$$\begin{aligned} C &:= \mathcal{E}\left(J^+(x) \begin{pmatrix} \frac{1}{\sigma}\varepsilon \\ 0 \end{pmatrix} \begin{pmatrix} \frac{1}{\sigma}\varepsilon \\ 0 \end{pmatrix}^T J^{+T}(x)\right) \\ &= J^+(x)\mathcal{E}\left(\begin{pmatrix} \frac{1}{\sigma}\varepsilon \\ 0 \end{pmatrix} \begin{pmatrix} \frac{1}{\sigma}\varepsilon \\ 0 \end{pmatrix}^T\right) J^{+T}(x) \\ &= J^+(x) \begin{pmatrix} \mathbb{I}_{m_1 \times m_1} & 0 \\ 0 & 0_{m_2 \times m_2} \end{pmatrix} J^{+T}(x). \end{aligned}$$

Obviously, the matrix $C$ is a symmetric positive semidefinite matrix with rank $C = \bar{m} := n - m_2$.

Now let us show how to compute confidence regions for all variables in constrained parameter estimation problems. For the unconstrained case the way of computation of confidence regions is well known, while it is less well known for the constrained case and was introduced by one of the authors in [4]. Generalizing the unconstrained case, we define a nonlinear confidence region for the solution $x^*$ of the nonlinear [illegible] parameter estimation problem (2.2) by

$$G_N(\alpha) := \{x |\, F_2(x) = 0,\ \|F_1(x)\|_2^2 - \|F_1(x^*)\|_2^2 \leq \gamma^2(\alpha)\},$$

where $\gamma^2(\alpha) := \chi^2_{\bar{m}}(1-\alpha)$ is the quantile of the $\chi^2$ distribution for value $\alpha$ with $\bar{m}$ degrees of freedom. The nonlinear confidence region $G_N(\alpha)$ can be approximated by a linearized confidence region

$$\begin{aligned} G_L(\alpha) := \{x |\ & F_2(x^*) + J_2(x^*)(x - x^*) = 0, \\ & \|F_1(x^*) + J_1(x^*)(x - x^*)\|_2^2 - \|F_1(x^*)\|_2^2 \leq \gamma^2(\alpha)\}. \end{aligned}$$

Note that since $x^*$ is optimal in (2.2), the latter expression can be rewritten as

$$G_L(\alpha) = \{x \mid J_2(x^*)(x - x^*) = 0,\ \|J_1(x^*)(x - x^*)\|_2^2 \leq \gamma^2(\alpha)\}. \tag{3.5}$$

Indeed, the optimality conditions for $x^*$ and the Lagrange vector $\lambda^*$ in problem (2.2), namely

$$F_1(x^*)^T J_1(x^*) + \lambda^{*T} J_2(x^*) = 0,$$

yield that for any $\Delta x$ satisfying $J_2 \Delta x = 0$, the following relations hold:

$$F_1(x^*)^T J_1(x^*) \Delta x = -\lambda^{*T} J_2(x^*) \Delta x = 0. \tag{3.6}$$

Taking into account relations (3.6) and the equality $F_2(x^*) = 0$ results in (3.5).

The following lemma gives another, more illustrative, representation of the linear confidence region.

LEMMA 3.1. [illegible] $x^*$ [illegible] (2.2) [illegible] $\varepsilon$ [illegible] (2.5) [illegible] (2.6) [illegible]

$$G_L(\alpha) = \bar{G}_L(\alpha) := \left\{ x^* + \Delta x \mid \Delta x = -J^+(x^*) \begin{pmatrix} \eta \\ 0 \end{pmatrix}, \ \ \|\eta\|_2^2 \le \gamma^2(\alpha) \right\}. \tag{3.7}$$

[illegible] Consider $x \in G_L(\alpha)$, and denote $\Delta x := x - x^*$. It follows from (3.5) that

$$\|J_1(x^*) \Delta x\|_2^2 \le \gamma^2(\alpha).$$

If we choose $\eta = -J_1(x^*)\Delta x$, then

$$\begin{aligned} \Delta x = J^+(x^*) J(x^*) \Delta x = J^+(x^*) \begin{pmatrix} J_1(x^*)\Delta x \\ J_2(x^*)\Delta x \end{pmatrix} = J^+(x^*) \begin{pmatrix} J_1(x^*)\Delta x \\ 0 \end{pmatrix} \\ = -J^+(x^*) \begin{pmatrix} \eta \\ 0 \end{pmatrix}. \end{aligned}$$

Hence, $x \in \bar{G}_L(\alpha)$.

Let us take $x \in \bar{G}_L(\alpha)$. Then, by definition of $J^+$ the vector $\Delta x$ satisfies the linear system

$$\begin{aligned} J_1^T(x^*) J_1(x^*) \Delta x + J_2^T(x^*) \lambda &= -J_1^T(x^*) \eta, \\ J_2(x^*) \Delta x &= 0, \end{aligned}$$

with some vector $\lambda$. Then

$$\begin{aligned} (\eta + J_1(x^*)\Delta x)^T J_1(x^*) \Delta x &= \eta^T J_1(x^*) \Delta x + \Delta x^T J_1^T(x^*) J_1(x^*) \Delta x \\ &= -\lambda^T J_2(x^*) \Delta x = 0. \end{aligned}$$

Now let us compute $||\eta + J_1(x^*)\Delta x||_2^2$ :

$$\begin{aligned} 0 \le ||\eta + J_1(x^*)\Delta x||_2^2 &= \|\eta\|_2^2 + 2\eta^T J_1(x^*)\Delta x + \Delta x^T J_1^T(x^*) J_1(x^*) \Delta x \\ &= \|\eta\|_2^2 - \|J_1(x^*)(x - x^*)\|_2^2. \end{aligned}$$

Hence, $\|J_1(x^*)\Delta x\|_2^2 \le \|\eta\|_2^2 \le \gamma^2(\alpha)$. This means that $x \in G_L(\alpha)$. ☐

The next result shows that the linearized confidence region $G_L(\alpha)$ is contained [illegible] in a minimal box, which is the cross product of so-called confidence intervals.

LEMMA 3.2. [illegible] $x^*$ [illegible] (3.1) [illegible] $\varepsilon$ [illegible] (2.5) [illegible] (2.6) [illegible]

$$G_L(\alpha) \subset \bigtimes_{i=1}^{n} [x_i^* - \theta_i, x_i^* + \theta_i],$$

[illegible] $\theta_i = C_{ii}\gamma(\alpha)$. [illegible] $C_{ii}^2$ [illegible] $C$ [illegible]

$$\max_{x \in G_L(\alpha)} |x_i - x_i^*| = \theta_i, \; i = 1, \dots, n.$$

[illegible] For each component of $x \in G_L(\alpha)$ we evaluate

$$|\Delta x_i|^2 = \left| e_i^T J^+(x^*) \begin{pmatrix} \eta \\ 0 \end{pmatrix} \right|^2 \le \left\| e_i^T J^+(x^*) \begin{pmatrix} \mathbb{I} \\ 0 \end{pmatrix} \right\|_2^2 \|\eta\|_2^2 \le C_{ii}^2 \gamma^2(\alpha).$$

Now we want to show that this bound is [illegible] Let us now compute the maximum value of $|\Delta x_i|^2$, that is, the maximum value of the cost function in the following problem:

$$\begin{aligned} &\max_{\eta} \; \left| e_i^T J^+(x^*) \begin{pmatrix} \mathbb{I} \\ 0 \end{pmatrix} \eta \right|^2 \\ &\text{s.t.} \; ||\eta||_2^2 \le \gamma^2(\alpha). \end{aligned}$$

Obviously, the solution in this problem is

$$\eta^{*T} = \gamma(\alpha) e_i^T J^+(x^*) \begin{pmatrix} \mathbb{I} \\ 0 \end{pmatrix} \Big/ \left\| e_i^T J^+(x^*) \begin{pmatrix} \mathbb{I} \\ 0 \end{pmatrix} \right\|_2,$$

and the optimal value of the cost function is equal to

$$\gamma^2(\alpha) \left\| e_i^T J^+(x^*) \begin{pmatrix} \mathbb{I} \\ 0 \end{pmatrix} \right\|_2^2 = C_{ii}^2 \gamma^2(\alpha). \qquad \square$$

Lemma 3.2 shows that the diagonal elements of the covariance matrix play an important role in the statistical assessment of the estimates, namely they are used to compute confidence intervals.

We finish this section with an example illustrating nonlinear and linearized confidence regions and a confidence box. Consider, for simplicity of visualization, an unconstrained problem in two variables (Rosenbrock-type example):

$$\min \frac{1}{2} ||F_1(x)||_2^2, \;\; F_1(x) := \begin{pmatrix} x_1/\sigma_1 \\ (x_2 + \frac{1}{200}(x_1 - 50)^2)/\sigma_2 \end{pmatrix}, \;\; \sigma_1 = 1. \tag{3.8}$$

By choosing the parameter $\sigma_2$ we may change the nonlinearity of the problem (3.8): the smaller $\sigma_2$, the larger the nonlinearity. The solution of problem (3.8) is $x^* = (0, -12.5)^T$.

Figure 3.1 shows that linear confidence regions are quite good approximations of nonlinear confidence regions.

## 4. Covariance matrix as a solution of a linear system.

In this section we will show that the covariance matrix $C \in \mathbb{R}^{n \times n}$ for the constrained parameter estimation problem

$$C := J^+ \begin{bmatrix} \mathbb{I} & 0 \\ 0 & 0 \end{bmatrix} (J^+)^T \tag{4.1}$$

satisfies a linear system of equations with coefficients which are uniquely determined by the matrix $J$ (see (2.6)). In this section, for simplicity of notations, we omit the

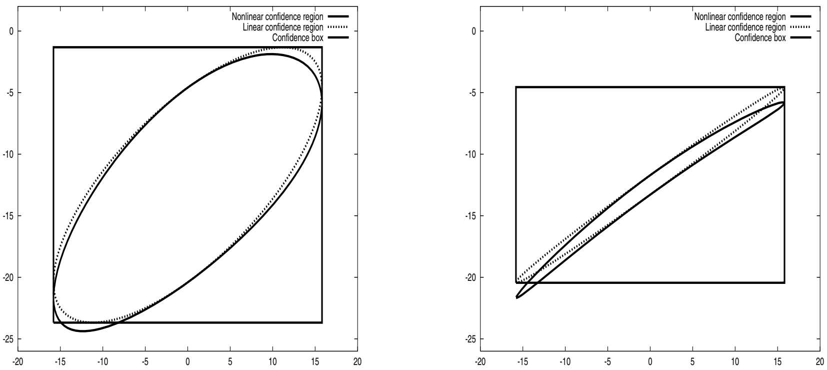

FIG. 3.1. *Nonlinear and linearized confidence regions and a confidence box for* $\gamma(\alpha) = 250$ *and for* $\sigma_2 = 0.5$ *(right) and* $\sigma_2 = 0.05$ *(left).*

dependence of $C$ on the linearization point $x$. Throughout this section we assume that the matrices $J_1$ and $J_2$ satisfy the regularity assumptions (2.5) and (2.6). Let us denote

$$M^{-1} = \begin{pmatrix} J_1^T J_1 & J_2^T \\ J_2 & 0 \end{pmatrix}^{-1} := \begin{pmatrix} X & Y \\ Z & T \end{pmatrix},$$
$$X \in \mathbb{R}^{n\times n},\ \ Y \in \mathbb{R}^{n\times m_2},\ \ Z = Y^T \in \mathbb{R}^{m_2\times n},\ \ T \in \mathbb{R}^{m_2\times m_2}.$$

LEMMA 4.1. [illegible] $C$ (4.1)[illegible] $X$[illegible] $C \in \mathbb{R}^{n\times n}$[illegible] $Z \in \mathbb{R}^{m_2\times n}$

$$\begin{aligned} J_1^T J_1 C + J_2^T Z &= \mathbb{I}, \\ J_2 C &= 0. \end{aligned} \tag{4.2}$$

[illegible]. According to (2.8) and (4.1) we have

$$\begin{aligned} C &= \begin{pmatrix} \mathbb{I} & 0 \end{pmatrix} M^{-1} \begin{pmatrix} J_1^T J_1 & 0 \\ 0 & 0 \end{pmatrix} M^{-1} \begin{pmatrix} \mathbb{I} \\ 0 \end{pmatrix} \\ &= \begin{pmatrix} X & Y \end{pmatrix} \begin{pmatrix} J_1^T J_1 & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} X \\ Z \end{pmatrix} = X J_1^T J_1 X. \end{aligned} \tag{4.3}$$

Since the blocks $X$ and $Z$ of the matrix $M^{-1}$ satisfy the linear system

$$\begin{aligned} J_1^T J_1 X + J_2^T Z &= \mathbb{I}, \\ J_2 X &= 0, \end{aligned} \tag{4.4}$$

relation (4.3) yields

$$C = X(\mathbb{I} - J_2^T Z) = X,$$

which means that $C = X$. □

Note that, according to Lemma 4.1 the covariance matrix $C$ is a generalized inverse of the matrix $J_1^T J_1$, that is, it satisfies $C(J_1^T J_1)C = C$.

LEMMA 4.2. [illegible] $X^{(i)}$ [illegible] $X$ [illegible]

$$\min_{\kappa} f_i(\kappa) = \frac{1}{2}\kappa^T J_1^T J_1 \kappa - e_i^T \kappa \qquad (4.5)$$
$$\text{[illegible]} \quad J_2\kappa = 0,$$

[illegible] $Z^{(i)}$ [illegible] $Z$ [illegible] (4.5) [illegible] (4.5) [illegible]

$$f_i(X^{(i)}) = -\frac{1}{2}X_i^{(i)}.$$

[illegible] $e_i$ [illegible] $i$ [illegible] $X_i^{(i)}$ [illegible] $i$ [illegible] $X^{(i)}$.

[illegible] Multiplying system (4.4) with $e_i$ yields

$$\begin{aligned} J_1^T J_1 X^{(i)} + J_2^T Z^{(i)} &= e_i, \\ J_2 X^{(i)} &= 0. \end{aligned} \qquad (4.6)$$

Under assumptions (2.5) and (2.6) this system has a unique solution. The system (4.6) is nothing but the Karush–Kuhn–Tucker system for the problem (4.5), thus defining the optimal solution $X^{(i)}$ and the optimal Lagrange variables $Z^{(i)}$.

Next, we compute the value of the cost function at $X^{(i)}$:

$$\begin{aligned} f_i(X^{(i)}) &= \frac{1}{2}X^{(i)T} J_1^T J_1 X^{(i)} - e_i^T X^{(i)} \\ &= \frac{1}{2}(X^{(i)T} e_i - X^{(i)T} J_2^T Z^{(i)}) - e_i^T X^{(i)} = -\frac{1}{2}X_i^{(i)}. \qquad \square \end{aligned}$$

The following corollary of Lemma 4.2 shows how to compute the trace of the covariance matrix in terms of the optimal values of the problems (4.5). The trace of the covariance matrix can be used as the cost functional for design of optimal experiments [1].

COROLLARY 4.3.

$$\text{tr } C = \sum_{i=1}^{n} e_i^T X^{(i)} = -2\sum_{i=1}^{n} f_i(X^{(i)}). \qquad (4.7)$$

Using the representation of the covariance matrix as a solution of the linear system, we may derive the derivatives of the covariance matrix $C$ and the matrix $Z$ as the functions of the matrices $J_1$ and $J_2$,

$$\begin{aligned} C &= C(J_1, J_2) = X(J_1, J_2), \\ Z &= Z(J_1, J_2). \end{aligned}$$

These derivatives are needed in numerical methods for design of optimal nonlinear experiments [1]. Let $J_1(t) = J_1 + t\Delta J_1$ and $J_2(\mu) = J_2 + \mu\Delta J_2$, and compute the partial derivatives

$$\begin{aligned}
\frac{\partial X(J_1(t),J_2(\mu))}{\partial t}\,\Big|_{t=0,\mu=0} &= \frac{\partial X(J_1(t),J_2(\mu))}{\partial J_1}\Delta J_1\,\Big|_{t=0,\mu=0} =: L_1,\\
\frac{\partial X(J_1(t),J_2(\mu))}{\partial \mu}\,\Big|_{t=0,\mu=0} &= \frac{\partial X(J_1(t),J_2(\mu))}{\partial J_2}\Delta J_2\,\Big|_{t=0,\mu=0} =: L_2,\\
\frac{\partial Z(J_1(t),J_2(\mu))}{\partial t}\,\Big|_{t=0,\mu=0} &= \frac{\partial Z(J_1(t),J_2(\mu))}{\partial J_1}\Delta J_1\,\Big|_{t=0,\mu=0} =: R_1,\\
\frac{\partial Z(J_1(t),J_2(\mu))}{\partial \mu}\,\Big|_{t=0,\mu=0} &= \frac{\partial Z(J_1(t),J_2(\mu))}{\partial J_2}\Delta J_2\,\Big|_{t=0,\mu=0} =: R_2.
\end{aligned}$$

Differentiating the linear system (4.2) with respect to $t$ yields

$$\begin{aligned}
(\Delta J_1^T J_1 + J_1^T \Delta J_1)X + J_1^T J_1 L_1 + J_2^T R_1 &= 0,\\
J_2 L_1 &= 0.
\end{aligned}$$

Here $X = C$ and $J_1 = J_1(0)$, $J_2 = J_2(0)$. Thus, the matrices $L_1$ and $R_1$ can be found by

$$\begin{aligned}
L_1 &= -X(\Delta J_1^T J_1 + J_1^T \Delta J_1)X,\\
R_1 &= -Z(\Delta J_1^T J_1 + J_1^T \Delta J_1)X.
\end{aligned}\tag{4.8}$$

Analogously,

$$\begin{aligned}
\Delta J_2^T Z + J_1^T J_1 L_2 + J_2^T R_2 &= 0,\\
\Delta J_2 X + J_2 L_2 &= 0,
\end{aligned}$$

and hence, the matrices $L_2$ and $R_2$ can be computed by

$$\begin{aligned}
L_2 &= -X\Delta J_2^T Z - Z^T \Delta J_2 X,\\
R_2 &= -Z\Delta J_2^T Z - T\Delta J_2 X,
\end{aligned}\tag{4.9}$$

where $T = -J_2^{+} J_1^T J_1 Z^T$.

In the case of the trace of the covariance matrix, which is one of the possible criteria for the design of the experiments, the computation of the derivatives is significantly simplified.

LEMMA 4.4.

$$\frac{\partial \mathrm{tr}\ C(J_1(t),J_2)}{\partial t} = -\sum_{i=1}^{n} X^{(i)T}(\Delta J_1^T J_1 + J_1^T \Delta J_1)X^{(i)},\tag{4.10}$$

$$\frac{\partial \mathrm{tr}\ C(J_1,J_2(\mu))}{\partial \mu} = -2\sum_{i=1}^{n} X^{(i)T}\Delta J_2 Z^{(i)},\tag{4.11}$$

[illegible] $X^{(i)}$ [illegible] $Z^{(i)}$ [illegible] $i$ [illegible] $X$ [illegible] $Z$ [illegible]. The proof follows from the relations (4.8) and (4.9) and the definition of the trace of a matrix tr $C = \sum_{i=1}^{n} e_i^T C e_i$. □

Note that, computing the derivative of the covariance matrix with respect to $J_2$ requires knowledge of the matrix $Z$.

1. The relations (4.10) and (4.11) can be derived from the duality theory for convex problems [7]. According to the theory, with the Lagrangian

$$L_i(\kappa,\pi,t,\mu)=\frac{1}{2}\kappa^T J_1(t)^T J_1(t)\kappa - e_i^T\kappa + \pi^T J_2(\mu)\kappa$$

for problem (4.5), one may compute partial derivatives of the optimal value of the cost function

$$\begin{aligned}\frac{\partial}{\partial t} f_i(X^{(i)}(J_1(t),J_2(\mu)))\Big|_{t=0,\mu=0} &= \max_{\kappa\in D_i^*}\min_{\pi\in\Lambda_i^*}\frac{\partial}{\partial t}L_i(\kappa,\pi,t,\mu)\Big|_{t=0,\mu=0},\\ \frac{\partial}{\partial \mu} f_i(X^{(i)}(J_1(t),J_2(\mu)))\Big|_{t=0,\mu=0} &= \max_{\kappa\in D_i^*}\min_{\pi\in\Lambda_i^*}\frac{\partial}{\partial \mu}L_i(\kappa,\pi,t,\mu)\Big|_{t=0,\mu=0},\end{aligned}\tag{4.12}$$

where $D_i^*\subset\mathbb{R}^n$, $\Lambda_i^*\subset\mathbb{R}^{m_2}$ denote the sets of optimal primal and dual solutions of problem (4.5) at $t=\mu=0$. From (4.7) we have that

$$\begin{aligned}\frac{\partial \mathrm{tr}C(J_1(t),J_2(\mu))}{\partial t} &= -2\sum_{i=1}^{n}\frac{\partial}{\partial t}f_i(X^{(i)}(J_1(t),J_2(\mu))),\\ \frac{\partial \mathrm{tr}C(J_1(t),J_2(\mu))}{\partial \mu} &= -2\sum_{i=1}^{n}\frac{\partial}{\partial \mu}f_i(X^{(i)}(J_1(t),J_2(\mu))),\end{aligned}$$

where $X^{(i)}(J_1(t),\,J_2(\mu))$ is an optimal solution in the problem (4.5) defined at $J_1(t)$ and $J_2(\mu)$, and $f_i(X^{(i)}(J_1(t),\,J_2(\mu)))$ denotes the optimal value of the cost function. In our case, by assumptions (2.5), (2.6) each set consists of only one element, namely

$$D_i^*=\{X^{(i)}\},\Lambda_i^*=\{-Z^{(i)}\}.\tag{4.13}$$

Hence, (4.12) results in (4.10) and (4.11). Let us note that relations (4.10) and (4.11) are true only under regularity conditions (2.5) and (2.6), while the more general conditions (4.12) hold also in case of violation of (2.5) and (2.6).

2. Let us note that $C=X$ is just an identity and does not suggest a good computation. The way to compute the matrix $C$ will be described later.

**5. Conjugate gradient method for constrained quadratic problems.** We saw that the columns $X^{(i)}$, $i=1,\dots,n$, of the covariance matrix (4.1), as well as the solution of problem (2.4), solve quadratic problems that can be formally written as

$$\begin{aligned}\min_{y\in\mathbb{R}^n} f(y) &= \frac{1}{2}y^T J_1^T J_1 y + b^T y\\ \text{s.t.}\quad J_2 y &= a\end{aligned}\tag{5.1}$$

for some vectors $a$ and $b$. As in previous sections, we assume that the matrices $J_2\in\mathbb{R}^{m_2\times n}$, $J_1\in\mathbb{R}^{m_1\times n}$ satisfy regularity conditions (2.5) and (2.6).

Let us apply the classical conjugate gradient method for solving the constrained problem (5.1). The traditional way is to project the conjugate gradient method onto the null-space of $J_2$; see, e.g., [5], [9], [13], [14]. Let $\mathcal{P}\in\mathbb{R}^{n\times n}$ denote a projector onto the null-space of the matrix $J_2$,

$$\mathcal{P}=\mathbb{I}-J_2^T J_2^+,\ J_2^+=(J_2J_2^T)^{-1}J_2,\tag{5.2}$$

where $J_2^+$ is a Moore–Penrose pseudoinverse of $J_2^T$. Let us note that the matrix $J_2J_2^T$ is nonsingular because of (2.5). The algorithm can be formulated as follows.

Algorithm 1.

**Input.** [illegible] $y_0$, [illegible] $J_2 y_0 = a$ [illegible] $k = 0$, [illegible] $\nabla f(y_0) = J_1^T J_1 y_0 + b$ [illegible]

$$p_1 = -\mathcal{P}\nabla f(y_0) \in \mathbb{R}^n.$$

**Step 1.** [illegible] $p_{k+1} = 0$ [illegible] $y_k$ [illegible] (5.1) [illegible] 2

**Step 2.** [illegible]

$$\alpha_{k+1} = -\frac{\nabla f^T(y_k) p_{k+1}}{||J_1 p_{k+1}||^2}, \quad y_{k+1} = y_k + \alpha_{k+1} p_{k+1} \tag{5.3}$$

[illegible]

$$p_{k+2} = -\mathcal{P}\nabla f(y_{k+1}) + \frac{||\mathcal{P}\nabla f(y_{k+1})||^2}{||\mathcal{P}\nabla f(y_k)||^2} p_{k+1}.$$

[illegible] $k = k + 1$ [illegible] 1

In exact arithmetic the method converges in at most $\bar{m} = n - m_2$ steps to the solution of the problem (5.1).

During the iterations (5.3) we need to compute projections $\mathcal{P}\nabla f(y_k)$ for each $k = 0, 1, 2, \ldots,$

$$\mathcal{P}\nabla f(y_k) = \nabla f(y_k) - J_2^T J_2^+ \nabla f(y_k) = \nabla f(y_k) - J_2^T u_k,$$

where

$$u_k := J_2^+ \nabla f(y_k). \tag{5.4}$$

We will use the fact that the vector $u_k$ is a solution of an unconstrained least squares problem

$$\min_{u \in \mathbb{R}^{m_2}} g(u) = \frac{1}{2} ||J_2^T u - r||^2 \tag{5.5}$$

with $r = \nabla f(y_k)$; see, e.g., [14].

Consequently, in order to compute the vector $u_k$ (5.4) we need to solve problem (5.5). This can be done again with the conjugate gradient method for the unconstrained least squares problem, which can be summarized as follows.

Algorithm 2.

**Input.** [illegible] $v_0$, [illegible] $l = 0$, [illegible] $q_1 = -\nabla g(v_0) = -J_2(J_2^T v_0 - r)$.

**Step 1.** [illegible] $q_{l+1} = 0$ [illegible] $v_l$ [illegible] (5.5) [illegible] 2

**Step 2.** [illegible]

$$\alpha_{l+1} = -\frac{\nabla g^T(v_l) q_{l+1}}{||J_2^T q_{l+1}||^2}, \quad v_{l+1} = v_l + \alpha_{l+1} q_{l+1}, \tag{5.6}$$

$$q_{l+2} = -\nabla g(v_{l+1}) + \frac{||\nabla g(v_{l+1})||^2}{||\nabla g(v_l)||^2} q_{l+1}.$$

[illegible] $l = l + 1$ [illegible] 1

Let us note that the conjugate gradient Algorithm 1 for solving the constrained quadratic problem (5.1), which we present here following [14], is equivalent to the preconditioned conjugate gradient method with residual update discussed in detail in [9].

We do not want to solve the problem (5.5) for each $\nabla f(y_k)$, $k = 2, 3, \dots, \bar{m}$ in order to construct vectors $J_2^T u_k$, but rather to use the results of some previous calculations. How are we to do this? Suppose we have solved the problem (5.5) for some $r = \nabla f(y_k)$ in $m_2$ iterations. As a result we have $m_2$ vectors

$$q_1, q_2, \dots, q_{m_2} \in \mathbb{R}^{m_2}, \tag{5.7}$$

which are linearly independent and are $J_2 J_2^T$ conjugate:

$$\begin{aligned} &q_i^T J_2 J_2^T q_j = 0,\ i \neq j, \\ &q_i^T J_2 J_2^T q_i \neq 0,\ i = 1, \dots, m_2. \end{aligned}$$

In what follows we show that

$$J_2^+ = \Big(q_1, \dots, q_{m_2}\Big) \operatorname{diag}(\beta_i, i = 1, \dots, m_2) \Big(q_1, \dots, q_{m_2}\Big)^T J_2, \tag{5.8}$$

where the numbers are computed by $\beta_i = 1/||J_2^T q_i||^2 \neq 0, i = 1, \dots, m_2$. Indeed, by construction,

$$\Big(q_1, \dots, q_{m_2}\Big)^T J_2 J_2^T \Big(q_1, \dots, q_{m_2}\Big) = \operatorname{diag}(\beta_i^{-1}, i = 1, \dots, m_2).$$

Then, obviously,

$$\begin{aligned} (5.9)\ &\Big(q_1, \dots, q_{m_2}\Big) \operatorname{diag}(\beta_i, i = 1, \dots, m_2) \Big(q_1, \dots, q_{m_2}\Big)^T \\ &= \Big(q_1, \dots, q_{m_2}\Big) \Big[\Big(q_1, \dots, q_{m_2}\Big)^T J_2 J_2^T \Big(q_1, \dots, q_{m_2}\Big)\Big]^{-1} \Big(q_1, \dots, q_{m_2}\Big)^T = (J_2 J_2^T)^{-1}, \end{aligned}$$

since the matrices $(q_1, \dots, q_{m_2})$ and $J_2 J_2^T$ are nonsingular. The formula (5.8) follows immediately from (5.9) and the representation of $J_2^+$. Thus, there is no necessity to solve the problem (5.5) for each $\nabla f(y_k)$, $k = 2, 3, \dots, \bar{m}$, in order to construct the vectors $J_2^T u_k$. The vectors $J_2^T u_k$ may be computed as

$$\begin{aligned} &J_2^T u_k = J_2^T J_2^+ \nabla f(y_k) \\ &= \Big(J_2^T q_1, \dots, J_2^T q_{m_2}\Big) \operatorname{diag}(1/||J_2^T q_i||^2,\ i = 1, \dots, m_2) \Big(J_2^T q_1, \dots, J_2^T q_{m_2}\Big)^T \nabla f(y_k), \end{aligned}$$

using the vectors $J_2^T q_i$ and the numbers $||J_2^T q_i||^2$, $i = 1, \dots, m_2$, that are constructed during the solution process of only one problem (5.5). This means that to compute each vector $J_2^T u_k$ we need two matrix-vector multiplications.

[illegible] 3. Assume that the solution process for solving problem (5.5) terminates after $k < m_2$ iterations, that is, we do not have the complete set of the vectors (5.7). This means that at the next iteration of Algorithm 1 we have to solve problem (5.5) again with the new right-hand side $r = r^{new}$. We may use already computed conjugate vectors $q_1, q_2, \dots, q_k$ from the previous iteration of Algorithm 1 and may start the solution process (5.6) for $l = k + 1, \dots$ with the vector

$$v_k = (q_1, q_2, \dots, q_k) \operatorname{diag}(\beta_1, \dots, \beta_k) (q_1, q_2, \dots, q_k)^T J_2 r^{new}.$$

As a result we get the sequence of the conjugate vectors

$$q_1, q_2, \dots, q_k, q_{k+1}, \dots, q_{\bar{k}}, \ \bar{k} \geq k. \tag{5.10}$$

At the next iteration of Algorithm 1 we proceed with the same procedure.

Let us summarize the properties of the constructed vectors $y_k \in \mathbb{R}^n$, $u_k \in \mathbb{R}^{m_2}$, $p_k \in \mathbb{R}^n$, $k = 1, \dots, \bar{m}$.

- The vectors $y_k$ and $-u_k$ are optimal primal and dual solutions in the problem

$$\min f(y), y \in y_0 + \mathrm{Span}\{p_1, \dots, p_k\}.$$

- $\mathcal{P}p_k = p_k$ and, hence, $J_2 p_k = 0$, meaning that the generated iterates remain in the null-space of the constraints.
- The vectors $p_1, \dots, p_{\bar{m}}$ are linearly independent.
- The vectors $p_1, \dots, p_{\bar{m}}$ form a basis of the null-space of the matrix $J_2$.
- The following relations are true:

$$p_i^T \mathcal{P} J_1^T J_1 \mathcal{P} p_j = p_i^T J_1^T J_1 p_j = \begin{cases} = 0, & i \neq j \\ \neq 0, & i = j. \end{cases} \tag{5.11}$$

[illegible] 4. Algorithms 1 and 2 are known to terminate in at most $\bar{m}$ and $m_2$ iterations in exact arithmetic. Roundoff errors destroy the conjugacy among search directions and finite termination after $\bar{m}$ and $m_2$ iterations usually will not appear. Detailed discussion of convergence aspects and influence of roundoff errors for conjugate gradient methods can be found in [5], [10], [12], [16], and many other references; see also surveys [8], [11], [15].

[illegible] 5. The other possibilities of computing projections without using iterative linear algebra methods are discussed in [9]. However, comparative analysis in [9] shows that the method discussed here (which is equivalent to a conjugate gradient method with residual update from [9]) is one of the most stable and robust against roundoff errors.

**6. Computation of the covariance matrix with the conjugate gradient method.** In this section we show how to use the information received in the course of the conjugate gradient method applied to (5.1) for computation of the covariance matrix $C$ (4.1).

Lemma 6.1. [illegible] $J_1$ [illegible] $J_2$ [illegible] (2.5) [illegible] (2.6) [illegible] (5.1) [illegible] $a$ [illegible] $b$ [illegible] (2.4) [illegible] $\Delta x^k$ [illegible] $p_1, \dots, p_{\bar{m}}$ [illegible] $||J_1 p_1||^2, \dots, ||J_1 p_{\bar{m}}||^2$ [illegible] (4.1) [illegible]

$$X = C = Q \mathrm{diag}(\gamma_i, i = 1, \dots, \bar{m}) Q^T, \tag{6.1}$$

[illegible]

$$Q = (p_1, \dots, p_{\bar{m}}) \in \mathbb{R}^{n \times \bar{m}}, \ \gamma_i = 1/||J_1 p_i||^2, \ i = 1, \dots, \bar{m}. \tag{6.2}$$

[illegible] Under assumptions (2.5) and (2.6) the system (4.2) has a unique solution. We want to show that the matrix $X$ (6.1) and the matrix $Z$,

$$Z = J_2^{+}(-J_1^T J_1 C + \mathbb{I}), \tag{6.3}$$

satisfy the linear system (4.2). Here again $J_2^+$ is a Moore–Penrose pseudoinverse of $J_2^T$.

Indeed,

$$J_2 X = J_2 Q \text{diag}(\gamma_i, i = 1, \dots, \bar{m}) Q^T = 0,$$

since $J_2 p_k = 0$ for all $k = 1, \dots, \bar{m}$, or in other words $J_2 Q = 0$. Now we want to show that the matrices $X$ (6.1) and $Z$ (6.3) satisfy the first equation in (4.2), namely that $J_1^T J_1 X + J_2^T Z = \mathbb{I}$. For this purpose we show that the matrix $N = 0$, where the matrix $N$ is defined by

$$N := J_1^T J_1 X + J_2^T Z - \mathbb{I} = J_1^T J_1 X + J_2^T J_2^+ (-J_1^T J_1 X + \mathbb{I}) - \mathbb{I}. \tag{6.4}$$

We represent the matrix $N$ in the form

$$N = (\mathbb{I} - J_2^T J_2^+) N + J_2^T J_2^+ N \tag{6.5}$$

and verify that

$$J_2^T J_2^+ N = 0, \tag{6.6}$$

$$(\mathbb{I} - J_2^T J_2^+) N = \mathcal{P} N = 0. \tag{6.7}$$

Indeed,

$$\begin{aligned} J_2^T J_2^+ N &= J_2^T J_2^+ J_1^T J_1 X + J_2^T J_2^+ J_2^T J_2^+ (-J_1^T J_1 X + \mathbb{I}) - J_2^T J_2^+ \\ &= J_2^T J_2^+ J_1^T J_1 X + J_2^T J_2^+ (-J_1^T J_1 X + \mathbb{I}) - J_2^T J_2^+ = 0, \end{aligned}$$

since $J_2^+ J_2^T = \mathbb{I}$. Next we show that (6.7) holds. Since the matrix $\mathcal{P}$ is a projector to the null-space of the matrix $J_2$, and the vectors $p_k$, $k = 1, \dots, \bar{m}$, form the basis of the null-space of the matrix $J_2$, then $\mathcal{P} N = 0$ if and only if $p_k^T N = 0$ for all $k = 1, \dots, \bar{m}$, or in other words $Q^T N = 0$. Hence, we need to validate $Q^T N = 0$:

$$\begin{aligned} Q^T N &= Q^T J_1^T J_1 Q \text{diag}(\gamma_i, i = 1, \dots, \bar{m}) Q^T - Q^T \\ &= \text{diag}\left(\frac{1}{\gamma_i}, i = 1, \dots, \bar{m}\right) \text{diag}(\gamma_i, i = 1, \dots, \bar{m}) Q^T - Q^T = 0. \qquad \square \end{aligned}$$

The lemma means that the covariance matrix $C \in \mathbb{R}^{n \times n}$ is uniquely defined according to formula (6.1) by the matrix $Q \in \mathbb{R}^{n \times \bar{m}}$ and the numbers $||J_1 p_i||^2$, $i = \overline{1, \bar{m}}$. Thus, we can store the matrix $Q$ and the numbers (6.2) instead of the matrix $C$.

[illegible] 6. The proof of Lemma 6.1 implies that to compute the covariance matrix $C$ by the formula (6.1) we may use any set of vectors $\bar{p}_1, \dots, \bar{p}_{\bar{m}}$, which satisfy the following conditions:

a) $\bar{p}_1, \dots, \bar{p}_{\bar{m}}$, are linearly independent;
b) $J_2 \bar{p}_k = 0,\ k = 1, \dots, \bar{m}$;
c) $\bar{p}_i^T J_1^T J_1 \bar{p}_j = 0,\ i \neq j;\ \bar{p}_i^T J_1^T J_1 \bar{p}_i,\ \neq 0,\ i, j = 1, \dots, \bar{m}$.

Let us now show how to compute the matrix $Z$. According to (6.3), in order to compute $Z$ we need to know $J_2^+$. In the case of the conjugate gradient method being applied to problem (5.1) we have, in a general case, the complete sequence of the vectors (5.7) as a result of solving problem (5.5). Using these vectors we can compute the matrix $J_2^+$ according to (5.8).

In order to compute the partial derivatives of the functions of the covariance matrix that are used in the design of optimal experiments [1] one can use the representation (6.1) of the covariance matrix and the formulas (4.8) and (4.9). For example, the derivatives of the trace of the covariance matrix have the following representation as a consequence of Lemma 4.4.

COROLLARY 6.2. $\frac{\partial \text{tr } C(J_1(t),J_2)}{\partial t}$ $\frac{\partial \text{tr } C(J_1,J_2(\mu))}{\partial \mu}$ (4.10) (4.11) $X^{(i)} = Q\text{diag}(\gamma_i, i = 1,\dots,\bar{m})Q_{i\cdot}$, $Q_{i\cdot}$ $i$ $Q \in \mathbb{R}^{\bar{m}\times n}$ $Z^{(i)} = J_2^+(-J_1^T J_1 X^{(i)} + e_i)$, $i = 1,\dots,n$.

7. As we noted before in the case of roundoff errors in Algorithms 1 and 2, the first $\bar{m}$ vectors $p_1,\dots,p_{\bar{m}}$ may be computed with numerical errors, and this leads to numerical errors in (6.1)–(6.3) and (4.8) for computing the covariance matrix $C$ and its derivatives. Analysis and estimation of such errors, as well as the development of approximate methods for computation of the matrix $C$, is a very important topic, but not the issue of this paper. This issue can be addressed using results from [5], [10], [12], [16], the formulas (6.1)–(6.3), and Remark 6.

Let us note further that according to Lemma 4.2 the columns $X^{(i)}$, $i = 1,\dots,n$, of the covariance matrix $C$ may be computed by applying conjugate gradient methods directly to problem (4.5). In this case all $n$ problems may be computed in parallel independently from each other until desired accuracy of the resulting vector $X^{(i)}$.

## 7. Conclusions.

For solving constraint parameter estimation and optimal design problems, we need the knowledge of the covariance matrix of the parameter estimates and its derivatives. Hence, development of effective methods for presentation and computation of the covariance matrix and its derivatives, based on iterative methods, is crucial for practical applications, which is the aim of this paper. In this paper, we have given suitable representations for the covariance matrix and confidence intervals as well as its derivatives and have shown that by solving nonlinear constrained least squares problems by conjugate gradient methods we get, as a by-product, these matrices and confidence intervals practically for free. The results can be generalized to other Krylov-type methods. This paper is the first of a series and its results are of a more theoretical nature. The forthcoming research will be devoted to numerical aspects including choice of effective preconditioners and effective implementation of the described methods for parameter estimation and design of optimal parameters in processes defined by PDEs.

**Acknowledgments.** We thank the anonymous referees and Lieven Vandenberghe whose comments and suggestions helped to improve the presentation of the results.

# COMBINED PERTURBATION BOUNDS: I. EIGENSYSTEMS AND SINGULAR VALUE DECOMPOSITIONS*

WEN LI† AND WEIWEI SUN‡

**Abstract.** In this paper we present some new combined perturbation bounds of eigenvalues and eigensubspaces for a Hermitian matrix $H$, particularly in an asymptotic sense, $\delta_{12}^2\|\sin\Theta(U_1,\widetilde{U}_1)\|_F^2+\sum_{i=1}^r(\lambda_i-\widetilde{\lambda}_i)^2\le\|\Delta HU_1\|_F^2+O(\|\Delta HU_1\|_F^4)$, where $\lambda_i$ denotes the eigenvalues of $H$ and $U_1$ the eigensubspace corresponding to the eigenvalues $\lambda_i$, $i=1,2,\dots,r$. The bound for each factor of eigensystems is optimal due to the sin$\Theta$ theorem and the Hoffman–Wielandt theorem. In addition, combined perturbation bounds for singular value decompositions and combined perturbation bounds in some, more general, measures are also obtained.

**Key words.** eigensystems, singular subspace, singular value, combined perturbation bound

## 1. Introduction.

Let $C^{m\times n}$ denote the set of complex $m\times n$ matrices, $A^*$ stand for the conjugate transpose of a matrix $A$, $\lambda(A)$ be the spectrum of $A$, and $\Re(A)$ be the column space of $A$. The Frobenius norm and spectral norm of a matrix $A$ are denoted by $\|A\|_F$ and $\|A\|_2$, respectively.

Let $H$ and $\widetilde{H}$ be two $n\times n$ Hermitian matrices with the following eigendecompositions:

$$\begin{aligned} H&=\begin{pmatrix} U_1 & U_2\end{pmatrix}\begin{pmatrix}\Lambda_1 & 0\\ 0 & \Lambda_2\end{pmatrix}\begin{pmatrix}U_1^*\\ U_2^*\end{pmatrix},\\ \widetilde{H}&=\begin{pmatrix} \widetilde{U}_1 & \widetilde{U}_2\end{pmatrix}\begin{pmatrix}\widetilde{\Lambda}_1 & 0\\ 0 & \widetilde{\Lambda}_2\end{pmatrix}\begin{pmatrix}\widetilde{U}_1^*\\ \widetilde{U}_2^*\end{pmatrix},\end{aligned}\tag{1.1}$$

where $U=\begin{pmatrix}U_1 & U_2\end{pmatrix}$, $\widetilde{U}=\begin{pmatrix}\widetilde{U}_1 & \widetilde{U}_2\end{pmatrix}$ are unitary, and

$$\begin{aligned}\Lambda_1&=\operatorname{diag}(\lambda_1,\lambda_2,\dots,\lambda_r), & \Lambda_2&=\operatorname{diag}(\lambda_{r+1},\lambda_{r+2},\dots,\lambda_n),\\ \widetilde{\Lambda}_1&=\operatorname{diag}(\widetilde{\lambda}_1,\widetilde{\lambda}_2,\dots,\widetilde{\lambda}_r), & \widetilde{\Lambda}_2&=\operatorname{diag}(\widetilde{\lambda}_{r+1},\widetilde{\lambda}_{r+2},\dots,\widetilde{\lambda}_n).\end{aligned}\tag{1.2}$$

Let

$$\delta_{ij}^{(k,l)}=\min_{\lambda\in\lambda(\Lambda_i),\widetilde{\lambda}\in\lambda(\widetilde{\Lambda}_j)}\frac{|\lambda-\widetilde{\lambda}|}{|\lambda|^k|\widetilde{\lambda}|^l},\quad i,j=1,2,\tag{1.3}$$

where $k$ and $l$ are nonnegative real numbers. For simplicity, we always use the notation $\delta_{ij}=\delta_{ij}^{(0,0)}$.

The perturbation bounds for eigensystems, eigenspaces, and eigenvalues have been studied by many authors; e.g., see [1, 2, 3, 4, 6, 7, 8, 9, 10, 12]. The perturbation of the eigenspace $\Re(U_1)$ is measured by the canonical angle between the subspaces $\Re(U_1)$ and $\Re(\widetilde{U}_1)$ (e.g., see [8]), defined by

$$\Theta(U_1, \widetilde{U}_1) = arc\cos(U_1^* \widetilde{U}_1 \widetilde{U}_1^* U_1)^{1/2}.$$

The classical perturbation bound for the subspace was given as the $Sin\Theta$ theorem by Davis and Kahan [3].

Theorem A (**sin**$\Theta$ theorem [3]). [illegible] $H$ [illegible] $\widetilde{H} = H + \Delta H$ [illegible] (1.1)–(1.2) [illegible]

$$\delta_{12} \| \sin \Theta(U_1, \widetilde{U}_1) \|_F \le \|R\|_F, \tag{1.4}$$

[illegible] $R = \widetilde{H} U_1 - U_1 \Lambda_1 = \Delta H U_1$

The corresponding perturbation bound for eigenvalues is

$$\sum_{i=1}^{r} (\lambda_i - \widetilde{\lambda}_i)^2 \le \|R\|_F^2 . \tag{1.5}$$

When $r = n$, the bound (1.5) is the well-known Hoffman–Wielandt theorem [6].

The perturbation bounds in (1.4) and (1.5) are given in the absolute measure $\|R\|_F$. Recently, a relative-type perturbation bound was introduced. A general form of the relative bound is

$$\| \sin \Theta(U_1, \widetilde{U}_1) \|_F \le \alpha_{lk} \| H^{-l} \Delta H \widetilde{H}^{-k} \|_F , \tag{1.6}$$

where $\alpha_{lk}$ is a positive real number. Dopico, Moro, and Molera [4], Chen and Li [2], Li [8], and Londre and Rhee [9] studied the bound for $l = k = 1/2$, and Ipsen [7] studied it for the more general case.

In this paper we focus on perturbation bounds in a combined form of eigenspaces and eigenvalues. In particular, we shall show the new perturbation bound

$$\delta_{12}^2 \| \sin \Theta(U_1, \widetilde{U}_1) \|_F^2 + (1 - \| \sin \Theta(U_1, \widetilde{U}_1) \|_2^2) \sum_{i=1}^{r} (\lambda_i - \widetilde{\lambda}_i)^2 \le \|R\|_F^2 , \tag{1.7}$$

which, in an asymptotic sense, leads to

$$\delta_{12}^2 \| \sin \Theta(U_1, \widetilde{U}_1) \|_F^2 + \sum_{i=1}^{r} (\lambda_i - \widetilde{\lambda}_i)^2 \le \|R\|_F^2 + O(\|R\|_F^4), \tag{1.8}$$

where $\delta_{12} > 0$. The bounds (1.7) and (1.8) contain both the bound for eigenspaces and the bound for eigenvalues. In comparison with Davis and Kahan's theorem, (1.7) is sharper than the bound in Davis and Kahan's theorem and it also leads to the Hoffman–Wielandt theorem. On the other hand, the bound in (1.4) can be calculated when $\lambda_i$, $\widetilde{\lambda}_i$, and $\|R\|_F$ are known. In this case, a more precise bound for eigenspaces can be obtained from (1.7). In addition, we have obtained some new bounds in a relative sense and extensions to perturbation bounds for singular values and singular subspaces.

**2. Combined bounds for eigensystems.** In this section we study combined perturbation bounds for eigensystems.

LEMMA 2.1 (see [5]). [illegible] $T \in C^{n\times n}$ [illegible] $\Lambda_i = \mathrm{diag}(\lambda_1^{(i)}, \ldots, \lambda_n^{(i)}) \in C^{n\times n}$, $i = 1, 2, 3, 4$ [illegible] $\tau$ [illegible] $\langle n \rangle$ [illegible]

$$\sigma_n^2(T) \sum |\lambda_i^{(1)}\lambda_{\tau(i)}^{(2)} - \lambda_i^{(3)}\lambda_{\tau(i)}^{(4)}|^2 \le ||\Lambda_1 T \Lambda_2 - \Lambda_3 T \Lambda_4||_F^2, \tag{2.1}$$

[illegible] $\sigma_n(T)$ [illegible] $T$

We have our main theorem below.

THEOREM 2.2. [illegible] $H$ [illegible] $\widetilde{H} = H + \Delta H$ [illegible] $n \times n$ [illegible] (1.1)–(1.2) [illegible]

$$(\delta_{12}^2 - \delta_{11}^2)\|\sin\Theta(U_1, \widetilde{U}_1)\|_F^2 + r\delta_{11}^2 \le ||R||_F^2 \tag{2.2}$$

[illegible]

$$\delta_{12}^2\|\sin\Theta(U_1, \widetilde{U}_1)\|_F^2 + (1 - \|\sin\Theta(U_1, \widetilde{U}_1)\|_2^2)\sum_{i=1}^{r}(\lambda_i - \widetilde{\lambda}_i)^2 \le ||R||_F^2. \tag{2.3}$$

[illegible] Left- and right-multiplying the equation $\widetilde{H} - H = \Delta H$ by $\widetilde{U}^*$ and $U_1$, respectively, leads to

$$\widetilde{\Lambda}\widetilde{U}^*U_1 - \widetilde{U}^*U_1\Lambda_1 = \widetilde{U}^*\Delta H U_1,$$

and in the block form,

$$\begin{pmatrix} \widetilde{\Lambda}_1\widetilde{U}_1^*U_1 - \widetilde{U}_1^*U_1\Lambda_1 \\ \widetilde{\Lambda}_2\widetilde{U}_2^*U_1 - \widetilde{U}_2^*U_1\Lambda_1 \end{pmatrix} = \widetilde{U}^*\Delta H U_1.$$

It follows that

$$\|\widetilde{\Lambda}_2\widetilde{U}_2^*U_1 - \widetilde{U}_2^*U_1\Lambda_1\|_F^2 + \|\widetilde{\Lambda}_1\widetilde{U}_1^*U_1 - \widetilde{U}_1^*U_1\Lambda_1\|_F^2 = ||\Delta H U_1||_F^2\,. \tag{2.4}$$

Since

$$\left|\left(\widetilde{\Lambda}_2\widetilde{U}_2^*U_1 - \widetilde{U}_2^*U_1\Lambda_1\right)_{ij}\right|^2 = (\widetilde{\lambda}_{i+r} - \lambda_j)^2|(\widetilde{U}_2^*U_1)_{ij}|^2 \ge \delta_{12}^2|(\widetilde{U}_2^*U_1)_{ij}|^2$$
$$i = 1, 2, \ldots, n-r;\ j = 1, 2, \ldots, r,$$

and

$$\left|\left(\widetilde{\Lambda}_1\widetilde{U}_1^*U_1 - \widetilde{U}_1^*U_1\Lambda_1\right)_{ij}\right|^2 = (\widetilde{\lambda}_i - \lambda_j)^2|(\widetilde{U}_1^*U_1)_{ij}|^2 \ge \delta_{11}^2|(\widetilde{U}_1^*U_1)_{ij}|^2,$$
$$i, j = 1, 2, \ldots, r,$$

we have

$$\delta_{12}^2\|\widetilde{U}_1^*U_2\|_F^2 + \delta_{11}^2\|\widetilde{U}_1^*U_1\|_F^2 \le \|\widetilde{\Lambda}_2\widetilde{U}_2^*U_1 - \widetilde{U}_2^*U_1\Lambda_1\|_F^2 + \|\widetilde{\Lambda}_1\widetilde{U}_1^*U_1 - \widetilde{U}_1^*U_1\Lambda_1\|_F^2\,. \tag{2.5}$$

Equation (2.2) is obtained by (2.4) and (2.5) and by noting the fact that

$$\|\widetilde{U}_1^*U_1\|_F^2 = r - \|\widetilde{U}_1^*U_2\|_F^2\,.$$

By Lemma 2.1,

$$\sigma_n^2(\widetilde{U}_1^* U_1) \sum_{i=1}^{r} |\widetilde{\lambda}_i - \lambda_i|^2 \le \|\widetilde{\Lambda}_1 \widetilde{U}_1^* U_1 - \widetilde{U}_1^* U_1 \Lambda_1\|_F^2 \, . \tag{2.6}$$

By the C-S decomposition theorem (see, e.g., [11]), we have

$$\sigma_n^2(\widetilde{U}_1^* U_1) = 1 - \|\sin\Theta(U_1, \widetilde{U}_1)\|_2^2,$$

and therefore,

$$\delta_{12}^2 \|\sin\Theta(U_1, \widetilde{U}_1)\|_F^2 + (1 - \|\sin\Theta(U_1, \widetilde{U}_1)\|_2^2) \sum_{i=1}^{r} |\widetilde{\lambda}_i - \lambda_i| \le ||R||_F^2,$$

which proves (2.3). □

Obviously the combined bounds in Theorem 2.2 contain perturbation bounds for both eigenspaces and eigenvalues. If we take $U_1 = U$ and $\widetilde{U}_1 = \widetilde{U}$, then $\|\sin\Theta(U_1, \widetilde{U}_1)\|_2 = \|\sin\Theta(U_1, \widetilde{U}_1)\|_F = 0$ and the bound (2.3) reduces to the Hoffman–Wielandt theorem. It is easy to obtain Davis and Kahan's sinΘ theorem from the bound (2.3) since $\|\sin\Theta(U_1, \widetilde{U}_1)\|_2 \le 1$.

[illegible] 2.1. Let

$$H = U\Lambda U^*, \qquad \widetilde{H} = (1+\epsilon) U \Lambda U^*,$$

where $\Lambda$ is positive and diagonal and

$$\Lambda = \begin{pmatrix} I_r & 0 \\ 0 & 2I_{n-r} \end{pmatrix}, \qquad U = \begin{pmatrix} U_{11} & 0 \\ 0 & U_{22} \end{pmatrix}.$$

Then

$$\Delta H = \epsilon U \begin{pmatrix} I_r & 0 \\ 0 & 2I_{n-r} \end{pmatrix} U^*, \qquad \Delta H U_1 = \epsilon \begin{pmatrix} U_{11} \\ 0 \end{pmatrix}.$$

A simple calculation gives

$$\|R\|_F^2 = \|\Delta H U_1\|_F^2 = r\epsilon^2, \qquad \delta_{12} = 1 + 2\epsilon, \qquad \delta_{11} = \epsilon.$$

The bound (1.4) becomes

$$\|\sin\Theta(U_1 \, \widetilde{U}_1)\|_F^2 \le \frac{\|R\|_F^2}{\delta_{12}^2} = \frac{r\epsilon^2}{(1+2\epsilon)^2},$$

and from our bound (2.2),

$$\|\sin\Theta(U_1 \, \widetilde{U}_1)\|_F^2 \le \frac{\|R\|_F^2 - r\delta_{11}^2}{\delta_{12}^2 - \delta_{11}^2} = 0\,,$$

which leads to $\|\sin\Theta(U_1, \widetilde{U}_1)\|_F^2 = 0$.

When $\delta_{12} > 0$,

$$\|\sin\Theta(U_1, \widetilde{U}_1)\|_F \le O(\|R\|_F), \qquad \sum_{i=1}^{r} (\lambda_i - \widetilde{\lambda}_i)^2 \le \|R\|_F^2$$

and we obtain the asymptotic bound in (1.8). However, the following example shows the absolute bound

$$\delta_{12}^2 \|\sin\Theta(U_1, \widetilde{U}_1)\|_F^2 + \sum_{i=1}^{r} (\lambda_i - \widetilde{\lambda}_i)^2 \le \|R\|_F^2$$

does not hold.

[illegible] 2.2. Let

$$H = \begin{pmatrix} 2 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad \text{and} \quad \widetilde{H} = (1+\epsilon)\widetilde{U}^T H \widetilde{U},$$

where $\epsilon > 0$ and

$$\widetilde{U} = \begin{pmatrix} \cos\theta & -\sin\theta & 0 \\ \sin\theta & \cos\theta & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

The eigenvalues of $H$ and $\widetilde{H}$ are $2, 1, 1$ and $2(1+\epsilon), (1+\epsilon), (1+\epsilon)$, respectively. For $r = 1$,

$$U_1 = \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix} \quad \text{and} \quad \widetilde{U}_1 = \begin{pmatrix} \cos\theta \\ \sin\theta \\ 0 \end{pmatrix}.$$

A simple calculation gives $\delta_{12} = 1 - \epsilon$ and

$$\begin{aligned} \delta_{12}^2 \|\sin\Theta(U_1, \widetilde{U}_1)\|_F^2 + \sum_{i=1}^{r} |\widetilde{\lambda}_i - \lambda_i|^2 &= (1-\epsilon)^2 \sin^2\theta + (2\epsilon)^2 \\ &> (1-\epsilon)^2 \sin^2\theta + 4\epsilon^2 \cos^2\theta = ||\Delta H U_1||_F^2 = \|R\|_F^2 . \end{aligned}$$

The perturbation bounds for eigenspaces in a relative measure have been studied by several authors; Dopico, Moro, and Molera [4] presented the relative perturbation bound

$$\delta_{12}^{(\frac{1}{2},\frac{1}{2})} \|\sin\Theta(U_1\, \widetilde{U}_1)\|_F \le \|H^{-1/2} \Delta H \widetilde{H}^{-1/2}\|_F$$

for nonsingular Hermitian matrices $H$ and $\widetilde{H}$. A sharper bound obtained by Chen and Li [2] is

$$\frac{2\delta_{12}^{(\frac{1}{2},\frac{1}{2})} \delta_{21}^{(\frac{1}{2},\frac{1}{2})}}{\sqrt{\left(\delta_{12}^{(\frac{1}{2},\frac{1}{2})}\right)^2 + \left(\delta_{21}^{(\frac{1}{2},\frac{1}{2})}\right)^2}} \|\sin\Theta(U_1\, \widetilde{U}_1)\|_F \le \|H^{-1/2} \Delta H \widetilde{H}^{-1/2}\|_F . \tag{2.7}$$

Li [8] and Londre and Rhee [9] studied perturbation bounds in a different relative measure. The perturbation bound in [8, 9] is given by

$$\delta_{12}^{(\frac{1}{2},\frac{1}{2})} \|\sin\Theta(U_1\, \widetilde{U}_1)\|_F \le \frac{\|H^{-1/2} \Delta H H^{-1/2}\|_F}{\sqrt{1-\mu_2}}, \tag{2.8}$$

where

$$\mu_2 = \|H^{-1/2} \Delta H H^{-1/2}\|_2 .$$

A modified bound in the relative measure given in [2] is

$$\min\left\{\delta_{12}^{(\frac{1}{2},\frac{1}{2})}, \delta_{21}^{(\frac{1}{2},\frac{1}{2})}\right\} \|\sin\Theta(U_1,\widetilde{U}_1)\|_F \le \frac{\sqrt{2}}{2}\frac{\|H^{-1/2}\Delta H H^{-1/2}\|_F}{\sqrt{1-\mu_2}}. \tag{2.9}$$

The perturbation bound of eigenvalues in the more general relative measure $\|H^{-k}\Delta H\widetilde{H}^{-l}\|_F$ with any nonnegative numbers $k$ and $l$ was studied by Ipsen [7]. The perturbation bound given in [7] is

$$\sum_{i=1}^{n} |\lambda_i^{-k}\widetilde{\lambda}_{\tau(i)}^{1-l} - \lambda_i^{1-k}\widetilde{\lambda}_{\tau(i)}^{-l}|^2 \le \|H^{-k}\Delta H\widetilde{H}^{-l}\|_F^2. \tag{2.10}$$

No perturbation bound for eigenspaces has been obtained.

Now we extend our analysis for combined perturbation bounds to these relative measures, instead of the measure $\|R\|_F$ used in Theorem 2.2. Since

$$H^{-k}\Delta H\widetilde{H}^{-l} = H^{-k}\widetilde{H}^{1-l} - H^{1-k}\widetilde{H}^{-l},$$

multiplying on the left by $U^*$ and the right by $\widetilde{U}$ gives

$$\Lambda^{-k}U^*\widetilde{U}\widetilde{\Lambda}^{1-l} - \Lambda^{1-k}U^*\widetilde{U}\widetilde{\Lambda}^{-l} = U^*H^{-k}\Delta H\widetilde{H}^{-l}\widetilde{U},$$

which can be rewritten in the block form as

$$\begin{pmatrix} \Lambda_1^{-k}U_1^*\widetilde{U}_1\widetilde{\Lambda}_1^{1-l} - \Lambda_1^{1-k}U_1^*\widetilde{U}_1\widetilde{\Lambda}_1^{-l} & \Lambda_1^{-k}U_1^*\widetilde{U}_2\widetilde{\Lambda}_2^{1-l} - \Lambda_1^{1-k}U_1^*\widetilde{U}_2\widetilde{\Lambda}_2^{-l} \\ \Lambda_2^{-k}U_2^*\widetilde{U}_1\widetilde{\Lambda}_1^{1-l} - \Lambda_2^{1-k}U_2^*\widetilde{U}_1\widetilde{\Lambda}_1^{-l} & \Lambda_2^{-k}U_2^*\widetilde{U}_2\widetilde{\Lambda}_2^{1-l} - \Lambda_2^{1-k}U_2^*\widetilde{U}_2\widetilde{\Lambda}_2^{-l} \end{pmatrix} = U^*H^{-k}\Delta H\widetilde{H}^{-l}\widetilde{U}.$$

It follows that

$$\begin{aligned} &\|\Lambda_1^{-k}U_1^*\widetilde{U}_1\widetilde{\Lambda}_1^{1-l} - \Lambda_1^{1-k}U_1^*\widetilde{U}_1\widetilde{\Lambda}_1^{-l}\|_F^2 + \|\Lambda_1^{-k}U_1^*\widetilde{U}_2\widetilde{\Lambda}_2^{1-l} - \Lambda_1^{1-k}U_1^*\widetilde{U}_2\widetilde{\Lambda}_2^{-l}\|_F^2 \\ &+\|\Lambda_2^{-k}U_2^*\widetilde{U}_1\widetilde{\Lambda}_1^{1-l} - \Lambda_2^{1-k}U_2^*\widetilde{U}_1\widetilde{\Lambda}_1^{-l}\|_F^2 + \|\Lambda_2^{-k}U_2^*\widetilde{U}_2\widetilde{\Lambda}_2^{1-l} - \Lambda_2^{1-k}U_2^*\widetilde{U}_2\widetilde{\Lambda}_2^{-l}\|_F^2 \\ &= \|U^*H^{-k}\Delta H\widetilde{H}^{-l}\widetilde{U}\|_F^2. \end{aligned} \tag{2.11}$$

We take the same approach as used for (2.5). Since

$$\begin{aligned} &|(\Lambda_1^{-k}U_1^*\widetilde{U}_2\widetilde{\Lambda}_2^{1-l} - \Lambda_1^{1-k}U_1^*\widetilde{U}_2\widetilde{\Lambda}_2^{-l})_{ij}|^2 = (\lambda_i^{-k}\widetilde{\lambda}_j^{1-l} - \lambda_i^{1-k}\widetilde{\lambda}_j^{-l})^2|(U_1^*\widetilde{U}_2)_{ij}|^2 \\ &\ge \left(\delta_{12}^{(k,l)}\right)^2 |(U_1^*\widetilde{U}_2)_{ij}|^2 \end{aligned}$$

and

$$\begin{aligned} &|(\Lambda_2^{-k}U_2^*\widetilde{U}_1\widetilde{\Lambda}_1^{1-l} - \Lambda_2^{1-k}U_2^*\widetilde{U}_1\widetilde{\Lambda}_1^{-l})_{ij}|^2 = (\lambda_j^{-k}\widetilde{\lambda}_i^{1-l} - \lambda_j^{1-k}\widetilde{\lambda}_i^{-l})^2|(U_2^*\widetilde{U}_1)_{ij}|^2 \\ &\ge \left(\delta_{21}^{(k,l)}\right)^2 |(U_2^*\widetilde{U}_1)_{ij}|^2, \end{aligned}$$

we obtain

$$\begin{aligned} &\left(\delta_{12}^{(k,l)}\right)^2 \|U_1^*\widetilde{U}_2\|_F^2 \le \|\Lambda_1^{-k}U_1^*\widetilde{U}_2\widetilde{\Lambda}_2^{1-l} - \Lambda_1^{1-k}U_1^*\widetilde{U}_2\widetilde{\Lambda}_2^{-l}\|_F^2, \\ &\left(\delta_{21}^{(k,l)}\right)^2 \|U_2^*\widetilde{U}_1\|_F^2 \le \|\Lambda_2^{-k}U_2^*\widetilde{U}_1\widetilde{\Lambda}_1^{1-l} - \Lambda_2^{1-k}U_2^*\widetilde{U}_1\widetilde{\Lambda}_1^{-l}\|_F^2. \end{aligned} \tag{2.12}$$

On the other hand, let

$$T = \begin{pmatrix} U_1^* \widetilde{U}_1 & \\ & U_2^* \widetilde{U}_2 \end{pmatrix}, \quad D_1 = \begin{pmatrix} \Lambda_1^{-k} & \\ & \Lambda_2^{-k} \end{pmatrix}, \quad D_3 = \begin{pmatrix} \Lambda_1^{1-k} & \\ & \Lambda_2^{1-k} \end{pmatrix}$$

and

$$D_2 = \begin{pmatrix} \widetilde{\Lambda}_1^{1-l} & \\ & \Lambda_2^{1-l} \end{pmatrix}, \quad D_4 = \begin{pmatrix} -\widetilde{\Lambda}_1^{-l} & \\ & -\widetilde{\Lambda}_2^{-l} \end{pmatrix}.$$

We have

$$\begin{aligned} &\|\Lambda_1^{-k} U_1^* \widetilde{U}_1 \widetilde{\Lambda}_1^{1-l} - \Lambda_1^{1-k} U_1^* \widetilde{U}_1 \widetilde{\Lambda}_1^{-l}\|_F^2 + \|\Lambda_2^{-k} U_2^* \widetilde{U}_2 \widetilde{\Lambda}_2^{1-l} - \Lambda_2^{1-k} U_2^* \widetilde{U}_2 \widetilde{\Lambda}_2^{-l}\|_F^2 \\ &= \|D_1 T D_2 - D_3 T D_4\|_F^2. \end{aligned} \tag{2.13}$$

By Lemma 2.1, there exists a permutation $\tau$ of $\langle n \rangle$ such that

$$\|D_1 T D_2 - D_3 T D_4\|_F^2 \geq \sigma_n^2(T) \sum_{i=1}^{n} |\lambda_i^{-k} \widetilde{\lambda}_{\tau(i)}^{1-l} - \lambda_i^{1-k} \widetilde{\lambda}_{\tau(i)}^{-l}|^2. \tag{2.14}$$

By the C-S decomposition theorem [11], it is easy to see that

$$\sigma_n^2(T) \geq \min\{\sigma_n^2(U_1^* \widetilde{U}_1),\ \sigma_n^2(U_2^* \widetilde{U}_2)\} = 1 - \|\sin\Theta(U_1, \widetilde{U}_1)\|_2^2.$$

It follows that

$$\begin{aligned} &(1 - \|\sin\Theta(U_1, \widetilde{U}_1)\|_2^2) \sum_{i=1}^{r} |\lambda_i^{-k} \widetilde{\lambda}_{\tau(i)}^{1-l} - \lambda_i^{1-k} \widetilde{\lambda}_{\tau(i)}^{-l}|^2 \\ &\leq \|\Lambda_1^{-k} U_1^* \widetilde{U}_1 \widetilde{\Lambda}_1^{1-l} - \Lambda_1^{1-k} U_1^* \widetilde{U}_1 \widetilde{\Lambda}_1^{-l}\|_F^2 + \|\Lambda_2^{-k} U_2^* \widetilde{U}_2 \widetilde{\Lambda}_2^{1-l} - \Lambda_2^{1-k} U_2^* \widetilde{U}_2 \widetilde{\Lambda}_2^{-l}\|_F^2. \end{aligned} \tag{2.15}$$

Substituting (2.12) and (2.15) into (2.11) leads to a combined bound in the following theorem.

THEOREM 2.3. [illegible] $H$ [illegible] $\widetilde{H} = H + \Delta H$ [illegible] $n \times n$ [illegible] (1.1)–(1.2) [illegible]

$$\begin{aligned} &\left((\delta_{12}^{(k,l)})^2 + (\delta_{21}^{(k,l)})^2\right) \|\sin\Theta(U_1, \widetilde{U}_1)\|_F^2 \\ &\qquad + (1 - \|\sin\Theta(U_1, \widetilde{U}_1)\|_2^2) \sum_{i=1}^{n} (\lambda_i^{-k} \widetilde{\lambda}_{\tau(i)}^{1-l} - \lambda_i^{1-k} \widetilde{\lambda}_{\tau(i)}^{-l})^2 \\ &\qquad \leq ||H^{-k} \Delta H \widetilde{H}^{-l}||_F^2. \end{aligned} \tag{2.16}$$

By an analogous approach, we can obtain

$$\begin{aligned} \left(\delta_{22}^{(k,l)}\right)^2 \|U_2^* \widetilde{U}_2\|_F^2 &\leq \|\Lambda_2^{-k} U_2^* \widetilde{U}_2 \widetilde{\Lambda}_2^{1-l} - \Lambda_2^{1-k} U_2^* \widetilde{U}_2 \widetilde{\Lambda}_2^{-l}\|_F^2, \\ \left(\delta_{11}^{(k,l)}\right)^2 \|U_1^* \widetilde{U}_1\|_F^2 &\leq \|\Lambda_1^{-k} U_1^* \widetilde{U}_1 \widetilde{\Lambda}_1^{1-l} - \Lambda_1^{1-k} U_1^* \widetilde{U}_1 \widetilde{\Lambda}_1^{-l}\|_F^2. \end{aligned} \tag{2.17}$$

It is easy to see that

$$\|\sin\Theta(U_1, \widetilde{U}_1)\|_F = \|U_1^* \widetilde{U}_2\|_F = \|U_2^* \widetilde{U}_1\|_F.$$

By the definition of $\cos\Theta$,

$$\|\cos\Theta(U_1,\widetilde{U}_1)\|_F = \|U_1^*\widetilde{U}_1\|_F\,, \qquad \|\cos\Theta(U_2,\widetilde{U}_2)\|_F = \|U_2^*\widetilde{U}_2\|_F,$$

and again by the C-S decomposition theorem [11], we have

$$\|\cos\Theta(U_2,\widetilde{U}_2)\|_F^2 = \|\cos\Theta(U_1,\widetilde{U}_1)\|_F^2 + n - 2r$$

and

$$\|\sin\Theta(U_1,\widetilde{U}_1)\|_F^2 = r - \|\cos\Theta(U_1,\widetilde{U}_1)\|_F^2\,.$$

A new bound is given in the following theorem. The proof can be obtained by following the proof of Theorem 2.3 and replacing (2.15) by (2.17).

THEOREM 2.4. [illegible] $H$ [illegible] $\widetilde{H} = H + \Delta H$ [illegible] $n \times n$ [illegible] (1.1)–(1.2) [illegible]

$$\begin{aligned}&\Big((\delta_{12}^{(k,l)})^2 + (\delta_{21}^{(k,l)})^2 - (\delta_{11}^{(k,l)})^2 - (\delta_{22}^{(k,l)})^2\Big)\|\sin\Theta(U_1,\widetilde{U}_1)\|_F^2\\ &\quad + r(\delta_{11}^{(k,l)})^2 + (n-r)(\delta_{22}^{(k,l)})^2\\ &\quad \le ||H^{-k}\Delta H\widetilde{H}^{-l}||_F^2.\end{aligned} \tag{2.18}$$

[illegible] 2.1. Let $H$ and $\widetilde{H}$ be Hermitian and the eigenvalues of $H$ and $\widetilde{H}$ be enumerated by

$$\lambda_1 \le \lambda_2 \le \cdots \le \lambda_n \quad \text{and} \quad \widetilde{\lambda}_1 \le \widetilde{\lambda}_2 \le \cdots \le \widetilde{\lambda}_n,$$

and assume that

$$\lambda_r < \lambda_{r+1}, \qquad \widetilde{\lambda}_r < \widetilde{\lambda}_{r+1}.$$

When the perturbation is small enough, we always have

$$\sum_{i=1}^n |\lambda_i^{-k}\widetilde{\lambda}_{\tau(i)}^{1-l} - \lambda_i^{1-k}\widetilde{\lambda}_{\tau(i)}^{-l}|^2 \le \sqrt{(\delta_{12}^{(k,l)})^2 + (\delta_{21}^{(k,l)})^2}$$

for some permutation $\tau$ of $\langle n\rangle$ and, therefore,

$$\begin{aligned}&\Big((\delta_{12}^{(k,l)})^2 + (\delta_{21}^{(k,l)})^2\Big)\,\|\sin\Theta(U_1,\widetilde{U}_1)\|_F^2 + \|\cos\Theta(U_1,\widetilde{U}_1)\|_2^2 \sum_{i=1}^n |\lambda_i^{-k}\widetilde{\lambda}_{\tau(i)}^{1-l} - \lambda_i^{1-k}\widetilde{\lambda}_{\tau(i)}^{-l}|^2\\ &\ge \Big(\|\sin\Theta(U_1,\widetilde{U}_1)\|_F^2 + 1 - \|\sin\Theta(U_1,\widetilde{U}_1)\|_2^2\Big)\sum_{i=1}^n |\lambda_i^{-k}\widetilde{\lambda}_{\tau(i)}^{1-l} - \lambda_i^{1-k}\widetilde{\lambda}_{\tau(i)}^{-l}|^2\\ &\ge \sum_{i=1}^n |\lambda_i^{-k}\widetilde{\lambda}_{\tau(i)}^{1-l} - \lambda_i^{1-k}\widetilde{\lambda}_{\tau(i)}^{-l}|^2,\end{aligned}$$

which implies that the bound (2.16) is strictly sharper than the bound in (2.10) for the eigenvalue perturbation. Since $\|\sin\Theta(U_1,\widetilde{U}_1)\|_F^2 = \min\{r\,, n-r\}$, we have the following corollary.

COROLLARY 2.5. [illegible] 2.4

$$({\delta_{12}^{(k,l)}}^2 + {\delta_{21}^{(k,l)}}^2)\|\sin\Theta(U_1,\widetilde{U}_1)\|_F^2 \le \begin{cases} ||H^{-k}\Delta H\widetilde{H}^{-l}||_F^2 - (n-2r){\delta_{22}^{(k,l)}}^2, & 2r \le n,\\ ||H^{-k}\Delta H\widetilde{H}^{-l}||_F^2 - (2r-n){\delta_{11}^{(k,l)}}^2, & 2r > n.\end{cases} \tag{2.19}$$

In comparison with the perturbation bound in (2.7), our bound (2.19) is sharper. The following corollary gives two combined perturbation bounds, in terms of the relative measure $\|H^{-k}\Delta H H^{-l}\|_F^2/(1-\mu_2)^{2l}$, which are sharper than the corresponding bounds obtained in [2, 8, 9].

Corollary 2.6. $\mu_2 = \left\|H^{-1/2}\Delta H H^{-1/2}\right\|_2 < 1$

$$\begin{aligned}\Big((\delta_{12}^{(k,l)})^2 + (\delta_{21}^{(k,l)})^2 - (\delta_{11}^{(k,l)})^2 - (\delta_{22}^{(k,l)})^2\Big)\|\sin\Theta(U_1,\widetilde{U}_1)\|_F^2 \\ + r(\delta_{11}^{(k,l)})^2 + (n-r)(\delta_{22}^{(k,l)})^2 \\ \le \frac{\left\|H^{-k}\Delta H H^{-l}\right\|_2^2}{(1-\mu_2)^{2l}}\end{aligned} \tag{2.20}$$

$$\begin{aligned}\Big((\delta_{12}^{(k,l)})^2 + (\delta_{21}^{(k,l)})^2\Big)\|\sin\Theta(U_1,\widetilde{U}_1)\|_F^2 \\ + (1 - \|\sin\Theta(U_1,\widetilde{U}_1)\|_2^2)\sum_{i=1}^{n}|\lambda_i^{-k}\widetilde{\lambda}_{\tau(i)}^{1-l} - \lambda_i^{1-k}\widetilde{\lambda}_{\tau(i)}^{-l}|^2 \\ \le \frac{\left\|H^{-k}\Delta H H^{-l}\right\|_2^2}{(1-\mu_2)^{2l}}.\end{aligned} \tag{2.21}$$

Taking the same approach as in [2], one may deduce that

$$||H^{-k}\Delta H\widetilde{H}^{-l}||_F \le \frac{\left\|H^{-k}\Delta H H^{-l}\right\|_2}{(1-\mu_2)^l}, \tag{2.22}$$

which together with Theorems 2.2 and 2.3 gives the desired bound. $\square$

**3. Combined bounds for singular value decompositions.** Let $A$, $\widetilde{A} \in C^{m\times n}$ have the singular value decompositions (SVDs)

$$A = U\Sigma V^* = \begin{pmatrix} U_1 & U_2 \end{pmatrix}\begin{pmatrix} \Sigma_1 & 0 \\ 0 & \Sigma_2 \end{pmatrix}\begin{pmatrix} V_1^* \\ V_2^* \end{pmatrix} \tag{3.1}$$

and

$$\widetilde{A} = \widetilde{U}\widetilde{\Sigma}\widetilde{V}^* = \begin{pmatrix} \widetilde{U}_1 & \widetilde{U}_2 \end{pmatrix}\begin{pmatrix} \widetilde{\Sigma}_1 & 0 \\ 0 & \widetilde{\Sigma}_2 \end{pmatrix}\begin{pmatrix} \widetilde{V}_1^* \\ \widetilde{V}_2^* \end{pmatrix}, \tag{3.2}$$

where $U = (\widetilde{U}_1\ \widetilde{U}_2)$ and $\widetilde{U} = (\widetilde{U}_1\ \widetilde{U}_2)$ are $m\times m$ unitary, $V = (\widetilde{V}_1\ \widetilde{V}_2)$ and $\widetilde{V} = (\widetilde{V}_1\ \widetilde{V}_2)$ are $n \times n$ unitary, and

$$\Sigma_1 = \operatorname{diag}(\sigma_1, \sigma_2, \ldots, \sigma_r), \quad \Sigma_2 = \operatorname{diag}(\sigma_{r+1}, \sigma_{r+2}, \ldots, \sigma_n), \tag{3.3}$$

$$\widetilde{\Sigma}_1 = \operatorname{diag}(\widetilde{\sigma}_1, \widetilde{\sigma}_2, \ldots, \widetilde{\sigma}_r), \quad \widetilde{\Sigma}_2 = \operatorname{diag}(\widetilde{\sigma}_{r+1}, \widetilde{\sigma}_{r+2}, \ldots, \widetilde{\sigma}_n). \tag{3.4}$$

Let $\sigma(A) = \lambda(\sqrt{A^*A})$ be the set of singular values of $A$ and

$$\sigma_{ext}(\Sigma_2) = \begin{cases} \sigma(\Sigma_2) \cup \{0\} & \text{if } m > n, \\ \sigma(\Sigma_2) & \text{if } m = n. \end{cases}$$

The perturbation of singular subspaces is usually measured by the angle between the subspaces $\Re(U_1)$ and $\Re(\widetilde{U}_1)$ and the angle between the subspaces $\Re(V_1)$ and $\Re(\widetilde{V}_1)$, denoted by

$$\|\sin\Theta\|_F = \|U_1^*\widetilde{U}_2\|_F, \qquad \|\sin\Phi\|_F = \|V_1^*\widetilde{V}_2\|_F,$$

respectively. Let

$$\epsilon_{ij}^{(k,l)} = \min_{\lambda\in\sigma_{ext}(\Sigma_i),\widetilde{\mu}\in\sigma(\widetilde{\Sigma}_j)} \frac{|\mu-\widetilde{\mu}|}{|\mu|^k|\widetilde{\mu}|^l}, \quad i,j=1,2.$$

Similarly we use the notation $\epsilon_{ij} = \epsilon_{ij}^{(0,0)}$.

The perturbation bound of singular subspace was given by Wedin [13] and the perturbation bound for singular values can be found in the literature. We summarize the results in the following theorem.

THEOREM B. $A$ $\widetilde{A} \in C^{m\times n}$ (3.1)–(3.4).

$$\epsilon_{12}^2(\|\sin\Theta\|_F^2 + \|\sin\Phi\|_F^2) \le \|R\|_F^2 + \|S\|_F^2 \tag{3.5}$$

$$2\sum_{i=1}^{r}(\sigma_i - \widetilde{\sigma}_{\tau(i)})^2 \le \|R\|_F^2 + \|S\|_F^2, \tag{3.6}$$

$$R = A\widetilde{V}_1 - \widetilde{U}_1\widetilde{\Sigma}_1 = -E\widetilde{V}_1, \qquad S = A^*\widetilde{U}_1 - \widetilde{V}_1\widetilde{\Sigma}_1 = -E^*\widetilde{U}_1.$$

To obtain a combined perturbation bound for SVDs, we consider the Jordan–Wielandt matrices

$$\mathbb{H} = \begin{pmatrix} 0 & A^* \\ A & 0 \end{pmatrix} \quad\text{and}\quad \widetilde{\mathbb{H}} = \begin{pmatrix} 0 & \widetilde{A}^* \\ \widetilde{A} & 0 \end{pmatrix}. \tag{3.7}$$

Let

$$\mathbb{U} = \frac{1}{\sqrt{2}}\begin{pmatrix} V_1 & V_1 & V_2 & V_2 \\ U_1 & -U_1 & U_2 & -U_2 \end{pmatrix} = \begin{pmatrix} \mathbb{U}_1 & \mathbb{U}_2 \end{pmatrix}$$

and

$$\widetilde{\mathbb{U}} = \frac{1}{\sqrt{2}}\begin{pmatrix} \widetilde{V}_1 & \widetilde{V}_1 & \widetilde{V}_2 & \widetilde{V}_2 \\ \widetilde{U}_1 & -\widetilde{U}_1 & \widetilde{U}_2 & -\widetilde{U}_2 \end{pmatrix} = \begin{pmatrix} \widetilde{\mathbb{U}}_1 & \widetilde{\mathbb{U}}_2 \end{pmatrix},$$

where

$$\mathbb{U}_1 = \frac{1}{\sqrt{2}}\begin{pmatrix} V_1 & V_1 \\ U_1 & -U_1 \end{pmatrix} \quad\text{and}\quad \widetilde{\mathbb{U}}_1 = \frac{1}{\sqrt{2}}\begin{pmatrix} \widetilde{V}_1 & \widetilde{V}_1 \\ \widetilde{U}_1 & -\widetilde{U}_1 \end{pmatrix}.$$

Then the eigendecomposition of $\mathbb{H}$ and $\widetilde{\mathbb{H}}$ can be rewritten as

$$\mathbb{H} = \mathbb{U}\begin{pmatrix} \Sigma_1 & & & \\ & -\Sigma_1 & & \\ & & \Sigma_2 & \\ & & & -\Sigma_2 \end{pmatrix}\mathbb{U}^* \quad\text{and}\quad \widetilde{\mathbb{H}} = \widetilde{\mathbb{U}}\begin{pmatrix} \widetilde{\Sigma}_1 & & & \\ & -\widetilde{\Sigma}_1 & & \\ & & \widetilde{\Sigma}_2 & \\ & & & -\widetilde{\Sigma}_2 \end{pmatrix}\widetilde{\mathbb{U}}^*,$$

respectively. Applying Theorems 2.2 and 2.3 to the matrices $\mathbb{H}$ and $\widetilde{\mathbb{H}}$, we have the following combined perturbation bounds for singular values and singular subspaces.

THEOREM 3.1. $A$ $\widetilde{A} = A + E$ $n \times n$ (3.1)–(3.4) $\tau$ $\langle n \rangle$

$$\epsilon_{12}^2 \left(\|\sin\Phi(U_1, \widetilde{U}_1)\|_F^2 + \|\sin\Theta(V_1, \widetilde{V}_1\right)\|_F^2) + \left(2 - \|\sin\Phi(U_1, \widetilde{U}_1)\|_2^2 - \|\sin\Theta(V_1, \widetilde{V}_1)\|_2^2\right)\sum_{i=1}^{r}(\sigma_i - \widetilde{\sigma}_{\tau(i)})^2 \le \|R\|_F^2 + \|S\|_F^2 \tag{3.8}$$

$$(\epsilon_{12}^2 - \epsilon_{11}^2)(\|\sin\Phi(U_1, \widetilde{U}_1)\|_F^2 + \|\sin\Theta(V_1, \widetilde{V}_1)\|_F^2) + 2r\epsilon_{11}^2 \le \|R\|_F^2 + \|S\|_F^2. \tag{3.9}$$

In an asymptotic sense, (3.9) becomes

$$\begin{aligned}&\epsilon_{12}^2 \left(\|\sin\Phi(U_1, \widetilde{U}_1)\|_F^2 + \|\sin\Theta(V_1, \widetilde{V}_1)\|_F^2\right) + 2\sum_{i=1}^{n}|\sigma_i - \widetilde{\sigma}_i|^2 \\ &\quad \le (\|R\|_F^2 + \|S\|_F^2) + O((\|R\|_F^2 + \|S\|_F^2)^2).\end{aligned} \tag{3.10}$$

From the SVDs (3.1) and (3.2), we obtain the left polar decomposition of the matrices $A$ and $\widetilde{A}$, defined by

$$A = QP_l \quad \text{and} \quad \widetilde{A} = \widetilde{Q}\widetilde{P}_l, \tag{3.11}$$

and, similarly, the right polar decomposition

$$A = P_rQ \quad \text{and} \quad \widetilde{A} = \widetilde{P}_r\widetilde{Q}, \tag{3.12}$$

where $Q$ is called the unitary polar factor of $A$ and $P_l$ and $P_r$ are called the left and right Hermitian factor, respectively. It is noted that Wedin's $\sin\theta$ theorem is given in an absolute measure $\|R\|_F^2 + \|S\|_F^2$. The perturbation bounds for singular values and singular subspaces in some relative measures was studied in [4], where the relative measures $\|P_l^{-k}E\widetilde{P}_r^{-l}\|_F$ and $\|\widetilde{P}_l^{-l}EP_r^{-k}\|_F$ are used. The extension to combined bounds is given in the following theorem and the proof is similar to the proofs for Theorems 2.3 and 2.4.

THEOREM 3.2. $A$ $\widetilde{A} = A + E$ $n \times n$ (3.1)–(3.4)

$$\begin{aligned}&\left(\left(\epsilon_{21}^{(k,l)}\right)^2 + \left(\epsilon_{12}^{(k,l)}\right)^2\right)\left(\|\sin\Phi(U_1, \widetilde{U}_1)\|_F^2 + \|\sin\Theta(V_1, \widetilde{V}_1)\|_F^2\right) \\ &\quad + \left(2 - \|\sin\Phi(U_1, \widetilde{U}_1)\|_2^2 - \|\sin\Theta(V_1, \widetilde{V}_1)\|_2^2\right)\sum_{i=1}^{n}(\sigma_i - \widetilde{\sigma}_{\tau(i)})^2 \\ &\quad \le \|P_l^{-k}E\widetilde{P}_r^{-l}\|_F^2 + \|\widetilde{P}_l^{-l}EP_r^{-k}\|_F^2\end{aligned} \tag{3.13}$$

$$\begin{aligned}&\left(\left(\epsilon_{21}^{(k,l)}\right)^2 + \left(\epsilon_{12}^{(k,l)}\right)^2 - \left(\epsilon_{11}^{(k,l)}\right)^2 - \left(\epsilon_{22}^{(k,l)}\right)^2\right)\left(\|\sin\Phi(U_1, \widetilde{U}_1)\|_F^2 + \|\sin\Theta(V_1, \widetilde{V}_1)\|_F^2\right) \\ &+ 2r\left(\epsilon_{11}^{(k,l)}\right)^2 + 2(n-r)\left(\epsilon_{22}^{(k,l)}\right)^2 \le \|P_l^{-k}E\widetilde{P}_r^{-l}\|_F^2 + \|\widetilde{P}_l^{-l}EP_r^{-k}\|_F^2,\end{aligned} \tag{3.14}$$

$P_l$ $P_r$ $\widetilde{P}_l$ $\widetilde{P}_r$ (3.11) (3.12)
3.1. A perturbation bound in Theorem 3.4 of [4] is as follows:

$$\left(\epsilon_{21}^{(\frac{1}{2},\frac{1}{2})}\right)^2 \left(\|\sin\Phi(U_1,\widetilde{U}_1)\|_F^2 + \|\sin\Theta(V_1,\ \widetilde{V}_1)\|_F^2\right)$$
$$\leq \|P_l^{-\frac{1}{2}} E \widetilde{P}_r^{-\frac{1}{2}}\|_F^2 + \|\widetilde{P}_l^{-\frac{1}{2}} E P_r^{-\frac{1}{2}}\|_F^2,$$

which can also be obtained from Theorem 3.2.

Finally, we consider the bounds for the right singular subspaces as in [9]. Let

$$\delta \equiv ||EA^\dagger||_2, \quad \delta_F \equiv ||EA^\dagger||_F.$$

Let $A$ and $\widetilde{A}$ have the SVDs (3.1)–(3.4) and let

$$\varsigma_{ij} = \min_{\mu\in\sigma(\Sigma_i),\widetilde{\mu}\in\sigma(\widetilde{\Sigma}_j)} \frac{|\widetilde{\mu}^2-\mu^2|}{\widetilde{\mu}\mu}.$$

Let $H = A^*A$ and $\widetilde{H} = \widetilde{A}^*\widetilde{A}$. Then $H$ and $\widetilde{H}$ have the eigendecompositions

$$H = (V_1, V_2)\begin{pmatrix} \Sigma_1^2 & 0 \\ 0 & \Sigma_2^2 \end{pmatrix}\begin{pmatrix} V_1^* \\ V_2^* \end{pmatrix}, \qquad \widetilde{H} = \begin{pmatrix} \widetilde{V}_1 & \widetilde{V}_2 \end{pmatrix}\begin{pmatrix} \widetilde{\Sigma}_1^2 & 0 \\ 0 & \widetilde{\Sigma}_2^2 \end{pmatrix}\begin{pmatrix} \widetilde{V_1}^* \\ \widetilde{V_2}^* \end{pmatrix}.$$

Applying Corollary 2.6 to $H$ and $\widetilde{H}$ with $l = k = 1/2$ by the same argument as in Theorem 2.1 of [9], we obtain the following estimate:

$$(\varsigma_{21}^2 + \varsigma_{12}^2 - \varsigma_{11}^2 - \varsigma_{22}^2)||\sin\Theta(V_1,\widetilde{V}_1)||_F^2 + r\varsigma_{11}^2 + (n-r)\varsigma_{22}^2 \leq \frac{(2\delta_F+\delta_F^2)^2}{1-3\delta} \tag{3.15}$$

for $\delta < 1/3$. A simpler form of (3.15) is

$$||\sin\Theta(V_1,\widetilde{V}_1)||_F \leq \frac{2\delta_F+\delta_F^2}{\sqrt{(1-3\delta)(\varsigma_{21}^2+\varsigma_{12}^2)}}. \tag{3.16}$$

It is easy to see that the bound in (3.16) is always sharper than those in Theorem 2.1 of [9].

**Acknowledgment.** The authors would like to thank the referee for valuable comments.

**DOI.** 10.1137/06065551

## 1. Introduction.

Let $\mathbb{C}^{m\times n}$ be a set of $m \times n$ complex valued matrices, and denote by $\mathcal{R}(m,n,k) \subseteq \mathbb{C}^{m\times n}$ the variety of all $m \times n$ matrices of, at most, rank $k$. Fix $A = [a_{ij}]_{i,j=1}^{m,n} \in \mathbb{C}^{m\times n}$; then $A^* \in \mathbb{C}^{n\times m}$ is the conjugate transpose of $A$ and $||A||_F := \sqrt{\sum_{i,j=1}^{m,n} |a_{ij}|^2}$ is the Frobenius norm of $A$. Recall that the *singular value decomposition* of $A$, abbreviated here as *SVD*, is given by $A = U_A \Sigma_A V_A^*$, where $U_A \in \mathbb{C}^{m\times m}, V_A \in \mathbb{C}^{n\times n}$ are unitary matrices and $\Sigma_A := \operatorname{diag}(\sigma_1(A), \ldots, \sigma_{\min(m,n)}(A)) \in \mathbb{C}^{m\times n}$ is a generalized diagonal matrix, with the singular values $\sigma_1(A) \geq \sigma_2(A) \geq \cdots \geq 0$ on the main diagonal. The number of positive singular values of $A$ is $r$, which is equal to the rank of $A$, denoted by $\operatorname{rank} A$. Let $U_A = [\mathbf{u}_1,\ \mathbf{u}_2, \ldots, \mathbf{u}_m], V_A = [\mathbf{v}_1,\ \mathbf{v}_2, \ldots, \mathbf{v}_n]$ be the representations of $U, V$ in terms of their $m, n$ columns. Then $\mathbf{u}_i$ and $\mathbf{v}_i$ are called the *left* and the *right* singular vectors of $A$ that correspond to the singular value $\sigma_i(A)$. Let

$$P_{A,L} := \sum_{i=1}^{\operatorname{rank} A} \mathbf{u}_i \mathbf{u}_i^* \in \mathbb{C}^{m\times m}, \quad P_{A,R} := \sum_{i=1}^{\operatorname{rank} A} \mathbf{v}_i \mathbf{v}_i^* \in \mathbb{C}^{n\times n} \tag{1.1}$$

be the orthogonal projections on the range of $A$ and $A^*$. Denote by

$$A_k := \sum_{i=1}^{k} \sigma_i(A) \mathbf{u}_i \mathbf{v}_i^* \in \mathbb{C}^{m\times n}$$

for $k = 1, \ldots, \operatorname{rank} A$. For $k > \operatorname{rank} A$, we define $A_k := A\ (= A_{\operatorname{rank} A})$. For $1 \leq k < \operatorname{rank} A$, the matrix $A_k$ is uniquely defined if and only if $\sigma_k(A) > \sigma_{k+1}(A)$.

The enormous application of the SVD in pure and applied mathematics is derived from the following approximation property:

$$\min_{X \in \mathcal{R}(m,n,k)} ||A - X||_F = ||A - A_k||_F, \quad k = 1, \ldots. \tag{1.2}$$

The latter is known as the Eckart–Young theorem [2]. We note that the work [2] implied a number of extensions and cite [4, 5, 7, 8] as some recent references. Another application of SVD is a formula for the Moore–Penrose inverse $A^\dagger := V_A \Sigma_A^\dagger U_A^* \in \mathbb{C}^{n\times m}$ of $A$, where

$$\Sigma_A^\dagger := \operatorname{diag}\left(\frac{1}{\sigma_1(A)}, \ldots, \frac{1}{\sigma_{\operatorname{rank} A}(A)}, 0, \ldots, 0\right) \in \mathbb{C}^{n\times m}.$$

See, for example, [1].

## 2. Main result.

Below, we provide generalizations of the classical minimal problem given in (1.2).

THEOREM 2.1. $A \in \mathbb{C}^{m\times n}$, $B \in \mathbb{C}^{m\times p}$ $C \in \mathbb{C}^{q\times n}$

$$X = B^\dagger (P_{B,L} A P_{C,R})_k C^\dagger \tag{2.1}$$

$$\min_{X\in\mathcal{R}(p,q,k)} ||A - BXC||_F, \tag{2.2}$$

$||X||_F$

$$k \geq \operatorname{rank} P_{B,L} A P_{C,R}$$

$$1 \leq k < \operatorname{rank} P_{B,L} A P_{C,R} \qquad \sigma_k(P_{B,L} A P_{C,R}) > \sigma_{k+1}(P_{B,L} A P_{C,R}).$$

2.1. Recall that the Frobenius norm is invariant under the multiplication from the left and right by the corresponding unitary matrices. Hence $||A - BXC||_F = ||\widetilde{A} - \Sigma_B \widetilde{X} \Sigma_C||_F$, where $\widetilde{A} := U_B^* A V_C$ and $\widetilde{X} := V_B^* X U_C$. Clearly, $X$ and $\widetilde{X}$ have the same rank and same Frobenius norm. Thus, it is enough to consider the minimal problem $\min_{\widetilde{X}\in\mathcal{R}(p,q,k)} ||\widetilde{A} - \Sigma_B \widetilde{X} \Sigma_C||_F$.

Let $s = \operatorname{rank} B$ and $t = \operatorname{rank} C$. Clearly, if $B$ or $C$ is a zero matrix, then $X = \mathbf{0}$ is the solution to the minimal problem (2.2). In this case, either $P_{B,L}$ or $P_{C,R}$ are zero matrices, and the theorem holds trivially in this case.

Let us consider the case $1 \leq s, 1 \leq t$. Define $B_1 := \operatorname{diag}(\sigma_1(B), \ldots, \sigma_s(B)) \in \mathbb{C}^{s\times s}, C_1 := \operatorname{diag}(\sigma_1(C), \ldots, \sigma_t(C)) \in \mathbb{C}^{t\times t}$. Partition $\widetilde{A}$ and $\widetilde{X}$ into four block matrices $A_{ij}$ and $X_{ij}$ with $i, j = 1, 2$ so that $\widetilde{A} = [A_{ij}]_{i,j=1}^2$ and $\widetilde{X} = [X_{ij}]_{i,j=1}^2$, where $A_{11}, X_{11} \in \mathbb{C}^{s\times t}$. (For certain values of $s$ and $t$, we may have to partition $\widetilde{A}$ or $\widetilde{X}$ to less than four block matrices.) Next, observe that $Z := \Sigma_B \tilde{X} \Sigma_C = [Z_{ij}]_{i,j=1}^2$, where $Z_{11} = B_1 X_{11} C_1$ and all other blocks $Z_{ij}$ are zero matrices. Since $B_1$ and $C_1$ are invertible we deduce that

$$\operatorname{rank} Z = \operatorname{rank} Z_{11} = \operatorname{rank} X_{11} \leq \operatorname{rank} \widetilde{X} \leq k.$$

The approximation property of $(A_{11})_k$ yields the inequality $||A_{11} - Z_{11}||_F \geq ||A_{11} - (A_{11})_k||_F$ for any $Z_{11}$ of, at most, rank $k$. Hence for any $Z$ of the above form,

$$||\widetilde{A} - Z||_F^2 = ||A_{11} - Z_{11}||_F^2 + \sum_{2<i+j\leq 4} ||A_{ij}||_F^2 \geq ||A_{11} - (A_{11})_k||_F^2 + \sum_{2<i+j\leq 4} ||A_{ij}||_F^2.$$

Thus, $\widehat{X} = [X_{ij}]_{i,j=1}^2$, where $X_{11} = B_1^{-1}(A_{11})_k C_1^{-1}$ and $X_{ij} = \mathbf{0}$ for all $(i,j) \neq (1,1)$ is a solution to the problem $\min_{\widetilde{X} \in \mathcal{R}(p,q,k)} ||\widetilde{A} - \Sigma_B \widetilde{X} \Sigma_C||_F$ with the minimal Frobenius norm. This solution is unique if and only if the solution $Z_{11} = (A_{11})_k$ is the unique solution to the problem $\min_{Z_{11} \in \mathcal{R}(s,t,k)} ||A_{11} - Z_{11}||_F$. This happens if either $k \geq \operatorname{rank} A_{11}$ or $1 \leq k < \operatorname{rank} A_{11}$ and $\sigma_k(A_{11}) > \sigma_{k+1}(A_{11})$. A straightforward calculation shows that $\widehat{X} = \Sigma_B^\dagger (P_{\Sigma_B,L} \widetilde{A} P_{\Sigma_C,R})_k \Sigma_C^\dagger$. Thus, a solution of (2.2) with the minimal Frobenius norm is given by

$$\begin{aligned} X &= B^\dagger U_B (P_{\Sigma_B,L} U_B^* A V_C P_{\Sigma_C,R})_k V_C^* C^\dagger \\ &= B^\dagger U_B (U_B^* P_{B,L} A P_{C,R} V_C)_k V_C^* C^\dagger \\ &= B^\dagger (P_{B,L} A P_{C,R})_k C^\dagger. \end{aligned}$$

This solution is unique if and only if either $k \geq \operatorname{rank} P_{B,L} A P_{C,R}$, or $1 \leq k < \operatorname{rank} P_{B,L} A P_{C,R}$ and $\sigma_k(P_{B,L} A P_{C,R}) > \sigma_{k+1}(P_{B,L} A P_{C,R})$. $\square$

**3. Examples.** First, observe that the classical approximation problem given by (1.2) is equivalent to the case $m = p, n = q, B = I_m, C = I_n$. (Here, $I_m$ is the $m \times m$ identity matrix.) Clearly, $P_{I_m,L} = I_m$, $P_{I_n,R} = I_n$, $I_m^\dagger = I_m$, $I_n^\dagger = I_n$. In this case we obtain the classical solution $B^\dagger (P_{B,L} A P_{C,R})_k C^\dagger = A_k$.

Second, if $p = m$, $q = n$, and $B$, $C$ are nonsingular, then $\operatorname{rank}(BXC) = \operatorname{rank} X$. In this case, $P_{B,L} = I_m$ and $P_{C,R} = I_n$, and the solution to (2.2) is given by $X = B^{-1} A_k C^{-1}$.

Next, a particular case of the problem (2.2) occurs in the study of a random vector estimation (see, for example, [6, 9]) as follows. Let $(\Omega, \Sigma, \mu)$ be a probability space, where $\Omega$ is the set of outcomes, $\Sigma$ a $\sigma$-field of measurable subsets of $\Omega$, and $\mu : \Sigma \mapsto [0,1]$ an associated probability measure on $\Sigma$ with $\mu(\Omega) = 1$. Suppose that $\mathbf{x} \in L^2(\Omega, \mathbb{R}^m)$ and $\mathbf{y} \in L^2(\Omega, \mathbb{R}^n)$ are random vectors such that $\mathbf{x} = (x_1, \ldots, x_m)^T$ and $\mathbf{y} = (y_1, \ldots, y_n)^T$ with $x_i, y_j \in L^2(\Omega, \mathbb{R})$ for $i = 1, \ldots, m$ and $j = 1, \ldots, n$, respectively. Let $E_{xy} = [e_{ij,xy}] \in \mathbb{R}^{m \times n}$, $E_{yy} = [e_{jk,yy}] \in \mathbb{R}^{n \times n}$ be correlation matrices with entries

$$e_{ij,xy} = \int_\Omega x_i(\omega) y_j(\omega) d\mu(\omega), \quad e_{jk,yy} = \int_\Omega y_j(\omega) y_k(\omega) d\mu(\omega),$$
$$i = 1, \ldots, m, \quad j,k = 1, \ldots, n, \quad \omega \in \Omega.$$

The problems considered in [6, 9] are reduced to finding a solution to the problem (2.2) with $A = E_{xy} E_{yy}^{1/2\dagger}$, $B = I_n$, and $C = E_{yy}^{1/2}$, where we write $E_{yy}^{1/2\dagger} = (E_{yy}^{1/2})^\dagger$. Let the SVD of $E_{yy}^{1/2}$ be given by $E_{yy}^{1/2} = V_n \Sigma V_n^*$ and let $\operatorname{rank} E_{yy}^{1/2} = r$. Here, $V_n = [\mathbf{v}_1, \ldots, \mathbf{v}_n]$ with $\mathbf{v}_i$ the $i$th column of $V_n$. By Theorem 2.1, the solution to this particular case of the problem (2.2) having the minimal Frobenius norm is given by $X = (E_{xy} E_{yy}^{1/2\dagger} V_r V_r^*)_k E_{yy}^{1/2\dagger}$, where $E_{yy}^{1/2\dagger} V_r V_r^* = E_{yy}^{1/2\dagger}$. Therefore, $X = (E_{xy} E_{yy}^{1/2\dagger})_k E_{yy}^{1/2\dagger}$. The conditions for the uniqueness follow directly from Theorem 2.1.

Finally, a special case of the minimal problem (2.2), where $X$ is a rank one matrix and $C$ the identity matrix, was considered by M. Elad [3] in the context of image processing.

## 1. Introduction.

Let $\{a_k\}_{k\in\mathbf{Z}}$ be a sequence of complex numbers and denote by $T_n$ the $n\times n$ Toeplitz matrix $(a_{j-k})_{j,k=0}^{n-1}$. We are interested in the behavior of the spectral norm $\|T_n\|$ as $n\to\infty$. Notice that if the matrix $T_n$ is positive definite, then $\|T_n\|$ is just the maximal eigenvalue of $T_n$.

If there is a function $a\in L^1(\mathbf{T})$ such that $\{a_k\}_{k\in\mathbf{Z}}$ is the sequence of the Fourier coefficients of $a$, that is, $a_k = \frac{1}{2\pi}\int_{-\pi}^{\pi} a(e^{i\theta})e^{-ik\theta}d\theta$, we call $a$ the symbol of the sequence $\{T_n\}$ and denote $T_n$ by $T_n(a)$. The case where $a$ is in $L^\infty(\mathbf{T})$ is easy, since then $\|T_n(a)\|\to\|a\|_\infty$ as $n\to\infty$. Things are more complicated for symbols $a$ in $L^1(\mathbf{T})\setminus L^\infty(\mathbf{T})$. We here focus our attention on so-called Fisher–Hartwig symbols with a single singularity; that is, we consider functions $a$ of the form

$$a(t) = |t-t_0|^{-2\alpha}\varphi_{\beta,t_0}(t)b(t) \quad (t\in\mathbf{T}),$$

where $t_0\in\mathbf{T}$, $\alpha$ is a complex number subject to the constraint $0<\operatorname{Re}\alpha<1/2$, $\beta$ is a complex number satisfying $-1/2<\operatorname{Re}\beta\le 1/2$, the function $\varphi_{\beta,t_0}$ is defined as

$$\varphi_{\beta,t_0}(t) = \exp(i\beta\arg(-t/t_0)) \quad (t\in\mathbf{T})$$

with $\arg z\in(-\pi,\pi]$, and $b$ is a function in $L^\infty(\mathbf{T})$ that is continuous at $t_0$ and does not vanish at $t_0$. The hypothesis $0<\operatorname{Re}\alpha<1/2$ ensures that $a\in L^1(\mathbf{T})\setminus L^\infty(\mathbf{T})$. We should mention that if $a$ is any piecewise continuous function on $\mathbf{T}$ with a single jump, say, at $t_0\in\mathbf{T}$, and $a(t_0\pm 0)\ne 0$, then $a$ can be written in the form $a=\varphi_{\beta,t_0}b$ with $-1/2<\operatorname{Re}\beta\le 1/2$ and a continuous function $b$. Indeed, since $\varphi_{\beta,t_0}(t_0-0)=e^{\pi i\beta}$ and $\varphi_{\beta,t_0}(t_0+0)=e^{-\pi i\beta}$, it suffices to choose $\operatorname{Im}\beta\in(-\infty,\infty)$ and $\operatorname{Re}\beta\in(-1/2,1/2]$ so that

$$\frac{a(t_0+0)}{a(t_0-0)} = e^{-2\pi i\beta} = e^{2\pi\operatorname{Im}\beta}\,e^{-2\pi i\operatorname{Re}\beta}.$$

---

Our main result says that

$$\|T_n(a)\| \sim C_{\alpha,\beta}\, n^{2\,\mathrm{Re}\,\alpha}\, |b(t_0)| \quad \text{as} \quad n \to \infty,$$

where $C_{\alpha,\beta}$ is a completely identified constant depending only on $\alpha$ and $\beta$ and where $x_n \sim y_n$ means that $x_n/y_n \to 1$. We will also establish results for symbols with more than one Fisher–Hartwig singularity.

For the exciting story behind Toeplitz matrices with Fisher–Hartwig symbols and their determinants we refer the reader to the books [4], [5] and the papers [1], [9]. For general Toeplitz matrices, the asymptotic distribution of the singular values and the asymptotics of the extreme singular values have been studied by many authors, and we abstain from giving an ample list of references here. These investigations are mainly directed to the collective distribution of the singular values (Szegö–Avram–Parter theorems) or to the behavior of the extreme singular values of $T_n(a)$ for symbols $a$ in $L^\infty(\mathbf{T})$. The asymptotics of the smallest singular value are governed by the nature of the zeros of the symbol $a$. This implies that the rate of convergence of the largest singular value (= the norm) of $T_n(a)$ to $\|a\|_\infty$ depends on the zeros of the function $\|a\|_\infty - |a(t)|$. These results are not applicable to Toeplitz matrices with symbols in $L^1(\mathbf{T}) \setminus L^\infty(\mathbf{T})$ or to Toeplitz matrices "without symbols." Such matrices are considered in [2], [3], [12], [13], [14], [15], for example, but the focus of these papers is not on the problem we are interested in here.

Under the sole assumption that $b$ is in $L^\infty(\mathbf{T})$, the method of [2] yields the estimate $\|T_n(a)\| \le C_2\, n^{2\,\mathrm{Re}\,\alpha}$ with some finite constant $C_2$. If $\alpha$ is real, $\varphi_\beta b$ is real-valued, and $\operatorname{ess\,inf} b > 0$, one can also proceed as in [2] to show the existence of a positive constant $C_1$ such that $\|T_n(a)\| \ge C_1\, n^{2\,\mathrm{Re}\,\alpha}$. Such estimates were also derived in [11] by different arguments. These two-sided bounds are useful in several contexts (see [11], for example), but they are clearly far away from the precise asymptotics $\|T_n(a)\| \sim C_{\alpha,\beta}\, n^{2\,\mathrm{Re}\,\alpha}\, |b(t_0)|$.

The approach of the present paper is based on an idea of Widom [16], [17], [18]: we construct integral operators $K_n$ on $L^2(0,1)$ such that $\|T_n(a)\| = n^{2\,\mathrm{Re}\,\alpha}\, \|K_n\|$ and prove that $K_n$ converges to some integral operator $K$ in the operator norm on $L^2(0,1)$, which implies that $\|K_n\| \to \|K\|$.

For nonnegative symbols, the results of this paper are of interest in the analysis of time series with long memory. The $n$th covariance matrix of a time series is a positive definite Toeplitz matrix $T_n(a) = (a_{j-k})_{j,k=1}^n$, and one wants to know its largest eigenvalue. If the series has a short memory, then $a_n$ goes rapidly to zero as $|n| \to \infty$, and hence $\{a_n\}$ is the sequence of the Fourier coefficients of a function $a \in L^\infty(\mathbf{T})$. However, in the case of a long range memory, the numbers $a_n$ may be of the order $|n|^{2\alpha-1}$ $(0 < \alpha < 1/2)$, which leads to symbols $a \in L^1(\mathbf{T}) \setminus L^\infty(\mathbf{T})$. The symbol $a(t) = |t - t_0|^{-2\,\alpha}\, b(t)$ is especially popular and will be considered in detail in section 5. For more on Toeplitz matrices in time series we refer the reader to [6], [7], [8], [10], [11].

**2. A special class of Toeplitz matrices.** We begin with a simple observation.

PROPOSITION 2.1. [illegible] $\gamma$ [illegible] $|a_{\pm n}| = O(n^\gamma)$ [illegible] $n \to \infty$ [illegible] $\|T_n\|$ [illegible] $\gamma < -1$ $\|T_n\| = O(\log n)$ [illegible] $\gamma = -1$ [illegible] $\|T_n\| = O(n^{\gamma+1})$ [illegible] $\gamma > -1$ [illegible] $|a_{\pm n}| = o(n^\gamma)$ [illegible] $n \to \infty$ [illegible] $\|T_n\| = o(\log n)$ [illegible] $\gamma = -1$ [illegible] $\|T_n\| = o(n^{\gamma+1})$ [illegible] $\gamma > -1$

[illegible] In the case $\gamma < -1$, the sequence $\{a_k\}$ is the sequence of the Fourier coefficients of a continuous function $a$, and hence $\|T_n\| = \|T_n(a)\| \to \|a\|_\infty$. The spectral norm of a Toeplitz matrix one diagonal of which is occupied by units and the remaining diagonals of which are zero equals 1. This implies that $\|T_n\| \le \sum_{k=-(n-1)}^{n-1} |a_k|$ and therefore yields the assertions concerning $\gamma = -1$ and $\gamma > -1$. □

Let $A_n = (a_{j,k})_{j,k=0}^{n-1}$ be an $n \times n$ matrix with complex entries. We denote by $G_n$ the integral operator on $L^2(0,1)$ with the kernel

$$g_n(x,y) = a_{[nx],[ny]}, \quad (x,y) \in (0,1)^2,$$

where $[\xi]$ denotes the integral part of $\xi$.

Lemma 2.2 (Widom). [illegible] $A_n$ [illegible] $G_n$ [illegible] $\|A_n\| = n\|G_n\|$

[illegible] Put $I_k = (k/n, (k+1)/n)$ and consider the operators

$$S_n : \{x_k\}_{k=0}^{n-1} \mapsto \sqrt{n} \sum_{k=0}^{n-1} x_k \chi_{I_k}, \quad T_n : f \mapsto \left\{ \sqrt{n} \int_{I_k} f(x)dx \right\}_{k=0}^{n-1}.$$

It is easily seen that $\|S_n\| = \|T_n\| = 1$ and that $T_n S_n$ is the identity operator on $\mathbf{C}^n$. Since $S_n A_n T_n = nG_n$ and thus $A_n = nT_n G_n S_n$ we obtain that $\|A_n\| \ge n\|G_n\|$ and $\|A_n\| \le n\|G_n\|$. □

Let $C^+$, $C^-$, $\gamma$ be complex numbers, let $\operatorname{Re}\gamma > -1$, let $a_{\pm n} = C^{\pm} n^{\gamma}$ for $n \ge 1$, and let $a_0$ be any complex number. Denote by $K_n$ and $K$ the integral operators on $L^2(0,1)$ with the kernels

$$k_n(x,y) = n^{-\gamma}\, a_{[nx]-[ny]} \quad \text{and} \quad k(x,y) = \begin{cases} C^+ (x-y)^{\gamma} & \text{for} \quad x > y, \\ C^-(y-x)^{\gamma} & \text{for} \quad x < y, \end{cases}$$

respectively.

Lemma 2.3. [illegible] $K_n$ [illegible] $K$ [illegible] $L^2(0,1)$

[illegible] Fix a $\mu \in (0,1)$ sufficiently close to 1 such that $(1-\mu)|\operatorname{Re}\gamma| < \mu$ and $2\,\mu \operatorname{Re}\gamma < 1 + 2\operatorname{Re}\gamma$. Put

$$k_n^1(x,y) = \begin{cases} k(x,y) & \text{if } |x-y| > n^{\mu-1}, \\ 0 & \text{otherwise}, \end{cases} \quad k_n^2(x,y) = \begin{cases} k(x,y) & \text{if } |x-y| < n^{\mu-1}, \\ 0 & \text{otherwise}, \end{cases}$$

$$\ell_n^1(x,y) = \begin{cases} k_n(x,y) & \text{if } |x-y| > n^{\mu-1}, \\ 0 & \text{otherwise}, \end{cases} \quad \ell_n^2(x,y) = \begin{cases} k_n(x,y) & \text{if } |x-y| < n^{\mu-1}, \\ 0 & \text{otherwise}, \end{cases}$$

and denote by $K_n^1, K_n^2, L_n^1, L_n^2$ the integral operators on $L^2(0,1)$ with the kernels $k_n^1, k_n^2, \ell_n^1, \ell_n^2$, respectively. We have $K = K_n^1 + K_n^2$ and $K_n = L_n^1 + L_n^2$. Thus,

$$\|K - K_n\| \le \|K_n^1 - L_n^1\| + \|K_n^2\| + \|L_n^2\|.$$

We show that each term on the right goes to zero as $n \to \infty$.

To prove that $\|K^1 - K_n^1\| \to 0$ it suffices to show that $|k_n^1(x,y) - \ell_n^1(x,y)|$ converges uniformly to zero for $|x-y| > n^{\mu-1}$. We may assume that $x > y$, since the case $x < y$ can be tackled analogously. Thus, let $x - y > n^{\mu-1}$. As $[nx] - [ny] = n(x-y) + \varepsilon_n$ with $|\varepsilon_n| = |\varepsilon_n(x,y)| \le 2$, we get

$$\begin{aligned} \ell_n^1(x,y) &= C^+ n^{-\gamma}([nx] - [ny])^{\gamma} = C^+ n^{-\gamma}(n(x-y) + \varepsilon_n)^{\gamma} \\ &= C^+ (x-y)^{\gamma} \left(1 + \frac{\varepsilon_n}{n(x-y)}\right)^{\gamma}. \end{aligned}$$

Since $n(x-y) > n^\mu$, it follows that $\ell_n^1(x,y) = C^+(x-y)^\gamma(1+O(n^{-\mu}))$ uniformly in $x$ and $y$. Hence

$$|k_n^1(x,y) - \ell_n^1(x,y)| = |(x-y)^\gamma|\, O(n^{-\mu}) = (x-y)^{\operatorname{Re}\gamma}\, O(n^{-\mu})$$

uniformly in $x$ and $y$. If $\operatorname{Re}\gamma \ge 0$, this goes to zero uniformly in $x$ and $y$. In the case where $\operatorname{Re}\gamma < 0$, we use the inequality $x - y > n^{\mu-1}$ to obtain that

$$(x-y)^{\operatorname{Re}\gamma}\, O(n^{-\mu}) = O\left(n^{(1-\mu)|\operatorname{Re}\gamma|} n^{-\mu}\right)$$

uniformly in $x$ and $y$, which is $o(1)$ because $(1-\mu)|\operatorname{Re}\gamma| < \mu$. We so have proved that $\|K^1 - K_n^1\| \to 0$ as $n \to \infty$.

The operator $K_n^2$ is the compression to $L^2(0,1)$ of the operator of convolution on $L^2(\mathbf{R})$ by the kernel

$$\kappa(x) = \begin{cases} C^+ x^\gamma & \text{for } \; 0 < x < n^{\mu-1}, \\ C^-|x|^\gamma & \text{for } \; -n^{\mu-1} < x < 0, \\ 0 & \text{for } \; |x| > n^{\mu-1}. \end{cases}$$

The norm of a convolution operator on $L^2(\mathbf{R})$ is the maximum of the modulus of the Fourier transform

$$(F\kappa)(\xi) = \int_{\mathbf{R}} \kappa(x) e^{i\xi x} dx \quad (\xi \in \mathbf{R})$$

of its convolution kernel $\kappa(x)$. Hence

$$\begin{aligned} \|K_n^2\| &\le \max_{\xi\in\mathbf{R}} |(F\kappa)(\xi)| \le \int_{\mathbf{R}} |\kappa(x)| dx \\ &= \int_{-n^{\mu-1}}^{1} C^-|x|^{\operatorname{Re}\gamma} dx + \int_0^{n^{\mu-1}} C^+ x^{\operatorname{Re}\gamma} dx = O\left(n^{(\mu-1)(\operatorname{Re}\gamma+1)}\right), \end{aligned}$$

which proves that $\|K_n^2\| \to 0$ as $n \to \infty$.

Let us consider the norm $\|L_n^2\|$. The kernel $\ell_n^2(x,y)$ is supported in the strip $|x-y| < n^{\mu-1}$. Let $\tilde{\ell}_n^2(x,y)$ be $k_n(x,y)$ for $(x,y)$ in the staircase-like bordered strip $|[nx] - [ny]| < n^\mu$ and zero otherwise. Denote by $\tilde{L}_n^2$ the corresponding integral operator. The difference $\ell_n^2(x,y) - \tilde{\ell}_n^2(x,y)$ is supported in about $4(n - n^\mu) = O(n)$ squares of side length $1/n$, and in these squares the absolute value of the difference is about $n^{-\gamma} a_{\pm[n^\mu]} = O(n^{-\operatorname{Re}\gamma} n^{\mu \operatorname{Re}\gamma})$. Consequently, the squared Hilbert–Schmidt norm $\|L_n^2 - \tilde{L}_n^2\|_2^2$ is at most a constant times $n\, n^{-2\operatorname{Re}\gamma} n^{2\mu\operatorname{Re}\gamma}(1/n)^2$, which goes to zero because $1 - 2\operatorname{Re}\gamma + 2\mu\operatorname{Re}\gamma - 2 = 2\mu\operatorname{Re}\gamma - (1 + 2\operatorname{Re}\gamma) < 0$. We are therefore left with proving that $\|\tilde{L}_n^2\| \to 0$. Let $T_n = (b_{j-k})_{j,k=0}^{n-1}$, where $b_k = a_k$ for $|k| \le n^\mu$ and $b_k = 0$ otherwise. Lemma 2.2 implies that $\|\tilde{L}_n^2\| = (1/n) n^{-\operatorname{Re}\gamma}\|T_n\|$, and since

$$\|T_n\| \le \sum_{k=-n^\mu}^{n^\mu} |b_k| = O\left(\sum_{k=-n^\mu}^{n^\mu} k^{\operatorname{Re}\gamma}\right) = O\left(n^{\mu(\operatorname{Re}\gamma+1)}\right),$$

we finally get $\|\tilde{L}_n^2\| = O\left(n^{(\mu-1)(\operatorname{Re}\gamma+1)}\right) = o(1)$. □

THEOREM 2.4. [illegible] $T_n = (a_{j-k})_{j,k=0}^{n-1}$ [illegible] $a_{\pm n} = C^{\pm} n^\gamma (1 + o(1))$ [illegible] $n \to \infty$ [illegible] $C^+$ $C^-$ $\gamma$ [illegible] $\operatorname{Re}\gamma > -1$ [illegible] $C^+$ [illegible] $C^-$ [illegible]

$$\|T_n\| \sim \|K\|\, n^{\operatorname{Re}\gamma+1},$$

[illegible] $K$ [illegible] $L^2(0,1)$ [illegible] $C^+(x-y)^\gamma$ [illegible] $x>y$ [illegible] $C^-(y-x)^\gamma$ [illegible] $x<y$

[illegible] Write $T_n = S_n + D_n$ with $S_n = (b_{j-k})_{j,k=0}^{n-1}$, $D_n = (d_{j-k})_{j,k=0}^{n-1}$, $b_{\pm n} = C^\pm n^\gamma$, $d_{\pm n} = o(n^\gamma)$. From Lemma 2.2 we deduce that $\|S_n\|/n$ equals the norm of the integral operator $n^\gamma K_n$, where $K_n$ has the kernel $n^{-\gamma} b_{[nx]-[ny]}$. Lemma 2.3 implies that $\|K_n - K\| \to 0$ and thus $\|K_n\| \to \|K\|$. Consequently,

$$\|S_n\| = \|K\| n^{\operatorname{Re}\gamma+1}(1+o(1)).$$

Proposition 2.1 yields $\|D_n\| = o(n^{\operatorname{Re}\gamma+1})$. □

THEOREM 2.5. [illegible] $B_1^+, \dots, B_Q^+, B_1^-, \dots, B_Q^-$ [illegible] $\gamma_1, \dots, \gamma_Q$ [illegible] $\operatorname{Re}\gamma_s > -1$ [illegible] $s$ [illegible] $\omega = e^{2\pi i/Q}$ [illegible] $T_n = (a_{j-k})_{j,k=0}^{n-1}$ [illegible]

$$a_{\pm n} = \sum_{s=1}^{Q} B_s^\pm \omega^{\pm sn} n^{\gamma_s}(1+o(1)) \quad n \to \infty.$$

[illegible] $\operatorname{Re}\gamma := \max_s \operatorname{Re}\gamma_s$ [illegible] $S = \{s : \operatorname{Re}\gamma_s = \operatorname{Re}\gamma\}$ [illegible]

$$\|T_n\| \sim \max_{s\in S} \|K_s\| \, n^{\operatorname{Re}\gamma+1},$$

[illegible] $K_s$ [illegible] $L^2(0,1)$ [illegible] $B_s^+(x-y)^{\gamma_s}$ [illegible] $x>y$ [illegible] $B_s^-(y-x)^{\gamma_s}$ [illegible] $x<y$

[illegible] Assume first that $n = mQ$ with a natural number $m$. We rearrange the rows of $T_{mQ}$ by first taking the rows $1, Q+1, 2Q+1, \dots$, then the rows $2, Q+2, 2Q+2, \dots$, and so on. Then we make the same rearrangement with the columns. The resulting matrix has the same spectral norm as $T_{mQ}$ and is a block Toeplitz matrix $(A_{j-k})_{j,k=0}^{Q-1}$ whose blocks are the Toeplitz matrices $A_k = (a_{k+(u-v)Q})_{u,v=0}^{m-1}$. For $0 \le |k| \le Q-1$, let $D_k$ be the Toeplitz matrix $D_k = (d_{u-v}^{(k)})_{u,v=0}^{m-1}$ given by $d_0^{(k)} = 0$ and

$$d_{\pm\nu}^{(k)} = \sum_{s=1}^{Q} B_s^\pm \omega^{sk} (\nu Q)^{\gamma_s} \quad (\nu \ge 1).$$

If $\nu \to \infty$, then eventually $k + \nu Q \ge 1$, and hence

$$a_{k+\nu Q} - d_\nu^{(k)} = \sum_{s=1}^{Q} B_s^+ \omega^{sk} \left[ (k+\nu Q)^{\gamma_s}(1+o(1)) - (\nu Q)^{\gamma_s} \right].$$

The modulus of the term in brackets is

$$\begin{aligned} &(\nu Q)^{\operatorname{Re}\gamma_s} \left| \left(1 + \frac{k}{\nu Q}\right)^{\gamma_s} (1+o(1)) - 1 \right| \\ &= (\nu Q)^{\operatorname{Re}\gamma_s} |(1+o(1))(1+o(1)) - 1| = (\nu Q)^{\operatorname{Re}\gamma_s} o(1) = o(\nu^{\operatorname{Re}\gamma_s}). \end{aligned}$$

An analogous estimate holds for $\nu \to -\infty$. From Proposition 2.1 we therefore deduce that $A_k = D_k + E_k$ with $\|E_k\| = o(m^{\operatorname{Re}\gamma+1})$. It follows that

$$\|T_{mQ}\| = \|(D_{j-k})_{j,k=0}^{Q-1}\| + o(m^{\operatorname{Re}\gamma+1}).$$

Now, for $s \in \{1, \ldots, Q\}$, put $H_s = (h^{(s)}_{u-v})_{u,v=0}^{m-1}$, where $h^{(s)}_0 = 0$ and $h^{(s)}_{\pm\nu} = B^{\pm}_s(\nu Q)^{\gamma_s}$ for $\nu \geq 1$. Then

$$D_{j-k} = \sum_{s=1}^{Q} \omega^{s(j-k)} H_s.$$

Let $F_\pm$ be the block Fourier matrices $F_\pm = (\omega^{\pm jk} I_{m\times m})_{j,k=1}^{Q}$. The $j, k$ block entry of $F_+ \operatorname{diag}(H_1, \ldots, H_Q) F_-$ equals $\sum_{s=1}^{Q} \omega^{js} H_s \omega^{-sk} = D_{j-k}$. Consequently,

$$(D_{j-k})_{j,k=0}^{Q-1} = (D_{j-k})_{j,k=1}^{Q} = F_+ \operatorname{diag}(H_1, \ldots, H_Q) F_-.$$

Since the matrices $(1/\sqrt{Q})\, F_\pm$ are unitary, we get

$$\|(D_{j-k})_{j,k=0}^{Q-1}\| = \sqrt{Q}\ \|\operatorname{diag}(H_1, \ldots, H_Q)\|\ \sqrt{Q} = Q \max_s \|H_s\|.$$

Theorem 2.4 gives

$$\|H_s\| = m^{\operatorname{Re}\gamma_s}\, Q^{\operatorname{Re}\gamma_s + 1}\, \|K_s\|\, (1 + o(1)).$$

In summary,

$$\begin{aligned} \|T_{mQ}\| &= Q \max_s m^{\operatorname{Re}\gamma_s+1}\, Q^{\operatorname{Re}\gamma_s}\, \|K_s\|\, (1+o(1)) + o(m^{\operatorname{Re}\gamma+1}) \\ &= (mQ)^{\operatorname{Re}\gamma+1} \max_{s\in S} \|K_s\| + o(m^{\operatorname{Re}\gamma+1}) \\ &\sim (mQ)^{\operatorname{Re}\gamma+1} \max_{s\in S} \|K_s\|. \end{aligned}$$

Finally, if $n$ is not divisible by $Q$, we can obtain $T_n$ from $T_{mQ}$ by adding at most $Q-1$ rows and columns. The spectral norm of a matrix with a single nonzero row or column is the $\ell^2$ norm of this row or column, which in the case at hand does not exceed the square root of $\sum_{j=-(n-1)}^{n-1} |a_j|^2 = O(n^{2\operatorname{Re}\gamma+1})$; that is, $O(n^{\operatorname{Re}\gamma+1/2}) = o(n^{\operatorname{Re}\gamma+1})$. This completes the proof. $\square$

**3. A single Fisher–Hartwig singularity.** We first consider the pure Fisher–Hartwig singularity at $t_0 = 1$, that is, the function

$$\sigma(t) = |t-1|^{-2\alpha} \varphi_{\beta,1}(t)$$

with $0 < \operatorname{Re}\alpha < 1/2$ and $-1/2 < \operatorname{Re}\beta \leq 1/2$. The Fourier coefficients of $\sigma$ are

$$\sigma_n = (-1)^n \frac{\Gamma(1-2\alpha)}{\Gamma(-\alpha+\beta+1-n)\Gamma(-\alpha-\beta+1+n)},$$

with the convention that $\sigma_n := 0$ for $n < 0$ if $\alpha = -\beta$ and $\sigma_n := 0$ for $n > 0$ if $\alpha = \beta$ (see [5, Lemma 6.18]). Using the formula

$$\Gamma(1-z) = \frac{\pi z}{\sin \pi z} \frac{1}{\Gamma(1+z)}$$

we see that

$$\begin{aligned} \sigma_n &= (-1)^n\, \Gamma(1-2\alpha) \frac{\sin \pi(n+\alpha-\beta)}{\pi(n+\alpha-\beta)} \frac{\Gamma(n+1+\alpha-\beta)}{\Gamma(n+1-\alpha-\beta)} \\ &= \Gamma(1-2\alpha) \frac{\sin \pi(\alpha-\beta)}{\pi(n+\alpha-\beta)} \frac{\Gamma(n+1+\alpha-\beta)}{\Gamma(n+1-\alpha-\beta)} \end{aligned}$$

for $n \geq 0$ and

$$\begin{aligned}\sigma_{-n} &= (-1)^n \frac{\Gamma(1-2\alpha)}{\Gamma(-\alpha+\beta+1+n)\Gamma(-\alpha-\beta+1-n)} \\ &= (-1)^n \,\Gamma(1-2\alpha)\,\frac{\sin\pi(n+\alpha+\beta)}{\pi(n+\alpha+\beta)}\,\frac{\Gamma(n+1+\alpha+\beta)}{\Gamma(n+1-\alpha+\beta)} \\ &= \Gamma(1-2\alpha)\,\frac{\sin\pi(\alpha+\beta)}{\pi(n+\alpha+\beta)}\,\frac{\Gamma(n+1+\alpha+\beta)}{\Gamma(n+1-\alpha+\beta)}\end{aligned}$$

for $n \geq 0$. The asymptotic formula $\Gamma(n+\gamma)/\Gamma(n+\delta) \sim n^{\gamma-\delta}$ $(n\to\infty)$ shows that

$$\sigma_n = C^{+}_{\alpha,\beta}\, n^{2\alpha-1}(1+o(1)), \quad \sigma_{-n} = C^{-}_{\alpha,\beta}\, n^{2\alpha-1}(1+o(1))$$

as $n \to \infty$, where

$$C^{\pm}_{\alpha,\beta} = \Gamma(1-2\alpha)\,\frac{\sin\pi(\alpha\mp\beta)}{\pi}.$$

We denote by $K$ the integral operator on $L^2(0,1)$ with the kernel

$$k(x,y) = \begin{cases} C^{+}_{\alpha,\beta}\,(x-y)^{2\alpha-1} & \text{for} \quad x>y, \\ C^{-}_{\alpha,\beta}\,(y-x)^{2\alpha-1} & \text{for} \quad x<y. \end{cases}$$

Obviously, $\|K\| > 0$.

THEOREM 3.1. [illegible] $\sigma(t) = |t-t_0|^{-2\alpha}\varphi_{\beta,t_0}(t)$ [illegible] $t_0 \in \mathbf{T}$ $0 < \operatorname{Re}\alpha < 1/2$ $-1/2 < \operatorname{Re}\beta \leq 1/2$ [illegible]

$$\|T_n(\sigma)\| \sim \|K\|\, n^{2\operatorname{Re}\alpha}.$$

[illegible] We change notation slightly and denote the function $\sigma$ defined as $\sigma(t) = |t-1|^{-2\alpha}\varphi_{\beta,1}(t)$ by $\sigma^0$. The $\sigma$ of the present theorem results from $\sigma^0$ by replacing $t_0 = 1$ with a general $t_0 \in \mathbf{T}$. The only change in the Fourier coefficients is that the $(-1)^n$ in $(\sigma^0)_n$ becomes $(-1/t_0)^n$ in $\sigma_n$, and hence $T_n(\sigma) = \Lambda\, T_n(\sigma^0)\,\Lambda^{-1}$, where $\Lambda := \operatorname{diag}(1, t_0^{-1}, \ldots, t_0^{-(n-1)})$. Therefore $\|T_n(\sigma)\| = \|T_n(\sigma^0)\|$. Taking into account that $(\sigma^0)_{\pm n} = C^{\pm}_{\alpha,\beta}\, n^{2\,\alpha-1}\,(1+o(1))$ and using Theorem 2.4 we arrive at the desired formula. □

PROPOSITION 3.2. [illegible] $\sigma$ [illegible] 3.1 [illegible] $c \in L^\infty(\mathbf{T})$ [illegible] $t_0$ [illegible]

$$\|T_n(\sigma c)\| = o(n^{2\operatorname{Re}\alpha}).$$

[illegible] Without loss of generality assume that $t_0 = 1$. Writing $\sigma = \operatorname{Re}\sigma + i\operatorname{Im}\sigma$ and $c = \operatorname{Re} c + i \operatorname{Im} c$ we get $T_n(\sigma c) = T_n(\operatorname{Re}\sigma \operatorname{Re} c) + \ldots$ (four terms) and thus $\|T_n(\sigma c)\| \leq \|T_n(\operatorname{Re}\sigma\operatorname{Re} c)\| + \ldots$. The matrix $T_n(\operatorname{Re}\sigma\operatorname{Re} c)$ is Hermitian, and hence

$$\begin{aligned}\|T_n(\operatorname{Re}\sigma\operatorname{Re} c)\| &= \max_{\psi\in\mathbf{C}^n\setminus\{0\}} \frac{|(T_n(\operatorname{Re}\sigma\operatorname{Re} c)\psi,\psi)|}{\|\psi\|^2} \\ &= \max_{\varphi\in\mathcal{P}_n\setminus\{0\}} \frac{1}{\|\varphi\|^2}\left|\int_{-\pi}^{\pi} \operatorname{Re}\sigma(x)\operatorname{Re} c(x)\,|\varphi(x)|^2\frac{dx}{2\pi}\right| \\ &\leq \max_{\varphi\in\mathcal{P}_n\setminus\{0\}} \frac{1}{\|\varphi\|^2}\int_{-\pi}^{\pi} |\operatorname{Re}\sigma(x)|\,|\operatorname{Re} c(x)|\,|\varphi(x)|^2\frac{dx}{2\pi},\end{aligned}$$

where $\mathcal{P}_n$ is the set of all trigonometric polynomials of the form $\varphi(x) = \varphi_0 + \varphi_1 e^{ix} + \cdots + \varphi_{n-1} e^{i(n-1)x}$. Notice that

$$\begin{aligned}\|\varphi\|_\infty^2 &= \|\varphi_0 + \varphi_1 e^{ix} + \cdots + \varphi_{n-1} e^{i(n-1)x}\|_\infty^2 \le (|\varphi_0| + |\varphi_1| + \cdots + |\varphi_{n-1}|)^2 \\ &\le n\,(|\varphi_0|^2 + |\varphi_1|^2 + \cdots + |\varphi_{n-1}|^2) = \frac{n}{2\pi}\int_{-\pi}^{\pi} |\varphi(x)|^2 dx = \frac{n}{2\pi}\,\|\varphi\|^2.\end{aligned}$$

Clearly,

$$\operatorname{Re}\sigma(x) = \left|2\,\sin\frac{x}{2}\right|^{-2\operatorname{Re}\alpha} \cos\left(\operatorname{Im}\alpha\,\log\left|2\sin\frac{x}{2}\right|\right)\,|\varphi_{\beta,1}(x)|,$$

which is $O(|x|^{-2\operatorname{Re}\alpha})$ as $x \to 0$. We split the integral into $\int_{|x|<\pi/n}$, $\int_{\pi/n<|x|<\pi/\sqrt{n}}$, and $\int_{\pi/\sqrt{n}<|x|<\pi}$. The integral over $|x| < \pi/n$ is at most

$$\begin{aligned}&C_1 \sup_{|x|<\pi/n} |\operatorname{Re} c(x)|\,\|\varphi\|_\infty^2 \int_{|x|<\pi/n} |x|^{-2\operatorname{Re}\alpha} dx \\ &\le C_2 \sup_{|x|<\pi/n} |\operatorname{Re} c(x)|\,\frac{n}{2\pi}\,\|\varphi\|^2\, n^{2\operatorname{Re}\alpha - 1} = o(n^{2\operatorname{Re}\alpha})\,\|\varphi\|^2\end{aligned}$$

because $\operatorname{Re} c(x) \to 0$ as $x \to 0$; here sup means esssup. The integral over the interval $\pi/n < |x| < \pi/\sqrt{n}$ has the upper bound

$$\begin{aligned}&C_3 \sup_{|x|<\pi/\sqrt{n}} |\operatorname{Re} c(x)| \int_{|x|>\pi/n} |x|^{-2\operatorname{Re}\alpha} |\varphi(x)|^2 dx \\ &\le C_3 \sup_{|x|<\pi/\sqrt{n}} |\operatorname{Re} c(x)|\,\frac{n^{2\operatorname{Re}\alpha}}{\pi^{2\operatorname{Re}\alpha}} \int_{|x|>\pi/n} |\varphi(x)|^2 dx \\ &\le C_3 \sup_{|x|<\pi/\sqrt{n}} |\operatorname{Re} c(x)|\,\frac{n^{2\operatorname{Re}\alpha}}{\pi^{2\operatorname{Re}\alpha}}\,\|\varphi\|^2 = o(n^{2\operatorname{Re}\alpha})\,\|\varphi\|^2,\end{aligned}$$

again because $\operatorname{Re} c(x) \to 0$ as $x \to 0$. Finally, the integral over $|x| > \pi/\sqrt{n}$ does not exceed

$$\begin{aligned}&C_4\,\|\operatorname{Re} c\|_\infty \int_{|x|>\pi/\sqrt{n}} |x|^{-2\operatorname{Re}\alpha} |\varphi(x)|^2 dx \\ &\le C_4\,\|\operatorname{Re} c\|_\infty\,\frac{n^{\operatorname{Re}\alpha}}{\pi^{2\operatorname{Re}\alpha}} \int_{|x|>\pi/\sqrt{n}} |\varphi(x)|^2 dx \\ &\le C_4\,\|\operatorname{Re} c\|_\infty\,\frac{n^{\operatorname{Re}\alpha}}{\pi^{2\operatorname{Re}\alpha}}\,\|\varphi\|^2 = O(n^{\operatorname{Re}\alpha})\,\|\varphi\|^2 = o(n^{2\operatorname{Re}\alpha})\,\|\varphi\|^2.\end{aligned}$$

This proves that $\|T_n(\operatorname{Re}\sigma\operatorname{Re} c)\| = o(n^{2\operatorname{Re}\alpha})$. Analogously one can show that

$$\|T_n(\operatorname{Re}\sigma\operatorname{Im} c)\|, \quad \|T_n(\operatorname{Im}\sigma\operatorname{Re} c)\|, \quad \|T_n(\operatorname{Im}\sigma\operatorname{Im} c)\|$$

are $o(n^{2\operatorname{Re}\alpha})$. □

THEOREM 3.3. [illegible] $a = \sigma b$ [illegible] $\sigma$ [illegible] 3.1 [illegible] $b$ [illegible] $L^\infty(\mathbf{T})$ [illegible] $t_0$ [illegible] $t_0$ [illegible]

$$\|T_n(a)\| \sim \|K\|\,|b(t_0)|\,n^{2\operatorname{Re}\alpha}.$$

[illegible] We have $b(t) = b(t_0) + c(t)$ with $b(t_0) \neq 0$ and a function $c \in L^\infty(\mathbf{T})$ that is continuous and zero at $t_0$. It follows that $T_n(a) = b(t_0)\, T_n(\sigma) + T_n(\sigma c)$. Theorem 3.1 yields

$$\|b(t_0)\, T_n(\sigma)\| = |b(t_0)|\, \|T_n(\sigma)\| = |b(t_0)|\, \|K\|\, n^{2\,\mathrm{Re}\,\alpha}\,(1 + o(1)),$$

and Proposition 3.2 gives $\|T_n(\sigma c)\| = o(n^{2\,\mathrm{Re}\,\alpha})$. □

**4. Several Fisher–Hartwig singularities.** Let $R \geq 2$ and

$$a(t) = b(t) \prod_{r=1}^{R} |t - t_r|^{-2\alpha_r} \varphi_{\beta_r,t_r}(t) \quad (t \in \mathbf{T}),$$

where $t_1, \ldots, t_R$ are distinct points on $\mathbf{T}$, $0 < \mathrm{Re}\,\alpha_r < 1/2$, $-1/2 < \mathrm{Re}\,\beta_r \leq 1/2$, $b \in L^\infty(\mathbf{T})$, $b$ is continuous at the points $t_1, \ldots, t_R$, and $b(t_r) \neq 0$ for all $r$. It is easily seen that $a$ can be written in the form

$$a(t) = \sum_{r=1}^{R} |t - t_r|^{-2\alpha_r} \varphi_{\beta_r,t_r}(t)\, b_r(t) \quad (t \in \mathbf{T})$$

with functions $b_r \in L^\infty(\mathbf{T})$ such that $b_r$ is continuous at $t_r$ and satisfies $b_r(t_r) \neq 0$. Let

$$\mathrm{Re}\,\alpha := \max\{\mathrm{Re}\,\alpha_1, \ldots, \mathrm{Re}\,\alpha_R\}, \qquad M = \{r : \mathrm{Re}\,\alpha_r = \mathrm{Re}\,\alpha\}.$$

If there is only one $r_0$ such that $\mathrm{Re}\,\alpha_{r_0} = \mathrm{Re}\,\alpha$, then Theorem 3.3 implies that

$$\|T_n(a)\| \sim \|K_{r_0}\|\, |b_{r_0}(t_{r_0})|\, n^{2\,\mathrm{Re}\,\alpha},$$

where $K_r$ denotes the integral operator on $L^2(0,1)$ associated with $|t - t_r|^{-2\alpha_r} \varphi_{\beta_r,t_r}(t)$, that is, the integral operator whose kernel is $C^+_{\alpha_r,\beta_r}(x-y)^{2\,\alpha_r - 1}$ for $x > y$ and equals $C^-_{\alpha_r,\beta_r}(y-x)^{2\,\alpha_r - 1}$ for $x < y$. The case where the maximum is attained at more than one $r$ is more difficult.

