{\wedge}-1}\overline{\bar{\gamma}_{n_{j+1}^{\wedge}-1,h_j^{\vee}-1}}\langle \mathbf{y}_{n_j^{\vee}}, \mathbf{x}_{n_j^{\wedge}}\rangle_{\mathbf{B}} = \langle \mathbf{y}_{n_{j+1}^{\wedge}-1}, \mathbf{A}\mathbf{u}_{n_j^{\vee}}\rangle_{\mathbf{B}},$$

(8.11d)
$$\begin{aligned}&\sum_{s=1}^{k} \varepsilon^{\vee}_{h_j^{\vee}-s-1,j}\overline{\bar{\gamma}_{n_{j+1}^{\wedge}-1,s}}\langle \mathbf{y}_{n_{j+1}^{\wedge}-s-1}, \mathbf{u}_{n_j^{\vee}+k}\rangle_{\mathbf{B}} \\ &= \langle \mathbf{A}^H\mathbf{y}_{n_{j+1}^{\wedge}-1} - \mathbf{y}_{n_{j+1}^{\wedge}-1}\overline{\alpha^{W}_{h_j^{\vee}-2}} - \mathbf{y}_{n_{j+1}^{\wedge}-2}\overline{\beta^{W}_{h_j^{\vee}-2}}\bar{\gamma}_{n_{j+1}^{\wedge}-1,1}, \mathbf{u}_{n_j^{\vee}+k}\rangle_{\mathbf{B}}, \\ &\qquad\qquad k = 1, \ldots, h_j^{\vee} - 1.\end{aligned}$$

Again, (8.11a) and (8.11c) are single linear equations, hence explicit formulas, for $\varphi_j^{\wedge}$ and $\varphi_j^{\vee}$, respectively. Equations (8.11b) and (8.11d) are triangular systems for the

coefficients $\varepsilon^{\wedge}_{s,j}$ and $\varepsilon^{\vee}_{s,j}$ in the representation (6.5) of the polynomials $e^{\wedge}_j$ and $e^{\vee}_j$. If $h^{\wedge}_j = 1$, the system (8.11b) is void, and, if $h^{\vee}_j = 1$, the system (8.11d) is void.

We now obtain the following algorithm.

ALGORITHM 4 (NONGENERIC BOBC ALGORITHM). *Given a bounded linear operator* $\mathbf{A} : \mathcal{H} \to \mathcal{H}$ *and two initial vectors* $\mathbf{x}_0, \mathbf{y}_0 \in \mathcal{H}$ *satisfying* $\langle \mathbf{y}_0, \mathbf{x}_0 \rangle_{\mathbf{B}} \neq 0$, *set* $\mathbf{u}_0 := \mathbf{x}_0$, $\mathbf{v}_0 := \mathbf{y}_0$, $h^{\wedge}_0 := 1$. *Then construct sequences* $\{\mathbf{x}_n\}_{n=0}^{\infty}$, $\{\mathbf{y}_n\}_{n=0}^{\infty}$, $\{\mathbf{u}_n\}_{n=0}^{\infty}$, *and* $\{\mathbf{v}_n\}_{n=0}^{\infty}$ *according to the inductive process, which, for* $j = 0, 1, \ldots$, *consists of:*

(i) *If* $h^{\wedge}_j > 1$, *then* $\{\mathbf{x}_{n^{\wedge}_j+k}\}_{k=1}^{h^{\wedge}_j-1}$, $\{\mathbf{y}_{n^{\wedge}_j+k}\}_{k=0}^{h^{\wedge}_j-1}$, *and* $h^{\wedge}_j$ *are defined by executing concurrently* (8.8a), *the corresponding conjugate recurrence for* $\mathbf{y}_{n^{\wedge}_j+k}$, *and* (8.10a); *if* $h^{\wedge}_j = \infty$, *then* $J^{\wedge} := j$, $J^{\vee} := j - 1$; *in particular, if* $\mathbf{x}_{n^{\wedge}_j} = \mathbf{0}$ *or* $\mathbf{y}_{n^{\wedge}_j} = \mathbf{0}$, *then* $h^{\wedge}_j = \infty$ *and* $\mathbf{x}_{n^{\wedge}_j+k} = \mathbf{0}$ $(\forall k \geq 0)$ *or* $\mathbf{y}_{n^{\wedge}_j+k} = \mathbf{0}$ $(\forall k \geq 0)$, *respectively, and the algorithm terminates (in practice,* $\mathbf{x}_{n^{\wedge}_j+k}$ *and* $\mathbf{y}_{n^{\wedge}_j+k}$ *are then not needed);*

(ii) *once* $h^{\wedge}_j$ *has been determined, the nonzero constant* $\varphi^{\wedge}_j$ *is given by* (8.11a) *and, if* $h^{\wedge}_j > 1$, *the coefficients* $\{\varepsilon^{\wedge}_{s,j}\}_{s=1}^{h^{\wedge}_j-2}$ *are obtained by solving the triangular linear system* (8.11b);

(iii) *depending on whether or not* $h^{\wedge}_j > 1$, $\mathbf{u}_{n^{\vee}_j}$ *and* $\mathbf{v}_{n^{\vee}_j}$ *are then given by* (8.9a) *or* (8.9e) *and the conjugate recurrence; if* $\langle \mathbf{v}_{n^{\vee}_j}, \mathbf{A}\mathbf{u}_{n^{\vee}_j} \rangle_{\mathbf{B}} \neq 0$, *set* $h^{\vee}_j := 1$; *otherwise* $h^{\vee}_j > 1$;

(iv) *If* $h^{\vee}_j > 1$, *then* $\{\mathbf{u}_{n^{\vee}_j+k}\}_{k=1}^{h^{\vee}_j-1}$, $\mathbf{y}_{n^{\vee}_j+1}$, $\{\mathbf{y}_{n^{\vee}_j+k}\}_{k=2}^{h^{\vee}_j-1}$, *and* $h^{\vee}_j$ *are defined by* (8.8d), (8.7b), *the recurrence conjugate to* (8.8b), *and by* (8.10b); *if* $h^{\vee}_j = \infty$, *then* $J^{\vee} := J^{\wedge} := j$; *in particular, if* $\mathbf{u}_{n^{\vee}_j} = \mathbf{0}$ *or* $\mathbf{v}_{n^{\vee}_j} = \mathbf{0}$, *then* $h^{\vee}_j = \infty$ *and* $\mathbf{x}_{n^{\wedge}_j+k} = \mathbf{0}$ $(\forall k \geq 1)$ *or* $\mathbf{y}_{n^{\wedge}_j+k} = \mathbf{0}$ $(\forall k \geq 1)$, *respectively, and the algorithm terminates (in practice,* $\mathbf{x}_{n^{\wedge}_j+k}$ *and* $\mathbf{y}_{n^{\wedge}_j+k}$ *are then not needed*);

(v) *once* $h^{\vee}_j$ *has been determined, the nonzero constant* $\varphi^{\vee}_j$ *is given by* (8.11c) *and, if* $h^{\vee}_j > 1$, *the coefficients* $\{\varepsilon^{\vee}_{s,j}\}_{s=1}^{h^{\vee}_j-2}$ *are obtained by solving the triangular linear system* (8.11d);

(vi) *depending on whether* $h^{\vee}_j > 1$ *or not,* $\mathbf{x}_{n^{\wedge}_{j+1}}$ *and* $\mathbf{y}_{n^{\wedge}_{j+1}}$ *are either given by* (8.9b) *and the conjugate recurrence to* (8.9d) *or by* (8.9f) *and its conjugate recurrence; if* $\langle \mathbf{v}_{n^{\wedge}_{j+1}}, \mathbf{u}_{n^{\wedge}_{j+1}} \rangle_{\mathbf{B}} \neq 0$, *set* $h^{\wedge}_{j+1} := 1$, *otherwise* $h^{\wedge}_{j+1} > 1$.

The recurrence coefficients α^{W}_m *and* β^{W}_m *in* (8.8) *and the nonvanishing scale factors* Γ_n, Γ'_n, $\bar{\Gamma}_n$, *and* $\bar{\Gamma}'_n$ $(n \in \mathbb{N})$, *which determine* $\gamma^{\wedge}_{n,i}$, $\gamma^{\vee}_{n,i}$, $\gamma_{n,i}$, $\gamma'_{n,i}$, $\bar{\gamma}^{\wedge}_{n,i}$, $\bar{\gamma}^{\vee}_{n,i}$, $\bar{\gamma}_{n,i}$, *and* $\bar{\gamma}'_{n,i}$ *according to* (8.5) *and* (8.6), *can be chosen freely. (For the sake of simplicity, we assume that* $\Gamma_0 := \Gamma'_0 := \bar{\Gamma}_0 := \bar{\Gamma}'_0 := 1$.)

As in Algorithm 1 (§4) we could set $\Gamma_n := \Gamma'_n := \bar{\Gamma}_n := \bar{\Gamma}'_n := 1$ $(n \in \mathbb{N})$, which would imply that $\gamma^{\wedge}_{n,i} = \gamma^{\vee}_{n,i} = \gamma_{n,i} = \gamma'_{n,i} = \bar{\gamma}^{\wedge}_{n,i} = \bar{\gamma}^{\vee}_{n,i} = \bar{\gamma}_{n,i} = \bar{\gamma}'_{n,i} = 1$ $(\forall n, \forall i)$, but might lead to overflow or underflow.

Of course, Algorithm 4 also has a matrix interpretation, which is analogous to the one for Algorithm 1 that was formulated in Theorem 4.2 of Part I.

THEOREM 8.1. *Gather the vectors generated by Algorithm* 4 *into*

$$\mathbf{X} := [\mathbf{x}_0, \mathbf{x}_1, \mathbf{x}_2, \ldots], \quad \mathbf{Y} := [\mathbf{y}_0, \mathbf{y}_1, \mathbf{y}_2, \ldots], \tag{8.12a}$$

$$\mathbf{U} := [\mathbf{u}_0, \mathbf{u}_1, \mathbf{u}_2, \ldots], \quad \mathbf{V} := [\mathbf{v}_0, \mathbf{v}_1, \mathbf{v}_2, \ldots], \tag{8.12b}$$

and the scale factors used into

$$\mathbf{\Gamma} := \operatorname{diag}[\Gamma_0, \Gamma_1, \Gamma_2, \ldots], \quad \bar{\mathbf{\Gamma}} := \operatorname{diag}[\bar{\Gamma}_0, \bar{\Gamma}_1, \bar{\Gamma}_2, \ldots], \tag{8.13a}$$

(8.13b) $$\mathbf{\Gamma}' := \operatorname{diag}[\Gamma'_0, \Gamma'_1, \Gamma'_2, \ldots], \quad \bar{\mathbf{\Gamma}}' := \operatorname{diag}[\bar{\Gamma}'_0, \bar{\Gamma}'_1, \bar{\Gamma}'_2, \ldots].$$

Let $\mathbf{D}^\wedge$ *and* $\mathbf{D}^\vee$ *be the block diagonal matrices*

(8.14) $$\mathbf{D}^\wedge := \Phi((\mathbf{p})^T\mathbf{p}), \quad \mathbf{D}^\vee := \Phi'((\mathbf{p}')^T\mathbf{p}')$$

expressing the formal orthogonality of the two sequences of FOP1*s, and let*

(8.15) $$\mathbf{D}^\wedge_\Gamma := \overline{\bar{\mathbf{\Gamma}}}\mathbf{D}^\wedge\mathbf{\Gamma}, \quad \mathbf{D}^\vee_\Gamma := \overline{\bar{\mathbf{\Gamma}}'}\mathbf{D}^\vee\mathbf{\Gamma}'$$

be corresponding diagonally scaled matrices.[4] *Furthermore, using the block matrices* $\mathbf{E}^\wedge$, $\mathbf{E}^\vee$, $\mathbf{F}^\wedge$, $\mathbf{F}^\vee$, $\mathbf{G}^\wedge$, *and* $\mathbf{G}^\vee$ *from* §6, *introduce the scaled matrices*

(8.16a) $$\mathbf{E}^\wedge_\Gamma := (\mathbf{\Gamma}')^{-1}\mathbf{E}^\wedge\mathbf{\Gamma}, \quad \overline{\mathbf{E}^\wedge_\Gamma} := (\bar{\mathbf{\Gamma}}')^{-1}\overline{\mathbf{E}^\wedge}\bar{\mathbf{\Gamma}},$$

(8.16b) $$\mathbf{E}^\vee_\Gamma := (\mathbf{\Gamma})^{-1}\mathbf{E}^\vee\mathbf{\Gamma}', \quad \overline{\mathbf{E}^\vee_\Gamma} := (\bar{\mathbf{\Gamma}})^{-1}\overline{\mathbf{E}^\vee}\bar{\mathbf{\Gamma}}',$$

(8.16c) $$\mathbf{F}^\wedge_\Gamma := (\mathbf{\Gamma})^{-1}\mathbf{F}^\wedge\mathbf{\Gamma}, \quad \overline{\mathbf{F}^\wedge_\Gamma} := (\bar{\mathbf{\Gamma}})^{-1}\overline{\mathbf{F}^\wedge}\bar{\mathbf{\Gamma}},$$

(8.16d) $$\mathbf{F}^\vee_\Gamma := (\mathbf{\Gamma}')^{-1}\mathbf{F}^\vee\mathbf{\Gamma}', \quad \overline{\mathbf{F}^\vee_\Gamma} := (\bar{\mathbf{\Gamma}}')^{-1}\overline{\mathbf{F}^\vee}\bar{\mathbf{\Gamma}}',$$

(8.16e) $$\mathbf{G}^\wedge_\Gamma := (\mathbf{\Gamma})^{-1}\mathbf{G}^\wedge\mathbf{\Gamma}', \quad \overline{\mathbf{G}^\wedge_\Gamma} := (\bar{\mathbf{\Gamma}})^{-1}\overline{\mathbf{G}^\wedge}\bar{\mathbf{\Gamma}}',$$

(8.16f) $$\mathbf{G}^\vee_\Gamma := (\mathbf{\Gamma}')^{-1}\mathbf{G}^\vee\mathbf{\Gamma}, \quad \overline{\mathbf{G}^\vee_\Gamma} := (\bar{\mathbf{\Gamma}}')^{-1}\overline{\mathbf{G}^\vee}\bar{\mathbf{\Gamma}}.$$

Then Algorithm 4 *induces the relations*

(8.17a) $$\mathbf{A}\mathbf{U}\mathbf{E}^\wedge_\Gamma = \mathbf{X}\mathbf{F}^\wedge_\Gamma, \quad \mathbf{A}^H\mathbf{V}\overline{\mathbf{E}^\wedge_\Gamma} = \mathbf{Y}\overline{\mathbf{F}^\wedge_\Gamma},$$

(8.17b) $$\mathbf{X}\mathbf{E}^\vee_\Gamma = \mathbf{U}\mathbf{F}^\vee_\Gamma, \quad \mathbf{Y}\overline{\mathbf{E}^\vee_\Gamma} = \mathbf{V}\overline{\mathbf{F}^\vee_\Gamma},$$

which imply

(8.18a) $$\mathbf{A}\mathbf{U} = \mathbf{X}\mathbf{G}^\wedge_\Gamma, \quad \mathbf{A}^H\mathbf{V} = \mathbf{Y}\overline{\mathbf{G}^\wedge_\Gamma},$$

(8.18b) $$\mathbf{X} = \mathbf{U}\mathbf{G}^\vee_\Gamma, \quad \mathbf{Y} = \mathbf{V}\overline{\mathbf{G}^\vee_\Gamma}.$$

Moreover, if we write the infinite matrix with (m,n)*-element* $\langle \mathbf{y}_m, \mathbf{x}_n\rangle_\mathbf{B}$ *formally as* $\mathbf{Y}^H\mathbf{X}$, *and the one with* (m,n)*-element* $\langle \mathbf{v}_m, \mathbf{A}\mathbf{u}_n\rangle_\mathbf{B}$ *as* $\mathbf{V}^H\mathbf{A}\mathbf{U}$, *then we have*

(8.19) $$\mathbf{Y}^H\mathbf{X} = \mathbf{D}^\wedge_\Gamma, \quad \mathbf{V}^H\mathbf{A}\mathbf{U} = \mathbf{D}^\vee_\Gamma.$$

Note that (8.9b) corresponds to (8.17a), while (8.9c) translates into the relation (8.18a), which is equivalent to (8.17a).

From Algorithm 4 it is a small step to a nongeneric version of the *BCG method*, which also goes under the names *Lanczos/ORTHOMIN* [16] and *BIOMIN* [11]. This *normalized nongeneric BIOMIN algorithm* is a nearly straightforward application of the above BOBC algorithm to the problem of solving a linear system of equations $\mathbf{A}\mathbf{z} = \mathbf{b}$. As in the generic case [11], the basic strategy is to define a sequence $\{\mathbf{z}_n\}$ of approximants in such a way that the vectors $\mathbf{x}_n$ generated by Algorithm 4 are the residuals, which means that $\Gamma_n P_n$ is the nth residual polynomial. Consequently, for the normalized algorithm we have to choose $\Gamma_n := 1/P_n(0)$, thus producing a breakdown whenever $P_n(0) = 0$. However, the latter equality holds whenever $h^\vee_j > 1$ and $n^\vee_j < n < n^\wedge_{j+1}$, cf. (5.28b). This mirrors the fact that the restriction of $\mathbf{A}$ that

[4] The solid overbar denotes complex conjugation.

is implicitly constructed at this stage is singular, and, hence, the projected system cannot be solved in general. Recall that the same difficulty occurred in the nongeneric normalized BIORES algorithm (Algorithm 2 of Part I). But here, the difficulty is easier to recognize since it corresponds exactly to the case $h_j^\vee > 1$. It is also easier to understand how to circumnavigate it.

By translating (8.9b) into a polynomial recurrence (i.e., by inserting (8.3) and (4.14)) we see that

$$P_{n_{j+1}^\wedge}(0)\,\Gamma_{n_{j+1}^\wedge} = -P_{n_j^\wedge}(0)\,\Gamma_{n_j^\wedge}\varphi_j^\vee\gamma_{n_{j+1}^\wedge,h_j^\vee+h_j^\wedge-1}, \tag{8.20}$$

so that normalization is inherited from $P_{n_j^\wedge}(0)\,\Gamma_{n_j^\wedge}$ to $P_{n_{j+1}^\wedge}(0)\,\Gamma_{n_{j+1}^\wedge}$, i.e., from $\mathbf{x}_{n_j^\wedge}$ to $\mathbf{x}_{n_{j+1}^\wedge}$, simply by choosing

$$\gamma_{n_{j+1}^\wedge,h_j^\vee+h_j^\wedge-1} := \frac{-1}{\varphi_j^\vee}. \tag{8.21}$$

In contrast to Algorithm 2, only the iterates $\mathbf{z}_{n_j^\wedge}$ are considered as approximants, and only the corresponding vectors $\mathbf{x}_{n_j^\wedge}$ are true residuals. (It is possible to modify Algorithm 2 accordingly, thus avoiding the breakdown due to normalization. The resulting version is, in fact, just the unnormalized Algorithm 3 with scale factors $\Gamma_{n_j^\wedge}$, which yield normalized iterates when $n = n_j^\wedge$.)

ALGORITHM 5 (NORMALIZED NONGENERIC BOBC ALGORITHM FOR LINEAR SYSTEMS: NORMALIZED NONGENERIC BIOMIN). *For solving* $\mathbf{Az} = \mathbf{b}$, *choose an initial approximation* $\mathbf{z}_0$, *set* $\mathbf{u}_0 := \mathbf{x}_0 := \mathbf{b} - \mathbf{Az}_0$, *choose* $\mathbf{v}_0 := \mathbf{y}_0$ *with* $\langle \mathbf{y}_0, \mathbf{x}_0\rangle_{\mathbf{B}} \neq 0$, *and apply Algorithm* 4 *with the special choice* (8.21) *for the relative scale factors* $\gamma_{n_{j+1}^\wedge,h_j^\vee+h_j^\wedge-1}$ (*which determine* $\Gamma_{n_{j+1}^\wedge}$, *while the other scale factors* Γ_n $(n \neq n_{j+1}^\wedge)$, Γ_n', $\bar{\Gamma}_n$, *and* $\bar{\Gamma}_n'$ *may be chosen arbitrarily nonzero*).

Additionally, compute for $j = 0, 1, \ldots$ *the approximant* $\mathbf{z}_{n_{j+1}^\wedge}$ *according to*

$$\begin{aligned}\mathbf{z}_{n_{j+1}^\wedge} = -[&\mathbf{u}_{n_{j+1}^\wedge-1}\gamma_{n_{j+1}^\wedge,1}^\wedge - \mathbf{u}_{n_{j+1}^\wedge-2}\varepsilon_{h_j^\vee-2,j}^\vee\gamma_{n_{j+1}^\wedge,2}^\wedge - \mathbf{u}_{n_{j+1}^\wedge-3}\varepsilon_{h_j^\vee-3,j}^\vee\gamma_{n_{j+1}^\wedge,3}^\wedge \\ &- \cdots - \mathbf{u}_{n_j^\vee}\varepsilon_{0,j}^\vee\gamma_{n_{j+1}^\wedge,h_j^\vee}^\wedge] + \mathbf{z}_{n_j^\wedge}\varphi_j^\vee\gamma_{n_{j+1}^\wedge,h_j^\vee+h_j^\wedge-1}.\end{aligned} \tag{8.22}$$

The algorithm terminates when $n = n_{j+1}^\wedge$ *and* $\mathbf{x}_n = \mathbf{0}$. *Then* $n_{j^\wedge}^\wedge = n$ *and* $\mathbf{z}_n$ *is the solution of* $\mathbf{Az} = \mathbf{b}$. *However, if* $n = n_{j+1}^\wedge = n_{j^\wedge}^\wedge$, *but* $\mathbf{x}_n \neq \mathbf{0}$, *the solution cannot be found using those initial vectors* (*a case of incurable breakdown*).

As an analogy to the generic case [11] and to Algorithm 3 of Part I, we also suggest an *unnormalized* version of the nongeneric BIOMIN algorithm. It not only avoids the danger of breakdown due to normalization (as our nongeneric normalized BIOMIN algorithm does too), but allows to monitor independently the damping effect of the Lanczos polynomials P_n and the often adverse effect of normalization at 0. In this unnormalized version of BIOMIN we can choose all the scale factors Γ_n arbitrarily. We keep track of them by evaluating a recurrence for $\rho_{n_j^\wedge} := \Gamma_{n_j^\wedge}P_n(0)$, which follows from (8.20). Note that $\rho_{n_j^\wedge} \neq 0$ $(\forall j)$ in view of $\varphi_j^\vee \neq 0$ $(\forall j)$. In contrast to our unnormalized nongeneric BIORES algorithm of Part I (Algorithm 3), we restrict ourselves here to this subsequence; thus there is now only a small difference between the normalized and the unnormalized version.

ALGORITHM 6 (UNNORMALIZED NONGENERIC BOBC ALGORITHM FOR LINEAR SYSTEMS: UNNORMALIZED NONGENERIC BIOMIN). *For solving* $\mathbf{Az} = \mathbf{b}$ *choose an*

initial approximation $\mathbf{z}_0$, *set* $\mathbf{u}_0 := \mathbf{x}_0 := \mathbf{b} - \mathbf{A}\mathbf{z}_0$, *choose* $\mathbf{v}_0 := \mathbf{y}_0$ *with* $\langle \mathbf{y}_0, \mathbf{x}_0 \rangle_{\mathbf{B}} \neq 0$, *and apply Algorithm* 4 (*with arbitrary nonzero scale factors* Γ_n, Γ'_n, $\bar{\Gamma}_n$, *and* $\bar{\Gamma}'_n$). *Additionally, compute recursively the vector sequence* $\{\mathbf{z}_{n_j^\wedge}\}$ *according to* (8.22) *and the scalar sequence* $\{\rho_{n_j^\wedge}\}$ *according to*

$$\rho_{n_{j+1}^\wedge} := -\varphi_j^\vee \gamma_{n_{j+1}^\wedge, h_j^\vee + h_j^\wedge - 1} \rho_{n_j^\wedge} \,. \tag{8.23}$$

The algorithm terminates when $n = n_{j+1}^\wedge$ *and* $\mathbf{x}_n = \mathbf{0}$. *Then,* $n_{J^\wedge}^\wedge = n$ *and* $\mathbf{z}_n/\rho_n$ *is the solution of* $\mathbf{A}\mathbf{z} = \mathbf{b}$. *However, if* $n = n_{j+1}^\wedge = n_{J^\wedge}^\wedge$, *but* $\mathbf{x}_n \neq \mathbf{0}$, *the solution cannot be found using those initial vectors* (*a case of incurable breakdown*).

By an induction argument we obtain the following theorem, which is analogous to Theorem 4.6.

THEOREM 8.2. (i) *In Algorithm* 5 (*normalized nongeneric* BIOMIN) *holds*

$$\mathbf{x}_{n_j^\wedge} = \mathbf{b} - \mathbf{A}\mathbf{z}_{n_j^\wedge}, \quad j = 0, 1, 2, \ldots \,. \tag{8.24}$$

(ii) *In Algorithm* 6 (*unnormalized nongeneric* BIOMIN) *holds*

$$\mathbf{x}_{n_j^\wedge} = \mathbf{b}\rho_{n_j^\wedge} - \mathbf{A}\mathbf{z}_{n_j^\wedge}, \quad j = 0, 1, 2, \ldots \,. \tag{8.25}$$

Proof. Assume that (8.25) holds up to a certain j. Using the formulas (8.23), (8.22), and (8.9b) of Algorithm 6 we get

$$\begin{aligned} \mathbf{b}\rho_{n_{j+1}^\wedge} - \mathbf{A}\mathbf{z}_{n_{j+1}^\wedge} = &- \mathbf{b}\varphi_j^\vee \gamma_{n_{j+1}^\wedge, h_j^\vee + h_j^\wedge - 1} \rho_{n_j^\wedge} + \mathbf{A}[\mathbf{u}_{n_{j+1}^\wedge - 1} \gamma^\wedge_{n_{j+1}^\wedge, 1} \\ &- \mathbf{u}_{n_{j+1}^\wedge - 2} \varepsilon^\vee_{h_j^\vee - 2, j} \gamma^\wedge_{n_{j+1}^\wedge, 2} - \mathbf{u}_{n_{j+1}^\wedge - 3} \varepsilon^\vee_{h_j^\vee - 3, j} \gamma^\wedge_{n_{j+1}^\wedge, 3} - \cdots \\ &- \mathbf{u}_{n_j^\vee} \varepsilon^\vee_{0,j} \gamma^\wedge_{n_{j+1}^\wedge, h_j^\vee}] - \mathbf{A}\mathbf{z}_{n_j^\wedge} \varphi_j^\vee \gamma_{n_{j+1}^\wedge, h_j^\vee + h_j^\wedge - 1} = \mathbf{x}_{n_{j+1}^\wedge} \,. \end{aligned} \tag{8.26}$$

Hence, (8.25) follows by induction. In Algorithm 5, (8.21) guarantees that $\rho_{n_j^\wedge}$, defined by (8.23), is 1 for all j, so that (8.24) holds. □

Finally, we want to sketch the nongeneric generalization of yet another important algorithm, namely, of *BIODIR* [11] (or *Lanczos/ORTHODIR* [16]). As in the generic case [11], we first define a "biconjugation algorithm," which is nothing more than the BO algorithm with the inner product $\langle ., . \rangle_{\mathbf{BA}}$ instead of $\langle ., . \rangle_{\mathbf{B}}$. This algorithm can be used to generate the sequences $\{\mathbf{u}_n\}$ and $\{\mathbf{v}_n\}$ alone, without concurrently building up $\{\mathbf{x}_n\}$ and $\{\mathbf{y}_n\}$.

ALGORITHM 7 (NONGENERIC "BICONJUGATION (BC) ALGORITHM"). *Given a bounded linear operator* $\mathbf{A} : \mathcal{H} \to \mathcal{H}$ *and two initial vectors* $\mathbf{u}_0, \mathbf{v}_0 \in \mathcal{H}$ *satisfying* $\langle \mathbf{u}_0, \mathbf{A}\mathbf{v}_0 \rangle_{\mathbf{B}} \neq 0$, *apply the nongeneric* BO *algorithm* (*Algorithm* 1) *with the inner product* $\langle ., . \rangle_{\mathbf{BA}}$ (*instead of* $\langle ., . \rangle_{\mathbf{B}}$) *to produce the two vector sequences* $\{\mathbf{u}_n\}$ *and* $\{\mathbf{v}_n\}$ *with scale factors* Γ'_n *and* $\bar{\Gamma}'_n$ *and the matrix* $\mathbf{H}'$ *containing the recurrence coefficients of the corresponding* FOP1*s. Denote the indices of the regular* FOP1*s by* n'_i, *and let* $h'_i := n'_{i+1} - n'_i$.

In view of their orthogonality properties, the resulting vector sequences are the same as the sequences $\{\mathbf{u}_n\}$, $\{\mathbf{v}_n\}$ generated by the BOBC algorithm (if the initial vectors and the scale factors are the same). By applying half a step of the nongeneric backward qd algorithm (specified by Theorem 7.3), we can find the factors $\mathbf{G}^\wedge$ and $\mathbf{G}^\vee$ of the relevant block UL decomposition of $\mathbf{H}'$. Finally, we can apply formulas

(8.9b) and (8.22) to compute the subsequences $\mathbf{x}_{n_j^\wedge}$ and $\mathbf{z}_{n_j^\wedge}$, and (8.23) to find the appropriate scale factors for the normalization given below.

ALGORITHM 8 (NORMALIZED NONGENERIC BIODIR). *For solving* $\mathbf{Az} = \mathbf{b}$, *choose an initial approximation* $\mathbf{z}_0$, *set* $\mathbf{u}_0 := \mathbf{x}_0 := \mathbf{b} - \mathbf{Az}_0$, *choose* $\mathbf{v}_0 := \mathbf{y}_0$ *with* $\langle \mathbf{y}_0, \mathbf{x}_0 \rangle_{\mathbf{B}} \neq 0$, *and apply Algorithm 7 (with arbitrary nonzero scale factors* Γ'_n *and* $\bar{\Gamma}'_n$*) in order to produce the two vector sequences* $\{\mathbf{u}_n\}$ *and* $\{\mathbf{v}_n\}$ *and the matrix* $\mathbf{H}'$ *of recurrence coefficients of the corresponding* FOP1*s. Concurrently, compute block by block the relevant block* UL *decomposition* $\mathbf{H}' = \mathbf{G}^\wedge \mathbf{G}^\vee$ *according to Theorem* 7.3. *The initial moments required for that are*

$$\phi_0 := \frac{\langle \mathbf{y}_0, \mathbf{x}_0 \rangle_{\mathbf{B}}}{\bar{\Gamma}_0 \Gamma_0}, \quad \phi_{n'_1} := \frac{\langle \mathbf{v}_0, \mathbf{A}\mathbf{u}_{n'_1 - 1} \rangle_{\mathbf{B}}}{\bar{\Gamma}'_0 \Gamma'_{n'_1 - 1}}. \tag{8.27}$$

Additionally, for $j = 0, 1, \ldots$ *compute the subsequences* $\{\mathbf{x}_{n_j}\}$ *and* $\{\mathbf{z}_{n_j}\}$ *according to* (8.9b) *and* (8.22), *the value of* $\gamma_{n_{j+1}^\wedge, h_j^\vee + h_j^\wedge - 1}$ *being given by* (8.21). (*This determines the scale factors* Γ_{n_j}, *while* Γ_n $(n \neq n_j)$ *can be chosen arbitrarily nonzero.*)

The algorithm terminates when $n = n_{j+1}^\wedge$ *and* $\mathbf{x}_n = \mathbf{0}$. *Then* $n_{j^\wedge}^\wedge = n$ *and* $\mathbf{z}_n$ *is the solution of* $\mathbf{Az} = \mathbf{b}$. *If* $n = n_{j+1}^\wedge = n_{j^\wedge}^\wedge$, *but* $\mathbf{x}_n \neq \mathbf{0}$, *the solution cannot be found using those initial vectors* (*a case of incurable breakdown*).

This algorithm is normalized in the same sense as Algorithm 5; the residual polynomials $\Gamma_{n_j} P_{n_j}$ of the approximants $\mathbf{z}_{n_j^\wedge}$ are normalized to 1 at 0. Of course, we could try to replace the backward qd step by the solution of an extra triangular system of equations similar to (8.11c) and (8.11d). But this would require computation of both extra vectors and inner products.

Note that the breakdown conditions for the nongeneric versions of unnormalized BIORES, normalized and unnormalized BIOMIN, and normalized BIODIR are all the same. This is in contrast to the generic versions of these algorithms [11].

9. The treatment of near-breakdown for diagonal sequences. So far we have assumed that we work with exact arithmetic and that, therefore, the regular formal orthogonal polynomials (FOP1s) are well defined, and the corresponding elements of the various vector sequences generated by Lanczos-type algorithms can be computed accurately. Index steps h_j of size greater than 1 between regular FOP1s occur as a consequence of serious, but curable, breakdown. However, in practice exact curable breakdown is very unlikely, but *near-breakdown* may occur as a consequence of either an exact breakdown contaminated by roundoff or a very small $|\delta_j|$. Any such near-breakdown means that the recurrence coefficients $\alpha_{j,i}$ and β_{j+1} are probably large and numerically not well determined; then the subsequent FOP1s and the corresponding Krylov space vectors must be expected to be inaccurate.

Therefore, one must find a way to treat near-breakdowns. The simplest approach would be to use exactly the same formulas as for the exact curable breakdown. This would mean that we proceed implicitly with slightly modified data, but process them in a stable way, instead of treating the original data in an instable way. However, in this section we show that we can do even better. It is possible to treat near-breakdown *exactly* and still fairly efficiently. If our previously defined algorithms are modified accordingly, then, in exact arithmetic, those regular FOP1s that are well conditioned are obtained independently of the threshold used to define near-breakdown. The same is true for the corresponding Krylov space vectors. (Of course, the number of "well-conditioned" regular FOP1s depends on the threshold.) Here we present only

the polynomial formulation of these algorithms. Details of implementation for the corresponding Lanzos-type algorithms are described in joint work with Freund and Nachtigal [8]

In this section we treat ordinary, diagonal sequences of FOP1s. Recall that $\{n_j\}_{j=0}^{J}$ denotes the index sequence of the regular FOP1s P_{n_j} for some functional Φ, and that this sequence is characterized by

$$\Phi(pP_{n_j}) = 0 \quad (\forall p \in \mathcal{P}_{n_{j+1}-2}), \tag{9.1a}$$

$$\Phi(z^{h_j-1}P_{n_j}^2) =: \delta_j \neq 0, \tag{9.1b}$$

where $h_j := n_{j+1} - n_j$, $j = 0, \ldots, J-1$ ($J \leq \infty$). This recursive definition of the sequence $\{n_j\}$ implies that for $j < J$ the diagonal blocks

$$\mathbf{D}_j = \begin{bmatrix} & & & & \delta_j \\ & & & \delta_j & \star \\ & & \iddots & \iddots & \vdots \\ & \delta_j & \iddots & & \star \\ \delta_j & \star & \cdots & \star & \star \end{bmatrix}$$

of the formal Gramian $\mathbf{D}$ in (3.23) and (8.14) are nonsingular. For the intermediate values of n (i.e., for those satisfying $n_j < n < n_{j+1}$ for some j) the FOP1s are not uniquely determined, and we made the particular choice (1.28) for these *inner* FOP1s.

Now, we want to extract an index subsequence $\{\tilde{n}_k\}_{k=0}^{K} \subset \{n_j\}_{j=0}^{J}$ that marks the well-conditioned regular FOP1s $P_{\tilde{n}_k}$. Before we come to its recursive definition we choose first, by analogy to (1.28), *tentative inner* FOP1*s* for this subsequence:

$$\check{p}_n(z) := W_{n-\tilde{n}_k}(z)P_{\tilde{n}_k}(z) \quad \text{if } \tilde{n}_k \leq n < \tilde{n}_{k+1}. \tag{9.2}$$

Here W_m is still a prescribed monic sequence, for example, one satisfying a three-term recurrence (2.10). In the latter case the tentative inner polynomials $\check{p}_n$ themselves are obtained by a three-term recurrence. For simplicity, we could choose $W_m(z) = z^m$, although in practice this is often a rather inappropriate basis. To simplify formulas we include in (9.2) $n = \tilde{n}_k$, where $\check{p}_n = P_{\tilde{n}_k}$ is regular and thus not inner. Actually, when computing the next well-conditioned regular FOP1 $P_{\tilde{n}_{k+1}}$, we also start from a polynomial of the form (9.2), with $n = \tilde{n}_{k+1}$, which is then orthogonalized with respect to the previous blocks. We assume here that for those FOP1s this orthogonalization process has already been carried out, so that (9.2) holds for $\tilde{n}_k \leq n < \tilde{n}_{k+1}$ instead of for $\tilde{n}_k < n \leq \tilde{n}_{k+1}$.

One is tempted to define the index steps $\tilde{h}_k := \tilde{n}_{k+1} - \tilde{n}_k$ by analogy to (9.1) by

$$\Phi(pP_{\tilde{n}_k}) = 0 \quad (\forall p \in \mathcal{P}_{\tilde{n}_k-1}), \tag{9.3a}$$

$$|\Phi(z^i P_{\tilde{n}_k}^2)| \leq \varepsilon \quad (0 \leq i \leq \tilde{h}_k - 2), \tag{9.3b}$$

$$\Phi(z^{\tilde{h}_k-1}P_{\tilde{n}_k}^2) =: \tilde{\delta}_k, \quad |\tilde{\delta}_k| > \varepsilon, \tag{9.3c}$$

where $\varepsilon > 0$ is some prescribed small constant. This would imply that

(9.4)

$$\Phi(\check{p}_m\check{p}_n) = \begin{cases} 0 & \text{if } \tilde{n}_k \leq n \leq \tilde{n}_{k+1} - 2 \text{ and } m+n < 2\tilde{n}_k, \\ O(\varepsilon) & \text{if } \tilde{n}_k \leq n \leq \tilde{n}_{k+1} - 2 \text{ and } 2\tilde{n}_k \leq m+n \\ & \qquad\qquad \leq \tilde{n}_k + \tilde{n}_{k+1} - 2, \\ \tilde{\delta}_k + O(\varepsilon) & \text{if } \tilde{n}_k \leq n \leq \tilde{n}_{k+1} - 1 \text{ and } m+n = \tilde{n}_k + \tilde{n}_{k+1} - 1. \end{cases}$$

For example, if $K = 5$ and $\tilde{n}_0 = 0$, $\tilde{n}_1 = 1$, $\tilde{n}_2 = 2$, $\tilde{n}_3 = 5$, $\tilde{n}_5 = 7$, and if $\tilde{\varepsilon}$, $\tilde{\delta}_k^{\varepsilon}$, and $\star$ are abbreviations for $O(\varepsilon)$, $\tilde{\delta}_k + O(\varepsilon)$, and $O(1)$, respectively, the formal Gramian of $\{\check{p}_n\}$ is then of the form

$$(9.5)\quad [\Phi(\check{p}_m \check{p}_n)]_{m,n=0}^{\infty} = \begin{bmatrix} \tilde{\delta}_0^{\varepsilon} & & & & & & & & & \\ & \tilde{\delta}_1^{\varepsilon} & & & & \tilde{\varepsilon} & & & & \\ & & \tilde{\delta}_2^{\varepsilon} & & \tilde{\varepsilon} & \tilde{\varepsilon} & & & & \\ & & & \tilde{\varepsilon} & \tilde{\varepsilon} & \tilde{\delta}_3^{\varepsilon} & & & & \\ & & \tilde{\varepsilon} & \tilde{\varepsilon} & \tilde{\delta}_3^{\varepsilon} & \star & & & & \\ & \tilde{\varepsilon} & \tilde{\varepsilon} & \tilde{\delta}_3^{\varepsilon} & \star & \star & & \tilde{\varepsilon} & & \\ & & & & & & \tilde{\varepsilon} & \tilde{\delta}_4^{\varepsilon} & & \ddots \\ & & & & & \tilde{\varepsilon} & \tilde{\delta}_4^{\varepsilon} & \star & & \tilde{\varepsilon} & \ddots \\ & & & & & & & \tilde{\varepsilon} & \tilde{\varepsilon} & \ddots \\ & & & & & & & \tilde{\varepsilon} & \tilde{\varepsilon} & \tilde{\varepsilon} & \\ & & & & & & \ddots & \ddots & \ddots & & \ddots \end{bmatrix}.$$

There are two serious problems with this approach: First, while the formal Gramian $\mathbf{D}$ of the FOP1s $\{P_n\}$ is block diagonal, this is obviously no longer true for the one of $\{\check{p}_n\}$. Here, small $O(\varepsilon)$ elements can penetrate into several off-diagonal blocks. As a consequence, it can be seen that the Hessenberg matrix of recurrence coefficients for $\{\check{p}_n\}$ is no longer block tridiagonal; the formula for the regular FOP1 $\check{p}_{\tilde{n}_{k+1}}$ may contain not only terms from the two previous blocks but even terms from older ones. Hence, the major advantage of the generic and the nongeneric Lanczos algorithms is lost here. Second, $\tilde{h}_k$ and thus the sequence $\{\tilde{n}_k\}$ is generally not appropriately defined. Since $|\tilde{\delta}_k|$ need not be much larger than ε, $|\tilde{\delta}_k + O(\varepsilon)|$ may be small or may even vanish, and the diagonal blocks of the formal Gramian may be singular.

The second difficulty can be overcome if we transform the sequence, $\{\check{p}_n\}$, by a block orthogonalization process[5] into a new formally block orthogonal sequence, $\{\tilde{p}_n\}$, whose formal Gramian is block diagonal. The index subsequence $\{\tilde{n}_k\}$ is then defined by requiring that the diagonal blocks

$$(9.6)\qquad \tilde{\mathbf{D}}_k = [\Phi(\tilde{p}_{\tilde{n}_k+i}\, \tilde{p}_{\tilde{n}_k+j})]_{i,j=0}^{\tilde{h}_k-1}$$

of this formal Gramian $\tilde{\mathbf{D}}$ are not only nonsingular, but neither near-singular nor ill conditioned:

$$(9.7)\qquad \sigma_{\min}(\tilde{\mathbf{D}}_k) > \varepsilon, \quad \kappa(\tilde{\mathbf{D}}_k) \leq \kappa'.$$

The appropriate order of magnitude of ε and of the upper bound κ' of the condition number κ depend on the functional Φ. If the latter or the inner polynomials are scaled such that $\sigma_{\max}(\tilde{\mathbf{D}}_k)$ is a priori bounded, it suffices—at least in theory—to make the first check. This is in accordance with the recommendation of Parlett [21]. Note that—also just in theory—the near-breakdown threshold ε need not be very small and the block size chosen need not be the minimal one satisfying (9.7). Unfortunately, in practice, roundoff spoils the orthogonality and the determination of the block size according to (9.7) may not work for large-scale systems. Therefore, a different strategy has to be chosen in the implementation (see [8] for details).

[5] Confer footnote 2 at the end of the introduction.

However, as is seen from (9.5), the block orthogonalization process suggested above also has the disadvantage that it may involve sums that contain elements from several previous blocks, i.e., the upper triangular matrix describing this process is not block bidiagonal, as one might have hoped. In fact, "long" recurrences may occur here not only for some $\tilde{p}_{\tilde{n}_k}$, but also for some inner $\tilde{p}_n$.

Things change if we build up the block orthogonal sequence $\{\tilde{p}_n\}$ directly by orthogonalizing $z\tilde{p}_n$ with respect to previous blocks. In fact, by a standard argument we are going to conclude that the Hessenberg matrix $\tilde{\mathbf{H}}$ of recurrence coefficients is then block tridiagonal. The freedom of choice present in (9.2) is gained from the possibility of adding any linear combination of polynomials that have already been computed in the block under construction. (The coefficients in this linear combination are the same as those in the recurrence (2.10).) Since this linear combination is already orthogonal to all previous blocks, it has no effect on the off-diagonal blocks of $\tilde{\mathbf{H}}$.

Let $\tilde{\mathbf{p}} := [\tilde{p}_0, \tilde{p}_1, \ldots]$ be the infinite row vector whose elements are the resulting monic block orthogonalized polynomials $\tilde{p}_n$. Then the block diagonal formal Gramian of these polynomials can be written as

$$\tilde{\mathbf{D}} := \Phi(\tilde{\mathbf{p}}^T\tilde{\mathbf{p}}) := [\Phi(\tilde{p}_m\tilde{p}_n)]_{m,n=0}^{\infty}\,. \tag{9.8}$$

(Recall that its diagonal blocks satisfy (9.7) by definition of $\{\tilde{n}_k\}$.)

Since the polynomials are monic of ascending degree, they can certainly be generated by a recurrence that has the matrix form

$$z\tilde{\mathbf{p}}(z) = \tilde{\mathbf{p}}(z)\tilde{\mathbf{H}}, \tag{9.9}$$

with $\tilde{\mathbf{H}}$ being unit upper Hessenberg. Consequently,

$$\tilde{\mathbf{D}}\tilde{\mathbf{H}} = \Phi(\tilde{\mathbf{p}}^T\tilde{\mathbf{p}})\tilde{\mathbf{H}} = \Phi(\tilde{\mathbf{p}}^T\tilde{\mathbf{p}}\tilde{\mathbf{H}}) = \Phi(\tilde{\mathbf{p}}^T z\tilde{\mathbf{p}}) \tag{9.10a}$$

$$= \Phi(\tilde{\mathbf{H}}^T\tilde{\mathbf{p}}^T\tilde{\mathbf{p}}) = \tilde{\mathbf{H}}^T\Phi(\tilde{\mathbf{p}}^T\tilde{\mathbf{p}}) = \tilde{\mathbf{H}}^T\tilde{\mathbf{D}}\,. \tag{9.10b}$$

Since $\tilde{\mathbf{H}}$ is upper Hessenberg and $\tilde{\mathbf{D}}$ is block diagonal, the left-hand side is upper block Hessenberg and the right-hand side is lower block Hessenberg. Consequently, both sides are block tridiagonal, and multiplication by $\tilde{\mathbf{D}}^{-1}$ shows that the same is true for $\tilde{\mathbf{H}}$ itself, i.e., by analogy to (3.6),

$$\tilde{\mathbf{H}} := \begin{bmatrix} \tilde{\mathbf{A}}_0 & \tilde{\mathbf{B}}_1 & & & \\ \tilde{\mathbf{C}}_0 & \tilde{\mathbf{A}}_1 & \tilde{\mathbf{B}}_2 & & \\ & \tilde{\mathbf{C}}_1 & \tilde{\mathbf{A}}_2 & \ddots & \\ & & \ddots & \ddots & (\tilde{\mathbf{B}}_K) \\ & & & (\tilde{\mathbf{C}}_{K-1}) & (\tilde{\mathbf{A}}_K) \end{bmatrix}. \tag{9.11}$$

In general the block structure is coarser here than in (3.6), but all block boundaries in this matrix are also present in the matrix $\mathbf{H}$ of (3.6). In view of $\tilde{\mathbf{H}}$ being unit upper Hessenberg, the blocks $\tilde{\mathbf{C}}_k$ have again just a 1 in the upper right corner, and the blocks $\tilde{\mathbf{A}}_k$ are either 1×1 or unit upper Hessenberg. It remains to investigate the upper triangular part of $\tilde{\mathbf{A}}_k$ and the superdiagonal blocks $\tilde{\mathbf{B}}_k$. Moreover, we have to discuss how to determine the elements of these blocks.

The only condition we are imposing is that $\{\tilde{p}_n\}$ be formally block orthogonal, i.e., $\Phi(\tilde{\mathbf{p}}^T\tilde{\mathbf{p}}) = \tilde{\mathbf{D}}$ is block diagonal. Splitting the row vector $\tilde{\mathbf{p}}$ into blocks of size $\tilde{h}_k$, we set $\tilde{\mathbf{p}} = [\tilde{\mathbf{p}}_0, \tilde{\mathbf{p}}_1, \ldots, (\tilde{\mathbf{p}}_K)]$ to get

$$\tilde{\mathbf{D}}_k = \Phi(\tilde{\mathbf{p}}_k^T\tilde{\mathbf{p}}_k)\,. \tag{9.12a}$$

From the kth block column of (9.10a) we extract the three conditions

$$\tilde{\mathbf{D}}_{k-1}\tilde{\mathbf{B}}_k = \Phi(\tilde{\mathbf{p}}_{k-1}^T z\tilde{\mathbf{p}}_k), \tag{9.12b}$$

$$\tilde{\mathbf{D}}_k\tilde{\mathbf{A}}_k = \Phi(\tilde{\mathbf{p}}_k^T z\tilde{\mathbf{p}}_k), \tag{9.12c}$$

$$\tilde{\mathbf{D}}_{k+1}\tilde{\mathbf{C}}_k = \Phi(\tilde{\mathbf{p}}_{k+1}^T z\tilde{\mathbf{p}}_k)\,. \tag{9.12d}$$

If $\tilde{\mathbf{p}}_{k-1}$, $\tilde{p}_{\tilde{n}_k}$, and $\tilde{\mathbf{D}}_{k-1}$ are known, (9.12a)–(9.12c) allow us, if they are used column by column and in parallel, to build up $\tilde{\mathbf{p}}_k$, $\tilde{\mathbf{B}}_k$, $\tilde{\mathbf{A}}_k$, and $\tilde{\mathbf{D}}_k$, and to determine $\tilde{h}_{k+1}$ and $\tilde{p}_{\tilde{n}_{k+1}}$. Actually, except for its last column, $\tilde{\mathbf{A}}_k$ can be chosen as an arbitrary unit upper Hessenberg matrix, hence we assume it given, except for the last column. For example, each of the other columns may be zero except for a 1 on the subdiagonal.

First, since $\Phi(p\tilde{\mathbf{p}}_k) = \mathbf{0}^T$ for all $p \in \mathcal{P}_{\tilde{n}_k-1}$, only the last line of (9.12b) is nonzero:

$$\tilde{\mathbf{D}}_{k-1}\tilde{\mathbf{B}}_k = \tilde{\mathbf{l}}_k\boldsymbol{\phi}_k^T, \tag{9.13a}$$

where

$$\boldsymbol{\phi}_k^T := \Phi(z\tilde{p}_{\tilde{n}_k-1}\tilde{\mathbf{p}}_k), \quad \tilde{\mathbf{l}}_k := [0,\ldots,0,1]^T \in \mathbb{C}^{\tilde{h}_k}\,. \tag{9.13b}$$

Hence, $\tilde{\mathbf{B}}_k$ has rank 1. Once $\tilde{p}_n$ is known for some n with $(\tilde{n}_k \le n \le \tilde{n}_{k+1} - 1)$, column n of $\tilde{\mathbf{B}}_k$ is obtained by solving a linear system with the coefficient matrix $\tilde{\mathbf{D}}_{k-1}$, which is no longer triangular, but has constant nonzero antidiagonal elements and a small upper left triangular part.[6] If $n < \tilde{n}_{k+1} - 1$, the corresponding column of $\tilde{\mathbf{A}}_k$ is prescribed, and thus $\tilde{p}_{n+1}$ can be computed according to (9.9). Moreover, the element $n+1$ in the first row (i.e., row $\tilde{n}_k + 1$) of $\tilde{\mathbf{D}}_k$ can be evaluated explicitly using the definition (9.12a) of $\tilde{\mathbf{D}}_k$. Once $n+1 = \tilde{n}_{k+1} - 1$, the whole first column of $\tilde{\mathbf{D}}_k$ is known, as is its first row, thanks to symmetry.

After splitting off the first row and column of $\tilde{\mathbf{D}}_k$ and the first row and the last column of $\tilde{\mathbf{A}}_k$, (9.12c) is seen to yield a set of $\tilde{h}_k - 1$ triangular systems for computing the yet unknown elements of $\tilde{\mathbf{D}}_k$. Then, by (9.12b), too, the last column $\tilde{\mathbf{a}}_k$ of $\tilde{\mathbf{A}}_k$ is also found by solving a linear system with coefficient matrix $\tilde{\mathbf{D}}_k$:

$$\tilde{\mathbf{D}}_k\tilde{\mathbf{a}}_k = \Phi(\tilde{\mathbf{p}}_k^T z\tilde{p}_{\tilde{n}_{k+1}-1})\,. \tag{9.14}$$

Finally, now that the last columns of $\tilde{\mathbf{A}}_k$ and $\tilde{\mathbf{B}}_k$ are known, the recurrence for the next well-conditioned regular FOP1, $\tilde{p}_{\tilde{n}_{k+1}}$ is ready.

Due to the special structure of $\tilde{\mathbf{C}}_k$, the only part of $\tilde{\mathbf{D}}_k$ that matters in (9.12d) is the first column. It is easy to see that for the elements in this first column (9.12d) provides formulas that are mathematically equivalent to those from the definition (9.12a) of $\tilde{\mathbf{D}}_k$.

Summarizing, we see that on the basis of the relations (9.12) we can build up $\tilde{\mathbf{H}}$ and $\tilde{\mathbf{D}}$ column by column.

One may wonder what can be said about the order of magnitude of the elements of $\tilde{\mathbf{D}}_k$ and $\tilde{\mathbf{B}}_k$ if (9.3) holds for some $\varepsilon << 1$ and with $|\tilde{\delta}'_k| >> 1$ $(k' = k-1, k)$. In

[6] Column n of $\tilde{\mathbf{B}}_k$ refers to the part of column n of $\tilde{\mathbf{H}}$ that lies in $\tilde{\mathbf{B}}_k$; rows and elements are referred to in an analogous fashion.

the notation of (9.5) we clearly have, for $0 \le k < K$,

$$\tilde{\mathbf{D}}_k = \begin{bmatrix} \tilde{\varepsilon} & \tilde{\varepsilon} & \cdots & \tilde{\varepsilon} & \tilde{\delta}_k^{\varepsilon} \\ \tilde{\varepsilon} & & & \iddots & \star \\ \vdots & & \iddots & & \vdots \\ \tilde{\varepsilon} & \iddots & & & \star \\ \tilde{\delta}_k^{\varepsilon} & \star & \cdots & \star & \star \end{bmatrix}. \tag{9.15}$$

(When $K < \infty$, the last diagonal block $\tilde{\mathbf{D}}_K$ is infinite and consists of elements of order $O(\varepsilon)$.) From (9.15) it is easy to conclude that

$$\tilde{\mathbf{D}}_k^{-1} = \begin{bmatrix} \star & \star & \cdots & \star \\ \star & & & \tilde{\varepsilon} \\ \vdots & & \iddots & \vdots \\ \star & \tilde{\varepsilon} & \cdots & \tilde{\varepsilon} \end{bmatrix}, \tag{9.16}$$

and, therefore, that

$$\tilde{\mathbf{B}}_k = \tilde{\mathbf{D}}_{k-1}^{-1} \tilde{\mathbf{l}}_k \boldsymbol{\phi}_k^T = \begin{bmatrix} \tilde{\varepsilon} & \cdots & \tilde{\varepsilon} & \star \\ \tilde{\varepsilon}^2 & \cdots & \tilde{\varepsilon}^2 & \tilde{\varepsilon} \\ \vdots & & \vdots & \vdots \\ \tilde{\varepsilon}^2 & \cdots & \tilde{\varepsilon}^2 & \tilde{\varepsilon} \end{bmatrix}, \tag{9.17}$$

where $\tilde{\varepsilon}^2 := O(\varepsilon^2)$.

Actually, the order-of-magnitude statement in (9.17) can be seen to be a consequence of the block diagonality of $\tilde{\mathbf{D}}$, the block tridiagonality of $\tilde{\mathbf{H}}$, and the special structure of the blocks $\tilde{\mathbf{D}}_k$ and $\tilde{\mathbf{C}}_k$. Comparing superdiagonal blocks in the relation (9.10), we get $\tilde{\mathbf{D}}_{k-1}\tilde{\mathbf{B}}_k = \tilde{\mathbf{C}}_{k-1}^T \tilde{\mathbf{D}}_k$; hence

$$\tilde{\mathbf{B}}_k = \tilde{\mathbf{D}}_{k-1}^{-1} \tilde{\mathbf{C}}_{k-1}^T \tilde{\mathbf{D}}_k = \begin{bmatrix} \star & \star & \cdots & \star \\ \star & & & \tilde{\varepsilon} \\ \vdots & & \iddots & \vdots \\ \star & \tilde{\varepsilon} & \cdots & \tilde{\varepsilon} \end{bmatrix} \begin{bmatrix} 0 & \cdots & 0 & 0 \\ \vdots & & \vdots & \vdots \\ 0 & \cdots & 0 & 0 \\ \tilde{\varepsilon} & \cdots & \tilde{\varepsilon} & \star \end{bmatrix} = \begin{bmatrix} \tilde{\varepsilon} & \cdots & \tilde{\varepsilon} & \star \\ \tilde{\varepsilon}^2 & \cdots & \tilde{\varepsilon}^2 & \tilde{\varepsilon} \\ \vdots & & \vdots & \vdots \\ \tilde{\varepsilon}^2 & \cdots & \tilde{\varepsilon}^2 & \tilde{\varepsilon} \end{bmatrix}. \tag{9.18}$$

Comparing (9.13), (9.17), and (9.18), we get the additional relation

$$\boldsymbol{\phi}_k^T := \Phi(z\tilde{p}_{\tilde{n}_k-1}\tilde{\mathbf{p}}_k) = \tilde{\mathbf{l}}_k \boldsymbol{\phi}_k^T = \tilde{\mathbf{C}}_{k-1}^T \tilde{\mathbf{D}}_k = \Phi(\tilde{p}_{\tilde{n}_k}\tilde{\mathbf{p}}_k), \tag{9.19}$$

which is, indeed, a consequence of $\tilde{p}_n$ ($n \ge \tilde{n}_k$) being orthogonal to $\mathcal{P}_{\tilde{n}_k-1}$.

10. The treatment of near-breakdown for staircase sequences. In this section we modify the ideas of the previous section in order to compute a block staircase sequence of well-conditioned FOP1s instead of a block diagonal sequence.

The aim is to determine two full sequences $\tilde{\mathbf{p}} := \{\tilde{p}_n\}_{n=0}^{\infty}$, $\tilde{\mathbf{p}}' := \{\tilde{p}'_n\}_{n=0}^{\infty}$ of monic polynomials ($\tilde{p}_n$ and $\tilde{p}'_n$ being of degree n) that are block orthogonal, well conditioned, and block compatible in the following sense. There are two (finite or infinite) index sequences $\{\tilde{n}_k^{\wedge}\}_{k=0}^{K^{\vee}}$, $\{\tilde{n}_k^{\vee}\}_{k=0}^{K^{\wedge}}$ (with $K^{\vee} \le K^{\wedge} \le K^{\vee}+1 \le \infty$) satisfying

$$\tilde{n}_k^{\wedge} \le \tilde{n}_k^{\vee} \ (k = 0, \ldots, K^{\vee}), \quad \tilde{n}_k^{\vee} < \tilde{n}_{k+1}^{\wedge} \ (k = 0, \ldots, K^{\wedge} - 1) \tag{10.1}$$

such that the following two conditions hold: First

$$\Phi(\tilde{p}_m \tilde{p}_n) = 0 \text{ if } m < \tilde{n}_k^{\wedge} \le n \text{ for some } k \quad \text{or } m \le \tilde{n}_k^{\vee} < n \text{ for some } k, \tag{10.2a}$$

$$\Phi'(\tilde{p}'_m \tilde{p}'_n) = 0 \text{ if } m < \tilde{n}_k^{\vee} \le n \text{ for some } k \quad \text{or } m < \tilde{n}_{k+1}^{\wedge} \le n \text{ for some } k, \tag{10.2b}$$

which means that the two formal Gramians

$$\tilde{\mathbf{D}}^{\wedge} := \Phi(\tilde{\mathbf{p}}^T \tilde{\mathbf{p}}), \quad \tilde{\mathbf{D}}^{\vee} := \Phi'((\tilde{\mathbf{p}}')^T \tilde{\mathbf{p}}') \tag{10.3}$$

are block diagonal, with blocks starting at the columns $\tilde{n}_k^{\wedge}$, $\tilde{n}_k^{\vee} + 1$ ($\le \tilde{n}_{k+1}^{\wedge}$) and $\tilde{n}_k^{\vee}$, $\tilde{n}_{k+1}^{\wedge}$ ($\le \tilde{n}_{k+1}^{\vee}$), respectively. Second, for their diagonal blocks

$$\tilde{\mathbf{D}}_k^{\wedge} := [\Phi(\tilde{p}_m \tilde{p}_n)]_{m,n=\tilde{n}_k^{\wedge}}^{\tilde{n}_k^{\vee}}, \quad \tilde{\mathbf{D}}_{k+\frac{1}{2}}^{\wedge} := [\Phi(\tilde{p}_m \tilde{p}_n)]_{m,n=\tilde{n}_k^{\vee}+1}^{\tilde{n}_{k+1}^{\wedge}-1}, \tag{10.4a}$$

$$\tilde{\mathbf{D}}_k^{\vee} := [\Phi'(\tilde{p}'_m \tilde{p}'_n)]_{m,n=\tilde{n}_k^{\vee}}^{\tilde{n}_{k+1}^{\wedge}-1}, \quad \tilde{\mathbf{D}}_{k-\frac{1}{2}}^{\vee} := [\Phi'(\tilde{p}'_m \tilde{p}'_n)]_{m,n=\tilde{n}_k^{\wedge}}^{\tilde{n}_k^{\vee}-1}, \tag{10.4b}$$

holds, by analogy to (9.7), (for some $\varepsilon > 0$, $\kappa' > 1$):

$$\sigma_{\min}(\tilde{\mathbf{D}}_k^{\wedge}) > \varepsilon, \quad \kappa(\tilde{\mathbf{D}}_k^{\wedge}) \le \kappa', \tag{10.5a}$$

$$\sigma_{\min}(\tilde{\mathbf{D}}_{k+\frac{1}{2}}^{\wedge}) > \varepsilon, \quad \kappa(\tilde{\mathbf{D}}_{k+\frac{1}{2}}^{\wedge}) \le \kappa', \tag{10.5b}$$

$$\sigma_{\min}(\tilde{\mathbf{D}}_k^{\vee}) > \varepsilon, \quad \kappa(\tilde{\mathbf{D}}_k^{\vee}) \le \kappa', \tag{10.5c}$$

$$\sigma_{\min}(\tilde{\mathbf{D}}_{k-\frac{1}{2}}^{\vee}) > \varepsilon, \quad \kappa(\tilde{\mathbf{D}}_{k-\frac{1}{2}}^{\vee}) \le \kappa'. \tag{10.5d}$$

Note that some of the blocks $\tilde{\mathbf{D}}_{k+(1/2)}^{\wedge}$ and $\tilde{\mathbf{D}}_{k-(1/2)}^{\vee}$ may be void. They exist only if the respective index step

$$\tilde{h}_k^{\vee} := \tilde{n}_{k+1}^{\wedge} - \tilde{n}_k^{\vee}, \quad \tilde{h}_k^{\wedge} := \tilde{n}_k^{\vee} - \tilde{n}_k^{\wedge} + 1 \tag{10.6}$$

is larger than 1. Then $\tilde{\mathbf{D}}_{k+(1/2)}^{\wedge}$ lies in $\tilde{\mathbf{D}}^{\wedge}$ between $\tilde{\mathbf{D}}_k^{\wedge}$ and $\tilde{\mathbf{D}}_{k+1}^{\wedge}$, and $\tilde{\mathbf{D}}_{k-(1/2)}^{\vee}$ lies in $\tilde{\mathbf{D}}^{\vee}$ between $\tilde{\mathbf{D}}_{k-1}^{\vee}$ and $\tilde{\mathbf{D}}_k^{\vee}$. The blocks in (10.4a) have order $\tilde{h}_k^{\wedge}$ and $\tilde{h}_k^{\vee} - 1$; those in (10.4b) have order $\tilde{h}_k^{\vee}$ and $\tilde{h}_k^{\wedge} - 1$, respectively.

The recursive process for constructing these two sequences, like the one in §5, alternates between the two sequences. The block structure generated in this way in the corresponding analog of the Padé table (which is a "near-FOP1 table") still resembles the one of Fig. 3, but at this point it is restricted to the two diagonals specified by l and $l + 1$. A conflict arises because we require the four conditions (10.5a)–(10.5d), although (10.5a) and (10.5c) would be enough to determine the two index sequences $\{\tilde{n}_k^{\wedge}\}$ and $\{\tilde{n}_k^{\vee}\}$. But it is important that $\tilde{p}'_{\tilde{n}_k^{\vee}}$ lies in the first row of a block, and $\tilde{p}_{\tilde{n}_{k+1}^{\wedge}}$ in the first column, as happens automatically in §5, cf. Fig. 3. This must now be enforced by a condition guaranteeing that the blocks $\tilde{\mathbf{D}}_{k+(1/2)}^{\wedge}$ and $\tilde{\mathbf{D}}_{k-(1/2)}^{\vee}$ are nonsingular. In order that $\tilde{p}'_{\tilde{n}_k^{\vee}}$ and $\tilde{p}_{\tilde{n}_{k+1}^{\wedge}}$ be well-conditioned regular FOP1s, these blocks can be neither near-singular nor ill conditioned. Consequently, on each diagonal the sizes of some blocks may turn out to be larger than when we apply the algorithm of the previous section to the respective diagonal. But this is the price we have to pay for a "compatible" block structure on the two diagonals, i.e., index sequences $\{\tilde{n}_k^{\wedge}\}, \{\tilde{n}_k^{\vee}\}$, which together define the blocks on both diagonals.

Now we come to the details of the algorithm. Its basic pattern is as follows:

(i) When $n = \tilde{n}_k^\wedge$, Φ-orthogonalize $z\tilde{p}'_{n-1}$ with respect to $\mathcal{P}_{\tilde{n}_k^\wedge - 1}$ to get $\tilde{p}_n$; check (10.5a) to determine whether $\tilde{\mathbf{D}}_k^\wedge$ is just 1×1. If yes, set $\tilde{n}_k^\vee := n$ and proceed with (iii).

(ii) If not, i.e., if $\tilde{n}_k^\vee > \tilde{n}_k^\wedge$, then, for $n = \tilde{n}_k^\wedge + 1, \tilde{n}_k^\wedge + 2, \ldots$, Φ'-orthogonalize $\tilde{p}_{n-1}$ with respect to $\mathcal{P}_{\tilde{n}_k^\wedge - 1}$ to get $\tilde{p}'_{n-1}$, and set $\tilde{p}_n := z\tilde{p}'_{n-1}$; check (10.5a) and (10.5d) to determine whether $\tilde{\mathbf{D}}_k^\wedge$ and $\tilde{\mathbf{D}}_{k-(1/2)}^\vee$ are completed, in which case $\tilde{n}_k^\vee := n$.

(iii) When $n = \tilde{n}_k^\vee$, Φ'-orthogonalize $\tilde{p}_n$ with respect to $\mathcal{P}_{\tilde{n}_k^\vee - 1}$ to get $\tilde{p}'_n$; check (10.5c) to determine whether $\tilde{\mathbf{D}}_k^\vee$ is just 1×1. If yes, set $\tilde{n}_{k+1}^\wedge := n$ and proceed with (i).

(iv) If not, i.e., if $\tilde{n}_{k+1}^\wedge > \tilde{n}_k^\vee + 1$, then, for $n = \tilde{n}_k^\vee + 1, \tilde{n}_k^\vee + 2, \ldots$, Φ-orthogonalize $z\tilde{p}'_{n-1}$ with respect to $\mathcal{P}_{\tilde{n}_k^\vee}$ to get $\tilde{p}_n$ and set $\tilde{p}'_n := \tilde{p}_n$; check (10.5c) and (10.5b) to determine whether $\tilde{\mathbf{D}}_k^\vee$ and $\tilde{\mathbf{D}}_{k-(1/2)}^\wedge$ are completed, in which case $\tilde{n}_{n+1}^\wedge := n + 1$.

Note that the choice $\tilde{p}_n := z\tilde{p}'_{n-1}$ in (ii) implies that $\tilde{p}_n$ is Φ-orthogonal to $\mathcal{P}_{\tilde{n}_k^\wedge - 1}$; analogously, the choice $\tilde{p}'_n := \tilde{p}_n$ in (iv) implies that $\tilde{p}'_n$ is Φ'-orthogonal to $\mathcal{P}_{\tilde{n}_k^\vee - 1}$.

By analogy to the generality introduced in §9, one can modify $\tilde{p}_{n-1}$ and $z\tilde{p}'_{n-1}$ (in (ii)), and $z\tilde{p}'_{n-1}$ and $\tilde{p}_n$ (in (iv)), by adding a linear combination of polynomials (of the other type) that have already been found in the respective substep.

Since the polynomials $\tilde{p}_n$ (and, likewise, $\tilde{p}'_n$) are not orthogonal to each other within the blocks, the orthogonalization procedures called in the algorithm have to make use of the inverses $(\tilde{\mathbf{D}}_k^\wedge)^{-1}$, $(\tilde{\mathbf{D}}_{k+(1/2)}^\wedge)^{-1}$, (and $(\tilde{\mathbf{D}}_{k-(1/2)}^\vee)^{-1}$, $(\tilde{\mathbf{D}}_k^\vee)^{-1}$, respectively).

As is seen from this recipe, another complication that arises is that the analog of (5.28) does not hold. We still have

$$\Phi(p\tilde{p}_n) = 0 \ (\forall p \in \mathcal{P}_{\tilde{n}_k^\wedge - 1}) \Rightarrow \Phi'(p\tilde{p}_n) = 0 \ (\forall p \in \mathcal{P}_{\tilde{n}_k^\wedge - 2}), \tag{10.7a}$$

$$\Phi'(p\tilde{p}'_{n-1}) = 0 \ (\forall p \in \mathcal{P}_{\tilde{n}_k^\vee - 1}) \Rightarrow \Phi(pz\tilde{p}'_{n-1}) = 0 \ (\forall p \in \mathcal{P}_{\tilde{n}_k^\vee - 1}), \tag{10.7b}$$

$$\Phi(p\tilde{p}_n) = 0 \ (\forall p \in \mathcal{P}_{\tilde{n}_k^\vee}) \Rightarrow \Phi'(p\tilde{p}_n) = 0 \ (\forall p \in \mathcal{P}_{\tilde{n}_k^\vee - 1}), \tag{10.7c}$$

$$\Phi'(p\tilde{p}'_{n-1}) = 0 \ (\forall p \in \mathcal{P}_{\tilde{n}_k^\wedge - 1}) \Rightarrow \Phi(pz\tilde{p}'_{n-1}) = 0 \ (\forall p \in \mathcal{P}_{\tilde{n}_k^\wedge - 1}), \tag{10.7d}$$

and we know that the left-hand sides are true when $\tilde{n}_k^\wedge \le n$ in (a), $\tilde{n}_k^\vee < n$ in (b) and (c), and $\tilde{n}_k^\wedge < n$ in (d), respectively; but, in general,

$$\Phi'(z^{\tilde{n}_k^\wedge - 1}\tilde{p}_n) \neq 0 \quad \text{and} \quad \Phi(z^{\tilde{n}_k^\vee} z\tilde{p}'_{n-1}) \neq 0\,. \tag{10.8}$$

Therefore, $\tilde{p}_n$ needs to be Φ'-orthogonalized with respect to $z^{\tilde{n}_k^\wedge - 1}$ or $\tilde{p}'_{\tilde{n}_k^\wedge - 1}$ to get $\tilde{p}'_n$; likewise $z\tilde{p}'_{n-1}$ needs to be Φ-orthogonalized with respect to $z^{\tilde{n}_k^\vee}$ or $\tilde{p}_{\tilde{n}_k^\vee}$ to get $\tilde{p}_n$. In the recurrence formulas for $\tilde{p}'_n$ (or $\tilde{p}_n$) the polynomials $\tilde{p}'_m$ (or $\tilde{p}_m$, respectively) of the previous block appear, but not those from older blocks.

There are other, theoretically equivalent formulations for the algorithm. Our version, which is truly sequential, suggests an implementation by recurrence formulas that have the matrix form

$$\tilde{\mathbf{p}}(z) = \tilde{\mathbf{p}}'(z)\tilde{\mathbf{G}}^\wedge, \quad z\tilde{\mathbf{p}}'(z) = \tilde{\mathbf{p}}(z)\tilde{\mathbf{G}}^\vee, \tag{10.9}$$

as in (6.15), with $\tilde{\mathbf{G}}^\wedge$ unit upper triangular and $\tilde{\mathbf{G}}^\vee$ unit upper Hessenberg. As in (7.1), elimination of $\tilde{\mathbf{p}}'$ or $\tilde{\mathbf{p}}$, respectively, leads to

$$z\tilde{\mathbf{p}}(z) = \tilde{\mathbf{p}}(z)\tilde{\mathbf{H}}^\wedge, \ \text{where} \ \tilde{\mathbf{H}}^\wedge := \tilde{\mathbf{G}}^\vee\tilde{\mathbf{G}}^\wedge, \tag{10.10a}$$

and

$$z\tilde{\mathbf{p}}'(z) = \tilde{\mathbf{p}}'(z)\tilde{\mathbf{H}}^{\vee}, \quad \text{where } \tilde{\mathbf{H}}^{\vee} := \tilde{\mathbf{G}}^{\wedge}\tilde{\mathbf{G}}^{\vee}. \tag{10.10b}$$

Each of these equalities is of the same type as (9.9). But as we mentioned above, if we apply the algorithm of §9 to Φ, the block structure of $\tilde{\mathbf{H}}$ in (9.9) may turn out to be finer than the one of $\tilde{\mathbf{H}}^{\wedge}$ in (10.10a), because here we have the four conditions (10.5) instead of the condition (9.7) determining the block sizes in (9.9). But we have also pointed out that there is no need to choose in §9 the minimum block sizes satisfying (9.7), and since each of the pairs (10.5a)–(10.5b) and (10.5c)–(10.5d) is equivalent to (9.7) (applied to the two different functionals Φ and Φ'), each of (10.10a) and (10.10b) is, indeed, identical to a case of (9.9). From §9 it follows in particular that $\tilde{\mathbf{H}}^{\wedge}$ and $\tilde{\mathbf{H}}^{\vee}$ are block tridiagonal unit Hessenberg matrices. Therefore, $\tilde{\mathbf{G}}^{\wedge}$ and $\tilde{\mathbf{G}}^{\vee}$ are block upper bidiagonal and block lower bidiagonal, respectively:

(10.11)

$$\tilde{\mathbf{G}}^{\vee} := \begin{bmatrix} \tilde{\mathbf{G}}_0^{\vee} & & & & \\ \tilde{\mathbf{L}}_0^{\vee} & \tilde{\mathbf{G}}_1^{\vee} & & & \\ & \tilde{\mathbf{L}}_1^{\vee} & \tilde{\mathbf{G}}_2^{\vee} & & \\ & & \ddots & \ddots & \\ & & & \tilde{\mathbf{L}}_{J^{\wedge}-1}^{\vee} & \tilde{\mathbf{G}}_{J^{\wedge}}^{\vee} \end{bmatrix}, \quad \tilde{\mathbf{G}}^{\wedge} := \begin{bmatrix} \tilde{\mathbf{G}}_0^{\wedge} & \tilde{\mathbf{F}}_1^{\wedge} & & & \\ & \tilde{\mathbf{G}}_1^{\wedge} & \tilde{\mathbf{F}}_2^{\wedge} & & \\ & & \tilde{\mathbf{G}}_2^{\wedge} & \ddots & \\ & & & \ddots & \tilde{\mathbf{F}}_{J^{\wedge}}^{\wedge} \\ & & & & \tilde{\mathbf{G}}_{J^{\wedge}}^{\wedge} \end{bmatrix},$$

analogous to (6.16). From (10.9) and our description of the algorithm, it is clear that the blocks $\tilde{\mathbf{L}}_k^{\vee}$ have again just a 1 in their upper right corner, that the blocks $\tilde{\mathbf{G}}_k^{\vee}$ are itself unit upper Hessenberg, and that the blocks $\tilde{\mathbf{G}}_k^{\wedge}$ are unit upper triangular. Further results on the structure of the blocks can be obtained by mixing the approach of §6 with the one of §9, but the details become somewhat tedious.

Conclusions. In the two parts of this paper we have reviewed the theory of formal orthogonal polynomials (FOPs) of the first and second kind (FOP1s and FOP2s, respectively), and we have derived old and new recurrences for recursively constructing certain sequences of such FOPs. From the beginning we dealt with the so-called nonnormal or nongeneric case, where some of the FOPs are not regular and the associated Padé table has singular blocks. This led to "nongeneric" algorithms for constructing such FOPs. By translating these nongeneric algorithms into algorithms for sequences of vectors in Krylov space, we found nongeneric versions of the Lanczos-type algorithms BIORES, BIOMIN, and BIODIR. They can overcome most exact breakdowns of the previously known standard versions of these algorithms. (The exception is the so-called incurable breakdown.)

Finally, in §§9 and 10, we addressed the near-breakdown and presented algorithms for generating sequences of FOP1s in a stable way. By translating these "look-ahead" algorithms for constructing FOP1s into algorithms for sequences of vectors in Krylov space, we readily find stable look-ahead versions of BIORES, BIOMIN, and BIODIR.

Since the FOP1s are denominators of Padé approximants, and since the numerators of Padé approximants satisfy the same recurrences, with different initial conditions, the algorithms given in this work can also be considered as algorithms for generating sequences of Padé approximants on either a diagonal or a generalized staircase of the Padé table. The look-ahead versions can be expected to be stable, in contrast to other algorithms [2], [4]–[6], [10] that have been proposed for nonnormal Padé tables and the related partial realization problem of systems theory. Applications to the fast solution of Hankel systems are also foreseeable.

Acknowledgment. The author would like to thank Susan Göldi for typing the first version of this manuscript and to Noël Nachtigal for making a number of linguistic corrections.

A BOTTOM-UP INDUCTIVE PROOF OF THE SINGULAR VALUE DECOMPOSITION*

C.-T. PAN† AND KERMIT SIGMON‡

Abstract. The singular value decomposition (SVD) has a long history. The first proofs of the SVD for real square matrices came out of the study of bilinear forms, first by Beltrami in 1873 and, independently, by Jordan in 1874. Beltrami recognized and used the relationship of the SVD to the eigenvalue decomposition of the matrices A^TA and AA^T, while Jordan used an inductive argument that constructs the SVD from the largest singular value and its associated singular vectors. Many proofs of the SVD in modern references are still based on one of these methods. The purpose of this note is to give a new simple "bottom-up" inductive proof of the SVD, starting from the smallest singular value, which is essentially different from either of these methods.

Key words. singular value decomposition

AMS subject classifications. 15A18, 15A23

The singular value decomposition (SVD) has a long history, a detailed survey of which is given in [6, pp. 134–144]. The first proofs of the SVD for real square matrices came out of the study of bilinear forms, first by Beltrami in 1873 [2] and, independently, by Jordan in 1874 [7]. Beltrami recognized and used the relationship of the SVD to the matrices A^TA and AA^T. Jordan used an inductive argument that constructs the SVD from the largest singular value and its associated singular vectors. The first proof of the SVD for square complex matrices seems to be by Autonne in 1915 [1] and, later in 1939, Eckart and Young [3] who dealt with the rectangular complex case. Many proofs of the SVD in modern references either rely on the eigenvalue decomposition of the positive semidefinite Hermitian matrices A^*A and AA^* [5], [8]–[10] or use a "top-down" inductive argument similar to Jordan's [4], [5, p. 427].

The purpose of this note is to give a new simple "bottom-up" inductive proof of the SVD, starting from the smallest singular value. One should note that this proof is essentially different from the "top-down" one; there does not appear to be a direct dual to the "top-down" proof. The QR decomposition is needed in our proof. The proof is motivated by ideas from a paper by Stewart [11]. Our proof also shows that, if the estimates of the smallest singular value and its associated right singular vector were exact in each step, Stewart's URV decomposition [11] renders the exact SVD.

In this paper, bold lowercase letters denote the column vectors, and $\|\cdot\|_2$ is either the Euclidean norm of a vector or the spectral norm of a matrix. The ith column of an identity matrix is denoted by $\mathbf{e}_i$.

LEMMA 1. *For a square nonsingular complex matrix A one has*

$$\min_{\|\mathbf{x}\|_2=1} \|A\mathbf{x}\|_2 = \frac{1}{\|A^{-1}\|_2}.$$

* Received by the editors March 23, 1992; accepted for publication (in revised form) April 21, 1992. This research was supported in part by the Institute for Mathematics and Its Applications with funds provided by the National Science Foundation.

† Department of Mathematical Sciences, Northern Illinois University, DeKalb, Illinois 60115 (pan@math.niu.edu).

‡ Department of Mathematics, University of Florida, Gainesville, Florida 32611 (sigmon@math.ufl.edu).

Proof. Since A is nonsingular, it is easy to see that

$$\|A^{-1}\|_2 = \max_{\mathbf{x}\neq 0} \frac{\|A^{-1}\mathbf{x}\|_2}{\|\mathbf{x}\|_2} = \max_{\mathbf{y}\neq 0} \frac{\|\mathbf{y}\|_2}{\|A\mathbf{y}\|_2} = \frac{1}{\min\limits_{\mathbf{y}\neq 0} \dfrac{\|A\mathbf{y}\|_2}{\|\mathbf{y}\|_2}} = \frac{1}{\min\limits_{\|\mathbf{y}\|_2=1} \|A\mathbf{y}\|_2}. \qquad \square$$

LEMMA 2. *If R is an $m \times n$ upper triangular matrix with $m \geq n$, then*

$$|r_{ii}| \geq \min_{\|\mathbf{x}\|_2=1} \|R\mathbf{x}\|_2$$

for each diagonal entry r_{ii} of R.

Proof. If R is rank deficient, the stated bound is immediate since $R\mathbf{x} = 0$ for some $\|\mathbf{x}\|_2 = 1$, so we may assume that R has full column rank.

First note that for any entry a_{ij} of a complex matrix A,

$$|a_{ij}| = |\mathbf{e}_i^* A \mathbf{e}_j| \leq \|\mathbf{e}_i\|_2 \|A\mathbf{e}_j\|_2 \leq \|\mathbf{e}_i\|_2 \|A\|_2 \|\mathbf{e}_j\|_2 = \|A\|_2.$$

The matrix R has the form $[R_1 \quad 0]$ with R_1 invertible and $(R_1^{-1})_{ii} = 1/r_{ii}$. Thus $\|R_1^{-1}\|_2 \geq |(R_1^{-1})_{ii}| = |1/r_{ii}|$, from which, by Lemma 1, the result follows since

$$\min_{\|\mathbf{x}\|_2=1} \|R\mathbf{x}\|_2 = \min_{\|\mathbf{x}\|_2=1} \|R_1\mathbf{x}\|_2 = \frac{1}{\|R_1^{-1}\|_2} \leq |r_{ii}|. \qquad \square$$

THEOREM 1. *Each matrix $A \in \mathbf{C}^{m\times n}$ has an* SVD. *That is, there exist unitary matrices*

$$U \in \mathbf{C}^{m\times m} \quad \textit{and} \quad V \in \mathbf{C}^{n\times n}$$

such that

$$U^* A V = \operatorname{diag}(\sigma_1, \ldots, \sigma_p) \in \mathbf{C}^{m\times n}, \qquad p = \min\{m, n\},$$

where $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_p \geq 0$.

If $A \in \mathbf{R}^{m\times n}$, then U and V may be taken to be real orthogonal matrices.

Proof. Assume that $m \geq n$ (otherwise, consider A^*). Let $\mathbf{x}_0$ be a unit vector such that $\|A\mathbf{x}_0\|_2 = \min_{\|\mathbf{x}\|_2=1} \|A\mathbf{x}\|_2$, and set $\sigma := \|A\mathbf{x}_0\|_2$. Let $V_1 \in \mathbf{C}^{n\times n}$ be a unitary matrix whose last column is $\mathbf{x}_0$ and let $U_1 \in \mathbf{C}^{m\times m}$ be a unitary matrix such that $U_1^*(AV_1) = R =: [r_{ij}]$ is upper triangular (here we use the QR decomposition).

Since

$$\|R\mathbf{e}_n\|_2 = \|U_1^* A V_1 \mathbf{e}_n\|_2 = \|U_1^* A \mathbf{x}_0\|_2 = \|A\mathbf{x}_0\|_2 = \sigma,$$

from Lemma 2 we have

$$|r_{1n}|^2 + \cdots + |r_{nn}|^2 = \sigma^2 \leq |r_{nn}|^2,$$

and hence $|r_{1n}|^2 + \cdots + |r_{n-1,n}|^2 = 0$. It follows that $|r_{nn}| = \sigma$ so that $r_{nn} = \sigma e^{it}$ for some t. Now define the diagonal unitary matrix $W_1 := \operatorname{diag}(1, \ldots, 1, e^{it}) \in \mathbf{C}^{n\times n}$ and observe that

$$A = U_1 R (V_1 W_1)^* \quad \text{with } R = \begin{bmatrix} R_1 & 0 \\ 0 & \sigma \\ 0 & 0 \end{bmatrix} \in \mathbf{C}^{m\times n}.$$

Since $R_1 \in \mathbf{C}^{(n-1)\times(n-1)}$ and $V_1 W_1$ is unitary, a straightforward inductive argument proves that there exist unitary matrices $U \in \mathbf{C}^{m\times m}$ and $V \in \mathbf{C}^{n\times n}$ such that

$$A = U \begin{bmatrix} \sigma_1 & & & 0 \\ & \ddots & & \\ & & & \sigma_n \\ - & - & - & - \\ & 0 & & \end{bmatrix} V^*. \qquad \square$$

PREDICTING STRUCTURE IN SPARSE MATRIX COMPUTATIONS*

JOHN R. GILBERT†

Abstract. Many sparse matrix algorithms—for example, solving a sparse system of linear equations—begin by predicting the nonzero structure of the output of a matrix computation from the nonzero structure of its input. This paper is a catalog of ways to predict nonzero structure. It contains known results for some problems, including various matrix factorizations, and new results for other problems, including some eigenvector computations.

Key words. sparse matrix algorithms, graph theory, matrix factorization, systems of linear equations, eigenvectors

AMS subject classifications. 15A18, 15A23, 65F50, 68R10

1. Introduction.

A sparse matrix algorithm is an algorithm that performs a matrix computation in such a way as to take advantage of the zero/nonzero structure of the matrices involved. Usually this means not explicitly storing or manipulating some or all of the zero elements; sometimes sparsity can also be exploited to work on different parts of a matrix problem in parallel. Large sparse matrix computations arise in structural design, geodetics, fluid dynamics, heat transport, semiconductor modeling, circuit analysis, molecular dynamics, geophysical reservoir analysis, and many other areas. It is common for problems to be so large that they could not be solved at all without sparse techniques.

Many sparse matrix algorithms [6], [15]–[17], [21] have a phase that predicts the nonzero structure of the solution from the nonzero structure of the problem, followed by a phase that does the numerical computation in a static data structure. This saves space, because the space used by the pointers in a dynamic data structure during the first phase can be reused by the numeric values in the second phase. Also, in many applications a sequence of problems with the same nonzero structure must be solved, and the structural phase can be done just once. The structural phase may also be used to schedule the numerical phase efficiently on a parallel machine [20], [29].

Structure prediction can be used to save time as well as space in sparse Gaussian elimination. The asymptotically fastest algorithms used to compute the Cholesky factorization of a symmetric positive definite matrix are those of the Yale Sparse Matrix Package [12] and Sparspak [15], which predict the structure of the triangular factor by a version of Theorem 4.3. Gilbert and Peierls [24] have used prediction of the structure of the solution of a triangular system of equations to develop the first algorithm that performs sparse LU factorization with partial pivoting in worst-case time proportional to the number of real arithmetic operations. (This method of prediction is a special case of Theorem 5.1.)

Graph theory is a useful language in which to state and prove the results of structure prediction. One reason for this is that the structural effect of a matrix computation often depends on path structure, which is easier to describe in terms of graphs than in terms of matrices. Parter [33] was among the first to use graph theory

as a tool to investigate sparse matrix computation; Fiedler [13] also pioneered many of these ideas.

This paper is a catalog of the effects of several common matrix computations on nonzero structure. It includes arithmetic, linear systems, various factorizations, and some eigenvector problems. Where appropriate, it cites algorithms to compute nonzero structure as well as theorems that describe it. Some of these results are not new. The known results are scattered among papers on various topics in linear algebra and algorithms that have been published in journals on numerical analysis, theoretical computer science, operations research, and engineering. Here they are presented in a common framework, together with a few new results.

Three or four different graph models are used for structure prediction. Undirected graphs model symmetric matrices; directed graphs model unsymmetric matrices under symmetric permutations; bipartite graphs model arbitrary rectangular matrices; and column intersection graphs can sometimes be used to apply undirected graph results to rectangular matrices. This paper describes results using all the models, but concentrates most heavily on those that use directed graphs to model unsymmetric matrices with nonzero diagonal elements.

Sections 3–6 contain the results of the paper: Roughly speaking, the results in §3 are immediate; those in §4 are known; most of those in §5 are consequences of known results; and those in §6 are new. This paper is based on an earlier technical report [19].

2. Definitions. We assume that the reader is familiar with such basic graph-theoretic terms as directed graph, undirected graph, and path. Harary [26] is a good general reference.

2.1. Directed graphs and matrix structures. Let A be an $n \times n$ matrix. The *structure* of A is its directed graph

$$\text{struct}(A) = G(A),$$

whose vertices are the integers $1, \ldots, n$ and whose edges are

$$\{ (i,j) : i \neq j \text{ and } A_{ij} \neq 0 \}.$$

When no ambiguity can arise, we shall sometimes not distinguish between a matrix, its graph, and the set of edges of its graph.

The graph $G(A)$ does not specify whether the diagonal elements of A are zero or not. In this paper we will use $G(A)$ only for matrices with nonzero diagonal elements; in the context of structure prediction, matrices with zero diagonal elements are more usefully studied by means of their bipartite graphs, as described below.

Applying the same permutation to the columns and rows of A corresponds to renumbering the vertices of the directed graph of A. In other words, if P is a permutation matrix, then the directed graph of PAP^T is isomorphic to the directed graph of A. In general, if P and Q are different permutation matrices, then the directed graph of PAQ^T is not isomorphic to that of A.

The *structure* of a vector x is

$$\text{struct}(x) = \{ i : x_i \neq 0 \},$$

which can be interpreted as a set of vertices of the directed graph of any $n \times n$ matrix.

We will use the notation $G_1 \subseteq G_2$ to mean that graph G_1 is a subgraph of graph G_2; that is, that both the edge and vertex sets of G_1 are subsets of those of G_2.

2.2. Predicting structure in a computation. To say more precisely what we mean by the structural effect of a computation, we make some remarks based on those of Brayton, Gustavson, and Willoughby [3] and Edenbrandt [10]. Let f be a function from one or more matrices or vectors to a matrix or vector. The structure of A may not determine the structure of $f(A)$; for example, in general the sum of two full vectors is full, but $(1,1)^T + (1,-1)^T$ is not full. We wish to ignore zeros created by coincidence in the numerical values of A and determine the smallest structure that is "big enough" for the result of f with any input of the given structure. That is, given f and $\mathrm{struct}(A)$, we want to determine

$$\bigcup_B \{\mathrm{struct}(f(B)) : \mathrm{struct}(B) \subseteq \mathrm{struct}(A)\}.$$

Brayton, Gustavson, and Willoughby called an algorithm "s-minimal" if it computes this structure from $\mathrm{struct}(A)$. We sometimes call this a "one-at-a-time" structure prediction, since each position in the predicted structure can be made nonzero, but there is no guarantee that all can be made nonzero at the same time.

Most of the functions we consider in this paper have the property that for each input structure S, there is a worst-case value A with $\mathrm{struct}(A) = S$ such that $\mathrm{struct}(B) \subseteq S$ implies $\mathrm{struct}(f(B)) \subseteq \mathrm{struct}(f(A))$. In other words, each input structure corresponds to a unique maximal output structure. We sometimes call such an analysis an "all-at-once" structure prediction.

A function for which there is no "all-at-once" structure prediction is $f(A) = U$, the upper triangular factor of A in Gaussian elimination with partial pivoting. Suppose the structure of A is

$$\begin{pmatrix} \times & & \\ \times & \times & \\ \times & & \times \end{pmatrix}.$$

Depending on the relative magnitudes of the elements in the first column, the structure of $f(A)$ may be

$$\begin{pmatrix} \times & & \\ & \times & \\ & & \times \end{pmatrix}, \quad \begin{pmatrix} \times & \times & \\ & \times & \times \\ & & \times \end{pmatrix}, \quad \begin{pmatrix} \times & \times & \\ & \times & \\ & & \times \end{pmatrix}, \quad \text{or} \quad \begin{pmatrix} \times & & \times \\ & \times & \times \\ & & \times \end{pmatrix}.$$

The smallest structure big enough for $f(A)$ is a full upper triangular matrix, even though $f(A)$ cannot be full.

2.3. Graph terminology. Representing a matrix structure as a graph has the advantage that it is easy to describe properties that depend on paths in the graph. Here we define several graph notions that depend on path structure.

The notation $i \xrightarrow{A} j$ means that there is an edge from i to j in $G(A)$; that is, that $A_{ij} \neq 0$. The notation $i \overset{A}{\Longrightarrow} j$ means that there is a directed path from i to j in $G(A)$. Such a path may have length zero; that is, $i \overset{A}{\Longrightarrow} i$ always holds. The matrix A may be omitted if it is clear from context.

Now let $G(A)$ be a directed graph, and let x be a subset of the vertices of G. We say x is *closed* (with respect to A) if there is no edge of G from a vertex not in x to a vertex in x; that is, if $x_j \neq 0$ and $A_{ij} \neq 0$ imply $x_i \neq 0$. The *closure* of x (with respect to A) is the smallest closed set containing x,

$$\mathrm{closure}(x) = \bigcap \{ y : x \subseteq y \text{ and } y \text{ is closed}\},$$

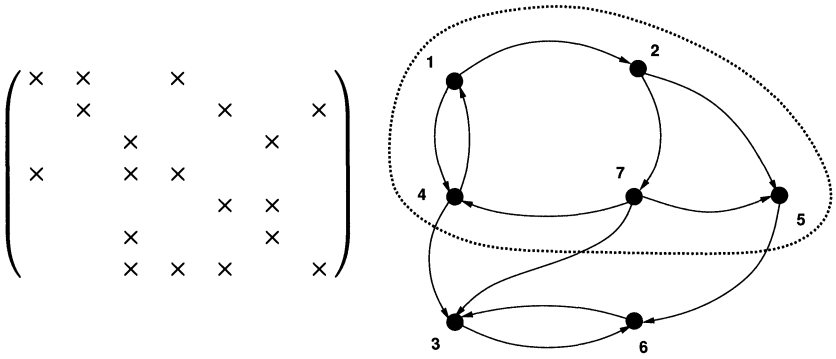

FIG. 1. *A matrix and its directed graph.* closure($\{5\}$) *is outlined.*

which is the set of vertices of A from which there are paths to vertices of x. Figure 1 shows a matrix and its graph, with closure($\{5\}$) outlined.

The *transitive closure* of A is the graph $G^*(A)$ whose edges correspond to paths in A. Thus

$$i \overset{G^*(A)}{\longrightarrow} j \quad \text{if and only if} \quad i \neq j \quad \text{and} \quad i \overset{A}{\Longrightarrow} j.$$

The structural effect of Gaussian elimination can be described in terms of a subgraph of $G^*(A)$ called the *filled graph* of A, which we write as $G^+(A)$. This graph has edges corresponding to paths whose highest-numbered vertices are their endpoints:

$$i \overset{G^+(A)}{\longrightarrow} j \quad \text{if and only if} \quad i \neq j \quad \text{and} \quad i \overset{A}{\Longrightarrow} j \quad \text{through vertices less than } \min(i,j).$$

Figure 2 is an example. Notice that the filled graph depends on the numbering of the vertices of A, whereas the transitive closure and the closure of a vertex are preserved under renumbering (that is, under graph isomorphism).

Remark 2.1. Rose [35] introduced the notation $G^*(A)$ for the filled graph of A, but that notation is also widely used for transitive closure. Since we want to refer to both transitive closures and filled graphs, we use $G^+(A)$ for the "smaller" of the two.

A graph G is *strongly connected* if there is a path from every vertex to every other vertex, or, equivalently, if G^* is a complete directed graph. A square matrix A is called *irreducible* if struct(A) is strongly connected. Clearly, for any permutation matrix P, PAP^T is irreducible if and only if A is. The *strongly connected components* (or just *strong components*) of a graph G are its maximal strongly connected subgraphs. Every vertex of a graph is in exactly one strong component, and every edge is in at most one strong component. If a square matrix A is permuted into block triangular form with as many diagonal blocks as possible, the diagonal blocks partition the rows and columns of A into sets corresponding to the strong components of struct(A). Figure 3 shows the strong components of the graph in Fig. 1, with the vertices renumbered so that the matrix has a diagonal block for each strong component.

A square matrix A is called *fully indecomposable* if struct(PAQ^T) is strongly connected for all permutation matrices P and Q. Clearly, this is equivalent to struct(PA)

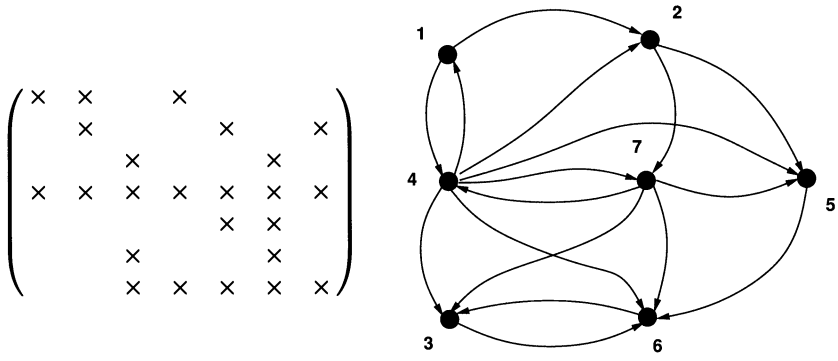

FIG. 2. *Filled graph of example from Fig.* 1.

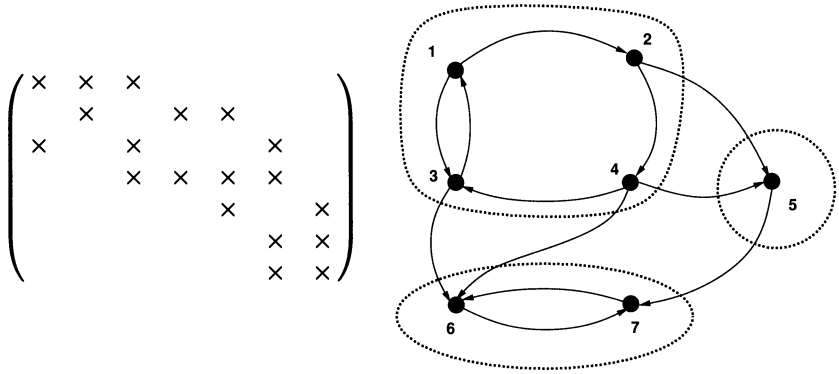

FIG. 3. *Matrix from Fig.* 1 *permuted to block triangular form. Strong components are outlined.*

being strongly connected for all permutations P. As we will remark in the next section, fully indecomposable matrices are the same as square strong Hall matrices.

If matrix A is symmetric, its directed graph contains edge (i, j) if and only if it contains edge (j, i). Informally, we shall not distinguish between this graph and the *undirected graph* of A, which has an undirected edge $\{i, j\}$ if $A_{ij} \neq 0$. Chordal graphs are undirected graphs that are useful for describing symmetric Gaussian elimination. An undirected graph is *chordal* if every cycle of length at least 4 has a *chord*; that is, if for every cycle $v_1, v_2, \ldots, v_k, v_1$ with $k \geq 4$ there is some edge $\{v_i, v_j\}$ for which $i \neq j \pm 1 \pmod{k}$.

2.4. Nonsquare matrices. This paper concentrates on structure prediction results that use directed graphs and that (for the most part) apply to square matrices with nonzero diagonals. For completeness, however, we include some results on matrices that need not be square, or that may have zero diagonal elements. Two other graph models are appropriate in that case.

If A has m rows and n columns, then $A^T A$ is an $n \times n$ symmetric matrix, whose

diagonal is nonzero if A has no zero columns. Its structure is related to the *column intersection graph* of A, which is the undirected graph $G_\cap(A)$ whose vertices are the integers $1, \ldots, n$ (corresponding to the columns of A), and whose edges are

$$\{\{i,j\} : i \neq j \text{ and } \exists k \text{ with } A_{ki} \neq 0 \text{ and } A_{kj} \neq 0\}.$$

Thus $G_\cap(A)$ has an edge between any pair of columns that share a nonzero row. This implies that

$$G(A^TA) \subseteq G_\cap(A),$$

with equality unless there is numerical cancellation in A^TA. Permuting the rows of A does not change the column intersection graph: if P is a row permutation matrix, then $G_\cap(PA)$ is the same as $G_\cap(A)$.

If A has m rows and n columns, the *bipartite graph* of A is the undirected graph $H(A)$ whose vertices are $1', 2', \ldots, m'$ and $1, 2, \ldots, n$, and whose edges are $\{\{i', j\} : A_{ij} \neq 0\}$. The superscript prime notation is intended to indicate that the row and column vertices of $H(A)$ are chosen from two different copies of the positive integers. Permuting the rows and columns of A only relabels the vertices of the bipartite graph: if P and Q are row and column permutation matrices, then $H(PAQ^T)$ is isomorphic to $H(A)$.

Several structure prediction problems use matchings and alternating paths in the bipartite graph of a matrix [4], [6], [7], [20], [23], [21], [32]. This paper does not consider such problems in detail, but we include enough definitions here to state some of these results in later sections.

Let A be an $m \times n$ matrix with $m \geq n$. We say that A has the *Hall property* if, for every k with $0 \leq k \leq n$, every set of k columns of A contains nonzeros in at least k rows. (That is, every set of k column vertices of $H(A)$ is adjacent to at least k row vertices.) We say that A has the *strong Hall property* if, for every k with $0 < k < n$, every set of k columns of A contains nonzeros in at least $k+1$ rows. The graph $H(A)$ has a matching that covers all of its columns if and only if A has the Hall property. A square matrix A with nonzero diagonal is irreducible if and only if $H(A)$ has the strong Hall property; an arbitrary square matrix A is fully indecomposable if and only if $H(A)$ has the strong Hall property. See Lovasz and Plummer [30] for background on bipartite matching. Our terminology is from Coleman, Edenbrandt, and Gilbert [4].

Incidentally, although permuting the rows and the columns of A independently can change the directed graph of A, it does not change the row partition and the column partition induced by the strong components of the graph of A. Another way to say this is that, given a matrix A, if we first permute rows and columns (asymmetrically) to make the diagonal elements nonzero, and then permute rows and columns symmetrically to block triangular form with as many diagonal blocks as possible, then regardless of the initial choice of nonzero diagonal we always get the same block triangular form, up to possible permutation of the diagonal blocks and reordering of the rows and columns within each block.

2.5. Other definitions. We will call a finite set $\{x_1, \ldots, x_n\}$ of complex numbers *algebraically independent* if the point $(x_1, \ldots, x_n)$ is not a zero of any nonzero n-variable polynomial with integer coefficients. Then x_i is transcendental over the field $\mathbf{Q}(x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_n)$ of the rationals extended by all the x's except x_i. There exist arbitrarily large algebraically independent sets, even of real numbers, by a simple countability argument.

3. Products. The following simple result is used in the proof of Theorem 6.1. The structure is the bipartite graph of the matrix in question.

THEOREM 3.1. *Let the structures of an $m \times n$ matrix A and an n-vector x be given.*

(i) *Whatever values A and x have,* struct(Ax) *is a subset of the row vertices of $H(A)$ adjacent to column vertices whose indices are in* struct(x).

(ii) *There exits values for the nonzeros of A and x such that* struct(Ax) *is equal to the set of row vertices described above.* □

The generalization to products of matrices is immediate, since each column of AB is A times a column of B. Theorem 3.1 also implies that $G(A^TA) \subseteq G_\cap(A)$.

4. Factorizations. In this section we describe the structural effect of several matrix factorizations. The necessary definitions are in §2.

4.1. LU factorization. For the factorization $A = LU$, where L is lower triangular with unit diagonal and U is upper triangular, we consider square matrices A with nonzero diagonal, and the graph in question is the directed graph of A. The square matrix $L + U - I$ represents the entire factorization. (Not all nonsingular matrices have LU factorizations without pivoting. In a later subsection we consider factorization with partial pivoting.)

THEOREM 4.1 (see [36]). *Let a structure $G(A)$ be given, with nonzero diagonal elements.*

(i) *If values are chosen for which A has an LU factorization as above, then $G(L+U-I) \subseteq G^+(A)$.*

(ii) *Values for the nonzeros of A exist with $G(L+U-I) = G^+(A)$.* □

Rose and Tarjan [36] gave an algorithm for computing $G^+(A)$ from A in $O(nm)$ time, where A is $n \times n$ with m nonzeros. They also showed that $G^*(A)$ can be computed in time asymptotically the same as that to compute $G^+(A)$, so a faster algorithm to compute $G^+(A)$ would give a faster algorithm to compute transitive closures than the best currently known. By using various transitively reduced graphs, Eisenstat, Gilbert, and Liu [11], [22] give algorithms to compute $G^+(A)$ that are more efficient in practice than transitive closure.

Remark 4.2. A nonsingular square matrix may have an LU factorization even though it has zeros on the diagonal. In this case, Theorem 4.1(i) still holds; but the converse, part (ii), is false. Brayton, Gustavson, and Willoughby [3] gave a counterexample. Let

$$\text{struct}(A) = \begin{pmatrix} \times & \times & \times & \\ \times & & & \\ \times & \times & \times & \\ \times & & & \times \end{pmatrix}.$$

The $(4,3)$ entry in $G^+(A)$ is nonzero, but $L_{4,3} = 0$ regardless of the nonzero values of A.

4.2. Cholesky factorization. Here we consider the factorization $A = LL^T$, where A is a symmetric, positive definite matrix, and L is lower triangular with positive diagonal. Then A has a nonzero diagonal because it is positive definite, and the directed graph of A corresponds to an undirected graph because A is symmetric.

THEOREM 4.3 (see [37]). *Let a symmetric structure $G(A)$ be given, with nonzero diagonal elements.*

(i) *No matter what values A has, if A has a Cholesky factorization $A = LL^T$ then $G(L) \subseteq G^+(A)$.*

(ii) *There exist symmetric values for the nonzeros of A such that $G(L + L^T) = G^+(A)$.* □

Rose, Tarjan, and Lueker [37] gave an $O(n + f)$ algorithm to compute $G^+(A)$ for a symmetric $n \times n$ matrix A with fill of size f. Another such algorithm is implemented in several standard sparse matrix computation packages [12], [15].

Rose showed that the graphs of Cholesky factors of symmetric matrices are exactly the chordal graphs; or, equivalently, that a structure can be reordered to have no fill if and only if it is chordal.

THEOREM 4.4 (see [37]). *Let a symmetric structure $G(A)$ be given, with nonzero diagonal elements.*

(i) *$G^+(A)$ is a chordal graph.*

(ii) *Conversely, if $G(A)$ is a chordal graph, then there is a permutation matrix P such that $G^+(PAP^T) = G(PAP^T)$.* □

Rose, Tarjan, and Lueker [37] and Tarjan and Yannakakis [39] gave linear-time algorithms to determine whether a $G(A)$ is chordal and, if so, to reorder its vertices so that $G^+(PAP^T) = G(PAP^T)$. Such a reordering is called a "perfect elimination order."

4.3. Partial pivoting. The example in §2 showed that a result of the form of Theorem 4.3 is not possible for LU factorization with partial pivoting, because no single choice of nonzero values for A is guaranteed to produce nonzeros in all possible positions of U. George and Ng [16] gave an upper bound. A few remarks are necessary to understand the bound.

There are two ways to write the LU factorization, with partial pivoting, of a square matrix A. One is as $A = PLU$, where L is unit lower triangular, U is upper triangular, and P is a permutation matrix. The other is as $A = P_1L_1P_2L_2 \ldots P_{n-1}L_{n-1}U$, where P_i is a permutation that just transposes row i and a higher-numbered row, and L_i is a Gauss transform (a unit lower triangular matrix with nonzeros only in column i). To get the first factorization, use the standard outer product form of Gaussian elimination to replace A by its triangular factors, pivoting by interchanging two rows of the matrix at the beginning of each major step; at major step k, each row thus interchanged contains entries of L in the first $k - 1$ positions and entries of the partially factored A in the remaining positions. To get the second factorization, pivot by interchanging, at the beginning of major step k, only columns k through n of the two rows in question. In this case an entry of the lower triangle is never moved once it is computed, and only the rows of the partially factored matrix are interchanged.

The factorizations are equivalent in the sense that the same arithmetic is performed in each case, the two U's are the same, and the values of the nonzeros in $L - I$ and $\hat{L} = \sum_{1 \le i < n}(L_i - I)$ are the same; only the positions of the nonzeros in the lower triangular factors are different. The George–Ng theorem describes the structures of $\hat{L}$ and U, saying that both of them are subsets of the structure of the symbolic Cholesky factor of A^TA, that is, of the filled graph of the column intersection graph of A.

THEOREM 4.5 (see [16]). *Let a structure $G(A)$ be given. Whatever values A has, if Gaussian elimination with partial pivoting gives the factors $\hat{L}$ and U as above, then $G(\hat{L} + U) \subseteq G_\cap^+(A)$.* □

The example in §2 showed that the converse of this theorem is not true. Various partial converses hold, however. If we restrict ourselves to structures that are strong Hall (fully indecomposable), which includes irreducible structures with nonzero diago-

nals, then there is a "one-at-a-time" converse to Theorem 4.5 for the upper triangular factor U:

THEOREM 4.6 (see [20]). *Let a square strong Hall structure $H(A)$ be given. For any choice of $i < j$ with $i \overset{G_\cap^+(A)}{\longrightarrow} j$, there is a choice of values for A for which the factorization with partial pivoting $PA = LU$ makes $U_{ij} \neq 0$.* □

The "all-at-once" version of this statement is not true even for irreducible matrices. For example, take $G(A)$ to be a tridiagonal matrix plus a full first column. Then $G(A)$ is irreducible (and strong Hall), and it is easy to see that $G_\cap^+(A)$ is full. As Theorem 4.6 states, it is possible to choose values for A to make any single position in U nonzero; however, the first row of U will always be some row of A, so the entire first row of U cannot be nonzero at the same time.

For the lower triangular factor L, Theorem 4.5 is not as tight as possible, even in the "one-at-a-time" sense for strong Hall structures. For example, let $G(A)$ be tridiagonal (and hence strong Hall). Then $G_\cap^+(A)$ is five-diagonal, predicting that $\hat{L}$ could be lower tridiagonal; but, in fact, $\hat{L}$ must be lower bidiagonal. George and Ng [17] suggest a way of predicting the structures of $\hat{L}$ and U by efficiently simulating all possible pivoting steps. Gilbert and Ng [23] have recently shown that this method (which we do not describe here in detail) gives a tight "one-at-a-time" prediction of the structures of both L and U in the strong Hall case.

4.4. QR factorization. Suppose A is an $m \times n$ matrix with $m \leq n$. Here we consider the factorization $A = QR$, where Q is an orthogonal matrix and R is upper triangular with nonnegative diagonal. George and Heath observed that, since this R is the same as the Cholesky factor of A^TA, the structure of R can be predicted by forming $G_\cap(A)$ and doing structural Cholesky factorization.

THEOREM 4.7 (see [14]). *Let the structure $H(A)$ be given for a rectangular matrix A with at least as many rows as columns. Whatever values A has, if A has full column rank, then its orthogonal factorization $A = QR$ satisfies $G(R) \subseteq G_\cap^+(A)$.* □

The converse of this theorem is false; for example, if A is upper triangular with a nonzero diagonal and a full first row, then $G_\cap(A) = G_\cap^+(A)$ is full, but the orthogonal factor R is equal to A. Coleman, Edenbrandt, and Gilbert supplied a converse in the strong Hall case.

THEOREM 4.8 (see [4]). *Let a structure $H(A)$ be given with at least as many rows as columns. If $H(A)$ has the strong Hall property, then there exist values for the nonzeros of A such that $G(R) = G_\cap^+(A)$, where R is the orthogonal factor of A as above.* □

Hare, Johnson, Olesky, and van den Driessche [27] gave a more complicated prediction of the structure of both R and the orthogonal factor Q. They showed that their prediction was tight in the "one-at-a-time" sense for all Hall structures, that is, for all structures with full symbolic column rank. Pothen [34] then proved that the prediction of Hare et al. was in fact tight in the "all-at-once" sense, thus finishing off the problem for both Q and R in the Hall case.

George and Ng [18] studied another representation of the structure of the orthogonal factor Q in the case that A is square and has nonzero diagonal elements. They showed that a suitable representation of Q has a structure that also satisfies Theorem 4.7. Suppose A is reduced to upper triangular form by a sequence of Householder transformations that zero the subdiagonal elements of the first column, then the second column, and so on. The Householder transformation used to zero column j (for $1 \leq j < n$) has the form $Q_j = I - w_j w_j^T$, where w_j is a column vector whose first $j-1$

entries are zero. The orthogonal factor $Q = Q_1^T Q_2^T \dots Q_{n-1}^T$ is conveniently represented by the lower triangular matrix W whose columns are the w_j. The George–Ng result describes the structure of this triangular matrix.

THEOREM 4.9 (see [18]). *Let a structure $G(A)$ be given for a square matrix A with nonzero diagonal elements. Whatever values A has, if its orthogonal factor is represented by the matrix W described above, then $G(W) \subseteq G_\cap^+(A)$.* □

This result is useful because in practice it often suffices to represent the orthogonal factor by the sequence of Householder vectors, and that representation is often sparser than an explicit representation of Q. For example, consider a symmetric structure whose graph $G(A)$ is a square grid with n vertices, corresponding to the standard five-point finite difference stencil on a $k \times k$ mesh with $n = k^2$. The number of nonzeros in A is $\Theta(n)$. Take the numeric values of A to be algebraically independent. It is straightforward to use the results cited above [18], [27] to show that a nested dissection ordering of $G_\cap(A)$ asymptotically minimizes the number of nonzeros in all of Q, R, and W, and that for such an ordering the number of nonzeros in both R and W is $\Theta(n \log n)$ while the number of nonzeros in Q is $\Theta(n^{3/2})$. Thus in this model problem W is a much more efficient way to store the orthogonal factor than Q.

5. Solutions of linear systems. In this section we determine the structure of the solution x to the square system of linear equations $Ax = b$. We solve the related problem of determining the structure of A^{-1}. These results have not appeared before in this form, but the upper bounds in Theorem 5.1 and Corollary 5.4 are straightforward consequences of Tarjan's work on elimination methods for solving path problems in graphs [40] and are closely related to work done by Fiedler [13]. The proofs here are somewhat different.

The extremes of path structure in directed graphs are a strongly connected graph (which corresponds to an irreducible matrix) and an acyclic graph (which corresponds to a permutation of a triangular matrix). Some of these results become almost trivial at the strongly connected extreme—for example, the inverse of an irreducible matrix is full in the absence of coincidental cancellation. In solving general nonsingular linear systems it is often advantageous to begin by partitioning the matrix into strong components and then to factor only the irreducible blocks of the partition. This approach is taken, for example, in the Duff and Reid MA28 code [9].

Curiously enough, the most important applications of the results in this section are at the opposite extreme, for triangular systems. Structure prediction for sparse triangular systems is used in efficient algorithms for LU factorization with partial pivoting [24] and in parallel triangular solution [1].

Throughout this section A is an $n \times n$ matrix with nonzero diagonal, and the graph in question is the directed graph $G(A)$.

THEOREM 5.1. *Let the structures of A and b be given.*

(i) *Whatever the values of the nonzeros in A and b, if A is nonsingular then*

$$\text{struct}(A^{-1}b) \subseteq \text{closure}(b).$$

(ii) *There exist nonzero values for which* $\text{struct}(A^{-1}b) = \text{closure}(b)$. *(In fact, all the nonzeros in b can have the value* 1.)

Proof. Part (i). Let values be given for which A is nonsingular. Renumber the vertices of A so that $\text{closure}(b) = \{1, 2, \dots, k\}$ for some $k \leq n$. Then $Ax = b$ can be partitioned as

$$\begin{pmatrix} B & D \\ C & E \end{pmatrix} \begin{pmatrix} y \\ z \end{pmatrix} = \begin{pmatrix} d \\ 0 \end{pmatrix},$$

where B is $k \times k$. By the definition of closure(b), there is no edge (i,j) with $i \notin$ closure(b) and $j \in$ closure(b). Therefore $C = 0$. Then $Ez = 0$. Since A is nonsingular and $C = 0$, matrix E is nonsingular. Therefore $z = 0$. Thus struct(x) $\subseteq \{1, \ldots, k\} =$ closure(b).

Part (ii). Choose algebraically independent values for the nonzeros of A, and let $b_i = 1$ if $i \in$ struct(b). Then A is nonsingular because $\det A$ is a nonzero polynomial in the nonzeros of A. Let $x = A^{-1}b$. Renumber the vertices of A so that struct(x) $= \{1, 2, \ldots, k\}$ for some $k \leq n$. Then $Ax = b$ can be partitioned as

$$\begin{pmatrix} B & D \\ C & E \end{pmatrix} \begin{pmatrix} y \\ 0 \end{pmatrix} = \begin{pmatrix} d \\ e \end{pmatrix},$$

where B is $k \times k$ and all entries of y are nonzero. Consider row i of C. We have

$$\sum_{1 \leq j \leq k} c_{ij} y_j = e_i. \tag{1}$$

Now B is nonsingular, since $\det B$ is a nonzero polynomial. By Cramer's rule, $By = d$ implies $y_j = \det(B|_j^d)/\det B$, where $B|_j^d$ is B with column j replaced by d. Then (1) implies

$$\sum_{i \leq j \leq k} c_{ij} \det(B|_j^d) - e_i \det B = 0. \tag{2}$$

This is a polynomial with rational coefficients in the entries of A, so it is the zero polynomial. Now $y_j \neq 0$ implies that $\det(B|_j^d)$ is not the zero polynomial, so c_{ij} must be zero. Thus $C = 0$. This implies that $x = \binom{y}{0}$ is closed. Furthermore, $\det B \neq 0$, so (2) implies $e_i = 0$. Thus $e = 0$, so $b = \binom{d}{0}$ and struct(b) $\subseteq$ struct(x) $=$ closure(x). Therefore closure(b) $\subseteq$ struct(x). With part (i), this gives closure(b) $=$ struct(x). □

Remark 5.2. The proof of part (i) never assumes that the "nonzero values" of A are in fact different from zero. Thus we have the slightly stronger result that if $G(\hat{A}) \subseteq G(A)$ and struct($\hat{b}$) $\subseteq$ struct(b) and $\hat{A}$ is nonsingular, then struct($\hat{A}^{-1}\hat{b}$) $\subseteq$ closure(b).

Remark 5.3. It seems natural to conjecture in part (i) that if A is singular and $Ax = b$ has a solution, then it has some solution with struct(x) $\subseteq$ closure(b). Oddly enough, this is false. Consider

$$A = \begin{pmatrix} 1 & 1 & 0 & 1 \\ 2 & 2 & 0 & 1 \\ 0 & 0 & 1 & -1 \\ 0 & 0 & 1 & -1 \end{pmatrix} \quad \text{and} \quad b = \begin{pmatrix} 1 \\ 1 \\ 0 \\ 0 \end{pmatrix}.$$

All solutions to $Ax = b$ are of the form $(\alpha, -\alpha, 1, 1)^T$, none of which is a subset of closure(b) $= (\times, \times, 0, 0)^T$.

COROLLARY 5.4. *Let the structure $G(A)$ be given.*

(i) *Whatever values A has, if A is nonsingular then $G(A^{-1}) \subseteq G^*(A)$.*

(ii) *Values exist for the nonzeros of A such that $G(A^{-1}) = G^*(A)$.*

Proof. Note that column j of $G^*(A)$ is closure($e^{(j)}$), where $e^{(j)}$ is the jth unit vector. The corollary is immediate from Theorem 5.1, noting that part (ii) of the theorem holds even if the right-hand-side entries are all zeros and ones. □

Corollary 5.4 implies that if A is irreducible with nonzero diagonal, then A^{-1} is full unless numerical coincidence occurs. Duff et al. [8] gave another proof of this special case.

The case where A is allowed to have zeros on the diagonal is a straightforward extension. First, for A^{-1} to exist, $H(A)$ must be Hall. That implies that a permutation P exists for which PA has nonzero diagonal. Then the structure of the solution to $Ax = b$ is the structure of $A^{-1}b = (PA)^{-1}(Pb)$, which is the closure of Pb with respect to the graph $G(PA)$ by Theorem 5.1. The structure of A^{-1} can be predicted similarly by permuting to nonzero diagonal, forming the transitive closure, and permuting back. This also implies a slightly stronger version of the result of Duff et al.: if nonsingular A is fully indecomposable, or, equivalently, strong Hall (with no restriction on the diagonal), then A^{-1} is full unless numerical coincidence occurs.

The case where A is symmetric is simpler and less interesting, but the puzzling examples such as the one in Remark 5.3 do not arise. If A is symmetric and its graph is not connected, then A is block diagonal, and a linear system splits into a separate problem for each block. If A is connected, then it is strongly connected and the closure of every nonempty set is the whole graph. Then the upper bound in part (i) of Theorem 5.1 is trivial, and values exist to achieve it.

THEOREM 5.5. *Let a symmetric structure for A be given along with a nonzero structure for b. If the structure for A is connected (i.e., irreducible, or not block diagonal), then there exist symmetric values for A such that* $\text{struct}(A^{-1}b) = \{1, 2, \ldots, n\}$; *that is, x is full. Also, in this case, A^{-1} is full.*

Proof. The proof is almost identical to that of Theorem 5.1 (ii), so this is just a sketch: Choose algebraically independent values for the lower triangle of A and make the upper triangle symmetric. Then A is nonsingular. The polynomial in (2) does not contain c_{ji}, so we can still conclude $c_{ij} = 0$ from the fact that it occurs multiplied by a nonzero polynomial. Therefore $A^{-1}b$ is closed. But if symmetric A is connected, then it is strongly connected, so the only nonempty closed set is $\{1, 2, \ldots, n\}$. □

6. Eigenvectors. In this section we determine the structure of the eigenvectors of a square matrix A. The results in this section are new. We deal only with the case of distinct eigenvalues. As described at the end of the section, the reason we cannot handle multiple eigenvalues is related to Remark 5.3 above.

Throughout this section A is an $n \times n$ matrix with nonzero diagonal, and the graph in question is the directed graph of A. Recall that $e^{(i)}$ is the ith unit vector and $\text{closure}(e^{(i)})$ is the structure of column i of the transitive closure of A.

THEOREM 6.1. *Let the structure $G(A)$ be given.*

(i) *Whatever the values of the nonzeros in A, if A has n distinct eigenvalues $\lambda_1, \ldots, \lambda_n$, then the eigenvectors of A can be numbered $u^{(1)}, \ldots, u^{(n)}$ such that* $\text{struct}(u^{(i)}) \subseteq \text{closure}(e^{(i)})$.

(ii) *There exist nonzero values for which A has n distinct eigenvalues, and the eigenvectors satisfy* $\text{struct}(u^{(i)}) = \text{closure}(e^{(i)})$.

Proof. Part (i). Let values be given for A. Renumber the vertices of A to put A in block upper triangular form—that is, to put the strongly connected components of A in topological order. Then A is partitioned as

$$A = \begin{pmatrix} B_1 & C_{1,2} & \cdots & C_{1,s} \\ & B_2 & \cdots & C_{2,s} \\ & & \ddots & \vdots \\ 0 & & & B_s \end{pmatrix},$$

where each B_j is square and strongly connected. Renumber the eigenvalues and eigenvectors in nondecreasing order of the highest-numbered nonzero in the eigenvector.

That is, if $u_k^{(i)} = u_{k+1}^{(i)} = \cdots = u_n^{(i)} = 0$, then $u_k^{(i-1)} = u_{k+1}^{(i-1)} = \cdots = u_n^{(i-1)} = 0$, for $1 < i \leq n$.

Consider some eigenvector $u^{(i)}$. Suppose its highest-numbered nonzero is in a row that runs through block B_j. Then $Au^{(i)} = \lambda_i u^{(i)}$ is partitioned as

$$\begin{pmatrix} D & E & F \\ 0 & B_j & G \\ 0 & 0 & H \end{pmatrix} \begin{pmatrix} v \\ w \\ 0 \end{pmatrix} = \lambda_i \begin{pmatrix} v \\ w \\ 0 \end{pmatrix}, \qquad \text{where } D = \begin{pmatrix} B_1 & \cdots & C_{1,j-1} \\ & \ddots & \vdots \\ 0 & & B_{j-1} \end{pmatrix}, \quad \text{etc.}$$

Then $B_j w = \lambda_i w$ with $w \neq 0$, so λ_i is an eigenvalue of B_j. In fact, each λ_i is an eigenvalue of one B_j, with j increasing as i increases. Since no B_j has more eigenvalues than its dimension, we conclude by counting rows that row i and column i of A run through B_j. Now B_j is strongly connected, so closure$(e^{(i)})$ = closure(B_j) (where closure(B_j) denotes the closure of the set of vertices of B_j with respect to A).

We have $Dv + Ew = \lambda_i v$, so

$$(D - \lambda_i I)v = Ew.$$

Since the eigenvalues of A are simple, λ_i is not an eigenvalue of D and $D - \lambda_i I$ is nonsingular. Thus, by Theorem 5.1,

$$\text{struct}(v) \subseteq \text{closure}(Ew).$$

Now if D is $m \times m$ and B_j is $t \times t$, struct$(w) \subseteq \{m+1, m+2, \ldots, m+t\}$ and struct$(Ew) \subseteq \{1 \leq k \leq m : a_{kl} \neq 0 \text{ for some } l \in \text{struct}(w)\}$ by Theorem 3.1, so struct$(Ew) \subseteq$ closure(w) (closure still with respect to A) and struct$(v) \subseteq$ closure(w). Therefore, struct$(u^{(i)})$ = struct$(v) \cup$ struct$(w) \subseteq$ closure(w). Since $w \subseteq B_j$, this implies that struct$(u^{(i)}) \subseteq$ closure(B_j) = closure$(e^{(i)})$.

Part (ii). Choose algebraically independent values for A, choosing the diagonal elements so far apart that no two are closer than $2 \max_j \sum_{i \neq j} |a_{ij}|$. By Gerschgorin's theorem [25], this guarantees that there are n distinct, simple eigenvalues. (It would be more elegant to conclude that the eigenvalues are simple from the algebraic independence of the elements, but I do not know how to prove it.)

First we will show that each eigenvector is closed. Let u be an eigenvector with $Au = \lambda u$. Renumber the vertices of A so that struct$(u) = \{1, 2, \ldots, t\}$ for some $t \leq n$. Then $Au = \lambda u$ can be partitioned as

$$\begin{pmatrix} B & D \\ C & E \end{pmatrix} \begin{pmatrix} v \\ 0 \end{pmatrix} = \lambda \begin{pmatrix} v \\ 0 \end{pmatrix}, \tag{3}$$

where B is $t \times t$ and $v_k \neq 0$ for $1 \leq k \leq t$. We will show $C = 0$. Intuitively, it seems clear that if $C \neq 0$, then v cannot be both an eigenvector of B and a null vector of C. A field-theoretic argument makes this intuition precise.

Since $Bv = \lambda v$ and the diagonal elements of B are far enough apart that their Gerschgorin discs do not overlap, λ is in the Gerschgorin disc of exactly one b_{kk}. Renumber vertices 1 through t so that b_{kk} is b_{11}. Choose v such that $v_1 = 1$. Then $Bv = \lambda v$ partitions into

$$\begin{pmatrix} b_{11} & f^T \\ g & B' \end{pmatrix} \begin{pmatrix} 1 \\ v_2 \\ \vdots \\ v_t \end{pmatrix} = \lambda \begin{pmatrix} 1 \\ v_2 \\ \vdots \\ v_t \end{pmatrix},$$

where f and g are $t-1$-vectors. Now we have

$$(B' - \lambda I)\begin{pmatrix} v_2 \\ \vdots \\ v_t \end{pmatrix} = -g.$$

By Gerschgorin's theorem, λ is not an eigenvalue of B', so $B' - \lambda I$ is nonsingular and

$$v_k = \frac{\det(B' - \lambda I)|_k^{-g}}{\det(B' - \lambda I)} \qquad \text{for } 2 \le k \le t. \tag{4}$$

Now we fix i and j and show that $c_{ij} = 0$ (for $1 \le i \le n-t$ and $1 \le j \le t$).

Let F be the field obtained by adjoining to $\mathbf{Q}$ (the rationals) all the nonzeros of B and all the nonzeros of row i of C except c_{ij}. Now $F[x]$ is the ring of one-variable polynomials with coefficients in F, and $F(\lambda)$ is the field obtained by adjoining λ to F. We know λ is a zero of a nonzero polynomial in $F[x]$, namely, $\det(B - xI)$. Therefore, λ is algebraic over F, so every element of $F(\lambda)$ is a zero of some nonzero polynomial in $F[x]$.

Since $Cv = 0$, we have

$$\sum_{1 \le k \le t} c_{ik} v_k = 0.$$

All the v_k are nonzero, so

$$c_{ij} = -\frac{1}{v_j} \sum_{k \ne j} c_{ik} v_k. \tag{5}$$

By (4), each v_k is a rational function of λ and elements of F, so $v_k \in F(\lambda)$. Each c_{ik} with $k \ne j$ is in F. Therefore, the whole right-hand side of (5) is in $F(\lambda)$, so $c_{ij} \in F(\lambda)$. This means that c_{ij} is a zero of a nonzero polynomial in $F[x]$. But if c_{ij} is nonzero, then c_{ij} was chosen to be transcendental over F. Thus $c_{ij} = 0$; and, since i and j were arbitrary, $C = 0$.

Recalling the partition of A in (3), $C = 0$ implies that the eigenvector $u = \binom{v}{0}$ is closed.

Now all the eigenvectors of A are closed. Renumber the eigenvectors so that λ_i is in the Gerschgorin disc of a_{ii}. The argument following (3) shows that λ_i is in a Gerschgorin disc whose index j corresponds to a nonzero $u_j^{(i)}$ of $u^{(i)}$; since λ_i is in only one disc, this means $u_i^{(i)} \ne 0$. Therefore, $\text{struct}(e^{(i)}) \subseteq \text{struct}(u^{(i)})$. Since $u^{(i)}$ is closed, $\text{closure}(e^{(i)}) \subseteq \text{struct}(u^{(i)})$. Part (i) gives the opposite containment, so $\text{struct}(u^{(i)}) = \text{closure}(e^{(i)})$. □

COROLLARY 6.2. *Let the structure of A be given.*

(i) *No matter what nonzero values A has, if A has only simple eigenvalues, then its eigenvectors can be ordered so that the matrix U whose columns are the eigenvectors has $G(U) \subseteq G^*(A)$.*

(ii) *There exist values for the nonzeros of A such that the eigenvectors can be ordered so that $G(U) = G^*(A)$.*

Proof. Similar to Corollary 5.4. □

Remark 6.3. It is natural to conjecture that if A has multiple eigenvalues, then there is some choice of a maximal set of eigenvectors whose structure is a subset of the

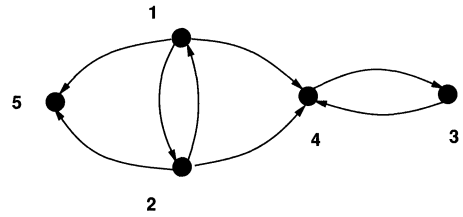

FIG. 4. *Graph of counterexample in Remark* 6.3.

transitive closure of A. Again, oddly, this is false. From the example in Remark 5.3 we can construct

$$A = \begin{pmatrix} 3 & 1 & 0 & 1 & -1 \\ 2 & 4 & 0 & 1 & -1 \\ 0 & 0 & 3 & -1 & 0 \\ 0 & 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 2 \end{pmatrix}, \quad \text{so } G^*(A) = \begin{pmatrix} \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \\ & & \times & \times & \\ & & \times & \times & \\ & & & & \times \end{pmatrix}.$$

The graph of A is shown in Fig. 4. The characteristic equation of A is $\det(xI - A) = (x-2)^4(x-5)$, so the eigenvalues are 2 and 5. The eigenspace of 5 is one-dimensional and consists of multiples of $(1,2,0,0,0)^T$, which comprise a column of the transitive closure. However, the eigenspace of 2 is also one-dimensional and consists of multiples of $(0,0,1,1,1)^T$, which do not form a subset of any column of the transitive closure.

Mascarenhas [31] has recently extended Theorem 6.1 to the case where A has multiple eigenvalues, provided that no two diagonal blocks of the block upper triangular form of A share an eigenvalue. He has also proved a similar result for the more general case where there are n linearly independent eigenvectors, that is, where each eigenvalue has equal geometric and algebraic multiplicity.

For symmetric A, the situation for eigenvectors is the same as for symmetric linear systems: If A is block diagonal, then each block is a separate problem; if A is not block diagonal (i.e., A is irreducible or connected), then the upper bounds are both trivial and tight.

THEOREM 6.4. *Let a symmetric structure for A be given. If the structure is connected, then there exist symmetric values for A such that A has n distinct eigenvalues, and all its eigenvectors are full.*

Proof. Just as in Theorem 5.5, the proof of Theorem 6.1 part (ii) goes through, even if A is required to be symmetric. □

7. Remarks, applications, and open problems. We have described several matrix computations in which the nonzero structure of the result of the computation can be inferred, partly or completely, from the nonzero structure of the input to the computation. The language of graph theory seems most appropriate to state these results, primarily because path structure is most easily described in graph-theoretic terms.

Matchings in bipartite graphs are important in several of the results of §4. Bipartite matching theory plays a central role in two other structural problems that we have not described here: finding the sparsest basis for the range space (McCormick [32]) and for the null space (Coleman and Pothen [5], [6], Gilbert and Heath [21]) of a rectangular matrix. It turns out that the structural range space problem can be solved in polynomial time, but the null space problem is NP-complete.

Several applications of structure prediction to solving systems of linear equations were cited in §1. Some of the present work was motivated by Gilbert and Peierls's use of structure prediction for triangular linear systems as part of an efficient algorithm for sparse LU factorization with partial pivoting [24]. Another application of structure prediction for triangular systems is in a practical problem in reservoir analysis. Here a finite-element model of an underground reservoir of hot water (to be tapped for power and heating for the city of Reykjavík) requires the solution of hundreds of positive definite linear systems with the same coefficient matrix. All the systems have very sparse right-hand sides, and, in addition, only a few of the unknown values are required for each system. Sigurðsson [38] has used structure prediction with a simpler version of Theorem 5.1 to speed up the Sparspak triangular solver for this problem.

We have been concerned exclusively with predicting nonzero structure in this paper. A related question is: Given a matrix and a matrix function, which entries of the matrix are unchanged in value by application of the function? Barrett, Johnson, Olesky, and van den Driessche [2], [28] have given such characterizations for functions including LU factorization and Schur complement.

A few open problems in structure prediction, some of which have already been mentioned, are as follows. Is it possible to give a tight bound on the nonzero structures of the factors in Gaussian elimination with partial pivoting (§4)? What can be said about solutions to singular linear systems in light of the counterexample in §5? What can be said about eigenvector structures for matrices with multiple eigenvalues ([31, §6])? What can be said about the structure of the singular value decomposition (SVD) of a rectangular matrix [25]? The relationship between the singular values of A and the eigenvalues of A^TA, together with Theorem 6.4 on eigenvectors of symmetric matrices, suggests that the SVD of a connected matrix is always full (ignoring numerical cancellation). This would certainly confirm the conventional wisdom that there is no such thing as an SVD with sparse singular vectors.

Acknowledgments. My thanks to Tom Coleman, Anders Edenbrandt, Mike Heath, Joseph Liu, Esmond Ng, Ragnar Sigurðsson, and Sven Sigurðsson for interesting and useful discussions of these problems. Earl Zmijewski gave this paper a careful and helpful critical reading. Gene Golub nudged me to finish revising it for publication.

CIRCULANT PRECONDITIONED TOEPLITZ LEAST SQUARES ITERATIONS*

RAYMOND H. CHAN†, JAMES G. NAGY‡, AND ROBERT J. PLEMMONS§

Abstract. The authors consider the solution of least squares problems $\min \|b - Tx\|_2$ by the preconditioned conjugate gradient method, for m-by-n complex Toeplitz matrices T of rank n. A circulant preconditioner C is derived using the T. Chan optimal preconditioner on n-by-n Toeplitz row blocks of T. For Toeplitz T that are generated by 2π-periodic continuous complex-valued functions without any zeros, the authors prove that the singular values of the preconditioned matrix TC^{-1} are clustered around 1, for sufficiently large n. The paper shows that if the condition number of T is of $O(n^\alpha)$, $\alpha > 0$, then the least squares conjugate gradient method converges in at most $O(cd\alpha \log n + 1)$ steps. Since each iteration requires only $O(m \log n)$ operations using the Fast Fourier Transform, it follows that the total complexity of the algorithm is then only $O(\alpha m \log^2 n + m \log n)$. Conditions for *superlinear convergence* are given and regularization techniques leading to superlinear convergence for least squares computations with ill-conditioned Toeplitz matrices arising from inverse problems are derived. Numerical examples are provided illustrating the effectiveness of the authors' methods.

1. Introduction.

The conjugate gradient (CG) method is an iterative method for solving Hermitian positive definite systems $Ax = b$ (see, for instance, Golub and Van Loan [21]). When A is a rectangular m-by-n matrix of rank n, one can still use the CG algorithm to find the solution to the least squares problem

$$\min \|b - Ax\|_2. \tag{1}$$

This can be done by applying the algorithm to the normal equations in factored form,

$$A^*(b - Ax) = 0, \tag{2}$$

which can be solved by conjugate gradients without explicitly forming the matrix A^*A (see Bjorck [7]).

The convergence of the CG algorithm and its variations depends on the singular values of the data matrix A (see Axelsson [5]). If the singular values cluster around a fixed point, convergence will be rapid. Thus, to make the algorithm a useful iterative method, one usually *preconditions* the system. The preconditioned conjugate gradient (PCG) algorithm then solves (1) by transforming the problem with a preconditioner M, applying the CG method to the transformed problem, and then transforming back. More precisely, one can use the CG method to solve

$$\min \|b - AM^{-1}y\|_2,$$

and then set $x = M^{-1}y$.

In this paper we consider the least squares problem (1), with the data matrix $A = T$, where T is a rectangular m-by-n Toeplitz matrix of rank n. The matrix $T = (t_{jk})$ is said to be *Toeplitz* if $t_{jk} = t_{j-k}$, i.e., T is constant along its diagonals. An n-by-n matrix C is said to be *circulant* if it is Toeplitz and its diagonals c_j satisfy $c_{n-j} = c_{-j}$ for $0 < j \leq n-1$. Toeplitz least squares problems occur in a variety of applications, especially in signal and image processing. (See Andrews and Hunt [3], Jain [24], and Oppenheim and Schafer [28].)

Recall that the solution to the least squares problem

$$\min \|b - Tx\|_2 \tag{3}$$

can be found by the PCG method by applying the method to the normal equations (2) in factored form, that is, using T and T^* without forming T^*T. The preconditioner M considered in this paper is given by an n-by-n circulant matrix $M = C$, where C^*C is then a circulant matrix that approximates T^*T.

The version of the PCG algorithm we use is given in [7] and can be stated as follows.

Algorithm PCG for Least Squares. *Let $x^{(0)}$ be an initial approximation to $Tx = b$, and let C be a given preconditioner. This algorithm computes the least squares solution, x, to $Tx = b$.*

$r^{(0)} = b - Tx^{(0)}$
$p^{(0)} = s^{(0)} = C^{-*}T^*r^{(0)}$
$\gamma_0 = \|s^{(0)}\|_2^2$
for $k = 0, 1, 2, \ldots$
  $q^{(k)} = TC^{-1}p^{(k)}$
  $\alpha_k = \gamma_k / \|q^{(k)}\|_2^2$
  $x^{(k+1)} = x^{(k)} + \alpha_k C^{-1}p^{(k)}$
  $r^{(k+1)} = r^{(k)} - \alpha_k q^{(k)}$
  $s^{(k+1)} = C^{-*}T^*r^{(k+1)}$
  $\gamma_{k+1} = \|s^{(k+1)}\|_2^2$
  $\beta_k = \gamma_{k+1}/\gamma_k$
  $p^{(k+1)} = s^{(k+1)} + \beta_k p^{(k)}$

The idea of using the PCG method with circulant preconditioners for solving square positive definite Toeplitz systems was first proposed by Strang [30], although the application of circulant approximations to Toeplitz matrices has been used for some time in image processing, e.g., in [6]. The convergence rate of the method was analyzed by R. Chan and Strang [9] for Toeplitz matrices that are generated by positive Wiener class functions. Since then, considerable research has been done in finding other good circulant preconditioners or extending the class of generating functions for which the method is effective. (See T. Chan [17], R. Chan [10], Tyrtyshnikov [32], Tismenetsky [31], Huckle [23], Ku and Kuo [25], R. Chan and Yeung [13], T. Chan and Olkin [18], R. Chan and Jin [12], and R. Chan and Yeung [14].)

Recently, the idea of using circulant preconditioners has been extended to non-Hermitian square Toeplitz systems by R. Chan and Yeung [15] and to Toeplitz least squares problems by Nagy [26] and by Nagy and Plemmons [27]. The main aims of this paper are to formalize and establish convergence results and to provide applications in the case where T is a rectangular Toeplitz (block) matrix.

For the purpose of constructing the preconditioner, we will see that by extending the Toeplitz structure of the matrix T and, if necessary, padding zeros to the bottom left-hand side, we may assume without loss of generality that $m = kn$ for some positive integer k. This padding is only for convenience in constructing the preconditioner and does not alter the original least squares problem. In the material to follow, we consider the case where k is a constant independent of n. More precisely, we consider in this paper, kn-by-n matrices T of the form

$$T = \begin{bmatrix} T_1 \\ T_2 \\ \vdots \\ T_k \end{bmatrix}, \tag{4}$$

where each square block T_j is a Toeplitz matrix. Notice that if T itself is a rectangular Toeplitz matrix, then each block T_j is necessarily Toeplitz.

Following [26], [27], for each block T_j, we construct a circulant approximation C_j. Then our preconditioner is defined as a square circulant matrix C, such that

$$C^*C = \sum_{j=1}^{k} C_j^* C_j.$$

Notice that each C_j is an n-by-n circulant matrix. Hence they can all be diagonalized by the Fourier matrix F, i.e.,

$$C_j = F \Lambda_j F^*,$$

where Λ_j is diagonal (see Davis [19]). Therefore, the spectrum of C_j, $j = 1, \ldots, k$, can be computed in $O(n \log n)$ operations by using the Fast Fourier Transform (FFT). Since

$$C^*C = F \sum_{j=1}^{k} (\Lambda_j^* \Lambda_j) F^*,$$

C^*C is also circulant and its spectrum can be computed in $O(kn \log n)$ operations. Here we choose, as in [26], [27],

$$C = F \left(\sum_{j=1}^{k} \Lambda_j^* \Lambda_j \right)^{1/2} F^*. \tag{5}$$

The number of operations per iteration in Algorithm PCG for Least Squares depends mainly on the work of computing the matrix-vector multiplications. In our case, this amounts to computing products:

$$Ty, \quad T^*z, \quad C^{-1}y, \quad C^{-*}y$$

for some n-vectors y and m-vectors z. Since

$$C^{-1}y = F \left(\sum_{j=1}^{k} \Lambda_j^* \Lambda_j \right)^{-1/2} F^* y,$$

the products $C^{-1}y$ and $C^{-*}y$ can be found efficiently by using the FFT in $O(n \log n)$ operations. For the products Ty and T^*z, with T in block form with k n-by-n blocks T_j, we have to compute n products of the form $T_j w$, where T_j is an n-by-n Toeplitz matrix and w is an n-vector. However, the product $T_j w$ can be computed using the FFT by first embedding T_j into a $2n$-by-$2n$ circulant matrix. The multiplication thus requires $O(2n \log(2n))$ operations. It follows that the operations for computing Ty and T^*z are of the order $O(m \log n)$, where $m = nk$. Thus we conclude that the cost per iteration in the PCG method is of the order $O(m \log n)$.

As already mentioned in the beginning, the convergence rate of the method depends on the distribution of the singular values of the matrix TC^{-1}, which are the same as the square roots of the eigenvalues of the matrix $(C^*C)^{-1}(T^*T)$. We will show, then, that if the generating functions of the blocks T_j are 2π-periodic continuous functions and if one of these functions has no zeros, then the spectrum of $(C^*C)^{-1}(T^*T)$ will be clustered around 1, for sufficiently large n. We remark that the class of 2π-periodic continuous functions contains the Wiener class of functions, which in turn contains the class of rational functions considered in Ku and Kuo [25].

By using a standard error analysis of the CG method, we then show that if the condition number $\kappa(T)$ of T is of $O(n^\alpha)$, then the number of iterations required for convergence, for sufficiently large n, is at most $O(\alpha \log n + 1)$, where $\alpha > 0$. Since the number of operations per iteration in the CG method is of $O(m \log n)$, the total complexity of the algorithm is therefore of $O(\alpha m \log^2 n + m \log n)$. In the case in which $\alpha = 0$, i.e., T is well conditioned, the method converges in $O(1)$ steps. Hence the complexity is reduced to just $O(m \log n)$ operations, for sufficiently large n. On the other hand, the superfast direct algorithms by Ammar and Gragg [2] require $O(n \log^2 n)$ operations for n-by-n Toeplitz linear systems. The stability of fast direct methods has been studied by Bunch [8].

The outline of the paper is as follows. In §2, we construct the circulant preconditioners C for the Toeplitz least squares problem and study some of the spectral properties of these preconditioners. In §3, we show that the iteration matrix TC^{-1} has singular values clustered around 1. In §4, we then establish the convergence rate of the PCG method when applied to the preconditioned system, and indicate when it is superlinear. In §5, we discuss the technique of regularization when the given Toeplitz matrix T is ill conditioned. Numerical results and concluding remarks are given in §6.

2. Properties of the circulant preconditioner. In this section, we consider circulant preconditioners for least square problems and study their spectral properties. We begin by recalling some results for square Toeplitz systems.

For simplicity, we denote by $C_{2\pi}$ the Banach space of all 2π-periodic continuous complex-valued functions equipped with the supremum norm $\|\cdot\|_\infty$. As already mentioned in §1, this class of functions contains the Wiener class of functions. For all $f \in C_{2\pi}$, let

$$a_k = \frac{1}{2\pi} \int_{-\pi}^{\pi} f(\theta) e^{-ik\theta} d\theta, \quad k = 0, \pm 1, \pm 2, \ldots,$$

be the Fourier coefficients of f. Let A be the n-by-n complex Toeplitz matrix with the (j,k)th entry given by a_{j-k}. The function f is called the generating function of the matrix A.

For a given n-by-n matrix A, we let C be the n-by-n circulant approximation of A as defined in T. Chan [17], i.e., C is the minimizer of $F(X) = \|A - X\|_F$ over all

circulant matrices X. For the special case where A is Toeplitz, the (j,ℓ)th entry of C is given by the diagonal $c_{j-\ell}$ where

$$c_k = \begin{cases} \dfrac{(n-k)a_k + ka_{k-n}}{n} & 0 \le k < n, \\ c_{n+k} & 0 < -k < n. \end{cases} \tag{6}$$

The following three lemmas are proved in R. Chan and Yeung [15]. The first two give the bounds of $||A||_2$ and $||C||_2$ and the last one shows that $A - C$ has a clustered spectrum for certain Toeplitz matrices A.

LEMMA 1. *Let $f \in C_{2\pi}$. Then we have*

$$||A||_2 \le 2||f||_\infty < \infty, \quad n = 1, 2, \ldots. \tag{7}$$

If, moreover, f has no zeros, i.e.,

$$\min_{\theta \in [-\pi,\pi]} |f(\theta)| > 0,$$

then there exists a constant $c > 0$ such that for all n sufficiently large, we have

$$||A||_2 > c. \tag{8}$$

LEMMA 2. *Let $f \in C_{2\pi}$. Then we have*

$$||C||_2 \le 2||f||_\infty < \infty, \quad n = 1, 2, \ldots. \tag{9}$$

If, moreover, f has no zeros, then for all sufficiently large n, we also have

$$||C^{-1}||_2 \le 2 \left\| \frac{1}{f} \right\|_\infty < \infty. \tag{10}$$

LEMMA 3. *Let $f \in C_{2\pi}$. Then for all $\epsilon > 0$, there exist N and $M > 0$, such that for all $n > N$,*

$$A - C = U + V,$$

where

$$\text{rank } U \le M$$

and

$$||V||_2 \le \epsilon.$$

Now let us consider the general least squares problem (3) where T is an m-by-n matrix with $m \ge n$. For the purpose of constructing the preconditioner, we assume that $m = kn$, without loss of generality, since otherwise the final block T_k can be extended to an $n \times n$ Toeplitz matrix by extending the diagonals and padding the lower left part with zeros. (This modification is only for constructing the preconditioner. The original least squares problem (3) is not changed.) Thus we can partition T as (4), without loss of generality. We note that the solution to the least square problem (3) can be obtained by solving the normal equations

$$T^*Tx = T^*b,$$

in factored form, where

$$T^*T = \sum_{j=1}^{k} T_j^* T_j.$$

Of course, one can avoid actually forming T^*T for implementing the CG method for the normal equations [7].

We will assume in the following that k is a constant independent of n and that each square block T_j, $j = 1, \ldots, k$ is generated by a generating function f_j in $\mathcal{C}_{2\pi}$. Following Nagy [26] and Nagy and Plemmons [27], we define a preconditioner for T based upon preconditioners for the blocks T_j.

For each block T_j, let C_j be the corresponding T. Chan circulant preconditioner as defined in (6). Then it is natural to consider the square circulant matrix

$$C^*C = \sum_{j=1}^{k} C_j^* C_j \tag{11}$$

as a circulant approximation to T^*T [27]. Note, however, that C is computed (or applied) using (5). Clearly C is invertible if one of the C_j is. In fact, using Lemma 2, we have the following lemma.

LEMMA 4. *Let $f_j \in \mathcal{C}_{2\pi}$ for $j = 1, 2, \ldots, k$. Then we have*

$$\|C\|_2^2 \leq 4 \sum_{j=1}^{k} \|f_j\|_\infty^2 < \infty, \quad n = 1, 2, \ldots. \tag{12}$$

If, moreover, one of the f_j (say, f_ℓ) has no zeros, then for all sufficiently large n, we also have

$$\|(C^*C)^{-1}\|_2 \leq 4 \left\| \frac{1}{f_\ell} \right\|_\infty^2 < \infty. \tag{13}$$

Proof. Equation (12) clearly follows from (11) and (9). To prove (13), we just note that $C_j^* C_j$ are positive semidefinite matrices for all $j = 1, \ldots, k$; hence

$$\lambda_{\min}(C^*C) \geq \lambda_{\min}(C_\ell^* C_\ell),$$

where $\lambda_{\min}(\cdot)$ denotes the smallest eigenvalue. Thus by (10), we then have

$$\|(C^*C)^{-1}\|_2 \leq \|(C_\ell^* C_\ell)^{-1}\|_2 = \|C_\ell^{-1}\|_2^2 \leq 4 \left\| \frac{1}{f_\ell} \right\|_\infty^2. \qquad \square$$

3. Spectrum of TC^{-1}. In this section, we show that the spectrum of the matrix

$$(C^*C)^{-1}(T^*T)$$

is clustered around 1. It will follow then, that the singular values of TC^{-1} are also clustered around 1, since $(C^*C)^{-1}(T^*T)$ is similar to $(TC^{-1})^*(TC^{-1})$. We begin by analyzing the spectrum of each block.

LEMMA 5. *For $1 \leq j \leq k$, if $f_j \in \mathcal{C}_{2\pi}$, then for all $\epsilon > 0$, there exist N_j and $M_j > 0$, such that for all $n > N_j$,*

$$T_j^* T_j - C_j^* C_j = U_j + V_j,$$

where U_j and V_j are Hermitian matrices with

$$\text{rank } U_j \leq M_j$$

and

$$||V_j||_2 \leq \epsilon.$$

Proof. We first note that by Lemma 3, we have for all $\epsilon > 0$, there exist positive integers N_j and M_j such that for all $n > N_j$,

$$T_j - C_j = \tilde{U}_j + \tilde{V}_j,$$

where rank $\tilde{U}_j \leq M_j$ and $||\tilde{V}_j||_2 \leq \epsilon$. Therefore,

$$\begin{aligned} & T_j^* T_j - C_j^* C_j \\ &= T_j^*(T_j - C_j) + (T_j - C_j)^* C_j \\ &= T_j^*(T_j - C_j) - (T_j - C_j)^*(T_j - C_j) + (T_j - C_j)^* T_j \\ &= T_j^*(\tilde{U}_j + \tilde{V}_j) - (\tilde{U}_j + \tilde{V}_j)^*(\tilde{U}_j + \tilde{V}_j) + (\tilde{U}_j + \tilde{V}_j)^* T_j \\ &\equiv U_j + V_j. \end{aligned}$$

Here

$$\begin{aligned} U_j &= T_j^* \tilde{U}_j + \tilde{U}_j^* T_j - \tilde{U}_j^* \tilde{U}_j - \tilde{U}_j^* \tilde{V}_j - \tilde{V}_j^* \tilde{U}_j \\ &= \tilde{U}_j^*(T_j - \tilde{U}_j - \tilde{V}_j) + (T_j - \tilde{V}_j)^* \tilde{U}_j \end{aligned}$$

and

$$V_j = \tilde{V}_j^* T_j + T_j^* \tilde{V}_j - \tilde{V}_j^* \tilde{V}_j.$$

It is clear that both U_j and V_j are Hermitian matrices. Moreover, we have rank $U_j \leq 2M_j$ and

$$||V_j||_2 \leq 2\epsilon ||T_j||_2 + \epsilon^2.$$

By (7), we then have

$$||V_j||_2 \leq 4\epsilon ||f_j||_\infty + 2\epsilon^2. \qquad \square$$

Using the facts that

$$T^*T - C^*C = \sum_{j=1}^{k} (T_j^* T_j - C_j^* C_j)$$

and that k is independent of n, we immediately have the following lemma.

LEMMA 6. *Let $f_j \in \mathcal{C}_{2\pi}$ for $j = 1, \ldots, k$. Then for all $\epsilon > 0$, there exist N and $M > 0$, such that for all $n > N$,*

$$T^*T - C^*C = \tilde{U} + \tilde{V},$$

where $\tilde{U}$ and $\tilde{V}$ are Hermitian matrices with

$$\text{rank } \tilde{U} \leq M \tag{14}$$

and

$$\|\tilde{V}\|_2 \leq \epsilon. \tag{15}$$

We now show that the spectrum of the preconditioned matrix

$$(C^*C)^{-1}(T^*T)$$

is clustered around 1. We note that this is equivalent to showing that the spectrum of $(C^*C)^{-1}(T^*T) - I$, where I is the n-by-n identity matrix, is clustered around zero.

THEOREM 1. *Let $f_j \in \mathcal{C}_{2\pi}$ for all $j = 1, \ldots, k$. If one of the f_j (say, f_ℓ) has no zeros, then for all $\epsilon > 0$, there exist N and $M > 0$, such that for all $n > N$, at most M eigenvalues of the matrix*

$$(C^*C)^{-1}(T^*T) - I$$

have absolute values larger than ϵ.

Proof. By Lemma 6, we have

$$(C^*C)^{-1}(T^*T) - I = (C^*C)^{-1}(T^*T - C^*C) = (C^*C)^{-1}(\tilde{U} + \tilde{V}).$$

Therefore, the spectra of the matrices

$$(C^*C)^{-1}(T^*T) - I \quad \text{and} \quad (C^*C)^{-1/2}(\tilde{U} + \tilde{V})(C^*C)^{-1/2}$$

are the same. However, by (14), we have

$$\operatorname{rank}\left\{(C^*C)^{-1/2}\tilde{U}(C^*C)^{-1/2}\right\} \leq M$$

and by (15) and (13), we have

$$\|(C^*C)^{-1/2}\tilde{V}(C^*C)^{-1/2}\|_2 \leq \|\tilde{V}\|_2\|(C^*C)^{-1}\|_2 \leq 4\hat{\epsilon}\left\|\frac{1}{f_\ell}\right\|_\infty^2,$$

where $\hat{\epsilon}$ replaces the ϵ specified in (15). Thus by applying the Cauchy interlace theorem (see Wilkinson [33]) to the Hermitian matrix

$$(C^*C)^{-1/2}\tilde{U}(C^*C)^{-1/2} + (C^*C)^{-1/2}\tilde{V}(C^*C)^{-1/2},$$

we see that its spectrum is clustered around zero. Hence the spectrum of the matrix $(C^*C)^{-1}(T^*T)$ is clustered around 1. □

From Theorem 1, we have the desired clustering result; namely, if $f_j \in \mathcal{C}_{2\pi}$ for all $j = 1, \ldots, k$ and if one of the f_j has no zeros, then the *singular values of the preconditioned matrix TC^{-1} are clustered around* 1.

4. Convergence rate of the method. In this section, we analyze the convergence rate of Algorithm PCG for Least Squares, for our circulant preconditioned Toeplitz matrix TC^{-1}. We show first that the method converges, for sufficiently large n, in at most $O(\alpha \log n + 1)$ steps where $O(n^\alpha)$ is the condition number of T. We begin by noting the following error estimate of the CG method.

LEMMA 7. *Let G be a positive definite matrix and x be the solution to $Gx = b$. Let x_j be the jth iterant of the ordinary CG method applied to the equation $Gx = b$. If the eigenvalues $\{\delta_k\}$ of G are such that*

$$0 < \delta_1 \leq \cdots \leq \delta_p \leq \gamma_1 \leq \delta_{p+1} \leq \cdots \leq \delta_{n-q} \leq \gamma_2 \leq \delta_{n-q+1} \leq \cdots \leq \delta_n,$$

then

$$\frac{||x - x_j||_G}{||x - x_0||_G} \leq 2\left(\frac{\gamma - 1}{\gamma + 1}\right)^{j-p-q} \cdot \max_{\delta \in [\gamma_1, \gamma_2]} \left\{ \prod_{k=1}^{p} \left(\frac{\delta - \delta_k}{\delta_k} \right) \right\}. \tag{16}$$

Here

$$\gamma \equiv \left(\frac{\gamma_2}{\gamma_1}\right)^{1/2} \geq 1$$

and $||v||_G \equiv v^* G v$.

Proof. It is well known that an error estimate of the CG method is given by the following minimax inequality:

$$\frac{||x - x_j||_G}{||x - x_0||_G} \leq \min_{\mathcal{P}_j} \max_{k=1,\ldots,n} |\mathcal{P}_j(\delta_k)|,$$

where $\mathcal{P}_j$ is any jth degree polynomial with constant term 1 (see Axelsson and Barker [4]). To obtain an upper bound, we first use linear polynomials of the form $(\delta - \delta_k)/\delta_k$ that pass through (i.e., have as roots) the outlying eigenvalues δ_k, $1 \leq k \leq p$ and $n - q + 1 \leq k \leq n$, in order to minimize the maximum absolute value of $\mathcal{P}_j$ at these eigenvalues. These polynomials are thus used as factors of the polynomials being constructed. Next we use a $(j - p - q)$th degree Chebyshev polynomial $\mathcal{T}_{j-p-q}$ to minimize the maximum absolute value of $\mathcal{P}_j$ in the interval $[\delta_{p+1}, \delta_{n-q}]$. Then we get

$$\frac{||x - x_j||_G}{||x - x_0||_G} \leq \mathcal{T}_{j-p-q}\left[\frac{\gamma_2 + \gamma_1}{\gamma_2 - \gamma_1}\right]^{-1} \max_{\delta \in [\gamma_1, \gamma_2]} \left\{ \prod_{k=1}^{p} \left(\frac{\delta - \delta_k}{\delta_k} \right) \prod_{k=n-q+1}^{n} \left(\frac{\delta_k - \delta}{\delta_k} \right) \right\}.$$

Equation (16) now follows by noting that for $\delta \in [\gamma_1, \gamma_2]$, we always have

$$0 \leq \frac{\delta_k - \delta}{\delta_k} \leq 1, \quad n - q + 1 \leq k \leq n$$

and that

$$\mathcal{T}_{j-p-q}\left[\frac{\gamma_2 + \gamma_1}{\gamma_2 - \gamma_1}\right]^{-1} \leq 2\left(\frac{\gamma - 1}{\gamma + 1}\right)^{j-p-q}$$

(see Axelsson and Barker [4]). □

For the system

$$(C^*C)^{-1}(T^*T)x = (C^*C)^{-1}T^*b, \tag{17}$$

the iteration matrix G is given by

$$G = (C^*C)^{-1/2}(T^*T)(C^*C)^{-1/2}.$$

By Theorem 1, we can choose $\gamma_1 = 1 - \epsilon$ and $\gamma_2 = 1 + \epsilon$. Then p and q are constants that depend only on ϵ but not on n. By choosing $\epsilon < 1$, we have

$$\frac{\gamma - 1}{\gamma + 1} = \frac{1 - \sqrt{1 - \epsilon^2}}{\epsilon} < \epsilon.$$

In order to use (16), we need a lower bound for δ_k, $1 \le k \le p$. We first note that

$$||G^{-1}||_2 = ||(T^*T)^{-1}(C^*C)||_2 \le \frac{||C||_2^2}{||T||_2^2}\kappa(T^*T).$$

If one of the f_ℓ has no zeros, then by (8), we have for n sufficiently large

$$||T||_2^2 \ge ||T_\ell||_2^2 \ge c$$

for some $c > 0$ independent of n. Combining this with (12), we then see that for all n sufficiently large,

$$||G^{-1}||_2 \le \tilde{c} \cdot \kappa(T^*T) \le \tilde{c}n^\alpha,$$

for some constant $\tilde{c}$ that does not depend on n. Therefore,

$$\delta_k \ge \min_\ell \delta_\ell = \frac{1}{||G^{-1}||_2} \ge cn^{-\alpha}, \quad 1 \le k \le n.$$

Thus for $1 \le k \le p$ and $\delta \in [1-\epsilon, 1+\epsilon]$, we have

$$0 \le \frac{\delta - \delta_k}{\delta_k} \le cn^\alpha.$$

Hence (16) becomes

$$\frac{||x - x_j||_G}{||x - x_0||_G} < c^p n^{p\alpha} \epsilon^{j-p-q}.$$

Given arbitrary tolerance $\tau > 0$, an upper bound for the number of iterations required to make

$$\frac{||x - x_j||_G}{||x - x_0||_G} < \tau$$

is therefore given by

$$j_0 \equiv p + q - \frac{p \log c + \alpha p \log n - \log \tau}{\log \epsilon} = O(\alpha \log n + 1).$$

Since by using FFTs, the matrix-vector products in Algorithm PCG for Least Squares can be done in $O(m \log n)$ operations for any n-vector v, the cost per iteration of the CG method is of $O(m \log n)$. Thus we conclude that the work of solving (17) to a given accuracy τ is $O(\alpha m \log^2 n + m \log n)$ when $\alpha > 0$ and for sufficiently large n.

The convergence analysis given above can be further strengthened. For T an m-by-n matrix of the form (4) with $m = kn$, let $\lambda_{\min}(T_j^* T_j) = O(n^{-\alpha_j})$ for $j = 1, \ldots, k$. By Lemma 1, we already know that

$$\lambda_{\min}(T_j^* T_j) \le \lambda_{\max}(T_j^* T_j) \le 2||f||_\infty^2,$$

therefore $\alpha_j \ge 0$. By the Cauchy interlace theorem, we see that

$$\lambda_{\min}(T^*T) \ge \sum_{j=1}^{k} \lambda_{\min}(T_j^* T_j) \ge O(n^{-\alpha}),$$

where

$$\alpha = \min_j \alpha_j \geq 0.$$

Therefore,

$$\kappa(T^*T) \leq \frac{\lambda_{\max}(T^*T)}{\lambda_{\min}(T^*T)} \leq O(n^\alpha).$$

In the case when one of the $\alpha_j = 0$, i.e., the block T_j is well conditioned independent of n, we see that the least squares problem is also well conditioned, so that $\kappa(T) = O(1)$.

When at least one $\alpha_j = 0$, i.e., $\kappa(T) = O(1)$, the number of iterations required for convergence is of $O(1)$. Hence the complexity of the algorithm reduces to $O(m \log n)$, for sufficiently large n. We remark that in this case, one can show further that the *method converges superlinearly* for the preconditioned least squares problem due to the clustering of the singular values for sufficiently large n (see R. Chan and Strang [9] or R. Chan [11] for details). In contrast, the method converges just linearly for the nonpreconditioned case. This contrast is illustrated very well in the section on numerical tests.

5. Preconditioned regularized least squares. In this section we consider solving least squares problems (3), where the rectangular matrix T is ill conditioned. Such systems arise in many applications, such as signal and image restoration; see [3], [24], [28]. Often, the ill-conditioned nature of T results from discretization of ill-posed problems in partial differential and integral equations. Here, for example, the problem of estimating an original image from a blurred and noisy observed image is an important case of an *inverse problem* and was first studied by Hadamard [22] in the inversion of certain integral equations. Because of the ill conditioning of T, naively solving $Tx = b$ will lead to extreme instability with respect to perturbations in b. The method of *regularization* can be used to achieve stability for these problems [7]. Stability is attained by introducing a stabilizing operator (called a regularization operator), which restricts the set of admissible solutions. Since this causes the regularized solution to be biased, a scalar (called a regularization parameter) is introduced to control the degree of bias. More specifically, the regularized solution is computed as

$$\min \left\| \begin{bmatrix} b \\ 0 \end{bmatrix} - \begin{bmatrix} T \\ \mu L \end{bmatrix} x(\mu) \right\|_2, \tag{18}$$

where μ is the regularization parameter and the $p \times n$ matrix L is the regularization operator.

The standard least squares solution to (3), given by $x = T^\dagger b$, is useless for these problems because it is dominated by rapid oscillations due to the errors. Hence in (18), one adds a term $\min \|Lx\|^2$ to (3) in order to *smooth* the solution x. Choosing L as a kth difference operator matrix forces the solution to have a small kth derivative. The regularization parameter μ controls the degree of smoothness (i.e., degree of bias) of the solution, and is usually small. Choosing μ is not a trivial problem. In some cases a priori information about the signal and the degree of perturbations in b can be used to choose μ [1], or generalized cross-validation techniques may be used, e.g., [7]. If no a priori information is known, then it may be necessary to solve (18) for several

values of μ [20]. Recent analytical methods for choosing an optimal parameter μ are discussed by Reaves and Mersereau [29].

Based on the discussion above, the regularization operator L is usually chosen to be the identity matrix or some discretization of a differentiation operator [6], [20]. Thus L is typically a Toeplitz matrix. Hence, if T has the Toeplitz block form (4), then the matrix

$$\tilde{T} = \begin{bmatrix} T \\ \mu L \end{bmatrix}$$

retains this structure, with the addition of one block (or two blocks if L is a difference operator with more rows than columns). Since $\tilde{T}$ has the block structure (4), we can form the circulant preconditioner C for $\tilde{T}$ and use the PCG algorithm for least squares problems to solve (18).

Notice that if L is chosen to be the identity matrix, then the circulant preconditioner for $\tilde{T}$ can be constructed by simply adding μ to each of the eigenvalues of the circulant preconditioner for T. In addition, the last block in $\tilde{T}$ (i.e., μI) has singular values μ. Thus, due to the remarks at the end of §4, if each block in T is generated by a function in $\mathcal{C}_{2\pi}$, and if $\mu \neq 0$, then $\kappa(\tilde{T}) \leq O(\mu^{-1})$ for all n. It follows then, for these problems, that (18) can be solved in $O(m \log n)$ operations, for sufficiently large n.

6. Numerical tests. In this section we report on some numerical experiments that use the preconditioner C given by (5) in §1 for the CG algorithm PCG for solving Toeplitz and block Toeplitz least squares problems. Here the preconditioner C is based on the T. Chan optimal preconditioner C_i, for each block T_i of T, as in §2. The experiments are designed to illustrate the performance of the preconditioner on a variety of problems, including some in which one or more Toeplitz blocks are very ill conditioned.

We use the stopping criteria $\|s^{(j)}\|_2/\|s^{(0)}\|_2 < 10^{-7}$ for all numerical tests given in this section. (Note that $s^{(j)}$ is the (normal equations) residual after j iterations, and the zero vector is our initial guess. Observe that the value $\|s^{(j)}\|_2$ is computed as part of the CG algorithm.) All experiments were performed using the Pro-Matlab software on our workstations. The machine epsilon for Pro-Matlab on this system is approximately 2.2×10^{-16}.

To describe most of the Toeplitz matrices used in the examples below, we use the following notation. Let the m-vector c be the first column of T and the n-vector r^T be the first row of T. Then

$$T = \text{Toep}(c, r).$$

The right-hand-side vector b is generally chosen to be the vector of all ones.

Example 1. In this example we construct $m \times n$ Toeplitz matrices generated by a positive function in the Wiener class, varying the number of rows and columns and fixing the number of blocks in the block form (4) to $k = 3$. This example is a rectangular generalization of test data used by Strang [30] and is defined as follows. Let

$$c(i) = \frac{1}{2^{i-1}}, \quad i = 1, \ldots, m, \quad \text{and} \quad r(j) = \frac{1}{2^{j-1}}, \quad j = 1, \ldots, n.$$

The convergence results for this example are shown in Table 1, which shows the number of iterations required for Algorithm PCG to converge using T (i.e., no

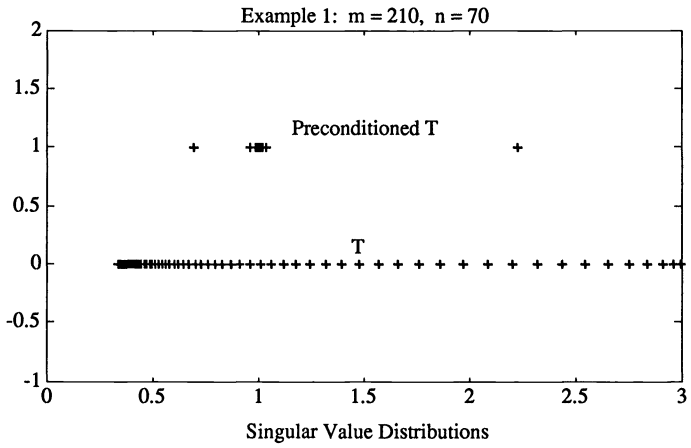

FIG. 1. *Singular values for T and TC^{-1} in Example* 1.

preconditioner) and our C. We can see from Table 1 that the use of our preconditioner does accelerate the convergence rate of the CG algorithm for this problem. Moreover, for this example the number of iterations remains essentially constant as m and n increase.

In Fig. 1 we plot the singular values of T and TC^{-1}. The plot of the singular value distributions shows that the preconditioner clusters the singular values very well for this example.

Example 2. In this example we use the following three generating functions in the Wiener class to construct a $3n \times n$ block Toeplitz matrix.

(i) Example (a) from R. Chan and Yeung [15]:
$c_1(j) = r_1(j) = (|j-1|+1)^{-1.1} + \sqrt{-1}(|j-1|+1)^{-1.1}, \quad j = 1, 2, \ldots, n.$

(ii) Example (b) from R. Chan and Yeung [15]:
$c_2(i) = (|i-1|+1)^{-1.1}, \quad i = 1, 2, \ldots, n,$
$r_2(j) = \sqrt{-1}(|j-1|+1)^{-1.1}, \quad j = 1, 2, \ldots, n.$

(iii) Example (f) from R. Chan and Yeung [15]:
$c_3(1) = r_3(1) = \frac{1}{5}\pi^4$
$c_3(j) = r_3(j) = 4(-1)^{(j-1)}\left(\frac{\pi^2}{(j-1)^2} - \frac{6}{(j-1)^4}\right), \quad j = 2, 3, \ldots, n.$

The matrix T is defined as

$$T^T = [T_1^T,\ T_2^T,\ T_3^T],$$

where T_1 =Toep(c_1, r_1), T_2 =Toep(c_2, r_2), and T_3 =Toep(c_3, r_3). For $n \times n$ systems R. Chan and Yeung [15] show that $\kappa_2(T_3) = O(n^4)$, while T_1 and T_2 are well conditioned. They also show that the T. Chan preconditioner works well for T_1 and T_2, but not well for T_3.

In Table 1 we show the convergence results for this example, using no preconditioner and C as a preconditioner, for several values of m and n. Figure 2 shows the singular values of T and TC^{-1} for $m = 210$ and $n = 70$. These results illustrate the good convergence properties using the preconditioner C for this example containing an ill-conditioned block. Moreover, our computations verify the fact that $\kappa_2(T)$ remains almost constant as n increases from 40 to 80.

TABLE 1

80	44	7	186	13	65	14

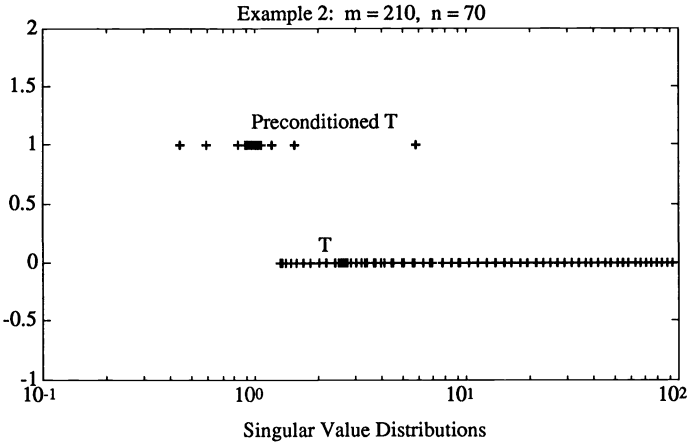

FIG. 2. *Singular values for T and TC^{-1} in Example* 2.

Example 3. In this example we form a $2n \times n$ block Toeplitz matrix using generating functions from R. Chan and Yeung [15] that construct ill-conditioned $n \times n$ Toeplitz matrices. Here $T_1 = T_2$ and thus both blocks of T are ill conditioned. The generating function, which is in the Wiener class, is:

Example (c) from R. Chan and Yeung [15]:

$c_1(1) = r_1(1) = 0$

$c_1(j) = r_1(j) = (|j-1|+1)^{-1.1} + \sqrt{-1}(|j-1|+1)^{-1.1}, \quad j = 2, \ldots, n.$

Using the above generating functions, we let

$$T^T = [T_1,\ T_2]^T,$$

where $T_1 = T_2 = \text{Toep}(c_1, r_1)$.

In Table 1 we show the convergence results for this example, using no preconditioner and C as a preconditioner, for several values of m and n. Figure 3 shows the singular values of T and TC^{-1} for $m = 140$ and $n = 70$. These results illustrate the good convergence properties of C for this example even though it contains all ill-conditioned blocks.

Example 4. Here we consider an application to one-dimensional image or signal-reconstruction computations. In this example we construct the 100×100 Toeplitz matrix T, whose i, j entry is given by

$$t_{ij} = \begin{cases} 0 & \text{if } |i-j| > 8, \\ \frac{4}{51} g(0.15, x_i - x_j) & \text{otherwise,} \end{cases} \tag{19}$$

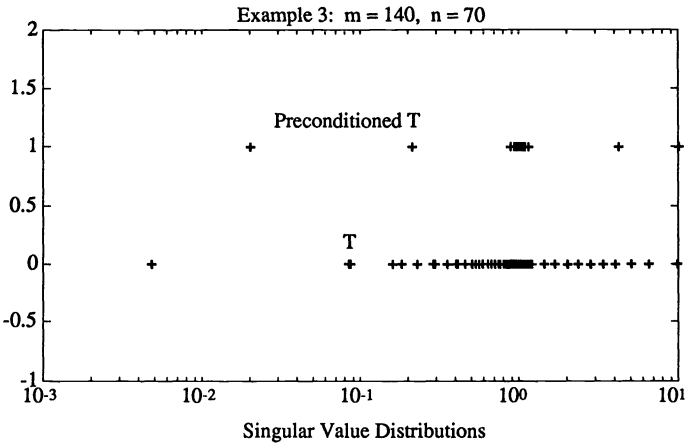

FIG. 3. *Singular values for T and TC^{-1} in Example 3.*

where

$$x_i = \frac{4i}{51}, \quad i = 1, 2, \ldots, 100,$$

and

$$g(\sigma, \gamma) = \frac{1}{2\sqrt{\pi}\sigma} \exp\left(-\frac{\gamma^2}{4\sigma^2}\right).$$

Matrices of this form occur in many image-restoration contexts as a "prototype problem" and are used to model certain degradations in the recorded image [20], [24]. Due to the bandedness of T, its generating function is in the Wiener class. The condition number of T is approximately 2.4×10^6.

Because of the ill conditioning of T, the system $Tx = b$ will be very sensitive to any perturbations in b (see §5). To achieve stability we regularize the problem using the identity matrix as the regularization operator. Eldén [20] uses this approach to solve a linear system by direct methods with the same data matrix T defined in (19). To test our preconditioner we will fix $\mu = 0.01$, where μ is chosen based on some tests made by Eldén.

Let

$$\hat{T} = \begin{bmatrix} T \\ \mu I \end{bmatrix} \quad \text{and} \quad \hat{b} = \begin{bmatrix} b \\ 0 \end{bmatrix}.$$

Then $\hat{T}$ is simply a block Toeplitz matrix. Thus we can apply our preconditioner C, and the PCG algorithm, to solve (18). The convergence results for solving $Tx = b$ and $\hat{T}x = \hat{b}$ with no preconditioner and $\hat{T}x = \hat{b}$ using C as a preconditioner are shown in Table 2. The singular values of T and $\hat{T}C^{-1}$ and the convergence history for solving $Tx = b$ and $\hat{T}x = \hat{b}$ using our preconditioner C are shown in Fig. 4. These results indicate that the PCG algorithm with our preconditioner C may be an effective method for solving this regularized least squares problem.

In summary, we have shown how to construct circulant preconditioners for the efficient solution of a wide class of Toeplitz least squares problems. The numerical

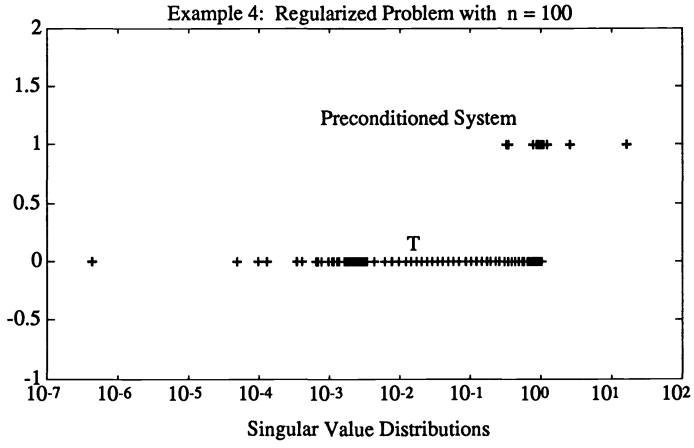

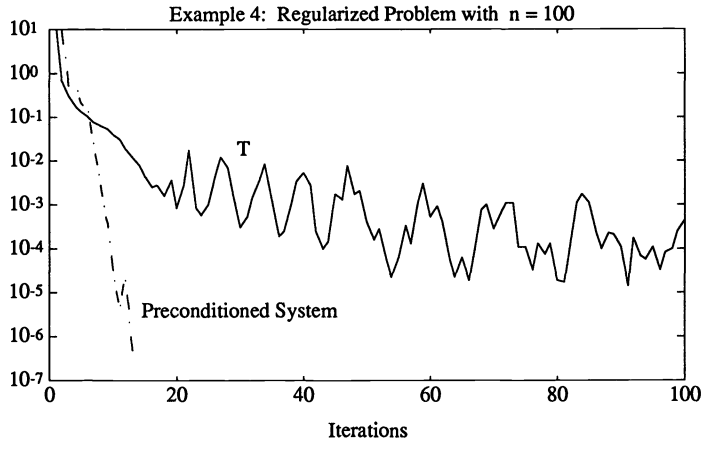

FIG. 4. *Singular values and convergence history for T and $\hat{T}C^{-1}$.*

experiments given collaborate our convergence analysis. Examples 1 and 2 both illustrate superlinear convergence for the PCG algorithm preconditioned by C, even when in Example 2 the matrix T contains an ill-conditioned block. In addition, even though the matrix T in Example 3 contains *all* ill-conditioned blocks, the scheme works well for the computations we performed.

Example 4 illustrates the applicability of the circulant PCG method to regularized least squares problems. The example comes from one-dimensional signal restoration. Two-dimensional signal or image restoration computations often lead to very large least squares problems where the coefficient matrix is block Toeplitz with Toeplitz

blocks. Block circulant preconditioners for this case are considered elsewhere [16].

In this paper we have used the T. Chan [17] optimal preconditioner for the Toeplitz blocks. Other circulant preconditioners such as ones studied by R. Chan [11], Huckle [23], Ku and Kuo [25], Strang [30], Tismenetsky [31], or Tyrtyshnikov [32], can be used, but the class of generating functions may need to be restricted for the convergence analysis to hold.

INVERSE OF STRICTLY ULTRAMETRIC MATRICES ARE OF STIELTJES TYPE*

SERVET MARTÍNEZ†, GÉRARD MICHON‡, AND JAIME SAN MARTÍN†

Abstract. This paper shows that a nonnegative ultrametric matrix A is nonsingular and that its inverse is a strictly diagonally dominant Stieltjes matrix. The method consists of studying the spectral decomposition of A by showing that A preserves a maximal filtration.

Key words. ultrametric matrices, Stieltjes matrices

AMS subject classifications. 15A09, 15A18

1. Introduction.

Our main result, which is Theorem 1, deals with the study of properties of strictly ultrametric matrices (see definitions below). We show that these matrices are nonsingular and that their inverses are Stieltjes matrices. In the proof of the main result we show the following properties:

(i) any strictly ultrametric matrix A has an equilibrium potential, i.e., there exists a measure ν such that $A\nu = \mathbf{1}$, the 1-constant vector;

(ii) the matrix Λ given by $\Lambda(i,j) = A(i,j)\mu(j)$, μ being the normalized vector proportional to ν, preserves a maximal filtration of partitions;

(iii) this last result allows us to explicitly obtain the spectral decomposition of Λ, and the monotone properties of its eigenvalues allow us to prove the theorem.

We remark that our results only concern finite ultrametric matrices. But these results can be extended to strictly ultrametric matrices in which an increasing sequence $(h_\alpha : \alpha \geq 1)$, defined analogously as in the proof of Theorem 1, has no finite accumulation point.

Ultrametricity was first introduced in relation with p-adic number theory. In applications like taxonomy [Be, p. 138], ultrametricity is an important notion because of its relation with partitions. On the other hand, strictly ultrametric matrices appear as covariance matrices of random energy models in statistical physics [CCP] as a generalization of the diagonal case. Since most of the relevant quantities depend on the inverse of the covariance matrix, our result concerning the inverse of a strictly ultrametric matrix might be useful in this theory.

Relations between ultrametric matrices and filtrations of partitions (or fields) were first developed by Dellacherie in [De]. A detailed study concerning ultrametric matrices, maximal filtrations, and the associated spectral decomposition for countable probability spaces was made in [DMS]. On the other hand, in [Mi] the study of strictly ultrametric matrices was done in relation with potential theory in compact ultrametric spaces.

Now let us give needed definitions as well as our main result. First, recall that a metric on a set X is said to be ultrametric if it verifies the ultrametric inequality

[Di, p. 37]

$$d(x,y) \leq \max\{d(x,z), d(z,y)\} \quad \text{for any } x,y,z \in X.$$

We shall only deal with ultrametric distances on finite sets. Denote by $I := \{1,\dots,N\}$ a finite set.

DEFINITION 1 (see [De]). A symmetric matrix $A = (A(i,j), i,j \in I)$ is said to be ultrametric if there exists an ultrametric distance d on I such that

$$d(i,j) = d(i,k) \quad \text{iff } A(i,j) = A(i,k). \tag{1}$$

DEFINITION 2. A symmetric nonnegative matrix A is said to be strictly ultrametric if there exists an ultrametric distance d on I such that

$$d(i,j) \leq d(i,k) \quad \text{iff } A(i,j) \geq A(i,k). \tag{2}$$

Recall that a symmetric nonnegative matrix A is strictly ultrametric if and only if (iff) it verifies the following two conditions:

$$A(i,j) \geq \inf\{A(i,k), A(k,j)\} \quad \text{for any } i,j,k \in I, \tag{3}$$

$$A(i,i) > \sup\{A(i,k) : k \in I - \{i\}\} \quad \text{for any } i \in I, \tag{4}$$

where, in the case $N = 1$, condition (4) means $A(i,i) > 0$.

In fact, if A is strictly ultrametric, condition (3) follows from property (2). Also (4) is implied by (2) and the strict inequality $d(i,i) < d(i,j)$ for any $i \neq j$. Reciprocally, if (3) and (4) are verified, the following metric d is an ultrametric and it verifies (2): $d(i,i) = 0$ for any $i \in I$ and $d(i,j) = R - A(i,j)$ if $i \neq j$, where $R > \max\{A(i,j) : i \neq j\}$.

DEFINITION 3. A symmetric matrix B is a Stieltjes matrix if its off-diagonal elements are nonpositive, it is nonsingular, and B^{-1} is nonnegative (see [LT, par. 15.2]).

Our main result is the following theorem.

THEOREM 1. *If A is a nonnegative strictly ultrametric matrix, then it is nonsingular, A^{-1} is a strictly diagonally dominant Stieltjes matrix, and $A^{-1}(i,j) = 0$ iff $A(i,j) = 0$ for $i \neq j$.*

2. Proof of the main theorem. Let us first show that a strictly ultrametric matrix has an equilibrium potential.

LEMMA 1. *Let A be a nonnegative, symmetric, strictly ultrametric matrix. Then, there exists a strictly positive vector $\nu = (\nu(i) : i \in I)$, such that*

$$A\nu = \mathbf{1}, \text{ where } \mathbf{1} \text{ is the 1-constant vector.} \tag{5}$$

Proof. Let $q(A) = |\{A(i,j) : i,j \in I\}|$ be the cardinality of the set of values taken by the elements of matrix A. We shall prove the result by induction on $q(A)$.

If $q(A) = 1$, the condition (4) implies $N = 1$. Since $A(N,N) > 0$, the result is evident.

Let $q(A) \geq 2$. Assume we have shown the result for any strictly ultrametric matrix A' with $q(A') < q(A)$.

Let $h := \sup\{A(i,j) : i \neq j\}$. Define the equivalence relation: $i \sim j$ if $i = j$ or $A(i,j) = h$. Denote by $\tilde{i}$ the equivalence class containing i and by $\tilde{I}$ the set of equivalence classes. We remark that if $\tilde{i} \neq \{i\}$, then $A(i,i) > h$.

Condition (3) and the definition of $\tilde{I}$ imply that if $\tilde{i} \neq \tilde{j}$, then $A(i',j') = A(i,j)$ for any $i' \in \tilde{i}, j \in \tilde{j}$. Then, the following matrix $\tilde{A} = (\tilde{A}(\tilde{i},\tilde{j}) : \tilde{i},\tilde{j} \in \tilde{I})$ is well defined:

$$\tilde{A}(\tilde{i},\tilde{j}) = A(i,j) \quad \text{if } \tilde{i} \neq \tilde{j}, \tag{6}$$

$$\tilde{A}(\tilde{i},\tilde{i}) = A(i,i) \quad \text{if } \tilde{i} = \{i\}, \tag{7}$$

$$\tilde{A}(\tilde{i},\tilde{i}) = h + (K(\tilde{i}))^{-1} \quad \text{if } \tilde{i} \neq \{i\}, \tag{8}$$

where

$$K(\tilde{i}) = \sum_{k \in \tilde{i}} (A(k,k) - h)^{-1}. \tag{9}$$

The matrix $\tilde{A}$ is symmetric and its coefficients are nonnegative. Let us show that it satisfies properties (3) and (4).

First, let us prove (4). Take $\tilde{i} \neq \tilde{j}$. Then $\tilde{A}(\tilde{i},\tilde{j}) = A(i,j)$. If $\tilde{i} = \{i\}$, it is evident that $\tilde{A}(\tilde{i},\tilde{i}) > \tilde{A}(\tilde{i},\tilde{j})$. If $\tilde{i} \neq \{i\}$, we have by definition that $\tilde{A}(\tilde{i},\tilde{i}) > h > \tilde{A}(\tilde{i},\tilde{j})$.

Now let us show inequality (3), which is evident in the cases $\tilde{i} = \tilde{j} = \hat{k}$ or $\tilde{i} \neq \tilde{j} \neq \tilde{k} \neq \tilde{i}$. The case $\tilde{i} = \tilde{j} \neq \tilde{k}$ is implied by property (4). If $\tilde{i} = \tilde{k} \neq \tilde{j}$, it is deduced from the equality $A(i,j) = A(j,k)$, and if $\tilde{i} \neq \tilde{j} = \tilde{k}$, it is obtained from $A(i,j) = A(i,k)$.

Thus, the matrix $\tilde{A}$ satisfies properties (3) and (4). On the other hand, $q(\tilde{A}) = |\{\tilde{A}(\tilde{i},\tilde{j}) : \tilde{i},\tilde{j} \in \tilde{I}\}| < q(A)$, so, from induction hypotheses, we deduce that there exists a strictly positive vector $\tilde{\nu} = (\tilde{\nu}(\tilde{i}) : \tilde{i} \in \tilde{I})$ such that $\tilde{A}\tilde{\nu} = \mathbf{1}$. This means that

$$\sum_{\tilde{j} \in \tilde{I}} \tilde{A}(\tilde{i},\tilde{j})\tilde{\nu}(\tilde{j}) = 1 \quad \text{for any } \tilde{i} \in \tilde{I}.$$

Now, define

$$\nu(i) = \tilde{\nu}(\tilde{i}) \quad \text{if } \tilde{i} = \{i\} \tag{10}$$

and

$$\nu(i) = \tilde{\nu}(\tilde{i})(A(i,i) - h)^{-1}(K(\tilde{i}))^{-1} \quad \text{if } \tilde{i} \neq \{i\}. \tag{11}$$

From the definition of $K(\tilde{i})$ given in (9), we get $\sum_{k \in \tilde{i}} \nu(k) = \tilde{\nu}(\tilde{i})$ for any $\tilde{i} \in \tilde{I}$. We have

$$\sum_{j \in I} A(i,j)\nu(j) = \sum_{\tilde{j} \neq \tilde{i}} \sum_{\ell \in \tilde{j}} A(i,\ell)\nu(\ell) + \sum_{k \in \tilde{i}} A(i,k)\nu(k).$$

Since $A(i,\ell) = \tilde{A}(\tilde{i},\tilde{\ell})$ when $\ell \in \tilde{j} \neq \tilde{i}$ and $\tilde{\nu}(\tilde{j}) = \sum_{\ell \in \tilde{j}} \nu(\ell)$, then to complete the induction, it suffices to show the equality

$$\tilde{A}(\tilde{i},\tilde{i})\tilde{\nu}(\tilde{i}) = \sum_{k \in \tilde{i}} A(i,k)\nu(k).$$

If $\tilde{i} = \{i\}$, the equality holds trivially, so assume $\tilde{i} \neq \{i\}$. Since $A(i,k) = h$ for any $k \in \tilde{i} - \{i\}$, we deduce

$$\begin{aligned}\sum_{k\in\tilde{i}} A(i,k)\nu(k) &= \tilde{\nu}(\tilde{i})(K(\tilde{i}))^{-1}\left(\sum_{k\in\tilde{i}-\{i\}} h(A(k,k)-h)^{-1} + A(i,i)(A(i,i)-h)^{-1}\right)\\ &= \nu(\tilde{i})(K(\tilde{i}))^{-1}(hK(\tilde{i}) + (A(i,i)-h)(A(i,i)-h)^{-1})\\ &= \nu(\tilde{i})(h + (K(\tilde{i}))^{-1}) = \tilde{\nu}(\tilde{i})\tilde{A}(\tilde{i},\tilde{i}).\end{aligned}$$

Then the result holds. □

Now, let us show our main result.

Proof of Theorem 1. Let $A = (A(i,j) : i,j \in I)$ be a nonnegative, symmetric, strictly ultrametric matrix. We must show that it is nonsingular and that its inverse $A^{-1} = (A^{-1}(i,j) : i,j \in I)$ satisfies

$$A^{-1}(i,j) \leq 0 \quad \text{for any pair } i \text{ and } j \text{ with } i \neq j; \tag{12}$$

$$A^{-1}(i,i) > \sum_{\substack{j=1\\ j\neq i}}^{N} |A^{-1}(i,j)|, \tag{13}$$

i.e., A^{-1} is strictly diagonally dominant;

$$A^{-1}(i,j) = 0 \text{ iff } A(i,j) = 0 \quad \text{for any pair } i \neq j. \tag{14}$$

From Lemma 1 there exists a strictly positive vector $\nu = (\nu(i) : i \in I)$ verifying (5). Define the probability vector $\mu = (\mu(i) : i \in I)$ by $\mu(i) = \nu(i)(\sum_{j\in I}\nu(j))^{-1}$. We have

$$A\mu = \rho\mathbf{1},$$

where

$$\rho = \left(\sum_{j\in I}\nu(j)\right)^{-1} > 0.$$

Define the following operator Λ acting on $\mathbb{R}^N$:

$$(\Lambda f)(i) = \sum_{j\in I} A(i,j)f(j)\mu(j) \quad \text{for } f \in \mathbb{R}^N. \tag{15}$$

Since A is symmetric, we see that Λ is selfadjoint with respect to the inner product $\langle , \rangle_\mu$ defined by

$$\langle f, g\rangle_\mu = \sum_{i\in I} f(i)g(i)\mu(i). \tag{16}$$

Let us order the set of values $\{A(i,j) : i \neq j\}$ and denote them by $h_1 < \cdots < h_p$. We remark that $0 \leq h_1$. For any $\alpha = 1,\ldots,p$, define the relation $i[\alpha]k$ if $i = k$ or $A(i,k) > h_\alpha$. Property (3) implies that the relation $[\alpha]$ is an equivalence relation.

Denote by $B_\alpha(i) := \{k \in I : i[\alpha]k\}$ the equivalence class of i. The partition constituted by this set of atoms is denoted by $\mathcal{B}_\alpha$, i.e., $\mathcal{B}_\alpha = \{B_\alpha(i)\}$. Observe that $\mathcal{B}_p = \{\{i\} : i \in I\}$ is the finest partition.

Let us introduce the coarsest partition $\mathcal{B}_0 = \{I\}$. Note that $\mathcal{B}_1$ is finer than $\mathcal{B}_0$. The sequence of partitions $\mathcal{B}_0 \subset \mathcal{B}_1 \subset \cdots \subset \mathcal{B}_p$ is strictly increasing (where $\subset$ means being strictly coarser than). Let $i \in I$. The sequence of atoms $(B_\alpha(i) : \alpha = 0, \ldots, p)$ is nondecreasing, i.e., $B_{\alpha-1}(i) \supseteq B_\alpha(i)$ for $\alpha = 1, \ldots, p$. We remark that if $k \in B_{\alpha-1}(i) - B_\alpha(i)$, then $A(i,k) = h_\alpha$. For $k \neq i$ denote by $T(i,k)$ the unique index $\alpha \in \{0, \ldots, p\}$, such that $k \in B_{\alpha-1}(i) - B_\alpha(i)$ (it does exist because $B_p(i) = \{i\}$). Then $A(i,k) = h_{T(i,k)}$. Thus, we deduce

$$k \in B_{\alpha-1}(i) \text{ implies } A(i,k) = h_{T(i,k)} \geq h_\alpha \tag{17}$$

and

$$k \notin B_\alpha(i) \text{ implies } A(i,k) = h_{T(i,k)} \leq h_\alpha. \tag{18}$$

Let us point out that (4) implies that $A(i,i) > h_{T(i,k)}$ for any $k \neq i$. On the other hand from property (3), we also get that if $B_\alpha(j) = B_\alpha(\ell) \neq B_\alpha(i)$, then $T(j,k) = T(\ell,k) \leq \alpha$ for any $k \in B_\alpha(i)$, so

$$A(j,k) = A(\ell,k) \leq h_\alpha.$$

Now we shall identify a partition $\mathcal{B}$ of I with the field it generates. Since I is finite, the field generated by $\mathcal{B}$ is $\{\bigcup_{B \in J} B : J \subset \mathcal{B}\}$. We remark that a function $f \in \mathbb{R}^I$ is $\mathcal{B}$-measurable iff $f(i) = f(j)$ for any i, j belonging to the same atom of $\mathcal{B}$. We say that an operator acting on $\mathbb{R}^I$ preserves $\mathcal{B}$ if it preserves the $\mathcal{B}$-measurable functions.

Let us show that the operator Λ defined in (15) preserves the filtration of fields $\{\mathcal{B}_\alpha : \alpha = 0, \ldots, p\}$. This means that for all $\alpha = 0, \ldots, p$, for all $f \in \mathbb{R}^I$ $\mathcal{B}_\alpha$-measurable, the function Λf is also $\mathcal{B}_\alpha$-measurable. For $\alpha = 0$ this is satisfied because a $\mathcal{B}_0$-measurable function is a constant $c\mathbf{1}$, and $\Lambda(c\mathbf{1}) = cA\mu = \rho c\mathbf{1}$. For $\alpha = p$ the property is also verified because $\mathcal{B}_p$ is the finest field. Now let us show the result for $\alpha \in \{1, \ldots, p-1\}$. We remark that it suffices to prove that $\Lambda \mathbf{1}_{B_\alpha(i)}$ is $\mathcal{B}_\alpha$-measurable for any $i \in I$, where $\mathbf{1}_{B_\alpha(i)}$ is the characteristic function of the atom $B_\alpha(i) \in \mathcal{B}_\alpha$.

Then, we must show that if

$$B_\alpha(j) = B_\alpha(\ell), \quad \text{then } (\Lambda \mathbf{1}_{B_\alpha(i)})(j) = (\Lambda \mathbf{1}_{B_\alpha(i)})(\ell). \tag{19}$$

First assume that $B_\alpha(j) = B_\alpha(\ell) \neq B_\alpha(i)$. Then $A(j,k) = A(\ell,k)$ for any $k \in B_\alpha(i)$. Thus,

$$(\Lambda \mathbf{1}_{B_\alpha(i)})(j) = \sum_{k \in B_\alpha(i)} A(j,k)\mu(k) = (\Lambda \mathbf{1}_{B_\alpha(i)})(\ell).$$

Now assume $B_\alpha(j) = B_\alpha(\ell) = B_\alpha(i)$. Since $(\Lambda \mathbf{1}_B)(j) = (\Lambda \mathbf{1}_B)(\ell)$ for any atom $B \in \mathcal{B}_\alpha$ such that $B \neq B_\alpha(i)$, and $(\Lambda \mathbf{1})(j) = (\Lambda \mathbf{1})(\ell)$ (because $\Lambda \mathbf{1}$ is constant), we deduce

$$(\Lambda \mathbf{1}_{B_\alpha}(i))(j) = (\Lambda \mathbf{1})(j) - \sum_{B \in \mathcal{B}_\alpha - \{B_\alpha(i)\}} (\Lambda \mathbf{1}_B)(j) = (\Lambda \mathbf{1}_{B_\alpha(i)})(\ell).$$

Then Λ preserves any $\mathcal{B}_\alpha$ for $\alpha = 0, \ldots, p$.

Now the filtration of fields $\mathcal{B}_0 \subset \cdots \subset \mathcal{B}_p$ is contained in a maximal filtration of fields $\mathcal{C}_0 \subset \cdots \subset \mathcal{C}_{N-1}$ (which is not necessarily unique). This means that $\{\mathcal{B}_\alpha : \alpha = 0, \ldots, p\} \subset \{\mathcal{C}_\gamma : \gamma = 0, \ldots, N-1\}$ and that if $\mathcal{C}$ is any field satisfying $\mathcal{C}_\gamma \subseteq \mathcal{C} \subseteq \mathcal{C}_{\gamma+1}$, then $\mathcal{C} = \mathcal{C}_\gamma$ or $\mathcal{C} = \mathcal{C}_{\gamma+1}$. This implies that $\mathcal{C}_{\gamma+1}$ is formed from $\mathcal{C}_\gamma$ by splitting a unique atom into two new atoms. This is why maximal filtrations of fields are also of cardinality N (the cardinality of the set I).

Recall that for any $\gamma \in \{0, \ldots, N-2\}$ there exists $\alpha(\gamma) \in \{1, \ldots, p\}$, such that $\mathcal{B}_{\alpha(\gamma)-1} \subseteq \mathcal{C}_\gamma \subset \mathcal{B}_{\alpha(\gamma)}$.

In the rest of this paper, $C_\gamma(i)$ shall denote the atom of $\mathcal{C}_\gamma$ containing i.

Now let us show that the operator Λ preserves the maximal filtration of fields $\{\mathcal{C}_\gamma : \gamma = 0, \ldots, N-1\}$. This is evident for $\mathcal{C}_0 = \mathcal{B}_0 = \{I\}$ and also for $\mathcal{C}_{N-1} = \mathcal{B}_p = \{\{i\} : i \in I\}$. So fix $\gamma \in \{1, \ldots, N-2\}$. Denote by $\alpha(\gamma) \in \{1, \ldots, p\}$ the point verifying $\mathcal{B}_{\alpha(\gamma)-1} \subseteq \mathcal{C}_\gamma \subset \mathcal{B}_{\alpha(\gamma)}$. We must prove that if $C_\gamma(j) = C_\gamma(\ell)$, then $(\Lambda \mathbf{1}_{C_\gamma(i)})(j) = (\Lambda \mathbf{1}_{C_\gamma(i)})(\ell)$ for any $C_\gamma(i) \in \mathcal{C}_\gamma$.

First, assume $C_\gamma(i) \neq C_\gamma(j) = C_\gamma(\ell)$. Then $B_{\alpha(\gamma)-1}(j) = B_{\alpha(\gamma)-1}(\ell)$ and $B_{\alpha(\gamma)}(j) \neq B_{\alpha(\gamma)}(i) \neq B_{\alpha(\gamma)}(\ell)$. If $B_{\alpha(\gamma)-1}(j) = B_{\alpha(\gamma)-1}(\ell) \neq B_{\alpha(\gamma)-1}(i)$, then $A(j,k) = A(\ell,k)$ for any $k \in B_{\alpha(\gamma)-1}(i) \supset C_\gamma(i)$. Thus

$$(\Lambda \mathbf{1}_{C_\gamma(i)})(j) = \sum_{k \in C_\gamma(i)} A(j,k)\mu(k) = (\Lambda \mathbf{1}_{C_\gamma(i)})(\ell).$$

Now, assume $B_{\alpha(\gamma)-1}(j) = B_{\alpha(\gamma)-1}(\ell) = B_{\alpha(\gamma)-1}(i)$. For any $k \in C_\gamma(i) \subset B_{\alpha(\gamma)-1}(i)$ we have $B_{\alpha(\gamma)}(j) \neq B_{\alpha(\gamma)}(k) \neq B_{\alpha(\gamma)}(\ell)$ and so $j, \ell \in B_{\alpha(\gamma)-1}(k) - B_{\alpha(\gamma)}(k)$. Then $A(j,k) = A(\ell,k)$, which implies $(\Lambda \mathbf{1}_{C_\gamma(i)})(j) = (\Lambda \mathbf{1}_{C_\gamma(i)})(\ell)$.

Now if j, ℓ are such that $C_\gamma(j) = C_\gamma(\ell) = C_\gamma(i)$, then the result follows from the equalities

$$(\Lambda \mathbf{1}_{C_\gamma(i)})(j) = (\Lambda \mathbf{1})(j) - \sum_{C \in \mathcal{C}_\gamma - \{C_\gamma(i)\}} (\Lambda \mathbf{1}_C)(j), \ (\Lambda \mathbf{1})(j) = (\Lambda \mathbf{1})(\ell),$$

and $\Lambda \mathbf{1}_C(j) = \Lambda \mathbf{1}_C(\ell)$, for $C \in \mathcal{C}_\gamma - \{C_\gamma(i)\}$. Thus Λ preserves $\{\mathcal{C}_\gamma : \gamma = 0, \ldots, N-1\}$.

Let us denote by $E_\gamma = E_\mu^{\mathcal{C}_\gamma}$ the mean expected value operator with respect to the field $\mathcal{C}_\gamma$ and the measure μ, i.e.,

$$(E_\gamma f)(i) = (\mu(C_\gamma(i)))^{-1} \sum_{k \in C_\gamma(i)} f(k)\mu(k).$$

Since Λ preserves $\mathcal{C}_\gamma$, we have $\Lambda E_\gamma = E_\gamma \Lambda E_\gamma$, and since Λ is selfadjoint, we also have $\Lambda(E_\gamma - E_{\gamma-1}) = (E_\gamma - E_{\gamma-1})\Lambda(E_\gamma - E_{\gamma-1})$ for any $\gamma \in \{0, \ldots, N-1\}$, with the convention $E_{-1} \equiv 0$. Since $(E_\gamma - E_{\gamma-1})\mathbb{R}^N$ is a one-dimensional subspace, we conclude that $(\Lambda(E_\gamma - E_{\gamma-1}))f = \rho_\gamma(E_\gamma - E_{\gamma-1})f$ for certain $\rho_\gamma \in \mathbb{R}$, for any $\gamma \in \{0, \ldots, N-1\}$. Then the spectral decomposition of Λ is

$$\Lambda = \sum_{\gamma=0}^{N-1} \rho_\gamma (E_\gamma - E_{\gamma-1}). \tag{20}$$

Let us compute the eigenvalues $\{\rho_\gamma : \gamma = 0, \ldots, N-1\}$ of the operator Λ. Since $A\mu = \Lambda \mathbf{1} = \rho_0 \mathbf{1}$, we get

$$\rho_0 = \left(\sum_{i \in I} \nu(i) \right)^{-1}, \tag{21}$$

where ν is the vector given by Lemma 1. An eigenvector associated to ρ_0 is $f_0 = 1$.

Now let us obtain the other values ρ_γ for $\gamma \in \{1, \dots, N-1\}$. Recall that the atoms of $\mathcal{C}_{\gamma-1}$ are the same as the atoms of $\mathcal{C}_\gamma$, except that one atom of $\mathcal{C}_{\gamma-1}$ has been split into two new atoms of $\mathcal{C}_\gamma$, which is denoted by $C_\gamma(i)$ and $C_\gamma(i')$. These last two atoms are disjoint and $C_{\gamma-1}(i) = C_{\gamma-1}(i') = C_\gamma(i) \cup C_\gamma(i')$. Take

$$f_\gamma = \mathbf{1}_{C_\gamma(i)} - \mu(C_\gamma(i))(\mu(C_{\gamma-1}(i)))^{-1}\mathbf{1}_{C_{\gamma-1}(i)}. \tag{22}$$

Then

$$(E_\gamma - E_{\gamma-1})f_\gamma = f_\gamma$$

and

$$\begin{aligned}\Lambda f_\gamma &= \Lambda \mathbf{1}_{C_\gamma(i)} - \mu(C_\gamma(i))(\mu(C_{\gamma-1}(i)))^{-1}\Lambda \mathbf{1}_{C_{\gamma-1}(i)} \\ &= \rho_\gamma\{\mathbf{1}_{C_\gamma(i)} - \mu(C_\gamma(i))(\mu(C_{\gamma-1}(i)))^{-1}\mathbf{1}_{C_{\gamma-1}(i)}\}.\end{aligned}$$

If we evaluate both functions at the point $i' \in C_{\gamma-1}(i) - C_\gamma(i)$, we get

$$\rho_\gamma = (\Lambda \mathbf{1}_{C_{\gamma-1}(i')})(i') - \mu(C_{\gamma-1}(i))(\mu(C_\gamma(i)))^{-1}(\Lambda \mathbf{1}_{C_\gamma(i)})(i').$$

For any $\gamma \geq 1$ denote by $\bar{\alpha}(\gamma)$ the point of $\{1, \dots, p\}$ satisfying $\mathcal{B}_{\bar{\alpha}(\gamma)-1} \subset \mathcal{C}_\gamma \subseteq \mathcal{B}_{\bar{\alpha}(\gamma)}$. Since $i' \in C_\gamma(i') = C_{\gamma-1}(i) - C_\gamma(i)$, for any $k \in C_\gamma(i)$ we have $i' \in B_{\bar{\alpha}(\gamma)-1}(k) - B_{\bar{\alpha}(\gamma)}(k)$. Then $A(i', k) = h_{\bar{\alpha}(\gamma)}$, and we find

$$\rho_\gamma = h_{\bar{\alpha}(\gamma)}\mu(C_\gamma(i)) + \sum_{\ell \in C_\gamma(i')} A(i', \ell)\mu(\ell) - \mu(C_{\gamma-1}(i))\mu(C_\gamma(i))^{-1}h_{\bar{\alpha}(\gamma)}\mu(C_\gamma(i)).$$

So,

$$\rho_\gamma = \sum_{\ell \in C_\gamma(i')} (A(i', \ell) - h_{\bar{\alpha}(\gamma)})\mu(\ell) = \rho_0 \left\{ \sum_{\ell \in C_\gamma(i')} (A(i', \ell) - h_{\bar{\alpha}(\gamma)})\nu(\gamma) \right\}. \tag{23}$$

Now, for $\ell \in C_\gamma(i') \subset B_{\bar{\alpha}(\gamma)-1}(i')$, inequality (14) implies $A(i', \ell) \geq h_{\bar{\alpha}(\gamma)}$. On the other hand, $A(i', i') > h_{\bar{\alpha}(\gamma)}$; hence $\rho_\gamma > 0$ for any $\gamma \in \{0, \dots, N-1\}$. Note that $C_0(i') = I$. Putting $\bar{\alpha}(0) = 0, h_0 = 0$, it is easy to verify that formula (23) also holds for $\gamma = 0$ because $A\nu = \mathbf{1}$.

Since $\rho_\gamma > 0$ for any $\gamma = 1, \dots, N-1$, we deduce that Λ is nonsingular; so, from (20),

$$\Lambda^{-1} = \sum_{\gamma=0}^{N-1} \rho_\gamma^{-1}(E_\gamma - E_{\gamma-1}).$$

Now, let G be a diagonal matrix with $G(j, j) = \mu(j)$ for any $j \in I$. From the definition of Λ given in (15), we get $\Lambda = AG$, so $A^{-1} = G\Lambda^{-1}$. Let $A^{-1}(i, j)$ and $\Lambda^{-1}(i, j)$ denote the (i, j) coefficients of the matrices A^{-1} and Λ^{-1}, respectively. Then $A^{-1}(i, j) = \mu(i)\Lambda^{-1}(i, j)$.

We have $A^{-1}\mathbf{1} = G(\Lambda^{-1}\mathbf{1}) = \rho_0^{-1}\mu$. Thus

$$\sum_{j \in I} A^{-1}(i, j) = \rho_0^{-1}\mu(i) > 0 \quad \text{for any } i \in I. \tag{24}$$

We shall prove now that (12) is satisfied. We have

$$A^{-1}(i,j) = \Lambda^{-1}(i,j)\mu(i) =< \Lambda^{-1}\mathbf{1}_{\{j\}}, \mathbf{1}_{\{i\}} >_\mu = \sum_{\gamma=0}^{N-1} \rho_\gamma^{-1} < (E_\gamma - E_{\gamma-1})\mathbf{1}_{\{j\}}, \mathbf{1}_{\{i\}} >_\mu .$$

Now, $(E_0 - E_{-1})\mathbf{1}_{\{j\}} = E_0\mathbf{1}_{\{j\}} = \mu(j)$, and for any $\gamma \in \{1, \dots, N-1\}$

$$(E_\gamma - E_{\gamma-1})\mathbf{1}_{\{j\}} = \mu(j)\{(\mu(C_\gamma(j)))^{-1}\mathbf{1}_{C_\gamma(j)} - (\mu(C_{\gamma-1}(j)))^{-1}\mathbf{1}_{C_{\gamma-1}}(j)\}.$$

Note that if we set $C_{-1}(j) = \phi$ for any $j \in I$, then the last formula also holds for $\gamma = 0$.

If $C_\gamma(j) = C_{\gamma-1}(j)$, we have $(E_\gamma - E_{\gamma-1})\mathbf{1}_{\{j\}} = 0$. When $i \notin C_{\gamma-1}(j)$, we also have $i \notin C_\gamma(j)$, so $< (E_\gamma - E_{\gamma-1})\mathbf{1}_{\{j\}}, \mathbf{1}_{\{i\}} >_\mu = 0$. Define the set

$$J(i,j) := \{0\} \cup \{\gamma \in \{1, \dots, N-1\} : C_\gamma(j) \neq C_{\gamma-1}(j) \quad \text{and} \quad i \in C_{\gamma-1}(j)\},$$

and denote its elements by $\gamma_0 = 0 < \gamma_1 < \cdots < \gamma_m$. We remark that $m \geq 1$. Set $\gamma_{-1} := -1$. Then from the definition of $J(i,j)$, we have that the equality $C_{\gamma_t-1}(j) = C_{\gamma_{(t-1)}}(j)$ holds for any $t = 0, \dots, m$. Hence

$$\begin{aligned} A^{-1}(i,j) &= \sum_{\gamma \in J(i,j)} \rho_\gamma^{-1} < (E_\gamma - E_{\gamma-1})\mathbf{1}_{\{j\}}, \mathbf{1}_{\{i\}} >_\mu \\ &= \mu(i)\mu(j)\Bigg\{\sum_{t=0}^{m-1} \rho_{\gamma_t}^{-1}[(\mu(C_{\gamma_t}(j)))^{-1} - (\mu(C_{\gamma_t-1}(j)))^{-1}] \\ &\qquad - \rho_{\gamma_m}^{-1}(\mu(C_{\gamma_m-1}(j)))^{-1}\Bigg\}. \end{aligned}$$

Therefore,

$$A^{-1}(i,j) = \mu(i)\mu(j)\sum_{t=0}^{m-1}(\mu(C_{\gamma_t}(j)))^{-1}(\rho_{\gamma_t}^{-1} - \rho_{\gamma_{t+1}}^{-1}). \tag{25}$$

From (20) we get that for any $t = 0, \dots, m-1$, we have

$$\rho_{\gamma_t} = \sum_{\ell \in C_{\gamma_t}(j)} (A(j,\ell) - h_{\bar{\alpha}(\gamma_t)})\mu(\ell). \tag{26}$$

For any $\ell \in C_{\gamma_t}(j)$, we have $A(j,\ell) - h_{\bar{\alpha}(\gamma_t)} \geq 0$. On the other hand, since $C_{\gamma_t}(j)$ is decreasing with t and $h_{\bar{\alpha}(\gamma_t)}$ is nondecreasing with t (in fact, strictly increasing, except perhaps at $t = 0$ when $\gamma_1 = 1$ since $h_1 = h_0 = 0$), we deduce that ρ_{γ_t} is nonincreasing: $\rho_0 = \rho_{\gamma_0} \geq \rho_{\gamma_1} \geq \cdots \geq \rho_{\gamma_m} > 0$. Hence $\rho_{\gamma_t}^{-1}$ is a nondecreasing sequence, and we get $(A^{-1})(i,j) \leq 0$. Now condition (24) implies $A^{-1}(i,i) > 0$ and $A^{-1}(i,i) > \sum_{j \neq i} |A^{-1}(i,j)|$ for any $i \in I$, so property (13) also holds. Let us now prove (14): $A^{-1}(i,j) = 0$ iff $A(i,j) = 0$ for $i \neq j$.

We have $i \in C_{\gamma_m-1}(j) - C_{\gamma_m}(j)$. Note that $B_{\bar{\alpha}(\gamma_m)-1}(j) \supset C_{\gamma_m}(j) \supseteq B_{\bar{\alpha}(\gamma_m)}(j)$, so $B_{\bar{\alpha}(\gamma_m)-1}(j) \supseteq C_{\gamma_m-1}(j) \supset C_{\gamma_m}(j) \supseteq B_{\bar{\alpha}(\gamma_m)}(j)$. Then $i \in B_{\bar{\alpha}(\gamma_m)-1}(j) - B_{\bar{\alpha}(\gamma_m)}(j)$. We remark that $T(i,j) = \bar{\alpha}(\gamma_m)$, so $A(i,j) = h_{\bar{\alpha}(\gamma_m)}$.

If $A(i,j) > 0$, then $h_{\bar{\alpha}(\gamma_m)} > h_{\bar{\alpha}(0)} = 0$, so there must exist an index $t \in \{0,\dots,m-1\}$ such that $h_{\bar{\alpha}(\gamma_t)} < h_{\bar{\alpha}(\gamma_{t+1})}$, which implies $\rho_{\gamma_t} > \rho_{\gamma_{t+1}}$ (see formula (26)). Equality (25) implies $A^{-1}(i,j) < 0$.

If $A(i,j) = 0$, then $m = \gamma_m = \bar{\alpha}(\gamma_m) = 1$ and $h_1 = 0$. Now, for any $\ell \in C_0(j) - C_1(j)$, we have $T(j,\ell) = 1$, which implies that $A(j,\ell) = 0$. Then

$$\begin{aligned}\rho_{\gamma_1} &= \sum_{\ell \in C_1(j)} (A(j,\ell) - h_1)\mu(\ell) = \sum_{\ell \in C_1(j)} A(j,\ell)\mu(\ell) \\ &= \sum_{\ell \in C_0(j)} A(j,\ell)\mu(\ell) = \sum_{\ell \in I} A(j,\ell)\mu(\ell) = \rho_0.\end{aligned}$$

From equality (25), we conclude $A^{-1}(i,j) = 0$. □

Remark. The proof also shows that any strictly ultrametric matrix is positive definite, but this is a general property of any Stieltjes matrix [LT, p. 532].

A LINEAR ALGEBRA PROOF THAT THE INVERSE OF A STRICTLY ULTRAMETRIC MATRIX IS A STRICTLY DIAGONALLY DOMINANT STIELTJES MATRIX*

REINHARD NABBEN† AND RICHARD S. VARGA‡

Abstract. It is well known that every $n \times n$ Stieltjes matrix has an inverse that is an $n \times n$ nonsingular symmetric matrix with nonnegative entries, and it is also easily seen that the converse of this statement fails in general to be true for $n > 2$. In the preceding paper by Martínez, Michon, and San Martín [*SIAM J. Matrix Anal. Appl.*, 15 (1994), pp. 98–106], such a converse result is in fact shown to be true for the new class of *strictly ultrametric matrices*. A simpler proof of this basic result is given here, using more familiar tools from linear algebra.

1. Introduction.

It is well known (cf. [3, p. 85]) that a *Stieltjes matrix* $A = [a_{i,j}]$ in $\mathbb{R}^{n,n}$, which is defined to be a real symmetric and positive definite matrix with $a_{i,j} \leq 0$ for all $i \neq j$ $(1 \leq i, j \leq n)$, has the property that its inverse is a real nonsingular and symmetric matrix, all of whose entries are nonnegative. Now, the converse of this result is not generally true for any $n \geq 3$, as the following simple matrix below shows. For $n = 3$, define the symmetric matrix B in $\mathbb{R}^{3,3}$ by

$$B := \begin{bmatrix} 4 & 0 & 2 \\ 0 & 4 & 3 \\ 2 & 3 & 4 \end{bmatrix},$$

so that B possesses only nonnegative entries. As the eigenvalues of B are $(4 + \sqrt{13}, 4, 4 - \sqrt{13})$, then B is positive definite. But its inverse,

$$B^{-1} = \frac{1}{12} \begin{bmatrix} 7 & 6 & -8 \\ 6 & 12 & -12 \\ -8 & -12 & 16 \end{bmatrix},$$

fails to be a Stieltjes matrix since its off-diagonal entries are not all nonpositive. For $n > 3$, the matrix

$$\begin{bmatrix} B & O \\ O & I_{n-3} \end{bmatrix} \quad \text{and its inverse} \quad \begin{bmatrix} B^{-1} & O \\ O & I_{n-3} \end{bmatrix},$$

where I_{n-3} is the identity matrix in $\mathbb{R}^{n-3,n-3}$, similarly furnishes a counterexample in $\mathbb{R}^{n,n}$.

In the preceding paper [2, Thm. 1] by Martínez, Michon, and San Martín, it is shown that a strictly ultrametric square matrix (to be defined below) is a nonsingular

matrix, with nonnegative entries, whose inverse is a strictly diagonally dominant Stieltjes matrix! As can be seen from their paper, their interesting result is proved by using a variety of impressive tools from topology and real analysis, tools that may prove useful for infinite dimensional extensions. The beauty of their result gave us the stimulus to try to find a proof of their result that was fashioned solely from more familiar tools from linear algebra, as such a proof might be more accessible to numerical analysts and linear algebraists. We give such a linear algebra proof below.

With the notation that $N := \{1, 2, \ldots, n\}$ for any positive integer n, we begin with the following definition of [2].

DEFINITION 1.1. *A matrix $A = [a_{i,j}]$ in $\mathbb{R}^{n,n}$ is strictly ultrametric if*

$$\text{(1.1)} \qquad \begin{cases} \text{(i)} & A \text{ is symmetric with nonnegative entries,} \\ \text{(ii)} & a_{i,j} \geq \min\{a_{i,k}; a_{k,j}\} \text{ for all } i, j, k \in N, \\ \text{(iii)} & a_{i,i} > \max\{a_{i,k} : k \in N \backslash \{i\}\} \text{ for all } i \in N, \end{cases}$$

where, if $n = 1$, (1.1)(iii) is interpreted as $a_{1,1} > 0$.

The result of [2, Thm. 1] is stated in the following theorem.

THEOREM 1.2. *If $A = [a_{i,j}]$ in $\mathbb{R}^{n,n}$ is strictly ultrametric, then A is nonsingular and its inverse, $A^{-1} := [\alpha_{i,j}]$ in $\mathbb{R}^{n,n}$, is a strictly diagonally dominant Stieltjes matrix (i.e., $\alpha_{i,j} \leq 0$ for all $i \neq j$ and $\alpha_{i,i} > \sum_{\substack{k=1 \\ k \neq i}}^{n} |\alpha_{i,k}|$, for all $1 \leq i, j \leq n$), with the additional property that*

$$\text{(1.2)} \qquad \alpha_{i,j} = 0 \quad \text{if and only if} \quad a_{i,j} = 0.$$

Our proof of Theorem 1.2 is given in §3, after some necessary constructions are given in §2.

2. Some constructions. For notation, on setting $\xi_n := (1, 1, \ldots, 1)^T$ in $\mathbb{R}^n$, then

$$\text{(2.1)} \qquad \xi_n \xi_n^T$$

is a rank-one matrix in $\mathbb{R}^{n,n}$, all of whose entries are unity.

Our first result, which is independent of results or techniques in [2], is necessary for our complete characterization of strictly ultrametric matrices.

PROPOSITION 2.1. *Let $A = [a_{i,j}]$ in $\mathbb{R}^{n,n}$ be symmetric with all its entries nonnegative, and set*

$$\text{(2.2)} \qquad \tau(A) := \min\{a_{i,j} : i, j \in N\}.$$

If $n > 1$, then A is strictly ultrametric if and only if $A - \tau(A)\xi_n\xi_n^T$ is completely reducible, i.e., there exists a positive integer r with $1 \leq r < n$ and a permutation matrix P in $\mathbb{R}^{n,n}$ such that

$$\text{(2.3)} \qquad P(A - \tau(A)\xi_n\xi_n^T)P^T = \begin{bmatrix} C & O \\ O & D \end{bmatrix},$$

where $C \in \mathbb{R}^{r,r}$ and $D \in \mathbb{R}^{n-r,n-r}$ are each strictly ultrametric.

Proof. For $n > 1$, assume that A is strictly ultrametric. Then, from (1.1) and (2.2), it follows that $\tilde{A} = [\tilde{a}_{i,j}] := A - \tau(A)\xi_n\xi_n^T$ is strictly ultrametric with $\tau(\tilde{A}) = 0$. Moreover, as $n > 1$ and as $\tau(\tilde{A}) = 0$, some off-diagonal entry of $\tilde{A}$ is necessarily zero.

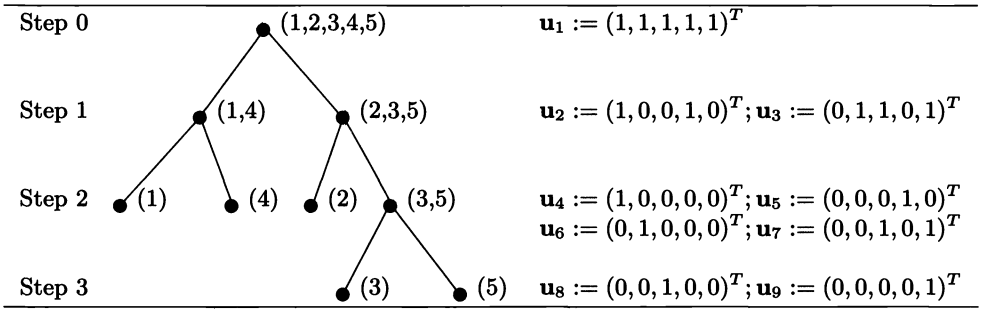

FIG. 1

By a suitable permutation of indices, we may assume, without loss of generality, that $\tilde{a}_{1,n} = 0$. Set

$$S := \{j \in N : \tilde{a}_{1,j} = 0\} \quad \text{and} \quad T := \{j \in N : \tilde{a}_{1,j} > 0\}. \tag{2.4}$$

As $\tilde{a}_{1,n} = 0$, then $n \in S$, and similarly, since $\tilde{A}$ is strictly ultrametric, then (cf. (1.1)(iii)) $\tilde{a}_{1,1} > 0$, so that $1 \in T$. Thus, S and T form a partition of N, i.e., S and T are nonempty disjoint sets with $S \cup T = N$. Again, by a suitable permutation of indices, we may assume, without loss of generality, that

$$T = \{1, 2, \ldots, r\} \quad \text{and} \quad S = \{r+1, r+2, \ldots, n\}, \tag{2.5}$$

where $1 \leq r < n$.

Next, consider any $j \in T$ and any $k \in S$. Since $\tilde{A}$ is a nonnegative matrix, (1.1)(ii) implies that

$$0 = \tilde{a}_{1,k} \geq \min\{\tilde{a}_{1,j}; \tilde{a}_{j,k}\} \geq 0 \qquad (j \in T, k \in S). \tag{2.6}$$

But as $\tilde{a}_{1,j} > 0$ from (2.4), the inequalities of (2.6) and the symmetry of $\tilde{A}$ give that

$$\tilde{a}_{j,k} = 0 = \tilde{a}_{k,j} \qquad (j \in T, k \in S), \tag{2.7}$$

which gives the desired representation of (2.3). That the block diagonal submatrices C and D in (2.3) are each strictly ultrametric is a consequence of the fact that $\tilde{A}$ is strictly ultrametric.

Conversely, if $n > 1$, if $C \in \mathbb{R}^{r,r}$ and if $D \in \mathbb{R}^{n-r,n-r}$ (with $1 \leq r < n$) are each strictly ultrametric, and if $\tau \geq 0$, then from Definition 1.1, the matrix

$$\begin{bmatrix} C & O \\ O & D \end{bmatrix} + \tau \xi_n \xi_n^T$$

is also strictly ultrametric. □

It is evident that the steps leading to the representation (2.3) can be similarly applied to each of the strictly ultrametric block submatrices C and D of (2.3), provided that their orders each exceed unity. More precisely, if $C \in \mathbb{R}^{r,r}$ and if $D \in \mathbb{R}^{n-r,n-r}$ where $1 < r < n-1$, then $C - \tau(C)\xi_r \xi_r^T$ and $D - \tau(D)\xi_{n-r}\xi_{n-r}^T$ are, from the proof of Proposition 2.1, each completely reducible strictly ultrametric matrices. This process can be continued until only 1×1 *positive* matrices remain. This entire reduction procedure can be described in terms of graph theory, as follows.

For illustration, consider an ultrametric matrix A in $\mathbb{R}^{5,5}$, and suppose that the block submatrices C and D in (2.3) are of orders 2 and 3, respectively. This is shown in (reduction) Step 1 in the rooted *reduction tree* of Fig. 1, where the top vertex of Step 0 is associated with the set (1,2,3,4,5). At Step 1, the set (1,2,3,4,5) is decomposed into the two nonempty disjoint sets (1,4) and (2,3,5), giving rise to two vertices in the tree at Step 1. This step corresponds to the complete reducibility of $A - \tau(A)\xi_5\xi_5^T$ in (2.3). In Step 2, each of the sets (1,4) and (2,3,5) is further decomposed into two disjoint nonempty sets, giving rise to four vertices in the tree at Step 2, and this procedure is continued until all remaining sets have single elements. In this way, the 5×5 ultrametric matrix A has the representation

$$A = \sum_{\ell=1}^{9} \tau_\ell \mathbf{u}_\ell \mathbf{u}_\ell^T, \tag{2.8}$$

where the sum over nine terms in (2.8) comes from the fact that there are nine vertices in the tree of Fig. 1. The associated vectors $\mathbf{u}_\ell$ are also explicitly given in Fig. 1. The scalars $\{\tau_\ell\}_{\ell=1}^9$ are nonnegative, with (cf. (1.1)(iii)) $\tau_4, \tau_5, \tau_6, \tau_8$, and τ_9 necessarily positive numbers. In fact, if the constants $\{\tau_1, \tau_2, \ldots, \tau_9\}$ in (2.8) are chosen to be $\{1,0,0,1,1,1,2,1,1\}$, then A can be computed from (2.8) to be

$$A = \begin{bmatrix} 2 & 1 & 1 & 1 & 1 \\ 1 & 2 & 1 & 1 & 1 \\ 1 & 1 & 4 & 1 & 3 \\ 1 & 1 & 1 & 2 & 1 \\ 1 & 1 & 3 & 1 & 4 \end{bmatrix}.$$

But, it is easy to verify (by induction) that for $N = (1, 2, \ldots, n)$, the reduction steps, as indicated in Fig. 1 for $n = 5$, give exactly $2n - 1$ vertices for its associated reduction tree. Hence, Proposition 2.1 gives the following representation for strictly ultrametric matrices in $\mathbb{R}^{n,n}$ for *all* $n \geq 1$, which goes beyond the results of [2].

THEOREM 2.2. *Given any strictly ultrametric matrix A in $\mathbb{R}^{n,n}$ ($n \geq 1$), there is an associated rooted tree for $N = \{1, 2, \ldots, n\}$, consisting of $2n - 1$ vertices, such that*

$$A = \sum_{\ell=1}^{2n-1} \tau_\ell \mathbf{u}_\ell \mathbf{u}_\ell^T, \tag{2.9}$$

where the vectors $\mathbf{u}_\ell$ in (2.9), determined from the vertices of the tree, are nonzero vectors in $\mathbb{R}^n$ having only 0 and 1 components, and, with the notation that

$$\chi(\mathbf{u}_\ell) := \textit{ sum of the components of } \mathbf{u}_\ell, \tag{2.10}$$

where the τ_ℓ's in (2.9) are nonnegative with $\tau_\ell > 0$ when $\chi(\mathbf{u}_\ell) = 1$. Conversely, given any tree for $N = \{1, 2, \ldots, n\}$, which determines the vectors $\mathbf{u}_\ell$ in $\mathbb{R}^n$, and given any nonnegative constants $\{\tau_\ell\}_{\ell=1}^{2n-1}$ with $\tau_\ell > 0$ when $\chi(\mathbf{u}_\ell) = 1$, then $\sum_{\ell=1}^{2n-1} \tau_\ell \mathbf{u}_\ell \mathbf{u}_\ell^T$ is strictly ultrametric in $\mathbb{R}^{n,n}$.

COROLLARY 2.3. *Any strictly ultrametric matrix in $\mathbb{R}^{n,n}$ is a real symmetric and positive definite matrix.*

Proof. From Theorem 2.2, any strictly ultrametric matrix admits a representation (2.9) as a sum of rank-one nonnegative definite symmetric matrices. But, as the condition that τ_ℓ be positive whenever $\chi(\mathbf{u}_\ell) = 1$ implies that the sum in (2.9) contains a positive diagonal matrix, the sum (2.9) is necessarily positive definite. □

3. Proof of Theorem 1.2. With the constructions of §2, we come to the proof of Theorem 1.2. The proof is an induction on n. If A is an $n \times n$ strictly ultrametric matrix, then from Corollary 2.3, A is nonsingular and A^{-1} exists. That A^{-1} is a strictly diagonally dominant Stieltjes matrix that also satisfies (1.2) of Theorem 1.2 is obvious for $n = 1$. Thus, by the inductive hypothesis, assume that Theorem 1.2 is valid for all ultrametric matrices in $\mathbb{R}^{j,j}$ with $1 \leq j \leq n-1$ where $n \geq 2$, and consider any strictly ultrametric matrix $A = [a_{i,j}]$ in $\mathbb{R}^{n,n}$. Up to a suitable permutation, we have from (2.2) and (2.3) that

$$A = \begin{bmatrix} C & O \\ O & D \end{bmatrix} + \tau(A)\xi_n\xi_n^T \quad \text{with } \xi_n := (1, 1, \ldots, 1)^T \in \mathbb{R}^n, \tag{3.1}$$

where, from Proposition 2.1, C in $\mathbb{R}^{r,r}$ and D in $\mathbb{R}^{n-r,n-r}$ (with $1 \leq r < n$) are both strictly ultrametric and nonsingular. But as r and $n - r$ are both less than n, the inductive hypothesis, applied to C and D, gives that C^{-1} and D^{-1} are strictly diagonally dominant Stieltjes matrices. Hence, if

$$M := \begin{bmatrix} C & O \\ O & D \end{bmatrix} \quad \text{so that } M^{-1} = \begin{bmatrix} C^{-1} & O \\ O & D^{-1} \end{bmatrix}, \tag{3.2}$$

then M^{-1} is also a strictly diagonally dominant Stieltjes matrix. Next, the Sherman–Morrison formula (cf. Golub and Van Loan [1, p. 51]), applied to (3.1), gives the following representation for A^{-1} of (3.1):

$$\left(M + \tau(A)\xi_n \cdot \xi_n^T\right)^{-1} = A^{-1} = M^{-1} - \frac{\tau(A)M^{-1}\xi_n\xi_n^T M^{-1}}{[1 + \tau(A)\xi_n^T M^{-1}\xi_n]}. \tag{3.3}$$

We first claim that the term in brackets in the denominator above is *positive*. To see this, M^{-1}, as previously noted, is a strictly diagonally dominant Stieltjes matrix, so that $M^{-1}\xi_n$ is a positive vector in $\mathbb{R}^n$. On writing $M^{-1}\xi_n := \mathbf{p} > 0$, this denominator is just

$$\left[1 + \tau(A)\xi_n^T M^{-1}\xi_n\right] = 1 + \tau(A)\xi_n^T \mathbf{p} \geq 1. \tag{3.4}$$

Moreover, since $M\mathbf{p} = \xi_n$ and since M is real symmetric, then the last term in (3.3) can be expressed as the matrix

$$-\frac{\tau(A)}{[1 + \tau(A)\xi_n^T \mathbf{p}]}\mathbf{p}\mathbf{p}^T, \tag{3.5}$$

which is obviously a real nonpositive definite symmetric matrix in $\mathbb{R}^{n,n}$, all of whose terms are zero if $\tau(A) = 0$, or negative if $\tau(A) > 0$. But, as the matrix of (3.5) is *added* in (3.3) to M^{-1}, which as noted above is a Stieltjes matrix, then all off-diagonal entries of A^{-1} are necessarily nonpositive.

To show that A^{-1} is strictly diagonally dominant, let

$$M^{-1}\xi_n = \mathbf{p} =: (p_1, p_2, \ldots, p_n)^T > \mathbf{0}.$$

For the ith row sum of A^{-1}, it follows from the second part of (3.3) and (3.5) that

$$(A^{-1}\xi_n)_i = p_i - \frac{\tau(A)p_i \sum_{j=1}^{n} p_j}{\left[1 + \tau(A)\sum_{j=1}^{n} p_j\right]} = \frac{p_i}{\left[1 + \tau(A)\sum_{j=1}^{n} p_j\right]} > 0 \quad (i \in N). \tag{3.6}$$

But, as all off-diagonal entries $\alpha_{i,j}$ of A^{-1} are nonpositive, (3.6) succinctly and precisely gives that A^{-1} is strictly diagonally dominant!

Finally, we establish (cf. (1.2)) that $\alpha_{i,j} = 0$ if and only if $a_{i,j} = 0$. First, if $\tau(A) > 0$, then the strictly ultrametric matrix $A = [a_{i,j}]$ is, up to a permutation matrix P, given from (3.1) by the sum

$$A = \begin{bmatrix} C & O \\ O & D \end{bmatrix} + \tau(A)\xi_n\xi_n^T, \tag{3.7}$$

which has only positive entries, i.e., $a_{i,j} > 0$ for all i, j in N. On the other hand, from (3.3) and (3.4),

$$A^{-1} = \begin{bmatrix} C^{-1} & O \\ O & D^{-1} \end{bmatrix} - \frac{\tau(A)\mathbf{p}\mathbf{p}^T}{[1 + \tau(A)\xi_n^T\mathbf{p}]}, \tag{3.8}$$

where every entry of the last matrix is negative. As the matrices C and D in (3.7) are strictly ultrametric from Proposition 2.1, then C^{-1} and D^{-1} are Stieltjes matrices. Thus, from (3.8), the entries $\alpha_{i,j}$ of A^{-1} satisfy $\alpha_{i,j} < 0$ for all $i \neq j$. Moreover, since A^{-1} is a strictly diagonal dominant matrix, then $\alpha_{i,i} > 0$ for all $1 \leq i \leq n$. Hence, in this case where $\tau(A) > 0$, (1.2) of Theorem 1.2 vacuously holds.

If $\tau(A) = 0$, then from (3.7) we have that

$$A = \begin{bmatrix} C & O \\ O & D \end{bmatrix} \quad \text{and} \quad A^{-1} = \begin{bmatrix} C^{-1} & O \\ O & D^{-1} \end{bmatrix},$$

so that A and A^{-1} have the same off-diagonal blocks of zeros. But we can evidently apply the inductive hypothesis to the block submatrices C and D, and we thus establish (1.2), namely, that the zero entries of A and A^{-1} are the same. □

Having established Theorem 1.2, we deduce from it the following corollary, which appears in [2, Lemma 1] as a step in establishing proof of Theorem 1.2.

COROLLARY 3.1. *Let A in $\mathbb{R}^{n,n}$ be strictly ultrametric. If $\xi_n := (1, 1, \ldots, 1)^T$ in $\mathbb{R}^n$, then there exists a vector $\mathbf{p}$ in $\mathbb{R}^n$, with all positive components, such that*

$$A\mathbf{p} = \xi_n. \tag{3.9}$$

Proof. From Theorem 1.2, A^{-1} is a strictly diagonally dominant Stieltjes matrix in $\mathbb{R}^{n,n}$. Hence $A^{-1}\xi_n =: \mathbf{p} > \mathbf{0}$, from which (3.9) directly follows. □

In conclusion, we note that the more general problem of determining which nonsingular matrices in $\mathbb{R}^{n,n}$, with nonnegative coefficients, have inverses that are M-matrices, has been studied by a number of authors over the years. Although we know of no overlap between the results of this paper and results from these more general investigations, we have nonetheless listed, for the benefit of interested readers, a number of papers [4]–[8] that deal with this more general problem.

Acknowledgment. We thank Professor C. R. Johnson for stimulating discussions related to this research.

GENERALIZED DISPLACEMENT STRUCTURE FOR BLOCK-TOEPLITZ, TOEPLITZ-BLOCK, AND TOEPLITZ-DERIVED MATRICES*

Dedicated to Gene H. Golub on the occasion of his 60th birthday.

T. KAILATH† AND J. CHUN†‡

Abstract. The concept of displacement structure has been used to solve several problems connected with Toeplitz matrices and with matrices obtained in some way from Toeplitz matrices (e.g., by combinations of multiplication, inversion, and factorization). Matrices of the latter type will be called Toeplitz-derived (or Toeplitz-like, close-to-Toeplitz). This paper introduces a generalized definition of displacement for block-Toeplitz and Toeplitz-block arrays. It will turn out that Toeplitz-derived matrices are perhaps best regarded as particular Schur complements obtained from suitably defined block matrices. The new displacement structure is used to obtain a generalized Schur algorithm for fast triangular and orthogonal factorizations of all such matrices and well-structured fast solutions of the corresponding exact and overdetermined systems of linear equations. Furthermore, this approach gives a natural generalization of the so-called Gohberg–Semencul formulas for Toeplitz-derived matrices.

Key words. Toeplitz matrix, displacement structure, factorization, generalized Gohberg–Semencul formulas, Schur complements

AMS subject classifications. primary 65F05, 65F30; secondary 15A06

1. Introduction. Fast algorithms for triangular and orthogonal matrix factorization, matrix inversions (least-squares) solutions of linear equations, and several related results are now widely known for Toeplitz matrices. The concept of displacement structure [30] was introduced to show, among other things, that fast algorithms could also be obtained for several related matrices that do not have such structure; for example, though not Toeplitz, matrices of the form T_1^{-1}, T_1T_2, $T_1 - T_2T_3^{-1}T_4$, $T_1T_2 - T_3T_4$, where the $\{T_i\}$ are Toeplitz matrices, all possess fast algorithms. The reason basically is that all these matrices have low displacement rank. The *displacement* of a (square) matrix A was defined in [30] as

$$\nabla A = A - Z_n A Z_n^T, \tag{1}$$

where Z_n is the $n \times n$ (lower) shift matrix with 1's on the first subdiagonal and 0's elsewhere. For a Toeplitz matrix, T, it is easy to see that ∇T will be identically zero except for the first row and first column, so that the displacement rank of T = rank $\nabla T \leqq 2$ no matter what the size of T. A significant fact is that, though T^{-1} is not in general Toeplitz, rank $\nabla T^{-1} \leqq 2$. So, also, though T_1T_2 is not in general Toeplitz, rank $\nabla T_1T_2 \leqq 4$. These facts have been exploited to obtain fast $O(n^2)$ algorithms for factoring matrices such as T^{-1} and T_1T_2 and others. Nevertheless we show in this article that matrices such as T^{-1}, $T_1 - T_2T_3^{-1}T_4$, $T_1T_2 - T_3T_4$, and so on may be better studied by first trying to find an appropriate "Toeplitz-block" matrix in which these

matrices appear as certain Schur-complement matrices and then analyzing these Toeplitz-block matrices by introducing a *suitably modified* definition of displacement; the key fact then used is that displacement structure is preserved under Schur complementation. Besides enabling us to solve several new problems, this procedure also provides a new and simpler approach to many of the problems studied in [4]–[6], [9]–[11], [13]–[15], [19]–[21], [23], [27], [36], [37], [41], [43], [44]. It will perhaps be clearest to present two simple examples.

Example 1. Study of T^{-1}. First note that T^{-1} is the Schur complement of the (1,1) block in the Toeplitz-block matrix

$$A = \begin{bmatrix} -T & 1 \\ 1 & O \end{bmatrix}. \tag{2}$$

It is a known result (see, e.g., [13], [37]) that the displacement rank of a Schur complement of A cannot exceed the displacement rank of A, which is 4, in general, because

$$\nabla A = \left[\begin{array}{ccc|ccc} -t_0 & -t_1 & -t_{n-1} & 1 & 0 & 0 \\ -t_1 & & & t_{n-1} & & \\ \vdots & & 0 & \vdots & & 0 \\ -t_{n-1} & & & t_1 & & \\ \hline 1 & t_{n-1} & t_1 & t_0 & 0 & 0 \\ 0 & & 0 & 0 & & \\ \vdots & & \vdots & \vdots & & 0 \\ 0 & & 0 & 0 & & \end{array}\right].$$

However, it is well known that the displacement rank of T^{-1} cannot exceed 2. Therefore, though the idea of studying matrices such as T^{-1} and $T_1 - T_2 T_3^{-1} T_4$ as Schur complements of suitable block matrices is not new (see especially the work of Delosme [13] and [14] and others [5], [37], [43], [44]), doing this with the definition (1) will lead to more complex algorithms than necessary.

On the other hand, suppose we define the modified displacement rank of A by the rank of the matrix

$$\nabla_{(F,F)} A = A - FAF^T, \qquad F = \begin{bmatrix} Z_n & O \\ O & Z_n \end{bmatrix} = Z_n \oplus Z_n.$$

Then note that

$$\nabla_{(F,F)} A = \begin{bmatrix} -\nabla_{(Z_n,Z_n)} T & \nabla_{(Z_n,Z_n)} I \\ \nabla_{(Z_n,Z_n)} I & O \end{bmatrix}$$

$$= \left[\begin{array}{ccc|ccc} -t_0 & -t_1 & -t_{n-1} & 1 & 0 & 0 \\ -t_1 & & & & & \\ \vdots & & 0 & & & 0 \\ -t_{n-1} & & & & & \\ \hline 1 & & & & & \\ 0 & & & & & \\ \vdots & & 0 & & & 0 \\ 0 & & & & & \end{array}\right]$$

so that the F displacement rank of A is 2. Now the previously mentioned result on Schur complements will show that $\nabla_{(Z_n,Z_n)} T^{-1} \leqq 2$. □

Example 2. Displacement rank of products. In [9], we gave a rather uninspiring proof of the inequality

$$\text{rank } [\nabla_{(Z_n,Z_n)}(B_1B_2)] \leqq \text{rank } [\nabla_{(Z_n,Z_n)}B_1] + \text{rank } [\nabla_{(Z_n,Z_n)}B_2] + 1. \tag{3}$$

An interesting proof follows by considering the block matrix

$$A = \begin{bmatrix} -I & B_2 \\ B_1 & O \end{bmatrix}. \tag{4}$$

Note that B_1B_2 is the Schur complement of $-I$ in A and that

$$\nabla_{(F,F)}A = \left[\begin{array}{c|c} -1 & \nabla_{(Z_n,Z_n)}B_2 \\ \hline 0 & \\ \hline \nabla_{(Z_n,Z_n)}B_1 & O \end{array}\right], \qquad F = Z_n \oplus Z_n.$$

Now, (3) follows from the fact that rank $[\nabla_{(Z_n,Z_n)}(B_1B_2)] \leqq$ rank $[\nabla_{(F,F)}A]$.

On the other hand, note that if (consistent with the original definition (1)) we had used Z_{2n} instead of $Z_n \oplus Z_n$, we would have obtained a looser bound,

$$\text{rank } [\nabla_{(Z_n,Z_n)}(A_1A_2)] \leqq \text{rank } [\nabla_{(Z_n,Z_n)}A_1] + \text{rank } [\nabla_{(Z_n,Z_n)}A_2] + 3.$$

Tighter bounds on the displacement rank of matrices are important because the operation count of fast algorithms increases according to these bounds rather than to the displacement rank. This is the feature made possible by using properly extended definitions of displacement rank. □

An appropriate generalization of the ideas in these simple examples is introduced in this article along with several applications. Section 2 gives the general definitions. The heart of the article is § 3, where a generalized Schur algorithm is derived. Several applications are given in § 4. The concluding section reviews the main idea and makes comparisons with earlier approaches also using Schur complements (e.g., [5], [13], [37]).

2. Definitions and notations. Let $A \in \mathbf{R}^{m\times n}$ be a given matrix and let F^f and F^b be *strictly* lower triangular matrices. The matrix

$$\nabla_{(F^f,F^b)}A \equiv A - F^fAF^{bT}, \qquad F^{bT} \equiv (F^b)^T \tag{5}$$

is called the *displacement* of A with respect to the *displacement operators* $\{F^f, F^b\}$. Any matrix pair $\{X, Y\}$ such that

$$\nabla_{(F^f,F^b)}A = XY^T, \quad X \equiv [\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_\alpha], \quad Y \equiv [\mathbf{y}_1, \mathbf{y}_2, \ldots, \mathbf{y}_\alpha] \tag{6}$$

is called a *generator* of A (with respect to $\{F^f, F^b\}$). The number α is called the *length* of the generator (with respect to $\{F^f, F^b\}$). A generator of A with the minimal possible length is called a *minimal* generator. The length of the minimal generator of A (i.e., rank $(\nabla_{(F^f,F^b)}A) \leqq \alpha$) is called the *displacement rank* of A (with respect to $\{F^f, F^b\}$) and is denoted as $\alpha_{(F^f,F^b)}(A)$.

If $\{X, Y\}$ is a generator of A with respect to $\{F^f, F^b\}$, then for any nonsingular matrix $S \in R^{\alpha\times\alpha}$, the matrix pair $\{XS, YS^{-T}\}$ is also a generator of A because

$$\nabla_{(F^f,F^b)}A = XY^T = XSS^{-1}Y^T.$$

Hence, generators (even minimal ones) are not unique. For block-Toeplitz or Toeplitz-block matrices, it is straightforward to obtain generators from the displacements by inspection.

Note that the displacement of a symmetric matrix A can be written as $\nabla_{(F,F)}A = X\Sigma X^T$ where Σ is a diagonal matrix with 1 or -1 along the main diagonal; we say that A has a *symmetric generator*, $\{X, X\Sigma\}$, with respect to F.

We should note that the following sum-of-products representation of a matrix A solves (5),

$$A = \sum_{i=1}^{\alpha} K_n(\mathbf{x}_i, F^f)K_n^T(\mathbf{y}_i, F^b), \qquad A \in \mathbf{R}^{m\times n}, \tag{7}$$

where $K_n(\mathbf{x}_i, F^f) \in \mathbf{R}^{m\times n}$ and $K_n(\mathbf{y}_i, F^b) \in \mathbf{R}^{n\times n}$ are the so-called Krylov matrices

$$K_n(\mathbf{x}_i, F^f) \equiv [\mathbf{x}_i, F^f\mathbf{x}_i, \ldots, (F^f)^{n-1}\mathbf{x}_i], \quad K_n(\mathbf{y}_i, F^b) \equiv [\mathbf{y}_i, F^b\mathbf{y}_i, \ldots, (F^b)^{n-1}\mathbf{y}_i].$$

The *strict* triangularity of $\{F^f, F^b\}$ is important in this result; otherwise the Krylov matrices would have an infinite number of columns. We shall show in § 4 that the representation (7) yields generalizations of the celebrated Gohberg–Semencul formula for the inverse of a Toeplitz matrix (see [22], [24]).

Choice of displacement operators. Let $\{X, Y\}$ be a generator of length α of A with respect to F^f and F^b. If the matrix-vector multiplications $F^f\mathbf{u}$ and $F^b\mathbf{v}$ take $f(n)$ and $b(n)$ operations, respectively, then the algorithms to be presented in § 3 will need $O(\alpha n g(n))$ operations, where $g(n) = \max(f(n), b(n))$. Therefore, the objective is to choose the "simplest" or sparse (to make $g(n)$ small) strictly lower triangular matrices F^f and F^b that also make α as small as possible. For a scalar $n \times n$ Toeplitz matrix, a natural choice of displacement operator is the $n \times n$ shift matrix, Z_n, with 1's along the first subdiagonal and 0's elsewhere. We give some heuristic choices for block-Toeplitz matrices, Toeplitz-block matrices, and their combinations.

For an $M \times N$ *Toeplitz-block array* with $m_i \times n_j$ Toeplitz matrices $T_{i,j}$,

$$A = \begin{bmatrix} T_{1,1} & T_{1,2} & \cdot & T_{1,N} \\ T_{2,1} & T_{2,2} & \cdot & T_{2,N} \\ \cdot & \cdot & \cdot & \cdot \\ T_{M,1} & T_{M,2} & \cdot & T_{M,N} \end{bmatrix} \in \mathbf{R}^{m\times n}, \tag{8}$$

we shall use the displacement operators,

$$F^f = \bigoplus_{i=1}^{M} Z_{m_i}, \qquad F^b = \bigoplus_{i=1}^{N} Z_{n_i},$$

where $\oplus_{i=1}^{M} F_i$ denotes the concatenated direct sum, i.e., the block diagonal matrix whose ith diagonal block is F_i.

For an $M \times N$ *block-Toeplitz array* with $r \times s$ rectangular blocks,

$$A = \begin{bmatrix} B_0 & B_{-1} & \cdot & B_{-N+1} \\ B_1 & B_0 & \cdot & B_{-N+2} \\ \cdot & \cdot & \cdot & \cdot \\ B_{M-1} & B_{M-2} & \cdot & B_{-N+M} \end{bmatrix}, \tag{9}$$

a natural choice is

$$F^f = Z_{Mr}^{M}, \qquad F^b = Z_{Ns}^{N},$$

where $Z_{kr}^{k} = [Z_{k\cdot r}]^k$ can be seen as a *block shift matrix*, i.e., a $k \times k$ array with $r \times r$ identity matrices on the first block subdiagonal and 0's elsewhere.

Example 3. Consider the matrix A,

$$A = \begin{bmatrix} I & B & O \\ B^T & O & I \\ O & I & O \end{bmatrix}, \qquad B \in \mathbf{R}^{m \times n}.$$

If B is a Toeplitz matrix, then choosing

$$F^f = F^b = Z_m \oplus Z_n \oplus Z_n$$

will give a displacement rank of 4 for A. If B is an $M \times N$ block-Toeplitz array with $r \times s$ blocks, we could choose

$$F^f = F^b = Z_{Mr}^M \oplus Z_{Ns}^N \oplus Z_{Ns}^N.$$

If B is a Toeplitz-block array, for example, $B = [T_1 \quad T_2]$, where $T_1 \in \mathbf{R}^{m_1 \times n}$ and $T_2 \in \mathbf{R}^{m_2 \times n}$, then we could choose

$$F^f = F^b = Z_{m_1} \oplus Z_{m_2} \oplus Z_n \oplus Z_n.$$

We can obtain a generator of A for each case by inspection. For example, for the case of Toeplitz $B = (b_{i-j})$, the following matrix

$$X = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & b_1 & 0 & b_1 \\ \cdot & \cdot & \cdot & \cdot \\ 0 & b_{m-1} & 0 & b_{m-1} \\ b_0 & .5 & b_0 & -.5 \\ b_{-1} & 0 & b_{-1} & 0 \\ \cdot & \cdot & \cdot & \cdot \\ b_{1-n} & 0 & b_{1-n} & 0 \\ 0 & 1 & 0 & 1 \\ \cdot & 0 & \cdot & 0 \\ \cdot & \cdot & \cdot & \cdot \\ 0 & 0 & 0 & 0 \end{bmatrix}, \qquad \Sigma = \begin{bmatrix} 1 & & & \\ & 1 & & \\ & & -1 & \\ & & & -1 \end{bmatrix}$$

is a generator of A with respect to $Z_m \oplus Z_n \oplus Z_n$. More systematic procedure is described in the Appendix.

Proper generators. Let $\{X, Y\}$ be a generator of a matrix A. We say that a generator is *proper* (with respect to the pivoting column j) if, for a certain i, all the elements in the ith row of X and above, except for the element $[X]_{i,j}$, are zero and all elements in the ith row of Y and above, except the element $[Y]_{i,j}$, are zero. Often we shall denote a proper generator as $\{X_p, Y_p\}$. If $\{X, Y\}$ is not proper, then by choosing an appropriate S, we can obtain a proper generator $\{XS, YS^{-T}\}$ under certain conditions on the matrix A. A procedure for doing this is described in § 3.

3. Generalized Schur algorithm. A fundamental method for triangular matrix factorization is the so-called *Schur reduction* process (see [40] and, e.g., [13], [14], [33], [34], [37], [38]), which successively computes the Schur complements of the leading submatrices iteratively; displacement structure allows the computation to be speeded up. Our fast algorithms will be based on the following theorem.

THEOREM 1. *Let* $\{X_p^{(1)}, Y_p^{(1)}\}$ *be a proper generator of a rectangular matrix* $A^{(1)} \in \mathbf{R}^{m \times n}$ *with respect to* $\{F^f, F^b\}$. *Also assume that* $\{X_p^{(1)}, Y_p^{(1)}\}$ *has been made proper with respect to a particular* (*pivoting*) *column, which we shall index as "pvt." If*

we denote the columns of $X_p^{(1)}$ *and* $Y_p^{(1)}$ *by*

$$X_p^{(1)} = [\mathbf{x}_1^{(1)}, \ldots, \mathbf{x}_{\text{pvt}}^{(1)}, \ldots, \mathbf{x}_\alpha^{(1)}], \qquad Y_p^{(1)} = [\mathbf{y}_1^{(1)}, \ldots, \mathbf{y}_{\text{pvt}}^{(1)}, \ldots, \mathbf{y}_\alpha^{(1)}],$$

then the matrix $A^{(2)}$ *defined by*

$$A^{(2)} \equiv A^{(1)} - \mathbf{x}_{\text{pvt}}^{(1)} \mathbf{y}_{\text{pvt}}^{(1)T}$$

has null first column and row, and has a generator $\{X^{(2)}, Y^{(2)}\}$, *with respect to* $\{F^f, F^b\}$ *of the form*

$$X^{(2)} = [\mathbf{x}_1^{(1)}, \ldots, F^f \mathbf{x}_{\text{pvt}}^{(1)}, \ldots, \mathbf{x}_\alpha], \qquad Y^{(2)} = [\mathbf{y}_1^{(1)}, \ldots, F^b \mathbf{y}_{\text{pvt}}^{(1)}, \ldots, \mathbf{y}_\alpha^{(1)}].$$

Remark 1. The matrix $A^{(2)}$ is the Schur complement of $A^{(1)}$ with respect to the (1,1) element of $A^{(1)}$.

Proof.

$$\begin{aligned} A^{(2)} - F^f A^{(2)} F^{bT} &= [A^{(1)} - \mathbf{x}_{\text{pvt}}^{(1)} \mathbf{y}_{\text{pvt}}^{(1)T}] - F^f [A^{(1)} - \mathbf{x}_{\text{pvt}}^{(1)} \mathbf{y}_{\text{pvt}}^{(1)T}] F^{bT} \\ &= A^{(1)} - F^f A^{(1)} F^{bT} - \mathbf{x}_{\text{pvt}}^{(1)} \mathbf{y}_{\text{pvt}}^{(1)T} + F^f \mathbf{x}_{\text{pvt}}^{(1)} \mathbf{y}_{\text{pvt}}^{(1)T} F^{bT} \\ &= X^{(1)} Y^{(1)T} - \mathbf{x}_{\text{pvt}}^{(1)} \mathbf{y}_{\text{pvt}}^{(1)T} + F^f \mathbf{x}_{\text{pvt}}^{(1)} \mathbf{y}_{\text{pvt}}^{(1)T} F^{bT} \\ &= X^{(2)} Y^{(2)T}. \end{aligned}$$

The first column and row of $A^{(2)}$ are null because

$$A^{(2)} \mathbf{e}_1 = [X^{(2)} Y^{(2)T}] \mathbf{e}_1 = 0, \qquad \mathbf{e}_1^T A^{(2)} = \mathbf{e}_1^T [X^{(2)} Y^{(2)T}] = 0,$$

where we have used the fact that F^f and F^b are strictly lower triangular and $\{X_p^{(1)}, Y_p^{(1)}]$ is proper. □

By applying the previous theorem using such a proper generator we can obtain a (possibly nonproper) generator of $A^{(2)}$. Converting this to proper form, we can proceed to find a generator $A^{(3)}$. By repeating this process r times, we shall generate the matrices

$$\begin{aligned} A^{(2)} &= A^{(1)} - \mathbf{x}_{\text{pvt}_1}^{(1)} \mathbf{y}_{\text{pvt}_1}^{(1)T}, \\ &\quad \cdots\cdots, \\ A^{(r)} &= A^{(r-1)} - \mathbf{x}_{\text{pvt}_{r-1}}^{(r-1)} \mathbf{y}_{\text{pvt}_{r-1}}^{(r-1)T}, \\ A^{(r+1)} &= A^{(r)} - \mathbf{x}_{\text{pvt}_r}^{(r)} \mathbf{y}_{\text{pvt}_r}^{(r)T}. \end{aligned} \tag{10}$$

It turns out that this process gives a *partial triangular factorization* of $A^{(1)}$, because (10) shows that

$$A^{(1)} = \sum_{i=1}^{r} \mathbf{x}_{\text{pvt}_i}^{(i)} \mathbf{y}_{\text{pvt}_i}^{(i)T} + A^{(r+1)}$$

$$= \begin{bmatrix} \mathbf{x}_{\text{pvt}_1}^{(1)} & \cdots & \mathbf{x}_{\text{pvt}_r}^{(r)} \end{bmatrix} \begin{bmatrix} \mathbf{y}_{\text{pvt}_1}^{(1)T} \\ \vdots \\ \mathbf{y}_{\text{pvt}_r}^{(r)T} \end{bmatrix} + A^{(r+1)},$$

where

$$A^{(r+1)} \equiv \left[\begin{array}{c|c} 0 & 0 \\ \hline 0 & S^{(r+1)} \end{array}\right].$$

Remark 2. The above r-step partial triangularization breaks down if and only if there is a singular leading principal submatrix of order less than or equal to r; we shall assume that this is not so, i.e., the matrix is assumed to be *strongly nonsingular* or strongly regular. Various authors, including ourselves, however, have obtained results for the indefinite matrices with singular leading principal submatrix case as well (see [38]).

The above process can be summarized in the following algorithm, which we shall call a *generalized Schur algorithm*.

GENERALIZED SCHUR ALGORITHM
Input: A generator $\{X, Y\}$ of $A \in \mathbf{R}^{m\times n}$ with respect to $\{F^f, F^b\}$.
Output: (i) Partial triangular factors $L \in \mathbf{R}^{m\times r}$ and $U \in \mathbf{R}^{r\times n}$ of A.

(ii) A generator $\{X, Y\}$ of the Schur complement of the $r \times r$ leading principal submatrix of A,
Procedure:

for $k := 1$ **to** r **do begin**
  Find a proper generator of $A^{(k)}$;
  The kth column of $L := \mathbf{x}_{\text{pvt}}$; The kth row of $U := \mathbf{y}_{\text{pvt}}^T$;
  Replace $\mathbf{x}_{\text{pvt}}$ with $F^f\mathbf{x}_{\text{pvt}}$ and $\mathbf{y}_{\text{pvt}}$ with $F^b\mathbf{y}_{\text{pvt}}$ to get a generator of $A^{(k+1)}$;
end
return $(L, U, \{X, Y\})$;

Note that the above procedure needs $O(\alpha pr)$ operations, where $p = \max(m, n)$ and α is the length of the given generator, if the operation of making a generator proper takes $O(\alpha p)$ operations. We now show how to do this.

Construction of proper generators. This can be done in various ways. We shall describe a method using elementary matrices known as *spinors*; for methods using Householder matrices, see, e.g., [7], [12], [13], [16], [32]. A spinor $S_{(j|i)} \in \mathbf{R}^{\alpha\times\alpha}$ is defined as the identity matrix except for the following four entries,

$$[S_{(j|i)}]_{i,i} = c, \quad [S_{(j|i)}]_{i,j} = s_2, \quad [S_{(j|i)}]_{j,i} = -s_1, \quad [S_{(j|i)}]_{j,j} = c,$$

where $[A]_{i,j}$ denotes the (i, j)th element of the matrix A and $c^2 + s_1s_2 = 1$. The inverse of a spinor is also a spinor, viz., $S_{(j|i)}^{-1}$ is the identity matrix except for the following four entries,

$$[S_{(j|i)}^{-1}]_{i,i} = c, \quad [S_{(j|i)}^{-1}]_{i,j} = -s_2, \quad [S_{(j|i)}^{-1}]_{j,i} = s_1, \quad [S_{(j|i)}^{-1}]_{j,j} = c.$$

Let $\mathbf{x}^T \in \mathbf{R}^{1\times\alpha}$ and $\mathbf{y}^T \in \mathbf{R}^{1\times\alpha}$ be row vectors. Let c, s_1, and s_2 be chosen as

$$c = \left[\frac{x_i y_i}{x_i y_i + x_j y_j}\right]^{1/2}, \quad s_2 = -c\cdot\frac{x_j}{x_i}, \quad s_1 = -c\cdot\frac{y_j}{y_i},$$

and define $\mathbf{x}'$ and $\mathbf{y}'$ by

$$\mathbf{x}'^T \equiv \mathbf{x}^T S_{(j|i)}, \qquad \mathbf{y}'^T \equiv \mathbf{y}^T S_{(j|i)}^{-T}.$$

Then it is easy to check that $x_j' = y_j' = 0$ and $\mathbf{x}'^T\mathbf{y}' = \mathbf{x}^T\mathbf{y}$. We shall call the elements x_i and y_i *pivoting elements*. Therefore, by repeating this process we can *annihilate* all ele-

ments of $\mathbf{x}$ and $\mathbf{y}$ except the pivoting elements, resulting in

$$[0, \ldots, 0, x_i, 0, \ldots, 0] = \mathbf{x}^T \prod_{j \neq i}^{\alpha} S_{(j|i)}, \qquad [0, \ldots, 0, y_i, 0, \ldots, 0] = \mathbf{y}^T \prod_{j \neq i}^{\alpha} S_{(j|i)}^{-T}.$$

An arbitrary choice of pivoting element or an arbitrary *ordering* of annihilation might result in $[1 + (x_j y_i / x_i y_i)] \leqq 0$ for some j, for which real spinors do not exist. This issue is handled by the following lemma, whose proof along with other related results can be found in [7].

LEMMA 1. *Let* $\gamma_i = x_i y_i$ *and* $s = \sum_i \gamma_i > 0$ (<0). *If we choose a pivot element such that* $\gamma_i > 0$ (<0), *and if we annihilate all elements with* $\gamma_i > 0$ (<0) *before annihilating elements with* $\gamma_i < 0$ (>0), *then* $[1 + (x_j x_j / x_i y_i)] > 0$ *for all* $1 \leqq j \leqq \alpha$, $j \neq i$.

Some special cases. If we are given a symmetric generator of a symmetric matrix A, i.e., if $Y = X\Sigma$, then the updating of Y in the above procedure is redundant, because the updated $\{X', Y'\}$ after annihilating a row still remains symmetric. To see this, let

$$\mathbf{x}^T = \mathbf{y}^T = [x_{\text{pvt}}, x_j].$$

Then the spinor that annihilates x_j will reduce to a *Givens rotation*,

$$G_{(j|\text{pvt})} = \begin{bmatrix} c & -s \\ s & c \end{bmatrix}, \qquad c^2 + s^2 = 1.$$

On the other hand, if

$$\mathbf{x}^T = [x_{\text{pvt}}, x_j], \qquad \mathbf{y}^T = [x_{\text{pvt}}, -x_j],$$

the spinor will become a *hyperbolic rotation*,

$$H_{(j|\text{pvt})} = \begin{bmatrix} ch & -sh \\ -sh & ch \end{bmatrix}, \qquad ch^2 - sh^2 = 1.$$

Notice that Givens and hyperbolic rotations preserve the symmetry of the updated generator, i.e.,

$$YS^{-T} = Y' = X'\Sigma, \quad X' = XS, \quad S\text{: a Givens or hyperbolic rotation.}$$

As another special case of spinors, consider the two row vectors

$$\mathbf{x}^T = [x_{\text{pvt}}, x_j], \qquad \mathbf{y}^T = [y_{\text{pvt}}, 0].$$

For this case, the spinor that annihilates x_j will reduce to the usual *elimination* matrix,

$$E_{(j|\text{pvt})} = \begin{bmatrix} 1 & -\kappa \\ 0 & 1 \end{bmatrix}, \qquad \kappa = \frac{x_j}{x_{\text{pvt}}}. \tag{11}$$

We may mention that Ahmed, Delosme, and Morf [2] showed the significance of such elementary operations for efficient hardware implementation.

Remark 3. For a square Toeplitz-block array $A \in \mathbf{R}^{n \times n}$ with $T_{i,j} \in \mathbf{R}^{m_i \times n_j}$, we can obtain the LU factorization of A by completing the generalized Schur algorithm with $r = n$. Other authors have suggested first transforming A into a block-Toeplitz matrix by pre- and postmultiplication with permutation matrices and then applying an algorithm for square block-Toeplitz matrix to get a row- and column-permuted triangular factorization of A; there is clearly a difficulty with this approach when $m_i \neq m_j$. More importantly, if A is not positive definite, the permuted matrix is not necessarily strongly nonsingular, for which ordinary LU factorization does not exist. Our approach does not have this problem because it directly factorizes A without permutations.

Remark 4. For a square block-Toeplitz array $A \in \mathbf{R}^{n\times n}$, with square blocks $B_i \in \mathbf{R}^{r\times r}$, there exist several fast block triangular factorization algorithms such as the Bareiss algorithm [4], the multichannel Levinson algorithm [3], [35], and the Schur algorithm [1] and [18], all of which require matrix (of the block size $r \times r$) operations. Our approach treats block-Toeplitz matrices in essentially the same way as *scalar* Toeplitz matrices and in particular will use only elementary scalar operations. We remark that the absence of matrix operations such as inversion may simplify the design of dedicated hardware implementations.

4. Applications. By applying the generalized Schur algorithm in § 3 to judiciously chosen block matrices, we can obtain interesting results including fast *QR* factorizations and generalized Gohberg–Semencul formulas. Generators of the block matrices used in this section can be easily found by inspection (see Appendix). The *floating operation* (flop) counts given below are confined to the number of multiplications.

Simultaneous factorization of a symmetric Toeplitz matrix and its inverse. Let $T = (t_{i-j}) \in \mathbf{R}^{n\times n}$, $t_0 = 1$, be a strongly nonsingular symmetric Toeplitz matrix. The matrix

$$A = \begin{bmatrix} T & I \\ I & O \end{bmatrix} \tag{12}$$

has a symmetric generator $\{X, X\Sigma\}$ with respect to $Z_n \oplus Z_n$, where

$$X = \begin{bmatrix} 1 & t_1 & \cdot & t_{n-1} & 1 & 0 & \cdot & 0 \\ 0 & t_1 & \cdot & t_{n-1} & 1 & 0 & \cdot & 0 \end{bmatrix}^T, \qquad \Sigma = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}.$$

After performing n steps of partial triangular factorization using the generalized Schur algorithm, we shall have the factors L and U in

$$A = \begin{bmatrix} L \\ U \end{bmatrix} [L^T, U^T] + \begin{bmatrix} O & O \\ O & S \end{bmatrix}. \tag{13}$$

Now, one can check by comparing the entries of A in (12) and (13) that

$$T = LL^T, \quad T^{-1} = UU^T, \quad U\text{: upper triangular.}$$

Recall that the classical Schur algorithm gives only the factorization $T = LL^T$, whereas the Levinson algorithm gives the factorization $T^{-1} = UU^T$. Here we get both simultaneously in $4n^2 + O(n)$ flops (or $2n^2 + O(n)$ if one uses fast rotations; see, e.g., [9] and [25]). The computation only of $T = LL^T$ needs just one half of the above flop counts. If one only needs the factorization of T^{-1}, the above method is slower than the Levinson algorithm; however, the above (Schur) method does not require inner products and therefore is better suited to parallel implementation than the Levinson algorithm.

Orthogonalization of a fully windowed Toeplitz matrix [10]. Let $T = (t_{i-j}) \in \mathbf{R}^{m\times n}$, $m > n$ be a *fully windowed* Toeplitz matrix, i.e.,

$$t_{i-j} = 0, \quad \text{if } j > i, \quad \text{or} \quad i > m - n + j.$$

Then it is easy to check that $B = (b_{i-j}) \equiv T^T T$ is also an (unwindowed) Toeplitz matrix. Now assume that $t_0 \neq 0$ and $t_{m-n} \neq 0$, and consider the following matrix

$$A = \begin{bmatrix} T^T T & T^T \\ T & O \end{bmatrix}, \tag{14}$$

for which it can be checked that a symmetric generator with respect to $Z_n \oplus Z_m$ is

$$X = \begin{bmatrix} \sqrt{b_0} & b_1/\sqrt{b_0} & \cdot & b_{n-1}/\sqrt{b_0} & t_0 & t_1 & \cdot & t_{m-n} & 0 & \cdot & 0 \\ 0 & b_1/\sqrt{b_0} & \cdot & b_{n-1}/\sqrt{b_0} & t_0 & t_1 & \cdot & t_{m-n} & 0 & \cdot & 0 \end{bmatrix}^T, \qquad \Sigma = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}.$$

After performing n steps of partial triangular factorization using the generalized Schur algorithm, we shall have the factors R and Q in

$$A = \begin{bmatrix} R^T \\ Q \end{bmatrix} [R, Q^T] + \begin{bmatrix} O & O \\ O & S \end{bmatrix}. \tag{15}$$

By comparing (14) and (15), one can easily see that

$$T^T T = R^T R, \qquad T = QR,$$

so that Q is orthogonal because $R^T Q^T Q R = R^T R$. The computation of $T^T T$ needs $nm - \frac{3}{2}n^2 + O(n)$ flops and the partial triangularization needs additional $8m^2 - 4nm + O(m)$ flops (or $4m^2 - 2nm + O(m)$ flops with fast rotations).

Orthogonalization of a Toeplitz matrix. Let $B \in \mathbf{R}^{m \times n}$ be a Toeplitz, block-Toeplitz, or Toeplitz-block matrix of full-column rank, and let us define the block matrix

$$A \equiv \begin{bmatrix} -I & B & O \\ B^T & O & B^T \\ O & B & I \end{bmatrix}. \tag{16}$$

We can easily find a generator of A with respect to $Z_m \oplus Z_n \oplus Z_m$ by inspection. For example, if B is Toeplitz, a generator of A is given by

$$X = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & \tilde{b}_1 & 0 & \tilde{b}_1 \\ \cdot & \cdot & \cdot & \cdot \\ 0 & \tilde{b}_{m-1} & 0 & \tilde{b}_{m-1} \\ -b_0 & 0 & 0 & b_0 \\ -b_{-1} & b_{-1} & b_{-1} & b_{-1} \\ \cdot & \cdot & \cdot & \cdot \\ -b_{1-n} & b_{-n+1} & b_{1-n} & b_{-n+1} \\ 0 & 1 & 1 & 1 \\ 0 & \tilde{b}_1 & 0 & \tilde{b}_1 \\ \cdot & \cdot & \cdot & \cdot \\ 0 & \tilde{b}_{m-1} & 0 & \tilde{b}_{m-1} \end{bmatrix}, \qquad \Sigma = \begin{bmatrix} -1 & & & \\ & -1 & & \\ & & 1 & \\ & & & 1 \end{bmatrix},$$

where $\tilde{b}_i = b_i / b_0$. If we apply the generalized Schur algorithm with the above generator, then after the mth step with $m^2 + 2nm + O(n) + O(m)$ flops, we shall have a generator of

$$A^{(m)} = \begin{bmatrix} B^T B & B^T \\ B & I \end{bmatrix}. \tag{17}$$

After another n steps of partial triangularization with $12mn + 6n^2 + O(m) + O(n)$ flops (or $6mn + 3n^2 + O(m) + O(n)$ flops with fast rotations), we shall have R and Q in

$$A^{(m)} = \begin{bmatrix} R^T \\ Q \end{bmatrix} [R, Q^T] + \begin{bmatrix} O & O \\ O & S \end{bmatrix},$$

such that $B = QR$. One can start with a generator of the block matrix (17), as in the fully windowed case. We note that a closed-form expression for a generator of (17) for block-Toeplitz and Toeplitz-block matrix B can be found in [7]. For a Toeplitz B, the closed-form expression for a generator of (17) can be evaluated in mn flops, and, therefore, it requires less computation to start with it. However, it would be necessary to work with a generator for (16) if B is non-Toeplitz and only its generator is given.

If one wishes to find R^{-1} directly, then one can perform the $(m + n)$ steps of partial triangularization with the matrix

$$A = \begin{bmatrix} -I & B & O \\ B^T & O & I \\ O & I & O \end{bmatrix}.$$

This is because

$$A^{(m)} = \begin{bmatrix} B^TB & I \\ I & O \end{bmatrix} = \begin{bmatrix} R^T \\ U \end{bmatrix} \cdot [R \quad U^T] + \begin{bmatrix} O & O \\ O & S \end{bmatrix},$$

and, therefore, $U = R^{-1}$ because $UR = I$.

Removing forward elimination in square systems. If one's primary interest in the factorization is in solving a square symmetric Toeplitz system of equations,

$$B\mathbf{x} = \mathbf{b}, \quad B = LL^T, \quad B \in \mathbf{R}^{n \times n}, \quad b_0 = 1, \tag{18}$$

then one might want to obtain the transformed right-side vector $\mathbf{y} \equiv L^{-1}\mathbf{b}$ during the course of the factorization process (see, e.g., [2], [25]). This can also be done using the generalized Schur algorithm by performing the following triangular factorization of the matrix A,

$$A \equiv [B \quad \mathbf{b}] = L \cdot [L^T, \mathbf{y}] \tag{19}$$

whence the solution to (18) can be obtained by solving the triangular system of equations

$$L^T\mathbf{x} = \mathbf{y}. \tag{20}$$

Note that the matrix A has displacement rank three with respect to $\{Z_n, Z_n \oplus Z_1\}$, $(Z_1 = 0)$, and a generator is given by

$$X = \begin{bmatrix} b_0 & 0 & \beta_0 \\ b_1 & b_1 & \beta_1 \\ \cdot & \cdot & \cdot \\ b_{n-1} & b_{n-1} & \beta_{n-1} \end{bmatrix}, \qquad Y = \begin{bmatrix} b_0 & 0 & 0 \\ b_1 & -b_1 & 0 \\ \cdot & \cdot & \cdot \\ b_{n-1} & -b_{n-1} & 0 \\ 0 & 0 & 1 \end{bmatrix},$$

where

$$\mathbf{b} = [\beta_0, \beta_1, \ldots, \beta_{n-1}]^T.$$

The triangularization in (19) needs $2n^2 + (n^2/2) + O(n)$ flops (or $n^2 + (n^2/2) + O(n)$ flops with fast rotations). Note that there is no saving in computing $\mathbf{y} = L^{-1}\mathbf{b}$, as above, over the conventional forward elimination method.

Removing back substitution in square systems. From a hardware implementation point of view, the back-substitution step in (20) can be quite cumbersome [17]. This

back-substitution process can also be eliminated by performing the partial triangularization of the matrix [20]

$$A = \begin{bmatrix} B & -\mathbf{b} \\ I & 0 \end{bmatrix} = \begin{bmatrix} L \\ U \end{bmatrix} [L^T, -\mathbf{y}] + \begin{bmatrix} O & 0 \\ O & \mathbf{s} \end{bmatrix}. \tag{21}$$

Notice that the solution $B^{-1}\mathbf{b}$ is the Schur complement of B in A. For Toeplitz B ($b_0 = 1$), a generator of A in (21) with respect to $\{Z_n \oplus Z_n, Z_n \oplus 0\}$ is given by

$$X = \begin{bmatrix} b_0 & 0 & \beta_0 \\ b_1 & b_1 & \beta_1 \\ \cdot & \cdot & \cdot \\ b_{n-1} & b_{n-1} & \beta_{n-1} \\ \mathbf{e}_1 & \mathbf{e}_1 & 0 \end{bmatrix}, \qquad Y = \begin{bmatrix} b_0 & 0 & 0 \\ b_1 & -b_1 & 0 \\ \cdot & \cdot & \cdot \\ b_{n-1} & -b_{n-1} & 0 \\ 0 & 0 & 1 \end{bmatrix},$$

where $\mathbf{e}_1 = [1, 0, \ldots, 0]^T$. After n steps of partial triangularization indicated in (21) with $5n^2 + O(n)$ flops (or $3n^2 + O(n)$ flops with fast rotations), we shall have a "generator of the solution vector," from which we can read out the solution after certain normalizations; see [29] for details.

Solving least-squares problems without back substitution. To solve the weighted least-squares problem of minimizing

$$\| B_2(B_1\mathbf{x} - \mathbf{b}) \|_2,$$

where B_1 and B_2 are full-rank block-Toeplitz or Toeplitz-block matrices, we form the matrix

$$A = \begin{bmatrix} -B_2 & B_1 & -\mathbf{b} \\ B_1^T & O & 0 \\ O & I & 0 \end{bmatrix}. \tag{22}$$

Now notice that the least-squares solution

$$\mathbf{x} = (B_1^T B_2^{-1} B_1)^{-1} B_2^T \mathbf{b} \tag{23}$$

is the Schur complement of the submatrix

$$\begin{bmatrix} -B_2 & B_1 \\ B_1^T & O \end{bmatrix}.$$

The displacement rank of the matrix A in (22) is five. After $m + n$ steps of the generalized Schur algorithm, we shall have the solution (23) [see [29] for a generator of (22)].

Regularization. If the given Toeplitz least-squares system is particularly ill conditioned, it is meaningless to compute the exact (least-squares) solution, because small perturbations of the matrix can cause very large perturbations in the solution. In such cases, we may solve the following regularized system [19], [36], [39], [44]

$$\begin{bmatrix} B \\ \eta L \end{bmatrix} \mathbf{x} = \begin{bmatrix} \mathbf{b} \\ 0 \end{bmatrix}, \quad B \in \mathbf{R}^{m \times n}, \quad L\text{: lower triangular banded Toeplitz matrix.}$$

This can be done by partial triangularization of the matrix

$$A = \left[\begin{array}{cc|cc} & & B & b \\ & -I & \eta L & 0 \\ \hline B^T & \eta L & O & 0 \\ O & & I & 0 \end{array}\right]. \tag{24}$$

The matrix A in (24) has displacement rank five. After $m + 2n$ steps of the generalized Schur algorithm, we shall have the solution. We may remark that this technique of regularization is known as the *leakage method* (adding white (if $L = I$) or colored (if L is banded) noise with variance η^2 to the data sample) in the signal processing literature.

Generalized Gohberg–Semencul formulas ([22], [24]). Generalized Gohberg–Semencul formulas for the matrices

$$(T^TT)^{-1}, \quad T_2^TT_1^{-1}T_2, \quad I - T(T^TT)^{-1}T^T, \quad (T^TT)^{-1}T^T,$$

can be obtained after partial triangularization of the (1,1) block of the matrices

$$\begin{bmatrix} T^TT & I \\ I & O \end{bmatrix}, \quad \begin{bmatrix} T_1 & T_2 \\ T_2^T & O \end{bmatrix}, \quad \begin{bmatrix} T^TT & T^T \\ T & I \end{bmatrix}, \quad \begin{bmatrix} T^TT & T^T \\ I & O \end{bmatrix}$$

using the generalized Schur algorithm (see [14], [26], [28], [31], [42] for related results).

5. Concluding remarks. We have generalized earlier definitions of the displacement for Toeplitz-like matrices and presented a correspondingly generalized Schur algorithm for obtaining their triangular factors and their displacement representations. Derived matrices obtained as products and inverses of Toeplitz matrices can be nicely handled by formulating them as Schur complements of entries in a suitably defined Toeplitz-block matrix. The extended definition allows us to efficiently handle block-Toeplitz and Toeplitz-block matrices and Schur complements with respect to the leading (block) entries of such matrices. Some interesting examples were given in § 4. Although the result that displacement rank is not increased under Schur complementation has been know for over a decade (see [5], [13], [37]), the failure to use a generalized definition of displacement made further analysis more cumbersome; similarly cumbersome were the efforts to find expressions for the generators of derived matrices such as $T_1 - T_2T_3^{-1}T_4$.

We may note that appropriate modifications of the above approach can be used to study Hankel, Vandermonde, Hilbert, and Cauchy matrices and derived matrices (see [8]). Among earlier studies of such matrices, we may mention [13], [23], [26], [32]–[34].

Finally, we remark that numerical stability issues are not examined here; studies are in progress on appropriate modifications that can improve the stability.

Appendix. Given the *displacement* of a matrix, we can obtain a generator of the matrix by representing each pair of nonzero columns and rows that cross at the main diagonal as a sum of two rank-one matrices. More precisely, the following procedure can be used to find a (possibly nonminimal) generator from the given displacement with $O(mn)$ flops.

Finding a generator
Input: The displacement $\nabla_{(F^f,F^b)}A$
Output: A generator $\{X, Y\}$ of A
Procedure:
  $X := \{\ \}$; $Y := \{\ \}$;
  while there is nonzero column or row
    for each pair of a column $\mathbf{u}$ and a row $\mathbf{v}^T$ that crosses in the ith position of the main diagonal of $\nabla_{(F^f,F^b)}A$
      if $u_i \neq 0$ **then**
        $\tilde{\mathbf{u}} := \mathbf{u}/u_i^{1/2}$; $\bar{\mathbf{u}} := \mathbf{u}$ except $\bar{u}_i = 0$;
        $\tilde{\mathbf{v}} := \mathbf{v}/u_i^{1/2}$; $\bar{\mathbf{v}} := \mathbf{v}$ except $\bar{v}_i = 0$;

else
$\tilde{\mathbf{u}} := \mathbf{u}$ except $\tilde{u}_i = 1/2$; $\bar{\mathbf{u}} := \mathbf{u}$ except $\bar{u}_i = -1/2$;
$\tilde{\mathbf{v}} := \mathbf{v}$ except $\tilde{v}_i = 1/2$; $\bar{\mathbf{v}} := \mathbf{v}$ except $\bar{v}_i = -1/2$;
end;
$X := [X, \tilde{\mathbf{u}}, \bar{\mathbf{u}}]$; $Y := [Y, \tilde{\mathbf{v}}, -\bar{\mathbf{v}}]$;
Remove **u** and **v**;
end;
for each an unpaired ith column **u**
$X := [X, \mathbf{u}]$; $Y := [y, \mathbf{e}_i]$;
Remove **u** and **v**;
end
for each an unpaired jth row $\mathbf{v}^T$
$X := [X, \mathbf{e}_j]$; $Y := [Y, \mathbf{v}]$;
Remove **u** and **v**;
end
return $\{X, Y\}$

ON THE CONTROLLABILITY OF MATRIX PAIRS (A, K) WITH K POSITIVE SEMIDEFINITE, II*

DAVID CARLSON†

Abstract. The subject of the previous article by David Carlson, B. N. Datta, and Hans Schneider [*SIAM Journal on Algebraic and Discrete Methods*, 5 (1984) pp. 346–350] is revisited to improve and clarify results given there and elsewhere.

Key words. controllability, Lyapunov matrix maps

AMS subject classifications. 15A24, 15A18

Introduction. For notation and terminology, we refer to the previous article [CDS]. In particular, A, H, and K are $n \times n$ complex matrices and H and K are hermitian. The following basic result, due independently to Chen [C] and Wimmer [Wi], has had many useful consequences (cf. [CD 1979a], [CD 1979b], [D]).

THEOREM A. *Suppose that* $K = AH + HA^* \geqq 0$. *If* (A, K) *is controllable, then* $\delta(A) = 0$ *and* H *is nonsingular* (*and* $\pi(H) = \pi(A)$, $\upsilon(H) = \upsilon(A)$).

In particular, a search for a converse to this theorem led to [CDS]. The principal result of that article, Theorem 4, is stated below as Theorem B.

If $\Delta(A) = \prod_{i,j=1}^{n} (\lambda_i + \bar{\lambda}_j)$, then the map $L_A(H) = AH + HA^*$ is one to one if and only if (iff) $\Delta(A) \neq 0$. Note that $\Delta(A) \neq 0$ implies that $\delta(A) = 0$ but not conversely.

We will often assume that A is a block-diagonal matrix,

$$A = \operatorname{diag}(A_{11}, \ldots, A_{pp}), \quad \text{with } A_{11}, \ldots, A_{pp} \text{ square.} \tag{1}$$

Under (1), we will assume that matrices $H = [H_{ij}]$ and $K = [K_{ij}]$ are partitioned conformably with A and will define $\hat{H} = \operatorname{diag}(H_{11}, \ldots, H_{pp})$ and $\hat{K} = \operatorname{diag}(K_{11}, \ldots, K_{pp})$. Observe that if $L_A(H) = K$, then also $L_A(\hat{H}) = \hat{K}$.

THEOREM B. *Let* A *be a block-diagonal matrix, as in* (1), *and suppose that* $\delta(A) = 0$ *and*

$$\sigma(A_{ii}) \cap \sigma(A_{jj}) = \varnothing, \qquad i, j = 1, \ldots, p, \ i \neq j. \tag{2}$$

Suppose that $K = AH + HA^* \geqq 0$. Then the following are equivalent:

(3a) (A, K) is controllable,
(3b) $(A, \hat{K})$ is controllable,
(4a) H is nonsingular and $(A^*, H^{-1}K)$ is controllable,
(4b) $\hat{H}$ is nonsingular,
(5a) $x^*Hx \neq 0$ for every eigenvector x of A^*,
(5b) $x^*\hat{H}x \neq 0$ for every eigenvector x of A^*.

We shall reprove and improve the lemmas in [CDS] that lead to Theorem B. We shall show that (3a), (3b), and (4a) are equivalent whenever $K = AH + HA^* \geqq 0$ (the assumptions that $\delta(A) = 0$ and that A is written in block-diagonal form are not necessary)

* Received by the editors December 10, 1990; accepted for publication (in revised form) March 21, 1992. This research was conducted at the Technion-Israel Institute of Technology, Haifa, Israel and was supported by the National Science Foundation grant DMS-8808237 and by the Technion.

† Mathematical Sciences Department, San Diego State University, San Diego, California 92182 (carlson@math.sdsu.edu).

and present an alternate form of Theorem B for block-diagonal A without the general assumption that $\delta(A) = 0$.

Given a matrix B, not necessarily square, the range of B is denoted in [CDS] by Im B and the controllability space of (A, B) (the smallest A-invariant space containing Im B) by $C(A, B)$. We shall emphasize here common aspects of these two concepts by denoting the range of B by $R(B)$ and the controllability space of (A, B) by $R_A(B)$. Note that always $R(B) \subseteq R_A(B)$.

The following result appears as Corollary II.2 of [CS]; we shall extend it to a bound on dim $R_A(K)$.

THEOREM C. *Suppose that* $K = AH + HA^* \geqq 0$. *Then*

$$\operatorname{rank}(K) \leqq \pi(A) + \nu(A) + \sum_{i=1}^{q} [\delta_i/2],$$

where $\delta_1, \ldots, \delta_q$ *are the degrees of the elementary divisors associated with imaginary eigenvalues of* A *and* $[x]$ *is the floor or greatest integer function.*

Finally, we shall improve the following result, which appeared as Theorem 4 of [CD 1979a].

THEOREM D. *Suppose that* $AH + HA^* = HBB^*H$ *and that*

(6) (A^*, B) *is controllable.*

Then the following are equivalent:

(7) H *is nonsingular,*

(8) (A, HB) *is controllable.*

Results on controllability spaces. In the proof of Lemma 1 of [CDS], the role of the critical assumption (2) is not made explicit. That role is explicit in the proof of our Proposition 1. It is closely related to Proposition 0.4 of [Wo] and provides a proof of Exercise 1.5 of [Wo].

PROPOSITION 1. *Let* A *be block diagonal as in* (1) *and suppose that* (2) *holds. Let* $B = (B_i)$ *be partitioned conformably with* A. *Then* $R_A(B) = \oplus_{i=1}^{p} R_{A_{ii}}(B_i)$.

Proof. It is clear that $R_A(B) \subseteq \oplus_{i=1}^{p} R_{A_{ii}}(B_i)$. To complete the proof, it is sufficient to show that for $i = 1, \ldots, p$,

$$0 \oplus \cdots \oplus 0 \oplus R_{A_{ii}}(B_i) \oplus 0 \oplus \cdots \oplus 0 \subseteq R_A(B).$$

By simultaneous permutation of the blocks of A and B, it is sufficient to show this for $i = 1$.

As $\sigma(A_{11}) \cap \sigma(\operatorname{diag}(A_{22}, \ldots, A_{pp})) = \varnothing$ by (2) there exists a polynomial $f(\lambda)$ over C for which $f(A_{11}) = I, f(\operatorname{diag}(A_{22}, \ldots, A_{pp})) = 0$. Thus,

$$f(A)B = \begin{bmatrix} I & & \\ & O & \\ & & \ddots \\ & & & 0 \end{bmatrix} \begin{bmatrix} B_1 \\ B_2 \\ \vdots \\ B_p \end{bmatrix} = \begin{bmatrix} B_1 \\ 0 \\ \vdots \\ 0 \end{bmatrix},$$

so that $R(B_1 \oplus 0 \oplus \cdots \oplus 0) \subseteq R_A(B)$. Similarly, for $j = 1, 2, \ldots,$

$$f(A)A^jB = \begin{bmatrix} I & & \\ & O & \\ & & \ddots \\ & & & 0 \end{bmatrix} \begin{bmatrix} A_{11}^j B_1 \\ A_{22}^j B_2 \\ \vdots \\ A_{pp}^j B_p \end{bmatrix} = \begin{bmatrix} A_{11}^j B_1 \\ 0 \\ \vdots \\ 0 \end{bmatrix}$$

so that $R(A_{11}^j B_1 \oplus 0 \oplus \cdots \oplus 0) \subseteq R_A(B)$. The result follows. □

It is clear from Proposition 1 that if A is block diagonal as in (1), $B = (B_i)$ and $C = (C_i)$ are partitioned conformably with A and $R(C_i) \subseteq R(B_i)$, $i = 1, \ldots, p$, then

$$R_A(C) = \bigoplus_{i=1}^{b} R_{A_{ii}}(C_i) \subseteq \bigoplus_{i=1}^{b} R_{A_{ii}}(B_i) = R_A(B).$$

This is true even if $R(C) \not\subseteq R(B)$, e.g., take

$$A = \left(\begin{array}{c|c} 1 & 0 \\ \hline 0 & -1 \end{array}\right), \quad B = \left(\begin{array}{c|c} 1 & 1 \\ \hline 1 & 1 \end{array}\right), \quad C = \left(\begin{array}{c|c} 1 & 0 \\ \hline 0 & 1 \end{array}\right).$$

It is known [A] that for $K = (K_{ij}) \geqq 0$,

$$R(K_{ii}) \supseteq R(K_{ij}), \quad i, j = 1, \ldots, p, \quad i \neq j.$$

Let $K_i = (K_{i1}, \ldots, K_{ii}, \ldots, K_{ip})$ and $\hat{K}_i = (0, \ldots, 0, K_{ii}, 0, \ldots, 0)$ for $i = 1, \ldots, p$; then

$$R(\hat{K}_i) = R(K_{ii}) = R(K_i),$$

so we have $R_A(\hat{K}) = R_A(K)$, thus completing the proof of Lemma 1, our version of Lemma 1 of [CDS].

LEMMA 1. *Let A be block diagonal as in* (1) *and suppose that* (2) *holds. For $K \geqq 0$, $R_A(\hat{K}) = R_A(K)$, and* (3a) *and* (3b) *are equivalent.*

We next show that the best possible bound on the rank of $K = AH + HA^* \geqq 0$ given in Theorem C extends to a bound on the dimension of $R_A(K)$. The proof of Theorem C in [CS] extends easily to show that the bound (9) is also best possible.

THEOREM 1. *Suppose that $K = AH + HA^* \geqq 0$. Then*

$$\text{rank } K \leqq \dim (R_A(K)) \leqq \pi(A) + \upsilon(A) + \sum_{i=1}^{q} [\delta_i/2]. \tag{9}$$

Proof. We follow and extend the proof of Corollary II.2 in [CS]. In this proof, $A = \text{diag}\,(A_{11}, \ldots, A_{q+1,q+1})$, where $A_{11}, \ldots, A_{q+1,q+1}$ are square, and, for $i = 1, \ldots, q$, A_{ii} is a single upper-triangular Jordan block of order δ_i associated with an imaginary eigenvalue of A. With $H = [H_{ij}]$ and $K = [K_{ij}]$ partitioned conformably, for $i = 1, \ldots, q$, K_{ii} has by Theorem II of [CS] at most $[\delta_i/2]$ nonzero rows; the bottom $\delta_i - [\delta_i/2]$ rows are zero.

Because $K \geqq 0$, this must also be true for $K_i = [K_{i1}, \ldots, K_{i,q+1}]$. And because for $j = 1, 2, \ldots$, A^j has conformable block-diagonal form, with upper-triangular diagonal blocks, this same statement about zero and possibly nonzero rows holds for $A^j K_i$. □

Suppose $K = AH + HA^* \geqq 0$ for some $H \neq 0$. As noted in the proof of Theorem IV of [CS], there exists a nonsingular S for which

$$SAS^{-1} = \begin{pmatrix} A_{11} & A_{12} \\ 0 & A_{22} \end{pmatrix}, \qquad SHS^* = \begin{pmatrix} H_{11} & 0 \\ 0 & 0 \end{pmatrix},$$

with H_{11} nonsingular, and then

$$SKS^* = (SAS^{-1})(SHS^*) + (SHS^*)(SAS^{-1})^* = \begin{pmatrix} A_{11}H_{11} + H_{11}A_{11}^* & 0 \\ 0 & 0 \end{pmatrix}.$$

It follows that (see also Lemma 3 of [CL])

$$R_A(K) \subseteq R(H), \tag{10}$$

which explains in a structural way the statement in Theorem A that H is nonsingular whenever (A, K) is controllable.

We next explore the case of equality in (10). Suppose first that A has a single eigenvalue, which is imaginary. Then by the argument leading to (10) and Theorem 1 applied to A_{11}, H_{11}, and K_{11}, if $K = AH + HA^* \geqq 0$, then whenever $H \neq 0$ we cannot have $R_A(K) = R(H)$. That is to say, $R_A(K) = R(H)$ iff $H = 0$.

We can now generalize Lemma 2 of [CDS]. A decomposition similar to that in our Lemma 2 appears in Theorem 4.7 of [HS].

LEMMA 2. *Let A be block diagonal as in* (1), *with* (2) *and*

(11) *either $\Delta(A_{ii}) \neq 0$, or A_{ii} has a single eigenvalue that is imaginary, $i = 1, \ldots, p$,*

holding. Suppose $K = AH + HA^* \geqq 0$.
Then $R_A(K) \subseteq R(\hat{H})$, with equality iff $H_{ii} = 0$ for all $i = 1, \ldots, p$ for which A_{ii} has a single imaginary eigenvalue.

Proof. Because $K = L_A(H) \geqq 0$, then also $\hat{K} = L_A(\hat{H}) \geqq 0$, so that

$$R_A(K) = R_A(\hat{K}) \subseteq R(\hat{H})$$

by Lemma 1 and (10). As

$$R_A(\hat{K}) = \bigoplus_{i=1}^{p} R_{A_{ii}}(K_{ii}) \quad \text{and} \quad R(\hat{H}) = \bigoplus_{i=1}^{p} R(H_{ii}),$$

the statement on equality follows from Corollary 2 of [CL] for A_{ii} with $\Delta(A_{ii}) \neq 0$ and from our remarks above for A_{ii} with a single imaginary eigenvalue. □

Note that every square complex matrix is similar to a block-diagonal matrix as in (1), with (2) and (11) holding.

Note also that Lemma 2 may be regarded as a more structural explanation of another part of Theorem A: if (A, K) is controllable, then so is $(A, \hat{K})$, and by (10) $\hat{H}$ is nonsingular, and A can have no imaginary eigenvalue.

Results on controllability. We first strengthen Theorem D.

THEOREM 2. *Suppose $AH + HA^* = HBB^*H$. Then* (8) *((A, HB) is controllable) iff* (6) *((A^*, B) is controllable) and* (7) *(H is nonsingular).*

Proof. That (6) and (7) together imply (8) is part of Theorem D. Suppose now that (8) holds, then also (A, HBB^*H) is controllable and $HBB^*H \geqq 0$.
It follows from Theorem A that H is nonsingular. Now

$$H^{-1}A + A^*H^{-1} = H^{-1}(HBB^*H)H^{-1} = BB^* \geqq 0$$

and, applying Theorem D again, $(A^*, H^{-1}(HB) = B)$ is controllable. □

Observe that (6) does not imply (7) or (8) (take $H = 0$) and that (7) does not imply (6) or (8) (take $A = 0$ and $B = 0$).

We may now reformulate and prove Theorem B without the assumption that $\delta(A) = 0$.

THEOREM 3. *Let A be block diagonal as in* (1), *with* (2) *and* (11) *holding. Suppose that $K = AH + HA^* \geqq 0$. The following are equivalent*: (3a), (3b), (4a), $\delta(A) = 0$ *and* (4b), $\delta(A) = 0$ *and* (5a), $\delta(A) = 0$ *and* (5b).

Proof. The proof in [CDS] that (3a) iff (5a) holds without the assumption that $\delta(A) = 0$.

Recall that (A, B) is controllable iff (A, BB^*) is. Now H is nonsingular if (3a) holds (by Theorem A) or if (4a) holds (by hypothesis). From $H^{-1}(AH + HA^* = K)H^{-1}$ we obtain

$$A^*H^{-1} + H^{-1}A = H^{-1}KH,$$

and now (3a) and (4a) are equivalent by Theorem 2 applied to A^*, H^{-1}, and $K = BB^*$.

The rest of the proof follows immediately from Theorems A and B. □

Acknowledgment. The author wishes to thank the referees, whose comments have significantly clarified the presentation.

REDUCTION OF A TRANSFER FUNCTION VIA AN OBSERVABILITY MATRIX*

STEPHEN BARNETT†

Abstract. An algorithm is given for reduction of a scalar transfer function $g(s)$ to its lowest terms. The main step is to reduce the observability matrix for a controllable canonical form state-space realization of $g(s)$ to a block-triangular form by row operations. No polynomial manipulations are required and only a single rank computation is needed. As a byproduct, other properties of the numerator and denominator of $g(s)$ are obtained with little extra effort. The method can be extended to the case when a basis of orthogonal polynomials is used.

Key words. transfer function reduction, observability matrix

AMS subject classifications. 15, 93

1. Introduction.

Consider a given proper transfer function

$$g(s) = \frac{b(s)}{a(s)} \tag{1.1}$$

$$= \frac{b_0 s^m + b_1 s^{m-1} + \cdots + b_m}{s^n + a_1 s^{n-1} + \cdots + a_n}, \tag{1.2}$$

where $b_0 \neq 0$ and $t = n - m \geq 1$. The state-space realization of (1.2) in controllable canonical form is

$$\dot{x} = Ax + du, \qquad y = cx, \tag{1.3}$$

where

$$d = [0, 0, \ldots, 0, 1]^T, \qquad c = [b_m, b_{m-1}, \ldots, b_0, 0, \ldots, 0], \tag{1.4}$$

and A is an $n \times n$ companion matrix associated with $a(s)$ in the form

$$A = \begin{bmatrix} 0 & & I_{n-1} \\ -a_n & \cdots & -a_1 \end{bmatrix}, \tag{1.5}$$

where I_{n-1} denotes the unit matrix of order $n - 1$. If the realization (1.3) is completely observable, then $g(s)$ is irreducible. If not, then $g(s)$ can be reduced to the form

$$\frac{\beta(s)}{\alpha(s)} = \frac{\beta_0 s^{m-k} + \beta_1 s^{m-k-1} + \cdots + \beta_{m-k}}{s^{n-k} + \alpha_1 s^{n-k-1} + \cdots + \alpha_{n-k}}, \tag{1.6}$$

where the greatest common divisor $d(s)$ of $a(s)$ and $b(s)$ has degree k. There are, of course, many ways of obtaining the reduced form (1.6): for example, determine $d(s)$ by constructing the Routh array associated with $a(s)$ and $b(s)$, and hence obtain $\alpha(s)$ and $\beta(s)$ by direct division; or, to avoid polynomial manipulations, use the Hankel matrix of Markov parameters [10]. A recent method that also avoids divisions has been suggested by Chui and Chen [11] and involves a Sylvester-type resultant matrix. This approach is interesting, because although it has long been known [2, p. 39] how to compute $d(s)$ from a Sylvester matrix, their algorithm produces the reduced form (1.6) directly by using appropriate row operations, without actually finding $d(s)$ itself. However, it seems to be true that for every algorithm involving a Sylvester matrix, there is a corresponding scheme based on using a companion matrix. The purpose of this article is to show how

* Received by the editors November 26, 1990; accepted for publication (in revised form) March 23, 1992.
† Department of Applied Mathematical Studies, University of Leeds, Leeds LS2 9JT, United Kingdom.

the problem of reducing $g(s)$ in (1.1) to the form (1.6) can also be solved in a "companionable" fashion.

2. The algorithm. There is no loss of generality in assuming from now on that $b_0 = 1$, $\beta_0 = 1$ in (1.2) and (1.6), respectively. The algorithm is as follows.

Step 1. Construct the observability matrix M having rows $c, cA, cA^2, \ldots, cA^{n-1}$, where A and c are defined in (1.3). Notice that the first t rows of M are obtained simply by performing repeated cyclic shifts on c, i.e.,

$$cA^i = [\underbrace{0, 0, \ldots, 0}_{i}, b_m, \ldots, b_1, 1, \underbrace{0, \ldots, 0}_{t-i-1}], \quad i = 0, 1, \ldots, t-1.$$

Step 2. Apply elementary row operations to the last m rows of the $n \times 2n$ matrix

$$X = [M, I_n] \tag{2.1}$$

so as to reduce it to $[X_1, X_2]$, where the $n \times n$ matrix X_1 has the block-triangular form

$$X_1 = \begin{matrix} \\ t \\ m \end{matrix}\!\!\begin{matrix} \begin{matrix} m & t \end{matrix} \\ \begin{bmatrix} X_{11} & X_{12} \\ X_{21} & 0 \end{bmatrix} \end{matrix}. \tag{2.2}$$

In (2.2) the first t rows of X_1 are precisely the first t rows of M constructed in Step 1, so in particular X_{12} is lower triangular and X_{21} is upper triangular relative to its secondary (northeast to southwest) diagonal.

Notice that when $t = 1$, then X_1 is itself upper triangular in this latter sense.

Step 3. The matrix X_{21} is nonsingular if and only if $g(s)$ in (1.1) is irreducible, so if X_{21} in (2.2) has no zero rows, then no reduction of $g(s)$ is possible. Otherwise, make the last k rows of X_{21} zero, and row $n-k+1$ of X_2 is then by Corollary 1.2 of [3]

$$[\alpha_{n-k}, \alpha_{n-k-1}, \ldots, \alpha_1, 1, 0, \ldots, 0],$$

which gives the required coefficients of the denominator in (1.6).

Step 4. Construct the triangular Hankel matrix

$$W = \begin{bmatrix} 0 & & & 0 & 1 \\ & & \iddots & 1 & w_1 \\ & \iddots & \iddots & \iddots & \vdots \\ 0 & 1 & w_1 & \cdots & w_{m-k-1} \\ 1 & w_1 & w_2 & \cdots & w_{m-k} \end{bmatrix} \tag{2.3}$$

of order $m-k+1$, where

$$w_j = -\sum_{i=1}^{j} a_i w_{j-i}, \quad w_0 = 1; \quad j = 1, 2, \ldots, m-k. \tag{2.4}$$

Step 5. The required coefficients of the numerator in (1.6) are given by

$$[\beta_{m-k}, \beta_{m-k-1}, \ldots, \beta_1, 1] = [\alpha_{m-k}, \alpha_{m-k-1}, \ldots, \alpha_1, 1]WT, \tag{2.5}$$

where T is the triangular Hankel matrix

$$T = \begin{bmatrix} b_{m-k} & b_{m-k-1} & \cdots & & b_1 & 1 \\ b_{m-k-1} & b_{m-k-2} & \cdots & b_1 & 1 & 0 \\ \vdots & \vdots & \iddots & \iddots & \iddots & \vdots \\ b_1 & 1 & \iddots & & 0 & \\ 1 & 0 & & & & \end{bmatrix}. \tag{2.6}$$

Proof. Steps 1, 2, and 3 are derived in [3] in a more general setting. The theory behind Steps 4 and 5 is developed in detail in [7] and relies on establishing a relationship between $b(A)$ and $a(B)$, where B is a companion matrix for $b(s)$. □

The procedure can in fact still be applied if the degrees of $b(s)$ and $a(s)$ are equal: simply replace the numerator in (1.1) by $b(s) - a(s)$, so that the vector c in (1.4) used in Step 1 becomes

$$[b_n - a_n, b_{n-1} - a_{n-1}, \ldots, b_1 - a_1] \tag{2.7}$$

and select the appropriate value of t in (2.2).

3. Illustrative examples.

Example 1. Consider the example used in [11] with $n = 4$, namely,

$$g(s) = \frac{s^4 + \frac{3}{2}s^3 + 2s^2 + s + \frac{1}{2}}{s^4 - \frac{1}{2}s^3 + 2s^2 + \frac{1}{2}s + 1}. \tag{3.1}$$

From (2.7) we have

$$c = [-\tfrac{1}{2}, \tfrac{1}{2}, 0, 2],$$

and from (1.5) the companion matrix for the denominator in (3.1) is

$$A = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ -1 & -\frac{1}{2} & -2 & \frac{1}{2} \end{bmatrix}.$$

After constructing the observability matrix M in Step 1, the matrix in (2.1) becomes

$$X = \left[\begin{array}{cccc:c} -\frac{1}{2} & \frac{1}{2} & 0 & 2 & \\ -2 & -\frac{3}{2} & -\frac{7}{2} & 1 & \\ -1 & -\frac{5}{2} & -\frac{7}{2} & -3 & I_4 \\ 3 & \frac{1}{2} & \frac{7}{2} & -5 & \end{array}\right].$$

M

Using appropriate row operations, this is easily reduced to the stated form in Step 2:

$$\left[\begin{array}{cccc:cccc} -\frac{1}{2} & \frac{1}{2} & 0 & 2 & 1 & 0 & 0 & 0 \\ -\frac{7}{4} & -\frac{7}{4} & -\frac{7}{2} & 0 & -\frac{1}{2} & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 2 & -1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 2 & 1 & 0 & 1 \end{array}\right]. \tag{3.2}$$

X_1 $\qquad$ X_2

Because the last two rows of X_1 in (3.2) are zero, it follows from Step 3 that $k = 2$, and hence row $n - k + 1 = 3$ of X_2 gives the denominator in (1.6) as $\alpha(s) = s^2 - s + 2$.

Using (2.4), the matrix in (2.3) is easily found to be

$$W = \begin{bmatrix} 0 & 0 & 1 \\ 0 & 1 & \frac{1}{2} \\ 1 & \frac{1}{2} & -\frac{7}{4} \end{bmatrix}$$

and from (2.6)

$$T = \begin{bmatrix} 2 & \frac{3}{2} & 1 \\ \frac{3}{2} & 1 & 0 \\ 1 & 0 & 0 \end{bmatrix}.$$

Finally, from (2.5) we have

$$[\beta_2, \beta_1, 1] = [2, -1, 1]WT$$
$$= [1, 1, 1]$$

so that the numerator in (1.6) is $\beta(s) = s^2 + s + 1$.

It should be noted that determination of k from X_1 is equivalent to finding the rank of M; in the solution of the reduction problem in [11], three separate rank calculations are necessary.

Example 2. Consider

$$g(s) = \frac{s^3 + 8s^2 + s - 42}{s^5 + 10s^4 + 22s^3 + 4s^2 - 23s - 14}$$

for which $n = 5$ and $t = n - m = 2$. Using A in (1.5) and Step 1, the matrix in (2.1) is found to be

$$X = \left[\begin{array}{ccccc:c} -42 & 1 & 8 & 1 & 0 & \\ 0 & -42 & 1 & 8 & 1 & \\ 14 & 23 & -46 & -21 & -2 & I_5 \\ -28 & -32 & 31 & -2 & -1 & \\ -14 & -51 & -28 & 53 & 8 & \end{array}\right].$$
$$M$$

This is reduced by row operations to the required form in Step 2 with

$$X_1 = \left[\begin{array}{ccc:cc} -42 & 1 & 8 & 1 & 0 \\ 0 & -42 & 1 & 8 & 1 \\ \hline -196 & -56 & -4 & 0 & 0 \\ 1008 & 144 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{array}\right], \tag{3.3}$$
$$X_{21}$$

$$X_2 = \left[\begin{array}{ccccc} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ \hline 5 & 2 & 1 & 0 & 0 \\ -26 & -7 & -4 & 1 & 0 \\ -2 & -3 & 1 & 3 & 1 \end{array}\right]. \tag{3.4}$$

It follows from Step 3 by inspection of X_1 that $k = 1$, and from row $n - k + 1 = 5$ of X_2 the denominator in (1.6) is

$$\alpha(s) = s^4 + 3s^3 + s^2 - 3s - 2.$$

The above part of the example is essentially as worked out in [3]. To determine $\beta(s)$, from (2.3), (2.4), and (2.6) we have

$$W = \begin{bmatrix} 0 & 0 & 1 \\ 0 & 1 & -10 \\ 1 & -10 & 78 \end{bmatrix}, \qquad T = \begin{bmatrix} 1 & 8 & 1 \\ 8 & 1 & 0 \\ 1 & 0 & 0 \end{bmatrix}$$

so that in (2.5)

$$[\beta_2, \beta_1, 1] = [1, 3, 1]WT = [-6, 1, 1],$$

whence the numerator in (1.6) is $\beta(s) = s^2 + s - 6$.

For the purposes of this article, only row $n - k + 1$ of X_2 needs to be recorded. However, it should be pointed out that the other rows of X_1 do in fact give the coefficients of the set of Euclidean remainders associated with $a(s)$ and $b(s)$, as described in [6]. In particular, a greatest common divisor $d(s)$ of $a(s)$ and $b(s)$, if required, is given by the last nonzero row in X_1. Thus, in Example 1, from (3.2) we have

$$d(s) = -\tfrac{7}{2}s^2 - \tfrac{7}{4}s - \tfrac{7}{4},$$

and, for Example 2, (3.3) gives

$$d(s) = 144s + 1008. \tag{3.5}$$

Furthermore, without additional effort, the solution $y(s)$ of the diophantine equation

$$a(s)x(s) + b(s)y(s) = d(s) \tag{3.6}$$

can be read off from row $n - k$ of X_2 [4]. Thus, in Example 2, the fourth row of X_2 in (3.4) gives

$$y(s) = s^3 - 4s^2 - 7s - 26,$$

where $d(s)$ is given in (3.5). Finally, following [7], the coefficients of $-x(s)$ in (3.6) are obtained by multiplying the elements in columns $n - m + 1$ to $n - k + 1$ of row $n - k$ of X_2 by WT. In Example 2, this gives

$$[-4, 1, 0]WT = [-6, 1, 0],$$

showing that $x(s) = -s + 6$.

4. Discussion and conclusions. It has been shown how a given transfer function $g(s)$ can be reduced to its lowest terms by performing row operations on the observability matrix of a controllable canonical form realization so as to reduce it to the block-triangular form (2.2). The reduction of the denominator of $g(s)$ was given in [3], but the complete algorithm is detailed above for the first time.

Like the scheme proposed in [11], there are no polynomial manipulations, but the algorithm in § 2 seems to have several advantages.

(i) There is only a single computation of rank, that of the observability matrix M in Step 3, whereas in [11] $k + 1$ separate calculations of rank are needed.

(ii) It is more natural in a control context to use an observability matrix rather than a Sylvester-type matrix. For example, if a minimal realization of $g(s)$ in state-space form is required, then a standard method [8] is to extract the completely observable part of the realization $\{A, d, c\}$ in (1.3) using a similarity transformation. However, recovering the reduced transfer function then requires inversion of a characteristic matrix, and this is difficult in general.

(iii) The procedure described in this article also produces the greatest common divisor between the numerator and denominator of $g(s)$, as well as the solution of a diophantine equation, and the associated Euclidean remainders, with little extra computational effort. It is interesting that the method still gives the greatest common divisor directly, even in cases where the Routh array applies to $\alpha(s)$ and $\beta(s)$ requires modifications. For example, if

$$g(s)0\,\frac{s^3 - s^2 + s - 1}{s^4 - 2s^3 + 2s^2 - s},$$

then the algorithm gives

$$X_1 = \left[\begin{array}{cccc} -1 & 1 & -1 & 1 \\ \hline 1 & 0 & -1 & 0 \\ 1 & -1 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{array}\right], \qquad X_2 = \begin{bmatrix} 1 & 0 & 0 & 0 \\ -1 & 0 & 1 & 0 \\ -1 & 1 & 0 & 0 \\ 0 & 1 & -1 & 1 \end{bmatrix}.$$

From the form of X_{21} we have $k = 1$, and $n - k + 1 = 4$ of X_2 gives the denominator of the reduced form of $g(s)$ as $s - s^2 + s^3$. The last nonzero row of X_1 shows that the greatest common divisor of the numerator and denominator of $g(s)$ is $s - 1$. The reader can easily check that the first column element in the fourth row of the corresponding Routh array is zero.

(iv) If the numerator and denominator of $g(s)$ are expressed relative to a basis of orthogonal polynomials, then the method described in § 2 for finding $\alpha(s)$ carries over with little modification, provided that the companion matrix is replaced by the comrade matrix [2, p. 372]. However, to find $\beta(s)$, it is necessary to reverse the roles of $a(s)$ and $b(s)$, since there is no analogue of Steps 4 and 5 (for details, see [3] and [5]). The method is therefore applicable to the model-reduction problem when, for example, a transfer function is represented as a ratio of Chebyshev polynomial series [1], [9]. There seems to be no corresponding generalization of the Sylvester-type matrix.

THE SCHUR ALGORITHM FOR MATRIX-VALUED MEROMORPHIC FUNCTIONS*

REUVEN ACKNER†, HANOCH LEV-ARI‡, AND THOMAS KAILATH†

Dedicated to Gene Golub on the occasion of his 60th birthday, with admiration and appreciation.

Abstract. This article extends the classical Schur algorithm to matrix-valued functions that are bounded on the unit circle and have a finite number of Smith–McMillan poles inside the unit disc. With each such function this article associates two infinite sequences: one is the well-known sequence of reflection coefficients (all less than one in magnitude), whereas the other is a sequence of signs. Under certain assumptions, the number of negative signs equals the number of poles within the unit disc. This article shows how to solve tangential interpolation problems using the algorithm and gives a simple proof for the connection between the number of poles inside the unit disc of each solution to the inertia of a certain Pick matrix. Also described is a numerically efficient procedure for carrying out the algorithm that involves only scalar operations.

Key words. Schur algorithm, tangential interpolation, fast algorithms

AMS subject classifications. 30C15, 30D30, 12D10

1. Introduction.

In 1917, Schur [1] introduced a recursive algorithm for parametrization of scalar functions that are analytic and bounded within the unit disc. Since then, the algorithm has been applied in many fields of engineering and mathematics. Among others, applications include estimation and modeling of stochastic processes [2], stability checking [3], [4], filter design [5], [6], fast algorithms for signal processing [7], and H^∞ control [8]. The survey article [7] contains a more detailed discussion of several of these applications. Since its introduction, Schur's algorithm, has been extended in many directions. One such extension is the Nevanlinna algorithm [9], [10]; another is the *modified* Schur algorithm [11]–[13] for meromorphic functions that have a finite number of poles inside the unit disc.

Yet another extension by Delsarte, Genin, and Kamp [14] is the block Schur algorithm for *analytic* matrix-valued functions. This algorithm cannot be applied to functions with poles, because it requires square roots and some of the matrices in the recursion may become indefinite (see also [4], [15]). Furthermore, this recursion is computationally expensive because it requires matrix operations. A first step in a simplification of the matrix algorithm was noted by Fedčina [16], who introduced the *tangential* or *directional* Schur algorithm; in this version the operations are performed in only one "direction" at a time, for example, row after row. This procedure is more attractive because it saves

computations. We also note that the tangential Schur algorithm implicitly appeared in the work of Dewilde and Dym [17]. One contribution of our article is in further reducing the operations in each direction to a set of elementary scalar operations. This process of "scalarization" of the algorithm avoids matrix or vector arithmetic, reduces the computation complexity, and provides the maximum degree of freedom in the implementation.

The main contribution of this article is the extension of the Schur algorithm to functions that are both matrix valued and meromorphic, with a finite number of Smith–McMillan poles inside the unit disc. We do so by combining the results of [17] on the matrix Schur algorithm with the earlier work on scalar meromorphic functions [11]–[13]. In the scalar case, functions with poles, or equivalently with reflection coefficients greater than one in magnitude, are handled by "switching" and performing the classical Schur algorithm on the reciprocal function $1/f_i(z)$ instead of on the original function $f_i(z)$, whenever (the ith reflection coefficient) $f_i(0)$ exceeds one in magnitude. This idea does not apply directly in the matrix case because the matrices involved might not even be square; however, scalarization enables us to use the same idea at each scalar step of the algorithm.

Our version of the algorithm produces a sequence of reflection coefficients $\{k_i\}_{i=0}^{\infty}$ with $|k_i| < 1$ and a sequence of signs $\{\varepsilon_i\}_{i=0}^{\infty}$. The latter contains the information on the number of (Smith–McMillan) poles inside the unit disc of the given function. Whenever the sign in the recursion is positive ($\varepsilon_i = 1$), this number does not change; each time the sign is negative ($\varepsilon_i = -1$), the number of poles decreases by one. As a result, the total number of poles of a function is greater than or equal to the number of negative signs in the sequence $\{\varepsilon_i\}_{i=0}^{\infty}$; equality of these two numbers holds under certain additional conditions (see § 2).

As an application, we show how to solve certain tangential interpolation problems [16], [18, ch. 18] using the Schur algorithm. We also give a simple proof of the fact that the minimum number of poles inside the unit disc of each interpolating function is equal to the number of negative eigenvalues of a Pick matrix that is determined by the given data.

Finally, for computational purposes we describe an array formulation of the algorithm, using coefficients of matrix Taylor expansions. The operations applied to the array are (orthogonal and hyperbolic) rotations and shifts.

As in [13], we shall assume regularity in the sense that no reflection coefficient has unit magnitude; nonregular cases have to be treated by a different approach.

2. Modified Schur algorithm. We shall base our discussion on [17] and extend the results therein to the meromorphic case.

Let $F(z)$ be a $p \times q$ matrix of rational functions with

$$\|F\|_{\infty} = \sup_{0 \leqq \theta < 2\pi} \sigma_{\max}(F(e^{j\theta})) \leqq 1,$$

where $\sigma_{\max}(\cdot)$ denotes the maximum singular value of the matrix. We can always write $F(z)$ as a ratio $F(z) = U_0^{-1}(z)V_0(z)$, where $U_0(z)$ and $V_0(z)$ are left coprime matrix polynomials of sizes $p \times p$ and $p \times q$, respectively [19, ch. 6]. We note that this representation is not unique; however, every such representation has the property that the poles of $F(z)$ are exactly the zeros of $U_0(z)$ (including multiplicity). Define the $p \times (p + q)$ generator matrix of $F(z)$ as

$$G_0(z) = [U_0(z) \quad V_0(z)].$$

Also, choose a sequence of constant $1 \times p$ vectors η_i and a sequence $\{z_i\}_0^\infty$ of extraction points inside the unit disc. Then the first step in the ith stage of the Schur recursion of [17] is

$$\bar{G}_i(z) = G_i(z)\Psi_i(z), \qquad i = 0, 1, \ldots, \tag{1a}$$

where

$$G_i(z) = [U_i(z) \quad V_i(z)], \tag{1b}$$

$$\bar{G}_i(z) = [\bar{U}_i(z) \quad \bar{V}_i(z)], \tag{1c}$$

$$\Psi_i(z) = [I_{p+q} + (B_i(z) - 1)J_{pq}\xi_i^*(\xi_i J_{pq}\xi_i^*)^{-1}\xi_i]W_i, \tag{1d}$$

$$B_i(z) = (z - z_i)/(1 - z_i^* z), \tag{1e}$$

$$\xi_i = \eta_i G_i(z_i), \tag{1f}$$

and W_i is any J_{pq} unitary matrix. Because $\Psi_i(z)$ is clearly analytic inside the unit disc, the first step of each stage of the algorithm preserves the analyticity of the generator. It can be also verified by a direct calculation that

$$\eta_i \bar{G}_i(z_i) = 0. \tag{1g}$$

The second step of the ith stage of the Schur algorithm is given by

$$G_{i+1}(z) = \Phi_i^{-1}(z)\bar{G}_i(z), \tag{2a}$$

where $\Phi_i(z)$ is a $p \times p$ Blaschke factor defined as

$$\Phi_i(z) = I_p + (B_i(z) - 1)\eta_i^*(\eta_i\eta_i^*)^{-1}\eta_i. \tag{2b}$$

The matrix

$$\Phi_i^{-1}(z) = I_p + (B_i^{-1}(z) - 1)\eta_i^*(\eta_i\eta_i^*)^{-1}\eta_i$$

is not analytic inside the unit disc because of the simple pole at $z = z_i$. Nevertheless, the resulting generator $G_{i+1}(z)$ in (2a) is analytic at $z = z_i$. To prove this, we rewrite (2a) in the form

$$G_{i+1}(z) = [I_p - \eta_i^*(\eta_i\eta_i^*)^{-1}\eta_i]\bar{G}_i(z) + \eta_i^*(\eta_i\eta_i^*)^{-1}[B_i^{-1}(z)\eta_i\bar{G}_i(z)].$$

Now, using (1g), we can easily see that $G_{i+1}(z)$ is finite at $z = z_i$.

Another property that is preserved by the algorithm is the boundedness of the norm of $F_i(z) = U_i^{-1}(z)V_i(z)$. This follows from the fact that the matrix $\Psi_i(z)$ is J_{pq} paraunitary; hence, $\|U_i^{-1}V_i\|_\infty \leqq 1$ implies that $\|\bar{U}_i^{-1}\bar{V}_i\|_\infty \leqq 1$. Now because

$$F_{i+1}(z) = U_{i+1}^{-1}(z)V_{i+1}(z) = [\Phi_i^{-1}(z)\bar{U}_i(z)]^{-1}[\Phi_i^{-1}(z)\bar{V}_i(z)] = \bar{U}_i^{-1}(z)\bar{V}_i(z),$$

we obtain that if $\|F_i\|_\infty \leqq 1$, then $\|F_{i+1}\|_\infty \leqq 1$.

Steps (1) and (2), which map $G_i(z)$ to $G_{i+1}(z)$, form the Schur algorithm for the matrix case. We remark that the algorithm in [17] contains a third step, which is irrelevant to our discussion, of producing a zero in $F_{i+1}(z)$ at some fixed point.

It is clear from the above presentation that the algorithm preserves the following two properties:

(i) $G_i(z)$ is analytic inside the unit disc.

(ii) $\|F_i\|_\infty = \|U_i^{-1}V_i\|_\infty \leqq 1$.

That is, if the above two properties are satisfied for the generator $G_i(z)$, then they are also satisfied for the generator $G_{i+1}(z)$.

Besides the analyticity of $G_i(z)$ in the unit disc and the property $\|F_i\|_\infty \leqq 1$, a third property is also preserved when $F_i(z)$ is analytic: $U_i(z)$ is nonsingular for every z inside the unit disc. This property is equivalent to $\nu_p(F_i) = 0$, where $\nu_p(\cdot)$ denotes the number of poles of the function inside the unit disc. A matrix $G_i(z)$ that has these three properties is said to be *admissible* in the language of Dewilde and Dym [17]. Thus, the Schur algorithm preserves the admissibility of $G_i(z)$ when $F_i(z)$ is analytic. We shall show below how to extend the third property to the case of meromorphic $F_i(z)$.

We now present a different formulation of the algorithm in [17] by introducing

$$\mu_i = \xi_i W_i,$$

which allows us to write (1a) in the form

$$\bar{G}_i(z) = G_i(z)W_i\left[I_{pq} + (B_i(z) - 1)\frac{J_{pq}\mu_i^*\mu_i}{\mu_i J_{pq}\mu_i^*}\right]. \tag{3}$$

Note that we still have complete freedom in choosing W_i. Let us now define

$$\varepsilon_i = \operatorname{sgn}(\mu_i J_{pq}\mu_i^*) = \operatorname{sgn}(\xi_i J_{pq}\xi_i^*) = \operatorname{sgn}[\eta_i G_i(z_i)J_{pq}G_i^*(z_i)\eta_i^*]. \tag{4}$$

It is convenient to consider separately the cases of $\varepsilon_i = \pm 1$ (the case $\varepsilon_i = 0$ leads to a singularity in the recursion and must be handled by different methods).

Case $\varepsilon_i = 1$. This case occurs, for example, if $F_i(z)$ is analytic and bounded by unity inside the unit disc (see [17]). It is well known that every two vectors with the same Euclidean norm can be (nonuniquely) related by an orthogonal rotation. Similarly, every two vectors with the same J norm can be related by a J-unitary matrix. Because ξ_i has positive J norm, there exists a J-unitary matrix W_i such that μ_i is collinear with $e_1 = [1, 0, \ldots]$, i.e.,

$$\xi_i W_i = (\xi_i J_{pq}\xi_i^*)^{1/2}e_1. \tag{5}$$

This particular choice of $\mu_i = \xi_i W_i$ reduces (1) to the simple form

$$\bar{G}_i(z) = G_i(z)W_i(B_i(z) \oplus I_{p+q-1}). \tag{6a}$$

Using this representation, it is easy to see that the first step in the algorithm consists of a multiplication of $G_i(z)$ from the right by a J_{pq} paraunitary matrix, which is a product of a constant part W_i, and a "dynamic part" $B_i(z) \oplus I_{p+q-1}$.

A similar transformation can also be applied to the second step of the algorithm. We choose a unitary matrix T_i (i.e., $T_i T_i^* = I$), such that

$$\eta_i T_i = \|\eta_i\| e_1.$$

Then, (2) can be written in the form

$$G_{i+1}(z) = T_i(B_i^{-1}(z) \oplus I_{p-1})T_i^*\bar{G}_i(z). \tag{6b}$$

We note that the choice to rotate in the direction of e_1 was for simplification purposes only and that one can choose other directions of rotation as well.

So far the matrix rotation W_i is subject to only one constraint (5). We present here one convenient way of choosing this matrix. First, we use the first entry of the row vector ξ_i as a pivot element and perform $p - 1$ elementary orthogonal rotations that annihilate the elements in positions 2 to p. Next, we use the last entry as a pivot element and annihilate the entries in positions from $p + 1$ to $p + q - 1$ using $q - 1$ elementary orthogonal rotations. The combined effect of these operations is to multiply $G_i(z)$ by a matrix of the form $P_i \oplus Q_i$, where P_i and Q_i are unitary. Because the matrix $P_i \oplus Q_i$ is

J_{pq} unitary, the resulting vector has the form $[x_i, 0, \ldots, 0 | 0, \ldots, 0, y_i]$ with $\xi_i J_{pq} \xi_i^* = |x_i|^2 - |y_i|^2 > 0$. As a result it follows that $|y_i/x_i| < 1$. Finally, we do a single elementary hyperbolic rotation that annihilates the last element of the vector. This last operation can be described as a multiplication by the matrix Θ_i, which is defined as

$$\Theta_i = \begin{pmatrix} L_i & -K_i \\ -K_i^* & M_i \end{pmatrix}, \tag{7a}$$

where

$$L_i = k_i^{-c} \oplus I_{p-1}, \quad M_i = I_{q-1} \oplus k_i^{-c}, \quad K_i = k_i k_i^{-c} e_1^* e_q \tag{7b}$$

and

$$k_i = y_i/x_i, \quad k_i^c = \sqrt{1 - |k_i|^2}, \quad k_i^{-c} = 1/k_i^c. \tag{7c}$$

We note that the condition $\varepsilon_i = 1$ enables us to do the last operation because it guarantees that $|k_i| < 1$. The three different operations can be represented as follows:

$$\xi_i \overset{P_i \oplus Q_i}{\longmapsto} [x_i, 0, \ldots, 0 | 0, \ldots, 0, y_i] \overset{\Theta_i}{\mapsto} [z_i, 0, \ldots, 0 | 0, \ldots, 0]. \tag{8}$$

In conclusion, our matrix W_i has the form

$$W_i = \begin{pmatrix} P_i & 0 \\ 0 & Q_i \end{pmatrix} \begin{pmatrix} L_i & -K_i \\ -K_i^* & M_i \end{pmatrix}. \tag{9}$$

This representation of the Schur algorithm makes it possible to extend the results proven in the scalar case [11]–[13] to matrix-valued functions.

LEMMA 1. *Let $F_i(z) = U_i^{-1}(z) V_i(z)$ be a ratio of two left coprime matrix polynomials and suppose that $\|F_i\|_\infty \leqq 1$ and $\varepsilon_i = 1$ (where ε_i is defined in (4)). Let $F_{i+1}(z) = U_{i+1}^{-1}(z) V_{i+1}(z)$, where $G_{i+1}(z) = [U_{i+1}(z) \quad V_{i+1}(z)]$ is defined by (6). Then*

(i) $\|F_{i+1}\|_\infty \leqq 1$.

(ii) $\nu_p(F_{i+1}) = \nu_p(F_i)$, *where $\nu_p(F)$ denotes the number of poles of $F(z)$ inside the unit disc. The poles here are defined using the Smith–McMillan form (see* [19]).

Proof. (i) Was already proved.

(ii) From (6)–(9) we obtain

$$U_{i+1}(z) = T_i [B_i^{-1}(z) \oplus I_{p-1}] T_i^* [U_i(z) P_i L_i - V_i(z) Q_i K_i^*] [B_i(z) \oplus I_{p-1}]. \tag{10}$$

Consequently,

$$\begin{aligned} \det U_{i+1} &= \det [U_i(z) P_i L_i - V_i(z) Q_i K_i^*] \\ &= \det [(U_i(z) - V_i(z) Q_i K_i^* L_i^{-1} P_i^*) P_i L_i] \\ &= k_i^{-c} \det [U_i(z) - V_i(z) Q_i K_i^* L_i^{-1} P_i^*] \end{aligned}$$

so that

$$\nu_z(U_{i+1}) = \nu_z(U_i - V_i Q_i K_i^* L_i^{-1} P_i^*), \tag{11}$$

where $\nu_z(\cdot)$ denotes the number of zeros of the function inside the unit disc. Now we observe that we can write

$$U_i(z) - V_i(z) Q_i K_i^* L_i^{-1} P_i^* = U_i(z) [I - U_i^{-1}(z) V_i(z) Q_i K_i^* L_i^{-1} P_i^*],$$

where

$$\|U_i^{-1} V_i Q_i K_i^* L_i^{-1} P_i^*\|_\infty \leqq \|U_i^{-1} V_i\|_\infty \|Q_i\|_\infty \|K_i^* L_i^{-1}\|_\infty \|P_i^*\|_\infty \leqq |k_i| < 1.$$

Thus, it follows from the matrix version of the Rouché theorem [15], [20] that

$$\nu_z(U_i - V_iQ_iK_i^*L_i^{-1}P_i^*) = \nu_z(U_i). \tag{12}$$

The last equation together with (11) imply

$$\nu_z(U_{i+1}) = \nu_z(U_i),$$

which is equivalent to (ii). Actually, because $K_i^*L_i^{-1} = k_ie_q^*e_1$ is a rank 1 matrix, we also observe that

$$\det[I - U_i^{-1}(z)V_i(z)Q_ik_ie_q^*e_1P_i^*] = 1 - e_1k_iP_i^*F_i(z)Q_ie_q^*.$$

Because $\|F_i\|_\infty \leqq 1$ and $|k_i| < 1$, it follows from the *scalar* Rouché theorem that

$$\nu_z[1 - e_1k_iP_i^*F_i(z)Q_ie_q^*] = \nu_p[1 - e_1k_iP_i^*F_i(z)Q_ie_q^*],$$

which also implies (12). □

For the analytic case, Lemma 1 provides a proof for the third property in the Dewilde and Dym definition of admissibility. Because an analytic function $F_i(z)$ satisfies $\nu_z(U_i) = 0$ and $\varepsilon_i = 1$, Lemma 1 implies that $\nu_z(U_{i+1}) = 0$; hence, $F_{i+1}(z)$ is also analytic.

Case $\varepsilon_i = -1$. Because in this case $\xi_i = \eta_iG_i(z_i)$ has *negative J* norm, we can rotate it so that μ_i will be collinear with $e_p = [0, \ldots, 0, 1]$. As a result, we find that (6a) is replaced by

$$\bar{G}_i(z) = G_i(z)W_i(I_{p+q-1} \oplus B_i(z)) \tag{13}$$

in complete analogy with the scalar case. Similarly, the form of W_i remains unchanged, but now k_i is selected to eliminate the first element of the vector ξ_i, i.e.,

$$\xi_i \overset{P_i \oplus Q_i}{\longmapsto} [x_i, 0, \ldots, 0 | 0, \ldots, 0, y_i] \overset{\Theta_i}{\mapsto} [0, \ldots, 0 | 0, \ldots, 0, z_i] \tag{14}$$

with $k_i = x_i^*/y_i^*$. We note that the second step in the recursion remains also unchanged and is given by (6b). Finally, when $\varepsilon_i = -1$, the number of poles of $F_i(z)$ decreases by one, as will be proved in the following lemma.

LEMMA 2. *Let* $F_i(z) = U_i^{-1}(z)V_i(z)$ *be a ratio of two left coprime matrix polynomials and suppose* $\|F_i\|_\infty \leqq 1$ *and* $\varepsilon_i = -1$ (*where* ε_i *is defined in* (4)). *Let* $F_{i+1}(z) = U_{i+1}^{-1}(z)V_{i+1}(z)$, *where* $G_{i+1}(z) = [U_{i+1}(z) \quad V_{i+1}(z)]$ *is defined by* (13) *and* (6b). *Then*

(i) $\|F_{i+1}\|_\infty \leqq 1$.

(ii) $\nu_p(F_{i+1}) = \nu_p(F_i) - 1$.

Proof. (i) The proof is the same as in Lemma 1.

(ii) In this case

$$U_{i+1}(z) = T_i[B_i^{-1}(z) \oplus I_{p-1}]T_i^*[U_i - V_i(z)Q_iK_i^*L_i^{-1}P_i^*]$$

(compare with (10)). Thus,

$$\nu_z(U_{i+1}) = \nu_z(U_i - V_iQ_iK_i^*L_i^{-1}P_i^*) - 1.$$

But the last equation and (12) from Lemma 1, which is also valid in this case, imply

$$\nu_z(U_{i+1}) = \nu_z(U_i) - 1,$$

which is equivalent to (ii). □

The following theorem summarizes the results of Lemmas 1 and 2.

THEOREM 1 (Schur algorithm for matrix-valued meromorphic functions). *Let* $F_i(z) = U_i^{-1}(z)V_i(z)$ *be a ratio of two left coprime matrix polynomials with* $\|F_i\|_\infty \leqq 1$

and let η_i *be any vector of dimension* $1 \times p$. *Define* $F_{i+1}(z) = U_{i+1}^{-1}(z)V_{i+1}(z)$ *by the following recursion.*

$$G_{i+1}(z) = \begin{cases} T_i(B_i^{-1}(z) \oplus I_{p-1})T_i^* G_i(z)W_i(B_i(z) \oplus I_{p+q-1}) & \text{if } \varepsilon_i = 1, \\ T_i(B_i^{-1}(z) \oplus I_{p-1})T_i^* G_i(z)W_i(I_{p+q-1} \oplus B_i(z)) & \text{if } \varepsilon_i = -1, \end{cases}$$

where ε_i is defined in (4), W_i is a J_{pq} unitary matrix defined in (9) and satisfies

$$\eta_i G_i(z_i)W_i = \begin{cases} [\eta_i G_i(z_i)J_{pq}G_i^*(z_i)\eta_i^*]^{1/2}[1, 0, \ldots, 0] & \text{if } \varepsilon_i = 1, \\ [-\eta_i G_i(z_i)J_{pq}G_i^*(z_i)\eta_i^*]^{1/2}[0, \ldots, 0, 1] & \text{if } \varepsilon_i = -1, \end{cases}$$

and T_i is a unitary matrix that satisfies

$$\eta_i T_i = \|\eta_i\|[1, 0, \ldots, 0].$$

Then,

(i) $\|F_{i+1}\|_\infty \leqq 1$.

(ii) $\nu_p(F_{i+1}) = \begin{cases} \nu_p(F_i) & \text{if } \varepsilon_i = 1, \\ \nu_p(F_i) - 1 & \text{if } \varepsilon_i = -1. \end{cases}$

COROLLARY. *The number of Smith–McMillan poles inside the unit disc is greater or equal to the number of negative signs in the sequence* $\{\varepsilon_i\}_{i=0}^{\infty}$.

Remarks. (1) Unlike the scalar case, equality does not always hold in the previous corollary. The reason for this is the poor choice of extraction directions η_i, which may not cover all possible directions of the zeros. Equality occurs when at some stage of the algorithm the generator becomes admissible, i.e., $U_i(z)$ does not have zeros inside the unit disc. Such a case happens, for example, when the directions of extraction are chosen to be the standard unit vectors in a cyclic order (see § 4). Another important case for which equality holds is in interpolation problems where the algorithm terminates after a finite number of steps with a constant or analytic (load) function. Yet, another case of equality is discussed in the next remark.

(2) When $U_i(z)$ has a zero inside the unit disc it is possible, by choosing an appropriate extraction point z_i and extraction direction η_i, to make $\varepsilon_i = -1$ and to extract this zero. Thus, by a proper choice of the first extraction points and extraction directions we can extract all the poles of $U_0(z)$ that are inside the unit disc to get an admissible generator.

(3) Although the proofs of Lemmas 1 and 2 use the special choice for the matrix W_i as in (9), Theorem 1 is valid for any matrix W_i that is J unitary. This follows from the fact that multiplication of the generator $G_i(z)$ by a constant J-unitary matrix does not change the number of zeros of $U_i(z)$ inside the unit disc.

(4) Limebeer and Green [21] obtained a similar result to Theorem 1 for the number of poles of the interpolating function arising in model reduction problems. Their derivation, however, is for functions that are meromorphic in a half plane and not in the unit disc and it uses a different method than ours.

(5) Theorem 1 is equivalent to a certain result of Alpay and Dym [22] on the dimension of reproducing kernel spaces associated with the Schur algorithm.

3. Interpolation problems. As an application of the Schur algorithm we describe how to solve the tangential Schur–Takagi problem [16], [18], which is defined as follows. Given a set of points z_i, $0 \leqq i \leqq n-1$ inside the unit disc and a set of vectors x_i, y_i,

$0 \leqq i \leqq n-1$ of dimension $1 \times p$ and $1 \times q$, respectively, find a matrix-valued function $F(z)$ of dimension $p \times q$ such that

(1) $\|F\|_\infty \leqq 1$.

(2) $x_i F(z_i) = y_i$, $0 \leqq i \leqq n-1$.

(3) $F(z)$ has k Smith–McMillan poles inside the unit disc ($k \geqq 0$).

Remarks. For simplicity of discussion we assume that the points z_i are distinct.

One solution of the problem that is described in [18, ch. 18] is as follows. We first find a matrix-valued function

$$M_n(z) = \begin{pmatrix} A_n(z) & B_n(z) \\ C_n(z) & D_n(z) \end{pmatrix}$$

that is J unitary on $|z| = 1$ and satisfies

$$[x_i\, y_i] M_n(z_i) = 0 \quad \text{for } i = 0, \ldots, n-1.$$

Then a parametrization of all the solutions to the tangential interpolation problem is given by

$$F(z) = (A_n(z)F_L(z) - B_n(z))(D_n(z) - C_n(z)F_L(z))^{-1}, \tag{15}$$

where $F_L(z)$ is such that $\|F_L\|_\infty \leqq 1$ and $(D_n(z) - C_n(z)F_L(z))^{-1}$ exists at the points z_i. To show that $F(z)$ satisfies the interpolation condition (2), we write

$$\begin{pmatrix} -F(z) \\ I \end{pmatrix} = M_n(z) \begin{pmatrix} -F_L(z) \\ I \end{pmatrix} (D_n(z) - C_n(z)F_L(z))^{-1},$$

and using the fact that

$$[x_i\, y_i] M_n(z_i) = 0,$$

we obtain

$$[x_i\, y_i] \begin{pmatrix} -F(z_i) \\ I \end{pmatrix} = 0,$$

which is condition (2).

Our results show that the matrix $M_n(z)$ can be found using the Schur algorithm in the following way. We define

$$M_n(z) = \Psi_0(z) \cdots \Psi_{n-1}(z),$$

where

$$\Psi_i = I_{p+q} + (B_i(z) - 1) J_{pq} \xi_i^* (\xi_i J_{pq} \xi_i^*)^{-1} \xi_i$$

(compare with (1)) and

$$\xi_i = [x_i\, y_i] \Psi_0(z_i) \cdots \Psi_{i-1}(z_i).$$

Then a simple calculation gives the desired condition

$$[x_i\, y_i] M_n(z_i) = \xi_i \Psi_i(z_i) \Psi_{i+1}(z_i) \cdots = 0.$$

We remark that the vectors $\xi_0, \ldots, \xi_{n-1}$ can be efficiently calculated in $O(n^2)$ operations.

From Theorem 1 we also obtain information on the number k of Smith–McMillan poles of $F(z)$ inside the unit disc:

$$k = \nu_p(F) = N_-(\varepsilon_0, \ldots, \varepsilon_{n-1}) + \nu_p(F_L),$$

where $N_-(\varepsilon_0, \ldots, \varepsilon_{n-1})$ is the number of negative elements in the sequence $\varepsilon_0, \ldots, \varepsilon_{n-1}$ (ε_i was defined in (4)). Note that a solution with the minimum number of poles ($k = N_-(\varepsilon_0, \ldots, \varepsilon_{n-1})$) is obtained by choosing a function $F_L(z)$ that is analytic.

An alternative way to obtain the number $N_-(\varepsilon_0, \ldots, \varepsilon_{n-1})$ is from the inertia of the Pick matrix

$$P = P_0 = \left(\frac{x_i x_j^* - y_i y_j^*}{1 - z_i z_j^*} \right)_{0 \leq i,j \leq n-1}. \tag{16}$$

One can easily check that P_0 is the solution of the following matrix equation

$$P_0 - F P_0 F^* = G_0 J G_0^*,$$

where $F = \operatorname{diag}(z_0, \ldots, z_{n-1})$ and

$$G_0 = \begin{pmatrix} x_0 & y_0 \\ \vdots & \vdots \\ x_{n-1} & Y_{n-1} \end{pmatrix}.$$

Similarly, we define the matrix P_i, $1 \leq i \leq n$ to be the solution of the equation

$$P_i - F P_i F^* = G_i J G_i^*$$

with

$$G_i = \begin{pmatrix} G_i^0 \\ \vdots \\ G_i^{n-1} \end{pmatrix},$$

where

$$G_i^j = [x_j y_j] \Psi_0(z_j) \Psi_1(z_j) \cdots \Psi_{i-1}(z_j).$$

We note that

$$(P_i)_{l,m} = \frac{1}{1 - z_l z_m^*} G_i^l J (G_i^m)^*,$$

and consequently

$$\begin{aligned}
(P_i)_{l,m} - (P_{i+1})_{l,m} &= \frac{1}{1 - z_l z_m^*} G_i^l J (G_i^m)^* - \frac{1}{1 - z_l z_m^*} G_{i+1}^l J (G_{i+1}^m)^* \\
&= \frac{1}{1 - z_l z_m^*} [G_i^l J (G_i^m)^* - G_i^l \Psi_i(z_l) J \Psi_i^*(z_m) (G_i^m)^*] \\
&= \frac{1}{1 - z_l z_m^*} G_i^l J [J - J \Psi_i(z_l) J \Psi_i^*(z_m) J] J (G_i^m)^* \\
&= \frac{1}{1 - z_l z_m^*} G_i^l J \left[\frac{(1 - |z_i|^2)(1 - z_l z_m^*)}{(1 - z_i^* z_l)(1 - z_i z_m^*)} \xi_i^* (\xi_i J \xi_i^*)^{-1} \xi_i \right] J (G_i^m)^* \\
&= \frac{1 - |z_i|^2}{\xi_i J \xi_i^*} \frac{1}{1 - z_i^* z_l} G_i^l J \xi_i^* \xi_i J (G_i^m)^* \frac{1}{1 - z_i z_m^*}.
\end{aligned}$$

Thus, we can write

$$P_i - P_{i+1} = \varepsilon_i u_i^* u_i,$$

where

$$u_i^* = \sqrt{\frac{1 - |z_i|^2}{|\xi_i J \xi_i^*|}} \begin{pmatrix} (1 - z_0 z_i^*)^{-1} G_i^0 J \xi_i^* \\ \vdots \\ (1 - z_{n-1} z_i^*)^{-1} G_i^{n-1} J \xi_i^* \end{pmatrix}.$$

Using the fact that $P_n = 0$, repeated application of the last equation gives the decomposition of the Pick matrix as

$$P = \varepsilon_0 u_0^* u_0 + \cdots \varepsilon_{n-1} u_{n-1}^* u_{n-1}.$$

Assuming that P is nonsingular, we obtain that $N_-(\varepsilon_0, \ldots, \varepsilon_{n-1})$ is equal to the number of negative eigenvalues of P.

Remark. The same technique of factorization of the Pick matrix was used in [23]. A similar factorization in the half-plane case was obtained in [21], [24].

4. Array formulation. For computational purposes it is more convenient to work with an array of coefficients rather than with functions. Here we describe the array formulation for the special case that all the extraction points are at the origin, i.e., $z_i = 0$ for all i. The array $\underline{G}_i = [\underline{U}_i \quad \underline{V}_i]$ is built of blocks of size $p \times (p + q)$, where each block is a coefficient of a (matrix) Taylor expansion

$$[I_p, zI_p, z^2 I_p \cdots] \underline{G}_i = \Phi_0(z) \cdots \Phi_{i-1}(z) G_i(z) = G_0(z) \Psi_0(z) \cdots \Psi_{i-1}(z).$$

Translating the modified Schur recursion in Theorem 1 to the array, we obtain

$$[I_p, zI_p, z^2 I_p \cdots] \underline{G}_{i+1} = [I_p, zI_p, z^2 I_p \cdots] \underline{G}_i W_i \begin{Bmatrix} z \oplus I_{p+q-1} \\ I_{p+q-1} \oplus z \end{Bmatrix}.$$

Consequently, one step of the algorithm is equivalent to a multiplication of the array from the right by the matrix W_i and then a downward shift of p places of the first or last column depending if $\varepsilon_i = 1$ or $\varepsilon_i = -1$, respectively.

Translating the property $\eta_i \bar{G}_i(0) = 0$, which we quoted as (1g), to the array, we can verify that the array $\underline{G}_i$ has i left null vectors

$$\{\eta_j \Phi_{j-1}(z^{-1}) \cdots \Phi_0(z^{-1}) [I_p, zI_p, z^2 I_p \cdots]\}|_{z=0} \underline{G}_i = 0 \quad \text{for } j = 0, \ldots, i-1.$$

Moreover, each additional step of the algorithm produces one more null vector. Thus, in the array domain the algorithm finds recursively an array that has a given set of left null vectors.

We now restrict our discussion to the case where each vector η_i is chosen to be one of the standard unit vectors $\{e_j\}_{j=1}^p$. In particular, we choose the vectors $\{\eta_i\}$ in a cyclic order: $\eta_0 = e_1, \ldots, \eta_{p-1} = e_p, \eta_p = e_1, \ldots$, and so on. For the choice $\eta_i = e_j$, where $j = i - 1 \bmod p$, the corresponding ξ_i, which is equal to the jth row of $G_i(0)$, is equal to the ith row of the array $\underline{G}_i$. Thus, for this case, the multiplication by W_i performs a special operation on the ith row of the array. Depending on whether $\varepsilon_i = 1$ or $\varepsilon_i = -1$, the multiplication by W_i annihilates all the elements in positions from 2 to $p + q$ or 1 to $p + q - 1$ on the ith row. Then, a downward shift of p places is done on the first or last column, respectively. As a result, the first i rows of the array $\underline{G}_i$ are equal to zero, and the corresponding i null vectors in this case are the first i standard unit vectors. Moreover, each cycle of p steps annihilates one complete block in the array and, therefore, corresponds to one step of the algorithm in block form [14].

5. Concluding remarks. In this article we present a new version of the classical Schur algorithm that is adapted to handle meromorphic matrix-valued functions. The new version leads to a new parametrization of matrix-valued meromorphic functions

that reflects the number of Smith–McMillan poles inside the unit disc in a very explicit way; it is also numerically efficient because it requires only scalar operations in contrast to the matrix and vector operations in previous versions. We also show how to solve tangential interpolation problems using this algorithm and we give a simple proof for the connection between the inertia of a certain Pick matrix and the number of poles of any interpolating function.

REDUCIBILITY CONDITION OF A CLASS OF RATIONAL FUNCTION MATRICES*

KAI SHENG LU† AND JIA NING WEI‡

Abstract. The reducibility condition of a class of rational function matrices is derived. It is pointed out that the coefficient matrix of any resistor-inductor-capacitor (RLC) network is such a rational function matrix, which implies that the results obtained here can be applied to RLC networks and this paper has the effects on connecting matrix algebra and electrical network theory.

Key words. rational function field, rational function matrix, reducibility, network

AMS subject classifications. 15A15, 15A04, 93A10, 94C05

1. Introduction. Since the concepts of controllability and observability were first introduced by Kalman [1], much has been written on the subject [2]–[7] of linear systems theory. The linear systems over the field of real numbers were heavily studied. A linear system is said to be the one over the field of real numbers if each entry of each coefficient matrix of the system is a real number. However, uncontrollability (unobservability) is a "singular" condition in the sense that if the system $\dot{X} = AX + BU$, $Y = CX + DU$ is uncontrollable (unobservable), then almost any small perturbation of the elements of A and B (A and C) will cause it to become controllable (observable) [8], where the elements of A, B, and C are considered to be the independent parameters. Lin [9] first proposed the concept and condition of structural controllability to analyze these issues. Shields and Pearson [10], Glover and Silverman [11], Davison [12], Hosoe and Matsumoto [13], and Mayeda [14] extended them to multivariable linear systems. In [9]–[14] a matrix is said to be a structured matrix (SM) if each entry in the matrix is either fixed zero or free nonzero. Corfmat and Morse [15], Anderson and Hong [16], and Willems [17] permit some dependent relationships among nonfixed entries that are one-degree polynomials of independently variable parameters (simply, such a matrix is called a one-degree polynomial matrix) for physical reasons. Murota [18]–[20] first defined and studied the mixed matrices. A matrix A of the form $A = Q + T$ is called a mixed matrix if the nonzero entries of T are algebraically independent over the field to which the entries of Q belong. The irreducibility condition of mixed matrices was derived in [19]. Yamada and Luenberger [21] investigated the properties of the matrices called column-structured matrices (CSMs), which lie between SMs and the rational function matrices (RFMs).

Let F_ξ denote the field of all rational functions with real coefficients in q independently variable parameters $\xi = (\xi_1, \xi_2, \ldots, \xi_q) \in R^q$. R^q is said to be a parameter space. Let the matrix $M = M(\xi)$. M is called an RFM or a matrix in the field F_ξ if each entry in M is a member in F_ξ.

First, we establish some results on reducibility of RFMs of the form $A = (C + V)^{-1}U$ and $G = C + D$ with $C = \operatorname{diag}(\xi_1, \ldots, \xi_n)$, where $\xi_1, \ldots, \xi_n$ are n independently variable parameters and the $n \times n$ matrices D, V, and U do not contain $\xi_1, \ldots, \xi_n$. Obviously, A and G are not the matrices over the field of real numbers, SMs

or CSMs. Also, A is not a one-degree polynomial-matrix or a mixed matrix. But when D is a constant matrix, G can be considered to be a matrix defined in [15]–[17]. Unfortunately, the reducibility problem was not studied in [15]–[17]. G is a mixed matrix and so the criterion of [19] is used to prove some important results of this paper.

Second, we present the following two properties.

Let $M(\xi)$ be an $n \times n$ RFM. $M(\xi)$ is said to be of property 2 if $\det(\lambda_0 I - M(\xi)) \neq 0$ over F_ξ, where λ_0 is an arbitrary nonzero constant; $M(\xi)$ is said to be of property 1 if its characteristic polynomial $\det(\lambda I - M(\xi))$ in $F_\xi[\lambda]$ has no nonzero multiple roots [22].

SMs and CSMs are of property 1, and it is not difficult to prove that they are of property 2. The two properties have an important application to the problem of structural controllability and observability [22]. The fact that the matrices A and G are also of properties 1 and 2 is pointed out here.

2. Lemmas and definitions. Consider a linear time-invariant structured system

$$\dot{X} = AX + Be, \tag{2.1}$$

where the $n \times n$ matrix $A = (C + V)^{-1}U$ has $n + m$ independent parameters $\xi = (\xi_1, \xi_2, \ldots, \xi_n; \xi_{n+1}, \ldots, \xi_{n+m}) \in R^{n+m}$, R^{n+m} is called the $(n + m)$-dimensional parameter space. F_ξ denotes the field of all rational functions of ξ. $C = \operatorname{diag}[\xi_1, \xi_2, \ldots, \xi_n]$. Each element in V and U is a rational function of only $\xi_{n+1}, \ldots, \xi_{n+m}$. So matrix A is an RFM. When $\xi_{n+1}, \ldots, \xi_{n+m}$ are fixed, V and U become two constant matrices.

Let R denote the real field and $R[x_1, x_2, \ldots, x_n]$ denote the ring of all real coefficient polynomials of n indeterminates $x_1, x_2, \ldots, x_n$. $R[x_1, \ldots, x_n]$ can be simply written as R_x or $R[X]$, $X = (x_1, x_2, \ldots, x_n)$. Let F_x denote the quotient field of R_x. The following lemma is a conclusion in algebraic theory [23].

LEMMA 1. *If a polynomial $f(\lambda)$ in ring $R_x[\lambda]$ can be decomposed in ring $F_x[\lambda]$, then $f(\lambda)$ can be also decomposed in ring $R_x[\lambda]$.*

When $f(\lambda) \in R_x[\lambda]$, the reducibility of $f(\lambda)$ in $R_x[\lambda]$ is equivalent to the reducibility for $f(\lambda)$ in $F_x[\lambda]$ by Lemma 1.

LEMMA 2. *If $f(\lambda) = a_0\lambda^n + a_1\lambda^{n-1} + \cdots + a_{n-1}\lambda + a_n$ is an n-degree polynomial in $R_x[\lambda]$ and $a_0 \neq 0$, $a_n \neq 0$, then $f(\lambda)$ is reducible in $R_x[\lambda]$ if and only if (iff) $g(\lambda) = a_0 + a_1\lambda + \cdots + a_{n-1}\lambda^{n-1} + a_n\lambda^n$ is reducible in $R_x[\lambda]$.*

Proof. This proof is obvious.

LEMMA 3. *Assume that $f(x_1, \ldots, x_n)$ is a polynomial in R_x and the highest degree term is $x_1 \cdots x_n$ (the degree of each of the other terms is less than n). Then $f(x_1, \ldots, x_n)$ is a reducible polynomial in R_x iff $f(x_1 - \lambda, \ldots, x_n - \lambda)$ is a reducible polynomial in $R_x[\lambda]$.*

Proof. This proof is obvious.

DEFINITION 1. If an $n \times n$ matrix exists

$$Q = \begin{pmatrix} 1 & & & & & & \\ & \ddots & & & & & \\ & & 1 & & & & \\ & & & 0 & \cdots & 1 & \\ & & & \vdots & 1 & \vdots & \\ & & & & \ddots & & \\ & & & 1 & \cdots & 0 & \\ & & & & & & 1 \\ & & & & & & & \ddots \\ & & & & & & & & 1 \end{pmatrix}, \tag{2.2}$$

then Q is called a type 1 elementary matrix. An $n \times n$ matrix P is said to be a permutation matrix if P is a product of some type 1 elementary matrices. PAP^{-1} is said to be a permutation transformation of the matrix A. Clearly, $P^{-1} = P'$.

DEFINITION 2. Let M be an $n \times n$ matrix over F_ξ. M is then said to be reducible under TMT^{-1} or simply to be reducible if there exists some nonsingular matrix T over F_ξ such that

$$TMT^{-1} = \begin{pmatrix} M_1 & 0 \\ M_{21} & M_2 \end{pmatrix}, \tag{2.3}$$

where M_1 is an $n_1 \times n_1$ matrix, $1 \leqq n_1 < n$; otherwise, M is irreducible (under TMT^{-1}). M is said to be reducible under QMP if there exists some nonsingular matrix Q over R and some permutation matrix P such that

$$QMP = \begin{pmatrix} M_1 & 0 \\ M_{21} & M_2 \end{pmatrix}, \tag{2.4}$$

where M_1 is an $n_1 \times n_1$ matrix, $1 \leqq n_1 < n$; otherwise, M is irreducible under QMP (see p. 287, [19]). M is said to be reducible under PMP' if there exists some permutation matrix P such that

$$PMP' = \begin{pmatrix} M_1 & 0 \\ M_{21} & M_2 \end{pmatrix}, \tag{2.5}$$

where M_1 is an $n_1 \times n_1$ matrix, $1 \leqq n_1 < n$; otherwise, M is irreducible under PMP'.

3. Reducibility condition.

THEOREM 1. *Let $G = C + D$, where $C = \operatorname{diag}[\xi_1, \ldots, \xi_n]$, $\xi_1, \ldots, \xi_n$ are algebraically independent over R, and D is an $n \times n$ matrix over R. G is reducible under PGP' if and only if it is reducible under QGP', where P is a permutation matrix and Q is a nonsingular matrix over R.*

Proof. The necessity of the proof is obvious.

For sufficiency, assume that G is irreducible under PGP'. Let

$$A = PGP' = \begin{pmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{pmatrix}, \qquad J = \begin{pmatrix} J_{11} & J_{12} \\ J_{21} & J_{22} \end{pmatrix}, \tag{3.1}$$

where P is any permutation matrix, J is any nonsingular matrix over R, J_{11}, and A_{11} are two $n_1 \times n_1$ matrices, $1 \leqq n_1 < n$. $A_{12} \neq 0$ (since G is irreducible under PGP') and it is a matrix over R because of $\xi_1, \ldots, \xi_n$ on the diagonal of A. Then,

$$\tilde{J} \triangleq JA = \begin{pmatrix} \tilde{J}_{11} & \tilde{J}_{12} \\ \tilde{J}_{21} & \tilde{J}_{22} \end{pmatrix}, \tag{3.2}$$

where

$$\tilde{J}_{12} = J_{11}A_{12} + J_{12}A_{22}. \tag{3.3}$$

We now prove $\tilde{J}_{12} \neq 0$. Conversely, suppose $\tilde{J}_{12} = 0$. Since $A_{12} \neq 0$ is a matrix over R, $J_{11}A_{12}$ is also a matrix over R.

(i) If $J_{11}A_{12} \neq 0$, then $J_{12}A_{22} = -J_{11}A_{12} \neq 0$ is a matrix over R. If $J_{12} \neq 0$, $J_{12}A_{22}$ is a matrix over F_ξ not over R and so $\tilde{J}_{12} \neq 0$. If $J_{12} = 0$, then $\tilde{J}_{12} = J_{11}A_{12} \neq 0$.

(ii) If $J_{11}A_{12} = 0$, then $J_{12}A_{22} = 0$. Since A_{22} has full rank, $J_{12} = 0$, which yields that J_{11} and J_{22} are invertible. Thus, $A_{12} = 0$ by $J_{11}A_{12} = 0$, which is a contradiction.

Hence, $\tilde{J}_{12} \neq 0$ from (i) and (ii). Let $J = QP'$, where Q is any nonsingular matrix over R. Then $\tilde{J} = JA = QGP'$ is not a block-triangular matrix, which means that G is irreducible under QGP'. □

THEOREM 2. *Let $G = C + D$, where $C = \operatorname{diag}[\xi_1, \ldots, \xi_n]$, $\xi_1, \ldots, \xi_n$ are algebraically independent over R, and D is an $n \times n$ matrix over R. G is reducible (under TGT^{-1}) iff G is reducible under PGP'.*

Proof. It is only necessary to prove the necessity.

It can be known by Lemma 3 that the reducibility of $\det(\lambda I - G)$ and the reducibility of $\det G$ are equivalent. Thus, when G is reducible, $\det G$ is a reducible polynomial in $R[\xi]$. Obviously, G is a nonsingular mixed matrix with respect to the field R. By Theorem 6.2 in [19], G is reducible under QGP'. Then G is reducible under PGP' by Theorem 1. □

COROLLARY 1. *Let $K \subseteq F$ be fields, $G = C + D$, where $C = \operatorname{diag}[\xi_1, \ldots, \xi_n]$ is a matrix over F such that $\xi_1, \ldots, \xi_n$ are algebraically independent over the field K, and D is an $n \times n$ matrix over K. Then the following propositions are equivalent.*

(i) G is reducible under TGT^{-1}, where T is a nonsingular matrix over F.

(ii) G is reducible under QGP', where Q is a nonsingular matrix over K and P is a permutation matrix.

(iii) G is reducible under PGP', where P is a permutation matrix.

COROLLARY 2. *Let $G = C + D$, where $C = \operatorname{diag}[\xi_1, \ldots, \xi_n]$, $\xi_1, \ldots, \xi_n$ are algebraically independent over R, and D is a matrix over R. Then G is of properties 1 and 2.*

Proof. Clearly, for any complex constant λ_0, $\det(\lambda_0 I - G)$ is an n-degree polynomial in $\xi_1, \ldots, \xi_n$. It is impossible that the polynomial is identically zero, that is, any constant cannot be an eigenvalue of G over F_ξ. G is of property 2.

G is of property 1 by Theorem 26.1 of [18]. □

It is well known that the characteristic polynomial of an $n \times n$ matrix A can be written as

$$\det(\lambda I - A) = \lambda^n + a_1\lambda^{n-1} + \cdots + a_{n-1}\lambda + a_n, \tag{3.4}$$

where $a_k = (-1)^k D_k$; D_k is a sum of all the principal minors of order k in the matrix A, $1 \leqq k \leqq n$. If $a_r \neq 0$ $(1 \leqq r \leqq n)$, but $a_{r+1} = \cdots = a_n = 0$, r is a generic order of A. If the generic order of A is r, then

$$\det(\lambda I - A) = \lambda^{n-r}\phi(\lambda), \tag{3.5}$$

where $\phi(\lambda) = \lambda^r + a_1\lambda^{r-1} + \cdots + a_{r-1}\lambda + a_r$, $a_r \neq 0$. $\phi(\lambda)$ is called a nonzero part of $\det(\lambda I - A)$.

THEOREM 3. *If $A = (C + V)^{-1}U$, where $C = \operatorname{diag}[\xi_1, \xi_2, \ldots, \xi_n]$, V and U are two $n \times n$ constant matrices, $U \neq 0$, then the following propositions are equivalent.*

1. The nonzero part $\phi(\lambda)$ of $\det(\lambda I - A)$ is a reducible polynomial in $F_\xi[\lambda]$.

2(i). There exists some permutation matrix P such that

$$P(C + V - Ut)P' = \begin{pmatrix} G_1 & & & 0 \\ & G_2 & & \\ & & \ddots & \\ * & & & G_k \end{pmatrix}, \tag{3.6}$$

where G_i is an $n_i \times n_i$ irreducible matrix, $G_i = C_i + V_i - U_i t$, $C_i = \operatorname{diag}[\xi_{i_1}, \xi_{i_2}, \ldots, \xi_{in_i}]$, $i = 1, 2, \ldots, k$ $(k > 1)$, $n_1 + n_2 + \cdots + n_k = n$; and $\xi_{11}, \ldots, \xi_{1n_1}; \xi_{21}, \ldots, \xi_{2n_2}; \ldots; \xi_{k1}, \ldots, \xi_{kn_k}$ are a permutation of $\xi_1, \xi_2, \ldots, \xi_n$.

2(ii). In (3.6) there exist at least two submatrices $U_i \neq 0$ and $U_j \neq 0$, $i \neq j$, $1 \leqq i, j \leqq k$ such that $\det [\lambda I - (C_i + V_i)^{-1}U_i]$ and $\det [\lambda I - (C_j + V_j)^{-1}U_j]$ have, respectively, nonzero parts that are irreducible polynomials in $F_\xi[\lambda]$.

3. There exists some permutation matrix P such that

$$PAP' = \begin{pmatrix} A_{11} & 0 \\ * & A_{22} \end{pmatrix}, \tag{3.7}$$

where A_{11} is a $\mu \times \mu$ matrix, $1 \leqq \mu < n$, and A_{11} and A_{22} have, respectively, nonzero eigenvalues.

Proof. We use the cyclic method.

$1 \Rightarrow 2(i)$. Assume that the nonzero part of $\det (\lambda I - A)$ is reducible. Then

$$\begin{aligned} \det (\lambda I - A) &= \det [\lambda I - (C + V)^{-1}U] = \det (C + V)^{-1} \det [\lambda(C + V) - U] \\ &= \lambda^n \det (C + V)^{-1} \det [(C + V) - Ut], \end{aligned} \tag{3.8}$$

where $t = 1/\lambda$. Suppose that the generic order of A is r, $r \leqq n$. Then

$$\phi(\lambda) = \lambda^r \det (C + V)^{-1} \det [(C + V) - Ut]. \tag{3.9}$$

By Lemma 2, $\phi(\lambda)$ is reducible iff $\det (C + V)^{-1} \det [(C + V) - Ut]$ is a reducible polynomial in $F_\xi[t]$. Thus, $\varphi(t) \triangleq \det [(C + V) - Ut]$ is a reducible polynomial in $F_\xi[t] \cdot \varphi(t) = \varphi_1(t)\varphi_2(t) \ldots \varphi_s(t)$, where $s \geqq 2$, $\varphi_i(t)$ $(1 \leqq i \leqq s)$ is prime polynomial. Certainly, every $\varphi_i(t)$ is a nonzero-degree polynomial of $\xi_1, \ldots, \xi_n$; otherwise contradicting the fact that the coefficient of the highest degree power $\xi_1\xi_2 \cdots \xi_n$ in $\varphi(t)$ is one. Thus, $\det [C + V - Ut]$ is a reducible polynomial in $F(t)[\xi]$, where $F(t)$ denotes the field of all rational functions in t. Obviously, $C + (V - Ut)$ is a mixed matrix with respect to $F(t)$. Thus, (3.6) holds by Corollary 1.

$1 \Rightarrow 2(ii)$. By the relation

$$PAP' = \begin{pmatrix} (C_1 + V_1)^{-1}U_1 & & & 0 \\ & (C_2 + V_2)^{-1}U_2 & & \\ & & \ddots & \\ * & & & (C_k + V_k)^{-1}U_k \end{pmatrix}, \tag{3.10}$$

one can know that there exists i_0 $(1 \leqq i_0 \leqq k)$ such that $U_{i_0} \neq 0$. Suppose that the nonzero part of $\det [\lambda I - (C_{i_0} + V_{i_0})^{-1}U_{i_0}]$ is equal to $\phi(\lambda)$. Then $C_{i_0} + V_{i_0} - U_{i_0}t$ is reducible by 2(i), which is a contradiction.

$2 \Rightarrow 3$. This proposition is obvious from (3.10).

$3 \Rightarrow 1$. This proposition is obvious. □

COROLLARY 3. *If* $A = (C + V)^{-1}U$, *where* $C = \operatorname{diag} [\xi_1, \xi_2, \ldots, \xi_n]$, *$V$ and U are two $n \times n$ matrices over R, and U is invertible, then* $\det (\lambda I - A)$ *is reducible if and only if there exists some permutation matrix P such that* (3.7) *holds.*

Proof. It is only necessary to note that if U is invertible, the nonzero part of $\det (\lambda I - A)$ is, itself, right, and so $\det (\lambda I - A)$ has no zero eigenvalues. Thus, (3.7) holds by Theorem 3, and A_{11} and A_{22} have nonzero eigenvalues, respectively. □

PROPOSITION 1. *Let* $A = (C + V)^{-1}U$, *where* $C = \operatorname{diag} [\xi_1, \xi_2, \ldots, \xi_n]$; *$V$ and U are two $n \times n$ matrices over R. Then A is of property* 2.

Proof. Conversely, suppose that there exists a complex constant $\lambda_0 \neq 0$ such that $\det (\lambda_0 I - A) = 0$ for all the parameters $\xi_1, \xi_2, \ldots, \xi_n$. By (3.8) there exists $t_0 = 1/\lambda_0 \neq 0$ such that for all the parameters $\xi_1, \xi_2, \ldots, \xi_n$,

$$\det [(C + V) - Ut_0] = \frac{\perp}{\lambda_0^n} \det (C + V) \det (\lambda_0 I - A) = 0. \tag{3.11}$$

However, the left-hand side of (3.11) is an n-degree polynomial of $\xi_1, \xi_2, \ldots, \xi_n$, which contradicts the fact that (3.11) is an identity. □

COROLLARY 4. *If* $A = (C + V)^{-1}U$, *where* $C = \operatorname{diag}[\xi_1, \xi_2, \ldots, \xi_n]$, *$V$ and U are two $n \times n$ matrices over R, then A is of property* 1.

Proof. If, on the contrary, A has nonzero multiple eigenvalues, then the nonzero part of $\det(\lambda I - A)$ is reducible. Then (3.10) holds and $\det(\lambda I - A) = \prod_{i=1}^{k} \det[\lambda I - (C_i + V_i)^{-1}U_i]$. But $\det[\lambda I - (C_i + V_i)^{-1}U_i]$ has no nonzero multiple roots for every $i = 1, 2, \ldots, k$; otherwise, $C_i + V_i - U_i t$ is reducible still. On the other hand, each $\det[\lambda I - (C_i + V_i)^{-1}U_i]$ has no nonzero constant roots by Proposition 1. Moreover, since $(C_i + V_i)^{-1}U_i$ and $(C_j + V_j)^{-1}U_j$ have no parameters in common, where $i, j = 1, 2, \ldots, k$, $i \neq j$, they have no nonzero roots in common, which contradicts the assumption. Hence, this corollary is true. □

The assumption of Theorem 3 is that $\det[\lambda I - A]$ has the nonzero part $\phi(\lambda)$. Theorem 4 and Corollary 5 indicate the condition under which $\deg[\phi(\lambda)] \geqq 1$.

Let $M = (m_{ij})_{n\times n}$, $i, j = 1, \ldots, n$. By the definition of determinant,

$$\det M = \sum (-1)^{\tau(j_1 j_2 \cdots j_n)} m_{1 j_1} m_{2 j_2} \cdots m_{n j_n}, \tag{3.12}$$

where $\sum$ denotes the sum of all permutations. Equation (3.12) is called the expansion of the determinant $\det M$ and $m_{1 j_1} \cdots m_{n j_n}$ is called a term in the expansion.

LEMMA 4. *Let* $M = (m_{ij}) = C + D$, *where* $C = \operatorname{diag}[\xi_1, \ldots, \xi_n]$, *and D is an $n \times n$ matrix over R. If the expansion of* $\det M$ *has two similar terms* $m_{i_1 i_2} \cdots m_{i_{r-1} i_r} m_{i_r i_1} \psi$ *and* $m_{j_1 j_2} \cdots m_{j_{r-1} j_r} m_{j_r j_1} \psi$, *where* $\{i_1, \ldots, i_r\} \subseteq \{1, \ldots, n\}$, $n \geqq r \geqq 3$; $j_1, \ldots, j_r$ *is a permutation of* $i_1, \ldots, i_r$ *and* $(i_1, \ldots, i_r) \neq (j_1, \ldots, j_r)$; $m_{i_b i_{b+1}} \neq 0$, $m_{i_r i_1} \neq 0$, $m_{j_b j_{b+1}} \neq 0$, $m_{j_r j_1} \neq 0$, $b = 1, \ldots, r - 1$; $\psi = \xi_1 \cdots \xi_n / \xi_{i_1} \xi_{i_2} \cdots \xi_{i_r}$, *then there is some nonzero term that contains nondiagonal entries and whose degree is greater than* $\deg \psi$.

Proof. Without loss generality, let $i_1 = j_1, \ldots, i_s = j_s$, $1 \leqq s < r - 1$; $(i_{s+1}, \ldots, i_r) \neq (j_{s+1}, \ldots, j_r)$, where $j_{s+1}, \ldots, j_r$ is a permutation of $i_{s+1}, \ldots, i_r$. If $j_{s+1} \neq i_{s+1}$, then there must exist $j_x \in \{j_{s+2}, \ldots, j_r\}$ such that $j_x = i_{s+1}$, $s + 2 \leqq x \leqq r$. This implies that the expansion of $\det M$ has a nonzero term $m_{i_1 i_2} \cdots m_{i_s i_{s+1}} m_{j_x j_{x+1}} \cdots m_{j_{r-1} j_r} m_{j_r j_1} \xi_{j_{s+1}} \xi_{j_{s+2}} \cdots \xi_{j_{x-1}} \psi$, whose degree is greater than $\deg \psi$. □

THEOREM 4. *Let* $\phi(\lambda)$ *be the nonzero part of* $\det[\lambda I - (C + V)^{-1}U]$ *and* $G = C + V - Ut$ *be irreducible, where* $C = \operatorname{diag}[\xi_1, \ldots, \xi_n]$, *$V$ and U are two $n \times n$ matrices over R, and t is a parameter independently of* $\xi_1, \ldots, \xi_n$. *Then* $\deg[\phi(\lambda)] \geqq 1$ *iff* $U \neq 0$.

Proof. Necessity is obvious. Sufficiency will be proven. Since the coefficient of the term $\xi_1, \xi_2 \cdots \xi_n$ in $\varphi(t) = \det G$ is equal to one, $\varphi(t) = 0$ has no zero roots. It is thus known by (3.9) that $\deg[\varphi(t)] = \deg[\phi(\lambda)]$. It is only necessary to prove $\deg[\varphi(t)] \geqq 1$.

Let $G = (g_{ij})_{n\times n}$, $V = (v_{ij})_{n\times n}$, and $U = (u_{ij})_{n\times n}$. Then $g_{ii} = \xi_i + v_{ii} - u_{ii}t$, $i = 1, 2, \ldots, n$; $g_{ij} = v_{ij} - u_{ij}t$, $i \neq j$, $i, j = 1, 2, \ldots, n$.

Since $U \neq 0$, assume the entry $u_{ij} \neq 0$. If there exists some i, $1 \leqq i \leqq n$, such that $u_{ii} \neq 0$, then in the expansion of $\det G$ there is a term $u_{ii} t \xi_1 \cdots \xi_{i-1} \xi_{i+1} \cdots \xi_n \neq 0$ that is unique and may not vanish when all the nonzero terms are added. Then, assume $u_{ii} = 0$, $i = 1, 2, \ldots, n$. If the symmetric entry g_{ji} of g_{ij} is not zero, $\det G$ has a nonzero term $u_{ij} g_{ji} t \xi_1 \cdots \xi_n / \xi_i \xi_j$, which is unique, and so this lemma holds also for $u_{ii} = 0$, but $g_{ji} \neq 0$. Assume further that $g_{ji} = 0$. Moreover, since any nondiagonal entry can be placed in the position with the nth row and $(n - 1)$th column by performing a permutation transformation, without loss of generality one can assume that $u_{n-1,n} \neq 0$, but $g_{n,n-1} = 0$.

Now it will be proven that the cofactor of $g_{n-1,n}$, denoted by $\det G_{n-1,n}$, is not zero. We have

$$\det G_{n-1,n} = \det \begin{pmatrix} G_{n-2} & \zeta \\ \eta' & 0 \end{pmatrix}, \tag{3.13}$$

where G_{n-2} is an $(n-2) \times (n-2)$ principal submatrix with the first $n-2$ rows and the first $n-2$ columns of G, $\zeta = (g_{1,n-1}, g_{2,n-1}, \ldots, g_{n-2,n-1})'$, $\eta = (g_{n1}, g_{n2}, \ldots, g_{n,n-2})'$. Since $g_{n,n-1} = 0$, G is reducible under PGP' when $\zeta = 0$ or $\eta = 0$. By Theorem 2, G is reducible, which is a contradiction. Hence, $\zeta \neq 0$ and $\eta \neq 0$. In the case of $\zeta \neq 0$ and $\eta \neq 0$, if $\det G_{n-1,n} = 0$, which is an identity for all the parameters ξ, then for any parameter λ, we have

$$\det \begin{pmatrix} \lambda I - G_{n-2} & \zeta \\ \eta' & 0 \end{pmatrix} = 0,$$

which means that (G_{n-2}, ζ) is uncontrollable and/or (G'_{n-2}, η) is unobservable. By duality, it is only necessary to discuss that (G_{n-2}, ζ) is uncontrollable. Since $\zeta \neq 0$, it is impossible that all the modes of G_{n-2} are uncontrollable. Then there must exist some invertible matrix $\tilde{P}_1$ over F_ξ (see § 2.4.2, [24]) such that

$$\tilde{G}_{n-2} = \tilde{P}_1 G_{n-2} \tilde{P}_1^{-1} = \begin{pmatrix} \tilde{G}_1 & 0 \\ \tilde{G}_{21} & \tilde{G}_2 \end{pmatrix}, \qquad \tilde{P}_1 \zeta = \begin{pmatrix} 0 \\ \tilde{\zeta}_2 \end{pmatrix},$$

where $\tilde{G}_1$ is an $r \times r$ matrix, $\tilde{\zeta}_2$ is an $(n-2-r)$-dimensional nonzero vector, and $(\tilde{G}_2, \tilde{\zeta}_2)$ is controllable, $r < n-2$. There exists some permutation matrix P_1 by Theorem 2 such that

$$\bar{G}_{n-2} = P_1 G_{n-2} P_1' = \begin{pmatrix} \bar{G}_1 & 0 \\ \bar{G}_{21} & \bar{G}_2 \end{pmatrix}, \qquad P_1 \zeta = \begin{pmatrix} 0 \\ \zeta_2 \end{pmatrix}, \tag{3.14}$$

where $\bar{G}_1$ is an $r \times r$ matrix whose eigenvalues are the same with the ones of $\tilde{G}_1$, ζ_2 is an $(n-2-r)$-dimensional nonzero vector, and $(\bar{G}_2, \zeta_2)$ is controllable, $r < n-2$.

Since G_{n-2} is invertible, $\bar{G}_1$ and $\bar{G}_2$ are also invertible. We take

$$P = \begin{pmatrix} P_1 & 0 \\ 0 & 1 \end{pmatrix}, \tag{3.15}$$

reduce (3.13), and obtain

$$\det \begin{pmatrix} \bar{G}_1 & 0 & 0 \\ \bar{G}_{21} & \bar{G}_2 & \zeta_2 \\ \eta_1' & \eta_2' & 0 \end{pmatrix} = 0. \tag{3.16}$$

Since $\det \bar{G}_1 \neq 0$,

$$\det \begin{pmatrix} \bar{G}_2 & \zeta_2 \\ \eta_2' & 0 \end{pmatrix} = 0. \tag{3.17}$$

Since $(\bar{G}_2, \zeta_2)$ is controllable, $\eta_2' = 0$. Then, let

$$\bar{P} = \begin{pmatrix} I_r & 0 & 0 \\ 0 & 0 & I_{n-1-r} \\ 0 & I_1 & 0 \end{pmatrix} \begin{pmatrix} P_1 & 0 \\ 0 & I_2 \end{pmatrix}, \tag{3.18}$$

where I_μ is a $\mu \times \mu$ unit matrix for each $\mu = 1, 2, r, n-1-r$. Thus,

$$\bar{P}G\bar{P}' = \begin{pmatrix} \bar{G}_1 & \text{x} & 0 & 0 \\ \eta_1' & g_{nn} & 0 & 0 \\ \bar{G}_{21} & \text{x} & \bar{G}_2 & \zeta_2 \\ \text{x} & g_{n-1,n} & \text{x} & g_{n-1,n-1} \end{pmatrix}, \tag{3.19}$$

which contradicts the fact that G is irreducible. Thus, $\det G_{n-1,n} \neq 0$. Thus, in the expansion of $\det G$ there exists at least one nonzero term $g_{1j_1}g_{2j_2}\cdots g_{nj_n}$ that is a nonzero degree term of t.

Now we shall prove that the sum of all nonzero terms containing t is not zero.

Let the nonzero term containing t with the highest degree of $\xi_1, \ldots, \xi_n$ be

$$g_{i_1i_2}g_{i_2i_3}\cdots g_{i_{r-1}i_r}g_{i_ri_1}\psi, \tag{3.20}$$

where $g_{i_1i_2} = v_{i_1i_2} - u_{i_1i_2}t$, $i_1 \neq i_2$, $u_{i_1i_2} \neq 0$, $\{i_1, \ldots, i_r\} \subseteq \{1, \ldots, n\}$, $3 \leqq r \leqq n$, $\psi = \xi_1\xi_2\cdots\xi_n/\xi_{i_1}\xi_{i_2}\cdots\xi_{i_r}$.

The term (3.20) is unique by Lemma 4, otherwise it is not the term containing t with the highest degree of $\xi_1, \ldots, \xi_n$. □

COROLLARY 5. *Let* $\phi(\lambda)$ *be the nonzero part of* $\det[\lambda I - (C+V)^{-1}U]$, $G = C + V - Ut$ *be reducible, and so*

$$PGP' = \begin{pmatrix} G_1 & & & 0 \\ & G_2 & & \\ & & \ddots & \\ * & & & G_k \end{pmatrix},$$

where $C = \operatorname{diag}[\xi_1, \ldots, \xi_n]$, *$V$ and U are two $n \times n$ matrices over R, t is a parameter independently of $\xi_1, \ldots, \xi_n$, P is a permutation matrix, $G_i = C_i + V_i - U_it$ is an $n_i \times n_i$ irreducible submatrix, $i = 1, \ldots, k$, $k \geqq 2$, $n_i \geqq 1$, $\sum_{i=1}^{k} n_i = n$.* $\operatorname{Deg}[\phi(\lambda)] \geqq 1$ *iff there is at least one submatrix $U_{i_0} \neq 0$, $i_0 \in \{1, 2, \ldots, k\}$.*

Remark 1. For Theorem 3, in (3.6), G_i is irreducible, $i = 1, \ldots, k$. Let the nonzero part $\phi(\lambda) = \phi_1(\lambda)\phi_2(\lambda)\cdots\phi_s(\lambda)$, where $2 \leqq s \leqq k$, $\deg[\phi_j(\lambda)] \geqq 1$, $\phi_j(\lambda)$ is a prime polynomial in $F_\xi[\lambda]$, $j = 1, \ldots, s$. Then there are only s submatrices $U_{i_1}, U_{i_2}, \ldots, U_{i_s}$ are not zero matrices, $\{i_1, i_2, \ldots, i_s\} \subseteq \{1, 2, \ldots, k\}$.

4. Applications to RLC networks. According to [25], the state equation of any RLC network can be written in the form (the notations in Table 2 [26] will be adopted here)

$$\dot{X} = AX + B_1e, \qquad Y = CX + D_1e + D_2\dot{e}, \tag{4.1}$$

where

$$A = A_1^{-1}A_2 \tag{4.2}$$

is an $n \times n$ matrix,

$$A_1 = \begin{pmatrix} C_t & 0 \\ 0 & L_l \end{pmatrix} + \begin{pmatrix} Q_{cc}C_lQ_{cc}' & 0 \\ 0 & Q_{LL}'L_tQ_{LL} \end{pmatrix},$$

$C_t = \operatorname{diag}[C_t(1), \ldots, C_t(n_c)]$, $C_t(1), \ldots, C_t(n_c)$ are n_c capacitor twigs; $L_l = \operatorname{diag}[L_l(1), \ldots, L_l(n_l)]$, $L_l(1), \ldots, L_l(n_l)$ are n_l inductor links; $n_c + n_l = n$; $C_l = \operatorname{diag}[C_l(1), \ldots, C_l(n_{cl})]$, $C_l(1), \ldots, C_l(n_{cl})$ are n_{cl} capacitor links; $L_t = \operatorname{diag}[L_t(1), \ldots, L_t(n_{Lt})]$, $L_t(1), \ldots, L_t(n_{Lt})$ are n_{Lt} inductor twigs; and Q_{cc} and Q_{LL} are both constant matrices. Assume that the network (4.1) has n_R resistors. By circuit theory, each entry of the matrix A_2 in (4.2) is a rational function of only n_R resistors. Thus, the network has, in number, $n + n_{cl} + n_{Lt} + n_R$ independently variable parameters. Obviously, the coefficient matrix

A of (4.1) is one of the matrices defined by (2.1). So the reducibility criteria in § 3 can be applied to RLC networks, and any RLC network expressed by eqn. (4.1) is of property 1 and property 2.

As an illustrative example consider an RLC network as shown in Fig. 1. The network has seven free parameters $\xi = (R_1, R_2, C_1, C_2, C_3, L, L_1) \in R^7$. The state equation is $\dot{X} = A_1^{-1}A_2X + \text{bu}$, where

$$X = \begin{pmatrix} u_1 \\ u_2 \\ u_3 \\ i \\ i_1 \end{pmatrix}, \quad A_1 = \begin{pmatrix} C_1 & & & & 0 \\ & C_2 & & & \\ & & C_3 & & \\ & & & L & \\ 0 & & & & L_1 \end{pmatrix} + [0]_{5\times 5},$$

$$A_2 = \begin{pmatrix} 0 & 0 & 0 & 0 & 1 \\ 0 & -R_2^{-1} & -R_2^{-1} & 0 & 0 \\ 0 & -R_2^{-1} & -R_2^{-1} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ -1 & 0 & 0 & 0 & -R_1 \end{pmatrix}.$$

By direct calculation we see

$$\det(\lambda I - A_1^{-1}A_2) = \lambda^2\left(\lambda^2 + \frac{R_1}{L_1}\lambda + \frac{1}{L_1C_1}\right)\left(\lambda + \frac{C_2 + C_3}{R_2C_2C_3}\right),$$

whose nonzero part is a reducible polynomial in $F_\xi[\lambda]$. $A_1 - A_2t$ is reducible by Theorem 3. Indeed, when

$$\bar{P} = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \end{pmatrix}, \qquad \bar{P}(A_1 - A_2t)\bar{P}' = \begin{pmatrix} G_1 & & 0 \\ & G_2 & \\ 0 & & G_3 \end{pmatrix},$$

where

$$G_1 = \begin{pmatrix} C_1 & 0 \\ 0 & L_1 \end{pmatrix} - \begin{pmatrix} 0 & 1 \\ -1 & -R_1 \end{pmatrix}t \triangleq H_1 - U_1t,$$

$$G_2 = \begin{pmatrix} C_2 & 0 \\ 0 & C_3 \end{pmatrix} - \begin{pmatrix} -1 & -1 \\ -1 & -1 \end{pmatrix}\frac{t}{R_2} \triangleq H_2 - U_2t, \quad G_3 = L - 0t \triangleq H_3 - U_3t.$$

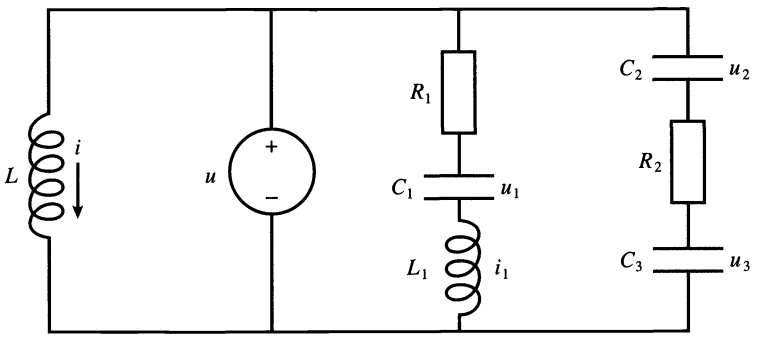

FIG. 1. *An* RLC *network.*

Clearly, G_i is irreducible under PG_iP', $i = 1, 2, 3$. Thus, G_i is irreducible under TG_iT^{-1} by Corollary 1, $i = 1, 2, 3$. Since $U_1 \neq 0$, $U_2 \neq 0$, but $U_3 = 0$, we know by Theorem 4 that

$$\det(\lambda I - H_1^{-1}U_1) = \lambda^2 + \frac{R_1}{L_1}\lambda + \frac{1}{L_1C_1} \quad \text{and} \quad \det(\lambda I - H_2^{-1}U_2) = \lambda\left(\lambda + \frac{C_2 + C_3}{R_2C_2C_3}\right)$$

have the irreducible nonzero parts, respectively, but $\det(\lambda I - H_3^{-1}U_3) = \lambda$ has no nonzero part.

5. Summary. As far as we know, the coefficient matrices of almost all linear physical systems can be considered to be RFMs. However, little is known about the properties of RFMs. To explore the properties of physical systems, particularly the effects of physical structures, it becomes necessary to investigate the properties of RFMs mathematically.

The reducibility criteria for a class of RFMs have been obtained here. What are the reducibility conditions of the other RFMs? This question is complex and interesting. The reducibility criteria will have an application to the problem of controllability and observability of RLC networks over the field F_ξ. These problems are left for further research.

Acknowledgments. We are grateful to the reviewers for their thoughtful comments that substantially improved this paper and to Prof. K. Murota of the University of Tokyo for supplying relevant literature.

FAST PLANE ROTATIONS WITH DYNAMIC SCALING*

ANDREW A. ANDA†‡ AND HAESUN PARK†§

Abstract. This paper presents fast plane rotations for orthogonal similarity and orthogonal one-sided transformations. Fast rotations have the advantage that they reduce the number of square roots and multiplications. The authors' new rotations have further advantages over the existing fast rotations: they obviate the rescaling that has been necessary to guard against underflow or overflow and they give higher efficiency, especially on vector processors. An error analysis, in the case of the *QR* decomposition, and computational results that illustrate the effects of the dynamic scaling are presented.

Key words. fast plane rotations, orthogonal transformations, scaling

AMS subject classifications. 65F25, 15A23, 15A18

1. Introduction.

A plane rotation $J(\theta, p, q)$ of order n through an angle θ in a (p, q) plane is the same as the identity matrix I_n, except for the four elements at the intersections of the pth and qth rows and columns. The general form of an $n \times n$ rotation matrix $J(\theta, p, q)$ in the (p, q) plane, which we will denote as J, is

$$J = J(\theta, p, q) = \begin{bmatrix} I_{p-1} & 0 & 0 & 0 & 0 \\ 0 & c & 0 & -s & 0 \\ 0 & 0 & I_{q-p-1} & 0 & 0 \\ 0 & s & 0 & c & 0 \\ 0 & 0 & 0 & 0 & I_{n-q} \end{bmatrix}, \tag{1}$$

where $c \equiv \cos\theta$, $s \equiv \sin\theta$. Plane rotations are used in various algorithmic contexts, e.g., the *QR* decomposition, the Jacobi and *QR* algorithms for eigendecompositions, the Hestenes algorithm for the singular value decomposition, and reduction to Hessenberg form. Although these algorithms differ in the purpose and range of the angles, we can classify them largely into two cases: those that apply similarity transformations

$$\tilde{X} = J(\theta, p, q)^T X J(\theta, p, q) \tag{2}$$

and others that apply one-sided transformations

$$\tilde{X} = XJ(\theta, p, q) \quad \text{or} \quad \tilde{X} = J^T(\theta, p, q)X. \tag{3}$$

We use the notations X_{pq} and J_{pq} to denote the 2×2 submatrices of X and $J(\theta, p, q)$ in the (p, q) plane, respectively, i.e.,

$$X_{pq} = \begin{bmatrix} x_{pp} & x_{pq} \\ x_{qp} & x_{qq} \end{bmatrix} \quad \text{and} \quad J_{pq} = \begin{bmatrix} c & -s \\ s & c \end{bmatrix}.$$

Fast rotations were developed with the motivations to reduce the number of scalar-vector multiplications and eliminate square roots from the calculation of the plane rotations. Gentleman [5] first formulated a method for a fast Givens rotation. Hammarling [9] later modified that formulation into several computational schemes and pointed out

§ The work of this author was supported in part by National Science Foundation grant CCR-8813493 and University of Minnesota Army High Performance Computing Research Center grant DAAL03-89-C-0038.

that the method can be applied to similarity transformations. There are other types of fast rotations that are developed for the purpose of reducing the number of multiplications in a product of plane rotations [1] or to reduce the device area on a systolic array [8]. However, a literature survey of research and production algorithms that utilize plane rotations has shown a pronounced avoidance of the fast plane rotation. This is partly a consequence of the fact that careful monitoring for the prevention of underflow and overflow is not conveniently achieved wherever the standard fast plane rotation algorithm is utilized [2], [7]. Hammarling [9] suggested that underflow can be avoided either by storing the exponent separately, by normalizing occasionally, or by performing row (or column) interchanges. Separate storage of the exponent is clearly not efficient for currently popular high level languages. Row (or column) interchanges introduce an overhead. Moreover, occasional normalization can be problematic to implement because a nontrivial amount of monitoring is necessary to successfully implement fast Givens transformations.

We present a set of new fast rotations that obviate the monitoring and periodic rescaling necessitated by the standard fast plane rotations. Our fast rotations dynamically scale the diagonal factor matrix to be close to an identity matrix. Variations on the standard fast rotation matrix are developed and algorithms that implement them are offered. Issues of accuracy and efficiency are also discussed. Computational results on the Cray-2 illustrating the effects of dynamic scaling are presented.

2. Fast rotations. Suppose one step of a one-sided transformation via a rotation $J(\theta, p, q)$ gives

$$\tilde{X} = XJ(\theta, p, q) \tag{4}$$

as in the one-sided Jacobi [4], [11] and the Hestenes [10] algorithms and in the QR decomposition (transposed). The essential idea of a fast rotation is that the number of multiplications is reduced by keeping the matrix X in the factored form YD, where D is a diagonal matrix and Y is accordingly scaled, and these two factors are updated separately. The calculation of the product of the two factors may be postponed until the explicit result is required. The diagonal matrix D is initialized as the identity matrix. The secondary advantage of the fast rotation is that the square roots for the computation of cosine and sine can be eliminated [13]. If $X = YD$, then the rotation from the right by J can be represented as

$$\tilde{X} = XJ = YDJ = YF(p, q)\tilde{D} = \tilde{Y}\tilde{D}, \tag{5}$$

where $\tilde{D}$ is a diagonal matrix and $F(p, q)$ is defined as

$$F(p, q) \equiv \begin{bmatrix} I_{p-1} & 0 & 0 & 0 & 0 \\ 0 & f_{pp} & 0 & f_{pq} & 0 \\ 0 & 0 & I_{q-p-1} & 0 & 0 \\ 0 & f_{qp} & 0 & f_{qq} & 0 \\ 0 & 0 & 0 & 0 & I_{n-q} \end{bmatrix}. \tag{6}$$

We will call $F(p, q)$ a *fast rotation* if the choices of f_{pp}, f_{pq}, f_{qp}, and f_{qq} result in halving the number of multiplications in applying the rotation J. If a typical step is represented as

$$X^{(k+1)} = X^{(k)}J^{(k)}, \tag{7}$$

then

$$X^{(k+1)} = Y^{(k+1)}D^{(k+1)} = Y^{(1)}F^{(1)}\cdots F^{(k)}D^{(k+1)} = X^{(1)}J^{(1)}\cdots J^{(k)}, \tag{8}$$

and we have

$$J^{(i)} = D^{(i)^{-1}} F^{(i)} D^{(i+1)}. \tag{9}$$

In the case of the two-sided transformations, if $X = DYD$, then

$$\tilde{X} = J^T X J = J^T DYDJ = \tilde{D} F^T Y F \tilde{D} = \tilde{D} \tilde{Y} \tilde{D}. \tag{10}$$

If a typical step is represented as $X^{(k+1)} = J^{(k)^T} X^{(k)} J^{(k)}$, then

$$\begin{aligned} X^{(k+1)} &= D^{(k+1)} Y^{(k+1)} D^{(k+1)} \\ &= D^{(k+1)} F^{(k)^T} \cdots F^{(1)^T} Y^{(1)} F^{(1)} \cdots F^{(k)} D^{(k+1)} \\ &= J^{(k)^T} \cdots J^{(1)^T} X^{(1)} J^{(1)} \cdots J^{(k)} \end{aligned}$$

and, again, we have

$$J^{(i)} = D^{(i)^{-1}} F^{(i)} D^{(i+1)}. \tag{11}$$

We discuss only column oriented one-sided transformations because we have implemented the new algorithms in Fortran in which the column oriented one-sided transformations give higher efficiency and our work has been motivated by one-sided Jacobi algorithms [11]. The results for row-oriented and the two-sided transformations follow easily.

2.1. Standard fast rotations. Suppose a fast rotation transforms $X = YD$ into $\tilde{X} = \tilde{Y}\tilde{D}$. The transformation can be shown as follows:

$$\begin{aligned} [\tilde{x}_p, \tilde{x}_q] &= [x_p, x_q] \begin{bmatrix} c & -s \\ s & c \end{bmatrix} \\ &= [y_p, y_q] \begin{bmatrix} d_p & 0 \\ 0 & d_q \end{bmatrix} \begin{bmatrix} c & -s \\ s & c \end{bmatrix} \\ &= [y_p, y_q] \begin{bmatrix} f_{pp} & f_{pq} \\ f_{qp} & f_{qq} \end{bmatrix} \begin{bmatrix} \tilde{d}_p & 0 \\ 0 & \tilde{d}_q \end{bmatrix} \\ &= [\tilde{y}_p, \tilde{y}_q] \begin{bmatrix} \tilde{d}_p & 0 \\ 0 & \tilde{d}_q \end{bmatrix}, \end{aligned}$$

where x_i denotes the ith column of X.

There are several ways to choose

$$F_{pq} = \begin{bmatrix} f_{pp} & f_{pq} \\ f_{qp} & f_{qq} \end{bmatrix}$$

and $\tilde{D}$ so that the number of multiplications is reduced by half compared to the standard rotation. The two most commonly used F_{pq} are either of the type $\left[\begin{smallmatrix} 1 & \alpha \\ \beta & 1 \end{smallmatrix}\right]$ or $\left[\begin{smallmatrix} \beta & 1 \\ 1 & \alpha \end{smallmatrix}\right]$. With the first type, we have

$$[\tilde{x}_p, \tilde{x}_q] = [y_p, y_q] \begin{bmatrix} 1 & -\alpha \\ \beta & 1 \end{bmatrix} \begin{bmatrix} cd_p & 0 \\ 0 & cd_q \end{bmatrix};$$

thus,

$$\left\{\begin{array}{c} \tilde{d}_p \Leftarrow cd_p \\ \tilde{d}_q \Leftarrow cd_q \\ \tilde{y}_p \Leftarrow y_p + \beta y_q \\ \tilde{y}_q \Leftarrow y_q - \alpha y_p \end{array}\right\}, \tag{12}$$

where $\alpha = t(d_p/d_q)$, $\beta = t(d_q/d_p)$, and $t = \tan\theta$.

When $|\theta| > (\frac{\pi}{4})$, especially when $|c| \ll 1$, successive multiplications by small factors in D can quickly lead to underflow. To bound the maximum decrease in the diagonal factor matrix D, one must use an alternative formulation of the fast rotation that updates the diagonal elements of D with sines rather than cosines:

$$[\tilde{x}_p, \tilde{x}_q] = [y_p, y_q]\begin{bmatrix} \beta & -1 \\ 1 & \alpha \end{bmatrix}\begin{bmatrix} sd_q & 0 \\ 0 & sd_p \end{bmatrix};$$

thus,

$$\left\{\begin{array}{c} \tilde{d}_p \Leftarrow sd_q \\ \tilde{d}_q \Leftarrow sd_p \\ \tilde{y}_p \Leftarrow y_q + \beta y_p \\ \tilde{y}_q \Leftarrow -y_p + \alpha y_q \end{array}\right\}, \tag{13}$$

where $\alpha = (1/t)(d_q/d_p)$ and $\beta = (1/t)(d_p/d_q)$.

Although, for any rotation, the decrease in magnitude of each element of the diagonal factor D can be bounded by $1/\sqrt{2}$, with the use of the above two formulations, the diagonal elements of D are reduced each time and may eventually cause underflow.

2.2. Modified fast rotations. In [3], de Rijk further developed the fast rotation for the Hestenes algorithm for computing the singular value decomposition on vector processors to eliminate a temporary copy of one of the columns. The idea is that the expression $\tilde{y}_p \Leftarrow y_p + \beta y_q$ in (12) can be rearranged as $y_p = \tilde{y}_p - \beta y_q$; thus, substituting it into the other triad, we get

$$\begin{aligned} \tilde{y}_q &= y_q - \alpha y_p \\ &= y_q - \alpha(\tilde{y}_p - \beta y_q) \\ &= \left(y_q - \left(\frac{\alpha}{1+t^2}\right)\tilde{y}_p\right)(1+t^2) \\ &= (y_q - (\alpha c^2)\tilde{y}_p)(c^{-2}). \end{aligned}$$

Letting the diagonal element d_q of D take care of the value c^{-2}, we get $\tilde{d}_q \Leftarrow \tilde{d}_q/c^2 = d_q/c$ and

$$[\tilde{x}_p, \tilde{x}_q] = [y_p, y_q]\begin{bmatrix} 1 & 0 \\ \beta & 1 \end{bmatrix}\begin{bmatrix} 1 & -\alpha \\ 0 & 1 \end{bmatrix}\begin{bmatrix} cd_p & 0 \\ 0 & c^{-1}d_q \end{bmatrix}$$

$$\left\{\begin{array}{c} \tilde{d}_p \Leftarrow cd_p \\ \tilde{d}_q \Leftarrow c^{-1}d_q \\ \tilde{y}_p \Leftarrow y_p + \beta y_q \\ \tilde{y}_q \Leftarrow y_q - \alpha \tilde{y}_p \end{array}\right\}, \tag{14}$$

where $\alpha \Leftarrow \alpha c^2 = cs(d_p/d_q)$ and $\beta = t(d_q/d_p)$. In the Hestenes algorithm for computing the singular value decomposition, the angle can be always chosen in $[-\frac{\pi}{4}, \frac{\pi}{4}]$, thus $1/\sqrt{2} \leqq |c|$.

The same procedures that yield expression (14) also yield a modification of expression (13) for angles $\theta \in [\frac{\pi}{4}, \frac{\pi}{2}]$ in magnitude to scale the diagonal factor:

$$[\tilde{x}_p, \tilde{x}_q] = [y_p, y_q]\begin{bmatrix}\beta & 1\\ 1 & 0\end{bmatrix}\begin{bmatrix}1 & \alpha\\ 0 & -1\end{bmatrix}\begin{bmatrix}sd_q & 0\\ 0 & s^{-1}d_p\end{bmatrix}$$

$$\left\{\begin{array}{c}\tilde{d}_p \Leftarrow sd_q\\ \tilde{d}_q \Leftarrow s^{-1}d_p\\ \tilde{y}_p \Leftarrow y_q + \beta y_p\\ \tilde{y}_q \Leftarrow -y_p + \alpha\tilde{y}_p\end{array}\right\}, \tag{15}$$

where $\alpha = cs(d_q/d_p)$ and $\beta = (1/t)(d_p/d_q)$.

For the fast rotations, presented in (12) and (13), the order in which the columns are updated is inconsequential providing that the correct vector has been copied for reuse. However, the de Rijk modified fast rotation presented in (14) requires that the pth column be updated before the updating of the qth column. A variant of the de Rijk rotation follows naturally from interchanging the order of the column updates, for angles $|\theta| \leqq \frac{\pi}{4}$:

$$[\tilde{x}_p, \tilde{x}_q] = [y_p, y_q]\begin{bmatrix}1 & -\alpha\\ 0 & 1\end{bmatrix}\begin{bmatrix}1 & 0\\ \beta & 1\end{bmatrix}\begin{bmatrix}c^{-1}d_p & 0\\ 0 & cd_q\end{bmatrix}$$

$$\left\{\begin{array}{c}\tilde{d}_q \Leftarrow cd_q\\ \tilde{d}_p \Leftarrow c^{-1}d_p\\ \tilde{y}_q \Leftarrow y_q - \alpha y_p\\ \tilde{y}_p \Leftarrow y_p + \beta\tilde{y}_q\end{array}\right\}, \tag{16}$$

where $\alpha = t(d_p/d_q)$ and $\beta = cs(d_q/d_p)$, and, for angles $\theta \in [\frac{\pi}{4}, \frac{\pi}{2}]$ in magnitude,

$$[\tilde{x}_p, \tilde{x}_q] = [y_p, y_q]\begin{bmatrix}0 & -1\\ 1 & \alpha\end{bmatrix}\begin{bmatrix}1 & 0\\ -\beta & 1\end{bmatrix}\begin{bmatrix}s^{-1}d_q & 0\\ 0 & sd_p\end{bmatrix}$$

$$\left\{\begin{array}{c}\tilde{d}_q \Leftarrow sd_p\\ \tilde{d}_p \Leftarrow s^{-1}d_q\\ \tilde{y}_q \Leftarrow -y_p + \alpha y_q\\ \tilde{y}_p \Leftarrow y_q - \beta\tilde{y}_q\end{array}\right\}, \tag{17}$$

where $\alpha = (1/t)(d_q/d_p)$ and $\beta = cs(d_p/d_q)$.

We call the new fast rotations presented in (14)–(17) *chained* fast rotations. The following simplified representations of three different methods for applying a plane rotation, $\left[\begin{smallmatrix}c & -s\\ s & c\end{smallmatrix}\right]$, to update the two vectors, w and $v \in \mathscr{R}^n$ illustrate that the new fast rotations can be chained.

Standard rotation:

$$[\tilde{v}, \tilde{w}] = [v, w]\begin{bmatrix}c & -s\\ s & c\end{bmatrix} = [cv + sw, -sv + cw]. \tag{18}$$

Standard fast rotation:

$$[\tilde{v}, \tilde{w}] = [v, w]\begin{bmatrix}1 & \alpha\\ \beta & 1\end{bmatrix} = [v + \beta w, w + \alpha v]. \tag{19}$$

Chained fast rotation:

$$[\tilde{v}, \tilde{w}] = [v, w]\begin{bmatrix} 1 & 0 \\ \beta & 1 \end{bmatrix}\begin{bmatrix} 1 & \alpha \\ 0 & 1 \end{bmatrix} = [v + \beta w,\ w + \alpha(v + \beta w)]. \tag{20}$$

The computational efficiency of the chained fast plane rotation over the standard fast plane rotation results from the elimination of the temporary vector store and read that are necessary for the standard fast plane rotation.

3. Self-scaling algorithms. Using the preceding expressions for fast plane rotations, we now construct algorithms that dynamically scale the elements of the diagonal matrix to be close to one. In the standard fast plane rotation, presented in (12) and (13), both diagonal elements are diminished at each rotation. In the chained fast rotations, presented in (14)–(17), one diagonal element is augmented by the same factor as the other diagonal element is diminished. Expressions (14) and (15) diminish the diagonal element having the smaller index and augment the element having the larger index. This way, the smaller the index is, the more often the corresponding diagonal element will be diminished. Likewise, the larger the index is, the more often the corresponding diagonal element will be augmented. The resulting distribution, after one or more cycles, tends to have the largest diagonal entries in the highest indexed locations and the smallest diagonal entries in the lowest indexed locations. We develop two fast plane rotation algorithms that avoid this unbalanced diagonal element distribution by incorporating dynamic scaling: a four-way branching algorithm and a two-way branching algorithm.

The motivation for the four-way branch algorithm is to force each diagonal element to be close to unity. Thus, the choice of the fast rotation expression will be based on whether each of the two diagonal elements is either greater than or less than unity in magnitude. This allows four possibilities that yield an absolute bound $1/\sqrt{2} \leqq |d_i| \leqq \sqrt{2}$ on the magnitude of the diagonal elements d_i's after any rotation. Table 1 presents the essential idea in the four-way branch algorithms.

The motivation for the two-way branch algorithm is to simplify the four-way branch algorithm and avoid the slow rotation, while constraining the diagonal elements from deviating far from unity. The relative sizes of the two diagonal elements, d_p and d_q, are compared before each rotation in a (p, q) plane is applied, and an appropriate choice from equations (14)–(17) is applied to achieve tighter clustering of the diagonal elements about unity. This idea is summarized in Table 2, where the typical fast rotation F_{pq} for

TABLE 1

	$\lvert\theta\rvert > \frac{\pi}{4}$	$\tilde{d}_p \leftarrow d_q/s$ $\tilde{d}_q \leftarrow sd_p$	$\tilde{d}_p \leftarrow 1$ $\tilde{d}_q \leftarrow 1$

TABLE 2
Two-way branch.

Expression	$\lvert\theta\rvert \leqq \frac{\pi}{4}$	$\lvert\theta\rvert > \frac{\pi}{4}$
$\lvert d_p\rvert \geqq \lvert d_q\rvert$	$\tilde{d}_p \Leftarrow cd_p$ $\tilde{d}_q \Leftarrow d_q/c$ $\alpha = csd_p/d_q$ $\beta = td_q/d_p$ $F_{pq} = \begin{pmatrix} 1 & 0 \\ \beta & 1 \end{pmatrix}\begin{pmatrix} 1 & -\alpha \\ 0 & 1 \end{pmatrix}$	$\tilde{d}_p \Leftarrow d_q/s$ $\tilde{d}_q \Leftarrow sd_p$ $\alpha = d_q/(td_p)$ $\beta = csd_p/d_q$ $F_{pq} = \begin{pmatrix} 0 & -1 \\ 1 & \alpha \end{pmatrix}\begin{pmatrix} 1 & 0 \\ -\beta & 1 \end{pmatrix}$
$\lvert d_p\rvert < \lvert d_q\rvert$	$\tilde{d}_p \Leftarrow d_p/c$ $\tilde{d}_q \Leftarrow cd_q$ $\alpha = td_p/d_q$ $\beta = csd_q/d_p$ $F_{pq} = \begin{pmatrix} 1 & -\alpha \\ 0 & 1 \end{pmatrix}\begin{pmatrix} 1 & 0 \\ \beta & 1 \end{pmatrix}$	$\tilde{d}_p \Leftarrow sd_q$ $\tilde{d}_q \Leftarrow d_p/s$ $\alpha = csd_q/d_p$ $\beta = d_p/(td_q)$ $F_{pq} = \begin{pmatrix} \beta & 1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 1 & \alpha \\ 0 & -1 \end{pmatrix}$

each case is also presented. In the two-way branch algorithm, if two diagonal elements are both greater than unity, the smaller will be augmented. Likewise, the larger of two subunity elements will be diminished. Thus, it allows larger deviations in the diagonal elements compared with the four-way branch algorithms. However, the results of numerical tests show that the bound in the two-way branch algorithms is kept within a small range around one.

The new fast rotations presented in relations (14)–(17) and employed in the two-way branch algorithms have the typical form

$$F_{pq} = \begin{bmatrix} 1 & \alpha \\ \beta & 1 + \alpha\beta \end{bmatrix}$$

or F_{pq} with its rows and/or columns permuted. Although only one element of F_{pq} is unity, the total multiplications required for the transformation by F_{pq} is the same as those for the standard fast rotations. This is because F_{pq} can be applied in two steps as shown in (14)–(17), e.g.,

$$F_{pq} = \begin{bmatrix} 1 & \alpha \\ \beta & 1 + \alpha\beta \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ \beta & 1 \end{bmatrix}\begin{bmatrix} 1 & \alpha \\ 0 & 1 \end{bmatrix}.$$

The implementation results are obtained for the Jacobi algorithm for symmetric eigenvalue decomposition, the Hestenes algorithm for the singular value decomposition, and the QR decomposition. The purpose of the tests is to compare the deviations from unity of the elements in the diagonal factor matrix in the standard fast rotation, the de Rijk fast rotation, and the new fast rotation presented in this paper. For the eigenvalue and singular value decompositions, the total number of sweeps was assigned to be $\log n$, where n is the matrix order. The test matrices were generated with random numbers in the interval $[-1, 1]$ having a uniform distribution. In Tables 3–5, the entries are the average, for 32 tests, of the minimum and maximum of the diagonal elements throughout each test with $\log_{10}$ scaling. The standard deviations of the $\log_{10}$ scaled data are within the parentheses. For the standard fast rotation, only the minimum is shown because the diagonal elements, which are initially 1, are only decreasing. Note that for all the tests

[1] Each entry denotes $\log_{10}$ scaling of the minimum or maximum diagonal elements in the diagonal factor matrix throughout each test. The standard deviations of the $\log_{10}$ scaled data are within the parentheses. Standard, the standard fast rotation; de Rijk, the de Rijk fast rotation; new, the new chained fast rotation with dynamic scaling.

(for the matrices of order up to 128 for the symmetric eigenvalue decomposition and the singular value decomposition and for the matrices of order up to 256 for the *QR* decomposition), the averages for the extremes of the elements in the diagonal factor of the new algorithms stay in $[\frac{1}{3}, 3]$. Also, the standard deviations for the new algorithms are extremely small. The average of the minimum diagonal elements in the standard fast algorithms diminished to as small as $10^{-4.62}$, and the range of the average extremes of the diagonal elements in the diagonal factor matrix in the de Rijk method was as large as $[10^{-3.70}, 10^{3.73}]$. We expect that as the matrix order becomes larger, the advantage of the new fast rotations will become more pronounced. The computational experiments indicate that only the new chained fast rotation algorithm can control the sizes of elements in the diagonal factor for larger matrices.

4. Error analysis.

4.1. Standard fast rotations. We first review the error analysis of the standard fast rotation for the *QR* decomposition, which is based on Parlett [12]. A rotation of two rows, p and q, may be represented as

$$\begin{bmatrix} \tilde{d}_p & 0 \\ 0 & \tilde{d}_q \end{bmatrix}\begin{bmatrix} \tilde{y}_{p1} & \tilde{y}_{p2} & \cdots & \tilde{y}_{pn} \\ 0 & \tilde{y}_{q2} & \cdots & \tilde{y}_{qn} \end{bmatrix} = \begin{bmatrix} c & -s \\ s & c \end{bmatrix}\begin{bmatrix} d_p & 0 \\ 0 & d_q \end{bmatrix}\begin{bmatrix} y_{p1} & y_{p2} & \cdots & y_{pn} \\ y_{q1} & y_{q2} & \cdots & y_{qn} \end{bmatrix},$$

where

$$\begin{bmatrix} \tilde{y}_{p1} & \tilde{y}_{p2} & \cdots & \tilde{y}_{pn} \\ 0 & \tilde{y}_{q2} & \cdots & \tilde{y}_{qn} \end{bmatrix} = \begin{bmatrix} 1 & -\alpha \\ \beta & 1 \end{bmatrix}\begin{bmatrix} y_{p1} & y_{p2} & \cdots & y_{pn} \\ y_{q1} & y_{q2} & \cdots & y_{qn} \end{bmatrix}.$$

Also, let $\tau \equiv \tan\theta$ and $\omega \equiv \cos^2\theta$.

Let ε, $|\varepsilon| \ll 1$, which may be different at every instance, be a tiny number close to *machine-ε*. The inclusion of floating point roundoff error in a computed quantity will be represented by the product of the exact theoretical value with $(1+\varepsilon)$, with the notational shorthand of representing $(1+\varepsilon_1)(1+\varepsilon_2)$ as $(1+\varepsilon)^2$. We will assume that the initial variables are exact, and computed quantities will be denoted by primes.

The computed scalars are

$$\begin{aligned} \alpha' &= \alpha(1+\varepsilon) && \{= y_{q1}/y_{p1}\}, \\ \beta' &= \beta(1+\varepsilon)^3 && \{= \alpha' d_q^2/d_p^2\}, \\ \omega' &= \omega(1+\varepsilon)^6 && \left\{= 1\Big/\left(1+\left(\frac{d_q y_q}{d_p y_p}\right)^2\right)\right\} \\ &\approx (c(1+\varepsilon)^3)^2. \end{aligned} \tag{21}$$

Although we have only the squared values of d_p and d_q in actual computation, we will use d_p and d_q in this analysis.

Then, after the rotation,

$$\begin{Bmatrix} \tilde{d}'_p = d_p c(1+\varepsilon)^4 \\ \tilde{d}'_q = d_q c(1+\varepsilon)^4 \end{Bmatrix}, \tag{22}$$

and the vector equations are

$$\begin{Bmatrix} \tilde{y}'_{pi} = [y_{pi} + \beta' y_{qi}(1+\varepsilon)](1+\varepsilon) = y_{pi}(1+\varepsilon) + \beta y_{qi}(1+\varepsilon)^5 \\ \tilde{y}'_{qi} = [y_{qi} - \alpha' y_{pi}(1+\varepsilon)](1+\varepsilon) = y_{qi}(1+\varepsilon) - \alpha y_{pi}(1+\varepsilon)^3 \end{Bmatrix}. \tag{23}$$

From (22) and (23),

$$\left.\begin{aligned} \tilde{d}'_p\tilde{y}'_{pi} &= d_p c y_{pi}(1+\varepsilon)^5 + d_p c\beta y_{qi}(1+\varepsilon)^9 \\ \tilde{d}'_q\tilde{y}'_{qi} &= d_q c y_{qi}(1+\varepsilon)^5 - d_q c\alpha y_{pi}(1+\varepsilon)^7 \end{aligned}\right\}, \tag{24}$$

and using the first order approximation, $1 + k\varepsilon \approx (1+\varepsilon)^k$, for any integer k,

$$\left.\begin{aligned} \tilde{d}'_p\tilde{y}'_{pi} &= d_p c y_{pi}(1+5\varepsilon) + d_q s y_{qi}(1+9\varepsilon) \\ \tilde{d}'_q\tilde{y}'_{qi} &= d_q c y_{qi}(1+5\varepsilon) - d_p s y_{pi}(1+7\varepsilon) \end{aligned}\right\}. \tag{25}$$

Extracting the error terms, we have the equation

$$\begin{bmatrix} \tilde{d}'_p\tilde{y}'_{pi} \\ \tilde{d}'_q\tilde{y}'_{qi} \end{bmatrix} = \begin{bmatrix} \tilde{d}_p\tilde{y}_{pi} \\ \tilde{d}_q\tilde{y}_{qi} \end{bmatrix} + \begin{bmatrix} 5c\varepsilon & 9s\varepsilon \\ -7s\varepsilon & 5c\varepsilon \end{bmatrix} \begin{bmatrix} d_p y_{pi} \\ d_q y_{qi} \end{bmatrix}, \tag{26}$$

which is of exactly the same form as the equation for the errors incurred in a standard Givens rotation [6]. The same analysis and conclusion holds for the large angle formulas. Equation (26) may be reformulated as the inequality

$$\left\| \begin{bmatrix} \tilde{d}'_p\tilde{y}'_{pi} \\ \tilde{d}'_q\tilde{y}'_{qi} \end{bmatrix} - \begin{bmatrix} \tilde{d}_p\tilde{y}_{pi} \\ \tilde{d}_q\tilde{y}_{qi} \end{bmatrix} \right\| \leqq \left\| \begin{bmatrix} 5c\varepsilon & 9s\varepsilon \\ 7s\varepsilon & 5c\varepsilon \end{bmatrix} \right\| \cdot \left\| \begin{bmatrix} d_p y_{pi} \\ d_q y_{qi} \end{bmatrix} \right\|, \tag{27}$$

where $|A| = (|a_{ij}|)$.

4.2. New fast rotations. To differentiate the computed scalars in the new fast rotations from those of the standard fast rotations, we will use the *hat* notation ($\hat{}$) whenever it is necessary. The computed scalars in the new fast rotations are the same as those in (21) except that α is redefined as $\hat{\alpha}$:

$$\hat{\alpha}' = \hat{\alpha}(1+\varepsilon)^8 \quad \{= \alpha'\omega' = \alpha\omega(1+\varepsilon)^8\}. \tag{28}$$

As before, the unsquared values of d_p and d_q will be used. However, the change from d_q to $\hat{d}_q$ should be noted:

$$\left.\begin{aligned} \tilde{d}'_p &= d_p c(1+\varepsilon)^4 \\ \hat{d}'_q &= (d_q/c)(1+\varepsilon)^4 \end{aligned}\right\}. \tag{29}$$

The chained vector equations are:

$$\left.\begin{aligned} \tilde{y}'_{pi} &= [y_{pi} + \beta' y_{qi}(1+\varepsilon)](1+\varepsilon) \\ \hat{y}'_{qi} &= [y_{qi} - \hat{\alpha}'\tilde{y}'_{pi}(1+\varepsilon)](1+\varepsilon) \end{aligned}\right\}. \tag{30}$$

Expanding (30), we get

$$\left.\begin{aligned} \tilde{y}'_{pi} &= y_{pi}(1+\varepsilon) + \beta y_{qi}(1+\varepsilon)^5 \\ \hat{y}'_{qi} &= y_{qi}(1+\varepsilon) - \alpha\omega[y_{pi}(1+\varepsilon) + \beta y_{qi}(1+\varepsilon)^5](1+\varepsilon)^{10} \\ &= [1 - \alpha\omega\beta(1+\varepsilon)^{14}]y_{qi}(1+\varepsilon) - \alpha\omega y_{pi}(1+\varepsilon)^{11} \end{aligned}\right\}. \tag{31}$$

Factoring in the diagonal elements by merging (29) and (31) with approximation of ε terms up to the first order, we have (noting that $(1 - \alpha\omega\beta(1+\varepsilon)^{14})(1+\varepsilon) \approx (c^2(1+\varepsilon) - 14s^2\varepsilon)$),

$$\left.\begin{aligned} \tilde{d}'_p\tilde{y}'_{pi} &= d_p c y_{pi}(1+5\varepsilon) + d_q s y_{qi}(1+9\varepsilon) \\ \hat{d}'_q\hat{y}'_{qi} &= d_q y_{qi}[c(1+5\varepsilon) - 14s\tau\varepsilon] - d_p s y_{pi}(1+15\varepsilon) \end{aligned}\right\}. \tag{32}$$

Separating out the error terms,

$$\begin{bmatrix} \tilde{d}'_p \tilde{y}'_{pi} \\ \hat{d}'_q \hat{y}'_{qi} \end{bmatrix} = \begin{bmatrix} \tilde{d}_p \tilde{y}_{pi} \\ \hat{d}_q \hat{y}_{qi} \end{bmatrix} + \begin{bmatrix} 5c\varepsilon & 9s\varepsilon \\ -15s\varepsilon & (5c - 15s\tau)\varepsilon \end{bmatrix} \begin{bmatrix} d_p y_{pi} \\ d_q y_{qi} \end{bmatrix}. \tag{33}$$

Because $|\theta| \leqq \frac{\pi}{4}$, $|5c - 14s\tau| \leqq |9c|$, and the following inequality may be formulated

$$\left\| \begin{bmatrix} \tilde{d}'_p \tilde{y}'_{pi} \\ \hat{d}'_q \hat{y}'_{qi} \end{bmatrix} - \begin{bmatrix} \tilde{d}_p \tilde{y}_{pi} \\ \hat{d}_q \hat{y}_{qi} \end{bmatrix} \right\| \leqq \left\| \begin{bmatrix} 5c\varepsilon & 9s\varepsilon \\ 15s\varepsilon & 9c\varepsilon \end{bmatrix} \right\| \cdot \left\| \begin{bmatrix} d_p y_{pi} \\ d_q y_{qi} \end{bmatrix} \right\|. \tag{34}$$

The error analysis for the fast rotation when the qth row is updated first is procedurally identical and yields proportional results:

$$\hat{\beta}' = \hat{\beta}(1 + \varepsilon)^{10} \quad \{ = \beta' \omega' = \beta\omega(1 + \varepsilon)^{10} \}, \tag{35}$$

$$\left\{ \begin{aligned} \tilde{d}'_q &= d_q c(1 + \varepsilon)^4 \\ \hat{d}'_p &= (d_p / c)(1 + \varepsilon)^4 \end{aligned} \right\}, \tag{36}$$

$$\left\{ \begin{aligned} \tilde{y}'_{qi} &= [y_{qi} - \alpha' y_{pi}(1 + \varepsilon)](1 + \varepsilon) \\ \hat{y}'_{pi} &= [y_{pi} - \hat{\alpha}' \tilde{y}'_{qi}(1 + \varepsilon)](1 + \varepsilon) \end{aligned} \right\}, \tag{37}$$

$$\left\{ \begin{aligned} \tilde{y}'_{qi} &= y_{qi}(1 + \varepsilon) - \alpha y_{pi}(1 + \varepsilon)^3 \\ \hat{y}'_{pi} &= y_{pi}(1 + \varepsilon) + \beta\omega[y_{qi}(1 + \varepsilon) - \alpha y_{pi}(1 + \varepsilon)^3](1 + \varepsilon)^{12} \\ &= [1 - \alpha\omega\beta(1 + \varepsilon)^{14}] y_{pi}(1 + \varepsilon) + \beta\omega y_{qi}(1 + \varepsilon)^{13} \end{aligned} \right\}, \tag{38}$$

$$\left\{ \begin{aligned} \tilde{d}'_q \tilde{y}'_{qi} &= d_q c y_{qi}(1 + 5\varepsilon) - d_p s y_{pi}(1 + 7\varepsilon) \\ \hat{\tilde{d}}'_p \hat{y}'_{pi} &= d_p y_{pi}[c(1 + 5\varepsilon) - 14s\tau\varepsilon] + d_q s y_{pi}(1 + 17\varepsilon) \end{aligned} \right\}, \tag{39}$$

$$\begin{bmatrix} \tilde{d}'_q \tilde{y}'_{qi} \\ \hat{d}'_p \hat{y}'_{pi} \end{bmatrix} = \begin{bmatrix} \tilde{d}_q \tilde{y}_{qi} \\ \hat{d}_p \hat{y}_{pi} \end{bmatrix} + \begin{bmatrix} 5c\varepsilon & -7s\varepsilon \\ 17s\varepsilon & (5c - 14s\tau)\varepsilon \end{bmatrix} \begin{bmatrix} d_q y_{qi} \\ d_p y_{pi} \end{bmatrix}. \tag{40}$$

Finally, (40) yields the inequality,

$$\left\| \begin{bmatrix} \tilde{d}'_q \tilde{y}'_{qi} \\ \hat{d}'_p \hat{y}'_{pi} \end{bmatrix} - \begin{bmatrix} \tilde{d}_q \tilde{y}_{qi} \\ \hat{d}_p \hat{y}_{pi} \end{bmatrix} \right\| \leqq \left\| \begin{bmatrix} 5c\varepsilon & 7s\varepsilon \\ 17s\varepsilon & 9c\varepsilon \end{bmatrix} \right\| \cdot \left\| \begin{bmatrix} d_q y_{qi} \\ d_p y_{pi} \end{bmatrix} \right\|. \tag{41}$$

As the derivations (for the error analyses of the large angle formulas) are similar to those of the small angle formulas, we state only the results. For $|\theta| > \frac{\pi}{4}$ and when the qth row is updated based on the updated pth row ($p < q$),

$$\begin{bmatrix} \tilde{d}'_p \tilde{y}'_{pi} \\ \hat{d}'_q \hat{y}'_{qi} \end{bmatrix} = \begin{bmatrix} \tilde{d}_p \tilde{y}_{pi} \\ \hat{d}_q \hat{y}_{qi} \end{bmatrix} + \begin{bmatrix} 9c\varepsilon & 5s\varepsilon \\ -(5s - 14c\tau^{-1})\varepsilon & 15c\varepsilon \end{bmatrix} \begin{bmatrix} d_p y_{pi} \\ d_q y_{qi} \end{bmatrix}, \tag{42}$$

$$\left\| \begin{bmatrix} \tilde{d}'_p \tilde{y}'_{pi} \\ \hat{d}'_q \hat{y}'_{qi} \end{bmatrix} - \begin{bmatrix} \tilde{d}_p \tilde{y}_{pi} \\ \hat{d}_q \hat{y}_{qi} \end{bmatrix} \right\| \leqq \left\| \begin{bmatrix} 9c\varepsilon & 5s\varepsilon \\ 9s\varepsilon & 15c\varepsilon \end{bmatrix} \right\| \cdot \left\| \begin{bmatrix} d_p y_{pi} \\ d_q y_{qi} \end{bmatrix} \right\|, \tag{43}$$

and, for the counter-chained rotation (the pth row is updated based on the updated qth row, $p < q$),

$$\begin{bmatrix} \tilde{d}'_q \tilde{y}'_{qi} \\ \hat{d}'_p \hat{y}'_{pi} \end{bmatrix} = \begin{bmatrix} \tilde{d}_q \tilde{y}_{qi} \\ \hat{d}_p \hat{y}_{pi} \end{bmatrix} + \begin{bmatrix} 7c\varepsilon & -5s\varepsilon \\ (5s - 14c\tau^{-1})\varepsilon & 17c\varepsilon \end{bmatrix} \begin{bmatrix} d_q y_{qi} \\ d_p y_{pi} \end{bmatrix}, \tag{44}$$

$$\left\| \begin{bmatrix} \tilde{d}'_q \tilde{y}'_{qi} \\ \hat{d}'_p \hat{y}'_{pi} \end{bmatrix} - \begin{bmatrix} \tilde{d}_q \tilde{y}_{qi} \\ \hat{d}_p \hat{y}_{pi} \end{bmatrix} \right\| \leqq \left\| \begin{bmatrix} 7c\varepsilon & 5s\varepsilon \\ 9s\varepsilon & 17c\varepsilon \end{bmatrix} \right\| \cdot \left\| \begin{bmatrix} d_q y_{qi} \\ d_p y_{pi} \end{bmatrix} \right\|. \tag{45}$$

As we can see from (34), (41), (43), and (45), because of the chaining between the two linked triads, there is the potential for roughly doubled error in the vector that is updated second, compared with the standard fast rotations. However, the rotation is still stable, as the magnitudes of the elements of the error matrix are bounded by a small constant. For stability, it is important that the small angle formulas must be used when $|\tau| \leqq 1$ and the large angle formulas are required otherwise. Error analyses of other algorithms that employ fast rotations, e.g., the Jacobi and Hestenes algorithms, would proceed similarly and would yield similar stability results.

5. Remarks. We have presented new fast plane rotation algorithms that solve the long-standing overflow and underflow problem that is inherent in the standard fast rotations. The new fast rotation algorithms dynamically scale the elements in the diagonal factor matrix by using a simple comparison for each rotation. An additional advantage of the new fast rotations comes from the fact that the temporary vector copy that is necessary in the standard fast rotations is also eliminated. Accordingly, vector updates can be chained and higher efficiency can be achieved especially on vector processors.

It is essential, for scaling and the numerical stability of the new fast rotations, to choose the appropriate rotation based on the relative size of the angle with $\pm\frac{\pi}{4}$. Certain algorithms, such as the Jacobi algorithm for the symmetric eigenvalue decomposition, do not require rotation angles to exceed $[-\frac{\pi}{4}, \frac{\pi}{4}]$, simplifying the choices in fast rotations. We have shown that the scaling in the chained fast rotation is highly dependent on the direction of the chaining, i.e., which of the two vectors uses the updated value of the other vector for its own update. Although the four-way branch algorithm (Table 1) can guarantee that the diagonal elements in the diagonal factor matrix are in the range $[1/\sqrt{2}, \sqrt{2}]$ at any stage, it can be much slower than the two-way branch algorithm because the standard slow rotations are occasionally required. The two-way branch algorithm (Table 2) is simpler and more efficient. Although we do not have any rigorous proof that the diagonal elements stay in a constant range in the two-way branch algorithm, it provides excellent control of scaling according to our substantial numerical tests. We have found no instance for which the two-way branch algorithm performs poorly in scaling of the diagonal factor. For the case of the QR decomposition, we have shown that the chained fast rotation algorithms have stability that is essentially the same as that of the standard fast rotations.

POSITIVE DEFINITENESS AND STABILITY OF INTERVAL MATRICES*

JIRI ROHN†

Abstract. Characterizations of positive definiteness, positive semidefiniteness, and Hurwitz and Schur stability of interval matrices are given. First it is shown that an interval matrix has some of the four properties if and only if this is true for a finite subset of explicitly described matrices, and some previous results of this type are improved. Second it is proved that a symmetric interval matrix is positive definite (Hurwitz stable, Schur stable) if and only if it contains at least one symmetric matrix with the respective property and is nonsingular (for Schur stability, two interval matrices are to be nonsingular). As a consequence, verifiable sufficient conditions are obtained for positive definiteness and Hurwitz and Schur stability of symmetric interval matrices.

Key words. interval matrix, positive definiteness, positive semidefiniteness, Hurwitz stability, Schur stability, nonsingularity

AMS subject classifications. 15A18, 15A48, 65G10, 93D09

Introduction. In this paper we study positive definiteness, positive semidefiniteness, and Hurwitz and Schur stability of square interval matrices defined in the following way: an interval matrix A^I is said to be positive definite (positive semidefinite, Hurwitz stable) if each matrix $A \in A^I$ is positive definite (positive semidefinite, Hurwitz stable); a slight deviation from this definition is made for Schur stability where a symmetric interval matrix A^I is said to be Schur stable if each *symmetric* $A \in A^I$ is Schur stable. Positive (semi)definiteness of interval matrices is studied in § 2, Hurwitz stability in § 3, and Schur stability in § 4. There are two main streams of results that run across these sections.

First, we show that for each of the four properties listed it holds that A^I (assumed to be symmetric in stability cases) has the property if and only if this is true for a finite subset of explicitly described matrices in A^I. The result for positive (semi)definiteness is given in Theorem 2, where the respective subset is shown to be of cardinality 2^{n-1} (in the worst case) for an $n \times n$ interval matrix A^I; this theorem improves considerably the earlier result by Shi and Gao [13], which used $2^{n(n-1)/2}$ test matrices. A similar result is given in Theorem 6 for Hurwitz stability of symmetric interval matrices, which is again characterized by a subset of matrices of cardinality 2^{n-1}. Hertz [6] has recently proved that stability of this subset implies stability of each symmetric matrix in A^I; our result shows that stability of this subset already implies stability of the whole of A^I.

Second, we show that a symmetric interval matrix A^I is positive definite (Hurwitz stable, Schur stable) if and only if it contains at least one symmetric matrix with the respective property and is regular (for Schur stability, two associated interval matrices are to be regular; A^I is called regular [9] if each $A \in A^I$ is nonsingular). These results, proved in Theorems 3, 8, and 11, reduce the number of test matrices to one but do not remove exponentiality from the verification process because all the necessary and sufficient regularity conditions known ([9], [12]) employ some subset of test matrices whose cardinality is exponential in the matrix size. Nevertheless, because there exists a sufficient regularity condition due to Beeck [2], which is known to cover most practical examples, employing it in the above characterizations leads to sufficient conditions for positive definiteness and Hurwitz and Schur stability of symmetric interval matrices (Theorems 4, 9, and 12), which can be expected to work well in practical cases. In the final remark in § 5, we give a modification of the Beeck's condition that enables us to use an approx-

imation of the inverse of the center matrix of A^I instead of the exact inverse as required in the original formulation.

1. Notations and auxiliary results. We introduce some notations and prove a theorem that sums up the basic technical results to be used later in the proofs of the main theorems.

For a square real matrix $A = (a_{ij})$, we denote the transpose by A^T, the spectral radius by $\rho(A)$, and we introduce its absolute value as the matrix $|A| = (|a_{ij}|)$. A matrix A is called symmetric if $A = A^T$. Symmetric matrices are known to have all eigenvalues real; we shall denote by $\lambda_{\min}(A)$ and $\lambda_{\max}(A)$, the minimum and maximum eigenvalue of A, respectively (obviously, $\lambda_{\min}(-A) = -\lambda_{\max}(A)$). Matrix inequalities, as $A \leqq B$ or $A < B$, are to be understood componentwise.

Let A_c and Δ be real $n \times n$ matrices, $\Delta \geqq 0$. The set of matrices

$$A^I = [A_c - \Delta, A_c + \Delta] = \{A; A_c - \Delta \leqq A \leqq A_c + \Delta\}$$

is called an interval matrix. A^I is said to be symmetric if both A_c and Δ are symmetric. With each interval matrix $A^I = [A_c - \Delta, A_c + \Delta]$ we shall associate the symmetric interval matrix

$$A_s^I = [A_c' - \Delta', A_c' + \Delta'],$$

where A_c' and Δ' are given by

$$A_c' = \tfrac{1}{2}(A_c + A_c^T)$$

and

$$\Delta' = \tfrac{1}{2}(\Delta + \Delta^T).$$

Obviously, if $A \in A^I$, then $\tfrac{1}{2}(A + A^T) \in A_s^I$ and A^I is symmetric if and only if $A^I = A_s^I$.

We introduce an auxiliary index set

$$Y = \{z \in R^n; |z_j| = 1 \quad \text{for } j = 1, \ldots, n\},$$

i.e., Y is the set of all ± 1-vectors; hence, its cardinality is 2^n. For each $z \in Y$ we shall denote by T_z the $n \times n$ diagonal matrix with diagonal vector z. Now for each $z \in Y$ let us define the matrix A_z by

$$A_z = A_c - T_z \Delta T_z.$$

Then for each i, j we have $(A_z)_{ij} = (A_c)_{ij} - z_i \Delta_{ij} z_j = (A_c - \Delta)_{ij}$ if $z_i z_j = 1$ and $(A_z)_{ij} = (A_c + \Delta)_{ij}$ if $z_i z_j = -1$; hence, $A_z \in A^I$ for each $z \in Y$ and because $A_{-z} = A_z$, the number of mutually different matrices A_z is at most 2^{n-1} (and equal to 2^{n-1} if $\Delta > 0$). If A^I is symmetric, then each A_z is symmetric. The matrices A_z, $z \in Y$, will be used in § 2 to characterize positive (semi)definiteness of an interval matrix by finite means.

Let us now introduce a function f: $R^{n \times n} \to R^1$ defined for a matrix $A \in R^{n \times n}$ by

$$f(A) = \min_{x \neq 0} \frac{x^T A x}{x^T x}. \tag{1}$$

Obviously, f is well defined. In the following theorem we sum up the basic properties of f that will be used in the proofs of the main theorems in the subsequent sections.

THEOREM 1. *The function f has the following properties*:

(i) $f(A) = f(\tfrac{1}{2}(A + A^T))$ *for each* $A \in R^{n \times n}$;

(ii) $f(A) = \lambda_{\min}(A)$ *for each symmetric* $A \in R^{n \times n}$;

(iii) $|f(A + D) - f(A)| \leqq \rho(\tfrac{1}{2}(D + D^T))$ *for each* $A, D \in R^{n \times n}$;

(iv) *f is continuous in $R^{n\times n}$*;

(v) *for each interval matrix A^I we have*

$$\min\{f(A); A\in A^I\} = \min\{f(A_z); z\in Y\};$$

(vi) *for each interval matrix A^I we have*

$$\min\{f(A); A\in A^I\} = \min\{f(A); A\in A_s^I\};$$

(vii) *each interval matrix $A^I = [A_c - \Delta, A_c + \Delta]$ satisfies*

$$\min\{f(A); A\in A^I\} \geqq f(A_c) - \rho(\Delta');$$

(viii) *if A is symmetric and $f(A) = 0$, then A is singular.*

Proof. (i) follows from the fact that $x^TAx = x^T(\frac{1}{2}(A + A^T))x$ for each $A\in R^{n\times n}$ and $x\in R^n$. (ii) is well known (cf., e.g., Parlett [10]). To prove (iii), first observe that from (1) it follows

$$f(A + D) \geqq f(A) + f(D)$$

for each A and D; this inequality implies

$$f(A) = f((A + D) + (-D)) \geqq f(A + D) + f(-D),$$

which together gives

$$\begin{aligned} |f(A + D) - f(A)| &\leqq \max\{|f(D)|, |f(-D)|\} \\ &= \max\{|f(\tfrac{1}{2}(D + D^T))|, |f(-\tfrac{1}{2}(D + D^T))|\} \\ &= \max\{|\lambda_{\min}(\tfrac{1}{2}(D + D^T))|, |\lambda_{\max}(\tfrac{1}{2}(D + D^T))|\} \\ &= \rho(\tfrac{1}{2}(D + D^T)). \end{aligned}$$

For (iv) take a matrix norm $\|\cdot\|$ such that $\|A^T\| = \|A\|$ for each A. Then from (iii) we obtain

$$|f(A + D) - f(A)| \leqq \|\tfrac{1}{2}(D + D^T)\| \leqq \|D\|$$

for each A and D, which proves that f is continuous in $R^{n\times n}$.

To prove (v), let $A\in A^I$ and $x\neq 0$. Because $|x^T(A - A_c)x| \leqq |x|^T\Delta|x|$, we obtain $x^TAx = x^TA_cx + x^T(A - A_c)x \geqq x^TA_cx - |x|^T\Delta|x|$. Define a $z\in Y$ as follows: $z_j = 1$ if $x_j \geqq 0$ and $z_j = -1$ otherwise ($j = 1, \ldots, n$), then $|x| = T_zx$ and we have

$$x^TAx \geqq x^TA_cx - x^TT_z\Delta T_zx = x^TA_zx;$$

hence,

$$\frac{x^TAx}{x^Tx} \geqq \frac{x^TA_zx}{x^Tx} \geqq f(A_z) \geqq \min\{f(A_z); z\in Y\},$$

which implies that

$$f(A) \geqq \min\{f(A_z); z\in Y\}$$

holds for each $A\in A^I$ and because $A_z\in A^I$ for each $z\in Y$, the assertion follows.

To prove (vi), for each $z\in Y$ denote by A'_z the matrix A_z for A_s^I, i.e.,

$$A'_z = A'_c - T_z\Delta'T_z = \tfrac{1}{2}(A_c + A_c^T) - T_z(\tfrac{1}{2}(\Delta + \Delta^T))T_z = \tfrac{1}{2}(A_z + A_z^T).$$

Then employing (i) we obtain

$$f(A_z) = f(\tfrac{1}{2}(A_z + A_z^T)) = f(A'_z);$$

hence, the assertion (v) implies that the minimum values of f over A^I and A_s^I are equal.

For (vii) let $A \in A^I$. Since $|A - A_c| \leqq \Delta$, using (iii) and Proposition 3.2.4 in [9] we obtain $|f(A) - f(A_c)| \leqq \rho(\frac{1}{2}(A - A_c) + \frac{1}{2}(A - A_c)^T) \leqq \rho(\frac{1}{2}(\Delta + \Delta^T)) = \rho(\Delta')$, which gives $f(A) \geqq f(A_c) - \rho(\Delta')$ and thus also

$$\min \{f(A); A \in A^I\} \geqq f(A_c) - \rho(\Delta').$$

For (viii) under the assumptions, zero is an eigenvalue of A due to (ii), hence A is singular. □

2. Positive (semi)definiteness of interval matrices. A square (not necessarily symmetric) matrix A is called positive semidefinite if $f(A) \geqq 0$, which, in view of (1), means that $x^T Ax \geqq 0$ for each x (hence our definition conforms to the usual one). Similarly, A is said to be positive definite if $f(A) > 0$ (i.e., $x^T Ax > 0$ for each $x \neq 0$). An *interval matrix* A^I is said to be positive (semi)definite if each $A \in A^I$ is positive (semi)definite. As a consequence of Theorem 1 we obtain this characterization.

THEOREM 2. *Let A^I be a square interval matrix. Then the following assertions are equivalent*:

(a) *A^I is positive (semi)definite*,

(b) *A_S^I is positive (semi)definite*,

(c) *A_z is positive (semi)definite for each $z \in Y$.*

Proof. We shall prove the theorem for the case of positive definiteness of A^I; the proof for positive semidefiniteness runs quite analogously. By definition, A^I is positive definite if and only if

$$\min \{f(A); A \in A^I\} > 0$$

holds. Then the equivalence of (a) and (b) follows from the assertion (vi) of Theorem 1 and that of (a) and (c) from the assertion (v) of the same theorem. □

The assertion (c) shows that positive (semi)definiteness of an interval matrix can be verified by testing 2^{n-1} matrices from A^I for positive (semi)definiteness. Hence, this theorem improves considerably the earlier result by Shi and Gao [13], which required testing $2^{n(n-1)/2}$ matrices from A^I (the so-called vertex matrices) for positive (semi)definiteness; moreover, their result was given for symmetric interval matrices only. We note that Białas and Garloff [4] proved a similar characterization of interval P-matrices (each $A \in A^I$ is a P-matrix if and only if each A_z, $z \in Y$ is a P-matrix), although they did not explicitly use the matrices A_z.

The equivalence "$(a) \Leftrightarrow (b)$" reveals another important property, namely that verification of positive (semi)definiteness of A^I always can be performed by inspecting the associated symmetric interval matrix A_S^I; hence, we can restrict our attention in the sequel to symmetric interval matrices only. First we have this corollary.

COROLLARY. *Let a symmetric interval matrix A^I be positive semidefinite. Then it is positive definite if and only if all the matrices A_z, $z \in Y$ are nonsingular.*

Proof. The "only if" part is obvious because each positive definite matrix is nonsingular. To prove the "if" part, assume to the contrary that A^I is positive semidefinite but not positive definite. Then from the assertion (c) of Theorem 2 it follows that there exists a matrix A_z that is positive semidefinite but not positive definite. Then $f(A_z) = 0$ and because A_z is symmetric, we have that A_z is singular (Theorem 1, (viii)), which is a contradiction. □

In the next theorem we prove that positive definiteness of symmetric interval matrices is closely related to regularity. Let us recall that a square interval matrix A^I is called regular [9] if each $A \in A^I$ is nonsingular.

THEOREM 3. *A symmetric interval matrix A^I is positive definite if and only if it is regular and contains at least one positive definite matrix.*

Proof. Again, the "only if" part is obvious. In the proof of the "if" part, assume to the contrary that A^I is regular and contains a positive definite matrix A_0 but is not positive definite, so that $x^T A_1 x \leqq 0$ for some $A_1 \in A^I$ and $x \neq 0$. Define $\tilde{A}_0 = \frac{1}{2}(A_0 + A_0^T)$ and $\tilde{A}_1 = \frac{1}{2}(A_1 + A_1^T)$, then both $\tilde{A}_0$ and $\tilde{A}_1$ are symmetric, belong to A^I, and satisfy

$$f(\tilde{A}_0) = f(A_0) > 0$$

and

$$f(\tilde{A}_1) = f(A_1) \leqq 0.$$

Now define a real function φ of one real variable by

$$\varphi(t) = f(t\tilde{A}_0 + (1 - t)\tilde{A}_1), \qquad t \in [0, 1].$$

Then φ is continuous by the assertion (iv) of Theorem 1 and because $\varphi(0)\varphi(1) = f(\tilde{A}_1)f(\tilde{A}_0) \leqq 0$, there exists a $t_0 \in [0, 1]$ with $\varphi(t_0) = 0$. Put

$$A = t_0\tilde{A}_0 + (1 - t_0)\tilde{A}_1,$$

then A is symmetric, $A \in A^I$ and $f(A) = 0$; hence, the assertion (viii) of Theorem 1 gives that A is singular, which is a contradiction. □

The necessary and sufficient condition of Theorem 3 requires only one matrix to be tested for positive definiteness. It bears a striking similarity with the characterization of nonnegative invertibility of interval matrices given in [11], Theorem 1 (each $A \in A^I$ is nonnegative invertible if and only if A^I is regular and $(A_c + \Delta)^{-1} \geqq 0$). However, the result is not as pleasant as it might seem because verifying regularity of an interval matrix is generally a difficult problem as it can be clearly seen from Theorem 5.1 in [12], where a number of necessary and sufficient regularity conditions are given, all of which require computation of at least 2^{n-1} quantities of some sort (as evaluating determinants, solving systems of linear equations, inverting matrices, and so on). Nevertheless, there exists an easily verifiable sufficient regularity condition that, in this author's experience, covers most practical examples. Employing it in Theorem 3 leads to this sufficient condition.

THEOREM 4. *Let $A^I = [A_c - \Delta, A_c + \Delta]$ be a symmetric interval matrix such that A_c is positive definite and*

$$\rho(|A_c^{-1}|\Delta) < 1 \tag{2}$$

holds. Then A^I is positive definite.

Proof. Because A_c is positive definite, it is invertible and the condition (2) guarantees regularity of A^I (see Beeck [2]). Hence, Theorem 3 gives that A^I is positive definite. □

We also note that if $(|A_c^{-1}|\Delta)_{jj} \geqq 1$ for some j, then A^I contains a singular matrix (assertion (iii) of Corollary 5.1 in [12]); hence, A^I is not positive definite.

Another sufficient condition can be derived from Theorem 1.

THEOREM 5. *Let a symmetric interval matrix $A^I = [A_c - \Delta, A_c + \Delta]$ satisfy*

$$\rho(\Delta) \leqq \lambda_{\min}(A_c). \tag{3}$$

Then A^I is positive semidefinite. Moreover, if the inequality (3) holds sharply, then A^I is positive definite.

Proof. According to the assertions (vii) and (ii) of Theorem 1, we have $\min\{f(A); A \in A^I\} \geqq \lambda_{\min}(A_c) - \rho(\Delta) \geqq 0$; hence, $f(A) \geqq 0$ for each $A \in A^I$, so that A^I is positive semidefinite. If (3) holds sharply, then $f(A) > 0$ for each $A \in A^I$; hence, A^I is positive definite. □

In the next section we shall apply the results obtained to characterize stability of symmetric interval matrices.

3. Hurwitz stability of interval matrices. A square matrix A is called Hurwitz stable (for the sake of brevity, we shall say only "stable") if $\operatorname{Re}\lambda < 0$ for each eigenvalue λ of A (in other words, if all its eigenvalues lie in the open left half of the complex plane). An interval matrix A^I is said to be stable if each $A \in A^I$ is stable. The problem of stability of interval matrices arises naturally in control theory in connection with the behavior of a linear time invariant system $\dot{x}(t) = Ax(t)$ under data perturbations and has been extensively studied recently; we refer the reader to the survey paper by Mansour [8] for a detailed list of references. We investigate here mainly stability of symmetric interval matrices, which turns out to be closely connected to the contents of the previous section due to the well-known result that states a symmetric matrix A is stable if and only if $-A$ is positive definite (see, e.g., [5]). However, some care must be taken because a symmetric interval matrix can contain nonsymmetric matrices whose eigenvalues are not real. As an example, consider the symmetric interval matrix $A^I = [A_c - \Delta, A_c + \Delta]$ with $A_c = 0$ and

$$\Delta = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix},$$

which contains the matrix

$$\begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$$

whose eigenvalues are $\pm i$.

In contrast to the previous section where we employed the matrices $A_z = A_c - T_z\Delta T_z$, here we shall characterize stability in terms of matrices

$$\bar{A}_z = A_c + T_z\Delta T_z, \qquad z \in Y.$$

Obviously, $\bar{A}_z \in A^I$ and all $\bar{A}_z$ are symmetric if A^I is symmetric.

THEOREM 6. *Let $A^I = [A_c - \Delta, A_c + \Delta]$ be a symmetric interval matrix. Then the following assertions are equivalent*:

(a) *A^I is stable*,

(b) *$[-A_c - \Delta, -A_c + \Delta]$ is positive definite*,

(c) *$\bar{A}_z$ is stable for each $z \in Y$.*

Proof. We shall prove that $(a) \Rightarrow (c) \Rightarrow (b) \Rightarrow (a)$. Let us denote $A_0^I = [-A_c - \Delta, -A_c + \Delta]$; notice that $A_0^I = \{-A; A \in A^I\}$.

$(a) \Rightarrow (c)$: The proof is obvious because $\bar{A}_z \in A^I$ for each $z \in Y$.

$(c) \Rightarrow (b)$: Let $z \in Y$. Because $\bar{A}_z$ is symmetric and stable, it follows that all its eigenvalues are negative; hence, the symmetric matrix

$$-\bar{A}_z = -A_c - T_z\Delta T_z$$

has all eigenvalues positive, so that it is positive definite [5]. But $-\bar{A}_z$ is just the matrix A_z for the interval matrix A_0^I; hence, A_0^I is positive definite by the assertion (c) of Theorem 2.

$(b) \Rightarrow (a)$: Let A_0^I be positive definite. Consider an eigenvalue λ of a matrix $A \in A^I$. Due to the Bendixson theorem ([15], p. 395), we have

$$\operatorname{Re}\lambda \leqq \lambda_{\max}(\tfrac{1}{2}(A + A^T)),$$

where the matrix $\tilde{A} = \frac{1}{2}(A + A^T)$ is symmetric and belongs to A^I; hence, $-\tilde{A} \in A_0^I$. Thus, $-\tilde{A}$ is positive definite so that all eigenvalues of $\tilde{A}$ are negative, which gives that $\operatorname{Re}\lambda \leqq \lambda_{\max}(\tilde{A}) < 0$. Hence, A is stable, and because it was chosen arbitrarily, A^I is also stable. □

There are several previous results relevant to the equivalence $(a) \Leftrightarrow (c)$. First, let us recall that a matrix $A \in A^I$ is called a vertex matrix of A^I if for each $i, j \in \{1, \ldots, n\}$, either $A_{ij} = (A_c - \Delta)_{ij}$ or $A_{ij} = (A_c + \Delta)_{ij}$ holds. Thus, there are exactly 2^{n^2} vertex matrices in the most disadvantageous case of $\Delta > 0$. Clearly, $\bar{A}_z$ is a vertex matrix for each $z \in Y$. The first attempt to use vertex matrices for characterizing stability was made by Białas [3], who proved that a general interval matrix A^I is stable if and only if all its vertex matrices are stable. His result was shown, however, to be erroneous by Karl, Greschak, and Verghese [7] and independently by Barmish and Hollot [1]. Soh [14] proved in 1990 that the conjecture is true for *symmetric* interval matrices in this form: if all the symmetric vertex matrices of A^I are stable, then each symmetric $A \in A^I$ is stable. This result required testing $2^{n(n+1)/2}$ vertex matrices for stability. This bound has been essentially improved recently by Hertz [6], who proved (using another notation) that if all the matrices $\bar{A}_z$ are stable, then each *symmetric* $A \in A^I$ is stable; this reduced the number of test matrices from $2^{n(n+1)/2}$ to 2^{n-1}. Theorem 6 shows that under the Hertz assumption *each* matrix $A \in A^I$ is already stable.

In Theorem 2 we showed that positive (semi)definiteness of a general interval matrix can be equivalently formulated in terms of the associated symmetric interval matrix A_s^I. Unfortunately, this nice property does not hold for stability, where only one implication is true.

THEOREM 7. *If A_s^I is stable, then A^I is also stable.*

Proof. Let λ be an eigenvalue of a matrix $A \in A^I$. Then by the Bendixson theorem we have $\operatorname{Re} \lambda \leqq \lambda_{\max}(\frac{1}{2}(A + A^T)) < 0$ because the symmetric matrix $\frac{1}{2}(A + A^T)$ belongs to A_s^I and thus has all eigenvalues negative. This proves that A^I is stable. □

The converse implication is generally not valid. Consider the interval matrix $A^I = [A_c - \Delta, A_c + \Delta]$ with

$$A_c = \begin{pmatrix} 1 & 7 \\ -1 & -2 \end{pmatrix}$$

and $\Delta = 0$. Here A^I is stable because A_c is stable ($\operatorname{Re} \lambda_1 = \operatorname{Re} \lambda_2 = -\frac{1}{2}$), but A_s^I is not because $\lambda_{\max}(A_c') = (\sqrt{45} - 1)/2 = 2.85\cdots$.

Finally, we give the respective versions of Theorems 3 and 4 for the case of stability. The reformulations are direct consequences of the equivalence $(a) \Leftrightarrow (b)$ of Theorem 6.

THEOREM 8. *A symmetric interval matrix A^I is stable if and only if it is regular and contains at least one stable symmetric matrix.*

Proof. The "only if" part follows from the fact that each stable matrix is nonsingular. Conversely, if A^I is regular and contains a stable symmetric matrix $\tilde{A}$, then $A_0^I = [-A_c - \Delta, -A_c + \Delta] = \{-A;\ A \in A^I\}$ is also regular and contains a positive definite matrix $-\tilde{A}$; hence, A_0^I is positive definite by Theorem 3 and A^I is stable by Theorem 6. □

The last result of this section follows from Theorem 4 applied to the interval matrix $[-A_c - \Delta, -A_c + \Delta]$ and its straightforward proof is omitted.

THEOREM 9. *Let $A^I = [A_c - \Delta, A_c + \Delta]$ be a symmetric interval matrix such that A_c is stable and*

$$\rho(|A_c^{-1}|\Delta) < 1$$

holds. Then A^I is stable.

For a practical verification, the results of this section can be used in the following way. Given an interval matrix A^I, first form the symmetric interval matrix A_s^I and test it for stability using Theorem 9. If the test is successful, then A^I is stable (Theorem 7).

This procedure will, however, fail whenever A^I is stable, whereas A_s^I is not, as, e.g., in the example following Theorem 7. In such a case another condition must be tried (cf. Mansour [8] for further results).

Example. Consider the interval matrix $A^I = [A_c - \Delta, A_c + \Delta]$ with

$$A_c = \begin{pmatrix} -1 & -1 & 2 \\ 3 & -2 & -5 \\ -2 & 1 & -5 \end{pmatrix}$$

and $\Delta_{ij} = 0.03$ for each i, j. Then for the associated symmetric interval matrix $A_s^I = [A_c' - \Delta', A_c' + \Delta']$, we have

$$A_c' = \begin{pmatrix} -1 & 1 & 0 \\ 1 & -2 & -2 \\ 0 & -2 & -5 \end{pmatrix}$$

and $\Delta' = \Delta$. Because A_c' is stable and $\rho(|(A_c')^{-1}|\Delta') = 0.9 < 1$, Theorems 7 and 9 imply that A^I is stable.

4. Schur stability of interval matrices. A square matrix A is called Schur stable if $\rho(A) < 1$, i.e., if $|\lambda| < 1$ for each eigenvalue λ of A. We shall consider here Schur stability of symmetric matrices only to avoid complex eigenvalues that seemingly cannot be easily handled by the method used. Therefore, we shall say that a symmetric interval matrix A^I is Schur stable if each *symmetric* matrix $A \in A^I$ is Schur stable; hence, we do not take into account the nonsymmetric matrices contained in A^I. This definition is in accordance with the approach employed in [14] or [6].

A necessary and sufficient condition for Schur stability has been recently given by Hertz [6], who proved that a symmetric interval matrix A^I is Schur stable if and only if all the matrices $A_z, \bar{A}_z, z \in Y$ are Schur stable. In Theorem 11 below we formulate another necessary and sufficient condition based on the following result that links Schur stability to Hurwitz stability.

THEOREM 10. *A symmetric interval matrix $A^I = [A_c - \Delta, A_c + \Delta]$ is Schur stable if and only if the symmetric interval matrices*

$$[(A_c - I) - \Delta, (A_c - I) + \Delta] \tag{4}$$

and

$$[(-A_c - I) - \Delta, (-A_c - I) + \Delta] \tag{5}$$

are stable, where I is the unit matrix.

Proof. Only if: Denote the interval matrix (4) by $\tilde{A}^I$ and let $\tilde{A}_z = (A_c - I) + T_z \Delta T_z = \bar{A}_z - I$ for $z \in Y$. Because $\bar{A}_z$ is symmetric and Schur stable, it has all eigenvalues in $(-1, 1)$; therefore, all the eigenvalues of $\tilde{A}_z$ belong to $(-2, 0)$; hence, $\tilde{A}_z$ is stable. In view of Theorem 6 this implies that $\tilde{A}^I$ is stable. Stability of (5) can be proved in a similar way if we consider the matrices $\tilde{\tilde{A}}_z = -A_z - I$, $z \in Y$.

If: Let $A \in A^I$ be symmetric and let λ be an eigenvalue of A. Then $\lambda - 1$ is an eigenvalue of the matrix $A - I$ that belongs to (4) and hence is stable, which gives $\lambda - 1 < 0$. In a similar way, stability of (5) implies $-\lambda - 1 < 0$. Hence, $|\lambda| < 1$; thus, A^I is Schur stable. □

Now we have this criterion that is again formulated along the lines of Theorems 3 and 8.

THEOREM 11. *A symmetric interval matrix A^I is Schur stable if and only if it contains at least one Schur stable symmetric matrix and both the interval matrices* (4) *and* (5) *are regular.*

Proof. Only if: If A^I is Schur stable, then both (4) and (5) are stable by Theorem 10; hence, regular. If: Let some symmetric $A_0 \in A^I$ be Schur stable and let (4) and (5) be regular. Then $A_0 - I$ is symmetric, stable, and belongs to (4); hence, (4) is stable by Theorem 8. Similarly, stability of (5) can be established by considering the matrix $-A_0 - I$. Then Theorem 10 gives that A^I is Schur stable. □

Again, using sufficient regularity condition, we obtain the following.

THEOREM 12. *Let $A^I = [A_c - \Delta, A_c + \Delta]$ be a symmetric interval matrix such that A_c is Schur stable and the conditions*

$$\rho(|A_c - I|^{-1}\Delta) < 1 \tag{6}$$

$$\rho(|A_c + I|^{-1}\Delta) < 1 \tag{7}$$

are satisfied. Then A^I is Schur stable.

Proof. This is a direct consequence of Theorem 11 because (6) and (7) are the Beeck sufficient regularity conditions [2] for the interval matrices (4) and (5). □

5. Final remark. In Theorems 4, 9, and 12 we formulated verifiable sufficient conditions for positive definiteness, Hurwitz and Schur stability of symmetric interval matrices. Each of them involved the sufficient condition (2) for regularity of an interval matrix $A^I = [A_c - \Delta, A_c + \Delta]$. This condition may be seen to be inappropriate for practical computations because the inverse matrix computed on a computer is usually afflicted with roundoff errors. Therefore, for practical purposes we propose a modified condition

$$\rho(|I - QA_c| + |Q|\Delta) < 1 \tag{8}$$

involving an arbitrary square matrix Q, because we have: *if* (8) *holds for some Q, then A^I is regular*. In fact, for an arbitrary $A \in A^I$, we have

$$QA = I - (I - QA_c + Q(A_c - A))$$

and because

$$\rho(I - QA_c + Q(A_c - A)) \leqq \rho(|I - QA_c| + |Q|\Delta) < 1,$$

it follows that QA is nonsingular; hence, A is nonsingular. Notice that (2) is a special case of (8) for $Q = A_c^{-1}$. In practical computations we recommend to set Q equal to the *computed* value of A_c^{-1}.

Acknowledgment. The author wishes to thank two anonymous referees for helpful suggestions.

ESPRIT DIRECTION-OF-ARRIVAL ESTIMATION IN THE PRESENCE OF SPATIALLY CORRELATED NOISE*

HAESUN PARK†

Abstract. An algorithm is presented for ESPRIT (estimation of signal parameters via rotational invariance techniques) direction of arrival estimation when the expected value of the covariance of the measurement noise is different from a constant multiple of an identity matrix. The algorithm is based on a modification of the generalized singular value decomposition (GSVD) of two data matrices and requires only unitary transformations. The modification results in a significant simplification of the GSVD-based ESPRIT algorithm and produces more accurate solutions than prewhitening.

Key words. correlated noise, direction of arrival, generalized singular value decomposition

AMS subject classifications. 15A18, 15A23

1. Introduction. ESPRIT is a recently developed method for signal parameter estimation with applications in array signal processing such as direction of arrival estimation [7], [8]. The method is based on a sensor array consisting of two identical subarrays separated by a known displacement vector. It provides estimates of the signal parameters by exploiting the eigenstructure of the underlying rotational invariance. For other applications where similar structures arise, see [8]. We briefly describe the array geometry and signal model assumed in ESPRIT and show how the algorithm is formulated. Since the goal of this paper is to develop an efficient and numerically robust algorithm to estimate the directions of arrival according to the ESPRIT method, we will state the problem in a matrix-oriented language. For the detailed description and assumptions on which the formulation is based, see [7] and [8]. Throughout this paper, the superscript asterisk (*) of a matrix denotes the complex conjugate transpose of the matrix and i denotes the pure imaginary number $\sqrt{-1}$.

The array considered in ESPRIT consists of m sensor pairs. The sensor array is grouped into two subarrays, X and Y, that are assumed to be displaced by a known translation vector. We denote the number of sources by d, which is unknown, and assume the relation that $m \geqq d$. Let $A \in C^{m \times d}$ be the unknown matrix with rank d, whose columns are the steering vectors associated with the sources, and let $\Phi = \operatorname{diag}(e^{i\gamma_1}, \ldots, e^{i\gamma_d}) \in C^{d \times d}$ be the unitary diagonal matrix that relates the measurements from subarray X to those from subarray Y. The sensor output $x(t)$, $y(t) \in C^{m \times 1}$ is modeled as

$$x(t) = As(t) + n_x(t), \qquad y(t) = A\Phi s(t) + n_y(t), \tag{1.1}$$

where $s(t) \in C^{d \times 1}$ is an unknown vector of impinging signals and $n_x(t)$, $n_y(t) \in C^{m \times 1}$ are unknown noise vectors. Combining the two equations in (1.1), we have

$$z(t) \equiv \begin{bmatrix} x(t) \\ y(t) \end{bmatrix} = \begin{bmatrix} A \\ A\Phi \end{bmatrix} s(t) + n_z(t), \tag{1.2}$$

where

$$n_z(t) = \begin{bmatrix} n_x(t) \\ n_y(t) \end{bmatrix}.$$

Assuming that the signals are uncorrelated with the noise and that the expected value of $s(t)s(t)^*$, $E(ss^*)$, is a positive definite covariance matrix R_{SS}, we have

$$E(zz^*) = \begin{bmatrix} A \\ A\Phi \end{bmatrix} R_{SS} \begin{bmatrix} A \\ A\Phi \end{bmatrix}^* + E(n_z n_z^*).$$

The problem is to find the unitary diagonal matrix Φ when we have the matrices $H_z \in C^{N_z \times 2m}$ and $H_n \in C^{N_n \times 2m}$ with full column rank that estimate $E(zz^*)$ and $E(n_z n_z^*)$, which is $E(zz^*) \approx H_z^* H_z$ and $E(n_z n_z^*) \approx \sigma^2 \Sigma = \sigma^2 H_n^* H_n$, with

$$H_z^* H_z \approx \begin{bmatrix} A \\ A\Phi \end{bmatrix} R_{SS} \begin{bmatrix} A \\ A\Phi \end{bmatrix}^* + \sigma^2 H_n^* H_n. \tag{1.3}$$

For notational convenience, we replace $\approx$ by $=$ in (1.3) in the following. Once the unitary diagonal matrix Φ is found, the directions of arrival can be derived from Φ by simple arithmetic. For details, see [7] and [8].

There have been many numerical algorithms developed for the ESPRIT direction of arrival methods [7], [8] where the noise is assumed to be white, i.e., the expected value of the covariance of the measurement noise has the form $E(n_z n_z^*) = \sigma^2 I$. In the more general case when $E(n_z n_z^*) = \sigma^2 \Sigma$, where $\Sigma \neq I$ is positive definite, prewhitening of the measurement noise using $\Sigma^{-1/2}$ avoids the generalized eigenvalue problem [8], [11]. However, when prewhitening is used, numerical difficulty can occur. To avoid the difficulty, a solution via a GSVD has been developed [13].

In this paper, we present an algorithm for the ESPRIT direction of arrival estimation when $E(n_z n_z^*) = \sigma^2 \Sigma$ where Σ is positive definite. The new algorithm produces numerically more accurate solutions than the prewhitening method and is more efficient than the existing GSVD-based method [13]. Our method is based on a special form of the GSVD, computation of which relies solely upon unitary transformations applied to the data matrices. The special form of the GSVD simplifies the computations in the ESPRIT by taking advantage of the structure of an intermediate matrix. Further advantages of the new form of the GSVD for ESPRIT will be discussed after the algorithm is introduced.

2. GSVD. The following theorem introduces the GSVD as was originally defined in Van Loan [12].

THEOREM 1. *Suppose that two matrices $H_z \in C^{N_z \times 2m}$ with $N_z \geqq 2m$ and $H_n \in C^{N_n \times 2m}$ are given. Then there exist unitary matrices $U_z \in C^{N_z \times N_z}$ and $U_n \in C^{N_n \times N_n}$ and a nonsingular matrix $X \in C^{2m \times 2m}$ such that*

$$\begin{aligned} U_z^* H_z X &= D_z = \operatorname{diag}(\alpha_1, \ldots, \alpha_{2m}) \in C^{N_z \times 2m}, \\ U_n^* H_n X &= D_n = \operatorname{diag}(\beta_1, \ldots, \beta_p) \in C^{N_n \times 2m}, \end{aligned} \tag{2.1}$$

where $p = \min(N_n, 2m)$, $\alpha_i \geqq 0$ for $1 \leqq i \leqq 2m$, and $\beta_i \geqq 0$ for $1 \leqq i \leqq p$. □

We will assume throughout this paper that $N_z \geqq 2m$ and $N_n \geqq 2m$, thus, $p = 2m$, since enough samples should be taken to provide good estimates for the directions of arrival. It is well known that a generalized eigenvalue problem for finding the scalars μ's that satisfy $\det(H_z^* H_z - \mu H_n^* H_n) = 0$ can be solved by computing the GSVD of H_z and H_n since

$$\det(H_z^* H_z - \mu H_n^* H_n) = \det(D_z^* D_z - \mu D_n^* D_n) \det(X^{-*} X^{-1}).$$

This gives better numerical solutions since the explicit formation of the products $H_z^* H_z$ and $H_n^* H_n$ is avoided.

Although the GSVD can produce numerically more accurate solutions, computing the GSVD is a difficult task when the matrices are ill conditioned [4]–[6]. If the nonsingular matrix X from the GSVD is required, then we can expect numerical difficulties when the data matrices H_z and H_n are ill conditioned. Paige and Saunders [5] suggest an alternative form of the GSVD that has better numerical properties. Paige [4] proposed an algorithm that computes this alternative form for the GSVD. We define yet another form of the GSVD in Theorem 2 upon which the new algorithm for the ESPRIT relies. The new GSVD of (2.2) is identical to the GSVD introduced by Paige and Saunders except that in [5], the matrix L is upper triangular. It will become clear that it is critical to have the lower triangular matrix L for simplifying the computation of the ESPRIT algorithm.

THEOREM 2. *Suppose that two matrices $H_z \in C^{N_z \times 2m}$ and $H_n \in C^{N_n \times 2m}$ with $N_z \geqq 2m$ and $N_n \geqq 2m$ are given. Then there exist unitary matrices $U_z \in C^{N_z \times N_z}$, $U_n \in C^{N_n \times N_n}$, and $Q \in C^{2m \times 2m}$, and lower triangular matrices $L_z \in C^{N_z \times 2m}$ and $L_n \in C^{N_n \times 2m}$, such that*

$$U_z^* H_z Q = L_z \quad \text{and} \quad U_n^* H_n Q = L_n, \tag{2.2}$$

where $L_z = D_z L$ and $L_n = D_n L$ for a nonsingular lower triangular matrix $L \in C^{2m \times 2m}$ and diagonal matrices $D_z = \operatorname{diag}(\alpha_1, \ldots, \alpha_{2m}) \in C^{N_z \times 2m}$ and $D_n = \operatorname{diag}(\beta_1, \ldots, \beta_{2m}) \in C^{N_n \times 2m}$ with $\alpha_i \geqq 0$ and $\beta_i \geqq 0$ for $1 \leqq i \leqq 2m$. Moreover, if each of H_z and H_n has full column rank, then the elements in D_z and D_n can be ordered so that

$$\frac{\alpha_1}{\beta_1} \geqq \frac{\alpha_2}{\beta_2} \geqq \cdots \geqq \frac{\alpha_{2m}}{\beta_{2m}} \tag{2.3}$$

is satisfied.

Proof. Let

$$U_z^* H_z X = D_z \quad \text{and} \quad U_n^* H_n X = D_n \tag{2.4}$$

be the GSVD of H_z and H_n according to Theorem 1. Consider the decomposition of X into a unitary matrix $Q \in C^{2m \times 2m}$ and a lower triangular matrix $L^{-1} \in C^{2m \times 2m}$: $X = QL^{-1}$. Then we have $U_z^* H_z Q = D_z L$ and $U_n^* H_n Q = D_n L$. The second part is obvious since the diagonal elements of D_z and D_n in the decomposition (2.4) can be ordered to satisfy the condition (2.3) via a permutation P, then the above process can be applied to XP. □

Although Theorem 2 introduces a modified form for the GSVD that gives a numerically more robust and efficient algorithm for ESPRIT, our algorithm to compute the GSVD of (2.2) would not follow the procedure given in the proof. A better way to compute the new GSVD is given in Algorithm GSVD_L in § 3, which is essentially the same as the algorithm due to Paige [4], except that a matrix W in each step is chosen to lower triangularize the 2×2 submatrices, whereas Paige upper triangularizes the submatrices.

THEOREM 3. *Suppose that $H_z \in C^{N_z \times 2m}$ and $H_n \in C^{N_n \times 2m}$ have full column rank and that they have the* GSVD *as in* (2.2) *and D_z and D_n are ordered to satisfy* (2.3). *Also, assume that $H_z^* H_z = \begin{bmatrix} A \\ A\Phi \end{bmatrix} R_{SS} \begin{bmatrix} A \\ A\Phi \end{bmatrix}^* + \sigma^2 H_n^* H_n$, where $A \in C^{m \times d}$ has rank d, $\Phi \in C^{d \times d}$ is unitary and diagonal, and R_{SS} is symmetric positive definite. Then*

$$\frac{\alpha_1}{\beta_1} \geqq \cdots \geqq \frac{\alpha_d}{\beta_d} \geqq \frac{\alpha_{d+1}}{\beta_{d+1}} = \cdots = \frac{\alpha_{2m}}{\beta_{2m}} = \sigma \tag{2.5}$$

and

$$\begin{bmatrix} A \\ A\Phi \end{bmatrix} R_{SS} \begin{bmatrix} A \\ A\Phi \end{bmatrix}^* = Q_1 L_{11}^* \Sigma L_{11} Q_1^*, \tag{2.6}$$

where $Q = [Q_1 \quad Q_2]$ *with* $Q_1 \in C^{2m \times d}$, $Q_2 \in C^{2m \times (2m-d)}$,

$$L = \begin{bmatrix} L_{11} & 0 \\ L_{21} & L_{22} \end{bmatrix}$$

with $L_{11} \in C^{d \times d}$, *and* $\Sigma = \operatorname{diag}(\alpha_1^2 - \sigma^2\beta_1^2, \alpha_2^2 - \sigma^2\beta_2^2, \ldots, \alpha_d^2 - \sigma^2\beta_d^2) \in R^{d \times d}$.

Proof. For the proof of the first part that involves (2.5), see [13].

$$\begin{aligned} \begin{bmatrix} A \\ A\Phi \end{bmatrix} R_{SS} \begin{bmatrix} A \\ A\Phi \end{bmatrix}^* &= H_z^* H_z - \sigma^2 H_n^* H_n = QL^*(D_z^* D_z - \sigma^2 D_n^* D_n) L Q^* \\ &= [Q_1 \quad Q_2] \begin{bmatrix} L_{11}^* & L_{21}^* \\ 0 & L_{22}^* \end{bmatrix} \begin{bmatrix} \Sigma & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} L_{11} & 0 \\ L_{21} & L_{22} \end{bmatrix} \begin{bmatrix} Q_1^* \\ Q_2^* \end{bmatrix} \\ &= Q_1 L_{11}^* \Sigma L_{11} Q_1^*. \qquad \square \end{aligned}$$

Dividing the matrix $Q_1 \in C^{2m \times d}$ further into two parts

$$Q_1 = \begin{bmatrix} Q_x \\ Q_y \end{bmatrix},$$

where $Q_x \in C^{m \times d}$ and $Q_y \in C^{m \times d}$, we have

$$\begin{bmatrix} A \\ A\Phi \end{bmatrix} R_{SS} \begin{bmatrix} A \\ A\Phi \end{bmatrix}^* = \begin{bmatrix} Q_x \\ Q_y \end{bmatrix} L_{11}^* \Sigma L_{11} \begin{bmatrix} Q_x \\ Q_y \end{bmatrix}^*. \tag{2.7}$$

Accordingly,

$$AR_{SS}A^* - \lambda AR_{SS}\Phi^*A^* = AR_{SS}(I - \lambda\Phi^*)A^* = Q_x L_{11}^* \Sigma L_{11}(Q_x^* - \lambda Q_y^*),$$

and rank $(AR_{SS}(I - \lambda\Phi^*)A^*) < d$ if and only if λ is the same as one of the diagonal elements of Φ. That is, to find Φ, we have only to find $\lambda_1, \ldots, \lambda_d$ that make

$$\text{rank}\,(Q_x L_{11}^* \Sigma L_{11}(Q_x^* - \lambda Q_y^*)) < d, \quad \text{i.e., rank}\,(Q_x^* - \lambda Q_y^*) < d. \tag{2.8}$$

The importance of the lower triangular structure of the matrix L in the GSVD of (2.2) is clear from Theorem 3, since only the upper left $d \times d$ submatrix L_{11} of L is required in representing the matrix $[{}^{A}_{A\Phi}]\, R_{SS} [{}^{A}_{A\Phi}]^*$ as shown in (2.7). In fact, none of the elements from L is needed: the lower triangular structure of the matrix L resulted in requiring only Q_x and Q_y for finding the matrix Φ as shown in (2.8). The difficult problem that remains is that the eigenvalues of a rectangular matrix pencil $Q_x^* - \lambda Q_y^* \in C^{d \times m}$ must be computed. We can apply one of two previously developed approaches [8], [13] for reducing the problem to an eigenproblem of a square pencil. From the relation in (2.7),

$$\text{null}\,(Q_x^*) = \text{null}\,(Q_y^*) = \text{null}\,(A^*). \tag{2.9}$$

Let a matrix $J_1 \in C^{m \times (m-d)}$ satisfy span $(J_1) =$ null (Q_x^*) and be expanded to a nonsingular matrix $J = [J_1 \quad J_2] \in C^{m \times m}$. Then

$$\text{rank}\,(Q_x^* - \lambda Q_y^*) = \text{rank}\,((Q_x^* - \lambda Q_y^*)J) < d, \quad \text{i.e., rank}\,(Q_x^* J_2 - \lambda Q_y^* J_2) < d, \tag{2.10}$$

and the values λ are the eigenvalues of a $d \times d$ square pencil. The matrix J can be obtained from the QR decomposition of Q_x [13].

We can also reduce the rectangular matrix pencil into a square pencil by using the total least squares (TLS) technique [2] as in TLS-ESPRIT [8]. Since

$$\text{Range}\,(Q_x) = \text{Range}\,(Q_y) = \text{Range}\,(A) \tag{2.11}$$

from (2.7), there must be a unique nonsingular matrix $T \in C^{d\times d}$ such that

$$Q_x = Q_y T. \tag{2.12}$$

Since

$$\text{rank}\,(Q_x^* - \lambda Q_y^*) = \text{rank}\,(T^* Q_y^* - \lambda Q_y^*) < d, \quad \text{i.e., rank}\,(T^* - \lambda I) < d,$$

we have only to find the eigenvalues of T^*. In practice, neither of the relations (2.9) or (2.11) can hold exactly in finite precision. We estimate the matrix T using the TLS idea as in TLS-ESPRIT, assuming that Q_x and Q_y are equally noisy [2], [8]. The algorithm is summarized in § 3.

3. New algorithm. In general, the matrices $H_z \in C^{N_z\times 2m}$ and $H_n \in C^{N_n\times 2m}$ in ESPRIT satisfy the relations that $N_z \gg 2m$ and $N_n \gg 2m$. The initial factorization of each matrix into a unitary matrix and a lower triangular form (we will call it a QL factorization),

$$H_z = Q_z \begin{bmatrix} L_z \\ 0 \end{bmatrix} \quad \text{and} \quad H_n = Q_n \begin{bmatrix} L_n \\ 0 \end{bmatrix},$$

reduces the computational costs for the GSVD substantially. If the GSVD of L_z and L_n is

$$U_1^* L_z Q = L_1, \qquad U_2^* L_n Q = L_2, \tag{3.1}$$

where $L_1 = D_1 L$ and $L_2 = D_2 L$, then the GSVD of H_z and H_n can be obtained as

$$\left(Q_z \begin{bmatrix} U_1 & 0 \\ 0 & I \end{bmatrix}\right)^* H_z Q = \begin{bmatrix} L_1 \\ 0 \end{bmatrix}, \qquad \left(Q_n \begin{bmatrix} U_2 & 0 \\ 0 & I \end{bmatrix}\right)^* H_n Q = \begin{bmatrix} L_2 \\ 0 \end{bmatrix}. \tag{3.2}$$

Note that the same unitary matrix Q appears in both (3.1) and (3.2), which is the only unitary matrix we need from the decomposition for our ESPRIT algorithm. Thus the problem is reduced to computing the GSVD of two lower triangular matrices L_z, $L_n \in C^{2m\times 2m}$, and there is no need to compute Q_z, Q_n, U_1, or U_2. The Paige algorithm [4] for computing the GSVD of two real matrices is similar to the Jacobi algorithm for computing the SVD. If we start with a triangular matrix and use cyclic-by-rows ordering, the matrix will alternate between upper and lower triangular forms after each sweep. Since the lower triangular structure of L is required in our algorithm, we can finish the iterations after an even number of sweeps when we start with two lower triangular matrices L_z and L_n. For parallel implementation, we can also use the odd-even ordering that preserves the original triangular structure. For details, see [1] and [4].

The algorithm for computing our GSVD is summarized in Algorithm GSVD_L. For a matrix X, X_{pq} denotes the 2×2 submatrix of X:

$$\begin{bmatrix} x_{pp} & x_{pq} \\ x_{qp} & x_{qq} \end{bmatrix}.$$

Similarly, for a 2×2 matrix Y, $Y(p, q)$ denotes a matrix of proper dimension that is like an identity matrix, except that its 2×2 submatrix in the (p, q) plane is Y.

ALGORITHM GSVD_L ($H_z \in C^{N_z \times 2m}$, $H_n \in C^{N_n \times 2m}$)

0. $Q := I_{2m}$.
1. Compute the QL decomposition of H_z and H_n:

$$H_z = Q_z \begin{bmatrix} A \\ 0 \end{bmatrix} \quad \text{and} \quad H_n = Q_n \begin{bmatrix} B \\ 0 \end{bmatrix}.$$

2. Repeat until convergence.
3. Iterate for one sweep using odd-even ordering.
   /* assume that the current index pair is (p, q).
3.1. Determine 2×2 unitary matrices U, V, and J
   so that $U^* A_{pq} J$ and $V^* B_{pq} J$ are lower triangular and
   the second row of $U^* A_{pq} J$ is parallel to the second row of $V^* B_{pq} J$.
3.2. {update the matrices}
   $A := U^*(p, q) A J(p, q)$,
   $B := V^*(p, q) B J(p, q)$,
   $Q := Q J(p, q)$.

The algorithm is terminated when each row of A is parallel to the corresponding row of B. Under the assumption that H_z and H_n have full column rank, the computed generalized singular values α_i / β_i can be obtained from a_{ii} / b_{ii}. For our application, none of the left unitary transformations need to be saved. Thus, the input matrices $H_z \in C^{N_z \times 2m}$ and $H_n \in C^{N_n \times 2m}$ can be overwritten by the lower triangular matrices $L_z \in C^{2m \times 2m}$ and $L_n \in C^{2m \times 2m}$. The discussions from § 2 are summarized in the following algorithm, using the TLS approximation.

ALGORITHM ESPRIT_GSVD_L

1. Form the matrices H_z and H_n from the available measurements.
2. Compute the GSVD of H_z and H_n

$$U_z^* H_z Q = L_z \quad \text{and} \quad U_n^* H_n Q = L_n$$

   according to Algorithm GSVD_L.
3. Estimate the number of sources d from L_z and L_n.
   Let

$$\begin{bmatrix} Q_x \\ Q_y \end{bmatrix}$$

   be the first d columns of Q.
4. Compute the SVD of

$$[Q_x \quad Q_y] = WD \begin{bmatrix} V_{11} & V_{12} \\ V_{21} & V_{22} \end{bmatrix}^*.$$

5. Compute the eigenvalues of $-V_{12} V_{22}^{-1}$.

Two existing algorithms, one based on the GSVD of form (2.2) due to Van Loan and the other based on the TLS-ESPRIT with prewhitening, are summarized in algorithms ESPRIT_GSVD and ESPRIT_PREWHITENING, respectively. For the definition of the CS decomposition used in Algorithm ESPRIT_GSVD, see Golub and Van Loan [3].

ALGORITHM ESPRIT_GSVD

1. Form the matrices H_z and H_n from the available measurements.
2. Compute the QR decomposition

$$\begin{bmatrix} H_z \\ H_n \end{bmatrix} = \begin{bmatrix} Q_1 \\ Q_2 \end{bmatrix} R,$$

   where $Q_1 \in C^{N_z \times 2m}$, $Q_2 \in C^{N_n \times 2m}$, and $R \in C^{2m \times 2m}$.
3. Compute the CS decomposition of Q_1 and Q_2:

$$U_1^* Q_1 Q = C \quad \text{and} \quad U_2^* Q_2 Q = S.$$

4. Estimate the number of sources d from C and S.
   Let

$$\begin{bmatrix} Q_x \\ Q_y \end{bmatrix}$$

   be the first d columns of R^*Q.
5. Compute the SVD of

$$[Q_x \quad Q_y] = WD \begin{bmatrix} V_{11} & V_{12} \\ V_{21} & V_{22} \end{bmatrix}^*.$$

6. Compute the eigenvalues of $-V_{12}V_{22}^{-1}$.

Note that the matrices Q_1, Q_2, and R from step 2 need to be saved for steps 3 and 4. Thus the storage requirement of Algorithm ESPRIT_GSVD is larger than that of Algorithm ESPRIT_GSVD_L. Assuming that the complexity for computing the GSVD in ESPRIT_GSVD_L and the complexity for the CS decomposition in ESPRIT_GSVD are about the same, ESPRIT_GSVD is more costly and the control is more complicated than that of ESPRIT_GSVD_L since Q_1, Q_2, and R^*Q should be computed.

ALGORITHM ESPRIT_PREWHITENING

1. Form the matrices H_z and H_n from the available measurements.
   Measure Σ such that $E(n_z n_z^*) = \sigma^2 \Sigma$ (or assume that Σ is known).
2. Compute $\Sigma^{-1/2}$.
3. Compute the SVD of $H_z\Sigma^{-1/2}$: $H_z\Sigma^{-1/2} = UDQ^*$.
4. Estimate the number of sources d from D.
   Let

$$\begin{bmatrix} Q_x \\ Q_y \end{bmatrix}$$

   be the first d columns of $\Sigma^{1/2}{}^*Q$.
5. Compute the SVD of

$$[Q_x \quad Q_y] = WD \begin{bmatrix} V_{11} & V_{12} \\ V_{21} & V_{22} \end{bmatrix}^*.$$

6. Compute the eigenvalues of $-V_{12}V_{22}^{-1}$.

All three algorithms were coded in MATLAB on a SUN 3/80 with the machine precision $\varepsilon = 2.2204E - 16$. Both algorithms ESPRIT_GSVD_L and ESPRIT_GSVD

produced solutions that are essentially the same in accuracy. When the condition number of the noise matrix H_n is large, prewhitening suffered from numerical difficulties. For example, when the condition number of $H_n \approx 1/\sqrt{\varepsilon}$, with the directions of arrival 14° and 15°, and signal-to-noise ratio 10, while two algorithms based on the GSVD produced answers accurate to the ninth digit, prewhitening failed (the eigenvalues produced in step 6 have absolute values far from unit or the algorithm broke down without completion) 25 times out of 30 tests.

Remarks. We have presented a new algorithm for the ESPRIT direction of arrival estimation in the presence of noise of which the expected value of the covariance is $\sigma^2\Sigma$, where Σ is not necessarily an identity matrix. The new algorithm has been shown to be more efficient than the existing GSVD-based algorithm in terms of storage and complexity. Also, it produces more accurate solutions than the prewhitening method. The fact that only the unitary matrix Q is needed would make the systolic array for the new algorithm simple. The implementation of the new algorithm on a two-dimensional mesh-connected array should be straightforward from the results presented in [6].

One difficulty in the parallel implementation of the proposed algorithm is that the generalized singular values need to be ordered in decreasing order. We have modified the Paige algorithm so that the generalized singular values of the 2×2 submatrices in each step are ordered. More research is needed regarding the relation between the ordering of the singular values and the convergence.

Recently, Stewart [9], [10] introduced new decompositions of a matrix based on two-sided unitary transformations, and they are called the URV and ULV decompositions. These can be generalized for the triangularization of a matrix pair analogous to the GSVD. The generalized URV and ULV decompositions have many potential applications, especially where the solutions should adapt to changing statistics. Note that (2.2) can be used as a starting point for such generalization of the URV and ULV decompositions. Rank estimation and recursive updating will need to be incorporated to fully realize the generalized URV and generalized ULV decompositions. The advantage of this approach is that the solution can be recursively updated in an efficient way, which will lead to an adaptive ESPRIT algorithm.

Acknowledgments. The author wishes to thank Professor M. Kaveh and Mr. R. Hamza for a program to generate simulated data for the direction of arrival estimation. She also thanks Mr. B. Drake for introducing her to the problem discussed in this paper.

FINDING THE BEST REGRESSION SUBSET BY REDUCTION IN NONFULL-RANK CASES*

ALAN H. FEIVESON†

Abstract. The computational problem of finding the best fitting subset of independent variables in least-squares regression with a fixed subset size is addressed, especially in the context of the nonfull-rank case with more variables than observations. For the full-rank case, the most efficient widely used methods work by finding the complementary subset with minimum reduction to the total regression sum of squares; a task that can usually be accomplished with far less computation than exhaustive evaluation of all subsets. Here, a method using Cholesky-type factorizations (Algorithm 2) has been developed, which also takes advantage of the computational savings offered by the "reduction" approach, but which can be used in nonfull-rank cases where existing methods are not applicable. Algorithm 2 is derived by examining the asymptotic properties of a full-rank procedure (Algorithm 1) used on a "ridge" perturbation of the cross-product matrix. In the course of testing, it was discovered that Algorithm 1, with the appropriate ridge parameter, usually selected the best subset with less computation than Algorithm 2; however, if one requires mathematical certitude, use of Algorithm 2 is indicated. Also, some new approaches are proposed for developing efficient methods of identifying the best subset directly, rather than by complement to the minimum-reduction subset.

1. Introduction.

Consider the standard linear regression model form

$$\mathbf{y} = \mathbf{X}\beta + \mathbf{e}, \tag{1.1}$$

where $\mathbf{y}$ is an $n \times 1$ vector of observations, $\mathbf{X}$ is an $n \times p$ matrix of n given values of p independent variables $\{\mathbf{x}_j;\ j = 1, \ldots, p\}$, β is a $p \times 1$ vector of unknown coefficients, and $\mathbf{e}$ is an error term with unspecified distribution. In the regression subset selection problem, given an integer $k < p$, we wish to find the subset S^* that maximizes $R(S, k)$, the regression sum of squares obtained by least-squares fitting of y to the k independent variables $\{\mathbf{x}_j | j \in S\}$, where S is a k-subset of the integers $1, 2, \ldots, p$.

In this paper, we are concerned only with the computational problem of finding S^*. Reasons for subset selection are discussed extensively in the literature, many involving minimizing estimation or prediction errors associated with a "true" underlying model, e.g., [3], [8], and [5]. In the estimation/prediction scenario, in addition to $R(S, k)$, the stability of the k-variate estimate of β should also be considered; cf. [2, p. 414]. Simulation results given by J. Hoerl, Schuenemeyer, and A. Hoerl [7] showed a tendency for subset models to be inferior to ridge regression for purposes of estimating β. A more efficacious application for subset selection by maximization of $R(S, k)$ is in the area of empirical modeling, where we observe $\mathbf{y}$ and $\mathbf{x}_1, \ldots, \mathbf{x}_{p^*}$, where $p^* < p$. No exact physical model of how $\mathbf{y}$ relates to $\mathbf{x}_1, \ldots, \mathbf{x}_{p^*}$ is known, but the goal is to interpolate the response between the experimental values of $\mathbf{x}_1, \ldots, \mathbf{x}_{p^*}$. This is done by generating $p - p^*$ *new* independent variables as functions of the originals (e.g., powers, ratios, etc.), with the intent of approximately representing the unknown response function by a linear combination of $\mathbf{x}_1, \ldots, \mathbf{x}_p$. No pretense is made about an unbiased estimation of β, since no actual underlying model of the form (1.1) is assumed. Indeed, if $\mathbf{y}$ is measured with no error, $\mathbf{e}$ may well be nonrandom, representing only model misspecification. The

† National Aeronautics and Space Administration, Lyndon B. Johnson Space Center, Houston, Texas 77058 (feiveson@astro.jsc.nasa.gov).

interpolating function should be reasonable in that (1) it fits the experimental data, and (2) it does not have excess "wiggles." The latter requirement can be generally satisfied by including only a limited number of terms (i.e., k) in the interpolating model; hence the selection problem.

Let $\mathbf{d} = \mathbf{X}'\mathbf{y}$ and $\mathbf{Q} = \mathbf{X}'\mathbf{X}$. For S a k-subset of $\{1, \ldots, p\}$, let $\mathbf{Q}_S$ be the principal submatrix (PSM) of $\mathbf{Q}$ corresponding to S. We shall assume $\mathbf{Q}_S$ to be nonsingular although $\mathbf{Q}$ may not be. Then $R(S, k) = \mathbf{d}_S'\mathbf{Q}_S^{-1}\mathbf{d}_S$, where $\mathbf{d}_S$ is the $k \times 1$ subvector of $\mathbf{d}$ also corresponding to S. Clearly, for large p and most values of k, it is not practical, especially on personal computers, to compute all $\binom{p}{k}$ values of $R(S, k)$ to find the maximum. Let $RTOT$ be the regression sum of squares on all p variables. We can ease the computational problem by searching for the complementary subset $\bar{S}$ of size $p - k$, which minimizes $L(\bar{S}, p - k) = RTOT - R(S, k)$, the reduction in the regression sum of squares due to removing $\{\mathbf{x}_j \mid j \in \bar{S}\}$. It has been shown, e.g., [4], that by solving this dual problem, we can avoid evaluating all subsets, because if a complementary subset of size less than $p - k$ exhibits a larger reduction than the candidate for the minimum, all subsets containing the smaller one will produce at least as large a reduction and hence will be ineligible to improve on the current candidate. In the remainder of this paper, this fact will be referred to as the monotone-reduction property.