CONJECTURE 4.1. [illegible]

$$\|T_n(a)\| \sim \max_{r \in M} \|K_r\|\, |b(t_r)|\, n^{2\,\mathrm{Re}\,\alpha}.$$

The following result confirms this conjecture in a sufficiently interesting special case.

THEOREM 4.2. [illegible] $t_0 \in \mathbf{T}$ [illegible] $r$ $t_r = e^{2\pi i \varphi_r} t_0$ [illegible] $\varphi_r$ [illegible] 4.1 [illegible]

[illegible] As passage from $a(t)$ to $a(t/t_0)$ does not change the spectral norm of the Toeplitz matrix (recall the proof of Theorem 3.1), we may without loss of generality assume that $t_0 = 1$. Put $\sigma_{\alpha,\beta,\tau}(t) = |t - \tau|^{-2\alpha} \varphi_{\beta,\tau}(t)$. The Fourier coefficients of $a$ are

$$a_n = \sum_{r=1}^{R} (\sigma_{\alpha_r,\beta_r,t_r}\, b_r)_n = \sum_{r=1}^{R} b_r(t_r)\, (\sigma_{\alpha_r,\beta_r,t_r})_n + f_n,$$

where $\{f_n\}$ is the sequence of the Fourier coefficients of a function $f \in L^1(\mathbf{T})$ for which $\|T_n(f)\| = o(n^{2\,\mathrm{Re}\,\alpha})$ (Proposition 3.2). Furthermore, $(\sigma_{\alpha_r,\beta_r,t_r})_n = t_r^{-n} (\sigma_{\alpha_r,\beta_r,1})_n$ (see once more the proof of Theorem 3.1). Thus,

$$a_n = \sum_{r=1}^{R} b_r(t_r)\, t_r^{-n}\, (\sigma_{\alpha_r,\beta_r,1})_n + f_n.$$

Let $t_r^{-1} = e^{2\pi i p_r/q_r}$ with a rational number $p_r/q_r \in (0,1]$ and denote by $Q$ the least common multiple of $q_1, \dots, q_R$. Put $\omega = e^{2\pi i/Q}$. Then each $t_r^{-1}$ is of the form $\omega^{k_r}$ with some $k_r \in \{1, 2, \dots, Q\}$. It follows that

$$a_n = \sum_{r=1}^{R} b_r(t_r)\, \omega^{k_r n}\, (\sigma_{\alpha_r,\beta_r,1})_n + f_n$$

with different $k_1, \dots, k_R$ belonging to $\{1, 2, \dots, Q\}$. From section 3 we know that

$$(\sigma_{\alpha,\beta,1})_{\pm n} = C^{\pm}_{\alpha,\beta}\, n^{2\alpha-1}(1 + o(1)).$$

Hence

$$a_{\pm n} = \sum_{r=1}^{R} b_r(t_r)\, \omega^{\pm k_r n}\, C^{\pm}_{\alpha_r,\beta_r}\, n^{2\alpha_r-1}(1 + o(1)) + f_n,$$

which can be written as

$$a_{\pm n} = \sum_{s=1}^{Q} B^{\pm}_s\, \omega^{\pm sn}\, n^{\gamma_s}(1 + o(1)) + f_n$$

with $B^{\pm}_{k_r} = b_r(t_r)\, C^{\pm}_{\alpha_r,\beta_r}$, $\gamma_{k_r} = 2\alpha_r - 1$ and $B^{\pm}_s = 0$, $\gamma_s = 0$ otherwise. Theorem 2.5 shows that the spectral norm of the Toeplitz matrix $T^0_n$ generated by

$$a^0_{\pm n} := \sum_{s=1}^{Q} B^{\pm}_s\, \omega^{\pm sn}\, n^{\gamma_s}(1 + o(1))$$

satisfies

$$\|T^0_n\| \sim \max_{s\in S} \|K^0_s\|\, n^{2\,\mathrm{Re}\,\alpha} \quad \text{with} \quad \mathrm{Re}\,\alpha := \max_s \mathrm{Re}\,\alpha_s, \quad S = \{s : \mathrm{Re}\,\alpha_s = \mathrm{Re}\,\alpha\},$$

where $K^0_s$ is the operator whose kernel is $B^+_s(x-y)^{\gamma_s}$ for $x > y$ and $B^-_s(y-x)^{\gamma_s}$ for $x < y$. This is equivalent to saying that

$$\|T^0_n\| \sim \max_{r\in M} |b_r(t_r)|\, \|K_r\|\, n^{2\,\mathrm{Re}\,\alpha},$$

where the kernel of $K_r$ is $C^+_{\alpha_r,\beta_r}(x-y)^{2\,\alpha_r-1}$ for $x > y$ and $C^-_{\alpha_r,\beta_r}(y-x)^{2\,\alpha_r-1}$ for $x < y$. Since $\|T_n(f)\| = o(n^{2\,\mathrm{Re}\,\alpha})$, we obtain that $\|T_n\| \sim \|T^0_n\|$. □

**5. A particular singularity.** We finally embark on the case where

$$a(t) = |t - t_0|^{-2\alpha} b(t) \quad (t \in \mathbf{T})$$

with a real number $\alpha \in (0, 1/2)$ and a function $b \in L^\infty(\mathbf{T})$ that is continuous and nonzero at $t_0$. Theorem 3.3 gives

$$\|T_n(a)\| \sim \Gamma(1-2\alpha)\, \frac{\sin \pi\alpha}{\pi}\, \|K_\alpha\|\, |b(t_0)|\, n^{2\alpha},$$

where the kernel of $K_\alpha$ is $|x-y|^{2\alpha-1}$.

PROPOSITION 5.1.

$$\frac{1}{2\alpha}\left(\frac{2}{4\alpha+1}+2\,\frac{\Gamma(2\alpha+1)\Gamma(2\alpha+1)}{\Gamma(4\alpha+2)}\right)^{1/2}\le\|K_\alpha\|\le\frac{1}{\alpha}.$$

We may think of $K_\alpha$ as the compression to $L^2(0,1)$ of the convolution operator on $L^2(\mathbf{R})$ whose convolution kernel $\kappa(x)$ is $|x|^{2\alpha-1}$ for $|x|<1$ and 0 for $|x|>1$. As in the proof of Lemma 2.3 we therefore see that

$$\|K_\alpha\|\le\max_{\xi\in\mathbf{R}}|(F\kappa)(\xi)|\le\int_{\mathbf{R}}|\kappa(x)|\,dx=\int_{-1}^{1}|x|^{2\alpha-1}\,dx=\frac{1}{\alpha}.$$

Let $\mathbf{1}$ be the function which is identically 1 on $(0,1)$. Taking into account that

$$\|K_\alpha\|^2\ge\|K_\alpha\mathbf{1}\|^2/\|\mathbf{1}\|^2=\|K_\alpha\mathbf{1}\|^2\quad\text{and}\quad(K_\alpha\mathbf{1})(x)=\frac{1}{2\alpha}\,(x^{2\alpha}+(1-x)^{2\alpha}),$$

we obtain that $\|K_\alpha\|^2$ is greater than or equal to

$$\frac{1}{4\alpha^2}\int_0^1(x^{2\alpha}+(1-x)^{2\alpha})^2\,dx=\frac{1}{4\alpha^2}\left(\frac{2}{4\alpha+1}+2\,\frac{\Gamma(2\alpha+1)\Gamma(2\alpha+1)}{\Gamma(4\alpha+2)}\right).$$

This proves the lower bound for $\|K_\alpha\|$. □

COROLLARY 5.2. $\|K_\alpha\|\sim 1/\alpha$ $\alpha\to 0$ $\|K_\alpha\|\sim 1$ $\alpha\to 1/2$

By Proposition 5.1, $\alpha^2\,\|K_\alpha\|^2\le 1$ and

$$\liminf_{\alpha\to 0}\alpha^2\,\|K_\alpha\|^2\ge\frac{1}{4}\left(2+2\,\frac{\Gamma(1)\Gamma(1)}{\Gamma(2)}\right)=1,$$

which implies that $\alpha\,\|K_\alpha\|\to 1$ as $\alpha\to 0$. Thinking of $K_\alpha-K_{1/2}$ as the convolution operator with the convolution kernel $|x|^{2\alpha-1}-1$ for $|x|<1$ and 0 for $|x|>1$, we get

$$\|K_\alpha-K_{1/2}\|\le\int_{-1}^{1}(|x|^{2\alpha-1}-1)\,dx=\frac{1}{\alpha}-2=o(1)\ \text{ as }\ \alpha\to\frac{1}{2}.$$

Thus, $\|K_\alpha\|\to\|K_{1/2}\|$ as $\alpha\to 1/2$. Since $(K_{1/2}f)(x)=\int_0^1 f(y)\,dy$, it is easily seen that $\|K_{1/2}\|=1$. □

COROLLARY 5.3.

$$\begin{aligned}\Gamma(1-2\alpha)\,\frac{\sin\pi\alpha}{\pi}\,\|K_\alpha\|&\sim 1\qquad \alpha\to 0,\\ \Gamma(1-2\alpha)\,\frac{\sin\pi\alpha}{\pi}\,\|K_\alpha\|&\sim\frac{1}{2\pi(1/2-\alpha)}\qquad \alpha\to\frac{1}{2}.\end{aligned}$$

The asymptotics for $\alpha\to 0$ are immediate from Corollary 5.2. For $\alpha$ going to $1/2$, Corollary 5.2 and the formulas

$$\Gamma(1-2\alpha)\,\frac{\sin\pi\alpha}{\pi}\sim\frac{\Gamma(1-2\alpha)}{\pi}=\frac{1}{\sin 2\pi\alpha}\,\frac{1}{\Gamma(2\alpha)}\sim\frac{1}{2\pi(1/2-\alpha)}$$

yield the asserted asymptotics. □

**Acknowledgments.** The authors thank Fanny Godet and Bernhard Beckermann for drawing their attention to the problem considered in this paper. They are also greatly indebted to Torsten Ehrhardt for many valuable remarks. Jani Virtanen thanks the Department of Mathematics for its hospitality during his visit to TU Chemnitz in Spring 2006.

# CONSTRAINT-STYLE PRECONDITIONERS FOR REGULARIZED SADDLE POINT PROBLEMS*

H. S. DOLLAR[†]

**Abstract.** The problem of finding good preconditioners for the numerical solution of an important class of indefinite linear systems is considered. These systems are of a regularized saddle point structure $\left[\begin{smallmatrix} A & B^T \\ B & -C \end{smallmatrix}\right]\left[\begin{smallmatrix} x \\ y \end{smallmatrix}\right] = \left[\begin{smallmatrix} c \\ d \end{smallmatrix}\right]$, where $A \in \mathbb{R}^{n\times n}$, $C \in \mathbb{R}^{m\times m}$ are symmetric and $B \in \mathbb{R}^{m\times n}$. In [*SIAM J. Matrix Anal. Appl.*, 21 (2000), pp. 1300–1317], Keller, Gould, and Wathen analyze the idea of using constraint preconditioners that have a specific 2 by 2 block structure for the case of $C$ being zero. We shall extend this idea by allowing the (2, 2) block to be symmetric and positive semidefinite. Results concerning the spectrum and form of the eigenvectors are presented, as are numerical results to validate our conclusions.

## 1. Introduction.

Recently, a large amount of work has been devoted to the problem of solving large linear systems in saddle point form. Such systems arise in a wide variety of technical and scientific applications. For example, interior point methods in both linear and nonlinear optimization require the solution of a sequence of systems in saddle point form [27]. Another popular field, which is a major source of saddle point problems, is that of mixed finite element methods in engineering fields; see [9] and [19, Chapters 7 and 9]. An excellent survey of numerical methods for algebraic saddle point problems has been written by Benzi, Golub, and Liesen [4].

We wish to find the solution of block $2 \times 2$ linear systems of the form

$$\underbrace{\begin{bmatrix} A & B^T \\ B & -C \end{bmatrix}}_{\mathcal{A}} \begin{bmatrix} x \\ y \end{bmatrix} = \underbrace{\begin{bmatrix} c \\ d \end{bmatrix}}_{b}, \tag{1.1}$$

where $A \in \mathbb{R}^{n\times n}$, $C \in \mathbb{R}^{m\times m}$ are symmetric and $B \in \mathbb{R}^{m\times n}$. We shall assume that $m \leq n$ and $\ker(C) \cap \ker(B^T) = \{0\}$, thus ensuring that $\mathcal{A}$ is nonsingular [4, Theorem 3.1]. If $A$ and $C$ are positive definite, then the matrix $\mathcal{A}$ is a permuted quasi-definite matrix [26]. Vanderbei has shown that quasi-definite matrices are strongly factorizable; i.e., a Cholesky-like factorization $LDL^T$ exists for any symmetric row and column permutation of the quasi-definite matrix [26]. The diagonal matrix has $n$ positive and $m$ negative pivots. However, we shall not confine ourselves to quasi-definite matrices.

It may be attractive to use iterative methods to solve systems such as (1.1), particularly for large $m$ and $n$. In particular, Krylov subspace methods might be used. It is often advantageous to use a preconditioner, $\mathcal{P}$, with such iterative methods. The preconditioner should reduce the number of iterations required for convergence but

[†] Computational Science and Engineering Department, Rutherford Appleton Laboratory, Chilton, Oxon OX11 0QX, UK (S.Dollar@rl.ac.uk).

not significantly increase the amount of computation required at each iteration [25, Chapter 13].

In section 2, we shall first review the well-known spectral properties of a technique commonly known as constraint preconditioning when $C = 0$ [14, 16]. For the case of $C = 0$, a constraint preconditioner exactly reproduces the (constraint) blocks $B$, $B^T$ and the $C = 0$ block. It is restrictive to assume that the matrix $C$ in the saddle point systems is always a zero matrix: a number of situations arise in which $C \neq 0$ [1, 15, 23]. In all these cases, $C$ is positive semidefinite, and hence we shall consider the idea of extending constraint preconditioners to the case of $C$ being positive semidefinite. In particular, the preconditioner will exactly reproduce the $B$, $B^T$ and $C$ blocks, while the $A$ block will be replaced by a symmetric block, which we refer to as $G$; this is considered in sections 3 and 4. Such a preconditioner has been considered before; for example, Perugia and Simoncini consider the case of $G$ being diagonal and positive definite [18], while $G$ is assumed to be nonsingular in [22] and positive definite in [3, 8, 24], but we show that these assumptions can be relaxed. In the past couple of years, the use of implicit factorization preconditioners has been proposed [7] with the aim of reducing the cost (both in CPU time and memory usage) of applying a preconditioner of the form suggested in this paper. However, such implicit factorization preconditioners will frequently generate a matrix $G$ which is symmetric and singular or indefinite, and thus the analysis of these preconditioners with such a $G$ is necessary.

**2. Constraint preconditioners.** Let us initially assume that $C = 0$. Lukšan and Vlček [17] and Keller, Gould, and Wathen [14] investigated the spectral properties of the resulting preconditioned system when we use a preconditioner of the form

$$\mathcal{P} = \begin{bmatrix} G & B^T \\ B & 0 \end{bmatrix}, \tag{2.1}$$

where $G$ is symmetric and approximates but (in general) is not the same as $A$. In [17], $G$ is additionally assumed to be positive definite. They were able to prove various results about the eigenvalues and eigenvectors for the preconditioned systems $\mathcal{P}^{-1}\mathcal{A}$, where $\mathcal{A}$ and $\mathcal{P}$ are defined in (1.1) and (2.1), respectively. $\mathcal{P}$ is called a [illegible]. The proof of the following theorem can be found in [14].

THEOREM 2.1. [illegible] $\mathcal{A} \in \mathbb{R}^{(n+m)\times(n+m)}$ [illegible]

$$\mathcal{A} = \begin{bmatrix} A & B^T \\ B & 0 \end{bmatrix},$$

[illegible] $A \in \mathbb{R}^{n\times n}$ [illegible] $B \in \mathbb{R}^{m\times n}$ [illegible] $Z$ [illegible] $n \times (n-m)$ [illegible] $B$ [illegible] $\mathcal{A}$ [illegible]

$$\mathcal{P} = \begin{bmatrix} G & B^T \\ B & 0 \end{bmatrix},$$

[illegible] $G \in \mathbb{R}^{n\times n}$ [illegible] $B \in \mathbb{R}^{m\times n}$ [illegible] $\mathcal{P}^{-1}\mathcal{A}$ [illegible]

- [illegible] $1$ [illegible] $2m$
- $n - m$ [illegible] $\lambda$ [illegible] $Z^TAZx_z = \lambda Z^TGZx_z$.

If either $Z^TAZ$ or $Z^TGZ$ is positive definite, then the indefinite preconditioner $\mathcal{P}$ applied to the indefinite saddle point matrix $\mathcal{A}$ with $C = 0$ yields a preconditioned matrix $\mathcal{P}^{-1}\mathcal{A}$ which has real eigenvalues [14]. If both $Z^TAZ$ and $Z^TGZ$ are positive definite, then we can use a projected preconditioned conjugate gradient method to find $x$ and $y$; see [12]. Results about the associated eigenvectors and the Krylov subspace dimension can also be found in [14].

## 3. Constraint preconditioners for the case of symmetric and positive definite *C*.

In this section, we shall assume that the matrix $C$ is symmetric and positive definite. The term [illegible] was used in [10] and [14] because the (1, 2) and (2, 1) matrix blocks of the preconditioner are exact representations of those in $\mathcal{A}$, where these blocks represent constraints. However, we also observe that the (2, 2) matrix block is an exact representation when $C = 0$. This motivates the generalization of the constraint preconditioner to take the form

$$\mathcal{P} = \begin{bmatrix} G & B^T \\ B & -C \end{bmatrix}, \tag{3.1}$$

where $G \in \mathbb{R}^{n\times n}$ approximates but is, in general, not the same as $A$.

We shall use the following assumptions in the theorems of this section.

A1 $C \in \mathbb{R}^{m\times m}$ is symmetric and positive definite.
A2 $A \in \mathbb{R}^{n\times n}$ is symmetric.
A3 $B \in \mathbb{R}^{m\times n}$ $(m < n)$.
A4 $G \in \mathbb{R}^{n\times n}$ is symmetric.
A5 $\mathcal{A} \in \mathbb{R}^{(n+m)\times(n+m)}$ is as defined in (1.1).
A6 $\mathcal{P} \in \mathbb{R}^{(n+m)\times(n+m)}$ is as defined in (3.1).

In the next section, A1 will be relaxed.

THEOREM 3.1. [illegible] A1–A6 [illegible] $\mathcal{P}^{-1}\mathcal{A}$ [illegible]

- [illegible] 1 [illegible] $m$,
- $n$ [illegible]

$$\left(A + B^TC^{-1}B\right)x = \lambda\left(G + B^TC^{-1}B\right)x.$$

[illegible]. The eigenvalues of the preconditioned coefficient matrix $\mathcal{P}^{-1}\mathcal{A}$ may be derived by considering the generalized eigenvalue problem

$$\begin{bmatrix} A & B^T \\ B & -C \end{bmatrix}\begin{bmatrix} x \\ y \end{bmatrix} = \lambda \begin{bmatrix} G & B^T \\ B & -C \end{bmatrix}\begin{bmatrix} x \\ y \end{bmatrix}. \tag{3.2}$$

Expanding this out, we obtain

$$Ax + B^Ty = \lambda Gx + \lambda B^Ty \tag{3.3}$$

and

$$Bx - Cy = \lambda Bx - \lambda Cy. \tag{3.4}$$

Equation (3.4) implies that either $\lambda = 1$ or $Bx - Cy = 0$. If the former holds, then (3.3) becomes

$$Ax = Gx. \tag{3.5}$$

Equation (3.5) is trivially satisfied by $x = 0$, and hence there are $m$ linearly independent eigenvectors of the form $\begin{bmatrix} 0^T & y^T \end{bmatrix}$ associated with the unit eigenvalue. If there exist any $x \neq 0$ which satisfy (3.5), then there will be $i$ $(0 \leq i \leq n)$ linearly independent eigenvectors of the form $\begin{bmatrix} x^T & y^T \end{bmatrix}$, where the components $x$ arise from the generalized eigenvalue problem $Ax = Gx$.

If $\lambda \neq 1$, then (3.4) implies that

$$y = C^{-1}Bx.$$

Substituting this into (3.3) yields the generalized eigenvalue problem

$$\left(A + B^TC^{-1}B\right)x = \lambda\left(G + B^TC^{-1}B\right)x. \tag{3.6}$$

Thus, the nonunit eigenvalues of $\mathcal{P}^{-1}\mathcal{A}$ are defined as the nonunit eigenvalues of (3.6). Noting that if (3.6) has any unit eigenvalues, then the values of $x(\neq 0)$ which satisfy this are exactly those which arise from the generalized eigenvalue problem $Ax = Gx$, we complete our proof. □

Theorem 3.1 generalizes the results of [8, Theorem 1] by removing the assumption that $G$ is positive definite. If $A + B^TC^{-1}B$ or $G + B^TC^{-1}B$ is positive definite, then the preconditioned system has real eigenvalues. If both $A + B^TC^{-1}B$ and $G + B^TC^{-1}B$ are positive definite, then we can apply a projected preconditioned conjugate gradient method to find $x$ and $y$ [7, 11]. We also observe that if $C$ has a small 2-norm, $\|A\|_2 = \mathcal{O}(1)$ and $\|G\|_2 = \mathcal{O}(1)$, then the $B^TC^{-1}B$ terms will dominate the generalized eigenvalue problem (3.6) for $Bx \neq 0$, and hence there will be at least $m$ further eigenvalues clustered about 1 for $\|C\|_2 \ll 1$. This additional clustering of part of the spectrum of $\mathcal{P}^{-1}\mathcal{A}$ will often translate into a speeding up of the convergence of a selected Krylov subspace method [2, section 1.3].

THEOREM 3.2. [illegible] A1–A6 [illegible] $G + B^TC^{-1}B$ [illegible] $\mathcal{P}^{-1}\mathcal{A}$ [illegible] $n+m$ [illegible] 3.1 [illegible] $m+i+j$ [illegible]

- $m$ [illegible] $\begin{bmatrix} 0^T & y^T \end{bmatrix}$ [illegible] $\lambda = 1$,
- $i$ $(0 \leq i \leq n)$ [illegible] $\begin{bmatrix} x^T & y^T \end{bmatrix}$ [illegible] $Ax = Gx$ [illegible] $i$ [illegible] $x$ [illegible] $\lambda = 1$,
- $j$ $(0 \leq j \leq n)$ [illegible] $\begin{bmatrix} x^T & y^T \end{bmatrix}$ [illegible] $\lambda \neq 1$.

[illegible]. The form of the eigenvectors follows directly from the proof of Theorem 3.1. It remains for us to show that the $m + i + j$ eigenvectors are linearly independent; that is, we need to show that

$$\begin{bmatrix} 0 & \cdots & 0 \\ y_1^{(1)} & \cdots & y_m^{(1)} \end{bmatrix} \begin{bmatrix} a_1^{(1)} \\ \vdots \\ a_m^{(1)} \end{bmatrix} + \begin{bmatrix} x_1^{(2)} & \cdots & x_i^{(2)} \\ y_1^{(2)} & \cdots & y_i^{(2)} \end{bmatrix} \begin{bmatrix} a_1^{(2)} \\ \vdots \\ a_i^{(2)} \end{bmatrix}$$
$$+ \begin{bmatrix} x_1^{(3)} & \cdots & x_j^{(3)} \\ y_1^{(3)} & \cdots & y_j^{(3)} \end{bmatrix} \begin{bmatrix} a_1^{(3)} \\ \vdots \\ a_j^{(3)} \end{bmatrix} = \begin{bmatrix} 0 \\ \vdots \\ 0 \end{bmatrix} \tag{3.7}$$

implies that the vectors $a^{(k)}$ $(k = 1, 2, 3)$ are zero vectors. Multiplying (3.7) by $\mathcal{P}^{-1}\mathcal{A}$, and recalling that in (3.7) the first matrix arises from the case $\lambda_k = 1$ $(k = 1, \ldots, m)$, the second matrix from the case $\lambda_k = 1$ $(k = 1, \ldots, i)$, and the last matrix from $\lambda_k \neq 1$ $(k = 1, \ldots, j)$, gives

$$\begin{bmatrix} 0 & \cdots & 0 \\ y_1^{(1)} & \cdots & y_m^{(1)} \end{bmatrix} \begin{bmatrix} a_1^{(1)} \\ \vdots \\ a_m^{(1)} \end{bmatrix} + \begin{bmatrix} x_1^{(2)} & \cdots & x_i^{(2)} \\ y_1^{(2)} & \cdots & y_i^{(2)} \end{bmatrix} \begin{bmatrix} a_1^{(2)} \\ \vdots \\ a_i^{(2)} \end{bmatrix}$$

$$+ \begin{bmatrix} x_1^{(3)} & \cdots & x_j^{(3)} \\ y_1^{(3)} & \cdots & y_j^{(3)} \end{bmatrix} \begin{bmatrix} \lambda_1 a_1^{(3)} \\ \vdots \\ \lambda_j a_j^{(3)} \end{bmatrix} = \begin{bmatrix} 0 \\ \vdots \\ 0 \end{bmatrix}. \tag{3.8}$$

Subtracting (3.7) from (3.8), we obtain

$$\begin{bmatrix} x_1^{(3)} & \cdots & x_j^{(3)} \\ y_1^{(3)} & \cdots & y_j^{(3)} \end{bmatrix} \begin{bmatrix} (\lambda_1 - 1) a_1^{(3)} \\ \vdots \\ (\lambda_j - 1) a_j^{(3)} \end{bmatrix} = \begin{bmatrix} 0 \\ \vdots \\ 0 \end{bmatrix}.$$

The assumption that $G + B^T C^{-1} B$ is positive definite implies that $x_k^{(3)}$ $(k = 1, \ldots, j)$ are linearly independent and thus that $(\lambda_k - 1) a_1^{(3)} = 0$ $(k = 1, \ldots, j)$. The eigenvalues $\lambda_k$ $(k = 1, \ldots, j)$ are nonunit, which implies that $a_k^{(3)} = 0$ $(k = 1, \ldots, j)$. We also have linear independence of $x_k^{(2)}$ $(k = 1, \ldots, i)$, and thus $a_k^{(2)} = 0$ $(k = 1, \ldots, i)$. Equation (3.7) simplifies to

$$\begin{bmatrix} 0 & \cdots & 0 \\ y_1^{(1)} & \cdots & y_m^{(1)} \end{bmatrix} \begin{bmatrix} a_1^{(1)} \\ \vdots \\ a_m^{(1)} \end{bmatrix} = \begin{bmatrix} 0 \\ \vdots \\ 0 \end{bmatrix}.$$

However, $y_k^{(1)}$ $(k = 1, \ldots, m)$ are linearly independent, and thus $a_k^{(1)} = 0$ $(k = 1, \ldots, m)$. □

Krylov subspace theory states that iteration with any method with an optimality property, e.g., GMRES [21], will terminate when the degree of the minimal polynomial is attained. This is also true of some other (nonoptimal) practical iteration methods such as BiCGTAB as long as failure (for example, through irregular convergence [25, Chapter 8]) does not occur. In particular, the degree of the minimal polynomial is equal to the dimension of the corresponding Krylov subspace $\mathcal{K}\left(\mathcal{P}^{-1}\mathcal{A}, b\right)$ (for general $b$) [20, Proposition 6.1], where

$$\mathcal{K}\left(\mathcal{P}^{-1}\mathcal{A}, b\right) = \operatorname{span}\{b, \mathcal{P}^{-1}\mathcal{A}b, (\mathcal{P}^{-1}\mathcal{A})^2 b, \ldots, (\mathcal{P}^{-1}\mathcal{A})^{n+m-1} b\}.$$

THEOREM 3.3. [illegible] A1–A6 [illegible] $G + B^T C^{-1} B$ [illegible] $\mathcal{K}\left(\mathcal{P}^{-1}\mathcal{A}, b\right)$ [illegible] $\min\{n+2, n+m\}$.

[illegible] As in the proof of Theorem 3.1, the generalized eigenvalue problem is

$$\begin{bmatrix} A & B^T \\ B & -C \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} = \lambda \begin{bmatrix} G & B^T \\ B & -C \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix}. \tag{3.9}$$

Suppose that the preconditioned matrix $\mathcal{P}^{-1}\mathcal{A}$ takes the form

$$\mathcal{P}^{-1}\mathcal{A} = \begin{bmatrix} \Theta_1 & \Theta_3 \\ \Theta_2 & \Theta_4 \end{bmatrix}, \tag{3.10}$$

where $\Theta_1 \in \mathbb{R}^{n\times n}$, $\Theta_2 \in \mathbb{R}^{m\times n}$, $\Theta_3 \in \mathbb{R}^{n\times m}$, and $\Theta_4 \in \mathbb{R}^{m\times m}$. It is straightforward to show that $\Theta_3 = 0$ and $\Theta_4 = I$. The precise forms of $\Theta_1$ and $\Theta_2$ are irrelevant for the argument that follows.

From the earlier eigenvalue derivation, it is evident that the characteristic polynomial of the preconditioned linear system (3.10) is

$$\left(\mathcal{P}^{-1}\mathcal{A} - I\right)^m \prod_{i=1}^{n} \left(\mathcal{P}^{-1}\mathcal{A} - \lambda_i I\right).$$

In order to prove the upper bound on the Krylov subspace dimension, we need to show that the order of the minimal polynomial is less than or equal to $\min\{n+2, n+m\}$. Expanding the polynomial $\left(\mathcal{P}^{-1}\mathcal{A} - I\right) \prod_{i=1}^{n} \left(\mathcal{P}^{-1}\mathcal{A} - \lambda_i I\right)$ of degree $n+1$, we obtain

$$\left[\begin{array}{cc} (\Theta_1 - I)\prod_{i=1}^{n}(\Theta_1 - \lambda_i I) & 0 \\ \Theta_2 \prod_{i=1}^{n}(\Theta_1 - \lambda_i I) & 0 \end{array}\right].$$

Since $\Theta_1$ has a full set of linearly independent eigenvectors, $\Theta_1$ is diagonalizable. Hence,

$$(\Theta_1 - I)\prod_{i=1}^{n}(\Theta_1 - \lambda_i I) = 0.$$

We therefore obtain

$$\left(\mathcal{P}^{-1}\mathcal{A} - I\right) \prod_{i=1}^{n} \left(\mathcal{P}^{-1}\mathcal{A} - \lambda_i I\right) = \left[\begin{array}{cc} 0 & 0 \\ \Theta_2 \prod_{i=1}^{n}(\Theta_1 - \lambda_i I) & 0 \end{array}\right]. \tag{3.11}$$

If $\Theta_2 \prod_{i=1}^{n}(\Theta_1 - \lambda_i I) = 0$, then the order of the minimal polynomial of $\mathcal{P}^{-1}\mathcal{A}$ is less than or equal to $\min\{n+1, n+m\}$. If $\Theta_2 \prod_{i=1}^{n}(\Theta_1 - \lambda_i I) \neq 0$, then the dimension of $\mathcal{K}\left(\mathcal{P}^{-1}\mathcal{A}, b\right)$ is at most $\min\{n+2, n+m\}$ since multiplication of (3.11) by another factor $\left(\mathcal{P}^{-1}\mathcal{A} - I\right)$ gives the zero matrix. ☐

Theorem 3.3 tells us that with preconditioner

$$\mathcal{P} = \left[\begin{array}{cc} G & B^T \\ B & -C \end{array}\right]$$

for

$$\mathcal{A} = \left[\begin{array}{cc} A & B^T \\ B & -C \end{array}\right]$$

the dimension of the Krylov subspace is no greater than $\min\{n+2, n+m\}$ under appropriate assumptions. Hence, termination (in exact arithmetic) is guaranteed in a number of iterations smaller than this.

**4. Constraint preconditioners for the case of symmetric and positive semi-definite *C*.** We shall relax assumption A1 and instead make the following assumptions in the theorems of this section:

B1 $C \in \mathbb{R}^{m\times m}$ is symmetric and positive semidefinite, and has rank $p$, where $0 < p < m$.

B2 $\ker(C) \cap \ker(B^T) = \{0\}$.

- B3 $C$ is factored as $C = EDE^T$, where $E \in \mathbb{R}^{m\times p}$, and $D \in \mathbb{R}^{p\times p}$ is symmetric and positive definite.
- B4 The matrix $F \in \mathbb{R}^{m\times(m-p)}$ is such that its columns span the nullspace of $C$.
- B5 $\begin{bmatrix} E & F \end{bmatrix} \in \mathbb{R}^{m\times m}$ is orthogonal.
- B6 The columns of $N \in \mathbb{R}^{n\times(n-m+p)}$ span the nullspace of $F^TB$.

Observe that assumption B2 implies that $F^TB$ has full rank $m-p$ : if $Cx = 0$, then we can write $x = Fy$ for some vector $y \in \mathbb{R}^{m-p}$. If also $B^Tx = 0$, then substituting into $x = Fy$ we obtain $B^TFy = 0$. Assumption B2 implies that $B^TFy = 0$ if and only if $y = 0$, and hence $F^TB$ has full rank $m-p$.

The exact form of the factorization of $C$ in B3 is clearly not relevant and, also, clearly not unique—a spectral decomposition is a possibility.

THEOREM 4.1. [illegible] A2–A6 [illegible] B1–B6 [illegible] $\mathcal{P}^{-1}\mathcal{A}$ [illegible]

- [illegible] 1 [illegible] $2m-p$,
- $n-m+p$ [illegible]

$$N^T\left(A + B^TED^{-1}E^TB\right)Nz = \lambda N^T\left(G + B^TED^{-1}E^TB\right)Nz.$$

[illegible]

[illegible]. Any $y \in \mathbb{R}^m$ can be written as $y = Ey_e + Fy_f$. Substituting this into the generalized eigenvalue problem (3.2) and premultiplying by

$$\begin{bmatrix} I & 0 \\ 0 & E^T \\ 0 & F^T \end{bmatrix},$$

we obtain

$$\left[\begin{array}{cc|c} A & B^TE & B^TF \\ E^TB & -D & 0 \\ \hline F^TB & 0 & 0 \end{array}\right]\begin{bmatrix} x \\ y_e \\ y_f \end{bmatrix} = \lambda\left[\begin{array}{cc|c} G & B^TE & B^TF \\ E^TB & -D & 0 \\ \hline F^TB & 0 & 0 \end{array}\right]\begin{bmatrix} x \\ y_e \\ y_f \end{bmatrix}. \tag{4.1}$$

Noting that the (3, 3) block has dimension $(m-p)\times(m-p)$ and is a zero matrix in both coefficient matrices, we can apply Theorem 2.1 from [14] to obtain that $\mathcal{P}^{-1}\mathcal{A}$ has

- an eigenvalue at 1 with multiplicity $2(m-p)$,
- $n-m+2p$ eigenvalues which are defined by the generalized eigenvalue problem

$$\overline{N}^T\begin{bmatrix} A & B^TE \\ E^TB & -D \end{bmatrix}\overline{N}w_n = \lambda\overline{N}^T\begin{bmatrix} G & B^TE \\ E^TB & -D \end{bmatrix}\overline{N}w_n, \tag{4.2}$$

where $\overline{N}$ is an $(n+p)\times(n-m+2p)$ basis for the nullspace of $\begin{bmatrix} F^TB & 0 \end{bmatrix} \in \mathbb{R}^{(m-p)\times(n+p)}$, and

$$\begin{bmatrix} x \\ y_e \end{bmatrix}^T = \overline{N}w_n + \begin{bmatrix} B^TF \\ 0 \end{bmatrix}w_b.$$

Letting $\overline{N} = \left[\begin{smallmatrix} N & 0 \\ 0 & I \end{smallmatrix}\right]$, then (4.2) becomes

$$\begin{bmatrix} N^TAN & N^TB^TE \\ E^TBN & -D \end{bmatrix}\begin{bmatrix} w_{n1} \\ w_{n2} \end{bmatrix} = \lambda\begin{bmatrix} N^TGN & N^TB^TE \\ E^TBN & -D \end{bmatrix}\begin{bmatrix} w_{n1} \\ w_{n2} \end{bmatrix}. \tag{4.3}$$

This generalized eigenvalue problem is exactly that of the form considered in Theorem 3.1, and so (4.3) has an eigenvalue at 1 with multiplicity $p$, and the remaining eigenvalues are defined by the generalized eigenvalue problem

$$N^T\left(A+B^TED^{-1}E^TB\right)Nw_{n1}=\lambda N^T\left(G+B^TED^{-1}E^TB\right)Nw_{n1}. \tag{4.4}$$

Hence, $\mathcal{P}^{-1}\mathcal{A}$ has an eigenvalue at 1 with multiplicity $2m-p$, and the other eigenvalues are defined by the generalized eigenvalue problem (4.4). ☐

Weaker forms of Theorem 4.1 can be found in [3, section 3.7] and [18, Proposition 5] for the case where $G$ is assumed to be symmetric and positive definite (and diagonal in [18]). We have relaxed this assumption to $G$ being symmetric and also increased the lower bound on the number of unit eigenvalues from $m$ to $2m-p$.

As for the cases $C=0$ and $C$ nonsingular, we are able to obtain conditions which guarantee that the eigenvalues are real and for which a projected preconditioned conjugate gradient method could be applied to find $x$ and $y$; respectively, these conditions are

- either $N^T\left(A+B^TED^{-1}E^TB\right)N$ or $N^T\left(G+B^TED^{-1}E^TB\right)N$ is positive definite,
- both $N^T\left(A+B^TED^{-1}E^TB\right)N$ and $N^T\left(G+B^TED^{-1}E^TB\right)N$ are positive definite.

Interestingly, the projected preconditioned conjugate gradient method is also derived by the use of a factorization of $C$ as in assumption B3; transformations are then used to remove the requirement of needing to factorize $C$ [7]. Additionally, in [7] the authors show that it can be easy to establish that $N^T\left(G+B^TED^{-1}E^TB\right)N$ is symmetric and positive definite through the use of implicit factorization constraint preconditioners: we emphasize that $G$ is often singular or indefinite in these cases.

Similarly to the case $p=m$, if $C$ has a small 2-norm, $\|A\|=\mathcal{O}(1)$ and $\|G\|=\mathcal{O}(1)$, then the $N^TB^TED^{-1}E^TBN$ terms will dominate the generalized eigenvalue problem (4.4) for $E^TBNw_{n1}\neq 0$ and hence there will be at least $p$ further eigenvalues clustered about 1 when $\|C\|_2 \ll 1$.

THEOREM 4.2. A2–A6 B1–B6 $G+B^TED^{-1}E^TB$ $\mathcal{P}^{-1}\mathcal{A}$ $n+m$ 3.1 $m+i+j$

- $m$ $\left[\begin{array}{cc} 0^T & y^T \end{array}\right]$ $\lambda=1$,
- $i$ $(0\le i\le n)$ $\left[\begin{array}{cc} x^T & y^T \end{array}\right]$ $Ax=Gx$ $i$ $x$ $\lambda=1$,
- $j$ $(0\le j\le n)$ $\left[\begin{array}{cc} x^T & y^T \end{array}\right]$ $\lambda\neq 1$.

The proof of the form and linear independence of the $m+i+j$ eigenvectors is obtained in a similar manner to the proof of Theorem 3.2. ☐

A weaker form of Theorem 4.2 can be found in [3]: this corresponds to the case of $G$ being symmetric and positive definite.

To show that both the lower and upper bounds on the number of linearly independent eigenvectors can be attained, we need only consider variations on Examples 2.5 and 2.6 from [14].

4.1 (minimum bound). Consider the matrices

$$\mathcal{A}=\begin{bmatrix}1&2&0&1\\2&2&1&0\\0&1&0&0\\1&0&0&-1\end{bmatrix},\quad \mathcal{P}=\begin{bmatrix}1&3&0&1\\3&4&1&0\\0&1&0&0\\1&0&0&-1\end{bmatrix}$$

such that $m = 2$, $n = 2$, $p = 1$, and $G$ is indefinite. The preconditioned matrix $\mathcal{P}^{-1}\mathcal{A}$ has an eigenvalue at 1 with multiplicity 4 but only two linearly independent eigenvectors which arise from the first case of Theorem 4.2. These eigenvectors may be taken to be $\begin{bmatrix} 0 & 0 & 1 & 0 \end{bmatrix}^T$ and $\begin{bmatrix} 0 & 0 & 0 & 1 \end{bmatrix}^T$.

[illegible] 4.2 (maximum bound). Let $\mathcal{A} \in \mathbb{R}^{4\times 4}$ be as defined in Example 4.1, but assume that $G = A$. The preconditioned matrix $\mathcal{P}^{-1}\mathcal{A}$ has an eigenvalue at 1 with multiplicity 4 and clearly a complete set of eigenvectors. These may be taken to be the columns of the identity matrix.

The linear independence of the $m + i + j$ eigenvectors allows us to obtain an upper bound on the dimension of the Krylov subspace $\mathcal{K}\left(\mathcal{P}^{-1}\mathcal{A}, b\right)$.

THEOREM 4.3. [illegible] A2–A6, B1–B6 [illegible] $G + B^TED^{-1}E^TB$ [illegible] $\mathcal{K}\left(\mathcal{P}^{-1}\mathcal{A}, b\right)$ [illegible] $\min\{n - m + p + 2, n + m\}$.

[illegible]. As in the proof of Theorem 3.3, the preconditioned matrix $\mathcal{P}^{-1}\mathcal{A}$ takes the form

$$\mathcal{P}^{-1}\mathcal{A} = \begin{bmatrix} \Theta_1 & 0 \\ \Theta_2 & I \end{bmatrix}, \tag{4.5}$$

where $\Theta_1 \in \mathbb{R}^{n\times n}$, and $\Theta_2 \in \mathbb{R}^{m\times n}$. The precise forms of $\Theta_1$ and $\Theta_2$ are irrelevant for the argument that follows.

From the earlier eigenvalue derivation, it is evident that the characteristic polynomial of the preconditioned linear system (4.5) is

$$\left(\mathcal{P}^{-1}\mathcal{A} - I\right)^{2m-p} \prod_{i=1}^{n-m+p} \left(\mathcal{P}^{-1}\mathcal{A} - \lambda_i I\right).$$

In order to prove the upper bound on the Krylov subspace dimension, we need to show that the order of the minimal polynomial is less than or equal to $\min\{n - m + p + 2, n + m\}$. Expanding the polynomial $\left(\mathcal{P}^{-1}\mathcal{A} - I\right) \prod_{i=1}^{n-m+p} \left(\mathcal{P}^{-1}\mathcal{A} - \lambda_i I\right)$ of degree $n + 1$, we obtain

$$\begin{bmatrix} (\Theta_1 - I) \prod_{i=1}^{n-m+p} (\Theta_1 - \lambda_i I) & 0 \\ \Theta_2 \prod_{i=1}^{n-m+p} (\Theta_1 - \lambda_i I) & 0 \end{bmatrix}.$$

Since $G + B^TED^{-1}E^TB$ is positive definite, $\Theta_1$ has a full set of linearly independent eigenvectors and is diagonalizable. Hence, $(\Theta_1 - I) \prod_{i=1}^{n-m+p} (\Theta_1 - \lambda_i I) = 0$. We therefore obtain

$$\left(\mathcal{P}^{-1}\mathcal{A} - I\right) \prod_{i=1}^{n-m+p} \left(\mathcal{P}^{-1}\mathcal{A} - \lambda_i I\right) = \begin{bmatrix} 0 & 0 \\ \Theta_2 \prod_{i=1}^{n-m+p} (\Theta_1 - \lambda_i I) & 0 \end{bmatrix}. \tag{4.6}$$

If $\Theta_2 \prod_{i=1}^{n-m+p} (\Theta_1 - \lambda_i I) = 0$, then the order of the minimal polynomial of $\mathcal{P}^{-1}\mathcal{A}$ is less than or equal to $\min\{n - m + p + 1, n + m\}$. If $\Theta_2 \prod_{i=1}^{n-m+p} (\Theta_1 - \lambda_i I) = 0$, then the dimension of $\mathcal{K}\left(\mathcal{P}^{-1}\mathcal{A}, b\right)$ is at most $\min\{n-m+p+2, n+m\}$ since multiplication of (4.6) by another factor $\left(\mathcal{P}^{-1}\mathcal{A} - I\right)$ gives the zero matrix. □

Thus, in exact arithmetic, iteration with any method with an optimality condition will terminate in at most $\min\{n - m + p + 2, n + m\}$ iterations (in practice, exact arithmetic is not available, and hence this theoretical bound may be exceeded). We observe that if $p = m$, then Theorem 4.3 gives the same bound on the Krylov subspace dimension as that in Theorem 3.3, and if $p = 0$, then we obtain the results of [14].

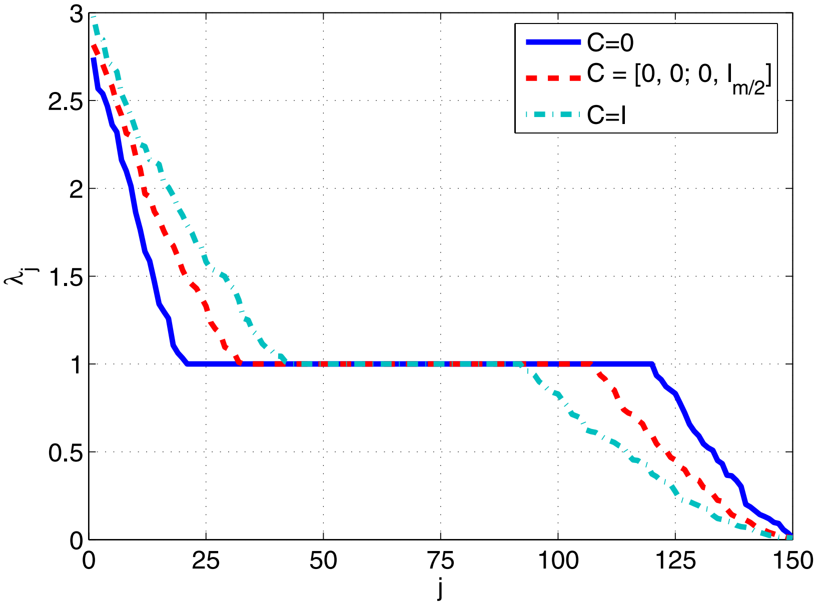

FIG. 5.1. *Distribution of the eigenvalues of* $\mathcal{P}^{-1}\mathcal{A}$ *for the CVXQP1_S problem* $(m = 50, n = 100)$ *with* $C = 0$, $C = [0, 0; 0, I_{m/2}]$, *and* $C = I$. *The eigenvalues are sorted such that* $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_{n+m}$.

## 5. Numerical results.

The CUTEr test set [13] provides a set of quadratic programming problems. We shall use a problem from this set to illustrate how changing the rank of $C$ affects the multiplicity of the unit eigenvalues and the termination of GMRES. All tests were performed in MATLAB 7.01.

The CVXQP1_S problem from the CUTEr test set is small with $n = 100$ and $m = 50$. It is a convex quadratic program whose constraints are linear; it is a purely academic problem which has been constructed specifically for test problems. “Barrier” penalty terms (in this case 1.1) are added to the diagonal of $A$ to simulate systems that might arise during an iteration of an interior point method for such problems. We shall set $G = \mathrm{diag}(A)$, $C = \mathrm{diag}(0, \ldots, 0, 1, \ldots, 1)$ and vary the number of zeros on the diagonal of $C$ so as to change its rank.

In Figure 5.1, we illustrate the change in the eigenvalues of the preconditioned system $\mathcal{P}^{-1}\mathcal{A}$ for three different choices of $C$. The eigenvalues are sorted so that

$$\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_{n+m}.$$

When $C = 0$, we expect there to be at least $2m$ unit eigenvalues [14]. We observe that our example has exactly $2m$ eigenvalues at 1. From Theorem 3.1, when $C = I$, there will be at least $m$ unit eigenvalues. Our example has exactly $m$ unit eigenvalues (Figure 5.1).

When $C$ has rank $\frac{m}{2}$, then the preconditioned system $\mathcal{P}^{-1}\mathcal{A}$ has at least $\frac{3m}{2}$ unit eigenvalues according to Theorem 4.1. Once again, the number of unit eigenvalues for our example is exactly the lower bound given by the theorem.

Now suppose that we use (full) GMRES preconditioned by our extended constraint preconditioner with $G = \mathrm{diag}(A)$ and vary the rank of $C$ by changing the

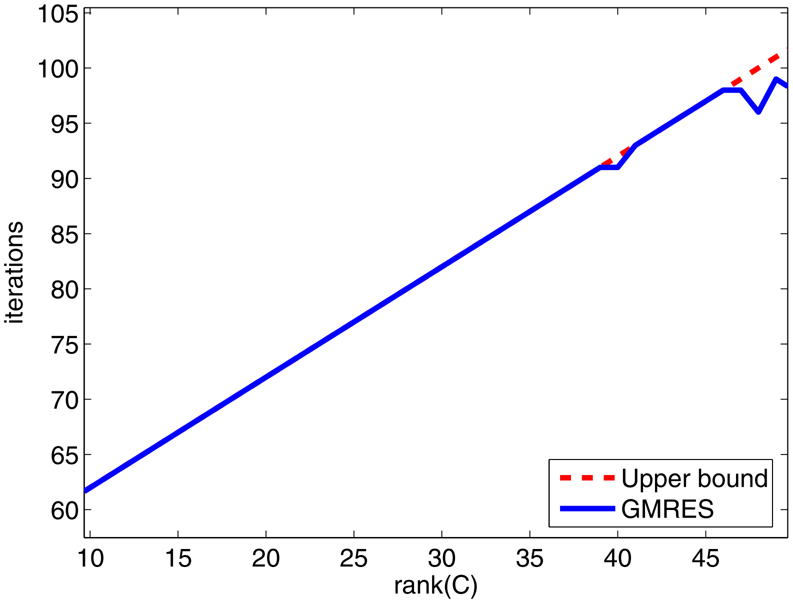

Fig. 5.2. *Comparison of upper bound on the Krylov subspace dimension and the number of iterations required to reduce the residual by* $10^{-12}$.

number of 1's along the diagonal of $C$ (all other entries are zero). Figure 5.2 shows that with this example and choice of $G$ there is a strong correlation between the upper bound on the Krylov subspace dimension and the number of iterations required to reduce the residual by at least a factor of $10^{-12}$. This has been chosen as an extreme example, and the number of iterations is often a lot lower than the upper bound on the Krylov subspace dimension. A comprehensive comparison (taking into account both CPU times and the number of iterations) for these preconditioners can be found in [7]: this study reveals the possible advantages of choosing $G$ to be singular or indefinite.

**6. Conclusions.** In this paper, we investigated a class of preconditioners for regularized saddle point matrix systems that incorporate the (1, 2), (2, 1), and (2, 2) blocks of the original matrix. We showed that the inclusion of these blocks in the preconditioner clusters at least $2m-p$ eigenvalues at 1, regardless of the structure of $G$. However, the standard convergence theory for Krylov subspace methods is not readily applicable because, in general, $\mathcal{P}^{-1}\mathcal{A}$ does not have a complete set of linearly independent eigenvectors. Using a minimal polynomial argument, we found a general (sharp) upper bound on the number of iterations required to solve linear systems of the form (1.1).

To confirm the analytical results of this paper, we used a subset of problems from the CUTEr test set. We used the CVXQP1_S problem and varied the rank of $C$ to confirm the lower bound on the number of unit eigenvalues and the upper bound on the Krylov subspace dimension.

We have assumed that the submatrices $B$, $B^T$ and $-C$ in (1.1) are exactly reproduced in the preconditioner. For truly large-scale problems, this will be unrealistic

[5, 6, 18], but the theorems in this paper may still be of some interest in the inexact setting as a guide for choosing preconditioners. We wish to investigate this possibility in our future work.

**Acknowledgments.** The author would like to thank Nick Gould, Wil Schilders, Andy Wathen, and the referees for their helpful input during the process of the work.

# THE A PRIORI TAN Θ THEOREM FOR EIGENVECTORS*

SERGIO ALBEVERIO[†], ALEXANDER K. MOTOVILOV[‡], AND ALEXEI V. SELIN[§]

**Abstract.** Let $A$ be a self-adjoint operator on a Hilbert space $\mathfrak{H}$. Assume that the spectrum of $A$ consists of two disjoint components $\sigma_0$ and $\sigma_1$ such that the convex hull of the set $\sigma_0$ does not intersect the set $\sigma_1$. Let $V$ be a bounded self-adjoint operator on $\mathfrak{H}$ off-diagonal with respect to the orthogonal decomposition $\mathfrak{H} = \mathfrak{H}_0 \oplus \mathfrak{H}_1$, where $\mathfrak{H}_0$ and $\mathfrak{H}_1$ are the spectral subspaces of $A$ associated with the spectral sets $\sigma_0$ and $\sigma_1$, respectively. It is known that if $\|V\| < \sqrt{2}d$, where $d = \operatorname{dist}(\sigma_0, \sigma_1) > 0$, then the perturbation $V$ does not close the gaps between $\sigma_0$ and $\sigma_1$. Assuming that $f$ is an eigenvector of the perturbed operator $A+V$ associated with its eigenvalue in the interval $(\min(\sigma_0)-d, \max(\sigma_0)+d)$, we prove that under the condition $\|V\| < \sqrt{2}d$ the (acute) angle $\theta$ between $f$ and the orthogonal projection of $f$ onto $\mathfrak{H}_0$ satisfies the bound $\tan\theta \le \frac{\|V\|}{d}$, and this bound is sharp.

## 1. Introduction.

Given a self-adjoint operator $A$ on a Hilbert space $\mathfrak{H}$, assume that $\sigma_0$ is an isolated part of its spectrum, that is,

$$d = \operatorname{dist}(\sigma_0, \sigma_1) > 0, \tag{1.1}$$

where $\sigma_1 = \operatorname{spec}(A) \setminus \sigma_0$ is the rest of the spectrum of $A$. In this case, we say that there are open gaps between the sets $\sigma_0$ and $\sigma_1$. It is well known (see, e.g., [10, section 135]) that a sufficiently small self-adjoint perturbation $V$ of $A$ does not close these gaps, which allows one to think of the corresponding disjoint spectral components $\sigma_0'$ and $\sigma_1'$ of the perturbed operator $L = A + V$ as a result of the perturbation of the spectral sets $\sigma_0$ and $\sigma_1$, respectively.

Assuming (1.1), in this note we are concerned with perturbations $V$ that are off-diagonal with respect to the partition $\operatorname{spec}(A) = \sigma_0 \cup \sigma_1$, i.e., with perturbations that anticommute with the difference $\mathsf{E}_A(\sigma_0) - \mathsf{E}_A(\sigma_1)$ of the spectral projections $\mathsf{E}_A(\sigma_0)$ and $\mathsf{E}_A(\sigma_1)$ associated with the spectral sets $\sigma_0$ and $\sigma_1$, respectively. In general, it is known (see [6, Theorem 1]) that such perturbations do not close the gaps between the sets $\sigma_0$ and $\sigma_1$ (which means that the inequality $\operatorname{dist}(\sigma_0', \sigma_1') > 0$ holds) whenever

$$\|V\| < \frac{\sqrt{3}}{2}d. \tag{1.2}$$

Moreover, if no assumptions are made about the location of $\sigma_0$ and $\sigma_1$ except the assumption (1.1), then condition (1.2) is sharp (see [6, Example 1.5]).

However, there are two important particular mutual positions of the spectral sets $\sigma_0$ and $\sigma_1$ that ensure the disjointness of the perturbed spectral sets $\sigma_0'$ and $\sigma_1'$ under conditions on $\|V\|$ much weaker than the general one of (1.2). The first of these two dispositions is the one where the sets $\sigma_0$ and $\sigma_1$ are subordinated, say

$$\sup \sigma_0 < \inf \sigma_1. \tag{1.3}$$

The second disposition corresponds to the case where one of the sets $\sigma_0$ and $\sigma_1$ is lying in a finite gap of the other set, say $\sigma_0$ lies in a finite gap of $\sigma_1$, which means that

$$\operatorname{conv}(\sigma_0) \cap \sigma_1 = \varnothing, \tag{1.4}$$

where $\operatorname{conv}(\sigma)$ denotes the convex hull of a set $\sigma \subset \mathbb{R}$. (We recall that by a finite gap of a closed Borel set $\Sigma$ on $\mathbb{R}$ one understands an open finite interval belonging to the complement $\mathbb{R} \setminus \Sigma$ of $\Sigma$ and such that both of its end points belong to $\Sigma$.)

It is known that if (1.3) holds, then for any bounded off-diagonal perturbation $V$ the interval $(\sup \sigma_0, \inf \sigma_1)$ belongs to the resolvent set of the perturbed operator $L = A + V$, and hence $\sigma_0' \subset (-\infty, \sup \sigma_0]$ and $\sigma_1' \subset [\inf \sigma_1, +\infty)$ (see [1, 4, 8]; cf. [5]). In the case of the disposition (1.4), it has been proven in [6] (see also [5]) that the gaps between $\sigma_0$ and $\sigma_1$ remain open if the off-diagonal perturbation $V$ satisfies the (sharp) condition

$$\|V\| < \sqrt{2}d.$$

Under this condition, the spectrum of $L = A + V$ consists of two disjoint components $\sigma_0'$ and $\sigma_1'$ such that

$$\sigma_0' \subset (\inf\, \sigma_0 - d, \sup\, \sigma_0 + d) \quad \text{and} \quad \sigma_1' \subset \mathbb{R} \setminus \Delta,$$

where $\Delta$ denotes the gap of $\sigma_1$ that contains $\sigma_0$. Notice that the norm bound $\|V\| < \sqrt{2}d$ is also sharp in the sense that, if it is violated, the spectrum of $L$ in the gap $\Delta$ may be empty at all (see [6, Example 1.6]).

Now assume that the perturbed spectral set $\sigma_0'$ contains an eigenvalue of the operator $L = A + V$ and let $f$, $f \neq 0$, be an eigenvector of $L$ corresponding to this eigenvalue. Denote by $\theta$ the (acute) angle between the vector $f$ and its projection $f_0 = \mathsf{E}_A(\sigma_0) f$ onto the spectral subspace $\mathfrak{H}_0 = \operatorname{Ran} \mathsf{E}_A(\sigma_0)$ of $A$ associated with the unperturbed spectral set $\sigma_0$.

Under the subordination condition (1.3), for any bounded off-diagonal perturbation $V$ the angle $\theta$ cannot exceed $\pi/4$. Moreover, the following sharp estimate holds:

$$\theta \leq \frac{1}{2} \arctan\left(\frac{2\|V\|}{d}\right) \quad \left(< \frac{\pi}{4}\right). \tag{1.5}$$

This bound is a simple corollary to the celebrated Davis–Kahan $\tan 2\Theta$ theorem [4] (see also [2, Theorem 5.1], [3, Theorem 6.1], and [7, Theorem 2.4]).

In the case of the spectral disposition (1.4), an a posteriori bound on the angle $\theta$ under condition $\|V\| < \sqrt{2}d$ follows from [6, Theorem 2.4]. This bound reads

$$\theta \leq \arctan\left(\frac{\|V\|}{\delta}\right), \tag{1.6}$$

where $\delta$ denotes the distance between the perturbed spectral set $\sigma_0'$ and unperturbed spectral set $\sigma_1$. Since $\delta$ may be arbitrarily small (see Example 2.5 below), the bound (1.6), in general, gives no a priori uniform estimate for $\theta$ except that $\theta < \pi/2$.

The present note is aimed just at giving an a priori sharp bound on the angle $\theta$ in the case of the disposition (1.4). In particular, we will prove that under condition $\|V\| < \sqrt{2}d$ this angle is strictly separated from $\pi/2$. Our main result is as follows.

Theorem 1.1. [illegible] $A$ [illegible] $\mathfrak{H}$ [illegible]

$$\operatorname{spec}(A) = \sigma_0 \cup \sigma_1, \quad \operatorname{dist}(\sigma_0, \sigma_1) = d > 0, \quad [illegible] \quad \operatorname{conv}(\sigma_0) \cap \sigma_1 = \varnothing.$$

[illegible] $V$ [illegible] $\mathfrak{H}$ [illegible] $\mathfrak{H} = \operatorname{Ran} \mathsf{E}_A(\sigma_0) \oplus \operatorname{Ran} \mathsf{E}_A(\sigma_1)$ [illegible]

$$\|V\| < \sqrt{2}d \tag{1.7}$$

[illegible] $L = A + V$ [illegible] $f$ [illegible]

$$z \in (\inf \sigma_0 - d, \sup \sigma_0 + d).$$

[illegible] $\theta$ [illegible] $f$ [illegible] $\mathsf{E}_A(\sigma_0)f$ [illegible] $\operatorname{Ran} \mathsf{E}_A(\sigma_0)$ [illegible]

$$\theta \le \arctan\left(\frac{\|V\|}{d}\right). \tag{1.8}$$

[illegible] 1.2. The bound (1.8) implies that under condition (1.7) the angle $\theta$ can never exceed the value of $\arctan\sqrt{2}$, i.e.,

$$\theta < \arctan\sqrt{2} \approx 0.304\,\pi.$$

We also remark that for $\|V\| < d$ the bound (1.8) follows from [9, Theorem 2].

Throughout the paper, by $\Xi(D, d, b)$ we will denote the function of three real variables $D$, $d$, and $b$ defined on the set

$$\Omega = \bigl\{(D, d, b) \mid \quad D > 0, \quad 0 < d \le D/2, \quad 0 \le b < \sqrt{dD}\bigr\}$$

by

$$\Xi(D, d, b) = \begin{cases} \tan^2\Bigl(\dfrac{1}{2}\arctan\dfrac{2b}{d}\Bigr) & \text{if } b^2 \le d\sqrt{D}\dfrac{\sqrt{D}-\sqrt{2d}}{2}, \\ 1 + \dfrac{2b^2}{D^2} - \dfrac{2}{D^2}\sqrt{(dD - b^2)\bigl((D-d)D - b^2\bigr)} & \\ \qquad\qquad\qquad \text{if } d\sqrt{D}\dfrac{\sqrt{D}-\sqrt{2d}}{2} < b^2 < dD. \end{cases} \tag{1.9}$$

Here and further on, by $\tan^2\theta$, $\theta \in \mathbb{R}$, we understand the square of the tangent of $\theta$, that is, $\tan^2\theta = (\tan\theta)^2$.

Theorem 1.1 appears to be a corollary to a more general statement (Theorem 3.2) that is proven under the condition

$$\|V\| < \sqrt{d|\Delta|}, \tag{1.10}$$

where $\Delta$ again denotes the (finite) gap of the set $\sigma_1$ that contains $\sigma_0$ and $|\Delta|$ stands for the length of the interval $\Delta$. It is known that if (1.10) holds, then the off-diagonal perturbation $V$ does not close the gaps between $\sigma_0$ and $\sigma_1$ (see [5, Theorem 1(i)]). Although condition (1.10) is in general weaker than (1.7), it involves the additional parameter $|\Delta|$. The claim of Theorem 3.2 is that under this condition the following inequality holds:

$$\tan\theta \le \bigl(\Xi(|\Delta|, d, \|V\|)\bigr)^{1/2}. \tag{1.11}$$

In particular, from formula (1.9) defining the function $\Xi$ one can see that if $|\Delta| > 2d$, then for $V$ small enough, namely for $V$ such that

$$\|V\|^2 \le d\sqrt{|\Delta|}\,\frac{\sqrt{|\Delta|}-\sqrt{2d}}{2},$$

the bound on $\theta$ is the same as the bound (1.5) prescribed by the $\tan 2\Theta$ theorem.

The paper is organized as follows. In section 2, we consider a three-dimensional version of the problem and prove the bound (1.11) in the case of $3\times 3$ matrices. The general finite- or infinite-dimensional case is studied in section 3. In the proof of the central result of this section, the one of Theorem 3.2, we essentially rely on Lemma 2.2 of section 2.

Throughout the paper, we use the standard notation $M^{\mathsf{T}}$ for the transpose of a matrix $M$.

**2. A three-dimensional case.** We start our consideration with the case where $\mathfrak{H} = \mathbb{C}^3$ and the operators $A$ and $V$ are $3\times 3$ matrices. Assume that

$$A = \begin{pmatrix} \lambda & 0 & 0 \\ 0 & \gamma_- & 0 \\ 0 & 0 & \gamma_+ \end{pmatrix} \quad\text{and}\quad V = \begin{pmatrix} 0 & b_- & b_+ \\ b_- & 0 & 0 \\ b_+ & 0 & 0 \end{pmatrix},$$

where

$$\lambda, \gamma_\pm, b_\pm \in \mathbb{R} \quad\text{and}\quad \gamma_+ > \gamma_-.$$

The matrices $A$ and $V$ are symmetric. Moreover, under the assumption that $\lambda \ne \gamma_\pm$, the matrix $V$ is off-diagonal with respect to the partition $\operatorname{spec}(A) = \sigma_0 \cup \sigma_1$ of the spectrum of $A$ into the disjoint sets

$$\sigma_0 = \{\lambda\} \quad\text{and}\quad \sigma_1 = \{\gamma_-, \gamma_+\}.$$

It is convenient for us to write the matrix $L = A + V$ in the following $2\times 2$ block form:

$$L = \begin{pmatrix} \lambda & B \\ B^* & A_1 \end{pmatrix}, \tag{2.1}$$

where $B$ and $A_1$ are $1\times 2$ and $2\times 2$ matrices given by

$$B = (\, b_- \quad b_+ \,), \quad A_1 = \begin{pmatrix} \gamma_- & 0 \\ 0 & \gamma_+ \end{pmatrix}, \tag{2.2}$$

respectively. Clearly, $\|V\| = \|B\| = \sqrt{|b_-|^2 + |b_+|^2}$.

Throughout this section, by $\Delta$ we will denote the spectral gap of the operator $A_1$ between its eigenvalues $\gamma_-$ and $\gamma_+$, i.e.,

$$\Delta = (\gamma_-, \gamma_+).$$

Lemma 2.1. [illegible] $L$ [illegible] (2.1) (2.2) [illegible] $\lambda \in \Delta$ [illegible]

$$\|B\| < \sqrt{d|\Delta|}, \tag{2.3}$$

[illegible] $|\Delta| = \gamma_+ - \gamma_-$ [illegible] $\Delta$ [illegible]

$$d = \operatorname{dist}(\sigma_0, \sigma_1) = \min\{\gamma_+ - \lambda, \lambda - \gamma_-\}.$$

[illegible] $L$ [illegible] $z$ [illegible] $\Delta$ [illegible]

$$\gamma_- < z_{\min} \le z \le z_{\max} < \gamma_+,$$

[illegible]

$$z_{\min} = \lambda - \|B\| \tan\left(\frac{1}{2} \arctan \frac{2\|B\|}{\gamma_+ - \lambda}\right), \tag{2.4}$$

$$z_{\max} = \lambda + \|B\| \tan\left(\frac{1}{2} \arctan \frac{2\|B\|}{\lambda - \gamma_-}\right). \tag{2.5}$$

[illegible]. Lemma 2.1 is an elementary corollary to [5, Theorem 3.2]. □

Lemma 2.2. [illegible] 2.1 [illegible] $z$ [illegible] $L$ [illegible] $\Delta$ [illegible] $f$ $f \neq 0$ [illegible] $Lf = zf$ [illegible] $\theta$ [illegible] $f$ [illegible] $f_0 = (1, 0, 0)^\mathsf{T}$ [illegible]

$$\tan^2 \theta \le \Xi(|\Delta|, d, \|B\|), \tag{2.6}$$

[illegible] $\Xi$ [illegible] (1.9)

[illegible]. Assume, without loss of generality, that $\gamma_+ = -\gamma_- = \gamma > 0$. Otherwise one can simply make the corresponding shift of the origin of the spectral parameter axis. Assume, in addition, that $B \neq 0$ and $\lambda \ge 0$. (There is no loss of generality in the latter assumption, since, for $\lambda < 0$, instead of $L$ one may consider the matrix $-L$.)

Thus, in the proof we will assume that

$$\Delta = (-\gamma, \gamma), \quad 0 \le \lambda < \gamma, \quad \text{and} \quad d = \gamma - \lambda.$$

Under the hypothesis that $\|B\| < \sqrt{d|\Delta|}$ $(= \sqrt{2d\gamma})$, from [5, Theorem 1(i)] it follows that if the eigenvalue $z$ of $L$ is in $\Delta$, then the corresponding eigenvector $f$, $Lf = zf$, may be chosen in the form

$$f = (1, x_-, x_+)^\mathsf{T},$$

with $x_\pm \in \mathbb{C}$ such that the matrix $X = (x_- \ x_+)^\mathsf{T}$ satisfies the Riccati equation

$$\lambda X - A_1 X + XBX = B^*. \tag{2.7}$$

Moreover,

$$z = \lambda + BX. \tag{2.8}$$

Taking into account (2.2), (2.7) and (2.8) imply

$$x_- = \frac{b_-}{\gamma + z} \quad \text{and} \quad x_+ = \frac{b_+}{-\gamma + z}. \tag{2.9}$$

Hence

$$\|X\|^2 = \frac{|b_-|^2}{(\gamma + z)^2} + \frac{|b_+|^2}{(-\gamma + z)^2}. \tag{2.10}$$

In addition, from (2.8) and (2.9) one concludes that $z$ is the solution to equation

$$z = \lambda + \frac{|b_-|^2}{\gamma + z} + \frac{|b_+|^2}{-\gamma + z}. \tag{2.11}$$

Let $t \in [0, 1]$ be such that

$$|b_+|^2 = t\|B\|^2 \tag{2.12}$$

and, hence,

$$|b_-|^2 = (1 - t)\|B\|^2. \tag{2.13}$$

Notice that under the assumptions we use, the points $z_{\min}$ of (2.4) and $z_{\max}$ of (2.5) can be written in the form

$$z_{\min} = \frac{\gamma + \lambda}{2} - \sqrt{\frac{(\gamma - \lambda)^2}{4} + \|B\|^2}, \tag{2.14}$$

$$z_{\max} = -\frac{\gamma - \lambda}{2} + \sqrt{\frac{(\gamma + \lambda)^2}{4} + \|B\|^2}. \tag{2.15}$$

It is easy to see that, given the value of $\|B\|$, for $t$ in (2.12) and (2.13) varying between 0 and 1 the solution $z$ to (2.11) fills the whole interval $[z_{\min}, z_{\max}]$. Moreover, with $t$ decreasing from 1 to 0 the value of $z$ is continuously and monotonously increasing from $z_{\min}$ to $z_{\max}$.

On the other hand, one can express $t$ through $z$. With $|b_\pm|$ given by (2.12) and (2.13), from (2.11) it follows that

$$t = \frac{1}{2\gamma\|B\|^2}[(z - \lambda)(z^2 - \gamma^2) - \|B\|^2(z - \gamma)]. \tag{2.16}$$

Taking this into account, we rewrite expression (2.10) in the form

$$\|X\|^2 = \varphi(z), \tag{2.17}$$

where the function $\varphi$ is given by

$$\varphi(z) = \frac{\|B\|^2 + 2(\lambda - z)z}{\gamma^2 - z^2}. \tag{2.18}$$

That is, given the value of $\|B\|$, the norm of the solution $X$ to the Riccati equation (2.7) may be considered as a function of the only variable $z$ that runs through the interval $[z_{\min}, z_{\max}]$.

There is a single point $z_0$ within the interval $(-\gamma, \gamma)$ where the derivative of the function $\varphi(z)$ is zero, namely

$$z_0 = \begin{cases} 0 & \text{if} \quad \lambda = 0, \\ \dfrac{2\gamma^2 - \|B\|^2}{2\lambda} - \sqrt{\left(\dfrac{2\gamma^2 - \|B\|^2}{2\lambda}\right)^2 - \gamma^2} & \text{if} \quad \lambda > 0. \end{cases} \tag{2.19}$$

It provides the function $\varphi(z)$ with a maximum.

One concludes by inspection that inequality (2.3) (along with the assumptions $\lambda \geq 0$ and $B \neq 0$) implies

$$z_0 < z_{\max}.$$

At the same time, $z_0 \leq z_{\min}$ if $0 < \|B\| \leq \beta$ and $z_0 > z_{\min}$ if $\beta < \|B\| < \sqrt{2d\gamma}$, where

$$\beta = \left[(\gamma - \lambda)\sqrt{\gamma}(\sqrt{\gamma} - \sqrt{\gamma - \lambda})\right]^{1/2} = \left[d\sqrt{|\Delta|}\frac{\sqrt{|\Delta|} - \sqrt{2d}}{2}\right]^{1/2}. \tag{2.20}$$

Therefore,

$$\max_{z \in [z_{\min}, z_{\max}]} \varphi(z) = \varphi(z_{\min}) \quad \text{if} \quad 0 < \|B\| \leq \beta \tag{2.21}$$

and

$$\max_{z \in [z_{\min}, z_{\max}]} \varphi(z) = \varphi(z_0) \quad \text{if} \quad \beta < \|B\| < \sqrt{d|\Delta|}. \tag{2.22}$$

By substituting (2.14) and (2.19) into (2.18), one arrives at

$$\varphi(z_{\min}) = \frac{d^2}{2\|B\|^2}\left(1 + \frac{2\|B\|^2}{d^2} - \sqrt{1 + \frac{4\|B\|^2}{d^2}}\right) = \tan^2\left(\frac{1}{2}\arctan\frac{2\|B\|}{d}\right) \tag{2.23}$$

and

$$\varphi(z_0) = 1 + \frac{2\|B\|^2}{|\Delta|^2} - \frac{2}{|\Delta|^2}\sqrt{(d|\Delta| - \|B\|^2)\big((|\Delta| - d)|\Delta| - \|B\|^2\big)}, \tag{2.24}$$

respectively. To get (2.6), it remains only to observe that $\tan\theta = \|X\|$, which by combining (2.17) and (2.21)–(2.24) means

$$\tan\theta \leq \left(\max_{z \in [z_{\min}, z_{\max}]} \varphi(z)\right)^{1/2} = \Xi(|\Delta|, d, \|B\|)^{1/2}.$$

The proof is complete. □

[illegible] 2.3. The bound (2.6) is optimal in the sense that given the values of $|\Delta| > 0$, $d \in (0, |\Delta|/2)$, and $\|B\| < \sqrt{d|\Delta|}$, it is possible to choose a matrix $L$ of the form (2.1), (2.2) such that for the eigenvector $f = (1, x_-, x_+)^\mathsf{T}$ associated with the (only) eigenvalue $z$ of $L$ within the interval $(\gamma_-, \gamma_+)$ inequality (2.6) turns into equality.

To prove this statement, set $\gamma = \frac{|\Delta|}{2}$, $\gamma_\pm = \pm\gamma$, and $\lambda = \gamma - d$. If $\|B\| \le \beta$, where $\beta$ is given by (2.20), then choose $b_- = 0$ and $b_+ = \|B\|$. Observe that in this case $z = z_{\min}$, and hence by (2.21) such a choice of $b_\pm$ just provides $\|X\|^2 = x_-^2 + x_+^2$ with its maximal possible value; i.e., the equalities $\tan^2\theta = \varphi(z_{\min}) = \Xi(|\Delta|, d, \|B\|)$ hold. If $\|B\| > \beta$, first compute $t$ by formula (2.16) for $z = z_0$ with $z_0$ given by (2.19). Then introduce $b_+ = \sqrt{t}\|B\|$ and $b_- = \sqrt{1-t}\,\|B\|$. In such a case, $z = z_0$ is the eigenvalue of the matrix $L$ in $\Delta$, and we have the equality $\tan^2\theta = \varphi(z_0)$; that is, again the equality $\tan^2\theta = \Xi(|\Delta|, d, \|B\|)$ holds.

Example 2.4. Again assume that $\gamma_+ = -\gamma_- = \frac{|\Delta|}{2} > 0$. Assume, in addition, that $\lambda = 0$ and $b_+ = b_- = \frac{b}{\sqrt{2}}$ for some $b \ge 0$. From (2.11), it is easy to see that in this case $z = 0$ is the (only) eigenvalue of the matrix $L$ within the interval $\Delta$. Moreover, for the corresponding eigenvector $f = (1, x_-, x_+)^\mathsf{T}$, by (2.9) one infers that $x_- = -\frac{b}{\sqrt{2}d}$ and $x_+ = \frac{b}{\sqrt{2}d}$, taking into account that $\gamma_- = -d$ and $\gamma_+ = d$. Since $\|B\| = b$, the equality $\tan\theta = \sqrt{|x_-|^2 + |x_+|^2}$ yields

$$\tan\theta = \frac{\|B\|}{d}.$$

Notice that in this example $\Xi(|\Delta|, d, \|B\|) = \Xi(2d, d, \|B\|) = \frac{\|B\|^2}{d^2}$, and thus the equality $\tan^2\theta = \Xi(|\Delta|, d, \|B\|)$ holds, too.

Example 2.5. Consider a matrix $L$ of the form (2.1) with $\gamma_-$, $\gamma_+$, and $\lambda$ as in Example 2.4, that is, with $\gamma_+ = -\gamma_- = d > 0$ and $\lambda = 0$. Set $b_+ = 0$ and let $b_-$ satisfy the inequalities $0 \le b_- < \sqrt{d|\Delta|}$. Obviously, $\|V\| = b_-$, $|\Delta| = 2d$, and thus we have $\|V\| < \sqrt{2}d$. The eigenvalue $z$ of the matrix $L$ in the interval $\Delta$ (which is the corresponding solution to (2.11)) simply coincides with $z_{\max}$ (cf. formula (2.15)),

$$z = -\frac{d}{2} + \sqrt{\frac{d^2}{4} + \|V\|^2}.$$

Clearly, $z \to d$ as $\|V\| \to \sqrt{2}d$. That is, in this case the distance $\delta = \operatorname{dist}(\sigma_0', \sigma_1)$ between the perturbed spectral set $\sigma_0' = \{z\}$ and unperturbed spectral set $\sigma_1 = \{-d, d\}$ can be made arbitrarily small.

**3. General case.** Recall that by a finite spectral gap of a self-adjoint operator $T$ one understands an *open* finite interval on $\mathbb{R}$ lying in the resolvent set of $T$ and being such that both of its end points belong to the spectrum of $T$.

In what follows, we adopt the following hypothesis.

Hypothesis 3.1. Let the Hilbert space $\mathfrak{H}$ be decomposed into the orthogonal sum of two subspaces, i.e.,

$$\mathfrak{H} = \mathfrak{H}_0 \oplus \mathfrak{H}_1. \tag{3.1}$$

Assume that, with respect to the decomposition (3.1), a self-adjoint operator $L$ on $\mathfrak{H}$ reads as a $2\times 2$ operator block matrix,

$$L = \begin{pmatrix} A_0 & B \\ B^* & A_1 \end{pmatrix}, \quad \operatorname{Dom}(L) = \mathfrak{H}_0 \oplus \operatorname{Dom}(A_1),$$

where $A_0$ is a bounded self-adjoint operator on $\mathfrak{H}_0$, $A_1$ a possibly unbounded self-adjoint operator on $\mathfrak{H}_1$, and $B$ a bounded operator from $\mathfrak{H}_1$ to $\mathfrak{H}_0$. Assume, in addition, that $A_1$ has a finite spectral gap $\Delta = (\gamma_-, \gamma_+)$, $\gamma_- < \gamma_+$, the spectrum of $A_0$ lies in $\Delta$, i.e., $\operatorname{spec}(A_0) \subset \Delta$, and

$$\|B\| < \sqrt{d|\Delta|}, \tag{3.2}$$

where

$$d = \operatorname{dist}(\operatorname{spec}(A_0), \operatorname{spec}(A_1)).$$

If $f$ is a nonzero element of the Hilbert space $\mathfrak{H}$ and $\mathfrak{K}$ is a subspace of $\mathfrak{H}$, by the angle between $f$ and $\mathfrak{K}$ we understand the acute angle $\theta$ between $f$ and its orthogonal projection $f_{\mathfrak{K}}$ onto $\mathfrak{K}$, that is, $\theta = \arccos(\|f_{\mathfrak{K}}\|/\|f\|)$.

THEOREM 3.2. [illegible] 3.1 [illegible] $L$ [illegible] $\Delta$ [illegible] $f$ [illegible] $L$ [illegible] $\theta$ [illegible] $f$ [illegible] $\mathfrak{H}_0$ [illegible]

$$\tan^2\theta \le \Xi(|\Delta|, d, \|B\|), \tag{3.3}$$

[illegible] $\Xi$ [illegible] (1.9)

[illegible]. Assume that the eigenvector $f = f_0 \oplus f_1$, $f_0 \in \mathfrak{H}_0$, $f_1 \in \operatorname{Dom}(A_1)$, of the operator $L$ is associated with an eigenvalue $z \in \Delta$. Then the following equalities hold:

$$A_0 f_0 + B f_1 = z f_0, \tag{3.4}$$

$$B^* f_0 + A_1 f_1 = z f_1. \tag{3.5}$$

Taking into account that $z$ is in the resolvent set of $A_1$, from (3.5) it follows that

$$f_1 = -(A_1 - z)^{-1} B^* f_0. \tag{3.6}$$

Hence, $f_0 \neq 0$ (otherwise, for $f_0 = 0$, one would have $f_1 = 0$ and then $f = 0$). Equations (3.4) and (3.6) yield

$$A_0 f_0 - B(A_1 - z)^{-1} B^* f_0 = z f_0,$$

which implies

$$\langle A_0 f_0, f_0\rangle - \langle B(A_1 - z)^{-1} B^* f_0, f_0\rangle = z\|f_0\|^2. \tag{3.7}$$

From now on, suppose that

$$\|f_0\| = 1 \tag{3.8}$$

and set $\lambda = \langle A_0 f_0, f_0\rangle$. Clearly,

$$\lambda \in [\inf \operatorname{spec}(A_0), \sup \operatorname{spec}(A_0)]. \tag{3.9}$$

By the spectral theorem, we have

$$\langle B(A_1 - z)^{-1} B^* f_0, f_0\rangle = \int_{\mathbb{R}\setminus(\gamma_-,\gamma_+)} \frac{\langle d\mathsf{E}_{A_1}(\mu) B^* f_0, B^* f_0\rangle}{\mu - z}, \tag{3.10}$$

where $\mathsf{E}_{A_1}(\mu)$, $\mu \in \mathbb{R}$, denotes the spectral family of $A_1$. Let

$$\Delta_- = (-\infty, \gamma_-] \quad \text{and} \quad \Delta_+ = [\gamma_+, \infty).$$

By the mean value theorem, there are real numbers $\mu_- \le \gamma_-$ and $\mu_+ \ge \gamma_+$ such that

$$\int_{\Delta_\pm} \frac{\langle d\mathsf{E}_{A_1}(\mu)B^*f_0, B^*f_0\rangle}{\mu - z} = \frac{\langle \mathsf{E}_{A_1}(\Delta_\pm)B^*f_0, B^*f_0\rangle}{\mu_\pm - z} = \frac{\|\mathsf{E}_{A_1}(\Delta_\pm)B^*f_0\|^2}{\mu_\pm - z}, \tag{3.11}$$

respectively. Introduce the nonnegative numbers $b_\pm$ by

$$b_\pm = \sqrt{\alpha_\pm}\|\mathsf{E}_{A_1}(\Delta_\pm)B^*f_0\|, \tag{3.12}$$

where

$$\alpha_\pm = \frac{|\gamma_\pm - z|}{|\mu_\pm - z|} \le 1. \tag{3.13}$$

Obviously,

$$\int_{\Delta_\pm} \frac{\langle d\mathsf{E}_{A_1}(\mu)B^*f_0, B^*f_0\rangle}{\mu - z} = \frac{b_\pm^2}{\gamma_\pm - z}. \tag{3.14}$$

Thus, taking into account (3.9), (3.10), and (3.11), (3.7) turns into

$$\lambda - \frac{b_-^2}{\gamma_- - z} - \frac{b_+^2}{\gamma_+ - z} = 0. \tag{3.15}$$

At the same time, by (3.6) we have

$$\|f_1\|^2 = \int_{\mathbb{R}\setminus(\gamma_-,\gamma_+)} \frac{\langle d\mathsf{E}_{A_1}(\mu)B^*f_0, B^*f_0\rangle}{(\mu - z)^2}. \tag{3.16}$$

The contributions of the intervals $(-\infty, \gamma_-]$ and $[\gamma_+, \infty)$ to the integral on the right-hand side of (3.16) are estimated separately. For the first interval, one derives

$$\int_{\Delta_-} \frac{\langle d\mathsf{E}_{A_1}(\mu)B^*f_0, B^*f_0\rangle}{(\mu - z)^2} \le \frac{1}{z - \gamma_-}\int_{\Delta_-} \frac{\langle d\mathsf{E}_{A_1}(\mu)B^*f_0, B^*f_0\rangle}{z - \mu},$$

which by (3.14) means

$$\int_{\Delta_-} \frac{\langle d\mathsf{E}_{A_1}(\mu)B^*f_0, B^*f_0\rangle}{(\mu - z)^2} \le \frac{b_-^2}{(\gamma_- - z)^2}. \tag{3.17}$$

In a similar way, one concludes that

$$\int_{\Delta_+} \frac{\langle d\mathsf{E}_{A_1}(\mu)B^*f_0, B^*f_0\rangle}{(\mu - z)^2} \le \frac{b_+^2}{(\gamma_+ - z)^2}. \tag{3.18}$$

Then by combining (3.16), (3.17), and (3.18) one infers that

$$\|f_1\|^2 \le x_-^2 + x_+^2, \tag{3.19}$$

where

$$x_\pm = -\frac{b_\pm}{\gamma_\pm - z}. \tag{3.20}$$

From (3.15), (3.20), it follows that the vector $y = (1, x_-, x_+)^{\mathsf{T}}$ is an eigenvector of the $3 \times 3$ matrix

$$\widetilde{L} = \begin{pmatrix} \lambda & b_- & b_+ \\ b_- & \gamma_- & 0 \\ b_+ & 0 & \gamma_+ \end{pmatrix}$$

associated with the eigenvalue $z$, that is, $\widetilde{L}y = zy$. By (3.9), for $\delta = \operatorname{dist}(\lambda, \{\gamma_-, \gamma_+\})$ we have

$$d \le \delta \le \frac{|\Delta|}{2}. \tag{3.21}$$

In addition, by (3.12) the square of the norm $\|\widetilde{B}\| = \sqrt{b_-^2 + b_+^2}$ of the $1 \times 2$ matrix-row $\widetilde{B} = (b_- \quad b_+)$ reads

$$\|\widetilde{B}\|^2 = \alpha_-^2 \langle \mathsf{E}_{A_1}(\Delta_-) B^* f_0, B^* f_0 \rangle + \alpha_+^2 \langle \mathsf{E}_{A_1}(\Delta_+) B^* f_0, B^* f_0 \rangle,$$

and hence

$$\begin{aligned} \|\widetilde{B}\|^2 &\le \langle \mathsf{E}_{A_1}(\Delta_-) B^* f_0, B^* f_0 \rangle + \langle \mathsf{E}_{A_1}(\Delta_+) B^* f_0, B^* f_0 \rangle \\ &= \langle B^* f_0, B^* f_0 \rangle = \|B^* f_0\|^2 \\ &\le \|B\|^2, \end{aligned} \tag{3.22}$$

taking into account first (3.13) and then (3.8). By the hypothesis, inequality (3.2) holds. Combining (3.21) and (3.22) with (3.2) implies

$$\|\widetilde{B}\|^2 < \sqrt{\delta |\Delta|}. \tag{3.23}$$

By Lemma 2.2, one then concludes that $x_-^2 + x_+^2 \le \Xi(|\Delta|, \delta, \|\widetilde{B}\|)$, which by (3.8) and (3.19) implies that

$$\tan^2 \theta \le \Xi(|\Delta|, \delta, \|\widetilde{B}\|). \tag{3.24}$$

Given $|\Delta| > 0$, $d \in (0, |\Delta|/2]$, and $\|B\|$ satisfying (3.2), it is easy to see that the function $\Xi(|\Delta|, \delta, \|\widetilde{B}\|)$ is monotonously increasing with increasing $\|\widetilde{B}\|$, $\|\widetilde{B}\| \le \|B\|$. For $d < |\Delta|/2$, it also monotonously increases if $\delta$ decreases from $\frac{|\Delta|}{2}$ to $d$. Therefore, from (3.24) it follows that $\tan^2 \theta \le \Xi(|\Delta|, d, \|B\|)$, completing the proof. □

*Remark* 3.3. The bound (3.3) is optimal. This follows from Remark 2.3.

*Remark* 3.4. Notice that under condition $\|B\| < \sqrt{d(|\Delta| - d)}$ from [9, Theorem 5.3] the operator angle $\Theta$ between the unperturbed and perturbed spectral subspaces $\operatorname{Ran} \mathsf{E}_A(\sigma_0)$ and $\operatorname{Ran} \mathsf{E}_L(\sigma_0')$ satisfies the following (sharp) estimate:

$$\Theta \le \frac{1}{2} \arctan \kappa(\|B\|), \tag{3.25}$$

where the function $\kappa(b)$ is defined for $0 \le b < \sqrt{d(|\Delta| - d)}$ by

$$\kappa(b) = \begin{cases} \dfrac{2b}{d} & \text{if } b \le \sqrt{\dfrac{d}{2}\left(\dfrac{|\Delta|}{2} - d\right)}, \\[2ex] \dfrac{b\dfrac{|\Delta|}{2} + \sqrt{d(|\Delta| - d)\left[\left(\dfrac{|\Delta|}{2} - d\right)^2 + b^2\right]}}{d(|\Delta| - d) - b^2} & \text{if } b > \sqrt{\dfrac{d}{2}\left(\dfrac{|\Delta|}{2} - d\right)}. \end{cases}$$

Surely, the bound (3.25) implies the corresponding estimate for the angle $\theta$:

$$\theta \leq \frac{1}{2} \arctan \kappa(\|B\|) \quad \text{whenever} \quad \|B\| < \sqrt{d(|\Delta| - d)}. \tag{3.26}$$

One observes by inspection that

$$\Xi(|\Delta|, d, b) \leq \tan^2 \left( \frac{1}{2} \arctan \kappa(b) \right), \quad 0 \leq b < \sqrt{d(|\Delta| - d)}.$$

Moreover, if $|\Delta| > 2d$, then for $\sqrt{\frac{d}{2}(\frac{|\Delta|}{2} - d)} < b < \sqrt{d(|\Delta| - d)}$ the strict inequality $\Xi(|\Delta|, d, b) < \tan^2 \left(\frac{1}{2} \arctan \kappa(b)\right)$ holds. Therefore, the bound (3.26) is not optimal in the case of eigenvectors.

Now we are in position to prove Theorem 1.1. This theorem appears to be a simple corollary to Theorem 3.2.

[illegible] 1.1. Set $\mathfrak{H}_0 = \operatorname{Ran} \mathsf{E}_A(\sigma_0)$ and $\mathfrak{H}_0 = \operatorname{Ran} \mathsf{E}_A(\sigma_1)$. With respect to the orthogonal decomposition $\mathfrak{H} = \mathfrak{H}_0 \oplus \mathfrak{H}_1$, the operators $A$ and $V$ read as $2 \times 2$ block operator matrices,

$$A = \begin{pmatrix} A_0 & 0 \\ 0 & A_1 \end{pmatrix} \quad \text{and} \quad V = \begin{pmatrix} 0 & B \\ B^* & 0 \end{pmatrix},$$

where $B = V|_{\mathfrak{H}_1}$; $\operatorname{Dom}(A) = \mathfrak{H}_0 \oplus \operatorname{Dom}(A_1)$ and $\operatorname{Dom}(L) = \operatorname{Dom}(A)$. Assume that $\Delta$ is a gap of the set $\sigma_1$ that contains the whole set $\sigma_0$. Surely, the length $|\Delta|$ of this gap satisfies the estimate $|\Delta| \geq 2d$, and the bound (1.7) implies the inequality $\|B\| < \sqrt{d|\Delta|}$. Then by Theorem 3.2 we have

$$\tan^2 \theta \leq \Xi(|\Delta|, d, \|V\|),$$

taking into account that $\|V\| = \|B\|$. Now it remains only to observe that $\Xi(D, d, \|V\|)$ is a nonincreasing function of the variable $D$, $D \geq 2d$. For $D$ varying in the interval $[2d, \infty)$, it achieves its maximal value just at $D = 2d$, and this value equals

$$\max_{D\colon D \geq 2d} \Xi(|\Delta|, d, \|V\|) = \frac{\|V\|^2}{d^2}.$$

Thus, the following inequality holds:

$$\tan \theta \leq \frac{\|V\|}{d}.$$

The proof is complete. □

[illegible] 3.5. Example 2.4 shows that the bound (1.8) is sharp.

# ON PSEUDOSPECTRA AND POWER GROWTH*

THOMAS RANSFORD†

**Abstract.** The celebrated Kreiss matrix theorem is one of several results relating the norms of the powers of a matrix to its pseudospectra (i.e., the level curves of the norm of the resolvent). But to what extent do the pseudospectra actually *determine* the norms of the powers? Specifically, let $A, B$ be square matrices such that, with respect to the usual operator norm $\|\cdot\|$, we have $\|(zI-A)^{-1}\| = \|(zI-B)^{-1}\|$ $(z \in \mathbb{C})$. (Call this $(*)$.) Then it is known that $1/2 \leq \|A\|/\|B\| \leq 2$. Are there similar bounds for $\|A^n\|/\|B^n\|$ for $n \geq 2$? Does the answer change if $A, B$ are diagonalizable? What if $(*)$ holds, not just for the norm $\|\cdot\|$, but also for higher-order singular values? What if we use norms other than the usual operator norm? The answers to all these questions turn out to be negative, and in a rather strong sense.

## 1. Introduction and statement of results.

Let $N \geq 1$, let $\mathbb{C}^N$ be complex Euclidean $N$-space, and let $\mathbb{C}^{N\times N}$ be the algebra of complex $N \times N$ matrices. We write $|\cdot|$ for the Euclidean norm on $\mathbb{C}^N$, defined by $|x| := (\sum_1^N |x_j|^2)^{1/2}$, and write $\|\cdot\|$ for the associated operator norm on $\mathbb{C}^{N\times N}$, defined by $\|A\| := \sup\{|Ax| : |x| = 1\}$.

It is well known that, given $A \in \mathbb{C}^{N\times N}$, the long-term growth of the norms of powers of $A$ is governed by the spectral radius $\rho(A)$. Indeed, by the spectral radius formula, we have

$$\|A^n\| \geq \rho(A)^n \quad (n \geq 1) \qquad \text{and} \qquad \lim_{n\to\infty} \|A^n\|^{1/n} = \rho(A).$$

However, in the shorter term, $\|A^n\|$ may well be significantly larger than $\rho(A)^n$. The recent book of Trefethen and Embree [4] contains an account of these transient effects, illustrated by examples drawn from many different fields. One of the main themes of the book is that, to accurately predict the growth of $\|A^n\|$, it is important to study not only the spectrum of $A$, but also its pseudospectra, which we now define.

Given $A \in \mathbb{C}^{N\times N}$ and $\epsilon > 0$, the $\epsilon$ [illegible] of $A$ is defined to be the set

$$\sigma_\epsilon(A) := \{z \in \mathbb{C} : \|(zI - A)^{-1}\| > \epsilon^{-1}\}.$$

Here and in what follows we adopt the useful convention that $\|(zI - A)^{-1}\| = \infty$ if $z \in \sigma(A)$, the spectrum of $A$. Thus $\sigma_\epsilon(A)$ shrinks to $\sigma(A)$ as $\epsilon \downarrow 0$. From a knowledge of the pseudospectra of $A$, it is possible to deduce both upper and lower bounds on the growth of $\|A^n\|$. A well-known result of this type is the Kreiss matrix theorem. We refer to [4] for this and several other such results. In addition, there are efficient methods for numerical computation of pseudospectra (see [4, Chapter IX]), so this approach is highly practical.

The purpose of this paper is to show that, in predicting power growth, not even pseudospectra tell the whole story. The issue was already addressed by Greenbaum and Trefethen in [3] (see also [4, section 47]). Suppose that two $N \times N$ matrices $A, B$ have identical pseudospectra, i.e., that

$$\|(zI - A)^{-1}\| = \|(zI - B)^{-1}\| \qquad (z \in \mathbb{C}). \tag{1.1}$$

Does it then follow that $\|p(A)\| = \|p(B)\|$ for every polynomial $p$? In particular, can we conclude that $\|A^n\| = \|B^n\|$ for all $n \geq 1$? The answer is no. An example was given in [3] (and again in [4]) of two matrices $A, B$ with identical pseudospectra such that $\|A\| = 1$ and $\|B\| = \sqrt{2}$. But this example leaves the following basic questions unresolved.

**1.1. What about higher powers?** By adapting the Greenbaum–Trefethen example, one can construct, for each $\epsilon > 0$, matrices $A, B$ with identical pseudospectra such that $\|A\|/\|B\| > 2 - \epsilon$. On the other hand, it is known that if $A, B$ satisfy (1.1), then we must have

$$1/2 \leq \|A\|/\|B\| \leq 2. \tag{1.2}$$

(For a proof, see [4, pp. 168–169]; see also the remark after Theorem 5.1 below.) Are there similar bounds for $\|A^n\|/\|B^n\|$ for $n \geq 2$? If this were the case, then we could justifiably say that pseudospectra determine power norms, at least up to a constant factor. However, our first result answers this question negatively, and in a fairly strong sense.

Recall that a (finite or infinite) sequence $(\alpha_k)$ is called [illegible] if $\alpha_{k+l} \leq \alpha_k \alpha_l$ for all $k, l$ for which the inequality makes sense. For example, the sequence $(\|A^k\|)_{k \geq 1}$ is submultiplicative for every matrix $A$.

THEOREM 1.1. [illegible] $n \geq 2$ [illegible] $\alpha_2, \dots, \alpha_n$ [illegible] $\beta_2, \dots, \beta_n$ [illegible] $N \geq 1$ [illegible] $A, B \in \mathbb{C}^{N \times N}$ [illegible]

$$\|(zI - A)^{-1}\| = \|(zI - B)^{-1}\| \qquad (z \in \mathbb{C}) \tag{1.3}$$

[illegible]

$$\|A^k\| = \alpha_k \quad \text{[illegible]} \quad \|B^k\| = \beta_k \qquad (k = 2, \dots, n). \tag{1.4}$$

[illegible] $N = 2n + 3$

This shows that matrices can have identical pseudospectra and yet their second and higher powers have norms that are completely unrelated to each other.

**1.2. What about diagonalizable matrices?** The matrices $A, B$ in the Greenbaum–Trefethen example are nilpotent, as are those constructed in the proof of Theorem 1.1 above. Obviously, these are rather special. What happens if, instead, we consider more generic matrices, for example, diagonalizable matrices? (By "diagonalizable" we mean similar to a diagonal matrix.) Could it be that, for such matrices at least, the pseudospectra completely determine the power growth? Until now, no counterexample was known. We obtain one by combining the construction in Theorem 1.1 with a perturbation argument.

THEOREM 1.2. [illegible] $n \geq 2$ [illegible] $\alpha_2, \dots, \alpha_n$ [illegible] $\beta_2, \dots, \beta_n$ [illegible] $\epsilon > 0$ [illegible] $N \geq 1$ [illegible] diagonalizable [illegible] $A, B \in \mathbb{C}^{N \times N}$ [illegible]

$$\|(zI - A)^{-1}\| = \|(zI - B)^{-1}\| \qquad (z \in \mathbb{C}) \tag{1.5}$$

$$\alpha_k - \epsilon < \|A^k\| < \alpha_k + \epsilon \qquad \beta_k - \epsilon < \|B^k\| < \beta_k + \epsilon \qquad (k = 2, \ldots, n). \tag{1.6}$$

**1.3. What if we use "higher-order" pseudospectra?** Given a matrix $A \in \mathbb{C}^{N\times N}$, its $s_1(A), \ldots, s_N(A)$ are the square roots of the eigenvalues of $A^*A$, listed in decreasing order. In particular, $s_1(A) = \|A\|$. One of the principal methods for computing the pseudospectra of $A$ is to calculate the singular values of $zI - A$ for $z \in \mathbb{C}$ (once done for one value of $z$, it is relatively inexpensive to do for many $z$), and then use the fact that

$$\|(zI - A)^{-1}\| = s_1\Big((zI - A)^{-1}\Big) = \frac{1}{s_N(zI - A)}.$$

It is thus reasonable to ask whether, by retaining the other singular values of the resolvent $(zI - A)^{-1}$, it is possible to determine $\|A^n\|$ for values of $n \geq 2$. The following result gives a partial positive answer.

THEOREM 1.3. $N \geq 1$ $A, B \in \mathbb{C}^{N\times N}$

$$s_j\Big((zI - A)^{-1}\Big) = s_j\Big((zI - B)^{-1}\Big) \qquad (z \in \mathbb{C},\ j = 1, \ldots, N). \tag{1.7}$$

$p$

$$\frac{1}{\sqrt{N}} \leq \frac{\|p(A)\|}{\|p(B)\|} \leq \sqrt{N}. \tag{1.8}$$

It would be interesting to know if these bounds can be improved so as to be independent of $N$. However, even if this were the case, the theorem would be a bit unrealistic, because it would require us to keep track of all $N$ singular values, which is probably too expensive in practice. Is there an analogous result where, by keeping track of just a few singular values, we can obtain inequalities like (1.8) at least for polynomials of low degree? The following generalization of Theorem 1.1 gives a negative answer.

THEOREM 1.4. $n \geq 2$ $\alpha_2, \ldots, \alpha_n$ $\beta_2, \ldots, \beta_n$ $m \geq 1$ $N \geq 1$ $A, B \in \mathbb{C}^{N\times N}$

$$s_j\Big((zI - A)^{-1}\Big) = s_j\Big((zI - B)^{-1}\Big) \qquad (z \in \mathbb{C},\ j = 1, \ldots, m) \tag{1.9}$$

$$\|A^k\| = \alpha_k \qquad \|B^k\| = \beta_k \qquad (k = 2, \ldots, n). \tag{1.10}$$

$N = (m + 1)(n + 2) - 1$

**1.4. What about other norms?** Though the Euclidean-norm case is undoubtedly the most important one, there are instances where it is more appropriate to consider pseudospectra defined with respect to other norms. In [4, sections 56, 57], several examples are given based on the 1-norm on $\mathbb{C}^N$, defined by $|x|_1 := \sum_{j=1}^N |x_j|$ and the associated operator norm $\|\cdot\|_1$, given by $\|A\|_1 := \sup\{|Ax|_1 : |x|_1 = 1\}$. There is no analogue of the Greenbaum–Trefethen example for this norm, because of the following theorem.

THEOREM 1.5. [illegible] $N \geq 1$ [illegible] $A, B \in \mathbb{C}^{N\times N}$ [illegible]

$$\|(zI - A)^{-1}\|_1 = \|(zI - B)^{-1}\|_1 \qquad (z \in \mathbb{C}). \tag{1.11}$$

[illegible] $\|A\|_1 = \|B\|_1$

Can we also deduce that $\|A^n\|_1 = \|B^n\|_1$ for $n \geq 2$? Once again, the answer turns out to be no, and not just for $\|\cdot\|_1$, but for a whole variety of possible norms. To make this precise, it is convenient to introduce some notation and terminology.

Given square matrices $A, B$, perhaps of different sizes, we shall write $A \oplus B$ for the block matrix

$$\begin{pmatrix} A & 0 \\ 0 & B \end{pmatrix}.$$

A norm $|||\cdot|||$ on $\mathbb{C}^{N\times N}$ will be called [illegible] if it satisfies the following three conditions:

- $|||\cdot|||$ is an algebra norm, i.e., $|||AB||| \leq |||A|||.|||B|||$ for all $A, B \in \mathbb{C}^{N\times N}$ and $|||I||| = 1$;
- every permutation matrix $Q \in \mathbb{C}^{N\times N}$ satisfies $|||Q||| = 1$;
- every block matrix $A \oplus B \in \mathbb{C}^{N\times N}$ satisfies

$$|||A \oplus B||| = \max(|||A \oplus 0|||, |||0 \oplus B|||).$$

For example, if $|\cdot|_p$ is the usual $p$-norm on $\mathbb{C}^N$, given by $|x|_p := (\sum_{j=1}^N |x_j|^p)^{1/p}$, then the associated operator norm on $\mathbb{C}^{N\times N}$ is admissible.

The following result is a generalization of Theorem 1.1 in this context.

THEOREM 1.6. [illegible] $n \geq 2$ [illegible] $\alpha_2, \ldots, \alpha_n$ [illegible] $\beta_2, \ldots, \beta_n$ [illegible] $N \geq 1$ [illegible] $A, B \in \mathbb{C}^{N\times N}$ [illegible] $|||\cdot|||$ [illegible] $\mathbb{C}^{N\times N}$

$$|||(zI - A)^{-1}||| = |||(zI - B)^{-1}||| \qquad (z \in \mathbb{C}) \tag{1.12}$$

[illegible]

$$|||A^k||| = \alpha_k \quad [illegible] \quad |||B^k||| = \beta_k \qquad (k = 2, \ldots, n). \tag{1.13}$$

[illegible] $N = 2n + 3$

We conclude by remarking that there is at least one well-known norm on $\mathbb{C}^{N\times N}$ for which matrices $A, B$ with identical pseudospectra [illegible] have identical power growth. This is the Hilbert–Schmidt (or Frobenius) norm, as was shown by Greenbaum and Trefethen in [3]. We shall need their result in section 4, where more details will be given. Of course, the Hilbert–Schmidt norm is not an admissible norm in our sense; in fact it fails all three parts of the definition.

The rest of the paper is devoted to the proofs of the six theorems above.

**2. Proof of Theorem 1.1.** The proof of Theorem 1.1 is based on a construction using weighted shifts, which will also serve as a model in several other proofs to follow. It is therefore written in such a way as to be easy to adapt to other situations.

Given $\omega_1, \ldots, \omega_n > 0$, we write

$$S(\omega_1, \ldots, \omega_n) := \begin{pmatrix} 0 & \omega_1 & 0 & \ldots & 0 \\ 0 & 0 & \omega_2/\omega_1 & \ldots & 0 \\ \vdots & \vdots & \vdots & & \vdots \\ 0 & 0 & 0 & \ldots & \omega_n/\omega_{n-1} \\ 0 & 0 & 0 & \ldots & 0 \end{pmatrix}. \tag{2.1}$$

Lemma 2.1. [illegible] $\omega_1, \dots, \omega_n$ [illegible] $S = S(\omega_1, \dots, \omega_n)$ [illegible]

$$\|S^k\| = \omega_k \qquad (k = 1, \dots, n) \tag{2.2}$$

[illegible]

$$1 + \max_{1 \le k \le n} \frac{\omega_k |z|^k}{2} \le \|(I - zS)^{-1}\| \le 1 + \sum_{k=1}^{n} \omega_k |z|^k \qquad (z \in \mathbb{C}). \tag{2.3}$$

[illegible] Let $k \in \{1, \dots, n\}$. Taking $Q$ to be an appropriate cyclic permutation matrix, we have $S^k Q = \operatorname{diag}(\omega_k, \omega_{k+1}/\omega_1, \dots, \omega_n/\omega_{n-k}, 0, \dots, 0)$. Using the submultiplicativity of the sequence $\omega_1, \dots, \omega_n$, we obtain

$$\|S^k Q\| = \max(\omega_k, \omega_{k+1}/\omega_1, \dots, \omega_n/\omega_{n-k}, 0, \dots, 0) = \omega_k.$$

Since $\|Q\| = 1 = \|Q^{-1}\|$, and $\|\cdot\|$ is an algebra norm, it follows that $\|S^k\| = \omega_k$. This proves (2.2).

For the upper bound in (2.3), note that $(I - zS)^{-1} = \sum_{k=0}^{n} z^k S^k$, whence

$$\|(1 - zS)^{-1}\| = \left\| \sum_{k=0}^{n} z^k S^k \right\| \le \sum_{k=0}^{n} |z|^k \|S^k\| = 1 + \sum_{k=1}^{n} |z|^k \omega_k \qquad (z \in \mathbb{C}).$$

For the lower bound, first fix $k \in \{1, \dots, n\}$ and $z \in \mathbb{C}$. Let $Q$ be the permutation matrix that exchanges rows 2 and $k+1$, and let $P := \operatorname{diag}(1, e^{i\theta}, 0, \dots, 0)$, where $\theta = -\arg(z^k)$. Then

$$\overline{P} Q (I - zS)^{-1} Q P = \begin{pmatrix} 1 & |z|^k \omega_k \\ 0 & 1 \end{pmatrix} \oplus 0,$$

and hence

$$\|(I - zS)^{-1}\| \ge \left\| \begin{pmatrix} 1 & |z|^k \omega_k \\ 0 & 1 \end{pmatrix} \oplus 0 \right\|.$$

Conjugating by the permutation matrix that swaps the first two rows, we have

$$\left\| \begin{pmatrix} 1 & |z|^k \omega_k \\ 0 & 1 \end{pmatrix} \oplus 0 \right\| = \left\| \begin{pmatrix} 1 & 0 \\ |z|^k \omega_k & 1 \end{pmatrix} \oplus 0 \right\|.$$

Taking averages, it follows that

$$\|(I - zS)^{-1}\| \ge \left\| \begin{pmatrix} 1 & |z|^k \omega_k / 2 \\ |z|^k \omega_k / 2 & 1 \end{pmatrix} \oplus 0 \right\|.$$

Since $\|\cdot\|$ is always at least as large as the spectral radius, we deduce that

$$\|(I - zS)^{-1}\| \ge \rho \left( \begin{pmatrix} 1 & |z|^k \omega_k / 2 \\ |z|^k \omega_k / 2 & 1 \end{pmatrix} \oplus 0 \right) = 1 + \frac{|z|^k \omega_k}{2}.$$

As this holds for each $k \in \{1, \dots, n\}$ and each $z \in \mathbb{C}$, we obtain the lower bound in (2.3). $\square$

[illegible] 1.1 First, choose $\alpha_1, \beta_1$ large enough so that the sequences $\alpha_1, \dots, \alpha_n$ and $\beta_1, \dots, \beta_n$ are submultiplicative, and set

$$A_0 := S(\alpha_1, \dots, \alpha_n) \quad \text{and} \quad B_0 := S(\beta_1, \dots, \beta_n).$$

Then set $A := A_0 \oplus C_0$ and $B := B_0 \oplus C_0$, where $C_0$ is the $(n+2) \times (n+2)$ matrix defined by

$$C_0 := S(\Gamma, \gamma^2, \gamma^3, \dots, \gamma^{n+1}).$$

Here $\Gamma, \gamma$ are positive numbers to be chosen later. Note that the sequence of numbers $\Gamma, \gamma^2, \dots, \gamma^{n+1}$ is submultiplicative provided that $\Gamma \geq \gamma$. Defined in this way, $A, B$ are $(2n+3) \times (2n+3)$ matrices, and we shall show that they satisfy (1.3) and (1.4) if $\gamma, \Gamma$ are chosen suitably.

We first choose $\gamma > 0$ small enough so that $\gamma^k < \min(\alpha_k, \beta_k)$ $(k = 2, \dots, n)$. With this choice,

$$\|A^k\| = \max(\|A_0^k\|, \|C_0^k\|) = \max(\alpha_k, \gamma^k) = \alpha_k \qquad (k = 2, \dots, n),$$

and likewise $\|B^k\| = \beta_k$ $(k = 2, \dots, n)$.

It remains to choose $\Gamma$ to ensure that $A, B$ have identical pseudospectra. This will be the case provided that

$$\left\{ \begin{array}{l} \|(I - zC_0)^{-1}\| \geq \|(I - zA_0)^{-1}\| \\ \|(I - zC_0)^{-1}\| \geq \|(I - zB_0)^{-1}\| \end{array} \right. \qquad (z \in \mathbb{C}). \tag{2.4}$$

By Lemma 2.1, this will be true if

$$\max\left(\frac{\Gamma t}{2}, \frac{\gamma^{n+1} t^{n+1}}{2}\right) \geq \sum_{k=1}^{n} \alpha_k t^k \quad \text{and} \quad \max\left(\frac{\Gamma t}{2}, \frac{\gamma^{n+1} t^{n+1}}{2}\right) \geq \sum_{k=1}^{n} \beta_k t^k \quad (t \geq 0).$$

Now there exists $t_0$, depending on $\alpha_1, \dots, \alpha_n, \beta_1, \dots, \beta_n, \gamma$, but not on $\Gamma$, such that

$$\frac{\gamma^{n+1} t^{n+1}}{2} \geq \sum_{k=1}^{n} \alpha_k t^k \quad \text{and} \quad \frac{\gamma^{n+1} t^{n+1}}{2} \geq \sum_{k=1}^{n} \beta_k t^k \qquad (t \geq t_0).$$

Hence it will suffice that

$$\frac{\Gamma t}{2} \geq \sum_{k=1}^{n} \alpha_k t^k \quad \text{and} \quad \frac{\Gamma t}{2} \geq \sum_{k=1}^{n} \beta_k t^k \qquad (0 \leq t \leq t_0).$$

This will certainly be true provided we choose $\Gamma$ large enough. With this choice, the construction is complete. □

**3. Proof of Theorem 1.2.** The basic idea is to perturb the construction in the proof of Theorem 1.1. However, keeping track of the norms of the resolvents requires a certain amount of care. We shall need two lemmas.

LEMMA 3.1. [illegible] $V, W \in \mathbb{C}^{N \times N}$ [illegible] $V$ [illegible] $\|V - W\| < 1/(2\|V^{-1}\|)$ [illegible] $W$ [illegible]

$$\|V^{-1} - W^{-1}\| \leq 2\|V^{-1}\|^2 \|V - W\|.$$

We have

$$\|I - V^{-1}W\| = \|V^{-1}(V - W)\| \le \|V^{-1}\|\,\|V - W\| \le 1/2.$$

Therefore $V^{-1}W$ is invertible, and hence so is $W$.

We also have

$$\|V^{-1} - W^{-1}\| = \|V^{-1}(W - V)W^{-1}\| \le \|V^{-1}\|\,\|W - V\|\,\|W^{-1}\|. \tag{3.1}$$

Since $\|W - V\| \le 1/(2\|V^{-1}\|)$, it follows that $\|V^{-1} - W^{-1}\| \le \|W^{-1}\|/2$, whence $\|W^{-1}\| \le 2\|V^{-1}\|$. Substituting this back into (3.1) gives the result. □

In the next lemma, adj denotes adjugate and $\rho$ denotes spectral radius.

LEMMA 3.2. $V \in \mathbb{C}^{N\times N}$

$$\|\mathrm{adj}(V) - (-V)^{N-1}\| \le 2^N \rho(V)\|V\|^{N-2}.$$

It suffices to prove this when $V$ is invertible, since invertible matrices are dense in $\mathbb{C}^{N\times N}$.

Let $p(z)$ be the characteristic polynomial of $V$. Since $p(z) = \prod_{j=1}^{N}(z - \lambda_j)$, where $\lambda_1, \dots, \lambda_N$ are the eigenvalues of $V$, we have $p(z) = \sum_{j=0}^{N} a_j z^j$, where

$$a_N = 1, \quad a_0 = (-1)^N \det(V) \quad \text{and} \quad |a_j| \le \binom{N}{j}\rho(V)^{N-j} \quad (j = 0, \dots, N). \tag{3.2}$$

Now by the Cayley–Hamilton theorem, $p(V) = 0$. Multiplying by $V^{-1}$ and rearranging gives

$$a_0 V^{-1} + a_N V^{N-1} = -\sum_{j=1}^{N-1} a_j V^{j-1}.$$

Using (3.2), it follows that

$$\|(-1)^N \det(V)V^{-1} + V^{N-1}\| \le \sum_{j=1}^{N-1}\binom{N}{j}\rho(V)^{N-j}\|V\|^{j-1}.$$

Since $\det(V)V^{-1} = \mathrm{adj}(V)$ and $\rho(V) \le \|V\|$, we deduce that

$$\|(-1)^N \mathrm{adj}(V) + V^{N-1}\| \le \sum_{j=1}^{N-1}\binom{N}{j}\rho(V)\|V\|^{N-j-1}\|V\|^{j-1} \le 2^N\rho(V)\|V\|^{N-2},$$

whence we have the result. □

1.2 Define $A_0, B_0, C_0$ as in the proof of Theorem 1.1. The choice of $\gamma$ is the same as before, so that $\|(A_0 \oplus C_0)^k\| = \alpha_k$ and $\|(B_0 \oplus C_0)^k\| = \beta_k$ for $k = 2, \dots, n$. This time, however, we choose $\Gamma$ a little differently, stipulating that $\Gamma \ge \gamma$ and

$$\frac{\Gamma t}{2} \ge \sum_{k=1}^{n}\alpha_k t^k + 2t \qquad \text{and} \qquad \frac{\Gamma t}{2} \ge \sum_{k=1}^{n}\beta_k t^k + 2t \qquad (0 \le t \le 1/\gamma). \tag{3.3}$$

The next step is to perturb $A_0, B_0, C_0$ so as to obtain diagonalizable matrices. To this end, we fix distinct complex numbers $\zeta_1, \dots, \zeta_{n+1}$ of modulus $1/2$, and set

$$D := \mathrm{diag}(\zeta_1, \dots, \zeta_{n+1}) \qquad \text{and} \qquad D' := \mathrm{diag}(\zeta_1, \dots, \zeta_{n+1}, 0).$$

Then, for each $\delta > 0$, we define

$$A_\delta := A_0 + \delta D, \qquad B_\delta := B_0 + \delta D, \qquad \text{and} \qquad C_\delta := C_0 + \delta D'.$$

Each of $A_\delta, B_\delta, C_\delta$ has distinct eigenvalues, so $A_\delta \oplus C_\delta$ and $B_\delta \oplus C_\delta$ are diagonalizable.

By continuity, if $\delta > 0$ is chosen small enough, then

$$\Big| \|(A_\delta \oplus C_\delta)^k\| - \alpha_k \Big| < \epsilon \quad \text{and} \quad \Big| \|(B_\delta \oplus C_\delta)^k\| - \beta_k \Big| < \epsilon \qquad (k = 2, \dots, n).$$

We next show that, reducing $\delta$ if necessary, we have

$$\left\{ \begin{array}{l} \|(C_\delta - zI)^{-1}\| \geq \|(A_\delta - zI)^{-1}\| \\ \|(C_\delta - zI)^{-1}\| \geq \|(B_\delta - zI)^{-1}\| \end{array} \right. \qquad (|z| \geq \gamma). \tag{3.4}$$

By Lemma 2.1, we have

$$\|(I - wC_0)^{-1}\| - \|(I - wA_0)^{-1}\| \geq (1 + \Gamma|w|/2) - \left(1 + \sum_{k=1}^{n} |\alpha_k||w|^k\right) \qquad (w \in \mathbb{C}).$$

From our choice of $\Gamma$ in (3.3), it follows that

$$\|(I - wC_0)^{-1}\| - \|(I - wA_0)^{-1}\| \geq 2|w| \qquad (|w| \leq 1/\gamma).$$

We now apply Lemma 3.1 with $V = I - wA_0$ and $W = I - wA_\delta$. We find that, if $\delta|w|\|D\| \leq 1/(2\|(I - wA_0)^{-1}\|)$, then

$$\|(I - wA_\delta)^{-1} - (I - wA_0)^{-1}\| \leq 2\|(I - wA_0)^{-1}\|^2 \delta|w|\|D\|.$$

It follows that, if $\delta$ is chosen small enough, then

$$\|(I - wA_\delta)^{-1} - (I - wA_0)^{-1}\| \leq |w| \qquad (|w| \leq 1/\gamma).$$

Likewise, if $\delta$ is small enough, then

$$\|(I - wC_\delta)^{-1} - (I - wC_0)^{-1}\| \leq |w| \qquad (|w| \leq 1/\gamma).$$

Putting all of this together, we find that, if $\delta$ is sufficiently small, then

$$\|(I - wC_\delta)^{-1}\| \geq \|(I - wA_\delta)^{-1}\| \qquad (|w| \leq 1/\gamma),$$

from which (3.4) follows for $A$. Evidently, a similar argument applies to $B$.

The next step is to show that, by reducing $\delta$ yet further, we may ensure that

$$\left\{ \begin{array}{l} \|(C_\delta - zI)^{-1}\| \geq \|(A_\delta - zI)^{-1}\| \\ \|(C_\delta - zI)^{-1}\| \geq \|(B_\delta - zI)^{-1}\| \end{array} \right. \qquad (|z| \leq \delta). \tag{3.5}$$

For this we use Lemma 3.2. Applying this lemma with $V = A_\delta - zI$, and recalling that this is an $(n+1) \times (n+1)$ matrix, we obtain

$$\|\operatorname{adj}(A_\delta - zI) - (zI - A_\delta)^n\| \leq 2^{n+1} \rho(A_\delta - zI) \|A_\delta - zI\|^{n-1}.$$

Now $\sigma(A_\delta - zI) = \sigma(\delta D - zI)$, so

$$\rho(A_\delta - zI) = \rho(\delta D - zI) \leq \|\delta D - zI\| \leq \delta + |z|.$$

It follows that

$$\|\operatorname{adj}(A_\delta - zI) - (zI - A_\delta)^n\| \le 2^{n+1}(\delta + |z|)\|A_\delta - zI\|^{n-1}.$$

Note also that $\sup_{|z|\le\delta} \|(zI - A_\delta)^n - (-A_0)^n\| = O(\delta)$ as $\delta \to 0$. Hence there exists a constant $K$, independent of $z, \delta$, such that

$$\|\operatorname{adj}(A_\delta - zI) - (-A_0)^n\| \le K\delta \qquad (|z| \le \delta).$$

Similarly, as $C_\delta$ is an $(n+2)\times(n+2)$ matrix, there exists a constant $K'$ such that

$$\|\operatorname{adj}(C_\delta - zI) - (-C_0)^{n+1}\| \le K'\delta \qquad (|z| \le \delta).$$

Since $A_0^n \ne 0$ and $C_0^{n+1} \ne 0$, it follows that if $\delta$ is small enough, then

$$\left\{\begin{array}{l} \|\operatorname{adj}(C_\delta - zI)\| \ge \|C_0^{n+1}\|/2 \\ \|\operatorname{adj}(A_\delta - zI)\| \le 2\|A_0^n\| \end{array}\right. \qquad (|z| \le \delta).$$

Now

$$\begin{aligned} \operatorname{adj}(C_\delta - zI) &= \det(C_\delta - zI)(C_\delta - zI)^{-1}, \\ \operatorname{adj}(A_\delta - zI) &= \det(A_\delta - zI)(A_\delta - zI)^{-1}, \end{aligned}$$

and

$$\frac{\det(C_\delta - zI)}{\det(A_\delta - zI)} = \frac{\det(\delta D' - zI)}{\det(\delta D - zI)} = -z.$$

Combining these facts, we obtain that, for sufficiently small $\delta > 0$,

$$\frac{\|(C_\delta - zI)^{-1}\|}{\|(A_\delta - zI)^{-1}\|} \ge \frac{1}{|z|}\frac{\|C_0^{n+1}\|}{4\|A_0^n\|} \ge \frac{1}{\delta}\frac{\|C_0^{n+1}\|}{4\|A_0^n\|} \qquad (|z| \le \delta).$$

Thus, if $\delta$ is chosen small enough, then (3.5) holds for $A$. The argument for $B$ is similar.

Fix $\delta > 0$ so that (3.4) and (3.5) hold. Summarizing what we have achieved so far, if we define $A := A_\delta \oplus C_\delta$ and $B := B_\delta \oplus C_\delta$, then $A, B$ are diagonalizable matrices satisfying (1.6) and

$$\|(A - zI)^{-1}\| = \|(B - zI)^{-1}\| \qquad (z \in \mathbb{C} \setminus Q),$$

where $Q$ is the annulus $\{z \in \mathbb{C} : \delta < |z| < \gamma\}$. Our remaining task is to deal with the case $z \in Q$, which we do as follows. Let $L$ be the maximum of $\sup_{z\in Q} \|(A - zI)^{-1}\|$ and $\sup_{z\in Q} \|(B - zI)^{-1}\|$. Cover $Q$ by a finite number of disks of radius $1/L$, with centers $\mu_1, \dots, \mu_m \in Q$, say. Define $E := \operatorname{diag}(\mu_1, \dots, \mu_m)$. Then we have

$$\left\{\begin{array}{l} \|(E - zI)^{-1}\| \ge \|(A - zI)^{-1}\| \\ \|(E - zI)^{-1}\| \ge \|(B - zI)^{-1}\| \end{array}\right. \qquad (z \in Q).$$

Thus, if we replace $A, B$ with $A \oplus E, B \oplus E$, respectively, then they have identical pseudospectra. Evidently the new $A, B$ are still diagonalizable. Finally, as $\mu_1, \dots, \mu_m \in Q$, we have $\|E^k\| \le \gamma^k \le \min(\alpha_k, \beta_k)$ for $k = 2, \dots, n$, and so (1.6) still holds. The construction is complete. $\square$

[illegible] The construction yields matrices $A, B$ having eigenvalues of multiplicity at most two. It would be interesting to obtain an example where the eigenvalues were all of multiplicity one.

**4. Proofs of Theorems 1.3 and 1.4.** Theorem 1.3 is an easy consequence of the following result of Greenbaum and Trefethen. Recall that the Hilbert–Schmidt norm of a square matrix $A$ is defined by

$$\|A\|_{HS} := \sqrt{\operatorname{trace}(A^*A)}.$$

THEOREM 4.1 (see [3, Theorem 3]). [illegible] $A, B \in \mathbb{C}^{N\times N}$ [illegible]

$$\|(zI - A)^{-1}\|_{HS} = \|(zI - B)^{-1}\|_{HS} \qquad (z \in \mathbb{C}). \tag{4.1}$$

[illegible] $p$

$$\|p(A)\|_{HS} = \|p(B)\|_{HS}. \tag{4.2}$$

Since [3] was never published, we also include a brief proof for the reader's convenience.

[illegible] Setting $\zeta = 1/z$, we see that (4.1) is equivalent to

$$\operatorname{trace}[(I - \overline{\zeta}A^*)^{-1}(I - \zeta A)^{-1}] = \operatorname{trace}[(I - \overline{\zeta}B^*)^{-1}(I - \zeta B)^{-1}] \qquad (\zeta \in \mathbb{C}). \tag{4.3}$$

Expanding, we deduce that, for some $r > 0$,

$$\sum_{k,l\geq 0} \operatorname{trace}(A^{*k}A^l)\overline{\zeta}^k\zeta^l = \sum_{k,l\geq 0} \operatorname{trace}(B^{*k}B^l)\overline{\zeta}^k\zeta^l \qquad (|\zeta| < r).$$

Taking $\left(\frac{\partial}{\partial\overline{\zeta}}\right)^k\left(\frac{\partial}{\partial\zeta}\right)^l$ of both sides and then setting $\zeta = 0$, we obtain

$$\operatorname{trace}(A^{*k}A^l) = \operatorname{trace}(B^{*k}B^l) \qquad (k, l \geq 0).$$

Now, let $p$ be a polynomial, say $p(z) = \sum_{j=0}^n a_j z^j$. Then

$$\begin{aligned}\operatorname{trace}(p(A)^*p(A)) &= \sum_{k,l=0}^n \overline{a}_k a_l \operatorname{trace}(A^{*k}A^l)\\ &= \sum_{k,l=0}^n \overline{a}_k a_l \operatorname{trace}(B^{*k}B^l)\\ &= \operatorname{trace}(p(B)^*p(B)),\end{aligned}$$

whence we have $\|p(A)\|_{HS} = \|p(B)\|_{HS}$. This completes the proof. □

[illegible] 1.3 Observe that $\|A\|_{HS}^2 = \sum_{j=1}^N s_j(A)^2$. Thus, hypothesis (1.7) implies that (4.1), and consequently also (4.2), holds. For each polynomial $p$, we therefore have

$$\sum_{j=1}^N s_j(p(A))^2 = \sum_{j=1}^N s_j(p(B))^2.$$

Recalling that the usual operator norm $\|\cdot\|$ is just the first singular value $s_1$, we thus obtain

$$\|p(A)\|^2 = s_1(p(A))^2 \leq \sum_{j=1}^N s_j(p(A))^2 = \sum_{j=1}^N s_j(p(B))^2 \leq Ns_1(p(B))^2 = N\|p(B)\|^2.$$

This gives the right-hand side of (1.8), and the left-hand side is proved similarly. □

[illegible] In going from (1.7) to (4.1), we are losing some information. In fact (1.7) is equivalent to the following, more complicated version of (4.3):

$$\operatorname{trace}\Big([(I-\overline{\zeta}A^*)^{-1}(I-\zeta A)^{-1}]^n\Big) = \operatorname{trace}\Big([(I-\overline{\zeta}B^*)^{-1}(I-\zeta B)^{-1}]^n\Big) \quad (\zeta \in \mathbb{C},\ n \geq 1).$$

Until now, we have not seen how to exploit this.

[illegible] 1.4 We repeat the construction in the proof of Theorem 1.1, defining $A_0, B_0, C_0$ exactly as in that proof. This time, however, we define

$$A := A_0 \oplus \overbrace{C_0 \oplus \cdots \oplus C_0}^{m} \qquad \text{and} \qquad B := B_0 \oplus \overbrace{C_0 \oplus \cdots \oplus C_0}^{m}.$$

Then $A, B \in \mathbb{C}^{N \times N}$, where $N = (n+1) + m(n+2) = (m+1)(n+2) - 1$. Just as before, we have

$$\|A^k\| = \max(\|A_0^k\|, \|C_0^k\|, \ldots, \|C_0^k\|) = \alpha_k \qquad (k = 2, \ldots, n),$$

which holds similarly for $B$, so (1.10) holds. Also, since

$$(zI - A)^{-1} = (zI - A_0)^{-1} \oplus \overbrace{(zI - C_0)^{-1} \oplus \cdots \oplus (zI - C_0)^{-1}}^{m},$$

and $\|(zI - C_0)^{-1}\| \geq \|(zI - A_0)^{-1}\|$ for all $z \in \mathbb{C}$ (see (2.4)), it follows that

$$s_j\Big((zI - A)^{-1}\Big) = \|(zI - C_0)^{-1}\| \qquad (z \in \mathbb{C},\ j = 1, \ldots, m).$$

Likewise, the same is true when $A$ is replaced with $B$. Thus (1.9) holds, and the proof is complete. □

## 5. Proofs of Theorems 1.5 and 1.6.

We shall in fact prove the following slight generalization of Theorem 1.5.

Theorem 5.1. [illegible] $A, B \in \mathbb{C}^{N \times N}$ [illegible]

$$\|(I - \zeta A)^{-1}\|_1 = \|(I - \zeta B)^{-1}\|_1 + o(\zeta) \qquad \text{[illegible]} \quad \zeta \to 0,\ \zeta \in \mathbb{C}.$$

[illegible] $\|A\|_1 = \|B\|_1$

[illegible] The norm $\|\cdot\|_1$ has the particularity that $\|A\|_1 = \max(|Ae_1|_1, \ldots, |Ae_N|_1)$, where $e_1, \ldots, e_N$ is the standard unit vector basis of $\mathbb{C}^N$. Fix a $j$ so that $\|A\|_1 = |Ae_j|_1$. Multiplying $A$ and $B$ by the same unimodular constant, we may suppose that $a_{jj} \geq 0$; in other words, the $j$th entry in $Ae_j$ is nonnegative. It then follows that, for all $t \geq 0$,

$$|(I + tA)e_j|_1 = 1 + t|Ae_j|_1 = 1 + t\|A\|_1.$$

On the other hand, as $t \to 0^+$, we have

$$\begin{aligned} |(I + tA)e_j|_1 \leq \|I + tA\|_1 &= \|(I - tA)^{-1}\|_1 + o(t) \\ &= \|(I - tB)^{-1}\|_1 + o(t) \leq 1 + t\|B\|_1 + o(t). \end{aligned}$$

Combining these facts, we deduce that $\|A\|_1 \leq \|B\|_1$. By symmetry, $\|B\|_1 \leq \|A\|_1$ as well. □

[illegible] This theorem may be viewed as a result about numerical ranges in Banach algebras. For background on numerical ranges, we refer to [1, 2]. Let $(\mathcal{A}, \|\cdot\|_{\mathcal{A}})$ be a Banach algebra with identity 1, and given $a \in \mathcal{A}$, let $\nu_{\mathcal{A}}(a)$ denote the numerical radius of $a$. It is well known that

$$\nu_{\mathcal{A}}(a) = \limsup_{\zeta \to 0} \frac{\|1 + \zeta a\|_{\mathcal{A}} - 1}{|\zeta|} \qquad (a \in \mathcal{A}),$$

and also that there exists a constant $n(\mathcal{A}) \in [e^{-1}, 1]$, called the [illegible] of $\mathcal{A}$, such that

$$n(\mathcal{A})\|a\|_{\mathcal{A}} \le \nu_{\mathcal{A}}(a) \le \|a\|_{\mathcal{A}} \qquad (a \in \mathcal{A}).$$

From these facts it follows easily that, if $a, b \in \mathcal{A}$ satisfy

$$\|(1 - \zeta a)^{-1}\| = \|(1 - \zeta b)^{-1}\| + o(\zeta) \qquad \text{as } \zeta \to 0,\ \zeta \in \mathbb{C},$$

then $\nu_{\mathcal{A}}(a) = \nu_{\mathcal{A}}(b)$, and hence

$$n(\mathcal{A}) \le \|a\|_{\mathcal{A}}/\|b\|_{\mathcal{A}} \le n(\mathcal{A})^{-1}.$$

Moreover, it is known that the numerical indices of $(\mathbb{C}^{N\times N}, \|\cdot\|)$ and $(\mathbb{C}^{N\times N}, \|\cdot\|_1)$ are equal to 1/2 and 1, respectively. We thus recover as special cases both the result (1.2) mentioned earlier and Theorem 5.1 above.