When $\mathbf{Q}$ has full rank, it is well known that

$$L(\bar{S}, p - k) = \mathbf{b}_{\bar{S}}'\mathbf{C}_{\bar{S}}^{-1}\mathbf{b}_{\bar{S}}, \tag{1.2}$$

where $\mathbf{b}_{\bar{S}}$ and $\mathbf{C}_{\bar{S}}$ are the respective $(p - k) \times 1$ subvector and $(p - k) \times (p - k)$ submatrix of $\mathbf{b} = \mathbf{Q}^{-1}\mathbf{d}$ and $\mathbf{C} = \mathbf{Q}^{-1}$, corresponding to the elements of $\bar{S}$. Methods for computing (1.2) through sequential modification of $\mathbf{C}_{\bar{S}}^{-1}$ have further reduced computation. The algorithm of Furnival and Wilson [1], which is more general in that it finds the best regressions for all values of k, is based on the above reasoning, and is perhaps the most widely used procedure for subset selection today.

In the empirical-modeling problem there is no limit to the number of transformations of the original independent variables that can be made to define new ones. As a consequence, p could exceed n, making $\mathbf{Q}$ singular and the reduction as given by (1.2) undefined. In this paper, a procedure (Algorithm 2) is developed for comparing $L(\bar{S}, p - k)$ to a specified value that lends itself to sequential modification with changes in $\bar{S}$ when $\mathbf{Q}$ is singular. This allows relatively efficient identification of the best subset without evaluation of all values of $L(\bar{S}, p - k)$ or $R(S, k)$. The method is derived by examining the asymptotic properties of a full-rank procedure (Algorithm 1) used with ridge regression.

2. Ridge selection. In the singular case, $L(\bar{S}, p - k)$ cannot be evaluated by (1.2); however, borrowing from Hoerl and Kennard [6], we may replace $\mathbf{Q}$ with a *ridge* adjustment $\mathbf{Q} + \varepsilon\mathbf{M}$, where $\mathbf{M}$ is symmetric and otherwise arbitrary as long as $\mathbf{Q}(\varepsilon) = \mathbf{Q} + \varepsilon\mathbf{M}$ is positive definite for all $\varepsilon > 0$. We shall refer to $\mathbf{M}$ as the *ridge matrix*. For $\varepsilon > 0$, let $\mathbf{C}(\varepsilon) = \mathbf{Q}^{-1}(\varepsilon)$ and $\mathbf{b}(\varepsilon) = \mathbf{Q}^{-1}(\varepsilon)\mathbf{d}$. Define $L(\bar{S}, p - k; \mathbf{M}, \varepsilon)$ to be (1.2) with $\mathbf{C}_{\bar{S}}(\varepsilon)$ and $\mathbf{b}_{\bar{S}}(\varepsilon)$, the corresponding submatrix of $\mathbf{C}(\varepsilon)$ and subvector of $\mathbf{b}(\varepsilon)$ replacing $\mathbf{C}_{\bar{S}}$ and $\mathbf{b}_{\bar{S}}$, respectively. We use the term *ridge selection* to mean finding the subset that minimizes $L(\bar{S}, p - k; \mathbf{M}, \varepsilon)$.

Let q be the rank of $\mathbf{Q}$. Then there exists a $p \times q$ matrix $\mathbf{V}$ such that $\mathbf{V}'\mathbf{V} = \mathbf{I}_q$ and $\mathbf{Q} = \mathbf{V}\mathbf{\Lambda}\mathbf{V}'$, where $\mathbf{\Lambda} = \operatorname{diag}(\lambda_1, \ldots, \lambda_q)$, λ_j being the jth positive eigenvalue of $\mathbf{Q}$. Let $\mathbf{H} = \mathbf{I}_p - \mathbf{V}\mathbf{V}'$. Then for $\varepsilon > 0$, $\mathbf{Q} + \varepsilon\mathbf{H}$ has eigenvalues $\lambda_1, \ldots, \lambda_q, \varepsilon, \ldots, \varepsilon$ and is thus positive definite. It will be shown by Theorem 2 that for ε sufficiently small, the subset chosen by ridge selection with $\mathbf{M} = \mathbf{H}$ is S^*. To prove Theorem 2, we first need Theorem 1.

THEOREM 1. *Given* $\mathbf{H}$ *defined as above,* $\lim_{\varepsilon \to 0+} L(\bar{S}, p-k; \mathbf{H}, \varepsilon) = L(\bar{S}, p-k)$ for all $(p-k)$-subsets $\bar{S} \subset \{1, 2, \ldots, p\}$.

Proof. For $\varepsilon > 0$, the relationship between regression and reduction sums of squares can be expressed by

$$\mathbf{d}'(\mathbf{Q} + \varepsilon\mathbf{H})^{-1}\mathbf{d} = \mathbf{d}'_{\bar{S}}(\mathbf{Q}_{\bar{S}} + \varepsilon\mathbf{H})^{-1}\mathbf{d}_{\bar{S}} + \mathbf{b}'_{\bar{S}}(\varepsilon)[\mathbf{C}_{\bar{S}}(\varepsilon)]^{-1}\mathbf{b}_{\bar{S}}(\varepsilon). \tag{2.1}$$

Denoting the terms in (2.1) by $a_1(\varepsilon)$, $a_2(\varepsilon)$, and $a_3(\varepsilon)$, respectively, it will be shown that $a_1(\varepsilon) = RTOT$ and that $\lim_{\varepsilon \to 0+} a_2(\varepsilon) = R(S, k)$. It follows that $\lim_{\varepsilon \to 0+} a_3(\varepsilon)$ must be equal to $RTOT - R(S, k) = L(\bar{S}, p-k)$.

Value of $a_1(\varepsilon)$. Recall $\mathbf{Q} = \mathbf{V}\Lambda\mathbf{V}'$ and $\mathbf{H} = \mathbf{I}_p - \mathbf{V}\mathbf{V}'$. The matrix $\mathbf{H}$ is symmetric, idempotent and satisfies $\mathbf{V}'\mathbf{H} = \mathbf{0}$; hence it is easily verified that

$$\mathbf{Q}^{-1}(\varepsilon) = [\mathbf{Q} + \varepsilon\mathbf{H}]^{-1} = \mathbf{V}\Lambda^{-1}\mathbf{V}' + \left(\frac{1}{\varepsilon}\right)\mathbf{H}. \tag{2.2}$$

Since $\mathbf{d} = \mathbf{X}'\mathbf{y}$, there exists a $p \times 1$ vector α such that $\mathbf{d} = \mathbf{X}'\mathbf{X}\alpha = \mathbf{V}\Lambda\mathbf{V}'\alpha$. ($\alpha$ is a solution to the normal equations; e.g., see Searle [9].) Using $\mathbf{V}'\mathbf{V} = \mathbf{I}_q$, $\mathbf{V}'\mathbf{H} = \mathbf{0}$, and (2.2) we obtain $\mathbf{d}'\mathbf{Q}^{-1}(\varepsilon)\mathbf{d} = \alpha'\mathbf{V}\Lambda\mathbf{V}'\alpha = \alpha'\mathbf{Q}\alpha$, the total regression sum of squares, or $RTOT$, which does not depend on ε and is unique even though α is not.

Limit of $a_2(\varepsilon)$. Since $\mathbf{Q}_{\bar{S}}$ is positive definite, $\lim_{\varepsilon \to 0+} \mathbf{d}'_{\bar{S}}(\mathbf{Q}_{\bar{S}} + \varepsilon\mathbf{H})^{-1}\mathbf{d}_{\bar{S}} = \mathbf{d}'_{\bar{S}}\mathbf{Q}_{\bar{S}}^{-1}\mathbf{d}_{\bar{S}} = R(S, k)$. □

Using Theorem 1, we can now prove Theorem 2, which states that ridge selection with $\mathbf{M} = \mathbf{H}$ is asymptotically correct.

THEOREM 2. *Let* $\bar{S}_\varepsilon$ *be the subset that minimizes* $L(\bar{S}, p-k; \mathbf{H}, \varepsilon)$. *Then for* ε *sufficiently small,* $\bar{S}_\varepsilon$ *minimizes* $L(\bar{S}, p-k)$.

Proof. Let $\bar{S}^*$ be the $(p-k)$-subset that minimizes $L(\bar{S}, p-k)$, and let $\delta = L(\bar{S}^*, p-k) - L(\bar{S}', p-k)$, where $L(\bar{S}', p-k)$ is the second-lowest reduction sum of squares. From Theorem 1, $\varepsilon > 0$ can be found such that $|L(\bar{S}, p-k; \mathbf{H}, \varepsilon) - L(\bar{S}, p-k)| < \frac{\delta}{3}$ for all $(p-k)$-subsets $\bar{S} \subset \{1, 2, \ldots, p\}$. Then

$$\begin{aligned}
L(\bar{S}_\varepsilon, p-k) &< L(\bar{S}_\varepsilon, p-k; \mathbf{H}, \varepsilon) + \frac{\delta}{3} \text{ (from Theorem 1)} \\
&\leqq L(\bar{S}^*, p-k; \mathbf{H}, \varepsilon) + \frac{\delta}{3} \text{ (by definition of } \bar{S}_\varepsilon) \\
&< \left[L(\bar{S}^*, p-k) + \frac{\delta}{3}\right] + \frac{\delta}{3} \text{ (from Theorem 1)} \\
&= L(\bar{S}^*, p-k) + \frac{2\delta}{3} = L(\bar{S}', p-k) - \frac{\delta}{3}.
\end{aligned}$$

Thus $\bar{S}_\varepsilon$ must be $\bar{S}^*$. □

Remark. If the ridge matrix is the $p \times p$ identity, it can be shown that Theorem 1 and hence Theorem 2 with $\mathbf{I}$ replacing $\mathbf{H}$ still hold. In this case, $[\mathbf{Q} + \varepsilon\mathbf{I}_p]^{-1} = \mathbf{V}(\Lambda + \varepsilon\mathbf{I}_q)^{-1}\mathbf{V}' + (\frac{1}{\varepsilon})\mathbf{H}$; hence $a_1(\varepsilon) = \alpha'\mathbf{V}\Lambda(\Lambda + \varepsilon\mathbf{I}_q)^{-1}\Lambda\mathbf{V}'\alpha$, which has the limit $\alpha'\mathbf{V}\Lambda\mathbf{V}'\alpha = RTOT$ as $\varepsilon \to 0$. It follows that $\lim_{\varepsilon \to 0+} a_3(\varepsilon)$ must still be equal to $L(\bar{S}, p-k)$.

Although ridge selection with $\mathbf{M} = \mathbf{H}$ is used later as a device to derive the main result (Algorithm 2), it was found that using $\mathbf{M} = \mathbf{I}$ for appropriate values of ε gives surprisingly good results by itself. Ridge selection with $\mathbf{M} = \mathbf{I}$ can be easily implemented by appending $\varepsilon^{1/2}$ times the $p \times p$ identity matrix as additional rows of $\mathbf{X}$ and p zeros as

additional elements of $\mathbf{y}$, then using conventional software to find the best subset. The degree of success of this subterfuge depends on how well calculations stand up on the ill-conditioned matrix $\mathbf{Q} + \varepsilon\mathbf{I}$. This type of ridge selection was tested using Algorithm 1 in § 3 on several data sets with more variables than observations (see § 7). With $\mathbf{X}'\mathbf{X}$ in correlation form, it was found that ε on the order of 10^{-4} worked well in that the best subset was usually identified.

3. Comparing $L(\bar{S}, p - k)$ to a specified value. Despite the knowledge that for "small" ε, ridge selection theoretically identifies the best subset, we can never be assured in practice that ε was small enough or that numerical accuracy problems caused by small values of ε did not give spurious results. We therefore seek an exact method that does not suffer these shortcomings.

For the moment, let us revert to the full-rank case. We construct a procedure (Algorithm 1) that finds the best subset by comparing $L(\bar{S}, p - k)$ with trial minimum values. In § 4, this procedure is applied to $\mathbf{Q}(\varepsilon)$ with ridge matrix $\mathbf{H}$ and the limiting form as $\varepsilon \to 0$ is derived. Because of Theorem 2, we are assured that the limiting form of the procedure will find the best subset. To develop Algorithm 1 we need Theorem 3.

THEOREM 3. *For $L^* > 0$, let $\mathbf{D} = \mathbf{C} - (1/L^*)\mathbf{b}\mathbf{b}'$, where $\mathbf{C} = \mathbf{Q}^{-1}$ and $\mathbf{b} = \mathbf{Q}^{-1}\mathbf{d}$ as before. Let $\mathbf{D}_{\bar{S}}$* be the PSM of $\mathbf{D}$ *corresponding to the elements of a reduction subset $\bar{S}$ of size $m = p - k$. Then $L(\bar{S}, m) < L^*$ if and only if $\mathbf{D}_{\bar{S}}$* is positive definite.

Proof.

$$
\begin{aligned}
&\mathbf{D}_{\bar{S}} = \mathbf{C}_{\bar{S}} - \left(\frac{1}{L^*}\right)\mathbf{b}_{\bar{S}}\mathbf{b}'_{\bar{S}}, \\
\Rightarrow\ &|\mathbf{D}_{\bar{S}}| = |\mathbf{C}_{\bar{S}}|\left|I_m - \left(\frac{1}{L^*}\right)\mathbf{C}_{\bar{S}}^{-1}\mathbf{b}_{\bar{S}}\mathbf{b}'_{\bar{S}}\right|, \\
&\qquad = |\mathbf{C}_{\bar{S}}|\left[1 - \left(\frac{1}{L^*}\right)\mathbf{b}'_{\bar{S}}\mathbf{C}_{\bar{S}}^{-1}\mathbf{b}_{\bar{S}}\right], \\
&\qquad = |\mathbf{C}_{\bar{S}}|\left[1 - \frac{L(\bar{S}, m)}{L^*}\right].
\end{aligned}
\tag{3.1}
$$

The matrix $\mathbf{D}_{\bar{S}}$ is a rank-one perturbation of the positive-definite matrix $\mathbf{C}_{\bar{S}}$. It can thus be shown (e.g., see [2, p. 270]) that $\mathbf{D}_{\bar{S}}$ has at most one negative eigenvalue (of multiplicity not exceeding one). It follows that $|\mathbf{D}_{\bar{S}}| > 0$ if and only if $\mathbf{D}_{\bar{S}}$ is positive definite. Since $|\mathbf{C}_{\bar{S}}| > 0$, it can be seen from (3.1) that $L(\bar{S}, m) < L^*$ if and only if $\mathbf{D}_{\bar{S}}$ is positive definite. □

Theorem 3 suggests the following algorithm to find the best subset.

ALGORITHM 1.

Step 1. Number the m-subsets lexicographically: $\bar{S}_1 = \{1, 2, \ldots, m\}$, $\bar{S}_2 = \{1, 2, \ldots, m-1, m+1\}, \ldots, \bar{S}_M = \{p - m + 1, \ldots, p\}$, where $M = \binom{p}{m}$.

Step 2. Find an initial candidate $\bar{S}^*$ for the best subset, say, by stepwise regression. Set $i = 1$.

Step 3. Let $L^* = L(\bar{S}^*, m)$ and $\mathbf{D} = \mathbf{C} - (1/L^*)\mathbf{b}\mathbf{b}'$.

Step 4. Check $\mathbf{D}_{\bar{S}_i}$ for positive definiteness by attempting the Cholesky factorization $\mathbf{D}_{\bar{S}_i} = \mathbf{B}_{\bar{S}_i}(\mathbf{B}_{\bar{S}_i})'$, where $\mathbf{B}_{\bar{S}_i}$ is lower triangular. If the factorization fails, increment i; if $i = M + 1$, go to Step 6, otherwise repeat Step 4. If the factorization succeeds, go to Step 5.

Step 5. $\mathbf{D}_{\bar{S}_i}$ is positive definite; hence $L(\bar{S}_i, m) < L(\bar{S}^*, m)$. Set $\bar{S}^* = \bar{S}_i$, increment i by 1. If $i = M + 1$, go to Step 6, otherwise go back to Step 3.

Step 6. Stop. The best subset is $\bar{S}^*$.

Algorithm 1 can be made to take advantage of the monotone-reduction property by proper incrementation of i in Step 4. Suppose that $\bar{S}_i = \{s_1, s_2, \ldots, s_m\}$ and that factorization failed on the fth row of $\mathbf{D}_{\bar{S}_i}$. Then any subset containing $\{s_1, s_2, \ldots, s_f\}$ will also have a higher reduction than $L(\bar{S}^*, m)$ and need not be checked. Therefore, in Step 4, we should increment i by c, where $\bar{S}_{i+c}$ is the first reduction subset after $\bar{S}_i$ that does not contain $\{s_1, s_2, \ldots, s_f\}$. Suppose that the first g members of $\bar{S}_{i+c}$ are identical to the first g members of $\bar{S}_i$. Then the first g rows of $\mathbf{B}_{\bar{S}_{i+c}}$ are the same as the first g rows of $\mathbf{B}_{\bar{S}_i}$ and need not be recomputed.

4. The singular case: Algorithm 2. If $\mathbf{Q}$ is not of full rank, we can accept the possibility of error and implement ridge selection; e.g., with $\mathbf{M} = \mathbf{I}$ for some $\varepsilon > 0$. As an alternative, we consider the behavior of ridge selection when the ridge matrix is $\mathbf{H}$ and $\varepsilon \to 0$. By Theorem 2, for ε sufficiently small (say, $\varepsilon < \varepsilon_1$), this ridge selection will result in the proper identification of S^*. Let $\mathbf{Q}(\varepsilon) = \mathbf{Q} + \varepsilon\mathbf{H}$, and let $\mathbf{C}(\varepsilon)$, $\mathbf{b}(\varepsilon)$, and $L(\bar{S}, m; \mathbf{H}, \varepsilon)$ be defined as in § 2, where $\bar{S}$ is a reduction subset of size $m = p - k$. For $L^* > 0$, let $\mathbf{D}(\varepsilon) = \mathbf{C}(\varepsilon) - (1/L^*)\mathbf{b}(\varepsilon)\mathbf{b}'(\varepsilon)$, and let $\mathbf{D}_{\bar{S}}(\varepsilon)$ be the PSM of $\mathbf{D}(\varepsilon)$ corresponding to $\bar{S}$. It will be shown (Theorem 4) that there exists $\varepsilon_2 > 0$ and a matrix $\mathbf{B}$ that depends on $\bar{S}$ but not on ε such that all matrices $\mathbf{D}_{\bar{S}}(\varepsilon)$ for $0 < \varepsilon < \varepsilon_2$ are or are not positive definite depending on whether $\mathbf{B}$ is or is not positive definite. In particular, the above relationship holds for $\varepsilon < \min(\varepsilon_1, \varepsilon_2)$. It follows from Theorem 3 that we may ascertain whether $L(\bar{S}, m) < L^*$ by checking for the positive definiteness of $\mathbf{B}$.

For any real symmetric matrix $\mathbf{A}$, let the notation $\mathbf{A} > 0$ mean that $\mathbf{A}$ is positive definite and let $\mathbf{A} \not\geqslant 0$ mean that $\mathbf{A}$ has at least one negative eigenvalue. Consider the following theorem.

THEOREM 4. *For $\varepsilon > 0$, let $\mathbf{D}$ be an $m \times m$ matrix of the form*

$$\mathbf{D} = \left(\frac{1}{\varepsilon}\right)\mathbf{G}\mathbf{G}' + \mathbf{A}, \quad \textit{where } \mathbf{A} = \begin{pmatrix} \mathbf{A}_{11} & \mathbf{A}_{12} \\ \mathbf{A}_{21} & \mathbf{A}_{22} \end{pmatrix}$$

is symmetric and $\mathbf{G} = (\mathbf{G}_1', \mathbf{G}_2')'$ with $\mathbf{A}_{11}$ and $\mathbf{G}_1$ having dimensions $r \times r$, and with $\mathbf{G}_2$ being $(m - r) \times r$. In addition, let $\mathbf{G}_1$ be nonsingular and let $\mathbf{T} = (\mathbf{T}_1', \mathbf{T}_2')'$ be partitioned as $\mathbf{G}$ and satisfy

$$\mathbf{G}\mathbf{T}' + \mathbf{T}\mathbf{G}' = \begin{pmatrix} \mathbf{A}_{11} & \mathbf{A}_{12} \\ \mathbf{A}_{21} & \mathbf{U} \end{pmatrix},$$

where $\mathbf{U}$ is arbitrary. Let $\mathbf{B} = \mathbf{A}_{22} - U$. Then for ε sufficiently small, $\mathbf{B} > 0 \Rightarrow \mathbf{D} > 0$ and $\mathbf{B} \not\geqslant 0 \Rightarrow \mathbf{D} \not\geqslant 0$.

Proof. The proof of Theorem 4 is given in the Appendix. It depends on showing (1) $\mathbf{B} > 0 \Rightarrow \mathbf{y}'\mathbf{D}\mathbf{y} > 0$ for all m-vectors $\mathbf{y} \neq 0$, and (2) $\mathbf{B} \not\geqslant 0 \Rightarrow$ there exists $\mathbf{y} \ni \mathbf{y}'\mathbf{D}\mathbf{y} < 0$.

Using the fact that $(Q + \varepsilon\mathbf{H})^{-1} = \mathbf{V}\Lambda^{-1}\mathbf{V}' + (\frac{1}{\varepsilon})\mathbf{H}$, we obtain $\mathbf{D}(\varepsilon) = \mathbf{A} + (\frac{1}{\varepsilon})\mathbf{H}$, where $\mathbf{A} = \mathbf{V}(\Lambda^{-1} - (1/L^*)\mathbf{u}\mathbf{u}')\mathbf{V}'$ and $\mathbf{u} = \Lambda^{-1}\mathbf{V}'\mathbf{d}$. Thus the $m \times m$ submatrix $\mathbf{D}_{\bar{S}}(\varepsilon)$ is equal to $\mathbf{A}_{\bar{S}} + (\frac{1}{\varepsilon})\mathbf{H}_{\bar{S}}$, where $\mathbf{A}_{\bar{S}}$ and $\mathbf{H}_{\bar{S}}$ are corresponding submatrices of $\mathbf{A}$ and $\mathbf{H}$. Since $\mathbf{H}$ is positive semidefinite, so at least is $\mathbf{H}_{\bar{S}}$. Let r be the rank of $\mathbf{H}_{\bar{S}}$ and write $\mathbf{H}_{\bar{S}}$ in the form

$$\mathbf{H}_{\bar{S}} = \begin{pmatrix} \mathbf{H}_{11} & \mathbf{H}_{12} \\ \mathbf{H}_{21} & \mathbf{H}_{22} \end{pmatrix},$$

where $\mathbf{H}_{11}$ is $r \times r$ and nonsingular. Then there exists a matrix $\mathbf{G}$ of the form $\mathbf{G} =$

$(\mathbf{G}_2', \mathbf{G}_2')'$ such that $\mathbf{GG}' = \mathbf{H}_{\bar{S}}$, where $\mathbf{G}_1$ is $r \times r$, nonsingular lower triangular, and $\mathbf{G}_2$ is $(m - r) \times r$. Writing

$$\mathbf{A}_{\bar{S}} = \begin{pmatrix} \mathbf{A}_{11} & \mathbf{A}_{12} \\ \mathbf{A}_{21} & \mathbf{A}_{22} \end{pmatrix},$$

where $\mathbf{A}_{11}$ is $r \times r$, we can find a matrix $\mathbf{T} = (\mathbf{T}_1', \mathbf{T}_2')'$ partitioned as $\mathbf{G}$, such that

$$\mathbf{GT}' + \mathbf{TG}' = \begin{pmatrix} \mathbf{A}_{11} & \mathbf{A}_{12} \\ \mathbf{A}_{21} & U \end{pmatrix}$$

(see the following paragraph), where $\mathbf{U} = \mathbf{G}_2\mathbf{T}_2' + \mathbf{T}_2\mathbf{G}_2'$. Letting $\mathbf{B} = \mathbf{A}_{22} - \mathbf{U}$ (which does not depend on ε) and applying Theorem 4, it is seen that for ε sufficiently small (say, $\varepsilon < \varepsilon_2$), $\mathbf{B} > 0 \Rightarrow \mathbf{D}(\varepsilon) > 0$ and $\mathbf{B} \ngeq 0 \Rightarrow \mathbf{D}(\varepsilon) \ngeq 0$.

From the above result, an exact algorithm is developed that can be used when $\mathbf{Q}$ is singular and has the same sequential computational properties as Algorithm 1. Let $(gt)_{ij}$ denote the i,jth element of $\mathbf{GT}' + \mathbf{TG}'$ and let $\mathbf{A} = (a_{ij})$. By letting $\mathbf{T}_1$ be lower triangular, the elements of $\mathbf{T}$ can be easily obtained by sequential solution of $(gt)_{ij} = a_{ij}$ for $(i, j) = (1, 1), (2, 1), (2, 2), \ldots, (r, r), (r + 1, 1), \ldots, (r + 1, r), (r + 2, 1), \ldots, (r + 2, r), \ldots, (m, r)$. For convenience, we call this method Procedure T. Thus we have Algorithm 2.

ALGORITHM 2.

Step 1. Number the m-subsets lexicographically: $\bar{S}_1 = \{1, 2, \ldots, m\}$, $\bar{S}_2 = \{1, 2, \ldots, m - 1, m + 1\}, \ldots, \bar{S}_M = \{p - m + 1, \ldots, p\}$, where $M = \binom{p}{m}$.

Step 2. Find an initial candidate $\bar{S}^*$ for the best subset, say, by stepwise regression. Find $\mathbf{V}$, $\mathbf{\Lambda}^{-1}$, $\mathbf{H}$, and $\mathbf{u}$. Set $i = 1$.

Step 3. Let $L^* = L(\bar{S}^*, m)$ and $\mathbf{A} = \mathbf{V}[\mathbf{\Lambda}^{-1} - (1/L^*)\mathbf{uu}']\mathbf{V}'$.

Step 4. Use Cholesky factorization of $\mathbf{H}_{\bar{S}_i}$ to obtain r and $\mathbf{G}_1$; use Procedure T to obtain $\mathbf{T}_1$.

Step 5. For $j > r$, continue to use Cholesky factorization and Procedure T to find the $(j - r)$th rows of $\mathbf{G}_2$, $\mathbf{T}_2$, and $\mathbf{B}$. As each row of $\mathbf{B}$ is obtained, check for $\mathbf{B} > 0$ by another Cholesky factorization $\mathbf{B} = \mathbf{WW}'$. If the factorization fails, increment i; if $i = M + 1$, go to Step 7, otherwise repeat Step 4. If the factorization succeeds, go to Step 6.

Step 6. $\mathbf{D}_{\bar{S}_i}$ is positive definite; hence $L(\bar{S}_i, m) < L(\bar{S}^*, m)$. Set $\bar{S}^* = \bar{S}_i$, increment i by 1. If $i = M + 1$, go to Step 7; otherwise go back to Step 3.

Step 7. Stop. The best subset is $\bar{S}^*$.

As with Algorithm 1, i can be incremented by a number c to avoid checking subsets known to be inferior to $\bar{S}^*$. Again, let g be the last common component of $\bar{S}_i$ and $\bar{S}_{i+c}$. If $g \geqq r$, then $\mathbf{G}_1$ and $\mathbf{T}_1$ remain the same for $\bar{S}_{i+c}$, and only the last $m - (g - r)$ rows of $\mathbf{G}_2$, $\mathbf{T}_2$, and $\mathbf{W}$ need to be recomputed. If $g < r$, then the last $(r - g)$ rows of $\mathbf{G}_1$ and $\mathbf{T}_1$, as well as all of $\mathbf{G}_2$ and $\mathbf{T}_2$, must be recomputed.

5. Efficiency. If the singularity in $\mathbf{Q}$ is caused by $n < p$, as opposed to $\mathbf{X}$ having a special structure as in analysis-of-variance models, the rank of $\mathbf{H}$ is $p - n$; hence r, the rank of $\mathbf{H}_{\bar{S}}$ is at most $p - n$. At least $r + 1$ variables must be removed from the regression before the reduction sum of squares exceeds zero; hence a lower bound of $\binom{p}{r}$ subsets of size $r + 1$ or greater must be checked before the one with minimum reduction is found. In terms of Algorithm 2, this means all $\binom{p}{r}$ $\mathbf{G}_1$ and $\mathbf{T}_1$ matrices must be computed. This makes the method less efficient as p is increased for fixed n, thus restricting the number of transformations in the empirical-modeling application. On the other hand, if p exceeds n by only a small amount, the method is almost as efficient as a full-rank reduction

search. The only way to circumvent this problem is to search for the best k-subset directly, not its m-dimensional complement by reduction. A possible approach for doing so is described in § 6.

In Algorithm 2, it is necessary to find $\mathbf{H}_{11}$ which is $r \times r$ and has rank r. Experiments on randomly generated data sets with more variables than observations have shown that not all $(p - n) \times (p - n)$ PSMs of $\mathbf{H}_{\bar{S}}$ have rank $p - n$; some may have rank $p - n - 1$. It is therefore possible to have $r = p - n$, but $\mathbf{H}_{11}$ consists of rows and columns $\{1, 2, \ldots, p - n - 1, x\}$ where $x > p - n$. In this case, some efficiency is lost in keeping track of the index x. The value of r can be calculated during the Cholesky factorization of $\mathbf{H}_{\bar{S}}$. If the $(p - n)$th diagonal element of $\mathbf{G}_1$ is less than some threshold, assume it is zero and test subsequent rows of $\mathbf{H}_{\bar{S}}$ to see if one is linearly independent of the first $p - n - 1$ rows. If no such row is found then take $r = p - n - 1$.

6. Direct search for the best regression. When $p - n$ is large, it has been noted in § 5 that any reduction search is inefficient. Let $\mathscr{P}_k$ be the set of all real symmetric matrices $\mathbf{A}$, such that all $k \times k$ PSMs of $\mathbf{A}$ are positive definite or semidefinite. One may use Theorem 3 to show that no k-variate regression sum of squares exceeds R^* if and only if $\mathbf{K} \in \mathscr{P}_k$, where $\mathbf{K} = \mathbf{Q} - (1/R^*)\mathbf{dd}'$. Thus, any PSM of $\mathbf{K}$ having a negative eigenvalue corresponds to a subset with a regression sum of squares that exceeds R^*. For small values of k, attempted factorization of all $k \times k$ PSMs of $\mathbf{K}$ might actually be more efficient than any reduction procedure; however, in most cases better methods need to be developed for checking if $\mathbf{K} \in \mathscr{P}_k$ without examining all possible PSMs.

A sufficient condition for $\mathbf{K} \in \mathscr{P}_k$ is that every $k \times k$ PSM is diagonally dominant (kDD). This condition is easy to check; merely sum the $k - 1$ largest absolute off-diagonal elements on each row of $\mathbf{K}$ and compare to the diagonal element. Unfortunately, $\mathbf{K}$ being kDD is not necessary for $\mathbf{K} \in \mathscr{P}_k$; however, it might be possible to make a series of transformations $\mathbf{K}_i = \mathbf{T}_i\{\mathbf{K}_{i-1}\}$, $i = 1, 2, \ldots$, such that $\mathbf{T}_i^{-1}$ preserves membership in $\mathscr{P}_k$ and for some i, $\mathbf{K}_i$ is kDD. Two such transformations are $\mathbf{T}\{\mathbf{K}\} = \mathbf{DKD}$, where $\mathbf{D}$ is diagonal nonsingular; or $\mathbf{T}\{\mathbf{K}\} = \mathbf{K} - \mathbf{P}$, where $\mathbf{P}$ is positive definite. Another approach is to search for any vector $\mathbf{x}$ with $n - k$ zero elements such that $\mathbf{x}'\mathbf{K}\mathbf{x} < 0$. If such a vector is found, then the position of the nonzero elements defines a regression subset that beats R^*.

7. Numerical results. Algorithm 1, with ridge selection ($\mathbf{M} = \mathbf{I}$), and Algorithm 2 were tested on four groups of randomly generated data, where the ith group consisted of N_i independent regression sets of $(\mathbf{X}, \mathbf{y})$-pairs with $n = n_i$, $p = p_i$, and $k = k_i$, as shown in Table 1.

For each regression set, the rows of the $n \times (p + 1)$ matrix $(\mathbf{X} \mid \mathbf{y})$ were generated independently as $N_{p+1}(0, \mathbf{\Sigma})$, where $\mathbf{\Sigma}$ was itself generated as a $(p + 1) \times (p + 1)$ sample covariance matrix based on $p + 1$ observations of $N(0, \mathbf{I}_{p+1})$ vectors. This two-stage process introduces many near-collinearities in the columns of $\mathbf{X}$, thus producing excellent

"nasty" test cases. All data was normalized so that $\mathbf{X}'\mathbf{X}$ was in correlation form with $\mathbf{y}'\mathbf{y} = 1$. Regressions were calculated without intercept terms.

The primary standard of efficiency was taken as the number of elements in the auxiliary matrices ($\mathbf{B}$ for Algorithm 1, $\mathbf{G}$, $\mathbf{T}$, and $\mathbf{B}$ for Algorithm 2) calculated in the process of finding the best subset. In Tables 2(a)–2(d), this number was expressed as a ratio F to the number of elements that would have had to be computed to find the best subset by "brute force" factorization of all $\binom{p}{k}$ submatrices of $\mathbf{K}$ in § 6. Algorithm 1 was tested with $\varepsilon = .001$ and .0001. Cases for which it failed to find the best subset are marked with an asterisk (*). Results for Algorithm 2 are listed under the heading Exact. The

[2] Algorithm 2.

value of $R(S, k)$ for the subset S found to be "best" is given in the three right-hand columns. Theoretically, the values of $R(S, k)$ for Algorithm 2 should be the true maxima. For the two smaller groups ($p = 15$ and $p = 18$), these values were verified by the brute force method. For comparison purposes, the value of the step-up regression sum of squares is also given.

It can be seen that, in most cases, ridge selection found the best subset, especially with $\varepsilon = .0001$. Generally, the efficiency of Algorithm 1 was three to ten times better than Algorithm 2. Some experimentation with $\varepsilon = .00001$ resulted in numerous errors that led to spurious identification of "better" subsets. When ridge selection failed to find the best subset, it generally came close in terms of the corresponding regression sum of squares. For the values of n, p, and k shown here, it can be seen that if exact results are desired, Algorithm 2 is still considerably more efficient than brute force. As discussed previously, when $k < p - n$, reduction-based methods are less efficient than examination of all k-subsets.

8. Summary. The computational problem of finding the best-fitting subset of independent variables in least-squares regression with a fixed subset size has been addressed, especially in the context of the nonfull-rank case with more variables than observations. Generally, there is a range of n, p, and k ($n < p$ and $k > p - n$) for which existing reduction-based methods cannot be used and where Algorithm 2 is able to find the best subset more efficiently than can exhaustive enumeration. In the development of Algorithm 2, it was discovered that ridge selection using a ridge matrix of $\mathbf{I}$ as implemented in Algorithm 1, usually finds the best subset, and that it is more efficient than Algorithm 2. The most likely circumstances of the application of Algorithm 2 are for empirical modeling situations where measurement or other random model errors are small or nonexistent. The region of n, p, k-space for which k is relatively small (regardless of whether n exceeds p), remains the most challenging for developing better selection methods. Possible approaches were put forth in § 6 as starting points for further investigation.

Appendix. Proof of Theorem 4. Let $\mathbf{y} = (\mathbf{y}_1', \mathbf{y}_2')'$ be any $m \times 1$ vector with $\|\mathbf{y}\|^2 = 1$, where $\mathbf{y}_1$ is $r \times 1$ and $\mathbf{y}_2$ is $(m - r) \times 1$. It will first be shown that $\mathbf{B} > 0 \Rightarrow \mathbf{y}'\mathbf{D}\mathbf{y} > 0$. We make use of the following lemma.

LEMMA. *Let γ_r be the minimum eigenvalue of $\mathbf{G}_1\mathbf{G}_1'$ and γ_2 be the maximum eigenvalue of $\mathbf{G}_2\mathbf{G}_2'$. Then $\|\mathbf{G}'\mathbf{y}\|^2 < c \Rightarrow \|\mathbf{y}_2\|^2 \geqq (\gamma_r - c)/(\gamma_r + \gamma_2)$.*

Proof. Suppose that $\|\mathbf{G}'\mathbf{y}\|^2 < c$. We have $\mathbf{G}_1'\mathbf{y}_1 = \mathbf{G}'\mathbf{y} - \mathbf{G}_2'\mathbf{y}_2$

$$\Rightarrow \|\mathbf{G}_1'\mathbf{y}_1\|^2 \leqq \|\mathbf{G}'\mathbf{y}\|^2 + \|\mathbf{G}_2'\mathbf{y}_2\|^2 < c + \|\mathbf{G}_2'\mathbf{y}_2\|^2$$

$$\Rightarrow \gamma_r\|\mathbf{y}_1\|^2 < c + \gamma_2\|\mathbf{y}_2\|^2$$

$$\Rightarrow \gamma_r(1 - \|\mathbf{y}_2\|^2) < c + \gamma_2\|\mathbf{y}_2\|^2$$

$$\Rightarrow \|\mathbf{y}_2\|^2 > \frac{(\gamma_r - c)}{(\gamma_r + \gamma_2)}. \qquad \square$$

Now, from the definitions of $\mathbf{G}$, $\mathbf{T}$, and $\mathbf{B}$, we have

$$\varepsilon\mathbf{y}'\mathbf{D}\mathbf{y} = \mathbf{y}'(\mathbf{G} + \varepsilon\mathbf{T})(\mathbf{G} + \varepsilon\mathbf{T})'\mathbf{y} + \varepsilon\mathbf{y}_2'\mathbf{B}\mathbf{y}_2 - \varepsilon^2\mathbf{y}'\mathbf{T}\mathbf{T}'\mathbf{y} \tag{A.1}$$

$$\geqq \varepsilon\beta\|\mathbf{y}_2\|^2 - \varepsilon^2\tau, \tag{A.2}$$

where β is the minimum eigenvalue of $\mathbf{B}$ and τ is the maximum eigenvalue of $\mathbf{T}\mathbf{T}'$.

Suppose that $\|\mathbf{G}'\mathbf{y}\|^2 < \gamma_r/2$. Then by the above lemma, it holds that

$$\|\mathbf{y}_2\|^2 > \left(\frac{1}{2}\right)\gamma_r \Big/ (\gamma_r + \gamma_2). \tag{A.3}$$

Let $\theta = (\frac{1}{2})\gamma_r/(\gamma_r + \gamma_2)$. Clearly $\theta > 0$, since $\gamma_2 \geqq 0$ and $\gamma_r > 0$, $\mathbf{G}_1$ being nonsingular. If $\mathbf{B} > 0$, then $\beta > 0$; hence by (A.2) and (A.3), we must have $\mathbf{y}'\mathbf{D}\mathbf{y} > 0$ for any $\varepsilon > 0$ if $\tau = 0$, and for $0 < \varepsilon < \beta\theta/\tau$, if $\tau > 0$.

Suppose now that $\|\mathbf{G}'\mathbf{y}\|^2 \geqq \gamma_r/2$. Equation (A.1) may be rewritten

$$\varepsilon\mathbf{y}'\mathbf{D}\mathbf{y} = \mathbf{y}'\mathbf{G}\mathbf{G}'\mathbf{y} + \varepsilon\mathbf{y}_2'\mathbf{B}\mathbf{y}_2 + \varepsilon\mathbf{y}'\mathbf{A}^*\mathbf{y}, \tag{A.4}$$

where $\mathbf{A}^* = \mathbf{G}\mathbf{T}' + \mathbf{T}\mathbf{G}'$. Hence $\varepsilon\mathbf{y}'\mathbf{D}\mathbf{y} > \gamma_r/2 - \varepsilon\alpha^*$, where $-\alpha^*$ is the minimum eigenvalue of $\mathbf{A}^*$. It follows that $\mathbf{y}'\mathbf{D}\mathbf{y} > 0$ for any $\varepsilon > 0$ if $\alpha^* = 0$, and for $0 < \varepsilon < \gamma_r/2\alpha^*$, if $\alpha^* > 0$. This completes the first part of the proof; i.e., $\mathbf{B} > 0 \Rightarrow \mathbf{y}'\mathbf{D}\mathbf{y} > 0$.

Suppose that $\mathbf{B} \ngeqq 0$. Then there exists $\mathbf{z}_2$ such that $\mathbf{z}_2'\mathbf{B}\mathbf{z}_2 < 0$. Let $\mathbf{z}_1 = -\mathbf{G}_1^{-1}\mathbf{G}_2'\mathbf{z}_2$ and $\mathbf{z} = (\mathbf{z}_1', \mathbf{z}_2')'$. Then $\mathbf{G}'\mathbf{z} = 0$; hence from (A.4) with $\mathbf{y} = \mathbf{z}$ and from the definition of $\mathbf{A}^*$, $\varepsilon\mathbf{z}'\mathbf{D}\mathbf{z} = \varepsilon\mathbf{z}_2'\mathbf{B}\mathbf{z}_2 < 0 \Rightarrow \mathbf{z}'\mathbf{D}\mathbf{z} < 0$ for $\varepsilon > 0$. Thus $\mathbf{B} \ngeqq 0 \Rightarrow \mathbf{D} \ngeqq 0$ for any $\varepsilon > 0$ and the theorem is proved. □

NUMERICAL SOLUTION OF THE EIGENPROBLEM FOR BANDED, SYMMETRIC TOEPLITZ MATRICES*

SUSAN L. HANDY† AND JESSE L. BARLOW‡

Abstract. A fast method for calculating the eigensystem of a banded, symmetric Toeplitz matrix is presented. The method is based on the use of rank-one updates and employs deflation to reduce problem size whenever possible.

Key words. eigenproblem, Toeplitz matrices, banded matrices

AMS subject classifications. 65F15, 65F50

1. Introduction. In this paper, we consider the problem of calculating the eigensystem of an $n \times n$ banded, symmetric Toeplitz (BST) matrix with bandwidth k. Recall that the distinguishing characteristic of a Toeplitz matrix is that its entries along any diagonal parallel to the main diagonal are constant. Formally we have the following definition.

DEFINITION 1.1. *A real, symmetric Toeplitz matrix T has the form*

$$T = (t_{ij})_{i,j=1}^{n} = (c_{|i-j|+1})_{i,j=1}^{n}, \tag{1.1}$$

where each c_i is real. Thus any such matrix T is of the form

$$T = \begin{bmatrix} c_1 & c_2 & c_3 & \cdot & \cdot & \cdot & c_n \\ c_2 & c_1 & c_2 & & & & \cdot \\ c_3 & c_2 & \ddots & & & & \cdot \\ \cdot & & & c_1 & & & \cdot \\ \cdot & & & & \ddots & c_2 & c_3 \\ \cdot & & & & c_2 & c_1 & c_2 \\ c_n & \cdot & \cdot & \cdot & c_3 & c_2 & c_1 \end{bmatrix}. \tag{1.2}$$

We can use the notation

$$T = \mathrm{Toep}_n(c_1, c_2, \ldots, c_n) \tag{1.3}$$

to denote the matrix given in (1.1) and (1.2).

DEFINITION 1.2. *A real $n \times n$ Toeplitz matrix T is said to be a* BST *matrix if it is symmetric and has the form*

$$T = \mathrm{Toep}_n(c_1, c_2, \ldots, c_k, 0, \ldots, 0) \tag{1.4}$$

for some index $k < n$.

T is then referred to as a $2k - 1$-diagonal BST matrix or as a BST matrix with bandwidth k. Let $T_{n,k}$ denote the matrix T defined in (1.4).

Another class of matrices whose structure is very similar to that of Toeplitz matrices is the class of Hankel matrices. Hankel matrices will play a significant role in the method that we present for solving the symmetric eigenvalue problem for BST matrices. A matrix

* Received by the editors March 25, 1991; accepted for publication (in revised form) June 29, 1992.

† HRB Systems, Inc., P.O. Box 60 Science Park Road, State College, Pennsylvania 16804 (slh@icf.hrb.com).

‡ Department of Computer Science, The Pennsylvania State University, University Park, Pennsylvania 16802 (barlow@cs.psu.edu). The research of this author was supported by the National Science Foundation grant CCR-90000526.

is said to be Hankel if its entries are constant along each cross-diagonal. Formally we have the following definition.

DEFINITION 1.3. *A real $n \times n$ Hankel matrix has the form*

$$H = (h_{ij})_{i,j=1}^{n} = (d_{i+j-1})_{i,j=1}^{n},$$

where each d_i is real. If H is also persymmetric (i.e., symmetric about the main cross-diagonal) then $d_{2n-j} = d_j$, $1 \leqq j \leqq n$ and H has the form

$$H = \begin{bmatrix} d_1 & d_2 & d_3 & \cdot & \cdot & \cdot & d_n \\ d_2 & d_3 & & & & & \cdot \\ d_3 & & & & \iddots & & \cdot \\ \cdot & & & d_n & & & \cdot \\ \cdot & & & & & & d_3 \\ \cdot & \iddots & & & & d_3 & d_2 \\ d_n & \cdot & \cdot & \cdot & d_3 & d_2 & d_1 \end{bmatrix}. \tag{1.5}$$

As with real, symmetric Toeplitz matrices, the first row of a persymmetric Hankel matrix completely determines the remaining entries. Thus we use the notation

$$H = \mathrm{Hank}_n(d_1, d_2, \ldots, d_n) \tag{1.6}$$

to denote the $n \times n$ real, persymmetric Hankel matrix and $H_{n,k}$ to denote the Hankel matrix

$$H_{n,k} = \mathrm{Hank}_n(d_1, d_2, \ldots, d_k, 0, \ldots, 0).$$

A third class of matrices in which we are strongly interested is the class of "cross-sum" matrices.

DEFINITION 1.4. *C_n is said to be a cross-sum matrix if it is an element of the set*

$$\Theta_n = \{B \equiv (b_{ij}) : b_{ij} \in \mathbf{R} \quad \textit{and} \quad b_{i-1,j} + b_{i+1,j} = b_{i,j-1} + b_{i,j+1},\ i, j = 1, 2, \ldots, n\}$$

with $b_{0,j} = b_{i,0} = b_{i,n+1} = b_{n+1,j} = 0$.

As with the symmetric Toeplitz and persymmetric Hankel matrices, the entries in the first row of a cross-sum matrix are enough to completely determine the remaining entries.

A number of other authors have developed methods for solving the symmetric, eigenvalue problem for banded Toeplitz matrices. Arbenz [2] investigates a technique that embeds the Toeplitz matrix into a higher-order circulant matrix, computes the eigensystem of the circulant, and then solves the Toeplitz eigenproblem as a restricted eigenvalue problem. Trench [12] calculates a formula for the characteristic polynomial of an nth-order Toeplitz matrix T with bandwidth k in terms of the zeroes of a kth degree polynomial whose coefficients are independent of n. Bini and Pan [6] present algorithms for computing $p(\lambda) = \det(T - \lambda I)$ and the ratio $p(\lambda)/p'(\lambda)$ in the case where T is a block BST matrix.

2. Numerical solution of the BST eigenproblem.

2.1. Solution of the rank-one updating problem. In this section, we will briefly summarize the solution from Bunch, Nielsen, and Sorensen to the rank-one eigensystem updating problem. (For complete details, we refer the reader to [7] and [9].) Given an $n \times n$ diagonal matrix $D = \mathrm{diag}(\delta_1, \delta_2, \ldots, \delta_n)$, $z = (z_1, z_2, \ldots, z_n)^T \in \mathbf{R}^n$, and ρ, a

nonzero scalar, we wish to calculate $(\hat{D}, \hat{Q})$ such that

$$D + \rho zz^T = \hat{Q}\hat{D}\hat{Q}^T, \tag{2.1}$$

where $\hat{D} = \text{diag}\,(\hat{\delta}_1, \hat{\delta}_2, \ldots, \hat{\delta}_n)$ and $\hat{Q}$ is orthogonal.

Initially, we make the assumptions that each δ_i is distinct and that no z_i is zero. It is then shown that the roots of

$$f(\lambda) \equiv 1 + \rho \sum_{j=1}^{n} \frac{z_j^2}{\delta_j - \lambda} \tag{2.2}$$

are exactly the eigenvalues $\hat{\delta}_i$ of $D + \rho zz^T$ and that the corresponding eigenvectors $\hat{q}_i$ are given by

$$\hat{q}_i = \gamma_i \Delta_i^{-1} z, \tag{2.3}$$

where

$$\Delta_i = \text{diag}\,(\delta_1 - \hat{\delta}_i, \ldots, \delta_n - \hat{\delta}_i) \tag{2.4}$$

and

$$\gamma_i = \|\Delta_i^{-1} z\|_2. \tag{2.5}$$

For each root $\hat{\delta}_i$, the function $f(\lambda)$ is separated into the sum of positive and negative terms of the form $f(\lambda) = 1 + \phi(\lambda) + \psi(\lambda)$, and the roots of $f(\lambda)$ are calculated iteratively by constructing rational interpolants to ϕ and ψ. The iteration converges quadratically to the roots $\hat{\delta}_i$ given an appropriate starting point. (Further details are available from Bunch, Nielsen, and Sorensen [7].)

In the implementation of this method by Dongarra and Sorensen , the iteration is reformulated so that they solve for the difference between successive iterates $\tau_i = \lambda_i - \lambda_{i-1}$ rather than λ_i itself. The quantities $\delta_j - \lambda_k$ used in (2.4) to calculate the eigenvectors are retained, and the iterative corrections τ_i are applied to these quantities as well as to the eigenvalue approximations. Cancellation in the calculation of these differences is avoided because the corrections decrease in size and are eventually applied to the lowest-order bits. Stringent convergence criteria are applied that ensure a small residual and orthogonality of the eigenvectors to full machine accuracy. The stopping criteria employed are $|f(\lambda)| \leq \mu \cdot \max(|\delta_1|, |\delta_n|)$ and $|\tau| \leqq \mu \cdot \min(|\delta_i - \lambda|, |\delta_{i+1} - \lambda|)$, where λ is the current iterate, τ is the last calculated iterative correction, and μ is a small tolerance close to the machine unit. In his paper on the numerical stability of updating methods for the symmetric eigenvalue problem, Barlow [4] discusses the use of the stopping criterion $|f(\lambda)|/|f'(\lambda)| \leqq \mu \cdot \min(|\delta_i - \lambda|, |\delta_{i+1} - \lambda|)$.

We made two assumptions about the problem originally: all components of z are nonzero and the eigenvalues of D are distinct. If either of these conditions does not hold, we may reduce the problem size. If $z_i = 0$ for some i, then the ith eigenvalue of D and its corresponding eigenvector already form an eigenpair for $D + \rho zz^T$. Numerically, we accept the pair and the problem size reduces by one if $|\rho z_i|$ is small. If $|\delta_i - \delta_{i+1}| \leqq \varepsilon$, then, by applying an appropriately constructed Givens rotation to (2.1), we can reduce this case to the previous one. Again the problem size can be reduced by one. Cuppen [8] used this updating procedure to solve the symmetric tridiagonal eigenproblem.

Improvements to the Dongarra and Sorensen implementation are discussed in Barlow [4] and in Sorensen and Tang [11].

2.2. Existence of the cross-sum representation for any BST matrix. To employ the updating technique above, first we must show that it is always possible for us to split a

Toeplitz matrix into the sum of a cross-sum matrix and a Hankel matrix. To show that the splitting

$$\begin{aligned}&\mathrm{Toep}_n(d_1, d_2, \ldots, d_k, 0, \ldots, 0)\\ &\quad = \mathrm{CrossSum}_n(d_1 - d_3, \ldots, d_{k-2} - d_k, d_{k-1}, d_k, 0, \ldots, 0)\\ &\qquad + \mathrm{Hank}_n(d_3, d_4, \ldots, d_k, 0, \ldots, 0)\end{aligned} \tag{2.6}$$

is valid for any n and for any $3 \leqq k \leqq n$, we must show that

$$\begin{aligned}C = &\mathrm{Toep}_n(d_1, d_2, \ldots, d_k, 0, \ldots, 0)\\ &- \mathrm{Hank}_n(d_3, d_4, \ldots, d_k, 0, \ldots, 0)\end{aligned} \tag{2.7}$$

satisfies the cross-sum property. Assume that d_r is defined as follows:

$$d_r = \begin{cases} 0, & k+1 \leqq r \leqq n,\\ d_{2n+r-4}, & n+1 \leqq r \leqq 2n+1.\end{cases}$$

By definition of the elements of a symmetric Toeplitz matrix and a persymmetric Hankel matrix, we have

$$c_{ij} = d_{|i+j|+1} - d_{i+j+1}, \qquad 0 \leqq i, j \leqq n+1. \tag{2.8}$$

THEOREM 2.1. *The matrix C as defined in* (2.8) *is an element of the set of cross-sum matrices.*

Proof. For C to be a cross-sum matrix, we require that c_{ij} be 0 for i or j equal to 0 or $n+1$ and that $c_{i-1,j} + c_{i+1,j} = c_{i,j-1} + c_{i,j+1}$. It is straightforward to verify that $c_{ij} = 0$ if either i or j is 0 or $n+1$. Define Δ_{ij} as

$$\Delta_{ij} = c_{i-1,j} + c_{i+1,j} - c_{i,j-1} - c_{i,j+1}.$$

Then we have

$$\begin{aligned}\Delta_{ij} = &(d_{|i-j-1|+1} - d_{i+j}) + (d_{|i-j+1|+1} - d_{i+j+2}) - (d_{|i-j+1|+1} - d_{i+j})\\ &- (d_{|i-j-1|+1} - d_{i+j+2}) = 0\end{aligned}$$

for $1 \leqq i, j \leqq n$. Thus C is a cross-sum matrix. This completes the proof. □

The class of cross-sum matrices is valuable in the context of our problem because solution of the eigenproblem for a cross-sum matrix is fast. From Bini and Capovani [5], it is known that the class of cross-sum matrices Θ_n, defined in the previous section, is equivalent to the algebra generated over $\mathbf{R}$ by the matrix

$$T = \mathrm{Toep}_n(0, 1, 0, \ldots, 0) = \begin{bmatrix} 0 & 1 & & & & & \\ 1 & 0 & 1 & & & & \\ & 1 & 0 & 1 & & & \\ & & & \ddots & & & \\ & & & 1 & 0 & 1 & \\ & & & & 1 & 0 & \end{bmatrix}.$$

Thus any A in Θ_n can be expressed as

$$A = \sum_{i=0}^{n-1} c_{i+1} T^i.$$

From Proposition 2.2 in [5, p. 102], it is shown that we may solve for the values $c_1, c_2, \ldots, c_n$ by solving an upper triangular system of the form $Sc = a$, where a is the first row of A in Θ_n and the entries of $S = [s_{ij}]$ are given by the equations

$$\begin{aligned} s_{ij} &= s_{i-1,j-1} + s_{i+1,j-1}, && 1 \leqq i \leqq j \leqq n, \\ s_{ij} &= 0, && 0 \leqq j < i \leqq n, \\ s_{0,j} &= 0, && 1 \leqq j \leqq n, \\ s_{0,0} &= 1. \end{aligned}$$

From [5], the eigendecomposition of $T = U^T D U$ is known to be

$$D = \operatorname{diag}(\lambda_1, \lambda_2, \ldots, \lambda_n),$$

where

$$\lambda_j = 2 \cos\left(\frac{\pi j}{n+1}\right) \qquad j = 1, 2, \ldots, n$$

and

$$U = [u_{ij}] \qquad i, j = 1, 2, \ldots, n,$$

where

$$u_{ij} = \sqrt{\frac{2}{n+1}} \sin\left(\frac{\pi ij}{n+1}\right).$$

Thus the eigenvalues of A in Θ_n are

$$\lambda_i(A) = \sum_{j=0}^{n-1} [\lambda_i(T)]^j \cdot c_{j+1}$$

as $i = 1, 2, \ldots, n$. The eigenvectors of A are exactly those of T, which are the column vectors of U.

We have shown that we can express a BST matrix as the sum of a cross-sum matrix (whose eigenvalues and eigenvectors can be easily calculated) and a persymmetric, "offset" Hankel matrix. Thus we have

$$T_{n,k} = C_{n,k} + H_{n,k-2}, \tag{2.9}$$

where

$$C_{n,k} = \operatorname{CrossSum}_n(c_1 - c_3, c_2 - c_4, \ldots, c_{k-2} - c_k, c_{k-1}, c_k, 0, \ldots, 0) \tag{2.10}$$

and

$$H_{n,k-2} = \operatorname{Hank}_n(c_3, c_4, \ldots, c_k, 0, \ldots, 0). \tag{2.11}$$

If the spectral decomposition of $C_{n,k}$ is given by

$$C_{n,k} = UDU^T,$$

then we have

$$T_{n,k} = UDU^T + H_{n,k-2} = U(D + U^T H_{n,k-2} U)U^T.$$

The problem of calculating the eigensystem of $T_{n,k}$ reduces to that of finding the eigensystem of

$$D + U^T H_{n,k-2} U, \tag{2.12}$$

where

$$UDU^T = \text{CrossSum}_n (c_1 - c_3, c_2 - c_4, \ldots, c_{k-2} - c_k, c_{k-1}, c_k, 0, \ldots, 0)$$

and

$$H_{n,k-2} = \text{Hank}_n (c_3, c_4, \ldots, c_k, 0, \ldots, 0).$$

The key to applying the updating procedure described above to (2.12) is in expressing the matrix $H_{n,k-2}$ as a sum of rank-one updates of the form $\rho z z^T$. Note that $H_{n,k-2}$, which has the form

$$H_{n,k-2} = \begin{bmatrix} a_3 & a_4 & \cdots & a_k & & \\ a_4 & a_5 & \iddots & & & \\ & & a_k & & & a_k \\ \vdots & \iddots & 0 & & \iddots & \\ a_k & & & a_k & & \vdots \\ & & \iddots & & a_5 & a_4 \\ & & a_k & \cdots & a_4 & a_3 \end{bmatrix}, \tag{2.13}$$

will be quite sparse for values of k that are small with respect to n. We also note that $H_{n,k-2}$ is a block diagonal matrix if we assume that $k \leqq n/2$. A logical way of expressing $H_{n,k-2}$ as a sum of matrices of the form $\rho z z^T$ is to calculate the eigensystem for the two small $k \times k$ blocks appearing in the upper left and lower right corners of (2.13). We use the EISPACK routines to solve this problem in $O(k^3)$ steps.

We express the complete process formally as Algorithm 2.1.

ALGORITHM 2.1.

(1) Form

$$v = [a_1 - a_3, a_2 - a_4, \ldots, a_{k-2} - a_k, a_{k-1}, a_k, 0, \ldots, 0]^T.$$

(2) Solve

$$Sc = v$$

for the vector $c \in \mathbf{R}^n$, where $S = [s_{ij}]_{i,j=1}^n$ such that

$$\begin{aligned} s_{ij} &= s_{i-1,j-1} + s_{i+1,j-1}, && 1 \leqq i \leqq j \leqq n, \\ s_{ij} &= 0, && 0 \leqq j < i \leqq n, \\ s_{0,j} &= 0, && 1 \leqq j \leqq n, \\ s_{0,0} &= 1. \end{aligned}$$

(3) Form the matrix Λ of eigenvalues of the matrix $\text{CrossSum}_n (v)$ as follows:

$$\Lambda = \text{diag} (\lambda_1, \lambda_2, \ldots, \lambda_n),$$

where

$$\lambda_i = \sum_{j=0}^{n-1} \left[2 \cos \left(\frac{i\pi}{n+1} \right) \right]^j \cdot c_{j+1} \qquad i = 1, 2, \ldots, n.$$

The eigenvectors of the cross-sum matrix are then the columns of the matrix $U = [u_{ij}]$ given by

$$u_{ij} = \left(\frac{2}{n+1}\right)^{1/2} \sin\left(\frac{\pi ij}{n+1}\right)$$

for $i = 1, 2, \ldots, n$ and $j = 1, 2, \ldots, n$.

(4) Set $M = U^T$ and $D = \Lambda$.

(5) Calculate the eigensystem of the $k \times k$ matrix

$$B_1 = \begin{bmatrix} a_3 & a_4 & \cdots & a_k \\ a_4 & a_5 & & \iddots \\ & & a_k & \\ \vdots & \iddots & & \\ a_k & & & \end{bmatrix}.$$

So we have B_1 expressed as

$$B_1 = \sum_{i=1}^{k} \lambda_i q_i q_i^T.$$

Then the lower right corner of $H_{n,k-2}$ given by

$$B_2 = \begin{bmatrix} & & & a_k \\ & & \iddots & \vdots \\ & a_k & & \\ \iddots & & a_5 & a_4 \\ a_k & \cdots & a_4 & a_3 \end{bmatrix},$$

and we have

$$B_2 = \sum_{i=1}^{k} \lambda_i (q_i)^R (q_i^T)^R$$

as B_2 is related to B_1 by a permutation.

(6) For $j = 1$ to $2k$:

(a) Form $z_j = (q_j, 0, 0, \ldots, 0) \in \mathbf{R}^n$ if $j \leqq k$ or $z_j = (0, 0, \ldots, 0, q_i^R) \in \mathbf{R}^n$ if $j > k$.

(b) Form $v_j = Mz_j$.

(c) Calculate the eigensystem $\bar{Q}_j \bar{D}_j \bar{Q}_j^T$ of

$$D + v_j v_j^T$$

by the updating procedure.

(d) Update the eigenvector matrix M, which equals $\bar{Q}_j^T M$.

(e) Set $D = D_j$.

(7) The eigensystem of $T_{n,k}$ is then given by

$$M^T D M = T_{n,k}.$$

We have not as yet discussed the stability of the updating procedure used in Algorithm 2.1. Barlow [4] provides a backward error analysis of Cuppen's method for solving the symmetric tridiagonal eigenproblem based on using the implementation by Dongarra and Sorensen with some additional assumptions made about the details of the implementation. The analysis shows the method to be stable in the classical sense. Barlow extends these results to general updating strategies for the symmetric eigenvalue problem

and particularly to the technique presented in this paper. He obtains the following bound: Let $\lambda_1, \lambda_2, \ldots, \lambda_n$ be the exact eigenvalues of a BST matrix $T_{n,k}$, and let $\hat{\lambda}_1, \hat{\lambda}_2, \ldots, \hat{\lambda}_n$ be the computed eigenvalues obtained for $T_{n,k}$, then we have

$$\sqrt{\sum_{i=1}^{n} (\lambda_i - \hat{\lambda}_i)^2} \leqq [n^{1/2}\mu + 2(n+1)^{1/2}u] \cdot \|T_{n,k}\|_F + O(u^2 + \mu^2),$$

where u is the machine unit and μ is the tolerance for the iteration. In general, μ should be approximately equal to the machine unit. The numerical results in § 3 support these conclusions.

3. Numerical results and conclusions. We compare the performance of Algorithm 2.1 with that of the EISPACK routines BANDR and TQL2 that calculate the complete set of eigenvalues and eigenvectors of a real, symmetric, banded matrix. For k small with respect to n, Algorithm 2.1 compares very favorably to the EISPACK routines. Our tests were run on a Sun 4 under the UNIX operating system. All code was written in FORTRAN. The updating routine was obtained from D. Sorensen.

First we generated a random set of 50 banded Toeplitz matrices with dimension between 8 and 100, bandwidth between 3 and 7, and matrix entries in the range (−1000.0, 1000.0). For this set of problems, the average error between the answer obtained by EISPACK and the answer obtained by the technique presented here was 2.52E−11. The average time required by BANDR and TQL2 was 7.45 seconds. The average time required by the update method was 4.90 seconds.

Next, we generated a set of test cases that were very sparse. In most cases, the only nonzero entries were in the main diagonal and the kth subdiagonal and superdiagonal. There were 25 problems in this set with dimension between 8 and 100 and bandwidth between 3 and 7. The matrix entries were in the range (−100.0, 100.0). For this set, the average error was 9.20E−13. The average time for the BANDR and TQL2 routines was 3.50 seconds and the average time used by the update method was 1.97 seconds.

We now consider some small examples showing how performance of the algorithms changes as k becomes small with respect to n. All times in the examples are given in seconds. Each ratio entry is the ratio of the time required by the updating method to the time required by the EISPACK routines. The error column contains the two-norm of the absolute error between the vectors of eigenvalues obtained by the two methods.

Example 3.1. $T_{n,k} = \text{Toep}_n(10.0, 5.0, 6.0, 0.0, \ldots, 0.0)$.

Dim	k	Time for BANDR/TQL2	Time for UPDATE	Ratio	Error
10	3	0.04	0.03	0.75	1.83E−14
20	3	0.20	0.11	0.55	6.68E−14
30	3	0.65	0.24	0.37	6.81E−14
40	3	1.47	0.49	0.33	7.52E−14

Example 3.2. $T_{n,k} = \text{Toep}_n(-1.0, 2.0, -3.0, 4.0, 0.0, \ldots, 0.0)$.

Dim	k	Time for BANDR/TQL2	Time for UPDATE	Ratio	Error
10	4	0.03	0.06	2.00	2.91E−14
14	4	0.10	0.08	0.80	2.49E−14
18	4	0.17	0.15	0.88	4.79E−14
22	4	0.30	0.24	0.80	8.02E−14
26	4	0.47	0.34	0.72	3.48E−14
30	4	0.73	0.47	0.64	4.46E−14

Example 3.3. $T_{n,k} = \text{Toep}_n(20.0, 1.0, 3.0, 5.0, 7.0, 9.0, 0.0, \ldots, 0.0)$.

Dim	k	Time for BANDR/TQL2	Time for UPDATE	Ratio	Error
20	6	0.26	0.35	1.35	1.18E−13
40	6	1.66	1.62	0.98	1.99E−13
60	6	5.19	4.46	0.86	3.22E−13
80	6	11.97	9.40	0.79	4.02E−13
100	6	22.15	17.79	0.80	6.19E−13
120	6	39.45	31.28	0.79	5.54E−13
140	6	62.61	49.45	0.79	7.47E−13
160	6	90.88	72.65	0.80	7.92E−13
180	6	129.39	101.53	0.79	8.00E−13
200	6	179.44	137.81	0.77	1.15E−12

Example 3.4. $T_{n,k} = \text{Toep}_n(13.0, 0.0, 0.0, 0.0, -6.0, 0.0, \ldots, 0.0)$.

Dim	k	Time for BANDR/TQL2	Time for UPDATE	Ratio	Error
20	5	0.06	0.08	1.33	3.04E−14
40	5	0.56	0.34	0.61	5.08E−14
60	5	1.78	0.85	0.48	1.09E−13
80	5	3.87	1.73	0.45	7.63E−14
100	5	7.87	2.98	0.38	1.24E−13

Finally, we give a worst-case complexity analysis of Algorithm 2.1. Assuming that no deflation in update size occurs, we obtain the following operation counts.

Step	Operation Count
1	n
2	$n^2/2$
3	$4n^2$
4	$n^2 + n$
5	$5k^3$
6	$2(k-2)9n^2$

The total operation count is approximately $18kn^2$. It is clear that k must be rather small with respect to n for Algorithm 2.1 to compete with the EISPACK routines. If deflation occurs, it will further reduce the operation count for calculating the update's eigenvalues.

4. Conclusions and open questions. In this section, we summarize the previous results and examine areas in which further work can be done. The Bini and Capovani splitting proved quite useful in developing a numerical method for calculating the eigensystem of BST matrices. The new method was based on a divide-and-conquer method developed by Cuppen [8] and further studied by Dongarra and Sorensen [9]. The Cuppen method employs a procedure due to Bunch, Nielsen, and Sorensen [7] that calculates the eigensystem of a matrix obtained from adding a rank-one update to a diagonal matrix. The method we derived is quite fast for BST matrices whose bandwidth is small relative to their dimension. Other methods exist for calculating eigenvalues of this type of update. For example, two different techniques are discussed in Chapter 12 of Golub and Van Loan [10]. These updating methods may yield faster performance or improved accuracy and should be explored.

It may also be possible to apply the divide-and-conquer algorithms of Cuppen to other types of eigenvalue problems. Barlow and Demmel [3] obtained error bounds on the computed solutions to certain matrix pencil problems that are much better than those derived from standard algorithms. They have shown that algorithms exist that achieve the relative accuracy promised by these bounds. One example of such an algorithm is bisection followed by inverse iteration. It may be possible to implement the divide and conquer approaches used here in such a way as to satisfy these new error bounds as well.

A number of problems in this area have been suggested by Arbenz and Golub [1]. Further research in this direction should prove to be quite interesting.

Acknowledgments. The authors would like to thank Jim Demmel for some useful insights and Danny Sorensen for lending us the software for the updating method in [9]. The authors would also like to thank the referees whose suggestions greatly improved the paper.

A NOTE ON JACOBI BEING MORE ACCURATE THAN *QR**

WALTER F. MASCARENHAS†

Abstract. In [*SIAM J. Matrix Anal. Appl.*, 13 (1992) pp. 1204–1245], Demmel and Veselić present a theoretical and experimental analysis to show that the Jacobi method is more accurate than the *QR* method when computing the eigenvalues of positive definite matrices. They show that the error caused by the Jacobi method depends on the size of a factor ρ, which is related to the singular values of certain matrices associated with the Jacobi iterates. Their experiments suggest that $\rho = O(1)$. However, in this note a family of matrices and orderings is presented for which $\rho = O(N)$, where N is the dimension of the matrix.

AMS subject classifications. 65F15, 65G05, 65H15

1. Introduction. In [DV], Demmel and Veselić present strong evidence that the Jacobi method for computing eigenvalues of symmetric matrices is optimally accurate when applied to a positive definite matrix. Their work starts by showing that if H is positive definite and P is such that $|P_{ij}| \leqq \eta |H_{ij}|$, then

$$\max_i \frac{|\lambda_i(H) - \lambda_i(H+P)|}{\lambda_i(H)} \leqq \frac{N\eta}{\sigma(H)}, \tag{1.1}$$

where λ_i denotes the ith eigenvalue and $\sigma(H)$ is the smallest singular value of the matrix $A = D^{-1}HD^{-1}$, where D is a diagonal matrix and $A_{ii} = 1$. We note that although Demmel and Veselić use the condition number A instead of $1/\sigma(H)$ in (1.1), a more careful look at their analysis shows that the sharper bound in (1.1) holds.

The bound in (1.1) is better than what can be expected from the usual perturbation theory. The usual analysis leads to a bound of the form (1.1), but with $\sigma(H)$ replaced by the smallest singular value of H, which can be much smaller than $\sigma(H)$.

The bound (1.1) is sharp, in the sense that there exists P for which equality is almost achieved in (1.1). Therefore, the best accuracy we can hope for when using a finite arithmetic with rounding ε is obtained by replacing η by ε in (1.1).

To show that the Jacobi method has optimal accuracy, Demmel and Veselić obtain a bound

$$\max_i \frac{|\lambda_i(H) - \bar{\lambda}_i(H)|}{\lambda_i(H)} \leqq \frac{cMN\varepsilon}{\theta(H, O)}, \tag{1.2}$$

for the relative error in the eigenvalues $\bar{\lambda}$ computed by the Jacobi method using an ordering O, i.e., the order in which the rotations are performed. In this last equation c is a constant, M is the number of rotations performed until convergence, and

$$\theta(H, O) = \min_k \sigma(H^{(k)}), \tag{1.3}$$

where $H^{(k)}$ are the iterates produced by the Jacobi method with ordering O to H.

Therefore, the ratio

$$\rho(H, O) = \frac{\sigma(H)}{\theta(H, O)}$$

gives an idea of how the accuracy obtained by the Jacobi method compares to the best accuracy we can expect to obtain in finite arithmetic. Demmel and Veselić conjecture that ρ is small. In fact, their numerical experiments suggest that $\rho = O(1)$ for the ordering by rows. The purpose of this note is to present matrices and orderings for which $\rho = O(N)$, where N is the dimension of the matrix. More formally, at the end of the next section we prove the following result.

THEOREM 1. *Given $N = 2^n$ and α, $0 < \alpha < \frac{1}{2}$, there exists an $N \times N$ symmetric positive definite matrix $H = H(N, \alpha)$ and a family of orderings O such that $\rho(H, O) \geqq \frac{N}{4}$.*

We emphasize, however, that a ρ of order N is not enough to invalidate the claims in [DV]. If ρ can be at most $O(N)$, then Jacobi is more accurate than QR. Our search for matrices and orderings with bigger ρ's was unsuccessful and leads us to believe that the growth above is maximal. As it was the case with Gaussian elimination, the use of clever optimization techniques can lead to bigger values of ρ. Even if such examples are found, they are likely to be complicated, and we believe that our example gives a nice and simple explanation of how ρ can grow.

Finally, in the appendix we present a very short Matlab program that simulates the behavior of the Jacobi method for the orderings and matrices from Theorem 1. The experiments show that the maximum relative error in this case is asymptotically equal to $\frac{N\varepsilon}{2}$, where N is the dimension of the matrix and ε is machine precision.

2. Description of H and O. We start this section by presenting the family $H(N, \alpha)$ and the orderings O. Then we present a lemma and finally a proof of Theorem 1.

The matrices $H = H(N, \alpha)$ are rather simple. They have ones on the diagonal and $1 - \alpha$ in all the other entries. In other words

$$H_{ii} = 1, \qquad H_{ij} = 1 - \alpha \text{ if } i \neq j.$$

These H are positive definite and $\lambda_{\min}(H) = \alpha$ if $\alpha < 1$.

We will say that an ordering O for applying the Jacobi method is *acceptable* if it can be obtained by the following recursive procedure:

- if $N = 2$, then pivot $(1, 2)$.
- If $N = 2^n$, $n > 1$, partition the matrix as

$$H = \begin{pmatrix} H_{11} & H_{12} \\ H_{12}^T & H_{22} \end{pmatrix},$$

where the H_{ij} are $2^{n-1} \times 2^{n-1}$ blocks, pivot the entries on the main diagonal of H_{12}, then rotate the remaining entries of H_{12} and the entries in H_{11} in any ordering. Finally, apply an acceptable ordering to H_{22}.

The iterates of the Jacobi method applied according to an acceptable ordering to the matrices $H(N, \alpha)$ above can be simply described, provided we assume that in the ambiguous case of repeated diagonal entries we choose the Jacobi rotation J as did, for example, Golub and Van Loan, that leads to the example below

$$J\begin{pmatrix} 1 & b \\ b & 1 \end{pmatrix}J^T = \begin{pmatrix} 1-b & 0 \\ 0 & 1+b \end{pmatrix}. \tag{2.1}$$

Let us call $\tilde{H}$ the matrix obtained after applying the rotations in the $\frac{N}{2} \times \frac{N}{2}$ blocks H_{12} and H_{11} of H. We now have the following lemma.

LEMMA 1. *If the ordering O is acceptable and, in the case of repeated diagonal entries, we rotate as in* (2.1), *then*

$$\tilde{H}(N, \alpha) = \begin{pmatrix} \alpha I_{N/2} & 0 \\ 0 & (2-\alpha)H(\frac{N}{2}, \frac{\alpha}{2-\alpha}) \end{pmatrix},$$

where I_k is the $k \times k$ identity matrix.

Proof of Lemma 1. We analyze here the case $N = 4$. The general case is analogous and is left to the reader. In this case we have

$$H = H(N, \alpha) = \begin{pmatrix} 1 & 1-\alpha & 1-\alpha & 1-\alpha \\ & 1 & 1-\alpha & 1-\alpha \\ & & 1 & 1-\alpha \\ & & & 1 \end{pmatrix}.$$

The first rotation is at (1, 3) and leads to the matrix

$$H^{(1)} = \begin{pmatrix} \alpha & 0 & 0 & 0 \\ & 1 & \frac{\sqrt{2}(1-\alpha)}{2} & 1-\alpha \\ & & 2-\alpha & \frac{\sqrt{2}(1-\alpha)}{2} \\ & & & 1 \end{pmatrix}.$$

Then we pivot at (2, 4), getting

$$H^{(2)} = \begin{pmatrix} \alpha & 0 & 0 & 0 \\ & \alpha & 0 & 0 \\ & & 2-\alpha & 2(1-\alpha) \\ & & & 2-\alpha \end{pmatrix}.$$

The rest of the pivots in the block H_{12}, (1, 4) and (2, 3), are zero, so we do not rotate. The only pivot in the block H_{11}, (1, 2), is also zero and again no rotation is performed. To complete the proof, note that

$$\begin{pmatrix} 2-\alpha & 2(1-\alpha) \\ & 2-\alpha \end{pmatrix} = (2-\alpha)\begin{pmatrix} 1 & \frac{2(1-\alpha)}{2-\alpha} \\ & 1 \end{pmatrix} = (2-\alpha)\begin{pmatrix} 1 & 1-\frac{\alpha}{2-\alpha} \\ & 1 \end{pmatrix}.$$

Proof of Theorem 1. Take O to be an acceptable ordering. Lemma 1 shows that applying the Jacobi method to $H(N, \alpha)$ according to O reduces to applying the Jacobi method to $(2-\alpha)H(\frac{N}{2}, \frac{\alpha}{2-\alpha})$, according to another acceptable ordering O'. Since the Jacobi method, and the smallest singular value of $A = D^{-1}HD^{-1}$, are scale invariant, this implies that

$$\theta(H(N, \alpha), 0) \leqq \theta\left(H\left(\frac{N}{2}, \frac{\alpha}{2-\alpha}\right), O'\right). \tag{2.2}$$

Therefore, if α_k is given by the recurrence relation

$$\alpha_0 = \alpha, \tag{2.3}$$

$$\alpha_{k+1} = \frac{\alpha_k}{2-\alpha_k}, \tag{2.4}$$

we have

$$\theta(H(N, a), O) \leqq \theta\left(H\left(\frac{N}{2^k}, \alpha_k\right), O'\right) \leqq \theta(H(2, \alpha_{\log N-1}), O'') = \alpha_{\log N-1}.$$

Fortunately, the recurrence relation (23) has a simple closed form solution:

$$\alpha_k = \frac{\alpha}{2^k(1-\alpha)+\alpha}.$$

Thus,

$$\theta(H(N,\alpha), O) = \frac{\alpha}{2^{\log N-1}(1-\alpha)+\alpha} = \frac{\alpha}{\frac{N}{2}(1-\alpha)+\alpha}.$$

Since we are assuming $0 < \alpha < \frac{1}{2}$, this implies that

$$\theta(H(N,\alpha), O) \leqq \frac{4\alpha}{N}.$$

Therefore, since $\sigma(H(N,\alpha)) = \alpha$,

$$\rho(H(N,\alpha), O) \geqq \frac{N}{4},$$

and the proof of Theorem 1 is complete.

3. Appendix. In this appendix we present the Matlab code to simulate the operations realized by the Jacobi method when applied to the matrices H and orderings O in Theorem 1. Given the special structure of these matrices and orderings, the operations performed by the Jacobi method can be described exactly by the Matlab program.

```
1 a=.5; d=1; ev=[]; % d = diagonal, ev = eigenvalues.
2 for i=1:n,        % N = 2^n is the dimension, to be given.
3   ev(i)=d-a;
4   d=d+a;
5   a=a*sqrt(.5)*sqrt(.5)*4; % or a = 2*a*(1+eps);
6 end
7   max(abs((ev-.5)./.5))/(eps*2^(n-1))
```

In this program

$$a = a_k = (1-\alpha_k)\prod_{i=0}^{k-1}(2-\alpha_i)$$

is the nonzero off-diagonal element of the matrices H, computed using the recursion in Lemma 1, and d is the diagonal entry of H.

The expression in line 5 of the program above is used to update a because the exact expression, `a = 2 a`, would be computed exactly in most computers, and we would not be able to see the effects of rounding. Line 5 is a good simulation of the rounding errors that will happen if we apply a usual implementation of the Jacobi method for computing the eigenvalues of H.

LARGE LEAST SQUARES PROBLEMS INVOLVING KRONECKER PRODUCTS*

DONALD W. FAUSETT† AND CHARLES T. FULTON†

Abstract. The general problem considered here is the least squares solution of $(A \otimes B)x = t$, where A and B are full rank, rectangular matrices, and $A \otimes B$ is the Kronecker product of A and B. Equations of this form arise in areas such as digital image and signal processing, photogrammetry, finite elements, and multidimensional approximation. An efficient method of solution is based on QR factorizations of the original matrices A and B. It is demonstrated how these factorizations can be used to obtain the Cholesky factorization of the least squares coefficient matrix without explicitly forming the normal equations. A similar approach based on singular value decomposition (SVD) factorizations also is indicated for the rank-deficient case.

Key words. Kronecker product, overdetermined least squares, QR factorization, SVD factorization, matrix algorithms

AMS subject classifications. 15A23, 65F05, 65F20, 65F30

1. Introduction.

In this paper we consider primarily the least squares problem of full rank

$$(A \otimes B)x = t, \tag{1.1}$$

where A and B are real matrices that are $m \times p$, $m > p$, and $n \times q$, $n > q$, respectively, with rank $(A) = p$, rank $(B) = q$, and where the Kronecker product [7], [12], [14] (also tensor or direct product) is defined by

$$A \otimes B = \begin{pmatrix} a_{11}B & a_{12}B & \cdots & a_{1p}B \\ a_{21}B & a_{22}B & \cdots & a_{2p}B \\ \vdots & \vdots & \ddots & \vdots \\ a_{m1}B & a_{m2}B & \cdots & a_{mp}B \end{pmatrix}.$$

Technically this definition is for a right Kronecker product; the left Kronecker product would have the matrix A multiplied by elements of B in each block [17], [18]. Here we make use of the notation $\mathbb{R}^k$ for the usual Euclidean vector space over the real field and $M_{k,l}$ for the vector space of $k \times l$ matrices over the real field, with $\mathbb{R}$ denoting the real numbers. Thus we have $A \in M_{m,p}$, $B \in M_{n,q}$, $A \otimes B \in M_{mn,pq}$, $x \in \mathbb{R}^{pq}$, and $t \in \mathbb{R}^{mn}$.

Least squares problems involving Kronecker products of the type (1.1) arise in several areas of application including signal and image processing [18], photogrammetry [17], fast transform algorithms [1], multidimensional approximation [15], the Lyapunov approach to stability theory [7], circuits and systems [4], and stochastic matrices [2]. In image processing applications, particularly where data collected by satellites or spacecraft are involved, the size of the matrices A and B can be very large, resulting in huge systems of linear equations of the form (1.1) involving literally hundreds of thousands, or even millions, of variables. A problem of Heap and Lindler [10], for example, on the algebraic restoration of astronomical images involves a linear model that gives rise to a system on the order of 250,000 linear equations with 250,000 unknowns. Similar problems arise rather commonly in photogrammetric applications, cf. Rauhala [17].

† Florida Institute of Technology, Department of Applied Mathematics, 150 West University Boulevard, Melbourne, Florida 32901 (dfausett@zach.fit.edu, fulton@zach.fit.edu).

The most common approach to computing the least squares solution of (1.1) is to form the normal equations

$$(A \otimes B)^T(A \otimes B)x = (A \otimes B)^T t. \tag{1.2}$$

Then the least squares solution of (1.1) (assuming $A \otimes B$ has full rank) is the exact solution of (1.2). Using standard properties of the Kronecker product [2], [7], [11], [12], [16], [17], the exact solution of (1.2) may be obtained in the form

$$x = (A^+ \otimes B^+)t \tag{1.3}$$

or the equivalent matrix form

$$X = B^+T(A^+)^T, \tag{1.4}$$

where

$$A^+ = (A^TA)^{-1}A^T \tag{1.5}$$

and

$$B^+ = (B^TB)^{-1}B^T$$

are the Moore–Penrose pseudoinverses of A and B, and the matrices T and X are related to the vectors t and x by

$$X = (x^{(1)}, x^{(2)}, \ldots, x^{(p)}) = \begin{pmatrix} x_1 & x_{q+1} & \cdots & x_{(p-1)q+1} \\ \vdots & \vdots & & \vdots \\ x_q & x_{2q} & \cdots & x_{pq} \end{pmatrix} \tag{1.6}$$

and

$$T = (t^{(1)}, t^{(2)}, \ldots, t^{(m)}) = \begin{pmatrix} t_1 & t_{n+1} & \cdots & t_{(m-1)n+1} \\ \vdots & \vdots & & \vdots \\ t_n & t_{2n} & \cdots & t_{mn} \end{pmatrix}. \tag{1.7}$$

For the details leading from (1.2) to (1.4) we refer to Rao and Mitra [16], Horn and Johnson [12], or Rauhala [17].

Since the dimensions of the matrices A, B, X, T are small compared to the dimensions of $A \otimes B$, the operation counts for the solution (1.4) are an order of magnitude smaller than the operation counts required for the explicit formation and solution of (1.2). In fact, it is this tremendous reduction in the amount of work in using (1.4) vis-à-vis (1.2) (or (1.3)) that forms the basis for Rauhala's concept of "array algebra" [17] and its generalizations.

The main drawback of the solution formula (1.4) is the instability associated with the explicit formation of A^TA and B^TB (which squares the condition number, cf. [6]). In this paper we propose a new method for solving (1.1) which also completely avoids the explicit formation of $A \otimes B$, and at the same time ensures a numerically stable solution. It is based on forming QR decompositions of A and B, which, upon algebraic simplification, give rise to a block diagonal system consisting of p blocks of upper triangular square $q \times q$ systems of equations. This has the particularly nice feature of being intrinsically parallel since the $q \times q$ blocks are mutually independent. Parallel implementations of the solution method described below are currently in progress.

2. QR factorization of the Kronecker product. Suppose that the full-rank matrices A and B have each been QR decomposed with column pivoting [6], so that

$$BP_1 = Q_1R_1 = Q_1\begin{pmatrix} R^{(1)} \\ 0^{(1)} \end{pmatrix} \tag{2.1}$$

and

$$AP_2 = Q_2R_2 = Q_2\begin{pmatrix} R^{(2)} \\ 0^{(2)} \end{pmatrix}, \tag{2.2}$$

where

$Q_1 \in M_{n,n}$	and	$Q_2 \in M_{m,m}$	are orthogonal matrices,
$R_1 \in M_{n,q}$	and	$R_2 \in M_{m,p}$	are upper triangular matrices,
$R^{(1)} \in M_{q,q}$	and	$R^{(2)} \in M_{p,p}$	are square, upper triangular matrices,
$0^{(1)} \in M_{n-q,q}$	and	$0^{(2)} \in M_{m-p,p}$	are zero matrices,

and

$P_1 \in M_{q,q}$ and $P_2 \in M_{p,p}$ are permutation matrices arising from the column pivoting.

Then

$$R^{(1)} = \begin{pmatrix} r_{11}^{(1)} & r_{12}^{(1)} & \cdots & r_{1q}^{(1)} \\ 0 & r_{22}^{(1)} & \cdots & r_{2q}^{(1)} \\ \vdots & \ddots & \ddots & \vdots \\ 0 & \cdots & 0 & r_{q,q}^{(1)} \end{pmatrix} \text{ and } R^{(2)} = \begin{pmatrix} r_{11}^{(2)} & r_{12}^{(2)} & \cdots & r_{1p}^{(2)} \\ 0 & r_{22}^{(2)} & \cdots & r_{2p}^{(2)} \\ \vdots & \ddots & \ddots & \vdots \\ 0 & \cdots & 0 & r_{p,p}^{(2)} \end{pmatrix}, \tag{2.3}$$

where the diagonal elements of $R^{(1)}$ and $R^{(2)}$ are nonzero. The permutation matrices P_1 and P_2 are used to keep the diagonal elements as far away from zero as possible.

For the following development, we need two basic properties of Kronecker products [12].

(2.4) Property 1. $(A \otimes B)^T = A^T \otimes B^T$ for any two rectangular matrices.

(2.5) Property 2. $(A \otimes B)(C \otimes D) = (AC) \otimes (BD)$,

where the matrices must be of proper dimensions to be conformable for the matrix multiplications indicated.

Also, the following two lemmas are readily established.

LEMMA 1. *The Kronecker product of two permutation matrices is a permutation matrix.*

LEMMA 2. *The Kronecker product of two orthogonal matrices is an orthogonal matrix.*

Our solution technique is based on the following two theorems.

THEOREM 1. *If A and B have the permuted* QR *factorizations* (2.1)–(2.2), *then $A \otimes B$ has the permuted* QR *factorization*

$$(AP_2) \otimes (BP_1) = [(Q_2 \otimes Q_1)P_3^T][P_3(R_2 \otimes R_1)], \tag{2.6}$$

where $P_3 \in M_{mn,mn}$ is the permutation matrix defined by the requirement

$$P_3(R_2 \otimes R_1) = \begin{pmatrix} R^{(2)} \otimes R^{(1)} \\ 0^{(3)} \end{pmatrix}, \tag{2.7}$$

with the zero matrix $0^{(3)} \in M_{mn-pq,pq}$.

Proof. By property (2.5) we have

$$(AP_2) \otimes (BP_1) = (Q_2R_2) \otimes (Q_1R_1)$$
$$= (Q_2 \otimes Q_1)(R_2 \times R_1).$$

By Lemma 2, $Q_2 \otimes Q_1$ is orthogonal. Now,

$$R_2 \otimes R_1 = \begin{pmatrix} R^{(2)} \\ 0^{(2)} \end{pmatrix} \otimes \begin{pmatrix} R^{(1)} \\ 0^{(1)} \end{pmatrix} = \begin{pmatrix} r_{11}^{(2)}R_1 & r_{12}^{(2)}R_1 & \cdots & r_{1p}^{(2)}R_1 \\ 0 & r_{22}^{(2)}R_1 & \cdots & r_{2p}^{(2)}R_1 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & \cdots & 0 & r_{pp}^{(2)}R_1 \\ 0 & & \cdots & 0 \\ \vdots & & & \vdots \\ 0 & & \cdots & 0 \end{pmatrix}.$$

In each of the first p block rows, the last $n - q$ rows are zero because the last $n - q$ rows of R_1 are zero as indicated in (2.1). Therefore, $R_2 \otimes R_1$ does not have the required upper triangular form for a QR decomposition. But this defect has an easy remedy; we introduce a permutation matrix as in (2.7), which performs the necessary row interchanges to move the last $n - q$ rows of each block row below the first pq rows of the permuted matrix. Then, inserting $I = P_3^TP_3$ between the $Q_2 \otimes Q_1$ and $R_2 \otimes R_1$ factors yields (2.6), where $P_3(R_2 \otimes R_1)$ is an upper triangular matrix and $(Q_2 \otimes Q_1)P_3^T$ is an orthogonal matrix (being the product of two orthogonal matrices). □

THEOREM 2. *Let*

$$R = R^{(2)} \otimes R^{(1)} \tag{2.8}$$

be the $pq \times pq$ upper triangular part of $P_3(R_2 \otimes R_1)$ as defined in (2.7). *Then*

$$R^TR = [(AP_2) \otimes (BP_1)]^T[(AP_2) \otimes BP_1)];$$

i.e., R^TR is the Cholesky factorization of $[(AP_2) \otimes (BP_1)]^T[(AP_2) \otimes (BP_1)]$.

Proof. Using properties (2.4)–(2.5), Lemma 2, and Theorem 1, a straightforward calculation yields

$$[(AP_2) \otimes (BP_1)]^T[(AP_2) \otimes (BP_1)] = R^TR. \quad \square$$

3. Application to the least squares problem. We now make use of the results of the previous section to transform the rectangular least squares problem (1.1) into a square block upper triangular system of dimension $pq \times pq$ whose exact solution is the least squares solution of (1.1). This is the analog of the QR method for least squares for a standard overdetermined system (cf. [9, p. 224]).

Inserting $I = (P_2 \otimes P_1)(P_2 \otimes P_1)^T$ into (1.1) and using property (2.5), we have

$$(A \otimes B)(P_2 \otimes P_1)(P_2 \otimes P_1)^Tx = (AP_2 \otimes BP_1)(P_2^T \otimes P_1^T)x = t. \tag{3.1}$$

Multiplying on the left by $(AP_2 \otimes BP_1)^T$, and making use of the Cholesky factorization in Theorem 2, we obtain the normal equations associated with (3.1) as

$$R^TRy = (AP_2 \otimes BP_1)^Tt$$
$$= [P_3(R_2 \otimes R_1)]^T[P_3(Q_2^T \otimes Q_1^T)]t \tag{3.2}$$
$$= [R^T \vdots (0^{(3)})^T][P_3(Q_2^T \otimes Q_1^T)]t,$$

where

$$y = (P_2^T \otimes P_1^T)x \tag{3.3}$$

is a permutation of the vector x. Here the last two lines make use of (2.6)–(2.7). Since $R = R^{(2)} \otimes R^{(1)}$ is $pq \times pq$ and $[0^{(3)}]^T$ is $pq \times (mn - pq)$, it follows that the last $mn - pq$ components of the $mn \times 1$ vector $[P_3(Q_2^T \otimes Q_1^T)]t$ do not contribute to the right-hand side vector. We therefore define

$$[P_3(Q_2^T \otimes Q_1^T)t]_{pq} \in \mathbb{R}^{pq} \tag{3.3}$$

to be the vector containing the first pq components of $P_3(Q_2^T \otimes Q_1^T)t$. Then the normal equations become

$$R^T R y = R^T [P_3(Q_2^T \otimes Q_1^T)]_{pq}, \tag{3.4}$$

where R is the square matrix in (2.8). Since A and B were assumed full rank, all diagonal elements of $R^{(1)}$ and $R^{(2)}$ are nonzero, so it follows that R is nonsingular. Multiplying by $(R^T)^{-1}$ in (3.4) thus yields the block upper triangular system

$$Ry = \begin{pmatrix} r_{11}^{(2)} R^{(1)} & r_{12}^{(2)} R^{(1)} & \cdots & r_{1p}^{(2)} R^{(1)} \\ 0 & r_{22}^{(2)} R^{(1)} & \cdots & r_{2p}^{(2)} R^{(1)} \\ \vdots & \ddots & \ddots & \vdots \\ 0 & \cdots & 0 & r_{pp}^{(2)} R^{(1)} \end{pmatrix} \begin{pmatrix} y^{(1)} \\ y^{(2)} \\ \vdots \\ y^{(p)} \end{pmatrix} = \begin{pmatrix} h^{(1)} \\ h^{(2)} \\ \vdots \\ h^{(p)} \end{pmatrix} = h, \tag{3.5}$$

where

$$y = (P_2^T \otimes P_1^T)x = \begin{pmatrix} y^{(1)} \\ y^{(2)} \\ \vdots \\ y^{(p)} \end{pmatrix}, \quad \text{with } y^{(i)} = \begin{pmatrix} y_1^{(i)} \\ y_2^{(i)} \\ \vdots \\ y_q^{(i)} \end{pmatrix} \quad \text{for } i = 1, \ldots, p; \tag{3.6}$$

and

$$h = [P_3(Q_2^T \otimes Q_1^T)t]_{pq} = \begin{pmatrix} h^{(1)} \\ h^{(2)} \\ \vdots \\ h^{(p)} \end{pmatrix}, \quad \text{with } h^{(i)} = \begin{pmatrix} h_1^{(i)} \\ h_2^{(i)} \\ \vdots \\ h_q^{(i)} \end{pmatrix} \quad \text{for } i = 1, \ldots, p. \tag{3.7}$$

Since $R^{(2)} \otimes R^{(1)}$ is upper triangular, (3.5) can be solved by block back substitution to obtain y. The least squares solution x to the original, unpermuted problem is then obtained by premultiplication by $P_2 \otimes P_1$:

$$(P_2 \otimes P_1)y = (P_2 \otimes P_1)(P_2^T \otimes P_1^T)x = (P_2 P_2^T) \otimes (P_1 P_1^T)x = x.$$

The right-hand-side vector h can be computed in a block manner as follows. Observe that

$$(Q_2^T \otimes Q_1^T)t = (Q_2^T \otimes I_1) \begin{pmatrix} Q_1^T t^{(1)} \\ Q_1^T t^{(2)} \\ \vdots \\ Q_1^T t^{(m)} \end{pmatrix}, \tag{3.8}$$

where the vector $t \in \mathbb{R}^{mn}$ has been partitioned into m subvectors, each of length n as indicated in (1.7). Recall that P_3 is the permutation matrix such that $P_3(R_2 \otimes R_1)$ is

upper triangular. In the right-hand-side vector h, P_3 performs the same interchanges on $(Q_2^T \otimes Q_1^T)t$. Therefore, the components of $h = [P_3(Q_2^T \otimes Q_1^T)t]_{pq}$ are precisely the same as those of $(Q_2^T \otimes Q_1^T)t$, which are located in rows in which $R_2 \otimes R_1$ has (some) nonzero elements. Since we know in advance in which rows those nonzero elements will appear, the permutation matrix P_3 need not be formed. For example, we can compute h by taking the first q components of

$$Q_1^T \sum_{k=1}^{m} q_{kj}^{(2)} t^{(k)} \quad \text{for } j = 1, \ldots, p.$$

The rows of $R_2 \otimes R_1$ that are zero, and hence are omitted from $R^{(2)} \otimes R^{(1)}$, along with the corresponding components of $(Q_2^T \otimes Q_1^T)t$ on the right-hand side, represent $p(n-q) + n(m-p)$ equations in the original linear system $(A \otimes B)x = t$. In general, those equations will not be satisfied by the least squares solution x. The omitted components of $(Q_2^T \otimes Q_1^T)t$ (as defined by (3.3)) constitute the "irreducible residual" of the least squares problem (cf. [5, p. 132]).

4. Reduction to block diagonal form. The upper block triangular system (3.5) can be brought into block diagonal form by computation of $(R^{(2)})^{-1}$. This can be done in parallel by back solving the triangular systems $R^{(2)}v_i = e_i$ for $i = 1, \ldots, p$ on different processors, where e_i is the ith column of the $p \times p$ identity matrix I_2. Since more computational effort is required to solve the triangular systems for larger values of i, $1 \le i \le p$, more of the systems corresponding to smaller values of i can be assigned to the same processor than for larger values. A scheme of this sort allows for the computation of $(R^{(2)})^{-1}$ with a reasonably well-balanced distribution of the computational load among the processors.

Once the inverse of $R^{(2)}$ has been obtained, the transformation to block diagonal form proceeds in the following manner. Starting from (3.5), we have

$$\begin{aligned} & (R^{(2)} \otimes R^{(1)})y = h, \\ \Leftrightarrow\ & (R^{(2)} I_2) \otimes (I_1 R^{(1)})y = h, \\ \Leftrightarrow\ & (R^{(2)} \otimes I_1)(I_2 \otimes R^{(1)})y = h, \end{aligned} \tag{4.1}$$

where I_1 is a $q \times q$ identity matrix.

Now $(R^{(2)} \otimes I_1)^{-1} = (R^{(2)})^{-1} \otimes I_1$, so we can multiply both sides of (4.1) by $(R^{(2)})^{-1} \otimes I_1$ to obtain

$$(I_2 \otimes R^{(1)})y = ((R^{(2)})^{-1} \otimes I_1)h \equiv \tilde{h}, \tag{4.2}$$

which has the block diagonal form

$$\begin{pmatrix} R^{(1)} & 0 & \cdots & 0 \\ 0 & R^{(1)} & & \vdots \\ \vdots & & \ddots & \\ 0 & \cdots & & R^{(1)} \end{pmatrix} \begin{pmatrix} y^{(1)} \\ y^{(2)} \\ \vdots \\ y^{(p)} \end{pmatrix} = \begin{pmatrix} \tilde{h}^{(1)} \\ \tilde{h}^{(2)} \\ \vdots \\ \tilde{h}^{(p)} \end{pmatrix}, \tag{4.3}$$

where

$$\tilde{h} = ((R^{(2)})^{-1} \otimes I_1)h. \tag{4.4}$$

The resulting block diagonal system (4.3) is perfectly parallel, so the upper triangular systems in each block row, $R^{(1)}y^{(j)} = \tilde{h}^{(j)}$, may be solved simultaneously. On a distributed memory computer the solution procedure for different blocks can be assigned to different processors and the computations performed independently. If the problem matrices are large, then each processor may have more than one block computation to perform.

5. Computational complexities. The QR decompositions of A and B require $2p^2(m - p/3)$ flops and $2q^2(n - q/3)$ flops, respectively, cf. [6]. The formation of h requires $p[n(2m - 1) + q(2n - 1)]$ flops. The computation of $(R^{(2)})^{-1}$ requires $p + p(p^2 - 1)/3$ flops; and the matrix multiplications to generate $\tilde{h}$ require p^2q flops.

Finally, back substitution for each block requires q^2 flops; therefore the total flops for all p blocks is pq^2. Thus the total work required to solve the least squares problem is $p^2[2(m - \frac{p}{3}) + q] + q^2[2(n - \frac{q}{3}) + p] + p[n(2m - 1) + q(2n - 1) + (p^2 - 1)/3 + 1] = O(p^2[2m + q - \frac{p}{3}] + q^2[2n + p - \frac{2q}{3}] + 2np(m + q))$ flops.

By way of comparison, the computational complexity for implementing the normal equations in the form (1.4), using Gaussian elimination for the inverses, is

$$p[4mp - (m + p)] + q[4nq - (n + q)] + 5(p^3 + q^3)/3 + p(p - 1)(2p - 1)/6 + q(q - 1)(2q - 1)/6 + mq(2n - 1) + pq(2m - 1) = O(2[p^2(2m + p) + q^2(2n + q) + mq(n + p)]) \text{ flops;}$$

while the computational complexity for implementing the solution formula (1.3) by explicitly forming $A^+ \otimes B^+$ is much greater, namely,

$$p[4mp - (m + p)] + q[4nq - (n + q)] + 5(p^3 + q^3)/3 + p(p - 1)(2p - 1)/6 + q(q - 1)(2q - 1)/6 + pm[q(2n - 1) + n] = O(2[p^2(2m + p) + q^2(2n + q) + mnp(q + \tfrac{1}{2})]).$$

For any $p > 0$ and $q > 0$, $p^3 + q^3 \geq pq(p + q)$. Therefore, the only term in the operations count for the QR approach that could possibly be larger than the corresponding term for (1.4) is the last one. Comparison of these terms shows that $2np[m + q] > 2mq[n + p]$ can occur only when $p > q$ or $n > m$ (or both). It would be very unusual for this term to dominate over the effects of the other terms in which the QR approach has the advantage. Thus the QR approach offers computational efficiency as well as computational stability.

6. SVD factorization of the Kronecker product. We briefly consider the case in which one or both of the matrices A and B is not full rank. In this case, the QR approach must be modified if it is to work at all so as to take account of rank (A) and rank (B) being smaller than p and q, respectively, and it therefore becomes necessary to compute the rank using a technique like that of Bischof [3], for example. Here we outline an alternative procedure using the SVD.

Assume that the matrices A and B already have been decomposed as in (2.1) and (2.2). It is computationally more efficient to proceed with complete orthogonal decompositions of R_1 and R_2 than it is to return to the original matrices A and B. Now we suppose that R_1 and R_2 have each been SVD decomposed [6], so that

$$R_1 = U_1 \Sigma_1 V_1^T \tag{6.1}$$

and

$$R_2 = U_2 \Sigma_2 V_2^T, \tag{6.2}$$

where $U_1 \in M_{n,n}$, $U_2 \in M_{m,m}$, $V_1 \in M_{q,q}$, and $V_2 \in M_{p,p}$ are orthogonal matrices, and $\Sigma_1 \in M_{n,p}$ and $\Sigma_2 \in M_{n,p}$ are diagonal matrices.

Then [12, p. 246]

$$R_2 \otimes R_1 = (U_2 \otimes U_1)(\Sigma_2 \otimes \Sigma_1)(V_2^T \otimes V_1^T); \tag{6.3}$$

and from (2.6) we have

$$(AP_2) \otimes (BP_1) = [(Q_1U_2) \otimes (Q_1U_1)](\Sigma_2 \otimes \Sigma_1)(V_2^T \otimes V_1^T), \tag{6.4}$$

which we premultiply on both sides by $[(Q_2U_2) \otimes (Q_1U_1)]^T$ to obtain

$$(\Sigma_2 \otimes \Sigma_1)(V_2^T \otimes V_1^T)[(P_2^T \otimes P_1^T)x] = [(U_2^TQ_2^T) \otimes (U_1^TQ_1^T)]t. \tag{6.5}$$

Let k_1 = rank (B) and k_2 = rank (A); and let $\zeta_i^{(1)}$, $i = 1, \ldots, k_1$; and $\zeta_i^{(2)}$, $i = 1, \ldots, k_2$ denote the first k_1 and k_2 diagonal elements of Σ_1 and Σ_2, respectively. None of those elements are zero, and all other elements of Σ_1 and Σ_2 are zero. Now we introduce the permutation matrices P_3 and P_4 such that $D = P_3(\Sigma_2 \otimes \Sigma_1)P_4$ is a diagonal matrix with its first k_1k_2 diagonal elements nonzero and the vector y defined by

$$y = P_4^T(V_2^T \otimes V_1^T)(P_2^T \otimes P_1^T)x.$$

Premultiplying both sides of (6.5) by P_3 gives

$$Dy = P_3(U_2^TQ_2^T) \otimes (U_1^TQ_1^T)t. \tag{6.6}$$

Finally, we introduce the vector

$$h = [P_3(U_2^TQ_2^T) \otimes (U_1^TQ_1^T)t]_{k_1k_2}$$

containing the first k_1k_2 components of the right-hand side of (6.6).

Since D is diagonal, (6.6) can be solved for each component independently of the minimum-norm least squares solution y:

$$y_j = \begin{cases} h_j/d_j & \text{for } j = 1, \ldots, k_1k_2, \\ 0 & \text{for } j > k_1k_2. \end{cases}$$

The least squares solution to the original problem is obtained from

$$x = (P_2 \otimes P_1)(V_2 \otimes V_1)P_4y.$$

For the usual rank deficient problem $Cx = b$, it is well known that the minimum-norm least squares solution may be represented by

$$x = C^+b. \tag{6.7}$$

In the case of the Kronecker product least squares problem (1.1), it can be shown [13, p. 474] that

$$(A \otimes B)^+ = A^+ \otimes B^+, \tag{6.8}$$

whether A and/or B are full rank or rank deficient. As a consequence an alternative approach, which can serve as a comparison for the algorithm of this paper as well as for the above-described SVD or QR methods for the rank-deficient case, would be to use schemes such as that of Greville ([8], [13, pp. 222–224]), a direct method, or Sen and Prabhu ([19], [13, pp. 247–254]), an iterative method, to compute A^+ and B^+, and then obtain the minimum-norm least squares solution as

$$x = (A^+ \otimes B^+)t. \tag{6.9}$$

This, of course, could also be written in the compact form of (1.4) to save operation counts even for rank-deficient problems.

7. Conclusion. We have presented an efficient method for the solution of large least squares problems involving Kronecker products, based on QR factorization of the matrices that occur in the Kronecker product. This method combines the desirable stability prop-

erties of the QR approach to least squares with a computational scheme that requires minimal computer storage. Since the coefficient matrix can be very large in some applications, this is an essential consideration.

Acknowledgments. The authors thank Professor James Ortega for suggesting this approach to the problem and Dr. Charles Romine for many helpful comments.

A SHIFTED BLOCK LANCZOS ALGORITHM FOR SOLVING SPARSE SYMMETRIC GENERALIZED EIGENPROBLEMS*

ROGER G. GRIMES†, JOHN G. LEWIS†, AND HORST D. SIMON‡

Abstract. An "industrial strength" algorithm for solving sparse symmetric generalized eigenproblems is described. The algorithm has its foundations in known techniques in solving sparse symmetric eigenproblems, notably the spectral transformation of Ericsson and Ruhe and the block Lanczos algorithm. However, the combination of these two techniques is not trivial; there are many pitfalls awaiting the unwary implementor. The focus of this paper is on identifying those pitfalls and avoiding them, leading to a "bomb-proof" algorithm that can live as a black box eigensolver inside a large applications code. The code that results comprises a robust shift selection strategy and a block Lanczos algorithm that is a novel combination of new techniques and extensions of old techniques.

Key words. Lanczos algorithm, sparse eigenvalue problems, structural analysis, symmetric generalized eigenvalue problem, orthogonalization methods

AMS subject classifications. 65F15, 15A18, 65F50, 73K99

1. Introduction.

The Lanczos algorithm [22] is widely appreciated in the numerical analysis community [6]–[9], [14], [15], [17], [23], [29], [30], [32], [35], [37] as a very powerful tool for extracting some of the extreme eigenvalues of a real symmetric matrix H, i.e., to find the largest and/or smallest eigenvalues and vectors of the symmetric eigenvalue problem

$$Hx = \lambda x.$$

It is often believed that the algorithm can be used directly to find the eigenvalues at both ends of the spectrum (both largest and smallest in value). In fact, many applications result in eigenvalue distributions that only allow effectively extracting the eigenvalues at one end of the spectrum. Typical eigenvalue distributions in structural engineering vibration problems have small eigenvalues of order unity with separations $|\lambda_{i+1} - \lambda_i|$ also of order unity, apparently well separated. However, for physical reasons the largest eigenvalues of these problems are very large, say, $\mathcal{O}(10^{10})$. The convergence rates for the eigenvalues is determined by the relative separation $\frac{|\lambda_{i+1}-\lambda_i|}{|\lambda_n-\lambda_1|}$, $\mathcal{O}(10^{-10})$ for the smallest eigenvalues. We expect and find very slow convergence to the small eigenvalues, which are the eigenvalues of interest. The dependence of convergence on *relative* separation between eigenvalues is often ignored.

It is also often believed that the Lanczos algorithm can be applied to the generalized symmetric problem

$$Hx = \lambda Mx$$

by using the naive reduction to standard form [16], [32]: factor M into its Cholesky decomposition $M = LL^T$ and then solve the ordinary eigenproblem $L^{-1}HL^{-T}y =$

λy. Suppose that we applied this algorithm to the *vibration* problem of structural engineering,

$$Kx = \lambda Mx, \tag{1}$$

where K is the stiffness matrix and M is the mass matrix. We would fail abysmally for three separate reasons:

- M is very often semidefinite—it may admit no Cholesky factorization.
- Even when M can be factored, the eigenvalues that are desired are often very badly separated.
- The eigenvectors x must be computed by a back transformation $x = L^{-T}y$. When it exists, L is usually poorly conditioned, which can lead to considerable numerical error in the back transformation.

When K is positive definite, the vibration problem can be addressed by applying the usual reduction to the reciprocal problem:

$$Kx = \lambda Mx \Leftrightarrow Mx = \frac{1}{\lambda}Kx \Leftrightarrow L^{-1}ML^{-T}y = \mu y, \tag{2}$$

where L is the Cholesky factor of K and $\mu = \frac{1}{\lambda}$. Often this is sufficient as a cure for the first two problems in (1), because the reciprocals of the eigenvalues are well separated. Eigenanalysis codes in structural engineering packages [24], [27] have been built upon this transformation. But this transformation is still inadequate when:

- the model has rigid body modes—K is positive semidefinite and has no Cholesky decomposition.
- a considerable number of eigenvalues are desired.
- the eigenvalues wanted are not the smallest eigenvalues.

Applications with these characteristics do arise. The stiffness matrix in aerospace applications often has a six-dimensional nullspace of rigid body modes. Detailed analyses of structures may require more than just a few eigenvalues and vectors. One of our test problems is an analysis of a nuclear reactor containment floor, where more than 200 eigenpairs were needed to adequately model the response of the structure to a simulated earthquake. Another problem we analyzed was a model of a large industrial ventilating fan mounted on a large concrete platform, for which we needed good approximations to the eigenvalues near the fan's rotational rate, eigenvalues that are in the interior of the spectrum.

There is a more elaborate transformation of the problem, the *spectral transformation* of Ericsson and Ruhe [14], which treats all of these difficulties. The spectral transformation is discussed in detail in §2, where we discuss an extension of the standard algorithm to buckling as well as to vibration problems. The general idea behind the spectral transformation comes from considering the shifted problem $(K-\sigma M)x = (\lambda-\sigma)Mx$. If we invert $(K-\sigma M)$, we transform the eigenvalues nearest the *shift* σ into the largest and well-separated eigenvalues of the reciprocal problem. Normally we need only to choose a shift σ near the eigenvalues we want. When the number of eigenvalues is large, the reduced convergence rate of the eigenvalues farthest from σ makes it worthwhile to choose additional shifts (and factorizations) in order to search through the spectrum.

Formally we cannot shift at an eigenvalue of the problem, because the shifted operator is singular. In fact, avoiding even near-singularity is an issue for the choice of shifts, particularly the very first shift, because shifts very close to eigenvalues are useful only for computing isolated clusters of eigenvalues.

In general, a well-chosen shift allows us to compute tens of eigenvalues with a single Lanczos run. There is a complicated tradeoff between the cost of a Lanczos run, which increases nonlinearly with increasing numbers of steps, and the cost of computing a new shift and its concomitant factorization. As an example, we consider the oceanography model (matrix PLAT1919 in the Harwell/Boeing sparse matrix collection [11]), with four different paradigms for choosing shifts:

- the heuristic described in this paper;
- a conservative modification of this heuristic;
- an aggressive modification of this heuristic;
- a fixed shift—compute all 200 eigenvalues with a single factorization.

All of these analyses begin with a Lanczos run using the factors of $A - .0001I$ to find the eigenvalues of $(A - .0001I)^{-1}$. Table 1 contains the salient results for these choices, demonstrating the complexity of the tradeoffs and, dramatically, the value of shifting.

TABLE 1
Computing the 200 *lowest eigenvalues in* [.0001, .24] *of* PLAT1919.

Choice of shift	Number of Lanczos runs	Total number of Lanczos steps	Execution cost
normal	8	192	208.1
conservative	13	243	257.4
aggressive	8	209	225.5
fixed shift	1	318	5382.2

(These results were obtained on a Sun 4/690 workstation. The code used a blocksize of three. Execution cost is the sum of central processor (cpu) and input/output (i/o) processor seconds.)

Shifting can provide reliability as well as efficiency. Each factorization provides eigenvalue location information in the form of *matrix inertias* (see §3.1). The collected inertias from a series of well-chosen shifts can provide an independent guarantee on the success of the eigenvalue computation and can be used to drive the choice of further shifts and Lanczos runs to ensure that all of the desired eigenvalues have been computed. Our heuristic strategy for choosing shifts is discussed in §3.

Our goal is a code that can serve as a "black-box" eigenextraction routine in large applications codes. Eigenvalues cannot be assumed to be simple, so our shifting strategy is prepared to continue looking at a small piece of the spectrum until it has determined the full multiplicity of the eigenvalues therein. The shifting scheme and the Lanczos algorithm interact to ensure that we find an orthogonal basis for the invariant subspace for each cluster (see §4.3.3). Most importantly, we use a *block* version of the Lanczos algorithm. The Lanczos algorithm usually will compute the full multiplicities of each cluster without any intervention from the shifting strategy, provided that we have been able to choose a blocksize as large as the largest multiplicity of any cluster we will encounter.

The block Lanczos algorithm also confronts the problem that applications codes often use general representations for their data, even when particular machine architectures would allow or favor alternatives. It is still common for general applications codes to represent their matrices as "out-of-core." The block Lanczos code substitutes, almost on a one-for-one basis, matrix-block multiplies and block solves for matrix-vector products and simple solves. This decreases the i/o cost essentially by the blocksize.

Our production eigenextraction code is a synthesis of the ideas of the spectral transformation and the block Lanczos algorithm. In §2 we begin to address the effects of the generalized problem on the recurrence. We explain what modifications to the Lanczos recurrence result from the use of shifted and inverted operators. With the exception of the development of a spectral transformation for buckling problems, our presentation is quite standard and is provided for the reader not already familiar with these results.

We present our heuristic shifting strategy in §3. There are eight subsections: a discussion of *trust intervals* and matrix inertias, our basic tools for robustness; our heuristic for choosing a shift in a generic case; the idea of *sentinels*, a tool for ensuring orthogonality of invariant subspaces; heuristics for choosing an initial shift; heuristics for determining how to expand the primary trust interval; analysis of a specified finite interval; treatment of various special and pathological cases; and, last, the modifications needed for the buckling problem.

The special characteristics of our block Lanczos algorithm are discussed in §4. This considers the effects due to the spectral transformation. One major problem is that vectors must be orthonormalized with respect to an inner product defined by a positive definite matrix M. We discuss the issues associated with implementing M-orthonormalization of vectors in the basic block Lanczos algorithm, including the further precautions needed to allow cases where M induces only a seminorm, in §4.1.

The block Lanczos recurrence by itself produces only a block tridiagonal matrix T. In §4.2 we describe how to compute eigenvalue and vector approximations, and error bounds on these approximations, from T and the Lanczos vectors. Section 4.3 contains our approach for dealing with the loss of orthogonality in the Lanczos vectors, with a novel combination of various reorthogonalization schemes that work effectively with the unusual distributions of eigenvalues that result from the spectral transformation. Section 4.4 concludes with discussions of when to end and how to start the recurrence. The integration of all of these techniques is a block Lanczos recurrence that will effectively find a limited number of eigenvalues and corresponding eigenvectors of a spectrally transformed operator.

We close with numerical experiments solving a small set of eigenproblems obtained from applications codes.

2. The spectral transformation block Lanczos algorithm. The eigenvalue problem in vibration analysis is given as

$$Kx = \lambda Mx, \tag{3}$$

where K and M are symmetric matrices, and M is positive semidefinite. Usually only the smallest eigenvalues of (3) are wanted, but they typically have very poor relative separation, rarely better than $\mathcal{O}(10^{-6})$. A priori estimates for the rate of convergence predict very slow convergence at the desired end of the spectrum. We can obtain rapid convergence to the desired eigenvalues by using the *spectral transformation* [14], [27] of (3).

2.1. The spectral transformation for vibration problems. Consider the problem

$$M(K - \sigma M)^{-1}Mx = \mu Mx, \tag{4}$$

where σ, the shift, is a real parameter. Assume for the moment that M is positive definite. It is easy to verify that (λ, x) is an eigenpair of (3) if and only if $(\frac{1}{\lambda-\sigma}, x)$ is

an eigenpair of (4). Hence, the transformation of the eigenvalue problem from (3) to (4) does not change the eigenvectors, and the eigenvalues are related by

$$\mu = \frac{1}{\lambda - \sigma}. \tag{5}$$

The form of the spectral transformation is dictated by our need to be able to apply the Lanczos algorithm even when M is semidefinite. Other advantages of this form are well documented in [38].

The main advantage of applying the Lanczos algorithm to (4) instead of to (3) becomes clear when the effect of the spectral transformation on the spectrum is considered. The results in Table 2 demonstrate this in detail. These are the values obtained using the initial shift described in §3.4; the generalized eigenproblem is the model of a nuclear reactor containment floor, given by the stiffness and mass matrices BCSSTK26 and BCSSTM26, respectively, from the Harwell–Boeing sparse matrix collection [11]. (We denote the generalized eigenproblem by BCSST_26.)

Relative separation is affected dramatically by the spectral transformation. The smallest eigenvalues are transformed into eigenvalues with good relative separation, even though their absolute separation is decreased. In addition, eigenvalues far from the shift are transformed to poorly separated values near zero. This spread of the eigenvalues ensures rapid convergence to the eigenvalues near σ. This example clearly demonstrates that the shift does not have to be very close in an absolute sense to work well.

TABLE 2
Vibration spectral transformation of BCSST_26, $\sigma_1 = 385.3$.

			Original		Transformed	
i	λ_i	μ_i	gap	relative gap	gap	relative gap
1	4.6×10^{3}	2.4×10^{-4}	6.4×10^{3}	1.2×10^{-11}	1.4×10^{-4}	6.0×10^{-1}
2	1.1×10^{4}	9.4×10^{-5}	2.5×10^{2}	4.6×10^{-13}	2.2×10^{-6}	9.2×10^{-3}
3	1.1×10^{4}	9.2×10^{-5}	2.5×10^{2}	4.6×10^{-13}	2.2×10^{-6}	9.2×10^{-3}
⋮	⋮	⋮	⋮	⋮	⋮	⋮
1920	3.0×10^{14}	3.3×10^{-15}	3.6×10^{11}	6.7×10^{-4}	3.9×10^{-18}	1.7×10^{-14}
1921	3.1×10^{14}	3.3×10^{-15}	3.6×10^{11}	6.7×10^{-4}	3.9×10^{-18}	1.7×10^{-14}
1922	5.4×10^{14}	1.8×10^{-15}	2.4×10^{14}	4.4×10^{-1}	1.4×10^{-15}	6.0×10^{-12}

The primary price for this rapid convergence is the cost of a factorization of $K - \sigma M$. The transformation $M(K - \sigma M)^{-1}M$ is realized implicitly as a sequence of operations in which we compute MQ for a block of vectors Q or solve the linear systems $(K - \sigma M)X = Q$. These operations are usually realized by independent subroutines, which allow tuning the matrix factorization and multiplication routines to the class of problem under consideration.

We must generalize the Lanczos algorithm itself to solve the transformed generalized symmetric eigenproblem. We make this generalization in three steps. We will first consider the ordinary block Lanczos algorithm for a symmetric matrix H. Next we consider a direct generalization of the Lanczos algorithm for an arbitrary generalized symmetric eigenproblem $Hx = \lambda Mx$, where we assume temporarily that M is positive definite. In these first two steps the issue of shifting disappears for the moment. In a third step we consider the much more effective form that results when H is a spectral transformation operator.

2.2. Basic block Lanczos algorithm. Consider first the ordinary eigenvalue problem

$$Hx = \lambda x,$$

where H is a real symmetric linear operator. An important characteristic of the Lanczos algorithm is that H is not required explicitly. All that is required is a subroutine that computes Hy for a given vector y. The block Lanczos iteration with *blocksize* p for an $n \times n$ matrix H is given in Fig. 1.

where B_{j+1} is upper triangular and Q_{j+1} is orthogonal
End loop

FIG. 1. *Basic block Lanczos algorithm.*

The matrices Q_j, U_j, R_j for $j = 1, 2, \ldots$ are $n \times p$, whereas A_j and B_j are $p \times p$, with A_j symmetric.

This formulation of the Lanczos loop is the one least susceptible to roundoff errors [31] and is the form that should be used in computation. In exact arithmetic, however, U_j and R_{j+1} can be eliminated from the Lanczos loop and the recurrence becomes

$$Q_{j+1}B_{j+1} = HQ_j - Q_j A_j - Q_{j-1}B_j^T. \tag{6}$$

This three-term recurrence simplifies theoretical discussion. It is shown in [6], [17] that the combined column vectors of the matrices $Q_1, Q_2, \ldots, Q_j$, the so-called *Lanczos vectors*, form an orthonormal set. The computational efficiency of the Lanczos algorithm rests on the fact that these vectors can be computed simply, with a fixed amount of work per iteration step.

The blocks of Lanczos vectors collectively form an $n \times jp$ matrix $\mathcal{Q}_j$, where

$$\mathcal{Q}_j = [Q_1, Q_2, Q_3, \ldots, Q_j].$$

The algorithm also defines a $jp \times jp$ block tridiagonal matrix T_j:

$$T_j = \begin{pmatrix} A_1 & B_2^T & 0 & \ldots & 0 \\ B_2 & A_2 & B_3^T & \ldots & 0 \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & \ldots & B_{j-1} & A_{j-1} & B_j^T \\ 0 & \ldots & 0 & B_j & A_j \end{pmatrix}.$$

Since the matrices B_j are upper triangular, T_j is a band matrix with half-bandwidth $p+1$ (rather than $2p$, if the B_j were full). The first j instances of formula (6) can be combined into a single formula:

$$HQ_j = Q_j T_j + Q_{j+1} B_{j+1} E_j^T. \tag{7}$$

Here E_j is an $n \times p$ matrix whose last $p \times p$ block is the $p \times p$ identity matrix and which is zero otherwise.

By premultiplying (7) by Q_j^T and using the orthogonality of the Lanczos vectors, we see that $Q_j^T H Q_j = T_j$. Hence T_j is the orthogonal projection of H onto the subspace span(Q_j) spanned by the columns of Q_j. It can be shown by induction that span(Q_j) = span$(Q_1, HQ_1, H^2Q_1, \ldots, H^{j-1}Q_1)$. From a different perspective, the (block) Lanczos algorithm is a method for constructing an orthonormal basis for the (block) Krylov subspace determined by H and Q_1. The orthogonal projection of H onto the (block) Krylov subspace is T_j. Hence the eigenvalues of T_j are the Rayleigh–Ritz approximations from span(Q_j) to the eigenvalues of H. In addition, if s is an eigenvector of T_j, the vector $y = Q_j s$ is an approximate eigenvector of H. Viewed in this form, the Lanczos algorithm replaces a large and difficult eigenvalue problem involving H by a small and easy eigenvalue problem involving the block tridiagonal matrix T_j.

How good are the approximations obtained by solving the block tridiagonal eigenvalue problem involving the matrix T_j? An a posteriori bound on the residual is given by Underwood [17]: Let θ, s be an eigenpair for T_j, i.e., $T_j s = s\theta$, and let $y = Q_j s$, then

$$\|Hy - y\theta\|_2 = \|B_{j+1} s_j\|_2, \tag{8}$$

where s_j are the last p components of the eigenvector s. The quantity $\|B_{j+1} s_j\|_2$ can be computed without computing the approximate eigenvector y. Hence, with some modifications described in §4.2, (8) provides an inexpensive a posteriori error bound.

Formula (8), however, does not guarantee that good approximations to eigenpairs will appear quickly. Such a priori estimates are provided by the Kaniel–Paige–Saad theory. Parlett [32] gives the most detailed discussion for the single vector case ($p = 1$). The generalizations to the block case were originally derived by Underwood [17]. Extensions to both of these presentations can be found in [36].

2.3. The spectral transformation block Lanczos algorithm. The next step is to consider the generalized symmetric eigenproblem $Hx = \lambda Mx$. Were we to reduce the problem to standard form by factoring M, the three-term recurrence (6) would become

$$Q_{j+1} B_{j+1} = M^{-1/2} H M^{-1/2} Q_j - Q_j A_j - Q_{j-1} B_j^T. \tag{9}$$

If we premultiply (9) by $M^{1/2}$ and make the transformation of variables $\hat{Q}_j = M^{-1/2} Q_j$, (9) becomes

$$\begin{aligned} M\hat{Q}_{j+1} B_{j+1} &= M^{1/2} M^{-1/2} H \hat{Q}_j - M\hat{Q}_j A_j - M\hat{Q}_{j-1} B_j^T \\ &= H\hat{Q}_j - M\hat{Q}_j A_j - M\hat{Q}_{j-1} B_j^T. \end{aligned} \tag{10}$$

The matrices $\hat{Q}_j$ are now M-orthogonal, since $Q_j^T Q_j = I$ implies $\hat{Q}_j^T M \hat{Q}_j = I$. This is also a property of the eigenvectors X of this generalized eigenproblem. The approximate eigenvectors will eventually be computed in the subspace span$(\hat{Q})$, regardless

For $j = 1, 2, 3 \ldots$ do
  Set $U_j \quad = H\hat{Q}_j - M\hat{Q}_{j-1}B_j^T$
  Set $A_j \quad = \hat{Q}_j^T M U_j$
  Set $W_{j+1} \quad = U_j - M\hat{Q}_j A_j$
  Solve $MR_{j+1} = W_{j+1}$
  Compute the M-orthogonal factorization $\hat{Q}_{j+1}B_{j+1} = R_{j+1}$
End loop

FIG. 2. *Inner loop of generalized symmetric block Lanczos algorithm.*

of the form used for the Lanczos recurrence. The inner loop of Lanczos recurrence in this subspace is given in Fig. 2.

The matrix M appears in several instances to assure the M-orthogonality of the Lanczos vectors. In particular, the last step requires computing the M-orthogonal factorization of R_{j+1}. Standard derivations of the orthogonality of the Lanczos vectors easily generalize to show that these vectors are M-orthonormal. It appears that $M^{-1/2}$ has disappeared from the standard recurrence, only to reappear at the penultimate step in disguise as a solution operation. Indeed, (10) applied to the original problem $Kx = \lambda Mx$ is merely an implicit form of the explicit reduction to standard form. This is not the case when H is taken as the operator in the spectral transformation. Substituting $M(K - \sigma M)^{-1}M$ for H gives:

$$M\hat{Q}_{j+1}B_{j+1} = M(K - \sigma M)^{-1}M\hat{Q}_j - M\hat{Q}_j A_j - M\hat{Q}_{j-1}B_j^T. \tag{11}$$

M now appears in *all* of the terms in the recurrence. Formally we can premultiply (11) by M^{-1} to obtain a recurrence

$$\hat{Q}_{j+1}B_{j+1} = (K - \sigma M)^{-1}M\hat{Q}_j - \hat{Q}_j A_j - \hat{Q}_{j-1}B_j^T \tag{12}$$

in which M^{-1} does not appear. This allows us to apply the same recurrence even when M is semidefinite. The justification for doing so appears later in §2.4.

At this point we shall no longer put "hats" on the matrices. The actual Lanczos recurrence for solving (4) is given in Fig. 3.

Assuming the matrix MQ_{j+1} is actually stored (at least temporarily), the algorithm as written requires only one multiplication by M per step and no factorization of M is required. The last step of the Lanczos loop, the *M-orthogonalization* of a set of p vectors, is discussed in §4.1.

Our next goal is to generalize the standard eigenvalue approximation results to the spectral transformation block Lanczos algorithm. As before, combining all j instances of (12) into one equation yields

$$(K - \sigma M)^{-1}MQ_j = Q_j T_j + Q_{j+1}B_{j+1}E_j^T, \tag{13}$$

where Q_j, T_j, and E_j are defined as in (7). Premultiplying (13) by $Q_j^T M$ and using the M-orthogonality of the Lanczos vectors, it follows that

$$Q_j^T M(K - \sigma M)^{-1}MQ_j = T_j.$$

Hence, T_j is the M-orthogonal projection of $(K - \sigma M)^{-1}$ onto the block Krylov subspace spanned by the columns of Q_j. The eigenvalues of T_j will approximate the

Initialization:

Set $Q_0 = 0$
Set $B_1 = 0$
Choose R_1 and orthonormalize the columns of R_1 to obtain Q_1 with $Q_1^T(MQ_1) = I_p$

Lanczos Loop:

For $j = 1, 2, 3 \ldots$ do
Set $U_j = (K - \sigma M)^{-1}(MQ_j) - Q_{j-1}B_j^T$
Set $A_j = U_j^T(MQ_j)$
Set $R_{j+1} = U_j - Q_jA_j$
Compute Q_{j+1} and (MQ_{j+1}) such that
a) $Q_{j+1}B_{j+1} = R_{j+1}$
b) $Q_{j+1}^T(MQ_{j+1}) = I_p$
End loop

FIG. 3. *Block Lanczos algorithm for the vibration problem.*

eigenvalues of (4). If (s, θ) is an eigenpair of T_j, i.e., $T_j s = s\theta$, then $(y = Q_j s, \nu = \sigma + \frac{1}{\theta})$ will be an approximate eigenpair of (3).

The generalization of the a posteriori residual bound (8) is

$$(K - \sigma M)^{-1}My - y\theta = Q_{j+1}B_{j+1}E_j^T s. \tag{14}$$

For $\theta \neq 0$ it follows that

$$(K - \nu M)y = -\frac{1}{\theta}(K - \sigma M)Q_{j+1}B_{j+1}E_j^T s.$$

The quantity on the right is computable without explicitly computing the eigenvector y, but only at the cost of a multiplication by $K - \sigma M$, which is not desirable. In §4.2 we present a better way to obtain a residual bound. (Note that $\theta = 0$ corresponds to an infinite eigenvalue of (3), which should not appear in T, as discussed below. Very small θ's correspond to eigenvalues far from the shift. These converge slowly—the division by θ in the residual bounds reflects their relative inaccuracy.)

2.4. Semidefiniteness in the matrix M. Throughout the discussion above, we assumed that M was a positive definite matrix. The formulation of the block Lanczos algorithm for the vibration problem does not require the factorization of M. Hence the spectral transformation Lanczos algorithm can be applied formally when M is semidefinite without further modifications. However, the eigenproblem (3) has infinite eigenvalues. Fortunately, we need only to make the obvious block modification of the analysis in [29] to remove the infinite eigenpairs from the recurrence. Following Nour-Omid et al., the starting block for the Lanczos algorithm should be computed as in Fig. 4.

The eigenvectors of $Kx = \lambda Mx$ corresponding to finite eigenvalues consist of a component orthogonal to the null vectors of M and a component in the nullspace of M. Ericsson [13] shows that the second, nullspace component is determined by an algebraic constraint from the non-nullspace component. The constraint expresses the

Choose	$\tilde{R}_1$
Compute	$R_1 = (K - \sigma M)^{-1} M \tilde{R}_1$
M-orthogonalize	$R_1 = Q_1 B_0$

FIG. 4. *Computation of the starting block.*

fact that all of these eigenvectors lie in the range of $(K - \sigma M)^{-1}M$. It is shown in [13], [29] that all of the Lanczos vectors lie in this subspace when the starting vectors are chosen in this subspace, as above. With this choice of starting block, infinite eigenvalues have no influence on the block Lanczos algorithm in exact arithmetic. In §4.2 we add a final postprocessing step to purge the approximate eigenvectors of components not satisfying the constraint in finite precision arithmetic.

2.5. A spectral transformation for buckling problems. The final point of this section is the spectral transformation for the buckling problem

$$Kx = \lambda K_\delta x, \tag{15}$$

where K is the symmetric positive semidefinite stiffness matrix and K_δ is the symmetric differential or geometric stiffness matrix. Typically only a few eigenvalues closest to zero are wanted. A simple approach would be to interchange the roles of K and K_δ and to compute the largest eigenvalues of the problem

$$K_\delta x = \mu K x, \tag{16}$$

with $\mu = \frac{1}{\lambda}$ by applying the simple Lanczos algorithm without shifts [21]. This reciprocal approach has the same drawbacks as (2). However, it is often effective when K is positive definite because the number of eigenvalues sought is rarely large.

Shifting and particularly the semidefinite K case require an alternative form of the spectral transformation [19]. The shifted and inverted problem

$$K(K - \sigma K_\delta)^{-1} K x = \mu K x \tag{17}$$

is solved instead of the original problem (15). The Lanczos recurrence is carried out using K-orthogonality among the Lanczos vectors. Each multiplication by the mass matrix M in the vibration case is replaced with a multiplication by the stiffness matrix K in the buckling case; the rest of the recurrence remains the same.

In the buckling spectral transformation (λ, x) is an eigenpair of (15) if and only if $(\frac{\lambda}{\lambda - \sigma}, x)$ is an eigenpair of (17). Hence the *buckling spectral transformation* does not change the eigenvectors, and the eigenvalues are related by $\mu = \frac{\lambda}{\lambda - \sigma}$. These results can be obtained directly, or by applying the vibration spectral transformation with reciprocated shifts to the reciprocal problem (16).

The advantages of the buckling spectral transformation are essentially the same as those of the vibration spectral transformation. Large eigenvalues of the buckling problem are transformed to a cluster of eigenvalues near unity. Eigenvalues near the shift σ are transformed into well-separated eigenvalues, which are easily computed by the Lanczos algorithm. The major difference is that a shift at $\sigma = 0$ is not allowed, since all eigenvalues would be transformed to one. This singularity in the transformation also affects shifts close to zero; very small shifts should not be taken in this form of the transformation. Table 3 gives details for the eigenproblem BCSST_28, treated as if it were a buckling problem. The initial shift is negative because we ordinarily

expect the first negative eigenvalue to be the eigenvalue of most interest in buckling problems (see §3.8). Just as in the case of the vibration spectral transformation, we see that the shift does not need to be close to the desired eigenvalues in any absolute sense. Indeed, in this case the shift is on the wrong side of the origin and yet still has the desired effect on relative separation.

TABLE 3
Buckling spectral transformation of BCSST_26, $\sigma_1 = -385.3$.

			Original		Transformed	
i	λ_i	μ_i	gap	relative gap	gap	relative gap
1	4.6×10^{3}	9.23×10^{-1}	6.4×10^{3}	1.2×10^{-11}	4.3×10^{-2}	5.6×10^{-1}
2	1.1×10^{4}	9.66×10^{-1}	2.5×10^{2}	4.6×10^{-13}	7.3×10^{-4}	9.5×10^{-3}
3	1.1×10^{4}	9.67×10^{-1}	2.5×10^{2}	4.6×10^{-13}	7.3×10^{-4}	9.5×10^{-3}
⋮	⋮	⋮	⋮	⋮	⋮	⋮
1920	3.0×10^{14}	1.00×10^{0}	3.6×10^{11}	6.7×10^{-4}	1.6×10^{-15}	2.0×10^{-14}
1921	3.1×10^{14}	1.00×10^{0}	3.6×10^{11}	6.7×10^{-4}	1.6×10^{-15}	2.0×10^{-14}
1922	5.4×10^{14}	1.00×10^{0}	2.4×10^{14}	4.4×10^{-1}	5.5×10^{-13}	7.1×10^{-12}

Except for the different role of the stiffness matrix K, all implementation details are the same for vibration and buckling analysis. Issues involving the M-orthogonality of the Lanczos vectors apply equally to the K-orthogonal Lanczos vectors in the buckling case. Since the stiffness matrix K is used in the initialization phase in the same way as M in the vibration case, the sequence of Lanczos vectors will be orthogonal to the space spanned by the eigenvectors corresponding to zero eigenvalues of K. Hence T_j will contain no approximations to the exactly zero eigenvalues of K, which are also zero eigenvalues of (15), which is desirable.

The eigenvalues of T_j approximate the eigenvalues of (17). Hence, if (s, θ) is an eigenpair of T_j, that is, $T_j s = s\theta$, then $(\frac{\sigma\theta}{\theta - 1}, Q_j s)$ is an approximate eigenpair of (15). The approximate eigenvectors form a K-orthonormal set. Bounds on the residuals of approximate eigenpairs are derived in §4.2.

3. A strategy for choosing shifts. Let us try to find some of the eigenvalues and eigenvectors of $KX = MX\Lambda$ or $KX = K_\delta X\Lambda$. We emphasize the fact that we want some, not all, of the eigenvalues, because the eigenvector matrix X is almost always dense. The problem can be written in its general form as:

- find the p eigenvalues of smallest magnitude in $[a, b]$ and their eigenvectors; or
- find the p eigenvalues of largest magnitude in $[a, b]$ and their eigenvectors; or
- find the p eigenvalues in $[a, b]$ closest to ξ and their eigenvectors; or
- find all eigenvalues and eigenvectors in $[a, b]$.

Here $[a, b]$ is the *computational interval*, which can be finite (both a and b finite), semi-infinite (only one of a and b finite), or infinite (no restrictions at all). Note that the problem of finding the algebraically least eigenvalues in an interval can be transformed into one of finding the eigenvalues of smallest magnitude by a suitable shift of origin.

The purpose of the spectral transformation is to transform the original problem into one whose dominant eigenvalues represent some of the desired eigenvalues. The dominant eigenvalues of the transformed problem correspond to the eigenvalues of the original problem nearest σ. There are two major goals that drive our strategy for choosing shifts. One is efficiency—we would like to choose a sequence of shifts $\sigma_1, \sigma_2, \ldots, \sigma_s$ so that the total cost, including the cost of the s factorizations and

the costs of the individual Lanczos runs, is minimized. Our heuristic approach to measuring and reducing cost is described in §§3.2 and 4.4. The second goal of our shift selection is robustness. A paramount objective for our design was a code that would be able to compute all of the desired eigenpairs accurately, except under extreme, pathological conditions. Furthermore, we wanted a code that could diagnose and report any failures. The tools we use to create robustness, trust intervals, and matrix inertias, are an appropriate place to begin the detailed discussion of our choices of shifts.

3.1. Trust intervals, matrix factorizations, and inertias. Suppose that during the course of eigenanalysis, we have computed a set of eigenvalues lying between two shifts σ_1 and σ_2. We would like to confirm that these are, in fact, all the eigenvalues in this interval.

Suppose that C is a real symmetric matrix, which has been decomposed as $C = LDL^T$, where D is diagonal. The *inertia* of C is the triple (π, ν, ζ) of integers, where π is the number of positive eigenvalues, ν the number of negative eigenvalues, and ζ the number of zero eigenvalues. Sylvester's Inertia Theorem [32, p. 10] states that the inertia of F^TCF is the same as that of C. Sylvester's theorem with $F = L^{-T}$ implies that the number of negative entries in D is the number of negative eigenvalues from C. The number of negative terms in D from the LDL^T decomposition of $C - \sigma I$ gives the number of eigenvalues smaller than σ. Frequently $\nu(C - \sigma I)$ is called the Sturm sequence number in engineering references.

It is easy to see that $\nu(C - \sigma_2 I) - \nu(C - \sigma_1 I)$ is the number of eigenvalues in the interval $[\sigma_1, \sigma_2]$ (assuming $\sigma_1 < \sigma_2$ and the two factorizations are nonsingular). When the number of eigenvalues expected in the interval agree with the number actually computed, we say that the interval $[\sigma_1, \sigma_2]$ is a *trust interval.* We want our shifting strategy to establish a trust interval around all of the desired eigenvalues.

However, applying these Sturm sequence results to generalized eigenproblems requires a transformation from the ordinary eigenvalue problem $CX = X\Lambda$ to the generalized problem $KX = MX\Lambda$. In order to guarantee that the generalized eigenvalue problems have real solutions, we assume that the pencils are definite; a positive definite linear combination of K and M must exist. In our code we assume that M or K is positive semidefinite. We compute $K - \sigma M = LDL^T$ (or $K - \sigma K_\delta = LDL^T$), and we want to draw conclusions from $\nu(LDL^T)$. The interpretation of $\nu(LDL^T)$ is given in Table 4; proofs are found in Appendix A. The major surprise in this table of the appearance of the null space dimension $\dim(\mathcal{N}(\cdot))$ when the matrix used as a norm is only a seminorm. This term corresponds to an assignment of signs to the infinite eigenvalues in the vibration case and the zero eigenvalues in the buckling case. We note that in most common vibration cases the term $\dim(\mathcal{N}(M))$ does not appear, because K is positive semidefinite. When it does appear, it is because the infinite eigenvalues have negative signs, which adds a serious complication to the problem of finding the algebraically smallest eigenvalues (the infinite eigenvalues are the algebraically smallest, but cannot be computed by the recurrence as written). However, the problem of finding the eigenvalues of smallest magnitude is only slightly more difficult in this case.

Semidefiniteness in buckling analysis is more significant, because the usual problem is to find the eigenvalues of smallest magnitude and the zero eigenvalues cannot be computed directly. The problem still can be solved if $\dim(\mathcal{N}(K))$ is known, either adventitiously or by a partial eigenanalysis of K. The problem of finding the eigenvalues of smallest magnitude in an interval bounded away from zero is still

TABLE 4
Interpretation of $\nu(K - \sigma M)$ *or* $\nu(K - \sigma K_\delta)$.

Vibration analysis:	
M positive definite	# of eigenvalues $< \sigma$
M positive semidefinite	(# of eigenvalues $< \sigma$) $+ \gamma$
	$\gamma = \begin{cases} 0 & \text{some cases} \\ \dim(\mathcal{N}(M)) & \text{other cases} \end{cases}$
Buckling analysis:	
K positive definite	# of eigenvalues in $(0, \sigma)$ or $(\sigma, 0)$
K positive semidefinite	(# of eigenvalues in $(0, \sigma)$ or $(\sigma, 0)$) $+ \gamma$
	$\gamma = \begin{cases} 0 & \sigma \text{ of one sign} \\ \dim(\mathcal{N}(K)) & \sigma \text{ of other sign} \end{cases}$

well posed.

The result of a successful eigenextraction is a trust interval containing all of the desired eigenvalues. This goal drives our selection of shifts. We create, as soon as possible, a trust interval containing some of the desired modes; thereafter, we extend the trust interval to contain more, and eventually all, of the desired modes. The process begins with an initial shift at some point σ_1. The factorization is followed by a Lanczos run with the shifted operator $(K - \sigma_1 M)^{-1} M$ (or its counterpart in buckling analysis). We will always compute a second factorization, if only to provide the inertia to close a trust interval. If only some of the desired eigenvalues were computed during the first Lanczos run, we would like to make the factorization at σ_2 serve both as a basis for an inertia computation and as the factorization for a new Lanczos run. Ideally we would choose σ_2 close enough to σ_1 that the second Lanczos run finds all the remaining eigenvalues in the interval; at the same time, we would like σ_2 to be far enough away from σ_1 so that the second Lanczos run stops, for efficiency reasons, exactly when it has computed all the missing eigenvalues. Thus, a simple description of our shift selection is that we choose each new shift to *maximally* extend an existing trust interval.

3.2. Shifting to extend a trust interval. In selecting each new shift, we try to use as much information as we have, including any computed eigenvalues, other knowledge about the existing trust interval, and additional information from the previous Lanczos runs. In general, each Lanczos run creates a set of approximations to eigenvalues, which provide a general picture of the spectrum. Figure 5 gives an illustration of the general situation, in which the last Lanczos run was at a shift σ_i that forms the right endpoint of a trust interval. The tall, thin lines denote approximations that we accept as eigenvalues. The lines of medium height and width are approximations that are not yet acceptable as eigenvalues, though they do have accuracy estimates good enough to know that at least one significant digit is correct. We call these *Ritz values*. (All of the Lanczos approximations are Ritz values, but we abuse the mathematical term to describe only those approximations that are not good enough to be accepted, and not bad enough to be meaningless.) The short, broad lines denote approximations whose accuracy estimates are larger than their values, which we ignore.

The shift selection assumes that the inverted spectrum as viewed from σ_{i+1} will be similar to the inverted spectrum as viewed from σ_i. One view of this similarity of inverted spectra is that if the Lanczos run from σ_i computed k eigenvalues to the right of σ_i efficiently, we expect that an efficient run at any σ_{i+1} should compute

k eigenvalues to its left. We use the first k Ritz values to estimate the missing eigenvalues and place the new shift σ_{i+1} between the kth and $(k+1)$st Ritz values. The choice of the bisector is intended to avoid a choice extremely close to an eigenvalue. Furthermore, we use a relaxed tolerance to detect "clusters" of eigenvalues and bisect clusters rather than Ritz values.

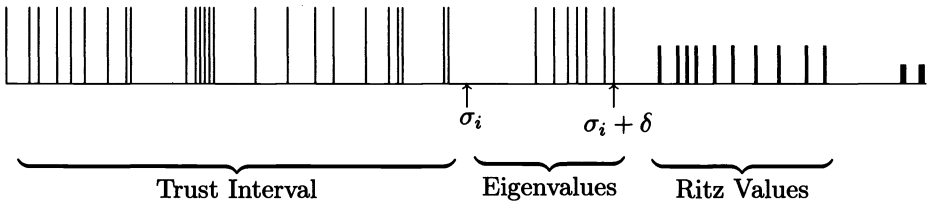

FIG. 5. *Trust intervals.*

If there are fewer than k Ritz values available to the right of σ_i, we use a second view of the inverted spectra based on the assumption that the "radius of convergence" should be about the same for each shift. We define δ to be the maximum of its previous value and the distance between the right endpoint of the trust interval and the rightmost computed eigenvalue (see Fig. 5). Initially, δ is set to the problem scale (see §3.4). Then a second choice for the next shift is $\sigma_{i+1} = \sigma_i + 2 * \delta$. We take the more aggressive choice, the maximum of the two possibilities, in the case where we still need to compute more eigenvalues than we have knowledge of Ritz values. If more Ritz values are available than there are eigenvalues left to compute, we choose the next shift based solely on the Ritz values, ignoring the shift based on δ.

Table 1 shows some results for normal, conservative, aggressive, and fixed shifting. For this table, we used a $1 * k$, $1 * \delta$ rule for conservative shifting and a $3 * k$, $3 * \delta$ rule for aggressive shifting.

We have described the general rule for choosing σ_{i+1} when σ_{i+1} is taken to the right of σ_i. Of course, we obtain two similar views of the spectra to the left of σ_i, which give another alternative for the next shift.. In general we do not know in which direction the next shift should be taken. Indeed, when finding eigenvalues nearest to an interior point we first move in one direction from σ_i and then in the other direction. At the completion of each Lanczos run in which we attempted to extend a trust interval, we compute, and save, the next shift that would extend the new trust interval further in the same direction. The first shift, unless it is at a finite endpoint of the computational interval, is treated as extending the null trust interval both to the left and to the right. The Ritz values are then discarded.

These two views of the inverted spectra, albeit simplistic, have proven to be effective. A model based on convergence rates of the eigenvalues [36] is far too pessimistic to be of any use here.

3.3. Sentinels. There are several aspects of our eigenanalysis code where the shift selection mechanism and the implementation of the Lanczos algorithm are closely tied together. For example, we do not want to recompute at later shifts eigenpairs that have been computed from earlier shifts. Any computation spent recomputing known eigenpairs is wasted. Even allowing accidental recomputation creates a difficult situation in which we must determine the correct multiplicity of a computed eigenvalue

for which several eigenvectors have been computed. We choose never to allow this situation to arise.

In theory there is a very simple fix. If the starting block for the Lanczos recurrence is chosen to be M-orthogonal to all previously computed eigenvectors, the recurrence should remain M-orthogonal to all previously computed eigenvectors. This is not sufficient in practice, as rounding errors introduce components of the excluded eigenvectors. We reorthogonalize the recurrence to specific eigenvectors only when necessary using *external selective orthogonalization* (see §4.3.3). This mechanism dramatically reduces the cost of preventing the reappearance of excluded eigenvectors.

A second mechanism for reducing this cost is in the purview of the shifting code. A common situation is depicted in Fig. 6. The new shift, σ_{i+1}, has been chosen; the nearest previous shift, σ_j, forms the end of a trust interval. (Figure 6 depicts the initial case where the trust interval including σ_j is trivial.) Between the two shifts lie a set of eigenvalues and Ritz values computed during the run at σ_j. Because the convergence rate for the eigenvalues in the Lanczos algorithm decreases as the distance from the shift increases, the usual pattern is that the accepted eigenvalues are those closest to σ_j and the Ritz values are those farther out with little or no interlacing of the two sets.

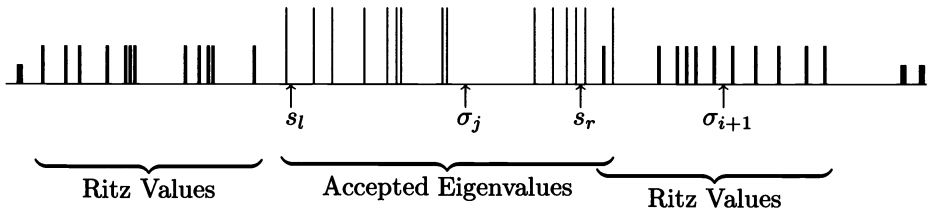

FIG. 6. *Sentinels.*

Consider in each direction the eigenvalue farthest from σ_j such that between it and σ_j no (unaccepted) Ritz values are found. There is such an eigenvalue to the right of a shift and similarly to the left, each being the last eigenvalue before a Ritz value is found. We call these two eigenvalues λ_r^* and λ_l^*. In normal circumstances we assume that there are no eigenvalues missing between σ_j and λ_r^* or λ_l^*.

We define the *right sentinel* s_r as the left endpoint of the interval of uncertainty for λ_r^*, based on the required accuracy tolerance. Thus the true value of λ_r^* lies to the right of the sentinel s_r. A *left sentinel* is defined similarly. Assume that $\sigma_{i+1} > \sigma_j$. The eigenvectors corresponding to λ_r^* and to any other eigenvalues found between s_r and σ_{i+1} are prevented from reappearing by use of external selective orthogonalization. We allow the recurrence to recompute eigenvalues which lie to the left of s_r, but these are discarded immediately. This technique allows us to trust any eigenpairs that are computed in the region in which we expect new eigenpairs to appear, without incurring the cost of extensive reorthogonalization. The reorthogonalization with respect to λ_r^*'s eigenvector removes any doubt that could exist about the exact location of this eigenvalue in the shifted and inverted spectrum for the new shift. At the same time, the eigenvector(s) most likely to reappear are suppressed.

We generalize the notion of sentinels slightly to handle clusters of eigenvalues. Should the sentinel s_r lie to the left of λ_{r-1}, we move the sentinel back to the endpoint

of the uncertainty interval for λ^*_{r-1}. We continue this process until the sentinel lies between the intervals of uncertainty for two eigenvalues, or until the shift itself is used as the sentinel.

3.4. The initial shift. The most difficult task is usually the first: getting started. The selection of the first shift must be made with no information about the spectrum other than the specification of the desired eigenvalues. We use any location information in the specification to make an initial choice for the first shift, σ_1,

$$\sigma_1 = \begin{cases} a \text{ if } |a| \le |b| \\ b \text{ if } |a| > |b| \end{cases} \Big\} \text{ if lowest modes or all modes wanted and } \min|a|,|b| < \infty,$$

$$\sigma_1 = \begin{cases} a \text{ if } |a| \ge |b| \\ b \text{ if } |a| < |b| \end{cases} \Big\} \text{ if highest modes wanted } (a \text{ and } b \text{ must both be finite}),$$

$$\sigma_1 = \xi \quad \text{if modes nearest } \xi \text{ wanted},$$

$$\sigma_1 = 0 \quad \text{otherwise.}$$

This choice of σ_1 gives a reference point in the spectrum as to which eigenvalues are important to the user. In cases where ξ is not specified by the user, we define ξ to be σ_1 as defined above. We note that 0 is a natural choice when we have no location information—in that common case we want the eigenvalues of least magnitude, i.e., closest to 0.

Unfortunately, a choice of $\sigma_1 = 0$ is fraught with difficulties. A shift at zero is not allowed in the buckling transformation and yields a singular operator in vibration analysis when K is semidefinite. If a shift at zero were taken in the latter case, it is unlikely that the singularity of the operator would be detected. It is more likely that only the zero eigenvalues would be computed and no other useful information could be extracted from the run. (The near-singularity of the operator would cause the Lanczos recurrence to break down after computing the invariant subspace of the zero eigenvalues.) This would leave us little better off than we were when we began, with no information as to where the nonzero eigenvalues are located. A better initial shift would be a shift somewhere in the vicinity of the first few nonzero eigenvalues. Such a shift would allow computing both the zero, rigid body modes and a number of the nonzero modes as well.

The difficulty is in getting some idea of the scale of the first nonzero eigenvalues. We have adopted a heuristic strategy recommended by Louis Komzsik of The MacNeal–Schwendler Corporation. This heuristic computes the geometric mean of the centers of the Gershgorin circles while excluding the centers smaller than 10^{-4}. This heuristic usually computes a reasonable *problem scale* χ. Specifically,

$$\chi = \frac{1}{l * \sum \frac{|m_{ii}|}{|k_{ii}|}},$$

where the summation is taken over all terms with $k_{ii} \neq 0$, $\frac{|m_{ii}|}{|k_{ii}|} < 10^4$; l is the number of entries included in the sum. Table 5 gives an idea of the reliability of this heuristic.

We use χ to correct the initial selection of σ_1 whenever $|\sigma_1| < \chi$. In either the vibration problem or ordinary eigenvalue problem we adjust σ_1 as

$$\sigma_1 = \begin{cases} \chi & \text{if } a \le \chi \le b, \\ -\chi & \text{otherwise, if } a \le -\chi \le b, \\ \max(|a|,|b|) & \text{otherwise.} \end{cases}$$

We adjust the initial shift in a similar fashion for the buckling problem. However, we try $\sigma_1 = -\chi$ first and then $\sigma_1 = \chi$ second, because the most common buckling analysis in structural analysis is computation of the smallest negative eigenvalue.

TABLE 5
Comparison of problem scale χ and lowest eigenvalues.

Matrix	χ	Lowest eigenvalue	Closest to eigenvalue
BCSST_08	1.8×10^{-2}	6.9×10^{0}	1
BCSST_09	1.3×10^{7}	2.9×10^{7}	1
BCSST_10	3.1×10^{-3}	7.9×10^{-2}	1

PLAT1919	2.1×10^{-6}	1.1×10^{-13}	315

3.5. Choosing a direction in which to expand a trust interval. The majority of vibration analyses result in a simple, monotonic expansion of the trust interval from lowest to higher values. In these cases we know that there are no additional eigenvalues of interest to the left of the trust interval; extending the interval to the right is the only reasonable action. Cases in which we need to choose a direction arise when a shift is taken in the interior of the spectrum by accident or by design. For example, ξ is a very reasonable initial shift when we want to find eigenvalues nearest ξ. In general, finding the eigenvalues of smallest magnitude for an ordinary eigenproblem or for buckling analysis is also such a case.

We use the reference value ξ, either as set in the problem description or from the initial shift (see §3.4), to determine the direction in which to move the shift. If multiple trust intervals exist, the trust interval including or closest to ξ is *primary*; §3.7.1 describes how multiple trust intervals can exist and the logic for determining a new shift in that case. In the most typical case we have only a single trust interval, which we attempt to extend.

We distinguish two subcases, when the trust interval includes an endpoint of the computational interval and when it does not. In the first case the trust interval can only be extended in one direction without moving outside the computational interval, so the choice of direction is trivial. When the trust interval includes neither endpoint, we further distinguish between cases where ξ is or is not in the trust interval. If the trust interval does not include ξ, we shift in the direction of ξ, because that is where the eigenvalues of most importance to the user lie.

The only remaining case is of a single trust interval that contains ξ, but neither endpoint of the computational interval. In this case we compute the interval $[z_l, z_r]$ that includes the entire trust interval and all computed eigenvalues, even those outside of the trust interval. We define $r = \min(\xi - z_l, z_r - \xi)$ to be the radius of a symmetric *umbrella* about ξ where we have some degree of confidence that we have computed all the eigenvalues in the umbrella. Note that this confidence may not be confirmed by inertia values. We try to enlarge this umbrella enough to include all of the eigenvalues that the user has requested or until one end of the umbrella is an endpoint of the computational interval. We move in whichever direction increases r. Ties are broken by shifting to the left.

3.6. Analysis in a finite interval. Frequently the user of the sparse eigensolver will specify a computational interval with finite endpoints. The number of eigenvalues in the interval is usually valuable information to the user and the eigenanalysis code, even when not all of these eigenvalues are actually computed. We obtain this information at the beginning of the analysis by computing the factorization for each endpoint. If these factorizations can be used in the eigenanalysis itself, the cost of gaining this information would be nominal. (Note that both factorizations will be required in any case when all eigenvalues in the interval are requested.) We save both factorizations off-line and use them whenever it appears to be appropriate.

As discussed in the previous section, we often choose the initial shift to be one of the endpoints. If so, one of the factorizations will be used immediately. We modify the shift strategy slightly in order to take advantage of the second factorization. When the natural choice of a shift would be near an otherwise unselected finite endpoint, and when a shift at the finite endpoint would not cause a large number of extra eigenvalues to be computed, we choose the endpoint as the shift. This may result in some additional work during the Lanczos iteration, but it will save the cost of a factorization. There are cases where we can extend a trust interval to a finite endpoint without making a Lanczos run at the endpoint. These occur when the analysis at another shift results in computation of all of the eigenvalues between the shift and the endpoint.

3.7. Special cases. Robustness is one of our goals. It is naive to expect that the heuristics described above will work for all problems. Here we describe a number of special cases that can and do arise in practice and our approaches for handling them smoothly.

3.7.1. Filling gaps. The shift selection is designed to extend the trust interval obtained from previous Lanczos runs. Strange, asymmetric distributions of eigenvalues or very high multiplicities may create situations in which the shift σ_{i+1} to extend the trust interval is taken too far from σ_i to allow computation of all the eigenvalues in (σ_i, σ_{i+1}) with a single run. The inertias from σ_i and σ_{i+1} will indicate that some eigenvalues between the two shifts have not been computed.

Our goal is to maintain a trust interval, so we find the missing eigenvalues *before* we attempt to extend our knowledge beyond σ_{i+1}. We attempt to fill the *gap* between the two *active* shifts σ_i and σ_{i+1}, before proceeding. We assume that the missing eigenvalues lie between the right sentinel s_i for the shift σ_i at the left and the left sentinel s_{i+1} for the shift σ_{i+1} at the right, that is, in $[s_i, s_{i+1}]$. If the sentinel values overlap we use $[\sigma_i, \sigma_{i+1}]$ instead. In either case we have an interval $[c, d]$ in which we want to chose a shift. We choose σ_{i+2} as

$$\sigma_{i+2} = \begin{cases} \sqrt{cd} & \text{if } 0 < 2c < d, \\ -\sqrt{cd} & \text{if } c < 2d < 0, \\ \frac{c+d}{2} & \text{otherwise.} \end{cases}$$

The gap between two trust intervals is not always filled on the first attempt. The shifting strategy will continue recursively, computing missing eigenvalues, until the primary trust interval has grown large enough to contain the requested eigenvalues or when all trust intervals have been merged into one.

3.7.2. Restart at the same shift. Economizing on the number of factorizations is also a goal. In two cases a single Lanczos run will not find all the desired eigenvalues near a given shift. These occur when eigenvalues with multiplicity greater

than the blocksize exist or when a shift has been taken very close to a eigenvalue. If we suspect either case we make an additional Lanczos run at the same shift. During this run we perform external selective reorthogonalization against all newly computed eigenvectors and any other eigenvectors in the interval between this shift and any neighboring shifts. We discard any use of sentinels because the assumption behind them has probably broken down.

3.7.3. Hole in the spectrum. A particularly difficult spectrum for our selection of shifts is one with a very large disparity in the magnitudes of the desired eigenvalues. In such cases our notion of a reasonable distance may be faulty and yet we may have no Ritz value information to help us choose a new shift.

Our code treats as special a situation in which no new information is obtained at consecutive shifts. That is, we compute no meaningful Ritz values and the inertias at the two shifts σ_i and σ_{i+1} are identical. We suspect that there is a "hole" in the spectrum, that the remaining eigenvalues are farther away than our notion of a reasonable distance. We expand the notion of a reasonable distance in an attempt to cross the hole. If the computational interval $[a, b]$ has a finite endpoint that has not been used previously as a shift (see §3.6), the shift strategy will select the new shift at that endpoint. Otherwise, assuming that we are expanding a trust interval to the right, we take the new shift $\sigma_{i+2} = \sigma_{i+1} + 10\delta$ (see §3.2 for a description of δ). If this Lanczos run still provides no new information, we take $\sigma_{i+3} = \sigma_{i+2} + 100\delta$. If we still obtain no new information, we make a final attempt to cross the gap with a shift $\sigma_{i+4} = \sigma_{i+3} + 1000\delta$. If this run still provides no new information, we terminate on the assumption that the remaining eigenvalues are infinite. We return the eigenvalues already computed, together with an appropriate warning.

3.7.4. Treatment of δ in no-Ritz value cases. The setting of the "reasonable distance" value, δ, must be made carefully in cases in which the Lanczos algorithm terminates abnormally. This value is not updated if no new information is available for the next shift.

3.7.5. Overly aggressive shifts. Unusual distributions of eigenvalues or unusual convergence patterns may cause situations in which a shift is selected much farther out than required for the desired eigenvalues. We determine that the shift is too far from the current trust interval if a run at this shift will have to compute more than 30 eigenvalues before computing eigenvalues of interest to us. (The number 30 is a heuristic estimate of the number of eigenvalues we can profitably find with a single run.) In such a case we record the current shift, to keep another shift from going out too far in that direction, and select a new shift. We choose the new shift by linear interpolation between the end of the trust interval, σ_t, and the shift we reject, σ_r. The new shift is:

$$\sigma = \sigma_t + \frac{q}{[\nu(K - \sigma_r M) - \nu(K - \sigma_t M)]}(\sigma_r - \sigma_t).$$

3.8. Modifications for buckling problems. The spectral transformation used in the buckling problem for the Lanczos iteration is ill posed for shifts at or near zero. The shift strategy for the buckling problem is similar to the vibration strategy except that shifts at zero are not allowed. A shift at zero is replaced by one half the minimum of the problem scale χ, the absolute value of the shift nearest to zero, and the absolute value of the computed eigenvalue nearest to zero.

4. Implementation of the block Lanczos algorithm. The underpinning of our eigenanalysis code is the block Lanczos algorithm, as specialized for the spectral transformations (§§2.3 and 2.5). The use of the block Lanczos algorithm in the context of the spectral transformation and within applications code necessitates careful attention to a series of details: the implications of M-orthogonality of blocks; block generalizations of single vector orthogonalization schemes; effect of the spectral transformation on orthogonality loss; and interactions between the Lanczos algorithm and the shifting strategy. The success of the algorithm hinges on all of these issues.

4.1. The M-orthogonal QR factorization. Each step of the block Lanczos recurrence generates an $n \times p$ matrix R, whose column vectors are to be orthogonalized with respect to an inner product defined by a positive definite matrix, which we will call M.

Given R, we must compute its orthogonal decomposition QB such that

- $R = QB$,
- $Q^T M Q = I$,
- Q is $n \times p$,
- B is $p \times p$ and upper triangular.

When M is not the identity, the number of good choices for computing an orthogonal factorization appear to be limited. In addition, we want to avoid repeated matrix-vector multiplications with M, because we expect M, though sparse, not to be stored in main memory; each multiplication by M may require accessing secondary storage. We have developed a generalization of the modified Gram–Schmidt process that requires only matrix-block products, never matrix-vector products. We save a set of p auxiliary vectors that represent the product MQ throughout the process. This matrix is initialized to MR when the matrix that will hold Q is initialized to R; thereafter, updates made to vectors in Q are shadowed by identical updates in MQ. As a result, M is used explicitly only in the initialization.

This way of enforcing M-orthogonality certainly suggests questions of numerical stability. Following [10], we repeat the orthogonalization process up to $2p$ times, another repetition being required whenever the norm of any of the q_j vectors is less than η times its norm at the beginning of the iteration. When another repetition is required we recompute the matrix MQ by an explicit multiplication by M. The choice of $\eta = \sqrt{2}/2$ from [10] guarantees that the final set of vectors is orthonormal.

In our algorithm for computing the M-orthogonal factorization (Fig. 7), the vectors w_j are the auxiliary vectors that represent the vectors Mq_j. The matrix $\hat{B}$ is the triangular matrix computed in one iteration of the algorithm; the M-orthogonal triangular factor B is the product of all of the individual triangular matrices $\hat{B}$.

It should be noted that this algorithm may encounter a rank deficient set of vectors q_j and identically zero vectors are possible. Further details can be found in our discussion on when to terminate a Lanczos run (§4.4).

We have assumed in the discussion above that M is positive definite. In the case of M positive semidefinite, the recurrence, when properly started, generates a sequence of blocks, all of whose columns lie in the range of $(K - \sigma M)^{-1} M$. This is the subspace from which the eigenvectors corresponding to finite eigenvalues must be drawn [13]. Clearly, the orthogonalization algorithm preserves this subspace. Further, this subspace has only the trivial intersection with the nullspace of M [13], [29]. Thus, the appearance of a nontrivial column with zero M-norm represents a breakdown equivalent to rank deficiency, since such a vector cannot lie in the range of $(K - \sigma M)^{-1} M$.

Initialization:

$Q = R$
$B = I$

Factorization:

Repeat
W = MQ

For $i = 1, 2, \ldots p$ do
$\hat{b}_{ii} = \sqrt{q_i^T w_i}$
$q_i = q_i / \hat{b}_{ii}$
$w_i = w_i / \hat{b}_{ii}$
For $j = i + 1, \ldots p$ do
$\hat{b}_{ij} = q_i^T w_j$
$q_j = q_j - \hat{b}_{ij} q_i$
$w_j = w_j - \hat{b}_{ij} w_i$
End
End

$B = \hat{B}B$

FIG. 7. *M-orthogonal modified Gram–Schmidt orthogonalization.*

4.2. Analysis of the block tridiagonal matrix T_j. The original eigenvalue problem is reduced by the block Lanczos algorithm to an eigenvalue problem of the form $T_j s = s\theta$, where T_j is a block tridiagonal matrix. In §2.2 we noted the standard result by which bounds on the accuracy of the computed eigenvalues can be computed without explicit computation of the eigenvectors. These bounds are used to determine whether to terminate the Lanczos recurrence and to evaluate which eigenpairs are accurate enough to be considered to have converged. The results in §2.2 generalize to provide a bound on the accuracy of the approximate eigenvalues of the spectrally transformed problem. However, our real interest is in the accuracy of our approximations to the original, untransformed problem. We need to determine which eigenpairs of the original problem have converged, and we need accuracy estimates for all of the Ritz values for use in the shift selection process. To get these estimates we need to unravel the effects of the spectral transformation. Throughout we must account for possibly multiple eigenvalues.

Recall that the following relation (14) holds for vibration analysis:

$$(K - \sigma M)^{-1} M y - y\theta = Q_{j+1} B_{j+1} E_j^T s.$$

Therefore, because Q_{j+1} is M-orthogonal,

$$\begin{aligned} \|M(K - \sigma M)^{-1} M - My\theta\|_{M^{-1}} &= \|MQ_{j+1} B_{j+1} E_j^T s\|_{M^{-1}} \\ &= \|B_{j+1} E_j^T s\|_2 \equiv \beta_j. \end{aligned}$$

For each eigenvector s the corresponding β_j is the Euclidean norm of the product of the upper triangular matrix B_{j+1} with the last p components of s. We apply a theorem on the error in eigenvalue approximations for the generalized eigenproblem from [32, p. 318] to obtain:

$$\left|\frac{1}{\lambda-\sigma}-\theta\right| \leq \frac{\|M(K-\sigma M)^{-1}My - My\theta\|_{M^{-1}}}{\|My\|_{M^{-1}}} = \beta_j. \tag{18}$$

Thus, as in the ordinary eigenproblem, β_j is a bound on how well the eigenvalue of T_j approximates an eigenvalue of the operator to which the Lanczos algorithm is applied. We extend this to find a bound on the error $|\lambda-\nu|$.

Ericsson and Ruhe [14] show that

$$|\lambda-\nu| \leq \frac{\beta_j}{\theta^2}. \tag{19}$$

This shows how the accuracy requirements are modified by the spectral transformation. When λ is close to the shift σ we need only a moderately small β_j to guarantee a good approximate eigenvalue ν because θ is large. Conversely, eigenvalues far from the shift are transformed to small values of θ, requiring smaller values of β_j than would otherwise be expected.

The bound (19) can be improved for well-separated eigenvalues. Define the gap γ as:

$$\gamma \equiv \min_{\lambda_i \neq \lambda} \left|\frac{1}{\lambda_i-\sigma} - \frac{1}{\lambda-\sigma}\right|,$$

The gap bound theorem from [32, p. 222] then results in

$$|\lambda-\nu| \leq \frac{\beta_j^2}{\theta^2\gamma}. \tag{20}$$

Both bounds (19) and (20) are valid. In general, the first is smaller than the second for clustered eigenvalues and larger for well-separated eigenvalues. In our implementation we use whichever bound is smaller:

$$|\lambda-\nu| \leq \min\left\{\frac{\beta_j}{\theta^2}, \frac{\beta_j^2}{\theta^2\gamma}\right\}. \tag{21}$$

The definition of γ should be modified to account for clusters of eigenvalues; the gap between sets of multiple eigenvalues is used. In practice we have only an approximation to γ, which we derive from the shifted and inverted eigenvalues of T_j.

Similar error bounds can be derived for buckling analysis. Let (ν, y) be a computed eigenpair of (K, K_δ). Then $\theta = \frac{\nu}{\nu-\sigma}$ and $|\frac{\lambda}{\lambda-\sigma} - \theta| \leq \beta_j$. From the fact that $\nu = \frac{\sigma\theta}{\theta-1}$, it follows that

$$\begin{aligned}
\lambda - \nu &= \lambda - \frac{\sigma\theta}{\theta-1} \\
&= \left(\frac{1}{\theta-1}\right)(\lambda(\theta-1) - \sigma\theta) \\
&= \left(\frac{1}{\theta-1}\right)(\lambda-\sigma)\left(\theta - \frac{\lambda}{\lambda-\sigma}\right) \\
&= \left(\frac{\sigma}{\theta-1}\right)\left(\frac{\lambda-\sigma}{\sigma}\right)\left(\theta - \frac{\lambda}{\lambda-\sigma}\right).
\end{aligned}$$

The Lanczos algorithm approximates θ by a projection onto a subspace. When the inversion of the operator is taken into account, the computed eigenvalues of the transformed problem are always closer to one than the true eigenvalues of the transformed problem. Therefore,

$$\left|\frac{\lambda-\sigma}{\sigma}\right| = \frac{1}{|\frac{\lambda}{\lambda-\sigma}-1|} \leq \frac{1}{|\theta-1|}.$$

The resulting simple error bound for buckling analyses is

$$|\lambda-\nu| \leq \frac{|\sigma|}{(\theta-1)^2}\beta_j.$$

The analogous refined gap error bound is

$$|\lambda-\nu| \leq \frac{|\sigma|\beta_j^2}{(\theta-1)^2}\gamma_b,$$

where γ_b is defined by

$$\gamma_b \equiv \min_{\lambda_i \neq \lambda}\left|\frac{\lambda}{\lambda_i-\sigma}-\frac{\lambda}{\lambda-\sigma}\right|.$$

As in the vibration case, the lesser of the two bounds

$$|\lambda-\nu| \leq \min\left\{\frac{|\sigma|}{(\theta-1)^2}\beta_j, \frac{|\sigma|\beta_j^2}{(\theta-1)^2}\gamma_b\right\} \tag{22}$$

is chosen, with the definition of γ_b modified in the presence of multiple eigenvalues.

The spectral transformation preserves the eigenvectors, so there is no need to account for the transformation *vis à vis* the approximate eigenvectors. However, Ericsson and Ruhe [14] introduced a correction term that results in improved eigenvector approximations for the untransformed problem. This was later discovered to have the additional benefit [29] of ensuring that the computed eigenvectors lie in the proper subspace in cases where the metric matrix is semidefinite.

Let $\nu = \sigma + \frac{1}{\theta}$ be the computed eigenvalue. The correction step is formally one step of inverse iteration with the computed eigenvector y; $\tilde{z}$ is computed to satisfy $(K-\sigma M)\tilde{z} = My$. By (14)

$$\tilde{z} = (K-\sigma M)^{-1}My = y\theta + Q_{j+1}B_{j+1}E_j^T s.$$

The vector

$$z = \frac{1}{\theta}\tilde{z} = y + \frac{1}{\theta}Q_{j+1}B_{j+1}E_j^T s$$

can be obtained cheaply by adding a linear combination of the vectors in the next block of Lanczos vectors to y. This gives a better approximation to the eigenvector of the vibration problem and ensures that the approximate eigenvectors are uncontaminated by the effects of a semidefinite M. The corresponding correction for a semidefinite K in buckling analysis is given by

$$z = y + \frac{1}{\theta-1}Q_{j+1}B_{j+1}E_j^T s.$$

During the course of the Lanczos algorithm we need an estimate of the residual bounds. The bounds in (21) or (22) require most of the eigenvalues and the corresponding entries in the bottom block row of the matrix of eigenvectors. Parlett and Nour-Omid [33] have a very efficient algorithm for the single vector Lanczos algorithm. Block generalizations have yet to be found, so we use a more straightforward approach. The eigenvalue problem for T_j is solved by reducing the band matrix T_j to tridiagonal form and then by applying the tridiagonal QL algorithm. We use subroutines from EISPACK [16], [41], with slight modifications, to obtain only the bottom p entries of the eigenvectors of T_j. These modifications reduce considerably both computation and storage requirements for each Lanczos step. Only $p^2 j$ words are needed as opposed to $(pj)^2$ for the full eigenvector matrix. We use the corresponding unmodified routines to obtain the full eigenvectors at the conclusion of a Lanczos run, at which time temporary space used during the recurrence is available to store the entirety of the eigenvector matrix for T.

4.3. Global loss of orthogonality and reorthogonalization. Up to this point our discussion of the block Lanczos algorithm has assumed exact arithmetic, but the various error bounds hold in finite precision as well. It is well known that there is a global loss of orthogonality among the computed Lanczos vectors in inexact arithmetic. A reasonable correction is to perform *limited* reorthogonalization to keep $\mathcal{Q}_j$ sufficiently close to orthogonal. Our approach is twofold—we identify mechanisms whereby orthogonality is lost and then apply a model of the loss of orthogonality to determine when to correct the situation. In the context of the block shifted Lanczos recurrence, orthogonality is lost in three different ways. First, there is a loss of orthogonality between adjacent blocks in $\mathcal{Q}_j$, the blocks the recurrence should make orthogonal. This is corrected by use of *local reorthogonalization.* Second, the recurrence suffers a global loss of orthogonality with respect to the blocks of $\mathcal{Q}_j$ not explicitly involved in the reorthogonalization. We correct for this with a block version of *partial reorthogonalization.* Lastly, it is important that a Lanczos run at some shift not recompute eigenvectors computed as a result of a previous Lanczos run. We present a new reorthogonalization scheme, *external selective reorthogonalization,* to ensure that this does not occur. Throughout the process our goal is to apply a minimal amount of extra work, particularly as it requires accessing the entirety of $\mathcal{Q}_j$, to maintain at least $\mathcal{O}(\sqrt{\epsilon})$-orthogonality in $\mathcal{Q}_j$.

The fundamental approach is to model the Lanczos recurrence in finite precision. The following recurrence is our model of what really happens:

$$Q_{j+1}B_{j+1} = (K - \sigma M)^{-1} M Q_j - Q_j A_j - Q_{j-1} B_j^T + F_j, \tag{23}$$

where F_j represents the roundoff error introduced at step j. Then,

$$\begin{aligned} Q_k^T M Q_{j+1} B_{j+1} = {} & Q_k^T M (K - \sigma M)^{-1} M Q_j - Q_k^T M Q_j A_j \\ & - Q_k^T M Q_{j-1} B_j^T + Q_k^T M F_j. \end{aligned}$$

For convenience we define $W_{j,k} \equiv Q_k^T M Q_j$, with which the previous equation becomes

$$W_{j+1,k} B_{j+1} = Q_k^T M (K - \sigma M)^{-1} M Q_j - W_{j,k} A_j - W_{j-1,k} B_j^T + Q_k^T M F_j. \tag{24}$$

This equation is nearly sufficient for our computational purposes. We can easily find norms for the blocks A_j and B_j during the recurrence, and we will compute bounds for all the other terms except for the first term on the right side of (24).

We eliminate $Q_k^T M(K - \sigma M)^{-1} M Q_j$ from (24) by obtaining an expression for its transpose by premultiplying the occurrence of (23) with $j = k$ by $Q_j^T M$:

$$Q_j^T M(K - \sigma M)^{-1} M Q_k = W_{j,k+1} B_{k+1} + W_{k,j} A_j + W_{k-1,j} B_k^T + Q_j^T M F_k.$$

The obvious substitution then results in

$$\begin{aligned} W_{j+1,k} B_{j+1} = {} & B_{k+1}^T W_{j,k+1} + A_k W_{j,k} + B_k W_{j,k-1} \\ & - W_{j,k} A_j - W_{j-1,k} B_j^T + G_{j,k}. \end{aligned} \tag{25}$$

Here $G_{j,k} \equiv Q_k^T M F_j - F_k^T M Q_j$ represents the local roundoff error. Formula (25) explains the global loss of orthogonality. We will use this model to estimate and bound the loss of orthogonality among the Lanczos vectors and thereby determine how to correct the loss of orthogonality.

4.3.1. Monitoring the loss of orthogonality. The development of our modeling procedure has two parts, both based on the bounds available by taking norms of (25):

$$\begin{aligned} \|W_{j+1,k}\|_2 \le {} & \|B_{j+1}^{-1}\|_2 (\|B_{k+1}\|_2 \|W_{j,k+1}\|_2 \\ & + \|B_k\|_2 \|W_{j,k-1}\|_2 + \|B_j\|_2 \|W_{j-1,k}\|_2 \\ & + (\|A_j\|_2 + \|A_k\|_2) \|W_{j,k}\|_2 + \|G_{j,k}\|_2). \end{aligned}$$

We use this equation to compute a bound $\omega_{j,k}$ on $\|W_{j,k}\|_2$ at each step.

The first part of our development addresses the bounds $\omega_{j+1,k}$ for $k \le j - 1$, that is, for blocks that are not explicitly involved in the orthogonalization of the Lanczos vectors within the recurrence itself. For these blocks the loss of orthogonalization depends on the loss already incurred at previous steps. Bounds on that loss of orthogonality will be available to us from previous steps of the simulation given in Fig. 8.

Initialize:

$\epsilon_s \equiv \epsilon p \sqrt{n}$, where $\epsilon \equiv$ roundoff unit, p is the blocksize
and $n =$ number of degrees of freedom
$\omega_{2,1} = \epsilon_s$

Loop:

For $j = 2, 3, 4, \ldots$ do
$\omega_{j+1,j} = \epsilon_s$
$\omega_{j+1,j-1} = \tilde{\beta}_{j+1}(2\beta_j \epsilon_s + (\alpha_j + \alpha_{j-1})\epsilon_s + \beta_{j-1}\omega_{j,j-2})$
For $k = 1, \ldots j - 2$ do
$\omega_{j+1,k} = \tilde{\beta}_{j+1}(\beta_{k+1}\omega_{j,k+1} + \beta_k \omega_{j,k-1} + \beta_j \omega_{j-1,k} + (\alpha_j + \alpha_k)\omega_{j,k})$
End
End

FIG. 8. *Simulation of loss of orthogonality* (ω-*recurrence*).

The following quantities from the Lanczos recurrence are required for the simulation:

$$\alpha_k \equiv \|A_k\|_2,$$

$\beta_k \equiv \|B_k\|_2$,
$\tilde{\beta}_k \equiv 1/\sigma_p(B_k)$, where $\sigma_p(B_k)$ is the smallest singular value of B_k.

In addition, we follow [32], [37], [39] in making a standard assumption on a bound for the error term: $\|G_{j,k}\|_2 \leq \epsilon_s = \epsilon p\sqrt{n}$. We have left unstated the origin of the two initializing terms, $\omega_{j+1,j}$ and $\omega_{j+1,j-1}$. In examining them we will uncover a particular artifact of the *block* Lanczos algorithm. By (25),

$$\begin{aligned} W_{j+1,j-1}B_{j+1} &= B_j^T W_{j,j} + A_{j-1}W_{j,j-1} + B_{j-1}W_{j,j-2} \\ &\quad -W_{j,j-1}A_j - W_{j-1,j-1}B_j^T + G_{j,j-1} \\ &= (B_j^T W_{j,j} - W_{j-1,j-1}B_j^T) \\ &\quad +(A_{j-1}W_{j,j-1} - W_{j,j-1}A_j) \\ &\quad +B_{j-1}W_{j,j-2} + G_{j,j-1}. \end{aligned}$$

By reason of the care with which we compute the QR factorization, we assume that $Q_j^T M Q_j = I + E$, where I is the identity matrix and $\|E\|_2 \leq \epsilon_s$. For reasons discussed below, we can assume that $\|W_{j,j-1}\|_2 \leq \epsilon_s$. From this it follows that

$$\|W_{j+1,j-1}\|_2 \leq \tilde{\beta}_{j+1}(2\beta_j\epsilon_s + (\alpha_j + \alpha_{j-1})\epsilon_s + \beta_{j-1}\omega_{j,j-2}). \tag{26}$$

Notice from (26) that $\omega_{j+1,j-1} > \tilde{\beta}_{j+1}\beta_j\epsilon_s$. At the next step this term will appear as $\tilde{\beta}_{j+2}\beta_j\omega_{j+1,j-1}$; in the following step it will be one of the contributions to $\tilde{\beta}_{j+3}\beta_{j+1}\omega_{j+2,j}$. Both $\tilde{\beta}_{j+1}$ and β_{j+1} appear in this last product. The growth of the bound occurs as fast as $\kappa(B_j) = \tilde{\beta}_{j+1}\beta_{j+1}$, the condition number of B_j. The analysis of the ordinary Lanczos algorithm has unity corresponding to the term $\kappa(B_j)$, because the condition number of a nonzero 1×1 matrix is always one. The loss of orthogonality occurs more rapidly in the block Lanczos algorithm, particularly when $\kappa(B_j)$ is significantly larger than one, but also in general.

A different, but related, analysis can be used to show that the term $\kappa(B_j)$ appears in the bound for $\omega_{j+1,j}$. This was first observed in [23], where this growth was also actually observed in the Lanczos recurrence. An inexpensive correction is needed to make the recurrence useful: at each step a *local reorthogonalization* between Q_{j+1} and Q_j is performed. Because the Lanczos recurrence is itself just a special form of Gram–Schmidt orthogonalization, local reorthogonalization can be seen as a simple generalization of the reorthogonalization required in computing the M-orthogonal factorization of a single block. Local reorthogonalization ensures that ϵ_s-orthogonality holds between successive blocks of Lanczos vectors. Note that a local orthogonalization step is also performed on completion of a partial reorthogonalization. If storage is not an issue, a local reorthogonalization between Q_{j+1} and Q_{j-1} should also be performed, in which the obvious modification should be made to the algorithm for computing the ω-recurrence.

4.3.2. Partial reorthogonalization. The global loss of orthogonality modeled by the ω-recurrence can be corrected by two different schemes. These are the selective orthogonalization scheme of Parlett and Scott [35] and the partial reorthogonalization scheme of Simon [40]. Selective orthogonalization takes advantage of the fact that orthogonality is lost exactly in the direction of eigenvectors that have become well represented in $\mathcal{Q}_j$. Selective orthogonalization is implemented in two steps. In the first, the Lanczos recurrence is "interrupted" when an eigenvector converges. The

eigenvector is computed, which requires access to all previous blocks in $\mathcal{Q}_j$. The second step occurs whenever the model indicates orthogonality is lost again in the direction of the eigenvector. The second step requires that the latest two Lanczos blocks be reorthogonalized against the computed eigenvector, but does not require access to preceding blocks of $\mathcal{Q}_j$.

Partial reorthogonalization interrupts the recurrence to reorthogonalize Q_j and Q_{j+1} against all preceding blocks whenever the simulation indicates too great a loss of orthogonality. Each reorthogonalization step requires access to all of $\mathcal{Q}_j$. For this reason partial reorthogonalization has previously been recommended for situations in which the eigenvectors were not of any interest (as in solving sparse linear equations [40]). The extra cost in an application of partial reorthogonalization does have an extra payoff; orthogonality is restored against all converged and nearly converged eigenvectors simultaneously.

TABLE 6
Comparison of partial and selective reorthogonalization.

Matrix	Eigen-values	Block steps	Partial reorthog. steps	Selective orthog. steps
BCSST_26[a]	211	181	51	98
PLAT1919[b]	636	579	143	291

[a] blocksize 3, lowest 200 modes.
[b] blocksize 3, all modes in [.000025, .24].

Shifting and the block recurrence each accelerate the convergence of eigenpairs; together they cause eigenpairs to converge very rapidly. Frequently one or more eigenpairs converge at *each* block step, once the recurrence is established. In this circumstance selective orthogonalization has possibly greater requirements for accessing $\mathcal{Q}_j$ than does partial reorthogonalization. Selective orthogonalization will require an eigenvector computation at almost each step; partial reorthogonalization will occur only every three to four steps in typical problems. It would be possible to combine the two schemes—to carry out partial reorthogonalization during the computation of an eigenvector for selective orthogonalization, but it is not clear that the combination would be more effective than partial reorthogonalization alone. (See [34] for a discussion of these issues for the ordinary Lanczos recurrence.) Table 6 summarizes the reorthogonalization requirements of two extensive eigencomputations. The number of selective orthogonalization steps given in this table is the number of block steps at which one or more eigenvalues converge; the number of partial reorthogonalization steps is the number of block steps at which partial reorthogonalization was performed.

Our implementation of the Lanczos recurrence uses the block generalization of partial reorthogonalization, based on the block ω-recurrence presented above. The single vector version of this simulation has been shown previously [40] to provide a good order of magnitude estimate of growth of the loss of orthogonality, as well as a bound. We use the block version to estimate the loss of orthogonality to determine when reorthogonalization is necessary. Previous work [32], [35], [39] indicates that reorthogonalization is needed whenever

$$\max_k \omega_{j+1,k} \geq \sqrt{\epsilon}.$$

The reorthogonalization should be carried out with both of the last two block of vectors Q_j and Q_{j+1}, in order that the next block generated by the recurrence, Q_{j+2},

be strictly orthogonal to all of its predecessors. This leads to the following *partial reorthogonalization* [40] algorithm (Fig. 9) for maintaining orthogonality:

At each Lanczos step, after computing Q_{j+1} and B_{j+1}, do:

Update the ω-recurrence as above

$\omega_{\max} \equiv \max_k \omega_{j+1,k}$
If $\omega_{\max} \geq \sqrt{\epsilon}$ then
  For $k = 1, \ldots, j-1$ do
    Orthogonalize Q_j against Q_k
    Orthogonalize Q_{j+1} against Q_k
  End
  Orthogonalize Q_{j+1} against Q_j
  Reinitialize ω-recurrence:
    $\omega_{j+1,k} = \omega_{j,k} = \epsilon_s, k = 1, \ldots, j$
End if

FIG. 9. *Partial reorthogonalization.*

Note that the orthogonalization of Q_j and Q_{j+1} involves M-inner products. This requires the storage of both the Lanczos vectors and their product with M in secondary storage, or, alternatively, reapplying M to the Lanczos vectors. The appropriate form depends on cost.

4.3.3. External selective orthogonalization. A different type of loss of orthogonality occurs in the context of the shifted and inverted Lanczos algorithm. It is possible that, after computing some eigenvalues with shift σ_1, the same eigenvalues and vectors are computed again with shift σ_2. External selective orthogonalization is an efficient way of keeping the current sequence of Lanczos vectors orthogonal to previously computed eigenvectors, and thereby avoiding the recomputation of eigenvalues that are already known. External selective orthogonalization is motivated by the classical selective orthogonalization algorithm [35], but the development here is entirely new.

In theory it would be sufficient to orthogonalize the starting block against known eigenvectors, because all subsequent Lanczos vectors would be orthogonal as well. Of course, this does not hold in practice. A global loss of orthogonality occurs, similar to the one among the Lanczos vectors themselves; in addition, the computed eigenvector is not exact. The contribution of both sources of error to the recomputation of eigenvalues and vectors is analyzed below.

Let (ν, y) be an approximate eigenpair of (K, M). For clarity, denote the current shift as σ_{new}. The relationship between the eigenvector y and the Lanczos vectors obtained with the shift σ_{new} is found by premultiplying the finite precision recurrence (23) by $y^T M$ to obtain

$$y^T M Q_{j+1} B_{j+1} = y^T M (K - \sigma_{\text{new}} M)^{-1} M Q_j - y^T M Q_j A_j - y^T M Q_{j-1} B_j^T + y^T M F_j. \tag{27}$$

We assume that B_{j+1} is nonsingular. Then we can obtain a bound on the loss of orthogonality between y and Q_j by taking norms of both sides of (27):

$$\|y^T M Q_{j+1}\|_2 \leq \|B_{j+1}^{-1}\|_2 (\|y^T M (K - \sigma_{\text{new}} M)^{-1} M Q_j - y^T M Q_j A_j\|_2$$

$$+ \|y^T M Q_{j-1}\|_2 \|B_j^T\|_2 + \|y^T M F_j\|_2).$$

As with partial reorthogonalization, we can define a recurrence relation for a quantity τ_j to bound the loss of orthogonality between y and the Lanczos vectors. Assuming that $\tau_i \geq \|y^T M Q_i\|_2$ for $i = 1, \ldots, j$, we obtain

$$\|B_{j+1}^{-1}\|_2(\|y^T M(K - \sigma_{\text{new}} M)^{-1} M Q_j - y^T M Q_j A_j\|_2 + \tau_{j-1}\|B_j^T\|_2 + \|y^T M F_j\|_2)$$

as a bound for the right-hand side of the $j+1$st step. Of the three terms on the right-hand side of this equation, the second is easily computed and we have a standard assumption for a bound on the third: $\|F_j\|_2 \leq \epsilon p\sqrt{n}$. We need then only to bound the first term $\|y^T M(K - \sigma_{\text{new}} M)^{-1} M Q_j - y^T M Q_j A_j\|_2$. The spectral transformations preserve eigenvectors, so y is also an approximate eigenvector of the spectrally transformed problem. Define the transformed residual vector z_{new} by

$$(K - \sigma_{\text{new}} M)^{-1} M y - \frac{1}{\nu - \sigma_{\text{new}}} y = z_{\text{new}}.$$

Then

$$y^T M(K - \sigma_{\text{new}} M)^{-1} M Q_j = \frac{1}{\nu - \sigma_{\text{new}}} y^T M Q_j + z_{\text{new}}^T M Q_j,$$

from which it follows that

$$\|y^T M(K - \sigma_{\text{new}} M)^{-1} M Q_j - y^T M Q_j A_j\|_2 \leq \left\| \left(\frac{1}{\nu - \sigma_{\text{new}}} I - A_j \right) \right\|_2 \tau_j + \|z_{\text{new}}^T M Q_j\|_2.$$

But

$$\begin{aligned} \|z_{\text{new}}^T M Q_j\|_2 &= \|(z_{\text{new}}^T M^{1/2})(M^{1/2} Q_j)\|_2 \\ &\leq \|z_{\text{new}}^T M^{1/2}\|_2 \|M^{1/2} Q_j\|_2 = \|z_{\text{new}}^T\|_M \|Q_j\|_M = \|z_{\text{new}}^T\|_M. \end{aligned}$$

Thus, the following simple recurrence for τ gives a bound for the loss of orthogonality observed in (27):

(28)

$$\tau_{j+1} = \|B_{j+1}^{-1}\|_2 \left(\tau_j \left\| \left(\frac{1}{\nu - \sigma_{\text{new}}} I - A_j \right) \right\|_2 + \tau_{j-1}\|B_j^T\|_2 + \|z_{\text{new}}\|_M + \epsilon p\sqrt{n} \right).$$

The same analysis applies to the buckling spectral transformation, where the eigenvector orthogonality error (27) becomes:

$$\begin{aligned} y^T K Q_{j+1} B_{j+1} = {} & y^T K(K - \sigma_{\text{new}} K_\delta)^{-1} K Q_j - y^T K Q_j A_j \\ & - y^T K Q_{j-1} B_j^T + y^T K F_j. \end{aligned}$$

The transformed residual vector z_{new} is

$$(K - \sigma_{\text{new}} K_\delta)^{-1} K y - \frac{\nu}{\nu - \sigma_{\text{new}}} y = z_{\text{new}}.$$

By the same analysis as above, the recurrence for τ in the buckling context is

(29)

$$\tau_{j+1} = \|B_{j+1}^{-1}\|_2 \left(\tau_j \left\| \left(\frac{\nu}{\nu - \sigma_{\text{new}}} I - A_j \right) \right\|_2 + \tau_{j-1}\|B_j^T\|_2 + \|z_{\text{new}}\|_K + \epsilon p\sqrt{n} \right).$$

The recurrences in (28) and (29) provide a mechanism for estimating the loss of orthogonality to externally computed eigenvectors, regardless of the source. Each requires computing the transformed residual vector, z_{new}, and its norm, but the recurrence applies to situations where eigenvectors are known adventitiously. For example, in the vibration analysis of structures where K is singular, the so-called rigid body modes, the zero eigenvalues and vectors, often can be computed at much less cost than a factorization. Typically, the cost of computing the residual norms for all of the vectors involved in external selective orthogonalization is less than the cost of one additional step of the Lanczos recurrence.

In the context of a Lanczos code within a larger shifting strategy, it would be attractive to use the information from the Lanczos recurrence to bound the errors in the computed eigenvectors and thereby avoid having to compute $\|z_{\text{new}}\|_M$. In [20] we provide an analysis for the case where the approximate eigenpair (ν, y) was computed by the Lanczos code at a previous shift σ_{old}. However, we use the more general form exclusively in our code.

As with partial reorthogonalization, we define a recurrence relation for a quantity τ_j that estimates the loss of orthogonality of the Lanczos vectors with respect to y. In the recurrence, τ_j is defined be:

$$\tau_{j+1} = \tilde{\beta}_{j+1}(\alpha_{\nu\sigma j}\tau_j + \beta_j\tau_{j-1} + \|z_{\text{new}}\|_M), \tag{30}$$

which we initialize with $\tau_0 \equiv 0$ and $\tau_1 = \epsilon p\sqrt{n}$. The terms β_j and $\tilde{\beta}_{j+1}$ are defined as in the ω-recurrence. The term $\alpha_{\nu\sigma j} \equiv \|(\nu - \sigma)^{-1}I - A_j\|_2$.

An external selective orthogonalization is performed whenever $\tau_{j+1} \geq \sqrt{\epsilon}$. A relatively large residual for the computed eigenvector will cause frequent reorthogonalization, but, as noted below, usually only a very small number of vectors are actually involved. External selective orthogonalization is implemented as in Fig. 10.

Before the Lanczos iteration:
    Determine the set of SO-vectors (eigenvectors for selective orthogonalization)
    Orthogonalize Q_1 against the SO-vectors.
    Orthogonalize Q_2 against the SO-vectors.

At each Lanczos step $j = 3, 4, \ldots$ do:
    Update the τ-recurrence according to (30) for each SO-vector;
    If (τ_j has been greater than $\sqrt{\epsilon}$ or $\tau_{j+1} \geq \sqrt{\epsilon}$) then
        Orthogonalize Q_{j+1} against y
        Set $\tau_{j+1} = \epsilon_s$
    End if

FIG. 10. *External selective orthogonalization.*

It is unnecessary to perform external selective orthogonalization against *all* previously computed eigenvectors. From (28) and (29) it is evident that one of the main driving forces in the loss of orthogonality is $(\nu - \sigma)^{-1}$. It would appear that loss of orthogonality should mostly occur in the direction of eigenvectors corresponding to eigenvalues close to the new shift. Furthermore, as discussed in §3.3, only a few eigenvectors, again usually those close to the new shift, need be considered in order to avoid confusing new eigenvectors with the old. In our implementation, we use sentinels to reduce the cost of maintaining orthogonality. The set of eigenvectors used

for external selective orthogonalization is usually the eigenvectors corresponding to any known eigenvalues closer to the shift than the sentinels. Eigenvalues beyond the sentinels are discarded in the analysis of the block tridiagonal system.

The effect of using sentinels on the work required for external selective orthogonalization is more dramatic than is suggested by the analysis above. Although proximity to the shift is the driving force in the growth of τ, neither recurrence (28) nor (29) begins at ϵ. The term $\|z_{\text{new}}\|_M$ is usually near $\sqrt{\epsilon}$. The eigenvalues themselves are only good to the convergence tolerance (usually $\epsilon^{2/3}$ in our code). Furthermore, the spectral transformations preserve eigenvectors, but do not preserve the property of being the best minimizers for approximate eigenvalues (see [14] for a discussion of the need to modify the approximate eigenvectors). As a result, external selective orthogonalization happens more often than we might expect, often at every step for the eigenpairs nearest the sentinels, which frequently are simultaneously least accurate and nearest the new shift.

Experimental results are shown for two examples in Table 7. The results shown as "with sentinels" refers to the selection described in §3.3; the results shown as "without sentinels" uses as SO-vectors all eigenvectors in the intervals between the current shift and any neighboring trust intervals. The figure given as "cpu cost" includes both cpu time and i/o processor time. The difference between the costs for the two variations gives only a rough idea of the added cost for complete selective orthogonalization because the difference in cost affects the termination decision for each run and thereby changes the choice of shifts.

TABLE 7
External selective orthogonalization.

[b] blocksize 3, all modes in [.000025, .24].

The orthogonalizations involve again both y and My. In order to avoid the repeated computation of My, all selective orthogonalization vectors are premultiplied by M and the result is stored on the same random access file as the eigenvectors y. This computation is performed before the actual Lanczos run begins.

4.3.4. Summary of reorthogonalization schemes. We now present in summary form the reorthogonalized block Lanczos algorithm we use in our production code. Our scheme consists of applying, in turn, external selective, partial, and local reorthogonalization to the result of a single block Lanczos step. The first two schemes are applied only when the respective model signals a need; each should be applied before orthogonality is lost badly enough that repeated orthogonalizations are needed. The local reorthogonalization is applied at each step. It may be applied repeatedly, but this normally occurs only when the recurrence has broken down, which will cause termination. The integration of these is indicated in Fig. 11.

4.4. Cost analysis and termination of a Lanczos run. The block Lanczos algorithm exists as part of a larger code, in which each Lanczos run solves only a

Initialization:

Set $Q_0 = 0$
Set $B_1 = 0$
Choose R_1 and orthonormalize the columns of R_1 to obtain Q_1 with $Q_1^T(MQ_1) = I_p$.

Lanczos Loop:

For $j = 1, 2, 3 \ldots$ do

Set $U_j = (K - \sigma M)^{-1}(MQ_j) - Q_{j-1}B_j^T$
Set $A_j = U_j^T(MQ_j)$
Set $R_{j+1} = U_j - Q_jA_j$
Compute Q_{j+1} and (MQ_{j+1}) such that
a) $Q_{j+1}B_{j+1} = R_{j+1}$
b) $Q_{j+1}^T(MQ_{j+1}) = I_p$

Evaluate γ-recurrence for each SO vector and perform selective orthogonalization if necessary
Evaluate ω-recurrence and perform partial reorthogonalization if necessary

Repeat up to $2p$ times:
Reorthogonalize Q_{j+1} to Q_j
Recompute M-orthogonal factor of Q_{j+1}
Until orthogonal factorization occurs in one step

End loop

FIG. 11. *Spectral transformation block Lanczos algorithm preserving semi-orthogonality.*

subproblem. In this environment there are three ways in which a given Lanczos run can terminate:

1. All eigenvalues required for this subproblem have converged.
2. The B_{j+1}-block is ill conditioned or singular. In this case a continuation of the Lanczos run is either numerically difficult or impossible. Singular or ill conditioned B_{j+1}-blocks can be encountered for the following reasons:
   - The shift is very close to an eigenvalue.
   - The effective space of Lanczos vectors is exhausted—we cannot compute more orthogonal vectors than the problem has finite eigenvalues.
   - Dependencies within the starting block cause a singular B_{j+1} at some later stage.
3. Eigenvalues farther from the shift appear to be converging slowly. The estimated cost for computing them in the current Lanczos run is great enough that a new shift should be chosen.

The first of these is easy to detect in most cases. There is a minor complication when we want the eigenvalues closest to some specified value because we do not know in advance how many eigenvalues are required on each side of ξ. At a given shift our

conservative code looks for as many eigenvalues as are required to complete the total, even if these may represent more than what is needed on one side of ξ. As a result, we may not terminate as early as we might with hindsight.

Breakdown in the recurrence is perhaps more likely than might otherwise be expected. The first of the causes we try to avoid during the shift selection process; the second occurs primarily during user evaluation of the code, when it is not uncommon to be faced with problems like finding all of the eigenvalues of 7×7 matrices using a blocksize of 5. The third we have never seen. Breakdown is detected by one of two mechanisms—the norm of the residual block is very small compared to the norm of the diagonal block or the off-diagonal block is ill conditioned and presumed rank-deficient. We use a relative norm of $1/\sqrt{\epsilon}$ for the first case. For the second we compute, at each step, the extreme singular values of the off-diagonal block B_i; we terminate if the condition number of $B_i \geq \frac{1}{\epsilon}$. We really want only the condition number of B_i, but the cost of a singular value decomposition of a $p \times p$ matrix is trivial compared to the cost of an $n \times n$ sparse block solve.

The most common reason for termination is that computing more eigenvalues in the current run is inefficient. Normally, eigenvalues far from the shift converge slowly and require a large number of steps. Usually the fastest convergence occurs early, with the number of eigenvalues converging per step tapering off as the length of the run increases. Initially the cost *per eigenvalue* decreases rapidly, as the cost of the factorization is amortized over several eigenvalues. Later, as the convergence rate slows and the other costs increase, the average cost also increases. Our goal is to stop at the minimum average cost.

The cost of a Lanczos run depends on a number of parameters, each a function of the number of steps taken. The factorization typically represents the largest single cost, but it occurs once. There is a large constant cost per step, comprising the matrix-block solve and multiplication and other operations in the recurrence. The cost of the eigenanalysis of T_j increases quadratically in the number of block steps. Inasmuch as the eigenvalue nearest the shift is usually the first to converge, and dominates the reappearance of banished subspaces, the frequency with which partial reorthogonalization is needed is generally independent of the number of eigenvalues that have converged and so represents another quadratic term. Terminating the run by computing the converged eigenvectors from the Lanczos vectors is a cubic term.

We determine when to terminate a given Lanczos run by modeling the cost of continuing the recurrence beyond the current step. The residual bounds estimating the accuracy of yet unconverged eigenvalues are monitored step by step; the observed changes are used to estimate future convergence. We attempt to locate a point in an individual run where the average cost per eigenvalue is minimized. This is itself a heuristic attempt to minimize the average cost for all eigenvalues. The effectiveness of the heuristic is demonstrated for a particular example in Table 8.

TABLE 8
Comparison of variations on termination model.

[a] blocksize 3, lowest 200 modes.
[b] blocksize 3, all modes in [.000025, .24].

We assume that a measure of the real user cost, including i/o, is available. We use this in a cubic model of cost, from which we obtain a least squares fit to the real cost over the preceding ten steps. From this model we predict the real cost over the next few steps. The cost of the final step, computing the eigenvectors, is estimated from measurements of components of the computation as they appear elsewhere in the recurrence. To start the process, we require that a certain minimum number of steps be taken. The number required is a function of blocksize and the type of problem, as indicated in Table 9. (The values in Table 9 are heuristic values derived from extensive empirical testing.)

The rate of convergence for the as yet unconverged eigenvalues is estimated by taking a weighted geometric average of the change in accuracy of the first unconverged Ritz value over the previous five steps. From this, we extrapolate to estimate the accuracy of the unconverged eigenvalues over a small number of additional steps. The number of extrapolated steps is also a function of blocksize and the type of problem; the actual values used are given in Table 9. We continue the Lanczos run if the estimated average cost per eigenvalue decreases for any of the steps over which we extrapolate convergence. In addition, if we predict that all of the eigenvalues remaining to be computed will converge in the steps corresponding to twice the number of steps given in Table 9, we continue the recurrence to avoid computing another factorization.

TABLE 9
Steps to initialize cost model and over which convergence is extrapolated.

	Vibration		Buckling		
			$\leq$ 10 modes	$>$ 10 modes

1	35	6	15	30	6
2	20	4	15	25	6
3	20	2	10	25	4
≥ 4	15	2	10	10	4

Our experience with this scheme is that the cost curve is relatively flat near its minimum, making the choice of where to stop appear to be flexible. This is misleading; the global minimum is quite sensitive to the local choice. To demonstrate the value of a well-tuned dynamic scheme for evaluating cost, we include some simple experiments here. We modified our standard scheme to make it terminate early and to force it to run ten steps beyond where it would normally stop. The results are given in Table 8 and show some sensitivity to small changes in the stopping procedure.

4.5. Choice of blocksize and starting block. The two largest benefits of the block algorithm are in i/o cost reduction and in treating multiple eigenvalues. However, the costs of obtaining the M-orthogonal factorization and of the eigenanalysis of T_j increase quadratically with the blocksize p. In general, it is best to choose a blocksize as large as the largest expected multiplicity if eigenvalues of moderate multiplicities are expected. This is particularly important if many clusters of eigenvalues are expected (Table 12). A blocksize of 6 or 7 works well in problems with rigid body modes. We rarely find that $p > 10$ is cost-effective.

The effect of input/output cost is considerable. Within the MacNeal–Schwendler NASTRAN product, which runs on a variety of commercial systems, extensive testing resulted in a default blocksize of 7 on all systems. Input and output is particularly expensive within NASTRAN. In an environment in which input/output cost is less costly, a blocksize of 3 was found to be more effective. We provide our results on a

small number of experiments in §5; it is likely that the optimal blocksize would change on other systems.

One would like to start the Lanczos algorithm with a good guess at a solution. We begin the first Lanczos run with a randomly generated starting block. Thereafter, the approximate eigenvectors (Ritz vectors) from unconverged Ritz values are available as estimates of the next eigenvectors to be found. At the time that the eigenvectors of T are available, we do not know where the next shift will be taken. Therefore, we take a starting block built from all of these Ritz vectors. If t vectors are available, each column in the starting block is taken to be the sum of t/p Ritz vectors. We fill the block out randomly when $t < p$. We adopted this approach after extensive experiments comparing various choices of starting blocks, including mixtures of Ritz vectors and random components. We did not find a significant change in the overall cost of the eigensolution with any of the approaches.

5. Experimental results. The algorithm described in the paper was developed as a general purpose eigensolver for the MacNeal–Schwendler Corporation's structural engineering package NASTRAN [18]. One of the goals in the software design was to make the eigensolver independent of the form of the sparse matrix operations representing the matrices involved: the matrix-block products, triangular block solves, and sparse factorizations. The eigensolver has been used in MSC NASTRAN with two different approaches to the sparse linear equations involved, a profile and a sparse multifrontal factorization. In both cases the factorization and solve modules are the standard operations of MSC NASTRAN, used directly by the eigensolver. The code has also been incorporated in four other structural engineering packages and in mathematics libraries supplied by Boeing Computer Services (BCSLIB-EXT)[1] [1] and Convex Computer Corporation (Veclib). In all of these implementations the sparse linear equations are solved with vectorized multifrontal codes based on the work in [2]–[4]. The multifrontal code computes a stable symmetric indefinite factorization, as described in [26].

In this section we report on experiments using our standard eigensolver from BCSLIB-EXT. The experiments were all performed on a Sun 4/690 workstation with 64 megabytes of main memory. The codes are all written in Fortran 77, and were run with the "-O" optimization option of the Sun Fortran compiler, which is quite effective with the inner loops of the numerical operations. We note that our code is always a block code, even when run with blocksize 1. This results in greater costs for the analysis of the tridiagonal system, where the results of Parlett and Nour-Omid would be available [33]. However, the cost of the tridiagonal analysis is less than 1% in general.

The test problems are drawn from the symmetric eigenproblems from the Harwell–Boeing test collection [11]. Our code has been used to solve eigenproblems with more than a million degrees of freedom, but the largest problem in the current test collection is of order 15,439 and most of the problems are much smaller. As a result, the order independent costs of the Lanczos algorithm, primarily the analysis of the block tridiagonal systems, are more important than they would be in large production problems. For most of the examples, we report the costs of the required eigenanalysis as a function of blocksize. For the largest problem we also report the breakdown of the cost in terms of the functional operations of the code.

[1] BCSLIB-EXT is available at no cost on all Cray Research, Inc. computers.

5.1. Some empirical examples. Throughout this paper we have used some of the problems from the Harwell–Boeing test collection [11] to demonstrate particular aspects of our algorithms. We close by using a small subset to illustrate some of the global behavior of the code, particularly as it concerns aspects over which the user exercises control. We chose four test problems, listed in Table 10, which were collected from actual industrial or research applications.

[a] ordinary eigenvalue problem.

Two of the problems have been used as the primary examples in this paper. They are BCSST_26, a model of a nuclear reactor containment floor used for seismic analysis, and PLAT1919, a finite difference model of tidal currents. These models were included in the test collection because of the large number of eigenpairs that were required of each. In both cases the number of modes is large because the analysis depended on knowing *all* of the modes in specified intervals.

Details of the eigenanalysis of the nuclear reactor containment floor problem, as a function of blocksize, are given in Table 11. These results exhibit a pattern common to all of the problems: The number of factorizations and Lanczos runs decrease rapidly as the blocksize increases; the cost of the eigenanalysis initially decreases as well, but then increases. This reflects the fact that as the blocksize increases, the length of the Lanczos runs increase in terms of the dimension of $\mathcal{Q}_j$. Longer runs involve greater costs, particularly for maintaining semi-orthogonality and for the back transformation of the eigenvectors. For these relatively small matrices, the costs of longer runs begin rather early to dominate the costs of factoring and applying the matrix operators. For reference, an analysis with a single Lanczos run with a blocksize of 3 had a cost of 543.4 for this problem, nearly three times the cost of the analysis with shifting.

TABLE 11

3	188.5	9	8	181	204
4	272.8	8	8	182	205
5	346.3	7	7	162	182
6	301.2	4	4	93	104

The desired eigenvalues in the oceanography problem are very much in the interior of the spectrum. There are 818 eigenvalues above and 465 eigenvalues below the values we want. This problem was analyzed without the use of the spectral transformation in [5], [23]. Without shifting, it was barely possible to compute the eigenvalues in the interval [.0001, .24]; the eigenvalues in [.000025, .0001] were also of interest, but

were impossible to compute. Secondly, all the eigenvalues, except a singleton at zero, are positive and occur in pairs. These multiple eigenvalues can play havoc with an ordinary, point Lanczos algorithm. With either a blocksize of 1 or 2, it is difficult for a code to be sure that it has exhibited the full multiplicities of the eigenvalues—the shifting strategy must be prepared to assist. Even with shifting, the single vector code of Ericsson and Ruhe [12], [15] was unable to cope with the multiplicities of the eigenvalues [25].

Table 12 shows the difficulty that arises with rank determination when the blocksize is the same as the multiplicity of the eigenvalues. When we use a blocksize of 2, we cannot distinguish between doubletons that are truly doubletons and those that are only two of a larger number of copies of a multiple eigenvalue. As a result, our code makes a large number of reruns to ensure that we have the full multiplicities of eigenvalues. This is shown by the discrepancy between the number of factorizations and the number of runs. Although the reruns incur no new cost for factorizations, they do require more extensive use of external selective orthogonalization than would an ordinary run. Surprisingly, the point version of the code is able to cope well with this problem. As expected, blocksize larger than the multiplicity of 2 have no difficulties.

BCSST_08 is a model of a building housing a television studio. Its claim to fame is the presence of isolated double and near triple eigenvalues. The lowest 24 eigenvalues are given in Table 13. The close eigenvalues cause relatively slow convergence, which causes our code to make more runs than we might expect. This problem can be solved easily enough with a single run, but at increased cost. We note that the multiple eigenvalues provide some challenges for blocksizes of 1 or 2. Details are given in Table 14.

BCSST_25 is an incomplete seismic model of the Columbia Center, a 76-story skyscraper in Seattle, Washington. The spectrum of this model is pathologically difficult—the lowest 132 eigenvalues are listed in Table 15. For reference, the largest eigenvalue of this structure is 1.51×10^8.

The smallest eigenvalues are nearly negligible when compared to the largest eigenvalue and they are very close to one another. Our code determines clusters of eigenvalues based on its accuracy tolerance, which defaults to 2.31×10^{-11} in IEEE arithmetic. We apply this tolerance to the transformed eigenvalues, which are *not* close enough to be treated as a cluster or even as two clusters and four isolated values. (Note that if we applied the tolerance to the untransformed eigenvalues, all of these values would be a cluster, which is not appropriate.) As a result, this problem counters our usual shifting strategy—in this case we must take a shift very close to the eigenvalues in order to overcome the very poor separation and slow convergence. This distribution, eigenvalues almost, but not quite, in a cluster represents a worst case. Table 16 documents the performance of our code on this problem. We see that for this problem the costs of larger blocksizes are more than offset by the additional power they provide in attacking the very close and large clusters of eigenvalues. In Table 17 we present the breakdown of cost by function within the algorithm for this, the largest of our test problems. This breakdown is typical of larger problems in that neither the cost of analyzing T nor of choosing shifts is significant. It is atypical in that the startup cost is high, a result of there being a large number of vectors involved in external selective orthogonalization.

5.2. Summary. The results in the previous section illustrate some of the characteristics of the shifted block Lanczos algorithm. Only BCSST_25 is large enough to begin to demonstrate the behavior of the algorithm on large problems. For larger

TABLE 17

problems we expect to see the cost of the factorization and linear equation solutions to increase faster than linearly. Assuming that the eigenvalue distributions do not change, the cost of reorthogonalization, of generating the starting block, and of the eigenvector computation will increase linearly with the change in problem size. The block tridiagonal eigenanalysis and the shift selection should remain constant and their contributions to cost will become even smaller. We note that the cost of the necessary reorthogonalizations is an important fraction of the cost—this is a strong argument for preserving only *semi-orthogonality* rather than complete orthogonality. We remind the reader that our cost measures include a factor for i/o traffic, an essential ingredient in preserving semi-orthogonality.

The reader will see the difficulty in making an a priori choice of blocksize. The advantages and disadvantages of the block algorithm are clearly demonstrated, but we see no optimal choice for blocksize. A choice of three is always good on these problems on our Sun workstation, but is likely to be less than optimal for a vibration problem with six rigid body modes. Systems that impose higher costs for i/o will make higher blocksizes more effective, particularly when the problems are large enough that the factored matrices must reside on secondary storage.

These issues should be kept in the perspective of the power of the spectral transformation. None of the problems described here is solvable in any practical sense using the naive reduction to standard form. For example, the oceanography problem, PLAT1919, was analyzed in [5], [23] without any transformation—the desired eigenvalues were not close to appearing after N steps. (In unreported experiments, $3N$ steps had resulted in little improvement.) Although it is possible to solve some of the simpler problems by inverting the problem, as in (2), this is clearly not sufficient for all of the problems. The oceanography problem, PLAT1919, is singular, so some nontrivial shift is required. Even with a shift at the lower endpoint, .000025, a single Lanczos run to compute the lowest 200 eigenvalues above this point had a cost of 5382 for blocksize 3. In contrast, our standard shifted code with the same blocksize had a cost of 696 for computing *all* 636 desired eigenvalues. The Columbia Center model has the same characteristics. The naive reduction would result in a problem with separations of 10^{-13} for the "well-separated" eigenvalues; the simple reciprocal transformation would be clearly inadequate to begin to solve this problem. It is only with the combined power of the block Lanczos algorithm and the spectral transformation that we can solve these problems in a reasonable amount of time.

A. Matrix inertias. We need to interpret the number of negative eigenvalues of $K - \sigma M$ and $K - \sigma K_\delta$ in terms of the eigenvalues of the original vibration or buckling problems. The result we want to prove follows in Table 18. We use this result to conclude that

$$\nu(K - \sigma_2 M) - \nu(K - \sigma_1 M) = \text{number of eigenvalues in } (\sigma_1, \sigma_2),$$

where we assume that $\sigma_2 > \sigma_1$. In the case of buckling analyses we further assume that both σ_1 and σ_2 have the same sign.

TABLE 18
Interpretation of $\nu(K - \sigma M)$ *or* $\nu(K - \sigma K_\delta)$.

Vibration analysis:	
M positive definite	# of eigenvalues $< \sigma$
M positive semidefinite	(# of eigenvalues $< \sigma$) $+ \gamma$
	$\gamma = \begin{cases} 0 & \text{some cases} \\ \dim(\mathcal{N}(M)) & \text{other cases} \end{cases}$
Buckling analysis:	
K positive definite	# of eigenvalues in $(0, \sigma)$ or $(\sigma, 0)$
K positive semidefinite	(# of eigenvalues in $(0, \sigma)$ or $(\sigma, 0)$) $+ \gamma$
	$\gamma = \begin{cases} 0 & \sigma \text{ of one sign} \\ \dim(\mathcal{N}(K)) & \sigma \text{ of other sign} \end{cases}$

There are four cases, which will be considered in pairs. In all cases we assume that the problem is a definite generalized symmetric eigenproblem, i.e., that there exists some linear combination $\alpha K + \beta M$ that is positive definite.

A.1. $Kx = \lambda Mx$ **with** M **positive definite.** We can apply the obvious reduction to standard form. The eigenvalues of $Kx = \lambda Mx$ are the same as the eigenvalues of $C = L_M^{-1} K L_M^{-T}$, where L_M is the Cholesky factor of M. It follows that the number of eigenvalues of C less than σ is the same as the number of eigenvalues of $Kx = \lambda Mx$ less than σ. But $C - \sigma I$ is congruent to $L_M(C - \sigma I)L_M^T$ and this is simply $K - \sigma M$. Thus, the decomposition of $K - \sigma M$ gives the number of eigenvalues less than σ. Obviously, the interpretation of the inertia has the same meaning here as in the ordinary eigenvalue problem.

A.2. $Kx = \lambda Mx$ **with** M **positive semidefinite.** Signs must be assigned to the infinite eigenvalues when M is singular. Assume that M is positive semidefinite, with p zero eigenvalues. Then there exists a nonsingular matrix W so that WMW^T is the two-by-two block-partitioned matrix

$$WMW^T = \begin{pmatrix} 0 & 0 \\ 0 & I \end{pmatrix},$$

where I is an $(n-p) \times (n-p)$ identity matrix. Partition $WKW^T = C$ conformally as

$$WKW^T = \begin{pmatrix} C_{11} & C_{21}^T \\ C_{21} & C_{22} \end{pmatrix}.$$

Some linear combination $\alpha K + \beta M$ is positive definite, from which it follows that $\alpha(WKW^T) + \beta(WMW^T)$ is positive definite. But a positive definite matrix has positive definite principal minors, which implies that αC_{11} is positive definite. Let y satisfy $(WKW^T)y = \lambda(WMW^T)y$ and partition y conformally as $[y_1, y_2]^T$. Then

$$C_{11}y_1 + C_{21}^T y_2 = 0 \tag{31}$$

and

$$C_{21}y_1 + C_{22}y_2 = \lambda y_2. \tag{32}$$

Equation (31) then implies that

$$y_1 = -C_{11}^{-1} C_{21}^T y_2.$$

Substituting in (32), we obtain

$$(C_{22} - C_{21} C_{11}^{-1} C_{21}^T) y_2 = \lambda y_2.$$

Thus, the finite eigenvalues of $Kx = \lambda Mx$ are the eigenvalues of the Schur complement of C_{11} in C.

By Sylvester's theorem the inertia of $(K - \sigma M)$ is the same as the inertia of $WKW^T - \sigma WMW^T$. But the partitioned form of the LDL^T decomposition of $WKW^T - \sigma WMW^T$ has as its (1,1) block the decomposition of C_{11}, and as its (2,2) block the decomposition of $(C_{22} - C_{21}C_{11}^{-1}C_{21}^T) - \sigma I$. The inertia for the entire matrix is offset by the inertia of the (1,1) block. The offset is constant—it describes the sign given to the infinite eigenvalues. That all of the infinite eigenvalues have the same sign is due to the fact that a positive definite linear combination of K and M exists, that is, that the problem is a definite generalized symmetric eigenproblem [13]. The difference between $\nu(K - \sigma_1 M)$ and $\nu(K - \sigma_2 M)$ will still be the number of eigenvalues in $[\sigma_1, \sigma_2)$, since the constant term cancels.

Furthermore, in vibration analysis, we know that both K and M are positive semidefinite. It follows that both α and β will be positive when M is only semidefinite. The positive semidefiniteness of K then implies that C_{11} is a positive definite matrix, so $\nu(C_{11}) = 0$. Thus, the inertia of the factored matrix retains exactly the same meaning for the positive semidefinite vibration case as for the positive definite case.

A.3. $Kx = \lambda K_\delta x$ **with** K **positive definite.** In buckling analysis, only K has any definiteness properties. We can invert the problem when K is positive definite. Thus

$$Kx = \lambda K_\delta x$$

implies

$$K_\delta x = \frac{1}{\lambda} Kx = \mu Kx,$$

and all the eigenvalues μ in the second equation are finite. This transformed problem is in the standard (K_δ, K) form in which the right-hand side matrix, K, is positive definite. We will determine the number of eigenvalues of (K_δ, K) that lie in the image of the interval of interest in the original problem. Thus, to determine the number of eigenvalues of $Kx = \lambda K_\delta x$ less than σ, we find the number of eigenvalues of the inverted problem (K_δ, K) in the interval(s) in the variable $\mu = \frac{1}{\lambda}$ that corresponds to the interval $(-\infty, \sigma)$ in the variable λ.

There are three subcases that must be considered. The first is the case $\sigma = 0$. The interval $(-\infty, 0)$ for λ is mapped to the interval $(-\infty, 0)$ in $\frac{1}{\lambda}$. Thus, the number of negative eigenvalues of $Kx = \lambda K_\delta x$ is the same as the number of eigenvalues of (K_δ, K) less than 0. This is simply the number of negative eigenvalues of $K_\delta, \nu(K_\delta)$.

The second case is the case $\sigma < 0$. The transformation from λ to $\frac{1}{\lambda}$ transforms σ to $\frac{1}{\sigma}$. The number of eigenvalues in $(-\infty, \sigma)$ is the same as the number of eigenvalues of (K_δ, K) in the interval $(\frac{1}{\sigma}, 0)$. This is

$$\nu(K_\delta) - \nu\left(K_\delta - \frac{1}{\sigma} K\right),$$

which, because σ is negative, is the same as

$$\nu(K_\delta) - \nu(K - \sigma K_\delta).$$

Note that the number of eigenvalues between σ and 0 is simply $\nu(K - \sigma K_\delta)$.

The third case is $\sigma > 0$. In this case, the interval $(-\infty, \sigma)$ in λ must be treated as the union of the interval $(-\infty, 0)$ and the interval $[0, \sigma)$. There are $\nu(K_\delta)$ eigenvalues in the first subinterval. The second subinterval is transformed into $(\frac{1}{\sigma}, +\infty)$. The union has

$$\nu(K_\delta) + \pi\left(K_\delta - \frac{1}{\sigma}K\right)$$

or

$$\nu(K_\delta) + \nu(K - \sigma K_\delta)$$

eigenvalues. Even in this case $\nu(K - \sigma K_\delta)$ is the number of eigenvalues between 0 and σ.

The buckling problem will have infinite eigenvalues if K_δ is singular. However, the signs of these eigenvalues are irrelevant to the interpretation of the inertias because the interpretation always considers only finite subintervals.

A.4. $Kx = \lambda K_\delta x$ **with** K **positive semidefinite.** The most general case we consider is a buckling analysis in which K is only positive semidefinite. We combine the analysis for the semidefinite vibration case with the positive definite buckling case to assign signs to the zero eigenvalues.

We assume K is semidefinite, with P zero eigenvalues. As before, there exists a nonsingular matrix $\widehat{W}$ such that

$$\widehat{W}K\widehat{W}^T = \begin{pmatrix} 0 & 0 \\ 0 & I \end{pmatrix}.$$

Partition $\widehat{W}K_\delta\widehat{W}^T = E$ conformally as

$$\begin{pmatrix} E_{11} & E_{21}^T \\ E_{21} & E_{22} \end{pmatrix}.$$

The eigenvalues of $KX = K_\delta X\Lambda$ are those of $\widehat{W}K\widehat{W}^TY = \widehat{W}K_\delta\widehat{W}^TY\Lambda$. Let y be an eigenvector, partitioned conformally as $[y_1, y_2]^T$. Then

$$E_{11}y_1 + E_{21}^Ty_2 = 0 \tag{33}$$

and

$$\lambda(E_{21}y_1 + E_{22})y_2 = y_2.$$

As before the (1,1) block of the transformed linear combination, βE_{11}, is a positive definite matrix. Equation (33) then implies that

$$y_1 = -E_{11}^{-1}E_{21}^Ty_2,$$

or

$$\lambda(E_{22} - E_{21}E_{11}^{-1}E_{21}^T)y_2 = y_2.$$

Thus, the finite, nonzero eigenvalues of $Kx = \lambda K_\delta x$ are the reciprocals of the nonzero eigenvalues of the Schur complement of E_{11} in E.

The partitioned form of the LDL^T decomposition of $\widehat{W}K\widehat{W}^T - \sigma\widehat{W}K_\delta\widehat{W}^T$ has as its (1,1) block the decomposition of $-\sigma E_{11}$, and as its (2,2) block the decomposition of $I - \sigma(E_{22} - E_{21}E_{11}^{-1}E_{21}^T)$. The Schur complement block is in the form of §A.3, taking the identity matrix as M. Again, the inertia of the full matrix is the inertia of $I - \sigma(E_{22} - E_{21}E_{11}^{-1}E_{21}^T)$ offset by the inertia of the (1,1) block. Notice that the offset depends on the sign of the shift—it describes the signs of the eigenvalues of $-\sigma E_{11}$. Because E_{11} is definite, either all the eigenvalues of $-\sigma E_{11}$ are positive or all are negative. Thus, the offset will be zero for shifts of one sign and nonzero for shifts of the other sign. Still, the difference between $\nu(K - \sigma_1 K_\delta)$ and $\nu(K - \sigma_2 K_\delta)$ will still be the number of eigenvalues in $[\sigma_1, \sigma_2)$, as long as both shifts have the same sign. The dimension of the nullspace of K, $\nu(E_{11})$, is often known adventitiously; if not, it can be estimated by factoring $K - \rho I$, where ρ is chosen smaller than the least nonzero eigenvalue of K, but large enough so that the factorization is stable.

Acknowledgments. The authors would like to thank David Scott for his participation in the initial design of this code and Thomas Ericsson and Bahram Nour-Omid for many enlightening discussions during the preparation of this code. We particularly thank Beresford Parlett for his interest and intellectual support, which led to important changes, even after we thought our work was done. We also are grateful to Louis Komzsik and The MacNeal–Schwendler Corporation for their support of this work. Finally, Linda Kaufman provided a fine example of careful and thorough editing.

FACTORING SYMMETRIC INDEFINITE MATRICES ON HIGH-PERFORMANCE ARCHITECTURES*

MARK T. JONES† AND MERRELL L. PATRICK‡

Abstract. The Bunch–Kaufman algorithm is the method of choice for factoring symmetric indefinite matrices in many applications. However, the Bunch–Kaufman algorithm uses matrix-vector operations and, therefore, may not take full advantage of high-performance architectures with a memory hierarchy. It is possible to modify the Bunch–Kaufman algorithm so that it uses rank-k updates. However, this straightforward modification allows unrestricted row/column interchanges during the algorithm, thus making it unsuitable for banded and sparse matrix factorization. A new algorithm, based on Bunch–Kaufman factorization, is described that uses rank-k updates to take advantage of high-performance architectures while limiting the number of row/column interchanges. Results from implementations on the CRAY Y-MP and the Alliant FX/8 are presented.

Key words. Bunch–Kaufman factorization algorithm, symmetric indefinite matrices, block algorithms

AMS subject classification. 65F05

1. Introduction.

The Bunch–Kaufman algorithm is considered to be one of the best stable methods for factoring full, symmetric, indefinite matrices [3], [4]. A modified version has been successfully used to factor sparse, indefinite matrices [7]. Recently, Bunch–Kaufman factorization has been shown to be the method of choice for a subset of banded, symmetric indefinite matrices [11]. The Bunch–Kaufman algorithm maintains the symmetry of the matrix during factorization and yields the inertia of the matrix essentially for free, an important consideration for eigenvalue calculations [9].

Much of the recent work in numerical linear algebra has focused on constructing algorithms appropriate for execution on high-performance architectures. Many of these algorithms utilize matrix-matrix operations to exploit the memory hierarchies used in many high-performance architectures [8]. The Bunch–Kaufman algorithm, as formulated in [4], uses matrix-vector operations. For dense matrices, the ratio

$$\frac{\textit{floating point operations}}{\textit{memory references}} \tag{1}$$

is often higher for algorithms that rely on matrix-matrix operations rather than for those that rely on matrix-vector operations. As a result, algorithms that use matrix-matrix operations can better exploit memory hierarchies. For sparse matrix factorization, it has been shown that by using matrix-matrix operations, the ratio

$$\frac{\textit{floating point operations}}{\textit{memory references and other overhead}} \tag{2}$$

is much smaller than when matrix-vector operations are used and that excellent performance can be achieved on a vector processor [2].

In the LAPACK project a simple modification to the Bunch–Kaufman algorithm allows the use of matrix-matrix operations [1]. However, this algorithm may require up to $n-1$ row/column interchanges during the algorithm. This could result in a large amount of fill-in during banded or sparse factorization.

Version D of the Bunch–Kaufman algorithm,[1] however, can be implemented such that the number of row/column interchanges is bounded by the number of negative eigenvalues [4].[2] We shall give a modification to version D that uses rank-k updates while maintaining the bound on the number of row/column interchanges. This algorithm could be used to factor banded or sparse matrices for which the number of negative eigenvalues is small relative to n.

Block algorithms are briefly discussed in §2. In §3, one of several variations of the Bunch–Kaufman algorithm is reviewed. We describe a new algorithm that uses rank-k updates while minimizing the number of row/column interchanges in §4. Results from implementations of the algorithm are given in §5. Finally, a summary is given in §6.

2. Block algorithms. Linear algebra kernel computations can be placed in three categories: (1) vector operations, e.g., vector inner product; (2) matrix-vector operations, e.g., multiplication of a matrix by a vector; and (3) matrix-matrix operations, e.g., rank-p update of a matrix. These three categories correspond to the three linear algebra subroutine collections: Level 1 BLAS, Level 2 BLAS, and Level 3 BLAS [5], [6], [15]. The computation rates that can be achieved on high-performance architectures are higher for the higher-level BLAS. Two benefits of matrix-matrix operations are (1) better use of the memory hierarchy via the reuse of data in closer, fast memory, and (2) increased flexibility in the way the computation can be structured, allowing for more efficient use of computational units. For example, on the CRAY Y-MP, a register-to-register machine with independent segmented computational units capable of being chained together, the use of matrix-matrix operations allows an increased ability to reuse data that have been loaded into the vector registers and an increased ability to structure the computations to enable maximum chaining between computational units and thus achieve better parallelism among the computational units.

As an example, consider the LDL^T decomposition of a symmetric positive definite full matrix. In the outer product version of LDL^T decomposition given in Fig. 1, the computation of a single pivot column in the loop in steps 2–5 is a vector operation, and the updating of the remaining submatrix in the nested loops in steps 6–10 is a matrix-vector operation. Because each iteration of the outer loop depends on results of previous iterations, if we wish to change the algorithm to use matrix-matrix operations, we must restructure it as a block algorithm [8]. Instead of computing a single pivot column, we compute a block of pivot columns and use this block to update the remaining submatrix. Such an algorithm is given in Fig. 2, where the block size is p. The block pivots are computed by using matrix-matrix operations involving $p \times p$ and $p \times (n-ip)$ matrices. The updating of the remaining submatrix is accomplished with matrix-matrix operations involving $p \times (n-ip)$ and $(n-ip) \times (n-ip)$ matrices.

[1] Four variants, A–D, of the Bunch–Kaufman algorithm were presented in [4].

[2] In many applications, the number of negative eigenvalues is much less than the order of the matrix.

```
1)      DO I = 1, N
    C       Solve for the pivot column
2)          DO J = I + 1, N
3)              V(J) = A(J, I)
4)              A(J, I) = A(J, I)/A(I, I)
5)          ENDDO
    C       Use the pivot column to update the remaining submatrix
6)          DO J = I + 1, N
7)              DO K = J, N
8)                  A(J, K) = A(J, K) − V(K) * A(J, I)
9)              ENDDO
10)         ENDDO
11)     ENDDO
```

FIG. 1. *The LDL^T algorithm.*

```
    C   Code assumes that N is divisible by p
1)      DO I = 1, N, p
    C       A_{i,i} is the ith p × p diagonal block of A
2)          Factor: A_{i,i} = L_{i,i} D_{i,i} L_{i,i}^T and store into A_{i,i}
    C       V_i is a (n − ip) × p matrix
    C       A_{i,2} is the (n − ip) × p matrix beneath A_{i,i}
3)          Solve: L_{i,i} V_i^T = A_{i,2}^T, D_{i,i} Â_{i,2}^T = V_i^T
    C       A_{2,2} is the (n − ip) × (n − ip) matrix in the bottom right corner of A
4)          Update: A_{2,2} = A_{2,2} − Â_{i,2} V_i^T
5)      ENDDO
```

FIG. 2. *The block LDL^T algorithm.*

The partitioning of A at Step i of the block algorithm is given in Fig. 3. Such a restructuring is what we desire for the Bunch–Kaufman algorithm.

3. The Bunch–Kaufman algorithm. The Bunch–Kaufman algorithm factors A, an $n \times n$ real symmetric indefinite matrix, into MDM^T while doing symmetric permutations on A to maintain stability, resulting in

$$PAP^T = MDM^T, \tag{3}$$

where P is a permutation matrix, M is a lower triangular matrix and D is a symmetric block diagonal matrix where the blocks are 1×1 or 2×2. Although several variations of the algorithm exist, the focus here is on Algorithm D from [4] because it is the one for which the number of row/column interchanges is restricted.

The Bunch–Kaufman algorithm maintains stability by using a 2×2 pivot combined with a symmetric permutation on A if a 1×1 pivot is not stable. Because this paper will focus on 1×1 pivots, only stability for these pivots will be discussed in detail. A 1×1 pivot operation for element $a_{i,j}$ at step k takes the form

$$a_{i,j} = a_{i,j} - \frac{a_{i,k} a_{j,k}}{a_{k,k}}. \tag{4}$$

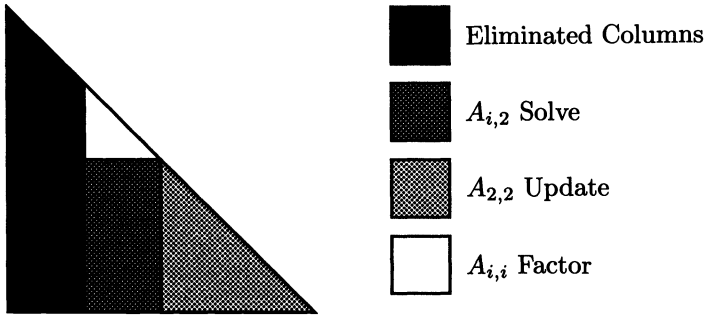

FIG. 3. *Partitioning of A at step i.*

Let μ_k be the maximum of the absolute values of the uneliminated elements at step k. Step 2 of the algorithm, shown in Fig. 4, finds the maximum element, λ_k, in the pivot column. By substituting μ_k and λ_k into (4), the bound on μ_{k+1} becomes

$$\mu_{k+1} \leq \mu_k + \frac{\lambda_k^2}{|\, a_{k,k} \,|} \leq \mu_k \left(1 + \frac{\lambda_k}{|\, a_{k,k} \,|}\right). \tag{5}$$

Step 4 ensures that a 1×1 pivot operation occurs if $\alpha < \frac{|a_{i,i}|}{\lambda_k}$, where the parameter α has been chosen to be 0.525 to maximize stability for Algorithm D [4]. By substituting α into (5),

$$\mu_{k+1} \leq \mu_k \left(1 + \frac{1}{\alpha}\right). \tag{6}$$

Therefore, the bound on the growth of an element resulting from a 1×1 pivot is 2.905.

If the test in step 4 fails, then a subsequent row search and another stability test determines whether a 2×2 pivot and a permutation are necessary. The stability checks and possible permutation at each step of the Bunch–Kaufman algorithm prevent the use of the same straightforward blocking that was used for LDL^T decomposition. Because the stability checks and permutation must be completed before a pivot column is computed, pivot columns cannot be grouped as they were in Fig. 2 without invalidating the bounds on element growth. In the 1×1 pivot case, solving for the pivot columns is a vector operation, and updating the remaining submatrix is a rank-1 update. The situation is slightly better for the 2×2 case for which solving for the two pivot columns is a matrix-matrix operation where the dimensions of the matrices are 2×2 and $2 \times (n - i - 1)$. Updating the remaining submatrix is a rank-2 update.

Two approaches have been taken to implement the Bunch–Kaufman algorithm on high-performance architectures. Kaufman has implemented Algorithm B, an inner-product formulation that uses matrix-vector products, and found that it performs much better than the outer-product formulations on machines like the Alliant and Convex but not on the CRAY X-MP [14]. The inner-product formulation works on rectangular matrices rather than triangular matrices; this is a significant advantage on the Alliant and Convex. Algorithm B, however, has unrestricted row/column interchanges and is, therefore, as formulated, not suitable for band or sparse matrices.

```
1)    DO k = 1, n
2)        λ_k = max_{j=k+1,n} | a_{j,k} |
3)        set r to the row number of λ_k
4)        IF λ_k α <| a_{k,k} | THEN
5)            perform a 1 × 1 pivot operation
6)        ELSE
7)            σ = max_{j=k+1,n} | a_{r,j} |
8)            IF α λ_k^2 < σ | a_{k,k} | THEN
9)                perform a 1 × 1 pivot operation
10)           ELSE
11)               exchange rows and columns r and k + 1
12)               perform a 2 × 2 pivot operation
13)               k = k + 1
14)           ENDIF
15)       ENDIF
16)   ENDDO
```

FIG. 4. *The Bunch–Kaufman factorization Algorithm D.*

In the LAPACK project, the Bunch–Kaufman algorithm has been restructured so that matrix-matrix operations can be used.[3] The LAPACK block algorithm, an outline of which is given in Fig. 5, requires a row/column interchange at every step and is therefore not suitable for band or sparse matrices. The LAPACK implementation allows a specific block size, p, to be specified. The LAPACK implementation requires a scratch space of size $n \times p$, however, if one is willing to slightly degrade performance, it is possible to implement the algorithm with a scratch space of $p \times p + 2n$ [14].

To compare the structural damage that occurs during factorization of a banded matrix when the LAPACK block algorithm and version D of the Bunch–Kaufman algorithm are used, we factored a 256×256 matrix with a semi-bandwidth of 50. The structure of the resulting factors is shown in Fig. 6.

An alternative to using the Bunch–Kaufman algorithm for symmetric banded matrices is to use LU factorization and ignore the symmetry of the matrix. Ignoring the symmetry can cost up to mn, where m is the semi-bandwidth, storage locations, and increase the operation count by a factor of 4. In addition, the inertia of the matrix cannot be determined by using LU factorization, making this an unacceptable choice for some applications. These disadvantages make LU factorization a poor choice for the factorization of symmetric indefinite matrices with a small number of negative eigenvalues.

4. New algorithm. In this section, a modification to the Bunch–Kaufman algorithm is developed that allows pivot columns to be put into a block without row/column interchanges and without updating each column as it is put into the block. The algorithm described in this section[4] is a variant of Algorithm D from [4], and therefore the number of row/column interchanges is bounded by the number of negative eigenvalues of the matrix being factored. Unlike the LAPACK block algorithm, the block sizes vary throughout the execution of the algorithm. The general

[3] The algorithm and code referenced in this paper are from preliminary release 2 of LAPACK.

[4] The authors give three other block algorithms in [10] and have determined that the algorithm described here is the most practical.

```
1)   DO k = 1, n
2)       bs = 0
3)       WHILE bs ≤ p and k + bs ≤ n DO
4)           Update column k + bs using the previous bs columns
5)           Find the largest element in column k + bs, i.e., row r
6)           IF stability tests dictate THEN
7)               Copy row/column r into a work vector
8)               Update this work vector using the previous bs columns
9)               IF stability tests dictate THEN
10)                  ignore this work vector
11)              ELSE IF further tests dictate THEN
12)                  copy this work vector into A as a 1 × 1 pivot
13)              ELSE
14)                  combine column k + bs and the work vector into a 2 × 2 pivot
15)              ENDIF
16)          ENDIF
17)          Increment bs by 1 or 2 (depending on the pivot step)
18)      ENDWHILE
19)      update the remaining submatrix using the block pivot
20)      increment k by bs
21)  ENDDO
```

FIG. 5. *The Bunch–Kaufman block variant in* LAPACK.

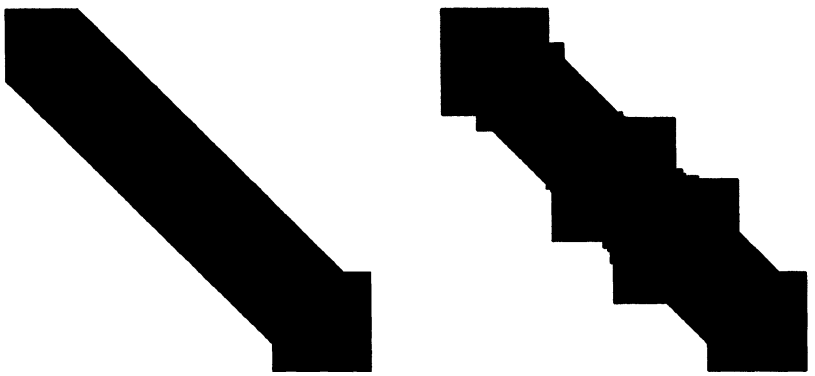

FIG. 6. *Structure of factored matrix for version D and* LAPACK *algorithms.*

strategy is to try to group several 1×1 pivots into a single step in a stable fashion. Because 2×2 pivots involve a permutation of A, they are not candidates for inclusion in a block.

The new algorithm uses an a priori error bound approach to maintain stability. The algorithm computes a bound on the maximum element growth if the next p columns are grouped into a pivot block. The bound is computed *without* actually computing the pivot block or performing any row/column interchanges. If the computed bound is small enough, then the p columns can be used as a pivot block. The

bound can be computed incrementally; if the bound is computed for p columns, then computing it for $p+1$ columns is cheap.

From (6), for p successive 1×1 pivots to maintain stability, the maximum element growth must be bounded by

$$\left(1+\frac{1}{\alpha}\right)^p. \tag{7}$$

We have from (5) that the growth for a 1×1 pivot at step k is

$$\mu_{k+1} \le \mu_k \left(1+\frac{\lambda_k}{|\,a_{k,k}\,|}\right). \tag{8}$$

Therefore, if one had a bound for μ_{k+1} and λ_{k+1}, and knew what $a_{k+1,k+1}$ was, then a bound for μ_{k+2} could be computed.

By factoring the 2×2 diagonal block, denoted $A_{i,i}$ in Fig. 3, $a_{k,k}$ and $a_{k+1,k}$ can be computed. The bound on λ_{k+1}, denoted $\hat{\lambda}_{k+1}$, after a 1×1 pivot at step k, is

$$\hat{\lambda}_{k+1} \le \lambda_{k+1} + \frac{\lambda_k a_{k+1,k}}{a_{k,k}}. \tag{9}$$

The bound on element growth for two columns becomes

$$\mu_{k+2} \le \mu_{k+1}\left(1+\frac{\hat{\lambda}_{k+1}}{a_{k+1,k+1}}\right). \tag{10}$$

To compute an element growth bound for p columns, one must factor the $p\times p$ submatrix, $A_{i,i}$, and search each of the p columns for its largest element. The new algorithm is given in Fig. 7.

The algorithm uses matrix-matrix operations for the computation of the pivot columns and the updating of the remaining submatrix. Like the LAPACK block algorithm implementation, our implementation currently requires $n\times p$ scratch space. However, the same technique used in [14] could be used here to reduce the scratch space. Also, it is possible to search for the λ values of several columns simultaneously. However, if the growth bound becomes large before all the λ's are examined, then some of the searches could be wasted. It is also possible to continue the combination of pivot columns (steps 5–14) beyond the step in which the growth bound becomes too large, in the hope that it will become acceptable again at a future step.

5. Results.

5.1. Uniprocessor implementation. A version of the algorithm described in §4 suitable for matrices with a variable bandwidth was implemented on a CRAY Y-MP. This implementation allows block sizes of up to 5. The matrix-matrix operations are implemented by using loop unrolling, because the structure of the matrices the authors are interested in do not allow for the efficient use of higher-level BLAS. When the maximum block size is fixed at 1, this implementation is identical to the Bunch–Kaufman algorithm.

The CRAY Y-MP is a register-to-register parallel/vector computer with up to eight processors. Each processor has independent, segmented functional units. To demonstrate the benefits of the new algorithm on the CRAY Y-MP, we factored three

```
1)  DO k = 1, n
2)      bs = 0
3)      μ = 1.0
4)      max_growth = 1.0
5)      WHILE (bs ≤ p_max) and (μ ≤ max_growth) DO
6)          Update the factor of the diagonal block A_{k,k}
7)          λ_{k+bs} = max_{j=k+bs+1,n} | a_{j,k+bs} |
8)          DO i = 0, bs − 1
9)              λ_{k+bs} = λ_{k+bs} + λ_i | a_{k+bs,k+i} |
10)         ENDDO
11)         μ = μ(1.0 + λ_{k+bs} / |a_{k+bs,k+bs}|)
12)         max_growth = max_growth(1 + 1/α)
13)         IF (μ ≤ max_growth) THEN bs = bs + 1
14)     ENDWHILE
15)     IF (bs = 0) THEN
16)         σ = max_{j=k+1,n} | a_{j,k} |
17)         depending on σ and λ_k perform a 1 × 1 or 2 × 2 pivot operation
18)         k = k + 1 or k = k + 2
19)     ELSE
20)         Solve for the pivot block using the factored A_{k,k}
21)         Updating the remaining submatrix using the pivot block
22)         k = k + bs
23)     ENDIF
24) ENDDO
```

indefinite matrices that arise from an application in structural engineering.[5] Each matrix has ten negative eigenvalues. Results from these computations showing a significant reduction in factorization time as the block size increases, are plotted in Fig. 8. The average block size used during each factorization was very close to the maximum block size specified.

5.2. Multiprocessor implementation. The algorithm in §4 also provides benefits for parallel implementation. The major benefit is a reduction in the number of synchronizations that are necessary because of the use of block operations.

The variable band matrix factorization implementation described in the preceding subsection was explicitly parallelized using the Force [13], a Fortran-based parallel programming language that has been shown to be useful for implementing parallel linear algebra algorithms [12]. The primary source of parallelism is the updating of the reduced matrix. The implementation was run on a four-processor CRAY Y-MP for block sizes 1–5. An examination of the results in Table 1 show that good speedup is maintained as the maximum block size increases for a matrix of order 12,054 and an average semi-bandwidth of 328. At the same time, the new algorithm achieves increased computational efficiency; reduction in the computation time is offset by the reduction in the amount of synchronization needed.

[5] The matrix being factored was actually the difference of two matrices, K and M. The factorization times reported include the cost of computing $K - \sigma M$.

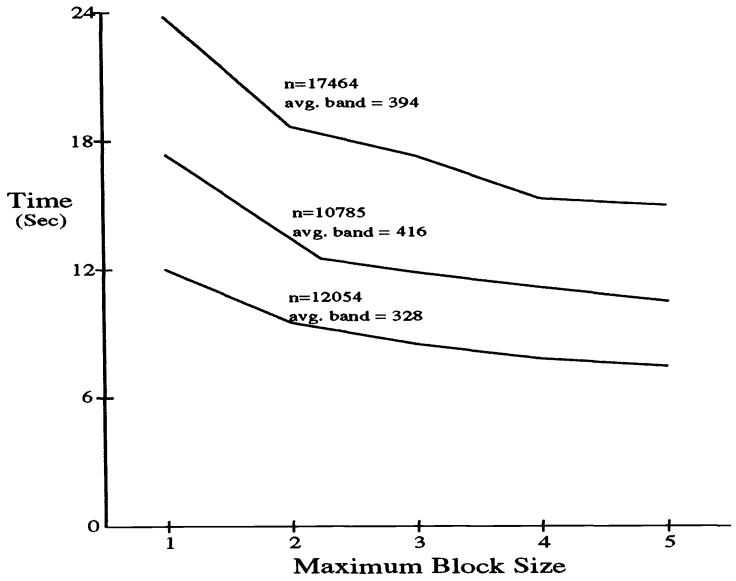

FIG. 8. *Uniprocessor factorization times on the* CRAY Y-MP.

4	6.70	3.54	2.46	1.92
5	6.54	3.45	2.39	1.87

5.3. Comparison with other methods. The algorithm presented in this paper is designed for factoring matrices with some structure that must be preserved, but it can, of course, be used to factor full, dense matrices. A comparison with other variants of the Bunch–Kaufman algorithm for factoring full, dense matrices is, therefore, of interest. Such a comparison will give some idea of how much more expensive this algorithm is than an algorithm that can specify the same block size every step, such as the LAPACK version, or how much better the block algorithms can do than algorithms that utilize matrix-vector operations only.

Four codes were used in the comparison: (1) an outer product variant using Level 2 BLAS from LAPACK, (2) the Level 3 BLAS variant from LAPACK described in §3, (3) the inner product variant using Level 2 BLAS described in §3, and (4) the Level 3 BLAS algorithm described in §4. The codes were run in double precision using eight processors on an Alliant FX/8 and compiled[6] using the Alliant Fortran compiler with optimization flags "-O -DAS -alt." Matrices of size 512 and 2,048 were used with 10 and 20 negative eigenvalues, respectively. The block size for the LAPACK Level 3 BLAS code was varied from 32 to 128, and the maximum block

[6] Optimized versions of the BLAS provided by Alliant were used.

size for the new algorithm was varied over the same range. The performance results are given in Table 2. In the "Block Size" column the numbers in parentheses for the new method are the average block size used. From the results, we can see that for realistic block sizes: (1) the LAPACK block algorithm has a slight edge over the new block algorithm, (2) the inner-product algorithm is slightly slower than the block algorithms, and (3) the Level 2 BLAS LAPACK algorithm is much worse than the other algorithms. Another interesting aspect of these results is that for very small block sizes, the LAPACK block algorithm performs very poorly. However, one should note that the LAPACK block algorithm will default to the unblocked algorithm if the unblocked algorithm will be faster. In Table 3, we give the norms of the residuals for each of the experiments in Table 2. We see that, as we might expect, the new block algorithm has a slightly larger residual than the other methods because of its somewhat relaxed stability test. At a sacrifice of some speed[7] the accuracy can be made comparable to that of the other algorithms by requiring the growth factor at each individual pivot to be less than $(1 + \frac{1}{\alpha})$ rather than requiring the growth factor of p pivots to be bounded by $(1 + \frac{1}{\alpha})^p$.

6. Summary. A block algorithm, based on the Bunch–Kaufman algorithm, suitable for factoring symmetric indefinite matrices on high-performance architectures was given. The algorithm, unlike other high-performance variants of Bunch–Kaufman factorization, limits the number of row/column interchanges to the number of negative

[7] In experiments on the Alliant, we found increases in execution time of approximately 10%.

eigenvalues in the matrix. Therefore, this algorithm does not destroy, to a large extent, the structure of a matrix and can be used for factoring banded or sparse matrices. The block algorithm was shown to be faster than its nonblocked counterpart for factoring banded matrices on a multivector computer. It was also shown to be only slightly more expensive than the block algorithm used in LAPACK for factoring indefinite dense matrices.

Acknowledgments. We thank Linda Kaufman for her many helpful comments and for the use of her factorization code. We thank Chris Bischof for comments that led to improvements of the paper. Finally, we thank the staff of the North Carolina Supercomputing Center for providing computer time on the CRAY Y-MP.

COMPUTATION OF STABLE INVARIANT SUBSPACES OF HAMILTONIAN MATRICES*

R. V. PATEL†, Z. LIN†, AND P. MISRA‡

Abstract. This paper addresses some numerical issues that arise in computing a basis for the stable invariant subspace of a Hamiltonian matrix. Such a basis is required in solving the algebraic Riccati equation using the well-known method due to Laub. Two algorithms based on certain properties of Hamiltonian matrices are proposed as viable alternatives to the conventional approach.

Key words. Hamiltonian matrices, eigenvalues, invariant subspaces, algebraic Riccati equation

AMS subject classifications. 65F15, 65H10, 93D15

1. Introduction.

A matrix $Z \in \mathcal{R}^{2n\times 2n}$ is called a Hamiltonian matrix if

$$JZJ^T = -Z^T, \tag{1.1}$$

where

$$J = \begin{bmatrix} O_n & I_n \\ -I_n & O_n \end{bmatrix}. \tag{1.2}$$

In (1.2), I_n denotes the $n\times n$ identity matrix and O_n denotes the $n\times n$ null matrix. In this paper we consider some numerical issues related to the problem of finding a basis for the invariant subspace of a Hamiltonian matrix corresponding to a certain subset of its eigenvalues. Such a problem arises in one of the more commonly used methods [1] for solving the well-known continuous-time algebraic Riccati equation (ARE):

$$\mathbf{CR}(X) \equiv A^TX + XA - XGX + F = O, \tag{1.3}$$

where $A \in \mathcal{R}^{n\times n}$; $G = BB^T \in \mathcal{R}^{n\times n}$ and $F = C^TC \in \mathcal{R}^{n\times n}$ are positive semidefinite matrices. If (A, B) is a stabilizable pair and (A, C) is a detectable pair [2], then (1.3) has a unique positive semidefinite solution $X = X^T \in \mathcal{R}^{n\times n}$, which is a stabilizing solution, i.e., $A - GX$ has all its eigenvalues in the open left half-plane. Numerical solutions of equations of the form (1.3) are required in several control system applications, e.g., the linear quadratic optimal control problem, Kalman filtering, and H^∞ robust control. It is not surprising, therefore, that many methods have been proposed for solving the ARE, e.g., see [3], [4] for an extensive bibliography. In this paper, we

shall concentrate on one of the more reliable and elegant methods for solving (1.3). The Hamiltonian matrix corresponding to (1.3) is given by

$$Z = \begin{bmatrix} A & G \\ F & -A^T \end{bmatrix}.$$

The method proposed by Laub [1] is based on the following results concerning the matrix Z:

(a) If $\lambda \in C$ is an eigenvalue of Z, then so is $-\lambda$.

(b) A symmetric matrix X is the desired stabilizing solution of (1.3) if and only if $X = -U_{21}U_{11}^{-1}$, where the columns of $[U_{11}^T \quad U_{21}^T]^T$ span the n-dimensional invariant subspace of Z corresponding to its stable eigenvalues.

The algorithm proposed by Laub for computing X involves the following steps:

Algorithm I

Step 1. Reduce Z to a real Schur form[1] (RSF), $\hat{R} \in \mathcal{R}^{2n\times 2n}$. Accumulate the orthogonal transformations in a matrix $\hat{U} \in \mathcal{R}^{2n\times 2n}$, i.e.,

$$\hat{R} = \hat{U}^T Z \hat{U}. \tag{1.4}$$

Comment: This step can be performed by first reducing Z to upper Hessenberg form and then using the QR Algorithm [5]. The reduction to upper Hessenberg form requires approximately $\frac{5}{3}(2n)^3$ flops (floating point operations) and the reduction of the resulting upper Hessenberg matrix to an RSF requires approximately $4\kappa(2n)^3$ flops, where κ represents the average number of QR steps required per eigenvalue (≈ 1.5).

Step 2. Rearrange the eigenvalues of $\hat{R}$ so that the n stable eigenvalues are in the top left corner.

Comment: This can be achieved by means of orthogonal transformations on $\hat{R}$ using the subroutines EXCHNG and HQR3 [6] (also note the corrections in [7]) and requires more than $4\kappa(2n)^3$ flops. Let this eigenvalue rearrangement operation be represented by

$$\tilde{R} = \tilde{U}^T \hat{R} \tilde{U}, \tag{1.5}$$

where the orthogonal transformations resulting from using EXCHNG and HQR3 are accumulated in $\tilde{U}$, and the submatrix $\tilde{R}_{11} \in \mathcal{R}^{n\times n}$ is in RSF with all its eigenvalues in the open left half-plane.

Step 3. Set $U = \hat{U}\tilde{U}$ and let

$$U = \begin{bmatrix} U_{11} & U_{12} \\ U_{21} & U_{22} \end{bmatrix}, \text{ where } U_{11}, U_{21} \in \mathcal{R}^{n\times n}.$$

Step 4. Solve $XU_{11} = -U_{21}$ for X.

Comment: This step can be performed using the appropriate subroutines from LINPACK and requires approximately $\frac{4}{3}n^3$ flops.

The above approach (also called the Schur vector approach) can be regarded as a generalization, and a numerically much more robust implementation, of the eigenvector approach of MacFarlane [8]. In the rest of this paper, we concentrate on Steps 1

[1] By a real Schur form, we mean an upper quasi-triangular real matrix with a scalar along the diagonal for each real eigenvalue and a 2×2 block for each pair of complex-conjugate eigenvalues.

and 2, and more specifically on the problem of numerically computing the columns of $[U_{11}^T \quad U_{21}^T]^T$ that span the n-dimensional invariant subspace of Z corresponding to its stable eigenvalues. Our intention is to suggest some ways of improving the efficiency and accuracy of the computations that are required in these steps.

2. Computing the eigenvalues of a Hamiltonian matrix. The method proposed by Laub uses an algorithm for reduction of a general matrix to upper Hessenberg form and the QR Algorithm to find the eigenvalues of Hessenberg matrices. Therefore, it does not take into account the special structure of Z, so that the transformations employed in this algorithm destroy the Hamiltonian structure of Z. On the other hand, if similarity transformations on Z are carried out using symplectic matrices, then its Hamiltonian structure will be preserved. In other words, the matrix $Z_0 = V^{-1}ZV$ will be a Hamiltonian matrix if V is a symplectic matrix. A matrix $V \in \mathcal{R}^{2n\times 2n}$ is symplectic if $V^TJV = J$, where J is defined by (1.2). From the point of view of numerical reduction of Z to a condensed form, such as a block upper triangular form, it is desirable to perform the required transformations using orthogonal symplectic matrices. The following result shows the existence of one such condensed form.

THEOREM 2.1. *If Z has no eigenvalues on the imaginary axis, then there exists an orthogonal symplectic matrix*

$$V = \begin{bmatrix} V_{11} & V_{21} \\ -V_{21} & V_{11} \end{bmatrix} \tag{2.1}$$

with V_{11}, $V_{12} \in \mathcal{R}^{n\times n}$, such that

$$V^TZV = \begin{bmatrix} R & \hat{G} \\ O_n & -R^T \end{bmatrix} \equiv \hat{Z}, \tag{2.2}$$

where $\hat{G} = \hat{G}^T \in \mathcal{R}^{n\times n}$, and $R \in \mathcal{R}^{n\times n}$ is in RSF with eigenvalues in the open left half-plane.

Proof. See [9].

There are two types of orthogonal symplectic matrices that are particularly useful in performing reductions on Hamiltonian matrices. The first type consists of Householder symplectic matrices defined by

$$P(k, \mathbf{u}) = \begin{bmatrix} \hat{P} & O_n \\ O_n & \hat{P} \end{bmatrix}, \quad \hat{P} \in \mathcal{R}^{n\times n}, \tag{2.3}$$

where

$$\hat{P} = I_n - \frac{2\mathbf{u}\mathbf{u}^T}{\mathbf{u}^T\mathbf{u}} \tag{2.4a}$$

and

$$\mathbf{u}^T = [0, \ldots, 0, u_k, \ldots, u_n] \neq \mathbf{0}^T. \tag{2.4b}$$

The second type consists of Givens symplectic matrices defined by

$$J(k, c, s) = \begin{bmatrix} C & S \\ -S & C \end{bmatrix}, \quad C, S \in \mathcal{R}^{n\times n}, \tag{2.5}$$

where

$$C = \text{diag}\{\underbrace{1,\ldots,1}_{k-1}, c, 1, \ldots, 1\},$$
$$S = \text{diag}\{\underbrace{0,\ldots,0}_{k-1}, s, 0, \ldots, 0\}, \tag{2.6}$$

and $c^2 + s^2 = 1$. Algorithms are given in [12] for computing $P(k, \mathbf{u})$ and $J(k, c, s)$ to zero specific entries in a vector.

Theorem 2.1 and its proof in [9] show that it is possible to reduce Z using the structure-preserving orthogonal symplectic transformations to the block upper triangular form (2.2), but no algorithm for doing so is provided. In fact, so far success in developing an *efficient* QR-type algorithm for this reduction has been reported only for a special case [10], [17], namely, when $\text{rank}(G) = 1$ or $\text{rank}(F) = 1$. In this case, Byers has provided an extension of the implicitly shifted QR algorithm that uses orthogonal symplectic transformations. However, because the method is only applicable for a special case, we shall not consider it further in this paper. It suffices to mention that in the algorithm proposed by Byers, a reordering of the eigenvalues is required to ensure that R is a stable matrix. This reordering is performed using EXCHNG and HQR3 to bring an unstable eigenvalue of R to its (n, n)th position followed by a Givens symplectic transformation, $J(n, c, s)$, to interchange the (n, n)th entry of R with that of $-R^T$. Also, it is worth mentioning that reduction of Z to a block triangular condensed form has been achieved in the general case using nonorthogonal symplectic similarity transformations [11]. However, the use of such transformations may cause numerical instability.

An elegant method that uses orthogonal symplectic matrices to "approximate" the eigenvalues of a Hamiltonian matrix has been proposed by Van Loan [12]. The algorithm given in [12] computes the eigenvalues of Z^2, i.e., of

$$M = \begin{bmatrix} M_{11} & M_{12} \\ M_{21} & M_{22} \end{bmatrix} \equiv \begin{bmatrix} A & G \\ F & -A^T \end{bmatrix}^2, \tag{2.7}$$

where

$$M_{11} = A^2 + GF = M_{22}^T, \tag{2.8a}$$

$$M_{12} = AG - GA^T = -M_{12}^T, \tag{2.8b}$$

and

$$M_{21} = FA - A^T F = -M_{21}^T. \tag{2.8c}$$

Note that M_{12} and M_{21} are skew-symmetric matrices. Also, it can be easily shown that the structure of M is preserved under symplectic similarity transformations [12]. Furthermore, if Z has eigenvalues $\{\lambda_1, -\lambda_1, \ldots, \lambda_n, -\lambda_n\}$, then the eigenvalues of M are $\{\lambda_1^2, \lambda_1^2, \ldots, \lambda_n^2, \lambda_n^2\}$. The eigenvalues of Z can, therefore, be easily obtained from those of M. However, it should be noted that the algorithm in [12] does not give us an RSF of Z, nor does it enable us to compute the stable invariant subspace of Z. The eigenvalues of M can be computed using the following steps:

Algorithm II

Step 1. Form $M = \begin{bmatrix} A & G \\ F & -A^T \end{bmatrix}^2$

Step 2. Compute an orthogonal symplectic matrix Q such that

$$Q^T M Q = \begin{bmatrix} H & N \\ O_n & -H^T \end{bmatrix}$$

where H is in upper Hessenberg form (see Algorithm SR in [12]).

Step 3. Compute the eigenvalues of H $(\mu_i, i = 1, \ldots, n)$ using the QR Algorithm.

Step 4. Compute $\lambda_i = \sqrt{\mu_i}, i = 1, \ldots, n$. Set $\lambda_{n+i} = -\lambda_i, i = 1, \ldots, n$.

The symplectic orthogonal matrix Q in Step 2 is a product of symplectic Householder and Givens transformation matrices and is structure-preserving. The complete algorithm for the reduction is given in [12] with implementation details and numerical properties. It suffices to mention here that the algorithm requires approximately $53n^3/3$ flops which is about 25–30% of the computation required by the QR Algorithm applied to Z. Furthermore, if floating point arithmetic with base b and precision t is used, then it can be shown that the computed eigenvalues of Z obtained using Algorithm II are the exact eigenvalues of a matrix $Z + E_s$, where $E_s \in \mathcal{R}^{2n \times 2n}$ satisfies

$$\|E_s\|_2 \approx \sqrt{b^{-t}} \|Z\|_2. \tag{2.9}$$

As a comparison, if the eigenvalues of Z are computed using the QR Algorithm (as is done in [1]), then the computed eigenvalues are the exact eigenvalues of a matrix $Z + E_Q$, where $E_Q \in \mathcal{R}^{2n \times 2n}$ satisfies

$$\|E_Q\|_2 \approx b^{-t} \|Z\|_2. \tag{2.10}$$

This implies that the error in computing the eigenvalues of Z using Algorithm II may be up to $\sqrt{b^t}$ times as large as that using the QR Algorithm. Also, in general, Algorithm II gives better accuracy for eigenvalues with larger magnitudes than those with smaller magnitudes.

The fact that Algorithm II computes the eigenvalues of Z less accurately than the QR Algorithm is not a matter of concern in our application. It is sufficient at this point to know approximately the set of n stable or unstable eigenvalues of Z. More accurate values of these will be obtained and at the same time reordered to get a stabilizing solution of the ARE.

3. Condensed forms for Z with specified eigenvalue ordering. We now consider the problem of reducing Z to condensed forms in which the eigenvalues of Z are separated into sets of stable and unstable eigenvalues, i.e., Z is reduced to a block triangular form

$$Z = \begin{bmatrix} Z_{11} & Z_{12} \\ O_n & Z_{22} \end{bmatrix}, \tag{3.1}$$

where Z_{11} and $Z_{22} \in \mathcal{R}^{n \times n}$ and have only stable and unstable eigenvalues, respectively. In this section, we show how two such condensed forms can be computed. Our approach uses a modification of the QR Algorithm. The algorithms described in this section can be regarded as alternatives to using the EXCHNG and HQR3 subroutines [6]. In this context, it is worth mentioning that since no interchanging of eigenvalues is done in our approach, we avoid the numerical difficulties that may be encountered in attempting to exchange nearly equal eigenvalues using EXCHNG and HQR3 [13].

We start by showing how a specified eigenvalue of Z can be made to appear in the bottom right (Algorithm QR-down) or top left (Algorithm QR-up) position. For the sake of brevity, we shall present only Algorithm QR-down in detail. Algorithm QR-up can be stated in an analogous manner. We assume that Z is in unreduced upper Hessenberg form and the eigenvalue to be positioned is given.

Algorithm QR-down(Z, n, λ, D)

Step 1. If the eigenvalue to be shifted (λ) is complex, go to Step 4.

Step 2. Form a real shift corresponding to λ: $Z := Z - \lambda I_{2n}$

Step 3. For $k = 1, 2, \ldots, 2n-1$, determine a Householder matrix $\hat{D}_k \in \mathcal{R}^{2\times 2}$ such that

$$\hat{D}_k \begin{bmatrix} z_{kk} \\ z_{k+1,k} \end{bmatrix} = \begin{bmatrix} \times \\ 0 \end{bmatrix} \tag{3.2}$$

$Z := D_k Z D_k^T$, where $D_k = \operatorname{diag}\{I_{k-1}, \hat{D}_k, I_{2n-k-1}\}$

$D := D_k D$

end

$Z := Z + \lambda I_{2n}$

exit

Step 4. Form an implicit double shift corresponding to the complex-conjugate pair (λ, λ^*):

$p_1 := z_{11}^2 - z_{11}(\lambda + \lambda^*) + \lambda\lambda^* + z_{12}z_{21}$

$q_1 := z_{21}[z_{11} + z_{22} - (\lambda + \lambda^*)]$

$r_1 := z_{21}z_{32}$

Determine a Householder matrix $\hat{D}_0 \in \mathcal{R}^{3\times 3}$ such that

$$\hat{D}_0 \begin{bmatrix} p_1 \\ q_1 \\ r_1 \end{bmatrix} = \begin{bmatrix} \times \\ 0 \\ 0 \end{bmatrix}$$

$Z := D_0 Z D_0^T$, where $D_0 = \operatorname{diag}\{\hat{D}_0, I_{2n-3}\}$

$D := D_0 D$

Step 5. For $k = 1, 2, \ldots, 2n-3$, determine a Householder matrix $\hat{D}_k \in \mathcal{R}^{3\times 3}$ such that

$$\hat{D}_k \begin{bmatrix} z_{k+1,k} \\ z_{k+2,k} \\ z_{k+3,k} \end{bmatrix} = \begin{bmatrix} \times \\ 0 \\ 0 \end{bmatrix} \tag{3.3}$$

$Z := D_k Z D_k^T$, where $D_k = \operatorname{diag}\{I_k, \hat{D}_k, I_{2n-k-3}\}$

$D := D_k D$

end

Determine a Householder matrix $\hat{D}_{2n-2} \in \mathcal{R}^{2\times 2}$ such that

$$\hat{D}_{2n-2} \begin{bmatrix} z_{2n-1,2n-2} \\ z_{2n,2n-2} \end{bmatrix} = \begin{bmatrix} \times \\ 0 \end{bmatrix}$$

$Z := D_{2n-2} Z D_{2n-2}^T$, where $D_{2n-2} = \operatorname{diag}\{I_{2n-2}, \hat{D}_{2n-2}\}$

$D := D_{2n-2} D$

exit

Remark 3.1. Algorithm QR-up (Z, n, λ, U) can be defined in a similar manner to the way in which QR-down was defined. In this case, the eigenvalue(s) corresponding to the shift are made to appear in the top left corner of Z.

Remark 3.2. Algorithms QR-down and QR-up perform one step (single for a real eigenvalue and double for a complex-conjugate pair of eigenvalues) of the QR Algorithm [5]. Explicit single shifts are used for real eigenvalues and implicit double shifts for complex-conjugate pairs of eigenvalues. The implicit shifts introduce nonzero terms in certain locations below the subdiagonal of the upper Hessenberg matrix. Algorithm QR-down uses row operations to "chase" these nonzero terms to the bottom right corner, whereas Algorithm QR-up uses column operations to "chase" the terms to the top left.

Remark 3.3. If a shift is an accurately computed eigenvalue of Z, then Algorithm QR-down will transform the matrix Z to the form

$$\begin{bmatrix} \hat{Z}_{11} & \hat{\mathbf{z}}_{12}^T \\ \mathbf{0} & \lambda \end{bmatrix}$$

for a real single shift λ, or to the form

$$\begin{bmatrix} \tilde{Z}_{11} & \tilde{Z}_{12} \\ O & \Phi \end{bmatrix},$$

where $\Phi \in \mathcal{R}^{2\times 2}$ for a double shift. Similarly, Algorithm QR-up will position λ and Φ in the top left corner of a quasi-triangular matrix. Now, if a shift is not equal to an accurately computed eigenvalue of Z, then the subdiagonal element(s) next to λ (Φ) (or below λ (Φ) in the case of QR-up) may not become zero after one iteration, in which case two or more iterations of the algorithm may be required. In this case the shifts for the second and subsequent iterations would correspond to the scalar (for a real eigenvalue) or the 2×2 matrix (for a complex-conjugate pair of eigenvalues) in the bottom right corner (Algorithm QR-down) or top left corner (Algorithm QR-up). The effect of performing these additional iterations would be to reduce the appropriate subdiagonal term(s) to zero and yield more accurate value(s) for the eigenvalue(s).

Remark 3.4. The orthogonal similarity transformations on Z are accumulated in $D \in \mathcal{R}^{2n\times 2n}$ for Algorithm QR-down and in $U \in \mathcal{R}^{2n\times 2n}$ for Algorithm QR-up.

Remark 3.5. It has been assumed in algorithms QR-down and QR-up that the upper Hessenberg matrix Z is unreduced. If this is not the case, then the sequence of transformations D_k (in QR-down) and U_k (in QR-up) cannot be completed. However, this is not a limitation because, if Z is not unreduced, then it can be made unreduced by applying an arbitrary QR shift to introduce coupling between the corresponding blocks [6].

3.1. A real Schur form with eigenvalue rearrangement. In this section we show how the algorithms QR-down and QR-up can be used to obtain the condensed form (3.1), in which $Z_{11} \in \mathcal{R}^{n\times n}$ and $Z_{22} \in \mathcal{R}^{n\times n}$ are in RSF and have only stable and unstable eigenvalues, respectively.

Algorithm III (RSF)

Input: A Hamiltonian matrix $Z \in \mathcal{R}^{2n\times 2n}$

Output: An orthogonal matrix $\hat{U} \in \mathcal{R}^{2n\times 2n}$ such that

$$\hat{U}^T Z \hat{U} = \begin{bmatrix} R_1 & \hat{Z}_{12} \\ O & R_2 \end{bmatrix} \tag{3.4}$$

where $R_1 \in \mathcal{R}^{n\times n}$ and $R_2 \in \mathcal{R}^{n\times n}$ are in RSF with stable and unstable eigenvalues, respectively.

Step 1. Reduce Z to an upper Hessenberg form Z_1:

$Z_1 := \hat{U}_1^T Z \hat{U}_1$
$n_1 := n$
$\rho := 0$

Step 2. For $k = 1, 2, \ldots, n$, compute an eigenvalue λ_k of Z_1 (using one or more iterations of Algorithm QR-down); accumulate the transformations in $\hat{U}_2$.

If $\mathrm{Re}(\lambda_k) > 0$,
  Call QR-up $(Z_k, n_k, -\lambda_k, U_k)$
else
  Call QR-down $(Z_k, n_k, \lambda_k, U_k^T)$
  Call QR-up $(Z_k, n_k, -\lambda_k, U_k)$
end
$\hat{U}_2 := \hat{U}_2 \ \mathrm{diag}\{I_\rho, U_k, I_\rho\}$
If λ_k is real,
  $Z_{k+1} := Z_k(2 : 2n_k - 1, 2 : 2n_k - 1)$
  $n_{k+1} := n_k - 1$
  $\rho := \rho + 1$
else
  $Z_{k+1} := Z_k(3 : 2n_k - 2, 3 : 2n_k - 2)$
  $n_{k+1} := n_k - 2$
  $\rho := \rho + 2$
end
end

Step 3. $\hat{U} := \hat{U}_1 \hat{U}_2$

Remark 3.6. Algorithm III computes only n eigenvalues of Z. After an eigenvalue λ_k has been determined using Algorithm QR-down, if λ_k is an unstable eigenvalue, then a shift $-\lambda_k$ is applied using Algorithm QR-up to position the stable eigenvalue $-\lambda_k$ in the top left corner. On the other hand, if λ_k is a stable eigenvalue, then a shift $-\lambda_k$ using Algorithm QR-down and another shift λ_k using Algorithm QR-up are applied to position the unstable eigenvalue $(-\lambda_k)$ in the bottom right corner and the stable eigenvalue (λ_k) in the top left corner, respectively. As an illustration, let us consider the case $k = 2$, $n = 4$, with computed real eigenvalues $\lambda_1 > 0$ and $\lambda_2 > 0$. Then the structure of the resulting matrix would be

$$\begin{bmatrix} -\lambda_1 & \times & \times & \times & \times & \times & \times & \times \\ 0 & -\lambda_2 & \times & \times & \times & \times & \times & \times \\ 0 & 0 & \times & \times & \times & \times & \times & \times \\ 0 & 0 & \times & \times & \times & \times & \times & \times \\ 0 & 0 & 0 & \times & \times & \times & \times & \times \\ 0 & 0 & 0 & 0 & \times & \times & \times & \times \\ 0 & 0 & 0 & 0 & 0 & 0 & \lambda_2 & \times \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & \lambda_1 \end{bmatrix}.$$

Thus, as k increases by 1, the eigenvalue problem deflates by 2. Therefore, since we compute only n eigenvalues of Z, the amount of computation required is approximately $\frac{1}{2}(4\kappa)(2n)^3$ flops, where κ represents the average number of QR steps required per eigenvalue and is usually overestimated by a factor of 1.5. Also, once λ_k has been determined, a shift of $-\lambda_k$ normally yields the eigenvalue $-\lambda_k$ in the appropriate location in one sweep of the QR Algorithm ($\kappa = 1$). Therefore, the remaining n eigenvalues require approximately $16n^3$ operations. The complete reduction of the upper Hessenberg matrix Z_1 to an RSF can thus be achieved using approximately $40n^3$

flops. For comparison, we note that the reduction of a $2n \times 2n$ upper Hessenberg matrix to RSF using the QR Algorithm requires approximately $4\kappa(2n)^3$ operations. Using $\kappa = 1.5$, this amounts to approximately $48n^3$ operations. If the ordering of the eigenvalues in the RSF requires about 25% additional operations, then we have approximately $60n^3$ operations for computing all $2n$ eigenvalues of an upper Hessenberg matrix *and* rearranging them in groups of stable and unstable eigenvalues using EXCHNG and HQR3.

Remark 3.7. Further speedup in Algorithm III may be achieved by *first* using Algorithm II to compute the eigenvalues of Z. The approach would then be reduced to performing shifts corresponding to these eigenvalues to position them in the appropriate blocks on the diagonal. However, as we shall see in the next section, we need only apply shifts corresponding to the unstable eigenvalues, thereby further reducing the computational effort required.

3.2. A Hessenberg–Schur form. We now describe the reduction of Z to a block upper triangular form (3.1) in which $Z_{11} \in \mathcal{R}^{n\times n}$ is in upper Hessenberg form and $Z_{22} \in \mathcal{R}^{n\times n}$ is in real Schur form. Furthermore, Z_{11} will have all its eigenvalues in the open left half of the complex plane. The corresponding columns of the accumulated transformation matrix will then immediately give us a basis for the stable invariant subspace of Z. The stabilizing solution of the ARE can then be obtained as mentioned in §1.

Algorithm IV (Hessenberg–Schur Form)

Input: A Hamiltonian matrix $Z \in \mathcal{R}^{2n\times 2n}$

Output: An orthogonal matrix $U \in \mathcal{R}^{2n\times 2n}$ such that

$$U^T Z U = \begin{bmatrix} H & Z_{12} \\ O_n & R \end{bmatrix} \tag{3.5}$$

where $H \in \mathcal{R}^{n\times n}$ is an upper Hessenberg matrix with only stable eigenvalues and $R \in \mathcal{R}^{n\times n}$ is in an RSF with only unstable eigenvalues.

Step 1. Compute the "approximate" *unstable* eigenvalues, $\tilde{\lambda}_i$, $i = 1, \ldots, n$ of Z using Algorithm II.

Step 2. Reduce Z to upper Hessenberg form : $Z_1 := U_1^T Z U_1$, and $n_1 := n$, $\rho := 0$, $U_2 := I_{2n}$.

Step 3. For $k = 1, 2, \ldots, n$,

Call QR-down $(Z_k, n_k, \tilde{\lambda}_k, \tilde{U}_k^T)$

$U_2 := U_2 \operatorname{diag}\{\tilde{U}_k,\ I_\rho\}$

If λ_k is real

$Z_{k+1} := Z_k(1 : 2n_k - 1, 1 : 2n_k - 1)$

$n_{k+1} := n_k - 1$

$\rho := \rho + 1$

else

$Z_{k+1} := Z_k(1 : 2n_k - 2, 1 : 2n_k - 2)$

$n_{k+1} := n_k - 2$

$\rho := \rho + 2$

end

end

Step 4. $U := U_1 U_2$

Remark 3.8. By partitioning U as

$$U = \begin{bmatrix} U_{11} & U_{12} \\ U_{21} & U_{22} \end{bmatrix},$$

where U_{11}, $U_{21} \in \mathcal{R}^{n\times n}$, it is easy to see that $[U_{11}^T \quad U_{21}^T]^T$ is a basis for the invariant subspace corresponding to the stable eigenvalues of Z. Therefore, a stabilizing solution of the ARE is $X = -U_{21}U_{11}^{-1}$.

Remark 3.9. It should be noted that only n shifts are applied to Z_1 using the QR Algorithm and these shifts correspond to the unstable eigenvalues of Z. If the transformations that are accumulated in U_1 and U_2 are performed on Z (via Algorithm QR-down), then the result will be a real Schur matrix R with the unstable eigenvalues of Z in the bottom right corner, leaving an upper Hessenberg matrix H with the stable eigenvalues of Z in the top left corner. However, if we are only interested in the solution X of the ARE, we do not need to store the matrix resulting from the operations on Z, since X can be computed from the first n columns of U.

Remark 3.10. If the eigenvalues $\tilde{\lambda}_i$, $i = 1, \ldots, n$, computed using Algorithm II are accurate, then the process of reducing Z to the Hessenberg–Schur form becomes finite because the required shifts are known a priori. In this case Algorithm IV will be slightly faster than Algorithm III. On the other hand, if the eigenvalues $\tilde{\lambda}_i$, $i = 1, \ldots, n$ are not computed accurately, then it may be necessary to perform two or more iterations of Algorithm QR-down with updated values of $\tilde{\lambda}_i$ to provide more accurate shifts. This will result in finer tuning of the shifts yielding more accurate values for the unstable eigenvalues, which in turn will improve the accuracy of H and U.

Remark 3.11. As mentioned in §2, computation of the eigenvalues of Z using Van Loan's method [12] requires approximately $53n^3/3$ operations. The ordering of n unstable eigenvalues to get the Hessenberg–Schur structure involves approximately $4\kappa(2n)^3/2$ operations. We can use $\kappa = 1$, since the shifts employed are the eigenvalues computed using Van Loan's method and, in general, one iteration per eigenvalue should suffice to "fine tune" the eigenvalues to the accuracy of the QR Algorithm. This results in an operations count of approximately $33.7n^3$ flops for the reduction of the upper Hessenberg matrix Z_1 to the Hessenberg–Schur form (3.5).

Remark 3.12. It is worth mentioning here that in a recent report [14], an algorithm has been proposed that uses the "approximate" eigenvalues computed using Van Loan's method to implement block shifts (of n eigenvalues at a time) on a condensed form of Z obtained by Paige and Van Loan [9] using orthogonal symplectic transformations. The algorithm in [14], therefore, uses only orthogonal symplectic transformations to obtain the RSF in (2.2); but no analysis or numerical experiments are given to show the efficiency or accuracy of the algorithm. As mentioned in [9], performing orthogonal symplectic updates of the condensed form destroys its nice zero structure. Consequently, carrying out implicit double shifts in this case becomes computationally expensive, so that no advantage is gained even though only orthogonal symplectic transformations are used. The use of implicit n simultaneous (block) shifts overcomes this problem, especially if the shifts are the "approximate" eigenvalues of Z. However, the buildup of rounding errors in implementing a large number of shifts simultaneously can cause difficulties with convergence of this symplectic block QR-type algorithm, particularly if one or more of the eigenvalues are badly conditioned.

4. Numerical examples. In this section, we illustrate the numerical performance and properties of the algorithms proposed in the preceding sections. All computations were performed on a SUN 4/370 computer using the f77 compiler.

Example 1. In this example, we use the model for the high-speed vehicle control problem described in [1]. State matrices of orders 9, 19, 29, 39, and 49 were considered and, with appropriate choice of matrices G and F, Hamiltonian matrices of orders 18, 38, 58, 78, and 98, respectively, were obtained. The eigenvalue problems for these

matrices are quite well conditioned. For each Hamiltonian matrix, the comparisons were performed for the following computations:

(a) Computing the eigenvalues and separating them into groups of stable and unstable eigenvalues.

(b) Computing the positive semidefinite solution of the corresponding ARE from the stable invariant subspace.

The above computations were done for three cases:

1. The QR Algorithm and the EXCHNG subroutine [6] were used to compute the eigenvalues and order them into groups of stable and unstable eigenvalues. The computations were performed using both single and double precision arithmetic.
2. Algorithm III was used in single precision to obtain the RSF in (3.4).
3. Algorithm IV was used in single precision to reduce the Hamiltonian matrix to the Hessenberg–Schur form in (3.5).

Note that case 3 requires the use of Van Loan's method [12] (Algorithm II) to "approximate" the unstable eigenvalues of the Hamiltonian matrix. In fact, since the Hamiltonian matrices in this example are well conditioned, the eigenvalues computed using Van Loan's method are almost as accurate as those obtained using the QR Algorithm (case 1). The accuracies of the unstable eigenvalues obtained using single precision arithmetic (as compared with the double precision results obtained in case 1) are shown in Table 4.1 for the three cases and the five Hamiltonian matrices.

TABLE 4.1
Maximum relative error in $\lambda(Z)$.

Size of Z	HQR3-EXCHNG	Algorithm III	Algorithm IV
18×18	9.68×10^{-7}	4.37×10^{-7}	2.76×10^{-7}
38×38	1.68×10^{-6}	6.97×10^{-7}	5.96×10^{-7}
58×58	2.29×10^{-6}	8.29×10^{-7}	1.43×10^{-6}
78×78	2.48×10^{-6}	4.53×10^{-6}	3.59×10^{-6}
98×98	3.14×10^{-6}	6.70×10^{-6}	2.35×10^{-6}

In this table and elsewhere, the "relative error" in the eigenvalues is the value $|\lambda_i^d - \lambda_i^s|/|\lambda_i^d|$, where λ_i^s and λ_i^d denote the ith eigenvalue computed using single and double precision arithmetic, respectively. The maximum is taken over all the eigenvalues of Z. It is clear from Table 4.1 that the accuracy obtained using Algorithms III and IV is comparable to or better than that obtained using the conventional approach (with the HQR3 and EXCHNG subroutines).

For the three cases and the five Hamiltonian matrices, we obtained bases for the stable invariant subspaces from the accumulated transformations and computed the positive semidefinite solutions of the corresponding AREs. All the computations were performed in single precision. For comparison, we also obtained the solution of each ARE in double precision for case 1. We used this to compute the relative errors in the single precision solutions of the AREs in the three cases, i.e., $\|X_d - X_s\|_2/\|X_d\|_2$, where X_d is the double precision solution of the ARE using Algorithm I with EXCHNG and HQR3 (case 1) and X_s is the single precision solution of the ARE computed using Algorithm I (case 1), Algorithm III (case 2), and Algorithm IV (case 3). The relative errors in the solutions are shown in Table 4.2 for the three cases and the five Hamiltonian matrices.

Example 2. In this example, we generated random matrices of orders 9, 19, 29, 39, and 49 for A. Also, the matrices G and F were constructed as $G = BB^T$ and

TABLE 4.2
Relative error in X.

Size of Z	HQR3-EXCHNG	Algorithm III	Algorithm IV
18×18	7.46×10^{-7}	7.29×10^{-7}	6.73×10^{-7}
38×38	1.61×10^{-6}	1.39×10^{-6}	1.37×10^{-6}
58×58	2.22×10^{-6}	2.25×10^{-6}	1.63×10^{-6}
78×78	2.86×10^{-6}	2.31×10^{-6}	2.29×10^{-6}
98×98	3.72×10^{-6}	2.71×10^{-6}	2.89×10^{-6}

$F = C^TC$, where B and C were random matrices. Therefore, once again we have Hamiltonian matrices of orders 18, 38, 58, 78, and 98, respectively. The computations (a) and (b) for the three cases (1–3) mentioned in Example 1 were performed on these matrices. The corresponding results are shown in Tables 4.3 and 4.4.

TABLE 4.3
Maximum relative error in $\lambda(Z)$.

Size of Z	HQR3-EXCHNG	Algorithm III	Algorithm IV
18×18	2.97×10^{-6}	1.05×10^{-6}	6.78×10^{-7}
38×38	3.49×10^{-6}	2.08×10^{-6}	1.74×10^{-6}
58×58	1.31×10^{-5}	1.11×10^{-5}	1.26×10^{-5}
78×78	4.44×10^{-6}	3.43×10^{-6}	2.05×10^{-6}
98×98	1.89×10^{-5}	1.90×10^{-5}	7.75×10^{-6}

In this example, we note again that the accuracy obtained using Algorithms III and IV is comparable to or better than that obtained using the conventional approach (with the HQR3 and EXCHNG subroutines).

TABLE 4.4
Relative error in X.

Size of Z	HQR3-EXCHNG	Algorithm III	Algorithm IV
18×18	4.82×10^{-6}	5.54×10^{-6}	3.26×10^{-6}
38×38	3.23×10^{-6}	3.15×10^{-6}	2.47×10^{-6}
58×58	7.91×10^{-6}	6.84×10^{-6}	7.87×10^{-6}
78×78	5.99×10^{-6}	5.55×10^{-6}	5.24×10^{-6}
98×98	6.79×10^{-6}	6.20×10^{-6}	5.03×10^{-6}

Example 3. This is an example of a Hamiltonian matrix of order 24 with some very ill-conditioned eigenvalues. The example is the same as that used by Van Loan [12], and the matrix A and its eigenvalues are given in [15]. The latter were used in obtaining the relative errors in the computed eigenvalues. The computations in Example 1 (a) were carried out for cases 1–3 in double precision. The results for the four most ill-conditioned eigenvalues are shown in Table 4.5, where the quantity $s(\lambda_i)$ is the cosine of the angle between the left and right eigenvectors associated with the eigenvalue λ_i. The reciprocal of $s(\lambda_i)$ denotes the conditioning of λ_i [15].

In this example, because of the ill conditioning, only double precision arithmetic was used. For the ill-conditioned eigenvalues, Van Loan's method (Algorithm II) was significantly less accurate than the QR Algorithm (case 1). Therefore, two or more QR steps (QR-down) are needed in Algorithm IV to improve the accuracy and to

0.0310	2.55×10^{-4}	9.72×10^{-7}

Example 4. Here we tested the algorithms for two scenarios: when some of the eigenvalues of the Hamiltonian matrices as well as the corresponding AREs are poorly conditioned, and when there are multiple eigenvalues. The computations (a) and (b) for the three cases (1–3) mentioned in Example 1 were performed for five Hamiltonian matrices. The relative errors in the eigenvalues and in the solutions of the AREs are shown in Tables 4.7 and 4.8, respectively. The three poorly conditioned examples correspond to Hamiltonian matrices, which were generated using the Frank matrix, the data for the boiler model [16], and an example given by Byers [17]. It should be noted that the values of $\min\{s(\lambda_i)\}$ in Tables 4.7 and 4.8 are for the closed-loop eigenvalues, i.e., for the eigenvalues of the Hamiltonian matrices with nonzero F and G matrices, whereas in Table 4.5, the values of $s(\lambda_i)$ are for the open-loop case, i.e., for the Frank matrix. The term κ_R in Table 4.8 denotes the "condition number" of the ARE [17] corresponding to a given Hamiltonian matrix, and is given by

$$\kappa_R = \frac{(1 + \|X\|)^2 \|Z\|}{\|X\| SEP[(A - GX), -(A - GX)^T]},$$

where $SEP[N, -N^T] = \min\{\|PN + N^T P\| \mid \|P\| = 1\}$. A large value of κ_R implies an ill-conditioned ARE.

From Tables 4.7 and 4.8, we note that the eigenvalues and the AREs corresponding to the Hamiltonian matrices with multiple eigenvalues are well conditioned. As expected, for these two cases the three algorithms give very good and comparable accuracy. In the first case, the Hamiltonian matrix has eigenvalues at ± 20, ± 30, ± 40, and ± 50 with multiplicity 3; in the second case, the eigenvalues are at ± 4 with multiplicity 6, and at ± 10, ± 20, and ± 30 each with multiplicity 2.

The three other Hamiltonian matrices considered in Tables 4.7 and 4.8 are relatively poorly conditioned. The boiler problem has the worst conditioning of the three cases, both with respect to the eigenvalues of the Hamiltonian matrix as well as the

corresponding ARE. This results in slightly lower accuracy for the computed closed-loop eigenvalues and the solution of the ARE than in the other two cases, for which the measures of conditioning have similar orders of magnitude.

From Tables 4.7 and 4.8, we note that both Algorithms III and IV perform as well as or slightly better than the conventional approach (HQR3-EXCHNG) in all cases except one. The exception corresponds to the results obtained using Algorithm IV for the boiler model, which is the most ill conditioned of the examples considered in Tables 4.7 and 4.8. The slightly lower accuracy in this case can be explained as follows: For a Hamiltonian matrix with some ill-conditioned eigenvalues, there is a significant loss of accuracy in computing the corresponding eigenvalues of the square of the Hamiltonian matrix using Van Loan's method [12]. Consequently, the shifts used in Algorithm IV for very ill-conditioned eigenvalues will have poor accuracy.

5. Concluding remarks. In this paper, some numerical issues in computing a basis for the stable invariant subspace of a Hamiltonian matrix have been discussed. In particular, two alternatives to the use of the EXCHNG subroutine for reordering eigenvalues of a Hamiltonian matrix have been proposed. These were derived using certain properties of Hamiltonian matrices and were shown to require significantly less computation than the conventional approach (using the HQR3 and EXCHNG subroutines). Numerical experiments that have been carried out suggest that the proposed algorithms give accuracy that is often comparable to or better than that obtained using the conventional approach.

Acknowledgments. The authors wish to thank the referees and the review editor for their helpful comments and suggestions.

SPARSITY PATTERNS WITH HIGH RANK EXTREMAL POSITIVE SEMIDEFINITE MATRICES*

J. WILLIAM HELTON†‡, DANIEL LAM†, AND HUGO J. WOERDEMAN†§

Abstract. This article concerns the positive semidefinite matrices $M_+(G)$ with zero entries in prescribed locations; that is, matrices with given sparsity graph G. The issue here is the rank of the extremals of the cone $M_+(G)$. It was shown in [J. Agler, J. W. Helton, S. McCullough, and L. Rodman, *Linear Algebra Appl.*, 107 (1988), pp. 101–149] that the key in constructing high rank extreme points resides in certain atomic graphs G called blocks and superblocks. The k-superblocks are defined to be sparsity graphs G that contain an extreme point of rank k while containing (in an extremely strong sense) no graph with the same property. The goal of this article is to write down all graphs that are superblocks. The article succeeds completely for $k \leq 4$ and it lists necessary conditions in general as well as sufficient conditions. The subject is closely related to orthogonal representations of graphs as studied earlier in [L. Lovász, M. Saks, and A. Schrijver, *Linear Algebra Appl.*, 114/115 (1989), pp. 439–454] and in the previously mentioned paper by Alger et al. Indeed, the paper is an extension of the findings of Alger et al.

Key words. extremal matrix, order of a graph, superblocks, orthogonal representation

AMS subject classifications. primary 05C50; secondary 05B20, 15A57

Introduction. Let G be an undirected graph without multiple edges or loops. Let $V(G)$ $(= \{1, \ldots, n\})$ denote the set of vertices of G and $E(G) \subset V(G) \times V(G)$ the set of edges. Note that the absence of loops means that $(i,i) \notin E(G)$, $i = 1, \ldots, n$. Define $M_+(G)$ to be the closed cone of all positive semidefinite $n \times n$ real symmetric matrices whose (i,j) entry is zero whenever $(i,j) \in E(G)$. (Note the difference in definition compared to preceding papers on the subject ([AHMR], [HPR]); in those papers the zero entries would correspond to edges in the complementary graph.)

A matrix A in $M_+(G)$ is called an extremal when each additive decomposition of A in $M_+(G)$ is a trivial one, i.e., A is an *extremal* when $A = B + C$ with $B, C \in M_+(G)$ yields that $B, C \in \operatorname{span}\{A\}$. We say that G has *order* k if k is the maximum of the ranks of extremals in $M_+(G)$.

We are interested in determining the order of a given graph. The graphs of order 1 have a very elegant characterization (see [AHMR], [PPS]) based on the main result in [GJSW]. The general case turns out to be very hard, and, therefore, some reductions must be made. Recall from [AHMR] the following definitions. A graph G is called a *k-block* if G has order k but no induced subgraph has order k. (The graph $\hat{G}$ is an *induced subgraph* of G if $V(\hat{G}) \subset V(G)$ and $E(\hat{G}) = E(G) \cap (V(\hat{G}) \times V(\hat{G}))$.) In terms of matrices this means that for a k-block G any rank k extremal in $M_+(G)$ does not have zero rows or columns. A full description of k-blocks, $k = 1, 2, \ldots$, would give a solution to our problem, since the order of a graph equals the maximal k for which the graph has a k-block as an induced subgraph ([AHMR, Thm. 1.2]). Classifying k-blocks is based on the study of much better behaved objects called k-superblocks.

§Supported by the Netherlands Organization for Scientific Research (NWO).

A graph G is called a *k-superblock* when it is a k-block that does not properly contain another k-block. (In this paper "$\hat{G}$ is *contained* in G" always means $V(\hat{G}) \subset V(G)$ and $E(\hat{G}) \subset E(G)$.) In terms of matrices, this means that as soon as you allow some of the zero entries prescribed by G to be nonzero there are no extremals of rank k anymore. It is true (see [AHMR]) that any k-block (or any order k graph, for that matter) contains a k-superblock. However, to obtain all k-blocks assuming one knows how to characterize k-superblocks still requires work.

The following theorem gives necessary conditions for a sparsity pattern to be a k-superblock.

THEOREM 0.1. *Let G be a k-superblock. Then the following are true:*

(i) $\#E(G) = \frac{1}{2}(k+2)(k-1)$;

(ii) *G contains no $K_{p,q}$, $p+q \geq k+1$;*

(iii) *For all $i_1, \ldots, i_m \in V(G)$ with $1 \leq m < k$ we have that*

$$(0.1)\quad \#\{(i,j) \in E(G) \mid i \text{ or } j \in \{i_1, \ldots, i_m\}\} < \frac{1}{2}(k+2)(k-1) - \frac{1}{2}(k-m+2)(k-m-1) = \frac{1}{2}m(2k+1-m)\,.$$

Conversely, when $k = 1, 2, 3,$ or 4 these conditions imply that G is a k-superblock.

Here $K_{p,q}$ denotes the bipartite graph described by

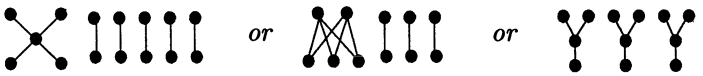
$$V(K_{p,q}) = \{1, \ldots, p+q\},\ E(K_{p,q}) = \{(i,j) \mid 1 \leq i \leq p,\ p+1 \leq j \leq p+q\}\,.$$

The necessary conditions (i) and (ii) were established earlier in [AHMR]. Condition (iii) is implied by (i) and (ii) when $k = 1, 2, 3$ but not when $k \geq 4$. For $k = 1, 2, 3$ the k-superblocks were described earlier in [AHMR], and indeed they are precisely the graphs which satisfy the necessary conditions in Theorem 0.1. For $k = 4$ this is also true (as stated in Theorem 0.1). This follows from the description of 4-superblocks given in the next theorem, which is the second main result in this paper.

THEOREM 0.2. *Let G be a graph with nine edges. The following are equivalent:*

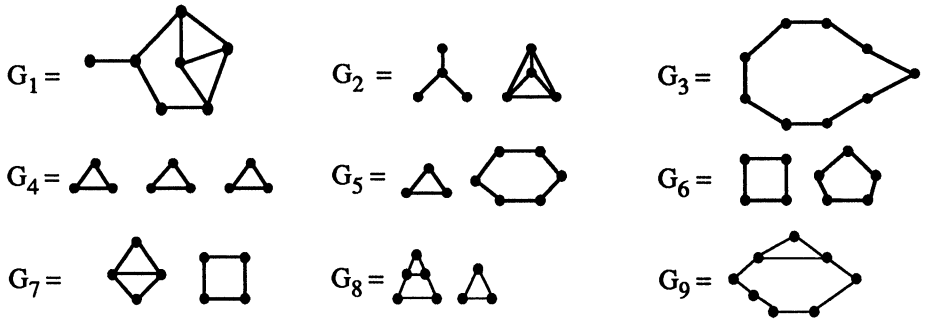
(i) *G is a 4-superblock;*

(ii) *G cannot be obtained from*

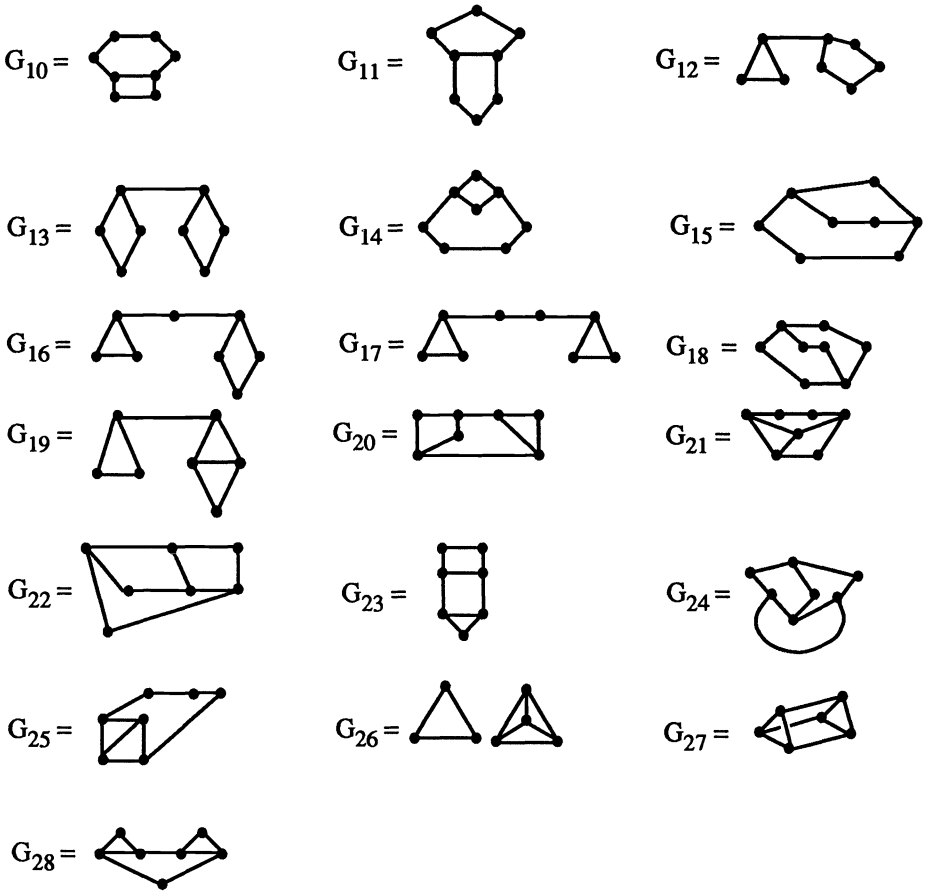


by identifying vertices;[1]

(iii) *G is a graph which, after identifying vertices, is one of the following* 28 *graphs:*



[1]See the definition of a collapse of a graph in §2.



Note that (ii) in Theorem 0.2 is a restatement of the necessary conditions in Theorem 0.1 for $k = 4$.

In §2 we develop some results which give sufficient conditions for a graph to be a k-superblock. Unfortunately these conditions do not equal the necessary conditions in Theorem 0.1. In the case when $k = 4$, for instance, 17 of the 28 graphs in Theorem 0.2(iii) meet the necessary conditions of Theorem 0.1, but not our general sufficient conditions. To prove that these 17 graphs are 4-superblocks, we used a computer program employing Mathematica (using integer arithmetic). It is natural to ask whether this gap in the theory can be dissolved in the following way.

SPECULATION 0.3. *Let G be a graph satisfying* (i), (ii), *and* (iii) *in Theorem* 0.1. *Then G is a k-superblock.*

We shall point out in the end of §1 what remains to be done in order to prove this speculation. We used our Mathematica program to check some likely candidates for counterexamples (with $k = 5$ and 6), but so far we have been unsuccessful (partly because the program is very slow when k is large).

1. Making extremals in $M_+(G)$. From [AHMR] one can deduce the following recipe for making *all* extremals in $M_+(G)$ of rank k.

Let G be a graph, and let $k \leq \#V(G)$.

(Step I) Find an assignment $f: V(G) = \{1, \dots, n\} \longrightarrow \mathbb{R}^k$ such that
(a) $\langle f(i), f(j) \rangle = 0$, $(i,j) \in E(G)$;
(b) span $\{f(j) \mid j \in V(G)\} = \mathbb{R}^k$.

(Step II) Check if all $M = M^T \in \mathbb{R}^{k \times k}$ satisfying

$$\langle Mf(i), f(j) \rangle = 0, \qquad (i,j) \in E(G)\,, \tag{1.1}$$

are multipliers of the $k \times k$ identity matrix I_k.

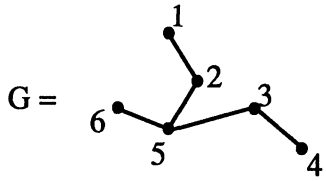
(Step III) If so, then

$$\begin{pmatrix} f(1)^T \\ \vdots \\ f(n)^T \end{pmatrix} \begin{pmatrix} f(1) \cdots f(n) \end{pmatrix}$$

is an extremal of rank k in $M_+(G)$.

An assignment $f: V(G) \longrightarrow \mathbb{R}^k$ such that (a) in Step I holds is called an *orthogonal representation* of G. Such representations were introduced and studied independently in [LSS] and [AHMR] (for quite different reasons).

Example. Let



Then

$$\begin{pmatrix} 1 \\ 0 \\ 0 \\ 1 \\ 1 \\ 0 \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 & 1 & 1 & 0 \end{pmatrix}, \quad \begin{pmatrix} 1 & 0 \\ 0 & 1 \\ 1 & 1 \\ 1 & -1 \\ 0 & 0 \\ 5 & 7 \end{pmatrix} \begin{pmatrix} 1 & 0 & 1 & 1 & 0 & 5 \\ 0 & 1 & 1 & -1 & 0 & 7 \end{pmatrix}$$

are extremals in $M_+(G)$ of ranks 1 and 2, respectively. There are no extremals of rank ≥ 3 because of dimension counting. Indeed, if $k = 3$, either $f(5) = 0$ or span $\{f(2), f(3), f(6)\}$ has dimension of at most 2. This results in at most four constraints, appearing in (1.1), on M. This can never force M to be a scalar multiple of I_3. Furthermore, when $k > 3$, the five constraints (1.1) on M are too few to force M to be a scalar multiple of I_k.

The type of arguments used in the example led in [AHMR] to the following result.

Let G be a graph. If order $G = k$, then $\#E(G) \geq \frac{1}{2}(k+2)(k-1)$. Furthermore, if order $G = k$ and $\#E(G) = \frac{1}{2}(k+2)(k-1)$, then G contains no $K_{p,q}$, $p+q \geq k+1$.

Let us now prove that a k-superblock must satisfy the conditions (i), (ii), and (iii) in Theorem 0.1.

Proof of the necessary part of Theorem 0.1. Let G be a k-superblock. In particular, order $G = k$, and thus the recipe works for a representation f, say. Let $i_1, \dots, i_k \in V(G)$ be such that $f(i_j)$, $j = 1, \dots, i_k$, span $\mathbb{R}^k$. Furthermore, choose

distinct $i_{k+1},\dots,i_l$ such that each edge in $E(G)$ has an endpoint in $\{i_1,\dots,i_l\}$ and write

$$f(i_p)=\sum_{j=1}^{k}\lambda_j^{(p)}f(i_j)\,,\qquad p=k+1,\dots,l.$$

Let M be a $k\times k$ matrix, and put $w_j=Mf(i_j)$, $j=1,\dots,k$. Let $u_1^{(j)},\dots,u_{p_j}^{(j)}$ denote the vertices adjacent to i_j that are not in the set $i_1,\dots,i_{j-1}$. Put

$$U_j=[f(u_1^{(j)})\cdots f(u_{p_j}^{(j)})]\,,\qquad j=1,\dots,l.$$

Put

$$W=\begin{bmatrix} U_1 & & & \lambda_1^{(k+1)}U_{k+1} & \cdots & \lambda_1^{(l)}U_l\\ & U_2 & & & & \\ & & \ddots & \vdots & & \vdots\\ & & U_k & \lambda_k^{(k+1)}U_{k+1} & \cdots & \lambda_k^{(l)}U_l\end{bmatrix}$$

and

$$\Sigma=\begin{bmatrix} -f(i_2) & -f(i_3) & 0 & \cdots & -f(i_k) & 0 & \cdots & 0\\ f(i_1) & 0 & -f(i_3) & \cdots & 0 & -f(i_k) & \cdots & 0\\ 0 & f(i_1) & f(i_2) & \cdots & 0 & 0 & & 0\\ \vdots & \vdots & \vdots & & \vdots & \vdots & \ddots & \vdots\\ 0 & 0 & 0 & \cdots & 0 & 0 & \cdots & -f(i_k)\\ 0 & 0 & 0 & \cdots & f(i_1) & f(i_2) & \cdots & f(i_{k-1})\end{bmatrix}.$$

That is to say, if $\frac{1}{2}j(j-1)<p\le\frac{1}{2}(j+1)j$ then column p in Σ has on the $p-\frac{1}{2}j(j-1)$ row the entry $-f(i_{j+1})$ and on the $(j+1)$ row the entry $f(i_{p-j(j-1)/2})$ $(j=1,\dots,k-1)$. Note that W is of size $k\times\#E(G)$ and Σ of size $k\times\frac{1}{2}k(k-1)$. The equations (1.1) are equivalent to

$$\operatorname{col}(w_i)_{i=1}^{k}\in\text{cokernel } W$$

and the symmetry of M is ensured by

$$\operatorname{col}(w_i)_{i=1}^{k}\in\text{cokernel }\Sigma\,.$$

Checking Step II in the recipe now comes down to checking that

$$\text{cokernel}\,[W,\Sigma]=\operatorname{span}\{\operatorname{col}(f(i_j))_{j=1}^{k}\}\,. \tag{1.2}$$

Note that the inclusion $\supset$ in (1.2) is always fulfilled since f is an orthogonal representation. We assume that the recipe works, and therefore (1.2) holds. Suppose that $\#E(G)>\frac{1}{2}(k+2)(k-1)$, then the number of columns in $[W,\Sigma]$ is $\ge k^2$. Since the columns in Σ are linearly independent, and because of (1.2), we can remove a column in W without changing the cokernel of $[W,\Sigma]$. But removing a column in W corresponds to removing an edge in G, yielding that G properly contains a k-block. Thus $\#E(G)=\frac{1}{2}(k+2)(k-1)$.

Now it follows from the quoted result before the proof that (ii) holds. It remains to prove (iii). First note that if the recipe works for f, it also works for an orthogonal representation $\tilde f$ with the property that $\|f(i)-\tilde f(i)\|$ is small enough. Indeed, such a perturbation will not destroy the invertibility of a $(k^2-1)\times(k^2-1)$ invertible submatrix

of $[W, \Sigma]$. Since the graph does not contain any $K_{p,q}$'s, $p+q \geq k+1$, we know from [LSS] that in any neighborhood of f we can find an orthogonal representation $\tilde{f}$ that has the property that any set of k representing vectors are linearly independent (in the terms of [LSS]: $\tilde{f}$ is in *general position*). Thus without loss of generality we may assume that f has the latter property. Choose now $i_1, \ldots, i_m \in V(G)$, $m < k$, arbitrary. Then $f(i_1), \ldots, f(i_m)$ are linearly independent. Choosing the $i_1, \ldots, i_m$ as the first m vertices in $\{i_1, \ldots, i_k, i_{k+1}, i_l\}$ we can set up the matrix W and Σ as before. After permutation of columns of the matrix $[W, \Sigma]$ we obtain the matrix

$$\begin{bmatrix} \Lambda_{11} & \Lambda_{12} \\ 0 & \Lambda_{22} \end{bmatrix}, \tag{1.3}$$

where

$$\Lambda_{11} = \begin{bmatrix} U_1 & & -f(i_2) & \cdots & -f(i_m) & 0 & \cdots & 0 \\ & U_2 & f(i_1) & & 0 & f(i_m) & & 0 \\ & \ddots & 0 & & 0 & 0 & & 0 \\ & & \vdots & & \vdots & \vdots & \ddots & \vdots \\ & & 0 & & 0 & 0 & & -f(i_{m-1}) \\ & U_m & 0 & & f(i_1) & f(i_2) & & f(i_{m-1}) \end{bmatrix}.$$

Note that

$$\operatorname{col}(f(i_j))_{j=1}^{m} \in \operatorname{coker} \Lambda_{11}.$$

But then, since the cokernel of (1.3) should have dimension exactly equal to 1, the matrix Λ_{22} should have at least as many columns as rows. Since Λ_{22} is of size

$$(k^2 - mk) \times \left[(k^2 - 1) - \left(\#\{(i,j) \in E(G) \mid i \text{ or } j \in \{i_1, \ldots, i_m\}\} + \frac{1}{2} m(m-1) \right) \right],$$

this inequality precisely yields (0.1). □

In order to prove Speculation 0.3, it remains to prove that for a graph satisfying (i), (ii), and (iii) there is an orthogonal representation f such that the matrix $[W, \Sigma]$, constructed in the proof of Theorem 0.1, has a one-dimensional cokernel.

2. A sufficiency result. For a vertex $v \in V(G)$ the *degree* is defined to be the number of adjacent vertices.

THEOREM 2.1. *Let P be a graph with an induced subgraph G that satisfies*

(i) $\#E(G) \geq \frac{1}{2}(k+2)(k-1)$;

(ii) *G contains no $K_{p,q}$'s, $p+q \geq k+1$;*

(iii) *for any $\{i_1, \ldots, i_m\} \subset V(G)$ with $1 \leq m \leq k-1$,*

$$\#\{(i,j) \in E(G) \mid i \text{ or } j \in \{i_1, \ldots, i_m\}\} < \#E(G) - \frac{1}{2}(k-m+2)(k-m-1); \tag{2.1}$$

(iv) *G has $k-1$ vertices $\{u_1, \ldots, u_{k-1}\}$ of degree $k-1$ such that one of the vertices u_j $(1 \leq j \leq k-1)$ is not adjacent to any u_i, $j \neq i \in \{1, \ldots, k-1\}$.*

Then order $P \geq k$.

The conclusion remains true when (iv) *is replaced by*

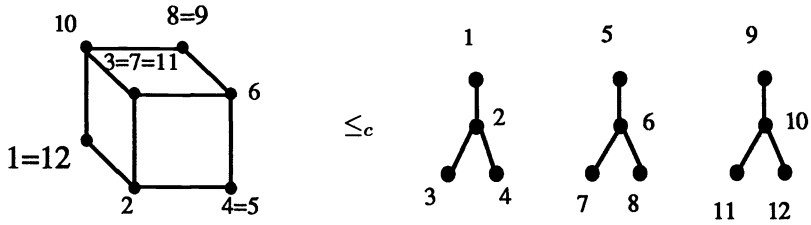
(v) *G has at least k vertices of degree $k-1$, and, after deleting m of these vertices, the remaining graph always contains a $K_{p,q}$, $p+q \geq k-m+1$, $m = 1, \ldots, k-2$.*

It should be noted that it follows from the last part of the proof of Theorem 0.1 that (iii) is a necessary condition for G to be of order $\geq k$.

Before proving the theorem, let us make some remarks. Condition (iv) is a very stringent one since it requires the subgraph G to be fairly condensed. However, combined with the next result from [AHMR] the theorem shows that a substantial number of graphs have order $\geq k$.

We introduce the following partial ordering on graphs. We say that $G \leq_c \tilde{G}$ (G is a *collapse* of $\tilde{G}$) if G can be obtained from $\tilde{G}$ by identifying vertices without identifying edges. For example,

(2.2)



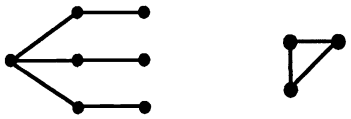
PROPOSITION 2.2. *Let G and $\tilde{G}$ be graphs satisfying $G \leq_c \tilde{G}$. Then*

$$\text{order } G \leq \text{ order } \tilde{G}.$$

This is a restatement of Theorem 4.7 in [AHMR].

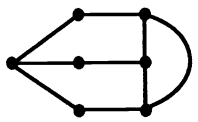
Example. Theorem 2.1 and Proposition 2.2 together prove that the order of

(2.3)



is ≥ 4. Indeed, the graph

(2.4)



has order ≥ 4 by Theorem 2.1, and (2.4) is a collapse of (2.3). Therefore, (2.3) has order ≥ 4. In fact, (2.3) has precisely order 4 since, by Theorem 0.1, a graph of order ≥ 5 should at least have 14 edges, the number of edges of a 5-superblock. □

In order to prove Theorem 2.1, we need some auxiliary results. Recall that an orthogonal representation $f : V(G) \to \mathbb{R}^k$ is in general position if any set of k representing vectors is linearly independent.

LEMMA 2.3. *Let G be a graph that does not contain $K_{p,q}$'s $p + q \geq k + 1$, and let $f: V(G) \to \mathbb{R}^k$ be an orthogonal representation in general position. If $M = M^T \in \mathbb{R}^{k \times k}$ satisfies* (1.1), *then for any $v \in V(G)$ with degree equal to $k - 1$ the vector $f(v)$ is an eigenvector of M.*

Proof. Both $f(v)$ and $Mf(v)$ belong to the orthogonal complement of span $\{f(u) \mid (u, v) \in E(G)\}$. Since deg $v = k - 1$, the vectors $Mf(v)$ and $f(v)$ both belong to a one-dimensional space. □

Recall from [LSS] that an orthogonal representation f of a graph G is called *faithful* if $\langle f(u), f(v)\rangle = 0$ if and only if $(u,v) \in E(G)$.

LEMMA 2.4. *Let G be a graph that contains no $K_{p,q}$'s, $p+q \geq k+1$. Further, suppose that u is a vertex of degree $k-1$ that has r nonadjacent vertices of degree $k-1$. Then for any faithful orthogonal representation f of G in $\mathbb{R}^k$ in general position the set of symmetric matrices M satisfying* (1.1) *is either* $\operatorname{span}\{I_k\}$ *or contains an element of* $\operatorname{rank} < k-r$.

Proof. Let M be symmetric such that (1.1) holds. Since $f(u)$ is an eigenvector of M (at λ_0, say), which is not orthogonal to r other eigenvectors, the dimension of the eigenspace of M at λ_0 is at least the dimension of the span of $f(u)$ and these other r eigenvectors. Since f is in general position we obtain that

$$\operatorname{rank}(M - \lambda_0 I) \leq \max\{0, k-(r+1)\}.$$

Since $M - \lambda_0 I$ is symmetric and satisfies (1.1), the lemma is proved. □

PROPOSITION 2.5. *Let G be a graph that contains no $K_{p,q}$'s, $p+q \geq k+1$. Then for every orthogonal representation $f: V(G) \to \mathbb{R}^k$ there exists a symmetric matrix M of rank* 1 *satisfying* (1.1) *if and only if there is a set V of at most $k-1$ vertices in G such that any edge in G has an endpoint in V.*

Proof. Suppose such a set V exists. Choose $0 \neq w \in \mathbb{R}^k$ such that $\langle w, f(v)\rangle = 0$ for any $v \in V$. It is easy to check that $M := ww^T$ satisfies (1.1).

In order to prove the *only if* part, let f be an orthogonal representation in general position (such an f exists: Theorem 1.1 in [LSS]). Also let $M = ww^T$ with $w \neq 0$ satisfy (1.1). Then for all edges $(i,j) \in E(G)$

$$\langle w, f(i)\rangle\langle w, f(j)\rangle = 0,$$

thus w is orthogonal to one of the endpoints of each edge in G. Since w can be orthogonal to at most $k-1$ linearly independent vectors we obtain the proposition above. □

We are now ready to prove Theorem 2.1.

Proof of Theorem 2.1. Suppose (i)–(iv) hold. We have to prove that order $G \geq k$. Let $f: V(G) \to \mathbb{R}^k$ be in general position and faithful (existence is assured by Theorem 1.1 and (the proof of) Corollary 1.4 in [LSS]). Lemma 2.4 yields, because G satisfies (iv), that either the set of symmetric matrices M satisfying (1.1) is span $\{I_k\}$ or has an element of rank 1. Since G satisfies condition (iii) in the theorem, the latter possibility is ruled out. (Since, if M is symmetric of rank 1 satisfying (1.1), then Proposition 2.5 yields that (2.1) is violated (for $m = k-1$).)

Now suppose that (i), (ii), (iii), and (v) hold. Let $f: V(G) \to \mathbb{R}^k$ be an orthogonal representation in general position. Further suppose that M is positive semidefinite, satisfies (1.1) and has rank d, with $1 < d < k$. (We can always assume that M is positive semidefinite, since if M satisfies (1.1) then any linear combination of M and I_k satisfies (1.1) also.) Since G has k vertices of degree $k-1$, the representing vectors corresponding to these vertices are a basis of eigenvectors of M. But then $k-d$ of these vertices represent the kernel. Delete those vertices. Then from (1.1) it easily follows that $M^{1/2}f$, defined by

$$(M^{1/2}f)(v) = M^{1/2}(f(v)),$$

is an orthogonal representation in general position of the remaining graph. Since (v) holds, this is impossible by Theorem 1.1 in [LSS]. As before, a symmetric M satisfying

(1.1) cannot have rank 1. But then all symmetric M satisfying (1.1) must be in span $\{I_k\}$. □

3. 4-superblocks. In this section we prove Theorem 0.2.

Proof of Theorem 0.2. The implication (i) ⇒ (ii) is merely a restatement of the necessary conditions in Theorem 0.1 in this special case.

For the proof of (ii) ⇒ (iii) we determine the $\leq_c$-minimal elements in the set of graphs $\mathfrak{G}$ described under (ii) in Theorem 0.1, i.e., $\mathfrak{G}$ is the set of graphs with nine edges that are not a collapse of one of the three graphs under (ii). The result is given in the following proposition.

PROPOSITION 3.1. *The $\leq_c$-minimal elements in $\mathfrak{G}$ are the graphs G_i, $i = 1, \ldots, 28$, defined in Theorem* 0.1(iii).

The proof requires a lemma.

LEMMA 3.2. *Let $G \in \mathfrak{G}$ be $\leq_c$-minimal. Then G does not have a vertex u of degree* 1 *and a vertex v of degree ≤ 2 such that the distance $d(u, v)$ between u and v is larger than* 2.

Proof. Suppose that G has vertices u and v with $\deg u = 1$, $\deg v \leq 2$ and $d(u, v) > 2$. By identifying u and v we do not create a degree-4 node. Suppose we create a $K_{2,3}$. Then we must have had

(1)  or (2) 

with three other edges. In case (1) these three other edges do not form a subgraph $K_{1,3}$; otherwise $G \leq_c 3 \times K_{1,3}$, which contradicts $G \in \mathfrak{G}$. Here $3 \times K_{1,3}$ denotes the graph on the right-hand side of (2.2). But then G must be disconnected. This yields that we can identify one of the vertices in a connected component of G not containing u with u and obtain a graph in G that is $\leq_c$-smaller than G. For the second possibility (2), the reasoning is similar.

Suppose that by identifying u and v we create a graph that is $\leq_c$-smaller than $3 \times K_{1,3}$. Since G has no vertices of degree 4, G must, in this case, have vertices of degree ≤ 2 besides u and v. But then u may be identified with one of these other vertices and stay in the class $\mathfrak{G}$. □

Proof of Proposition 3.1. In the reasoning to follow we shall quite frequently use the fact that a nine-edge graph satisfies

$$\sum_{u \in V(G)} \deg(u) = 18. \tag{3.1}$$

Let us now determine the $\leq_c$-minimal elements G in $\mathfrak{G}$.

Case 1. G has a vertex u of degree 1.

Let v denote the vertex adjacent to u. When $\deg v = 1$ the remaining vertices should have degree 3 (Lemma 3.2). This is impossible by (3.1). Consider now the case when $\deg v = 2$, and let $w \neq u$ be the other neighbor of v. The cases, $\deg w = 1$ and $\deg w = 2$, are quickly disregarded again by using Lemma 3.2 and (3.1). When $\deg w = 3$, the only graph one obtains by requiring that all other vertices have degree 3 (which must be the case because of Lemma 3.2) contains a $K_{2,3}$ and is therefore not in $\mathfrak{G}$. Consequently, we are left with the case that $\deg v = 3$. Let $\{u, w_1, w_2\}$ denote the adjacency set of v. When $\deg w_1 = \deg w_2 = 1$ we obtain G_2 as the only possibility. The cases $\{\deg w_1 = 1,\ \deg w_2 = 2\}$, $\{\deg w_1 = \deg w_2 = 2\}$, and

$\{\deg w_1 = \deg w_2 = 3\}$ are quickly discarded, leaving the case $\{\deg w_1 = 2, \deg w_2 = 3\}$. From this we obtain G_1 as the only possibility.

Case 2. All vertices of G have degree 2.

Then G must have nine vertices and consist of circuits. The only possibilities are G_3, G_4, G_5, and G_6.

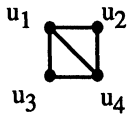
We are left with the cases that G has some vertices of degree 3 and some of degree 2. Because of (3.1), the number of degree-3 vertices must be even.

Case 3. G has two vertices of degree 3 and six of degree 2.

First we consider the case when the vertices of degree 3 are adjacent. Disconnected graphs with these requirements are easily recognized to be G_7 and G_8. Considering the possible paths between the vertices of degree-3 nodes, one obtains the graphs G_9, G_{10}, and G_{11} in case there are three different paths; when there is only one path, the graphs G_{12} and G_{13} are obtained (note that two paths between the degree-3 nodes is impossible). In a similar way, one obtains the graphs G_{14}–G_{18} for the case when vertices of the degree 3 have distance 2 or 3.

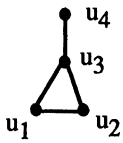
Case 4. G has four vertices of degree 3 and three of degree 2.

Since $G \not\geq_c 3 \times K_{1,3}$, there should be no three vertices of degree 3 that are all nonadjacent. Let u_1, u_2, u_3, and u_4 denote the vertices of degree 3. When $u_1, \ldots, u_4$ are all adjacent to one another, one obtains the only possibility, G_{26}. When they form



,

one obtains G_{25}. When $u_1, \ldots, u_4$ form a square ($K_{2,2}$), one obtains G_{23}. When $u_1, \ldots, u_4$ form



,

one obtains G_{19} and G_{21}. The case when $u_1, \ldots, u_4$ form a connected line gives possibilities G_{20}, G_{22}, and G_{28}. The last case is when $u_1, \ldots, u_4$ form a line of three vertices and an isolated vertex. This gives as the only possibility, G_{24}.

Case 5. G only has vertices of degree 3.

Here G_{27} is the only possibility.

This proves Proposition 3.1. □

This concludes the proof of (ii) $\Longrightarrow$ (iii).

To prove (iii) $\Rightarrow$ (i) we need to show that for the graphs G_1–G_{28} we can find a rank-4 extremal in $M_+(G)$. Then Proposition 2.2 yields that all graphs under (iii) have a rank-4 extremal. The graphs G_1, G_2, G_{19}, G_{20}, G_{21}, G_{22}, G_{24}, G_{27}, and G_{28} have a vertex of degree 3 that is not adjacent to two other vertices of degree 3. Therefore, by Theorem 2.1 (i)–(iv), the order of these graphs is ≥ 4. But then, since the numbers of edges is smaller than 14 we obtain that the order is at most 4, giving equality. The graph G_{26} has as its complement the graph $K_{3,4}$. Consequently, G_{26} has order 4, by Theorem 6.1 in [HPR]. The graphs G_{23} and G_{28} are recognized to have order ≥ 4 by Theorem 2.1 using (i)–(iii) and (v).

The remaining graphs G_3–G_{18} and G_{25} are dealt with by "brute force." A program using Mathematica (using integer arithmetic) produced for us the following rank-4 extremals in $M_+(G)$ for G in G_3–G_{18}, G_{25}. For each G_i this rank-4 extremal is given by $A_i^T A_i$, where A_i, $i = 3, \ldots, 18, 25$, is given by

$$A_3 = \begin{pmatrix} 1 & 0 & 0 & 2 & -2 & -2 & \frac{9}{22} & \frac{37}{4} & -\frac{32}{45} \\ 0 & 2 & -2 & -\frac{5}{2} & -\frac{9}{2} & -3 & \frac{8}{11} & -3 & -\frac{386}{135} \\ 0 & -3 & 3 & -2 & -1 & -3 & 1 & 1 & 2 \\ 0 & 1 & 2 & -1 & -3 & -2 & -3 & -2 & 2 \end{pmatrix}$$

$$A_4 = \begin{pmatrix} 1 & 2 & -3 & 0 & 0 & -3 & -5 & -6 & \frac{11}{7} \\ 0 & 1 & 3 & 2 & 4 & 3 & -5 & -1 & \frac{39}{7} \\ 0 & 3 & 2 & 2 & -1 & 3 & 3 & -3 & -3 \\ 0 & 2 & -3 & -3 & 2 & -3 & 3 & 3 & 2 \end{pmatrix}$$

$$A_5 = \begin{pmatrix} 1 & 3 & \frac{1}{3} & -\frac{2}{3} & -12 & 0 & 0 & 6 & \frac{13}{12} \\ 0 & 1 & 2 & -1 & 2 & -2 & \frac{7}{2} & 3 & \frac{1}{2} \\ 0 & -2 & 3 & -2 & 3 & 3 & 2 & -3 & 3 \\ 0 & 1 & 3 & -1 & -3 & 1 & 1 & -1 & -1 \end{pmatrix}$$

$$A_6 = \begin{pmatrix} 1 & 0 & -2 & 1 & \frac{1}{2} & 0 & -3 & -6 & \frac{14}{5} \\ 0 & -2 & -1 & -3 & 1 & 1 & -9 & -2 & -\frac{47}{5} \\ 0 & -3 & 3 & -1 & 2 & 2 & 5 & -1 & 3 \\ 0 & 3 & 2 & 1 & -2 & 1 & -1 & -1 & -1 \end{pmatrix}$$

$$A_7 = \begin{pmatrix} 1 & 2 & \frac{3}{2} & 0 & 0 & \frac{3}{2} & -1 & -1 \\ 0 & -1 & 1 & 3 & \frac{2}{3} & -1 & \frac{1}{2} & -\frac{9}{11} \\ 0 & 1 & -1 & -2 & 2 & -2 & -2 & -\frac{8}{11} \\ 0 & 1 & -1 & 1 & 2 & -2 & 1 & 1 \end{pmatrix}$$

$$A_8 = \begin{pmatrix} 1 & 0 & 0 & -1 & 2 & -14 & 16 & -\frac{9}{50} \\ 0 & -3 & -1 & 3 & -\frac{8}{3} & -9 & 2 & -\frac{103}{50} \\ 0 & -3 & -1 & 2 & 2 & 3 & 3 & 1 \\ 0 & -2 & 3 & 2 & 1 & -2 & 2 & 2 \end{pmatrix}$$

$$A_9 = \begin{pmatrix} 1 & 0 & 0 & 1 & 1 & -\frac{15}{2} & -\frac{2}{5} & \frac{97}{8} \\ 0 & 2 & 6 & -\frac{11}{2} & \frac{5}{2} & -1 & 3 & -\frac{1}{20} \\ 0 & -3 & 3 & -3 & -3 & -2 & 1 & 2 \\ 0 & -1 & 3 & -2 & -2 & 2 & 1 & 3 \end{pmatrix}$$

$$A_{10} = \begin{pmatrix} 1 & 0 & 0 & 2 & 1 & 2 & 7 & -\frac{5}{2} \\ 0 & -1 & -3 & -2 & \frac{4}{3} & 0 & -3 & -\frac{35}{6} \\ 0 & 1 & 1 & -1 & 1 & 1 & -1 & 2 \\ 0 & -1 & 3 & 1 & 1 & -3 & -2 & -1 \end{pmatrix}$$

$$A_{11} = \begin{pmatrix} 1 & 0 & 0 & -2 & -\frac{59}{6} & -\frac{10}{3} & \frac{6}{59} & \frac{1062}{277} \\ 0 & -3 & 1 & -\frac{5}{3} & 7 & -2 & 1 & -\frac{2324}{277} \\ 0 & -2 & -1 & 1 & 1 & -1 & -3 & -2 \\ 0 & 1 & -2 & -3 & 3 & 3 & -1 & -2 \end{pmatrix}$$

$$A_{12} = \begin{pmatrix} 1 & 0 & 1 & -3 & 0 & 0 & 9 & \frac{5}{6} \\ 0 & -1 & 5 & 2 & -2 & 4 & -2 & \frac{1}{4} \\ 0 & -3 & -3 & -2 & 2 & 1 & 1 & -3 \\ 0 & 2 & -2 & -2 & -2 & -3 & -2 & 2 \end{pmatrix}$$

$$A_{13} = \begin{pmatrix} 1 & 0 & 0 & 0 & -1 & -2 & -1 & \frac{18}{11} \\ 0 & 3 & 3 & 1 & 4 & \frac{2}{3} & \frac{1}{2} & \frac{75}{22} \\ 0 & 2 & -3 & 3 & -3 & 1 & -\frac{1}{2} & 3 \\ 0 & -2 & 3 & -1 & 3 & 2 & -1 & -1 \end{pmatrix}$$

$$A_{14} = \begin{pmatrix} 1 & 0 & 0 & -1 & 3 & 2 & 7 & \frac{16}{11} \\ 0 & 2 & -3 & -4 & 0 & \frac{4}{3} & 1 & -\frac{57}{11} \\ 0 & 2 & -1 & 3 & -1 & -2 & 3 & -1 \\ 0 & -2 & 1 & -1 & -1 & 2 & -2 & 1 \end{pmatrix}$$

$$A_{15} = \begin{pmatrix} 1 & 0 & 0 & 0 & 1 & -\frac{27}{4} & 2 & -\frac{48}{223} \\ 0 & 2 & 2 & 2 & -\frac{3}{2} & \frac{11}{2} & \frac{5}{2} & -\frac{140}{223} \\ 0 & -3 & -1 & -2 & 3 & 3 & 2 & 2 \\ 0 & 1 & 3 & -3 & -3 & -2 & -1 & 2 \end{pmatrix}$$

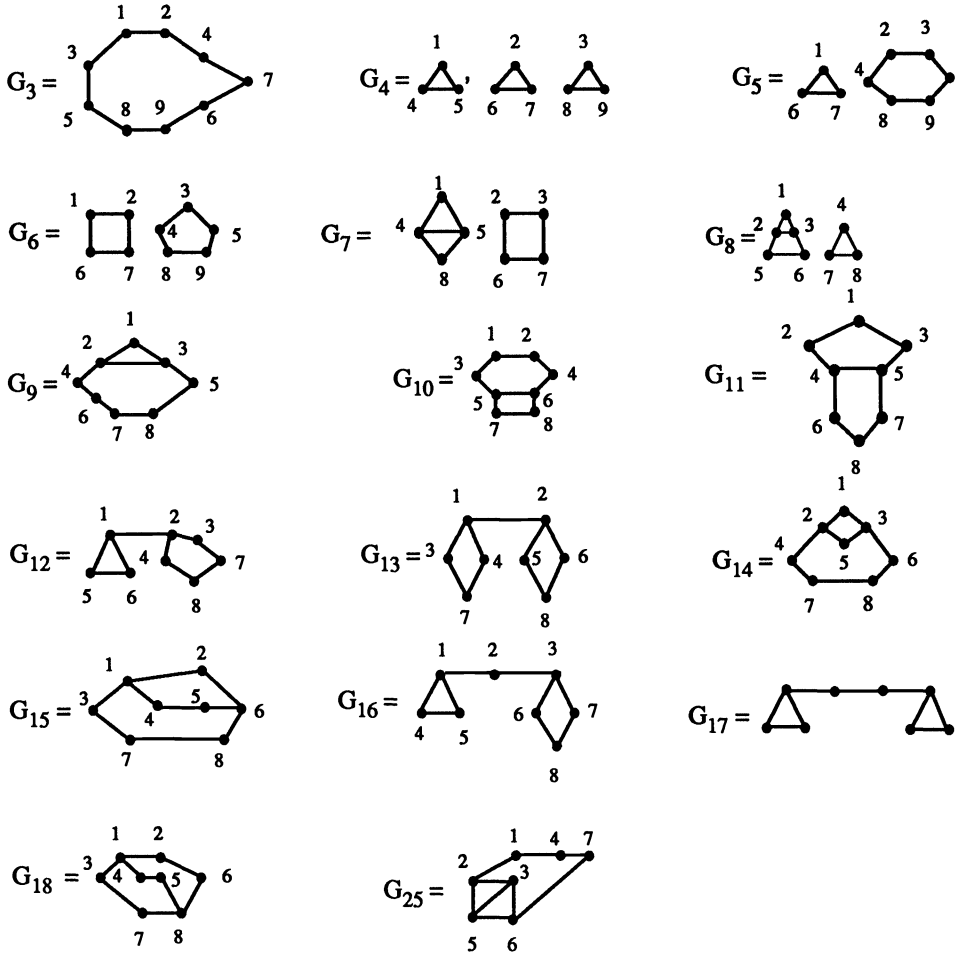
$$A_{16} = \begin{pmatrix} 1 & 0 & 2 & 0 & 0 & \frac{25}{2} & \frac{47}{2} & \frac{8}{11} \\ 0 & -1 & 12 & -3 & -5 & -3 & -3 & \frac{48}{11} \\ 0 & -2 & -3 & 3 & -3 & -3 & 3 & -2 \\ 0 & 3 & 2 & -2 & 3 & 1 & -1 & -2 \end{pmatrix}$$

$$A_{17} = \begin{pmatrix} 1 & 0 & -2 & -\frac{5}{2} & 0 & 0 & -\frac{6}{5} & -\frac{80}{61} \\ 0 & 2 & -3 & 3 & -3 & -\frac{5}{3} & -1 & \frac{96}{61} \\ 0 & -3 & -3 & -2 & 2 & 2 & -3 & 2 \\ 0 & 3 & -1 & 2 & -3 & 3 & -3 & -2 \end{pmatrix}$$

$$A_{18} = \begin{pmatrix} 1 & 0 & 0 & 0 & -3 & -1 & 3 & \frac{294}{151} \\ 0 & -1 & -3 & 1 & 12 & 10 & -\frac{5}{3} & -\frac{99}{302} \\ 0 & 3 & 1 & 3 & -2 & 2 & 1 & -\frac{117}{302} \\ 0 & -2 & -3 & 2 & -3 & -2 & 2 & -3 \end{pmatrix}$$

$$A_{25} = \begin{pmatrix} 1 & 0 & -2 & 0 & \frac{2}{3} & \frac{30}{7} & -\frac{81}{20} \\ 0 & 3 & -\frac{4}{3} & -1 & 2 & -\frac{27}{14} & -9 \\ 0 & -1 & 2 & -3 & 3 & 1 & 2 \\ 0 & 3 & 2 & 3 & -1 & 2 & -1 \end{pmatrix}$$

Here the numbering of the nodes is basically from top to bottom and from left to right, or, more explicitly, given by the following.



It is easy to check by hand that the representations of G_3–G_{18} and G_{25}, indicated by A_3–A_{18} and A_{25}, respectively, satisfy the conditions in Step I of the recipe. In order to check that Step II is satisfied, one has to go through more elaborate calculations. These checks were made using the Mathematica program. □

NORMS OF HADAMARD MULTIPLIERS*

CARL C. COWEN†, MICHAEL A. DRITSCHEL†, AND RICHARD C. PENNEY†

Abstract. For B a fixed matrix, the authors consider the problem of finding the norm of the map $X \mapsto X \bullet B$, where $\bullet$ is the Hadamard or entrywise product of matrices and the norm of a matrix is its spectral norm. Using techniques from the theory of Kreĭn spaces, the problem is rewritten for Hermitian matrices as a minimization problem whose solution, for small matrices, can be obtained from standard optimization software. The Hadamard multiplier norm for an arbitrary matrix is given in terms of a Hermitian extension. The results are applied to refute a conjecture of R. V. McEachin concerning the value of a constant in an operator inequality.

Key words. Hadamard product, Schur product, Kreĭn space, operator inequality

1. Introduction and definitions.

By the *Hadamard product*, also called the Schur product, we mean the entry-wise product of matrices: if A and B are $m \times n$ matrices, their Hadamard product, $A \bullet B$ is the $m \times n$ matrix whose entries are $a_{jk}b_{jk}$. In this paper, we study the norm of the operator on the set $\mathcal{M}_n$ of $n \times n$ matrices given by $X \mapsto X \bullet B$, for a fixed B. Throughout, $\langle \cdot, \cdot \rangle$ will denote the standard Euclidean inner product on $\mathbf{C}^n$ and by the norm of a vector, we will mean the Euclidean norm. The norm of a matrix is its norm as an operator on this Hilbert space (i.e., the spectral norm), and the norm K_B of the Hadamard multiplier is its norm as a linear map on the operators in $\mathcal{M}_n$. If A is in $\mathcal{M}_n$, we will denote its (Hilbert space) adjoint by A^*. For A an $n \times n$ matrix with columns $A_1, A_2, \ldots, A_n$, let

$$c(A) = \max\{\|A_1\|, \|A_2\|, \ldots, \|A_n\|\}.$$

Haagerup [3] (or see [8, pp. 110–116] or [6]) showed that if B is an $n \times n$ matrix, then the norm of B as a Hadamard multiplier is

$$K_B = \min\{c(S)c(R) : S^*R = B\}.$$

We show that when B is Hermitian, there is a Kreĭn space (defined below) associated with B and an optimal factorization for which S^* is $R^\times$, the Kreĭn space adjoint of R. We then obtain K_B as a minimum of $c(UR_0)^2$ over the set of Kreĭn unitaries, U, where $B = R_0^\times R_0$ is a particular factorization of B. In addition, we show that K_B is the value at all local minima of this function, so we can use this factorization and standard software to approximate K_B, confident that the minimizing sequence generated is not approaching an uninteresting local minimum. We can restrict our attention to Hermitian matrices because if A is any matrix, it is easily seen that K_A is the same as K_B, where B is the Hermitian matrix

$$B = \begin{pmatrix} 0 & A \\ A^* & 0 \end{pmatrix}.$$

A vector space $\mathcal{K}$ with a scalar product $[\cdot, \cdot]$ is a Kreĭn space if there is an inner product $\langle \cdot, \cdot \rangle$ that makes $\mathcal{K}$ a Hilbert space so that $[x, y] = \langle Jx, y \rangle$, where J is self-adjoint and unitary, that is, $J = J^* = J^{-1}$. The matrix J is called a *fundamental*

† Department of Mathematics, Purdue University, West Lafayette, Indiana 47907 (cowen@math.purdue.edu; mad@math.purdue.edu; rcp@math.purdue.edu).

symmetry of the Kreĭn space. The prototypic example of a finite dimensional Kreĭn space is the vector space $\mathbf{C}^n$, together with the scalar product obtained from the diagonal matrix whose first diagonal entries are 1's and whose remaining diagonal entries are -1's. If $J = I$, the resulting Kreĭn space is the Euclidean (Hilbert) space.

If $\mathcal{K}_1$ and $\mathcal{K}_2$ are Kreĭn spaces with fundamental symmetries J_1 and J_2, respectively, and $A: \mathcal{K}_1 \to \mathcal{K}_2$ is a linear map, its Kreĭn space adjoint, denoted $A^\times$, is $J_1 A^* J_2$. Indeed,

$$[Ax, y]_2 = \langle J_2 Ax, y\rangle = \langle x, A^* J_2^* y\rangle = \langle J_1 x, J_1 A^* J_2 y\rangle = [x, J_1 A^* J_2 y]_1.$$

We will need to use the fact that if $\mathcal{K}$, $\mathcal{K}_1$, and $\mathcal{K}_2$ are Kreĭn spaces with fundamental symmetries J, J_1, and J_2 and $R : \mathcal{K} \longrightarrow \mathcal{K}_1$ and $S : \mathcal{K} \longrightarrow \mathcal{K}_2$ are invertible and satisfy $R^\times R = S^\times S$, then there is a Kreĭn unitary $U : \mathcal{K}_1 \longrightarrow \mathcal{K}_2$ so that $S = UR$. Indeed, the invertibility of R and S shows that for v and w in $\mathcal{K}_1$, if $v = Rx$ and $w = Ry$, then $U = SR^{-1}$ is Kreĭn unitary:

$$[v, w]_1 = [Rx, Ry]_1 = [R^\times Rx, y] = [S^\times Sx, y] = [Sx, Sy]_2 = [Uv, Uw]_2.$$

(An infinite dimensional version of this fact is addressed by Theorem 2.12 of [2].) In particular, this means that $\mathcal{K}_1$ and $\mathcal{K}_2$ are equivalent as Kreĭn spaces. For maps between Kreĭn spaces, J-selfadjoint, J-unitary, and so forth, will have the obvious meanings.

2. The results. We begin by showing that when the Hadamard multiplier is Hermitian, there is a solution of the Haagerup extremal problem that has a special symmetry. (This is an extension of Theorem 3 of [1] and its proof.)

THEOREM 2.1. *Let B be a Hermitian matrix. There is a fundamental symmetry J and an $n \times n$ matrix R (regarded as a map from Euclidean space to the Kreĭn space determined by J) so that*

$$K_B = c(R)^2 \quad \textit{and} \quad B = R^\times R.$$

Proof. We first assume that B is invertible.

Paulsen, Power, and Smith prove [9, p. 161] that among all positive matrices of the form

$$P = \begin{pmatrix} X & B \\ B & Y \end{pmatrix},$$

K_B is the smallest $\max\{x_{jj}, y_{jj} : j = 1, \ldots, n\}$ that can occur (see also [6, Thm. 3.1]). If P_0 is a matrix of this form with $K_B = \max\{x_{jj}, y_{jj}\}$ and

$$J_0 = \begin{pmatrix} 0 & I \\ I & 0 \end{pmatrix},$$

then J_0 is selfadjoint and

$$J_0 P_0 J_0 = \begin{pmatrix} Y & B \\ B & X \end{pmatrix}$$

is positive. Now, $P_1 = (P_0 + J_0 P_0 J_0)/2$ is positive and

$$P_1 = \begin{pmatrix} W & B \\ B & W \end{pmatrix},$$

where $W = (X + Y)/2$. Moreover,

$$K_B \le \max\{w_{jj}\} \le \frac{1}{2}\max\{x_{jj}\} + \frac{1}{2}\max\{y_{jj}\} \le K_B,$$

so P_1 is also an extension of B that gives K_B.

Let

$$\mathcal{E} = \left\{ P = \begin{pmatrix} Z & B \\ B & Z \end{pmatrix} : P \text{ positive and } K_B = \max\{z_{jj}\} \right\}.$$

From the above symmetrization argument, the set $\mathcal{E}$ is nonempty and it is clearly closed. Therefore, $\mathcal{E}$ contains minimal elements with respect to the usual order on positive matrices. We claim that any minimal element has rank n.

To this end, suppose P is a minimal element of $\mathcal{E}$. Let

$$P = \begin{pmatrix} S & R \\ 0 & Q \end{pmatrix}^* \begin{pmatrix} S & R \\ 0 & Q \end{pmatrix}$$

be the Cholesky factorization of P (see, for example, [5, pp. 114 and 407]) in which Q, R, and S are $n \times n$ matrices with Q and S upper triangular having nonnegative diagonal entries. This means

$$\begin{pmatrix} Z & B \\ B^* & Z \end{pmatrix} = \begin{pmatrix} S^*S & S^*R \\ R^*S & R^*R + Q^*Q \end{pmatrix}.$$

Since $B = S^*R$ has rank n, each diagonal entry of S is positive, and it is easily seen that the rank of P is n if and only if $Q = 0$. If Q were not zero, then define $\tilde{P}$ by

$$\tilde{P} = \begin{pmatrix} S & R \\ 0 & 0 \end{pmatrix}^* \begin{pmatrix} S & R \\ 0 & 0 \end{pmatrix} = \begin{pmatrix} S^*S & S^*R \\ R^*S & R^*R \end{pmatrix}, \tag{1}$$

and let $\tilde{P}_0 = (\tilde{P} + J_0\tilde{P}J_0)/2$. Since the diagonal entries of R^*R are no more than those of $R^*R + Q^*Q = Z$, the largest diagonal entry of $\tilde{P}_0$ is no more than K_B. On the other hand, since $\tilde{P}_0$ is a positive matrix with B in the upper right corner, the largest diagonal entry of $\tilde{P}_0$ is at least K_B. Thus, $\tilde{P}_0$ is in $\mathcal{E}$. Since

$$P = \tilde{P}_0 + \frac{1}{2}\begin{pmatrix} Q^*Q & 0 \\ 0 & Q^*Q \end{pmatrix},$$

$\tilde{P}_0$ is strictly less than P unless $Q = 0$. The minimality of P in $\mathcal{E}$ implies $Q = 0$ and rank P is n.

Therefore, a minimal element of $\mathcal{E}$ has the form (1), and there are $n \times n$ matrices R and S satisfying $B = S^*R$ with $S^*S = R^*R$ and $K_B = c(S)c(R)$. Since the diagonal entries of R^*R and S^*S are the squares of the column norms of R and S, respectively, it follows that $c(R) = c(S)$ and $K_B = c(R)^2$. The equality $S^*S = R^*R$ implies that there is a unitary matrix J so that $S = JR$. Since B is Hermitian, we find

$$R^*JR = R^*S = B^* = B = S^*R = R^*J^*R.$$

The invertibility of B implies R is invertible, so the above equality means $J = J^*$. Thus, J is a fundamental symmetry. Now the equality $S = JRI$ gives $S^* = IR^*J = R^\times$, as we were to show.

Now if B is not invertible, we can find a sequence B_k of invertible Hermitian matrices so that $\lim B_k = B$. Continuity gives $\lim K_{B_k} = K_B$. For each k, there are fundamental symmetries J_k and matrices R_k so that $B_k = R_k^\times R_k$, that is, $J_k^* = J_k^{-1} = J_k$ and $B_k = R_k^* J_k R_k$, and $K_{B_k} = c(R_k)^2$. Since all matrices are finite and their entries are uniformly bounded (the J_k's are Euclidean unitary and $\lim c(R_k)^2 = K_B$), we can find subsequences converging to J and R, respectively, and by continuity,

$$J^* = J^{-1} = J, \qquad B = R^* J R = R^\times R,$$

and $K_B = \lim K_{B_k} = \lim c(R_k)^2 = c(R)^2$. Thus, the conclusion holds in this case as well. □

This theorem is an extension of Schur's theorem on the norm of a Hadamard multiplier of a positive matrix. To see this, note that if B is positive, then J is the identity and the theorem reduces to $K_B = c(R)^2$, where $R^*R = B$. Since the diagonal entries of B are just the squares of the norms of the columns of R, as Schur proved [10], K_B is the largest entry on the diagonal of B. (This is not a new proof of the Schur theorem as the Schur theorem was one of the ingredients of the Paulsen, Power, and Smith result.)

Theorem 2.1, together with the observation that $B = R^\times R = R_0^\times R_0$ implies $R = UR_0$ for some Kreĭn unitary map, means we can reformulate the extremal problem of Haagerup.

COROLLARY 2.2. *If B is Hermitian and J is a fundamental symmetry so that $B = R_0^\times R_0$, then*

$$K_B = \min\{c(UR_0)^2 : U \text{ is } J\text{-unitary}\}.$$

Moreover, if B is Hermitian, it is easy to find R_0 satisfying $B = R_0^\times R_0$. There is a unitary U so that UBU^* is diagonal. Now if J is the sign of the diagonal matrix and E is the positive diagonal matrix so that $E^2 J = UBU^*$, then we may take $R_0 = EU$ viewed as an operator from Euclidean space to the Kreĭn space $\mathcal{K}$ determined by J. In this case,

$$R_0^\times R_0 = (EU)^* JEU = U^* EJEU = U^* E^2 JU = B.$$

If J_1 and J are unitarily equivalent, say $W^* J_1 W = J$, then we can use $\tilde{R}_0 = WEU$, viewed as an operator from Euclidean space to $\mathcal{K}_1$, the Kreĭn space determined by J_1. The remarks made at the end of the introduction show that all such factorizations of B arise in this way.

Theorem 2.1 can be extended trivially to a slightly more general setting: if J_0 is a fundamental symmetry whose entries are 1's, 0's, and -1's and B is J_0-selfadjoint, instead of just Euclidean Hermitian (I-selfadjoint), then the conclusion of the theorem holds. This is easily seen to be true since in this case $J_0 B$ is Hermitian and $K_B = K_{J_0 B}$. An important example of such a fundamental symmetry is the matrix J_0 whose nonzero entries are 1's on the cross diagonal, that is, $u_{i,n-i+1} = 1$ and $u_{ij} = 0$ otherwise. In [1], the triangular truncation matrix was viewed as a J_0-selfadjoint matrix and the other Kreĭn space of the factorization $R^\times R$ was also taken to be the space with $J = J_0$.

If we define the function γ on the group $\mathcal{G}$ of Kreĭn unitaries by $\gamma(U) = c(UR_0)^2$, Corollary 2.2 shows that K_B is the minimum of γ on $\mathcal{G}$. In most cases, the minimum is attained on a set that includes a nontrivial subgroup of $\mathcal{G}$, so it is not attained at a unique point. It is computationally important to know whether γ has uninteresting

local minima, that is, local minima at which the value is larger than the value at the absolute minimum. We prove that it does not!

It is well known, and easily shown by taking second derivatives, that if H is Hermitian and v is a vector in $\mathbf{C}^n$ with $Hv \neq 0$, then $t \mapsto \|e^{tH}v\|^2$ is strictly convex.

The following lemma is the particular case of the Cartan decomposition of a semisimple Lie group that applies to our situation (see, for example, [11, p. 162]). We give an elementary proof for the sake of completeness.

LEMMA 2.3. *If U is Kreĭn unitary, then U may be written uniquely as $U = VP$, where V is Kreĭn and Euclidean unitary and P is Kreĭn unitary and Euclidean positive.*

Proof. Let U be Kreĭn unitary and let $U = VP$ be the unique (Euclidean) polar decomposition of U, where V is Euclidean unitary and P is Euclidean positive. Since U is invertible, so are V and P and

$$U = (U^\times)^{-1} = (V^\times)^{-1}(P^\times)^{-1}.$$

Since P is positive and since congruence preserves positivity, $P^\times = JP^*J = J^*PJ$ is positive, and this implies $(P^\times)^{-1}$ is positive. Since V and J are Euclidean unitary and the Euclidean unitaries are a group,

$$(V^\times)^{-1} = (JV^*J)^{-1} = J^{-1}(V^*)^{-1}J^{-1} = JVJ$$

is also Euclidean unitary. This means $U = (V^\times)^{-1}(P^\times)^{-1}$ is a (Euclidean) polar decomposition of U also. Since the polar decomposition is unique, we find $V = (V^\times)^{-1}$ and $P = (P^\times)^{-1}$, which means that V and P are Kreĭn unitary. □

COROLLARY 2.4. *If U is Kreĭn unitary, U can be factored as $U = Ve^H$, where V is Kreĭn and Euclidean unitary and $H = H^* = -H^\times$.*

Proof. We need only prove that $P = e^H$ where H has the required properties. Since P is Euclidean positive, P has a unique Hermitian logarithm, H. The fact that P is Kreĭn unitary means $e^{H^\times} = P^\times = P^{-1} = e^{-H}$ from which it follows that $H = -H^\times$. □

We are now ready to prove that no uninteresting local minima exist.

THEOREM 2.5. *Let R be an $n \times n$ matrix and let γ be the function on the group $\mathcal{G}$ of Kreĭn unitaries given by $\gamma(U) = c(UR)^2$. If γ has a local minimum at U_1, then*

$$\gamma(U_1) = \min\{\gamma(U) : U \in \mathcal{G}\}.$$

Proof. Let U_0 be a Kreĭn unitary so that $\gamma(U_0)$ is the minimum value of γ on $\mathcal{G}$. Replacing R by U_0R in the definition of γ if necessary, we see that, without loss of generality, we may assume $U_0 = I$.

Suppose γ has a local minimum at the Kreĭn unitary U_1. By Corollary 2.4, U_1 can be factored as Ve^H, where V is both Kreĭn and Euclidean unitary and H satisfies $H^* = H = -H^\times$. Let f be defined by $f(t) = \gamma(Ve^{tH})$, that is, $f(t)$ is the maximum of $\|Ve^{tH}R_j\|^2 = \|e^{tH}R_j\|^2$, where $R_1, R_2, \ldots, R_n$ are the columns of R. We noted above that each of the functions $\|e^{tH}R_j\|^2$ is convex. Since the maximum of convex functions is convex, it follows that f is convex. Now V is Euclidean unitary so $\gamma(V) = \gamma(I)$ is the global minimum, and

$$f(0) = \gamma(V) \leq \gamma(U_1) = \gamma(Ve^H) = f(1).$$

If $\gamma(U_1) > \gamma(I)$, the convexity of f implies

$$\gamma(Ve^{tH}) = f(t) \leq (1-t)f(0) + tf(1) < f(1) = \gamma(U_1)$$

for $0 < t < 1$. In particular, this is true for t arbitrarily close to 1, so $\gamma(U_1)$ cannot be a local minimum.

Thus, the only local minima of γ are those points at which γ achieves a global minimum. □

These results may be used for calculating the Hadamard multiplier norm of Hermitian matrices. We begin by factoring B as $B = R_0^{\times} R_0$. Lemma 2.3 permits expressing K_B as the solution of the minimization problem

$$K_B = \min\{c(PR_0)^2 : \ P \text{ is Euclidean positive and Kreĭn unitary}\}, \tag{2}$$

and Corollary 2.4 permits expressing K_B as the solution of the minimization problem

$$K_B = \min\{c(e^H R_0)^2 : H^* = H = -H^{\times}\}. \tag{3}$$

These minimization problems can be approached with standard software since if J is the fundamental symmetry

$$J = \begin{pmatrix} I & 0 \\ 0 & -I \end{pmatrix},$$

then P is Euclidean positive and J–unitary if and only if there is a matrix X so that

$$P = \begin{pmatrix} \sqrt{I + XX^*} & X \\ X^* & \sqrt{I + X^*X} \end{pmatrix},$$

and $H^* = H = -H^{\times}$ if and only if there is a matrix Y so that

$$H = \begin{pmatrix} 0 & Y \\ Y^* & 0 \end{pmatrix}.$$

We have used both methods to approximate K_B for some small matrices B. Our limited experience suggests that using (3) gives slightly better results and that the minimum is relatively shallow, which causes difficulty with the convergence.

Equations (2) and (3) express K_B as minimization problems that can be parametrized as above by matrix variables X and Y. Using $X_0 = Y_0 = (1, 0)$ and $X_1 = Y_1 = (0, 1)$, examples of matrices R_0 can be found to show that these functions are not necessarily convex in the variables X and Y, so the convexity property in the proof of Theorem 2.5 is not the restriction of such a broader convexity property.

We believe the results above form the theoretical basis of an approach for finding the norms of matrices as Hadamard multipliers on $\mathcal{M}_n$.

3. Application to the conjecture of McEachin. In the analysis of a perturbation problem of interest in operator theory, McEachin [7] needed to estimate the Hadamard multiplier norm of matrices such as

$$M = \begin{pmatrix} \frac{1}{7} & \frac{1}{5} & \frac{1}{3} & 1 \\ \frac{1}{5} & \frac{1}{3} & 1 & -1 \\ \frac{1}{3} & 1 & -1 & -\frac{1}{3} \\ 1 & -1 & -\frac{1}{3} & -\frac{1}{5} \end{pmatrix}.$$

McEachin conjectured that

$$K_M = \sqrt{\frac{410 + \sqrt{30}}{864}} + \sqrt{\frac{410 - \sqrt{30}}{864}} > 1.37770223779394.$$

We used MATLAB on a Macintosh II, with the function `minimax` from MATLAB's Optimization Toolbox. We factored M through the Kreĭn space whose fundamental symmetry is the matrix with 1's on the cross diagonal and used the minimization problem from (3). We found that if

```
R =
   0.29345772706387  -0.87151443181904  -0.38760407738941   0.75646065056181
  -0.82107382515359  -0.30980696295447  -0.19650488973146  -0.12891228276962
  -0.78049759723731   0.17648441164311   0.47999514387418   0.82208465702786
   0.09080760857704  -0.70074080677351   0.87900753539208  -0.33619623611316
```

and J is the fundamental symmetry with diagonal 1, 1, -1, and -1, then $M = R^{\times}R = R^*JR$ and the corresponding estimate for K_M is 1.37770218499455. Of course, in the absence of error estimates, this calculation does not really mean a great deal. However, using the calculated value for R and *exact arithmetic* with MAPLE on a Macintosh II to find S satisfying $S^*R = M$, the Haagerup result shows that

$$K_M \leq c(S)c(R) < 1.37770218499457,$$

from which it follows that McEachin's conjectured value for K_M is too large.

While the above calculations do prove McEachin's conjecture is incorrect, they do not really show that our estimate for K_M is close to correct. Because the unitary matrices are the extreme points of the unit ball in the space of matrices, there is a unitary U_0 at which K_M is achieved, that is, $\|M \bullet U_0\| = K_M$. After a slight modification, Corollary 7 of [1] applies to this case and the discussion there indicates how a maximizing unitary may be computed from an optimal factorization $M = R_0^{\times}R_0$. We will use this construction to get a lower bound for K_M.

In [1], the important fundamental symmetry is the matrix with 1's on the cross diagonal, denoted J', and the relation $T^* = J'TJ'$ replaces selfadjointness. Since M and J' each have two positive eigenvalues, the Kreĭn space induced by J' can be used for the Kreĭn space occurring in the factorization of M so that Corollary 7 of [1] applies to $T = J'M$. Suppose $M = R_0^{\times}R_0$ is an optimal factorization of M so that $J'M = J'R_0^{\times}R_0 = S_0^*R_0$ is an optimal factorization of $J'M$ where $S_0^* = J'R_0^{\times}$. It was shown that, in this case, there is a positive diagonal matrix D so that $U_0 = D^{-1}S_0^{-1}R_0J'DJ'$ is a maximizing unitary and $U_0^* = J'U_0J'$. Writing W for $S_0^{-1}R_0$ and d_j for the jth diagonal entry of D, the symmetry relation for U_0 implies

$$d_j^2 = \frac{w_{jn}}{w_{1,n-j+1}}d_1^2.$$

Since we may choose $d_1 = 1$, the optimal factorization leads to D and to U_0. Using our approximate optimal factorization, we computed what we expected to be approximately an optimal unitary. This calculation (using MATLAB on a Macintosh II) produces a matrix U that is close to unitary, and we computed a lower bound for K_M from U. Interestingly, however, better results are achieved by using the unitary V from the polar factorization, $U = VP$ where $P = P^*$, of our approximate unitary:

```
V =
   0.52557371154599   0.29440955823111   0.31639397962744   0.73279610766532
   0.29440955823111   0.28352110536812   0.67353109047329  -0.61586903234281
   0.31639397962744   0.67353109047329  -0.62858513101496  -0.22612265010007
   0.73279610766532  -0.61586903234281  -0.22612265010007  -0.18050968589915
```

From this unitary, we get the estimate

$$K_M \geq \frac{\|V \bullet M\|}{\|V\|} = 1.37770218499280.$$

Combining the two estimates, we find that $K_M = 1.37770218499$ to 11 decimal digits.

CYCLIC REDUCTION FOR SPECIAL TRIDIAGONAL SYSTEMS*

S. BONDELI†‡ AND W. GANDER†

Dedicated to G. H. Golub, on the occasion of his 60th birthday.

Abstract. The solution of linear, tridiagonal systems having real, symmetric, diagonally dominant coefficient matrices with constant diagonals is considered. Details of cyclic reduction to solve such systems are discussed. It is proved that the sequence of the diagonal elements produced by the reduction phase of cyclic reduction converges quadratically. This fact is exploited to reduce the number of steps of the reduction phase (special cyclic reduction). An estimate of the rate of convergence of the diagonal elements will be proved, which can be used to determine the number of steps of the reduction phase.

Several possibilities to compute the diagonal elements are discussed and compared.

Key words. cyclic reduction, diagonally dominant matrices, direct methods, symmetric matrices, Toeplitz matrices, tridiagonal matrices

1. Introduction.

In this paper we study linear systems of n equations of the form

$$(1)\qquad T\mathbf{x} = \begin{pmatrix} a & 1 & & & \\ 1 & a & 1 & & \\ & 1 & \ddots & \ddots & \\ & & \ddots & a & 1 \\ & & & 1 & a \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_{n-1} \\ x_n \end{pmatrix} = \begin{pmatrix} d_1 \\ d_2 \\ \vdots \\ d_{n-1} \\ d_n \end{pmatrix} = \mathbf{d} \in \mathbb{R}^n,$$

$|a| \geq 2$. The coefficient matrix T has a very special form: it is tridiagonal, symmetric, and a Toeplitz matrix. Such systems arise, for example, when using finite difference methods to solve linear constant-coefficient boundary-value problems in various contexts [8], [12], [17] or in cubic spline interpolation problems with equidistant knots [7], [16].

A number of methods have been proposed for solving such systems: Toeplitz factorization [1], [2], [5], [6], [15]; cyclic reduction [2], [11], [14], [17], [18]; and specialized variants of Gaussian elimination [7], [13], [18]. Each of these requires $O(n)$ scalar operations. Such systems may also be solved using Fourier transforms, but this leads to an $O(n \log n)$ algorithm [2].

In Toeplitz factorization methods one seeks an LU factorization of T in which L is a lower bidiagonal Toeplitz matrix and U is an upper bidiagonal Toeplitz matrix: $T{=}LU$. The diagonal elements of U form a sequence that converges linearly [7], [13] to

$$u = [\, a - \operatorname{sign}(a)\sqrt{a^2 - 4}\,] \,/\, 2\,,$$

assuming $|a| > 2$. This allows the factorization to be terminated early.

Another form of early convergence has been observed for cyclic reduction [9]: in the case where T is a block tridiagonal matrix, the norms of the matrix of the off-diagonal elements decrease quadratically with each reduction step. When this norm is less than the machine precision, then the system can be considered diagonal and back-substitution can be started immediately.

In this paper, however, we prove that the diagonal elements a_i form a sequence that converges quadratically to

$$\lim_{i\to\infty} a_i \;=\; \operatorname{sign}(a)\sqrt{a^2-4}$$

for $|a|>2$; furthermore, we give an explicit formula for a_i.

The major goal of this paper is an analysis of cyclic reduction and, consequently, a better understanding of this widely used method. The paper is arranged as follows. First, we will present cyclic reduction. Then we discuss a special cyclic reduction that reduces the number of reduction steps. In a third part, different algorithms to compute the sequence of diagonal elements are discussed. Finally, we give some concluding remarks.

2. Cyclic reduction. The two fundamental operations of cyclic reduction (cyclic odd-even reduction [9]) are the elimination of odd-indexed unknowns and their eventual recovery through back-substitution.

For simplicity we assume that $n=2^m-1$. (Only a simple modification is necessary to generalize cyclic reduction to any n. For more details see [2].)

We multiply equation 1,3, ..., n of (1) by $-1/a$. If we add to each even-numbered equation the two adjacent equations, the result is

$$(2)\qquad \begin{pmatrix} a_1 & b_1 & & & \\ b_1 & a_1 & b_1 & & \\ & b_1 & \ddots & \ddots & \\ & & \ddots & a_1 & b_1 \\ & & & b_1 & a_1 \end{pmatrix} \begin{pmatrix} x_2 \\ x_4 \\ \vdots \\ x_{n-3} \\ x_{n-1} \end{pmatrix} = \begin{pmatrix} d_{2,1} \\ d_{4,1} \\ \vdots \\ d_{n-3,1} \\ d_{n-1,1} \end{pmatrix} \in \mathbb{R}^{(n-1)/2},$$

where $a_1 = a - 2/a$, $b_1 = -1/a$ and $d_{j,1} = d_j - (d_{j-1} + d_{j+1})/a$ $(j=2,4,\ldots,n-1)$. This first reduction step decoupled the even-numbered equations from the odd ones, yielding a reduced system of order $(n-1)/2$. The reduced equations have the same form as the original ones: the coefficient matrix is a tridiagonal, symmetric, Toeplitz matrix. Therefore, analogously to the elimination above, the reduction process may be applied on (2). We multiply equation 1,3, ...,$(n-1)/2$ of (2) by $-b_1/a_1$ and add adjacent equations. Again a tridiagonal, symmetric Toeplitz system of order $(n-3)/4$ results with diagonal elements $a_2 = a_1 - 2b_1^2/a_1$ and off-diagonal elements $b_2 = -b_1^2/a_1$. Thus, the reduction process may be applied recursively: after $m-1$ reduction steps, only one equation in the unknown $x_{(n+1)/2}$ is left.

The reduction phase may be summarized as follows.

ALGORITHM 2.1. Cyclic reduction: Reduction phase

```
s = 1
for i = 1, 2, ..., m - 1
    b_i = -b_{i-1}^2 / a_{i-1}
    a_i = a_{i-1} - 2 b_{i-1}^2 / a_{i-1}
    t = s
```

$s = 2s$
for $k = s, 2s, 3s, \ldots, (2^{n2-i} - 1)s = n + 1 - s$
$d_{k,i} = d_{k,i-1} - b_{i-1}(d_{k-t,i-1} + d_{k+t,i-1})/a_{i-1}$
end
end

(Here we have taken $a_0 = a$, $b_0 = 1$, and $d_{k,0} = d_k$.)

The back-substitution phase begins by computing $x_{(n+1)/2}$. All the other unknowns may then be determined by applying back-substitution recursively.

ALGORITHM 2.2. Cyclic reduction: Back substitution
$s = (n + 1)/2$
$x_s = d_{s,m-1}/a_{m-1}$
for $i = m - 2, m - 3, \ldots, 0$
$t = s$
$s = s/2$
for $k = s, s + t, s + 2t, \ldots, n + 1 - s$
$x_k = (d_{k,i} - b_i(x_{k-s} + x_{k+s}))/a_i$
end
end

(Note $x_0 = x_{n+1} = 0$.) Algorithms 2.1 and 2.2 require $O(8n)$ floating-point operations.

Since a_i occurs only in the denominator in the reduction as well as in the back-substitution phase we compute the inverse of a_i. Furthermore, since the sequence a_i converges rapidly in the reduction phase, scalar overhead can be saved by using a special cyclic reduction.

3. Special cyclic reduction.

THEOREM 3.1. *Suppose* $|a| > 2$. *Then the sequence of the diagonal elements* a_i *produced by the reduction phase* (*Algorithm* 2.1) *converges quadratically to*

$$\operatorname{sign}(a)\sqrt{a^2 - 4}\,. \tag{3}$$

Proof. Using the identity $b_i = -b_{i-1}^2/a_{i-1}$ (see Algorithm 2.1), it follows for the computation of the diagonal elements

$$\begin{aligned} a_i &= a_{i-1} - 2b_{i-1}^2/a_{i-1} \;=\; a_{i-1} + 2b_i, \\ (a_i - a_{i-1})/2 &= b_i. \end{aligned} \tag{4}$$

Substituting (4) into $b_i = -b_{i-1}^2/a_{i-1}$, we obtain

$$\begin{aligned} (a_i - a_{i-1})/2 &= -\left(\frac{a_{i-1} - a_{i-2}}{2}\right)^2 /a_{i-1}, \\ a_i &= \frac{a_{i-1}^2 + 2a_{i-1}a_{i-2} - a_{i-2}^2}{2a_{i-1}}, \\ &= a_{i-1} - \frac{(a_{i-1} - a_{i-2})^2}{2a_{i-1}}. \end{aligned} \tag{5}$$

Thus we transform (5) into

$$2a_ia_{i-1} - 2a_{i-1}a_{i-2} - a_{i-1}^2 + a_{i-2}^2 = 0, \tag{6}$$

which is a nonlinear homogeneous difference equation of order-two with initial conditions

$$a_0 = a, \qquad a_1 = \frac{a^2 - 2}{a}.$$

We define for $i = 1, 2, \ldots$

$$r_i = 2a_i a_{i-1} - a_{i-1}^2 , \tag{7}$$

and substituting (7) into (6) gives

$$r_i - r_{i-1} = 0 . \tag{8}$$

This linear homogeneous difference equation (8) has constant solutions: $i = 1, 2, \ldots$

$$r_i = r . \tag{9}$$

The initial conditions yield

$$r = r_1 = 2a_0 a_1 - a_0^2 = 2a\frac{a^2 - 2}{a} - a^2 = a^2 - 4 . \tag{10}$$

Substituting (9) into (7) and rearranging gives

$$\begin{aligned} r &= 2a_i a_{i-1} - a_{i-1}^2, \\ a_i &= \frac{a_{i-1}}{2} + \frac{r}{2a_{i-1}}. \end{aligned} \tag{11}$$

Iteration (11) is Newton's method [10, p. 81] to solve the equation $F(x) = x^2 - r = 0$. Since $F'(\sqrt{r}) = 2\sqrt{r} \neq 0$, the sequence a_i defined by (11) converges quadratically to $\sqrt{r} = \sqrt{a^2 - 4}$.

For every choice of $|a_0| > 2$, the sequence is monotone and thus

$$\lim_{i \to \infty} a_i = \operatorname{sign}(a)\sqrt{a^2 - 4}. \qquad \square \tag{12}$$

Table 1 shows some sequences for different initial values a_0=a>2. The last value of each column is equivalent to $\lim_{i \to \infty} a_i = \sqrt{a^2 - 4}$ of each sequence. The values a_i converge very fast to the limit as $|a|$ moves away from 2 (see Table 1).

Before we discuss special cyclic reduction in detail, we show an explicit formula for a_i.

LEMMA 3.2. *Suppose* $|a|>2$. *Then the diagonal elements produced by the reduction phase* (*Algorithm* 2.1) *are given by*

$$a_i = \operatorname{sign}(a)\sqrt{a^2-4}\,\coth\left(|y_0|2^i\right), \tag{13}$$

where

$$y_0 = \begin{cases} \ln\left(\sqrt{a^2-4}+a\right) - \ln 2 & \text{if } a > 2, \\ -\ln\left(\sqrt{a^2-4}-a\right) + \ln 2 & \text{if } a < -2. \end{cases}$$

If $|a| = 2$, *then the diagonal and off-diagonal elements are* ($k = 1, 2, \ldots$)

$$b_k = -\operatorname{sign}(a)/2^k, \tag{14}$$

$$a_k = \operatorname{sign}(a)/2^{k-1}\,. \tag{15}$$

Proof. Equations (14) and (15) follow by induction using the formula for the computation of the diagonal elements a_i and off-diagonal elements b_i in the reduction phase (see Algorithm 2.1). For details see [3, pp. 117ff].

We discuss the case $|a|>2$. Using the identity

$$\coth(2\alpha) = \frac{\coth(\alpha)^2+1}{2\coth(\alpha)},$$

and substituting $a_i = \sqrt{r}\coth(y_i)$ into (11), we obtain

$$\begin{aligned} \sqrt{r}\coth(y_i) &= \frac{\sqrt{r}\coth(y_{i-1})}{2} + \frac{r}{2\sqrt{r}\coth(y_{i-1})}, \\ \coth(y_i) &= \coth(2y_{i-1}). \end{aligned} \tag{16}$$

Since $\coth(x)$ is an injective function for $x\in\mathbb{R}\setminus\{0\}$, (16) implies

$$y_i = 2y_{i-1}, \tag{17}$$

which is a first-order linear homogeneous difference equation with solution

$$y_i = y_0 2^i. \tag{18}$$

The initial value y_0 of (18) is given by

$$\coth(y_0) = a_0/\sqrt{r},$$

$$y_0 = \operatorname{arctanh}\left(\frac{\sqrt{a^2-4}}{a}\right).$$

Using the identity

$$\operatorname{arctanh}(\alpha) = \frac{1}{2}\ln\left(\frac{1+\alpha}{1-\alpha}\right) \quad \text{if } |\alpha|<1,$$

and taking into consideration the sign of the initial value $a_0=a$, it follows that

$$y_0 = \begin{cases} \ln\left(\sqrt{a^2-4}+a\right) - \ln 2 & \text{if } a > 2, \\ -\ln\left(\sqrt{a^2-4}-a\right) + \ln 2 & \text{if } a < -2\,. \end{cases}$$

Finally, we obtain the explicit formula

$$a_i = \operatorname{sign}(a)\sqrt{a^2-4}\,\coth\left(|y_0|2^i\right). \qquad \square \tag{19}$$

LEMMA 3.3. *Suppose* $|a_0|>2$. *On a computer with precision* ε, *the sequence* a_i *becomes constant for* $i \geq k_a$, *where*

$$k_a = \left\lceil \frac{\log\left(\log\left(2/\varepsilon+1\right)\right) - \log\left(\log\left(|a|+\sqrt{a^2-4}\right) - \log\left(2\right)\right)}{\log\left(2\right)} - 1 \right\rceil. \tag{20}$$

Here log *denotes the logarithm to the base* 10 *and* $a = a_0$.

Proof. We will assume that $a_0=a>2$, since if a_i is the sequence corresponding to the initial value a, then $-a_i$ is the sequence corresponding to $a_0 = -a$.

We know that the sequence a_i is monotone and converges quadratically to

$$\lim_{i\to\infty} a_i = \sqrt{a^2-4}\,. \tag{21}$$

Therefore, the sequence has converged numerically if

$$\frac{a_i - \lim_{i\to\infty} a_i}{\lim_{i\to\infty} a_i} \leq \varepsilon. \tag{22}$$

Using the identity

$$\tanh\left(\alpha\right) = \frac{\exp\left(2\alpha\right)-1}{\exp\left(2\alpha\right)+1}$$

and formula (13), we obtain

$$a_i = \sqrt{a^2-4}\,\frac{z_i+1}{z_i-1} \quad \text{with} \quad z_i = \left(\frac{a}{2}+\sqrt{\left(\frac{a}{2}\right)^2-1}\right)^{2^{i+1}}. \tag{23}$$

Using (21) we see that

$$\begin{aligned}\frac{a_i - \lim_{i\to\infty} a_i}{\lim_{i\to\infty} a_i} &= \frac{\sqrt{a^2-4}\left(\dfrac{z_i+1}{z_i-1}-1\right)}{\sqrt{a^2-4}} \\ &= \frac{2}{z_i-1}\,,\end{aligned}$$

and to guarantee inequality (22), we must have

$$z_i \geq \frac{2}{\varepsilon}+1. \tag{24}$$

Using definition (23), some elementary computations give

$$i \geq \frac{\log\left(\log\left(2/\varepsilon+1\right)\right) - \log\left(\log\left(a+\sqrt{a^2-4}\right) - \log\left(2\right)\right)}{\log\left(2\right)} - 1, \tag{25}$$

where log denotes the logarithm to the base 10. $\square$

Table 2 shows k_a for the same initial values $a_0 = a$ that are used in Table 1.

This leads to the following algorithm for the solution to (1) with $|a|>2$.

TABLE 2
Values of the convergence index k_a for ε=1.0e−15.

	a=3.8	a=3.2	a=2.5	a=2.1	a=2.02
$i \geq$	3.81	4.08	4.67	5.81	6.97
$k_a =$	4	5	5	6	7

ALGORITHM 3.4. Special cyclic reduction

$z = \log\big(\log(2/\varepsilon + 1.0)\big) - \log\big(\log(|a| + \sqrt{a^2-4}) - \log(2)\big)$
$k_a = \min\{m-1, \lceil z/\log(2)\rceil - 1\}$
$b_0 = 1$
$\alpha_0 = 1/a$
$s = 1$
for $i = 1, 2, \ldots, k_a$
  $b_i = -\alpha_{i-1} b_{i-1}^2$
  $\alpha_i = \alpha_{i-1}/(1 + 2b_i\alpha_{i-1})$
  $t = s$
  $s = 2s$
  for $k = s, 2s, 3s, \ldots, (2^{n2-i} - 1)s = n + 1 - s$
    $d_{ki} = d_{k,i-1} - \alpha_{i-1} b_{i-1}\,(d_{k-t,i-1} + d_{k+t,i-1})$
  end
end

for $k = s, 2s, 3s, \ldots, n + 1 - s$ $\qquad x_k = \alpha_{k_a} d_{s,k_a}$

for $i = k_a - 1, k_a - 2, \ldots, 0$
  $t = s$
  $s = s/2$
  for $k = s, s + t, s + 2t, \ldots, n + 1 - s$
    $x_k = \alpha_i\,(d_{ki} - b_i(x_{k-s} + x_{k+s}))$
  end
end

Note that we put $x_0 = x_{n+1} = 0$, and to save operations we set $\alpha_i = 1/a_i$. The operation count of this method is reduced to $O((8 - 4/2^{k_a})n)$. Significant savings are obtained only when $|a|$ is so large that k_a is small. This means that the reduction process may stop after a few steps. The reason for this is that since the work is reduced by a factor of two at each step in the reduction phase, most of the work is done in the first few steps.

4. Sequence a_i. In this section we discuss and compare several possibilities to compute the diagonal elements of each reduction step of cyclic reduction and present the results of some time measurements.

Table 3 gives two possibilities to compute the sequence a_i using a nonlinear recurrence of order-two or order-one, respectively (see also (5) and (11)). For $|a|>2$ and i large $a_i \approx a_{i-1}$. Therefore, by computing $a_i - a_{i-1}$ in the numerator of (5), cancellation will occur. For that reason the computation of a_i using the recurrence of order-two is unstable.

However, the nonlinear recurrence of order-one (see Algorithm 2 of Table 3) is stable.

TABLE 3
Computation of the sequence a_i using nonlinear recurrences.

Algorithm 1: Nonlinear recurrence of order 2	Algorithm 2: Nonlinear recurrence of order 1
$a_0 = a$ $a_1 = a - 2/a$ for $i = 2, 3, \ldots, m$ $\quad a_i = a_{i-1} - (a_{i-1} - a_{i-2})^2 / (2a_{i-1})$ end	$r = a^2 - 4$ $a_0 = a$ for $i = 1, 2, \ldots, m$ $\quad a_i = (r/a_{i-1} + a_{i-1})/2$ end

TABLE 4
Explicit formulas for the sequence a_i.

Algorithm 3: Explicit formula using tanh	Algorithm 4: Explicit formula
$q = \sqrt{a^2 - 4}$ $y = \log \lvert a + q \rvert - \log 2$ $a_0 = a$ $t = \tanh y$ for $i = 1, 2, \ldots, m$ $\quad t = 2t/(1 + t^2)$ $\quad a_i = q/t$ end	$q = \sqrt{a^2 - 4}$ $c = (a + q)/2$ if $\lvert c \rvert > 1$ then $\quad c = 1.0/c$ $\quad q = -q$ end for $i = 0, 1, \ldots, m$ $\quad c = c^2$ $\quad a_i = q(c+1)/(c-1)$ end

In Table 4, two different explicit formulas for a_i are shown. Equation (19) leads to Algorithm 3 of Table 4, where the identity

$$\tanh(2\alpha) = \frac{2\tanh(\alpha)}{1 + \tanh^2(\alpha)}$$

is used.

Using (23) we derive the second explicit formula for a_i. If $a_0 = a > 2$, then $c = (a+q)/2 > 1$, and hence formula (23) presents the danger of floating-point overflow. However, this can be turned to our advantage by using the identity

$$\frac{(c+1)}{(c-1)} = -\frac{1/c + 1}{1/c - 1} \quad .$$

Note, with the fact that the sequence a_i is monotone for every initial value $|a_0| > 2$, the computation of a_i by each algorithm in Tables 3 and 4 can be stopped machine independently when the monotonicity is violated.

4.1. Comparison of methods. Table 5 summarizes the floating-point operation counts for the methods shown in Tables 3 and 4. Since the scalar overhead of Algorithm 2 is smaller than the other ones, this method is the fastest on a scalar machine.

On a vector computer, such as the CRAY Y/MP, both algorithms using explicit formulas (Table 4) can be vectorized. Therefore, these two methods are faster on a vector machine than the two others using a nonlinear recurrence (see Fig. 1).

TABLE 5
Operation counts.

Algorithm	Scalar operations
Nonlinear recurrence of order 2	$6m - 4$
Nonlinear recurrence of order 1	$3m + 2$
Explicit formula using tanh	$5m + 5$
Explicit formula	$5m + 10$

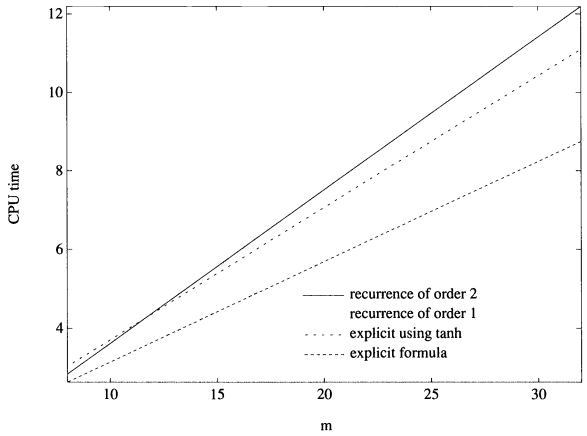

FIG. 1. *Time measurements on a* CRAY Y/MP.

5. Conclusions. For the solution of linear tridiagonal linear symmetric Toeplitz systems we have presented the details of cyclic reduction. We have proved that the sequence of the diagonal elements of the tridiagonal matrices, produced by the reduction phase of cyclic reduction, converge quadratically. This is exploited to reduce the number of steps of the reduction phase of cyclic reduction. In addition, we have developed a formula to compute an a priori estimation of the number of steps of the reduction phase and to compute the diagonal elements to full floating-point precision. Furthermore, we have discussed several algorithms to compute the sequence of the diagonal elements: nonlinear recurrences and two different explicit formulas. On a vector computer the explicit formulas are much faster than the nonlinear recurrences. Without vector facilities, nonlinear recurrence of order-one is the fastest.

Acknowledgment. The authors would like to thank G. H. Golub, one of the inventors of cyclic reduction, for many helpful suggestions.

DYNAMIC CONDITION ESTIMATION AND RAYLEIGH–RITZ APPROXIMATION*

PING TAK PETER TANG†

Abstract. It is shown here that the well-known Rayleigh–Ritz approximation method is applicable in dynamic condition estimation. In fact, it can be used as a common framework from which many recently proposed dynamic condition estimators can be viewed and understood. This framework leads to natural generalizations of some existing dynamic condition estimators as well as more convenient alternatives. Numerical examples are also provided to illustrate these claims.

Key words. condition number, singular values, incremental condition estimation

AMS subject classifications. 65F35, 65F05

1. Introduction. Recently a number of dynamic condition estimation schemes have been proposed for a variety of computational situations [1], [9], [6], [10]. These schemes all try to estimate the condition numbers of a sequence of matrices as they evolve in time in some computational process such as QR factorization or recursive least-squares calculations. These estimation schemes are mostly heuristic, and researchers have little theoretical insight on why the schemes work so well in practice. Moreover, although the schemes look alike and are applied to closely related problems, no common framework has been formulated to explain them. Thus, each scheme has been regarded as a different method: incremental condition estimation (ICE), adaptive condition estimation (ACE), adaptive Lanczos estimation (ALE), and ACE for general rank-1 updates (GRACE).

In this paper, we show that many of these dynamic condition-estimation schemes can be viewed from a common and, in fact, well-known framework of Rayleigh–Ritz approximation. This framework provides a number of advantages. The details of the various condition estimators can now be derived naturally and therefore need not be memorized; many known properties of Rayleigh–Ritz approximations can be used directly and thus help in understanding these estimators. The common framework often allows natural generalization of the estimation schemes, and this framework will likely allow relatively easy construction of different estimators for different computational situations.

The rest of the paper is organized as follows. Section 2 discusses the application of Rayleigh–Ritz approximation to condition estimation in general. Section 3 discusses some of the eigenvalue problems that arise from Rayleigh–Ritz approximation; these problems will appear again in subsequent dynamic condition estimators. Section 4 presents the general connection between Rayleigh–Ritz approximations and dynamic condition estimations, and also illustrates how the Rayleigh–Ritz framework can indeed lead to the various dynamic condition estimators. Explanations and generalizations of the various schemes are discussed whenever appropriate. Section 5 presents numerical experiments that illustrate the various points raised in §4. Section 6 offers some concluding remarks.

2. Condition estimation by Rayleigh–Ritz approximation. The condition number we are concerned with is

$$\kappa_2(R) \equiv \|R\|\|R^{-1}\| = \frac{\sigma_{\max}(R)}{\sigma_{\min}(R)} \quad \text{(all } \|\cdot\| \text{ are 2-norms, unless otherwise stated)},$$

where R is n-by-n upper triangular. In our context, R is always the triangular factor in the QR factorization of an m-by-n matrix A, $m \geq n$; thus $A^TA = R^TR$. Hence, $\sigma_{\max}(R) = \sigma_{\max}(A)$ and $\sigma_{\min}(R) = \sigma_{\min}(A)$. We shall concentrate on estimating the two extreme singular values of A. This task, in turn, can be related to estimating the two extreme eigenvalues of A^TA or the extreme eigenvalues of AA^T (provided the $m - n$ zero eigenvalues are disregarded). It is for these estimations that we employ the Rayleigh–Ritz approximation.

Let the singular value decomposition of A be $A = U\Sigma V^T$, where

$$U = [u_1, u_1, \ldots, u_n], \quad V = [v_1, v_2, \ldots, v_n], \quad \Sigma = \operatorname{diag}(\sigma_1, \sigma_2, \ldots, \sigma_n),$$
$$\text{and} \quad \sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_n.$$

Let $F = [x_1, x_2, \ldots, x_k]$ for some $k \leq n$ be a matrix of k orthonormal vectors; thus $F^TF = I$. The Rayleigh–Ritz approximation is obtained by calculating the eigensystem

$$(F^TAA^TF)W = W\operatorname{diag}(\tau_1^2, \tau_2^2, \ldots, \tau_k^2), \quad \tau_1^2 \geq \tau_2^2 \geq \cdots \geq \tau_k^2.$$

The Cauchy interlace theorem tells us that $\sigma_j^2 \geq \tau_j^2$, $j = 1, 2, \ldots, k$. The matrix $F^T(AA^T)F$ is a Rayleigh quotient of AA^T; the vectors $x_j = Fw_j$ are known as Ritz vectors, and the (τ_j^2, x_j)'s are known as Ritz pairs. If $\operatorname{span}(F) \approx \operatorname{span}(U^{(k)})$, $U^{(k)} = [u_1, u_2, \ldots, u_k]$, then the (τ_j, x_j)'s are reasonable estimates of (σ_j, u_j). In particular, we have a reasonable estimate of σ_1. Here we use the convenient notation $\operatorname{span}(\cdot)$ to denote the space spanned by the columns of the matrix inside the parentheses.

Similarly, we can estimate σ_n if we have a corresponding F approximating $[u_n, u_{n-1}, \ldots, u_{n-k+1}]$. The inequalities $\sigma_j^2 \leq \tau_j^2$, $j = n, n-1, \ldots, n-k+1$, would hold as long as $m = n$, or $\operatorname{span}(F)$ is orthorgonal to $\operatorname{span}(U)^\perp$. Analogous estimation can be performed by approximations of V and by the Rayleigh quotients of A^TA.

Various a priori bounds can be derived relating the quality of σ_j's estimates to the closeness of the subspaces $\operatorname{span}(F)$ and $\operatorname{span}(U^{(k)})$. These bounds are not useful in the quantitative sense, however, because we seldom know the closeness of the subspaces. Moreover, even in the case where $\operatorname{span}(F)$ is far from $\operatorname{span}(U^{(k)})$, good approximations to σ_j are still possible. For an extreme example, consider A with equal singular values $\sigma_1 = \sigma_2 = \cdots = \sigma_n$. On the other hand, the kind of analysis giving those bounds is sometimes useful in explaining why specific condition estimators are effective and in identifying situations where they may perform poorly. We shall carry out such analyses whenever they are appropriate. We refer the interested reader to Chapter 11 of [8] for a lucid discussion on Rayleigh–Ritz approximation.

3. Eigenproblems related to Rayleigh quotients. Consider $A = U\Sigma V^T$, $U = [u_1, u_2, \ldots, u_n]$, and

$$U^{(k)} = [u_1, u_2, \ldots, u_k] \quad \text{or} \quad U^{(k)} = [u_n, u_{n-1}, \ldots, u_{n-k+1}]$$

as before. Computations involved in determining the Ritz pairs differ depending on the information determining the space $\mathcal{F} \approx \operatorname{span}(U^{(k)})$. (The situation where we have $\mathcal{G} \approx \operatorname{span}(V^{(k)})$ is analogous, and its discussion is omitted in the rest of this section.)

3.1. Orthonormal basis. The orthornormal basis is the simplest case. $\mathcal{F}$ is given as span(F), where $F^TF = I$. The Ritz pairs are (τ_j^2, x_j), $x_j = Fw_j$, where (τ_j^2, w_j) are the eigenpairs of the Rayleigh quotient $F^T(AA^T)F$.

3.2. General basis. In some situations, $\mathcal{F}$ is given as span(F) but $F^TF \neq I$, although F has full rank. There are two approaches. One is to perform a QR factorization of F:

$$F = QR, \qquad Q \text{ is } n\text{-by-}k \quad \text{and} \quad Q^TQ = I.$$

The Ritz pairs are then (τ_j^2, x_j), where $x_j = Qw_j$ and the (τ_j^2, w_j) are the eigenpairs of $Q^T(AA^T)Q$.

At times, however, the matrix $F^T(AA^T)F$ is readily available. Thus,

$$Q^T(AA^T)Q = R^{-T}F^T(AA^T)FR^{-1}.$$

Then, the Ritz pairs are (τ_j^2, x_j), where $x_j = Fw_j$ and the (τ_j^2, w_j) are the eigenpairs of the generalized eigenvalue problem

$$F^T(AA^T)Fw = \tau^2(R^TR)w = \tau^2(F^TF)w.$$

3.3. General basis and a projection. In certain situations, we may know of an "undesirable" subspace $\mathcal{C}$ given by an orthonormal basis $C = [c_1, c_2, \ldots, c_\ell]$. For example, we may be estimating small singular values and span(C) = span(U)$^\perp$ (in particular $\ell = m-n$). It is quite natural, then, to use the space $\mathcal{F} = \text{span}(F)$ projected to $\mathcal{C}^\perp$. If we assume that $(I - CC^T)F$ has full rank, the Ritz pairs (according to the previous subsection) are obtained either from the eigenpairs of $Q^T(AA^T)Q$, where

$$(I - CC^T)F = QR, \qquad Q \text{ is } n\text{-by-}k \quad \text{and} \quad Q^TQ = I,$$

or from the eigenpairs of the generalized eigenvalue problem

$$\left[F^T(I - CC^T)(AA^T)(I - CC^T)F\right] w = \tau^2 \left[F^T(I - CC^T)F\right] w.$$

3.4. Krylov subspace. The Krylov subspace is the best-known subspace associated with Rayleigh–Ritz approximation. Here, the subspace is

$$\begin{aligned} \mathcal{F} &= \text{span}\{q_1, (AA^T)q_1, \ldots, (AA^T)^{k-1}q_1\}, \\ &= \text{span}\{q_1, q_2, \ldots, q_k\}, \qquad Q^TQ = I. \end{aligned}$$

Moreover, the tridiagonal Rayleigh quotient $T = Q^T(AA^T)Q$ is generated by the Lanczos tridiagonalization procedure. The Ritz pairs are obtained easily from T's eigenpairs.

4. Dynamic condition estimation. In practice, using the Rayleigh–Ritz method for condition estimation is especially attractive when the Ritz pairs can be computed economically. This is indeed often the case in the so-called dynamic condition estimation. A typical scenario is the following. At a certain stage, we have a matrix A and Ritz pairs (τ_j^2, x_j), such that

$$X^T(AA^T)X = \text{diag}(\tau_1^2, \tau_2^2, \ldots, \tau_k^2).$$

The τ_j's approximate A's largest or smallest singular values, or both. (It may also be the case that the Ritz pairs are (μ_j^2, y_j)'s where

$$Y^T(A^TA)Y = \operatorname{diag}(\mu_1^2, \mu_2^2, \ldots, \mu_k^2),$$

but we shall concentrate on AA^T, in general.)

At the next stage, which usually corresponds to new data coming in or a new iteration of some iterative process, we wish to obtain new Ritz pairs for a new matrix $\tilde{A}$. The situation in question usually suggests a convenient basis $\tilde{F} = [\tilde{x}_1, \tilde{x}_2, \ldots, \tilde{x}_{\tilde{k}}]$ ($\tilde{k}$ need not be k, and in fact $\tilde{k} = k+1$ frequently) such that the Ritz pairs for $\tilde{A}$ corresponding to the subspace $\tilde{\mathcal{F}} = \operatorname{span}(\tilde{F})$ can be computed economically, usually with the help of A's Ritz pairs. ($\tilde{F}$ is usually closely related to X.) Then, k appropriate Ritz pairs $(\tilde{\tau}_j^2, \tilde{x}_j)$ of $\tilde{A}$ with respect to $\tilde{\mathcal{F}}$ are chosen, and we have

$$\tilde{X}^T(\tilde{A}\tilde{A}^T)\tilde{X} = \operatorname{diag}(\tilde{\tau}_1^2, \tilde{\tau}_2^2, \ldots, \tilde{\tau}_k^2).$$

As pointed out earlier, depending on the nature of $\tilde{\mathcal{F}}$ and $\tilde{F}$, the computation may involve an eigenvalue problem or a generalized eigenvalue problem.

We now show that a number of different dynamic condition estimation schemes are in fact Rayleigh–Ritz methods. This view not only allows us to better understand these schemes, but also suggests generalizations or alternatives.

4.1. ICE. In his paper on ICE [1], Bischof considers the condition number of the growing upper triangular factor in a QR factorization. At a given stage, the subject is an n-by-n upper triangular matrix A. The estimate of A's smallest singular value is given by a large norm solution p to a unit norm right-hand side r, $p^TA = r^T$, $\|r\| = 1$. Thus, $\tau = \|p\|^{-1}$ is an estimate for $\sigma_{\min}(A)$. At the next stage, one more column of the triangular factor is generated:

$$\tilde{A} = \begin{bmatrix} A & a \\ 0^T & \alpha \end{bmatrix}.$$

To obtain a large norm solution $\tilde{p}$ to a new unit norm right-hand side for $\tilde{A}$, Bischof tries to

$$\text{maximize } \left\| [\, sp^T \quad \beta \,] \right\| \quad \text{subject to } \left\| [\, sp^T \quad \beta \,]\, \tilde{A} \right\| = 1.$$

Let $[sp^T\ \beta]\tilde{A} = [sp^TA\ \ c]$. The constraint becomes $s^2+c^2 = 1$. Algebraic manipulation gives

$$\left\| [\, sp^T \quad \beta \,] \right\|^2 = w^TMw, \qquad w^T = [\, s \quad c \,],$$

where M is a positive definite matrix given in terms of p^Ta, α, and τ. Consequently, the maximum is attained at M's largest eigenvalue, and $\tilde{p}^T = [\tilde{s}p^T\ \tilde{\beta}]$ can be computed from the corresponding eigenvector $[\tilde{s}\ \tilde{c}]^T$. The estimate for $\sigma_{\min}(\tilde{A})$ is given by $\tilde{p}$ and $\tilde{\tau} = \|\tilde{p}\|^{-1}$.

We now show that the above process is really a Rayleigh–Ritz method. The estimation of $\sigma_{\min}(A)$ is given by the Ritz pair (τ^2, x), where $x = p/\|p\|$, of the Rayleigh quotient $x^T(AA^T)x$. To estimate $\sigma_{\min}(\tilde{A})$, we simply use the subspace

$$\tilde{\mathcal{F}} = \operatorname{span}(\tilde{F}), \qquad \tilde{F} = \begin{bmatrix} x & 0 \\ 0 & 1 \end{bmatrix}.$$

Clearly, $\tilde{F}^T\tilde{F} = I$, and the two Ritz pairs are $(\tilde{\tau}_j^2, \tilde{x}_j = \tilde{F}\tilde{w}_j)$, where $(\tilde{\tau}_j^2, \tilde{w}_j)$ are the eigenpairs of

$$\tilde{F}^T(\tilde{A}\tilde{A}^T)\tilde{F} = \operatorname{diag}(\tau^2, 0) + zz^T, \qquad z = \begin{bmatrix} x^T a \\ \alpha \end{bmatrix}.$$

The new estimate $(\tilde{\tau}_1, \tilde{x}_1)$ is derived from the small Ritz pair $(\tilde{\tau}_1^2, \tilde{x}_1)$.

To show that ICE is equivalent to the Rayleigh–Ritz method just described, we first show that $\tilde{\tau}_1 = \tilde{\tau}$:

$$\begin{aligned} 1 &= \left\|\tilde{w}_1^T\tilde{F}^T\tilde{A}\right\| \cdot \tilde{\tau}_1^{-1}, \quad \tilde{w}_1^T = [\gamma_1 \quad \gamma_2], \quad \text{and} \quad \|\tilde{q}_1\| = 1 \\ &= \left\|[\gamma_1 p^T/\|p\| \quad \gamma_2]\,\tilde{A}\right\| \cdot \tilde{\tau}_1^{-1}. \end{aligned}$$

Thus,

$$1 = \left\|[(\gamma_1/\tilde{\tau}_1\|p\|)p^T \quad (\gamma_2/\tilde{\tau}_1)]\,\tilde{A}\right\|,$$

giving

$$\left\|[(\gamma_1/\tilde{\tau}_1\|p\|)p^T \quad (\gamma_2/\tilde{\tau}_1)]\right\| \le \tilde{\tau}^{-1}.$$

Consequently, $\tilde{\tau}_1 \ge \tilde{\tau}$. On the other hand,

$$\begin{aligned} 1 &= \left\|\tilde{p}^T\tilde{A}\right\| \\ &= \left\|[\tilde{s}\|p\| \quad \tilde{\beta}]\,\tilde{F}^T\tilde{A}\right\| \end{aligned}$$

implies $\tilde{\tau} = \|\tilde{w}^T\tilde{F}^T\tilde{A}\|$, $\tilde{w}^T = [\tilde{s}\|p\| \ \tilde{\beta}]^T$ normalized. Thus $\tilde{\tau} \ge \tilde{\tau}_1$. Thus, we have $\tilde{\tau} = \tilde{\tau}_1$. We omit the proof that $\tilde{x}_1 = \tilde{p}/\|\tilde{p}\|$, which is straightforward. Similar arguments show that the estimation of $\sigma_{\max}(\tilde{A})$ in [1] is also a Rayleigh–Ritz method with an initial Ritz pair (τ^2, x) where $\tau^2 = x^T(AA^T)x \approx \sigma_{\max}^2(A)$. The Ritz pair for $\tilde{A}$ is obtained by using the subspace

$$\tilde{\mathcal{F}} = \operatorname{span}(\tilde{F}), \qquad \tilde{F} = \begin{bmatrix} x & 0 \\ 0 & 1 \end{bmatrix}.$$

Indeed, viewing ICE as a Rayleigh–Ritz method leads to convenient generalizations (some of which were explored in [2]). At a given stage, we have Ritz pairs (τ_j^2, x_j) such that

$$X^T(AA^T)X = \operatorname{diag}(\tau_1^2, \tau_2^2, \ldots, \tau_k^2), \quad \tau_1 \ge \tau_2 \ge \cdots \ge \tau_k \ge 0,$$

where $\tau_1 \approx \sigma_{\max}(A)$, $\tau_k \approx \sigma_{\min}(A)$, and the interlacing property

$$\sigma_{\max-j+1}(A) \ge \tau_j \ge \sigma_{\min+k-j}(A), \qquad j = 1, 2, \ldots, k$$

holds. At the next stage, we have

$$\tilde{A} = \begin{bmatrix} A & a \\ 0^T & \alpha \end{bmatrix}.$$

The subspace is chosen to be the $\tilde{k} = k + 1$ dimensional

$$\tilde{\mathcal{F}} = \operatorname{span}(\tilde{F}), \qquad \tilde{F} = \begin{bmatrix} X & 0 \\ 0^T & 1 \end{bmatrix}.$$

Clearly, $\tilde{F}^T\tilde{F} = I$, and the problem becomes that of determining the eigensystem of the Rayleigh quotient

$$\tilde{F}^T(\tilde{A}\tilde{A}^T)\tilde{F} = \operatorname{diag}(\tau_1^2, \tau_2^2, \ldots, \tau_k^2, 0) + zz^T, \qquad z = \begin{bmatrix} X^T a \\ \alpha \end{bmatrix}.$$

Thus, both the Rayleigh quotient and its eigensystem can be determined economically (see [4] and [11]). Note that if we were to formulate this generalization following the approach in [1] as a maximization problem in terms of $k+1$ parameters and try to realize the objective function as a quadratic form, the algebraic manipulation would have been quite involved.

Understanding ICE as a Rayleigh–Ritz method sheds some light on its effectiveness as well as its ineffectiveness. The analysis usually assumes that some of the extreme left singular vectors of A (or, equivalently, the extreme eigenvectors of AA^T) are close to $\mathcal{F} = \operatorname{span}(X)$; thus $\angle(u_j, \mathcal{F}) = \theta_j$ is small for $j = 1, 2, \ldots, \ell$ or $j = n, n-1, \ldots, n-\ell+1$, or both, for some ℓ. We then try to identify situations where $\angle(\tilde{u}_j, \tilde{\mathcal{F}})$ will also be small, where

$$\tilde{A} = \tilde{U}\tilde{\Sigma}\tilde{V} \quad \text{and} \quad \tilde{A}\tilde{A}^T = \tilde{U}\tilde{\Sigma}^2\tilde{U}^T.$$

Since the nature of these analyses is more qualitative than quantitative, we shall not call the results theorems or lemmas.

PHENOMENON 1. Suppose $\sigma_{\min}(A) = \sigma_n$ is not small (say, $\sigma_n \geq 1$) and that there is a drastic drop of the smallest singular value of $\tilde{A}$ (say, $\sigma_{\min}(\tilde{A}) = \tilde{\sigma}_{n+1} \leq \sqrt{\varepsilon}$, where ε is the machine precision). Furthermore, assume that the vector a has a moderate norm (say, $\|a\| \leq 2$). Then, ICE is effective in tracking $\tilde{\sigma}_{n+1}$.

Explanation. Let M be the matrix

$$M = \begin{bmatrix} AA^T & \\ & 0 \end{bmatrix}.$$

Then,

$$\tilde{A}\tilde{A}^T = M + \tilde{a}\tilde{a}^T, \qquad \tilde{a} = \begin{bmatrix} a \\ \alpha \end{bmatrix}.$$

Let U be the left singular vectors of A. Therefore, the eigenvalues of $\tilde{A}\tilde{A}^T$ are the eigenvalues of

$$\begin{bmatrix} U & 0 \\ 0^T & 1 \end{bmatrix}^T (M + \tilde{a}\tilde{a}^T) \begin{bmatrix} U & 0 \\ 0^T & 1 \end{bmatrix}$$
$$= \operatorname{diag}(\sigma_1^2, \sigma_2^2, \ldots, \sigma_n^2, 0) + bb^T, \qquad b^T = [\beta_1 \beta_2 \cdots \beta_{n+1}] = [a^T U \ \alpha].$$

Thus, $\tilde{\sigma}_{n+1}$ satisfies the equation (see [7])

$$\begin{aligned} \frac{\alpha^2}{\tilde{\sigma}_{n+1}^2} &= 1 + \sum_{j=1}^{n} \frac{\beta_j^2}{\sigma_j^2 - \tilde{\sigma}_{n+1}^2} \\ &\leq 1 + \sum_{j=1}^{n} \frac{\beta_j^2}{1 - \tilde{\sigma}_{n+1}^2} \\ &\leq \left(1 + \frac{\|a\|^2}{1 - \tilde{\sigma}_{n+1}^2}\right) \tilde{\sigma}_{n+1}^2 \\ &\leq 4\tilde{\sigma}_{n+1}^2. \end{aligned}$$

Now, since ICE applies Rayleigh–Ritz method to $\tilde{A}\tilde{A}^T$ with span($\tilde{F}$) that contains $[0\ 1]^T$, we have

$$\begin{aligned}\tilde{\tau}_{\min}^2 &\le [0\ 1]^T \tilde{A}\tilde{A}^T \begin{bmatrix} 0 \\ 1 \end{bmatrix} \\ &\le \alpha^2 \\ &\le 4\tilde{\sigma}_{n+1}^2.\end{aligned}$$

Moreover, we may even say something about the direction of the corresponding left singular vector by invoking well-known results in [5] on rotation of eigenvectors by perturbation. Now,

$$[0\ 1]^T M \begin{bmatrix} 0 \\ 1 \end{bmatrix} = 0,$$

and the residual

$$(M + \tilde{a}\tilde{a}^T) \begin{bmatrix} 0 \\ 1 \end{bmatrix} - \begin{bmatrix} 0 \\ 1 \end{bmatrix} \cdot 0 = \alpha\tilde{a}$$

has norm less than $5\sqrt{\varepsilon}$. Furthermore, $M + \tilde{a}\tilde{a}^T$ has a large separation between the smallest and the next smallest eigenvalue. We have, therefore, by the "sin θ" theorem in [5]

$$\sin\theta \le 5\sqrt{\varepsilon}/(1-\varepsilon),$$

where θ is the angle between $\tilde{A}\tilde{A}^T$'s smallest eigenvector and $[0\ 1]^T$.

Thus ICE is effective in tracking $\tilde{\sigma}_{\min}$ whenever there is a sudden big drop of the smallest singular value from A to $\tilde{A}$, *regardless* of the quality of the estimate of $\sigma_{\min}(A)$. This phenomenon can be generalized.

PHENOMENON 2. Suppose $\sigma_{\min-\ell}(A) = \sigma_{n-\ell} \ge 1$; $\sigma_j \le \sqrt{\varepsilon}$ for $j > n-\ell$ for some $\ell < k$, the dimension of the space $\mathcal{F}$. Let $\angle(u_j, \mathcal{F}) \le \theta$, $j = n, n-1, \ldots, n-\ell+1$ for some small θ (say, $\theta \le \sqrt{\varepsilon}$). If $\tilde{\sigma}_{n-\ell+1}$ is also small (say, $\tilde{\sigma}_{n-\ell+1} \le \sqrt{\varepsilon}$), ICE is effective in tracking $\tilde{\sigma}_{n+1}, \ldots, \tilde{\sigma}_{n-\ell+1}$ and the corresponding singular vectors $\tilde{u}_{n+1}, \ldots, \tilde{u}_{n-\ell+1}$.

The analysis is similar to the preceding one, and the crux is to show that $\sum_{j=n-\ell+1}^{n} \beta_j^2$ is small where $b^T = [U^T a\ \alpha]$. Note that the direction of the vector a, where

$$\tilde{A}\tilde{A}^T = \begin{bmatrix} AA^T & \\ & 0 \end{bmatrix} + \begin{bmatrix} a \\ \alpha \end{bmatrix} [a^T \quad \alpha],$$

does not play any direct role in the above phenomena. Moreover, the analyses so far indicate that ICE is reasonably effective *in general* in tracking small singular values when a large gap separates them from the large singular values. But we must emphasize the phrase "in general" because our analyses assume that k is large enough to cover all the values on the left of the gap, and that a gap in the singular values of a triangular matrix does not necessarily give existence of similar well-defined gaps in the singular value spectra of its principal submatrices.

The analysis above also suggests that the problem is likely to arise when $\|a\|$ is disproportionately large. This observation is confirmed in Experiment 1 in §5.

What about the effectiveness of ICE in estimating large singular values? Since the Rayleigh–Ritz method is known to be effective in tracking large eigenvalues, ICE

is generally effective in tracking large singular values. This fact is illustrated by the many experiments in [1]. We must, however, be aware that the Rayleigh–Ritz method need not give a good approximation to the corresponding large eigenvectors. Consider, for example, a matrix AA^T with one small eigenvalue close to $\sqrt{\varepsilon}$, while all the rest of the eigenvalues are large, but all within a factor of four to each other. Then any space $\mathcal{F}$ with dimension two or more will give a reasonable estimate to the maximum eigenvalue, but the corresponding Ritz vector may be even orthogonal to the exact largest eigenvector. Along this line, we also point out an obviously bad situation for ICE in estimating large singular values. Suppose $\dim(\mathcal{F}) = k$ is close to the k largest eigenvectors of AA^T. Furthermore, $\sigma_{\max}(A) \approx 1$. Now, if we have

$$\tilde{A} = \begin{bmatrix} A & a \\ 0^T & \alpha \end{bmatrix}$$

as usual, but $\angle(a, \mathrm{span}([u_1 u_2 \cdots u_k])) \approx 90°$, u_j's being A's exact singular vectors, $\|a\| \approx 10^5$, and $|\alpha| \approx 1$, then ICE will estimate $\sigma_{\max}(\tilde{A})$ poorly. One can argue, of course, that this is a rare case from a probablistic point of view.

Before discussing the next condition estimation scheme, we mention that the simple choice of α^2 as an (upper) estimate of $\lambda_{\min}(\tilde{A}\tilde{A}^T) = \sigma^2_{\min}(\tilde{A})$ is also a Rayleigh–Ritz method. The subspace is simply $\mathrm{span}([0\ 1]^T)$. This is the estimation used implicitly in the QR factorization with column pivoting. In particular, because the subspace used in ICE always contains $[0\ 1]^T$, the estimate of ICE is always better than α^2.

4.2. ACE. ACE was designed by Pierce and Plemmons [9] to track the condition number of the information matrix (or, equivalently, that of the covariance matrix) in recursive least-squares problems using a forgetting factor. At a certain stage, one has an n-by-n upper triangular matrix A, which is the Cholesky factor of the information matrix. An estimate of $\sigma_{\min}(A)$ is given by a unit norm vector x such that $\|x^T A\| \approx \sigma_{\min}(A)$. At the next stage, a row is added to A:

$$\tilde{A} = \begin{bmatrix} A \\ a^T \end{bmatrix} \quad \text{and} \quad Q \begin{bmatrix} A \\ a^T \end{bmatrix} = \begin{bmatrix} \tilde{R} \\ 0^T \end{bmatrix},$$

where $\tilde{R}$ is the Cholesky factor for $\tilde{A}^T\tilde{A}$. The goal is to estimate $\sigma_{\min}(\tilde{A})$, and the means is by minimizing $\|z^T\tilde{R}\|/\|z\|$ over some convenient choices of z. The choice used in [9] is

$$z = \text{first } n \text{ component of } Q \begin{bmatrix} \alpha x \\ \beta \end{bmatrix}.$$

To solve this minimization problem requires some algebra. Since the last row of $Q\tilde{A}$ is zero, it is obvious that the last row of Q must be $q^T = [-c^T\gamma\ \gamma]$, where $\gamma = (1 + c^T c)^{-1/2}$ and $c^T A = a^T$. (Computing c requires $O(n)$ operations and is relatively inexpensive.) Because Q is orthogonal and $\|x\| = 1$, we have

$$\left\| Q \begin{bmatrix} \alpha x \\ \beta \end{bmatrix} \right\|^2 = \alpha^2 + \beta^2.$$

Thus,

$$\|z\|^2 = \alpha^2 + \beta^2 - \left\| q^T \begin{bmatrix} \alpha x \\ \beta \end{bmatrix} \right\|^2$$

$$= [\alpha \quad \beta] \begin{bmatrix} 1-\gamma^2(c^Tx)^2 & \gamma^2 c^Tx \\ \gamma^2 c^Tx & 1-\gamma^2 \end{bmatrix} \begin{bmatrix} \alpha \\ \beta \end{bmatrix}$$
$$= [\alpha \quad \beta] N \begin{bmatrix} \alpha \\ \beta \end{bmatrix}.$$

Finally,

$$\|z^T\tilde{R}\|^2 = \left\| [\alpha x^T \quad \beta] Q^T \begin{bmatrix} \tilde{R} \\ 0^T \end{bmatrix} \right\|^2$$
$$= \left\| [\alpha x^T \quad \beta] \begin{bmatrix} A \\ a^T \end{bmatrix} \right\|^2$$
$$= [\alpha \quad \beta] \begin{bmatrix} b^Tb & b^Ta \\ a^Tb & a^Tb \end{bmatrix} \begin{bmatrix} \alpha \\ \beta \end{bmatrix}, \qquad b = Ax,$$
$$= [\alpha \quad \beta] M \begin{bmatrix} \alpha \\ \beta \end{bmatrix}.$$

Thus, the minimization problem is equivalent to

$$\text{minimize}_{\alpha,\beta} \frac{[\alpha \quad \beta] M \begin{bmatrix} \alpha \\ \beta \end{bmatrix}}{[\alpha \quad \beta] N \begin{bmatrix} \alpha \\ \beta \end{bmatrix}},$$

which is the minimum eigenpair of the generalized eigenvalue problem $Mw = \lambda Nw$. (Note that N is positive definite whenever a is not a multiple of b, cf. [9].) To estimate $\sigma_{\max}(\tilde{A})$, one simply starts with x such that $\|x^TA\| \approx \sigma_{\max}(A)$ and carries out the algebra. The result is the problem of determining the maximum eigenpair of $Mw = \lambda Nw$.

We now show that this method is also a Rayleigh–Ritz method. First, consider the estimation of $\sigma_{\min}(\tilde{A})$. A convenient space for $\tilde{A}\tilde{A}^T$ is

$$\tilde{\mathcal{F}} = \text{span}(\tilde{F}), \qquad \tilde{F} = \begin{bmatrix} x & 0 \\ 0 & 1 \end{bmatrix}.$$

The $(n+1)$th eigenvalue $\lambda_{n+1}(\tilde{A}\tilde{A}^T) = 0$ may cause a gross underestimate of $\sigma_n(\tilde{A})$. An obvious remedy is to further project $\tilde{\mathcal{F}}$ onto the orthogonal complement of the eigenspace of $\lambda_{n+1}(\tilde{A}\tilde{A}^T)$. Recall the vector q, $q^T = [-c^T\gamma \ \ \gamma]$ in the preceding discussion, where $q^T\tilde{A} = 0$. Clearly,

$$\tilde{A}\tilde{A}^Tq = 0 = \lambda_{n+1}(\tilde{A}\tilde{A}^T)q,$$

and the desired subspace is thus $\tilde{\mathcal{F}}$ projected onto $\text{span}(q)^\perp$. From §3.3, this results in the generalized eigenvalue problem

$$\tilde{F}^T(I-qq^T)(\tilde{A}\tilde{A}^T)(I-qq^T)\tilde{F}w = \lambda\tilde{F}(I-qq^T)\tilde{F}w.$$

But $q^T\tilde{A} = 0$, and we have

$$\tilde{F}^T(I-qq^T)(\tilde{A}\tilde{A}^T)(I-qq^T)\tilde{F} = \tilde{F}^T(\tilde{A}\tilde{A}^T)\tilde{F}$$
$$= \begin{bmatrix} b^Tb & b^Ta \\ a^Tb & a^Ta \end{bmatrix}$$

and

$$\tilde{F}^T(I - qq^T)\tilde{F} = I - (\tilde{F}^T q)(q^T \tilde{F}) = \begin{bmatrix} 1 - \gamma^2(c^T x)^2 & \gamma^2 c^T x \\ \gamma^2 c^T x & 1 - \gamma^2 \end{bmatrix}.$$

The derivation for estimating $\sigma_{\max}(\tilde{A})$ is exactly the same.

Using the Rayleigh–Ritz framework, we can easily combine the estimations of largest and smallest singular values and also generalize them. At any given stage, we have k Ritz pairs (τ_j^2, x_j), $j = 1, 2, \ldots, k$, such that

$$X^T(AA^T)X = B^T B = \operatorname{diag}(\tau_1^2, \tau_2^2, \ldots, \tau_k^2),$$

where some of the τ_j approximates A's large singular values, while the others approximate A's small singular values. At the next stage, we have

$$\tilde{A} = \begin{bmatrix} A \\ a^T \end{bmatrix},$$

and we use the subspace $\tilde{\mathcal{F}}$ projected to $\operatorname{span}(q)^\perp$, where

$$\tilde{\mathcal{F}} = \operatorname{span}(\tilde{F}), \qquad \tilde{F} = \begin{bmatrix} X & 0 \\ 0^T & 1 \end{bmatrix}.$$

The corresponding generalized eigenvalue problem is $Mw = \lambda N w$, where

$$M = \begin{bmatrix} \operatorname{diag}(\tau_1^2, \tau_2^2, \ldots, \tau_k^2) & B^T a \\ a^T B & a^T a \end{bmatrix} \quad \text{and} \quad N = \begin{bmatrix} I - \gamma^2(X^T c)(c^T X) & \gamma^2 X^T c \\ \gamma^2 c^T X & 1 - \gamma^2 \end{bmatrix}.$$

The problem is that, unlike the generalization of ICE, which leads to an eigenproblem of rank-1 perturbed diagonal matrices, computational schemes that can exploit the structure of the matrix pencil here seem to be lacking.

There is, however, a rather natural alternative in view of the Rayleigh–Ritz approximation. If we use the space $\mathcal{H} = \operatorname{span}[\tilde{F}\ q]$, we will have $(0, q)$ as the smallest Ritz pair—which can be discarded because it corresponds to the spurious zero singular value of $\tilde{A}$. Moreover, because the remaining Ritz vectors are orthogonal to q, they will be reduced back to n-vectors from $(n+1)$-vectors after a transformation by Q, where

$$Q\tilde{A} = \begin{bmatrix} R \\ 0^T \end{bmatrix}.$$

Let us now consider the calculation of these Ritz pairs. A sequence of $k+2$ Householder transformations can be used to determine a vector g such that $[\tilde{F}\ g]$ forms an orthonormal basis of $\mathcal{H}$. This requires only order $n+1$ amount of work. The Rayleigh quotient is thus

$$\begin{bmatrix} \tilde{F}^T \\ g^T \end{bmatrix} (\tilde{A}\tilde{A}^T) [\tilde{F} \quad g] = \begin{bmatrix} \tilde{F}^T(\tilde{A}\tilde{A}^T)\tilde{F} & \tilde{F}^T(\tilde{A}\tilde{A}^T)g \\ g^T(\tilde{A}\tilde{A}^T)\tilde{F} & g^T(\tilde{A}\tilde{A}^T)g \end{bmatrix}.$$

The eigensystem can be determined by an efficient (order k^2 work) rank-1 update method as follows. First,

$$\tilde{F}^T(\tilde{A}\tilde{A}^T)\tilde{F} = \begin{bmatrix} \operatorname{diag}(\tau_1^2, \tau_2^2, \ldots, \tau_k^2) & B^T a \\ a^T B & a^T a \end{bmatrix}.$$

Let $\Sigma = \operatorname{diag}(\tau_1, \tau_2, \ldots, \tau_k)$ and let $z = \Sigma^{-1} B^T a$. Since $\Sigma^{-1} B^T B \Sigma^{-1} = I_k$, z is an othorgonal projection of a to a k-dimension subspace. Thus, $a^T a \geq z^T z$ and we can define $\alpha^2 = a^T a - z^T z$. Then,

$$\tilde{F}^T (\tilde{A}\tilde{A}^T)\tilde{F} = \begin{bmatrix} \Sigma^2 & \Sigma z \\ z^T \Sigma & z^T z \end{bmatrix} + \begin{bmatrix} 0 \\ \alpha \end{bmatrix} \cdot [0^T \quad \alpha].$$

The eigensystem of the first matrix on the right can be solved efficiently by the method given in [3]. In particular, when all the τ_j's are distinct, the $k+1$ eigenvalues λ_j are zero and the k roots of a secular equation

$$1 + \sum_{j=1}^{k} \frac{\zeta_j^2}{\tau_j^2 - \lambda}, \quad \text{where } [\zeta_1 \zeta_2 \cdots \zeta_k] = z^T.$$

The eigenvectors are given by

$$\begin{bmatrix} \left(\Sigma^2 - \lambda_j I\right)^{-1} \Sigma z \\ -1 \end{bmatrix}.$$

The case of $\tau_j = \tau_{j+1}$ for some j can be handled easily by deflation techniques described in [3]. Once these quantities are computed, the eigensystem of $\tilde{F}^T (\tilde{A}\tilde{A}^T)\tilde{F} = U\tilde{\Sigma}^2 U^T$ can be determined by applying another round of rank-1 update technique. Finally,

$$\begin{bmatrix} \tilde{F}^T \\ g^T \end{bmatrix} (\tilde{A}\tilde{A}^T) [\tilde{F} \quad g] = \begin{bmatrix} U & \\ & 1 \end{bmatrix} \begin{bmatrix} \tilde{\Sigma}^2 & \tilde{\Sigma}\tilde{z} \\ \tilde{z}^T \tilde{\Sigma} & \tilde{z}^T \tilde{z} \end{bmatrix} \begin{bmatrix} U^T & \\ & 1 \end{bmatrix},$$

where $\tilde{z} = U^T g$. The rank-1 update method in the preceding discussions is clearly applicable here, too.

We see two advantages of this alternative that do not require solving a generalized eigenvalue problem. First, exploiting the structure of the resulting eigenvalue problem as suggested above leads to an order k^2 computation, as opposed to an order k^3 computation for the generalized eigenvalue problem. This advantage is likely to be minor since k is usually very small. The second advantage, however, is more significant. The original scheme that requires solving $Mw = \lambda N w$ is quite complicated in its additional processing when N is ill conditioned. In fact, it is unclear if this processing can be generalized when N has dimension higher than two. Our alternative here, however, is free from such complications. The reason is as follows. Even under conditions that would lead to an ill-conditioned N, our computation that tries to find an orthonormal basis for span$([\tilde{F}, q])$ would still produce a set of orthonormal vectors. This set is all that is required for our Rayleigh–Ritz method to be valid numerically. Thus, the proposed alternative does not have numerical breakdown.

4.3. ALE. ALE is a condition estimation scheme proposed recently by Ferng, Golub, and Plemmons [6]. At a given stage, the subject is an upper triangular matrix A (the Cholesky factor of a covariance matrix). Estimates of A's largest singular values are given by approximate left and right singular vectors $x_1, x_2, \ldots, x_k$ and $y_1, y_2, \ldots, y_k$, respectively, satisfying

$$X^T A Y = \operatorname{diag}(\tau_1, \tau_2, \ldots, \tau_k), \quad \tau_1 \geq \tau_2 \cdots \geq \tau_k,$$

where

$$X = [x_1 x_2 \cdots x_k], \quad Y = [y_1 y_2 \cdots y_k], \quad X^T X = Y^T Y = I.$$

Estimates on A's smallest singular values are given by A^{-1}'s approximate largest singular vectors satisfying analogous conditions.

At the next stage, $\tilde{A}$ is the Cholesky factorization of A^TA+aa^T or A^TA-aa^T. To obtain new estimates of $\tilde{A}'s$ largest singular values, we apply k steps of the Lanczos algorithm to the matrix B with the starting vector q_1:

$$B = \begin{bmatrix} & \tilde{A} \\ \tilde{A}^T & \end{bmatrix}, \qquad q_1 = \begin{bmatrix} x_1 \\ y_1 \end{bmatrix}.$$

It is therefore abundantly clear that ALE is a Rayleigh–Ritz method using the Krylov subspace $\text{span}\{q_1, Bq_1, \ldots, B^{k-1}q_1\}$ given by an orthonormal basis. Because the Krylov subspaces are used, this method is effective only in estimating B's extreme eigenvalues. Because B's eigenvalues are $\{\pm\sigma_1(\tilde{A}), \pm\sigma_2(\tilde{A}), \ldots, \pm\sigma_n(\tilde{A})\}$, this method on $\tilde{A}$ is effective only in estimating $\tilde{A}$'s largest singular values. To estimate the smallest singular values, Ferng, Golub, and Plemmons apply the Lanczos method to $\tilde{A}^{-1}$ (using a back-solve involving $\tilde{A}$ instead of $\tilde{A}^{-1}$ explicitly).

The generalization of this scheme is obvious. In fact, the discussion in [6] is for a general k, although its implementation restricts k to two so that eigenproblems of the Rayleigh quotients are reduced to finding roots of quadratic equations.

The advantages of this method are several. Many well-established a priori or a posterori bounds can be obtained (see [8] for an excellent discussion on the Lanczos algorithm) if one cares to pay the price for them. Since estimation of small singular values is achieved by estimating the large singular values of $\tilde{A}^{-1}$, this method generally yields the best estimate compared to other condition estimation schemes discussed so far. Furthermore, by suitably applying a posterori bounds on the large and small singular values, rather reliable upper and lower bounds on $\tilde{A}$'s condition number can be obtained.

The main disadvantage of this method is obviously its cost: while the preceding schemes require order n amount of work, ALE requires order n^2. Judging the price one must pay for this estimation, it seems natural that one should increase the value of k to at least three or four. The resulting eigenproblem can be readily solved by standard QR iteration, or using rank-1 update techniques as the (implicit) tridiagonal Rayleigh quotient (or the explicit bidiagonal) is being built column by column.

4.4. GRACE. GRACE is developed by Shroff and Bischof in [10] to estimate the condition of $QR + wv^T$. The method essentially combines two ICE steps and one ACE step. Consequently, we can also use our Rayleigh–Ritz framework to understand GRACE. It is worthwhile, however, to investigate if one Rayleigh–Ritz step can be applied to obtain condition estimate for $QR + wv^T$.

5. Numerical experiments. We present a number of experiments that illustrate the preceding discussions.

Experiment 1. This experiment relates to the direction and scaling of the added column a in ICE. Here, ICE is applied to a sequence of updates: $A_1 \in \mathbf{R}$,

$$\tilde{A}_\ell := \begin{bmatrix} A_\ell & a_\ell \\ 0^T & \alpha_\ell \end{bmatrix}; \quad A_{\ell+1} := \tilde{A}_\ell, \quad \ell = 1, 2, \ldots, n-1.$$

We noted previously that as long as $\|a\|$ remains moderate compared to $\|A\|$, the directions of those vectors do not, in general, affect the quality of the ICE estimates. But if $\|a\|$ is large, it is crucial that the subspace used in the approximation not be far away from $\|a\|$. To illustrate this point, we do the following. A_n, $n = 30$, is an

upper triangular matrix generated by applying a QR factorization to $U\Sigma V^T$, where U and V are random orthogonal matrices generated by the method described in [12], and Σ is a diagonal matrix with entries chosen randomly in $[0, 1]$.

We apply ICE with $k = 2$ (that is, one vector to estimate $\sigma_{\max}$ and one vector to estimate $\sigma_{\min}$). After the estimate is obtained for A_{n-1}, we modify a_n by

$$a_n := \text{normalize}\left((I - 0.999XX^T)a_n\right),$$

where $X = [x_1 x_2]$ are the two approximate vectors generated by ICE to estimate A's extreme singular values. We denote the resulting matrix B. This way, the last added column is nearly orthogonal to the subspace to be used in B's estimate. Because $\|a_n\| = 1$ is moderate, we do not expect great degradation in the ICE estimate. Indeed,

$$\sigma_{\max}(B)/\tau_{\max} = 1.3 \quad \text{and} \quad \tau_{\min}/\sigma_{\min}(B) = 2.6.$$

Next, we scale a_n up by a factor of 10^3. We call the resulting matrix $B^{(s)}$:

$$B^{(s)} = \begin{bmatrix} A_{n-1} & 10^3 a_n \\ 0^T & \alpha_n \end{bmatrix}.$$

The result of ICE is drastically changed:

$$\sigma_{\max}(B^{(s)})/\tau_{\max} = 1100 \quad \text{and} \quad \tau_{\min}/\sigma_{\min}(B^{(s)}) = 480.$$

Finally, we increase the dimension of the subspace used by two; that is, we use two vectors to estimate the maximum singular values and two vectors to estimate the minimum singular values. The quality of the ICE estimates are restored:

$$\sigma_{\max}(B^{(s)})/\tau_{\max} = 3.4 \quad \text{and} \quad \tau_{\min}/\sigma_{\min}(B^{(s)}) = 1.3.$$

Experiment 2. We apply ACE and our alternative to track the condition numbers of a sequence of Cholesky factors produced by recursive least-squares computations employing an exponential window. The process is initiated by a 30-by-30 identity matrix, and the forgetting factor used is 0.95. Three condition estimators are used. The first one is ACE. The second one is our alternative with $k = 2$: one vector for $\sigma_{\max}$ and one vector for $\sigma_{\min}$. The third one is our alternative with $k = 3$: one vector for $\sigma_{\max}$, but two vectors for $\sigma_{\min}$.

We test two cases. In the first test case, 60 steps of updates are performed where the 60 rows of data are numbers chosen randomly in $[-1, 1]$ with outliers of magnitude 10^4 added to six random places. In the second test case, 30 steps of updates are performed where 30 rows of data are $s_j a_j^T$, where a_j's entries are randomly chosen from $[-1, 1]$ and $s_j = 10^{4j/30}$. One can consider the incoming data as exponentially scaled. The results are summarized in Fig. 1 by the ratios of

$$\frac{\text{actual condition number}}{\text{estimated condition number}}.$$

The experiment illustrates that our alternative is comparable to ACE. Moreover, by increasing k—which is made practical by not having to solve a generalized eigenvalue problem—the estimates can become more reliable.

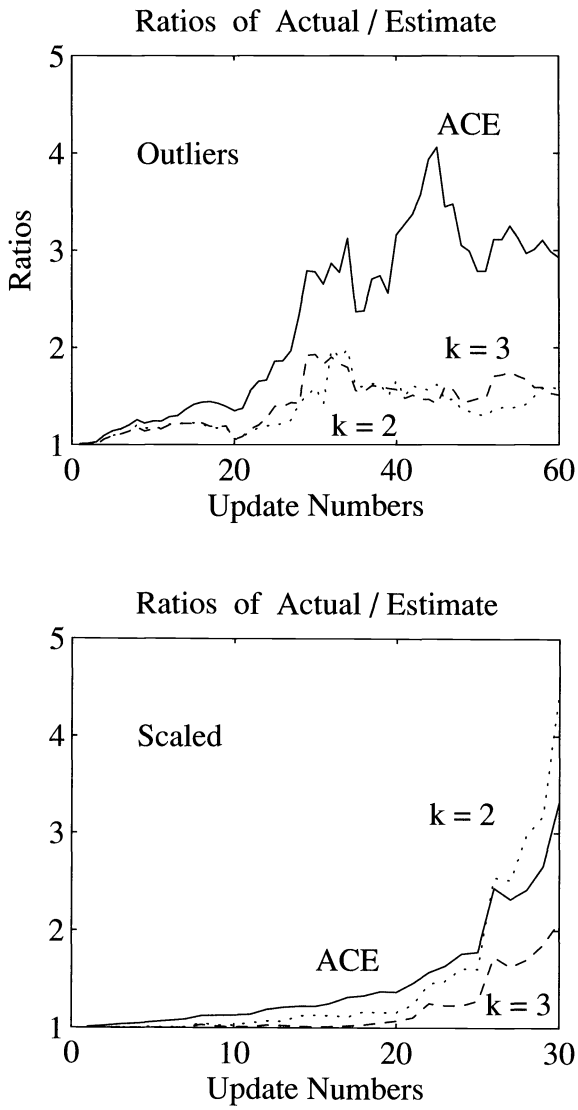

FIG. 1. ACE *on random matrices with outliers added or exponentially scaled.*

Experiment 3. As pointed out earlier, ALE is generally accurate. This experiment illustrates the benefit of increasing the number of Lanczos iterations k (which is the dimension of the Krylov subspace). Here, ALE is applied to estimate the condition numbers of a sequence of Cholesky factors generated by recursive least-squares computations employing a sliding window. Hence, both up and downdatings are involved. The process is initiated by a 20-by-20 identity matrix, and the up and downdatings are performed on 20 rows of data composed of numbers chosen randomly in $[-1, 1]$ with outliers of magnitude 10^4 added to six random places. The results are summarized in

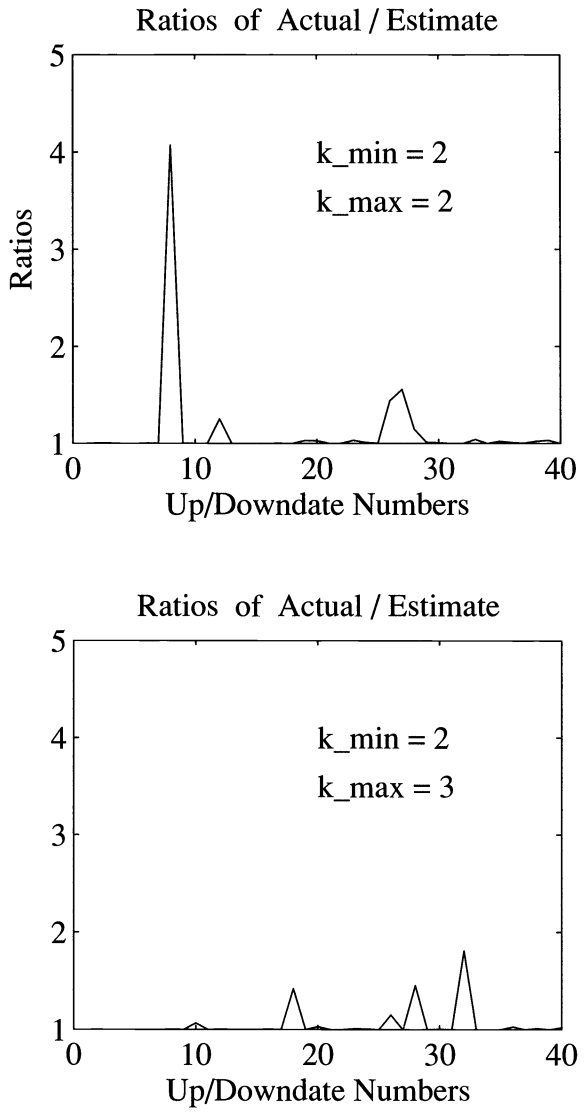

FIG. 2. ALE *on random matrices with outliers added.*

Fig. 2 by the ratios of

$$\frac{\text{actual condition number}}{\text{estimated condition number}}.$$

6. Conclusions. We have shown that the Rayleigh–Ritz approximation is applicable to dynamic condition estimations. Viewing many existing dynamic condition estimators as Rayleigh–Ritz approximation allows better understanding of, and natural generalization to, such estimators. Moreover, this viewpoint is likely to lead to other condition estimators tailored to other specific situations.

Acknowledgments. This work was motivated by a discussion with Professor Robert Plemmons during a matrix theory conference held at the University of Hong Kong in the Summer of 1991. The author also acknowledges the hospitality of the organizers of that conference, Drs. Yik-Hoi Au-Yeung and Raymond Chan. The source codes of ACE and ALE are provided by Drs. Daniel Pierce and William Ferng, respectively. The author has also benefitted from discussions with Drs. Christian Bischof and Daniel Pierce.

ON THE STRUCTURE OF GENERALIZED SINGULAR VALUE AND QR DECOMPOSITIONS*

BART DE MOOR†

Abstract. This paper analyzes in detail the structure of generalizations of the singular value decomposition and the QR decomposition for any number of matrices. The structure is completely determined as a function of the ranks of the matrices or their products and concatenations.

Key words. ordinary, product, quotient, restricted singular value decomposition, QR decomposition, complete orthogonal factorization

AMS subject classifications. 15A09, 15A18, 15A21, 15A24, 65F20

1. Introduction.

In a previous paper [4], we introduced an infinite tree of generalizations of the ordinary singular value decomposition (OSVD) and we derived a constructive proof of it. All decompositions in this tree are considered as generalized singular value decompositions (GSVDs) and it was shown in [4] how all of them can be labeled with a sequence of the letters P and Q, where P stands for *product* and Q stands for *quotient*. In [5], we introduced a corresponding set of generalizations of the QR decomposition, which could be denoted by appropriate enumerations of the letters L (lower) and U (upper). It is the purpose of this paper to discuss in more detail the structure of these generalizations. In particular, we shall derive formulas for the dimensions of the blocks in the quasi-diagonal matrices of the GSVDs of [4] (Theorem 1.1 of this paper), or the triangular matrices in the GQRDs (generalized QR decompositions) of [5] (Theorem 1.2 of this paper), in terms of the ranks of the matrices involved and concatenations and products of these matrices.

This paper is organized as follows. In the remainder of this section, we summarize the main results on generalized SVDs and QRDs obtained in [4] and [5]. Since there is a one-to-one correspondence between these two generalizations, we will concentrate on the generalizations of the SVD, while the results will apply for the GQRDs as well. In §2, we analyze in detail the structure of a GSVD that only consists of P-steps. In §3, we analyze GSVDs that only contain Q-steps. In §4, we discuss the general case where we exploit the obtained insights from §§2 and 3. Instead of providing rigorous proofs, we have chosen to indicate our methods of deriving these results with illustrative examples.

Let us first state the main result of [4] in the following theorem.

THEOREM 1.1 (GSVDs for k matrices). *Consider a set of k matrices with compatible dimensions: A_1 $(n_0 \times n_1), A_2$ $(n_1 \times n_2), \ldots, A_{k-1}$ $(n_{k-2} \times n_{k-1}), A_k$ $(n_{k-1} \times n_k)$. Then there exist*

- *unitary matrices U_1 $(n_0 \times n_0)$ and V_k $(n_k \times n_k)$;*

0 & \ldots & \ldots & \ldots & \ldots & 0 & 0 \\
\ldots & \ldots & \ldots & \ldots & \ldots & \ldots & \ldots \\
0 & \ldots & \ldots & \ldots & \ldots & S_k^k & 0 \\
0 & 0 & \ldots & \ldots & \ldots & 0 & 0
\end{pmatrix}
\end{array}
\end{array}.
$$

The $r_k^i \times r_k^i$ *matrices* S_k^i *are diagonal with positive diagonal elements.*

- *Nonsingular matrices* X_j $(n_j \times n_j)$ *and* Z_j*,* $j = 1, 2, \ldots, (k-1)$*, where* Z_j *is either* $Z_j = X_j^{-*}$ *or either* $Z_j = X_j$ *(i.e., both choices are always possible), such that the given matrices can be factorized as*

$$
\begin{aligned}
A_1 &= U_1 D_1 X_1^{-1}, \\
A_2 &= Z_1 D_2 X_2^{-1}, \\
A_3 &= Z_2 D_3 X_3^{-1}, \\
\cdots &= \cdots, \\
A_i &= Z_{i-1} D_i X_i^{-1}, \\
\cdots &= \cdots, \\
A_k &= Z_{k-1} S_k V_k^*.
\end{aligned}
$$

Expressions for the integers r_j^i *are given below; they are ranks of certain matrices in the constructive proof of this theorem* [4].

Observe that the matrices D_j and S_k are generally not diagonal. Their only nonzero blocks however are diagonal block matrices. Observe that we always take the

last factor in every factorization as the inverse of a nonsingular matrix, which is only a matter of convention. (Another convention would result in a modified definition of the matrices Z_i.) As to the name of a certain GSVD, we propose to adopt the following convention.

DEFINITION 1 (Nomenclature for GSVDs). If $k = 1$ in Theorem 1.1, then the corresponding factorization of the matrix A_1 will be called the OSVD. If for a matrix pair $A_i, A_{i+1}, 1 \le i \le k-1$ in Theorem 1.1, we have that $Z_i = X_i$ then, the factorization of the pair will be said to be of P-type. If, on the other hand, for a matrix pair $A_i, A_{i+1}, 1 \le i \le k-1$ in Theorem 1.1, we have that $Z_i = X_i^{-*}$ the factorization of the pair will be said to be of Q-type. The name of a GSVD of the matrices A_i, $i = 1, 2, \ldots, k > 1$ as in Theorem 1.1, is then obtained by simply enumerating the different factorization types.

We now give some examples.

Example 1. Consider two matrices A_1 $(n_0 \times n_1)$ and A_2 $(n_1 \times n_2)$. Then, we have the following two possible GSVDs.

	P-type	Q-type
A_1	$U_1 D_1 X_1^{-1}$	$U_1 D_1 X_1^{-1}$
A_2	$X_1 S_2 V_2^*$	$X_1^{-*} S_2 V_2^*$

The P-type factorization corresponds to the PSVD (product singular value decomposition) as in [9] (called ΠSVD there) and in [1] and [3], while the Q-type factorization is nothing else than the QSVD (quotient singular value decomposition) in [8], [10], and [11] (called generalized SVD there). A P-type factorization is precisely the kind of transformation that occurs in the PSVD while a Q-type factorization occurs in the QSVD.

Example 2. Let us write down the PQQP-SVD for five matrices:

$$\begin{aligned} A_1 &= U_1 D_1 X_1^{-1}, \\ A_2 &= X_1 D_2 X_2^{-1}, \\ A_3 &= X_2^{-*} D_3 X_3^{-1}, \\ A_4 &= X_3^{-*} D_4 X_4^{-1}, \\ A_5 &= X_4 S_5 V_5^*. \end{aligned}$$

In [5], we derived the following generalization of the QR decomposition for a chain of k matrices.

THEOREM 1.2 (Generalized QR decompositions for k matrices). *Given k complex matrices A_1 $(n_0 \times n_1)$, A_2 $(n_1 \times n_2)$, ..., A_k $(n_{k-1} \times n_k)$. There always exist unitary matrices $Q_0, Q_1, \ldots, Q_k$ such that $\tilde{T}_i = Q_{i-1}^* A_i Q_i$, where $\tilde{T}_i$ is a lower triangular or upper triangular matrix (both cases are always possible) with the following structure.*

Lower triangular (which will be denoted by a superscript l):

$$\tilde{T}_i^l = \begin{array}{c} \\ r_{i-1}^1 \\ r_{i-1}^2 \\ \vdots \\ r_{i-1}^i \end{array} \begin{array}{c} \begin{array}{cccccc} r_i^1 & r_i^2 & \ldots & r_i^i & r_i^{i+1} \end{array} \\ \begin{pmatrix} R_{i,1} & 0 & \ldots & 0 & 0 \\ * & R_{i,2} & \ldots & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ * & * & \ldots & R_{i,i} & 0 \end{pmatrix} \end{array}, \quad \text{where } R_{i,j} = \begin{pmatrix} 0 \\ R_{i,j}^l \end{pmatrix},$$

and $R_{i,j}^l$ is a square nonsingular lower triangular matrix.

Upper triangular (which will be denoted by a superscript u):

$$\tilde{T}_i^u = \begin{array}{c} \\ r_{i-1}^1 \\ r_{i-1}^2 \\ \vdots \\ r_{i-1}^i \end{array} \begin{array}{c} \begin{array}{ccccc} r_i^{i+1} & r_i^1 & \dots & r_i^{i-1} & r_i^i \end{array} \\ \begin{pmatrix} 0 & R_{i,1} & * & \dots & * \\ 0 & 0 & R_{i,2} & \dots & * \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \dots & 0 & R_{i,i} \end{pmatrix} \end{array}, \quad \text{where } R_{i,j} = \begin{pmatrix} R_{i,j}^u \\ 0 \end{pmatrix},$$

and $R_{i,j}^u$ is a square nonsingular upper triangular matrix. The block dimensions r_i^j coincide with those of Theorem 1.1.

As to the nomenclature of these GQRDs, we propose the following definition.

DEFINITION 2 (Nomenclature for GQRD). The name of a GQRD of k matrices of compatible dimensions is generated by enumerating the letters L (for lower) and U (for upper), according to the lower or upper triangularity of the matrices $\tilde{T}_i, i = 1, \dots, k$ in the decomposition of Theorem 1.2.

For k matrices, there are 2^k different sequences with two letters. For instance, for $k = 3$, there are eight GQRDs (LLL, LLU, LUL, LLU, ULL, ULU, UUL, UUU).

The relation between the two generalizations, the GSVDs and the GQRDs, is the following:

(i) A pair of identical letters, i.e., L-L or U-U that occurs in the factorization of A_i, A_{i+1} corresponds to a P-type factorization of the pair;

(ii) A pair of alternating letters, i.e., L-U or U-L that occurs in the factorization of A_i, A_{i+1} corresponds to a Q-type factorization of the pair.

As an example, for a PQP-SVD of four matrices, there are two possible corresponding GQRDs, namely, an LLUL decomposition and an UULU decomposition. As with the GSVD, we can also introduce the convention to use powers of (a sequence of) letters. For instance, for a P^3Q^2-SVD (which is short for a PPPQQ-SVD), there are two QR decompositions, namely, an L^4UL-QR and an U^4LU-QR.

2. Structure of a GSVD with only P-steps. The main purpose of this section is to derive expressions for the block dimensions r_p^q when all steps in the GSVD are P-steps. These block dimensions will be expressed as a function of the ranks of products of the form

$$\operatorname{rank}(A_i A_{i+1}, \dots, A_{j-1} A_j),$$

which will be denoted by $r_{i(i+1)\dots(j-1)j}$. This will be done in two steps. First, we derive an implicit characterization of the block dimensions. This leads directly to an explicit determination of these block dimensions.

LEMMA 2.1. *The rank of the product of the matrices $D_i, D_{i+1}, \dots, D_j$ that appears in a* P^{k-1}-SVD (*or the rank of the product $A_i A_{i+1}, \dots, A_j$ in an* L^k-QR *or a* U^k-QR) *is given by*

$$\operatorname{rank}(D_i D_{i+1} \dots D_j) = r_{(i)(i+1)\dots(j)} = r_j^1 + r_j^2 + \dots + r_j^i.$$

As the examples will reveal, the following theorem follows directly from this lemma.

THEOREM 2.2. *Consider a* P^{k-1}-SVD *of the matrices $A_1, A_2, \dots, A_k$. Then, the block dimensions r_p^q, $p = 1, \dots, k$, $q = 1, \dots, p$ are given by*

$$r_j^1 = r_{(1)(2)\dots(j)},$$
$$r_j^i = r_{i(i+1)\dots(j)} - r_{(i-1)(i)\dots(j)},$$

with $r_{(i)\ldots(j)} = r_i$ *if* $i = j$.

Let us analyze an example from which we will see the general result.

Example 3 (P^3-SVD). Let us derive expressions for the block dimensions $r_4^1, r_4^2, r_4^3, r_4^4$ of the matrix S_4 in terms of $r_1, r_2, r_3, r_{(3)(4)}, r_{(2)(3)(4)}, r_{(1)(2)(3)(4)}$. The matrices D_1, D_2, D_3, S_4 have the following structure:

$$D_1 = \begin{array}{c} \\ r_1^1 \\ n_0 - r_1 \end{array} \begin{array}{c} \begin{array}{cc} r_1^1 & n_1 - r_1^1 \end{array} \\ \begin{pmatrix} I & 0 \\ 0 & 0 \end{pmatrix} \end{array}, \qquad D_2 = \begin{array}{c} \\ r_2^1 \\ r_1^1 - r_2^1 \\ r_2^2 \\ n_1 - r_2^2 - r_1^1 \end{array} \begin{array}{c} \begin{array}{ccc} r_2^1 & r_2^2 & n_2 - r_2 \end{array} \\ \begin{pmatrix} I & 0 & 0 \\ 0 & 0 & 0 \\ 0 & I & 0 \\ 0 & 0 & 0 \end{pmatrix} \end{array},$$

$$D_3 = \begin{array}{c} \\ r_3^1 \\ r_2^1 - r_3^1 \\ r_3^2 \\ r_2^2 - r_3^2 \\ r_3^3 \\ n_2 - r_2 - r_3^3 \end{array} \begin{array}{c} \begin{array}{cccc} r_3^1 & r_3^2 & r_3^3 & n_3 - r_3 \end{array} \\ \begin{pmatrix} I & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & I & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & I & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \end{array},$$

$$S_4 = \begin{array}{c} \\ r_4^1 \\ r_3^1 - r_4^1 \\ r_4^2 \\ r_3^2 - r_4^2 \\ r_4^3 \\ r_3^3 - r_4^3 \\ r_4^4 \\ n_3 - r_3 - r_4^4 \end{array} \begin{array}{c} \begin{array}{ccccc} r_4^1 & r_4^2 & r_4^3 & r_4^4 & n_4 - r_4 \end{array} \\ \begin{pmatrix} S_4^1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & S_4^2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & S_4^3 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & S_4^4 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix} \end{array}.$$

From the structure and dimensions of these matrices, we see that (we only show block dimensions that are relevant)

$$D_3 S_4 = \begin{array}{c} \\ r_4^1 \\ r_3^1 - r_4^1 \\ r_2^1 - r_3^1 \\ r_4^2 \\ r_3^2 - r_4^2 \\ r_2^2 - r_3^2 \\ r_4^3 \\ r_3^3 - r_4^3 \\ n_2 - r_2 - r_3^3 \end{array} \begin{array}{c} \begin{array}{ccccc} r_4^1 & r_4^2 & r_4^3 & & \end{array} \\ \begin{pmatrix} S_4^1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & S_4^2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & S_4^3 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix} \end{array}, \qquad D_2 D_3 S_4 = \begin{array}{c} \\ r_4^1 \\ \\ \\ r_4^2 \\ \\ \\ \\ \end{array} \begin{array}{c} \begin{array}{ccccc} r_4^1 & r_4^2 & & & \end{array} \\ \begin{pmatrix} S_4^1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & S_4^2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix} \end{array},$$

$$D_1 D_2 D_3 S_4 = \begin{array}{c} \\ r_4^1 \\ \\ \\ \\ \end{array} \begin{array}{c} \begin{array}{c} r_4^1 \end{array} \\ \begin{pmatrix} S_4^1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix} \end{array}.$$

We see by inspection that

$$\begin{aligned} r_{(1)(2)(3)(4)} &= r_4^1, \\ r_{(2)(3)(4)} &= r_4^1 + r_4^2, \\ r_{(3)(4)} &= r_4^1 + r_4^2 + r_4^3, \\ r_4 &= r_4^1 + r_4^2 + r_4^3 + r_4^4, \end{aligned}$$

from which it follows that

$$\begin{aligned} r_4^1 &= r_{(1)(2)(3)(4)}, \\ r_4^2 &= r_{(2)(3)(4)} - r_{(1)(2)(3)(4)}, \\ r_4^3 &= r_{(3)(4)} - r_{(2)(3)(4)}, \\ r_4^4 &= r_4 - r_{(3)(4)}. \end{aligned}$$

The same expressions apply for the blocks in the corresponding U^4- or L^4-QR.

Observe that in the product D_3 and S_4, only the diagonal blocks of S_4 with dimensions r_4^1, r_4^2, r_4^3 survive. In the product $D_2D_3S_4$ only the blocks with dimensions r_4^1 and r_4^2 survive, and in $D_1D_2D_3S_4$ only the block with dimension r_4^1 survives. This observation can easily be generalized to the following survival rule for a pure PSVD, which is the essence of the proof of Lemma 2.1.

In a product of matrices $D_i, D_{i+1}, \ldots, D_j$ (or S_k) only the blocks with block dimensions $r_j^1, r_j^2, \ldots, r_j^i$ survive.

Once this observation has been established, a proof of Theorem 3.2 is straightforward.

3. A GSVD with only Q-steps. Let us now look closer at the structure of a GSVD with only Q-steps. We will see that we can derive expressions for the block dimensions $r_p^q, p = 1, \ldots, k, q = 1, \ldots, p$ in two steps. First, we obtain an implicit formula where the required block dimensions are unknowns in a set of linear equations. In a second step, these are solved to obtain an expression for the block dimensions r_p^q in terms of the ranks of the block matrices

$$\begin{pmatrix} A_i & 0 & 0 & \ldots & 0 & 0 & 0 \\ A_{i+1}^* & A_{i+2} & 0 & \ldots & 0 & 0 & 0 \\ 0 & A_{i+3}^* & A_{i+4} & \ldots & 0 & 0 & 0 \\ 0 & \ldots & \ldots & \ldots & \ldots & \ldots & 0 \\ 0 & \ldots & \ldots & \ldots & A_{j-3}^* & A_{j-2} & 0 \\ 0 & \ldots & \ldots & \ldots & 0 & A_{j-1}^* & A_j \end{pmatrix}.$$

Their rank is denoted by $r_{i|i+1|\ldots|j-1|j}$.

We will proceed in the same way as in §2. Instead of proving our results rigorously, we prefer to reveal the mechanisms by some clarifying examples. First, we obtain the following implicit characterization.

LEMMA 3.1. *Consider a* Q^{k-1}-SVD *of the matrices* $A_1, A_2, \ldots, A_k$. *Then if* $j - i$ *even*

$$r_{i|\ldots|j} = r_{i|\ldots|j-1} + (r_j^1 + r_j^2 + \cdots + r_j^i) + r_j^{i+2} + r_j^{i+4} + \cdots + r_j^{j-2} + r_j^j;$$

if $j - i$ *odd*

$$r_{i|\ldots|j} = r_{i|\ldots|j-1} + (r_j^{i+1} + r_j^{i+3} + \cdots + r_j^{j-2} + r_j^j).$$

As will be shown, this lemma leads to the following theorem.

THEOREM 3.2. *Consider a* Q^{k-1}*-SVD of the matrices* $A_1, A_2, \dots, A_k$*. Then*

$$
\begin{aligned}
r_k^1 &= (-1)^{k+1}(r_{1|\dots|k} - r_{1|\dots|k-1} - r_{2|\dots|k} + r_{2|\dots|k-1}),\\
r_k^j &= (-1)^{j+k+1}(r_{(j+1)|\dots|k} - r_{(j+1)|\dots|k-1} - r_{(j-1)|\dots|k} + r_{(j-1)|\dots|k-1})\\
&\qquad \textit{for } 2 \le j \le k-2,\\
r_k^{k-1} &= r_k - r_{k-2|k-1|k} + r_{k-2|k-1},\\
r_k^k &= r_{k-1|k} - r_{k-1}.
\end{aligned}
$$

Observe that in all cases, no more than four ranks $r_{i|\dots|j}$ are involved. Also, the third case may be recognized as Grassman's dimension theorem, giving the dimension of the intersection of the column spaces of the matrices

$$
\begin{pmatrix} A_{k-2} \\ A_{k-1}^* \end{pmatrix} \quad \text{and} \quad \begin{pmatrix} 0 \\ A_k \end{pmatrix}.
$$

Let us derive the result of Theorem 3.2 by an example.

Example 4 (QQ-SVD).[1] A QQ-SVD of three matrices A_1 $(n_0 \times n_1)$, $A_2(n_1 \times n_2)$, and A_3 $(n_2 \times n_3)$ takes the form

$$
\begin{aligned}
A_1 &= U_1 D_1 X_1^{-1},\\
A_2 &= X_1^{-*} D_2 X_2^{-1},\\
A_3 &= X_2^{-*} S_3 V_3^*,
\end{aligned}
$$

where

$$
D_1 = \begin{array}{c} \\ r_1^1 \\ n_0 - r_1 \end{array} \begin{array}{c} \begin{array}{cc} r_1^1 & n_1 - r_1^1 \end{array} \\ \begin{pmatrix} I & 0 \\ 0 & 0 \end{pmatrix} \end{array}, \qquad
D_2 = \begin{array}{c} \\ r_2^1 \\ r_1^1 - r_2^1 \\ r_2^2 \\ n_1 - r_2^2 - r_1 \end{array} \begin{array}{c} \begin{array}{ccc} r_2^1 & r_2^2 & n_2 - r_2 \end{array} \\ \begin{pmatrix} I & 0 & 0 \\ 0 & 0 & 0 \\ 0 & I & 0 \\ 0 & 0 & 0 \end{pmatrix} \end{array},
$$

$$
S_3 = \begin{array}{c} \\ r_3^1 \\ r_2^1 - r_3^1 \\ r_3^2 \\ r_2^2 - r_3^2 \\ r_3^3 \\ n_3 - r_2 - r_3^3 \end{array} \begin{array}{c} \begin{array}{cccc} r_3^1 & r_3^2 & r_3^3 & n_3 - r_3 \end{array} \\ \begin{pmatrix} S_3^1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & S_3^2 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & S_3^3 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \end{array}.
$$

Observe that

$$
\begin{pmatrix} A_1 & 0 \\ A_2^t & A_3 \end{pmatrix} = \begin{pmatrix} U_1 & 0 \\ 0 & X_2^{-*} \end{pmatrix} \begin{pmatrix} D_1 & 0 \\ D_2^t & S_3 \end{pmatrix} \begin{pmatrix} X_1^{-1} & 0 \\ 0 & V_3^* \end{pmatrix}.
$$

[1] A complete detailed analysis of the QQ-SVD (which is also called the restricted singular value decomposition (RSVD)) together with numerous applications can be found in [2].

The left and right factors are nonsingular. Hence, we can obtain expressions for all dimensions involved by analyzing the block bidiagonal matrix

$$\left(\begin{array}{c|c} D_1 & 0 \\ \hline D_2^t & S_3 \end{array}\right) = \begin{array}{l} r_3^1 \\ r_2^1 - r_3^1 \\ r_1 - r_2^1 \\ n_0 - r_1 \\ \hline r_3^1 \\ r_2^1 - r_3^1 \\ r_3^2 \\ r_2^2 - r_3^2 \\ r_3^3 \\ n_2 - r_2 - r_3^3 \end{array} \left(\begin{array}{ccc|ccc|cccc} I & 0 & 0 & & & & & & & \\ 0 & I & 0 & & & & & & & \\ 0 & 0 & I & & & & & & & \\ 0 & 0 & 0 & & & & & & & \\ \hline I & 0 & 0 & & & & S_3^1 & 0 & 0 & 0 \\ 0 & I & 0 & & & & 0 & 0 & 0 & 0 \\ & & & I & 0 & 0 & 0 & S_3^2 & 0 & 0 \\ & & & 0 & I & 0 & 0 & 0 & 0 & 0 \\ & & & & & & 0 & 0 & S_3^3 & 0 \\ & & & & & & 0 & 0 & 0 & 0 \end{array}\right),$$

where we have used the finest possible subdivision of matrices (i.e., a partitioning based upon the block dimensions r_3^1, r_3^2, r_3^3). All nonzero blocks are diagonal. Elements not shown are zero. First, it is straightforward to see that $r_3 = r_3^1 + r_3^2 + r_3^3$. Next, we concentrate on the submatrix $\begin{pmatrix} D_2^t & S_3 \end{pmatrix}$. In this matrix, the block columns with the matrices S_3^1 and S_3^2 are linearly dependent on the previous ones. The block column with S_3^3 is linearly independent. Hence $\operatorname{rank}\begin{pmatrix} D_2^t & S_3 \end{pmatrix} = r_{2|3} = r_2 + r_3^3$. Next, we will relate the rank $r_{1|2} = \operatorname{rank}\begin{pmatrix} D_1^t & D_2 \end{pmatrix}^t$ to

$$r_{1|2|3} = \operatorname{rank}\begin{pmatrix} D_1 & 0 \\ D_2^t & S_3 \end{pmatrix}.$$

It can be seen that when the block column with S_3^1 is appended to $\begin{pmatrix} D_1^t & D_2 \end{pmatrix}^t$, the rank will increase with

$$r_3^1 \times \left[\operatorname{rank}\begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix} - \operatorname{rank}\begin{pmatrix} 1 \\ 1 \end{pmatrix}\right] = r_3^1.$$

If the block column with S_3^2 is appended to $\begin{pmatrix} D_1^t & D_2 \end{pmatrix}^t$, the rank will not increase. Finally, if the block column with S_3^1 is appended, then the rank will increase with $r_3^3 \times [\operatorname{rank}(0 \;\; 1) - \operatorname{rank}(0)] = r_3^3$. Hence

$$\begin{aligned} r_{1|2|3} = r_{1|2} &+ r_3^1 \times \left[\operatorname{rank}\begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix} - \operatorname{rank}\begin{pmatrix} 1 \\ 1 \end{pmatrix}\right] \\ &+ r_3^2 \times [\operatorname{rank}(1 \;\; 1) - \operatorname{rank}(1)] \\ &+ r_3^3 \times [\operatorname{rank}(0 \;\; 1) - \operatorname{rank}(0)] = r_{1|2} + r_3^1 + r_3^3. \end{aligned}$$

We can now set up a set of linear equations as

$$\begin{pmatrix} 1 & 1 & 1 \\ 0 & 0 & 1 \\ 1 & 0 & 1 \end{pmatrix} \begin{pmatrix} r_3^1 \\ r_3^2 \\ r_3^3 \end{pmatrix} = \begin{pmatrix} r_3 \\ r_{2|3} - r_2 \\ r_{1|2|3} - r_{1|2} \end{pmatrix},$$

which can be solved as

$$\begin{pmatrix} r_3^1 \\ r_3^2 \\ r_3^3 \end{pmatrix} = \begin{pmatrix} 0 & -1 & 1 \\ 1 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix} \begin{pmatrix} r_3 \\ r_{2|3} - r_2 \\ r_{1|2|3} - r_{1|2} \end{pmatrix} = \begin{pmatrix} r_{1|2|3} - r_{1|2} + r_2 - r_{2|3} \\ r_3 + r_{1|2} - r_{1|2|3} \\ r_{2|3} - r_2 \end{pmatrix}.$$

The same expressions will appear in the ULU- or LUL-QR.

Example 5 (Q^7-SVD). The courageous reader may wish to verify that for $k = 7$, the following set of linear equations needs to be solved:

$$\begin{pmatrix} r_7 \\ r_{6|7} - r_6 \\ r_{5|6|7} - r_{5|6} \\ r_{4|5|6|7} - r_{4|5|6} \\ r_{3|4|5|6|7} - r_{3|4|5|6} \\ r_{2|3|4|5|6|7} - r_{2|3|4|5|6} \\ r_{1|2|3|4|5|6|7} - r_{1|2|3|4|5|6} \end{pmatrix} = \begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 1 & 1 & 1 & 1 & 1 & 0 & 1 \\ 0 & 0 & 0 & 0 & 1 & 0 & 1 \\ 1 & 1 & 1 & 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 0 & 1 & 0 & 1 \\ 1 & 0 & 1 & 0 & 1 & 0 & 1 \end{pmatrix} \begin{pmatrix} r_7^1 \\ r_7^2 \\ r_7^3 \\ r_7^4 \\ r_7^5 \\ r_7^6 \\ r_7^7 \end{pmatrix}.$$

This set of equations can be solved as

$$\begin{pmatrix} r_7^1 \\ r_7^2 \\ r_7^3 \\ r_7^4 \\ r_7^5 \\ r_7^6 \\ r_7^7 \end{pmatrix} = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & -1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 0 & -1 \\ 0 & 0 & 0 & -1 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & -1 & 0 & 0 \\ 0 & -1 & 0 & 1 & 0 & 0 & 0 \\ 1 & 0 & -1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} r_7 \\ r_{6|7} - r_6 \\ r_{5|6|7} - r_{5|6} \\ r_{4|5|6|7} - r_{4|5|6} \\ r_{3|4|5|6|7} - r_{3|4|5|6} \\ r_{2|3|4|5|6|7} - r_{2|3|4|5|6} \\ r_{1|2|3|4|5|6|7} - r_{1|2|3|4|5|6} \end{pmatrix}.$$

The pattern of the inverse matrix now becomes clear. We have a triantidiagonal matrix with a sequence of alternating 1 and -1, ending in a 1 in the top right-hand corner. As a matter of fact, this observation constitutes the essence of a proof of Theorem 3.2.

4. On the structure of a GSVD. For the analysis of the structure of a completely general GSVD, in which the letters P and Q can appear in any order, we need a mixture of the two preceding notations for block bidiagonal matrices, the blocks of which can be products of matrices, such as

$$\begin{pmatrix} A_{i_0} A_{i_0+1} \dots A_{i_1-1} & 0 & 0 & \dots & 0 \\ (A_{i_1} \dots A_{i_2-1})^* & A_{i_2} \dots A_{i_3-1} & 0 & \dots & 0 \\ 0 & (A_{i_3} \dots A_{i_4-1})^* & A_{i_4} \dots A_{i_5-1} & \dots & 0 \\ \dots & \dots & \dots & \dots & \dots \\ 0 & \dots & \dots & \dots & A_{i_l} \dots A_j \end{pmatrix},$$

where $1 \le i_0 < i_1 < i_2 < i_3 < \cdots < i_l \le j \le k$. Their rank will be denoted by

$$r_{(i_0)\dots(i_1-1)|i_1\dots(i_2-1)|\dots|i_l\dots(j)}.$$

For instance, the rank of the matrix

$$\begin{pmatrix} A_2 A_3 & 0 & 0 \\ A_4^* & A_5 A_6 A_7 & 0 \\ 0 & (A_8 A_9)^* & A_{10} \end{pmatrix}$$

will be represented by $r_{(2)(3)|4|(5)(6)(7)|(8)(9)|(10)}$.

In the following theorem, we derive an implicit expression of the block dimensions $r_p^q, p = 1, \dots, k, q = 1, \dots, p$ of a **GSVD** of $A_1, A_2, \dots, A_k$. We proceed in two steps. The first part of the theorem is based on the survival rule described in Lemma 2.1, and the second part is then an application of the pure Q-step SVD in Lemma 3.1.

THEOREM 4.1 (On the structure of a GSVD or GQRD). *The rank*

$$r_{(i_0)(i_0+1)\dots(i_1-1)|i_1\dots(i_2-1)|\dots|i_l\dots j}$$

can be expressed as follows:

1. *Calculate the* $l+1$ *integers* $s_j^i, i = 1, 2, \dots, l+1$.

$$\begin{aligned} s_j^1 &= r_j^1 + r_j^2 + \cdots + r_j^{i_0}, \\ s_j^2 &= r_j^{i_0+1} + r_j^{i_0+2} + \cdots + r_j^{i_1}, \\ \cdots &= \cdots, \\ s_j^{l+1} &= r_j^{i_{l-1}+1} + r_j^{i_{l-1}+2} + \cdots + r_j^{i_l}. \end{aligned}$$

2. *Depending on* l *even or* l *odd there are two cases.*

l *even*:

$$\begin{aligned} & r_{(i_0)\dots(i_1-1)|(i_1)\dots(i_2-1)|\dots|(i_l)\dots j} \\ & = r_{(i_0)\dots(i_1-1)|(i_1)\dots(i_2-1)|\dots|(i_{l-1})\dots(i_l-1)} + s_j^1 + s_j^3 + \cdots + s_j^{l+1}. \end{aligned}$$

l *odd*:

$$\begin{aligned} & r_{(i_0)\dots(i_1-1)|(i_1)\dots(i_2-1)|\dots|(i_l)\dots j} \\ & = r_{(i_0)\dots(i_1-1)|(i_1)\dots(i_2-1)|\dots|(i_{l-1})\dots(i_l-1)} + s_j^2 + s_j^4 + \cdots + s_j^{l+1}. \end{aligned}$$

Again, we will not give an unreadable algebraic proof of this theorem, but instead we illustrate it with an example.

Example 6 (QPPQ-SVD). A QPPQ-SVD of five matrices A_1, A_2, A_3, A_4, A_5 can be analyzed in terms of the ranks of the matrices

$$\begin{pmatrix} D_1 & 0 \\ (D_2D_3D_4)^t & S_5 \end{pmatrix}, \quad \begin{pmatrix} (D_2D_3D_4)^t & S_5 \end{pmatrix}, \quad \begin{pmatrix} (D_3D_4)^t & S_5 \end{pmatrix}, \quad \begin{pmatrix} D_4^t & S_5 \end{pmatrix}.$$

Let us first consider the first matrix

$$\left(\begin{array}{c||c} D_1 & 0 \\ \hline\hline (D_2D_3D_4)^t & S_5 \end{array}\right) =$$

$$\begin{array}{c} r_5^1 \\ \\ \\ \\ \\ \\ \hline\hline r_5^1 \\ r_4^1 - r_5^1 \\ \hline r_5^2 \\ r_4^2 - r_5^2 \\ \hline r_5^3 \\ \\ \hline r_5^4 \\ \\ \hline r_5^5 \\ \\ \hline \end{array} \left(\begin{array}{ccccc|ccccc||cccccc} 1 & 0 & 0 & 0 & 0 & & & & & & & & & & & \\ 0 & 1 & 0 & 0 & 0 & & & & & & & & & & & \\ 0 & 0 & 1 & 0 & 0 & & & & & & & & & & & \\ 0 & 0 & 0 & 1 & 0 & & & & & & & & & & & \\ 0 & 0 & 0 & 0 & 1 & & & & & & & & & & & \\ 0 & 0 & 0 & 0 & 0 & & & & & & & & & & & \\ \hline\hline 1 & 0 & 0 & 0 & 0 & & & & & & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & & & & & & 0 & 0 & 0 & 0 & 0 & 0 \\ \hline & & & & & 1 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ & & & & & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ \hline & & & & & & & & & & 0 & 0 & 1 & 0 & 0 & 0 \\ & & & & & & & & & & 0 & 0 & 0 & 0 & 0 & 0 \\ \hline & & & & & & & & & & 0 & 0 & 0 & 1 & 0 & 0 \\ & & & & & & & & & & 0 & 0 & 0 & 0 & 0 & 0 \\ \hline & & & & & & & & & & 0 & 0 & 0 & 0 & 1 & 0 \\ & & & & & & & & & & 0 & 0 & 0 & 0 & 0 & 0 \end{array}\right).$$

Elements not shown are represented by 0 while 1 represents a nonzero square diagonal matrix. Obviously, $r_5 = r_5^1+r_5^2+r_5^3+r_5^4+r_5^5$. Also, $r_{(2)(3)(4)|5} = r_{(2)(3)(4)}+(r_5^3+r_5^4+r_5^5)$. Using the notation of Theorem 4.1, we have $s_5^1 = r_5^1 + r_5^2$ and $s_5^2 = r_5^3 + r_5^4 + r_5^5$, so that indeed $r_{(2)(3)(4)|5} = r_{(2)(3)(4)} + s_5^2$. Also,

$$r_{1|(2)(3)(4)|5} = r_{1|(2)(3)(4)} + r_5^1 \times \left[\operatorname{rank}\begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix} - \operatorname{rank}\begin{pmatrix} 1 \\ 1 \end{pmatrix}\right] + r_5^2 \times [\operatorname{rank}(1\ \ 1) - \operatorname{rank}(1)] + (r_5^3 + r_5^4 + r_5^5).$$

With the notation of Theorem 4.1, we have for this case $s_5^1 = r_5^1$, $s_5^2 = r_5^2$, $s_5^3 = r_5^3+r_5^4+r_5^5$, so that indeed $r_{1|234|5} = r_{1|234}+s_5^1+s_5^3$. Up to now, we have three implicit equations for the five unknowns $r_5^1, r_5^2, r_5^3, r_5^4, r_5^5$. The remaining two are found from the matrix $(D_4^t \ \ S_5)$ as $r_{4|5} = r_4 + r_5^5$ and from

$$((D_3D_4)^t \ \ S_5) = \begin{array}{l} r_5^1 \\ r_4^1 - r_5^1 \\ \hline r_5^2 \\ r_4^2 - r_5^2 \\ \hline r_5^3 \\ r_4^3 - r_5^3 \\ \hline r_5^4 \\ \\ \hline r_5^5 \\ \\ \hline \end{array} \left(\begin{array}{ccc|ccc|ccc|c||cccccc} 1 & 0 & 0 & & & & & & & & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & & & & & & & & 0 & 0 & 0 & 0 & 0 & 0 \\ \hline & & & 1 & 0 & 0 & & & & & 0 & 1 & 0 & 0 & 0 & 0 \\ & & & 0 & 1 & 0 & & & & & 0 & 0 & 0 & 0 & 0 & 0 \\ \hline & & & & & & 1 & 0 & 0 & & 0 & 0 & 1 & 0 & 0 & 0 \\ & & & & & & 0 & 1 & 0 & & 0 & 0 & 0 & 0 & 0 & 0 \\ \hline & & & & & & & & & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ & & & & & & & & & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ \hline & & & & & & & & & & 0 & 0 & 0 & 0 & 1 & 0 \\ & & & & & & & & & & 0 & 0 & 0 & 0 & 0 & 0 \end{array}\right).$$

From this we find that

$$r_{34|5} = r_{3|4} + (r_5^1 + r_5^2 + r_5^3) \times [\operatorname{rank}(1\ \ 1) - \operatorname{rank}(1)] + r_5^4 + r_5^5 = r_{3|4} + (r_5^4 + r_5^5).$$

With the notation of Theorem 4.1 we have $s_5^1 = r_5^1 + r_5^2 + r_5^3$ and $s_5^2 = r_5^4 + r_5^5$, so that indeed $r_{(3)(4)|5} = r_{3|4} + s_5^2$. From these equations we now find

$$\begin{pmatrix} 1 & 1 & 1 & 1 & 1 \\ 0 & 0 & 1 & 1 & 1 \\ 1 & 0 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 & 1 \end{pmatrix} \begin{pmatrix} r_5^1 \\ r_5^2 \\ r_5^3 \\ r_5^4 \\ r_5^5 \end{pmatrix} = \begin{pmatrix} r_5 \\ r_{234|5} - r_{234} \\ r_{1|234|5} - r_{1|234} \\ r_{4|5} - r_4 \\ r_{34|5} - r_{34} \end{pmatrix},$$

which, upon solution, results in

$$\begin{aligned} r_5^1 &= r_{1|234|5} - r_{1|234} - r_{234|5} + r_{234}, \\ r_5^2 &= r_5 - r_{1|234|5} + r_{1|234}, \\ r_5^3 &= r_{234|5} - r_{234} - r_{34|5} + r_{34}, \\ r_5^4 &= r_{34|5} - r_{34} - r_{4|5} + r_4, \\ r_5^5 &= r_{4|5} - r_4. \end{aligned}$$

5. Conclusions. In this paper, we have analyzed in detail the structure of some recently introduced generalizations of the singular value and the QR decomposition. The structure is completely determined in terms of the ranks of the involved matrices

and other matrices that are formed from products and concatenations of these matrices. Some more examples and details can be found in the technical report [6] and the papers [2]–[5], and [7].

STRONG HALL MATRICES*

RICHARD A. BRUALDI† AND BRYAN L. SHADER‡

Abstract. The authors develop an inductive structure for nonsquare strong Hall matrices that is quite analogous to the well-known inductive structure of square strong Hall (i.e., fully indecomposable) matrices. Other properties of strong Hall matrices are also discussed.

Key words. Hall matrices, trees, matchings, bipartite graphs

AMS subject classifications. 05B20, 05C50, 15A21

1. Introduction. Let M be an m by n matrix with $m \geq n$. Then M is a *Hall matrix* provided there does not exist a zero submatrix of M of size r by s with $r + s > m$. If in addition there does not exist a zero matrix with $1 \leq s \leq n - 1$ and $r + s = m$, then M is a *strong Hall matrix.* For example, each of the matrices

$$\begin{bmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ 1 & 0 & 1 \end{bmatrix}, \quad \begin{bmatrix} 1 & 1 \\ 1 & 1 \\ 0 & 0 \end{bmatrix}, \quad \text{and} \quad \begin{bmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{bmatrix}$$

is a strong Hall matrix. Replacing any 1 in the first matrix with a 0 gives a Hall matrix that is not a strong Hall matrix. A square strong Hall matrix is usually called a *fully indecomposable matrix.* Strong Hall matrices are important in sparse matrix analysis. For instance, in [4] an algorithm is given that correctly predicts the nonzero structure of the upper triangular factor R in the QR factorization of a strong Hall matrix. In [5] and [7], the nonzero structure of Q is correctly computed. Strong Hall matrices also arise in computing the fill in the Cholesky factorization [3].

Since whether or not a matrix is a Hall matrix or strong Hall matrix depends only on the locations of its 0's, we henceforth consider only (0,1)-matrices.

Let M be an m by n (0,1)-matrix with $m \geq n$. A *k-diagonal* of M is a collection of k ones of M with no two in the same row or column. An n-diagonal contains a unique one from each column of M and is also called a *column-diagonal.* A *cover* of M is a set of rows and columns of M that contain all the ones of M. A *minimum cover* of M is a cover of smallest cardinality. A *proper cover* is a cover with at least one row and at least one column. The next two lemmas follow from the well-known theorem of Hall(see, e.g., [2]) and the above definitions.

LEMMA 1.1. *Let M be an m by n $(0,1)$-matrix. Then the following are equivalent:*

(i) *M is a Hall matrix;*

(ii) *M has a column-diagonal;*

(iii) *Every cover of M has cardinality at least n;*

(iv) *For each k with $1 \leq k \leq n$, every set of k columns of M contain 1's in at least k different rows.*

If $n = 1$, then M is a strong Hall matrix if and only if M is a Hall matrix.

LEMMA 1.2. *Let M be an m by n $(0,1)$-matrix with $n \geq 2$. Then the following are equivalent:*

(i) *M is a strong Hall matrix;*

(ii) *Every $m-1$ by $n-1$ submatrix of M is a Hall matrix;*

(iii) *M is a Hall matrix and no minimum cover is proper;*

(iv) *For each k with $1 \leq k \leq n-1$, every set of k columns of M contain 1's in at least $k+1$ different rows.*[1]

An immediate consequence of (ii) in Lemma 1.2 is that every 1 of a strong Hall matrix belongs to at least one column-diagonal.

Let M be an m by n (0,1)-matrix with no zero rows. Then it follows from Lemmas 1.1 and 1.2 that if $m = n$, then M is a strong Hall matrix if and only if the cover consisting of all the rows and the cover consisting of all the columns are the only minimum covers of M, and if $m > n$, then M is a strong Hall matrix if and only if the cover consisting of all the columns is the only minimum cover of M. This implies that the direct sum of two strong Hall matrices neither of which has a zero row is a strong Hall matrix if and only if neither is a square matrix.

We now define the usual bipartite graph associated with a matrix. Let $M = [m_{ij}]$ be an m by n (0,1)-matrix. Let $G = G(M)$ be the bipartite graph with vertices $X = \{x_1, \ldots, x_m\}$ and $Y = \{y_1, \ldots, y_n\}$ and an edge joining x_i and y_j if and only if $m_{ij} = 1$ $(1 \leq i \leq m, 1 \leq j \leq n)$. We call the vertices in X the *row vertices* and the vertices in Y the *column vertices* of G. Note that there is a one-to-one correspondence between the k-diagonals of M and *matchings* of G with k edges. A *column-matching* of G is a matching with n edges and hence corresponds to a column-diagonal of M. If M is a Hall matrix, respectively, a strong Hall matrix, then we say that $G(M)$ is a *Hall graph*, respectively, *strong Hall graph*. Let S be a subset of the edges of G and let $\overline{S}$ denote the set of edges of G not in S. A path from a vertex v to a vertex w is an *S-alternating path* provided that the first, third, ... edges belong to S and the second, fourth, ... edges belong to $\overline{S}$. Thus if v is a row vertex and w is a column vertex (or the other way around) the last edge of an S-alternating path belongs to S. If both v and w are row vertices or both are column vertices, the last edge of an S-alternating path belongs to $\overline{S}$.

A square strong Hall matrix is also known as a *fully indecomposable matrix*. A square matrix M is fully indecomposable if and only if the graph $G(M)$ is elementary, where a bipartite graph is *elementary* provided it is connected and each edge is in a column matching. There is a well-known inductive structure for fully indecomposable matrices M (see, e.g., [2]). This inductive structure is equivalent to an *ear decomposition* of $G(M)$ as defined in [6]. Our main purpose is to develop an inductive structure for nonsquare strong Hall matrices M. This inductive structure could be derived from either the inductive structure of M or an ear decomposition of $G(M)$, but we have taken a more revealing approach using the concept of a strong Hall tree defined

[1] Because of (iv) in Lemma 1.2, our definition of a strong Hall matrix is equivalent to the original definition given in [3]. There is another definition of a strong Hall matrix that is used in the literature[4],[5],[7],[8]. It is that property (iv) holds for each k with $1 \leq k < m$. The only difference is that an m by n matrix with $m > n$, which has $m - n$ zero rows and is a strong Hall matrix by our definition, is not a strong Hall matrix by the other definition. All of the results in §§2 and 3 hold regardless of which definition is used.

in this paper. As an application, we strengthen and make more transparent some results of Gilbert [4] concerning S-alternating paths where S is a column-matching of a bipartite graph with the strong Hall property.[2]

In §2 we study strong Hall matrices whose graphs are trees and characterize them in three ways. In §3 we use strong Hall trees to obtain two charaterizations of strong Hall matrices. We also obtain an upper bound on the number of 1's in strong Hall matrices with n columns that are minimal in a sense to be made precise later. We assume that the reader is familiar with standard graph theory terminology.

2. Strong Hall trees. In this section we study strong Hall matrices whose associated bipartite graphs are trees, that is, strong Hall trees. Our first result gives a simple characterization of strong Hall trees. Recall that a *leaf* (*pendant vertex*) of a tree is a vertex that belongs to exactly one edge.

THEOREM 2.1. *Let M be an m by n $(0,1)$-matrix with $m+n \geq 3$, and assume that the bipartite graph $G(M)$ is a tree. Then $G(M)$ is a strong Hall graph if and only if no column vertex of $G(M)$ is a leaf.*

Proof. If some column vertex of $G(M)$ is a leaf, then M has a minimum cover that is proper, and hence by Lemma 1.2 $G(M)$ is not strong Hall. Now assume that $G(M)$ is not a strong Hall graph. It follows from Lemma 1.2 that after row and column permutations,

$$M = \begin{bmatrix} M_1 & O \\ M_2 & M_3 \end{bmatrix},$$

where M_3 is a square matrix of order $b \geq 1$. The bipartite graph $G(M_3)$ is an induced subgraph of $G(M)$ and hence has no cycles. Since $G(M_3)$ has $2b$ vertices, it has at most $2b-1$ edges and hence some column of M_3 and the corresponding column of M contains a unique 1. Therefore some column vertex of $G(M)$ is a leaf. □

Note that the theorem implies that if M is an m by n strong Hall matrix with $m+n \geq 3$ such that $G(M)$ is a tree, then $m > n$. Using Theorem 2.1 we now obtain an inductive structure for strong Hall trees. This inductive structure is a consequence of being able to carry out the algorithm described below.

ALGORITHM

Let M be an m by n $(0,1)$-matrix such that $G(M)$ is a tree.

(0) Set $i = 0$.

(1) Choose a path γ_0 joining two row vertices and let T_0 be the subgraph of $G(M)$ determined by γ_0.

(2) While there exists a row vertex not in T_i, do: Choose a path γ_{i+1} joining a row vertex not in T_i to a vertex in T_i, all of whose intermediate vertices are not in T_i, and let T_{i+1} be the graph obtained by adjoining γ_{i+1} to T_i. Replace i by $i+1$.

(3) Let $k = i$.

THEOREM 2.2. *Let M be an m by n strong Hall $(0,1)$-matrix with $m+n \geq 3$ and assume that $G(M)$ is a tree. Then each of the trees $T_0, T_1, \ldots, T_k$ constructed in the above algorithm is a strong Hall tree and $T_k = G(M)$.*

Proof. Since $m+n \geq 3$, there is a path γ_0 joining two row vertices. It follows inductively that each T_i is a tree in which no column vertex is a leaf and hence by

[2] This was our original motivation for considering strong Hall matrices.

Theorem 2.1 each is a strong Hall tree. Suppose that $T_k \neq G(M)$. Then there exists at least one vertex y of $G(M)$ that is not a vertex of T_k and all such vertices are column vertices. Since $G(M)$ is a tree, this implies that y is a leaf, contradicting Theorem 2.1. □

COROLLARY 2.3. *Let M be an m by n strong Hall $(0,1)$-matrix such that $G(M)$ is a tree. Let γ_0 be any path from a row vertex v to a row vertex w. Then there exists a column matching F such that γ_0 is an F-alternating path.*

Proof. We refer to the above algorithm. Let F be the set of edges consisting of the first, third, ... edges of the paths γ_i of even length and the second, fourth, ... edges of the paths γ_i of odd length. The result now follows by induction. □

We now obtain two more characterizations of strong Hall trees.

THEOREM 2.4. *Let M be an m by n $(0,1)$-matrix with $m+n \geq 3$ and assume that $G(M)$ is a tree. Then the following are equivalent:*

(i) *M is a strong Hall matrix;*

(ii) *Given any two distinct vertices v and w there exist column-matchings F_1 and F_2 such that the path from v to w in $G(M)$ is F_1-alternating and $\overline{F}_2$-alternating.*

(iii) *Every edge of $G(M)$ is in a column-matching.*

Proof. We first suppose that (i) holds and prove (ii). Let v and w be distinct row vertices. By Corollary 2.3 F_1 exists, and by interchanging the roles of v and w we see that F_2 also exists. By Theorem 2.1, no column vertex of $G(M)$ is a leaf and this implies that each path of $G(M)$ is a subpath of a path joining two row vertices. Hence (ii) holds. Clearly (ii) implies (iii). We now suppose that (iii) holds and prove that M is a strong Hall matrix. Let O be an r by s zero submatrix of M. Since $G(M)$ is connected, the submatrix complementary to O contains a 1. By (iii) the $m-1$ by $n-1$ matrix obtained from M by deleting the row and column of this 1 is a Hall matrix. By Lemma 1.1, $r+s \leq m-1$, and hence by Lemma 1.2, M is a strong Hall matrix. □

We conclude this section with the following observation about extremal strong Hall trees. The identity matrix of order k is denoted by I_k.

THEOREM 2.5. *Let M be an m by n strong Hall $(0,1)$-matrix with $n \geq 3$. Assume that $G(M)$ is a tree and that each matrix obtained from M by deleting a row is not a strong Hall matrix. Then $m \leq 2n-2$ with equality if and only if there exist permutation matrices P and Q so that*

$$PMQ = \left[\begin{array}{c|c} & 1 \\ I_{n-1} & \vdots \\ & 1 \\ \hline & 0 \\ I_{n-1} & \vdots \\ & 0 \end{array}\right]. \tag{1}$$

Proof. By Theorem 2.1 no column vertex of $G(M)$ is a leaf. A simple calculation shows that the number k of row vertices of $G(M)$ that are leaves satisfies $k \geq m-n+1$. Let x be a row vertex that is a leaf and let y be the unique column vertex adjacent to x. If the degree of y is greater than 2, then it follows from Theorem 2.1 that the matrix obtained from M by deleting the row corresponding to x is a a strong Hall matrix. Since $n \geq 2$, we conclude that the degree of y equals 2 and no column vertex

is adjacent to two leaves and hence $k \leq n$. Therefore $m \leq 2n-1$. Suppose that $m = 2n-1$. Then $k = n$ and the degree of each column vertex equals 2, implying that the number of edges of $G(M)$ equals $2n$. Since the number of edges of $G(M)$ also equals $3n-2$, we contradict our assumption that $n \geq 3$. Hence $m \leq 2n-2$. Assume that $m = 2n-2$. Then $k = n-1$ and the column sums of M are $2, \ldots, 2, n-1$. The column vertex with degree equal to $n-1$ is adjacent to the $n-1$ row vertices that are not leaves, and it is easy to see that there exist permutation matrices P and Q such that (1) holds. Since the matrix in (1) satisfies the assumptions in the theorem when $n \geq 3$, the theorem now follows. □

3. Strong Hall matrices with connected graphs. Let M be an m by n strong Hall (0,1)-matrix with $m > n$. We show that if the graph $G(M)$ is connected, then $G(M)$ has a strong Hall spanning tree and this enables us to apply many of the results of the previous section. We first review a special form for strong Hall matrices given in [1] and [2; Exer. 1, p. 117] (although not called strong Hall matrices in these references).

By Lemma 1.2, M has a column diagonal and after row and column permutations, we may assume that M has the form

$$\begin{bmatrix} B_2' & * \\ F_2' & B_1 \\ O & F_1 \end{bmatrix},$$

where B_1 and B_2' are square matrices and have only 1's on their main diagonals, and where F_1 is a nonvacuous matrix with at least one 1 in each column. By Lemma 1.2, M has no minimum cover, which is proper and hence the matrix F_2', if not vacuous, contains at least one 1. Hence we may further permute the rows and columns of M so that M has the form

$$\begin{bmatrix} B_3' & * & * \\ F_3' & B_2 & * \\ O & F_2 & B_1 \\ O & O & F_1 \end{bmatrix},$$

where B_2 and B_3' are square matrices and have only 1's on their main diagonals, and where F_2 is a nonvacuous matrix with at least one 1 in each column. If the matrix F_3' is not vacuous, then it contains at least one 1. We may continue like this and eventually obtain, after row and column permutations, a matrix of the form

$$\begin{bmatrix} B_k & * & * & \cdots & * & * \\ F_k & B_{k-1} & * & \cdots & * & * \\ O & F_{k-1} & B_{k-2} & \cdots & * & * \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ O & O & O & \cdots & B_2 & * \\ O & O & O & \cdots & F_2 & B_1 \\ O & O & O & \cdots & O & F_1 \end{bmatrix}, \tag{2}$$

where k is a positive integer, the square matrices $B_1, B_2, \ldots, B_k$ have only 1's on their main diagonals, and the matrices $F_1, F_2, \ldots, F_k$ are nonvacuous matrices with at least one 1 in each column. Conversely, a matrix of the form (2) satisfying these

conditions is a strong Hall matrix. This implies that any matrix M' obtained from M by replacing all the off-diagonal 1's of each B_i with 0's, all but exactly one 1 in each column of each F_i with 0's, and all submatrices marked with a $*$ with zero matrices is a strong Hall matrix. Such a matrix M' has exactly two 1's in each column.

An almost immediate corollary of the form (2) is the following theorem in [5,Thm. 3.1].

COROLLARY 3.1. *Let M be an m by n strong Hall $(0,1)$-matrix with $m > n$. Let k be an integer with $1 \leq p \leq n$ and assume that column p of M contains at least three 1's. Then for all but at most one 1 in column p of M, the matrix obtained from M by replacing the 1 with 0 is a strong Hall matrix.*

Proof. Without loss of generality we assume that M has the form (2). Let M' be any matrix as defined above. Then M' is a strong Hall matrix and hence all but at most two 1's in column p of M have the property stated in the corollary. Consider a 1 in column p of M that is not a 1 of M'. By Lemma 1.2, this 1 belongs to some column diagonal of M. Taking the form (2) with respect to this column diagonal we now see that at most one 1 in column p does not have the property stated in the corollary. □

THEOREM 3.2. *Let M be an m by n strong Hall $(0,1)$-matrix with $m > n$ and assume that the graph $G(M)$ is connected. Then there exists a $(0,1)$-matrix M^* obtained from M by replacing certain 1's by 0's such that M^* is a strong Hall matrix and the graph $G(M^*)$ is a tree.*

Proof. We may assume that M has the form (2), and we let M' be a matrix as defined above. Then M' is a strong Hall matrix and the graph $G(M')$ is a spanning forest of $G(M)$. Since $G(M)$ is connected, it is possible to replace certain 0's of M' by 1's so that the bipartite graph of the resulting matrix M^* is a spanning tree of $G(M)$. Since M' is a strong Hall matrix, so is M^*. □

Theorems 2.2 and 3.2 provide an inductive structure for any nonsquare strong Hall matrix with a connected graph that is quite analogous to that of a square strong Hall (i.e., fully indecomposable) matrix. The role of cycles in the square case is played by paths in the nonsquare case.

Theorems 2.4 and 3.2 immediately imply the following result.

COROLLARY 3.3. *Let M be an m by n strong Hall $(0,1)$-matrix with $m > n$ and assume that $G(M)$ is connected. Then given any two distinct vertices v and w there exist column matchings F' and F'' and a path from v to w in $G(M)$ that is both F'-alternating and $\overline{F''}$-alternating.*

We now obtain two new characterizations of strong Hall matrices whose graphs are connected. The fact that (ii) below is a property of such matrices is equivalent to Lemma 2.5 in [4].

THEOREM 3.4. *Let M be an m by n $(0,1)$-matrix with $m \geq n$ and assume that $G(M)$ is connected. Then the following are equivalent:*

(i) *M is a strong Hall matrix;*

(ii) *Given any column vertex v and row vertex w there exists a column matching F and a path γ from v to w in $G(M)$ that is F-alternating.*

(iii) *Every edge of $G(M)$ is in a column-matching.*

Proof. We first assume that (i) holds and prove that (ii) holds. If $m > n$, then (ii) follows from Corollary 3.3. Now assume that $m = n$. Let M' be the $n+1$ by n matrix obtained from M by appending a new row whose only nonzero entry is a 1 in the column corresponding to v. Then M' is a strong Hall matrix and the graph $G(M')$ is the connected graph obtained from $G(M)$ by adjoining a new row vertex

u and a new edge joining u and v. By Corollary 3.3 there is column-matching F of $G(M')$ and an F-alternating path γ in $G(M')$ from v to w. Since the first edge of γ belongs to F, F is a column-matching of $G(M)$. Since u is a leaf of $G(M')$, γ is a path of $G(M)$. Thus (ii) holds.