We now turn to the proof of Theorem 1.6. Recall that the notion of admissible norm on $\mathbb{C}^{N\times N}$ was defined in the introduction, and that the weighted shift $S(\omega_1, \ldots, \omega_n)$ was defined in (2.1).

LEMMA 5.2. [illegible] $\omega_1, \ldots, \omega_n$ [illegible] $S = S(\omega_1, \ldots, \omega_n)$ [illegible] $|||\cdot|||$ [illegible] $\mathbb{C}^{(n+1)\times(n+1)}$ [illegible]

$$|||S^k||| = \omega_k \qquad (k = 1, \ldots, n)$$

[illegible]

$$1 + \max_{1\le k\le n} \frac{\omega_k |z|^k}{2} \le |||(I - zS)^{-1}||| \le 1 + \sum_{k=1}^{n} \omega_k |z|^k \qquad (z \in \mathbb{C}).$$

[illegible] Repeat the proof of Lemma 2.1, observing that it is valid for every admissible norm. □

[illegible] 1.6 Repeat the proof of Theorem 1.1, using Lemma 5.2 in place of Lemma 2.1. Note that the choices of $\gamma$ and $\Gamma$ depend only on the $\alpha_j$ and $\beta_j$, and not on the particular norm. Thus, the same pair of matrices $A, B$ works simultaneously for all admissible norms $|||\cdot|||$. □

**Acknowledgments.** I am greatly indebted to Nick Trefethen for introducing me to this topic, for making available the article [3], and for numerous invaluable discussions. This work was carried out while I was visiting the Mathematical Institute of the University of Oxford and the Oxford University Computing Laboratory, and I am grateful to both institutions for their hospitality.

# MEAN-SQUARED ERROR ESTIMATION FOR LINEAR SYSTEMS WITH BLOCK CIRCULANT UNCERTAINTY*

AMIR BECK†, YONINA C. ELDAR‡, AND AHARON BEN-TAL§

**Abstract.** We consider the problem of estimating a vector $\mathbf{x}$ in the linear model $\mathbf{Ax} \approx \mathbf{y}$, where $\mathbf{A}$ is a block circulant (BC) matrix with $N$ blocks and $\mathbf{x}$ is assumed to have a weighted norm bound. In the case where both $\mathbf{A}$ and $\mathbf{y}$ are subjected to noise, we propose a minimax mean-squared error (MSE) approach in which we seek the linear estimator that minimizes the worst-case MSE over a BC structured uncertainty region. For an arbitrary choice of weighting, we show that the minimax MSE estimator can be formulated as a solution to a semidefinite programming problem (SDP), which can be solved efficiently. For a Euclidean norm bound on $\mathbf{x}$, the SDP is reduced to a simple convex program with $N+1$ unknowns. Finally, we demonstrate through an image deblurring example the potential of the minimax MSE approach in comparison with other conventional methods.

## 1. Introduction.

Many problems in data fitting and estimation give rise to a system of linear equations $\mathbf{Ax} \approx \mathbf{y}$, where both the matrix $\mathbf{A}$ and the right-hand side $\mathbf{y}$ are contaminated by noise. Given the observation $\mathbf{y}$, we seek an estimator $\hat{\mathbf{x}}$ of $\mathbf{x}$ that is close in some sense to $\mathbf{x}$. This estimation problem arises in a large variety of areas in science and engineering, e.g., communication, economics, signal processing, seismology, and control.

Several approaches for dealing with uncertainties in the model matrix $\mathbf{A}$ and right-hand side vector $\mathbf{y}$ are known in the literature. In the *total least-squares* (TLS) strategy [11, 15], one seeks the minimal norm perturbations $\mathbf{\Delta A}, \mathbf{\Delta y}$ of the nominal model matrix $\mathbf{A}$ and observation vector $\mathbf{y}$ such that the linear system $(\mathbf{A}+\mathbf{\Delta A})\mathbf{x} = \mathbf{y}+\mathbf{\Delta y}$ is consistent. An alternative strategy is the *robust least-squares* (RLS) method [10, 22, 6]. Here the underlying assumption is that the perturbation matrix $\mathbf{\Delta A}$ and the perturbation vector $\mathbf{\Delta y}$ belong to some bounded uncertainty set $\mathcal{U}$. The solution (or estimator) is chosen to minimize the worst-case data error (or "residual") over the uncertainty region:

$$\hat{\mathbf{x}}_{\mathrm{RLS}} \in \operatorname*{argmin}_{\mathbf{x}} \max_{(\mathbf{\Delta A},\mathbf{\Delta y})\in\mathcal{U}} \|(\mathbf{A}+\mathbf{\Delta A})\mathbf{x} - \mathbf{y} - \mathbf{\Delta y}\|^2. \tag{1.1}$$

Both the RLS and TLS solutions optimize a criterion that is based on the *data error*

*residual* ($\|\mathbf{A}\mathbf{x}-\mathbf{y}\|$ or $\|(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A})\mathbf{x}-\mathbf{y}-\boldsymbol{\Delta}\mathbf{y}\|$) and therefore might provide poor solutions in terms of the *estimation error* $\|\mathbf{x}-\hat{\mathbf{x}}\|$. In view of this, the work [8] suggests seeking an estimator $\hat{\mathbf{x}}$ that minimizes the *mean-squared error* (MSE):

$$\text{MSE} = E(\|\mathbf{x}-\hat{\mathbf{x}}\|^2),$$

and restricting attention to *linear estimators* of the form $\hat{\mathbf{x}} = \mathbf{G}\mathbf{y}$. The expectation is with respect to the noise vector $\boldsymbol{\Delta}\mathbf{y}$, which is assumed to have a zero mean and a positive definite covariance matrix $\mathbf{C}$. For a linear estimator, the MSE is equal to the sum of the variance $V(\hat{\mathbf{x}})$ and the squared norm of the bias $B(\hat{\mathbf{x}})$:

$$E(\|\mathbf{x}-\hat{\mathbf{x}}\|^2) = \underbrace{\operatorname{Tr}(\mathbf{G}\mathbf{C}\mathbf{G}^*)}_{V(\hat{\mathbf{x}})} + \underbrace{\mathbf{x}^*(\mathbf{I}-\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}))^*(\mathbf{I}-\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}))\mathbf{x}}_{\|B(\hat{\mathbf{x}})\|^2}.$$

Since the bias depends on the unknown vector $\mathbf{x}$ and the unknown perturbation matrix $\boldsymbol{\Delta}\mathbf{A}$, we cannot choose an estimator to directly minimize the MSE. The approach advocated in [8, 7], in order to minimize the MSE, is to use additional a priori information on the vector $\mathbf{x}$, such as an upper bound on its weighted norm, $\mathbf{x}^*\mathbf{T}\mathbf{x} \le L^2$, where $\mathbf{T}$ is a positive definite matrix, and minimize the worst-case MSE. This leads to the following optimization problem:

$$\min_{\mathbf{G}} \max_{\mathbf{x}^*\mathbf{T}\mathbf{x}\le L^2,\, \Delta\mathbf{A}\in\mathcal{U}} E(\|\mathbf{x}-\hat{\mathbf{x}}\|^2), \tag{1.2}$$

where $\mathcal{U}$ is an uncertainty set associated with the matrix $\mathbf{A}$. The optimal solution $\mathbf{G}$ of the latter problem is called the *minimax MSE matrix*, and the associated linear estimator $\hat{\mathbf{x}} = \mathbf{G}\mathbf{y}$ is termed the *minimax MSE estimator*. In the case when $\mathcal{U}$ is given by a single norm bound, it was shown in [8] that the optimal $\mathbf{G}$ can be obtained by solving a semidefinite programming (SDP) problem. In practice, if $L$ is unknown, then we can estimate it from the data, for example by using the LS estimator [3].

In this paper we study the minimax MSE estimator when the matrix $\mathbf{A}$ has a *block circulant* (BC) structure:

$$\mathbf{A} = \begin{pmatrix} \mathbf{A}_0 & \mathbf{A}_1 & \cdots & \mathbf{A}_{N-1} \\ \mathbf{A}_{N-1} & \mathbf{A}_0 & \cdots & \mathbf{A}_{N-2} \\ \vdots & \vdots & & \vdots \\ \mathbf{A}_1 & \mathbf{A}_2 & \cdots & \mathbf{A}_0 \end{pmatrix}, \tag{1.3}$$

where $\mathbf{A}_j \in \mathbb{C}^{n\times m}$, $0 \le j \le N-1$. We use the notation $\mathbf{A} = \mathcal{C}(\mathbf{A}_0,\dots,\mathbf{A}_{N-1})$ for brevity. The BC structure of $\mathbf{A}$ imposes the same structure on the perturbation matrix, i.e., $\boldsymbol{\Delta}\mathbf{A} = \mathcal{C}(\boldsymbol{\Delta}\mathbf{A}_0,\dots,\boldsymbol{\Delta}\mathbf{A}_{N-1})$ with $\boldsymbol{\Delta}\mathbf{A}_j \in \mathbb{C}^{n\times m}$. We also assume that both the covariance matrix $\mathbf{C}$ and weighting matrix $\mathbf{T}$ are positive definite BC (which includes the case $\mathbf{C} = \sigma^2\mathbf{I}$ and $\mathbf{T} = \mathbf{I}$). Thus, the optimization problem we consider is

$$\min_{\mathbf{G}} \max_{\mathbf{x}^*\mathbf{T}\mathbf{x}\le L^2,\, \Delta\mathbf{A}\in\mathcal{U}_\Delta} \left\{\operatorname{Tr}(\mathbf{G}\mathbf{C}\mathbf{G}^*) + \mathbf{x}^*(\mathbf{I}-\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}))^*(\mathbf{I}-\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}))\mathbf{x}\right\}, \tag{1.4}$$

where the set $\mathcal{U}_\Delta$, which is the set of possible values of $\boldsymbol{\Delta}\mathbf{A}$, is given by

$$\mathcal{U}_\Delta \overset{\triangle}{=} \{\boldsymbol{\Delta} = \mathcal{C}(\boldsymbol{\Delta}_0,\dots,\boldsymbol{\Delta}_{N-1}) : \|\boldsymbol{\Delta}_k\| \le \rho_k,\ 0 \le k \le N-1\}. \tag{1.5}$$

Here $\|\mathbf{M}\|$ denotes the Frobenius norm of $\mathbf{M}$.

The BC model has previously been used in a variety of signal processing problems, including image restoration [17], cyclic convolution filter banks [20], texture synthesis and recognition [24], and detection techniques for CDMA systems [26]. Moreover, in many practical scenarios $\mathbf{A}$ is a block Toeplitz matrix which can be approximated by a BC matrix [12, 9]. We refer the reader to the example in section 5 that describes a usage of this Toeplitz/circulant approximation in an image deblurring context. The BC structure also includes the multiple observation model in which the matrix $\mathbf{A}$ is a block diagonal matrix with the same diagonal matrix (corresponding to $\mathbf{A}_1 = \mathbf{A}_2 = \cdots = \mathbf{A}_{N-1} = \mathbf{0}$ in (1.3)). The minimax MSE estimator for the multiple observation model was studied in [2].

Besides including several cases of practical interest, one of the attributes of the BC structure is its analytical tractability. In fact the minimax MSE problem (1.4) is intractable for most choices of uncertainty sets $\mathcal{U}_\Delta$. However, in the BC model we are able to exploit properties of BC matrices (in particular, the matrix discrete Fourier transform (DFT)) that will enable us to develop a computationally tractable scheme for computing the minimax MSE estimator.

The BC model has been investigated in the context of structured TLS problems in [1], where it was shown that by using the matrix DFT, the problem can be decomposed into several unstructured TLS problems.

The paper is organized as follows. We begin by reviewing in section 2 some properties of BC matrices and the matrix DFT. In section 3 we first show that under the BC model, the optimal minimax MSE estimator $\hat{\mathbf{x}} = \mathbf{G}\mathbf{y}$ is such that $\mathbf{G}$ is a BC matrix. This allows us to formulate the minimax MSE estimator as a solution to an SDP, which is a tractable (i.e., polynomial solvable) convex optimization problem that can be solved, e.g., using interior point methods [21, 25, 4]. In section 4 we treat the case where the weighting matrix $\mathbf{T}$ is the identity matrix $\mathbf{I}$. When the matrix $\mathbf{A}$ is [illegible], we derive an explicit formula for the minimax MSE estimator. When $\mathbf{A}$ is [illegible] but the noise vector consists of independent and identically distributed random variables ($\mathbf{C} = \sigma^2\mathbf{I}$), we show that the task of computing the minimax MSE estimator reduces to solving a simple convex program in $N+1$ variables. Finally, we demonstrate through an image deblurring example, in section 5, the potential of the minimax MSE approach in comparison with other conventional strategies.

[illegible]. We denote vectors by boldface lowercase letters and matrices by boldface uppercase letters. The identity matrix of appropriate dimension is denoted by $\mathbf{I}$, $(\cdot)^*$ and $(\cdot)^T$ denote the Hermitian conjugate and the transpose of the corresponding matrices, respectively, and $\hat{(\cdot)}$ denotes an estimated vector. For two Hermitian matrices $\mathbf{A}, \mathbf{B}$, the notation $\mathbf{A} \succeq \mathbf{B}$ means that $\mathbf{A} - \mathbf{B}$ is a positive semidefinite matrix. For a Hermitian matrix $\mathbf{A}$, $\lambda_{\max}(\mathbf{A})$ denotes the largest eigenvalue of $\mathbf{A}$. We denote by $\|\mathbf{v}\|$ the Euclidean norm of the vector $\mathbf{v}$ and by $\|\mathbf{A}\| = \sqrt{\mathrm{Tr}(\mathbf{A}^*\mathbf{A})}$ the Frobenius norm of the matrix $\mathbf{A}$. For a given matrix $\mathbf{M}$, $\mathbf{m} = \mathrm{vec}(\mathbf{M})$ denotes the vector obtained by stacking the columns of $\mathbf{M}$.

## 2. BC matrices and the DFT.

The aim of this short section is to give a brief review of results on BC matrices and the DFT defined on them that will be used later in the paper. These results can also be found in [1, 2], and they are presented here for completeness.

We begin by noting that the result of multiplication, addition, and conjugation of BC matrices is also a BC matrix. Let $\mathbf{A} = \mathcal{C}(\mathbf{A}_0, \mathbf{A}_1, \dots, \mathbf{A}_{N-1})$; then the DFT of $\mathbf{A}$ is also a BC matrix of the same dimensions given by

$$\mathbf{F}(\mathbf{A}) = \mathcal{C}(\mathbf{F}_0(\mathbf{A}), \mathbf{F}_1(\mathbf{A}), \dots, \mathbf{F}_{N-1}(\mathbf{A})),$$

where $\mathbf{F}_j(\mathbf{A})$ are defined as

$$\mathbf{F}_j(\mathbf{A}) \triangleq \sum_{k=0}^{N-1} \omega^{kj}\mathbf{A}_k, \quad 0 \le j \le N-1,$$

with $\omega = e^{-\frac{2\pi i}{N}}$ (here $i = \sqrt{-1}$). The matrices $\mathbf{F}_j(\mathbf{A})$ are called the [illegible]. The inverse DFT, denoted by $\mathbf{F}^{-1}$, is defined by $\mathbf{F}^{-1}(\mathbf{A}) = (\mathbf{F}_0^{-1}(\mathbf{A}), \mathbf{F}_1^{-1}(\mathbf{A}), \dots, \mathbf{F}_{N-1}^{-1}(\mathbf{A}))$, where

$$\mathbf{F}_j^{-1}(\mathbf{A}) = \frac{1}{N}\sum_{k=0}^{N-1} \omega^{-kj}\mathbf{A}_k, \quad 0 \le j \le N-1.$$

Note that $\mathbf{F}^{-1}$ is indeed an inverse of $\mathbf{F}$ in the sense that for every BC matrix $\mathbf{A}$

$$\mathbf{F}^{-1}(\mathbf{F}(\mathbf{A})) = \mathbf{A}, \quad \mathbf{F}(\mathbf{F}^{-1}(\mathbf{A})) = \mathbf{A}.$$

The following properties of $\mathbf{F}_j$ are generalizations of well-known properties of the DFT.

LEMMA 2.1. [illegible] $\mathbf{A}$ $\mathbf{B}$ [illegible] $\mathbf{C}$ [illegible] $0 \le j \le N-1$ [illegible]

1. $(\mathbf{F}_j(\mathbf{A}))^* = \mathbf{F}_j(\mathbf{A}^*)$
2. $\mathbf{F}_j(\mathbf{I}_{mN}) = \mathbf{I}_m$
3. $\mathbf{F}_j(\mathbf{A}+\mathbf{C}) = \mathbf{F}_j(\mathbf{A}) + \mathbf{F}_j(\mathbf{C})$
4. $\mathbf{F}_j(\mathbf{AB}) = \mathbf{F}_j(\mathbf{A})\mathbf{F}_j(\mathbf{B})$
5. [illegible] $\mathbf{A}$ [illegible] $\mathbf{F}_j(\mathbf{A}^{-1}) = (\mathbf{F}_j(\mathbf{A}))^{-1}$

Theorem 2.1 shows that the eigenvalues of a Hermitian BC matrix are exactly the eigenvalues of its discrete Fourier components. Theorem 2.1 below is an extension of a well-known result on circulant matrices to the case of Hermitian block circulant matrices; for a proof, see, e.g., [2, Theorem A.1].

THEOREM 2.1. [illegible] $\mathbf{A}_0, \mathbf{A}_1, \dots, \mathbf{A}_{N-1} \in \mathbb{C}^{k\times k}$ [illegible] $\mathbf{A} = \mathcal{C}(\mathbf{A}_0, \mathbf{A}_1, \dots, \mathbf{A}_{N-1})$ [illegible] $0 \le j \le N-1$ [illegible] $\lambda_{j,0}, \lambda_{j,1}, \dots, \lambda_{j,k-1}$ [illegible] $\mathbf{F}_j(\mathbf{A})$ [illegible] $\mathbf{A}$ [illegible] $N \cdot k$ [illegible] $\lambda_{j,i}$ $0 \le i \le k-1$ $0 \le j \le N-1$

## 3. Minimax MSE estimator for BC systems.

We now use the properties of BC matrices and the DFT discussed in the previous section in order to find a $\mathbf{G}$ which is a solution to (1.4). Section 3.1 establishes the fact that $\mathbf{G}$ can always be chosen as a BC matrix. In section 3.2 we use this structure of $\mathbf{G}$ to find an SDP formulation of the estimation problem (1.4), where an SDP is the problem of minimizing a linear objective subject to linear matrix inequality (LMI) constraints, i.e., constraints of the form $\mathcal{B}(\mathbf{x}) \succeq 0$, where the matrix $\mathcal{B}$ depends linearly on $\mathbf{x}$. The advantage in this formulation is that it readily lends itself to efficient computational methods. Indeed, by exploiting the many well-known algorithms for solving SDPs, e.g., interior point methods [21, 25, 23], the optimal estimator can be computed efficiently in polynomial time. Furthermore, SDP-based algorithms are guaranteed to converge to the global optimum.

### 3.1. The structure of G.

Before proceeding, we introduce some notation. The set of all permutations of $\{0, 1, \dots, N-1\}$ is denoted by $S_N$. For every permutation

$\sigma \in S_N$ and a positive integer $l$, we associate an $lN \times lN$ matrix $\mathbf{P}_{\sigma,l}$ comprised of $N \times N$ blocks of size $l \times l$. The $(k, j)$ block of $\mathbf{P}_{\sigma,l}$ is defined as

$$(\mathbf{P}_{\sigma,l})_{k,j} = \delta_{j,\sigma(k)}\mathbf{I}_l,$$

where

$$\delta_{k,j} = \begin{cases} 0, & k \neq j, \\ 1, & k = j \end{cases}$$

is the Kronecker delta. For example, if $N = 3$ and $\sigma(0) = 1$, $\sigma(1) = 0$, and $\sigma(2) = 2$, then

$$\mathbf{P}_{\sigma,3} = \begin{pmatrix} \mathbf{0} & \mathbf{I}_3 & \mathbf{0} \\ \mathbf{I}_3 & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{I}_3 \end{pmatrix},$$

where $\mathbf{I}_3$ is the identity matrix of size $3 \times 3$. We will be interested particularly in a special class of permutations,

$$\mathcal{A} = \{\sigma_0, \sigma_1, \ldots, \sigma_{N-1}\},$$

where $\sigma_k(j) = (j + k) \bmod N$. For example, if $N = 3$, then

$$\mathbf{P}_{\sigma_0,3} = \begin{pmatrix} \mathbf{I}_3 & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{I}_3 & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{I}_3 \end{pmatrix}, \quad \mathbf{P}_{\sigma_2,3} = \begin{pmatrix} \mathbf{0} & \mathbf{0} & \mathbf{I}_3 \\ \mathbf{I}_3 & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{I}_3 & \mathbf{0} \end{pmatrix}.$$

Permutation matrices $\mathbf{P}_{\sigma,l}$ satisfy some interesting properties that will be useful later on in the proof of Theorem 3.1.

[illegible] A. For every $\sigma \in S_N$ and positive integer $l$, $\mathbf{P}_{\sigma,l}\mathbf{P}^*_{\sigma,l} = \mathbf{P}^*_{\sigma,l}\mathbf{P}_{\sigma,l} = \mathbf{I}$.

[illegible] B. For every BC matrix $\mathbf{A} = \mathcal{C}(\mathbf{A}_0, \mathbf{A}_1, \ldots, \mathbf{A}_{N-1})$, where $\mathbf{A}_k \in \mathbb{C}^{m,n}$, and every permutation $\sigma$ in the class $\mathcal{A}$, we have that $\mathbf{P}_{\sigma,m}\mathbf{A}\mathbf{P}^*_{\sigma,n} = \mathbf{A}$ or, equivalently, $\mathbf{P}_{\sigma,m}\mathbf{A} = \mathbf{A}\mathbf{P}_{\sigma,n}$.

The main result of this section is presented in Theorem 3.1, where we show that the solution of (1.4) is a BC matrix, i.e., $\mathbf{G} = \mathcal{C}(\mathbf{G}_0, \mathbf{G}_1, \ldots, \mathbf{G}_{N-1})$ for some $\mathbf{G}_0, \ldots, \mathbf{G}_{N-1} \in \mathbb{C}^{m \times n}$.

THEOREM 3.1. [illegible] $\mathbf{x}$ [illegible] $\mathbf{y} = (\mathbf{A} + \mathbf{\Delta A})\mathbf{x} + \mathbf{\Delta y}$ [illegible] $\mathbf{A}$ [illegible] $\mathbf{\Delta A}$ [illegible] $\mathbf{\Delta A} \in \mathcal{U}_\Delta$ [illegible] $\mathcal{U}_\Delta$ [illegible] (1.5) [illegible] $\mathbf{\Delta y}$ [illegible] $\mathbf{C}$ [illegible] $\mathbf{T}$ [illegible]

$$\min_{\mathbf{G}} \max_{\mathbf{x}^*\mathbf{T}\mathbf{x} \le L^2,\, \Delta\mathbf{A} \in \mathcal{U}_\Delta} E(\|\hat{\mathbf{x}} - \mathbf{x}\|^2)$$

[illegible] $\mathbf{G}$ [illegible]

[illegible]. We first rewrite problem (1.2) as

$$\min_{\mathbf{G} \in \mathbb{C}^{m \times n}} \Gamma(\mathbf{G}), \tag{3.1}$$

where

$$\Gamma(\mathbf{G}) = \max_{\mathbf{x}^*\mathbf{T}\mathbf{x} \le L^2,\, \Delta\mathbf{A} \in \mathcal{U}_\Delta} E(\|\hat{\mathbf{x}} - \mathbf{x}\|^2).$$

The function $\Gamma$ can be decomposed as follows (see (1.4)):

$$\Gamma(\mathbf{G}) = \theta_1(\mathbf{G}) + \theta_2(\mathbf{G}),$$

where

$$\begin{aligned}
\theta_1(\mathbf{G}) &= \operatorname{Tr}(\mathbf{G}\mathbf{C}\mathbf{G}^*),\\
\theta_2(\mathbf{G}) &= \max_{\mathbf{x}^*\mathbf{T}\mathbf{x}\le L^2,\, \Delta\mathbf{A}\in\mathcal{U}_\Delta} \varphi(\mathbf{G},\mathbf{x},\boldsymbol{\Delta}\mathbf{A}),
\end{aligned}$$

and $\varphi(\mathbf{G},\mathbf{x},\boldsymbol{\Delta}\mathbf{A}) \overset{\triangle}{=} \mathbf{x}^*(\mathbf{I}-\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}))^*(\mathbf{I}-\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}))\mathbf{x}$. It is easy to see that the positive definiteness of $\mathbf{C}$ implies strict convexity of $\theta_1$. Moreover, since $\varphi$ is a convex function with respect to $\mathbf{G}$, it follows that $\theta_2$, being a maximum of convex functions, is also a convex function. Thus, $\Gamma = \theta_1 + \theta_2$ is a strictly convex function, and hence it has a unique optimal solution.

Using Properties A and B, we have

$$\begin{aligned}
\theta_1(\mathbf{G}) = \operatorname{Tr}(\mathbf{G}\mathbf{C}\mathbf{G}^*) &\overset{A}{=} \operatorname{Tr}(\mathbf{P}^*_{\sigma,m}\mathbf{P}_{\sigma,m}\mathbf{G}\mathbf{C}\mathbf{G}^*)\\
&= \operatorname{Tr}(\mathbf{P}_{\sigma,m}\mathbf{G}\mathbf{C}\mathbf{G}^*\mathbf{P}^*_{\sigma,m})\\
&\overset{B}{=} \operatorname{Tr}(\mathbf{P}_{\sigma,m}\mathbf{G}\mathbf{P}^*_{\sigma,n}\mathbf{C}\mathbf{P}_{\sigma,n}\mathbf{G}^*\mathbf{P}^*_{\sigma,m})\\
&= \operatorname{Tr}((\mathbf{P}_{\sigma,m}\mathbf{G}\mathbf{P}^*_{\sigma,n})\mathbf{C}(\mathbf{P}_{\sigma,m}\mathbf{G}\mathbf{P}^*_{\sigma,n})^*)\\
&= \theta_1(\mathbf{P}_{\sigma,m}\mathbf{G}\mathbf{P}^*_{\sigma,n})
\end{aligned}$$

and

$$\begin{aligned}
\theta_2(\mathbf{G}) &= \max_{\mathbf{x}^*\mathbf{T}\mathbf{x}\le L^2,\, \Delta\mathbf{A}\in\mathcal{U}_\Delta} \{\mathbf{x}^*(\mathbf{I}-\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}))^*(\mathbf{I}-\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}))\mathbf{x}\}\\
&= \max_{\mathbf{x}^*\mathbf{P}^*_{\sigma,m}\mathbf{T}\mathbf{P}_{\sigma,m}\mathbf{x}\le L^2,\, \Delta\mathbf{A}\in\mathcal{U}_\Delta} \{\mathbf{x}^*\mathbf{P}^*_{\sigma,m}(\mathbf{I}-\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}))^*(\mathbf{I}-\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}))\mathbf{P}_{\sigma,m}\mathbf{x}\}\\
&\overset{B}{=} \max_{\mathbf{x}^*\mathbf{T}\mathbf{x}\le L^2,\, \Delta\mathbf{A}\in\mathcal{U}_\Delta} \{\mathbf{x}^*\mathbf{P}^*_{\sigma,m}(\mathbf{I}-\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}))^*(\mathbf{I}-\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}))\mathbf{P}_{\sigma,m}\mathbf{x}\}\\
&\overset{A}{=} \max_{\mathbf{x}^*\mathbf{T}\mathbf{x}\le L^2,\, \Delta\mathbf{A}\in\mathcal{U}_\Delta} \{\mathbf{x}^*\mathbf{P}^*_{\sigma,m}(\mathbf{I}-\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}))^*\mathbf{P}_{\sigma,m}\mathbf{P}^*_{\sigma,m}(\mathbf{I}-\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}))\mathbf{P}_{\sigma,m}\mathbf{x}\}\\
&\overset{A}{=} \max_{\mathbf{x}^*\mathbf{T}\mathbf{x}\le L^2,\, \Delta\mathbf{A}\in\mathcal{U}_\Delta} \{\mathbf{x}^*(\mathbf{I}-\mathbf{P}_{\sigma,m}\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A})\mathbf{P}^*_{\sigma,m})^*(\mathbf{I}-\mathbf{P}_{\sigma,m}\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A})\mathbf{P}^*_{\sigma,m})\mathbf{x}\}\\
&\overset{B}{=} \max_{\mathbf{x}^*\mathbf{T}\mathbf{x}\le L^2,\, \Delta\mathbf{A}\in\mathcal{U}_\Delta} \{\mathbf{x}^*(\mathbf{I}-(\mathbf{P}_{\sigma,m}\mathbf{G}\mathbf{P}^*_{\sigma,n})(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}))^*(\mathbf{I}-(\mathbf{P}_{\sigma,m}\mathbf{G}\mathbf{P}^*_{\sigma,n})(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}))\mathbf{x}\}\\
&= \theta_2(\mathbf{P}_{\sigma,m}\mathbf{G}\mathbf{P}^*_{\sigma,n}).
\end{aligned}$$

Therefore, $\Gamma(\mathbf{G}) = \Gamma(\mathbf{P}_{\sigma,m}\mathbf{G}\mathbf{P}^*_{\sigma,n})$. We conclude that if $\mathbf{G}$ is an optimal solution of (3.1), then so is $\mathbf{P}_{\sigma,m}\mathbf{G}\mathbf{P}^*_{\sigma,n}$ for all $\sigma\in\mathcal{A}$. Hence, by the convexity of $\Gamma$ it follows that the convex combination $\frac{1}{N}\sum_{\sigma\in\mathcal{A}}\mathbf{P}_{\sigma,m}\mathbf{G}\mathbf{P}^*_{\sigma,n}$ is also an optimal solution. However, it can be easily verified that $\frac{1}{N}\sum_{\sigma\in\mathcal{A}}\mathbf{P}_{\sigma,m}\mathbf{G}\mathbf{P}^*_{\sigma,n} = \mathcal{C}(\mathbf{G}_0,\mathbf{G}_1,\ldots,\mathbf{G}_{N-1})$ for some matrices $\mathbf{G}_0,\mathbf{G}_1,\ldots,\mathbf{G}_{N-1}\in\mathbb{C}^{m\times n}$. Specifically, if

$$\mathbf{G} = \begin{pmatrix}
\mathbf{G}_{00} & \mathbf{G}_{01} & \cdots & \mathbf{G}_{0,N-1}\\
\mathbf{G}_{10} & \mathbf{G}_{11} & \cdots & \mathbf{G}_{1,N-1}\\
\vdots & \vdots & & \vdots\\
\mathbf{G}_{N-1,0} & \mathbf{G}_{N-1,1} & \cdots & \mathbf{G}_{N-1,N-1}
\end{pmatrix},$$

then $\mathbf{G}_k = \frac{1}{N}\sum_{i=0}^{N-1}\mathbf{G}_{i,i+k}$, $0\le k\le N-1$. $\square$

**3.2. SDP formulation of the estimation problem.** We now use Theorem 3.1 to develop an SDP formulation of (1.4). We first consider the inner maximization problem

$$\max_{\mathbf{x}^*\mathbf{T}\mathbf{x}\le L^2} \mathbf{x}^*(\mathbf{I}-\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}))^*(\mathbf{I}-\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}))\mathbf{x}. \tag{3.2}$$

As a result of Theorem 3.1, we can assume that $\mathbf{G}$ is a BC matrix. Since $\mathbf{I}$, $\mathbf{T}$, and $\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}$ are also BC matrices, it follows that $\mathbf{H}\equiv\mathbf{T}^{-1/2}(\mathbf{I}-\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}))^*(\mathbf{I}-\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}))\mathbf{T}^{-1/2}$ is a BC matrix. By the properties listed in Lemma 2.1, we can deduce that for every $0\le j\le N-1$

$$\begin{aligned}\mathbf{F}_j(\mathbf{H}) &= \mathbf{F}_j(\mathbf{T})^{-1/2}\mathbf{F}_j((\mathbf{I}-\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}))^*(\mathbf{I}-\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A})))\mathbf{F}_j(\mathbf{T})^{-1/2}\\ &= \mathbf{S}_j\left(\mathbf{I}-\mathbf{E}_j(\mathbf{F}_j(\mathbf{A})+\mathbf{F}_j(\boldsymbol{\Delta}\mathbf{A}))\right)^*\left(\mathbf{I}-\mathbf{E}_j(\mathbf{F}_j(\mathbf{A})+\mathbf{F}_j(\boldsymbol{\Delta}\mathbf{A}))\right)\mathbf{S}_j,\end{aligned} \tag{3.3}$$

where $\mathbf{S}_j=\mathbf{F}_j(\mathbf{T})^{-1/2}$ and $\mathbf{E}_j=\mathbf{F}_j(\mathbf{G})$. Therefore, by Theorem 2.1, we have

$$\begin{aligned}&\max_{\mathbf{x}^*\mathbf{T}\mathbf{x}\le L^2,\,\boldsymbol{\Delta}\mathbf{A}\in\mathcal{U}_\Delta} \mathbf{x}^*(\mathbf{I}-\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}))^*(\mathbf{I}-\mathbf{G}(\mathbf{A}+\boldsymbol{\Delta}\mathbf{A}))\mathbf{x}\\ &\quad= NL^2\max_{\boldsymbol{\Delta}\mathbf{A}\in\mathcal{U}_\Delta}\max_{0\le j\le N-1}\alpha_j(\boldsymbol{\Delta}\mathbf{A}),\end{aligned} \tag{3.4}$$

where $\alpha_j(\boldsymbol{\Delta}\mathbf{A})$ is given by

$$\lambda_{\max}\left(\mathbf{S}_j(\mathbf{I}-\mathbf{E}_j(\mathbf{F}_j(\mathbf{A})+\mathbf{F}_j(\boldsymbol{\Delta}\mathbf{A})))^*(\mathbf{I}-\mathbf{E}_j(\mathbf{F}_j(\mathbf{A})+\mathbf{F}_j(\boldsymbol{\Delta}\mathbf{A})))\mathbf{S}_j\right). \tag{3.5}$$

We can therefore express (3.4) as the solution to the problem

$$\min_{\tau} NL^2\tau \tag{3.6}$$

subject to

$$\mathbf{S}_j(\mathbf{I}-\mathbf{E}_j(\mathbf{F}_j(\mathbf{A})+\mathbf{F}_j(\boldsymbol{\Delta}\mathbf{A})))^*(\mathbf{I}-\mathbf{E}_j(\mathbf{F}_j(\mathbf{A})+\mathbf{F}_j(\boldsymbol{\Delta}\mathbf{A})))\mathbf{S}_j\preceq\tau\mathbf{I} \tag{3.7}$$

for every $\boldsymbol{\Delta}\mathbf{A}\in\mathcal{U}_\Delta$. Invoking Schur's lemma [4], we can rewrite the constraint (3.7) as

$$\begin{pmatrix}\tau\mathbf{I} & \mathbf{S}_j(\mathbf{I}-\mathbf{E}_j(\mathbf{F}_j(\mathbf{A})+\mathbf{F}_j(\boldsymbol{\Delta}\mathbf{A})))^*\\ (\mathbf{I}-\mathbf{E}_j(\mathbf{F}_j(\mathbf{A})+\mathbf{F}_j(\boldsymbol{\Delta}\mathbf{A})))\mathbf{S}_j & \mathbf{I}\end{pmatrix}\succeq 0,$$

which can be further written as

$$\mathbf{R}_j\succeq\mathbf{P}_j^*\mathbf{F}_j(\boldsymbol{\Delta}\mathbf{A})\mathbf{Q}_j+\mathbf{Q}_j^*\mathbf{F}_j(\boldsymbol{\Delta}\mathbf{A})^*\mathbf{P}_j\quad\forall\boldsymbol{\Delta}\mathbf{A}\in\mathcal{U}_\Delta, \tag{3.8}$$

where

$$\mathbf{R}_j=\begin{pmatrix}\tau\mathbf{I} & \mathbf{S}_j(\mathbf{I}-\mathbf{E}_j\mathbf{F}_j(\mathbf{A}))^*\\ (\mathbf{I}-\mathbf{E}_j\mathbf{F}_j(\mathbf{A}))\mathbf{S}_j & \mathbf{I}\end{pmatrix},$$
$$\mathbf{P}_j=\begin{pmatrix}\mathbf{0} & \mathbf{E}_j^*\end{pmatrix},\quad \mathbf{Q}_j=\begin{pmatrix}\mathbf{S}_j & \mathbf{0}\end{pmatrix}.$$

We now exploit the following lemma, the proof of which is very similar to the proof of Lemma 2 in [8] and thus is omitted here.

LEMMA 3.1. $\mathbf{P},\mathbf{Q},\mathbf{R}$ $\mathbf{R}=\mathbf{R}^*$ $\mathcal{U}_\Delta$ (1.5)

$$\mathbf{R}\succeq\mathbf{P}^*\mathbf{F}_j(\mathbf{X})\mathbf{Q}+\mathbf{Q}^*\mathbf{F}_j(\mathbf{X})^*\mathbf{P}\qquad\mathbf{X}\in\mathcal{U}_\Delta\qquad 0\le j\le N-1$$

[illegible] $\lambda \geq 0$ [illegible]

$$\begin{pmatrix} \mathbf{R} - \lambda \mathbf{Q}^*\mathbf{Q} & -\rho \mathbf{P}^* \\ -\rho \mathbf{P} & \lambda \mathbf{I} \end{pmatrix} \succeq 0,$$

[illegible] $\rho = \sum_{j=0}^{N-1} \rho_j$

From Lemma 3.1, it follows that (3.8) is satisfied if and only if there exists $\lambda_j \geq 0$, $0 \leq j \leq N-1$, such that

$$\begin{pmatrix} \tau \mathbf{I} - \lambda_j \mathbf{F}_j(\mathbf{T})^{-1} & \mathbf{S}_j(\mathbf{I} - \mathbf{E}_j \mathbf{F}_j(\mathbf{A}))^* & \mathbf{0} \\ (\mathbf{I} - \mathbf{E}_j \mathbf{F}_j(\mathbf{A}))\mathbf{S}_j & \mathbf{I} & -\rho \mathbf{E}_j \\ \mathbf{0} & -\rho \mathbf{E}_j^* & \lambda_j \mathbf{I} \end{pmatrix} \succeq 0 \tag{3.9}$$

with $\rho = \sum_{j=0}^{N-1} \rho_j$. Summarizing the above derivations, we see that problem (1.4) reduces to

$$\min_{\tau, \lambda_j, \mathbf{G}} \left\{ \mathrm{Tr}(\mathbf{G}\mathbf{C}\mathbf{G}^*) + NL^2 \tau \right\}$$

subject to (3.9).

Since $\mathbf{C}$ and $\mathbf{G}$ are both BC matrices, the product $\mathbf{G}\mathbf{C}\mathbf{G}^*$ is also a BC matrix. Let $\mathbf{G}\mathbf{C}\mathbf{G}^* = \mathcal{C}(\mathbf{S}_0, \mathbf{S}_2, \ldots, \mathbf{S}_{N-1})$ for some $\mathbf{S}_0, \mathbf{S}_2, \ldots, \mathbf{S}_{N-1} \in \mathbb{C}^{m \times m}$. Then $\mathrm{Tr}(\mathbf{G}\mathbf{C}\mathbf{G}^*) = N \,\mathrm{Tr}(\mathbf{S}_0)$. However,

$$N\mathbf{S}_0 = N\mathbf{F}_0^{-1}(\mathbf{F}(\mathbf{G}\mathbf{C}\mathbf{G}^*)) = \sum_{j=0}^{N-1} \mathbf{F}_j(\mathbf{G}\mathbf{C}\mathbf{G}^*) = \sum_{j=0}^{N-1} \mathbf{E}_j \mathbf{F}_j(\mathbf{C}) \mathbf{E}_j^*. \tag{3.10}$$

We thus arrive at the following formulation of problem (1.4):

$$\min_{\tau, \lambda_j, \mathbf{E}_j} \left\{ NL^2 \tau + \sum_{j=0}^{N-1} \mathrm{Tr}(\mathbf{E}_j \mathbf{F}_j(\mathbf{C}) \mathbf{E}_j^*) \right\} \tag{3.11}$$

subject to

$$\begin{pmatrix} \tau \mathbf{I} - \lambda_j \mathbf{F}_j(\mathbf{T})^{-1} & \mathbf{S}_j(\mathbf{I} - \mathbf{E}_j \mathbf{F}_j(\mathbf{A}))^* & \mathbf{0} \\ (\mathbf{I} - \mathbf{E}_j \mathbf{F}_j(\mathbf{A}))\mathbf{S}_j & \mathbf{I} & -\rho \mathbf{E}_j \\ \mathbf{0} & -\rho \mathbf{E}_j^* & \lambda_j \mathbf{I} \end{pmatrix} \succeq 0, \quad 0 \leq j \leq N-1, \tag{3.12}$$

which is equivalent to

$$\min_{\tau, t_j, \mathbf{E}_j, \lambda_j} \left\{ \sum_{j=0}^{N-1} t_j + NL^2 \tau \right\} \tag{3.13}$$

subject to the LMI (3.12) and

$$\mathrm{Tr}(\mathbf{E}_j \mathbf{F}_j(\mathbf{C}) \mathbf{E}_j^*) \leq t_j, \quad 0 \leq j \leq N-1, \tag{3.14}$$

which can clearly be expressed as an LMI (see (3.15)). Thus, our problem reduces finally to an SDP.

We summarize our results in Theorem 3.2, where we present the SDP formulation for the circulant model.

Theorem 3.2 (SDP formulation). [illegible] 3.1 [illegible] (1.4) [illegible] $\mathbf{G}=\mathcal{C}(\mathbf{G}_0,\dots,\mathbf{G}_{N-1})$ [illegible]

$$\mathbf{G}_j=\frac{1}{N}\sum_{k=0}^{N-1}\omega^{-kj}\mathbf{E}_k,\quad 0\le j\le N-1.$$

[illegible] $\omega=e^{-\frac{2\pi i}{N}}$ [illegible] $\mathbf{E}_j$ $0\le j\le N-1$ [illegible]

$$\min_{\tau,\lambda_j,t_j,\mathbf{E}_j}\left\{NL^2\tau+\sum_{j=0}^{N-1}t_j\right\}$$

[illegible]

$$\begin{pmatrix} t_j & \mathbf{e}_j^* \\ \mathbf{e}_j & \mathbf{I}\end{pmatrix}\succeq 0,\quad 0\le j\le N-1, \tag{3.15}$$

$$\begin{pmatrix} \tau\mathbf{I}-\lambda_j\mathbf{F}_j(\mathbf{T})^{-1} & \mathbf{S}_j(\mathbf{I}-\mathbf{E}_j\mathbf{F}_j(\mathbf{A}))^* & \mathbf{0} \\ (\mathbf{I}-\mathbf{E}_j\mathbf{F}_j(\mathbf{A}))\mathbf{S}_j & \mathbf{I} & -\rho\mathbf{E}_j \\ \mathbf{0} & -\rho\mathbf{E}_j^* & \lambda_j\mathbf{I}\end{pmatrix}\succeq 0,$$

[illegible] $\mathbf{e}_j=\mathrm{vec}(\mathbf{E}_j\mathbf{F}_j(\mathbf{C})^{1/2})$ $\mathbf{S}_j=\mathbf{F}_j(\mathbf{T})^{-1/2}$ [illegible] $\rho=\sum_{j=0}^{N-1}\rho_j$

**4. Minimax MSE estimator for $\mathbf{T}=\mathbf{I}$.** In this section we discuss a special case of the minimax MSE estimator problem where $\mathbf{T}=\mathbf{I}$. When $\mathbf{A}$ is certain, we find an explicit expression for the optimal minimax MSE estimator. In the case of uncertain $\mathbf{A}$, we show that the SDP problem of Theorem 3.2 can be reduced to a simple convex optimization problem in $N+1$ unknowns.

**4.1. Minimax MSE estimator for $\mathbf{T}=\mathbf{I}$ with known $\mathbf{A}$.** In the case of known $\mathbf{A}$, we return to the problem of a single system $\mathbf{y}=\mathbf{A}\mathbf{x}+\mathbf{\Delta y}$ with $\mathbf{x}^*\mathbf{T}\mathbf{x}\le L^2$. This problem was discussed in [8], where it was shown that the minimax MSE estimator for the case $\mathbf{T}=\mathbf{I}$ is given by $\hat{\mathbf{x}}=\mathbf{G}\mathbf{y}$ with

$$\mathbf{G}=\alpha(\mathbf{A}^*\mathbf{C}^{-1}\mathbf{A})^{-1}\mathbf{A}^*\mathbf{C}^{-1}, \tag{4.1}$$

where $\alpha=\frac{L^2}{L^2+B}$ and

$$B=\mathrm{Tr}\left((\mathbf{A}^*\mathbf{C}^{-1}\mathbf{A})^{-1}\right). \tag{4.2}$$

The estimator of (4.1) is a [illegible] proposed by Mayer and Willke [19], which is simply a scaled version of the LS estimator with an optimal choice of shrinkage factor.

Note that the dominant computation in (4.1) and (4.2) is the inversion of the $mN\times mN$ matrix $\mathbf{A}^*\mathbf{C}^{-1}\mathbf{A}$, which requires $O(m^3N^3)$ operations. This number is prohibitively large even for medium size problems. On the other hand, the calculation stemming from Theorem 4.1, which exploits the BC structure, requires the inversion of $N$ DFT components, each an $m\times m$ matrix resulting in a total of only $O(m^3N)$ operations. For example, if $N=100$, then our computation is 10000 cheaper than the direct computation.

Theorem 4.1. [illegible] $\mathbf{x}$ [illegible] $\mathbf{y}=\mathbf{A}\mathbf{x}+\mathbf{\Delta y}$ [illegible] $\mathbf{A}$ [illegible] $\mathbf{\Delta y}$ [illegible] $\mathbf{C}$ [illegible]

$\min_{\mathbf{G}} \max_{\|\mathbf{x}\|^2 \le L^2} E(\|\hat{\mathbf{x}} - \mathbf{x}\|^2)$ [illegible] $\mathbf{G} = \mathcal{C}(\mathbf{G}_0, \mathbf{G}_1, \ldots, \mathbf{G}_{N-1})$ [illegible]

$$\mathbf{G}_j = \frac{1}{N} \sum_{k=0}^{N-1} \omega^{-kj} \mathbf{E}_k, \quad 0 \le j \le N-1.$$

[illegible]

$$\mathbf{E}_j = \frac{L^2}{L^2 + B} \left(\mathbf{F}_j(\mathbf{A})^* \mathbf{F}_j(\mathbf{C})^{-1} \mathbf{F}_j(\mathbf{A})\right)^{-1} \mathbf{F}_j(\mathbf{A})^* \mathbf{F}_j(\mathbf{C})^{-1}, \quad 0 \le j \le N-1,$$

[illegible] $B = \sum_{j=0}^{N-1} \operatorname{Tr}\left((\mathbf{F}_j(\mathbf{A})^* \mathbf{F}_j(\mathbf{C})^{-1} \mathbf{F}_j(\mathbf{A}))^{-1}\right)$

[illegible] First, we note that $B$ of (4.2) is equal to $\sum_{i=1}^{mN} \frac{1}{\lambda_i}$, where $\lambda_1, \lambda_2, \ldots, \lambda_{mN}$ are the eigenvalues of $\mathbf{A}^* \mathbf{C}^{-1} \mathbf{A}$. From Theorem 2.1, it follows that

$$B = \sum_{j=0}^{N-1} \operatorname{Tr}\left((\mathbf{F}_j(\mathbf{A})^* \mathbf{F}_j(\mathbf{C})^{-1} \mathbf{F}_j(\mathbf{A}))^{-1}\right).$$

By Theorem 3.1, $\mathbf{G}$ is a BC matrix and thus is equal to $\mathcal{C}(\mathbf{G}_0, \mathbf{G}_1, \ldots, \mathbf{G}_{N-1})$ for some $\mathbf{G}_0, \mathbf{G}_1, \ldots, \mathbf{G}_{N-1} \in \mathbb{C}^{m \times n}$. Using the properties listed in Lemma 2.1, we can calculate the $j$th DFT component of $\mathbf{G}$ (denoted by $\mathbf{E}_j$):

$$\begin{aligned} \mathbf{E}_j &= \mathbf{F}_j \left( \frac{L^2}{L^2 + B} (\mathbf{A}^* \mathbf{C}^{-1} \mathbf{A})^{-1} \mathbf{A}^* \mathbf{C}^{-1} \right) \\ &= \frac{L^2}{L^2 + B} (\mathbf{F}_j(\mathbf{A})^* \mathbf{F}_j(\mathbf{C})^{-1} \mathbf{F}_j(\mathbf{A}))^{-1} \mathbf{F}_j(\mathbf{A})^* \mathbf{F}_j(\mathbf{C})^{-1}. \end{aligned}$$

Applying the inverse DFT, we obtain the desired expression for $\mathbf{G}_j$, and the result follows. □

As can be expected intuitively, when $L \to \infty$, the minimax MSE estimator $\hat{\mathbf{x}} = \mathbf{G}\mathbf{y}$ of Theorem 4.1 reduces to the LS estimator. Indeed, when the norm of $\mathbf{x}$ can be made arbitrarily large, the MSE will also be arbitrarily large unless the bias is equal to zero. Therefore, in this limit, the worst-case estimation error is minimized by choosing an estimator with zero bias that minimizes the variance, which leads to the LS solution.

### 4.2. Minimax estimator for $\mathbf{T} = \mathbf{I}$, $\mathbf{C} = \sigma^2\mathbf{I}$, and unknown model matrix.

We now show that in the case where $\mathbf{T} = \mathbf{I}$ and $\mathbf{C} = \sigma^2 \mathbf{I}$, the minimax MSE estimator reduces to a simple convex optimization problem in $N+1$ unknowns.

THEOREM 4.2. [illegible] 3.1 [illegible] $\mathbf{C} = \sigma^2 \mathbf{I}$ [illegible] $0 \le j \le N-1$ [illegible] $\mathbf{F}_j(\mathbf{A}) = \mathbf{U}_j \Sigma_j \mathbf{V}_j^*$ [illegible] $\mathbf{F}_j(\mathbf{A})$ [illegible] $j$ [illegible] $\mathbf{A}$ [illegible] $\Sigma_j$ [illegible] $n \times m$ [illegible] $\sigma_{j,k} > 0$ $1 \le k \le m$ [illegible] $\mathbf{U}_j$ [illegible] $\mathbf{V}_j$ [illegible] $\min_{\mathbf{G}} \max_{\|\mathbf{x}\|^2 \le L^2, \Delta\mathbf{A} \in \mathcal{U}_\Delta} E(\|\hat{\mathbf{x}} - \mathbf{x}\|^2)$ [illegible] $\mathbf{G} = \mathcal{C}(\mathbf{G}_0, \mathbf{G}_1, \ldots, \mathbf{G}_{N-1})$ [illegible] $\mathbf{G}_j = \mathbf{F}_j^{-1}(\mathbf{E})$ $\mathbf{E} = \mathcal{C}(\mathbf{E}_0, \ldots, \mathbf{E}_{N-1})$ [illegible]

$$\mathbf{E}_j = \mathbf{V}_j \mathbf{Z}_j \mathbf{V}_j^* (\mathbf{F}_j(\mathbf{A})^* \mathbf{F}_j(\mathbf{A}))^{-1/2} \mathbf{F}_j(\mathbf{A})^*, \quad 0 \le j \le N-1,$$

[illegible] $\mathbf{Z}_j$ [illegible] $m \times m$ [illegible] $z_{j,k} = f_{j,k}(\tau, \lambda_j)$ [illegible]

$$f_{j,k}(\tau, \lambda_j) = \frac{\sigma_{j,k}\lambda_j - \sqrt{\lambda_j(\tau - \lambda_j)\left(\sigma_{j,k}^2 \lambda_j - \rho^2(1 + \lambda_j - \tau)\right)}}{(\tau - \lambda_j)\rho^2 + \sigma_{j,k}^2 \lambda_j},$$

[illegible] $\rho = \sum_{j=0}^{N-1} \rho_j$, [illegible] $\lambda_0, \dots, \lambda_{N-1}$, [illegible] $\tau$ [illegible]

$$\min_{\tau, \lambda_j} \left\{ \sigma^2 \sum_{j=0}^{N-1} \sum_{k=1}^{m} f_{j,k}^2(\tau, \lambda_j) + NL^2\tau \right\}$$

[illegible]

$$\begin{aligned} \lambda_j \sigma_{j,k}^2 &\geq \rho^2(1 + \lambda_j - \tau), \quad 1 \leq k \leq m, \quad 0 \leq j \leq N-1, \\ \lambda_j &\geq 0, \quad 0 \leq j \leq N-1, \\ \tau &\geq \lambda_j, \quad 0 \leq j \leq N-1. \end{aligned}$$

[illegible] From Theorem 3.2, the optimal estimator $\mathbf{G}$ is equal to $\mathcal{C}(\mathbf{G}_0, \dots, \mathbf{G}_{N-1})$, where $\mathbf{G}_j = \frac{1}{N} \sum_{k=0}^{N-1} \omega^{-kj} \mathbf{E}_k$ and $(\mathbf{E}_j)_{j=0}^{N-1}$ is the solution to

$$\min_{\tau, \mathbf{E}_j, \lambda_j} \left\{ \sigma^2 \sum_{j=0}^{N-1} \operatorname{Tr}(\mathbf{F}_j(\mathbf{E}) \mathbf{F}_j(\mathbf{E})^*) + NL^2\tau \right\}, \tag{4.3}$$

subject to

$$\mathbf{M}_j \triangleq \begin{pmatrix} (\tau - \lambda_j)\mathbf{I} & (\mathbf{I} - \mathbf{E}_j \mathbf{F}_j(\mathbf{A}))^* & \mathbf{0} \\ (\mathbf{I} - \mathbf{E}_j \mathbf{F}_j(\mathbf{A})) & \mathbf{I} & -\rho \mathbf{E}_j \\ \mathbf{0} & -\rho \mathbf{E}_j^* & \lambda_j \mathbf{I} \end{pmatrix} \succeq 0. \tag{4.4}$$

The proof of the theorem is comprised of three parts. First, we show that the optimal solution $(\mathbf{E}_j)_{j=0}^{N-1}$ to (4.3) and (4.4) is of the form

$$\mathbf{E}_j = \mathbf{V}_j \mathbf{Z}_j \mathbf{V}_j^* \left( \mathbf{F}_j(\mathbf{A})^* \mathbf{F}_j(\mathbf{A}) \right)^{-1/2} \mathbf{F}_j(\mathbf{A})^*, \quad 0 \leq j \leq N-1, \tag{4.5}$$

for some $m \times m$ matrices $\mathbf{Z}_0, \mathbf{Z}_1, \dots, \mathbf{Z}_{N-1}$. We then show that $\mathbf{Z}_0, \mathbf{Z}_1, \dots, \mathbf{Z}_{N-1}$ can be chosen as diagonal matrices. Finally, we find the diagonal elements of $\mathbf{Z}_0, \mathbf{Z}_1, \dots, \mathbf{Z}_{N-1}$.

We begin by showing that the optimal $(\mathbf{E}_j)_{j=0}^{N-1}$ has the form (4.5). The constraint (4.4) is equivalent to $\mathbf{Q}_j \mathbf{M}_j \mathbf{Q}_j^* \succeq 0$ for any invertible $\mathbf{Q}_j$. Choosing

$$\mathbf{Q}_j = \begin{pmatrix} \mathbf{V}_j^* & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{V}_j^* & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{U}_j^* \end{pmatrix}, \quad 0 \leq j \leq N-1,$$

(4.4) becomes

$$\begin{pmatrix} (\tau - \lambda_j)\mathbf{I} & \mathbf{V}_j^* (\mathbf{I} - \mathbf{E}_j \mathbf{F}_j(\mathbf{A}))^* \mathbf{V}_j & \mathbf{0} \\ \mathbf{V}_j^* (\mathbf{I} - \mathbf{E}_j \mathbf{F}_j(\mathbf{A})) \mathbf{V}_j & \mathbf{I} & -\rho \mathbf{V}_j^* \mathbf{E}_j \mathbf{U}_j \\ \mathbf{0} & -\rho \mathbf{U}_j^* \mathbf{E}_j^* \mathbf{V} & \lambda_j \mathbf{I} \end{pmatrix} \succeq 0. \tag{4.6}$$

Making the change of variables

$$\mathbf{B}_j \triangleq \mathbf{V}_j^* \mathbf{E}_j \mathbf{U}_j, \tag{4.7}$$

so that

$$\mathbf{E}_j = \mathbf{V}_j \mathbf{B}_j \mathbf{U}_j^*, \tag{4.8}$$

the problem of (4.3) and (4.6) can be expressed as

$$\min_{\tau,\lambda_j,\mathbf{B}_j}\left\{\sigma^2\sum_{j=0}^{N-1}\mathrm{Tr}(\mathbf{B}_j^*\mathbf{B}_j)+NL^2\tau\right\} \tag{4.9}$$

subject to

$$\begin{pmatrix} (\tau-\lambda_j)\mathbf{I} & (\mathbf{I}-\mathbf{B}_j\Sigma_j)^* & \mathbf{0}\\ (\mathbf{I}-\mathbf{B}_j\Sigma_j) & \mathbf{I} & -\rho\mathbf{B}_j\\ \mathbf{0} & -\rho\mathbf{B}_j^* & \lambda_j \end{pmatrix}\succeq 0. \tag{4.10}$$

Let $\mathbf{B}_j=(\mathbf{Z}_j\ \mathbf{W}_j)$, where $\mathbf{Z}_j$ is the $m\times m$ matrix consisting of the first $m$ columns of $\mathbf{B}_j$, and let $\widetilde{\Sigma}_j$ denote the $m\times m$ matrix with diagonal elements $\sigma_{j,k}$, $1\le k\le m$, for every $0\le j\le N-1$. Then we can express the constraint (4.10) as

$$\mathbf{L}(\mathbf{B}_j)\triangleq\begin{pmatrix} (\tau-\lambda_j)\mathbf{I} & (\mathbf{I}-\mathbf{Z}_j\widetilde{\Sigma}_j)^* & \mathbf{0} & \mathbf{0}\\ (\mathbf{I}-\mathbf{Z}_j\widetilde{\Sigma}_j) & \mathbf{I} & -\rho\mathbf{Z}_j & -\rho\mathbf{W}_j\\ \mathbf{0} & -\rho\mathbf{Z}_j^* & \lambda_j\mathbf{I} & \mathbf{0}\\ \mathbf{0} & -\rho\mathbf{W}_j^* & \mathbf{0} & \lambda_j\mathbf{I} \end{pmatrix}\succeq 0. \tag{4.11}$$

Clearly, if (4.11) is satisfied, then

$$\mathbf{K}(\mathbf{Z}_j)\triangleq\begin{pmatrix} (\tau-\lambda_j)\mathbf{I} & (\mathbf{I}-\mathbf{Z}_j\widetilde{\Sigma}_j)^* & \mathbf{0}\\ (\mathbf{I}-\mathbf{Z}_j\widetilde{\Sigma}_j) & \mathbf{I} & -\rho\mathbf{Z}_j\\ \mathbf{0} & -\rho\mathbf{Z}_j^* & \lambda_j \end{pmatrix}\succeq 0. \tag{4.12}$$

Now let $\mathbf{B}_j=(\mathbf{Z}_j\ \mathbf{W}_j)$ be any matrix satisfying (4.11), and define $\widetilde{\mathbf{B}}_j=(\mathbf{Z}_j\ \mathbf{0})$. Then

$$\mathbf{L}(\widetilde{\mathbf{B}}_j)=\begin{pmatrix} \mathbf{K}(\mathbf{Z}_j) & \mathbf{0}\\ \mathbf{0} & \lambda_j \end{pmatrix}\succeq\mathbf{0},$$

since $\mathbf{K}(\mathbf{Z}_j)\succeq\mathbf{0}$. In addition,

$$\mathrm{Tr}(\widetilde{\mathbf{B}}_j^*\widetilde{\mathbf{B}}_j)=\mathrm{Tr}(\mathbf{Z}_j^*\mathbf{Z}_j)\le\mathrm{Tr}(\mathbf{Z}_j^*\mathbf{Z}_j)+\mathrm{Tr}(\mathbf{W}_j^*\mathbf{W}_j)=\mathrm{Tr}(\mathbf{B}_j^*\mathbf{B}_j).$$

Therefore, the optimal value of $\mathbf{B}_j$ satisfies $\mathbf{W}_j=\mathbf{0}$ for every $0\le j\le N-1$, so that the problem of (4.9) and (4.10) reduces to

$$\min_{\tau,\mathbf{Z}_j,\lambda_j}\left\{\sigma^2\sum_{j=0}^{N-1}\mathrm{Tr}(\mathbf{Z}_j^*\mathbf{Z}_j)+NL^2\tau\right\}, \tag{4.13}$$

subject to (4.12). Once we find the optimal $(\mathbf{Z}_j)_{j=0}^{N-1}$, the optimal $(\mathbf{E}_j)_{j=0}^{N-1}$ can be found from (4.8) as

$$\mathbf{E}_j=\mathbf{V}_j\mathbf{Z}_j(\mathbf{I}\ \mathbf{0})\mathbf{U}_j^*=\mathbf{V}_j\mathbf{Z}_j\mathbf{V}_j^*(\mathbf{F}_j(\mathbf{A})^*\mathbf{F}_j(\mathbf{A}))^{-1/2}\mathbf{F}_j(\mathbf{A})^*,$$

thus completing the first part of the proof.

We now show that the optimal values of $(\mathbf{Z}_j)_{j=0}^{N-1}$ can be chosen as diagonal matrices. To this end, we first note that if $(\mathbf{Z}_j)_{j=0}^{N-1}$ satisfies (4.12), then for every

$0 \le j \le N-1$

$$
\begin{aligned}
&\widetilde{\mathbf{J}}\begin{pmatrix} (\tau-\lambda_j)\mathbf{I} & (\mathbf{I}-\mathbf{Z}_j\widetilde{\Sigma}_j)^* & \mathbf{0} \\ (\mathbf{I}-\mathbf{Z}_j\widetilde{\Sigma}_j) & \mathbf{I} & -\rho\mathbf{Z}_j \\ \mathbf{0} & -\rho\mathbf{Z}_j^* & \lambda_j \end{pmatrix}\widetilde{\mathbf{J}} \\
&= \begin{pmatrix} (\tau-\lambda_j)\mathbf{I} & (\mathbf{I}-\mathbf{J}\mathbf{Z}_j\mathbf{J}\widetilde{\Sigma}_j)^* & \mathbf{0} \\ (\mathbf{I}-\mathbf{J}\mathbf{Z}_j\mathbf{J}\widetilde{\Sigma}_j) & \mathbf{I} & -\rho\mathbf{J}\mathbf{Z}_j\mathbf{J} \\ \mathbf{0} & -\rho\mathbf{J}\mathbf{Z}_j^*\mathbf{J} & \lambda_j \end{pmatrix} \succeq 0, \qquad (4.14)
\end{aligned}
$$

where $\mathbf{J}$ is any diagonal matrix with diagonal elements $\pm 1$, $\widetilde{\mathbf{J}} = \operatorname{diag}(\mathbf{J},\mathbf{J},\mathbf{J})$, and we have used the fact that diagonal matrices commute and that $\mathbf{J}^*\mathbf{J} = \mathbf{J}^2 = \mathbf{I}$. It follows from (4.14) that $\mathbf{K}(\widetilde{\mathbf{Z}}_j) \succeq \mathbf{0}$ for any $\mathbf{J}$, where $\widetilde{\mathbf{Z}}_j = \mathbf{J}\mathbf{Z}_j\mathbf{J}$. In addition, we have that $\operatorname{Tr}(\widetilde{\mathbf{Z}}_j^*\widetilde{\mathbf{Z}}_j) = \operatorname{Tr}(\mathbf{Z}_j^*\mathbf{Z}_j)$. Therefore, if $(\mathbf{Z}_j)_{j=0}^{N-1}$ is an optimal solution, then so is $(\mathbf{J}\mathbf{Z}_j\mathbf{J})_{j=0}^{N-1}$. Since our problem is convex, the set of optimal solutions is also convex [18], which implies that $(\mathbf{Z}'_j)_{j=0}^{N-1} = ((1/2^m)\sum_{\mathbf{J}}\mathbf{J}\mathbf{Z}_j\mathbf{J})_{j=0}^{N-1}$ is also a solution, where the summation is over all $2^m$ diagonal matrices $\mathbf{J}$ with diagonal elements $\pm 1$. It is easy to see that $\mathbf{Z}'_j$ is a diagonal matrix. Therefore, we have shown that there exists an optimal diagonal solution $\mathbf{Z}_j$ for every $0 \le j \le N-1$.

Denote the diagonal elements of $\mathbf{Z}_j$ by $z_{j,k}$, $1 \le k \le m$, and let $\operatorname{diag}(\alpha_1,\dots,\alpha_m)$ denote the $m \times m$ diagonal matrix with diagonal elements $\alpha_j$. By permuting the rows and the columns of the matrix $\mathbf{K}(\mathbf{Z}_j)$, it can be seen that the constraint $\mathbf{K}(\mathbf{Z}_j) \succeq \mathbf{0}$ can be written as

$$
\begin{pmatrix} \tau-\lambda_j & 1-\sigma_{j,k}z_{j,k} & 0 \\ 1-\sigma_{j,k}z_{j,k} & 1 & -\rho z_{j,k} \\ 0 & -\rho z_{j,k} & \lambda_j \end{pmatrix}, \quad 1 \le k \le m. \qquad (4.15)
$$

Thus, the problem of (4.13) and (4.12) becomes

$$
\min_{\tau, z_{j,k}, \lambda_j} \left\{ \sigma^2 \sum_{j=0}^{N-1}\sum_{i=1}^{m} z_{j,k}^2 + NL^2\tau \right\} \qquad (4.16)
$$

subject to

$$
\begin{pmatrix} \tau-\lambda_j & 1-\sigma_{j,k}z_{j,k} & 0 \\ 1-\sigma_{j,k}z_{j,k} & 1 & -\rho z_{j,k} \\ 0 & -\rho z_{j,k} & \lambda_j \end{pmatrix} \succeq 0 \qquad (4.17)
$$

for every $1 \le k \le m$, $0 \le j \le N-1$. We now show that the problem of (4.16) subject to (4.17) can be further simplified. First, we note that to satisfy (4.17) we must have that

$$
\tau \ge \max_{0 \le j \le N-1} \lambda_j.
$$

Suppose first that $\tau > \max_{0 \le j \le N-1}\lambda_j$. In this case, by Schur's lemma, (4.17) is equivalent to

$$
\begin{aligned}
&\begin{pmatrix} 1 & -\rho z_{j,k} \\ -\rho z_{j,k} & \lambda_j \end{pmatrix} - \frac{1}{\tau-\lambda_j}\begin{pmatrix} 1-\sigma_{j,k}z_{j,k} \\ 0 \end{pmatrix}\begin{pmatrix} 1-\sigma_{j,k}z_{j,k} & 0 \end{pmatrix} \\
&= \begin{pmatrix} 1-\frac{(1-\sigma_{j,k}z_{j,k})^2}{\tau-\lambda} & -\rho z_{j,k} \\ -\rho z_{j,k} & \lambda_j \end{pmatrix} \succeq 0. \qquad (4.18)
\end{aligned}
$$

Now a $2 \times 2$ matrix is positive semidefinite if and only if the diagonal elements and the determinant are nonnegative. Therefore, (4.18) is equivalent to the conditions

$$\lambda_j \geq 0, \tag{4.19}$$

$$\tau - \lambda_j \geq (1 - \sigma_{j,k} z_{j,k})^2, \tag{4.20}$$

$$\lambda_j \left(1 - \frac{(1 - \sigma_{j,k} z_{j,k})^2}{\tau - \lambda_j}\right) - \rho^2 z_{j,k}^2 \geq 0. \tag{4.21}$$

Clearly, (4.21) and (4.19) together imply (4.20). Furthermore, we can express (4.21) as

$$z_{j,k}^2 \left((\lambda_j - \tau)\rho^2 - \sigma_{j,k}^2 \lambda_j\right) + 2 z_{j,k} \sigma_{j,k} \lambda_j + \lambda_j (\tau - \lambda_j - 1) \geq 0. \tag{4.22}$$

Since the coefficient multiplying $z_{j,k}^2$ in (4.22) is negative, it follows that there exists a $z_{j,k}$ satisfying (4.22) if and only if the discriminant is nonnegative, i.e, if and only if

$$\sigma_{j,i}^2 \lambda_j + \left((\tau - \lambda_j)\rho^2 + \sigma_{j,i}^2 \lambda_j\right)(\tau - \lambda_j - 1) \geq 0.$$

Using the fact that $\tau - \lambda_j > 0$ for every $0 \leq j \leq N - 1$, the latter inequality is equivalent to

$$\lambda_j \sigma_{j,k}^2 \geq \rho^2 (1 + \lambda_j - \tau). \tag{4.23}$$

If (4.23) is satisfied, then the set of $z_{j,k}$'s satisfying (4.22) are

$$z_{j,k}^- \leq z_{j,k} \leq z_{j,k}^+,$$

where $z_{j,k}^- \leq z_{j,k}^+$ are the roots of the quadratic function in (4.22). Since we would like to choose $z_{j,k}$ to minimize (4.16), it follows that the optimal $z_{j,k}$ is

$$\begin{aligned} z_{j,k} &= f_{j,k}(\tau, \lambda_j) \\ &= \frac{\sigma_{j,k}\lambda_j - \sqrt{\lambda_j(\tau - \lambda_j)\left(\sigma_{j,k}^2 \lambda_j - \rho^2(1 + \lambda_j - \tau)\right)}}{(\tau - \lambda_j)\rho^2 + \sigma_{j,k}^2 \lambda_j}. \end{aligned} \tag{4.24}$$

Thus, if $\tau > \max_{0 \leq j \leq N-1} \lambda_j$, then the optimal value of $z_{j,k}$ is given by (4.24), where, in addition, conditions (4.23) and (4.19) must be satisfied.

Next, suppose that $\tau = \lambda_j$ for some $j$. In this case, to ensure that (4.17) is satisfied, we must have that

$$z_{j,i} = \frac{1}{\sigma_{j,k}}, \tag{4.25}$$

$$\lambda_j \geq \frac{\rho^2}{\sigma_{j,k}^2}. \tag{4.26}$$

We can immediately verify that (4.25) and (4.26) are special cases of (4.24) and (4.23) with $\tau = \lambda_j$. We therefore conclude that the optimal value of $z_{j,k}$ is given by (4.24) subject to (4.23) and (4.19). Substituting the optimal value of $z_{j,k}$ into (4.16), our problem becomes

$$\min_{\tau, \lambda_j} \left\{ \sigma^2 \sum_{j=0}^{N-1} \sum_{k=1}^{m} f_{j,k}^2(\tau, \lambda_j) + N L^2 \tau \right\} \tag{4.27}$$

subject to

$$\begin{aligned} \lambda_j \sigma_{j,k}^2 &\geq \rho^2(1+\lambda_j-\tau), \quad 1 \leq k \leq m, \quad 0 \leq j \leq N-1, \\ \lambda_j &\geq 0, \quad 0 \leq j \leq N-1, \\ \tau &\geq \lambda_j, \quad 0 \leq j \leq N-1. \end{aligned} \tag{4.28}$$

Since the problem of (4.16) subject to (4.17) is convex, and the reduced problem (4.27) subject to (4.28) is obtained by minimizing over some of the variables in (4.16), the reduced problem is also convex, completing the proof of the theorem. □

[illegible] 4.1. The line of analysis employed in Theorem 4.2 can also be carried out when $\mathbf{T} = (\mathbf{A}^*\mathbf{A})^{\alpha}$ for some real number $\alpha$. The resulting optimization problem is very similar to the one derived in Theorem 4.2. In some applications such as the image deblurring examples described in [8], choosing a negative $\alpha$ provides better results than the Euclidean weighting (i.e., $\alpha = 0$).

**5. An image deblurring example.** To illustrate the effectiveness of the minimax MSE approach, we consider an image deblurring example from the "Regularization Tools" [14].

We consider the square system

$$\mathbf{A}_{\text{true}}\mathbf{x}_{\text{true}} = \mathbf{y}_{\text{true}},$$

where $\mathbf{x}_{\text{true}} \in \mathbb{R}^{1024}$ is obtained by stacking the columns of the $32 \times 32$ image and $\mathbf{A}_{\text{true}}$ is a $1024 \times 1024$ matrix that represents an atmospheric turbulence blur originating from [13] and implemented in the function blur(n,3,0.5) from the "Regularization Tools" [14] (3 is the half bandwidth and 0.5 is the standard deviation associated with the corresponding point spread function). The image corresponding to $\mathbf{x}_{\text{true}}$ is shown at the top of Figure 1. The matrix $\mathbf{A}_{\text{true}}$ is a block Toeplitz matrix with half bandwidth 3. We note that, in fact, any matrix representing a two-dimensional convolution has a block Toeplitz structure [16].

The observed matrix $\mathbf{A}$ was generated by the function blur(n,3,0.7), and so essentially the uncertainty in the model matrix is due to lack of knowledge of the standard deviation. The observed vector was generated by adding white noise $\mathbf{y} = \mathbf{y}_{\text{true}} + \sigma\mathbf{e}$, where each component of $\mathbf{e} \in \mathbb{R}^{1024}$ was generated from a standard normal distribution.

In our experiment the standard deviation $\sigma$ was chosen to be 0.1, which results with the noisy image shown in Figure 1 (Observation). We considered several estimation methods:

- [illegible]. The LS estimator is given by $\hat{\mathbf{x}}_{\text{LS}} = (\mathbf{A}^*\mathbf{A})^{-1}\mathbf{A}^*\mathbf{y}$. As can be seen in Figure 1, the resulting image is of a poor quality.
- [illegible]. The structured TLS (STLS) solution $\hat{\mathbf{x}}_{\text{STLS}}$ to the problem is the $\mathbf{x}$-part of the solution to the optimization problem

  $$\min_{\Delta\mathbf{A},\Delta\mathbf{y},\mathbf{x}} \{\|\mathbf{\Delta A}\|^2 + \|\mathbf{\Delta y}\|^2 : (\mathbf{A}+\mathbf{\Delta A})\mathbf{x} = \mathbf{y}+\mathbf{\Delta y},\ \mathbf{\Delta A} \text{ is BC}\}.$$

  The STLS problem with BC structure can be solved by decomposing the problem into several unstructured TLS problems (for details see [1]). As can be seen from Figure 1, the STLS method generates an even worse image than $\hat{\mathbf{x}}_{\text{LS}}$. This poor performance of the STLS solution stems from the fact that the unstructured TLS solution is a deregularization [15] of the LS solution and as such is rather unstable. The STLS solution for BC systems is constructed

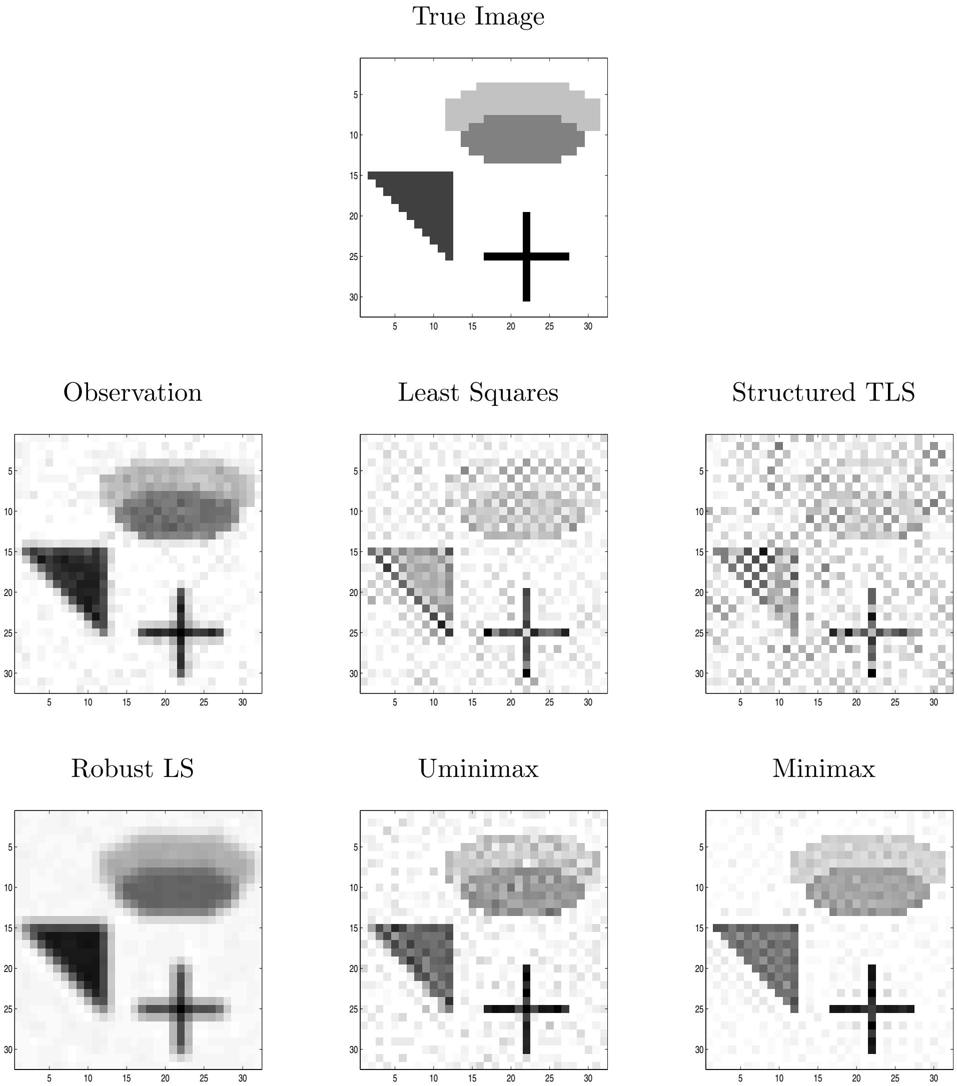

FIG. 1. *Comparison between different estimators.*

from several solutions of unstructured TLS problems and is therefore unstable as well.

- [illegible]. We also considered the RLS method defined in (1.1), where the uncertainty set $\mathcal{U}$ is given by a simple norm constraint $\mathcal{U} = \{(\boldsymbol{\Delta}\mathbf{A}, \boldsymbol{\Delta}\mathbf{y}) : \|(\boldsymbol{\Delta}\mathbf{A}, \boldsymbol{\Delta}\mathbf{y})\| \leq \rho_{\mathrm{R}}\}$ and $\rho_{\mathrm{R}}$ is chosen as $1.1 \cdot \|(\mathbf{A} - \mathbf{A}_{\mathrm{true}}, \mathbf{y} - \mathbf{y}_{\mathrm{true}})\|$. The resulting figure is quite blurred. The reason for not using a complicated set such as $\mathcal{U}_{\Delta}$ (given in (1.5)) to describe the uncertainty in $\mathbf{A}$ is that problem (1.1) appears to be intractable in this case, since the uncertainty set involves [illegible] norm constraints. Another alternative would be to use the structured RLS problem [10] and to relax the multiple norm constraints in $\mathcal{U}_{\Delta}$ into a single norm constraint. However, the generated SDP needed to be solved in our example here is too large to handle with standard software.

- *Uminimax*. Unstructured minimax is the minimax estimator for the unstructured case (see [8]). This estimator minimizes the worst-case MSE across all values of $\mathbf{x}$ satisfying $\mathbf{x}^*\mathbf{T}\mathbf{x} \leq L^2$ and perturbation matrices $\mathbf{\Delta A}$ satisfying $\|\mathbf{\Delta A}\| \leq \rho_B$. Note, however, that it ignores the special structure of $\mathbf{\Delta A}$. We have chosen the parameters $L, \rho_B$ to be 10 percent larger than their true values (for example, $L$ was chosen to be $1.1 \cdot \mathbf{x}_{\text{true}}^*\mathbf{T}\mathbf{x}_{\text{true}}$). $\mathbf{T}$ was chosen to be $(\mathbf{A}^*\mathbf{A})^{-1}$. This choice of $\mathbf{T}$ reflects the fact that components corresponding to small singular values of $\mathbf{A}^*\mathbf{A}$ should receive a smaller weight than components corresponding to large singular values. The resulting image for this method is of good quality.
- *Minimax*. Finally, we compared the above-mentioned methods with the minimax MSE estimator for BC systems developed in this paper. In implementing the Minimax estimator, we have used a BC approximation of the block Toeplitz matrix $\mathbf{A}$ as follows:

$$\begin{pmatrix}
\mathbf{A}_0 & \mathbf{A}_1 & \mathbf{A}_2 & \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} & \mathbf{0} & \mathbf{0} \\
\mathbf{A}_{-1} & \mathbf{A}_0 & \mathbf{A}_1 & \mathbf{A}_2 & \mathbf{0} & \dots & \mathbf{0} & \mathbf{0} & \mathbf{0} \\
\mathbf{A}_{-2} & \mathbf{A}_{-1} & \mathbf{A}_0 & \mathbf{A}_1 & \mathbf{A}_2 & \dots & \mathbf{0} & \mathbf{0} & \mathbf{0} \\

\mathbf{A}_2 & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \dots & \mathbf{A}_{-1} & \mathbf{A}_0 & \mathbf{A}_1 \\
\mathbf{A}_1 & \mathbf{A}_2 & \mathbf{0} & \mathbf{0} & \mathbf{0} & \dots & \mathbf{A}_{-2} & \mathbf{A}_{-1} & \mathbf{A}_0
\end{pmatrix}.$$

  The approximation is made by adding three block matrices to the northeast and southwest corners of $\mathbf{A}$. As in the Uminimax estimator, all parameters are chosen to be 10 percent larger than their true value. It can be seen that Minimax gives even a better result than Uminimax.

We note that the Minimax estimate was not calculated by solving the SDP formulation of Theorem 3.2, since its size was too big for standard software such as SeDuMi [23]. Instead we applied a gradient projection algorithm with armijo-type line search [5] on the convex optimization formulation of Theorem 4.2. In this algorithm the dominant computational effort is the calculation of the orthogonal projection onto the polyhedral feasible set, which amounts to solving a quadratic minimization problem in 1025 variables. Since the linear system describing the feasible set is extremely sparse, the CPU time required to calculate a single projection (using SeDuMi) was a small fraction of a second. The resulting image was obtained after 10 iterations in an overall CPU time of 0.8 seconds (on a Pentium 4, 1.8 Ghz). The stopping criterion was chosen to be $|f_k - f_{k-1}| < \varepsilon$, where $\varepsilon = 10^{-3}$ and $f_j$ denotes the objective function value at the $j$th iteration. We noticed that the quality of the image does not improve if we choose a smaller value of $\varepsilon$.

As can be seen from this example, the structured minimax MSE estimator gives better results than the LS, STLS, RLS, and Uminimax estimators.

# ACCURATE COMPUTATIONS WITH TOTALLY NONNEGATIVE MATRICES*

PLAMEN KOEV†

**Abstract.** We consider the problem of performing accurate computations with rectangular ($m \times n$) totally nonnegative matrices. The matrices under consideration have the property of having a unique representation as products of nonnegative bidiagonal matrices. Given that representation, one can compute the inverse, LDU decomposition, eigenvalues, and SVD of a totally nonnegative matrix to high relative accuracy in $\mathcal{O}(\max(m^3, n^3))$ time—much more accurately than conventional algorithms that ignore that structure. The contribution of this paper is to show that the high relative accuracy is preserved by operations that preserve the total nonnegativity—taking a product, re-signed inverse (when $m = n$), converse, Schur complement, or submatrix of a totally nonnegative matrix, any of which costs at most $\mathcal{O}(\max(m^3, n^3))$. In other words, the class of totally nonnegative matrices for which we can do numerical linear algebra very accurately in $\mathcal{O}(\max(m^3, n^3))$ time (namely, those for which we have a product representation via nonnegative bidiagonals) is closed under the operations listed above.

**Key words.** high relative accuracy, totally positive matrix, totally nonnegative matrix, bidiagonal decomposition

## 1. Introduction.

The matrices with all minors nonnegative are called [illegible] and appear in a wide variety of applications [5, 10, 12, 14, 15, 18, 25]. They are often very ill conditioned, which means that conventional matrix algorithms such as LAPACK [1] may deliver little or no accuracy when solving totally nonnegative linear systems or computing inverses, eigenvalues, or SVDs.

Our goal is to derive algorithms for performing accurate and efficient computations with $m \times n$ totally nonnegative matrices. The types of computations we would like to perform include computing the inverse, LDU decomposition, eigenvalues, and SVD. By [illegible] we mean that each quantity must be computed [illegible]—it must have a correct sign and leading digits. By [illegible] we mean [illegible] $\mathcal{O}(\max(m^3, n^3))$ [illegible].

It turns out that the problem of performing accurate computations with totally nonnegative matrices is very much a [illegible]. If, instead of representing a matrix by its entries, we represent it as a product of nonnegative bidiagonal matrices

$$A = L^{(1)} L^{(2)} \cdots L^{(m-1)} D U^{(n-1)} U^{(n-2)} \cdots U^{(1)}; \tag{1.1}$$

then given the entries of $L^{(k)}$, $D$, and $U^{(k)}$, we can compute $A^{-1}$, the LDU decomposition, the eigenvalues, and the SVD of $A$ accurately and efficiently (see section 3).

The existence and uniqueness of the bidiagonal decomposition (1.1) is critical to the design of our algorithms. Therefore we restrict the class of totally nonnegative matrices under consideration to only those that are [illegible]. If the matrix under consideration

†Department of Mathematics, Massachusetts Institute of Technology, Cambridge, MA 02139 (plamen@math.mit.edu).

is square ($m = n$), the above restriction means that the matrix itself is [illegible]

We will call the matrices in the above described class TN for short.

The representation (1.1) is intrinsic [19] and immediately reveals the TN structure of an $m \times n$ TN matrix $A$. The $m \cdot n$ nontrivial nonnegative entries in the factors of (1.1) parameterize the set of all $m \times n$ TN matrices and determine the quantities that we would like to compute (the entries of $A^{-1}$, the entries of the LDU decomposition, the eigenvalues, and the SVD) accurately (section 3).

TN matrices can be obtained in a variety of ways as a result of matrix operations that preserve the total nonnegativity. The following result is well known [19, 20, 25].

PROPOSITION 1.1. [illegible] $A = [a_{ij}]$ [illegible] $AB$ [illegible] $B$ [illegible] converse $[a_{m+1-i,n+1-j}]$ [illegible] $R$ [illegible] $A$ [illegible] $r_{ii} > 0$ [illegible] $a_{11}$ [illegible] $A$ [illegible] $A$ [illegible] $A$ [illegible] re-signed inverse $[(-1)^{i+j}a_{ij}]^{-1}$ [illegible] $A$ [illegible] $A$ [illegible] $R$ [illegible]

If $A$ is a TN matrix obtained from other TN matrices by any sequence of these operations, the question becomes: Can we perform accurate matrix computations with $A$? In other words, if these other TN matrices are represented by their corresponding bidiagonal decompositions (1.1), can we accurately and efficiently compute the bidiagonal decomposition of $A$?

Our main contribution in this paper is to answer this question affirmatively. In section 5 we present accurate and efficient algorithms that perform these computations. These algorithms prove the following theorem.

THEOREM 1.2. [illegible] (1.1) [illegible] $m = n$ [illegible] 1.1 [illegible]

For example, we could take the product of the Hilbert matrix and the Pascal matrix, compute a Schur complement, take a submatrix of its converse, and then compute the SVD of the resulting matrix highly accurately, all in $\mathcal{O}(\max(m^3, n^3))$ time. In contrast, on examples similar to this one, the conventional algorithms may fail to compute even the largest singular value accurately (see section 7).

As an application of Theorem 1.2, in section 6 we derive a new algorithm for computing the bidiagonal decomposition of a TN generalized Vandermonde matrix based on removing appropriate columns of an ordinary Vandermonde matrix. This is a major improvement over previous such algorithms in [8, 34].

In the design of our algorithms we take the following approach.

First, we identify the source of large relative errors in conventional matrix algorithms. Relative accuracy in these algorithms is lost due to [illegible] in the subtraction of approximate same-sign quantities. Conversely, the relative accuracy is preserved in multiplication, division, addition, and taking of square roots.

Second, we perform any and all transformations listed in Proposition 1.1 as a combination of the following [illegible] (EETs):

EET1: Subtracting a multiple of a row (column) from the next in order to create a zero in such a way that the transformed matrix is still TN;

EET2: Adding a multiple of a row (column) to the previous one;

EET3: Adding a multiple of a row (column) to the next one;

EET4: Scaling by a positive diagonal matrix.

Each of these EETs preserves the total nonnegativity [19].

Third, instead of applying an EET directly on a TN matrix $A$, we carry it out [illegible] by transforming the entries of its bidiagonal decomposition, and arrange the computations in such a way that subtractions are not required. Thus the accuracy is preserved.

This paper is organized as follows. In section 2 we review the bidiagonal decompositions of TN matrices. In section 3 we review algorithms for accurate computations with TN matrices, given their bidiagonal decompositions. In section 4 we review algorithms from [27] for performing EET1 and EET2 and present new algorithms for performing EET3 and EET4. In section 5 we present algorithms for computing accurate bidiagonal decompositions of derivative TN matrices, obtained as described in Proposition 1.1. We present our new algorithm for computing the bidiagonal decomposition of a generalized Vandermonde matrix in section 6. In section 7 we present numerical results demonstrating the accuracy of our algorithms. We draw conclusions and present open problems in section 8.

[illegible] Throughout this paper we use MATLAB [32] notation for vectors and submatrices.

**2. Bidiagonal decompositions of TN matrices.** The TN matrices possess a very elegant structure, which is not revealed by their entries. Additionally, small relative perturbations in the entries of a TN matrix $A$ can cause enormous relative perturbations in the small eigenvalues, singular values, and entries of $A^{-1}$ [27, section 1]. Thus the matrix entries are ill suited as parameters in numerical computations with TN matrices.

Instead, following [27], we choose to represent a TN matrix as a product of nonnegative bidiagonal matrices. This representation arises naturally in the process of [illegible], which we now review, following [19] (see also [35]).

In the process of Neville elimination a matrix is reduced to upper triangular form using only [illegible] rows. A zero is introduced in position $(m, 1)$ by subtracting a multiple $b_{m1} = a_{m1}/a_{m-1,1}$ of row $m-1$ from row $m$. Subtracting the multiple $b_{m-1,1} = a_{m-1,1}/a_{m-2,1}$ of row $m-2$ from row $m-1$ creates a zero in position $(m-1, 1)$, and so on. The total nonnegativity is preserved during Neville elimination [19], and therefore all multipliers $b_{ij}$ are nonnegative.

This yields the decomposition

$$A = \left( \prod_{k=1}^{m-1} \prod_{j=m-k+1}^{m} E_j(b_{j,k+j-m}) \right) \cdot U,$$

where $U$ is $m \times n$ upper triangular and

$$E_j(x) \equiv \begin{bmatrix} 1 & & & & \\ & \ddots & & & \\ & x & 1 & & \\ & & & \ddots & \\ & & & & 1 \end{bmatrix}$$

is $m \times m$ and differs from the identity only in the $(j, j-1)$ entry.

Applying the same process to $A^T$, we obtain the decomposition

$$A = \left( \prod_{k=1}^{m-1} \prod_{j=m-k+1}^{m} E_j(b_{j,k+j-m}) \right) \cdot D \cdot \left( \prod_{1}^{k=n-1} \prod_{n-k+1}^{j=n} E_j^T(b_{k+j-n,j}) \right), \tag{2.1}$$

where $D$ is a diagonal $m \times n$ matrix and $E_j^T$ are $n \times n$. In the notation of (2.1) and throughout this paper, $\prod_1^{k=n-1}$ indicates that the product is taken for $k$ from $n-1$ down to 1. Although somewhat nonstandard, this notation allows us to preserve the symmetry in (2.1).

The matrices

$$L^{(k)} \equiv \prod_{j=m-k+1}^{m} E_j(b_{j,k+j-m}) = \begin{bmatrix} 1 & & & & & \\ & \ddots & & & & \\ & b_{k,m-k+1} & 1 & & & \\ & & b_{k+1,m-k+2} & 1 & & \\ & & & \ddots & \ddots & \\ & & & & b_{m,m-1} & 1 \end{bmatrix}$$

and

$$U^{(k)} \equiv \prod_{n-k+1}^{j=n} E_j^T(b_{k+j-n,j}) = \begin{bmatrix} 1 & & & & & \\ & \ddots & b_{n-k+1,k} & & & \\ & & 1 & b_{n-k+2,k+1} & & \\ & & & 1 & \ddots & \\ & & & & \ddots & b_{n-1,n} \\ & & & & & 1 \end{bmatrix}$$

are $m \times m$ lower- and $n \times n$ upper bidiagonal, respectively. The decomposition (2.1) now becomes

$$A = L^{(1)} \cdots L^{(n-1)} \cdot D \cdot U^{(n-1)} \cdots U^{(1)}.$$

We denote the off-diagonal entries in $L^{(k)}$ and $U^{(k)}$ as

$$l_i^{(k)} \equiv L_{i+1,i}^{(k)} = b_{i+1,k+i+1-m} \quad \text{and} \quad u_i^{(k)} \equiv U_{i,i+1}^{(k)} = b_{k+i+1-n,i+1}. \tag{2.2}$$

We will use either $l_i^{(k)}$ or $b_{i+1,k+i+1-m}$ to denote the nontrivial entries of $L^{(k)}$ (and similarly with $U^{(k)}$). In different contexts one notation may be more convenient than the other, so we will keep (2.2) in mind when switching back and forth.

We now present the fundamental structure theorem for TN matrices.

THEOREM 2.1 (Gasca and Peña [19]). [illegible] $m \times n$ [illegible] $A$ [illegible]

$$A = L^{(1)} \cdots L^{(m-1)} \cdot D \cdot U^{(n-1)} \cdots U^{(1)}, \tag{2.3}$$

[illegible] $D$ [illegible] $m \times n$ [illegible] $d_i, i = 1, 2, \ldots, \min(n, m)$. $L^{(k)}$ [illegible] $U^{(k)}$ [illegible] $m \times m$ [illegible] $n \times n$ [illegible]

1. $d_i > 0$ for $i = 1, 2, \ldots, \min(m, n)$.
2. $l_i^{(k)} = 0,\ i < m - k$; $u_i^{(k)} = 0,\ i < n - k$; and $l_i^{(k)} = u_i^{(k)} = 0,\ i > m + n - k$.
3. $l_i^{(k)} \geq 0,\ m - k \leq i \leq m + n - k$ and $u_i^{(k)} \geq 0,\ n - k \leq i \leq m + n - k$.
4. $l_i^{(k)} = 0$ implies $l_{i+1}^{(k-1)} = 0$. $u_i^{(k)} = 0$ implies $u_{i+1}^{(k-1)} = 0$

We will refer to Theorem 2.1 to verify whether a particular decomposition of a TN matrix $A$ as a product of bidiagonal matrices is in fact its unique bidiagonal decomposition.

Following [27], we denote the bidiagonal decomposition (2.3) of a TN matrix $A$ as $\mathcal{BD}(A)$. We store the nontrivial entries of $\mathcal{BD}(A)$ compactly in an $m \times n$ array, which we also refer to as $\mathcal{BD}(A)$:

$$(\mathcal{BD}(A))_{ij} = \begin{cases} l_{i-1}^{(n-i+j)}, & i > j, \\ u_{j-1}^{(n-j+i)}, & i < j, \\ d_i, & i = j. \end{cases}$$

The $(i, j)$th entry in $\mathcal{BD}(A)$ equals the multiplier $(b_{ij})$ used to set the $(i, j)$th entry in $A$ to zero (when $i \neq j$), or the $i$th entry on the diagonal of $D$ (when $i = j$).

For example,

$$\begin{bmatrix} 2 & 6 \\ 8 & 29 \\ 48 & 209 \end{bmatrix} = \begin{bmatrix} 1 & & \\ & 1 & \\ & 6 & 1 \end{bmatrix} \begin{bmatrix} 1 & & \\ 4 & 1 & \\ & 7 & 1 \end{bmatrix} \begin{bmatrix} 2 & \\ & 5 \\ & \end{bmatrix} \begin{bmatrix} 1 & 3 \\ & 1 \end{bmatrix}$$

is stored as

$$\mathcal{BD}\left( \begin{bmatrix} 2 & 6 \\ 8 & 29 \\ 48 & 209 \end{bmatrix} \right) = \left\{ \begin{matrix} 2 & 3 \\ 4 & 5 \\ 6 & 7 \end{matrix} \right\}.$$

This notation is convenient since we can formally transpose $\mathcal{BD}(A)$ to obtain $\mathcal{BD}(A^T) = (\mathcal{BD}(A))^T$ [27, section 4].

In the language of the $m \times n$ array $B = \mathcal{BD}(A)$, conditions 1–4 in Theorem 2.1 are equivalent to the following:

1. $b_{ii} > 0, i = 1, 2, \ldots, \min(m, n)$;
2. $b_{ij} = 0$, unless $1 \leq i \leq m$ and $1 \leq j \leq n$;
3. $b_{ij} \geq 0,\ i = 1, 2, \ldots, m,\ j = 1, 2, \ldots, n$;
4. $b_{ij} = 0$ implies $b_{i+1,j} = 0$ if $i < j$, and $b_{i,j+1} = 0$ if $i > j$.

If the TN matrix $A$ is also totally positive (i.e., if all its minors are positive), then the entries $b_{ij}, i = 1, 2, \ldots, m,\ j = 1, 2, \ldots, n$, are products and quotients of minors of $A$ [27, section 3], [16]:

$$b_{ij} = \frac{\det A(i-j+1 : i, 1 : j)}{\det A(i-j+1 : i-1, 1 : j-1)} \cdot \frac{\det A(i-j : i-2, 1 : j-1)}{\det A(i-j : i-1, 1 : j)}, \quad i > j,$$

$$b_{ii} = \frac{\det A(1 : i, 1 : i)}{\det A(1 : i-1, 1 : i-1)}; \tag{2.4}$$

$$b_{ji} = \frac{\det A(1 : j, i-j+1 : i)}{\det A(1 : j-1, i-j+1 : i-1)} \cdot \frac{\det A(1 : j-1, i-j : i-2)}{\det A(1 : j, i-j : i-1)}, \quad i > j.$$

One can use the formulas (2.4) to compute explicit formulas for the bidiagonal decompositions of Vandermonde [10, 23, 33], [27, section 3], Cauchy [4], [27, section 3], Cauchy–Vandermonde [29, 30, 31], generalized Vandermonde [8], and Bernstein–Vandermonde [28] matrices.

Neville elimination is just one of eight analogous, but slightly different methods to eliminate a TN matrix $A$ using only adjacent rows and columns [19, section 4]. Each method yields a decomposition of $A$ as a product of nonnegative bidiagonal matrices with analogous but different nonzero patterns. In section 5.1 we show how to obtain an accurate $\mathcal{BD}(A)$ (and then perform accurate computations with $A$) starting with any decomposition of $A$ as a product of nonnegative bidiagonal matrices. Therefore the particular choice of elimination pattern in Neville elimination and the resulting nonzero pattern in the factors of the decomposition (2.3) do not result in any loss of generality.

## 3. Performing accurate matrix computations given $\mathcal{BD}(A)$.

The entries of $\mathcal{BD}(A)$ determine accurately the entries of the inverse, the entries of the LDU decomposition, and the values of any minor, eigenvalue, or singular value. Furthermore, given $\mathcal{BD}(A)$, many matrix computations with $A$ can be performed accurately and efficiently. We review these results below.

### 3.1. Computing the inverse.

If $A$ is a square $n \times n$ TN matrix, we can compute its inverse accurately by inverting (2.1):

$$A^{-1} = \left( \prod_{i=1}^{n-1} \prod_{j=n-i+1}^{n} E_j^T(-b_{i+j-n,j}) \right) \cdot D^{-1} \cdot \left( \prod_{1}^{i=n-1} \prod_{n-i+1}^{j=n} E_j(-b_{j,i+j-n}) \right). \tag{3.1}$$

Using (3.1) and the Cauchy–Binet identity [13, Vol. 1, p. 9], we conclude that each entry of $A^{-1}$ is a linear function in each entry $b_{ij}$ of $\mathcal{BD}(A)$ with either nonnegative or nonpositive coefficients. Therefore small relative perturbations in the $b_{ij}$ cause small relative perturbations in any entry of $A^{-1}$. In other words, $\mathcal{BD}(A)$ determines every entry of $A^{-1}$ accurately.

We can form $A^{-1}$ by multiplying out (3.1) in $\mathcal{O}(n^3)$ time. Each entry of $A^{-1}$ will be computed accurately, since the multiplication (3.1) involves no subtractive cancellation. (All matrices in (3.1), their partial products, and $A^{-1}$ have checkerboard sign patterns.)

### 3.2. Solving $Ax = b$.

We can use (3.1) to compute the solution to $Ax = b$ in $\mathcal{O}(n^2)$ time by multiplying out the expression

$$x = A^{-1}b = \left( \prod_{i=1}^{n-1} \prod_{j=n-i+1}^{n} E_j^T(-b_{i+j-n,j}) \right) D^{-1} \left( \prod_{1}^{i=n-1} \prod_{n-i+1}^{j=n} E_j(-b_{j,i+j-n}) \right) b \tag{3.2}$$

right-to-left. The computed solution $\hat{x}$ has a small componentwise relative backward error [4]; i.e., a matrix $\hat{A}$ exists such that $\hat{A}\hat{x} = b$ and $|A - \hat{A}| \le \mathcal{O}(\epsilon)|A|$, where the inequality is meant componentwise.

If $b$ has alternating sign pattern (i.e., sign $b_i = (-1)^i$ or sign $b_i = (-1)^{i-1}$), then (3.2) involves no subtractive cancellation, and each component of $x$ is computed accurately [23].

This approach for solving $Ax = b$ is the basis of the so-called Björck–Pereyra-type methods for solving structured TN linear systems. Derived originally for Vandermonde linear systems [3], these methods received deserved attention because of their remarkable accuracy[1] [22]. Generalizations were later developed for Cauchy [4],

---

[1] In the scope of Newton interpolation with positive and increasing nodes (i.e., the conditions under which the corresponding Vandermonde matrix is TN), the accuracy observation dates back to 1963 and was made by Kahan and Farkas [24].

Cauchy–Vandermonde [29, 30, 31], generalized Vandermonde [8], and Bernstein–Vandermonde [28] matrices. Each of these methods is either explicitly or implicitly based on a decomposition of the corresponding $A^{-1}$ as a product of simple bidiagonal matrices analogous to (3.1).

**3.3. Computing a minor.** The value of any minor of a TN matrix $A$ is determined accurately by $\mathcal{BD}(A)$ [6, section 9]. It can be computed accurately and efficiently given $\mathcal{BD}(A)$—see section 5.8.

**3.4. Computing the LDU decomposition.** Let $A$ be a square TN nonsingular $n \times n$ matrix. Define

$$L \equiv L^{(1)} \cdots L^{(n-1)} \quad \text{and} \quad U \equiv U^{(n-1)} \cdots U^{(1)}. \tag{3.3}$$

Now (2.3) implies that $A = LDU$ is the LDU decomposition of $A$. The Cauchy–Binet identity and (3.3) imply that $\mathcal{BD}(A)$ determines each entry of $L$, $D$, and $U$ accurately. Multiplying out (3.3) involves no subtractions and yields every entry of $L$ and $U$ accurately. The decompositions $\mathcal{BD}(L)$ and $\mathcal{BD}(U)$ are given by (3.3).

**3.5. Computing the eigenvalues and the SVD.** In [27, section 7] we proved that $\mathcal{BD}(A)$ accurately determines the eigenvalues and the SVD of a TN matrix $A$. In the same paper we presented algorithms for computing the eigenvalues and the SVD of $A$ accurately and efficiently, given $\mathcal{BD}(A)$. These algorithms implicitly reduce both the eigenvalue and SVD problems to the bidiagonal SVD problem using only EETs. The resulting bidiagonal SVD problem is then solved accurately using known means [7, 11].

## 4. Performing EETs accurately.

Let the TN matrix $C$ be obtained from the $m \times n$ TN matrix $A$ by applying an EET to $A$. In this section we show how, given $\mathcal{BD}(A)$, the decomposition $\mathcal{BD}(C)$ can be computed without performing any subtractions.

In [27, section 4.1] we showed that EET1 is equivalent to simply setting an entry of $\mathcal{BD}(A)$ to zero; EET2 involved some "bulge chasing" in $\mathcal{BD}(A)$ [27, section 4.2] and cost at most $6(m+2)$ operations.

Next, we show how to perform EET3 and EET4 accurately.

**4.1. Adding a multiple of a row to the next one.** Let $A$ be TN and $C$ be obtained from $A$ by adding a multiple of row $i-1$ of $A$ to row $i$:

$$C = E_i(x)A, \quad x > 0.$$

In this section we show how to accurately compute $\mathcal{BD}(C)$, given $x$ and $\mathcal{BD}(A)$.

The following lemma shows how to compute the bidiagonal decomposition of the product of two bidiagonal matrices. It is the main building block of Algorithm 4.2 later in this section.

Lemma 4.1. [illegible] $B$ [illegible] $C$ [illegible] $n \times n$ [illegible] $b_i \geq 0$ [illegible] $c_i \geq 0$ $i = 1, 2, \ldots, n-1$ [illegible] $b_i = 0$ [illegible] $c_{i-1} = 0$ [illegible] $B'$ [illegible] $C'$ [illegible] $b_i' \geq 0$ [illegible] $c_i' \geq 0$ $i = 1, 2, \ldots, n-1$ [illegible] $B'C' = BC$ [illegible] $b_1' = 0$ [illegible] $b_i'$ [illegible] $c_i'$ [illegible] $4n$ [illegible]

*Proof.* We compare the entries on both sides of $B'C' = BC$,

$$\begin{bmatrix} 1 & & & & \\ 0 & 1 & & & \\ & b_2' & 1 & & \\ & & \ddots & \ddots & \\ & & & b_{n-1}' & 1 \end{bmatrix} \begin{bmatrix} 1 & & & & \\ c_1' & 1 & & & \\ & c_2' & 1 & & \\ & & \ddots & \ddots & \\ & & & c_{n-1}' & 1 \end{bmatrix} = \begin{bmatrix} 1 & & & & \\ b_1 & 1 & & & \\ & b_2 & 1 & & \\ & & \ddots & \ddots & \\ & & & b_{n-1} & 1 \end{bmatrix} \begin{bmatrix} 1 & & & & \\ c_1 & 1 & & & \\ & c_2 & 1 & & \\ & & \ddots & \ddots & \\ & & & c_{n-1} & 1 \end{bmatrix}, \tag{4.1}$$

to obtain $c_1' = b_1 + c_1$,

$$\begin{aligned} b_i' &= \frac{b_i c_{i-1}}{c_{i-1}'}, \\ c_i' &= b_i + c_i - b_i', \end{aligned} \tag{4.2}$$

for $i = 2, 3, \ldots, \min\{j | b_j = 0\}$, and $b_i' = b_i, c_i' = c_i$ otherwise. The subtraction in (4.2) can be eliminated by introducing auxiliary variables $d_i \equiv b_i - b_i'$. Then $d_1 = b_1 - b_1' = b_1$ and

$$\begin{aligned} d_i &= b_i - b_i' \\ &= b_i - \frac{b_i c_{i-1}}{c_{i-1}'} \\ &= \frac{b_i}{c_{i-1}'}(c_{i-1}' - c_{i-1}) \\ &= \frac{b_i}{c_{i-1}'}(b_{i-1} - b_{i-1}') \\ &= \frac{b_i d_{i-1}}{c_{i-1}'}. \end{aligned} \tag{4.3}$$

The subtraction-free (and therefore accurate) version of (4.2) is

$$\begin{aligned} b_i' &= \frac{b_i c_{i-1}}{c_{i-1}'}, \\ d_i &= \frac{b_i d_{i-1}}{c_{i-1}'}, \\ c_i' &= c_i + d_i. \end{aligned}$$

This computation clearly costs not more than $4n$ arithmetic operations. Since $c_i' = 0$ implies $b_{i+1}' = 0$, the product $B'C'$ is $\mathcal{BD}(BC)$. ☐

We implement the procedure from Lemma 4.1 in Algorithm 4.1 below. We overwrite $d_i$ by $d_{i+1}$, and the arrays $b$ and $c$ by $b'$ and $c'$, respectively. The quantity $e = b_{i+1}/c_i'$ is computed only once and used to update both $b_{i+1}$ and $d_{i+1}$, thus saving one division.

ALGORITHM 4.1. [illegible] 4.1 [illegible] $i$ [illegible] (4.4)[illegible]

```
function $[b, c, i]$ = dqd2$(b, c)$
$t = c_1$
$c_1 = b_1 + c_1$
$d = b_1$
$b_1 = 0$
$i = 1$
while $(i <$ length$(b))$ and $(b_{i+1} > 0)$
    $e = b_{i+1}/c_i$
    $d = ed$
    $b_{i+1} = et$
    $t = c_{i+1}$
    $c_{i+1} = c_{i+1} + d$
    $i = i + 1$
end
```

Note: The only way the product $BC$ differs from $\mathcal{BD}(BC)$ is in that $b_1 \neq 0$. The purpose of Algorithm 4.1 is to make $b_1$ zero without changing the product $BC$. No other zeros are introduced in $B$ or $C$, and no nonzeros are introduced in $B$. At most one nonzero may be introduced in $C$. Algorithm 4.1 returns the index $i$ where this may have happened ($c_i = 0$ on input, $c_i > 0$ on output). Although such an introduction of a nonzero in $C$ causes no problems in the scope of Lemma 4.1, it may require additional work and bulge chasing in Algorithm 4.2 below, which uses Algorithm 4.1 as an intermediate step.

THEOREM 4.2. [illegible] $A$ [illegible] $m \times n$ [illegible] $x > 0$[illegible] $\mathcal{BD}(A)$ [illegible] $\mathcal{BD}(E_i(x)A)$ [illegible] $4m$[illegible]

[illegible]. Let $\mathcal{BD}(A)$ be given as in (2.3),

$$A = L^{(1)}L^{(2)}\cdots L^{(m-1)}DU^{(n-1)}U^{(n-2)}\cdots U^{(1)},$$

and let $L \equiv L^{(1)}L^{(2)}\cdots L^{(m-1)}$. The TN matrix $E_i(x)L$ is TN unit lower triangular. The idea is to compute the decomposition $\mathcal{BD}(E_i(x)\cdot L)$:

$$E_i(x)L = \mathcal{L}^{(1)}\mathcal{L}^{(2)}\cdots\mathcal{L}^{(m-1)}.$$

Then $\mathcal{BD}(E_i(x)A)$ is

$$E_i(x)A = \mathcal{L}^{(1)}\mathcal{L}^{(2)}\cdots\mathcal{L}^{(m-1)}DU^{(n-1)}U^{(n-2)}\cdots U^{(1)}.$$

We use Lemma 4.1 and Algorithm 4.1 to "chase the bulge" $E_i(x)$:

$$\begin{aligned} E_i(x)L &= E_i(x)L^{(1)}L^{(2)}\cdots L^{(m-1)} \\ &= \mathcal{L}^{(1)}E_{i_1}(x_1)L^{(2)}\cdots L^{(m-1)} \\ &= \mathcal{L}^{(1)}\mathcal{L}^{(2)}E_{i_2}(x_2)\cdots L^{(m-1)} \\ &= \dots \\ &= \mathcal{L}^{(1)}\mathcal{L}^{(2)}\cdots\mathcal{L}^{(m-1)}. \end{aligned}$$

We start with $k = 1$ and repeat the following process. We apply Algorithm 4.1 to the trailing principal submatrices of $E_i(x)$ and $L^{(k)}$ consisting of rows and columns $i$ though $n$. The only nonzero in $E_i(x)$ disappears, and we obtain a new matrix $\bar{L}^{(k)} = E_i(x)L^{(k)}$.

If one of these three condition holds:

1. $k = m - 1$, or
2. no nonzeros were introduced in $\bar{L}^{(k)}$ that were not in $L^{(k)}$, or
3. a nonzero $\bar{l}_j^{(k)}$ was introduced in $\bar{L}^{(k)}$, but $l_{j-1}^{(k+1)} \neq 0$,

then we set $\mathcal{L}^{(k)} \equiv \bar{L}^{(k)}$; the "bulge chasing" is thus over, and we are done.

Otherwise (a nonzero $\bar{l}_j^{(k)}$ was introduced in $\bar{L}^{(k)}$, and $l_{j-1}^{(k+1)} = 0$, $k < m - 1$), we have $\bar{L}^{(k)} = \mathcal{L}^{(k)} \cdot E_j(\bar{l}_j^{(k)})$, where $\mathcal{L}^{(k)}$ has the same nonzero pattern as $L^{(k)}$. We set $i = j$, $x = l_j^{(k)}$, increase $k$ by one, and repeat the same process.

The computation of $\mathcal{BD}(E_i(x)A)$ is subtraction-free. At most $2n - 3$ entries in $\mathcal{BD}(A)$ are changed at not more than two arithmetic operations per entry (see Algorithm 4.1). The total cost therefore does not exceed $4n$. □

The following algorithm implements the procedure from Theorem 4.2.

ALGORITHM 4.2. [illegible] $A$ [illegible] $m \times n$ [illegible] $B = \mathcal{BD}(A)$ [illegible] $\mathcal{BD}(E_i(x)A)$ [illegible] $4n$ [illegible] $b_{jl} = 0$ [illegible] $j \notin \{1, 2, \ldots, m\}$ [illegible] $l \notin \{1, 2, \ldots, n\}$

```
function $B =$ TNAddToNext$(B, x, i)$
$[m, n] =$ size$(B)$
$z = 0$
$b_{i0} = x$
while $(z < \min(i-1, n))$ and $(b_{i-1,z} = 0)$
    for $j = 1 : m - i + 1$
        $[c_j, d_j] = b_{j+i+1, z+j-1:z+j}$
    end
    $[c, d, q] =$ dqd2$(c, d)$
    for $j = 1 : m - i + 1$
        $b_{j+i+1, z+j-1:z+j} = [c_j, d_j]$
    end
    $i = i + q - 1$
    $z = z + q$
end
```

**4.2. Multiplication by a diagonal matrix.** The product of a diagonal matrix $F = \text{diag}(f_1, \ldots, f_m)$, $f_i > 0, i = 1, 2, \ldots, m$, and an $m \times n$ TN matrix $A$ is TN. We now show how to compute $\mathcal{BD}(FA)$, given $F$ and $\mathcal{BD}(A)$.

We propagate $F$ through the factors $L^{(k)}$ in $\mathcal{BD}(A)$ using

$$\begin{bmatrix} f_1 & & & \\ & f_2 & & \\ & & \ddots & \\ & & & f_m \end{bmatrix} \begin{bmatrix} 1 & & & \\ c_1 & 1 & & \\ & \ddots & \ddots & \\ & & c_{m-1} & 1 \end{bmatrix} = \begin{bmatrix} 1 & & & \\ b_1 & 1 & & \\ & \ddots & \ddots & \\ & & b_{m-1} & 1 \end{bmatrix} \begin{bmatrix} f_1 & & & \\ & f_2 & & \\ & & \ddots & \\ & & & f_m \end{bmatrix},$$

where $b_i = c_i f_{i+1} / f_i$, $i = 1, 2, \ldots, m - 1$.

Algorithm 4.3. [illegible] $B = BD(A)$ [illegible] $(f_1, f_2, \ldots, f_m)$ [illegible] $\mathcal{BD}(\operatorname{diag}(f_1, f_2, \ldots, f_m) \cdot A)$ [illegible] $2mn$ [illegible]

```
function $B =$ TNDiagonalScale$(f, B)$
$[m, n] =$ size$(B)$
$b_{11} = b_{11} f_1$
for $i = 2 : m$
    if $i \le n$
        $b_{ii} = b_{ii} f_i$
    end
    $b_{i,1:\min(i-1,n)} = b_{i,1:\min(i-1,n)} \cdot f_i / f_{i-1}$
end
```

## 5. The bidiagonal decomposition of derivative TN matrices.

Let $A$ be a TN matrix obtained from other TN matrices using one of the operations listed in Proposition 1.1 that preserve the total nonnegativity.

In this section we present accurate and efficient subtraction-free algorithms for computing $\mathcal{BD}(A)$, given the corresponding bidiagonal decompositions of the input TN matrices.

MATLAB implementation of all algorithms for performing accurate computations with TN matrices presented in this paper and [27] are available online from [26].

### 5.1. A product of EETs.

Let the TN matrix $A$ be given as

$$A = F^{(1)} F^{(2)} \cdots F^{(k)},$$

where $F^{(i)}$ represents an EET; namely, it equals either $E_j(x)$, $E_j^T(x)$, or a positive diagonal matrix. Then $\mathcal{BD}(A)$ can be accurately accumulated using Algorithms 4.2, 4.3, as well as Proposition 4.1 and Algorithm 4.1 from [27].

We will use this approach throughout this section. Say we want to compute $\mathcal{BD}(A)$, where the TN matrix $A$ is obtained from other TN matrices using operations that preserve the total nonnegativity. We will represent $A$ as a product of EETs, which we will then accumulate.

Since any nonnegative bidiagonal matrix is a product of EETs, [illegible] representation $A$ as a product of nonnegative bidiagonal matrices is a good starting point for performing accurate computations with $A$. Given any such representation, we can accumulate $\mathcal{BD}(A)$ without loss of accuracy.

### 5.2. The product of TN matrices.

Let $F$ and $C$ be $m \times n$ and $n \times p$ TN matrices such that $m \le n$ or $n \ge p$. Their product $FC$ is a TN matrix. If $B = \mathcal{BD}(C)$, then from (2.1) we have

$$C = \left( \prod_{i=1}^{n-1} \prod_{j=n-i+1}^{n} E_j(b_{j,i+j-n}) \right) \cdot D \cdot \left( \prod_{1}^{i=p-1} \prod_{p-i+1}^{j=p} E_j^T(b_{i+j-p,j}) \right).$$

Therefore, forming the product $FC$ is equivalent to applying a number of EETs to $F$.

Algorithm 5.1 (product). [illegible] $F$ [illegible] $C$ [illegible] $m \times n$ [illegible] $n \times p$ [illegible] $m \le n$ [illegible] $n \ge p$ [illegible] $A = \mathcal{BD}(F)$ [illegible] $B = \mathcal{BD}(C)$ [illegible] $\mathcal{BD}(FC)$ [illegible] $\mathcal{O}(mnp)$ [illegible]

```
function $A =$ TNProduct$(A, B)$
$[m, n] =$ size$(A)$
$p =$ size$(B, 2)$
for $i = 1 : n-1$
    for $j = n-i+1 : \min(n, n+p-i)$
        $A =$ TNAddToPrevious$(A, b_{j,i+j-n}, 1, j)$
    end
end
$A = A(:, 1 : \min(n, p))$
$A =$ TNDiagonalScale$(\mathrm{diag}(B), A^T)^T$
for $i = p-1 : -1 : 1$
    for $j = p : -1 : p-i+1$
        $A =$ TNAddToNext$(A^T, b_{i+j-p,j}, j)^T$
    end
end
```

The function `TNAddToPrevious`$(A, x, 1, i)$ "adds" a multiple $x$ of column $i$ to column $i-1$ and costs at most $6(m+2)$ [27, Algorithm 4.1].

**5.3. The re-signed inverse.** Let $A$ be an $n \times n$ TN matrix, and let $J$ be a diagonal matrix of alternating 1's and $-1$'s ($J_{ii} = (-1)^{i-1}$, $i = 1, 2, \ldots, n$). The [illegible] of $A$,

$$A^* \equiv \left[(-1)^{i+j} a_{ij}\right]^{-1} = (JAJ)^{-1} = JA^{-1}J,$$

is also TN [14]. Using $J^2 = I$, $(E_i(x))^{-1} = E_i(-x)$, $JE_i(-x)J = E_i(x)$, and (2.1),

$$\begin{aligned} A^* &= J \cdot \left( \prod_{i=1}^{n-1} \prod_{j=n-i+1}^{n} E_j^T(-b_{i+j-n,j}) \right) \cdot D^{-1} \cdot \left( \prod_{1}^{i=n-1} \prod_{n-i+1}^{j=n} E_j(-b_{j,i+j-n}) \right) \cdot J \\ &= \left( \prod_{i=1}^{n-1} \prod_{j=n-i+1}^{n} JE_j^T(-b_{i+j-n,j})J \right) \cdot JD^{-1}J \cdot \left( \prod_{1}^{i=n-1} \prod_{n-i+1}^{j=n} JE_j(-b_{j,i+j-n})J \right) \\ &= \left( \prod_{i=1}^{n-1} \prod_{j=n-i+1}^{n} E_j^T(b_{i+j-n,j}) \right) \cdot D^{-1} \cdot \left( \prod_{1}^{i=n-1} \prod_{n-i+1}^{j=n} E_j(b_{j,i+j-n}) \right). \end{aligned}$$

ALGORITHM 5.2 (re-signed inverse). [illegible] $A$ [illegible] $n \times n$ [illegible] $B = \mathcal{BD}(A)$ [illegible] $C = \mathcal{BD}(A^*)$ [illegible] $\mathcal{O}(n^3)$ [illegible]

```
function $C =$ TNRSInverse$(B)$
$n =$ size$(B, 1)$
$C = I$
for $i = 1 : n-1$
    for $j = n-i+1 : n$
        $C =$ TNAddToNext$(C, b_{j,i+j-n}, j)$
    end
end
$C =$ TNDiagonalScale$((1/b_{11}, \ldots, 1/b_{nn}), C)$
for $i = n-1 : -1 : 1$
    for $j = n : -1 : n-i+1$
        $C =$ TNAddToPrevious$(C^T, b_{i+j-n,j}, 1, j)^T$
    end
end
```

**5.4. The converse.** If the $m \times n$ matrix $A = [a_{ij}]_{i,j=1}^{m,n}$ is TN, then so is its [illegible] [19]

$$A^{\#} \equiv [a_{m+1-i,n+1-j}]_{i,j=1}^{m,n}.$$

Let $B = \mathcal{BD}(A)$, and let $Y_k \equiv [\delta_{k+1-i,j}]_{i,j=1}^{k}$ be the [illegible] of size $k$. Using $Y_k^2 = I$ and $E_i^{\#}(x) = Y_k E_i(x) Y_k = E_{k+2-i}^T(x)$, we obtain

$$\begin{aligned}
A^{\#} &= Y_m A Y_n \\
&= Y_m \left( \prod_{i=1}^{m-1} \prod_{j=m-i+1}^{m} E_j(b_{j,i+j-m}) \right) D \left( \prod_{1}^{i=n-1} \prod_{n-i+1}^{j=n} E_j^T(b_{i+j-n,j}) \right) Y_n \\
&= \left( \prod_{i=1}^{m-1} \prod_{j=m-i+1}^{m} Y_m E_j(b_{j,i+j-m}) Y_m \right) Y_m D Y_n \left( \prod_{1}^{i=n-1} \prod_{n-i+1}^{j=n} Y_n E_j^T(b_{i+j-n,j}) Y_n \right) \\
&= \left( \prod_{i=1}^{m-1} \prod_{j=m-i+1}^{m} E_{m+2-j}^T(b_{j,i+j-m}) \right) D^{\#} \left( \prod_{1}^{i=n-1} \prod_{n-i+1}^{j=n} E_{n+2-j}(b_{i+j-n,j}) \right),
\end{aligned} \tag{5.1}$$

where $D^{\#} = Y_m D Y_n$ is an $m \times n$ diagonal matrix, $D_{ii}^{\#} = b_{k+1-i,k+1-i}$, $k = \min(m,n)$, $i = 1, 2, \ldots, k$. We compute $\mathcal{BD}(A^{\#})$ as the bidiagonal decomposition of the product of all EETs in (5.1).

ALGORITHM 5.3 (converse). [illegible] $B = \mathcal{BD}(A)$ [illegible] $m \times n$ [illegible] $A$ [illegible] $\mathcal{BD}(A^{\#})$ [illegible] $\mathcal{O}(mn^2)$ [illegible]

```
function $C$ = TNConverse($B$)
$[m, n]$ = size($B$)
$C$ = eye($m, n$)
for $i = 1 : m-1$
    for $j = m-i+1 : m$
        $C$ = TNAddToNext($A^T, b_{j,i+j-m}, m+2-j)^T$
    end
end
$e$ = diag($B$)
$C$ = TNDiagonalScale($e(\min(m,n) : -1 : 1), C^T)^T$
for $i = n-1 : -1 : 1$
    for $j = n : -1 : n-i+1$
        $A$ = TNAddToPrevious($A, b_{i+j-n,j}, 1, n+2-j$)
    end
end
```

**5.5. QR decomposition.** Let $A$ be TN, and let $A = QR$ be its QR decomposition such that $R$ has a positive diagonal. Then $R$ is TN and can be obtained by applying Givens rotations to $A$. Each Givens rotation preserves the TN structure of $A$ and equals the product of three EETs [27, section 4.3].

ALGORITHM 5.4 (QR decomposition). [illegible] $A$ [illegible] $m \times n$ [illegible] $A = QR$ [illegible] $A$ [illegible] $r_{ii} > 0$, $i = 1, 2, \ldots, \min(m,n)$ [illegible] $B = \mathcal{BD}(A)$ [illegible] $\mathcal{BD}(R)$ [illegible] $\mathcal{O}(mn^2)$ [illegible]

```
function $B = $ TNQR($B$)
$[m, n] = $ size($B$)
for $i = 1 : n$
    for $j = m : -1 : i+1$
        $x = b_{ji}$
        $b_{ji} = 0$
        $c = \sqrt{1 + x^2}$
        $B = ($TNAddToPrevious$(B^T, x/c, c, j))^T$
    end
end
```

**5.6. QR iteration.** Gladwell showed in [20] that if $A$ is TN and symmetric, then one step of $QR$ iteration without pivoting (provided $R$ has a positive diagonal) preserves the TN structure. We will now show how to compute the result of this iteration accurately using algorithms we already have.

Let $A$ be TN and symmetric, and let $A = LDU = QR$ be its $LDU$ and $QR$ decompositions, respectively, with $R$ having a positive diagonal.[2] Let $Q = LD_1U_1$ be the $LDU$ decomposition of $Q$ ($Q$ and $A$ share the $L$ factor).

Let $F = RQ$ be the result of one step of QR iteration performed on $A$. Then $F = RQ = RLD_1U_1$. Since $F$ is symmetric, it suffices to compute the lower bidiagonal factors and the diagonal factor of $\mathcal{BD}(F)$. Since $U_1$ is unit upper triangular, it thus suffices to compute $\mathcal{BD}(RLD_1)$. Since the factors are TN, this task is easy. We first use `TNQR` to obtain $\mathcal{BD}(R)$ and then `TNProduct` to obtain $\mathcal{BD}(RLD_1)$. We obtain $D_1$ by comparing the diagonals of the upper triangular matrices $DU = D_1U_1R$.

**5.7. The Schur complement.** Let $A$ be an $m \times n$ TN matrix, and let $A'$ be obtained from $A$ after one step of Gaussian elimination. We have $A' = KA$, where

$$
\begin{aligned}
K &= \begin{bmatrix} 1 & & & & \\ -\frac{a_{21}}{a_{11}} & 1 & & & \\ -\frac{a_{32}}{a_{11}} & & 1 & & \\ \vdots & & & \ddots & \\ -\frac{a_{m1}}{a_{11}} & & & & 1 \end{bmatrix} \\
&= \begin{bmatrix} 1 & & & & \\ & 1 & & & \\ & & \ddots & & \\ & & & 1 & \\ & & & \frac{a_{m1}}{a_{m-1,1}} & 1 \end{bmatrix} \begin{bmatrix} 1 & & & & \\ & 1 & & & \\ & & \ddots & & \\ & & \frac{a_{m-1,1}}{a_{m-2,1}} & 1 & \\ & & & & 1 \end{bmatrix} \cdots \begin{bmatrix} 1 & & & \\ & 1 & & \\ & \frac{a_{31}}{a_{21}} & 1 & \\ & & & \ddots & \\ & & & & 1 \end{bmatrix} \\
&\quad \times \begin{bmatrix} 1 & & & & \\ -\frac{a_{21}}{a_{11}} & 1 & & & \\ & -\frac{a_{31}}{a_{21}} & 1 & & \\ & & \ddots & \ddots & \\ & & & -\frac{a_{m1}}{a_{m-1,1}} & 1 \end{bmatrix} \\
&= \prod_{3}^{i=m} E_i(b_{i1}) \times \prod_{i=2}^{m} E_i(-b_{i1})
\end{aligned}
$$

---

[2] Technically, since $A$ is symmetric, $U = L^T$, but this is unimportant here.

is a product of EETs. Forming the product

$$\left(\prod_{i=2}^{m} E_i(-b_{i1})\right) \cdot A$$

is equivalent to using adjacent rows to zero out the first column of $A$. It is therefore equivalent to simply setting $b_{i1} = 0,\ i = 2, 3, \ldots, m$ [27, section 4.1].

The multiplications by $E_i(b_{i1}),\ i = m, \ldots, 3$, are performed using Algorithm 4.2.

ALGORITHM 5.5 (Schur complement). [illegible] $A$ [illegible] $m \times n$ [illegible] $A'$ [illegible] $A$ [illegible] $B = \mathcal{BD}(A)$ [illegible] $\mathcal{BD}(A')$ [illegible] $\mathcal{O}(mn)$

```
function $B$ = TNSchurComplement($B$)
$m$ = size($B, 1$)
$c = B(:, 1)$
$B(2 : m, 1) = 0$
for $i = 3 : m$
    $B$ = TNAddToNext($B, c_i, i$)
end
```

**5.8. A submatrix.** Any submatrix $C$ of a TN matrix $A$ is TN. In this section we show how to compute $\mathcal{BD}(C)$, given $\mathcal{BD}(A)$. It suffices to describe how to compute $\mathcal{BD}(C)$ when $C$ is obtained by removing row $i$ from $A$. We assume that $C$ is TN.

Consider first the case $i = 1$, i.e., $C$ is obtained by removing the first row of $A$:

$$A = \begin{bmatrix} a_{11} & a_{12} & \ldots & a_{1n} \\ a_{21} & a_{22} & \ldots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{m1} & a_{m2} & \ldots & a_{mn} \end{bmatrix}, \quad C = \begin{bmatrix} a_{21} & a_{22} & \ldots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{m1} & a_{m2} & \ldots & a_{mn} \end{bmatrix}.$$

Let

$$\mathcal{BD}(A) = \left\{ \begin{matrix} b_{11} & b_{12} & \ldots & b_{1n} \\ b_{21} & b_{22} & \ldots & b_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ b_{m1} & b_{m2} & \ldots & b_{mn} \end{matrix} \right\}, \quad \mathcal{BD}(C) = \left\{ \begin{matrix} f_{21} & f_{22} & \cdots & f_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ f_{m1} & f_{m2} & \cdots & f_{mn} \end{matrix} \right\}.$$

Let $A'$ be obtained from $A$ by using adjacent columns to zero out the first row of $A$ above the main diagonal:

$$A' = A \cdot E_n^T(-b_{1n}) \cdot E_{n-1}^T(-b_{1,n-1}) \cdots E_2^T(-b_{12}). \tag{5.2}$$

Then

$$A' = \begin{bmatrix} a'_{11} & 0 & \ldots & 0 \\ a'_{21} & a'_{22} & \ldots & a'_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a'_{m1} & a'_{m2} & \ldots & a'_{mn} \end{bmatrix} \quad \text{and} \quad \mathcal{BD}(A') = \left\{ \begin{matrix} b_{11} & 0 & \ldots & 0 \\ b_{21} & b_{22} & \ldots & b_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ b_{m1} & b_{m2} & \ldots & b_{mn} \end{matrix} \right\}.$$

Let $C'$ be obtained by removing the first row of $A'$. From (5.2) we have

$$C' = C \cdot E_n^T(-b_{1n}) \cdot E_{n-1}^T(-b_{1,n-1}) \cdots E_2^T(-b_{12}),$$

which implies

$$C = C' \cdot E_2^T(b_{12}) \cdot E_3^T(b_{13}) \cdots E_n^T(b_{1n}). \tag{5.3}$$

Therefore, it suffices to obtain $\mathcal{BD}(C')$. (Then we will use Algorithm 4.2 to obtain $\mathcal{BD}(C)$ using (5.3).)

Let

$$C' = \begin{bmatrix} a'_{21} & a'_{22} & \cdots & a'_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a'_{m1} & a'_{m2} & \cdots & a'_{mn} \end{bmatrix} \quad \text{and} \quad \mathcal{BD}(C') = \left\{ \begin{array}{cccc} f'_{21} & f'_{22} & \cdots & f'_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ f'_{m1} & f'_{m2} & \cdots & f'_{mn} \end{array} \right\}.$$

Consider the process of Neville elimination applied to $A'$ and $C'$ to eliminate the entries $a'_{jk}$, $j \neq k, k+1$, and reduce $A'$ and $C'$ to lower and upper bidiagonal matrices $\bar{A}$ and $\bar{C}$, respectively. The same multipliers will be used in this elimination:

$$f'_{jk} = b_{jk} \quad \text{for} \quad j \neq k, k+1.$$

The matrix

$$\bar{C} = \begin{bmatrix} f'_{21} & & & \\ & f'_{32} & & \\ & & f'_{43} & \\ & & & \ddots \end{bmatrix} \begin{bmatrix} 1 & f'_{22} & & \\ & 1 & f'_{33} & \\ & & 1 & \\ & & & \ddots \end{bmatrix} \tag{5.4}$$

is obtained by removing the first row of

$$\bar{A} = \begin{bmatrix} 1 & & & \\ b_{21} & 1 & & \\ & b_{32} & 1 & \\ & & & \ddots \end{bmatrix} \begin{bmatrix} b_{11} & & & \\ & b_{22} & & \\ & & b_{33} & \\ & & & \ddots \end{bmatrix}. \tag{5.5}$$

By comparing entries in (5.4) and (5.5), we obtain

$$f'_{i+1,i} = b_{i+1,i} b_{ii} \quad \text{and} \quad f'_{i+1,i+1} = \frac{b_{i+1,i+1}}{b_{i+1,i} b_{ii}}.$$

We have obtained the entire $\mathcal{BD}(C')$.

Now consider the general case—we remove the $i$th row of $A$ to obtain $C$. In the process of Neville elimination, the same multipliers will be used to eliminate the first row of $C$ that were used to eliminate the first row of $A$.

We emulate the Neville elimination of the first [illegible] of $C$ by eliminating the first column of $A$ in a slightly different order. We use adjacent rows to eliminate the entries of the first column of $A$ with the exception of $a_{i+1,1}$. We use row $i-1$ to eliminate $a_{i+1,1}$—the exact same row that would be used to eliminate $a_{i+1,1}$ in $C$ using [illegible] rows.

This Gaussian-type elimination of rows $i$ and $i+1$ in $A$ can be handled in the same way as in section 5.7. We represent the elimination of rows $i$ and $i+1$ as a sequence of three EETs:

$$\begin{bmatrix} 1 & & \\ -\frac{a_i}{a_{i-1}} & 1 & \\ -\frac{a_{i+1}}{a_{i-1}} & & 1 \end{bmatrix} = \begin{bmatrix} 1 & & \\ -b_{i1} & 1 & \\ -b_{i+1,1}b_{i1} & & 1 \end{bmatrix}$$

$$= \begin{bmatrix} 1 & & \\ & 1 & \\ & b_{i+1,1} & 1 \end{bmatrix} \begin{bmatrix} 1 & & \\ -b_{i1} & 1 & \\ & -b_{i+1,1} & 1 \end{bmatrix}$$

$$= E_{i+1}(b_{i+1,1})E_i(-b_{i1})E_{i+1}(-b_{i+1,1}).$$

We then proceed by induction. We eliminate the second row and the second column of $A$ and so on until we have eliminated the first $i$ rows and the first $i$ columns of $A$. Now we are in familiar territory—we need to remove the first row of the trailing submatrix $A(i:m, i:n)$.