We now assume that (ii) holds and show that (iii) also holds. Let α be an edge joining a column vertex v to a row vertex w. Let γ and F be as guaranteed by (ii). If α is the only edge of γ, then α is in F. Otherwise, γ and α form a cycle, and by interchanging matching and nonmatching edges on this cycle, we obtain a column-matching containing α. Hence (iii) holds.

Just as in the proof of Theorem 2.4, (iii) implies (ii). □

The implication (i) implies that (ii) in Theorem 3.4 is equivalent to Lemma 2.5 in [4]. The fact that (i) and (iii) are equivalent has also been noted by Gilbert (private communication).

We conclude with the following result.

THEOREM 3.5. *Let M be an m by n strong Hall matrix with $n \geq 3$. Then there exists an m' by n strong Hall submatrix M' of M with $m' \leq 2n$. If $G(M)$ is connected, then M' can be chosen so that $G(M')$ is connected and $m' \leq 2n - 2$.*

Proof. The first assertion is trivial if m does not exceed $2n$. We may assume that M has the special form (2), where B_1 has order $p \leq n$. There exists a submatrix F_1' of F_1 of order p that has at least one 1 in each of its columns. The matrix obtained from M by deleting the $m - n - p$ rows that intersect F_1, but not F_1', is a strong Hall matrix with $n + p \leq 2n$ rows. The second conclusion of the theorem follows from Theorems 2.5 and 3.2. □

Direct sums of matrices, each of which equals the 2 by 1 matrix of all 1's, show that the first inequality in Theorem 3.5 is best possible.

Acknowledgment. It is a pleasure to thank John Gilbert for a stimulating lecture at the IMA on strong Hall matrices and for helpful comments.

COMPUTING THE PSVD OF TWO 2×2 TRIANGULAR MATRICES*

GARY E. ADAMS†, ADAM W. BOJANCZYK†, AND FRANKLIN T. LUK‡

Abstract. In this paper, the authors propose a method for computing the singular value decomposition (SVD) of a product of two 2×2 triangular matrices. The method shown is numerically desirable in that all relevant residual elements will be numerically small.

Key words. singular value decomposition, Jacobi methods

AMS subject classifications. 65F15, 15A18, 15A23

1. Introduction.

The problem of computing the SVD of a product of two matrices has many applications; see, e.g., [4] and [5]. The problem is also closely related to finding a generalized SVD of two matrices (cf. [6]). A crucial step in either the product SVD (PSVD) or the generalized SVD (GSVD) problem is the accurate computation of the PSVD of two 2×2 triangular matrices.

We wish to achieve two objectives: first, to ensure that the transformations applied to the triangular matrices must leave the matrices triangular and, second, to ensure that the SVD of the product is computed accurately. As discussed in a recent paper by Bai and Demmel [1], these two properties are essential to guarantee the stability of the GSVD method [6]. Several strategies have been proposed to preserve these two properties. In [1], examples are presented where these strategies can fail and a new method that overcomes the exposed drawbacks is then proposed.

In this paper we propose an alternative approach. Our new method, which we will call a *half-recursive* method, is a slight variation of the *fully recursive* method proposed in [2] for computing the SVD of a product of several matrices. An alternative method for the SVD of several matrices appears in [7]. We show that our algorithm is *simpler* to implement and enjoys the same nice numerical properties as the method in [1].

Our paper is organized as follows. In §2 we describe the PSVD of two 2×2 upper triangular matrices. A criterion for numerical stability is given in §3. We present our new algorithm in §4, and an error analysis in §5. Finally, some detailed proofs can be found in Appendices A and B and a numerical example in Appendix C.

2. Problem definition.

Given two upper triangular matrices:

$$A_1 = \begin{pmatrix} a_1 & b_1 \\ 0 & d_1 \end{pmatrix} \cdot \text{ and } \quad A_2 = \begin{pmatrix} a_2 & b_2 \\ 0 & d_2 \end{pmatrix},$$

we call the product A

$$A = A_1 A_2 \ ,$$

and let

$$A = \begin{pmatrix} a & b \\ 0 & d \end{pmatrix} .$$

Our objective is to find three orthogonal matrices Q_1, Q_2, Q_3, such that

$$A' = Q_1 A Q_3^T = \begin{pmatrix} a' & 0 \\ 0 & d' \end{pmatrix} \tag{2.1}$$

and

$$A'_i = Q_i A_i Q_{i+1}^T = \begin{pmatrix} a'_i & b'_i \\ 0 & d'_i \end{pmatrix} , \tag{2.2}$$

for $i = 1, 2$. Equations (2.1) and (2.2) imply that

$$A' = A'_1 A'_2 .$$

In other words, we would like to find *three* transformations Q_1, Q_2, and Q_3 to zero out *four* elements, namely, the off-diagonal elements of A and the subdiagonal elements of A_1 and A_2. The extra requirement, although mathematically feasible, may cause numerical difficulty if not treated with care; see examples in [1] and [2]. Our goal is to develop an algorithm so that properties (2.1) and (2.2) will be satisfied except for very small numerical errors. In this paper, we use the vector and matrix 2-norms

$$\| \cdot \| = \| \cdot \|_2 .$$

2.1. Relationship with GSVD. The basic step in a GSVD of two 2×2 triangular matrices A_1 and A_2 is to compute the SVD of the product $A_1 \cdot \mathrm{adj}(A_2)$, where adj denotes the adjoint of a matrix. We have

$$\mathrm{adj}(A_2) = \begin{pmatrix} d_2 & -b_2 \\ 0 & a_2 \end{pmatrix} .$$

It is therefore obvious that our two-by-two PSVD method can also be applied to the two-by-two GSVD problem.

3. Criterion for numerical stability. For the purpose of this analysis, an overbar ($\bar{}$) denotes a computed quantity that is perturbed as the result of inexact arithmetic. We assume that exact arithmetic may be performed using these perturbed values. The tilde symbol ($\tilde{}$) is used to denote conceptual values computed exactly from perturbed data. For example, let $\tilde{A}$ be the exactly computed A using quantities $\bar{A}_1$ and $\bar{A}_2$. Let $\bar{Q}_1$, $\bar{Q}_2$, and $\bar{Q}_3$ be transformations computed with floating point arithmetic. Recall that A'_1, A'_2, and A' denote the three matrices A_1, A_2, and A, respectively, after the equivalence transformations as defined in (2.1) and (2.2) have been performed. Define

$$\tilde{A}' := \bar{Q}_1 \bar{A} \bar{Q}_3^T = \begin{pmatrix} \tilde{a}' & \tilde{b}' \\ \tilde{e}' & \tilde{d}' \end{pmatrix} \tag{3.1}$$

and

$$\tilde{A}'_i := \bar{Q}_i A_i \bar{Q}_{i+1}^T = \begin{pmatrix} \tilde{a}'_i & \tilde{b}'_i \\ \tilde{e}'_i & \tilde{d}'_i \end{pmatrix} . \tag{3.2}$$

Let ϵ denote the relative machine precision. The best that we can aim for is to compute $\bar{A}_i'$, such that

$$\| \tilde{A}_i' - A_i' \| = O(\epsilon \ \| A_i \|) . \tag{3.3}$$

The relation (3.3) implies that the (2,1) element $\tilde{e}_i'$ of $\tilde{A}_i'$ will satisfy

$$| \tilde{e}_i' | = O(\epsilon \ \| A_i \|) , \tag{3.4}$$

for $i = 1, 2$. Condition (3.4) implies that e_i' may be safely truncated to zero. Thus, $\tilde{e}'$ is also forced to zero.

We prove in §5 that by using our new method, the computed matrices $\tilde{A}_1'$ and $\tilde{A}_2'$ will satisfy condition (3.4) and $\tilde{A}'$ will satisfy the conditions that

$$|\tilde{b}'| = O(\epsilon \ \| \bar{A} \|) \tag{3.5}$$

and

$$|\tilde{e}'| = O(\epsilon \ \| \bar{A} \|) . \tag{3.6}$$

The conditions proposed in [1] for computing the GSVD of two matrices, A_1 and $\mathrm{adj}(A_2)$, follow from (3.4), (3.5), (3.6), and the similar construction of the two algorithms.

4. New algorithm. In this section, we propose a new algorithm for the PSVD problem. Our algorithm is a modification of the algorithm presented in [2] for a product of several matrices. The tool we use is a transformation discussed in Charlier, Vanbegin, and Van Dooren [3]:

$$Q = \begin{pmatrix} s & c \\ -c & s \end{pmatrix} , \tag{4.1}$$

where $c^2 + s^2 = 1$. We may regard the transformation as a permuted reflection

$$Q = \begin{pmatrix} c & s \\ s & -c \end{pmatrix} \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} .$$

The reason behind using permuted reflections is that we actually deal with an $n \times n$ problem. The permutation that is incorporated into Q corresponds to the so-called odd-even order of eliminations in one sweep of a Jacobi SVD procedure.

While each transformation Q_i is defined by the cosine-sine pair

$$c_i = \cos\theta_i \quad \text{and} \quad s_i = \sin\theta_i ,$$

we also associate Q_i with the tangent

$$t_i = \tan\theta_i .$$

Given t_i, we can easily recover c_i and s_i using the relations

$$c_i = \frac{1}{\sqrt{1 + t_i^2}} \quad \text{and} \quad s_i = t_i c_i . \tag{4.2}$$

Following the exposition in [2], we consider the result of applying the left and right transformations Q_l and Q_r to a 2 × 2 upper triangular matrix A:

$$A' = Q_l A Q_r^T = \begin{pmatrix} a' & b' \\ e' & d' \end{pmatrix} = \begin{pmatrix} s_l & c_l \\ -c_l & s_l \end{pmatrix} \begin{pmatrix} a & b \\ 0 & d \end{pmatrix} \begin{pmatrix} s_r & c_r \\ -c_r & s_r \end{pmatrix}^T . \tag{4.3}$$

We can derive from (4.3) these four relations:

$$e' = c_l c_r(-at_r + dt_l - b) , \tag{4.4}$$

$$b' = c_l c_r(-at_l + dt_r + bt_l t_r) , \tag{4.5}$$

$$a' = c_l c_r(bt_l + d + at_l t_r) , \tag{4.6}$$

$$d' = c_l c_r(a - bt_r + dt_l t_r) , \tag{4.7}$$

where $t_l = \tan\theta_l$ and $t_r = \tan\theta_r$. The postulates that both e' and b' be zeros define two conditions on t_l and t_r, so that (4.3) represents an SVD of A. The postulate that e' be zero defines a condition relating θ_l to θ_r, so that if one is known the other can be computed to reduce A' to an upper triangular form. For ease of exposition, assume for now that $abd \neq 0$. This condition will be removed in §5.2. It implies that $c_l c_r \neq 0$, and so the postulate that $e' = 0$ in (4.4) becomes

$$-at_r + dt_l - b = 0 . \tag{4.8}$$

The consequence of (4.8) is that (4.6) and (4.7) simplify to

$$a' = c_l c_r(t_l^2 + 1)d \tag{4.9}$$

and

$$d' = c_l c_r(t_r^2 + 1)a , \tag{4.10}$$

respectively. The relations (4.9) and (4.10) imply that

$$a'd' = ad .$$

For the SVD problem, both e' and b' are zeros, and we can use (4.8) to reduce (4.5) either to an equation in t_l:

$$b' = c_l c_r\left(\frac{bd}{a}\right)\left(t_l^2 + 2t_l\sigma_l - 1\right) , \tag{4.11}$$

where

$$\sigma_l = \frac{1}{2d}\left(\frac{d^2 - a^2}{b} - b\right)$$

or to an equation in t_r:

$$b' = c_l c_r\left(\frac{ab}{d}\right)\left(t_r^2 + 2t_r\sigma_r - 1\right) , \tag{4.12}$$

where

$$\sigma_r = \frac{1}{2a}\left(\frac{d^2 - a^2}{b} + b\right).$$

From (4.11) we get a quadratic equation by setting b' to zero:

$$t_l^2 + 2\sigma_l t_l - 1 = 0 \tag{4.13}$$

and from (4.12) we get

$$t_r^2 + 2\sigma_r t_r - 1 = 0\,. \tag{4.14}$$

Equations (4.13) and (4.14) are solved by the formulas given in [2]:

$$r = \frac{(d-a)(d+a)}{b}\,, \tag{4.15}$$

$$\sigma_l = \frac{r-b}{2d}\,, \tag{4.16}$$

$$\sigma_r = \frac{r+b}{2a}\,, \tag{4.17}$$

$$t_l = \frac{1}{\sigma_l + \operatorname{sign}(\sigma_l)\sqrt{\sigma_l^2 + 1}}\,, \tag{4.18}$$

$$t_r = \frac{1}{\sigma_r + \operatorname{sign}(\sigma_r)\sqrt{\sigma_r^2 + 1}}\,. \tag{4.19}$$

In finite-precision arithmetic, either one of t_l and t_r can be computed with a higher relative precision. In particular, if

$$\operatorname{sign}(r) = -\operatorname{sign}(b)\,,$$

then (4.18) will produce a very accurate t_l; whereas if

$$\operatorname{sign}(r) = \operatorname{sign}(b)\,,$$

then (4.19) will produce a very precise t_r. If $r = 0$, then both t_l and t_r will be computed with the same relative accuracy.

Now, let $r \neq 0$. We first present a lemma relating the sizes of t_l and t_r to those of a and d.

LEMMA 4.1. *Let abdr* $\neq 0$. *If* $|\, a \,| > |\, d \,|$, *then* $|\, \sigma_l \,| > |\, \sigma_r \,|$ *and* $|\, t_l \,| < |\, t_r \,|$. *Conversely, if* $|\, a \,| < |\, d \,|$, *then* $|\, \sigma_l \,| < |\, \sigma_r \,|$ *and* $|\, t_l \,| > |\, t_r \,|$.

Proof. See [2]. □

We are ready to present an algorithm for computing the three orthogonal matrices Q_1, Q_2, and Q_3, such that (2.1) and (2.2) are satisfied. The algorithm proceeds in two stages. In the first stage, we calculate the product A explicitly:

$$a = a_1 a_2\,, \tag{4.20}$$

$$b = a_1 b_2 + b_1 d_2 \,, \tag{4.21}$$

$$d = d_1 d_2 \,. \tag{4.22}$$

We use (4.15) to calculate r, and then we compute either σ_l or σ_r so that the corresponding tangent defines the smaller angular rotation. Hence we obtain either t_1 or t_3. In the second stage, we use the relation (4.8) with t_1 or t_3 as the reference tangent to compute the remaining transformations. Suppose that t_1 is known, then t_2 and t_3 are generated by the forward substitutions

$$t_2 = \frac{d_1 t_1 - b_1}{a_1} \,, \tag{4.23}$$

$$t_3 = \frac{d t_1 - b}{a} \,. \tag{4.24}$$

On the other hand, if t_3 is known, then t_2 and t_1 are generated by the backward substitutions

$$t_2 = \frac{a_2 t_3 + b_2}{d_2} \,, \tag{4.25}$$

$$t_1 = \frac{a t_3 + b}{d} \,. \tag{4.26}$$

If t_1 is computed first as the reference tangent, then (4.23) will guarantee that A_1' will be numerically upper triangular and (4.24) will guarantee that A' will be numerically diagonal. As will be shown later, these two properties will guarantee that A_2' will be numerically upper triangular and hence (3.4), (3.5), and (3.6) will be satisfied.

We refer to the method defined by (4.23)–(4.24) or (4.25)–(4.26) as *half recursive*, to differentiate it from the *fully recursive* method proposed in [2] for computing the PSVD of several matrices. The fully recursive method also picks the smaller outer angular rotation as the starting point for the recursion, from which all remaining rotations are computed. However in [2], the other outer rotation is computed from the previous rotation in the sequence. For example, in the case of a product of two matrices, the tangent t_3 in (4.24) would be computed from t_2 using (4.8):

$$t_3 = \frac{d_2 t_2 - b_2}{a_2} \,. \tag{4.27}$$

Note how (4.24) uses the product A whereas (4.27) uses the matrix A_2. It was shown in [1] that the fully recursive method may fail to satisfy (3.5) and (3.6) and thus is not recommended for the GSVD problem. On the other hand, the fully recursive method easily extends to any number of factors in the product. It is not clear what is an appropriate extension of the half-recursive method for the case of a product of more than two matrices.

Our half-recursive method is equivalent to the method proposed by Bai and Demmel in [1] in the sense that it also computes a very accurate PSVD of $A_1 A_2$, and that it uses essentially the same criterion in choosing whether to compute the middle transformation Q_2 from Q_1 or from Q_3. A proof that the two methods use the same condition for computing Q_2 is given in Appendix B.

5. Backward error analysis. In this section, we present a backward error analysis of our computation. The function $\mathrm{fl}(a)$ will be used to denote the floating point approximation of a. For example, instead of a, b, and d, we have the perturbed values $\bar{a}$, $\bar{b}$, and $\bar{d}$, which result from floating point computation, $\mathrm{fl}(\ A_1A_2)$. Recall that a tilde denotes a quantity computed exactly from perturbed data. For example, $\tilde{r}$ denotes the result of using formula (4.15) in exact arithmetic with the perturbed data $\bar{a}$, $\bar{b}$, and $\bar{d}$.

In our error analysis, we adopt a convention that involves a liberal use of Greek letters. For example, by α we mean a relative perturbation of an absolute magnitude not greater than ϵ, where ϵ denotes the machine precision. All terms of order ϵ^2 or higher will be ignored in this first-order analysis.

We start our procedure by computing elements of the product matrix A:

$$\bar{a} := \mathrm{fl}(a_1a_2) = a_1a_2(1+\alpha)\ , \tag{5.1}$$

$$\bar{d} := \mathrm{fl}(d_1d_2) = d_1d_2(1+\delta)\ , \tag{5.2}$$

$$\bar{b} := \mathrm{fl}(a_1b_2 + b_1d_2) = a_1b_2(1+2\beta_1) + b_1d_2(1+2\beta_2)\ , \tag{5.3}$$

where, according to our convention, the parameters α_1, δ_1, β_1, β_2, and β_3 are all quantities whose absolute values are bounded by ϵ. From (5.1)–(5.3) it follows that

$$\bar{A} = (A_1 + \delta A_1)(A_2 + \delta A_2)\ ,$$

with $\| \delta A_i \| \leq \epsilon \ \| A_i \|$. This property, which generally does not hold for a product of more than two 2×2 upper triangular matrices, will allow us to prove backward error type assertions on the half-recursive method.

Our analysis is divided into two parts. In §5.1, we consider a regular case where all elements of the computed matrix product are numerically significant with respect to the maximal-in-magnitude element; i.e.,

$$\min(|\ \bar{a}\ |\ ,\ |\ \bar{b}\ |\ ,\ |\ \bar{d}\ |\ ) > \epsilon\ \max(|\ \bar{a}\ |\ ,|\ \bar{b}\ |\ ,|\ \bar{d}\ |\ )\ . \tag{5.4}$$

In §5.2, we consider special cases where at least one element of the computed A is numerically insignificant.

5.1. Regular case. Without loss of generality, we assume that $rb < 0$; i.e., $\mathrm{sign}(r) = -\mathrm{sign}(b)$. Thus we compute t_1 first as the reference tangent from which t_2 and t_3 will be next determined via (4.23) and (4.24), respectively. We recall several lemmas from [2].

LEMMA 5.1. *Let $\tilde{t}_1$ and $\bar{t}_1$ be the exact and computed solutions, respectively, of* (4.18) *with data $\bar{a}, \bar{b}, \bar{d}$. Moreover, let $\tilde{c}_1, \tilde{s}_1$ and $\bar{c}_1, \bar{s}_1$ be the exact and computed cosines and sines using* (4.2) *with the tangent value $\bar{t}_1$. Then*

$$\bar{t}_1 = \tilde{t}_1(1 + 10\epsilon_1)\ , \tag{5.5}$$

$$\bar{c}_1 = \tilde{c}_1(1 + 3\mu_1)\ , \tag{5.6}$$

$$\bar{s}_1 = \tilde{s}_1(1 + 4\nu_1)\ , \tag{5.7}$$

where $|\epsilon_1| < \epsilon$, $|\mu_1| < \epsilon$, *and* $|\nu_1| < \epsilon$.

Proof. See [2]. □

In other words, Lemma 5.1 states that the procedure (4.15)–(4.19) for solving (4.13) is numerically stable in the forward sense. Two lemmas follow, leading to our main result of Theorem 5.5.

LEMMA 5.2. *The recurrences* (4.23) *and* (4.24) *yield* $\bar{t}_2$ *and* $\bar{t}_3$, *such that*

$$\tilde{a}_1\bar{t}_2 - \tilde{d}_1\bar{t}_1 + b_1 = 0\,, \tag{5.8}$$

$$\tilde{a}\bar{t}_3 - \tilde{d}\bar{t}_1 + \bar{b} = 0\,, \tag{5.9}$$

with

$$\tilde{a}_1 = a_1(1+2\psi_1)\,, \qquad \tilde{d}_1 = d_1(1+\phi_1)\,, \tag{5.10}$$

$$\tilde{a} = \bar{a}(1+2\psi)\,, \qquad \tilde{d} = \bar{d}(1+\phi). \tag{5.11}$$

Proof. The proof easily follows from (4.23) and (4.24). □

LEMMA 5.3. *The recurrence* (4.24) *yields* $\bar{t}_3$, *such that* $\bar{t}_3 = \tilde{t}_3(1+13\gamma)$.

Proof. From (4.24), it holds that

$$\begin{aligned}
\bar{t}_3 &= \left(\frac{\bar{d}\tilde{t}_1(1+11\psi) - \bar{b}}{\bar{a}}\right)(1+2\gamma_1) \\
&= \left(\frac{\bar{d}\tilde{t}_1 - \bar{b}}{\bar{a}} + \frac{11\psi\bar{d}\tilde{t}_1}{\bar{a}}\right)(1+2\gamma_1) \\
&= \left(\tilde{t}_3 + 11\psi\tilde{t}_3\frac{\bar{d}}{\bar{a}}\frac{\tilde{t}_1}{\tilde{t}_3}\right)(1+2\gamma_1)\,.
\end{aligned}$$

Since $|\bar{d}/\bar{a}| \le 1$ and $|\tilde{t}_1/\tilde{t}_3| \le 1$, we get $\bar{t}_3 = \tilde{t}_3(1+13\gamma)$. □

We now show that $\bar{a}'$ and $\bar{d}'$ are computed with high relative precision.

LEMMA 5.4. *Let* $\tilde{a}'$ *and* $\tilde{d}'$ *be the exact singular values of the computed product* $\bar{A}$. *If* $\tilde{a}'$ *and* $\tilde{d}'$ *are computed via relations* (4.6) *and* (4.7), *then the computed singular values* $\bar{a}'$ *and* $\bar{d}'$ *satisfy the following relations*:

$$\bar{a}' = \tilde{a}'(1+\alpha_4)\,, \qquad \bar{d}' = \tilde{d}'(1+\delta_4)\,. \tag{5.12}$$

Proof. From (4.9) and (4.10), we get

$$\tilde{a}' = \bar{d}(\tilde{t}_1^2+1)\hat{c}_1\hat{c}_3 \quad \text{and} \quad \tilde{d}' = \bar{a}(\tilde{t}_3^2+1)\hat{c}_1\hat{c}_3\,,$$

where $\tilde{t}_1$ and $\tilde{t}_3$ are the exact tangents corresponding to the data $\bar{a}$, $\bar{b}$, and $\bar{d}$, and $\tilde{t}_i = \hat{s}_i/\hat{c}_i$. Thus, the lemma follows from Lemmas 5.1 and 5.3. □

THEOREM 5.5. *Suppose that the computed tangent values are* $\bar{t}_1$ *and* $\bar{t}_3$. *Let* $\tilde{c}_1$, $\tilde{s}_1$, $\tilde{c}_3$, *and* $\tilde{s}_3$ *be the corresponding exact cosine and sine values. Let*

$$\tilde{e}' := \tilde{c}_1\tilde{c}_3[-\bar{a}\bar{t}_3 + \bar{d}\bar{t}_1 - \bar{b}]\,, \tag{5.13}$$

$$\tilde{b}' := \tilde{c}_1\tilde{c}_3[-\bar{a}\bar{t}_1 + \bar{d}\bar{t}_3 + \bar{b}\bar{t}_1\bar{t}_3]\,. \tag{5.14}$$

That is, $\tilde{e}'$ and $\tilde{b}'$ are the exact values of e' and b', respectively, corresponding to the computed data $\bar{a}$, $\bar{b}$, $\bar{d}$, $\bar{t}_1$, and $\bar{t}_3$. Then

$$| \tilde{e}' | \leq K_1 \epsilon \ \| \bar{A} \| \ , \tag{5.15}$$

$$| \tilde{b}' | \leq K_2 \epsilon \ \| \bar{A} \| \ , \tag{5.16}$$

where K_1 and K_2 are some positive constants.

Proof. See Appendix A. □

Lemma 5.4 and Theorem 5.5 together state that the SVD of the upper triangular matrix $\bar{A}$ is computed very accurately. We now justify why the (2,1) element in the computed matrix A_i' can be set to zero by showing that $| \tilde{e}_i' |$ corresponds to a relative and elementwise perturbation of A_i' of the order of ϵ. Let the cosine and sine pairs $\tilde{c}_i$ and $\tilde{s}_i$ satisfy $\bar{t}_i = \tilde{s}_i / \tilde{c}_i$ for $i = 1, 2, 3$. From (4.2) we can derive that

$$\bar{c}_i := \mathrm{fl}(\tilde{c}_i) = \tilde{c}_i(1 + 3\mu_i) \ , \tag{5.17}$$

$$\bar{s}_i := \mathrm{fl}(\tilde{s}_i) = \tilde{s}_i(1 + 4\nu_i) \ . \tag{5.18}$$

Let $\tilde{A}_i'$ denote the exact updated matrix derived from A_i, $\bar{c}_i$, $\bar{s}_i$, $\bar{c}_{i+1}$, and $\bar{s}_{i+1}$. Our next results provide a bound on the element $\tilde{e}_i'$, $i = 1, 2$, defined by the relation

$$\tilde{e}_i' := -\bar{c}_i \bar{s}_{i+1} a_i + \bar{s}_i \bar{c}_{i+1} d_i - \bar{c}_i \bar{c}_{i+1} b_i \ . \tag{5.19}$$

THEOREM 5.6. *The matrices $\tilde{A}_1'$ and $\tilde{A}_2'$ are almost upper triangular in that their* (2.1) *elements $\tilde{e}_1'$ and $\tilde{e}_1'$ satisfy the inequalities*

$$| \tilde{e}_1' | \ \leq 3 \ \epsilon \ \| A_1 \| \tag{5.20}$$

and

$$| \tilde{e}_2' | \ \leq K_3 \ \epsilon \ \| A_2 \| \ . \tag{5.21}$$

Proof. Note that $\tilde{A}_1'$ is the same for both fully recursive and half-recursive methods. The proof that $\tilde{A}_1'$ is almost upper triangular in the sense that (5.20) holds can be found in [2].

To prove the second part of the theorem from (5.8)–(5.11) and (5.1)–(5.3), we get the following two relations to first order of the machine precision:

$$a_1(1 + 2\psi_1)\bar{t}_2 - d_1(1 + \phi_1)\bar{t}_1 + b_1 = 0 \ , \tag{5.22}$$

$$\begin{aligned} a_1 a_2(1 + \alpha + 2\psi)\bar{t}_3 - d_1 d_2(1 + \delta + \phi)\bar{t}_1 + a_1 b_2(1 + 2\beta_1) \\ + b_1 d_2(1 + 2\beta_2) = 0 \ . \end{aligned} \tag{5.23}$$

By multiplying both sides of (5.22) by $d_2(1 + 2\beta_2)$ and subtracting from (5.23), we obtain

$$\begin{aligned} a_1 \Bigg\{ a_2(1 + \alpha + 2\psi)\bar{t}_3 - \left(\frac{d_1 d_2}{a_1} \right) \\ \times (\delta + \phi - \phi_1 + 2\beta_2)\bar{t}_1 + b_2(1 + 2\beta_1) - d_2(1 + 2\beta_2 + 2\psi_1)\bar{t}_2 \Bigg\} = 0 \ , \end{aligned}$$

or, since $a_1 \neq 0$,

$$a_2(1+\alpha+2\psi)\bar{t}_3 - \left(\frac{d_1 d_2}{a_1}\right)(\delta+\phi-\phi_1+2\beta_2)\bar{t}_1 + b_2(1+2\beta_1) - d_2(1+2\beta_2+2\psi_1)\bar{t}_2 = a_2\bar{t}_3 - d_2\bar{t}_2 + b_2 + \Delta = 0\,,$$

where

$$\Delta = a_2(\alpha+2\psi)\bar{t}_3 - \left(\frac{d}{a}\right)a_2(\delta+\phi-\phi_1+2\beta_2)\bar{t}_1 + b_2\beta_1 - d_2(2\beta_2+2\psi_1)\bar{t}_2\,.$$

Thus, we can rewrite (5.19) for $i = 2$ as

$$\tilde{e}_2' = -\bar{c}_2\bar{s}_3 a_2 + \bar{s}_2\bar{c}_3 d_2 - \bar{c}_2\bar{c}_3 b_2 + \tilde{c}_3\tilde{c}_2(a_2\bar{t}_3 - d_2\bar{t}_2 + b_2 + \Delta)\,. \tag{5.24}$$

Now, as we start the half-recursive method from t_1, it means that $|\bar{t}_1| \leq |\bar{t}_3|$ and $|\bar{d}| \leq |\bar{a}|$. Hence from (5.17), (5.18), and (5.24), we derive the inequality:

$$\begin{aligned}|\tilde{e}_2'| &\leq |\tilde{s}_3\tilde{c}_2 a_2(\alpha+2\psi)| + |\tilde{c}_3\tilde{c}_2 a_2(\delta+\phi-\phi_1+2\beta_2)| \\ &\quad + |\tilde{c}_3\tilde{c}_2 b_2\beta_2| + |\tilde{c}_3\tilde{s}_2 d_2(2\beta_2+2\psi_1)| \\ &\leq K_3\epsilon||A_2||\,,\end{aligned}$$

completing the proof. □

In summary, we have proved two results using backward error analysis. First, the transformed matrix $\bar{A}'$ is almost diagonal in that inequalities (5.15) and (5.16) both hold. Second, we can safely set each computed matrix $\bar{A}_i'$, $i = 1, 2$, to a triangular form because (5.20) and (5.21) are valid. As a final note, even though we have assumed that $rb < 0$, we can easily prove similar results for the case where $rb \geq 0$.

5.2. Special cases. In this subsection, we assume that inequality (5.4) is violated. To be specific, define

$$\gamma := \min\,(|\,\bar{a}\,|\,,\ |\,\bar{b}\,|\,,\ |\,\bar{d}\,|\,) \tag{5.25}$$

and

$$\Gamma := \max\,(|\,\bar{a}\,|\,,\ |\,\bar{b}\,|\,,\ |\,\bar{d}\,|\,)\,. \tag{5.26}$$

Now,

$$\gamma \leq \epsilon\,\Gamma\,; \tag{5.27}$$

i.e., one of the elements of $\bar{A}$ is numerically insignificant. This situation requires modifications to our algorithm, since the proposed formulas may break down. In particular, we do not solve a quadratic equation to determine either $\bar{t}_1$ or $\bar{t}_3$. Instead, we set one of the two tangents to zero and attempt to compute all the other tangents from the recurrences. We divide the special cases into three groups: first,

$$|\,\bar{a}\,| + |\,\bar{d}\,| \neq 0 \quad \text{and} \quad |\,\bar{b}\,| \neq 0\,; \tag{5.28}$$

second,

$$|\,\bar{a}\,| + |\,\bar{d}\,| = 0 \quad \text{and} \quad |\,\bar{b}\,| \neq 0\,; \tag{5.29}$$

and third,

$$|\bar{b}| = 0\,. \tag{5.30}$$

First, assume that (5.28) holds. Hence at least one, but not all, of the following three conditions hold:

$$\gamma = \bar{b}, \quad \gamma = \bar{a}, \quad \text{or} \quad \gamma = \bar{d}\,.$$

We set $\bar{t}_1$ to zero if

$$|\bar{a}| > |\bar{d}|\,, \tag{5.31}$$

and set $\bar{t}_3$ to zero if

$$|\bar{a}| \leq |\bar{d}|\,. \tag{5.32}$$

Thus, the sizes of the diagonal elements of $\bar{A}$ will be compared to determine which one of $\bar{t}_1$ or $\bar{t}_3$ should be zeroed. Without loss of generality, assume that (5.31) holds; hence, $\bar{t}_1$ becomes the reference angle. So, $\bar{t}_2$ and $\bar{t}_3$ are computed from recurrence (4.23) and (4.24). Furthermore, since $\bar{t}_1 = 0$, it follows that $\bar{t}_3 = -\bar{b}/\bar{a}$. Substituting these values into (5.22)–(5.25), we can verify that Theorem 5.5 holds. Similarly, Theorem 5.6 follows from (5.19). We note that it is very important to decide which reference angle to choose, even for the case when $\bar{b}$ is numerically zero. At first, the choice of the reference angle may seem arbitrary for a "small" $\bar{b}$, since either $\bar{t}_1$ or $\bar{t}_3$ can be set to zero. However, an unnecessarily large error may occur unless we pay special care.

Second, assume that (5.29) holds. Then, at least one of the a_i's equals zero and at least one of the d_j's also equals zero, for $i, j = 1, 2$. A solution is to permute either the rows or the columns to ensure that the transformed product is diagonal and that the data are reordered. Hence for this case, we may set the two extreme tangents $\{\bar{t}_1, \bar{t}_3\}$ to $\{0, \infty\}$, resulting in the transformations being rotations of negative ninety and zero degrees, respectively. To be specific, consider the case where one or more a_i's equal zero. If $a_1 = 0$, set $\bar{t}_1 = 0$ and $\bar{t}_2 = \bar{t}_3 = \infty$. If $a_1 \neq 0$ and $a_2 = 0$, set $\bar{t}_1 = 0$, compute $\bar{t}_2$ from the forward recurrence and set $\bar{t}_3 = \infty$. Note that we may also choose to determine the tangents using the values of the d_j's.

Third, assume that (5.30) holds. We need to account for the fact that we are really solving an $n \times n$ problem. Although the 2×2 subproblem is already numerically diagonal, it is not sufficient to set $\bar{t}_1 = \bar{t}_3 = \infty$, which will leave the 2×2 product unchanged. The $n \times n$ data need to be reordered, calling for $\bar{t}_1 = \bar{t}_3 = 0$, i.e., the affected rows and columns will be permuted. Unfortunately, while applying the symmetric permutation, the triangular structures of both $\bar{A}_1$ and $\bar{A}_2$ are destroyed. Therefore, $\bar{t}_2$ is determined from the recurrence.

6. Concluding remark. In this paper we have presented a simple and accurate way to calculate the PSVD or GSVD of two 2×2 upper triangular matrices. In Appendix C, we present an example that shows that our half-recursive method produces identical numerical results as the method in [1]. A significant issue in the design of PSVD algorithms is how to compute the middle transformation. The method used in our half-recursive algorithm is computationally more efficient than the method in [1] and yields identical results. The following table lists the number of floating point operations used to compute the three transformations, Q_1, Q_2, and Q_3, for the three

different algorithms in the regular case. The column labeled Simplified direct lists the operation count for the Bai and Demmel algorithm if our simplified method is substituted for their method of computing the middle transformation.

TABLE 1
Floating point operation counts.

	Direct	Simplified direct	Half-recursive
Addition	20	13	11
Multiplication	25	17	15
Division	13	11	8
Square root	4	4	4

The half-recursive method is less expensive than the direct method and similar in cost to the simplified direct algorithm. In addition, the upper-triangular structure of the 2×2 matrices is maintained by the half-recursive method. Application of the 2×2 half-recursive algorithm to $n \times n$ problems is a topic for further investigation.

Appendix A. Proof of Theorem 5.5. We first present a lemma.

LEMMA A.1. *Let $\tilde{\sigma}_1$ and $\tilde{t}_1$ be the exact values corresponding to the given data $\bar{a}$, $\bar{b}$, and $\bar{d}$, and let $\bar{t}_1$ be the computed value of $\tilde{t}_1$. Define a residual r_1 by*

$$r_1 := \frac{\bar{b}\bar{d}}{\bar{a}}(\bar{t}_1^2 + 2\tilde{\sigma}_1\bar{t}_1 - 1) . \tag{A.1}$$

Then

$$| r_1 | \leq K_4\epsilon|\bar{b}| , \tag{A.2}$$

where K_4 is a positive constant.

Proof. See the proof of Lemma 5.2 in [2]. □

We now have the necessary tools for proving Theorem 5.5.

Proof. First, from Lemma 5.2 and relation (5.9) we get

$$\tilde{e}' = \tilde{c}_1\tilde{c}_3[(-\bar{a}\bar{t}_3 + \bar{d}\bar{t}_1 - \bar{b}) + (\tilde{a}\bar{t}_3 - \tilde{d}\bar{t}_1 + \bar{b})] = (\tilde{a} - \bar{a})\tilde{c}_1\tilde{s}_3 - (\tilde{d} - \bar{d})\tilde{s}_1\tilde{c}_3 .$$

Using (5.1)–(5.2) and (5.11), we prove the inequality:

$$| \tilde{e}' | \leq K\epsilon (| a | + | d |) \leq K_1\epsilon \| \bar{A} \| . \tag{A.3}$$

Second, rewrite (A.1) as

$$r_1 = \frac{1}{\bar{a}}[\bar{d}\bar{b}\bar{t}_1^2 + \bar{t}_1(\bar{d}^2 - \bar{a}^2 - \bar{b}^2) - \bar{d}\bar{b}] = \frac{1}{\bar{a}}[(\bar{d}\bar{t}_1 - \bar{b})(\bar{b}\bar{t}_1 + \bar{d}) - \bar{t}_1\bar{a}^2] . \tag{A.4}$$

From (5.22)–(5.24), we obtain

$$\frac{1}{\bar{a}}(\bar{d}\bar{t}_1 - \bar{b}) = \bar{t}_3 + \frac{\tilde{e}'}{\tilde{c}_1\tilde{c}_3\bar{a}} . \tag{A.5}$$

Substituting (A.5) into (A.4) and rearranging terms, we get

$$-\bar{a}\bar{t}_1 + \bar{d}\bar{t}_3 + \bar{b}\bar{t}_1\bar{t}_3 = r_1 - \frac{\tilde{e}'(\bar{b}\bar{t}_1 + \bar{d})}{\tilde{c}_1\tilde{c}_3\bar{a}} ,$$

and so

$$\tilde{b}' = \tilde{c}_1\tilde{c}_3 r_1 - \frac{\tilde{e}'(\bar{b}\bar{t}_1 + \bar{d})}{\bar{a}} \,. \tag{A.6}$$

From (4.18), we derive

$$| \tilde{t}_1\tilde{\sigma}_1 | \leq \frac{1}{2} \,,$$

and from (4.16), we get

$$| \tilde{\sigma}_1 | = \left| \frac{\tilde{r} - \bar{b}}{2\bar{d}} \right| \geq \left| \frac{\bar{b}}{2\bar{d}} \right| .$$

It follows that

$$| \tilde{t}_1 | \leq \left| \frac{\bar{d}}{\bar{b}} \right| < \left| \frac{\bar{a}}{\bar{b}} \right| \,, \tag{A.7}$$

since we have assumed that $| \bar{d} | < | \bar{a} |$. Finally, recall from (5.3) that $\bar{t}_1 = \tilde{t}_1(1+10\epsilon_5)$, and use (A.6), Lemma A.1 and (A.5) to obtain

$$| \tilde{b}' | \leq \tilde{c}_1\tilde{c}_2 | r_1 | + 2 | \tilde{e}' | \leq K_2\epsilon \, \| \bar{A} \| \,, \tag{A.8}$$

thus completing the proof. □

Appendix B. How to compute the middle transformation. As pointed out by Bai and Demmel in [1], a critical issue concerns how the middle transformation should be computed. They proposed the following scheme for its computation after both end transformations have been determined. To relate the test for computing Q_2 in [1] to the test in the half-recursive method, we first translate our setting to that in [1]. Let

$$U^T \equiv \begin{pmatrix} c_1 & -s_1 \\ s_1 & c_1 \end{pmatrix}, \quad Q^T \equiv \begin{pmatrix} c_2 & -s_2 \\ s_2 & c_2 \end{pmatrix}, \quad \text{and} \quad V^T \equiv \begin{pmatrix} c_3 & -s_3 \\ s_3 & c_3 \end{pmatrix}.$$

Note that the relation, given by

$$Q_1 A_1 = \begin{pmatrix} s_1 & c_1 \\ -c_1 & s_1 \end{pmatrix} \begin{pmatrix} a_1 & b_1 \\ 0 & d_1 \end{pmatrix} = \begin{pmatrix} s_1 a_1 & s_1 b_1 + c_1 d_1 \\ -c_1 a_1 & -c_1 b_1 + s_1 d_1 \end{pmatrix} \tag{B.1}$$

upon permuting rows and changing the signs of the top row, is equivalent to

$$U^T A_1 = \begin{pmatrix} c_1 & -s_1 \\ s_1 & c_1 \end{pmatrix} \begin{pmatrix} a_1 & b_1 \\ 0 & d_1 \end{pmatrix} = \begin{pmatrix} c_1 a_1 & c_1 b_1 - s_1 d_1 \\ s_1 a_1 & s_1 b_1 + c_1 d_1 \end{pmatrix} \equiv G \,. \tag{B.2}$$

Similarly,

$$A_2 Q_3^T = \begin{pmatrix} a_2 & b_2 \\ 0 & d_2 \end{pmatrix} \begin{pmatrix} s_3 & -c_3 \\ c_3 & s_3 \end{pmatrix} = \begin{pmatrix} s_3 a_2 + c_3 b_2 & -c_3 a_2 + s_3 b_2 \\ c_3 d_2 & s_3 d_2 \end{pmatrix} \,. \tag{B.3}$$

By changing the sign of the second columns and permuting columns, we obtain

$$V^T \mathrm{adj}(A_2) = \begin{pmatrix} c_3 & -s_3 \\ s_3 & c_3 \end{pmatrix} \begin{pmatrix} d_2 & -b_2 \\ 0 & a_2 \end{pmatrix} = \begin{pmatrix} c_3 d_2 & -c_3 b_2 - s_3 a_2 \\ s_3 d_2 & -s_3 b_2 + c_3 a_2 \end{pmatrix} \equiv H. \tag{B.4}$$

In [1], Bai and Demmel used (B.2) and (B.4) as a starting point for computing Q_2. Their argument is as follows. After postmultiplications of both (B.2) and (B.4) by Q_2, the (1,2) elements of G and H should become zeros. Now, one should compute Q_2 from the one product, either G or H, for which the computed element in the (1,2) position has a smaller error relative to the norm of the row in which it resides. The magnitude of that error can be only bounded and hence the test for the choice is based on the bounds of the errors. It is easy to see that the bound g for the relative error in the (1,2) element of the computed G is

$$g = \frac{|c_1 b_1| + |s_1 d_1|}{|c_1 a_1| + |c_1 b_1 - s_1 d_1|}, \tag{B.5}$$

while the bound h for the relative error in the (1,2) element of the computed H is

$$h = \frac{|c_3 b_2| + |s_3 a_2|}{|c_3 d_2| + |c_3 b_2 + s_3 a_2|}. \tag{B.6}$$

Now if $g \leq h$, then Bai and Demmel compute Q_2 from $U^T A$ and otherwise from $V^T B$. The next lemma shows that the conditions specifying how Q_2 is computed by Bai and Demmel and by the half-recursive method are essentially equivalent.

LEMMA B.1. *In exact arithmetic, the condition*

$$g \leq h \tag{B.7}$$

where g is defined by (B.5) *and h is defined by* (B.6) *is equivalent to the condition*

$$|a| \geq |d|. \tag{B.8}$$

Proof. First note that (B.5) and (B.6) can be simplified to

$$g = \frac{|b_1| + |t_1 d_1|}{|a_1| + |t_1 d_1 - b_1|} \tag{B.9}$$

and

$$h = \frac{|b_2| + |t_3 a_2|}{|d_2| + |t_3 a_2 + b_2|}, \tag{B.10}$$

respectively. Through (4.23) and (4.25), the relations (B.5) and (B.6) simplify further to

$$g = \frac{|b_1| + |t_1 d_1|}{|a_1|(1 + |t_2|)} \tag{B.11}$$

and

$$h = \frac{|b_2| + |t_3 a_2|}{|d_2|(1 + |t_2|)}, \tag{B.12}$$

respectively. Hence (B.7) is equivalent to

$$|b_1 d_2| + |t_1 d| \leq |a_1 b_2| + |a t_3| \,. \tag{B.13}$$

We now prove that (B.8) implies (B.7). The proof that $|a| < |d|$ implies that $g < h$ is analogous and is omitted. Our proof is elementary but tedious as it requires us to consider a large number of cases. Assume that $|a| \geq |b|$. Then Lemma 4.1 implies that $t_3 \geq t_1$. From (4.24) we see that

$$|a t_3 + b| = |d t_1| \,,$$

and as $|a t_3| \geq |a t_1|$, we conclude that

$$\operatorname{sign}(a t_3) = -\operatorname{sign}(b) = -\operatorname{sign}(a_1 b_2 + b_1 d_2) \,, \tag{B.14}$$

as from (4.21) $b = a_1 b_2 + b_1 d_2$. Substituting (4.24) into (B.13) and using (4.21) again, we get that (B.13) is equivalent to the following inequality:

$$|b_1 d_2| + |a t_3 + a_1 b_2 + b_1 d_2| \leq |a_1 b_2| + |a t_3| \,. \tag{B.15}$$

Case 1. $-|b| \geq |b_1 d_2| - |a_1 b_2|$. Then

$$|a t_3| \geq |d t_1| - |b| \geq |d t_1| + |b_1 d_2| - |a_1 b_2| \,,$$

establishing (B.13).

Case 2a. $-|b| > |b_1 d_2| - |a_1 b_2|$ and $|a t_3| > |b|$. Then $|a_1 b_2| > |b_1 d_2|$ and using (B.8) we obtain that

$$|b_1 d_2| + |d t_1| = |b_1 d_2| + |a t_3 + a_1 b_2 + b_1 d_2| = |a t_3| + 2\,|b_1 d_2| - |a_1 b_2| \,,$$

from which (B.13) follows.

Case 2b. $-|b| > |b_1 d_2| - |a_1 b_2|$ and $|a t_3| \leq |b|$. Then again $|a_1 b_2| > |b_1 d_2|$. Now from (B.14)

$$\begin{aligned} |b_1 d_2| + |d t_1| &= |b_1 d_2| + |a t_3 + a_1 b_2 + b_1 d_2| \\ &= |b_1 d_2| - |a t_3| + |a_1 b_2| - |b_1 d_2| = |a_1 b_2| - |a t_3| \,, \end{aligned}$$

from which (B.13) again follows. □

Remark. Note that there might be a slight difference in using (B.7) or (B.8) as the lemma holds only in exact arithmetic. In finite precision computation, the relations (B.7) and (B.8) may not always be equivalent. However, we have not been able to find any numerical example where these two conditions are not equivalent. Moreover, as shown in this paper, the consequences of numerical nonequivalence are numerically insignificant.

Appendix C. Numerical example. It has been proved in Appendix B that the half-recursive procedure computes essentially the same numerical results as the direct method of [1]. For both methods, the end transformations are computed explicitly from the product $A = A_1 A_2$, and the middle transformation is computed from the same direction. The greatest difference between the fully recursive method and the other two occurs when there is cancellation in forming the product $A = A_1 A_2$. In the

following PSVD example, A_1 and A_2 each has an $O(1)$ norm, but the product A_1A_2 has an $O(10^{-5})$ norm. Hence errors which are small relative to the initial matrices may be large relative to the product.

$$A_1 = \begin{pmatrix} 2.316797292247488e+00 & -1.437687878748196e-01 \\ 0 & -5.208536329107726e-06 \end{pmatrix},$$
$$A_2 = \begin{pmatrix} 2.472499811756353e-05 & 2.624474233535929e-01 \\ 0 & 4.229273187671001e+00 \end{pmatrix},$$
$$A_1A_2 = \begin{pmatrix} 5.728280868959543e-05 & -1.110223024625157e-16 \\ 0 & -2.202832304370565e-05 \end{pmatrix}.$$

The three methods all compute the left transformation from the explicit product and calculate the middle transformation from A_1. We use the subscripts dir, hr, and fr to distinguish between results computed via the direct, half-recursive, and fully recursive methods, respectively. The computed values of $A'_{1,\mathrm{dir}}$, $A'_{1,\mathrm{hr}}$, and $A'_{1,\mathrm{fr}}$ are *numerically identical* in that the corresponding entries are numerically equal:

$$\bar{A}'_{1,\mathrm{dir}} = \begin{pmatrix} 2.321253790030786e+00 & 2.775557561562891e-17 \\ 3.225930076892087e-07 & -5.198536633811768e-06 \end{pmatrix},$$
$$\bar{A}'_{1,\mathrm{hr}} = \begin{pmatrix} -5.198536633811768e-06 & -3.225930076892087e-07 \\ -2.775557561562891e-17 & 2.321253790030786e+00 \end{pmatrix},$$
$$\bar{A}'_{1,\mathrm{fr}} = \begin{pmatrix} -5.198536633811768e-06 & -3.225930076892087e-07 \\ -2.775557561562891e-17 & 2.321253790030786e+00 \end{pmatrix}.$$

The computed matrices $A'_{2,\mathrm{dir}}$, $A'_{2,\mathrm{hr}}$, and $A'_{2,\mathrm{fr}}$ are numerically triangular, but now the (1,2) element of $\bar{A}'_{2,\mathrm{fr}}$ is significantly different from the corresponding elements in $\bar{A}'_{1,\mathrm{dir}}$ and $\bar{A}'_{1,\mathrm{hr}}$:

$$\bar{A}'_{2,\mathrm{dir}} = \begin{pmatrix} 2.467752941777026e-05 & 5.551115123125783e-17 \\ 1.531353724707768e-06 & 4.237408446913959e+00 \end{pmatrix},$$
$$\bar{A}'_{2,\mathrm{hr}} = \begin{pmatrix} 4.237408446913959e+00 & -1.531353724707768e-06 \\ -5.551115123125783e-17 & 2.467752941777026e-05 \end{pmatrix},$$
$$\bar{A}'_{2,\mathrm{fr}} = \begin{pmatrix} 4.237408446913959e+00 & -1.531363626946 76e-06 \\ 0 & 2.467752941777026e-05 \end{pmatrix}.$$

To maintain triangularity, $\bar{A}'_1$ and $\bar{A}'_2$ are truncated by setting the appropriate elements to zero. Let A''_1 and A''_2 denote the truncated matrices. The product $\bar{A}'' = A''_1 \cdot A''_2$ should be diagonal:

$$\bar{A}''_{\mathrm{dir}} = \begin{pmatrix} 5.728280868959542e-05 & 0 \\ 1.615587133892632e-27 & -2.202832304370564e-05 \end{pmatrix},$$
$$\bar{A}''_{\mathrm{hr}} = \begin{pmatrix} -2.202832304370564e-05 & -1.615587133892632e-27 \\ 0 & 5.728280868959542e-05 \end{pmatrix},$$
$$\bar{A}''_{\mathrm{fr}} = \begin{pmatrix} -2.202832304370564e-05 & 5.010342801562901e-17 \\ 0 & 5.728280868959542e-05 \end{pmatrix}.$$

Clearly, $\bar{A}''_{\text{hr}}$ and $\bar{A}''_{\text{dir}}$ are numerically diagonal, but $\bar{A}''_{\text{fr}}$ fails the criterion of diagonality. Forcing $\bar{A}''_{\text{fr}}$ to be a diagonal matrix requires a truncation of $O(10^{-17})$, which is significant with respect to $\|\bar{A}''\|$. The matrices $\bar{A}''_{\text{dir}}$ and $\bar{A}''_{\text{hr}}$ require only insignificant truncations to obtain diagonality, but we have previously made $O(10^{-17})$ truncations during their computation to force $\bar{A}''_{2,\text{dir}}$ and $\bar{A}''_{2,\text{hr}}$ to triangular forms. Thus, equal amounts of absolute truncation errors have been committed by all three methods. The only difference is that the relative truncation error is largest for the fully recursive method.

It is interesting to note that if triangularity is not enforced and the factors $\bar{A}'_1$ and $\bar{A}'_2$ are multiplied, then none of the products can be considered diagonal. One may say that the numerical diagonality of $\bar{A}''_{\text{hr}}$ and $\bar{A}''_{\text{dir}}$ is a consequence of the truncation to triangular forms.

$$\bar{A}'_{1,\text{dir}} \cdot \bar{A}'_{2,\text{dir}} = \begin{pmatrix} 5.728280868959542e-05 & 2.464671807471544e-16 \\ 1.615587133892632e-27 & -2.202832304370564e-05 \end{pmatrix},$$

$$\bar{A}'_{1,\text{hr}} \cdot \bar{A}'_{2,\text{hr}} = \begin{pmatrix} -2.202832304370564e-05 & -1.615587133892632e-27 \\ -2.464671807471544e-16 & 5.728280868959542e-05 \end{pmatrix},$$

$$\bar{A}'_{1,\text{fr}} \cdot \bar{A}'_{2,\text{fr}} = \begin{pmatrix} -2.202832304370564e-05 & 5.010342801562901e-17 \\ -1.176117105626251e-16 & 5.728280868959542e-05 \end{pmatrix}.$$

In conclusion, our example shows that the half-recursive and direct methods produce numerically identical results, while the fully recursive method fails to meet the diagonality criterion.

NONLOCAL PERTURBATION ANALYSIS OF THE SCHUR SYSTEM OF A MATRIX*

M. M. KONSTANTINOV†, P. HR. PETKOV‡, AND N. D. CHRISTOV‡

Abstract. The sensitivity of the Schur system (the Schur basis and the Schur form) of a general matrix relative to perturbations, is studied. The estimates obtained are nonlocal and sharp. Asymptotic bounds (condition numbers particularly) in the form of power series are derived as a particular case.

Key words. Schur canonical form, perturbation analysis, conditioning of the Schur form

AMS subject classifications. Primary 15A21; Secondary 93B35, 65F15

1. Introduction. Basic notations. The Schur system of a matrix is a useful tool in many theoretical and computational problems (see, for example, [1]–[8]). Although much less sensitive to perturbations compared with Jordan and Frobenius systems, the Schur system nevertheless may be ill conditioned or even ill posed. Obtaining perturbation bounds for the Schur system is very important from both a theoretical and a practical point of view. In particular, the following problems, essential in numerical linear algebra and control theory, exploit the Schur form of a general matrix, and the solutions depend on the sensitivity of the corresponding Schur system.

(a) The computation of matrix exponential [6], [9], [10].

(b) The solution of Riccati equations by the Schur approach [2], [11].

(c) The pole assignment problem [12].

However, in contrast to other problems in linear algebra, the sensitivity of the Schur system of a matrix has not been studied to a sufficient extent. In particular, the sensitivity of invariant subspaces corresponding to clusters of equal or close eigenvalues have been examined [1]. At the same time, an invariant subspace is usually much less sensitive to perturbations compared with the corresponding basis. This phenomenon is especially important when studying the whole Schur system of an $n \times n$ matrix. Here the maximum invariant subspace is the basic n-dimensional space itself and is not sensitive at all, while the Schur basis may be infinitely sensitive.

In this paper we present a complete perturbation analysis of the whole Schur system without the assumption that the perturbations in the original matrix are asymptotically small. For small perturbations in the data, we give asymptotic bounds in the form of power series expansions.

We shall use the following notations:

$\mathbb{R}$ ($\mathbb{C}$), the set of real (complex) numbers;

$\mathbb{R}_+ = [0, \infty)$;

$\mathbb{C}^{m.n}$, the space of $m \times n$ complex matrices $\mathbf{A} = [a_{ij}]$ ($\mathbb{C}^{n.1} = \mathbb{C}^n$);

$\mathbf{A}^T$, the transpose of $\mathbf{A}$;

$\mathbf{A}^H = \bar{A}^T$, the complex conjugate transpose of $\mathbf{A}$;

$\mathbf{I}_n$, the unit $n \times n$ matrix;

$\mathbb{U}_n \subset \mathbb{C}^{n.n}$, the group of unitary matrices $\mathbf{U}$ ($\mathbf{U}^H\mathbf{U} = \mathbf{I}_n$);

$\mathbb{T}_n \subset \mathbb{C}^{n.n}$, the set of upper triangular matrices;

$\lambda_i(\mathbf{A})$, the eigenvalues of $\mathbf{A}$;

$\sigma_1(\mathbf{A}) \geq \cdots \geq \sigma_r(\mathbf{A}) > 0$, the singular values of $\mathbf{A}$;
$\|\mathbf{x}\|$, the Euclidean norm of $\mathbf{x} \in \mathbb{C}^n$;
$\|\mathbf{A}\|_2 = \sigma_1(\mathbf{A})$, the spectral norm of $\mathbf{A}$;
$\|\mathbf{A}\|_F = [\sigma_1^2(\mathbf{A}) + \cdots + \sigma_r^2(\mathbf{A})]^{1/2}$, the Frobenius norm of $\mathbf{A}$.
The set $\mathbb{C}^{m,n}$ is identified with $\mathbb{C}^{mn}$ as a linear space.
Each matrix $\mathbf{A} \in \mathbb{C}^{n,n}$ $(n \geq 2)$ is decomposed as the sum

$$\mathbf{A} = \text{low}\,(\mathbf{A}) + \text{diag}\,(\mathbf{A}) + \text{up}\,(\mathbf{A}) = \mathbf{A}_1 + \mathbf{A}_2 + \mathbf{A}_3$$

of its strictly lower, diagonal, and strictly upper parts, say,

$$\begin{bmatrix} a & b \\ c & d \end{bmatrix} = \begin{bmatrix} 0 & 0 \\ c & 0 \end{bmatrix} + \begin{bmatrix} a & 0 \\ 0 & d \end{bmatrix} + \begin{bmatrix} 0 & b \\ 0 & 0 \end{bmatrix}.$$

Low $(\cdot)$, diag $(\cdot)$, and up $(\cdot)$ are linear operators (projections) in $\mathbb{C}^{n,n}$ of ranks $n(n-1)/2$, n and $n(n-1)/2$, respectively.

2. Statement of the problem. Let $\mathbf{A} \in \mathbb{C}^{n,n}$. Then there exists $\mathbf{U} \in \mathbb{U}_n$ such that

$$\mathbf{U}^H\mathbf{A}\mathbf{U} = \mathbf{T}, \quad \text{or} \quad \mathbf{A}\mathbf{U} = \mathbf{U}\mathbf{T},\ \mathbf{T} \in \mathbb{T}_n,$$

where the matrix $\mathbf{T}$ is referred as the *Schur canonical form* of $\mathbf{A}$. The columns of $\mathbf{U}$ form the *Schur basis* of $\mathbf{A}$. If the matrix $\mathbf{A}$ is real and has real spectrum, then $\mathbf{T}$ is also real and $\mathbf{U}$ may be chosen real and orthogonal. The pair $(\mathbf{U}, \mathbf{T}) = (\mathbf{U}, \mathbf{U}^H\mathbf{A}\mathbf{U})$ is said to be the *Schur system* of $\mathbf{A}$. Note that the matrices $\mathbf{U}$ and (generally) $\mathbf{T}$ are not uniquely determined. Indeed, if $\mathbf{U}^H\mathbf{A}\mathbf{U} \in \mathbb{T}_n$, then $\mathbf{V}^H\mathbf{A}\mathbf{V} \in \mathbb{T}_n$, $\mathbf{V} = \mathbf{U}\mathbf{D}$, for each $\mathbf{D} = \text{diag}\,[d_1, d_2, \ldots, d_n]$, $|d_1| = |d_2| = \cdots = |d_n| = 1$. Moreover, we can achieve a Schur form $\mathbf{T}$ with any prescribed ordering of the eigenvalues of $\mathbf{A}$ on the diagonal of $\mathbf{T}$.

Denote by

$$\mathbb{B}(\mathbf{A}) = \{\mathbf{U} \in \mathbb{U}_n\colon \text{low}\,(\mathbf{U}^H\mathbf{A}\mathbf{U}) = \mathbf{0}\} \subset \mathbb{U}_n,$$

the set of all $\mathbf{U} \in \mathbb{U}_n$, whose columns form a Schur basis for $\mathbf{A}$, and let

$$\mathbb{S}(\mathbf{A}) = \{(\mathbf{U}, \mathbf{U}^H\mathbf{A}\mathbf{U})\colon \mathbf{U} \in \mathbb{B}(\mathbf{A})\} \subset \mathbb{U}_n \times \mathbb{T}_n$$

be the set of Schur systems of $\mathbf{A}$. It follows from the definitions that $\mathbb{B}(\mathbf{A})$ and $\mathbb{S}(\mathbf{A})$ are compact sets.

We assume for definiteness that the Schur system $(\mathbf{U}, \mathbf{T})$ of the unperturbed matrix $\mathbf{A}$ is chosen so that

$$\|\mathbf{I}_n - \mathbf{U}\|_F = \min\{\|\mathbf{I}_n - \mathbf{V}\|_F\colon \mathbf{V} \in \mathbb{B}(\mathbf{A})\}.$$

Suppose that $\mathbf{A}$ is subject to a perturbation $\Delta\mathbf{A} \in \mathbb{C}^{n,n}$. Then there exists $\Delta\mathbf{U} \in \mathbb{C}^{n,n}$ such that $\mathbf{U} + \Delta\mathbf{U} \in \mathbb{U}_n$ and

$$(\mathbf{A} + \Delta\mathbf{A})(\mathbf{U} + \Delta\mathbf{U}) = (\mathbf{U} + \Delta\mathbf{U})(\mathbf{T} + \Delta\mathbf{T}), \qquad \mathbf{T} + \Delta\mathbf{T} \in \mathbb{T}_n,$$

where $\mathbf{T} + \Delta\mathbf{T}$ is the Schur form of $\mathbf{A} + \Delta\mathbf{A}$.

The perturbation analysis problem (PAP) consists in estimating the norms of the perturbations $\Delta\mathbf{U}$, $\Delta\mathbf{T}$ as functions of the norm of $\Delta\mathbf{A}$. A major difficulty here is the nonuniqueness of the Schur system.

Note that there exists an "exact" minimax bound for the perturbation in $\mathbf{U}$. Indeed, for each $\delta \geq 0$, the quantity

$$\varphi_U(\delta) := \max_{\|\mathbf{Y}\|_F = \delta} \min_{\mathbf{W} \in \mathbb{B}(\mathbf{A}+\mathbf{Y})} \|\mathbf{W} - \mathbf{U}\|_F$$

is well defined according to the Weierstrass theorem: $\varphi_U(\delta) = \|\mathbf{W}^* - \mathbf{U}\|_F$, where $\mathbf{W}^* = \mathbf{U} + \Delta\mathbf{U}^* \in \mathbb{B}(\mathbf{A} + \mathbf{Y})$ for some $\mathbf{Y}^*$ with $\|\mathbf{Y}^*\|_F = \delta$. The matrix $\Delta\mathbf{A}^* = \mathbf{Y}^*$ is the "worst" perturbation of $\mathbf{A}$, which causes a maximum norm perturbation in $\mathbf{U}$.

It follows from the definition of φ_U that:

(i) For each $\Delta\mathbf{A}$ there exists $\mathbf{U} + \Delta\mathbf{U} \in \mathbb{B}(\mathbf{A} + \Delta\mathbf{A})$ such that $\|\Delta\mathbf{U}\|_F \le \varphi_U(\|\Delta\mathbf{A}\|_F)$;

(ii) There exists $\Delta\mathbf{A}^*$ such that $\|\Delta\mathbf{U}\|_F \ge \varphi_U(\|\Delta\mathbf{A}^*\|_F)$ for each $\mathbf{U} + \Delta\mathbf{U} \in \mathbb{B}(\mathbf{A} + \Delta\mathbf{A}^*)$, but $\|\Delta\mathbf{U}^*\|_F = \varphi_U(\|\Delta\mathbf{A}^*\|_F)$ for some $\mathbf{U} + \Delta\mathbf{U}^* \in \mathbb{B}(\mathbf{A} + \Delta\mathbf{A}^*)$.

Consider briefly the properties of the function φ_U: $\mathbb{R}_+ \to \mathbb{R}_+$. Obviously, $\varphi_U(0) = 0$ and the "ideal" case would be if φ_U is continuous or even differentiable in certain interval $[0, \beta)$. Unfortunately, φ_U may be discontinuous at $\delta = 0$ if, for example, $\mathbf{A}$ has multiple eigenvalues. In this case the Schur basis is *infinitely sensitive* and the PAP is *ill posed.*

The Schur form $\mathbf{T} = \mathbf{U}^T\mathbf{A}\mathbf{U}$ is usually less sensitive compared with the Schur basis $\mathbf{U}$. In fact, consider the quantity

$$\varphi_T(\delta) := \max_{\|\mathbf{Y}\|_F = \delta} \min_{(\mathbf{W},\mathbf{S}) \in \mathbb{S}(\mathbf{A}+\mathbf{Y})} \|\mathbf{S} - \mathbf{T}\|_F.$$

It characterizes the sensitivity of the Schur form in the sense that for each $\Delta\mathbf{A}$, one has

$$\|\Delta\mathbf{T}\|_F \le \varphi_T(\|\Delta\mathbf{A}\|_F)$$

for some $(\mathbf{U} + \Delta\mathbf{U}, \mathbf{T} + \Delta\mathbf{T}) \in \mathbb{S}(\mathbf{A} + \Delta\mathbf{A})$.

It may be shown that for some matrices $\mathbf{A}$, the function φ_U is discontinuous at $\delta = 0$, while φ_T is continuous and $\varphi_T(\delta)$ is of order at most $O(\delta^{1/n})$, $\delta \to 0$.

The construction of the exact minimax bounds $\varphi_U(\delta)$, $\varphi_T(\delta)$ is practically impossible. That is the reason we look for upper bounds $e_U(\delta) \ge \varphi_U(\delta)$, $e_T(\delta) \ge \varphi_T(\delta)$.

We denote

$$\delta_A = \|\Delta\mathbf{A}\|_F, \quad \delta_U = \|\Delta\mathbf{U}\|_F, \qquad \delta_T = \|\Delta\mathbf{T}\|_F.$$

The practical PAP for the Schur system of $\mathbf{A}$ may be formulated in the following way: Determine an interval $J = [0, \alpha)$ and two continuous nondecreasing functions e_U: $J \to \mathbb{R}_+$, e_T: $J \to \mathbb{R}_+$ such that $e_U(0) = e_T(0) = 0$ and

$$\delta_U \le e_U(\delta_A), \quad \delta_T \le e_T(\delta_A); \quad \delta_A \in J \tag{1}$$

for at least one pair $(\mathbf{U} + \Delta\mathbf{U}, \mathbf{T} + \Delta\mathbf{T}) \in \mathbb{S}(\mathbf{A} + \Delta\mathbf{A})$ and all $\Delta\mathbf{A}$ with $\|\Delta\mathbf{A}\|_F = \delta_A$.

Note that (1) may be violated for some Schur systems of the perturbed matrix $\mathbf{A} + \Delta\mathbf{A}$. This property of the perturbation bounds is inevitable due to the nonuniqueness of the Schur system.

It must be pointed out that the estimates (1) are *nonlocal* since they are valid for a finite (although possibly small) interval J of perturbations δ_A.

If the functions e_U and e_T are twice differentiable, we get the asymptotic estimates

$$\delta_U \le k_U\delta_A + O(\delta_A^2), \quad \delta_T \le k_T\delta_A + O(\delta_A^2); \quad \delta_A \to 0, \tag{2}$$

where $k_U = e'_U(0)$ and $k_T = e'_T(0)$ are estimates of the *absolute condition numbers* (relative to $\mathbf{U}$ and $\mathbf{T}$) of the problem of computing the Schur system of $\mathbf{A}$. Estimates of the *relative condition numbers* are $c_U = k_U\|\mathbf{A}\|_F/\sqrt{n}$ and $c_T = k_T$, respectively.

When the bounds (2) exist, the PAP for the Schur system is *well posed*, otherwise it is *ill posed.* Note that the ill-posed problems include infinitely sensitive problems when a continuous bound for δ_U does not exist.

3. Main results. In this section we present a complete perturbation analysis of the Schur system of a general matrix $\mathbf{A}$ under certain natural assumptions. We first reformulate the problem of obtaining and estimating the Schur system $(\mathbf{U} + \Delta\mathbf{U}, \mathbf{T} + \Delta\mathbf{T})$ of $\mathbf{A} +$

$\Delta\mathbf{A}$ as an operator equation $\mathbf{X} = \mathcal{U}(\mathbf{X})$, $\mathbf{X} = \mathbf{U}^H\Delta\mathbf{U}$, in $\mathbb{C}^{n,n}$ with a continuous mapping $\mathcal{U}(\cdot)$. Then we show that $\mathcal{U}(\cdot)$ maps certain compact set $\mathbf{M} \subset \mathbb{C}^{n,n}$ into itself, where $\mathbf{M}$ is "small" of order $O(\delta_A)$. Hence according to the Schauder fixed point principle, there exists a solution $\mathbf{X} \in \mathbf{M}$ and its norm may be estimated in terms of the perturbation δ_A. Note that an attempt to apply the Banach fixed point principle seems to be inappropriate here since $\Delta\mathbf{U}$ (and hence $\mathbf{X}$) is always nonunique.

We assume that $\mathbf{A}$ has n pairwise distinct eigenvalues. This condition is not restrictive since its violation may cause not only illposedness of the Schur system, but even nonexistence of a continuous band for δ_U as shown by the following simple example.

Example 1. Let $n = 2$ and $\mathbf{A} = \mathbf{I}_2$. Here $\mathbb{S}(\mathbf{A}) = \mathbb{U}_2 \times \{\mathbf{A}\}$ and $\mathbf{U} = \mathbf{I}_2$, $\mathbf{T} = \mathbf{A}$. If $\Delta\mathbf{A}$ has a nonzero element only in position (2, 1), then $\mathbb{B}(\mathbf{A} + \Delta\mathbf{A})$ consists of the matrices $\pm\mathbf{U}_1, \pm\mathbf{U}_2$, where $u_{1,12} = -u_{1,21} = u_{2,12} = u_{2,21} = 1$. Hence the minimum norm perturbation satisfies $\|\Delta\mathbf{U}\|_F = \|\mathbf{I}_2 \pm \mathbf{U}_i\|_F = 2$ and, for this type of perturbations $\Delta\mathbf{A}$, the norm δ_U is not continuous as a function of δ_A: $\delta_U = 0$ for $\delta_A = 0$ and $\delta_U = 2$ for $\delta_A > 0$.

Setting $\mathbf{X} = \mathbf{U}^H\Delta\mathbf{U}$ and $\mathbf{E} = \mathbf{U}^H\Delta\mathbf{A}\mathbf{U}$, we get

$$(\mathbf{T} + \mathbf{E})(\mathbf{I}_n + \mathbf{X}) = (\mathbf{I}_n + \mathbf{X})(\mathbf{T} + \Delta\mathbf{T})$$

and

$$\mathbf{T}\mathbf{X} - \mathbf{X}\mathbf{T} = (\mathbf{I}_n + \mathbf{X})\Delta\mathbf{T} - \mathbf{E}(\mathbf{I}_n + \mathbf{X}). \tag{3}$$

Since $\mathbf{I}_n + \mathbf{X} \in \mathbb{U}_n$, we have

$$\mathbf{X}^H + \mathbf{X} + \mathbf{X}^H\mathbf{X} = \mathbf{0}. \tag{4}$$

Equation (3) yields

$$\Delta\mathbf{T} = \mathbf{G}(\mathbf{X}) = (\mathbf{I}_n + \mathbf{X}^H)[\mathbf{T}\mathbf{X} - \mathbf{X}\mathbf{T} + \mathbf{E}(\mathbf{I}_n + \mathbf{X})] \tag{5}$$

and

$$\begin{aligned} \delta_T &= \|\mathbf{G}(\mathbf{X})\|_F = \|\mathbf{T}\mathbf{X} - \mathbf{X}\mathbf{T} + \mathbf{E}(\mathbf{I} + \mathbf{X})\|_F \\ &\le \|\mathbf{T}\mathbf{X} - \mathbf{X}\mathbf{T}\|_F + \|\mathbf{E}\|_F \le \omega_A\|\mathbf{X}\|_F + \delta_A, \end{aligned} \tag{6}$$

where

$$\omega_A := \|\mathbf{I}_n \otimes \mathbf{T} - \mathbf{T}^T \otimes \mathbf{I}_n\|_2 = \|\mathbf{I}_n \otimes \mathbf{A} - \mathbf{A}^T \otimes \mathbf{I}_n\|_2.$$

Note that obviously $\omega_A \le 2\|\mathbf{A}\|_F$. However, this bound is probably pessimistic since, e.g., $\omega_A \le \sqrt{2}\|\mathbf{A}\|_F$ for $n = 2$.

Represent $\mathbf{X}$ as

$$\mathbf{X} = \text{low}\,(\mathbf{X}) + \text{diag}\,(\mathbf{X}) + \text{up}\,(\mathbf{X}) = \mathbf{X}_1 + \mathbf{X}_2 + \mathbf{X}_3$$

and take operation low $(\cdot)$ from both sides of (3):

$$\text{low}\,(\mathbf{T}\mathbf{X} - \mathbf{X}\mathbf{T}) = \text{low}\,(\Delta\mathbf{T}) + \text{low}\,(\mathbf{X}\Delta\mathbf{T}) - \text{low}\,[\mathbf{E}(\mathbf{I}_n + \mathbf{X})].$$

Since low $(\Delta\mathbf{T}) = \mathbf{0}$, low $(\mathbf{T}\mathbf{X}) = \text{low}\,(\mathbf{T}\mathbf{X}_1)$, low $(\mathbf{X}\mathbf{T}) = \text{low}\,(\mathbf{X}_1\mathbf{T})$, and low $(\mathbf{X}\Delta\mathbf{T}) = \text{low}\,(\mathbf{X}_1\Delta\mathbf{T})$, then

$$\text{low}\,(\mathbf{T}\mathbf{X}_1 - \mathbf{X}_1\mathbf{T}) = \text{low}\,(\mathbf{X}_1\Delta\mathbf{T}) - \text{low}\,[\mathbf{E}(\mathbf{I}_n + \mathbf{X})]. \tag{7}$$

Consider the linear operator $\mathcal{L}(\cdot)$ in $\mathbb{C}^{n,n}$ defined by

$$\mathcal{L}(\mathbf{X}) = \text{low}\,(\mathbf{T}\mathbf{X} - \mathbf{X}\mathbf{T}).$$

Since $\mathfrak{L}(\mathbf{X}) = \mathfrak{L}(\mathbf{X}_1)$, then $\mathfrak{L}(\cdot)$ maps the subspace $\mathbf{M}_1 \subset \mathbb{C}^{n,n}$ of strictly lower triangular matrices into itself. Moreover, the eigenvalues of the restriction $\mathfrak{L}_1(\cdot)$ of $\mathfrak{L}(\cdot)$ on $\mathbb{C}^{n,n}/\mathbf{M}_1$ are $\lambda_i(\mathbf{A}) - \lambda_j(\mathbf{A})$, $i > j$, and hence $\mathfrak{L}_1(\cdot)$ is invertible. If we denote by vec $(\mathbf{X}_1) \in \mathbb{R}^{\mathfrak{v}}$, $\mathfrak{v} = n(n-1)/2$, the columnwise vector representation of $\mathbf{X}_1$, then vec $(\mathfrak{L}_1(\mathbf{X}_1)) =$ mat $(\mathfrak{L}_1)$ vec $(\mathbf{X}_1)$, where the matrix mat $(\mathfrak{L}_1) = \Omega = [\Omega_{ij}] \in \mathbb{R}^{\mathfrak{v},\mathfrak{v}}$ of the operator $\mathfrak{L}_1(\cdot)$ is block lower triangular ($\Omega_{ij} = \mathbf{0}$ for $i < j$). For $n = 5$, the matrix Ω is

$$\Omega = \begin{bmatrix} \tau_{21} & t_{23} & t_{24} & t_{25} & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & \tau_{31} & t_{34} & t_{35} & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & \tau_{41} & t_{45} & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & \tau_{51} & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & -t_{12} & 0 & 0 & \tau_{32} & t_{34} & t_{35} & 0 & 0 & 0 \\ 0 & 0 & -t_{12} & 0 & 0 & \tau_{42} & t_{45} & 0 & 0 & 0 \\ 0 & 0 & 0 & -t_{12} & 0 & 0 & \tau_{52} & 0 & 0 & 0 \\ 0 & 0 & -t_{13} & 0 & 0 & -t_{23} & 0 & \tau_{43} & t_{45} & 0 \\ 0 & 0 & 0 & -t_{13} & 0 & 0 & -t_{23} & 0 & \tau_{53} & 0 \\ 0 & 0 & 0 & -t_{14} & 0 & 0 & -t_{24} & 0 & -t_{34} & \tau_{54} \end{bmatrix},$$

where t_{ij} are the elements of $\mathbf{T}$ and $\tau_{ij} = \mathbf{t}_{ii} - \mathbf{t}_{jj} = \lambda_i(\mathbf{A}) - \lambda_j(\mathbf{A})$.

Denoting

$$\eta_A := \min \{\|\text{low } (\mathbf{TY} - \mathbf{YT})\|_F : \mathbf{Y} \in \mathbf{M}_1, \|\mathbf{Y}\|_F = 1\},$$

we have $\|\mathfrak{L}_1^{-1}\|_F = \|\Omega^{-1}\|_2 = \eta_A^{-1}$. Therefore, (7) may be rewritten as

$$\mathbf{X}_1 = \mathfrak{U}_1(\mathbf{X}) := \Lambda\{\mathbf{X}_1\Delta\mathbf{T} - \text{low } [\mathbf{E}(\mathbf{I}_n + \mathbf{X})]\}, \tag{8}$$

where $\Lambda(\cdot)$: $\mathbb{C}^{n,n} \to \mathbb{C}^{n,n}$ is a linear operator such that $\mathfrak{L}(\Lambda(\mathbf{X})) = \mathbf{X}_1$ and

$$\|\Lambda(\mathbf{X})\|_F \le \eta_A^{-1}\|\mathbf{X}\|_F. \tag{9}$$

Since we may choose $\mathbf{X}$ in (3), (4) with real diagonal elements x_{ii}, it follows from (4) that $x_{ii} = -0.5\|\mathbf{x}_i\|^2$; $\mathbf{X} = [\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n]$, $\mathbf{x}_i \in \mathbb{C}^n$, and

$$\begin{aligned} \mathbf{X}_2 = \mathfrak{U}_2(\mathbf{X}) &:= -0.5 \text{ diag } [\|\mathbf{x}_1\|^2, \|\mathbf{x}_2\|^2, \ldots, \|\mathbf{x}_n\|^2] \\ &= -0.5 \text{ diag } (\mathbf{X}^H\mathbf{X}).. \end{aligned} \tag{10}$$

Relation (4) also gives

$$\mathbf{X}_3 = \mathfrak{U}_3(\mathbf{X}) := -\text{up } (\mathbf{X}^H) - \text{up } (\mathbf{X}^H\mathbf{X}). \tag{11}$$

Equations (8), (10), and (11) form an operator equation

$$\mathbf{X} = \mathfrak{U}(\mathbf{X}), \ \mathfrak{U} = \mathfrak{U}_1 + \mathfrak{U}_2 + \mathfrak{U}_3.$$

Consider now the set

$$\mathbf{M} = \{\mathbf{X}: \|\mathbf{X}_i\|_F \le c_i;\ i = 1, 2, 3\} \subset \mathbb{C}^{n,n}, \tag{12}$$

where c_i are positive constants that will be determined later.

For $\mathbf{X} \in \mathbf{M}$, we have

$$\|\mathbf{X}\|_F^2 = \|\mathbf{X}_1\|_F^2 + \|\mathbf{X}_2\|_F^2 + \|\mathbf{X}_3\|_F^2 \le c_1^2 + c_2^2 + c_3^2 = \|\mathbf{c}\|^2,$$

$$\mathbf{c} = [c_1, c_2, c_3]^T,$$

and in view of (8), (9), and (5), (6)

$$\begin{aligned} \|\mathfrak{U}_1(\mathbf{X})\|_F &\le \eta_A^{-1}\|\text{low}\,(\mathbf{X}_1\Delta\mathbf{T}) - \text{low}\,[\mathbf{E}(\mathbf{I}_n + \mathbf{X})]\|_F \\ &\le \eta_A^{-1}(\|\mathbf{X}_1\|_F\|\Delta\mathbf{T}\|_F + \|\mathbf{E}\|_F) \\ &\le \eta_A^{-1}[c_1(\omega_A\|\mathbf{c}\| + \delta_A) + \delta_A] = c_1(\gamma\|\mathbf{c}\| + \varepsilon) + \varepsilon, \end{aligned} \tag{13}$$

where

$$\gamma := \frac{\omega_A}{\eta_A}, \qquad \varepsilon := \frac{\delta_A}{\eta_A}.$$

Since

$$\sum_{i=1}^{n} \|\mathbf{x}_i\|^2 = \|\mathbf{X}\|_F^2,$$

we get

$$\frac{\|\mathbf{X}\|_F^4}{n} \le \sum_{i=1}^{n} \|\mathbf{x}_i\|^4 \le \|\mathbf{X}\|_F^4. \tag{14}$$

Hence (10) yields

$$\|\mathfrak{U}_2(\mathbf{X})\|_F = 0.5\left(\sum_{i=1}^{n} \|\mathbf{x}_i\|^4\right)^{1/2} \le 0.5\|\mathbf{X}\|_F^2 = 0.5\|\mathbf{c}\|^2. \tag{15}$$

On the other hand,

$$\|\mathbf{X}^H\mathbf{X}\|_F^2 = 2\|\text{up}\,(\mathbf{X}^H\mathbf{X})\|_F^2 + \sum_{i=1}^{n} \|\mathbf{x}_i\|^4$$

and (14) yields

$$\|\text{up}\,(\mathbf{X}^H\mathbf{X})\|_F^2 = 0.5\left(\|\mathbf{X}^H\mathbf{X}\|_F^2 - \sum_{i=1}^{n} \|\mathbf{x}_i\|^4\right) \le 0.5\left(1 - \frac{1}{n}\right)\|\mathbf{X}\|_F^4.$$

Thus

$$\|\text{up}\,(\mathbf{X}^H\mathbf{X})\|_F \le \mu_n\|\mathbf{X}\|_F^2, \qquad \mu_n := \left[0.5\left(1 - \frac{1}{n}\right)\right]^{1/2}. \tag{16}$$

Having in mind that $\|\text{up}\,(\mathbf{X}^H)\|_F = \|\mathbf{X}_1\|_F$, it follows from (11) and (16)

$$\begin{aligned} \|\mathfrak{U}_3(\mathbf{X})\|_F &\le \|\text{up}\,(\mathbf{X}^H)\|_F + \|\text{up}\,(\mathbf{X}^H\mathbf{X})\|_F \le \|\mathbf{X}_1\|_F + \mu_n\|\mathbf{X}\|_F^2 \\ &\le c_1 + \mu_n\|\mathbf{c}\|^2. \end{aligned} \tag{17}$$

Now we shall show that under certain conditions there exists a vector

$$\mathbf{c} = \mathbf{c}(\varepsilon), \quad \mathbf{c} = [c_1, c_2, c_3]^T; \quad c_i = c_i(\varepsilon), \tag{18}$$

whose components satisfy the nonlinear algebraic system

$$c_1 = f_1(\mathbf{c}, \varepsilon) := \gamma c_1(c_1^2 + c_2^2 + c_3^2)^{1/2} + c_1\varepsilon + \varepsilon, \tag{19}$$

$$c_2 = f_2(\mathbf{c}) := 0.5(c_1^2 + c_2^2 + c_3^2), \tag{20}$$

$$c_3 = f_3(\mathbf{c}) := c_1 + \mu_n(c_1^2 + c_2^2 + c_3^2), \tag{21}$$

(or $\mathbf{c} = \mathbf{f}(\mathbf{c}, \varepsilon) = [f_1(\mathbf{c}, \varepsilon), f_2(\mathbf{c}), f_3(\mathbf{c})]^T$) and the limits

$$\lim_{\varepsilon \to 0} c_i(\varepsilon) = 0; \qquad i = 1, 2, 3. \tag{22}$$

Denote by $\mathbf{M}_\varepsilon$ the set (12), (18). Then in view of (13), (15), (17), and (19)–(21), it follows that $\mathfrak{U}(\mathbf{M}_\varepsilon) \subset \mathbf{M}_\varepsilon$. Hence according to the Schauder fixed-point principle, there exists a solution $\mathbf{X} \in \mathbf{M}_\varepsilon$ of equation $\mathbf{X} = \mathfrak{U}(\mathbf{X})$ and $\|\mathbf{X}\|_F \le \|\mathbf{c}(\varepsilon)\| = \|\mathbf{c}(\delta_A/\eta_A)\|$.

Next we shall derive conditions for solvability of (19)–(21) and upper bounds for $c_i(\varepsilon)$ and $\|\mathbf{c}(\varepsilon)\|$.

There is a critical relation $\varepsilon = \varepsilon_n(\gamma)$, $\gamma \in \mathbb{R}_+$, such that:

(i) For $0 \le \varepsilon \le \varepsilon_n(\gamma)$ the solution (18), (22) of (19)–(21) exists. Moreover, the functions $c_i(\cdot)$ are analytic in $\varepsilon < \varepsilon_n(\gamma)$ and are continuous (but not differentiable) for $\varepsilon = \varepsilon_n(\gamma)$;

(ii) For $\varepsilon > \varepsilon_n(\gamma)$ the solution (18) does not exist.

In case (i), we can take

$$\delta_U \le e_U(\delta_A) := \|\mathbf{c}(\varepsilon)\| = [2c_2(\varepsilon)]^{1/2} = \left[2c_2\left(\frac{\delta_A}{\eta_A}\right)\right]^{1/2} \tag{23}$$

and, in view of (6),

$$\delta_T \le \omega_A \delta_U + \delta_A \le e_T(\delta_A) := \omega_A\left[2c_2\left(\frac{\delta_A}{\eta_A}\right)\right]^{1/2} + \delta_A. \tag{24}$$

The critical value $\varepsilon_n = \varepsilon_n(\gamma)$ is such that the Jacobi matrix $\mathbf{J}(\mathbf{c}, \varepsilon) := \partial\mathbf{f}(\mathbf{c}, \varepsilon)/\partial\mathbf{c}$ has an eigenvalue 1 for $\varepsilon = \varepsilon_n$, $\mathbf{f}(\mathbf{c}, \varepsilon_n) = \mathbf{c}$. This may be proved using the method of Lyapunov majorant functions [13]. However, as shown below, there is an easier way to determine the relation $\varepsilon = \varepsilon_n(\gamma)$.

Equations (20) and (21) give

$$c_2 = c_1^2 + 2\mu_n c_1 c_2 + (0.5 + 2\mu_n^2)c_2^2, \tag{25}$$

while (19) and (20) yield

$$c_1 = \varepsilon + \varepsilon c_1 + \gamma c_1 (2c_2)^{1/2}. \tag{26}$$

Rewrite (25) and (26) as

$$c_1 = g(t) := \varepsilon[1 - \varepsilon - \gamma(2t)^{1/2}]^{-1},$$

$$c_1 = h(t) := -\mu_n t + [t - (0.5 + \mu_n^2)t^2]^{1/2},$$

where $t := c_2 < \min\{t_g, t_h\}$ and

$$t_g := 0.5(1 - \varepsilon)^2\gamma^{-2}, \quad t_h := (0.5 + 2\mu_n^2)^{-1}, \quad h(t_h) = 0.$$

The relation $\varepsilon = \varepsilon_n(\gamma)$ may be determined in parametric form using the conditions $g(t) = h(t)$ and $g'(t) = h'(t)$:

$$\gamma = \gamma^0(t) := (2t)^{1/2}h'(t)[2th'(t) + h(t) + h^2(t)]^{-1},$$

$$\varepsilon = \varepsilon^0(t) := h^2(t)[2th'(t) + h(t) + h^2(t)]^{-1};$$

$$0 < t \le t_{\max} := [1 + 4\mu_n^2 + \mu_n(2 + 8\mu_n^2)^{1/2}]^{-1},$$

where the function h has maximum for $t = t_{\max}$. In addition, we must impose the restriction $\gamma \ge 1$ since $\omega_A \ge \eta_A$. Thus we obtain domains in the plane (γ, ε) for which alternative (i) holds true.

A disadvantage of this result is that the relation $c_2 = c_2(\varepsilon)$ in (23), (24) is not in explicit form. However, explicit (but slightly pessimistic) bounds for δ_U, δ_T may be found in the following way.

Since in view of (25) $c_1^2 \le c_2$, we get from (26) $c_1 \le \sqrt{2\gamma}c_2 + \varepsilon c_1 + \varepsilon$. Hence if we consider the system

$$x_1 = \sqrt{2\gamma}x_2 + \varepsilon x_1 + \varepsilon, \tag{27}$$

$$x_2 = x_1^2 + 2\mu_n x_1 x_2 + (0.5 + 2\mu_n^2)x_2^2, \tag{28}$$

instead of (25), (26), we shall have $c_1 \le x_1$, $c_2 \le x_2$. Setting the expression for x_1 obtained from (27) in (28), we get

$$x_2 = p(\varepsilon) + q(\varepsilon)x_2 + r(\varepsilon)x_2^2, \tag{29}$$

where

$$\begin{aligned} p(\varepsilon) &:= \varepsilon^2(1-\varepsilon)^{-2}, \\ q(\varepsilon) &:= 2\varepsilon(1-\varepsilon)^{-2}[\sqrt{2\gamma} + \mu_n(1-\varepsilon)], \\ r(\varepsilon) &:= (1-\varepsilon)^{-2}[\sqrt{2\gamma} + \mu_n(1-\varepsilon)]^2 + 0.5 + \mu_n^2. \end{aligned} \tag{30}$$

The condition for existence of a solution of (29) is $[1 - q(\varepsilon)]^2 \ge 4p(\varepsilon)r(\varepsilon)$ or $q(\varepsilon) + 2[p(\varepsilon)r(\varepsilon)]^{1/2} \le 1$, which is equivalent to

$$2\varepsilon\{[(\sqrt{2\gamma} + \mu_n(1-\varepsilon)]^2 + (0.5 + \mu_n^2)(1-\varepsilon)^2\}^{1/2} + 2\varepsilon[\sqrt{2\gamma} + \mu_n(1-\varepsilon)] \le (1-\varepsilon)^2. \tag{31}$$

Inequality (31) may be strengthened to

$$2\varepsilon[\sqrt{2\gamma} + \mu_n(1-\varepsilon)] + 2\varepsilon\alpha_n(\gamma) \le (1-\varepsilon)^2, \tag{32}$$

where

$$\alpha_n(\gamma) := [(\sqrt{2\gamma} + \mu_n)^2 + \mu_n^2 + 0.5]^{1/2}. \tag{33}$$

Using (32), (33), it is easy to show that

$$\begin{aligned} \varepsilon \le \varepsilon_n^*(\gamma) &= [\beta_n(\gamma) - [\beta_n^2(\gamma) - 1 - 2\mu_n]^{1/2}]/(1 + 2\mu_n), \\ \beta_n(\gamma) &:= 1 + \sqrt{2\gamma} + \mu_n + \alpha_n(\gamma). \end{aligned} \tag{34}$$

If ε satisfies (31) or (34), then

$$\begin{aligned} x_2 = x_2(\varepsilon) &= [2r(\varepsilon)]^{-1}[1 - q(\varepsilon) - d^{1/2}(\varepsilon)], \\ d(\varepsilon) &:= [1 - q(\varepsilon)]^2 - 4p(\varepsilon)r(\varepsilon), \end{aligned} \tag{35}$$

and

$$\delta_U \le e_U^*(\delta_A) := [2x_2(\varepsilon)]^{1/2} = \left[2x_2\left(\frac{\delta_A}{\eta_A}\right)\right]^{1/2}, \tag{36}$$

$$\delta_T \le e_T^*(\delta_A) := \omega_A\left[2x_2\left(\frac{\delta_A}{\eta_A}\right)\right]^{1/2} + \delta_A. \tag{37}$$

Consider finally the case when δ_A and hence ε is asymptotically small. It may be shown that the solution of (25), (26) admits the power series expansion

$$\begin{aligned} c_1(\varepsilon) &= \varepsilon + (1 + \sqrt{2\gamma})\varepsilon^2 + [1 + \sqrt{2}(3 + \mu_n)\gamma + \gamma^2]\varepsilon^3 + \cdots, \\ c_2(\varepsilon) &= \varepsilon^2 + 2(1 + \sqrt{2\gamma} + \mu_n)\varepsilon^3 \\ &\quad + [3.5 + 6\mu_n + 6\mu_n^2 + 8\sqrt{2}(1 + \mu_n)\gamma + 10\gamma^2]\varepsilon^4 + \cdots, \end{aligned}$$

and

$$\delta_U \le e_U(\delta_A) = [2c_2(\varepsilon)]^{1/2} = \sqrt{2}\{\varepsilon + (1 + \sqrt{2}\gamma + \mu_n)\varepsilon^2 + [1.25 + 2\mu_n + 2.5\mu_n^2 + 3\sqrt{2}(1 + \mu_n)\gamma + 4\gamma^2]\varepsilon^3 + \cdots\}. \tag{38}$$

In particular, the condition numbers are

$$k_U = \frac{\sqrt{2}}{\eta_A}, \quad c_U = \left(\frac{2}{n}\right)^{1/2} \frac{\|\mathbf{A}\|_F}{\eta_A}; \quad k_T = c_T = 1 + \frac{\sqrt{2}\omega_A}{\eta_A}.$$

The solution of (27), (28) has the expansion

$$x_1(\varepsilon) = c_1(\varepsilon) + \sqrt{2}\gamma\mu_n\varepsilon^3 + O(\varepsilon^4),$$
$$x_2(\varepsilon) = c_2(\varepsilon) + 2\sqrt{2}\gamma\mu_n\varepsilon^4 + O(\varepsilon^5),$$

and

$$\delta_U \le e_U^*(\delta_A) = [2x_2(\varepsilon)]^{1/2} = [2c_2(\varepsilon)]^{1/2} + 2\gamma\mu_n\varepsilon^3 + O(\varepsilon^4), \tag{39}$$

i.e., the estimates e_U, e_U^*, defined by (38), (39) coincide within terms of second order with respect to ε.

The estimates derived above are relatively sharp as shown by the following examples.

Example 2. Let $\mathbf{A} \in \mathbb{R}^{5,5}$ and $\Delta\mathbf{A} = 10^{-k}\mathbf{B}$ be determined from

$$\mathbf{A} = \begin{bmatrix} 4.5 & 0.9 & -1.9 & 4.4 & -9.7 \\ 4.3 & 1.9 & -1.9 & 5.2 & -11.3 \\ -3.1 & 0.0 & 2.0 & -3.6 & 6.7 \\ 1.7 & 0.9 & -1.9 & 4.6 & -7.1 \\ 3.0 & 0.9 & -1.9 & 4.4 & -8.2 \end{bmatrix}, \qquad \mathbf{B} = \begin{bmatrix} -3 & 1 & 7 & -4 & 1 \\ 6 & 0 & 4 & 2 & 9 \\ -3 & -2 & 7 & 1 & -5 \\ 8 & 6 & -9 & -3 & 4 \\ 7 & 4 & -3 & 2 & 6 \end{bmatrix}$$

for k being an integer. The set of eigenvalues of $\mathbf{A}$ is $\{0.1, 0.2, 1.0, 1.5, 2.0\}$. The results obtained from (36), (37) are shown in Table 1.

Our last example shows that the estimates obtained are asymptotically exact.

Example 3. Let $\mathbf{A} = \operatorname{diag}[\lambda_1, \lambda_2] \in \mathbb{R}^{2,2}$, where $\lambda_1 > \lambda_2$. We have $\omega_A = \eta_A = \lambda_1 - \lambda_2 > 0$ and hence $\gamma = 1$. If we choose $\Delta\mathbf{A}$ in the form

$$\Delta\mathbf{A} = \begin{bmatrix} -a_1 & 0 \\ -a & a_2 \end{bmatrix}; \qquad a_1, a_2 \ge 0,$$

where

$$\delta_A = (a_1^2 + a_2^2 + a^2)^{1/2} < \frac{\eta_A}{\sqrt{2}}, \tag{40}$$

TABLE 1

k	δ_A	δ_U	e_U^*	δ_T	e_T^*
11	2.492×10^{-10}	3.413×10^{-9}	1.408×10^{-8}	2.843×10^{-8}	4.721×10^{-7}
12	2.492×10^{-11}	3.412×10^{-10}	1.408×10^{-9}	2.843×10^{-9}	4.721×10^{-8}
13	2.492×10^{-12}	3.411×10^{-11}	1.407×10^{-10}	2.842×10^{-10}	4.720×10^{-9}

then

$$\mathbf{X} = \begin{bmatrix} c-1 & s \\ -s & c-1 \end{bmatrix}; \quad s^2 + c^2 = 1, \quad \frac{s}{c} = \frac{a}{\eta_A - a_1 - a_2}.$$

Hence

$$\delta_U = \|\mathbf{X}\|_F = 2(1-c)^{1/2}, \qquad c = [1 + a_1^2(\eta_A - a_1 - a_2)^{-2}]^{-1/2}. \tag{41}$$

According to (41), the maximum of δ_A in (a_2, a_2, a) subject to the constraint (40) is achieved for

$$a_1 = a_2 = \frac{\delta_A^2}{\eta_A} = \delta_A \varepsilon, \quad a = \delta_A(1 - 2\varepsilon^2)^{1/2}; \quad \varepsilon = \frac{\delta_A}{\eta_A},$$

and is equal to

$$\begin{aligned} \delta_{U,\max}(\varepsilon) &= 2[1 - c_{\min}(\varepsilon)]^{1/2}, \\ c_{\min}(\varepsilon) &= [1 - \varepsilon^2(1-\varepsilon^2)^{-1}]^{1/2}, \\ \varepsilon &< \frac{1}{\sqrt{2}} \approx 0.7071. \end{aligned} \tag{42}$$

Thus the exact bound (42) has the expansion

$$\begin{aligned} \delta_{U,\max}(\varepsilon) &= \sqrt{2}\varepsilon\left[1 + \left(\frac{5}{8}\right)\varepsilon^2 + \left(\frac{79}{128}\right)\varepsilon^4 + \cdots\right] \\ &\approx \sqrt{2}\varepsilon(1 + 0.625\varepsilon^2 + 0.617\varepsilon^4 + \cdots) \end{aligned}$$

while the bound (36) and the inequality (34) give

$$\delta_U \le e_U(\varepsilon\eta_A) \approx \sqrt{2}\varepsilon(1 + 2.914\varepsilon + 13.239\varepsilon^2 + \cdots),$$

$$\varepsilon < \varepsilon_2^*(1) \approx 0.2035,$$

and the difference between the exact (42) and approximate (39) bound is of asymptotic order $4.121\varepsilon^2$.

AN ALGORITHM FOR THE SINGLE-INPUT POLE ASSIGNMENT PROBLEM*

RAFAEL BRU†, JOSÉ MAS†, AND ANA M. URBANO†

Abstract. B. N. Datta and K. Datta have proposed an efficient parallel algorithm for the single-input pole assignment problem when the spectrum set to be assigned is pairwise distinct and disjoint from the spectrum of the dynamical matrix. This paper first presents a theoretical analysis of that algorithm and then presents the necessary modifications on it for an arbitrary spectrum. Based on the modified algorithm, the authors present two new algorithms for the problem and give some results on controllability that are of independent interests.

Key words. eigenvalue assignment, single-input, controllability, Jordan form

AMS subject classifications. 93B55, 93B60, 15A18

1. Introduction.

Given the time-invariant linear dynamical system

$$\dot{x}(t) = Ax(t) + bu(t),$$

where $A \in \mathbb{R}^{n\times n}$ and $b \in \mathbb{R}^{n\times 1}$, an important problem in control theory is the eigenvalue assignment problem commonly known as the pole-assignment problem; that is, to find a vector f such that the spectrum of the matrix, $A - bf^T$ is equal to the prespecified and conjugated complex number set $\Omega = \{\mu_1, \mu_2, \ldots, \mu_n\}$. One application of this problem is the stabilization of a controllable system; that is, if the dynamic system has some disturbance, how to choose a vector f such that the closed-loop system comes back to the stable position. It is well known that this problem has a unique solution if and only if the pair (A, b) is controllable [10].

There exist several sequential methods for computing the vector f. Some well-known and important methods are found in [1], [2], [5]–[7], and [9].

In [4], B. N. Datta and K. Datta proposed a *parallel* algorithm for solving the above problem. This algorithm implicitly assumes that the eigenvalues to be assigned are pairwise distinct and different from those of A. The main aim of this paper is to modify that method for any self-conjugated set Ω, proposing some modifications of that parallel algorithm to obtain the vector f such that $A - bf^T$ has the desired spectrum for any set Ω. We point out here that a multi-input version of the Datta–Datta single-input parallel algorithm was also proposed in [3]. This multi-input version also implicitly assumes that the set of eigenvalues to be assigned is disjoint from the spectrum of A and pairwise distinct.

The paper is organized as follows. First, in §2 we present a short description of the algorithm given in [4] that is the starting point of our analysis. Then in §3 we give some controllability results and theoretical analysis of that algorithm proving necessary and sufficient conditions on the validity of that algorithm. In §4 we study the modification when $\Omega \cap \sigma(A) \neq \emptyset$ (where $\sigma(A)$ denotes the spectrum of A), and in §5 we give a general algorithm when $\Omega \cap \sigma(A) \neq \emptyset$ and some eigenvalue has multiplicity greater than one. Finally, in §6 we illustrate our algorithms with some numerical experiments with the help of MATLAB.

2. A single-input parallel algorithm for eigenvalue assignment by Datta and Datta. Given the controllable pair (A, b) and the set $\Omega = \{\mu_1, \mu_2, \ldots, \mu_n\}$, the algorithm proposed in [4] computes a vector f such that $\sigma(A - bf^T) = \Omega$. The algorithm is suitable for parallel implementation and is described as follows.

Stage I. Transform the pair (A, b) by orthogonal similarity to the pair (H, c), where $QAQ^T = H$ is an unreduced upper Hessenberg matrix and $Qb = c = [\alpha, 0, \ldots, 0]^T$, $\alpha \neq 0$.

Stage II. Solve the n Hessenberg systems in PARALLEL:

$$(H - \mu_i I)t_i = c, \quad i = 1, \quad 2, \ldots, n.$$

Stage III. Solve for d:

$$T^T d = r,$$

where $T = [t_1, t_2, \ldots, t_n]$ and $r = [\alpha, \alpha, \ldots, \alpha]^T$.

Stage IV. Compute $f^T = \alpha^{-1} d^T Q$.

In Stage I of the algorithm, the orthogonal similarity Q transforms the pair (A, b) to the equivalent pair (H, c), where H is an upper Hessenberg matrix and $c = [\alpha, 0, \ldots, 0]^T$. It is well known that (A, b) is controllable if and only if the matrix H is unreduced (that is, $h_{i,i-1} \neq 0$, $i = 2, \ldots, n$) and $\alpha \neq 0$ (see [6] and [7]).

Since

$$Q(A - bf^T)Q^T = H - cf^T Q^T,$$

the problem of finding the vector f such that $\sigma(A - bf^T) = \Omega$ is equivalent to finding the vector g, defined by $g^T = f^T Q^T$, such that

$$\sigma(H - cg^T) = \Omega.$$

Stage II of the algorithm solves the systems

$$(H - \mu_i I)t_i = c, \quad i = 1, \quad 2, \ldots, n. \tag{1}$$

Assuming that T is nonsingular, it computes the vector $d^T = r^T T^{-1}$ in Stage III. In Stage IV the vector f is computed as

$$f^T = \alpha^{-1} d^T Q = [1, 1, \ldots, 1]T^{-1}Q = g^T Q.$$

Theorem 2.2 of [4] proves that the above algorithm provides the vector f such that $\sigma(A - bf^T) = \Omega$, assuming that the matrix T obtained in Stage II is invertible. We prove that the nonsingularity of T is guaranteed when the elements of the set Ω are pairwise distinct and when no element of Ω is in $\sigma(A)$ (see Proposition 3). Thus the above assumptions in the algorithm given in [4] are not a restriction because it works implicitly with these conditions. As we shall see in the next section, the nonsingularity of T is related with the consistency of the systems $(H - \mu I)t = c$ of Stage II.

3. Consistency and nonsingularity. In general, the matrix T obtained by solving (1) is not invertible if some eigenvalue has multiplicity greater than one as Proposition 1 shows. Furthermore, in the case that $\Omega \cap \sigma(A) \neq \varnothing$, the matrix T cannot be constructed from the systems of Stage II, as can be seen in Proposition 2. From the above remarks, we observe that the algorithm given in [4] is valid if and only if $\Omega \cap \sigma(A) = \varnothing$ and Ω is a pairwise disjoint set, as the following theorem proves. Since $\sigma(A) = \sigma(H)$, we state our results for an unreduced upper Hessenberg matrix H.

THEOREM 1. *Let (H, c) be a controllable pair. Let Ω be a conjugated complex number set. The algorithm given in* [4] *is valid if and only if the following conditions are satisfied*: (i) $\Omega \cap \sigma(H) = \varnothing$, and (ii) *the elements of Ω are pairwise distinct.*

The proof of Theorem 1 is based on the following results.

PROPOSITION 1. *Let (H, c) be a controllable pair. Let $\Omega = \{\mu_1, \mu_2, \ldots, \mu_n\}$ be a conjugated complex number set. If $\Omega \cap \sigma(H) = \varnothing$, but $\mu_i = \mu_j$ for some $i \neq j$, then the matrix T constructed in Stage* II *is singular.*

Proof. Since $\Omega \cap \sigma(H) = \varnothing$, then rank $(H - \mu_i I) = n$. Therefore, the system $(H - \mu_i I)x = c$ has a unique solution and hence the matrix T has the ith and jth columns equal. Hence T is singular. □

The following lemma gives a basic result on the controllable systems with single input, and we will use it in the next proposition. Moreover, the remark below is the main point for constructing the general algorithm given in §5.

LEMMA 1. *Let (H, c) be a controllable pair. Then*

(i) dim Ker $[H - \mu I, c] = 1$, *for all μ.*

(ii) If $\mu \in \sigma(H)$, *then the geometric multiplicity of μ is* 1.

Proof. (i) If $\mu \notin \sigma(H)$, it is obvious. Otherwise, since (H, c) is controllable, rank $[H - \mu I, c] = n$ and hence dim Ker $[H - \mu I, c] = 1$.

(ii) Since rank $[H - \mu I, c] = n$ and considering that $\mu \in \sigma(H)$, we deduce that dim Ker $(H - \mu I) = 1$. □

Remark. Let γ_j be the jth column of the matrix $H - \mu I$, $j = 1, 2, \ldots, n$.

(a) Then by Lemma 1(ii), and since $H - \mu I$ is an unreduced upper Hessenberg matrix, we have

$$\text{span } \{\gamma_1, \gamma_2, \ldots, \gamma_{n-1}, \gamma_n\} = \text{span } \{\gamma_1, \gamma_2, \ldots, \gamma_{n-1}\}.$$

(b) By Lemma 1(i) and the last remark, we have the following direct sums:

$$\mathbb{C}^n = \text{span } \{\gamma_1, \gamma_2, \ldots, \gamma_{n-1}, \gamma_n\} \oplus \text{span } \{c\}$$

$$= \text{span } \{\gamma_1, \gamma_2, \ldots, \gamma_{n-1}\} \oplus \text{span } \{c\}.$$

PROPOSITION 2. *Consider the controllable pair (H, c). Let Ω be a conjugated complex number set. If $\mu \in \Omega \cap \sigma(H)$, then the system $(H - \mu I)x = c$ is inconsistent.*

Proof. If $\mu \in \sigma(H)$, then by Lemma 1(ii), we have that rank $(H - \mu I) = n - 1$, and since (H, c) is a controllable pair, rank $[H - \mu I, c] = n$. Thus, the system $(H - \mu I)x = c$ is inconsistent. □

For the next proposition we consider, for each $p = 1, 2, \ldots, n$, the following partition of the matrix $H - \mu_i I$ and the vectors t_i and c.

$$H - \mu_i I = \left[\begin{array}{c|c} \underset{n-p}{H_1 - \mu_i I} & \underset{p}{S} \\ \hline \underset{n-p}{R} & \underset{p}{H_2 - \mu_i I} \end{array}\right]^{n-p}_{p}$$

$$t_i = \begin{bmatrix} t_{1i} \\ \cdot \\ \cdot \\ t_{n-p,i} \\ \hline t_{n-p+1,i} \\ \cdot \\ \cdot \\ t_{n,i} \end{bmatrix} = \begin{bmatrix} t_i^{n-p} \\ \hline t_i^{p} \end{bmatrix}, \qquad c = \begin{bmatrix} \alpha \\ 0 \\ \cdot \\ \cdot \\ 0 \\ \hline 0 \\ \cdot \\ \cdot \\ 0 \end{bmatrix} = \left[\begin{array}{c} c^{n-p} \\ \hline 0 \end{array}\right]^{n-p}_{p}$$

for each $i = 1, 2, \ldots, p$.

PROPOSITION 3. *Let (H, c) be a controllable pair. Let $\Omega = \{\mu_1, \mu_2, \ldots, \mu_n\}$ be a conjugated complex number set, pairwise distinct. Consider, in addition, that $\Omega \cap \sigma(H) = \varnothing$. Let t_i be the solution of the system*

$$(H - \mu_i I)t_i = c \quad \text{for each } i = 1, 2, \ldots, n. \tag{2}$$

Then the rank of the matrix $[t_1^p, t_2^p, \ldots, t_p^p]$ is equal to p for each $p = 1, 2, \ldots, n$.

Proof. We proceed by induction over p. For $p = 1$, it is evident that $t_{1n} \neq 0$. Otherwise, since H is unreduced Hessenberg matrix and using back substitution we deduce that the vector t_1 is the zero vector, which is not a solution of the nonhomogeneous system $(H - \mu_1 I)x = c$.

Suppose by induction that the rank of the matrix $[t_1^p, t_2^p, \ldots, t_p^p]$ is p. Obviously, the rank of the matrix

$$[t_1^{p+1}, t_2^{p+1}, \ldots, t_p^{p+1}, t_{p+1}^{p+1}]$$

is p or $p + 1$. Suppose the rank of this matrix is p instead of $p + 1$. Then by the induction hypothesis we have the following linear combination:

$$t_{p+1}^{p+1} = \sum_{j=1}^{p} \beta_j t_j^{p+1}. \tag{3}$$

For each $i = 1, 2, \ldots, p + 1$, by the above partitions, we can write system (2) as

$$\left[\begin{array}{c|c} H_1 - \mu_i I & S \\ \hline R & H_2 - \mu_i I \end{array}\right] \left[\begin{array}{c} t_i^{n-p-1} \\ \hline t_i^{p+1} \end{array}\right] = \left[\begin{array}{c} c^{n-p-1} \\ \hline 0 \end{array}\right]. \tag{4}$$

Now restricting ourselves to the second subsystem of (4), for $i = 1, 2, \ldots, p$, we have

$$Rt_i^{n-p-1} + (H_2 - \mu_i I)t_i^{p+1} = 0, \tag{5}$$

and for $i = p + 1$, taking into account (3), we get

$$Rt_{p+1}^{n-p-1} + (H_2 - \mu_{p+1} I) \sum_{j=1}^{p} \beta_j t_j^{p+1} = 0. \tag{6}$$

Subtracting expression (6) from the sum of all p subsystems (5) each one multiplied by β_i, $i = 1, 2, \ldots, p$, we obtain

$$R\left[\sum_{i=1}^{p} \beta_i t_i^{n-p-1} - t_{p+1}^{n-p-1}\right] + \sum_{i=1}^{p} \beta_i(\mu_{p+1} - \mu_i)t_i^{p+1} = 0.$$

Since the matrix R has only the $(1, n - p)$th entry different from zero, we have that the last p rows satisfy

$$\sum_{i=1}^{p} \beta_i(\mu_{p+1} - \mu_i)t_i^p = 0.$$

Hence the rank of matrix $[t_1^p, t_2^p, \ldots, t_p^p]$ is less than p, which contradicts the induction hypothesis. □

We are now ready to prove Theorem 1.

Proof of Theorem 1. Sufficiency: Follows from Proposition 3. Necessity: If $\Omega \cap \sigma(H) \neq \varnothing$, by Proposition 2, the matrix T cannot exist. On the other hand if multiplicity of $\mu > 1$, for some $\mu \in \Omega$, by Proposition 1, T is singular. □

4. Proposed pole placement algorithm. If $\mu \in \Omega \cap \sigma(H)$, we then have seen in Proposition 2 that the Datta–Datta algorithm is not valid. However, it is always possible to find an eigenvector of H associated with μ, solving the system $(H - \mu I)x = 0$. In fact, we shall see in Theorem 2 that in this case (that is, when $\Omega \cap \sigma(H) \neq \varnothing$) the matrix T constructed in (7) is nonsingular. We will thus have the following modified algorithm.

ALGORITHM I

Stage I. Transform the pair (A, b) by orthogonal similarity to the pair (H, c), where H is an upper unreduced Hessenberg matrix and $c = [\alpha, 0, \ldots, 0]^T$, with $\alpha \neq 0$.

Stage II. For $i = 1, 2, \ldots, n$.

If $\mu_i \notin \sigma(H)$, then

Solve the Hessenberg systems in PARALLEL

$$(H - \mu_i I)t_i = c.$$

Else

Solve the Hessenberg systems in PARALLEL for the nonzero solution

$$(H - \mu_i I)t_i = 0.$$

Stage III. Form the vector u as follows: assign 1 to the ith entry if $\mu_i \in \sigma(H)$, otherwise assign 0 to this entry.

Stage IV. Solve for g:

$$g^T T = u^T,$$

where

$$T = [t_1, t_2, \ldots, t_n].$$

Stage V. Compute $f^T = g^T Q$.

The following result proves the validity of the above algorithm.

THEOREM 2. *Let (H, c) be a controllable pair and let $\Omega = \{\mu_1, \mu_2, \ldots, \mu_n\}$ be a conjugated complex number set pairwise distinct. If t_i, $i = 1, 2, \ldots, n$, is a solution of the systems*

$$(H - \mu_i I)t_i = \begin{cases} 0 & \text{if } \mu_i \in \sigma(H), \\ c & \text{if } \mu_i \notin \sigma(H), \end{cases} \tag{7}$$

where $c = [\alpha, 0, \ldots, 0]^T$, $\alpha \neq 0$, then the matrix

$$[t_1^p, t_2^p, \ldots, t_p^p]$$

has rank p, *for each* $p = 1, 2, \ldots, n$.

Proof. The proof is analogous to that of Proposition 3. □

The assumption that the complex numbers of Ω are pairwise distinct in Theorem 2 is necessary as the following example shows.

Example 1. Let

$$H = \begin{bmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ 0 & 1 & 1 \end{bmatrix} \quad \text{and} \quad c = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix},$$

and suppose that we want to assign the spectrum $\Omega = \{1, 1, 2\}$. The solution of the systems (7) yields the singular matrix

$$T = \begin{bmatrix} 0 & 0 & -1 \\ 0 & 0 & -1 \\ 1 & 1 & 1 \end{bmatrix}.$$

5. The general algorithm. With the hypothesis of Theorem 2, solving the systems (7) is equivalent to solving the matrix system

$$HT - cu^T = T \operatorname{diag}(\mu_i), \tag{8}$$

where u^T is a row vector constructed in the proposed algorithm: its ith entry is 0 if $\mu_i \in \sigma(H)$ and 1 otherwise. From (8) note that the matrix $H - cu^T T^{-1}$ is diagonalizable as in the case of [4]. However, in the general case where the spectrum to be assigned has some eigenvalue with multiplicity greater than one, the matrix $H - cu^T T^{-1}$ is not similar to a diagonal matrix as the following proposition shows.

PROPOSITION 4. *Let (H, c) be a controllable pair, and let $\Omega = \{\mu_1, \mu_2, \ldots, \mu_p\}$ be the spectrum to be assigned with multiplicities $m(1), m(2), \ldots, m(p)$, respectively. If g is the vector such that $\sigma(H - cg^T) = \Omega$, then the Jordan form of $H - cg^T$ is*

$$J = \begin{bmatrix} J_1 & 0 & \cdots 0 \\ 0 & J_2 & \cdots 0 \\ \cdots & \cdots & \cdots \\ 0 & 0 & \cdots J_p \end{bmatrix}, \tag{9}$$

where J_k is the $m(k) \times m(k)$ Jordan matrix

$$J_k = \begin{bmatrix} \mu_k & 0 & \cdots 0 & 0 \\ 1 & \mu_k & \cdots 0 & 0 \\ \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & \cdots 1 & \mu_k \end{bmatrix}.$$

Proof. Let $\mu \in \sigma(H - cg^T)$; we need to prove that dim Ker $(H - cg^T - \mu I) = 1$. Suppose that t_1 and t_2 are solutions of $(H - cg^T - \mu I)x = 0$. Then

$$(H - \mu I)t_i = cg^T t_i = \xi_i c, \qquad i = 1, 2. \tag{10}$$

Now we distinguish two cases. (i) $\mu \in \sigma(H)$. Then $\xi_i = 0$, $i = 1, 2$, otherwise the systems (10) are inconsistent by Proposition 2. Therefore the vectors t_1 and t_2 are in Ker $(H - \mu I)$ which, by Lemma 1(ii), has dimension 1. Hence the vectors t_1 and t_2 are linearly dependent.

(ii) $\mu \notin \sigma(H)$. In this case $\xi_i \neq 0$, $i = 1, 2$ (otherwise the unique solution is the trivial one). Equation (10) becomes

$$(H - \mu I)(\xi_i^{-1} t_i) = c, \qquad i = 1, 2.$$

Since the system $(H - \mu I)x = c$ has unique solution, then t_1 and t_2 are linearly dependent. We conclude that dim Ker $(H - cg^T - \mu I) = 1$. □

Remark. Proposition 4 suggests that when there are in the set Ω eigenvalues with multiplicity greater than one, the matrix diag (μ_i) in (8) may be substituted by the matrix J defined in (9) to compute the matrix T. Now we discuss how to choose the vector u so that the matrix system

$$HT - cu^T = TJ \tag{11}$$

provides n consistent linear systems. Later, we shall see in Theorem 3 that the matrix T constructed from the solutions of these consistent systems is invertible.

Remark. To see the consistency of the system (11) as a function of the vector u, we partition this vector as

$$u = [u_{(1)}^T, u_{(2)}^T, \ldots, u_{(p)}^T]^T,$$

where the ith block of u^T is

$$u_{(i)} = [\beta_1^{(i)}, \beta_2^{(i)}, \ldots, \beta_{m(i)}^{(i)}]^T$$

and $m(i)$ is the multiplicity of μ_i. Also we write the matrix T by blocks as

$$T = [t_{(1)}, t_{(2)}, \ldots, t_{(p)}],$$

where the block $t_{(i)}$ is

$$t_{(i)} = [t_1^{(i)}, t_2^{(i)}, \ldots, t_{m(i)}^{(i)}]$$

for $i = 1, 2, \ldots, p$. The superscripts represent the corresponding eigenvalues. From the matrix system (11), using this notation, we obtain the following linear systems:

$$(H - \mu_i I)t_j^{(i)} = t_{j+1}^{(i)} + \beta_j^{(i)} c, \qquad j = 1, 2, \ldots, m(i), \qquad i = 1, 2, \ldots, p, \tag{12}$$

where $t_{m(i)+1}^{(i)} = 0$.

The systems (12) can be grouped into p subsystems corresponding to each eigenvalue μ_i, $i = 1, 2, \ldots, p$. Let us study the consistency of a subsystem (the same study can be done for the other subsystems). To simplify the notation, we drop the scripts (i) and work with the linear systems

$$(H - \mu I)t_j = t_{j+1} + \beta_j c, \qquad j = m, m-1, \ldots, 1, \tag{13}$$

where $t_{m+1} = 0$.

We consider two cases: (i) $\mu \notin \sigma(H)$. In this case $H - \mu I$ is nonsingular and the m linear systems (13) have unique solutions. The last system (i.e., $j = m$)

$$(H - \mu I)t_m = \beta_m c$$

is consistent for every scalar β_m. In particular, we obtain a nontrivial solution for $\beta_m = 1$. The remaining systems are consistent for any value of β_j; in particular, we shall take $\beta_j = 0, j = m-1, m-2, \ldots, 2, 1$.

(ii) $\mu \in \sigma(H)$. Suppose that the multiplicity in $\sigma(H)$ is r. Since (H, c) is controllable, by Lemma 1(ii) the r systems

$$(H - \mu I)t_m = 0,$$
$$(H - \mu I)t_{m-1} = t_m,$$
$$\cdots\cdots\cdots\cdots$$
$$(H - \mu I)t_{m-r+1} = t_{m-r+2}$$

are consistent.

(iia) In the case $m \leq r$, then the systems (13) are consistent for $\beta_m = \beta_{m-1} = \cdots = \beta_1 = 0$.

Exploiting the structure of the unreduced Hessenberg matrix, a particular solution of the systems (13) has the structure

(14) $$[t_1, t_2, \ldots, t_m] = \begin{bmatrix} \square & \\ & \ddots \\ 0 & \end{bmatrix} \begin{matrix} n-m \\ \hline \\ m \end{matrix}.$$

(iib) In the case $m > r$, the first r systems (13) are consistent for $\beta_m = \beta_{m-1} = \cdots = \beta_{m-r+1} = 0$. Then the next system of (13) to solve is

(15) $$(H - \mu I)t_{m-r} = t_{m-r+1} + \beta_{m-r}c,$$

or equivalently

(16) $$(H - \mu I)t_{m-r} - \beta_{m-r}c = t_{m-r+1},$$

which is equivalent to

(17) $$[H - \mu I, c] \begin{bmatrix} \delta_1 \\ \delta_2 \\ \vdots \\ \delta_n \\ \Gamma_{m-r} \end{bmatrix} = t_{m-r+1}.$$

By the remark of Lemma 1, we can also write

$$t_{m-r+1} = \delta_1\gamma_1 + \delta_2\gamma_2 + \cdots + \delta_{n-1}\gamma_{n-1} + \Gamma_{m-r}c,$$

where γ_i represents the ith column of the matrix $H - \mu I$, $i = 1, 2, \ldots, n-1$. Hence we can find a particular solution of (17) setting $\delta_n = 0$. Then a solution of (16) is $\beta_{m-r} = -\Gamma_{m-r}$ and

$$t_{m-r} = [\delta_1\ \delta_2 \cdots \delta_{n-1}\ 0]^T.$$

The other vectors $t_{m-r-1}, t_{m-r-2}, \ldots, t_1$ can similarly be obtained.

Again, by the structure of the matrix $[H - \mu I, c]$, we can get a partial solution of (13) with the following structure:

(18) $$[t_1, \ldots, t_r, t_{r+1}, \ldots, t_m] = \begin{bmatrix} \square & \\ & \ddots \\ 0 & \end{bmatrix} \begin{matrix} n-m \\ \hline \\ m \end{matrix}.$$

Example 2. Let

$$H = \begin{bmatrix} 2 & 0 & 0 \\ 1 & 1 & 0 \\ 0 & 1 & -1 \end{bmatrix} \quad \text{and} \quad c = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}.$$

Suppose that we want to assign the spectrum $\Omega = \{1, 1, 1\}$. Since $1 \in \sigma(H)$, with multiplicity 1, we are in the case (iib), and we must solve the systems

$$(H - I)t_3 = 0,$$

$$(H - I)t_2 = t_3 + \beta_2 c,$$

$$(H - I)t_1 = t_2 + \beta_1 c.$$

A solution of the first system is $t_3 = [0, 2, 1]^T$. By (16) we get $\beta_2 = 2$, so a solution of the second system will be $t_2 = [2, 1, 0]^T$. With this solution and (17), we obtain $\beta_1 = -1$ and then one solution of the last system will be $t_1 = [1, 0, 0]^T$, and hence $u = [-1, 2, 0]^T$.

ALGORITHM II

This algorithm finds the vector f such that given the controllable pair (A, b) and the conjugated complex number set $\Omega = \{\mu_1, \mu_2, \ldots, \mu_p\}$, the matrix $A - bf^T$ has the spectrum Ω, where μ_i has multiplicity $m(i)$, $i = 1, 2, \ldots, p$. For the description of the algorithm it is assumed that the spectrum of A (and so the spectrum of H) and the multiplicities $r(1), r(2), \ldots, r(m)$ of its eigenvalues are known.

In the algorithm we represent by $u_{(s)}$ the block of the vector u that has coordinates from $m(1) + \cdots + m(s-1) + 1$ to $m(1) + \cdots + m(s-1) + m(s)$, and by $\gamma_j^{(i)}$, $j = 1, 2, \ldots, n$ the columns of matrix $H - \mu_i I$.

Stage I. Transform the pair (A, b) by orthogonal similarity Q to the pair (H, c), where H is an upper unreduced Hessenberg matrix and $c = [\alpha, 0, \ldots, 0]^T$, with $\alpha \neq 0$.

Stage II. For $i = 1, 2, \ldots, p$.

If $\mu_i \notin \sigma(H)$.

Solve the system

$$(H - \mu_i I)t_{m(i)}^{(i)} = c.$$

For $j = m(i) - 1, m(i) - 2, \ldots, 1$ solve the systems

$$(H - \mu_i I)t_j^{(i)} = t_{j+1}^{(i)}.$$

Form the $m(i)$-dimensional vector $u_{(i)} = [0, 0, \ldots, 0, 1]^T$.

Else

If $r(i) \geq m(i)$, solve the system for the nonzero solution

$$(H - \mu_i I)t_{m(i)}^{(i)} = 0.$$

For $j = m(i) - 1, m(i) - 2, \ldots, 1$ solve the systems

$$(H - \mu_i I)t_j^{(i)} = t_{j+1}^{(i)}.$$

Form the $m(i)$-dimensional vector $u_{(i)} = [0, 0, \ldots, 0]^T$.

Else solve the system for the nontrivial solution

$$(H - \mu_i I)t_{m(i)}^{(i)} = 0.$$

For $j = m(i) - 1, m(i) - 2, \ldots, m(i) - r(i) + 1$ solve the systems

$$(H - \mu_i I)t_j^{(i)} = t_{j+1}^{(i)}.$$

For $j = m(i) - r(i), m(i) - r(i) - 1, \ldots, 2, 1$, solve the systems

$$t_{j+1}^{(i)} = \delta_1^{(i)}\gamma_1^{(i)} + \delta_2^{(i)}\gamma_2^{(i)} + \cdots + \delta_{n-1}^{(i)}\gamma_{n-1}^{(i)} + \Gamma_j^{(i)}c.$$

Form the $m(i)$-dimensional vector

$$u_{(i)} = [u_1^{(i)}, u_2^{(i)}, \ldots, u_{m(i)}^{(i)}],$$

where $u_j^{(i)} = -\Gamma_j^{(i)}$, $j = 1, 2, \ldots, m(i) - r(i)$, and 0 elsewhere.

Form $t_{(j)} = [\delta_1^{(i)}, \delta_2^{(i)}, \ldots, \delta_{n-1}^{(i)}, 0]^T$.

Stage III. Form the vector $u = [u_{(1)}, u_{(2)}, \ldots, u_{(p)}]^T$.

Stage IV. Solve for g:

$$g^T T = u^T,$$

where

$$T = [t_{(1)}, t_{(2)}, \ldots, t_{(p)}]$$

and $t_{(i)}$ is

$$t_{(i)} = [t_1^{(i)}, t_2^{(i)}, \ldots, t_{m(i)}^{(i)}].$$

Stage V. Compute $f^T = g^T Q$.

The following theorem proves the validity of Algorithm II.

THEOREM 3. *Let (H, c) be a controllable pair. Let $\Omega = \{\mu_1, \mu_2, \ldots, \mu_p\}$ be an arbitrary conjugated complex number set. Suppose that the multiplicity of μ_i is $m(i)$ and $r(i)$ in Ω and $\sigma(H)$, respectively, $i = 1, 2, \ldots, p$. Then the solutions of the systems*

$$(H - \mu_i I)t_j^{(i)} = t_{j+1}^{(i)} + \beta_j^{(i)} c,$$

$$j = 1, 2, \ldots, m(i), \qquad i = 1, 2, \ldots, p$$

are linearly independent, where

(a) $t_{m(i)+1}^{(i)} = 0$.

(b) *If $\mu_i \notin \sigma(H)$, then $\beta_{m(i)}^{(i)} = 1$ and $\beta_j^{(i)} = 0$ for $j = m(i) - 1, m(i) - 2, \ldots, 2, 1$.*

(c) *If $\mu_i \in \sigma(H)$ and*

(c1) *$r(i) \geq m(i)$, then $\beta = 0$, $j = m(i), m(i) - 1, \ldots, 2, 1$.*

(c2) *$r(i) < m(i)$, then $\beta_j^{(i)} = 0$, $j = m(i), \ldots, m(i) - r(i) + 1$ and the others $\beta_j^{(i)}$ are calculated by* (16).

Proof. We need to prove that the matrix

$$T = [t_{(1)}, t_{(2)}, \ldots, t_{(p)}],$$

where

$$t_{(i)} = [t_1^{(i)}, t_2^{(i)}, \ldots, t_{m(i)}^{(i)}], \qquad i = 1, 2, \ldots, p$$

is nonsingular. We will proceed in three steps.

Step 1. $\mu_i \notin \sigma(H)$. We can proceed by induction on $m(i)$ as in the proof of Proposition 3. We start in this case in the reverse order because the first linear system we solve is $(H - \mu_i I)t_{m(i)}^{(i)} = c$. Then we obtain that the rank of

$$t_{(i)} = [t_1^{(i)}, t_2^{(i)}, \ldots, t_{m(i)}^{(i)}]$$

corresponding to this eigenvalue is $m(i)$.

Step 2. $\mu_i \in \sigma(H)$. Taking into account the structure of the particular solutions (14) and (18), the block

$$t_{(i)} = [t_1^{(i)}, t_2^{(i)}, \ldots, t_{m(i)}^{(i)}]$$

has rank $m(i)$.

Step 3. It remains to prove the independence of the blocks $t_{(i)}$ of T corresponding to the eigenvalues μ_i for all $i = 1, 2, \ldots, p$. For that, proceeding similarly to the proof

of Proposition 3, we obtain that T is nonsingular. In this case, again, the induction is applied in the reverse order as Step 1 of this theorem. □

6. Results. In this section we present numerical results obtained by our algorithms on two test problems: the Frank and Wilkinson matrices. These matrices were used in [3] as test matrices.

The accuracy obtained compares favorably with that obtained by Datta and Datta [4] in their algorithm. We performed experiments with Algorithms I and II. MATLAB [8] was used for implementing our algorithms.

Example 1. The Wilkinson matrix

$$W = \begin{bmatrix}
20 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
20 & 19 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\

BACKWARD ERROR ESTIMATES FOR TOEPLITZ SYSTEMS*

J. M. VARAH†

Abstract. Given a computed approximate solution $\bar{x}$ to $Ax = b$, it is interesting to find nearby systems with $\bar{x}$ as exact solution and that have the same structure as A. This paper shows that the distance to these nearby structured systems can be much larger than for the corresponding general perturbation for general and symmetric Toeplitz systems. In fact, even the correctly rounded solution $\hat{x}$ may require a structured perturbation with terms as large as $\|\hat{x}\|$ times the machine precision.

Key words. backward error, stability, Toeplitz system

AMS subject classifications. 65F05, 65F35

1. Introduction. Given the linear system $Ax = b$ and a computed solution $\bar{x}$, it is interesting to find nearby systems for which $\bar{x}$ is the exact solution. That is, to find δA and δb such that

$$(A + \delta A)\bar{x} = b + \delta b \tag{1.1}$$

with δA and δb small. If we define the associated residual vector

$$r = r(\bar{x}) = b - A\bar{x},$$

then (1.1) becomes

$$(\delta A)\bar{x} = r + \delta b. \tag{1.2}$$

If we consider general perturbations δA and δb, then conditions (1.1) or (1.2) do not specify them fully, and we must impose additional conditions (such as minimizing some measure of the size of δA and δb). If however the matrix A has some special form, and we are interested in maintaining this form in the allowable perturbations, then the solution of (1.1) or (1.2) becomes more complicated. In this paper, we consider the case of A being of Toeplitz form. This issue of restricted perturbations for structured systems has also been considered by Higham and Higham [7] who provide a framework for dealing with general structured perturbations and define the notion of structured condition numbers. They use Toeplitz matrices as one of their examples, and the work presented here should be considered as an extension of their work.

Note that the scaling of the problem is important; we assume throughout that $\|A\| \simeq 1$ and $\|b\| \simeq 1$, so that ill conditioning of A is reflected in $\|x\|$ being (possibly) large, but not small. We assume Hölder vector norms and corresponding subordinate matrix norms. Then, in fact,

$$\frac{\|b\|}{\|A\|} \leq \|x\| \leq \kappa(A)\left(\frac{\|b\|}{\|A\|}\right),$$

where $\kappa(A) = \|A\|\,\|A^{-1}\|$ is the (standard) condition number of A in any norm. We also assume throughout that A is nonsingular.

† Computer Science Department, University of British Columbia, Vancouver, British Columbia, Canada V6T 1W5 (varah@cicsr.ubc.ca).

To get some sense of the size of the residual $r(\bar{x})$, it is useful to consider what happens in the best possible case, when $\bar{x} = \hat{x}$, the correctly rounded solution. Since

$$\hat{x}_i = x_i(1 + \eta_i),$$

where $|\eta_i| \leq \eta$ = machine round-off level, we can write

$$\hat{x} = (I + D_\eta)x,$$

and then

$$r = r(\hat{x}) = b - A\hat{x} = -AD_\eta x, \tag{1.3}$$

giving

$$\frac{\|r\|}{\|x\|} \leq \eta\|A\|.$$

In particular, $\|r\|/\|x\| \simeq \eta$ independent of the solution x. We also remark that (1.3) implies

$$|r| \leq \eta|A|\,|x|, \tag{1.4}$$

where the inequality is meant to be taken componentwise.

Thus, the most we can expect for a computed solution $\bar{x}$ is that $\|r(\bar{x})\|/\|\bar{x}\| \simeq \eta$. Such behaviour occurs, for example, with solutions computed by Gaussian elimination with partial pivoting (generally) or with Cholesky factorization on positive definite symmetric systems. As a result, it is not generally appropriate to solve (1.1) or (1.2) by taking $\delta A = \mathrm{O}$. This gives $\delta b = -r$, which for $\|\bar{x}\|$ large means a large backward error $\|\delta b\| = \|r\| \simeq \eta\|\hat{x}\|$ even for the correctly rounded solution. Instead, one attempts to find solutions δA, δb with

$$\max(\|\delta A\|, \|\delta b\|) \leq c\left(\frac{\|r\|}{\|x\|}\right) \tag{1.5}$$

for c some constant close to 1.

Allowing general perturbations δA, δb, one can indeed find solutions satisfying (1.5), as has been known for some time, and we review this material in §2. See, also, the excellent survey paper by Higham [6]. Then in §3 we consider symmetric Toeplitz perturbations of symmetric Toeplitz matrices. We are motivated to do this from interest in the stability properties of special methods available for solving Toeplitz systems, such as the Levinson method (see Golub and Van Loan [5, p. 183], for example). One might hope that the computed solution obtained from such a method is the exact solution of a nearby Toeplitz system. Indeed, Bunch [3] refers to this behaviour as "strong stability." However, we find that under these restrictions, the perturbations δA and δb satisfy not (1.5), but

$$\max(\|\delta A\|, \|\delta b\|) \leq c\|r\|. \tag{1.6}$$

This means that for ill-conditioned Toeplitz systems, computed solutions (even correctly rounded solutions) satisfy Toeplitz systems that are as much as $\kappa(A)\eta$ away from the original system. We illustrate this behaviour with some numerical examples in §4. Finally in §5, we discuss the same problem for general Toeplitz systems, where the conclusion is similar.

2. General backward error. Consider the basic system (1.2). The equations decouple and we consider the first one in detail:

$$((\delta A)_{11} \cdots (\delta A)_{1n})\bar{x} = r_1 + (\delta b)_1.$$

If $r_1 = 0$, we can take all unknowns = 0. So assume that $r_1 \neq 0$ and let

$$(\delta A)_{1i} = r_1 e_i z_i, \qquad (\delta b)_1 = r_1 f y,$$

where $\{e_i\}_1^n$ and f are fixed scaling factors and $\{z_i\}_1^n$ and y are to be determined. Then the defining equation can be written

$$(e_1\bar{x}_1 \cdots e_n\bar{x}_n - f)\begin{pmatrix} z_1 \\ \vdots \\ z_n \\ y \end{pmatrix} = 1 \tag{2.1}$$

or $u^T v = 1$.

Normally, besides satisfying (2.1), we want to make the perturbations as small as possible in some sense, which amounts to minimizing $\|v\|$ for some norm. In particular, if we use a Hölder norm $\|v\|_q$, with $\frac{1}{p} + \frac{1}{q} = 1$,

$$1 = |u^T v| \leq \|u\|_p \|v\|_q$$

for any u and v satisfying (2.1), and

$$\min_v \|v\|_q = \frac{1}{\|u\|_p}.$$

We could use $p = q = 2$, but it is more natural to use $p = 1$, $q = \infty$, giving

$$\min_v \|v\|_\infty = \frac{1}{\|u\|_1} = \frac{1}{f + \sum e_i |\bar{x}_i|}, \tag{2.2}$$

which is attained by using v with $v_i = \operatorname{sgn}(u_i)/\|u\|_1$.

This max norm solution translates into

$$(\delta A)_{1i} = \frac{\pm r_1 e_i}{f + \sum e_i |\bar{x}_i|}, \qquad \delta_1 = \frac{\pm r_1 f}{f + \sum e_i |\bar{x}_i|},$$

which replicates the Oettli–Prager result [8] for general scaling factors E and f. One particular case deserves special mention: $e_i = \|A\|, f = \|b\|$. Then

$$(\delta A)_{1i} = \frac{\pm r_1 \|A\|}{\|b\| + \|A\| \, \|\bar{x}\|_1}, \qquad (\delta b)_1 = \frac{\pm r_1 \|b\|}{\|b\| + \|A\| \, \|\bar{x}\|_1},$$

and similarly for the other rows. Note that in this case, we do obtain

$$\max(\|\delta A\|, \|\delta b\|) \leq c\left(\frac{\|r\|}{\|\bar{x}\|}\right)$$

as predicted in §1, where c involves $\|A\|$ and $\|b\|$, and is close to 1.

3. The symmetric Toeplitz case. Now assume A is a symmetric Toeplitz matrix, and that we want δA to be symmetric and Toeplitz as well. That is,

$$\delta A = \begin{bmatrix} \varepsilon_0 & \varepsilon_1 & \cdots & \varepsilon_{n-1} \\ \varepsilon_1 & \varepsilon_0 & \cdots & \varepsilon_{n-2} \\ \vdots & \vdots & \ddots & \vdots \\ \varepsilon_{n-1} & \cdots & \cdots & \varepsilon_0 \end{bmatrix}.$$

In the defining equation (1.2), the key observation (noted also in [7]) is to rewrite $(\delta A)\bar{x}$ as $X\varepsilon$, where ε is the vector $(\varepsilon_0, \ldots, \varepsilon_{n-1})^T$ and (for n odd):

$$X = \begin{bmatrix} \bar{x}_1 & \bar{x}_2 & \bar{x}_3 & \cdots & \cdots & \cdots & \bar{x}_{n-1} & \bar{x}_n \\ \bar{x}_2 & (\bar{x}_1 + \bar{x}_3) & \bar{x}_4 & \cdots & \cdots & \cdots & \bar{x}_n & 0 \\ \bar{x}_3 & (\bar{x}_2 + \bar{x}_4) & (\bar{x}_1 + \bar{x}_5) & \cdots & \cdots & & & \vdots \\ \vdots & & & \ddots & & & & \vdots \\ \bar{x}_{(n+1)/2} & \cdots & \cdots & \cdots & (\bar{x}_1 + \bar{x}_n) & 0 & \cdots & 0 \\ \vdots & & & & & \ddots & & \vdots \\ \bar{x}_{n-1} & (\bar{x}_{n-2} + \bar{x}_n) & \bar{x}_{n-3} & \cdots & \cdots & \cdots & \bar{x}_1 & 0 \\ \bar{x}_n & \bar{x}_{n-1} & \bar{x}_{n-2} & \cdots & \cdots & \cdots & \bar{x}_2 & \bar{x}_1 \end{bmatrix}. \tag{3.1}$$

For n even, the middle row and column are not present. Note that each $\bar{x}_i$ appears once in each row, and note that $\|X\|_\infty = \|\bar{x}\|_1$. Also, note that X can be singular: if $\sum \bar{x}_i = 0$ for example, then $Xe = 0$ for $e = (1, 1, \ldots, 1)^T$. On the other hand, $\bar{x} = (1, 0, \ldots, 0)^T$ gives $X = I$, the identity matrix.

Using this matrix, the defining equation (1.2) reads

$$X\varepsilon - \delta = r,$$

where $\delta = \delta b$, which is n equations in the $2n$ unknowns ε and δ. This can also be expressed as

$$(X - I)\begin{pmatrix} \varepsilon \\ \delta \end{pmatrix} = r \quad \text{or} \quad Gv = r. \tag{3.2}$$

Again, we would like the perturbation to be as small as possible, and thus we are led to the constrained optimization problem

$$\min_v \|v\| \quad \text{with } Gv = r.$$

Note that we can include componentwise scaling factors in ε, δ by using diagonal scaling factors D_e, D_f giving $G = (XD_e - D_f)$.

Again, the most natural norm is $\|v\|_\infty$ giving a constrained Chebyshev optimization problem, which can be rewritten using $\delta = X\varepsilon - r$ as the overdetermined discrete Chebyshev problem

$$\min_\varepsilon \left\| \begin{pmatrix} X \\ I \end{pmatrix}\varepsilon - \begin{pmatrix} r \\ 0 \end{pmatrix} \right\|_\infty.$$

This problem is difficult to solve explicitly, although algorithms have been developed to solve individual cases (see [1] or [2]). The basic question here is whether the solution $\|v\|_\infty \simeq \|r\|/\|\bar{x}\|$.

The following example shows that this is not always true, and the consequence is that even for a rounded solution $\hat{x}$, the closest perturbed symmetric Toeplitz system with $\hat{x}$ as exact solution can be $\eta\|\hat{x}\|$ away.

Example.

$$A = \begin{bmatrix} 1 & 1-\mu & 1-\alpha \\ 1-\mu & 1 & 1-\mu \\ 1-\alpha & 1-\mu & 1 \end{bmatrix}$$

with μ and α small and positive. (In fact, μ is not crucial in what follows.) One eigenvalue $\lambda_1 = \alpha$ with corresponding eigenvector $(1, 0, -1)^T$.

Hence when $b = (1, 0, -1)^T$, the solution $x = \frac{1}{\alpha}(1, 0, -1)^T$. Now take the rounded solution $\hat{x} = \frac{1}{\alpha}(1 + \eta_1, 0, -(1 + \eta_3))^T$. A short calculation gives, using $\hat{\eta} = \eta_1 - \eta_3$,

$$r(\hat{x}) = -\frac{\hat{\eta}}{\alpha}(1, 1, 1)^T + 0(\eta)$$

and

$$X = \frac{1}{\alpha}\begin{bmatrix} 1 + \eta_1 & 0 & -(1 + \eta_3) \\ 0 & \hat{\eta} & 0 \\ -(1 + \eta_3) & 0 & 1 + \eta_1 \end{bmatrix}.$$

Thus the equations $Gv = r$ are (to first order in η):

$$(1 + \eta_1)v_1 - (1 + \eta_3)v_3 - \alpha v_4 = -\hat{\eta},$$

$$\hat{\eta}v_2 - \alpha v_5 = -\hat{\eta},$$

$$-(1 + \eta_3)v_1 + (1 + \eta_1)v_3 - \alpha v_6 = -\hat{\eta}.$$

It is easy to see that the minimax solution of these equations has all $|v_i| = |\hat{\eta}|/(\alpha + \hat{\eta})$. In fact,

$$v_1 = v_2 = v_3 = -\hat{\eta}/(\alpha + \hat{\eta}), \qquad v_4 = v_5 = v_6 = \hat{\eta}/(\alpha + \hat{\eta}).$$

Hence, for this example, we have explicitly

$$\frac{\|\hat{x} - x\|}{\|x\|} \simeq \eta, \qquad \frac{\|r(\hat{x})\|}{\|x\|} \simeq \eta,$$

$$\|\delta A\| = \|\delta b\| \simeq \frac{\eta}{\alpha}.$$

Also, one can find a much closer *general* perturbation δA with $(A + \delta A)\hat{x} = b$; in fact

$$\delta A = \frac{-\hat{\eta}}{2}\begin{bmatrix} 1 & 0 & -1 \\ 1 & 0 & -1 \\ 1 & 0 & -1 \end{bmatrix} + 0(\eta^2).$$

Later on, we provide numerical evidence of the same behaviour, using rounded solutions, and solutions computed by the Cholesky and Levinson algorithms. All exhibit the same behavior as above.

Now return to the basic problem (3.2). Although an explicit form of the solution in the max norm is not available, we can find an approximate solution by solving the corresponding constrained least squares problem

$$\min \|v\|_2 \quad \text{with } Gv = r.$$

If $M_2 = \min_v \|v\|_2$ and $M_\infty = \min_v \|v\|_\infty$, then

$$\frac{1}{\sqrt{n}} M_2 \leq M_\infty \leq M_2,$$

and hence the solutions differ in value by at most a factor $\sqrt{n}$.

Moreover, the constrained least squares solution has a simple form

$$v = G^T z, \qquad Gv = r,$$

where z is the vector of Lagrange multipliers (see, for example, [4, p. 156]). That is,

$$(I + XX^T)z = r, \qquad \begin{pmatrix} \varepsilon \\ \delta \end{pmatrix} = \begin{pmatrix} X^T z \\ -z \end{pmatrix}. \tag{3.3}$$

Alternatively, one can solve the overdetermined problem

$$\min_{\varepsilon} \left\| \begin{pmatrix} X \\ I \end{pmatrix} \varepsilon - \begin{pmatrix} r \\ 0 \end{pmatrix} \right\|_2,$$

with solution $(I + X^T X)\varepsilon = X^T r$ and $\delta = X\varepsilon - r$.

Note that from this formulation, it easily follows that if $r(\bar{x})$ is such that $r^T X = 0$, then $\varepsilon = 0$ and $\delta = -r$, which gives a solution (as we mentioned earlier) that is unacceptably large when $\|\bar{x}\|$ is large. However, this is by no means the only troublesome case, as we see below.

Of course, the more acceptable computational method for finding v, at least in cases where X is ill conditioned, is to use the QR decomposition (Golub and Van Loan [5, p. 567]):

(i) $$\text{set } G^T = \begin{pmatrix} X^T \\ -I \end{pmatrix} = Q \begin{pmatrix} R \\ 0 \end{pmatrix} = (Q_1 \mid Q_2) \begin{pmatrix} R \\ 0 \end{pmatrix},$$

(ii) $$\text{find } w = Q^T v \text{ via } \begin{Bmatrix} R^T w^{(1)} = r \\ w^{(2)} = 0 \end{Bmatrix},$$

(iii) $$\text{find } v = Qw = Q_1 w^{(1)}.$$

An even more explicit formulation of the minimum least squares solution can be derived from (3.3) using the singular value decomposition (SVD).

THEOREM 1. *Let $X = UDV^T$ be the* SVD *of the matrix X in* (3.1), *and let $r = \sum \beta_i u^{(i)}$ be the expansion of $r = r(\bar{x})$ in the singular vectors $\{u^{(i)}\}$. Then the solution z to* (3.3) *has the expansion*

$$z = \sum \left(\frac{\beta_i}{1 + \sigma_i^2} \right) u^{(i)},$$

and the minimal least squares solution v has

$$\|v\|_2^2 = z^T r = \sum \frac{\beta_i^2}{1 + \sigma_i^2}.$$

Proof. The proof follows by substitution.

Theorem 1 above gives a reformulation of the minimum restricted perturbation in the ℓ_2 sense, which makes $\bar{x}$ exact. This basic result can be applied in various ways as we now explore.

THEOREM 2. *Suppose that the computed solution $\bar{x}$ is such that the* SVD *coefficients $\{\beta_i\}$ of $r(\bar{x})$ satisfy*

$$|\beta_i| \leq c\sqrt{1 + \sigma_i^2}\,\eta$$

for c not much bigger than 1. *Then $\|v\|_2 \leq c\sqrt{n}\,\eta$, and hence the minimum perturbation is close to the round-off level.*

Proof. Again, the proof follows by direct substitution.

To clarify the situation, it helps to separate the cases where the solution x does and does not reflect the ill condition of A. When x does not, that is, when $\|x\| \simeq 1$, Theorem

2 applies as long as the computed solution $\bar{x}$ produces $\|r(\bar{x})\|$ close to the round-off level η. Since $\|X\|_\infty = \|\bar{x}\|_1$, $1 \simeq \sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_n$, and the requirements of Theorem 2 hold since the $\{\beta_i\}$ are all at the round-off level. Note that the near singularity of X is immaterial in this case.

Now consider large $\|x\|$, and recall that $\|x\|$ can be as large as $\kappa(A)$. Assume that $\bar{x}$ produces a residual with $\|r(\bar{x})\| \simeq \eta\|\bar{x}\|$, as occurs with $\bar{x} = \hat{x}$, the correctly rounded solution. Then *some* $\{\beta_i\}$ are also this large, and *some* $\{\sigma_i\}$ are as large as $\|\bar{x}\|$. If the large $\{\beta_i\}$ occur *only* for large $\{\sigma_i\}$, then the conditions required for Theorem 2 still hold. However, experimental evidence with ill-conditioned symmetric positive definite Toeplitz systems indicates that typically *all* $\beta_i \simeq \eta\|\bar{x}\|$, whether $\bar{x}$ is the correctly rounded solution, the Cholesky solution, or the solution computed using the Levinson algorithm. We present some examples in the next section. We can quantify the situation as follows: Assume that

$$\beta_i = c_i\eta\|\bar{x}\| \text{ with } |c_i| \leq \bar{c},$$
$$\sqrt{1+\sigma_i^2} = d_i\|\bar{x}\| \quad \text{for } i = 1, \ldots, n.$$

Note that $1 \simeq d_1 \geq d_2 \geq \cdots \geq d_n \geq 1/\|\bar{x}\|$.

THEOREM 3. *With the above definitions of* $\{c_i\}$ *and* $\{d_i\}$,

$$\min \|v\|_2 = \eta\left(\sum_1^n \frac{c_i^2}{d_i^2}\right)^{1/2}.$$

Thus

$$\eta|c_n|\frac{\|\bar{x}\|}{\sqrt{1+\sigma_n^2}} \leq \min\|v\|_2 \leq \eta n\bar{c}\frac{\|\bar{x}\|}{\sqrt{1+\sigma_n^2}}. \tag{3.4}$$

Proof. Again, the proof follows by direct substitution.

Thus, the actual minimum symmetric Toeplitz perturbation is very dependent on the particular problem and can vary in size from η to $\kappa(A)\eta$. To realize a large perturbation, the data vector b must give rise to a solution x that reflects the ill condition of A and that also results in an appreciable spread in the singular values of the matrix X.

4. Some numerical results. The first example is the 3×3 matrix from §3:

$$A = \begin{bmatrix} 1 & 1-\mu & 1-\alpha \\ 1-\mu & 1 & 1-\mu \\ 1-\alpha & 1-\mu & 1 \end{bmatrix}.$$

We took $\alpha = 10^{-6}$, $\mu = \frac{\alpha}{3}$. A has then two eigenvalues near 10^{-6}. For various data vectors b, we computed solutions to $Ax = b$ as follows:

(i) $\bar{x}$ = Cholesky solution,

(ii) $\bar{\bar{x}}$ = Levinson solution,

(iii) $\hat{x}$ = Correctly rounded solution, obtained from $\bar{x}$ using double precision iterative refinement.

Working precision was long precision on an IBM mainframe, with special routines for "double long" calculations, so that $\eta \simeq 10^{-16}$. For each approximate solution, we computed the residual r, the minimal least squares solution $v = \binom{\varepsilon}{\delta}$ from (3.3), the singular values $\sigma_i(X)$, and the coefficients $\beta_i(r)$.

In Case 1 below, b reflects the ill condition of A and $\|x\|$ is large. For each approximate solution, the closest symmetric Toeplitz system with that exact solution is roughly

$\eta\|x\|$ away. In Case 2, however, $\|x\|$ is near 1 and, even though X is singular, the smallest perturbation is now close to the round-off level η.

Case 1.

$$b = (-0.72, 0.55, 0.22)^T, \qquad \|x\|_\infty = 4.8 \times 10^6,$$

$$\sigma_i(X)\text{: } 1.0 \times 10^7, \quad 2.9 \times 10^6, \quad 0.32.$$

	$\|r\|_\infty$	$\|v_{\min}\|_2$	β
$\bar{x}$	1.0×10^{-10}	4.7×10^{-11}	$-.25 \times 10^{-10}$, $-.14 \times 10^{-9}$, $.50 \times 10^{-10}$.
$\bar{\bar{x}}$	3.2×10^{-10}	3.9×10^{-11}	$-.15 \times 10^{-9}$, $-.33 \times 10^{-9}$, $-.41 \times 10^{-10}$.
$\hat{x}$	1.8×10^{-10}	8.7×10^{-11}	$-.86 \times 10^{-10}$, $.28 \times 10^{-9}$, $-.92 \times 10^{-10}$.

Case 2.

$$b = (-0.58, -.58, 0.58)^T \|x\|_\infty = 0.19,$$

$$\sigma_i(X)\text{: } .60, \quad .21, \quad .84 \times 10^{-9}.$$

	$\|r\|_\infty$	$\|v_{\min}\|_2$	β
$\bar{x}$	1.0×10^{-17}	1.4×10^{-17}	$-.16 \times 10^{-16}$, $.47 \times 10^{-18}$, $.93 \times 10^{-18}$.
$\bar{\bar{x}}$	2.4×10^{-17}	3.2×10^{-17}	$-.37 \times 10^{-16}$, $.37 \times 10^{-17}$, $.31 \times 10^{-17}$.
$\hat{x}$	2.1×10^{-17}	3.1×10^{-17}	$.36 \times 10^{-16}$, $-.40 \times 10^{-17}$, $-.88 \times 10^{-26}$.

As a second example, consider the prolate matrix (see Slepian [9]) of order 11 with $a_{ij} = \gamma_{|j-i|}$,

$$\gamma_k = \frac{\sin(\pi k/2)}{\pi k}, \qquad \gamma_0 = \frac{1}{2}.$$

This matrix is positive definite symmetric and Toeplitz and its smallest eigenvalue λ_1 is near 10^{-7}. Generally, the behaviour with various data vectors b is similar to that of the first example, and we mention only one case where b is the eigenvector corresponding to λ_1. For this case (and for b = other eigenvectors as well), the matrix X is near singular, giving more than enough spread in the singular values to result in a minimum perturbation of nearly $\kappa(A)\eta$. The β-coefficients are all near 10^{-10}.

$$b = \text{first eigenvector}, \qquad \|x\|_\infty = 5.4 \times 10^6,$$

$$\sigma_i(X)\text{: } 3.3 \times 10^7, \ldots, \qquad 7.3 \times 10^{-8}.$$

	$\|r\|_\infty$	$\|v_{\min}\|_2$
$\bar{x}$	3.1×10^{-10}	2.5×10^{-10}.
$\bar{\bar{x}}$	1.5×10^{-10}	1.1×10^{-10}.
$\hat{x}$	3.7×10^{-11}	2.1×10^{-11}.

5. The general Toeplitz case. If A is a general (unsymmetric) Toeplitz matrix, and we allow similar perturbations δA, then

$$\delta A = \begin{bmatrix} \varepsilon_0 & \varepsilon_1 & \cdots & \varepsilon_{n-1} \\ \varepsilon_{-1} & \varepsilon_0 & \cdots & \varepsilon_{n-2} \\ \vdots & \ddots & \ddots & \vdots \\ \varepsilon_{-n+1} & \cdots & \varepsilon_{-1} & \varepsilon_0 \end{bmatrix},$$

giving $(2n-1)$ parameters $\{\varepsilon_i\}$, plus n more in δb. The defining equation (1.2) can again be rewritten

$$X\varepsilon - \delta = r \qquad \text{or} \quad (X-I)\begin{pmatrix}\varepsilon\\ \delta\end{pmatrix} = r \quad \text{or} \quad Gv = r,$$

as in (3.2), but now we have n equations in $(3n-1)$ unknowns, and X is the $n \times (2n-1)$ matrix

$$\begin{bmatrix} \bar{x}_1 & \bar{x}_2 & \cdots & \bar{x}_n & 0 & \cdots & 0 \\ 0 & \bar{x}_1 & \bar{x}_2 & \cdots & \bar{x}_n & & \vdots \\ \vdots & \ddots & \ddots & & & \ddots & 0 \\ 0 & \cdots & 0 & \bar{x}_1 & \bar{x}_2 & \cdots & \bar{x}_n \end{bmatrix}. \tag{5.1}$$

(We have reversed the order of the equations to make X look triangular.)

The situation now is somewhat different from the symmetric case discussed in §3, although the theorems still apply. There are more parameters and thus fewer restrictions on the perturbations. This is manifested in X (or really the rows of X) being better conditioned than the X of §3, making it harder to effect a large minimum perturbation.

It is instructive to compare results with those of §3. Take again the prolate matrix with $n = 11$; for the correctly rounded solution $\hat{x}$, the results are as follows:

$$b = \text{first eigenvector}, \qquad \|\hat{x}\|_\infty = 5.4 \times 10^6,$$
$$\sigma_i(X)\text{: } 2.4 \times 10^7, \ldots, 3.3 \times 10^3.$$

$\|r\|_\infty$	$\|v_{\min}\|_2$
3.7×10^{-11}	1.0×10^{-14}

(In all the examples quoted here, the $\{\beta_i\}$ were all in magnitude close to $\eta\|\hat{x}\|$.) Note that the spread in X's singular values is much less here with a corresponding decrease in the size of the perturbation.

One can increase the perturbation by taking a larger n. For $n = 15$, the results are

$$b = \text{first eigenvector}, \qquad \|\hat{x}\|_\infty = 4.8 \times 10^9,$$
$$\sigma_i(X)\text{: } 2.6 \times 10^{10}, \ldots, 1.0 \times 10^5.$$

$\|r\|_\infty$	$\|v_{\min}\|_2$
2.0×10^{-7}	3.3×10^{-12}

In both examples, note that the minimum ℓ_2 perturbation lies *between* the round-off level and the size of the residual in accordance with (3.4). In particular, to effect a minimum perturbation as large as $\kappa(A)\eta$, the vector $\bar{x}$ must yield a matrix X with $\kappa(X)$ approaching $\kappa(A)$.

Acknowledgment. The author would like to thank the (anonymous) referees for suggestions that significantly improved the paper.

MOORE–PENROSE INVERSION OF SQUARE TOEPLITZ MATRICES*

GEORG HEINIG† AND FRANK HELLINGER†

Abstract. Fast algorithms for the computation of the Moore–Penrose inverse A^+ of a square Toeplitz matrix A are constructed based on Bezoutian representations of A^+. Two approaches are presented. The first approach is a recursion of the nested submatrices, the second approach uses generalized inverses of A that are Bezoutians and a global formula.

Key words. Toeplitz matrix, Moore–Penrose inverse, fast algorithm

AMS subject classifications. 15A09, 47B35, 65F20

1. Introduction.

In this paper we consider square Toeplitz matrices

$$A = \begin{bmatrix} a_0 & a_{-1} & \dots & a_{-n+1} \\ a_1 & a_0 & \dots & a_{-n+2} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n-1} & a_{n-2} & \dots & a_0 \end{bmatrix} \tag{1.1}$$

with complex entries $a_i \in \mathbb{C}$. The main aim is the construction of fast algorithms for the computation of the Moore–Penrose inverse (MPI) of A. Algorithms presented in this paper are based on a matrix representation for the MPI of A that was established for the Hankel analogues in the authors' paper [8]. In this sense, this paper is a continuation of [8]; however, we tried to make the presentations fairly self-contained. Recall that the MPI of a matrix C is a matrix C^+ defined by the following four relations:

$$CC^+C = C, \tag{1.2a}$$

$$C^+CC^+ = C^+, \tag{1.2b}$$

$$(CC^+)^* = CC^+, \tag{1.2c}$$

$$(C^+C)^* = C^+C. \tag{1.2d}$$

Here the asterisk denotes the conjugate complex transpose. The MPI exists always and is unique.

When speaking about fast algorithms, we have in mind algorithms that have a computational complexity of less than $O(n^3)$. Actually, the algorithms presented in this paper have complexity $O(n^2)$ or less.

Before explaining our approach for the Moore–Penrose (MP) inversion of Toeplitz matrices, let us remember some facts concerning Toeplitz matrix inversion. The history starts with the famous paper of Levinson [17], in which, in principle, an algorithm for the fast solution of linear systems with a positive definite Toeplitz coefficient matrix is presented. The algorithm was further developed by other authors. A fast algorithm for the inverse matrix was first presented by Trench [21]. Other relevant sources are, for

instance, [5] and [23]. In [6], formulas for the inverse of a Toeplitz matrix A are established, which have the form

$$A^{-1} = L_1U_1 - L_2U_2, \tag{1.3}$$

where L_1, L_2 are certain lower and U_1, U_2 are upper triangular Toeplitz matrices. The entries of these matrices are determined by the first and last columns of A^{-1}. The importance of the formula consists of the fact that it allows the solution of a system $Ax = b$ with complexity $O(n \log n)$, since multiplication of a vector by a triangular Toeplitz matrix requires $O(n \log n)$ flops if the fast Fourier transform (FFT) is utilized.

To be more precise, let us note that (1.3) with L_1, L_2, U_1, U_2 being determined by the first and last columns of A^{-1} actually holds only under some additional conditions. Formulas of the form (1.3) without additional conditions can be established with the help of the concept of a fundamental system of A (see [9], [10], [11][1]).

If A is nonsingular then a fundamental system is, by definition, a basis of the (two-dimensional) kernel of the $(n-1) \times (n+1)$ matrix $(a_{i-j})_{i=1}^{n-1, n}_{j=0}$. The definition of the fundamental system concept in the singular case is given in §7.

From our viewpoint today, the construction of fast inversion algorithms for Toeplitz matrices, and other structured matrices as well, can be divided into two stages: (i) representation of A^{-1} with the help of a certain "fundamental system" (a system of $O(n)$ parameters), and (ii) evaluation of the fundamental system.

To construct fast algorithms for MP inversion, we also followed the two-stage strategy as for the inversion in the usual sense. In our paper [8], we discussed the first stage for Hankel matrices, even for the general rectangular case. The main result of this paper is that the MPI of a Hankel matrix is a 4-Bezoutian. For Toeplitz matrices, this means that there is a formula of the form (1.3) for A^+ with the difference that four instead of two matrix products are involved. The precise formulation of the corresponding result and the idea of the proof are presented in §2.

In our situation, a fundamental system is by definition a basis of a four-dimensional space, which is the kernel of a certain matrix related to A. Of course, there are many fundamental systems, but among them there are two "canonical" ones. These are fundamental systems from which we get the MPI of A immediately. However, it is sometimes convenient to use not the pure canonical systems, but a mixture of them.

The properties of the canonical systems and some of the relations between them are discussed in §3.

The main aim of this paper is to treat the second stage of MP inversion, i.e., the evaluation of a fundamental system. In view of the well-known algorithms for Toeplitz matrix inversion, the first idea is to consider two subsequent nested submatrices of the family $A^{(k)} = [a_{i-j}]_0^{k-1}$ $(k = 1, \ldots, n)$. It developed that the recursion formulas for the canonical fundamental systems are rather complicated, but quite a few other fundamental systems exist with simpler recursion formulas. One version is presented in §4.

The recursion formulas lead to an $O(n^2)$ complexity algorithm for the computation of the MPI of the Toeplitz matrix A, as shown in §5. This algorithm is of the Levinson type, which means that it involves inner product calculations; hence it is not very convenient for parallel computing. In §6 for one case we show that the algorithm has also a Schur-type version that avoids inner product calculations and leads to an $O(n)$ complexity algorithm for an n-processor computer.

---

[1] In [11] instead of "fundamental system" the name "characteristic polynomials" is used.

In §7 another approach for the evaluation of a fundamental system is presented. This approach is based on the fact that there are generalized inverses of A, i.e., matrices B satisfying condition (1.2a), which have the form (1.3) and can be computed with usual Toeplitz matrix inversion algorithms. If B is a generalized inverse of A, then

$$A^+ = (I - P)BQ, \tag{1.4}$$

where Q is the orthogonal projection onto Im A and P is the orthogonal projection onto ker A. The projections P and Q can also be determined by usual Toeplitz algorithms, and formula (1.4) can be transformed into a form containing only triangular Toeplitz matrices. This allows us to compute the vectors occurring in the matrix representation of A^+ with $O(n \log^2 n)$ complexity at a sequential or $O(n)$ complexity at an n-processor parallel computer.

We point out that the methods presented in this paper are only two of many thinkable possibilities for constructing fast algorithms for the MP inversion of Toeplitz matrices. Various other ideas evolve from the literature on least squares problems in adaptive filtering and related topics (see, e.g., [18]–[20] and references therein). One suggestion is to look for recursion formulas for the MPI of the rectangular Toeplitz matrices $\partial^k A$ that are introduced in §7. The recursion will start then with the MP inversion of a column vector, which is a simple task. Furthermore, it is interesting to study the behavior of the MPI after one row and one column extension, as it appears in adaptive filtering. Moreover, a QR decomposition approach seems to be convenient for MP inversion. We hope to connect these ideas with our approach and to continue the discussion on MP inversion of structured matrices in a subsequent paper.

Finally, let us define some notations. The elements of $\mathbb{C}^n$ are identified with column vectors and the components are numbered from 0 to $n - 1$. If $x \in \mathbb{C}^n$, then we denote by $(x)_k$ its $(k + 1)$th coefficient. For $x = (x_k)_0^{n-1}$, we denote by $x(\lambda)$ the polynomial $x(\lambda) = x_0 + x_1\lambda + \cdots + x_{n-1}\lambda^{n-1}$.

After this paper had been completed, Zhong [22] published an article containing formulas for the MPI of square Toeplitz matrices that are more involved (but are related to) than those we used in §2 as the starting point of our considerations.

2. Matrix representation of the MPI. For the construction of matrix representations of MPI of Toeplitz matrices, we employ the familiar extension approach described in Lemma 2.1 (cf. [3]).

LEMMA 2.1. *Let C be an arbitrary matrix, and let U and V be matrices the columns of which form a basis of the kernel of C, C^*, respectively. Then the matrix*

$$\mathscr{C} = \begin{bmatrix} C & V \\ U^* & 0 \end{bmatrix} \tag{2.1}$$

is nonsingular and the inverse has the form

$$\mathscr{C}^{-1} = \begin{bmatrix} C^+ & (U^*)^+ \\ V^+ & 0 \end{bmatrix}. \tag{2.2}$$

Now we consider the special case of a square Toeplitz matrix $C = A$. To get information about the structure of A^+, we utilize the following kernel structure property.

LEMMA 2.2. *Let A be a singular $n \times n$ Toeplitz matrix, and let $\kappa = \dim \ker A$ $(=n - \operatorname{rank} A)$. Then there exists a vector $u = (u_i)_0^r$, $r = n - \kappa$, such that the columns of the matrix*

$$M = \begin{bmatrix} u_0 & & 0 \\ \vdots & u_0 & \\ u_r & \vdots & \ddots \\ & u_r & & u_0 \\ & 0 & \ddots & \vdots \\ & & & u_r \end{bmatrix} \quad \text{(2.3)}$$

(κ columns)

form a basis of $\ker A$.

Lemma 2.2 was first stated and proved in a slightly different form in [7]. Concerning the case of rectangular Toeplitz matrices, we refer to [11] (see, also, [8]).

Let us note that the vector u is uniquely determined by A, up to a constant factor, and can be computed with the help of usual Toeplitz matrix inversion algorithms. The details are discussed in the Appendix.

Let J_n denote the matrix of the reflection operator,

$$J_n = \begin{bmatrix} 0 & & & 1 \\ & & \iddots & \\ & \iddots & & \\ 1 & & & 0 \end{bmatrix} \Bigg\} n.$$

Then we have

$$J_n A J_n = A^T;$$

hence

$$A^* = J_n \bar{A} J_n, \quad \text{(2.4)}$$

where the bar denotes the matrix with conjugate complex entries. From relation (2.4) we conclude that the columns of the matrix

$$N = \begin{bmatrix} \bar{u}_r & & 0 & \\ \vdots & \bar{u}_r & & \\ \bar{u}_0 & \vdots & \ddots & \\ & \bar{u}_0 & & \bar{u}_r \\ & 0 & \ddots & \vdots \\ & & & \bar{u}_0 \end{bmatrix} \quad \text{(2.5)}$$

form a basis of $\ker A^*$.

To compute the MPI of Toeplitz matrix $\mathscr{A}$, we must form the matrix

$$\mathscr{A} = \begin{bmatrix} A & N \\ M^* & 0 \end{bmatrix} \quad \text{(2.6)}$$

and evaluate its inverse. Matrix $\mathscr{A}$ is a matrix consisting of Toeplitz blocks. Such a matrix is called a *Toeplitz mosaic matrix*. The theory of Toeplitz mosaic matrices is quite similar

to the theory of block Toeplitz matrices and generalizes this theory, since any block Toeplitz matrix can be transformed into a Toeplitz mosaic matrix by permuting rows and columns. So it is shown (see [12]) that the inverse of a Toeplitz mosaic matrix is of a certain Bezoutian type, where the corresponding Bezoutian concept generalizes a concept of Anderson–Jury (see [2], [15], [16]).

If we apply the general result on the inverse of Toeplitz mosaic matrices in our special situation and consider the left upper corner of the inverse matrix; then we will obtain a representation of A^+ as a 4-Bezoutian, where the r-Bezoutian concept is understood in the sense of Lerer–Tismenetsky (see [15], [16]). We do not present the exact definition here, because in this paper we are dealing only with square Toeplitz matrices, and in this case all can be reduced to the classical Bezoutian concept. Concerning the rectangular case we refer to [8].

It is convenient to introduce classical Bezoutians with the help of their generating functions.

The generating function of a matrix $C = [c_{ij}]_0^{m-1,n-1}$ is defined as the polynomial in two variables

$$C(\lambda, \mu) = \sum_{i=0}^{m-1} \sum_{j=0}^{n-1} c_{ij}\lambda^i\mu^j.$$

DEFINITION 2.1. *An $n \times n$ matrix B is said to be a* (Toeplitz) Bezoutian *if and only if there are polynomials $a(\lambda)$, $b(\lambda)$ such that*

$$B(\lambda, \mu) = \frac{a(\lambda)b^{\#}(\mu) - b(\lambda)a^{\#}(\mu)}{1 - \lambda\mu}, \tag{2.7}$$

where

$$a^{\#}(\mu) = \mu^n a(\mu^{-1}), \qquad b^{\#}(\mu) = \mu^n b(\mu^{-1}).$$

The matrix B will be called the Bezoutian *of a and b and denoted by* Bez (a, b).

Bezoutians permit matrix representations that are very important from a computational viewpoint. We note one of these representations as follows:

$$\begin{aligned}\text{Bez}\,(a, b) = &\begin{bmatrix} a_0 & & & 0 \\ a_1 & a_0 & & \\ \vdots & \ddots & \ddots & \\ a_{n-1} & \cdots & a_1 & a_0 \end{bmatrix}\begin{bmatrix} b_n & b_{n-1} & \cdots & b_1 \\ & b_n & \ddots & \vdots \\ & 0 & \ddots & b_{n-1} \\ & & & b_n \end{bmatrix} \\ &- \begin{bmatrix} b_0 & & & 0 \\ b_1 & b_0 & & \\ \vdots & \ddots & \ddots & \\ b_{n-1} & \cdots & b_1 & b_0 \end{bmatrix}\begin{bmatrix} a_n & a_{n-1} & \cdots & a_1 \\ & a_n & \ddots & \vdots \\ & 0 & \ddots & a_{n-1} \\ & & & a_n \end{bmatrix}.\end{aligned} \tag{2.8}$$

There are many other representations of Bez (a, b). Among them are formulas involving circulant matrices that are, as shown in [1], more effective in numerical computation.

Furthermore, there are also recursion formulas of Trench type [21], e.g., let c_{ij} denote the entries of the matrix Bez (a, b), then

$$\begin{aligned} c_{i0} &= a_i b_n - b_i a_n, \\ c_{0j} &= a_0 b_{n-j} - b_0 a_{n-j}, \\ c_{ij} &= c_{i-1,j-1} + a_i b_{n-j} - b_i a_{n-j}, \qquad (i, j = 1, \ldots, n-1). \end{aligned} \tag{2.9}$$

As a consequence of the representation of the inverse of the Toeplitz mosaic matrix $\mathscr{A}$, we get the following theorem.

THEOREM 2.1. *Let A be a singular $n \times n$ Toeplitz matrix and let $\mathscr{A}$ be defined by* (2.6). *Furthermore, let the vectors $x_+, y_+, z_+, w_+ \in \mathbb{C}^n$, $\xi_+, \eta_+, \zeta_+, \omega_+ \in \mathbb{C}^\kappa$ be defined via equations*

$$\mathscr{A}\begin{bmatrix} x_+ \\ \xi_+ \end{bmatrix} = \begin{bmatrix} e_0 \\ 0 \end{bmatrix}, \qquad \mathscr{A}\begin{bmatrix} y_+ \\ \eta_+ \end{bmatrix} = \begin{bmatrix} g_+ \\ 0 \end{bmatrix}, \tag{2.10}$$
$$\mathscr{A}\begin{bmatrix} w_+ \\ \omega_+ \end{bmatrix} = \begin{bmatrix} 0 \\ e_0 \end{bmatrix}, \qquad \mathscr{A}\begin{bmatrix} z_+ \\ \zeta_+ \end{bmatrix} = \begin{bmatrix} h_+ \\ 0 \end{bmatrix},$$

where

$$e_0 = [1\ 0\ \cdots\ 0]^T, \qquad g_+ = [a_{-n}\ a_{1-n}\ \cdots\ a_{-1}]^T, \qquad h_+ = [0\ \cdots\ 0\ \bar{u}_r\ \cdots\ \bar{u}_1]^T,$$

0 *is a zero vector of suitable length, and a_{-n} is an arbitrary fixed number.*

Then

$$A^+ = \mathrm{Bez}\,(\tilde{y}_+, x_+) + \mathrm{Bez}\,(z_+, w_+), \tag{2.11}$$

where

$$\tilde{y}_+(\lambda) = y_+(\lambda) - \lambda^n.$$

The proof of the theorem is completely analogous to the corresponding Hankel matrix theorem that was stated and proved for the more general rectangular case in [8]. Therefore, we do not present it here.

The recursion formula (2.9) allows us to compute A^+ with an amount of $O(n^2)$ flops, provided that the vectors x_+, y_+, z_+, w_+ are known. Moreover, with the help of formula (2.8), any pseudo solution A^+y of a system $Ax = y$ can be computed with complexity $O(n \log n)$ if the FFT is utilized.

Vectors g_+ and h_+ appear as prolongation of the blocks in the matrix $\mathscr{A}$ to the right. If we take the analogous prolongation to the left, we get the formula described in the following theorem.

THEOREM 2.2. *Let A be a singular $n \times n$ Toeplitz matrix and let $\mathscr{A}$ be defined by* (2.6). *Furthermore, let vectors $x_-, y_-, z_-, w_- \in \mathbb{C}^n$, $\xi_-, \eta_-, \zeta_-, \omega_- \in \mathbb{C}^\kappa$ be defined via equations*

$$\mathscr{A}\begin{bmatrix} x_- \\ \xi_- \end{bmatrix} = \begin{bmatrix} e_{n-1} \\ 0 \end{bmatrix}, \qquad \mathscr{A}\begin{bmatrix} y_- \\ \eta_- \end{bmatrix} = \begin{bmatrix} g_- \\ 0 \end{bmatrix}, \tag{2.12}$$
$$\mathscr{A}\begin{bmatrix} w_- \\ \omega_- \end{bmatrix} = \begin{bmatrix} 0 \\ e_{\kappa-1} \end{bmatrix}, \qquad \mathscr{A}\begin{bmatrix} z_- \\ \zeta_- \end{bmatrix} = \begin{bmatrix} h_- \\ 0 \end{bmatrix},$$

where $e_{n-1}(e_{\kappa-1})$ is the last unit vector in $\mathbb{C}^n$ ($\mathbb{C}^\kappa$), $g_- = [a_1\ a_2\ \cdots\ a_n]^T$, $h_- = [\bar{u}_{r-1}\ \cdots\ \bar{u}_0\ 0\ \cdots\ 0]^T$, 0 is a zero vector of suitable length, and a_n is an arbitrary fixed number.

Then

$$A^+ = \mathrm{Bez}\,(\tilde{y}_-, \tilde{x}_-) + \mathrm{Bez}\,(\tilde{z}_-, \tilde{w}_-), \tag{2.13}$$

where $\tilde{x}_-(\lambda) = \lambda x_-(\lambda)$, $\tilde{y}_-(\lambda) = -1 + \lambda y_-(\lambda)$, $\tilde{w}_-(\lambda) = \lambda w_-(\lambda)$, and $\tilde{z}_-(\lambda) = \lambda z_-(\lambda)$.

3. Fundamental systems. In the previous section, we presented two formulas for the MPI of a Toeplitz matrix A. In this section we first show that there is actually a

variety of such formulas. This variety is connected with a four-dimensional space, and any choice of a basis corresponds with a representation of A^+. Later, it will be clear that a convenient choice of the basis has great influence on the complexity of the formulas and, therefore, of the algorithm.

Let us start with some notation. If $C = [c_{i-j}]_{i=0,j=0}^{p-1,q-1}$ is a $p \times q$ Toeplitz matrix, then ∂C will denote the $(p-1) \times (q+1)$ Toeplitz matrix

$$\partial C := [c_{i-j}]_{i=1,j=0}^{p-1,q}.$$

For $\mathscr{A}$ given by (2.6), we define

$$\partial\mathscr{A} = \begin{bmatrix} \partial A & \partial N \\ \partial M^* & 0 \end{bmatrix}. \tag{3.1}$$

Since $\mathscr{A}$ is nonsingular, $\partial\mathscr{A}$ has a kernel of dimension four.

DEFINITION 3.1. *Any basis of* $\ker \partial\mathscr{A}$ *is called a fundamental system of* $\mathscr{A}$.

We can observe immediately that the following two systems are fundamental:

$$X_+ = \begin{bmatrix} x_+ \\ 0 \\ \hline \xi_+ \\ 0 \end{bmatrix}, \quad Y_+ = \begin{bmatrix} y_+ \\ -1 \\ \hline \eta_+ \\ 0 \end{bmatrix}, \quad W_+ = \begin{bmatrix} w_+ \\ 0 \\ \hline \omega_+ \\ 0 \end{bmatrix}, \quad Z_+ = \begin{bmatrix} z_+ \\ 0 \\ \hline \zeta_+ \\ -1 \end{bmatrix} \tag{3.2}$$

and

$$X_- = \begin{bmatrix} 0 \\ x_- \\ \hline 0 \\ \xi_- \end{bmatrix}, \quad Y_- = \begin{bmatrix} -1 \\ y_- \\ \hline 0 \\ \eta_- \end{bmatrix}, \quad W_- = \begin{bmatrix} 0 \\ w_- \\ \hline 0 \\ \omega_- \end{bmatrix}, \quad Z_- = \begin{bmatrix} 0 \\ z_- \\ \hline -1 \\ \zeta_- \end{bmatrix}. \tag{3.3}$$

The quantities appearing here are defined by (2.10) and (2.12).

Fundamental systems (3.2) and (3.3) will be referred to as *canonical*; system (3.2) will be called the (+)-*system* and (3.3) will be called the (−)-*system*. Let us point out that the canonical fundamental systems depend on fixed numbers a_n and a_{-n}.

Any fundamental system can be transformed into canonical systems. To show how to do this, we introduce matrices $\Phi_\pm$:

$$\Phi_+ = \left[\begin{array}{ccccccc|ccccc} a_0 & a_{-1} & & & \cdots & a_{-n} & & \bar{u}_r & 0 & \cdots & & 0 \\ 0 & & \cdots & & 0 & -1 & & 0 & & \cdots & & 0 \\ \bar{u}_0 & \cdots & \bar{u}_r & 0 & \cdots & 0 & & 0 & & \cdots & & 0 \\ 0 & 0 & & & \cdots & 0 & & 0 & & \cdots & 0 & -1 \end{array}\right],$$

$$\Phi_- = \left[\begin{array}{ccccccc|ccccc} a_n & a_{n-1} & & & \cdots & a_0 & & 0 & & \cdots & 0 & \bar{u}_0 \\ -1 & 0 & & & \cdots & 0 & & 0 & & \cdots & & 0 \\ 0 & \cdots & 0 & \bar{u}_0 & \cdots & \bar{u}_r & & 0 & & \cdots & & 0 \\ 0 & 0 & & & \cdots & 0 & & -1 & 0 & \cdots & & 0 \end{array}\right].$$

It can be easily seen that

$$\Phi_+[X_+Y_+W_+Z_+] = \Phi_-[X_-Y_-W_-Z_-] = I_4. \tag{3.4}$$

From this relation, we get the following proposition.

PROPOSITION 3.1. *Let* X_1, X_2, X_3, X_4 *be a fundamental system of* $\mathscr{A}$ *and let* X *be the matrix with the columns* X_i $(i = 1, \ldots, 4)$. *Then* $\Lambda_\pm := \Phi_\pm X$ *is nonsingular and the columns of* $X\Lambda_\pm^{-1}$ *form the* (±)-*canonical fundamental system of* $\mathscr{A}$.

Our next aim is to get more information about the vectors of the canonical fundamental systems. For this we need the MPI of the matrices M^* and N occurring in the definition of $\mathscr{A}$. Since M and N have full rank, we have

$$(M^*)^+ = M(M^*M)^{-1}, \qquad N^+ = (N^*N)^{-1}N^*. \tag{3.5}$$

We introduce the matrix

$$T = M^*M. \tag{3.6}$$

Obviously, T is a positive definite $\kappa \times \kappa$ Toeplitz matrix. Furthermore, we have

$$N = J_n \bar{M} J_\kappa. \tag{3.7}$$

From (3.7), we obtain

$$N^*N = J_\kappa \bar{M}^* \bar{M} J_\kappa = J_\kappa \bar{T} J_\kappa = T.$$

Hence the following lemma is true.

LEMMA 3.1. *It holds that*

$$(M^*)^+ = MT^{-1}, \qquad N^+ = T^{-1}N^*. \tag{3.8}$$

Now we can start our investigation of the vectors of the canonical fundamental systems. We use all notations from above. Furthermore, we define

$$c = T^{-1}e_0. \tag{3.9}$$

In view of (2.4), we have

$$T^{-1}e_{\kappa-1} = J_\kappa \bar{c} =: \hat{c}. \tag{3.10}$$

First we consider vectors $W_\pm$ that have the simplest structure.

PROPOSITION 3.2. *It holds that*

(a) $\omega_+ = \omega_- = 0$,

(b) $w_+ = Mc, \quad w_- = M\hat{c}$.

The assertion follows immediately from Lemma 2.1 and (3.8).

In the sequel, the numbers $\sigma_\pm$ defined by

$$\sigma_+ = [a_{-1} \quad \cdots \quad a_{-n}]u_+, \qquad \sigma_- = [a_n \quad \cdots \quad a_1]u_-, \tag{3.11}$$

where

$$u_+ = [0 \quad \cdots \quad 0 \quad u_0 \quad \cdots \quad u_r]^T, \qquad u_- = [u_0 \quad \cdots \quad u_r \quad 0 \quad \cdots \quad 0]^T$$

will play an important role. They appear in the following lemma, which is easily verified.

LEMMA 3.2. *Let $u'_\pm \in \mathbb{C}^n$ be defined by*

$$u'_+ = [0 \quad \cdots \quad 0 \quad u_0 \quad \cdots \quad u_{r-1}]^T, \qquad u'_- = [u_1 \quad \cdots \quad u_r \quad 0 \quad \cdots \quad 0]^T.$$

Then

$$Au'_+ = \sigma_+ e_0 - u_r g_+ \quad \text{and} \quad Au'_- = \sigma_- e_{n-1} - u_0 g_-. \tag{3.12}$$

From the relation (3.12), we obtain the following fact that will be important in the sequel.

COROLLARY 3.1. *At least one of the numbers, σ_+ and u_r, and one of the numbers, σ_- and u_0, are different from zero.*

In fact, $\sigma_+ = u_r = 0$ would imply that $u'_+ \in \ker A$, i.e., $u'_+ \in \operatorname{Im} M$. But u'_+ is linearly independent of the columns of M. An analogous argument provides $\sigma_- \neq 0$ or $u_0 \neq 0$.

Let M_k denote the matrix of the form (2.3) with k columns. Furthermore, we define

$$T_k := M_k^* M_k = [t_{i-j}]_0^{k-1} \quad \text{and} \quad c_k = T_k^{-1} e_0, \qquad \hat{c}_k = T_k^{-1} e_{k-1}.$$

In particular, $M_\kappa = M$, $T_\kappa = T$, $c_\kappa = c$. Let us note that T_j is a principal submatrix of T_k if $j \le k$. We denote by d and $\hat{d}$ the solutions of equations

$$Td = (t_{-\kappa+k})_{k=0}^{\kappa-1}, \qquad T\hat{d} = (t_{1+k})_{k=0}^{\kappa-1}. \tag{3.13}$$

In view of $t_{-k} = \bar{t}_k$, we have $\hat{d} = \overline{J_\kappa d}$. Furthermore, d is connected with $c_{\kappa+1}$ via

$$\begin{bmatrix} d \\ -1 \end{bmatrix} = -\frac{1}{\varepsilon_{\kappa+1}} \hat{c}_{\kappa+1}, \qquad \begin{bmatrix} -1 \\ \hat{d} \end{bmatrix} = -\frac{1}{\varepsilon_{\kappa+1}} c_{\kappa+1}, \tag{3.14}$$

where

$$\varepsilon_{\kappa+1} = (c_{\kappa+1})_0 = (c_{\kappa+1})_\kappa. \tag{3.15}$$

In the next two propositions we describe the structure of vectors X_+, X_-, Y_+, Y_- of the canonical fundamental systems.

PROPOSITION 3.3. *It holds that*

(a) $\xi_+ = u_r c$, $\xi_- = u_0 \hat{c}$.

(b) *If* $u_r = 0$, *then* $\sigma_+ \neq 0$ *and*

$$\begin{bmatrix} x_+ \\ 0 \end{bmatrix} = -\frac{1}{\sigma_+} M_{\kappa+1} \begin{bmatrix} d \\ -1 \end{bmatrix}. \tag{3.16a}$$

(c) *If* $u_0 = 0$, *then* $\sigma_- \neq 0$, *and*

$$\begin{bmatrix} 0 \\ x_- \end{bmatrix} = -\frac{1}{\sigma_-} M_{\kappa+1} \begin{bmatrix} -1 \\ \hat{d} \end{bmatrix}. \tag{3.16b}$$

Proof. Two relations (a) follow from Lemma 2.1 and Lemma 3.1.

Now let $u_r = 0$. According to Lemma 3.2, we have $Au'_+ = \sigma_+ e_0$, where $\sigma_+ \neq 0$ holds due to Corollary 3.1. Since $x_+ = A^+ e_0$, we conclude that

$$x_+ = \frac{1}{\sigma_+} u'_+ - M\alpha, \tag{3.17}$$

where $\alpha \in \mathbb{C}^\kappa$ must be chosen in such a way that x_+ is orthogonal to $\ker A$, which means that $M^* x_+ = 0$. Hence $T\alpha = M^* M\alpha = \frac{1}{\sigma_+} M^* u'_+$. Since $M^* u'_+ = (t_{-\kappa+k})_0^{\kappa-1}$, we conclude that $\alpha = \frac{1}{\sigma_+} d$ and $x_+ = -\frac{1}{\sigma_+}(Md - u'_+)$. This is equivalent to (3.16a), and so (b) is proved.

Assertion (c) is proved analogously. □

PROPOSITION 3.4. *It holds that*

(a) $\eta_+ = \sigma_+ c$, $\eta_- = \sigma_- \hat{c}$.

(b) *If* $\sigma_+ = 0$, *then* $u_r \neq 0$ *and*

$$\begin{bmatrix} y_+ \\ -1 \end{bmatrix} = \frac{1}{u_r} M_{\kappa+1} \begin{bmatrix} d \\ -1 \end{bmatrix}. \tag{3.18}$$

(c) *If* $\sigma_- = 0$, *then* $u_0 \neq 0$, *and*

$$\begin{bmatrix} -1 \\ y_- \end{bmatrix} = \frac{1}{u_0} M_{\kappa+1} \begin{bmatrix} -1 \\ \hat{d} \end{bmatrix}. \tag{3.19}$$

The proof is completely analogous to the one of Proposition 3.3.

Finally we state a proposition concerning the vectors $Z_{\pm}$.

PROPOSITION 3.5. *It holds that* $\zeta_+ = d$, $\zeta_- = \hat{d}$.

Proof. By Lemmas 2.1 and 3.1 we have

$$\zeta_+ = N^+h_+ = T^{-1}N^*h_+ = T^{-1}(t_{-\kappa+k})_{k=0}^{\kappa-1} = d$$

and

$$\zeta_- = N^+h_- = T^{-1}N^*h_- = T^{-1}(t_{1+k})_{k=0}^{\kappa-1} = \hat{d}. \qquad \square$$

Now we are able to indicate a collection of fundamental systems different from the canonical ones.

THEOREM 3.1. *The following systems are fundamental.*

System (A). *Case* (I) $u_0u_r \neq 0$, X_+, X_-, W_+, W_-.
Case (II) $u_0\sigma_+ \neq 0$, Y_+, X_-, W_+, W_-.
Case (III) $u_r\sigma_- \neq 0$, X_+, Y_-, W_+, W_-.
Case (IV) $\sigma_+\sigma_- \neq 0$, Y_+, Y_-, W_+, W_-.
System (B). W_+, W_-, Z_+, Z_-.
System (C). X_+, X_-, Y_+, Y_-.

Proof. It suffices to show the linear independence of the system. The linear independence of Systems (A) and (B) follows from Propositions 3.2–3.5 and the fact that the vectors

$$\begin{bmatrix} c \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ \hat{c} \end{bmatrix}$$

are linearly independent since $(c)_0 \neq 0$ and the vectors

$$\begin{bmatrix} d \\ -1 \end{bmatrix}, \begin{bmatrix} -1 \\ \hat{d} \end{bmatrix}$$

are linearly independent in view of (3.14).

It remains to verify that System (C) is linearly independent. Suppose that for $\alpha_{\pm}$, $\beta_{\pm} \in \mathbb{C}$,

$$\alpha_+X_+ + \alpha_-X_- + \beta_+Y_+ + \beta_-Y_- = 0.$$

By Propositions 3.3 and 3.4, we obtain for the second parts of the considered vectors

$$a_+u_r\begin{bmatrix} c \\ 0 \end{bmatrix} + \alpha_-u_0\begin{bmatrix} 0 \\ \hat{c} \end{bmatrix} + \beta_+\sigma_+\begin{bmatrix} c \\ 0 \end{bmatrix} + \beta_-\sigma_-\begin{bmatrix} 0 \\ \hat{c} \end{bmatrix} = 0.$$

Since the vectors

$$\begin{bmatrix} c \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ \hat{c} \end{bmatrix}$$

are linearly independent, we conclude that

$$\alpha_+u_r + \beta_+\sigma_+ = \alpha_-u_0 + \beta_-\sigma_- = 0.$$

Hence the second parts of the vectors

$$V_+ := \alpha_+X_+ + \beta_+Y_+ \quad \text{and} \quad V_- := \alpha_-X_- + \beta_-Y_-$$

vanish and their first parts depend linearly. Repeating the arguments of the proof of Proposition 3.3, we obtain that the first parts of $V_\pm$ are multiples of the vectors

$$M_{\kappa+1}\begin{bmatrix} d \\ -1 \end{bmatrix} \quad \text{and} \quad M_{\kappa+1}\begin{bmatrix} -1 \\ \hat{d} \end{bmatrix},$$

respectively. But the latter two vectors are linearly independent. Consequently, $V_+ = V_- = 0$. In view of the linear independence of X_+, Y_+ and X_-, Y_-, we may conclude that $\alpha_\pm = \beta_\pm = 0$, which proves the linear independence of the system. □

In view of Corollary 3.1, all possible situations are covered by Cases (I)–(IV) of System (A) of Theorem 3.1.

In the next two sections, we establish a recursive algorithm that is based on System (A) of Theorem 3.1. In this connection, we must show how to jump from one of the cases (I)–(IV) to another one. It follows from the algebraic theory of Toeplitz matrices that only the following changes are possible:

(3.20) $$\text{(I)} \to \text{(II–IV)}, \quad \text{(II)} \to \text{(IV)}, \quad \text{(III)} \to \text{(IV)}.$$

For the jumps indicated in (3.20) we need the following relation.

PROPOSITION 3.6. *It holds that*

(a) *if* $u_r \neq 0$, *then*

$$Y_+ = \frac{\sigma_+}{u_r} X_+ - \frac{1}{\varepsilon u_r}(W_- - \bar{\alpha} W_+), \tag{3.21}$$

where

$$\varepsilon = (c)_0, \tag{3.22a}$$

$$\alpha = [t_\kappa \quad \cdots \quad t_1]c. \tag{3.22b}$$

(b) *If* $u_0 \neq 0$, *then*

$$Y_- = \frac{\sigma_-}{u_0} X_- - \frac{1}{\varepsilon u_0}(W_+ - \alpha W_-), \tag{3.23}$$

where ε *and* α *are defined as above.*

Proof. We prove only (a). The proof of (b) is analogous.

Suppose that $u_r \neq 0$. In view of Corollary 3.1, we may assume that $u_0 \neq 0$ or $\sigma_- \neq 0$.

Since $Y_+ \in \ker \partial\mathscr{A}$, Y_+ is by Theorem 3.1 a linear combination of the vectors X_+, X_-, W_+, W_- if $u_0 \neq 0$ and a linear combination of X_+, Y_-, W_+, W_- if $\sigma_- \neq 0$. We recall that according to Propositions 3.2, 3.3, and 3.4, the second parts of the vectors $W_\pm$ vanish and the second parts of X_+, X_-, Y_+, Y_- are given by

$$\begin{bmatrix} u_r c \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ u_0 \hat{c} \end{bmatrix}, \begin{bmatrix} \sigma_+ c \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ \sigma_- \hat{c} \end{bmatrix},$$

respectively. Since the last component of $\hat{c}$ is nonzero, we conclude that Y_+ is already a linear combination of X_+, W_+, and W_- in both cases $u_0 \neq 0$ and $\sigma_- \neq 0$. From this and (3.22), we conclude that

$$Y_+ = \frac{\sigma_+}{u_r} X_+ + \mu_+ W_+ + \mu_- W_- \tag{3.24}$$

for certain $\mu_\pm \in \mathbb{C}$.

To evaluate $\mu_{\pm}$, we apply the functionals

$$f_1^T = [0 \ \cdots \ 0 \ -1 \,|\, 0 \ \cdots \ 0], \qquad f_2^T = [\bar{u}_0 \ \cdots \ \bar{u}_r \ 0 \ \cdots \ 0 \,|\, 0 \ \cdots \ 0],$$

which are the second and third rows of the matrix Φ_+, to (3.24). As the result, we get

$$1 = -\mu_-(w_-)_{n-1} \quad \text{and} \quad 0 = \mu_+ + \bar{\alpha}\mu_-,$$

where

$$\bar{\alpha} = [\bar{u}_1 \ \cdots \ \bar{u}_r \ 0 \ \cdots \ 0]w_-.$$

This can be transformed into

$$\mu_- = -\frac{1}{(w_-)_{n-1}} \quad \text{and} \quad \mu_+ = -\frac{\bar{\alpha}}{(w_-)_{n-1}}. \tag{3.25}$$

From Proposition 3.2, we get $(w_-)_{n-1} = u_r(\hat{c})_{\kappa-1} = u_r c_0$ and

$$\bar{\alpha} = [\bar{u}_1 \ \cdots \ \bar{u}_r \ 0 \ \cdots \ 0]M\hat{c} = [t_{-1} \ \cdots \ t_{-\kappa}]\hat{c}.$$

Inserting this and (3.25) into (3.24), we obtain (3.21), (3.22). □

Remark. We have proved that ε and α are also given by

$$\begin{aligned} \varepsilon &= (\hat{c})_{\kappa-1}, \\ \bar{\alpha} &= [\bar{u}_1 \ \cdots \ \bar{u}_r \ 0 \ \cdots \ 0]w_-, \\ \alpha &= [0 \ \cdots \ 0 \ \bar{u}_0 \ \cdots \ \bar{u}_{r-1}]w_+. \end{aligned} \tag{3.26}$$

COROLLARY 3.2. *It holds that*

(a) *if* $u_r \neq 0$, *then*

$$\begin{bmatrix} y_+ \\ -1 \end{bmatrix} = \frac{\sigma_+}{u_r}\begin{bmatrix} x_+ \\ 0 \end{bmatrix} - \frac{1}{\varepsilon u_r}\left(\begin{bmatrix} 0 \\ w_- \end{bmatrix} - \bar{\alpha}\begin{bmatrix} w_+ \\ 0 \end{bmatrix}\right). \tag{3.27}$$

(b) *If* $u_0 \neq 0$, *then*

$$\begin{bmatrix} -1 \\ y_- \end{bmatrix} = \frac{\sigma_-}{u_0}\begin{bmatrix} 0 \\ x_- \end{bmatrix} - \frac{1}{\varepsilon u_0}\left(\begin{bmatrix} w_+ \\ 0 \end{bmatrix} - \alpha\begin{bmatrix} 0 \\ w_- \end{bmatrix}\right), \tag{3.28}$$

where α *and* ε *are given by* (3.22) *or* (3.26).

We discuss some specifications for the case of a Hermitian or positive semidefinite Toeplitz matrix A.

Suppose that $A^* = A$, i.e., $a_{-i} = \bar{a}_i$ $(i = 0, \ldots, n-1)$. In this case the vector $u = (u_i)_0^r$ appearing in Lemma 2.2 can be chosen in such a way that $\hat{u} = u$, i.e., $u_i = \bar{u}_{r-i}$ $(i = 0, \ldots, r)$. Hence matrix $\mathscr{A}$ is Hermitian.

In view of the relation

$$\begin{bmatrix} J_n & 0 \\ 0 & J_n \end{bmatrix}\mathscr{A}\begin{bmatrix} J_n & 0 \\ 0 & J_n \end{bmatrix} = \begin{bmatrix} \bar{A} & \bar{N} \\ \bar{M}^* & 0 \end{bmatrix},$$

we obtain the following relations.

Remark 3.1. If A is Hermitian, then $x_- = \hat{x}_+$, $y_- = \hat{y}_+$, $w_- = \hat{w}_+$, $z_- = \hat{z}_+$. Furthermore, $\sigma_- = \bar{\sigma}_+$. The latter relation implies the following remark.

Remark 3.2. If A is Hermitian, then only Cases (I) and (IV) of Theorem 3.1 appear. For semidefinite matrices still more is true.

Remark 3.3. If A is positive or negative semidefinite, then only Case (I) of Theorem 3.1 appears.

Remark 3.3 is a consequence of Iohvidov's rule for the signature of a Toeplitz matrix (see [13] and [11]).

4. Recursions of fundamental systems. In this section we consider, besides the Toeplitz matrix $A = [a_{i-j}]_0^{n-1}$, an extension A' of A of the form

$$A' = [a_{i-j}]_0^n.$$

The problem we discuss is how a fundamental system for the Toeplitz mosaic matrix $\mathscr{A}'$ associated with A' can be obtained from a fundamental system of $\mathscr{A}$. The recursion will then lead to a fast algorithm for computing a fundamental system of an arbitrary square Toeplitz matrix.

Since there are many fundamental systems, we must decide which system provides the simplest recursion formulas. The first idea is to take one of the canonical fundamental systems. However, the corresponding formulas for this approach seem to be rather complicated. All Systems (A)–(C) described in Theorem 3.1 lead to simpler formulas. So far, we do not really know which version is the simplest. From a certain viewpoint, System (A) seems to be the most natural, therefore we describe it in detail.

Let us agree upon some notational convention. All quantities corresponding to matrix A' will be denoted by the same symbols as the analogous quantities corresponding to A, only supplemented by a prime.

The first question we must answer is that of the structure of matrix $\mathscr{A}'$. For this, we must determine the kernel of A' in dependence on ker A. The following lemma is well known (see [11]).

LEMMA 4.1. *Let the numbers $\sigma_\pm$ be defined by* (3.11). *Then*

(I) $$\kappa' = \kappa + 1, \quad u' = u, \quad M' = M_{\kappa+1} \quad \text{if } \sigma_+ = \sigma_- = 0;$$

(II) $$\kappa' = \kappa, \quad u' = \begin{bmatrix} u \\ 0 \end{bmatrix}, \quad M' = \begin{bmatrix} M_\kappa \\ 0 \end{bmatrix} \quad \text{if } \sigma_+ \neq \sigma_- = 0;$$

(III) $$\kappa' = \kappa, \quad u' = \begin{bmatrix} 0 \\ u \end{bmatrix}, \quad M' = \begin{bmatrix} 0 \\ M_\kappa \end{bmatrix} \quad \text{if } \sigma_+ = \sigma_- \neq 0;$$

(IV) $$\kappa' = \kappa - 1, \quad u' = \begin{bmatrix} 0 \\ u \\ 0 \end{bmatrix}, \quad M' = \begin{bmatrix} 0 \\ M_{\kappa-1} \\ 0 \end{bmatrix} \quad \text{if } \sigma_+\sigma_- \neq 0.$$

In all cases $N' = J_{n+1}\bar{M}'J_{\kappa'}$.

The simplest recursion formulas are those for vectors $w_\pm$. They are based on the following lemma.

LEMMA 4.2. *For the first and last columns, c_κ and $\hat{c}_\kappa$ of T_κ^{-1} ($T_\kappa = M_\kappa^* M_\kappa$), the following recursions hold true*:

(4.1) (i) $$[c_{\kappa+1}(\lambda) \quad \hat{c}_{\kappa+1}(\lambda)] = \frac{1}{1 - |\alpha^2|}[c(\lambda) \quad \lambda\hat{c}(\lambda)]\begin{bmatrix} 1 & -\bar{\alpha} \\ -\alpha & 1 \end{bmatrix},$$

where

(4.2) $$\alpha = [t_\kappa \quad \cdots \quad t_1]c \quad (\bar{\alpha} = [t_{-1} \quad \cdots \quad t_{-\kappa}]\hat{c}),$$

and

(4.3) (ii) $$[c_{\kappa-1}(\lambda) \quad \lambda\hat{c}_{\kappa-1}(\lambda)] = [c(\lambda) \quad \hat{c}(\lambda)]\begin{bmatrix} 1 & \bar{\delta} \\ \delta & 1 \end{bmatrix},$$

where

$$\delta = -\frac{(c)_{\kappa-1}}{(c)_0}. \tag{4.4}$$

Formulas (4.1) and (4.2) are well known and easily checked. Formula (4.1) provides only the classical Levinson algorithm.

Remark 4.1. For $c_{\kappa+1} := T_{\kappa+1}^{-1} e_0$, the relation $\alpha_\kappa = (c_{\kappa+1})_\kappa/(c_{\kappa+1})_0$ holds.

THEOREM 4.1. *Let* $\sigma_\pm$ *be defined by* (3.11). *The vectors* $w'_\pm$ *are obtained from* w_+ *and* w_- *via the following formulas*:

(I) Case $\sigma_+ = \sigma_- = 0$:

$$[w'_+(\lambda) \quad w'_-(\lambda)] = \frac{1}{1-|\alpha^2|}[w_+(\lambda) \quad w_-(\lambda)]\begin{bmatrix}1 & 0\\ 0 & \lambda\end{bmatrix}\begin{bmatrix}1 & -\bar{\alpha}\\ -\alpha & 1\end{bmatrix}, \tag{4.5}$$

where

$$\alpha = [t_\kappa \quad \cdots \quad t_1]c = [0 \quad \cdots \quad 0 \quad \bar{u}_0 \quad \cdots \quad \bar{u}_{r-1}]w_+ \tag{4.6a}$$

and

$$\bar{\alpha} = [t_{-1} \quad \cdots \quad t_{-\kappa}]\hat{c} = [\bar{u}_1 \quad \cdots \quad \bar{u}_r \quad 0 \quad \cdots \quad 0]w_-. \tag{4.6b}$$

(II) Case $\sigma_+ \neq 0$, $\sigma_- = 0$:

$$[w'_+(\lambda) \quad w'_-(\lambda)] = [w_+(\lambda) \quad w_-(\lambda)]. \tag{4.7}$$

(III) Case $\sigma_+ = 0$, $\sigma_- \neq 0$:

$$[w'_+(\lambda) \quad w'_-(\lambda)] = [\lambda w_+(\lambda) \quad \lambda w_-(\lambda)]. \tag{4.8}$$

(IV) Case $\sigma_+\sigma_- \neq 0$:

$$[w'_+(\lambda) \quad w'_-(\lambda)] = [w_+(\lambda) \quad w_-(\lambda)]\begin{bmatrix}1 & \bar{\delta}\\ \delta & 1\end{bmatrix}\begin{bmatrix}\lambda & 0\\ 0 & 1\end{bmatrix}, \tag{4.9}$$

where

$$\delta = -\frac{(c)_{\kappa-1}}{(c)_0} = -\frac{(w_+)_t}{(w_-)_t} \tag{4.10a}$$

and

$$\bar{\delta} = -\frac{(\hat{c})_0}{(c)_0} = -\frac{(w_-)_s}{(w_+)_s}, \tag{4.10b}$$

where $(w_\pm)_s$ *is the first and* $(w_\pm)_t$ *the last nonzero component of* $w_\pm$.

Proof. (I). By Proposition 3.2 and Lemma 4.1, we have

$$w'_+ = M_{\kappa+1}c_{\kappa+1}, \qquad w' = M_{\kappa+1}\hat{c}_{\kappa+1}.$$

Taking (4.1) into account, we obtain (4.5) with α being defined by the first equalities of (4.6a) or (4.6b).

To get the second expressions for constant α, we remark that

$$\mathscr{A}'\begin{bmatrix}w_+\\ \hline 0\\ 0\end{bmatrix} = \begin{bmatrix}0\\ \hline e_0 + \alpha_1 e_\kappa\end{bmatrix} \quad \text{and} \quad \mathscr{A}'\begin{bmatrix}0\\ \hline w_-\\ 0\end{bmatrix} = \begin{bmatrix}0\\ \hline \alpha_2 e_0 + e_\kappa\end{bmatrix},$$

where

$$\alpha_1 = [0 \quad \cdots \quad 0 \quad \bar{u}_0 \quad \cdots \quad \bar{u}_{r-1}]w_+, \qquad \alpha_2 = [\bar{u}_1 \quad \cdots \quad \bar{u}_r \quad 0 \quad \cdots \quad 0]w_-.$$

From this relation, we conclude that

$$w'_+(\lambda) = \frac{1}{1 - \alpha_1\alpha_2}(w_+(\lambda) - \alpha_1\lambda w(\lambda))$$

and

$$w'_-(\lambda) = \frac{1}{1 - \alpha_1\alpha_2}(\lambda w_-(\lambda) - \alpha_2 w_+(\lambda)).$$

Comparing this with (4.5), we obtain $\alpha_1 = \alpha$ and $\alpha_2 = \bar{\alpha}$.

(II). By Lemma 4.1, we have in this case

$$M' = \begin{bmatrix} M \\ 0 \end{bmatrix}.$$

Hence $T' = (M')^*M' = M^*M = T$, which implies that $c' = c$. Thus by Proposition 3.2

$$w'_+ = M'c' = \begin{bmatrix} w_+ \\ 0 \end{bmatrix}, \qquad w'_- = M'\hat{c}' = \begin{bmatrix} w_- \\ 0 \end{bmatrix},$$

which is the same as (4.7).

(III). By Lemma 4.1, we have

$$M' = \begin{bmatrix} 0 \\ M \end{bmatrix},$$

which implies that $T' = (M')^*M' = M^*M = T$ and $c' = c$. Hence by Proposition 3.2

$$w'_+ = M'c' = \begin{bmatrix} 0 \\ w_+ \end{bmatrix}, \qquad w'_- = M'\hat{c}' = \begin{bmatrix} 0 \\ w_- \end{bmatrix},$$

which is equivalent to (4.8).

(IV). Again, applying Lemma 4.1, we get

$$T' = (M')^*M' = M^*_{\kappa-1}M_{\kappa-1} = T_{\kappa-1} \quad \text{and} \quad c' = c_{\kappa-1}.$$

According to Proposition 3.2, we have

$$w'_+ = \begin{bmatrix} 0 \\ M_{\kappa-1}c' \\ 0 \end{bmatrix}, \qquad w'_- = \begin{bmatrix} 0 \\ M_{\kappa-1}\hat{c}' \\ 0 \end{bmatrix}, \tag{4.11}$$

and by Lemma 4.2, we have

$$\begin{bmatrix} M_{\kappa-1}c' \\ 0 \end{bmatrix} = M_\kappa \begin{bmatrix} c' \\ 0 \end{bmatrix} = M_\kappa(c - \delta\hat{c}) = w_+ - \delta w_- \tag{4.12a}$$

and

$$\begin{bmatrix} 0 \\ M_{\kappa-1}c' \end{bmatrix} = M_\kappa \begin{bmatrix} 0 \\ \hat{c}' \end{bmatrix} = M_\kappa(\hat{c} - \bar{\delta}c) = w_- - \bar{\delta}w_+. \tag{4.12b}$$

Taking (4.11) and (4.12) together, we get (4.9) with δ being defined by the first equalities of (4.10). The second expressions follow from $w_+ = Mc$, $w_- = M\hat{c}$. □

Remark 4.2. The number δ appearing in Case (IV) can also be expressed in the form

$$\delta = -\frac{f_+^T w_+}{f_+^T w_-} \quad \text{and} \quad \bar{\delta} = -\frac{f_-^T w_-}{f_-^T w_+}, \tag{4.13}$$

where

$$f_+^T = [a_{-1} \quad \cdots \quad a_{-n}] \quad \text{and} \quad f_-^T = [a_n \quad \cdots \quad a_1].$$

This follows from the relations

$$\mathscr{A}'\begin{bmatrix} 0 \\ w_+ \\ \hline 0 \end{bmatrix} = \begin{bmatrix} f_+^T w_+ e_0 \\ \hline e_0 \end{bmatrix}, \qquad \mathscr{A}'\begin{bmatrix} 0 \\ w_- \\ \hline 0 \end{bmatrix} = \begin{bmatrix} f_+^T w_- e_0 \\ \hline 0 \end{bmatrix},$$

$$\mathscr{A}'\begin{bmatrix} w_+ \\ 0 \\ \hline 0 \end{bmatrix} = \begin{bmatrix} f_-^T w_+ e_n \\ \hline 0 \end{bmatrix}, \quad \text{and} \quad \mathscr{A}'\begin{bmatrix} w_- \\ 0 \\ \hline 0 \end{bmatrix} = \begin{bmatrix} f_-^T w_- e_0 \\ \hline e_{\kappa-2} \end{bmatrix}.$$

Now we are going to construct recursion formulas for vectors $x_\pm$, $y_\pm$ according to System (A) of Theorem 3.1. We begin with Case (I).

THEOREM 4.2. *Suppose that* $\sigma_+ = \sigma_- = 0$. *Then* $u_0 u_r \neq 0$ *and*

$$[x'_+(\lambda) \quad x'_-(\lambda)] = \frac{1}{1 - \alpha_+\alpha_-}[x_+^0(\lambda) \quad x_-^0(\lambda)]\begin{bmatrix} 1 & -\alpha_- \\ -\alpha_+ & 1 \end{bmatrix}, \tag{4.14}$$

where

$$x_+^0(\lambda) = x_+(\lambda) - \beta_+ w'_-(\lambda), \qquad x_-^0(\lambda) = \lambda x_-(\lambda) - \beta_- w'_+(\lambda), \tag{4.15a}$$

$$\alpha_+ = \alpha u_r/u_0, \qquad \alpha_- = \bar{\alpha} u_0/u_r, \tag{4.15b}$$

$$\beta_+ = [0 \ \cdots \ 0 \ \bar{u}_0 \ \cdots \ \bar{u}_{r-1}]x_+, \qquad \beta_- = [\bar{u}_1 \ \cdots \ \bar{u}_r \ 0 \ \cdots \ 0]x_-, \tag{4.15c}$$

and α *is defined by* (4.6).

Proof. We have

$$\mathscr{A}'\begin{bmatrix} x_+ \\ 0 \\ \hline \xi_+ \\ 0 \end{bmatrix} = \begin{bmatrix} e_0 + \rho_+ e_n \\ \hline \beta_+ e_\kappa \end{bmatrix} \quad \text{and} \quad \mathscr{A}'\begin{bmatrix} 0 \\ x_- \\ \hline 0 \\ \xi_- \end{bmatrix} = \begin{bmatrix} \rho_- e_0 + e_n \\ \hline \beta_- e_0 \end{bmatrix}, \tag{4.16}$$

where

$$\rho_+ = [a_n \quad \cdots \quad a_1]x_+, \qquad \rho_- = [a_{-1} \quad \cdots \quad a_{-n}]x_-. \tag{4.17}$$

Hence

$$\mathscr{A}'\begin{bmatrix} x_+^0 \\ \xi_+ \\ \hline 0 \end{bmatrix} = \begin{bmatrix} e_0 + \rho_+ e_n \\ \hline 0 \end{bmatrix} \quad \text{and} \quad \mathscr{A}'\begin{bmatrix} x_-^0 \\ 0 \\ \hline \xi_- \end{bmatrix} = \begin{bmatrix} \rho_- e_0 + e_n \\ \hline 0 \end{bmatrix}.$$

This leads to (4.14) with $\alpha_\pm$ being replaced by $\rho_\pm$. It remains to show that $\alpha_\pm = \rho_\pm$.

Note that (4.16) implies the following recursion for $\xi_\pm$:

$$[\xi'_+(\lambda) \quad \xi'_-(\lambda)] = \frac{1}{1 - \rho_+\rho_-}[\xi_+(\lambda) \quad \lambda\xi_-(\lambda)]\begin{bmatrix} 1 & -\rho_- \\ -\rho_+ & 1 \end{bmatrix}. \tag{4.18}$$

On the other hand according to Proposition 3.3 we have

$$\xi_+ = u_r c, \quad \xi_- = u_0 \hat{c}, \quad \xi'_+ = u_r c_{\kappa+1}, \quad \xi'_- = u_0 \hat{c}_{\kappa+1}.$$

Taking (4.1) into account, we obtain

$$[\xi'_+(\lambda) \quad \xi'_-(\lambda)] = \frac{1}{1-|\alpha^2|}[\xi_+(\lambda) \quad \lambda\xi_-(\lambda)]\begin{bmatrix} 1 & -\bar{\alpha}u_0/u_r \\ -\alpha u_r/u_0 & 1 \end{bmatrix}.$$

A comparison with (4.18) yields

$$\rho_+ = \alpha u_r/u_0 = \alpha_+ \quad \text{and} \quad \rho_- = \bar{\alpha}u_0/u_r = \alpha_-. \qquad \square$$

Remark 4.3. For constants $\beta_\pm$ defined by (4.15c), the following is true:

$$\beta_+ = (z_-)_{n-1}, \qquad \beta_- = (z_+)_0.$$

In fact, since $x_+ = A^+ e_0$ and $J_n A^+ J_n = (A^+)^T$, we have

$$\begin{aligned} \beta_+ &= [0 \quad \cdots \quad 0 \quad \bar{u}_0 \quad \cdots \quad \bar{u}_{r-1}]A^+ e_0 \\ &= e_0^T J_n A^+ J_n [0 \quad \cdots \quad 0 \quad \bar{u}_0 \quad \cdots \quad \bar{u}_{r-1}]^T \\ &= e_{n-1}^T A^+ [\bar{u}_{r-1} \quad \cdots \quad \bar{u}_0 \quad 0 \quad \cdots \quad 0]^T \\ &= e_{n-1}^T z_-. \end{aligned}$$

The second relation is proved analogously.

The treatment of Case (II) will be started with some preliminary consideration.

LEMMA 4.3. *Suppose that* $\sigma_+ \neq 0$ *and* $\sigma_- = 0$. *Then* $\xi'_+ = 0$ *and*

$$x'_+(\lambda) = \frac{1}{\varepsilon\sigma_+}(\lambda w_-(\lambda) - \bar{\alpha} w_+(\lambda)), \tag{4.19}$$

where

$$\varepsilon = (\hat{c})_{\kappa-1} = \frac{1}{\sigma_+}[a_{-1} \quad \cdots \quad a_{-n}]w_- \tag{4.20a}$$

and

$$\bar{\alpha} = [t_{-1} \quad \cdots \quad t_{-\kappa}]\hat{c} = [\bar{u}_1 \quad \cdots \quad \bar{u}_r \quad 0 \quad \cdots \quad 0]w_-. \tag{4.20b}$$

Proof. We have

$$\mathscr{A}'\begin{bmatrix} w_+ \\ 0 \\ \hline 0 \end{bmatrix} = \begin{bmatrix} 0 \\ \hline e_0 \end{bmatrix} \quad \text{and} \quad \mathscr{A}'\begin{bmatrix} 0 \\ w_- \\ \hline 0 \end{bmatrix} = \begin{bmatrix} \rho_1 e_0 \\ \hline \rho_2 e_0 \end{bmatrix},$$

where according to Proposition 3.2,

$$\rho_1 = [a_{-1} \quad \cdots \quad a_{-n}]w_- = [a_{-1} \quad \cdots \quad a_{-n}]M\hat{c} = \sigma_+ e_{\kappa-1}^T \hat{c} = \varepsilon\sigma_+$$

and

$$\rho_2 = [\bar{u}_1 \quad \cdots \quad \bar{u}_r \quad 0 \quad \cdots \quad 0]w_- = [\bar{u}_1 \quad \cdots \quad \bar{u}_r \quad 0 \quad \cdots \quad 0]M\hat{c} = [t_{-1} \quad \cdots \quad t_{-\kappa}]\hat{c} = \bar{\alpha}.$$

This implies that

$$\mathscr{A}'\begin{bmatrix} x'_+ \\ \hline 0 \end{bmatrix} = \begin{bmatrix} e_0 \\ \hline 0 \end{bmatrix},$$

where x'_+ is given by (4.19), which is just our assertion. $\square$

THEOREM 4.3. *Assume that* $\sigma_+ \neq 0$ *and* $\sigma_- = 0$. *Then vectors* x'_- *and* y'_+ *can be computed via the formulas*

$$x'_-(\lambda) = \lambda x_-(\lambda) + \left(\frac{\bar{\alpha}\tau_-}{\varepsilon\sigma_+} - \beta_-\right)w_+(\lambda) - \frac{\tau_-}{\varepsilon\sigma_+}\lambda w_-(\lambda) \tag{4.21}$$

and

$$y'_+(\lambda) = \lambda y_+(\lambda) + \left(\frac{\bar{\alpha}(\phi_+ - a_{-n-1})}{\varepsilon\sigma_+} - \gamma_+\right)w_+(\lambda) - \frac{\phi_+ - a_{-n-1}}{\varepsilon\sigma_+}\lambda w_-(\lambda), \tag{4.22}$$

where

$$\begin{aligned} \tau_- &= [a_{-1} \ \cdots \ a_{-n}]x_- = (y_+)_0, \qquad \phi_+ = [a_{-1} \ \cdots \ a_{-n}]y_+, \\ \beta_- &= [\bar{u}_1 \ \cdots \ \bar{u}_r \ 0 \ \cdots \ 0]x_-, \qquad \gamma_+ = [\bar{u}_1 \ \cdots \ \bar{u}_r \ 0 \ \cdots \ 0]y_+, \end{aligned} \tag{4.23}$$

and $\bar{\alpha}$, ε *are defined by* (4.20).

Proof. We have

$$\mathscr{A}'\begin{bmatrix} 0 \\ \hline x_- \\ \hline \xi_- \end{bmatrix} = \begin{bmatrix} \tau_- e_0 + e_n \\ \hline \beta_- e_0 \end{bmatrix} \quad \text{and} \quad \mathscr{A}'\begin{bmatrix} 0 \\ \hline y_+ \\ \hline \eta_+ \end{bmatrix} = \begin{bmatrix} \phi_+ e_0 + g' \\ \hline \gamma_+ e_0 \end{bmatrix},$$

where $g' = [0 \ \ a_{-n} \ \cdots \ a_{-1}]^T$ and β_-, γ_+, ϕ_+, τ_- are given by (4.23). From these relations, we conclude that

$$x'_-(\lambda) = \lambda x(\lambda) - \tau_- x'_+(\lambda) - \beta_- w_+(\lambda)$$

and

$$y'_+(\lambda) = \lambda y_+(\lambda) - (\phi_+ - a_{-n-1})x'_+(\lambda) - \gamma_+ w_+(\lambda).$$

Taking (4.19) into account, we obtain (4.21) and (4.22).

It remains to prove that $\tau_- = (y_+)_0$. However, we have $x_- = A^+ e_{n-1}$. Hence

$$\tau_- = [a_{-1} \ \cdots \ a_{-n}]A^+ e_{n-1}.$$

In view of

$$J_n A^+ J_n = (A^+)^T,$$

we conclude that

$$\tau_- = e_{n-1}^T J_n A^+ J_n [a_{-1} \ \cdots \ a_{-n}]^T = e_0^T A^+ [a_{-n} \ \cdots \ a_{-1}]^T = e_0^T y_+,$$

which is the assertion. □

Remark 4.4. If there is a change from Case (I) to Case (II), vector y_+ appearing in (4.22) is not immediately available, but it can be computed with the help of (3.27) since in this case we still have $u_r = 0$.

Case (III) can be treated analogously to Case (II). We formulate only the corresponding results.

LEMMA 4.4. *Suppose that* $\sigma_+ = 0$ *and* $\sigma_- \neq 0$. *Then* $\xi'_- = 0$ *and*

$$x'_-(\lambda) = \frac{1}{\varepsilon\sigma_-}(w_+(\lambda) - \alpha\lambda w_-(\lambda)), \tag{4.24}$$

where

$$\varepsilon = (c_+)_0 = \frac{1}{\sigma_-}[a_n \quad \cdots \quad a_1]w_+ \tag{4.25a}$$

and

$$\alpha = [t_\kappa \quad \cdots \quad t_1]c = [0 \quad \cdots \quad 0 \quad \bar{u}_0 \quad \cdots \quad \bar{u}_{r-1}]w_+. \tag{4.25b}$$

Moreover, α and ε are the same as in Lemma 4.3.

THEOREM 4.4. *Assume that $\sigma_+ = 0$ and $\sigma_- \neq 0$. Then the vectors x'_+ and y'_- can be computed via the formulas*

$$x'_+(\lambda) = x_+(\lambda) - \frac{\tau_+}{\varepsilon\sigma_-} w_+(\lambda) + \left(\frac{\alpha\tau_+}{\varepsilon\sigma_-} - \beta_+\right)\lambda w_-(\lambda) \tag{4.26}$$

and

$$y'_-(\lambda) = y_-(\lambda) - \frac{\phi_- - a_{n+1}}{\varepsilon\sigma_-} w_+(\lambda) + \left(\frac{\alpha(\phi_- - a_{n+1})}{\varepsilon\sigma_-} - \gamma_-\right)\lambda w_-(\lambda), \tag{4.27}$$

where

$$\begin{aligned} \tau_+ &= [a_n \quad \cdots \quad a_1]x_+ = (y_-)_{n-1}, \qquad \phi_- = [a_n \quad \cdots \quad a_1]y_-, \\ \beta_+ &= [0 \quad \cdots \quad 0 \quad \bar{u}_0 \quad \cdots \quad \bar{u}_{r-1}]x_+, \qquad \gamma_+ = [0 \quad \cdots \quad 0 \quad \bar{u}_0 \quad \cdots \quad \bar{u}_{r-1}]y_-, \end{aligned} \tag{4.28}$$

and α, ε are defined by (4.25).

It remains to consider Case (IV).

LEMMA 4.5. *Assume that $\sigma_+\sigma_- \neq 0$. Then $\xi'_+ = \xi'_- = 0$ and*

$$x'_+ = \frac{1}{\varepsilon\sigma_+}\begin{bmatrix} 0 \\ w \end{bmatrix}, \qquad x'_- = \frac{1}{\varepsilon\sigma_-}\begin{bmatrix} w_+ \\ 0 \end{bmatrix}, \tag{4.29}$$

where

$$\varepsilon = (c)_0 = \frac{1}{\sigma_-}[a_n \quad \cdots \quad a_1]w_+ = \frac{1}{\sigma_+}[a_{-1} \quad \cdots \quad a_{-n}]w_-. \tag{4.30}$$

Proof. We have

$$\mathscr{A}'\begin{bmatrix} w_+ \\ 0 \\ \hline 0 \end{bmatrix} = \begin{bmatrix} \rho_1 e_n \\ \hline 0 \end{bmatrix} \quad \text{and} \quad \mathscr{A}'\begin{bmatrix} 0 \\ w_- \\ \hline 0 \end{bmatrix} = \begin{bmatrix} \rho_2 e_0 \\ \hline 0 \end{bmatrix},$$

where

$$\rho_1 = [a_n \quad \cdots \quad a_1]w_+ = [a_n \quad \cdots \quad a_1]Mc = \sigma_- e_0^T c = \varepsilon\sigma_-$$

and

$$\rho_2 = [a_{-1} \quad \cdots \quad a_{-n}]w_- = [a_{-1} \quad \cdots \quad a_{-n}]M\hat{c} = \sigma_+ e_{n-1}^T \hat{c} = \varepsilon\sigma_+.$$

From these relations we get (4.29) immediately. □

Now we can establish a recursion from $w_\pm$, $y_\pm$ to $y'_\pm$. However, the formula will be a little nicer for $y_\pm$, $y'_\pm$ being replaced by $\tilde{y}_\pm$, $\tilde{y}'_\pm$, which are the first parts of the corresponding vectors of the canonical fundamental systems and which are defined by

$$\begin{aligned} \tilde{y}_+(\lambda) &= y_+(\lambda) - \lambda^n, \qquad \tilde{y}'_+(\lambda) = y'_+(\lambda) - \lambda^{n-1}, \\ \tilde{y}_-(\lambda) &= -1 + \lambda y_-(\lambda), \qquad \tilde{y}'_-(\lambda) = -1 + \lambda y'_-(\lambda). \end{aligned} \tag{4.31}$$

THEOREM 4.5. *Assume that* $\sigma_+\sigma_- \neq 0$. *Then the vectors* $\tilde{y}'_\pm$ *can be computed from* $\tilde{y}_\pm$ *and* $w_\pm$ *with the help of the formulas*

$$\tilde{y}'_+(\lambda) = y^0_+(\lambda) + \frac{a_{-n-1} - \nu_+}{\varepsilon\sigma_+}\lambda w_-(\lambda),$$

$$\tilde{y}'_-(\lambda) = y^0_-(\lambda) + \frac{a_{n+1} - \nu_-}{\varepsilon\sigma_-} w_+(\lambda), \tag{4.32}$$

where

$$[y^0_+(\lambda) \quad y^0_-(\lambda)] = [\tilde{y}_+(\lambda) \quad \tilde{y}_-(\lambda)]\begin{bmatrix}\lambda & 0\\ 0 & 1\end{bmatrix}\begin{bmatrix}1 & -\mu_-\\ -\mu_+ & 1\end{bmatrix} \tag{4.33}$$

and

$$\mu_+ = \frac{\delta\sigma_+}{\sigma_-}, \quad \mu_- = \frac{\bar{\delta}\sigma_-}{\sigma_+}, \quad \delta = \frac{(c)_{\kappa-1}}{(c)_0}, \tag{4.34}$$

$$\begin{aligned} \nu_+ &= \phi_+ - \mu_+(\psi_- - a_0), & \nu_- &= \phi_- - \mu_-(\psi_+ - a_0),\\ \phi_+ &= [a_{-1} \quad \cdots \quad a_{-n}]y_+, & \psi_- &= [a_{-1} \quad \cdots \quad a_{-n}]y_-,\\ \psi_+ &= [a_n \quad \cdots \quad a_1]y_+, & \phi_- &= [a_n \quad \cdots \quad a_1]y_-. \end{aligned} \tag{4.35}$$

Moreover,

$$\psi_- = \psi_+. \tag{4.36}$$

Proof. Let $V\eta_\pm$, $\Lambda\eta_\pm$ denote the vectors obtained from $\eta_\pm$ after cancelling the first or last component, respectively. Then we observe that

$$\mathscr{A}'\begin{bmatrix}0\\ y_+\\ \hline \Lambda\eta_+\end{bmatrix} = \begin{bmatrix}\phi_+e_0 + g^0_+\\ \hline 0\end{bmatrix} - (\eta_+)_{\kappa-1}\begin{bmatrix}h'_+\\ \hline 0\end{bmatrix},$$

$$\mathscr{A}'\begin{bmatrix}-1\\ y_-\\ \hline \Lambda\eta_-\end{bmatrix} = \begin{bmatrix}(\psi_- - a_0)e_0\\ \hline 0\end{bmatrix} - (\eta_-)_{\kappa-1}\begin{bmatrix}h'_+\\ \hline 0\end{bmatrix},$$

and

$$\mathscr{A}'\begin{bmatrix}y_+\\ -1\\ \hline V\eta_+\end{bmatrix} = \begin{bmatrix}(\psi_+ - a_0)e_{n-1}\\ \hline 0\end{bmatrix} - (\eta_+)_0\begin{bmatrix}h'_-\\ \hline 0\end{bmatrix},$$

$$\mathscr{A}'\begin{bmatrix}y_-\\ 0\\ \hline V\eta_-\end{bmatrix} = \begin{bmatrix}\phi_-e_{n-1} + g^0_-\\ \hline 0\end{bmatrix} - (\eta_-)_0\begin{bmatrix}h'_-\\ \hline 0\end{bmatrix},$$

where

$$\begin{aligned} h'_+ &= [0 \quad \cdots \quad 0 \quad \bar{u}_r \quad \cdots \quad \bar{u}_0]^T, & h'_- &= [\bar{u}_r \quad \cdots \quad \bar{u}_0 \quad 0 \quad \cdots \quad 0]^T,\\ g^0_+ &= [0 \quad a_{-n} \quad \cdots \quad a_{-1}]^T, & g^0_- &= [a_1 \quad \cdots \quad a_n \quad 0]^T \end{aligned}$$

and $\phi_\pm$, $\psi_\pm$ are defined by (4.35).

We introduce auxiliary vectors

$$\left[\begin{array}{c} y_+^0 \\ \hline \eta_+^0 \end{array}\right] := \left[\begin{array}{c} 0 \\ \hline y_+ \\ \hline \Lambda\eta_+ \end{array}\right] - \mu_+ \left[\begin{array}{c} -1 \\ \hline y_- \\ \hline \Lambda\eta_- \end{array}\right], \qquad \left[\begin{array}{c} y_-^0 \\ \hline \eta_-^0 \end{array}\right] := \left[\begin{array}{c} y_- \\ \hline 0 \\ \hline V\eta_- \end{array}\right] - \mu_- \left[\begin{array}{c} y_+ \\ \hline -1 \\ \hline V\eta_+ \end{array}\right], \tag{4.37}$$

where

$$\mu_+ = (\eta_+)_{\kappa-1}/(\eta_-)_{\kappa-1}, \qquad \mu_- = (\eta_-)_0/(\eta_+)_0. \tag{4.38}$$

Then we have

$$\begin{aligned} \mathscr{A}' \left[\begin{array}{c} y_+^0 \\ \hline \eta_+^0 \end{array}\right] &= \left[\begin{array}{c} (\phi_+ - \mu_+(\psi_- - a_0))e_0 + g_+^0 \\ \hline 0 \end{array}\right], \\ \mathscr{A}' \left[\begin{array}{c} y_-^0 \\ \hline \eta_-^0 \end{array}\right] &= \left[\begin{array}{c} (\phi_- - \mu_-(\psi_+ - a_0))e_{n-1} + g_-^0 \\ \hline 0 \end{array}\right]. \end{aligned} \tag{4.39}$$

Hence

$$y'_+ = y_+^0 + (a_{-n-1} - \phi_+ + \mu_+(\psi_- - a_0))x'_+$$

and

$$y'_- = y_-^0 + (a_{n+1} - \phi_- + \mu_-(\psi_+ - a_0))x'_-.$$

Taking Lemma 4.5 into account, we obtain (4.32).

Relation (4.33) follows from (4.37) for $\mu_\pm$ being defined by (4.38). It remains to show that $\mu_\pm$ can also be expressed by (4.34).

By Proposition 3.4, we have $\eta_+ = \sigma_+ c$, $\eta_- = \sigma_- \hat{c}$. Hence

$$(\eta_+)_{\kappa-1} = \sigma_+(c)_{\kappa-1} = \delta\varepsilon\sigma_+, \qquad (\eta_-)_{\kappa-1} = \sigma_-(\hat{c})_{\kappa-1} = \varepsilon\sigma_-,$$
$$(\eta_+)_0 = \sigma_+(c)_0 = \varepsilon\sigma_+, \qquad (\eta_-)_0 = \sigma_-(\hat{c})_0 = \bar{\delta}\varepsilon\sigma_-,$$

where

$$\varepsilon = (c)_0.$$

This implies the equivalence of (4.38) and (4.34).

It remains to prove (4.36). We have

$$\psi_- = [a_{-1} \quad \cdots \quad a_{-n}]A^+[a_1 \quad \cdots \quad a_n]^T.$$

In view of $J_n A^+ J_n = (A^+)^T$, we conclude that

$$\psi_- = [a_n \quad \cdots \quad a_1]A^+[a_{-n} \quad \cdots \quad a_{-1}]^T = [a_n \quad \cdots \quad a_1]y_+ = \psi_+. \qquad \square$$

Remark 4.5. Constants $\nu_\pm$ can also be expressed as

$$\nu_+ = [a_0 \quad \cdots \quad a_{-n}]y_+^0, \qquad \nu_- = [a_n \quad \cdots \quad a_0]y_-^0.$$

That means, for the computation of $y'_\pm$, only two inner product calculations are needed.

If A is Hermitian, then all recursions can be simplified. First we recall that, in this case, we need only the recursion of Theorems 4.1, 4.2, and 4.5. In the case of a semidefinite A, only Theorems 4.1 and 4.2 must be applied. Furthermore,

$$x_- = \hat{x}_+, \quad y_- = \hat{y}_+, \quad w_- = \hat{w}_+, \quad z_- = \hat{z}_+,$$

and the same is true, of course, for the corresponding vectors for $\mathscr{A}'$. Moreover,

$$\beta_- = \bar{\beta}_+ \quad \text{and} \quad \phi_- = \bar{\phi}_+.$$

5. Complete nested recursion.

5.1. Classification. In this section, we consider the family of all principal submatrices

$$A^{(k)} = [a_{i-j}]_0^{k-1} \ (k = 1, \ldots, n)$$

of Toeplitz matrix A given by (1.1). All quantities introduced in previous sections for matrix A are denoted by the same symbol in the case of matrix $A^{(k)}$ supplemented by superscript (k). For example, $\mathscr{A}^{(k)}$ is the regular extension of $A^{(k)}$ of the form (2.6), $x_\pm^{(k)}$, $y_\pm^{(k)}$, $w_\pm^{(k)}$, $z_\pm^{(k)}$ denote the first parts of the solutions of fundamental equations (2.10) and (2.12) for $\mathscr{A}$ replaced by $\mathscr{A}^{(k)}$. Furthermore, $u^{(k)}$ denotes the vector spanning ker $A^{(k)}$ according to Lemma 2.2, $\kappa^{(k)} = \dim \ker A^{(k)}$, and

$$\sigma_+^{(k)} := [a_{-1} \quad \cdots \quad a_{-k}]\begin{bmatrix} 0 \\ u^{(k)} \end{bmatrix}, \qquad \sigma_-^{(k)} := [a_k \quad \cdots \quad a_1]\begin{bmatrix} u^{(k)} \\ 0 \end{bmatrix}. \tag{5.1}$$

Thereby, 0 denotes a zero vector of length $\kappa^{(k)} - 1$; a_n and a_{-n} are arbitrary but fixed numbers.

The aim of this section is to establish a procedure for the computation of the vectors involved in the matrix representation of A^+ (cf. Theorem 2.1), which is based on a recursion of fundamental systems of the sequence of Toeplitz mosaic matrices $\mathscr{A}^{(k)}$.

Let r denote the largest index k for which matrix $A^{(k)}$ is nonsingular. If all $A^{(k)}$ are singular, we put $r = 0$. Then $\dim \ker A^{(r+1)} = 1$. Suppose that

$$\ker A^{(r+1)} = \operatorname{lin}\{u\}, \qquad u = (u_i)_0^r. \tag{5.2}$$

Then $u_0 u_r \neq 0$.

It is a remarkable fact that, with the help of the vector u, the kernels of all matrices $A^{(k)}$ for $k > r$ can be described. For this we still introduce the numbers

$$\sigma_{k,-} := [a_k \quad \cdots \quad a_{k-r}]u, \qquad \sigma_{k,+} := [a_{r-k} \quad \cdots \quad a_{-k}]u. \tag{5.3}$$

Clearly, $\sigma_{k,-} = \sigma_{k,+}$ for $k = 0, \ldots, r$. Let s denote the smallest integer for which $\sigma_{k,-} \neq 0$ and t the smallest integer for which $\sigma_{k,+} \neq 0$. In case that all $\sigma_{k,-}$ or $\sigma_{k,+}$ vanish, we set $s = n$ or $t = n$, respectively.

LEMMA 5.1. *Let $u^{(k)}$ denote the vector spanning* ker $A^{(k)}$ *according to Lemma* 2.2. *Then*:

(I) *For* $r < k < \min\{s, t\}$

$$u^{(k+1)} = u^{(k)}, \qquad \kappa^{(k+1)} = \kappa^{(k)} + 1.$$

(II) *For* $t \leq k < s$

$$u^{(k+1)} = \begin{bmatrix} u^{(k)} \\ 0 \end{bmatrix}, \qquad \kappa^{(k+1)} = \kappa^{(k)}.$$

(III) *For* $s \leq k < t$

$$u^{(k+1)} = \begin{bmatrix} 0 \\ u^{(k)} \end{bmatrix}, \qquad \kappa^{(k+1)} = \kappa^{(k)}.$$

(IV) *For* $\max\{s, t\} \leq k$

$$u^{(k+1)} = \begin{bmatrix} 0 \\ u^{(k)} \\ 0 \end{bmatrix}, \qquad \kappa^{(k+1)} = \kappa^{(k)} - 1.$$

The assertion of the lemma follows from the considerations in [11, I.5.9].

As a consequence we get the following corollary.

COROLLARY 5.1. *The following relations hold true.*

$$\sigma_+^{(k)} = \begin{cases} \sigma_{k,+} = 0 & r \le k < t, \\ \sigma_{t,+} \ne 0 & t \le k, \end{cases} \qquad \sigma_-^{(k)} = \begin{cases} \sigma_{k,-} = 0 & r \le k < s, \\ \sigma_{s,-} \ne 0 & s \le k. \end{cases}$$

That means the recursion part of the algorithm involves merely numbers $\sigma_+ := \sigma_{t,+}$ and $\sigma_- := \sigma_{s,-}$.

Furthermore, we may conclude the following corollary.

COROLLARY 5.2. *It holds that*

(a)
$$(u^{(k)})_0 = u_0 \ne 0 \quad \text{for } r < k \le s,$$
$$(u^{(k)})_0 = 0 \qquad \text{for } s < k.$$

(b)
$$(u^{(k)})_{r(k)-1} = u_r \ne 0 \quad \text{for } r < k \le t,$$
$$(u^{(k)})_{r(k)-1} = 0 \qquad \text{for } t < k, \text{ where } r(k) = k - \kappa^{(k)}.$$

Now we can classify matrices $A^{(k)}$ according to Cases (I)–(IV) of System (A) in Theorem 3.1.

$$\text{Case (I) } ((u^{(k)})_0 (u^{(k)})_{r(k)-1} \ne 0)\text{: } r < k \le \min\{s, t\}$$
$$\text{Case (II) } ((u^{(k)})_0 \sigma_+^{(k)} \ne 0)\text{: } t \le k \le s$$
$$\text{Case (III) } (\sigma_-^{(k)} (u^{(k)})_{r(k)-1} \ne 0)\text{: } s \le k \le t$$
$$\text{Case (IV) } (\sigma_-^{(k)} \sigma_+^{(k)} \ne 0)\text{: } \max\{s, t\} \le k.$$

Let us point out that the cases have some nonempty intersections that are levels t and s. This allows us to change the fundamental system with the help of Proposition 3.6 as it is required for the continuation of the recursive procedure.

Now we are able to describe an algorithm for MPI computation.

5.2. Initialization. The first step is the computation of the integer r, the vector u satisfying the conditions of Lemma 2.2, and the quantities $\sigma_{k,-}$ and $\sigma_{k,+}$ for $k = r+1$, $r+2, \ldots$ up to the first nonzero number. This can be done by standard algorithms of the Levinson type for Toeplitz matrix inversion. In the Appendix we present a version that is convenient for our purposes and is a slight modification of the algorithm proposed in [10] (for Hankel matrices see [9]).

The second step consists in the computation of first parts of the fundamental system of the matrix

$$\mathscr{A}^{(r+1)} = \begin{bmatrix} A^{(r+1)} & \hat{u} \\ u^* & 0 \end{bmatrix}.$$

Since we have for $k = r+1$ Case (I) of Theorem 3.1, we must evaluate $x_\pm^{(r+1)}$ and $w_\pm^{(r+1)}$. This can be done by the following relations.

PROPOSITION 5.1. *It holds that*

(5.4)
$$\text{(a)} \quad w_+^{(r+1)} = w_-^{(r+1)} = \frac{1}{u^* u}\, u.$$

(b) *If $r > 0$ and $p_\pm$ are the solutions of the equations*

(5.5)
$$A^{(r)} p_+ = (\bar{u}_{r-i})_{i=1}^{r}, \qquad A^{(r)} p_- = (\bar{u}_{r-i})_{i=0}^{r-1},$$

then

$$\rho_+ := [a_{-1} \quad \cdots \quad a_{-r}]p_+ - \bar{u}_r \neq 0, \qquad \rho_- := [a_r \quad \cdots \quad a_1]p_- - \bar{u}_0 \neq 0 \tag{5.6}$$

and

$$x_+^{(r+1)} = \frac{1}{\rho_+}\left(\begin{bmatrix} 0 \\ p_+ \end{bmatrix} - \theta_+ u\right), \qquad x_-^{(r+1)} = \frac{1}{\rho_-}\left(\begin{bmatrix} p_- \\ 0 \end{bmatrix} - \theta_- u\right), \tag{5.7}$$

where

$$\theta_+ = \frac{1}{u^*u}[\bar{u}_1 \quad \cdots \quad \bar{u}_r]p_+, \qquad \theta_- = \frac{1}{u^*u}[\bar{u}_0 \quad \cdots \quad \bar{u}_{r-1}]p_-. \tag{5.8}$$

(c) *If* $r = 0$ *then* $x_\pm^{(r+1)} = 0$.

Proof. Obviously,

$$\mathscr{A}^{(r+1)}\begin{bmatrix} u \\ 0 \end{bmatrix} = \begin{bmatrix} 0 \\ u^*u \end{bmatrix}, \tag{5.9}$$

which implies (5.4).

Furthermore, we have

$$\mathscr{A}^{(r+1)}\begin{bmatrix} 0 \\ p_+ \\ -1 \end{bmatrix} = \begin{bmatrix} \rho_+ \\ 0 \\ \theta'_+ \end{bmatrix} \quad \text{and} \quad \mathscr{A}^{(r+1)}\begin{bmatrix} p_- \\ 0 \\ -1 \end{bmatrix} = \begin{bmatrix} 0 \\ \rho_- \\ \theta'_+ \end{bmatrix},$$

where $\theta'_\pm = u^*u\theta_\pm$ and $\rho_\pm$, $\theta_\pm$ are defined by (5.6) and (5.8). Taking (5.9) into account, we obtain (5.7).

Assertion (c) is obvious. □

Vectors $p_\pm$ can be computed with the help of a standard recursive algorithm for the solution of Toeplitz systems or with the help of a matrix representation (e.g., a Gohberg–Semencul formula) for $(A^{(r)})^{-1}$ (see the Appendix).

5.3. Recursion. We arrive at the main part of the algorithm, which is the recursion of the first parts of fundamental systems of $\mathscr{A}^{(k)}$.

For $k \leq \min\{s, t\}$ we successively compute vectors $w_\pm^{(k)}$ and $x_\pm^{(k)}$ according to formulas (4.5) and (4.14), (4.15) for $w_\pm$, $x_\pm$ being replaced by $w_\pm^{(k)}$ and $x_\pm^{(k)}$, $w'_\pm$, $x'_\pm$ being replaced by $w_\pm^{(k+1)}$, $x_\pm^{(k+1)}$ and $\kappa = k - r$.

If $k = \min\{s, t\}$, then we use Corollary 3.2 to change to one of the Cases (II), (III), or (IV) depending on whether $t < s$, $s < t$, or $s = t$.

For $t \leq k \leq s$, the $w_\pm^{(k)}(\lambda)$ remain unchanged, and the $x_-^{(k)}$, $y_+^{(k)}$ are computed with the help of (4.21), (4.22). Analogously, case $s \leq k \leq t$ is treated using recursions (4.8), (4.26), and (4.27).

If $k = \max\{s, t\}$, then we must employ Corollary 3.2 to compute y_+ or y_- of the corresponding level.

As a result of the described recursive procedure, we get the first parts of the fundamental systems of $\mathscr{A}^{(n)} = \mathscr{A}$ according to Cases (I)–(IV) of Theorem 3.1. Let us note that these cases can equivalently be characterized by

$$\text{(I) } s = t = n, \quad \text{(II) } t < s < n, \quad \text{(III) } s < t < n, \quad \text{(IV) } s, t < n. \tag{5.10}$$

This follows from considerations at the end of §5.1.

In the subsequent section, it will be seen that the presented recursion formulas will be useful further on.

5.4. Canonical fundamental system. The final step will be the computation of one of the canonical fundamental systems. Since the formulas for A^+ involve only the first parts of the corresponding vectors, it suffices to evaluate them. We show how to determine the first parts of the (+)-system.

Of course, we must distinguish the four Cases (I)–(IV) listed in (5.10) (or Theorem 3.1). In these cases the following vectors must be computed:

$$\begin{aligned}
&\text{(I)} && y_+,\ z_+ && \text{from } x_\pm,\ w_\pm,\\
&\text{(II)} && x_+,\ z_+ && \text{from } x_-,\ y_+,\ w_\pm,\\
&\text{(III)} && y_+,\ z_+ && \text{from } x_+,\ y_-,\ w_\pm,\\
&\text{(IV)} && x_+,\ z_+ && \text{from } y_\pm,\ w_\pm.
\end{aligned}$$

The computation of the corresponding linear combinations can be carried out by applying matrix Φ_+ introduced in §3 to the corresponding vectors. This leads to two 4×4 systems of simple form that can be solved explicitly. However, the explicit formulas are rather complicated. We get simpler formulas if we use vectors of levels $n-1$ and $n+1$. Vectors $x_\pm^{(n+1)}$ and $w_\pm^{(n+1)}$ are obtained by adding another recursion of the same type as from $n-1$ to n. In the case where a_{n+1} or a_{-n-1} occurs in the corresponding recursion, it can be chosen arbitrary. We present the formulas without proofs. The proofs are a straightforward checking.

PROPOSITION 5.2. *It holds that*

(I) *If* $s = t = n$, *then*

$$\tilde{y}_+(\lambda) = \frac{-1}{u_r \varepsilon_{\kappa+1}} w_-^{(n+1)}(\lambda), \tag{5.11}$$

$$z_+(\lambda) = \frac{-1}{u_0 \varepsilon_{\kappa+1}} \left(x_-^{(n+1)}(\lambda) - \frac{(x_-^{(n+1)})_n}{u_r \varepsilon_{\kappa+1}} w_-^{(n+1)}(\lambda) \right). \tag{5.12}$$

(II) *If* $t < s = n$, *then*

$$x_+(\lambda) = \frac{1}{\sigma_+ \varepsilon_{\kappa+1}(1 - |\alpha_\kappa|^2)} (\lambda w_-(\lambda) - \bar{\alpha}_\kappa w_+(\lambda)), \tag{5.13}$$

$$z_+(\lambda) = \frac{-1}{u_0 \varepsilon_\kappa} (x_-^{(n+1)}(\lambda) + (x_-^{(n+1)})_n \tilde{y}_+(\lambda)). \tag{5.14}$$

(III) *If* $s < t = n$, *then*

$$\tilde{y}_+(\lambda) = \frac{-1}{(x_-^{(n+1)})_n} (x_-^{(n+1)}(\lambda) - \psi w_+(\lambda)), \tag{5.15}$$

$$z_+(\lambda) = \frac{-1}{\sigma_- \varepsilon_-} (\tilde{y}_-^{(n-1)}(\lambda) - \phi x_+(\lambda)), \tag{5.16}$$

where

$$\phi = [a_0 \quad \cdots \quad a_{-1+n}] \tilde{y}_-^{(n-1)},$$

$$\psi = [\bar{u}_0 \quad \cdots \quad \bar{u}_r \quad 0 \quad \cdots \quad 0] x_-^{(n+1)}.$$

(IV) *If* $s, t < n$, *then*

$$x_+(\lambda) = \frac{1}{\sigma_+ \varepsilon_{\kappa+1}} \lambda w_-^{(n-1)}(\lambda), \tag{5.17}$$

$$z_+(\lambda) = \frac{-1}{\sigma_- \varepsilon_{\kappa+1}} (\tilde{y}_-^{(n-1)}(\lambda) - \phi x_+(\lambda)), \tag{5.18}$$

where

$$\phi = [a_0 \quad \cdots \quad a_{-1+n}]\tilde{y}_-^{(n-1)}.$$

Recall that

$$\tilde{y}_+(\lambda) = y_+(\lambda) - \lambda^n,$$

$$\tilde{y}_-^{(n-1)}(\lambda) = \lambda y_-^{(n-1)}(\lambda) - 1,$$

$$\varepsilon_k = (T_k^{-1} e_0)_0 \quad (k = \kappa, \kappa + 1).$$

6. Schur-type algorithm. The disadvantage of the algorithm presented in the previous section is that it involves inner product calculations at each level. Therefore it requires $O(n \log n)$ steps in parallel computation, but an amount of $O(n)$ is desirable. In this section we show that, similar to the Toeplitz matrix inversion algorithms, there are modifications without this disadvantage. The corresponding algorithms are related to the famous Schur algorithm and will be referred to as Schur type (cf. [14], [4], [10]).

For simplicity we present here only formulas of Case (I) of Theorem 3.1. Let us recall that we only have Case (I) in the event that matrix A is semidefinite. Formulas for other cases are quite similar, but a little more complicated. We do not present them here because we think that the approach offered in the subsequent section provides more effective algorithms for parallel processing.

We use all the notations of §5.

First let us note that vector u generating the kernel of A can be computed with a Schur-type version of the algorithm, described in the Appendix, which requires $O(n)$ steps at an n-processor computer (see [9], [10]).

Since we only consider Case (I), i.e., we assume $s = t = n$, we only have to apply recursions (4.5) and (4.14) for $x_\pm$, $w_\pm$ being replaced by $x_\pm^{(k)}$, $w_\pm^{(k)}$, and $x'_\pm$; $w'_\pm$ being replaced by $x_\pm^{(k+1)}$, $w_\pm^{(k+1)}$, respectively, to obtain vectors involved in the formula for the MPI of A.

The main task is now to evaluate constants $\alpha_\pm^{(k)}$ and $\beta_\pm^{(k)}$ appearing in these formulas recursively. Constants $\alpha_\pm^{(k)}$ are, by (4.15b), up to constant factors, the same as they appear in the Schur algorithm for the inversion of the positive definite Toeplitz matrix $T_{n-r} = M_{n-r}^* M_{n-r} = [t_{i-j}]_0^{n-r-1}$. We present the corresponding formulas.

We introduce parameters $\alpha_j^{(k)}$ $(j = 1 + r - n, \ldots, 2n - 2r - 2)$ by

$$\alpha_j^{(k)} := [t_j \quad \cdots \quad t_{j-k+r+1}]c_{k-r}, \tag{6.1}$$

where we set $t_j = 0$ for $j \notin \{1 + r - n, \ldots, n - r - 1\}$ and

$$c_{k-r} = T_{k-r}^{-1} e_0.$$

Then formula (4.1) leads to the following proposition.

PROPOSITION 6.1. *Numbers* $\alpha_j^{(k)}$ *fulfill the recursion*

$$\alpha_j^{(k+1)} = \frac{1}{1 - |\alpha^{(k)}|^2} (\alpha_j^{(k)} - \alpha^{(k)} \alpha_{k-j-r}^{(k)}), \tag{6.2}$$

where

$$\alpha^{(k)} := \alpha_{k-r}^{(k)}.$$

Initial values of $\alpha_j^{(k)}$ are $\alpha_j^{(r+1)} = \frac{1}{t_0} t_j$. Note that, by definition, $\alpha_j^{(k)} = 0$ for $j = 1, \ldots, k-1-r$ and $\alpha_0^{(k)} = 1$.

Formula (6.2), together with Proposition 3.2, allows us to compute the vectors $w_\pm$ in $O(n)$ parallel steps.

It remains to find a recursion for constants $\beta_\pm^{(k)}$ defined by

$$\beta_+^{(k)} := [0 \ \cdots \ 0 \ \bar{u}_0 \ \cdots \ \bar{u}_{r-1}]x_+^{(k)}, \qquad \beta_-^{(k)} := [\bar{u}_1 \ \cdots \ \bar{u}_r \ 0 \ \cdots \ 0]x_-^{(k)} \tag{6.3}$$

appearing in the recursion (4.14) for A being replaced by $A^{(k)}$.

Let N_k denote the matrix of the form (2.5) with k columns. We need the following formula.

LEMMA 6.1. *It holds that*

$$N_k w_\pm^{(k)} = a_\pm^{(k)},$$

where

$$a_+^{(k)} = (\alpha_j^{(k)})_{j=-r}^{k-1} \quad \textit{and} \quad a_-^{(k)} = \hat{a}_+^{(k)}. \tag{6.4}$$

Proof. By Proposition 3.2, we have

$$w_+^{(k)} = M_{k-r} c_{k-r} \quad \text{and} \quad w_-^{(k)} = M_{k-r} \hat{c}_{k-r}.$$

Hence

$$N_k w_+^{(k)} = N_k M_{k-r} c_{k-r} = \tilde{T}_{k-r} c_{k-r}, \tag{6.5}$$

where

$$\tilde{T}_{k-r} = \begin{bmatrix} t_{1-\kappa} & & 0 \\ \vdots & \ddots & \\ t_{k-n} & & t_{1-\kappa} \\ \vdots & & \vdots \\ t_{\kappa-1} & & t_{n-k} \\ & \ddots & \vdots \\ 0 & & t_{\kappa-1} \end{bmatrix}, \qquad (\kappa = n-r),$$

and we get

$$N_k w_-^{(k)} = \tilde{T}_{k-r} \hat{c}_{k-r}. \tag{6.6}$$

Formula (6.5) implies the first relation of (6.4) immediately. The second relation follows after taking into account that

$$\tilde{T}_{k-r} J_{k-r} = J_m \bar{\tilde{T}}_{k-r},$$

where $m = 2\kappa - r + k - 2$. □

We now introduce vectors $b_\pm^{(k)}$ by

$$b_\pm^{(k)} := N_k x_\pm^{(k)}.$$

Suppose that

$$b_\pm^{(k)} = (\beta_{\pm,j}^{(k)})_{j=-r}^{k-1}.$$

Then we have, in particular,

$$\beta_{+}^{(k)} = \beta_{+,k-r}^{(k)} \quad \text{and} \quad \beta_{-}^{(k)} = \beta_{-,-1}^{(k)}. \tag{6.7}$$

PROPOSITION 6.2. *Parameters $\beta_{\pm,j}^{(k)}$ fulfill recursions*

$$\beta_{+,j}^{(k+1)} = \frac{1}{1 - |\alpha^{(k)}|^2}\left(\beta_{+,j}^{0} - \frac{u_r}{u_0}\,\alpha^{(k)}\beta_{-,j}^{0}\right), \tag{6.8a}$$

$$\beta_{-,j}^{(k+1)} = \frac{1}{1 - |\alpha^{(k)}|^2}\left(-\frac{u_0}{u_r}\,\bar{\alpha}^{(k)}\beta_{+,j}^{0} + \beta_{-,j}^{0}\right), \tag{6.8b}$$

where

$$\beta_{+,j}^{0} := \beta_{+,j}^{(k)} - \beta_{+}^{(k)}\bar{\alpha}_{k-r-j}^{(k+1)}, \qquad \beta_{-,j}^{0} := \beta_{-,j-1}^{(k)} - \beta_{-}^{(k)}\alpha_{j}^{(k+1)}. \tag{6.9}$$

These formulas follow from (4.14) after applying N_{k+1} to both sides and taking Lemma 6.1 into account.

Now recursions (6.2), (6.8), (6.9), together with (4.5) and (4.14), provide an $O(n)$ step parallel algorithm to compute vectors $w_{\pm}$, $x_{\pm}$. Vectors $y_{\pm}$, $z_{\pm}$ are obtained according to Proposition 5.2.

7. Nonrecursive approach. In this section we present another approach to obtain vectors x_+, y_+, w_+, z_+ appearing in formula (2.11), which is based on formula (1.4) for the MPI. The complexity of the corresponding algorithm equals $O(n\ (\log n)^2)$.

The first step is the construction of a generalized inverse of A that possesses a simple structure. In [11], two approaches are offered for Hankel matrices. We choose the second approach and adopt it to the case of Toeplitz matrices. The approach is based on the following well-known fact (see [11]).

LEMMA 7.1. *Suppose that C is an $n \times n$ singular matrix with defect κ and let C_+ be a $\kappa \times n$ and C_- a $n \times \kappa$ matrix such that $[C \quad C_-]$ and $\begin{bmatrix} C \\ C_+ \end{bmatrix}$ have full rank. Then*

$$\tilde{C} = \begin{bmatrix} C & C_- \\ C_+ & C_0 \end{bmatrix}$$

is nonsingular for any $\kappa \times \kappa$ matrix C_0. Furthermore, if

$$\tilde{C}^{-1} = \begin{bmatrix} B & B_+ \\ B_- & B_0 \end{bmatrix},$$

where B is $n \times n$, then B is generalized inverse to C, i.e., $CBC = C$.

In our case of a Toeplitz matrix A, we choose $C_{\pm}$ and C_0 in such a way that $\tilde{C} = A^{(n+\kappa)} = [a_{i-j}]_0^{n+\kappa-1}$, i.e., $\tilde{C}$ is a Toeplitz extension of A. To find such an extension, we introduce the concept of a fundamental system of a singular Toeplitz matrix A.

We introduce the family of Toeplitz matrices

$$\partial^k A = [a_{i-j}]_{i=k}^{n-1}{}_{j=0}^{n-1+k} \quad (k = 0, \pm 1, \ldots, \pm(n-1)). \tag{7.1}$$

Then the following lemma is true (cf. [11]).

LEMMA 7.2. *Suppose that κ denotes the defect of A, and A is not the zero matrix. Then there are two vectors $u \in \mathbb{C}^{n-\kappa+1}$ and $v \in \mathbb{C}^{n+\kappa+1}$ such that $\mathscr{C}_k := \{x(\lambda)\colon x \in \ker \partial^k A\}$, $\mathscr{C}_n := \{x(\lambda)\colon x \in \mathbb{C}^{2n}\}$ is given by*

$$\mathscr{C}_k = \begin{cases} \operatorname{lin}\{u(\lambda), \lambda u(\lambda), \ldots, \lambda^{k-1+\kappa}u(\lambda)\} & k = 1-\kappa, \ldots, \kappa, \\ \operatorname{lin}\{u(\lambda), \ldots, \lambda^{k-1+\kappa}u(\lambda), v(\lambda), \ldots, \lambda^{k-1-\kappa}v(\lambda)\} & k = \kappa+1, \ldots, n. \end{cases} \tag{7.2}$$

From Lemma 7.2 we can conclude, in particular, that the first (last) component of one of the vectors u or v is nonzero and that the polynomials $u(\lambda)$ and $v(\lambda)$ are coprime.

Any pair of vectors u, v is said to be a *fundamental system* of A. Clearly, u is unique up to a constant factor, but v is not unique. It can be changed by linear combinations of $\lambda^i u(\lambda)$. This leads to the following remark.

Remark 7.1. Vector $v = (v_i)_0^{n+\kappa}$ can be chosen in such a way that $v_0 v_{n+\kappa} \neq 0$.

With the help of vector v, we extend A to a nonsingular matrix. We define successively

$$a_k := -\frac{1}{v_0} \sum_{i=1}^{n+\kappa} a_{k-i} v_i \quad (k = n, \ldots, n+\kappa-1) \tag{7.3a}$$

and

$$a_{-k} := -\frac{1}{v_{n+\kappa}} \sum_{i=0}^{n+\kappa-1} a_{n-k+\kappa-i} v_i \quad (k = n, \ldots, n+\kappa-1). \tag{7.3b}$$

LEMMA 7.3. *Matrix $A^{(n+\kappa)}$ is nonsingular and $\{\lambda^\kappa u(\lambda), v(\lambda)\}$ is a fundamental system of $A^{(n+\kappa)}$.*

Proof. By construction $\tilde{u}, v \in \ker \partial A^{(n+\kappa)}$, where $\tilde{u}(\lambda) = \lambda^\kappa u(\lambda)$. We still must show that $A^{(n+\kappa)}$ is nonsingular. If $\tilde{\kappa} = \dim \ker A^{(n+\kappa)} > 0$, then, by Lemma 7.2, $\ker \partial A^{(n+\kappa)}$ is the linear hull of vectors corresponding to polynomials $\lambda^i w(\lambda)$ for a certain vector w. That means that all polynomials corresponding to vectors in $\ker \partial A^{(n+\kappa)}$ would have a common zero. But $\tilde{u}(\lambda)$ and $v(\lambda)$ are coprime. Consequently, $\tilde{\kappa} = 0$. □

With the arguments of the proof of Lemma 7.3, we may check that the assumptions of Lemma 7.1 are fulfilled. Hence the following lemma is true.

LEMMA 7.4. *If $(A^{(n+\kappa)})^{-1}$ is decomposed in the form*

$$(A^{(n+\kappa)})^{-1} = \begin{bmatrix} B & B_- \\ B_+ & B_0 \end{bmatrix},$$

where B is $n \times n$, then B is a generalized inverse of A.

Now we employ the well-known results on the inverse of a nonsingular Toeplitz matrix (see [10], [11]) and obtain the following theorem.

THEOREM 7.1. *Suppose that A is a Toeplitz matrix with defect $\kappa > 0$ and $u = (u_i)_0^{n-\kappa}$, $v = (v_i)_0^{n+\kappa}$ is a fundamental system of A with $v_0 v_{n+\kappa} \neq 0$. Let a_{-n} be defined according to* (7.3b). *Then the $n \times n$ principal submatrix $B^{(n)}$ of the matrix*

$$B = \frac{1}{\sigma} \operatorname{Bez}(\lambda^\kappa u(\lambda), v(\lambda)), \tag{7.4}$$

where

$$\sigma = v_{n+\kappa}[a_{-\kappa} \quad \cdots \quad a_{-n}]u \tag{7.5}$$

is a generalized inverse of A.

The fundamental system of A can be computed by standard Toeplitz matrix algorithms (see the Appendix).

To make the application of formula (1.4) possible, we must determine orthogonal projections P and Q onto $\ker A$ and $\operatorname{Im} A$, respectively.

Since by Lemma 2.2 we have $\ker A = \operatorname{Im} M$ and M has full rank, we get the following expression for P:

$$P = MT^{-1}M^*, \tag{7.6}$$

where $T = M^*M$ is a positive definite Toeplitz matrix.

Since $I - Q$ is the orthogonal projection onto $\ker A^*$, taking (3.8) into account, we obtain

$$Q = I - NT^{-1}N^*. \tag{7.7}$$

From (1.4) and Theorem 7.1 we conclude the following corollary.

COROLLARY 7.1. *If $B^{(n)}$ is the matrix from Theorem* 7.1, *then the* MPI *of A is given by*

$$A^+ = (I - MT^{-1}M^*)B^{(n)}(I - NT^{-1}N^*). \tag{7.8}$$

Since T^{-1} can be represented as the product sum of triangular Toeplitz matrices, and other matrices involved in (7.8) are also of this type, the application of A^+ to a vector with the help of formula (7.8) requires only $O(n \log n)$ flops.

To make it possible to use the somehow simpler formula (2.11), we must evaluate vectors x_+, y_+, w_+, z_+. Vector w_+ is, according to Proposition 3.2, given by $w_+ = Mc$, where $c = T^{-1}e_0$. The other three vectors are pseudo solutions of certain equations, i.e., they can be computed with the help of (7.8).

However, it is more convenient to replace x_+, y_+, w_+, z_+ by other systems that also determine A^+. A convenient choice is $z_\pm$, $w_\pm$, which corresponds to System (B) of Theorem 3.1.

Vector w_- is given by $w_- = M\hat{c}$ and vectors $z_\pm$ by

$$z_+ = A^+h_+, \qquad z_- = A^+h_-, \tag{7.9}$$

where

$$h_+ = [0 \ \cdots \ 0 \ \bar{u}_{n-\kappa} \ \cdots \ \bar{u}_1]^T, \qquad h_- = [\bar{u}_{n-\kappa-1} \ \cdots \ \bar{u}_0 \ 0 \ \cdots \ 0]^T.$$

PROPOSITION 7.1. *Vectors $z_\pm$ defined by* (7.9) *are given by*

$$\begin{aligned} z_+ &= (I_n - MT^{-1}M^*)B^{(n)}(h_+ - Nd), \\ z_- &= (I_n - MT^{-1}M^*)B^{(n)}(h_- - N\hat{d}), \end{aligned} \tag{7.10}$$

where d is given by (3.14) *and $B^{(n)}$ by Theorem* 7.1.

Proof. We have

$$N^*h_- = (t_{1+i})_0^{\kappa-1} \quad \text{and} \quad N^*h_+ = (t_{i-\kappa})_0^{\kappa-1}.$$

Thus

$$T^{-1}N^*h_- = \hat{d} \quad \text{and} \quad T^{-1}N^*h_+ = d.$$

The rest follows from (7.8). □

It remains to compute x_+ and y_+.

PROPOSITION 7.2. *It holds that*

(a) *if $u_r = 0$, then*

$$x_+(\lambda) = \frac{1}{\sigma_+\varepsilon_{\kappa+1}(1 - |\alpha|^2)}(\bar{\alpha}w_+(\lambda) - \lambda w_-(\lambda)), \tag{7.11}$$

$$\tilde{y}_+(\lambda) = -\sigma_+\varepsilon_{\kappa+1}(\lambda z_-(\lambda) + \alpha z_+(\lambda)) - \rho_+ w_+(\lambda) - \rho_-\lambda w_-(\lambda), \tag{7.12}$$

where

$$\rho_- = -\frac{\psi + |\alpha|^2 \bar{u}_r}{1 - |\alpha|^2},$$

$$\psi = [a_{-1} \quad \cdots \quad a_{-n}]z_-,$$

$$\rho_+ = \bar{\alpha}\rho_- - \sigma_+ \varepsilon_{\kappa+1} \chi,$$

$$\chi = [\bar{u}_1 \quad \cdots \quad \bar{u}_r \quad 0 \quad \cdots \quad 0]z_-.$$

(b) *If* $u_r \neq 0$, *then*

$$x_+(\lambda) = -u_r \varepsilon_{\kappa+1}(\lambda z_-(\lambda) + \alpha z_+(\lambda)) + \left(\rho - \frac{\bar{\alpha}}{1 - |\alpha|^2}\right) w_+(\lambda) + \frac{(z_-)_{n-1}}{1 - |\alpha|^2} \lambda w_-(\lambda), \tag{7.13}$$

$$\tilde{y}_+(\lambda) = \frac{\sigma_+}{u_r} x_+(\lambda) - \frac{1}{\varepsilon u_r}(\lambda w_-(\lambda) - \bar{\alpha} w_+(\lambda)), \tag{7.14}$$

where

$$\rho = u_r \varepsilon_{\kappa+1}[\bar{u}_1 \quad \cdots \quad \bar{u}_r \quad 0 \quad \cdots \quad 0]z_-.$$

Recall that

$$\varepsilon_{\kappa+1} = (c_{\kappa+1})_0, \qquad \varepsilon = \varepsilon_\kappa = (c)_0,$$

$$\alpha = \alpha_\kappa = -(c_{\kappa+1})_\kappa / (c_{\kappa+1})_0,$$

$$\tilde{y}_+(\lambda) = y_+(\lambda) - \lambda^n.$$

Relation (7.4) coincides with (3.27), and (7.11) is a consequence of Proposition 3.3. The other two equalities can be verified by applying matrices $\Phi_\pm$ introduced in §3. Corresponding proofs are straightforward but cumbersome, therefore we omit the details.

Appendix. Computation of a fundamental system of a square Toeplitz matrix. For the convenience of the reader, we present here an algorithm for the computation of a fundamental system of a square Toeplitz matrix A. This algorithm can be used to get vector u, which is necessary for the initialization of the algorithm described in §5 or to establish a generalized inverse of A, which is needed to apply the approach of §7.[2]

The algorithm presented below is a slight modification of the algorithm described in [10] and the two-step Hankel matrix algorithm discussed in [9]. Different from many classical procedures, our algorithm works without additional assumption.

For brevity, we describe only the Levinson-type version of the algorithm. For the Schur-type version, which is convenient for parallelisation, a divide-and-conquer procedure, and some historical comments, we refer to [9] and [10].

As above, let $A^{(k)}$ denote the principal submatrices of A, $A^{(k)} = [a_{i-j}]_0^{k-1}$. Suppose that $\kappa_k := \dim \ker A^{(k)}$. Let $\{u^{(k)}, v^{(k)}\}$ be a fundamental system of $A^{(k)}$, where $u^{(k)}$, $v^{(k)}$ are vectors of length $k - \kappa_k + 1$, $k + \kappa_k + 1$, respectively. We show how to evaluate a fundamental system for $A^{(k+1)}$. We must distinguish different cases. Indicators for these cases are the numbers

$$\sigma_{11}^{(k)} = [a_{-\kappa_k} \quad \cdots \quad a_{-k}]u^{(k)}, \qquad \sigma_{12}^{(k)} = [a_k \quad \cdots \quad a_{\kappa_k}]u^{(k)},$$

$$\sigma_{21}^{(k)} = [a_{\kappa_k} \quad \cdots \quad a_{-k}]v^{(k)}, \qquad \sigma_{22}^{(k)} = [a_k \quad \cdots \quad a_{-\kappa_k}]v^{(k)}.$$

For brevity we omit superscript (k).

[2] The definition of the fundamental system concept is given following Lemma 7.2.

THEOREM A.1. *A fundamental system of* $A^{(k+1)}$ *is given by*

$$[u^{(k+1)}(\lambda) \quad v^{(k+1)}(\lambda)] = [u^{(k)}(\lambda) \quad v^{(k)}(\lambda)]E_k(\lambda),$$

where $E_k(\lambda)$ *and* κ_{k+1} *are defined as follows*:

(1) *Case* $\kappa_k > 0$.

(1a) $\sigma_{11} = \sigma_{12} = 0$,

$$E_k(\lambda) = \begin{bmatrix} 1 & 0 \\ 0 & \lambda \end{bmatrix}, \qquad \kappa_{k+1} = \kappa_k + 1.$$

(1b) $\sigma_{11} \neq 0 = \sigma_{12}$,

$$E_k(\lambda) = \begin{bmatrix} 1 & -\lambda^s \sigma_{21}/\sigma_{11} \\ 0 & \lambda \end{bmatrix}, \qquad \kappa_{k+1} = \kappa_k$$

with $s = 2\kappa_k + 1$.

(1c) $\sigma_{11} = 0 \neq \sigma_{12}$,

$$E_k(\lambda) = \begin{bmatrix} \lambda & -\sigma_{22}/\sigma_{12} \\ 0 & 1 \end{bmatrix}, \qquad \kappa_{k+1} = \kappa_k.$$

(1d) $\sigma_{11}\sigma_{22} \neq 0$,

$$E_k(\lambda) = \begin{bmatrix} \lambda & -\sigma_{22}/\sigma_{12} - \lambda^s \sigma_{21}/\sigma_{11} \\ 0 & 1 \end{bmatrix}, \qquad \kappa_{k+1} = \kappa_k - 1$$

with $s = 2\kappa_k$.

(2) *Case* $\kappa_k = 0$.

(2a) $\sigma_{11}\sigma_{22} - \sigma_{12}\sigma_{21} \neq 0$,

$$E_k(\lambda) = \begin{bmatrix} \sigma_{22} & -\sigma_{21} \\ -\sigma_{12} & \sigma_{11} \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & \lambda \end{bmatrix}, \qquad \kappa_{k+1} = 0.$$

(2b) $\sigma_{11}\sigma_{22} - \sigma_{12}\sigma_{21} = 0$,

$$E_k(\lambda) = \begin{bmatrix} 1 & 0 \\ -\sigma_{11}/\sigma_{21} & \lambda \end{bmatrix} \quad \text{if } \sigma_{21} \neq 0, \qquad \kappa_{k+1} = 1$$

or

$$E_k(\lambda) = \begin{bmatrix} -\sigma_{21}/\sigma_{11} & \lambda \\ 1 & 0 \end{bmatrix} \quad \text{if } \sigma_{11} \neq 0, \qquad \kappa_{k+1} = 1.$$

In the case of a strongly nonsingular matrix A, we only have case (2a). The formula corresponding to this case is the classical Levinson recursion except for a scaling factor. Furthermore, it is worth mentioning that the algorithm essentially simplifies if matrix A is symmetric or Hermitian.

Let us note that, in numerical computation, it is useful to make some scaling during the computation to improve the numerical stability of the algorithm.

Finally, let us describe how to initialize the recursion.

If $a_0 \neq 0$, then we put

$$u^{(1)}(\lambda) = 1, \qquad v^{(1)}(\lambda) = \lambda.$$

In case that $a_{1-l} \neq 0 = a_{2-l} = \cdots = a_{l-1}$, we have $\kappa_l = l - 1$ and we may choose

$$u^{(l)}(\lambda) = 1, \qquad v^{(l)}(\lambda) = \lambda^{2l-1}.$$

In case that $a_{l-1} \neq 0 = a_{l-2} = \cdots = a_{1-l}$, we have $\kappa_l = l - 1$ and we may choose

$$u^{(l)}(\lambda) = \lambda, \qquad v^{(l)}(\lambda) = 1.$$

If $a_{1-l} \neq 0 = a_{2-l} = \cdots = a_{l-2} \neq a_{l-1}$, then $\kappa_l = l - 2$ and

$$u^{(l)}(\lambda) = \lambda, \qquad v^{(l)}(\lambda) = a_{1-l} - a_{l-1}\lambda^{2l-2}$$

is a fundamental system of $A^{(l)}$.

FAST TRIANGULAR FACTORIZATION AND INVERSION OF HANKEL AND RELATED MATRICES WITH ARBITRARY RANK PROFILE*

DEBAJYOTI PAL† AND THOMAS KAILATH‡

Abstract. The authors present a fast procedure for computing a "modified" triangular factorization of Hankel, quasi-Hankel (matrices congruent in a certain sense to Hankel matrices) and sign-modified quasi-Hankel (products of quasi-Hankel and signature matrices) matrices. A fast procedure for computing inverse of Hankel and quasi-Hankel matrices is also presented. A modified triangular factorization is an LDL^* factorization, where L is lower triangular with unit diagonal entries and D is a block diagonal matrix with possibly varying block sizes. Only matrices with all leading minors nonzero, often called strongly regular, will always have a purely diagonal and nonsingular D matrix. The matrices studied in this paper have diagonal blocks with a particular Hankel-(like) structure.

The algorithms presented here are obtained by extending a generating function approach of Lev-Ari and Kailath for matrices with a generalized displacement structure. A particular application of the results is a fast method of computing the rank profile and inertia of the matrices involved.

1. Introduction.

Triangular factorization and inversion of a general $n \times n$ matrix requires $O(n^3)$ elementary operations. The special structure of Hankel matrices,

$$H_{n-1} = [h_{i+j}], \qquad 0 \le i, j \le n-1$$

allows one to invert them or to solve a Hankel system of linear equations by fast algorithms that require only $O(n^2)$ operations (see, e.g., Trench [18], Berlekamp [1], Kung [9], Heinig and Rost [6], Citron [3], Chun [2], Labahn, Choi, and Cabay [10], and the references therein).

However, the particular problem of explicitly computing their triangular factors in $O(n^2)$ operations did not receive as much attention. Among early investigators are Phillips [14], Rissanen [16], [17], and Gragg [4]. Later, Kung [9] and Gragg and Lindquist [5] considered this problem in the context of partial realization problems.

Recently Lev-Ari and Kailath [12] and Chun [2] considered the factorization of Hankel and quasi-Hankel (QH) matrices as a special case of their work on generalized displacement structure. A QH matrix has the form $L_t H L_t^T$, where L_t and H are lower triangular Toeplitz and Hankel, respectively. QH structure arises naturally in the process of factoring a Hankel matrix, because the Schur complement of the top left corner entry of a Hankel matrix is QH. Such matrices arise in other contexts also, e.g., in the computation of the greatest common divisor (GCD) of two polynomials and in the problem of root-distribution of polynomials with respect to (w.r.t.) the real axis. In studying the closely related imaginary axis problem we encounter products

of QH matrices and certain signature matrices, which we shall call sign-modified QH (SMQH) matrices.

However, the results of [12] and [2] or those of [14], [16], and [4] are only for matrices that are *strongly regular*, i.e., with all its leading principal minors nonzero. We should mention here that a strict triangular factorization is not possible unless all the leading minors are nonzero. What can be achieved otherwise is a modified triangular factorization (MTF) of the form

$$M = LD_BL^T,$$

where L is lower triangular with unit diagonal, while D_B is a block diagonal matrix with possibly varying block sizes.

Gragg [4] mentions the possibility of block triangularization via generalized Lanczos polynomials, the so-called lower triangular Hankel structures of the block diagonal entries and their relationship to nontrivial blocks in the Padé table. However Gragg [4] does not provide an algorithm for computing the sought block triangular factorization. These issues have been studied further in Gragg and Lindquist [5], where the algorithm of Kung [9] (which is mentioned in the next paragraph) was used to obtain the results. Rissanen [15] studied the factorization of Hankel matrices that are not strongly regular; however, while his method is recursive it is not fast (i.e., not an $O(n^2)$ procedure). Then, in 1974, Rissanen [17] derived a fast (i.e., $O(n^2)$) procedure for factoring nonstrongly regular Hankel matrices. Although this procedure is recursive, the need for computation of an inner product at each step it makes does not parallelize well (i.e., each recursive step requires a constant number of parallel steps so that the whole algorithm takes $O(n)$ parallel steps) and requires $O(n \log n)$ parallel steps.

Kung [9] presented a method that is fast as well as recursive; however, his procedure is not completely recursive in the sense that it utilizes the block pivots in the presence of vanishing principal minors. Moreover, Kung's procedure requires computation of an inner product at each step, so that this algorithm also does not parallelize well (as explained earlier). The determination of the number of consecutive zero principal minors for a block step is not straightforward in this procedure, and it requires computation of certain "predicted Markov parameters" until a mismatch between the "predicted" and the "given" Markov parameters is observed (see [9] for details).

Recently Citron [3] refined Kung's method to avoid block pivots and the computation of inner products; the determination of the number of consecutive zero minors for a block step was also greatly simplified.

In this paper we present a recursive $O(n^2)$ algorithm for such a factorization. Possibly this is the first paper to give a fast and completely recursive procedure for computing an MTF of Hankel, QH, and SMQH matrices. Furthermore, following the ideas of Chun [2], we develop fast $O(n^2)$ algorithms for factorizing certain block matrices that allow us to obtain alternative $O(n^2)$ algorithms to those mentioned above for solving linear equations and obtaining the inverse of the coefficient matrix.

A characteristic of all these new algorithms is that the coefficients in the recursions are all computed without invoking inner products, a fact that sets them apart from all Berlekamp–Massey-related algorithms. The absence of inner products makes parallel computation more feasible in the sense that with $O(n)$ processors, the computation time for the direct factorization methods can be reduced to $O(n)$, assuming unit time for each elementary computation; because of the inner products, the corresponding number for the Barlekamp–Massey-type algorithms is $O(n \log n)$.

To close this introduction, we make the following observation: all the fast algorithms mentioned above (including those in this paper) either compute the direct triangular factors of the given matrix or the triangular factors of its inverse. Some of these algorithms require that the matrices be strongly regular, i.e., with all its leading principal minors nonzero, while the other algorithms work without this requirement. Although all these procedures are recursive, the need for the computation of an inner product at each step for some of these algorithms makes it difficult to parallelize them well (i.e., each recursive step requires a constant number of parallel steps so that the whole algorithm takes $O(n)$ parallel steps) and requires $O(n \log n)$ parallel steps.

Table 1.1 summarizes these classifications.

In §2, we explain the general (Jacobi) triangular factorization procedure for an arbitrary matrix. Then in §3 we show how the structure of Hankel and QH matrices can be exploited to obtain a fast recursive procedure for computing a modified triangular factorization of Hankel and QH matrices. It is shown that the diagonal blocks are lower triangular Hankel. Following Lev-Ari and Kailath [12], we introduce a "generating function" representation of Hermitian matrices and derive all our results in the form of certain polynomial recursions. In §4 we extend the results of §3 to include

certain SMQH matrices. In §5 we introduce the notions of *block generating functions* and *block quasi-Hankel* (BQH) matrices. It is shown that inverse of a QH matrix can be obtained by computing a block Schur complement of a certain associated BQH matrix. Next we discuss the so-called *admissibility conditions* and derive polynomial recursions for Schur complementation of BQH matrices with regular and arbitrary rank profiles. At this point we discuss the transmission line interpretation of these polynomial recursions and indicate that this procedure works under all circumstances including those where a Gohberg–Heinig-type formula does not hold to be good. We end this section with an example. In §6 we show how to adopt the procedure of §5 towards obtaining solutions to linear equations with a nonsingular QH coefficient matrix and an arbitrary right-hand side. Section 7 contains some concluding remarks. Appendix A provides a proof of (17) and Appendix B describes certain inertia rules of Iohvidov [7].

The related problem of factoring Toeplitz and quasi-Toeplitz (QT) matrices with arbitrary rank profile has been considered in a separate publication [13]. This is because of the fact that although an elegant unified derivation of fast triangularization procedures for structured matrices with a so-called generalized displacement structure has been obtained in the strongly regular case by Lev-Ari and Kailath [12], a unified treatment in the nonstrongly regular cases largely remains an open problem.

2. Triangular factorization of real symmetric matrices. Strongly regular real symmetric matrices $M \epsilon \mathbf{R}^{n \times n}$ can be factored as

$$M = LDL^T, \tag{1}$$

where L is a lower triangular matrix with unit diagonal elements and D is a nonsingular diagonal matrix and the superscript T denotes matrix transpose.

Let us denote the columns of matrix L by $\{\underline{l}_i, \quad i = 1, 2, \ldots, n\}$ and the diagonal elements of the matrix D by $\{d_i\}$. Then we can write

$$M = LDL^T = \sum_{i=1}^{n} d_i \underline{l}_i \underline{l}_i^T, \tag{2}$$

which suggests the following recursive computational procedure:

$$M_{i+1} = M_i - d_i \underline{l}_i \underline{l}_i^T; \qquad M_1 = M, \tag{3}$$

$$d_i = \underline{e}_i^T M_i \underline{e}_i \quad \text{and} \quad \underline{l}_i = M_i \underline{e}_i d_i^{-1}, \tag{4}$$

where $\underline{e}_i$ is the unit vector with nonzero entry at the ith position.

This is the celebrated Jacobi procedure (see [12]). Equations (2)–(4) show that the first $i-1$ rows and columns of M_i contain only zero entries, d_i is the (i,i)th element of M_i, and $d_i \underline{l}_i$ is the ith column of M_i, so that M_i has the form

$$M_i = \left[\begin{array}{c|c} O & O \\ - & - \\ O & P_i \end{array}\right].$$

P_i is called the Schur complement of the matrix M with regard to the leading $(i-1) \times (i-1)$ principal submatrix; note that P_{i+1} is the Schur complement of the $(1,1)$ entry of P_i, i.e., we compute one Schur complement at every step of the triangular factorization procedure (3)–(4).

Singularities. Given a real symmetric matrix M, it will be impossible to compute the Schur complement of the $(1,1)$ element if and only if the $(1,1)$ element is zero. The following are the possibilities:

(i) $M = 0$;

(ii) $M \neq 0$, but the first row and column of M are identically zero;

(iii) $M \neq 0$, the first row and column of M are also not identically zero, but $m_{11} = 0$.

In case (i) finding a triangular factorization is trivial. In case (ii) there is no need to find the Schur complement of m_{11}. We can simply choose the first column of L to be $\underline{e}_1$, and $d_1 = 0$; then resume the triangular factorization procedure. In case (iii) we must find the block Schur complement of the smallest nonsingular block available at the top-left corner of the matrix M. This will lead to a *modified* triangular factorization $M = LDL^T$, where $L \epsilon \mathbf{R}^{n\times n}$ is a lower triangular matrix with unit diagonal elements and $D \epsilon \mathbf{R}^{n\times n}$ is a matrix with scalar as well as block entries along the diagonal, while all the other entries are zero. Such a factorization always exists; however, it is nonunique.

3. Modified triangular factorization of Hankel and QH matrices. Since triangular factorization is nested, factorization of the leading minors does not depend on the actual size of the matrix. Hence we can consider without loss of generality that all matrices under consideration are in fact semi-infinite. Following [12], it is useful to associate M with a "generating" function

$$M(z,w) = [1 \; z \; z^2 \; \ldots \; \ldots] M [1 \; w \; w^2 \ldots \; \ldots]^*, \tag{5}$$

where * denotes the Hermitian transpose. A Hankel matrix of order n has the form $H_{n-1} = [h_{i+j}]_{i,j=0}^{n-1}$, where h_k are arbitrary $(k = 0, 1, 2, \ldots, 2n-2)$. We shall define the semi-infinite extension $H_{n-1,\infty}$ of a finite Hankel matrix H_{n-1} as a Hankel matrix with first row

$$[\, h_0 \; h_1 \; \ldots \; \ldots \; h_{2n-2} \; 0 \; 0 \; \ldots \; \ldots \,].$$

The generating function of this semi-infinite extension can be seen to be (see, e.g., [12])

$$H_{n-1,\infty}(z,w) = \frac{zh(z) - w^* h^*(w)}{z - w^*}, \tag{6}$$

where

$$h(z) = \sum_{k=0}^{2n-2} h_k z^k. \tag{7}$$

Next we shall define a matrix Q to be QH if its generating function $Q(z,w)$ has the form

$$Q(z,w) = \frac{a(z)b^*(w) - b(z)a^*(w)}{z - w^*}, \tag{8}$$

where $a(\cdot)$ and $b(\cdot)$ are real power series. The reason for this definition and for the name will appear soon (see (14) below). First, however, it is convenient to add a "normalizing" assumption that, unless otherwise specified,

$$a(0) = 0. \tag{9}$$

This is justified, except when $a(0) \neq 0$ and $b(0) = 0$ because *given any two real power serieses* $a(z)$ *and* $b(z)$, *we can construct two other real power serieses* $\alpha(z)$ *and* $\beta(z)$ *such that* $a(z)b^*(w) - b(z)a^*(w) = \alpha(z)\beta^*(w) - \beta(z)\alpha^*(w)$ *and* $\alpha(z) = 0$. The exception can be handled by simply interchanging $a(.)$ and $b(.)$. We will postpone the discussion of the so-called singular cases that include case $a(0) = 0 = b(0)$ until §3.1.

THEOREM 3.1. *The Schur complement of the* $(0,0)$ *element* h_0, *of* $H_{n-1,\infty}$ *is* QH.

Proof. If $h_0 = 0$, the Schur complement does not exist. When $h_0 \neq 0$, the Schur complement of h_0 in $H_{n-1,\infty}$ is obtained by subtracting from M the outer product of the first column and the first row, normalized by the inverse of h_0. The generating function $H^c_{n-1,\infty}(z,w)$ of this Schur complement is

$$(zw^*)H^c_{n-1,\infty}(z,w) = H_{n-1,\infty}(z,w) - H_{n-1,\infty}(z,0)[H_{n-1,\infty}(0,0)]^{-1}H_{n-1,\infty}(0,w).$$

Therefore using (7),

$$(zw^*)H^c_{n-1,\infty}(z,w) = H_{n-1,\infty}(z,w) - h(z)h^*(w)/h_0 \ .$$

After some algebra this reduces to

$$H^c_{n-1,\infty}(z,w) = \left(\frac{1}{h_0}\right)\left[\frac{h_1(z)h^*(w) - h(z)h_1^*(w)}{z - w^*}\right]; \qquad h_1(z) = \sum_{k=0}^{2n-3} h_{k+1}z^k, \tag{10}$$

which is QH. □

Given $Q(z,w)$ as in (8), where $a(\cdot)$ and $b(\cdot)$ are real polynomials, say

$$a(z) = \sum_{k=0}^{m} a_k z^k \quad \text{and} \quad b(z) = \sum_{k=0}^{q} b_k z^k,$$

let us define

$$g(z) = \frac{a(z)}{b(z)} = \sum_{k=0}^{\infty} g_k z^k \tag{11}$$

in some disc σ, centered at the origin. Also let

$$f(z) = z^{-1}(g(z) - g(0)) = \sum_{k=0}^{\infty} g_{k+1}z^k. \tag{12}$$

Then in the disc σ,

$$Q(z,w) = b(z)\frac{[zf(z) - w^*f^*(w)]}{(z - w^*)}b^*(w) \ . \tag{13}$$

The central term is the generating function of a Hankel matrix. We shall say that (13) is a congruous relationship because of the following matrix interpretation of (13):

$$Q = B_L F_H B_L^T, \tag{14}$$

where F_H is a semi-infinite Hankel matrix with first row $[\ g_1\ g_2\ g_3\ \ldots\ \ldots\ ]$ and B_L is a semi-infinite lower triangular Toeplitz matrix with first column

$$[\ b_0\ b_1\ \ldots\ \ldots\ b_q\ 0\ 0\ \ldots\ \ldots\ ]^T.$$

Note that since $b(0) \neq 0$, B_L in (14) is always full rank, so that the rank profile of Q is the same as that of F_H. The representation (14) is the reason for the name quasi-Hankel; the QH structure is preserved under Schur complementation.

THEOREM 3.2. *The Schur complement of the* $(0,0)$ *element,* g_1, *of* F_H *is* QH.

Proof. If $g_1 = 0$, then the Schur complement does not exist. So we assume $g_1 \neq 0$. By Theorem 3.1 (see (10)) the generating function $F_H^c(z,w)$ of the Schur complement of the $(0,0)$ element g_1 of F_H is

$$F_H^c(z,w) = \left(\frac{1}{g_1}\right)\left[\frac{f_1(z)f^*(w) - f(z)f_1^*(w)}{z - w^*}\right]; \qquad f_1(z) = \sum_{k=0}^{\infty} g_{k+2}z^k \quad \text{and} \quad g_1 \neq 0.$$

The congruence (13) then shows that the generating function $Q^c(z,w)$ of the Schur complement of the $(0,0)$ element of Q is

$$\begin{aligned} Q^c(z,w) &= \left(\frac{1}{g_1}\right) b(z)\left[\frac{f_1(z)f^*(w) - f(z)f_1^*(w)}{z - w^*}\right] b^*(w) \\ &= \left(\frac{1}{g_1}\right)\left[\frac{f_2(z)f^*(w) - f(z)f_2^*(w)}{z - w^*}\right]; \qquad f_2(z) = b(z)f_1(z), \end{aligned}$$

which is QH.

3.1. Singularities of the QH family of matrices. Given a QH matrix Q with generating function $Q(z,w)$ as in (8), it will be impossible to compute the Schur complement of the $(0,0)$ element if and only if the $(0,0)$ element is zero or, equivalently, $Q(0,0) = 0$. The following are the possibilities (see §2).

(i) $Q = 0$, i.e., $Q(z,w) = 0$, which will happen if and only if $a(z)/b(z) = c$, a constant.

(ii) $Q \neq 0$, but the first row and column of Q are identically zero or, in other words, $Q(z,w) \neq 0$, but $Q(z,0) = Q(0,w) = 0$. Using our assumption (9), this is *equivalent* to having $a(0) = 0 = b(0)$.

(iii) $Q \neq 0$, the first row and column of Q are also not identically zero, but $q_{00} = 0$ or, in other words, $Q(z,w) \neq 0$, $Q(z,0) \neq 0$, $Q(0,w) \neq 0$, but $Q(0,0) = 0$. Now recalling our assumption (9) that $a(0) = 0$, we must have $b(0) \neq 0$ (if not we would be in case (ii)). Then $Q(0,0) = a'(0)b^*(0) = 0 \Rightarrow a'(0) = 0$ and $Q(z,0) = a(z)b^*(0)/z \neq 0 \Rightarrow a(z) \neq 0$. Thus $a(0) = a'(0) = 0$, but $a(z) \neq 0$. This implies there exists a positive integer $t > 1$, such that $\lim_{z\to 0} z^{-t}a(z) \neq 0$. Now it is clear from (11) that *if* $b(0) \neq 0$, *then* $z^{-j}g(z)|_{z=0} = 0$ *if and only if* $z^{-j}a(z)|_{z=0} = 0$, $0 \leq j \leq t-1$ *for* $t \leq m$. *This leads to the observations that* $\{a_i = 0\}_{i=1}^{t-1} \Leftrightarrow \{g_i = 0\}_{i=1}^{t-1}$ *and that* the first $t-1$ leading principal minors of F_H are zero if and only if $g_j = 0$, $1 \leq j \leq t-1$.

We can summarize the above discussion as follows.

LEMMA 3.1. *The first nonsingular leading principal submatrix of* F_H *is of dimension* t *if and only if* t *is the smallest positive integer such that* $\lim_{z\to 0} z^{-t}a(z) \neq 0$, *provided* $b(0) \neq 0$.

Because $g_j = 0, \quad 0 \le j \le t-1$, this submatrix, say $\tilde{F}_{H(t)}$, must have the form

$$\tilde{F}_{H(t)}\tilde{I}_t = \begin{bmatrix} g_t & 0 & 0 & \dots & 0 \\ g_{t+1} & g_t & 0 & & \vdots \\ \vdots & & & & 0 \\ \vdots & & & & 0 \\ g_{2t-1} & \dots & \dots & g_{t+1} & g_t \end{bmatrix}, \tag{15}$$

where $\tilde{I}_t$ is a $t \times t$ antidiagonal unit matrix. Then $\tilde{I}_t[\tilde{F}_{H(t)}]^{-1}$ will also be lower triangular Toeplitz, say

$$\tilde{I}_t[\tilde{F}_{H(t)}]^{-1} = \begin{bmatrix} p_1 & 0 & \dots & \dots & 0 \\ p_2 & p_1 & \ddots & & \vdots \\ \vdots & \ddots & \ddots & & \vdots \\ p_{t-1} & \ddots & \ddots & & 0 \\ p_t & p_{t-1} & \dots & p_2 & p_1 \end{bmatrix} = \mathcal{P}\tilde{I}_t, \text{ say.} \tag{16}$$

Furthermore, some calculation shows (see Appendix A) that

$$\begin{bmatrix} a_t & 0 & \dots & 0 \\ a_{t+1} & a_t & & \vdots \\ \vdots & a_{t+1} & & 0 \\ a_{2t-1} & \dots & a_{t+1} & a_t \end{bmatrix} \begin{bmatrix} p_1 \\ p_2 \\ \vdots \\ p_t \end{bmatrix} = \begin{bmatrix} b_0 \\ b_1 \\ \vdots \\ b_{t-1} \end{bmatrix}. \tag{17}$$

Now we can analyze the block Schur complement of $F_{H(t)}$ and derive a recursive procedure for computing the block factorization in t scalar steps.

The Schur complement $\tilde{F}^{c}_{H(t)}$ with respect to $\tilde{F}_{H(t)}$ as in (15) is

$$\tilde{F}^{c}_{H(t)} = F_H - \mathcal{G}_t\mathcal{P}\mathcal{G}_t^T, \tag{18}$$

where

$$\mathcal{G}_t = \begin{bmatrix} g_t & 0 & 0 & \dots & 0 \\ g_{t+1} & g_t & 0 & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & 0 \\ \vdots & \ddots & g_{t+1} & g_t & 0 \\ \vdots & \ddots & \ddots & \ddots & g_t \\ \vdots & \ddots & \ddots & \ddots & \ddots \\ \vdots & \ddots & \ddots & \ddots & \ddots \end{bmatrix} \quad \text{and} \quad \mathcal{P} = \begin{bmatrix} 0 & \dots & 0 & p_1 \\ \vdots & & \ddots & p_2 \\ 0 & \ddots & \ddots & \vdots \\ p_1 & p_2 & \dots & p_t \end{bmatrix}_{t\times t}.$$

Equation (18) corresponds to a block factorization step. The block diagonal entry of dimension t is the Hankel matrix $\mathcal{P}$ and the corresponding t columns of the lower triangular factor are down-shifted versions of the same infinite vector $[g_t \;\; g_{t+1} \;\; \dots \;\; \dots]^T$.

The generating function of this block factor is

$$\begin{aligned}
&[1\ z\ z^2\ \ldots]\mathcal{G}_t\mathcal{P}\mathcal{G}_t^T[1\ w\ w^2\ \ldots]^* \\
&\quad = g_t(z)[1\ z\ z^2\ \ldots\ z^{t-1}]\mathcal{P}[1\ w\ w^2\ \ldots\ w^{t-1}]^* g_t^*(w) \\
&\quad = g_t(z)\left[\sum_{k=0}^{t-1} p_{t-k}\left(\frac{z^{k+1}-(w^*)^{k+1}}{z-w^*}\right)(zw^*)^{t-1-k}\right] g_t^*(w),
\end{aligned}$$

where

$$g_t(z) = \sum_{j=0}^{\infty} g_{j+t}z^j = z^{-t}g(z).$$

Then since $Q^c(z,w) = b(z)\tilde{F}^c_{H(t)}(z,w)b^*(w)$, we have the following result.

LEMMA 3.2. Generating function of the Schur complement. *If $b(0) \neq 0$ and the first nonsingular principal submatrix of Q is of dimension t, then the block Schur complement Q_t^c of this first $t\times t$ nonsingular leading principal submatrix has generating function*

(19)

$$(zw^*)^t Q_t^c(z,w) = Q(z,w) - a_t(z)a_t^*(w)\left[\sum_{k=0}^{t-1} p_{t-k}\left(\frac{z^{k+1}-(w^*)^{k+1}}{z-w^*}\right)(zw^*)^{t-1-k}\right],$$

where $a_t(z) = z^{-t}a(z)$ and $\{p_j\}_{j=1}^t$ are given by (17).

Although computation of $\{p_j\}_{j=1}^t$ via (17) is sufficient to find the required block factors in (18), it is not yet clear how to express the generating function $Q_t^c(z,w)$ of the QH block Schur complement in the standard form (8). Some further exploration will show how to do this.

We can try to rewrite (19) to show one step at a time:

$$\begin{aligned}
(zw^*)^t Q_t^c(z,w) &= Q(z,w) - a_t(z)a_t^*(w)\left[\sum_{k=0}^{t-1} p_{t-k}\left(\frac{z^{k+1}-(w^*)^{k+1}}{z-w^*}\right)(zw^*)^{t-1-k}\right] \\
&= \frac{z^t a_t(z)[b^*(w) - p_1 a_t^*(w)] - (w^*)^t a_t^*(w)[b(z) - p_1 a_t(z)]}{z-w^*} \\
&\quad -a_t(z)a_t^*(z)\left[\sum_{k=0}^{t-2} p_{t-k}\left(\frac{z^{k+1}-(w^*)^{k+1}}{z-w^*}\right)(zw^*)^{t-1-k}\right].
\end{aligned}$$

Now by (17), $b(z) - p_1 a_t(z)$ is divisible by z. So if we define

$$z^{t-1}a_t(z) = a_1(z), \qquad zb_1(z) = b(z) - p_1 a_t(z),$$

and

$$Q_1^p(z,w) = \frac{a_1(z)b_1^*(w) - b_1(z)a_1^*(w)}{z-w^*},$$

then

$$(zw^*)^{t-1}Q_t^c(z,w) = Q_1^p(z,w) - a_t(z)a_t^*(w)\left[\sum_{k=0}^{t-2} p_{t-k}\left(\frac{z^{k+1}-(w^*)^{k+1}}{z-w^*}\right)(zw^*)^{t-2-k}\right].$$

This suggests the following result.

LEMMA 3.3. Recursive form for $Q_t^c(z,w)$. *It holds that*

$$Q_t^c(z,w) = \frac{a_t(z)b_t^*(w) - b_t(z)a_t^*(w)}{z - w^*}, \tag{20}$$

where $b_t(z)$ *is defined by the recursion,*

$$zb_{j+1}(z) = b_j(z) - p_{j+1}a_t(z); \quad p_{j+1} = \frac{b_j(0)}{a_t(0)}, \quad b_0(z) = b(z). \tag{21}$$

Proof. The lemma is proved by induction.

Define

$$Q_j^p(z,w) = \frac{a_j(z)b_j^*(w) - a_j^*(w)b_j(z)}{z - w^*},$$

where, $a_j(z) = z^{t-j}a_t(z)$ and $\{b_j(z)\}_{j=1}^t$ is as defined above. Then,

$$\begin{aligned} &Q_j^p(z,w) - a_t(z)a_t^*(w)p_{j+1}\left(\frac{z^{t-j} - (w^*)^{t-j}}{z - w^*}\right) \\ &= \frac{a_j(z)[b_j^*(w) - p_{j+1}a_t^*(w)] - a_j^*(w)[b_j(z) - p_{j+1}a_t(z)]}{z - w^*} \\ &= (zw^*)\left[\frac{a_{j+1}(z)b_{j+1}^*(w) - a_{j+1}^*(w)b_{j+1}(z)}{z - w^*}\right] = (zw^*)Q_{j+1}^p(z,w). \end{aligned}$$

Therefore

$$\begin{aligned} &Q(z,w) - a_t(z)a_t^*(w)\left[\sum_{k=0}^{t-1} p_{t-k}\left(\frac{z^{k+1} - (w^*)^{k+1}}{z - w^*}\right)(zw^*)^{t-1-k}\right] \\ &= (zw^*)^t Q_t^p(z,w) = (zw^*)^t Q_t^c(z,w). \end{aligned}$$

Hence,

$$Q_t^c(z,w) = Q_t^p(z,w) = \frac{a_t(z)b_t^*(w) - a_t^*(w)b_t(z)}{z - w^*}.$$

The recursions (20) and (21) provide an efficient means of computing the block factorization step in (19) via a sequence of t scalar recursions. It is clear that the $\{Q_j^p(z,w)\}_{j=0}^{t-1}$ do not represent any Schur complement; only the final member of this sequence, viz., $Q_t^p(z,w)$, represents the desired block Schur complement and allows us to continue with the factorization process.

Now we are ready to describe a general triangular factorization algorithm by putting together the steps described above.

3.2. Algorithm for triangular factorization of QH matrices. Let us first express the general factorization formulas (3) and (4) in generating function terms,

$$\bar{M}_{j+1}(z,w) = \bar{M}_j(z,w) - \bar{M}_j(z,0)\bar{M}_j^{-1}(0,0)\bar{M}_j(0,w), \tag{22}$$

$$d_j = \bar{M}_j(0,0), \bar{l}_j(z) = \bar{M}_j(z,0)d_j^{-1} \quad \text{when} \quad d_j \neq 0, \tag{23}$$

where

$$(zw^*)^{-1}\bar{M}_j(z,w) = M_j(z,w) = [1\ z\ z^2\ \dots\ \dots\ ]\ M_j\ [1\ w\ w^2\ \dots\ \dots\ ]^*$$

and

$$z^j\bar{l}_j(z) = l_j(z) = [1\ z\ z^2\ \dots\ \dots\ ]\ \underline{l}_j.$$

The following cases represent all the possibilities that may be encountered at any step j.

Case 1. (a) $a_j(0) \neq 0$, $b_j(0) \neq 0$. In this case, we generate two other polynomials $a_{j+1}(0)$ and $b_{j+1}(0)$, such that $a_{j+1}(0) = 0$ and $b_{j+1}(0) \neq 0$, so that $Q_j(z,w) = Q_{j+1}(z,w)$:

$$\begin{aligned} a_{j+1}(z) &= a_j(z) - \zeta_j b_j(z)\ ;\ \zeta_j = a_j(0)/b_j(0), \\ b_{j+1}(z) &= b_j(z). \end{aligned}$$

(b) $a_j(0) \neq 0$, $b_j(0) = 0$. This is just an exchange step. We simply assign

$$a_{j+1}(z) = b_j(z), \qquad b_{j+1}(z) = a_j(z)$$

so that $Q_j(z,w) = -Q_{j+1}(z,w)$.

Case 2. (a) $a_j(0) = 0$, $b_j(0) \neq 0$, $\lim_{z\to 0} z^{-1}a_j(z) \neq 0$. This is a strongly regular step (the Schur complement of the (1,1) entry can be computed) for which the recursion is

$$\begin{aligned} za_{j+1}(z) &= a_j(z), \\ zb_{j+1}(z) &= b_j(z) - \zeta_j z^{-1}a_j(z);\ \zeta_j = \lim_{z\to 0} \frac{b_j(z)}{z^{-1}a_j(z)}. \end{aligned}$$

This implies that

$$(zw^*)Q_{j+1}(z,w) = Q_j(z,w) - \zeta_j a_{j+1}(z)a_{j+1}^*(w),$$

from which we can identify

$$d_{(j-\delta_j-\gamma_j)} = (-1)^{\gamma_j}Q_j(0,0) = (-1)^{\gamma_j}\zeta_j|a_{j+1}(0)|^2,$$

and

$$l_{(j-\delta_j-\gamma_j)}(z) = z^{(j-\delta_j-\gamma_j)}a_{j+1}(z)/a_{j+1}(0),$$

where δ_j and γ_j denote the number of times Cases 1(a) and 1(b) have been encountered before step j.

Case 3. $a_j(0) = 0$, $b_j(0) \neq 0$ and there exists a positive integer $t > 1$, such that $z^{-t}a_j(z)$ is a polynomial in z and $\lim_{z\to 0} z^{-t}a_j(z) \neq 0$. The Schur complement of the (1,1) entry cannot be computed in this case; however, a block Schur complement can be computed via repeated (t times) application of (21). So the recursion is

$$\begin{aligned} za_{j+1}(z) &= a_j(z), \\ zb_{j+1}(z) &= b_j(z) - \zeta_j z^{-t}a_j(z);\ \zeta_j = \lim_{z\to 0} \frac{b_j(z)}{z^{-t}a_j(z)}. \end{aligned}$$

This implies that

$$(zw^*)^t Q^p_{j+t}(z,w) = Q^p_j(z,w) - a_{j+t}(z)a^*_{j+t}(w)\left[\sum_{k=0}^{t-1}\zeta_{j+t+k}\left(\frac{z^{k+1}-(w^*)^{k+1}}{z-w^*}\right)(zw^*)^{t-1-k}\right].$$

So, in Case 3, the block diagonal is the $t \times t$ matrix $(-1)^{\gamma_j} D_{(j-\delta_j-\gamma_j)}$, where

$$D_{(j-\delta_j-\gamma_j)} = \begin{bmatrix} 0 & 0 & \dots & 0 & \zeta_j \\ 0 & \ddots & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & \ddots & \ddots & \ddots & \vdots \\ \zeta_j & \dots & \dots & \dots & \zeta_{j+t-1} \end{bmatrix}. \tag{24}$$

The t columns contributing to the lower triangular factor L form the $n \times t$ Toeplitz matrix whose first column is $[\underbrace{0,\dots,0}_{j-\delta_j-\gamma_j}, a_{j+t,0}, a_{j+t,1}, \dots, \dots, a_{j+t,m}, 0, 0, \dots, 0]^T_{n\times 1}$ where

$$a_{j+t}(z) = \sum_{k=0}^{m} a_{j+t,k} z^k.$$

Case 4. $a_j(0) = 0$ and $b_j(0) = 0$. In this case both the first column and row of Q_j must be zeros. So the recursion for the polynomials is

$$za_{j+1}(z) = a_j(z),$$
$$zb_{j+1}(z) = b_j(z).$$

This implies that

$$(zw^*)Q_{j+1}(z,w) = Q_j(z,w).$$

Therefore

$$d_{(j-\delta_j-\gamma_j)} = 0 \quad \text{and} \quad l_{(j-\delta_j-\gamma_j)}(z) = z^{(j-\delta_j-\gamma_j)}.$$

We have just discussed the relationship of the polynomial recursions and the factors of triangular factorization in all of the four cases. It is important to note that at any step one only needs to compute a linear update of the polynomials $a_j(\cdot)$ and $b_j(\cdot)$. This is true irrespective of the presence of a singularity. Hence the *modified triangular factorization* of QH matrices can be computed in $O(n^2)$ computations using the recursions of this subsection.

Example. Let

$$H_4 = \begin{bmatrix} 1 & 1 & 1 & 2 & 2 \\ 1 & 1 & 2 & 2 & 2 \\ 1 & 2 & 2 & 2 & 2 \\ 2 & 2 & 2 & 2 & 2 \\ 2 & 2 & 2 & 2 & 2 \end{bmatrix}.$$

TABLE 3.1
Recursions for triangular factorization.

Step j	$a_{j+1}(z)$ $b_{j+1}(z)$	ζ_j	t_j	δ_j	γ_j	Comment

Now defining a semi-infinite extension $H_{4,\infty}$ as in (10), we get, $H_{4,\infty}(z,w) = [zh(z)-w^*h^*(w)]/[z-w^*]$, where $h(z) = 1+z+z^2+2z^3+2z^4+2z^5+2z^6+2z^7+2z^8$. Using the procedure described earlier, we get the polynomials $\{a_j(z),\ b_j(z)\}_{j=0}^{15}$, starting with $a_0(z) = zh(z)$ and $b_0(z) = 1$. The results are summarized in Table 3.1.

This yields the following factorization,

$$H_4 = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 \\ 1 & 0 & 1 & 0 & 0 \\ 2 & 0 & 0 & 1 & 0 \\ 2 & 0 & 0 & 1 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & -2 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} 1 & 1 & 1 & 2 & 2 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix}.$$

4. SMQH matrices. A matrix N is said to be an SMQH matrix if its generating function admits the representation

$$N(z,w) = \frac{p(z)q^*(w) - q(-z)p^*(-w)}{z+w^*}, \tag{25}$$

where $p(z)$ and $q(z)$ are real polynomials. An important special case is when $p(z) = q(z)$, which arises in studying the problem of root distribution of the polynomial $p(z)$ with respect to the imaginary axis (see Krein and Naimark [8] and Lev-Ari, Bistritz, and Kailath [11]). Then

$$N(z,w) = \frac{p(z)p^*(w) - p^*(-w)p(-z)}{z + w^*} \tag{26}$$

and we shall call it the imaginary axis Bezoutian. Note that this is not QH, as defined in (8). However we can obtain a related QH Bezoutian as follows.

Let $m(z)$ and $n(z)$, be the even and the odd parts of $p(z)$; in terms of which we can write

$$N(z,w) = \frac{2[m(z)n^*(w) + n(z)m^*(w)]}{z + w^*} = 2I(z,w), \text{ say.} \tag{27}$$

Then note that

$$I(-z,w) = I(z,-w) = \frac{2[n(z)m^*(w) - m(z)n^*(w)]}{z - w^*} \tag{28}$$

represents a QH matrix.

Now we can apply the algorithm of the last section; certain simplifications ensue because of the special structure of $I(-z,w)$ (alternate entries of the corresponding matrix are zero). Assign $a(z) = n(z)$ and $b(z) = m(z)$. Then $a_0(z) = n(z)$ and $b_0(z) = m(z)$. Since $a_0(0) = 0$, the transformation step is not necessary. Now if $b_0(0) \neq 0$ and $\lim_{z\to 0} z^{-1}a_0(z) \neq 0$, then Case 2 yields

$$za_1(z) = a_0(z) = n(z)$$

and

$$zb_1(z) = b_0(z) - \zeta_0 z^{-1}a_0(z) = m(z) - \zeta_0 z^{-1}n(z); \qquad \zeta_0 = \lim_{z\to 0} zm(z)/n(z).$$

In this case, $a_1(z)$ is an even polynomial and $b_1(z)$ becomes an odd polynomial. However, if $b_0(0) \neq 0$ but $\lim_{z\to 0} z^{-1}a_0(z) = 0$, then Case 3 applies provided $a_0(z) \neq 0$. If then t is the smallest positive integer such that $\lim_{z\to 0} z^{-t}a_0(z) \neq 0$, then

$$za_1(z) = a_0(z) = n(z)$$

and

$$zb_1(z) = b_0 - \zeta_0 z^{-t}a_0(z) = m(z) - \zeta_0 z^{-t}n(z); \qquad \zeta_0 = \lim_{z\to 0} z^t m(z)/n(z).$$

Once again, $a_1(z)$ is an even polynomial whereas $b_1(z)$ is an odd one. But if $b_0(0) = 0$, then Case 4 applies and we get

$$za_1(z) = a_0(z) = n(z)$$

and

$$zb_1(z) = b_0(z) = m(z).$$

Even in this case, $a_1(z)$ is an even polynomial and $b_1(z)$ is an odd one. Thus,

$$I_1(z,-w) = \frac{a_1(z)b_1^*(w) - a_1^*(w)b_1(z)}{z - w^*},$$

where $a_1(z)$ is an even polynomial and $b_1(z)$ is an odd polynomial. The structure of $I(z,-w)$ makes it clear that not only is it QH, but QH with a certain structure, since

at every step of recursion one of the polynomials must be even while the other one must be odd. This leads to the elimination of any possible encounter with the Case 1(a). Since we are dealing with even and odd polynomials, we shall use $\{m_j(z)\}$ and $\{n_j(z)\}$ as variables of recursion. Define

$$I_j(z,-w) = \frac{n_j(z)m_j^*(w) - m_j(z)n_j^*(w)}{z - w^*}. \tag{29}$$

Then the recursions for $\{m_j(\cdot)\}$ and $\{n_j(\cdot)\}$ are as follows: Assign $m_0(z) = m(z)$ and $n_0(z) = n(z)$.

Case (i). If $m_j(z) \neq 0$ and $\lim_{z\to 0} z^{-1}n_j(z) \neq 0$, then

$$zn_{j+1}(z) = n_j(z),$$

$$zn_{j+1}(z) = m_j(z) - \zeta_j z^{-1}n_j(z); \qquad \zeta_j = \lim_{z\to 0}\frac{zm_j(z)}{n_j(z)}.$$

Also,

$$I_j(z,-w) = \zeta_j M_{j+1}(z)m_{j+1}^*(w) - (zw^*)I_{j+1}(z,-w)$$

or

$$I_j(z,w) = \zeta_j m_{j+1}(z)m_{j+1}^* + zw^* I_{j+1}(z,w).$$

Then the diagonal factor and the generating function of the jth column of the triangular factor are

$$d_j = I_j(0,0) = \zeta_j|m_{j+1}(0)|^2$$

and

$$l_j = m_{j+1}(z)/m_{j+1}(0).$$

Case (ii). If $m_j(0) \neq 0, \lim_{z\to 0} z^{-1}n_j(z) = 0$ while there exists a positive integer t such that $z^{-t}n_j(z)$ is a polynomial and $\lim_{z\to 0} z^{-t}n_j(z) \neq 0$, then t must be odd. Let $t = 2\psi + 1$, then

$$zm_{j+1}(z) = n_j(z)$$

and

$$zn_{j+1}(z) = m_j(z) - \zeta_j z^{-t}n_j(z); \qquad \zeta_j = \lim_{z\to 0}\frac{z^t m_j(z)}{n_j(z)}.$$

Case (iii). If $m_j(0) = 0$, then

$$zm_{j+1}(z) = n_j(z), \qquad zn_{j+1}(z) = m_j(z).$$

A close examination reveals that an occurrence of Case (iii) without a prior occurrence of Case (ii) can happen only if Case (iii) occurs before any other case. Otherwise, if an instance of Case (ii) is encountered then 2ψ consecutive singular leading principal minors of the given matrix must be followed by a nonsingular leading principal minor. In that situation, occurrence of the Cases (ii) and (iii) will alternate ψ times each and then an occurrence of Case (i) must be encountered. All this reflects itself in the following formula:

$$(zw^*)^{2\psi+1}I_{j+2\psi+1}(z,w) =$$

$$- m_{j+2\psi+1}(z)m_{j+2\psi+1}^*(w)\left[\sum_{k=0}^{\psi}\zeta_{j+2k}^{(zw^*)^{2k}}\left[\frac{z^{2(\psi-k)+1} + (w^*)^{2(\psi-k)+1}}{\Delta(z+w^*)}\right]\right] + I_j(z,w).$$

So the block diagonal entry

$$D_j = \begin{bmatrix} 0 & 0 & \cdots & \cdots & \cdots & 0 & \zeta_j \\ 0 & \ddots & \ddots & \ddots & 0 & -\zeta_j & 0 \\ \vdots & \ddots & \ddots & \ddots & \ddots & \ddots & \zeta_{j+2} \\ \vdots & \ddots & \ddots & \ddots & \ddots & \ddots & 0 \\ \vdots & \ddots & \ddots & \ddots & \ddots & \ddots & \vdots \\ 0 & 0 & \zeta_j & \ddots & \ddots & \ddots & \vdots \\ 0 & -\zeta_j & \ddots & \ddots & \ddots & \ddots & 0 \\ \zeta_j & 0 & \zeta_{j+2} & \cdots & \cdots & 0 & \zeta_{j+2\psi} \end{bmatrix}_{(2\psi+1)\times(2\psi+1)} \tag{30}$$

and the corresponding $2\psi+1$ columns of the triangular factor L must be the $n\times(2\psi+1)$ Toeplitz matrix whose first column is

$$[\underbrace{0,\ldots,0}_{j}, m_{j+2\psi+1,0}, 0, m_{j+2\psi+2,0}, \ldots, m_{j+2\psi+1,2q}, 0, 0, \ldots, 0]^T_{n\times 1},$$

where

$$m_{j+2\psi+1}(z) = \sum_{k=0}^{q} m_{j+2\psi+1,\,2k} z^{2k}.$$

However, an independent occurrence of Case (iii) will reflect itself as

$$I_{j+1}(z,w) = zw^* I_j(z,w).$$

Then

$$d_j = 0 \quad \text{and} \quad l_j(z) = z^j.$$

We have just connected the recursions in $\{m_j(z)\}$ and $\{n_j(z)\}$ with the factors of triangular factorization. Extensions of the procedure just described to find a "modified triangular factorization" of an arbitrary SMQH matrix are straightforward. Extensions for factoring Bezout matrices (associated with the imaginary axis Bezoutians) derived from a complex polynomial are also straightforward and will be presented elsewhere (see [19]).

5. Inversion of Hankel and QH matrices: Block generating function approach. Consider a nonsingular Hankel matrix of order n $H_{n-1} = [h_{i+j}]_{i,j=0}^{n-1}$, where h_k are arbitrary ($k = 0,1,2,\ldots,2n-2$). We shall define the $2n \times 2n$ Hankel block matrix

$$H_b = \left[\begin{array}{c|c} H_{n-1} & I \\ \hline I & O \end{array}\right]_{2n\times 2n}. \tag{31}$$

H_{n-1} is the first $n \times n$ principal submatrix of H_b and the corresponding block Schur complement is $-H_{n-1}^{-1}$. We define the following semi-infinite matrix

$$H_{b,\infty} = \left[\begin{array}{c|c} H_{n-1,\infty} & I_\infty \\ \hline I_\infty & O_\infty \end{array}\right], \tag{32}$$

where $H_{n-1,\infty}$ is the semi-infinite extension of H_{n-1}, I_∞ is a semi-infinite identity matrix, and O_∞ is a semi-infinite zero matrix. It is useful to associate a semi-infinite block structured matrix

$$M = \left[\begin{array}{c|c} M_{11} & M_{12} \\ M_{21} & M_{22} \end{array}\right]$$

(with structured semi-infinite blocks M_{ij}, $1 \le i,j \le 2$) with a block "generating" function

$$M(z,w) = \left[\begin{array}{cccc|cccc} 1 & z & z^2 & \dots & O & \dots & \dots & O \\ O & \dots & \dots & O & 1 & z^{-1} & z^{-2} & \dots \end{array}\right] \left[\begin{array}{c|c} M_{11} & M_{12} \\ M_{21} & M_{22} \end{array}\right] \cdot \left[\begin{array}{cccc|cccc} 1 & w & w^2 & \dots & O & \dots & \dots & O \\ O & \dots & \dots & O & 1 & w^{-1} & w^{-2} & \dots \end{array}\right]^* . \tag{33}$$

Then the block generating function (which is obtained by replacing each of the semi-infinite Hankel blocks by their generating functions)

$$H_{b,\infty}(z,w) = \left[\begin{array}{c|c} H_{n-1,\infty}(z,w) & \frac{-w^*}{z-w^*} \\ \frac{z}{z-w^*} & O \end{array}\right]_{2\times 2}, \tag{34}$$

where

$$H_{n-1,\infty}(z,w) = \frac{zh(z) - w^*h^*(w)}{z-w^*}, \tag{35}$$

such that

$$h(z) = \sum_{k=0}^{2n-2} h_k z^k.$$

For now we restrict ourselves to real symmetric matrices only, so that $h(z) = h^*(z^*)$. For simplicity assume that $h_0 \neq 0$ for now. Then note that

$$H_{b,\infty}(z,w) = \frac{\left[\begin{array}{c|c} zh(z) & 1 \\ z & 0 \end{array}\right] \left[\begin{array}{c|c} O & 1 \\ -1 & O \end{array}\right] \left[\begin{array}{c|c} wh(w) & 1 \\ w & 0 \end{array}\right]^*}{z-w^*}. \tag{36a}$$

Clearly, then

$$H_{b,\infty}(z,w) = \frac{G_b(z)JG_b^*(w)}{z-w^*}, \tag{36b}$$

where

$$J = \left[\begin{array}{c|c} O & 1 \\ -1 & O \end{array}\right] \quad \text{and} \quad G_b(z) = \left[\begin{array}{c|c} zh(z) & 1 \\ z & O \end{array}\right].$$

Next we shall define a matrix Q_b to be BQH if its block generating function $Q_b(z,w)$ can be represented in the form

$$Q_b(z,w) = \frac{1}{z-w^*} \left[\begin{array}{c|c} a(z) & b(z) \\ c(z) & d(z) \end{array}\right] \left[\begin{array}{c|c} O & 1 \\ -1 & O \end{array}\right] \left[\begin{array}{c|c} a(w) & b(w) \\ c(w) & d(w) \end{array}\right]^*, \tag{37}$$

where $a(z)$, $b(z)$, $c(z)$, and $d(z)$ are all polynomials (functions) in z and z^{-1}.

THEOREM 5.1. *The Schur complement of the* 1×1 *leading principal submatrix of* $H_{b,\infty}$ *is* BQH.

Proof. If $h_1 = 0$, then the Schur complement does not exist. So we assume $h_1 = 1$. The block generating function $H^c_{b,\infty}(z,w)$ of this Schur complement is

$$\begin{bmatrix} z & | & O \\ O & | & 1 \end{bmatrix} H^c_{b,\infty}(z,w) \begin{bmatrix} w^* & | & O \\ O & | & 1 \end{bmatrix} = H_{b,\infty}(z,w) - \begin{bmatrix} H_{n-1,\infty}(z,0) \\ 1 \end{bmatrix} [H_{n-1,\infty}(0,0)]^{-1} \begin{bmatrix} H_{n-1,\infty}(0,w) & | & 1 \end{bmatrix},$$

which implies that

(38)
$$H^c_{b,\infty}(z,w) = \frac{1}{z-w^*} \begin{bmatrix} h(z) & | & h_1(z) \\ z & | & -1 \end{bmatrix} \begin{bmatrix} O & | & 1 \\ -1 & | & O \end{bmatrix} \begin{bmatrix} h(w) & | & h_1(w) \\ w & | & -1 \end{bmatrix}^*,$$

where we have defined

$$h_1(z) = \sum_{k=0}^{2n-3} h_{k+1} z^k. \qquad \square$$

Since $H^c_{b,\infty}$ is BQH, a question naturally arises about the structure of the Schur complement of a BQH matrix. This is answered in the following theorem.

THEOREM 5.2. *The Schur complement of the* 1×1 *leading principal submatrix of a* BQH *matrix is also* BQH.

Proof. Define the partition

$$Q_b(z,w) = \begin{bmatrix} q_{b,11}(z,w) & | & q_{b,12}(z,w) \\ q_{b,21}(z,w) & | & q_{b,22}(z,w) \end{bmatrix}.$$

The generating function $Q^c_b(z,w)$ of the Schur complement is given by

(39)
$$\begin{bmatrix} z & | & O \\ O & | & 1 \end{bmatrix} Q^c_b(z,w) \begin{bmatrix} w^* & | & O \\ O & | & 1 \end{bmatrix} = Q_b(z,w) - \begin{bmatrix} q_{b,11}(z,0) \\ q_{b,21}(z,0) \end{bmatrix} q^{-1}_{b,11}(0,0) \begin{bmatrix} q_{b,11}(0,w) & | & q_{b,12}(0,w) \end{bmatrix},$$

where $Q_b(z,w)$ in (37) is the block generating function of BQH matrix Q_b. At this point, we make the same normalizing assumption $a(0) = 0$ as in §3. Then

$$\begin{bmatrix} q_{b,11}(z,0) \\ q_{b,21}(z,0) \end{bmatrix} = \begin{bmatrix} z^{-1}a(z)b^*(0) \\ z^{-1}c(z)b^*(0) \end{bmatrix} = b^*(0) \begin{bmatrix} a_1(z) \\ c_1(z) \end{bmatrix}, \text{ say.}$$

It is clear that $a_1(z)$ and $c_1(z)$ are polynomials in z and z^{-1}, respectively. Now if $Q_b(0,0) \neq 0$, then after some algebra we get

(40)
$$Q^c_b(z,w) = \frac{|b(0)|^2 \begin{bmatrix} a_1(z)b_1^*(w) - b_1(z)a_1^*(w) & | & -(b_1(z)w^*c_1^*(w) - a_1(z)d_1^*(w)) \\ b_1^*(w)zc_1(z) - a_1^*(w)d_1(z) & | & zc_1(z)d_1^*(w) - w^*c_1^*(w)d_1(z) \end{bmatrix}}{z-w^*}$$
$$= \frac{|b(0)|^2 \begin{bmatrix} a_1(z) & | & b_1(z) \\ zc_1(z) & | & d_1(z) \end{bmatrix} \begin{bmatrix} O & | & 1 \\ -1 & | & O \end{bmatrix} \begin{bmatrix} a_1(w) & | & b_1(w) \\ wc_1(w) & | & d_1(w) \end{bmatrix}^*}{z-w^*},$$

where we have defined

$$b_1(z) = [a_1(0)b(z) - b(0)a_1(z)]/z \quad \text{and} \quad d_1(z) = [d(z)a_1(0) - c_1(z)b(0)]. \tag{41}$$

It is clear that $b_1(z)$ is a polynomial since the numerator in (41) has a root at the origin, while $d_1(z)$ is a polynomial in z^{-1}. This completes the proof of the theorem, since $Q_b^c(z,w)$ is clearly BQH. □

Thus making any distinction between the block Hankel and BQH families is not material in the context of Schur complementation.

5.0.1. Generator for H_{n-1}^{-1}. It is clear that n steps of Schur reduction on the block generating function $H_{b,\infty}(z,w)$ would directly lead to the generating function of H_{n-1}^{-1} by way of the computed polynomials (functions) $c_{n-1}(z)$ and $d_{n-1}(z)$ starting with $c_0(z) = z$ and $d_0(z) = 0$ as in (36). In particular,

$$\begin{aligned}
&H_{n-1}^{-1}(z^{-1}, w^{-1}) \\
&\quad = [1\ z^{-1}\ z^{-2}\ \ldots] H_{n-1}^{-1} [1\ w^{-1}\ w^{-2}\ \ldots]^* \\
&\quad = -\frac{[c_{n-1}(z)d_{n-1}^*(w) - d_{n-1}(z)c_{n-1}^*(w)]}{z - w^*} \\
&\quad = -\frac{[w^{-*}c_{n-1}^*(w)z^{-1}d_{n-1}(z) - w^{-*}c_{n-1}^*(w)z^{-1}\gamma_{n-1}(z)]}{z^{-1} - w^{-*}} \\
&\quad = \frac{[z^{-1}c_{n-1}(z) \mid z^{-1}d_{n-1}(z)] \left[\begin{array}{c|c} O & 1 \\ -1 & O \end{array}\right] [w^{-1}c_{n-1}(w) \mid w^{-1}d_{n-1}(w)]^*}{z^{-1} - w^{-*}}.
\end{aligned}$$

Thus the generator for H_{n-1}^{-1} must be $[z^{-1}c_{n-1}(z)\ \ z^{-1}d_{n-1}(z)]$.

5.1. Singularities and block Schur complements. The Schur complement $Q_b^c(z,w)$ of the 1×1 leading principal submatrix of a BQH matrix cannot be computed if $[1\ 0]Q_b(0,0)[1\ 0]^* = Q(0,0) = 0$ (see (39)). Since we are interested in inverting Q, the first two cases (see §3.1) of singularity are not material. The third case, which requires computing a block Schur complement, must be understood in terms of its impact on the block generating function procedure.

5.1.1. The structure of Q_b. Let

$$\begin{aligned}
Q_b(z,w) &= \frac{\left[\begin{array}{c|c} a(z)b^*(w) - b(z)a^*(w) & a(z)d^*(w) - b(z)c^*(w) \\ c(z)b^*(w) - d(z)a^*(w) & c(z)d^*(w) - d(z)c^*(w) \end{array}\right]}{z - w^*} \\
&= \left[\begin{array}{c|c} Q(z,w) & Q_Y^*(w,z) \\ Q_Y(z,w) & Q_I(z,w) \end{array}\right], \text{ say.}
\end{aligned} \tag{42}$$

Let $a(z) = z^t a_t(z)$ (see (19) and Lemma 3.2). Since congruence preserves rank profile and inertia the BQH form $Q_b(z,w)$ defined as follows:

$$\begin{aligned}
&\left[\begin{array}{c|c} b(z) & O \\ O & z^{-1}d(z) \end{array}\right] R_b(z,w) \left[\begin{array}{c|c} b^*(w) & O \\ O & w^{-*}d^*(w) \end{array}\right] \\
&\quad = \left[\begin{array}{c|c} R_H(z,w) & R_Y^*(w,z) \\ R_Y(z,w) & R_I(z,w) \end{array}\right], \text{ say,}
\end{aligned} \tag{43}$$

must have the same rank profile and inertia as $Q_b(z,w)$. Let $R_b(z,w)$ be partitioned as

$$R_b(z,w) = \left[\begin{array}{c|c} R_H(z,w) & R_Y^*(w,z) \\ R_Y(z,w) & R_I(z,w) \end{array}\right], \text{ say.} \tag{44}$$

5.1.2. Structures of R_H, R_Y, and R_I. The structure of R_H has been studied in §3. Let us examine the structure of R_Y first.

$$R_Y(z,w) = \frac{y(z) - (w^*)^t g_t^*(w)}{1 - z^{-1}w^*}, \tag{45a}$$

where (see (18))

$$\begin{aligned} y(z) &= c(z)/d(z) = \textstyle\sum_{i=0}^{\infty} y_i z^{-i} \text{ and} \\ g_t(z) &= a_t(z)/b(z) = \textstyle\sum_{i=0}^{\infty} g_{t+i} z^i. \end{aligned} \tag{45b}$$

The $t \times t$ block Schur complementation on R_H modifies R_Y and produces R_Y^c as follows:

$$\left[\begin{array}{c|ccc} O & \cdot & \cdot & \cdot \\ O & \cdot & R_Y^c & \cdot \\ O & \cdot & \cdot & \cdot \end{array}\right] = R_Y - \mathcal{Y}\mathcal{U}(\underline{p})\mathcal{G}^T, \tag{46}$$

where $\mathcal{Y}$ is a t columns wide lower triangular Toeplitz matrix with the first column $[y_0^* \; y_1^* \; \dots \; \dots]^*$, $\mathcal{G}_t$ is as in (18) and $U(\underline{p})$ is a $t \times t$ upper triangular Toeplitz matrix with first row $[p_1 \; p_2 \; \dots \; p_t]$. The parameters $\{p_j\}_1^t$ are as in (16). It can be shown that the generating function $R_Y^c(z,w)$ of the above matrix R_Y^c is given by

(47a)

$$(w^*)^t R_Y^c(z,w) = R_Y(z,w) - z^{-(t-1)} y(z) \left[\sum_{k=0}^{t-1} p_{t-k} \left(\frac{z^{k+1} - (w^*)^{k+1}}{z - w^*}\right) (zw^*)^{t-1-k}\right] g_t^*(w).$$

After some algebra, (47a) reduces to

$$R_Y^c(z,w) = \frac{y(z)[1 - p^*(w)g^*(w)] - g_t^*(w)[1 - z^{-t}p(z)y(z)]}{1 - z^{-1}w^*}, \tag{47b}$$

where $p(z) = p_1 + p_2 z + \cdots + p_t z^{t-1}$. Since $c(z) = y(z)d(z)$, $a_t(z) = g_t(z)b(z)$, and $z^t b_t(z) = b(z)[1 - p(z)g_t(z)]$ (see (21)), we get

$$Q_Y^c(z,w) = \frac{c(z)b_t^*(w) - a_t^*(w)d_t(z)}{z - w^*}, \tag{48}$$

where we have defined $d_t(z) = d(z) - z^{-t}p(z)c(z)$. Next we examine the structure of R_I.

$$R_I(z,w) = \frac{y(z) - y^*(w)}{w^{-*} - z^{-1}}, \tag{49}$$

where $y(z)$ has been defined above. Then the $t \times t$ block Schur complementation on R_H modifies R_I and produces R_I^c as follows:

$$R_I^c = R_I - \mathcal{Y}\tilde{I}_t\mathcal{P}\tilde{I}_t\mathcal{Y}^*, \tag{50}$$

where $\mathcal{Y}$ is as defined before and $\mathcal{P}$ is as in (18). It can be shown that the generating function $R_I^c(z,w)$ of the above matrix R_I^c is given by

$$\begin{aligned} R_I^c(z,w) &= R_I(z,w) - z^{-(t-1)}y(z) \\ &\quad \cdot \left[\textstyle\sum_{k=0}^{t-1} p_{t-k} \left(\frac{z^{k+1} - (w^*)^{k+1}}{z - w^*}\right) (zw^*)^{t-1-k}\right] y^*(w)(w^*)^{-(t-1)} \\ &= \frac{y(z)\,[1 - (w^*)^{-t}p^*(w)y^*(w)] - [1 - z^{-t}p(z)y(z)]\,y^*(w)}{w^{-*} - z^{-1}}. \end{aligned}$$

Then the generating function of the $t \times t$ block Schur complement Q_I^c of Q_I is given by

$$R_I^c(z,w) = \frac{c(z)d_t^*(w) - d_t(z)c^*(w)}{z - w^*}. \tag{51}$$

Thus the $t \times t$ block Schur complement Q_I^c of Q_I must be BQH, viz.,

$$Q_I^c(z,w) = \frac{\left[\begin{array}{c|c} a_t(z) & b_t(z) \\ c_t(z) & d_t(z) \end{array}\right]\left[\begin{array}{c|c} O & 1 \\ -1 & O \end{array}\right]\left[\begin{array}{c|c} a_t(w) & b_t(w) \\ c_t(w) & d_t(w) \end{array}\right]^*}{(z - w^*)}, \text{ say,} \tag{52}$$

where $c_t(z) = c(z)$ and $d_t(z) = d(z) - z^{-t}p(z)c(z)$.

Since (21) provides a recursive procedure for computing $b_t(z)$ it may be possible to obtain one such recursion for computing $d_t(z)$ too. Next we show that it is indeed so.

5.1.3. Recursions for updating $a_t(z)$, $b_t(z)$, $c_t(z)$, and $d_t(z)$. Since $c_t(z) = c(z)$ and $d_t(z) = d(z) - z^{-t}p(z)c(z)$, the following linear recursion

$$\begin{aligned} &c_0(z) = c(z) \quad \text{and} \quad d_0(z) = d(z), \\ &c_{j+1}(z) = c_j(z), \\ &d_{j+1}(z) = d_j(z) - p_{j+1}z^{-(t-j)}c_j(z), \end{aligned} \tag{53}$$

recursively computes $c_t(z)$ and $d_t(z)$ using the $\{p_j\}$ in (16). Then we can combine the recursions (21) with the above recursion (53) and write

$$\left[\begin{array}{c|c} z & O \\ O & 1 \end{array}\right]\left[\begin{array}{c|c} a_{j+1}(z) & b_{j+1}(z) \\ c_{j+1}(z) & d_{j+1}(z) \end{array}\right] = \left[\begin{array}{c|c} a_j(z) & b_j(z) \\ c_j(z) & d_j(z) \end{array}\right]\left[\begin{array}{c|c} 1 & -p_{j+1}z^{-(t-j)} \\ O & 1 \end{array}\right]. \tag{54}$$

5.2. Polynomial recursions for Schur complementation. We can rewrite (40) as follows:

$$\begin{aligned} Q_b^c(z,w) &= \frac{|b(0)|^2\left[\begin{array}{c|c} a_1(z) & b_1(z) \\ zc_1(z) & d_1(z) \end{array}\right]\left[\begin{array}{c|c} O & 1 \\ -1 & O \end{array}\right]\left[\begin{array}{c|c} a_1(w) & b_1(w) \\ wc_1(w) & d_1(w) \end{array}\right]^*}{(z - w^*)} \\ &= \frac{\left[\begin{array}{c|c} z & O \\ O & 1 \end{array}\right]\left[\begin{array}{c|c} a(z) & b(z) \\ c(z) & d(z) \end{array}\right]\Theta(z)\left[\begin{array}{c|c} O & 1 \\ -1 & O \end{array}\right]\Theta^*(w)\left[\begin{array}{c|c} a(w) & b(w) \\ c(w) & d(w) \end{array}\right]^*}{z - w^*}, \end{aligned} \tag{55}$$

where the 2×2 matrix $\Theta(z)$ assumes three different forms that are discussed below.

5.2.1. $\Theta(z)$ for a strongly regular step. It is clear that a strongly regular step of Schur complementation is translated into a univariate map $G_b(z) \rightarrow G_b(z)\Theta(z)$ of form

$$\left[\begin{array}{c|c} z & O \\ O & 1 \end{array}\right] G_{b_{j+1}}(z) = G_{b_j}(z)\Theta_j(z)\ . \tag{56}$$

Let us define the partitions,

$$G_{b_j}(z) = \left[\begin{array}{c|c} a_j(z) & b_j(z) \\ c_j(z) & d_j(z) \end{array}\right]\ . \tag{57}$$

It should be noted that the transformation $\Theta_j(z)$ is completely determined by $a_j(z)$ and $b_j(z)$.

Case 1a. $a_j(0) \neq 0$, $b_j(0) \neq 0$. This is only a transformation step (see §3.2 for details), for which the recursion is

$$\begin{aligned} z a_{j+1}(z) &= a_j(z) - \zeta_j b_j(z), \\ b_{j+1}(z) &= b_j(z), \end{aligned} \tag{58}$$

where $\zeta_j = a_j(0)/b_j(0)$. This implies that

$$\Theta_j(z) = \left[\begin{array}{c|c} 1 & O \\ -\zeta_j & 1 \end{array}\right]. \tag{59}$$

Case 1b. $a_j(0) \neq 0$, $b_j(0) = 0$. This is only an exchange step (see §3.2 for details), for which the recursion is

$$\begin{aligned} a_{j+1}(z) &= b_j(z), \\ b_{j+1}(z) &= -a_j(z). \end{aligned} \tag{60a}$$

This implies that

$$\Theta_j(z) = \left[\begin{array}{c|c} O & -1 \\ 1 & O \end{array}\right]. \tag{60b}$$

Case 2. $a_j(0) = 0$, $b_j(0) \neq 0$, $\lim_{z\to 0} z^{-1} a_j(z) \neq 0$. This is also a strongly regular step for which the recursion is

$$\begin{aligned} z a_{j+1}(z) &= a_j(z), \\ z b_{j+1}(z) &= b_j(z) - \zeta_j z^{-1} a_j(z), \end{aligned} \tag{61}$$

where

$$\zeta_j = \lim_{z\to 0} \frac{b_j(z)}{z^{-1} a_j(z)}.$$

This implies that

$$\Theta_j(z) = \left[\begin{array}{c|c} 1 & -\zeta_j z^{-1} \\ O & 1 \end{array}\right]. \tag{62}$$

5.2.2. $\Theta(z)$ for a nonstrongly regular step. *Case* 2. $a_j(z) = k b_j(z)$ for some constant k. Since $Q_j(z, w) = 0$ all the following principal submatrices of Q are singular. Thus at this step there is no need to proceed any further.

Case 3. $a_j(0) = 0$, $b_j(0) \neq 0$ and there exists a positive integer $t_j > 1$, such that $\lim_{z\to 0} z^{-t_j} a_j(z) \neq 0$. In this case we need to find a $t \times t$ block Schur complement. At this point one needs to make repeated (t times) use of the linear recursion

$$\begin{aligned} z a_{j+1}(z) &= a_j(z), \\ z b_{j+1}(z) &= b_j(z) - \zeta_j z^{-(t-j)} a_j(z), \\ c_{j+1}(z) &= c_j(z), \\ d_{j+1}(z) &= d_j(z) - \zeta_j z^{-(t-j)} c_j(z), \end{aligned} \tag{63}$$

where

$$\zeta_j = \lim_{z\to 0} z^{t-j} b_j(z)/a_j(z) = p_{j+1}.$$

This implies that the univariate map $G_b(z) \to G_b(z)\Theta(z)$ assumes the form

$$\left[\begin{array}{c|c} z & O \\ O & 1 \end{array}\right] G_{b_{j+1}}(z) = G_{b_j}(z)\Theta_j(z), \tag{64a}$$

where

$$\Theta_j(z) = \left[\begin{array}{c|c} 1 & -\zeta_j z^{-(t-j)} \\ O & 1 \end{array}\right]. \tag{64b}$$

Case 4. $a_j(0) = b_j(0) = 0$. Since $Q_j(z,0) = 0 = Q_j(0,w)$, Q_j and all the following principal submatrices are singular, there is no need to proceed any further.

Example. Next we shall consider inverting a 3×3 nonsingular real Hankel matrix whose 2×2 principal minor is zero. Consider the 3×3 symmetric Hankel matrix T with first and last rows [1 1 1] and [1 2 2], respectively. The starting generator

$$G_0(z) = \left[\begin{array}{c|c} a_0(z) & b_0(z) \\ c_0(z) & d_0(z) \end{array}\right] = \left[\begin{array}{c|c} z(1+z+z^2+2z^3+2z^4) & 1 \\ z & O \end{array}\right]. \tag{65a}$$

Thus we have a strongly regular step and hence using (65a)–(65b), we get

$$\zeta_0 = 1, \quad t_0 = 1, \quad \text{and} \quad \Theta_0(z) = \left[\begin{array}{c|c} 1 & -z^{-1} \\ O & 1 \end{array}\right],$$

which implies

$$G_1(z) = \left[\begin{array}{c|c} a_1(z) & b_1(z) \\ c_1(z) & d_1(z) \end{array}\right] = \left[\begin{array}{c|c} 1+z+z^2+2z^3+2z^4 & -(1+z+2z^2+2z^3) \\ z & -1 \end{array}\right]. \tag{65b}$$

Its clear that the next step is just a transformation step. Thus, using (58)–(59), we get

$$\zeta_1 = -1 \quad \text{and} \quad \Theta_1(z) = \left[\begin{array}{c|c} 1 & O \\ 1 & 1 \end{array}\right],$$

which implies

$$G_2(z) = \left[\begin{array}{c|c} a_2(z) & b_2(z) \\ c_2(z) & d_2(z) \end{array}\right] = \left[\begin{array}{c|c} -z^2+2z^4 & -(1+z+z^2+2z^3) \\ z-1 & -1 \end{array}\right]. \tag{65c}$$

This takes us into a nonstrongly regular step. Using (64a)–(64b), we get

$$\zeta_2 = 1, \quad t_2 = 2, \quad \text{and} \quad \Theta_2(z) = \left[\begin{array}{c|c} 1 & -z^{-2} \\ O & 1 \end{array}\right],$$

which gives

$$G_3(z) = \left[\begin{array}{c|c} a_3(z) & b_3(z) \\ c_3(z) & d_3(z) \end{array}\right] = \left[\begin{array}{c|c} -z+2z^3 & -(1+3z+2z^2) \\ z-1 & -(1+z^{-1}-z^{-2}) \end{array}\right] \tag{65d}$$

and brings us back to a strongly regular step. Next, using (61)–(62), we get

$$\zeta_3 = 1, \quad t_3 = 1, \quad \text{and} \quad \Theta_3(z) = \left[\begin{array}{c|c} 1 & -z^{-1} \\ O & 1 \end{array}\right],$$

which implies

$$G_4(z) = \left[\begin{array}{c|c} a_4(z) & b_4(z) \\ c_4(z) & d_4(z) \end{array}\right] = \left[\begin{array}{c|c} -1+2z^2 & -(3+4z) \\ z-1 & -(2-z^{-2}) \end{array}\right]. \tag{65e}$$

The generator for the inverse of H must be $[z^{-1}c_4(z),\ z^{-1}d_4(z)] = [1-z^{-1},\ -2z^{-1}+z^{-3}]$.

A straightforward calculation verifies this claim.

5.3. QH matrices and admissibility condition. From our previous experience with QT matrices (see [13] and [20]), we may expect that inverting a QH matrix may require some preprocessing. This is generally true. However, for a special class of QH matrices, it is not required. We shall call this family of matrices admissible.

For an admissible $Q_{n-1,\infty}(z,w)$, the given $a(z)$ and $b(z)$ are such that there exist complex numbers λ and μ satisfying

$$\lambda a(z) + \mu b(z) = 1.$$

Next choose

$$Q_b(z,w) = \frac{1}{z-w^*}\left[\begin{array}{c|c} a(z) & b(z) \\ \mu z & -\lambda z \end{array}\right]\left[\begin{array}{c|c} O & 1 \\ -1 & O \end{array}\right]\left[\begin{array}{c|c} a(w) & b(w) \\ \mu w & -\lambda w \end{array}\right]^*, \tag{66}$$

which implies that

$$Q_{b,\infty} = \left[\begin{array}{c|c} Q_{n-1,\infty} & I_\infty \\ I_\infty & O_\infty \end{array}\right]. \tag{67}$$

Hence after n steps of Schur reduction, one obtains the generators for the inverse.

It is shown in Appendix A that for an arbitrary nonsingular QH matrix Q_{n-1}, it is $Q_{n-1}^{-\sharp}$ and not Q_{n-1}^{-1} that possesses the same displacement rank. This naturally raises the question: Is it possible to compute $Q_{n-1}^{-\sharp}$ in a similar fashion? The answer is yes, and we provide an explanation below.

It is clear that

$$Q_{n-1} = L_{n-1}\{\underline{b}-\underline{a}\}HL_{n-1}^*\{\underline{b}-\underline{a}\}, \tag{68a}$$

where H is the first $n \times n$ principal submatrix of the infinite Hankel matrix of the Markov parameters of $(b(z)+a(z))/(b(z)-a(z))$ (assuming invertibility of $L_{n-1}\{\underline{b}-\underline{a}\}$; otherwise we shall use $-\underline{a}$ instead of $\underline{a}$).

So

$$\begin{aligned} Q_{n-1}^{-\sharp} &= L_{n-1}^{-1}\{\underline{b}-\underline{a}\}\tilde{I}H^{-1}\tilde{I}L_{n-1}^{-*}\{\underline{b}-\underline{a}\}, \\ &= L_{n-1}^{-1}\{\underline{b}-\underline{a}\}\tilde{I}L_{n-1}^{*}\{\underline{b}-\underline{a}\}Q_{n-1}^{-1}L_{n-1}\{\underline{b}-\underline{a}\}\tilde{I}L_{n-1}^{-*}\{\underline{b}-\underline{a}\}. \end{aligned} \tag{68b}$$

Choose

$$Q_b(z,w) = \frac{1}{z-w^*}\left[\begin{array}{c|c} a(z) & b(z) \\ z & z \end{array}\right]\left[\begin{array}{c|c} O & 1 \\ -1 & O \end{array}\right]\left[\begin{array}{c|c} a(w) & b(w) \\ w & w \end{array}\right]^*, \tag{69}$$

which implies that

$$Q_{b,\infty} = \left[\begin{array}{c|c} Q_{n-1,\infty} & L_{n-1,\infty}\{\underline{b}-\underline{a}\} \\ L^*_{n-1,\infty}\{\underline{b}-\underline{a}\} & O_\infty \end{array}\right] . \tag{70}$$

Hence after n steps of Schur reduction, one obtains the generators for $L^*_{n-1}\{\underline{b}-\underline{a}\}Q^{-1}_{n-1}L_{n-1}\{\underline{b}-\underline{a}\}$. It is clear that if $[z^{-1}c_n(z)\ ,\ z^{-1}d_n(z)]$ is the generator for this matrix then $[d^\sharp_n(z)\ ,\ c^\sharp_n(z)]$ is the generator of $\tilde{I}L^*_{n-1}\{\underline{b}-\underline{a}\}Q^{-1}_{n-1}L_{n-1}\{\underline{b}-\underline{a}\}\tilde{I}$. It is possible to directly compute $c^\sharp_n(z)$ and $d^\sharp_n(z)$ instead of $c_n(z)$ and $d_n(z)$; thus we can also compute the generator for $Q^{-\sharp}_{n-1}$ directly as explained below.

If

$$\left[\begin{array}{c|c} c_{j+1}(z) & d_{j+1}(z) \end{array}\right] = \left[\begin{array}{c|c} c_j(z) & d_j(z) \end{array}\right]\Theta_j(z),$$

then we must have

$$\left[\begin{array}{c|c} c^\sharp_{j+1}(z) & d^\sharp_{j+1}(z) \end{array}\right] = \left[\begin{array}{c|c} c^\sharp_j(z) & d^\sharp_j(z) \end{array}\right]\left[\Theta^\sharp_j(z)\right]^T .$$

Given $a(z)$ and $b(z)$, it is possible to find $c_e(z)$ such that

$$[a(z)-b(z)]c_e(z) = 1 + O(z^n) . \tag{71}$$

Partition $c_e(z)$ as $c_e(z) = \hat{c}_e(z) + O(z^n)$. Then the recursions

$$\left[\begin{array}{c|c} a_{j+1}(z) & b_{j+1}(z) \end{array}\right] = \left[\begin{array}{c|c} a_j(z) & b_j(z) \end{array}\right]\Theta_j(z),$$

$$\left[\begin{array}{c|c} c^\sharp_{j+1}(z) & d^\sharp_{j+1}(z) \end{array}\right] = \left[\begin{array}{c|c} c^\sharp_j(z) & d^\sharp_j(z) \end{array}\right]\left[\Theta^\sharp_j(z)\right]^T .$$

with

$$c^\sharp_0(z) = d^\sharp_0(z) = \hat{c}_e(z) \tag{72}$$

would be sufficient and the Schur procedure would compute the generator $[d^\sharp_n(z)\ ,\ c^\sharp_n(z)]$ for $Q^{-\sharp}$ in n steps.

6. Solution to linear equations. It is clear that the solutions to the Yule–Walker type equations are obtained directly from the generators of the inverse. However, solution to a system of linear equations with an arbitrary right-hand side requires extension of the notion block QH generating function (37) to

$$Q_b(z,w) = \frac{1}{z-w^*}\left[\begin{array}{c|c} a(z) & b(z) \\ c(z) & d(z) \end{array}\right]\left[\begin{array}{c|c} O & 1 \\ -1 & O \end{array}\right]\left[\begin{array}{c|c} a(w) & b(w) \\ p(w) & q(w) \end{array}\right]^* , \tag{73}$$

where $a(z)$, $b(z)$, $c(z)$, $d(z)$, $p(z)$, and $q(z)$ are all polynomials (functions) in z and z^{-1}.

The linear equation

$$Q\underline{x} = \underline{y}$$

for an arbitrary column vector $\underline{y}$ can be solved by choosing $c(z) = c_e(z) = d(z)$ (see (71)–(72)) and $p(z) = c_e(z)y(z) = q(z)$, where $y(z) = [1\ z\ z^2\ \dots\ z^n]\underline{y}$. It develops that the Schur complements can be computed via trivial modification of the linear recursions in §5.2. In fact, the $\Theta_j(z)$s in (56)–(64b) remain the same while the Schur complementation steps are translated into two univariate maps $G^i_b(z) \to G^i_b(z)\Theta(z)$, $1 \le i \le 2$ of form

$$\left[\begin{array}{c|c} z & O \\ O & 1 \end{array}\right] G^i_{b_{j+1}}(z) = G^i_{b_j}(z)\Theta_j(z). \tag{74}$$

Let us define the partitions

$$G^1_{b_j}(z) = \left[\begin{array}{c|c} a_j(z) & b_j(z) \\ c_j(z) & d_j(z) \end{array}\right] \tag{75a}$$

and

$$G^2_{b_j}(z) = \left[\begin{array}{c|c} a_j(z) & b_j(z) \\ p_j(z) & q_j(z) \end{array}\right]. \tag{75b}$$

7. Concluding remarks. A new approach that provides a unified framework for fast and completely recursive procedures for computing modified triangular factorization of Hankel, QH, and SMQH matrices has been developed.

This recursive procedure is based on the fact that the Schur complement (or the block Schur complement) of the top-left entry (or block) of a Hankel or a QH matrix is QH, while that of a SMQH matrix is SMQH; except for Lev-Ari and Kailath [12] or Chun [2], earlier papers did not utilize this fact. The procedure presented here does not require computation of inner products and parallelizes well. Determination of the size of a block factor is done by counting the number of repeated zeros at the origin of a polynomial (see also [3]).

It also turns out that the block diagonal entries are either lower triangular Hankel matrices[1] (for Hankel and QH cases) or products of a signature matrix and a lower triangular Hankel matrix (for SMQH matrices); see (24) and (30). The inertia of such matrices (and hence the inertia of the original matrices) is determinable by inspection using certain rules due to Iohvidov [7] (see Appendix B). Computation of the inertia of SMQH matrices has applications in the problems of stability checking of linear time invariant continuous time systems and root distribution of polynomials with regard to the imaginary axis (see [11], [19], and [20]).

Using the results on modified triangular factorization, we have extended the Schur complement-based approach of Chun [2] for solving linear equations and inverting strongly regular Hankel matrices to Hankel and QH matrices with arbitrary rank profile. This leads to simultaneous derivation of the type of recursions of Lanczos (Schur) and Berlekamp–Massey (Levinson). The inversion procedures will work as long as the underlying matrices are nonsingular. Unlike most previous approaches (see Heinig and Rost [6]) no special requirement on the rank profile is needed.

Since theoretical detection of a singularity and the number of consecutive zero minors require infinite precision, it is clear that a floating point implementation of the algorithm would contain serious problems. This raises the issue of devising a numerically sound general algorithm that could deal with "nearly singular cases." Such a question goes beyond the scope of the paper and deserves a thorough investigation.

Appendix A. Derivation of (17). From (15)–(16),

$$p(z)\tilde{g}_t(z) = 1, \tag{A.1}$$

where

$$p(z) = \sum_{j=0}^{t-1} p_{j+1} z^j \quad \text{and} \quad \tilde{g}_t(z) = \sum_{j=0}^{t-1} g_{j+t} z^j.$$

[1] A matrix is called lower triangular Hankel if it has only zero entries above the main antidiagonal.

Define

$$g_{2t}(z) = \sum_{j=0}^{\infty} g_{j+2t} z^j \quad \text{then} \quad g_t(z) = \tilde{g}_t(z) + z^t g_{2t}(z), \qquad \Rightarrow \quad g_t(z) = \sum_{j=0}^{\infty} g_{j+t} z^j.$$

But if the first $t-1$ leading principal minors of Q are singular so are the first $t-1$ leading principal minors of F_H, which implies that $z^t g_t(z) = g(z)$. Therefore under this condition,

$$\frac{a(z)}{b(z)} = g(z) = z^t[\tilde{g}_t(z) + z^t g_{2t}(z)]. \tag{A.2}$$

Then from (A.1)–(A.2),

$$\frac{p(z)a_t(z)}{b(z)} = 1 + z^t p(z) g_{2t}(z), \qquad \Rightarrow p(z)a_t(z) = b(z) + z^t p(z) g_{2t}(z) b(z). \tag{A.3}$$

Since the second term $z^t p(z) g_{2t}(z) b(z)$ does not affect the coefficients of $\{z^0, \ldots, z^{t-1}\}$, the entries $\{p_j\}_{j=1}^t$ can be computed via the matrix equation (17) (see §3.1).

Appendix B. Iohvidov's inertia rules. If none of the principal minors of a matrix is zero, computing inertia is easy. Computing inertia is generally hard if a number of zero principal minors are followed by a nonzero principal minor. However, for Hankel matrices this difficulty can be avoided using a nice set of rules due to Iohvidov [7].

Iohvidov's rules. Let the sequence of successive principal minors of an $n \times n$ Hankel matrix H_{n-1} contain an isolated group of p (≥ 1) zeros:

$$(\Delta_{h-1} \neq 0), \quad \Delta_h = \Delta_{h+1} = \cdots = \Delta_{h+p-1} = 0, \quad (\Delta_{h+p} \neq 0).$$

Also, let a number of extra positive and negative eigenvalues that H_{h+p} has as compared to H_{h-1} be $\pi(h-1, h+p)$ and $\nu(h-1, h+p)$, respectively. These can be computed by formulas in Table B.1 where $\theta = (-1)^{p/2}$ Sign $(\Delta_{h+p})/(\Delta_{h-1})$.

TABLE B.1

	p odd	p even
$\pi(h-1, h+p)$	$\frac{p+1}{2}$	$\frac{p+1+\theta}{2}$
$\nu(h-1, h+p)$	$\frac{p+1}{2}$	$\frac{p+1-\theta}{2}$

However, this rule simplifies even further, since it turns out that θ = Sign ζ, where ζ is the entry on the main antidiagonal of the corresponding block diagonal factor (see (24)).

Acknowledgments. The authors would also like to thank Professor Hanoch Lev-Ari of the Northeastern University for his suggestions for improvement and constructive criticism. The first author would like to thank Drs. Victor B. Lawrence, Joseph G. Kneuer, William H. Ninke, and Bryan D. Ackland of the AT&T Bell Laboratories for encouragement and support.

THE ARNOLDI METHOD FOR NORMAL MATRICES*

THOMAS HUCKLE†

Abstract. For large Hermitian matrices the preconditionend conjugate gradient algorithm and the Lanczos algorithm are the most important methods for solving linear systems and for computing eigenvalues. There are various generalizations to the nonsymmetric case based on the Arnoldi method or on the nonsymmetric Lanczos algorithm, e.g., generalized minimal residual ((GMRES), residual minimization in a Krylov space) and conjugate gradient squared ((CGS), a biorthogonalization algorithm adapted from the biconjugate gradient method) for linear equations and the incomplete orthogonalization method and the look-ahead Lanczos algorithm for computing eigenvalues. The aim of this paper is to analyse the Arnoldi method applied to a normal matrix. It is shown that for a normal matrix A, the Arnoldi projection H_p is a normal upper Hessenberg matrix if and only if A is (1)-normal. Only in this case, H_p is tridiagonal and the Arnoldi method has the same properties as in the Hermitian case.

Key words. large linear systems, normal matrices, Krylov subspace methods, Arnoldi method, Lanczos method

AMS subject classifications. 65F10

1. Introduction.

Normal matrices appear in some applications, such as in the solution of the complex Helmholtz equation [7]. Furthermore, there exist methods for normalizing a given general matrix, for example, by Jacobi-like algorithms. In this paper, we examine the Arnoldi method applied to normal matrices. The Arnoldi process [1] is a method for transforming a general real or complex $n \times n$ matrix A to Hessenberg form. Set

$$K_p := \text{span}\ \{b, Ab, \ldots, A^{p-1}b\}, \qquad p = 1, 2, \ldots,$$

the Krylov subspace of order p related to matrix A and vector b, and H_p the orthogonal projection of A on K_p. The orthonormal vectors v_i, $i = 1, 2, \ldots, v_1 = b/\|b\|$ that form a basis of K_p can be computed iteratively by equations

$$h_{p+1,p}v_{p+1} = Av_p - \sum_{i=1}^{p} h_{i,p}v_i, \qquad h_{i,p} = v_i^H Av_p \quad \text{for } i = 1, \ldots, p. \tag{1}$$

The matrices H_p and V_p built up from $h_{i,k}, i, k = 1, \ldots, p$ and $v_i, i = 1, \ldots, p$ can be used to give estimates for the solution of the linear system $Ax = b$ and the eigenvalues of A [16], [18]. The eigenvalues of H_p are the Ritz values of A with respect to K_p.

For the following, denote by p^* the minimal p with $K_p = K_{p+1}$ or the maximal p with $\dim(K_p) = p$.

ARNOLDI ALGORITHM
$v_1 = b/\|b\|$;
for $j := 1, p$
  $w := Av_j$;
  for $i := 1, j$
    $h_{i,j} := v_i^H Av_j; w := w - h_{i,j}v_i$;
  end

* Received by the editors September 30, 1991; accepted for publication (in revised form) November 4, 1992.

† Institut für Angewandte Mathematik und Statistik, Universität Würzburg, D-97074 Würzburg, Germany (huckle@vax.rz.uni-wuerzburg.dbp.de).

$h_{j+1,j} := \|w\|$; if $h_{j+1,j} = 0$, then stop; $v_{j+1} := w/h_{j+1,j}$;
end

For this algorithm the following holds (see, e.g., [11], [13], [17]).

(i) $v_1, \ldots, v_p$ form an orthonormal basis of K_p; $H_p = V_p^H A V_p$ is an upper $p \times p$ Hessenberg matrix.

(ii) If $h_{j+1,j} = 0$ for an integer j and the algorithm stops after j steps, then $j = p^*$ and the eigenvalues of H_j are eigenvalues of A.

(iii) The Ritz values of A with respect to K_p are the eigenvalues $\lambda^{(p)}$ of H_p, and the Ritz vectors are $z^{(p)} = V_p y^{(p)}$, where $y^{(p)}$ are the normalized eigenvalues of H_p associated with $\lambda^{(p)}$.

(iv) If $e_p = (0, \ldots, 0, 1)^T$, then

$$AV_p = V_p H_p + h_{p+1,p} v_{p+1} e_p^T, \tag{2}$$

and the residual of the Ritz pair $(\lambda^{(p)}, z^{(p)})$ satisfies

$$\left\| \left(A - \lambda^{(p)} I \right) z^{(p)} \right\| = \left| h_{p+1,p} e_p^T y^{(p)} \right| . \tag{3}$$

The matrices that appear in the Arnoldi algorithm can be also represented by means of orthogonal projections [3], [4]. Let π_p be the orthogonal projection on the subspace K_p, and A_p the orthogonal projection of A on K_p; thus $A_p = \pi_p A|_{K_p}$. The operator A_p can be characterized by the equations

$$A_p(A^i b) = \begin{cases} A^{i+1} b & \text{for } i < p-1, \\ \pi_p A^p b = \sum_{j=0}^{p-1} \varepsilon_j A^j b & \text{for } i = p-1, \end{cases} \tag{4}$$

where ε_j and γ_{p+1} must be chosen in such a way that $q_{p+1} := \gamma_{p+1}(A^p - \pi_p A^p)b$ is orthogonal to K_p and has Euclidean length 1. Then, for $p < p^*, q_{p+1} \neq 0$. With

$$F_p := \begin{pmatrix} 0 & 0 & \cdots & 0 & \varepsilon_0 \\ 1 & 0 & \cdots & 0 & \varepsilon_1 \\ 0 & 1 & & 0 & \varepsilon_2 \\ \vdots & & \ddots & \vdots & \vdots \\ 0 & & \cdots & 1 & \varepsilon_{p-1} \end{pmatrix} ,$$

$L_p := (b, Ab, \ldots, A^{p-1}b)$ and $Q_p := (q_1, \ldots, q_p)$, there exists a matrix R with $L_p = Q_p R$, and there holds

$$AL_p = L_p F_p + q_{p+1} e_p^T$$

or

$$AQ_p = Q_p(RF_pR^{-1}) + (1/r_{p,p}) q_{p+1} e_p^T . \tag{5}$$

Comparing (5) with (1) and (2) we see that for $p \leq p^*$ we can set $Q_p = V_p$ and then $H_p = Q_p^T A Q_p = RF_pR^{-1}$. Hence, F_p and H_p have the same spectrum and the characteristic polynomial of H_p is of the form (see, e.g., [15])

$$p(x) = x^p - \sum_{i=0}^{p-1} \varepsilon_i x^i .$$

For symmetric A the Arnoldi method coincides with the symmetric Lanczos method [2], [12] and H_p is tridiagonal. In the general case, H_p is a full upper Hessenberg matrix, and thus the Arnoldi algorithm often has to be used with restarts or with incomplete orthogonalization [16]. In this last method the new vector v_{j+1} is computed by orthogonalizing Av_j against the previous $k+1$ vectors $v_{j-k}, \ldots, v_j$, rather than against all the previous vectors $v_1, \ldots, v_j$. Then, the resulting Hessenberg matrix is a band matrix.

The GMRES algorithm [18] for solving $Ax = b$ is based on the Arnoldi method applied to the matrix A with starting vector $v_1 = r_0/\|r_0\|$, $r_0 = Ax_0 - b$. In this process, one computes that $z \in \text{span}\,(r_0, Ar_0, \ldots, A^k r_0)$, for which the residual $\|b - A(x_0 + z)\|_2$ takes its minimal value.

For nonsymmetric matrices the Arnoldi method and the nonsymmetric Lanczos algorithm lead to different methods for computing eigenvalues and solutions of linear systems [9], [14].

2. Is H_p normal for normal A? For symmetric A the Arnoldi method yields a symmetric tridiagonal matrix H_p. If A is unitary, then the operator A_p, the orthogonal projection of A on the Krylov subspace $K_p(A, b)$, is nearly unitary [3]. This means that for $p < p^*$, there holds

$$A_p A_p^H = I + E \quad \text{with } \operatorname{rank}(E) = 1 \ .$$

Furthermore, A and A_p are both unitary if and only if $p = p^*$. This consideration leads to the question whether for normal A, A_p is normal, too.

THEOREM 1. *Let A be normal and $1 < p < p^*$. Then, A_p is normal too if and only if*

$$A^H b \in K_2(A, b) \ ,$$

or there exist γ_0 and γ_1 with

$$A^H b = \gamma_0 b + \gamma_1 A b \ .$$

Proof. Let $q_{i+1} = (A^i - \pi_i A^i)b$ be the orthogonal vectors that constitute a basis of the Krylov subspaces $K_j(A, b)$. Thus, $q_{i+1} \perp K_i$ and there exists a decomposition

$$A^H b = c + q \quad \text{with } c = \sum_{j=0}^{p-1} \gamma_j A^j b \quad \text{and} \quad q \perp K_p \ . \tag{6}$$

Furthermore, there holds

$$A_p^H = (\pi_p A \pi_p)^H = \pi_p A^H \pi_p = \pi_p A^H \quad \text{in } K_p \ .$$

The condition that A_p is normal is equivalent to the equations

$$A_p A_p^H (A^i b) = A_p^H A_p (A^i b), \qquad i = 0, 1, \ldots, p-1 \ . \tag{7}$$

For $i < p - 1$, the left and right sides of (7) can be written in the form

$$\begin{aligned} A_p A_p^H A^i b &= \pi_p A \pi_p A^H A^i b = \pi_p A \pi_p A^i A^H b \\ &= \pi_p A \pi_p A^i (c + q) = \pi_p A \pi_p \sum_{j=0}^{p-1} \gamma_j A^{i+j} b + \pi_p A \pi_p A^i q \end{aligned} \tag{8}$$

and

$$A_p^H A_p A^i b = \pi_p A^H \pi_p A A^i b = \pi_p A^H \pi_p A^{i+1} b = \pi_p A^H A^{i+1} b$$

(9)

$$= \pi_p A^{i+1} A^H b = \pi_p A^{i+1}(c+q) = \pi_p \sum_{j=0}^{p-1} \gamma_j A^{i+j+1} b + \pi_p A^{i+1} q \ .$$

For the following, let us suppose that A_p is normal and $i < p-1$. For $i = 0$, (6), (7), and (8) yield $\pi_p A q = \pi_p q = 0$, and thus $Aq \perp K_p$. With $b \in K_p$, we get

$$0 = (Aq)^H b = q^H (A^H b) = q^H (c+q) = \|q\|^2 \ ,$$

and hence, $q = 0$.

Now we prove by induction that $\gamma_{p-i} = 0$ for $i = 0, 1, \ldots, p-2$: the case when $i = 0$ is obvious. Now assume that the proposition holds for an integer $i-1$ with $0 \le i-1 \le p-3$, and $\gamma_p = \cdots = \gamma_{p-i+1} = 0$. Thus, we have

$$A^H b = \sum_{j=0}^{p-i} \gamma_j A^j b \ .$$

With (4), equation (8) can be written in the form

$$\begin{aligned} A_p A_p^H A^i b &= \pi_p A \sum_{j=0}^{p-i-1} \gamma_j A^{j+i} b + \gamma_{p-i} \pi_p A \pi_p A^p b \\ &= \pi_p \sum_{j=0}^{p-i-1} \gamma_j A^{j+i+1} b + \gamma_{p-i} \pi_p A (A^p b - q_{p+1}) \\ &= \pi_p \sum_{j=0}^{p-i} \gamma_j A^{j+i+1} b - \gamma_{p-i} \pi_p A q_{p+1} \ , \end{aligned}$$

and (9) yields

$$A_p^H A_p A^i b = \pi_p \sum_{j=0}^{p-i} \gamma_j A^{i+j+1} b \ .$$

With (7) it follows that $\gamma_{p-i} \pi_p A q_{p+1} = 0$ and, therefore, $\gamma_{p-i} A q_{p+1} \perp K_p$. For $A^i b$ we get

$$\begin{aligned} 0 &= (\gamma_{p-i} A q_{p+1})^H A^i b = \bar{\gamma}_{p-i} q_{p+1}^H (A^H A^i b) = \bar{\gamma}_{p-i} q_{p+1}^H A^i A^H b \\ &= \bar{\gamma}_{p-i} q_{p+1}^H \sum_{j=0}^{p-i} \gamma_j A^{j+i} b = \bar{\gamma}_{p-i} q_{p+1}^H * \bar{\gamma}_{p-i} A^p b \\ &= |\gamma_{p-i}|^2 q_{p+1}^H (\pi_p A^p b + q_{p+1}) = |\gamma_{p-i}|^2 \|q_{p+1}\|^2 \end{aligned}$$

and thus, because of $p < p^*$, $\gamma_{p-i} = 0$.

All in all, we have proved that for A and A_p normal, $A^H b \in K_2$.

Now, let us assume that A is a normal matrix and $A^H b = \gamma_0 b + \gamma_1 A b$. Then, for $i < p-1$ there follows

$$\begin{aligned} A_p A_p^H A^i b &= \pi_p A \pi_p A^i (\gamma_0 b + \gamma_1 A b) = \pi_p A^{i+1} (\gamma_0 b + \gamma_1 A b) \\ &= \pi_p A^{i+1} A^H b = \pi_p A^H A^{i+1} b = \pi_p A^H \pi_p A \pi_p A^i b = A_p^H A_p A^i b \ , \end{aligned}$$

and furthermore, for $i = p-1$ and using (4), we get

$$\begin{aligned} A_p A_p^H A^{p-1} b &= \pi_p A \pi_p (\gamma_0 A^{p-1} + \gamma_1 A^p) b = \gamma_0 \pi_p A^p b + \gamma_1 \pi_p A \pi_p A^p b \\ &= \sum_{j=0}^{p-1} \varepsilon_j \gamma_0 A^j b + \gamma_1 \pi_p A \sum_{j=0}^{p-1} \varepsilon_j A^j b = \sum_{j=0}^{p-1} \varepsilon_j \pi_p A^j (\gamma_0 b + \gamma_1 A b) \\ &= \sum_{j=0}^{p-1} \varepsilon_j \pi_p A^j A^H b = \pi_p A^H \sum_{j=0}^{p-1} \varepsilon_j A^j b = \pi_p A^H \pi_p A^p b = A_p^H A_p A^{p-1} b \ . \end{aligned}$$

Hence, (7) is fulfilled, and A_p is normal too. □

Remark. A_1 is always normal, and, for normal A, A_{p^*} is normal, too.

COROLLARY 1. *Let $1 < p < p^*$ and A normal. Then A_p is normal too if and only if $A_p^H = \gamma_0 I_p + \gamma_1 A_p$ holds in K_p.*

Proof. From Theorem 1 we get $A^H b = (\gamma_0 I + \gamma_1 A) b$ and thus for $i = 0, 1, \ldots, p-1$, it holds that

$$A_p^H (A^i b) = \pi_p A^i (\gamma_0 b + \gamma_1 A b) = \gamma_0 A^i b + \gamma_1 \pi_p A^{i+1} b = (\gamma_0 I_p + \gamma_1 A_p) A^i b \ .$$

On the other hand, $A_p^H = \gamma_0 I_p + \gamma_1 A_p$ yields immediately $A_p^H A_p = A_p A_p^H$. □

COROLLARY 2. *If A and A_p are normal for an integer p with $1 < p < p^*$, then A_i is normal for all $i \le p^*$.*

COROLLARY 3. *Let A be normal. Then A_p is normal for every b and $p \le p^*$ if and only if $A^H = \gamma_0 I + \gamma_1 A$.*

Proof. Let x_j, $j = 1, \ldots, n$ be orthogonal eigenvectors connected with eigenvalues λ_j of A and set $b = \sum_{j=1}^n x_j$. From $A^H b = \gamma_0 b + \gamma_1 A b$, we get

$$\sum_{j=1}^n \bar{\lambda}_j x_j = \sum_{j=1}^n (\gamma_0 + \gamma_1 \lambda_j) x_j \ .$$

Therefore, the eigenvalues of A satisfy the equation $\bar{\lambda}_j = \gamma_0 + \gamma_1 \lambda_j$ for fixed γ_0, γ_1, and it holds that $A^H = \gamma_0 I + \gamma_1 A$.

On the other hand, a normal matrix A with $A^H = \gamma_0 I + \gamma_1 A$ satisfies the assumptions of Theorem 1 and, therefore, A_p is normal. □

For normal A, the representation $A^H = \gamma_0 I + \gamma_1 A$ yields further properties of γ_0 and γ_1. Suppose that A has two different eigenvalues μ and ν. Then it follows that $\bar{\mu} - \bar{\nu} = \gamma_1 (\mu - \nu)$ and, therefore, γ_1 has absolute value 1, say $\gamma_1 = e^{i\psi}$. Furthermore, with $\gamma_0 = \bar{\mu} - e^{i\psi}\mu$, the number $i\gamma_0 e^{-i\psi/2}$ must be real.

Theorem 1 shows that for unitary matrices A, A_p is not normal.

THEOREM 2. *Let A be unitary and $1 < p < p^*$ for a given b. Then A_p is not normal.*

Proof. Let $1 < p < p^*$. From Theorem 1 we get $A^H b = (\gamma_0 I + \gamma_1 A) b$, and this leads to

$$(\gamma_1 A^2 + \gamma_0 A - I) b = 0 \ .$$

Now it is possible to choose orthogonal eigenvectors x_j of A connected with pairwise different eigenvalues λ_j, such that b has the representation

$$b = \sum_{j=1}^k \alpha_j x_j \quad \text{and} \quad \alpha_j \neq 0 \ . \tag{10}$$

This yields $\gamma_1\lambda_j^2 + \gamma_0\lambda_j - 1 = 0$ for $j = 1, \ldots, k$. Therefore, there must hold $k \leq 2$, and this implies that $p^* \leq 2$. □

The representation (10) of b shows how p^* depends on b and shows that $p^* = k$. This is a consequence of the equation

$$(b, Ab, \ldots, A^{p-1}b) = (\alpha_1 x_1, \ldots, \alpha_k x_k) \begin{pmatrix} 1 & \lambda_1 & \cdots & \lambda_1^{p-1} \\ 1 & \lambda_2 & \cdots & \lambda_2^{p-1} \\ \vdots & \vdots & & \vdots \\ 1 & \lambda_k & \cdots & \lambda_k^{p-1} \end{pmatrix} .$$

A Theorem of Gantmacher [8] states that a matrix A is normal if and only if there exists a polynomial p of degree $\leq n$ with $A^H = p(A)$. For what follows we set

$$n(A) := \text{the minimal degree of a polynomial } p \text{ with } A^H = p(A) . \tag{11}$$

It is easy to see that $n(A)$ is less or equal to the degree of the minimal polynomial of A. With this notation we get the following theorem.

THEOREM 3. *Let A be normal and $1 < p < p^*, p - 1 \geq k > 1$ for given b. Furthermore, assume that $A^H b = p(A)b$ with a polynomial of degree $\leq k$. Then it holds that*

$$A_p^H A_p - A_p A_p^H =: E \quad \textit{and} \quad \text{rank } (E) \leq k .$$

Proof. For $i = 0, 1, \ldots, p - 1 - k$, we get

$$A_p A_p^H A^i b = \pi_p A \pi_p A^i p(A) b = \pi_p A^{i+1} A^H b$$

and

$$A_p^H A_p A^i b = \pi_p A^H \pi_p A A^i b = \pi_p A^{i+1} A^H b .$$

Therefore, $Ex = 0$ for all $x \in K_{p-k}(A, b)$. Hence, the null space of E is at least of dimension $p - k$. □

The matrices that satisfy $B^H = \gamma_0 I + \gamma_1 B$ form an important class with interesting properties. Faber and Manteuffel [6] showed that these matrices coincide with the class of matrices that can be written in the form

$$B = aI + e^{i\phi} S \quad \text{with Hermitian } S . \tag{12}$$

Thereby, (12) means that B is normal, and the eigenvalues of B are collinear and lie on a straight line $a + e^{i\psi} t, t$ real. The class (12) is the weakest generalisation of the class of Hermitian matrices. Furthermore, γ_0, γ_1 and a, ϕ are connected by

$$\gamma_1 = e^{-2i\phi} \quad \text{and} \quad \text{imaginary part}(ae^{-i\phi}) = -\frac{i}{2}\gamma_0 e^{i\phi} . \tag{13}$$

Following [6], these matrices are the only matrices for which one can define a conjugate gradient method with three-term recursion. This class appears also in applications, e.g., in connection with the complex Helmholtz equation [7].

Now, the representation (10) allows a new formulation of Theorem 1.

COROLLARY 4. *For normal A, A_p is also normal, $1 < p < p^*$, if and only if in the representation* (10) *of b all eigenvalues λ_i, $i = 1, \ldots, k$, are collinear.*

Proof. Theorem 1 and (10) show that A_p is normal if and only if

$$\bar{\lambda}_i = \gamma_0 + \gamma_1 \lambda_i, \qquad i = 1, \ldots, k \ .$$

But this means that all λ_i lie on a straight line $a + e^{i\psi}t$ with a and ϕ determined by (13). □

Hence, for normal A, A_p is also normal if and only if all eigenvalues of A_{p^*}—and therefore all eigenvalues of A_p, $p = 1, \ldots, p^*$—are collinear.

Furthermore, there holds the following theorem.

THEOREM 4. *Nondecomposable, normal, tridiagonal matrices are of the form* (12) *and have collinear eigenvalues.*

Proof. With

$$T = \begin{pmatrix} a_1 & b_1 & & & \\ c_1 & a_2 & \ddots & & \\ & \ddots & \ddots & \ddots & \\ & & \ddots & a_{n-1} & b_{n-1} \\ & & & c_{n-1} & a_n \end{pmatrix} ,$$

the main diagonal of

$$TT^H = T^H T \ , \tag{14}$$

shows that $|c_j| = |b_j|$ for $j = 1, \ldots, n-1$. Considering the subdiagonal elements $a_{j,j-2}$, we can see that $c_j = e^{i\delta}\bar{b}_j$ with fixed δ. All b_j and c_j are different from zero and thus (14) yields

$$a_{j+1} - a_j = e^{i\delta}(\bar{a}_{j+1} - \bar{a}_j) \ .$$

Therefore, for all $j = 1, \ldots, n-1$, there holds

$$a_{j+1} - a_j = r_j e^{i\delta/2}, \qquad r_j \text{ real} \ ,$$

or

$$a_j = a_1 + \sum_{k=1}^{j-1} r_k e^{i\delta/2} \ .$$

All in all, we get

$$T = a_1 I + e^{i\delta/2} \begin{pmatrix} 0 & e^{-i\delta/2}b_1 & & & \\ e^{i\delta/2}\bar{b}_1 & r_1 & \ddots & & \\ & \ddots & \ddots & \ddots & \\ & & \ddots & \sum_{k=1}^{n-2} r_k & e^{-i\delta/2}b_{n-1} \\ & & & e^{-i\delta/2}\bar{b}_{n-1} & \sum_{k=1}^{n-1} r_k \end{pmatrix} . \qquad \square$$

3. Properties of the projected matrix H_p for normal A. For the following, let A be a normal $n \times n$ matrix. In §2 we showed that the matrix H_p that arises in the Arnoldi process is generally no longer normal. But H_{p^*} is also normal. Therefore,

there exists a polynomial of degree $n(A_{p^*})$, defined in (11), with $A_{p^*}^H = p(A_{p^*})$ or $A^H b = p(A)b$. With $q_i = v_i$ defined by the Arnoldi algorithm, there follows

$$\overline{h_{i,j}} = q_j^H (A^H q_i) = q_j^H (p(A)b) = 0$$

for $i > n(A_{p^*}) + j$. Thereby, p is a polynomial of degree less or equal $n(A_{p^*}) + i - 1$. Hence, we have proved the following theorem.

THEOREM 5. *The upper Hessenberg matrix generated by the Arnoldi process has upper bandwidth* $n(A_{p^*}) \leq n(A)$.

Remarks. If A_p and also H_p are normal for $1 < p < p^*$ and have the form (12), then there holds $n(A_{p^*}) \leq 1$, and H_p is a normal tridiagonal matrix for every p. Therefore, H_p is of the form described in Theorem 4. In particular, the linear system that must be solved in the GMRES algorithm is of tridiagonal form if A satisfies (12).

Faber and Manteuffel showed in [6] that for a normal matrix B with $n(B) > 1$, the degree of the minimal polynomial of B is less than or equal to $n(B)^2$. Hence, in this case, $n(A_{p^*})$ will be very large and the band structure of H_p will be visible only for large p.

Further properties of H_p result from the consideration that H_p is a leading principal submatrix of the normal upper Hessenberg matrix H_{p^*}.

LEMMA 1. *Let A be normal and partitioned in the form*

$$A = \begin{pmatrix} B & C \\ D & E \end{pmatrix}$$

with quadratic matrices B and E. Then, $\|C\|_F = \|D\|_F$, and the departure of normality of B is given by

$$\left\|BB^H - B^H B\right\|_F \leq \|D\|_F^2 + \|C\|_F^2 = 2\|C\|_F^2 \ .$$

Proof. Equation $AA^H = A^H A$ yields

$$BB^H - B^H B = D^H D - CC^H \ . \tag{15}$$

Considering only the trace of (15) and estimating the right side of (15) proves the lemma. □

Hence, for the upper Hessenberg matrix H_p generated by the Arnoldi process, we get

$$\left\|H_p H_p^H - H_p^H H_p\right\|_F \leq 2\left|h_{p+1,p}\right|^2 \ .$$

Furthermore, there holds the theorem that follows.

THEOREM 6. *For normal A, the departure of normality of H_p satisfies*

$$\left\|H_p H_p^H - H_p^H H_p\right\|_F \leq 2\|A\|^2 \sqrt{n-p} \ .$$

Proof. It holds that

$$H_p H_p^H - H_p^H H_p = Q_p^H \left(A(\pi_p - I_p)A^H + A^H(I_p - \pi_p)A\right) Q_p \ . \qquad \square$$

Without loss of generality, from now on we assume that $p^* = n$ holds. Lemma 1 shows that for the normal Hessenberg matrix $H_n = (h_{i,j})_{i,j=1}^n$,

$$\left|h_{p+1,p}\right|^2 = \sum_{i=1}^{p} \sum_{j=p+1}^{n} \left|h_{i,j}\right|^2 \tag{16}$$

for $p = 1, 2, \ldots, n-1$. For what follows denote by D_i the mean value of the squared absolute values of the elements on the ith superdiagonal,

$$D_i = \frac{1}{n-i} \sum_{j=1}^{n-i} |h_{j,i+j}|^2 \ ,$$

and M_i is the maximum of this value. In the same way, set D the mean value of the squared subdiagonal elements,

$$D = \frac{1}{n-1} \sum_{j=1}^{n-1} |h_{j+1,j}|^2 \ ,$$

and M is the maximum. By summing (16) and taking into consideration the multiplicities of the superdiagonal elements in this sum, we get

$$D = \sum_{i=1}^{n-1} \frac{i(n-i)}{(n-1)} D_i \ .$$

For each superdiagonal this gives

$$D_i \leq \frac{(n-1)}{i(n-i)} D, \qquad i = 1, \ldots, n-1$$

and

$$M_i \leq \frac{n-1}{i} D, \qquad M_i \leq M \ .$$

More precisely, with Lemma 1 we get even

$$|h_{i,i+j}| \leq \min_{k=1}^{j} |h_{i+k,i+k-1}| \ ,$$

especially for $i = 1$ and $i = n-1$

$$|h_{1,2}| \leq |h_{2,1}| \quad \text{and} \quad |h_{1,n}| \leq \min_{k=1}^{n-1} |h_{k+1,k}| \ .$$

Then, using

$$\sum_{i=1}^{n-1} (n-i) D_i \leq \sum_{i=1}^{n-1} i(n-i) D_i \leq (n-1) D \ ,$$

we can estimate the Frobenius norm of H_n by

$$\|H_n\|_F^2 \leq n D_0 + 2(n-1) D \leq n M_0 + 2(n-1) M \ .$$

The mean value of the squared superdiagonal elements is bounded from above by

$$\frac{2D}{n} \leq \frac{2M}{n} \ .$$

Because of

$$\left(\sum_{k=1}^{m} |a_k| \right)^2 \leq m \sum_{k=1}^{m} |a_k|^2 \ ,$$

the mean value of the absolute values of these elements is bounded by

$$\sqrt{2D/n} \le \sqrt{2M/n} \, .$$

For the submatrix H_p, $p \le p^*$, (16) yields

$$|h_{k+1,k}|^2 \ge \sum_{i=1}^{k} \sum_{j=k+1}^{p} |h_{i,j}|^2 \tag{17}$$

for $k = 1, 2, \ldots, p-1$. Let us denote by d, d_i, m, and m_i the quantities of H_p corresponding to D, D_i, M, and M_i. Therefore,

$$d_i = \frac{1}{p-i} \sum_{j=1}^{p-i} |h_{j,j+i}|^2, \qquad d = \frac{1}{p-1} \sum_{j=1}^{p-1} |h_{j+1,j}|^2 \, ,$$

and m and m_i are the associated maxima. Then, from (17) we get the following theorem.

THEOREM 7. *For normal A, the matrix H_p generated by the Arnoldi process has the following properties*:

(i) $d_i \le [(p-1)/i(p-i)]d$ *and* $m_i \le (p-1/i)d$;

(ii) $\|H_p\|_F^2 \le pd_0 + 2(p-1)d \le pm_0 + 2(p-1)m$;

(iii) *the mean value of all squared superdiagonal elements of H_p is less than or equal to $2d/p$*;

(iv) *the mean value of the absolute values of all superdiagonal elements of H_p is less than or equal to $\sqrt{2d/p}$.*

(v) $|h_{i,i+j}| \le \min_{k=1}^{j} |h_{k+i,k+i-1}|$.

Similar results can be found in [5]. If we number the superdiagonals in such a way that the main diagonal is associated with $i = 0$, and $h_{1,p}$ is the diagonal with $i = p$, then Theorem 7(i) states that the mean value of all elements in a superdiagonal is maximal for $i = 1$ and $i = p$ and is minimal for $i = \lfloor p/2 \rfloor$. Furthermore, by (v), we get an upper bound for $|h_{i,i+j}|$ that is decreasing for increasing j. This gives an explanation for the observation of Saad [16] that in many examples the elements $|h_{i,j}|$ become slowly smaller as j increases with i fixed.

A normal matrix with extreme behaviour in the sense of Theorem 7 is the unitary Frobenius matrix

$$\begin{pmatrix} 0 & & & 1 \\ 1 & 0 & & \\ & \ddots & \ddots & \\ & & 1 & 0 \end{pmatrix} . \tag{18}$$

This matrix is also an example with bad behaviour for the Arnoldi method and for GMRES with starting vector e_1; the Ritz values are all zero up to the last iteration, and both algorithms give no improvement of the starting values up to that point.

In the Hermitian case, we get for the Ritz values generated by the Arnoldi process from (3), that for every Ritz value $\lambda_i^{(p)}$ there exists an eigenvalue λ of A with

$$\left| \lambda_i^{(p)} - \lambda \right| \le \left| h_{p+1,p} e_p^T y_i^{(p)} \right| \, . \tag{19}$$

Furthermore, all Ritz values and eigenvalues can be ordered in such a way that (see [10], [13])

$$\sum_{i=1}^{p} \left|\lambda_{\pi(i)} - \lambda_i^{(p)}\right|^2 \leq 2\,|h_{p+1,p}|^2 \ . \tag{20}$$

In view of (3), equation (19) remains true for normal A. But, example (18) shows that (20) is not always true for normal A.

4. Conclusions. The Arnoldi method applied to a normal matrix leads to upper Hessenberg matrices H_p with special properties. But H_p is tridiagonal only for the well-known class (12). For this class, the Arnoldi method shows the same behaviour as for symmetric matrices and is thus superior to all other Lanczos-type methods. In nearly all the remaining cases, the convergence behaviour of the Arnoldi method can be very poor.

Acknowledgment. I would like to thank Roland Freund for bringing some important references to my attention and also the referees for some helpful comments.

UNICITY OF BIPROPORTION*

LOUIS DE MESNARD†

Abstract. The biproportion of S on margins of M is called the intern composition law, K: $(S, M) \mapsto X = K(S, M)/X = ASB$.

A and B are diagonal matrices, algorithmically computed, providing the respect of margins of M. Biproportion is an empirical concept. In this paper, the author shows that any algorithm used to compute a biproportion leads to the same result. Then the concept is unique and no longer empirical. Some special properties are also indicated.

Key words. biproportion, biproportional, RAS, updating matrices

AMS subject classifications. 15A15, 14N05, 65Q05

1. Introduction. For many years, economists have used biproportion. For example, R. Stone and M. Bacharach used the RAS method in the sixties, as well as many others (see a short survey in [3]). This method is useful when we want to update or filter a matrix, by projecting this matrix on the margins of another matrix, (i.e., equip it with the margins of another matrix).

For a long time biproportion lacked theoretical basis: RAS is a purely empirical method.[1] It is possible to give theoretical foundations to biproportion [3], but numerous algorithms must exist to compute a biproportion. It is not satisfactory because of this multiplicity of algorithms, biproportion remains empirical. However, we do not want to compare different algorithms from the standpoint of numerical computation as in [2].

In this paper, we show that any possible algorithm leads to the same result. This settles the theory that biproportion is unique as proportion and is no longer an empirical concept. Some parts of arguments and demonstrations still come from [3].

1. Definition of biproportion.

1.1. Ordinary proportion. We present this well-known concept in a special form. Let x and s be two real vectors. There exists a *proportion* behind these two vectors, that is to say, x is proportional to s with the ratio k, if

$$x_i = ks_i \quad \forall i,$$

where k is the ratio of the margins

$$k = \frac{x.}{s.} \quad \text{with } x. = \sum_i x_i \quad \text{and} \quad s. = \sum_i s_i.$$

1.2. Biproportion. Let E be the set of $(n \times m)$ matrices of real positive numbers. S and M are two matrices belonging to this set, and A and B are two diagonal matrices having the same dimensions. The margins of M are the numbers $m_{i.}$ and $m_{.j}$ so that

$$\sum_j m_{ij} = m_{i.} \quad \forall i \quad \text{and} \quad \sum_i m_{ij} = m_{.j} \quad \forall j.$$

† Faculty of Economics, University of Dijon, 4 Boulevard Gabriel, 21000 Dijon, France (lmesnard@satie.u-bourgogne.fr).

[1] The term RAS comes from rAs, where r and s are vectors and A is a matrix.

We call *biproportion* of S on margins of M, the intern composition law K, of $E \times E \mapsto E$, such that

$$(S, M) \overset{K}{\mapsto} X = K(S, M): \quad X = ASB \quad \text{and} \quad \sum_j x_{ij} = m_{i.} \quad \forall i \quad \text{and} \quad \sum_i x_{ij} = m_{.j} \quad \forall j.$$

With Bacharach, we can say that X is biproportional to S according to M [1].

The solution can be found, for example, using the algorithm (A_i and B_j are scalars)

$$A_i = m_{i.}\left(\sum_j B_j s_{ij}\right)^{-1} \quad \forall i \quad \text{and} \quad B_j = m_{.j}\left(\sum_i A_i s_{ij}\right)^{-1} \quad \forall j.$$

We call these equations the K algorithm; they satisfy marginal constraints of M:

$$\sum_j x_{ij} = A_i \sum_j B_j s_{ij} = m_{i.}\left(\sum_j B_j s_{ij}\right)^{-1} \sum_j B_j s_{ij} = m_{i.} \quad \forall i,$$

$$\sum_i x_{ij} = B_j \sum_i A_i s_{ij} = m_{.j}\left(\sum_i A_i s_{ij}\right)^{-1} \sum_i A_i s_{ij} = m_{.j} \quad \forall j.$$

Many justifications may be found. For example, we may use the theory of information, transforming it a little [3]:

$$\text{Min} \sum_i \sum_j x_{ij} \operatorname{Log} \frac{x_{ij}}{s_{ij}} \quad \text{with} \quad \sum_i x_{ij} = m_{.j} \quad \forall j, \quad \text{and} \quad \sum_j x_{ij} = m_{i.} \quad \forall i.$$

Many other algorithms may be used such as RAS or modified RAS [2].

2. Unicity of biproportion. The algorithm K corresponding to the equations of A_i and B_j allows one to calculate biproportion[2] as it is a converging process toward the solution. We may think that an undetermined number of other algorithms can play this role. Some algorithms, like RAS, are known. Bachem and Korte [2] demonstrate identity of the algorithms of RAS and K, but do not demonstrate universality of biproportion, because they only demonstrate RAS. The question is whether or not all of them give the same solution as K. If not, biproportion seriously lacks consistency, because its result depends on the choices of the algorithm. Otherwise, biproportion appears as universal, and so has a very stable basis.

2.1. Idempotency. Biproportion of a matrix on its own margins is a neutral operation.

THEOREM 1. *$K(S, S') = S$, where S' has the same margins as S. In particular, we have $K(S, S) = S$.*

Proof. Suppose, without loss of generality, that we start the algorithm of biproportion by $B'_j = 1$ for all j. At the first step, we obtain the following equilibrating factors A'_i:

$$A'_i(1) = \frac{s_{i.}}{\sum_j B'_j(0) s_{ij}} = \frac{s_{i.}}{\sum_j s_{ij}} = 1 \quad \forall i,$$

because S is equipped with its own margins. Then,

$$B'_j(1) = \frac{s_{.j}}{\sum_i A'_i(0) s_{ij}} = \frac{s_{.j}}{\sum_i s_{ij}} = 1 \quad \forall j.$$

[2] The conditions of convergence are given, and unicity of the solution is proved in [3].

By induction, we can show that the two series (A') and (B') are uniformly unitary. Let us suppose that $A'_i(t) = 1$ for all i, and $B'_j(t) = 1$ for all j is true until t, and let us verify that this is true for $t + 1$:

$$A'_i(t+1) = \frac{s_{i.}}{\sum_j B'_j(t) s_{ij}} = \frac{s_{i.}}{\sum_j s_{ij}} = 1 \quad \forall i$$

and

$$B'_j(t+1) = \frac{s_{.j}}{\sum_i A'_i(t+1) s_{ij}} = \frac{s_{.j}}{\sum_i s_{ij}} = 1 \quad \forall j.$$

Therefore, $A' = l$ and $B' = l$. □

2.2. Composition of biproportions and associativity. Biproportion is not linear regarding to the variables, even if it is a generalisation of the proportion, which is linear because it is one dimensional. In an ordinary proportion, a double use of proportion remains a proportion:

$$x = sm \quad \text{and} \quad x' = xm' \Rightarrow x' = smm' \Rightarrow x' = sm''.$$

In the same way, a double use of biproportion remains a biproportion: biproportion is globally linear. Furthermore, the composition of two biproportions is identical to the second biproportion.

THEOREM 2. $K[K(S, M), M'] = K[S, M']$. *Note that it could be generalised to compositions of biproportions*

$$K\{K \cdots K[K(S, M), M'] \ldots, M^{(n)}\} = K\{S, M^{(n)}\}.$$

Proof. Let S and M be two matrices. We write a first biproportion

$$X = K(S, M) = ASB \text{ with } x_{ij} = A_i s_{ij} B_j \quad \forall i, j,$$

and

$$A_i = m_{i.} \left(\sum_j B_j s_{ij} \right)^{-1} \quad \forall i,$$

$$B_j = m_{.j} \left(\sum_i A_i s_{ij} \right)^{-1} \quad \forall j.$$

Consider then the composition with a second biproportion

$$X' = K(X, M') = A'XB' \text{ with } x'_{ij} = A'_i x_{ij} B'_j \quad \forall i, j,$$

and

$$A'_i = m'_{i.} \left(\sum_j B'_j x_{ij} \right)^{-1} \quad \forall i,$$

$$B'_j = m'_{.j} \left(\sum_i A'_i x_{ij} \right)^{-1} \quad \forall j.$$

Let us calculate A' and B':

$$A'_i = m'_{i.}\left(\sum_j B'_j A_i s_{ij} B_j\right)^{-1} \quad \forall i,$$

$$\Leftrightarrow A'_i A_i = m'_{i.}\left(\sum_j B'_j B_j s_{ij}\right)^{-1} \quad \forall i,$$

$$\Leftrightarrow A''_i = m'_{i.}\left(\sum_j B''_j s_{ij}\right)^{-1} \quad \forall i,$$

with

$$A'_i A_i = A''_i \quad \text{and} \quad B'_j B_j = B''_j.$$

In the same way

$$B''_j = m'_{.j}\left(\sum_i A''_i s_{ij}\right)^{-1} \quad \forall j$$

and

$$x'_{ij} = A'_i A_i s_{ij} B'_j B_j = A''_i s_{ij} B''_j \quad \forall i, j.$$

Therefore, X', biproportional to $K(S, M)$ according to M', is also biproportional to S according to M'. □

Also, the intern composition law K is associative.

COROLLARY. *It holds that* $K[K(S\,M), M'] = K\{S, [K(M, M')]\}$.

Proof. The proof is clear. $K[K(S, M), M'] = K(S, M')$ and $K\{S, [K(M, M')]\} = K(S, M')$. □

2.3. Unicity. We have the following lemma.

LEMMA 1. *If* K^q *is any nonspecified algorithm (the form of U and V is unknown), with* $X = K^q(S, M) = USV$, *and if* $X' = K(X, M) = AXB$, *then* $X' = X$, *i.e.,* $K[K^q(S, M), M] = K^q(S, M)$. *As a special case, we get* $K[K(S, M), M] = K(S, M)$.

Proof. $K[K^q(S, M), M] = K(X, M)$. X has the same margins as M, then $K(X, M) = K(X, X)$. From the property of idempotency, $K(X, X) = X = K^q(S, M)$. □

Whatever algorithm is used, let us show that one biproportion is identical to another. Then choosing K or any other algorithm is of no consequence.

THEOREM OF UNICITY. *If* K^q *is any nonspecified algorithm (the form of U and V is unknown), with* $X = K^q(S, M) = USV$, *then U and V may be put in the standard form K.*

Proof. Let $X' = K(X, M) = AXB$; K is the specified algorithm. According to Lemma 1, this composition of biproportions is a neutral operation. Therefore, matrices A and B are the identity matrix: $A_i = 1$ for all i and $B_j = 1$ for all j.

Then, as $x_{ij} = U_i s_{ij} V_j$ for all ij

$$A_i = \frac{m_{i.}}{\sum_j B_j x_{ij}} \Leftrightarrow 1 = \frac{m_{i.}}{\sum_j U_i s_{ij} V_j} \Leftrightarrow U_i = \frac{m_{i.}}{\sum_j s_{ij} V_j} \quad \forall i,$$

$$B_j = \frac{m_{.j}}{\sum_i A_i x_{ij}} \Leftrightarrow 1 = \frac{m_{.j}}{\sum_i U_i s_{ij} V_j} \Leftrightarrow V_j = \frac{m_{.j}}{\sum_i s_{ij} U_i} \quad \forall j.$$

Therefore, U_i and V_j have the same form as the equilibrating factors of the biproportion. □

This result was obtained without specifying the algorithm of the projector K^q. It is sufficient to know that K^q is a biproportion of S on the margins of M.

We may apply this result to RAS. The solution of K and the solution of RAS are identical. RAS is an algorithm that plays the role of K^q, and the proof we have given does not need to be specified in terms of its algorithm. Then, the necessary and sufficient conditions of existence and convergence of the solution (not presented here, see [1] or [3]) are identical for K, for RAS, and for any biproportional algorithm. Nonnegativity of elements of S and M is required.

Biproportion appears to be as universal as proportion is in the one-dimensional world. This should end the discussion about the theoretical character of biproportion.

3. Some properties specific to biproportion.

3.1. Ineffectiveness of separability. Let us show that if we multiply every term of a same row or column of the matrix S by the same value, we do not change anything in a biproportion. Therefore such a modification of the s_{ij} is ineffective because it is separable in rows and columns.

We name *separable modification* of the terms of a matrix S with n rows and m columns, a modification of S that can be reduced to the left product by a diagonal matrix U of size n, and to the right product by another diagonal matrix V of size m: $S' = USV$. A separable modification does not change a biproportion.

THEOREM 3. *Let* $X = K(S, M) = ASB$ *and* $X' = K(S', M) = A'S'B'$ *with* $S' = USV$. *Then* $X' = ASB = K(S, M)$.

Proof. It holds that $X' = A'S'B' = A'USVB' = A''SB''$, putting $A'' = A'U$ and $B'' = B'V$.

Let us prove that $A'' = A$ and $B'' = B$.

$$A'_i = m_{i.}\left(\sum_j B'_j s'_{ij}\right)^{-1} \quad \forall i, j,$$

$$\Rightarrow A'_i = m_{i.}\left(\sum_j B'_j u_i s_{ij} v_j\right)^{-1} \quad \forall i, j,$$

$$\Rightarrow A''_i = m_{i.}\left(\sum_j B''_j s_{ij}\right)^{-1} \quad \forall i, j,$$

and

$$B'_j = m_{.j}\left(\sum_i A'_i s'_{ij}\right)^{-1} \quad \forall i, j,$$

$$\Rightarrow B'_j = m_{.j}\left(\sum_i A'_i u_i s'_{ij} v_j\right)^{-1} \quad \forall i, j,$$

$$\Rightarrow B''_j = m_{.j}\left(\sum_i A''_i s_{ij}\right)^{-1} \quad \forall i, j.$$

Then, the iterative form will be

$$B''_j(t) = m_{.j}\left(\sum_i A''_i(t) s_{ij}\right)^{-1} \quad \forall i, j,$$

$$A''_i(t+1) = m_{i.}\left(\sum_j B''_j(t) s_{ij}\right)^{-1} \quad \forall i, j.$$

If we start with $A_i''(1) = A_i(1)$, we get

$$B_j''(1) = B_j(1) \quad \forall j,$$

$$A_i''(2) = A_i(2) \quad \forall i,$$

and by induction

$$B_j''(t) = B_j(t) \quad \forall j,$$

$$A_i''(t+1) = A_i(t+1) \quad \forall i.$$

Therefore, in the limit, $A'' = A$ and $B'' = B$. Then, $X' = A''SB'' = ASB = X$. □

3.2. Nonreciprocality. Proportion has the property of *reciprocality*. If a vector V_2 is proportional to a vector V_1 according to k, then V_1 is proportional to V_2, according to $\frac{1}{k}$, and

$$V_2 - V_1 k = 0 \Rightarrow V_1 - V_2/k = 0.$$

On the other hand, biproportion does not verify the property of reciprocality. (The proof is given by counter-examples in [3].) Consider two matrices T_1 and T_2.

$$T_{2ij} - K(T_{1ij}, T_{2ij}) \# T_{1ij} - K(T_{2ij}, T_{1ij}) \quad \forall i, j.$$

If the indices 1 and 2 represent periods of time, we can describe the first term $T_{2ij} - K(T_{1ij}, T_{2ij})$ as *prospective*, and the second term $T_{1ij} - K(T_{2ij}, T_{1ij})$ as *retrospective*. In practical applications, nonreciprocality implies that we must calculate twice, once in the prospective way and once in the retrospective way, and compare the results [3].

Another difficulty is due to nonreciprocality. As proportion is reciprocal, if $V_2 = V_1 k$, we can retrieve V_1 knowing k. As biproportion is not reciprocal, given a biproportion $X = K(S, M)$, we cannot retrieve S without knowing the initial margins of S, even if we know M, because of the transcendent nature of K.

The property of nonreciprocality could be used to build a coding system for matrices. To code a matrix is to use a transformation of it that is sufficiently hard to reverse, to prevent a return from the transformed matrix toward the original matrix. The transformed matrix X (it could be a matrix of numbers, such as a computer image) is then coded. Only authorised persons could retrieve the original matrix S, knowing the margins of S; with the simple proportion applied to a vector, any person could know the elements of this vector with a factor of proportionality and so, nothing is coded.

However, the system is limited because the coding person who knows the matrix S to be coded also knows the decoding key, i.e., the margins of S.

4. Conclusion. Since the choice of the algorithm of biproportion is indifferent, biproportion appears as universal as proportion. Then, biproportion is no longer empirical, and it is possible to make the systematic mathematical treatment of biproportion. However, biproportion is not a simple generalisation of proportion: it is iteratively computed, it is only partially linear, and it does satisfy reciprocality.

CHARACTERIZATIONS OF SCALING FUNCTIONS: CONTINUOUS SOLUTIONS*

DAVID COLELLA† AND CHRISTOPHER HEIL‡

Abstract. A dilation equation is a functional equation of the form $f(t) = \sum_{k=0}^{N} c_k f(2t-k)$, and any nonzero solution of such an equation is called a scaling function. Dilation equations play an important role in several fields, including interpolating subdivision schemes and wavelet theory. This paper obtains sharp bounds for the Hölder exponent of continuity of any continuous, compactly supported scaling function in terms of the joint spectral radius of two matrices determined by the coefficients $\{c_0, \ldots, c_N\}$. The arguments lead directly to a characterization of all dilation equations that have continuous, compactly supported solutions.

Key words. dilation equation, joint spectral radius, scaling function, two-scale difference equation, wavelet

AMS subject classifications. 26A16, 39A10

Functional equations of the form

$$f(t) = \sum_{k=0}^{N} c_k f(2t-k) \tag{1}$$

play an important role in several fields, including wavelet theory and interpolating subdivision schemes. Such equations are referred to as *dilation equations* or *two-scale difference equations*, and any nonzero solution f is called a *scaling function.* The coefficients $\{c_0, \ldots, c_N\}$ may be real or complex; if they are real then the scaling function f will be real-valued.

In this paper we obtain sharp bounds for the Hölder exponent of continuity of any continuous, compactly supported scaling function. Our arguments lead directly to a characterization of all dilation equations that have continuous, compactly supported solutions. These methods also enable us to examine how certain properties of scaling functions, such as the Hölder exponent, behave as a function of the coefficients, and we provide several examples to illustrate the basic structure present. Our work was inspired by an early preprint of [DL2], in which sufficient conditions for the existence of continuous, compactly supported scaling functions were obtained and lower bounds for the Hölder exponent of continuity were derived. In that paper the assumption was made that the coefficients satisfy

$$\sum_k c_{2k} = \sum_k c_{2k+1} = 1. \tag{2}$$

Conditions and bounds were then expressed in terms of the joint spectral radius $\hat{\rho}(T_0|_V, T_1|_V)$ of two matrices T_0, T_1 (determined by the coefficients $\{c_0, \ldots, c_N\}$) restricted to a certain subspace V of $\mathbf{C}^N$. We have extended these results in the

sense that all dilation equations possessing continuous, compactly supported solutions, without restriction on the coefficients, are now described in terms of a joint spectral radius $\hat{\rho}(T_0|_W, T_1|_W)$, with the subspace V replaced by a (possibly different) subspace W, and that sharp bounds for the Hölder exponent follow from the value of $\hat{\rho}(T_0|_W, T_1|_W)$. The replacement of V by W is not without cost: W depends explicitly on the coefficients $\{c_0, \ldots, c_N\}$, while V is independent of them. This dependency nonetheless yields a number of interesting facts about the behavior of scaling functions as a function of the coefficients $\{c_0, \ldots, c_N\}$. For example, we show that the maximum Hölder exponent of continuity is not continuous as a function of the coefficients. We give several methods of determining the subspace W explicitly. The results presented here implicitly characterize those dilation equations having compactly supported, n-times differentiable solutions, and are generalizable to positive integer dilation factors other than two and to higher dimensions. An application of the results of this paper to the specific case $N \leq 3$ can be found in [CH1]. The sequel [CH2] discusses more general characterizations, including discontinuous and noncompactly supported scaling functions. Finally, we wish it noted that a revised version of [DL2] brought to our attention the work [MP2], which was the first work to provide necessary and sufficient conditions for the existence of continuous, compactly supported scaling functions. However, those results are not stated in terms of a joint spectral radius and do not yield estimates for the Hölder exponent of continuity; in addition, the behavior of the properties of scaling functions as a function of the coefficients is not examined.

We say that a function h on $\mathbf{R}$ is (globally) *Hölder continuous* if there exist constants α, K such that $|h(x) - h(y)| \leq K\,|x - y|^{\alpha}$ for all $x, y \in \mathbf{R}$. The constants α and K are referred to as a *Hölder exponent* and *Hölder constant* for h, respectively. We refer to

$$\alpha_{\max} = \sup\{\alpha : h \text{ is Hölder continuous with exponent } \alpha\}$$

as the *maximum Hölder exponent* of h, although it should be noted that the supremum need not be attained, i.e., h need not be Hölder continuous with exponent $\alpha = \alpha_{\max}$. We make similar definitions for *local Hölder continuity* at a point x, i.e., x is fixed in the inequality and only y varies.

The application of dilation equations to subdivision schemes is discussed in the important papers [CDM], [DD], [Du], [DGL], [MP1], and [MP2]. Our own interest in dilation equations arose from their application to wavelet theory. We briefly outline this relation below; the basic results can be found in the research papers [D], [L], [M], or in the expository surveys [H], [S]. Assume that the coefficients $\{c_0, \ldots, c_N\}$ satisfy (2) and

$$\sum_k c_k\,\bar{c}_{k+2j} = \begin{cases} 2, & \text{if } j = 0, \\ 0, & \text{if } j \neq 0, \end{cases} \tag{3}$$

where we take $c_k = 0$ if $k < 0$ or $k > N$. It can then be shown that there exists an integrable and square-integrable scaling function f. Define the *wavelet*

$$g(t) = \sum_k (-1)^k\,c_{N-k}\,f(2t - k), \tag{4}$$

and construct $g_{n,k}(t) = 2^{n/2}\,g(2^n t - k)$ by dilation and translation of g. If the scaling function f is orthogonal to its integer translates (i.e., $\int f(t)\,\overline{f(t-k)}\,dt = 0$ for $k \neq 0$), then $\{g_{n,k}\}_{n,k \in \mathbf{Z}}$ will form an orthonormal basis for $L^2(\mathbf{R})$ after a suitable normalization of g. It can be shown that for nearly all choices of coefficients $\{c_0, \ldots, c_N\}$

satisfying (2) and (3) the associated scaling function f is orthogonal to its integer translates and therefore determines a wavelet orthonormal basis.

Example 1. Consider the dilation equation where $N = 1$ and $c_0 = c_1 = 1$. Both (2) and (3) are satisfied, and the associated scaling function $f = \chi_{[0,1)}$ is orthogonal to its integer translates (where χ_E denotes the characteristic function of the set E). The wavelet g given by (4) is then $g = \chi_{[0,1/2)} - \chi_{[1/2,1)}$. The orthonormal basis $\{g_{n,k}\}$ determined by this g is known as the *Haar system.* □

The Haar system has the desirable property that the wavelet g is compactly supported. However, the fact that this wavelet is discontinuous severely limits its usefulness. An important problem for wavelet theory is therefore the construction of smooth, compactly supported wavelets. By (4), it suffices to construct smooth, compactly supported scaling functions. The construction of such scaling functions is also important in subdivision theory; however, in that framework (3) is irrelevant and (2) may or may not be assumed. Several authors have proved conditions for the existence of smooth, compactly supported scaling functions, with varying interpretations of "smooth," and with varying restrictions on the coefficients. As suggested by the "self-similar" nature of the dilation equation, a continuous scaling function f is often "fractal" in nature, in the sense that if it is n-times differentiable then its nth derivative is Hölder continuous with Hölder exponent strictly less than one. Daubechies and Lagarias have proved that compactly supported, infinitely differentiable scaling functions are impossible [DL1].

The methods used to prove the conditions referred to above generally fall into the following three categories or combinations thereof: Fourier transform methods (e.g., [D], [DL1], [E], [M], [V]), iterated function system methods (e.g., [W], [D], [DL1], [DD], [DGL]), and dyadic interpolation methods (e.g., [W], [DL2], [MP2]). In this paper we use the dyadic interpolation method to characterize all dilation equations that have continuous, compactly supported solutions, without any restrictions on the coefficients. However, since a number of facts that will be important to us are more easily proved using the Fourier transform technique, we briefly review that method. This technique is based on the equivalent form of the dilation equation on the Fourier transform side, namely,

$$\hat{f}(2\gamma) = m_0(\gamma)\,\hat{f}(\gamma), \tag{5}$$

where $m_0(\gamma) = (\frac{1}{2}) \sum c_k\, e^{ik\gamma}$ and $\hat{f}(\gamma) = \int f(t)\, e^{i\gamma t}\, dt$. If $m_0(0) = (\frac{1}{2}) \sum c_k = 1$ then it follows that

$$\hat{\mu}(\gamma) = \prod_{j=1}^{\infty} m_0(2^{-j}\gamma) \tag{6}$$

converges uniformly on compact sets to a continuous function and is a solution to (5). The inverse Fourier transform μ of this function is therefore a solution to (1), at least in the sense of distributions. One can show that μ has support contained in $[0, N]$, and is the only distributional solution to (1) with a continuous Fourier transform (up to multiplication by a constant). In particular, there can be at most one integrable solution to a dilation equation satisfying $\sum c_k = 2$ (up to multiplication by a constant and with uniqueness interpreted as usual as equality almost everywhere), and if one exists it will have the form (6) and have compact support. More generally, Daubechies and Lagarias have proved the following theorem.

THEOREM 1 (see [DL1]). *Let coefficients $\{c_0, \ldots, c_N\}$ be given. If there exists an integrable, compactly supported solution f to the dilation equation* (1), *then* $\operatorname{supp}(f) \subset$

$[0, N]$ *and there exists an integer* $n \geq 0$ *such that the following statements hold.*

(a) $\sum c_k = 2^{n+1}$.

(b) f *is unique up to multiplication by a constant and has Fourier transform* $\hat{f}(\gamma) = \gamma^n \prod_{j=1}^{\infty} 2^{-n} m_0(2^{-j}\gamma)$.

(c) *There is an integrable, compactly supported solution* F *to the dilation equation determined by the coefficients* $\{2^{-n}c_0, \ldots, 2^{-n}c_N\}$ *and (with the proper choice of scale)* f *is the* n*th distributional derivative of* F.

In particular, continuous, compactly supported scaling functions can exist only when $\sum c_k = 2^{n+1}$, and for $n > 0$ are the (usual) nth derivatives of scaling functions satisfying $\sum c_k = 2$. Dilation equations satisfying $\sum c_k = 2$ are therefore in some sense fundamental. Additional assumptions on the coefficients $\{c_0, \ldots, c_N\}$ can impose enough regularity on the infinite product in (6) so that the scaling function can be proved to be continuous or n-times differentiable, and to bound from below the Hölder exponent of continuity of the scaling function or its nth derivative. Eirola [E] has nicely demonstrated that Fourier transform methods are well suited to estimating Sobolev, rather than Hölder, exponents of continuity of scaling functions.

We turn now to the dyadic interpolation method and our own results. Since we are concerned mainly with questions of continuity, we assume that scaling functions, even if discontinuous, are defined for all points in $\mathbf{R}$ and satisfy the dilation equation at all points, not just almost everywhere, as is the case in the Fourier transform method. This has the seemingly paradoxical effect that a given dilation equation may have more than one distinct integrable, compactly supported solution. For example, if f is one such scaling function and if $c \in \mathbf{C}$ and $S \subset \mathbf{R}$ are given so that both S and its complement are measurable and invariant under the mapping $t \mapsto 2t - k$ for all $k \in \mathbf{Z}$, then

$$\tilde{f}(t) = \begin{cases} f(t), & t \in S, \\ c\,f(t), & t \notin S, \end{cases}$$

is also an integrable, compactly supported scaling function. However, by Theorem 1, either S or its complement must have measure zero (more fundamentally, this also follows from ergodicity considerations). This leads us to pose the following problem, which affects the interpretation of Theorem 4 at the end of this paper: Is it possible that such differing representatives of a compactly supported scaling function may have differing properties, e.g., if one representative is unbounded, must all representatives be unbounded?

The dyadic interpolation method is based on this key observation: if the values of the scaling function at the integers are known then the dilation equation determines the values of the scaling function at the half-integers, and by recursion at every *dyadic point* $x = k/2^n$ where $k, n \in \mathbf{Z}$. If f is continuous then this determines its values at all points (thereby giving an easily programmable method for graphing a continuous scaling function). Daubechies and Lagarias [DL2] and Micchelli and Prautzsch [MP2] independently implemented this recursion via products of two $N \times N$ matrices, and used this implementation to obtain conditions for the existence of continuous scaling functions. We explain this now, using the notation of [DL2].

Given coefficients $\{c_0, \ldots, c_N\}$, define the $N \times N$ matrices T_0 and T_1 by $(T_0)_{ij} =$

c_{2i-j-1} and $(T_1)_{ij} = c_{2i-j}$, i.e.,

$$T_0 = \begin{pmatrix} c_0 & 0 & 0 & \cdots & 0 & 0 \\ c_2 & c_1 & c_0 & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & c_N & c_{N-1} \end{pmatrix}$$

and

$$T_1 = \begin{pmatrix} c_1 & c_0 & 0 & \cdots & 0 & 0 \\ c_3 & c_2 & c_1 & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & 0 & c_N \end{pmatrix}.$$

Given $x \in [0,1]$ with $x \neq \frac{1}{2}$, define

$$\tau x = 2x \bmod 1 = \begin{cases} 2x, & 0 \leq x < \frac{1}{2}, \\ 2x - 1, & \frac{1}{2} < x \leq 1, \end{cases}$$

i.e., if $x \neq \frac{1}{2}$ and $x = .d_1 d_2 \ldots$ is a binary expansion of x then $\tau x = .d_2 d_3 \ldots$. The value of $\tau(\frac{1}{2})$ is undefined. Note that a dyadic point x has two binary expansions, one ending in infinitely many zeros, and one ending in infinitely many ones. The former expansion will be termed the *upper* or *finite* binary expansion, and the latter the *lower* binary expansion. All nondyadic points have unique binary expansions.

The following result allows questions about scaling functions to be translated into questions about certain vector-valued (specifically, $\mathbf{C}^N$-valued) functions on $[0,1]$. The definition of *Hölder continuity* for vector-valued functions is analogous to the definition for ordinary functions, with the absolute value replaced by any norm on $\mathbf{C}^N$. The Hölder exponent of continuity for a vector-valued function is independent of the choice of norm.

PROPOSITION 1. *Let coefficients* $\{c_0, \ldots, c_N\}$ *be given.*

(a) *Assume* f *is a scaling function with* $\operatorname{supp}(f) \subset [0, N]$. *Define the vector-valued function* $v : [0,1] \to \mathbf{C}^N$ *by*

$$v(x) = \begin{pmatrix} f(x) \\ f(x+1) \\ \vdots \\ f(x+N-1) \end{pmatrix}. \tag{7}$$

Then v *satisfies*

$$v_{i+1}(0) = v_i(1), \qquad i = 1, \ldots, N-1, \tag{8}$$

$$v(x) = T_0 v(\tau x), \qquad 0 < x < \frac{1}{2}, \tag{9}$$

$$v(x) = T_1 v(\tau x), \qquad \frac{1}{2} < x < 1, \tag{10}$$

where $v_i(x)$ *is the* i*th component of* $v(x)$. *If* $f(0) = f(N) = 0$ (*e.g., if* f *is continuous*)

then v also satisfies

$$v_1(0) = v_N(1) = 0, \tag{11}$$

$$v(0) = T_0 v(0), \tag{12}$$

$$v(1) = T_1 v(1), \tag{13}$$

$$v\left(\frac{1}{2}\right) = T_0 v(1) = T_1 v(0). \tag{14}$$

If f is continuous then so is v. If f is Hölder continuous with Hölder exponent α, then the same is true of v.

(b) *Assume $v : [0,1] \to \mathbf{C}^N$ is a vector-valued function satisfying* (8)–(14). *Define the function f by*

$$f(x) = \begin{cases} 0, & x \le 0 \text{ or } x \ge N, \\ v_i(x), & i-1 \le x \le i,\ i = 1, \dots, N. \end{cases} \tag{15}$$

Then f is a scaling function with $\operatorname{supp}(f) \subset [0, N]$. *If v is continuous then so is f. If v is Hölder continuous with Hölder exponent α then the same is true of f.*

A vector-valued function $v : [0,1] \to \mathbf{C}^N$ satisfying (8)–(14) will be called a *scaling vector*. If v is a scaling vector then (9), (10), and (12)–(14) can be summarily written

$$v(x) = T_{d_1} v(\tau x), \qquad 0 \le x \le 1, \tag{16}$$

where $x = .d_1 d_2 \dots$ is any binary expansion of x, since, by (14), the ambiguity at $x = \frac{1}{2}$ is nonproblematic.

Note that if f is a scaling function supported in $[0, N]$ and v is defined by (7) then (12)–(14) follow immediately from (11). Also, note from (1) that c_0, $c_N \neq 1$ implies $f(0) = f(N) = 0$. Thus, for c_0, $c_N \neq 1$ there is an exact equivalence between scaling functions and scaling vectors. If $c_0 = 1$ then it is possible that $f(0) \neq 0$, and in this case it is easy to see that (12)–(14) may fail (a specific example is the Haar system, i.e., $N = 1$, $c_0 = c_1 = 1$, and $f = \chi_{[0,1)}$). Similar remarks hold if $c_N = 1$. However, it follows directly from the dilation equation that if $|c_0| \ge 1$ then f must be discontinuous at 0, and if $|c_N| \ge 1$ then f must be discontinuous at N.

If v is a scaling vector then, by (11), $v(0) = (0, a_1, \dots, a_{N-1})^{\mathrm{t}}$ for some $a = (a_1, \dots, a_{N-1})^{\mathrm{t}}$. It follows then from (12) that $Ma = a$, where M is the $(N-1) \times (N-1)$ submatrix of T_0 and T_1 defined by $M_{ij} = c_{2i-j}$, i.e.,

$$M = \begin{pmatrix} c_1 & c_0 & 0 & \cdots & 0 & 0 \\ c_3 & c_2 & c_1 & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & c_N & c_{N-1} \end{pmatrix}. \tag{17}$$

Thus scaling vectors can only exist when M has 1 as an eigenvalue. This is true, for example, when (2) is satisfied, for then $(1, \dots, 1)$ is a left eigenvector for M for the eigenvalue 1.

CONSTRUCTION 1. We demonstrate that if 1 is an eigenvalue of M, then it is possible to construct a vector-valued function v, *defined for dyadic $x \in [0,1]$ only*, which satisfies (8)–(14). This construction need not be unique if the eigenvalue 1 has multiplicity greater than 1. In general, it may not be possible to extend this function to a scaling vector defined at all points in $[0,1]$ so that the associated scaling function defined by (15) is integrable. Equivalently, every dilation equation such that 1 is an

eigenvalue for M can be solved on the restricted domain of the dyadic points in $\mathbf{R}$, but not necessarily for all points in $\mathbf{R}$.

To construct v, let $a = (a_1, \ldots, a_{N-1})^t$ be any right eigenvector for M for the eigenvalue 1. Define $v(0) = (0, a_1, \ldots, a_{N-1})^t$ and $v(1) = (a_1, \ldots, a_{N-1}, 0)^t$; then (8) and (11) are satisfied. Given a dyadic $x \in (0,1)$, let $x = .d_1 \ldots d_m$ be its upper binary expansion, and define

$$v(x) = T_{d_1} \cdots T_{d_m} v(0). \tag{18}$$

Then (9), (10), and (12)–(14) follow immediately for dyadic x. □

As pointed out above, the matrix M must have 1 as an eigenvalue in order that a scaling vector exist; in particular, this must be the case if a continuous, compactly supported scaling function exists. Since the derivative of a differentiable scaling function is itself a scaling function for the dilation equation determined by the coefficients $\{2c_0, \ldots, 2c_N\}$, it follows immediately that if a compactly supported scaling function is n-times differentiable, then $1, 2^{-1}, \ldots, 2^{-n}$ must all be eigenvalues for M. In particular, $n < N - 1$, and no compactly supported scaling function can be infinitely differentiable.

Example 2. Consider the case $N = 3$. If $\{c_0, c_1, c_2, c_3\}$ satisfy (2) then $c_1 = 1 - c_3$ and $c_2 = 1 - c_0$. Restricting our attention to real-valued coefficients (as we will do in all specific examples in this paper), the collection of four-coefficient dilation equations satisfying (2) can therefore be identified with the (c_0, c_3)-plane, so that each point in the plane determines a four-coefficient dilation equation and conversely. We make this identification throughout when we discuss the case $N = 3$. Despite the fact that the dilation equation can be solved at dyadic points for any coefficient choice (c_0, c_3), it is proved in [CH2] that it is impossible to construct integrable, compactly supported scaling functions for any point (c_0, c_3) on or outside the ellipse shown in Fig. 1, with the single exception of the point $(1,1)$. Conversely, integrable, compactly supported scaling functions do exist for all points in the shaded region of Fig. 1. These scaling functions are continuous for those points in the shaded region that are also inside the triangle of Fig. 1, and are differentiable for those points lying on the solid portion of the dashed line [CH1]. A scaling function for the point $(1,1)$ is $\chi_{[0,3)}$. However, the function v defined in Construction 1 for this point is highly oscillatory, e.g., $v(x)$ takes each of the values $(0,1,1)^t$, $(1,0,1)^t$, and $(1,1,0)^t$ on a dense set of dyadic x. □

Let us now consider the question of continuity of scaling vectors. Given a scaling vector v and a dyadic point $x = .d_1 \ldots d_m$, consider points $y = .d_1 \ldots d_m d_{m+1} \ldots d_n$ close to x. If v is continuous then $T_{d_1} \cdots T_{d_m}\big(v(0) - v(\tau^m y)\big) = v(x) - v(y) \to 0$ as $y \to x$. This suggests that a characterization of continuity for scaling functions requires consideration of all possible products $T_{d_1} \cdots T_{d_m}$ of T_0 and T_1 operating on all possible differences $v(x) - v(y)$. The correct tool for this turns out to be the *joint spectral radius* of T_0, T_1 restricted to a certain subspace of $\mathbf{C}^N$. We therefore digress to define the joint spectral radius of general matrices and to give some of its properties relevant to the results in this paper. Let $\|\cdot\|$ be any norm on $\mathbf{C}^N$, with corresponding operator norm $\|A\| = \sup_{u \neq 0} \|Au\|/\|u\|$ defined for $N \times N$ matrices A.

DEFINITION 1. *The joint spectral radius* $\hat{\rho}(A_0, A_1)$ *of two matrices* A_0, A_1 *is*

$$\hat{\rho}(A_0, A_1) = \limsup_{m \to \infty} \hat{\rho}_m,$$

where

$$\hat{\rho}_m = \hat{\rho}_m(A_0, A_1) = \max_{d_j = 0,1} \|A_{d_1} \cdots A_{d_m}\|^{1/m}.$$

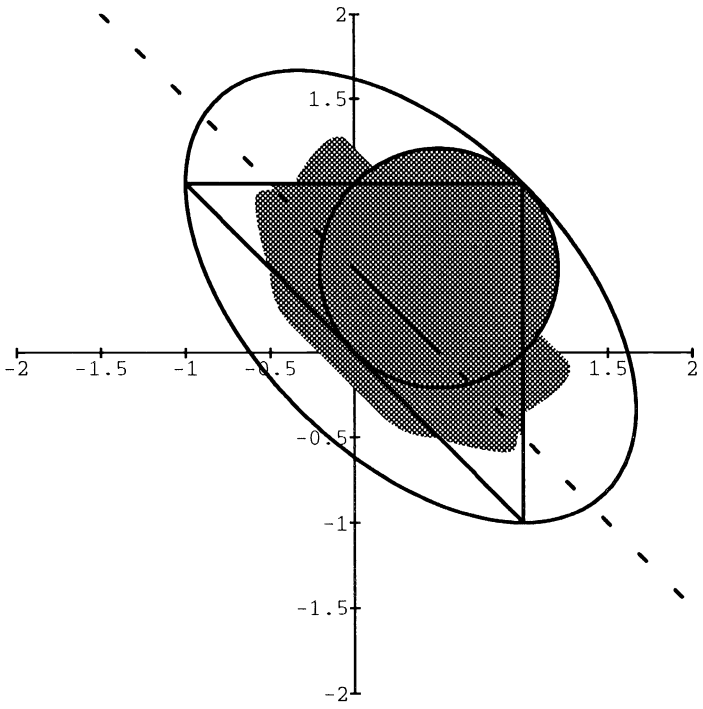

FIG. 1. *The (c_0, c_3)-plane, identified with real-valued, four-coefficient dilation equations satisfying* (2).

This definition generalizes the usual spectral radius $\rho(A)$ of a single matrix A, which is given by the formula

$$\rho(A) = \limsup_{m\to\infty} \|A^m\|^{1/m} = \max\{|\lambda| : \lambda \text{ is an eigenvalue of } A\}.$$

An extension of the joint spectral radius to larger collections of matrices, and to matrices restricted to subspaces, is made in the obvious way. The joint spectral radius was introduced by Rota and Strang [RS]; some recent papers include [BW] and [DL3].

The joint spectral radius is independent of the choice of norm $\|\cdot\|$, and of the choice of basis, that is, $\hat{\rho}(A_0, A_1) = \hat{\rho}(B_0, B_1)$ whenever $B_i = BA_iB^{-1}$ for any fixed invertible matrix B. Set

$$\hat{\sigma}_m = \hat{\sigma}_m(A_0, A_1) = \max_{d_j=0,1} \rho(A_{d_1} \cdots A_{d_m})^{1/m},$$

so that $\hat{\sigma}_m$ is the mth root of the largest absolute eigenvalue that occurs among all products of length m of the matrices A_0, A_1. Then $\hat{\sigma}_m \le \hat{\rho}(A_0, A_1) \le \hat{\rho}_m$ for every m. In particular, $\hat{\rho}(A_0, A_1) \ge \hat{\sigma}_1$ and generally one expects $\hat{\rho}(A_0, A_1)$ to be strictly larger than $\hat{\sigma}_1$. Wang [W] proves the nontrivial result that $\hat{\rho}(A_0, A_1) = \limsup \hat{\sigma}_m$. It therefore follows that $\sup \hat{\sigma}_m = \hat{\rho}(A_0, A_1) = \lim \hat{\rho}_m = \inf \hat{\rho}_m$. As each $\hat{\sigma}_m$ is a continuous function of the entries of A_0 and A_1, $\sup \hat{\sigma}_m$ is lower semicontinuous as a function of those entries. Similarly, $\inf \hat{\rho}_m$ is upper semicontinuous, and therefore $\hat{\rho}(A_0, A_1)$ is continuous as a function of the entries of A_0 and A_1 [HS].

The exact evaluation of the joint spectral radius is difficult, except in special cases such as the following.

LEMMA 1. *If A_0 and A_1 can be simultaneously symmetrized, i.e., there exists an invertible matrix B such that BA_iB^{-1} is real and symmetric for $i = 0, 1$, then* $\hat{\rho}(A_0, A_1) = \hat{\sigma}_1 = \max\{\rho(A_0), \rho(A_1)\}$.

The conclusion of Lemma 1 holds more generally when A_0, A_1 can be simultaneously Hermitianized.

It is easy to see that given any $\theta > \hat{\rho}(A_0, A_1)$, there exists a constant $C > 0$ such that $\hat{\rho}_m \leq C^{1/m}\,\theta$ for every m. This need not be true with $\theta = \hat{\rho}(A_0, A_1)$. One case where it is true with $\theta = \hat{\rho}(A_0, A_1)$ is if A_0, A_1 are simultaneously symmetrizable, for then $\hat{\sigma}_1 = \hat{\rho}_1$ (using the Euclidean space norm), and therefore $\hat{\rho}_m \leq \hat{\rho}_1 = \hat{\sigma}_1 \leq \hat{\rho}(A_0, A_1)$ for every m.

Another case in which some simplification of the joint spectral radius occurs is the following.

LEMMA 2. *If A_0, A_1 can be simultaneously block upper-triangularized, i.e., there exists an invertible matrix B such that BA_iB^{-1} has the block form*

$$BA_iB^{-1} = \begin{pmatrix} C_i^1 & & * \\ & \ddots & \\ 0 & & C_i^k \end{pmatrix}, \qquad i = 0, 1,$$

for some square submatrices $C_i^1, \ldots, C_i^k$, then $\hat{\rho}(A_0, A_1) = \max_{j=1,\ldots,k}\{\hat{\rho}(C_0^j, C_1^j)\}$.

In particular, if each block C_i^j is a single number—meaning that A_0, A_1 can be simultaneously upper-triangularized—then $\hat{\rho}(A_0, A_1) = \hat{\sigma}_1 = \max\{\rho(A_0), \rho(A_1)\}$. The proof of Lemma 2 follows easily from block matrix multiplication and consideration of the eigenvalues of the products $BA_{d_1} \cdots A_{d_m}B^{-1}$.

We return now to the matrices T_0, T_1 and the scaling vector v. Assume that (2) holds; then $(1, \ldots, 1)$ is a common left eigenvector for both T_0 and T_1. Hence the $(N-1)$-dimensional subspace

$$V = \{u \in \mathbf{C}^N : u_1 + \cdots + u_N = 0\}$$

is invariant under both of those operators since it is the orthogonal complement of $(1, \ldots, 1)$ in $\mathbf{C}^N$. By (18), V contains every difference $v(x) - v(y)$ for dyadic x, $y \in [0, 1]$. This observation suggests consideration of the joint spectral radius $\hat{\rho}(T_0|_V, T_1|_V)$ of T_0, T_1 restricted to the subspace V. Note that since V is invariant under both T_0 and T_1, there exists a change-of-basis matrix B such that

$$BT_iB^{-1} = \begin{pmatrix} S_i & * \\ 0 & 1 \end{pmatrix}, \qquad i = 0, 1, \tag{19}$$

where S_0, S_1 are $(N-1)\times(N-1)$ matrices, and $\hat{\rho}(T_0|_V, T_1|_V) = \hat{\rho}(S_0, S_1)$. A sufficient condition for continuity and a lower bound for the maximum Hölder exponent of continuity is provided by the following theorem of Daubechies and Lagarias.

THEOREM 2 (see [DL2]). *Assume that coefficients $\{c_0, \ldots, c_N\}$ satisfying (2) are given. If $\hat{\rho}(T_0|_V, T_1|_V) < 1$ then a continuous scaling vector v exists, and is Hölder continuous with $\alpha_{\max} \geq -\log_2 \hat{\rho}(T_0|_V, T_1|_V)$. The exponent $\alpha = -\log_2 \hat{\rho}(T_0|_V, T_1|_V)$ is allowed if there exists a constant $C > 0$ such that $\hat{\rho}_m \leq C^{1/m}\,\hat{\rho}(T_0|_V, T_1|_V)$ for every m.*

We emphasize that the value $-\log_2 \hat{\rho}(T_0|_V, T_1|_V)$ in Theorem 2 is only a lower bound for the maximum Hölder exponent, i.e., the theorem does not imply that v

cannot be Hölder continuous for exponents $\alpha > -\log_2 \hat{\rho}(T_0|_V, T_1|_V)$.

Note that if (2) does not hold, then V need not be invariant under both T_0 and T_1, and therefore $\hat{\rho}(T_0|_V, T_1|_V)$ need not be well defined. The necessary and sufficient conditions for the existence of continuous, compactly supported scaling functions presented below do not depend on (2).

The problem of characterizing all choices of coefficients $\{c_0, \ldots, c_N\}$ for which $\hat{\rho}(T_0|_V, T_1|_V) < 1$ is difficult. Of course, $\hat{\rho}(T_0|_V, T_1|_V) \leq \hat{\rho}_m$ for each m and $\hat{\rho}_m$ depends on only finitely many matrices; however, the number of matrices involved grows exponentially with m and therefore $\hat{\rho}_m$ can be computed in practice only for small m. A recursive algorithm, based on the *building blocks* idea of [DL2], for bounding a joint spectral radius from above with minimal computation is given in [CH1].

Theorem 2 implies that continuous scaling vectors exist for every coefficient choice in the set

$$C_V = \{\{c_0, \ldots, c_N\} \text{ satisfying (2)} : \hat{\rho}(T_0|_V, T_1|_V) < 1\}.$$

This is an open set since $\hat{\rho}(T_0|_V, T_1|_V)$ is a continuous function of the coefficients $\{c_0, \ldots, c_N\}$. The lower bound $-\log_2 \hat{\rho}(T_0|_V, T_1|_V)$ for the maximum Hölder exponent given in Theorem 2 is also a continuous function of the coefficients. However, we show in Example 7 that $\alpha_{\max}$ itself is *not* continuous as a function of the coefficients, even for coefficients in C_V. Despite this, we can prove that if (2) holds then the corresponding scaling functions change in a continuous manner (with respect to the sup-norm) as the coefficients change within C_V. This result takes advantage of the fact that V is independent of the coefficients.

PROPOSITION 2. *Fix $\{c_0, \ldots, c_N\} \in C_V$ and let f be the corresponding scaling function. For each $\varepsilon > 0$ there exists a $\delta > 0$ such that if $\{\tilde{c}_0, \ldots, \tilde{c}_N\}$ satisfies (2) and $|c_i - \tilde{c}_i| < \delta$ for $i = 0, \ldots, N$ then there is a continuous, compactly supported scaling function $\tilde{f}$ corresponding to $\{\tilde{c}_0, \ldots, \tilde{c}_N\}$ with $\sup |f(t) - \tilde{f}(t)| < \varepsilon$.*

Proof. For each $\eta > 0$ set

$$U_\eta = \{\{\tilde{c}_0, \ldots, \tilde{c}_N\} \text{ satisfying (2)} : |c_i - \tilde{c}_i| \leq \eta,\ i = 0, \ldots, N\}.$$

Since $\{c_0, \ldots, c_N\} \in C_V$, there must exist an integer m such that $\hat{\rho}(T_0|_V, T_1|_V) \leq \hat{\rho}_m < 1$. As $\hat{\rho}_m$ depends on only finitely many matrix products, there must be $\theta, \eta > 0$ such that if $\{\tilde{c}_0, \ldots, \tilde{c}_N\} \in U_\eta$ then $\hat{\rho}(\tilde{T}_0|_V, \tilde{T}_1|_V) \leq \tilde{\rho}_m < \theta < 1$, where $\tilde{T}_0$, $\tilde{T}_1$ are the matrices corresponding to $\{\tilde{c}_0, \ldots, \tilde{c}_N\}$ and $\tilde{\rho}_m = \max_{d_j=0,1} \|(\tilde{T}_{d_1} \cdots \tilde{T}_{d_m})|_V\|^{1/m}$. Therefore, for each $\{\tilde{c}_0, \ldots, \tilde{c}_N\} \in U_\eta$, there exists a corresponding continuous scaling vector $\tilde{v}$ that is Hölder continuous with exponent $\tilde{\alpha}$ satisfying

$$\tilde{\alpha} \geq \alpha = -\log_2 \theta.$$

Careful examination of the proof of Theorem 2 given in [DL2] reveals that corresponding Hölder constants $\tilde{K}$ for $\tilde{v}$ satisfy

$$\tilde{K} \leq \frac{2\tilde{C}\tilde{R}}{\tilde{\rho}_m},$$

where

$$\tilde{C} = \max_{r=0,\ldots,m-1} \left\{ \left(\frac{\tilde{\rho}_r}{\tilde{\rho}_m} \right)^r \right\}$$

and

$$\tilde{R} = \sup_{t \in [0,1]} \|\tilde{v}(t)\| \leq \left(\frac{\tilde{C}\,(\max\{\|\tilde{T}_0\|, \|\tilde{T}_1\|\} + 1)}{1 - \tilde{\rho}_m} + 1 \right) \|\tilde{v}(0)\|.$$

The quantities $\tilde{C}$ and $\tilde{R}$ are continuous as functions of the coefficients, so $K = \sup_{\{\tilde{c}_0,\ldots,\tilde{c}_N\}\in U_\eta} \tilde{K} < \infty$.

Now let ε be given and choose n large enough that $2^{-n\alpha}K < \frac{\varepsilon}{4}$. Let S_n be the set of all dyadic points in $[0,1]$ with finite binary expansions of length n or less. The functions $\tilde{v}$ are completely determined on S_n by $\tilde{v}(0)$ and the 2^n matrices of the form $\tilde{T}_{d_1}\cdots\tilde{T}_{d_n}$. Hence, there exists a $\delta < \eta$ such that $\sup_{x\in S_n} \|v(x) - \tilde{v}(x)\| < \frac{\varepsilon}{2}$ for all $\{\tilde{c}_0,\ldots,\tilde{c}_N\} \in U_\delta$. Given $y \in [0,1]$ arbitrary, there is an $x \in S_n$ with $|y-x| < 2^{-n}$, so

$$\begin{aligned}\|v(y) - \tilde{v}(y)\| &\le \|v(y) - v(x)\| + \|v(x) - \tilde{v}(x)\| + \|\tilde{v}(x) - \tilde{v}(y)\| \\ &\le K\,|y-x|^\alpha + \frac{\varepsilon}{2} + K\,|x-y|^\alpha \\ &< \varepsilon.\end{aligned}$$

The result now follows once we recall that all norms on $\mathbf{C}^N$ are equivalent, and note that the sup-norm for scaling vectors is equivalent to the sup-norm for the associated scaling functions. □

Theorem 2 states that the condition $\hat{\rho}(T_0|_V, T_1|_V) < 1$ implies the existence of a continuous, compactly supported scaling function. The following example, inspired by [W], shows that $\hat{\rho}(T_0|_V, T_1|_V) < 1$ is not, in general, necessary for the existence of a continuous, compactly supported scaling function.

Example 3. Fix N, choose coefficients $\{c_0,\ldots,c_N\}$ satisfying (2), and let f be the associated scaling function. Let $d > 1$ be any odd integer, set $\tilde{N} = Nd$, and define coefficients $\{\tilde{c}_0,\ldots,\tilde{c}_{\tilde{N}}\}$ by

$$\tilde{c}_k = \begin{cases} c_j, & \text{if } k = jd, \\ 0, & \text{if } k \ne jd. \end{cases}$$

Let $\tilde{T}_0$, $\tilde{T}_1$ be the matrices corresponding to $\{\tilde{c}_0,\ldots,\tilde{c}_{\tilde{N}}\}$, and let $\tilde{V}$ be the corresponding subspace of $\mathbf{C}^{\tilde{N}}$. By construction, the coefficients $\{\tilde{c}_0,\ldots,\tilde{c}_{\tilde{N}}\}$ satisfy (2), and the associated scaling function is $\tilde{f}(t) = f(\frac{t}{d})$. It must be the case that $\hat{\rho}(\tilde{T}_0|_{\tilde{V}}, \tilde{T}_1|_{\tilde{V}}) \ge \rho(\tilde{T}_0|_{\tilde{V}}) \ge 1$ since both $(1,1,\ldots,1)$ and $(1,0,0,1,0,0,\ldots,1,0,0)$ are left eigenvectors for $\tilde{T}_0$ and $\tilde{T}_1$ for the eigenvalue 1 and $\dim(\tilde{V}) = \tilde{N} - 1$. However, if $\hat{\rho}(T_0|_V, T_1|_V) < 1$ then f, and therefore $\tilde{f}$, will be continuous. The dilation equation defined by the coefficients $\{\tilde{c}_0,\ldots,\tilde{c}_{\tilde{N}}\}$ is referred to as a *stretched dilation equation.* Wang examined stretched dilation equations using iterated function system techniques. □

For a stretched dilation equation, the differences $v(x) - v(y)$ are contained in a lower-dimensional subspace of V, and therefore the value of $\hat{\rho}(T_0|_V, T_1|_V)$ may be determined by vectors not directly related to the scaling vector v. This suggests that better results might be obtained by replacing V with the subspace

$$\begin{aligned} W &= \operatorname{span}\{v(x) - v(y) : \text{dyadic } x, y \in [0,1]\} \\ &= \operatorname{span}\{v(x) - v(0) : \text{dyadic } x \in [0,1]\}. \end{aligned}$$

Note that W is invariant under T_0, T_1 by construction, without the need to assume (2). If (2) does hold then $W \subset V$. Note also that W depends explicitly on the scaling vector v, while V does not. We show in Theorem 3 below that $\hat{\rho}(T_0|_W, T_1|_W) < 1$ is sufficient to ensure the existence of a continuous scaling function, and we give several examples illustrating the distinction between V and W and its consequences. Moreover, by considering W instead of V, we obtain necessary conditions for the

existence of continuous scaling functions. These necessary conditions can be illustrated by the following example.

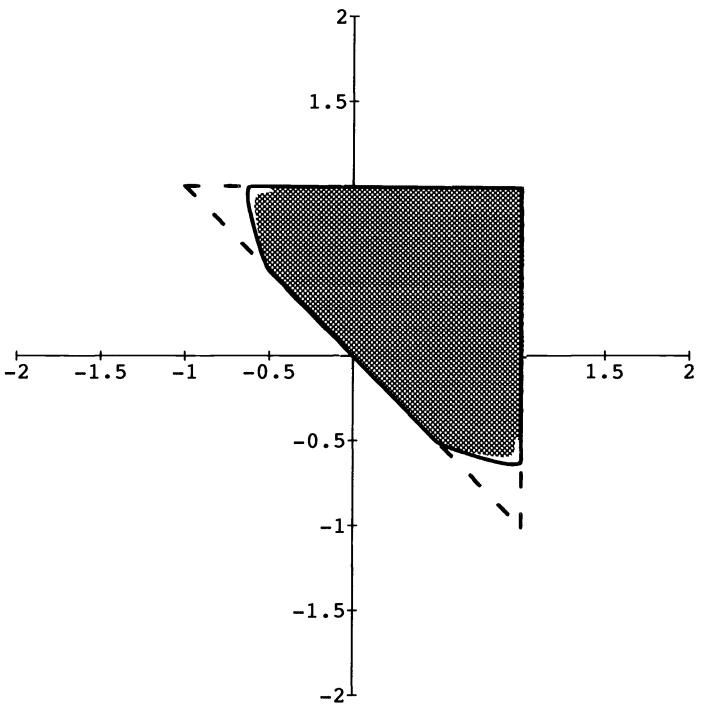

FIG. 2. *Subsets of the* (c_0, c_3)*-plane: region where either* $\hat{\rho}_{20} < 1$ *or* $\hat{\rho}(T_0|_V, T_1|_V) < 1$ *due to simultaneous symmetrization (shaded area); boundary of the region where* $\hat{\sigma}_{20} < 1$ *(solid curve).*

Example 4. Consider $N = 3$ as in Example 2. The shaded region in Fig. 2 is the union of the set of points (c_0, c_3) where $\hat{\rho}_{20}(T_0|_V, T_1|_V) < 1$ (obtained by numerical computation using the Euclidean norm) and the set of points (c_0, c_3) such that S_0, S_1 defined by (19) are simultaneously symmetrizable with $\hat{\rho}(T_0|_V, T_1|_V) = \hat{\rho}(S_0, S_1) < 1$. Theorem 2 therefore implies that continuous, compactly supported scaling functions exist for each point in the shaded region.

To derive a necessary condition, consider the behavior of the scaling vector v near the point 0. If v is continuous, then necessarily $v(2^{-m}) \to v(0)$ as $m \to \infty$. It is straightforward to check by evaluating $v(2^{-m}) = T_0^m v(1)$ directly that this occurs if and only if $|c_0|$, $|1 - c_0 - c_3| < 1$. Similarly, the continuity of v at 1 implies $|c_3|$, $|1 - c_0 - c_3| < 1$. The eigenvalues of $T_0|_V$, $T_1|_V$ combined are c_0, c_3, and $1 - c_0 - c_3$, so if v is continuous then $\hat{\sigma}_1(T_0|_V, T_1|_V) < 1$. Moreover, this analysis shows that $\|v(2^{-m}) - v(0)\|$ is on the order of $\hat{\sigma}_1^m$, so the maximum Hölder exponent of continuity of v is at most $-\log_2 \hat{\sigma}_1$. The region of points (c_0, c_3) such that $\hat{\sigma}_1 < 1$ is the interior of the triangle shown in Fig. 2, i.e, continuous scaling vectors are restricted to points in the interior of that triangle. □

The case $N = 3$ is simple enough that the result of Example 4 can be obtained directly by evaluating $v(2^{-m})$ as a function of the coefficients $\{c_0, \ldots, c_N\}$. Although this exact evaluation cannot be done at arbitrary points, the spirit of the approach of Example 4 is used in the proof of Theorem 3(b) below to obtain that continuity

implies $\hat{\sigma}_m(T_0|_W, T_1|_W) < 1$ for every m. Specifically, the matrices T_0, T_1 are replaced by products $T = T_{d_1} \cdots T_{d_m}$, the eigenvalues c_0, c_3, $1 - c_0 - c_3$ of $T_0|_V$, $T_1|_V$ by eigenvalues of $T|_W$, and the points 2^{-m}, 0 by points X_m, Y_m depending on the product T. We must replace V by W to ensure that $v(X_m) - v(Y_m)$ will have a component in the required eigenspace of T. This was unnecessary for the case $N = 3$ since the dilation equations for that case are very restrictive, cf. Example 5. For $N = 3$, the set of points (c_0, c_3) such that $\hat{\sigma}_{20} < 1$ is the interior of the solid curve shown in Fig. 2, i.e., continuous scaling vectors are restricted not only to the interior of the triangle, but to the interior of the region bounded by the solid curve.

Since $\hat{\rho}(T_0|_W, T_1|_W) = \sup \hat{\sigma}_m$, the preceding remarks suggest that the value of $\hat{\rho}(T_0|_W, T_1|_W)$ is essentially the single determining factor for the existence of a continuous scaling function. This is made precise in the following theorem. Recall that scaling vectors can exist only when the matrix M defined by (17) has 1 as an eigenvalue.

THEOREM 3. *Assume the coefficients* $\{c_0, \ldots, c_N\}$ *are such that* 1 *is an eigenvalue for* M.

(a) *Let* v *be the vector-valued function defined for dyadic* x *constructed in Construction* 1. *If* $\hat{\rho}(T_0|_W, T_1|_W) < 1$ *then* v *extends to a continuous scaling vector.*

(b) *If* v *is any continuous scaling vector then* $\hat{\rho}(T_0|_W, T_1|_W) < 1$. *In this case* v *is Hölder continuous with* $\alpha_{\max} = -\log_2 \hat{\rho}(T_0|_W, T_1|_W)$, *and the exponent* $\alpha = \alpha_{\max}$ *is achieved if and only if there exists a constant* $C > 0$ *such that* $\hat{\rho}_m \le C^{1/m} \hat{\rho}(T_0|_W, T_1|_W)$ *for every* m.

The proof of Theorem 3 is given below; we first make some remarks on its statement, consider how to determine W, and examine the relationship between V and W for those dilation equations satisfying (2).

First, note that the subspace W depends explicitly on v. Thus, in the hypothesis of Theorem 3(a), the vector-valued function of Construction 1 must be determined before W and $\hat{\rho}(T_0|_W, T_1|_W)$ can be evaluated.

Second, in the hypotheses of Theorem 3(b), note that if v is a continuous scaling vector, then it agrees at dyadic points with the vector-valued function given in Construction 1. Thus

$$C_W = \{\{c_0, \ldots, c_N\} \text{ satisfying (2)} : \hat{\rho}(T_0|_W, T_1|_W) < 1\}$$

is the precise set of all dilation equations satisfying (2) that have continuous, compactly supported solutions, cf. the definition of C_V following Theorem 2. Example 7 below presents a specific case where $C_W \neq C_V$ for reasons other than trivial cases such as stretched dilation equations.

Finally, note that since the derivative of a differentiable scaling function is itself a solution of another dilation equation (with coefficients multiplied by two), Theorem 3 implicitly characterizes those dilation equations having compactly supported, n-times differentiable solutions. This higher-order characterization, and the fact that computation of the joint spectral radius can often be simplified when the coefficients satisfy $\sum c_k = 2$ and the *sum rules* $\sum (-1)^k k^j c_k = 0$ for $j = 0, \ldots, n$, is elaborated on in [HC].

We now discuss several methods of determining the subspace W explicitly. Note that W is one subspace that is invariant under both T_0 and T_1. The following proposition provides a means of recognizing which invariant subspace is W by examination of the single vector $v(1) - v(0)$. This vector is easily computable since $v(0) = (0, a_1, \ldots, a_{N-1})^t$ and $v(1) = (a_1, \ldots, a_{N-1}, 0)^t$ for some eigenvector $a =$

$(a_1, \dots, a_{N-1})^t$ of the matrix M for the eigenvalue 1. If the multiplicity of this eigenvalue is one, then $v(0)$ and $v(1)$ are uniquely determined up to multiplication by a constant.

PROPOSITION 3. *W is the smallest subspace of $\mathbf{C}^N$ invariant under both T_0 and T_1 which contains the vector $v(1) - v(0)$.*

Proof. Let U be the smallest subspace of $\mathbf{C}^N$ invariant under both T_0 and T_1 which contains the vector $v(1) - v(0)$. Then $U \subset W$, and $v(1) = v(0) + u$ for some $u \in U$. Since $T_0 v(1) = T_1 v(0) = v(\frac{1}{2})$ we have $v(\frac{1}{2}) - v(0) = T_0 v(1) - v(0) = T_0 u \in U$. Continuing in this manner we obtain that if $x = .d_1 \dots d_m \in [0,1]$ is dyadic, then $v(x) - v(0) = T_{d_1} \cdots T_{d_m} v(0) - v(0) \in U$, whence $U \supset W$. □

The following corollary gives sufficient conditions for W to be all of V, assuming that (2) is satisfied. A *hyperplane* in $\mathbf{C}^N$ is any translate of a subspace of $\mathbf{C}^N$.

COROLLARY 1. *Assume (2) holds. If $\{v(x) : \text{dyadic } x \in [0,1]\}$ is not contained in any hyperplane in $\mathbf{C}^N$ of dimension $N-2$ or less, then $W = V$. In particular, if $\operatorname{span}\{v(x) : \text{dyadic } x \in [0,1]\} = \mathbf{C}^N$, then $W = V$.*

Proof. It follows from the hypotheses that $\{v(x) - v(0) : \text{dyadic } x \in [0,1]\}$ is not contained in any hyperplane of dimension $N-2$ or less. Since this set is contained in the $(N-1)$-dimensional subspace V, it follows that V is its span, and therefore is W. □

If the components of $v(0)$ add to zero then $v(x) \in V$ for every dyadic x and therefore $\operatorname{span}\{v(x) : \text{dyadic } x \in [0,1]\} \subset V \neq \mathbf{C}^N$, yet it may still be the case that $\{v(x) : \text{dyadic } x \in [0,1]\}$ is not contained in any hyperplane of dimension $N-2$ or less. If the components of $v(0)$ do not add to zero then $\operatorname{span}\{v(x) : \text{dyadic } x \in [0,1]\} = \mathbf{C}^N$ if and only if $\{v(x) : \text{dyadic } x \in [0,1]\}$ is not contained in any hyperplane of dimension $N-2$ or less. Lawton [L] proved that if (2) holds then an integrable, compactly supported scaling function f satisfies $\sum f(t+k) = \int f = \hat{f}(0)$ almost everywhere. Since f must also satisfy $\hat{f}(\gamma) = \hat{f}(0) \prod_1^\infty m_0(\gamma/2^j)$, cf. (6), it must be the case that $\hat{f}(0) \neq 0$, and thus $\sum_{i=1}^N v_i(x) = \hat{f}(0) \neq 0$ almost everywhere. In particular, if (2) holds and the components of $v(0)$ add to zero then v cannot be continuous.

Corollary 1 is easily implemented only for small values of N. In general, the hypotheses of the following proposition are easier to check.

PROPOSITION 4. *Assume (2) holds, and let $T = T_{d_1} \cdots T_{d_m}$ be any product of T_0, T_1 such that*

(a) *T has distinct eigenvalues, and*

(b) *there is some dyadic $z \in [0,1]$ such that $v(z)$ has a component in each of the eigenspaces of T.*

Let $z = .z_1 z_2 \dots$ be any binary expansion of z, and define $x_0, \dots, x_{N-1}$ by $x_0 = z$, $x_1 = .d_1 \dots d_m z_1 z_2 \dots$, $x_2 = .d_1 \dots d_m d_1 \dots d_m z_1 z_2 \dots$, etc. Then $\{v(x_0), \dots, v(x_{N-1})\}$ forms a basis for $\mathbf{C}^N$, and therefore $W = V$.

Proof. Note that $v(x_i) = T^i v(z)$ for $i = 0, \dots, N-1$. Let $\lambda_1, \dots, \lambda_N$ be the distinct eigenvalues of T; then, by hypothesis, $v(z) = u_1 + \cdots + u_N$ where each u_i is a nonzero eigenvector for T corresponding to the eigenvalue λ_i. Assume that $\{v(z), \dots, T^{N-1} v(z)\}$ was not a basis for $\mathbf{C}^N$; then there exist scalars $\alpha_1, \dots, \alpha_N$, not all zero, such that

$$0 = \alpha_1 v(z) + \alpha_2 T v(z) + \cdots + \alpha_N T^{N-1} v(z)$$

$$
\begin{aligned}
&= \alpha_1 u_1 + \cdots + \alpha_1 u_N \\
&\quad + \alpha_2 \lambda_1 u_1 + \cdots + \alpha_2 \lambda_N u_N \\
&\quad \vdots \\
&\quad + \alpha_N \lambda_1^{N-1} u_1 + \cdots + \alpha_N \lambda_N^{N-1} u_N.
\end{aligned}
$$

As $\{u_1, \ldots, u_N\}$ forms a basis for $\mathbf{C}^N$ we must therefore have $\alpha_1 + \alpha_2 \lambda_i + \cdots + \alpha_N \lambda_i^{N-1} = 0$ for $i = 1, \ldots, N$, i.e., $\lambda_1, \ldots, \lambda_N$ are roots of the polynomial $p(\lambda) = \alpha_1 + \alpha_2 \lambda + \cdots + \alpha_N \lambda^{N-1}$. As p has degree at most $N-1$, this is therefore a contradiction. □

Typically, the product T and the value of z in the hypotheses of Proposition 4 are chosen so as to simplify computations, as in the following example.

Example 5. Fix $N = 3$ as in Example 2 and consider Proposition 4 with $T = T_0$ and $z = 1$. The eigenvalues of T_0 are 1, c_0, and $1 - c_0 - c_3$; assume these are distinct. Corresponding eigenvectors of T_0 are $u_1 = v(0) = (0, c_0, c_3)^t$, $u_2 = (1 - 2c_0 - c_3, 2c_0 - 1, c_3)^t$, and $u_3 = (0, 1, -1)^t$. Up to multiplication by a constant, $v(1) = (c_0, c_3, 0)^t$. Since $1 - 2c_0 - c_3 \neq 0$,

$$
v(1) = u_1 + \frac{c_0}{1 - 2c_0 - c_3} u_2 + \frac{c_3 (1 - c_0 - c_3)}{1 - 2c_0 - c_3} u_3.
$$

Thus $v(1)$ has a component in each of the eigenspaces of T_0, and therefore $W = V$, provided that c_0, c_3, $1 - c_0 - c_3 \neq 0$.

Compare the above computation to the result proved in [CH1], that $\{v(x) : \text{dyadic } x \in [0,1]\}$ is not contained in any line in $\mathbf{C}^3$ if c_0, c_3, $1 - c_0 - c_3 \neq 0$; hence W is all of V in that case. When $1 - c_0 - c_3 = 0$, then W has dimension 1 and hence is a proper subset of V. This case is not the result of a stretched dilation equation, but rather arises from the presence of zero eigenvalues. In particular, the eigenvalues of $T_0|_V$ are c_0 and $1 - c_0 - c_3$ and the eigenvalues of $T_1|_V$ are c_3 and $1 - c_0 - c_3$. If $1 - c_0 - c_3 = 0$ then zero is a common eigenvalue of $T_0|_V$ and $T_1|_V$; moreover, the corresponding eigenspaces are identical. Note, however, that $\hat{\rho}(T_0|_V, T_1|_V) = \hat{\rho}(T_0|_W, T_1|_W)$ despite the fact that $V \neq W$, since the zero eigenvalue does not impact the value of the joint spectral radius. □

The next example is another simple illustration of how W may differ from V without the joint spectral radius being affected.

Example 6. Given coefficients $\{c_0, \ldots, c_N\}$ satisfying (2), define $\tilde{c}_i = c_i$ for $i = 0, \ldots, N$ and $\tilde{c}_{N+1} = 0$. Let f, v, W, etc., be the usual items associated with $\{c_0, \ldots, c_N\}$, and let $\tilde{f}$, $\tilde{v}$, $\tilde{W}$, etc., be the corresponding items associated with $\{\tilde{c}_0, \ldots, \tilde{c}_{N+1}\}$. Clearly $\tilde{f} = f$, yet $\tilde{W} \neq \tilde{V}$, even if $W = V$, since $\tilde{W} \subset \{u \in \mathbf{C}^{N+1} : u_1 + \cdots + u_N = 0, u_{N+1} = 0\} \neq \tilde{V}$. Wang [W] demonstrates that $\hat{\rho}(T_0|_V, T_1|_V) = \hat{\rho}(\tilde{T}_0|_{\tilde{V}}, \tilde{T}_1|_{\tilde{V}})$, and it follows similarly that $\hat{\rho}(T_0|_W, T_1|_W) = \hat{\rho}(\tilde{T}_0|_{\tilde{W}}, \tilde{T}_1|_{\tilde{W}})$. If $W = V$ then these four numbers are equal, despite the fact that $\tilde{W} \neq \tilde{V}$. □

The calculations in the preceding example are carried out by placing T_0 and T_1 in block upper-triangular form, as follows. Suppose we are given any dilation equation satisfying (2) such that W is a proper subspace of V, say $J = \dim(W) < N - 1$. Since both W and V are invariant under T_0 and T_1, there will be a change-of-basis matrix B such that BT_0B^{-1} and BT_1B^{-1} have the block upper-triangular forms

$$BT_iB^{-1} = \begin{pmatrix} P_i & * & * \\ 0 & Q_i & * \\ 0 & 0 & 1 \end{pmatrix}, \qquad i = 0, 1,$$

where the matrices P_i are $J \times J$ and the matrices Q_i are $(N-J-1) \times (N-J-1)$. Hence,

$$\hat{\rho}(T_0|_W, T_1|_W) = \hat{\rho}(P_0, P_1)$$

and

$$\hat{\rho}(T_0|_V, T_1|_V) = \max\{\hat{\rho}(P_0, P_1), \hat{\rho}(Q_0, Q_1)\}.$$

One such basis choice is the eigenvector basis for T_0 (if it exists), in which case T_0 is diagonalized and T_1 can be block upper-triangularized.

Our next example presents a class of dilation equations for which the distinction between V and W plays an important role in determining the continuity of the associated scaling vectors. In particular, this example illustrates the fact that the maximum Hölder exponent is not continuous as a function of the coefficients $\{c_0, \ldots, c_N\}$.

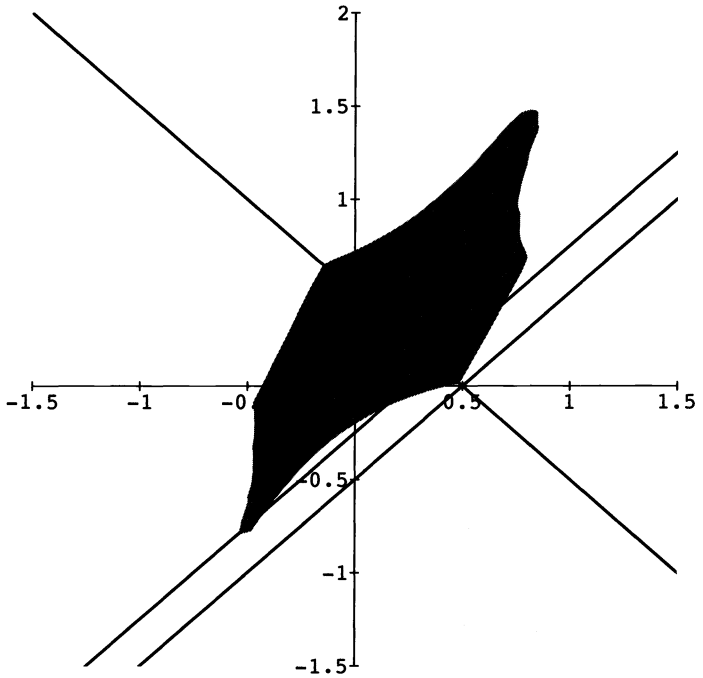

FIG. 3. *The (c_0, c_1)-plane, identified with symmetric, real-valued, seven-coefficient dilation equations satisfying* (2).

Example 7. Set $N = 6$ and consider the two-parameter family of all symmetric sets $\{c_0, c_1, \frac{1}{2} - c_0, 1 - 2c_1, \frac{1}{2} - c_0, c_1, c_0\}$ of real coefficients which satisfy (2). We identify these dilation equations with the (c_0, c_1)-plane. The shaded region in Fig. 3 is a numerical approximation of the region $\{(c_0, c_1) : \hat{\rho}_{16}(T_0|_V, T_1|_V) < 1\}$ (using the norm $\|u\| = |u_1| + \cdots + |u_6|$) and is therefore a subset of C_V, i.e., all points in this region give rise to continuous, compactly supported scaling functions. We discuss

several subfamilies of the (c_0, c_1)-plane below; in particular, the three lines shown in Fig. 3 are discussed in parts (b), (c), and (d).

(a) The point $(\frac{1}{2}, 0)$ corresponds to a stretched dilation equation, and the associated scaling vector is $v(x) = (x, x+1, x+2, 3-x, 2-x, 1-x)^t$. Therefore W is a line in $\mathbf{C}^6$ and hence is a proper subset of V. Although $\hat{\rho}(T_0|_V, T_1|_V) = 1$ we have $\hat{\rho}(T_0|_W, T_1|_W) = \frac{1}{2}$, and v is Hölder continuous with Hölder exponent 1. In particular, C_V is a proper subset of C_W.

(b) Consider now those dilation equations in the (c_0, c_1)-plane lying on the line $(c_0, c_1) = (\frac{1}{2} + \delta, -\delta)$, $\delta \in \mathbf{R}$. When $\delta = 0$ this is the stretched dilation equation discussed in part (a). When $\delta \neq 0$, Proposition 3 can be used to show that $\dim(W) = 3$. Furthermore, P_0, P_1 can be simultaneously block upper-triangularized to the form

$$\begin{pmatrix} R_i & * \\ 0 & \frac{1}{2} \end{pmatrix},$$

where R_0, R_1 are 2×2 matrices. If $\delta < -\frac{3}{8}$ or $\delta > -\frac{1}{4}$ then R_0, R_1 can be simultaneously symmetrized. The 2×2 matrices Q_0, Q_1 can be simultaneously symmetrized for all δ, whence

$$\hat{\rho}(T_0|_W, T_1|_W) = \max\left\{\tfrac{1}{2}, |\tfrac{1}{2} + \delta|, |\tfrac{1}{2} + 2\delta|\right\}$$

and

$$\hat{\rho}(T_0|_V, T_1|_V) = \max\left\{\tfrac{1}{2}, |\tfrac{1}{2} + \delta|, |\tfrac{1}{2} + 2\delta|, |1 + 3\delta|\right\},$$

at least for $\delta \notin [-\frac{3}{8}, -\frac{1}{4}]$. In particular,

$$\begin{cases} \hat{\rho}(T_0|_W, T_1|_W) = \hat{\rho}(T_0|_V, T_1|_V) = \frac{1}{2}, & -\frac{1}{4} < \delta < -\frac{1}{6}, \\ \hat{\rho}(T_0|_W, T_1|_W) = \frac{1}{2} < \hat{\rho}(T_0|_V, T_1|_V) < 1, & -\frac{1}{6} < \delta < 0, \\ \hat{\rho}(T_0|_W, T_1|_W) < 1 < \hat{\rho}(T_0|_V, T_1|_V), & 0 < \delta < \frac{1}{4}. \end{cases}$$

The stretched dilation equation $(\frac{1}{2}, 0)$ is therefore a boundary point of C_V, yet belongs to C_W, and there exist nonstretched dilation equations in C_W that are not in C_V.

(c) Consider next the dilation equations lying on the line $(c_0, c_1) = (\frac{1}{2} + \delta, \delta)$. Again, $\delta = 0$ corresponds to the stretched dilation equation $(\frac{1}{2}, 0)$. Applying Proposition 4 we find that $W = V$ for all $\delta \neq 0$ (we can ignore those finitely many δ for which the eigenvalues of T_0 are not distinct). Therefore $\hat{\rho}(T_0|_W, T_1|_W) \geq \rho(T_0|_W) > 1$ for $\delta \notin [(-3 - \sqrt{57})/8, -\frac{5}{4}]$, i.e., there do not exist any continuous scaling functions corresponding to $\delta \notin [(-3 - \sqrt{57})/8, -\frac{5}{4}]$. Thus, although $\hat{\rho}(T_0|_W, T_1|_W) < 1$ at the point $(\frac{1}{2}, 0)$, an arbitrarily small change in the coefficients can result in a dilation equation with $\hat{\rho}(T_0|_W, T_1|_W) > 1$, i.e., $\hat{\rho}(T_0|_W, T_1|_W)$ is *not* a continuous function of the coefficients since the subspace W can change abruptly. Proposition 2 with W in place of V is therefore false.

(d) Finally, consider those dilation equations lying on the line $(c_0, c_1) = (\frac{3}{8} + \delta, \frac{1}{8} + \delta)$. The point $(\frac{3}{8}, \frac{1}{8})$, corresponding to $\delta = 0$, also lies on the line considered in part (a), and satisfies $\hat{\rho}(T_0|_W, T_1|_W) = \frac{1}{2}$, $\hat{\rho}(T_0|_V, T_1|_V) = \frac{5}{8}$, and its associated scaling vector is continuous with Hölder exponent 1. For $\delta \neq 0$, Proposition 4 can be used to show that $W = V$. Since $\hat{\rho}(T_0|_V, T_1|_V)$ is a continuous function of the coefficients (c_0, c_1), given ε small we can find a $\delta_0 > 0$ such that $|\hat{\rho}(T_0|_V, T_1|_V) - \frac{5}{8}| < \varepsilon$ when $0 < |\delta| < \delta_0$. Thus the scaling vectors for $0 < |\delta| < \delta_0$ are continuous, with maximum Hölder exponent $\alpha \leq -\log_2(\frac{5}{8} - \varepsilon) < 1$. However, the maximum Hölder exponent corresponding to $\delta = 0$ is exactly 1. As a function of the coefficients

(c_0, c_1), the maximum Hölder exponent is therefore *not* continuous. By comparison, $\hat{\rho}(T_0|_V, T_1|_V) < 1$ for $0 \le |\delta| < \delta_0$, so by Proposition 2 the associated scaling vectors deform continuously with respect to the sup-norm as δ varies. □

In the examples we have considered, the sets W and V are equal except under restricted conditions. We therefore conjecture that for each fixed N, the set of coefficients $\{c_0, \ldots, c_N\}$ satisfying (2) such that $W \neq V$ is a set of measure zero in the set of all coefficients satisfying (2).

We turn now to the proof of Theorem 3, for which we require a definition and lemma. In the statement of Proposition 4, the matrix T was assumed to have distinct eigenvalues, and hence T had a full set of linearly independent eigenvectors. Therefore, the definition of "component" used in hypothesis (b) of Proposition 4 was obvious. Now let A be an arbitrary $N \times N$ matrix with complex entries. If $\lambda \in \mathbf{C}$ is an eigenvalue of A, then $U_\lambda = \{u \in \mathbf{C}^N : (A - \lambda)^k u = 0 \text{ for some } k > 0\}$ is an A-invariant subspace of $\mathbf{C}^N$, for if $u \in U_\lambda$, then $Au = (A - \lambda)u + \lambda u \in U_\lambda$. By standard Jordan decomposition techniques we can write $\mathbf{C}^N = U_\lambda \oplus Z$, where Z is a unique A-invariant subspace of $\mathbf{C}^N$ [Her]. Any vector $u \in \mathbf{C}^N$ can therefore be uniquely written $u = u_\lambda + z$ where $u_\lambda \in U_\lambda$ and $z \in Z$. We say that u *has a component in* U_λ if $u_\lambda \neq 0$; note this implies $u \neq 0$.

One of the basic tools of our analysis is given in the next lemma.

LEMMA 3. *Let A be an $N \times N$ matrix and let λ be any eigenvalue of A. If $u \in \mathbf{C}^N$ has a component in U_λ, then there is a constant $C > 0$ such that $\|A^n u\| \ge C\,|\lambda|^n$ for all $n > 0$.*

Proof. As all norms on $\mathbf{C}^N$ are equivalent, it suffices to prove the result for the Euclidean space norm $\|u\| = (|u_1|^2 + \cdots |u_N|^2)^{1/2}$.

Let $\mathbf{C}^N = U_\lambda \oplus Z$ be the standard Jordan decomposition induced by A. The subspace U_λ can be written $U_\lambda = U_1 \oplus \cdots \oplus U_p$, where each U_i is a nontrivial, A-invariant subspace of U_λ that cannot be further decomposed into A-invariant subspaces. As u has a component in U_λ it must therefore have a component in some U_i, say U_1. Let $Z_1 = U_2 \oplus \cdots \oplus U_p \oplus Z$, so $\mathbf{C}^N = U_1 \oplus Z_1$ and U_1, Z_1 are A-invariant.

Since U_1 is finite-dimensional there must exist a smallest positive integer m such that $(A - \lambda)^m w = 0$ for all $w \in U_1$. Let $u_1 \in U_1$ be such that $(A - \lambda)^{m-1} u_1 \neq 0$ and set $u_k = (A - \lambda)^{k-1} u_1$ for $k = 2, \ldots, m$. Since U_1 is indecomposable, $\{u_1, \ldots, u_m\}$ comprises a basis for U_1. Moreover, the $\{u_k\}$ satisfy the relationships

$$\begin{aligned} Au_k &= u_{k+1} + \lambda u_k \quad \text{for } k = 1, \ldots, m-1, \\ Au_m &= \lambda u_m. \end{aligned} \tag{20}$$

Consider now the vector u; we have $u = v_1 + \cdots + v_m + z$ where each v_k is a scalar multiple of u_k and $z \in Z_1$. Since u has a component in U_1, at least one of the v_k is nonzero. Let k^* be that positive integer such that $v_{k^*} \neq 0$ while $v_k = 0$ for $k < k^*$. Then (20) implies that

$$A^n u = \lambda^n v_{k^*} + \sum_{k > k^*} P_{k,n}\, v_k + A^n z, \tag{21}$$

where each $P_{k,n}$ is a polynomial in λ of degree at most n. Now let Z_2 denote the proper subspace of $\mathbf{C}^N$ generated by Z_1 and $\{u_k : k \neq k^*\}$. Since $\dim(Z_2) = N - 1$, there exist unique vectors $z^* \in Z_2$ and $u^* \in Z_2^{\perp}$ such that $v_{k^*} = u^* + z^*$. Moreover, $u^* \neq 0$ since $v_{k^*} \notin Z_2$. It follows then from (21) that for each $n > 0$,

$$A^n u = \lambda^n u^* + \lambda^n z^* + \sum_{k > k^*} P_{k,n}\, v_k + A^n z = \lambda^n u^* + z_n,$$

where $z_n \in Z_2$. Since u^* is orthogonal to z_n, we therefore have

$$\|A^n u\|^2 = \|\lambda^n u^*\|^2 + \|z_n\|^2 \geq |\lambda|^{2n} \|u^*\|^2. \qquad \square$$

The proof of Lemma 3 can be simplified if A is diagonalizable.

Proof of Theorem 3. (a) The fact that the hypothesis $\hat{\rho}(T_0|_V, T_1|_V) < 1$ in Theorem 2 can be replaced by $\hat{\rho}(T_0|_W, T_1|_W) < 1$ and that the assumption of (2) is then no longer necessary is a simple observation following from the proof of Theorem 2 given in [DL2]. Moreover, the same proof implies that v is Hölder continuous for each exponent $0 \leq \alpha < -\log_2 \hat{\rho}(T_0|_W, T_1|_W)$, or $0 \leq \alpha \leq -\log_2 \hat{\rho}(T_0|_W, T_1|_W)$ if there exists a constant $C > 0$ such that $\hat{\rho}_m \leq C^{1/m} \hat{\rho}(T_0|_W, T_1|_W)$ for every m. In particular, $\alpha_{\max} \geq -\log_2 \hat{\rho}(T_0|_W, T_1|_W)$.

(b) Assume that v is a continuous scaling vector; then v is Hölder continuous for some exponent α in the range $0 \leq \alpha \leq 1$. Let K be any corresponding Hölder constant.

Choose any $m > 0$, and let $T = T_{d_1} \cdots T_{d_m}$ be any fixed product of the matrices T_0, T_1. Let λ be any eigenvalue of $T|_W$. By definition of W, there must be dyadic points $x, y \in [0,1]$ such that $v(x) - v(y)$ has a component in $U_\lambda = \{u \in W : (T-\lambda)^k u = 0 \text{ for some } k > 0\}$. Let $x = .x_1 x_2 \ldots$ and $y = .y_1 y_2 \ldots$ be binary expansions of x and y, respectively, and define the dyadic points X_k, Y_k for $k > 0$ by

$$\begin{aligned} X_1 &= .d_1 \ldots d_m x_1 x_2 \ldots, & Y_1 &= .d_1 \ldots d_m y_1 y_2 \ldots, \\ X_2 &= .d_1 \ldots d_m d_1 \ldots d_m x_1 x_2 \ldots, & Y_2 &= .d_1 \ldots d_m d_1 \ldots d_m y_1 y_2 \ldots, \end{aligned}$$

etc., so $v(X_k) = T^k v(x)$ and $v(Y_k) = T^k v(y)$ for all $k > 0$. We then have by Lemma 3 that

$$\|v(X_k) - v(Y_k)\| = \|T^k\big(v(x) - v(y)\big)\| \geq C\,|\lambda|^k$$

for some constant $C > 0$ independent of k. Since $|X_k - Y_k| \to 0$ as $k \to \infty$ and v is continuous, we must therefore have $|\lambda| < 1$. In fact, $|X_k - Y_k| = 2^{-mk}\,|x - y|$, so

$$\|v(X_k) - v(Y_k)\| \geq K_\lambda\,|X_k - Y_k|^{\alpha_\lambda}$$

for all k, where $\alpha_\lambda = -\log_2 |\lambda|^{1/m}$ and $K_\lambda = C\,|x-y|^{-\alpha_\lambda}$. However, by the Hölder continuity of v,

$$\|v(X_k) - v(Y_k)\| \leq K\,|X_k - Y_k|^{\alpha}$$

for all k, so $|X_k - Y_k|^{\alpha - \alpha_\lambda} \geq K_\lambda / K$ for all k. Since $|X_k - Y_k| \to 0$ as $k \to \infty$, this implies $\alpha \leq \alpha_\lambda$.

Taking the supremum over all eigenvalues of $T = T_{d_1} \cdots T_{d_m}$ for all choices of $d_j = 0, 1$, we obtain $\hat{\sigma}_m < 1$ and $\alpha \leq -\log_2 \hat{\sigma}_m$. Thus $\hat{\rho}(T_0|_W, T_1|_W) = \sup \hat{\sigma}_m \leq 1$ and $\alpha \leq -\log_2 \hat{\rho}(T_0|_W, T_1|_W)$, so $\alpha_{\max} \leq -\log_2 \hat{\rho}(T_0|_W, T_1|_W)$. Combining this with the proof of part (a), we obtain $\alpha_{\max} = -\log_2 \hat{\rho}(T_0|_W, T_1|_W)$.

Suppose that $\alpha = \alpha_{\max}$. Then given any $x = .x_1 x_2 \ldots$ and $y = .y_1 y_2 \ldots$, we have

$$\|T_{d_1} \cdots T_{d_m}(v(x) - v(y))\| = \|v(X) - v(Y)\| \leq K\,|X - Y|^{\alpha} = K\,(2^{-m}\,|x-y|)^{\alpha},$$

where $X = .d_1 \ldots d_m x_1 x_2 \ldots$ and $Y = .d_1 \ldots d_m y_1 y_2 \ldots$. By considering a basis $\{v(x_j) - v(y_j)\}_{j=1}^J$ for W, we obtain that there is a constant $C > 0$ such that $\|T_{d_1} \cdots T_{d_m} w\| \leq C\,2^{-m\alpha}\,\|w\|$ for every $w \in W$, and therefore $\hat{\rho}_m \leq C^{1/m}\,2^{-\alpha} = C^{1/m}\,\hat{\rho}(T_0|_W, T_1|_W)$.

The proof is now complete except for the case of a dilation equation satisfying

$$\sup_m \hat{\sigma}_m = \hat{\rho}(T_0|_W, T_1|_W) = 1 \quad \text{and} \quad \hat{\sigma}_m < 1 \quad \text{for every } m. \tag{22}$$

Assume therefore that a continuous scaling vector exists for a dilation equation satisfying (22). Then each $\hat{\rho}_m \geq 1$, and so for every $m > 0$ there is some product of $T_0|_W$, $T_1|_W$ of length m having norm greater than or equal to 1. Using a diagonalization process, we can therefore construct a sequence $d_1, d_2, \ldots$ so that $S_m = T_{d_1} \cdots T_{d_m}$ satisfies $\|S_m|_W\| \geq 1$ for all m. Let $\{v(x_j) - v(y_j)\}_{j=1}^J$ be a basis for W. Then there exist vectors $u_m = \sum_{j=1}^J a_{m,j}\,(v(x_j) - v(y_j)) \in W$ such that $\|u_m\| = 1$ and $\|S_m u_m\| \geq 1$ for every m. Since W is finite dimensional, we can (by taking subsequences if necessary) suppose that for each j the limit $a_j = \lim_{m\to\infty} a_{m,j}$ exists. Then $S_m u_m \to u$ with $\|u\| = \lim_{m\to\infty} \|S_m u_m\| \geq 1$. Now, by the continuity of v, we have that $S_m v(x_j)$, $S_m v(y_j) \to v(x)$ as $m \to \infty$, where $x = .d_1 d_2 \ldots$, so

$$u = \lim_{m\to\infty} S_m u_m = \lim_{m\to\infty} \sum_{j=1}^J a_{m,j}\, S_m(v(x_j) - v(y_j)) = \sum_{j=1}^J a_j\,(v(x) - v(x)) = 0,$$

a contradiction. □

The proof of Theorem 3(b) raises an interesting question: Do there exist dilation equations such that (22) holds? A scaling function for such a dilation equation must be discontinuous by Theorem 3(b). More generally, the same existence question can be asked with the value 1 in (22) replaced by any positive number; we do not know of any specific examples of such dilation equations, i.e., dilation equations for which the supremum $\sup \hat{\sigma}_m$ is not achieved for any m. Note that $\sup \hat{\sigma}_m = \hat{\sigma}_1$ when simultaneous symmetrization occurs; however, the supremum may be achieved even though simultaneous symmetrization does not occur. For example, consider the dilation equation defined by $N = 3$ and $(c_0, c_3) = (\frac{1}{3}, \frac{1}{3})$. In this case $V = W$ and $\sup \hat{\sigma}_m = \hat{\sigma}_2 > \hat{\sigma}_1$. Lagarias and Wang have conjectured that the supremum must always be achieved; in [LW] they prove several results related to this conjecture.

Theorem 3 discusses only global Hölder exponents. It is possible for a local Hölder exponent at a particular point to be strictly greater than the maximum global Hölder exponent. For example, assume $\hat{\rho}(T_0|_W, T_1|_W) < 1$; then v is continuous by Theorem 3, and its maximum global Hölder exponent of continuity is $\alpha_{\max} = -\log_2 \hat{\rho}(T_0|_W, T_1|_W)$. Fix any product $T = T_{d_1} \cdots T_{d_m}$, and let z be any rational point whose binary expansion is of the form $z = .z_1 \ldots z_n d_1 \ldots d_m d_1 \ldots d_m \ldots$. If $y > z$ with $2^{-n-(k+1)m} \leq y - z < 2^{-n-km}$, then the first $n + km$ digits of y are the same as those of z (using the upper binary expansion of z if z is dyadic). Therefore

$$\begin{aligned}
\|v(y) - v(z)\| &= \|T_{z_1} \cdots T_{z_n} T^k \big(v(\tau^{n+km} y) - v(\tau^{n+km} z)\big)\| \\
&\leq C\, \|(T_{z_1} \cdots T_{z_n})|_W\|\, \|T^k|_W\| \\
&\leq C'\, \theta^k \\
&= C'\, \theta^{-(n+m)/m}\, (2^{-n-(k+1)m})^{-\log_2 \theta^{1/m}} \\
&\leq C'\, \theta^{-(n+m)/m}\, |y - z|^{-\log_2 \theta^{1/m}},
\end{aligned}$$

where $\rho(T|_W) < \theta < 1$ and C and C' are constants independent of k. Using a similar argument from the left (with the lower binary expansion for z if z is dyadic), we conclude that v is locally Hölder continuous at z at least for each exponent α_z in the range

$$0 \leq \alpha_z < \begin{cases} -\log_2 \rho(T|_W)^{1/m}, & \text{if } m > 1, \\ -\log_2 \max\{\rho(T_0|_W),\, \rho(T_1|_W)\}, & \text{if } m = 1. \end{cases} \tag{23}$$

Thus the maximum local Hölder exponent at z is bounded below by the right-hand side of (23). This quantity depends only on the single product T (or on T_0 and T_1 if z is dyadic), and therefore can be strictly greater than the maximum global exponent, which depends on all possible products of T_0 and T_1. The proof of Theorem 3(b) demonstrates that the right-hand side of (23) is the maximum local Hölder exponent at the point $x = .d_1 \dots d_m d_1 \dots d_m \dots$. If $T_0|_W$ and $T_1|_W$ are invertible, then

$$\|v(\tau^m y) - v(x)\| \leq \|(T_{z_1} \cdots T_{z_n}|_W)^{-1}\| \, \|v(y) - v(z)\|,$$

and therefore in this case the right-hand side of (23) is also the maximum local Hölder exponent at any z of the form $z = .z_1 \dots z_n d_1 \dots d_m d_1 \dots d_m \dots$.

Example 8. Consider $N = 3$ as in Example 2. Given coefficients (c_0, c_3), the maximum local Hölder exponent of continuity at any dyadic point is $\alpha_{\text{dyadic}} = -\log_2 \max\{|c_0|, |c_3|, |1 - c_0 - c_3|\}$. Consider the following specific examples.

(a) In [CH1] we determined that the scaling function determined by $(c_0, c_3) = (0.6, -0.2)$ is Hölder continuous with maximum global Hölder exponent somewhere in the range $0.598 \leq \alpha_{\max} \leq 0.600$. However, $\alpha_{\text{dyadic}} = -\log_2 0.6 \approx 0.737$. This is the largest maximum local Hölder exponent at dyadic points for (c_0, c_3) satisfying both (2) and (3).

(b) If $\max\{|c_0|, |c_3|, |1-c_0-c_3|\} < \frac{1}{2}$ then α_{dyadic} strictly exceeds 1. It follows that v is differentiable at all dyadic z with $v'(z) = 0$. If v was differentiable everywhere, then this would imply that v was identically constant, which is not the case. For example, for $(c_0, c_3) = (\frac{1}{3}, \frac{1}{3})$, the maximum global Hölder exponent is only $\alpha_{\max} \approx 0.891$. □

Finally, we use the techniques applied in the proof of Theorem 3 to make some observations about discontinuous scaling functions. In particular, we obtain the following theorem.

THEOREM 4. *Assume v is a scaling vector.*

(a) *If $\hat{\rho}(T_0|_W, T_1|_W) \geq 1$ with $\hat{\sigma}_m \geq 1$ for some m, then v is discontinuous. If $T_0|_W$, $T_1|_W$ are invertible, then discontinuities occur on a dense set of rational points in $[0, 1]$.*

(b) *If $\hat{\rho}(T_0|_W, T_1|_W) > 1$, then v is unbounded. If $T_0|_W$, $T_1|_W$ are invertible, then singularities occur on a dense set of rational points in $[0, 1]$.*

Proof. (a) If $\hat{\sigma}_m \geq 1$ for some m then there is some product $T = T_{d_1} \cdots T_{d_m}$ and some eigenvalue λ of $T|_W$ such that $|\lambda| \geq 1$. Let X_k, Y_k be as in the proof of Theorem 3(b); it follows then that $\|v(X_k) - v(Y_k)\| \geq C\,|\lambda|^k$ for some constant $C > 0$ independent of k. As X_k, $Y_k \to X = .d_1 \dots d_m d_1 \dots d_m \dots$, it follows that v cannot be continuous at X. An argument similar to the one following (23) shows that if $T_0|_W$, $T_1|_W$ are invertible, then discontinuities also occur at every point z of the form $z = .z_1 \dots z_n d_1 \dots d_m d_1 \dots d_m \dots$.

(b) If $\hat{\rho}(T_0|_W, T_1|_W) > 1$ then $\hat{\sigma}_m > 1$ for some m, and therefore there is some product $T = T_{d_1} \cdots T_{d_m}$ and some eigenvalue λ of $T|_W$ such that $|\lambda| > 1$. The remainder of the proof follows just as in part (a). □

As a final comment, suppose we are given a scaling vector v with $\hat{\rho}(T_0|_W, T_1|_W) > 1$. We have then by Theorem 4(b) that v is unbounded. The singularities constructed in the proof of this result occur only at rational points. Consider then the function $\tilde{v}$ obtained by setting $\tilde{v}(x) = v(x)$ for nonrational x and $\tilde{v}(x) = 0$ for rational x. This is also a scaling vector, and $\hat{\rho}(\tilde{T}_0|_{\tilde{W}}, \tilde{T}_1|_{\tilde{W}}) = 0$. However, $\tilde{v}$ is clearly discontinuous; note that Theorem 3(a) does not imply continuity since $\tilde{v}$ is not given at dyadic points by the method of Construction 1. Since $\hat{\rho}(\tilde{T}_0|_{\tilde{W}}, \tilde{T}_1|_{\tilde{W}}) < 1$, Theorem 4(b) does not

imply that $\tilde{v}$ is unbounded. We therefore ask whether it is possible that $\tilde{v}$ be bounded. As pointed out by the referee, the subspaces W or $\tilde{W}$ are probably not the best for dealing with this question. A more relevant subspace might be

$$\bigcap_S \operatorname{span}\{v(x) - v(y) : x, y \in S\},$$

where the intersection is taken over all subsets $S \subset [0,1]$ with measure one that are invariant under τ.

Acknowledgments. We thank George Benke of The MITRE Corporation and Gil Strang of MIT for many stimulating discussions and valuable insights on this subject.

LINEAR OPERATORS PRESERVING COMPLEX ORTHOGONAL EQUIVALENCE ON MATRICES*

ROGER A. HORN†, CHI-KWONG LI‡, AND DENNIS I. MERINO§

Abstract. Two complex matrices A and B are said to be (complex) orthogonally equivalent if there exist (complex) orthogonal matrices Q_1 and Q_2 such that $A = Q_1BQ_2$. In this note the authors obtain characterization of linear operators that preserve complex orthogonal equivalence.

Key words. linear preservers, complex orthogonal matrix

AMS subject classifications. 15A04, 15A57, 15A24

1. Introduction and statement of result.

Let $M_{m,n}$ be the set of all m-by-n matrices with complex entries; and we write $M_n \equiv M_{n,n}$. A matrix $Q \in M_n$ is said to be (complex) *orthogonal* if $Q^TQ = I$. Two matrices $A, B \in M_{m,n}$ are said to be (complex) *orthogonally equivalent*, denoted $A \sim B$, if $A = Q_1BQ_2$ for some orthogonal matrices $Q_1 \in M_m$ and $Q_2 \in M_n$. One checks that $\sim$ is an equivalence relation on $M_{m,n}$. We are interested in studying *linear orthogonal equivalence preservers* on $M_{m,n}$; that is, $T : M_{m,n} \to M_{m,n}$ and $T(A) \sim T(B)$ whenever $A \sim B$. We prove the following, which is our main result.

THEOREM 1.1. *Let T be a given linear operator on $M_{m,n}$. Then T preserves orthogonal equivalence if and only if there exist complex orthogonal $Q_1 \in M_m$ and $Q_2 \in M_n$ and a scalar $\alpha \in \mathbb{C}$ such that either:*

(1) *$T(A) = \alpha Q_1AQ_2$ for all $A \in M_{m,n}$; or*

(2) *$m = n$ and $T(A) = \alpha Q_1A^TQ_2$ for all $A \in M_n$.*

We have divided the proof of the theorem into three parts. In § 2, we establish that either $T = 0$ or T is nonsingular. In § 3, we show that T has the form asserted in the theorem, except that Q_1 and Q_2 are nonsingular, but are not necessarily orthogonal. Finally, in § 4, the theorem is proved.

Similar problems have been studied in [5] and [7], and we use their general approach. We analyse the *orbits*

$$\mathcal{O}(A) = \{X \in M_{m,n} : X \sim A\}$$

and their corresponding tangent spaces $\mathcal{T}_A$. It is known that these orbits are homogeneous differentiable manifolds [1]. As in [5] and [7], it is necessary to develop some special techniques to supplement the general approach in solving the problem. Unlike the relations considered in [7], little is known about complex orthogonal equivalence and a simple canonical form is not available. This makes the problem more difficult and more interesting. In fact, the results obtained in this paper may give more insight into, and better understanding of, the orthogonal equivalence relation.

We denote the standard basis of $M_{m,n}$ by $\{E_{11}, E_{12}, \ldots, E_{m,n}\}$. When $E_{ij} \in M_n$, we set $F_{ij} \equiv E_{ij} - E_{ji}$ and, to avoid confusion when $E_{ij} \in M_m$, we set $G_{ij} \equiv E_{ij} - E_{ji}$. Note that all F_{ij} and G_{ij} are skew-symmetric matrices. We denote the standard basis of $\mathbb{C}^n$ by $\{e_1, \ldots, e_n\}$. The n-by-n identity matrix is denoted by I, or when necessary for clarity, by I_n. A vector $x \in \mathbb{C}^n$ is said to be *isotropic* if $x^T x = 0$.