ALGORITHM 5.6 (submatrix). [illegible] $A$ [illegible] $m \times n$ [illegible] $C$ [illegible] $i$ [illegible] $A$ [illegible] $\mathcal{BD}(A)$ [illegible] $\mathcal{BD}(C)$ [illegible] $\mathcal{O}(n^2)$ [illegible].

```
function $B$ = TNSubmatrix($B, i$)
$[m, n]$ = size($B$)
if $i < m$
    for $j = 1 : \min(i-1, n)$
        $B(j+1:m, j+1:n)$ = TNAddToNext($B(j+1:m, j+1:n), b_{i+1,j}, i-j+1$)
        $b_{i+1,j} = b_{i+1,j}b_{ij}$
    end
    for $j = \min(n, m) + (m > n) : -1 : i+1$
        $b_{j,j-1} = b_{j,j-1}b_{j-1,j-1}$
        if $j \le n$
            $b_{jj} = b_{jj}/b_{j,j-1}$
        end
    end
    for $j = i+1 : n$
        $B(i+1:m, i:n)$ = TNAddToNext($B(i+1:m, i:n)^T, b_{ij}, j-i+1)^T$
    end
end
Remove the $i$th row of $B$
```

**6. Generalized Vandermonde matrices.** In this section we describe how to easily, accurately, and efficiently compute the bidiagonal decomposition of a TN generalized Vandermonde matrix

$$G \equiv \left[x_i^{j-1+\lambda_{n-j+1}}\right]_{i,j=1}^n$$

with $\lambda_1 \ge \lambda_2 \ge \cdots \ge \lambda_n \ge 0$, $\lambda_i \in \mathbb{Z}, i = 1, 2, \ldots, n$. The matrix $G$ is well known to be TN when $0 < x_1 < x_2 < \cdots < x_n$ [14, p. 76]. The nodes $x_i$ and the [illegible] $\lambda = (\lambda_1, \lambda_2, \ldots, \lambda_n)$ of $|\lambda| = \lambda_1 + \lambda_2 + \cdots + \lambda_n$ are typical parameters used to describe generalized Vandermonde matrices. When $\lambda = (0, \ldots, 0)$, $G$ reduces to the ordinary Vandermonde matrix $V \equiv \left[x_i^{j-1}\right]_{i,j=1}^n$.

There have been a couple of attempts at deriving accurate algorithms for this class of matrices, and both have shortcomings.

In 1977 Van de Vel [34] proposed a subtraction-free algorithm for the LDU decomposition of $G$. While accuracy was clearly guaranteed, efficiency was not. Recently, motivated by this result and some theoretical arguments [6, section 9.1(2)], Demmel and the current author presented an accurate algorithm for computing $\mathcal{BD}(G)$ [8, 9]. While this algorithm is accurate and efficient (its complexity is bounded by $\mathcal{O}(n^2|\lambda|^{2+\rho}\lambda_1^{3+\rho})$, where $\rho$ is tiny [8, (3.9)]), it requires extended precision arithmetic when computing the Schur function in the intermediate steps [9]. This is a drawback.

With the results of this paper we are finally able to put this issue to rest by presenting a new very simple algorithm for computing $\mathcal{BD}(G)$, which is accurate and efficient—it costs only $\mathcal{O}(n^2\lambda_1)$ (and is thus much more efficient than the algorithm in [8]) and does not require the use of extended precision arithmetic. Once we have $\mathcal{BD}(G)$, we can clearly perform virtually all linear algebra with $G$ at a modest $\mathcal{O}(n^3)$ additional cost.

Our idea is very simple: Start with the rectangular (ordinary) TN Vandermonde matrix

$$F = \left[x_i^{j-1}\right]_{i=1,j=1}^{n,n-1+\lambda_1}.$$

The decomposition $\mathcal{BD}(F)$ is readily available in $\mathcal{O}(n(n+\lambda_1))$ time using the formulas in [27, section 3, (3.6)]. We can then use Algorithm 5.6 to remove the appropriate $\lambda_1$ columns of $F$ (at the cost of $\mathcal{O}(n^2)$ per column) to obtain $\mathcal{BD}(G)$. The total cost is nicely bounded by $\mathcal{O}(n^2\lambda_1)$.

## 7. Numerical experiments.

The algorithms presented in this paper can be used to perform a variety of accurate computations with TN matrices. We performed many tests to confirm their correctness and accuracy. In this section we present two numerical examples which incorporate several techniques for computing with TN matrices and demonstrate the accuracy and significance of our new algorithms.

For our experiments we selected two well-known notoriously ill-conditioned TN matrices—Hilbert and Pascal:

$$H = \left[\frac{1}{i+j-1}\right]_{i,j=1}^{m,n} \quad \text{and} \quad P = \left[\binom{i+j}{i}\right]_{i,j=1}^{n,p}.$$

We selected $m = 20, n = 30$, and $p = 20$, yielding fairly ill-conditioned $H$ and $P$: $\kappa(H) = 3.3 \cdot 10^{25}$ and $\kappa(P) = 1.2 \cdot 10^{20}$. Both experiments involved the product $T = HP$, which was also severely ill-conditioned: $\kappa(T) = 6 \cdot 10^{45}$.

In our first experiment, we computed the singular values of $T = HP$ using the MATLAB implementations of our accurate algorithms[3]

(7.1) `TNSingularValues(TNProduct(TNCauchyBD(1:m,0:n-1),ones(n,p)))`

and also via the conventional MATLAB call

(7.2) `svd(H*P).`

For verification, we formed $H$ and $P$, computed their product $T$, and computed $T$'s singular values in 70-digit decimal floating point arithmetic using the MATLAB function `vpa`. Since $\kappa(T) = 6 \cdot 10^{45}$, `vpa` returned the singular values of $T$ with at least 16 correct decimal digits in each. The results of `vpa` agreed to at least 14 digits with the ones computed using (7.1), confirming the accuracy of our algorithms.

---

[3] `TNSingularValues` is Algorithm 6.1 from [27], `TNProduct` is Algorithm 5.1 (see section 5); `TNCauchyBD` computes the bidiagonal decomposition of $H$ accurately using the formulas from [27, section 3]; the entries of $\mathcal{BD}(P)$ are all ones, i.e., $\mathcal{BD}(P)$ equals `ones(n,p)`.

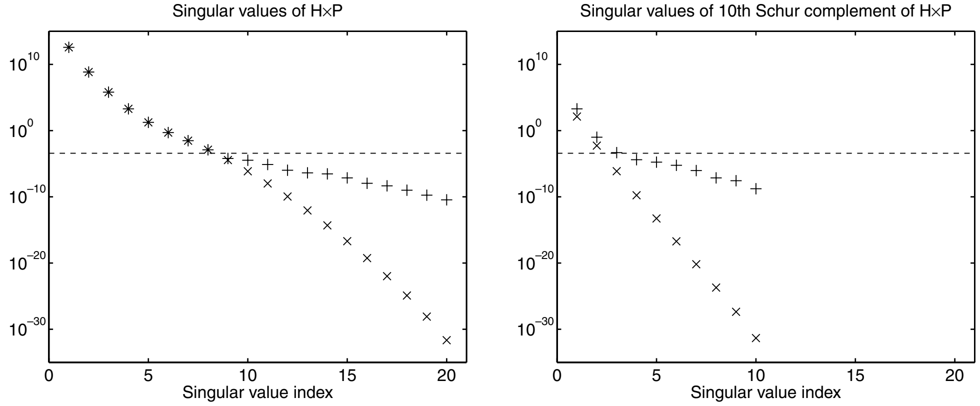

FIG. 7.1. *The singular values of the product $T$ of the $20 \times 30$ Hilbert matrix $H$ and the $30 \times 20$ Pascal matrix $P$ (left plot) and the* 10*th Schur complement of $T$ (right plot); "$\times$" = new, accurate algorithms, "$+$" = conventional. The dashed line represents the roundoff threshold, $\|T\| \cdot \varepsilon$.*

In contrast, the conventional singular value algorithms (7.2) in double precision [2] binary floating point arithmetic computed only the largest ones ($\sigma_i > \sigma_1\varepsilon = \|T\|\varepsilon$, where $\varepsilon \approx 10^{-16}$ is the machine precision) with any relative accuracy at all.

The results of this experiment are plotted in Figure 7.1, left.

In our second experiment, we computed the singular values of the 10th Schur complement of $T$ using the same three methods—our new algorithms (in particular, `TNSchurComplement`, Algorithm 5.5) and a conventional MATLAB call, and finally verified the results in extended precision arithmetic. As expected, our new algorithms computed all singular values of the 10th Schur complement of $T$ accurately, while the conventional MATLAB call failed to compute even a single singular value accurately (Figure 7.1, right).

Although this experiment is somewhat artificially contrived, it shows that very simple TN-preserving operations can result in a situation where the conventional matrix algorithms fail to deliver any accuracy at all.

## 8. Conclusions and open problems.

Using the intrinsic representation of TN matrices as a products of bidiagonal matrices allows for accurate computations with these matrices. The cost is similar to that of the conventional algorithms, but the computations are performed to high [illegible] accuracy, as opposed to the high [illegible] accuracy of the conventional algorithms.

The singular (square) totally nonnegative matrices may not have a bidiagonal decomposition, or it may not be unique. Designing new algorithms (or adapting the ones in this paper) to perform accurate computations with these matrices is still an open problem.

The problem of finding algorithms for computing accurate eigenvectors of TN matrices is also open. In particular, such algorithms should guarantee the intrinsic properties of the eigenvector matrix—the $j$th computed eigenvector should have $j-1$ changes of sign in its entries, and the eigenvector matrix should have an LU decomposition such that $L$ and $U^{-1}$ are TN [14, 17].

The caveat in our algorithms is that every TN matrix must be represented by its bidiagonal decomposition. While every TN matrix intrinsically possesses such a decomposition, and for many classes of structured matrices this decomposition is very easy to obtain accurately (see section 2), there are important TN matrices for which we know of no accurate and efficient way to compute their bidiagonal decompositions. Two such examples are the following:

- the TN generalized Vandermonde matrix $\left[x_i^{y_j}\right]_{i,j=1}^n$, where $0 < x_1 < \cdots < x_n$, $0 < y_1 < y_2 < \cdots < y_n$, and at least one $y_i$ is not an integer;
- the TN matrices appearing in the study of the hypergeometric function of a matrix argument [21].

**Acknowledgments.** I am deeply indebted to James Demmel for suggesting this problem and for providing motivation and insights during the preparation of this work. I also thank Froilán Dopico and Juan Manuel Peña for the careful reading of the manuscript and for pointing out inconsistencies in its earlier versions.

# SYMMETRIC INDEFINITE PRECONDITIONERS FOR SADDLE POINT PROBLEMS WITH APPLICATIONS TO PDE-CONSTRAINED OPTIMIZATION PROBLEMS*

JOACHIM SCHÖBERL[†] AND WALTER ZULEHNER[‡]

**Abstract.** We consider large scale sparse linear systems in saddle point form. A natural property of such indefinite 2-by-2 block systems is the positivity of the (1,1) block on the kernel of the (2,1) block. Many solution methods, however, require that the positivity of the (1,1) block is satisfied everywhere. To enforce the positivity everywhere, an augmented Lagrangian approach is usually chosen. However, the adjustment of the involved parameters is a critical issue. We will present a different approach that is not based on such an explicit augmentation technique. For the considered class of symmetric and indefinite preconditioners, assumptions are presented that lead to symmetric and positive definite problems with respect to a particular scalar product. Therefore, conjugate gradient acceleration can be used. An important class of applications are optimal control problems. It is typical for such problems that the cost functional contains an extra regularization parameter. For control problems with elliptic state equations and distributed control, a special indefinite preconditioner for the discretized problem is constructed, which leads to convergence rates of the preconditioned conjugate gradient method that are not only independent of the mesh size but also independent of the regularization parameter. Numerical experiments are presented for illustrating the theoretical results.

## 1. Introduction.

In this paper we consider large scale sparse linear systems of equations in saddle point form

$$\begin{pmatrix} A & B^T \\ B & 0 \end{pmatrix} \begin{pmatrix} x \\ p \end{pmatrix} = \begin{pmatrix} f \\ g \end{pmatrix}, \tag{1.1}$$

where $A$ is a real, symmetric, and positive semidefinite $n$-by-$n$ matrix, $B$ is a real $m$-by-$n$ matrix with full rank $m \leq n$, and $B^T$ denotes the transposed matrix of $B$. Such systems typically result from the discretization of mixed variational problems for systems of partial differential equations (PDEs) (see Brezzi and Fortin [8]) in particular, from the discretization of optimization problems with PDE-constraints. A natural property of such a problem is that $A$ is positive definite on the kernel of $B$, i.e.,

$$(Aw, w) > 0 \quad \text{for all } w \in \ker B \text{ with } w \neq 0, \tag{1.2}$$

---

where $(x, w)$ denotes the Euclidean scalar product. This condition guarantees, in combination with the full rank of $B$, that the matrix

$$\mathcal{K} = \begin{pmatrix} A & B^T \\ B & 0 \end{pmatrix}$$

is nonsingular.

Under the assumptions stated above, the system (1.1) can be interpreted as the Karush–Kuhn–Tucker (KKT) conditions, which characterize the solution $x$ of the following constrained optimization problem (see, e.g., Fletcher [14]):

$$\text{Minimize} \quad J(x) \equiv \frac{1}{2}(Ax, x) - (f, x) \quad \text{subject to the constraints} \quad Bx = g$$

with associated Lagrangian parameter $p$.

Most of the work on efficient iterative methods for solving (1.1) has been done under the assumption that the matrix $A$ is positive definite not only on $\ker B$ but on the whole space $\mathbb{R}^n$, with the consequence that the (negative) Schur complement $S = BA^{-1}B^T$ is well defined. Most of the proposed methods can be viewed as preconditioned Richardson methods for (1.1) typically accelerated by a Krylov subspace method; see Saad and van der Vorst [23] for a review of iterative methods for linear systems. The discussed preconditioners for $\mathcal{K}$ are 2-by-2 block matrices $\hat{\mathcal{K}}$ depending on a preconditioner $\hat{A}$ for approximating $A$ and a preconditioner $\hat{S}$, which is either interpreted as an approximation of the Schur complement $S$ or as an approximation of the so-called inexact Schur complement $H = B\hat{A}^{-1}B^T$. Typical classes of such preconditioners which rely on a positive definite matrix $A$ are block diagonal preconditioners (see, e.g., Rusten and Winther [22], Silvester and Wathen [24]), block triangular preconditioners (originating from the classical Uzawa method [2]; see also, e.g., Elman and Golub [12], Bramble, Pasciak, and Vassilev [7]), symmetric indefinite preconditioners (see, e.g., Dyn and Ferguson [11], Bank, Welfert, and Yserentant [3], Rozložník and Simoncini [21], Al-Jeiroudi, Gondzio, and Hall [1], and Dollar [9]), and symmetric positive definite block (but not block diagonal) preconditioners; see Vassilevski and Lazarov [26]. Depending on the properties of the preconditioned systems, Krylov subspace methods either for symmetric indefinite or for nonsymmetric systems like MINRES, BiCG, or GMRES were proposed. In Bramble and Pasciak [6], a block triangular preconditioner was used in order to obtain a preconditioned system which is symmetric and positive definite and, therefore, can be solved by the conjugate gradient method (CG), which is usually considered the best or at least the best-understood Krylov subspace method. The block triangular preconditioner in [6] requires a symmetric and positive definite approximation $\hat{A}$ with $A - \hat{A}$ positive definite. In [21] an interesting equivalence between the right preconditioned simplified BiCG and a preconditioned conjugate gradient method (PCG) was obtained for the proposed indefinite preconditioner for a particular choice of the residuals. Yet another strategy to use CG was discussed, e.g., in Fischer et al. [13] and in Benzi and Simoncini [5], where the saddle point problem (1.1) was reformulated by multiplying the second block row by $-1$ leading to a positive stable but nonsymmetric system matrix.

In this paper, however, we will focus on systems where $A$ is positive definite in a stable way (to be specified later) only on $\ker B$, a typical situation for certain classes of optimization problems with PDE-constraints. One strategy is to enforce the definiteness on the whole space $\mathbb{R}^n$ by the augmented Lagrangian approach, where the matrix $A$ and the vector $f$ in (1.1) are replaced by a matrix of the form $A_W = A + B^T W B$ and a vector $f_W = f + B^T W g$, respectively, with an appropriate matrix $W$; see, e.g., Fortin and Glowinski [15]. This does not change the solution of the problem, and the new (1,1) block $A_W$ becomes positive definite if $W$ is properly chosen, e.g., if it is positive definite and all methods from above applied to the augmented system could be used, in principle. It is, however, a delicate issue to choose the matrix $W$ in order to obtain good convergence properties; see the discussions in Golub and Greif [16], Golub, Greif, and Varah [17]. Another approach is offered by a particular class of symmetric indefinite preconditioners; the so-called constraint preconditioners; see, e.g., Keller, Gould, and Wathen [20], Gould, Hribar, and Nocedal [18], and Dollar et al. [10]. These preconditioners are not restricted to the case of positive definite matrices $A$. For this class of preconditioners (projected), PCG was successfully used as an acceleration technique. One possible drawback of this class of preconditioners is the computational costs involved in the application of the preconditioner, where in some way or another some projection onto $\ker B$ has to be realized.

For a much more detailed discussion of available methods for saddle point problems, we refer to the review article by Benzi, Golub, and Liesen [4].

Here we will take a different approach and discuss preconditioners $\hat{\mathcal{K}}$ for the original system matrix $\mathcal{K}$ (without augmentation), which, nevertheless, also work well in the case that $A$ is positive definite only on the kernel of $B$. Under appropriate assumptions it will be shown that the preconditioned matrix $\hat{\mathcal{K}}^{-1}\mathcal{K}$ is even symmetric and positive definite in some appropriate scalar product. Therefore, CG acceleration can be applied. In contrast to Bramble and Pasciak [6], this new technique requires a symmetric and positive definite approximation $\hat{A}$ with $\hat{A} - A$ positive definite, which is easier to achieve and can also be applied if $A$ itself is only positive definite on the kernel of $B$.

An important field of applications are PDE-constrained optimization problems, in particular, optimal control problems; see, e.g., Tröltzsch [25]. It is typical for optimal control problems that the cost functional contains an extra regularization parameter. If discretized by an appropriate finite element method, the resulting KKT system is of the form (1.1), where the matrices $A$ and $B$ depend on the underlying subdivision, say with mesh size $h$, and on the regularization parameter, say $\nu$. For optimal control problems with elliptic state equations and distributed control, a special symmetric indefinite preconditioner will be constructed, and convergence rate estimates are given which are robust in $h$ as well as in $\nu$.

The paper is organized as follows: In section 2 the considered class of preconditioners is introduced and analyzed. Section 3 describes how the algebraic conditions for the preconditioners are linked to the conditions of Brezzi's theorem for mixed variational problems, and a general framework for constructing the preconditioners is sketched. In section 4 a problem from optimal control is discussed and preconditioners are constructed which are robust with respect to the mesh size as well as to the involved regularization parameter. Implementation issues are discussed in section 5 and numerical experiments are presented in section 6, followed by some concluding remarks.

Throughout the paper the following notations are used: $M < N$ ($N > M$) iff $N - M$ is positive definite, and $M \leq N$ ($N \geq M$) iff $N - M$ is positive semidefinite for symmetric matrices $M$ and $N$. For a symmetric and positive definite matrix $M$, the associated scalar product $(v, w)_M$ and norm $\|v\|_M$ are given by

$$(v, w)_M = (Mv, w) \quad \text{and} \quad \|v\|_M = (v, v)_M^{1/2},$$

where $(v, w)$ (without index) denotes the Euclidean scalar product. The Euclidean norm of a vector $v$ is denoted by $\|v\|$ (without index).

## 2. A class of symmetric and indefinite preconditioners.

A well-known class of preconditioners is given by

$$\hat{\mathcal{K}} = \begin{pmatrix} \hat{A} & B^T \\ B & B\hat{A}^{-1}B^T - \hat{S} \end{pmatrix},$$

where $\hat{A}$ and $\hat{S}$ are symmetric and positive definite matrices; see Bank, Welfert, and Yserentant [3]. More precisely, we will assume that $\hat{A}$ and $\hat{S}$ are preconditioners; i.e., efficient evaluations of $\hat{A}^{-1}s$ and $\hat{S}^{-1}t$ are available for given vectors $s$ and $t$.

We have the following factorization:

$$\hat{\mathcal{K}} = \begin{pmatrix} I & 0 \\ B\hat{A}^{-1} & I \end{pmatrix} \begin{pmatrix} \hat{A} & B^T \\ 0 & -\hat{S} \end{pmatrix},$$

which implies that $\hat{\mathcal{K}}$ is nonsingular and that the solution of a linear system

$$\hat{\mathcal{K}} \begin{pmatrix} w \\ q \end{pmatrix} = \begin{pmatrix} s \\ t \end{pmatrix}$$

reduces to the consecutive solution of the following three linear systems:

$$\hat{A}\hat{w} = s,$$

$$\hat{S}\,q = B\hat{w} - t,$$

$$\hat{A}w = s - B^T q.$$

So, one application of the preconditioner $\hat{\mathcal{K}}$ requires two applications of the preconditioner $\hat{A}$ and one application of the preconditioner $\hat{S}$.

In Bank, Welfert, and Yserentant [3] and later in Zulehner [27], this preconditioner has been analyzed for the case that $A$ is positive definite. One important part of the analysis easily carries over to the case considered here.

THEOREM 2.1. [illegible] $A \ge 0$ [illegible] (1.2) [illegible] $\operatorname{rank} B = m$ [illegible] $\hat{A} > 0$ [illegible] $\hat{S} > 0$

1. [illegible]

$$\hat{A} \ge A \qquad \hat{S} \le B\hat{A}^{-1}B^T, \tag{2.1}$$

[illegible] $\hat{\mathcal{K}}^{-1}\mathcal{K}$ [illegible]

2. [illegible]

$$\hat{A} > A \qquad \hat{S} < B\hat{A}^{-1}B^T, \tag{2.2}$$

[illegible] $\hat{\mathcal{K}}^{-1}\mathcal{K}$ [illegible]

$$\left( \begin{pmatrix} x \\ p \end{pmatrix}, \begin{pmatrix} w \\ q \end{pmatrix} \right)_{\mathcal{D}} = ((\hat{A} - A)x, w) + ((B\hat{A}^{-1}B^T - \hat{S})p, q). \tag{2.3}$$

[illegible]. Apply Theorem 5.2 from Zulehner [27] to the regularized matrices $A + \varepsilon I$ and $\hat{A} + \varepsilon I$ for $\varepsilon > 0$, take the limit $\varepsilon \to 0$, and observe that $\mathcal{K}$ is nonsingular. ☐

Estimates for the extreme eigenvalues of $\hat{\mathcal{K}}^{-1}\mathcal{K}$ were derived in Zulehner [27] under the assumption that $A$ is positive definite on the whole space. However, the estimate for the smallest eigenvalue degenerates, if directly applied to the case considered here. In this paper this gap will be closed.

First of all, we have to discuss reasonable assumptions on $\hat{A}$ and $\hat{S}$, which measure the quality of these preconditioners. Comparing the matrix $\mathcal{K}$ and the preconditioner $\hat{\mathcal{K}}$, it seems to be natural to consider $\hat{A}$ as an approximation to $A$ at least on $\ker B$ and to consider $\hat{S}$ as an approximation to the so-called inexact Schur complement $H$, given by

$$H = B\hat{A}^{-1}B^T.$$

Therefore, we assume that constants $\alpha > 0$ and $\beta > 0$ exist such that

$$(Aw, w) \geq \alpha\,(\hat{A}w, w) \quad \text{for all } w \in \ker B$$

and

$$B\hat{A}^{-1}B^T \leq \beta\,\hat{S}.$$

Observe that we will still require condition (2.1); therefore $\alpha \leq 1$ and $\beta \geq 1$. The closer $\alpha$ and $\beta$ are to 1 the better we expect the preconditioner $\hat{\mathcal{K}}$ will be. This results in the following theorem.

THEOREM 2.2. [illegible] $A \geq 0$ [illegible] (1.2) [illegible] $\operatorname{rank} B = m$ [illegible] $\hat{A} > 0$ [illegible] $\hat{S} > 0$ [illegible]

$$(Aw, w) \geq \alpha\,(\hat{A}w, w) \quad [illegible] \quad w \in \ker B \quad [illegible] \quad \hat{A} \geq A, \tag{2.4}$$

[illegible]

$$\hat{S} \leq B\hat{A}^{-1}B^T \leq \beta\,\hat{S} \tag{2.5}$$

[illegible] $\alpha$ [illegible] $\beta$ [illegible] $0 < \alpha \leq 1$ [illegible] $0 < \beta \leq 1$ [illegible]

$$\lambda_{max}(\hat{\mathcal{K}}^{-1}\mathcal{K}) \leq \beta + \sqrt{\beta^2 - \beta} = \beta\,(1 + \sqrt{1 - 1/\beta})$$

[illegible]

$$\begin{aligned}\lambda_{min}(\hat{\mathcal{K}}^{-1}\mathcal{K}) &\geq \frac{1}{2}\left[2 + \alpha - 1/\beta - \sqrt{(2 + \alpha - 1/\beta)^2 - 4\alpha}\right] \\ &\geq \alpha\left[\frac{2}{\sqrt{1 - 1/\beta} + \sqrt{5 - 1/\beta}}\right]^2 > 0.\end{aligned}$$

[illegible]. The upper bound directly follows from Theorem 5.2 in Zulehner [27] again by considering the regularized matrices $A + \varepsilon I$ and $\hat{A} + \varepsilon I$ for $\varepsilon > 0$ with $\varepsilon \to 0$.

For the lower bound we consider an eigenvalue $\lambda$ of the matrix $\hat{\mathcal{K}}^{-1}\mathcal{K}$:

$$\mathcal{K}\begin{pmatrix} x \\ p \end{pmatrix} = \lambda\,\hat{\mathcal{K}}\begin{pmatrix} x \\ p \end{pmatrix},$$

which is equivalent to the eigenvalue problem

$$\mathcal{K}\begin{pmatrix} x \\ p \end{pmatrix} = \mu\,\mathcal{D}\begin{pmatrix} x \\ p \end{pmatrix}$$

with

$$\lambda = \frac{\mu}{1+\mu} \quad \text{and} \quad \mathcal{D} = \hat{\mathcal{K}} - \mathcal{K} = \begin{pmatrix} \hat{A} - A & 0 \\ 0 & B\hat{A}^{-1}B^T - \hat{S} \end{pmatrix},$$

or, in an equivalent variational form,

$$\begin{aligned} (Ax, w) + (Bw, p) &= \mu\,((\hat{A} - A)x, w) && \text{for all } w \in \mathbb{R}^n, \\ (Bx, q) &= \mu\,((B\hat{A}^{-1}B^T - \hat{S})p, q) && \text{for all } q \in \mathbb{R}^m. \end{aligned}$$

Now, two cases are distinguished: First, for the case $\mu \le 0$, it follows that $\lambda = \mu/(1+\mu) > 1$, since $\lambda$ must be positive by Theorem 2.1. (The case $\mu = -1$ can be excluded, since $\hat{\mathcal{K}}$ is nonsingular.) So, in this case, the eigenvalues $\lambda$ are bounded from below by 1.

Next, we consider the remaining case $\mu > 0$. Let

$$W = \ker B, \quad W^\perp = \{x \in \mathbb{R}^n : (\hat{A}x, w) = 0 \text{ for all } w \in W\}.$$

Then there is a unique representation of $x$ of the following form:

$$x = x_1 + x_2 \quad \text{with } x_1 \in W \text{ and } x_2 \in W^\perp.$$

Now the variational form reads

$$\begin{aligned} (Ax_1, w_1) + (Ax_2, w_1) &= \mu\,\Big[((\hat{A} - A)x_1, w_1) - (Ax_2, w_1)\Big], \\ (Ax_1, w_2) + (Ax_2, w_2) + (Bw_2, p) &= \mu\,\Big[-(Ax_1, w_2) + ((\hat{A} - A)x_2, w_2)\Big], \\ (Bx_2, q) &= \mu\,((B\hat{A}^{-1}B^T - \hat{S})p, q) \end{aligned}$$

for all $w_1 \in W$, $w_2 \in W^\perp$, $q \in \mathbb{R}^m$. From the first equation we obtain for $w_1 = x_1$ that

$$\alpha\,(x_1, x_1)_{\hat{A}} \le (Ax_1, x_1) = \mu\,((\hat{A} - A)x_1, x_1) - (\mu + 1)(Ax_2, x_1).$$

Using

$$\begin{aligned} |(Aw_2, w_1)| = |((\hat{A} - A)w_2, w_1)| &\le ((\hat{A} - A)w_1, w_1)^{1/2}((\hat{A} - A)w_2, w_2)^{1/2} \\ &\le \sqrt{1-\alpha}\,\|w_1\|_{\hat{A}}\,\|w_2\|_{\hat{A}} \quad \text{for all } w_1 \in W,\ w_2 \in W^\perp, \end{aligned}$$

it follows that

$$\alpha\,(x_1, x_1)_{\hat{A}} \le \mu\,(1-\alpha)\,(x_1, x_1)_{\hat{A}} + (\mu + 1)\sqrt{1-\alpha}\,\|x_1\|_{\hat{A}}\|x_2\|_{\hat{A}},$$

which implies

$$\alpha\,\|x_1\|_{\hat{A}} \le \mu\,(1-\alpha)\,\|x_1\|_{\hat{A}} + (\mu + 1)\sqrt{1-\alpha}\,\|x_2\|_{\hat{A}}.$$

From the second equation we obtain

$$\sup_{w_2 \in W^\perp} \frac{(Bw_2, p)}{\|w_2\|_{\hat{A}}} = \sup_{w_2 \in W^\perp} \frac{-(\mu+1)(Ax_1, w_2) + ((\mu(\hat{A}-A)-A)x_2, w_2)}{\|w_2\|_{\hat{A}}}.$$

Using

$$|(Ax_1, w_2)| = |(Aw_2, x_1)| \le \sqrt{1-\alpha}\, \|x_1\|_{\hat{A}}\, \|w_2\|_{\hat{A}}$$

and

$$\begin{aligned} |([\mu(\hat{A}-A)-A]x_2, w_2)| &= |(\hat{A}^{-1}[\mu(\hat{A}-A)-A]x_2, w_2)_{\hat{A}}| \\ &\le \|\hat{A}^{-1}[\mu(\hat{A}-A)-A]\|_{\hat{A}} \|x_2\|_{\hat{A}}\, \|w_2\|_{\hat{A}} \end{aligned}$$

with

$$\|\hat{A}^{-1}[\mu(\hat{A}-A)-A]\|_{\hat{A}} \le \mu\, \|\hat{A}^{-1}(\hat{A}-A)\|_{\hat{A}} + \|\hat{A}^{-1}A\|_{\hat{A}} \le \mu+1,$$

it follows that

$$\sup_{w_2 \in W^\perp} \frac{(Bw_2, p)}{\|w_2\|_{\hat{A}}} \le (\mu+1)\sqrt{1-\alpha}\, \|x_1\|_{\hat{A}} + (\mu+1)\, \|x_2\|_{\hat{A}}.$$

From the third equation we obtain

$$\sup_{0 \ne q} \frac{(Bx_2, q)}{\|q\|_H} = \sup_{0 \ne q} \frac{\mu\, ((B\hat{A}^{-1}B^T - \hat{S})p, q)}{\|q\|_H} \le \mu\, (1 - 1/\beta)\, \|p\|_H.$$

Observe that, for the left-hand sides of the last two inequalities, we have the following well-known representations:

$$\sup_{w_2 \in W^\perp} \frac{(Bw_2, p)}{\|w_2\|_{\hat{A}}} = \sup_{w \in \mathbb{R}^n} \frac{(Bw, p)}{\|w\|_{\hat{A}}} = (B\hat{A}^{-1}B^T p, p)^{1/2} = \|p\|_H$$

and

$$\begin{aligned} \sup_{0 \ne q \in \mathbb{R}^m} \frac{(Bx_2, q)}{\|q\|_H} &= (B^T H^{-1} B x_2, x_2)^{1/2} = (\hat{A}^{-1} B^T H^{-1} B x_2, x_2)_{\hat{A}}^{1/2} \\ &= (x_2, x_2)_{\hat{A}}^{1/2} = \|x_2\|_{\hat{A}}, \end{aligned}$$

since $P = \hat{A}^{-1}B^T H^{-1} B$ is a projection onto $W^\perp$, so $Px_2 = x_2$ for $x_2 \in W^\perp$.

Hence, in summary,

$$\underbrace{\begin{pmatrix} \alpha & -\sqrt{1-\alpha} & 0 \\ -\sqrt{1-\alpha} & -1 & 1 \\ 0 & 1 & 0 \end{pmatrix}}_{K} \underbrace{\begin{pmatrix} \|x_1\|_{\hat{A}} \\ \|x_2\|_{\hat{A}} \\ \|p\|_H \end{pmatrix}}_{e}$$

$$\le \mu \underbrace{\begin{pmatrix} 1-\alpha & \sqrt{1-\alpha} & 0 \\ \sqrt{1-\alpha} & 1 & 0 \\ 0 & 0 & 1-1/\beta \end{pmatrix}}_{D} \underbrace{\begin{pmatrix} \|x_1\|_{\hat{A}} \\ \|x_2\|_{\hat{A}} \\ \|p\|_H \end{pmatrix}}_{e}. \tag{2.6}$$

Since $K^{-1}$ is nonnegative elementwise, it follows that

$$e \le \mu\, K^{-1} D e.$$

Elementary calculations show that

$$\nu_+ = \frac{1}{2\alpha}\left[2 - \alpha - 1/\beta + \sqrt{(2 - \alpha - 1/\beta)^2 + 4\alpha(1 - 1/\beta)}\right]$$

is a nonnegative eigenvalue of $K^{-1}D$ with componentwise nonnegative left eigenvector $l_+^T$, given by

$$l_+^T = \left(\sqrt{1-\alpha}, 1, \alpha\nu_+ - 1 + \alpha\right).$$

Then

$$l_+^T e \le \mu\nu_+ l_+^T e.$$

Obviously, $l_+^T e \ge 0$. One can easily show that $\nu_+ > 0$ and $l_+^T e > 0$: $\nu_+ = 0$ implies $\alpha = \beta = 1$, then (2.6) implies $e = 0$. In a similar way the case $l_+^T e = 0$ can be excluded.

Therefore, after dividing by $l_+^T e > 0$, we obtain

$$\mu \ge \frac{1}{\nu_+}.$$

Consequently,

$$\begin{aligned}\lambda &= \frac{\mu}{1+\mu} \ge \frac{1}{1+\nu_+} = \frac{1}{2}\left[2 + \alpha - 1/\beta - \sqrt{(2 + \alpha - 1/\beta)^2 - 4\alpha}\right] \\ &= \frac{2\alpha}{2 + \alpha - 1/\beta + \sqrt{(2 + \alpha - 1/\beta)^2 - 4\alpha}} \\ &\ge \frac{2\alpha}{3 - 1/\beta + \sqrt{(3 - 1/\beta)^2 - 4}} = \alpha\left[\frac{2}{\sqrt{1 - 1/\beta} + \sqrt{5 - 1/\beta}}\right]^2 > 0.\end{aligned}$$

This lower bound is obviously smaller than 1, which was the lower bound for the first case $\mu \le 0$. This completes the proof. ∎

By slightly strengthening the conditions (2.4) and (2.5) to

$$(Aw, w) \ge \alpha\,(\hat{A}w, w) \quad \text{for all } w \in \ker B \quad \text{and} \quad \hat{A} > A \tag{2.7}$$

and

$$\hat{S} < B\hat{A}^{-1}B^T \le \beta\,\hat{S}, \tag{2.8}$$

the scalar product (2.3) is well defined, and, by Theorem 2.1, the standard CG can be applied to the preconditioned system

$$\hat{\mathcal{K}}^{-1}\mathcal{K}\begin{pmatrix} x \\ p \end{pmatrix} = \hat{\mathcal{K}}^{-1}\begin{pmatrix} f \\ g \end{pmatrix} \tag{2.9}$$

with respect to the scalar product (2.3).

The actual construction of the preconditioners $\hat{A}$ and $\hat{S}$ is usually done in two steps. First, some preliminary candidates $\hat{A}_0$ and $\hat{S}_0$ are chosen which approximate the matrices $A$ and $B\hat{A}_0^{-1}B^T$. In the second step, these candidates are properly scaled: $\hat{A} = (1/\sigma)\,\hat{A}_0$ and $\hat{S} = (\sigma/\tau)\,\hat{S}_0$, where the positive parameters $\sigma$ and $\tau$ must be chosen such that (2.2) are satisfied, i.e.,

$$\frac{1}{\sigma}\,\hat{A}_0 > A \quad \text{and} \quad \frac{1}{\tau}\,\hat{S}_0 < B\hat{A}_0^{-1}B^T.$$

So, the correct choice of the parameters $\sigma$ and $\tau$ requires some rough information of the size of the largest eigenvalue of $A$ relative to $\hat{A}_0$, which is, in general, quite easy to obtain and of the size of the smallest eigenvalue of $B\hat{A}_0^{-1}B^T$ relative to $\hat{S}_0$, which, in general, is more costly, but which is available here from the analysis for the problem discussed in section 4. The values of $\alpha$ and $\beta$ in (2.7) and (2.8) are not needed for the construction, but only for the analysis.

It is well known (see, e.g., Hackbusch [19]) that the error $e^{(k)}$ for the $k$th iterate $(x^{(k)}, p^{(k)})^T$ measured in the corresponding energy norm can be estimated by

$$e^{(k)} \le \frac{2q^k}{1+q^{2k}}\,e^{(0)} \quad \text{with} \quad q = \frac{\sqrt{\kappa(\hat{\mathcal{K}}^{-1}\mathcal{K})}-1}{\sqrt{\kappa(\hat{\mathcal{K}}^{-1}\mathcal{K})}+1},$$

where $\kappa(\hat{\mathcal{K}}^{-1}\mathcal{K})$ denotes the relative condition number

$$\kappa(\hat{\mathcal{K}}^{-1}\mathcal{K}) = \frac{\lambda_{\max}(\hat{\mathcal{K}}^{-1}\mathcal{K})}{\lambda_{\min}(\hat{\mathcal{K}}^{-1}\mathcal{K})}.$$

From Theorem 2.2 the following upper bound for the relative condition number follows:

$$\begin{aligned}\kappa(\hat{\mathcal{K}}^{-1}\mathcal{K}) &\le \frac{2(\beta+\sqrt{\beta^2-\beta})}{2+\alpha-1/\beta-\sqrt{(2+\alpha-1/\beta)^2-4\alpha}} \equiv \kappa(\alpha,\beta)\\ &\le \frac{\beta}{\alpha}\,(1+\sqrt{1-1/\beta})\left[\frac{\sqrt{1-1/\beta}+\sqrt{5-1/\beta}}{2}\right]^2.\end{aligned}$$

This shows that the convergence rate $q$ can be bounded by $\alpha$ and $\beta$ only. If the preconditioners are chosen such that $\alpha$ and $\beta$ are independent of certain parameters like the mesh size $h$ of some discretization or some involved regularization parameter $\nu$, then the convergence rate is also robust with respect to such parameters.

Furthermore, for $\alpha \to 1$ and $\beta \to 1$, the lower and upper bounds for the eigenvalues in Theorem 2.2 both approach 1 (implying that all eigenvalues of the preconditioned matrix $\hat{\mathcal{K}}^{-1}\mathcal{K}$ approach 1), leading to a relative condition number approaching 1 and a convergence factor $q$ approaching 0.

In the limit case $\alpha = 1$ and $\beta = 1$, one can easily derive the following representations for the preconditioners from the conditions (2.4) and (2.5):

$$\hat{A} = A + B^T\,W\,B \quad \text{and} \quad \hat{S} = B\hat{A}^{-1}B^T$$

for some matrix $W \ge 0$. Then, we obtain:

$$\hat{\mathcal{K}} = \begin{pmatrix} A + B^TWB & B^T \\ B & 0 \end{pmatrix}.$$

From the previous considerations, it follows in this case that all eigenvalues of $\hat{\mathcal{K}}^{-1}\mathcal{K}$ must be equal to 1. Moreover, it can easily be shown that

$$\left[I - \hat{\mathcal{K}}^{-1}\mathcal{K}\right]^2 = 0.$$

So, the corresponding preconditioned Richardson method terminates at the solution after two steps.

In a simplified way one could describe the proposed strategy as follows: Good preconditioners $\hat{A}$ can be interpreted as good approximations to some augmented matrix $A + B^T W B$, but we do not change the matrix $A$ itself in the system matrix $\mathcal{K}$. This seems to be only a slight variant to the augmented Lagrangian approach, where first $A$ itself is replaced by $A + B^T W B$ in $\mathcal{K}$. However, the actual construction of the preconditioner is not based on first selecting some augmentation matrix $W$ and then preconditioning the augmented matrix. Instead, as will be detailed in the next section, the construction is guided by the analysis of an underlying (infinite-dimensional) variational problem, whose discretization leads to the discussed large scale linear systems of equations in saddle point form.

## 3. Application to mixed variational problems.

Consider an (infinite-dimensional) mixed variational problem of the following form: Find $x \in X$ and $p \in Q$ such that

$$\begin{aligned} a(x, w) \ + \ b(w, p) &= \langle F, w\rangle \quad \text{for all } w \in X, \\ b(x, q) &= \langle G, q\rangle \quad \text{for all } q \in Q. \end{aligned}$$

Here, $X$ and $Q$ are real Hilbert spaces, $a : X \times X \longrightarrow \mathbb{R}$ and $b : X \times Q \longrightarrow \mathbb{R}$ are bilinear forms, $F : X \longrightarrow \mathbb{R}$ and $G : Q \longrightarrow \mathbb{R}$ are continuous linear functionals, and $\langle F, w\rangle$ ($\langle G, q\rangle$) denotes the evaluation of $F$ ($G$) at the element $w$ ($q$).

The existence and uniqueness of a solution to this mixed variational problem is well established (Brezzi's theorem; see Brezzi and Fortin [8]) under the following conditions:

1. The bilinear form $a$ is bounded:

$$a(x, w) \le \|a\| \, \|x\|_X \|w\|_X \quad \text{for all } x, w \in X.$$

2. The bilinear form $a$ is coercive on $\ker B = \{w \in X : b(w, q) = 0 \text{ for all } q \in Q\}$: There exists a constant $\alpha_0 > 0$ such that

$$a(w, w) \ge \alpha_0 \, \|w\|_X^2 \quad \text{for all } w \in \ker B.$$

3. The bilinear form $b$ is bounded:

$$\sup_{0 \ne w \in X} \frac{b(w, q)}{\|w\|_X} \le \|b\| \, \|q\|_Q \quad \text{for all } q \in Q.$$

4. The bilinear form $b$ satisfies the inf-sup condition: There exists a constant $k_0 > 0$ such that

$$\sup_{0 \ne w \in X} \frac{b(w, q)}{\|w\|_X} \ge k_0 \, \|q\|_Q \quad \text{for all } q \in Q.$$

Under the additional assumptions that

5. the bilinear form $a$ is symmetric on $X$:

$$a(x, w) = a(w, x) \quad \text{for all } x, w \in X, \text{ and}$$

6. the bilinear form $a$ is nonnegative on $X$:

$$a(w, w) \geq 0 \quad \text{for all } w \in X,$$

Brezzi's theorem implies the equivalence of the mixed variational problem to the following constrained optimization problem: Find $x \in X$ such that

$$J(x) = \min_{w \in X_g} J(w) \tag{3.1}$$

with

$$J(w) = \frac{1}{2} a(w, w) - \langle F, w \rangle$$

and

$$X_g = \{w \in X : b(w, q) = \langle G, q \rangle \text{ for all } q \in Q\}.$$

For discretizing the infinite-dimensional problem the spaces $X$ and $Q$ are replaced by finite-dimensional subspaces $X_h \subset X$ and $Q_h \subset Q$, which results in the following finite-dimensional variational problem: Find $x_h \in X_h$ and $p_h \in Q_h$ such that

$$\begin{aligned} a(x_h, w_h) \;+\; b(w_h, p_h) &= \langle F, w_h \rangle \quad && \text{for all } w_h \in X_h, \\ b(x_h, q_h) &= 0 && \text{for all } q_h \in Q_h. \end{aligned}$$

By introducing suitable basis functions in $X_h$ and $Q_h$, we finally obtain the following saddle point problem in matrix-vector notation:

$$\begin{aligned} A_h \underline{x}_h \;+\; B_h^T \underline{p}_h &= \underline{f}_h, \\ B_h \underline{x}_h &= \underline{g}_h, \end{aligned}$$

where $\underline{x}_h$ and $\underline{p}_h$ denote the corresponding vectors of coefficients with respect to these basis functions.

We assume that the conditions of Brezzi's theorem are also satisfied in $X_h$ and $Q_h$. This is trivial for the first and third conditions. The second and fourth conditions must be proven for the particular equations and elements. To simplify the notation the same symbols are used to denote the constants.

The scalar products $(x, q)_X$ and $(p, q)_Q$ are bilinear forms on $X_h$ and $Q_h$. The associated matrices representing these scalar products are denoted by $\underline{X}_h$ and $\underline{Q}_h$, respectively, i.e.,

$$(x_h, w_h)_X = (\underline{X}_h \underline{x}_h, \underline{w}_h), \quad (p_h, q_h)_Q = (\underline{Q}_h \underline{p}_h, \underline{q}_h).$$

Using matrix-vector notations, the conditions of Brezzi's theorem on $X_h$ and $Q_h$ are

$$A_h \leq \|a\| \, \underline{X}_h, \tag{3.2}$$

$$(A_h, \underline{w}_h, \underline{w}_h) \geq \alpha_0 \, (\underline{X}_h \underline{w}_h, \underline{w}_h) \quad \text{for all } \underline{w}_h \in \ker B_h, \tag{3.3}$$

$$B_h \underline{X}_h^{-1} B_h^T \leq \|b\|^2 \, \underline{Q}_h, \tag{3.4}$$

$$B_h \underline{X}_h^{-1} B_h^T \geq k_0^2 \, \underline{Q}_h. \tag{3.5}$$

For the third and fourth condition we used the well-known representation

$$\sup_{0 \neq w_h \in X_h} \frac{b(w_h, q_h)}{\|w_h\|_X} = (B_h \underline{X}_h^{-1} B_h^T \underline{q}_h, \underline{q}_h)^{1/2}.$$

Comparing (3.2)–(3.5) with the conditions (2.7) and (2.8) it seems to be reasonable to choose for $\hat{A}_h$ a suitable multiple of the matrix $\underline{X}_h$ and for $\hat{S}_h$ a suitable multiple of the matrix $\underline{Q}_h$. However, since the application of the preconditioner $\hat{\mathcal{K}}_h$ requires the solution of linear systems with the matrices $\hat{A}_h$ and $\hat{S}_h$, this would require the inversion of these matrices $\underline{X}_h$ and $\underline{Q}_h$. In typical applications (see the next section) (parts of) $\underline{X}_h$ and $\underline{Q}_h$ are the stiffness matrices of second order differential operators. So, the exact inversion could be too costly. Therefore, it is recommended to use approximations, say $\hat{X}_h$ and $\hat{Q}_h$, that are easy to invert (i.e., preconditioners) instead of $\underline{X}_h$ and $\underline{Q}_h$:

$$\hat{A}_h = \frac{1}{\sigma} \hat{X}_h \quad \text{and} \quad \hat{S}_h = \frac{\sigma}{\tau} \hat{Q}_h \tag{3.6}$$

for some real parameters $\sigma > 0$ and $\tau > 0$, which are needed for a suitable scaling. We assume that the quality of these preconditioners can be described by spectral estimates, e.g., of the form

$$(1 - q_X) \hat{X}_h \leq \underline{X}_h \leq \hat{X}_h \quad \text{and} \quad (1 - q_Q) \hat{Q}_h \leq \underline{Q}_h \leq \hat{Q}_h \tag{3.7}$$

with constants $q_X, q_Q \in [0, 1)$. The smaller these constants are the better the preconditioners $\hat{X}_h$ and $\hat{Q}_h$ approximate the matrices $\underline{X}_h$ and $\underline{Q}_h$.

Combining all estimates we easily obtain the following lemma.

LEMMA 3.1. [illegible] (3.2)–(3.7) [illegible] (2.7) [illegible] (2.8) [illegible]

$$\alpha = \sigma (1 - q_X) \alpha_0 \quad [illegible] \quad \beta = \tau \|b\|^2$$

[illegible] $\sigma$ [illegible] $\tau$ [illegible]

$$\sigma < \frac{1}{\|a\|} \quad [illegible] \quad \tau > \frac{1}{(1 - q_X)(1 - q_Q) k_0^2}.$$

[illegible]. We have

$$A_h \leq \|a\| \underline{X}_h \leq \|a\| \hat{X}_h = \sigma \|a\| \hat{A}_h < \hat{A}_h$$

if $\sigma < 1/\|a\|$. Next

$$(A_h \underline{w}_h, \underline{w}_h) \geq \alpha_0 (\underline{X}_h \underline{w}_h, \underline{w}_h) \geq (1 - q_X) \alpha_0 (\hat{X}_h \underline{w}_h, \underline{w}_h) = \alpha (\hat{A}_h \underline{w}_h, \underline{w}_h)$$

with $\alpha = \sigma (1 - q_X) \alpha_0$. Next

$$B_h \hat{A}_h^{-1} B_h^T = \sigma B_h \hat{X}_h^{-1} B_h^T \leq \sigma B_h \underline{X}_h^{-1} B_h^T \leq \sigma \|b\|^2 \underline{Q}_h \leq \sigma \|b\|^2 \hat{Q}_h = \beta \hat{S}_h$$

with $\beta = \tau \|b\|^2$. Finally

$$\begin{aligned} B_h \hat{A}_h^{-1} B_h^T &= \sigma B_h \hat{X}_h^{-1} B_h^T \geq \sigma (1 - q_X) B_h \underline{X}_h^{-1} B_h^T \geq \sigma (1 - q_X) k_0^2 \underline{Q}_h \\ &\geq \sigma (1 - q_X) (1 - q_Q) k_0^2 \hat{Q}_h = \tau (1 - q_X) (1 - q_Q) k_0^2 \hat{S}_h > \hat{S}_h \end{aligned}$$

if $\tau > 1/[(1-q_X)(1-q_Q)k_0^2]$. ☐

Good and efficient preconditioners $\hat{X}_h$ and $\hat{Q}_h$ are usually available, as will be shown for a particular problem in the next section. Therefore, the quantities $q_X$ and $q_Q$ are typically small, say 0.1.

Roughly speaking, the parameter $\sigma$ has to be sufficiently small, while the parameter $\tau$ has to be sufficiently large in order to guarantee the conditions (2.7) and (2.8). On the other hand, in order to obtain a small upper bound $\kappa(\alpha, \beta)$ for the condition number of the preconditioned matrix $\hat{\mathcal{K}}^{-1}\mathcal{K}$, $\alpha$ should be as large as possible and $\beta$ should be as small as possible, i.e., $\sigma$ should be as large as possible and $\tau$ should be as small as possible. This, of course, requires at least a rough quantitative knowledge of the constants $\|a\|$ and $k_0$, which are involved in the choice of $\sigma$ and $\tau$.

Next, we will study a particular problem from optimal control, where the parameters $\|a\|$, $\alpha_0$, $\|b\|$, and $k_0$ are known.

## 4. A problem from optimal control.

Let $\Omega \subset \mathbb{R}^d$ be an open and bounded set. We consider the following optimization problem with PDE-constraints: Find the state $y \in H^1(\Omega)$ and the control $u \in L^2(\Omega)$ such that

$$J(y,u) = \min_{(z,v)\in H^1(\Omega)\times L^2(\Omega)} J(z,v)$$

subject to the state equation with distributed control $u$

$$\begin{aligned} -\Delta y + y &= u \quad \text{in } \Omega, \\ \frac{\partial y}{\partial n} &= 0 \quad \text{on } \partial\Omega, \end{aligned}$$

where the cost functional is given by

$$J(y,u) = \frac{1}{2}\int_\Omega (y - y_d)^2 \, dx + \frac{\nu}{2}\int_\Omega u^2 \, dx.$$

More precisely, we prescribe the state equation in weak form:

$$\int_\Omega \nabla y \cdot \nabla q \, dx + \int_\Omega y\, q \, dx = \int_\Omega u\, q \, dx \quad \text{for all } q \in H^1(\Omega).$$

Let $X = Y \times U$ with $Y = H^1(\Omega)$, $U = L^2(\Omega)$, and $Q = H^1(\Omega)$. With $x = (y,u) \in X$, $w = (z,v) \in X$, and $q \in Q$, we introduce the following bilinear forms and linear functionals:

$$\begin{aligned} a(x,w) &= \int_\Omega y\, z \, dx + \nu \int_\Omega u\, v \, dx, \\ b(w,q) &= \int_\Omega \nabla z \cdot \nabla q \, dx + \int_\Omega z\, q \, dx - \int_\Omega v\, q \, dx, \\ \langle F, w\rangle &= \int_\Omega y_d\, z \, dx, \\ \langle G, q\rangle &= 0. \end{aligned}$$

With this setting the optimization problem is of the standard form (3.1).

The conditions of Brezzi's theorem can easily be verified for the Hilbert spaces $X = Y \times U$ and $Q$ introduced above and equipped with the standard scalar products $(y,z)_{H^1(\Omega)}$ in $Y$, $(u,v)_{L^2(\Omega)}$ in $U$, and $(p,q)_{H^1(\Omega)}$ in $Q$. Then, however, the parameters $\|a\|$, $\alpha_0$, $\|b\|$, and $k_0$ depend on the regularization parameter $\nu$, eventually resulting in convergence rates also depending on $\nu$.

With a different scaling of the scalar products in $Y$, $U$, and $Q$ we obtain parameters $\|a\|$, $\alpha_0$, $\|b\|$, and $k_0$ independent of $\nu$, eventually leading to preconditioners with convergence rates robust in $\nu$. In particular, we consider the following new scalar products $(y,z)_Y$ in $Y = H^1(\Omega)$, $(u,v)_U$ in $U = L^2(\Omega)$, and $(p,q)_Q$ in $Q = H^1(\Omega)$:

$$(y,z)_Y = (y,z)_{L^2(\Omega)} + \sqrt{\nu}\,(y,z)_{H^1(\Omega)}, \quad (u,v)_U = \nu\,(u,v)_{L^2(\Omega)},$$

and

$$(p,q)_Q = \frac{1}{\nu}\,(p,q)_{L^2(\Omega)} + \frac{1}{\sqrt{\nu}}\,(p,q)_{H^1(\Omega)},$$

and we set $(x,w)_X = (y,z)_Y + (u,v)_U$ for $x = (y,u), w = (z,v) \in X = Y \times U$. Observe that the corresponding new norms are equivalent to the standard norms in these spaces for fixed $\nu > 0$.

With these definitions of the scalar products the following properties can be verified.

LEMMA 4.1.

1. [illegible] $a$ [illegible]

$$a(x,w) \le \|x\|_X \|w\|_X \quad \text{[illegible]} \quad x, w \in X.$$

2. [illegible] $a$ [illegible] $\ker B$

$$a(w,w) \ge \alpha_0\,\|w\|_X^2 \quad \text{[illegible]} \quad w \in \ker B \quad \text{[illegible]} \quad \alpha_0 = \frac{2}{3}.$$

3. [illegible] $b$ [illegible]

$$\sup_{0 \ne w \in X} \frac{b(w,q)}{\|w\|_X} \le \|q\|_Q \quad \text{[illegible]} \quad q \in Q.$$

4. [illegible] $b$ [illegible] inf-sup [illegible]

$$\sup_{0 \ne w \in X} \frac{b(w,q)}{\|w\|_X} \ge k_0\,\|q\|_Q \quad \text{[illegible]} \quad k_0 = \sqrt{\frac{3}{4}}.$$

[illegible] 1 of Lemma 4.1 is trivial since $a$ is symmetric and $a(w,w) \le \|w\|_X^2$. For 2 take $w = (z,v) \in \ker B$. Then

$$(z,q)_{H^1(\Omega)} = (v,q)_{L^2(\Omega)} \quad \text{for all } q \in H^1(\Omega).$$

In particular, it follows for $q = z$ that

$$\|z\|_{H^1(\Omega)}^2 = (v,z)_{L^2(\Omega)} \le \|v\|_{L^2(\Omega)} \|z\|_{L^2(\Omega)},$$

which implies

$$\|w\|_X^2 = \|z\|_Y^2 + \|v\|_U^2 \le \|z\|_{L^2(\Omega)}^2 + \sqrt{\nu}\,\|z\|_{L^2(\Omega)} \|v\|_{L^2(\Omega)} + \nu\,\|v\|_{L^2(\Omega)}^2.$$

Then

$$a(w,w) \ge \alpha_0 \, \|w\|_X^2$$

is certainly satisfied if

$$a(w,w) \ge \alpha_0 \, \left[ \|z\|_{L^2(\Omega)}^2 + \sqrt{\nu} \, \|z\|_{L^2(\Omega)} \|v\|_{L^2(\Omega)} + \nu \, \|v\|_{L^2(\Omega)}^2 \right],$$

which is equivalent to

$$(1-\alpha_0) \, \|z\|_{L^2(\Omega)}^2 - \alpha_0 \sqrt{\nu} \, \|z\|_{L^2(\Omega)} \|v\|_{L^2(\Omega)} + (1-\alpha_0) \, \nu \, \|v\|_{L^2(\Omega)}^2 \ge 0.$$

This is obviously the case for $\alpha_0 = 2/3$, since

$$\frac{1}{3} \|z\|_{L^2(\Omega)}^2 - \frac{2}{3} \sqrt{\nu} \, \|z\|_{L^2(\Omega)} \|v\|_{L^2(\Omega)} + \frac{1}{3} \nu \, \|v\|_{L^2(\Omega)}^2 = \frac{1}{3} \left[ \|z\|_{L^2(\Omega)} - \sqrt{\nu} \|v\|_{L^2(\Omega)} \right]^2.$$

To show 3 and 4, we start with the following formula:

$$\begin{aligned}
\sup_{0 \ne w \in X} \frac{b(w,q)^2}{\|w\|_X^2} &= \sup_{0 \ne (z,v) \in Y \times U} \frac{\left[ (z,q)_{H^1(\Omega)} - (v,q)_{L^2(\Omega)} \right]^2}{\|z\|_Y^2 + \|v\|_U^2} \\
&= \sup_{0 \ne z \in Y} \frac{(z,q)_{H^1(\Omega)}^2}{\|z\|_Y^2} + \sup_{0 \ne v \in U} \frac{(v,q)_{L^2(\Omega)}^2}{\|v\|_U^2} \\
&= \sup_{0 \ne z \in Y} \frac{(z,q)_{H^1(\Omega)}^2}{\|z\|_Y^2} + \frac{1}{\nu} \, \|q\|_{L^2(\Omega)}^2.
\end{aligned}$$

Then 3 easily follows from the estimates

$$\begin{aligned}
\sup_{0 \ne z \in Y} \frac{(z,q)_{H^1(\Omega)}^2}{\|z\|_Y^2} + \frac{1}{\nu} \, \|q\|_{L^2(\Omega)}^2 &\le \sup_{0 \ne z \in Y} \frac{\|z\|_{H^1(\Omega)}^2 \|q\|_{H^1(\Omega)}^2}{\|z\|_Y^2} + \frac{1}{\nu} \, \|q\|_{L^2(\Omega)}^2 \\
&= \sup_{0 \ne z \in Y} \frac{\|z\|_{H^1(\Omega)}^2 \|q\|_{H^1(\Omega)}^2}{\|z\|_{L^2(\Omega)}^2 + \sqrt{\nu} \, \|z\|_{H^1(\Omega)}^2} + \frac{1}{\nu} \|q\|_{L^2(\Omega)}^2 \\
&\le \frac{1}{\sqrt{\nu}} \|q\|_{H^1(\Omega)}^2 + \frac{1}{\nu} \, \|q\|_{L^2(\Omega)}^2 = \|q\|_Q^2.
\end{aligned}$$

For 4 observe that

$$\begin{aligned}
\sup_{0 \ne z \in Y} \frac{(z,q)_{H^1(\Omega)}^2}{\|z\|_Y^2} + \frac{1}{\nu} \, \|q\|_{L^2(\Omega)}^2 &\ge \frac{\|q\|_{H^1(\Omega)}^4}{\|q\|_Y^2} + \frac{1}{\nu} \, \|q\|_{L^2(\Omega)}^2 \\
&= \frac{\|q\|_{H^1(\Omega)}^4}{\|q\|_{L^2(\Omega)}^2 + \sqrt{\nu} \, \|q\|_{H^1(\Omega)}^2} + \frac{1}{\nu} \, \|q\|_{L^2(\Omega)}^2.
\end{aligned}$$

Then the inf-sup condition

$$\sup_{0 \ne w \in X} \frac{b(w,q)}{\|w\|_X} \ge k_0 \, \|q\|_Q$$

is certainly satisfied if

$$\frac{\|q\|^4_{H^1(\Omega)}}{\|q\|^2_{L^2(\Omega)} + \sqrt{\nu}\,\|q\|^2_{H^1(\Omega)}} + \frac{1}{\nu}\,\|q\|^2_{L^2(\Omega)} \geq k_0^2\,\|q\|^2_Q = k_0^2\left[\frac{1}{\nu}\,\|q\|^2_{L^2(\Omega)} + \frac{1}{\sqrt{\nu}}\,\|q\|^2_{H^1(\Omega)}\right],$$

which is equivalent to

$$(1-k_0^2)\,\|q\|^4_{H^1(\Omega)} + (1-2k_0^2)\frac{1}{\sqrt{\nu}}\,\|q\|^2_{L^2(\Omega)}\|q\|^2_{H^1(\Omega)} + (1-k_0^2)\frac{1}{\nu}\,\|q\|^4_{L^2(\Omega)} \geq 0.$$

This is obviously the case for $k_0^2 = 3/4$ since

$$\begin{aligned}&\frac{1}{4}\,\|q\|^4_{H^1(\Omega)} - \frac{1}{2}\frac{1}{\sqrt{\nu}}\,\|q\|^2_{L^2(\Omega)}\|q\|^2_{H^1(\Omega)} + \frac{1}{4}\frac{1}{\nu}\,\|q\|^4_{L^2(\Omega)}\\ &\quad = \frac{1}{4}\left[\|q\|^2_{H^1(\Omega)} - \frac{1}{\sqrt{\nu}}\,\|q\|^2_{L^2(\Omega)}\right]^2. \qquad \square\end{aligned}$$

By Brezzi's theorem it now follows that the optimization problem is equivalent to the following mixed variational problem: Find $x \in H^1(\Omega) \times L^2(\Omega)$ and $p \in H^1(\Omega)$ such that

$$\begin{aligned} a(x,w) \;+\; b(w,p) &= \langle F, x\rangle \quad \text{for all } w \in H^1(\Omega)\times L^2(\Omega),\\ b(x,q) &= 0 \qquad\quad\; \text{for all } q \in H^1(\Omega).\end{aligned}$$

For the spaces $Y_h = U_h = Q_h$ we choose, as an example, the space of piecewise linear and continuous functions on a simplicial subdivision of $\Omega$. By introducing the standard nodal basis, we finally obtain the following saddle point problem in matrix-vector notation:

$$\begin{aligned} A_h\underline{x}_h \;+\; B_h^T\underline{p}_h &= \underline{f}_h,\\ B_h\underline{x}_h &= 0,\end{aligned}$$

with

$$A_h = \begin{pmatrix} M_h & 0\\ 0 & \nu\,M_h\end{pmatrix} \quad\text{and}\quad B_h = \begin{pmatrix} K_h & -M_h\end{pmatrix},$$

where $M_h$ denotes the mass matrix representing the $L^2(\Omega)$ inner product on $Y_h$ and $K_h$ denotes the stiffness matrix representing the bilinear form (on $Y$) of the state equation, here $(\nabla y, \nabla q)_{L^2(\Omega)} + (y,q)_{L^2(\Omega)}$, on $Y_h$.

For the matrices $\underline{X}_h$ and $\underline{Q}_h$ representing the scalar products $(x,w)_X = (y,z)_Y + (u,v)_U$ and $(p,q)_Q$ on $X_h$ and $Q_h$, we obtain

$$\underline{X}_h = \begin{pmatrix} \underline{Y}_h & 0\\ 0 & \nu\,M_h\end{pmatrix} \quad\text{and}\quad \underline{Q}_h = \frac{1}{\nu}\underline{Y}_h$$

with

$$\underline{Y}_h = \sqrt{\nu}\,K_h + M_h.$$

Observe that $\underline{Y}_h$ is the stiffness matrix representing the bilinear form $\sqrt{\nu}(\nabla y, \nabla q)_{L^2(\Omega)} + (\sqrt{\nu}+1)\,(y,q)_{L^2(\Omega)}$ on $Y_h$, which is of the same type as the bilinear form (on $Y$) of the state equation, but with modified coefficients.

It is easy to see that Lemma 4.1 remains valid with the same constants if $Y$, $U$, $Q$ are replaced by the finite-dimensional spaces $Y_h$, $U_h$, $Q_h$, as long as $Y_h = Q_h \subset U_h$.

As discussed before, it is reasonable to use a (properly scaled) preconditioner for $\underline{X}_h$ to approximate $\hat{A}_h$ and to use a (properly scaled) preconditioner for $\underline{Q}_h$ to approximate $\hat{S}_h$. For $\underline{Y}_h$, which appears in the first diagonal block of $\underline{X}_h$ and in $\underline{Q}_h$, we use, e.g., a standard multigrid preconditioner $\hat{Y}_h$ for the second order elliptic differential operator represented by the bilinear form $\sqrt{\nu}\,(\nabla y, \nabla q)_{L^2(\Omega)} + (\sqrt{\nu}+1)\,(y,q)_{L^2(\Omega)}$. For the well-conditioned matrix $M_h$, which appears in the second diagonal block of $\underline{X}_h$, a simple preconditioner $\hat{M}_h$, e.g., a few steps of a symmetric Gauss–Seidel iteration, is used. So, eventually we set

$$\hat{A}_h = \frac{1}{\sigma}\,\hat{X}_h = \frac{1}{\sigma}\begin{pmatrix}\hat{Y}_h & 0\\ 0 & \nu\,\hat{M}_h\end{pmatrix} \quad\text{and}\quad \hat{S}_h = \frac{\sigma}{\tau}\,\frac{1}{\nu}\,\hat{Y}_h \tag{4.1}$$

with real parameters $\sigma > 0$ and $\tau > 0$.

In summary, the preconditioner

$$\hat{\mathcal{K}}_h = \begin{pmatrix}\hat{A}_h & B_h^T\\ B_h & B_h\hat{A}_h^{-1}B_h^T - \hat{S}_h\end{pmatrix}$$

for the matrix

$$\mathcal{K}_h = \begin{pmatrix}A_h & B_h^T\\ B_h & 0\end{pmatrix}$$

is given by (4.1), where $\hat{Y}_h$ is a preconditioner for the second order elliptic differential operator represented by the bilinear form $\sqrt{\nu}\,(\nabla y, \nabla q)_{L^2(\Omega)} + (\sqrt{\nu}+1)\,(y,q)_{L^2(\Omega)}$ and a simple preconditioner $\hat{M}_h$ for the mass matrix.

It is reasonable to assume that

$$(1-q_X)\,\hat{Y}_h \le \underline{Y}_h \le \hat{Y}_h \quad\text{and}\quad (1-q_X)\,\hat{M}_h \le M_h \le \hat{M}_h$$

for some small value $q_X \in [0,1)$. The factor $q_X$ describes the quality of the preconditioners $\hat{Y}_h$ and $\hat{M}_h$.

The discussion in the previous section shows that the conditions (2.7) and (2.8) are satisfied with

$$\alpha = \sigma\,(1-q_X)\,\frac{2}{3} \quad\text{and}\quad \beta = \tau$$

for parameters $\sigma$ and $\tau$ satisfying

$$\sigma < 1 \quad\text{and}\quad \tau > \frac{4}{3(1-q_X)^2}.$$

In particular, assuming that $q_X \approx 0$, we can expect $\alpha \approx 2/3$ and $\beta \approx 4/3$ for $\sigma \approx 1$ and $\tau \approx 4/3$, leading to a rough estimate of the condition number $\kappa \approx \kappa(2/3, 4/3) \approx 4$, which implies a convergence factor $q \approx 1/3$ for the CG method.

## 5. Implementation issues.

The proposed method in this paper is the standard CG method applied to the preconditioned system

$$\hat{\mathcal{K}}_h^{-1}\mathcal{K}_h \begin{pmatrix} \underline{x}_h \\ \underline{p}_h \end{pmatrix} = \hat{\mathcal{K}}_h^{-1} \begin{pmatrix} \underline{f}_h \\ \underline{g}_h \end{pmatrix}$$

with the nonstandard scalar product

$$\left( \begin{pmatrix} \underline{x}_h \\ \underline{p}_h \end{pmatrix}, \begin{pmatrix} \underline{w}_h \\ \underline{q}_h \end{pmatrix} \right)_{\mathcal{D}_h} = ((\hat{A}_h - A_h)\underline{x}_h, \underline{w}_h) + ((B_h \hat{A}_h^{-1} B_h^T - \hat{S}_h)\underline{p}_h, \underline{q}_h).$$

For the matrices $\hat{A}_h$ and $\hat{S}_h$, preconditioners $\hat{X}_h$ and $\hat{Q}_h$ are needed which approximate the matrices $\underline{X}_h$ and $\underline{Q}_h$ representing the scalar products on the discrete spaces $X_h$ and $Q_h$, respectively. The discrete spaces $X_h$ and $Q_h$ typically involve discretizations of Sobolev spaces, whose scalar products are the bilinear forms associated with elliptic differential operators. So, in the end, good preconditioners for these elliptic differential operators are required, such as multilevel or multigrid preconditioners.

A straightforward implementation of the CG method would require the evaluation of the nonstandard scalar product, which can be done if the operation

$$\mathcal{D}_h \begin{pmatrix} \underline{w}_h \\ \underline{q}_h \end{pmatrix} \quad \text{with } \mathcal{D}_h = \begin{pmatrix} \hat{A}_h - A_h & 0 \\ 0 & B_h \hat{A}_h^{-1} B_h^T - \hat{S}_h \end{pmatrix} = \hat{\mathcal{K}}_h - \mathcal{K}_h$$

is available. This would involve matrix-vector products with the preconditioners $\hat{A}_h$ and $\hat{S}_h$, which is, in general, prohibitively costly for multilevel or multigrid preconditioners $\hat{A}_h$ and $\hat{S}_h$. A closer look at the CG method reveals that this operation is only required for vectors of the form

$$\begin{pmatrix} \underline{w}_h \\ \underline{q}_h \end{pmatrix} = \hat{\mathcal{K}}_h^{-1} \begin{pmatrix} \underline{s}_h \\ \underline{t}_h \end{pmatrix}.$$

But then

$$\mathcal{D}_h \begin{pmatrix} \underline{w}_h \\ \underline{q}_h \end{pmatrix} = \hat{\mathcal{D}}_h \hat{\mathcal{K}}_h^{-1} \begin{pmatrix} \underline{s}_h \\ \underline{t}_h \end{pmatrix} = (\hat{\mathcal{K}}_h - \mathcal{K}_h)\hat{\mathcal{K}}_h^{-1} \begin{pmatrix} \underline{s}_h \\ \underline{t}_h \end{pmatrix} = \begin{pmatrix} \underline{s}_h \\ \underline{t}_h \end{pmatrix} - \mathcal{K}_h \begin{pmatrix} \underline{w}_h \\ \underline{q}_h \end{pmatrix},$$

which shows that direct matrix-vector products with the preconditioners $\hat{A}$ and $\hat{S}_h$ are not needed. As discussed in section 2, the operation

$$\hat{\mathcal{K}}_h^{-1} \begin{pmatrix} \underline{s}_h \\ \underline{t}_h \end{pmatrix}$$

requires only operations of the form $\hat{A}_h^{-1}\tilde{\underline{s}}_h$ and $\hat{S}_h\tilde{\underline{t}}_h$, which are, of course, available for multilevel or multigrid preconditioners.

## 6. Numerical experiments.

We consider the optimal control problem from the previous section on the unit cube $\Omega = (0,1)^3$ and with homogeneous data $y_d \equiv 0$. Starting from an initial mesh of 24 tetrahedra (starting level $l = 1$), we obtain a hierarchy of nested meshes by uniform refinement up to some final level $l = L$. On each tetrahedral mesh, piecewise linear and continuous finite elements are used for $Y_h = U_h = Q_h$.

The discretized mixed problem is solved on the finest mesh (level $l = L$) by using the CG method for the preconditioned system (2.9) with the scalar product

(2.3) as described before. For the preconditioner we used the proposed symmetric block preconditioner, where $\hat{Y}_h$ is one $V$-cycle of the multigrid method with $m_1$ forward Gauss–Seidel steps for presmoothing and $m_1$ backward Gauss–Seidel steps for postsmoothing (in short $V(m_1, m_1)$) for the second order elliptic differential operator represented by the bilinear form $\sqrt{\nu}\,(\nabla y, \nabla q)_{L^2(\Omega)} + (\sqrt{\nu}+1)\,(y, q)_{L^2(\Omega)}$. For $\hat{M}_h$ we use $m_2$ steps of the symmetric Gauss–Seidel method (in short $SGS(m_2)$).

Starting values $\underline{x}_h^{(0)}$ and $\underline{p}_h^{(0)}$ are generated randomly. The exact solution of the problem is the trivial solution $\underline{x}_h = 0$ and $\underline{p}_h = 0$. The quality of an approximation $(\underline{x}_h^{(k)}, \underline{p}_h^{(k)})$ is measured by either the energy norm $e^{(k)}$ of the error, which here is given by

$$e^{(k)} = \left\| \begin{pmatrix} \underline{x}_h^{(k)} \\ \underline{p}_h^{(k)} \end{pmatrix} \right\|_{\mathcal{D}_h \hat{\mathcal{K}}_h^{-1} \mathcal{K}_h},$$

or the residual $r^{(k)}$:

$$r^{(k)} = \left\| \mathcal{K}_h \begin{pmatrix} \underline{x}_h^{(k)} \\ \underline{p}_h^{(k)} \end{pmatrix} \right\|.$$

All computations were performed on a Linux-PC with a 2.0GHz 64-bit processor and 3GB memory.

Figure 6.1 shows a typical convergence history (number of iterations $k$ versus $e^{(k)}/e^{(0)}$ and $r^{(k)}/r^{(0)}$) for level $L = 5$ (number of unknowns $3 \times 17{,}985$) and regularization parameter $\nu = 1$ using a $V(3,3)$-cycle for $\hat{Y}_h$ and $SGS(3)$ for $\hat{M}_h$ and parameters $\sigma = 0.9$ and $\tau = 1.1/k_0^2$ with $k_0^2 = 3/4$. The solid straight line with the circular markers illustrates the theoretically predicted behavior (convergence factor $q = 1/3$; see the discussion at the end of section 4), which is in good agreement with the observed behavior.

[illegible] 1. The convergence rate of the proposed method was shown to be bounded below 1 independently of $\nu$ (and $h$). However, the norm itself depends on $\nu$. This might lead to the suspicion that, nevertheless, the performance depends on the parameter $\nu$. Observe that the Euclidean norm of the residuals shows a similar behavior as the energy norm, which is not predicted by the theory. So, after a fixed number of iterations (here 30 iterations), the values of the residuals cannot be distinguished from 0 relative to the initial residual within machine precision. In this sense the numerical experiments confirm that the method is really robust in $\nu$.

Table 6.1 shows that the number of iterations does not depend on the level of refinement. $L$ denotes the level of refinement, $n+m$ the total number of all unknowns $\underline{y}_h$, $\underline{u}_h$, and $\underline{p}_h$, $k$ the number of iterations needed to satisfy the stopping rule

$$r^{(k)} \le \varepsilon\, r^{(0)} \quad \text{with } \varepsilon = 10^{-8},$$

and $t$ the total CPU time in seconds.

Table 6.2 shows that the number of iterations does not depend on the regularization parameter $\nu$ either. The results are given for refinement level $L = 5$.

**7. Concluding remarks.** Comparing the matrix $\mathcal{K}_h$ and the preconditioner $\hat{\mathcal{K}}_h$, a first remarkable observation is that the mass matrix $M_h$ (representing the $L^2$ inner product on $Y_h$) in the first diagonal block of $A_h$ is preconditioned by a preconditioner for a second order elliptic differential operator. Of course, such a preconditioner cannot be a good preconditioner for $M_h$ on the whole space $Y_h$, but it is a good

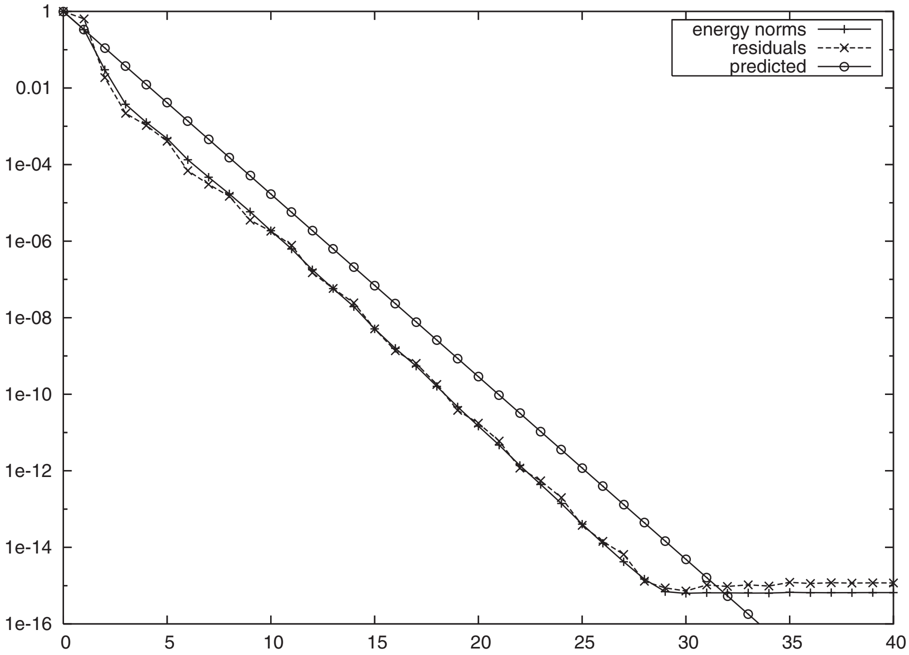

Fig. 6.1. *Convergence history: Number of iterations versus relative accuracy.*

Table 6.1
*Dependence of the number of iterations on the mesh size for fixed $\nu = 1$.*

| Level $L$ | Number of unknowns $n + m$ | Iterations $k$ | CPU time $t$ (in seconds) |
|---|---|---|---|
| 3 | 1,107 | 14 | 0.06 |
| 4 | 7,395 | 15 | 0.61 |
| 5 | 53,955 | 15 | 6.96 |
| 6 | 412,035 | 16 | 62.04 |
| 7 | 3,200,227 | 15 | 559.16 |

Table 6.2
*Dependence of the number of iterations on $\nu$ for fixed refinement level $L = 5$.*

| $\nu$ | Iterations $k$ |
|---|---|
| $10^{-4}$ | 15 |
| $10^{-2}$ | 14 |
| 1 | 15 |
| $10^{2}$ | 14 |
| $10^{4}$ | 15 |

preconditioner on the kernel of $B_h$, as it was shown. This suffices for the convergence analysis.

A more straightforward alternative would be to use some lumped mass matrix for preconditioning $M_h$ or even to use $M_h$ itself because it is well conditioned and, therefore, easy to invert. However, the resulting inexact Schur can then be interpreted as a discretized fourth order elliptic differential operator, for which it is much harder to find an efficient preconditioner. With our choice of the preconditioner for the mass matrix, the inexact Schur complement remains a discretized second order differential operator of the same complexity as the discretized second order differential operator of the state equation, for which an efficient preconditioner is usually available.

So in this context, it pays to invest (a little) more in preconditioning the mass matrix by a (properly scaled) Laplace-type preconditioner instead of some simple preconditioner. This would normally be considered a very obscure strategy. However, it is a very natural thing to do here because it just reflects the standard conditions of Brezzi's theorem.

A second remarkable observation concerns the discussed problem from optimal control. For the considered case of distributed control, it was shown theoretically and confirmed experimentally that the proposed preconditioner leads to convergence rates not only robust with respect to the mesh size $h$ but also robust with respect to the regularization parameter $\nu$.

**Acknowledgments.** We would like to thank the anonynmous referees for their valuable comments and suggestions which helped to improve this manuscript.

# A HYBRID APPROACH COMBINING CHEBYSHEV FILTER AND CONJUGATE GRADIENT FOR SOLVING LINEAR SYSTEMS WITH MULTIPLE RIGHT-HAND SIDES*

GENE H. GOLUB[†], DANIEL RUIZ[‡], AND AHMED TOUHAMI[§]

**Abstract.** One of the most powerful iterative schemes for solving symmetric, positive definite linear systems is the conjugate gradient algorithm of Hestenes and Stiefel [*J. Res. Nat. Bur. Standards*, 49 (1952), pp. 409–435], especially when it is combined with preconditioning (cf. [P. Concus, G.H. Golub, and D.P. O'Leary, in *Proceedings of the Symposium on Sparse Matrix Computations*, Argonne National Laboratory, 1975, Academic, New York, 1976]). In many applications, the solution of a sequence of equations with the same coefficient matrix is required. We propose an approach based on a combination of the conjugate gradient method with Chebyshev filtering polynomials, applied only to a part of the spectrum of the coefficient matrix, as preconditioners that target some specific convergence properties of the conjugate gradient method. We show that our preconditioner puts a large number of eigenvalues near one and do not degrade the distribution of the smallest ones. This procedure enables us to construct a lower dimensional Krylov basis that is very rich with respect to the smallest eigenvalues and associated eigenvectors. A major benefit of our method is that this information can then be exploited in a straightforward way to solve sequences of systems with little extra work. We illustrate the performance of our method through numerical experiments on a set of linear systems.

## 1. Introduction.

The preconditioned conjugate gradient algorithm is among the most powerful techniques for solving linear systems of the form

$$\mathbf{A}\mathbf{x}^\star = \mathbf{b}, \tag{1.1}$$

where $\mathbf{A} \in \mathbb{R}^{n\times n}$ is large and symmetric positive definite, and $\mathbf{b} \in \mathbb{R}^n$ is a given right-hand side (see, e.g., [8]). Concerning preconditioning, the use of polynomial preconditioners is one attractive possibility, considered by several authors [18, 24]. The polynomial preconditioner is generally chosen so that the preconditioned matrix has an eigenvalue distribution that is favorable to the conjugate gradient method, i.e., either with a largely reduced condition number so that the conjugate gradient method applied to the preconditioned system converges rapidly and/or with eigenvalues confined to a small number of intervals.

For the Chebyshev iteration, estimates of $\lambda_{\min}$ and $\lambda_{\max}$ are needed. Often, good upper bounds $\lambda_{\max}$ can be obtained easily, using simple techniques such as Gershgorin's theorem [24]. It is far more difficult to estimate the smallest eigenvalue. Saad [24] proposed a polynomial preconditioning technique that requires only an upper bound for the largest eigenvalue, while the trivial bound $\lambda_{\min} = 0$ is used for the smallest eigenvalue of $\mathbf{A}$. His technique is based on the least-squares polynomials associated with the family of Jacobi weights [28]. Another way to avoid the computation of $\lambda_{\min}$ and $\lambda_{\max}$ is to use the conjugate gradient polynomial itself as a preconditioner. This approach was investigated by O'Leary [22]. The disadvantage of this technique is that the preconditioned system is not guaranteed to be positive definite. Golub and Kent [14] gave a method for estimating the extreme eigenvalues based on modified moments. Ashby, Manteuffel, and Otto [3] demonstrated in a variety of numerical examples that the effectiveness of Chebyshev and least-squares polynomial preconditioners depends on the eigenvalue distribution of the coefficient matrix $\mathbf{A}$.

Here, a different approach is proposed that aims at putting the conjugate gradient in [illegible] mode, where the condition number of the preconditioned matrix is not so much reduced but its spectrum is largely clustered around one. Our preconditioner, called the ChebFilter, consists of applying the Chebyshev filtering polynomials only to a part of the spectrum of the given iteration matrix in an attempt to shift the maximum number of eigenvalues of the coefficient matrix close to one without degrading the distribution of the smallest eigenvalues. With this preconditioning technique, the conjugate gradient method still exhibits plateaus in its convergence behavior and does not enter linear mode as usually expected. These plateaus, which are mostly due to the combination of ill-conditioning and clusters of eigenvalues at the extremes, are greatly reduced in length, and the resulting method distinguishes itself by its ability to construct small dimensional Krylov bases that are very rich with respect to the smallest eigenvalues and associated eigenvectors.

In the following, we assume that $\mathbf{A}$ is a large s.p.d. matrix with a spectrum largely clustered, and the goal is to solve a sequence of large linear systems involving the same matrix but different right-hand sides. For simultaneous right-hand sides, block Krylov linear solvers [21] might be appropriate; for a sequence of right-hand sides that do not vary much, a straightforward idea is to use the former solution as an initial guess for the next solution. If only one right-hand side is available at a time, the method of Fischer [11], the deflated conjugate gradient method (deflated CG) [26], or the hybrid method of Simoncini and Gallopoulos [27] may be employed. Fischer's method first looks for a solution in the space spanned by the previous solution vectors in the sequence, which is helpful only if the solution vectors are correlated. In the deflated CG method, only a small number of the initial Lanczos vectors for every system are used to update the approximate invariant subspace. This is efficient, in both computation and memory use, but the convergence to an invariant subspace is slow. Hence, the improvement in the number of iterations is modest. The hybrid method of Simoncini and Gallopoulos is most effective only when the right-hand sides share common spectral information.

The alternative approach that we shall investigate in this work is not much different in spirit from these techniques but takes advantage of the particular Chebyshev preconditioners to construct a Krylov basis of small dimension very rich with respect to the eigeninformation linked to the smallest eigenvalues, without the need for any postprocessing. The main idea is to solve the first linear system with conjugate gradient combined with Chebyshev filters as a preconditioner and to exploit the resulting complete Krylov basis, generated at the first solution in the sequence, either to deflate the initial residual before using the classical conjugate gradient in the next solutions, or to build some particular preconditioned or deflated conjugate gradient algorithms. This approach is also rather independent of the right-hand sides, because the Chebyshev polynomial filters act uniformly on the eigencomponents independently of the residual vectors. The conjugate gradient, on the other hand, constructs a polynomial explicitly linked with these eigencomponents to minimize the **A**-norm of the current error vector.

The outline of the paper is as follows. Section 2 presents our preconditioner and discusses some of its properties. In section 3, we illustrate the efficiency of the proposed technique on a set of model problems arising from the discretization via finite elements of some 2D heterogeneous diffusion PDE problems. Section 4 shows how we can use the Chebyshev filter with the conjugate gradient to solve a sequence of linear systems involving the same matrix but different right-hand sides. In section 5, we analyze in more detail the computational complexity of our approach. This technique is better than the conjugate gradient only for the solution of a sequence of linear systems with the same matrix but changing right-hand sides. We analyze in particular how quickly the extra work at the beginning, when solving the first system in the sequence, can be paid back after a few consecutive solutions. Finally, we conclude with some remarks and perspectives in section 6.

**2. Chebyshev filtering polynomials as a preconditioner.** The present section is devoted to the description of the proposed combination of conjugate gradients with Chebyshev filtering polynomials as preconditioners called ChebFilterCG. To describe this in detail, we first introduce the eigendecomposition of the s.p.d. matrix **A**:

$$\mathbf{A} = \mathbf{U}\mathbf{\Lambda}\mathbf{U}^T = \mathbf{U}_1\mathbf{\Lambda}_1\mathbf{U}_1^T + \mathbf{U}_2\mathbf{\Lambda}_2\mathbf{U}_2^T,$$

where the spectrum of **A** is split in two parts: $\mathbf{\Lambda}_1$ is the diagonal matrix containing all eigenvalues of **A** less than a given positive number $\mu$, where $0 < \mu < \lambda_{\max}$ is fixed (user-given) and denotes the [illegible]. $\mathbf{U}_1$ is the rectangular matrix whose columns are the corresponding orthonormal set of eigenvectors in matrix form, and $\mathbf{\Lambda}_2$ and $\mathbf{U}_2$ are the corresponding complementary matrices.

Let $\mathbf{x}^{(0)} \in \mathbb{R}^n$ be any initial guess for the solution of (1.1), and let $\mathbf{r}^{(0)} = \mathbf{b} - \mathbf{A}\mathbf{x}^{(0)}$ be the associated residual vector. We then introduce the [illegible] vector

$$\mathbf{w}_f = \mathcal{F}_m(\mathbf{A})\,\mathbf{r}^{(0)} = \mathbf{U}_1\mathcal{F}_m(\mathbf{\Lambda}_1)\mathbf{U}_1^T\,\mathbf{r}^{(0)} + \mathbf{U}_2\mathcal{F}_m(\mathbf{\Lambda}_2)\mathbf{U}_2^T\,\mathbf{r}^{(0)}, \tag{2.1}$$

where $\mathcal{F}_m$ is a polynomial function of degree $m$ given by

$$\mathcal{F}_m(\lambda) = \frac{T_m(\Theta_\mu(\lambda))}{T_m(\Theta_\mu(0))}, \tag{2.2}$$

with $T_m$ being the usual Chebyshev polynomial of degree $m$, and $\Theta_\mu$ is the linear mapping function that maps the interval $[\mu, \lambda_{\max}]$ onto the unit interval $[-1, 1]$ (with $\Theta_\mu(\mu) = 1$ and $\Theta_\mu(\lambda_{\max}) = -1$).

For given values of $\mu$, $\lambda_{\max}(\mathbf{A})$, and $\varepsilon$, we can fix the degree $m$ of $T_m$ such that $1/|T_m(\Theta_\mu(0))| < \varepsilon$ and consequently $||\mathcal{F}_m(\lambda)||_\infty < \varepsilon$ on $[\mu, \lambda_{\max}]$. Using (2.1), we can then write

$$||\mathbf{U}_2^T\,\mathbf{w}_f||_2 \le ||\mathcal{F}_m(\mathbf{\Lambda}_2)||_2\,||\mathbf{U}_2^T\,\mathbf{r}^{(0)}||_2 \le \varepsilon\,||\mathbf{U}_2^T\,\mathbf{r}^{(0)}||_2\,. \tag{2.3}$$

Equation (2.3) explains explicitly how the action of the Chebyshev filtering in **A** applied on a given vector $\mathbf{r}^{(0)}$ can reduce, below a value $\varepsilon$, the eigencomponents in

ALGORITHM 2.1: CHEBFILTER

```
$[\mathbf{w}_f, \mathbf{x}_f] = \text{ChebFilter}\,\big(\mathbf{A}, \mathbf{b}, \mu, \lambda_{\max}(\mathbf{A}), \mathbf{x}^{(0)}, \varepsilon\big)$

Begin
  1. $\alpha_\mu = \frac{2}{\lambda_{\max}(\mathbf{A}) - \mu}$ and $d_\mu = \frac{\lambda_{\max}(\mathbf{A}) + \mu}{\lambda_{\max}(\mathbf{A}) - \mu}$
  2. Given the initial guess $\mathbf{x}^{(0)}$
  3. $\mathbf{x}_f = \mathbf{x}^{(0)}$, set $\mathbf{w}_f = \mathbf{b} - \mathbf{A}\mathbf{x}_f$
  4. $\mathbf{y} = \mathbf{x}_f,\ m = 1,\ \sigma_0 = 1$, and $\sigma_1 = d_\mu$
  5. $\mathbf{x}_f = \mathbf{x}_f + \frac{\alpha_\mu}{d_\mu}\mathbf{w}_f$ and $\mathbf{w}_f = \mathbf{b} - \mathbf{A}\mathbf{x}_f$
  6. Do While $1/\sigma_m \geq \varepsilon$
      i. $\sigma_{m+1} = 2\, d_\mu\, \sigma_m - \sigma_{m-1}$
      ii. $\mathbf{p} = 2\,\frac{\sigma_m}{\sigma_{m+1}}\Big(d_\mu \mathbf{x}_f + \alpha_\mu \mathbf{w}_f\Big) - \frac{\sigma_{m-1}}{\sigma_{m+1}}\,\mathbf{y}$
      iii. $\mathbf{y} = \mathbf{x}_f$ and $\mathbf{x}_f = \mathbf{p}$
      iv. $\mathbf{w}_f = \mathbf{b} - \mathbf{A}\mathbf{x}_f$
      v. $m = m + 1$
  7. EndDo
End
```

$\mathbf{r}^{(0)}$ associated to all eigenvalues in the range $[\mu, \lambda_{\max}(\mathbf{A})]$ relative to the others. The number of Chebyshev steps required to achieve a given level of filtering $\varepsilon$ is directly related to the rate of convergence of Chebyshev polynomials on the interval $[\mu, \lambda_{\max}]$ (see, e.g., [14], [16, p. 47]), which depends only on the ratio $\lambda_{\max}/\mu$.

We can then introduce the Algorithm 2.1, which we call ChebFilter and which corresponds to the application of a Chebyshev polynomial in $\mathbf{A}$ to reduce by a factor $\varepsilon$ the eigencomponents in $\mathbf{r}^{(0)} = \mathbf{b} - \mathbf{A}\mathbf{x}^{(0)}$ associated with all eigenvalues in the range $[\mu, \lambda_{\max}(\mathbf{A})]$. As a result, the algorithm provides the filtered residual $\mathbf{w}_f = \mathcal{F}_{m+1}(\mathbf{A})\,\mathbf{r}^{(0)}$ and the corresponding iterate approximation $\mathbf{x}_f$ such that $\mathbf{b} - \mathbf{A}\mathbf{x}_f = \mathbf{w}_f$. In this algorithm, steps 6.ii and 6.iii are connected together with the following relation:

$$\mathbf{w}_f = \mathbf{w}^{(m+1)} = \mathcal{F}_{m+1}(\mathbf{A})\,\mathbf{r}^{(0)} = \frac{T_{m+1}(\Theta_\mu(\mathbf{A}))\,\mathbf{r}^{(0)}}{T_{m+1}(d_\mu)} = \frac{1}{\sigma_{m+1}}\,T_{m+1}\Big(d_\mu\,\mathbf{I} - \alpha_\mu\,\mathbf{A}\Big)\,\mathbf{r}^{(0)},$$

where we note $d_\mu = \frac{\lambda_{\max}+\mu}{\lambda_{\max}-\mu}$, $\alpha_\mu = \frac{2}{\lambda_{\max}-\mu}$, and $\sigma_m = T_m(d_\mu)$ for all $m \geq 0$. In that respect, step 6.iv can also be replaced by the equivalent following three-term recurrence relation:

$$\mathbf{w}_f = \mathbf{w}^{(m+1)} = 2\,\frac{\sigma_m}{\sigma_{m+1}}\Big(d_\mu \mathbf{w}^{(m)} - \alpha_\mu \mathbf{A}\mathbf{w}^{(m)}\Big) - \frac{\sigma_{m-1}}{\sigma_{m+1}}\,\mathbf{w}^{(m-1)}, \tag{2.4}$$

which corresponds to the usual Chebyshev three-term recurrence formula giving $\mathbf{w}^{(m+1)}$ in a function of $\mathbf{w}^{(m)}$ and $\mathbf{w}^{(m-1)}$ for $m \geq 1$, with $\mathbf{w}^{(0)}$ set to $\mathbf{r}^{(0)}$ at the beginning and $\mathbf{w}^{(1)}$ set to $\big(\mathbf{I} - \frac{\alpha_\mu}{d_\mu}\mathbf{A}\big)\mathbf{r}^{(0)}$.

Let us denote now by $\mathbf{x}^{(i)}$ the $i$th iterate in the preconditioned conjugate gradient and by $\mathbf{r}^{(i)} = \mathbf{b} - \mathbf{A}\mathbf{x}^{(i)} = \mathbf{A}(\mathbf{x} - \mathbf{x}^{(i)})$ the associated residual. The application of the ChebFilter polynomial as a preconditioner consists in solving approximatively the linear system $\mathbf{A}\mathbf{z}^{(i)} = \mathbf{r}^{(i)}$ such that its final residual is given by $\mathbf{r}^{(i)} - \mathbf{A}\mathbf{z}^{(i)} = \mathcal{F}_m(\mathbf{A})\,\mathbf{r}^{(i)}$, which can be expressed as

$$\mathbf{z}^{(i)} = \mathbf{A}^{-1}\big(\mathbf{I} - \mathcal{F}_m(\mathbf{A})\big)\mathbf{r}^{(i)} = \mathbf{M}^{-1}\mathbf{r}^{(i)}. \tag{2.5}$$

We mention that our polynomial preconditioner, in the way it is implemented, carries out a fixed number of steps for given values of $\lambda_{\max}(\mathbf{A})$, $\mu$, and $\varepsilon$, independently of the right-hand side.

The $i$th iteration in the preconditioned conjugate gradient consists of searching $\mathbf{x}^{(i)} \in \{\mathbf{x}^{(0)}\} + \mathcal{K}_i(\mathbf{M}^{-1}\mathbf{A}, \mathbf{z}^{(0)})$, with $\mathbf{z}^{(0)} = \mathbf{M}^{-1}\mathbf{b}$ and $\mathbf{r}^{(i)} \perp \mathcal{K}_i(\mathbf{M}^{-1}\mathbf{A}, \mathbf{z}^{(0)})$. $\mathcal{K}_i(\mathbf{M}^{-1}\mathbf{A}, \mathbf{z}^{(0)})$ is the $i$th Krylov subspace and is given by

$$\begin{aligned}\mathcal{K}_i\big(\mathbf{M}^{-1}\mathbf{A}, \mathbf{z}^{(0)}\big) &= \mathrm{Span}\Big(\mathbf{z}^{(0)}, \dots, \big(\mathbf{M}^{-1}\mathbf{A}\big)^{\mathrm{i}-1}\mathbf{z}^{(0)}\Big)\\ &= \mathrm{Span}\Big(\mathbf{z}^{(0)}, \dots, \big(\mathbf{I} - \mathcal{F}_{\mathrm{m}}(\mathbf{A})\big)^{\mathrm{i}-1}\mathbf{z}^{(0)}\Big)\\ &= \mathrm{Span}\Big(\mathbf{z}^{(0)}, \dots, \big(\mathcal{F}_{\mathrm{m}}(\mathbf{A})\big)^{\mathrm{i}-1}\mathbf{z}^{(0)}\Big),\end{aligned} \tag{2.6}$$

since $\mathbf{A}^{-1}\mathcal{F}_m(\mathbf{A}) = \mathcal{F}_m(\mathbf{A})\mathbf{A}^{-1}$, and consequently $\mathbf{M}^{-1}\mathbf{A} = \mathbf{A}^{-1}\big(\mathbf{I} - \mathcal{F}_m(\mathbf{A})\big)\mathbf{A} = \big(\mathbf{I} - \mathcal{F}_m(\mathbf{A})\big)\mathbf{A}^{-1}\mathbf{A}$. Equation (2.6) shows explicitly that the Chebyshev preconditioned conjugate gradient search directions remain in a filtered Krylov subspace.

Note that, since $\mathbf{A}$ is s.p.d., then $\mathbf{M}^{-1} = \mathbf{A}^{-1}\big(\mathbf{I} - \mathcal{F}_m(\mathbf{A})\big)$ is symmetric positive definite. Indeed, since $\mathbf{A}^{-1}$ and $\mathcal{F}_m(\mathbf{A})$ commute, it is easy to see that $\mathbf{M}^{-1}$ is symmetric. Finally, using the eigendecomposition of the s.p.d. matrix $\mathbf{A}$, $\mathbf{A} = \mathbf{U}\boldsymbol{\Lambda}\mathbf{U}^T$, we can write $\mathbf{M}^{-1} = \mathbf{U}\boldsymbol{\Lambda}^{-1}\big(\mathbf{I} - \mathcal{F}_m(\boldsymbol{\Lambda})\big)\mathbf{U}^T$, where $\boldsymbol{\Lambda}^{-1}\big(\mathbf{I} - \mathcal{F}_m(\boldsymbol{\Lambda})\big)$ is diagonal positive definite since $\mathcal{F}_m(\lambda) \in [-\varepsilon, 1[$ for all $\lambda$ in $]0, \lambda_{\max}]$. In addition we can see that the matrices $\mathbf{M}^{-1}\mathbf{A}$ and $\mathbf{A}\mathbf{M}^{-1}$ have the same eigenvalues, which are those of $(\mathbf{I} - \mathcal{F}_m(\mathbf{A}))$. Therefore, the eigenvalues of $\mathbf{M}^{-1}\mathbf{A}$ are given by $1 - \mathcal{F}_m(\lambda_i)$, with $\lambda_i$, $i \in \{1, \dots, n\}$, the eigenvalues of $\mathbf{A}$.

An important aspect in the use of such a Chebyshev filter as a preconditioner is that it acts uniformly on the range $[\mu, \lambda_{\max}(\mathbf{A})]$, independently of the right-hand side, as opposed to the conjugate gradient, which finds the polynomial minimizing the $\mathbf{A}$-norm of the error in the given linear system.

## 3. Numerical experiments.

In this section, we illustrate with some numerical experiments the efficiency of the polynomial preconditioner introduced above. Our test problems PDE1 and PDE2 are extracted from the finite element discretization using MATLAB of the partial differential equation problem:

$$\left\{\begin{array}{rcl} -\mathrm{div}\Big(\Lambda(x)\cdot\nabla u\Big) & = & f \quad \text{in} \quad \Omega,\\ u_{|\partial\Omega} & = & 0, \end{array}\right.$$

where $\Omega \subset \mathbb{R}^2$ is an L-shaped region as described in Figure 3.1.

The major differences between PDE1 and PDE2 are in the settings for $\Lambda(x)$ and in the size of discretization.

In the PDE1 problem, $f = 10$, and the function $\Lambda(x) \in L^\infty(\Omega)$ takes different scalar values in each subdomain:

$$\Lambda(x) = \left\{\begin{array}{ll} 1 & x \in \Omega_1 \cup \Omega_4,\\ 10^6 & x \in \Omega_2,\\ 10^4 & x \in \Omega_3. \end{array}\right.$$

The resulting linear system (1.1) has 7,969 degrees of freedom, the number of nonzero elements in the coefficient matrix $\mathbf{A}$ is $\mathit{nnz}\,(\mathbf{A}) = 55,131$, and the norm of $\mathbf{A}$ is equal to $9.54 \cdot 10^6$.

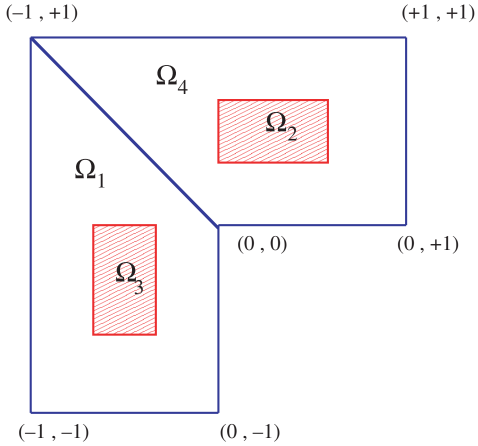

FIG. 3.1. *Geometry of the domain* $\Omega$.

In the PDE2 problem, $f = 200$, and the PDE problem incorporates some heterogeneity and anisotropy with the matrix $\Lambda(x)$ that takes the following values:

$$\Lambda(x) = \begin{cases} \begin{bmatrix} 1 & 4\,\lambda_1 \\ 4\,\lambda_1 & \lambda_1 \end{bmatrix} & \text{if } x \in \Omega_1 \quad \text{and} \quad \lambda_2\,\mathbf{I}_2 \quad \text{if } x \in \Omega_2, \\ \begin{bmatrix} \lambda_1 & -2\,\lambda_1 \\ -2\,\lambda_1 & 1 \end{bmatrix} & \text{if } x \in \Omega_4 \quad \text{and} \quad \lambda_3\,\mathbf{I}_2 \quad \text{if } x \in \Omega_3, \end{cases}$$

where $\lambda_1 = 6 \cdot 10^{-2}$, $\lambda_2 = 1 \cdot 10^6$, $\lambda_3 = 1 \cdot 10^2$, and $\mathbf{I}_2$ denotes the $(2 \times 2)$ identity matrix. The resulting linear system (1.1) has 161,313 degrees of freedom, the number of nonzero elements in the coefficient matrix $\mathbf{A}$ is $\mathit{nnz}\,(\mathbf{A}) = 1,125,897$, and the norm of $\mathbf{A}$ is equal to $1.00 \cdot 10^7$.

Moreover, we use three kinds of the first level of preconditioners: the classical Jacobi diagonal matrix $\mathbf{M}_1 = \text{diag}(\mathbf{A})$, the incomplete Cholesky decomposition of $\mathbf{A}$ with no fill-in, and the incomplete Cholesky decomposition of $\mathbf{A}$ with drop tolerance $10^{-2}$, $\mathsf{cholinc}(\mathbf{A}, 10^{-2})$ as in MATLAB notations.

Using the incomplete Cholesky decompositions, we compute the lower triangular matrix $\mathbf{L}$ such that $\mathbf{M}_1 = \mathbf{L}\mathbf{L}^T$. The purpose of this first level of preconditioner is to better cluster the spectrum of our iteration matrix, which is favorable to the solution technique we propose here. Additionally, in the different figures illustrating the experimental results, we shall denote by "Classical CG" the preconditioned conjugate gradient with the classical Jacobi or the incomplete Cholesky factorization as the first level of preconditioner only.

First, we consider the case of the PDE1 problem. In Table 3.1, we report on the values of the condition numbers $\kappa(\mathbf{A})$ and $\kappa(\mathbf{M}_1^{-1}\mathbf{A})$ for the Jacobi and the incomplete Cholesky with no fill-in and with drop tolerance $10^{-2}$. The condition number of $\mathbf{A}$ is of order $10^9$; after incomplete Cholesky preconditioning with drop tolerance $10^{-2}$, $\kappa(\mathbf{M}_1^{-1}\mathbf{A})$ is of order $10^6$.

In Table 3.2, we indicate the number of eigenvalues in the interval $[\lambda_{\min}, \mu]$ in the case of the PDE1 problem for a large range of the value of the parameter $\mu$ for each preconditioner. From these data, we can see that the original matrix is very badly scaled, and that the Jacobi preconditioner is able to cluster the eigenvalues quite substantially, although the condition number remains very large.

| 10 | | | 68 | 3 |
| 5 | | | 157 | 9 |
| 2 | | | >200 | 40 |

In the following tables, the CPU times will not be shown, since all of our experiments were performed using MATLAB, to illustrate the numerical features of the proposed approach.

**3.1. Impact of the cutoff value and level of filtering.** The CHEBFILTER preconditioner developed in section 2 depends on two different parameters, namely, the choice of the cutoff filtering value $\mu$ and the filtering level $\varepsilon$. In Table 3.3, we consider the case of the PDE1 problem; the initial guess is $\mathbf{x}^{(0)} = 0$, and the right-hand side is chosen so that the solution $\mathbf{x}^\star$ of the linear system is the vector of all ones. In this table, we display the number of Chebyshev filtering steps (`ChebIt`), the number of iterations of CG (`CGIt`), and the total number matrix-vector products (`ChebIt`×`CGIt`) for different values of the filtering level $\varepsilon$ and for the cutoff filtering value $\mu$. In these tests, we have stopped the CG iterations when $\|\mathbf{x}^\star - \mathbf{x}^{(k)}\|_{\mathbf{A}} \leq 10^{-9}\ \|\mathbf{x}^\star\|_{\mathbf{A}}$. From these data, we can observe the combined effects of these two parameters on our test examples.

The parameter $\mu$ splits the spectrum of the matrix $\mathbf{A}$ in two subsets and determines the convergence rate of the classical Chebyshev iterations that will be performed in each conjugate gradient iteration for preconditioning, since this defines the damping interval $[\mu, \lambda_{\max}]$ where the Chebyshev polynomial uniformly converges to 0. The rapid change in the Chebyshev rate of convergence with smaller values of $\mu$ induces many more Chebyshev filtering steps at each iteration, and this can be counterbalanced only by a very strong reduction in the total number of iterations in the preconditioned conjugate gradient algorithm. In other words, it is worth reducing the value of $\mu$ only if there is a very strong clustering of eigenvalues in the spectrum of the iteration matrix. In that respect, a first level of preconditioning $\mathbf{M}_1$ is a key issue that may help to enforce this situation in the iteration matrix $\mathbf{M}_1^{-1}\mathbf{A}$.

Table 3.3

| $10^{-1}$ | 7 | 15 | 105 | 5 | 16 | 80 | 4 | 17 | 68 |

The second parameter, the filtering level $\varepsilon$, directly influences the number of Chebyshev steps. Note that, for a fixed level of filtering $\varepsilon$, the total number of matrix-vector products (`ChebIt`×`CGIt`) does not change dramatically when varying $\mu$.

For a fixed value of $\mu$, if we consider the total number of matrix-vector products (`ChebIt`×`CGIt`), it is clear that the conjugate gradient alone performs better than the combination of conjugate gradient with Chebyshev filters, simply because the Chebyshev polynomial is not optimal in the **A**-norm and acts uniformly and independently of the eigencomponents of the given residual. We shall see, however, that if we intend to reuse the generated filtered Krylov basis for the acceleration of further solutions, the size of this basis is of great importance, and smaller values of the filtering level $\varepsilon$ should be considered to minimize that size.

If we consider a filtering value $\varepsilon$ close to $10^{-1}$ to minimize the effort within each Chebyshev filtering step, we can observe that the total number of matrix-vector

Table 3.4

products achieved is not that far from that achieved by the conjugate gradient alone. The important point to highlight is the substantial reduction of the dimension of the Krylov basis generated with this combination of CG with Chebyshev filters. This basis is indeed reduced by a factor of 3 in the case of IC($10^{-2}$), by a factor of about 6 with incomplete Cholesky no fill-in, and by a factor of about 10 with a simple Jacobi as the first level of preconditioner. This reduction is even stronger with smaller values for the filtering level $\varepsilon$. These different issues will be analyzed in more detail in terms of floating-point operations in section 5.

**3.2. Relevance of the Krylov basis.** In this section, we consider the case of the PDE1 problem. We evaluate the relevance of the information stored in the Krylov subspace $\mathbf{W}_k$ obtained from the CG method, after $k$ iterations of ChebFilterCG. To do so, we perform Ritz's spectral analysis of $\mathbf{W}_k$, and we also study the cosines of the principal angles between this Krylov subspace and the corresponding invariant subspace $\mathbf{U}_k$, associated with the $k$ smallest eigenvalues in the given matrix. $\mathbf{U}_k$ is computed with ARPACK [19].

**3.2.1. Ritz's spectral analysis.** The Ritz values $\delta_i$, $1 \leq i \leq k$, are the eigenvalues of the Rayleigh matrix $\mathbf{W}_k^T \mathbf{A} \mathbf{W}_k$, where $\mathbf{W}_k$ is a $n \times k$ matrix whose columns are the corresponding orthonormalized set of Krylov vectors. In Table 3.4, we give the relative residual corresponding to the smallest eigenvalues $\lambda_i$, $1 \leq i \leq 7$, which indicates the number of correct digits in each approximated eigenvalue $\delta_i$, $1 \leq i \leq 7$, for a level of filtering $\varepsilon = 10^{-4}$ and for different cutoff filtering values $\mu$. For instance, the conjugate gradient with a Chebyshev filter as preconditioner (ChebFilterCG) gives a good approximation of the three smallest eigenvalues (ten correct digits) for the preconditioned matrix with IC($10^{-2}$) and $\mu = \lambda_{\max}/10$. We can observe that, with $\mu = \lambda_{\max}/10$, the other four larger eigenvalues are not well approximated. This is simply because these eigenvalues fall directly in the interval $[\lambda_{\max}/10, \lambda_{\max}]$, where the Chebyshev polynomials used for preconditioning uniformly converge to 0.

This table proves the interest of the spectral information stored inside the Krylov basis generated by ChebFilterCG and which gives a good approximation of the spectral part in the range $]0, \mu[$.

**3.2.2. Cosines of the principal angles.** In Table 3.5, we give the cosines of the principal angles between the two subspaces $\mathbf{W}_k$ and $\mathbf{U}_k$, where $\mathbf{W}_k$ is the orthonormal basis for the Krylov subspace generated by the ChebFilterCG algorithm, and $\mathbf{U}_k$ is the subspace spanned by the $k$ smallest eigenvectors of the given matrix. The index $k$ refers to the number of iterations of the conjugate gradient with a Chebyshev filter as

Table 3.5

*Cosines of the principal angles between* Range $(\mathbf{W}_k)$ *and* Range $(\mathbf{U}_k)$*, the invariant subspace associated with the k smallest eigenvalues. The matrix is initially preconditioned with incomplete Cholesky with drop tolerance (*$10^{-2}$*), and the cutoff filtering value in the* ChebFilterCG *algorithm has been fixed to* $\mu = \lambda_{\max}/10$*. The problem considered is PDE1.*

| | 8.998E-01 | 9.999E-01 | 8.192E-01 |
| | | 9.999E-01 | 6.219E-01 |

the preconditioner. The computation is done using the singular value decomposition (SVD), as proposed in [15], since the singular values of $\mathbf{W}_k^T\,\mathbf{U}_k$ correspond to the cosines of the principal angles between the two subspaces Range $(\mathbf{W}_k)$ and Range $(\mathbf{U}_k)$. As we can see in Table 3.5, these principal angles stay very close to zero.

We deduce from these cosines of the principal angles that the two subspaces Range $(\mathbf{W}_k)$ and Range $(\mathbf{U}_k)$ are very collinear and especially for the directions which are related to the interval $]0, \mu[$.

**4. Reusing the filtered Krylov subspaces in further runs.** Let us now consider the case of a series of linear systems with different right-hand sides and the same coefficient matrix, viz.

$$\mathbf{A}\mathbf{x}_\ell = \mathbf{b}_\ell,\ \ \ell = 1, \ldots, s, \tag{4.1}$$

where $\mathbf{A}$ is a symmetric positive definite matrix in $\mathbb{R}^{n\times n}$; $\mathbf{x}_\ell$ and $\mathbf{b}_\ell$ are vectors of $\mathbb{R}^n$. The main idea is to solve the first system $\mathbf{A}\mathbf{x}_1 = \mathbf{b}_1$ in this sequence by means of the conjugate gradient with a Chebyshev filter as the preconditioner (ChebFilterCG) and to exploit the resulting complete Krylov basis to compute the solution of the remaining systems.

Once this Krylov basis $\mathbf{W}_k$ is obtained from the CG method, after $k$ iterations of ChebFilterCG when solving the first system in (4.1), we can use it in the Init-CG algorithm; see, e.g., [6, 7, 10, 12, 13, 23, 25, 26, 29] for the computation of the solutions in each of the following linear systems (4.1). We insist on the fact that we keep the same precomputed basis $\mathbf{W}_k$ for the solution of all of the remaining systems in the sequence. The Init-CG algorithm performs an oblique projection of the initial residual (i.e., a projection onto Span$(\mathbf{A}\mathbf{W}_k)$ along Ker$({\mathbf{W}_k}^T)$), in order to get the eigencomponents in the solution corresponding to the smallest eigenvalues, and then performs a classical conjugate gradient to compute the remaining part of the solution vector.

For the practical details, we use the conjugate gradient to solve $\mathbf{M}_1^{-1}\mathbf{A}\mathbf{x}_\ell = \mathbf{M}_1^{-1}\mathbf{b}_\ell$ $(\ell \geq 2)$ with the starting guess $\mathbf{x}_\ell^{(0)} = \mathbf{W}_k(\mathbf{W}_k^T\mathbf{A}\mathbf{W}_k)^{-1}\mathbf{W}_k^T\mathbf{b}_\ell$, where $\mathbf{W}_k$, of dimension $k$, is equal to the Krylov basis obtained after $k$ iterations of the ChebFilterCG when solving the first system with the preconditioned matrix $\mathbf{M}_1^{-1}\mathbf{A}$. Our Krylov basis $\mathbf{W}_k$ generated by ChebFilterCG is formed by the search direction vectors and not by the residuals. In this case $\mathbf{W}_k$ is already an $\mathbf{A}$-orthogonal basis

Algorithm 4.1:

```
Begin
    1. $[\mathbf{x}_1, \mathbf{W}] = \textsc{ChebFilterCG}\ (\mathbf{A}, \mathbf{b}_1, \mathbf{x}^{(0)}, \mathrm{tol}_1, \mathbf{M}_1)$
    2. $\mathbf{A}_c = \mathbf{W}^T\mathbf{A}\mathbf{W}$ is a diagonal matrix
    3. For $\ell = 2, \ldots, s$ Do
        i. $\mathbf{x}^{(0)} = \mathbf{W}\mathbf{A}_c^{-1}\mathbf{W}^T\mathbf{b}_\ell$
        ii. $\mathbf{x}_\ell = \mathrm{PCG}\ (\mathbf{A}, \mathbf{b}_\ell, \mathbf{x}^{(0)}, \mathrm{tol}_2, \mathbf{M}_1)$
    4. EndFor
End
```

of the Krylov subspace, and $\mathbf{A}_c = \mathbf{W}_k^T\mathbf{A}\mathbf{W}_k$ is a diagonal matrix. Note that we do not project the given matrix in any way but that we use the preconditioned conjugate gradient with the original matrix and the first level of preconditioning $\mathbf{M}_1$ and with an initial guess which, we expect, will remove all of the difficulties that the conjugate gradient algorithm would encounter otherwise, e.g., the plateaus that can be observed in the convergence history. This approach is resumed in Algorithm 4.1.

To illustrate this strategy, we consider the case of the PDE1 problem, and we present some numerical experiments where we solve a first system and then a second system. The initial guess is $\mathbf{x}^{(0)} = 0$, and the first right-hand side $\mathbf{b}_1$ is chosen so that the solution $\mathbf{x}^\star$ of the linear system is the vector of all ones and the solution in ChebFilterCG of this first linear system is stopped when the $\mathbf{A}$-norm of the error is below $10^{-9}$. The second right-hand side $\mathbf{b}_2$ is chosen so that the solution of the linear system is a vector with normally distributed random numbers. In these runs, we have monitored the $\mathbf{A}$-norm of the error down to machine precision in order to illustrate and study the complete convergence history. For all of the numerical experiments reported in this work, the ChebFilterCG algorithm is used for the first right-hand side $\mathbf{b}_1$, while the Init-CG algorithm is used for the second right-hand side $\mathbf{b}_2$.

Figures 4.1 and 4.2 summarize the improvement when reusing the Krylov subspaces generated by the ChebFilterCG algorithm in the solution of linear systems with the same matrix and with changing right-hand sides. We plot the convergence history, in the Init-CG method, of the error measured in the energy norm, respectively, for the Jacobi preconditioner and for the incomplete Cholesky with no fill-in preconditioner. We also plot the curve of the errors measured in the energy norm when the conjugate gradient method is used without this deflation of the initial residual.

Figure 4.1 shows the effectiveness of the Krylov basis generated by the conjugate gradient with a Chebyshev filter as the preconditioner for different values of filtering level $\varepsilon$. We observe that, for a fixed value of $\mu$, the convergence history of Init-CG for different values of filtering level $\varepsilon$ yields a constant numerical behavior, since all of these curves coincide almost completely, except perhaps after stagnation. We can also observe that the number of iterations is reduced by a factor of about 4 to reach an $\mathbf{A}$-norm of the error of $10^{-8}$, which illustrates the relevance of the information contained in the Krylov subspaces generated by the conjugate gradient with a Chebyshev as the preconditioner. An important property of the ChebFilter preconditioner is that it does not need a level of filtering $\varepsilon$ close to $10^{-16}$ for the Krylov basis to be efficient.

In Figure 4.2, we consider the case when the filtering value is fixed (for instance, $\varepsilon = 10^{-1}$) and the cutoff value $\mu$ is varied. The convergence history of the Init-

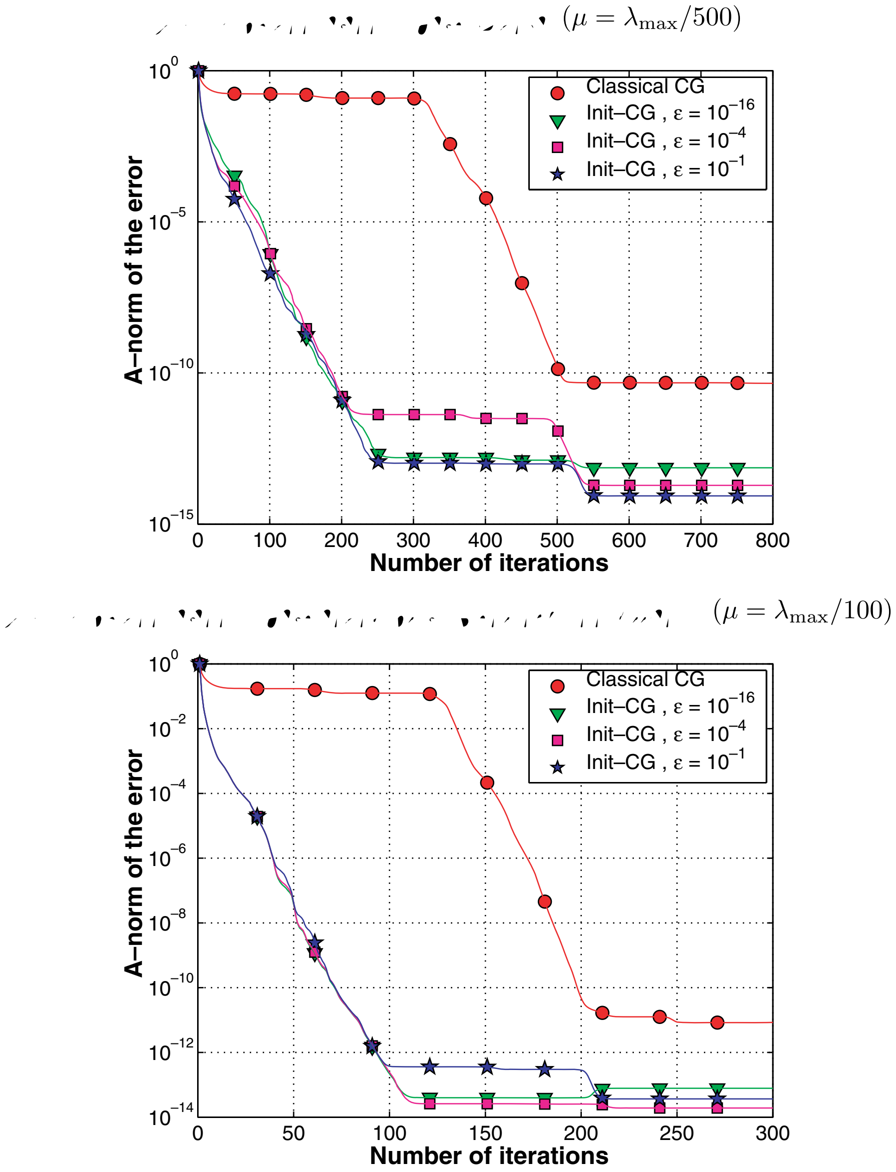

FIG. 4.1. *Convergence history of the* INIT-CG *algorithm when solving the second linear system* $\mathbf{A}\mathbf{x}_2 = \mathbf{b}_2$ *and exploiting the Krylov basis generated by the conjugate gradient with a Chebyshev filter as the preconditioner from the first solution. This for different values of* $\varepsilon$ *and for a fixed value of* $\mu$*. The problem considered is PDE*1.

CG with the Krylov basis generated by the conjugate gradient with a Chebyshev as the preconditioner (CHEBFILTERCG), for different values of $\mu$, exhibits the same numerical behavior. Although these runs are restricted to only two systems, the gains obtained can easily be extended to longer sequences of linear systems with the same coefficient matrix.

Finally, the different histograms show that the level of filtering $\varepsilon$ and the cutoff eigenvalue $\mu$ do not have a big effect on the quality of the Krylov basis, since the

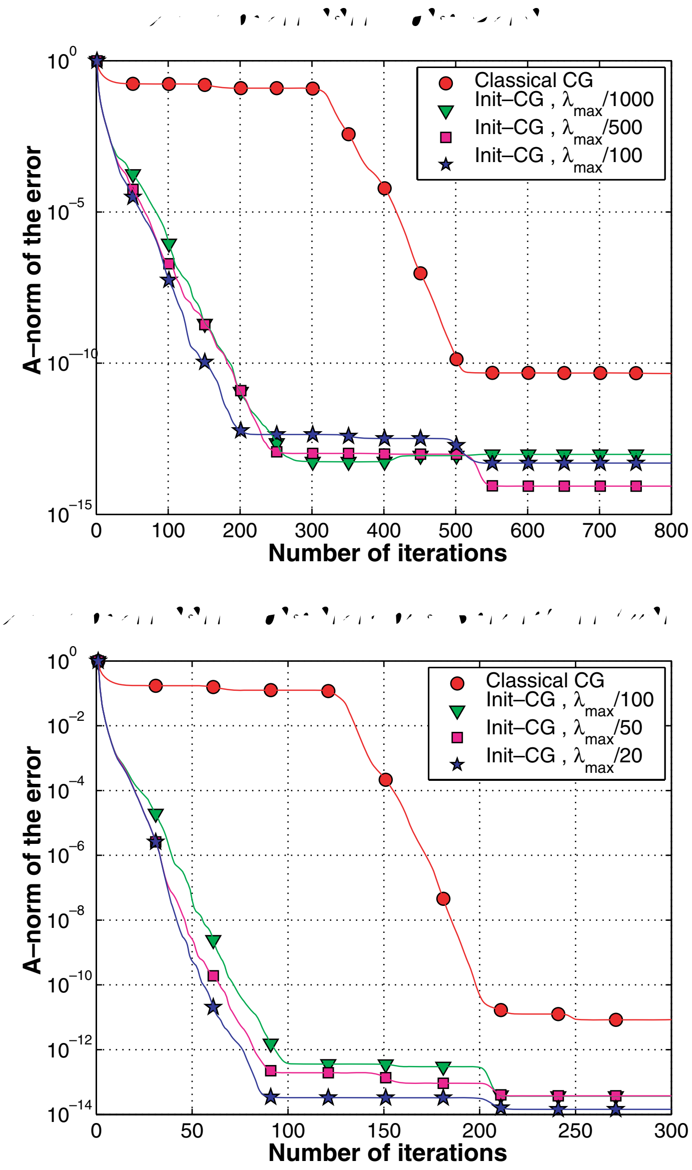

FIG. 4.2. *Convergence history of* INIT-CG *when solving the second linear system* $\mathbf{A}\mathbf{x}_2 = \mathbf{b}_2$ *and exploiting the Krylov basis generated by the conjugate gradient with a Chebyshev as the preconditioner from the first solution. This for* $\varepsilon = 10^{-1}$ *and different values of* $\mu$. *The problem considered is PDE1.*

convergence behavior of the INIT-CG algorithm does not vary much for a basis **W** obtained with different values for these parameters. Nevertheless, these parameters certainly act on the size of the resulting basis **W**, which remains at any rate relatively small and very rich with respect to the smallest eigenvalues and associated eigenvectors.

**5. Practical considerations.** We consider the operations count for the CHEB-FILTERCG and INIT-CG algorithms. All costs are evaluated in number of floating-point operations. The cost for a matrix-vector product is given by

$$\mathcal{C}_{\mathbf{A}} \approx 2\, \mathit{nnz}\,(\mathbf{A}) - n, \tag{5.1}$$

where $\mathit{nnz}\,(\mathbf{A})$ is the number of nonzero elements in $\mathbf{A}$.

In the conjugate gradient method with a Chebyshev filter as the preconditioner, we use the Chebyshev filtering polynomials in the matrix $\mathbf{A}$ at each conjugate gradient iteration to reduce, under the level of filtering $\varepsilon$, the eigencomponents in the residual associated with all eigenvalues in the range $[\mu, \lambda_{\max}]$ relatively to the others. The cost of one Chebyshev filtering step (one iteration in Algorithm 2.1) involves one sparse matrix-vector product with $\mathbf{A}$ and three vector updates (`_AXPY`). This cost can be estimated by

$$\mathcal{C}_{\mathtt{ChebFilter}} = \mathcal{C}_{\mathbf{A}} + 3\,\mathcal{C}_{\mathtt{\_AXPY}}, \text{ where } \mathcal{C}_{\mathtt{\_AXPY}} \approx 2\,n. \tag{5.2}$$

In addition to the sparse matrix-vector product with $\mathbf{A}$, the conjugate gradient method merely adds two dot products (`_DOT`) and three vector updates (`_AXPY`). The cost of these operations is given by

$$\mathcal{C}_{\mathtt{CG}} = \mathcal{C}_{\mathbf{A}} + 2\,\mathcal{C}_{\mathtt{\_DOT}} + 3\,\mathcal{C}_{\mathtt{\_AXPY}}, \text{ where } \mathcal{C}_{\mathtt{\_DOT}} \approx 2\,n. \tag{5.3}$$

Thus, the total cost of our scheme is of order

$$\mathcal{C}_{\mathtt{ChebFilterCG}} = \Big(\mathcal{C}_{\mathtt{CG}} + \mathtt{ChebIt} \times \mathcal{C}_{\mathtt{ChebFilter}}\Big) \times \mathtt{CGIt}, \tag{5.4}$$

where `ChebIt` is the number of Chebyshev filtering steps performed at each conjugate gradient iteration, and `CGIt` is the number of conjugate gradient iterations.

**5.1. Cost benefits and remarks.** In this paragraph, we show the cost benefits of our technique for solving large linear systems with different right-hand sides and the same coefficient matrix (4.1). We solve the first system by the conjugate gradient with a Chebyshev filter as the preconditioner, and we use the resulting complete Krylov basis $\mathbf{W}$ in the INIT-CG algorithm (see section 4) for the computation of the solutions in each of the following global iterations.

As mentioned at the beginning of section 3, a first level left preconditioner $\mathbf{M}_1$ is also used, whose purpose is to better cluster the spectrum of our iteration matrix. The cost of the multiplication of $\mathbf{M}_1$ by a vector is represented by $\mathcal{C}_{\mathbf{M}_1}$. Since $\mathbf{M}_1$ is constructed in our experiments by means of the incomplete Cholesky factorization or Jacobi, $\mathcal{C}_{\mathbf{M}_1}$ can be estimated as

$$\mathcal{C}_{\mathbf{M}_1} \approx 4\, \mathit{nnz}\,(\mathbf{L}) - 2\,n, \tag{5.5}$$

where $\mathit{nnz}\,(\mathbf{L})$ is the number of nonzero elements in the factor $\mathbf{L}$ from the incomplete Cholesky factorization or Jacobi, and $n$ is the size of the linear system. The cost of this first level of preconditioning $\mathbf{M}_1$ must be incorporated in the floating-point counts detailed in section 5. This simply results in adding $\mathcal{C}_{\mathbf{M}_1}$ explicitly at each Chebyshev filtering step and each conjugate gradient (CG) and (INIT-CG) iteration (see (5.2), (5.3), and (5.8)).

Our implementation of the INIT-CG algorithm performs, at the beginning of the conjugate gradient algorithm, an oblique projection of the right-hand side $\mathbf{b}$ to construct the starting guess $\mathbf{x}^{(0)} = \mathbf{W}_k \mathbf{A}_c^{-1} \mathbf{W}_k^T \mathbf{b}$, where $\mathbf{A}_c = \mathbf{W}_k^T \mathbf{A} \mathbf{W}_k$ is a matrix of order $k$, and sets $\mathbf{r}^{(0)} = \mathbf{b} - \mathbf{A}\mathbf{x}^{(0)}$ and $\mathbf{p}^{(0)} = \mathbf{r}^{(0)}$. The computation of $\mathbf{A}_c$ is a BLAS3 operation whose cost is given by

$$\mathcal{C}_{\mathbf{A}_c} \approx n\,k^2 + 2\,\mathit{nnz}\,(\mathbf{A})\,k - n\,k. \tag{5.6}$$

We note that $\mathbf{A}_c$ is factored once at the beginning of the Init-CG algorithm, and these factors are used for any subsequent solution with $\mathbf{A}_c$.

We mention again that, if the basis $\mathbf{W}_k$ is formed from the set of $\mathbf{A}$-orthogonal Krylov vectors in the CG iterations, $\mathbf{A}_c$ is diagonal and does not need to be factored, and this cost can be ignored in this case. We have incorporated this cost to be general and to consider also the case when $\mathbf{W}_k$ is obtained with other techniques. In particular, for a basis coming from Lanczos, $\mathbf{A}_c$ is tridiagonal. If $\mathbf{W}_k$ is obtained with any of the classical spectral factorization techniques, $\mathbf{A}_c$ is also diagonal as with the $\mathbf{A}$-orthogonal vectors in CG. However, if $\mathbf{W}_k$ is just a very rough approximation to all of these, $\mathbf{A}_c$ should be considered dense.

With $\mathbf{A}_c$ precomputed and factored, the computation of an oblique projection and an update of the initial residual can be done using common BLAS2 operations. The total cost of these operations is represented by

$$\mathcal{C}_{\mathrm{Proj}} \approx 4\,(k+1)\,n, \tag{5.7}$$

where the costs in $\mathcal{O}(k^3)$ operations have been neglected.

In addition, each iteration also requires one sparse matrix-vector product with $\mathbf{A}$, two dot products (`_DOT`), and three vector updates (`_AXPY`) (see (5.1) and (5.3)). The total cost of the Init-CG algorithm is represented by

$$\mathcal{C}_{\texttt{InitCG}} = \Big( \underbrace{\mathcal{C}_{\mathbf{A}} + \mathcal{C}_{\mathrm{Proj}}}_{\text{At the beginning}} \Big) + \Big( \underbrace{\mathcal{C}_{\mathbf{A}} + 3\,\mathcal{C}_{\texttt{\_AXPY}} + 2\,\mathcal{C}_{\texttt{\_DOT}}}_{\text{At each iteration}} \Big) \times \texttt{Nit}, \tag{5.8}$$

where `Nit` is the total number of Init-CG iterations.

In Table 5.1, we report the number of floating-point operations ($\mathcal{C}_{\texttt{ChebFilterCG}}$) of the ChebFilterCG algorithm (in millions, `Mflop`), when solving the first linear system $\mathbf{A}\mathbf{x}_1 = \mathbf{b}_1$ in the sequence (4.1). We also illustrate the cost benefit of the Init-CG algorithm when solving the second linear system $\mathbf{A}\mathbf{x}_2 = \mathbf{b}_2$ and exploiting the spectral information obtained from the first solution. We stop the conjugate gradient iterations when $\|\mathbf{x}^\star - \mathbf{x}^{(k)}\|_{\mathbf{A}} \le 10^{-9}\ \|\mathbf{x}^\star\|_{\mathbf{A}}$. For each level of filtering $\varepsilon$, we indicate in this table the cost $\mathcal{C}_{\mathbf{A}_c}$ (see formula (5.6)) in `Mflop`, the size $k$ of the resulting Krylov basis from the solution of the first linear system with ChebFilterCG (this number $k$ also corresponds to `CGIt` in Table 3.3), the number of Init-CG iterations (`Nit`), and the number of floating-point operations ($\mathcal{C}_{\texttt{InitCG}}$) to reach the above stopping criterion for the $\mathbf{A}$-norm of the error.

We also compute the number of right-hand sides that have to be considered in subsequent consecutive solutions before the extra cost $\mathcal{C}_{\texttt{ChebFilterCG}}$, for solving the first linear system and computing the Krylov basis $\mathbf{W}$, is compensated. This is indicated as the number of amortization vectors (`Amor`). To compute this number, we must compare the number of floating-point operations needed to reach the given level of the $\mathbf{A}$-norm of the error with the conjugate gradient algorithm and the number of floating-point operations to reach the same level with the Init-CG algorithm. Note that $\mathbf{A}_c$ is factored once at the end of the first solution, and these factors are used for any solution with $\mathbf{A}_c$. Consequently, the number of amortization vectors (`Amor`)

is given by

$$\texttt{Amor} = \left\lceil \frac{\mathcal{C}_{\texttt{ChebFilterCG}} + \mathcal{C}_{\mathbf{A}_c} - \mathcal{C}_{\texttt{CG}}}{\mathcal{C}_{\texttt{CG}} - \mathcal{C}_{\texttt{InitCG}}} \right\rceil. \tag{5.9}$$

This formula takes into account the fact that construction of $\mathbf{W}_k$ also provides the solution for the first linear system $\mathbf{A}\mathbf{x}_1 = \mathbf{b}_1$ in the sequence (4.1).

For instance, to reach an **A**-norm of the error of $10^{-9}$, the conjugate gradient algorithm performs 485 iterations in the case of the matrix preconditioned with Jacobi, with a cost of 95.79 `Mflop`, and 191 iterations in the case of the matrix preconditioned with incomplete Cholesky (no fill-in), with a cost of 55.52 `Mflop`, and 54 iterations in the case of the matrix preconditioned with incomplete Cholesky with drop tolerance $10^{-2}$, with a cost of 22.91 `Mflop`.

If we consider the case of the matrix preconditioned with incomplete Cholesky with drop tolerance $10^{-2}$, with a level of filtering $\varepsilon = 10^{-4}$ and a parameter $\mu = \lambda_{\max}/10$, in particular, 46.92 `Mflop` are needed for solving the first linear system and computing the Krylov basis $\mathbf{W}_k$, out of which INIT-CG convergence is achieved in 18 iterations (see Table 5.1), i.e., a reduction of 66% compared to the run of the conjugate gradient algorithm. The 46.92 extra `Mflop` are paid back after three consecutive runs of INIT-CG (see Table 5.1). In this particular case, the eigenvalues of the preconditioned matrix are indeed well clustered (see Tables 3.2 and 3.4) and enable a strong reduction in the number of iterations with a subspace $\mathbf{W}_k$ of dimension 4 already. This shows how this spectral approximation technique can be an effective complementary tool to other classical preconditioning techniques.