2. Preliminary results. The following observation is used repeatedly in our arguments.

LEMMA 2.1. *Let* $\mathbf{V}$ *be a subspace of* $M_{m,n}$ *that is invariant under orthogonal equivalence, and let* $T : \mathbf{V} \to M_{m,n}$ *be a linear transformation that preserves orthogonal equivalence. Then*

$$T(\text{span } \mathcal{O}(A)) \subset \text{span } \mathcal{O}(T(A)) \text{ and } T(\mathcal{T}_A) \subset \mathcal{T}_{T(A)}$$

for every $A \in \mathbf{V}$. *Consequently, if* T *is nonsingular, then*

$$\dim \text{span } \mathcal{O}(A) \leq \dim \text{span } \mathcal{O}(T(A)) \text{ and } \dim \mathcal{T}_A \leq \dim \mathcal{T}_{T(A)}$$

for every $A \in \mathbf{V}$.

LEMMA 2.2. *Let* X, $Y \in M_{m,n}$ *be given, let* T *be a linear operator on* $M_{m,n}$ *that preserves orthogonal equivalence, and suppose* $X \in \mathcal{T}_X$. *If* $Y \notin \mathcal{T}_Y$, *then* $T(X) \notin \mathcal{O}(Y)$.

Proof. Suppose $T(X) = Q_1 Y Q_2$ for some orthogonal $Q_1 \in M_m$ and $Q_2 \in M_n$. Let $T_1 \equiv Q_1^T T Q_2^T$. Then $Y = Q_1^T T(X) Q_2^T = T_1(X) \in T_1(\mathcal{T}_X) \subset \mathcal{T}_{T_1(X)} = \mathcal{T}_Y$. □

Remark. The argument used to prove the preceding lemma can be used to obtain its conclusion under more general hypotheses: Let $\mathcal{G}$ be a given group of nonsingular linear operators on $M_{m,n}$, and say $A \sim B$ if $A = L(B)$ for some $L \in \mathcal{G}$. Let T be a given linear operator on $M_{m,n}$ such that $T(A) \sim T(B)$ whenever $A \sim B$. If $X \in \mathcal{T}_X$ and $Y \notin \mathcal{T}_Y$, then $T(X) \neq L(Y)$ for all $L \in \mathcal{G}$.

LEMMA 2.3. Span $\mathcal{O}(A) = M_{m,n}$ *for every nonzero* $A \in M_{m,n}$.

Proof. Let $A \in M_{m,n}$ be a given nonzero matrix. There exists orthogonal (in fact, permutation matrices) $P \in M_m$ and $Q \in M_n$ such that the (1,1)-entry of $B = PAQ$, say, b_{11}, is nonzero. For a given positive integer k, define the diagonal orthogonal matrix

$$D_k \equiv \text{diag}(1, -1, -1, \ldots, -1) \in M_k.$$

Then $4b_{11}E_{11} = (I_m + D_m)B(I_n + D_n) = B + D_m B + B D_n + D_m B D_n \in \text{span } \mathcal{O}(A)$, so $E_{11} \in \text{span } \mathcal{O}(A)$. Since there exist permutation (and hence, orthogonal) matrices $P_i \in M_m$ and $P_j \in M_n$ such that $E_{ij} = P_i E_{11} P_j$, every $E_{ij} \in \text{span } \mathcal{O}(A)$ and hence span $\mathcal{O}(A) = M_{m,n}$. □

LEMMA 2.4. *Let* T *be a given linear operator on* $M_{m,n}$. *If* T *preserves orthogonal equivalence, then either* $T = 0$ *or* T *is nonsingular.*

Proof. Suppose that ker T contains a nonzero matrix A. By Lemma 2.1,

$$T(\text{span } \mathcal{O}(A)) \subset \text{span } \mathcal{O}(T(A)) = \{0\}.$$

Now, Lemma 2.3 guarantees that span $\mathcal{O}(A) = M_{m,n}$. Hence, $T = 0$. □

We use the following result, which is Lemma (1) in [3].

LEMMA 2.5. *Let* $X_1, X_2 \in M_{n,k}$ *with* $1 \leq k \leq n$. *There exists a complex orthogonal* $Q \in M_n$ *such that* $X_1 = QX_2$ *if and only if the following two conditions are satisfied*:

(a) $X_1^T X_1 = X_2^T X_2$, *and*

(b) *there exists a nonsingular* $B \in M_n$ *such that* $X_1 = BX_2$.

Note that if $X_1, X_2 \in M_{n,k}$ have full rank, Lemma 2.5 ensures that there exists an orthogonal $Q \in M_n$ such that $X_1 = QX_2$ if and only if $X_1^T X_1 = X_2^T X_2$. In particular, for $n \geq 2$ and any given nonzero $z \in \mathbb{C}^n$, there are two possibilities:

(a) If $z^T z \neq 0$, then $z = \alpha Q e_1$ for some orthogonal $Q \in M_n$ and some nonzero $\alpha \in \mathbb{C}$; and

(b) if $z \neq 0$ and $z^T z = 0$, then $z = Q(e_1 + ie_2)$ for some orthogonal $Q \in M_n$.

Let $A \in M_{m,n}$ be given. Then $\mathcal{O}(A) = \{Q_1 A Q_2 : Q_1 \in M_m, Q_2 \in M_n, Q_1^T Q_1 = I_m$, and $Q_2^T Q_2 = I_n\}$. If $B \sim A$, then $A^T A$ is similar to $B^T B$ and AA^T is similar to BB^T. Suppose A has rank 1, so $A = xy^T$ for some $x \in \mathbb{C}^m$ and $y \in \mathbb{C}^n$. Then rank $A^T A = 0$ or 1 according to whether $x^T x$ is zero or nonzero, and rank $A^T A = 0$ or 1 according to whether $y^T y$ is zero or nonzero. Depending on the four possibilities for the pair (rank $A^T A$, rank AA^T), it follows that for some nonzero scalar $\alpha \in \mathbb{C}$, $\mathcal{O}(A)$ contains exactly one of the following: (a) αE_{11}; (b) $\alpha(E_{11} + iE_{12})$; (c) $\alpha(E_{11} + iE_{21})$; or (d) $\alpha(E_{11} - E_{22} + iE_{12} + iE_{21})$.

The same reasoning leads immediately to the following lemma.

LEMMA 2.6. *Let* m *and* n *be given integers with* $m, n \geq 2$, *let* $E_{11}, E_{12}, E_{21}, E_{22} \in M_{m,n}$ *be standard basis matrices, and let* $E \equiv E_{11} - E_{22} + iE_{12} + iE_{21}$. *Then*

(a) $\mathcal{O}(E_{11}) = \{q_1 q_2^T : q_1 \in \mathbb{C}^m$, $q_2 \in \mathbb{C}^n$, *and* $q_1^T q_1 = q_2^T q_2 = 1\}$.

(b) $\mathcal{O}(E_{11} + iE_{12}) = \{qy^T : q \in \mathbb{C}^m$, $y \in \mathbb{C}^n, q^T q = 1$, *and* $y^T y = 0\}$.

(c) $\mathcal{O}(E_{11} + iE_{21}) = \{xq^T : x \in \mathbb{C}^m$, $q \in \mathbb{C}^n, x^T x = 0$, *and* $q^T q = 1\}$.

(d) $\mathcal{O}(E) = \{xy^T : x \in \mathbb{C}^m$, $y \in \mathbb{C}^n$, *and* $x^T x = y^T y = 0\}$.

If $Q(t) \in M_n$ is a differentiable family of orthogonal matrices with $Q(0) = I$, then differentiation of the identity $Q(t)Q(t)^T = I$ at $t = 0$ shows that $Q'(0) + Q'(0)^T = 0$, that is, $Q'(0)$ is skew-symmetric. Conversely, if $B \in M_n$ is a given skew-symmetric matrix, then $Q(t) \equiv e^{tB}$ is a differentiable family of orthogonal matrices such that $Q(0) = I$ and $Q'(0) = B$ [6]. If $A \in M_{m,n}$ is given and $Q_1(t) \in M_m$ and $Q_2(t) \in M_n$ are given differentiable families of orthogonal matrices with $Q_1(0) = I_m$ and $Q_2(0) = I_n$, one computes that

$$\frac{d}{dt}\{Q_1(t) A Q_2(t)\}|_{t=0} = Q_1'(0)A + AQ_2'(0).$$

Thus, the tangent space to $\mathcal{O}(A)$ at A is given explicitly by

$$\mathcal{T}_A = \{XA + AY : X \in M_m, Y \in M_n, X + X^T = 0, \text{ and } Y + Y^T = 0\}. \tag{2.1}$$

DEFINITION 2.7. *Let* $A \in M_{m,n}$ *with* $n \geq 2$. *Then*

$$\mathcal{S}_A \equiv \{AF_{ij} : i = 1, 2, \text{ and } i < j \leq n\}.$$

Note that $\mathcal{S}_A \subset \mathcal{T}_A$ for every $A \in M_{m,n}$.

Suppose $A \in M_{m,n}$ and rank $A \geq 2$. Then there exists a permutation matrix $Q \in M_n$ such that the first two columns of AQ are linearly independent. Since $F_{ij} = E_{ij} - E_{ji} \in M_n$ is skew-symmetric, $\mathcal{S}_{AQ} \subset \mathcal{T}_{AQ}$ is a linearly independent subset with $2n - 3$ elements. Thus, dim $\mathcal{T}_A =$ dim $\mathcal{T}_{AQ} \geq 2n - 3$ whenever rank $A \geq 2$. A similar argument shows that dim $\mathcal{T}_A \geq 3n - 6$ whenever rank $A \geq 3$.

Now suppose $A \in M_{m,n}$, rank $A \geq 2$, and dim $\mathcal{T}_A = 2n - 3$. Let $Q \in M_n$ be a permutation matrix such that the first two columns of

$$B \equiv AQ = [\, b_1 \; b_2 \; b_3 \; \ldots \; b_n]$$

are independent. Then $\mathcal{S}_B \subset \mathcal{T}_B$ and dim span $\mathcal{S}_B = 2n-3 = \dim \mathcal{T}_A = \dim \mathcal{T}_B$, so $\mathcal{T}_B = \text{span } \mathcal{S}_B = \{BY : Y \in M_n \text{ and } Y + Y^T = 0\}$. If $n > 3$ and $j > 3$, note that

$$BF_{3j} = [\,0\ 0\ -b_j\ 0\ \dots\ 0\ b_3\ 0\ \dots\ 0]$$

and the only matrices in $\mathcal{S}_B$ with nonzero entries in the third column are $BF_{13} = [\,-b_3\ 0\ b_1\ 0\ \dots\ 0\,]$ and $BF_{23} = [\,0\ -b_3\ b_2\ 0\ \dots\ 0\,]$; thus, $b_3 = 0$ and b_j is a linear combination of b_1 and b_2. Hence, rank A = rank $B = 2$ if $n > 3$. Note that if $n = 2$ or $m = 2$ and if $A \in M_{m,n}$ with rank $A \geq 2$, then rank $A = 2$.

LEMMA 2.8. *Let $A \in M_{m,n}$ be nonzero. Then*

$$\mathcal{T}_A = \{XA + AY : X \in M_m, Y \in M_n \text{ and } X + X^T = 0, Y + Y^T = 0\}$$

and

(a) dim $\mathcal{T}_A = m + n - 2$ *if* $A \in \{E_{11}, E_{11} + iE_{12}, E_{11} + iE_{21}\}$;
(b) dim $\mathcal{T}_A = m + n - 3$ *if* $A = E_{11} - E_{22} + iE_{12} + iE_{21}$;
(c) dim $\mathcal{T}_A \geq 2n - 3$ *if* rank $A \geq 2$. *Moreover, if* $n > 3$, rank $A \geq 2$, *and* dim $\mathcal{T}_A = 2n - 3$, *then* rank $A = 2$ *and there exists a permutation matrix* $Q \in M_n$ *such that* $\mathcal{T}_{AQ} = \text{span } \mathcal{S}_{AQ}$;
(d) dim $\mathcal{T}_A \geq 3n - 6$ *if* rank $A \geq 3$.
(e) *If* rank $A = 2$ *and* dim $\mathcal{T}_A = 2n - 3$, *then there exists a permutation matrix* $Q \in M_n$ *such that* dim span $\mathcal{S}_{AQ} = 2n - 3$.

Proof. The asserted form of $\mathcal{T}_A$, as well as assertions (c) and (d), have been verified. Assertions (a) and (b) follow from direct computations. We consider in detail only the case in which $A = E_{11} + iE_{12}$; the other cases can be dealt with similarly. Let $X = [x_{ij}] \in M_m$ and $Y = [y_{ij}] \in M_n$ be skew-symmetric. Then

$$XA = \begin{bmatrix} 0 & 0 & 0 \cdots 0 \\ x_{21} & ix_{21} & 0 \cdots 0 \\ \vdots & \vdots & \vdots \ddots \vdots \\ x_{m1} & ix_{m1} & 0 \cdots 0 \end{bmatrix}$$

and

$$AY = \begin{bmatrix} iy_{21} & y_{12} & y_{13} + iy_{23} & \cdots & y_{1n} + iy_{2n} \\ 0 & 0 & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 0 \end{bmatrix}.$$

Since $y_{21} = -y_{12}$, dim $\mathcal{T}_A = m + n - 2$. □

3. A rank-preserving property of T^{-1}.

PROPOSITION 3.1. *Let T be a nonsingular linear operator on $M_{m,n}$ that preserves orthogonal equivalence. Then $T^{-1}(E)$ has rank 1 whenever E has rank 1.*

We have organized the proof of Proposition 3.1 into a sequence of ten lemmata.

LEMMA 3.2. *Let T be a nonsingular linear operator on $M_{m,n}$ that preserves orthogonal equivalence. If $E \in M_{m,n}$ and* rank $E = 1$, *then* dim $\mathcal{T}_{T^{-1}(E)} \leq m + n - 2$.

Proof. Lemma 2.1 shows that dim $\mathcal{T}_{T^{-1}(E)} \leq$ dim $\mathcal{T}_E$, while Lemma 2.6 and Lemma 2.8 (a), (b) give dim $\mathcal{T}_E \leq m + n - 2$. □

LEMMA 3.3. *Proposition 3.1 holds if $m = 1$ or $m + 1 < n$.*

Proof. If $m = 1$, then the nonsingularity of T implies that $T^{-1}(E) \neq 0$ whenever $E \neq 0$, and this is equivalent to the asserted rank property in this case. Let $E \in M_{m,n}$

be given with $3 \leq m+1 < n$. If rank $E = 1$, then dim $\mathcal{T}_{T^{-1}(E)} \leq n+m-2 < 2n-3$. The first inequality is from Lemma 3.2 and the strict inequality is from our assumption that $3 \leq m+1 < n$. Lemma 2.8(c) now shows that $T^{-1}(E)$ must have rank 1. □

LEMMA 3.4. *Let T be a nonsingular linear operator on $M_{m,n}$ that preserves orthogonal equivalence. If $m+1 = n > 3$ or $m = n > 4$, and if $E \in M_{m,n}$ and* rank $E = 1$, *then* rank $T^{-1}(E) \leq 2$.

Proof. If rank $E = 1$, then Lemma 3.2 guarantees that dim $\mathcal{T}_{T^{-1}(E)} \leq m+n-2$. If $m+1 = n > 3$, then $m+n-2 = 2n-3 < 2n-2 \leq 3n-6$. If $m = n > 4$, then $m+n-2 = 2n-2 < 3n-6$. Thus, under the stated hypotheses we have dim $\mathcal{T}_{T^{-1}(E)} < 3n-6$ and hence rank $T^{-1}(E) \leq 2$ by Lemma 2.8(d). □

Let rank $A = 2$ and suppose that $A = [\, a_1\ a_2\ \ldots\ a_n\,] \in M_{m,n}$. There are two possibilities: at least one a_i is not isotropic, in which case we may suppose $a_1^T a_1 \neq 0$, or all of them are isotropic. Moreover, we may assume that $\{a_1, a_2\}$ is linearly independent.

Case 1. $a_1^T a_1 \neq 0$. Let $\alpha = \sqrt{a_1^T a_1}$, so $\alpha \neq 0$. Lemma 2.5 ensures that $Qa_1 = [\, \alpha\ 0\ \ldots\ 0\,]^T$ for some orthogonal $Q \in M_m$, so

$$QA = \begin{bmatrix} \alpha & * \\ 0 & A_1 \end{bmatrix}.$$

If we write $A_1 \equiv [b_2\ b_3\ \ldots\ b_n]$, then $b_2 \neq 0$ since a_1 and a_2 are linearly independent. There are two possibilities: b_2 is isotropic or is not isotropic.

(i) Suppose $b_2^T b_2 \neq 0$. After applying the preceding argument to A_1, we see that there exists an orthogonal $Q_1 \in M_m$ such that

$$B \equiv Q_1 A = \begin{bmatrix} \alpha & \delta & * \\ 0 & \beta & * \\ 0 & 0 & A_2 \end{bmatrix},\ \alpha, \beta, \delta \in \mathbb{C}, \quad \text{with } \alpha\beta \neq 0,$$

but $A_2 = 0$ since rank $A = 2$. For $n \geq m \geq 3$, and referring to the discussion after Definition 2.7, we see that that $\{G_{13}B, G_{23}B\} \cup \mathcal{S}_B$ is a linearly independent subset of $\mathcal{T}_B$. Hence, dim $\mathcal{T}_A$ = dim $\mathcal{T}_B \geq 2n-1 > m+n-2$.

(ii) If $b_2^T b_2 = 0$, a similar argument shows that there is an orthogonal $Q_1 \in M_m$ such that

$$B \equiv Q_1 A = \begin{bmatrix} \alpha & \delta & * \\ 0 & \beta & z \\ 0 & i\beta & iz \\ 0 & 0 & 0 \end{bmatrix},$$

where $z \in M_{1,n-2}$ and $\beta \neq 0$. Let $X = [\, x_1 \ldots\ x_n\,] \in \mathcal{S}_B$. Then the columns of X have the form

$$x_j = \begin{bmatrix} * \\ a_j \\ ia_j \\ 0 \end{bmatrix}, \qquad j = 1, \ldots, n$$

for some $a_j \in \mathbb{C}$. Hence, for $n \geq m \geq 3$, $\{G_{12}B, G_{13}B\} \cup \mathcal{S}_B$ is a linearly independent subset of $\mathcal{T}_B$. Hence, dim $\mathcal{T}_A$ = dim $\mathcal{T}_B \geq 2n-1 > m+n-2$.

Case 2. $a_1^T a_1 = a_2^T a_2 = 0$. Because $a_1^T a_1 = 0$, there exists an orthogonal $Q \in M_m$ and $\alpha \neq 0$ such that

$$QA = \begin{bmatrix} \alpha & \delta & * \\ i\alpha & \beta & * \\ 0 & b_2 & * \end{bmatrix}.$$

Note that the second column of QA is isotropic and independent of the first column.

(i) If $b_2 = 0$, then there is $\delta \neq 0$ such that

$$B \equiv QA = \begin{bmatrix} \alpha & \delta & * \\ i\alpha & -i\delta & * \\ 0 & 0 & 0 \end{bmatrix}.$$

For $n \geq m \geq 3$, $\{G_{13}B, G_{23}B\} \cup \mathcal{S}_B$ is a linearly independent subset of $\mathcal{T}_B$. Hence, $\dim \mathcal{T}_A \geq 2n - 1 > m + n - 2$.

(ii) If $b_2 \neq 0$ and $b_2^T b_2 \neq 0$, there exists an orthogonal $Q_1 \in M_m$ and $\lambda \neq 0$ such that

$$B \equiv Q_1 A = \begin{bmatrix} \alpha & \delta & * \\ i\alpha & \beta & * \\ 0 & \lambda & * \\ 0 & 0 & 0 \end{bmatrix}.$$

For $n \geq m \geq 4$, $\{G_{14}B, G_{34}B\} \cup \mathcal{S}_B$ is a linearly independent subset of $\mathcal{T}_A$, and $\dim \mathcal{T}_A \geq 2n - 1 > m + n - 2$.

(iii) If $b_2 \neq 0$ and $b_2^T b_2 = 0$, there exists an orthogonal $Q_1 \in M_m$ and $\lambda \neq 0$ such that

$$B \equiv Q_1 A = \begin{bmatrix} \alpha & \delta & * \\ i\alpha & \beta & * \\ 0 & \lambda & * \\ 0 & i\lambda & * \\ 0 & 0 & 0 \end{bmatrix}.$$

Just as in Case 1(ii), $\{G_{13}B, G_{23}B\} \cup \mathcal{S}_B \subset \mathcal{T}_B$ is linearly independent. Hence, for $n \geq m \geq 4$, $\dim \mathcal{T}_A = \dim \mathcal{T}_B \geq 2n - 1 > m + n - 2$.

Therefore, if $A \in M_{m,n}$, $n \geq m \geq 4$, and rank $A = 2$, then $\dim \mathcal{T}_A \geq 2n - 1 > m + n - 2 \geq \dim \mathcal{T}_E$ for any $E \in M_{m,n}$ with rank $E = 1$ by Lemma 2.8(a), (b). Combining this result with Lemma 3.4 proves the following lemma.

LEMMA 3.5. *Proposition* 3.1 *holds if* $n > 4$ *and* $m = n$ *or* $m = n - 1$.

Let $\psi = \{(2,2), (2,3), (3,3), (3,4), (4,4)\}$. If $E \in M_{m,n}$ with $n \geq m$ and $(m,n) \notin \psi$, we have shown that rank $T^{-1}(E) = 1$ whenever rank $E = 1$. We treat the five special cases $(m,n) \in \psi$ separately. We use the following two results.

LEMMA 3.6. *Let* $A \in M_n$. *Then* XA *is skew-symmetric for every skew-symmetric* $X \in M_n$ *if and only if* $A = \alpha I$ *for some* $\alpha \in \mathbb{C}$.

Proof. If $A = \alpha I$, then $XA = \alpha X$ is evidently skew-symmetric. Conversely, if X and XA are skew-symmetric, then $XA = -(XA)^T = -(A^T X^T) = A^T X$. Let $A = [a_{ij}]$ and consider the skew-symmetric matrices $F_{1k} = E_{1k} - E_{k1}$ for $k = 1, \ldots n$.

Then

$$F_{1k}A = \begin{bmatrix} a_{k1} & a_{k2} & \cdots & a_{kk} & \cdots & a_{kn} \\ 0 & 0 & \cdots & 0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ -a_{11} & -a_{12} & \cdots & -a_{1k} & \cdots & -a_{1n} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & 0 & \cdots & 0 \end{bmatrix}$$

and

$$A^T F_{1k} = \begin{bmatrix} -a_{k1} & 0 & \cdots & a_{11} & \cdots & 0 \\ -a_{k2} & 0 & \cdots & a_{12} & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ -a_{kk} & 0 & \cdots & a_{1k} & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ -a_{nk} & 0 & \cdots & a_{1n} & \cdots & 0 \end{bmatrix}.$$

Hence, $a_{kk} = a_{11}$ and $a_{ki} = 0$ for all $i \neq k$. Thus, $A = a_{11}I$. □

LEMMA 3.7. *Let $A \in M_{m,n}$. If* dim $\mathcal{T}_A$ = dim span $\mathcal{S}_{AQ}$ *for some orthogonal $Q \in M_n$, then $AA^T = \alpha I_m$ for some $\alpha \in \mathbb{C}$.*

Proof. Suppose dim $\mathcal{T}_A$ = dim span $\mathcal{S}_{AQ}$. Since dim $\mathcal{T}_A$ = dim $\mathcal{T}_{AQ}$, we have $\mathcal{T}_{AQ}$ = span $\mathcal{S}_{AQ}$. Hence, for each skew-symmetric $Y \in M_m$ there exists a skew-symmetric $X \in M_n$ such that $YAQ = AQX$. Thus $YAA^T = YAQ^T(AQ^T)^T = (AQ)X(AQ)^T$ is skew-symmetric for every skew-symmetric Y, and hence $AA^T = \alpha I_m$ by Lemma 3.6. □

LEMMA 3.8. *Proposition* 3.1 *holds if* $(m, n) = (2, 3)$.

Proof. Suppose $E \in M_{2,3}$ has rank 1. Since rank $T^{-1}(E) \leq m = 2$, there are only two possibilities: rank $T^{-1}(E) = 1$ (which is the assertion of Proposition 3.1), or rank $T^{-1}(E) = 2$. We wish to exclude the latter possibility.

We look at

$$\mathcal{D} \equiv \{Y \in M_{2,3} : \text{ dim } \mathcal{T}_Y \leq 3\}.$$

Since dim $\mathcal{T}_{T^{-1}(Y)} \leq$ dim $\mathcal{T}_Y$, it must be the case that $T^{-1}(Y) \in \mathcal{D}$ whenever $Y \in \mathcal{D}$. If E has rank 1, then Lemma 2.8(a), (b) show that $E \in \mathcal{D}$. Suppose $X \in \mathcal{D}$ and rank $X = 2$. Then Lemma 2.8(c) ensures that dim $\mathcal{T}_X \geq 3$, so that dim $\mathcal{T}_X = 3$ for this case. Hence, Lemma 2.8(e) ensures that there exists an orthogonal $Q \in M_3$ such that dim span $\mathcal{S}_{XQ} = 3$. Lemma 3.7 now guarantees that $XX^T = \beta^2 I_2$ for some $\beta \in \mathbb{C}$. Moreover, Lemma (4.4) of [5] shows that $\beta \neq 0$. It follows from Lemma 2.5 that there exists an orthogonal $Q_1 \in M_3$ such that

$$X = \begin{bmatrix} \beta & 0 & 0 \\ 0 & \beta & 0 \end{bmatrix} Q_1. \tag{3.2}$$

We will show that $T^{-1}(X) \in \mathcal{O}(\alpha X)$ for some $\alpha \neq 0$. Since $X \in \mathcal{D}$, it suffices to show that $T(E) \notin \mathcal{O}(X)$ for each $E \in \mathcal{E} \equiv \{E_{11}, E_{11} + iE_{12}, E_{11} + iE_{21}, E_{11} - E_{22} + iE_{12} + iE_{21}\}$.

Let

$$A \equiv \begin{bmatrix} \beta & 0 & 0 \\ 0 & \beta & 0 \end{bmatrix},$$

so that $\mathcal{O}(A) = \mathcal{O}(X)$. One checks that

$$\mathcal{T}_A = \left\{ \begin{bmatrix} 0 & x & y \\ -x & 0 & z \end{bmatrix} : x, y, z \in \mathbb{C} \right\}.$$

Let $B \in \mathcal{O}(A) \cap \mathcal{T}_A$. Then

$$\begin{bmatrix} x^2 + y^2 & yz \\ yz & x^2 + z^2 \end{bmatrix} = BB^T = \beta^2 I_2.$$

Hence, $y = z = 0$ and $x^2 = \beta^2$. Thus, $\mathcal{O}(A) \cap \mathcal{T}_A$ consists of exactly two vectors.

Let $E \equiv E_{11} - E_{22} + iE_{12} + iE_{21}$. Then $\dim \mathcal{T}_{T^{-1}(E)} \leq \dim \mathcal{T}_E = 2 < \dim \mathcal{T}_B$ for any $B \notin \{0\} \cup \mathcal{O}(E)$. It follows that $T^{-1}(E) \in \mathcal{O}(E)$ and hence, $T(E) \in \mathcal{O}(E)$. Thus, $T(E) \notin \mathcal{O}(A)$.

Suppose that $T(E_{11}) \in \mathcal{O}(A)$, say $T(E_{11}) = Q_2 A Q_3$. Let $T_1 \equiv Q_2^T T Q_3^T$. Then, $A = Q_2^T T(E_{11}) Q_3^T = T_1(E_{11})$. Note that

$$\mathcal{T}_{E_{11}} = \left\{ \begin{bmatrix} 0 & x & y \\ z & 0 & 0 \end{bmatrix} : x, y, z \in \mathbb{C} \right\}.$$

Thus, $\{E_{12}, E_{13}, E_{21}\} \subset \mathcal{O}(E_{11}) \cap \mathcal{T}_{E_{11}}$ so that $\mathcal{O}(E_{11}) \cap \mathcal{T}_{E_{11}}$ contains at least three vectors. Moreover, $\chi \equiv \{T_1(E_{12}), T_1(E_{13}), T_1(E_{21})\}$ contains three vectors since T_1 is nonsingular. However, $\chi \subset T_1(\mathcal{O}(E_{11}) \cap \mathcal{T}_{E_{11}}) \subset \mathcal{O}(T_1(E_{11})) \cap \mathcal{T}_{T_1(E_{11})} = \mathcal{O}(A) \cap \mathcal{T}_A$, which contains exactly two vectors. This contradiction shows that $T(E_{11}) \notin \mathcal{O}(A)$.

Now let $E \equiv E_{11} + iE_{12}$. Then $E = E(-iF_{12}) \in \mathcal{T}_E$. Since $A \notin \mathcal{T}_A$,we have $T(E) \notin \mathcal{O}(A)$ by Lemma 2.2. Similarly, if $E \equiv E_{11} + iE_{21} = (-iG_{12})E$, then $T(E) \notin \mathcal{O}(A)$.

Thus, $T^{-1}(A)$ cannot have rank 1, and hence it has rank 2 and $T^{-1}(A) \in \mathcal{O}(\alpha A)$ for some $\alpha \neq 0$. It follows that $T(\mathcal{O}(A)) \subset \mathcal{O}(\frac{1}{\alpha} A)$ and hence, $T^{-1}(E) \notin \mathcal{O}(\alpha A)$ for all rank-1 $E \in M_{2,3}$, and all $\alpha \neq 0$. Combining this result with the observation that $T^{-1}(Y) \in \mathcal{D}$ for any $Y \in \mathcal{D}$, we see that rank $T^{-1}(E) = 1$ whenever rank $E = 1$. □

LEMMA 3.9. *Proposition* 3.1 *holds if* $(m, n) = (3, 4)$.

Proof. Let $E \in M_{3,4}$ have rank 1 and let $A \equiv T^{-1}(E)$. Lemma 3.4 shows that rank A is either 1 or 2. Suppose rank $A = 2$. We apply the analysis of the proof of Lemma 3.5 to A. Note that Cases 1(i), (ii) and 2(i), (iii) are not possible here. Thus, A has the form covered in Case 2(ii):

$$A = \begin{bmatrix} \alpha & \delta & x_1 & x_4 \\ i\alpha & \beta & x_2 & x_5 \\ 0 & \lambda & x_3 & x_6 \end{bmatrix}$$

with $\lambda \neq 0$ and all the columns of A are isotropic vectors. It now follows from Lemma 2.8(a), (c) and Lemma 2.1 that $\dim \mathcal{T}_A = 5$. Moreover, Lemma 2.8(e) ensures that $\dim \operatorname{span} \mathcal{S}_{AP} = 5$ for some permutation matrix $P \in M_4$. Hence, Lemma 3.7 guarantees that there exists $a \in \mathbb{C}$ such that $AA^T = aI_3$. Since it is always the case that rank $A \geq$ rank AA^T, we must have $a = 0$, that is, the rows of A are also isotropic vectors. Thus, there exists an orthogonal $Q \in M_4$ such that the first row of AQ is $[\ \alpha\ i\alpha\ 0\ 0\ ]$. Since $AA^T = 0$, the third row of AQ has the form $[\ 0\ 0\ c\ d\ ]$, where $c^2 + d^2 = 0$ and $d \neq 0$. It follows that

$$AQ = \begin{bmatrix} \alpha & i\alpha & 0 & 0 \\ i\alpha & -\alpha & ebd & ed \\ 0 & 0 & bd & d \end{bmatrix}$$

with $e^2 = b^2 = -1$ and $\alpha d \neq 0$. By considering all the possible cases, one checks that $G_{12}AQ \notin \text{span } \mathcal{S}_{AQ}$. We show one such case: $b = e = i$. Suppose that $G_{12}AQ = AQ(a_1F_{12} + a_2F_{13} + a_3F_{14} + a_4F_{23} + a_5F_{24})$. Examining the $(1,1), (2,1), (3,1)$, and $(2,4)$ entries, we get $a_1 = -1, a_2 = a_3 = a_5 = 0$. This is a contradiction since for any a_4, $G_{12}AQ \neq -AQF_{12} + a_4AQF_{23}$. Hence, $\dim \mathcal{T}_A = \dim \mathcal{T}_{AQ} \geq 6$, again a contradiction. Since we can exclude all the possibilities associated with rank $A = 2$, it follows that rank $A = 1$. □

LEMMA 3.10. *Proposition* 3.1 *holds if* $(m,n) = (4,4)$.

Proof. If $A \in M_4$ has rank 2, then $\dim \mathcal{T}_A \geq 7$ as shown on the proof of Lemma 3.5. Let $B \equiv E_{11} - E_{22} + iE_{12} + iE_{21}$. Then $\dim \mathcal{T}_{T^{-1}(B)} \leq \dim \mathcal{T}_B \leq \dim \mathcal{T}_C$ for any $C \notin \{0\} \cup \mathcal{O}(B)$ and hence, $T^{-1}(B) \in \mathcal{O}(B)$ has rank 1. Let $D \equiv \text{diag}\,(1, -1, 1, 1)$. Then $E_{11} + iE_{12} = \frac{1}{2}(B + DB)$ and $T^{-1}(E_{11} + iE_{12}) = \frac{1}{2}(T^{-1}(B) + T^{-1}(DB))$, a sum of two rank 1 matrices. Hence, $T^{-1}(E_{11} + iE_{12})$ has rank at most 2. But since $\dim \mathcal{T}_C \leq 6 < 7 \leq \dim \mathcal{T}_A$ for all $A, C \in M_4$ such that rank $C = 1$ and rank $A = 2$, we must have rank $T^{-1}(C) \neq 2$ so that rank $T^{-1}(E_{11} + iE_{12}) = 1$. Similarly, since $E_{11} + iE_{21} = \frac{1}{2}(B + BD)$ and $E_{11} = \frac{1}{2}((E_{11} + iE_{12}) + (E_{11} + iE_{12})D)$, both $T^{-1}(E_{11} + iE_{21})$ and $T^{-1}(E_{11})$ have rank 1. Thus, if $E \in M_4$ has rank 1, then $T^{-1}(E)$ must also have rank 1. □

Let T be a nonsingular linear orthogonal equivalence preserver on $M_{m,n}$, with $m \leq n$ and $(m,n) \notin \{(2,2),(3,3)\}$. Our arguments up to this point show that T^{-1} preserves rank 1 matrices, that is, $T^{-1}(E)$ has rank 1 whenever $E \in M_{m,n}$ has rank 1. Theorem 1 of [8] guarantees that there exist nonsingular $X \in M_m$ and $Y \in M_n$ such that either $T^{-1}(A) = XAY$ for all $A \in M_{m,n}$, or $m = n$ and $T^{-1}(A) = XA^TY$ for all $A \in M_n$. Hence, either $T(A) = MAN$ for all $A \in M_{m,n}$, or $m = n$ and $T(A) = MA^TN$ for all $A \in M_n$, where $M \equiv X^{-1}$ and $N \equiv Y^{-1}$. We will now show that the same conclusion can be drawn for the two remaining cases $(m,n) = (2,2), (3,3)$, from which Proposition 3.1 follows in these two cases.

LEMMA 3.11. *Let* T *be a nonsingular linear operator on* M_n *that preserves orthogonal equivalence. If* $n = 2$ *or* $n = 3$, *then there exists a scalar* $\alpha \neq 0$ *such that* $T^{-1}(I_n) \in \mathcal{O}(\alpha I_n)$.

Proof. First note that $X_n \equiv E_{11} - E_{22} + iE_{12} + iE_{21} = X_n(iF_{12}) \in \mathcal{T}_{X_n}$ for all $n = 2, 3, \ldots$, where $E_{ij}, X_n \in M_n$. Note also that, $\mathcal{T}_{I_n} = \{X \in M_n : X + X^T = 0\}$ is the set of all skew symmetric matrices in M_n. Hence, $\dim \mathcal{T}_{I_n} = \frac{n(n-1)}{2}$. Moreover, $I_n \notin \mathcal{T}_{I_n}$ for each n.

Let $n = 2$. Then $\dim \mathcal{T}_{I_2} = 1$. It follows from Lemma 2.8(a)–(c) that either $T^{-1}(I_2)$ is nonsingular or $T^{-1}(I_2) \in \mathcal{O}(X_2)$. However, $T^{-1}(I_2) \notin \mathcal{O}(X_2)$ by Lemma 2.2. Thus, $T^{-1}(I_2)$ is nonsingular and Lemma 2.8(e) implies that $\dim \mathcal{T}_{T^{-1}(I_2)} = 1 = \dim \text{span } \mathcal{S}_{I_2Q}$ for some permutation matrix $Q \in M_2$. Lemma 3.7 guarantees that $T^{-1}(I_2) \in \mathcal{O}(\beta I_2)$ for some $\beta \neq 0$.

Let $n = 3$. A similar argument shows that either

$$\text{rank } T^{-1}(I_3) \geq 2 \quad \text{or} \quad T^{-1}(I_3) \in \mathcal{O}(X_3),$$

and that the latter possibility is excluded. Hence, rank $T^{-1}(I_3) \geq 2$. Let $A \equiv T^{-1}(I_3)$. Then $\dim \mathcal{T}_A = 3 = \dim \text{span } \mathcal{S}_{AQ}$ for some permutation matrix $Q \in M_3$. Hence, $AA^T = \alpha I_3$ by Lemma 3.7, and Lemma 4.4 of [5] again guarantees that $\alpha \neq 0$. Therefore, $T^{-1}(I_3) \in \mathcal{O}(\beta I_3)$ with $\beta^2 = \alpha \neq 0$. □

Suppose $n = 2$ or 3. Then Lemma 3.11 ensures that $T^{-1}(I_n) \in \mathcal{O}(\alpha I_n)$. Hence, $T_1 \equiv \alpha T$ satisfies $T_1^{-1}(I_n) \in \mathcal{O}(I_n)$. It follows that $T_1(\mathcal{O}(I_n)) \subset \mathcal{O}(I_n)$. Lemma 1 of [4] guarantees that $T_1(\mathcal{O}(I_n)) = \mathcal{O}(I_n)$. Thus, Lemma 6 of [2] guarantees that there

exist nonsingular $M, N \in M_n$ such that either $T_1(A) = MAN$ or $T_1(A) = MA^TN$ for all $A \in M_n$. It follows that Proposition 3.1 holds for these two cases as well.

The preceding ten lemmata constitute a proof of all cases of Proposition 3.1 in which $m \leq n$. The remaining cases follow from considering $T_1(X) \equiv T(X^T)$ and applying the known cases to $T_1 : M_{n,m} \to M_{n,m}$.

The following proposition summarizes the main conclusions of this section.

PROPOSITION 3.12. *Let T be a nonsingular linear operator on $M_{m,n}$ that preserves orthogonal equivalence. Then there exist nonsingular $M \in M_m$ and $N \in M_n$ such that either*

(1) *$T(A) = MAN$ for all $A \in M_{m,n}$, or*

(2) *$m = n$ and $T(A) = MA^TN$ for all $A \in M_{m,n}$.*

4. Proof of the main theorem. Let T be a given linear operator on $M_{m,n}$. Suppose T preserves orthogonal equivalence. Then Lemma 2.4 guarantees that either $T = 0$ or T is nonsingular. If $T = 0$, then Theorem 1.1 holds with $\alpha = 0$. If $T \neq 0$, we will use the following to show that Theorem 1.1 still holds.

PROPOSITION 4.1. *Let $A \in M_n$ be nonsingular. Suppose that*

$$x^TA^TAx = x^TP^TA^TAPx$$

for all orthogonal $P \in M_n$ and all $x \in \mathbb{C}^n$. Then there exist an orthogonal $Q \in M_n$ and a scalar $\alpha \neq 0$ such that $A = \alpha Q$.

Proof. An easy polarization argument shows that if $C \in M_n$ is symmetric and $x^TCx = 0$ for all $x \in \mathbb{C}^n$, then $C = 0$. Since $x^TA^TAx = x^TP^TA^TAPx$ for all $x \in \mathbb{C}^n$, it follows that $A^TA = P^TA^TAP$ for all orthogonal $P \in M_n$. Hence,

$$A^TA = \begin{bmatrix} \alpha & \beta & \cdots & \beta \\ \beta & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \beta \\ \beta & \cdots & \beta & \alpha \end{bmatrix}.$$

Let $x \equiv [\ 1\ 1\ 0\ \ldots\ 0\ ]^T$ and $y \equiv [\ \sqrt{2}\ 0\ 0\ \ldots\ 0\ ]^T \in \mathbb{C}^n$. Then $x^Tx = y^Ty$ and hence there exists an orthogonal $Q_1 \in M_n$ such that $y = Q_1x$. Now, $2\alpha + 2\beta = x^TA^TAx = x^TQ_1^TA^TAQ_1x = y^TA^TAy = 2\alpha$. Hence, $\beta = 0$ and $A^TA = \alpha I$ with $\alpha \neq 0$ since A is nonsingular. Thus, $Q \equiv \frac{1}{\sqrt{\alpha}}A$ is orthogonal and $A = \sqrt{\alpha}Q$. □

LEMMA 4.2. *Let T be a given nonsingular linear operator on $M_{m,n}$. Then T preserves orthogonal equivalence if and only if there exist orthogonal matrices $Q_1 \in M_m$, $Q_2 \in M_n$, and a scalar $\beta \neq 0$ such that either*

(1) *$T(A) = \beta Q_1AQ_2$ for all $A \in M_{m,n}$, or*

(2) *$m = n$ and $T(A) = \beta Q_1A^TQ_2$ for all $A \in M_n$.*

Proof. Under the stated assumptions, Proposition 3.12 ensures that there exist nonsingular $M \in M_m$ and $N \in M_n$ such that either $T(A) = MAN$ for all $A \in M_{m,n}$, or $m = n$ and $T(A) = MA^TN$ for all $A \in M_{m,n}$. We consider only the case $T(A) = MAN$; the case $T(A) = MA^TN$ can be dealt with similarly. Let an orthogonal $P \in M_n$ be given. Since T preserves orthogonal equivalence, for each $A \in M_{m,n}$ there exist orthogonal matrices $Q \in M_m$ and $Z \in M_n$ (which depend on A and P) such that $T(A) = QT(AP)Z$. Hence,

$$\begin{aligned} MAN(MAN)^T &= T(A)T(A)^T \\ &= QT(AP)Z(QT(AP)Z)^T \\ &= QMAPN(MAPN)^TQ^T. \end{aligned} \tag{4.1}$$

Choose

$$A \equiv M^{-1} \begin{bmatrix} x^T \\ 0 \end{bmatrix},$$

where $x \in \mathbb{C}^n$. Then (4.1) becomes

$$\begin{bmatrix} x^T NN^T x & 0 \\ 0 & 0 \end{bmatrix} = Q \begin{bmatrix} x^T PNN^T P^T x & 0 \\ 0 & 0 \end{bmatrix} Q^T.$$

Since $Q^T = Q^{-1}$, taking the trace of both sides shows that $x^T NN^T x = x^T PNN^T P^T x$. Since this identity holds for all $x \in \mathbb{C}^n$ and all orthogonal $P \in M_n$, Proposition 4.1 ensures that $N = \alpha_2 Q_2$ for some orthogonal $Q_2 \in M_n$ and some scalar $\alpha_2 \neq 0$. A similar analysis of $T(A)^T T(A)$ shows that $M = \alpha_1 Q_1$ for some orthogonal $Q_1 \in M_m$ and some scalar $\alpha_1 \neq 0$. □

This completes the proof of the forward implication of Theorem 1.1. The converse can be easily verified.

A PARALLEL ALGORITHM FOR COMPUTING THE SINGULAR VALUE DECOMPOSITION OF A MATRIX*

E. R. JESSUP† AND D. C. SORENSEN‡

Abstract. A parallel algorithm for computing the singular value decomposition of a matrix is presented. The algorithm uses a divide and conquer procedure based on a rank one modification of a bidiagonal matrix. Numerical difficulties associated with forming the product of a matrix with its transpose are avoided, and numerically stable formulae for obtaining the left singular vectors after computing updated right singular vectors are derived. A deflation technique is described that, together with a robust root finding method, assures computation of the singular values to full accuracy in the residual and also assures orthogonality of the singular vectors.

Key words. bidiagonal matrix, singular value decomposition, divide and conquer algorithm

AMS subject classifications. 15A18, 65Y05

1. Introduction.

The singular value decomposition (SVD) of a real $m \times n$ matrix A can be written

$$A = U\Sigma V^T,$$

where U and V are both orthogonal matrices and Σ is a diagonal matrix with nonnegative diagonal elements. The columns of U and V are, respectively, the left and right singular vectors of A; the diagonal elements of Σ are its singular values. A standard algorithm for computing the SVD involves first reducing a matrix A to upper bidiagonal form B using elementary orthogonal transformations [12], [13] as follows:

$$A = \hat{U}B\hat{V}^T$$

and then computing the SVD of $B = \hat{Y}\Sigma\hat{X}^T$. Combining the two results gives

$$A = \hat{U}(\hat{Y}\Sigma\hat{X}^T)\hat{V}^T = U\Sigma V^T,$$

where $U = \hat{U}\hat{Y}$ and $V = \hat{V}\hat{X}$.

This paper focuses on the computation of the SVD of the bidiagonal matrix B by divide and conquer mechanisms based on rank one tearing of the bidiagonal matrix B. Algorithms founded on this technique have proven accurate and efficient for both serial and parallel computation of eigensystems of symmetric tridiagonal matrices [6], [10]. The notable speed and accuracy of the rank one updating process for that problem motivate application of rank one updating techniques to the SVD.

The presentation of the updating technique begins in §2 with a review of the rank one updating techniques used for the symmetric tridiagonal eigenproblem. Section 3 continues with a discussion of some difficulties arising in the design of an SVD

algorithm that is both accurate and efficient. Section 4 describes a basic divide and conquer step for the SVD equivalent to a rank one tearing of a symmetric tridiagonal matrix.

Sections 5 and 6 are devoted to finite precision deflation rules and the orthogonality of the computed singular vectors. Section 7 covers implementation of the divide and conquer algorithm PSVD and the results of numerical experiments.

In all sections, we consider only the case $m = n$. If $m > n$, the initial reduction may be preceded by computing a QR factorization of A and using the $n \times n$ triangular matrix R in place of A. A similar procedure is appropriate for the case $m < n$.

Throughout this paper, unless otherwise specified, capital Roman letters represent matrices, lower case Roman letters represent column vectors, and lower case Greek letters represent scalars. A superscript T denotes transpose. All matrices and vectors are real.

2. Divide and conquer for the symmetric tridiagonal eigenproblem. In [6], Cuppen presents a divide and conquer technique for finding the eigenvalues and eigenvectors of a symmetric tridiagonal matrix. Rank one tearing is applied to divide the tridiagonal matrix T of order n into

$$T = \begin{pmatrix} \tilde{T}_1 & \beta e_k e_1^T \\ \beta e_1 e_k^T & \tilde{T}_2 \end{pmatrix} = \begin{pmatrix} T_1 & 0 \\ 0 & T_2 \end{pmatrix} + \beta \begin{pmatrix} e_k \\ e_1 \end{pmatrix} (e_k^T, \quad e_1^T),$$

where $1 \leq k \leq n$, and e_j represents the jth canonical vector of appropriate length. If the eigensystems of the two submatrices are $T_1 = Q_1 D_1 Q_1^T$ and $T_2 = Q_2 D_2 Q_2^T$, then

$$T = Q \left[D + \beta \begin{pmatrix} z_1 \\ z_2 \end{pmatrix} (z_1^T, \quad z_2^T) \right] Q^T = Q \left[D + \rho z z^T \right] Q^T,$$

where

$$Q = \begin{pmatrix} Q_1 & 0 \\ 0 & Q_2 \end{pmatrix}, \qquad D = \begin{pmatrix} D_1 & 0 \\ 0 & D_2 \end{pmatrix},$$

z_1^T is the last row of Q_1, z_2^T is the first row of Q_2, and ρ is chosen so that $\| z \|_2 = 1$. The problem is then reduced to finding the eigensystem of a diagonal matrix plus a rank one change. The eigenvalues of T are equal to the eigenvalues of $D + \rho z z^T$; the eigenvectors of T are the eigenvectors of $D + \rho z z^T$ premultiplied by the matrix Q.

An updating technique described in [5], [6], and [11] is employed to determine the eigensystem of $D + \rho z z^T$. When the diagonal elements of D are distinct and the elements of z are nonzero, the eigenvalues of $D + \rho z z^T$ are equal to the roots of

$$w(\lambda) = 1 + \rho z^T (D - \lambda I)^{-1} z^T$$

and can be determined efficiently by a rational interpolation scheme developed in [5]. The eigenvector corresponding to the ith eigenvalue λ_i is found directly from

$$u_i = (D - \lambda_i I)^{-1} z.$$

When the diagonal elements of $D = \mathrm{diag}(\delta_1, \ldots, \delta_n)$ are not distinct (i.e., $\delta_k = \delta_{k+1} = \cdots = \delta_{k+l}$), the eigenvector basis is rotated to zero out the components $\zeta_{k+1}, \ldots, \zeta_{k+l}$ of z corresponding to the repeated diagonal elements of D [5]. When the jth element of z is zero, the element δ_j is an eigenvalue of $D + \rho z z^T$, and the jth unit vector e_j is its corresponding eigenvector.

Multiple diagonal elements of D and zero elements of z result in significant reduction in the work required to compute the eigensystem of $D+\rho zz^T$. This phenomenon called *deflation* has been refined for use in finite precision arithmetic where *nearly equal* diagonal elements of D and *small* elements of z are deflated [10]. As shown in [6], [10], and [15], substantial deflation and resulting savings in computation time occurs for a wide variety of symmetric tridiagonal eigenproblems. The computed eigensystem is obtained to high accuracy, and the computed eigenvectors are orthogonal [10], [14], and [20].

An experimental comparison in [16] finds the implementation TREEQL [10] of the divide and conquer method and bisection with inverse iteration to be the fastest serial techniques for solving the symmetric tridiagonal eigenproblem. TREEQL is generally fastest when deflation is significant. The QL method (implemented as EISPACK's TQL2 [18]) is generally slowest. All three demonstrate comparable high accuracy in practice, although only TREEQL, TQL2, and bisection can be proven to be backward stable [3], [7]. TREEQL is also fast on shared-memory multiprocessors [10], but is less efficient on statically scheduled distributed-memory multiprocessors [14].

3. Background. The bidiagonal SVD is closely related to the symmetric tridiagonal eigenproblem. For example, the matrix products $\hat{T}_1 = B^TB$ and $\hat{T}_2 = BB^T$ are symmetric tridiagonal matrices of order n having as eigenvalues the squares of the singular values of B and having as eigenvectors, respectively, the left and right singular vectors of B. Thus, one way to determine the SVD of B is to compute the eigendecompositions $\hat{T}_1 = X\Sigma^2X^T$ and $\hat{T}_2 = Y\Sigma^2Y^T$. This approach, however, can be both inefficient and inaccurate. In this section, we review the drawbacks of using eigensolvers to compute $B = Y\Sigma X^T$.

First, finding the eigendecomposition of $\hat{T}_1$ gives only the singular values and the left singular vectors of B. Computing the eigendecomposition of $\hat{T}_2$ gives the left vectors Y but requires redundant computation of the singular value matrix Σ. Because X and Y are computed independently, it is also generally impossible to correctly pair the left and right singular vectors associated with equal or nearly equal singular values. It is preferable to compute each right singular vector using suitable relationships to its corresponding left singular vector.

The vector pairing problem can be overcome by computing the matrix of right singular vectors directly from $X = B^TY\Sigma^{-1}$. This approach fails, however, when Σ has a zero diagonal element. Moreover, numerical experiments have shown an increased residual and degraded orthogonality of right singular vectors computed this way for matrices with large condition numbers. This is particularly disturbing as the SVD is often called upon when a matrix has a large condition number. Attempts to avoid conditioning problems through a combination of the two equations such as

$$(B+\sigma I)x = (B+\sigma I)^T y \tag{1}$$

can fail when there are a significant number of small singular values. However, Arbenz and Golub [2] suggest an iterative procedure using a modified Lanczos process that essentially corrects initial numerical errors made in (1).

Inaccuracies in the small singular values can also result from multiplication of B and its transpose in finite precision arithmetic [13]. For example, suppose that $\mathrm{fl}(1+\epsilon^2) = 1$ in finite precision arithmetic. If

$$B = \begin{pmatrix} 1 & 0 \\ 1 & \epsilon \end{pmatrix},$$

then the computed product $T^T = BB^T$ is

$$\text{fl}\left[\begin{pmatrix} 1 & 0 \\ 1 & \epsilon \end{pmatrix}\begin{pmatrix} 1 & 1 \\ 0 & \epsilon \end{pmatrix}\right] = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$$

with exact eigenvalues 0 and 2. The computed singular values of B are then 0 and $\sqrt{2}$, while the true singular values are

$$\left(\frac{2\epsilon^2}{2+\epsilon^2+\sqrt{4+\epsilon^4}}\right)^{1/2}$$

and

$$\left(\frac{2+\epsilon^2+\sqrt{4+\epsilon^4}}{2}\right)^{1/2}.$$

For this matrix, the relative error in the smallest computed singular value is 1.

Some existing techniques for the solution of the singular value problem bypass these numerical problems by operating on the matrix B and implicitly forming the product BB^T. The Golub–Reinsch QL method [12], [13] for computing the SVD, for example, has been implemented as the LINPACK routine DSVDC. When using rank one updating techniques, however, it is not convenient to represent the torn matrix as the product of bidiagonal matrices in this way; it is necessary to devise a different way to work with the matrix product implicitly.

A final alternative that permits computation of a correct SVD is to embed the order n bidiagonal matrix in an order $2n$ symmetric banded matrix: the eigenvalues of the $2n \times 2n$ matrix

$$M_1 = \begin{pmatrix} 0 & B^T \\ B & 0 \end{pmatrix}$$

are the singular values of B and their negatives. To compute the SVD of B, the columns and rows of M_1 are permuted to the order $1, n+1, 2, n+2, \ldots, n, 2n$ to form the $2n \times 2n$ tridiagonal matrix M_2 with a zero diagonal. The eigenvector u_i of M_2 corresponding to eigenvalue $\lambda_i = \sigma_i$ has as its odd-numbered components, the components of the ith left singular vector $y_i = (\nu_{1i}, \ldots, \nu_{ni})^T$ and has as its even-numbered components, the components of the ith right singular vector $x_i = (\mu_{1i}, \ldots, \mu_{ni})^T$ [12]:

$$M_2 \begin{pmatrix} \nu_{1i} \\ \mu_{1i} \\ \vdots \\ \nu_{ni} \\ \mu_{ni} \end{pmatrix} = \sigma_i \begin{pmatrix} \nu_{1i} \\ \mu_{1i} \\ \vdots \\ \nu_{ni} \\ \mu_{ni} \end{pmatrix}.$$

Methods for the symmetric tridiagonal eigenproblem are then applied directly to the matrix M_2. This approach is efficient for methods that can take advantage of the zero structure of M_2 and that can compute the first n eigenpairs independently of the second n eigenpairs. Bisection with inverse iteration, for example, falls into this category; the divide and conquer method of [6] and [10] described in §2 does not [15]. A divide and conquer strategy that maintains the zero diagonal in the torn submatrices is described in [1].

The remainder of this paper discusses a method for computing the SVD that is both efficient and stable. It implicitly formulates the matrix product BB^T in a way that avoids cancellation in finite precision arithmetic, and it computes each right singular vector from its corresponding left singular vector. The formulation presented here is the most accurate of several alternatives considered in [17].

4. Divide and conquer for the bidiagonal SVD. This section presents a divide and conquer technique designed for use with the matrix B. It is an efficient alternative to the divide and conquer eigensolver applied to a $2n \times 2n$ tridiagonal matrix. It avoids the numerical difficulties associated with explicit formation of BB^T or B^TB by reformulating the product to prevent cancellation. The algorithm relies on rank one tearing. Specifically, the rank one modification of the matrix B

$$B = \begin{pmatrix} B_1 & \beta e_k e_1^T \\ 0 & B_2 \end{pmatrix} = \begin{pmatrix} B_1 & 0 \\ 0 & B_2 \end{pmatrix} + \beta \begin{pmatrix} e_k \\ 0 \end{pmatrix} (0, e_1^T), \tag{2}$$

where $\beta = \beta_k$ allows implicit formation of BB^T as follows:

$$\begin{aligned} BB^T &= \begin{pmatrix} B_1 & \beta e_k e_1^T \\ 0 & B_2 \end{pmatrix} \begin{pmatrix} B_1^T & 0 \\ \beta e_1 e_k^T & B_2^T \end{pmatrix} \\ &= \begin{pmatrix} B_1 B_1^T & 0 \\ 0 & B_2(I - e_1 e_1^T) B_2^T \end{pmatrix} + \begin{pmatrix} \beta e_k \\ B_2 e_1 \end{pmatrix} (\beta e_k^T, e_1^T B_2^T) \\ &= \begin{pmatrix} B_1 B_1^T & 0 \\ 0 & \hat{B}_2 \hat{B}_2^T \end{pmatrix} + \begin{pmatrix} \beta e_k \\ \alpha e_1 \end{pmatrix} (\beta e_k^T, \alpha e_1^T), \end{aligned} \tag{3}$$

where the matrix

$$\hat{B}_2 = B_2 \begin{pmatrix} 0 & 0 \\ 0 & I \end{pmatrix}$$

is the bidiagonal matrix B_2 with its first column replaced by the zero vector and $\alpha e_1 = B_2 e_1$. This splitting may be considered a special case of the general rank one updates to the SVD described in [4].

The SVDs $B_1 = U_1 \Sigma_1 V_1^T$ and $\hat{B}_2 = \hat{U}_2 \hat{\Sigma}_2 \hat{V}_2^T$ can be computed independently and used with (4) to produce

$$\begin{aligned} BB^T &= \begin{pmatrix} U_1 \Sigma_1^2 U_1^T & 0 \\ 0 & \hat{U}_2 \hat{\Sigma}_2^2 \hat{U}_2^T \end{pmatrix} + \begin{pmatrix} \beta e_k \\ \alpha e_1 \end{pmatrix} (\beta e_k^T, \alpha e_1^T), \\ &= \begin{pmatrix} U_1 & 0 \\ 0 & \hat{U}_2 \end{pmatrix} \left[\begin{pmatrix} \Sigma_1^2 & 0 \\ 0 & \hat{\Sigma}_2^2 \end{pmatrix} + \begin{pmatrix} u_1 \\ \hat{u}_2 \end{pmatrix} (u_1^T, \hat{u}_2^T) \right] \begin{pmatrix} U_1^T & 0 \\ 0 & \hat{U}_2^T \end{pmatrix}, \end{aligned} \tag{4}$$

where $u_1 = \beta U_1^T e_k$ and $\hat{u}_2 = \alpha \hat{U}_2^T e_1$. The eigendecomposition of the diagonal plus rank one matrix can be found via the updating techniques derived in [5], [10], and [11] and summarized in §2.

This computation requires that the diagonal elements of the matrix

$$\begin{pmatrix} \Sigma_1^2 & 0 \\ 0 & \hat{\Sigma}_2^2 \end{pmatrix}$$

be distinct and that the elements of $(u_1^T, \hat{u}_2^T)$ be nonzero. When these assumptions do not hold, the problem deflates. However, because the squares of the singular

values less than one are not as well separated as the singular values themselves, the deflation rules of [10] concerning nearly equal diagonal values are not appropriate. To develop deflation rules for the SVD, it is necessary to reformulate the basic step of the updating process and to provide rules based on the original data rather than on the squared data appearing in (4).

To this end, let the $(n-k) \times (n-k-1)$ matrix $\tilde{B}_2$ be defined by

$$(0, \tilde{B}_2) \equiv \hat{B}_2 \equiv B_2 \left(I - e_1 e_1^T\right).$$

Now consider the SVD of $\tilde{B}_2 = \tilde{U}_2 \tilde{\Sigma}_2 \tilde{V}_2^T$, and note that

$$\hat{B}_2 = \begin{pmatrix} \tilde{U}_2 & \tilde{u} \end{pmatrix} \begin{pmatrix} \tilde{\Sigma}_2 \\ 0^T \end{pmatrix} \tilde{V}_2^T,$$

where $\tilde{u}$ is a unit vector orthogonal to the columns of $\tilde{U}_2$. When $B_1 = U_1 \Sigma_1 V_1^T$,

$$B = \begin{pmatrix} U_1 & 0 & 0 \\ 0 & \tilde{U}_2 & \tilde{u} \end{pmatrix} \begin{pmatrix} \Sigma_1 & u_1 & 0 \\ 0 & u_2 & \tilde{\Sigma}_2 \\ 0 & \mu & 0 \end{pmatrix} \begin{pmatrix} V_1^T & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & \tilde{V}_2^T \end{pmatrix}. \tag{5}$$

For notational convenience, we permute (5) to obtain

$$B = \begin{pmatrix} U_1 & 0 & 0 \\ 0 & \tilde{U}_2 & \tilde{u} \end{pmatrix} \begin{pmatrix} \Sigma_1 & 0 & u_1 \\ 0 & \tilde{\Sigma}_2 & u_2 \\ 0 & 0 & \mu \end{pmatrix} \begin{pmatrix} V_1^T & 0 & 0 \\ 0 & 0 & \tilde{V}_2^T \\ 0 & 1 & 0 \end{pmatrix}.$$

Deflation rules are then needed for the interior matrix

$$\bar{M} \equiv \begin{pmatrix} \bar{\Sigma} & \bar{u} \\ 0 & \mu \end{pmatrix} \equiv \begin{pmatrix} \Sigma_1 & 0 & u_1 \\ 0 & \tilde{\Sigma}_2 & u_2 \\ 0 & 0 & \mu \end{pmatrix}, \tag{6}$$

where $\bar{\Sigma} = \operatorname{diag}(\bar{\sigma}_1, \ldots, \bar{\sigma}_{n-1})$ and $\bar{u} = (\bar{\mu}_1, \ldots, \bar{\mu}_{n-1})$. (The matrices of (5) are not explicitly permuted in the implementation of PSVD described in §7.)

The deflation procedure for $\bar{M}$ resembles that for tridiagonal matrices. In exact arithmetic, the problem deflates whenever any of the following cases occur:

1. An element of $\bar{u}$ is zero: $\bar{\mu}_j = 0$.
2. Diagonal elements of $\bar{\Sigma}$ are equal: $\bar{\sigma}_i = \bar{\sigma}_j$, $i \neq j$.
3. A diagonal element of $\bar{\Sigma}$ is zero: $\bar{\sigma}_j = 0$.

It is easily verified that if $\bar{\mu}_j = 0$, $\bar{\sigma}_j$ is a singular value of $\bar{M}$ with left and right singular vectors equal to the jth canonical vector e_j providing the deflation for case 1. The other two cases may be reduced to case 1 using appropriate plane rotations to introduce a zero component in the vector $\bar{u}$.

When $\bar{\sigma}_i = \bar{\sigma}_j$, two-sided rotations are applied as in the tridiagonal case. A plane rotation G_1 in the (i,j)-plane is constructed and applied to $\bar{M}$ (and to the other matrix factors in (6) as well) so that

$$\bar{M} \leftarrow \begin{pmatrix} G_1 & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} \bar{\Sigma} & \bar{u} \\ 0 & \mu \end{pmatrix} \begin{pmatrix} G_1^T & 0 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} G_1 \bar{\Sigma} G_1^T & G_1 \bar{u} \\ 0 & \mu \end{pmatrix}.$$

A 2×3 submatrix of $\bar{M}$ is affected as follows:

$$\begin{pmatrix} c & -s \\ s & c \end{pmatrix} \begin{pmatrix} \sigma & 0 & \bar{\mu}_i \\ 0 & \sigma & \bar{\mu}_j \end{pmatrix} \begin{pmatrix} c & s & 0 \\ -s & c & 0 \\ 0 & 0 & 1 \end{pmatrix} = \begin{pmatrix} \sigma & 0 & 0 \\ 0 & \sigma & \tau \end{pmatrix},$$

where $\sigma = \bar{\sigma}_i = \bar{\sigma}_j$, with $\tau^2 = (\bar{\mu}_i)^2 + (\bar{\mu}_j)^2$, $c = \bar{\mu}_j/\tau$, and $s = \bar{\mu}_i/\tau$.

When $\bar{\sigma}_i = 0$, a one-sided rotation G_2 in the (i,n)-plane is applied from the left using μ to zero out $\bar{\mu}_i$: In this case

$$\bar{M} \leftarrow G_2 \bar{M}$$

and a 2×2 submatrix is affected as follows:

$$\begin{pmatrix} c & -s \\ s & c \end{pmatrix} \begin{pmatrix} \bar{\sigma}_i & \bar{\mu}_i \\ 0 & \mu \end{pmatrix} = \begin{pmatrix} 0 & 0 \\ 0 & \tau \end{pmatrix}$$

because $\bar{\sigma}_i = 0$.

In practice, these deflation rules must be modified to accommodate the limitations of finite precision arithmetic. Finite precision rules are given in §7 that apply when $\bar{\Sigma}$ or $\bar{u}$ has small elements or when $\bar{\Sigma}$ has close elements.

Permuting so that all zero elements in the last column are grouped together, the result of deflation is a matrix of the form

$$\bar{M}' = PH\bar{M}G^T P^T = \begin{pmatrix} \hat{\Sigma}_1 & 0 & 0 \\ 0 & \tilde{\Sigma} & u \\ 0 & 0 & \mu \end{pmatrix},$$

where $\tilde{\Sigma}$ has distinct, positive elements, and the vector u has only nonzero elements. P is the appropriate permutation matrix, and G and H are matrices consisting of accumulated products of the rotations constructed at each of the deflation steps.

After deflation, one only needs to compute the SVD of

$$M \equiv \begin{pmatrix} \tilde{\Sigma} & u \\ 0 & \mu \end{pmatrix} \equiv Y \Sigma X^T. \tag{7}$$

The diagonal elements of $\hat{\Sigma}_1$ are taken as singular values of $\bar{M}$ with appropriate canonical vectors as singular vectors. The squares of the singular values of M and its left singular vectors are given by the eigendecomposition

$$Y\Sigma^2 Y^T \equiv MM^T \equiv \begin{pmatrix} \tilde{\Sigma}^2 & 0 \\ 0 & 0 \end{pmatrix} + \begin{pmatrix} u \\ \mu \end{pmatrix} (u^T, \quad \mu).$$

An eigenvalue σ^2 of MM^T is a root of the secular equation

$$f(\sigma^2) = 1 + u^T(\tilde{\Sigma}^2 - \sigma^2 I)^{-1} u - \left(\frac{\mu}{\sigma}\right)^2 \tag{8}$$

and can be computed using the root-finder from [5]. If the sorted diagonal elements of $\mathrm{diag}(\tilde{\Sigma}^2, 0)$ are $0 = \tilde{\sigma}_1^2 < \tilde{\sigma}_2^2 < \cdots < \tilde{\sigma}_n^2$, the jth eigenvalue σ_j^2 of MM^T lies in the interval $(\tilde{\sigma}_j^2, \tilde{\sigma}_{j+1}^2)$ [5], and all eigenvalues are positive. The jth singular value of B is σ_j, and the left singular vector of B associated with σ_j for $j = 1, \ldots, n$ is

$$y_j = \begin{pmatrix} (\tilde{\Sigma}^2 - \sigma_j^2 I)^{-1} u \\ -\mu/\sigma_j^2 \end{pmatrix} \theta,$$

where θ is a normalization factor. The corresponding right singular vector is

$$x_j = \frac{M^T y_j}{\| M^T y_j \|_2}.$$

That is, a vector in the direction of the right singular vector x_j is given by

$$M^T y_j = \begin{pmatrix} \tilde{\Sigma}^2 & 0 \\ u^T & \mu \end{pmatrix} \begin{pmatrix} (\tilde{\Sigma}^2 - \sigma_j^2 I)^{-1} u \\ -\mu/\sigma_j^2 \end{pmatrix} \theta$$

$$= \begin{pmatrix} \tilde{\Sigma}^2 (\tilde{\Sigma}^2 - \sigma_j^2 I)^{-1} u \\ u^T (\tilde{\Sigma}^2 - \sigma_j^2 I)^{-1} u - \mu/\sigma_j^2 \end{pmatrix} \theta.$$

Recall from (8) that σ_j satisfies

$$u^T (\tilde{\Sigma}^2 - \sigma_j^2 I)^{-1} u + \left(\frac{\mu}{\sigma_j}\right)^2 = -1.$$

Thus, the quantities σ_j, x_j, and y_j can be computed as follows

PROCEDURE 4.1 (SOLUTION OF THE DEFLATED UPDATING PROBLEM).

1. Solve (8) for σ_j.
2. $y = \begin{pmatrix} v_j \\ \eta_j \end{pmatrix} = \begin{pmatrix} (\tilde{\Sigma}^2 - \sigma_j^2 I)^{-1} u \\ -\mu/\sigma_j^2 \end{pmatrix}$.
3. $x = \begin{pmatrix} \tilde{\Sigma}^2 v_j \\ -1 \end{pmatrix}$.
4. $y_j = \frac{y}{\|y\|_2}$, $\quad x_j = \frac{x}{\|x\|_2}$.

The orthogonality of the singular vectors computed according to this procedure is examined in §6.

The singular values of $B = \hat{Y}\Sigma\hat{X}^T$ are those of $\bar{M}$ and its singular vectors are derived from those of $\bar{M}$. Specifically,

$$\hat{\Sigma} = \begin{pmatrix} \hat{\Sigma}_1 & 0 \\ 0 & \Sigma \end{pmatrix},$$

$$\hat{Y} = \begin{pmatrix} U_1 & 0 & 0 \\ 0 & \tilde{U}_2 & \tilde{u} \end{pmatrix} \begin{pmatrix} I & 0 \\ 0 & Y \end{pmatrix},$$

and

$$\begin{pmatrix} V_1^T & 0 & 0 \\ 0 & 0 & \tilde{V}_2^T \\ 0 & 1 & 0 \end{pmatrix}^T \begin{pmatrix} I & 0 \\ 0 & X \end{pmatrix},$$

where I is the identity matrix of the same order as $\hat{\Sigma}_1$.

5. Deflation rules for finite precision arithmetic. Section 4 gives rules for deflating the problem when the matrix $\bar{M} = \begin{pmatrix} \bar{\Sigma} & \bar{u} \\ 0 & \mu \end{pmatrix}$ from (7) when $(\bar{\Sigma} \quad \bar{u})$ has equal diagonal elements, $\bar{\sigma}_i = \bar{\sigma}_j$, $i \neq j$, or zeros in the last column, $\bar{\mu}_j = 0$. As in the tridiagonal case, these rules can be extended to deflate the problem when $\bar{M}$ has *close* diagonal elements, $\bar{\sigma}_i \approx \bar{\sigma}_j$, or *small* elements $|\bar{\mu}_j| < \epsilon$ for some small positive value of ϵ. In this section, we present deflation rules for finite precision arithmetic followed by an analysis to show that the errors imposed by deflation are small.

The finite precision rules are summarized in Procedure 5.1 below. They follow the same three basic steps as in exact arithmetic, but small elements of $\bar{u}$ or $\bar{\Sigma}$ are approximated as zero and close diagonal elements of $\bar{\Sigma}$ are approximated as equal. To keep track of deflation, two lists are used: *deflate_list* holds the indices of all small elements in the last column of the matrix, and *solve_list* holds the remaining indices. The list *solve_list* is initialized with the indices $1, \ldots, n-1$ of all diagonal elements in $\bar{\Sigma}$. When deflation is complete, the list *deflate_list* holds the indices of the diagonal elements of the transformed matrix to be accepted as singular values of $\bar{M}$, and *solve_list* holds the indices of the rows of $\bar{M}$ retained in the deflated matrix.

PROCEDURE 5.1 (DEFLATION IN FINITE PRECISION ARITHMETIC).

1. *For all* $k \in$ *solve_list,*
   if $|\bar{\mu}_k| < \epsilon$, *move* k *from solve_list to deflate_list.*
2. *Permute the indices so the elements of solve_list are increasing adjacent integers and* $\bar{\sigma}_k \leq \bar{\sigma}_{k+1}$. *(That is, replace* M *by* $P^T M P$ *such that* $Pe_n = e_n$ *with* $k' \in$ *deflate_list for* $1 \leq k' \leq |$*deflate_list*$|$ *and* $k' \in$ *solve_list for* $|$*deflate_list*$| + 1 \leq k' \leq n-1$.)
3. *For all but the last* $k \in$ *solve_list,*
   if $|\bar{\sigma}_k - \bar{\sigma}_{k+1}|$ *is small, apply a two-sided plane rotation so that* $\mu_k \leftarrow 0$, *and move* k *from solve_list to deflate_list.*
   {*In PSVD, the two-sided rotation is applied as follows:*
   $\tau^2 = (\bar{\mu}_k^2 + \bar{\mu}_{k+1}^2)$
   if $|(\bar{\sigma}_k - \bar{\sigma}_{k+1})\bar{\mu}_k\bar{\mu}_{k+1}| < \epsilon\tau^2$ *then*
   $c = \bar{\mu}_{k+1}/\tau$ *and* $s = \bar{\mu}_k/\tau$
   $\bar{\sigma}_k \leftarrow c^2\bar{\sigma}_k + s^2\bar{\sigma}_{k+1}$
   $\bar{\sigma}_{k+1} \leftarrow s^2\bar{\sigma}_k + c^2\bar{\sigma}_{k+1}$
   $\bar{\mu}_{k+1} \leftarrow \tau$
   $\bar{\mu}_k \leftarrow 0$ }
4. *For* $k \in$ *solve_list,*
   if $|\bar{\sigma}_k|$ *is small, apply a one-sided plane rotation so that* $\mu_k \leftarrow 0$, *and move* k *from solve_list to deflate_list.*
   {*In PSVD, the one-sided rotation is applied as follows:*
   $\tau^2 = (\bar{\mu}_k^2 + \mu^2)$
   if $|\bar{\sigma}_k\mu_k| < \epsilon\tau^2$ *then*
   $c = \bar{\mu}_k/\tau$ *and* $s = \frac{\mu}{\tau}$
   $\bar{\sigma}_k \leftarrow c\bar{\sigma}_k$
   $\mu \leftarrow \tau$
   $\bar{\mu}_k \leftarrow 0$ }

We now examine the errors introduced by Procedure 5.1. The first source of error is the transformation of the matrix at steps 2 and 3. The exact result of one of the two-sided rotations would be

$$\begin{pmatrix} c & -s \\ s & c \end{pmatrix} \begin{pmatrix} \bar{\sigma}_k & 0 & \bar{\mu}_k \\ 0 & \bar{\sigma}_{k+1} & \bar{\mu}_{k+1} \end{pmatrix} \begin{pmatrix} c & s & 0 \\ -s & c & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

$$= \begin{pmatrix} \hat{\sigma}_k & 0 & 0 \\ 0 & \hat{\sigma}_{k+1} & \tau \end{pmatrix} + cs(\hat{\sigma}_k - \hat{\sigma}_{k+1}) \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \end{pmatrix}, \tag{9}$$

where $\hat{\sigma}_k = c^2\bar{\sigma}_k^2 + s^2\sigma_{k+1}$ and $\hat{\sigma}_{k+1} = s^2\bar{\sigma}_k^2 + c^2\sigma_{k+1}$. In step 2, the second term in the matrix sum in (9) is set to zero. Thus, with each rotation an error is imposed of the form

$$E_k^{(2)} = \epsilon_k \left(e_{k+1}{e_k}^T + e_k{e_{k+1}}^T\right),$$

where $\epsilon_k = (\bar{\sigma}_k - \bar{\sigma}_{k+1})\bar{\mu}_k\bar{\mu}_{k+1}/(\bar{\mu}_k^2 + \bar{\mu}_{k+1}^2)$. The test to decide when rotations should be performed guarantees that $|\epsilon_k| < \epsilon$ for all k. Similarly, the exact result of one of the one-sided rotations would be

$$\begin{pmatrix} c & -s \\ s & c \end{pmatrix}\begin{pmatrix} \bar{\sigma}_k & \bar{\mu}_k \\ 0 & \mu \end{pmatrix} = \begin{pmatrix} \hat{\sigma}_k & 0 \\ 0 & \tau \end{pmatrix} - s\bar{\sigma}_k \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix},$$

so that each rotation in step 3 causes an error of the form

$$E_k^{(3)} = \epsilon_k \left(e_n{e_k}^T\right),$$

with $|\epsilon_k| < \epsilon$ for all k.

As in the exact case, the resulting matrix may then be permuted to form

$$\begin{pmatrix} \hat{\Sigma}_1 & & \bar{u}_1 \\ 0 & \tilde{\Sigma} & u \\ 0 & 0 & \mu \end{pmatrix} + E_1 = \begin{pmatrix} \hat{\Sigma}_1 & & 0 \\ 0 & \tilde{\Sigma} & u \\ 0 & 0 & \mu \end{pmatrix} + E, \tag{10}$$

where

$$E = \begin{pmatrix} 0 & 0 & \bar{u}_1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} + E_1 .$$

In these equations, E_1 is a matrix with elements bounded by ϵ, $\bar{u}_1 = \{\bar{\mu}_k | k \in$ *deflate_list*$\}$, and $u = \{\bar{\mu}_k | k \in$ *solve_list*$\}$. Thus, $|e_i^T\bar{u}_1| < \epsilon$ for all i and $|e_i^T u| \geq \epsilon$ for all i.

We approximate the vector $\bar{u}_1$ as zero, accept the diagonal elements of $\hat{\Sigma}$ as singular values of $\bar{M}$, and compute the SVD of the deflated submatrix

$$\begin{pmatrix} \tilde{\Sigma} & u \\ 0 & \mu \end{pmatrix}$$

by the procedure outlined in §4. Because the constituent errors are small, the SVD of $\bar{M}$ computed in this way is the exact SVD of a matrix close to $\bar{M}$.

The magnitude of the total error E depends on the deflation tolerance ϵ. A reasonable choice for ϵ is *macheps* $\times\ \tilde{\sigma}_{\max}$ where *macheps* is machine precision and $\tilde{\sigma}_{\max}$ is the largest diagonal element of $\tilde{\Sigma}$ in the undeflated matrix $\bar{M}$. Because the accurate determination of the small singular values may be important, however, it is also possible to vary the tolerance at each step of deflation according to the size of the singular value at that deflation step.

6. Orthogonality of the singular vectors. Let us now consider the possible limitations on orthogonality of singular vectors due to nearly equal singular values. Many of the results concerning this issue for the symmetric eigenvalue problem apply directly. In particular, the recent results of Sorensen and Tang [20] concerning the numerical orthogonality of the computed eigenvectors will apply. Our first result in

this section is a perturbation lemma that demonstrates the inherent difficulty with nearly equal roots.

For purposes of this discussion, we denote the diagonal elements of $\tilde{\Sigma}$ of the deflated matrix M by $\tilde{\sigma}_j$ and the corresponding components of the vector u by μ_j for $j = 1, 2, \ldots, n-1$ so that the secular equation (8) becomes

$$f(\sigma^2) = 1 + \sum_{j=1}^{n-1} \frac{\mu_j^2}{\tilde{\sigma}_j^2 - \sigma^2} - \frac{\mu^2}{\sigma^2}. \tag{11}$$

Let

$$y_\sigma^T = \left(\frac{\mu_1}{\tilde{\sigma}_1^2 - \sigma^2}, \frac{\mu_2}{\tilde{\sigma}_2^2 - \sigma^2}, \ldots, \frac{\mu_n - 1}{\tilde{\sigma}_{n-1}^2 - \sigma^2}, \frac{\mu}{-\sigma^2} \right) \left[\frac{1}{f'(\sigma^2)} \right]^{1/2}, \tag{12}$$

and let

$$x_\sigma^T = \left(\frac{\tilde{\sigma}_1 \mu_1}{\tilde{\sigma}_1^2 - \sigma^2}, \frac{\tilde{\sigma}_1 \mu_2}{\tilde{\sigma}_2^2 - \sigma^2}, \ldots, \frac{\tilde{\sigma}_1 \mu_{n-1}}{\tilde{\sigma}_{n-1}^2 - \sigma^2}, -1 \right) \left[\frac{1}{1 + \sum_{j=1}^{n-1} \frac{(\tilde{\sigma}_j \mu_j)^2}{(\tilde{\sigma}_j^2 - \sigma^2)^2}} \right]^{1/2}. \tag{13}$$

Note that the squares of the singular values of M are roots of f and that the unit vectors x_σ and y_σ are just permuted left and right singular vectors of M corresponding to σ when σ^2 is a root of f.

LEMMA 6.1. *Let y_σ and x_σ be given by* (12) *and* (13), *respectively. Then for any* $\sigma, \gamma \notin \{\tilde{\sigma}_i : i = 1, \ldots, n-1\} \cup \{0\}$,

$$|y_\sigma^T y_\gamma| = \frac{1}{|\sigma^2 - \gamma^2|} \frac{|f(\sigma^2) - f(\gamma^2)|}{(f'(\sigma^2) f'(\gamma^2))^{1/2}}, \tag{14}$$

and

$$|x_\sigma^T x_\gamma| = \left| \frac{\sigma^2 (f(\sigma^2) - f(\gamma^2))}{(\sigma^2 - \gamma^2)} + f(\gamma^2) \right| \times \left[\left(1 + \sum_{j=1}^{n-1} \frac{(\tilde{\sigma}_j \mu_j)^2}{(\tilde{\sigma}_j^2 - \sigma^2)^2} \right) \left(1 + \sum_{j=1}^{n-1} \frac{(\tilde{\sigma}_j \mu_j)^2}{(\tilde{\sigma}_j^2 - \gamma^2)^2} \right) \right]^{-1/2}. \tag{15}$$

Proof. Equation (14) is just the result implied by Lemma 4.2 in [10]. To derive (15), we note that

$$\begin{aligned} & 1 + \sum_{j=1}^{n-1} \frac{\tilde{\sigma}_j^2 \mu_j^2}{(\tilde{\sigma}_j^2 - \sigma^2)(\tilde{\sigma}_j^2 - \gamma^2)} \\ &= 1 + \sum_{j=1}^{n-1} \frac{(\tilde{\sigma}_j^2 - \sigma^2)\mu_j^2}{(\tilde{\sigma}_j^2 - \sigma^2)(\tilde{\sigma}_j^2 - \gamma^2)} - \frac{\mu^2}{\gamma^2} + \frac{\sigma^2 \mu^2}{\sigma^2 \gamma^2} + \sigma^2 \sum_{j=1}^{n-1} \frac{\mu_j^2}{(\tilde{\sigma}_j^2 - \sigma^2)(\tilde{\sigma}_j^2 - \gamma^2)} \\ &= 1 + \sum_{j=1}^{n-1} \frac{\mu_j^2}{\tilde{\sigma}_j^2 - \gamma^2} - \frac{\mu^2}{\gamma^2} + \sigma^2 \left(\frac{\mu^2}{\sigma^2 \gamma^2} + \sum_{j=1}^{n-1} \frac{\mu_j^2}{(\tilde{\sigma}_j^2 - \sigma^2)(\tilde{\sigma}_j^2 - \gamma^2)} \right) \\ &= f(\gamma^2) + y_\sigma^T y_\gamma \left(f'(\sigma^2) f'(\gamma^2) \right)^{1/2}. \end{aligned} \tag{16}$$

Equation (15) follows from (14) applied to the second term in (16). □

Note that in (12) and (13), y_σ and x_σ are always vectors of unit length and that the set of n vectors selected by setting σ^2 equal to the roots of (11) provides the set of left and right singular vectors for the deflated matrix M in (7). Moreover, (14) shows that the set of left vectors are mutually orthogonal, and (15) shows that the set of right vectors are mutually orthogonal whenever σ^2 and γ^2 are set to distinct roots of f. Finally, the term $|\sigma^2 - \gamma^2|$ appearing in the denominator of (14) warns that it may be difficult to attain orthogonal singular vectors when the roots σ and γ are close.

We now wish to examine the situation of close roots. With an argument similar to that given in Lemma 4.6 of [10], one can show that $\tilde{\sigma}_i - \sigma$ must be bounded away from zero due to the deflation process. Because of this, we can expect to compute the differences $\tilde{\sigma}_j - \sigma$ to high relative accuracy. This is quite important with regard to orthogonality of the computed singular vectors as the following lemma shows.

LEMMA 6.2. *Suppose that $\hat{\sigma}^2$ and $\hat{\gamma}^2$ are numerical approximations to exact roots σ^2 and γ^2 of f. Assume that these roots are distinct and let the relative errors for the quantities $\tilde{\sigma}_i - \sigma$ and $\tilde{\sigma}_i - \gamma$ be denoted by θ_i and η_i, respectively. That is, the computed differences are*

$$\tilde{\sigma}_i^2 - \hat{\sigma}^2 = (\tilde{\sigma}_i^2 - \sigma^2)(1+\theta_i) \quad \text{and} \quad \tilde{\sigma}_i^2 - \hat{\gamma}^2 = (\tilde{\sigma}_i{}^2 - \gamma^2)(1+\eta_i), \tag{17}$$

for $i = 1, 2, \ldots, n$. Let $y_{\hat{\sigma}}$ and $y_{\hat{\gamma}}$ be defined according to (12), *and let $x_{\hat{\sigma}}$ and $x_{\hat{\gamma}}$ be defined according to* (13) *using the computed quantities given in* (17). *If $|\theta_i|, |\eta_i| \leq \epsilon << 1$, then*

$$|y_{\hat{\sigma}}^T y_{\hat{\gamma}}| \leq \epsilon(2+\epsilon)\left(\frac{1+\epsilon}{1-\epsilon}\right)^2$$

and

$$|x_{\hat{\sigma}}^T x_{\hat{\gamma}}| \leq \frac{\epsilon(2+\epsilon)}{(1-\epsilon)^2}.$$

Proof. A proof of the bound on the inner product of the left vectors is given in Lemma 4.7 of [10]. For the right vectors, note that

$$\begin{aligned}
&1 + \sum_{j=1}^{n-1} \frac{\tilde{\sigma}_j^2 \mu_j^2}{(\tilde{\sigma}_j^2 - \sigma^2)(1+\theta_j)(\tilde{\sigma}_j^2 - \gamma^2)(1+\eta_j)} \\
&= -\sum_{j=1}^{n-1} \frac{\tilde{\sigma}_j^2 \mu_j^2}{(\tilde{\sigma}_j^2 - \sigma^2)(\tilde{\sigma}_j^2 - \gamma^2)} + \sum_{j=1}^{n-1} \frac{\tilde{\sigma}_j^2 \mu_j^2}{(\tilde{\sigma}_j^2 - \sigma^2)(1+\theta_j)(\tilde{\sigma}_j^2 - \gamma^2)(1+\eta_j)} \\
&= -\sum_{j=1}^{n-1} \frac{\tilde{\sigma}_j^2 \mu_j^2}{(\tilde{\sigma}_j^2 - \sigma^2)(\tilde{\sigma}_j^2 - \gamma^2)} \left(\frac{\theta_j + \eta_j + \theta_j \eta_j}{(1+\theta_j)(1+\eta_j)}\right).
\end{aligned}$$

Thus,

$$|x_{\hat{\sigma}}^T x_{\hat{\gamma}}| = \left| \sum_{j=1}^{n-1} \frac{\tilde{\sigma}_j^2 \mu_j^2}{(\tilde{\sigma}_j^2 - \sigma^2)(\tilde{\sigma}_j^2 - \gamma^2)} \left(\frac{\theta_j + \eta_j + \theta_j \eta_j}{(1+\theta_j)(1+\eta_j)}\right) \right.$$

$$\cdot \left[\left(1 + \sum_{j=1}^{n-1} \frac{(\tilde{\sigma}_j \mu_j)^2}{(\tilde{\sigma}_j^2 - \sigma^2)^2} \right) \left(1 + \sum_{j=1}^{n-1} \frac{(\tilde{\sigma}_j \mu_j)^2}{(\tilde{\sigma}_j^2 - \gamma^2)^2} \right) \right]^{-1/2} \Bigg|$$

$$\leq \left| \left(\sum_{j=1}^{n-1} \left| \frac{\tilde{\sigma}_j^2 \mu_j^2}{(\tilde{\sigma}_j^2 - \sigma^2)(\tilde{\sigma}_j^2 - \gamma^2)} \right| \right) \left(\frac{\epsilon(2+\epsilon)}{(1-\epsilon)^2} \right) \right.$$

$$\cdot \left[\left(1 + \sum_{j=1}^{n-1} \frac{(\tilde{\sigma}_j \mu_j)^2}{(\tilde{\sigma}_j^2 - \sigma^2)^2} \right) \left(1 + \sum_{j=1}^{n-1} \frac{(\tilde{\sigma}_j \mu_j)^2}{(\tilde{\sigma}_j^2 - \gamma^2)^2} \right) \right]^{-1/2} \Bigg|$$

$$\leq \left(\frac{\epsilon(2+\epsilon)}{(1-\epsilon)^2} \right),$$

and the lemma is proved. □

This lemma shows that orthogonality can be assured whenever it is possible to provide small relative errors in the computed differences $\tilde{\sigma}_j - \sigma$. The results of [20] indicate that this condition may be achieved in practice.

We have applied the root-finder used in [10] directly to (11) and have taken the square root of σ^2 to get a singular value without any apparent difficulty even when very difficult problems were solved. Nevertheless, it is certainly conceivable that problems could arise. Namely, it may be necessary to further refine the root-finding process to prevent loss of accuracy in terms of the form

$$\frac{\mu_j^2}{\tilde{\sigma}_j^2 - \sigma^2},$$

when $\tilde{\sigma}_j$ is small and σ is near to σ_j.

Both of the following two modifications to the root-finder remove the dependence on σ^2 from all terms other than the term $\frac{\mu}{\sigma^2}$. First, one could use

$$\frac{\mu_j^2}{\tilde{\sigma}_j^2 - \sigma^2} = \frac{\mu_j^2}{(\tilde{\sigma}_j + \sigma)(\tilde{\sigma}_j - \sigma)}$$

and update both $\tilde{\sigma}_j - \sigma$ and $\tilde{\sigma}_j + \sigma$ to avoid unnecessary cancellation caused by the squaring. Alternatively, one could use

$$\frac{\mu_j^2}{\tilde{\sigma}_j^2 - \sigma^2} = \frac{\mu_j^2}{2\tilde{\sigma}_j} \left(\frac{1}{(\tilde{\sigma}_j + \sigma)} + \frac{1}{(\tilde{\sigma}_j - \sigma)} \right),$$

and the results of [20] would apply directly to the evaluation of f in this form.

If either of these last two schemes are employed, then it is possible to show that the hypothesis (17) of Lemma 6.2 will be satisfied when the differences $\tilde{\sigma}_j - \sigma$ are computed to high relative accuracy.

7. Experimental results. In this section, we present computational results from the implementation PSVD of the divide and conquer method developed in §§4–5. PSVD splits the matrix B recursively into submatrices of order 8 and solves the subproblems using DSVDC if B is of order 16 or greater and calls DSVDC without matrix splitting otherwise. DSVDC is the fastest serial method for solving the problems of very small order [15]. The results reported here concern only the computation of the

SVD of a bidiagonal matrix B and not reduction of a general matrix to bidiagonal form. In all cases, the full sets of left and right singular vectors were computed along with the singular values.

The first set of experiments include serial timings and accuracy tests. These were carried out in double precision on a single Sequent Symmetry S81 processor using the Weitek floating point accelerator. On this machine, *macheps*$= 2.22 \times 10^{-16}$. We compare the results from PSVD to those from the LINPACK code DSVDC [8] and the implementation of bisection and inverse iteration B/III developed in [16].

The five bidiagonal matrices tested are introduced below. A pair of computed eigenvalues $\hat{\lambda}_i$, $\hat{\lambda}_{i+1}$ belong to a *cluster* if $\hat{\lambda}_i - \hat{\lambda}_{i+1} \leq 10^{-14}|\hat{\lambda}|_{\max}$.

1. Matrix [2,1]: All diagonal elements are 2, and all off-diagonal elements are 1. All singular values lie within the interval [1,3]. For all tested matrix orders, the singular values are computationally distinct.

2. Random: These matrices have uniformly distributed random entries between -1 and 1 generated by the uniform pseudorandom number generator RAND available from NETLIB on both diagonal and off-diagonal elements. The matrices tested turn out to have singular values with minimum magnitude $O(10^{-5})$.

3. B_W: Inspired by the Wilkinson matrix W^+ [21], this matrix of even order has diagonal elements $\frac{n}{2}, \ldots, 1, 1, \ldots, \frac{n}{2}$ and all off-diagonal elements equal to one. Its smallest singular value is $O(10^{-3})$, and, in finite precision, its largest singular values have multiplicity two for matrix orders of about ten and larger.

4. Matrix $[2, u]/n$: The matrix $[2, u]/n$ of order n has the value $2/n$ in each off-diagonal position and the value $\frac{i}{n}$ in the ith diagonal position. This matrix is ill conditioned and has one singular value less than 10^{-14} for orders greater than eighty.

5. Modified matrix [2,1]: This matrix is formed from matrix [2,1] by setting the sixth through ninth diagonal elements $\alpha_6, \ldots, \alpha_9$ and fifth through eighth off-diagonal elements $\beta_5, \ldots, \beta_8$ equal to 10^{-14}. This matrix is severely ill conditioned, having between four and eight singular values less than 10^{-8} and between two and four singular values less than 10^{-14} for all tested orders.

Let $\hat{X}\hat{\Sigma}\hat{Y}^T$ denote the computed SVD of B. To determine the accuracy of the result, we measure the residual error and the deviation from orthogonality of both sets of singular vectors:

$$\mathcal{R} = \frac{1}{\hat{\sigma}_1} \max_i \| B\hat{x}_i - \hat{\sigma}_i \hat{y}_i \|_2,$$
$$\mathcal{O}_X = \| \hat{X}^T\hat{X} - I \|_\infty,$$
$$\mathcal{O}_Y = \| \hat{Y}^T\hat{Y} - I \|_\infty.$$

When all of these quantities are small, the computed SVD of B is nearly the SVD of a matrix near B [15]. In other words, $(\hat{X} + \delta\hat{X})\hat{\Sigma}(\hat{Y} + \delta\hat{Y})^T$ is the exact SVD of a matrix $B + E$ with small $\delta\hat{X}$, $\delta\hat{Y}$, and E.

Table 1 shows the greatest residual and deviation from orthogonality measured for the five test problems solved by B/III, PSVD, and DSVDC for matrix orders 32, 100, and 200. Even for ill-conditioned matrices, PSVD attains full orthogonality of singular vectors and a small residual. Although only PSVD, DSVDC, and bisection (B) are provably stable methods, all three methods tested achieve similarly good results.

The run times for computing the full SVDs of the five matrices are compared in Figs. 1–4 for problem [2,1] and B_W. (These are representative samples from the

full set presented in [15].) For small order problems, PSVD is consistently the fastest method except when PSVD simply calls DSVDC, and B/III is the slowest. For larger order problems (greater than about 50), performance depends more strongly on the matrix characteristics. Namely, when significant deflation occurs, PSVD is the fastest of the three methods. Table 2 shows the fraction of singular values actually computed (as opposed to deflated) by PSVD for matrices [2,1] and B_W. The greater degree of deflation for B_W accounts for the lower runtime of PSVD relative to B/III for B_W.

Similar tests were performed on an Alliant FX/8. The operating system was Concentrix 3.0 and the optimization level for the subroutines comprising the units of computation were options -Ogv. Parallelism was invoked and controlled explicitly through the use of the SCHEDULE package [19]. Implementation details are quite similar to the those for the symmetric eigenvalue routine TREEQL [8]. The recursive matrix splitting leads to a hierarchy of subproblems with a data dependency graph

in the form of a binary tree of height h. The smallest subproblems are of order $n/2^h$ and lie at the leaves of the tree (tree level 0). At level 0, the subproblems are solved independently in parallel, one problem per processor. At level l, $1 \leq l \leq h$, each problem of order $n/2^{h-l}$ is solved by updating the solutions to a pair of order $n/2^{h-l+1}$ subproblems from level $l-1$. At these levels, parallelism is achieved by dynamically assigning root-finding and singular vector computation tasks to processors [17]. As in the symmetric case, this parallel algorithm can be pipelined with block reduction of a matrix to bidiagonal form [9, 10, 17]. (An implementation of PSVD for distributed-memory machines without dynamically scheduled processes is described in [15]. Experiments with a similar implementation of the symmetric eigensolver suggest that PSVD would not be efficient on statically scheduled multiprocessors [14], [15].)

Table 3 shows the speedup of PSVD run on eight processors relative to the PSVD and DSVDC run on one processor for matrix [2,1]. As can be seen, the performance of the parallel algorithm compared to DSVDC on a single processor is quite impressive. The somewhat disappointing results in the second column of this table are not yet understood. We attribute it to two aspects of the implementation. First, the deflation step within each SVD update step is done serially and must be completed before any dynamic allocation is done for root-finding. This limits the expected speedup. Second, there is potential for cache conflict when explicit parallel processing is done on the Alliant FX/8. We have not quantified either of these phenomena, however. Speedup of PSVD on eight processors as compared to one processor is limited to about 5. When the same comparison is done with four processors, speedup is limited to about 3. In all cases, the accuracies of DSVDC and PSVD were comparable.

The results in this section suggest that, as for the symmetric tridiagonal eigenproblem, PSVD provides a fast and accurate serial alternative to DSVDC and B/III. More care is needed in the parallel implementation to increase the speedup observed when PSVD is compared to itself using one processor and eight processors. Moreover, a careful study of the effects of deflation is in order. A cursory examination of the results seemed to indicate that deflation is not nearly as prevalent in this setting as it has been in the symmetric tridiagonal case.

Acknowledgments. We are grateful to Peter Arbenz and Gene Golub for several enlightening discussions. In particular, their paper [2] motivated us to consider the formulation developed in §3. We also wish to acknowledge a stimulating discussion during a special session on divide and conquer methods during the Gatlinburg X meeting held at Fairfield Glade in October 1987. A question from Gene Wachspress prompted us to reconsider the computation of right singular vectors so that we ultimately discovered the method described in §6.

ACCURATE DOWNDATING OF LEAST SQUARES SOLUTIONS*

Å. BJÖRCK†, H. PARK‡, AND L. ELDÉN†

Abstract. Solutions to a sequence of modified least squares problems, where either a new observation is added (updating) or an old observation is deleted (downdating), are required in many applications. Stable algorithms for downdating can be constructed if the complete QR factorization of the data matrix is available. Algorithms that only downdate R and do not store Q require less operations. However, they do not give good accuracy and may not recover accuracy after an ill-conditioned problem has occurred. The authors describe a new algorithm for accurate downdating of least squares solutions and compare it to existing algorithms. Numerical test results are also presented using the sliding window method, where a number of updatings and downdatings occur repeatedly.

Key words. downdating, iterative refinement, least squares, seminormal equations

1. Introduction.

Many problems in signal processing can be formulated as a least squares problem

$$\min_w \|Xw - s\|_2, \quad X \in \mathbf{R}^{p\times n}, \quad p > n. \tag{1.1}$$

If rank $(X) = n$ and the QR decomposition of the data matrix $(X\ s)$ is

$$Q^T(X\ s) = \begin{pmatrix} R & u \\ 0 & \rho \\ 0 & 0 \end{pmatrix} \in \mathbf{R}^{p\times(n+1)}, \tag{1.2}$$

where $Q \in \mathbf{R}^{p\times p}$, then the least squares solution w is obtained from

$$Rw = u, \tag{1.3}$$

and the residual vector r and its norm satisfy

$$r = s - Xw, \qquad \|r\|_2 = |\rho|.$$

(Throughout this paper, we assume that X and s are scaled to have norms $O(1)$.)

Frequently, we know the factorization in (1.2) and wish to find the solution to a modified problem

$$\min_w \|\tilde{X}w - \tilde{s}\|_2,$$

where a new observation $(y^T\ \eta)$ is added (updating):

$$\tilde{X} = \begin{pmatrix} X \\ y^T \end{pmatrix}, \qquad \tilde{s} = \begin{pmatrix} s \\ \eta \end{pmatrix},$$

or an old observation $(z^T\ \sigma)$ is removed (downdating):

$$X = \begin{pmatrix} z^T \\ \tilde{X} \end{pmatrix}, \qquad s = \begin{pmatrix} \sigma \\ \tilde{s} \end{pmatrix}.$$

Often the modified problem involves both an updating and a downdating. From (1.3), we see that the solution to the modified problem can be obtained by modifying the R factor of the corresponding augmented matrix $(\tilde{X}\ \tilde{s})$. If R and $\tilde{R}$ are the R factors of X and $\tilde{X}$, respectively, then we have for updating

$$\tilde{R}^T\tilde{R} = R^TR + yy^T,$$

and for downdating

$$\tilde{R}^T\tilde{R} = R^TR - zz^T.$$

Throughout this paper, we will assume that the data matrices X and $\tilde{X}$ have full column rank. Hence, the problem of modifying the R factor of X after a row is added or deleted is mathematically, but not numerically, equivalent to that of updating or downdating a Cholesky factorization under a rank-one perturbation. Thus, when we deal with the solution of the least squares problem (1.1), it is essential to consider the matrix X as the data rather than the upper triangular factor R. Note that an algorithm that is stable merely for the problem of downdating R^TR, may not be stable for downdating least squares solutions.

From the relation $\sigma_i^2(A) = \lambda_i(A^TA)$ and classical perturbation theory for eigenvalues [8], it follows that the singular values $\tilde{\sigma}_i = \sigma_i(\tilde{R})$ interleave with $\sigma_i = \sigma_i(R)$, where for downdating

$$\sigma_1 \geq \tilde{\sigma}_1 \geq \sigma_2 \geq \cdots \geq \sigma_n \geq \tilde{\sigma}_n \geq 0.$$

In downdating, the smallest singular value may decrease and we can have $\tilde{\sigma}_n \approx 0$, even when R has full column rank. Moreover, any singular value may decrease by a considerable amount, which indicates that downdating can be a sensitive problem [15]. On the other hand, updating R will increase all its singular values.

Important applications where the recursive least squares problems arise include speech echo cancellation, speech coding, and adaptive radar signal processing. The following issues are critical for these applications [1].

1. The modification should be performed with *as few operations* (*real time applications*) *and as little storage requirement as possible.* Recomputing the QR factorization is too costly since it requires $O(pn^2)$ operations, and, thus, a modification technique must be used.

2. The solution should be accurate up to the limitations of data and conditioning of the problem, i.e., a *stable numerical method* must be used. It should be possible to use a computer with *short word length.* This rules out the use of the method of normal equations, which requires twice the word length as methods based on the QR decomposition.

The purpose of this paper is to discuss accurate and efficient algorithms for downdating least squares solutions. We consider the LINPACK algorithm and indicate that it does not give an accurate solution when the downdating problem is ill conditioned. Then we discuss more accurate algorithms: the downdating algorithm based on Gram–Schmidt orthogonalization and an algorithm based on corrected seminormal equations.

The paper is organized as follows. In §2, we review the algorithms for updating and downdating the QR decomposition when both Q and R factors are available. In §3, the downdating algorithm based on the Gram–Schmidt (GS) orthogonalization method is summarized. In §§4 and 5, the LINPACK algorithm for downdating the Cholesky factor and its stability properties are presented. A downdating algorithm based on the corrected seminormal equation method is described in §6. In §7, we describe the application of the methods of this paper to the problem of downdating R^{-1}. Finally, we compare the algorithms discussed in this paper and present the results of numerical tests in §8.

2. Updating and downdating the QR decomposition. Assume that we have computed the QR decomposition of $(X\ s)$ as in (1.2). Then we have

$$\begin{pmatrix} Q^T & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} X & s \\ y^T & \eta \end{pmatrix} = \begin{pmatrix} R & u \\ 0 & \rho \\ 0 & 0 \\ y^T & \eta \end{pmatrix}. \tag{2.1}$$

The row $(y^T\ \eta)$ can now be annihilated and the updated factor is computed by a sequence of plane rotations $U = G_1 \cdots G_{n+1}$, where G_k is a rotation in the plane $(k, p+1)$. We obtain

$$U^T \begin{pmatrix} R & u \\ 0 & \rho \\ 0 & 0 \\ y^T & \eta \end{pmatrix} = \begin{pmatrix} \tilde{R} & \tilde{u} \\ 0 & \tilde{\rho} \\ 0 & 0 \end{pmatrix}. \tag{2.2}$$

It then follows that

$$\tilde{Q} = \begin{pmatrix} Q & 0 \\ 0 & 1 \end{pmatrix} U \tag{2.3}$$

is the updated factor $\tilde{Q}$. *Note that Q is not needed for the construction of U and of the updated factor $\tilde{R}$.* This algorithm for updating is backward stable [9]. Indeed, if we construct the upper triangular factor by a sequence of such modifications, the resulting algorithm is equivalent to the sequential row orthogonalization method for computing the QR decomposition.

Assume that we have the QR decomposition

$$(X \quad s) = \begin{pmatrix} z^T & \sigma \\ \tilde{X} & \tilde{s} \end{pmatrix} = Q \begin{pmatrix} R & u \\ 0 & \rho \\ 0 & 0 \end{pmatrix} \tag{2.4}$$

and want to *remove* the first row $(z^T\ \sigma)$. We now show that this is equivalent to updating the QR factorization when a special column $e_1 = (1, 0, \ldots, 0)^T$ is *added* to the left of $(X\ s)$,

$$(e_1 \quad X \quad s) = \begin{pmatrix} 1 & z^T & \sigma \\ 0 & \tilde{X} & \tilde{s} \end{pmatrix}.$$

Using (2.4) it follows that

$$Q^T (e_1 \quad X \quad s) = \begin{pmatrix} q_1 & R & u \\ \psi & 0 & \rho \\ q_2 & 0 & 0 \end{pmatrix},$$

where $q^T \equiv (q_1^T \ \psi \ q_2^T)$ is the first row of Q. We can now determine a sequence of plane rotations J_k, $k = p-1, p-2, \ldots, 1$, in the plane $(k, k+1)$ such that

$$U^T \begin{pmatrix} q_1 & R & u \\ \psi & 0 & \rho \\ q_2 & 0 & 0 \end{pmatrix} = \begin{pmatrix} 1 & v^T & \tau \\ 0 & \tilde{R} & \tilde{u} \\ 0 & 0 & \tilde{\rho} \\ 0 & 0 & 0 \end{pmatrix}, \qquad U^T = J_1 \cdots J_{p-2} J_{p-1}. \tag{2.5}$$

Here J_k is chosen to annihilate the $(k+1)$st component in q. Then we have

$$\hat{Q}^T \begin{pmatrix} 1 & z^T & \sigma \\ 0 & \tilde{X} & \tilde{s} \end{pmatrix} = \begin{pmatrix} 1 & v^T & \tau \\ 0 & \tilde{R} & \tilde{u} \\ 0 & 0 & \tilde{\rho} \\ 0 & 0 & 0 \end{pmatrix},$$

where $\hat{Q} = QU$. Note that by an extra reflection we could ensure that $\tilde{\rho} \geq 0$, but we do not assume this in the following. Equating the first columns on both sides we see that $\hat{Q}^T e_1 = e_1$, so the first row in $\hat{Q}$ equals e_1. Hence, $\hat{Q}$ must have the form

$$\begin{pmatrix} 1 & 0 \\ 0 & \tilde{Q} \end{pmatrix},$$

and it follows that $(v^T \ \tau) = (z^T \ \sigma)$. Dropping the first row and column gives the downdated QR decomposition of

$$(\tilde{X} \ \tilde{s}) = \tilde{Q} \begin{pmatrix} \tilde{R} & \tilde{u} \\ 0 & \tilde{\rho} \\ 0 & 0 \end{pmatrix}.$$

Note the important fact that in the downdating case, we need the first row of the square orthogonal factor Q to construct the matrix U. Paige [9] has proved that this downdating algorithm is *mixed stable*, i.e., the computed $\tilde{R}, \tilde{u}$, and $\tilde{\rho}$ are close to the corresponding quantities in the exact factor of

$$(\tilde{X} + E, \tilde{s} + f), \quad \|E\|_2 = c_1 \mu, \quad \|f\|_2 = c_2 \mu,$$

where c_1 and c_2 are constants depending on the dimension of X, and μ is the round-off unit.

3. Modifying the GS factorization. In many applications, especially if $p \gg n$, *it is too costly to save and modify the full QR decomposition.* When we use the GS QR factorization, the storage requirement for the Q factor is reduced to pn from p^2, which is for the full QR decomposition. In [5], stable algorithms are derived for modifying the GS QR factorization of a matrix A when A is changed by a matrix of rank one, or when a row or column is added or deleted. A principal tool of the algorithms is the GS process *with reorthogonalization.* A slightly simplified algorithm given in Reichel and Gragg [13] relies on the fact that in the full-rank case, one reorthogonalization is always enough; see Parlett [12].

The algorithm given in §2 for adding a row also applies with trivial modifications to the GS factorization. Assume now that we have the QR factorization

$$(X \quad s) = \begin{pmatrix} z^T & \sigma \\ \tilde{X} & \tilde{s} \end{pmatrix} = \begin{pmatrix} q_1^T & \psi \\ Q_1 & y \end{pmatrix} \begin{pmatrix} R & u \\ 0 & \rho \end{pmatrix}, \tag{3.1}$$

and want to delete the first row $(z^T \quad \sigma)$. Note that (3.1) can be written as

$$\begin{pmatrix} z^T & \sigma \\ \tilde{X} & \tilde{s} \end{pmatrix} = \begin{pmatrix} q_1^T & \psi & 1 \\ Q_1 & y & 0 \end{pmatrix} \begin{pmatrix} R & u \\ 0 & \rho \\ 0 & 0 \end{pmatrix}. \tag{3.2}$$

Following [5], we first apply the GS process (with reorthogonalization) so that $e_1 = (1, 0 \cdots, 0)^T$ is orthogonalized to

$$\hat{Q}_1 \equiv \begin{pmatrix} q_1^T & \psi \\ Q_1 & y \end{pmatrix} \in \mathbf{R}^{p \times (n+1)}.$$

Because of the special form of the appended column, the result has the form

$$\begin{pmatrix} q_1^T & \psi & 1 \\ Q_1 & y & 0 \end{pmatrix} = \begin{pmatrix} q_1^T & \psi & \bar{\gamma} \\ Q_1 & y & h \end{pmatrix} \begin{pmatrix} I & 0 & q_1 \\ 0 & 1 & \psi \\ 0 & 0 & \hat{\gamma} \end{pmatrix} \tag{3.3}$$

for some $h \in \mathbf{R}^{(p-1)\times 1}$, $\hat{\gamma}$, and $\bar{\gamma} \in \mathbf{R}$. Here $q_1^T q_1 + \psi^2 + \hat{\gamma}^2 = \|e_1\|_2^2 = 1$, and equating the first element in the last column in (3.3) $q_1^T q_1 + \psi^2 + \bar{\gamma}\hat{\gamma} = 1$. Hence we have $\hat{\gamma} = \bar{\gamma}$. If e_1 is linearly dependent on the columns of $\hat{Q}_1$, then we get $\bar{\gamma} = 0$, $h = 0$, and the orthogonalization will fail. In this case we can take a random vector in $\mathbf{R}^{(p-1)\times 1}$ and reorthogonalize to find a unit vector h that is orthogonal to $(Q_1 \; y)$; see [5].

We now write using (3.2) and (3.3)

$$\begin{pmatrix} z^T & \sigma \\ \tilde{X} & \tilde{s} \end{pmatrix} = \begin{pmatrix} q_1^T & \psi & \bar{\gamma} \\ Q_1 & y & h \end{pmatrix} \begin{pmatrix} R & u \\ 0 & \rho \\ 0 & 0 \end{pmatrix},$$

and determine a sequence of plane rotations J_k, $k = n+1, n, \ldots, 1$, in the plane $(k, n+2)$ such that

$$\begin{pmatrix} q_1^T & \psi & \bar{\gamma} \\ Q_1 & y & h \end{pmatrix} U = \begin{pmatrix} 0 & 0 & \tau \\ \tilde{Q}_1 & \tilde{y} & \tilde{h} \end{pmatrix}, \qquad U = J_{n+1} J_n \cdots J_1,$$

where J_k is chosen to annihilate the kth component in $(q_1^T \; \psi \; \bar{\gamma})$. Since orthogonal transformations preserve length we can make $\tau = 1$. The transformed matrix has orthonormal columns and so $\tilde{h} = 0$. It follows that

$$\begin{pmatrix} z^T & \sigma \\ \tilde{X} & \tilde{s} \end{pmatrix} = \begin{pmatrix} 0 & 0 & 1 \\ \tilde{Q}_1 & \tilde{y} & 0 \end{pmatrix} \begin{pmatrix} \tilde{R} & \tilde{u} \\ 0 & \tilde{\rho} \\ z^T & \sigma \end{pmatrix},$$

where

$$U^T \begin{pmatrix} R & u \\ 0 & \rho \\ 0 & 0 \end{pmatrix} = \begin{pmatrix} \tilde{R} & \tilde{u} \\ 0 & \tilde{\rho} \\ z^T & \sigma \end{pmatrix}$$

with $\tilde{R}$ upper triangular, and the downdated QR decomposition becomes

$$(\tilde{X} \quad \tilde{s}) = (\tilde{Q}_1 \; \tilde{y}) \begin{pmatrix} \tilde{R} & \tilde{u} \\ 0 & \tilde{\rho} \end{pmatrix}. \tag{3.4}$$

Summarizing the above, we get the following algorithm.

GS downdating algorithm. Given

$$\hat{Q}_1 = \begin{pmatrix} q_1^T & \psi \\ Q_1 & y \end{pmatrix} \in \mathbf{R}^{p\times(n+1)} \quad \text{and} \quad \begin{pmatrix} R & u \\ 0 & \rho \end{pmatrix} \in \mathbf{R}^{(n+1)\times(n+1)},$$

the following algorithm computes the downdated quantities $\tilde{Q}_1, \tilde{R}, \tilde{u}, \tilde{\rho}$ and $\tilde{w}$.

1. Orthogonalize e_1 to $\hat{Q}_1$ by the GS process with one reorthogonalization step:
   (a) $s := (q_1^T \ \psi)^T$
   (b) $v := e_1 - \hat{Q}_1 s$
   (c) if $\|v\|_2 \geq 1/\sqrt{2}$, $v := v/\|v\|_2$
   (d) else
      i. $s' := \hat{Q}_1^T v$; $v' := v - \hat{Q}_1 s'$
      ii. if $\|v'\|_2 \leq \|v\|_2/\sqrt{2}$, $\bar{\gamma} = 0$;
      determine h with unit length orthogonal to $(Q_1 \ y)$
      iii. else $v := v'/\|v'\|_2$
   (e) $\bar{\gamma} := v(1)$; $h := v(2:p)$.

2. Determine an orthogonal matrix U as a product of Givens rotations such that

$$\begin{pmatrix} 0 & 0 & 1 \\ \tilde{Q}_1 & \tilde{y} & \tilde{h} \end{pmatrix} := \begin{pmatrix} q_1^T & \psi & \bar{\gamma} \\ Q_1 & y & h \end{pmatrix} U. \tag{3.5}$$

3. Update the R factor by U^T:

$$\begin{pmatrix} \tilde{R} & \tilde{u} \\ 0 & \tilde{\rho} \\ z^T & \sigma \end{pmatrix} := U^T \begin{pmatrix} R & u \\ 0 & \rho \\ 0 & 0 \end{pmatrix}. \tag{3.6}$$

4. Compute the new solution $\tilde{w}$ from $\tilde{R}\tilde{w} = \tilde{u}$ and take $\tilde{\rho}$ as the new residual norm.

With one reorthogonalization process, the GS downdating algorithm requires about $7pn + 2.5n^2$ flops. This can be reduced to $5pn + 1.5n^2$ flops when fast scaled rotations [2], [8] are used in (3.5) and (3.6). Note that the data matrix X is never needed: to delete the first row of X, the R factor and the corresponding row in $\hat{Q}_1$ are needed. Thus, the storage requirement is about $pn + 0.5n^2$ for $\hat{Q}_1$ and R.

4. Downdating the Cholesky factor. There are several algorithms for *downdating the Cholesky factor* of A^TA, which is mathematically the same as downdating the R factor of the QR decomposition of A. These algorithms have the property that the Q factor is never used. One important algorithm of this type, which uses hyperbolic rotations, has been analyzed by Alexander, Pan, and Plemmons [1]. Another standard algorithm is the LINPACK algorithm due to Saunders [14].

To derive the LINPACK algorithm for downdating R, note that downdating the ith row of the data matrix $(X \quad s)$ by the method in §2 requires the ith row of the orthogonal factor Q. Also note that the transformations $J_{n+2}, \ldots, J_{p-1}$ in (2.5) do not affect $\left(\begin{smallmatrix} R & u \\ 0 & \rho \end{smallmatrix}\right)$, but the vector q_2, which is replaced by $\bar{\gamma}e_1$, $\bar{\gamma} = \|q_2\|_2$. Thus, mathematically it suffices to know the first $n+1$ components $(q_1^T \ \psi)$ of the ith row

of Q and $\bar{\gamma} \equiv \|q_2\|_2 = \sqrt{1-(\|q_1\|^2+\psi^2)}$ to delete the ith row of $(X \quad s)$. From the first row of the QR decomposition (2.4), we have

$$(z^T \quad \sigma) = (q_1^T \quad \psi \quad q_2^T)\begin{pmatrix} R & u \\ 0 & \rho \\ 0 & 0 \end{pmatrix} = (q_1^T \quad \psi)\begin{pmatrix} R & u \\ 0 & \rho \end{pmatrix}.$$

It follows that q_1 and ψ can be computed by solving the triangular system

$$\begin{pmatrix} R^T & 0 \\ u^T & \rho \end{pmatrix}\begin{pmatrix} q_1 \\ \psi \end{pmatrix} = \begin{pmatrix} z \\ \sigma \end{pmatrix}.$$

Using the relation $u^T q_1 = u^T R^{-T} z = w^T z$, we obtain

$$q_1 = R^{-T} z, \quad \psi = (\sigma - z^T w)/\rho \qquad (\rho \neq 0). \tag{4.1}$$

Next we should determine a product of plane rotations U such that

$$U^T \begin{pmatrix} q_1 & R & u \\ \psi & 0 & \rho \\ \bar{\gamma} & 0 & 0 \end{pmatrix} = \begin{pmatrix} 1 & z^T & \sigma \\ 0 & \tilde{R} & \tilde{u} \\ 0 & 0 & \tilde{\rho} \end{pmatrix}. \tag{4.2}$$

The first rotation in the $(n+1, n+2)$ plane only affects the 2×2 matrix

$$\begin{pmatrix} c & s \\ -s & c \end{pmatrix}\begin{pmatrix} \psi & \rho \\ \bar{\gamma} & 0 \end{pmatrix} = \begin{pmatrix} \gamma & \hat{\rho} \\ 0 & \tilde{\rho} \end{pmatrix},$$

and a short calculation gives

$$\gamma^2 = \bar{\gamma}^2 + \psi^2 = 1 - \|q_1\|_2^2, \quad \hat{\rho} = (\sigma - z^T w)/\gamma, \quad \tilde{\rho} = (\rho^2 - \hat{\rho}^2)^{1/2}. \tag{4.3}$$

(Note that ψ in (4.1) need not be computed so the assumption that $\rho \neq 0$ is not needed.)

Collecting these results we get the following algorithm

LINPACK downdating algorithm. Given R, u, ρ, w, and $(z^T \sigma)$, the following algorithm computes the downdated quantities $\tilde{R}, \tilde{u}, \tilde{\rho}$, and $\tilde{w}$.

1. Compute q_1, γ, and $\hat{\rho}$ from

$$R^T q_1 = z, \quad \gamma := (1 - \|q_1\|_2^2)^{1/2}, \quad \hat{\rho} := (\sigma - z^T w)/\gamma. \tag{4.4}$$

2. Determine an orthogonal matrix $\hat{U}$ as a product of Givens rotations such that

$$\begin{pmatrix} 1 & z^T & \sigma \\ 0 & \tilde{R} & \tilde{u} \end{pmatrix} := \hat{U}^T \begin{pmatrix} q_1 & R & u \\ \gamma & 0 & \hat{\rho} \end{pmatrix}. \tag{4.5}$$

3. Compute the new solution $\tilde{w}$ and the residual norm from

$$\tilde{R}\tilde{w} = \tilde{u}, \qquad \tilde{\rho} := (\rho^2 - \hat{\rho}^2)^{1/2}.$$

This algorithm requires about $3n^2$ flops for two triangular solves and updating in (4.5), which can be reduced to $2n^2$ flops when fast rotations are used in (4.5). Unlike the GS downdating algorithm, the LINPACK algorithm does not require the Q factor. However, the row $(z^T\ \sigma)$ to be deleted should be known to recover the necessary elements in the Q factor. Thus, for solving recursive least squares problems with the sliding window method, all the rows in the data matrix X need to be stored for future downdating. Accordingly, the storage requirement is $pn + 0.5n^2$. This means that *the storage requirement for the LINPACK downdating algorithm can be about as large as that for the* GS*-based downdating algorithm for recursive least squares problems* contrary to a widespread misconception. In special cases such as when X is sparse or its elements can be generated by a formula, the cost of storing X can be much smaller than that of storing Q.

5. Stability properties of the LINPACK algorithm. It is well known that downdating the Cholesky factor can be very ill conditioned and can fail. We first note that

$$R^TR - zz^T = R^T(I - q_1q_1^T)R = \tilde{R}^T\tilde{R}. \tag{5.1}$$

If we put $I - q_1q_1^T = LL^T$, then $\tilde{R} = L^TR$, where

$$\kappa(L) = \frac{1}{\gamma}, \qquad \gamma = \sqrt{1 - \|q_1\|^2}. \tag{5.2}$$

Stewart [15] considered the effect of a perturbation δz in z on the downdated factor $\tilde{R}$. He showed that if

$$\|\delta z\|_2 \le \mu\sigma_1, \qquad \sigma_1 = \|R\|_2,$$

where μ is the round-off unit, then, neglecting higher-order terms

$$|\delta\tilde{\sigma}_i| \le 2\mu\sigma_1(\sigma_1/\tilde{\sigma}_i), \tag{5.3}$$

where $\tilde{\sigma}_i = \sigma_i(\tilde{R})$. This shows that the method can break down if $\tilde{\sigma}_i/\sigma_1 \approx \mu^{1/2}$, i.e., if we downdate to an ill-conditioned matrix $\tilde{R}$. The analysis in [15] also shows that the downdating problem is ill conditioned if any singular value is reduced significantly (not necessarily becoming small). This happens, for example, if the row to be downdated contains an *outlier*, i.e., an erroneous and large element.

Pan [10] has given a detailed perturbation analysis of the downdating problem for the Cholesky factor and has proved the following result.

THEOREM 5.1. *Let $\alpha > 0$ be small enough so that the factorization*

$$\tilde{R}(\epsilon)^T\tilde{R}(\epsilon) = (R + \epsilon E)^T(R + \epsilon E) - (z + \epsilon f)^T(z + \epsilon f) \tag{5.4}$$

exists for all $\epsilon \in (-\alpha, \alpha)$, where E is an upper triangular matrix. Then we have the bound

$$\begin{aligned}\frac{\|\tilde{R}(\epsilon) - \tilde{R}\|_2}{\|\tilde{R}\|_2} \le |\epsilon|\kappa^2(R)C\Bigg[&2n(n^{1/2}C + 1)\frac{\|f\|_2}{\|z\|_2} \\ &+ (2n^{3/2}C + 2n + 1)\frac{\|E\|_2}{\|R\|_2}\Bigg] + O(\epsilon^2),\end{aligned} \tag{5.5}$$

where $\kappa(R)$ is the condition number of R, and $C = \|q_1\|^2/\gamma$.

The above perturbation analysis shows that *using R to form the downdating transformations may be a much more ill-conditioned problem than downdating the original matrix X.* This is because the original row in X is not perturbed in the same way as the vector $(q_1^T \gamma)$, which is computed by solving a triangular system to determine the downdating transformation in the LINPACK algorithm. Hence, any method that uses R alone to recover the necessary elements of Q cannot be *backward stable in the same sense as the downdating algorithm that uses Q directly.*

We now illustrate the perturbation result, and the possible failure of the LINPACK algorithm using a simple example.

Example 1. Let $X = \binom{\tau}{1}$, where $\tau = 1/\sqrt{\mu}$, and let $s = \binom{1}{1}$. We may think of the first row of X as an outlier. Then the QR decomposition of X, correctly rounded to single precision, is

$$X = \begin{pmatrix} \tau \\ 1 \end{pmatrix} = \begin{pmatrix} 1 & -\epsilon \\ \epsilon & 1 \end{pmatrix} \begin{pmatrix} \tau \\ 0 \end{pmatrix},$$

where $\epsilon = 1/\tau$. The LINPACK algorithm will compute

$$q_1 = \tau/\tau = 1, \quad \gamma^2 = 1 - 1 = 0, \quad J_1 = I,$$

and we obtain the downdated factor $\tilde{R} = 0$, and the least squares solution is not defined. It is easily verified that if we downdate using Q, we get the correct result $\tilde{R} = 1$ and $\tilde{w} = 1$.

The information from the second row in X is not present in R, only in Q. Therefore *no method working only from R can hope to do better.*

6. Downdating using seminormal equations. We now consider a downdating algorithm in which the method of iterative refinement is incorporated. The method is based on the *seminormal equations* (SNE)

$$R^T R w = X^T s,$$

for solving a least squares problem $\min_w \|Xw - s\|_2$. This method is generally no more accurate than the method of normal equations. We instead consider the method of *corrected seminormal equations* (CSNE)

$$\begin{aligned} R^T R w &= X^T s, & r &= s - Xw, \\ R^T R \delta w &= X^T r, & w_c &= w + \delta w. \end{aligned} \tag{6.1}$$

Here a corrected solution w_c is computed by performing one step of iterative refinement on the solution computed from the SNE. Note that we assume that *all computations* are performed in *single precision.*

Assume that the computed $R = \bar{R}$ is such that there exists an exactly orthogonal matrix $\hat{Q}$ such that

$$X + E = \hat{Q}\bar{R}, \qquad \|E\|_F \le c_1 \mu \|X\|_F.$$

Then in Björck [4] the following error bound is given for the solution $\bar{w}_c$ computed by CSNE.

THEOREM 6.1. *Let $\bar{w}_c$ be the least squares solution computed by the* CSNE *method, and assume that $\rho = c_1 n^{1/2} \mu \kappa < 1$, where κ is the spectral condition number*

of X. Then the following error estimate holds up to terms of higher order in $\mu\kappa$:

$$\begin{aligned}\|w-\bar{w}_c\|_2 \le \sigma\mu\kappa\Big(c_2\|w\|_2 + n^{1/2}p\frac{\|s\|_2}{\|X\|_2}\Big)\\ + n^{1/2}\mu\kappa\Big(n\|w\|_2 + p\kappa\frac{\|r\|_2}{\|X\|_2}\Big) + n^{1/2}\mu\|w\|_2,\end{aligned} \tag{6.2}$$

where

$$\sigma = c_3\mu\kappa^2, \quad c_2 = 2n^{1/2}(c_1+n), \quad c_3 \le 2n^{1/2}(c_1+2n+p/2). \tag{6.3}$$

Hence, provided that $c_3\mu\kappa^2 < 1$, the forward error will not be worse than for a backward stable method.

In [4], it was shown how the CSNE method can be used to update the R factor when a new column is added. This can be adopted to reconstruct the vector $(q_1^T\ \gamma)$ as follows.

THEOREM 6.2. *Let v be the solution to*

$$\min_v \|e_1 - Xv\|_2,$$

and R the R factor of X. Then the R factor of $(X\ e_1)$ is

$$\begin{pmatrix} R & q_1 \\ 0 & \gamma \end{pmatrix}, \quad q_1 = Rv, \quad |\gamma| = \|e_1 - Xv\|_2. \tag{6.4}$$

The downdated R factor is then obtained by applying orthogonal transformations to transform the last column into the vector e_1. We now apply this result to downdate the *augmented* R factor by solving the least squares problem

$$\min_{x,\phi} \left\| e_1 - (X\ s)\begin{pmatrix} x \\ \phi \end{pmatrix} \right\|_2$$

using the CSNE.

The first step is similar to the LINPACK algorithm. Assuming $\rho \neq 0$, from

$$\begin{pmatrix} R^T & 0 \\ u^T & \rho \end{pmatrix}\begin{pmatrix} q_1 \\ \psi \end{pmatrix} = \begin{pmatrix} z \\ \sigma \end{pmatrix},$$

we get

$$q_1 = R^{-T}z, \qquad \psi = (\sigma - z^T w)/\rho.$$

Next we solve

$$\begin{pmatrix} R & u \\ 0 & \rho \end{pmatrix}\begin{pmatrix} x \\ \phi \end{pmatrix} = \begin{pmatrix} q_1 \\ \psi \end{pmatrix},$$

which gives

$$\phi = \psi/\rho, \qquad x = R^{-1}(q_1 - u\phi) = v - \phi w.$$

We have $|\gamma| = \|e_1 - Xv\|_2$, and ϕ and x are only needed to compute $|\bar{\gamma}| = \|t\|_2$, where

$$t = e_1 - (X\ s)\begin{pmatrix} x \\ \phi \end{pmatrix} = e_1 - Xv - \psi\hat{r}, \qquad \hat{r} = (s - Xw)/\rho. \tag{6.5}$$

In exact computing it holds that

$$\rho^2 = \|Xw - s\|_2^2 = \|\tilde{X}w - \tilde{s}\|_2^2 + (\sigma - z^T w)^2,$$

and $\hat{r}$ is the residual normalized to unit length with first component equal to ψ. Hence $\rho = 0$ implies that $\hat{\rho} = 0$, and $\tilde{\rho} = \|\tilde{X}\tilde{w} - \tilde{s}\|_2 = 0$. In floating point computation the division $\bar{r}/\rho$, where $\bar{r} = fl(s - Xw)$ is the *computed* residual, may not be safe to perform if $\rho \neq 0$ but very small. If we recompute $\rho = fl(\|\bar{r}\|_2)$, then if $fl(1 + \rho) = 1$ the true residual norm certainly is of the order of machine precision. In this case we put $\psi\hat{r} = 0$ in (6.5) and take $\hat{\rho} = \tilde{\rho} = 0$. Otherwise, ρ will equal $\|\bar{r}\|_2$ with small relative error, and the division in computing $\hat{r}$ can be carried out safely. Following (4.3), we then compute

$$\hat{\rho} = \rho\psi/\gamma, \qquad \tilde{\rho} = \rho\bar{\gamma}/\gamma,$$

and continue as in the LINPACK downdating algorithm.

We remark that because the condition number of the augmented R factor is large when ρ is small, it is important to refine q_1 before ψ is computed, i.e., to perform the algorithm in Gauss–Seidel rather than Jacobi fashion!

CSNE downdating algorithm. Given R, u, w, the data $(X \ s)$ the following algorithm deletes the first row $(z^T \ \sigma)$ and computes the downdated quantities $\tilde{R}, \tilde{u}, \tilde{\rho}$, and $\tilde{w}$.

1. Compute q_1, v and t from

$$R^T q_1 = z, \quad Rv = q_1, \quad t := e_1 - Xv.$$

2. Update q_1, v and compute γ:

$$\begin{aligned} R^T \delta q_1 &= X^T t, \qquad q_1 := q_1 + \delta q_1, \\ R\delta v &= \delta q_1, \quad t := t - X\delta v, \quad \gamma := \|t\|_2. \end{aligned}$$

3. Set $\tilde{\rho} := \hat{\rho} := 0$ and compute the residual:

$$r := s - Xw, \qquad \rho = \|r\|_2.$$

If $fl(1 + \rho) \neq 1$,
   (a) normalize the residual: $\hat{r} = r/\rho$,
   (b) modify t: $\psi := e_1^T \hat{r}, \quad t := t - \psi\hat{r}$,
   (c) update ψ and t: $\delta\psi := \hat{r}^T t, \quad \psi := \psi + \delta\psi, \quad t := t - \delta\psi\hat{r}$,
   (d) compute $\bar{\gamma} = \|t\|_2, \quad \hat{\rho} = \psi\rho/\gamma, \quad \tilde{\rho} = \rho\bar{\gamma}/\gamma$.

4. Determine an orthogonal matrix U^T as a product of Givens rotations such that

$$\begin{pmatrix} 1 & z^T & \sigma \\ 0 & \tilde{R} & \tilde{u} \end{pmatrix} := U^T \begin{pmatrix} q_1 & R & u \\ \gamma & 0 & \hat{\rho} \end{pmatrix}.$$

5. Compute the new solution $\tilde{w}$ from

$$\tilde{R}\tilde{w} = \tilde{u}.$$

Example 2. Let X be as in Example 1. In the method of seminormal equations, we compute

$$q_1 = 1, \quad v = \frac{1}{\tau}, \quad \gamma = \left\| \begin{pmatrix} 1 \\ 0 \end{pmatrix} - \begin{pmatrix} \tau \\ 1 \end{pmatrix} \tau^{-1} \right\|_2 = \epsilon = \frac{1}{\tau}.$$

There is no need for the refinement steps 2 and 3 here, and we get

$$U^T \begin{pmatrix} 1 & \tau \\ \epsilon & 0 \end{pmatrix} = \begin{pmatrix} 1 & \tau \\ 0 & 1 \end{pmatrix}, \qquad \tilde{R} = 1,$$

which is the correct result.

Algorithm CSNE requires three more triangular solves than the LINPACK method, if the iterative refinement is carried out. Also, four extra matrix times vector multiplications with X and X^T are required. Hence, the added computational complexity is quite high, $\approx 4pn + 1.5n^2$ flops. However, sometimes X may have a special structure and the matrix-vector multiplications can be performed by fast algorithms. This is the case, for example, when X is a sparse or Toeplitz matrix. The storage requirement is the same as that for the LINPACK algorithm.

When the CSNE algorithm is too expensive to use in every step, we suggest a *hybrid algorithm* [6], where the CSNE algorithm is used if the downdating is ill conditioned and the LINPACK algorithm is used otherwise. As a measure of conditioning of the downdating problem for R augmented by the right-hand side u and residual ρ, we have used the quantity (cf. [15])

$$\gamma^2 = 1 - \|q_1\|_2^2. \tag{6.6}$$

If γ^2 is less than a user-specified constant tol, then the downdating is performed with CSNE. Our numerical experiments indicate the hybrid method with tol in the range $[0.25, 0.5]$ produces much more accurate results than the LINPACK algorithm.

7. Updating and downdating the inverse of R. The problem of updating and downdating the inverse of the matrix R in the QR decomposition has been studied in [11] for methods based on orthogonal as well as hyperbolic rotations. One motivation for working with R^{-1} instead of R itself is that such an algorithm can be parallelized more easily. Furthermore, there are applications (see [11]) where the elements of the inverse are needed.

The downdating methods described in this paper can be modified to downdate the inverse of R. We first describe how the inverse and the solution vector w can be downdated recursively.

Consider the transformation

$$U^T \begin{pmatrix} q_1 & R \\ \gamma & 0 \end{pmatrix} = \begin{pmatrix} 1 & z^T \\ 0 & \tilde{R} \end{pmatrix}, \qquad U^T \begin{pmatrix} u \\ \hat{\rho} \end{pmatrix} = \begin{pmatrix} \sigma \\ \tilde{u} \end{pmatrix}. \tag{7.1}$$

By simply inverting the matrices in the first equation in (7.1) we get the following formula for downdating the inverse $S = R^{-1}$:

$$\begin{pmatrix} 0 & \frac{1}{\gamma} \\ S & -\frac{1}{\gamma} v \end{pmatrix} U = \begin{pmatrix} 1 & -z^T \tilde{S} \\ 0 & \tilde{S} \end{pmatrix}, \tag{7.2}$$

where $v = R^{-1} q_1 = S q_1$. Hence the same orthogonal transformation U downdates the inverse. U can be determined as a product of plane rotations that zeros the diagonal in S from bottom to top

$$U = J_{n,n+1} \cdots J_{23} J_{12}.$$

This determines $\tilde{S} = \tilde{R}^{-1}$. Using the second equation in (7.1), we can determine $\tilde{u}$

$$(u^T \quad \hat{\rho})\, U = (\sigma \quad \tilde{u}^T), \tag{7.3}$$

and the downdated solution is obtained from $\tilde{w} = \tilde{S}\tilde{u}$.

A different downdating formula for $\tilde{w}$ is obtained as follows. Combining (7.2) and the second equation in (7.1), we see that

$$\begin{pmatrix} \sigma - z^T\tilde{S}\tilde{u} \\ \tilde{S}\tilde{u} \end{pmatrix} = \begin{pmatrix} 1 & -z^T\tilde{S} \\ 0 & \tilde{S} \end{pmatrix} \begin{pmatrix} \sigma \\ \tilde{u} \end{pmatrix} = \begin{pmatrix} 1 & -z^T\tilde{S} \\ 0 & \tilde{S} \end{pmatrix} U^T \begin{pmatrix} u \\ \hat{\rho} \end{pmatrix}$$
$$= \begin{pmatrix} 0 & \frac{1}{\gamma} \\ S & -\frac{1}{\gamma}v \end{pmatrix} \begin{pmatrix} u \\ \hat{\rho} \end{pmatrix} = \begin{pmatrix} \frac{\hat{\rho}}{\gamma} \\ Su - \frac{\hat{\rho}}{\gamma}v \end{pmatrix},$$

and hence

$$\tilde{w} = w - \frac{\hat{\rho}}{\gamma}v. \tag{7.4}$$

Since we assume that $\operatorname{rank}(\tilde{X}) = n$, we have $\gamma \neq 0$. The LINPACK, the CSNE, and the hybrid algorithms only differ in the way the vector $(q_1^T \ \gamma)$ is computed. For determining this vector, triangular systems with the matrices R and R^T need to be solved. This can be replaced by the corresponding multiplication by the inverse. Therefore these methods can also be used in connection with inverse downdating.

For updating the inverse factor, we consider the relation

$$U^T \begin{pmatrix} y^T & \eta \\ R & u \\ 0 & \rho \end{pmatrix} = \begin{pmatrix} \tilde{R} & \tilde{u} \\ 0 & \tilde{\rho} \\ 0 & 0 \end{pmatrix}. \tag{7.5}$$

By adding a column e_1, we write the first part of this equation as

$$U^T \begin{pmatrix} 1 & y^T \\ 0 & R \end{pmatrix} = \begin{pmatrix} p_1 & \tilde{R} \\ \xi & 0 \end{pmatrix},$$

where $(p_1 \quad \xi)$ is the first row of U. We then invert this equation to get

$$\begin{pmatrix} 1 & -y^T S \\ 0 & S \end{pmatrix} U = \begin{pmatrix} 0 & \frac{1}{\xi} \\ \tilde{S} & -\frac{1}{\xi}\tilde{S}p_1 \end{pmatrix}. \tag{7.6}$$

Here we first choose $U = \hat{U}$ as a product of plane rotations

$$\hat{U} = J_{12}J_{23}\cdots J_{n,n+1},$$

where $J_{i,i+1}$, $i = 1, \ldots, n$ are chosen to zero elements in the first row from left to right. The same transformation $\hat{U}$ is then applied to

$$(\eta \quad u^T \quad \rho)\,\hat{U} = (\tilde{u}^T \quad \bar{\rho} \quad \rho). \tag{7.7}$$

(Compare the last column of (7.5), and note that $\hat{U}$ does not affect column $n+2$.) Finally we choose $J_{n+1,n+2}$ to zero the element ρ. This will not affect $\tilde{u}$ and $\tilde{S}$ and determines

$$\tilde{\rho} = (\bar{\rho}^2 + \rho^2)^{1/2}. \tag{7.8}$$

Inverse updating algorithm. Given $S = R^{-1}, u, \rho, w$, the data $(X \ s)$, the following algorithm adds a row $(y^T \ \eta)$ and computes the updated quantities $\tilde{S}, \tilde{u}, \tilde{\rho}$, and $\tilde{w}$.

1. Determine $\tilde{u}$ and $\tilde{S}$

$$\begin{pmatrix} 0 & \frac{1}{\xi} \\ \tilde{u}^T & \bar{\rho} \\ \tilde{S} & -\frac{1}{\xi}\tilde{S}p_1 \end{pmatrix} := \begin{pmatrix} 1 & -y^T S \\ \eta & u^T \\ 0 & S \end{pmatrix} \hat{U}, \tag{7.9}$$

where $\hat{U}$ is a product of Givens rotations

$$\hat{U} = J_{12}J_{23}\cdots J_{n,n+1}.$$

2. Compute $\tilde{\rho}$ and the updated solution $\tilde{w}$ from

$$\tilde{\rho} = (\bar{\rho}^2 + \rho^2)^{1/2}, \qquad \tilde{w} = \tilde{S}\tilde{u}.$$

LINPACK inverse downdating algorithm. Given $S = R^{-1}, u, \rho, w$, the data $(X\ s)$, the following algorithm deletes the first row $(z^T\ \sigma)$ and computes the downdated quantities $\tilde{S}$, $\tilde{u}$, $\tilde{\rho}$, and $\tilde{w}$:

1. Compute q_1, v, and γ from

$$q_1 = S^T z, \quad v = Sq_1, \quad \gamma = \left(1 - \|q_1\|_2^2\right)^{1/2}.$$

2. Compute: $\hat{\rho} = (\sigma - z^T w)/\gamma, \quad \tilde{\rho} = (\rho^2 - \hat{\rho}^2)^{1/2}.$
3. Determine $\tilde{u}$ and $\tilde{S}$ from

$$\begin{pmatrix} \sigma & \tilde{u}^T \\ 1 & -z^T\tilde{S} \\ 0 & \tilde{S} \end{pmatrix} := \begin{pmatrix} u^T & \hat{\rho} \\ 0 & \frac{1}{\gamma} \\ S & -\frac{1}{\gamma}v \end{pmatrix} U,$$

where U is a product of Givens rotations

$$U = J_{n,n+1}\cdots J_{23}J_{12}.$$

4. Compute the new solution $\tilde{w}$ from

$$\tilde{w} = \tilde{S}\tilde{u} = w - \frac{1}{\gamma}\hat{\rho}v.$$

CSNE inverse downdating algorithm. Given $S = R^{-1}, u, \rho, w$, the data $(X\ s)$, the following algorithm deletes the first row $(z^T\ \sigma)$ and computes the downdated quantities $\tilde{S}, \tilde{u}, \tilde{\rho}$, and $\tilde{w}$:

1. Compute q_1, v, and t from

$$q_1 = S^T z, \quad v = Sq_1, \quad t := e_1 - Xv.$$

2. Update v and compute γ:

$$\begin{aligned} \delta q_1 &= S^T X^T t, \quad q_1 := q_1 + \delta q_1, \quad \delta v = S\delta q_1, \\ v &:= v + \delta v, \quad t := t - X\delta v, \quad \gamma := \|t\|_2. \end{aligned}$$

3. Set $\psi := \tilde{\rho} := \hat{\rho} := 0$ and compute the residual:

$$r := s - Xw, \qquad \rho = \|r\|_2.$$

If $fl(1+\rho) \neq 1$,

(a) normalize the residual: $\hat{r} = r/\rho$,
(b) modify t: $\psi := e_1^T \hat{r}, \quad t := t - \psi \hat{r}$,
(c) update ψ and t: $\delta\psi := \hat{r}^T t, \quad \psi := \psi + \delta\psi, \quad t := t - \delta\psi\hat{r}$,
(d) compute: $\tilde{\rho} = \|t\|_2 \rho/\gamma, \quad \hat{\rho} = \psi\rho/\gamma$.

4. Determine $\tilde{u}$ and $\tilde{S}$ from

$$\begin{pmatrix} \sigma & \tilde{u}^T \\ 1 & -z^T\tilde{S} \\ 0 & \tilde{S} \end{pmatrix} := \begin{pmatrix} u^T & \hat{\rho} \\ 0 & \frac{1}{\gamma} \\ S & -\frac{1}{\gamma}v \end{pmatrix} U,$$

where U is a product of Givens rotations

$$U = J_{n,n+1} \cdots J_{23} J_{12}.$$

5. Compute the new solution $\tilde{w}$ from

$$\tilde{w} = \tilde{S}\tilde{u} = w - \frac{1}{\gamma}\hat{\rho}v.$$

8. Numerical experiments. In a sliding window method, a least squares solution is computed based on the p latest rows of an observation matrix A, where p is the number of rows in the window matrix [1]. In step k, the new row of observation, $A(k,:)$, is updated into the QR decomposition, and the existing row $A(k-p,:)$ of the data matrix is downdated from the decomposition. If an outlier occurs at step j, then in exact arithmetic its influence will not be seen after step $j+p$. However, the downdating problem is very ill conditioned in the step when the outlier is to be removed, and any algorithm that does not explicitly use Q or the original data X, e.g., the LINPACK algorithm or a hyperbolic rotation-based algorithm [1], is likely to introduce a large error into the decomposition.

In the sliding window context, the storage requirements of the four algorithms presented in the previous sections are the same in the general case, $pn + 0.5n^2$. The GS algorithm requires the orthogonal factor but not the data matrix in storage, while the other algorithms require the data matrix but not the orthogonal factor. However, when X has a special structure, the storage requirement for X can be much smaller than that for Q.

The computational complexities of the four algorithms for each downdating are compared in Table 8.1. We give the operation counts (1 flop = 1 addition and 1 multiplication) for standard and fast [2], [8] Givens rotations. For the hybrid algorithm, the computational complexity is either the same as that for the LINPACK algorithm or the CSNE algorithm. The LINPACK algorithm has a clear advantage in computational complexity. In a sliding window context, the GS algorithm is more expensive also in the updating stage, since the Q factor needs to be modified. For the CSNE algorithm the updating stage is the same as for the LINPACK method. Hence for a complete up/downdating step using standard Givens rotations the GS algorithm requires $11pn + 4.5n^2$, but the CSNE algorithm requires only $4pn + 6.5n^2$ flops. Finally, note that if, for example, X is Toeplitz the term $4pn$ in the operation count for the CSNE algorithm can be reduced by using a fast algorithm for the matrix-vector products with X and X^T.

One application area where downdating is used in connection with the sliding window method is adaptive filtering. In [3] it is noted that in certain situations this method does not perform well as rounding errors accumulate and eventually destroy

TABLE 8.1
Computational complexity of downdating algorithms (flops).

Algorithm	Standard Givens rotations	Fast Givens rotations
GS	$7pn + 2.5n^2$	$5pn + 1.5n^2$
LINPACK	$3n^2$	$2n^2$
CSNE	$4pn + 4.5n^2$	$4pn + 3.5n^2$
Hybrid	$3n^2$ or $4pn + 4.5n^2$	$2n^2$ or $4pn + 3.5n^2$

the solution. Our numerical tests indicate that these difficulties are not to be ascribed to the sliding window method itself, but rather to the downdating algorithm used.

Numerical tests using the sliding window method have been performed in Pro-Matlab with IEEE double precision floating point arithmetic to compare the accuracy of the four downdating algorithms. The solution obtained from the QR decomposition of the window matrix was used as a reference and a window of size 8 was used throughout. In each figure, we present the relative error in Euclidean norm in the downdated solution vector by the LINPACK, CSNE, hybrid, and GS algorithms. The spectral condition number κ_X of the window matrix to be downdated and $1/\gamma^2$, which is a measure of the conditioning of the downdating problem (6.6), are also shown. The values of $1/\gamma^2$ are from the hybrid method. A plus (+) sign in the plot shows where iterative refinement is made in the hybrid method. We have used the following criterion: if $\gamma^2 < 0.25$, then downdating is performed with the CSNE method.

The following test problems are similar to those in [6]. They were also used in the context of adaptive condition number estimation in [7]. Tests I and II illustrate the downdating of R and Test III illustrates the downdating of R^{-1}.

Test I. A random matrix $A \in \mathbf{R}^{50\times 5}$ was constructed with elements taken from a uniform distribution in $(0, 1)$. An outlier equal to $r \cdot 10^3$, where r is random number from the same distribution, was added in position (18,3). The right-hand side vector b was taken to be $b = Ax_0 + b_r$, where b_r has random elements uniformly distributed in $(0, 10^{-6})$, and x_0 is 5×1 vector with ones as its components.

The results are shown in Fig. 8.1. It is seen that the relative error in the solution using the LINPACK algorithm is considerably magnified in the ill-conditioned downdating step and that it remains on that high level even if the subsequent downdating steps are well conditioned. The other algorithms are much less affected by the ill-conditioned downdating and the errors remain on a low level throughout.

Test II. A 50×5 matrix was constructed by taking a 25×5 Hilbert matrix as the first 25 rows, and the same rows in reversed order as the 25 last rows. Then a perturbation from a uniform distribution in $(0, \delta)$ was added to each matrix element. Two different cases were studied, with $\delta = 10^{-5}$ and 10^{-9}, respectively. The right-hand side was constructed as in Test I, but here with a random perturbation in $(0, 10^{-6})$.

In Fig. 8.2 we show the results obtained with $\delta = 10^{-5}$. Throughout this test the downdating problem is rather ill conditioned, so iterative refinement is performed in most steps in the hybrid algorithm. It is remarkable that the LINPACK algorithm performs so much worse than the others. This is probably due to the fact that the window matrix is very ill conditioned, which leads to large errors in the computed approximations of q_1. In the CSNE method this vector is refined and much better accuracy is attained.

In Fig. 8.3 we show the results obtained with $\delta = 10^{-9}$. Here the window matrix

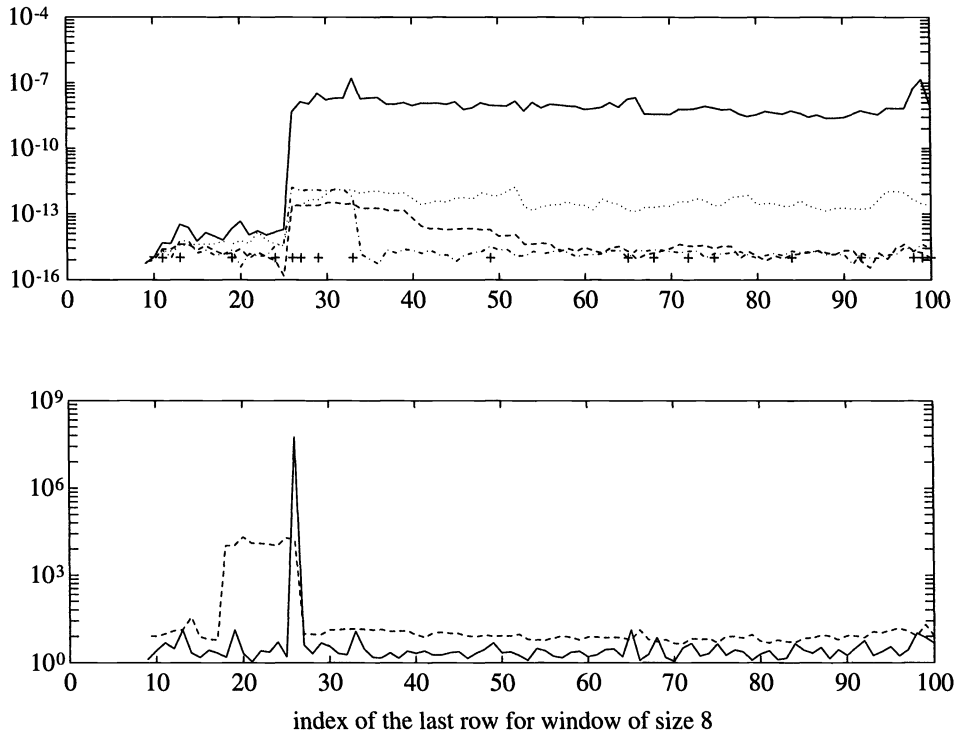

FIG. 8.1. *Test* I. *The upper graph shows the relative error in Euclidean norm in the downdated solution vector by the* LINPACK (*solid line*), CSNE (*dashed*), *hybrid* (*dotted*), *and* GS (*dot-dashed*) *algorithms. A plus* (+) *sign in the plot shows where iterative refinement is made in the hybrid method. The lower graph shows the condition number* κ_X *of the window matrix to be downdated* (*dotted*) *and* $1/\gamma^2$ (*solid line*).

is even more ill conditioned, and after some steps the LINPACK algorithm breaks down because a computed q_1 has norm larger than 1.

Test III. Two problems were solved. The first is the same as in Test I, and the second is the same as in Test II with $\delta = 10^{-5}$. The results are for LINPACK, CSNE, and hybrid *inverse* downdating and are shown in Fig. 8.4.

9. Concluding remarks. We have studied two standard methods for downdating least squares solutions: the LINPACK and the GS algorithms; and two new methods, the CSNE algorithm and a hybrid algorithm CSNE/LINPACK. In terms of storage requirements the four algorithms are all the same in the general case. However, when X has a special structure, the storage requirement for the LINPACK and CSNE algorithms can be much smaller than that for the GS algorithm.

The algorithms differ considerably in efficiency and accuracy. The LINPACK algorithm is the fastest, but the analysis and the tests show that it can be much less accurate or even fail. It is clear that the CSNE algorithm is more accurate but considerably slower than the LINPACK algorithm. However, if X has some special structure, the difference in efficiency may be less pronounced. The hybrid algorithm has almost as good accuracy as the CSNE algorithm and it can be much more efficient. The GS algorithm is comparable in accuracy to the CSNE algorithm, but it is also

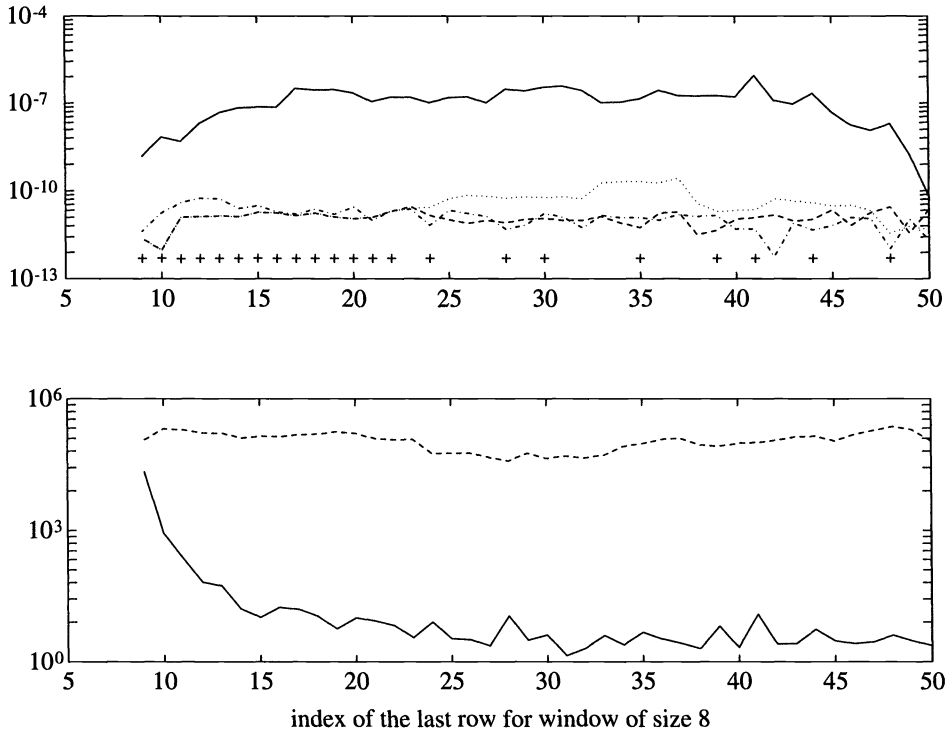

FIG. 8.2. *Test* IIa. *Modified Hilbert matrix with perturbations from a uniform distribution in* $(0, 10^{-5})$.

the slowest of the four algorithms.

The reason why the LINPACK algorithm is inferior in terms of accuracy to the three others is that it uses less information, i.e., only the R factor. The others use both R and either the Q factor (GS) or the original data matrix X (CSNE and hybrid). Note that other methods which only use R (e.g., methods based on hyperbolic transformations) will show a similar loss of accuracy as the LINPACK algorithm.

Our results indicate that in cases where, for example, outliers occur, the CSNE and the GS algorithms are the safest choices. If accuracy and efficiency are both important, then the hybrid method may be a better alternative than the LINPACK algorithm. Further study is needed in deciding how to choose the tolerance used in the hybrid algorithm to switch between the CSNE and LINPACK algorithms.

We have also shown that the new methods for downdating R can be extended to downdate R^{-1}. More numerical experiments are needed in this area.

Acknowledgments. A large part of this work was performed when Å. Björck and L. Eldén visited the Institute for Mathematics and its Applications at the University of Minnesota, Minneapolis, during the Applied Linear Algebra year. We are grateful for the pleasant working conditions and for the stimulating environment.

We are also grateful to R. J. Plemmons for suggesting the application of the algorithms to the problem of downdating the inverse of R.

ITERATIVE CONSISTENCY: A CONCEPT FOR THE SOLUTION OF SINGULAR SYSTEMS OF LINEAR EQUATIONS*

M. HANKE†

Abstract. This paper deals with the computation of generalized solutions of singular linear systems of equations by *semi-iterative methods*. A new concept called *iterative consistency* is introduced to characterize linear fixed-point equations which lead to certain prescribed generalized solutions of the original problem. Several properties of this concept are discussed.

Perturbations of such iteratively consistent fixed-point equations give rise to the computation of perturbed limit points. These approximants can still be interpreted as appropriate generalized solutions of the original system. Error expressions and first order derivatives are derived. The results are illustrated by the successive overrelaxation (SOR) and by the symmetric SOR (SSOR) method.

Key words. singular linear systems, iterative methods, SOR method, generalized inverses

AMS subject classifications. 65F10, 65F20

1. Introduction and definition.

Consider the singular linear system of equations

$$A\mathbf{x} = \mathbf{b} + \epsilon =: \hat{\mathbf{b}}, \tag{1.1}$$
$$A \in \mathbb{C}^{m\times n}, \qquad \mathbf{b}, \hat{\mathbf{b}}, \epsilon \in \mathbb{C}^m.$$

Here, $\mathbf{b}$ denotes some available approximation of the correct right-hand side $\hat{\mathbf{b}}$, $\epsilon = \hat{\mathbf{b}} - \mathbf{b}$ the corresponding error, and $\mathbf{x} \in \mathbb{C}^n$ the unknown solution. In engineering applications it is typically assumed that ϵ has certain statistical properties, e.g., that ϵ is a random variable with zero mean (cf. Björck [3]).

Appropriate estimates for $\mathbf{x}$ in (1.1) are

$$\mathbf{x} = A^-\mathbf{b},$$

where here and further on, the term A^- is used to denote some arbitrarily specified *generalized inverse* of A. The reader should be familiar with the basic terminology of this subject. The notations used here agree with those used in the standard reference book by Ben-Israel and Greville [1].

According to the Gauss–Markov theory of linear estimation, it is optimal in a certain sense to select for A^- a *weighted generalized inverse* $A^{(1,2)}_{(W,U)}$ ([1, §III.3]), where W^{-1} is the Hermitian, positive definite covariance matrix associated with ϵ. For $\mathbf{x} = A^{(1,2)}_{(W,U)}\mathbf{b}$, $\mathbf{x}' \in \mathbb{C}^n \setminus \{\mathbf{x}\}$ arbitrary, it is

$$\|\mathbf{b} - A\mathbf{x}\|_W^2 := (\mathbf{b} - A\mathbf{x})^* W(\mathbf{b} - A\mathbf{x}) \le \|\mathbf{b} - A\mathbf{x}'\|_W^2$$

and

$$\|\mathbf{b} - A\mathbf{x}\|_W = \|\mathbf{b} - A\mathbf{x}'\|_W \;\Rightarrow\; \|\mathbf{x}\|_U^2 := \mathbf{x}^* U\mathbf{x} < \|\mathbf{x}'\|_U^2.$$

Thus, $\mathbf{x}$ is the unique solution of a *generalized least squares problem.*

† Institut für Praktische Mathematik, Universität Karlsruhe, Englerstr. 2, W-7500 Karlsruhe, Germany.

The idea behind this paper is to compute linear approximations $\mathbf{x}_k$ fulfilling

$$\mathbf{x}_k = X_k \mathbf{b} \;\to\; A^{(1,2)}_{(W,U)} \mathbf{b}, \qquad k \to \infty. \tag{1.2}$$

More precisely, it will be assumed that $\mathbf{x}_k$ are *polynomial iterates* of a fixed-point equation

$$\mathbf{x} = T\mathbf{x} + Q\mathbf{b}, \qquad Q \in \mathbb{C}^{n\times m},\ T \in \mathbb{C}^{n\times n}, \tag{1.3}$$

i.e., there exist polynomials q_{k-1} of degree $k-1$ such that

$$\mathbf{x}_k = q_{k-1}(T)Q\mathbf{b}. \tag{1.4}$$

Such $\mathbf{x}_k$ may be computed efficiently by a *semi-iterative method* [7], [6],

$$\mathbf{x}_k = \mu_{0,k}(T\mathbf{x}_{k-1} + Q\mathbf{b}) + \mu_{1,k}\mathbf{x}_{k-1} + \cdots + \mu_{k,k}\mathbf{x}_0, \qquad \mathbf{x}_0 = \mathbf{0},$$

$$\mu_{0,k} \neq 0, \quad \mu_{0,k} + \cdots + \mu_{k,k} = 1, \quad k \geq 0,$$

where the weights $\mu_{j,k}$ are the coefficients of the recursive definition of the so-called *residual polynomials*

$$p_k(z) = 1 + (z-1)q_{k-1}(z).$$

Designing such a semi-iterative method, one must pay special attention to the difficulties arising from the potential singularity of (1.3): Relevant to this, it has been shown by Eiermann, Marek, and Niethammer [6] how to select polynomials q_{k-1} such that

$$q_{k-1}(T) \to (I-T)^{(d)}, \qquad k \to \infty,$$

the *Drazin generalized inverse* of $I - T$.

Comparing (1.2) and (1.4), this leads to the stipulation

$$(I-T)^{(d)}Q\mathbf{b} = A^{(1,2)}_{(W,U)}\mathbf{b},$$

and, due to the unknown value of ϵ in (1.1), this requirement should be fulfilled for every $\mathbf{b} \in \mathbb{C}^m$.

DEFINITION 1.1. *The fixed-point equation* (1.3) *is called iteratively consistent with A via the generalized inverse A^- of A if*

$$(I-T)^{(d)}Q = A^-. \tag{1.5}$$

It is called iteratively consistent with A if (1.5) *is a weighted generalized inverse of A.*

This definition, which was introduced in the author's dissertation [9], differs significantly from definitions of Young [17], Kammerer and Plemmons [12], and Berman and Neumann [2]. In these works, $\mathbf{b}$ and $Q\mathbf{b}$ were assumed to be fixed, and, instead of (1.5), conditions were imposed on certain sets of generalized solutions to (1.1) and (1.3).

In the following sections, fixed-point equations are investigated that are iteratively consistent with A. Section 2 presents a survey of certain properties of such equations; some of these results have been derived in an earlier paper with Neumann [10]. Reasonings of perturbation theoretical nature are included in §3. Section 4 contains some applications that include positive definite preconditionings of the normal equations and the SOR and the SSOR methods.

2. Basic properties. In the beginning, the special case is considered where A is of full column rank. This is a common assumption that, for itself, is of interest.

PROPOSITION 2.1. *Let A be of full column rank. If* (1.3) *is iteratively consistent with A then $T = I - QA$.*

Proof. Let A^- denote the weighted generalized inverse in (1.5). Since $\mathcal{N}(A) = \{\mathbf{0}\}$, it follows that $A^-A = I$. Inserting this in (1.5) yields

$$(I - T)^{(d)}QA = A^-A = I,$$

whence $I - T$ is regular. Multiplying $I - T$ from the left verifies the assertion. □

Compare Proposition 2.1 with analogous characterizations of Young [17, Thm. 3-2.6] and Chen [5, Thm. 2.2-3] or [10, Thm. C] concerning their definition of consistency.

If $T = I - QA$ then the fixed-point equation (1.3) may be written as

$$\mathbf{x} = \mathbf{x} + Q(\mathbf{b} - A\mathbf{x}) \tag{2.1}$$

and thus looks like a *preconditioning* of the original problem; Q is called the *preconditioner*. Other fixed-point equations have been derived in the literature from *splittings* of A; they are not considered here. However, many of the present results can be carried over to such equations (cf. [9]): The clue to doing this may be found in [10, Thm. 4].

In the following theorem ([10, Thm. 2]) iteratively consistent fixed-point equations with A are characterized.

THEOREM 2.2. *The following four statements are equivalent:*

(i) *The fixed-point equation* (2.1) *is iteratively consistent with A,*
(ii) $\mathcal{N}(AQ) \oplus \mathcal{R}(A) = \mathbb{C}^m$,
(iii) $\mathcal{R}(QA) \oplus \mathcal{N}(A) = \mathbb{C}^n$,
(iv) $\operatorname{index}(QA) \leq 1$ *and* $\mathcal{R}(A) \cap \mathcal{N}(Q) = \{\mathbf{0}\}$.

Notice that equations of the form (2.1) automatically lead to a $\{2\}$-inverse (1.5) of A ([10, Lemma 1]). Thus, for fixed-point equations of such a form, iterative consistency with A is equivalent to iterative consistency with A via some $\{1\}$-inverse of A.

Let one of the conditions of Theorem 2.2 be fulfilled and define A^- as in (1.5). Then,

$$\mathcal{N}(AQ) = \mathcal{N}(A^-), \qquad \mathcal{R}(QA) = \mathcal{R}(A^-) \tag{2.2}$$

([10, Thm. 2]) and

$$\mathcal{N}(QA) = \mathcal{N}(A), \qquad \mathcal{R}(AQ) = \mathcal{R}(A) \tag{2.3}$$

([10, Coro. 3]). With the help of these equations, it is easy to characterize those preconditioners Q for which A^- is a $\{1,2,3\}$- or a $\{1,2,4\}$-inverse of A; the case $A^- = A^\dagger$ has been dealt with in [10].

Finally, it must be emphasized that iterative consistency with A implies that index $(QA) \leq 1$. This enables the construction of efficient semi-iterative schemes (1.4). Such schemes were explored in [9], and the corresponding results will be published elsewhere.

3. Derivatives and error terms of Wedin's type. The following analysis concerns the stability of (1.5) relative to perturbations of the preconditioner. Therefore, it will be convenient to consider perturbations of oblique projectors; closely related results may be found in Nashed [14] and in Golub and Pereyra [8].

Let $B, B_\omega \in \mathbb{C}^{n\times n}$ be such that $\operatorname{index}(B) = \operatorname{index}(B_\omega) = 1$; occasionally, B_ω is required to be a continuous matrix function of $\omega \in \mathbb{C}^r$ fulfilling the above properties in an environment of $\omega = 0$ with $B_0 = B$.

THEOREM 3.1. *Let* $P = P_{\mathcal{R}(B),\mathcal{N}(B)}$, $P_\omega = P_{\mathcal{R}(B_\omega),\mathcal{N}(B_\omega)}$. *Then*

$$P_\omega - P = B_\omega^{\#}(B_\omega - B)(I - P) + (I - P_\omega)(B_\omega - B)B^{\#}. \tag{3.1}$$

If B_ω *has a Fréchet derivative* $\mathbf{D}B$ *in* $\omega = 0$ *and if the rank of* B_ω *is constant in an environment of* $\omega = 0$, *then* P_ω *is Fréchet differentiable in* $\omega = 0$ *with derivative*

$$\mathbf{D}P = B^{\#}\mathbf{D}B(I - P) + (I - P)\mathbf{D}BB^{\#}.$$

Proof. Equation (3.1) is easily checked using the identities

$$P = B^{\#}B = BB^{\#}, \qquad P_\omega = B_\omega^{\#}B_\omega = B_\omega B_\omega^{\#}.$$

Under the given assumptions, $B_\omega^{\#} \to B^{\#}$ as $\omega \to 0$ [4] and the derivative $\mathbf{D}P$ can be obtained from (3.1) by letting $\omega \to 0$. □

The following lemma is required to prove the main result of this section.

LEMMA 3.2. *Let* (2.1) *be iteratively consistent with* A. *Then* $\operatorname{index}(AQ) \le 1$ *and*

$$(QA)^{\#}Q = Q(AQ)^{\#}, \qquad (AQ)^{\#}A = A(QA)^{\#}. \tag{3.2}$$

Proof. Define A^- as in (1.5). It follows from (2.2) and (2.3) that $\operatorname{index}(AQ) \le 1$ because A^- is a weighted generalized inverse.

Now, $\mathbf{x} \in \mathcal{N}(AQ)$ implies $Q(AQ)^{\#}\mathbf{x} = \mathbf{0}$ as well as $Q\mathbf{x} \in \mathcal{N}(A) \subset \mathcal{N}(QA)$. Therefore, $(QA)^{\#}Q\mathbf{x} = \mathbf{0}$, also.

Let $\mathbf{x} \in \mathcal{R}(AQ)$. Since $\mathcal{R}(AQ) = \mathcal{R}((AQ)^2)$, there exists some vector $\mathbf{u} \in \mathbb{C}^m$ such that $\mathbf{x} = (AQ)^2\mathbf{u}$. As a consequence,

$$\begin{aligned}(QA)^{\#}Q\mathbf{x} &= (QA)^{\#}(QA)^2Q\mathbf{u} = QAQ\mathbf{u}\\ &= Q(AQ)^{\#}(AQ)^2\mathbf{u} = Q(AQ)^{\#}\mathbf{x}.\end{aligned}$$

The first equation in (3.2) has thus been verified for $\mathbf{x} \in \mathbb{C}^n = \mathcal{N}(AQ) \oplus \mathcal{R}(AQ)$; the second equation follows in the same way. □

Let Q_ω be an approximation of $Q \in \mathbb{C}^{n\times m}$. As before, Q_ω may be a matrix function of $\omega \in \mathbb{C}^r$ with $Q_0 = Q$. Theorem 3.3 considers the consistency of the perturbed fixed-point equation

$$\mathbf{x} = \mathbf{x} + Q_\omega(\mathbf{b} - A\mathbf{x}). \tag{3.3}$$

THEOREM 3.3. *Let* (2.1) *be iteratively consistent with* A *via the weighted generalized inverse* A^- *and let* $\mathcal{R} = \mathcal{R}(A^-)$, $\mathcal{N} = \mathcal{N}(A^-)$. *If* $Q_\omega - Q$ *is sufficiently small, then* (3.3) *is iteratively consistent with* A. *If the latter holds, and if* A_ω^- *denotes the corresponding weighted generalized inverse of* A, *then*

$$A_\omega^- - A^- = P_{\mathcal{N}(A),\mathcal{R}(Q_\omega A)}(Q_\omega - Q)(AQ)^{\#} + (Q_\omega A)^{\#}(Q_\omega - Q)P_{\mathcal{N},\mathcal{R}(A)}. \tag{3.4}$$

If Q_ω is Fréchet differentiable in $\omega = 0$ with derivative $\mathbf{D}Q$ then the Fréchet derivative of A_ω^- in $\omega = 0$ exists and is given by

$$\mathbf{D}A^- = P_{\mathcal{N}(A),\mathcal{R}}\mathbf{D}Q(AQ)^\# + (QA)^\#\mathbf{D}QP_{\mathcal{N},\mathcal{R}(A)}.$$

Proof. Recall that $\mathcal{R}$ and $\mathcal{N}(A)$ are complementary subspaces. By Theorem 2.2, $\mathcal{N}(A) = \mathcal{N}(AQA)$, whence there exists a positive number α such that

$$\|AQA\mathbf{x}\| \geq \alpha \quad \forall\, \mathbf{x} \in \mathcal{R},\ \|\mathbf{x}\| = 1$$

($\|\cdot\|$ always denotes the Euclidean norm or the spectral norm, respectively). If $\|Q_\omega - Q\| < \alpha/\|A\|^2$, this implies

$$AQ_\omega A\mathbf{x} \neq \mathbf{0} \quad \forall\, \mathbf{x} \in \mathcal{R}\{\mathbf{0}\}.$$

Thus, $\mathcal{N}(AQ_\omega A) = \mathcal{N}(A)$ so that

$$\mathcal{R}(Q_\omega A) \cap \mathcal{N}(A) = \{\mathbf{0}\}.$$

Since $\dim \mathcal{R}(Q_\omega A) \geq \dim \mathcal{R}(QA)$ as Q_ω is sufficiently close to Q, it follows from Theorem 2.2 (iii) that (3.3) is iteratively consistent with A.

A fundamental equality for weighted generalized inverses is used next (cf., e.g., [1, Thm. 2.10c] or [14, p. 348]):

$$A_\omega^- = P_{\mathcal{R}(A_\omega^-),\mathcal{N}(A)}A^-P_{\mathcal{R}(A),\mathcal{N}(A_\omega^-)}. \tag{3.5}$$

Since $\mathcal{N}(A) = \mathcal{N}(QA) = \mathcal{N}(Q_\omega A)$ and $\mathcal{R}(A) = \mathcal{R}(AQ) = \mathcal{R}(AQ_\omega)$ (cf. (2.3)), it is

$$P_{\mathcal{R}(A_\omega^-),\mathcal{N}(A)} = (Q_\omega A)^\# Q_\omega A, \qquad P_{\mathcal{R}(A),\mathcal{N}(A_\omega^-)} = (AQ_\omega)^\# AQ_\omega.$$

Substituting (3.1) for $P_\omega = P_{\mathcal{R}(A),\mathcal{N}(A_\omega^-)}$ in (3.5) gives

$$A_\omega^- = P_{\mathcal{R}(A_\omega^-),\mathcal{N}(A)}A^-[P_{\mathcal{R}(A),\mathcal{N}} + (AQ_\omega)^\# A(Q_\omega - Q)P_{\mathcal{N},\mathcal{R}(A)}]$$

because the last term in (3.1) vanishes. Using Lemma 3.2, one has

$$\begin{aligned} A_\omega^- &= P_{\mathcal{R}(A_\omega^-),\mathcal{N}(A)}A^- + P_{\mathcal{R}(A_\omega^-),\mathcal{N}(A)}P_{\mathcal{R}(A^-),\mathcal{N}(A)}(Q_\omega A)^\#(Q_\omega - Q)P_{\mathcal{N},\mathcal{R}(A)} \\ &= P_{\mathcal{R}(A_\omega^-),\mathcal{N}(A)}A^- + (Q_\omega A)^\#(Q_\omega - Q)P_{\mathcal{N},\mathcal{R}(A)}. \end{aligned}$$

Now (3.4) follows in a similar way by inserting (3.1) for $P_\omega = P_{\mathcal{R}(A_\omega^-),\mathcal{N}(A)}$.

The derivative is obtained from (3.4) by letting $\omega \to 0$. □

Theorem 3.3 may be interpreted as follows: Iterative consistency with A is a property that remains valid under small perturbations of the preconditioner; in a sense, iterative consistency with A is thus a *robust property.*

Different proofs are possible to derive (3.4) and the present one may not be the most straightforward one. It is given, though, because it is based on formula (3.5). In fact, it will be seen in the following section that in certain special cases the projectors in (3.5) can be expressed explicitly in terms of Q and Q_ω only.

Formulas of type found in (3.1) and (3.4) are similar to the well-known expression of Wedin [16] for the difference of the Moore–Penrose inverses of A and B:

$$B^\dagger - A^\dagger = -B^\dagger(B - A)A^\dagger + P_{\mathcal{N}(B)}(B - A)^\star(AA^\star)^\dagger + (B^\star B)^\dagger(B - A)^\star P_{\mathcal{R}(A)^\perp}.$$

The reader may find further formulae of this kind together with some applications in the survey paper of Stewart [15].

Estimates for the difference of two weighted generalized inverses of the *same* matrix A may be found in [14].

4. Some applications. Let (1.3) have the form

$$\mathbf{x} = \mathbf{x} + D^{-1}A^*(\mathbf{b} - A\mathbf{x}), \qquad D \in \mathbb{C}^{n\times n}. \tag{4.1}$$

If D is Hermitian, positive definite, the *preconditioned conjugate gradient method* may be applied for the iteration of (4.1). With such a choice of D, it is easy to see that (4.1) is iteratively consistent with A.

Let $\mathbf{y} \in \mathbb{C}^m$ be some arbitrary vector; if

$$\mathbf{y}^*AD^{-1}A^*\mathbf{y} = \|D^{-1/2}A^*\mathbf{y}\|^2 = 0,$$

then this implies $D^{-1/2}A^*\mathbf{y} = \mathbf{0}$, whence $\mathbf{y} \in \mathcal{R}(A)^\perp$. Therefore,

$$\mathcal{N}(AD^{-1}A^*) = \mathcal{R}(A)^\perp$$

and the assertion follows from Theorem 2.2(ii).

As an example, let D be the (block-)diagonal part of A^*A: In this case, (4.1) is the fixed-point equation of the (*block-*)*Jacobi method* for the normal equations system. Applications to SOR and SSOR theory follow from the investigation of fixed-point equations of the form

$$\mathbf{x} = \mathbf{x} + \omega D_\omega^{-1}A^*(\mathbf{b} - A\mathbf{x}), \qquad D_\omega \in \mathbb{C}^{n\times n}, \tag{4.2}$$

where D_ω is connected to D in (4.1).

THEOREM 4.1. *Let D and D_ω be regular matrices in $\mathbb{C}^{n\times n}$ and $E_\omega = D_\omega - D$. Assume that* (4.1) *is iteratively consistent with A via the weighted generalized inverse A^-. Then, the fixed-point equation* (4.2) *is iteratively consistent with A if and only if $I + P_{\mathcal{N}(A),\mathcal{R}(A^-)}D^{-1}E_\omega$ is regular, in which case the corresponding generalized inverse of A is defined as*

$$A_\omega^- = (I + P_{\mathcal{N}(A),\mathcal{R}(A^-)}D^{-1}E_\omega)^{-1}A^-. \tag{4.3}$$

Proof. Denote $\mathcal{R}_\omega = \mathcal{R}(D_\omega^{-1}A^*A)$ and let

$$Z = I + P_{\mathcal{N}(A),\mathcal{R}(A^-)}D^{-1}E_\omega = P_{\mathcal{R}(A^-),\mathcal{N}(A)} + P_{\mathcal{N}(A),\mathcal{R}(A^-)}D^{-1}D_\omega.$$

Since $D^{-1}D_\omega$ maps $\mathcal{R}_\omega$ onto $\mathcal{R}(A^-) = \mathcal{R}(D^{-1}A^*A)$, it follows that

$$Z : \begin{cases} \mathcal{R}_\omega & \to \quad \mathcal{R}(A^-), \\ \mathcal{N}(A) & \to \quad \mathcal{N}(A). \end{cases} \tag{4.4}$$

Let Z be regular. Since (4.1) is iteratively consistent with A, Theorem 2.2(iii) states that $\mathcal{R}(A^-) \oplus \mathcal{N}(A) = \mathbb{C}^n$. From (4.4) and the regularity of Z, it follows that

$$\mathcal{R}_\omega \oplus \mathcal{N}(A) = \mathbb{C}^n$$

(note that $\dim \mathcal{R}_\omega = \dim \mathcal{R}(A^-)$). Therefore, (4.2) is iteratively consistent with A. The respective weighted generalized inverse A_ω^- fulfills (cf. (2.2))

$$\mathcal{R}(A_\omega^-) = \mathcal{R}_\omega, \qquad \mathcal{N}(A_\omega^-) = \mathcal{N}(AD_\omega^{-1}A^*) = \mathcal{R}(A)^\perp = \mathcal{N}(A^-).$$

Using (3.5),

$$A_\omega^- = P_{\mathcal{R}_\omega,\mathcal{N}(A)}A^-P_{\mathcal{R}(A)} = P_{\mathcal{R}_\omega,\mathcal{N}(A)}A^-.$$

With the help of (4.4), it is readily checked that

$$P_{\mathcal{R}_\omega,\mathcal{N}(A)} = Z^{-1}P_{\mathcal{R}(A^-),\mathcal{N}(A)}Z,$$

whence (4.3) follows:

$$A_\omega^- = Z^{-1}P_{\mathcal{R}(A^-),\mathcal{N}(A)}(I + P_{\mathcal{N}(A),\mathcal{R}(A^-)}D^{-1}E_\omega)A^- = Z^{-1}A^-.$$

Now, let (4.2) be iteratively consistent with A and suppose $\mathbf{x} \in \mathcal{N}(Z)$. This implies

$$\mathbf{0} = (I + P_{\mathcal{N}(A),\mathcal{R}(A^-)}D^{-1}E_\omega)\mathbf{x} = \mathbf{x} + \mathbf{z}$$

with $\mathbf{z} \in \mathcal{N}(A)$. Therefore, $\mathbf{x} \in \mathcal{N}(A)$ and, consequently,

$$\mathbf{0} = (P_{\mathcal{R}(A^-),\mathcal{N}(A)} + P_{\mathcal{N}(A),\mathcal{R}(A^-)}D^{-1}D_\omega)\mathbf{x} = P_{\mathcal{N}(A),\mathcal{R}(A^-)}D^{-1}D_\omega\mathbf{x}.$$

Hence, $D^{-1}D_\omega\mathbf{x} \in \mathcal{R}(A^-)$ so that

$$\mathbf{x} \in D_\omega^{-1}D(\mathcal{R}(A^-)) = \mathcal{R}_\omega.$$

By assumption, $\mathcal{R}_\omega \cap \mathcal{N}(A) = \{\mathbf{0}\}$, which implies $\mathcal{N}(Z) = \{\mathbf{0}\}$. □

COROLLARY 4.2. *Under the conditions of Theorem* 4.1, (4.2) *is iteratively consistent with* A *via* A_ω^- *of* (4.3) *if*

$$\|P_{\mathcal{N}(A),\mathcal{R}(A^-)}D^{-1}E_\omega\| < 1.$$

In this case, the following estimate is valid:

$$\frac{\|A_\omega^- - A^-\|}{\|A^-\|} \leq \frac{\|P_{\mathcal{N}(A),\mathcal{R}(A^-)}D^{-1}E_\omega\|}{1 - \|P_{\mathcal{N}(A),\mathcal{R}(A^-)}D^{-1}E_\omega\|}. \tag{4.5}$$

Proof. If $\|P_{\mathcal{N}(A),\mathcal{R}(A^-)}D^{-1}E_\omega\| < 1$ then $I + P_{\mathcal{N}(A),\mathcal{R}(A^-)}D^{-1}E_\omega$ is invertible, whence (4.2) is iteratively consistent with A via A_ω^- of (4.3). Inserting the convergent Neumann series expansion gives

$$A_\omega^- = \sum_{\nu=0}^{\infty}(-P_{\mathcal{N}(A),\mathcal{R}(A^-)}D^{-1}E_\omega)^\nu A^-,$$

whence

$$\|A_\omega^- - A^-\| \leq \sum_{\nu=1}^{\infty}\|P_{\mathcal{N}(A),\mathcal{R}(A^-)}D^{-1}E_\omega\|^\nu \, \|A^-\|.$$

This proves (4.5). □

Suppose that the triangular splitting of A^*A is given, i.e., let

$$A^*A = D - L - L^*, \tag{4.6}$$

where L is a strictly lower (block-)triangular matrix and D is a (block-)diagonal matrix. Choosing

$$D_\omega = D - \omega L,$$

(4.2) is the fixed-point equation of the SOR method relative to (4.6). If

$$D_\omega = \frac{1}{2-\omega}(D-\omega L)D^{-1}(D-\omega L^*),$$

then (4.2) corresponds to the SSOR method (cf. [17]). In both instances it follows from results of Keller [13] that

$$\mathcal{R}(D_\omega^{-1}A^*A) \oplus \mathcal{N}(D_\omega^{-1}A^*A) = \mathbb{C}^n, \qquad 0 < \omega < 2,$$

which proves the iterative consistency of (4.2) with A for ω in the given range. The respective weighted generalized inverses are defined by (4.3). (For the SSOR method, one should substitute $E_\omega = 2D_\omega - D$.)

Moreover, since $E_\omega \to 0$ as $\omega \to 0$, the conditions of Corollary 4.2 are fulfilled for ω sufficiently close to 0.

For a more specific example, let A be normalized such that $D = I$. Choose $0 < \omega < \min\{2, 1/\|L\|\}$. With this choice of ω the SOR method converges according to [13]; denote the limit by $\hat{\mathbf{x}}$. As in (4.5), it follows that

$$\frac{\|\hat{\mathbf{x}} - A^\dagger \mathbf{b}\|}{\|A^\dagger \mathbf{b}\|} \le \omega \frac{\|L\|}{1-\omega\|L\|}.$$

Using (4.3), the following à-posteriori estimate may be obtained:

$$\|\hat{\mathbf{x}} - A^\dagger \mathbf{b}\| \le \omega \|L\hat{\mathbf{x}}\|.$$

Analogous results have been developed in [9] for fixed-point equations of the form

$$\mathbf{x} = \mathbf{x} + \omega A^* D_\omega^{-1}(\mathbf{b} - A\mathbf{x}),$$

where $D_\omega \in \mathbb{C}^{m\times m}$ is a regular matrix; some of these results have been published in [11].

Acknowledgments. I would like to thank all those who contributed to the accomplishment of my dissertation, especially Professor Wilhelm Niethammer for raising my interest in this topic and advising me through this thesis, Professor Michael Neumann for many valuable discussions and a pleasant stay in Connecticut, and the Deutsche Forschungsgemeinschaft for their financial support.

ALGORITHMS FOR COMPUTING BASES FOR THE PERRON EIGENSPACE WITH PRESCRIBED NONNEGATIVITY AND COMBINATORIAL PROPERTIES*

MICHAEL NEUMANN† AND HANS SCHNEIDER‡

Abstract. Let P be an $n \times n$ nonnegative matrix. In this paper the authors introduce a method called the SCANBAS algorithm for computing a union of (Jordan) chains $\mathcal{C}$ corresponding to the Perron eigenvalue of P, such that $\mathcal{C}$ consists of nonnegative vectors only and such that at each height, $\mathcal{C}$ contains the maximal number of nonnegative vectors of that height possible in a height basis for the Perron eigenspace of P. It is further shown that $\mathcal{C}$ can be extended to a height basis for the Perron eigenspace of P. The chains are extracted from transform components of P that are, in turn, polynomials in P. When the Perron eigenspace has a Jordan basis consisting of nonnegative vectors only, this algorithm computes such a basis. The paper concludes with various examples computed by the algorithm using MATLAB. The work here continues and deepens work on computing nonnegative bases for the Perron eigenspace from polynomials in the matrix already begun by Hartwig, Neumann, and Rose and by Neumann and Schneider.

1. Introduction.

In this paper we continue an investigation begun by Hartwig, Neumann, and Rose [6] and Neumann and Schneider [11] on nonnegative and combinatorial properties of bases for the Perron eigenspace of a nonnegative matrix, which can be extracted from certain polynomials in the matrix.

More specifically, let P be an $n \times n$ nonnegative matrix and $\rho(P)$ its spectral radius which is well known to be an eigenvalue of P, called its *Perron root.* A more comprehensive explanation and detailed background to some of the concepts used in this introduction and appropriate references are given in the next sections. Let Z be the eigenprojection of P at $\rho(P)$. In [6] it was shown that for sufficiently small $\epsilon > 0$, the matrix

$$J(\epsilon) = [(\epsilon + \rho(P))I - P]^{-1}Z \tag{1.1}$$

is nonnegative and its columns contain a basis of nonnegative vectors for the (generalized) eigenspace of P corresponding to $\rho(P)$ known as the *Perron eigenspace of* P. Furthermore, an algorithm for computing ϵ and hence a method for computing such a basis was suggested in [6, Thm. 2.2].

In [11] it was observed that since $J(\epsilon)$ is an analytic function in P, it is a polynomial in P, so that if P is put, say, in block lower triangular Frobenius normal form, then $J(\epsilon)$ would be a block lower triangular matrix conforming to the block partitioning in the Frobenius normal form of P. Thus combinatorial properties possessed by certain nonnegative bases for the Perron eigenspace of P that were present in the first proofs of the existence of such basis for the Perron eigenspace of P obtained by Rothblum [13] and Richman and Schneider [12] could be extracted from the columns

of $J(\epsilon)$, and this idea led to the investigation in [11]. The combinatorial properties that the authors of [11] had in mind to recapture from the columns of $J(\epsilon)$ were access relations in the directed graph of P or, more precisely, in the block directed graph that can be associated with the Frobenius normal form of P known as the *reduced graph of* P. Indeed, in [11], it was shown that for sufficiently small $\epsilon > 0$, nonnegative bases from the columns of $J_T(\epsilon)$ could be chosen that are *strongly combinatorial.* (See §2 and [11] for precise definitions of these terms.)

The purpose of this paper is to go one step deeper in search of combinatorial and algebraic properties of bases that can be extracted from the columns of $J(\epsilon)$ and certain other nonnegative matrices that are polynomials in the matrix P and to compute such bases. Actually, we think of $J^{(0)}(\epsilon) := \epsilon J(\epsilon)$ as a zeroth *transform component of* P. Other nonnegative matrices that are polynomials in P, which we will work with later, are the higher-order transform components

$$J^{(k)}(\epsilon) = \epsilon^{k+1}(P - \rho(P)I)^k J(\epsilon), \quad k = 1, \ldots, \nu - 1.$$

Here ν is the index of the Perron root as an eigenvalue of P.

Hershkowitz [7] defines the *peak characteristic tuple* $(\xi_1, \ldots, \xi_\nu)$ of the Perron root as an eigenvalue of P, and he shows that for each $h = 1, \ldots, \nu$, ξ_h is the maximal number of nonnegative vectors of height h in a height basis for the Perron eigenspace and that a height basis for the eigenspace exists with that many nonnegative vectors at each height $h = 1, \ldots, \nu$.

The principal question that we shall answer in this paper is this: Can we extract from the columns of the transformed components $J^{(0)}(\epsilon), \ldots, J^{(\nu-1)}(\epsilon)$, a union $\mathcal{C}$ of nonnegative Jordan chains that contains exactly ξ_h vectors of height h, $h = 1, \ldots, \nu$, where the tuple $(\xi_1, \ldots, \xi_\nu)$ is the peak characteristics mentioned above? Moreover, can this union be extended to a height basis for the eigenspace? We achieve this via a *scanning process of the transform components* that begins by stacking the transform components on each other from the lowest to the highest. We call this process the SCANBAS algorithm. The algorithm is set out in §5 after some preparations and preliminary results from §§2–4. We go on to show in Corollary 4 that if $(\eta_1, \ldots, \eta_\nu)$ is the *height characteristic of the* Perron root as an eigenvalue of P with $\eta_k = \xi_k$ for $k = t, \ldots, \nu$, so that by Hershkowitz and Schneider [8, Thm. (6.6)] there is a Jordan basis for the Perron eigenspace of P corresponding to its Perron root such that all Jordan chains of length t and higher consist of nonnegative vectors only, then our SCANBAS algorithm produces such chains. In particular, if the Perron eigenspace of P has a Jordan basis consisting entirely of nonnegative chains, our SCANBAS algorithm computes such a basis. In §6 we conclude the paper by presenting various examples of bases that were produced by our SCANBAS algorithm implemented by using MATLAB. These examples show that generally $\mathcal{C}$ cannot be extended to a Jordan basis for the eigenspace. We end the section with a brief description of the MATLAB programs that were actually used in the computation of the examples.

Finally, we find it convenient to work and state the results of this paper in terms of the minus M–matrix $A = P - \rho(P)I$ that can be associated with our nonnegative matrix P.

2. Notations and preliminaries. For a positive integer n, we denote by $\langle n \rangle$ the set $\{1, \ldots, n\}$.

In all our considerations we assume that A is an $n \times n$ real matrix given in a block lower triangular form with p square diagonal blocks as follows:

$$A = \begin{pmatrix} A_{1,1} & 0 & \dots & 0 \\ A_{2,1} & A_{2,2} & & 0 \\ \vdots & & \ddots & \vdots \\ A_{p,1} & \dots & \dots & A_{p,p} \end{pmatrix}, \tag{2.1}$$

where each diagonal block is either an irreducible matrix or the 1×1 null matrix. The above form is called the *Frobenius normal form* of A. It is well known that any square matrix is symmetrically permutable to such a form. The *reduced graph of* A, $\mathcal{R}(A)$, is defined to be the graph with vertices $\{1, \dots, p\}$, where (i, j) is an arc from i to j if $A_{i,j} \neq 0$. A vertex i in $\mathcal{R}(A)$ is said to be singular if $A_{i,i}$ is singular. Otherwise the vertex is called *nonsingular*. The set of all singular vertices in $\mathcal{R}(A)$ will be denoted by $\mathcal{S}(A)$. A sequence of vertices $(i_1, \dots, i_k)$ in $\mathcal{R}(A)$ is said to be a *path* from i_1 to i_k if there is an arc in $\mathcal{R}(A)$ from i_j to i_{j+1} *for all* $j \in \langle k-1 \rangle$. The path is said to be *simple* if $i_1, \dots, i_k$ are distinct. The empty path will be considered a simple path linking every vertex $i \in \mathcal{R}(A)$ to itself. If there is a path (in $\mathcal{R}(A)$) from i to j, we write that $i \succeq j$. If $i \neq j$ and there is a path from i to j, we write that $i \succ j$.

Let $x \in R^n$. We partition $x = ((x_1)^T, \dots, (x_p)^T)^T$ in conformity with (2.1). Let $i \in \langle p \rangle$. We say that that the *level of* i in $\mathcal{R}(A)$ is k ($\mathrm{lev}(i) = k$) if the maximal number of singular vertices on a path ending at i is k. We say that the *level of* $x \in R^n$ is k ($\mathrm{lev}(x) = k$) if

$$k = \max\{\mathrm{lev}(i) \mid x_i \neq 0\}.$$

For an $n \times n$ matrix A we denote by:

$N(A)$, the nullspace of A;

$E(A)$, the generalized nullspace of A, viz., $N(A^n)$;

$\nu(A)$, the index of 0 as an eigenvalue of A, viz., the size of the largest Jordan block associated with 0. Where no confusion is likely to arise, we write ν for $\nu(A)$.

We let $Z^{(0)}(A)$ be the eigenprojection of A corresponding to the eigenvalue 0 and we put $Z^{(k)}(A) = A^k Z^{(0)}(A)$, $k = 0, \dots, \nu - 1$. Where no confusion is likely to arise, we write $Z^{(k)}$ for $Z^{(k)}(A)$, $k = 1, \dots, \nu - 1$. The matrices $Z^{(k)}$, $k = 0, \dots, \nu - 1$, are called *the principal components of* A (*corresponding to the eigenvalue* 0). For background material on the principal components, see Lancaster and Tismenetski [10, p. 314] and, in the case of nonnegative matrices, see Neumann and Schneider [11].

Let $\alpha \subseteq \langle n \rangle$. By $A[\alpha]$ we denote the principal submatrix of A whose rows and columns are determined by α. Similarly, for an n-vector x, we denote by $x[\alpha]$ the subvector of x whose entries are indexed by α. For an array C, we use $C \geq 0$ to denote when all its entries are nonnegative numbers. $C > 0$ denotes the fact that $C \geq 0$, but $C \neq 0$. $C \gg 0$ denotes the fact that all of the entries of C are positive numbers.

Let P be an $n \times n$ nonnegative matrix. The Perron Frobenius theory (cf. Berman and Plemmons [2]) tells us that the spectral radius of P, given by the quantity

$$\rho(P) = \max\{|\lambda| : \det(P - \lambda I) = 0\},$$

is an eigenvalue of P that corresponds to a nonnegative eigenvector. In particular, if P is irreducible, then $\rho(P)$ is simple and the corresponding eigenvector is, up to

a multiple by a scalar positive. The matrix $A = P - \rho(P)I$, which has all its off-diagonal entries nonnegative, is the $n \times n$ minus M–matrix that we associate with P and, in several sections of our paper, it will be convenient to work with A rather than with P. (We call A a *minus* M-*matrix* if $-A$ is an M-matrix. For the many equivalent conditions for a real matrix with nonpositive off-diagonal entries to be an M-matrix, see Berman and Plemmons [2, Chap. 6].) Suppose now that $m = \dim(E(A))$. It is known that m is equal to the number of singular vertices in $\mathcal{R}(A)$. Rothblum [13] has shown that $\nu(A)$ is equal to the maximum over all lengths of the simple paths in $\mathcal{R}(A)$, a result we shall refer to as the *Rothblum index theorem.* Let $\mathcal{S}(A) = \{\alpha_1, \ldots, \alpha_m\}$. Rothblum [13] and, independently, Richman and Schneider [12] (See also [14]) have shown that $E(A)$ possesses a basis of nonnegative vectors that is strongly combinatorial in the sense defined in Definition 1.

DEFINITION 1. *Let A be the $n \times n$ minus* M-*matrix given in form* (2.1) *and consider $\mathcal{R}(A)$.*

(i) *A nonnegative basis $u^{(1)}, \ldots, u^{(m)}$ is a* (nonnegatively) proper combinatorial basis *for $E(A)$ if*

$$u^{(j)}[i] > 0 \Rightarrow i \succeq \alpha_j$$

and

$$u^{(j)}[\alpha_j] \gg 0$$

for all $i \in \langle p \rangle$ and $j \in \langle m \rangle$.

(ii) *A nonnegative basis $u^{(1)}, \ldots, u^{(m)}$ is called a* (nonnegatively) strongly combinatorial basis *for $E(A)$ if*

$$u^{(j)}[i] = \begin{cases} \gg 0 & \text{iff } i \succeq \alpha_j, \\ 0 & \text{otherwise.} \end{cases}$$

Let $x \in E(A)$. We say that the *height of* x is k ($\mathrm{ht}(x) = k$) if k is the smallest nonnegative integer such that $A^k x = 0$. The *fundament of* x is, according to Hershkowitz and Schneider [9], the vector $A^{k-1}x$. For a set of vectors $\mathcal{S} = \{x, y, \ldots\}$ in $E(A)$, the *fundament of* $\mathcal{S}$ is the set of vectors formed from the fundaments of the elements of $\mathcal{S}$.

Let A be a minus M-matrix. Then it is known that $\mathrm{ht}(x) \leq \mathrm{lev}(x)$ for all $x \in E(A)$, cf. [8, Cor. (4.17)]. A vector $x \in E(A)$ for which $\mathrm{ht}(x) = \mathrm{lev}(x)$ is called a *peak vector.* If x is a peak vector, then $\mathrm{lev}(Ax) = \mathrm{lev}(x) - 1$ by [9, Prop. 6.5]. Also every nonnegative vector in $E(A)$ is a peak vector.

3. Jordan bases with nonnegative chains. Let $A \in R^{nn}$ be given as in (2.1). We shall use the following notation subsequently:

R^n_+ – the set of nonnegative vectors in $\mathcal{R}^n$.
$F = E(A) \cap R^n_+$.
$F_k = N(A^k) \cap R^n_+$, $k = 0, \ldots, \nu$.
$E_k = \mathrm{span}(F_k)$, $k = 0, \ldots, \nu$.
$S_k = A^{k-1}E_k$, $k = 1, \ldots, \nu$.

Henceforth, we let $A \in R^{nn}$ be a (singular) minus M-matrix of index ν. Since every nonnegative vector in $E(A)$ is a peak vector, we have the following graph theoretic classification of F_k and E_k.

$$F_k = \{x \in F : \mathrm{lev}(x) \leq k\}, \quad k = 0, \ldots, \nu. \tag{3.1}$$

$$E_k = \{x \in E(A) \ : \ \mathrm{lev}(x) \leq k \ \}, \quad k = 0, \ldots, \nu. \tag{3.2}$$

We note that

$$\{0\} = E_0 \subseteq E_1 \subseteq \cdots \subseteq E_\nu = E(A). \tag{3.3}$$

Now by (3.1) and (3.2) and because $\mathrm{lev}(Ax) = \mathrm{lev}(x) - 1$ for $x \in F_k$, it follows that

$$AE_k \subseteq E_{k-1}, \quad k = 1, \ldots, \nu. \tag{3.4}$$

Hence we have

$$\{0\} \subseteq S_\nu \subseteq \cdots \subseteq S_1 = E_1 \subseteq N(A). \tag{3.5}$$

DEFINITION 2. (i) (Hershkowitz and Schneider [8, Def. (2.6)]) *The* height characteristic *of A is defined to be the ν-tuple*

$$\eta(A) = (\eta_1(A), \ldots, \eta_\nu(A)),$$

where $\eta_k(A) = \dim(N(A^k)) - \dim N(A^{k-1})$, $k = 1, \ldots, \nu$.

(ii) *The* peak characteristic *of A is defined to be the ν-tuple*

$$\xi(A) = (\xi_1(A), \ldots, \xi_\nu(A)),$$

where $\xi_k(A) = \dim(S_k)$, $k = 1, \ldots, \nu$.

Where no confusion is likely to arise, we denote the height characteristic of A by $\eta = (\eta_1, \ldots, \eta_\nu)$ and the peak characteristic of A by $\xi = (\xi_1, \ldots, \xi_\nu)$. In [7, Def. (4.1)], Hershkowitz defines the peak characteristic of A by letting $\xi_k = \dim E_k - \dim(N(A^{k-1}) \cap E_k)$. Since S_k is isomorphic to $E_k/(N((A)^{k-1}) \cap E_k)$, $k = 1, \ldots, \nu$, it follows that his definition of the peak characersitic of A coincides with the definition given above.

For the sake of completeness, we prove the following proposition that forms part of [7, Thm. (6.5)]. Recall, cf. [8, Def. (3.1)], that a basis $\mathcal{B}$ for E(A) is called a *height basis* if the number of basis elements of height k is equal to η_k, $k = 1, \ldots, \nu$.

PROPOSITION 1. *Let A be a minus* M*-matrix and let $\mathcal{B}$ be a height basis for $E(A)$. Let β_k be the number of peak vectors in $\mathcal{B}$ of height k, $k = 1, \ldots, \nu$. Then $\beta_k \leq \xi_k$, $k = 1, \ldots, \nu$.*

Proof. Let $1 \leq k \leq \nu$ and let $x^{(1)}, \ldots, x^{(s)}$ be peak vectors of height k in the height basis $\mathcal{B}$ for E. Then $x^{(1)}, \ldots, x^{(s)}$ are linearly independent mod $N(A^{k-1})$ by [8, Prop. (3.14)]. Hence $A^{k-1}x^{(1)}, \ldots, A^{k-1}x^{(s)}$ are linearly independent vectors. □

Hershkowitz [7, Thm. (6.5)] also proves that for every minus M-matrix, there exists a height basis that has ξ_k nonnegative vectors of height k, for $k = 1, \ldots, \nu$. In §5 we give an algorithm that (in exact arithmetic) computes such a basis.

4. The transform components. We begin by introducing the (ϵ) transform components of A.

DEFINITION 3. *For $\epsilon > 0$ and for $k = 0, \ldots, \nu - 1$, we define the* kth transform component of A *by*

$$J^{(k)}(\epsilon) = Z^{(k)} + \frac{Z^{(k+1)}}{\epsilon} + \cdots + \frac{Z^{(\nu-1)}}{\epsilon^{\nu-k-1}}. \tag{4.1}$$

In [6] it was shown that provided $\epsilon > 0$ is sufficiently small, a basis of nonnegative vectors for $E(A)$ can be chosen from the columns of $J^{(0)}(\epsilon)$. Moreover, a method was given for determining such ϵ's, cf. [6, Thm. 2.2]. The results of [6] were improved in [11], where it was shown that provided $\epsilon > 0$ is sufficiently small, the nonnegative basis for $E(A)$ chosen from the columns of $J^{(0)}(\epsilon)$ can be chosen to be strongly combinatorial. We now strengthen the results of both papers by showing that the method used in [6] can be adapted to compute ϵ's that ensure that the columns of $J^{(0)}(\epsilon)$ contain a strongly combinatorial basis and that all transform components are nonnegative and have interesting combinatorial properties. To this end, for $1 \le i, j \le p$ and for $0 \le k \le \nu - 1$, let $\mu_{i,j}^{(k)}$ be the least element in $Z_{i,j}^{(k)}$ and let

$$\gamma_{i,j}^{(k)} = |\min\{\mu_{i,j}^{(k)}, 0\}|.$$

We note that by [11, Thm. 1], $\mu_{i,j}^{(d-1)} > 0$, when $d = d(i,j) \ge 1$. Let

$$\mu = \min \frac{\mu_{i,j}^{(d-1)}}{\gamma_{i,j}^{(k)} + \cdots + \gamma_{i,j}^{(d-2)}}, \tag{4.2}$$

where the minimum is taken over all i, j, k such that $1 \le i, j \le p$, $0 \le k \le \nu - 1$, and $d = d(i,j) > k$. We comment that we here take a ratio $p/0$, where $p > 0$, to be $+\infty$.

LEMMA 1. *Let A be a minus* M*-matrix and suppose $1 \le i, j \le p$ and $0 \le k \le \nu - 1$. Let $0 < \epsilon \in \min\{1, \mu\}$, where μ is given by* (4.2).

(i) *If $d(i,j) \le k$, then $J_{i,j}^{(k)}(\epsilon) = 0$.*

(ii) *If $d(i,j) > k$, then $J_{i,j}^{(k)}(\epsilon) \gg 0$.*

Proof. (i) By [11, Lemma 2], if $d(i,j) \le k$, then $Z_{i,j}^{(q)} = 0$ for all q such that $k \le q \le \nu - 1$ and the result follows.

(ii) Let $d = d(i,j) > k$. Then

$$J_{i,j}^{(k)}(\epsilon) = Z_{i,j}^{(k)} + \frac{Z_{i,j}^{(k+1)}}{\epsilon} + \cdots + \frac{Z_{i,j}^{(d-1)}}{\epsilon^{d-k+1}}.$$

By [11, Thm. 1] $Z_{i,j}^{(d-1)} \gg 0$ and so $\mu_{i,j}^{(d-1)} > 0$. Let $0 < \epsilon < 1$ and let α be the least element in $J_{i,j}^{(k)}(\epsilon)$. Then

$$\begin{aligned} \alpha &\ge -\gamma_{i,j}^{(k)} - \cdots - \frac{\gamma^{(d-2)}}{\epsilon^{d-k-2}} + \frac{\mu_{i,j}^{(k-1)}}{\epsilon^{d-k-1}} \\ &\ge -\frac{1}{\epsilon^{d-k-2}}(\gamma_{i,j}^{(k)} + \cdots + \gamma_{i,j}^{(d-2)}) + \frac{\mu_{i,j}^{(k-1)}}{\epsilon^{d-k-1}}. \end{aligned}$$

Hence $\alpha > 0$ if

$$\epsilon < \frac{\mu_{i,j}^{(k-1)}}{\gamma_{i,j}^{(k)} + \cdots + \gamma_{i,j}^{(d-2)}}$$

and the result follows. □

We now make more precise a result mentioned in [11].

COROLLARY 1. *Let $\alpha_1, \ldots, \alpha_m$ be the singular vertices of $\mathcal{R}(A)$. Let $v^{(j)}$ be a column of $J^{(0)}(\epsilon)$ chosen from the columns of the α_jth block column of $J^{(0)}(\epsilon)$, $j = 1, \ldots, m$. Then $v^{(1)}, \ldots, v^{(m)}$ is a strongly combinatorial basis for $E(A)$ and, what is more, they satisfy:*

$$(A^k v^{(j)})_i \gg 0 \quad \text{if } d(i, \alpha_j) > k,$$
$$(A^k v^{(j)})_i = 0 \quad \text{if } d(i, \alpha_j) \leq k.$$

Proof. We observe that $A^k v^{(j)}$ is a column of $J^{(k)}(\epsilon)$ belonging to the α_jth block column $J^{(k)}(\epsilon)$, $k = 0, \ldots, \nu - 1$ and $j = 1, \ldots, m$. □

We note that this basis satisfies the properties of Rothblum, [13, Thm. 3.1]. Additionally we have the following corollary.

COROLLARY 2. *Let $v^{(1)}, \ldots, v^{(m)}$ be a basis of $E(A)$ which satisfies the conclusion of Corollary 1. The subset consisting of those vectors whose level does not exceed k forms a basis for E_k, $k = 0, \ldots, \nu - 1$.*

Proof. It holds that $v^{(1)}, \ldots, v^{(m)}$ is a strongly combinatorial basis for $E(A)$. □

5. The SCANBAS algorithm. From now on we shall assume that ϵ has been chosen so that the transform components $J^{(k)}(\epsilon)$, $k = 0, \ldots, \nu - 1$ satisfy the conclusions of Lemma 1.

Observe that in the algorithm below, the index h is decreased in each iteration. Thus when we determine the sets $\mathcal{F}_h$ and the chains $\mathcal{C}_{i,h}$, the sets $\mathcal{F}_k$ and $\mathcal{C}_{i,k}$ are already determined for $k = h + 1, \ldots, \nu$.

THE SCANBAS ALGORITHM

Set $h = \nu$.

Step 1. Scan $J^{(h-1)}(\epsilon)$ to extract a set

$$\mathcal{F}_h = \{u^{(h,1,h)}, \ldots, u^{(h,s_h,h)}\}$$

of null vectors of A, which is maximal with respect to the property that the union $\mathcal{G}_h$ of $\mathcal{F}_h$ and the sets $\mathcal{F}_k$, $k = h + 1, \ldots, \nu$ is linearly independent.

Step 2. Then for each $u^{(h,i,h)}$, $i = 1, \ldots, s_h$, select the chain

$$\mathcal{C}_{i,h} = \{u^{(j,i,h)} \mid j = 1, \ldots, h\},$$

which consists of the columns in $J^{(0)}(\epsilon), \ldots, J^{(h-1)}(\epsilon)$ corresponding to $u^{(h,i,h)}$, i.e., if $u^{(h,i,h)}$ is the rth column of $J^{(h-1)}(\epsilon)$, then $u^{(j,i,h)}$ is the rth column of $J^{(j-1)}(\epsilon)$, $j = 1, \ldots, h$.

If $h > 1$, reduce h by 1, and repeat.
If $h = 1$, then stop.

Remark. Note that $u^{(j,i,h)}$ is the vector of height $h - j + 1$ in the ith chain of length h.

THEOREM 1. *Let $\mathcal{C}$ be the union of the chains*

$$\mathcal{C}_{i,h} = \{u^{(j,i,h)} \mid j = 1, \ldots, h\}, \quad i = 1, \ldots, s_h, \quad h = 1, \ldots, \nu.$$

Then

(i) *$\mathcal{C}$ consists of nonnegative vectors.*
(ii) *$\mathcal{C}$ is a linearly independent set of vectors.*
(iii) *Let $1 \le h \le \nu$. Then $\mathcal{G}_h = \cup_{k=h}^{\nu} \mathcal{F}_k$ is a basis for S_h.*
(iv) *$\mathcal{C}$ contains exactly ξ_h vectors of height h, $h = 1, \ldots, \nu$.*
(v) *$\mathcal{C}$ can be extended to a height basis for $E(A)$.*

Proof. (i) Each vector in $\mathcal{C}$ appears in a column in some $J^{(h)}$, $h = 0, \ldots, \nu - 1$, and these matrices are nonnegative.

(ii) The set $\mathcal{G}_1$ defined above is the fundament of $\mathcal{C}$ and, by construction, $\mathcal{G}_1$ is linearly independent. Hence $\mathcal{C}$ is linearly independent, e.g., Bru and Neumann [3].

(iii) Let $1 \le h \le \nu$. First, let $x \in \mathcal{G}_h$. Then $x \in \mathcal{F}_k$ for some k, $h \le k \le \nu$. Hence x is a column of $J^{(k-1)}(\epsilon)$ and therefore $x = A^{k-1}y$, where y is a column of $J^{(0)}(\epsilon)$. Since $x \in N(A)$, it follows that y must be in F_k. Hence $x \in A^{k-1}E_k = S_k \subseteq S_h$.

Conversely, let $x \in S_h$. Then $x = A^{h-1}y$, where $y \in E_h$ and so, by Corollary 2, y is a linear combination of columns of $J^{(0)}(\epsilon)$ that lie in F_h. Hence x is a linear combination of columns of $J^{(h-1)}(\epsilon)$ that lie in $N(A)$. Since by the first part of the proof of (iii), $\mathcal{F}_k \subseteq S_h$, $k = h + 1, \ldots, \nu$, it now follows that the set $\mathcal{G}_h$ obtained in Step 2 of the SCANBAS algorithm is a basis for S_h.

(iv) Let $\mathcal{C}_h$ be the set of all vectors in $\mathcal{C}$ of height h. Then the map $x \to A^{h-1}x$ is a bijection of $\mathcal{C}_h$ onto $\mathcal{F}_h$, and hence (iv) follows from (iii).

(v) Since, by (iv), $A^{h-1}\mathcal{C}_h = \mathcal{F}_h$ and $\mathcal{F}_h$ is linearly independent, it follows that $\mathcal{C}_h$ is linearly independent mod E_{h-1}. Hence we can extend $\mathcal{C}_h$ to a set $\mathcal{B}_h$, which is a basis E_h mod E_{h-1}. It follows that $\mathcal{B} = \cup_{h=1}^{\nu} \mathcal{B}_h$ is a height basis for $E(A)$, cf. [8, Prop. 3.14]. □

COROLLARY 3. *It holds that*

$$\xi_h = s_h + \cdots + s_\nu, \quad h = 1, \ldots, \nu.$$

Let $x \in E(A)$ be a vector of height k. Then the *the chain derived from x* is defined to be the set $\{x, Ax, \ldots, A^{k-1}x\}$. The *chains derived from a subset* of $E(A)$ is the union of all chains derived from the vectors in this set. The technique used to prove the following important corollary is related to the proof of Hershkowitz and Schneider [8, Prop. (6.1)].

COROLLARY 4. *Let $1 \le t \le \nu$ and let $\eta_k = \xi_k$, $k = t, \ldots, \nu$. Then the chains $\mathcal{C}_{i,h}$, where $1 \le i \le s_h$ and $t - 1 \le h \le \nu$, can be embedded (extended) to a Jordan basis for $E(A)$.*

Proof. For $k = t, \ldots, \nu$, let $\mathcal{H}_k$ consist of all vectors $u^{(1,i,k)} \in \mathcal{C}$, $i = 1, \ldots, s_k$. Since $\mathrm{ht}(u^{(1,i,k)}) = k$ and $\xi_k = \eta_k$, it follows that $\cup_{r=k}^{\nu} A^{r-k}\mathcal{H}_r$ is a basis for $N(A^k)$ mod $(N(A^{k-1}))$. Now let $k = t - 1$. Then the set of vectors $u^{(1,i,k)}$, $i = 1, \ldots, s_k$, can be completed to a set $\mathcal{H}_k$ such that $\cup_{r=k}^{\nu} A^{r-k}\mathcal{H}_r$ is a basis for $N(A^k)$ mod $(N(A^{k-1}))$. Furthermore, for $k = 1, \ldots, t-2$, there exist sets $\mathcal{H}_k$ such that $\cup_{r=k}^{\nu} A^{r-k}\mathcal{H}_r$ is a basis

for $N(A^k)$ mod $N(A^{k-1})$. The chains derived from $\cup_{k=1}^{\nu}\mathcal{H}_k$ now form a Jordan basis for $E(A)$ with the required properties. □

Remark. In [7, Thm. (6.6)] it is shown that there exists a Jordan basis for $E(A)$ such that all chains of length greater than or equal to t are nonnegative if and only if $\xi_k = \eta_k$, $k = t, \ldots, \nu$. Thus, if a Jordan basis exists such that all chains of length t or greater are nonnegative, then the SCANBAS algorithm will produce such chains. In particular, if a nonnegative Jordan basis for $E(A)$ exists (viz., $\xi_k = \eta_k$, $k = 2, \ldots, \nu$ or see [9, Thm. 6.6] for many other equivalent conditions), then the SCANBAS algorithm produces a nonnegative Jordan basis for $E(A)$. Finally, since we always have $\xi_\nu = \eta_\nu$, cf. [8, Prop. (4.2)], the SCANBAS algorithm always produces a set of nonnegative chains of length ν which can be extended to a Jordan basis $E(A)$ by adding chains of length at most $\nu - 1$. The result that there is a Jordan basis for $E(A)$ such that all chains of length ν are nonnegative is known; see [8, Cor. (6.12)] for the existence of such chains.

6. Examples and concluding remarks. We call a set $\mathcal{C}$ of vectors a maximal nonnegative union of chains (MNUC) provided $\mathcal{C}$ is a union of nonnegative chains, $\mathcal{C}$ is linearly independent, and $\mathcal{C}$ contains ξ_h vectors of height h. By Theorem 1, the SCANBAS alogorithm produces an MNUC. In this section we give several examples of MNUCs for various matrices and the relation of these MNUCs to Jordan bases.

We call a diagram of pluses with ξ_h pluses in row h (counting from the bottom) the *Peak diagram* of the matrix. Similarly we call a diagram of stars with η_h pluses in row h (counting from the bottom) the *Jordan diagram* of the matrix. (As is very well known, the number of stars in each column, read from the left, yields the Jordan (Segre) characteristic of the matrix.)

Example 1. We begin with an example where the MNUC consists of complete Jordan chains and may be completed to a Jordan basis by adjoining an eigenvector.

Let

$$a = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 1 & -1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 0 & 1 & 0 & 0 \\ 2 & 1 & 2 & 1 & 1 & 0 & 0 \end{pmatrix}.$$

We put $sca = \text{scanbas}(a)$. Then

$$sca = \begin{pmatrix} 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 1 \\ 0 & 1 & 1 & 0 & 1 \\ 0 & 1 & 1 & 0 & 0 \\ 2 & 3 & 3 & 1 & 1 \\ 4 & 6 & 6 & 3 & 2 \end{pmatrix}.$$

Then

$$jna = \begin{pmatrix} 0 & 0 & 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & -1 \\ 0 & 1 & 1 & 0 & 1 & -1 \\ 0 & 1 & 1 & 0 & 1 & 0 \\ 0 & 1 & 1 & 0 & 0 & 1 \\ 2 & 3 & 3 & 1 & 1 & 0 \\ 4 & 6 & 6 & 3 & 2 & 0 \end{pmatrix}$$

is a Jordan basis since

$$a \times jna = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 2 & 3 & 0 & 1 & 0 \\ 0 & 4 & 6 & 0 & 3 & 0 \end{pmatrix}.$$

We observe that the Jordan and Peak diagrams can be combined as

$$\begin{matrix} + & & & & \\ + & + & & & \\ + & + & * & . \end{matrix}$$

Example 2. We now give an example of a minus M-matrix whose Perron eigenspace has a nonnegative Jordan basis and the basis with such specifications produced by our SCANBAS algorithm. Let

$$b = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 & 0 \\ 2 & 1 & 0 & 0 & 0 & 0 \\ 2 & 1 & 1 & 1 & 0 & 0 \\ 1 & 1 & 2 & 1 & 0 & 0 \end{pmatrix}.$$

Here the SCANBAS algorithm yields the MNUC $scb = \text{scanbas}(b)$ given by

$$scb = \begin{pmatrix} 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 1 & 1 & 0 & 1 & 1 \\ 0 & 2 & 2 & 0 & 1 & 1 \\ 3 & 5 & 5 & 2 & 3 & 3 \\ 4 & 5 & 5 & 3 & 4 & 4 \end{pmatrix}.$$

This is easily seen to be a nonnegative Jordan basis consisting of two chains each of length 3.

Example 3. We give an example of a matrix that possesses an MNUC that can be embedded in a Jordan basis, but where no MNUC can consist of complete Jordan chains.

Let

$$c = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 & 0 \\ 2 & 1 & 1 & 1 & 0 & 0 \\ 1 & 1 & 1 & 1 & 0 & 0 \end{pmatrix}.$$

Then the index of c is 3 and, if we choose $\epsilon = 1$, we obtain the transform components

$$j0c = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 1 & 0 & 0 \\ 4 & 3 & 1 & 1 & 1 & 0 \\ 3 & 3 & 1 & 1 & 0 & 1 \end{pmatrix},$$

$$j1c = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 & 0 \\ 4 & 3 & 1 & 1 & 0 & 0 \\ 3 & 3 & 1 & 1 & 0 & 0 \end{pmatrix},$$

and

$$j2c = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 2 & 2 & 0 & 0 & 0 & 0 \\ 2 & 2 & 0 & 0 & 0 & 0 \end{pmatrix}.$$

As we can see by inspection of the transform components, our SCANBAS algorithm yields $scc = \text{scanbas}(c)$ given by

$$scc = \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 1 & 1 & 0 \\ 2 & 4 & 4 & 1 \\ 2 & 3 & 3 & 0 \end{pmatrix}.$$

This set may be extended to a Jordan basis

$$jnc = \begin{pmatrix} 0 & 0 & 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & -1 & 0 \\ 0 & 1 & 1 & 0 & 0 & 1 \\ 0 & 1 & 1 & 0 & 0 & -1 \\ 2 & 4 & 4 & 1 & 0 & 0 \\ 2 & 3 & 3 & 0 & 0 & 0 \end{pmatrix},$$

where

$$c \times jnc = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 2 & 4 & 0 & 1 & 0 \\ 0 & 2 & 3 & 0 & 0 & 0 \end{pmatrix}.$$

Thus the combined Peak and Jordan diagrams here are

$$\begin{array}{cccc} + & & & \\ + & * & & \\ + & + & * & . \end{array}$$

We label the columns of jnc (from left to right) by v^{11}, v^{12}, v^{13}, v^{21}, v^{22}, v^{31}. Then we have the Jordan chains (v^{13}, v^{12}, v^{11}), (v^{22}, v^{21}) and (v^{31}). If some MNUC can be extended to a Jordan basis, then we would also get a combined Peak and Jordan diagram for c of the form

$$\begin{array}{cccc} + & & & \\ + & * & & \\ + & * & + & . \end{array}$$

We shall show that this is impossible; for let (w^{13}, w^{12}, w^{13}), (w^{22}, w^{21}), and (w^{31}) be another Jordan basis. Note that w^{31} is a linear combination of v^{11}, v^{21}, and v^{31} with nonzero coefficients for v^{31}, since w^{31} does not belong to range(c), see Bru, Rodman, and Schneider [4] for arguments of this type. But then, by inspection of the vectors, w^{31} cannot be nonnegative.

Example 4. We give an example of a matrix for which it is impossible to embed the chains of any MNUC into a Jordan basis.

Let

$$d = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 2 & 1 & 1 & 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 & 1 & 1 & 0 & 0 & 0 \end{pmatrix}.$$

Then the SCANBAS algorithm yields the MNUC $scd = \text{scanbas}(d)$

$$scd = \begin{pmatrix} 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 1 & 1 & 0 & 0 \\ 0 & 1 & 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 2 & 4 & 4 & 4 & 1 & 1 \\ 2 & 3 & 3 & 3 & 0 & 0 \end{pmatrix}.$$

A Jordan basis for d is given by

$$jnd = \begin{pmatrix} 0 & 0 & 0 & 1 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 & -1 \\ 0 & 1 & 1 & 1 & 0 & 0 & 0 & 1 & 0 \\ 0 & 1 & 1 & 1 & 0 & 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 \\ 2 & 4 & 4 & 4 & 1 & 0 & 0 & 0 & 0 \\ 2 & 3 & 3 & 3 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}.$$

Thus the peak diagram for d is

```
+
+
+   +
+   +
```

and the Jordan diagram is

```
*
*   *
*   *
*   *   *   *.
```

We claim that no Jordan basis for d is an extension of an MNUC. We label the columns of *jnd* (from left to right) as x^{11}, x^{12}, x^{13}, x^{14}, x^{21}, x^{22}, x^{23}, x^{31}, x^{41}.

Suppose that there is a Jordan basis whose elements of height 3 are w^{13} and w^{23}, where w^{13} is of form $d(w^{14})$. Then, w^{13} is a multiple of x^{13}, while w^{23} is a linear combination of x^{13} and x^{23}, where x^{23} must have a nonzero coefficient. Hence w^{23} is not nonnegative. But if the Jordan basis is an extension of an MNUC, w^{23} must be nonnegative. Our claim follows.

Finally, we outline how our SCANBAS algorithm is implemented using MATLAB. The entire process is controlled by a function called *scanbas.m* whose input is the minus M-matrix A and whose output is an MNUC. This function first calls another MATLAB function *nnb.m* that returns an $\epsilon > 0$ and $J^{(0)} \geq 0$. The value value of $\epsilon > 0$, which is returned, is also sufficient to ensure that all higher-order transform components of A are nonnegative. To achieve its purpose, *nnb.m* initially determines the eigenprojection $Z^{(0)}$ by calling on a function *drazin.m*. The original version of *drazin.m* was written by Professor Robert E. Hartwig of North Carolina State University. This function computes the eigenprojection via the evaluation of the Drazin inverse A^D, viz., $Z^{(0)} = I - AA^D$, which is carried out using an algorithm due to Hartwig [5]. (For other methods of computing the Drazin inverse of a matrix, see the *shuffle* algorithm due to Anstreicher and Rothblum [1].) We mention that in *drazin.m*, the reduction steps used to implement Hartwig's algorithm are executed using the [q,r]=qr(·) command of MATLAB, not only for accuracy, but for the convenience of having the reducing matrices that this method needs from step to step [5]. The function *drazin.m* also returns ν, the index of A at 0. With $Z^{(0)}$ and ν at hand, *nnb.m* calls the function *macse.m*, which computes an $\epsilon > 0$ such that all transform components are nonnegative. This is done by generating iteratively all the principal

components of A. With all this data at hand, *nnb.m* finally computes $J^{(0)}$ and returns the control to *scanbas.m* which now proceeds to compute an MNUC according to Steps 1 and 2 of the SCANBAS algorithm given in §5. This segment of *scanbas.m* starts by setting up an array W that contains, juxtaposed, all, say up to a multiple, transform components generated iteratively from $J^{(0)}$. Steps 1 and 2 are now carried out using a nested for/if loops.

ON RANK-REVEALING FACTORISATIONS*

SHIVKUMAR CHANDRASEKARAN† AND ILSE C. F. IPSEN†

Abstract. The problem of finding a rank-revealing QR (RRQR) factorisation of a matrix A consists of permuting the columns of A such that the resulting QR factorisation contains an upper triangular matrix whose linearly dependent columns are separated from the linearly independent ones. In this paper a systematic treatment of algorithms for determining RRQR factorisations is presented.

In particular, the authors start by presenting precise mathematical formulations for the problem of determining a RRQR factorisation, all of them optimisation problems. Then a hierarchy of "greedy" algorithms is derived to solve these optimisation problems, and it is shown that the existing RRQR algorithms correspond to particular greedy algorithms in this hierarchy. Matrices on which the greedy algorithms, and therefore the existing RRQR algorithms, can fail arbitrarily badly are presented.

Finally, motivated by an insight from the behaviour of the greedy algorithms, the authors present "hybrid" algorithms that solve the optimisation problems almost exactly (up to a factor proportional to the size of the matrix). Applying the hybrid algorithms as a follow-up to the conventional greedy algorithms may prove to be useful in practice.

Key words. condition estimation, pivoting, orthogonal factorisation, numerical rank, singular values

AMS subject classifications. 65F20, 65F25, 65F35, 15A42

1. Introduction.

The problem of finding a rank-revealing QR (RRQR) factorisation of a matrix A consists of permuting the columns of A such that the resulting QR factorisation contains an upper triangular matrix whose linearly dependent columns are separated from the linearly independent ones. RRQR factorisations are useful in problems such as subset selection and linear dependence analysis [21], [29], [37], [39], subspace tracking [6], [14], and rank determination [9]. Further applications are given in [12] and [17].

To determine a RRQR factorisation one could just adopt the brute force approach and inspect all possible column permutations until one has found a factorisation to one's liking. The operation count, of course, is guaranteed to be combinatorial. Consequently, much effort has gone in designing RRQR algorithms whose operation count is polynomial in the size of the matrix.

The first such algorithm, the QR factorisation with column pivoting [7], [16], [19], was developed by Golub in 1965 and by Faddeev, Kublanovskaya, and Faddeeva in 1966. It makes use of column permutations and orthogonal rotations to maintain the triangular structure of the matrix. About ten years later a second algorithm was published by Golub, Klema, and Stewart [20], based on applying the first algorithm to certain singular vectors of the matrix. At about the same time, a third algorithm appeared in a paper by Gragg and Stewart [22] that works on the inverse of the matrix. These three algorithms constitute the basis for all known RRQR algorithms.

Yet, it took another ten years for the next batch of algorithms by Stewart [32], Foster [17], and Chan [9] to appear. By this time it was known that there are matrices

* Received by the editors December 23, 1991; accepted for publication (in revised form) October 26, 1992. The work presented in this paper was supported by National Science Foundation grant CCR-9102853.

† Department of Computer Science, Yale University, New Haven, Connecticut 06520 (ipsen@math.ncsu.edu, chandras@math.ncsu.edu).

for which Golub's RRQR algorithm [7], [16], [19] can fail arbitrarily badly; Kahan's matrix [28] is such an example.

Again the field lay fallow for several years. Recently Hong and Pan [26] proved that an optimal RRQR factorisation is able to produce an estimate of a singular value that is accurate up to a factor proportional to the matrix size. This result implies that, in exact arithmetic and with a combinatorial operation count, RRQR factorisations have the potential of being accurate and reliable. (Much more than that, though, the result represents a statement about the relation between matrix columns and singular values: it says that there are k columns in the matrix that can reproduce, up to a factor in the matrix size, the kth singular value of the matrix.)

These days, the potential of RRQR factorisations is investigated for use in truncated singular value decompositions [10], [23], Lanczos methods [14], total least squares [37], and sparse matrix computations [3]–[5], [30]. Stewart has extended the RRQR factorisation by allowing orthogonal rotations from the right, resulting in the so-called URV decomposition [1], [31], [35], [36].

The state of affairs regarding RRQR factorisations can be summed up as follows. Despite the variety of algorithms, the problem of what it means to find a RRQR decomposition has never been clearly defined. Most definitions of a RRQR factorisation are about as fuzzy as the one we gave in the first sentence of this paper. Relationships or connections among the different RRQR algorithms are not known. All algorithms have the potential of failing badly. For some, we know the matrices where they fail badly. No criteria, other than a few test matrices, are known for comparing algorithms and judging their quality. Surprisingly, in numerical experiments, most RRQR algorithms turn out to be accurate and fast.

In this paper we present a systematic treatment of algorithms for determining RRQR factorisations. We start by presenting three precise mathematical formulations for the problem of determining a RRQR factorisation: one is a maximisation problem, one is a minimisation problem, and a third one is a combination of the two. We derive a hierarchy of "greedy" algorithms to solve the maximisation problem. It turns out that algorithms for solving the minimisation problem can be obtained by running algorithms for the maximisation problem on the inverse of the matrix and vice versa. This gives two parallel hierarchies of greedy algorithms for determining RRQR factorisations. We show that the existing RRQR algorithms correspond to particular greedy algorithms in this hierarchy. Moreover, we present matrices on which the greedy algorithms, and therefore the existing RRQR algorithms, fail arbitrarily badly.

Finally, motivated by our insight from the behaviour of the greedy algorithms, we present three "hybrid" algorithms that solve the optimisation problems with an accuracy given by the bounds of Hong and Pan [26]. Although the worst-case operation count of the hybrid algorithms may be combinatorial, we have not been able to find a matrix where this occurs. We present a few numerical experiments to demonstrate that applying the hybrid algorithms as a follow-up to the conventional RRQR algorithms may prove to be useful in practice.

2. The problem. In this section we give mathematical formulations of the problem of determining a rank-revealing QR (RRQR) factorisation of a matrix M.

Let M be a real $m \times n$ matrix and $m \geq n$. We assume that the singular values $\sigma_i(M)$ of M are arranged in decreasing order

$$\sigma_1(M) \geq \cdots \geq \sigma_n(M).$$

We also assume that k is a given integer such that $1 \leq k < n$ and $\sigma_k(M) > 0$. In the

applications where rank-revealing factorisations are of relevance, $\sigma_k(M)$ and $\sigma_{k+1}(M)$ are usually "well-separated," and $\sigma_{k+1}(M)$ is "small," of the order of the error in the computation, which means that the matrix has numerical rank k. Although our algorithms do not use this, it is useful to keep it in mind.

Denote by

$$M\Pi = QR$$

the QR factorisation of M with its columns permuted according to the $n \times n$ permutation matrix Π. The real $m \times n$ matrix Q has orthonormal columns, and the real $n \times n$ matrix R is upper triangular with positive diagonal elements. We block-partition R as

$$\begin{array}{c} \\ k \\ n-k \end{array} \begin{array}{c} \begin{array}{cc} k & n-k \end{array} \\ \begin{pmatrix} R_{11} & R_{12} \\ 0 & R_{22} \end{pmatrix} \end{array} = R,$$

where R_{11} is a $k \times k$ matrix.

The RRQR problem. The problems to be discussed in this paper are how to choose permutations Π such that

$$\sigma_{\min}(R_{11}) \approx \sigma_k(M)$$

or

$$\sigma_{\max}(R_{22}) \approx \sigma_{k+1}(M)$$

or both hold simultaneously. So there are three objectives leading to three different problems, all of which we refer to as "rank-revealing problems." It is an open question whether these are really three *different* objectives. That is, if we find a permutation such that $\sigma_{\min}(R_{11}) \approx \sigma_k(M)$, does it imply that $\sigma_{\max}(R_{22}) \approx \sigma_{k+1}(M)$? Our attempts at answering this question have not yielded sufficiently good answers, and in this paper we will consider them as three independent objectives.

Satisfaction of the third objective, where both bounds are satisfied simultaneously, implies that the leading k columns of $M\Pi$ have condition number $\sigma_1(M)/\sigma_k(M)$ and approximate the range space of M to an "accuracy" of $\sigma_{k+1}(M)$.

Before proceeding any further we should be more specific about those $\approx$ signs. According to the interlacing properties of singular values (Corollary 8.3.3 in [21] applied to R^T) the bounds

$$(I1) \qquad \sigma_{\min}(R_{11}) \leq \sigma_k(M),$$
$$(I2) \qquad \sigma_{\max}(R_{22}) \geq \sigma_{k+1}(M)$$

hold for *any* permutation Π. So the RRQR problems can be precisely formulated as

Problem-I: $\max_\Pi \sigma_{\min}(R_{11})$;
Problem-II: $\min_\Pi \sigma_{\max}(R_{22})$

or that both can be solved simultaneously, though that may not be possible all the time.

Because we believe that the time complexity of these problems is combinatorial, we are content to find permutations Π that guarantee

$$\sigma_{\min}(R_{11}) \geq \frac{\sigma_k(M)}{p(n)}$$

or

$$\sigma_{\max}(R_{22}) \leq q(n)\sigma_{k+1}(M)$$

or that both bounds hold simultaneously. Here $p(n)$ and $q(n)$ are low degree polynomials in n. We say that a permutation Π that achieves one or both of these inequalities gives rise to a RRQR factorisation $M\Pi = QR$. An algorithm that attempts to solve Problem-I is called a Type-I algorithm and has the suffix I in its name. An algorithm that attempts to solve Problem-II is called a Type-II algorithm and has the suffix II in its name.

3. Overview of RRQR algorithms. We accomplish two tasks in this paper: first, we demonstrate that all existing RRQR algorithms form a hierarchy of greedy algorithms; and second, we present a set of new algorithms that are more accurate than the existing RRQR algorithms.

The existing algorithms in the literature guarantee that

$$\sigma_{\min}(R_{11}) \geq \frac{\sigma_k(M)}{n2^k} \qquad \text{or} \qquad \sigma_{\max}(R_{22}) \leq \sigma_{k+1}(M)n2^{n-k},$$

where the bounds are worst-case bounds. In practice, however, the existing algorithms perform quite well and the worst-case bounds are rarely obtained. There also exists an algorithm [20] with simultaneous worst-case bounds

$$\sigma_{\min}(R_{11}) \geq \frac{\sigma_k(M)}{n2^{\min(k,n-k)}}, \qquad \sigma_{\max}(R_{22}) \leq \sigma_{k+1}(M)n2^{\min(k,n-k)}.$$

In contrast, our new algorithms guarantee

$$\sigma_{\min}(R_{11}) \geq \frac{\sigma_k(M)}{\sqrt{k(n-k+1)}}$$

or

$$\sigma_{\max}(R_{22}) \leq \sigma_{k+1}(M)\sqrt{(k+1)(n-k)},$$

or both. The *existence* of such RRQR factorisations was established in [26]. Although we believe that the operation count of our new algorithms is combinatorial in the worst case, preliminary numerical experiments indicate that they may be fast in practice.

We ignore brute force algorithms for finding permutations Π because they do not exploit any properties of the matrix. Their operation count is therefore *always* combinatorial.

Now we start with the presentation of a unified approach to the existing RRQR algorithms. Our approach simplifies the presentation and analysis of these algorithms, and it also directly motivates our new algorithms. To this end, we make the following simplification. If $M\Pi = QR$ is a QR factorisation of M for some permutation Π, and if $R\bar{\Pi} = \bar{Q}\bar{R}$ is a RRQR factorisation of R, then

$$M\Pi\bar{\Pi} = Q\bar{Q}\bar{R}$$

is a RRQR factorisation of M. Hence one can ignore the original matrix M and work with the triangular matrix R instead.

4. Type-I greedy algorithms. It is our goal to find algorithms to solve Problem-I

$$\max_{\Pi} \sigma_{\min}(R_{11})$$

that guarantee

$$\sigma_{\min}(R_{11}) \geq \frac{\sigma_k(M)}{p(n)},$$

where $p(n)$ is a low degree polynomial in n. Problem-I is likely to represent a combinatorial optimisation problem, and this suggests that a greedy algorithm might do well.

The basic idea for our greedy algorithm, which we call Greedy-I, is very simple. The objective of Problem-I is to find k well-conditioned columns of M. So suppose that we already have $l < k$ well-conditioned columns of M. Then Greedy-I picks a column from the remaining $n - l$ columns of M such that the smallest singular value of the given l columns plus the new column is as large as possible. Starting with $l = 0$ this is done k times to pick k well-conditioned columns of M. Note that Greedy-I does not discard a column once it has been chosen.

ALGORITHM GREEDY-I
$R^{(0)} = R$
For $l = 0$ **to** $k - 1$ **do**
Set

$$\begin{array}{c} \\ l \\ n-l \end{array} \begin{array}{c} \begin{array}{cc} l & n-l \end{array} \\ \begin{pmatrix} A & B \\ & C \end{pmatrix} \end{array} = R^{(l)}.$$

Denote the columns of B and C by $b_i = Be_i$ and $c_i = Ce_i$.

1. Find the next column $l + j$ of $R^{(l)}$ such that

$$\max_{1 \leq i \leq n-l} \sigma_{\min} \begin{pmatrix} A & b_i \\ & c_i \end{pmatrix} = \sigma_{\min} \begin{pmatrix} A & b_j \\ & c_j \end{pmatrix}.$$

2. Exchange columns $l + 1$ and $l + j$ of $R^{(l)}$, and retriangularise it from the left with orthogonal transformations to get $R^{(l+1)}$.

In iteration $l = 0$, Greedy-I selects the column of R with largest norm. If everything goes right, then $R^{(k)}$ should be a rank-revealed upper triangular matrix. It is important to keep in mind that the dimensions of A, B, and C change with every iteration of Greedy-I.

Step 1 of Greedy-I, which selects the next column to be added to A, is very expensive. We make it cheaper, while at the same time retaining the greedy strategy, by performing step 1 only approximately. Thus the algorithm becomes less greedy and more efficient. Since Greedy-I can only find an approximate solution at best, further approximations will hopefully not make matters much worse.

Before continuing we make a small simplification. If $\gamma_i = \|c_i\|$, where $\|\cdot\|$ represents the two-norm, then

$$\sigma_{\min} \begin{pmatrix} A & b_i \\ 0 & c_i \end{pmatrix} = \sigma_{\min} \begin{pmatrix} A & b_i \\ 0 & \gamma_i \end{pmatrix}.$$

This means, only the two-norm of the columns of C matters rather than individual elements in a column. Therefore the problem amounts to determining the smallest singular values of an upper triangular matrix of order $l+1$.

Now we present a sequence of successively less greedy approximations to step 1 of Greedy-I that give rise to most of the existing RRQR algorithms. In other words, we show that most existing RRQR algorithms can be viewed as approximations to algorithm Greedy-I.

In the first approximation, the determination of the smallest singular values $\sigma_{\min}(\cdot)$ is replaced by directly computable quantities. We choose to approximate the smallest singular value of a matrix by the reciprocal of the largest two-norm of the rows of its inverse: if D is a nonsingular matrix of order n and

$$D^{-1} = \begin{pmatrix} r_1^T \\ r_2^T \\ \vdots \\ r_n^T \end{pmatrix},$$

then

$$\sigma_{\min}(D) \leq \min_{1 \leq i \leq n} \frac{1}{\|r_i\|} \leq \sigma_{\min}(D)\sqrt{n}.$$

Consequently, the smallest singular value of a nonsingular matrix of order n can be estimated up to a factor of $\sqrt{n}$.

ALGORITHM GREEDY-I.1
Replace step 1 in algorithm Greedy-I by:
Find the next column $l+j$ of $R^{(l)}$ such that

$$\max_{1 \leq i \leq n-l} \min_h \left\| e_h^T \begin{pmatrix} A & b_i \\ 0 & \gamma_i \end{pmatrix}^{-1} \right\|^{-1} = \min_h \left\| e_h^T \begin{pmatrix} A & b_j \\ 0 & \gamma_j \end{pmatrix}^{-1} \right\|^{-1},$$

where e_h^T is the hth row of the identity matrix of order $l+1$.

An algorithm similar to Greedy-I.1 was proposed by Stewart [34] where, for reasons of efficiency, the Frobenius norm rather than the two-norm is used.

Although we say that Greedy-I.1 is an approximation to Greedy-I, this does not necessarily imply that Greedy-I reveals the rank better than Greedy-I.1. It only means that Greedy-I.1 is less greedy than Greedy-I. In particular, if in iteration l Greedy-I and Greedy-I.1 have the same submatrix A, then the $\sigma_{\min}$ of the leading $l+1$ columns from Greedy-I is larger than or equal to the $\sigma_{\min}$ of the corresponding columns from Greedy-I.1. But there is no guarantee that in the subsequent iteration $l+1$ the $\sigma_{\min}$ of the leading $l+2$ columns of Greedy-I will be larger than or equal to the $\sigma_{\min}$ of the corresponding columns of Greedy-I.1. This is because the greedy algorithms are not allowed to change their minds and to throw out a column selected in a previous iteration, and the best local choice in one step does not necessarily lead to the global optimum.

Because

$$\begin{pmatrix} A & b_i \\ 0 & \gamma_i \end{pmatrix}^{-1} = \begin{pmatrix} A^{-1} & -A^{-1}b_i\gamma_i^{-1} \\ 0 & \gamma_i^{-1} \end{pmatrix},$$

the upper left $l \times l$ block A^{-1} is already available from the previous step, and only the last column of the inverse needs to be computed for each i, which requires $n - l$ matrix vector multiplications. But carrying the inverse along with us at every stage is costly in terms of space and we first get rid of that.

If the greedy algorithms have not failed at the lth stage, the l leading columns must be "well conditioned." Hence A must be a well-conditioned matrix. Therefore $\sigma_{\min}(A)$ cannot be "small," which in turn implies that no row of A^{-1} can have a large two-norm. But if the addition of a new column, say the ith, produces a small singular value, then the two-norm of some row of the inverse of the corresponding matrix must be large. But since we assumed that no row of A^{-1} is large, this must mean that some component of the last column of the inverse

$$\begin{pmatrix} -A^{-1}b_i\gamma_i^{-1} \\ \gamma_i^{-1} \end{pmatrix}$$

must be large in magnitude. Thus the second approximation to step 1 of Greedy-I,

$$\left\| e_h^T \begin{pmatrix} A & b_i \\ 0 & \gamma_i \end{pmatrix}^{-1} \right\| \approx \left| \begin{pmatrix} -A^{-1}b_i\gamma_i^{-1} \\ \gamma_i^{-1} \end{pmatrix}_h \right|,$$

still avoids the selection of a very bad column.

ALGORITHM GREEDY-I.2
Replace step 1 in algorithm Greedy-I by:
Find the next column $l + j$ of $R^{(l)}$ such that

$$\max_{1 \le i \le n-l} \min_h \left| \begin{pmatrix} -A^{-1}b_i\gamma_i^{-1} \\ \gamma_i^{-1} \end{pmatrix}_h \right|^{-1} = \min_h \left| \begin{pmatrix} -A^{-1}b_j\gamma_j^{-1} \\ \gamma_j^{-1} \end{pmatrix}_h \right|^{-1}.$$

To eliminate the $n - l$ backsolves $A^{-1}b_i$ in Greedy-I.2, we make further use of the observation that A is probably well conditioned, so $\|A^{-1}b_i\| \approx 1$, and any large value must come from γ_i. Thus the third approximation to step 1 of Greedy-I,

$$\min_h \left| \begin{pmatrix} -A^{-1}b_i\gamma_i^{-1} \\ \gamma_i^{-1} \end{pmatrix}_h \right|^{-1} \approx \gamma_i,$$

still tries to avoid selecting a very bad column. This is nothing but the standard QR algorithm with column pivoting [7], [19], which is also described in [16].

ALGORITHM GREEDY-I.3 (GOLUB-I)
Replace step 1 in algorithm Greedy-I by:
Find the next column $l + j$ of $R^{(l)}$ such that $\max_{1 \le i \le n-l} \gamma_i = \gamma_j$.

This algorithm can be implemented efficiently because the column norms γ_i need only be updated during each iteration, rather than recomputed from scratch [7].

The approximations still to be discussed do not result in algorithms that are faster than Golub-I; in fact, they may be slower, but they are necessary to derive the remaining existing RRQR algorithms.

The goal is to make a further approximation to

$$\max_{1 \le i \le n-l} \gamma_i \equiv \alpha_{l+1}$$

in iteration l, where α_l is the lth diagonal element in the final upper triangular matrix in Golub-I. To this end, compute the right singular vector of the submatrix C of $R^{(l)}$ corresponding to its largest singular value $\|C\|$. Therefore the next approximation consists of finding the $(n-l) \times 1$ vector v such that

$$Cv = \|C\|u, \qquad \|v\| = \|u\| = 1,$$

and choosing as the next column the column j that corresponds to the largest component in magnitude of v,

$$|v_j| = \max_{1 \le i \le n-l} |v_i|.$$

ALGORITHM GREEDY-I.4 (CHAN-I)
Replace step 1 in algorithm Greedy-I by:
Find the next column $l+j$ of $R^{(l)}$ for which $|v_j| = \max_{1 \le i \le n-l} |v_i|$.

This algorithm was discovered independently by Chan and Hansen [11] and is related to the algorithm in [9]. Its choice of column j can be justified as follows. The Cauchy–Schwartz inequality gives

$$\gamma_j = \|Ce_j\| = \|u\| \, \|Ce_j\| \ge |u^T Ce_j| = \|C\| \, |v_j|.$$

As v has $n-l$ elements and satisfies $\|v\| = 1$, it must have a component v_j for which $|v_j| \ge 1/\sqrt{n-l}$. This is true in particular for the largest component in magnitude of v. Using this in $\gamma_j \ge \|C\| \, |v_j|$ gives

$$\frac{\alpha_{l+1}}{\sqrt{n-l}} \le \gamma_j \le \alpha_{l+1}, \qquad \alpha_{l+1} = \max_{1 \le i \le n-l} \gamma_i.$$

That is, the γ_j from algorithm Chan-I will be almost as large as that from algorithm Golub-I, if both algorithms were given the same l columns in A.

5. Threshold pivoting algorithms. We can make even further approximations to Chan-I. Algorithms Golub-I and Chan-I can be viewed as selecting large diagonal elements (*pivots*) at each stage to keep the smallest singular value as large as possible. According to the interlacing property (*I2*) of singular values, $\|C\| \ge \sigma_{l+1}(M)$, so

$$\alpha_{l+1} \ge \frac{\sigma_{l+1}(M)}{\sqrt{n-l}}, \quad 0 \le l \le k-1, \quad \text{where } \alpha_{l+1} = \max_{1 \le i \le n-l} \|Ce_i\|.$$

But all that is really needed is

$$\sigma_{\min}(R_{11}) \approx \sigma_k(M),$$

which means one may be able to get away with choosing pivots that are only as large as $\sigma_k(M)$. That is, instead of trying to achieve

$$|(R_{11})_{ll}| \approx \sigma_l(M), \qquad 1 \le l \le k,$$

we only try to ensure that

$$|(R_{11})_{ll}| \approx \sigma_k(M), \qquad 1 \le l \le k.$$

Golub-I and Chan-I try to keep all the pivots as large as possible at each stage. But since $\sigma_{\min}(R_{11})$ will be smaller than the smallest pivot, we are hoping that only the size of the smallest pivot is important, so that the conditions on the larger pivots can be relaxed.

Versions of Golub-I based on this approximation also go by the name of "threshold pivoting," and we now present two such algorithms. The first algorithm represents one of the first RRQR algorithms [20], [21] and, as we will show later, has the distinction of being able to solve both Problem-I and Problem-II simultaneously. Our name for the algorithm derives from the last names of its authors, Golub, Klema, and Stewart.

ALGORITHM GKS-I
Let $R = U\Sigma V^T$ be the singular value decomposition of R with

$$V = \begin{array}{c} \begin{array}{cc} k & n-k \end{array} \\ \begin{pmatrix} V_1 & V_2 \end{pmatrix} \end{array}.$$

1. Compute V_1.
2. Apply algorithm Golub-I to the rows of V_1, $V_1^T\Pi = Q_v\bar{V}_1^T$.
3. Compute the QR decomposition $R\Pi = \bar{Q}\bar{R}$, which is the required rank-revealing factorisation.

To see that this is indeed a threshold pivoting algorithm, partition the singular value decomposition (SVD) of R as follows

$$R = U \begin{pmatrix} \Sigma_1 & 0 \\ 0 & \Sigma_2 \end{pmatrix} \begin{pmatrix} V_1 & V_2 \end{pmatrix}^T.$$

Substituting the result of step 3, $\bar{Q}^T R\Pi = \bar{R}$, in step 2 gives

$$\bar{V}_1^T \bar{R}^{-1} = Q_v^T \Sigma_1^{-1} U^T \bar{Q}.$$

Since $\bar{R}^{-1}$ and the leading k columns of $\bar{V}_1^T$ represent upper triangular matrices,

$$\frac{\left|(\bar{V}_1)_{ii}\right|}{\left|(\bar{R})_{ii}\right|} \leq \|\bar{V}_1^T \bar{R}^{-1}\| = \|\Sigma_1^{-1}\| \leq \frac{1}{\sigma_k(M)}.$$

Because $\bar{V}_1^T$ is the result of QR with column pivoting on a matrix with orthonormal rows, the largest element in magnitude in the ith row of $\bar{V}_1^T$ is $(\bar{V}_1)_{ii}$ and $|(\bar{V}_1)_{ii}| \geq 1/\sqrt{n}$. Combining the inequalities gives a lower bound on the pivots,

$$\left|(\bar{R})_{ii}\right| \geq \frac{\sigma_k(M)}{\sqrt{n}}.$$

So algorithm GKS-I behaves like a threshold pivoting algorithm.

We now describe a threshold pivoting algorithm that we call Foster-I because it is related to an algorithm proposed by Foster (see Algorithm 2 in [17]). For a given δ, where δ is presumably about as big as $\sigma_k(M)$, Foster-I tries to achieve $\sigma_{\min}(R_{11}) \approx \delta$ by choosing pivots greater than or equal to δ. To this end it searches the rows of R, bottom up, for an element of magnitude greater than δ. When it finds such an element it adds the corresponding column to R_{11} and continues the search. As in all greedy algorithms for Problem-I, once a column has been added to R_{11} it is never discarded again. The algorithm halts when it has finished searching n rows. If it

succeeds in finding k elements larger than δ, then the first k pivots are at least as large as δ.

ALGORITHM FOSTER-I
$i = n$, *count* $= n$, $l = 0$
While (*count* ≥ 1) **do**
  Find the maximal element in row i: $|R_{ij}| = \max\{|R_{ii}|, \ldots, |R_{in}|\}$
  If ($|R_{ij}| \geq \delta$) **then**
    Insert column j between the lth and $(l+1)$st columns
    Retriangularise R
    $l = l + 1$
  else
    $i = i - 1$
  count $=$ *count* $- 1$

Here we have come to the end of our approximations to Greedy-I, which was a greedy algorithm for solving the Type-I problem

$$\max_{\Pi} \sigma_{\min}(R_{11}).$$

6. (Pessimistic) analysis of the greedy algorithms. In the previous sections we presented a succession of approximations to algorithm Greedy-I with little formal justification. Now we need to investigate how big $\sigma_k(M)/\sigma_{\min}(R_{11})$ from these algorithms can be. Algorithm Greedy-I represents the "best" method in the greedy sense, so we expect its worst-case behaviour to be indicative of that of the other greedy algorithms.

Suppose Greedy-I has already set aside l columns

$$R^{(l)} = \begin{pmatrix} A & B \\ 0 & C \end{pmatrix},$$

where A is a $l \times l$ matrix. It then chooses as the $(l+1)$st column that column j which when added to A maximises the smallest singular value, so

$$\bar{\sigma}_{l+1} = \max_{1 \leq i \leq n-l} \sigma_{\min} \begin{pmatrix} A & b_i \\ 0 & c_i \end{pmatrix} = \sigma_{\min} \begin{pmatrix} A & b_j \\ 0 & c_j \end{pmatrix}.$$

To estimate how small $\bar{\sigma}_{l+1}$ can be we need to compute a lower bound on the smallest singular value. To this end we compute a lower bound instead for the column Golub-I would select, given the same A, because this also serves as a lower bound for the column Greedy-I picks. So assume that Golub-I picks column q. This column has the largest norm among all columns of C.

Just as in algorithm Greedy-I.1, we estimate $\sigma_{\min}$ by the reciprocal of the largest two-norm of the rows of the inverse

$$\begin{pmatrix} A & b_q \\ 0 & \gamma_q \end{pmatrix}^{-1} = \begin{pmatrix} A^{-1} & -A^{-1} b_q \gamma_q^{-1} \\ 0 & \gamma_q^{-1} \end{pmatrix}.$$

The norm of the row with the largest norm among the leading l rows of the inverse is bounded from above by

$$\max_i \|e_i^T A^{-1}\| + \|A^{-1} b_q\| \gamma_q^{-1} \leq \frac{1}{\bar{\sigma}_l} + \frac{\|b_q\|}{\bar{\sigma}_l} \gamma_q^{-1} \leq \sqrt{2} \frac{\sqrt{\gamma_q^2 + \|b_q\|^2}}{\bar{\sigma}_l} \gamma_q^{-1} \leq \sqrt{2} \frac{\|M\|}{\bar{\sigma}_l} \gamma_q^{-1},$$

where the penultimate inequality is a result of the Cauchy–Schwartz inequality. The norm of the $(l+1)$st row of the inverse clearly cannot exceed the upper bound on the maximal norm of the leading l rows. Since the maximal row norm of the inverse approximates the smallest singular value of the matrix, we have

$$\bar{\sigma}_{l+1} \geq \frac{1}{\sqrt{2(l+1)}} \frac{\bar{\sigma}_l}{\sigma_1(M)} \gamma_q.$$

Using the interlacing property $(I2)$

$$\gamma_q = \max_{1 \leq i \leq n-l} \gamma_i \geq \frac{\sigma_{l+1}(M)}{\sqrt{n-l}}$$

with the above inequality gives a lower bound for the smallest singular value

$$\bar{\sigma}_{l+1} \geq \sigma_{l+1}(M) \frac{\bar{\sigma}_l}{\sigma_1(M)} \frac{1}{\sqrt{2(l+1)(n-l)}}.$$

This goes to show that even if the leading l columns had been selected so that $\bar{\sigma}_l$ was as accurate as possible, there could be a potentially serious deterioration in the quality of estimation from lth to $(l+1)$st singular value if the $(l+1)$st column is chosen according to a greedy strategy. This is because a greedy algorithm, once it has decided on a column, can never get rid of it. And a column that participates in an *accurate* estimation of $\bar{\sigma}_l$ may not be a column to be included in an accurate estimation of $\bar{\sigma}_{l+1}$. In particular, the estimate $\bar{\sigma}_{l+1}$ worsens with the ill conditioning of the leading l columns in $R^{(l)}$.

In fact, there exist matrices that almost achieve the above bound. One such example is the Kahan matrix [28]

$$K_n = \begin{pmatrix} 1 & 0 & \cdots & 0 \\ 0 & s & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0 \\ 0 & \cdots & 0 & s^{n-1} \end{pmatrix} \begin{pmatrix} 1 & -c & \cdots & -c \\ 0 & 1 & \ddots & \vdots \\ \vdots & \ddots & \ddots & -c \\ 0 & \cdots & 0 & 1 \end{pmatrix},$$

where $c^2 + s^2 = 1$. Greedy-I, Greedy-I.1, Greedy-I.2, and Golub-I do not cause any permutation of the columns of K_n. We prove this for Greedy-I by induction. Since all columns of K_n have unit norm, no column permutations are necessary in the first iteration of Greedy-I. Suppose no permutations are necessary during the first l iterations, so

$$K_n = \begin{pmatrix} K_l & b_1 & \cdots & b_{n-l} \\ & c_1 & \cdots & c_{n-l} \end{pmatrix}.$$

In the $(l+1)$st iteration Greedy-I selects the $(l+1)$st column by examining

$$\sigma_{\min} \begin{pmatrix} K_l & b_i \\ & c_i \end{pmatrix} = \sigma_{\min} \begin{pmatrix} K_l & b_i \\ & \gamma_i \end{pmatrix}, \quad \gamma_i = \|c_i\|, \quad 1 \leq i \leq n-l.$$

But all b_i are identical for the Kahan matrix, as are all γ_i; hence no permutations are necessary in iteration $l+1$.

Yet K_n is not in rank-revealed form. For $n = 100$, $k = 99$, and $c = 0.2$, the singular values are

$$\sigma_{100}(K_{100}) \approx 3 \times 10^{-9},$$
$$\sigma_{99}(K_{100}) \approx 0.1482,$$
$$\bar{\sigma}_{99} \approx 4 \times 10^{-9}.$$

Although the 99th and 100th singular values are well separated, the smallest singular value of the first 99 columns chosen by the greedy algorithms is exponentially smaller than $\sigma_{99}(K_{100})$.

Traditionally, the Kahan matrix has served as an example to demonstrate the failure of algorithm Golub-I to make the *last* diagonal element of the same order of magnitude as $\sigma_{100}(K_{100})$. But from our discussion it is clear that Golub-I pursues a different mission: it wants to make $\bar{\sigma}_{99} \approx \sigma_{99}(K_{100})$. And it fails in *that*.

7. (Optimistic) analysis of the greedy algorithms. Now that we have seen how badly the greedy algorithms do, we wonder why they do so well in practice? This question seems to be related to other rare matrix events like pivot growth in Gaussian elimination with partial pivoting. Foster [18] considers this question for QR without column pivoting. The case of QR with column pivoting seems to be much harder to analyse, and we can only give informal reasons why the greedy algorithms Golub-I, Chan-I, and GKS-I are so effective.

The basic idea is to derive a lower bound for $\sigma_{\min}(R_{11})$ of the form

$$\frac{\sigma_k(M)}{n\|W^{-1}\|} \leq \sigma_{\min}(R_{11}) \leq \sigma_k(M),$$

where W is a $k \times k$ triangular matrix with

$$|W| \leq 1, \qquad |W_{ii}| = 1,$$

and the inequality is componentwise. The lower triangular matrix in Gaussian elimination with partial pivoting satisfies these same two properties as the W matrices and is usually well conditioned. (Or as Kahan [28] would say, "intolerable pivot growth is a phenomenon that happens only to numerical analysts who are looking for that phenomenon.") Of course, this does not prove anything and more work is needed in this regard.

We start with the derivation of the above bound for algorithm Golub-I. Here we define the matrix W by

$$R_{11} = DW, \qquad D = \operatorname{diag}(R_{11}),$$

where $\operatorname{diag}(R_{11})$ is a diagonal matrix whose diagonal elements are the same as those of R_{11}. The diagonal elements of R_{11} in Golub-I satisfy $|(R_{11})_{ii}| \geq |(R_{11})_{ij}|$; hence W fulfills the required conditions

$$|W| \leq 1, \qquad |W_{ii}| = 1.$$

The interlacing properties $(I2)$ of singular values and the first few inequalities in § 5 imply that

$$|(R_{11})_{ii}| = \alpha_i \geq \frac{\sigma_i(M)}{\sqrt{n-i+1}}, \qquad 1 \leq i \leq k.$$

Since D is a diagonal matrix, its singular values equal its diagonal elements, so

$$\frac{1}{\sigma_{\min}(D)} = \|D^{-1}\| \leq \frac{\sqrt{n}}{\sigma_k(M)}.$$

From $\sigma_{\min}(R_{11}) \geq \sigma_{\min}(D)\sigma_{\min}(W)$ the desired bound for Golub-I follows

$$\sigma_{\min}(R_{11}) \geq \frac{\sigma_k(M)}{\sqrt{n}\|W^{-1}\|}.$$

Next we derive the bound for algorithm Chan-I. The proof is similar to that of Theorem 3.1 in [9]. We first define the $n \times k$ auxiliary matrix Z. Its columns are composed of the right singular vectors $v^{(l)}$ associated with the largest singular values of the lower right block of order $n-l+1$, $R_{22}^{(l)}$, of the final triangular matrix R. That is, Z is a lower trapezoidal matrix with columns

$$Ze_l = Z_l = \begin{pmatrix} 0 \\ \vdots \\ 0 \\ v^{(l)} \end{pmatrix}, \qquad 1 \leq l \leq k,$$

where $R_{22}^{(l)} v^{(l)} = \|R_{22}^{(l)}\| u^{(l)}$ and $\|v^{(l)}\| = \|u^{(l)}\| = 1$. Then the lower triangular matrix W for Chan-I is given by

$$Z = \begin{pmatrix} W \\ * \end{pmatrix} D, \qquad D = \operatorname{diag}(Z_{11} \quad \ldots \quad Z_{kk}),$$

where Z_{ii} are the diagonal elements of Z.

According to algorithm Chan-I, the first component of $v^{(l)}$ is the largest in magnitude, hence

$$|W| \leq 1, \qquad |W_{ii}| = 1.$$

Moreover, $\|v^{(l)}\| = 1$ implies

$$|Z_{ll}| = |v_1^{(l)}| \geq \frac{1}{\sqrt{n}}, \qquad 1 \leq l \leq k,$$

and

$$\frac{1}{\|D^{-1}\|} = \sigma_{\min}(D) \geq \frac{1}{\sqrt{n}}.$$

From the interlacing property $(I2)$ of singular values, $\|R_{22}^{(l)}\| \geq \sigma_l(M)$, and the fact that $v^{(l)}$ is a right singular vector with

$$[v^{(l)}]^T [R_{22}^{(l)}]^{-1} = \frac{1}{\|R_{22}^{(l)}\|} [u^{(l)}]^T,$$

we get

$$\|Z_l^T R^{-1}\| = \|[v^{(l)}]^T [R_{22}^{(l)}]^{-1}\| \leq \frac{1}{\sigma_l(M)}.$$

Since Z^T and R are upper triangular this implies

$$\|DW^T R_{11}^{-1}\| \leq \|Z^T R^{-1}\| \leq \sqrt{k} \max_{1 \leq l \leq k} \|Z_l^T R^{-1}\| \leq \frac{\sqrt{k}}{\sigma_k(M)}.$$

Hence

$$\frac{\|R_{11}^{-1}\|}{\|D^{-1}\| \, \|W^{-1}\|} \leq \frac{\sqrt{k}}{\sigma_k(M)}$$

gives the desired bound for algorithm Chan-I

$$\sigma_{\min}(R_{11}) \geq \frac{\sigma_k(M)}{n\|W^{-1}\|}.$$

At last we derive the bound for algorithm GKS-I, which is also given in [20] and in Theorem 12.2.1 in [21]. Let $R = U\Sigma V^T$ be the SVD of R and partition

$$\begin{matrix} & k & n-k \\ V = & (V_1 & V_2\ ). \end{matrix}$$

Algorithm GKS applies algorithm Golub-I to V_1^T, so

$$V_1^T \Pi = Q_v \bar{V}_1^T,$$

where $\bar{V}_1$ is a lower trapezoidal matrix. The matrix W for GKS-I is defined by

$$\bar{V}_1 = \begin{pmatrix} W \\ * \end{pmatrix} D, \qquad D = \operatorname{diag}(\, \bar{V}_{11} \quad \dots \quad \bar{V}_{kk}\,),$$

where $\bar{V}_{ii}$ are diagonal elements of $\bar{V}_1$ and W is a lower triangular matrix. Because $\bar{V}_1$ comes from algorithm Golub-I, its diagonal elements are the largest elements in magnitude in each column, so $|\bar{V}_{ii}| \geq |\bar{V}_{ji}|$ and the matrix W satisfies the required properties

$$|W| \leq 1, \qquad |W_{ii}| = 1.$$

Since each column of $\bar{V}_1$ has unit norm, $|\bar{V}_{ii}| \geq 1/\sqrt{n}$, and since W^T and the final matrix R are upper triangular, one gets

$$\frac{\|R_{11}^{-1}\|}{\sqrt{n}\|W^{-1}\|} \leq \frac{\|R_{11}^{-1}\|}{\|W^{-T}\| \, \|D^{-1}\|} \leq \|DW^T R_{11}^{-1}\| \leq \|\bar{V}_1^T R^{-1}\|.$$

Moreover, from § 5 we know that (with $\bar{R}$ now renamed R)

$$\|\bar{V}_1^T R^{-1}\| = \|\Sigma_1^{-1}\| = \frac{1}{\sigma_k(M)}.$$

Combining the last two inequalities yields

$$\sigma_{\min}(R_{11}) \geq \frac{\sigma_k(M)}{\sqrt{n}\|W^{-1}\|}.$$

To summarise, we have demonstrated in this section that the failure of algorithms Golub-I, Chan-I, and GKS-I depends on $\|W^{-1}\|$, where W is a triangular matrix satisfying

$$|W| \leq 1, \qquad |W_{ii}| = 1.$$

The lower triangular matrix L in Gaussian elimination with partial pivoting satisfies the same properties as W, and it generally turns out that $\|L^{-1}\|$ is small, say, like $O(n)$. Although this does not prove anything, it does show that all these rare matrix events are closely related. The probability of pivot growth in Gaussian elimination with partial pivoting is closely related to the probabilities of Golub-I, Chan-I, and GKS-I failing.

For the above matrices W of order k a tight upper bound on $\|W^{-1}\|$ is [16], [28]

$$\|W^{-1}\| \leq \frac{1}{3}\sqrt{4^k + 6k - 1} \leq \sqrt{k}2^k, \qquad k > 1,$$

and, as illustrated in § 6, the Kahan matrix essentially achieves this bound.

8. Unification. After having discussed greedy algorithms for the solution of Problem-I

$$\max_{\Pi} \sigma_{\min}(R_{11}),$$

we now turn to greedy algorithms for Problem-II

$$\min_{\Pi} \sigma_{\max}(R_{22}).$$

Fortunately, a simple observation greatly reduces this task.

Section 3 explains why it suffices to solve Problem-I for triangular matrices $\bar{R}$ and to consider

$$\bar{R}\Pi = QR, \qquad R = \begin{pmatrix} R_{11} & R_{12} \\ 0 & R_{22} \end{pmatrix}.$$

Suppose that $\bar{R}$ is nonsingular, invert both sides of the above equation,

$$\Pi^T \bar{R}^{-1} = \begin{pmatrix} R_{11}^{-1} & -R_{11}^{-1}R_{12}R_{22}^{-1} \\ 0 & R_{22}^{-1} \end{pmatrix} Q^T,$$

and take transposes on both sides

$$\bar{R}^{-T}\Pi = Q \begin{pmatrix} R_{11}^{-T} & 0 \\ -R_{22}^{-T}R_{12}^T R_{11}^{-T} & R_{22}^{-T} \end{pmatrix}.$$

Now Problem-II can be formulated as

$$\begin{aligned} \min_{\Pi} \sigma_{\max}(R_{22}) &= \min_{\Pi} \frac{1}{\sigma_{\min}(R_{22}^{-1})} \\ &= \frac{1}{\max_{\Pi} \sigma_{\min}(R_{22}^{-1})} \\ &= \frac{1}{\max_{\Pi} \sigma_{\min}(R_{22}^{-T})}. \end{aligned}$$

Hence solving Problem-II is equivalent to solving Problem-I for the inverse. We call this *the unification principle* as it lets us unify the algorithms and analyses of Problem-I and Problem-II.

Applying a Type-I algorithm to the inverse gives

$$\bar{R}^{-T}\bar{\Pi} = \bar{Q}\begin{pmatrix} P_{11} & P_{12} \\ 0 & P_{22} \end{pmatrix},$$

where P_{11} is an upper triangular matrix of order $n-k$, P_{22} is an upper triangular matrix of order k, and (hopefully) $\sigma_{\min}(P_{11}) \approx \sigma_{n-k}(\bar{R}^{-T})$. Hence we need to make some adjustments as P_{11} should correspond to R_{22}^{-T}, which is lower triangular. Moreover, P_{11} should really have been the lower right block.

The necessary adjustments are achieved by a sequence of permutations, which can be accumulated in Q and Π. First permute the two block columns and the two block rows,

$$\begin{pmatrix} P_{11} & P_{12} \\ 0 & P_{22} \end{pmatrix} \rightarrow \begin{pmatrix} P_{12} & P_{11} \\ P_{22} & 0 \end{pmatrix} \rightarrow \begin{pmatrix} P_{22} & 0 \\ P_{12} & P_{11} \end{pmatrix}.$$

Then reverse the ordering of the columns and of the rows in P_{11} and P_{22} separately. This is accomplished by means of permutation matrices J_p of order p that have ones on the antidiagonal,

$$\begin{pmatrix} P_{22} & 0 \\ P_{12} & P_{11} \end{pmatrix} \rightarrow \begin{pmatrix} J_k P_{22} J_k & 0 \\ J_{n-k} P_{12} J_k & J_{n-k} P_{11} J_{n-k} \end{pmatrix}.$$

Now the resulting matrix has the desired form; it is lower triangular with P_{11} in the lower right corner.

Therefore, the postprocessing step consisting of the above permutations proves that applying a Type-I algorithm to the rows of the inverse amounts to executing a Type-II algorithm. In fact, we call such an algorithm the *Type-II version* of the *Type-I algorithm*. This notion is completely symmetric with respect to the two types, as one can equally well construct a *Type-I version* of a *Type-II algorithm* to solve Problem-I.

Unification principle. Running a Type-I algorithm on the rows of the inverse of the matrix yields a Type-II algorithm.

9. Type-II greedy algorithms. In this section we illustrate the unification principle by exhibiting the Type-II version of algorithm Golub-I, and by proving that algorithm GKS-I also solves Problem-II.

We use the name Stewart-II for the Type-II version of algorithm Golub-I, as it

was first proposed in [33], though not quite in the form in which we are presenting it.

ALGORITHM STEWART-II
$R^{(0)} = R$
For $l = 0$ **to** $n - k - 1$ **do**
Set

$$\begin{array}{c} \\ n-l \\ l \end{array} \begin{array}{c} \begin{array}{cc} n-l & l \end{array} \\ \begin{pmatrix} A & B \\ & C \end{pmatrix} \end{array} = R^{(l)},$$

1. Find the next column j of $R^{(l)}$ such that

$$\max_{1 \le i \le n-l} \|e_i^T A^{-1}\| = \|e_j^T A^{-1}\|.$$

2. Exchange columns $n-l$ and j of $R^{(l)}$, and retriangularise it from the left with orthogonal transformations to get $R^{(l+1)}$.

Clearly, algorithm Stewart-II obtains the right ordering of the columns by sending the selected columns to the right end of the matrix. In all other matters it is completely equivalent to running Golub-I on the rows of the inverse.

A few clarifying remarks may be in order. Just because a Type-II version of an algorithm can be constructed by applying a Type-I algorithm to the rows of the inverse of the matrix, this does not mean that is also how it should be implemented. There may very well be a way to reformulate the Type-II version so that it avoids explicit dealings with inverses.

Furthermore, it is important to realise that a Type-I algorithm and its Type-II version, in general, come up with different column permutations; and that solving Problem-I does not entail solving Problem-II. All the unification principle says is that if there is an algorithm for solving Problem-I, then a simple modification will give an algorithm for solving Problem-II and vice versa.

There is another advantage of the unification principle. It allows us to carry over the analyses and worst-case examples for a Type-I algorithm, with suitable modifications, to its Type-II version and vice versa. A few examples follow.

In § 6 we explained that the lower bounds for the singular value estimates from algorithms Golub-I, Chan-I, and GKS-I can be cast in the form

$$\sigma_{\min}(R_{11}) \ge \frac{\sigma_k(M)}{n\|W^{-1}\|},$$

where W are triangular matrices satisfying

$$|W| \le 1, \qquad |W_{ii}| = 1.$$

The unification principle therefore admits upper bounds for the singular value estimates from the Type-II versions of Golub-I, Chan-I, and GKS-I of the form

$$\sigma_{\max}(R_{22}) \le \sigma_{k+1}(M) n \|W^{-1}\|,$$

where, again, W are triangular matrices satisfying

$$|W| \le 1, \qquad |W_{ii}| = 1.$$

As for other existing Type-II algorithms, the Type-II version of Chan-I, which we call Chan-II, was published apparently independently in [22], [9], [17]. The Type-II version of GKS-I was first published in [20] and will be called GKS-II. The Type-II version of Foster-I, which we refer to as Foster-II, was first published in [17]. The detailed exposition of Foster-II in [17] also serves to illuminate our algorithm Foster-I.

We still owe a justification of our claim that GKS-I also solves Problem-II [20], [21]. Let $R = U\Sigma V^T$ be the SVD of the final triangular matrix R, where

$$\begin{array}{c} \\ k \\ n-k \end{array} \begin{array}{c} \begin{array}{cc} k & n-k \end{array} \\ \begin{pmatrix} V_{11} & V_{12} \\ V_{21} & V_{22} \end{pmatrix} \end{array} = V, \qquad \Sigma = \begin{pmatrix} \Sigma_1 & \\ & \Sigma_2 \end{pmatrix}.$$

This implies

$$\frac{1}{\sigma_{\min}(R_{11})\|V_{11}^{-1}\|} = \frac{\|R_{11}^{-1}\|}{\|V_{11}^{-1}\|} \leq \|V_{11}^T R_{11}^{-1}\| \leq \|\Sigma_1^{-1}\| = \frac{1}{\sigma_k(M)},$$

and

$$\frac{1}{\|R_{22}\|} = \sigma_{\min}(R_{22}^{-1}) \geq \sigma_{\min}(\Sigma_2^{-1}V_{22}) \geq \sigma_{\min}(\Sigma_2^{-1})\sigma_{\min}(V_{22}) = \frac{1}{\sigma_{k+1}(M)\|V_{22}^{-1}\|},$$

so

$$\sigma_{\min}(R_{11}) \geq \frac{\sigma_k(M)}{\|V_{11}^{-1}\|}, \qquad \|R_{22}\| \leq \sigma_{k+1}(M)\|V_{22}^{-1}\|.$$

According to the CS decomposition, §2.6 in [21],

$$\|V_{11}^{-1}\| = \|V_{22}^{-1}\|.$$

Since GKS-I attempts to keep $\|V_{11}^{-1}\|$ small, it therefore automatically also tries to keep $\|V_{22}^{-1}\|$ small. Therefore GKS-I solves both, Problem-I and Problem-II.

At last we demonstrate how the worst-case example of a Type-I algorithm can be converted to a worst-case example for its Type-II version. Section 6 illustrates that the Kahan matrix

$$K_n = \begin{pmatrix} 1 & 0 & \cdots & 0 \\ 0 & s & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0 \\ 0 & \cdots & 0 & s^{n-1} \end{pmatrix} \begin{pmatrix} 1 & -c & \cdots & -c \\ 0 & 1 & \ddots & \vdots \\ \vdots & \ddots & \ddots & -c \\ 0 & \cdots & 0 & 1 \end{pmatrix}$$

represents a worst case for algorithms Greedy-I, Greedy-I.1, Greedy-I.2, and Golub-I. It follows from the unification principle that the modified Kahan matrix whose inverse is given by

$$\bar{K}_n^{-1} = \begin{pmatrix} 1 & -c & \cdots & -c \\ 0 & 1 & \ddots & \vdots \\ \vdots & \ddots & \ddots & -c \\ 0 & \cdots & 0 & 1 \end{pmatrix} \begin{pmatrix} s^{n-1} & 0 & \cdots & 0 \\ & s^{n-2} & \ddots & \vdots \\ & & \ddots & 0 \\ 0 & \cdots & 0 & 1 \end{pmatrix},$$

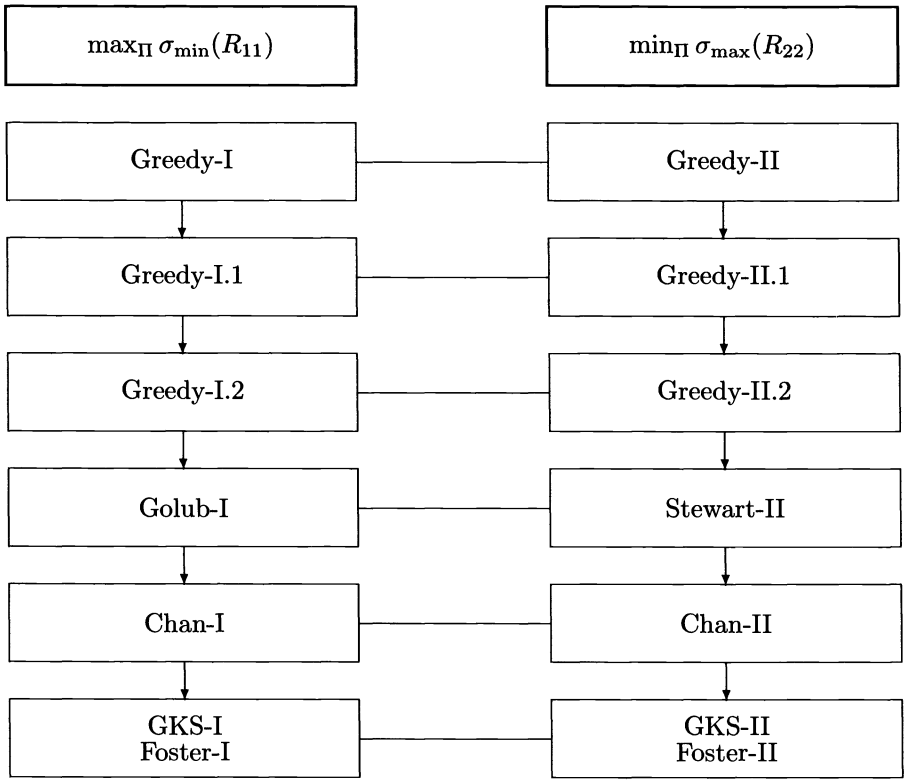

FIG. 10.1. *The greedy algorithms.*

where $c^2 + s^2 = 1$, represents a worst case for algorithms Greedy-II, Greedy-II.1, Greedy-II.2, and Stewart-II, the Type-II versions of the respective Type-I algorithms.

10. Summary. This ends our presentation of the existing RRQR algorithms. We gave three mathematical problems that we called rank-revealing problems,

Problem-I: $\max_\Pi \sigma_{\min}(R_{11})$,
Problem-II: $\min_\Pi \sigma_{\max}(R_{22})$,

and the third was to solve Problem-I and Problem-II simultaneously. We then exhibited a sequence of successively less greedy algorithms to solve Problem-I. By means of the unification principle, we demonstrated the existence of Type-II versions of these algorithms, which are also greedy but solve Problem-II instead. Figure 10.1 illustrates the two parallel hierarchies made up from the Type-I and Type-II algorithms, where the corresponding Type-I and Type-II algorithms are next to each other, and each algorithm is less greedy than the one above it. Each of the existing RRQR algorithms has a place in this hierarchy. Examples of exponential failure of these greedy algorithms are provided by the Kahan and modified Kahan matrices.

We have ignored the greedy algorithms based on condition number estimators for triangular matrices, e.g., [2]–[5], [25], [34], because their behaviour depends very much on the particular condition number estimator.

The worst-case bounds

$$\sigma_{\min}(R_{11}) \geq \frac{\sigma_k(M)}{n2^k}, \qquad \|R_{22}\| \leq \sigma_{k+1}(M)n2^{n-k}$$

reveal that Type-I greedy algorithms work pretty well for small k, while Type-II greedy algorithms work well when k is close to n. This prompts the question whether a Type-I and a Type-II greedy algorithm can be combined into a single algorithm that works all the time. The answer is given in the next section.

11. Overview of the hybrid algorithms. In this section we present algorithms Hybrid-I and Hybrid-II. They are guaranteed to solve Problem-I and Problem-II, respectively. We also present algorithm Hybrid-III. It is guaranteed to solve both Problem-I and Problem-II simultaneously.

In particular, Algorithm Hybrid-I guarantees that

$$\sigma_{\min}(R_{11}) \geq \frac{\sigma_k(M)}{\sqrt{k(n-k+1)}},$$
$$\sigma_{\max}(R_{22}) \leq \sigma_{\min}(R_{11})\sqrt{k(n-k+1)}.$$

Note that Hybrid-I does *not* solve Problem-II. According to the unification principle, the Type-II version of Hybrid-I, which we call Hybrid-II, must guarantee that

$$\sigma_{\max}(R_{22}) \leq \sigma_{k+1}(M)\sqrt{(k+1)(n-k)},$$
$$\sigma_{\min}(R_{11}) \geq \frac{\sigma_{\max}(R_{22})}{\sqrt{(k+1)(n-k)}}.$$

Note again that Hybrid-II does not solve Problem-I. Hybrid-III does solve both Problem-I and Problem-II simultaneously, and it guarantees that

$$\sigma_{\min}(R_{11}) \geq \frac{\sigma_k(M)}{\sqrt{k(n-k+1)}},$$
$$\sigma_{\max}(R_{22}) \leq \sigma_{k+1}(M)\sqrt{(k+1)(n-k)}.$$

Of course, the brute force algorithm, which tries every combination of columns, also solves these problems, but its operation count is combinatorial. What about the hybrid algorithms? Unfortunately, we lack a complete analysis of the worst-case operation count of the hybrid algorithms, although we believe that it may be combinatorial as well. However, preliminary experimental results in §15 demonstrate that the hybrid algorithms are rather efficient in practice.

As in the previous sections we assume that k is given. Although this may not be a realistic assumption, a proper choice of k depends very much on the problem to be solved, and we refer to [20], [33] for the discussion of this issue.

12. Algorithm Hybrid-I. The algorithm Hybrid-I is a combination of Golub-I and Stewart-II, though in a practical implementation one may want to replace Stewart-II by Chan-II.

The obvious strategy of running Stewart-II after Golub-I is not guaranteed to solve Problem-I because Golub-I and Stewart-II almost always produce a unique ordering of columns, so the result of this strategy would merely equal the result of Stewart-II.

Instead, our idea is to alternate between Golub-I and Stewart-II and to let each work on a different part of the matrix: Stewart-II works on the (1,1) block of order k,

and Golub-I works on the (2,2) block of order $n-k+1$ of the matrix. Suppose Golub-I has picked the best column from the (2,2) block and put it in position k. Stewart-II then determines whether the kth column is indeed a good column. If not, it puts the worst column from the (1,1) block into position k. Now it is again Golub-I's turn to put the best column from the (2,2) block in position k. This process continues until Golub-I and Stewart-II agree on the kth column. To understand the resulting algorithm Hybrid-I, we briefly review Golub-I and Stewart-II.

Golub-I is good at approximating the largest singular value of $M\Pi = QR$. In its first iteration it finds the "most linearly independent" column of R, i.e., the column with largest norm. Suppose we permute this column to the first position and retriangularise the matrix. Then the first column $r_{11}e_1$ of the resulting triangular matrix approximates the largest singular value of M,

$$|r_{11}| \leq \sigma_{\max}(M) \leq \sqrt{n}|r_{11}|.$$

Since Stewart-II is the Type-II version of Golub-I, it is good at approximating the largest singular value of M^{-1} by finding the most linearly independent row of R^{-1}. Suppose we permute this row of R^{-1} to the last position and retriangularise the inverse to get the triangular matrix $\bar{R}^{-1} = \bar{\Pi}R^{-1}\bar{Q}$. Then the last column $r_{nn}^{-1}e_n$ of $\bar{R}^{-1}$ approximates the largest singular value of M^{-1},

$$|r_{nn}^{-1}| \leq \sigma_{\max}(M^{-1}) \leq \sqrt{n}|r_{nn}^{-1}|.$$

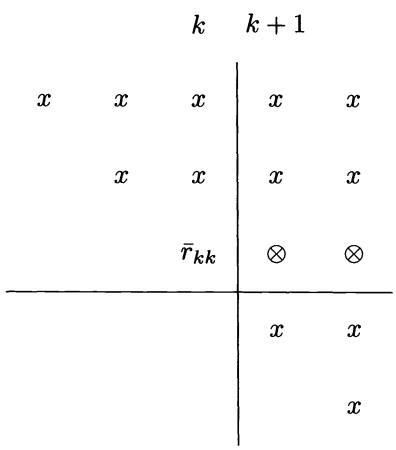
But since $\bar{R}^{-1}$ is triangular, r_{nn} is the trailing diagonal element of $\bar{R}$ and it approximates the smallest singular value of M,

$$\sigma_{\min}(M) \leq |r_{nn}| \leq \sqrt{n}\sigma_{\min}(M).$$

We illustrate Hybrid-I on a 5×5 example, where $k = 3$ and the symbol "x" represents nonzero matrix elements. First we run Golub-I on the $(2,2)$ block of order $n-k+1$ so that diagonal element r_{kk} has largest norm among all columns of the $(2,2)$ block

$$\begin{array}{cc|ccc} & & k-1 & k & \\ x & x & x & x & x \\ & x & x & x & x \\ \hline & & r_{kk} & x & x \\ & & & x & x \\ & & & & x \end{array}$$

Now we enlarge the $(1,1)$ block from order $k-1$ to order k so that the kth diagonal element can transfer information between the two algorithms. Then we run Stewart-II on the $(1,1)$ block of order k so that the (modified) diagonal element $\bar{r}_{kk}$ has smallest norm.



A run of Golub-I followed by Stewart-II constitutes one iteration. The circled elements in the $(1,2)$ block are modified by orthogonal rotations from the left due to retriangularisation in Stewart-II. They are part of the $(2,2)$ block for the subsequent run of Golub-I and illustrate how one algorithm changes the part of the matrix associated with the other algorithm. The $(1,1)$ block input to Stewart-II undergoes similar changes in column k due to column permutations during Golub-I.

ALGORITHM HYBRID-I(k)
$\bar{R}^{(0)} = R$, $l = 0$
Repeat
$l = l + 1$, *permuted* $= 0$
Set

$$\bar{R}^{(l)} = \begin{pmatrix} \bar{A} & \bar{B} \\ & \bar{C} \end{pmatrix},$$

where $\bar{A}$ is of order $k-1$ and $\bar{C}$ is of order $n-k+1$.
Golub-I:
1. Find the column $k+j-1$ of $\bar{R}^{(l)}$ such that $\|\bar{C}e_j\| = \max_{1\le i\le n-k+1} \|\bar{C}e_i\|$
2. **If** $\|\bar{C}e_1\| < \|\bar{C}e_j\|$ **then**
   permuted $= 1$
   Exchange columns k and $k+j-1$ of $\bar{R}^{(l)}$
   Retriangularise it from the left with orthogonal transformations to get

$$R^{(l)} = \begin{pmatrix} A & B \\ & C \end{pmatrix},$$

   where A is of order k and C is of order $n-k$.
Stewart-II:
3. Find the column j of $R^{(l)}$ such that $\|e_j^T A^{-1}\| = \max_{1\le i\le k} \|e_i^T A^{-1}\|$
4. **If** $\|e_k^T A^{-1}\| < \|e_j^T A^{-1}\|$ **then**
   permuted $= 1$
   Exchange columns j and k of $R^{(l)}$
   Retriangularise it from the left with orthogonal transformations to get $\bar{R}^{(l+1)}$.

until not *permuted*

The final matrix is

$$R = \begin{pmatrix} \bar{R}_{11} & \bar{R}_{12} \\ & \bar{R}_{22} \end{pmatrix} = \begin{pmatrix} R_{11} & R_{12} \\ & R_{22} \end{pmatrix},$$

where $\bar{R}_{11}$ is of order $k-1$ and R_{11} is of order k.

The two if statements assure that permutations are performed only in case of a strict inequality but not in case of a tie.

We proceed with an analysis of Hybrid-I because it is not clear that Hybrid-I eventually halts, and that it indeed increases $\sigma_{\min}(R_{11})$. We first show that *if* Hybrid-I halts then

$$\sigma_{\min}(R_{11}) \geq \frac{\sigma_k(M)}{\sqrt{k(n-k+1)}},$$
$$\sigma_{\max}(R_{22}) \leq \sigma_{\min}(R_{11})\sqrt{k(n-k+1)}.$$

Suppose Hybrid-I halts. Then Golub-I applied to $\bar{R}_{22}$ does not change the first column $r_{kk}e_1$ of $\bar{R}_{22}$, where r_{kk} is the kth diagonal element of R. Hence

$$|r_{kk}| \geq \frac{\sigma_{\max}(\bar{R}_{22})}{\sqrt{n-k+1}} \geq \frac{\sigma_{\max}(R_{22})}{\sqrt{n-k+1}}$$

since R_{22} is a submatrix of $\bar{R}_{22}$. Moreover, Stewart-II applied to R_{11} does not change the last row $r_{kk}e_k^T$ of R_{11}, and

$$|r_{kk}| \leq \sigma_{\min}(R_{11})\sqrt{k}.$$

Combining the two inequalities for r_{kk} gives the first desired bound

$$\sigma_{\max}(R_{22}) \leq \sigma_{\min}(R_{11})\sqrt{k(n-k+1)}.$$

Applying the interlacing property $(I2)$ to $\bar{R}_{22}$,

$$|r_{kk}| \geq \frac{\sigma_{\max}(\bar{R}_{22})}{\sqrt{n-k+1}} \geq \frac{\sigma_k(M)}{\sqrt{n-k+1}},$$

and combining the previous two inequalities yields the second desired bound

$$\sigma_{\min}(R_{11}) \geq \frac{\sigma_k(M)}{\sqrt{k(n-k+1)}}.$$

Thus, if Hybrid-I halts, it solves Problem-I.

To prove that Hybrid-I indeed halts, we make use of the fact that columns are permuted only in case of strict inequalities. The basic idea is to show that $|\det(A)|$ is a strictly increasing function during the algorithm. Remember that A is the leading principal submatrix of order k. Since $|\det(A)|$ is unique for any given column ordering, no column ordering repeats if $|\det(A)|$ is strictly increasing. As there are only a finite number of column orderings, Hybrid-I must eventually halt.

It remains to show that $|\det(A)|$ is strictly increasing during Hybrid-I. By assumption from § 2 we have that $\sigma_k(M) > 0$. So we can assume that our initial ordering of columns is such that $|\det(A)| > 0$. Stewart-II does not change $\det(A)$ because $|\det(A)|$ is invariant under application of orthogonal transformations from

the left to $(A \quad B)$ and to C; and under permutation of the columns of A and of the columns of $\binom{B}{C}$. To see how Golub-I affects $\det(A)$, we divide Golub-I into two phases: the first phase keeps $|\det(A)|$ invariant, while the second one may change $|\det(A)|$. Accordingly, we identify and separate the first column $(b^T \quad \gamma e_1^T)^T$ of the matrix affected by Golub-I,

$$\begin{pmatrix} \bar{B} \\ \bar{C} \end{pmatrix} = \begin{pmatrix} b & \tilde{B} \\ \gamma e_1 & \tilde{C} \end{pmatrix}.$$

In the first phase the columns of $\binom{\tilde{B}}{\tilde{C}}$ are permuted, so that the first column of the permuted $\tilde{C}$ has largest norm among all columns of $\tilde{C}$, and then the permuted $\tilde{C}$ is retriangularised to give $\dot{C}$. In the second phase, the relevant matrix elements are γ and the nonzero elements α and β of $\dot{C}e_1$,

$$\begin{array}{c} \\ k \\ k+1 \end{array} \begin{array}{c} \begin{array}{cccc} k & k+1 & & \end{array} \\ \begin{pmatrix} * & * & * & * \\ & \gamma & \alpha & * \\ & & \beta & * \\ & & & * \end{pmatrix} \end{array}.$$

Golub-I permutes columns k and $k+1$ if $\gamma^2 < \alpha^2 + \beta^2$, in which case the matrix becomes

$$\begin{array}{c} \\ k \\ k+1 \end{array} \begin{array}{c} \begin{array}{cccc} k & k+1 & & \end{array} \\ \begin{pmatrix} * & * & * & * \\ & \alpha & \gamma & * \\ & \beta & & * \\ & & & * \end{pmatrix} \end{array}.$$

The matrix is retriangularised by eliminating β via a Givens rotations from the left, which affects only rows k and $k+1$ and results in

$$\begin{array}{c} \\ k \\ k+1 \end{array} \begin{array}{c} \begin{array}{cccc} k & k+1 & & \end{array} \\ \begin{pmatrix} * & * & * & * \\ & \sqrt{\alpha^2+\beta^2} & x & * \\ & & x & * \\ & & & * \end{pmatrix} \end{array},$$

where the two x represent new numbers. Other than the kth diagonal element, which changed from γ to $\sqrt{\alpha^2+\beta^2}$, no diagonal element of A changed. But the kth diagonal element underwent a strict increase in magnitude since $|\gamma| < \sqrt{\alpha^2+\beta^2}$, and therefore $|\det(A)|$ is a strictly increasing function during Hybrid-I. Consequently, algorithm Hybrid-I must halt.

Section 15 presents some numerical experiments on the running time of Hybrid-I.

13. Algorithm Hybrid-II. In this section we present algorithm Hybrid-II, the Type-II version of Hybrid-I. According to the unification principle, Hybrid-II guarantees that

$$\sigma_{\max}(R_{22}) \leq \sigma_{k+1}(M)\sqrt{(k+1)(n-k)}$$
$$\sigma_{\min}(R_{11}) \geq \frac{\sigma_{\max}(R_{22})}{\sqrt{(k+1)(n-k)}}$$

From the interlacing properties $(I1)$ and $(I2)$ it follows that Hybrid-I(k+1) guarantees the same bounds as Hybrid-II(k). Thus, one way to implement Hybrid-II(k) is via Hybrid-I(k+1).

ALGORITHM HYBRID-II(k)
Hybrid-I(k+1)

Although nonsingularity is needed for the application of the unification principle, this implementation of Hybrid-II(k) has the advantage of doing without the requirement that the matrix be nonsingular. However, to reduce the proof that Hybrid-I(k+1) halts to the proof for Hybrid-I(k) requires $\sigma_{k+1}(M) > 0$, which may not be true. Our proof that Hybrid-II halts does so without this assumption, and it also enables us to design the more accurate algorithm Hybrid-III by providing additional insight into the nature of the problem.

The basic idea of the proof is again to demonstrate the strict increase of the determinant of the leading $k \times k$ principal submatrix during Hybrid-II. Unfortunately, we cannot prove that the absolute value of the determinant of the leading $(k+1) \times (k+1)$ block is strictly increasing because that would necessitate the assumption $\sigma_{k+1}(M) > 0$. To facilitate understanding of the proof, we first describe in more detail the implementation of Hybrid-II(k) based on Hybrid-I(k+1).

ALGORITHM HYBRID-II(k)
$R^{(0)} = R$, $l = 0$
Repeat
$l = l + 1$, *permuted* $= 0$
Set

$$R^{(l)} = \begin{pmatrix} A & B \\ & C \end{pmatrix},$$

where A is of order k and C is of order $n-k$.
Golub-I:

1. Find the column $k+j$ of $R^{(l)}$ such that $\|Ce_j\| = \max_{1 \leq i \leq n-k} \|Ce_i\|$
2. **If** $\|Ce_1\| < \|Ce_j\|$ **then**
   permuted $= 1$
   Exchange columns $k+1$ and $k+j$ of $R^{(l)}$
   Retriangularise it from the left with orthogonal transformations to get

$$\hat{R}^{(l)} = \begin{pmatrix} \hat{A} & \hat{B} \\ & \hat{C} \end{pmatrix},$$

where $\hat{A}$ is of order $k+1$ and $\hat{C}$ is of order $n-k-1$.
Stewart-II:

3. Find the column j of $\hat{R}^{(l)}$ such that $\|e_j^T \hat{A}^{-1}\| = \max_{1 \le i \le k+1} \|e_i^T \hat{A}^{-1}\|$
4. **If** $\|e_{k+1}^T \hat{A}^{-1}\| < \|e_j^T \hat{A}^{-1}\|$ **then**
   permuted = 1
   Exchange columns j and $k+1$ of $\hat{R}^{(l)}$
   Retriangularise it from the left with orthogonal transformations to get $R^{(l+1)}$.

until not *permuted*
The final matrix is

$$R = \begin{pmatrix} \hat{R}_{11} & \hat{R}_{12} \\ & \hat{R}_{22} \end{pmatrix} = \begin{pmatrix} R_{11} & R_{12} \\ & R_{22} \end{pmatrix},$$

where $\hat{R}_{11}$ is of order $k+1$ and R_{11} is of order k.

As in Hybrid-I, the two if statements assure that permutations are performed only in case of a strict inequality but not in case of a tie.

Again, as we had assumed that $\sigma_k(M) > 0$, we can assume that our initial ordering of columns is such that $|\det(A)| > 0$. Although this proof is based on Hybrid-I(k+1) it is slightly different from the proof we gave for Hybrid-I(k) because now we are focusing on column k instead of column $k+1$. Clearly, Golub-I does not affect $|\det(A)|$ but Stewart-II does. We divide Stewart-II into two phases. The first phase keeps $|\det(A)|$ invariant while the second phase may change $|\det(A)|$. Accordingly, we identify and separate the last column $(\, a^T \quad \alpha e_1^T \,)^T$ of the matrix affected by Stewart-II,

$$\hat{A} = \begin{pmatrix} \tilde{A} & a \\ & \alpha \end{pmatrix}.$$

In the first phase the columns of $\tilde{A}$ are permuted, so that the last row of $\tilde{A}^{-1}$ has largest norm among all rows of $\tilde{A}^{-1}$, and then the permuted $\tilde{A}^{-1}$ is retriangularised from the right to give $\dot{A}^{-1}$. In the second phase the relevant matrix elements are α, the element β above it, and the trailing nonzero γ of $e_k^T \dot{A}$,

$$\begin{array}{c} \\ k \\ k+1 \end{array} \begin{array}{c} \begin{array}{ccc} k & k+1 & \end{array} \\ \begin{pmatrix} * & * & * \\ & \gamma & \beta \\ & & \alpha \end{pmatrix} \end{array}.$$

Since Stewart-II is the Type-II version of Golub-I, it permutes to the last position the column corresponding to the row with largest norm in the inverse, whose relevant elements are

$$\begin{array}{c} \\ k \\ k+1 \end{array} \begin{array}{c} \begin{array}{ccc} k & k+1 & \end{array} \\ \begin{pmatrix} * & * & * \\ & \frac{1}{\gamma} & -\frac{\beta}{\gamma\alpha} \\ & & \frac{1}{\alpha} \end{pmatrix} \end{array}.$$

Stewart-II permutes columns k and $k+1$ if

$$\frac{1}{\gamma^2} + \frac{\beta^2}{\gamma^2\alpha^2} > \frac{1}{\alpha^2} \qquad \text{or} \qquad \gamma^2 < \alpha^2 + \beta^2.$$

But this is the same situation as in Hybrid-I(k), and it follows that the kth diagonal element of R_{11} changes from γ to $\sqrt{\alpha^2+\beta^2}$ while all other diagonal elements of R_{11} remain unchanged. As we just proved that $|\gamma| < \sqrt{\alpha^2+\beta^2}$, $|\det(A)|$ is strictly increasing during Hybrid-II.

Because we were able to prove that Hybrid-II halts, requiring only that $\sigma_k(M) > 0$, we can show directly that Hybrid-II(k) satisfies

$$\sigma_{\max}(R_{22}) \leq \sigma_{k+1}(M)\sqrt{(k+1)(n-k)},$$
$$\sigma_{\min}(R_{11}) \geq \frac{\sigma_{\max}(R_{22})}{\sqrt{(k+1)(n-k)}}.$$

The proof is similar to the one that establishes the bounds for Hybrid-I.

14. Algorithm Hybrid-III. Our last new algorithm is Hybrid-III, which satisfies

$$\sigma_{\min}(R_{11}) \geq \frac{\sigma_k(M)}{\sqrt{k(n-k+1)}},$$
$$\sigma_{\max}(R_{22}) \leq \sigma_{k+1}(M)\sqrt{(k+1)(n-k)}.$$

There are several implementations of Hybrid-III. We present the one that is simplest to describe. This implementation, motivated by the fact that the determinant of the leading principal submatrix of order k is a strictly increasing function in both Hybrid-I and Hybrid-II, consists of running Hybrid-I and Hybrid-II in alternation until no more permutations take place.

ALGORITHM HYBRID-III(k)
Repeat
    Hybrid-I(k)
    Hybrid-II(k)
Until no permutations occur

The halting argument for Hybrid-III follows easily from the halting of Hybrid-I and Hybrid-II. We had shown earlier that during Hybrid-I and Hybrid-II, the determinant of the leading $k \times k$ principal submatrix is a strictly increasing function. So it must be true during Hybrid-III also. Hence Hybrid-III halts.

When Hybrid-III has halted, both Hybrid-I and Hybrid-II do not cause any further permutations in the matrix. Therefore the bounds guaranteed by Hybrid-I and Hybrid-II must hold simultaneously now. That is

$$\sigma_{\min}(R_{11}) \geq \frac{\sigma_k(M)}{\sqrt{k(n-k+1)}},$$
$$\sigma_{\max}(R_{22}) \leq \sigma_{k+1}(M)\sqrt{(k+1)(n-k)}$$

must be true.

Because we do not know whether the solution of Problem-I also implies the solution of Problem-II or vice versa, it is not clear whether the output of algorithm Hybrid-I also satisfies the bounds that govern the output from Hybrid-II. In particular we are therefore not able to compare the operation counts of Hybrid-III with those of Hybrid-I or Hybrid-II.

REMARK 14.1. As we mentioned earlier, it is more practical to replace algorithm Stewart-II in the hybrid algorithms with algorithm Chan-II.

Moreover, there are other ways of implementing algorithm Hybrid-III. For example, replacing the Stewart-II part of Hybrid-I with a simpler algorithm results in an Hybrid-III algorithm: Instead of moving the most linearly dependent column to the kth position, in turn permute *every* one of the leading k columns to the kth position. Obviously, this algorithm solves Problem-I and Problem-II simultaneously. The corresponding Type-II version, which involves replacing the Golub-I part of Hybrid-II, also solves Problem-I and Problem-II simultaneously according to the unification principle. This idea has been taken up in [32].

However, we believe that the original version of Hybrid-III described at the beginning of this section is more efficient in practice than the latter two (provided it is properly implemented with good condition number estimators in place of Golub-I and Stewart-II, and run as a postprocessor to either Golub-I or Chan-II).

15. Some numerical experiments. Although we have demonstrated that the three hybrid algorithms halt in exact arithmetic, we know very little about their worst-case running times. In this section we present some preliminary numerical results for Hybrid-I, which also apply to Hybrid-II and Hybrid-III as the implementations for the latter two algorithms can be based on Hybrid-I. In practice, the hybrid algorithms are best run as postprocessors to the more efficient greedy algorithms, like Golub-I or Chan-II.

In the experiments to follow, we counted the number of iterations in Hybrid-I when it is run after Golub-I. To prevent cycling in the algorithm due to roundoff errors, we carried out permutations only if the pivot increased by more than $n^2\epsilon$, where ϵ is the machine precision. To estimate the dependence of the running time of Hybrid-I on the matrix size n and the separation of the singular values $\sigma_k(M)/\sigma_{k+1}(M)$, we generated fifty random matrices of size fifty, to which we applied Hybrid-I with $k = 37$. Then we multiplied the last $n - k$ singular values of these fifty matrices by 0.1 to increase the separation between the singular values but did not change the singular vectors. Hybrid-I was applied to these fifty new matrices. The same process was repeated on one hundred random matrices of size one hundred with $k = 75$. Table 15.1 shows how many times Hybrid-I required a certain number of iterations. Hybrid-I seems to require fewer iterations when the gap between $\sigma_k(M)$ and $\sigma_{k+1}(M)$ is larger, and—in these experiments, at least—the number of iterations does not deteriorate too much with increase in matrix size.

16. Conclusion. In this paper we proposed three optimisation problems which we called rank-revealing QR (RRQR) problems. We presented a unifying treatment of the existing algorithms by placing them in a hierarchy of greedy algorithms. Finally, we presented three new hybrid algorithms for solving the three rank-revealing problems. Unfortunately, we were not able to estimate the worst-case running time of the hybrid algorithms.

Most of the discussion for the RRQR factorisations can be extended in a simple manner to rank-revealing LU (RRLU) factorisations [8], [27] by replacing orthogonal transformations with elementary Gauss transformations and row interchanges for partial pivoting. Partial pivoting prevents the ill conditioning of the Gauss transformations. Compared to RRQR factorisations, the bounds for RRLU factorisations

are generally worse and, due to pivoting and the resulting fill-in, their operation are counts higher. It is not clear to us which applications would benefit from RRLU factorisations.

In a subsequent paper [13] we show that very naturally the hybrid algorithms give rise to new algorithms for computing the URV decomposition [34]–[36] and also to a new divide-and-conquer algorithm for the SVD. In fact, using a preceding RRQR algorithm to accelerate the computation of eigenvalues or singular values is not new, see for instance [15], [24], [38] where a Jacobi method is preceded by QR with column pivoting.

In this paper, we present only one algorithm for each of the three optimisation problems, but one can easily design other kinds of approximate and exact algorithms. Our motivation for the three hybrid algorithms was to perform column interchanges based on what we believed would result in a high rate of convergence. But sometimes one may want to trade off number of column exchanges for maintainance of sparsity [3], [4], [30] or minimisation of communication costs.

The ideas presented in this paper may aid in the design of special-purpose algorithms. Instead of choosing the best two columns to exchange, one could compromise and choose a column exchange that maintains sparsity or keeps communication costs low, while still ensuring that the determinant of the leading $k \times k$ principal submatrix increases strictly so that the algorithm halts. We hope that the ideas presented in this paper prove helpful in developing algorithms for such problems.

Acknowledgments. We thank Françoise Chatelin and Axel Ruhe for helpful discussions and for bringing reference [16] to our attention.

SYMMETRIC TOEPLITZ MATRICES WITH TWO PRESCRIBED EIGENPAIRS*

MOODY T. CHU†‡ AND MELISSA A. ERBRECHT†

Abstract. The inverse problem of constructing a real symmetric Toeplitz matrix based on two prescribed eigenpairs is considered. Two new results are obtained. First, it is shown that the dimension of the subspace of Toeplitz matrices with two generically prescribed eigenvectors is independent of the size of the problem, and, in fact, is either two, three, or four, depending upon whether the eigenvectors are symmetric or skew-symmetric and whether n is even or odd. This result is quite notable in that when only one eigenvector is prescribed the dimension is known to be at least $[(n+1)/2]$. Taking into account the prescribed eigenvalues, the authors then show how each unit vector in the null subspace of a certain matrix uniquely determines a Toeplitz matrix that satisfies the prescribed eigenpairs constraint. The cases where two prescribed eigenpairs uniquely determine a Toeplitz matrix are explicitly characterized.

Key words. Toeplitz matrix, eigenvector, inverse problem

AMS subject classifications. 65F15, 15A18

1. Introduction.

A real $n \times n$ matrix $T = (t_{ij})$ is symmetric and Toeplitz if there exist real scalars $r_1, \ldots, r_n$ such that

$$t_{ij} = r_{|i-j|+1}$$

for all i and j. Clearly a symmetric Toeplitz matrix is uniquely determined by the entries of its first column. Thus we shall denote a symmetric Toeplitz matrix by $T(r)$ if its first column is given by the vector $r \in R^n$.

Due to their role in important applications like the trigonometric moment problem, the Szegö theory, and signal processing, many properties of Toeplitz matrices have been studied over the years. For example, efficient algorithms have been devised to solve a Toeplitz system of equations in $O(n^2)$ time. Brief discussions of algorithms and more references for solving Toeplitz systems can be found in [7, §4.7]. In this paper, we are more interested in the spectral properties of a symmetric Toeplitz matrix.

It is easy to see that if $Tv = \lambda v$ and λ is an eigenvalue of multiplicity one, then either $Ev = v$ or $Ev = -v$, where $E = (e_{ij}) \in R^{n \times n}$ is the exchange matrix defined by

$$e_{ij} = \begin{cases} 1 & \text{if } i + j = n + 1, \\ 0 & \text{otherwise.} \end{cases}$$

Accordingly, we call such an eigenvector either symmetric or skew-symmetric. For eigenvalues of multiplicity greater than one, the corresponding eigenspace has an orthonormal basis that splits as evenly as possible between symmetric and skew-symmetric eigenvectors [5, Thm. 8]. Thus it is sensible to say that the eigenvectors of a symmetric Toeplitz matrix can be split into two classes. More specifically, as any

symmetric centrosymmetric matrix [2, Thm. 2], a symmetric Toeplitz matrix of order n has $\lceil n/2 \rceil$ symmetric and $\lfloor n/2 \rfloor$ skew-symmetric eigenvectors. For convenience, we use $\sigma^+(T)$ and $\sigma^-(T)$ to denote, respectively, the spectrum of eigenvalues corresponding to symmetric and skew-symmetric eigenvectors. Other spectral properties of Toeplitz matrices can be found in [2], [5], [9], [10], and the references contained therein.

The inverse Toeplitz eigenvalue problem (ITEP) has been an interesting yet difficult question studied in the literature. The problem is to find a vector $r \in R^n$ such that the Toeplitz matrix $T(r)$ has a prescribed real spectrum $\{\lambda_1, \ldots, \lambda_n\}$. At present, the ITEP remains unsolved when $n \geq 5$ [5]. (See the note added in proof at the end of this paper.) Partial results and numerical algorithms for the ITEP can be found in, for example, [3], [6], [8], and [11].

In [2, Thm. 3] it is claimed that any real $n \times n$ matrix that has a set of n real orthonormal eigenvectors, each being either symmetric or skew-symmetric, is both symmetric and centrosymmetric. Apparently it is another interesting and difficult problem to identify an orthogonal matrix so that its columns are eigenvectors of some Toeplitz matrix.

In [4] it is proved that being symmetric or skew-symmetric is sufficient for a single vector to be an eigenvector of a Toeplitz matrix. In fact, let

$$S_0(v) := \{r \in R^n | T(r)v = 0\} \tag{1}$$

denote the collection of (the first columns of) all symmetric Toeplitz matrices for which v is an eigenvector corresponding to the eigenvalue 0. It can be shown that $S_0(v)$ is a linear subspace with dimension [4, Cor. 1]

$$\dim(S_0(v)) = n - \pi(v), \tag{2}$$

where

$$\pi(v) := \begin{cases} \lceil n/2 \rceil & \text{if } v \text{ is symmetric,} \\ \lfloor n/2 \rfloor & \text{if } v \text{ is skew-symmetric} \end{cases} \tag{3}$$

is called the index of v. Clearly $T(r)v = \lambda v$ if and only if $r - \lambda w \in S_0(v)$, where $w = [1, 0, \ldots, 0]^T$ is the first standard basis vector in R^n. Thus the set

$$S(v) := \{r \in R^n | T(r)v = \lambda v \text{ for some } \lambda \in R\} \tag{4}$$

is precisely the direct sum $\langle w \rangle \oplus S_0(v)$.

Suppose now $\{v^{(1)}, \ldots, v^{(k)}\}$, $k \geq 1$, is a set of real orthonormal vectors, each being symmetric or skew-symmetric. Then $\cap_{i=1}^k S(v^{(i)})$ contains all symmetric Toeplitz matrices for which each v_i is an eigenvector. Evidently, $w \in S(v^{(i)})$ for all i. So $\cap_{i=1}^k S(v^{(i)})$ is at least of dimension 1. We are interested in studying the following problem.

Problem 1. Obtain a nontrivial lower bound on the dimension of $\bigcap_{i=1}^k S(v^{(i)})$.

Toward this end, we show in this paper that for the case $k = 2$, the dimension of $\bigcap_{i=1}^2 S(v^{(i)})$ is almost always independent of of the size of the problem, and, in fact, is either two, three, or four, depending upon whether the eigenvectors are symmetric or skew-symmetric.

In view of the ITEP, another interesting inverse problem arises.

Problem 2. Given a set of real orthonormal vectors, $\{v^{(1)}, \ldots, v^{(k)}\}$, $k \geq 1$, each symmetric or skew-symmetric, and a set of real numbers $\{\lambda_1, \ldots, \lambda_k\}$, find a symmetric Toeplitz matrix T (other than a scalar matrix) such that

$$Tv^{(i)} = \lambda_i v^{(i)}, \qquad i = 1, \ldots, k. \tag{5}$$

We note in Problem 2 that T is required to be Toeplitz; thus the description of the given eigenpairs cannot be totally arbitrary. For instance, it is improper to request that all vectors be symmetric while $k > \lceil n/2 \rceil$. We recall a conjecture in [5] that a *universal* distribution of eigenvalues for Toeplitz matrices should be such that $\sigma^+(T)$ and $\sigma^-(T)$ interlace. Thus a Toeplitz matrix whose spectrum does not satisfy the interlaced distribution is perhaps more difficult to find [8]. On the other hand, as far as Problem 2 is concerned, there is a possibility that the remaining unspecified eigenpairs could make up the total spectrum so that the interlaced condition is eventually realized.

For the case $k = 2$, we show in this paper that in each direction in the subspace $\bigcap_{i=1}^{2} S(v^{(i)})$ there is one and only one Toeplitz matrix for Problem 2. In particular, we show that if n is odd and if at least one of the given eigenvectors is symmetric, or if n is even and one eigenvector is symmetric and the other is skew-symmetric, then the Toeplitz matrix is uniquely determined.

2. An example. As we shall only consider the case $k = 2$ throughout the paper, it is more convenient to denote, henceforth, the eigenvectors $v^{(1)}$ and $v^{(2)}$ by u and v, respectively.

We begin our study of the set $S(u) \cap S(v)$ with the special case where $n = 3$. The example should shed some insights on the higher dimensional case.

Due to the special eigenstructure of symmetric Toeplitz matrices, it is necessary that one of the two given eigenvectors, say u, must be symmetric. Denote $u = [u_1, u_2, u_1]^T$ where $2{u_1}^2 + u_2^2 = 1$. It can also be proved that the skew-symmetric vector $\hat{u} = [1/\sqrt{2}, 0, -1/\sqrt{2}]^T$ is a universal eigenvector for every symmetric Toeplitz matrix of order 3. Thus, given u, we imply from the orthogonality condition that the second prescribed eigenvector v must be either the second or the third column of the matrix

$$Q = \begin{bmatrix} u_1 & \frac{1}{\sqrt{2}} & -\frac{u_2}{\sqrt{2}} \\ u_2 & 0 & u_1\sqrt{2} \\ u_1 & -\frac{1}{\sqrt{2}} & -\frac{u_2}{\sqrt{2}} \end{bmatrix}. \tag{6}$$

In other words, one symmetric eigenvector completely determines all three orthonormal eigenvectors (up to a $\pm$ sign). It follows, from [4], that $\dim S(u) \cap S(v) = 2$. (Note that if the orthogonality condition is violated, then trivially $S(u) \cap S(v) = \langle w \rangle$.)

Let $\Lambda = \operatorname{diag}\{\lambda_1, \lambda_2, \lambda_3\}$. We already know $Q\Lambda Q^T$ is a centrosymmetric matrix. It is not difficult to see that $Q\Lambda Q^T$ is Toeplitz if and only if

$$(3{u_1}^2 - 1)\lambda_1 + \frac{\lambda_2}{2} + \left(\frac{1}{2} - 3{u_1}^2\right)\lambda_3 = 0. \tag{7}$$

From (7), the following facts can easily be observed.

LEMMA 2.1. *Let* $2{u_1}^2 + u_2^{21} = 1$. *Then:*

(i) *If λ_1 and λ_3 are given scalars, there is a unique symmetric Toeplitz matrix T such that*

$$T\begin{bmatrix} u_1 & -\frac{u_2}{\sqrt{2}} \\ u_2 & u_1\sqrt{2} \\ u_1 & -\frac{u_2}{\sqrt{2}} \end{bmatrix} = \begin{bmatrix} u_1 & -\frac{u_2}{\sqrt{2}} \\ u_2 & u_1\sqrt{2} \\ u_1 & -\frac{u_2}{\sqrt{2}} \end{bmatrix} \begin{bmatrix} \lambda_1 & 0 \\ 0 & \lambda_3 \end{bmatrix}. \tag{8}$$

(ii) *If $u_1 \neq \pm\sqrt{1/6}$ and λ_1 and λ_2 are given scalars, there is a unique symmetric Toeplitz matrix T such that*

$$T\begin{bmatrix} u_1 & \frac{1}{\sqrt{2}} \\ u_2 & 0 \\ u_1 & -\frac{1}{\sqrt{2}} \end{bmatrix} = \begin{bmatrix} u_1 & \frac{1}{\sqrt{2}} \\ u_2 & 0 \\ u_1 & -\frac{1}{\sqrt{2}} \end{bmatrix} \begin{bmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{bmatrix}. \tag{9}$$

(iii) *If $u_1 = \pm\sqrt{1/6}$, then there are infinitely many symmetric Toeplitz matrices T that satisfy* (9) *if $\lambda_1 = \lambda_2$; however, if $\lambda_1 \neq \lambda_2$, then* (9) *does not hold for any symmetric Toeplitz matrix T.*

3. General consideration. We now consider the case for general n. When v is an eigenvector, the idea of rewriting the matrix-vector product [4]

$$T(r)v = M(v)r \tag{10}$$

can be very useful. The following lemma can be observed.

LEMMA 3.1. *The columns of $M(v)$ have the same symmetry as v has. That is, $EM(v) = \pm M(v)$ if and only if $Ev = \pm v$.*

Thus only the first $\pi(v)$ rows of $M(v)$ need to be considered. For convenience, let $p := \lceil n/2 \rceil$ and let $N(v)$ denote the $p \times n$ submatrix of the first p rows of $M(v)$. It is easy to verify that $N(v)$ can be decomposed into blocks

$$N(v) = [h(v), H(v), 0] + [0, L(v), 0] + [0, 0, U(v)], \tag{11}$$

where $h(v)$ is a $p \times 1$ column vector, $\tilde{H}(v) := [h(v), H(v)] = (\tilde{h}_{ij}(v))$ is the $p \times p$ Hankel matrix

$$\tilde{h}_{ij}(v) := v_{i+j-1}, \tag{12}$$

$\tilde{L}(v) := [0, L] = (\tilde{l}_{ij}(v))$ is the $p \times p$ lower triangular matrix

$$\tilde{l}_{ij}(v) := \begin{cases} v_{i-j+1} & \text{if } 1 < j \leq i, \\ 0 & \text{otherwise,} \end{cases} \tag{13}$$

and $U(v) = (u_{ij}(v))$ is the $p \times (n-p)$ triangular matrix

$$u_{ij}(v) := \begin{cases} v_{p+i+j-1} & \text{if } i + j \leq n - p + 1, \\ 0 & \text{otherwise.} \end{cases} \tag{14}$$

We note that the last row of $N(v)$ is identically zero when n is odd and v is skew-symmetric. The rows of $N(u)$ and $N(v)$ will be used to construct a larger matrix.

Suppose that

$$\begin{aligned} T(r)u &= \lambda_1 u, \\ T(r)v &= \lambda_2 v. \end{aligned} \tag{15}$$

Then the vector r must be such that the linear equations

$$\begin{aligned} N(u)(r - \lambda_1 w) &= 0, \\ N(v)(r - \lambda_2 w) &= 0 \end{aligned} \tag{16}$$

are satisfied. If we write

$$x := [r_1 - \lambda_2, r_1 - \lambda_1, r_2, \ldots, r_n]^T, \tag{17}$$

then the system (16) is equivalent to

$$\tilde{M}(u, v)x = 0, \tag{18}$$

where $\tilde{M}(u, v)$ is the $(2p) \times (n + 1)$ matrix defined by

$$\tilde{M}(u, v) := \begin{bmatrix} 0 & h(u) & H(u) + L(u) & U(u) \\ h(v) & 0 & H(v) + L(v) & U(v) \end{bmatrix}. \tag{19}$$

Given symmetric or skew-symmetric vectors u and v, a solution to (18) can be used to construct a Toeplitz matrix in the following way.

LEMMA 3.2. *Suppose that* $[x_0, x_1, \ldots, x_n]^T$ *is a solution to* (18). *For arbitrary real numbers* λ_1 *and* α, *define*

$$\begin{aligned} r_1 &:= \alpha x_1 + \lambda_1, \\ r_i &:= \alpha x_i \quad \text{for } i = 2, \ldots, n, \end{aligned} \tag{20}$$

and

$$\lambda_2 := \alpha(x_1 - x_0) + \lambda_1. \tag{21}$$

Then u *and* v *are eigenvectors of the Toeplitz matrix* $T(r)$. *In other words,* $S(u) \cap S(v)$ *is the direct sum of the subspace spanned by* w *and the subspace obtained by deleting the first component from* $\ker(\tilde{M})$.

On the other hand, suppose the two eigenvalues λ_1 and λ_2 are prescribed. Then (21) implies that the constant α in (20) must be

$$\alpha = \frac{\lambda_1 - \lambda_2}{x_0 - x_1}, \tag{22}$$

provided $x_0 \neq x_1$. The conclusion is made in the following lemma.

LEMMA 3.3. *Suppose that* x *is a nontrivial solution of* (18) *satisfying* $x_0 \neq x_1$. *Then corresponding to the direction of* x, *there is a unique solution to Problem* 2 *when* $k = 2$.

The question now is to determine the null space of $\tilde{M}(u, v)$. It is convenient to use the abbreviated notation $\tilde{M} = \tilde{M}(u, v)$. It turns out that the dimension depends upon whether n is even or odd and whether the two eigenvectors are symmetric or skew-symmetric. In any case, we shall show that $\tilde{M}$ has a nontrivial null space. It is most interesting to note that the dimension does not depend upon the size of n. We discuss the following different cases.

Case 1. n is odd and both eigenvectors are symmetric. When n is odd, the Hankel matrix $\tilde{H}(v)$ for a symmetric vector v takes the special form

$$\tilde{H}(v) = \begin{bmatrix} v_1 & v_2 & \cdots & v_{p-1} & v_p \\ v_2 & v_3 & & v_p & v_{p-1} \\ \vdots & & & & \vdots \\ v_{p-1} & v_p & \cdots & v_3 & v_2 \\ v_p & v_{p-1} & \cdots & v_2 & v_1 \end{bmatrix}. \tag{23}$$

The corresponding $U(v)$ becomes

$$U(v) = EL(v) = \begin{bmatrix} v_{p-1} & v_{p-2} & \cdots & v_2 & v_1 \\ v_{p-2} & & \cdots & v_1 & 0 \\ \vdots & & & & \vdots \\ v_1 & 0 & \cdots & & 0 \\ 0 & & \cdots & & 0 \end{bmatrix}. \tag{24}$$

It is useful to illustrate the basic structure of $\tilde{M}$ with a simple example when both u and v are symmetric. When $n = 5$, we have

$$\tilde{M} = \begin{bmatrix} 0 & u_1 & u_2 & u_3 & u_2 & u_1 \\ 0 & u_2 & u_3 + u_1 & u_2 & u_1 & 0 \\ 0 & u_3 & 2u_2 & 2u_1 & 0 & 0 \\ v_1 & 0 & v_2 & v_3 & v_2 & v_1 \\ v_2 & 0 & v_3 + v_1 & v_2 & v_1 & 0 \\ v_3 & 0 & 2v_2 & 2v_1 & 0 & 0 \end{bmatrix}. \tag{25}$$

The matrix $\tilde{M}$ in general is a square matrix of order $n + 1$. The determinant of $\tilde{M}$ is an algebraic expression involving independent variables $v_1, \ldots, v_p, u_1, \ldots, u_p$. It would not be too surprising if $\det(\tilde{M}) \neq 0$ for generic u and v (see the Appendix). Nevertheless, under the additional condition that u and v are perpendicular to each other, we will show by elementary row operations that $\tilde{M}$ is in fact rank deficient.

For any symmetric vector v, let the $p \times p$ upper triangular matrix $G(v)$ be defined by

$$G(v) := \begin{bmatrix} 2v_1 & 2v_2 & \cdots & 2v_{p-1} & v_p \\ 0 & 2v_1 & & 2v_{p-2} & v_{p-1} \\ \vdots & 0 & \ddots & \vdots & \vdots \\ 0 & & & 2v_1 & v_2 \\ 0 & 0 & 0 & 0 & v_1 \end{bmatrix}. \tag{26}$$

We also define the $2p \times 2p$ matrix

$$\tilde{G} = \tilde{G}(u, v) := \begin{bmatrix} I & 0 \\ -G(v) & G(u) \end{bmatrix}, \tag{27}$$

which, in fact, is the accumulation of a sequence of elementary row operations. We remark here that the ordering of u and v is immaterial. If $u_1 = 0$, then the roles of u and v may as well be switched. The extremely rare case where both $u_1 = v_1 = 0$ can be reduced to a lower dimensional problem. Without loss of generality, therefore, we

may assume that $u_1 \neq 0$ and, hence, the matrix $\tilde{G}(u,v)$ is a nonsingular matrix. It follows that the product $\tilde{W} := \tilde{G}\tilde{M}$ has the same rank as $\tilde{M}$.

We now make an important claim.

LEMMA 3.4. *Suppose that n is odd and that the two symmetric vectors u and v are orthogonal. Then the matrix $\tilde{W}$ is rank deficient. In fact,*

$$p+1 \leq \operatorname{rank}(\tilde{\mathrm{W}}) \leq \mathrm{n}. \tag{28}$$

Proof. The proof is tedious but straightforward. For $i = 1, \ldots, p$, the ith component of $G(u)h(v)$ is given by

$$2 \sum_{\substack{s=1 \\ t-s=i-1}}^{p-i} u_s v_t + u_{p-i+1} v_p. \tag{29}$$

The first component is trivially seen to be

$$2 \sum_{s=1}^{p-1} u_s v_s + u_p v_p, \tag{30}$$

which is zero because u and v are perpendicular to each other. For the same reason, the first component of $-G(v)h(u)$ is zero.

The product $G(u)U(v)$ has the same triangular structure as $U(v)$. On the other hand, the (i,j)th component of $G(u)U(v)$ with $i+j \leq p$ is given by

$$2 \sum_{s+t=p-i-j+2} u_s v_t. \tag{31}$$

It is important to note that the summation (31) is a symmetric function of u and v. It follows that the $p \times (n-p)$ block

$$-G(v)U(u) + G(u)U(v) \tag{32}$$

is identically zero.

For $i = 1, \ldots, p$ and $j = 1, \ldots, p-1$, the (i,j)th component of $G(u)H(v)$ is given by

$$2 \sum_{\substack{s=1 \\ t-s=i+j-1}}^{p-i-j+1} u_s v_t + 2 \sum_{\substack{s=p-i-j+2 \\ t+s=2p-i-j+1}}^{p-i} u_s v_t + u_{p-i+1} v_{p-j} \tag{33}$$

if $j < p-i+1$; or

$$2 \sum_{\substack{s=1 \\ t+s=2p-i-j+1}}^{p-i} u_s v_t + u_{p-i+1} v_{p-j} \tag{34}$$

if $j \geq p-i+1$. The (i,j)th component of $G(u)L(v)$ is given by

$$2 \sum_{\substack{s=1 \\ t-s=i-j-1}}^{p-i} u_s v_t + u_{p-i+1} v_{p-j} \tag{35}$$

if $j \leq i-1$; or

$$2 \sum_{\substack{s=j-i+2 \\ t-s=i-j-1}}^{p-i} u_s v_t + u_{p-i+1} v_{p-j} \tag{36}$$

if $j > i-1$. Using (33) and (36), it follows that the $(1,j)$th component of $G(u)(H(v)+L(v))$ is given by

$$2 \sum_{\substack{s=1 \\ t-s=j}}^{p-j} u_s v_t + 2 \sum_{\substack{s=p-j+1 \\ t+s=2p-j}}^{p-1} u_s v_t + 2 \sum_{\substack{t=1 \\ s-t=j}}^{p-j} u_s v_t. \tag{37}$$

The first and the last summations in (37) are symmetric to each other. The second summation in (37) is a symmetric function of u and v. Overall, (37) is a symmetric function of u and v, which will be completely canceled by its counterpart in $-G(v)(H(u)+L(u))$.

By now we have proved that the $(p+1)$th row of $\tilde{W}$ is identically zero. If follows that the null space of $\tilde{M}$ is at least of dimension one.

Using (34), (35), and (36), it is further observed that the $(i, p-1)$th component of $G(u)(H(v)+L(v))$ is given by

$$2 \sum_{\substack{s=1 \\ t+s=p+2-i}}^{p} u_s v_t, \tag{38}$$

which, once again, is a symmetric function of u and v, and will be completely canceled by its counterpart in $-G(v)(H(u)+L(u))$. The zero structure of $\tilde{W}$ clearly indicates that (28) is true. □

The following example for the case $n = 5$ illustrates the typical structure of $\tilde{W}$:

$$\tilde{W} = \begin{bmatrix} 0 & u_1 & u_2 & u_3 & u_2 & u_1 \\ 0 & u_2 & u_3+u_1 & u_2 & u_1 & 0 \\ 0 & u_3 & 2u_2 & 2u_1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 2v_2u_1+v_3u_2 & -2v_1u_2-v_2u_3 & 2v_3u_1-2v_1u_3 & 0 & 0 & 0 \\ v_3u_1 & -v_1u_3 & 2v_2u_1-2v_1u_2 & 0 & 0 & 0 \end{bmatrix}. \tag{39}$$

Let W denote the lower left $(p-1) \times p$ submatrix of $\tilde{W}$. That is, W is the matrix obtained by deleting the first row and the last column of

$$[G(u)h(v), -G(v)h(u), -G(v)(H(u)+L(u)) + G(u)(H(v)+L(v))]. \tag{40}$$

The rank of $\tilde{W}$ can be less than n if and only if W is rank deficient, which will be true if and only if values of u_i and v_i are such that $\det(WW^T) = 0$. We note that $\det(WW^T)$ is a polynomial in the independent variables u_i and v_i. We note also that $\det(WW^T)$ is not identically zero (see the Appendix for a proof). Thus rank($\tilde{W}$) < n if and only if u_i and v_i come from a codimension-one surface. We conclude, therefore, that for almost all u and v satisfying $u^Tv = 0$, the matrix $\tilde{W}$ is of rank n. Unfortunately, even for the case $n = 5$ (see (39)), it is fairly complicated to express the rank deficiency of W in terms of components of u and v. At present

we cannot provide a further characterization of the set where W is rank deficient. Given the fact that the orthogonality of u and v has already been used to prove the rank deficiency of $\tilde{W}$, it is conceivably true that the orthogonality condition cannot be used again to reduce the rank of W.

In conclusion, we have proved the following theorem.

THEOREM 3.5. *Suppose that n is odd and that u and v are two symmetric vectors satisfying $u^T v = 0$. Then:*

1. *The dimension of $S(u) \cap S(v)$ is at least two.*
2. *For almost all u and v, the dimension of $S(u) \cap S(v)$ is exactly two.*
3. *For almost all u and v and for any values of λ_1 and λ_2, there exists a unique symmetric Toeplitz matrix T satisfying $Tu = \lambda_1 u$ and $Tv = \lambda_2 v$.*

Case 2. n is odd and both eigenvectors are skew-symmetric. When n is odd, the Hankel matrix $\tilde{H}(v)$ for a skew-symmetric vector v takes the form

$$\tilde{H}(v) = \begin{bmatrix} v_1 & v_2 & \cdots & v_{p-1} & 0 \\ v_2 & v_3 & & 0 & -v_{p-1} \\ \vdots & & & & \vdots \\ v_{p-1} & 0 & \cdots & -v_3 & -v_2 \\ 0 & -v_{p-1} & \cdots & -v_2 & -v_1 \end{bmatrix}. \tag{41}$$

The corresponding $U(v)$ becomes

$$U(v) = -EL(v) = \begin{bmatrix} -v_{p-1} & -v_{p-2} & \cdots & -v_2 & -v_1 \\ -v_{p-2} & & \cdots & -v_1 & 0 \\ \vdots & & & & \vdots \\ -v_1 & 0 & \cdots & & 0 \\ 0 & 0 & \cdots & & 0 \end{bmatrix}. \tag{42}$$

It follows that the last row of $N(v)$ is identically zero. For (18), it is now obvious that the kernel of $\tilde{M}$ is of dimension at least two. In fact, we can show the following lemma.

LEMMA 3.6. *Suppose that n is odd and that the skew-symmetric vectors u and v are perpendicular. Then*

$$p \leq \operatorname{rank}(\tilde{\mathrm{W}}) \leq \mathrm{n} - 2. \tag{43}$$

Indeed, for almost all u and v, $\operatorname{rank}(\tilde{\mathrm{W}}) = \mathrm{n} - 2$.

Proof. The proof is very similar to that of Lemma 3.4. So we simply outline a recipe for constructing the transformation matrix that does the elimination. The details of justification are omitted.

It suffices to consider the $2(p-1) \times (n+1)$ submatrix $\hat{M}$ obtained by deleting the pth and the $2p$th rows of $\tilde{M}$. For a skew-symmetric vector v, define the $(p-1) \times (p-1)$ matrix $G(v)$ by

$$G(v) := \begin{bmatrix} -v_1 & -v_2 & \cdots & -v_{p-2} & -v_{p-1} \\ 0 & v_1 & & v_{p-3} & v_{p-2} \\ \vdots & 0 & \ddots & \vdots & \vdots \\ 0 & & & v_1 & v_2 \\ 0 & 0 & 0 & 0 & v_1 \end{bmatrix}. \tag{44}$$

Then construct the $2(p-1) \times 2(p-1)$ transformation matrix $\tilde{G}(u,v)$ in the same way as is defined in (27). It can be proved now that the pth row of the product $\hat{W} := \tilde{G}\hat{M}$ is identically zero. Furthermore, the lower right $(p-1) \times (p-1)$ submatrix of $\hat{W}$ is also identically zero. The assertion follows from these observations. □

As an example, for $n = 5$, the matrix $\hat{M}$ takes the form

$$\hat{M} = \begin{bmatrix} 0 & u_1 & u_2 & 0 & -u_2 & -u_1 \\ 0 & u_2 & u_1 & -u_2 & -u_1 & 0 \\ v_1 & 0 & v_2 & 0 & -v_2 & -v_1 \\ v_2 & 0 & v_1 & -v_2 & -v_1 & 0 \end{bmatrix}, \tag{45}$$

and after the transformation the matrix $\hat{W}$ looks like

$$\hat{W} = \begin{bmatrix} 0 & u_1 & u_2 & 0 & -u_2 & -u_1 \\ 0 & u_2 & u_1 & -u_2 & -u_1 & 0 \\ -v_1u_1 - v_2u_2 & v_1u_1 + v_2u_2 & 0 & 0 & 0 & 0 \\ u_1v_2 & -v_1u_2 & 0 & v_1u_2 - u_1v_2 & 0 & 0 \end{bmatrix}. \tag{46}$$

The third row of $\hat{W}$ is identically zero because $u^Tv = 0$.

We conclude this case by the following theorem.

THEOREM 3.7. *Suppose that $n \geq 5$ is odd and that u and v are two skew-symmetric vectors satisfying $u^Tv = 0$. Then:*

1. *The dimension of $S(u) \cap S(v)$ is at least four.*
2. *For almost all u and v, the dimension of $S(u) \cap S(v)$ is exactly four.*
3. *For almost all u and v and for any values of λ_1 and λ_2, the symmetric Toeplitz matrices T satisfying $Tu = \lambda_1 u$ and $Tv = \lambda_2 v$ form a two-dimensional manifold.*

Proof. By Lemma 3.6, the dimension of $\ker(\tilde{W})$ is almost always three. The first two assertions then follow from Lemma 3.2. The last assertion follows from Lemma 3.3. □

Case 3. n is odd, one eigenvector is symmetric and the other is skew-symmetric. A symmetric vector is always orthogonal to a skew-symmetric vector regardless of what the values of the components are. Thus, unlike the previous two cases, the orthogonality condition $u^Tv = 0$ no longer helps to reduce the rank of $\tilde{M}$. As $\tilde{M}$ does contain an identically zero row, we should have the same conclusion as in Theorem 3.5, which is given in Theorem 3.8.

THEOREM 3.8. *Suppose that n is odd and that u and v are symmetric and skew-symmetric vectors, respectively. Then:*

1. *The dimension of $S(u) \cap S(v)$ is at least two.*
2. *For almost all u and v, the dimension of $S(u) \cap S(v)$ is exactly two.*
3. *For almost all u and v and for any values of λ_1 and λ_2, there exists a unique symmetric Toeplitz matrix T satisfying $Tu = \lambda_1 u$ and $Tv = \lambda_2 v$.*

Case 4. n is even and both eigenvectors are symmetric. When n is even, the Hankel matrix $\tilde{H}(v)$ for a symmetric vector v takes the special form

$$\tilde{H}(v) = \begin{bmatrix} v_1 & v_2 & \cdots & v_{p-1} & v_p \\ v_2 & v_3 & & v_p & v_p \\ \vdots & & & & \vdots \\ v_{p-1} & v_p & \cdots & v_4 & v_3 \\ v_p & v_p & \cdots & v_3 & v_2 \end{bmatrix}. \tag{47}$$

Once again, we define

$$G(v) := \begin{bmatrix} v_1 & v_2 & \cdots & v_{p-1} & v_p \\ 0 & v_1 & & v_{p-2} & v_{p-1} \\ \vdots & 0 & \ddots & \vdots & \vdots \\ 0 & & & v_1 & v_2 \\ 0 & 0 & 0 & 0 & v_1 \end{bmatrix} \tag{48}$$

and construct $\tilde{G}(u, v)$ according to (27). If the two symmetric vectors u and v are orthogonal, then it can be shown that the rank of the $n \times (n+1)$ matrix $\tilde{W} := \tilde{G}\tilde{M}$ satisfies

$$p + 1 \leq \operatorname{rank}(\tilde{W}) \leq n - 1 \tag{49}$$

and for almost all u and v, the dimension of $\ker(\tilde{M})$ is exactly two. So the following theorem is true.

THEOREM 3.9. *Suppose that n is even and that u and v are two symmetric vectors satisfying $u^T v = 0$. Then:*

1. *The dimension of $S(u) \cap S(v)$ is at least three.*
2. *For almost all u and v, the dimension of $S(u) \cap S(v)$ is exactly three.*
3. *For almost all u and v and for any values of λ_1 and λ_2, the symmetric Toeplitz matrices T satisfying $Tu = \lambda_1 u$ and $Tv = \lambda_2 v$ form a one-dimensional manifold.*

Case 5. n is even and both eigenvectors are skew-symmetric. When n is even, the Hankel matrix $\tilde{H}(v)$ for a skew-symmetric vector v takes the special form

$$\tilde{H}(v) = \begin{bmatrix} v_1 & v_2 & \cdots & v_{p-1} & v_p \\ v_2 & v_3 & & v_p & -v_p \\ \vdots & & & & \vdots \\ v_{p-1} & v_p & \cdots & -v_4 & -v_3 \\ v_p & -v_p & \cdots & -v_3 & -v_2 \end{bmatrix}. \tag{50}$$

To construct the transformation matrix $\tilde{G}(u, v)$, the matrix $G(v)$ for a skew-symmetric vector v is defined in exactly the same way as (48). The conclusion is stated in Theorem 3.10.

THEOREM 3.10. *Suppose that n is even and that u and v are two skew-symmetric vectors satisfying $u^T v = 0$. Then:*

1. *The dimension of $S(u) \cap S(v)$ is at least three.*
2. *For almost all u and v, the dimension of $S(u) \cap S(v)$ is exactly three.*
3. *For almost all u and v and for any values of λ_1 and λ_2, the symmetric Toeplitz matrices T satisfying $Tu = \lambda_1 u$ and $Tv = \lambda_2 v$ form a one-dimensional manifold.*

Case 6. n is even, one eigenvector is symmetric and the other is skew-symmetric. Just like Case 3, the orthogonality condition does not help to reduce the rank of $\tilde{M}$. The $n \times (n+1)$ matrix $\tilde{M}$ in general is of full rank. The conclusion in Theorem 3.11, therefore, is similar to Theorem 3.8.

THEOREM 3.11. *Suppose that n is even and that u and v are symmetric and skew-symmetric vectors, respectively. Then:*

1. *The dimension of $S(u) \cap S(v)$ is at least two.*
2. *For almost all u and v, the dimension of $S(u) \cap S(v)$ is exactly two.*
3. *For almost all u and v and for any values of λ_1 and λ_2, there exists a unique symmetric Toeplitz matrix T satisfying $Tu = \lambda_1 u$ and $Tv = \lambda_2 v$.*

4. Conclusion. We have shown by symbolic computation that the dimension of the subspace $S(u) \cap S(v)$ of Toeplitz matrices with two generically prescribed eigenvectors u and v is independent of the size of the problem. We have further shown that the dimension is either two, three, or four, depending upon whether the eigenvectors are symmetric or skew-symmetric. All the cases are justified to the extent that the transformation matrices that result in the desired elimination are fully described in terms of the components of u and v. Only one proof (Lemma 3.4) is detailed, but the rest can be done in a very similar way.

Our result extends a previous result by Cybenko [4] who considers the structure of Toeplitz matrices with only one prescribed eigenvector. On the other hand, our discovery that the dimension is independent of the size of the problem is quite a surprising and remarkable fact.

We also have studied the inverse problem of constructing a Toeplitz matrix from two prescribed eigenpairs. We have shown that in almost every direction of $\ker(\tilde{M})$, there is one and only one Toeplitz matrix with the prescribed eigenpairs. In particular, it is shown that if n is odd and if at least one of the given eigenvectors is symmetric, or if n is even and one eigenvector is symmetric and the other is skew-symmetric, then the Toeplitz matrix is unique.

Appendix. In the proof of Theorem 3.5 we need to show that $\det(WW^T)$ is not identically zero. This can be done by simply showing that $\det(WW^T) \neq 0$ for a certain u and v. In particular, choose

$$u_i = \begin{cases} 1 & \text{if } i = 1, \\ 0 & \text{if } 1 < i \leq p; \end{cases}$$

$$v_i = \begin{cases} 1 & \text{if } i = p, \\ 0 & \text{if } 1 \leq i < p. \end{cases}$$

Then it is easy to see that the $(p-1) \times p$ submatrix W is given by

$$\begin{bmatrix} 0 & 0 & 0 & 0 & \dots & 0 & 0 & 2 \\ 0 & 0 & 0 & 0 & \dots & 0 & 2 & 0 \\ 0 & 0 & 0 & 0 & & 2 & 0 & 0 \\ \vdots & \vdots & & & & & \vdots & \vdots \\ 0 & 0 & 0 & 2 & & & 0 & \\ 0 & 0 & 2 & 0 & \dots & & 0 & 0 \\ 1 & 0 & \dots & & \dots & & 0 & 0 \end{bmatrix}.$$

Obviously W is of full rank $p-1$.

With the same choice of u and v, it is also easy to see that

$$x = \left[0, -\sqrt{.5}, 0, \dots, 0, \sqrt{.5}\right]^T$$

is a solution to (18). Specifically, we have proved that x_0 cannot be identical to x_1 for all u and v.

Similar arguments can be deduced for the proof of other cases.

Note added in proof. As the paper was being printed, Landau announced that he has proved that every set of n real numbers is the set of eigenvalues of an $n \times n$ real symmetric Toeplitz matrix. See [12].

PERTURBATION ANALYSIS OF A CONDITION NUMBER FOR LINEAR SYSTEMS*

ZHI-QUAN LUO† AND PAUL TSENG‡

Abstract. In 1952, A. J. Hoffman [*J. Res. Natl. Bur. Standards*, 49 (1952), pp. 263–265] published a bound on the distance from any point to the solution set of a linear system. This bound subsequently has found applications in the sensitivity analysis of linear/integer programs and the convergence analysis of descent methods for linearly constrained minimization. A certain constant in Hoffman's bound may be interpreted as a condition number for the linear system and, in this paper, the authors give simple necessary and sufficient conditions for the constant to be uniformly bounded under perturbations on the problem data. Also, these conditions are related to a uniform boundedness condition on the vertex solutions proposed by J.-S. Pang.

Key words. Hoffman's bound, condition number, linear system, perturbation analysis

AMS subject classifications. 90C31, 65F35, 15A39

1. Introduction.

For any $m \times n$ matrix A and any m-vector a ($m \geq 1, n \geq 1$), we denote the polyhedral set

$$P(A, a) = \{ x \in \Re^n \mid Ax \leq a \}.$$

In many practical settings, it is of interest to estimate the Euclidean distance from a point x to its nearest point in $P(A, a)$ when this set is nonempty. One particularly useful estimate is given by A. J. Hoffman [Hof52] who showed that this distance is bounded above by some scalar constant (depending on A only) times the Euclidean norm of the residual error

$$[Ax - a]_+,$$

where, for any vector z, $[z]_+$ denotes the positive part of z. This bound and its relatives have been studied quite extensively and important applications have been found in the sensitivity analysis of linear programs (see [Rob73a], [Rob77]) and in the convergence analysis of descent methods for linearly constrained minimization (see [Gof80], [Gül92], [IuD90], [LuT92], [TsB93], [TsL92]). Moreover, the constant in the bound provides a measure of the "condition" of the linear system $Ax \leq a$ (see [Gof80], [Man81b]).

Since real-world problems typically have inaccurate data, it is of practical as well as theoretical interest to know how Hoffman's bound behaves under perturbations on the constraint matrix A and the right-hand side a. Specifically, when would the constant in this bound be uniformly bounded under such perturbations? This question was posed to us by Professor J.-S. Pang [Pan91] who also conjectured that this uniform boundedness property would hold if and only if $P(A, a)$ contains a Slater point and its vertex set is nonempty and is in some sense uniformly bounded under local

perturbations on A and a. Surprisingly, the above question has been little studied and the available results mainly treat the case where a is perturbed.

In this paper, we address the above and related questions regarding the behaviour of Hoffman's bound under perturbations on the problem data. To be precise, let us define, for each $m \times n$ matrix A and m-vector a such that $P(A, a)$ is nonempty, the quantity

$$\tau(A, a) = \sup_{x \notin P(A,a)} \frac{d(x, P(A, a))}{\|[Ax - a]_+\|}. \tag{1.1}$$

(Here and throughout, we denote, for every vector x and every closed set C in some Euclidean space,

$$d(x, C) = \min_{y \in C} \|x - y\|,$$

where $\|y\|$ is the usual Euclidean norm of a vector y.) By the preceding result of Hoffman, $\tau(A, a)$ is finite and, in fact, bounded above by a scalar depending on A only. The quantity $\tau(A, a)$ may be viewed geometrically as a condition number for measuring the "sharpness" of the corners of $P(A, a)$ (see [Gof80]), i.e., the larger $\tau(A, a)$ is, the sharper is some corner of $P(A, a)$ (assuming that each row of A is normalized to have a norm of one). We note that in [Gof80] (see Theorem 4.4 therein), the L_∞-norm is used in place of the Euclidean norm but this difference is minor. For ease of reference, we will refer to $\tau(A, a)$ as the *Hoffman condition number* for the linear system $Ax \leq a$.

We say that the system of linear inequalities $Ax \leq a$ is *well-conditioned* under a set of perturbations on the problem data A and a if $Ax \leq a$ remains solvable and $\tau(A, a)$ is uniformly bounded under perturbations from this set. This criterion of well-conditionedness based on a variational principle is more stringent than the traditional criterion, which only requires that the normalized condition number $\|A\| \cdot \tau(A, a)$ be less than some threshold value. This criterion is also, in some sense, more natural since it takes into account the effects of data perturbation and is not dependent on an (arbitrarily chosen) threshold value. (Like the traditional criterion, it is independent of scaling on A and a (assuming that the set of perturbations is independent of scaling on A and a).)

We will distinguish between the following sets of perturbations on A and a. We say that a set of perturbations is *local* if the size of the perturbations is restricted to be less than some scalar (depending on A and a) and is *global* if no such restriction is made. We say that a set of perturbations is *feasible* if the perturbations are restricted to those that maintain the perturbed system to be solvable. Feasible perturbations are of interest since they arise in various practical contexts. For example, in the classical situation where a nonlinear system is linearized around one of its feasible solutions, any perturbation in the feasible solution would induce a feasible perturbation on the linearized system.

The main goal of this paper is to establish (computationally tractable) necessary and sufficient conditions for a linear system to be well-conditioned under any combination of the preceding set of perturbations. First, we show that the system $Ax \leq a$ is well-conditioned under feasible local perturbations on A and feasible global perturbations on a if and only if every row-wise submatrix of A is either strongly stable or has full column rank (see Theorem 2.2). (A matrix M is said to be strongly stable if $Mx < 0$ has a solution. See [Man81a] and [Bra88] for applications of such matrices

to the stability analysis of linear systems.) Similarly, this system is well-conditioned under feasible local perturbations on A and a if and only if every row-wise submatrix of A possessing a certain structure is either strongly stable or has full column rank (see Theorem 2.4). Second, we show that the system $Ax \leq a$ is well-conditioned under arbitrary local perturbations on A and arbitrary global perturbations on a if and only if A is strongly stable (see Theorem 3.1). Similarly, this system is well-conditioned under arbitrary local perturbations on A and a if and only if either A is strongly stable or the system $Ax \leq a$ is regular and has a bounded solution set (see Theorem 3.3). (A system $Ax \leq a$ is regular if it satisfies the Slater condition that $Ax < a$ be solvable.) The "if" part of these results have already been shown by Brady [Bra88, Chap. 5], but the "only if" part was not known. Third, we relate one of the (algebraic) characterizations of well-conditionedness to a geometric characterization, conjectured by Pang, involving a uniform boundedness condition on the vertex solutions. In particular, we show that the latter condition together with a regularity assumption on the system implies the well-conditionedness of the system under arbitrary local perturbations on the problem data, but the converse does not hold (see §4). Fourth, we show that all of the above results extend to the case where linear equalities are also present in the system (see §5), and we discuss how these results can be applied to determine whether a polyhedral set has a well-conditioned algebraic representation (see §6).

We briefly survey related results. Many estimates of the Hoffman condition number $\tau(A, a)$ have been proposed, beginning with the original work of Hoffman [Hof52] with subsequent refinements made by Robinson [Rob73a], Mangasarian [Man81b], Mangasarian and Shiau [MaS87], Cook et al. [CGST86], and, most recently, by Li [Li91] and Bergthaller and Singer [BeS91]. (Also see the early work of Rosenbloom [Ros51] for a local estimate.) Unfortunately, these estimates typically involve the solution of an optimization problem and are too complicated to be useful for a perturbation analysis. In a different direction, Robinson [Rob75a] (also see [Rob77] and Lemma 3.2 in this paper) showed that the system $Ax \leq a$ remains solvable under local perturbations on A and a if and only if it is regular. This implies that regularity is a necessary condition for a system of linear inequalities to be well-conditioned under (arbitrary) local perturbations on the problem data. However, it is not sufficient (see Theorem 3.3). Another direction in which Hoffman's bound has been extended is the sensitivity analysis of linear systems. In particular, Hoffman's bound implies that a solution of a linear system changes in a Lipschitzian manner relative to changes on the problem data, with the Lipschitz constant depending on the solution. Robinson [Rob75a] (also see [Rob72] and [Rob73b]) showed that the latter dependence can be removed to some extent if the system is regular. Daniel [Dan73], [Dan75] proposed restricting the allowable perturbations as an alternative way to remove the dependence. Further elaborations of Robinson's result are given by Brady [Bra88]. Our results can be applied to sharpen some of the results above although, for brevity, we will not discuss such applications here. Finally, Hoffman's bound has also been extended to convex programs and to systems of convex inequalities. The first result of this kind was given by Robinson [Rob75b] under a Slater condition and assuming boundedness of the solution set. This result was then extended by Mangasarian [Man85] to a system of differentiable convex inequalities in which the boundedness assumption is replaced by an asymptotic constraint qualification. Further extensions were made by Auslender and Crouzeix [AuC88], among which is the release of the differentiability assumption. It is unclear whether our analysis can be extended to the convex case.

We adopt the following notations throughout. All vectors are column vectors and superscript T denotes transpose. For any vector $x \in \Re^n$ and any $I \subseteq \{1, \ldots, n\}$, we

denote by x_i the ith component of x and x_I the vector with components $x_i \in I$ (with the x_i's arranged in the same order as in x). For any two vectors x and y of the same dimension, we denote by $\langle x, y\rangle$ the usual Euclidean inner product of x with y, i.e., $\langle x, y\rangle = \sum_i x_i y_i$. Thus, the Euclidean norm of x is given by $\|x\| = \sqrt{\langle x, x\rangle}$. For any $m \times n$ matrix M and any $I \subseteq \{1, \ldots, m\}$, we denote by M_i the ith row of M and by M_I the submatrix of M obtained by removing all rows $i \notin I$; we denote by $\|M\|$ the matrix norm of M as induced by the vector norm $\|\cdot\|$ (i.e., $\|M\| = \max_{\|x\|=1} \|Mx\|$). We say that a sequence of matrices $\{M^r\}$ converges to M ("$\{M^r\} \to M$" for short) if $\|M^r - M\| \to 0$ as $r \to \infty$. For any $I \subseteq \{1, 2, \ldots\}$, we denote by $|I|$ the number of elements of I. Finally, we say that a set of perturbations on A and a is *semilocal* if the perturbations on A are local but the perturbations on a are global.

2. Well-conditionedness under feasible perturbations In this section we study the well-conditionedness of the system $Ax \leq a$ under feasible perturbations on A and a, i.e., perturbations under which $Ax \leq a$ remains solvable. We divide the analysis into two subsections. In §2.1, we show that this system is well-conditioned under feasible local perturbations on A and feasible global perturbations on a if and only if, for every nonempty $I \subseteq \{1, \ldots, m\}$, the submatrix A_I either is strongly stable or has full column rank (see Theorem 2.2). In §2.2, we show that this system is well-conditioned under feasible local perturbations on A and a if and only if, for every nonempty $I \subseteq \{1, \ldots, m\}$ such that either $Ax \leq a, A_I x = a_I$ or $Ax \leq 0,\ A_I x = 0, x \neq 0$ is solvable, the submatrix A_I either is strongly stable or has full column rank (see Theorem 2.4). Moreover, these characterizations of well-conditionedness simplify considerably under some mild assumptions on the solution set $P(A, a)$ (see Propositions 2.3, 2.5, 2.6).

2.1. Well-conditionedness under feasible semilocal perturbations First we state and prove a key property of matrices that are either strongly stable or of full column rank. This property will be used in the proof of the main result of this subsection, namely, Theorem 2.2.

LEMMA 2.1. *Let E be an $l \times n$ matrix ($l \geq 1$).*

(a) *If there exists an n-vector u with $Eu > 0$, then for every l-vector $\theta \geq 0$, we have*

$$\|[EE^T\theta]_+\| \geq \frac{\min_i\{E_i u\}}{\|u\|}\|E^T\theta\|.$$

(b) *If E has full column rank, then for every l-vector $\theta \geq 0$, there is an $J \subseteq \{1, \ldots, l\}$ with $|J| = n$ and E_J invertible such that*

$$\|[EE^T\theta]_+\| \geq \left(\min_{\|\nu\|=1} \|(E_J)^T\nu\|\right)\|E^T\theta\|.$$

Proof. Fix any l-vector $\theta \geq 0$. If $E^T\theta = 0$, then the claims follow trivially. Thus, it suffices to consider the case where $E^T\theta \neq 0$. Using the Cauchy–Schwarz inequality and the nonnegativity of θ, we have

$$\|\theta\|\|[EE^T\theta]_+\| \geq \langle\theta, [EE^T\theta]_+\rangle \geq \langle\theta, EE^T\theta\rangle = \|E^T\theta\|^2,$$

so dividing both sides by $\|E^T\theta\|\|\theta\|$ gives

$$\frac{\|[EE^T\theta]_+\|}{\|E^T\theta\|} \geq \frac{\|E^T\theta\|}{\|\theta\|}. \tag{2.1}$$

(a) Suppose that there is an n-vector u with $Eu > 0$. Using the Cauchy–Schwarz inequality and the nonnegativity of θ, we have

$$\|u\|\|E^T\theta\| \geq \langle u, E^T\theta\rangle = \langle Eu, \theta\rangle \geq \min_i\{E_iu\}\|\theta\|.$$

Thus, $\|E^T\theta\|/\|\theta\| \geq \min_i\{E_iu\}/\|u\|$. Using this to bound the right-hand side of (2.1) yields the desired inequality.

(b) Suppose that E has rank n. Then, by Carathéodory's Theorem (see [Roc70]), there exists an n-vector $\nu \geq 0$ and a subset $J \subseteq \{1,\ldots,l\}$ with $|J| = n$ and E_J invertible such that $(E_J)^T\nu = E^T\theta$. Since (2.1) holds for any E and any nonnegative vector θ with $E^T\theta \neq 0$, it also holds when E and θ are replaced by, respectively, E_J and ν. This gives

$$\frac{\|[E_J(E_J)^T\nu]_+\|}{\|(E_J)^T\nu\|} \geq \frac{\|(E_J)^T\nu\|}{\|\nu\|}.$$

The right-hand quantity is clearly bounded below by $\min_{\|\nu\|=1}\|(E_J)^T\nu\|$; the left-hand quantity is, using $(E_J)^T\nu = E^T\theta$, equal to $\|[E_JE^T\theta]_+\|/\|E^T\theta\|$ which is clearly bounded above by $\|[EE^T\theta]_+\|/\|E^T\theta\|$. This proves the desired inequality. □

Given below is the main result of this subsection, which establishes a necessary and sufficient condition for the system $Ax \leq a$ to be well-conditioned under feasible local perturbations on A and feasible global perturbations on a. The proof of sufficiency is based on bounding $\tau(A,a)$ by $\|(A_I)^T\lambda\|/\|[A_I(A_I)^T\lambda]_+\|$ for some nonzero vector $\lambda \geq 0$ and some $I \subseteq \{1,\ldots,m\}$. Then, Lemma 2.1 is invoked to bound the latter. The proof of necessity amounts to constructing a set of feasible local perturbations on A and feasible global perturbations on a under which $\tau(A,a)$ is not uniformly bounded (see (2.5) and (2.6)).

THEOREM 2.2. (*Well-conditionedness under feasible semilocal perturbations*). *For any $m \times n$ matrix A, the following conditions are equivalent.*

(a) *For each nonempty index set $I \subseteq \{1,\ldots,m\}$, we have that either $A_Ix < 0$ is solvable or A_I has full column rank.*

(b) *There exist scalars $\delta > 0$ and $\beta > 0$ such that, for any (A',a') with $\|A'-A\| < \delta$ and $A'x \leq a'$ solvable, we have $\tau(A',a') \leq \beta$.*

Proof. (a) $\Rightarrow$ (b). Suppose that condition (a) holds. For each nonempty $I \subseteq \{1,\ldots,m\}$ such that $A_Ix < 0$ is solvable, let u^I be any n-vector with $A_Iu^I > 0$. Define the scalars:

$$\rho_1 = \min_I\left\{\min_{i\in I}\{A_iu^I\}/\|u^I\|\right\}, \qquad \rho_2 = \min_J\left\{\min_{\|\nu\|=1}\|(A_J)^T\nu\|\right\}, \tag{2.2}$$

where the minimization with respect to I is taken over all nonempty $I \subseteq \{1,\ldots,m\}$ for which $A_Ix < 0$ is solvable (with $\rho_1 = \infty$ if no such I exists); the minimization with respect to J is taken over all nonempty $J \subseteq \{1,\ldots,m\}$ for which $|J| = n$ and A_J is invertible (with $\rho_2 = \infty$ if no such J exists). Notice that ρ_1 is positive.

Consider any $m \times n$ matrix A' satisfying

$$\|A' - A\| < \min\{\rho_1,\rho_2\}/2, \tag{2.3}$$

and any m-vector a' for which $A'x \leq a'$ is solvable (so $P(A',a')$ is nonempty). Fix any n-vector $x \notin P(A',a')$ and let z denote the orthogonal projection of x onto $P(A',a')$ (so $\|x-z\| = d(x,P(A',a'))$). Let I denote the nonempty set of indices $i \in \{1,\ldots,m\}$

for which $A'_i z = a'_i$. Then, $A'_I z = a'_I$ and the Kuhn–Tucker conditions associated with this projection yield $x - z = (A'_I)^T \lambda$ for some $\lambda \geq 0$, so

$$\frac{d(x, P(A', a'))}{\|[A'x - a']_+\|} = \frac{\|x - z\|}{\|[A'x - a']_+\|} \leq \frac{\|x - z\|}{\|[A'_I x - a'_I]_+\|} = \frac{\|(A'_I)^T \lambda\|}{\|[A'_I (A'_I)^T \lambda]_+\|}. \tag{2.4}$$

Since condition (a) holds by hypothesis, it suffices to consider only the following two cases.

Case 1. $A_I x < 0$ is solvable. Then, u^I is defined and (cf. $\|A' - A\| < \rho_1/2$ and $A_I u^I > 0$) $A'_I u^I \geq A_I u^I/2 > 0$, so we can apply Lemma 2.1(a) with $E = A'_I$ to obtain

$$\frac{\|(A'_I)^T \lambda\|}{\|[A'_I (A'_I)^T \lambda]_+\|} \leq \frac{\|u^I\|}{\min_{i \in I}\{A'_i u^I\}} \leq \frac{2\|u^I\|}{\min_{i \in I}\{A_i u^I\}} \leq \frac{2}{\rho_1},$$

where the last inequality follows from (2.2).

Case 2. A_I has full column rank. Then, for any subset J of I with $|J| = n$ and A_J invertible, we have from the triangle inequality and (2.2) and (2.3) that

$$\min_{\|\nu\|=1} \|(A'_J)^T \nu\| \geq \min_{\|\nu\|=1} \|(A_J)^T \nu\| - \|(A_J)^T - (A'_J)^T\| \geq \rho_2 - \frac{\rho_2}{2} = \frac{\rho_2}{2}.$$

This shows that A'_J has full column rank, so A'_I also has full column rank. Then, we can apply Lemma 2.1(b) with $E = A'_I$ and, together with the above relation, obtain that

$$\frac{\|(A'_I)^T \lambda\|}{\|[A'_I (A'_I)^T \lambda]_+\|} \leq \frac{1}{\min_{\|\nu\|=1} \|(A'_J)^T \nu\|} \leq \frac{2}{\rho_2},$$

where J is some subset of I with $|J| = n$ and A_J invertible.

Since either the above relation or the relation in Case 1 holds, the right-hand side of (2.4) is bounded above by the maximum of $2/\rho_1$ and $2/\rho_2$. Then, (2.4) yields

$$\frac{d(x, P(A', a'))}{\|[A'x - a']_+\|} \leq \max\left\{\frac{2}{\rho_1}, \frac{2}{\rho_2}\right\}.$$

Our choice of x above was arbitrary, so the above inequality holds for all n-vectors $x \notin P(A', a')$. Taking the supremum of both sides over all $x \notin P(A', a')$ and using (1.1), we obtain $\tau(A', a') \leq \max\{2/\rho_1, 2/\rho_2\}$.

(b) $\Rightarrow$ (a). Suppose that condition (a) does not hold. Then, there exists some nonempty $I \subseteq \{1, \ldots, m\}$ such that $A_I x < 0$ has no solution and A_I lacks full column rank. Fix any m-vector a such that $Ax \leq a$ has a solution and let $\bar{x}$ be any such solution. Since $A_I x < 0$ has no solution, by the Farkas Lemma (see [Roc70] or [Sch86]), there exists a nonzero vector $\theta_I \geq 0$ with $(A_I)^T \theta_I = 0$. Also, since A_I lacks full column rank, there exists a nonzero z with $A_I z = 0$. Normalizing if necessary, we will assume that $\|\theta_I\| = 1$ and $\|z\| = 1$. Using I, θ_I, and z, we construct below a set of local perturbations on A and global perturbations on a such that the perturbed systems are solvable but whose respective Hoffman condition numbers are not uniformly bounded. The key is to perturb each row of A_I by a scalar multiple of z^T and, because z^T is orthogonal to these rows, this will induce in the solution set of the perturbed system a corner whose "sharpness" is inversely proportional to the size of the perturbation.

By reordering the rows of A and a if necessary, we can assume that

$$A = \begin{bmatrix} A_I \\ A_{\bar{I}} \end{bmatrix}, \qquad a = \begin{bmatrix} a_I \\ a_{\bar{I}} \end{bmatrix},$$

where $\tilde{I}$ denotes the complement of I relative to $\{1,\ldots,m\}$. For each scalar $\epsilon > 0$, we define the perturbed matrix A^ϵ by:

$$A_I^\epsilon = A_I + \epsilon\theta_I z^T, \qquad A_{\tilde{I}}^\epsilon = A_{\tilde{I}}, \tag{2.5}$$

and the perturbed right-hand side a^ϵ by:

$$a_I^\epsilon = A_I\bar{x} + \epsilon(\langle z, \bar{x}\rangle + \epsilon)\theta_I, \qquad a_{\tilde{I}}^\epsilon = a_{\tilde{I}} + 2\epsilon[A_{\tilde{I}}z]_+. \tag{2.6}$$

Let $x^\epsilon = \bar{x} + \epsilon z$. We claim that x^ϵ belongs to $P(A^\epsilon, a^\epsilon)$. To see this, notice that

$$\begin{aligned} A_I^\epsilon x^\epsilon &= (A_I + \epsilon\theta_I z^T)(\bar{x} + \epsilon z) \\ &= A_I\bar{x} + \epsilon(\langle z, \bar{x}\rangle + \epsilon)\theta_I \\ &= a_I^\epsilon, \end{aligned} \tag{2.7}$$

where the second equality follows from $A_I z = 0$ and $\|z\| = 1$, and the last equality follows from the definition of a_I^ϵ. Similarly, we have

$$\begin{aligned} A_{\tilde{I}}^\epsilon x^\epsilon &= A_{\tilde{I}}(\bar{x} + \epsilon z) \\ &\le a_{\tilde{I}} + 2\epsilon[A_{\tilde{I}}z]_+ \\ &= a_{\tilde{I}}^\epsilon, \end{aligned} \tag{2.8}$$

where the inequality follows from $A_{\tilde{I}}\bar{x} \le a_{\tilde{I}}$ and $A_{\tilde{I}}z \le 2[A_{\tilde{I}}z]_+$; the last equality is due to the definition of $a_{\tilde{I}}^\epsilon$.

Since $(A_I)^T\theta_I = 0$ and $\|\theta_I\| = 1$, we have from (2.5) that

$$(A_I^\epsilon)^T\theta_I = (A_I + \epsilon\theta_I z^T)^T\theta_I = \epsilon z.$$

This together with $\theta_I \ge 0$ and (2.7)–(2.8) implies that z is a normal to the polyhedral set $P(A^\epsilon, a^\epsilon)$ at x^ϵ. Thus, if we move along the direction z from x^ϵ and then project back onto $P(A^\epsilon, a^\epsilon)$, we always get x^ϵ. In particular, the projection of $x^\epsilon + \epsilon z$ onto $P(A^\epsilon, a^\epsilon)$ is x^ϵ, so that

$$d(x^\epsilon + \epsilon z, P(A^\epsilon, a^\epsilon)) = \epsilon\|z\| = \epsilon. \tag{2.9}$$

On the other hand, we have from the definitions of A^ϵ and a^ϵ (cf. (2.5) and (2.6)) that

$$\begin{aligned} A_I^\epsilon(x^\epsilon + \epsilon z) &= (A_I + \epsilon\theta_I z^T)(\bar{x} + 2\epsilon z) \\ &= A_I\bar{x} + \epsilon(\langle z, \bar{x}\rangle + 2\epsilon)\theta_I \\ &= a_I^\epsilon + \epsilon^2\theta_I, \end{aligned}$$

where the second equality follows from $A_I z = 0$ and $\|z\| = 1$. Similarly, we have

$$\begin{aligned} A_{\tilde{I}}^\epsilon(x^\epsilon + \epsilon z) &= A_{\tilde{I}}(\bar{x} + 2\epsilon z) \\ &\le a_{\tilde{I}} + 2\epsilon[A_{\tilde{I}}z]_+ \\ &= a_{\tilde{I}}^\epsilon, \end{aligned}$$

where the inequality follows from $A_{\bar{I}}\bar{x} \leq a_{\bar{I}}$ and $A_{\bar{I}}z \leq [A_{\bar{I}}z]_+$. Combining the above two relations yields

$$[A^\epsilon(x^\epsilon + \epsilon z) - a^\epsilon]_+ = \begin{bmatrix} \epsilon^2\theta_I \\ 0 \end{bmatrix},$$

so that $\|[A^\epsilon(x^\epsilon + \epsilon z) - a^\epsilon]_+\| = \epsilon^2\|\theta_I\| = \epsilon^2$. This together with (2.9) implies

$$\frac{d(x^\epsilon + \epsilon z, P(A^\epsilon, a^\epsilon))}{\|[A^\epsilon(x^\epsilon + \epsilon z) - a^\epsilon]_+\|} = \frac{\epsilon}{\epsilon^2} = \frac{1}{\epsilon}.$$

Because the right-hand side tends to infinity as $\epsilon \to 0$, it follows (cf. (1.1)) that $\tau(A^\epsilon, a^\epsilon) \to \infty$ as $\epsilon \to 0$. Since $A^\epsilon \to A$ as $\epsilon \to 0$, this shows that condition (b) cannot hold. □

In general, condition (a) in Theorem 2.2 is quite difficult to verify. The next result shows that, in the case where the system $Ax \leq a$ has an unbounded solution set, this condition simplifies considerably.

PROPOSITION 2.3. *For any $m \times n$ matrix A such that $Ax \leq 0$ has a nonzero solution, condition* (a) *in Theorem* 2.2 *holds if and only if the system $Ax < 0$ has a solution.*

Proof. The "if" direction is obvious. To prove the "only if" direction, suppose that condition (a) in Theorem 2.2 holds. By hypothesis, there is a nonzero n-vector x satisfying $Ax \leq 0$. Let I be the set of indices i such that $A_i x = 0$. Then, the submatrix A_I must lack full column rank, so condition (a) in Theorem 2.2 implies that there is an n-vector x' satisfying $A_I x' < 0$. For any scalar $\epsilon > 0$ sufficiently small, we have that $A(x + \epsilon x') < 0$. □

Checking the solvability of $Ax < 0$ amounts to solving the linear program $\min\{\ \mu \in \Re \mid Ax \leq \mu e\ \}$ with e denoting the m-vector of all 1's, for which many efficient algorithms exist. Checking whether $Ax \leq 0$ has a nonzero solution can similarly be accomplished by solving a single linear program, as was pointed out to us by one of the referees and by R. Freund. In particular, one first determines if A has full column rank. If not, then $Ax \leq 0$ trivially has a nonzero solution; if A does have full column rank, then it can be seen that the linear program $\max\{\ \langle e, u\rangle \mid Ax + u \leq 0,\ 0 \leq u \leq e\ \}$ has a positive optimal cost if and only if $Ax \leq 0$ has a nonzero solution (also see [FRT85]). Thus, the conditions in Proposition 2.3 can be checked relatively easily.

2.2. Well-conditionedness under feasible local perturbations. Below we give a necessary and sufficient condition (see condition (a) in Theorem 2.4) for the system $Ax \leq a$ to be well-conditioned under feasible local perturbations on A and a. This condition is similar to condition (a) in Theorem 2.2, but only requires that $A_I x < 0$ be solvable or A_I has full column rank for certain special index sets I (rather than for every I). (Roughly speaking, the special index sets are those I for which, under small perturbations on A and a, the perturbed system can be satisfied with the inequalities indexed by I as equalities. See the proof of (a) $\Rightarrow$ (b) in Theorem 2.4.) The proof techniques are, for the most part, similar to those used in proving Theorem 2.2. The major departure comes in proving the necessity of the condition, in which a new set of "destabilizing" perturbations must be constructed to handle the case where the solution set is unbounded (see (2.11)).

THEOREM 2.4 (*Well-conditionedness under feasible local perturbations*). *For any $m \times n$ matrix A and any m-vector a such that $Ax \leq a$ is solvable, the following conditions are equivalent.*

(a) *For each nonempty index set* $I \subseteq \{1,\ldots,m\}$ *such that either* $Ax \leq a, A_I x = a_I$ *or* $Ax \leq 0, A_I x = 0, x \neq 0$ *is solvable, we have that either* $A_I x < 0$ *is solvable or* A_I *has full column rank.*

(b) *There exist scalars* $\delta > 0$ *and* $\beta > 0$ *such that for any* (A', a') *with* $\|(A', a') - (A, a)\| < \delta$ *and* $A'x \leq a'$ *solvable, we have* $\tau(A', a') \leq \beta$.

Proof. (a) $\Rightarrow$ (b). First, we claim that there exists a scalar $\bar{\rho} > 0$ (depending on A only) such that, for any nonempty $I \subseteq \{1,\ldots,m\}$ and any (A', a') with $\|(A', a') - (A, a)\| < \bar{\rho}$, solvability of the system $A'x \leq a', A'_I x = a'_I$ implies the solvability of either $Ax \leq a, A_I x = a_I$ or $Ax \leq 0, A_I x = 0, x \neq 0$. To see this, suppose the contrary so that, for some nonempty $I \subseteq \{1,\ldots,m\}$ and some sequence $(A^1, a^1), (A^2, a^2), \ldots$ converging to (A, a), there exists a sequence $z^1, z^2, \ldots$ satisfying $A^r z^r \leq a^r$, $A^r_I z^r = a^r_I$ for all r and yet neither $Ax \leq a, A_I x = a_I$ nor $Ax \leq 0, A_I x = 0, x \neq 0$ is solvable. Since $Ax \leq a, A_I x = a_I$ is not solvable, the sequence $\{z^r\}$ must be unbounded (for otherwise any cluster point of $\{z^r\}$ would be a solution to this system). Thus, we have

$$\limsup_{r\to\infty} \frac{A^r z^r}{\|z^r\|} \leq 0, \qquad \lim_{r\to\infty} \frac{A^r_I z^r}{\|z^r\|} = 0,$$

so any cluster point of the bounded sequence $\{z^r/\|z^r\|\}$ solves $Ax \leq 0, A_I x = 0, x \neq 0$. This contradicts the hypothesis that the latter system is unsolvable.

The remainder of the proof is essentially identical to the proof of (a) $\Rightarrow$ (b) in Theorem 2.2, except that in (2.3) we take $\|A' - A\|$ to be, in addition, less than $\bar{\rho}$. The latter, together with condition (a), guarantees that either Case 1 or Case 2 therein holds.

(b) $\Rightarrow$ (a). Suppose that condition (a) does not hold. Then, there exists some nonempty $J \subseteq \{1,\ldots,m\}$ such that either $Ax \leq a$, $A_J x = a_J$ or $Ax \leq 0$, $A_J x = 0$, $x \neq 0$ is solvable, but $A_J x < 0$ is not solvable and A_J lacks full column rank. Since $A_J x < 0$ is not solvable, by the Farkas Lemma (see [Roc70] or [Sch86]), there exists a nonzero vector $\theta_J \geq 0$ with components θ_i, $i \in J$, satisfying $(A_J)^T \theta_J = 0$. Let $I \subseteq J$ be the set of indices i with $\theta_i > 0$ and let θ_I be the vector obtained by removing from θ_J all components θ_i, $i \notin I$. Then, $\theta_I > 0$ and $(A_I)^T \theta_I = 0$. Since $I \subseteq J$, we also have that A_I lacks full column rank and that either $Ax \leq a$, $A_I x = a_I$ or $Ax \leq 0$, $A_I x = 0$, $x \neq 0$ is solvable. We consider the following two cases.

Case 1. $Ax \leq a$, $A_I x = a_I$ is solvable. Then, there is an $\bar{x}$ with $A\bar{x} \leq a$ and $A_I \bar{x} = a_I$. Exactly as in the proof of Theorem 2.2, we construct matrices A^ϵ and vectors a^ϵ according to (2.5) and (2.6), with I, $\bar{x}$ and θ_I as given above, so that $A^\epsilon \to A$ and $\tau(A^\epsilon, a^\epsilon) \to \infty$ as $\epsilon \downarrow 0$. Because $A_I \bar{x} = a_I$, (2.6) implies, in addition, that $a^\epsilon \to a$. Hence condition (b) cannot hold.

Case 2. $Ax \leq a$, $A_I x = a_I$ is not solvable. Then, the system $Ax \leq 0$, $A_I x = 0$ has a nonzero solution. Let z be any such solution. Normalizing if necessary, we can assume that $\|z\| = 1$. Since $Ax \leq a$ is solvable by hypothesis, there exists an n-vector $\bar{x}$ with $A\bar{x} \leq a$. Since $Ax \leq a$, $A_I x = a_I$ is not solvable, we have $A_I \bar{x} \neq a_I$. Using I, z, and $\bar{x}$, we construct below a set of local perturbations on A and a such that the perturbed systems are solvable but whose respective Hoffman condition numbers are not uniformly bounded. As in the proof of Theorem 2.2, the key is to perturb each row of A_I by a scalar multiple of z^T. First, by reordering the rows of A and a if necessary, we will assume that

$$A = \begin{bmatrix} A_I \\ A_{\bar{I}} \end{bmatrix}, \qquad a = \begin{bmatrix} a_I \\ a_{\bar{I}} \end{bmatrix},$$

where $\tilde{I}$ denotes the complement of I relative to $\{1,\dots,m\}$. Correspondingly, we define an m-vector b given by

$$b_I = a_I - A_I\bar{x}, \qquad b_{\tilde{I}} = 0. \tag{2.10}$$

Notice that $b \geq 0$ and $b_I \neq 0$. Fix any scalar $\epsilon > 0$ with $1/\epsilon > \langle z, \bar{x}\rangle$. We associate with ϵ the perturbed matrix

$$A^\epsilon = A + \epsilon b z^T. \tag{2.11}$$

(Thus $A^\epsilon \to A$ as $\epsilon \to 0$.) Let

$$x^\epsilon = \bar{x} + \alpha z, \tag{2.12}$$

with

$$\alpha = 1/\epsilon - \langle z, \bar{x}\rangle. \tag{2.13}$$

We claim that z is a normal to the set $P(A^\epsilon, a)$ at x^ϵ. To see this, notice that

$$\begin{aligned} A^\epsilon x^\epsilon - a &= (A + \epsilon b z^T)(\bar{x} + \alpha z) - a \\ &= A\bar{x} + \epsilon(\langle z, \bar{x}\rangle + \alpha)b + \alpha A z - a \\ &= \begin{bmatrix} (1 - \epsilon(\langle z, \bar{x}\rangle + \alpha))(A_I\bar{x} - a_I) \\ A_{\tilde{I}}\bar{x} - a_{\tilde{I}} + \alpha A_{\tilde{I}} z \end{bmatrix}, \end{aligned}$$

where the last inequality follows from (2.10) and $A_I z = 0$. Since $1 = \epsilon(\langle z, \bar{x}\rangle + \alpha)$ by (2.13) and $Az \leq 0$, we obtain

$$A^\epsilon_I x^\epsilon = a_I, \qquad A^\epsilon_{\tilde{I}} x^\epsilon \leq a_{\tilde{I}}. \tag{2.14}$$

Thus, the first $|I|$ inequalities of $A^\epsilon x \leq a$ are binding at x^ϵ. Also, we have from (2.11) and $(A_I)^T\theta_I = 0$ that

$$(A^\epsilon_I)^T\theta_I = (A_I)^T\theta_I + \epsilon z\langle b_I, \theta_I\rangle = \epsilon\langle b_I, \theta_I\rangle z.$$

Since b_I is nonnegative but nonzero and $\theta_I > 0$, we have $\langle b_I, \theta_I\rangle > 0$ so z is a positive combination of the columns of $(A^\epsilon_I)^T$. This together with (2.14) shows that z is a normal to the set $P(A^\epsilon, a)$ at x^ϵ so if we move along the direction z from x^ϵ and then project back onto $P(A^\epsilon, a)$, we always get x^ϵ. In particular, the projection of $x^\epsilon + \alpha z$ onto $P(A^\epsilon, a)$ is x^ϵ, which implies

$$d(x^\epsilon + \alpha z, P(A^\epsilon, a)) = \alpha\|z\| = \alpha. \tag{2.15}$$

On the other hand, we have from using (2.14) and (cf. (2.11), $\|z\| = 1$ and $A_I z = 0$) $A^\epsilon_I z = \epsilon b_I$, and (cf. (2.11), (2.10), and $A_{\tilde{I}} z \leq 0$) $A^\epsilon_{\tilde{I}} z \leq 0$ that

$$\|[A^\epsilon(x^\epsilon + \alpha z) - a]_+\| = \left\| \begin{bmatrix} \alpha\epsilon b_I \\ 0 \end{bmatrix}_+ \right\|. \tag{2.16}$$

As $\epsilon \to 0$, we have $\alpha\epsilon \to 1$ (cf. (2.13)) so the right-hand side of (2.16) is bounded above, implying that the left-hand side of (2.16) is bounded above. On the other

hand, we also have $\alpha \to \infty$ (cf. (2.13)), so the left-hand side of (2.15) tends to ∞. Combining these two observations yields

$$\frac{d(x^\epsilon + \alpha z, P(A^\epsilon, a))}{\|[A^\epsilon(x^\epsilon + \alpha z) - a]_+\|} \to \infty,$$

so (cf. (1.1)) $\tau(A^\epsilon, a) \to \infty$, as $\epsilon \to 0$. Thus, condition (b) cannot hold. □

As with Theorem 2.2, Theorem 2.4 is not a practical result since condition (a) therein is very difficult to verify. Nonetheless, the following proposition shows that in the case where the system $Ax \leq a$ has multiple solutions, this latter condition simplifies considerably.

PROPOSITION 2.5. *For any $m \times n$ matrix A and any m-vector a such that the system $Ax \leq a$ has at least two solutions, condition* (a) *in Theorem* 2.4 *holds if and only if either $Ax < 0$ has a solution or $Ax \leq a$ is regular (i.e., there exists an x with $Ax < a$) and has a bounded solution set.*

Proof. First, we prove the "if" part. If $Ax < 0$ has a solution, then condition (a) in Theorem 2.4 holds trivially. Suppose instead that the system $Ax \leq a$ is regular and has a bounded solution set. Then, $A\bar{x} < a$ for some $\bar{x}$ and, for every nonempty $I \subseteq \{1, \ldots, m\}$, the system $Ax \leq 0, A_I x = 0, x \neq 0$ has no solution. On the other hand, for every nonempty $I \subseteq \{1, \ldots, m\}$ such that $Ax \leq a, A_I x = a_I$ has a solution, say z, we have $A_I(\bar{x} - z) < 0$ and so the system $A_I x < 0$ is solvable. This shows that condition (a) in Theorem 2.4 holds.

Next, we prove the "only if" part. Suppose that condition (a) in Theorem 2.4 holds. We first show that the system $Ax \leq a$ is regular. Let y and z be two distinct solutions of $Ax \leq a$. Let $\bar{x} = (y + z)/2$ and let I be the set of indices i such that $A_i y = A_i z = a_i$. Then, $A_I \bar{x} = a_I$ and $A_i \bar{x} < a_i$ for all $i \notin I$. Thus, if I is empty, then $\bar{x}$ solves $Ax < a$. Otherwise, we have from $A_I(y - z) = 0$ that A_I lacks full column rank, so condition (a) in Theorem 2.4 implies that $A_I u < 0$ for some u. Then, we have $A(\bar{x} + \epsilon u) < a$ for any scalar $\epsilon > 0$ sufficiently small. Hence, in either case the system $Ax \leq a$ is regular.

If the system $Ax \leq a$ has a bounded solution set, then the "only if" part immediately follows. Otherwise, there is a nonzero n-vector z satisfying $Az \leq 0$. If $Az < 0$, then again we are done. Otherwise, let I denote the set of indices i for which $A_i z = 0$. Then, z solves $Ax \leq 0, A_I x = 0$, so condition (a) in Theorem 2.4 implies that $A_I x < 0$ has a solution, say z'. (A_I cannot have full column rank since $A_I x = 0$.) It is easily seen that $A(z + \epsilon z') < 0$ for any scalar $\epsilon > 0$ sufficiently small, so the "only if" part follows. □

In the case where $Ax \leq a$ has a unique solution, condition (a) in Theorem 2.4 can again be simplified, albeit only slightly.

PROPOSITION 2.6. *For any $m \times n$ matrix A and any m-vector a such that the system $Ax \leq a$ has a unique solution, say x^*, condition* (a) *in Theorem* 2.4 *holds if and only if, for each nonempty index set $I \subseteq \{1, \ldots, m\}$ with $A_I x^* = a_I$, either $A_I x < 0$ is solvable or A_I has full column rank.*

Proof. Since $Ax \leq a$ has a unique solution, the system $Ax \leq 0, A_I x = 0$ cannot have a nonzero solution for any nonempty $I \subseteq \{1, \ldots, m\}$. Thus, in condition (a) of Theorem 2.4 it suffices to consider only those nonempty I for which $Ax \leq a$, $A_I x = a_I$ is solvable or, equivalently, $A_I x^* = a_I$. □

Although the characterization of well-conditionedness under feasible local perturbations is weaker than that under feasible semilocal perturbations (compare condition (a) in Theorems 2.2 and 2.4, respectively), the two characterizations are, surprisingly,

equivalent in some sense. In particular, notice that when $a = 0$, condition (a) in Theorem 2.4 reduces to condition (a) in Theorem 2.2 (since, for every nonempty $I \subseteq \{1, \ldots, m\}$, the system $Ax \leq a$, $A_I x = a_I$ has a solution, namely, the zero vector). Then, we immediately obtain from Theorems 2.2 and 2.4 the following result.

COROLLARY 2.7. *For any $m \times n$ matrix A, the system $Ax \leq a$ is well-conditioned under feasible local perturbations on A and feasible global perturbations on a if and only if it is well-conditioned under feasible local perturbations on both A and a when $a = 0$.*

3. Well-conditionedness under arbitrary perturbations. In this section, we continue with our study of the well-conditionedness of a system of linear inequalities under perturbations on the problem data. In contrast to the previous section, we no longer restrict the perturbations to be feasible and, as a consequence, the characterizations of well-conditionedness simplify significantly. In particular, we show that the system $Ax \leq a$ is well-conditioned under local perturbations on A and global perturbations on a if and only if A is strongly stable. Similarly, we show that this system is well-conditioned under local perturbations on A and a if and only if either A is strongly stable or $Ax \leq a$ is regular and has a bounded solution set. The proof of these results is, in great part, based on the results from the previous section.

Below we give the first main result of this section, characterizing when the system $Ax \leq a$ is well-conditioned under local perturbations on A and global perturbations on a. Its proof is based on Theorem 2.2 and the well-known fact that $Ax \leq a$ is solvable for all a if and only if A is strongly stable.

THEOREM 3.1 (*Well-conditionedness under semilocal perturbations*). *For any $m \times n$ matrix A, the following conditions are equivalent.*

(a) *$Ax < 0$ is solvable.*

(b) *There exist scalars $\delta > 0$ and $\beta > 0$ such that, for any (A', a') with $\|A' - A\| < \delta$, the system $A'x \leq a'$ is solvable and $\tau(A', a') \leq \beta$.*

Proof. (a) $\Rightarrow$ (b). Suppose that condition (a) holds. Then, condition (a) in Theorem 2.2 clearly holds, so, by Theorem 2.2, there exist scalars $\delta_1 > 0$ and $\beta > 0$ such that, for any (A', a') with $\|A' - A\| < \delta_1$ and $A'x \leq a'$ solvable, we have $\tau(A', a') \leq \beta$. Let z be any fixed n-vector satisfying $Az < 0$. Then, for any A' with $\|A' - A\| < \delta_2 = \min_i\{-A_i z\}/(2\|z\|)$, we have $A'z < 0$, so $A'x \leq a'$ is solvable (since it contains αz for any α sufficiently positive). Take δ to be the minimum of δ_1 and δ_2.

(b) $\Rightarrow$ (a). Suppose that condition (a) does not hold, so the system $Ax < 0$ has no solution. Then, for any m-vector a' with $a' < 0$, the system $Ax \leq a'$ also has no solution, so condition (b) cannot hold. □

As was noted in the introduction, the (a) $\Rightarrow$ (b) part of Theorem 3.1 is not new and was proved by Brady (see [Bra88, Thm. 5.4.13]), complete with estimates of the scalars δ and β in condition (b). We have included this part for completeness.

Although Theorem 3.1 treats the case where a is perturbed globally, it also offers some insight into the case where a is perturbed only locally. Suppose that condition (a) in Theorem 3.1 fails, so there exists a nonzero m-vector $\theta \geq 0$ with $A^T\theta = 0$. Then, if $\langle a, \theta \rangle \leq 0$, a local perturbation of a can result in $\langle a, \theta \rangle < 0$ in which case (cf. the Farkas Lemma) $Ax \leq a$ has no solution. Thus, the only unresolved case occurs when $\langle a, \theta \rangle > 0$ and this is the case on which we focus below. For this purpose, we need the following result of Robinson [Rob75a, Thm. 3] (also see [Rob77, Lemma 3] for a simpler version of the result) which uses the Slater condition to characterize solvability of the system $Ax \leq a$ under local perturbations on A and a.

LEMMA 3.2. *For any $m \times n$ matrix A and m-vector a, the following conditions are equivalent.*

(a) *The system $Ax \leq a$ is regular (i.e., there exists an x with $Ax < a$).*

(b) *There exists a scalar $\delta > 0$ such that for any (A', a') with $\|(A', a') - (A, a)\| < \delta$, the system $A'x \leq a'$ is solvable.*

By combining Lemma 3.2 with Theorems 2.4 and 3.1, we obtain the second main result of this section, characterizing when the system $Ax \leq a$ is well-conditioned under local perturbations on A and a.

THEOREM 3.3 (*Well-conditionedness under local perturbations*). *For any $m \times n$ matrix A and any m-vector a, the following conditions are equivalent.*

(a) *Either $Ax < 0$ is solvable or $Ax \leq a$ is regular and has a bounded solution set.*

(b) *There exist scalars $\delta > 0$ and $\beta > 0$ such that for any (A', a') with $\|(A', a') - (A, a)\| < \delta$, the system $A'x \leq a'$ is solvable and $\tau(A', a') \leq \beta$.*

Proof. (a) $\Rightarrow$ (b). Suppose that condition (a) holds. If $Ax < 0$ is solvable, then condition (b) holds by Theorem 3.1. Otherwise, suppose that $Ax \leq a$ is regular and has a bounded solution set. Let $\bar{x}$ be any n-vector satisfying $A\bar{x} < a$. We now verify that condition (a) in Theorem 2.4 holds. Since $Ax \leq a$ has a bounded solution set, it suffices to verify that, for each nonempty $I \subseteq \{1, \ldots, m\}$ such that $Ax \leq a$, $A_I x = a_I$ is solvable, we have that $A_I x < 0$ is solvable. For any such I and any x satisfying $A_I x = a_I$, we have $A_I(\bar{x} - x) < 0$, so $A_I x < 0$ is solvable. Hence condition (a) in Theorem 2.4 holds. Then, by Theorem 2.4, there exist scalars $\delta_1 > 0$ and $\beta > 0$ such that for any (A', a') with $\|(A', a') - (A, a)\| < \delta_1$ and $A'x \leq a'$ solvable, we have $\tau(A', a') \leq \beta$. Since $Ax < a$ is regular, Lemma 3.2 implies that there is a scalar $\delta_2 > 0$ such that $A'x \leq a'$ is solvable for all (A', a') with $\|(A', a') - (A, a)\| < \delta_2$. Take δ to be the minimum of δ_1 and δ_2.

(b) $\Rightarrow$ (a). Suppose that condition (a) does not hold, so $Ax < 0$ is not solvable and the system $Ax \leq a$ either is not regular or has an unbounded solution set. If $Ax \leq a$ is not regular, then condition (b) cannot hold by Lemma 3.2. Thus, it suffices to show that, when $Ax \leq a$ is regular and has an unbounded solution set, condition (b) cannot hold. Let z be any nonzero n-vector satisfying $Az \leq 0$. Since $Ax < 0$ is not solvable, we have, via the Farkas Lemma, that there exists a nonzero m-vector $\theta \geq 0$ with $A^T\theta = 0$. Let I denote the set of indices i for which $\theta_i > 0$. Since $0 = \langle z, A^T\theta \rangle = \langle A_I z, \theta_I \rangle$, we obtain from $A_I z \leq 0$ and $\theta_I > 0$ that $A_I z = 0$, so A_I lacks full column rank. In addition, since $(A_I)^T\theta_I = 0$, the Farkas Lemma states that $A_I x < 0$ is not solvable. Thus, we have found a nonempty $I \subseteq \{1, \ldots, m\}$ such that $Ax \leq 0$, $A_I x = 0$ has a nonzero solution but $A_I x < 0$ is not solvable and A_I lacks full column rank. Then, condition (a) in Theorem 2.4 does not hold, so, by Theorem 2.4, condition (b) therein does not hold. Since the system $Ax \leq a$ is regular so, by Lemma 3.2, condition (b) in Theorem 2.4 holds if and only if condition (b) holds, this shows that condition (b) cannot hold. □

We close this section with a comparison of the characterization of well-conditionedness under feasible perturbations on the problem data (condition (a) in Theorems 2.2 and 2.4) and under arbitrary perturbations on the problem data (condition (a) in Theorems 3.1 and 3.3). Clearly, if condition (a) in Theorem 3.1 (respectively, Theorem 3.3) holds, then condition (a) in Theorem 2.2 (respectively, Theorem 2.4) holds. Surprisingly, the converse also holds for certain linear systems. In particular, if the system $Ax \leq 0$ has a nonzero solution, then Proposition 2.3 shows that condition (a) in Theorem 2.2 holds if and only if condition (a) in Theorem 3.1 holds. In

other words, a system of linear inequalities having an unbounded solution set is well-conditioned under arbitrary semilocal perturbations on the problem data if and only if it is well-conditioned under feasible semilocal perturbations on the problem data. Similarly, if the system $Ax \leq a$ has multiple solutions, then Proposition 2.5 shows that condition (a) in Theorem 2.4 holds if and only if condition (b) in Theorem 3.3 holds. In other words, for a system of linear inequalities having multiple solutions, the release of the feasibility restriction on the local perturbations does not affect whether the system is well-conditioned.

4. Relation to uniform boundedness of vertex solutions. As was pointed out in §1, the Hoffman condition number $\tau(A, a)$ may be interpreted as a measure of the "sharpness" of the corners (or, more formally, the tangent cones) of the solution set for $Ax \leq a$. Thus, the well-conditionedness of the system $Ax \leq a$ may be interpreted geometrically as a uniform boundedness condition on the sharpness of the corners of its solution set (under perturbations on A and a). What other geometrical conditions are related to well-conditionedness? J.-S. Pang [Pan91] conjectured that the uniform boundedness of the vertex solutions may be one such condition. Intuitively, Pang's conjecture is reasonable since, in the case where the solution set is full dimensional, a corner can be unbounded in sharpness only if its vertex is unbounded. In this section, we verify that the preceding intuition is essentially sound. In particular, we show, by using Theorem 3.3, that Pang's uniform boundedness of vertices condition, together with some mild assumptions on the system, implies the well-conditionedness of the system under local perturbations on the problem data. On the other hand, we show that the implication does not go in the other direction and we indicate exactly where the failure occurs.

We say that a system $Ax \leq a$ satisfies the *uniform boundedness of the vertex solutions* (u.b.v.) condition if there exist scalars $\delta > 0$ and $\beta > 0$ such that, for any (A', a') with $\|(A', a') - (A, a)\| < \delta$, the vertices of $P(A', a')$, if any exist, all have Euclidean norm less than β. Notice that $Ax \leq a$ need not have a vertex solution to satisfy the u.b.v. condition, so long as none of the vertex solutions created by perturbation goes off to infinity.

The u.b.v. condition may be viewed as an alternative criterion for a system of linear inequalities to be well-conditioned in a variational sense. This condition, as defined above, is geometrical in description. Below we give an equivalent algebraic description of this condition which, coupled with Theorem 3.3, will enable us to show that the u.b.v. condition, together with some mild assumptions on the system, implies the well-conditionedness of the system $Ax \leq a$ under local perturbations on A and a.

THEOREM 4.1. *For any $m \times n$ matrix A and any m-vector a such that the system $Ax \leq a$ is regular and has a vertex solution, the following conditions are equivalent.*

(a) *There exists a nonzero n-vector z such that $Az \leq 0$ and the rows of A_I are linearly dependent, where $I = \{\, i \in \{1, \ldots, m\} \mid A_i z = 0 \,\}$.*

(b) *$Ax \leq a$ does not satisfy the u.b.v. condition.*

Proof. (b) $\Rightarrow$ (a). Suppose that condition (b) holds. Then, there exists a sequence $A^1, A^2, \ldots$ converging to A, a sequence $a^1, a^2, \ldots$ converging to a, and a sequence $x^1, x^2, \ldots$ with $\|x^r\| \to \infty$ and x^r being a vertex of $P(A^r, a^r)$ for all r. Thus, $A^r x^r \leq a^r$ for all r and, by passing into a subsequence if necessary, we can assume that there is a nonempty $I \subseteq \{1, \ldots, m\}$ of size at least n such that $A^r_I x^r = a^r_I$ for all r. This together with $\|x^r\| \to \infty$ implies

$$\limsup_{r \to \infty} \frac{A^r x^r}{\|x^r\|} \leq 0, \qquad \lim_{r \to \infty} \frac{A^r_I x^r}{\|x^r\|} = 0,$$

so, upon letting z be any cluster point of $\{x^r/\|x^r\|\}$ and using $A^r \to A$, we obtain $Az \leq 0$ and $A_I z = 0$. Since $z \neq 0$, A_I must have rank strictly less than n. Since A_I has at least n rows, this implies the rows must be linearly dependent.

(a) $\Rightarrow$ (b). Suppose that condition (a) holds, so there exists a nonzero n-vector z such that $Az \leq 0$ and the rows of A_I are linearly dependent, where $I = \{\, i \in \{1,\ldots,m\} \mid A_i z = 0 \,\}$. First, we claim that we can, without loss of generality, assume that A_I has a rank of exactly $n-1$ (so $|I| \geq n$). We argue this constructively. Since $Ax \leq a$ has a vertex solution, the polyhedral cone $\{\, x \in \Re^n \mid Ax \leq 0 \,\}$ cannot contain a straight line. Thus, this cone can be generated by a finite number of extreme rays, which we denote by $z^1,\ldots,z^k$ (see [Sch86, §8.8]). Since z clearly belongs to this cone, we can express it as $z = \sum_{i=1}^k \theta_i z^i$, for some nonnegative scalars $\theta_1,\ldots,\theta_k$, not all zero. Fix any index j with $\theta_j > 0$. Then, $0 = A_I z = \sum_{i=1}^k \theta_i A_I z^i \leq \theta_j A_I z^j \leq 0$, so that $A_I z^j = 0$. Let J denote the set of indices i for which $A_i z^j = 0$. Then, $I \subseteq J$. Since z^j is an extreme ray, the rank of A_J is exactly $n-1$ (see [Sch86, §8.7]). Now replace z by z^j and I by J.

Normalizing if necessary, we will assume that $\|z\| = 1$. Also, since $Ax \leq a$ is regular, there exists an n-vector $\bar{x}$ with $A\bar{x} < a$. Finally, since the rows of A_I are linearly dependent, there exist an index $j \in I$ and scalars γ_i, $i \in I$ with $i \neq j$, such that

$$A_j = \sum_{i \in I, i \neq j} \gamma_i A_i. \tag{4.1}$$

Then, we perturb A and a almost exactly as in the proof of Theorem 2.4 with z, $\bar{x}$, and I as given above, except for a slight difference in the jth row. More precisely, let b be given by (2.10) and, for each scalar $\epsilon > 0$ with $1/\epsilon > \langle z, \bar{x}\rangle$, we define x^ϵ by (2.12)–(2.13) and A^ϵ and a^ϵ by

$$A^\epsilon = A + \epsilon b z^T + \epsilon^2 e^j z^T, \qquad a^\epsilon = a + \epsilon e^j, \tag{4.2}$$

where e^j denotes the m-vector whose jth component is 1 and whose other components are all 0. Then, it is readily seen that, as $\epsilon \to 0$, we have $A^\epsilon \to A$, $a^\epsilon \to a$ and (cf. (2.12) and (2.13)) $\|x^\epsilon\| \to \infty$. Thus it only remains to show that x^ϵ is a vertex solution of $A^\epsilon x \leq a^\epsilon$ for all $\epsilon > 0$ sufficiently small. Now, it can be verified by following the proof of Theorem 2.4 (compare with (2.14)) that

$$A^\epsilon_I x^\epsilon = a^\epsilon_I, \qquad A^\epsilon_{\tilde{I}} x^\epsilon \leq a^\epsilon_{\tilde{I}}$$

for all $\epsilon > 0$, so it suffices to show that A^ϵ_I has rank n for all $\epsilon > 0$ sufficiently small. It is straightforward to verify, using (4.1) and (4.2), that

$$A^\epsilon_j - \sum_{i \in I, i \neq j} \gamma_i A^\epsilon_i = \epsilon \left[\epsilon + \left(b_j - \sum_{i \in I, i \neq j} \gamma_i b_i \right) \right] z^T$$

for all $\epsilon > 0$. Since the quantity inside the brackets is nonzero for all ϵ sufficiently small, this implies that z^T is in the space spanned by the rows of A^ϵ_I for all $\epsilon > 0$ sufficiently small. Since A^ϵ_I is obtained from A_I by adding to every row some scalar multiple of z^T (cf. (4.2)), this implies that the rows of A_I are also in the space spanned by the rows of A^ϵ_I for all $\epsilon > 0$ sufficiently small. Since the rows of A_I together with z^T have rank n, this completes the proof. □

Combining Theorems 3.3 and 4.1, we obtain the following corollary showing that the u.b.v. condition, together with regularity and the existence of a vertex solution, implies the well-conditionedness of the system $Ax \leq a$ under local perturbations on A and a.

COROLLARY 4.2. *For any $m \times n$ matrix A and any m-vector a, if the system $Ax \leq a$ is regular, has a vertex solution, and satisfies the u.b.v. condition, then condition* (b) *in Theorem* 3.3 *holds.*

Proof. Since $Ax \leq a$ is regular, by Theorem 3.3, it suffices to show that either there exists an n-vector x with $Ax < 0$ or there does not exist a nonzero n-vector z with $Az \leq 0$. We argue by contradiction. Suppose the contrary, so there exists a nonzero m-vector $\theta \geq 0$ with $A^T\theta = 0$ (cf. the Farkas Lemma) and a nonzero n-vector z with $Az \leq 0$. Let I denote the set of indices i with $\theta_i > 0$. Since $0 = \langle z, A^T\theta \rangle = \langle A_I z, \theta_I \rangle$, we obtain from $A_I z \leq 0$ and $\theta_I > 0$ that $A_I z = 0$. Also, since $(A_I)^T\theta = 0$, the rows of A_I are linearly dependent. Then, by Theorem 4.1, the system $Ax \leq a$ does not satisfy the u.b.v. condition, a contradiction. □

Theorem 4.1 and Corollary 4.2 help to pinpoint where the u.b.v. condition fails to be necessary for the well-conditionedness of the system $Ax \leq a$ under local perturbations on A and a. First, this system can be well-conditioned under such perturbations without having a vertex solution. (Consider the system $x_1 + 0 \cdot x_2 \leq 0$.) Second, even when this system is regular and has a vertex solution, it can be well-conditioned under such perturbations without satisfying the u.b.v. condition. From Theorems 3.3 and 4.1 we see that this would happen precisely when, for every z specified by condition (a) in Theorem 4.1, the rows of A_I fail to contain the origin in their convex hull, where $I = \{ i \in \{1, \ldots, m\} \mid A_i z = 0 \}$. An example of such a system is $x_1 \leq 1,\ x_1 \leq 0,\ x_2 \leq 0$.

5. Systems with equalities and inequalities. In this section, we extend the results of previous sections to linear systems in which equalities are also present. In particular, we consider a system of the form

$$Ax \leq a, \quad Bx = b, \tag{5.1}$$

where A is an $m \times n$ matrix ($m \geq 1,\ n \geq 1$), B is an $l \times n$ matrix ($l \geq 1$), a is an m-vector and b is an l-vector. Accordingly, we let

$$P(A, B, a, b) = \{ x \in \Re^n \mid Ax \leq a, Bx = b \},$$

and define the Hoffman condition number for (5.1) as the quantity

$$\tau(A, B, a, b) = \sup_{x \notin P(A,B,a,b)} \frac{d(x, P(A, B, a, b))}{\left\| \begin{matrix} [Ax - a]_+ \\ Bx - b \end{matrix} \right\|}, \tag{5.2}$$

whenever $P(A, B, a, b)$ is nonempty. Analogous to the case when only linear inequalities are present, we are interested in finding necessary and sufficient conditions for (5.1) to be well-conditioned (or, equivalently, $\tau(A, B, a, b)$ to be uniformly bounded) under a given set of perturbations on A, B, a, and b. We show below that the results from the previous sections extend in a fairly straightforward manner to this general situation.

The idea of our analysis is to reduce the system (5.1) to one without linear equalities, at which time the results of §§2 and 3 can be applied. To motivate our

reduction, suppose that B has full row rank. It will turn out that, excepting some simple cases, this is a necessary assumption for well-conditionedness (see Lemma 5.2 and the proof of Theorem 5.5). Then, by rearranging columns if necessary, we can write

$$A = [A_r \quad A_s], \qquad B = [B_r \quad B_s], \tag{5.3}$$

for some matrices A_r, A_s, B_r, and B_s with B_r invertible. We partition

$$x = \begin{bmatrix} x_r \\ x_s \end{bmatrix},$$

accordingly. Then, by using equation $Bx = b$ to eliminate x_r, we see that an $\bar{x}$ solves the system (5.1) if and only if $\bar{x}_s$ solves the reduced system

$$(A_s - A_r(B_r)^{-1}B_s)x_s \leq a - A_r(B_r)^{-1}b, \tag{5.4}$$

and $\bar{x}_r = (B_r)^{-1}(b - B_s\bar{x}_s)$. Below we show that regularity conditions and the Hoffman condition number for the two systems (5.1) and (5.4) are intimately related. By exploiting this relationship, we can then extend the results of §§2 and 3 to the general system (5.1).

LEMMA 5.1. *Consider any $m \times n$ matrix A and any $l \times n$ matrix B with full row rank. Partition A and B according to* (5.3) *with B_r invertible. Let $\bar{A} = A_s - A_r(B_r)^{-1}B_s$ and $\bar{a} = a - A_r(B_r)^{-1}b$. Then, the following results hold.*

(a) *For any m-vector a and l-vector b and any (possibly empty) index set $I \subseteq \{1, \ldots, m\}$, the system $Ax \leq a$, $A_I x = a_I$, $Bx = b$ has a solution if and only if the system $\bar{A}x_s \leq \bar{a}$, $\bar{A}_I x_s = \bar{a}_I$ has a solution. The same holds when all inequalities are replaced by strict inequalities.*

(b) *For any (possibly empty) index set $I \subseteq \{1, \ldots, m\}$, the system $Ax \leq 0$, $A_I x = 0$, $Bx = 0$ has a nonzero solution if and only if the reduced system $\bar{A}x_s \leq 0$, $\bar{A}_I x_s = 0$ has a nonzero solution.*

(c) *For any (possibly empty) index set $I \subseteq \{1, \ldots, m\}$, the system $A_I x < 0$, $Bx = 0$ has a solution if and only if the reduced system $\bar{A}_I x_s < 0$ has a solution.*

(d) *For any (possibly empty) index set $I \subseteq \{1, \ldots, m\}$, the matrix*

$$\begin{bmatrix} A_I \\ B \end{bmatrix}$$

has full column rank if and only if $\bar{A}_I$ has full column rank.

(e) *There holds*

$$\frac{1}{\|(B_r)^{-1}B_s\| + 1}\left[\frac{\tau(A, B, a, b)}{2(1 + \|A_r(B_r)^{-1}\|)} - \|(B_r)^{-1}\|\right] \leq \tau(\bar{A}, \bar{a}) \leq \tau(A, B, a, b). \tag{5.5}$$

Proof. (a) It is easily verified using (5.3) and the definition of $\bar{A}$ and $\bar{a}$ that the vector

$$\begin{bmatrix} \bar{x}_r \\ \bar{x}_s \end{bmatrix}$$

solves the system $Ax \leq a$, $A_I x = a_I$, $Bx = b$ if and only if $\bar{x}_s$ solves the system $\bar{A}x_s \leq \bar{a}$, $\bar{A}_I x_s = \bar{a}_I$, and $\bar{x}_r = (B_r)^{-1}(b - B_s\bar{x}_s)$. The same argument applies when the inequalities in the systems are all replaced by strict inequalities.

(b) and (c) The argument is entirely analogous to that for part (a).

(d) It is easily seen using (5.3) and the definition of $\bar{A}$ that the vector

$$\begin{bmatrix} \bar{x}_r \\ \bar{x}_s \end{bmatrix}$$

solves the system $A_I x = 0$, $Bx = 0$ if and only if $\bar{x}_s$ solves the system $\bar{A}_I x_s = 0$ and $\bar{x}_r = -(B_r)^{-1}B_s\bar{x}_s$. Thus, one system has a nonzero solution if and only if the other does.

(e) Fix any n-vector

$$x = \begin{bmatrix} x_r \\ x_s \end{bmatrix} \notin P(A, B, a, b).$$

By letting $\bar{x}_s$ be the element of $P(\bar{A}, \bar{a})$ nearest to x_s and using the fact that

$$\begin{bmatrix} (B_r)^{-1}(b - B_s\bar{x}_s) \\ \bar{x}_s \end{bmatrix}$$

solves $Ax \leq a, Bx = b$, we obtain

$$\begin{aligned} d(x, P(A, B, a, b)) &\leq \left\| \begin{matrix} x_r - (B_r)^{-1}(b - B_s\bar{x}_s) \\ x_s - \bar{x}_s \end{matrix} \right\| \\ &= \left\| \begin{matrix} (B_r)^{-1}(Bx - b + B_s(\bar{x}_s - x_s)) \\ x_s - \bar{x}_s \end{matrix} \right\| \\ &\leq \|(B_r)^{-1}\|\|Bx - b\| + (\|(B_r)^{-1}B_s\| + 1)\|\bar{x}_s - x_s\| \\ &= \|(B_r)^{-1}\|\|Bx - b\| + (\|(B_r)^{-1}B_s\| + 1)d(x_s, P(\bar{A}, \bar{a})). \end{aligned} \tag{5.6}$$

Also, simple algebra using (5.3) gives

$$Ax - a + A_r(B_r)^{-1}(b - Bx) = (A_s - A_r(B_r)^{-1}B_s)x_s - (a - A_r(B_r)^{-1}b) = \bar{A}x_s - \bar{a},$$

so that

$$\begin{aligned} \|[\bar{A}x_s - \bar{a}]_+\| &= \|[Ax - a + A_r(B_r)^{-1}(b - Bx)]_+\| \\ &\leq \|[Ax - a]_+\| + \|A_r(B_r)^{-1}\|\|Bx - b\|. \end{aligned}$$

Adding $\|Bx - b\|$ to both sides and using the fact $\|\alpha\| + \|\beta\| \leq \sqrt{2}\left\|\begin{matrix}\alpha \\ \beta\end{matrix}\right\|$ for any two vectors α and β, we obtain

$$\|Bx - b\| + \|[\bar{A}x_s - \bar{a}]_+\| \leq \sqrt{2}(1 + \|A_r(B_r)^{-1}\|) \left\| \begin{matrix} [Ax - a]_+ \\ Bx - b \end{matrix} \right\|. \tag{5.7}$$

Dividing the left-hand side of (5.6) by the right-hand side of (5.7) and then using (5.6), (5.7), and the fact $(\alpha\chi+\beta)/(\chi+\delta) \le \alpha+\beta/\delta$ for any four nonnegative scalars $\alpha, \beta, \chi, \delta$ such that the two fractions are defined (with the convention $0/0 = 0$), we obtain

$$\frac{1}{2(1+\|A_r(B_r)^{-1}\|)} \frac{d(x, P(A,B,a,b))}{\left\| \begin{bmatrix} [Ax-a]_+ \\ Bx-b \end{bmatrix} \right\|} \le \|(B_r)^{-1}\| + (\|(B_r)^{-1}B_s\|+1) \frac{d(x_s, P(\bar{A},\bar{a}))}{\|[\bar{A}x_s - \bar{a}]_+\|}.$$

The choice of x above was arbitrary, so the above relation holds for all $x \notin P(A,B,a,b)$. Taking the supremum of both sides over all $x \notin P(A,B,a,b)$ and observing that the x_s corresponding to x is not in $P(\bar{A},\bar{a})$, we obtain (cf. (1.1) and (5.2))

$$\frac{\tau(A,B,a,b)}{2(1+\|A_r(B_r)^{-1}\|)} \le \|(B_r)^{-1}\| + (\|(B_r)^{-1}B_s\|+1)\tau(\bar{A},\bar{a}).$$

Rearranging terms and the first inequality in (5.5) is proved.

To prove the second inequality in (5.5), fix any $x_s \notin P(\bar{A},\bar{a})$. By letting $\bar{x}$ be the element of $P(A,B,a,b)$ nearest to

$$x = \begin{bmatrix} (B_r)^{-1}(b - B_s x_s) \\ x_s \end{bmatrix}$$

and observing that $\bar{x}_s$ solves (5.4) so it is in $P(\bar{A},\bar{a})$, we obtain

$$d(x_s, P(\bar{A},\bar{a})) \le \|x_s - \bar{x}_s\| \le \|x - \bar{x}\| = d(x, P(A,B,a,b)). \tag{5.8}$$

Also, using the definition of x and (5.3), we have $Bx = b$ so

$$\left\| \begin{bmatrix} [Ax-a]_+ \\ Bx-b \end{bmatrix} \right\| = \|[Ax-a]_+\|$$

$$= \|[(A_s - A_r(B_r)^{-1}B_s)x_s - (a - A_r(B_r)^{-1}b)]_+\| \tag{5.9}$$

$$= \|[\bar{A}x_s - \bar{a}]_+\|. \tag{5.10}$$

Dividing the left-hand side of (5.8) by the right-hand side of (5.10), we obtain

$$\frac{d(x_s, P(\bar{A},\bar{a}))}{\|[\bar{A}x_s - \bar{a}]_+\|} \le \frac{d(x, P(A,B,a,b))}{\left\| \begin{bmatrix} [Ax-a]_+ \\ Bx-b \end{bmatrix} \right\|}.$$

The choice of x_s above was arbitrary, so the above relation holds for all $x_s \notin P(\bar{A},\bar{a})$. Taking the supremum of both sides over all $x_s \notin P(\bar{A},\bar{a})$ and observing that the x corresponding to x_s is not in $P(A,B,a,b)$, we obtain (cf. (1.1) and (5.2))

$$\tau(\bar{A},\bar{a}) \le \tau(A,B,a,b).$$

This proves the second inequality in (5.5). □

5.1. Well-conditionedness under feasible perturbations. Lemma 5.1, though essential to our analysis, covers only the case where B has full row rank. We need in addition the following lemma to cover the case where B lacks full row rank. According to this lemma, that B has either full row rank or full column rank is a necessary condition for the system (5.1) to be well-conditioned under feasible local perturbations on the problem data. The proof of this is patterned after that of (b) $\Rightarrow$ (a) in Theorem 2.2.

LEMMA 5.2. *Suppose that the system $Ax \leq a, Bx = b$ has a solution. For there to exist scalars $\delta > 0$ and $\beta > 0$ such that $\tau(A', B', a', b') \leq \beta$ for all (A', a') and (B', b') with $\|(A', a') - (A, a)\| + \|(B', b') - (B, b)\| < \delta$ and $A'x \leq a', B'x = b'$ solvable, it is necessary that B has either full row rank or full column rank.*

Proof. Suppose that B has neither full row rank nor full column rank. We will show that there cannot exist any scalars $\delta > 0$ and $\beta > 0$ with the stated properties.

Since B lacks full row rank and full column rank, there exist a nonzero l-vector θ and a nonzero n-vector z satisfying $B^T\theta = 0$ and $Bz = 0$. Normalizing if necessary, we will assume that $\|\theta\| = \|z\| = 1$. Let $\bar{x}$ be any solution of the system $Ax \leq a, Bx = b$ and let I denote the set of indices i for which $A_i\bar{x} = a_i$. Then, $A_I\bar{x} = a_I$, $A_{\tilde{I}}\bar{x} < a_{\tilde{I}}$ and $B\bar{x} = b$, where $\tilde{I}$ denotes the complement of I relative to $\{1, \ldots, m\}$. By reordering the rows of A and a if necessary, we can assume that

$$A = \begin{bmatrix} A_I \\ A_{\tilde{I}} \end{bmatrix}, \qquad a = \begin{bmatrix} a_I \\ a_{\tilde{I}} \end{bmatrix}.$$

For each scalar $\epsilon > 0$, we define the perturbed right-hand side a^ϵ by

$$a_I^\epsilon = a_I + 2\epsilon[A_I z]_+, \qquad a_{\tilde{I}}^\epsilon = a_{\tilde{I}},$$

and, similarly, we define

$$B^\epsilon = B + \epsilon\theta z^T, \qquad b^\epsilon = b + \epsilon(\langle \bar{x}, z\rangle + \epsilon)\theta.$$

Clearly, $B^\epsilon \to B$, $a^\epsilon \to a$ and $b^\epsilon \to b$ as $\epsilon \to 0$. Let $x^\epsilon = \bar{x} + \epsilon z$. Then,

$$A_I x^\epsilon = A_I\bar{x} + \epsilon A_I z \leq a_I + 2\epsilon[A_I z]_+ = a_I^\epsilon \tag{5.11}$$

and, for ϵ sufficiently small,

$$A_{\tilde{I}} x^\epsilon = A_{\tilde{I}}\bar{x} + \epsilon A_{\tilde{I}} z < a_{\tilde{I}}. \tag{5.12}$$

By a similar calculation, we also have that $B^\epsilon x^\epsilon = b^\epsilon$. Thus, the vector x^ϵ belongs to $P(A, B^\epsilon, a^\epsilon, b^\epsilon)$ for all ϵ sufficiently small. Finally, we have from $(B^\epsilon)^T\theta = (B + \epsilon\theta z^T)^T\theta = \epsilon z$ that z is a linear combination of the columns of $(B^\epsilon)^T$, which, together with (5.11) and (5.12), implies that z is a normal to the polyhedral set $P(A, B^\epsilon, a^\epsilon, b^\epsilon)$ at x^ϵ, for all ϵ sufficiently small. Then, if we move along the direction z from x^ϵ and then project back onto this set, we always get x^ϵ. In particular, the projection of $x^\epsilon + \epsilon z$ onto $P(A, B^\epsilon, a^\epsilon, b^\epsilon)$ is x^ϵ, so that

$$d(x^\epsilon + \epsilon z, P(A, B^\epsilon, a^\epsilon, b^\epsilon)) = \|\epsilon z\|.$$

By a calculation similar to that used in (5.11) and (5.12), we see that $A(x^\epsilon + \epsilon z) \leq a^\epsilon$ for all ϵ sufficiently small, in which case $[A(x^\epsilon + \epsilon z) - a^\epsilon]_+ = 0$. Also, we have from

$Bz = 0$ and $\|z\| = 1$ that $B^\epsilon(x^\epsilon + \epsilon z) = b^\epsilon + \epsilon^2\theta$. Combining these two results with the relation above and using $\|z\| = \|\theta\| = 1$, we obtain

$$\frac{d(x^\epsilon + \epsilon z, P(A, B^\epsilon, a^\epsilon, b^\epsilon))}{\left\| \begin{matrix} [A(x^\epsilon + \epsilon z) - a^\epsilon]_+ \\ B^\epsilon(x^\epsilon + \epsilon z) - b^\epsilon \end{matrix} \right\|} = \frac{\|\epsilon z\|}{\|\epsilon^2\theta\|} = \frac{1}{\epsilon},$$

for all ϵ sufficiently small. By (5.2), the left-hand side in the above relation is bounded above by $\tau(A, B^\epsilon, a^\epsilon, b^\epsilon)$. Thus, $\tau(A, B^\epsilon, a^\epsilon, b^\epsilon) \geq 1/\epsilon \to \infty$ as $\epsilon \to 0$. □

By combining Lemmas 5.1 and 5.2 with Theorem 2.2, we obtain the first main result of this section, which may be viewed as an extension of Theorem 2.2 to the general system (5.1).

THEOREM 5.3 (*Well-conditionedness under feasible semilocal perturbations*). *For any $m \times n$ matrix A and any $l \times n$ matrix B, the following conditions are equivalent.*

(a) *B has either full column rank or full row rank and, if B has full row rank, then, for each nonempty index set $I \subseteq \{1, \ldots, m\}$, we have that either $A_I x < 0$, $Bx = 0$ is solvable or*

$$\begin{bmatrix} A_I \\ B \end{bmatrix}$$

has full column rank.

(b) *There exist scalars $\delta > 0$ and $\beta > 0$ such that, for any (A', a') and (B', b') with $\|A' - A\| + \|B' - B\| < \delta$ and $A'x \leq a'$, $B'x = b'$ solvable, we have $\tau(A', B', a', b') \leq \beta$.*

Proof. We consider two separate cases. First, suppose that B has full row rank. Partition A and B according to (5.3) with B_r invertible, and let $\bar{A} = A_s - A_r(B_r)^{-1}B_s$. Then, the following statements are equivalent.

Condition (a) holds $\iff$ $\bar{A}$ satisfies condition (a) in Theorem 2.2, (by Lemma 5.1(c)–(d)),
$\iff$ $\tau(\bar{A}, \bar{a})$ is uniformly bounded under feasible local perturbations on $\bar{A}$ and feasible global perturbations on $\bar{a}$, (by Theorem 2.2),
$\iff$ $\tau(A, B, a, b)$ is uniformly bounded under feasible local perturbations on A, B and feasible global perturbations on a, b, (by Lemma 5.1(e)),
$\iff$ condition (b) holds.

The third equivalence also uses the observation that any feasible local perturbation on $\bar{A}$ and feasible global perturbation on $\bar{a}$ translates into a feasible local perturbation on A, B and a feasible global perturbation on a, b (more precisely, we associate with each perturbed version of $\bar{A}$ and $\bar{a}$, say $\bar{A}'$ and $\bar{a}'$, the following perturbed versions of A, B, a, b respectively: $A' = [\, A_r \quad A_s + (\bar{A}' - \bar{A})\,]$, $B' = B$, $a' = a + (\bar{a}' - \bar{a})$, and $b' = b$); and vice versa. Second, suppose that B lacks full row rank. If condition (b) holds, then, by Lemma 5.2, B must have full column rank. Conversely, if B has full column rank, then, upon letting I be any nonempty subset of $\{1, \ldots, l\}$ with B_I invertible, we see that $P(A, B, a, b)$ comprises the single point $(B_I)^{-1}b_I$ whenever it

is nonempty, in which case

$$d(x, P(A,B,a,b)) = \|x - (B_I)^{-1}b_I\| \leq \|(B_I)^{-1}\|\|Bx - b\| \quad \forall x.$$

This implies $\tau(A,B,a,b) \leq \|(B_I)^{-1}\|$ (cf. (5.2)), so $\tau(A,B,a,b)$ is uniformly bounded under feasible local perturbations on A,B and feasible global perturbations on a,b. □

Analogous to Proposition 2.3, in the case where the system (5.1) has an unbounded solution set, condition (a) in Theorem 5.3 simplifies to: B has full row rank and the system $Ax < 0$, $Bx = 0$ has a solution. For brevity, we omit the proof.

By combining Lemmas 5.1 and 5.2 with Theorem 2.4, we obtain the second main result of this section, which may be viewed as an extension of Theorem 2.2 to the general system (5.1).

THEOREM 5.4 (*Well-conditionedness under feasible local perturbations*). *For any $m \times n$ matrix A and any $l \times n$ matrix B such that the system $Ax \leq a$, $Bx = b$ is solvable, the following conditions are equivalent.*

(a) *B has either full column rank or full row rank and, if B has full row rank, then, for each nonempty index set $I \subseteq \{1,\ldots,m\}$ such that either $Ax \leq a$, $A_I x = a_I$, $Bx = b$ or $Ax \leq 0$, $A_I x = 0$, $Bx = 0$, $x \neq 0$ is solvable, we have that either $A_I x < 0$, $Bx = 0$ is solvable or*

$$\begin{bmatrix} A_I \\ B \end{bmatrix}$$

has full column rank.

(b) *There exist scalars $\delta > 0$ and $\beta > 0$ such that for any (A',a') and (B',b') with $\|(A',a') - (A,a)\| + \|(B',b') - (B,b)\| < \delta$ and $A'x \leq a', B'x = b'$ solvable, we have $\tau(A',B',a',b') \leq \beta$.*

Proof. The proof is essentially identical to that of Theorem 5.3, except that "feasible global perturbations," "Theorem 2.2," and "Lemma 5.1(c)–(d)" are replaced by, respectively, "feasible local perturbations," "Theorem 2.4," and "Lemma 5.1(a)–(d)." □

Analogous to Proposition 2.5, in the case where the system (5.1) has multiple solutions, condition (a) in Theorem 5.4 simplifies to: either B has full row rank and the system $Ax < 0$, $Bx = 0$ is solvable or the system (5.1) is regular (i.e., B has full row rank and $Ax < a$, $Bx = b$ is solvable) and has a bounded solution set. In the case where (5.1) has a unique solution, this condition can again be simplified as in Proposition 2.6, albeit only slightly.

5.2. Well-conditionedness under arbitrary perturbations. By combining Lemma 5.1 with Theorem 3.1, the third main result of this section, which may be viewed as an extension of Theorem 3.1 to the general system (5.1), readily follows.

THEOREM 5.5 (*Well-conditionedness under semilocal perturbations*). *For any $m \times n$ matrix A and any $l \times n$ matrix B, the following conditions are equivalent.*

(a) *B has full row rank and the system $Ax < 0$, $Bx = 0$ is solvable.*

(b) *There exist scalars $\delta > 0$ and $\beta > 0$ such that for any (A',a') and (B',b') with $\|A'-A\|+\|B'-B\| < \delta$, the system $A'x \leq a', B'x = b'$ is solvable and $\tau(A',B',a',b') \leq \beta$.*

Proof. First, suppose that B has full row rank. Then, by applying the argument used in the proof of Theorem 5.3 with the word "feasible" removed and with

"Theorem 2.2" and "Lemma 5.1(c)–(d)" replaced by, respectively, "Theorem 3.1" and "Lemma 5.1(c) with $I = \{1, \ldots, m\}$," we see that condition (a) holds if and only if condition (b) holds. Second, suppose that B lacks full row rank. Then, there is some l-vector b' for which $Bx = b'$ has no solution, so that $Ax \leq a', Bx = b'$ has no solution for any m-vector a'. Hence, both conditions (a) and (b) fail to hold. □

As with Theorem 3.1, the (a) ⇒ (b) part of Theorem 5.5 is not new (see [Bra88, Thm. 5.4.13]) and is included for completeness only. Also, we note in passing that condition (a) in Theorem 5.5 is simply the Mangasarian–Fromovitz constraint qualification condition applied to the system (5.1) (see [MaF67]). This shows yet another application of this well-known constraint qualification condition.

By combining Lemma 5.1 with Theorem 3.3, we obtain the fourth main result of this section, which may be viewed as an extension of Theorem 3.3 to the general system (5.1).

THEOREM 5.6 (*Well-conditionedness under local perturbations*). *For any $m \times n$ matrix A, any $l \times n$ matrix B, any m-vector a and l-vector b, the following conditions are equivalent.*

(a) *Either B has full row rank and the system $Ax < 0$, $Bx = 0$ is solvable or the system* (5.1) *is regular and has a bounded solution set.*

(b) *There exist scalars $\delta > 0$ and $\beta > 0$ such that for any (A', a') and (B', b') with $\|(A', a') - (A, a)\| + \|(B', b') - (B, b)\| < \delta$, the system $A'x \leq a', B'x = b'$ is solvable and $\tau(A', B', a', b') \leq \beta$.*

Proof. The proof is essentially identical to that of Theorem 5.5, except that "global perturbations," "Theorem 3.1" and "Lemma 5.1(c)" are replaced by, respectively, "local perturbations," "Theorem 3.3," and "Lemma 5.1(a)–(c)." □

Analogous to the definition given in §4, let us say that the system (5.1) satisfies the u.b.v. condition if there exist scalars $\delta > 0$ and $\beta > 0$ such that, for any (A', a'), (B', b') with $\|(A', a') - (A, a)\| + \|(B', b') - (B, b)\| < \delta$, the vertices of $P(A', B', a', b')$, if any exist, all have Euclidean norm less than β. By combining parts (a)–(b), (d) of Lemma 5.1 with Theorem 4.1, we readily obtain the final result of this section, which is an extension of Theorem 4.1 to the general system (5.1).

THEOREM 5.7. *For any $m \times n$ matrix A, any $l \times n$ matrix B, any m-vector a and any l-vector b such that the system* (5.1) *is regular and has a vertex solution, the following conditions are equivalent.*

(a) *There exists a nonzero n-vector z satisfying $Az \leq 0, Bz = 0$ and the rows of*

$$\begin{bmatrix} A_I \\ B \end{bmatrix}$$

are linearly dependent, where $I = \{\, i \in \{1, \ldots, m\} \mid A_i z = 0 \,\}$.

(b) *The system* (5.1) *does not satisfy the u.b.v. condition.*

As a corollary of Theorems 5.6 and 5.7, we have that the system (5.1) is well-conditioned under local perturbations on (A, a) and (B, b), whenever it is regular, has a vertex solution, and satisfies the u.b.v. condition.

6. Conclusion and extensions. In this paper, we have studied in detail the well-conditionedness of a linear system under each of four sets of perturbations on the problem data. In particular, we gave a necessary and sufficient condition for the system to be well-conditioned under each set of perturbations. We also related

well-conditionedness (under one of the sets of perturbations) to Pang's uniform boundedness condition on the vertex solutions.

We are presently investigating applications of our results to a number of problems, amongst which are (i) the sensitivity analysis of convex programs/complementarity problems, (ii) the convergence analysis of descent methods for nonlinearly constrained minimization, and (iii) the derivation of local error bounds for nonlinearly constrained problems. Also, a question closely related to our work concerns the classification of those polyhedral sets that admit a well-conditioned algebraic representation. Some preliminary results in this direction have been obtained, but much remains to be done.

Acknowledgments. We thank Professors J.-S. Pang and O. L. Mangasarian for several stimulating discussions on the subject of this paper. We are particularly indebted to Professor Pang for suggesting the main problem of this study. Also, we thank an anonymous referee for making a careful reading of this paper and offering many helpful comments on the presentation.

A SECOND-ORDER PERTURBATION EXPANSION FOR THE SVD*

RICHARD J. VACCARO†

Abstract. Let A be a rank-deficient matrix and let N be a matrix whose norm is small compared with that of A. The left singular vectors of A can be grouped into two matrices U_1 and U_2 whose columns provide orthonormal bases for the p-dimensional column space of A and for its $n-p$ dimensional orthogonal complement. The left singular vectors of $\tilde{A} = A + N$ can also be partitioned into the first p columns, $\tilde{U}_1$, and the last $n-p$ columns $\tilde{U}_2$. When analyzing a variety of signal processing algorithms, it is useful to know how different the spaces spanned by U_1 and $\tilde{U}_1$ (or U_2 and $\tilde{U}_2$) are. This question can be answered by developing a perturbation expansion for the subspace spanned by a set of singular vectors. A first-order expansion of this type has recently been developed and used to analyze the performance of direction-finding algorithms in array signal processing. In this paper, a new second-order expansion is derived and the result is illustrated with two examples.

Key words. singular value decomposition, perturbation expansion, singular subspaces

AMS subject classifications. 15A18, 15A52, 15A60

1. Introduction.

Let A be an $m \times n$ matrix of rank p, where $p < \min(m,n)$. The singular value decomposition (SVD) of A can be partitioned as follows:

$$A = [U_s \quad U_\perp] \begin{bmatrix} \Sigma_s & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} V_s^H \\ V_\perp^H \end{bmatrix}, \tag{1}$$

where the columns of U_s and $U_\perp$ provide a basis for the column-space of A and its orthogonal complement, respectively. The matrix A could be complex valued, and the superscript H means complex conjugate transpose. The column-space of A is called the *signal subspace* in the signal processing literature, and we will use the subscript s to refer to this subspace. The signal subspace S of the matrix A is the span of the p columns of U_s. We will refer to the orthogonal complement of the signal subspace by the abbreviated title *orthogonal subspace* in this paper. The orthogonal subspace $S^\perp$ is the span of the $n-p$ columns in $U_\perp$. Thus,

$$S \stackrel{\text{def}}{=} \text{span}(U_s) \quad \text{and} \quad S^\perp \stackrel{\text{def}}{=} \text{span}(U_\perp).$$

In practice, the matrix A is not available, but only a noise-corrupted matrix

$$\tilde{A} = A + N.$$

An SVD of the perturbed matrix $\tilde{A}$ can be partitioned similar to that in (1)

$$\tilde{A} = [\tilde{U}_s \quad \tilde{U}_\perp] \begin{bmatrix} \tilde{\Sigma}_s & 0 \\ 0 & \tilde{\Sigma}_\perp \end{bmatrix} \begin{bmatrix} \tilde{V}_s^H \\ \tilde{V}_\perp^H \end{bmatrix}, \tag{2}$$

where $\tilde{U}_s$ has p columns and $\tilde{U}_\perp$ has $n-p$ columns. Although $\tilde{A}$ will generally have full rank, it will be "close" to a matrix of rank p (if N is small), and the p-dimensional subspace spanned by the columns of $\tilde{U}_s$ will be called the *perturbed signal subspace*

$$\tilde{S} \stackrel{\text{def}}{=} \text{span}(\tilde{U}_s). \tag{3}$$

* Received by the editors December 30, 1991; accepted for publication (in revised form) November 4, 1992. This research was supported in part by the Office of Naval Research under grant N00014-90-J1283.

† Department of Electrical Engineering, The University of Rhode Island, Kingston, Rhode Island 02881 (vaccaro@ele.uri.edu).

We also define the *perturbed orthogonal subspace* $\tilde{S^{\perp}}$ as

$$\tilde{S^{\perp}} \stackrel{\text{def}}{=} \text{span}(\tilde{U}_{\perp}). \tag{4}$$

We would like to know how different the perturbed subspace $\tilde{S}$ ($\tilde{S^{\perp}}$) is from the unperturbed subspace S ($S^{\perp}$) as a function of the noise matrix N.

In a series of papers, the performance of algorithms for estimating the directions-of-arrival of plane waves impinging on an array of sensors was studied [2]–[6]. Many algorithms in array signal processing can be expressed in terms of an SVD of a matrix formed from array data. The performance of such algorithms can be analyzed using a perturbation expansion for the SVD. This was done in [2]–[6] using a first-order expansion to derive expressions for the variance of estimated directions-of-arrival. However, a first-order expansion will always predict zero bias when the additive noise is zero mean, because the resulting perturbation terms are linear in the noise matrix. To analyze bias, a second-order perturbation expansion is necessary. This is one motivation for the second-order expansion that is derived in this paper.

For the purpose of *performance analysis*, the matrices A and N are individually known. In a statistical performance analysis, only the statistics of N are known (e.g., its elements are independent and identically distributed (i.i.d.)). In any case, the perturbation formulas derived in this paper, which are functions of the perturbation matrix N, can be used directly for performance analysis. A second use for the perturbation formulas is the development of new signal processing algorithms. In this case only the matrix $\tilde{A}$ is observed, but the matrix N is described statistically, up to a scale factor. The first-order perturbation expansion has been used to derive algorithms for signal estimation [7] and for direction-finding in array signal processing [11].

2. A second-order perturbation expansion.

2.1. Preliminaries. To be useful, the perturbed subspaces must not be "too far" from the unperturbed subspaces. This will be true if the noise matrix N is "small enough." In this case, basis vectors for the perturbed signal and orthogonal subspaces can be found by appropriately combining the unperturbed singular vectors, as shown in the following lemma.

LEMMA. *Let $\tilde{A} = A + N$ with SVDs of A and $\tilde{A}$ given by* (1) *and* (2), *respectively. Assume that $\|N\|_2$ is less than the smallest nonzero singular value of A. Let the perturbed signal and orthogonal subspaces be defined by* (3) *and* (4), *respectively. Then $\tilde{S^{\perp}}$ is spanned by the columns of $U_{\perp} + U_s Q$ and $\tilde{S}$ is spanned by the columns of $U_s + U_{\perp} R$, where Q and R are matrices whose norms are of the order of $\|N\|$.*

The proof of this lemma can be found in [5], and this result is also implicit in a paper by Stewart [8]. In the lemma the assumption that $\|N\|_2$ is less than the smallest nonzero singular value of A is equivalent to assuming a high signal-to-noise ratio. If the signal-to-noise ratio is not high enough, the subspaces of the perturbed and unperturbed matrices A and $\tilde{A}$ may be quite different (e.g., they may not have the same dimension), and so the perturbation expansions given in the lemma are not useful. The case when $\|N\|$ is greater than the smallest nonzero singular value of A is treated using other techniques in [10].

The main result of this paper is the derivation of expressions for the coefficient matrices Q and R, which are correct up to second-order terms in the noise matrix N. Before presenting that derivation, we first show two preliminary calculations.

The lemma above gives bases for the perturbed signal and orthogonal subspaces. However, it is easy to show that the given bases are not orthonormal. In particular,

for the orthogonal subspace, we have

$$(U_\perp^H + Q^H U_s^H)(U_\perp + U_s Q) = (I + Q^H Q).$$

The above equation shows how the basis for the perturbed orthogonal subspace can be normalized, and a similar equation holds for the perturbed signal subspace. The result is that an orthonormal basis for the perturbed orthogonal subspace is given by

$$(U_\perp + U_s Q)(I + Q^H Q)^{-1/2} \tag{5}$$

and an orthonormal basis for the perturbed signal subspace is given by

$$(U_s + U_\perp R)(I + R^H R)^{-1/2}.$$

We now show that the coefficient matrices Q and R are related in a simple way. Because the perturbed signal and orthogonal subspaces are orthogonal to each other, it must be true that the (unnormalized) basis vectors given in the lemma are orthogonal. That is,

$$\begin{aligned}(U_\perp^H + Q^H U_s^H)(U_s + U_\perp R) &= 0,\\ R + Q^H &= 0,\end{aligned}$$

or

$$R = -Q^H.$$

Thus in the derivation that follows, we only need to compute Q to some desired accuracy, and then use the above equation to get R.

2.2. Derivation of the perturbation expansion. Let the matrices A and $\tilde{A}$ have SVDs given by (1) and (2), respectively. We can expand the SVD of $\tilde{A}$ to get

$$\tilde{A} = A + N = \tilde{U}_s \tilde{\Sigma}_s \tilde{V}_s^H + \tilde{U}_\perp \tilde{\Sigma}_\perp \tilde{V}_\perp^H.$$

Premultiply the above equation by $(U_\perp + U_s Q)^H$ to get

$$(U_\perp^H + Q^H U_s^H)(U_s \Sigma_s V_s^H + N) = (U_\perp^H + Q^H U_s^H)(\tilde{U}_\perp \tilde{\Sigma}_\perp \tilde{V}_\perp^H). \tag{6}$$

From the lemma we know that $(U_\perp + U_s Q)$ and $\tilde{U}_\perp$ span the same space, and thus their columns are related by a nonsingular matrix X as follows:

$$\tilde{U}_\perp = (U_\perp + U_s Q)X. \tag{7}$$

We can now simplify (6) using (7) to yield

$$\begin{aligned}U_\perp^H N + Q^H(\Sigma_s V_s^H + U_s^H N) &= (U_\perp^H + Q^H U_s^H)(\tilde{U}_\perp \tilde{\Sigma}_\perp \tilde{V}_\perp^H)\\ &= X\tilde{\Sigma}_\perp \tilde{V}_\perp^H + Q^H Q X \tilde{\Sigma}_\perp \tilde{V}_\perp^H\\ &\overset{2}{=} X\tilde{\Sigma}_\perp \tilde{V}_\perp^H.\end{aligned}$$

We use the notation "$\overset{i}{=}$" to mean "equal up to terms of order $\|N\|^i$" for i=0,1, or 2. The last line in the above equation is obtained by noting that Q and $\tilde{\Sigma}_\perp$ are

first-order terms, and so the omitted term from the second line is third order. After taking conjugate transposes of both sides of the above equation and letting

$$M = N^H U_s + V_s \Sigma_s, \tag{8}$$

we can solve for Q to obtain

$$\begin{aligned} Q &\overset{2}{=} -M^\dagger (N^H U_\perp + \tilde{V}_\perp \tilde{\Sigma}_\perp^H X^H) \\ &\overset{2}{=} -M^\dagger N^H U_\perp - M^\dagger \tilde{V}_\perp \tilde{\Sigma}_\perp^H X^H \\ &\overset{2}{=} -T_1 - T_2, \end{aligned} \tag{9}$$

where T_1 and T_2 are implicitly defined in the above equation. Since T_1 has N as a factor, a first-order expression for Q is obtained by using a zeroth-order expansion of $M^\dagger$ in the term T_1. Similarly, since $\tilde{\Sigma}_\perp$ is a first-order term, a first-order expression for Q is obtained by using zeroth-order expansions for $M^\dagger$ and $\tilde{\Sigma}_\perp$ in T_2. The zeroth-order expansion of $M^\dagger$ is obtained by setting N to zero in the definition of M and computing

$$M^\dagger = (M^H M)^{-1} M^H \overset{0}{=} [(V_s \Sigma_s)^H (V_s \Sigma_s)]^{-1} \Sigma_s V_s^H = \Sigma_s^{-1} V_s^H.$$

Substituting this into (9) yields the previously known result (see [4], [6])

$$Q \overset{1}{=} -\Sigma_s^{-1} V_s^H N^H U_\perp.$$

For future reference, we define this first-order expression for Q to be Q_1; that is,

$$Q_1 = -\Sigma_s^{-1} V_s^H N^H U_\perp. \tag{10}$$

We can use (9) to generate a perturbation expansion of second order by using a first-order expansion of $M^\dagger$ in (9), and also considering the term T_2. It can be shown that T_2 contains only two second-order terms, and these terms sum to zero. Thus

$$T_2 \overset{2}{=} 0. \tag{11}$$

The derivation of (11) is tedious, but it is similar to the calculation of the T_1, which we give below.

The required first-order expansion of $M^\dagger$ is obtained as follows

(12)

$$\begin{aligned} M^\dagger &= [(U_s^H N + \Sigma_s V_s^H)(N^H U_s + V_s \Sigma_s)]^{-1} (U_s^H N + \Sigma_s V_s^H) \\ &= [U_s^H N N^H U_s + U_s^H N V_s \Sigma_s + \Sigma_s V^H N^H U_s + \Sigma_s^2]^{-1} (U_s^H N + \Sigma_s V_s^H) \\ &= [\Sigma_s^{-2} U_s^H N N^H U_s + \Sigma_s^{-2} U_s^H N V_s \Sigma_s + \Sigma_s^{-1} V^H N^H U_s + I]^{-1} \Sigma_s^{-2} (U_s^H N + \Sigma_s V_s^H). \end{aligned}$$

Consider approximating the expression in the last line of the equation above. Since we only need a first-order expansion of $M^\dagger$, the first term in brackets can be omitted. The inverse can be represented by the Neumann expansion

$$(I + Y)^{-1} = I - Y + Y^2 - \cdots. \tag{13}$$

If we let Y be the terms linear in N in the first bracketed term of (12), keep up to the linear term in (13), and substitute the resulting expression for $M^\dagger$ into T_1 in (9), we get

$$Q \stackrel{2}{=} -[I - \Sigma_s^{-1} V_s^H N^H U_s - \Sigma_s^{-2} U_s^H N V_s \Sigma_s] \Sigma_s^{-2} [U_s^H N + \Sigma_s V_s^H] N^H U_\perp.$$

The above equation is correct up to second-order terms, but it also contains some third-order terms that can be deleted. The result is, after some simplification, a second-order expression for Q which is denoted Q_2

$$Q_2 = Q_1 + (-\Sigma_s^{-2} U_s^H N V_\perp V_\perp^H + \Sigma_s^{-1} V_s^H N^H U_s \Sigma_s^{-1} V_s^H) N^H U_\perp. \tag{14}$$

From the above development, we know that

$$\tilde{S^\perp} \stackrel{2}{=} \text{span}(U_\perp + U_s Q_2) \quad \text{and} \quad \tilde{S} \stackrel{2}{=} \text{span}(U_s - U_\perp Q_2^H).$$

However, the basis vectors in the above equation are not orthonormal up to second order. They can be normalized as shown in (5). The normalization only has to be computed up to second-order terms. The result for the orthogonal subspace is

$$(I + Q^H Q)^{-1/2} \stackrel{2}{=} I - \frac{1}{2} Q_1^H Q_1.$$

Applying this normalization and dropping terms higher than second order yields an orthogonal basis for the perturbed orthogonal subspace

$$\tilde{S^\perp} \stackrel{2}{=} \text{span}\left[U_\perp \left(I - \frac{1}{2} Q_1^H Q_1\right) + U_s Q_2\right], \tag{15}$$

where Q_1 is defined in (10) and Q_2 is defined in (14). The corresponding result for the perturbed signal subspace is

$$\tilde{S} \stackrel{2}{=} \text{span}\left[U_s \left(I - \frac{1}{2} Q_1 Q_1^H\right) - U_\perp Q_2^H\right].$$

3. Statistics of estimated projection matrices. Once the signal and orthogonal subspaces of a data matrix are estimated, many signal processing tasks require projection onto an estimated subspace. Thus it is useful to characterize the estimated orthogonal projection matrix.

To be specific, we consider the orthogonal subspace in this section. From (2), the projection onto the estimated orthogonal subspace is given by

$$\tilde{P}_\perp = \tilde{U}_\perp \tilde{U}_\perp^H.$$

For future reference, we define the projection matrices for the unperturbed signal and orthogonal subspaces as

$$P_s = U_s U_s^H \quad \text{and} \quad P_\perp = U_\perp U_\perp^H,$$

respectively. Suppose we want to characterize $\tilde{P}_\perp$ in terms of the unperturbed projection matrices and the noise matrix N. For example, if we assume that the elements of N are i.i.d. random variables with variance σ^2, we can calculate the expected value of $\tilde{P}_\perp$. Using the subspace perturbation expansions developed in the previous

sections, we can approximate the perturbed projection matrices as follows. Using the first-order expression, we get

$$\tilde{P}_\perp \stackrel{1}{=} (U_\perp + U_s Q_1)(U_\perp + U_s Q_1)^H \stackrel{\text{def}}{=} P_1.$$

This expression is exact to first order and contains some, but not all, of the second-order terms, as shown by expanding the expression as

$$P_1 = U_\perp U_\perp^H + U_\perp Q_1^H U_s^H + U_s Q_1 U_\perp^H + U_s Q_1 Q_1^H U_s^H. \tag{16}$$

A similar approximation for the perturbed projection matrix can be obtained using the second-order perturbation expansion as follows

$$\tilde{P}_\perp \stackrel{2}{=} \left[\left(I - \frac{1}{2}Q_1^H Q_1\right) + U_s Q_2\right]\left[\left(I - \frac{1}{2}Q_1^H Q_1\right) + U_s Q_2\right]^H.$$

If we expand this equation, keeping up to second-order terms, the result, which we denote P_2, is

$$P_2 = U_\perp U_\perp^H - U_\perp Q_1^H Q_1 U_\perp^H + U_\perp Q_2^H U_\perp^H + U_s Q_2 U_\perp^H + U_s Q_1 Q_1^H U_s^H. \tag{17}$$

To take expected values of P_1 and P_2, we need to be able to compute the expectation of the following matrices:

$$\begin{aligned} Q_1 &= -\Sigma_s^{-1} V_s^H N^H U_\perp, \\ Q_1^H Q_1 &= U_\perp^H N V_s \Sigma_s^{-2} V_s^H N^H U_\perp, \\ Q_1 Q_1^H &= \Sigma_s^{-1} V_s^H N^H U_\perp U_\perp^H N V_s \Sigma_s^{-1}, \\ Q_2 &= Q_1 - (\Sigma_s^{-2} U_s^H N V_\perp V_\perp^H + \Sigma_s^{-1} V_s^H N^H U_s \Sigma_s^{-1} V_s^H) N^H U_\perp. \end{aligned} \tag{18}$$

The required expectations can be derived using the following result from [3]

$$E[N\beta\beta^H N^H] = \|\beta\|^2 \sigma^2 I \tag{19}$$

for any constant vector β and matrix N consisting of i.i.d. random variables with variance σ^2. (If N contains complex elements, we assume that the real and imaginary parts are i.i.d. with variance $\sigma^2/2$.) It is also shown in [3] that

$$E[N^H \alpha\alpha^H N^H] = 0. \tag{20}$$

We can also show that for real-valued noise samples,

$$E[N\alpha\beta^T N] = \sigma^2 \beta\alpha^T. \tag{21}$$

It is easy to see that the expected value of Q_1 is zero. Equations (19)–(21) can be used to calculate the expected values of the other matrices in (18). As an example, we derive the expected value of Q_2 as follows:

$$E[Q_2] = -\Sigma_s^{-2} U_s^H E[N V_\perp V_\perp^H N^H] U_\perp - \Sigma_s^{-1} V_s E[N^H U_s \Sigma_s^{-1} V_s^H N^H] U_\perp. \tag{22}$$

The first expectation on the right-hand side of the above equation using (19) is

$$\begin{aligned} E[N V_\perp V_\perp^H N^H] &= \sum_{i=1}^{q} E[N v_{\perp i} v_{\perp i}^H N^H] \\ &= \sum_{i=1}^{q} \|v_{\perp i}\|^2 \sigma^2 I = q\sigma^2 I, \end{aligned} \tag{23}$$

where $v_{\perp i}$ is the ith column of $V_\perp$, and $q = n - p$ (see (1)). The second expectation on the right-hand side of (22) is zero if the noise samples are zero-mean i.i.d. complex random variables from (20). For real-valued noise samples, this expectation can be evaluated using (21) as

$$\begin{aligned} E[N^T U_s \Sigma_s^{-1} V_s^T N^T] &= \sum_{i=1}^{p} \frac{1}{\sigma_{si}} E[N^T u_{si} v_{si}^T N^T] \\ &= \sum_{i=1}^{p} \frac{\sigma^2}{\sigma_{si}} v_{si} u_{si}^T \\ &= \sigma^2 V_s \Sigma_s^{-1} U_s^T, \end{aligned} \tag{24}$$

where σ_{si} is the ith singular value of A and u_{si} and v_{si} are the ith columns of U_s and V_s, respectively. Substituting (23) (and (24) if N is real-valued) into (22) yields

$$E[Q_2] = 0. \tag{25}$$

The expectations of $Q_1^H Q_1$ and $Q_1 Q_1^H$ are determined in a similar fashion to be

$$E[Q_1^H Q_1] = \frac{\sigma^2}{x} I, \quad \text{and} \quad E[Q_1 Q_1^H] = q\sigma^2 \Sigma_s^{-2}, \tag{26}$$

where x equals the sum of the squares of the singular values of A. Using (25) and (26), the expected values of the first- and second-order expressions (16) and (17) can be computed to yield

$$\begin{aligned} E[P_1] &= U_\perp U_\perp^H + q\sigma^2 U_s \Sigma_s^{-2} U_s^H \stackrel{\text{def}}{=} \bar{P}_1(\sigma) \\ E[P_2] &= U_\perp U_\perp^H \left(1 - \frac{\sigma^2}{x}\right) + q\sigma^2 U_s \Sigma_s^{-2} U_s^H \stackrel{\text{def}}{=} \bar{P}_2(\sigma). \end{aligned} \tag{27}$$

In the next section, we give an example to compare the accuracy of these expressions. The results of this section can be extended to handle noise matrices with correlated elements using results from [9].

4. Examples and discussion. We give two examples in this section to demonstrate the validity of our results. In the first example, we compare the results predicted by (27) with sample expectations in a simulation experiment. In the second example, we compute the distance between the actual perturbed subspace, and the perturbed subspace generated by a first- or second-order perturbation expansion.

4.1. Expected value of a projection matrix. To demonstrate the results of the previous section, consider the following matrix:

$$A = \begin{bmatrix} 1 & 2 & 3 & 4 \\ 1 & 2 & 3 & 4 \\ 1 & 2 & 3 & 4 \end{bmatrix} = [U_s \quad U_\perp] \begin{bmatrix} 9.4868 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} V_s^H \\ V_\perp^H \end{bmatrix},$$

where

$$U_s = \begin{bmatrix} 0.5774 \\ 0.5774 \\ 0.5774 \end{bmatrix}, \quad \text{and} \quad U_\perp = \begin{bmatrix} -0.8165 & 0.0000 \\ 0.4082 & 0.7071 \\ 0.4082 & -0.7071 \end{bmatrix}.$$

The projection matrices for the signal and orthogonal subspaces are

$$P_s = U_s U_s^T = \begin{bmatrix} 0.3333 & 0.3333 & 0.3333 \\ 0.3333 & 0.3333 & 0.3333 \\ 0.3333 & 0.3333 & 0.3333 \end{bmatrix}$$

and

$$P_\perp = U_\perp U_\perp^T = \begin{bmatrix} 0.6667 & -0.3333 & -0.3333 \\ -0.3333 & 0.6667 & -0.3333 \\ -0.3333 & -0.3333 & 0.6667 \end{bmatrix}.$$

Suppose that instead of the matrix A, only the perturbed matrix

$$\tilde{A} = A + \sigma N \tag{28}$$

were available, where the elements of N are i.i.d. Gaussian random variables with zero-mean and unit variance. An SVD for $\tilde{A}$ gives bases for the estimated signal and orthogonal subspaces

$$\tilde{A} = [\tilde{U}_s \quad \tilde{U}_\perp]\tilde{\Sigma}\tilde{V}^T, \tag{29}$$

and the projection matrix for the estimated orthogonal subspace is

$$\tilde{P}_\perp = \tilde{U}_\perp \tilde{U}_\perp^T. \tag{30}$$

The following simulation was performed. Values of σ from 0.2–2 in increments of 0.2 were generated and used to form matrices $\tilde{A}$ as in (28). For each value of σ, 10,000 realizations of the noise matrix N were generated, and the corresponding projection matrices were computed using (29) and (30). The estimated projection matrices were averaged to produce a matrix $\bar{\tilde{P}}_\perp(\sigma)$ for each value of σ. The experimentally determined matrices $\bar{\tilde{P}}_\perp(\sigma)$ were compared with the theoretical expressions in (27) by computing the following error norms:

$$e_1(\sigma) = \|\bar{\tilde{P}}_\perp(\sigma) - \bar{P}_1(\sigma)\|_2,$$

$$e_2(\sigma) = \|\bar{\tilde{P}}_\perp(\sigma) - \bar{P}_2(\sigma)\|_2.$$

The error norms $e_1(\sigma)$ and $e_2(\sigma)$ result from using the first- and second-order perturbation expansions, respectively, for the perturbed orthogonal subspace. For comparison, we also consider an error norm corresponding to a zeroth-order perturbation expansion, namely,

$$e_0(\sigma) = \|\bar{\tilde{P}}_\perp(\sigma) - P_\perp\|_2.$$

Note that the error norms $e_i(\sigma)$ are the distances between the actual average perturbed subspace and the average subspace predicted by a perturbation expansion of order i.

We can gain some insight into the functional form of the error norms by looking at (16) and (17). Specifically, we see from (16) that the zeroth-order projection matrix $U_\perp U_\perp^T$ does not model terms that are first- and second-order in N (recall that Q_1 is linear in N). However, since first-order terms in N have zero mean, the zeroth-order projection matrix incurs errors of second order. From the manner in which the data

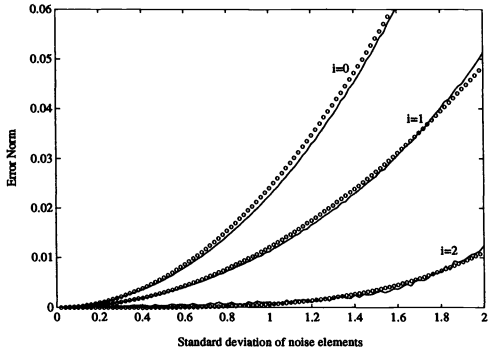

FIG. 1. *The error norms $e_i(\sigma)$ defined by* (55) *and* (56) *for $i = 1, 2, 3$. The solid lines are experimentally computed curves; the circles are least-squares polynomial fits.*

is constructed in (28), we see that the norm of N is proportional to σ. Thus the functional form of $e_0(\sigma)$ is essentially quadratic in σ

$$e_0(\sigma) = \alpha_0 \sigma^2 + O(\sigma^4).$$

In a similar way we can compare (17) and (16) and see that the first-order approximation P_1 contains some but not all of the terms that are second order in N. Thus $e_1(\sigma)$ will also be approximately a quadratic function of σ

$$e_1(\sigma) = \alpha_1 \sigma^2 + O(\sigma^4).$$

We would suspect that $\alpha_1 < \alpha_0$ since P_1 contains some second-order terms while P_0 does not.

Finally, we recall that P_2 is exact up to second-order terms. Since third- and fifth-order terms have zero mean, the error norm $e_2(\sigma)$ should be approximately proportional to σ^4

$$e_2(\sigma) = \alpha_2 \sigma^4 + O(\sigma^6).$$

The above conclusions on the functional form of the error norms are verified in the simulation results in Fig. 1. In this figure, the solid lines are the experimentally computed curves $e_i(\sigma)$ for $i = 0, 1, 2$. The circles show the functional forms deduced above with the optimal amplitudes. The amplitudes for a least-squares fit were found to be

$$\alpha_0 = 2.4 \times 10^{-2} \quad \text{quadratic},$$

$$\alpha_1 = 1.2 \times 10^{-2} \quad \text{quadratic},$$

$$\alpha_2 = 7.0 \times 10^{-4} \quad \text{quartic}.$$

We can draw several conclusions from Fig. 1. First we see that both $e_1(\sigma)$ and $e_2(\sigma)$ are proportional to σ^2. The only difference is that $e_2(\sigma)$ has a smaller constant.

Thus the advantage of using a first-order perturbation expansion over a zeroth-order expansion is a scale factor in the error norm, which for this example equals 0.5. However, since $e_2(\sigma)$ is proportional to σ^4, there is a substantial benefit to using a second-order expansion. For example, $e_2(\sigma) < 0.01$ for $\sigma < 1.9$ whereas the same error bound for $e_1(\sigma)$ requires $\sigma < 0.92$, and for $e_1(\sigma)$ requires $\sigma < 0.66$. We also see from (27) that the expressions resulting from a second-order expansion are not necessarily more complicated than those from a first-order expansion.

4.2. Distance between subspaces. For each realization of the noise matrix N, the results of a first- or second-order perturbation expansion can be used to obtain a basis for the perturbed orthogonal (or signal) subspace. That is

$$\tilde{U}_\perp \overset{0}{=} \operatorname{span}(U_\perp) \overset{\text{def}}{=} \tilde{U}_\perp^0,$$

$$\tilde{U}_\perp \overset{1}{=} \operatorname{span}(U_\perp + U_s Q_1) \overset{\text{def}}{=} \tilde{U}_\perp^1,$$

$$\tilde{U}_\perp \overset{2}{=} \operatorname{span}(U_\perp + U_s Q_2) \overset{\text{def}}{=} \tilde{U}_\perp^2,$$

where Q_1 and Q_2 are given as functions of the noise matrix N in (10) and (14), respectively.

For each realization of N, a basis for the actual orthogonal subspace $\tilde{U}_\perp$ can be obtained from an SVD of $\tilde{A}$. In this section we compute the distance between the actual perturbed subspaces computed by an SVD of $\tilde{A}$ and the subspaces generated by perturbation expansions of order zero, one, and two. These distances are denoted by

$$\text{(31)} \qquad \operatorname{dist}_i(\sigma) \overset{\text{def}}{=} \operatorname{dist}(\tilde{U}_\perp, \tilde{U}_\perp^i), \qquad i = 0, 1, 2.$$

The distance between two subspaces S_1 and S_2 is defined to be [1]

$$\operatorname{dist}(S_1, S_2) \overset{\text{def}}{=} \|P_1 - P_2\|,$$

where P_i is the orthogonal projection matrix onto S_i.

We plot $E[\operatorname{dist}_i(\sigma)]$ versus σ in Fig. 2. Since the zeroth-order expansion neglects linear terms, we expect $E[\operatorname{dist}_0(\sigma)]$ to be linear. Since first- and second-order expansions neglect second- and third-order terms, respectively, we expect $E[\operatorname{dist}_1(\sigma)]$ to be quadratic and $E[\operatorname{dist}_2(\sigma)]$ to be cubic. That is in fact what we see in Fig. 2. The circles show the functional forms deduced above with the optimal amplitudes. The amplitudes for a least-squares fit were found to be

$$\alpha_0 = 1.4 \times 10^{-1} \quad \text{linear},$$

$$\alpha_1 = 2.8 \times 10^{-2} \quad \text{quadratic},$$

$$\alpha_2 = 7.2 \times 10^{-3} \quad \text{cubic}.$$

4.3. Discussion. We are currently using the second-order expansion to analyze the performance of sensor array processing algorithms for direction-of-arrival estimation. The analysis in [2]–[6] used the first-order expansion. By using the second-order expansion derived in this paper, we hope to be able to develop performance expressions that are accurate at lower signal-to-noise ratios and that predict bias.

PROBABILISTIC BOUNDS ON THE EXTREMAL EIGENVALUES AND CONDITION NUMBER BY THE LANCZOS ALGORITHM*

J. KUCZYŃSKI† AND H. WOŹNIAKOWSKI‡

Abstract. The authors analyze the Lanczos algorithm with a random start for approximating the extremal eigenvalues of a symmetric positive definite matrix. They present some bounds on the Lebesgue measure (probability) of the sets of these starting vectors for which the Lanczos algorithm gives at the kth step satisfactory approximations to the largest and smallest eigenvalues. Combining these bounds gets similar estimates for the condition number of a matrix.

Key words. extreme eigenvalues, Lanczos algorithm, condition number, random start

AMS subject classification. 65

1. Introduction.

There are many algorithms for approximating the extremal eigenvalues of $n \times n$ symmetric positive definite matrices. Algorithms based on a factorization of A usually require $\Theta(n^3)$ arithmetic operations and if n is large then such algorithms are too expensive. On the other hand, large matrices are usually sparse and the matrix-vector multiplication Av can be performed cheaply. This suggests that algorithms based on vectors Av_i for some vectors v_i may be efficient.

The Lanczos algorithm is probably the most popular algorithm that uses a few vectors Av_i for approximating eigenvalues. In particular, at the kth step it gives approximations to the largest eigenvalue λ_1 and to the smallest eigenvalue λ_n of A as the maximal and minimal Rayleigh quotient $(Ax, x)/(x, x)$ over nonzero vectors x from the kth Krylov subspace $A_k = \text{span}(b, Ab, \ldots, A^{k-1}b)$, where $b \neq 0$. Of course, the quality of such approximations strongly depends both on the matrix A and on the starting vector b. It is known (see [15]) that a poor choice of the vector b can cause a bad behaviour of the Lanczos algorithm. The analysis of the Lanczos algorithm for a fixed vector b may be found in many books and papers, particularly, [2],[5],[7],[8],[10]–[12], and [14]–[16]. The analysis of the Lanczos algorithm for a random vector b can be found in [9], where average case and probabilistic estimates on the largest eigenvalue are given. These estimates are independent of the distribution of the eigenvalues of A.

In §2, we first translate the estimates of [9] for approximating the smallest eigenvalue λ_n of A. We estimate the average relative error of the Lanczos algorithm over all starting vectors b. We also provide an upper bound on the Lebesgue measure (probability) of the set of those b's from the unit ball for which the Lanczos algorithm fails to give an ε-approximation to the smallest eigenvalue at the kth step.

In §3, we present new probabilistic estimates for the Lanczos algorithm for approximating the largest and smallest eigenvalue of A. These estimates depend on the distribution of the eigenvalues of A.

In §4, we apply estimates on the smallest and largest eigenvalue to approximate the condition number, $\text{cond}\, A$, of A in the two-norm,

$$\text{cond}\, A = \frac{\lambda_1}{\lambda_n}.$$

An approximation to the condition number of a matrix is often wanted when one deals with matrix calculations; see [1] and [4]. We provide bounds on the probability of the set of these b's for which the Lanczos algorithm gives at the kth step the approximation κ_k of the condition number of A such that

$$\kappa_k \leq \operatorname{cond} A \leq \alpha \kappa_k$$

for any $\alpha > 1$. In many cases, only a rough approximation of $\operatorname{cond} A$ is needed. Then α may be quite large, say, $\alpha = 10$.

A similar problem of approximating the condition number has been considered by Dixon [3] for arbitrary matrices and by using modified power and inverse power methods. His results are computationally applicable if the vector $A^{-1}z$ can be computed cheaply for any vector z. This is the case when a factorization of A is given. However, if n is large and the matrix A is given only via the subroutine performing a matrix-vector multiplication, the vector $A^{-1}z$ may be approximated by an iterative method but its computation may be expensive. In this case, the Lanczos algorithm is preferable since it does not use the vector $A^{-1}z$.

2. Lanczos algorithm for approximating extremal eigenvalues. Let $A = A^T > 0$ be an $n \times n$ symmetric positive definite matrix with eigenvalues $\lambda_1(A) \geq \lambda_2(A) \geq \cdots \geq \lambda_n(A) > 0$. The kth step of the Lanczos algorithm produces approximations to the largest and smallest eigenvalues of A defined as

$$\hat{\xi}_k = \hat{\xi}(A, b, k) = \max \left\{ \frac{(Ax, x)}{(x, x)} : x \in A_k, x \neq 0 \right\}$$

and

$$\xi_k = \xi(A, b, k) = \min \left\{ \frac{(Ax, x)}{(x, x)} : x \in A_k, x \neq 0 \right\},$$

where $A_k = \operatorname{span}(b, Ab, \ldots, A^{k-1}b)$ for some nonzero vector b. Without loss of generality we may assume that $b \in S_n = \{b \in \mathcal{R}^n : ||b|| = 1\}$, where $||\cdot||$ is the Euclidean norm of vectors.

First we discuss the error of the Lanczos approximation ξ_k to the smallest eigenvalue λ_n. The most natural error criterion is probably the relative error $(\xi_k - \lambda_n)/\lambda_n$. It is shown in Remark 1, §6, that unfortunately even the *average* value of

$$\frac{\xi(A, b, k) - \lambda_n(A)}{\lambda_n(A)},$$

with respect to the uniform distribution of b, is arbitrary large for some matrices A.

Therefore we have to switch to a different error criterion. One may consider the relative error with respect to the largest eigenvalue $(\xi_k - \lambda_n)/\lambda_1$, or the gap ratio $(\xi_k - \lambda_n)/(\lambda_1 - \lambda_n)$. In Remark 2, §6, it turns out that the results both for the average error and probabilistic failure are the same for these two error criteria. Therefore we only consider the relative error with respect to the largest eigenvalue, i.e.,

$$e(A, b, k) = \frac{\xi(A, b, k) - \lambda_n(A)}{\lambda_1(A)}.$$

It is easy to see that there exist vectors b and matrices A for which the error $e(A, b, k)$ can be arbitrary close to 1. Indeed, $\hat{\xi}(A, b, k) \leq \lambda_1(A)$ and $\lambda_n(A) \leq \xi(A, b, k)$ and therefore

$$e(A, b, k) < \xi(A, b, k)/\hat{\xi}(A, b, k) \leq 1.$$

In general, this bound cannot be improved since if b is an eigenvector belonging to the largest eigenvalue $\lambda_1(A)$, then for all k, $\xi(A,b,k) = \hat{\xi}(A,b,k) = \lambda_1(A)$, and yet $\lambda_n(A)$ can be arbitrary close to 0.

Thus, we cannot guarantee that the error of the Lanczos algorithm is smaller than 1 for all matrices A and all vectors b. Moreover, if b is orthogonal to the eigenspace generated by the smallest eigenvalue, then the Lanczos error $e(A,b,k) > 0$ for all k. On the other hand, if b is not orthogonal to this subspace, then $e(A,b,k) = 0$ for $k \geq m$, where m denotes the number of distinct eigenvalues of A.

It is clear that if we pick the vector b randomly according to the uniform distribution over the unit sphere, then with probability one b is *not* orthogonal to the eigenspace of λ_n. This suggests that for any symmetric positive definite matrix, the average relative error of the Lanczos algorithm with respect to vectors b should be small for large k. Also, the measure of the set of these b for which the Lanczos algorithm fails to compute a good approximation to the smallest eigenvalue should be small.

Let μ be the uniform distribution over the unit sphere S_n with $\mu(S_n) = 1$. By the average relative error of the kth step of the Lanczos algorithm, we mean

$$e^{\text{avg}}(A,k) = \int_{S_n} e(A,b,k)\, \mu(db).$$

Let

$$f^{\text{prob}}(A,k,\varepsilon) = \mu\{b \in S_n : e(A,b,k) > \varepsilon\}$$

denote the probability that the kth step of the Lanczos algorithm fails to approximate the smallest eigenvalue with relative error at most ε. For brevity we call this the probabilistic failure.

We now present an upper bound on the average error of the Lanczos algorithm. It turns out that this bound is the same as the one obtained in [9] for the Lanczos algorithm approximating the largest eigenvalue λ_1. For simplicity, as in [9], we assume that $n \geq 8$ and $k \geq 4$.

THEOREM 1. *Let A be a symmetric positive definite matrix.*

(a) *Let m denote the number of distinct eigenvalues of A. Then for $k \geq m$,*

$$e^{\text{avg}}(A,k) = 0,$$

for $k \in [4, m-1]$,

$$e^{\text{avg}}(A,k) \leq 0.103 \left(\frac{\ln\left(n(k-1)^4\right)}{k-1}\right)^2 \leq 2.575 \left(\frac{\ln n}{k-1}\right)^2.$$

(b) *Let $p, p < n$, denote the multiplicity of the smallest eigenvalue λ_n, and let λ_{n-p} be the second smallest eigenvalue of A. Then*

$$e^{\text{avg}}(A,k) \leq 2.589\sqrt{n} \left(\frac{1 - \sqrt{(\lambda_{n-p} - \lambda_n)/(\lambda_1 - \lambda_n)}}{1 + \sqrt{(\lambda_{n-p} - \lambda_n)/(\lambda_1 - \lambda_n)}}\right)^{k-1}.$$

Proof. For the proof it is enough to apply Theorem 3.2 of [9] to the matrix $B = \lambda_1 I - A$. □

Theorem 1 states that $e^{\text{avg}}(A,k) = 0$ for $k \geq m$, which means that the Lanczos algorithm converges in $m, m \leq n$, steps. For $k < m$ the average relative error is bounded by $2.6 \ln^2 n/(k-1)^2$. We do not know if this bound is sharp. Numerical tests suggest that for some matrices A we have

$$e^{\text{avg}}(A,k) = \Theta(k^{-2}).$$

Part (b) of Theorem 1 contains nonasymptotic bounds in terms of the gap ratio of the matrix A.

We now turn to the bound on the probabilistic failure of the Lanczos algorithm for the smallest eigenvalue.

THEOREM 2. *Let A be a symmetric positive definite matrix.*

(a) *Let m denote the number of distinct eigenvalues of A. Then for any $\varepsilon \in (0,1]$,*

$$f^{\text{prob}}(A,k,\varepsilon) = 0 \quad \textit{for } k \geq m,$$

$$f^{\text{prob}}(A,k,\varepsilon) \leq 1.648\sqrt{n}\, e^{-(2k-1)\sqrt{\varepsilon}} \quad \textit{for any } k\,.$$

(b) *Let $p, p < n$, denote the multiplicity of the smallest eigenvalue λ_n and let λ_{n-p} be the second smallest eigenvalue of A. Then for $\varepsilon > 0$,*

$$f^{\text{prob}}(A,k,\varepsilon) \leq 1.648\sqrt{n/\varepsilon}\left(\frac{1-\sqrt{(\lambda_{n-p}-\lambda_n)/(\lambda_1-\lambda_n)}}{1+\sqrt{(\lambda_{n-p}-\lambda_n)/(\lambda_1-\lambda_n)}}\right)^{k-1}.$$

Proof. For the proof it is enough to apply Theorem 4.2 of [9] for the matrix $B = \lambda I - A$. □

Theorem 2 gives upper bounds on the probabilistic failure of the Lanczos algorithm for approximating the smallest eigenvalue. For $k \geq m$, $f^{\text{prob}}(A,k,\varepsilon) = 0$, which means that the Lanczos algorithm converges in m steps, where $m \leq n$. For $k < m$, the probabilistic failure is bounded by $1.65\sqrt{n}\, e^{-(2k-1)\sqrt{\varepsilon}}$.

Suppose we wish to find an ε-approximation to the smallest eigenvalue with a δ-failure, i.e., $f^{\text{prob}}(A,k,\varepsilon) \leq \delta$. Then from Theorem 2 we conclude that we have to perform at most roughly

$$k = \lceil \ln(3n/\delta^2) \,/\, (4\sqrt{\varepsilon}) \rceil$$

steps. Note a weak dependence on δ and the strong dependence on ε.

3. Bounds dependent on distribution of eigenvalues. In this section we provide new probabilistic bounds on extemal eigenvalues that depend on distribution of eigenvalues of the matrix A. For any symmetric positive definite matrix A, consider two sets

$$L_k = \{b \in S_n : \hat{\xi}(A,b,k) \leq \lambda_1(A) \leq \theta\hat{\xi}(A,b,k)\} \quad \text{for} \quad \theta > 1$$

and

$$M_k = \{b \in S_n : \eta\,\xi(A,b,k) \leq \lambda_n(A) \leq \xi(A,b,k)\} \quad \text{for} \quad \eta < 1.$$

Obviously, the first inequality in the set L_k and the second one in M_k hold for any vector $b \in S_n$. We now find lower bounds on $\mu(L_k)$ and $\mu(M_k)$. We begin with $\mu(L_k)$.

THEOREM 3. *For any symmetric positive definite matrix A let m denote the number of distinct eigenvalues of A. Then for $k \geq m$, or $\theta \geq \operatorname{cond} A$,*

$$\mu(L_k) = 1,$$

and for $k < m$ and $1 < \theta < \operatorname{cond} A$,

$$\begin{aligned}\mu(L_k) &\geq 1 - \frac{2\,\Gamma((n-j)/2+1)}{\sqrt{\pi}\,\Gamma((n-j+1)/2)} \frac{1}{\sqrt{\theta-1}\,U_{2(k-1)}(\sqrt{\theta})} \\ &\geq 1 - \frac{2\,\Gamma(n/2)}{\sqrt{\pi}\,\Gamma((n-1)/2)} \frac{1}{\sqrt{\theta-1}\,U_{2(k-1)}(\sqrt{\theta})},\end{aligned}$$

where the index j is defined by $\lambda_j \leq \lambda_1/\theta < \lambda_{j-1}$, $2 \leq j \leq n$, U_k is the Chebyshev polynomial of the second kind of degree k, and Γ is the Euler Γ-function.

Proof. The idea of the proof is similar to the proof of Theorem 4.2 in [9]. Let $b = \sum_{i=1}^n b_i v_i$, where $v_i, i = 1, \ldots, n$ are orthonormal eigenvectors of A. Consider the set

$$L_k' = S_n - L_k = \{b \in S_n : \lambda_1(A) > \theta \hat{\xi}(A, b, k)\}.$$

Then we have

$$L_k' = \left\{ b \in S_n : \lambda_1 > \theta \sup_{P \in \mathcal{P}_k} \frac{\sum_{i=1}^n \lambda_i P^2(\lambda_i) b_i^2}{\sum_{i=1}^n b_i^2 P^2(\lambda_i)} \right\},$$

where $\mathcal{P}_k$ denotes the set of nonzero polynomials of degree smaller than k.

Assume that $k \geq m$. Then the set $\{\lambda_1, \ldots, \lambda_n\}$ contains m distinct elements $\{t_1, \ldots, t_m\}$, $\lambda_1 = t_1 > \cdots > t_m$ and for the polynomial $P(x) = \prod_{i=2}^m (x - t_i)$ the supremum takes the value λ_1 for $b_1 \neq 0$. Thus, since $\theta \geq 1$, the set L_k' is empty with probability one. Thus $\mu(L_k) = 1$ as claimed.

Assume now that $k < m$. Then after simple calculations, we get

$$L_k' = \left\{ b \in S_n : \sup_{P \in \mathcal{P}_k} \frac{\sum_{i=1}^n b_i^2 P^2(\lambda_i)(\theta\lambda_i - \lambda_1)}{\sum_{i=1}^n b_i^2 P^2(\lambda_i)} < 0 \right\}.$$

Observe that the supremum is negative if and only if the enumerator is negative. Thus

$$L_k' = \left\{ b \in S_n : \sup_{P \in \mathcal{P}_k} \sum_{i=1}^n b_i^2 P^2(\lambda_i)(\theta\lambda_i - \lambda_1) < 0 \right\}.$$

Assume that $\theta \geq \operatorname{cond} A$. Then $\theta\lambda_i - \lambda_1 \geq 0$ for all $i = 1, 2, \ldots, m$ and the set L_k' is empty. Thus $\mu(L_k) = 1$ as claimed.

Assume now that $\theta < \operatorname{cond} A$. Note that using a continuity argument, we may restrict ourselves to polynomials for which $P(\lambda_1) \neq 0$. Let $x_i = \lambda_i/\lambda_1$ and $Q(x) = P(\lambda_1 x)/P(\lambda_1)$. Then $x_i \in (0, 1]$ and

$$L_k' = \left\{ b \in S_n : \sup_{Q \in \mathcal{P}_k(1)} \sum_{i=1}^n b_i^2 Q^2(x_i)(\theta x_i - 1) < 0 \right\},$$

where $\mathcal{P}_k(\alpha) = \{w \in \mathcal{P}_k : w(\alpha) = 1\}$.

Clearly, for any polynomial $Q \in \mathcal{P}_k(1)$, we have

$$L_k' \subset \left\{ b \in S_n : \sum_{i=1}^{n} b_i^2 Q^2(x_i)(\theta x_i - 1) < 0 \right\}.$$

From the definition of the index j, we have $\theta x_j \leq 1 < \theta x_{j-1}$ and

$$\begin{aligned}
\mu(L_k') &\leq \mu \left\{ b \in S_n : \sum_{i=j}^{n} b_i^2 Q^2(x_i)(1 - \theta x_i) > \sum_{i=1}^{j-1} b_i^2 Q^2(x_i)(\theta x_i - 1) \right\} \\
&\leq \mu \left\{ b \in S_n : \sum_{i=j}^{n} b_i^2 Q^2(x_i)(1 - \theta x_i) > b_1^2(\theta - 1) \right\} \\
&\leq \mu \left\{ b \in S_n : \sum_{i=j}^{n} b_i^2 \max_{x \in [0, x_j]} [Q^2(x)(1 - \theta x)] > b_1^2(\theta - 1) \right\}.
\end{aligned}$$

Let

$$\omega_k(x_j, \theta) = \inf_{Q \in \mathcal{P}_k(1)} \max_{x \in [0, x_j]} Q^2(x)(1 - \theta x).$$

We now find an upper bound on $\omega_k(x_j, \theta)$. It is easy to check that

$$\omega_k(x_j, \theta) = \inf_{Q \in \mathcal{P}_k(\theta)} \max_{x \in [0, \gamma]} Q^2(x)(1 - x),$$

where $\gamma = \theta x_j \leq 1$. Let

$$\hat{Q}(x) = \frac{U_{2(k-1)}(\sqrt{x})}{U_{2(k-1)}(\sqrt{\theta})},$$

where $U_{2(k-1)}$ is the Chebyshev polynomial of the second kind of degree $2(k-1)$. Since $U_{2(k-1)}$ is even, $\hat{Q}$ is a polynomial of degree $k-1$. Obviously $\hat{Q}(\theta) = 1$, so $\hat{Q} \in \mathcal{P}_k(\theta)$. Then

$$\omega_k(x_j, \theta) \leq \max_{x \in [0, \gamma]} \frac{U_{2(k-1)}^2(\sqrt{x})}{U_{2(k-1)}^2(\sqrt{\theta})} (1 - (\sqrt{x})^2) = \frac{1}{U_{2(k-1)}^2(\sqrt{\theta})} =: \sigma,$$

since $U_{2(k-1)}(t)\sqrt{1-t^2} \leq 1$ and this inequality is sharp (see, e.g., [13]). We note in passing that if $\gamma > \cos^2(\pi/(2(2k-1)))$, then $\omega_k(x_j, \theta) = \sigma$ (see the proof of Theorem 4.2 of [9]). Clearly,

$$\mu(L_k') \leq \mu \left\{ b \in S_n : \sum_{i=j}^{n} b_i^2 > \beta^{-2} b_1^2 \right\},$$

where $\beta^2 = \sigma/(\theta - 1)$.

Let c_i be the Lebesgue measure of the unit ball in $\mathcal{R}^i$, $c_i = \pi^{i/2}/\Gamma(1 + i/2)$. As in [9], Remark 7.2, instead of integrating over the unit sphere S_n, we may integrate over the unit ball $||b|| \leq 1$ with respect to normalized Lebesgue measure,

$$\mu \left\{ b \in S_n : \sum_{i=j}^{n} b_i^2 > \beta^{-2} b_1^2 \right\} = \frac{1}{c_n} \int_{||b|| \leq 1} \chi \left(\sum_{i=j}^{n} b_i^2 > \beta^{-2} b_1^2 \right) db,$$

where $\chi(Z)$ is the characteristic function of the set Z. Then

$$\mu(L_k') \le \frac{1}{c_n} \int_{[-1,1]} \int_{\sum_{i=j}^n b_i^2 > \beta^{-2} b_1^2} \int_{\sum_{i=2}^{j-1} b_i^2 \le 1 - b_1^2 - \sum_{i=j}^n b_i^2} db \, .$$

The last integral is the measure of the ball in $\mathcal{R}^{j-2}$, and

$$\begin{aligned}
\mu(L_k') &\le \frac{2\,c_{j-2}}{c_n} \int_{[0,1]} \int_{\sum_{i=j}^n b_i^2 > \beta^{-2} b_1^2} \left(1 - b_1^2 - \sum_{i=j}^n b_i^2\right)_+^{(j-2)/2} \\
&= \frac{2\,c_{j-2}}{c_n} \int_{[0,1]} \int_{\sum_{i=j}^n b_i^2 < 1} \chi\left(\sum_{i=j}^n b_i^2 > \beta^{-2} b_1^2\right) \left(1 - b_1^2 - \sum_{i=j}^n b_i^2\right)_+^{(j-2)/2}
\end{aligned}$$

Changing variables by $t = \sqrt{\sum_{i=j}^n b_i^2}$ and $x = b_1$, formula 4.642 of [6] yields

$$\mu(L_k') \le \frac{2\,c_{j-2}\,c_{n-j+1}}{c_n}(n-j+1)$$

$$\cdot \int_0^1 \int_0^1 \chi(t^2 > \beta^{-2} x^2)\,(1 - x^2 - t^2)_+^{(j-2)/2}\, t^{n-j}\, dx\, dt$$

$$\begin{aligned}
&\le \frac{2\,c_{j-2}\,c_{n-j+1}}{c_n}(n-j+1) \int_0^1 \int_0^{\beta t} (1 - x^2 - t^2)_+^{(j-2)/2}\, t^{n-j}\, dx\, dt \\
&\le \frac{2\,c_{j-2}\,c_{n-j+1}}{c_n}(n-j+1)\beta \int_0^1 (1-t^2)^{j/2-1}\, t^{n-j+1}\, dt \\
&= \frac{c_{j-2}\,c_{n-j+1}}{c_n}(n-j+1)\beta B((n-j+2)/2, j/2),
\end{aligned}$$

where $B(i,j) = \Gamma(i)\Gamma(j)/\Gamma(i+j)$ is the beta function. Finally,

$$\mu(L_k') \le \frac{\beta\,(n-j+1)\Gamma((n-j)/2+1)}{\sqrt{\pi}\,\Gamma((n-j+1)/2+1)}$$

and

$$\mu(L_k') \le \frac{2\Gamma((n-j)/2+1)}{\sqrt{\pi}\,\Gamma((n-j+1)/2)\,\sqrt{\theta-1}\,U_{2(k-1)}(\theta)},$$

which completes the first inequality of Theorem 3.

Let

$$s_j = \frac{2\Gamma((n-j)/2+1)}{\sqrt{\pi}\,\Gamma((n-j+1)/2)}.$$

Then

$$\mu(L_k) \ge 1 - s_j/\sqrt{\theta-1}/U_{2(k-1)}(\sqrt{\theta}),$$

and since s_j is a decreasing function of j, the proof is completed. □

We now explain how Theorem 3 is related to Theorem 4.2 of [9]. Observe that using formula (13) of [9] for $n \geq 8$, we get

$$s_n = \frac{2}{\pi} < s_{n-1} = 1 < \cdots < s_2 = \frac{2\Gamma(n/2)}{\sqrt{\pi}\,\Gamma((n-1)/2)} \leq 0.824\sqrt{n-1}.$$

Take $j = 2$. Then from Theorem 3 it follows that for any $\theta > 1$, we have

$$\mu\{b \in S_n : \lambda_1(A) \leq \theta\,\hat{\xi}(A,b,k)\} \geq 1 - 0.824\,\frac{\sqrt{n-1}}{\sqrt{\theta-1}\,U_{2(k-1)}(\sqrt{\theta})}.$$

Let $\theta = 1/(1-\varepsilon)$ for some $\varepsilon \in (0,1)$. Then

$$\mu(L_k) = \mu\left\{b \in S_n : \frac{\lambda_1(A) - \hat{\xi}(A,b,k)}{\lambda_1(A)} < \varepsilon\right\}$$
$$\geq 1 - 0.824\,\frac{\sqrt{(n-1)\,\varepsilon}}{\sqrt{1-\varepsilon}\,U_{2(k-1)}(1/\sqrt{1-\varepsilon})}.$$

Observe that

$$U_{2(k-1)}(1/\sqrt{1-\varepsilon}) = 0.5\sqrt{(1-\varepsilon)/\varepsilon}\left(\left(\frac{1+\sqrt{\varepsilon}}{\sqrt{1-\varepsilon}}\right)^{2k-1} - \left(\frac{1-\sqrt{\varepsilon}}{\sqrt{1-\varepsilon}}\right)^{2k-1}\right),$$

and after some calculations, we obtain

$$U_{2(k-1)}(1/\sqrt{1-\varepsilon}) = 0.5\,\sqrt{(1-\varepsilon)/\varepsilon}\,c^{-1}\,(1-c^2),$$

where $c = ((1-\sqrt{\varepsilon})/(1+\sqrt{\varepsilon}))^{k-1/2}$. Thus we get

$$\mu\left\{b \in S_n : \frac{\lambda_1(A) - \hat{\xi}(A,b,k)}{\lambda_1(A)} < \varepsilon\right\} \geq 1 - 1.648\,\sqrt{n-1}\,c\,(1-c^2)^{-1}.$$

Recall that Theorem 4.2 of [9] yields

$$\mu\left\{b \in S_n : \frac{\lambda_1(A) - \hat{\xi}(A,b,k)}{\lambda_1(A)} < \varepsilon\right\} \geq 1 - 1.648\,\sqrt{n}\,c \geq 1 - 1.648\,\sqrt{n}\,e^{-(2k-1)\sqrt{\varepsilon}}.$$

Thus for $j = 2$, Theorem 3 gives essentially the same bound as Theorem 4.2. For $j > 2$, the bound of Theorem 3 is better. Usually we do not know the index j. However, for large θ or for many eigenvalues close to the largest eigenvalue λ_1, the index j is large and s_j becomes independent on n. In this case, $\mu(L_k)$ goes quickly to 1 even for very large n.

We now find a lower bound on the probability of the set M_k. Recall that

$$M_k = \{b \in S_n : \eta\,\xi(A,b,k) \leq \lambda_n(A) \leq \xi(A,b,k)\} \quad \text{for} \quad \eta \leq 1.$$

THEOREM 4. *For any symmetric positive definite matrix A, let m denote the number of distinct eigenvalues. Then we have*

$$\mu(M_k) = 1 \quad \textit{for } k \geq m \quad \textit{or} \quad \eta \leq 1/\operatorname{cond} A$$

and for any $k < m$ *and any* $1/\operatorname{cond} A < \eta < 1$,

$$\mu(M_k) \geq 1 - \frac{2\Gamma(j/2)}{\sqrt{\pi}\,\Gamma((j-1)/2)}$$

$$\cdot \sqrt{\frac{\eta \operatorname{cond} A - 1}{1-\eta}}\, U^{-1}_{2(k-1)}\left(\sqrt{1 + (1-\eta)/(\eta \operatorname{cond} A - 1)}\right)$$

$$\geq 1 - \frac{2\Gamma(n/2)}{\sqrt{\pi}\,\Gamma((n-1)/2)} \sqrt{\frac{\eta \operatorname{cond} A - 1}{1-\eta}}\, U^{-1}_{2(k-1)}\left(\sqrt{1 + (1-\eta)/(\eta \operatorname{cond} A - 1)}\right),$$

where the index j *is defined by* $\lambda_n/\lambda_{j-1} < \eta \leq \lambda_n/\lambda_j$, $2 \leq j \leq n$.

Proof. The proof of Theorem 4 is similar to the proof of Theorem 3. As before, we consider the set M_k',

$$M_k' = S_n - M_k = \{b \in S_n : \lambda_n(A) < \eta\, \xi(A, b, k)\}.$$

Using the same notation and reasoning as in the proof of Theorem 3, we can easily get

$$\mu(M_k') = \mu\left\{ b \in S_n : \inf_{Q \in \mathcal{P}_k(1)} \sum_{i=1}^{n} b_i^2 Q^2(x_i)(\eta x_i - 1) > 0 \right\},$$

where now $x_i = \lambda_i/\lambda_n$, $1 = x_n \leq x_{n-1} \leq \cdots \leq x_1 = \operatorname{cond} A$. Clearly, if $k \geq m$ or if $\eta \leq \lambda_n/\lambda_1 = 1/x_1$, then $\mu(M_k') = 0$ and the first part of Theorem 4 is proved.

Assume now that $k < m$ and $1/x_1 < \eta < 1$. We have $1/x_{j-1} < \eta \leq 1/x_j$ and, as in Theorem 3, we can show that

$$\mu(M_k') \leq \mu\left\{ b \in S_n : \sum_{i=1}^{j-1} b_i^2 Q^2(x_i)(\eta x_i - 1) > b_n^2 Q^2(1)(1-\eta) \right\}$$

for any $Q \in \mathcal{P}_k(1)$. Hence

$$\mu(M_k') \leq \mu\left\{ b \in S_n : \sigma \sum_{i=1}^{j-1} b_i^2 > b_n^2(1-\eta) \right\},$$

where

$$\sigma = \inf_{Q \in \mathcal{P}_k(1)} \max_{x \in [1/\eta, \operatorname{cond} A]} (Q^2(x)(\eta x - 1)).$$

Changing variables by $y = (\operatorname{cond} A - x)/(\operatorname{cond} A - 1/\eta)$, we get

$$\sigma = (\xi - 1) \inf_{Q \in \mathcal{P}_k(\delta)} \max_{y \in [0,1]} (Q^2(y)(1-y)),$$

where $\xi = \eta \operatorname{cond} A$ and $\delta = (\xi - \eta)/(\xi - 1) > 1$. Using the estimate of $\omega_k(x_j, \theta)$ from the proof of Theorem 3, we obtain

$$\sigma \leq \frac{\xi - 1}{U^2_{2(k-1)}(\sqrt{\delta})},$$

and consequently

$$\mu(M_k') \le \mu\left\{ b \in S_n : \sum_{i=1}^{j-1} b_i^2 > U_{2(k-1)}^2(\sqrt{\delta})\,(1-\eta)/(\xi-1)\; b_n^2 \right\}.$$

As in the proof of Theorem 3, we thus conclude that

$$\mu(M_k') \le \frac{2\,\Gamma(j/2)}{\sqrt{\pi}\,\Gamma((j-1)/2)} \sqrt{\frac{\eta\,\mathrm{cond}\,A - 1}{1-\eta}}\, U_{2(k-1)}^{-1}\left(\sqrt{1 + \frac{1-\eta}{\eta\,\mathrm{cond}\,A - 1}}\right),$$

which completes the first inequality of Theorem 4. To get the second inequality, it is enough to observe that

$$s_j' = \frac{2\,\Gamma(j/2)}{\sqrt{\pi}\,\Gamma((j-1)/2)} < \frac{2\,\Gamma(n/2)}{\sqrt{\pi}\,\Gamma((n-1)/2)} = s_n'$$

for $j = 2, 3, \ldots, n$. Hence the proof is completed. □

We now show how Theorem 4 is related to Theorem 2. Clearly, for $n \ge 8$, we have

$$s_2' = \frac{2}{\pi} < s_3' = 1 < \cdots < s_n' = \frac{2\,\Gamma(n/2)}{\sqrt{\pi}\,\Gamma((n-1)/2)} \le 0.824\sqrt{n-1}.$$

Take $j = n$. Then from Theorem 4 it follows that for any η: $0 < \eta < 1$, we have

$$\mu\{b \in S_n : \eta\,\xi(A,b,k) \le \lambda_n(A)\} \ge 1 - 0.824\sqrt{(n-1)\,z}\;/U_{2(k-1)}(\sqrt{1+1/z}\,),$$

where $z = (\eta\,\mathrm{cond}\,A - 1)/(1-\eta)$. Let $\eta = 1/(1+\varepsilon\,\mathrm{cond}\,A)$ for some $\varepsilon \in (0,1)$. Then

$$\mu(M_k) = \mu\left\{ b \in S_n : \frac{\xi(A,b,k) - \lambda_n(A)}{\lambda_1(A)} < \varepsilon \right\}$$

$$\ge 1 - 0.824\sqrt{(n-1)(1-\varepsilon - 1/\mathrm{cond}\,A)/\varepsilon}\;/U_{2(k-1)}\left(\sqrt{1 + \varepsilon/(1-\varepsilon - 1/\mathrm{cond}\,A)}\right).$$

Since

$$U_{2(k-1)}\left(\sqrt{1+1/z}\right) = 0.5\sqrt{z}\,c^{-1}\,(1-c^2),$$

where now

$$c = \left(\left(1 - \sqrt{\varepsilon/(1-1/\mathrm{cond}\,A)}\right) / \left(1 + \sqrt{\varepsilon/(1-1/\mathrm{cond}\,A)}\right)\right)^{k-1/2}$$

(see the proof of Theorem 4), we get

$$\mu\left\{ b \in S_n : \frac{\xi(A,b,k) - \lambda_n(A)}{\lambda_1(A)} < \varepsilon \right\} \ge 1 - 1.648\sqrt{n-1}\,c\,(1-c^2)^{-1}.$$

Recall that Theorem 2 yields

$$\mu\left\{ b \in S_n : \frac{\xi(A,b,k) - \lambda_n(A)}{\lambda_1(A)} < \varepsilon \right\} \ge 1 - 1.648\sqrt{n}\left(\frac{1-\sqrt{\varepsilon}}{1+\sqrt{\varepsilon}}\right)^{k-1/2}$$

$$\ge 1 - 1.648\sqrt{n}\,e^{-(2k-1)\sqrt{\varepsilon}}.$$

Thus even for $j = n$, Theorem 4, generally gives a better bound than Theorem 2. Let us stress that if we know that j is small, which is the case for small η or cluster eigenvalues, the bound of Theorem 4 is even more attractive than that of Theorem 2.

The bound given in Theorem 4 depends on the condition number of A, which is not known. We can avoid this difficulty if we know an upper bound of the condition number of the matrix A. The following corollary holds (the proof is the same as the proof of Theorem 4).

COROLLARY 1. *Let M be any number, $M > 1$. For any symmetric positive definite matrix A of size $n \geq 8$ such that* cond $A \leq M$ *let m denote the number of distinct eigenvalues. Then we have*

$$\mu(M_k) = 1 \quad \text{for } k \geq m \quad \text{or} \quad \eta \leq 1/M$$

and

$$\mu(M_k) \geq 1 - \frac{2\Gamma(n/2)}{\sqrt{\pi}\,\Gamma((n-1)/2)} \sqrt{\frac{\eta M - 1}{1-\eta}}\, U^{-1}_{2(k-1)}\left(\sqrt{1 + (1-\eta)/(\eta M - 1)}\right)$$

$$\geq 1 - 0.824\sqrt{n} \sqrt{\frac{\eta M - 1}{1-\eta}}\, U^{-1}_{2(k-1)}\left(\sqrt{1 + (1-\eta)/(\eta M - 1)}\right)$$

for $k < m$ and $1/M < \eta < 1$.