Table 5.1 also shows the impact of varying the filtering level $\varepsilon$ and the parameter $\mu$ on the actual number of amortization vectors. We can observe that the number of amortization vectors (`Amor`) does not change dramatically for the INIT-CG algorithm for a given level of filtering $\varepsilon$ and that in all cases the amortization of the cost of the computation of the Krylov basis $\mathbf{W}_k$ is very fast.

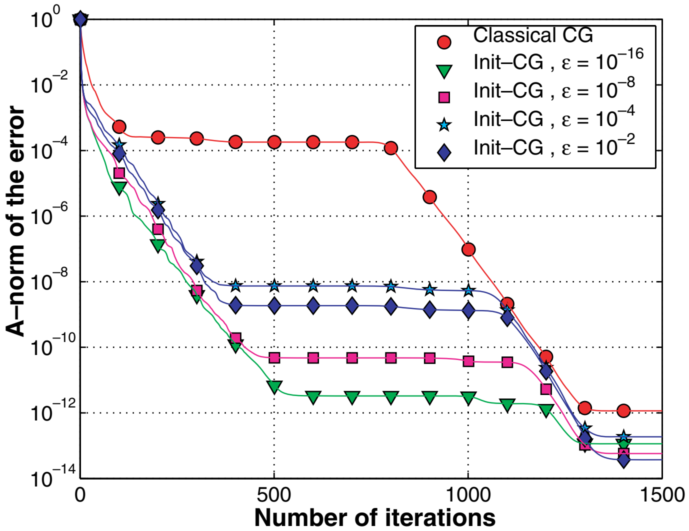
In summary, when the sequence of several linear systems with the same matrix but different right-hand sides is very long, the strategy of choice is to compute the solution of the first linear system by the conjugate gradient with a Chebyshev filter as the preconditioner using a level of filtering $\varepsilon$ close $10^{-16}$, in order to minimize the size of the Krylov basis $\mathbf{W}_k$, and to exploit the resulting complete Krylov basis in the INIT-CG algorithm to compute the solution of remaining systems. Indeed, a level of filtering very close to machine precision enables us to obtain, on the one hand, a smaller dimensional Krylov basis and at the same time less memory requirements and, on the other hand, an optimal cost of the INIT-CG algorithm or not far from the optimal one.

### 5.2. Application to the anisotropic problem PDE2 of larger size.

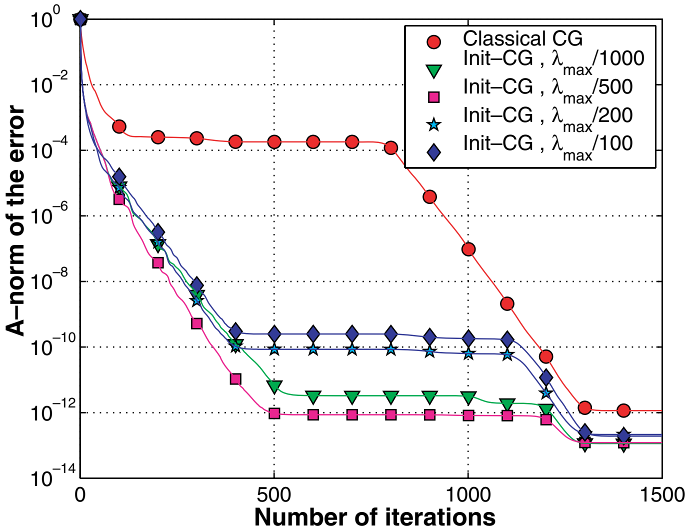
We have also considered the larger test problem PDE2 introduced in section 3. In this case, we have used the incomplete Cholesky decomposition of $\mathbf{A}$ with no fill-in as the first level of the left preconditioner $\mathbf{M}_1 = \mathbf{L}\mathbf{L}^T$, where $\mathit{nnz}(\mathbf{L}) = 643{,}605$.

In Figure 5.1, we plot the convergence history of the error measured in the energy norm in the INIT-CG algorithm (when solving $\mathbf{A}\mathbf{x}_2 = \mathbf{b}_2$), with different values of the level of filtering $\varepsilon$ and a fixed value of $\mu$ on the top figure and with different values of the cutoff value $\mu$ and a fixed filtering level $\varepsilon$ on the bottom figure. We also plot the history of the errors measured in the energy norm when the conjugate gradient method is used without the deflation of the initial residual. We can observe that the number of iterations is reduced by a factor of 4 to reach an $\mathbf{A}$-norm of the error of $10^{-8}$, which shows the effectiveness of the information stored inside the orthonormal basis of the filtered Krylov subspace.

In this larger size test case, we have stopped all iterations at a level of $10^{-8}$. It can be observed in Figure 5.1 that the phenomenon of plateaus occurs again at that level of convergence of the INIT-CG algorithm. This is due to the sensitivity of the oblique projector to the total size of the linear system [2]. If better accuracy is required, however, a possibility is to use the TWO-GRID cycle scheme presented in [5, 12, 29] or to perform iterative refinement in the usual way. In [12], [29, section 3.3.4], for instance, the effectiveness of this strategy has been experimented with either



(a) [illegible] $\mu = \lambda_{\max}/1000$



(b) [illegible] $\varepsilon = 10^{-16}$

FIG. 5.1. *Convergence history of the preconditioned conjugate gradient without the deflation of the initial residual and the* INIT-CG *algorithm with different values of the level of filtering $\varepsilon$ and for different values of $\mu$, on the PDE2 problem.*

conjugate gradient or Chebyshev polynomials or even a Richardson iteration as the smoother.

In Table 5.2, we display the number of Chebyshev filtering steps (`ChebIt`) performed at each conjugate gradient step, the number of conjugate gradient iterations (`CGIt`), and the number of floating-point operations ($\mathcal{C}_{\texttt{ChebFilterCG}}$) (in thousand million, `Gflop` ), and this with different values of level of filtering $\varepsilon$. The cost of the first level of preconditioning $\mathbf{M}_1$ has also been incorporated in the floating-point counts of the conjugate gradient with a Chebyshev filter as the preconditioner.

In Table 5.3, we illustrate the cost benefit of the Init-CG algorithm. We stop the conjugate gradient iterations when the **A**-norm of the error is below $10^{-8}$. The preconditioned conjugate gradient method (no initial deflation) performs 1060 iterations with a cost of 6.31 `Gflop`. We also indicate the cost $\mathcal{C}_{\mathbf{A}_c}$ in `Gflop`, the number of conjugate gradient iterations (`Nit`), the number of floating-point operations ($\mathcal{C}_{\texttt{InitCG}}$) in `Gflop`, and the number of amortization vectors (`Amor`). All of this information is given for each level of filtering $\varepsilon$. We derive, from these data, the same general conclusions as with the smaller size test cases in the previous section. In particular, for a fixed value of the level of filtering $\varepsilon$, the number of floating-point operations (`Gflop`) does not change dramatically when varying the parameter $\mu$. In Table 5.3, we can observe that the number of iterations is cut from 1060 to under 349 and as low as 230.

**5.3. Comments about the parameter $\boldsymbol{\lambda}_{\mathbf{max}}$ and its estimation.** In the various test examples used for discussion in this article, the value of $\lambda_{\max}(\mathbf{A})$ has been obtained rather accurately with the use of ARPACK [19]. The purpose of this spectral precomputation of the spectrum of **A** was to ease the analysis of the various results and to understand better the behavior of our algorithm in the different situations.

Of course, this has a cost, and it is not mandatory that either parts of the spectrum of **A** or even $\lambda_{\max}(\mathbf{A})$ only be accurately precomputed. An estimate $\widetilde{\lambda}_{\max}$ of $\lambda_{\max}$ should be sufficient as a parameter in this approach. The only requirement, to keep

Table 5.4
$\lambda_{\max}$ *and its estimation* $\widetilde{\lambda}_{\max}$ *for the PDE*1 *problem.*

| First level preconditioner | $\lambda_{\max}$ | $\widetilde{\lambda}_{\max}$ | $2 \times \widetilde{\lambda}_{\max}$ |
|---|---|---|---|
| $\mathbf{M}_1 = \mathbf{I}$ | $9.6 \cdot 10^6$ | $5.18 \cdot 10^6$ | $1.03 \cdot 10^7$ |
| $\mathbf{M}_1 = \text{diag}(\mathbf{A})$ | 2.08 | 1.28 | 2.56 |
| $\mathbf{M}_1 = \text{IC}(0)$ | 1.6 | 1.01 | 2.03 |
| $\mathbf{M}_1 = \text{IC}(10^{-2})$ | 1.1 | $9.78 \cdot 10^{-1}$ | 1.95 |

the Chebyshev polynomial filters bounded on the spectrum of **A**, is that this estimate $\widetilde{\lambda}_{\max}$ be an upper bound of the actual largest eigenvalue. A cheap way to achieve this is to perform a few steps of the power method and to multiply the final Rayleigh quotient by some factor to ensure the overestimation. Let's suppose, for instance, that we multiply by "2" a value giving the order of magnitude of $\lambda_{\max}$. The consequence of this will be that the choice of the cutoff value $\tilde{\mu} = \widetilde{\lambda}_{\max}/\gamma$ ($\gamma = 10$ or 100, for instance) will be larger than the actual value $\lambda_{\max}/\gamma$. Therefore, the effective filtering interval will become $[\widetilde{\mu}, \lambda_{\max}]$ (and not $[\mu, \lambda_{\max}]$ as in our experiments), because the behavior of Chebyshev on $]\lambda_{\max}, \widetilde{\lambda}_{\max}]$ does not have any impact on the preconditioning of **A**.

Still, and this is illustrated in the results in Table 3.3, choosing $\lambda_{\max}/100$ or $\lambda_{\max}/50$ as in the case of the matrix preconditioned with incomplete Cholesky (no fill-in) does not change much the size of the resulting Krylov basis in the ChebFilterCG algorithm. The major impact is the increase of the total number of Chebyshev steps for the same resulting Krylov basis, and the amortization will take a little longer, but not a lot more, as shown in Table 5.1. We can conclude that an overestimation $\widetilde{\lambda}_{\max}$ of $\lambda_{\max}$ is not very crucial with respect to the conclusions and observations made in the previous sections.

A more crucial issue is to find the range of values of $\mu$ in which the behavior of the algorithm is rather stable, as observed in the various experiments. This is specifically linked to the actual eigenvalue distribution of the given iteration matrix and depends on the problem and on the first level of preconditioner (when used). We must not forget also that the total number of systems to solve in the sequence may lead to different strategies when choosing $\mu$ or $\varepsilon$ to minimize the total amount of work.

In the previous discussions, we have not included the cost of the precomputation of $\widetilde{\lambda}_{\max}$ for two reasons. The first one is that we have not investigated the most powerful techniques for such computation, such as, for instance, power method, polynomial, and Krylov techniques and combinations of these. The second reason is that, in some cases, as with row projection techniques [1, 4, 9], for instance, that also yield a symmetrizable iteration matrix, the preconditioning technique can readily provide a more or less sharp estimate of $\lambda_{\max}(\mathbf{A})$. Finally, at the expense of one usual CG run, we can be sure to get a "[illegible]" estimate of $\lambda_{\max}$. Therefore, we can consider that the cost for precomputing $\lambda_{\max}$ will at most increase the amortization value of "1."

As an illustration, we indicate in Table 5.4 the values of $\lambda_{\max}$ and the corresponding estimation $\widetilde{\lambda}_{\max}$ obtained in the case of the PDE1 problem for each first level preconditioner. The largest eigenvalue $\lambda_{\max}$ is computed with ARPACK [19] and $\widetilde{\lambda}_{\max}$ results from three iterations of the power method with a random initial vector. We also report in this table the "[illegible]" estimation of $\lambda_{\max}$, which corresponds to $2 \times \widetilde{\lambda}_{\max}$ and which is not too far from the largest eigenvalue.

**6. Conclusion.** In this paper, we have proposed a solution technique suited for the solution of a sequence of linear systems with the same matrix but changing right-hand sides. This technique uses Chebyshev filtering polynomials, applied only to a part of the spectrum of the coefficient matrix, as a preconditioner that helps the conjugate gradient method to generate a low dimensional Krylov basis that is very rich with respect to the smallest eigenvalues and associated eigenvectors. The proposed approach is guaranteed to put a large number of eigenvalues near one, without degrading the distribution of the smallest ones.

We have illustrated, on a set of MATLAB examples, the behavior of this technique on sparse linear systems arising from the discretization via a finite element of some 2D heterogeneous and anisotropic diffusion PDE problems. An analysis of the computational costs in section 5.1 has shown that the gains can be rather substantial and the cost for precomputing the Krylov basis can rapidly be amortized when solving several linear systems with multiple right-hand sides.

An important aspect of our approach is that the proposed CHEBFILTERCG algorithm requires only matrix-vector products plus some vector updates and many fewer dot products, since these do not appear in the Chebyshev steps that are performed at each conjugate gradient iteration during the solution of the first system. This is of some importance in the context of parallel computing and, in particular, in distributed memory environments where the computation of the dot product requires particular attention.

Our perspectives are to investigate also this approach to construct multilevel preconditioners combining Chebyshev filters and a Krylov basis generated by CHEBFILTERCG when solving the first system of the sequence. In the case of the resolution of nonlinear problems, it is possible to benefit simply from the low intrinsic dimension of these Krylov bases to construct an adaptive preconditioner based on the Krylov space information generated at previous steps in the nonlinear iteration (cf. [20, 29]).

**Acknowledgments.** We thank Iain Duff and Gérard Meurant for their constructive comments and fruitful discussions during the development of this work and also for their careful reading and remarks which were very helpful to improve the paper.

# TWO VARIABLE ORTHOGONAL POLYNOMIALS ON THE BICIRCLE AND STRUCTURED MATRICES*

JEFFREY S. GERONIMO[†] AND HUGO WOERDEMAN[‡]

**Abstract.** We consider bivariate polynomials orthogonal on the bicircle with respect to a positive linear functional. The lexicographical and reverse lexicographical orderings are used to order the monomials. Recurrence formulas are derived between the polynomials of different degrees. These formulas link the orthogonal polynomials constructed using the lexicographical ordering with those constructed using the reverse lexicographical ordering. Relations between the coefficients in the recurrence formulas are derived and used to give necessary and sufficient conditions for the existence of a positive linear functional. These results are then used to construct a class of two variable measures supported on the bicircle that are given by one over the magnitude squared of a stable polynomial. Applications to Fejér–Riesz factorization are also given.

**Key words.** bivariate orthogonal polynomials, positive definite linear functionals, moment problem, doubly Toeplitz matrices, recurrence coefficients

**AMS subject classifications.** 42C05, 30E05, 47A57, 15A48, 47B35

## 1. Introduction.

Bivariate polynomials orthogonal on the bicircle have been investigated mostly in the electrical engineering community in relation to the design of stable recursive filters for two-dimensional filtering. In particular we note the work of Genin and Kamp [7] who were interested in the following problem. Given any two variable polynomials $q(z,w)$, with $q(0,0) \neq 0$, let $a_{k,l}(z,w)$ be its planar least squares inverse polynomial of degree $(k,l)$; i.e., $a_{k,l}$ minimizes the mean quadratic value of $1 - a_{k,l}q$ on the bicircle. What properties does $a_{k,l}$ have? At the time it was conjectured the minimizing polynomials were stable, i.e., $a_{k,l}(z,w) \neq 0,\ |z| \leq 1,\ |w| \leq 1$, which they showed was false. Their investigation was carried further by Delsarte, Genin, and Kamp [4] who developed the connection between these polynomials and matrix polynomials orthogonal on the unit circle [3]. In the development of this connection these authors were led to examine moment matrices that were block Toeplitz matrices where each block entry is itself a Toeplitz matrix. Such structured matrices are called doubly Toeplitz matrices and arise naturally in the bivariate trigonometric moment problem. These types of matrices arose more recently in the work of Geronimo and Woerdeman [8] in their investigation of the bivariate Fejér–Riesz factorization theorem. These authors were able to resolve the question when a strictly positive bivariate trigonometric polynomial of a certain degree can be written as the magnitude squared of a stable polynomial of the same degree. In this work the authors used the fact that the theory of orthogonal polynomials on the unit circle provides a proof of the one variable Fejér–Riesz theorem which does not use the fundamental theorem of algebra. We intend here to continue to investigate the properties of bivariate polynomials orthogonal on the bicircle and clarify their role in the Fejér–Riesz theorem.

A major difficulty encountered in the theory of orthogonal polynomials of more than one variable is which monomial ordering to use. For bivariate real orthogonal polynomials the preferred ordering is the total degree ordering which is the one set by Jackson [14]. For polynomials with the same total degree the ordering is lexicographical. As noted in Delgado et al. [2] in their study of orthogonal polynomials associated with doubly Hankel matrices, there is a good reason for choosing this ordering which is that if new orthogonal polynomials of higher degree are to be constructed, then their orthogonality relations will not affect the relations governing the lower degree polynomials. However, in order for the moment matrix to be doubly Toeplitz the monomial orderings that need to be used are lexicographical and reverse lexicographical.

We begin in section 2 by considering finite-dimensional subspaces spanned by the monomials $z^i w^j, |i| \leq n$, $|j| \leq m$, and exhibiting the connection between positive linear functionals defined on this space and positive definite doubly Toeplitz matrices. We then introduce certain matrix orthogonal polynomials and show how they give the Cholesky factors for the inverse of the doubly Toeplitz matrices considered above. The results in [8] show that these polynomials play a role in the parametric moment problem. In section 3 we construct two variable orthogonal polynomials, where the monomials are ordered according to the lexicographical ordering. When these polynomials are organized into vector orthogonal polynomials, they can be related to the matrix orthogonal polynomials constructed previously. From this relation it is shown that these vector polynomials are the minimizers of a certain quadratic functional. Using the orthogonality relation, recurrence relations satisfied by the vector polynomials and their counterparts in the reverse lexicographical ordering are derived, and relations between these recurrence coefficients are exhibited. In section 4 a number of Christoffel–Darboux-like formulas are derived. In section 5 we use the relations between the coefficients derived in section 3 to develop an algorithm to construct the coefficients in the recurrence formulas at a particular level $(n, m)$, say, in terms of the coefficients at the previous levels plus a certain number of unknowns. The collection of these unknowns is in one to one correspondence with the number of moments needed to construct the vector polynomials up to level $(n, m)$. This is used in section 6 to construct a positive linear functional from the recurrence coefficients. The construction allows us to find necessary and sufficient conditions on the recurrence coefficients for the existence of a positive linear functional which is in one to one correspondence with the set of positive definite doubly Toeplitz matrices. In section 7 we examine conditions under which the linear functional can be represented as a positive measure supported on the bicircle having the form of one over the magnitude squared of a stable polynomial. This gives a new proof of the Fejér–Riesz result of [8]. Finally in section 8 examples are given that illustrate various aspects of the theory developed.

## 2. Positive linear functionals and doubly Toeplitz matrices.

In this section we consider moment matrices associated with the lexicographical ordering, which is defined by

$$(k, \ell) <_{\text{lex}} (k_1, \ell_1) \Leftrightarrow k < k_1 \text{ or } (k = k_1 \text{ and } \ell < \ell_1),$$

and the reverse lexicographical ordering, defined by

$$(k, \ell) <_{\text{revlex}} (k_1, \ell_1) \Leftrightarrow (\ell, k) <_{\text{lex}} (\ell_1, k_1).$$

Both of these orderings are linear orders, and in addition they satisfy

$$(k, \ell) < (m, n) \Rightarrow (k + p, \ell + q) < (m + p, n + q).$$

In such a case, one may associate a half-space with the ordering which is defined by $\{(k,l) : (0,0) < (k,l)\}$. In the case of the lexicographical ordering we shall denote the associated half-space by $H$ and refer to it as [illegible]. In the case of the reverse lexicographical ordering we shall denote the associated half-space by $\tilde{H}$. Instead of starting with the ordering, one may also start with a half-space $\hat{H}$ of $\mathbb{Z}^2$ (i.e., a set $\hat{H}$ satisfying $\hat{H} + \hat{H} \subset \hat{H}$, $\hat{H} \cap (-\hat{H}) = \emptyset$, $\hat{H} \cup (-\hat{H}) \cup \{(0,0)\} = \mathbb{Z}^2$) and define an ordering via

$$(k,l) <_{\hat{H}} (k_1,l_1) \Longleftrightarrow (k_1 - k, l_1 - l) \in \hat{H}.$$

We shall refer to the order $<_{\hat{H}}$ as [illegible] $\hat{H}$. Note that the lexicographical and reverse lexicographical orderings do not respect total degree.

Let $\prod^{n,m}$ denote the bivariate Laurent linear subspace span$\{z^i w^j, -n \le i \le n, -m \le j \le m\}$. Let $\mathcal{L}_{n,m}$ be a linear functional defined on $\prod^{n,m}$ by

$$\mathcal{L}_{n,m}(z^{-i}w^{-j}) = c_{i,j} = \overline{\mathcal{L}(z^i w^j)}.$$

We will call $c_{i,j}$ the $(i,j)$ moment of $\mathcal{L}_{n,m}$ and $\mathcal{L}_{n,m}$ a moment functional. If we form the $(n+1)(m+1) \times (n+1)(m+1)$ matrix $C_{n,m}$ for $\mathcal{L}_{n,m}$ in the lexicographical ordering, then, as noted in the introduction, it has the special block Toeplitz form

$$C_{n,m} = \begin{bmatrix} C_0 & C_{-1} & \cdots & C_{-n} \\ C_1 & C_0 & \cdots & C_{-n+1} \\ \vdots & & \ddots & \vdots \\ C_n & C_{n-1} & \cdots & C_0 \end{bmatrix}, \tag{2.1}$$

where each $C_i$ is an $(m+1) \times (m+1)$ Toeplitz matrix as follows:

$$C_i = \begin{bmatrix} c_{i,0} & c_{i,-1} & \cdots & c_{i,-m} \\ \vdots & & \ddots & \vdots \\ c_{i,m} & & \cdots & c_{i,0} \end{bmatrix}, \qquad i = -n, \ldots, n. \tag{2.2}$$

Thus $C_{n,m}$ has a doubly Toeplitz structure. If the reverse lexicographical ordering is used in place of the lexicographical ordering, we obtain another moment matrix $\tilde{C}_{n,m}$ where the roles of $n$ and $m$ are interchanged.

Let us introduce the notion of centrotranspose symmetry. We denote the transpose of a matrix $A$ by $A^T$. A square matrix $A$ is said to be [illegible] if $JAJ = A^T$, where $J$ is the matrix with ones on the antidiagonal and zeros elsewhere. Note that a Toeplitz matrix is centrotranspose symmetric. We have the following useful lemmas which characterize Toeplitz and doubly Toeplitz matrices in terms of centrotranspose symmetry.

LEMMA 2.1. [illegible] $(n+1) \times (n+1)$ [illegible] $A = (a_{i,j})_{i,j=0}^{n}$ [illegible] $A$ [illegible] $\hat{A} := (a_{i,j})_{i,j=0}^{n-1}$ [illegible]

[illegible] Notice that $JAJ = A^T$ is equivalent to $a_{n-i,n-j} = a_{j,i}$, $0 \le i,j \le n$. Similarly, the centrotranspose symmetry of $\hat{A}$ is equivalent to $a_{n-1-i,n-1-j} = a_{j,i}$, $0 \le i,j \le n-1$. But then

$$a_{i+1,j+1} = a_{n-j-1,n-i-1} = a_{i,j}, \quad 0 \le i,j \le n-1,$$

and thus it follows that $A$ is Toeplitz.

As $A$ and $\hat{A}$ are Toeplitz, the converse is immediate. □

LEMMA 2.2. [illegible] $A = (A_{i,j})$ $i,j = 1,\dots,k$ [illegible] $A_{i,j}$ [illegible] $m \times m$ [illegible] $A$ [illegible] $A^T = JAJ$ $A_1^T = J_1A_1J_1$ [illegible] $A_2^T = J_1A_2J_1$ [illegible] $A_1$ [illegible] $A$ [illegible] $A_2$ [illegible] $A$ [illegible] $A_{i,j}$ [illegible] $J$ [illegible] $J_1$ [illegible]

[illegible]. Again the necessary conditions follow from the structure of $A$. To see the converse note that $A^T = JAJ$ implies that $A_{j,i}^T = J_2A_{k-i,k-j}J_2$, where $J_2$ is the $m\times m$ matrix with ones on the reverse diagonal and zeros everywhere else. This coupled with the condition on $A_1$ implies that $A$ is a block Toeplitz matrix from Lemma 2.1 and $J_2A_{i,j}J_2 = A_{i,j}^T$. These relations plus the condition on $A_2$ and Lemma 2.1 give the result. □

[illegible] 2.3. The conclusions of the above lemmas hold if we replace deleting the last (last block) row and column by deleting the first (first block) row and column.

We say that the moment functional $\mathcal{L}_{n,m} : \prod^{n,m} \to \mathbb{C}$ is positive definite or positive semidefinite if

$$\mathcal{L}_{n,m}(|p|^2) > 0 \quad \text{or} \quad \mathcal{L}_{n,m}(|p|^2) \geq 0 \tag{2.3}$$

for every nonzero polynomial $p \in \prod^{n,m}$. It follows from a simple quadratic form argument that $\mathcal{L}_{n,m}$ is positive definite or positive semidefinite if and only if its moment matrix $C_{n,m}$ is positive definite or positive semidefinite, respectively.

We will say that $\mathcal{L}$ is positive definite or positive semidefinite if

$$\mathcal{L}(|p|^2) > 0 \qquad \text{or} \qquad \mathcal{L}(|p|^2) \geq 0$$

for all nonzero polynomials, respectively. Again these conditions are equivalent to the moment matrices $C_{n,m}$ being positive definite or positive semidefinite for all positive integers $n$ and $m$. The above discussion leads to the following.

LEMMA 2.4. [illegible] $C_{n,m}$ [illegible] $(n+1)(m+1) \times (n+1)(m+1)$ [illegible] (2.1) [illegible] (2.2) [illegible] $\mathcal{L}_{n,m} : \prod^{n,m} \to \mathbb{C}$ [illegible] $C_{n,m}$ [illegible]

$$c_{i,j} = \mathcal{L}_{n,m}(z^{-i}w^{-j}) = \overline{\mathcal{L}_{n,m}(z^iw^j)}, \qquad -n \leq i \leq n, \qquad -m \leq j \leq m.$$

[illegible]

Let $\prod_{m+1}^n$ be the set of all $(m+1)\times(m+1)$ complex-valued matrix polynomials of degree $n$ or less, $\prod_{m+1}$ the set of all $(m+1)\times(m+1)$ complex-valued matrix polynomials, and $M^{m,n}$ the space of $m \times n$ matrices. For a matrix $M$ we let $M^\dagger$ denote the conjugate transpose (or the adjoint) of $M$. For a polynomial $Q(z,w)$ we let $Q^\dagger(z,w)$ denote the polynomial in $z^{-1}$ and $w^{-1}$ defined by $Q(z,w)^\dagger = Q^\dagger(\frac{1}{\bar{z}}, \frac{1}{\bar{w}})^\dagger$. If the positive moment functional $\mathcal{L}_{n,m} : \prod^{n,m} \to \mathbb{C}$ is extended to two variable polynomials with matrix coefficients in the obvious way, we can associate it with a positive matrix function $\mathcal{L}_m : \prod_{m+1}^n \times \prod_{m+1}^n \to M^{m+1,m+1}$ defined by

$$[\mathcal{L}_m(P(z), Q(z))]_{i,j} = \mathcal{L}_{n,m}(\big[P(z,w)\ Q^\dagger(z,w)\big]_{i,j}), \quad 1 \leq i,j \leq m+1 \tag{2.4}$$

where

$$P(z,w) = P(z)\begin{bmatrix} w^m \\ \vdots \\ 1 \end{bmatrix} \text{ and } Q(z,w) = Q(z)\begin{bmatrix} w^m \\ \vdots \\ 1 \end{bmatrix}.$$

Equation (2.4) shows that if $\mathcal{L}_{n,m}$ can be represented in terms of a positive measure $\mu$ supported on the bicircle, then for $f$ an $(m+1)\times(m+1)$ matrix function continuous on the unit circle,

$$\mathcal{L}_m(f) = \int_{-\pi}^{\pi} f(\theta)dM_m(\theta),$$

where $M_m$ is the $(m+1)\times(m+1)$ matrix measure given by

$$dM_m(\theta) = \int_{\phi=-\pi}^{\pi} \begin{bmatrix} w^m \\ \vdots \\ 1 \end{bmatrix} d\mu(\theta,\phi) \begin{bmatrix} w^m \\ \vdots \\ 1 \end{bmatrix}^{\dagger},$$

which shows that $M_m$ is Toeplitz.

Because of the structure of $C_{n,m}$ we can associate with $\mathcal{L}_m$ matrix valued orthogonal polynomials in the following manner [3], [4], [8]. Let $\{R_i^m(z)\}_{i=0}^n$ and $\{L_i^m(z)\}_{i=0}^n$ be $(m+1)\times(m+1)$ complex-valued matrix polynomials given by

$$R_i^m(z) = R_{i,i}^m z^i + R_{i,i-1}^m z^{i-1} + \cdots, \qquad i = 0,\ldots,n, \tag{2.5}$$

and

$$L_i^m(z) = L_{i,i}^m z^i + L_{i,i-1}^m z^{i-1} + \cdots, \qquad i = 0,\ldots,n, \tag{2.6}$$

satisfying

$$\mathcal{L}_m(R_i^{m\dagger}, R_j^{m\dagger}) = \delta_{ij} I_{m+1} \tag{2.7}$$

and

$$\mathcal{L}_m(L_i^m, L_j^m) = \delta_{ij} I_{m+1}, \tag{2.8}$$

respectively, where $I_{m+1}$ denotes the $(m+1)\times(m+1)$ identity matrix. The above relations uniquely determine the sequences $\{R_i^m\}_{i=0}^n$ and $\{L_i^m\}_{i=0}^n$ up to a unitary factor, and this factor will be fixed by requiring $R_{i,i}^m$ and $L_{i,i}^m$ to be upper triangular matrices with positive diagonal entries. We write

$$L_i^m(z) = [0 \cdots 0 \ L_{i,i}^m \ L_{i,i-1}^m \ \cdots \ L_{i,0}^m] \begin{bmatrix} z^n I_{m+1} \\ z^{n-1} I_{m+1} \\ \vdots \\ I_{m+1} \end{bmatrix}, \tag{2.9}$$

and

$$\hat{L}_n^m(z) = \begin{bmatrix} L_n^m(z) \\ L_{n-1}^m(z) \\ \vdots \\ L_0^m(z) \end{bmatrix} = L \begin{bmatrix} z^n I_{m+1} \\ z^{n-1} I_{m+1} \\ \vdots \\ I_{m+1} \end{bmatrix}, \tag{2.10}$$

where

$$L = \begin{bmatrix} L_{n,n}^m & L_{n,n-1}^m & \cdots & L_{n,0}^m \\ 0 & L_{n-1,n-1}^m & \cdots & L_{n-1,0}^m \\ \vdots & & \ddots & \\ 0 & 0 & \cdots & L_{0,0}^m \end{bmatrix}. \tag{2.11}$$

In an analogous fashion write

$$\hat{R}_n^m(z) = \begin{bmatrix} R_0^m(z) \\ R_1^m(z) \\ \vdots \\ R_n^m(z) \end{bmatrix} = \begin{bmatrix} I_{m+1} & \dots & z^n I_{m+1} \end{bmatrix} R, \tag{2.12}$$

where

$$R = \begin{bmatrix} R_{0,0}^m & R_{1,0}^m & \cdots & R_{n,0}^m \\ 0 & R_{1,1}^m & \cdots & R_{n,1}^m \\ \vdots & & \ddots & \\ 0 & 0 & \cdots & R_{n,n}^m \end{bmatrix}. \tag{2.13}$$

By lower (respectively, upper) Cholesky factor $A$ (respectively, $B$) of a positive definite matrix $M$, we mean

$$M = AA^\dagger = BB^\dagger, \tag{2.14}$$

where $A$ is a lower triangular matrix with positive diagonal elements, and $B$ is an upper triangular matrix with positive diagonal elements. With the above we have the following well known lemma [15].

Lemma 2.5. [illegible] $C_{n,m}$ [illegible] (2.1). [illegible] $L^\dagger$ [illegible] $R$ [illegible] $C_{n,m}^{-1}$ [illegible]. To obtain (2.14) note that (2.8) implies that

$$I = \mathcal{L}_m(\hat{L}_n^m, \hat{L}_n^m) = L\mathcal{L}_m\left( \begin{bmatrix} z^n I_{m+1} \\ z^{n-1} I_{m+1} \\ \vdots \\ I_{m+1} \end{bmatrix}, \begin{bmatrix} z^n I_{m+1} \\ z^{n-1} I_{m+1} \\ \vdots \\ I_{m+1} \end{bmatrix} \right) L^\dagger = LC_{n,m}L^\dagger,$$

where $I$ is the $(n+1)(m+1) \times (n+1)(m+1)$ identity matrix. Since $C_{n,m}$ is invertible we find

$$C_{n,m}^{-1} = L^\dagger L.$$

The result for $R$ follows in an analogous manner. □

From this formula and (2.11) we find

$$L_n^m(z) = \left[ ({L_{n,n}^m}^\dagger)^{-1}, 0, 0, \dots 0 \right] C_{n,m}^{-1} [z^n I_{m+1}, z^{n-1} I_{m+1}, \dots, I_{m+1}]^T, \tag{2.15}$$

and

$$R_n^m(z) = [I_{m+1}, zI_{m+1}, \dots, z^n I_{m+1}]\, C_{n,m}^{-1} \left[0, 0, \dots, 0, (\bar{R}_{n,n}^m)^{-1}\right]^T. \tag{2.16}$$

Note that ${L_{n,n}^m}^\dagger$ is the lower Cholesky factor of $[I_{m+1}, 0, \cdots, 0] C_{n,m}^{-1} \, [I_{m+1}, 0, \cdots, 0]^T$, while $R_{n,n}^m$ is the upper Cholesky factor of $[0, \cdots, I_{m+1}] C_{n,m}^{-1} \, [0, \cdots, I_{m+1}]^T$.

The theory of matrix orthogonal polynomials (see [3], [15], [17], [19]) can be applied to obtain the recurrence formulas

$$\begin{aligned} A_{i+1,m} L_{i+1}^m(z) &= zL_i^m(z) - E_{i+1,m} \overleftarrow{R}_i^m(z), \quad i = 0, \dots, n-1, \\ R_{i+1}^m(z)\hat{A}_{i+1,m} &= zR_i^m(z) - \overleftarrow{L}_i^m(z) E_{i+1,m}, \quad i = 0, \dots, n-1, \end{aligned} \tag{2.17}$$

where

$$E_{i+1,m} = \mathcal{L}_m(zL_i^m, \overleftarrow{R}_i^m) = \mathcal{L}_m\big(\overleftarrow{L}_i^{m\,\dagger}, (zR_i^m)^\dagger\big) \tag{2.18}$$

and

$$\begin{aligned} A_{i+1,m} &= \mathcal{L}_m(zL_i^m,\ L_{i+1}^m) = L_{i,i}^m(L_{i+1,i+1}^m)^{-1}, \\ \hat{A}_{i+1,m} &= \mathcal{L}_m\big(R_{i+1}^{m\dagger}, (zR_i^m)^\dagger\big) = (R_{i+1,i+1}^m)^{-1}R_{i,i}^m. \end{aligned} \tag{2.19}$$

For a matrix polynomial $B$ of degree $n$ in $z$, $\overleftarrow{B}(z) = z^n\sum_{i=0}^n B_i^\dagger z^{-i}$. By multiplying the first equation in (2.17) on the left by $\bar{z}L_i^m(z)^\dagger$ and the second equation on the right by $\bar{z}R_i^m(z)^\dagger$ and then integrating, we see that

$$\begin{aligned} A_{i+1,m}A_{i+1,m}^\dagger &= I_{m+1} - E_{i+1,m}E_{i+1,m}^\dagger, \\ \hat{A}_{i+1,m}^\dagger\hat{A}_{i+1,m} &= I_{m+1} - E_{i+1,m}^\dagger E_{i+1,m}. \end{aligned} \tag{2.20}$$

The above equations and the properties of $A_{i+1,m}$ and $\hat{A}_{i+1,m}$ show that $E_{i+1,m}$ is a strictly contractive matrix and that $A_{i+1,m}$ is the upper Cholesky factor of $I_{m+1} - E_{i+1,m}E_{i+1,m}^\dagger$. Similarly $\hat{A}_{i,m}^\dagger$ is the lower Cholesky factor of $I_{m+1} - E_{i+1,m}^\dagger E_{i+1,m}$. Furthermore (2.19) and (2.20) show that

$$\det((L_{i+1,i+1}^m)^\dagger L_{i+1,i+1}^m)^{-1} = \det(C_0)\prod_{j=1}^{i+1}\det(I_{m+1} - E_{j,m}E_{j,m}^\dagger). \tag{2.21}$$

The recurrence formulas (2.17) can be inverted in the following manner. Multiply the reverse of the second equation in (2.17) on the right by $E_{i+1,m}$ to obtain

$$E_{i+1,m}\hat{A}_{i+1,m}^\dagger\overleftarrow{R}_{i+1}^m(z) = E_{i+1,m}\overleftarrow{R}_i^m(z) - zE_{i+1,m}E_{i+1,m}^\dagger L_i^m(z).$$

Add this equation to the first equation in (2.17) and then use (2.20) to eliminate $A_{i+1,m}$ and $\hat{A}_{i+1,m}^\dagger$ to find

$$(A_{i+1,m}^\dagger)^{-1}L_{i+1}^m(z) + E_{i+1,m}(\hat{A}_{i+1,m})^{-1}\overleftarrow{R}_{i+1}^m(z) = zL_i^m(z). \tag{2.22}$$

In a similar manner we find

$$R_{i+1}^m(z)(\hat{A}_{i+1,m}^\dagger)^{-1} + \overleftarrow{L}_{i+1}^m(z)(A_{i+1,m})^{-1}E_{i+1,m} = zR_i^m(z). \tag{2.23}$$

From the recurrence formulas it is not difficult to derive the Christoffel–Darboux formulas [3]:

$$\begin{aligned} \overleftarrow{R}_k^m(z)^\dagger\overleftarrow{R}_k^m(z_1) - \bar{z}z_1L_k^m(z)^\dagger L_k^m(z_1) &= (1-\bar{z}z_1)\sum_{i=0}^k L_i^m(z)^\dagger L_i^m(z_1), \\ \overleftarrow{L}_k^m(z_1)\overleftarrow{L}_k^m(z)^\dagger - \bar{z}z_1R_k^m(z_1)R_k^m(z)^\dagger &= (1-\bar{z}z_1)\sum_{i=0}^k R_i^m(z_1)R_i^m(z)^\dagger. \end{aligned} \tag{2.24}$$

These formulas give rise to the matrix Gohberg–Semencul formulas [11], [15] when the linear equations obtained by equating like powers of $\bar{z}^iz_1^j$ are put in matrix form.

Some properties that follow from the above formulas [3, Theorems 9, 14, and 15] are that $\overleftarrow{R}_i^m(z)$ and $\overleftarrow{L}_k^m(z)$ have empty kernels for $|z| \le 1$; i.e.,

$$\det(\overleftarrow{R}_i^m(z)) \ne 0 \ne \det(\overleftarrow{L}_k^m(z)), \ |z| \le 1. \tag{2.25}$$

Such polynomials are called stable matrix polynomials, and if we write

$$W_k(z) = \left[\overleftarrow{L}_k^m(z)\overleftarrow{L}_k^m(z)^\dagger\right]^{-1} \tag{2.26}$$

and

$$C_j^k = \frac{1}{2\pi}\int_{-\pi}^{\pi} e^{-ij\theta} W_k(e^{i\theta})d\theta,$$

then

$$C_j^k = C_j, \quad |j| \le k. \tag{2.27}$$

Furthermore

$$W_k = \left[\overleftarrow{R}_k^m(z)^\dagger \overleftarrow{R}_k^m(z)\right]^{-1}. \tag{2.28}$$

If $\overleftarrow{L}_k^m(z)$ ($\overleftarrow{R}_k^m(z)$) satisfies (2.25) and (2.27), we will say it is stable and has spectral matching (up to level $k$). Another useful result shown in [3] is

$$\log\det((L_{i+1,i+1}^m)^\dagger L_{i+1,i+1}^m)^{-1} = \frac{1}{2\pi}\int_{-\pi}^{\pi} \log\det W_k(\theta)d\theta. \tag{2.29}$$

From the stability of $\overleftarrow{R}_{i+1}^m$ and $\overleftarrow{L}_{i+1}^m$, (2.22) and (2.23) give the following formulas for the recurrence coefficients $E_{i+1,m}$:

$$\begin{aligned} E_{i+1,m} &= -(A_{i+1,m}^\dagger)^{-1} L_{i+1}^m(0)\overleftarrow{R}_{i+1}^m(0)^{-1}\hat{A}_{i+1,m} \\ &= -A_{i+1,m}\overleftarrow{L}_{i+1}^m(0)^{-1}R_{i+1}^m(0)(\hat{A}_{i+1,m}^\dagger)^{-1}. \end{aligned} \tag{2.30}$$

We also note that $\overleftarrow{L}_k^m(z)$ and $\overleftarrow{R}_k^m(z)$ are minimizers of certain quadratic functions. To see this denote the set of $(m+1)\times(m+1)$ hermitian matrices as $\mathrm{Herm}(m+1)$, and let $\mathcal{M} : \prod_{m+1} \to \mathrm{Herm}(m+1)$ be given by

$$\mathcal{M}[X(z)] = \mathcal{L}_m(X, X) - (X(0) + X(0)^\dagger), \tag{2.31}$$

then Delsarte, Genin, and Kamp have shown [3] that for a given degree $k$, $\mathcal{M}$ is minimized by $\overleftarrow{L}_k^m(z)L_{k,m}^m$ with the value $(L_{k,m}^m)^\dagger L_{k,m}^m$. Likewise $\hat{\mathcal{M}} : \prod_{m+1} \to \mathrm{Herm}(m+1)$ given by

$$\hat{\mathcal{M}}[X(z)] = \mathcal{L}_m(X^\dagger, X^\dagger) - (X(0) + X(0)^\dagger) \tag{2.32}$$

is minimized by $R_{k,m}^m\overleftarrow{R}_k^m(z)$ and takes the value $R_{k,m}^m(R_{k,m}^m)^\dagger$. Thus we find

$$(L_{k,m}^m)^\dagger L_{k,m}^m \ge (L_{k+1,m}^m)^\dagger L_{k+1,m}^m \tag{2.33}$$

and

$$R^m_{k,m}(R^m_{k,m})^\dagger \geq R^m_{k+1,m}(R^m_{k+1,m})^\dagger. \tag{2.34}$$

Here $A \geq B$ for two $(m+1) \times (m+1)$ matrices means that $A - B$ is positive semidefinite. The above discussion leads to Burg's entropy theorem. Consider the class of $M^m$ of $(m+1) \times (m+1)$ matrix Borel measures on the unit circle, and for each such measure $\mu$ write the Lebesgue decomposition of $\mu = \mu_{ac} + \mu_s$, where $d\mu_{ac}/d\theta = W(\theta)$. Let $S^m_n$ be the subset of $M^m$ such that each $\mu \in S^m_n$ has the same Fourier coefficients $C_i$, $|i| \leq n$, and $\mathcal{E}(\mu) = \frac{1}{2\pi}\int_{-\pi}^{\pi} \ln\det(W)d\theta > -\infty$. Then there is a unique measure which maximizes the above entropy function $\mathcal{E}(\mu)$, and this measure is given by $d\mu = W(\theta)d\theta$, with $W(\theta) = Q^m_n(\theta)^{-1}$, where $Q^m_n(\theta)$ is a positive $(m+1) \times (m+1)$ matrix trigonometric polynomial of degree $n$.

This leads to a simple proof of the matrix Fejér–Reisz factorization theorem (Helson [13], Dritschel [5], McLean and Woerdeman [16], Geronimo and Lai [10]) which will be useful later.

LEMMA 2.6. [illegible] $Q^m_n(\theta)$ [illegible] $(m+1)\times(m+1)$ [illegible] $Q^m_n(\theta) = \overleftarrow{L}^m_n(z)(\overleftarrow{L}^m_n(z))^\dagger$, $z = e^{i\theta}$ [illegible] $\overleftarrow{L}^m_n$ [illegible] $(m+1) \times (m+1)$ [illegible] $n$ [illegible] $L^m_n$ [illegible] (2.15)

[illegible] Since $Q^m_n(\theta)$ is strictly positive we can compute the moments $C_j = \frac{1}{2\pi}\int_{-\pi}^{\pi} e^{-ij\theta}Q^m_n(\theta)^{-1}d\theta$. If we compute the matrix orthogonal polynomials associated with these Fourier coefficients, we find that $W_n$ has spectral matching up to $n$. That is, its Fourier coefficients match $C_i$ for $|i| \leq n$. The maximum entropy theorem implies that $Q^m_n(\theta) = W_n^{-1}$, which gives the result. □

The matrix Fejér–Riesz theorem now follows.

THEOREM 2.7. [illegible] $Q^m_n(\theta) \geq 0$ [illegible] $(m+1)\times(m+1)$ [illegible] $Q^m_n(\theta) = P^m_n(z)(P^m_n(z))^\dagger$, $z = e^{i\theta}$ [illegible] $P^m_n$ [illegible] $|z| < 1$ $(m+1) \times (m+1)$ [illegible]

[illegible] Let $Q^m_{n,\epsilon} = \epsilon I + Q^m_n$ , $\epsilon > 0$; then $Q^m_{n,\epsilon}$ satisfies the hypotheses of the above lemma. Thus $Q^m_{n,\epsilon} = P^m_{n,\epsilon}(P^m_{n,\epsilon})^\dagger$. The proof now follows by taking the limit as $\epsilon$ tends to zero. □

It was observed by Delsarte et al. [4] that if the $C_k$ in $C_{n,m}$ are centrotranspose symmetric, then

$$(L^{m\dagger}_{i,i}L^m_i(z))^T = J_m R^m_i(z)R^{m\dagger}_{i_i}J_m, \quad i = 0, \ldots, n, \tag{2.35}$$

where $J_m$ is the $(m+1) \times (m+1)$ matrix with ones on the reverse diagonal and zeros everywhere else. This can easily be seen from (2.15) and (2.16) since in this case from Lemma 2.2 $C^T_{n,m} = JC_{n,m}J$, with $J$ the $(n+1)(m+1) \times (m+1)(n+1)$ matrix with ones down the antidiagonal and zeros everywhere else. This leads to the following characterization of positive definite doubly Toeplitz matrices in terms of certain recurrence coefficients. We will denote by $C^m_0$ the $m \times m$ matrix obtained from $C_0$ by eliminating the first row and first column of $C_0$.

THEOREM 2.8. [illegible] $C_{n,m}$ [illegible] $C_i, |i| \leq n$ [illegible] $E_{k,m}, k = 1, \ldots, n$ [illegible] $C_0$ [illegible] $C_{n,m}$ [illegible] $E_{k,i}, k = 1, \ldots, n, i = m-1, m$ $C_0$ [illegible] $C^m_0$ [illegible]

[illegible] Examining the leading coefficients in (2.35) and using the fact that $L^m_{i,i}$ and $R^m_{i,i}$ are upper triangular, we find that (see also [4]) $(L^m_{i,i})^T = J_m R^m_{i,i}J_m$ for $i = 0, \ldots, n$. Thus

$$L^m_i(z)^T = J_m R^m_i(z)J_m, \; i = 0, \ldots, n. \tag{2.36}$$

The above equation and (2.19) imply that

$$J_m A_{i+1,m} J_m = A_{i+1,m}^T. \tag{2.37}$$

Using this coupled with (2.36) and its reverse in (2.30) yields

$$\begin{aligned} J_m E_{i+1,m} J_m &= -J_m (A_{i+1,m}^\dagger)^{-1} L_{i+1}^m(0) \overleftarrow{R}_{i+1}^m(0)^{-1} \hat{A}_{i+1,m} J_m \\ &= -(A_{i+1,m} \overleftarrow{L}_{i+1}^m(0)^{-1} R_{i+1}^m(0) (\hat{A}_{i+1,m}^\dagger)^{-1})^T = E_{i+1,m}^T. \end{aligned} \tag{2.38}$$

To show the converse note that if $E_{i,m}$ is centrotranspose symmetric, then from (2.20) we obtain

$$J_m (A_{i,m} A_{i,m}^\dagger)^T J_m = J_m (I_m - E_{i,m} E_{i,m}^\dagger) J_m = \overline{(I - E_{i,m}^\dagger E_{i,m})} = \hat{A}_{i,m}^T \overline{\hat{A}_{i,m}},$$

which gives (2.37). Since $C_0$ is centrotranspose symmetric and $L_{0,m}^\dagger(z)$ is the lower Cholesky factor of $C_0$, we see that $J_m L_0^m J_m = R_0^{mT}$. Thus by induction using (2.17) we find that $J_m L_n^m(z) J_m = R_n^m(z)^\top$. The first part of the result now follows from the spectral matching of $W_n$, (2.26), and (2.28). The second part of the theorem follows by applying the above argument to $C_{n,m-1}$ and $C_0^m$ and then using Lemma 2.1. ☐

In the next two sections we present recurrence formulas and an algorithm that computes recurrence coefficients for a positive definite doubly Toeplitz matrix.

**3. Bivariate orthogonal polynomials.** In this section we examine the properties of two variable orthogonal polynomials where the monomial ordering is either lexicographical or reverse lexicographical. The study of orthogonal polynomials on the bicircle with this ordering was begun by Delsarte et al. [4] and extended in [8]. Given a positive definite linear functional $\mathcal{L}_{N,M} : \prod^{N,M} \to \mathbb{C}$ we perform the Gram–Schmidt procedure using the lexicographical ordering and define the orthonormal polynomials $\phi_{n,m}^l(z,w)$, $0 \le n \le N$, $0 \le m \le M$, $0 \le l \le m$, by the equations

$$\begin{aligned} &\mathcal{L}_{N,M}(\phi_{n,m}^l z^{-i} w^{-j}) = 0, \quad 0 \le i < n \text{ and } 0 \le j \le m \quad \text{ or } i = n \text{ and } 0 \le j < l, \\ &\mathcal{L}_{N,M}(\phi_{n,m}^l (\phi_{n,m}^l)^\dagger) = 1, \end{aligned} \tag{3.1}$$

and

$$\phi_{n,m}^l(z,w) = k_{n,m,l}^{n,l} z^n w^l + \sum_{(i,j) <_{\text{lex}} (n,l)} k_{n,m,l}^{i,j} z^i w^j. \tag{3.2}$$

With the convention $k_{n,m,l}^{n,l} > 0$, the above equations uniquely specify $\phi_{n,m}^l$. Polynomials orthonormal with respect to $\mathcal{L}_{N,M}$ but using the reverse lexicographical ordering will be denoted by $\tilde{\phi}_{n,m}^l$. They are uniquely determined by the above relations with the roles of $n$ and $m$ interchanged.

Set

$$\Phi_{n,m} = \begin{bmatrix} \phi_{n,m}^m \\ \phi_{n,m}^{m-1} \\ \vdots \\ \phi_{n,m}^0 \end{bmatrix} = K_{n,m} \begin{bmatrix} z^n w^m \\ z^n w^{m-1} \\ \vdots \\ 1 \end{bmatrix}, \tag{3.3}$$

where the $(m+1) \times (n+1)(m+1)$ matrix $K_{n,m}$ is given by

$$K_{n,m} = \begin{bmatrix} k_{n,m,m}^{n,m} & k_{n,m,m}^{n,m-1} & \cdots & \cdots & \cdots & k_{n,m,m}^{0,0} \\ 0 & k_{n,m,m-1}^{n,m-1} & \cdots & \cdots & \cdots & k_{n,m,m-1}^{0,0} \\ \vdots & \ddots & \ddots & \ddots & \ddots & \ddots \\ 0 & \cdots & k_{n,m,0}^{n,0} & k_{n,m,0}^{n-1,m} & \cdots & k_{n,m,0}^{0,0} \end{bmatrix}. \tag{3.4}$$

As indicated above denote

$$\tilde{\Phi}_{n,m} = \begin{bmatrix} \tilde{\phi}^{n}_{n,m} \\ \tilde{\phi}^{n-1}_{n,m} \\ \vdots \\ \tilde{\phi}^{0}_{n,m} \end{bmatrix} = \tilde{K}_{n,m} \begin{bmatrix} w^m z^n \\ w^m z^{n-1} \\ \vdots \\ 1 \end{bmatrix}, \tag{3.5}$$

where the $(n+1) \times (n+1)(m+1)$ matrix $\tilde{K}_{n,m}$ is given similarly to (3.4) with the roles of $n$ and $m$ interchanged. For the bivariate polynomials $\phi^l_{n,m}(z,w)$ above we define the reverse polynomials $\overleftarrow{\phi}^{l}_{n,m}(z,w)$ by the relation

$$\overleftarrow{\phi}^{l}_{n,m}(z,w) = z^n w^m \bar{\phi}^l_{n,m}(1/z, 1/w). \tag{3.6}$$

With this definition $\overleftarrow{\phi}^{l}_{n,m}(z,w)$ is again a polynomial in $z$ and $w$, and furthermore

$$\overleftarrow{\Phi}_{n,m}(z,w) := \begin{bmatrix} \overleftarrow{\phi}^{m}_{n,m} \\ \overleftarrow{\phi}^{m-1}_{n,m} \\ \vdots \\ \overleftarrow{\phi}^{0}_{n,m} \end{bmatrix}^T . \tag{3.7}$$

An analogous procedure is used to define $\overleftarrow{\tilde{\phi}}^{l}_{n,m}$.

In order to ease the notation to find recurrence formulas for the vector polynomials $\Phi_{n,m}$, we introduce the inner product

$$\langle X, Y \rangle = \mathcal{L}_{N,M}(XY^\dagger). \tag{3.8}$$

Let $\hat{\prod}^{n,m}$ be the linear span of $z^i w^j$, $0 \le i \le n, 0 \le j \le m$, $\hat{\prod}^{n,m}_k$ be the vector space of $k$ dimensional vectors with entries in $\hat{\prod}^{n,m}$, and $\hat{\prod}^{m}_{m+1} = \hat{\prod}^{\infty,m}_{m+1}$.

Utilizing the orthogonality relations (3.1) we obtain the following auxiliary results.

Lemma 3.1. [illegible] $\Phi \in \hat{\prod}^{n,m}_k$ [illegible] $\Phi$ [illegible]

$$\langle \Phi, z^i w^j \rangle = 0, \quad 0 \le i < n, \quad 0 \le j \le m, \tag{3.9}$$

[illegible] $\Phi = T\Phi_{n,m}$ [illegible] $T$ [illegible] $k \times (m+1)$ [illegible] $k = m+1$ $T$ [illegible] $\langle \Phi, \Phi \rangle = I_{m+1}$ [illegible] $T = I_{m+1}$

Lemma 3.2. [illegible] $\tilde{\Phi} \in \hat{\prod}^{n,m}_k$ [illegible] $\tilde{\Phi}$ [illegible]

$$\langle \tilde{\Phi}, z^i w^j \rangle = 0, \quad 0 \le i \le n, \quad 0 \le j < m, \tag{3.10}$$

[illegible] $\tilde{\Phi} = T\tilde{\Phi}_{n,m}$ [illegible] $T$ [illegible] $k \times (n+1)$ [illegible] $k = n+1$ $T$ [illegible] $\langle \tilde{\Phi}, \tilde{\Phi} \rangle = I_{n+1}$ [illegible] $T = I_{n+1}$

With the above we can make contact with the matrix orthogonal polynomials introduced in section 2. This was observed by Delsarte et al. [4].

Lemma 3.3. [illegible] $\Phi_{n,m}$ [illegible] (3.3) [illegible]

$$\Phi_{n,m} = L^m_n(z)[w^m, w^{m-1}, \ldots, 1]^T, \tag{3.11}$$

$$\overleftarrow{\Phi}_{n,m} = [1, w, \ldots, w^m] J_m \overleftarrow{R}^m_n(z)^T J_m, \tag{3.12}$$

[illegible]

$$\begin{bmatrix} \Phi_{n,m}(z,w) \\ \Phi_{n-1,m}(z,w) \\ \vdots \\ \Phi_{0,m}(z,w) \end{bmatrix} = \begin{bmatrix} L_n^m(z) \\ L_{n-1}^m(z) \\ \vdots \\ L_0^m(z) \end{bmatrix} [w^m, w^{m-1}, \dots, 1]^T$$

$$= L \begin{bmatrix} z^n I_{m+1} \\ z^{n-1} I_{m+1} \\ \vdots \\ I_{m+1} \end{bmatrix} [w^m, w^{m-1}, \dots, 1]^T. \tag{3.13}$$

[illegible] If we substitute the equation

$$\Phi_{n,m} = \hat{L}_n(z)[w^m \ \cdots \ 1]^T = \sum_i \hat{L}_{n,i} z^i [w^m \ \cdots \ 1]^T$$

into (3.9), where $\hat{L}_n(z)$ is an $(m+1) \times (m+1)$ matrix polynomial of degree $n$, we find, for $j = 0, \dots, n-1$,

$$\begin{aligned} 0 &= \left\langle \Phi_{n,m},\, z^j \begin{bmatrix} w^m \\ \vdots \\ 1 \end{bmatrix} \right\rangle = \sum_{i=0}^{n} \hat{L}_{n,i} \left\langle z^i \begin{bmatrix} w^m \\ \vdots \\ 1 \end{bmatrix},\, z^j \begin{bmatrix} w^m \\ \vdots \\ 1 \end{bmatrix} \right\rangle \\ &= \sum_{i=1}^{n} \hat{L}_{n,i} \begin{bmatrix} \mathcal{L}_{NM}(z^{i-j}) & \cdots & \mathcal{L}_{NM}(z^{i-j} w^{-m}) \\ \vdots & & \vdots \\ \mathcal{L}_{NM}(z^{i-j} w^m) & \cdots & \mathcal{L}_{NM}(z^{i-j}) \end{bmatrix} \\ &= \sum_{i=1}^{n} \hat{L}_{n,i} \mathcal{L}_m(z^i,\, z^j) = \mathcal{L}_m(\hat{L}_n(z),\, z^j). \end{aligned}$$

Similarly,

$$\langle \Phi_{n,m},\, \Phi_{n,m} \rangle = I_{m+1} = \mathcal{L}_m \langle \hat{L}_n(z),\, \hat{L}_n(z) \rangle.$$

This, coupled with (2.8) and the fact that (3.3) implies that $\hat{L}_{n,m}$ is upper triangular with positive diagonal entries, gives (3.11). Equation (3.12) follows from (3.11) and (2.36), while (3.13) follows from (3.11) and the definition of $L$. □

Analogous formulas for bivariate orthogonal polynomials in the reverse lexicographical ordering are obtained by interchanging the roles on $n$ and $m$.

The function $\mathcal{M}$ given by (2.31) can be used to show that $\overleftarrow{\Phi}_{n,m}$ satisfies a minimization condition. Define $\bar{\mathcal{M}} : \hat{\prod}_{m+1}^{m} \to \operatorname{Herm}(m+1)$ by

$$\bar{\mathcal{M}}(\Phi) = \langle \Phi^\dagger,\, \Phi^\dagger \rangle - (\Phi_0 + \Phi_0^\dagger).$$

We find the following.

Lemma 3.4. [illegible] $\overleftarrow{\Phi}_{n,m}$ [illegible] $\hat{\prod}_{m+1}^{n,m}$

[illegible] Since $\Phi \in \hat{\prod}_{m+1}^{n,m}$ can be represented as

$$\Phi(z,w) = [1, w, \dots, w^m] \hat{\Phi}(z) = [1, w, \dots, w^m] \sum_{i=0}^{n} \Phi_i z^i,$$

and from (2.4)

$$\left\langle z^i \begin{bmatrix} w^m \\ \vdots \\ 1 \end{bmatrix}, z^j \begin{bmatrix} w^m \\ \vdots \\ 1 \end{bmatrix} \right\rangle = \begin{bmatrix} \mathcal{L}_{NM}(z^{i-j}) & \cdots & \mathcal{L}_{NM}(z^{i-j}w^{-m}) \\ \vdots & & \vdots \\ \mathcal{L}_{NM}(z^{i-j}w^{m}) & \cdots & \mathcal{L}_{NM}(z^{i-j}) \end{bmatrix} = \mathcal{L}_m(z^i, z^j),$$

we find $\bar{\mathcal{M}}(\Phi) = \hat{\mathcal{M}}(\hat{\Phi})$. The result now follows from (3.12) and the fact that $R^m_{n,m}\overleftarrow{R}^m_n(z)$ minimizes $\hat{\mathcal{M}}$ on $\prod^n_{m+1}$. ∎

We can now derive recurrence relations between the various polynomials.

Theorem 3.5. [illegible] $\{\Phi_{n,m}\}$ [illegible] $\{\tilde{\Phi}_{n,m}\}$ $0 \le n \le N$ $0 \le m \le M$ [illegible]

$$A_{n,m}\Phi_{n,m} = z\Phi_{n-1,m} - \hat{E}_{n,m}\overleftarrow{\Phi}^T_{n-1,m}, \tag{3.14}$$

$$\Phi_{n,m} + A^\dagger_{n,m}\hat{E}_{n,m}(A^T_{n,m})^{-1}\overleftarrow{\Phi}^T_{n,m} = A^\dagger_{n,m}z\Phi_{n-1,m}, \tag{3.15}$$

$$\Gamma_{n,m}\Phi_{n,m} = \Phi_{n,m-1} - \mathcal{K}_{n,m}\tilde{\Phi}_{n-1,m}, \tag{3.16}$$

$$\Gamma^1_{n,m}\Phi_{n,m} = w\Phi_{n,m-1} - \mathcal{K}^1_{n,m}\overleftarrow{\tilde{\Phi}}^T_{n-1,m}, \tag{3.17}$$

$$\Phi_{n,m} = I_{n,m}\tilde{\Phi}_{n,m} + \Gamma^\dagger_{n,m}\Phi_{n,m-1}, \tag{3.18}$$

$$\overleftarrow{\Phi}^T_{n,m} = I^1_{n,m}\tilde{\Phi}_{n,m} + (\Gamma^1_{n,m})^T\overleftarrow{\Phi}^T_{n,m-1}, \tag{3.19}$$

[illegible]

$$\hat{E}_{n,m} = \langle z\Phi_{n-1,m}, \overleftarrow{\Phi}^T_{n-1,m}\rangle = E_{n,m}J_m = \hat{E}^T_{n,m} \in M^{m+1,m+1}, \tag{3.20}$$

$$A_{n,m} = \langle z\Phi_{n-1,m}, \Phi_{n,m}\rangle \in M^{m+1,m+1}, \tag{3.21}$$

$$\mathcal{K}_{n,m} = \langle \Phi_{n,m-1}, \tilde{\Phi}_{n-1,m}\rangle \in M^{m,n}, \tag{3.22}$$

$$\Gamma_{n,m} = \langle \Phi_{n,m-1}, \Phi_{n,m}\rangle \in M^{m,m+1}, \tag{3.23}$$

$$\mathcal{K}^1_{n,m} = \langle w\Phi_{n,m-1}, \overleftarrow{\tilde{\Phi}}^T_{n-1,m}\rangle \in M^{m,n}, \tag{3.24}$$

$$\Gamma^1_{n,m} = \langle w\Phi_{n,m-1}, \Phi_{n,m}\rangle \in M^{m,m+1}, \tag{3.25}$$

$$I_{n,m} = \langle \Phi_{n,m}, \tilde{\Phi}_{n,m}\rangle \in M^{m+1,n+1}, \tag{3.26}$$

$$I^1_{n,m} = \langle \overleftarrow{\Phi}^T_{n,m}, \tilde{\Phi}_{n,m}\rangle \in M^{m+1,n+1}. \tag{3.27}$$

[illegible] 3.6. Formulas similar to (3.14)–(3.19) hold for $\tilde{\Phi}_{n,m}$ and will be denoted by $(\tilde{3}.14)$–$(\tilde{3}.19)$. Throughout the rest of the paper we use the same notation to denote the extension to $\tilde{\Phi}_{n,m}$ of existing formulas stated for $\Phi_{n,m}$.

[illegible]. Equation (3.14) follows from Lemma 3.3, (2.17), (2.36), and (2.37). Likewise (3.15) follows in an analogous manner from (2.22). To prove (3.16) note that, because of the linear independence of the entries of $\Phi_{n,m}$, there is an $m \times (m+1)$ matrix $\Gamma_{n,m}$ such that $\Gamma_{n,m}\Phi_{n,m} - \Phi_{n,m-1} \in \hat{\prod}^{n-1,m}_m$. Furthermore

$$\langle \Gamma_{n,m}\Phi_{n,m} - \Phi_{n,m-1}, z^i w^j\rangle = 0, \qquad 0 \le i \le n-1, \quad 0 \le j \le m-1.$$

Thus Lemma 3.2 implies that

$$\Gamma_{n,m}\Phi_{n,m} - \Phi_{n,m-1} = H_{n,m}\tilde{\Phi}_{n-1,m}.$$

The remaining recurrence formulas follow in a similar manner. ∎

3.7. As indicated in the proof, (3.14) follows from the theory of matrix orthogonal polynomials and so allows us to compute in the $n$ direction along a strip of size $m+1$. This formula does not mix the polynomials in the two orderings. However, to increase $m$ by one for polynomials constructed in the lexicographical ordering, the remaining relations show that orthogonal polynomials in the reverse lexicographical ordering must be used.

Using the orthogonality relations from Lemmas 3.1 and 3.2 and (3.1), we find the following relations.

PROPOSITION 3.8. $\tilde{\Phi}$ $\Phi$

$$\tilde{\mathcal{K}}_{n,m} = \mathcal{K}^{\dagger}_{n,m}, \ \ \tilde{I}_{n,m} = I^{\dagger}_{n,m}, \tag{3.28}$$

$$\tilde{I}^{1}_{n,m} = (I^{1}_{n,m})^{T}, \ \ \tilde{\mathcal{K}}^{1}_{n,m} = (\mathcal{K}^{1}_{n,m})^{T}. \tag{3.29}$$

$$A_{n,m}A^{\dagger}_{n,m} = I_m - \hat{E}_{n,m}\hat{E}^{\dagger}_{n,m}, \tag{3.30}$$

$$\Gamma_{n,m}\Gamma^{\dagger}_{n,m} = I_m - \mathcal{K}_{n,m}\mathcal{K}^{\dagger}_{n,m}, \tag{3.31}$$

$$\Gamma^{1}_{n,m}(\Gamma^{1}_{n,m})^{\dagger} = I_m - \mathcal{K}^{1}_{n,m}(\mathcal{K}^{1}_{n,m})^{\dagger}, \tag{3.32}$$

$$I_{n,m}I^{\dagger}_{n,m} + \Gamma^{\dagger}_{n,m}\Gamma_{n,m} = I_{m+1}, \tag{3.33}$$

$$I^{1}_{n,m}(I^{1}_{n,m})^{\dagger} + (\Gamma^{1}_{n,m})^{\dagger}\Gamma^{1}_{n,m} = I_{m+1}. \tag{3.34}$$

3.9. The matrix $\Gamma_{n,m}$ has a zero in the entries $(i,j), i \geq j$, and has positive $(i, i+1)$ entries. Since $\Gamma_{n,m}\Gamma^{\dagger}_{n,m} = \Gamma_{n,m}U^{\dagger}_{m}U_{m}\Gamma^{\dagger}_{n,m}$, where $U_m$ is the $m \times m+1$ matrix given by

$$U_m = \begin{bmatrix} 0, & I_m \end{bmatrix}, \tag{3.35}$$

we see that $\Gamma_{n,m}U^{\dagger}_{m}$ is the upper Cholesky factorization of the right-hand side of (3.31). From this $\Gamma_{n,m}$ can be obtained once $\mathcal{K}_{n,m}$ is specified. The matrix $\Gamma^{1}_{n,m}$ has zeros in the entries $(i,j), i > j$, with positive $(i,i)$ entries. The matrix $I_{n,m}$ has the first row and column equal to zero except for a one in the $(1,1)$ entry.

The above recurrence formulas also give pointwise formulas for the recurrence coefficients. In order to obtain these formulas we define the $m \times m+1$ matrix $U^{1}_{m}$ as

$$U^{1}_{m} = \begin{bmatrix} I_m, & 0 \end{bmatrix}, \tag{3.36}$$

and the $(n+1)(m+1) \times (n+1)(m+1)$ matrix $P^{n,m}_{rl}$, which takes monomials in the lexicographical ordering to those in the reverse lexicographical ordering; i.e.,

$$P^{n,m}_{rl}[z^n w^m, z^n w^{m-1}, \ldots, 1]^T = [w^m z^n, w^m z^{n-1}, \ldots, 1]^T. \tag{3.37}$$

Analogous equations hold for the $n \times (n+1)$ matrices $\tilde{U}_n$ and $\tilde{U}^{1}_{n}$.

PROPOSITION 3.10.

$$\Phi_{n,m}(z,w) = \Phi^{m}_{n}(z)\begin{bmatrix} w^m \\ \vdots \\ 1 \end{bmatrix} \text{ and } \tilde{\Phi}_{n,m}(z,w) = \tilde{\Phi}^{n}_{m}(w)\begin{bmatrix} z^n \\ \vdots \\ 1 \end{bmatrix}, \tag{3.38}$$

$$\Phi^{m}_{n}(z) = \Phi^{m}_{n,n}z^{n} + \Phi^{m}_{n,n-1}z^{n-1} + \cdots,$$

$$\tilde{\Phi}^{n}_{m}(w) = \tilde{\Phi}^{n}_{m,m}w^{m} + \tilde{\Phi}^{n}_{m,m-1}w^{m-1} + \cdots; \tag{3.39}$$

[illegible]

$$\Gamma_{n,m} = \Phi^{m-1}_{n,n} U_m (\Phi^m_{n,n})^{-1}, \tag{3.40}$$

$$\Gamma^1_{n,m} = \Phi^{m-1}_{n,n} U^1_m (\Phi^m_{n,n})^{-1}, \tag{3.41}$$

$$\mathcal{K}_{n,m} = -\Gamma_{n,m} I_{n,m} \tilde{F}_{n,m}, \tag{3.42}$$

$$\mathcal{K}^1_{n,m} = -\Gamma^1_{n,m} \bar{I}^1_{n,m} \bar{\tilde{F}}^1_{n,m}, \tag{3.43}$$

$$I_{n,m} = ({\Phi^m_{n,n}}^{\dagger})^{-1} [I_{m+1}, 0, \dots, 0] C^{-1}_{n,m} {P^{n,m}_{rl}}^T [I_{n+1}, 0, \dots, 0]^T (\tilde{\Phi}^n_{m,m})^{-1}, \tag{3.44}$$

$$I^1_{n,m} = ({\Phi^m_{n,n}}^{T})^{-1} [0, \dots, 0, J_{m+1}] C^{-1}_{n,m} {P^{n,m}_{rl}}^T [I_{n+1}, 0, \dots, 0]^T (\tilde{\Phi}^n_{m,m})^{-1}, \tag{3.45}$$

[illegible] $\tilde{F}_{n,m} = \tilde{\Phi}^n_{m,m} U^T_n (\tilde{\Phi}^{n-1}_{m,m})^{-1}$ [illegible] $\tilde{F}^1_{n,m} = \tilde{\Phi}^n_{m,m} (U^1_n)^T (\tilde{\Phi}^{n-1}_{m,m})^{-1}$

[illegible]. Equation (3.41) follows by equating the coefficients of $z^n$ in (3.17) on the left. The same argument gives (3.41). To show (3.42) multiply (3.18) on the left by $\Gamma_{n,m}$ and then subtract the resulting equation from (3.16). Now equating the coefficients of $w^m$ gives the result. Equation (3.43) follows by taking the transpose of the reverse of (3.17), then multiplying (3.19) on the left by $\bar{\Gamma}^1_{n,m}$, and subtracting the resulting equations. Equating powers of $w^m$ then gives the result. Equation (3.44) follows by equating the highest powers of $w$ in (3.18), and (3.45) follows in a similar manner from (3.19) and the fact that $C_{n,m}$ is a doubly Toeplitz matrix. □

[illegible] 3.11. From (3.11) and Lemma 2.5 we see that $(\Phi^m_{n,n})^\dagger$ is the lower Cholesky factor of $[I_{m+1}, 0, \dots, 0] C_{n,m} [I_{m+1}, 0, \dots, 0]^T$ and a similar relation holds between $\tilde{\Phi}^n_{m,m}$and $\tilde{C}_{n,m}$. Thus (3.44) and (3.45) give the relation between $I_{n,m}$ and $I^1_{n,m}$ and the Fourier coefficients of $\mathcal{L}_{N,M}$. These coupled with (3.42) and (3.43) relate the Fourier coefficients of $\mathcal{L}_{N,M}$ to $\mathcal{K}_{n,m}$ and $\mathcal{K}^1_{n,m}$.

We now give relations between the coefficients in the recurrence formulas at one level in terms of those at previous levels.

LEMMA 3.12 (relations for $\mathcal{K}_{n,m}$). [illegible] $0 < n, m$

$$\Gamma^1_{n,m-1} \mathcal{K}_{n,m} = \mathcal{K}_{n,m-1} (\tilde{A}^{-1}_{n-1,m})^\dagger - \mathcal{K}^1_{n,m-1} \hat{\bar{E}}^\dagger_{n-1,m} (\tilde{A}^{-1}_{n-1,m})^\dagger, \tag{3.46}$$

$$\mathcal{K}_{n,m} (\tilde{\Gamma}^1_{n-1,m})^\dagger = A^{-1}_{n,m-1} \mathcal{K}_{n-1,m} - A^{-1}_{n,m-1} \hat{E}_{n,m-1} \bar{\mathcal{K}}^1_{n-1,m}. \tag{3.47}$$

[illegible]. To show (3.46) multiply (3.22) on the left by $\Gamma^1_{n,m-1}$ and then use (3.17) with $m$ reduced by one to obtain

$$\Gamma^1_{n,m-1} \mathcal{K}_{n,m} = \langle w \Phi_{n,m-2}, \tilde{\Phi}_{n-1,m} \rangle.$$

Eliminating $\tilde{\Phi}_{n-1,m}$ using ($\tilde{3}$.14) and then applying (3.22) and (3.24) gives (3.46). Equation (3.47) follows in an analogous manner. □

LEMMA 3.13 (relations for $\mathcal{K}^1_{n,m}$). [illegible] $0 < n, m$

$$\Gamma_{n,m-1} \mathcal{K}^1_{n,m} = \mathcal{K}^1_{n,m-1} (\tilde{A}^{-1}_{n-1,m})^T - \mathcal{K}_{n,m-1} (\hat{\bar{E}}_{n-1,m})^T (\tilde{A}^{-1}_{n-1,m})^T, \tag{3.48}$$

$$\mathcal{K}^1_{n,m} (\tilde{\Gamma}_{n-1,m})^T = A^{-1}_{n,m-1} \mathcal{K}^1_{n-1,m} - A^{-1}_{n,m-1} \hat{E}_{n,m-1} \bar{\mathcal{K}}_{n-1,m}. \tag{3.49}$$

[illegible]. To show (3.48) multiply (3.24) on the left by $\Gamma_{n,m-1}$ and then use (3.16) to obtain

$$\Gamma_{n,m-1} \mathcal{K}^1_{n,m} = \langle w \Phi_{n,m-2}, \overleftarrow{\tilde{\Phi}}{}^T_{n-1,m} \rangle.$$

Now use $(\tilde{3}.14)$ with $n$ reduced by one and then (3.24) and (3.22) to find (3.48). Equation (3.49) follows in a similar manner. ☐

LEMMA 3.14 (relations for $\hat{E}_{n,m}$). *Let* $0 < n, m$

$$\Gamma_{n-1,m}\hat{E}_{n,m} = A_{n,m-1}\mathcal{K}_{n,m}(I^1_{n-1,m})^\dagger + \hat{E}_{n,m-1}\bar{\Gamma}^1_{n-1,m}, \tag{3.50}$$

$$\hat{E}_{n,m}(\Gamma^1_{n-1,m})^T = I_{n-1,m}(\mathcal{K}^1_{n,m})^T A^T_{n,m-1} + \Gamma^\dagger_{n-1,m}\hat{E}_{n,m-1}. \tag{3.51}$$

*Proof.* To establish (3.50) multiply (3.20) on the left by $\Gamma_{n-1,m}$ and then use (3.16) to obtain

$$\Gamma_{n-1,m}\hat{E}_{n,m} = \langle z\Phi_{n-1,m-1}, \overleftarrow{\Phi}^T_{n-1,m}\rangle.$$

With the use of (3.14) to eliminate $z\Phi_{n-1,m-1}$, we find

$$\Gamma_{n-1,m}\hat{E}_{n,m} = A_{n,m-1}\langle\Phi_{n,m-1}, \overleftarrow{\Phi}^T_{n-1,m}\rangle + \hat{E}_{n,m-1}\langle\overleftarrow{\Phi}^T_{n-1,m-1}, \overleftarrow{\Phi}^T_{n-1,m}\rangle.$$

The second inner product on the right-hand side of the above equation evaluates to $\bar{\Gamma}^1_{n-1,m}$, while the first may be evaluated using (3.19) followed by (3.22) to give the claimed equation. To obtain (3.51) multiply (3.20) on the right by $(\Gamma^1_{n-1,m})^T$ and then use (3.17) to get

$$\hat{E}_{n,m}(\Gamma^1_{n-1,m})^T = \langle z\Phi_{n-1,m}, \overleftarrow{\Phi}^T_{n-1,m-1}\rangle.$$

Using (3.14) to eliminate $\overleftarrow{\Phi}^T_{n-1,m-1}$ yields

$$\hat{E}_{n,m}(\Gamma^1_{n-1,m})^T = \langle z\Phi_{n-1,m}, \overleftarrow{\Phi}^T_{n,m-1}\rangle A^T_{n,m-1} + \langle\Phi_{n-1,m}, \Phi_{n-1,m-1}\rangle\hat{E}^T_{n,m-1}.$$

Equation (3.23) can be used to evaluate the second inner product on the right-hand side of the above equation, while the reverse transpose of (3.17) and (3.26) can be used to obtain the first inner product. ☐

LEMMA 3.15 (relation for $\Gamma^1_{n,m}$). *Let* $0 < n, m$

$$\begin{aligned}\Gamma^1_{n,m}\Gamma^\dagger_{n,m} = {}& I_{n,m-1}\tilde{\hat{E}}_{n,m}(I^1_{n,m-1})^T + \Gamma^\dagger_{n,m-1}\Gamma^1_{n,m-1}\\ &+ \mathcal{K}^1_{n,m}\tilde{\bar{A}}^{-1}_{n-1,m}\tilde{\hat{E}}^\dagger_{n-1,m}\tilde{A}_{n-1,m}\mathcal{K}^\dagger_{n,m}.\end{aligned} \tag{3.52}$$

*Proof.* To show (3.52) multiply (3.25) on the left by $\Gamma^\dagger_{n,m}$ and use (3.16) to find

$$\Gamma^1_{n,m}\Gamma^\dagger_{n,m} = \langle w\Phi_{n,m-1}, \Phi_{n,m-1}\rangle - \langle w\Phi_{n,m-1}, \tilde{\Phi}_{n-1,m}\rangle\mathcal{K}^\dagger_{n,m}. \tag{3.53}$$

Eliminating $w\Phi_{n,m-1}$ in the second term on the right-hand side of the above equation using (3.17) and then applying $(\tilde{3}.15)$ gives the third term on the right-hand side of (3.52). In the first term on the right-hand side of the above equation, substitute the reverse transpose of (3.19) to find

$$\langle w\Phi_{n,m-1}, \Phi_{n,m-1}\rangle = \langle w\Phi_{n,m-1}, \overleftarrow{\tilde{\Phi}}^T_{n,m-1}\rangle(I^1_{n,m-1})^T + \Gamma^\dagger_{n,m-1}\Gamma^1_{n,m-1},$$

where (3.23) has been used to obtain the second term on the right-hand side of the above equation. The result may now be obtained by applying (3.18) for $\Phi_{n,m-1}$ and then using $(\tilde{3}.20)$. ☐

LEMMA 3.16 (relations for $I_{n,m}$ and $I^1_{n,m}$).

$$I_{n,m}\tilde{\Gamma}^\dagger_{n,m} = -\Gamma^\dagger_{n,m}\mathcal{K}_{n,m}, \tag{3.54}$$

$$I^1_{n,m} = -\bar{A}^{-1}_{n,m}\hat{E}^\dagger_{n,m}A_{n,m}I_{n,m} + A^T_{n,m}I^1_{n-1,m}\tilde{\Gamma}_{n,m}, \quad 0 < n. \tag{3.55}$$

Equation (3.54) follows by multiplying (3.26) on the right by $\tilde{\Gamma}^\dagger_{n,m}$ and then using ($\tilde{3}$.16) and (3.23). In (3.27) use ($\tilde{3}$.18) and (3.28) to find

$$I^1_{n,m} = \langle \overleftarrow{\Phi}^T_{n,m}, \Phi_{n,m}\rangle I_{n,m} + \langle \overleftarrow{\Phi}^T_{n,m}, \tilde{\Phi}_{n-1,m}\rangle \tilde{\Gamma}_{n,m}.$$

The first inner product on the right-hand side may be evaluated using (3.15). To evaluate the second inner product, eliminate $\overleftarrow{\Phi}^T_{n,m}$ using the reverse transpose of (3.15) and then use (3.27) to obtain the claimed equation. □

**4. Christoffel–Darboux formulas.** The Christoffel–Darboux formula plays an important role in the theory of one variable scalar and matrix orthogonal polynomials. Using the connection between two variable orthogonal polynomials and matrix orthogonal polynomials, we derive two variable analogs of the Christoffel–Darboux formula. These will play an important role in the theory of two variable stable polynomials discussed later.

LEMMA 4.1. $\{\Phi_{n,m}\}$ $\{\tilde{\Phi}_{n,m}\}$

$$\begin{aligned}
&\overleftarrow{\Phi}_{n,m}(z,w)\overleftarrow{\Phi}^\dagger_{n,m}(z_1,w_1) - \bar{z}_1 z\Phi^T_{n,m}(z,w)\Phi^\dagger_{n,m}(z_1,w_1)^T && \text{(4.1a)}\\
&\quad = (1-\bar{z}_1 z)\Phi_{n,m}(z,w)^T\Phi^\dagger_{n,m}(z_1,w_1)^T \\
&\quad + \overleftarrow{\Phi}_{n-1,m}(z,w)\overleftarrow{\Phi}^\dagger_{n-1,m}(z_1,w_1) - \bar{z}_1 z\Phi^T_{n-1,m}(z,w)\Phi^\dagger_{n-1,m}(z_1,w_1)^T && \text{(4.1b)}\\
&\quad = (1-\bar{z}_1 z)\tilde{\Phi}_{n,m}(z,w)^T\tilde{\Phi}^\dagger_{n,m}(z_1,w_1)^T \\
&\quad + \overleftarrow{\Phi}_{n,m-1}(z,w)\overleftarrow{\Phi}_{n,m-1}(z_1,w_1)^T - \bar{z}_1 z\Phi_{n,m-1}(z,w)^T\Phi^\dagger_{n,m-1}(z_1,w_1)^T. && \text{(4.1c)}
\end{aligned}$$

The equality (4.1a)=(4.1b) follows by subtracting (2.24) with $n$ reduced by one from the original equation and then using Lemma 3.3. The equality (4.1a)=(4.1c) can be obtained in the following manner. Let

$$Z_{n,m}(z,w) = [1, w, \ldots, w^m][I_{m+1}, zI_{m+1}, \ldots, z^n I_{m+1}],$$

and let $\tilde{Z}_{n,m}(z,w)$ be given by a similar formula with the roles of $z$ and $w$ and $n$ and $m$ interchanged. Then from Lemma 2.5, (2.24), and (3.11) we find

$$\begin{aligned}
&\frac{\overleftarrow{\Phi}_{n,m}(z,w)\overleftarrow{\Phi}^\dagger_{n,m}(z_1,w_1) - \bar{z}_1 z\Phi^T_{n,m}(z,w)\Phi^\dagger_{n,m}(z_1,w_1)^T}{1-\bar{z}_1 z}\\
&\qquad = Z_{n,m}(z,w)C^{-1}_{n,m}Z_{n,m}(z_1,w_1)^\dagger = \tilde{Z}_{n,m}(z,w)\tilde{C}^{-1}_{n,m}\tilde{Z}_{n,m}(z_1,w_1)^\dagger\\
&\qquad = \tilde{\Phi}^T_{n,m}(z,w)\tilde{\Phi}^\dagger_{n,m}(z_1,w_1)^T + \tilde{Z}_{n,m-1}(z,w)\tilde{C}^{-1}_{n,m-1}\tilde{Z}_{n,m-1}(z_1,w_1)^\dagger.
\end{aligned}$$

Switching back to the lexicographical ordering in the second term in the last equation and then using Lemma 2.5 yields the result. □

As an immediate application of the above lemma we obtain the following.

THEOREM 4.2 (Christoffel–Darboux formula). [illegible] $\{\Phi_{n,m}\}$ [illegible] $\{\tilde{\Phi}_{n,m}\}$

$$\begin{aligned}&\frac{\overleftarrow{\Phi}_{n,m}(z,w)\overleftarrow{\Phi}^{\dagger}_{n,m}(z_1,w_1)-\bar{z}_1 z\Phi^T_{n,m}(z,w)\Phi^{\dagger}_{n,m}(z_1,w_1)^T}{1-\bar{z}_1 z}\\ &\qquad=\sum_{k=0}^{n}\Phi^T_{k,m}(z,w)\Phi^{\dagger}_{k,m}(z_1,w_1)^T\\ &\qquad=\sum_{j=0}^{m}\tilde{\Phi}^T_{n,j}(z,w)\tilde{\Phi}^{\dagger}_{n,j}(z_1,w_1)^T.\end{aligned}$$

In the first line of the above equation, the terms $\bar{z}_1 z$ may be replaced by $\bar{w}_1 w$ if we switch to $\tilde{\Phi}_{n,m}$.

An interesting variant of (4.1c) is the following.

LEMMA 4.3.

$$\begin{aligned}&\Phi_{n,m}(z,w)^T\Phi^{\dagger}_{n,m}(z_1,w_1)^T-\Phi^T_{n,m-1}(z,w)\Phi^{\dagger}_{n,m-1}(z_1,w_1)^T\\ &=\ \tilde{\Phi}_{n,m}(z,w)^T\tilde{\Phi}^{\dagger}_{n,m}(z_1,w_1)^T-\tilde{\Phi}^T_{n-1,m}(z,w)\tilde{\Phi}^{\dagger}_{n-1,m}(z_1,w_1)^T.\end{aligned}\tag{4.2}$$

[illegible]. Equating the sums in the above theorem yields

$$\Phi_{n,m}(z,w)^T\Phi^{\dagger}_{n,m}(z_1,w_1)^T-\sum_{j=0}^{m-1}\tilde{\Phi}^T_{n,j}(z,w)\tilde{\Phi}^{\dagger}_{n,j}(z_1,w_1)^T\tag{4.3}$$

$$=\tilde{\Phi}_{n,m}(z,w)^T\tilde{\Phi}^{\dagger}_{n,m}(z_1,w_1)^T-\sum_{j=0}^{n-1}\Phi^T_{j,m}(z,w)\Phi^{\dagger}_{j,m}(z_1,w_1)^T.\tag{4.4}$$

Switching to the lexicographical ordering in the sum on the left-hand side of the above equation and reverse lexicographical ordering in the sum on the right-hand side, extracting the highest terms, and then using the Christoffel–Darboux formula to eliminate the remaining sums gives the result. ☐

[illegible] 4.4. The above equations can be derived from the recurrence formulas in the previous sections. However, the derivation of (4.1c) is rather tedious.

**5. Algorithm.** In this section we use the relations developed earlier to provide an algorithm that allows us to compute the coefficients in the recurrence formula at higher levels in terms of those at lower levels plus some indeterminates that are equivalent to the moments. This will allow us to construct positive definite doubly Toeplitz matrices. As a byproduct we construct the orthogonal polynomials associated with these matrices. More precisely, at each level we use the new indeterminates and the coefficients on the levels $(n, m-1)$ and $(n-1, m)$ to construct $\mathcal{K}_{n,m}$ and $\mathcal{K}^1_{n,m}$. With this we can construct the other coefficients needed to proceed to the next level. The $\hat{E}_{n,m}$ are closely related to the matrix recurrence coefficients needed to compute $C_{n,m}$. Furthermore $\Phi_{n,m}$ and $\tilde{\Phi}_{n,m}$ can also be computed. In order to construct the above matrices we will have need of the $m\times(m+1)$ matrices $U_m$ and $U^1_m$ given by (3.35) and (3.36), respectively, and the vector $e^m_1\in\mathbb{R}^m$, which is the vector with one in the first entry and zeros everywhere else. From the definition of $\mathcal{K}^1_{n,m}$ we see that

$$\begin{aligned}\mathcal{K}^1_{n,m} &= \langle w\Phi_{n,m-1}, \overleftarrow{\tilde{\Phi}}^T_{n-1,m}\rangle \\ &= \left\langle w\begin{bmatrix}\phi^{m-1}_{n,m-1}\\ \vdots \\ \phi^0_{n,m-1}\end{bmatrix}, \begin{bmatrix}\overleftarrow{\tilde{\phi}}^{n-1}_{n-1,m}\\ \vdots\\ z^n\overleftarrow{\tilde{\phi}}^0_{n-1,m}\end{bmatrix}\right\rangle \\ &= c_{-n,-m}d_{n,m}e_1^m(e_1^n)^T + R_{n,m}, \qquad (5.1)\end{aligned}$$

where $R_{n,m}$ is an $m\times n$ matrix containing moments $c_{i,j}, \{|i| \le n, |j| \le m\}\backslash\{(\pm n, \pm m)\}$. Likewise, with the help of (3.38) and its tilde counterpart we find

$$\begin{aligned}\mathcal{K}_{n,m} &= \langle \Phi_{n,m-1}, \tilde{\Phi}_{n-1,m}\rangle \\ &= c_{-n,m}\Phi^{n,m-1}_{n,m-1}\begin{bmatrix}0\\ \vdots\\ 1\end{bmatrix}\left(\tilde{\Phi}^{m,n-1}_{m,n-1}\begin{bmatrix}0\\ \vdots\\ 1\end{bmatrix}\right)^{\dagger} + \hat{R}_{n,m}, \qquad (5.2)\end{aligned}$$

where $\hat{R}_{n,m}$ contains only moments from lower levels.

We proceed as follows: At level $(0,0)$ we have the parameter $u_{0,0} > 0$, which corresponds to $c_{0,0}$. The polynomials $\Phi_{0,0}$ and $\tilde{\Phi}_{0,0}$ are chosen as $\frac{1}{\sqrt{u_{0,0}}}$. From (3.26) and (3.27) we see that $I_{0,0} = 1 = I^1_{0,0}$. At level $(i,0)$ there is one new parameter $u_{i,0}$, which can be taken to correspond with the one-dimensional recurrence coefficient i.e., $u_{i,0} = \alpha_i = \hat{E}_{i,0}$, corresponding to the $(i,0)$ level and must be less than one in magnitude. From (3.30) and the normalization chosen for the polynomials, $A_{i,0} = \sqrt{1-|\hat{E}_{i,0}|^2}$. This allows us to compute $\Phi_{i,0}$, and $\overleftarrow{\Phi}_{i,0}$. The sizes of the matrices given in (3.22), (3.23), (3.24), and (3.25) show that

$$\mathcal{K}_{i,0} = \tilde{\mathcal{K}}_{i,0} = \Gamma_{i,0} = \mathcal{K}^1_{i,0} = \tilde{\mathcal{K}}^1_{i,0} = \Gamma^1_{i,0} = 0,$$

where (3.28) and (3.29) have also been used. Furthermore (3.33) and Remark 3.9 imply that $I_{i,0} = (e_1^{i+1})^T = \tilde{I}^{\dagger}_{i,0}$ where (3.28) has been used. Equation $(\tilde{3}.31)$ implies that $\tilde{\Gamma}_{i,0} = U_i$, while (3.55) and (3.29) allow us to compute

$$I^1_{i,0} = (\tilde{I}^1_{i,0})^T = -\begin{bmatrix}\hat{E}^{\dagger}_{i,0} & A_{i,0}\hat{E}^{\dagger}_{i-1,0} & \cdots & -\prod_{j=1}^{i} A_{j,0}\end{bmatrix}. \qquad (5.3)$$

$\tilde{\Phi}_{i,0}$ can now be computed from $(\tilde{3}.18)$.

At level $(0,j)$ there is one new parameter $u_{0,j}$, which as above can be taken to correspond with the one-dimensional recurrence coefficient, i.e., $u_{0,j} = \alpha_j = \tilde{\hat{E}}_{0,j}$, corresponding to the $(0,j)$ level and must be less than one in magnitude. The analysis for the $(i,0)$ level can be carried over with the roles of the lexicographical and reverse lexicographical orderings interchanged. Thus from $(\tilde{3}.30)$ and the normalization chosen for the polynomials, $\tilde{A}_{0,j} = \sqrt{1-|\tilde{\hat{E}}_{0,j}|^2}$, which allows us to compute $\tilde{\Phi}_{0,j}$. Again

$$\tilde{\mathcal{K}}_{0,j} = \mathcal{K}_{0,j} = \tilde{\Gamma}_{0,j} = \tilde{\mathcal{K}}^1_{0,j} = \mathcal{K}^1_{0,j} = \tilde{\Gamma}^1_{0,j} = 0.$$

Likewise $\tilde{I}_{0,j} = (e_1^{j+1})^T = I^{\dagger}_{0,j}$ and $\Gamma_{0,j} = U_j$. Equations $(\tilde{3}.55)$ and (3.29) allow us to compute $\tilde{I}^1_{0,j}$ as above with $i$ and $j$ interchanged as well as the orderings. Equation (3.18) now allows us to compute $\Phi_{0,j}$.

At level $(n,m)$, with $n,m>0$, there are two new parameters $u_{n,m}$ and $u_{-n,m}$ since $u_{-n,-m}=\overline{u}_{n,m}$ and $u_{n,-m}=\overline{u}_{-n,m}$. These along with the coefficients on the $(n-1,m)$ and $(n,m-1)$ level will be used to compute $\mathcal{K}_{n,m}$ and $\mathcal{K}^1_{n,m}$. This will be sufficient to compute the remaining coefficients on level $(n,m)$. We begin with the following.

$\mathcal{K}_{n,m}$ If $n=1, m=1$, then (3.22) shows that $\mathcal{K}_{1,1}$ is a scalar which we choose as $\bar{u}_{1,-1}$. If $m>1$, we see from (3.41) and (3.36) that

$$\Gamma^1_{n,m-1}\Phi^{m-1}_{n,n}e^m_m=0,$$

where $e^m_m$ is the $m$-dimensional vector with zeros in all its entries except the last, which is one. Since $\Phi^{m-1}_{n,n}=A^{-1}_{n,m-1}\cdots A^{-1}_{1,m-1}\Phi^{m-1}_{0,0}$ is an upper triangular invertible matrix, we find

$$\Gamma^1_{n,m-1}\Phi^{m-1}_{n,n}((U^1_{m-1})^TU^1_{m-1}+e^m_m(e^m_m)^T)=\Gamma^1_{n,m-1}\Phi^{m-1}_{n,n}(U^1_{m-1})^TU^1_{m-1},$$

and from (3.41) $\Gamma^1_{n,m-1}\Phi^{m-1}_{n,n}(U^1_{m-1})^T=\Phi^{m-2}_{n,n}$. Thus (3.46) can be written as

$$\begin{aligned}
&U^1_{m-1}(\Phi^{m-1}_{n,n})^{-1}\mathcal{K}_{n.m}((\tilde{\Phi}^{n-1}_{m,m})^\dagger)^{-1}\\
&=(\Phi^{m-2}_{n,n})^{-1}(\mathcal{K}_{n,m-1}(\tilde{A}^{-1}_{n-1,m})^\dagger-\mathcal{K}^1_{n,m-1}\hat{\tilde{E}}^\dagger_{n-1,m}(\tilde{A}^{-1}_{n-1,m})^\dagger)((\tilde{\Phi}^{n-1}_{m,m})^\dagger)^{-1}\\
&=(\Phi^{m-2}_{n,n})^{-1}(\mathcal{K}_{n,m-1}-\mathcal{K}^1_{n,m-1}\hat{\tilde{E}}^\dagger_{n-1,m})((\tilde{\Phi}^{n-1}_{m-1,m-1})^\dagger)^{-1}\\
&=H_{n,m-1}.
\end{aligned}$$

In the last equality we have used the fact that $\tilde{A}_{n-1,m}\tilde{\Phi}^{n-1}_{m,m}=\tilde{\Phi}^{n-1}_{m-1,m-1}$. Likewise,

$$\begin{aligned}
&(\Phi^{m-1}_{n,n})^{-1}\mathcal{K}_{n,m}((\tilde{\Phi}^{n-1}_{m,m})^{-1})^\dagger(U^1_{n-1})^T\\
&=(\Phi^{m-1}_{n-1,n-1})^{-1}(\mathcal{K}_{n-1,m}-\hat{E}_{n,m-1}\bar{\mathcal{K}}^1_{n-1,m})((\tilde{\Phi}^{n-2}_{m,m})^\dagger)^{-1}\\
&=\tilde{H}_{n-1,m}.
\end{aligned}$$

If

$$(e^m_m)^T(\Phi^{m-1}_{n,n})^{-1}\mathcal{K}_{n,m}((\tilde{\Phi}^{n-1}_{m,m})^\dagger)^{-1}e^n_n=\bar{u}_{n,-m}, \tag{5.4}$$

then $\mathcal{K}_{n,m}$ can be solved for as

(5.5)

$$\begin{aligned}
&\mathcal{K}_{n,m}\\
&=\Phi^{m-1}_{n,n}\left(u_{-n,m}e^m_m(e^n_n)^T+(U^1_{m-1})^TH_{n,m-1}+e^m_m(e^m_m)^T\tilde{H}_{n-1,m}(U^1_{n-1})\right)(\tilde{\Phi}^{n-1}_{m,m})^\dagger.
\end{aligned}$$

A necessary condition in order to be able to continue is that $||\mathcal{K}_{n,m}||<1$.

$\Gamma_{n,m}$ Since $\mathcal{K}_{n,m}$ is presumed to be a contraction, Remark 3.9 shows that $\Gamma_{n,m}$ and $\tilde{\Gamma}_{n,m}$ may be computed from the upper Cholesky factor of $I-\mathcal{K}_{n,m}\mathcal{K}^\dagger_{n,m}$ and $I-\mathcal{K}^\dagger_{n,m}\mathcal{K}_{n,m}$, respectively.

$\mathcal{K}^1_{n,m}$ In $\mathcal{K}^1_{n,m}$ we see from (5.1) that the only new entry is $(\mathcal{K}_{n,m})_{1,1}$. If $n=1, m=1$, set $\mathcal{K}_{1,1}=\bar{u}_{1,1}$. If $m>1$, we will show that all of the rows except the first can be obtained from (3.48). The structure of $\Gamma_{n,m-1}$ implies that $\Gamma_{n,m-1}e^m_1=0$ so that

$$\Gamma_{n,m-1}=\Gamma_{n,m-1}(U^T_{m-1}U_{m-1}+e^m_1(e^m_1)^T)=\Gamma_{n,m-1}U^T_{m-1}U_{m-1}.$$

But $\Gamma_{n,m-1}U_{m-1}^T$ is an invertible matrix, which allows us to rewrite (3.48) as follows:

$$U_{m-1}\mathcal{K}_{n,m}^1 = (\Gamma_{n,m-1}U_{m-1}^T)^{-1}(\mathcal{K}_{n,m-1}^1(\tilde{A}_{n-1,m}^{-1})^T - \mathcal{K}_{n,m-1}\hat{\hat{E}}_{n-1,m}^T(\tilde{A}_{n-1,m}^{-1})^T).$$

This gives all of the entries in $\mathcal{K}_{n,m}^1$ except the first row.

Similarly, if $n > 1$ we can write

$$\tilde{\Gamma}_{n-1,m} = \tilde{\Gamma}_{n-1,m}(U_{n-1}^T U_{n-1} + e_1^n(e_1^n)^T) = \tilde{\Gamma}_{n-1,m}U_{n-1}^T U_{n-1},$$

i.e., $\tilde{\Gamma}_{n-1,m}^T = U_{n-1}^T U_{n-1}\tilde{\Gamma}_{n-1,m}^T$, and (3.49) can be rewritten as

$$\mathcal{K}_{n,m}^1 U_{n-1}^T = (A_{n,m-1}^{-1}\mathcal{K}_{n-1,m}^1 - A_{n,m-1}^{-1}\hat{E}_{n,m-1}\bar{\mathcal{K}}_{n-1,m})(U_{n-1}\tilde{\Gamma}_{n-1,m}^T)^{-1}. \tag{5.6}$$

Thus the $m \times (n-1)$ matrix $\mathcal{K}_{n,m}^1 U_{n-1}^T$, which is obtained from $\mathcal{K}_{n,m}^1$ by deleting the first column, is known from the previous levels. This allows us to compute all entries in the first row of $\mathcal{K}_{n,m}^1$ except $(\mathcal{K}_{n,m}^1)_{1,1}$, and we put

$$(\mathcal{K}_{n,m}^1)_{1,1} = \bar{u}_{n,m}. \tag{5.7}$$

A necessary condition on the parameters in order to be able to continue is that $||\mathcal{K}_{n,m}^1|| < 1$, which implies that $|u_{n,m}| < 1$.

[illegible] $\hat{E}_{n,m}$. We begin by taking the transpose of (3.51), using the fact that $\hat{E}_{n,m}$ is symmetric, and then multiplying on the left by the matrix $e_1^{m+1}(e_1^m)^T$. Now multiply (3.50) by $U_m^T$ and add the resulting equations. If $\hat{\Gamma}_{n-1,m}$ is the $(m+1) \times (m+1)$ matrix obtained by stacking the first row of $\Gamma_{n-1,m}^1$ on $\Gamma_{n-1,m}$, we find

$$\begin{aligned}\hat{\Gamma}_{n-1,m}\hat{E}_{n,m} =& U_m^T(A_{n,m-1}\mathcal{K}_{n,m}(I_{n-1,m}^1)^\dagger + \hat{E}_{n,m-1}\bar{\Gamma}_{n-1,m}^1)\\ &+ e_1^{m+1}(e_1^m)^T(A_{n,m-1}\mathcal{K}_{n,m}^1 I_{n-1,m}^T + \hat{E}_{n,m-1}\bar{\Gamma}_{n-1,m}).\end{aligned} \tag{5.8}$$

From the structure of $\Gamma^1$ and $\Gamma$ we see that $\hat{\Gamma}_{n-1,m}$ is an upper triangular matrix with positive diagonal entries and is hence invertible. Thus $\hat{E}_{n,m}$ can be computed from the above equation. If $||\hat{E}_{n,m}|| < 1$, then $\hat{\hat{E}}_{n,m}$ may be computed from ($\tilde{3}.50$) and ($\tilde{3}.51$). We may also compute $A_{n,m}$, $\tilde{A}_{n,m}$, and the polynomials $\Phi_{n,m}$ and $\tilde{\Phi}_{n,m}$. While the condition that $\hat{E}_{n,m}$ be a contraction is necessary and sufficient to be able to continue, it is not optimal in the sense that it does not take into account the redundancy inherent in the equations giving $\hat{E}_{n,m}$. This will be taken into account in the computation of $\Gamma_{n,m}^1$.

[illegible] $\Gamma_{n,m}^1$. As above we see that (3.52) gives

$$\begin{aligned}\Gamma_{n,m}^1 U_m^T =& (I_{n,m-1}\hat{\hat{E}}_{n,m}(I_{n,m-1}^1)^T + \Gamma_{n,m-1}^\dagger\Gamma_{n,m-1}^1\\ &+ \mathcal{K}_{n,m}^1\bar{\bar{\tilde{A}}}_{n-1,m}^{-1}\hat{\hat{E}}_{n-1,m}^\dagger\tilde{A}_{n-1,m}\mathcal{K}_{n,m}^\dagger)(U_m\Gamma_{n,m}^\dagger)^{-1},\end{aligned} \tag{5.9}$$

which allows the computation of all of the entries of $\Gamma_{n,m}^1$ except the $(1,1)$ entry. Since $(e_1^m)^T I_{n,m-1} = (e_1^m)^T$, $(e_1^m)^T\Gamma_{n,m-1}^\dagger = 0$, and likewise, with $I_{n,m-1}$ and $\Gamma_{n,m-1}^\dagger$ replaced by $\tilde{I}_{n,m}$ and $\tilde{\Gamma}_{n,m-1}^T$, respectively, we find with the help of (5.8)

$$(e_1^m)^T\Gamma_{n,m}^1 U_m^T = (e_1^m)^T H_{n,m}^2 + (e_1^m)^T\mathcal{K}_{n,m}^1 H_{n,m}^1, \tag{5.10}$$

where

$$H^2_{n,m} = I_{n,m-1}((I^1_{n,m-1})^\dagger \bar{\mathcal{K}}_{n,m}\tilde{A}^T_{n-1,m} + (\tilde{\Gamma}^1_{n,m-1})^\dagger \hat{\tilde{E}}_{n-1,m}) \\ \times U_n(\tilde{\tilde{\Gamma}}^T_{n,m-1})^{-1}(I^1_{n,m-1})^T(U_m\Gamma^\dagger_{n,m})^{-1}, \tag{5.11}$$

and

$$H^1_{n,m} = \tilde{A}^T_{n-1,m}e^n_1(e^{n+1}_1)^T(\tilde{\tilde{\Gamma}}^T_{n,m-1})^{-1}(I^1_{n,m-1})^T(U_m\Gamma^\dagger_{n,m})^{-1} \\ + \bar{\tilde{A}}^{-1}_{n-1,m}\hat{\tilde{E}}^\dagger_{n-1,m}\tilde{A}_{n-1,m}\mathcal{K}^\dagger_{n,m}(U_m\Gamma^\dagger_{n,m})^{-1}. \tag{5.12}$$

Thus the first entry $\Gamma^1$ can be computed using the first row of (5.10) and (3.32), which gives

$$|(\Gamma^1_{n,m})_{(1,1)}|^2 = 1 - (e^m_1)^T H^3_{n,m}(e^m_1), \tag{5.13}$$

where

$$H^3_{n,m} = (H^2_{n,m} + \mathcal{K}^1_{n,m}H^1_{n,m})(H^2_{n,m} + \mathcal{K}^1_{n,m}H^1_{n,m})^\dagger + \mathcal{K}^1_{n,m}(\mathcal{K}^1_{n,m})^\dagger. \tag{5.14}$$

[illegible]. Using the arguments above we see that the relevant part of $I_{n,m}$ may be computed from (3.54) and $I^1_{n,m}$ may be computed from (3.55). The matrix $\tilde{\Gamma}^1_{n,m}$ can be computed in the same manner as $\Gamma^1_{n,m}$.

## 6. Construction of a positive linear functional.

The above algorithm allows us to find a linear functional given the coefficients in the recurrence formulas. More precisely, it is as follows.

THEOREM 6.1. [illegible] $u_{i,j} \in \mathbb{C}$ $0 \le i \le n, |j| \le m$ $u_{-i,j} = \bar{u}_{i,-j}$ [illegible]

- [illegible] $\hat{E}_{i,0}$ $i = 1, \dots, n$ [illegible] $\hat{\tilde{E}}_{0,j}$ $j = 1, \dots, m$.
- $i \times j$ [illegible] $\mathcal{K}_{i,j}$ $i = 1, \dots, n$ $j = 1, \dots, m$. [illegible]
- $i \times j$ [illegible] $(e^j_1)^T H^3_{i,j}e^j_1$ $i = 1, \dots, n$ $j = 1, \dots, m$

[illegible]

$$u_{0,0} > 0,\ |\hat{E}_{i,0}| < 1, |\hat{\tilde{E}}_{0,j}| < 1,\ ||\mathcal{K}_{i,j}|| < 1, \text{ [illegible] } {e^j_1}^T H^3_{i,j}e^j_1 < 1, \tag{6.1}$$

[illegible] $\mathcal{L}$ [illegible] $\prod^{n,m}$ [illegible]

$$\mathcal{L}(\Phi_{i,m}\Phi^\dagger_{j,m}) = \delta_{i,j}I_{m+1} \text{ [illegible] } \mathcal{L}(\tilde{\Phi}_{n,i}\tilde{\Phi}^\dagger_{n,j}) = \delta_{i,j}I_{n+1}. \tag{6.2}$$

[illegible] (6.1) [illegible]

[illegible]. We construct the linear functional by induction. First, if $n = m = 0$ we set

$$\mathcal{L}(1) = u_{0,0} \text{ and } \Phi_{0,0} = \tilde{\Phi}_{0,0} = \frac{1}{\sqrt{u_{0,0}}},$$

and thus $\mathcal{L}(\Phi_{0,0}\Phi^\dagger_{0,0}) = \mathcal{L}(\tilde{\Phi}_{0,0}\tilde{\Phi}^\dagger_{0,0}) = 1$.

If $m = 0$, we construct $A_{i,0} = \sqrt{1 - |\hat{E}_{i,0}|^2}$, where $\hat{E}_{i,0} = u_{i,0}$. The polynomials $\Phi_{i,0}, i = 0, \dots n$, are now computed using (3.14), and then we define

$$\mathcal{L}(\Phi_{i,0}\Phi^\dagger_{j,0}) = \delta_{i,j}.$$

This gives a well-defined positive linear functional on $z^j$ for $|j| \le n$.

Likewise, if $n = 0$, we construct $\tilde{\Phi}_{0,k}$ using ($\tilde{3}$.14) and define

$$\mathcal{L}(\tilde{\Phi}_{0,i}\tilde{\Phi}_{0,j}^{\dagger}) = \delta_{i,j},$$

which gives the linear functional on $w^j$ for $|j| \leq m$. Thus (6.2) will hold if $m = 0$ or $n = 0$.

Assume now that the functional $\mathcal{L}$ is well defined and positive for all levels $0 \leq i \leq n-1$, $0 \leq j \leq m$ and $0 \leq i \leq n$, $0 \leq j \leq m-1$ before $(n, m)$. To ease notation we will use the bracket given in (3.8) with $\mathcal{L}_{N,M}$ replaced by $\mathcal{L}$. We first extend $\mathcal{L}$ so that

$$\langle \Phi_{n,m-1}, \tilde{\Phi}_{n-1,m} \rangle = \mathcal{K}_{n,m}. \tag{6.3}$$

To check that the above equation is consistent with how $\mathcal{L}$ is defined on the previous levels, note that from (3.46)

$$\langle \Gamma^1_{n,m-1}\Phi_{n,m-1}, \tilde{\Phi}_{n-1,m} \rangle = \Gamma^1_{n,m-1}\mathcal{K}_{n,m}, \tag{6.4}$$

which follows from the construction of $\mathcal{K}_{n,m}$ and the definition of $\mathcal{L}$ on the previous levels (see Lemma 3.12). Similarly, using the second defining relation of $\mathcal{K}_{n,m}$ (i.e., the last row of (3.47)) we see that

$$\langle \Phi_{n,m-1}, \tilde{\Gamma}^1_{n-1,m}\tilde{\Phi}_{n-1,m} \rangle = \mathcal{K}_{n,m}(\tilde{\Gamma}^1_{n-1,m})^{\dagger}. \tag{6.5}$$

Equations (6.4) and (6.5) show that most of (6.3) is automatically true. We now define $\mathcal{L}(z^n w^{-m})$ so that (5.4) holds, which completes (6.3).

Using an analogous argument we can use the construction of $\mathcal{K}^1_{n,m}$ to extend the functional to $z^n w^m$ so that

$$\mathcal{K}^1_{n,m} = \langle w\Phi_{n,m-1}, \overleftarrow{\tilde{\Phi}}{}^{T}_{n-1,m} \rangle. \tag{6.6}$$

This completes the extension of $\mathcal{L}$. What remains to be shown is that (6.2) holds. This is accomplished by first constructing $\tilde{\tilde{E}}_{n,m}$ from ($\tilde{5}$.8). The condition on $(e_1^m)^T H^3_{n,m} e_1^m$ and (5.9) shows that the first row of $\Gamma^1_{n,m}$ may be computed and that we may choose

$$(\Gamma^1_{n,m})_{1,1} > 0.$$

With the first row of $\Gamma^1_{n,m}$ and all of $\Gamma_{n,m}$ (which is calculated from the Cholesky factorization of $\mathcal{K}_{n,m}\mathcal{K}^{\dagger}_{n,m}$), $\Phi_{n,m}$ may be constructed from (3.16) and (3.17). Equations (6.3) and (6.6), coupled with (3.16), (3.17), and the orthogonality relations on the previous levels show that

$$\langle \Gamma_{nm}\Phi_{n,m},\ \tilde{\Phi}_{n-1,k} \rangle = 0, \quad k = 0, 1, \ldots, m,$$

and

$$\left\langle (e_1^m)^T \Gamma^1_{nm}\Phi_{n,m},\ w^k \begin{bmatrix} z^{n-1} \\ \vdots \\ 1 \end{bmatrix} \right\rangle = 0, \quad k = 1, 2, \ldots, m. \tag{6.7}$$

Equations (6.7) and (3.17) show

$$0 = \langle (e_1^m)^T \Gamma^1_{n,m}\Phi_{n,m},\ \overleftarrow{\tilde{\Phi}}{}^{T}_{n-1,m} \rangle = \left\langle (e_1^m)^T \Gamma^1_{nm}\Phi_{n,m},\ \begin{bmatrix} z^{n-1} \\ \vdots \\ 1 \end{bmatrix} \right\rangle.$$

The fact that $\overleftarrow{\tilde{\Phi}}^{T}_{n-1,m}$ has an invertible coefficient multiplying

$$\begin{bmatrix} z^{n-1} \\ \vdots \\ 1 \end{bmatrix}$$

has been used to obtain the second equality in the above equation. The above implies that

$$\langle \Phi_{n,m},\ \tilde{\Phi}_{n-1,k} \rangle = 0, \qquad k = 0, 1, \ldots, m,$$

which in turn implies that

$$\langle \Phi_{n,m},\ \Phi_{j,m} \rangle = 0, \qquad j = 0, 1, \ldots, n-1.$$

To show that

$$\langle \Phi_{n,m},\ \Phi_{n,m} \rangle = I_{m+1}$$

we note that (3.16), (3.17), and (3.52) imply that

$$\langle (e_1^m)^T \Gamma^1_{nm} \Phi_{n,m},\ \Gamma_{nm} \Phi_{n,m} \rangle = (e_1^m)^T \Gamma^1_{n,m} \Gamma^\dagger_{n,m}$$

and (3.32) implies that

$$\langle (e_1^m)^T \Gamma^1_{nm} \Phi_{n,m},\ (e_1^m)^T \Gamma^1_{nm} \Phi_{nm} \rangle = (e_1^m)^T \Gamma^1_{nm} (\Gamma^1_{nm})^\dagger (e_1^m).$$

Thus $\mathcal{L}$ is a positive linear functional. The orthogonality relations for the polynomials $\tilde{\Phi}_{i,j}$ now follow. □

Let $C(\mathbb{T}^2)$ denote the set of continuous functions on the bicircle; above the theorem now allows the following.

THEOREM 6.2. [illegible] $u_{i,j} \in \mathbb{C}$ [illegible] $u_{i,-j} = \bar{u}_{-i,j}$ [illegible] (6.1) [illegible] $0 \le i, j,$ [illegible] $\mu$ [illegible] $f \in C(\mathbb{T}^2)$

$$\mathcal{L}(f) = \left(\frac{1}{2\pi}\right)^2 \int_{\mathbb{T}^2} f(\theta, \phi) d\mu(\theta, \phi).$$

[illegible] From the hypotheses imposed above, Theorem 6.1 shows that $C_{n,m}$ is positive definite for all $n$ and $m$, so the result follows from Bochner's theorem [18, section 1.4.3]. □

[illegible] 6.3. The above construction gives a criterion for the existence of a one step extension of the functional. That is, given moments so that there exists a positive linear functional on $\prod^{n-1,m} \cup \prod^{n,m-1}$, any set

$$\{u_{n,m},\ u_{-n,m}\},\ u_{-n,-m} = \bar{u}_{n,m}, \quad u_{n,-m} = \bar{u}_{-n,m},$$

that satisfies (6.1) can be used to extend the functional to $\prod^{n,m}$. However it is not difficult to construct examples where no extension exists. See section 8.

**7. Two variable stable polynomials and Fejér–Riesz factorization.** In this section we study the consequences of $\mathcal{K}_{n,m} = 0$. This will make a connection with the results in [8] on stable polynomials and the Fejér–Riesz factorization theorem.

We say that a polynomial $p(z,w)$ is stable if $p(z,w)\neq 0,\ |z|\leq 1,\ |w|\leq 1$. A polynomial $p$ is of degree $(n,m)$ if

$$p(z,w)=\sum_{i=0}^{n}\sum_{j=0}^{m}k_{i,j}z^iw^j,$$

with $k_{n,m}\neq 0$. Finally we say that the polynomial $p_{n,m}$ of degree $(n,m)$ has the spectral matching property (up to $(n,m)$) if

$$\mathcal{L}(z^kw^j)=\frac{1}{(2\pi)^2}\int_{\mathbb{T}^2}\frac{z^kw^j}{|p_{n,m}(z,w)|^2}d\theta d\phi,\quad z=e^{i\theta},\ w=e^{i\phi},$$

for $|k|\leq n,\ |j|\leq m$.

LEMMA 7.1. [illegible] $\mathcal{L}$ [illegible] $\prod^{n,m}$ [illegible] $\mathcal{K}_{n,m}=0$. [illegible]

$$\begin{aligned}&\overleftarrow{\phi}^{m}_{n,m}(z,w)\overline{\overleftarrow{\phi}^{m}_{n,m}(z_1,w_1)}-\phi^{m}_{n,m}(z,w)\overline{\phi^{m}_{n,m}(z_1,w_1)}\\&\quad=(1-w\bar{w}_1)\overleftarrow{\Phi}_{n,m-1}(z,w)\overleftarrow{\Phi}^{\dagger}_{n,m-1}(z_1,w_1)\\&\qquad+(1-z\bar{z}_1)\tilde{\Phi}_{n-1,m}(z,w)^T\tilde{\Phi}^{\dagger}_{n-1,m}(z_1,w_1).\end{aligned}\tag{7.1}$$

[illegible]. If $\mathcal{K}_{n,m}=0$, then (3.16) shows that $\Gamma_{n,m}\Phi_{n,m}(z,w)=\Phi_{n,m-1}(z,w)$. Thus $\overleftarrow{\Phi}_{n,m}(z,w)\Gamma^{\dagger}_{n,m}=w\overleftarrow{\Phi}_{n,m-1}(z,w)$. Also (3.31) implies that $(\Gamma_{n,m})_{(i,i+1)}=1,\ i=1,\dots,m$ with all other entries zero. Thus we find

$$\begin{aligned}&\overleftarrow{\Phi}_{n,m}(z,w)\overleftarrow{\Phi}_{n,m}(z_1,w_1)^{\dagger}\\&\quad=\overleftarrow{\phi}^{m}_{n,m}(z,w)\overline{\overleftarrow{\phi}^{m}_{n,m}(z_1,w_1)}+\overleftarrow{\Phi}_{n,m}(z,w)\Gamma^{\dagger}_{n,m}\Gamma_{n,m}\overleftarrow{\Phi}_{n,m}(z_1,w_1)^{\dagger}\\&\quad=\overleftarrow{\phi}^{m}_{n,m}(z,w)\overline{\overleftarrow{\phi}^{m}_{n,m}(z_1,w_1)}+w\bar{w}_1\overleftarrow{\Phi}_{n,m-1}(z,w)\overleftarrow{\Phi}_{n,m-1}(z_1,w_1)^{\dagger}.\end{aligned}\tag{7.2}$$

From (4.1c) observe that

$$\begin{aligned}&\overleftarrow{\phi}^{m}_{n,m}(z,w)\overline{\overleftarrow{\phi}^{m}_{n,m}(z_1,w_1)}-z\bar{z}_1\phi^{m}_{n,m}(z,w)\overline{\phi^{m}_{n,m}(z_1,w_1)}\\&\quad=(1-w\bar{w}_1)\overleftarrow{\Phi}_{n,m-1}(z,w)\overleftarrow{\Phi}^{\dagger}_{n,m-1}(z_1,w_1)\\&\qquad+(1-z\bar{z}_1)\tilde{\Phi}_{n,m}(z,w)^T\tilde{\Phi}^{\dagger}_{n,m}(z_1,w_1).\end{aligned}$$

Using ($\tilde{3}$.16) and the fact that $\tilde{\phi}^{n}_{n,m}(z,w)=\phi^{m}_{n,m}$ gives the result. □

We now have the following.

THEOREM 7.2. [illegible] $\mathcal{L}$ [illegible] $\prod^{n,m}$ [illegible] $\mathcal{K}_{n,m}=0$. [illegible] $\overleftarrow{\phi}^{m}_{n,m}(z,w)$ [illegible]

$$\mathcal{L}(e^{-ik\theta}e^{-il\phi})=\left(\frac{1}{2\pi}\right)^2\int_{\mathbb{T}^2}\frac{e^{-ik\theta}e^{-il\phi}}{|\phi^{m}_{n,m}(e^{i\theta},e^{i\phi})|^2}d\theta d\phi,\quad |k|\leq n,\ |l|\leq m.$$

[illegible] $\pi_{n,m}(z,w)$ [illegible] $(n,m)$ [illegible] $\overleftarrow{\pi}_{n,m}$ [illegible]

$$\mathcal{L}(e^{-ik\theta}e^{-il\phi})=\left(\frac{1}{2\pi}\right)^2\int_{\mathbb{T}^2}\frac{e^{-ik\theta}e^{-il\phi}}{|\pi_{n,m}(e^{i\theta},e^{i\phi})|^2}d\theta d\phi,\quad |k|\leq n,\ |l|\leq m,$$

[illegible] $\mathcal{K}_{n,m}=0$

[illegible]. If $\mathcal{L}$ is positive definite and $\mathcal{K}_{n,m}$ is equal to zero, then Lemma 7.1 shows that $\overleftarrow{\phi}^{\,n}_{n,m}(z,w)$ satisfies (7.1). The first part of the result now follows from the proof of Theorem 2.3.1 in [8]. To show the second part, let $f(z,w)=1/|\overleftarrow{\pi}_{n,m}(z,w)|^2, |z|=1=|w|$ be the spectral density function associated with $\pi_{n,m}$. Then from (2.1.5) in [8] and Lemma 3.3 we find that

$$\overleftarrow{\Phi}_{n,m}(z,w)=[\overleftarrow{\pi}_{n,m}(z,w), w\overleftarrow{\Phi}_{n,m-1}(z,w)].$$

But this implies that $\Phi_{n,m}(z,w)=[\pi_{n,m}(z,w),\Phi_{n,m-1}(z,w)^T]^T$. Hence from (3.16) $\mathcal{K}_{n,m}=0$. □

This leads to the following alternative proof of the two-variable Fejér–Riesz theorem in [8].

THEOREM 7.3. [illegible] $f(z,w)=\sum_{k=-n}^{n}\sum_{l=-m}^{m} f_{kl}z^kw^l$ [illegible] $|z|=|w|=1$ [illegible]

$$p(z,w)=\sum_{k=0}^{n}\sum_{l=0}^{m} p_{kl}z^kw^l,$$

[illegible] $p(z,w)\neq 0$ [illegible] $|z|,|w|\le 1$ [illegible] $f(z,w)=|p(z,w)|^2$ [illegible] $\mathcal{K}_{n,m}=0$

[illegible]. For $g\in C(\mathbb{T}^2)$ let $\mathcal{L}(g)=\frac{1}{(2\pi)^2}\int_{\mathbb{T}^2}\frac{g(\theta,\phi)}{|p(e^{i\theta},e^{i\phi})|^2}d\theta d\phi$. Then $\mathcal{L}$ is a positive definite linear functional on $\mathbb{T}^2$. The necessary part of the above result now follows from Theorem 7.2. The sufficiency also follows from the above theorem and the maximal entropy condition [1]. □

An alternative approach for finding a factorization as above may be done using the notion of intersecting zeros (see [9]). Also, the question of factorizing a nonnegative trigonometric polynomial as a modulus square of an outer polynomial was addressed in [6], allowing for generalizations in the operator valued case. When such a factorization of the desired degree does not exist, one can approximate the trigonometric polynomial with one that does have the desired factorization. This question was pursued in [12].

The vanishing of $\mathcal{K}_{n,m}$ has the following geometric interpretation.

LEMMA 7.4. [illegible] $\mathcal{L}$ [illegible] $\prod^{n,m}$ [illegible] $\mathcal{K}_{n,m}=0$ [illegible] $\Phi_{n,m-1}$ [illegible] (3.3)

$$\langle\Phi_{n,m-1}, z^iw^m\rangle=0,\quad 0\le i\le n-1. \tag{7.3}$$

[illegible]. The definition of $\Phi_{n,m-1}$ shows that it is already orthogonal to $z^iw^j$, $0\le i<n,\ 0\le j\le m-1$. The remaining orthogonality conditions show that $\Phi_{n,m-1}$ is orthogonal to all of the monomials in $\tilde{\Phi}_{n-1,m}$. Thus the sufficiency part of the theorem follows from (3.22). To see the necessary part note that from the definition of $\Phi_{n,m-1}$

$$\mathcal{K}_{n,m}=\left\langle\Phi_{n,m-1},\tilde{\Phi}^{n-1}_{n-1,m}\begin{bmatrix}z^{n-1}\\ \vdots\\ 1\end{bmatrix}w^m\right\rangle, \tag{7.4}$$

with $\tilde{\Phi}^{n-1}_{n-1,m}$ an invertible matrix. Thus (7.3) follows. □

Unfortunately at this point we are unable to see what the condition $\mathcal{K}_{n,m}=0$ implies for $u_{i,j},\ |i|\le n,\ |j|\le m$, except for $u_{n,-m}=0$, which follows from (5.4). We can, however, get a partial characterization for when a positive measure on the bicircle can be written as the reciprocal of the magnitude square of a stable polynomial. We begin with the following auxiliary result.

LEMMA 7.5. [illegible] $\hat{E}_{i,j}=0$ [illegible] $K^1_{i,j}$ [illegible] $u_{i,j}=0$ [illegible] $\hat{E}_{i,j}$, $\mathcal{K}_{i,j}$ [illegible] $\mathcal{K}_{i-1,j}$ [illegible] $\hat{E}_{i,j-1}$ [illegible] $\mathcal{K}_{i,j}$, $K_{i-1,j}$ $\hat{E}_{i,j-1}$ [illegible] $u_{i,j}$ [illegible] $\hat{E}_{i,j}=0$ [illegible] $\mathcal{K}^1_{i,j}=[0,\mathcal{K}^1_{i-1,j}]$ [illegible] $\hat{\hat{E}}_{i,j}=0$ [illegible] $K^1_{i,j}$ [illegible] $\hat{\hat{E}}_{i,j}$, $\mathcal{K}_{i,j}$ [illegible] $\mathcal{K}_{i,j-1}$ [illegible] $\hat{\hat{E}}_{i,j-1}$ [illegible] $\mathcal{K}_{i,j}$, $K_{i,j-1}$ $\hat{E}_{i-1,j}$ [illegible] $u_{i,j}$ [illegible] $\hat{\hat{E}}_{i,j}=0$ [illegible] $\mathcal{K}^1_{i,j}=[0,(\mathcal{K}^1_{i,j-1})^T]^T$

[illegible] If $\hat{E}_{i,j}=0$, then (3.51) and Remark 3.9 show that the first column of $\mathcal{K}^1_{i,j}$ is zero. If $\mathcal{K}_{i-1,j}$ is equal to zero, then (3.54) shows that all of the entries of $I_{i-1,j}$ are zero except for a one in the first entry. Thus (3.50) and (3.51) imply that if $\hat{E}_{i,j}=0$, $\mathcal{K}_{i,j}=0$, and $\mathcal{K}_{i-1,j}=0$, then $\hat{E}_{i,j-1}\bar{\Gamma}^1_{i-1,j}=0$ and $\hat{E}_{i,j-1}\bar{\Gamma}_{i-1,j}=0$. Following the argument in the construction of $\hat{E}_{n,m}$ we see that $\hat{E}_{i,j-1}=0$. The above hypothesis on $\mathcal{K}_{i-1,j}$ shows that $\tilde{\Gamma}_{i-1,j}=U_{i-1}$; thus (5.6) and the fact that the first column of $\mathcal{K}^1_{i,j}$ is zero gives $\mathcal{K}^1_{i,j}=[0,\mathcal{K}^1_{i-1,j}]$. The converse statement follows from (5.8). The remaining statements follow in an analogous fashion using Proposition 3.8. ☐

LEMMA 7.6. [illegible] $\mu$ [illegible] $\mu$ [illegible]

$$d\mu(\theta,\phi)=\frac{1}{|p_{n,m}|^2}d\theta d\phi,$$

[illegible] $p_{n,m}$ [illegible] $(n,m)$ [illegible] $\overleftarrow{p}_{n,m}(z,w)$ [illegible]

$$\mathcal{K}_{i,j}=0,\ \hat{E}_{i+1,j}=0,\ \text{[illegible]}\ \hat{\hat{E}}_{n,j+1}=0,\ i\ge n, j\ge m.$$

[illegible] Suppose that $d\mu=\frac{1}{|p_{n,m}(z,w)|^2}d\theta d\phi$, with $\overleftarrow{p}_{n,m}$ stable; then the sequence

$$\{\psi_{i,j}(z,w)\}\quad \psi_{i,j}(z,w)=z^{i-n}w^{j-m}p_{n,m}(z,w),\ i\ge n,\ j\ge m,$$

is a set of polynomials with degrees $(i,j)$, respectively, such that $\overleftarrow{\psi}_{i,j}=\overleftarrow{p}_{n,m}$ are stable and have the spectral matching property. Thus Theorem 7.2 implies that $\mathcal{K}_{i,j}=0$ for $i\ge n,\ j\ge m$. Since $\overleftarrow{\psi}_{i+1,j}=\overleftarrow{\psi}_{i,j}$, $i\ge n,\ j\ge m$, we see from (2.1.5) in [8] that $\overleftarrow{\Phi}_{i+1,j}=\overleftarrow{\Phi}_{i,j}$ for $i\ge n,\ j\ge m$. This implies that $A_{i+1,j}=I_{j+1}$ so that (3.14) shows that $\hat{E}_{i+1,j}=0$, $i\ge n, j\ge m$. Since $\overleftarrow{\tilde{\phi}}{}^i_{i,j+1}=\overleftarrow{\tilde{\phi}}{}^i_{i,j}$, $i\ge n,\ j\ge m$, the preceding argument shows that $\tilde{E}_{i,j+1}=0$, $i\ge n, j\ge m$. This proves the necessary part.

To prove sufficiency note that if $\mathcal{K}_{i,j}=0, i\ge n,\ j\ge m$, there exist polynomials $\psi_{i,j}$ of degree $(i,j)$ where $\overleftarrow{\psi}_{i,j}$ is a stable polynomial which has the spectral matching property. In order to show that $\overleftarrow{\psi}_{i,j}=\overleftarrow{\psi}_{n,m}$ we note that since $\hat{E}_{i+1,j}=0$ (3.14) implies that $\Phi_{i+1,j}=\Phi_{i,j}$, $i\ge n,\ j\ge m$. Furthermore $\hat{\hat{E}}_{n,j+1}=0$, $j\ge m$, implies that $\tilde{\Phi}_{n,j+1}=\tilde{\Phi}_{n,m}$. Since $\psi_{i,j}=\phi^j_{i,j}=\tilde{\phi}^i_{i,j}$ for $i\ge n,\ j\ge m$, the result follows. ☐

The conditions on $\mathcal{K}_{i,j}$, $E_{i,j}$, and $\tilde{E}_{n,j}$ given in Lemma 7.6 are not optimal since they are redundant. Some of this redundancy is removed in the next theorem.

THEOREM 7.7. [illegible] $\mu$ [illegible] $\mu$ [illegible] $d\mu=\frac{d\theta d\phi}{|p_{n,m}|^2}$ [illegible] $p_{n,m}$ [illegible] $(n,m)$ [illegible] $\overleftarrow{p}_{n,m}$ [illegible]

(a) $\mathcal{K}_{n,j} = 0$ $\tilde{\hat{\hat{E}}}_{n-1,j+1} = 0$ [illegible] $u_{n,j+1} = 0$ $j \geq m$.
(b) $\mathcal{K}_{i,m} = 0$ $\hat{E}_{i,m-1} = 0$ [illegible] $u_{i,m} = 0$ $i > n$.
(c) $u_{|i|,j} = 0, i > n,\ j > m$

[illegible] 7.8. Equation (5.4) and Lemma 7.5 show that $u_{-n,j}$, $u_{-i,m}$, $u_{n-1,j+1}$, and $u_{i,m-1}$ are also equal to zero for $j \geq m, i > n$.

[illegible] If $\mu$ has the form indicated in the hypotheses, then Lemma 7.6 says that $\mathcal{K}_{i,j} = 0,\ i \geq n,\ j \geq m$, which coupled with (5.4) implies that $u_{-i,j} = 0$, $i \geq n,\ j \geq m$; the remaining conditions on the coefficients follow from Lemma 7.5. If the coefficients obey (a)–(c), then Lemma 7.5 shows that $\hat{E}_{i+1,m}$ and $\hat{\hat{E}}_{n,j+1}$ are equal to zero for $i \geq n$ and $j \geq m$. Since $\hat{E}_{n,m+1} = 0$, $\hat{\hat{E}}_{n+1,m} = 0$, and by hypothesis $u_{-n-1,m+1} = 0$, (5.5) shows that $\mathcal{K}_{n+1,m+1} = 0$. With this Lemma 7.5 shows that $\hat{E}_{n+1,m+1} = 0$ and $\hat{\hat{E}}_{n+1,m+1} = 0$. The result now follows by induction. ☐

It is possible to modify slightly the hypotheses of Theorem 7.7 to obtain a statement just on the coefficients in the recurrence formulas.

THEOREM 7.9. [illegible] $u_{i,j}$ [illegible] (6.1) [illegible] $0 \leq i \leq n$, $|j| \leq m$ [illegible] 7.7 [illegible] $f \in C(\mathbb{T}^2)$

$$\mathcal{L}(f) = \left(\frac{1}{2\pi}\right)^2 \int_{\mathbb{T}^2} f(\theta, \phi) d\mu(\theta, \phi),$$

[illegible] $\mu$ [illegible] $d\mu = \frac{d\theta d\phi}{|p_{n,m}|^2}$ [illegible] $p_{n,m}$ [illegible] $(n, m)$ [illegible] $\overleftarrow{p}_{n,m}$ [illegible]

[illegible] From Theorem 6.1 there exists a positive definite linear functional on $\prod^{n,m}$ with the above parameters, and from Theorem 7.2 the functional has the representation

$$\mathcal{L}(e^{-ik\theta}e^{-il\phi}) = \left(\frac{1}{2\pi}\right)^2 \int_{\mathbb{T}^2} \frac{e^{-ik\theta}e^{-il\phi}}{|p_{n,m}(e^{i\theta}e^{i\phi})|^2} d\theta d\phi, \quad |k| \leq n,\ |l| \leq m,$$

with $p_{n,m}$ a polynomial of degree $(n, m)$ with $\overleftarrow{p}_{n,m}$ stable. The result now follows from Theorem 7.7. ☐

**8. Examples.** We now give some examples that illustrate various aspects of the results presented earlier. We begin with the case $n = 1, m = 1$, with $u_{0,0} = 1$, $\mathcal{K}_{1,1} = u_{-1,1} = 0$, and $\mathcal{K}^1_{1,1} = \bar{u}_{1,1}$. From Theorem 6.1 we see that we must choose $|u_{0,1}| < 1$ and $|u_{1,0}| < 1$. Since $\mathcal{K}_{1,1} = 0$ the only remaining condition for $\mathcal{L}$ to be a positive linear functional on $\prod^{1,1}$ is for $e^{1\,T}_1 \tilde{H}^3_{1,1} e^1_1 < 1$. From (5.9) we see that $\Gamma^1_{1,1} U^T_1 = I_{1,0} \hat{\hat{E}}_{1,1} (I^1_{1,0})^T$. The construction of $I_{1,0}$, $I^1_{1,0}$, and (5.8) shows that $e^{1\,T}_1 \tilde{H}^3_{1,1} e^1_1 < 1$ is given by

$$a|u_{1,1}|^2 + b(\bar{u}_{1,1}\bar{u}_{0,1}u_{1,0} + u_{1,1}u_{0,1}\bar{u}_{1,0}) + c < 1,$$

with $a = \frac{1-|u_{0,1}u_{1,0}|^2}{1-|u_{1,0}|^2}$, $b = \frac{\sqrt{1-|u_{0,1}|^2}}{\sqrt{1-|u_{1,0}|^2}}$, and $c = |u_{0,1}|^2$. This simplifies to

$$|\hat{u}_{1,1}| < 1,$$

where

$$\hat{u}_{1,1} = \frac{(1 - |u_{0,1}u_{1,0}|^2)u_{1,1}}{\sqrt{1 - |u_{0,1}|^2}\sqrt{1 - |u_{1,0}|^2}} + u_{0,1}\bar{u}_{1,0}.$$

Thus from Theorems 6.1 and 7.2 we see that with $u_{0,0} = 1$

$$\mathcal{L}(e^{-ik\theta}e^{-ij\phi}) = \left(\frac{1}{2\pi}\right)^2 \int_{\mathbb{T}^2} \frac{e^{-ik\theta}e^{-ij\phi}}{|\phi_{1,1}(e^{i\theta}, e^{i\phi})|^2} d\theta d\phi, \ |k| \le 1, \ |j| \le 1,$$

where $\phi_{1,1}$ constructed using (3.16) and the top row of (3.17) is a polynomial of degree (1,1) with $\overleftarrow{\phi}_{1,1}$ stable if and only if $|u_{0,1}| < 1$, $|u_{1,0}| < 1$, $u_{-1,1} = 0$, and $|\hat{u}_{1,1}| < 1$. Furthermore if we set $u_{j,0}$, $u_{0,j}$, $u_{i,j}$ equal to zero for $i > 1, |j| > 1$, then Theorem 7.9 shows that the above representation for $\mathcal{L}$ extends to all continuous functions on $\mathbb{T}^2$.

We can also use the previous results to investigate contractive Toeplitz matrices. In this case we find

$$C_{1,1} = \begin{bmatrix} I & C_{-1} \\ C_1 & I \end{bmatrix}, \tag{8.1}$$

where $C_{-1} = C_1^\dagger$ is a $2 \times 2$ Toeplitz matrix. In this case $u_{0,0} = 1$ and $u_{0,1} = 0$ so that $\tilde{E}_{0,1} = 0$, $\tilde{A}_{0,1} = 1$. Since $\mathcal{K}_{1,1} = u_{-1,1}$, we find $\Gamma_{1,1} = [0, \sqrt{1 - |u_{-1,1}|^2}]$. This plus the computation of $\tilde{\Gamma}^1_{1,0}$ described in the construction of $\mathcal{L}$ yields

$$\begin{aligned} I &= (e_1^1)^T \tilde{H}^3_{1,1} (\tilde{H}^3_{1,1})^\dagger (e_1^1) \\ &= (1 + d)|u_{1,1}|^2 + d(u_{1,1}u_{-1,1} + \bar{u}_{1,1}\bar{u}_{-1,1}) + d|u_{-1,1}|^2 < 1, \end{aligned} \tag{8.2}$$

where

$$d = \frac{|u_{1,0}|^2}{(1 - |u_{1,0}|^2)(1 - |u_{-1,1}|^2)}.$$

By completing the square this can be simplified to

$$|\hat{u}_{1,1}| < 1,$$

where

$$\hat{u}_{1,1} = (1 + d)\sqrt{1 - |u_{1,0}|^2} u_{1,1} + d_1 \bar{u}_{-1,1},$$

and

$$d_1 = \frac{|u_{1,0}|^2}{(1 - |u_{-1,1}|^2)\sqrt{1 - |u_{1,0}|^2}},$$

which puts constraints on $u_{-1,1}$. Thus we find that the conditions for $\mathcal{L}$ to be a positive linear functional and hence $C_1$ to be a contractive Toeplitz matrix are $|u_{1,0}| < 1$, $|u_{-1,1}| < 1$, and $|\hat{u}_{1,1}| < 1$. These constraints may not be strong enough to allow $\mathcal{L}$ to be extended. To see this suppose $n = 1, m = 2$, $u_{0,2} = 0$, and $u_{1,0} = 0$. It is not difficult to see then that $\hat{E}_{1,1} = \operatorname{diag}(\bar{u}_{1,1}, u_{-1,1})$. With $u_{1,0} = 0$ the constraint on $\hat{u}_{1,1}$ above reduces to $|u_{1,1}| < 1$. However,

$$K_{1,2} = \begin{pmatrix} \frac{u_{-1,1}}{(1-|u_{1,1}|^2)^{1/2}} \\ \frac{u_{-1,2}}{(1-|u_{-1,1}|^2)^{1/2}} \end{pmatrix},$$

so we see that in order for $K_{1,2}$ to be a contraction $\frac{|u_{-1,1}|}{\sqrt{1-|u_{1,1}|^2}} < 1$, which may not be satisfied.

# PARALLEL BIDIAGONALIZATION OF A DENSE MATRIX*

CARLOS CAMPOS[†], DAVID GUERRERO[‡], VICENTE HERNÁNDEZ[‡], AND RUI RALHA[§]

**Abstract.** A new stable method for the reduction of rectangular dense matrices to bidiagonal form has been proposed recently. This is a one-sided method since it can be entirely expressed in terms of operations with (full) columns of the matrix under transformation. The algorithm is well suited to parallel computing and, in order to make it even more attractive for distributed memory systems, we introduce a modification which halves the number of communication instances. In this paper we present such a modification. A block organization of the algorithm to use level 3 BLAS routines seems difficult and, at least for the moment, it relies upon level 2 BLAS routines. Nevertheless, we found that our sequential code is competitive with the LAPACK DGEBRD routine. We also compare the time taken by our parallel codes and the ScaLAPACK PDGEBRD routine. We investigated the best data distribution schemes for the different codes and we can state that our parallel codes are also competitive with the ScaLAPACK routine.

## 1. Introduction.

The problem of computing the singular value decomposition (SVD) of a matrix is one of the most important operations in numerical linear algebra and is employed in a variety of applications. The SVD is defined as follows.

For any rectangular matrix $A \in \mathbb{R}^{m\times n}$ (we will assume that $m \geq n$), there exist two orthogonal matrices $U \in \mathbb{R}^{m\times m}$ and $V \in \mathbb{R}^{n\times n}$ and a matrix $\Sigma = \left[\begin{smallmatrix}\Sigma_A\\0\end{smallmatrix}\right] \in \mathbb{R}^{m\times n}$, where $\Sigma_A = \operatorname{diag}(\sigma_1, \ldots, \sigma_n)$ is a diagonal matrix, such that $A = U\Sigma V^t$. The values $\sigma_1 \geq \cdots \geq \sigma_n \geq 0$ are called the singular values of $A$.

To compute the SVD of a dense matrix, an important class of methods starts with [illegible] [11], [12], [14], [15], [19], [20], [21], reducing $A$ to upper bidiagonal form $B \in \mathbb{R}^{n\times n}$, from which the singular values are computed in an iterative manner [2], [16], [18], [22].

The Householder bidiagonalization computes $U_B \in \mathbb{R}^{m\times m}$ and $V_B \in \mathbb{R}^{n\times n}$, as products of Householder matrices, such that

$$A = U_B \begin{bmatrix} B \\ 0 \end{bmatrix} V_B^t, \qquad \text{where} \qquad B = \begin{bmatrix} \alpha_1 & \beta_2 & & \\ & \alpha_2 & \ddots & \\ & & \ddots & \beta_n \\ & & & \alpha_n \end{bmatrix}. \tag{1}$$

The classical method for producing this decomposition is a two-sided algorithm which employs both premultiplication and postmultiplication by Householder matri-

ces. In order to establish an algorithm which is better suited to parallel implementation than the standard bidiagonalization method, Ralha [25], [26], and Ralha and Mackiewicz [27] proposed a new technique that uses only multiplication on the right side of $A$ by Householder matrices. Inspired by Ralha's method, Barlow, Bosner, and Drmač [4] proposed a new stable method for the reduction of rectangular dense matrices to the bidiagonal form.

In this paper we present both methods and propose a modification to the Barlow method which halves the number of communication instances in the parallel implementation, making the algorithm even more attractive for distributed memory systems.

This paper is organized as follows. In section 2 we describe the new bidiagonalization methods. Section 3 deals with the sequential and parallel implementations, using LAPACK [1] and ScaLAPACK [8] routines. In section 4 we analyze the experimental results of our numerical tests. Section 5 summarizes our conclusions and future work.

## 2. New bidiagonalization methods.

### 2.1. Ralha bidiagonal reduction.

Given a rectangular dense matrix $A \in \mathbb{R}^{m\times n}$, the bidiagonalization method proposed by Ralha is comprised of two stages. The first stage consists of a sequence of $n-2$ Householder transformations

$$A_r = A_{r-1} \cdot \mathrm{diag}\,(I_r, H_r) \qquad (r = 1, \ldots, n-2), \tag{2}$$

where $I_r$ is the identity matrix of order $r$, $A_0 = A$, and the columns $a_i$ and $a_j$ of the final matrix $A_{n-2}$ satisfy

$$a_i^t a_j = 0 \qquad \text{for} \qquad |i-j| > 1. \tag{3}$$

This can be understood as an implicit reduction of the symmetric semidefinite positive matrix $A^tA$ to tridiagonal form. In the $r$th step, the construction of the Householder vector $v_r$ in

$$H_r = I_{n-r} - \frac{2}{v_r^t v_r} v_r v_r^t \tag{4}$$

requires the computation of $n-r$ dot products involving the appropriate columns of $A_{r-1}$.

Having produced $A_{n-2}$, the second stage is a variant of the Gram–Schmidt orthogonalization method that produces the factorization $A_{n-2} = QB$, where $B$ is the required upper bidiagonal matrix.

Representing by $a_i$ and $q_i$ the columns of $A_{n-2}$ and $Q$, respectively, we have

$$\begin{bmatrix} a_1 \cdots & a_i \cdots & a_n \end{bmatrix} = \begin{bmatrix} q_1 \cdots & q_i \cdots & q_n \end{bmatrix} \begin{bmatrix} \alpha_1 & \beta_2 & & & & \\ & \alpha_2 & \ddots & & & \\ & & \ddots & \beta_i & & \\ & & & \alpha_i & \ddots & \\ & & & & \ddots & \beta_n \\ & & & & & \alpha_n \end{bmatrix} \tag{5}$$

with

$$q_1 = \frac{a_1}{\alpha_1}, \qquad q_i = \frac{a_i - \beta_i q_{i-1}}{\alpha_i} \quad (i = 2, \ldots, n)\,. \tag{6}$$

Each $\beta_i$ is chosen to make $q_i$ orthogonal to $q_{i-1}$, and each $\alpha_i$ is such that $\|q_i\|_2 = 1$; with these conditions, we get from (6)

$$\begin{aligned} \alpha_1 &= \|a_1\|_2\,, \\ \beta_i &= a_i^t q_{i-1} \quad (i = 2, \ldots, n)\,, \\ \alpha_i &= \|a_i - \beta_i q_{i-1}\|_2 \quad (i = 2, \ldots, n)\,. \end{aligned} \tag{7}$$

The first stage of this method is perfectly stable in the sense that the computed $\widetilde{A}_{n-2}$ satisfies

$$\widetilde{A}_{n-2} = (A + E)P, \tag{8}$$

where $P$ is exactly orthogonal and

$$\|E\|_2 \leq g(m, n)\varepsilon_M \|A\|_2 \tag{9}$$

for some modestly growing function $g(m, n)$ and machine epsilon $\varepsilon_M$ [24, pp. 94–96]. Furthermore, if $A = DX$, where $D$ is diagonal and $cond(X) \ll cond(A)$, then these one-sided orthogonal transformations preserve the small singular values better than two-sided transformations [10].

It may happen that some nonadjacent columns of $\widetilde{A}_{n-2}$ are not orthogonal to working precision[1] and, even when all those columns are numerically orthogonal, the process of producing a bidiagonal $B$ from $\widetilde{A}_{n-2}$ may bring trouble. To give an insight into the problem, consider the following triangular matrix:

$$R = \begin{bmatrix} 1 & 1 & 0 & 0 & 0 \\ 0 & 10^{-9} & 1 & 10^{-9} & 10^{-7} \\ 0 & 0 & 10^{-3} & 10^{-6} & -10^{-4} \\ 0 & 0 & 0 & 1 & 10^{-11} \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix}.$$

We have

$$R^t R = \begin{bmatrix} 1 & 1 & 0 & 0 & 0 \\ 1 & 1 + 10^{-18} & 10^{-9} & 10^{-18} & 10^{-16} \\ 0 & 10^{-9} & 1 + 10^{-6} & 2 \times 10^{-9} & 0 \\ 0 & 10^{-18} & 2 \times 10^{-9} & 1 + O(10^{-12}) & O(-10^{-10}) \\ 0 & 10^{-16} & 0 & O(-10^{-10}) & 1 + O(10^{-8}) \end{bmatrix},$$

which differs from a tridiagonal matrix by quantities not larger than $10^{-16}$. If $A = QR$, with $Q$ orthogonal, then $A^t A = R^t R$ and the nonadjacent columns of $A$ are orthogonal to working precision; however, from the uniqueness of the QR decomposition, it follows that there is no bidiagonal $B$ satisfying $A = QB$; in other words, small perturbations outside the tridiagonal band of $A^t A$ cause much larger (as large as $O(10^{-4})$ in this case) perturbations in $B$; i.e., the problem is ill-conditioned.

---

[1] See [26] for an example: the Lauchli matrix $L(n, \mu)$ with $n = 7$ and $\mu = \varepsilon_M$.

**2.2. Barlow bidiagonal reduction.** Barlow, Bosner, and Drmač [4] recently proposed a stable algorithm which consists, essentially, in interleaving the two stages of Ralha's method. More precisely,

1. the vector $q_r$ is computed immediately after applying the Householder transformation $H_r$; and
2. the Householder vector used in the transformation $H_{r+1}$ is computed from $x_r = A\left(:, r+1:n\right)^t q_r$.

Those authors also noted that the computation of the dot product $\beta_r = q_{r-1}^t A\left(:, r\right)$ may be avoided (this is also the case with Ralha's algorithm); in [4], an extensive error analysis of the proposed algorithm is carried out which shows that the method is always able to compute an upper bidiagonal matrix $B$ in a backward stable manner. That is, we have, for each $k = 1, \ldots, n$,

$$|\sigma_k(B) - \sigma_k(A)| \leq f(m,n)\varepsilon_M \left\|A\right\|_2 + O\left(\varepsilon_M^2\right) \tag{10}$$

for some modestly growing function $f(m,n)$. As was already the case with Ralha's bidiagonalization, there are ill-conditioned matrices where this algorithm obtains small relative errors for all the singular values [26], [10]. Furthermore, the orthogonality of the columns of $U$ is similar to that of the matrix $Q$ in the QR factorization by the modified Gram–Schmidt method [6], [7]; that is, $U$ may be far from orthogonal (see [4, Example 3.1]). Nevertheless, the leading left singular vectors of $A$ can be recovered with good orthogonality (see [4, Corollary 3.20]).

The algorithm may be stated simply as follows (for a more complete statement see [4]).

Algorithm 1 (Barlow bidiagonal reduction).

```
[illegible] $r = 1 : n-2$
    $\alpha_r = \left\|A\left(:, r\right)\right\|_2$
    $q_r = \frac{A(:,r)}{\alpha_r}$
    $x_r = A\left(:, r+1:n\right)^t q_r$
    [illegible] $H_r$ [illegible] $H_r^t x_r = \beta_{r+1} e_1$
    $A\left(:, r+1:n\right) = A\left(:, r+1:n\right) H_r$
    $A\left(:, r+1\right) = A\left(:, r+1\right) - \beta_{r+1} q_r$

[illegible]
$\alpha_{n-1} = \left\|A\left(:, n-1\right)\right\|_2$
$q_{n-1} = \frac{A(:,n-1)}{\alpha_{n-1}}$

$\beta_n = q_{n-1}^t A\left(:, n\right)$
$A\left(:, n\right) = A\left(:, n\right) - \beta_n q_{n-1}$
$\alpha_n = \left\|A\left(:, n\right)\right\|_2$
$q_n = \frac{A(:,n)}{\alpha_n}$
```

**2.3. Modified Barlow bidiagonal reduction.** The advantages of one-sided transformations for parallel bidiagonalization on a multiprocessor system with distributed memory were first discussed in [25]. The best data decomposition consists in assigning to each one of $p$ processors a number of rows of the matrix under transformation, that is, a segment of length $m/p$ of each column (we are assuming, for simplicity, that $p$ is a divisor of $m$; if this is not the case, then each processor should get either $floor(m/p)$ or $floor(m/p) + 1$ rows). According to the ideas proposed in [25], in the $r$th step, each processor gets a copy of the entire vector $x_r$ and computes its own copy of the corresponding Householder vector. So, there is some redundancy in the computation, but its negative effect in the overall efficiency is not dramatic when $m/p$ is large (see [25]). The reward for this approach is two-fold: the load balancing is optimal and interprocessor communication is required only for the $n-r+1$ dot products involved in the computation of the norm $\alpha_r$ and the vector $x_r$.

Following this strategy, in the parallel implementation of Barlow's method, a communication event, involving all processors, is required to compute $\alpha_r$ alone. Then, a normalization is carried out to produce $q_r$, and this will be followed by a second communication event involving the processors in the computation of the $n-r$ dot products $x_r = A\left(:, r+1:n\right)^t q_r$.

These two communication events may be reduced to only one if we postpone the normalization of the $r$th column of $A_r$; that is, the processors cooperate in the global task of computing the $n-r+1$ dot products $x_r = A\left(:, r:n\right)^t A\left(:, r\right)$ and, from these, each processor will compute locally $\alpha_r = \sqrt{x_r\left(1\right)}$, where $x_r\left(1\right) = A\left(:, r\right)^t A\left(:, r\right)$, and the local segment of $q_r = A\left(:, r\right)/\alpha_r$. Observe that $x_r(2:n-r+1)$ differs from the vector $x_r$ computed in Barlow's method by a factor equal to $\alpha_r$, but there is no need to perform a scaling of $x_r(2:n-r+1)$ since the resulting Householder reflector in (4) is invariant under such a scaling. However, in the computation of the off-diagonal element we must take into account that the relation

$$\beta_{r+1} = \frac{\|x_r(2:n-r+1)\|_2}{\alpha_r} \tag{11}$$

holds in each step.

An essential ingredient in the proof presented in [4] for the error bound given in (10) is the fact that, in each step, the computed $A_r$ is the exact product $(A_{r-1}+E_r)\cdot \operatorname{diag}\left(I_r, H_r\right)$, where $H_r$ is the exact Householder reflector corresponding to the vector $x_r$ of the inner products and $\|E_r\|_2 \leq \quad (\varepsilon_M)\,\|A_{r-1}\|_2$. This matrix $E_r$ encapsulates the errors in the approximation $\hat{v}_r$ computed for the exact vector $v_r$ and also the errors produced in the update $A_{r-1}\cdot \operatorname{diag}(I_r, \hat{H}_r)$, with $\hat{H}_r = I_{n-r} - \frac{2}{\hat{v}_r^t\hat{v}_r}\hat{v}_r\hat{v}_r^t$. In the modified method, a slightly different approximation $\tilde{v}_r$ will be produced (for a detailed error analysis in the computation of the Householder vector see [30, pp. 152–157]), but, similarly to $\hat{v}_r$, $\tilde{v}_r$ defines a Householder reflector, say, $\tilde{H}_r$, that is very close to the exact one; i.e., we have $\|\tilde{H}_r - H_r\|_2 = \quad (\varepsilon_M)$. We therefore claim that the error analysis given in [4] also applies to our modified method.

Our proposal does not change the arithmetic complexity of Barlow's method and does not reduce the volume of data to be transferred but halves the number of communication events, therefore reducing the overhead caused by the latency in the communications. The total cost of communication depends upon the parallel computation of the inner products only; in [25] it is shown that, on a simple chain of processors, this cost is approximately given by

$$p\frac{n^2}{2}\left(t_{flop} + 2t_{com}\right), \tag{12}$$

where $t_{flop}$ represents the time taken by one floating point operation and $t_{com}$ stands for the time required to pass a floating point number from one processor to another. The factor $p$ in (12) essentially reflects the diameter of the network and may be replaced by $\sqrt{p}$ in the case of a square grid.

The computation of $\alpha_{n-1}$ and $\beta_n$ may also be arranged in a way that saves one communication event in the parallel implementation. As in the previous steps, we may use communication to get $x_{n-1} = A\left(:, n-1:n\right)^t A\left(:, n-1\right)$ in each processor;

then, we have

$$\alpha_{n-1} = \sqrt{x_{n-1}(1)} \qquad \text{and} \qquad \beta_n = x_{n-1}(2)/\alpha_{n-1}. \tag{13}$$

In practical implementations of these algorithms, $q_r$ may overwrite $A(:,r)$ to reduce the volume of the storage required. In the next section we do so.

## 3. Sequential and parallel implementations.

In this section we describe the methodology used to develop our sequential and parallel implementations. The same methodology was applied to all implementations, but from now on we will refer only to the sequential and parallel implementations of the modified Barlow method.

In order to obtain high portability and efficiency, all our implementations use, as much as possible, LAPACK and ScaLAPACK routines. It must be stressed that our implementations rely on level 2 BLAS routines [17]. A block organization of the Barlow method has been under development by Bosner and Barlow (see [9]), who have reported significant reduction in the execution time of the sequential algorithm, depending upon the size of the matrices. However, those authors also found that for parallel processing the nonblocked algorithm is preferred due to large overheads in the block version.

From our sequential codes we obtained the corresponding parallel codes by translating the BLAS and the LAPACK routines into calls of the equivalent parallel routines of PBLAS [13] and ScaLAPACK. This translation process takes into account the data distribution and the corresponding rules to convert sequential LAPACK-based programs into parallel ScaLAPACK-based programs.

Our parallel implementation of the modified Barlow method, including the corresponding PBLAS and ScaLAPACK routines, is stated as follows.

Algorithm 2 (parallel implementation).

```
[illegible]                                                        [illegible]
[illegible] $x_r$                                                  [illegible]
[illegible] $r = 1 : n-2$
    $x_r = A(:,r:n)^t A(:,r)$                                      [illegible]
    $\alpha_r = \sqrt{x_r(1)}$
    $A(:,r) = \frac{A(:,r)}{\alpha_r}$                             [illegible]
    [illegible] $H_r$ [illegible] $H_r^t x_r(2:n-r+1) = \phi_r e_1$    [illegible]
    $A(:,r+1:n) = A(:,r+1:n) H_r$                                  [illegible]
    $\beta_{r+1} = \frac{\phi_r}{\alpha_r}$

$\alpha_{n-1} = \sqrt{x_{n-1}(1)}$
$\beta_n = x_{n-1}(2)/\alpha_{n-1}$
$A(:,n-1) = \frac{A(:,n-1)}{\alpha_{n-1}}$                         [illegible]
$A(:,n) = A(:,n) - \beta_n A(:,n-1)$                               [illegible]
$\alpha_n = \|A(:,n)\|_2$                                          [illegible] 2
$A(:,n) = \frac{A(:,n)}{\alpha_n}$                                 [illegible]
```

With the ScaLAPACK data distribution, which follows a two-dimensional block cyclic scheme, we manage to assign $m/p$ rows (not contiguous) to each processor by reducing the grid to a single column of processors. We emphasize that, as a direct consequence of the use of the routines from ScaLAPACK, we have not fully implemented the parallel algorithm as presented in the previous section. In our implementation, the computation of the inner products is carried out with PxGEMV and, as follows from the array descriptor that we have used, the resulting vector $x_r$ is stored on a single processor (processor 0, say). As a consequence of this distribution, during the execution of PxLARFG, the computation of $\phi_r$ is carried out on processor 0 only and no communication is required. The application of the Householder reflectors (with PxLARF) requires communication to make the value $\phi_r$ available on each processor.

Finally, we note that, in applications where it is not necessary to produce a matrix $Q$ with normalized columns, we may change Algorithm 2 in a way that reduces the number of floating point divisions. This consists of removing the scaling operations $A(:,r) = A(:,r)/\alpha_r$ (PxSCAL) for $r = 1, \ldots, n$ and rewriting the PxAXPY operations as $A(:,r+1) = A(:,r+1) - \frac{\beta_{r+1}}{\alpha_r} A(:,r)$ for $r = 1, \ldots, n-1$, with a total savings of $mn - (n-1)$ divisions.

## 4. Experimental results.

**4.1. Introduction.** In this section we analyze the execution times of our implementations, obtained on a cluster with 20 biprocessor nodes where each node is a Pentium Xeon at 2GHz, 1GB of RAM, and Redhat Linux operating system. The nodes are connected through a SCI network, organized in a $4 \times 5$ 2D torus grid. Each node has been treated as a single processor machine and the biprocessor feature has not been exploited. Unfortunately, only 10 nodes of the cluster were available for our computational tests.

All experiments were performed using Fortran 90 and IEEE standard double precision floating point arithmetic [23]. As already said, we made use of LAPACK and ScaLAPACK routines in order to ensure a high level of portability and efficiency of our implementations. The communications in ScaLAPACK were carried out using Scali MPI [28], which is an optimized implementation of the standard MPI communication library [29] for SCI networks.

In all experiments, the execution times were measured in seconds, and the test matrices (rectangular matrices with sizes ranging from $10000 \times 1000$ to $10000 \times 4500$ and square matrices with sizes ranging from $1000 \times 1000$ to $4500 \times 4500$) were generated randomly.

The execution times that will be reported are strictly for the process of producing the bidiagonal; i.e., no accumulation of the orthogonal transformations was carried out.

**4.2. Sequential codes.** In Figure 1 we compare the execution times of the LAPACK routine DGEBRD and our sequential codes for the case of rectangular matrices. If $m$ is much larger than $n$, it is more efficient to carry out an initial QR decomposition [11]. In our tests we have not done this, mainly because PDGEBRD (from ScaLAPACK) also does not perform such a decomposition. As can be seen, the new bidiagonalization methods have similar execution times, and, in general, our sequential codes are competitive with DGEBRD.

The number of flops involved in the new methods is approximately equal to $3mn^2$ flops and the operation count for DGEBRD is $4mn^2 - 4/3n^3$; therefore, the new methods require fewer flops whenever $m > \frac{4}{3}n$ [4], [25]. For $m$ fixed, the new methods are less competitive as $n$ grows. For $m = 10000$ and $n = 4000$, DGEBRD uses about $\frac{4}{3}$ the number of flops required by the new method. However, looking at Figure 1, we see that the execution times are almost equal. This is because DGEBRD applies block updates of the form $A - UX^t - YV^t$ using two calls to the level 3 BLAS routine DGEMM; these calls account for about half the work [1] and make the code more

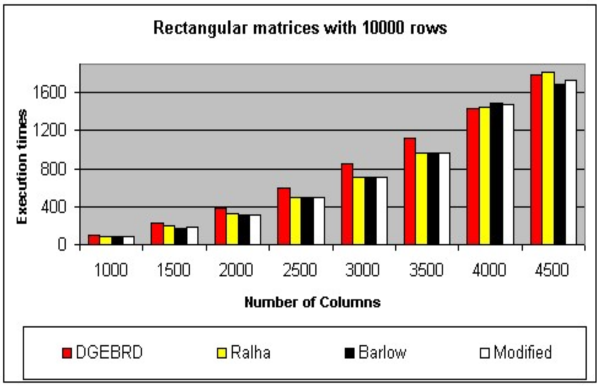

Fig. 1. *DGEBRD versus new methods (rectangular matrices).*

efficient. The new methods are based upon level 2 BLAS routines; i.e., the ratio of floating point operations to memory references is lower.

**4.3. Parallel codes.** In this section we compare, in terms of the execution times measured, the ScaLAPACK routine PDGEBRD and our parallel codes. We have observed that there is a nonnegligible influence of the sizes of the rectangular grid used for the configuration of the processors. Unlike the ScaLAPACK routine, our parallel implementations perform better on a grid with a single column. In the following comparisons we will always use the best execution time.

In Figure 2 we report the execution times of the Barlow and the modified Barlow parallel codes running on 2, 4, 6, 8, and 10 processors for rectangular matrices. For each $n$ (number of columns), there are five pairs of consecutive bars, one pair for each value of $p$ (number of processors). On each pair, the dark bar corresponds to the Barlow method, and the white bar corresponds to the modified method. The gain that can be observed for the parallel implementation of the modified method is not impressive. This is not surprising because our computational platform has efficient communication, as one can conclude from the high efficiency obtained for all the parallel algorithms. Since the modified method reduces the communication overheads, we expect the gain to be much more significant on a system where the cost of the communications is heavier (a loosely coupled network of personal computers, for example).

Figure 3 allows a comparison of the execution times of PDGEBRD and the modified method on 2, 4, 6, 8, and 10 processors. Again, for each $n$, there are five pairs of consecutive bars, dark and white, the dark bar corresponding to PDGEBRD, and the white bar to the modified method. As can be seen, on two processors our code is slower than PDGEBRD, but the situation is reversed as we increase the number of processors. At this point, in our experiments, we were very sorry to not have the opportunity to use many more processors since we do believe that the new method has better scalability than the ScaLAPACK routine. In section 5 we justify this conviction with some arguments.

In Figure 4, for each $n$, we give the efficiency obtained for PDGEBRD (dark) and for the parallel code of the modified Barlow algorithm (white), running on 2, 4, 6, 8,

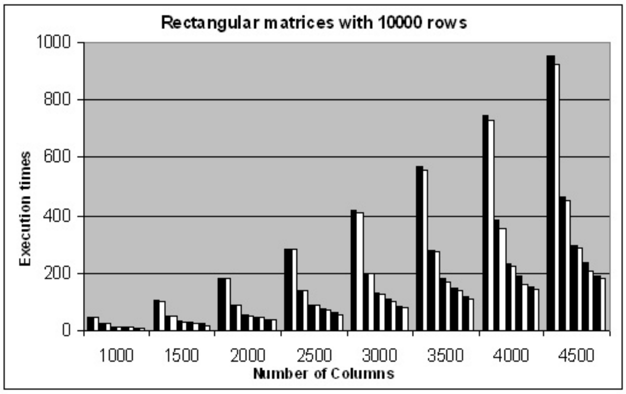

FIG. 2. *Barlow's versus modified (rectangular matrices).*

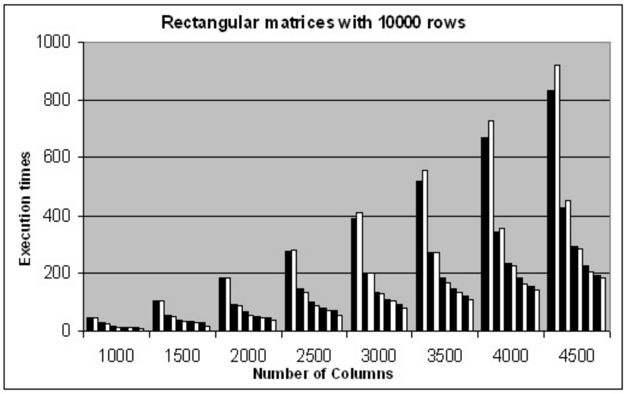

FIG. 3. *PDGEBRD versus modified (rectangular matrices).*

and 10 processors. The efficiency is computed according to the usual formula:

$$\text{Efficiency} = \frac{\text{Execution time on a single processor}}{p \times (\text{Execution time on } p \text{ processors})}. \tag{14}$$

Finally, to illustrate the influence of the processors grid, we ran PDGEBRD on a linear array of processors. This causes a significant degradation of the efficiency of PDGEBRD (compare the dark bars for efficiency in Figures 4 and 5), and, in this case, the new code is clearly more efficient.

**5. Conclusions and future work.** Inspired by an algorithm proposed by one of us, Barlow, Bosner, and Drmač recently presented a backward stable method for the reduction of a matrix to bidiagonal form.

We have presented parallel implementations of the method as proposed by those authors and also of a modified method that halves the number of communication events.

The advantages of one-sided transformations over two-sided methods for parallel bidiagonalization have been explained in detail in [25]. The parallel code for the one-sided algorithm is essentially the sequential code with a procedure to compute the dot

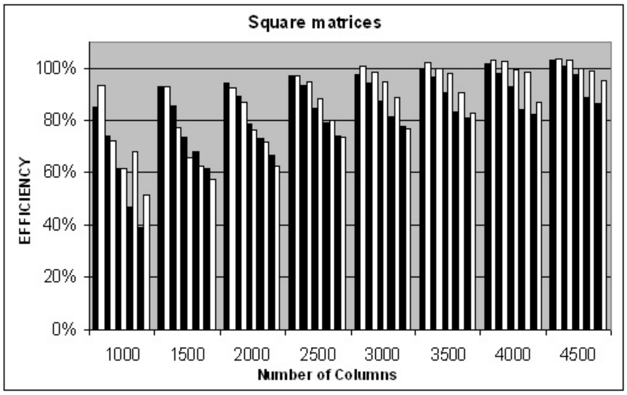

FIG. 4. *PDGEBRD versus modified (efficiency).*

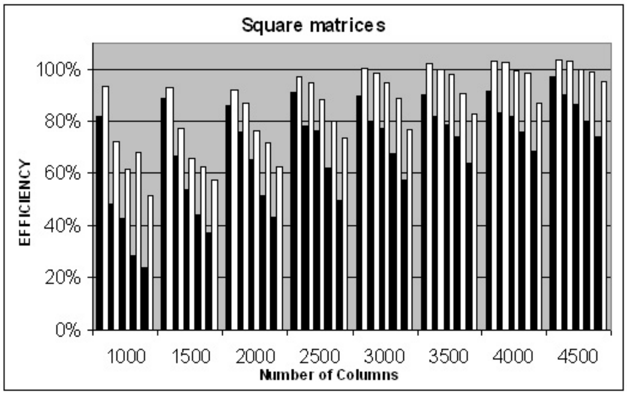

FIG. 5. *PDGEBRD versus modified (efficiency on a linear array of processors).*

products in parallel. This procedure (dubbed GLOBAL.SDOT in [25]) encapsulates all the communication that is required in the parallel algorithm, provided that each processor gets full rows of the matrix. For this reason we do not use a two-dimensional block cyclic distribution. Note that the ScaLAPACK routine PDGEBRD does require communication not only to compute the dot products but also to compute and apply the Householder reflectors. Our one-dimensional distribution, together with the acceptance of some redundancy in the arithmetic, due to the computation of the Householder vectors, produces a parallel algorithm which is well load-balanced and reduces significantly the communication needs, as compared to the ScaLAPACK code. The communication overhead expressed in (12) allows us to conclude (see [25]) that our parallel algorithm is efficient provided that $m/p$ is large enough.

We have described the methodology employed to develop our sequential and parallel codes which intends to use, as much as possible, calls of LAPACK and ScaLAPACK routines, in order to obtain high levels of portability and efficiency.

Our results show that the sequential code for the new method is competitive with the LAPACK routine DGEBRD; although for square matrices we found DGEBRD to be faster. This is not surprising since DGEBRD requires in this case about $\frac{8}{3}n^3$ flops and the new method uses $\frac{1}{3}n^3$ additional flops. Furthermore, DGEBRD has a better ratio of floating point operations to memory references, because it uses level 2 and level 3 BLAS, whereas the new algorithm does not use any level 3 BLAS routine. Even so, without an initial QR decomposition, the new method is faster than DGEBRD if $m$ is much larger than $n$ (in our tests, this happened with $m = 10000$ and $n = 3500$).

Our experimental results on a multiprocessor system do not show as clearly as we expected initially the superiority of the new method. There is a very good reason for this: the ScaLAPACK routine PDGEBRD proved to be very efficient in our tests; this is due to the fact that the communications in our machine are fast and also because we used a maximum of 10 processors only. Since the new algorithm reduces the communication overheads, its virtues will emerge whenever the cost of communication becomes higher comparatively to computation time (a larger number of processors and/or slower communications). Nevertheless, for rectangular matrices our parallel code was marginally faster than PDGEBRD. We expect to be able to use a larger number of processors in the very near future in order to be able to support our claim that the new method has better scalability than the ScaLAPACK routine.

The modification proposed in this paper for the new algorithm reduces to half the number of communication events. In our tests, the gain has not been dramatic, but it may be much more significant on systems with a larger number of processors and/or larger latency in the communications.

To conclude, let us express our view that the new algorithm is very promising for parallel processing. There is still scope to optimize our code and to make it even more competitive with the highly optimized code of the ScaLAPACK routine.

# ON NORMWISE STRUCTURED BACKWARD ERRORS FOR SADDLE POINT SYSTEMS*

HUA XIANG† AND YIMIN WEI‡

**Abstract.** We derive the explicit expressions of the normwise structured backward errors of saddle point systems; we extend the previous results of Sun [*Linear Algebra Appl.*, 288 (1999), pp. 75–88] to a general $2 \times 2$ block linear system, where the (1,1) block is general and not symmetric. We also compare the structured backward error with the unstructured one and find that the difference can be arbitrarily large.

**Key words.** saddle point systems, Karush–Kuhn–Tucker (KKT) systems, backward error

**AMS subject classifications.** 15A06, 65F99, 65G99

**DOI.** 10.1137/060663684

## 1. Introduction.

Backward error is of great importance in numerical analysis. It can answer how close the problem that is actually solved is to the one we want to solve and reveals the stability of a numerical method [12]. For solving a general linear system, there exist explicit expressions for the normwise and componentwise backward errors [15, 16]. Here we consider a special kind of linear system—the saddle point system—as follows:

$$\begin{bmatrix} A & B^T \\ B & 0 \end{bmatrix} \begin{bmatrix} u \\ p \end{bmatrix} = \begin{bmatrix} f \\ g \end{bmatrix}, \tag{1.1}$$

where $A \in \mathbb{R}^{m\times m}$, $B \in \mathbb{R}^{n\times m}$. When the (1,1) block $A$ is symmetric, (1.1) is called a Karush–Kuhn–Tucker (KKT) system. In addition, (1.1) is also called an equilibrium equation [19, 22] or an augmented system [2, 11]. Saddle point systems occur in many areas of computational science and engineering (see [1] and the references therein) such as computational fluid dynamics (CFD) [6, 7, 8, 14], electrical circuits and networks [18, 19], and constrained optimization [25, 26], constrained and weighted least squares problems [5, 10, 21, 24].

For simplicity, we rewrite (1.1) as

$$\mathcal{A}z = d. \tag{1.2}$$

Assuming that the computed solution is $\widetilde{z} = [\widetilde{u}^T, \widetilde{p}^T]^T$, we define the normwise unstructured backward error $\eta(\widetilde{z})$ as

$$\eta(\widetilde{z}) := \min_{\Delta\mathcal{A},\Delta d} \left\{ \left\| \begin{bmatrix} \frac{\|\Delta\mathcal{A}\|_F}{\|\mathcal{A}\|_F}, & \frac{\|\Delta d\|_2}{\|d\|_2} \end{bmatrix} \right\|_2 : (\mathcal{A} + \Delta\mathcal{A})\widetilde{z} = d + \Delta d \right\},$$

---

which can be expressed as

$$\eta(\widetilde{z}) = \frac{\|d - \mathcal{A}\widetilde{z}\|_2}{\sqrt{\|\mathcal{A}\|_F^2 \|\widetilde{z}\|_2^2 + \|d\|_2^2}}. \tag{1.3}$$

We have discussed the structured condition numbers of (1.1) [28]. Here we will consider its structured backward error. Taking into consideration the special block structure of (1.1), we define the normwise structured backward error as

$$\eta_S(\widetilde{u}, \widetilde{p}) := \min_{\{\Delta A,\ \Delta B,\ \Delta f,\ \Delta g\} \in\ \mathcal{F}} \left\| \left[ \tfrac{\|\Delta A\|_F}{\|A\|_F}, \tfrac{\|\Delta B\|_F}{\|B\|_F}, \tfrac{\|\Delta f\|_2}{\|f\|_2}, \tfrac{\|\Delta g\|_2}{\|g\|_2} \right] \right\|_2,$$

where $\mathcal{F}$ is defined by

$$\mathcal{F} = \left\{ \{\Delta A,\ \Delta B,\ \Delta f,\ \Delta g\} : \begin{bmatrix} A + \Delta A & (B + \Delta B)^T \\ B + \Delta B & 0 \end{bmatrix} \begin{bmatrix} \widetilde{u} \\ \widetilde{p} \end{bmatrix} = \begin{bmatrix} f + \Delta f \\ g + \Delta g \end{bmatrix} \right\}.$$

Following the definition in [20], we further define

$$\eta^{(\theta,\ \lambda,\ \mu)}(\widetilde{u}, \widetilde{p}) := \min_{\{\Delta A,\ \Delta B,\ \Delta f,\ \Delta g\} \in \mathcal{F}} \left\| \left[ \|\Delta A\|_F, \theta\|\Delta B\|_F, \lambda\|\Delta f\|_2, \mu\|\Delta g\|_2 \right] \right\|_2.$$

If $A \neq 0$, $B \neq 0$, $f \neq 0$, and $g \neq 0$, then taking $\theta_* = \|A\|_F / \|B\|_F$, $\lambda_* = \|A\|_F / \|f\|_2$, $\mu_* = \|A\|_F / \|g\|_2$, we have $\eta_S(\widetilde{u}, \widetilde{p}) = \frac{1}{\|A\|_F} \eta^{(\theta_*,\ \lambda_*,\ \mu_*)}(\widetilde{u}, \widetilde{p})$.

If $\eta(\widetilde{z})$ is small, then the computed solution $\widetilde{z}$ satisfies a nearby system $(\mathcal{A} + \Delta\mathcal{A})\widetilde{z} = d + \Delta d$, where $\|\Delta A\|_F$ and $\|\Delta d\|_2$ are relatively small. We can say that the algorithm is normwise backward stable. But the perturbed coefficient $\mathcal{A} + \Delta\mathcal{A}$ may not have the saddle point form like (1.1). If we require the perturbation $\Delta\mathcal{A}$ to preserve its original structure, $\|\Delta\mathcal{A}\|_F$ may not be small anymore; that is, the structured backward error $\eta_S(\widetilde{u}, \widetilde{p})$ may be large. However, if $\eta_S(\widetilde{u}, \widetilde{p})$ is small, then the algorithm is strongly stable [3, 4], and we solve a nearby saddle point system. A stable algorithm for solving saddle point systems is not necessarily a strongly stable one [20].

In many cases, there is no perturbation in the (1,1) block; for example, in linear least squares problems (LLSPs), the (1,1) block $A$ is the identity matrix $I$ and is not allowed to be perturbed. So we define

$$\gamma_S(\widetilde{u}, \widetilde{p}) := \min_{\{\Delta B,\ \Delta f,\ \Delta g\} \in\ \mathcal{G}} \left\| \left[ \tfrac{\|\Delta B\|_F}{\|B\|_F}, \tfrac{\|\Delta f\|_2}{\|f\|_2}, \tfrac{\|\Delta g\|_2}{\|g\|_2} \right] \right\|_2,$$

where $\mathcal{G}$ is determined by

$$\mathcal{G} = \left\{ \{\Delta B,\ \Delta f,\ \Delta g\} : \begin{bmatrix} A & (B + \Delta B)^T \\ B + \Delta B & 0 \end{bmatrix} \begin{bmatrix} \widetilde{u} \\ \widetilde{p} \end{bmatrix} = \begin{bmatrix} f + \Delta f \\ g + \Delta g \end{bmatrix} \right\}.$$

To derive $\gamma_S(\widetilde{u}, \widetilde{p})$, we need

$$\gamma^{(\lambda,\mu)}(\widetilde{u}, \widetilde{p}) := \min_{\{\Delta B,\ \Delta f,\ \Delta g\} \in\ \mathcal{G}} \left\| \left[ \|\Delta B\|_F, \lambda\|\Delta f\|_2, \mu\|\Delta g\|_2 \right] \right\|_2.$$

We can verify that $\gamma_S(\widetilde{u}, \widetilde{p}) = \frac{1}{\|B\|_F} \gamma^{(\lambda^*,\mu^*)}(\widetilde{u}, \widetilde{p})$, where $\lambda^* = \frac{\|B\|_F}{\|f\|_2}$, $\mu^* = \frac{\|B\|_F}{\|g\|_2}$.

Let us review some previous results. In [20] Sun investigated the case where the (1,1) block $A$ is symmetric and defined

$$\eta_{\mathrm{sym}}(\widetilde{u}, \widetilde{p}) := \min_{\{\Delta A,\ \Delta B,\ \Delta f,\ \Delta g\} \in\ \mathcal{E}} \left\| \left[ \tfrac{\|\Delta A\|_F}{\|A\|_F}, \tfrac{\|\Delta B\|_F}{\|B\|_F}, \tfrac{\|\Delta f\|_2}{\|f\|_2}, \tfrac{\|\Delta g\|_2}{\|g\|_2} \right] \right\|_2,$$

where

$$\mathcal{E} = \left\{\{\Delta A,\ \Delta B,\ \Delta f,\ \Delta g\} : \{\Delta A,\ \Delta B,\ \Delta f,\ \Delta g\} \in \mathcal{F}, (\Delta A)^T = \Delta A\right\}.$$

In the deduction, the following definition is also needed:

$$\eta_{\text{sym}}^{(\theta,\ \lambda,\ \mu)}(\widetilde{u}, \widetilde{p}) := \min_{\{\Delta A,\ \Delta B,\ \Delta f,\ \Delta g\} \in \mathcal{E}} \left\| \left[\|\Delta A\|_F, \theta\|\Delta B\|_F, \lambda\|\Delta f\|_2, \mu\|\Delta g\|_2\right] \right\|_2.$$

A special case, where $A = I$ and $g = 0$, is considered in [13]. In that case, there are no perturbations in $A$ and $g$. In this paper, we first consider the case where $\Delta A \neq 0$ and the (1,1) block $A$ is a general matrix, which is the case arising from CFD. We then investigate the case where no perturbation in the (1,1) block is permitted; i.e., $\Delta A = 0$. We categorize the problem into two classes because we should treat these two cases with different methods. We give the explicit expressions for the normwise structured backward errors of these two cases. The special case $\Delta B = 0$, $\Delta f = 0$, or $\Delta g = 0$ can be derived directly.

Before our discussion, we need the following three lemmas, which can be found in [20].

LEMMA 1. [illegible] $f \neq 0 \in \mathbb{R}^m$ [illegible] $g \in \mathbb{R}^n$ [illegible] $Xf = g$ [illegible]

$$X^T = f^{\dagger^T} g^T + (I - ff^\dagger)Z,$$

[illegible] $Z \in \mathbb{R}^{m \times n}$ [illegible] $f^\dagger$ [illegible] [23].

LEMMA 2. [illegible] $F \in \mathbb{R}^{p \times m}, G \in \mathbb{R}^{n \times q}$, [illegible] $K \in \mathbb{R}^{p \times q}$ [illegible] $X_* = F^\dagger K G^\dagger$. [illegible]

$$\min_{X \in \mathbb{R}^{m \times n}} \|FXG - K\|_F = \|FX_*G - K\|_F.$$

LEMMA 3. [illegible] $\Phi$ [illegible]

$$\Phi = \begin{bmatrix} \alpha I_m + \beta\xi uu^T & -\xi up^T \\ -\xi pu^T & \gamma I_n + \xi pp^T \end{bmatrix},$$

[illegible] $u \in \mathbb{R}^m, p \in \mathbb{R}^n$ $\alpha, \beta, \gamma,$ [illegible] $\xi$ [illegible] $\alpha, \beta, \gamma > 0$ [illegible]

$$\Phi^{-1} = \begin{bmatrix} \Psi_{11} & \Psi_{12} \\ \Psi_{12}^T & \Psi_{22} \end{bmatrix}, \quad \Psi_{11} \in \mathbb{R}^{m \times m}.$$

[illegible]

$$\Psi_{11} = \frac{1}{\alpha}\Big(I_m - \xi(\beta\gamma + \beta\gamma\|p\|_2^2 - \xi\|p\|_2^2)uu^T/\psi\Big),$$

$$\Psi_{22} = \frac{1}{\gamma}\Big(I_n - \xi(\alpha + \beta\xi\|u\|_2^2 - \xi\|u\|_2^2)pp^T/\psi\Big), \quad \Psi_{12} = \xi up^T/\psi,$$

[illegible] $\psi = \alpha(\gamma + \xi\|p\|_2^2) + \xi\|u\|_2^2(\beta\gamma + \beta\xi\|p\|_2^2 - \xi\|p\|_2^2)$

The rest of this paper is organized as follows. In section 2, we derive the explicit expression of $\eta^{(\theta,\ \lambda,\ \mu)}(\widetilde{u}, \widetilde{p})$, which yields the normwise structured backward error. In section 3, we give an upper bound of $\eta^{(\theta,\ \lambda,\ \mu)}(\widetilde{u}, \widetilde{p})$ and show that the structured backward error can be arbitrarily larger than the normal unstructured one. Then numerical examples are illustrated in section 4.

**2. Expression of $\boldsymbol{\eta^{(\theta,\ \lambda,\ \mu)}(\tilde{u},\tilde{p})}$.** Let $[\widetilde{u}^T,\widetilde{p}^T]^T$ be the computed solution, and let $\widetilde{u}\neq 0$. To derive the expression of $\eta^{(\theta,\ \lambda,\ \mu)}(\widetilde{u},\widetilde{p})$, we need $\eta^{(\theta)}(\widetilde{u},\widetilde{p})$ first, which is defined as

$$\eta^{(\theta)}(\widetilde{u},\widetilde{p}) := \min\left\{ \big\| \left[ \|\Delta A\|_F, \theta\|\Delta B\|_F \right] \big\|_2 : \begin{bmatrix} A+\Delta A & (B+\Delta B)^T \\ B+\Delta B & 0 \end{bmatrix} \begin{bmatrix} \widetilde{u} \\ \widetilde{p} \end{bmatrix} = \begin{bmatrix} f \\ g \end{bmatrix} \right\}.$$

We now consider only the perturbation of the coefficient matrix, such that

$$\begin{bmatrix} A+\Delta A & (B+\Delta B)^T \\ B+\Delta B & 0 \end{bmatrix} \begin{bmatrix} \widetilde{u} \\ \widetilde{p} \end{bmatrix} = \begin{bmatrix} f \\ g \end{bmatrix}. \tag{2.1}$$

Let $r_f := f - A\widetilde{u} - B^T\widetilde{p}$, $r_g := g - B\widetilde{u}$ be the computed residuals. In the following $\|\cdot\|$ stands for the 2-norm, where we omit the subscript for simplicity. The following lemma gives the explicit expression of $\eta^{(\theta)}(\widetilde{u},\widetilde{p})$.

LEMMA 4. [illegible] $\eta^{(\theta)}(\widetilde{u},\widetilde{p})$ [illegible]

$$\left[\eta^{(\theta)}(\widetilde{u},\widetilde{p})\right]^2 = \frac{\theta^2\|r_g\|^2}{\|\widetilde{u}\|^2} + \frac{(r_f^T\widetilde{u} - r_g^T\widetilde{p})^2}{\|\widetilde{u}\|^4} + \frac{\theta^2[\|\widetilde{u}\|^2\|r_f\|^2 - (r_f^T\widetilde{u})^2]}{\|\widetilde{u}\|^2(\theta^2\|\widetilde{u}\|^2 + \|\widetilde{p}\|^2)}. \tag{2.2}$$

[illegible]. According to the second formula of (2.1), we have

$$\Delta B\ \widetilde{u} = r_g.$$

Using Lemma 1, we get

$$(\Delta B)^T = \widetilde{u}^{\dagger^T} r_g^T + (I - \widetilde{u}\widetilde{u}^\dagger)Z,$$

where $Z \in \mathbb{R}^{m\times n}$, $\widetilde{u}^\dagger$ denotes the Moore–Penrose inverse of $\widetilde{u}$. Substituting it into the first formula of (2.1), we obtain

$$\Delta A\ \widetilde{u} = r_f - (r_g^T\widetilde{p})\widetilde{u}^{\dagger^T} - (I - \widetilde{u}\widetilde{u}^\dagger)Z\widetilde{p}.$$

Again applying Lemma 1, we deduce that

$$\Delta A^T = \widetilde{u}^{\dagger^T}[r_f - (r_g^T\widetilde{p})\widetilde{u}^{\dagger^T} - (I - \widetilde{u}\widetilde{u}^\dagger)Z\widetilde{p}\ ]^T + (I - \widetilde{u}\widetilde{u}^\dagger)W,$$

where $W \in \mathbb{R}^{m\times m}$. With the definition $F := (I - \widetilde{u}\widetilde{u}^\dagger)Z$, $G := r_f\widetilde{u}^\dagger - (r_g^T\widetilde{p})\widetilde{u}^{\dagger^T}\widetilde{u}^\dagger$, we have

$$\begin{aligned}
\|\Delta A\|_F^2 + \theta^2\|\Delta B\|_F^2 &= \theta^2\|r_g\widetilde{u}^\dagger\|_F^2 + \theta^2\|F\|_F^2 + \|G^T - \widetilde{u}^{\dagger^T}\widetilde{p}^T F^T\|_F^2 + \|(I - \widetilde{u}\widetilde{u}^\dagger)W\|_F^2 \\
&= \theta^2\mathrm{tr}(FF^T) + \mathrm{tr}\Big((G - F\widetilde{p}\widetilde{u}^\dagger)(G^T - \widetilde{u}^{\dagger^T}\widetilde{p}^T F^T)\Big) + \theta^2\|r_g\widetilde{u}^\dagger\|_F^2 + \|(I - \widetilde{u}\widetilde{u}^\dagger)W\|_F^2 \\
&= \mathrm{tr}\Big(F[\theta^2 I + \widetilde{p}\widetilde{u}^\dagger(\widetilde{p}\widetilde{u}^\dagger)^T]F^T - F(\widetilde{p}\widetilde{u}^\dagger G^T) - (\widetilde{p}\widetilde{u}^\dagger G^T)^T F^T\Big) \\
&\quad + \theta^2\|r_g\widetilde{u}^\dagger\|_F^2 + \|G\|_F^2 + \|(I - \widetilde{u}\widetilde{u}^\dagger)W\|_F^2.
\end{aligned}$$

The formula above can be rewritten as

$$\|\Delta A\|_F^2 + \theta^2\|\Delta B\|_F^2 = \|M - N\|_F^2 - \|N\|_F^2 + \theta^2\|r_g\widetilde{u}^\dagger\|_F^2 + \|G\|_F^2 + \|(I - \widetilde{u}\widetilde{u}^\dagger)W\|_F^2,$$

where $M := F[\theta^2 I + \widetilde{p}\widetilde{u}^\dagger(\widetilde{p}\widetilde{u}^\dagger)^T]^{\frac{1}{2}}, N^T := [\theta^2 I + \widetilde{p}\widetilde{u}^\dagger(\widetilde{p}\widetilde{u}^\dagger)^T]^{-\frac{1}{2}}\widetilde{p}\widetilde{u}^\dagger G^T$.

Applying Lemma 2, we can obtain

$$\min_Z \|M - N\|_F^2 = \min_Z \left\|(I - \widetilde{u}\widetilde{u}^\dagger)Z[\theta^2 I + \widetilde{p}\widetilde{u}^\dagger(\widetilde{p}\widetilde{u}^\dagger)^T]^{\frac{1}{2}} - N\right\|_F^2 = \|\widetilde{u}\widetilde{u}^\dagger N\|_F^2,$$

and the minimum is obtained at $Z_{\min} = -(I - \widetilde{u}\widetilde{u}^\dagger)^\dagger N[\theta^2 I + \widetilde{p}\widetilde{u}^\dagger(\widetilde{p}\widetilde{u}^\dagger)^T]^{-\frac{1}{2}}$. Noticing that $\widetilde{u}\widetilde{u}^\dagger$, $I - \widetilde{u}\widetilde{u}^\dagger$ are orthogonal projectors, we get $\|N\|_F^2 - \|\widetilde{u}\widetilde{u}^\dagger N\|_F^2 = \operatorname{tr}(N^T(I - \widetilde{u}\widetilde{u}^\dagger)N) = \|(I - \widetilde{u}\widetilde{u}^\dagger)N\|_F^2$, and so

$$\left[\eta^{(\theta)}(\widetilde{u},\widetilde{p})\right]^2 = \min_{Z,W}\left\{\|\Delta A\|_F^2 + \theta^2\|\Delta B\|_F^2\right\} = \theta^2\|r_g\|^2\|\widetilde{u}^\dagger\|^2 + \|G\|_F^2 - \|(I - \widetilde{u}\widetilde{u}^\dagger)N\|_F^2.$$

Therefore,

$$\begin{aligned}\left[\eta^{(\theta)}(\widetilde{u},\widetilde{p})\right]^2 &= \frac{\theta^2\|r_g\|^2}{\|\widetilde{u}\|^2} + \frac{1}{\|\widetilde{u}\|^4}\left\|r_f\widetilde{u}^T - \frac{r_g^T\widetilde{p}}{\|\widetilde{u}\|^2}\widetilde{u}\widetilde{u}^T\right\|_F^2 \\ &\quad - \frac{1}{\|\widetilde{u}\|^4}\left\|\left(\theta^2 I + \frac{\widetilde{p}\widetilde{p}^T}{\|\widetilde{u}\|^2}\right)^{-\frac{1}{2}}\left(\widetilde{p}r_f^T - \frac{r_f^T\widetilde{u}}{\|\widetilde{u}\|^2}\widetilde{p}\widetilde{u}^T\right)\right\|_F^2. \qquad (2.3)\end{aligned}$$

The formula above can be simplified. The second term of (2.3) is equal to

$$\begin{aligned}&\frac{1}{\|\widetilde{u}\|^4}\operatorname{tr}\left[\left(\widetilde{u}r_f^T - \frac{r_g^T\widetilde{p}}{\|\widetilde{u}\|^2}\widetilde{u}\widetilde{u}^T\right)\left(r_f\widetilde{u}^T - \frac{r_g^T\widetilde{p}}{\|\widetilde{u}\|^2}\widetilde{u}\widetilde{u}^T\right)\right] \\ &= \frac{1}{\|\widetilde{u}\|^4}\left[\|\widetilde{u}\|^2\|r_f\|^2 - 2(r_f^T\widetilde{u})(r_g^T\widetilde{p}) + (r_g^T\widetilde{p})^2\right].\end{aligned}$$

And the third term of (2.3) is equivalent to

$$\begin{aligned}&-\frac{1}{\|\widetilde{u}\|^4}\operatorname{tr}\left[\left(r_f\widetilde{p}^T - \frac{r_f^T\widetilde{u}}{\|\widetilde{u}\|^2}\widetilde{u}\widetilde{p}^T\right)\left(\theta^2 I + \frac{\widetilde{p}\widetilde{p}^T}{\|\widetilde{u}\|^2}\right)^{-1}\left(\widetilde{p}r_f^T - \frac{r_f^T\widetilde{u}}{\|\widetilde{u}\|^2}\widetilde{p}\widetilde{u}^T\right)\right] \\ &= -\frac{\|\widetilde{p}\|^2}{\|\widetilde{u}\|^2(\theta^2\|\widetilde{u}\|^2 + \|\widetilde{p}\|^2)}\left[\|r_f\|^2 - \frac{(r_f^T\widetilde{u})^2}{\|\widetilde{u}\|^2}\right],\end{aligned}$$

where we use the Sherman–Morrison–Woodbury formula [9]

$$\left(\theta^2 I + \frac{\widetilde{p}\widetilde{p}^T}{\|\widetilde{u}\|^2}\right)^{-1} = \theta^{-2}\left(I - \frac{\widetilde{p}\widetilde{p}^T}{\theta^2\|\widetilde{u}\|^2 + \|\widetilde{p}\|^2)}\right).$$

Hence, $\eta^{(\theta)}(\widetilde{u},\widetilde{p})$ can be expressed as

$$\begin{aligned}\left[\eta^{(\theta)}(\widetilde{u},\widetilde{p})\right]^2 &= \frac{\theta^2\|r_g\|^2}{\|\widetilde{u}\|^2} + \frac{(r_g^T\widetilde{p})^2}{\|\widetilde{u}\|^4} - \frac{2(r_f^T\widetilde{u})(r_g^T\widetilde{p})}{\|\widetilde{u}\|^4} + \frac{\theta^2\|r_f\|^2}{\theta^2\|\widetilde{u}\|^2 + \|\widetilde{p}\|^2} \\ &\quad + \frac{\|\widetilde{p}\|^2(r_f^T\widetilde{u})^2}{\|\widetilde{u}\|^4(\theta^2\|\widetilde{u}\|^2 + \|\widetilde{p}\|^2)},\end{aligned}$$

which is equivalent with the expression (2.2). $\square$

In the case where (1,1) block $A$ is symmetric, we define

$$\eta^{(\theta)}_{\text{sym}}(\widetilde{u},\widetilde{p}) := \min_{\{\Delta A,\ \Delta B,\ 0,\ 0\}\in\mathcal{E}} \left\| \left[\|\Delta A\|_F, \theta\|\Delta B\|_F\right] \right\|_2 .$$

Its expression is given by Sun [20]:

$$\left[\eta^{(\theta)}_{\text{sym}}(\widetilde{u},\widetilde{p})\right]^2 = \frac{\theta^2\|r_g\|^2}{\|\widetilde{u}\|^2} + \frac{(r_f^T\widetilde{u} - r_g^T\widetilde{p})^2}{\|\widetilde{u}\|^4} + \frac{2\theta^2[\|\widetilde{u}\|^2\|r_f\|^2 - (r_f^T\widetilde{u})^2]}{\|\widetilde{u}\|^2(\theta^2\|\widetilde{u}\|^2 + 2\|\widetilde{p}\|^2)}.$$

For convenience, we denote $\eta^{(\theta)}(\widetilde{u},\widetilde{p})$ as

$$\left[\eta^{(\theta)}(\widetilde{u},\widetilde{p})\right]^2 = \theta^2\tau\|r_g\|^2 + (\tau-\sigma)\|r_f\|^2 + \tau^2(r_g^T\widetilde{p})^2 - 2\tau^2(r_f^T\widetilde{u})(r_g^T\widetilde{p}) + \tau\sigma(r_f^T\widetilde{u})^2,$$

where $\tau := \|\widetilde{u}\|^{-2}$, $\sigma := \tau^2\|\widetilde{p}\|^2(\theta^2 + \tau\|p\|^2)^{-1}$. In addition we define $\rho := \tau - \sigma + \lambda^2$.

We now consider perturbations both in the coefficient matrix and the right-hand side:

$$\begin{bmatrix} A+\Delta A & (B+\Delta B)^T \\ B+\Delta B & 0 \end{bmatrix} \begin{bmatrix} \widetilde{u} \\ \widetilde{p} \end{bmatrix} = \begin{bmatrix} f+\Delta f \\ g+\Delta g \end{bmatrix}, \tag{2.4}$$

where $\widetilde{u} \neq 0$. We use $\eta^{(\theta)}(\widetilde{u},\widetilde{p})$ to derive the expression of $\eta^{(\theta,\ \lambda,\ \mu)}(\widetilde{u},\widetilde{p})$, which is given in the following theorem.

THEOREM 1. [illegible]

$$\begin{aligned}[\eta^{(\theta,\ \lambda,\ \mu)}(\widetilde{u},\widetilde{p})]^2 = {} & \frac{\theta^2\mu^2}{\Omega_0}\|r_g\|^2 + \frac{\lambda^2\mu^4\|\widetilde{u}\|^2}{\Omega_0\Omega}(r_g^T\widetilde{p})^2 - \frac{2\lambda^2\mu^2}{\Omega}(r_f^T\widetilde{u})(r_g^T\widetilde{p}) \\ & + \frac{\theta^2\lambda^2}{\Omega_1}\|r_f\|^2 + \frac{\lambda^4\mu^2\|\widetilde{p}\|^2}{\Omega_1\Omega}(r_f^T\widetilde{u})^2, \end{aligned} \tag{2.5}$$

[illegible]

$$\begin{aligned} \Omega_0 &:= \theta^2 + \mu^2\|\widetilde{u}\|^2, \\ \Omega_1 &:= \theta^2 + \lambda^2\|\widetilde{p}\|^2 + \theta^2\lambda^2\|\widetilde{u}\|^2, \\ \Omega\ &:= \theta^2 + \mu^2\|\widetilde{u}\|^2 + \lambda^2\|\widetilde{p}\|^2 + \theta^2\lambda^2\|\widetilde{u}\|^2 + \lambda^2\mu^2\|\widetilde{u}\|^4. \end{aligned}$$

[illegible]. By the definition, we have

$$\begin{aligned}[\eta^{(\theta,\ \lambda,\ \mu)}(\widetilde{u},\widetilde{p})]^2 &= \min_{\Delta f,\ \Delta g}\left\{\lambda^2\|\Delta f\|^2 + \mu^2\|\Delta g\|^2 + \min_{\Delta A,\ \Delta B}\|[\|\Delta A\|_F, \theta\|\Delta B\|_F]\|_F^2\right\} \\ &:= \min_{\Delta f,\ \Delta g}\chi(\Delta f, \Delta g), \end{aligned}$$

where

$$\begin{aligned}\chi(\Delta f,\Delta g) &= \lambda^2\|\Delta f\|^2 + \mu^2\|\Delta g\|^2 + \theta^2\tau\|r_g + \Delta g\|^2 + (\tau-\sigma)\|r_f + \Delta f\|^2 \\ &\quad + \tau^2[(r_g+\Delta f)^T\widetilde{p}]^2 - 2\tau^2[(r_f+\Delta f)^T\widetilde{u}][(r_g+\Delta g)^T\widetilde{p}] \\ &\quad + \tau\sigma[(r_f+\Delta f)^T\widetilde{u}]^2 \\ &= [\eta^{(\theta)}(\widetilde{u},\widetilde{p})]^2 + 2\begin{bmatrix}\Delta f \\ \Delta g\end{bmatrix}^T \begin{bmatrix}(\tau-\sigma)r_f + (\tau\sigma r_f^T\widetilde{u} - \tau^2 r_g^T\widetilde{p})\widetilde{u} \\ \tau\theta^2 r_g + \tau^2(r_g^T\widetilde{p} - r_f^T\widetilde{u})\widetilde{p}\end{bmatrix} \\ &\quad + \begin{bmatrix}\Delta f \\ \Delta g\end{bmatrix}^T \begin{bmatrix}\rho I_m + \tau\sigma\widetilde{u}\widetilde{u}^T & -\tau^2\widetilde{u}\widetilde{p}^T \\ -\tau^2\widetilde{p}\widetilde{u}^T & (\tau\theta^2+\mu^2)I_n + \tau^2\widetilde{p}\widetilde{p}^T\end{bmatrix}\begin{bmatrix}\Delta f \\ \Delta g\end{bmatrix}.\end{aligned}$$

We denote the formula above as

$$\chi(w) = [\eta^{(\theta)}(\widetilde{u}, \widetilde{p})]^2 + 2w^T b + w^T \Phi w.$$

Obviously, the minimum is obtained when $w = -\Phi^{-1} b$. Correspondingly,

$$[\eta^{(\theta,\ \lambda,\ \mu)}(\widetilde{u}, \widetilde{p})]^2 = [\eta^{(\theta)}(\widetilde{u}, \widetilde{p})]^2 - b^T \Phi^{-1} b. \tag{2.6}$$

Applying Lemma 3, we have

$$\Phi^{-1} = \begin{bmatrix} \Psi_{11} & \Psi_{12} \\ \Psi_{12}^T & \Psi_{22} \end{bmatrix},$$

and

$$\begin{aligned} \Psi_{11} &= \frac{1}{\rho}\left(I_m - \frac{\tau\xi}{\psi}\widetilde{u}\widetilde{u}^T\right), \\ \Psi_{22} &= \frac{1}{\tau\theta^2 + \mu^2}\left(I_n - \frac{\tau^2\lambda^2}{\psi}\widetilde{p}\widetilde{p}^T\right), \\ \Psi_{12} &= \frac{\tau^2}{\psi}\widetilde{u}\widetilde{p}^T, \end{aligned}$$

where $\xi := \sigma(\tau\theta^2 + \mu^2) + \tau^2(\sigma - \tau)\|\widetilde{p}\|^2$, and $\psi := \rho(\tau\theta^2 + \mu^2 + \tau^2\|\widetilde{p}\|^2) + \xi$. After tedious computation, we obtain

$$b^T \Phi^{-1} b = K_{0f}\|r_f\|^2 + K_{0g}\|r_g\|^2 + K_{1f}(r_f^T \widetilde{u})^2 + K_{1g}(r_g^T \widetilde{p})^2 + K_{fg}(r_f^T \widetilde{u})(r_g^T \widetilde{p}),$$

where

$$\begin{aligned} K_{0f} &:= \frac{\theta^4}{(\theta^2\|\widetilde{u}\|^2 + \|\widetilde{p}\|^2)\Omega_1}, \\ K_{0g} &:= \frac{\theta^4}{\|\widetilde{u}\|^2\Omega_0}, \\ K_{1f} &:= \frac{\|\widetilde{p}\|^2}{\|\widetilde{u}\|^4(\theta^2\|\widetilde{u}\|^2 + \|\widetilde{p}\|^2)} - \frac{\lambda^4\mu^2\|\widetilde{p}\|^2}{\Omega_1\Omega}, \\ K_{1g} &:= \frac{1}{\|\widetilde{u}\|^4} - \frac{\lambda^2\mu^4\|\widetilde{u}\|^2}{\Omega_0\Omega}, \\ K_{fg} &:= -\frac{2}{\|\widetilde{u}\|^4} + \frac{2\lambda^2\mu^2}{\Omega}. \end{aligned}$$

Combining this with the expression of $\eta^{(\theta)}(\widetilde{u}, \widetilde{p})$, we obtain (2.5). ∎

[illegible] 1. If we let $\sigma = (2\tau^2\|\widetilde{p}\|^2 - \tau\theta^2)(\theta^2 + 2\tau\|p\|^2)^{-1}$ in the former deduction, we can get

$$\begin{aligned} [\eta_{\text{sym}}^{(\theta,\ \lambda,\ \mu)}(\widetilde{u}, \widetilde{p})]^2 = {} & \frac{\theta^2\mu^2}{\Omega_0}\|r_g\|^2 + \frac{\lambda^2\mu^4\|\widetilde{u}\|^2}{\Omega_0\Omega}(r_g^T \widetilde{p})^2 - \frac{2\lambda^2\mu^2}{\Omega}(r_f^T \widetilde{u})(r_g^T \widetilde{p}) \\ & + \frac{2\theta^2\lambda^2}{\Omega_2}\|r_f\|^2 + \frac{2\lambda^4\mu^2\|\widetilde{p}\|^2 - \theta^2\lambda^4\Omega_0}{\Omega_2\Omega}(r_f^T \widetilde{u})^2, \end{aligned} \tag{2.7}$$

where $\Omega_2 := 2\theta^2 + 2\lambda^2\|\tilde{p}\|^2 + \theta^2\lambda^2\|\tilde{u}\|^2 = 2\Omega_1 - \theta^2\lambda^2\|\tilde{u}\|^2$. We can show that (2.7) is equivalent to Sun's result [20].

2. The induction above is taken under the assumption that $\tilde{u} \neq 0$. In the case $\tilde{u} = 0$, we can also derive a similar result:

$$\eta^{(\theta,\ \lambda,\ \mu)}(0, \tilde{p}) = \sqrt{\frac{\theta^2\lambda^2\|r_f\|^2}{\theta^2 + \lambda^2\|\tilde{p}\|^2} + \mu^2\|r_g\|^2}.$$

This is just a special case of (2.5).

3. In many cases where $g = 0$, there should be no perturbation in $g$, i.e., $\Delta g = 0$. For this case, we define

$$\eta^{(\theta,\ \lambda)}(\tilde{u}, \tilde{p}) := \min_{\{\Delta A,\ \Delta B,\ \Delta f\} \in \mathcal{F}_g} \left\| \left[ \|\Delta A\|_F, \theta\|\Delta B\|_F, \lambda\|\Delta f\| \right] \right\|,$$

where

$$\mathcal{F}_g = \left\{ \{\Delta A,\ \Delta B,\ \Delta f\} : \begin{bmatrix} A + \Delta A & (B + \Delta B)^T \\ B + \Delta B & 0 \end{bmatrix} \begin{bmatrix} \tilde{u} \\ \tilde{p} \end{bmatrix} = \begin{bmatrix} f + \Delta f \\ g \end{bmatrix} \right\}.$$

Let $\mu$ tend to $\infty$ in (2.5); we then obtain

$$\begin{aligned} [\eta^{(\theta,\ \lambda)}(\tilde{u}, \tilde{p})]^2 = {} & \frac{\theta^2\lambda^2\|r_f\|^2}{\Omega_1} + \frac{\theta^2\|r_g\|^2}{\|\tilde{u}\|^2} + \frac{\lambda^4\|\tilde{p}\|^2(r_f^T\tilde{u})^2}{\|\tilde{u}\|^2(1 + \lambda^2\|\tilde{u}\|^2)\Omega_1} \\ & + \frac{\lambda^2(r_g^T\tilde{p})^2}{\|\tilde{u}\|^2(1 + \lambda^2\|\tilde{u}\|^2)} - \frac{2\lambda^2(r_f^T\tilde{u})(r_g^T\tilde{p})}{\|\tilde{u}\|^2(1 + \lambda^2\|\tilde{u}\|^2)}. \end{aligned} \tag{2.8}$$

We can also obtain (2.8) the same way we derive $\eta^{\theta,\lambda,\mu}(\tilde{u}, \tilde{p})$. Here we provide a simple and efficient way. Similarly, we can treat the case of $\Delta f = 0$, or $\Delta B = 0$.

4. In the case where the (1,1) block $A$ is not perturbed, we can derive $\gamma^{(\lambda,\ \mu)}(\tilde{u}, \tilde{p})$ [27], which is given by

$$\begin{aligned} [\gamma^{(\lambda,\ \mu)}(\tilde{u}, \tilde{p})]^2 = {} & \frac{\lambda^2}{\Theta_\lambda}\|r_f\|^2 + \frac{\mu^2}{\Theta_\mu}\|r_g\|^2 - \frac{2\lambda^2\mu^2}{\Theta}(r_f^T\tilde{u})(r_g^T\tilde{p}) \\ & + \frac{\lambda^2\mu^2(\Theta_\lambda - 1)}{\Theta_\lambda\Theta}(r_f^T\tilde{u})^2 + \frac{\lambda^2\mu^2(\Theta_\mu - 1)}{\Theta_\mu\Theta}(r_g^T\tilde{p})^2, \end{aligned} \tag{2.9}$$

where $\Theta_\lambda := 1 + \lambda^2\|\tilde{p}\|^2$, $\Theta_\mu := 1 + \mu^2\|\tilde{u}\|^2$ , and $\Theta := 1 + \mu^2\|\tilde{u}\|^2 + \lambda^2\|\tilde{p}\|^2$.

For the case $\Delta g = 0$, we can let $\mu$ tend to $\infty$ in (2.9) and then obtain the result of [13]. We can deal with the case $\Delta f = 0$ or $\Delta B = 0$ similarly.

**3. Comparison between $\eta_S(\tilde{u}, \tilde{p})$ and $\eta(\tilde{z})$.** From (2.4), we have $\Delta\tilde{u} + (\Delta B)^T\tilde{p} - \Delta f = r_f$, $\Delta B\tilde{u} - \Delta g = r_g$. That is,

$$\left[\Delta A,\quad \beta(\Delta B)^T,\quad \lambda\Delta f\right] \begin{bmatrix} \tilde{u} \\ \frac{1}{\beta}\tilde{p} \\ -\frac{1}{\lambda} \end{bmatrix} = r_f, \quad \left[\alpha\Delta B,\quad \mu\Delta g\right] \begin{bmatrix} \frac{1}{\alpha}\tilde{u} \\ -\frac{1}{\mu} \end{bmatrix} = r_g.$$

Using Lemma 1, we obtain

$$\begin{bmatrix}\Delta A, & \beta(\Delta B)^T, & \lambda\Delta f\end{bmatrix}^T = \begin{bmatrix}\widetilde{u}\\ \frac{1}{\beta}\widetilde{p}\\ -\frac{1}{\lambda}\end{bmatrix}^{\dagger^T} r_f^T + \left(I - \begin{bmatrix}\widetilde{u}\\ \frac{1}{\beta}\widetilde{p}\\ -\frac{1}{\lambda}\end{bmatrix}\begin{bmatrix}\widetilde{u}\\ \frac{1}{\beta}\widetilde{p}\\ -\frac{1}{\lambda}\end{bmatrix}^{\dagger}\right) W,$$

$$\begin{bmatrix}\alpha\Delta B, & \mu\Delta g\end{bmatrix}^T = \begin{bmatrix}\frac{1}{\alpha}\widetilde{u}\\ -\frac{1}{\mu}\end{bmatrix}^{\dagger^T} r_g^T + \left(I - \begin{bmatrix}\frac{1}{\alpha}\widetilde{u}\\ -\frac{1}{\mu}\end{bmatrix}\begin{bmatrix}\frac{1}{\alpha}\widetilde{u}\\ -\frac{1}{\mu}\end{bmatrix}^{\dagger}\right) Z,$$

where $W \in \mathbb{R}^{(m+n+1)\times m}$, $Z \in \mathbb{R}^{(m+1)\times n}$. Therefore,

$$\begin{aligned}
&\left[\eta^{(\theta,\ \lambda,\ \mu)}(\widetilde{u},\widetilde{p})\right]^2\\
&= \min_{\substack{Z,W\\ \alpha^2+\beta^2=\theta^2}} \left\{ \left\|[\Delta A, \beta(\Delta B)^T, \lambda\Delta f]\right\|_F^2 + \left\|[\alpha(\Delta B)^T, \mu\Delta g]\right\|_F^2 \right\}\\
&\geqslant \min_{\alpha^2+\beta^2=\theta^2} \left\{ \min_W \left\|[\Delta A, \beta(\Delta B)^T, \lambda\Delta f]\right\|_F^2 + \min_Z \left\|[\alpha(\Delta B)^T, \mu\Delta g]\right\|_F^2 \right\}\\
&= \min_{\alpha^2+\beta^2=\theta^2} \left\{ \frac{\|r_f\|^2}{\beta^{-2}\|\widetilde{p}\|^2 + \|\widetilde{u}\|^2 + \lambda^{-2}} + \frac{\|r_g\|^2}{\alpha^{-2}\|\widetilde{u}\|^2 + \mu^{-2}} \right\}\\
&= \frac{(\|\widetilde{u}\|\|r_f\| - \|\widetilde{p}\|\|r_g\|)^2 + \theta^2\mu^{-2}\|r_f\|^2 + \theta^2(\|\widetilde{u}\|^2 + \lambda^{-2})\|r_g\|^2}{(\|\widetilde{u}\|^2 + \theta^2\mu^{-2})(\|\widetilde{u}\|^2 + \lambda^{-2}) + \mu^{-2}\|\widetilde{p}\|^2}.
\end{aligned}$$

Supposing $\theta > 1$, we have

$$\begin{aligned}
\frac{\eta_S(\widetilde{u},\widetilde{p})}{\eta(\widetilde{z})} &\geqslant \left( \frac{\theta^2(\|\widetilde{u}\|^2 + \lambda^{-2})\|r_g\|^2}{(\|\widetilde{u}\|^2 + \theta^2\mu^{-2})(\|\widetilde{u}\|^2 + \|\widetilde{p}\|^2 + \lambda^{-2})} \frac{\|\widetilde{u}\|^2 + \|\widetilde{p}\|^2}{\|r_f\|^2 + \|r_g\|^2} \right)^{\frac{1}{2}}\\
&= \theta\sqrt{\frac{\|\widetilde{u}\|^2 + \lambda^{-2}}{\|\widetilde{u}\|^2 + \theta^2\mu^{-2}}}\sqrt{\frac{\|\widetilde{u}\|^2 + \|\widetilde{p}\|^2}{\|\widetilde{u}\|^2 + \|\widetilde{p}\|^2 + \lambda^{-2}}}\sqrt{\frac{\|r_g\|^2}{\|r_f\|^2 + \|r_g\|^2}}.
\end{aligned}$$

If $\theta \gg 1$, and

$$\|r_f\| \sim \|r_g\|, \theta\mu^{-1} \sim \mathcal{O}(1), \lambda \sim \mathcal{O}(1), \tag{3.1}$$

then

$$\frac{\eta_S(\widetilde{u},\widetilde{p})}{\eta(\widetilde{z})} \sim \mathcal{O}(\theta) \gg 1,$$

which shows that the structured backward error can be arbitrarily larger than the unstructured one.

## 4. Numerical examples.

In this section we will examine two numerical cases and compare the normwise structured and unstructured backward errors.

[illegible] 1. Consider the saddle point systems with

$$B = \begin{bmatrix} 0 & 0 & 1 & 0 & 0 & 0\\ 0 & 1 & 0 & 0 & 0 & 0\\ 10^{-3} & 0 & 0 & 0 & 0 & 0 \end{bmatrix}, \qquad A = DMD,$$

$$M = \text{magic}(6) + \text{eye}(6), \qquad D = \text{diag}([1, 5, 10, 50, 100, 10000]),$$

$$f = [10^8, 10, 0, 0, 0, 0]^T, \qquad g = [10^{-8}, 0, 0]^T.$$

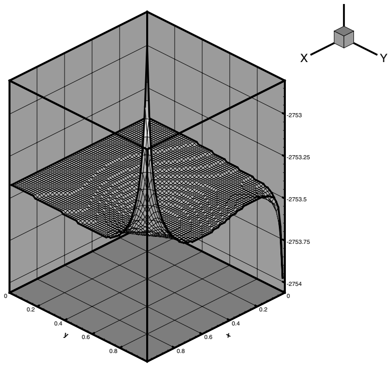

FIG. 1. *Three-dimensional surface plot of pressure.*

This unsymmetric case is slightly adapted from the example in [20]. We use the MATLAB backslash function (or matrix left division) to solve this problem and obtain the following computed solutions:

$$\widetilde{u} = \begin{pmatrix} -3.430234778891480 \times 10^{-09} \\ 4.517200836796800 \times 10^{-10} \\ 9.834679521009126 \times 10^{-09} \\ -1.139022982251766 \times 10^{-09} \\ -3.743828054634186 \times 10^{-10} \\ -1.254493123951351 \times 10^{-11} \end{pmatrix},$$

$$\widetilde{p} = \begin{pmatrix} 4.563714591880652 \times 10^{-05} \\ 1.000002220308359 \times 10^{+01} \\ 1.000000000000047 \times 10^{+11} \end{pmatrix}.$$

By (1.3) we get the unstructured backward error

$$\eta(\widetilde{z}) = 4.0 \times 10^{-30}.$$

But the structured backward error is given by

$$\eta_S(\widetilde{u}, \widetilde{p}) = 2.7 \times 10^{-2}.$$

We can see that Gaussian elimination with partial pivoting for solving this saddle point systems is backward stable but not strongly stable.

[illegible] 2. Consider the impressible flow in $\Omega = (0,1) \times (0,1)$, with Dirichlet boundary conditions on $\partial\Omega$. Let $\mathbf{u} = (u_1, u_2)^T$ denote the velocity field and $p$ the pressure. On the boundaries the velocities are zeros except for the horizontal velocity, which is $u_1 = 1$ on the upper boundary. The governing equations are Navier–Stokes equations:

$$\begin{aligned} -\nu\Delta\mathbf{u} + (\mathbf{u} \cdot \nabla)\mathbf{u} + \nabla p &= 0, \\ -\nabla \cdot \mathbf{u} &= 0. \end{aligned}$$

Using the MAC finite difference scheme, where the discrete velocities and pressures are defined on staggered grids, we have the saddle point systems (1.1) with $g = 0$.

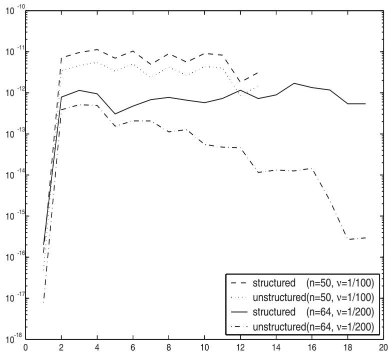

FIG. 2. *Backward error.*

In practical computation, we take $64 \times 64$ grids, choose $\nu = 1/200$, and apply GMRES [17] to solve (1.1). After 19 Picard iterations, we obtain the converged pressure field as shown in Figure 1. Using (2.8) the structured backward error of the last Picard iteration is $5.43 \times 10^{-13}$, while the unstructured backward error is $2.96 \times 10^{-16}$ (see Figure 2). Though the structured backward error is about three orders larger than the unstructured one, they are both small. When $\nu$ becomes larger, the difference between structured and unstructured backward error is smaller. For example, if we take $\nu = 1/100$ and $50 \times 50$ grids, the structured backward error is only two times the unstructured one at each Picard iteration, as shown in Figure 2. We can conclude that the algorithm is strongly stable for this problem.

**Acknowledgments.** The authors would like to thank the editor Andy Wathen and two referees for their very useful and detailed suggestions on our early version.

# UNITARILY INVARIANT NORMS OF TOEPLITZ MATRICES WITH FISHER–HARTWIG SINGULARITIES*

SEAK-WENG VONG† AND XIAO-QING JIN†

**Abstract.** We provide upper bounds for unitarily invariant norms of finite Toeplitz matrices generated by functions with a Fisher–Hartwig singularity. These bounds are sharp as the matrix size goes to infinity. Our results improve previous estimates and confirm a conjecture recently raised by Böttcher.

**Key words.** unitarily invariant norm, Schatten norm, Ky Fan norm, Toeplitz matrix, Fisher–Hartwig singularity

**AMS subject classifications.** 47B35, 15A60, 65F10

**DOI.** 10.1137/070681065

## 1. Introduction.

Denote by $T_n(a)$ the $n \times n$ Toeplitz matrix $(a_{j-k})_{j,k=1}^n$, where

$$a_m = \frac{1}{2\pi}\int_{-\pi}^{\pi} a(x)e^{-imx}dx, \qquad m = 0, \pm 1, \pm 2, \ldots,$$

are the Fourier coefficients of a function $a \in L^1(-\pi,\pi)$. In this paper, we consider asymptotic properties of unitarily invariant norms of $T_n(a)$ when $a$ has a singularity of the Fisher–Hartwig type. An archetypal example [2, 3] of such a function is

$$\omega_\alpha^+(x) = \begin{cases} 0, & x \in (-\pi, 0), \\ x^{-\alpha}, & x \in (0, \pi), \end{cases} \tag{1}$$

where $0 < \alpha < 1$.

Now, we introduce a class of unitarily invariant norms called the Schatten $p$-norms [1]. For $1 \le p < \infty$, the Schatten $p$-norms $\|T_n(a)\|_p$ are defined by

$$\|T_n(a)\|_p \equiv \left[\sum_{j=1}^n s_j^p(T_n(a))\right]^{1/p}, \tag{2}$$

and $\|T_n(a)\|_\infty$ is defined as $s_1(T_n(a))$, where $s_1(T_n(a)) \ge \cdots \ge s_n(T_n(a))$ are the singular values of $T_n(a)$. For $\omega_\alpha^+$ given by (1), one can compute the Frobenius norm, which is just the case $p = 2$ in (2), to obtain that

$$\|T_n(\omega_\alpha^+)\|_2 \le \begin{cases} C_2(\alpha)n^{1/2}, & \alpha < 1/2, \\ C_2(\alpha)(n\log n)^{1/2}, & \alpha = 1/2, \\ C_2(\alpha)n^\alpha, & \alpha > 1/2, \end{cases} \tag{3}$$

---

†Department of Mathematics, University of Macau, Macao, China (swvong@umac.mo, xqjin@umac.mo).

where $C_2(\alpha)$ is a positive constant depending on $\alpha$ [2].

Note that if we put $\omega_\alpha^-(x) = \omega_\alpha^+(-x)$, then functions of the form

$$a(x) = \omega_\alpha^-(x)b(x) + \omega_\alpha^+(x)c(x),$$

where $b$, $c \in L^\infty$, include all functions with a Fisher–Hartwig singularity. It is proved in [2] that for a given $0 < \alpha < 1$, one has the following bound for the Schatten $p$-norms:

$$\|T_n(a)\|_p \leq \begin{cases} C_p(a)n^\alpha(\log n)^{1+\alpha}, & p = 1/\alpha, \\ C_p(a)n^\alpha \log n, & 1/\alpha < p < \infty, \\ C_p(a)n^\alpha, & p = \infty, \end{cases} \tag{4}$$

where $C_p(a)$ is a positive constant depending on $p$ and $a$.

Comparing the above two estimates (3) and (4), it seems that there is room for improvement. Böttcher [2] conjectured that the $n^\alpha(\log n)^{1+\alpha}$ in (4) can be replaced by $(n \log n)^\alpha$ and that the $n^\alpha \log n$ in (4) can be improved to $n^\alpha$. The proof of these conjectures is the objective of this paper. We would like to mention that the results in [2] were obtained through a subtle analysis on the Dirichlet kernel. Our method goes in another direction and depends mainly on a basic theory of unitarily invariant norms.

It is well known [1] that a function $\|\cdot\|$ defined on $n \times n$ matrices is a unitarily invariant norm if and only if there exists a symmetric gauge function $\Phi$ on $\mathbf{R}^n$ such that

$$\|A\| = \Phi(s_1(A), \ldots, s_n(A)).$$

We recall that a function $\Phi : \mathbf{R}^n \to \mathbf{R}_+$ is called a symmetric gauge function if it satisfies the following properties:

(i) $\Phi$ is a norm.
(ii) $\Phi(Px) = \Phi(x)$ for all $x \in \mathbf{R}^n$ and all permutation matrices $P$.
(iii) $\Phi(\varepsilon_1 x_1, \ldots, \varepsilon_n x_n) = \Phi(x_1, \ldots, x_n)$ if $\varepsilon_j = \pm 1$ for any $j$.
(iv) $\Phi(1, 0, \ldots, 0) = 1$.

In the following discussion, we use $\|\cdot\|_\Phi$ to denote the unitarily invariant norm corresponding to a given symmetric gauge function $\Phi$.

The paper is organized as follows. In section 2, by using the Fan dominance theorem and Ky Fan $k$-norms, a general estimate on unitarily invariant norms is established. In section 3, we apply the estimate obtained in section 2 to get an improved bound on the Schatten $p$-norms.

## 2. An estimate on unitarily invariant norms.

We first concentrate on $\omega_\alpha^\pm(x)$. Our analysis depends mainly on the following theorem [1].

Theorem 1 (Fan dominance theorem). [illegible] $A, B$ [illegible] $n \times n$ [illegible]

$$\|A\|_{(k)} \leq \|B\|_{(k)} \qquad [illegible] \quad k = 1, 2, \ldots, n,$$

[illegible]

$$|||A||| \leq |||B|||$$

[illegible]

$$\|A\|_{(k)} \equiv \sum_{j=1}^{k} s_j(A)$$

[illegible] $k$ [illegible]

Theorem 1 implies that in order to compare any given unitarily invariant norm of two matrices, one needs only to compare the Ky Fan $k$-norms. This gives the importance of the Ky Fan $k$-norms among unitarily invariant norms and inspires one to estimate the Ky Fan $k$-norms of $\omega_\alpha^\pm$. Using that $T_n(h)$ may be interpreted as a compression of the operator of multiplication by $h$ on $L^2(-\pi,\pi)$, we see that $s_1(T_n(h)) = \|T_n(h)\|_\infty \le \|h\|_\infty = h_{\max}$. This implies the following.

THEOREM 2. [illegible] $1 \le k \le n$ [illegible]

$$\|T_n(\omega_\alpha^\pm)\|_{(k)} \le \frac{(2\pi)^{-1} + 1 - \alpha}{1-\alpha}\, k^{1-\alpha} n^\alpha \le \frac{C}{1-\alpha}\, k^{1-\alpha} n^\alpha.$$

[illegible] $C$ [illegible] $n$, $k$ [illegible] $\alpha$

[illegible]. We need only to work out the proof for $\omega_\alpha^+(x)$. The case for $\omega_\alpha^-(x)$ is similar. For a fixed $k$, we write

$$\omega_\alpha^+(x) = g(x) + h(x),$$

where

$$g(x) = \begin{cases} 0, & x \in (-\pi, 0), \\ x^{-\alpha}, & x \in (0, k/n), \\ 0, & x \in (k/n, \pi), \end{cases} \qquad (g \in L^1),$$

$$h(x) = \begin{cases} 0, & x \in (-\pi, k/n), \\ x^{-\alpha}, & x \in (k/n, \pi), \end{cases} \qquad (h \in L^\infty).$$

We clearly have

$$T_n(\omega_\alpha^+) = T_n(g) + T_n(h).$$

This implies that

$$\begin{aligned} &\|T_n(\omega_\alpha^+)\|_{(k)} \le \|T_n(g)\|_{(k)} + \|T_n(h)\|_{(k)} \\ &\le \sum_{j=1}^{n} s_j(T_n(g)) + \sum_{j=1}^{k} s_j(T_n(h)) \\ &\le \operatorname{tr}(T_n(g)) + k s_1(T_n(h)) \le \frac{n}{2\pi}\int_{-\pi}^{\pi} g(x)dx + k h_{\max} \\ &= \frac{(2\pi)^{-1} n}{1-\alpha}\left(\frac{k}{n}\right)^{1-\alpha} + k\left(\frac{k}{n}\right)^{-\alpha} = \frac{(2\pi)^{-1} + 1 - \alpha}{1-\alpha} k^{1-\alpha} n^\alpha. \qquad \square \end{aligned}$$

As mentioned above, a function with a Fisher–Hartwig singularity of degree $\alpha$ can be written as

$$a(x) = b(x)\omega_\alpha^-(x) + c(x)\omega_\alpha^+(x).$$

By the fact that

$$|a(x)| \leq \|b\|_\infty \omega_\alpha^-(x) + \|c\|_\infty \omega_\alpha^+(x),$$

we thus have [4]

$$\|T_n(a)\|_{(k)} \leq \|b\|_\infty \|T_n(\omega_\alpha^-)\|_{(k)} + \|c\|_\infty \|T_n(\omega_\alpha^+)\|_{(k)}.$$

This gives by Theorem 2 the following.

THEOREM 3. [illegible] $a(x)$ [illegible] $\alpha$ [illegible]

$$\|T_n(a)\|_{(k)} \leq \frac{C}{1-\alpha} k^{1-\alpha} n^\alpha, \qquad 1 \leq k \leq n.$$

A direct consequence of Theorems 1 and 2 is an estimate on unitarily invariant norms of $T_n(\omega_\alpha^\pm)$. To this end, we compare the Ky Fan $k$-norms of $T_n(\omega_\alpha^\pm)$ and that of the diagonal matrix

$$D_\alpha \equiv \frac{(2\pi)^{-1} + 1 - \alpha}{1-\alpha} n^\alpha \operatorname{diag}(1, 2^{1-\alpha}-1, \ldots, k^{1-\alpha}-(k-1)^{1-\alpha}, \ldots, n^{1-\alpha}-(n-1)^{1-\alpha}).$$

By Theorem 2, it is easy to see that

$$\|T_n(\omega_\alpha^\pm)\|_{(k)} \leq \|D_\alpha\|_{(k)}$$

for $k = 1, 2, \ldots, n$. Recall that every unitarily invariant norm is induced by a symmetric gauge function $\Phi$ on $R^n$. We thus conclude the following.

THEOREM 4. [illegible] $\|\cdot\|_\Phi$ [illegible] $\Phi$ [illegible] $\mathbf{R}^n$ [illegible]

$$\|T_n(\omega_\alpha^\pm)\|_\Phi \leq \|D_\alpha\|_\Phi = \frac{(2\pi)^{-1} + 1 - \alpha}{1-\alpha} n^\alpha$$

$$\times \Phi(1, 2^{1-\alpha} - 1, \ldots, k^{1-\alpha} - (k-1)^{1-\alpha}, \ldots, n^{1-\alpha} - (n-1)^{1-\alpha}).$$

**3. Application to the Schatten *p*-norms.** Recall the definition of the Schatten $p$-norms defined by (2). By Theorem 4, in order to estimate $\|T_n(\omega_\alpha^\pm)\|_p$, we need to get an upper bound for

$$\left[\sum_{k=1}^n (k^{1-\alpha} - (k-1)^{1-\alpha})^p\right]^{1/p}.$$

Using that $\varphi(k) - \varphi(k-1) = \varphi'(\xi_k)$ with $k-1 \leq \xi_k \leq k$, we see that, for $2 \leq k \leq n$,

$$0 < k^{1-\alpha} - (k-1)^{1-\alpha} = (1-\alpha)\xi_k^{-\alpha} \leq (1-\alpha)(k-1)^{-\alpha}.$$

Hence, Theorem 4 gives

$$\|T_n(\omega_\alpha^+)\|_p \leq \frac{Cn^\alpha}{1-\alpha}\left(1 + \sum_{k=1}^{n-1} k^{-\alpha p}\right)^{1/p} \leq \frac{Cn^\alpha}{1-\alpha}\left(2 + \int_1^{n-1} x^{-\alpha p} dx\right)^{1/p}.$$

The right-hand side can be bounded with respect to $p$ as

$$\begin{cases} C\dfrac{1}{(1-\alpha)(1-\alpha p)^{1/p}}n^{1/p}, & \alpha p < 1, \\[2ex] C\dfrac{1}{1-\alpha}\,n^{\alpha}(\log n)^{1/p}, & \alpha p = 1, \\[2ex] C\dfrac{1}{(1-\alpha)(\alpha p-1)^{1/p}}n^{\alpha}, & \alpha p > 1. \end{cases}$$

Similar to the discussion given in the case of the Ky Fan $k$-norms, we get the following.

THEOREM 5. [illegible] $a(x)$ [illegible] $\alpha$ [illegible] $1 \le p < \infty$ [illegible]

$$\|T_n(a)\|_p \le \begin{cases} C\dfrac{1}{(1-\alpha)(1-\alpha p)^{1/p}}\,n^{1/p}, & \alpha p < 1, \\[2ex] C\dfrac{1}{1-\alpha}\,(n\log n)^{\alpha}, & \alpha p = 1, \\[2ex] C\dfrac{1}{(1-\alpha)(\alpha p-1)^{1/p}}\,n^{\alpha}, & \alpha p > 1. \end{cases}$$

[illegible] Theorem 5 is clearly better than (4) and is consistent with (3). This theorem confirms a conjecture raised in [2]. Moreover, the method we used here is elementary.

# NUMERICALLY STABLE IMPLEMENTATIONS OF THE STRUCTURED COVARIANCE EXPECTATION-MAXIMIZATION ALGORITHM*

DANIEL R. FUHRMANN†

**Abstract.** Numerically stable methods for the computations required in the expectation-maximization (EM) algorithm for maximum-likelihood structured covariance estimation are presented. It is shown that the basic computational task at each iteration is the calculation of a pseudoinverse of a certain linear system of equations. In the no-noise case this is a hard-decision, or Moore–Penrose, pseudoinverse, whereas in the additive noise case it is a soft-decision pseudoinverse. An approach to computing the soft-decision pseudoinverse, which can handle all combinations of dimension and rank in this system of equations, based on the singular value decomposition (SVD), is proposed. An alternative method based on the LQ factorization, which is applicable in certain circumstances, is also proposed. The intermediate calculations required in the EM algorithm can be used to calculate the log-likelihood and the gradient of the log-likelihood.

## 1. Introduction.

The estimation of the second-order statistics of time series or sensor array data is a central problem in statistical signal processing. When the model for the data involves a linear transformation of a large number of independent components, or perhaps of a continuous independent-increments process, then the problem is one of spectrum estimation. When one considers the variance or covariance of the discrete data themselves, as determined by the spectrum, then the problem is one of structured covariance estimation. These problems are obviously closely related and have been well studied; see, e.g., [1, 2, 3, 4, 5, 6] and the many references contained therein.

The canonical problem in this class is one in which the spectrum denotes the power or power density of independent sinusoidal or complex exponential components, and the resulting time series has a Toeplitz covariance structure [6, 7, 8]. However, there are many generalizations and extensions of this basic problem. In problems involving space, or space and time, the spectrum could represent power or power density as a function of spatial variables or angle of arrival [9, 10]. The sensors could be placed in some arbitrary geometry and have relatively unstructured response vectors [11]. The relationship between the underlying independent-increments process and the data may be nonstationary, as in radio astronomy or time-varying arrays [12, 13]. In the radar imaging problem described in [14, 15], the scattering function parameters are indexed

by the radar-centered parameters of range and Doppler, leading to the estimation of a block-diagonal matrix with independent Toeplitz blocks. In our recent work in radar imaging [16], we showed how the scattering function may be estimated in an active way, with the illumination under the control of the data collection instrumentation.

When the underlying spectrum is discretized, many of these problems are based on the complex multivariate statistical model[1]

$$\mathbf{y}_k \sim CN(0, \mathbf{R}_k), \tag{1.1}$$

where

$$\mathbf{R}_k = \mathbf{A}_k \Sigma \mathbf{A}_k^{\mathrm{H}}. \tag{1.2}$$

The maximum-likelihood estimation of the diagonal matrix $\Sigma$ given the data $\mathbf{y}_1 \ldots \mathbf{y}_K$ is an interesting statistical inference problem with no known closed-form solution. The expectation-maximization (EM) algorithm [17] has been developed and implemented for a number of versions of this problem [7, 9, 10, 11, 12, 13, 14, 15, 16].

Our concern here is with the computational aspects of the steps of the EM algorithm. Recent work in scattering function estimation shows that one can have, in the same problem, several different matrices $\mathbf{A}_k$ which can be either wide or long[2] and can be either full-rank or rank-deficient. The standard derivations of the structured covariance EM algorithm assume that $\mathbf{A}_k$ is wide and full-rank. Other possibilities do not invalidate the basic maximum-likelihood approach; they simply require more care. This paper presents a computational approach that handles all combinations of dimension and rank in a numerically stable[3] way. It is based on the singular value decomposition (SVD) of the matrix $\mathbf{A}_k \Sigma^{\frac{1}{2}}$, which can be viewed as a square root of the covariance $\mathbf{R}_k$. Although the SVD itself is often seen as computationally expensive, calculations that are based on it are straightforward and have an intuitive appeal. Computational methods for the SVD are well understood, have been optimized over several decades of numerical linear algebra research and software development, and may not be the bottleneck commonly presumed.

In the standard case ($\mathbf{A}$ wide and full-rank), a computationally efficient method can be built on the LQ factorization rather than the SVD. Both the SVD and the LQ approaches have the advantage of not requiring data-squaring or sample covariance calculations; algorithms such as these are often called data-domain algorithms.

The quantities computed in the course of the structured covariance EM algorithm are essentially the same as those needed for the computation of the log-likelihood and the gradient of the log-likelihood with respect to the spectrum. Thus the algorithms presented here may have applicability beyond the EM algorithm itself.

Section 2 reviews the maximum-likelihood estimation problem and the derivation of the EM algorithm, for both the no-noise and additive noise cases. Section 3 shows how the basic computational task can be interpreted as either a hard-decision (Moore–Penrose) or a soft-decision pseudoinverse, for the no-noise and additive noise cases,

---

[1] (1.1) is shorthand for "$\mathbf{y}_k$ is subject to a complex multivariate Gaussian distribution with mean 0 and covariance $\mathbf{R}_k$," and this notation will be used throughout. The superscript H denotes Hermitian transpose.

[2] An $M \times N$ matrix $\mathbf{A}$ is said to be *wide* if $M < N$, *square* if $M = N$, and *long* if $M > N$.

[3] By "numerically stable" it is meant simply that the numerical or round-off behavior does not deteriorate badly as the rank of $\mathbf{A}$ goes to 0 or as $\mathbf{R}$ becomes singular. This paper contains no formal round-off analysis of the proposed methods; rather, we appeal to the favorable numerical properties of SVD and LQ factorizations and the least-squares methods based on them.

respectively. Section 4 shows how the pseudoinverses can be computed with the aid of the SVD and LQ factorizations. Finally, we show how the intermediate computations can be applied to the calculation of the log-likelihood and the gradient of the log-likelihood.

## 2. Structured covariance estimation and the EM algorithm.

**2.1. Basic model.** We begin with a brief review of the structured covariance estimation problem and an abbreviated derivation of the EM algorithm.

Suppose that there exist $K$ independent and identically distributed (i.i.d.) complex Gaussian random vectors $\mathbf{x}_1 \dots \mathbf{x}_K$, with mean 0 and diagonal covariance $\Sigma$. This is denoted by

$$\mathbf{x}_k \sim CN(0, \Sigma), \quad k = 1 \dots K, \text{ i.i.d.,} \tag{2.1}$$

where

$$\Sigma = \operatorname{diag}(\sigma(1) \dots \sigma(N)). \tag{2.2}$$

The diagonal elements of $\Sigma$ can be thought of as a discrete power spectrum that we wish to estimate.[4] If the $\mathbf{x}_k$ were observable, the sufficient statistic for $\sigma(n)$ would be

$$\tau(n) = \frac{1}{K} \sum_{k=1}^{K} |x_k(n)|^2, \quad n = 1 \dots N, \tag{2.3}$$

and the maximum-likelihood estimate of $\sigma(n)$ would be equal to $\tau(n)$.

Suppose now that, instead of observing the $\mathbf{x}_k$ directly, one is only able to observe the $\mathbf{x}_k$ through a linear transformation $\mathbf{A}$. That is, the data are complex Gaussian random vectors $\mathbf{y}_k$, $k = 1 \dots K$, described by

$$\mathbf{y}_k = \mathbf{A}\mathbf{x}_k. \tag{2.4}$$

It follows that the distribution of the $\mathbf{y}_k$ is

$$\mathbf{y}_k \sim CN(0, \mathbf{R}), \tag{2.5}$$

where

$$\mathbf{R} = \mathbf{A}\Sigma\mathbf{A}^{\mathrm{H}}. \tag{2.6}$$

The maximum-likelihood estimation problem is to estimate $\Sigma$ from the $\mathbf{y}_k$, which is generally a much more difficult problem than estimating $\Sigma$ from the $\mathbf{x}_k$. We refer to the $\mathbf{x}_k$ as the [illegible] and the $\mathbf{y}_k$ as the [illegible]. Because $\mathbf{R}$, the covariance for $\mathbf{y}_k$, is constrained to belong to a proper subset of the space of the nonnegative Hermitian matrices, as given in (2.6), the estimation problem is often called [illegible].

The sufficient statistic for $\mathbf{R}$, as in any covariance estimation problem, is the sample covariance given by

$$\mathbf{S} = \frac{1}{K} \sum_{k=1}^{K} \mathbf{y}_k \mathbf{y}_k^{\mathrm{H}}. \tag{2.7}$$

---

[4] Although $\sigma$ is commonly used for standard deviation, here we use it for variance to maintain a consistency in notation for $\sigma$ and $\Sigma$.

The incomplete-data log-likelihood, with constant terms removed, is

$$l(\mathbf{R};\mathbf{S}) = -K\log\det\mathbf{R} - K\mathrm{tr}\mathbf{R}^{-1}\mathbf{S}. \tag{2.8}$$

The maximum-likelihood estimation problem is to maximize (2.8) with respect to either $\Sigma$ or the constrained $\mathbf{R}$. It is usually convenient to cast the optimization problem as one of searching in $\Sigma$-space.

The following two identities, stated here without proof (see [6]), are useful in determining the gradient of the log-likelihood and thus the necessary conditions for a maximizer. They are

$$\delta\log\det\mathbf{R} = \mathrm{tr}\mathbf{R}^{-1}\delta\mathbf{R} \tag{2.9}$$

and

$$\delta\mathbf{R}^{-1} = -\mathbf{R}^{-1}\delta\mathbf{R}\mathbf{R}^{-1}, \tag{2.10}$$

where the symbol $\delta$ denotes the first variation. From (2.6) it is clear that

$$\delta\mathbf{R} = \mathbf{A}\delta\Sigma\mathbf{A}^{\mathrm{H}}. \tag{2.11}$$

It follows then that the variation of the log-likelihood is given by

$$\delta l = \mathrm{tr}\mathbf{A}^{\mathrm{H}}(\mathbf{R}^{-1}\mathbf{S}\mathbf{R}^{-1} - \mathbf{R}^{-1})\mathbf{A}\delta\Sigma. \tag{2.12}$$

One way to interpret (2.12) is that the diagonal elements of $\mathbf{A}^{\mathrm{H}}(\mathbf{R}^{-1}\mathbf{S}\mathbf{R}^{-1} - \mathbf{R}^{-1})\mathbf{A}$ form a gradient vector $\mathbf{g}$ for the parameter vector $\sigma$. The $\sigma(n)$ are nonnegative but are otherwise unconstrained. It follows that the Kuhn–Tucker conditions for a maximizer of the log-likelihood are (a) for any $\sigma(n) \neq 0$, the corresponding $g_n = 0$, and (b) for any $\sigma(n) = 0$, the corresponding $g_n \leq 0$.

The EM algorithm [17] for the structured covariance estimation problem is an iterative algorithm whose stationary points satisfy the Kuhn–Tucker conditions just given. Define $\Sigma^{(p)}$ as the estimate of $\Sigma$ at iteration $p$. Each iteration of the EM algorithm comprises two steps, the E-step (expectation) and the M-step (maximization). The E-step is to compute the conditional expected value of the complete-data sufficient statistics, given the current estimate $\Sigma^{(p)}$ and the incomplete-data sufficient statistic $\mathbf{S}$. In this case, the complete-data sufficient statistics are the $s(n)$ as given in (2.3). The M-step is the trivial operation of setting the next iterate $\sigma^{(p)}(n)$ equal to the estimated $s(n)$.

The expected squared magnitude of $x_k(n)$ is the squared magnitude of the conditional mean, plus the conditional variance. The conditional mean is given by

$$\begin{aligned}\mathrm{E}\{\mathbf{x}_k|\mathbf{y}_k,\Sigma^{(p)}\} &= \mathbf{R}_{\mathbf{xy}}(p)\mathbf{R}_{\mathbf{yy}}^{-1}(p)\mathbf{y}_k \\ &= \Sigma^{(p)}\mathbf{A}^{\mathrm{H}}\mathbf{R}_{\mathbf{yy}}^{-1}(p)\mathbf{y}_k,\end{aligned} \tag{2.13}$$

where $\mathbf{R}_{\mathbf{yy}}(p)$ is the covariance of $\mathbf{y}_k$ at iteration $p$, and $\mathbf{R}_{\mathbf{xy}}(p)$ is the cross-covariance of $\mathbf{x}_k$ and $\mathbf{y}_k$, both constructed with the assumed value of $\Sigma^{(p)}$.

The conditional covariance of the $\mathbf{x}_k$ is given by

$$\begin{aligned}cov\{\mathbf{x}_k|\mathbf{y}_k,\Sigma^{(p)}\} &= \mathbf{R}_{\mathbf{xx}}(p) - \mathbf{R}_{\mathbf{xy}}(p)\mathbf{R}_{\mathbf{yy}}^{-1}(p)\mathbf{R}_{\mathbf{yx}} \\ &= \Sigma - \Sigma^{(p)}\mathbf{A}^{\mathrm{H}}\mathbf{R}_{\mathbf{yy}}^{-1}(p)\mathbf{A}\Sigma^{(p)}.\end{aligned} \tag{2.14}$$

Substituting these conditional expectations in place of the actual $\mathbf{x}_k$ in (2.3), and using the fact that

$$\mathbf{R}_{\mathbf{yy}}(p) = \mathbf{R}(p) = \mathbf{A}\Sigma^{(p)}\mathbf{A}^{\mathrm{H}}, \tag{2.15}$$

we have finally the EM iteration given by

$$\begin{aligned}\Sigma^{(p+1)} = \Sigma^{(p)} &+ \operatorname{diag}\left[\Sigma^{(p)}\mathbf{A}^{\mathrm{H}}\mathbf{R}^{-1}(p)\mathbf{S}\mathbf{R}^{-1}(p)\mathbf{A}\Sigma^{(p)}\right] \\ &- \operatorname{diag}\left[\Sigma^{(p)}\mathbf{A}^{\mathrm{H}}\mathbf{R}^{-1}(p)\mathbf{A}\Sigma^{(p)}\right].\end{aligned} \tag{2.16}$$

**2.2. Nonstationary observation model.** In many applications, such as radio astronomy or airborne radar, the relationship between the observed and the observer is changing over time. An extension of the model presented in the previous subsection is one in which each observation is taken through a different linear transformation $\mathbf{A}_k$. In this case, one cannot aggregate all of the data into a single sample covariance, but rather the conditional expectation of the complete-data sufficient statistics must be taken on each data vector or perhaps the sample covariance for a subset of the data vectors.

The extended model for the data is described by

$$\mathbf{y}_k = \mathbf{A}_k x_k, \tag{2.17}$$

and the incomplete-data distribution is thus given by

$$\mathbf{y}_k \sim CN(0, \mathbf{R}_k), \tag{2.18}$$

where

$$\mathbf{R}_k = \mathbf{A}_k \Sigma \mathbf{A}_k^{\mathrm{H}}. \tag{2.19}$$

We now have an estimation problem in which one must estimate not just a single covariance $\mathbf{R}$ but rather an entire sequence $\mathbf{R}_1 \dots \mathbf{R}_K$. The "thread" that ties all of the $\mathbf{R}_k$ together is the desired spectrum $\Sigma$, which is considered constant over time.

The EM algorithm for this estimation problem requires that we determine the conditional expectation of the squared magnitudes of the components of $\mathbf{x}_k$, as before. The results are then averaged together in the M-step of the algorithm.

Denote the estimated covariance for data vector $\mathbf{y}_k$ at EM iteration $p$ as $\mathbf{R}_{\mathbf{yy}}(p,k)$. Given $\Sigma^{(p)}$ and $\mathbf{y}_k$, the conditional mean of $\mathbf{x}_k$ is

$$\begin{aligned}\mathrm{E}\{\mathbf{x}_k|\mathbf{y}_k, \Sigma^{(p)}\} &= \mathbf{R}_{\mathbf{xy}}(p,k)\mathbf{R}_{\mathbf{yy}}^{-1}(p,k)\mathbf{y}_k \\ &= \Sigma^{(p)}\mathbf{A}_k^{\mathrm{H}}\mathbf{R}_{\mathbf{yy}}^{-1}(p,k)\mathbf{y}_k.\end{aligned} \tag{2.20}$$

The conditional covariance of $\mathbf{x}_k$ is given by

$$\begin{aligned}cov\{\mathbf{x}_k|\mathbf{y}_k, \Sigma^{(p)}\} &= \mathbf{R}_{\mathbf{xx}}(p,k) - \mathbf{R}_{\mathbf{xy}}(p,k)\mathbf{R}_{\mathbf{yy}}^{-1}(p,k)\mathbf{R}_{\mathbf{yx}}(p,k) \\ &= \Sigma - \Sigma^{(p)}\mathbf{A}_k^{\mathrm{H}}\mathbf{R}_{\mathbf{yy}}^{-1}(p,k)\mathbf{A}_k\Sigma^{(p)}.\end{aligned} \tag{2.21}$$

The desired conditional variances are the diagonal elements of (2.21). Averaging the conditional expectations of the squared magnitudes of the $\mathbf{x}_k$ components, we arrive at the EM algorithm step

$$\begin{aligned}\Sigma^{(p+1)} = \Sigma^{(p)} &+ \frac{1}{K}\sum_{k=1}^{K}\operatorname{diag}\left[\Sigma^{(p)}\mathbf{A}_k^{\mathrm{H}}\mathbf{R}^{-1}(p,k)\mathbf{S}_k\mathbf{R}^{-1}(p,k)\mathbf{A}_k\Sigma^{(p)}\right] \\ &- \frac{1}{K}\sum_{k=1}^{K}\operatorname{diag}\left[\Sigma^{(p)}\mathbf{A}_k^{\mathrm{H}}\mathbf{R}^{-1}(p,k)\mathbf{A}_k\Sigma^{(p)}\right],\end{aligned} \tag{2.22}$$

where

$$\mathbf{R}(p,k) = \mathbf{A}_k \Sigma^{(p)} \mathbf{A}_k^{\mathrm{H}}. \tag{2.23}$$

Here $\mathbf{S}_k$ is either $\mathbf{y}_k \mathbf{y}_k^{\mathrm{H}}$ or the sample covariance for the $k$th observation interval, should that include more than one observation for the same $\mathbf{A}_k$.

**2.3. Additive noise model.** In some applications, such as radar imaging, the data are observed in the presence of additive white instrument or background noise. In this case, the data model is (reverting to the stationary observation case)

$$\mathbf{y}_k = \mathbf{A}\mathbf{x}_k + \mathbf{n}_k, \tag{2.24}$$

where $\mathbf{n}_k$ is $CN(0, \epsilon\mathbf{I})$ and independent of $\mathbf{x}_k$. It follows that

$$\mathbf{y}_k \sim CN(0, \mathbf{A}\Sigma\mathbf{A}^{\mathrm{H}} + \epsilon\mathbf{I}). \tag{2.25}$$

Again the basic task in the EM algorithm is to compute the conditional distribution for $\mathbf{x}_k$ given $\mathbf{y}_k$ and $\Sigma$. The conditional mean is

$$\begin{aligned} \mathrm{E}\{\mathbf{x}_k | \mathbf{y}_k, \Sigma\} &= \mathbf{R}_{\mathbf{xy}} \mathbf{R}_{\mathbf{yy}}^{-1} \mathbf{y}_k \\ &= \Sigma \mathbf{A}^{\mathrm{H}} (\mathbf{A}\Sigma\mathbf{A}^{\mathrm{H}} + \epsilon\mathbf{I})^{-1} \mathbf{y}_k. \end{aligned} \tag{2.26}$$

The conditional covariance is

$$\begin{aligned} cov\{\mathbf{x}_k | \mathbf{y}_k, \Sigma\} &= \mathbf{R}_{\mathbf{xx}} - \mathbf{R}_{\mathbf{xy}} \mathbf{R}_{\mathbf{yy}}^{-1} \mathbf{R}_{\mathbf{yx}} \\ &= \Sigma - \Sigma \mathbf{A}^{\mathrm{H}} (\mathbf{A}\Sigma\mathbf{A}^{\mathrm{H}} + \epsilon\mathbf{I})^{-1} \mathbf{A}_k \Sigma. \end{aligned} \tag{2.27}$$

Folding these into the EM algorithm as before we get

$$\begin{aligned} \Sigma^{(p+1)} = \Sigma^{(p)} &+ \mathrm{diag}\left[\Sigma^{(p)} \mathbf{A}^{\mathrm{H}} (\mathbf{A}\Sigma^{(p)}\mathbf{A}^{\mathrm{H}} + \epsilon\mathbf{I})^{-1} \mathbf{S} (\mathbf{A}\Sigma^{(p)}\mathbf{A}^{\mathrm{H}} + \epsilon\mathbf{I})^{-1} \mathbf{A}\Sigma^{(p)}\right] \\ &- \mathrm{diag}\left[\Sigma^{(p)} \mathbf{A}^{\mathrm{H}} (\mathbf{A}\Sigma^{(p)}\mathbf{A}^{\mathrm{H}} + \epsilon\mathbf{I})^{-1} \mathbf{A}\Sigma^{(p)}\right]. \end{aligned} \tag{2.28}$$

This result can be extended to the the nonstationary observation model in the obvious way, by averaging the complete-data sufficient statistics over the $K$ observations.

## 3. Basic computational tasks.

In the derivation above, no mention was made of the size or rank of the matrices $\mathbf{A}$ or $\mathbf{A}_k$, or even whether or not the covariances $\mathbf{R}$ or $\mathbf{R}_k$ are invertible. In fact, the results obtained above for the no-noise case are valid only in the case where $\mathbf{A}$ ($\mathbf{A}_k$) is wide and full-rank. Nevertheless, we now show that there exists a single interpretation of the E-step for the underdetermined, overdetermined, full-rank, and rank-deficient cases of the basic problem. The basic computations for the stationary and nonstationary observation cases are the same, the only difference being in the aggregation of data into sample covariance matrices under the stationary observation case. The result is slightly different for the additive noise case, so it will be treated separately.

**3.1. No-noise model.** The essential computational task at iteration $p$ is to compute the conditional distribution of the $\mathbf{x}_k$ given the incomplete data $\mathbf{y}_k$ and the current $\Sigma^{(p)}$. For notational simplicity, we will drop the superscript $p$ (iteration number) and the subscript $k$ (data index) and concern ourselves with the calculation of the conditional distribution of $\mathbf{x}$ given $\mathbf{y}$ and $\Sigma$. We assume without loss of generality that all elements of $\Sigma$ are positive. If any $\sigma(n) = 0$, then the conditional expected value of $s(n)$ is zero as well, and the $n$th column of $\mathbf{A}$ can be removed from consideration.

Let $\mathbf{A}$ be $M \times N$, with rank $r \leq \min(M, N)$. For the purposes of this derivation, it is assumed that $r$ is known and that the $\min(M, N) - r$ singular values of $\mathbf{A}$ are exactly 0. In section 4, the results will be applied to the case more commonly encountered in practice, in which $r$ is the "numerical rank" determined by comparing the smallest singular values to a small but nonzero threshold.

Define the matrix $\mathbf{B}$ by

$$\mathbf{B} = \mathbf{A}\Sigma^{\frac{1}{2}}. \tag{3.1}$$

Let the SVD of $\mathbf{B}$ be given by

$$\mathbf{A}\Sigma^{\frac{1}{2}} = \mathbf{U}\mathbf{D}\mathbf{V}^{\mathrm{H}}. \tag{3.2}$$

This is the "full-size" SVD, where $\mathbf{U}$ and $\mathbf{V}$ are unitary matrices of size $M \times M$ and $N \times N$, respectively, and $\mathbf{D}$ is a diagonal rectangular $M \times N$ matrix, with

$$\begin{aligned} \mathbf{D}(i,i) &= d_i, \quad i = 1 \ldots r, \\ &= 0, \quad \text{otherwise.} \end{aligned} \tag{3.3}$$

The $d_i$ are the singular values of $\mathbf{B}$, and the columns of $\mathbf{U}$ and $\mathbf{V}$ are the left and right singular vectors, respectively, of $\mathbf{B}$.

Define

$$\mathbf{z} = \mathbf{U}^{\mathrm{H}}\mathbf{y} \tag{3.4}$$

and

$$\mathbf{w} = \Sigma^{-\frac{1}{2}}\mathbf{x}. \tag{3.5}$$

Both of these mappings are one-to-one; hence, observation of $\mathbf{z}$ is equivalent to observation of $\mathbf{y}$, and the conditional distribution of $\mathbf{x}$ can be determined from the conditional distribution of $\mathbf{w}$. It suffices to determine the conditional distribution of $\mathbf{w}$ given $\mathbf{z}$. These two vectors are related by the linear transformation

$$\mathbf{z} = \mathbf{D}\mathbf{V}^{\mathrm{H}}\mathbf{w}. \tag{3.6}$$

The unconditional distribution for $\mathbf{w}$ is

$$\mathbf{w} \sim CN(0, \mathbf{I}_N). \tag{3.7}$$

Now define $\tilde{\mathbf{w}} = \mathbf{V}^{\mathrm{H}}\mathbf{w}$. $\mathbf{V}$ is a unitary, and hence invertible, transformation, and

$$\tilde{\mathbf{w}} \sim CN(0, \mathbf{I}_N). \tag{3.8}$$

Since $\mathbf{Z} = \mathbf{D}\tilde{\mathbf{w}}$ there are $r$ observed components of $\tilde{\mathbf{w}}$, namely, $\tilde{w}(1) \ldots \tilde{w}(r)$, and the remaining $N - r$ entries of $\tilde{\mathbf{w}}$ are unobserved. Furthermore, these other $N - r$ entries are uncorrelated with the first $r$, so their distribution is not changed under conditioning. Thus we have

$$\begin{aligned} \mathrm{E}\{\tilde{w}(n)|\mathbf{z}\} &= \frac{z(n)}{d_n}, \quad n = 1 \ldots r, \\ &= 0, \qquad n = r+1 \ldots N \end{aligned} \tag{3.9}$$

and

$$cov\{\tilde{\mathbf{w}}|\mathbf{z}\} = \begin{bmatrix} \mathbf{0}_{r\times r} & \mathbf{0}_{(N-r)\times r} \\ \mathbf{0}_{r\times (N-r)} & \mathbf{I}_{(N-r)\times(N-r)} \end{bmatrix}. \tag{3.10}$$

The conditional distribution for $\mathbf{w}$ given $\mathbf{y}$ follows immediately from the conditional distribution for $\tilde{\mathbf{w}}$ given $\mathbf{z}$. Using $\mathbf{w} = \mathbf{V}\tilde{\mathbf{w}}$ and $\mathbf{z} = \mathbf{U}^{\mathrm{H}}\mathbf{y}$ we have

$$\mathrm{E}\{\mathbf{w}|\mathbf{y}\} = \mathbf{V}\,\mathrm{diag}\left[d_1^{-1}\dots d_r^{-1} 0 \dots 0\right] \mathbf{U}^{\mathrm{H}}\mathbf{y} \tag{3.11}$$

and

$$cov\{\mathbf{w}|\mathbf{y}\} = \mathbf{V}_2\mathbf{V}_2^{\mathrm{H}}. \tag{3.12}$$

In (3.12), $\mathbf{V}_2$ comprises columns $r+1\dots N$ of the unitary matrix $\mathbf{V}$ and spans the orthogonal complement of the row space of $\mathbf{B} = \mathbf{A}\Sigma^{\frac{1}{2}}$.

The conditional mean in (3.11) is the [illegible] (MNLS) solution to the rectangular system of equations

$$\mathbf{y} = \mathbf{B}\mathbf{w}, \tag{3.13}$$

which we denote as $\hat{\mathbf{w}}_{MNLS}$. As the name implies, there are two aspects of the MNLS solution: the least-squares part and the minimum-norm part. The solution is [illegible] because the reconstruction $\mathbf{B}\hat{\mathbf{w}}_{MNLS}$ is as close as possible to $\mathbf{y}$ and lies in the column space of $\mathbf{B}$. It is [illegible] because $\hat{\mathbf{w}}_{MNLS}$ is orthogonal to the row space of $\mathbf{B}$. The matrix that multiplies $\mathbf{y}$ in (3.11) is called the [illegible] of the matrix $\mathbf{B}$ [18, 19].

The conditional distribution of $\mathbf{x}$ now follows immediately from (3.11)–(3.12) and (3.5). It is given by

$$E\{\mathbf{x}|\mathbf{y}\} = \Sigma^{\frac{1}{2}}\hat{\mathbf{w}}_{MNLS} \tag{3.14}$$

and

$$cov\{\mathbf{x}|\mathbf{y}\} = \Sigma^{\frac{1}{2}}\mathbf{V}_2\mathbf{V}_2^{\mathrm{H}}\Sigma^{\frac{1}{2}}. \tag{3.15}$$

The EM algorithm requires the computation of the squared magnitudes of the components of (3.14) and the diagonal elements of (3.15). If there are multiple observations $\mathbf{y}_1\dots\mathbf{y}_K$, then either the calculation in (3.14) is repeated $K$ times or an operation can be carried out on the sample covariance $\mathbf{S}$. The diagonal elements of (3.15) are found by summing the squared magnitudes of the rows of $\Sigma\mathbf{V}_2$.

When $\mathbf{A}$ is rectangular with $M \leq N$ and full-rank, then the required matrix inverses exist, and the iteration obtained here coincides with the usual EM algorithm. Note that, in this case, (2.16) can be written

$$\begin{aligned} \Sigma^{(p+1)} = \mathrm{diag}\Big[&\Sigma^{(p)\frac{1}{2}}\mathbf{B}^{\mathrm{H}}(\mathbf{B}\mathbf{B}^{H})^{-1}\mathbf{S}(\mathbf{B}\mathbf{B}^{H})^{-1}\mathbf{B}\Sigma^{(p)\frac{1}{2}} \\ &+\Sigma^{(p)} - \Sigma^{(p)\frac{1}{2}}\mathbf{B}^{H}(\mathbf{B}\mathbf{B}^{\mathrm{H}})^{-1}\mathbf{B}\Sigma^{(p)\frac{1}{2}}\Big]. \end{aligned} \tag{3.16}$$

In summary, each iteration of the EM algorithm in the no-noise case requires (a) the MNLS solution to the rectangular system of equations

$$\mathbf{y} = (\mathbf{A}\Sigma^{\frac{1}{2}})\mathbf{w} \tag{3.17}$$

and (b) an orthogonal basis for the row space of $\mathbf{A}\Sigma^{\frac{1}{2}}$.

**3.2. Additive noise case.** In the presence of additive noise, the basic computation changes somewhat. In a certain sense, the problem is better-posed in this case since the matrix inverses in the EM iterations of section 2.3 exist, independent of $M$, $N$, and $r$.

Again the basic computational task is the calculation of the conditional distribution of $\mathbf{x}$ given $\mathbf{y}$ and $\Sigma$. Define $L = \min(M, N)$ and write the "economy-size" SVD of $\mathbf{B} = \mathbf{A}\Sigma^{\frac{1}{2}}$ as

$$\mathbf{B} = \mathbf{U}\mathbf{D}\mathbf{V}^{\mathrm{H}}, \tag{3.18}$$

where $\mathbf{U}$ is $M \times L$, $\mathbf{D}$ is $L \times L$, and $\mathbf{V}$ is $N \times L$. The conditional mean of $\mathbf{x}$ is

$$\mathrm{E}\{\mathbf{x}|\mathbf{y};\Sigma\} = \Sigma^{\frac{1}{2}}(\mathbf{V}\mathbf{D}\mathbf{U}^{\mathrm{H}})(\mathbf{U}\mathbf{D}^2\mathbf{U}^{\mathrm{H}} + \epsilon\mathbf{I})^{-1}\mathbf{y}. \tag{3.19}$$

The matrix inverse in (3.19) exists independent of $M$, $N$, and $r$. We have that

$$\begin{aligned} \mathbf{U}\mathbf{D}^2\mathbf{U}^{\mathrm{H}} + \epsilon\mathbf{I} &= \mathbf{U}(\mathbf{D}^2 + \epsilon\mathbf{I})\mathbf{U}^{\mathrm{H}} \quad (M < N) && \text{(3.20a)} \\ &= \mathbf{U}(\mathbf{D}^2 + \epsilon\mathbf{I})\mathbf{U}^{\mathrm{H}} + \epsilon\mathbf{U}_2\mathbf{U}_2^{\mathrm{H}} \quad (M > N), && \text{(3.20b)} \end{aligned}$$

where, in the $M > N$ case, $\mathbf{U}_2$ is the orthonormal matrix whose columns span the orthogonal complement of the column range of $\mathbf{U}$. In either case, we have

$$\begin{aligned} \mathrm{E}\{\mathbf{x}|\mathbf{y};\Sigma\} &= \Sigma^{\frac{1}{2}}\mathbf{V}\mathbf{D}\mathbf{U}^{\mathrm{H}}\mathbf{U}(\mathbf{D}^2 + \epsilon\mathbf{I})^{-1}\mathbf{U}^{\mathrm{H}}\mathbf{y} \\ &= \Sigma^{\frac{1}{2}}\mathbf{V}\begin{bmatrix} \frac{d_1}{d_1^2 + \epsilon} & & \\ & \ddots & \\ & & \frac{d_L}{d_L^2 + \epsilon} \end{bmatrix}\mathbf{U}^{\mathrm{H}}\mathbf{y}. \end{aligned} \tag{3.21}$$

Note that when $r < L$, there are no singularities or discontinuities; $L - r$ elements of the diagonal matrix in (3.21) go to 0 continuously as $d_i \to 0$. For this reason we define the matrix in (3.21) as a [illegible], in contrast to the Moore–Penrose pseudoinverse, which requires a hard decision as to whether a singular value is above or below some tolerance.

Using the same economy-size SVD, the conditional covariance of $\mathbf{x}$ is

$$\begin{aligned} cov\{\mathbf{x}|\mathbf{y};\Sigma\} &= \Sigma^{\frac{1}{2}}\mathbf{V}\mathbf{D}\mathbf{U}^{\mathrm{H}}\mathbf{U}(\mathbf{D}^2 + \epsilon\mathbf{I})^{-1}\mathbf{U}\mathbf{U}^{\mathrm{H}}\mathbf{D}\mathbf{V}^{\mathrm{H}}\Sigma^{\frac{1}{2}} \\ &= \Sigma^{\frac{1}{2}}\mathbf{V}\begin{bmatrix} \frac{d_1^2}{d_1^2 + \epsilon} & & \\ & \ddots & \\ & & \frac{d_L^2}{d_L^2 + \epsilon} \end{bmatrix}\mathbf{V}^{\mathrm{H}}\Sigma^{\frac{1}{2}}. \end{aligned} \tag{3.22}$$

Since only the diagonal elements of (3.22) are required, it suffices to compute $\mathbf{V}$ first, then to compute the weighted inner products

$$\sum_{j=1}^{L} \alpha_j |v(i,j)|^2, \tag{3.23}$$

with

$$\alpha_j = \frac{d_j^2}{d_j^2 + \epsilon}, \tag{3.24}$$

followed by pointwise multiplication by the elements of $\Sigma$.

**4. Computational alternatives.** As shown in section 2.2 above, the primary computational task at each iteration of the EM algorithm is the calculation of some sort of pseudoinverse of the system of equations

$$\mathbf{y} = \mathbf{B}\mathbf{w}, \tag{4.1}$$

where $\mathbf{B} = \mathbf{A}\Sigma^{\frac{1}{2}}$. Any routine that does this must be general-purpose and numerically stable, meaning that it should handle any combination of $(M, N)$ (the size of $\mathbf{A}$) and rank $r$. In the no-noise case, we need the Moore–Penrose pseudoinverse (or hard-decision pseudoinverse) given by

$$\mathbf{B}_{MP}^{\#} = \mathbf{V}\mathbf{E}_{MP}\mathbf{U}^{\mathrm{H}}, \tag{4.2}$$

with

$$\begin{aligned} e_{MP}(i,i) &= \frac{1}{d_i}, \quad d_i > tol, \\ &= 0, \quad\ \ d_i < tol. \end{aligned} \tag{4.3}$$

In the additive-noise case, the solution is given by the soft-decision pseudoinverse

$$\mathbf{B}_{SD}^{\#} = \mathbf{V}\mathbf{E}_{SD}\mathbf{U}^{\mathrm{H}}, \tag{4.4}$$

with

$$e_{SD}(i,i) = \frac{d_i}{d_i^2 + \epsilon}. \tag{4.5}$$

To calculate the conditional covariance term of the EM algorithm we must also know an orthonormal basis for the row space of $\mathbf{A}\Sigma^{\frac{1}{2}}$.

**4.1. SVD-based approach.** We advocate a computational approach based on the SVD, following exactly the development in section 3. There is obviously a significant computational overhead associated with computing the SVD of $\mathbf{A}\Sigma^{\frac{1}{2}}$; however, all of the required quantities in the EM algorithm follow trivially from the SVD, as has already been shown. Furthermore, all computations are numerically stable, and all possible combinations of $M$, $N$, and $r$ are unified in a single algorithm.

The use of the soft-decision pseudoinverse could also unify the additive-noise and no-noise models. Since it can be argued that any data acquisition system has some level of additive noise, one could always use the additive-noise model with some small value of $\epsilon$. One very important advantage of the soft-decision pseudoinverse is that it is continuous with respect to small changes in the matrix $\mathbf{B}$. Since $\Sigma$ is changing through the course of the EM algorithm, the fact that the Moore–Penrose pseudoinverse is discontinuous may lead to unpredictable numerical behavior—say, for example, when the numerical rank of $\mathbf{A}\Sigma^{\frac{1}{2}}$ changes from one iteration to the next.

A second recommendation, for computational efficiency, is to replace the data matrix $\mathbf{Y} = [\mathbf{y}_1 \ldots \mathbf{y}_K]$ with the lower-triangular Cholesky factor of the sample covariance matrix when $K > M$. Note that

$$\mathbf{S} = \frac{1}{K}\mathbf{Y}\mathbf{Y}^{\mathrm{H}}. \tag{4.6}$$

When $K > M$, one can write the LQ factorization of $\mathbf{Y}$ as

$$\mathbf{Y} = \mathbf{L}\mathbf{Q}, \tag{4.7}$$

where $\mathbf{L}$ is an $M \times M$ lower-triangular matrix, and $\mathbf{Q}$ is an $M \times K$ matrix with orthonormal rows. Since $\mathbf{Q}\mathbf{Q}^{\mathrm{H}} = \mathbf{I}$, we have that

$$\mathbf{S} = \frac{1}{K}\mathbf{L}\mathbf{L}^{\mathrm{H}}, \tag{4.8}$$

or, put another way, $\mathbf{L}$ is the lower Cholesky factor of $K\mathbf{S}$. In the algorithm summary below, the matrix $\mathbf{Y}$ can represent either this triangular factor, which needs to be computed only once, or in the $K < M$ case it can represent the data matrix directly.

We summarize here the basic computational step of the EM algorithm, using the SVD and the soft-decision pseudoinverse. This description is for the stationary observation model; the extension to the nonstationary observation is to repeat the calculation below for each of the observations and average the $\Sigma$'s which result.

Algorithm 1 (SVD). [illegible] $\mathbf{A}$ [illegible] $\mathbf{Y}$ [illegible] $\epsilon$ [illegible] $\Sigma^{(p)}$ [illegible]

1. [illegible] $\mathbf{A}\Sigma^{\frac{1}{2}}$

$$\mathbf{A}(\Sigma^{(p)})^{\frac{1}{2}} = \mathbf{U}\mathbf{D}\mathbf{V}^{\mathrm{H}}. \tag{4.9}$$

2. [illegible]

$$\mathbf{T}_1 = \mathbf{V}\mathbf{E}_{SD}\mathbf{U}^{\mathrm{N}}\mathbf{Y}, \tag{4.10}$$

[illegible]

$$\mathbf{E}_{SD} = \mathrm{diag}\left[\frac{d_1}{d_1^2+\epsilon}\cdots\frac{d_M}{d_M^2+\epsilon}\right]. \tag{4.11}$$

3. [illegible]

$$\mathbf{T}_2 = \mathbf{V}. \tag{4.12}$$

4. [illegible] $n = 1 \ldots N$ [illegible]

$$\sigma_n^{(p+1)} = \sigma_n^p\left[1 + \frac{1}{K}\sum_{j=1}^{min(K,M)}|t_1(n,j)|^2 - \sum_{j=1}^{M}\alpha_j|t_2(n,j)|^2\right], \tag{4.13}$$

[illegible]

$$\alpha_j = \frac{d_j^2}{d_j^2+\epsilon}. \tag{4.14}$$

**4.2. LQ-based approach.** The SVD-based algorithm described above has desirable numerical properties and works for all combinations of $M$, $N$, and $r$ but does suffer from the overhead of computing the SVD itself. We describe now an alternative method which is applicable in the commonly encountered situation in which (a) no noise is included in the model, (b) $M < N$, and (c) $\mathbf{A}\Sigma^{\frac{1}{2}}$ is full-rank. Condition (c) is guaranteed as long as $\mathbf{A}$ is full-rank and $\Sigma$ is all-positive, or, alternatively, if $\mathbf{A}$ has the property that any collection of $M$ columns is linearly independent, and at least $M$ diagonal elements of $\Sigma$ are nonzero.

Under the conditions stated above, there exists a decomposition of $\mathbf{B} = \mathbf{A}\Sigma^{\frac{1}{2}}$, called the LQ decomposition, given by

$$\mathbf{B} = \mathbf{L}\mathbf{Q}, \tag{4.15}$$

where $\mathbf{L}$ is an $M \times M$ lower-triangular matrix, and $\mathbf{Q}$ is an $M \times N$ matrix with orthonormal rows. (This is the transpose of the QR decomposition of $\mathbf{B}^{\mathrm{H}}$.) Calculation of the LQ decompositions requires $O(M^2N)$ flops.

Given the LQ decomposition of $\mathbf{B}$, the conditional mean of $\mathbf{x}$ given $\mathbf{y}$ and $\Sigma$ is

$$\begin{aligned} E\{\mathbf{x}|\mathbf{y}\} &= \Sigma^{\frac{1}{2}}\mathbf{B}^{\mathrm{H}}(\mathbf{B}\mathbf{B}^{\mathrm{H}})^{-1}\mathbf{y} \\ &= \Sigma^{\frac{1}{2}}\mathbf{Q}^{\mathrm{H}}\mathbf{L}^{\mathrm{H}}(\mathbf{L}\mathbf{Q}\mathbf{Q}^{\mathrm{H}}\mathbf{L}^{\mathrm{H}})^{-1}\mathbf{y} \\ &= \Sigma^{\frac{1}{2}}\mathbf{Q}^{\mathrm{H}}\mathbf{L}^{-1}\mathbf{y}. \end{aligned} \tag{4.16}$$

The triangular backsolve $\mathbf{L}^{-1}\mathbf{y}$ requires $O(M^2)$ flops, and multiplication by $\Sigma^{\frac{1}{2}}\mathbf{Q}^{\mathrm{H}}$ requires $O(NM)$ flops. For $K$ vectors $\mathbf{y}_1 \dots \mathbf{y}_K$, or some other factorization of the sample covariance matrix with $K$ columns, the above computational estimates are multiplied by a factor of $K$.

The conditional covariance of $\mathbf{x}$ given $\mathbf{y}$ is

$$\begin{aligned} cov\{\mathbf{x}|\mathbf{y}\} &= \Sigma - \Sigma^{\frac{1}{2}}\mathbf{B}^{\mathrm{H}}(\mathbf{B}\mathbf{B}^{\mathrm{H}})^{-1}\mathbf{B}\Sigma^{\frac{1}{2}} \\ &= \Sigma^{\frac{1}{2}}(\mathbf{I} - \mathbf{Q}^{\mathrm{H}}\mathbf{Q})\Sigma^{\frac{1}{2}}. \end{aligned} \tag{4.17}$$

The diagonal elements of (4.17) are found by computing the column sums $\sum_{i=1}^{M} |q_{ij}|^2$ and then weighting by $\sigma_j$. This requires $O(MN)$ operations.

The summary of the LQ algorithm is as given below.

ALGORITHM 2 (LQ). [illegible] $\mathbf{A}$ [illegible] $\mathbf{Y}$ [illegible] $\Sigma^{(p)}$

1. [illegible] $\mathbf{A}\Sigma^{\frac{1}{2}}$

$$\mathbf{A}(\Sigma^{(p)})^{\frac{1}{2}} = \mathbf{L}\mathbf{Q}. \tag{4.18}$$

2. [illegible]

$$\mathbf{T}_1 = \mathbf{Q}^{\mathrm{H}}\mathbf{L}^{-1}\mathbf{Y}. \tag{4.19}$$

3. [illegible]

$$\mathbf{T}_2 = \mathbf{Q}^{\mathrm{H}}. \tag{4.20}$$

4. [illegible] $n = 1 \dots N$ [illegible]

$$\sigma_n^{(p+1)} = \sigma_n^p \left[ 1 + \frac{1}{K}\sum_{j=1}^{K} |t_1(n,j)|^2 - \sum_{j=1}^{M} |t_2(n,j)|^2 \right] \tag{4.21}$$

Given the respective decompositions, both the LQ and the SVD methods require a similar computational load. An informal study of the QR and SV decompositions indicates that, while both are $O(NM^2)$ algorithms, the SVD requires about 3 times the computation of the QRD. This suggests that the LQ approach may be an attractive alternative as long as the conditions set forth at the beginning of this section are satisfied. The primary benefit of using the SVD is the "peace of mind" that comes with knowing that no special efforts must be made to ensure invertibility of matrices involved in the calculations. We also point out that, as $K$ (the number of columns in the factor of the sample covariance matrix) approaches $M$, the calculations in the EM algorithm after the decomposition become comparable with the decomposition itself, and thus the relative advantage of the LQ over the SVD method begins to disappear.

**4.3. Calculation of related quantities.** The calculations described above are central not only to the structured covariance EM algorithm but to closely related quantities in the maximum-likelihood estimation problem, namely, the log-likelihood and the gradient of the log-likelihood. The log-likelihood is given by

$$l(\mathbf{R};\mathbf{S}) = -\log\det\mathbf{R} - \mathrm{tr}\mathbf{R}^{-1}\mathbf{S}, \tag{4.22}$$

and the gradient of the log-likelihood, with respect to $\Sigma$ and expressed as a diagonal matrix, is

$$\mathbf{G}(\Sigma;\mathbf{S}) = \mathrm{diag}\left[\mathbf{A}^{\mathrm{H}}(\mathbf{R}^{-1}\mathbf{S}\mathbf{R}^{-1} - \mathbf{R}^{-1})\mathbf{A}^{\mathrm{H}}\right]. \tag{4.23}$$

We use here only the additive noise model for which $\mathbf{R} = \mathbf{A}\Sigma\mathbf{A}^{\mathrm{H}} + \epsilon\mathbf{I}$.

Let the SVD of $\mathbf{A}\Sigma^{\frac{1}{2}}$ be $\mathbf{U}\mathbf{D}\mathbf{V}^{\mathrm{H}}$ as before. Then the expression for $\mathbf{R}$ is

$$\mathbf{R} = \mathbf{U}\mathbf{D}^2\mathbf{U}^{\mathrm{H}} + \epsilon\mathbf{I}. \tag{4.24}$$

It follows that the first term in the log-likelihood is

$$\log\det\mathbf{R} = \sum_{i=1}^{M}\log(d_i^2+\epsilon) \quad (M \le N) \tag{4.25a}$$

$$= \sum_{i=1}^{M}\log(d_i^2+\epsilon) + (M-N)\log\epsilon \quad (M > N). \tag{4.25b}$$

The second term in the log-likelihood is

$$\mathrm{tr}\mathbf{R}^{-1}\mathbf{S} = \mathrm{tr}\mathbf{Y}^{\mathrm{H}}(\mathbf{U}\mathbf{D}^2\mathbf{U}^{\mathrm{H}} + \epsilon\mathbf{I})^{-1}\mathbf{Y} \tag{4.26a}$$

$$= \sum_{i=1}^{M}\frac{1}{d_i^2+\epsilon}\sum_{j=1}^{K}|(\mathbf{U}^{\mathrm{H}}\mathbf{Y})(i,j)|^2 \quad (M \le N) \tag{4.26b}$$

$$= \sum_{i=1}^{M}\frac{1}{d_i^2+\epsilon}\sum_{j=1}^{K}|(\mathbf{U}^{\mathrm{H}}\mathbf{Y})(i,j)|^2 + \frac{1}{\epsilon}\sum_{i=1}^{M-N}\sum_{j=1}^{K}|(\mathbf{U}_2^{\mathrm{H}}\mathbf{Y})(i,j)|^2 \quad (M > N), \tag{4.26c}$$

where, in the second $M > N$ case, $\mathbf{U}_2$ is an orthonormal basis spanning the orthogonal complement of the range of $\mathbf{U}$.

Calculation of the gradient is easy as long as none of the $\sigma_i$ are equal to 0. The EM iteration itself can be written as

$$\Sigma^{(p+1)} = \Sigma^{(p)} + (\Sigma^{(p)})^2\mathbf{G}^{(p)}, \tag{4.27}$$

where

$$\mathbf{G}^{(p)} = \mathbf{G}(\Sigma^{(p)};\mathbf{S}) \tag{4.28}$$

as given in (4.23). If $\mathbf{T}^{(p)}$ is defined as the diagonal matrix of quantities inside the square brackets in (4.13), then

$$\Sigma^{(p+1)} = \Sigma^{(p)} + \Sigma^{(p)}\mathbf{T}^{(p)}. \tag{4.29}$$

It follows that

$$\mathbf{G}^{(p)} = (\Sigma^{(p)})^{-1}\mathbf{T}^{(p)}. \tag{4.30}$$

The difficulty with the expression in (4.30) is that some of the $\sigma_i$ may be 0. The effect of this on $\mathbf{T}$, by the SVD of $\mathbf{A}\Sigma^{\frac{1}{2}}$, is that the corresponding $t_{ii}$ is also 0, and thus the correct value of the gradient is indeterminate from (4.30).

When the possibility exists for some of the $\sigma_j$ to be equal to 0, then an approach to computing the gradient that relies on direct calculation with $\mathbf{A}$ is required. Given the SVD of $\mathbf{A}\Sigma^{\frac{1}{2}} = \mathbf{U}\mathbf{D}\mathbf{V}^{\mathrm{H}}$ as before, the gradient can be written

$$\begin{aligned}\mathbf{G}(\Sigma;\mathbf{S}) = \operatorname{diag}&\left[\mathbf{A}^{\mathrm{H}}(\mathbf{U}\mathbf{D}^2\mathbf{U}^{\mathrm{H}} + \epsilon\mathbf{I})^{-1}\mathbf{Y}\mathbf{Y}^{\mathrm{H}}(\mathbf{U}\mathbf{D}^2\mathbf{U}^{\mathrm{H}} + \epsilon\mathbf{I})^{-1}\mathbf{A}\right] \\ &- \operatorname{diag}\left[\mathbf{A}^{\mathrm{H}}(\mathbf{U}\mathbf{D}^2\mathbf{U}^{\mathrm{H}} + \epsilon I)^{-1}\mathbf{A}\right].\end{aligned} \tag{4.31}$$

For the case $M < N$, define $\mathbf{B} = \mathbf{U}^{\mathrm{H}}\mathbf{A}$ and $\mathbf{Z} = \mathbf{U}^{\mathrm{H}}\mathbf{Y}$. Further define

$$\mathbf{T}_1 = \mathbf{B}^{\mathrm{H}}(\mathbf{D}^2 + \epsilon\mathbf{I})^{-1}\mathbf{Z} \tag{4.32}$$

and

$$\mathbf{T}_2 = (\mathbf{D}^2 + \epsilon\mathbf{I})^{-\frac{1}{2}}\mathbf{B}. \tag{4.33}$$

Then the $j$th term of the gradient (the $j$th diagonal element of $\mathbf{G}$) is given by

$$g_j = \sum_{i=1}^{M} |t_1(i,j)|^2 - \sum_{i=1}^{M} |t_2(i,j)|^2. \tag{4.34}$$

Some extra calculations are required for the $M > N$ case. Define $\mathbf{B}_2 = \mathbf{U}_2^{\mathrm{H}}\mathbf{A}$ and $\mathbf{Z}_2 = \mathbf{U}_2\mathbf{Y}$, where $\mathrm{U}_2$ is any orthogonal matrix spanning the orthogonal complement of $\mathbf{U}$. Then the definitions of $\mathbf{T}_1$ and $\mathbf{T}_2$ change to

$$\mathbf{T}_1 = \mathbf{B}^{\mathrm{H}}(\mathbf{D}^2 + \epsilon\mathbf{I})^{-1}\mathbf{Z} + \epsilon^{-1}\mathbf{B}_2^{\mathrm{H}}\mathbf{Z}_2 \tag{4.35}$$

and

$$\mathbf{T}_2 = \begin{bmatrix} (\mathbf{D}^2 + \epsilon\mathbf{I})^{-\frac{1}{2}}\mathbf{B} \\ \epsilon^{-\frac{1}{2}}\mathbf{B}_2 \end{bmatrix}. \tag{4.36}$$

With these new definitions for $\mathbf{T}_1$ and $\mathbf{T}_2$, the expression for the gradient given in (4.34) remains the same. If special care is taken to ensure that the range of $\mathbf{A}$ and the range of $\mathbf{U}$ are the same, even when some values of $\sigma_j$ are zero (which causes $\mathbf{A}\Sigma^{\frac{1}{2}}$ to be rank-deficient), then $\mathbf{B}_2 = 0$, and the modifications to $\mathbf{T}_1$ and $\mathbf{T}_2$ for the $M > N$ case become unnecessary.

**5. Conclusion.** Numerically stable methods for the computations required in the EM algorithm for maximum-likelihood structured covariance estimation have been presented. The basic computational task at each iteration is the calculation of a pseudoinverse of a certain linear system of equations, which is either a hard-decision or Moore–Penrose inverse in the no-noise case or a soft-decision pseudoinverse in the additive-noise case. An approach to computing this pseudoinverse that can handle all combinations of dimension and rank in this system of equations, based on the SVD, was proposed. An alternative method based on the LQ decomposition, which is applicable in the case where $\mathbf{A}$ is wide and full-rank, was also proposed. Finally, it was shown how the intermediate calculations required in the EM algorithm can be used to calculate the log-likelihood and the gradient of the log-likelihood for this maximum-likelihood structured covariance estimation problem.

# A MULTIGRID METHOD TO SOLVE LARGE SCALE SYLVESTER EQUATIONS*

LARS GRASEDYCK† AND WOLFGANG HACKBUSCH†

**Abstract.** We consider the Sylvester equation $AX - XB + C = 0$, where the matrix $C \in \mathbb{R}^{n\times m}$ is of low rank and the spectra of $A \in \mathbb{R}^{n\times n}$ and $B \in \mathbb{R}^{m\times m}$ are separated by a line. The solution $X$ can be approximated in a data-sparse format, and we develop a multigrid algorithm that computes the solution in this format. For the multigrid method to work, we need a hierarchy of discretizations. Here the matrices $A$ and $B$ each stem from the discretization of a partial differential operator of elliptic type. The algorithm is of complexity $\mathcal{O}(n+m)$, or, more precisely, if the solution can be represented with $(n+m)k$ data ($k \sim \log(n+m)$), then the complexity of the algorithm is $\mathcal{O}((n+m)k^2)$.

## 1. Introduction.

In this article we consider the matrix Sylvester equation

$$AX - XB + C = 0,$$

where $A \in \mathbb{R}^{n\times n}, B \in \mathbb{R}^{m\times m}$, and $C \in \mathbb{R}^{n\times m}$ are given input matrices, and the sought solution is $X \in \mathbb{R}^{n\times m}$. We make two assumptions concerning the matrices $A, B, C$.

First, $A$ and $-B$ are stiffness matrices from the discretization of a linear elliptic partial differential operator. This allows for the use of a multigrid method to solve the Sylvester equation in $\mathcal{O}(nm)$ for a general matrix $C$. In the outlook we comment on the case when $A$ and $B$ are general sparse matrices.

Second, the matrix $C$ is of low rank $k_C$, i.e., given in factorized form $C = UV^T$, with matrices $U \in \mathbb{R}^{n\times k}, V \in \mathbb{R}^{m\times k}$. Under these assumptions the solution $X$ can be approximated by a matrix $\tilde{X}$ of rank $k = \mathcal{O}(|\log\varepsilon|k_C)$ such that $\|X - \tilde{X}\|_2 \le \varepsilon$. The multigrid method can be adapted so that it is of linear complexity $\mathcal{O}((n+m)k^2)$ instead of quadratic complexity.

In the following section we will consider a simple model problem where the multigrid techniques are applicable without further complications. The model is an optimal control problem that leads to an algebraic matrix Riccati equation, which can be solved iteratively by Newton's method so that in each step a Lyapunov equation $A^TX + XA = C$ has to be solved. Such a Lyapunov equation is a special case of the more general Sylvester equation. We also give an example from model reduction where the Sylvester equation appears directly for the computation of cross-Gramians. In section 2 we give a short introduction to low rank arithmetics. Section 3 examines the tensor structure of a Sylvester equation, and as a special case we consider diagonal Sylvester equations in section 4. This special case is the basis for the Jacobi iteration introduced in section 5. In section 6 we derive the multigrid method and prove its convergence. Last we present numerical results for large scale matrix equations.

**1.1. Model problem.** The model problem to be introduced in this section is the (distributed) control of the two-dimensional heat equation (cf. [13] and the references therein) which is used, e.g., in optimal control problems for the selective cooling of steel [14]. The domain where the PDE is posed is the unit square. Using a uniform tensor mesh, it allows for a simple discretization. Of course, the method that we propose is in no way limited to regular grids or simple PDEs, but it simplifies both the implementation and the presentation.

**1.1.1. Continuous model.** We fix the domain $\Omega := (0,1) \times (0,1)$ and the boundary $\Gamma := \partial\Omega$. The goal is to minimize the quadratic performance index

$$J(u) := \int_0^\infty \left(y(t)^2 + u(t)^2\right) \mathrm{d}t$$

for $u \in L^2(0,\infty)$ and the output $y \in L^2(0,\infty)$ of the corresponding control system

$$\begin{array}{llll} \partial_t x(t,\xi) & = \partial^2_{\xi_1} x(t,\xi) + \partial^2_{\xi_2} x(t,\xi) + \kappa(\xi)u(t), & \xi \in \Omega, & t \in (0,\infty), \\ x(t,\xi) & = 0, & \xi \in \Gamma, & t \in (0,\infty), \\ x(0,\xi) & = x_0, & \xi \in \Omega, & \\ y(t) & := \int_\Omega \omega(\xi) x(t,\xi) d\xi, & & t \in (0,\infty). \end{array} \tag{1.1}$$

The values of $\kappa$ and $\omega$ are

$$\kappa(\xi) := \begin{cases} 1 & \xi \in (\frac{1}{2},1) \times (0,1), \\ 0 & \text{otherwise,} \end{cases} \qquad \omega(\xi) := \begin{cases} 1 & \xi \in (0,1) \times (\frac{1}{2},1), \\ 0 & \text{otherwise.} \end{cases}$$

Here we focus on a single-input–single-output system, but a generalization to multiple inputs and multiple outputs is straightforward.

We seek the optimal control $u^*$ in linear state feedback form

$$u^*(t,\cdot) = \Pi x(t,\cdot),$$

but since an analytic solution is available only for special cases, we construct a sequence of (semi)discretizations. For each discretization level $\ell = 0, 1, \dots$ an approximation $\Pi_\ell$ to the operator $\Pi$ is computed so that $\Pi_\ell \to \Pi$ [4, 13].

**1.1.2. Semidiscretization by finite differences.** The differential equation (1.1) is discretized by finite differences on a uniform mesh of $[0,1]^2$ with $n$ interior grid points $(x_i)_{i=1}^n$ and mesh width $h = (\sqrt{n}+1)^{-1}$. By $\phi_i$ we denote the piecewise linear interpolant on the mesh with $\phi_i(x_i) = 1$ and $\phi_i(x_j) = 0$ for $j \neq i$. The corresponding space-discrete system is

$$\begin{array}{lll} \partial_t x(t) & = Ax(t) + Ku(t), & t \in (0,\infty), \\ x(0) & = x_0, & \\ y(t) & := Wx(t), & t \in (0,\infty), \end{array} \tag{1.2}$$

where $A := A^{FD} \in \mathbb{R}^{n\times n}$ is the standard finite difference discretization of the 2d Laplacian, $x(t) \in \mathbb{R}^n$, $u(t), y(t) \in \mathbb{R}$, and the vectors $K := K^{FD} \in \mathbb{R}^n$ and $W \in \mathbb{R}^n$ are

$$K_i^{FD} := \kappa(x_i), \qquad W_i := \int_\Omega \omega(\xi)\phi_i(\xi)\mathrm{d}\xi. \tag{1.3}$$

The stiffness matrix $A$ is symmetric negative definite, sparse, and ill-conditioned.

**1.1.3. Semidiscretization by finite elements.** Instead of the finite difference discretization from the previous section we can as well discretize (1.1) in the weak or variational form by finite elements on a uniform mesh of $[0,1]^2$ with $n$ interior grid points $(x_i)_{i=1}^n$, mesh width $h = (\sqrt{n}+1)^{-1}$, and piecewise linear basis functions $(\phi_i)_{i=1}^n$. The corresponding space-discrete system is (1.2), where $W$ is defined as in (1.3), $K := K^{FEM} := E^{-1}K^{FD}$ for the matrix $K^{FD}$ from (1.3), and $A := E^{-1}A^{FEM}$ for the matrices

$$A_{i,j}^{FEM} := \int_\Omega \langle \nabla\phi_i(\xi), \nabla\phi_j(\xi)\rangle \mathrm{d}\xi, \qquad E_{i,j} := \int_\Omega \phi_i(\xi)\phi_j(\xi)\mathrm{d}\xi. \tag{1.4}$$

The mass matrix $E$ is symmetric positive definite, well-conditioned, and sparse. The system matrix $A = E^{-1}A^{FEM}$ has a negative spectrum and is nonsymmetric, dense, and ill-conditioned. Therefore, one avoids working with $A$ and instead uses a generalized formulation; see (1.7).

**1.1.4. Linear state feedback control.** The discrete optimal control $u$ can be realized in linear state feedback form [12]

$$u(t) = -K^T X x(t), \qquad t \in [0,\infty),$$

where $X$ is the unique solution—in the set of symmetric positive semidefinite matrices—to the algebraic matrix Riccati equation

$$A^T X + XA - XKK^T X + WW^T = 0. \tag{1.5}$$

The matrix $A$ is of size $n \times n$. The matrices $KK^T$ and $WW^T$ are of size $n \times n$ and are data-sparse in the sense that only $K$ and $W$ have to be stored, i.e., $2n$ entries.

**1.1.5. Solution of the algebraic matrix Riccati equation.** The nonlinear equation (1.5) can be solved by Newton's method [11]. The initial guess $X_0 := 0$ is sufficient to guarantee global convergence, but in the context of multilevel methods a good initial guess can also be obtained by a coarser level solution in the nested iteration. In each step $i$ of Newton's method, we have to solve a Lyapunov equation

$$A_i^T X_i + X_i A_i + C_i = 0, \tag{1.6}$$

where the matrices $A_i$ and $C_i$ are of the form

$$A_i := A - KK^T X_{i-1}, \qquad C_i := WW^T - X_{i-1}KK^T X_{i-1}.$$

For the finite difference discretization $A = A^{FD}$ the negative definite matrix $A_i$ in the $i$th step of Newton's method is data-sparse in the sense that only the sparse $n \times n$ matrix $A$, the vector $K$, and the vector $K^T X_{i-1}$ have to be stored. For $C_i$ we have to store $W$ and $X_{i-1}K$ in addition.

For the finite element discretization it is advantageous to consider the generalized Lyapunov equation.

LEMMA 1.1. [illegible] $A, K, W$ [illegible] (1.2) [illegible] (1.4) [illegible] $\widehat{X}_i$ [illegible]

$$\widehat{A}_i^T \widehat{X}_i E + E\widehat{X}_i \widehat{A}_i + \widehat{C}_i = 0, \tag{1.7}$$

[illegible] $\widehat{A}_i, \widehat{C}_i$ [illegible]

$$\widehat{A}_i := A^{FEM} - K^{FD}(K^{FD})^T \widehat{X}_{i-1}E, \quad \widehat{C}_i := WW^T - E\widehat{X}_{i-1}K^{FD}(K^{FD})^T \widehat{X}_{i-1}E.$$

[illegible] $X_i$ [illegible] (1.6) [illegible] $X_i = E\widehat{X}_i E$

By inserting $\widehat{X}_i = E^{-1}X_iE^{-1}$ we get

$$\begin{aligned}\widehat{A}_i^T\widehat{X}_iE &= (A^{FEM} - K^{FD}(K^{FD})^T\widehat{X}_{i-1}E)^TE^{-1}X_iE^{-1}E\\ &= (E^{-1}A^{FEM} - E^{-1}K^{FD}(K^{FD})^TE^{-1}E\widehat{X}_{i-1}E)^TX_i\\ &= (E^{-1}A^{FEM} - KK^TX_{i-1})^TX_i\\ &= A_i^TX_i\end{aligned}$$

and analogously for $E\widehat{X}_i\widehat{A}_i = X_iA_i$. The right-hand side fulfils

$$\widehat{C}_i = WW^T - E\widehat{X}_{i-1}K^{FD}(K^{FD})^T\widehat{X}_{i-1}E = WW^T - X_{i-1}KK^TX_{i-1} = C_i. \qquad \square$$

The matrices $\widehat{A}_i$ in the generalized Lyapunov equation (1.7) are data-sparse in the sense that $A^{FEM}$ is sparse and the matrix $K^{FD}(K^{FD})^T\widehat{X}_{i-1}M$ of rank 1.

The Lyapunov equation (1.6) is a special Sylvester equation which is of the form

$$AX - XB + C = 0 \tag{1.8}$$

for the matrices $A := A_i^T$, $B := -A_i$, and $C := C_i$. A Sylvester equation is uniquely solvable for all matrices $C$ if and only if the spectra of $A$ and $B$ are disjoint. In our setting the matrix $A_i$ is negative definite, and therefore $A < 0$ and $B > 0$ such that the existence of a unique solution is guaranteed.

In the following subsection 1.3 we determine a suitable format for an approximation to the solution $X$ of the Sylvester equation (1.8) where the matrix $C$ is of low rank.

### 1.2. Second model problem.

The model problem of this section is identical to the linear time invariant control problem (1.1) except that the governing PDE is now

$$\dot{x}(t,\xi) = \partial_{\xi_1}^2 x(t,\xi) + \partial_{\xi_2}^2 x(t,\xi) + \beta\partial_{\xi_1}x(t,\xi) + \kappa(\xi)u(t),$$

leading to a discrete system

$$\dot{x}(t) = Ax(t) + Ku(t), \quad y(t) = W^Tx(t)$$

with a nonsymmetric matrix $A$. We aim at finding a lower order system

$$\dot{\hat{x}}(t) = \hat{A}\hat{x}(t) + \hat{K}u(t), \quad y(t) = \hat{W}^T\hat{x}(t)$$

so that $\hat{A}$ is considerably smaller than $A$ while the input-output error is bounded and the reduced system stable [2]. The reduced system can be constructed based on a low rank approximation $\tilde{X}$ of the so-called cross-Gramian $X$ which is the solution of the Sylvester equation [2]

$$AX + XA + KW^T = 0.$$

### 1.3. Structure of the solution.

In the $i$th step of Newton's method to solve the algebraic matrix Riccati equation (1.5), we have to solve a Sylvester equation (1.8) where the matrix $C$ is of rank at most

$$\operatorname{rank}(C) \le \operatorname{rank}(WW^T) + \operatorname{rank}(X_{i-1}KK^TX_{i-1}) \le 2.$$

Since the discrete system (1.2) involves a discretization error, it is reasonable to solve the Sylvester equation only up to an accuracy $\varepsilon$ of the size of the discretization error; i.e., we seek an approximation $\tilde{X}$ to the solution $X$ of (1.8) such that

$$\|X - \tilde{X}\|_2 \leq \varepsilon \|X\|_2.$$

The idea now is to choose a matrix $\tilde{X}$ that allows for a data-sparse representation.

Definition 1.2 ($R(k)$-matrix representation). [illegible] $k, n, m \in \mathbb{N}$ [illegible] $R \in \mathbb{R}^{n\times m}$ [illegible] $R(k)$ [illegible] $R(k)$ [illegible] $R$ [illegible]

$$R = UV^T, \qquad U \in \mathbb{R}^{n\times k}, V \in \mathbb{R}^{m\times k}, \tag{1.9}$$

[illegible] $U, V$ [illegible]

The two factors in the representation (1.9) of an $R(k)$-matrix involve $k(n+m)$ values to be stored. The matrix-vector multiplication $y := Rx$ can be done in two steps involving the two matrix-vector products $z := V^T x$ and $y := Uz$ that consist of $\mathcal{O}(k(n+m))$ basic arithmetic operations.

The $R(k)$-matrix format is a suitable representation for matrices of rank at most $k$: Each matrix of rank at most $k$ can be written in the factorized form (1.9) by use of a (reduced) singular value decomposition, and each matrix of the form (1.9) is of rank at most $k$. The next theorem proves the existence of a low rank approximant $\tilde{X}$ to the solution $X$ of (1.8).

Theorem 1.3 (existence of a low rank approximant). [illegible] $A \in \mathbb{R}^{n\times n}$ [illegible] $B \in \mathbb{R}^{m\times m}$ [illegible] $\sigma(A)$ [illegible] $\sigma(B)$ [illegible] $C \in \mathbb{R}^{n\times m}$ [illegible] $k_C$ [illegible] $0 < \varepsilon < 1$ [illegible] $\tilde{X} \in \mathbb{R}^{n\times m}$ [illegible] $X$ [illegible] (1.8) [illegible]

$$\|X - \tilde{X}\|_2 \leq \varepsilon \|X\|_2, \tag{1.10}$$

[illegible] $\tilde{X}$ [illegible] $\operatorname{rank}(\tilde{X}) \leq k_C k_\varepsilon$ $k_\varepsilon = \mathcal{O}(\log(1/\varepsilon))$

The proof of Theorem 1.3 is given in [6] (see also [16, 1]). One should note that the rank $k_\varepsilon$ depends on the location of the spectra of $A$ and $B$. In our model problem this is $k = \mathcal{O}(\log(1/\varepsilon)\log(n))$.

**1.4. Large scale Sylvester equations.** A fixed Sylvester equation (1.8) can, e.g., be solved by the Bartels–Stewart algorithm [3], which is of complexity $\mathcal{O}(n^3)$. In the context of large scale Sylvester equations (i.e., $n > 10^5$) one is interested in reducing the complexity for a certain class of matrices $A, B, C$.

Hu and Reichel [20] propose to use Krylov subspace methods for the solution of the Sylvester equation. In each iterative step the equation is projected to a small dimension where one can use, e.g., the Bartels–Stewart algorithm as a solution. The authors do not exploit some kind of low rank structure but the fact that $A$ and $B$ allow for a fast matrix-vector multiplication. One step of their algorithm is of complexity $\mathcal{O}(nm)$, and the necessary number of iterations increases as the condition of the Sylvester equation increases.

Li and White [15] propose an iterative method for the solution of the Lyapunov equation based on the factorization of the matrix $C$ and the solution $X$. Their method is a special implementation of the classical ADI algorithm (previously proposed by Penzl [18]) and requires the solution of a shifted linear system $A - \lambda I$ in each step. The number $J$ of steps necessary to gain a good approximation $\tilde{X}$ to $X$ depends on the choice of the shifts $\lambda$. For the nonsymmetric case there is no nontrivial upper bound for $J$. The main problem is that the approximation of rank $J$ (after $J$ steps of ADI) is not necessarily close to a best approximation of rank $J$.

Penzl [17] presents a multigrid method to compute the solution $X$ to the Lyapunov equation, but he does not exploit the fact that $X$ can—at least if $C$ is of low rank—be approximated by a low rank matrix $\tilde{X}$; therefore, the complexity of one multigrid step is $\mathcal{O}(n^2)$. He also gives a convergence analysis for a simple model problem and proves that the convergence rate is bounded independently of the problem size $n$.

In this paper, we explain how one can compute a low rank approximation $\tilde{X}$ to the solution $X$ of (1.8) by use of the multigrid method. We use the usual Jacobi smoother and standard prolongation and restriction operators but extend the basic multigrid cycle by a projection step $X_i \mapsto \mathcal{T}_k(X_i)$ that ensures that the rank of the $i$th iterate $X_i$ is bounded. For a sufficiently large rank $k$ the error $\|X_i - \mathcal{T}_k(X_i)\|$ due to the projection of the iterate $X_i$ (cf. section 2) can be regarded as the standard truncation error due to limited machine precision.

Each multigrid step is of complexity $\mathcal{O}(n+m)$, and a nested iteration combined with a level independent good convergence rate guarantees that we need only $\mathcal{O}(1)$ steps to solve the equation up to the discretization error.

The convergence analysis for simple model problems turns out to be fairly trivial. The structure of the Sylvester equation allows us to carry results for linear systems $Ax = b$ over to the Sylvester equation such that the convergence rate can be bounded also for general domains and operators. The effect of the projection to low rank in the multigrid cycle can be regarded as a reduction of the machine precision. In our numerical tests the convergence rate is not deteriorated by the projection.

## 2. $\boldsymbol{R(k)}$-matrix arithmetics.

The set of $n \times m$ $R(k)$-matrices is not a linear space because the addition of two matrices of rank at most $k$ might result in a matrix of rank larger than $k$. In this sense the $R(k)$-matrix format is not suitable for iterative solution schemes for the Sylvester equation.

However, $R(k)$-matrices allow for an efficient singular value decomposition such that the projection (a best approximation) to lower rank is of complexity $\mathcal{O}(k^2(n+m))$. This projection can be used to keep the iterates in the set $R(k)$.

LEMMA 2.1 (reduced SVD, truncation). (a) [illegible] $R = UV^T \in \mathbb{R}^{n\times m}$ [illegible] $R(k)$ [illegible] $R$ [illegible] $N_{R,\mathrm{SVD}}(n,m,k) \lesssim 6k^2(n+m) + 23k^3$ [illegible]

1. [illegible] $U = Q_U R_U$ [illegible] $U$ $Q_U \in \mathbb{R}^{n\times k}, R_U \in \mathbb{R}^{k\times k}$
2. [illegible] $V = Q_V R_V$ [illegible] $V$ $Q_V \in \mathbb{R}^{m\times k}, R_V \in \mathbb{R}^{k\times k}$
3. [illegible] $R_U R_V^T = \widetilde{U}\Sigma\widetilde{V}^T$
4. [illegible] $\widehat{U} := Q_U\widetilde{U}$ [illegible] $\widehat{V} := Q_V\widetilde{V}$

[illegible] $R = \widehat{U}\Sigma\widehat{V}^T$ [illegible] [5, [illegible] 5.2.9 [illegible] 5.4.5] [illegible]

| | | |
|---|---|---|
| [illegible] $U$ | $4nk^2$ | |
| [illegible] $V$ | $4mk^2$ | |
| [illegible] $R_U R_V^T$ | | $2k^3$ |
| [illegible] $R_U R_V^T$ | | $\approx 21k^3$ |
| [illegible] $Q_U\widetilde{U}$ [illegible] $Q_V\widetilde{V}$ | $2nk^2 + 2mk^2$ | |

TABLE 2.1

*Time in seconds for the reduced SVD of an $n \times n$ $R(k)$-matrix, $n = 1024^2$.*

| Rank | $k = 4$ | $k = 8$ | $k = 16$ | $k = 32$ | $k = 64$ | $k = 128$ |
|---|---|---|---|---|---|---|
| Time | 6.19 | 15.32 | 49.37 | 172.73 | 653.40 | 2637.5 |

(b) [illegible] $R(k)$ [illegible] $R$ [illegible] $k' \leq k$ [illegible] $R$ [illegible] $R(k')$ [illegible] $k'$ [illegible] $\widehat{U}\Sigma$ [illegible] $\widehat{V}$ [illegible] $R$ [illegible] $k'$ [illegible]

$$\mathcal{T}_{k'}. \tag{2.1}$$

[illegible] $k' \geq k$ [illegible] $\mathcal{T}_{k'}$ [illegible] $R(k)$ [illegible] (1.9) [illegible] $U, V$ [illegible] $k' - k$ [illegible]

We remark that the truncation in part (b) becomes nonunique when the $k'$th and $(k'+1)$st singular values are equal.

LEMMA 2.2 (spectral and Frobenius norm). [illegible] $n \times m$ $R(k)$ [illegible] $R$ [illegible] 2.1a [illegible] $N_{R,\|\cdot\|}(n, m, k) \lesssim 4k^2(n + m) + 23k^3$

[illegible] The norms can be obtained from the singular values; i.e., steps 1–3 from Lemma 2.1a are to be performed. □

[illegible] 2.3 (complexity of the truncation in practice). We implement the truncation procedure of Lemma 2.1 on a SUN ULTRASPARC III with 900 MHz CPU clock rate and 150 MHz memory clock rate by use of the LAPACK subroutines `dgeqrf` and `dgesvd` for the QR-factorization and singular value decomposition of full matrices. The $1024^2 \times 1024^2$ matrix $R$ of rank $k$ is given in $R(k)$-matrix representation and has random entries in the factors $U, V$. We truncate $R$ down to rank $k/2$. The time in seconds to compute the result is given in Table 2.1.

**3. Tensor structure of the Sylvester equation.** In order to formulate and analyze the iterative solutions for the Sylvester equation, we need to reformulate the matrix equation in terms of a standard linear system of equations. For notational purposes we also introduce the Kronecker product formulation.

**3.1. Algebraic structure.** The Sylvester equation (1.8) can be written (for each entry $(i, j)$) in the form

$$\sum_{\nu=1}^{n} A_{i\nu} X_{\nu j} - \sum_{\nu=1}^{m} X_{i\nu} B_{\nu j} = -C_{ij},$$

which means that the entries of the Sylvester operator $\mathcal{S}^{A,B} : \mathbb{R}^{n\times m} \to \mathbb{R}^{n\times m}$, $X \mapsto AX - XB$ are

$$\mathcal{S}^{A,B}_{ij,pq} = \delta_{jq} A_{ip} - \delta_{ip} B_{qj}, \qquad \delta_{jq} = \begin{cases} 1 & \text{if } j = q, \\ 0 & \text{otherwise.} \end{cases} \tag{3.1}$$

If we order the indices columnwise (rowwise), the matrix representation is

$$\mathcal{S}^{A,B}_{col} = \begin{bmatrix} A & & \\ & \ddots & \\ & & A \end{bmatrix} - \begin{bmatrix} B_{11}I & \cdots & B_{m1}I \\ \vdots & \ddots & \vdots \\ B_{1m}I & \cdots & B_{mm}I \end{bmatrix},$$

$$\mathcal{S}^{A,B}_{row} = \begin{bmatrix} A_{11}I & \cdots & A_{1n}I \\ \vdots & \ddots & \vdots \\ A_{n1}I & \cdots & A_{nn}I \end{bmatrix} - \begin{bmatrix} B & & \\ & \ddots & \\ & & B \end{bmatrix}.$$

The Kronecker product

$$X \otimes Y := \begin{bmatrix} X_{11}Y & \cdots & X_{1n}Y \\ \vdots & \ddots & \vdots \\ X_{n1}Y & \cdots & X_{nn}Y \end{bmatrix}$$

allows us to use the short notation

$$\mathcal{S}^{A,B} := \mathcal{S}^{A,B}_{col} = I \otimes A - B^T \otimes I.$$

For the finite element discretization it was advantageous to consider the generalized Sylvester operator

$$\mathcal{S}^{A,B,E} : \mathbb{R}^{n\times m} \to \mathbb{R}^{n\times m}, \quad X \mapsto AXE - EXB,$$

which can be written in terms of the Kronecker product by

$$\mathcal{S}^{A,B,E} = E \otimes A - B^T \otimes E;$$

i.e., the entries of the matrix $\mathcal{S}^{A,B,E}$ are

$$\mathcal{S}^{A,B,E}_{ij,pq} = E_{jq}A_{ip} - E_{ip}B_{qj}.$$

**3.2. Analytic structure.** In this section we want to identify the matrices $\mathcal{S}^{A,B}$ and $\mathcal{S}^{A,B,E}$ of the (generalized) Sylvester operator as the discretization of a tensor product operator on the tensor domain $\Omega \times \Omega$. This will enable us to use proofs of multigrid convergence for the product operator.

**3.2.1. Finite element discretization.** We consider the finite element Galerkin discretization of the operator $\mathcal{A} : H^1_0(\Omega \times \Omega) \times H^1_0(\Omega \times \Omega) \to H^{-1}(\Omega \times \Omega)$

$$\mathcal{A}[u](x,y) = -\sum_{\nu=1}^{2} \partial^2_{x_\nu} u(x,y) - \sum_{\nu=1}^{2} \partial^2_{y_\nu} u(x,y) \tag{3.2}$$

using the set $V_{n^2} := \{\varphi_{ij} \mid i,j = 1,\dots,n\}$ of tensor product basis functions based on the basis functions $\phi_i$ from section 1.1.3:

$$\varphi_{ij}(x,y) := \phi_i(x)\phi_j(y), \qquad x,y \in \Omega.$$

The Galerkin stiffness matrix is the matrix $\mathbb{A}$ with entries

$$\begin{aligned}\mathbb{A}_{ij,pq} &= \int_\Omega \int_\Omega \langle \nabla_x \varphi_{ij}(x,y), \nabla_x \varphi_{pq}(x,y)\rangle + \langle \nabla_y \varphi_{ij}(x,y), \nabla_y \varphi_{pq}(x,y)\rangle \,\mathrm{d}x\mathrm{d}y \\ &= \int_\Omega \int_\Omega \langle \nabla \phi_i(x), \nabla \phi_p(x)\rangle \phi_j(y)\phi_q(y) + \langle \nabla \phi_j(y), \nabla \phi_q(y)\rangle \phi_i(x)\phi_p(x) \,\mathrm{d}x\mathrm{d}y \\ &= \int_\Omega \langle \nabla \phi_i(x), \nabla \phi_p(x)\rangle \,\mathrm{d}x \int_\Omega \phi_j(y)\phi_q(y)\,\mathrm{d}y \\ &\quad + \int_\Omega \langle \nabla \phi_j(y), \nabla \phi_q(y)\rangle \,\mathrm{d}y \int_\Omega \phi_i(x)\phi_p(x)\,\mathrm{d}x \\ &= A_{ip}E_{jq} + E_{ip}A_{jq} = \mathcal{S}^{A,A,E}_{ij,pq},\end{aligned}$$

where $A, E$ are the stiffness and mass matrices from section 1.1.3 and $\mathcal{S}^{A,A,E}$ is the Sylvester operator from section 3.1. Therefore, $\mathbb{A}$ is just another notation for $\mathcal{S}^{A,A,E}$, but it allows us to regard it as a standard finite element discretization of an elliptic operator; hence, standard multigrid theory can be applied.

**3.2.2. Finite difference discretization.** For a finite difference discretization of the operator (3.2) one can derive as in the previous section

$$\mathbb{A}^{FD}_{ij,pq} = \mathcal{S}^{A,A}_{ij,pq}, \text{ i.e., } \quad \mathbb{A}^{FD} = \mathcal{S}^{A,A},$$

where $A$ is the finite difference matrix from section 1.1.2.

Before we introduce the multigrid method, we first consider one important ingredient, namely, the smoother. The standard smoother used in a multigrid method is Jacobi (or Gauss–Seidel), which requires in our setting the solution of diagonal Sylvester equations (resp., diagonal generalized Sylvester equations).

## 4. Diagonal Sylvester equation.

A diagonal Sylvester equation

$$\begin{bmatrix} a_1 & & \\ & \ddots & \\ & & a_n \end{bmatrix} X - X \begin{bmatrix} b_1 & & \\ & \ddots & \\ & & b_m \end{bmatrix} + C = 0 \tag{4.1}$$

with $a_i < b_j$ for all $1 \le i \le n$ and $1 \le j \le m$ allows for a direct solution by

$$X_{ij} = C_{ij}/(b_j - a_i). \tag{4.2}$$

If the matrix $C$ is of rank 1 with $R(1)$-matrix representation $C = cd^T$, then

$$X = \begin{bmatrix} c_1 & & \\ & \ddots & \\ & & c_n \end{bmatrix} \begin{bmatrix} (b_1 - a_1)^{-1} & \cdots & (b_m - a_1)^{-1} \\ \vdots & \ddots & \vdots \\ (b_1 - a_n)^{-1} & \cdots & (b_m - a_n)^{-1} \end{bmatrix} \begin{bmatrix} d_1 & & \\ & \ddots & \\ & & d_m \end{bmatrix}.$$

The following Lemma 4.2 proves that the Cauchy matrix $\mathcal{C}_{ij} = (b_j - a_i)^{-1}$ allows for a low rank approximation (a special case of Theorem 1.3). The idea is to construct a separable representation for the function

$$f(x,y) := \frac{1}{x-y} \approx \sum_{\nu=1}^{k} g_\nu(x) h_\nu(y)$$

so that

$$\mathcal{C}_{ij} \approx \sum_{\nu=1}^{k} g_\nu(b_j)h_\nu(a_i).$$

However, if the distance between the sets

$$I_a := \{a_1, \dots, a_n\} \quad \text{and} \quad I_b := \{b_1, \dots, b_m\}$$

is small compared to their diameters, then the separable approximation requires a large rank $k$. Therefore we subdivide the sets $I_a$ and $I_b$ into subsets $t \subset I_a$ and $s \subset I_b$ so that they fulfil the admissibility condition

$$\min\{\text{diam}(t), \text{diam}(s)\} \le \text{dist}(t, s). \tag{4.3}$$

An explicit construction is given in the following.

CONSTRUCTION 4.1 (local $R(k)$-matrix approximation of the Cauchy matrix). $t \subset I_a$ $s \subset I_b$ (4.3)

$$t_0 := \frac{1}{2}(\min_{a_i \in t} a_i + \max_{a_i \in t} a_i), \quad s_0 := \frac{1}{2}(\min_{b_j \in s} b_j + \max_{b_j \in s} b_j).$$

$i \in t$ $j \in s$

$$\tilde{\mathcal{C}}_{ij} := \begin{cases} \sum_{\nu=0}^{k}(t_0 - b_j)^{-\nu-1}(t_0 - a_i)^\nu & \text{diam}(t) \le \text{diam}(s), \\ \sum_{\nu=0}^{k}(a_i - s_0)^{-\nu-1}(b_j - s_0)^\nu & \end{cases}$$

$\tilde{\mathcal{C}}_{i\in t, j\in s}$ $k$ $U, V$

$$U_{i\nu} := \begin{cases} (t_0 - a_i)^\nu & \text{diam}(t) \le \text{diam}(s), \\ (a_i - s_0)^{-\nu-1} & \end{cases}$$

$$V_{j\nu} := \begin{cases} (t_0 - b_j)^{-\nu-1} & \text{diam}(t) \le \text{diam}(s), \\ (b_j - s_0)^\nu & \end{cases}$$

LEMMA 4.2 (local approximation error). $t$ $s$ $\tilde{\mathcal{C}}$ 4.1 $0 < \varepsilon < 1$

$$|\tilde{\mathcal{C}}_{ij} - \mathcal{C}_{ij}| \le \varepsilon |\mathcal{C}_{ij}| \tag{4.4}$$

$i \in t$ $j \in s$

$$k := \lceil \log_3(1/\varepsilon) \rceil + 1.$$

Without loss of generality we assume $\text{diam}(t) \le \text{diam}(s)$. The exact Taylor expansion of $f$ with respect to $x$ is

$$f(x, y) = \sum_{\nu=0}^{\infty} \frac{1}{\nu!} \partial_x^\nu f(t_0, b_j)(a_i - t_0)^\nu = \sum_{\nu=0}^{\infty}(t_0 - b_j)^{-\nu-1}(t_0 - a_i)^\nu.$$

Using this representation and the assumption (4.3) we get

$$\begin{aligned} |\tilde{\mathcal{C}}_{ij} - \mathcal{C}_{ij}| &= \Big|\sum_{\nu=k}^{\infty}(t_0 - b_j)^{-\nu-1}(t_0 - a_i)^\nu\Big| \le \sum_{\nu=k}^{\infty} |t_0 - b_j|^{-\nu-1}|t_0 - a_i|^\nu \\ &\le \sum_{\nu=k}^{\infty} \left(\text{dist}(t, s) + \frac{1}{2}\text{diam}(t)\right)^{-\nu} \left(\frac{1}{2}\text{diam}(t)\right)^\nu |t_0 - b_j|^{-1} \\ &\overset{(4.3)}{\le} \sum_{\nu=k}^{\infty} 3^{-\nu}|t_0 - b_j|^{-1} = 3^{-k+1}\frac{1}{2}|t_0 - b_j|^{-1} \le \varepsilon |\mathcal{C}_{ij}|. \qquad \square \end{aligned}$$

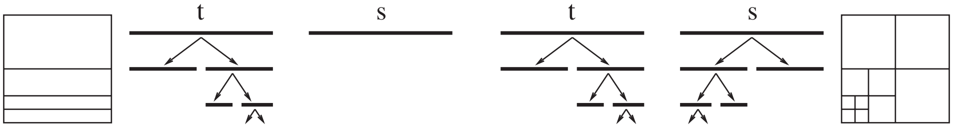

FIG. 4.1. *Recursive subdivision of one (left) or two (right) subintervals and the corresponding partitions of the Cauchy matrix $\mathcal{C}$.*

In order to satisfy the admissibility condition (4.3) there are two strategies.

First, we can subdivide the set $t$ recursively into two parts $t_1$ and $t_2$ of half the diameter so that one of the two is admissible to $s$ (cf. Figure 4.1). The other one is then further subdivided until the diameter is less than the distance to $s$. This strategy produces blocks $t' \times s$, $t' \subset t$, for which we can apply Construction 4.1. The number of blocks is $p := \lceil \log_2(\frac{\mathrm{diam}(t)}{\mathrm{dist}(t,s)}) \rceil + 1$. In total we have to store and compute $\mathcal{O}(pk(n+m))$ entries of the R($k$)-matrix representation.

Second, we can subdivide always both sets $s$ and $t$ each into two parts of half the diameter so that three of the four pairs are admissible and the fourth one has to be subdivided further (cf. Figure 4.1). This strategy will then produce $p := 3\lceil \log_2(\frac{\mathrm{diam}(t)}{\mathrm{dist}(t,s)}) \rceil + 1$ blocks (more than the first strategy), but they are of different size which is decaying geometrically. Therefore we have to store and compute only $\mathcal{O}(k(n+m))$ entries of the R($k$)-matrix representations.

In both cases, the rank of the approximation $\tilde{\mathcal{C}}$ is $pk$. In the second case we can exploit the hierarchical structure for the efficient computation of an approximation for $X$. We will give the details later in Construction 4.5.

COROLLARY 4.3 (approximation error). [illegible] $\tilde{\mathcal{C}}$ [illegible] $\varepsilon$ [illegible] $|\tilde{\mathcal{C}}_{ij} - \mathcal{C}_{ij}| \le \varepsilon |\mathcal{C}_{ij}|$ [illegible] $1 \le i \le n$ [illegible] $1 \le j \le m$ [illegible] $C$ [illegible] $R(k_C)$ [illegible] $C_{ij} = \sum_{\nu=1}^{k_C} c_i^{(\nu)} d_j^{(\nu)}$ [illegible] $\tilde{X}_{ij} := \sum_{\nu=1}^{k_C} c_i^{(\nu)} \tilde{\mathcal{C}}_{ij} d_j^{(\nu)}$ [illegible] $X$ [illegible] (4.1) [illegible]

$$|X_{ij} - \tilde{X}_{ij}| \le \varepsilon |X_{ij}|, \qquad \|X - \tilde{X}\|_F \le \varepsilon \|X\|_F.$$

[illegible]

$$|X_{ij} - \tilde{X}_{ij}| = \left| \sum_{\nu=1}^{k_C} c_i^{(\nu)} d_j^{(\nu)} \right| |\tilde{\mathcal{C}}_{ij} - \mathcal{C}_{ij}| \le \varepsilon \left| \sum_{\nu=1}^{k_C} c_i^{(\nu)} d_j^{(\nu)} \right| |\mathcal{C}_{ij}| = \varepsilon |X_{ij}|. \qquad \square$$

REMARK 4.4 (adaptive choice of the rank). In practice, one is interested in a good approximation $\tilde{\mathcal{C}}$ to the Cauchy matrix $\mathcal{C}$, preferably an approximation with minimal rank for a prescribed accuracy $\varepsilon$. Our construction yields only a suboptimal candidate where the rank is higher than necessary. In the multigrid method the approximation $\tilde{\mathcal{C}}$ will be used several times, such that it pays to spend more effort in the computation of $\tilde{\mathcal{C}}$. One way to do this is to compute a candidate $\tilde{\mathcal{C}}_1$ as above up to accuracy $\varepsilon/10$ and compute an approximant $\tilde{\mathcal{C}}$ to $\tilde{\mathcal{C}}_1$ up to accuracy $\varepsilon$ with minimal rank by use of the reduced singular value decomposition of Lemma 2.1.

The construction of a good [illegible] approximant $\tilde{\mathcal{C}}$ to the Cauchy matrix bears two bottlenecks:

First, one has to store a matrix of rank $pk$. For a large scale problem with $n = m = 10^6$, $|b_1 - a_n| = 10^{-3}$, $|a_n - a_1| = 1$, and $\varepsilon = 10^{-6}$, there are more than 300 million entries to be stored, which requires more than two Gigabytes of memory in double precision arithmetic.

Second, the estimated rank *pk* (in the above example $pk = 154$) is typically too large. The truncation to lower rank is of quadratic complexity in the rank, which means prohibitively expensive (cf. Example 2.3).

CONSTRUCTION 4.5 (hierarchical construction). [illegible] $\mathcal{C}$ [illegible] 4.1 [illegible] 1 [illegible] $\mathcal{C}$ [illegible] 2 [illegible] $X$ [illegible] 3 [illegible] $\tilde{X}$ [illegible] $X$

[illegible] 1 [illegible] $t \times s \subset I_a \times I_b$ [illegible] $\tilde{\mathcal{C}}|_{t\times s}$ [illegible] 4.1 [illegible] $k' := \lceil \log_3(\varepsilon^{-1}/3)\rceil + 1$

[illegible] 2 [illegible] $C = \sum_{\nu=1}^{k_C} c^{(\nu)}(d^{(\nu)})^T$ [illegible] $X$ [illegible]

$$X|_{t\times s} = \sum_{\nu=1}^{k_C} \operatorname{diag}(c^{(\nu)}|_t)\, \mathcal{C}|_{t\times s} \operatorname{diag}(d^{(\nu)}|_s),$$

[illegible]

$$\tilde{X}'|_{t\times s} := \sum_{\nu=1}^{k_C} \operatorname{diag}(c^{(\nu)}|_t)\, \tilde{\mathcal{C}}|_{t\times s} \operatorname{diag}(d^{(\nu)}|_s).$$

[illegible] $\tilde{X}''|_{t\times s}$ [illegible]

$$\|\tilde{X}'|_{t\times s} - \tilde{X}''|_{t\times s}\|_F \le \frac{\varepsilon}{3}\|\tilde{X}'|_{t\times s}\|_F.$$

[illegible] 3 [illegible] $\tilde{X}$ [illegible] $I_a \times I_b$ [illegible] $\ell = 1$ [illegible] $\ell = 2$ [illegible] $t \times s$ [illegible]

$$\varepsilon_\ell := 2^{-\ell}\frac{\varepsilon}{3}\|\tilde{X}''\|_F.$$

[illegible] $t \times s$ [illegible] $t_1 \times s_1, t_2 \times s_1, t_1 \times s_2, t_2 \times s_2$ [illegible]

$$\tilde{X}^{t,s} := \mathcal{T}_k\left(\left[\begin{array}{c|c} \tilde{X}''|_{t_1\times s_1} & \tilde{X}''|_{t_1\times s_2} \\ \hline \tilde{X}^{t_2,s_1} & \tilde{X}''|_{t_2\times s_2} \end{array}\right]\right)$$

[illegible] (2.1) [illegible] $\varepsilon_\ell$ [illegible]

[illegible] $\|X - \tilde{X}\|_F / \|X\|_F$ [illegible] $\tilde{X} := \tilde{X}^{I_a, I_b}$ [illegible]

LEMMA 4.6. [illegible] $\tilde{X}$ [illegible] 4.5 [illegible]

$$\|X - \tilde{X}\|_F \le \varepsilon\|X\|_F + \mathcal{O}(\varepsilon^2).$$

[illegible] $\mathcal{O}((n+m)(k_C^2(k')^2 + k_{final}^2))$ [illegible] $k'$ [illegible] $k_C$ [illegible] $C$ [illegible] $k_{final}$ [illegible] $X$

(1) Approximation error. The Cauchy matrix approximation in part 1 of Construction 4.5 was chosen such that $|\mathcal{C}_{ij} - \tilde{\mathcal{C}}_{ij}| \leq \varepsilon|\mathcal{C}_{ij}|/3$. From Corollary 4.3 we conclude $\|\tilde{X}' - X\|_F \leq \varepsilon\|X\|_F/3$. In part 2 of Construction 4.5 the matrix $\tilde{X}'$ is recompressed so that

$$\|X - \tilde{X}''\|_F \leq \|X - \tilde{X}'\|_F + \|\tilde{X}' - \tilde{X}''\|_F \leq \varepsilon\|X\|_F/3 + \varepsilon\|X\|_F/3 + \mathcal{O}(\varepsilon^2).$$

Next we will show that $\|\tilde{X}'' - \tilde{X}\|_F \leq \varepsilon\|X\|_F/3 + \mathcal{O}(\varepsilon^2)$, which gives the desired estimate.

The truncation accuracy in part 3 of Construction 4.5 yields on each level $\ell$ of a block $t \times s$

$$\|\tilde{X}^{t,s} - \tilde{X}''|_{t\times s}\|_F \leq \varepsilon_\ell = 2^{-\ell}\varepsilon\|\tilde{X}''\|_F/3.$$

Over all levels $\ell = 1, \dots$ this sums up to

$$\sum_{\ell=1}^{\infty} \varepsilon_\ell = \frac{1}{3}\varepsilon\|\tilde{X}''\|_F = \frac{1}{3}\varepsilon\|X\|_F + \mathcal{O}(\varepsilon^2).$$

(2) Complexity. Part 1 of Construction 4.5 is of complexity $2^{1-\ell}k'n$ for a block on level $\ell$. On each level there are at most three blocks so that this sums up to

$$\sum_{\ell=1}^{\infty} 2^{1-\ell}3k'n \leq 6k'n.$$

In part 2 we truncate each of the blocks (we neglect the diagonal scaling). Due to Lemma 2.1 the complexity is bounded by

$$\sum_{\ell=1}^{\infty} 2^{1-\ell}3n(k_C k')^2 \leq 6k_C^2(k')^2 n.$$

At last we combine the blocks levelwise. On each level we add four matrices, each of rank at most $k_{final}$, so that the complexity is bounded by

$$\sum_{\ell=1}^{\infty} 2^{1-\ell}nk_{final}^2 \leq 2k_{final}^2 n. \qquad \square$$

In order to illustrate the benefits and the complexity of Construction 4.1 and the alternatives from Remark 4.4 and Construction 4.5, we test the method for a simple artificial model problem.

4.7. The entries of the diagonal matrices $A$ and $B$ are

$$a_i = -i, \qquad b_j = j, \qquad 1 \leq i, j \leq 1024^2.$$

We want to approximate the solution $X$ and the Cauchy matrix $\mathcal{C}$ for a matrix $C$ of rank $k_C = 5$ up to an accuracy of $\varepsilon := 10^{-6}$ by approximations $\tilde{\mathcal{C}}$ and $\tilde{X}$ of minimal rank.

According to Construction 4.5 we compute the approximant in three steps:

1. (Part 1) Hierarchical approximation of $\mathcal{C}$ by $\tilde{\mathcal{C}}$. Since the entries of $\tilde{\mathcal{C}}$ are derived analytically, this is very fast. The blockwise rank $k$ is 15 (as defined in Construction 4.5).

2. (Part 2) Blockwise approximation in the $R(k)$-matrix format.
3. (Part 3) Hierarchical conversion to the $R(k)$-matrix format.

The following table displays the times the three steps take and the amount of storage needed (in the first step for $\tilde{\mathcal{C}}$ and in the second and third step for $\tilde{X}''$ and $\tilde{X}$, respectively). The numerical tests were performed on a SUN UltraSPARC III with 900 MHz CPU clock rate and 150 MHz memory clock rate.

| | time (seconds) | storage (Megabyte) |
|---|---|---|
| Part 1 | 10.3 | 720 |
| Part 2 | 943 | 180 |
| Part 3 | 422 | 360 |

The amount of storage needed in step 1 can be omitted by immediate truncation of each block to lower rank. The final approximation $\tilde{X}$ has a rank of $k_{\tilde{X}} = 22$.

The previous example illustrates that the hierarchical truncation is an efficient way to generate a best approximation either to the Cauchy matrix or to the solution of a diagonal Sylvester equation. In practice, we will use the construction to solve diagonal Sylvester equations as they appear in the Jacobi iteration. There the diagonal entries are of similar size; i.e., the matrix is well-conditioned such that the number of levels is small (typically one). The situation simplifies if all diagonal entries are equal.

4.8. The entries of the diagonal matrices $A$ and $B$ are

$$a_i \equiv a, \qquad b_j \equiv b, \qquad 1 \le i \le n, 1 \le j \le m.$$

Then the Cauchy matrix is $\mathcal{C} = (b-a)^{-1} I$ ($I$ is the identity), and the solution is $X = (b-a)^{-1} C$.

In the following example we want to compare our construction with an iterative scheme that approximates the solution $X$ to (4.1). For this example we fix a matrix $C$ of rank $k_C := 5$.

4.9. The entries of the diagonal matrices $A$ and $B$ are

$$a_i = -i, \qquad b_j = j, \qquad 1 \le i, j \le 1024^2.$$

The ADI iteration from [18] to solve $AX - XB + C = 0$ starts with $X_0 := 0$ and generates the matrices

$$\begin{aligned} X_{i+1} := {} & (A - p_i I)(A + p_i I)^{-1}\, X_i\, (A - p_i I)(A + p_i I)^{-1} \\ & -2p_i (A + p_i I)^{-1}\, C\, (A + p_i I)^{-1}, \end{aligned}$$

where the parameters $p_i$ for $J$ steps of the iteration are given by $\kappa := (a_1/a_n)^{1/J}, t_0 := a_1, t_j := \kappa\, t_{j-1}, p_j := -\sqrt{t_{j-1} t_j}$ for $j = 1, \ldots, J$. This parameter choice allows for an explicit bound on the relative error, such that the number $J$ of steps can be determined a priori. The rank of the resulting approximant $\tilde{X}^{ADI}$ to $X$ is equal to $Jk_C$. In this example the number of iterations $J = 81$ ensures that the a priori error bound is less than $10^{-6}$.

The computation of an approximation $\tilde{X}^{ADI}$ takes ca. 580 seconds (this time can be reduced by using the ADI variant from [15]). However, the rank used in the representation of $\tilde{X}^{ADI}$ is $k = 405$ so that a truncation to smaller (minimal) rank would require approximately 25000 seconds (cf. Table 2.1). Alternatively, one could truncate in intermediate steps (no control of the accuracy) so that the time reduces to approximately 5000 seconds. The complexity is higher than for the hierarchical Construction 4.5 because the local blockwise ranks are much smaller than the global rank $Jk_C$ from the ADI iteration.

**4.1. Diagonal generalized Sylvester equation.** At last we want to comment on diagonal [illegible] Sylvester equations. There the system

$$\begin{bmatrix} a_1 & & \\ & \ddots & \\ & & a_n \end{bmatrix} X \begin{bmatrix} e_1 & & \\ & \ddots & \\ & & e_m \end{bmatrix} - \begin{bmatrix} \hat{e}_1 & & \\ & \ddots & \\ & & \hat{e}_n \end{bmatrix} X \begin{bmatrix} b_1 & & \\ & \ddots & \\ & & b_m \end{bmatrix} + C = 0$$

has to be solved. We assume that $e_j > 0, \hat{e}_i > 0, a_i < 0$, and $b_j > 0$ for all entries of the diagonal matrices. This system can, by multiplication with $\mathrm{diag}(\hat{e}_1^{-1}, \dots, \hat{e}_n^{-1})$ from the left and $\mathrm{diag}(e_1^{-1}, \dots, e_m^{-1})$ from the right, be transformed into a standard Sylvester equation for which the techniques from above are applicable, in particular

$$X_{ij} = \hat{e}_i^{-1} C_{ij} e_j^{-1} / (b_j/e_j - a_i/\hat{e}_i). \tag{4.5}$$

**5. Smoothing iterations.** In this section we will consider possible smoothing iterations that are useful in the context of the multigrid method. The two simplest ones are Richardson and Jacobi, and these will be given in detail in the following.

**5.1. Richardson iteration.** For linear systems of equations $Mx = b$ the (stationary) Richardson iteration is defined by

$$x_0 := 0, \qquad x_i := x_{i-1} - \theta(Mx_{i-1} - b) \qquad \text{for } i \geq 1.$$

Convergence is guaranteed for positive definite matrices $M$ if the parameter $\theta \in \mathbb{R}$ fulfils $0 < \theta < 2\|M\|_2^{-1}$ (see, e.g., [8] and also for a generalization to nonsymmetric systems). For the linear system $AX - XB + C = 0$ the iteration reads

$$X_0 := 0, \qquad X_i := X_{i-1} - \theta(AX_{i-1} - X_{i-1}B + C) \qquad \text{for } i \geq 1. \tag{5.1}$$

The optimal damping factor is $\theta = 2/(\|M\|_2 + \|M^{-1}\|_2^{-1})$, which can be estimated by $\theta \approx \frac{3}{2}\|M\|_2^{-1}$, where $\|M\|_2 = \|A\|_2 + \|B\|_2$ is easily computable via the power iteration (here we assumed $A < 0$ and $B > 0$).

If the iterate $X_{i-1}$ is an $R(k)$-matrix and the right-hand side $C$ is an $R(k_C)$-matrix, then the next iterate $X_i$ is an $R(2k + k_C)$-matrix whose representation can be computed by $k$ matrix-vector multiplications for the matrices $A$ and $B$. In order to stay in the set of $R(k)$-matrices one can truncate the resulting matrix $X_i$ to lower rank $k$. This will be called the $R(k)$-Richardson iteration:

$$X_0 := 0, \qquad X_i := \mathcal{T}_k(X_{i-1} - \theta(AX_{i-1} - X_{i-1}B + C)) \qquad \text{for } i \geq 1. \tag{5.2}$$

Lemma 5.1. [illegible] $A \in \mathbb{R}^{n \times n}$ [illegible] $B \in \mathbb{R}^{m \times m}$ [illegible] $A$ [illegible] $B$ [illegible] $\mathcal{O}(n)$ [illegible] $\mathcal{O}(m)$

(a) [illegible] (5.1) [illegible] $\mathcal{O}(nm)$

(b) [illegible] $R(k)$ [illegible] (5.2) [illegible] $\mathcal{O}(k^2(n+m))$

Although the Richardson iteration is convergent for sufficiently small $\theta$, the rate of convergence can be poor. In the context of multigrid methods one is not necessarily interested in convergence properties but in the smoothing property (cf. [8]). The next lemma provides the necessary assumptions.

Lemma 5.2. [illegible] $A \in \mathbb{R}^{n \times n}$ [illegible] $B \in \mathbb{R}^{m \times m}$ [illegible] $\sigma(A) > \sigma(B)$ [illegible] $E$ [illegible]

[illegible] $\mathcal{S}^{A,B}$ [illegible] $\mathcal{S}^{A,B,E}$ [illegible]

[illegible] If $\sigma(A) = \{\lambda_1, \dots, \lambda_n\}$ and $\sigma(B) = \{\mu_1, \dots, \mu_m\}$, then the $nm$ eigenvalues of the (linear) Sylvester operator $S : X \mapsto AX - XB$ are $\lambda_i - \mu_j$. By assumption all eigenvalues are positive. The symmetry follows from $\mathcal{S}^{A,B}_{ij,pq} = \delta_{jq}A_{ip} - \delta_{ip}B_{qj} = \delta_{qj}A_{pi} - \delta_{pi}B_{jq} = \mathcal{S}^{A,B}_{pq,ij}$. Analogously symmetry holds for the generalized Sylvester operator $\mathcal{S}^{A,B,E}$. From $\sigma(A) > \sigma(B)$ and the symmetry of $A, B$ we conclude $\sigma(E^{-\frac{1}{2}}AE^{-\frac{1}{2}}) > \sigma(E^{-\frac{1}{2}}BE^{-\frac{1}{2}})$. From the first part we know $S = I \otimes E^{-\frac{1}{2}}AE^{-\frac{1}{2}} - E^{-\frac{1}{2}}BE^{-\frac{1}{2}} \otimes I > 0$ and thus by multiplying $E^{\frac{1}{2}} \otimes E^{\frac{1}{2}}$ from the left and right: $\mathcal{S}^{A,B,E} = E \otimes A - B \otimes E > 0$. ☐

**5.2. Jacobi iteration.** The [illegible] is defined by

$$X_0 := 0, \qquad X_i := X_{i-1} - \theta \operatorname{diag}(\mathcal{S})^{-1}(AX_{i-1} - X_{i-1}B + C) \qquad \text{for } i \geq 1, \tag{5.3}$$

where $\mathcal{S}$ is the Sylvester operator. The diagonal entries of the Sylvester operator are

$$\mathcal{S}^{A,B}_{ij,ij} = A_{ii} - B_{jj}, \quad \mathcal{S}^{A,B,E}_{ij,ij} = E_{jj}A_{ii} - E_{ii}B_{jj},$$

so that the corresponding Sylvester equations are

$$\operatorname{diag}(A)X - X\operatorname{diag}(B) = C_i, \quad \operatorname{diag}(A)X\operatorname{diag}(E) - \operatorname{diag}(E)X\operatorname{diag}(B) = \tilde{C}_i.$$

We have to solve the diagonal (generalized) Sylvester equations for the right-hand side $C_i = AX_{i-1} - X_{i-1}B + C$ and $\tilde{C}_i = AX_{i-1}E - EX_{i-1}B + C$, respectively. The solution is given by (4.2) and (4.5). The optimal damping factor for the Jacobi iteration is $\theta := 2/(\Lambda + \lambda)$ [8], where $\Lambda$ and $\lambda$ are the best bounds for

$$\lambda \operatorname{diag}(M) \leq M \leq \Lambda \operatorname{diag}(M), \qquad M = \mathcal{S}^{A,B} \text{ or } \mathcal{S}^{A,B,E}.$$

Later we will use the parameter $\theta := 1/2$, which is sufficient to guarantee the smoothing property [8] needed for the multigrid method.

If the iterate $X_{i-1}$ is an $R(k)$-matrix and the right-hand side $C$ is an $R(k_C)$-matrix, then the right-hand side is an $R(2k + k_C)$-matrix. A low rank approximation $X_{i+1}$ to the solution of the diagonal Sylvester equation can be computed by means of the hierarchical Construction 4.5. The effect is the same if we solve the diagonal equation exactly and truncate the result to a fixed rank $k$ or a fixed accuracy $\varepsilon$. Therefore, the $R(k)$-Jacobi iteration can be written in the form

$$X_0 := 0, \qquad X_i := \mathcal{T}_k(X_{i-1} - \theta \operatorname{diag}(\mathcal{S})^{-1}(AX_{i-1} - X_{i-1}B + C)). \tag{5.4}$$

LEMMA 5.3. [illegible] $A \in \mathbb{R}^{n \times n}$ [illegible] $B \in \mathbb{R}^{m \times m}$ [illegible] $A$ [illegible] $B$ [illegible] $\mathcal{O}(n)$ [illegible] $\mathcal{O}(m)$

(a) [illegible] (5.3) [illegible] $\mathcal{O}(nm)$

(b) [illegible] $R(k)$ [illegible] (5.4) [illegible] $\mathcal{O}(k^2(n+m))$

**5.3. ADI iteration as a smoother.** Apart from Richardson and Jacobi there are many other popular smoothers such as Gauss–Seidel, SOR, ILU, etc. Since these are not compatible with the low rank format, they are not of interest here. The only notable exception that we are aware of is the ADI iteration from Example 4.9. There we have to solve systems of the form

$$Ax = b,$$

which can be accomplished, e.g., by a multigrid method. However, one has to be careful with the choice of the shift parameters $p_i$, since the optimal parameters for the smoothing property differ from the usual ones that yield the optimal convergence rate [7].

For sure, the Richardson iteration is the most simple of the smoothers under consideration. The Jacobi iteration is necessary for nonuniform grids (e.g., locally refined) in order to get mesh-independent good convergence rates. The same goal is reached by the ADI iteration.

**6. Multigrid method.** The Richardson and Jacobi iterations introduced in the previous section smooth the defect in the multigrid method on one level (=grid). In the multigrid method we transfer the smoothed defect to a coarser grid and compute a defect correction on the coarser grid. The coarse grid correction is then transferred to the fine grid in order to reduce the smooth parts of the defect. On the coarsest level we use a standard solution for the Sylvester equation. For the transfer between different grids ranging from coarse ($n_0 = 9$ degrees of freedom) to fine ($n_8 = 1046529$ degrees of freedom), we need the prolongation and restriction operator defined in the following. Whereas the Richardson and Jacobi iteration had to be adopted to the low rank setting, this is not necessary for the grid transfer operators.

Let $X \in \mathbb{R}^{n\times n}$ be a matrix, and let $\hat{p} : \mathbb{R}^n \to \mathbb{R}^m$ be a linear mapping, the so-called prolongation. Then the corresponding matrix mapping $p$ is defined by

$$p(X) := \hat{p}X\hat{p}^T. \tag{6.1}$$

The adjoint operator $r$, the so-called restriction, is given by

$$r(Y) := \hat{p}^T Y \hat{p} \tag{6.2}$$

for $Y \in \mathbb{R}^{m\times m}$. Since the linear mapping $p$ does not increase the rank of a matrix, we stay in the set of $R(k)$ matrices (only of different size $n, m$). Moreover, if $X = AB^T$ is an $R(k)$-matrix, then

$$p(X) = (\hat{p}A)(\hat{p}B)^T,$$

so that the prolonged (or restricted in the case $r(Y)$) matrix is naturally given in the desired $R(k)$ format. In the notation of section 3.1 the prolongation is of the tensor structure $p = \hat{p} \otimes \hat{p}$.

**6.1. Multigrid algorithm and convergence results.** Let $\ell = 0, \dots, L$ be the level numbers, and assume that on each level we have a discrete linear equation[1]

$$\mathfrak{A}_\ell \mathfrak{x}_\ell = \mathfrak{b}_\ell \qquad (0 \le \ell \le L),$$

with symmetric and positive definite $n_\ell \times n_\ell$ matrices $\mathfrak{A}_\ell$, while $\mathfrak{b}_\ell$ is some right-hand side and $\mathfrak{x}_\ell$ the corresponding solution. For some domains (e.g., the unit square from our model problem) the hierarchy $(\mathfrak{A}_\ell)_{\ell=0}^L$ of discrete problems is naturally given by successive refinement of the coarsest grid. For more complicate domains one needs suitable coarsening algorithms, e.g., composite finite elements [10] or algebraic multigrid [19, 21].

We recall the general multigrid algorithm (for details of the algorithm or the following statements we refer to Hackbusch [7], [8]):

---

[1] The Fraktur style letters indicate matrices and vectors which will be later identified with corresponding quantities of the Sylvester equation. For instance, the vector $\mathfrak{x}_\ell$ will become the unknown solution matrix $X_\ell$.

```
function $MGM(\ell,\mathfrak{x},\mathfrak{b})$;                              (returns the new iterate)
if $\ell = 0$ then $\mathfrak{x} := \mathfrak{A}_0^{-1} f$ else
begin

    $\mathfrak{d} := r(\mathfrak{A}_\ell \mathfrak{x} - \mathfrak{b})$;                             (restriction of the defect)
    $\mathfrak{y} := 0$;                                  (starting value for the corrections)
    for $i := 1$ to $\gamma$ do $v := MGM(\ell - 1, \mathfrak{y}, \mathfrak{d})$;
    $\mathfrak{x} = \mathfrak{x} - p\mathfrak{y}$;                                       (coarse-grid correction)
    for $i := 1$ to $\nu$ do $\mathfrak{x} := \mathcal{S}_\ell(\mathfrak{x},\mathfrak{b})$;                        (postsmoothing)
end;
$MGM := \mathfrak{x}$                                                 (new iterate returned)
```

The $V$-cycle ($W$-cycle) corresponds to $\gamma = 1$ ($\gamma = 2$). $\nu$ is the number of pre- and postsmoothing steps using the smoothing procedure $\mathcal{S}_\ell$ (e.g., Richardson, Jacobi, or the $R(k)$ counterparts). $p$ is the prolongation from (6.1), e.g., the piecewise linear interpolation in the case of difference schemes, or the canonical finite element transfer in the case of finite element subspaces $V_{\ell-1} \subset V_\ell$).

The essential conditions for the convergence of the $W$-cycle are the smoothing and approximation properties. A simplified version of the smoothing property is

$$\|\mathfrak{A}_\ell \mathfrak{S}_\ell^\nu\| \leq C_{\mathrm{sm}} \|\mathfrak{A}_\ell\| \, \sigma_\ell \eta(\nu) \qquad \text{for } \nu \geq 1 \text{ with } \lim_{\nu\to\infty} \eta(\nu) = 0, \tag{6.3}$$

where $\mathfrak{S}_\ell$ is the iteration matrix of the iteration $\mathcal{S}_\ell$ (i.e., $\mathcal{S}_\ell(\mathfrak{x},\mathfrak{b}) = \mathfrak{S}_\ell\mathfrak{x} + \mathfrak{T}_\ell\mathfrak{b}$) and $C_{\mathrm{sm}}$ is a constant independent of $\ell$, while $\sigma_\ell$ is any scaling quantity (except of section 6.6, only $\sigma_\ell = 1$ will occur). For convenience, $\|\cdot\|$ may be considered as the spectral norm, but other norms are possible. Often $\eta(\nu)$ equals

$$\eta_0(\nu) := \nu^\nu / (\nu+1)^{\nu+1}. \tag{6.4}$$

The approximation property reads

$$\|\mathfrak{A}_\ell^{-1} - p\mathfrak{A}_{\ell-1}^{-1} r\| \leq C_{\mathrm{app}} / (\|\mathfrak{A}_\ell\| \, \sigma_\ell), \tag{6.5}$$

with an $\ell$-independent constant $C_{\mathrm{app}}$ and the same scaling quantity $\sigma_\ell$ as in (6.3). Under these assumptions (and simple technical conditions on $p$, $r$, and $\mathfrak{S}_\ell$), the $W$-cycle converges with the rate $\mathrm{const} \cdot \eta(\nu)$ (under standard symmetry conditions on $p$, $r$, and $\mathfrak{S}_\ell$, even $\nu = 1$ leads to convergence).

**6.2. Approximation property.** Assuming a finite element discretization with subspaces $V_{\ell-1} \subset V_\ell$ with quasi-uniform grid sizes $h_{\ell-1}$, $h_\ell$ ($h_{\ell-1}/h_\ell \leq \mathrm{const}$), one obtains the estimate $\|\mathfrak{A}_\ell^{-1} - p\mathfrak{A}_{\ell-1}^{-1} r\| \leq \mathrm{const} \cdot \|\mathfrak{A}_\ell^{-1}\| h_\ell^2$ for the spectral norm, provided that full regularity holds; i.e., the underlying boundary value problem satisfies $\|u\|_{H^2(\omega)} \leq \mathrm{const}\, \|f\|_{L^2(\omega)}$ for the solution of $Lu = f$. If the coefficients are sufficiently smooth and $\omega$ is convex (or an image of a convex domain under a smooth mapping), full regularity holds (cf. Hackbusch [9, Theorem 9.1.22]). In our application, the domain $\omega$ is the product $\Omega \times \Omega$. Convexity of $\Omega$ implies convexity of $\omega$.

Since the scaling of the stiffness matrix is such that $\|\mathfrak{A}_\ell\| \|\mathfrak{A}_\ell^{-1}\|$ is proportional to $h_\ell^{-2}$, the inequality $\|\mathfrak{A}_\ell^{-1} - p\mathfrak{A}_{\ell-1}^{-1} r\| \leq \mathrm{const} \cdot \|\mathfrak{A}_\ell^{-1}\| h_\ell^2$ is equivalent to (6.5) with $\sigma_\ell := 1$.

Weaker regularity can also be treated (see section 6.6).

**6.3. Smoothing property without truncation.** First we consider the Richardson iteration

$$\mathcal{S}_\ell(\mathfrak{x}_\ell, \mathfrak{b}_\ell) = \mathfrak{S}_\ell \mathfrak{x}_\ell + \mathfrak{T}_\ell \mathfrak{b}_\ell, \qquad \text{with } \mathfrak{S}_\ell = I - \vartheta_\ell \mathfrak{A}_\ell, \quad \mathfrak{T}_\ell \mathfrak{b}_\ell = \vartheta_\ell \mathfrak{b}_\ell,$$

with the damping factor $\vartheta_\ell = 1/\|\mathfrak{A}_\ell\|_2$ (also $\vartheta_\ell = 1/\rho(\mathfrak{A}_\ell)$ because of the symmetry of $\mathfrak{A}_\ell$).

Lemma 6.1 (see [8, Theorem 10.6.5]). [illegible] $\mathfrak{A}_\ell$ [illegible] $\vartheta_\ell = 1/\|\mathfrak{A}_\ell\|_2$ [illegible] $\eta(\nu) = \eta_0(\nu)$ [illegible] (6.4) [illegible] $C_{\mathrm{sm}}\sigma_\ell = 1$.

For the application to the Sylvester equation, we have to make use of $\vartheta_\ell = 1/\rho(\mathfrak{A}_\ell) = 1/(\max_{\lambda\in\sigma(A)} \lambda - \min_{\mu\in\sigma(B)} \mu)$. Since the matrices $\mathfrak{A}_\ell = \mathcal{S}^{A,B}$ and $\mathfrak{A}_\ell = \mathcal{S}^{A,B,M}$ are symmetric and positive definite (Lemma 5.2), the previous lemma applies.

Next, we consider the damped Jacobi iteration

$$\mathcal{S}_\ell(\mathfrak{x}_\ell, \mathfrak{b}_\ell) = \mathfrak{S}_\ell \mathfrak{x}_\ell + \mathfrak{T}_\ell \mathfrak{b}_\ell, \qquad \text{with } \mathfrak{S}_\ell = I - \vartheta_\ell \mathfrak{D}_\ell^{-1} \mathfrak{A}_\ell, \quad \mathfrak{T}_\ell \mathfrak{b}_\ell = \vartheta_\ell \mathfrak{D}_\ell^{-1} \mathfrak{b}_\ell, \tag{6.6}$$

where $\mathfrak{D}_\ell$ is the diagonal part of $\mathfrak{A}_\ell$ with $\vartheta_\ell$ such that $\vartheta_\ell \rho(\mathfrak{D}_\ell^{-1}\mathfrak{A}_\ell) \le 1$. Then we obtain the following.

Lemma 6.2 (see [7, section 6.2]). [illegible] $\mathfrak{A}_\ell$ [illegible] (6.6) [illegible]

$$\vartheta_\ell \le 1/\rho(\mathfrak{D}_\ell^{-1}\mathfrak{A}_\ell) \quad [illegible] \quad \|\mathfrak{D}_\ell\|_2 \le C_{\mathrm{sm}} \vartheta_\ell \|\mathfrak{A}_\ell\|_2 \tag{6.7}$$

[illegible] $\eta(\nu) = \eta_0(\nu)$ [illegible] $C_{\mathrm{sm}}\sigma_\ell = 1$. [illegible] $\mathfrak{D}_\ell$ [illegible] (6.7)

The Jacobi iteration (5.3) for the Sylvester equation with suitable $\theta$ satisfies the assumptions of the previous lemma (due to Lemma 5.2); therefore, the smoothing property holds. In the case that the matrix $\mathfrak{D}_\ell$ is replaced by an approximation $\mathfrak{D}'_\ell$ due to the fact that we solve the diagonal Sylvester equation with a perturbed Cauchy matrix, we chose a symmetric $R(k)$-approximation of the Cauchy matrix. Since $\mathfrak{D}_\ell$ is well-conditioned, the approximation remains positive definite and satisfies the inequalities (6.7) with a possibly modified constant $C_{\mathrm{sm}}$. Hence, the Jacobi iteration with $R(k)$-Cauchy matrix approximation also possesses the smoothing property. In combination with the approximation property from above, we obtain level-independent convergence of the $W$-cycle. Similarly, the $V$-cycle proof from [7] can be applied. The iterates $X_i$ are all treated as full matrices, and the multigrid method therefore has a complexity of $\mathcal{O}(n_\ell)$, where $X_i \in \mathbb{R}^{\sqrt{n_\ell}\times\sqrt{n_\ell}}$.

**6.4. Truncation of the iterates.** The effect of the truncation in each step of the multigrid method (during the smoothing iteration and defect correction) can be regarded as an artificially limited machine precision. After one full multigrid cycle, the $i$th iterate $\mathfrak{x}_\ell^i$ on level $\ell$ is perturbed by $\mathfrak{s}_\ell^i$ so that the equation

$$\mathfrak{A}_\ell \mathfrak{x}_\ell^i = \mathfrak{b}_\ell - \mathfrak{A}_\ell \mathfrak{s}_\ell^i$$

holds. The vector $\mathfrak{s}_\ell^i$ accumulates all of the perturbations of size $\varepsilon$ during the $i$th cycle (due to the truncation to a fixed rank), $\|\mathfrak{s}_\ell^i\| \le C_{n_\ell}\varepsilon$. Since we expect a convergence rate of

$$\|\mathfrak{x}_\ell^i - \mathfrak{x}_\ell\| < \rho \|\mathfrak{x}_\ell^{i-1} - \mathfrak{x}_\ell\|, \qquad \rho < 1,$$

we immediately get

$$\|(\mathfrak{x}_\ell^i + \mathfrak{s}_\ell^i) - \mathfrak{x}_\ell\| \;<\; \rho\|\mathfrak{x}_\ell^{i-1} - \mathfrak{x}_\ell\| + C_{n_\ell}\varepsilon \;\le\; \underbrace{\left(\rho + \frac{C_{n_\ell}\varepsilon}{\|\mathfrak{x}_\ell^{i-1} - \mathfrak{x}_\ell\|}\right)}_{\tilde\rho} \|\mathfrak{x}_\ell^{i-1} - \mathfrak{x}_\ell\|.$$

As long as we can represent $\mathfrak{x}_\ell^{i-1}$ sufficiently well, the term $C_{n_\ell}\varepsilon$ is small and the perturbed convergence rate $\tilde\rho \approx \rho$. As we come closer to the solution $\mathfrak{x}_\ell$ and fix the accuracy $\varepsilon$ (the rank $k$, resp.), the convergence will break down (the iteration stagnates). This is also observed in the numerical tests.

REMARK 6.3 (nonsymmetry). Although the analysis given here requires the symmetry of the system matrix $\mathfrak{A}_\ell$ (which is induced by the symmetry of $A$ and $B$), the multigrid method still works well for the nonsymmetric case.

In principle, the whole machinery of (algebraic) multigrid methods can be transferred to the Sylvester case by the tensor product relation. The crucial point is the connection between the hierarchies of the $A$ matrices and the $B$ matrices since these are generated independently. This "natural" anisotropy is considered in the next section.

**6.5. Anisotropic case.** As seen from (3.2) and the derived approximation, the stiffness matrix $\mathbb{A}$ is the sum $\mathbb{A}_x + \mathbb{A}_y$, where $\mathbb{A}_x, \mathbb{A}_y$ belong to the $x$- and $y$-variables. In the case of (3.2), the differential operator $\mathcal{A}[u](x,y)$ is $\mathcal{A} = -\Delta_x - \Delta_y$; i.e., the $x$- and $y$-parts are equal so that $\mathbb{A}_x$ and $\mathbb{A}_y$ have identical eigenvalues. A typical anisotropic differential operator is $\mathcal{A} = -\Delta_x - \varepsilon\Delta_y$, with small, positive $\varepsilon$. In this case the approximation property contains an additional factor $1/\varepsilon$, which may be formulated by the choice $\sigma_\ell = \varepsilon$. Therefore, we need a smoothing procedure such that the estimate (6.3) is improved by the same factor $\sigma_\ell = \varepsilon$. This can be obtained by the iteration

$$\mathcal{S}_\ell(\mathfrak{x}_\ell, \mathfrak{b}_\ell) = \mathfrak{S}_\ell\mathfrak{x}_\ell + \mathfrak{T}_\ell\mathfrak{b}_\ell, \qquad \text{with } \mathfrak{S}_\ell = I - \mathfrak{A}_{x,\ell}^{-1}\mathfrak{A}_\ell, \quad \mathfrak{T}_\ell\mathfrak{b}_\ell = \mathfrak{A}_{x,\ell}^{-1}\mathfrak{b}_\ell, \tag{6.8}$$

where $\mathfrak{A}_\ell = \mathfrak{A}_{x,\ell} + \varepsilon\mathfrak{A}_{y,\ell}$. The terms $\mathfrak{A}_{x,\ell}$ and $\varepsilon\mathfrak{A}_{y,\ell}$ are the discretizations $\mathbb{A}_x, \mathbb{A}_y$ at level $\ell$.

LEMMA 6.4 (see [7, Lemma 10.1.2]). [illegible] $\mathfrak{A}_{x,\ell}, \mathfrak{A}_{y,\ell}$ [illegible]

$$\mathfrak{A}_{x,\ell} \cdot \mathfrak{A}_{y,\ell} = \mathfrak{A}_{y,\ell} \cdot \mathfrak{A}_{x,\ell}, \qquad \|\mathfrak{A}_{y,\ell}\|_2 \le \text{const}\ \|\mathfrak{A}_\ell\|_2\,.$$

[illegible] (6.8) [illegible] $\eta(\nu) = \eta_0(\nu - 1)$ [illegible] $C_{\mathrm{sm}}\sigma_\ell = \varepsilon$.

[illegible] For convenience, we repeat the proof, which is based on the identity

$$\begin{aligned}
\mathfrak{A}_\ell\mathfrak{S}_\ell^\nu &= (\mathfrak{A}_{x,\ell} + \varepsilon\mathfrak{A}_{y,\ell})\,\mathfrak{S}_\ell^\nu = \mathfrak{A}_{x,\ell}\mathfrak{S}_\ell^\nu + \varepsilon\mathfrak{A}_{y,\ell}\mathfrak{S}_\ell^\nu = \mathfrak{A}_{x,\ell}\left(I - \mathfrak{A}_{x,\ell}^{-1}\mathfrak{A}_\ell\right)\mathfrak{S}_\ell^{\nu-1} + \varepsilon\mathfrak{A}_{y,\ell}\mathfrak{S}_\ell^\nu \\
&= (\mathfrak{A}_{x,\ell} - \mathfrak{A}_\ell)\,\mathfrak{S}_\ell^{\nu-1} + \varepsilon\mathfrak{A}_{y,\ell}\mathfrak{S}_\ell^\nu = -\varepsilon\mathfrak{A}_{y,\ell}\mathfrak{S}_\ell^{\nu-1} + \varepsilon\mathfrak{A}_{y,\ell}\mathfrak{S}_\ell^\nu \\
&= \varepsilon\mathfrak{A}_{y,\ell}\,(I - \mathfrak{S}_\ell)\,\mathfrak{S}_\ell^{\nu-1}.
\end{aligned}$$

The commutativity is used to show that $\mathfrak{S}_\ell$ is symmetric with eigenvalues in $[0,1]$. This implies $\|(I - \mathfrak{S}_\ell)\mathfrak{S}_\ell^{\nu-1}\|_2 = \rho((I - \mathfrak{S}_\ell)\mathfrak{S}_\ell^{\nu-1}) \le \eta_0(\nu - 1)$ (cf. [8, Lemma 10.6.1]). The final result follows from $\|\mathfrak{A}_\ell\mathfrak{S}_\ell^\nu\|_2 = \varepsilon\|\mathfrak{A}_{y,\ell}(I - \mathfrak{S}_\ell)\mathfrak{S}_\ell^{\nu-1}\|_2 \le \varepsilon\|\mathfrak{A}_{y,\ell}\|_2$ $\|(I - \mathfrak{S}_\ell)\mathfrak{S}_\ell^{\nu-1}\|_2 \le \varepsilon \cdot \text{const} \cdot \|\mathfrak{A}_\ell\|_2\eta_0(\nu - 1)$. $\square$

Since the extra factor $\varepsilon$ from the smoothing property cancels with the $1/\varepsilon$ factor in the approximation property, the estimate of the multigrid convergence rate is independent of $\ell$ and $\varepsilon$.

The commutativity $\mathfrak{A}_{x,\ell} \cdot \mathfrak{A}_{y,\ell} = \mathfrak{A}_{y,\ell} \cdot \mathfrak{A}_{x,\ell}$ holds in the case of the Sylvester equation because of the tensor structure.

The solution of the system $\mathfrak{A}_{x,\ell}$ in each step of the iteration (6.8) requires the solution of a system

$$A_\ell X_\ell = C_\ell, \qquad X_\ell \in \mathbb{R}^{\sqrt{n_\ell} \times \sqrt{n_\ell}},$$

which can be done columnwise for full matrices or just for the $k$ column vectors of $U$ in the $R(k)$-matrix representation of Definition 1.2.

**6.6. Weaker regularity.** In the case of a reentrant corner of $\Omega$, the full regularity is not satisfied, but $\mathcal{A} : H^{2-s}(\Omega \times \Omega) \to H^{-s}(\Omega \times \Omega)$ is an isomorphism for some $s \in [0, 1)$ (cf. [9]). In this case, one has to modify the matrix norms in (6.3) and (6.5):

$$\left\| \mathfrak{A}_\ell^{1-s/2} \mathfrak{S}_\ell^\nu \, \mathfrak{A}_\ell^{-s/2} \right\|_2 \le C_{\mathrm{sm}} \left\| \mathfrak{A}_\ell \right\|_2^{1-s} \sigma_\ell \eta(\nu), \tag{6.9a}$$

$$\| \mathfrak{A}_\ell^{-s/2} \left( \mathfrak{A}_\ell^{-1} - p \mathfrak{A}_{\ell-1}^{-1} r \right) \mathfrak{A}_\ell^{s/2} \|_2 \le C_{\mathrm{app}} / \left( \| \mathfrak{A}_\ell \|_2^{1-s} \sigma_\ell \right), \tag{6.9b}$$

involving fractional powers of $\mathfrak{A}_\ell$. In the case of $\mathfrak{A}_{x,\ell} \cdot \mathfrak{A}_{y,\ell} = \mathfrak{A}_{y,\ell} \cdot \mathfrak{A}_{x,\ell}$, it follows that $\mathfrak{A}_\ell^\alpha$ $(0 \le \alpha \le 1)$, with $\mathfrak{A}_\ell = \mathfrak{A}_{x,\ell} + \varepsilon \mathfrak{A}_{y,\ell}$, is spectrally equivalent with $\mathfrak{A}_{x,\ell}^\alpha + \varepsilon^\alpha \mathfrak{A}_{y,\ell}^\alpha$. Using these matrices in (6.9) instead of $\mathfrak{A}_\ell^\alpha$, one can repeat the proof of Lemma 6.4 with $\sigma_\ell = \varepsilon^{1-s}$ and $\eta(\nu) = (\eta_0(\nu))^{1-s}$.

**7. Numerical results.** In this section we apply the $R(k)$-multigrid algorithm developed in the previous sections to the model problem of section 1.1 with $\omega := 1$ in (1.1), namely, the first step of the Newton method where we have to solve (1.6) with a rank one right-hand side $C$ and the two-dimensional discrete Laplacian $A$. The simple geometry allows us to use two-dimensional bilinear (tensor) basis functions $\phi_i$ and a nested hierarchy of grids with a coarse grid that contains $n_0 = 9$ degrees of freedom; see Figure 7.1.

The computations are performed on a SUN ULTRASPARC III with 900 MHz CPU clock rate and 150 MHz memory clock rate. We make use of the LAPACK and BLAS libraries (`http://www.netlib.org`) for the truncation procedure and use the standard C programming language otherwise.

The initial approximation on level $\ell$ is obtained by prolongation of a solution from level $\ell - 1$; i.e., we use a nested iteration so that only $\mathcal{O}(1)$ steps on the fine grid are necessary in order to reduce the error down to the size of the discretization error. The rank on level $\ell - 1, \ldots, 0$ is chosen as twice the rank $k$ on the fine grid $\ell$ on which we want to compute the solution. In the $V$-cycle multigrid we use $\nu = 2$ pre- and postsmoothing steps.

**7.1. Discretization error.** First, we perform the multigrid method with rank $k = 20$ in order to produce a reference solution on each level $\ell = 0, \ldots, 9$. The solution on level $\ell = 9$ is used to estimate the discretization error on level $\ell = 0, \ldots, 8$; see Table 7.1. The rank $k$ is large enough so that the truncation has no influence.

Alternatively, one could use the multigrid method without truncation working with full matrices instead of the $R(k)$-matrix format. For level $\ell = 3$ this takes only 2.6 seconds to compute an accurate solution, but the complexity is quadratic in $n$, so that on level $\ell = 5$ we need more than 600 seconds for the solution and on level $\ell = 8$ we would (theoretically) need approximately 775 hours.

**7.2. Truncation error.** Next, we perform the multigrid cycle on level $\ell = 6$ with fixed rank $k = 2$, so that the truncation error $\varepsilon$ due to the small rank $k$ becomes dominant; see Table 7.2. As was expected from the theory, the convergence breaks down after we get close to the solution. Since we are already at the size of the discretization error, we can stop the iteration after three steps which takes 9.7 seconds.

**7.3. Large scale problems.** The last three levels $\ell = 7, 8, 9$ in our numerical test would require storing (and computing) solution matrices $X_\ell$ of size up to $4190209 \times 4190209$. Without the low rank format the storage in double precision of these requires 128 Terabyte. In the $R(k)$-matrix format we need only 256 MB. In the following numerical example we use the $R(k)$-multigrid algorithm based on the $R(k)$-Richardson iteration. The time in seconds for the computation of a solution that is accurate up to the discretization error is given in Table 7.3.

The nested iteration combined with the multigrid method has a complexity of $\mathcal{O}(k^2 n_\ell)$ to solve the discrete system $\mathfrak{A}_\ell \mathfrak{x}_\ell = \mathfrak{b}_\ell$ on level $\ell$. Although the dependency is linear in $n_\ell$, the rank $k$ for the representation of the solution depends on $n_\ell$, typically $k = \log(n_\ell)$. Therefore, the overall complexity of our algorithm is $\mathcal{O}(n_\ell \log^2(n_\ell))$. A goal for future research is to reduce this complexity down to $\mathcal{O}(n_\ell)$.

**7.4. Second model problem.** For the second model problem from section 1.2 we consider the dependency on the parameter $\beta$ that governs the nonsymmetry of the system. For $\beta = 0$ the model problem is identical to the one considered in the previous section.

Table 7.4

*The first $k = 1, \dots, 9$ singular values of the solution $X_\ell$ on level $\ell = 5$ for the parameter $\beta \in \{1, 10, 100\}$.*

| $k$ | $\beta = 1$ | $\beta = 10$ | $\beta = 100$ |

|---|---|---|---|---|---|---|---|---|
| 1 | $1.3 \times 10^{-2}$ | .55 | $1.3 \times 10^{-2}$ | .44 | $1.9 \times 10^{-2}$ | .43 | $2.4 \times 10^{-2}$ | .41 |
| 2 | $7.1 \times 10^{-3}$ | .55 | $7.5 \times 10^{-3}$ | .57 | $1.0 \times 10^{-2}$ | .54 | $1.4 \times 10^{-2}$ | .58 |
| 3 | $4.1 \times 10^{-3}$ | .57 | $2.2 \times 10^{-3}$ | .29 | $3.6 \times 10^{-3}$ | .35 | $5.6 \times 10^{-3}$ | .40 |
| 4 | $2.4 \times 10^{-3}$ | .58 | $1.2 \times 10^{-3}$ | .55 | $3.0 \times 10^{-3}$ | .83 | $3.4 \times 10^{-3}$ | .60 |
| 5 | $1.4 \times 10^{-3}$ | .59 | $5.6 \times 10^{-4}$ | .46 | $8.5 \times 10^{-4}$ | .29 | $2.0 \times 10^{-3}$ | .58 |
| 6 | $8.1 \times 10^{-4}$ | .59 | $2.5 \times 10^{-4}$ | .45 | $4.5 \times 10^{-4}$ | .53 | $1.8 \times 10^{-3}$ | .91 |
| 7 | $4.8 \times 10^{-4}$ | .59 | $8.8 \times 10^{-5}$ | .35 | $2.4 \times 10^{-4}$ | .52 | $1.3 \times 10^{-3}$ | .74 |

For larger $\beta$ we face two distinct problems: First, the required rank for the accurate representation of the solution will increase, because the spectrum of the system matrix $A$ will become complex and approach the imaginary axis. Second, the convergence rate of the multigrid method will not be bounded away from 1 as $\beta \to \infty$, because the smoother (in this case $R(k)$-Richardson) is not suitable for convection-dominated problems.

In Table 7.4 we can clearly see that for $\beta = 100$ the decay of the singular values of the solution is less steep than for $\beta = 1$. In the multigrid method we use the damping parameter $\theta := 1/\|\mathfrak{A}_\ell\|_2$, but the coarsest grid level will now depend on the parameter $\beta$: For $\beta = 1$ we choose the coarsest grid level $\ell = 0$, and for $\beta = 20, 40, 80$ we take $\ell = 1, 2, 3$, so that the ratio $\beta \cdot h_\ell$ is constant on the coarsest grid. Of course, for larger values of $\beta$ the coarsest grid on which we have to solve the Sylvester equation by some other means will grow. The convergence rates of the multigrid iteration are given in Table 7.5. If either the damping parameter $\theta$ is chosen too large or the coarsest grid too coarse, then the multigrid iteration diverges.

**7.5. First model problem.** At last we consider the first model problem from section 1.1 (parameter $\kappa(\xi) = 10000$ for $\xi \in (\frac{1}{2}, 1) \times (0, 1)$), where a Riccati equation has to be solved. In each step of Newton's method (initial guess $X_{\ell-1}$ from the coarse grid) we have to solve a Lyapunov equation, which is done by using the multigrid method. Here we employ the Jacobi smoother, where the damping factor is computed as in section 5 for the coarsest grid solver on level $\ell = 1$, i.e., $\theta := 2/\|\mathrm{diag}(\mathfrak{A}_\ell)^{-1/2}\, \mathfrak{A}_\ell\, \mathrm{diag}(\mathfrak{A}_\ell)^{-1/2}\|_2$. In the first three steps of the multigrid method we use the same choice of the damping parameter. From step 4 on we use $\theta := 1/2$. The Cauchy matrix approximation $\tilde{\mathcal{C}}$ uses a rank of 1. We fix the discretization level $\ell = 5$ with $n_\ell = 16129$ degrees of freedom and a solution matrix

Table 7.6

*Convergence rates for the first $i = 1, \ldots, 10$ steps of the multigrid iteration in the Newton step $j = 1, 2, 3$, based on the Jacobi smoother (left: relative error; right: convergence rate).*

| $i$ | NS $j = 1$ | | NS $j = 2$ | | NS $j = 3$ | |
|---|---|---|---|---|---|---|
| 1 | $6.1 \times 10^{-3}$ | .13 | $7.5 \times 10^{-6}$ | .08 | $3.3 \times 10^{-7}$ | .74 |
| 2 | $7.8 \times 10^{-3}$ | .13 | $5.1 \times 10^{-6}$ | .67 | $2.4 \times 10^{-7}$ | .74 |
| 3 | $1.3 \times 10^{-4}$ | .16 | $3.8 \times 10^{-6}$ | .75 | $1.8 \times 10^{-7}$ | .74 |
| 4 | $7.4 \times 10^{-5}$ | .58 | $2.8 \times 10^{-6}$ | .74 | $1.3 \times 10^{-7}$ | .74 |
| 5 | $5.1 \times 10^{-5}$ | .69 | $2.1 \times 10^{-6}$ | .74 | $9.8 \times 10^{-8}$ | .74 |
| 6 | $3.6 \times 10^{-5}$ | .71 | $1.5 \times 10^{-6}$ | .74 | $7.3 \times 10^{-8}$ | .74 |
| 7 | $2.6 \times 10^{-5}$ | .73 | $1.1 \times 10^{-6}$ | .74 | $5.4 \times 10^{-8}$ | .74 |
| 8 | $1.9 \times 10^{-5}$ | .73 | $8.3 \times 10^{-7}$ | .74 | $4.0 \times 10^{-8}$ | .74 |
| 9 | $1.4 \times 10^{-5}$ | .73 | $6.1 \times 10^{-7}$ | .74 | $2.9 \times 10^{-8}$ | .74 |
| 10 | $1.0 \times 10^{-5}$ | .73 | $4.5 \times 10^{-7}$ | .74 | $2.1 \times 10^{-8}$ | .74 |

$X \in \mathbb{R}^{n_\ell \times n_\ell}$. The rank for the $R(k)$-multigrid algorithm is fixed to $k = 20$. We perform three Newton steps and apply $i = 10$ multigrid steps each.

By $X^j$ we denote the (almost) exact solution of the Lyapunov equation in the $j$th Newton step (NS) on level $\ell$. By $X_i^j$ we denote the $i$th iterate of the multigrid iteration in the $j$th Newton step. In Table 7.6 the relative error $\|X^j - X_i^j\|_2 / \|X^j\|_2$ is reported for the three Newton steps $j = 1, 2, 3$.

We conclude that the $R(k)$-multigrid method is well-suited for the solution of the linear matrix equations in each step of Newton's method to solve the algebraic matrix Riccati equation. The Jacobi smoother yields uniformly bounded convergence rates $\rho \approx 0.74$. If the parameter $\kappa$ is much smaller, i.e., $\kappa(\xi) = \mathcal{O}(1)$, then the convergence rate is $\rho \approx 0.52$.

# A HESSENBERG REDUCTION ALGORITHM FOR RANK STRUCTURED MATRICES*

STEVEN DELVAUX† AND MARC VAN BAREL†

**Abstract.** In this paper, we show how to perform the Hessenberg reduction of a rank structured matrix under unitary similarity operations in an efficient way, using the Givens-weight representation. This reduction can be used as a first step for eigenvalue computation. We also show how the algorithm can be modified to compute the bidiagonal reduction of a rank structured matrix, this latter method being a preprocessing step for computing the singular values of the matrix. For the main cases of interest, the algorithms we describe in this paper are of complexity $O((ar + bs)n^2)$, where $n$ is the matrix size, $r$ is some measure for the average rank index of the rank structure, $s$ is some measure for the bandwidth of the unstructured matrix part around the main diagonal, and $a, b \in \mathbb{R}$ are certain weighting parameters. Numerical experiments demonstrate the stability of this approach.

## 1. Introduction.

In this paper, we describe how for a rank structured matrix with given Givens-weight representation, we can efficiently compute its Hessenberg form using unitary similarity transformations. The algorithm is particularly useful when the underlying matrix is Hermitian.

Hessenberg reduction is often the first step for computing the eigenvalues of a given matrix $A \in \mathbb{C}^{n\times n}$. This process transforms the given matrix into Hessenberg form using a unitary similarity transformation $A \mapsto Q^H AQ$, which may be based on either Givens or Householder transformations [9, 18]. Since the resulting Hessenberg matrix has the same eigenvalues as the original matrix, the eigenvalue problem reduces to finding the eigenvalues of a Hessenberg matrix, for which efficient algorithms can then be applied such as the QR-algorithm [9, Chapters 7 and 8] and [14, Chapter 8].

Classical algorithms for the Hessenberg reduction of banded matrices are contained in [16, 15]. Concerning Hessenberg reduction for rank structured matrices, we may refer to [7, 13] for the case of weakly semiseparable matrices of semiseparability rank one and to [1] for semiseparable plus banded matrices of arbitrary semiseparability rank. But we should mention that these papers use what we call a *uv*-representation for representing these matrices, this latter condition implying some

intrinsic restrictions to the class of matrices for which the algorithm can be applied. In this paper, we will not assume such a restriction.

For the main cases of interest, the algorithm we describe in this paper is of complexity $O((ar + bs)n^2)$, where $n$ is the matrix size, $r$ is some measure for the average rank index of the rank structure, $s$ is some measure for the bandwidth of the unstructured matrix part around the main diagonal, and $a, b \in \mathbb{R}$ are certain weighting parameters.

Rank structured matrices arise in a variety of ways in the literature. For example, they arise in the study of time-varying linear systems [6]. Another example is the hierarchical $\mathcal{H}$- and $\mathcal{H}^2$-matrices of Hackbusch, Khoromskij, and Sauter [11], which appear from the discretization of integral equations. Rank structured matrices can also be successfully used for the numerical approximation of Toeplitz matrices [12].

This paper is organized as follows. In section 2, we review some topics of the Givens-weight representation from [3], paying particular attention to the so-called zero-creating Givens-weight representation. Section 3 handles the Hessenberg reduction algorithm for a lower rank structured matrix. This section contains both a theoretical part concerning structure inheritance, as well as a practical part concerning the exploitation of these inheritance results. Section 4 deals with some variants of the algorithm, showing how to exploit symmetry or general rank structure in the upper triangular part during the algorithm. We also explain here how the algorithm can be modified to compute the bidiagonal reduction of a given rank structured matrix. Section 5 deals with some numerical experiments.

## 2. Givens-weight representation.

Before proceeding to the algorithm, in this section we provide and recall some topics concerning the Givens-weight representation.

### 2.1. General definitions.

In this subsection we review the basic ideas of the Givens-weight representation from [3]. This subsection is a summary of the ideas in [3], except that Definition 1 is more general here. Readers familiar with these ideas might wish to move directly to section 2.2.

First, we define the class of rank structured matrices.

DEFINITION 1 (see [2]). [illegible] rank structure $\mathcal{R}$ [illegible] $\mathbb{C}^{m\times n}$ [illegible] $\mathcal{R} = \{\mathcal{B}_k\}_k$ [illegible] $\mathcal{B}_k$ [illegible] 4 [illegible]

$$\mathcal{B}_k = (i_k, j_k, r_k, \lambda_k),$$

[illegible] $i_k$ [illegible] $j_k$ [illegible] $r_k$ [illegible] $\lambda_k \in \mathbb{C}$ [illegible] $A \in \mathbb{C}^{m\times n}$ [illegible] $\mathcal{R}$ [illegible] $k$

$$\operatorname{rank} A_k(i_k : m, 1 : j_k) \leq r_k, \qquad [illegible] \qquad A_k = A - \lambda_k I.$$

[illegible] $\lambda_k$ [illegible]

[illegible] $\mathcal{B}_k$ [illegible] pure [illegible] $\mathcal{B}_{\text{pure},k}$

Figure 2.1 shows an example with two structure blocks.

In practice, it often happens that the block [illegible] triangular part is also rank structured, i.e., that the matrix $A^T$ also satisfies rank structure in the sense of Definition 1. We will indiscriminately use the term [illegible] also in this case.

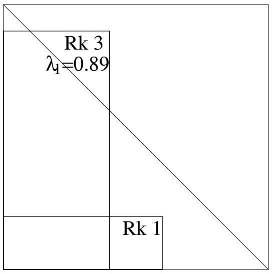

FIG. 2.1. *Example of a rank structure with two structure blocks. The left structure block* $\mathcal{B}_1$ *intersects the diagonal and has shift* $\lambda_1 = 0.89$*, while the second structure block* $\mathcal{B}_2$ *is "pure." The notation "*Rk $r$*" denotes that the structure block is of rank at most* $r$*.*

We will assume in what follows that we are working with a rank structure $\mathcal{R}$ for which there are no structure blocks that are "contained" in each other, i.e., for which the structure blocks $\mathcal{B}_k$ can be ordered such that both their row and column indices $i_k$ and $j_k$ increase in a strictly monotonic way.

Now we will try to indicate the underlying ideas of unitary-weight representations, following [3]. To this end we will take the structure in Figure 2.2 as a didactical example. First, it may be noted that this figure does not show the surrounding matrix box anymore: this reflects the fact that only the area spanned by the structure blocks will be relevant for the representation, and that the "outside world" will be inaccessible.

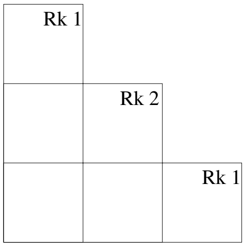

FIG. 2.2. *Example of a rank structure with three structure blocks* $\mathcal{B}_1, \mathcal{B}_2$*, and* $\mathcal{B}_3$*. We will use this example to explain the mechanism of the unitary-weight and Givens-weight representation during the following paragraphs. From now on the surrounding matrix box, as in Figure* 2.1*, will not be shown anymore.*

In what follows, we will often work with [illegible]. These are defined as unitary matrices having a block diagonal form $U = I_a \oplus Q \oplus I_b$, where $I_a, I_b$ denote identity matrices of suitable sizes. When such a unitary operation $U$ acts on the rows of a given matrix, we will represent it in a pictorial way by a vertical line segment, placed on the position of the rows on which it acts (see further).

The unitary-weight representation is obtained by reducing the structure blocks into blocks of zeros by the use of unitary row transformations. First, we apply an (elementary) unitary transformation to transform the bottom Rk 1 block into a block of zeros with one row less; see Figure 2.3.

Note that this unitary transformation acts only on the columns on the left of the vertical line which is indicated in boldface in the figure: we say that this line borders the [illegible] of the unitary transformation. Thus the action radius of the current unitary transformation is equal to 9.

Having applied this operation, note that in columns 7, 8, and 9 we have already reached the "top" of the structure. Therefore, this is now the right moment to consider the top elements of these columns and to store them. These elements will be called [illegible] and they are visualized on a grey background in Figure 2.3.

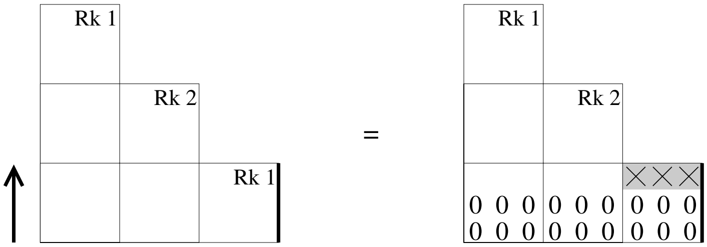

Fig. 2.3. *We apply a unitary transformation to transform the bottom two rows of the structure into zeros. This transformation acts only on the columns on the left of the vertical line which is indicated in boldface in the figure; we say that this line borders the* action radius *of the unitary transformation. Having performed this unitary transformation, the elements indicated on a grey background are stored and are called* weights.

From now on we consider columns 7, 8, and 9 as finished, and we restrict our perspective to the previous columns. We can then apply a unitary transformation to transform the middle Rk 2 block into a block of zeros, with two rows less; see Figure 2.4.

Note that again, this unitary operation acts only on the columns on the left of the vertical line indicated in boldface in the figure. Thus the action radius of the current unitary transformation is equal to 6.

Having applied this operation, note that also in columns 4, 5, and 6 we have reached the top of the structure. Therefore, this is now the right moment to consider the top elements of these columns and to store them. This yields us a second block of weights, which is again visualized on a grey background in Figure 2.4.

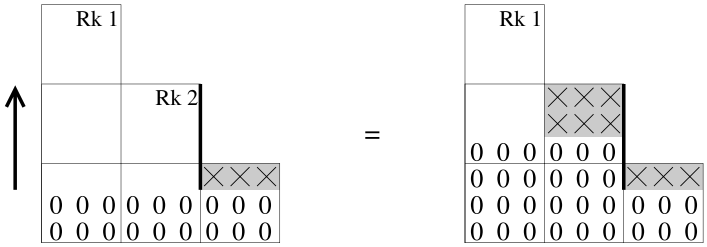

Fig. 2.4. *We apply the next unitary transformation and store the new block of weights.*

From now on we drop columns 4, 5, and 6 from our perspective. We can then apply a unitary transformation to transform the top Rk 1 block into a block of zeros with one row less; see Figure 2.5. We conclude by storing the final block of weights.

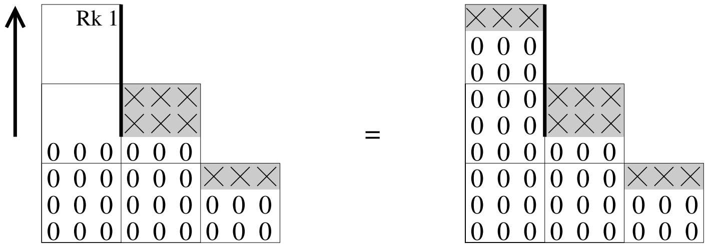

FIG. 2.5. *We apply the final unitary transformation and store the new block of weights.*

The weights can now be collected into a single matrix, which we call the [illegible]. Together with the computed unitary transformations, this matrix yields us the complete [illegible] of the given matrix; see Figure 2.6.

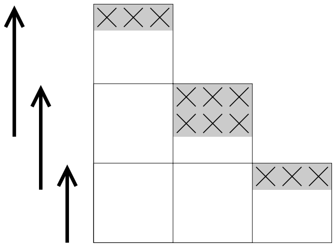

FIG. 2.6. *Schematic picture of the unitary-weight representation for the rank structure in Figure* 2.2.

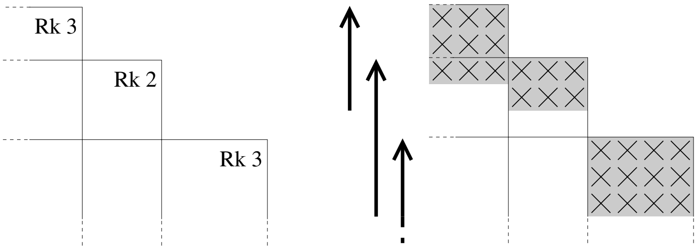
Of course, to be a useful representation, the unitary-weight representation should allow the possibility to restore the original matrix which we started from. This can be done by reversing the previous steps. This reversal process is called [illegible] the unitary-weight representation and is described in [3].

Now we can come to the general definition of unitary-weight representations.

DEFINITION 2 (index sets). [illegible] $\mathcal{R} = \{\mathcal{B}_k\}_{k=1}^K$ [illegible] $I_k = \{i_k, \ldots, i_{k+1} - 1\}$ $I_{k,\mathrm{top}} = \{i_k, \ldots, i_k + r_k - 1\}$ [illegible] $J_k = \{j_{k-1} + 1, \ldots, j_k\}$ [illegible] $k = 1, \ldots, K$ [illegible] $i_{K+1} := N + 1$ [illegible] $j_0 := 0$ [illegible] $r_{K+1} := 0$

DEFINITION 3 (unitary-weight representation). [illegible] $A \in \mathbb{C}^{m\times n}$ [illegible] $\mathcal{R} = \{\mathcal{B}_k\}_{k=1}^K$ [illegible] unitary-weight representation [illegible] $A$ [illegible] $\mathcal{R}$ [illegible] $(\{U_k\}_{k=1}^K, W)$. [illegible] $U_k$ [illegible] $I_k \cup I_{k+1,\mathrm{top}}$ [illegible] $\bigcup_{l=1}^k J_l$ [illegible] $I_{k,\mathrm{top}}$ [illegible] $U_k$ [illegible] $k = K, K-1, \ldots, 1$ [illegible] $W \in \mathbb{C}^{m\times n}$ [illegible] weight matrix [illegible] $I_{k,\mathrm{top}}$ [illegible] $J_k$ [illegible] $U_k$ [illegible] 2.7



(a) (b)

FIG. 2.7. *For the rank structure in the left picture, the right figure shows a schematic picture of the unitary-weight representation.*

We can now specify from unitary-weight to Givens-weight representations. In what follows, we will use the term [illegible] to denote an elementary unitary operation which differs from the identity matrix only in two subsequent rows and columns $i$ and $i+1$. This transformation will sometimes be denoted as $G_{i,i+1}$, and the index $i$ will be called the [illegible] of the Givens transformation. Similar to our notation for elementary unitary operations, we will graphically denote the Givens transformation $G_{i,i+1}$ by means of a vertical line segment, with the height at which this line segment is standing in the figure determined by the row index $i$ (see further).

Rather than individual Givens transformations, it will be useful to work with [illegible]: these are defined as products of the form $G_{i+k,i+k+1} \dots G_{i,i+1}$, for some $k \geq 0$. Graphically, this can be considered as a collection of Givens transformations where each Givens transformation is situated precisely one position below the previous one; see Figure 2.8.

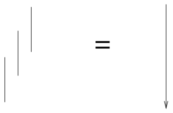


FIG. 2.8. *A Givens arrow $G_{i+2,i+3}G_{i+1,i+2}G_{i,i+1}$ consisting of three Givens transformations. Concerning this figure, we remind the reader that we consider each Givens transformation as "acting" on the rows of an (invisible) matrix standing on the right of it, and hence that the Givens transformations in the figure should be evaluated from right to left, hereby explaining the downward direction of the Givens arrow.*

The number of Givens transformations of which a Givens arrow consists will be called the [illegible] of the Givens arrow. Moreover, we define the [illegible] and the [illegible] of the Givens arrow to be the largest and the smallest row index of the Givens transformations of which the Givens arrow consists, respectively. These notions have an obvious graphical interpretation.

DEFINITION 4 (Givens-weight representation; see [3]). [illegible] $A \in \mathbb{C}^{m \times n}$ [illegible] $\mathcal{R} = \{\mathcal{B}_k\}$ [illegible] Givens-weight representation [illegible] $A$ [illegible] $\mathcal{R}$ [illegible] $U_k$ [illegible]

- [illegible] $r_k$

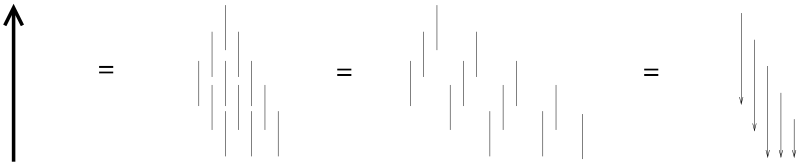

FIG. 2.9. *Suppose that the current structure block is* Rk 3*, and that the corresponding unitary transformation $U_k$ spans over six rows. Then we assume for this unitary transformation a decomposition into a product of Givens arrows of width at most* 3.

- [illegible] $U_k$ [illegible]

[illegible] 2.9

We should still explain why the assumption is made that each Givens arrow in the decomposition of $U_k$ has width at most $r_k$. To this end, recall that the unitary transformation $U_k$ serves to create zeros in a certain $\mathrm{Rk}(r_k)$ submatrix, except for its top $r_k$ rows. This effect can always be realized by a succession of Givens arrows as prescribed; see [3, section 3] for more details.

Note that by decomposing each unitary transformation $U_k$ as specified in Definition 4, we formally obtain a decomposition into a product of [illegible] Givens transformations, in the sense that the beginning and trailing Givens transformations of two subsequent unitary transformations $U_k$ may overlap. But we will not be concerned about this here, since we will work with a very special kind of Givens-weight representation to be described next.

**2.2. Zero-creating Givens-weight representation.** The algorithm to be described in this paper requires a very special kind of Givens-weight representation. Namely, we must assume it to be in "zero-creating" form, which means, loosely speaking, that each Givens transformation has to create a zero in the matrix. If this condition is not satisfied yet, then it has to be imposed, and the way to do this will be the subject of the present subsection.

DEFINITION 5 (zero-creating Givens-weight representation). [illegible] 4 [illegible] zero-creating [illegible]

(i) [illegible] $U_k$ [illegible]

(ii) [illegible] $W_{k-1}, W_k$ [illegible] $W$ [illegible] $r_{k-1} < r_k$ [illegible] $r_k - r_{k-1}$ [illegible] $W_k$ [illegible] $k = 1, \dots, K$

[illegible] $\mathcal{B}_0 : (i, j, r) = (1, 0, 0)$ [illegible]

Note that condition (i) in Definition 5 implies that the Givens transformations can be stored in a 2-dimensional array in a natural way, by storing at the $(i, j)$th block entry of this array, the $j$th Givens transformation of the Givens arrow with tail index $i$ (which must then be unique). This property is convenient for implementation purposes.

On the other hand, condition (ii) in Definition 5 might seem strange at first, but this turns out to be nothing but a natural consequence of the zero-creating character. Note that this condition implies, in particular, that the top weight block $W_1$ must be upper triangular. In fact, we will need only a weaker version of this condition.

DEFINITION 6 (weakly zero-creating Givens-weight representation). [illegible] 5 [illegible] (ii) [illegible] (ii') [illegible] $W_1$ [illegible] weakly zero-creating [illegible]

Let us transform a given Givens-weight representation into (weakly) zero-creating form. Part of this process has already been sketched in [3], but we will provide here a detailed description. First we recall the pull-through lemma from [3].

LEMMA 7 (pull-through lemma). [illegible] 3 [illegible] 3 [illegible] $Q$ [illegible]

$$Q = G'_{1,2}G_{2,3}G_{1,2},$$

[illegible]

$$Q = \tilde{G}'_{2,3}\tilde{G}_{1,2}\tilde{G}_{2,3}.$$

[illegible] 2.10

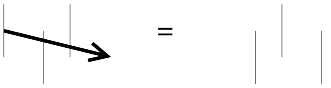

FIG. 2.10. *Pull-through lemma applied in the downward direction. One could imagine that the leftmost Givens transformation is really "pulled through" the two rightmost Givens transformations.*

Now in order to transform an arbitrary Givens-weight representation into a zero-creating one, we start on top of the matrix. We are concerned with condition (ii), and so we apply extra Givens transformations to bring the top weight block $W_1$ into upper triangular form. These Givens transformations are then simply "concatenated" to the top unitary transformation $U_1$. Next, we restore condition (i) by applying the pull-through lemma a maximal number of times in the downward direction inside this unitary transformation $U_1$; see Figure 2.11.

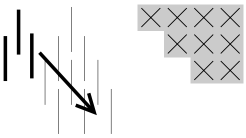

FIG. 2.11. *After applying Givens transformations to bring the top weight block in upper triangular form (indicated by the thick black lines), we apply pull-through operations to bring the top unitary operation $U_1$ of the Givens-weight representation to zero-creating form.*

Note that these operations have led to the top unitary operation $U_1$ being in zero-creating form. We can then split $U_1 = U_{1,\text{new}}U_{1,2}$, where $U_{1,2}$ consists of the bottom $r_2 - 1$ Givens arrows, i.e., those which act entirely on the rows of the next weight block $W_2$. These Givens transformations are then "transferred" to the unitary operation $U_2$ by enlarging their action radius. This means that these transformations are applied to all the columns lying between their current and their future radius, as indicated by the thick black vertical lines in Figure 2.12.

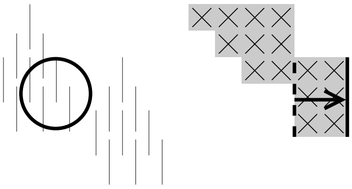

FIG. 2.12. *Having brought $U_1$ into zero-creating form in Figure* 2.11*, its bottom Givens arrows (which are encircled by the thick black line) can be transferred to the next unitary operation $U_2$ by enlarging their action radius as indicated.*

Suppose then that in the reduction process to zero-creating form, we have arrived at the unitary transformation $U_k$ for certain $2 \leq k \leq K$. We can then do the same as before: first, we apply extra Givens transformations to bring the bottom $r_k - r_{k-1}$ rows of the weight block $W_k$ into upper triangular form, provided that this number is greater than or equal to two. These Givens transformations are then just concatenated to the unitary transformation $U_k$; this is valid since it can be shown that for these bottom $r_k - r_{k-1}$ rows, there is no overlap with the Givens transformations of the unitary operations $U_{k-1}, \dots, U_1$ above. We can then again restore condition (i) by applying the pull-through lemma a maximal number of times in the downward direction inside this unitary transformation $U_k$. We can then split $U_k = U_{k,\text{new}} U_{k,k+1}$, as before and so on.

At the end of this process we will obtain a Givens-weight representation in zero-creating form. A piece of this is shown in Figure 2.13. Note that the tails of the subsequent Givens arrows in this figure (indicated by the thick black lines) are indeed strictly monotonically proceeding upwards.

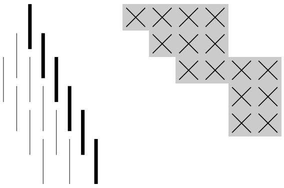

FIG. 2.13. *Part of a zero-creating Givens-weight representation.*

To explain the name zero-creating, it can be shown that each of the Givens transformations of a zero-creating Givens-weight representation has to create a zero in an appropriate place of the matrix. We will need only a weaker version of this result.

LEMMA 8 (weakly zero-creating). [illegible] $n, n-1, \dots, i_1 + 1$ [illegible]

[illegible]. Suppose that we compress the given matrix by means of the unitary operations of the Givens-weight representation. At the moment that we apply the tail of the first Givens arrow $G_{k,k+1}$, we can apply the remaining Givens transformations of which the Givens arrow consists. But instead of doing this, we can already apply the tail of the next Givens arrow $G_{k-1,k}$, because this operation acts on rows $k-1, k$, which are strictly disjoint from the rows $k+1, k+2, \dots$ on which the remaining part of the current Givens arrow acts. Repeating this argument, we can rearrange the compressing unitary operations as $V_2V_1$, where $V_1$ consists of the succession of all the subsequent tails of the Givens arrows and $V_2$ contains the remaining parts of the Givens arrows. Since the weakly zero-creating character implies that the first column of the top weight block $W_1$ must be in upper triangular form, and because $V_2$ acts only on rows strictly below the top nonzero entry of this column, we see that these zeros in the first column must have been created purely by means of the [illegible] of the subsequent Givens arrows. ☐

This lemma states that the tails of the Givens arrows, which are indicated by the thick black lines in Figure 2.13, have to create zeros in the first column of the underlying matrix. Both the meaning and the proof of this lemma can be illuminated by interpreting them in terms of this figure.

A similar property holds for the actual zero-creating Givens-weight representation. The idea is that the corresponding Givens transformations must create zeros in the subsequent columns of the matrix. Due to the presence of the low rank blocks, extra zeros will be induced automatically in the further columns during this process. We can then look further and create zeros in the first column which has not been zeroed out yet. It is possible to give an exact expression for the subsequent places where the zeros have to be created, but this expression is rather complicated and we believe that it does not provide extra insight. Moreover, we will not need to know these details for this paper.

Finally, we describe here an alternative construction of zero-creating Givens-weight representations. Since this construction will not be used in the remainder of this paper, the reader may skip the following paragraphs.

The starting point is that we must possess at least a "dual" Givens-weight representation, which we describe now.

Definition 9 (rank-decreasing). [illegible] $U_k$ [illegible]

Note that this definition is the same as in condition (i) of Definition 5 above, except that the word tails has been replaced by tops. Such Givens-weight representations were called [illegible] 2 in [3].

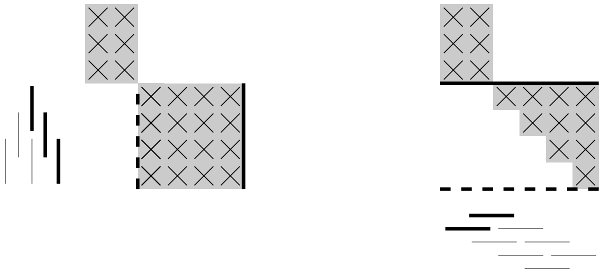
Just as zero-creating Givens-weight representations are "efficient" in the sense that each Givens transformation effectively creates a zero in the matrix, the efficiency of the rank-decreasing version consists of the fact that each Givens arrow definitively eliminates a row of the matrix, which is not touched by the next Givens arrows anymore, due to the monotonicity of the tops of the Givens arrows. The reader should try to see this. Moreover, this feature is important since it allows rank-decreasing Givens-weight representations to arise in several, natural ways; see [3].

We recall here the general fact that Givens-weight representations can also be constructed by means of unitary [illegible] instead of row operations. In particular, the rank-decreasing concept can be translated to the case of a column-based Givens-weight representation as well, by replacing in Definition 9 the word upwards by rightwards.

Concerning this last paragraph, we recall that there has been described a so-called [illegible] in [3] to transform a column-based into a row-based Givens weight representation, or vice versa. This process will be illustrated in a moment. Let us now motivate our interest in this process.

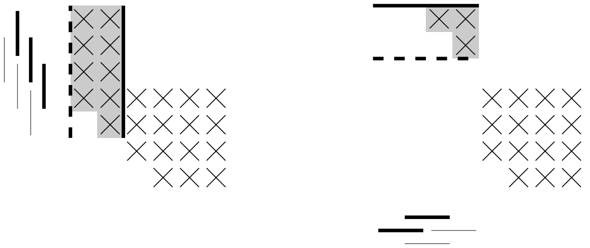
Theorem 10 (duality theorem). [illegible] [3] [illegible]

[illegible] We consider here the case of a rank-decreasing, column-based Givens-weight representation. The swapping process is illustrated in Figure 2.14.



(a) Apply row operations to compress the bottom weight block $W_K$.

(b) Spread out $W_K$ by means of the rank-decreasing unitary operation $U_K^H$.



(c) Apply further row operations to compress the next weight block.

(d) We can now go on to spread out by means of the next rank-decreasing unitary operation $U_{K-1}^H$.

FIG. 2.14. *Swapping from a rank-decreasing, column-based into a zero-creating, row-based Givens-weight representation.*

Let us comment on this figure. We start by bringing the bottom weight block $W_K$ in upper triangular form by a series of auxiliary row operations. We can obviously do this in a “zero-creating” way, a fact which is indicated by highlighting the tails of the subsequent Givens arrows in Figure 2.14(a); see also Figure 2.15.

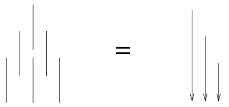


FIG. 2.15. *Zero-creating character of Figure* 2.14(a).

Next, we spread out the bottom weight block $W_K$ by applying the “decompressing" unitary operation $U_K^H$ to it. This operation $U_K^H$ is shown in Figure 2.14(b), where we assume that the subsequent decompressing Givens transformations have to be applied from top to bottom. Since we assumed the given Givens-weight representation to be rank-decreasing, it can be checked that the operation $U_K^H$ is such that its leftmost Givens transformations, highlighted in Figure 2.14(b), monotonically proceed leftwards. This property implies the crucial observation that the upper triangularity of the current weight block is [illegible] during the spreading-out process.

In particular, this preservation of upper triangularity implies that condition (ii) in the definition of zero-creating Givens-weight representation holds, i.e., when $r_k > r_{k-1}$, then the $r_k - r_{k-1}$ bottommost rows of the swapped weight block $W_k$ are upper triangular; see, e.g., the vanishing of the (7,3) element in Figure 2.14(c).

We have now arrived at the next weight block $W_{K-1}$. We compress this weight block by means of some new auxiliary row operations. By the fact that the upper triangularity of the previous weights was preserved, we can do this by just continuing the zero-creating pattern of Givens transformations on the rows; see Figure 2.14(c).

If follows from the above observations that the swapped Givens-weight representation must indeed be zero-creating. The final weight matrix is shown in Figure 2.16.

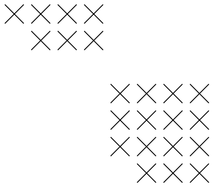

Fig. 2.16. *Final weight matrix of the resulting zero-creating, row-based Givens-weight representation at the end of the swapping process.*

Conversely, we can swap from a zero-creating, row-based into a rank-decreasing, column-based Givens-weight representation. Since this process is "dual" to the one above, it will not be shown anymore. □

Summarizing, we have described two ways of constructing (weakly) zero-creating Givens-weight representations, namely, either by the use of [illegible] techniques, as in Figures 2.11 and 2.12, starting from an arbitrary Givens-weight representation, or by the use of [illegible] techniques, as in Figure 2.14, assuming that a rank-decreasing Givens-weight representation is available. The pull-through scheme will be the one that we use in practice.

In the next section, we will come to the main theme of this paper.

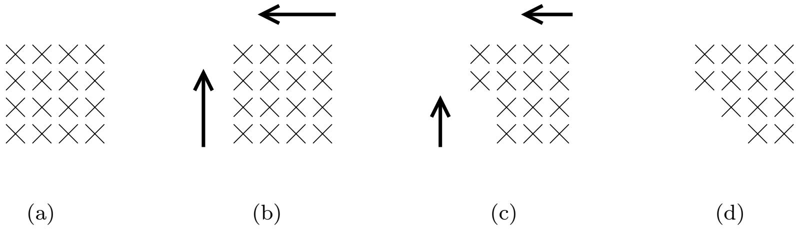
## 3. Hessenberg reduction.

Assuming now that we have a weakly zero-creating Givens-weight representation to our disposal, we can start the reduction algorithm into Hessenberg form.

### 3.1. Structure propagation.

First, we will consider the structures which are propagated during the reduction of a matrix into Hessenberg form. First, by the fact that we use only unitary similarity transformations, it is easy to see that the properties of being Hermitian plus low rank, unitary plus low rank, and so on will be preserved by the reduction process. This corresponds to what were called "polynomial structures" in [2].

Still, following the analogy with [2], we would also like rank structures to be preserved during the Hessenberg reduction process. To this end, we have to make the assumption that the reduction process is based on Givens transformations, i.e., that in the $k$th step of this process, $k = 1, \ldots, n-1$, the $k$th column of the matrix is brought in Hessenberg form by an upwards pointing sequence of Givens transformations $G_{n-1,n}, \ldots, G_{k+1,k+2}$. In order to preserve the eigenvalue spectrum, we then multiply with the Hermitian transposes of these Givens transformations $G^H_{n-1,n}, \ldots, G^H_{k+1,k+2}$ to the columns, hereby not destroying the created zeros anymore. This process is illustrated by a 4 by 4 example in Figure 3.1.



(a) (b) (c) (d)

FIG. 3.1. *Hessenberg reduction for a 4 by 4 matrix.*

Clearly, it will be sufficient if we can characterize the structure propagation after the Hessenberg reduction of the [illegible] column.

THEOREM 11 (structure propagation). [illegible] $A \in \mathbb{C}^{n\times n}$ [illegible] $\mathcal{B} = (i, j, r, \lambda)$ [illegible] $i \geq 2$ [illegible] $A|_{\mathcal{B}}$ [illegible] $A|_{\mathcal{B}}$ [illegible] $A$ [illegible] $\mathcal{B}$ [illegible] $A$ [illegible] $\mathcal{B}$ [illegible] $\tilde{\mathcal{B}} = (i+1, j+1, r, \lambda)$. [illegible] 3.2

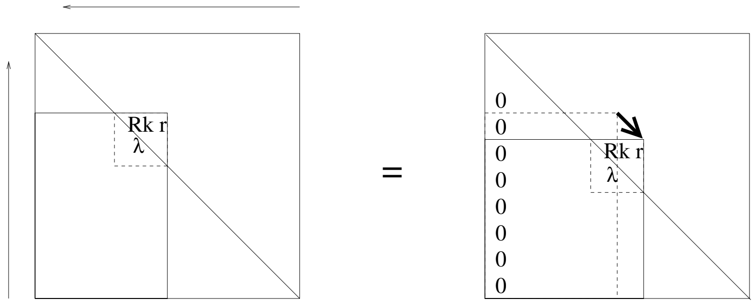


FIG. 3.2. *Structure propagation after the Hessenberg reduction of the first column.*

[illegible]. First, we show that the proof can be reduced to the case of a [illegible] structure block. To this end, note that by definition, the matrix $A_{\text{pure}} := A - \lambda I$ satisfies the pure structure block $\mathcal{B}_{\text{pure}}$ which is obtained from $\mathcal{B}$ by putting the shift element equal to zero. Now let us denote with $Q^H$ the unitary row transformation which reduces the first column of $A$ into Hessenberg form. Since $Q^H$ does not involve the top row of the matrix, it must also reduce the first column of $A_{\text{pure}} = A - \lambda I$ into Hessenberg form. Moreover, it holds that $Q^H AQ = Q^H A_{\text{pure}}Q + Q^H(\lambda I)Q = Q^H A_{\text{pure}}Q + \lambda I$. Hence indeed, it will suffice to prove the theorem for the matrix $A_{\text{pure}}$.

To prove this remaining case, we use an easy argument based directly on the Givens transformations, as shown in Figure 3.3.

Let us comment on this figure. The figure starts by applying Givens transformations to the rows, in order to make the first column Hessenberg. Thus at the moment that we are at the point of "leaving" the structure block $\mathcal{B}$, the first column of $A|_{\mathcal{B}}$ will be entirely zero, except for its top element, which is nonzero by the assumptions in the theorem. The key observation is then that the top row of $A|_{\mathcal{B}}$ cannot be written as a linear combination of the further rows, and hence the structure block obtained by removing this top row from $\mathcal{B}$ must be of rank at most $r - 1$; see Figures 3.3(a) and 3.3(b).

The proof can now be finished by remarking that this $\text{Rk}(r-1)$ structure block cannot be destroyed anymore by the next row operations. On the other hand, the application of the column operations will result in the structure block being enlarged by one column and with rank increased by one; see Figures 3.3(c) and 3.3(d). ☐

It should be noted that the above theorem holds only under the condition that the first column of $A|_{\mathcal{B}}$ is nonzero. Although this condition is very mild, it excludes the case of rank zero structure blocks; in this case, one should work with the top induced rank one structure block instead; see Figure 3.4.

Let us note some more topics concerning the above proof.

[illegible] 12.

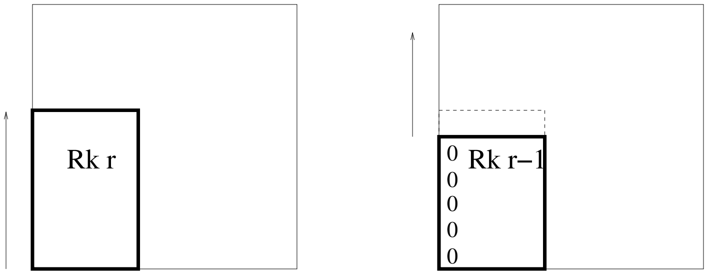
1. By repeating the argument in Figures 3.3(a) and 3.3(b) several times, it follows that the given structure block can be transformed into a new structure block with $k$ rows less, and with rank diminished by $k$, by means of a sequence of Givens arrows of width $k$ creating zeros in the first $k$ columns; see also [4].
2. It is clear that in finite precision arithmetic, creating zeros in the first column and then expecting the rank to decrease, as in Figures 3.3(a) and 3.3(b), is likely to be an unstable procedure. This is because if the first column is close to the zero vector, then it can severely deviate from the overall column space of the low rank block, due to round-off errors. The solution to this problem will be to compute the zero-creating Givens-weight representation by means of the [illegible] techniques which were described in section 2.2.

Although Theorem 11 was stated for general shift elements $\lambda$, we will first exploit it for [illegible] rank structures in what follows. This process will be described in the next subsection.

**3.2. Hessenberg reduction algorithm.** In this subsection we describe the algorithm for the Hessenberg reduction of the given rank structured matrix. We start with an algorithm for bringing the first column into Hessenberg form. The upper triangular part of the matrix will currently be assumed to be unstructured.

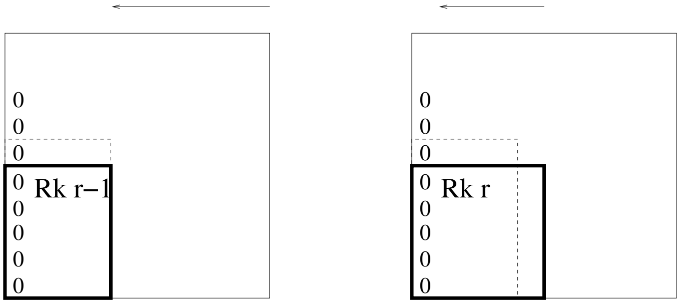
Note that the Givens transformations that bring the first column in Hessenberg form have already been [illegible], precisely by the concept of weakly zero-creating Givens-weight representation. Indeed, Lemma 8 guarantees that these transformations are nothing but the tails of the subsequent Givens arrows, as highlighted by the thick black lines in Figure 2.13. This means that the algorithm will suffice with "peeling off" these tails from the subsequent Givens arrows, in a sense to be made exact later.

The idea of the algorithm will be illustrated for the starting rank structure shown in Figure 3.5(a). The corresponding weakly zero-creating Givens-weight representa-



(a) Apply the first Givens transformations to the rows. They will transform the given Rk $r$ block into a Rk$(r-1)$ structure block with one row less.

(b) Apply the remaining Givens transformations to the rows.



(c) Apply the transposed Givens transformations to the columns, until the Rk$(r-1)$ structure block is reached.

(d) Enlarge the Rk$(r-1)$ block into a Rk $r$ structure block with one more column, and apply the remaining Givens transformations to the columns.

FIG. 3.3. *The figure shows the propagation of pure structure blocks by the Hessenberg reduction process directly in terms of the Givens transformations.*

tion is shown in Figure 3.5(b). Note that this figure shows a [illegible]-weight rather than a [illegible]-weight representation, in order not to overload the figure.

The application of the Givens transformations $G_{k,k+1}$ to the rows will be achieved by what we call a [illegible]. On the other hand, the application of the Givens transformations $G^H_{k,k+1}$ to the columns makes use of the general techniques for updating the Givens-weight representation under the influence of Givens transformations reported in [3], in the form of what we called there a [illegible]. These processes are shown in Figure 3.6.

Let us comment on this figure. Figure 3.6(a) shows the starting Givens-weight representation. It is assumed here that the first Givens transformations have already

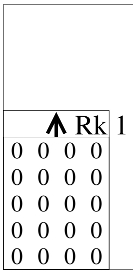


FIG. 3.4. *In case of a rank zero structure block, one should work with the top induced* Rk 1 *structure block which is indicated in the figure.*

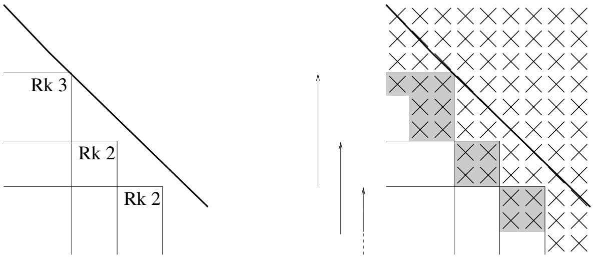


(a) (b)

FIG. 3.5. *Starting rank structure with corresponding weakly zero-creating Givens-weight representation.*

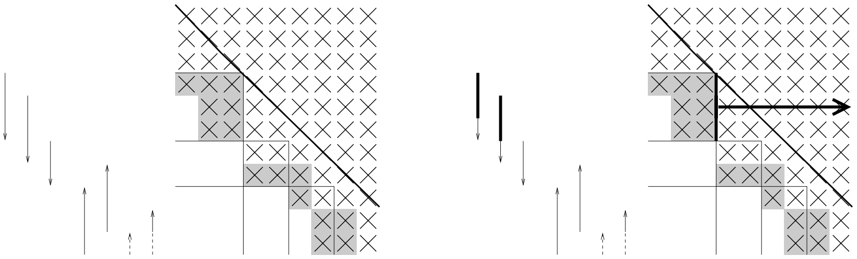
been peeled off from the structure, up to the transformation $G_{6,7}$, and that they have been applied to the rows and the columns.

The application of the [illegible] operations has led to the fact that the Givens arrows in several unitary transformations have " shrunk" because they have "lost their tail." Correspondingly, some of the originally grey elements of the two bottom structure blocks have turned white in Figure 3.6(a), since there is no Givens transformation anymore which acts upon them. We note that this peeling-off process corresponds to the Rk $r$ structure blocks turning into Rk$(r-1)$ structure blocks with one row less, as explained before.

The application of the [illegible] operations has led to the fact that the original unitary operations $U_k$ are now interlaced with some auxiliary Givens arrows which were computed during the algorithm. Furthermore, some of the elements, such as the $(9,6)$ element in Figure 3.6(a), are assumed to be disturbances coming from the application of the previous Givens transformations to the columns.

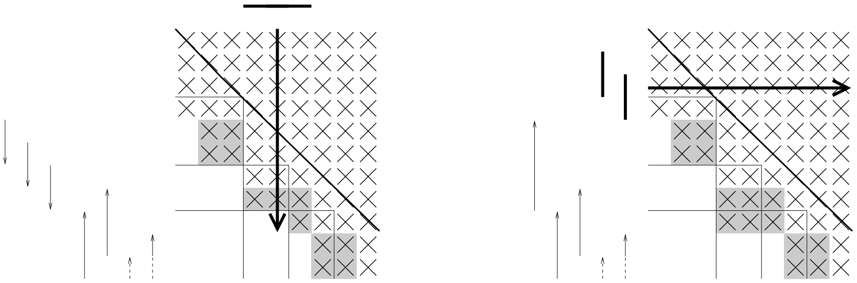
Now we are at the moment of peeling off the next Givens transformations. This will cause the corresponding Givens arrows to lose their tail. While applying these Givens transformations, we exploit the fact that the result after their application has already been partially precomputed. This is why we apply them only to the columns strictly on the right of their current action radius; see Figure 3.6(b).

Note that after their application, the top row of the top weight block will have been "completely released" in the sense that there are no Givens transformations anymore which act upon it. This means that these elements turn from grey into



(a) Starting situation. We assume that the tails of the Givens arrows up to $G_{6,7}$ have already been peeled off. Only the top unitary transformation is shown as a decomposition of Givens arrows.

(b) Peel off the tails of the next Givens arrows and apply them to the rows.



(c) Multiply the transposes of the Givens transformations of Figure 3.6(b) to the columns.

(d) Apply the final Givens transformations to the rows.

FIG. 3.6. *Hessenberg reduction of the first column (a-d).*

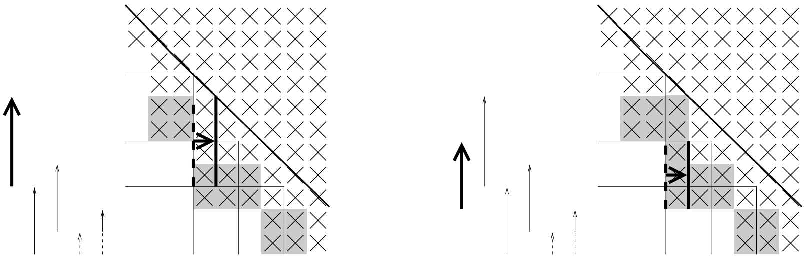
white; see Figures 3.6(b) and 3.6(c).

To complete the similarity transformation, we should apply the Hermitian transposed operations to the columns. This is done in Figure 3.6(c).

We can then go on to apply the final Givens transformations for bringing the first column in Hessenberg form; see Figure 3.6(d). We would then like to complete the similarity transformation and apply these final Givens transformations on the columns too. But this means that we are at the point of contaminating the structure block in columns 2, 3 with some of the elements in the column on the right of it. This contamination would lead to a mix of real-size elements and weights, which is definitely not allowed.

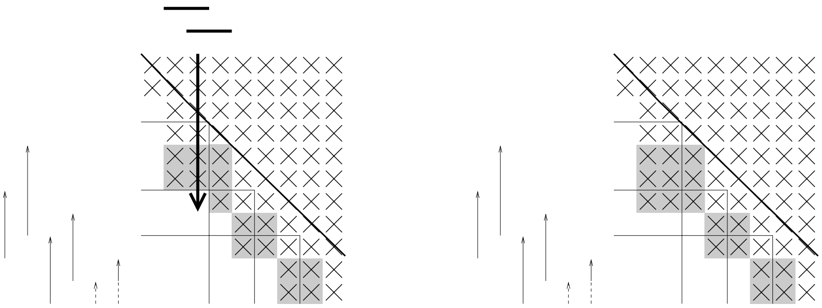
The solution consists of enlarging the action radius of the Givens-weight representation. This means that we bring the contaminating column, which is standing just on the right of the structured part, "into" the representation; see Figure 3.6(e). The corresponding elements in Figure 3.6(f) have then turned from white into grey.

Having done this, it is now safe to apply the desired Givens transformations to the columns. But we do not do this yet, since applying all these column operations would lead to a complete fill-in in the lower triangular part. We want to minimize this fill-in



(e) Enlarge the action radius of the row representation.

(f) Apply auxiliary Givens transformations to the rows to bring the weights as much as possible to the top.



(g) Multiply the transposes of the Givens transformations of Figure 3.6(d) to the columns.

(h) We have reduced the first column into Hessenberg form.

FIG. 3.6. *(cont.) Hessenberg reduction of the first column (e-h).*

as far as possible, and therefore we first apply some auxiliary Givens transformations to the rows, to bring the newly introduced weights as far as possible to the top; see Figure 3.6(f).

Having done all of these preparations, we can finally apply the desired Givens transformations to the columns; see Figure 3.6(g). We have then completely reduced the first column of the matrix into Hessenberg form.

Figure 3.6(h) shows the final Givens-weight representation. Note that the weight blocks have uniformly moved one position to the bottom right position, as predicted by Theorem 11.

Note that the algorithm has led to a Givens-weight representation in [illegible] form, i.e., a unitary-weight representation for which each unitary transformation $U_k$ has a natural decomposition of the form $U_k = \tilde{V}_k V_k$, where $V_k$ is a unitary transformation situated on "top" of $U_k$, containing what is left of the original Givens-weight representation, and $\tilde{V}_k$ is a unitary transformation situated on the "bottom" of $U_k$, containing the chain of auxiliary Givens transformations computed during the Hessenberg reduction algorithm; see Figure 3.6(h).

Now we would like to go on by making the second column Hessenberg. This means that we should first bring the Givens-weight representation back to its weakly zero-creating form, using the pull-through techniques of section 2.2. In fact, these techniques must be slightly modified since we are working here with a Givens-weight representation in [illegible] form, which is not a Givens-weight representation in the strict sense anymore.

Let us briefly apply these techniques to the present situation. First, we apply an extra upwards pointing Givens arrow, in order to restore the upper triangularity of the first column of the top left weight block in Figure 3.6(h); see Figure 3.7.

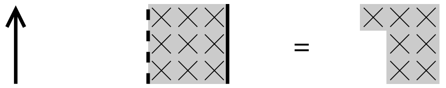


FIG. 3.7. *We apply an extra unitary operation to bring the first column of the top weight block in Figure* 3.6(h) *in upper triangular form.*

The resulting unitary transformations, to which this extra Givens arrow is added, are shown in Figure 3.8.

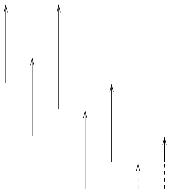

FIG. 3.8. *Resulting unitary transformations of Figure* 3.6(h).

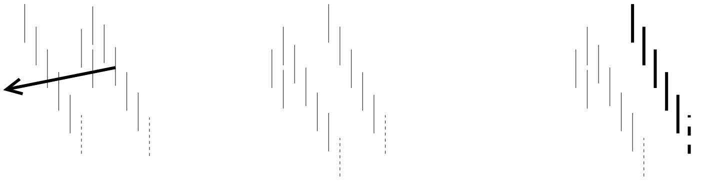
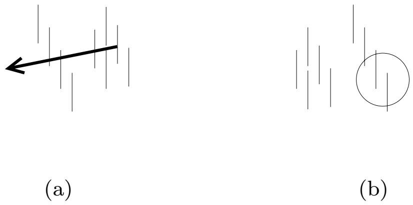
Next, we apply the pull-through lemma a maximal number of times in the downward direction, in order to bring the representation back into (weakly) zero-creating form; see Figure 3.9.

While the pull-through process proceeds from top to bottom of the matrix, one should not forget to appropriately enlarge the action radii of the involved Givens transformations, as explained in section 2.2. The treatment of a single step in this process is shown in Figure 3.10.



(a) (b) (c)

FIG. 3.9. *The left picture shows a decomposition of Figure* 3.8 *in terms of individual Givens transformations. It is then brought to weakly zero-creating form by repeatedly using the pull-through lemma, resulting in the situation of the middle picture.*



(a) (b)

FIG. 3.10. *The picture shows a specification of Figure* 3.9. *After applying the pull-through operations inside the top unitary operation* $U_1$ *as shown in the left picture, the resulting unitary operation is decomposed as* $U_1 = U_{1,\mathrm{new}} U_{1,2}$*, where the Givens transformations of* $U_{1,2}$ *are circled in the right picture. One can then enlarge the action radius of* $U_{1,2}$ *so that it is transferred to the next unitary operation* $U_2$*. This scheme can then be repeated for the next unitary operations* $U_2, U_3, \ldots$.

At the end of the pull-through process, the Givens transformations indicated by the thick black lines in Figure 3.9(c) will constitute the new tails of the Givens arrows, which will hence be peeled off during the Hessenberg reduction of the second column.

From the schematic illustration of the pull-through process in Figure 3.9, we can note the interesting fact that the (updated) chain of auxiliary Givens transformations, used for the auxiliary upward movement during the Hessenberg reduction algorithm, replaces the original tails of the Givens arrows at the end of the pull-through process; see Figure 3.9(c). Hence they will be precisely the Givens transformations to be peeled off during the Hessenberg reduction of the second column.

Finally, we have now obtained a Givens-weight representation which is back in weakly zero-creating form. We are then ready to bring the second column in Hessenberg form as well. Since this problem is completely similar to the Hessenberg reduction of the first column, it will not be explained anymore.

## 4. Some modifications to the algorithm.

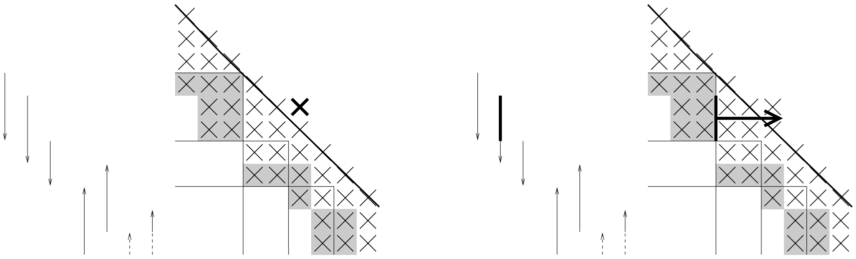
In this section we describe some variants to the Hessenberg reduction algorithm of the previous section. We start with a treatment of rank structure lying in the upper triangular part.

### 4.1. Exploiting rank structure in the upper triangular part.

In this subsection we describe how the efficiency of the algorithm can be improved by an order of magnitude in case the matrix $A$ has rank structure in its upper triangular part as well. The total algorithm complexity will decrease in this way from the cubic $O(n^3)$ to the quadratic $O((ar + bs)n^2)$, where $r$ is some measure for the average semiseparability rank, $s$ is some measure for the bandwidth of the unstructured matrix part around the main diagonal, and $a, b \in \mathbb{R}$ are certain weighting parameters.

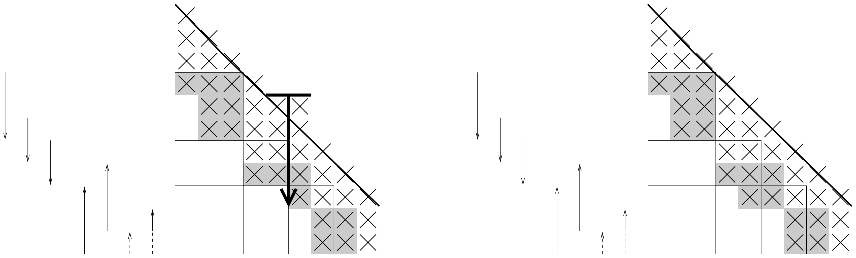
We start with the case of rank structure originating from the fact that $A$ is Hermitian, or more generally, when it is Hermitian plus a low rank correction in the sense that $A - A^H = \mathrm{Rk}\ k$ with $\mathrm{Rk}\ k$ a matrix of rank at most $k$. The algorithm can proceed then by just keeping track of the lower triangular part, since then the upper triangular part is known by symmetry. In the case where $A$ is Hermitian up to some low rank correction, one should also keep track of the low rank correction matrix $\mathrm{Rk}\ k$. The algorithm proceeds then by only computing each time the required superdiagonal element, by symmetry, next applying the row and column operation, and then again removing the superdiagonal element; see Figure 4.1.

It is easy to check that in this way, the complexity of the Hessenberg reduction



(a) Compute the required superdiagonal element, and fill it in the weight matrix.

(b) Apply the current Givens transformation to the rows.



(c) Apply the transposed Givens transformation to the columns.

(d) The current superdiagonal element has no role anymore, and therefore it is removed from the weight matrix.

FIG. 4.1. *Exploiting symmetry.*

algorithm for the $k$th column decreases to $O((ar+bs)n)$, for suitable $a, b \in \mathbb{R}$. Hence the [illegible] cost of the Hessenberg reduction algorithm reduces to $O((ar+bs)n^2)$.

Next, we describe how, even if the matrix is not Hermitian up to some low rank correction, rank structure in the upper triangular part can be exploited. To this end, the reader should reacquaint familiarity with the propagation mechanism for structure blocks in the [illegible] triangular part in Figure 3.3. It can then be noted that the argument in Figures 3.3(a) and 3.3(b) crucially depends on the fact that zeros are created in the lower triangular part of the matrix during the Hessenberg reduction process.

The corresponding propagation of rank structure in the upper triangular part does [illegible] benefit from such a creation of zeros, as shown in Figure 4.2.

It should be clear from Figure 4.2 that the ranks could soon start to increase. After a few columns have been transformed into Hessenberg form, there will probably be not much left of the rank structure, due to the growth of the rank indices of the rank structure.

There is one notable exception to this idea, namely, we know that the ranks should stay constant also in the case where $A$ is a [illegible] matrix, or unitary up to some low rank correction, because then the rank structure in the upper triangular part is a direct consequence of that in the lower triangular part; see, e.g., [5]. We will

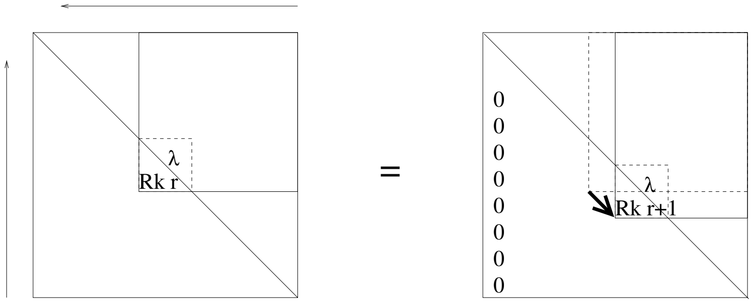


FIG. 4.2. *Structure propagation in the upper triangular part after the Hessenberg reduction of the first column. Note that the structure block moves one position to the bottom right position, but that the original rank index* $r$ *can increase to* $r + 1$.

come back to this later.

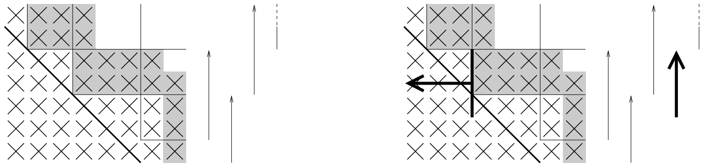
Anyway, also in the case of arbitrary rank structure in the upper triangular part, and where the ranks increase, we will give the tools to update the representation. These tools are based on the methods for updating a Givens-weight representation under the action of Givens transformations described in [3]. We saw there how to update the representation using what was called concatenation, pull-through, generalized swapping, and generalized regression techniques.

Essentially, the only difference with respect to [3] is that we want to apply the disturbing Givens transformations [illegible] on rows and columns. This will lead to two methods being applied at the same time. We consider here the case where the Givens-weight representation of the upper triangular part is based on [illegible] operations. We will then simultaneously have a mixture of concatenation (for the row operations) and generalized regression techniques (for the column operations). See Figure 4.3.

Let us comment on this figure. Figure 4.3(a) shows the starting Givens-weight representation for the structured upper triangular part. Note that we preferred here to show the [illegible] rather than the compressing unitary operations of the Givens-weight representation, i.e., in order to obtain the full matrix, we should spread out by means of the subsequent unitary operations shown in Figure 4.3(a), evaluating from left to right. The bottommost unitary transformation is assumed to be a disturbance coming from previous steps.

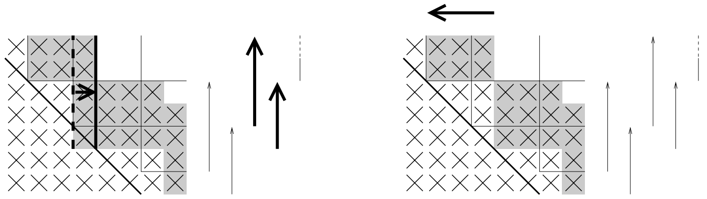
We are now at the moment of applying the next Givens transformations to the rows; see Figure 4.3(b). We apply these transformations only to columns $1, \ldots, 3$. For the application to the structured upper triangular part in columns $4, \ldots$, we do not actually apply these Givens transformations, but instead just [illegible] them to the Givens-weight representation. To see what this means, the reader should recall that the weight matrix contains a kind of "compressed" information about the full matrix. Moreover, in order to obtain the real values of these elements, we should spread out the weight matrix by applying all the subsequent unitary operations, evaluating from left to right. The concatenation process means then simply that, at the very end of this decompressing process, one should apply the newly added Givens transformations as well, so that they can be considered from now on as being part of the Givens-weight representation.

Now we would like to apply the transpose of these Givens transformations to the columns. To do this in a valid way, we have to avoid a mixture of real-size elements and weights. Therefore we first regress the action radius of the representation; see



(a) Starting Givens-weight representation. The arrows on the right denote the unitary transformations used to *spread out* the structure.

(b) Apply the next Givens transformations to columns 1,. . . ,3, and concatenate them to the representation.



(c) Regress the action radius of the representation.

(d) Apply the transposed Givens transformations of Figure 4.3(b) to the columns.

FIG. 4.3. *Updating the structured upper triangular part during the Hessenberg reduction algorithm, assuming that it is represented by a row-based Givens-weight representation.*

Figure 4.3(c). We can then safely apply the Givens transformations to the columns; see Figure 4.3(d). The next operations are not shown anymore.

Finally, let us come back to the case where the rank structured matrix is [illegible] [illegible]. In this case, the above algorithm will yield that the ranks increase from $r$ to $r+1$ in each step, although we know that they should stay constant. Thus it should be possible to perform a [illegible] of the structure after each step to approximate the ranks again by their actual values. If the structure blocks in the upper triangular part have been chosen wisely, this implies an extra term $O(r^2n)$ for the complexity in each step; see [3]. This [illegible] term in the rank index can be avoided by just performing the numerical approximation procedure [illegible] $O(r)$ [illegible] in the Hessenberg reduction process. The above $O(r^2n)$ term can then be distributed over $O(r)$ different steps, so that the total algorithm complexity becomes $O((ar+bs)n^2)$, for suitable $a, b \in \mathbb{R}$, just as in the Hermitian case.

Summarizing, we have now described how the Hessenberg reduction algorithm can be modified to take advantage of the rank structure in the upper triangular matrix part. The next subsection considers a second modification to the algorithm.

**4.2. Bidiagonal reduction algorithm.** In this subsection we will explain how a rank structured matrix can be reduced to bidiagonal form. This means that we will apply an operation of the form $A \mapsto UAV$, where $U$ and $V$ are possibly different unitary transformations. Such a reduction does not preserve the eigenvalue spectrum, but it can be used as the first step for computing the [illegible] of the given matrix [8, 9].

Before starting, we recall that during the [illegible] reduction process, the ranks in the lower triangular part were preserved, but those in the upper triangular part could increase from $r$ to $r+1$ in each step. The reason underlying this was that the Hessenberg reduction created zeros only in the lower triangular part of the matrix, implying that the argument of Figures 3.3(a) and 3.3(b) is invalid for the structure blocks in the upper triangular part.

This conclusion does not hold anymore for the bidiagonal reduction process. Indeed, by exploiting the freedom of applying possibly different unitary transformations $U$ and $V$ to rows and columns, this reduction succeeds in a creation of zeros in [illegible] the lower and upper triangular part of the matrix. Hence it is easy to see that the structure propagation argument of Figures 3.3(a) and 3.3(b) will be valid now for [illegible] the lower and the upper triangular part, without any increase of ranks, in any case. On the other hand, a small price has to be paid in the sense that the structure propagation will hold now only for [illegible] rank structures; see Figure 4.4.

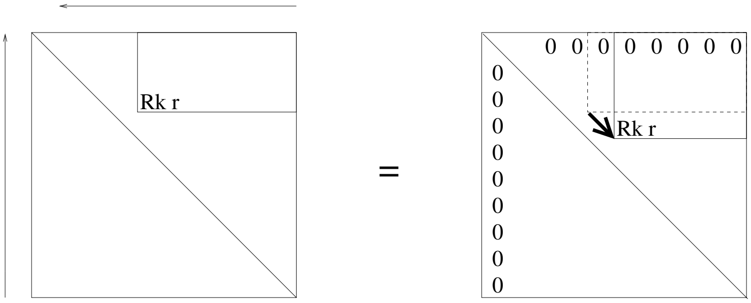


FIG. 4.4. *Structure propagation in the upper triangular part after the bidiagonal reduction of the first column and row. Note that the given, pure structure block moves one position to the bottom right corner, with rank index r being preserved. A similar result holds for the lower triangular part as well.*

Let us now discuss the practical implementation of the bidiagonal reduction process. The algorithm will closely follow the Hessenberg reduction process of section 3. The starting point will be that we have available a row-based Givens-weight representation for the lower triangular part and a column-based Givens-weight representation for the upper triangular part of the given rank structured matrix.

By induction, let us assume then that zeros have been created already in the first $k-1$ columns and rows of the matrix, $1 \leq k \leq n-1$. We assume that the Givens-weight representation of the lower triangular part is in weakly zero-creating form. We can then peel off its tails $G_{n-1,n}, \ldots, G_{k,k+1}$ to bring the $k$th column of the matrix in upper triangular form. During this process, the rank structure in the [illegible] triangular part can be updated in much the same way as in section 3, but now with the role of rows and columns interchanged. Having done this, we bring the Givens-weight representation of the upper triangular part back to its weakly zero-creating form. We can then peel off its tails $\tilde{G}^H_{n-1,n}, \ldots, \tilde{G}^H_{k+1,k+2}$ and apply them to the [illegible], to create zeros in the $k$th [illegible] of the matrix. During this process, the rank structure in the lower triangular part can be updated in the same way as in section 3, and so on.

Summarizing, we have now described how the Hessenberg reduction algorithm could be modified to a bidiagonal reduction algorithm. We now turn to a final modification of the algorithm.

**4.3. The case of nonpure structure blocks.** We assumed in section 3 that the structure blocks were [illegible] and lying strictly below the main diagonal. In this subsection, we will explain how the Hessenberg reduction algorithm can be adapted to work for nonpure structure blocks as well. Along this line, further in this subsection we will describe how to reduce a matrix to lower semiseparable plus diagonal instead of Hessenberg form.

First, we have to explain what the Givens-weight representation for such a nonpure rank structure looks like. We have to assume that the shift elements are [illegible] in the sense that two structure blocks intersecting each other on the main diagonal have the same shift element. If the shift elements are compatible, then we can just represent the rank structured matrix as $D_\lambda + A_{\text{pure}}$, where $D_\lambda$ is the diagonal matrix containing the shift elements, and $A_{\text{pure}}$ is a matrix satisfying a pure rank structure. The latter matrix can now be represented by a usual Givens-weight representation.

Let us explain how the nonpure Givens-weight representation, as just described, can be updated during the algorithm. For simplicity, we will restrict this explanation to the case where only the lower triangular part of the matrix is rank structured.

Starting from the example of Figure 4.5, the algorithm is shown in Figure 4.6.

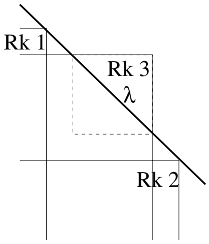

FIG. 4.5. *Starting nonpure rank structure.*

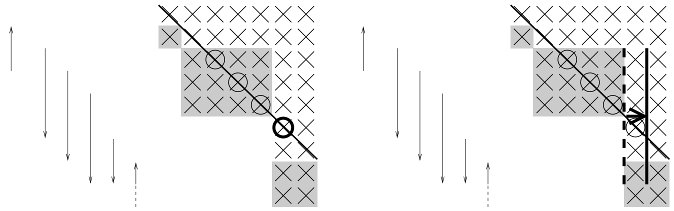
Let us comment on this figure. The starting situation is shown in Figure 4.6(a); it is assumed here that the tails of the subsequent Givens arrows until $G_{6,7}$ have already been peeled off from the representation. Hence the next operations are at the point of entering the nonpure diagonal part of the nonpure structure block $\mathcal{B}$.

Still concerning this figure, let us note that the circle notation expresses that, after spreading out the matrix, the value $\lambda$ should be added to each of the three originally circled entries of the structure block.

Since we are going to enter the nonpure part of $\mathcal{B}$, it is now the right moment to subtract the shift element $\lambda$ from the entry in the bottom right position of the structure block; this is indicated by the highlighted circle in Figure 4.6(a). Note that this subtraction will allow us to split a multiple of the identity matrix $\lambda I_4$ from the structure.

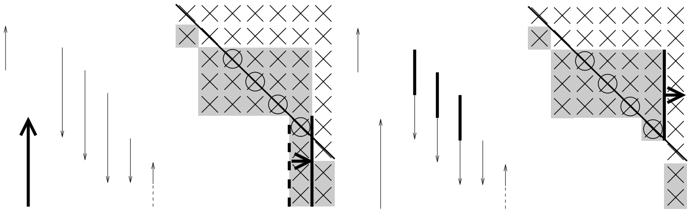
We will now apply the next operations. First, we enlarge the current action radius, and we apply an auxiliary unitary operation to bring the weights upwards; see Figures 4.6(b) and 4.6(c). Note that these operations can be performed exactly as in the shift-free case, since they involve only the [illegible] part of the representation, so that the shift element $\lambda$ is not involved.

We can then peel off the tails of the next Givens arrows and apply them to rows and columns. Since the shift element $\lambda$ appears only in the form of a multiple of the identity matrix $\lambda I_4$, which will clearly be preserved by this unitary similarity



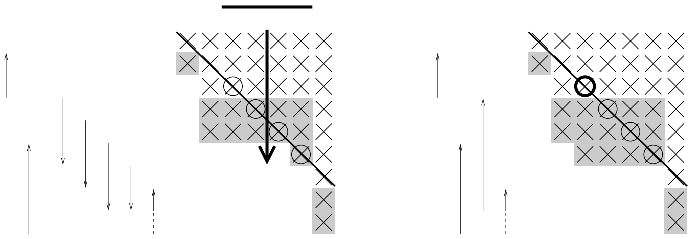
(a) Starting situation; subtract the shift element $\lambda$ from the indicated entry.

(b) Enlarge the action radius of the representation.



(c) Apply auxiliary unitary operations to bring the weights upwards.

(d) Apply the tails of the next Givens arrows to the rows.



(e) Multiply the transposed operations of Figure 4.6(b) to the columns.

(f) Add the shift element $\lambda$ to the indicated entry.

FIG. 4.6. *The case of nonpure structure blocks.*

operation, we can carry out these operations exactly as in the shift-free case; see Figures 4.6(d) and 4.6(e).

These peeling-off operations have caused the structure block $\mathcal{B}$ to move one position to the bottom right matrix corner. This means that the element which was originally situated in the top left position of $\mathcal{B}$ has now come for free. We can restore this element to its real-size form by adding the shift element $\lambda$ to it; see the highlighted circle in Figure 4.6(f). The next operations are not shown anymore.

Summarizing, we have now completely propagated through the nonpure structure block $\mathcal{B}$. During this process, the entry on the bottom right of the structure block was "brought into" the influence of the shift element in Figure 4.6(a), while the top left entry was “released” in Figure 4.6(f), corresponding to the structure block propagating to the bottom right matrix corner.

We note that similar techniques for manipulating shift elements under the action of unitary similarity operations were used in [17], for the special case of reducing an arbitrary matrix into a diagonal plus semiseparable matrix of semiseparability rank one.

The connection with the paper [17] can be made even tighter. More precisely, we will describe how the Hessenberg reduction algorithm can be modified so as to transform a given rank structured matrix $A$ into [illegible] form. Although this reduction could be achieved by first performing the Hessenberg reduction, and subsequently using this as input for the algorithm in [17], we will describe here an intermingled version of the algorithm.

For definiteness, let us denote with $\lambda_k \in \mathbb{C}$, $k = 1, \ldots, n$, the subsequent shift elements of the required, lower semiseparable plus diagonal structure. The corresponding structure blocks are defined as

$$\mathcal{B}_k : (i_k, j_k, r_k, \lambda_k) = (k, k, 1, \lambda_k).$$

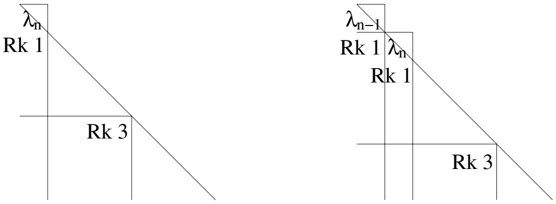
The algorithm proceeds by introducing the shift elements in the [illegible] order $\lambda_n, \ldots, \lambda_1$ on top of the matrix and chasing them to the bottom right. We can start this process by adding the [illegible] shift element $\lambda_n$ on top of the matrix, where it trivially satisfies a structure block $\mathcal{B} : (i, j, r, \lambda) = (1, 1, 1, \lambda_n)$; see Figure 4.7(a).

Let us note that in terms of the Givens-weight representation, this extra structure block $\mathcal{B}$ of Figure 4.7(a) can be incorporated in the factorization $D_\lambda + A_{\text{pure}}$ by placing the value $\lambda_n$ at the $(1, 1)$ element of $D_\lambda$ and subtracting it from the corresponding element of $A_{\text{pure}}$. It also implies an extra unitary transformation $U_0$ to be added to the Givens-weight representation of $A_{\text{pure}}$, in order to compress the [illegible] variant of this extra structure block, which we denote as $\mathcal{B}_{\text{pure}}$, by bringing its weight completely to the top row of the matrix $A_{\text{pure}}$. Since the structure block $\mathcal{B}_{\text{pure}}$ is Rk 1, the Givens arrows of $U_0$ will be of width one.

Now we create zeros in the first column of $A_{\text{pure}}$ by applying the tails of the subsequent Givens arrows $G_{n-1,n}, \ldots, G_{1,2}$ to the rows and their transposes $G^H_{n-1,n}, \ldots, G^H_{1,2}$ to the columns. Since the first column is also involved in this process, the created zeros in the first column will be destroyed again. On the other hand, each of the existing structure blocks will be chased one position to the bottom right position, according to the implementation in Figure 4.6. In particular, it follows that the extra structure block $\mathcal{B}$ will transform into a new structure block $\widetilde{\mathcal{B}} : (i, j, r, \lambda) = (2, 2, 1, \lambda_n)$; see Figure 4.7(b).

Suppose then that we have already created $k-1$ lower semiseparable plus diagonal structure blocks in the top left corner of the matrix, and suppose that we are at the point of applying the $k$th upward sweep of Givens transformations, $2 \leq k \leq n-1$. Before doing this, we add the new shift element $\lambda_{n+1-k}$ on top of the matrix, where it trivially satisfies a structure block $\mathcal{B} : (i, j, r, \lambda) = (1, 1, 1, \lambda_{n+1-k})$. We can then correspondingly update the Givens-weight representation. Next, we can do the same as above, i.e., we apply similarity transformations based on the subsequent tails of the Givens arrows $G_{n-1,n}, \ldots, G_{1,2}$ of the matrix $A_{\text{pure}}$ in order to chase each of the existing structure blocks one position to the bottom right matrix corner.

Note that at the end of this process, the given rank structured matrix will be brought completely into lower semiseparable plus diagonal form, with the required shift elements $\lambda_k$.



(a) (b)

Fig. 4.7. *The left picture shows the starting situation for the lower semiseparable plus diagonal reduction algorithm. The first extra structure block $\mathcal{B}$ has already been added to the top left corner. The right picture shows the situation after applying the first sweep of Givens transformations of the lower semiseparable plus diagonal reduction algorithm. Note that the structure blocks have moved to the bottom right corner, and that the next extra structure block has already been added to the top left corner.*

Let us point out one more thing about the previous reduction algorithm. In principle, one should be cautious about the validity of the structure propagation mechanism for the trivially satisfied structure block $\mathcal{B}$ in the top left matrix corner, since this structure block involves the first row of the matrix, so that the result of Theorem 11 does [illegible] hold anymore. Still, the structure propagation argument [illegible] remain valid, by the fact that, by construction, the applied Givens transformations created zeros in the first column of the [illegible] component $A_{\text{pure}}$, rather than $A$ itself, and this was precisely the necessary condition needed in the first paragraph of the proof of Theorem 11.

[illegible] 13.

1. The presence of rank structure in the upper triangular part was left out of the previous discussion, but can be handled similarly as before. Let us assume, e.g., that the matrix is Hermitian. Then we will suffice with having access over the Givens-weight representation of the lower triangular part, having now a "bulge" at each place where the structure goes beyond the main diagonal. Let us consider, e.g., the situation in Figure 4.6(b). Here we need to have access over the three top elements lying in between the two thick vertical lines. Each of these elements could then be computed by the Hermitian character, using the knowledge of the corresponding element in the lower triangular part, which can be obtained by means of some auxiliary spreading-out operations of the corresponding column of the lower triangular part (one should use an auxiliary variable for doing this). Let us note that these spreading-out operations become more expensive when the required element is situated further from the main diagonal.
2. The Hessenberg reduction algorithm can be seen as a special case of the lower semiseparable plus diagonal reduction algorithm, provided that one chooses $\lambda_k = \infty$ for each $k$, in the sense described in [5].
3. When the required diagonal plus semiseparable structure is close to Hessenberg form, i.e., $\lambda_k \approx \infty$, it can be expected that numerical problems may arise due to large values of the $\lambda_k$. To solve this problem, we may observe that the only place where information about the shift elements is needed is for the determination of each top Givens transformation $G_{1,2}$. Once this has been

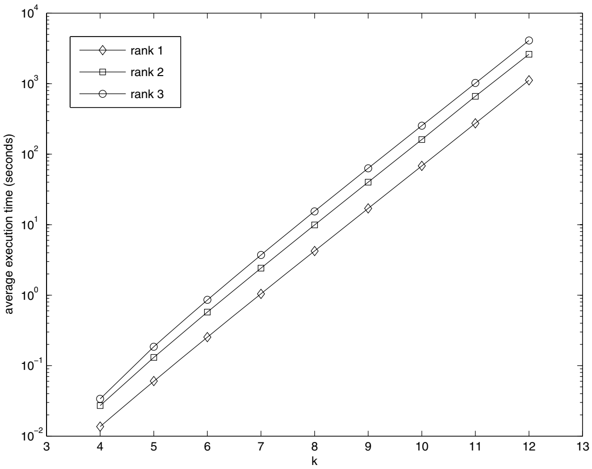


FIG. 5.1. *Average execution time for five random samples of size* $n = 2^k$ *and rank* $r = 1, 2, 3$.

done, the application of this and other Givens transformations can be applied in a "shift-free" way, by working with the induced pure structure blocks, lying just below the main diagonal. Our numerical experiments indicate that this shift-free variant is indeed more stable than the variant described previously, even for moderate sizes of the shift elements $\lambda_k$.

**5. Numerical experiments.** In this section we report on the results of some numerical experiments. The algorithms were implemented in MATLAB.[1] The experiments were executed on an Intel PC running MATLAB Version 7.0.1.24704 (R14) under Linux having 1GByte of memory and an Intel Pentium 4 processor running at 3.2 GHz. The software of these experiments can be requested from the authors.

We constructed symmetric rank structured matrices in $\mathbb{R}^{n \times n}$, with $n = 2^k$ for $k = 4, \ldots, 12$. Starting from a diagonal matrix containing the desired eigenvalues, which were uniformly randomly chosen in the interval $[-1, 1]$, we applied to this matrix a similarity transformation based on a "disturbing" sequence of Givens arrows of width $r$. This resulted in a rank structure whose structure blocks are situated just below the main diagonal, following immediately one after the other. The upper triangular part is then known by symmetry.

Since it can be argued that the above construction yields rather special rank structured matrices, we next applied a "randomization" procedure. We did this by applying an additional similarity transformation based on Givens transformations, computed in a structure-preserving way. Note that symmetry is preserved during all these operations. A detailed description of this randomization method will not be given here.

For each size $n$, the above scheme was carried out for subsequent rank indices $r = 1, 2, 3$. For each of these sizes and each of these rank indices, there were considered five samples. Figure 5.1 shows for each size $n = 2^k$ and each rank index $r$ the execution time $T_{k,r}$ averaged over the five samples of performing the reduction to Hessenberg form.

To check that the computational complexity is quadratic in the size of the matrix,

---

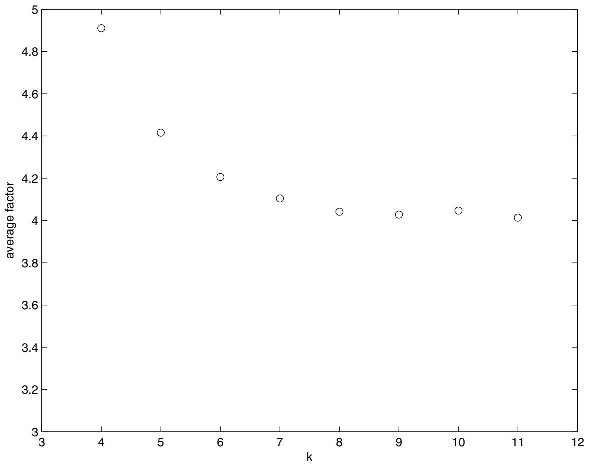

FIG. 5.2. *Fraction* $T_{k+1,r}/T_{k,r}$ *averaged over five random samples and over ranks* $r = 1, 2, 3$ *in function of the size* $n = 2^k$.

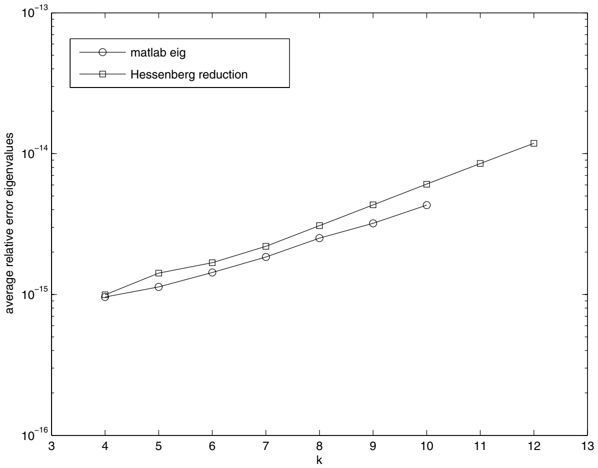

FIG. 5.3. *Relative* 2-norm of the error of the eigenvalues averaged over five random samples and over ranks $r = 1, 2, 3$ in function of the size $n = 2^k$.

Figure 5.2 shows the fraction $T_{k+1,r}/T_{k,r}$ averaged over the five samples and over the ranks $r = 1, 2, 3$.

To measure the accuracy of the algorithm, we computed the relative norm $\frac{||\lambda-\lambda_0||_2}{||\lambda_0||_2}$, where $\lambda_0, \lambda \in \mathbb{R}^n$ denote the vectors containing the exact and computed eigenvalues. Figure 5.3 shows the relative 2-norm of the error averaged over the five samples and the rank indices $r = 1, 2, 3$.[2]

The computation of Givens transformations during the algorithm was performed according to the implementation described in [9, section 5.1]. We note that the accuracy of the algorithm turns out to be slightly sensitive to the choice of the used

---

[2] The eigenvalues of the resulting tridiagonal matrix at the end of the Hessenberg reduction process were computed using the MATLAB routine "trideig" due to P.-O. Persson. This routine is available at http://www.mit.edu/~persson/mltrid/index.html.

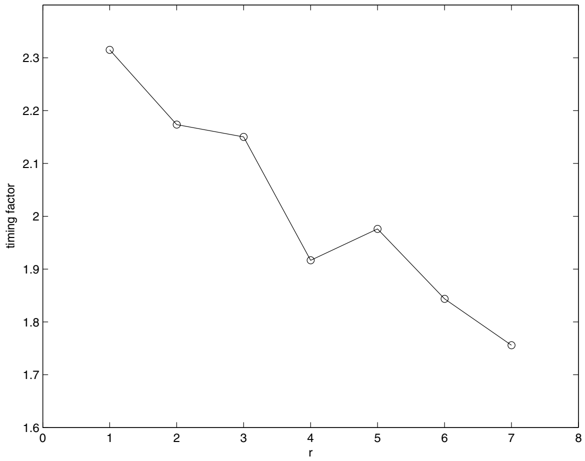

FIG. 5.4. *Fraction $T_{2r}/T_r$ for size $n = 2^9$ in function of the rank index $r = 2^l$ with $l = 0, 1, \dots, 6$.*

Givens routine, but this effect is rather modest.

The pull-through lemma was implemented in the trivial way. This means that, using the notations of Lemma 7, we explicitly computed the 3 by 3 matrix $G'_{1,2}G_{2,3}G_{1,2}$ in its full form. Subsequently, we computed Givens transformations such that

$$(\tilde{G}_{2,3})^H(\tilde{G}_{1,2})^H(\tilde{G}'_{2,3})^H G'_{1,2}G_{2,3}G_{1,2} \tag{5.1}$$

is upper triangular, with positive diagonal elements. Hence (5.1) is a unitary, upper triangular matrix with positive diagonal elements, so that this must be the identity matrix. Rewriting this fact leads to the desired refactorization of Lemma 7. We note that our future work will describe in more detail the implementation of the pull-through lemma, including a nontrivial speed-up which was already implicit in [10].

To check that the computational complexity is linear as a function of the rank index $r$, we considered the execution time $T_r$ for matrices of fixed size $n = 2^9 = 512$ and varying rank index $r = 2^l$ with $l = 0, 1, \dots, 7$. Figure 5.4 gives the fraction $T_{2r}/T_r$ for subsequent rank indices. Note that the fraction tends to approximate 2 for large rank indices $r$. In fact, the fraction tends to go even below this value of 2; but we note that this is artificial since for high ranks the ranks become relatively large with respect to the size $n = 2^9$, so that the distribution of Givens transformations on the "borders" of the matrix start to have a nonneglible impact on the timings.

We note that similar experiments have also been performed for other kinds of rank structures, which are less regular than the one we took for the above numerical experiments. The results of these experiments were similar to those reported above.

**6. Conclusion.** In this paper we described an algorithm for performing the Hessenberg reduction of rank structured matrices. Numerical experiments indicated that this approach leads to a stable computation of the eigenvalues of the given matrix. We showed that the algorithm has complexity $O((ar + bs)n^2)$ in case of a Hermitian plus low rank matrices for suitable $a, b \in \mathbb{R}$. We explained that this complexity holds also for unitary plus low rank matrices, provided that one agrees to perform numerical approximations during the algorithm. Our future work includes an alternative algorithm for the Hessenberg reduction of unitary and related matrices, using an appropriate representation.

# BLOCK AND PARALLEL VERSIONS OF ONE-SIDED BIDIAGONALIZATION*

NELA BOSNER† AND JESSE L. BARLOW‡

**Abstract.** Two new algorithms for one-sided bidiagonalization are presented. The first is a block version which improves execution time by improving cache utilization from the use of BLAS 2.5 operations and more BLAS 3 operations. The second is adapted to parallel computation. When incorporated into singular value decomposition software, the second algorithm is faster than the corresponding ScaLAPACK routine in most cases. An error analysis is presented for the first algorithm. Numerical results and timings are presented for both algorithms.

## 1. Introduction.

There are two main types of algorithms for computing the complete singular value decomposition (SVD) of a matrix $A$: one-sided Jacobi methods [12] and algorithms based upon bidiagonalization. Recently there have been significant improvements in both types of methods [2], [3], [17], [18], [23], [24]; this work considers bidiagonalization-based algorithms. Such algorithms use orthogonal transformations to obtain a bidiagonal form and then apply a fast algorithm to obtain the SVD of the bidiagonal matrix [19], [24], [32].

Let $A \in \mathbb{R}^{m\times n}$, $m \geq n$ (for $m < n$, consider $A^T$). Then there exist a [illegible] matrix $U \in \mathbb{R}^{m\times n}$ (i.e., $U^TU = I_n$), an [illegible] matrix $V \in \mathbb{R}^{n\times n}$ (i.e., $V^TV = VV^T = I_n$), and a bidiagonal matrix

$$B = \begin{bmatrix} \psi_1 & \phi_2 & & & \\ & \psi_2 & \phi_3 & & \\ & & \ddots & \ddots & \\ & & & \psi_{n-1} & \phi_n \\ & & & & \psi_n \end{bmatrix} \tag{1.1}$$

such that

$$A = UBV^T. \tag{1.2}$$

Equation (1.2) describes [illegible] of the matrix $A$. There are several algorithms for bidiagonalization of a matrix, and they differ in the way they construct the matrices $U$ and $V$. The most commonly used algorithms for computing (1.2) are given by Golub and Kahan in [20], and Golub and Reinsch in [21], where the matrices $U$ and $V$ are products of Householder reflectors. Lawson and Hanson in [27,

p. 119] and Chan in [10] present a modification of the Golub–Kahan algorithm, which performs a QR factorization of the matrix $A$ before bidiagonalization, resulting in an algorithm with fewer operations if $m > 5/3n$ and $U$ is not explicitly formed. A bidiagonalization algorithm based on Givens rotations, which can attain higher accuracy, is given by Barlow [2]. Grosser and Lang in [23] propose a two-stage method, where in the first stage a matrix is reduced to a banded matrix and then in the second stage a banded matrix is bidiagonalized. This algorithm performs the majority of calculations in matrix-matrix products and can be faster than the ScaLAPACK bidiagonalization routine. Another different approach is described in [20], where the bidiagonal form is obtained by means of the Lanczos algorithm. This approach is fast but can be numerically unstable. Still there are many applications that do not suffer from this instability, and there is a simple procedure that corrects the possible loss of orthogonality; cf. [31].

Recently, in [28], [30], and [29] Ralha proposed a new approach for bidiagonalizing a matrix, the so-called [illegible]. The main idea is to implicitly tridiagonalize the matrix $A^TA$:

$$V^TA^TAV = T, \qquad T = \text{tridiagonal matrix},$$

by a one-sided orthogonal transformation of $A$

$$F = AV.$$

$V$ is computed as a product of Householder reflectors without explicitly forming $A^TA$. Then the Gram–Schmidt QR factorization of the matrix $F$ is performed to obtain

$$UB = F = AV,$$

where $B$ is upper triangular. In the case when $A$ has full rank, the matrix $B$ is the Cholesky factor of $T$, that is, $T = B^TB$, and hence $B$ must be bidiagonal. That property results in a fast bidiagonalization algorithm, which is much more suitable for parallel computing than the standard bidiagonalization algorithms. Here the modified Gram–Schmidt QR factorization of $F$ is computed by orthogonalizing the $k$th column of $F$ against the $(k-1)$th column of $U$ and normalizing. Unfortunately, this procedure is not always numerically stable and may lead to a matrix $U$ that is far from being left orthogonal in finite precision arithmetic.

To improve Ralha's algorithm, Barlow, Bosner, and Drmač [3] proposed a modification, where one step of Gram–Schmidt orthogonalization and postmultiplication with one Householder reflector are performed simultaneously, resulting in a direct bidiagonalization algorithm. This algorithm produces exactly the same result as Ralha's algorithm in exact arithmetic, but it turns out to be numerically stable in finite precision arithmetic.

The rest of this paper is organized as follows. The recently developed one-sided bidiagonalization from [3] is presented in section 2, together with a bound on its backward error. In section 3, a block version of the new one-sided bidiagonalization is introduced, and a detailed numerical analysis is given in Theorem 3.4. The results of numerical tests regarding efficiency of the block one-sided bidiagonalization are presented in section 4. Sections 5 and 6 deal with parallel versions of the new one-sided bidiagonalization and its efficiency.

## 2. The new stable one-sided bidiagonalization.

The main difference between Ralha's algorithm and the new stable algorithm proposed in [3] is that, in the new bidiagonalization algorithm, transformations with Householder reflectors and the Gram–Schmidt orthogonalization are interlaced, whereas Ralha's bidiagonalization separates these processes. The criteria for choosing Householder reflectors are also different.

Let $u_k$ be the $k$th column of the matrix $U$, and let $U_k = [u_1, \ldots, u_k]$ be a matrix containing the first $k$ columns of $U$. Further, let $V_k$ denote a Householder reflector such that

$$V_k = I - v_k v_k^T, \qquad \text{where } \|v_k\|_2 = \sqrt{2}.$$

Then the new stable bidiagonalization can be described in its simplest form as follows:

- $A_0 = A$.
- For $k = 1, 2, \ldots,$
  - ○ $u_k$ is produced from the $k$th column of $A_{k-1}$ by orthogonalization against $u_{k-1}$ (if $k > 1$) and normalization

    $$U_k = [u_1, \ldots, u_k], \quad k = 1, \ldots, n.$$

  - ○ Householder reflector $\mathbf{V}_k$ is chosen so that

    $$U_k^T A_{k-1} \mathbf{V}_k = B_k \in \mathbb{R}^{k \times n}, \qquad B_k \text{ is bidiagonal,} \tag{2.1}$$

    and the matrix $A_{k-1}$ is postmultiplied with $\mathbf{V}_k$

    $$A_k = A_{k-1} \mathbf{V}_k, \quad k = 1, \ldots, n-2.$$

- End of loop.
- $V$ is produced by accumulation of the Householder reflectors

$$V = \mathbf{V}_1 \cdots \mathbf{V}_{n-2}, \qquad F = A_{n-2} = AV. \tag{2.2}$$

[illegible] 2.1. The elements of $A_{k-1}$ denoted by $\circ$ are used in the current step of the algorithm to compute the vector $z_k$, which determines the Householder reflector $\mathbf{V}_k$. The Householder reflector $\mathbf{V}_k$ is defined as

$$\mathbf{V}_k = \begin{bmatrix} I_k & 0 \\ 0 & V_k \end{bmatrix}, \tag{2.3}$$

and the Householder reflector $V_k \in \mathbb{R}^{(n-k)\times(n-k)}$ is chosen so that $V_k z_k = \pm\|z_k\|_2 e_1$. The elements denoted by $\bullet$ are computed columns of $F$, and in the next steps they remain unchanged. The computed elements of $B$ are denoted by $\diamond$.

[illegible] 2.2. In order to produce $U$ with $n$ columns, the matrix $A$ should have full column rank. If rank $(A) < n$, then $\psi_k = 0$ for some $k$. In [3], it is shown that this case can be easily handled by an $O(mn+n^2)$ postprocessing procedure that produces a decomposition

$$A = U_c B_c V_c^T,$$

where $U_c \in \mathbb{R}^{m\times p}$ and $V_c \in \mathbb{R}^{n\times p}$ are left orthogonal, $B_c \in \mathbb{R}^{p\times p}$ is upper bidiagonal and nonsingular, and $p = \mathrm{rank}(A)$.

The following pseudocode provides the details of the described algorithm.[1]

ALGORITHM 2.1. [illegible] $A \in \mathbb{R}^{m\times n}$ $\mathrm{rank}(A) = n > 2$ [illegible] $U = [u_1, \dots, u_n]$ [illegible] $B$ [illegible] (1.1) [illegible] $V = V^{(n-2)}$ [illegible] $A = UBV^T$

```
(1)  $A_0 = A$.
(2)  $f_1 = A(:,1)$.  $\psi_1 = \|f_1\|_2$.
(3)  $u_1 = f_1/\psi_1$.
for $k = 1: n-2$
    (4) $z_k = A_{k-1}(:,k+1:n)^T u_k$.
    (5) $[\phi_{k+1}, v_k] =$ householder$(z_k)$.
    (6) $A_k(:,1:k) = A_{k-1}(:,1:k)$.
    (7) $A_k(:,k+1:n) = A_{k-1}(:,k+1:n) - A_{k-1}(:,k+1:n)v_k v_k^T$.
    (8) $f_{k+1} = A_k(:,k+1)$.
    (9) $s_{k+1} = f_{k+1} - \phi_{k+1}u_k$.  $\psi_{k+1} = \|s_{k+1}\|_2$.
    (10) $u_{k+1} = s_{k+1}/\psi_{k+1}$.
end.
(11)  $f_n = A_{n-2}(:,n)$.  $\phi_n = u_{n-1}^T f_n$.
(12)  $s_n = f_n - \phi_n u_{n-1}$.  $\psi_n = \|s_n\|_2$.
(13)  $u_n = s_n/\psi_n$.
(14) $V^T =$ householder_product$(v_1, \dots, v_{n-2})$
end.
```

The auxiliary functions **householder**() and **householder_product**() are defined as follows.

**function** $[\phi, v]$=**householder**$(z)$
{[illegible] **householder**() [illegible] $\phi$ [illegible] $v$ [illegible] $\|v\|_2 = \sqrt{2}$ [illegible] [25, [illegible] 19]. The Householder reflector is then formed as $V = I - vv^T$ with property that $Vz = \phi e_1$.}

**function** $V^T =$ **householder_product**$(v_1, \dots, v_n)$
{[illegible] **householder_product**() [illegible] $V^T$ [illegible] $n$ [illegible] $V^T = \mathbf{V}_n \cdots \mathbf{V}_1$ $\mathbf{V}_k$ [illegible] $k = 1, \dots, n$ [illegible] (2.3) [illegible] $V_k = I - v_k v_k^T$ [illegible] `sorgbr()` [1] }

In [3], the following theorem about the numerical stability of Algorithm 2.1 was proved. Here we denote the unit roundoff with $\varepsilon$.

THEOREM 2.1. [illegible] $\tilde{B}$ [illegible] 2.1 [illegible] $(m+n)\times(m+n)$ [illegible] $\mathcal{P}$ [illegible] $n\times n$ [illegible] $V$

---

[1] FORTRAN routines for the SVD using the one-sided bidiagonalization methods described in this paper are available from the first author.

[illegible] $\Delta A$ $\delta A$ [illegible]

$$\begin{bmatrix} \tilde{B} \\ 0 \end{bmatrix} = \hat{\mathcal{P}}^T \begin{bmatrix} \Delta A \\ A + \delta A \end{bmatrix} \hat{V}, \quad \left\| \begin{bmatrix} \Delta A \\ \delta A \end{bmatrix} \right\|_F \leq \xi \|A\|_F, \tag{2.4}$$

[illegible] $\xi = O(mn + n^3)\varepsilon$ [illegible] $\tilde{V}$ [illegible] $\hat{V}$ [illegible] $\|\tilde{V} - \hat{V}\|_F \leq O(n^2)\varepsilon$ [illegible] $\breve{U}$ [illegible] $\breve{\delta A}$ [illegible]

$$A + \breve{\delta A} = \breve{U} \tilde{B} \hat{V}^T, \quad \|\breve{\delta A}\|_F \leq \sqrt{2}\xi \|A\|_F. \tag{2.5}$$

Although this result implies that Algorithm 2.1 is numerically stable for computing $B$ and $V$, we cannot guarantee that the computed matrix $U$ is numerically orthogonal. In many circumstances, the possible loss of orthogonality is irrelevant [8]. One can also get nearly orthogonal bases for the parts associated with the leading singular values of $A$ [3, Theorem 3.19 and Corollary 3.20].

Another important characteristic of an algorithm is its efficiency, and the preferable way to evaluate efficiency is through execution time. The execution time of a numerical algorithm depends on two properties: the floating point operation count and the time spent on communication among hierarchically organized computer memory. We are concerned about the efficiency of full SVD algorithms that include bidiagonalization, when computing all of the SVD factors: $P$, $Q$, and $\Sigma = \mathrm{diag}(\sigma_1, \ldots, \sigma_n)$ such that $A = P\Sigma Q^T$.

Extensive numerical tests were performed to test the efficiency of the SVD algorithms. Even though an SVD routine with Algorithm 2.1 requires fewer floating point operations (see [3]), a straightforward implementation of Algorithm 2.1 is often slower than the current LAPACK [1] routine in `sgesvd()`, since the LAPACK routine optimizes cache memory usage, whereas Algorithm 2.1 does not. In order to decrease cache communication time, we develop a block version of Algorithm 2.1 next.

**3. Block version of the new stable one-sided bidiagonalization.** The new block version of Algorithm 2.1 improves the usage of fast cache memory by performing as many operations as possible on the data that are currently stored in the cache. In order to do that, one has to transform the original algorithm. The first modification of the algorithm is that transformations by Householder reflectors are aggregated, where the WY representation is used for a product of Householder reflectors [4]. In the WY representation the product of $j$ Householder reflectors is presented as $V_j \cdots V_1 = I - WY^T$, where $W$ and $Y$ have $j$ columns. This means that the matrix $A$ is updated after every $b$ steps, where $m \times b$ is the block dimension. Most of the operations in Algorithm 2.1 are matrix-vector operations, coded as BLAS 2 operations [13]. Memory hierarchy is utilized more efficiently if such algorithms are written in terms of matrix-matrix operations, coded as BLAS 3 operations [14], [15], or grouped matrix-vector operations, called BLAS 2.5 operations [11], [26]. Employing the WY representation of products of Householder transformations results in more BLAS 3 operations; using the BLAS 2.5 approach of Howell et al. [26] leads to further improvement. Operations on the same data, but performed in different places in Algorithm 2.1, are now performed simultaneously. These operations are

$$\boxed{\begin{array}{rcl} x & \leftarrow & x + A^T y \\ w & \leftarrow & Ax \end{array}} \quad \text{or} \quad \boxed{\begin{array}{rcl} A & \leftarrow & A + uv^T \\ x & \leftarrow & A^T y \\ w & \leftarrow & Ax \end{array}}\,. \tag{3.1}$$

Now we discuss our modifications of Algorithm 2.1. As an input to the algorithm we will take the matrix $A \in \mathbb{R}^{m\times n}$ and partition it into block columns. Let $n = b\cdot g+r$, $r \leq b+1$, where $b$ is a given block column dimension and $g = \lfloor (n-2)/b \rfloor$ is the number of blocks of dimension $m\times b$. We choose the last two columns to be outside of the block partition, because the last two steps of the one-sided bidiagonalization (corresponding to the last two columns) do not involve computation of a Householder reflector. The $g$ blocks will be updated by means of aggregated Householder transformations and BLAS 2.5 transformations related to the first group of transformations in (3.1). The remaining $r = n - b \cdot g$ columns will be updated with nonaggregated Householder transformations and the second group of BLAS 2.5 transformations in (3.1). As each block consists of $b$ columns, the steps of the algorithm will be organized in two loops: the outer loop going through $g$ blocks and the inner loop going through $b$ columns of the block. Thus we will denote by $A_{j,k}$ the matrix $A$ after the first $j-1$ blocks, and the first $k$ columns in the $j$th block have been updated.

The main difference between the stable bidiagonalization and its block version is the way Householder reflectors are computed and applied to the matrix $A$. In the $k$th step of Algorithm 2.1, columns $k+1$ through $n$ of the matrix $A$ are updated with the Householder reflector $\mathbf{V}_k$. After this step, the $(k+1)$th column is not changed anymore and is consequently equal to the $(k+1)$th column of the matrix $F$ defined in (2.2).

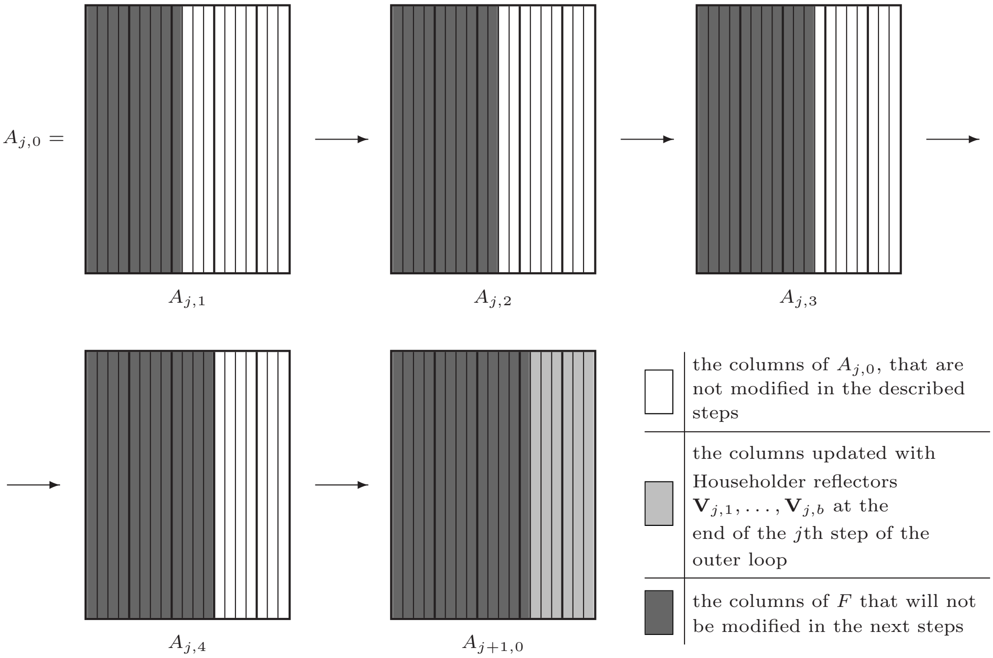
In the block version of the stable bidiagonalization, updates with Householder reflectors are done blockwise. This means that, only when all of the columns in one block are updated and assigned to $F$ (they will not be modified in the next steps), the rest of the matrix will then be updated with $b$ Householder reflectors in aggregated form that correspond to $b$ steps of Algorithm 2.1. Until then, only the current column is updated. Let us assume that we have computed the first $(j-1)$ blocks of the matrix $F$ obtaining the matrix $A_{j,0}$ and that we are observing the operations in the $j$th step of the outer loop. Then for $k = 2, \ldots, b$ only the $((j-1)b+k)$th column is updated by Householder reflectors from the steps $1, \ldots, k-1$ of the same block, obtaining the matrix $A_{j,k}$, and a new Householder reflector $\mathbf{V}_{(j-1)b+k}$ is computed. $\mathbf{V}_{(j-1)b+k}$ will affect the columns $((j-1)b+k+1)$ through $n$, but no updates are done. The matrix $A_{j,1}$ is equal to $A_{j,0}$ because the $((j-1)b+1)$th column is already updated; only the Householder reflector $\mathbf{V}_{(j-1)b+1}$ is computed. We use the WY form for a product of Householder reflectors described in [4] to write

$$\mathbf{V}_{(j-1)b+1} \ldots \mathbf{V}_{(j-1)b+k-1} = I - Y_j(:, 1\colon k-1) W_j(:, 1\colon k-1)^T. \tag{3.2}$$

After the $(jb)$th column has been updated, the columns $jb+1$ through $n$ are updated with the product $\mathbf{V}_{(j-1)b+1}, \ldots, \mathbf{V}_{jb}$ in WY form (3.2). This process is illustrated in Figure 3.1 with notation defined in (3.3). The $(g+1)$th block is updated with Householder reflectors in the usual way, as it is done in Algorithm 2.1.

This is the same approach as in the LAPACK routine `sgebrd()` [16], where the routine `slabrd()` is called first, followed by the routine `sgebd2()`. `slabrd()` performs the two-sided aggregated Householder transformation over the first $g$ blocks, and `sgebd2()` performs the unblocked transformations. The differences are that in the block version of Algorithm 2.1 only one-sided Householder transformations are performed and that the dimension of the block is computed differently.

Aggregated Householder transformations represent only one modification of Algorithm 2.1. The other modification is achieved by using the ideas described in [26].



$A_{j,0} =$
$A_{j,1}$
$A_{j,2}$
$A_{j,3}$
$A_{j,4}$
$A_{j+1,0}$
the columns of $A_{j,0}$, that are not modified in the described steps
the columns updated with Householder reflectors $\mathbf{V}_{j,1}, \ldots, \mathbf{V}_{j,b}$ at the end of the $j$th step of the outer loop
the columns of $F$ that will not be modified in the next steps

FIG. 3.1. *Column update in the $j$th block of the matrix $A$.*

Let us define the following correspondence:

$$\begin{aligned} &\ell = (j-1)b + k, && \text{current } \ell\text{th column is the } k\text{th column in the } j\text{th block,} \\ &\ell \leftrightarrow (j,k) && \text{the indices with } \ell \text{ are replaced by } (j,k). \end{aligned} \tag{3.3}$$

This correspondence is introduced only for notational convenience. Now we will investigate the lines **(4)**, **(5)**, and **(7)** in Algorithm 2.1, but with the index $k$ replaced by $\ell$. In all of these statements the vector $z_\ell \to z_{j,k}$ is directly or indirectly used. In line **(4)** $u_\ell$ is multiplied by $A_{\ell-1}(:, \ell+1\colon n)^T \to A_{j,k-1}(:, \ell+1\colon n)^T$ in order to obtain $z_{j,k}$. On the other hand, in line **(7)** the vector $v_\ell \to v_{j,k}$ is multiplied by $A_{j,k-1}(:, \ell+1\colon n)$, and $v_{j,k}$ is realized from $z_{j,k}$ through line **(5)** and the function **householder**(). From the definition of **householder**(), we have

$$\begin{aligned} z_{j,k} &= A_{j,k-1}(:, \ell+1, n)^T u_\ell, \\ v_{j,k} &= \frac{\sqrt{2}(z_{j,k} - \phi_{\ell+1}e_1)}{\|z_{j,k} - \phi_{\ell+1}e_1\|_2}, \quad \text{and thus} \end{aligned} \tag{3.4}$$

$$A_{j,k-1}(:, \ell+1\colon n)v_{j,k} = \frac{\sqrt{2}[A_{j,k-1}(:, \ell+1\colon n)z_{j,k} - \phi_{\ell+1}A_{j,k-1}(:, \ell+1)]}{\|z_{j,k} - \phi_{\ell+1}e_1\|_2}.$$

From the previous observations concerning the update of the matrix $A_{j,0}$ with Householder reflectors, in the $\ell$th step (which in the block version will correspond to the $j$th step of the outer loop and the $k$th step of the inner loop) columns $\ell+1, \ldots, n$ are not yet updated. Since $A_{j,k-1} = A_{j,0}\mathbf{V}_{j,1} \ldots \mathbf{V}_{j,k-1}$, (3.2) and (3.4) imply that

$$\begin{aligned} z_{j,k} = {} & A_{j,0}(:, \ell+1, n)^T u_\ell \\ & -W_j(\ell+1\colon n, 1\colon k-1)Y_j(:, 1\colon k-1)^T A_{j,0}^T u_\ell, \end{aligned} \tag{3.5}$$

$$\begin{aligned} A_{j,k-1}(:\,,\ell+1\colon n)v_{j,k} &= A_{j,0}(:\,,\ell+1\colon n)v_{j,k} \\ &\quad -A_{j,0}Y_j(:\,,1\colon k-1)W_j(\ell+1\colon n,1\colon k-1)^T v_{j,k} \\ &= \frac{\sqrt{2}[A_{j,0}(:\,,\ell+1\colon n)z_{j,k}-\phi_{\ell+1}A_{j,0}(:\,,\ell+1)]}{\|z_{j,k}-\phi_{\ell+1}e_1\|_2} \\ &\quad -A_{j,0}Y_j(:\,,1\colon k-1)W_j(\ell+1\colon n,1\colon k-1)^T v_{j,k}. \end{aligned} \tag{3.6}$$

If we define

$$z_{j,k}^{(1)} = -W_j(\ell+1\colon n,1\colon k-1)Y_j(:\,,1\colon k-1)^T A_{j,0}^T u_\ell$$

as the first phase in the computation of $z_{j,k}$ and

$$x_{j,k}^{(1)} = A_{j,0}(:\,,\ell+1\colon n)z_{j,k}$$

as the first phase in the computation of the vector $x_{j,k}^{(4)} = A_{j,k-1}(:\,,\ell+1\colon n)v_{j,k}$, then

$$\boxed{\begin{array}{rcl} z_{j,k} & = & z_{j,k}^{(1)} + A_{j,0}(:\,,\ell+1\colon n)^T u_\ell \\ x_{j,k}^{(1)} & = & A_{j,0}(:\,,\ell+1\colon n)z_{j,k} \end{array}} \qquad \begin{array}{l} \text{from (3.5)} \\ \text{from (3.6)} \end{array}$$

will be computed simultaneously, and they comprise the first group of BLAS 2.5 transformations in (3.1). By simultaneous computation we mean that as soon as one component of $z_{j,k}$ is computed, $x_{j,k}^{(1)}$ is updated with this new data by the BLAS 1 `saxpy()` operation. The components of $z_{j,k}$ can be partitioned in blocks of dimension $c$, so that BLAS 2 `segmv()` is used in the simultaneous computation instead of BLAS 1 operations. This improves the cache memory usage even more.

In the $k$th step of the inner loop for the last $(g+1)$th block update with $\mathbf{V}_{g+1,k-1}$, computation of $z_{g+1,k}$ and $x_{g+1,k}^{(1)}$ will be done simultaneously. Again let $\ell = gb+k$. First, we have

$$\begin{aligned} A_{g+1,k-1}(:\,,\ell+1\colon n) &= A_{g+1,k-2}(:\,,\ell+1\colon n) \\ &\quad -A_{g+1,k-2}(:\,,\ell\colon n)v_{g+1,k-1}v_{g+1,k-1}(2\colon n-\ell+1)^T \\ &= A_{g+1,k-2}(:\,,\ell+1\colon n) - x_{g+1,k-1}^{(3)}v_{g+1,k-1}(2\colon n-\ell+1)^T, \end{aligned}$$

where $x_{g+1,k}^{(3)} = A_{g+1,k-1}(:\,,\ell+1\colon n)v_{g+1,k}$, and from (3.4) it follows that

$$\begin{aligned} &A_{g+1,k-1}(:\,,\ell+1\colon n)v_{g+1,k} \\ &\quad = \frac{\sqrt{2}[A_{g+1,k-1}(:\,,\ell+1\colon n)z_{g+1,k}-\phi_{\ell+1}A_{g+1,k-1}(:\,,\ell+1)]}{\|z_{g+1,k}-\phi_{\ell+1}e_1\|_2}. \end{aligned} \tag{3.7}$$

Again, if we define

$$x_{g+1,k}^{(1)} = A_{g+1,k-1}(:\,,\ell+1\colon n)z_{g+1,k}$$

as the first phase in the computation of the vector $x_{g+1,k}^{(3)}$, then

$$\boxed{\begin{array}{rcl} A_{g+1,k-1}(:\,,\ell+1\colon n) & = & A_{g+1,k-2}(:\,,\ell+1\colon n) \\ & & -x_{g+1,k-1}^{(3)}v_{g+1,k-1}(2\colon n-\ell+1)^T \\ z_{g+1,k} & = & A_{g+1,k-1}(:\,,\ell+1\colon n)^T u_\ell \\ x_{g+1,k}^{(1)} & = & A_{g+1,k-1}(:\,,\ell+1\colon n)z_{g+1,k} \end{array}}$$

comprises the second group of BLAS 2.5 transformations in (3.1).

The reason why these operations are performed simultaneously is that the same parts of the matrix $A$ are involved, as well as the same parts of the vector $z_{j,k}$. Thus, when a particular block of the matrix and the vector is stored in the fast cache memory, all of the operations can be done without transferring blocks from slower memory to the cache, saving some of the time spent on memory by Algorithm 2.1.

Before stating a detailed algorithm, we have to introduce one more definition. The update of the $\ell$th column of the matrix $A_{j,k}$, where $\ell = (j-1)b+k$, is done by the following relations:

$$\begin{aligned} A_{j,k}(:,\ell) &= [A_{j,0}\mathbf{V}_{j,1}\dots\mathbf{V}_{j,k-1}](:,\ell) \\ &= A_{j,0}(:,\ell) - A_{j,0}Y_j(:,1\colon k-1)W_j(\ell,1\colon k-1)^T. \end{aligned}$$

The term $A_{j,0}Y_j(:,1\colon k-1)$ also occurs in relations (3.5) and (3.6); hence, we define $X_j = A_{j,0}Y_j$. From the definition of the matrices $Y_j$ and $W_j$ in [4], $W_j$ and $X_j$ satisfy the following recurrences:

$$\begin{aligned} W_j(:,1) &= \mathbf{v}_{j,1}, \\ W_j(:,1\colon k) &= [W_j(:,1\colon k-1),\ \mathbf{v}_{j,k}], \\ X_j(:,1) &= A_{j,0}Y_j(:,1) = A_{j,0}\mathbf{v}_{j,1}, \\ X_j(:,1\colon k) &= A_{j,0}Y_j(:,1\colon k) \\ &= [X_j(:,1\colon k-1),\ A_{j,0}\mathbf{v}_{j,k} \\ &\qquad -X_j(:,1\colon k-1)W_j(:,1\colon k-1)^T\mathbf{v}_{j,k}]. \end{aligned} \tag{3.8}$$

Now we can state the complete algorithm.

ALGORITHM 3.1. [illegible] $A \in \mathbb{R}^{m\times n}$ rank$(A) = n > 2$ [illegible] $U$ [illegible] $B$ [illegible] $V$ [illegible] $A = UBV^T$

```

```

[illegible] 3.1. The choice of block dimensions $b$ and $c$ depends upon which computer executes Algorithm 3.1. Their sizes are chosen to obtain optimal efficiency. In LAPACK routines, the function *ilaenv()* is used to determine the optimal block size for block algorithms. Section 5.2 in [1] explains how *ilaenv()* works: "The version of *ilaenv()* supplied with the package contains default values that led to good behavior over a reasonable number of the test machines, but to achieve optimal performance, it may be beneficial to tune *ilaenv()* for the particular machine environment." Our optimal block dimensions were obtained through tests.

Algorithm 2.1 is numerically backward stable for computing $B$ and $V$, but what about Algorithm 3.1? The answer to this question is given by Theorem 3.4. Before stating a proof of Theorem 3.4, we will need the results of three technical lemmas. The lemmas are based on the numerical analysis of basic numerical algorithms given by Higham [25] and the analysis of the modified Gram–Schmidt algorithm given by Björck and Paige [5]. The proofs of the lemmas can be found in [7]. In our numerical analysis we will use the following notation: Tildes (˜) will mark computed quantities, and hats (ˆ, ˘ ) will denote vectors and matrices that correspond to certain exact relations and exist only as theoretical entities, not actually computed.

LEMMA 3.1. [illegible] 3.1 [illegible] $\varepsilon$ [illegible]

$$\tilde{v}_{j,k} = \hat{v}_{j,k} + \delta\hat{v}_{j,k}, \qquad \|\delta\hat{v}_{j,k}\|_2 \le O(n-l)\varepsilon,$$

$$\tilde{W}_j(:\,,1\colon k) = \hat{W}_j(:\,,1\colon k) + \delta\hat{W}_j(:\,,1\colon k), \qquad \|\delta\hat{W}_j(:\,,1\colon k)\|_F \le O(\sqrt{k}n)\varepsilon,$$

$$\tilde{X}_j(:\,,k) = \tilde{A}_{j,0}\hat{Y}_j(:\,,k) + \delta\hat{X}_j(:\,,k), \qquad \|\delta\hat{X}_j(:\,,k)\|_2 \le O(kn)\varepsilon\|\tilde{A}_{j,0}\|_F,$$

[illegible] $\hat{v}_{j,k}$ [illegible] $\hat{V}_{j,k}$ [illegible] $\hat{W}_j$ $\hat{Y}_j$ [illegible] $\hat{X}_j = \tilde{A}_{j,0}\hat{Y}_j$ [illegible] $\hat{v}_{j,k}$ [illegible] (3.8) [illegible]

$$\|\hat{W}_j(:,1\colon k)\|_F \le \sqrt{2}\sqrt{k},$$
$$\|\hat{X}_j(:,1\colon k)\|_F = \|\tilde{A}_{j,0}\hat{Y}_j(:,1\colon k)\|_F \le 2\sqrt{2}\sqrt{k}\|\tilde{A}_{j,0}\|_F.$$

LEMMA 3.2. [illegible] $\tilde{B}$ [illegible] 3.1 [illegible]

$$\begin{bmatrix} \tilde{\phi}_{k+1}e_k + \tilde{\psi}_{k+1}e_{k+1} \\ 0 \end{bmatrix} = \hat{P}_{k+1}\hat{P}_k \left( \begin{bmatrix} 0 \\ f_{k+1} \end{bmatrix} + \begin{bmatrix} \Delta f_{k+1} \\ \delta f_{k+1} \end{bmatrix} \right),$$
$$\left\| \begin{bmatrix} \Delta f_{k+1} \\ \delta f_{k+1} \end{bmatrix} \right\|_2 \le O(bm)\varepsilon\|F\|_F,$$

[illegible] $\hat{P}_k$ $k = 1,\dots,n$ [illegible] $(m+n)\times(m+n)$ [illegible] [5]

LEMMA 3.3. [illegible] $\tilde{u}_\ell$ [illegible] $\tilde{A}_{g+1,r-1}(:,\ell+2\colon n)$ [illegible] 3.1 [illegible]

$$\|\tilde{u}_\ell^T\tilde{A}_{g+1,r-1}(:,\ell+2\colon n)\|_2 \le O(b^2n + bm + bn^2)\varepsilon\|A\|_F.$$

THEOREM 3.4. [illegible] $\tilde{B}$ [illegible] 3.1 [illegible] $(m+n)\times(m+n)$ [illegible] $\hat{\mathcal{P}}$ [illegible] $n\times n$ [illegible] $\hat{V}$ [illegible] $\Delta A$ $\delta A$ [illegible]

$$\begin{bmatrix} \tilde{B} \\ 0 \end{bmatrix} = \hat{\mathcal{P}}^T \begin{bmatrix} \Delta A \\ A+\delta A \end{bmatrix} \hat{V}, \quad \left\| \begin{bmatrix} \Delta A \\ \delta A \end{bmatrix} \right\|_F \le \xi\|A\|_F, \tag{3.9}$$

[illegible] $0 \le \xi \le O(b(mn+n^3))\varepsilon$ [illegible] $\tilde{V}$ [illegible] $\hat{V}$ [illegible] $\|\tilde{V} - \hat{V}\|_F \le O(n^2)\varepsilon$ [illegible] $\breve{U}$ [illegible] $\delta\breve{A}$ [illegible]

$$A + \delta\breve{A} = \breve{U}\tilde{B}\hat{V}^T, \quad \|\delta\breve{A}\|_F \le \sqrt{2}\xi\|A\|_F. \tag{3.10}$$

[illegible]. The proof is rather technical and we will divide it into three steps.

[illegible] 1. We will set $F = \mathrm{fl}(AV) = \tilde{A}_{g+1,r-1}$, $\ell = (j-1)b + k$ and $r = n - gb$, where $\tilde{A}_{g+1,r-1}$ is the result of Algorithm 3.1 performed in finite precision arithmetic. Thus, in floating point computation we can use $f_\ell = F(:,\ell)$ instead of

$$f_\ell = \begin{cases} \tilde{A}_{j,k}(:,\ell) & \text{for } j = 1,\dots g,\ k = 1,\dots,b,\ \ell = 1,\dots,gb, \\ \tilde{A}_{g+1,k}(:,\ell) & \text{for } k = 1,\dots,r-1,\ \ell = gb+1,\dots,n-1, \\ \tilde{A}_{g+1,r-1}(:,n) & \text{for } \ell = n, \end{cases}$$

because the denoted column will not be modified in successive steps of the algorithm (see Figure 3.1).

In this step of the proof we will analyze the application of Householder reflectors to the matrix $A$, in floating point arithmetic. This application is divided into $g$ steps, where $b$ columns of $F$ are computed in each step, and $r$ remaining steps, where only one column of $F$ is computed per step. First, we are investigating the computations performed in one block $j \in \{1,2,\dots,g\}$.

Lemma 3.1 gives the error estimate

$$\tilde{X}_j(:,1\colon k) = \tilde{A}_{j,0}\hat{Y}_j(:,1\colon k) + \delta\hat{X}_j(:,1\colon k),$$

where

$$\|\delta\hat{X}_j(:,1\colon k)\|_F = \sqrt{\sum_{i=1}^{k} \|\delta\hat{X}_j(:,i)\|_2^2} \le O(k^{\frac{3}{2}}n)\varepsilon\|\tilde{A}_{j,0}\|_F,$$

and

$$\tilde{W}_j(:,1\colon k) = \hat{W}_j(:,1\colon k) + \delta\hat{W}_j(:,1\colon k),$$

with

$$\|\delta\hat{W}_j(:,1\colon k)\|_F \le O(\sqrt{k}n)\varepsilon.$$

The only thing that remains is to find a bound on the error introduced by the application of Householder reflectors to the matrix $A$. First, for $\ell = (j-1)b + k$, $k = 1, \ldots, b$, we define the matrices $\hat{V}_{j,k}, \tilde{V}_{j,k} \in \mathbb{R}^{(n-l)\times(n-l)}$ as (see [7] for the proof of Lemma 3.1 and [1] for the documentation of the LAPACK routine `slarfg()`)

$$\hat{V}_{j,k} = I - \hat{\tau}_{j,k}\hat{v}_{j,k}\hat{v}_{j,k}^T, \quad \tilde{V}_{j,k} = I - \tilde{\tau}_{j,k}\tilde{v}_{j,k}\tilde{v}_{j,k}^T,$$

and $\hat{Q}_j, \tilde{Q}_j \in \mathbb{R}^{n\times n}$ as

$$\hat{Q}_j = \begin{bmatrix} I_{jb} & 0 \\ 0 & \hat{V}_{j,b} \end{bmatrix} \cdots \begin{bmatrix} I_{(j-1)b+2} & 0 \\ 0 & \hat{V}_{j,2} \end{bmatrix} \begin{bmatrix} I_{(j-1)b+1} & 0 \\ 0 & \hat{V}_{j,1} \end{bmatrix},$$
$$\tilde{Q}_j = \begin{bmatrix} I_{jb} & 0 \\ 0 & \tilde{V}_{j,b} \end{bmatrix} \cdots \begin{bmatrix} I_{(j-1)b+2} & 0 \\ 0 & \tilde{V}_{j,2} \end{bmatrix} \begin{bmatrix} I_{(j-1)b+1} & 0 \\ 0 & \tilde{V}_{j,1} \end{bmatrix},$$

where $\hat{Q}_j = I - \hat{W}_j\hat{Y}_j^T$ and $\tilde{Q}_j = I - \tilde{W}_j\tilde{Y}_j^T$.

Then, for $\hat{X}_j, \tilde{X}_j \in \mathbb{R}^{m\times b}$ and $\hat{W}_j, \tilde{W}_j \in \mathbb{R}^{n\times b}$, from Lemma 3.1 it follows that

$$\begin{aligned} \tilde{A}_{j+1,0} &= \mathrm{fl}(\tilde{A}_{j,0}\tilde{Q}_j^T) = \mathrm{fl}(\tilde{A}_{j,0} - \mathrm{fl}(\tilde{X}_j\tilde{W}_j^T)) \\ &= \tilde{A}_{j,0} - [(\hat{X}_j + \delta\hat{X}_j)(\hat{W}_j^T + \delta\hat{W}_j^T) + \delta_1 A_{j+1,0}] + \delta_2 A_{j+1,0} \\ &= \tilde{A}_{j,0} - \hat{X}_j\hat{W}_j^T + \delta A_{j+1,0} = \tilde{A}_{j,0} - \tilde{A}_{j,0}\hat{Y}_j\hat{W}_j^T + \delta A_{j+1,0} \\ &= \tilde{A}_{j,0}\hat{Q}_j^T + \delta A_{j+1,0}, \end{aligned}$$

where

$$\|\delta_1 A_{j+1,0}\|_F \le O(b^2)\varepsilon\|\tilde{A}_{j,0}\|_F, \qquad \|\delta_2 A_{j+1,0}\|_F \le O(b)\varepsilon\|\tilde{A}_{j,0}\|_F,$$

which implies

$$\|\delta A_{j+1,0}\|_F \le O(b^2 n)\varepsilon\|\tilde{A}_{j,0}\|_F.$$

Finally, we obtain the result for $F = \tilde{A}_{g+1,r-1}$, where the first $g$ updates are performed as shown above, and the last $r - 1 = n - gb - 1$ updates can be considered in the same framework but with $b = 1$. Let us denote $g_t = g + r - 1$ as the total number of update steps. We can note that

$$\begin{aligned}\|F\|_F &\leq \|\tilde{A}_{g+1,r-2}\|_F + O(\varepsilon) \leq \cdots \leq \|\tilde{A}_{g+1,1}\|_F + O(\varepsilon) \leq \|\tilde{A}_{g+1,0}\|_F + O(\varepsilon)\\ &\leq \|\tilde{A}_{g,0}\|_F + O(\varepsilon) \leq \cdots \leq \|\tilde{A}_{2,0}\|_F + O(\varepsilon) \leq \|A\|_F + O(\varepsilon).\end{aligned}$$

Then by induction we have

$$\begin{aligned}F &= ((\ldots((A\hat{Q}_1^T + \delta A_{2,0})\hat{Q}_2^T + \delta A_{3,0})\ldots)\hat{Q}_{g_t-1}^T + \delta A_{g+1,r-2})\hat{Q}_{g_t}^T + \delta A_{g+1,r-1}\\ &= A\hat{Q}_1^T\hat{Q}_2^T\cdots\hat{Q}_{g_t}^T + \sum_{j=1}^{g}\delta A_{j+1,0}\hat{Q}_{j+1}^T\ldots\hat{Q}_{g_t}^T + \sum_{k=1}^{r-1}\delta A_{g+1,k}\hat{Q}_{g+k+1}^T\ldots\hat{Q}_{g_t}^T\\ &= A\hat{V} + \delta_1 F,\end{aligned}$$

where

$$\|\delta_1 F\|_F \leq [O(gb^2n) + O((n-gb)n)]\varepsilon\|A\|_F \leq O(bn^2)\varepsilon\|A\|_F.$$

At the end of this step of the proof, for $\hat{V} = \hat{Q}_1^T\hat{Q}_2^T\ldots\hat{Q}_{g_t}^T$ we can state that

$$F = (A + \delta_1 A)\hat{V}, \qquad \|\delta_1 A\|_F \leq \eta_F\|A\|_F, \quad \eta_F \leq O(bn^2)\varepsilon,$$

where $\delta_1 A = \delta_1 F \cdot \hat{V}^T$.

2. Since the computation of $\tilde{B}$ from $F = [f_1, \ldots, f_n]$ corresponds to the modified Gram–Schmidt algorithm, we can use the results from [5] and represent the computation in an equivalent form, as the Householder QR factorization of the augmented matrix

$$\begin{bmatrix} 0 \\ F \end{bmatrix} = \begin{bmatrix} 0 \\ A + \delta_1 A \end{bmatrix}\hat{V}.$$

By Lemma 3.2, the following relations hold:

$$\begin{bmatrix} \tilde{\phi}_{k+1}e_k + \tilde{\psi}_{k+1}e_{k+1} \\ 0 \end{bmatrix} = \hat{P}_{k+1}\hat{P}_k\left\{\begin{bmatrix} 0 \\ f_{k+1} \end{bmatrix} + \begin{bmatrix} \Delta f_{k+1} \\ \delta f_{k+1} \end{bmatrix}\right\},$$

$$\left\|\begin{bmatrix} \Delta f_{k+1} \\ \delta f_{k+1} \end{bmatrix}\right\|_2 \leq O(bm)\varepsilon\|F\|_F,$$

where

$$\hat{P}_k = I_{m+n} - \begin{bmatrix} -e_k \\ \hat{u}_k \end{bmatrix}\begin{bmatrix} -e_k^T & \hat{u}_k^T \end{bmatrix},$$

and $\hat{u}_k = \tilde{s}_k/\|\tilde{s}_k\|_2$ is the exact vector with $\|\hat{u}_k\|_2 = 1$. Putting all columns of $\tilde{B}$ together, we get

$$\begin{aligned}\begin{bmatrix} \tilde{B} \\ 0 \end{bmatrix} &= \left[\begin{bmatrix} \tilde{\psi}_1 e_1 \\ 0 \end{bmatrix}, \begin{bmatrix} \tilde{\phi}_2 e_1 + \tilde{\psi}_2 e_2 \\ 0 \end{bmatrix}, \ldots, \begin{bmatrix} \tilde{\phi}_n e_{n-1} + \tilde{\psi}_n e_n \\ 0 \end{bmatrix}\right]\\ &= \left[\hat{P}_1\begin{bmatrix} \Delta f_1 \\ f_1 + \delta f_1 \end{bmatrix}, \hat{P}_2\hat{P}_1\begin{bmatrix} \Delta f_2 \\ f_2 + \delta f_2 \end{bmatrix}, \ldots, \hat{P}_n\hat{P}_{n-1}\begin{bmatrix} \Delta f_n \\ f_n + \delta f_n \end{bmatrix}\right],\end{aligned}$$

and using the fact that

$$\hat{P}_i \begin{bmatrix} \tilde{B}(:,j) \\ 0 \end{bmatrix} = \begin{bmatrix} \tilde{\phi}_j e_{j-1} + \tilde{\psi}_j e_j \\ 0 \end{bmatrix} = \begin{bmatrix} \tilde{B}(:,j) \\ 0 \end{bmatrix} \quad \text{for all } i \neq j, j-1,$$

we obtain

$$\begin{aligned} \begin{bmatrix} \tilde{B} \\ 0 \end{bmatrix} = \Bigg[ & \hat{P}_n \hat{P}_{n-1} \dots \hat{P}_2 \hat{P}_1 \begin{bmatrix} \Delta f_1 \\ f_1 + \delta f_1 \end{bmatrix}, \hat{P}_n \hat{P}_{n-1} \dots \hat{P}_2 \hat{P}_1 \begin{bmatrix} \Delta f_2 \\ f_2 + \delta f_2 \end{bmatrix}, \\ & \hat{P}_n \hat{P}_{n-1} \dots \hat{P}_3 \hat{P}_2 \begin{bmatrix} \Delta f_3 \\ f_3 + \delta f_3 \end{bmatrix}, \hat{P}_n \hat{P}_{n-1} \dots \hat{P}_4 \hat{P}_3 \begin{bmatrix} \Delta f_4 \\ f_4 + \delta f_4 \end{bmatrix}, \\ & \dots, \hat{P}_n \hat{P}_{n-1} \hat{P}_{n-2} \begin{bmatrix} \Delta f_{n-1} \\ f_{n-1} + \delta f_{n-1} \end{bmatrix}, \hat{P}_n \hat{P}_{n-1} \begin{bmatrix} \Delta f_n \\ f_n + \delta f_n \end{bmatrix} \Bigg]. \end{aligned}$$

The $k$th column of the computed bidiagonal matrix is of the form

$$\hat{P}_n \hat{P}_{n-1} \dots \hat{P}_k \hat{P}_{k-1} \begin{bmatrix} \Delta f_k \\ f_k + \delta f_k \end{bmatrix},$$

and the desired form is

$$\hat{P}_n \hat{P}_{n-1} \dots \hat{P}_2 \hat{P}_1 \begin{bmatrix} \hat{\Delta} f_k \\ f_k + \hat{\delta} f_k \end{bmatrix} = \hat{\mathcal{P}}^T \begin{bmatrix} \hat{\Delta} f_k \\ f_k + \hat{\delta} f_k \end{bmatrix}, \quad \mathcal{P} = \hat{P}_1 \hat{P}_2 \dots \hat{P}_{n-1} \hat{P}_n.$$

The first two columns ($k = 1, 2$) are already in the desired form and $\hat{\Delta} f_k = \Delta f_k$, $\hat{\delta} f_k = \delta f_k$. For $k \geq 3$ we write

$$\begin{bmatrix} \tilde{B}(:,k) \\ 0 \end{bmatrix} = (\hat{P}_n \hat{P}_{n-1} \dots \hat{P}_k \hat{P}_{k-1} \overbrace{\hat{P}_{k-2} \dots \hat{P}_2 \hat{P}_1)(\hat{P}_1 \hat{P}_2 \dots \hat{P}_{k-2})}^{I} \begin{bmatrix} \Delta f_k \\ f_k + \delta f_k \end{bmatrix},$$

and then

$$\begin{aligned} \hat{P}_1 \hat{P}_2 \dots \hat{P}_{k-2} \begin{bmatrix} \Delta f_k \\ f_k + \delta f_k \end{bmatrix} &= \begin{bmatrix} 0 \\ f_k \end{bmatrix} + \begin{bmatrix} \Delta_1 f_k \\ \delta_1 f_k \end{bmatrix} + \hat{P}_1 \begin{bmatrix} \Delta_2 f_k \\ \delta_2 f_k \end{bmatrix} + \hat{P}_1 \hat{P}_2 \begin{bmatrix} \Delta_3 f_k \\ \delta_3 f_k \end{bmatrix} \\ &\quad + \dots + \hat{P}_1 \dots \hat{P}_{k-3} \begin{bmatrix} \Delta_{k-2} f_k \\ \delta_{k-2} f_k \end{bmatrix} + \hat{P}_1 \dots \hat{P}_{k-2} \begin{bmatrix} \Delta f_k \\ \delta f_k \end{bmatrix} \\ &= \begin{bmatrix} 0 \\ f_k \end{bmatrix} + \begin{bmatrix} \hat{\Delta} f_k \\ \hat{\delta} f_k \end{bmatrix}, \end{aligned}$$

where

$$\begin{bmatrix} \Delta_j f_k \\ \delta_j f_k \end{bmatrix} = \begin{bmatrix} e_j \\ -\hat{u}_j \end{bmatrix} (\hat{u}_j^T f_k), \quad j = 1, \dots, k-2,$$

with

$$\begin{bmatrix} \hat{\Delta} f_k \\ \hat{\delta} f_k \end{bmatrix} = \hat{P}_1 \cdots \hat{P}_{k-2} \begin{bmatrix} \Delta f_k \\ \delta f_k \end{bmatrix} + \begin{bmatrix} \Delta_1 f_k \\ \delta_1 f_k \end{bmatrix} + \sum_{j=2}^{k-2} \hat{P}_1 \dots \hat{P}_{j-1} \begin{bmatrix} \Delta_j f_k \\ \delta_j f_k \end{bmatrix}.$$

Hence,

$$\begin{aligned} \begin{bmatrix} \tilde{B} \\ 0 \end{bmatrix} &= \hat{\mathcal{P}}^T \left[ \begin{bmatrix} \hat{\Delta} f_1 \\ f_1 + \hat{\delta} f_1 \end{bmatrix}, \dots, \begin{bmatrix} \hat{\Delta} f_k \\ f_k + \hat{\delta} f_k \end{bmatrix}, \dots, \begin{bmatrix} \hat{\Delta} f_n \\ f_n + \hat{\delta} f_n \end{bmatrix} \right] \\ &= \hat{\mathcal{P}}^T \left\{ \begin{bmatrix} 0 \\ F \end{bmatrix} + \begin{bmatrix} \Delta F \\ \delta F \end{bmatrix} \right\}, \end{aligned}$$

where, after suitable reordering of the entries in the sums,

$$\begin{bmatrix}\Delta F\\ \delta F\end{bmatrix} = \left[\begin{bmatrix}\Delta f_1\\ \delta f_1\end{bmatrix}, \begin{bmatrix}\Delta f_2\\ \delta f_2\end{bmatrix}, \dots, \hat{P}_1\dots\hat{P}_{k-2}\begin{bmatrix}\Delta f_k\\ \delta f_k\end{bmatrix}, \dots, \hat{P}_1 \dots \hat{P}_{n-2}\begin{bmatrix}\Delta f_n\\ \delta f_n\end{bmatrix}\right]$$
$$+ \sum_{j=1}^{n-2}\hat{P}_1\dots\hat{P}_{j-1}\left[\underbrace{0,\ \dots\ ,0,}_{j+1}\ \begin{bmatrix}\Delta_j f_{j+2}\\ \delta_j f_{j+2}\end{bmatrix},\dots,\begin{bmatrix}\Delta_j f_n\\ \delta_j f_n\end{bmatrix}\right].$$

Taking norms, we obtain

$$\begin{aligned}\left\|\begin{bmatrix}\Delta F\\ \delta F\end{bmatrix}\right\|_F &\leq O(bm\sqrt{n})\varepsilon\|F\|_F + \sqrt{2}\sum_{j=1}^{n-2}\|\hat{u}_j^T\begin{bmatrix} f_{j+2} & f_{j+3} & \dots & f_n\end{bmatrix}\|_2\\ &\leq O(bm\sqrt{n})\varepsilon\|F\|_F + \sqrt{2}\sum_{j=1}^{n-2}(\|\tilde{u}_j^T\tilde{A}_{g+1,r-1}(:,j+2\colon n)\|_2\\ &\quad +\|\delta\hat{u}_j\|_2\|F(:,j+2\colon n)\|_F).\end{aligned}$$

It remains to estimate the products $\tilde{u}_i^T f_\ell$ for $\ell = 3,\dots,n$ and $i = 1,\dots,\ell-2$, where $\ell = (j-1)b+k$, $k = 1,\dots,b$. For this estimate, the important role plays the choice of the vector $z_{j,k}$. From Lemma 3.3 it follows that

$$\|\tilde{u}_\ell^T\tilde{A}_{g+1,r-1}(:,\ell+2\colon n)\|_2 \leq O(b^2n + bm + bn^2)\varepsilon\|A\|_F.$$

Then

$$\left\|\begin{bmatrix}\Delta F\\ \delta F\end{bmatrix}\right\|_F \leq O(b(mn+n^3))\varepsilon\|F\|_F \leq O(b(mn+n^3))(1+\eta_F)\|A\|_F.$$

To get the relation (3.9), we collect the perturbations from both implicit tridiagonalization and the Gram-Schmidt computation

$$\begin{aligned}\begin{bmatrix}\tilde{B}\\ 0\end{bmatrix} &= \hat{\mathcal{P}}^T\left\{\begin{bmatrix}0\\ F\end{bmatrix} + \begin{bmatrix}\Delta F\\ \delta F\end{bmatrix}\right\} = \hat{\mathcal{P}}^T\left\{\begin{bmatrix}0\\ A+\delta_1 A\end{bmatrix}\hat{V} + \begin{bmatrix}\Delta F\\ \delta F\end{bmatrix}\right\}\\ &= \hat{\mathcal{P}}^T\left\{\begin{bmatrix}0\\ A+\delta_1 A\end{bmatrix} + \begin{bmatrix}\Delta F\\ \delta F\end{bmatrix}\hat{V}^T\right\}\hat{V}.\end{aligned}$$

3. Finally, using $\mathcal{P}_{11} = \mathcal{P}(1\colon n, 1\colon n)$, $\mathcal{P}_{21} = \mathcal{P}(n+1\colon n+m, 1\colon n)$, we have

$$\begin{bmatrix}\Delta A\\ A+\delta A\end{bmatrix}\hat{V} = \begin{bmatrix}\mathcal{P}_{11}\\ \mathcal{P}_{21}\end{bmatrix}\tilde{B},\ \ \mathcal{P}_{11}^T\mathcal{P}_{11} + \mathcal{P}_{21}^T\mathcal{P}_{21} = I,$$

and (3.10) follows by an application of [5, Lemma 3.1]. The proof that (3.10) holds for the nonblock version of the algorithm is given in Theorem 3.18 [3]. The same arguments can be applied to the block version.

Note that in (3.10) we can write $A + \breve{\delta A} = \breve{U}\tilde{B}\tilde{V}^T(I+\Gamma)$, $\|\Gamma\|_F \leq O(n^2)\varepsilon$. □

In our numerical experiments, the optimal choice for the block dimension $b$ was usually 16, so the accuracy predicted by the bound in Theorem 3.4 is close to the accuracy predicted by Theorem 2.1.

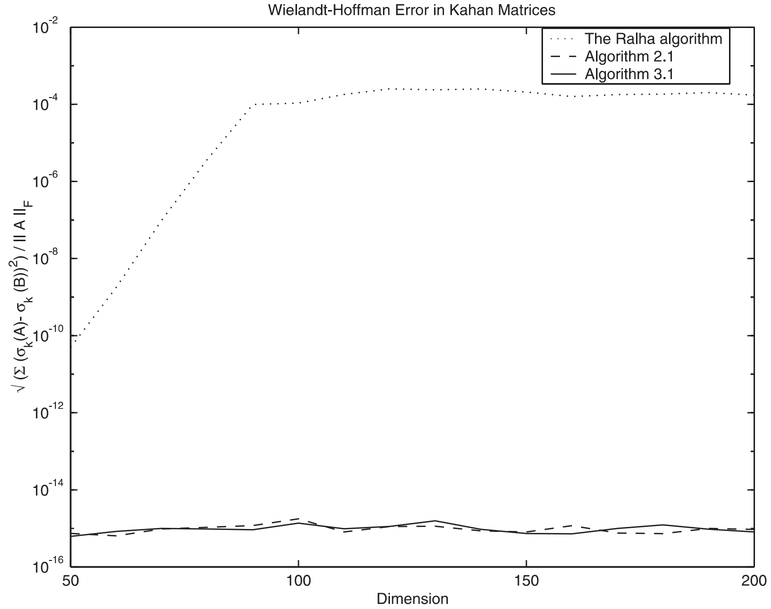

FIG. 3.2. *Error in singular values from Example* 3.1.

[illegible] 3.1. Let $A = [a_{ij}]$ be the $n \times n$ Kahan matrix as in [3], with

$$a_{ij} = \begin{cases} \alpha^{i-1} & i = j, \\ -\alpha^{j-1}\beta & i > j, \end{cases}$$

where $\alpha^2 + \beta^2 = 1$ and $\alpha, \beta > 0$. For our tests we chose $\alpha = \sin(1.2)$ and $n = 50, 60, \ldots, 200$. In this case the matrices are ill-conditioned. The first $n-1$ singular values gradually decay and are bounded away from zero, but, on the other hand, the smallest singular value decays rapidly with $n$.

We compare the accuracy of Algorithm 3.1 with Algorithm 2.1 and Ralha's one-sided bidiagonalization, by using the Wielandt–Hoffman measure

$$\frac{\sqrt{\displaystyle\sum_{k=1}^{n}(\sigma_k(A) - \sigma_k(B))^2}}{\|A\|_F}. \tag{3.11}$$

This example is performed in MATLAB and in double precision. The one-sided bidiagonalization routines are implemented in the same way as the FORTRAN routines in the next section. The singular values $\sigma_k(A)$ of the matrix $A$ are computed by the MATLAB command `svd()`. The results are shown in Figure 3.2.

We can note that Algorithm 3.1 sometimes produces the bidiagonal matrix $B$ with slightly less accurate singular values than Algorithm 2.1. Theorem 3.4 asserts that the bound on (3.11) for Algorithm 3.1 is $b$ times larger than the corresponding bound for Algorithm 2.1, where $b$ is the block dimension. In our case, we took $b = 16$. If we compare the computed errors measured by (3.11), we can see that the largest difference is obtained for $n = 180$, where the error of Algorithm 3.1 is 1.67 times larger than the error of Algorithm 2.1. In this case, the estimation of the error bounds on

(3.11) from Theorems 2.1 and 3.4 are

| Algorithm 2.1 | Algorithm 3.1 |
|---|---|
| $(n^2+n^3)\varepsilon = 6.51 \cdot 10^{-10}$ | $b(n^2+n^3)\varepsilon = 1.04 \cdot 10^{-8}$ |

Hence, our computed results are in accordance with the approximate bounds in Theorems 2.1 and 3.4 and reveal that these bounds can significantly overestimate the actual error.

Similar to the results of Björck and Paige in [5], Corollary 3.18 in [3] states that for the nonblock version of one-sided bidiagonalization algorithm we have

$$\|\tilde{U}^T\tilde{U} - I\|_F \leq p(m,n)\kappa_2(\tilde{B})\varepsilon + O(\varepsilon^2), \tag{3.12}$$

where $\tilde{U}$ is the computed matrix of left singular vectors, $p(m,n)$ is a polynomial with modest degree, and $\kappa_2(\tilde{B}) = \|\tilde{B}\|_2\|\tilde{B}^{-1}\|_2$. In fact, arguments given in the proof of this corollary hold for any bidiagonalization algorithm for which Theorem 3.4 can be proved. That means that if $B$ is ill-conditioned, $\tilde{U}$ might be far from left orthogonal matrix, but sometimes the bound in (3.12) is too pessimistic.

On the other hand, suppose that a numerically backward stable SVD is performed on the matrix $\tilde{B}$ from Theorem 3.4, obtaining matrices $\tilde{Y}$, $\tilde{\Sigma}$, and $\tilde{W}$. From [3, Theorem 3.7] it follows that there exists a perturbation $\hat{\delta A}$ such that $A + \hat{\delta A} = \tilde{P}\tilde{\Sigma}\tilde{Q}^T$, where $\tilde{P} = \tilde{U}\tilde{Y}$, $\tilde{Q} = \tilde{V}\tilde{W}$, and $\|\hat{\delta A}\|_F \leq O(\varepsilon)\|A\|_F$. $\tilde{P}$ can be considered as a matrix of computed left singular vectors of $A$, $\tilde{Q}$ as a matrix of computed right singular vectors of $A$, and $\tilde{\Sigma} = \mathrm{diag}(\tilde{\sigma}_1, \ldots, \tilde{\sigma}_n)$, where $\tilde{\sigma}_1 \geq \cdots \geq \tilde{\sigma}_n$, is a matrix of computed singular values. By the same argument as in Corollary 3.20 in [3], we can state that

$$\|\tilde{P}_1^T\tilde{P}_1 - I\|_F \leq q(m,n)\frac{\tilde{\sigma}_1}{\tilde{\sigma}_k}\varepsilon + O(\varepsilon^2),$$

where $\tilde{P}_1$ is a matrix which contains $k$ computed left singular vectors that correspond to the $k$ largest singular values, and $q(m,n)$ is a polynomial with modest degree. This shows that the basis for the leading principal subspace of left singular vectors can be computed with near orthogonality.

## 4. Efficiency of the stable block one-sided bidiagonalization.

For the block version of the new stable one-sided bidiagonalization, extensive testing was carried out. Computations were performed in the Advanced Computing Laboratory of the Department of Mathematics, University of Zagreb. The laboratory consists of 20 computers, connected in a local 1Gb network. The specifications of the computers are shown in Table 4.1.

The computers are working under a Debian GNU/Linux operating system. The tests were written in FORTRAN 77 programming language, and a GNU (v0.5.24)

compiler with optimization (option "-O") was used to obtain executable files. LAPACK and BLAS routines were called in these programs, and ATLAS (Automatically Tuned Linear Algebra Software) tuned for Athlon processors was used to implement BLAS routines. Tests were done in single precision. Matrices in the tests were generated as products $A = U\Sigma V^T$, where $\Sigma$ is a diagonal matrix with fixed singular values $\{1, 2, \dots, n\}$, and $U$ and $V$ are random orthogonal matrices.

The block dimensions $b$ and $c$ in the tests were chosen to obtain the best execution time. In our case it turned out to be $b = 16$, and we took $c = 8$. Table 4.2 gives average execution times for full SVD algorithms, expressed in seconds.

The meaning of the headers in Table 4.2 are as follows:

$t_1$ — the SVD with Algorithm 2.1 for bidiagonalization. The LAPACK routine `sbdsqr()` is used for the SVD of a bidiagonal matrix, which implements the bidiagonal QR algorithm.

$t_2$ — the SVD with Algorithm 3.1 for bidiagonalization. The LAPACK routine `sbdsqr()` is used for the SVD of a bidiagonal matrix, which implements the bidiagonal QR algorithm.

$t_L$ — the LAPACK `sgesvd()` routine.

$p_{2,1} = 100(t_1 - t_2)/t_1$ — the percentage of time decrease, when the SVD with Algorithm 3.1 is compared to the SVD with Algorithm 2.1.

$p_{2,L} = 100(t_L - t_2)/t_L$ — the percentage of time decrease, when the SVD with Algorithm 3.1 is compared to the LAPACK routine.

* — the time was measured for 10 consecutive executions of the routines and then divided by 10.

** — QR factorization is performed before the SVD with Algorithms 2.1 and 3.1 for bidiagonalization.

We can conclude that the block version of the one-sided bidiagonalization algorithm did decrease the execution time of Algorithm 2.1, as expected. Compared to the SVD with Algorithm 2.1 the most significant time decrease is 25.00% for matrix dimensions 1000 × 100. The SVD routine with Algorithm 3.1 produces a code that is not slower than the LAPACK `sgesvd()` routine in most cases when all of the SVD factors are required, although this varies with the dimensions of the matrix. In many cases we observed some gains in speed. Here it should be emphasized that the QR factorization was not applied before the one-sided bidiagonalization algorithms except in cases denoted by $^{**}$, and we can note that the one-sided bidiagonalization algorithms achieved the largest speedup compared to the LAPACK routine when $m$ is much larger than $n$. This can be explained by the fact that the SVD with the one-sided bidiagonalization algorithm has a smaller operation count than the LAPACK `sgesvd()` routine (see [3, Table 1]). On the other hand, for dimensions $1000 \times 500$, $2000 \times 200$, and $2000 \times 1000$ the QR factorization was necessary to make Algorithm 3.1 faster than the `sgesvd()` routine. It seems that the memory hierarchy was utilized better that way. If the matrix $U$ is not needed, then the advantage of the one-sided bidiagonalization over the LAPACK routine might be lost. That happens because $U$ is always computed, whether it is needed or not (see [3, Table 1]). When solving the problems described in [8], our algorithm would be preferable since possible loss of orthogonality of the matrix $\tilde{U}$ is irrelevant in these cases, and the SVD with the one-sided bidiagonalization algorithm is often faster than the LAPACK routine.

**5. Parallel version of the new stable one-sided bidiagonalization.** The parallel bidiagonalization algorithm is performed on several processors simultaneously. Each matrix is distributed over the memories of all processors, and this distribution is balanced. This means that the dimensions of the submatrices assigned to each processor are almost the same. It is important to minimize communication between processors, as the time spent for communication can be expected to be a significant part of the overall execution time.

In our case we used the following setting:

- the processors were organized in linear order:

$$\boxed{\;1\;} \longleftrightarrow \boxed{\;\mathbf{2}\;} \longleftrightarrow \boxed{\;\mathbf{3}\;} \longleftrightarrow \boxed{\;\mathbf{4}\;};$$

- we used ScaLAPACK [6] for the computation;
- we used the message passing interface [22] for the interprocessor communication.

The matrix distribution over the processors is performed rowwise, because the algorithm is one-sided and column-oriented.

The most important features of the parallel version of the stable one-sided bidiagonalization algorithm are the following:

1. The matrix layout is one-dimensional block-cyclic row distribution. Each $m \times n$ matrix is divided in $m_b \times n$ blocks of contiguous rows, where $m_b$ is the block row dimension. Then the blocks are distributed across the processors in cyclic order, which guarantees good load balancing (see Figure 5.1 and [6]).
2. The algorithm is performed in the same way as Algorithm 2.1, with extra interprocessor communication. Interprocessor communication is required for:
    - computation of $z_k$ as matrix–vector multiplication,
    - broadcasting the vector $z_k$ to all processors,
    - computing scalar products.

   The rest of the computations consist of BLAS 1 operations (operations with vectors), as well as computation and application of Householder reflectors, which need no additional communication.

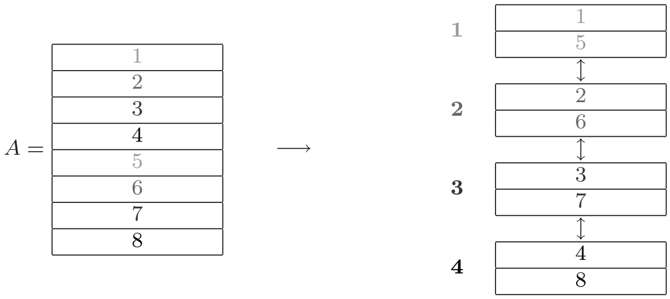

FIG. 5.1. *The block distribution of the matrix A.*

The complete parallel algorithm with explanations is listed in Algorithm 5.1.

ALGORITHM 5.1. [illegible] $A \in \mathbb{R}^{m\times n}$ rank$(A) = n > 2$ [illegible] $U = [u_1, \dots, u_n]$ [illegible] $B$ [illegible] $V$ [illegible] $A = UBV^T$

```
(1) Distribute $\Psi = [\ \psi_1 \ \dots \ \psi_n\ ]^T$ over the processors;
(2) distribute $\Phi = [\ \phi_1 \ \dots \ \phi_{n-1}\ ]^T$ over the processors;
(3) $A_0 = A$.
(4) $f_1 = A(:,1)$. $\psi_1 = \|f_1\|_2$.                         [illegible]
(5) $u_1 = f_1/\psi_1$.                                          [illegible] 1 [illegible]
                                                                 [illegible]
for $k = 1: n-2$
    (6) $z_k = A_{k-1}(:, k+1: n)^T u_k$.                        [illegible]
    (7) $[\phi_{k+1}, v_k] = $ householder$(z_k)$.                [illegible] $v_k$ [illegible] $\phi_{k+1}$.
    (8) $A_k(:, 1: k) = A_{k-1}(:, 1: k)$.
    (9) $A_k(:, k+1: n) = A_{k-1}(:, k+1: n) - A_{k-1}(:, k+1: n)v_k v_k^T$.
                                                                 [illegible]
    (10) $f_{k+1} = A_k(:, k+1)$.
    (11) $s_{k+1} = f_{k+1} - \phi_{k+1}u_k$.                    [illegible] 1 [illegible]
                                                                 [illegible]
    (12) $\psi_{k+1} = \|s_{k+1}\|_2$.                            [illegible]
    (13) $u_{k+1} = s_{k+1}/\psi_{k+1}$.                          [illegible] 1 [illegible]
                                                                 [illegible]
end.
(14) $f_n = A_{n-2}(:, n)$. $\phi_n = u_{n-1}^T f_n$.             [illegible]
(15) $s_n = f_n - \phi_n u_{n-1}$.                                [illegible] 1 [illegible]
                                                                 [illegible]
(16) $\psi_n = \|s_n\|_2$.                                        [illegible]
(17) $u_n = s_n/\psi_n$.                                          [illegible] 1 [illegible]
                                                                 [illegible]
(18) $V^T = $ householder_product$(v_1, \dots, v_{n-2})$           [illegible]
end.
```

The parallel version of the stable bidiagonalization algorithm performs the same operations as the serial nonblock version. Preliminary numerical experiments showed that a parallel block version, applying Algorithm 3.1 in parallel, has a large overhead on our computers; thus, it was almost always slower than the ScaLAPACK routine. The results of Theorem 2.1 hold for Algorithm 5.1 as well.

## 6. Efficiency of the stable parallel one-sided bidiagonalization.

**6.1. Tests performed at the Advanced Computing Laboratory.** The tests for the parallel version of the new stable bidiagonalization algorithm were done over a large variety of matrix dimensions. The computations were performed in the computational environment described in section 4 and matrices were generated in the same way. QR factorization was not performed before bidiagonalization, because Algorithm 5.1 is suitable for the parallel computing in its original form. The QR factorization would just increase the interprocessor communication. The tests confirmed this statement even for the ScaLAPACK `psgesvd()` routine, where in most cases the QR factorization introduced before bidiagonalization caused a slowdown in producing the full SVD. The block cyclic distribution was also used for testing the ScaLAPACK routine, but the linear layout of the processors may not always be optimal for this routine. So in this case we performed our test with all possible layouts for the fixed processor number, and we chose the best execution time. The parallel tests were performed over a variety of block dimensions, where block column and row dimensions were the same. The block dimensions were chosen from the set $\{8, 16, 32, 64, 128, 256\}$, and the best execution time among block dimensions was displayed in Table 6.1. For the SVD with Algorithm 5.1 the block dimension was equal to 8 in most cases, and for the ScaLAPACK SVD routine it was equal to 32 in most cases. Table 6.1 gives the average execution times expressed in seconds for full SVD algorithms when computed on $p$ processors. The meaning of the headers in Table 6.1 are as follows:

$t_3$ — the parallel SVD with Algorithm 5.1.
$p_m \times p_n$ — processor layout with the best execution time of the ScaLAPACK routine.
$t_S$ — the ScaLAPACK `psgesvd()` routine.
$p_{3,S} = 100(t_S - t_3)/t_S$ — the percentage of time decrease, when the parallel SVD with Algorithm 5.1 is compared to the ScaLAPACK routine.
$\eta_{3,p} = (t_2/t_3)/p$ — the efficiency of the parallel SVD with Algorithm 5.1 on $p$ processors.
$\eta_{S,p} = (t_L/t_S)/p$ — the efficiency of the ScaLAPACK routine on $p$ processors.

As we can see from Table 6.1, we accomplished a considerable decrease in execution time for $m \times n$ matrices when $m > n$. In that case the SVD with the described parallel version of the one-sided bidiagonalization algorithm is much faster than the ScaLAPACK routine `psgesvd()`. Compared to the ScaLAPACK routine, the most significant time decrease is 68.28% for matrix dimensions $5000 \times 100$ and for 8 processors. On the other hand, for squared matrices the ScaLAPACK routine is up to 55.08% faster, and in this case a block version of the parallel one-sided algorithm is required. Efficiency of such block algorithms is described in the next subsection.

Another important feature of parallel algorithms is the efficiency. In an ideal situation an algorithm executed on $p$ processors should be $p$ times faster than the same algorithm executed on only one processor. The efficiency measures departure from the ideal execution time. Table 6.1 shows the efficiency for both SVD algorithms applied

Table 6.1

to matrices with small dimensions. In the case of larger dimensions we were not able to run the codes on a single processor due to memory limitations, and therefore the efficiency is not computed. We can see that the parallel SVD with Algorithm 5.1 has better efficiency than the ScaLAPACK routine `psgesvd()` in all cases. The new algorithm has also better scalability than the ScaLAPACK routine when the number of processors is increased from 4 to 8 processors, which is illustrated in Figure 6.1. The $y$ axis in Figure 6.1 represents the reduction factor in execution time when the number of processors is doubled and the matrix dimensions are fixed. The labels on the $x$ axis denote matrix dimensions and ratios $p_1/p_2$, which indicate that the number of processors is increased from $p_1$ to $p_2$. Theoretically, the reduction factor in the execution time, when the number of processors is doubled, is bounded by 2. However, in two cases we obtained a reduction factor greater than 2, once for the one-sided bidiagonalization and once for the ScaLAPACK routine. This "superlinear speedup" is usually explained by the fact that, as we reduce the amount of data per processor, a larger percentage of the local data is stored in the caches, thus reducing the memory traffic overheads. So it appears that, in this case, such savings in time are more than enough to pay for the extra time required by the communication involving twice as many processors. We can conclude that, for squared matrices in case the number of processors is increased from 8 to 16 processors, the ScaLAPACK routine becomes much more efficient since it is a blocked algorithm. This illustrates the importance of the block algorithms and gives us a motivation for developing an efficient block parallel version of the one-sided bidiagonalization algorithm.

**6.2. Tests performed at the High Performance Computing Center North.** The same tests as in subsection 6.1 were also performed on the "Sarek" cluster at the High Performance Computing Center North Sweden. The cluster con-

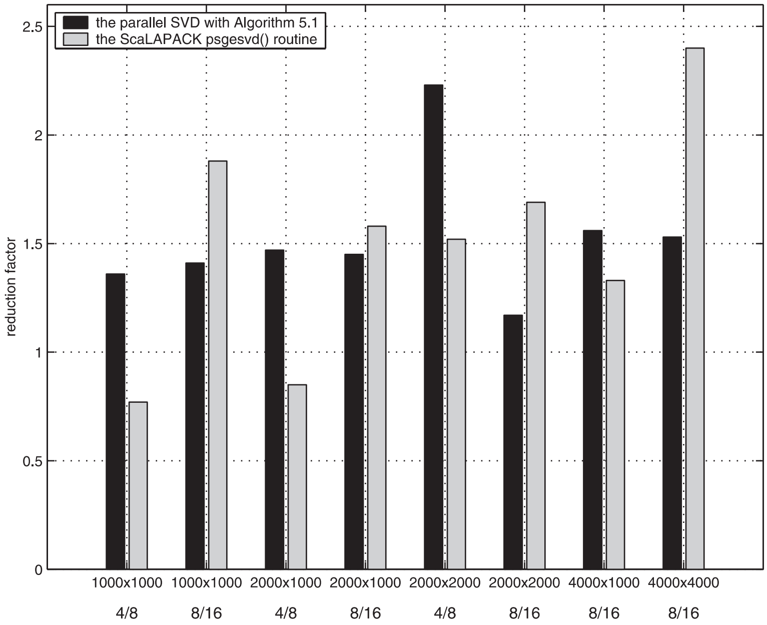

FIG. 6.1. *Reduction in execution time in the case when the number of processors is doubled.*

sists of 190 nodes, connected to a Gigabit ethernet communication network and to a Myrinet high-performance network. The specifications of the nodes are shown in Table 6.2. The nodes are working under a Debian GNU/Linux operating system. The test codes were compiled with MPIF77 1.2.5.12 and PGF77 with optimization (option "-fast"). "Goto BLAS" (r0.94) was used to implement BLAS routines. QR factorization was not performed before bidiagonalization. Table 6.3 gives the execution times expressed in seconds for full SVD algorithms when computed on $p$ processors. Four rounds of tests were performed with four different parallel variants of the stable one-sided bidiagonalization algorithm. In each round the one-sided bidiagonalization routine was executed together with the ScaLAPACK `psgesvd()` routine for comparison. Due to the lack of space in Table 6.3, instead of the execution time of the ScaLAPACK routine $t_S$ we present the ratio $t_i/t_S$, where $t_i$ is the execution time of the $i$th version of the parallel bidiagonalization algorithm.

The meaning of the headers in Table 6.3 are as follows:

| | | |
|---|---|---|
| $t_S$ | — | the ScaLAPACK `psgesvd()` routine. |
| $t_3$ | — | the parallel SVD with Algorithm 5.1. |
| $t_4$ | — | the parallel SVD with a modified one-sided bidiagonalization algorithm. Campos et al. [9] have proposed a modification of the stable one-sided bidiagonalization. This version reduces communications events |

$t_5$ — the parallel SVD with a block one-sided bidiagonalization algorithm. It is a simplified block version of the one-sided bidiagonalization. Only the application of the Householder reflectors is aggregated, but the BLAS 2.5 approach is not used since it introduces one matrix-vector product more per iteration.

$t_6$ — the parallel SVD with a modified block one-sided bidiagonalization algorithm. It is the blocked version with the modification of Campos et al.

As we can see from Table 6.3, the situation on the Sarek cluster is a little bit different from the situation described in subsection 6.1. The Sarek cluster has very fast interprocessor communication and Algorithm 5.1 is not so favorable as it was on the cluster of computers in the Advanced Computing Laboratory in the case when $m > n$. The worst result was obtained for matrix dimensions $10000 \times 1000$ and 16 processors when the execution time of the parallel SVD with Algorithm 5.1 was 1.46 times longer than the execution time of `psgesvd()`. This was the reason for developing three additional implementations of the parallel stable one-sided bidiagonalization routines, which are explained in the description of Table 6.3. The modification of Campos and his coauthors proposes reduction in communication events. This is achieved by simultaneous execution of the operations in steps **(6)** and **(12)** of Algorithm 5.1, since each of these operations presents a communication event. Thus instead of two communication events, only one is performed per iteration. The work of Campos et al. was developed independently of the work presented in this paper. The block parallel implementation is similar to Algorithm 3.1, except that BLAS 2.5 operations are not implemented. We can conclude that the presented variants of Algorithm 3.1 did gain some speedup and that block and modified block algorithms are faster than the

ScaLAPACK routine in most cases. For some matrix dimensions these two variants are up to 21.5% faster. On the other hand, the matrix dimension 10000 × 1000 for 16 processors remains critical. We achieved a reduction in slowdown from 45.53% to 18.25%, but the ScaLAPACK routine is still faster in this case. There is still an open question of whether we can make our parallel implementation of the one-sided bidiagonalization more efficient on the clusters with a fast network. This will be the subject of our future work.

**7. Conclusion.** Ralha's one-sided bidiagonalization [29] performs fewer operations than the standard Golub–Kahan bidiagonalization [20], but it is numerically unstable. Barlow's modification [3] of Ralha's algorithm avoided this problem, so the new algorithm became numerically backward stable for computing the matrices $\Sigma$ and $V$, with the same operation count. On modern computers, a smaller operation count does not necessarily lead to reduced execution times, due to the time spent on communication between different levels of memory. This is the reason why we have developed block and parallel versions of the new stable one-sided bidiagonalization algorithm. The block version optimizes the usage of faster memory, without sacrificing numerical backward stability. As numerical tests demonstrate, the SVD algorithm with the block one-sided bidiagonalization is faster than the corresponding LAPACK routine. The stable one-sided bidiagonalization is more suitable for parallelization than the corresponding ScaLAPACK routine. The tests established improvement of the parallel one-sided bidiagonalization when compared with the ScaLAPACK routine in most cases. In the best case our algorithm is 68.28% faster than the ScaLAPACK routine on a cluster with slow interprocessor communication and 21.5% faster on a cluster with fast interprocessor communication. From the numerical point of view it is equivalent to the original stable one-sided algorithm proposed in [3] or its block version and thus numerically stable in the same way. In the future we will work on the more efficient parallel version of the stable one-sided bidiagonalization.

**Acknowledgments.** We thank Zlatko Drmač and Daniel Kressner for carefully reading the paper and making many helpful suggestions. Rui Ralha and Carlos Campos are developing one-sided bidiagonalization software, and we thank them for their support. We also thank both referees for helping us to make this paper better. This research was conducted using the resources of the High Performance Computing Center North (HPC2N).

# A CHEBYSHEV–DAVIDSON ALGORITHM FOR LARGE SYMMETRIC EIGENPROBLEMS*

YUNKAI ZHOU† AND YOUSEF SAAD‡

**Abstract.** A polynomial filtered Davidson-type algorithm is proposed for symmetric eigenproblems, in which the correction-equation of the Davidson approach is replaced by a polynomial filtering step. The new approach has better global convergence and robustness properties when compared with standard Davidson-type methods. The typical filter used in this paper is based on Chebyshev polynomials. The goal of the polynomial filter is to amplify components of the desired eigenvectors in the subspace, which has the effect of reducing both the number of steps required for convergence and the cost in orthogonalizations and restarts. Numerical results are presented to show the effectiveness of the proposed approach.

**Key words.** polynomial filter, Davidson-type method, global convergence, Krylov subspace, correction-equation, eigenproblem

## 1. Introduction.

We consider a Davidson-type method for the standard eigenvalue problem

$$Au = \lambda u, \tag{1.1}$$

where $A \in \mathbb{R}^{n\times n}$ is symmetric, $n$ is large, and a large number of eigenpairs need to be computed. We assume throughout that the eigenvalues wanted are the smallest ones. There is a growing need for solving this type of problem efficiently. To cite just one example, symmetric eigenvalue problems usually constitute the most time-consuming part of electronic structure calculations [18, 12, 6].

The original Davidson method [11] was initially designed for diagonally dominant matrices, which for eigenvalue problems means matrices whose off-diagonal elements are small compared with the changes in magnitude between diagonal elements [19]. The Davidson approach sacrifices the attractive Krylov subspace structure, at the cost of having to compute eigenpairs and associated residual vectors of a projection matrix at each (outer) iteration. The trade-off is that the Davidson approach can augment the subspace by a new vector potentially much better than the one based on a strict Krylov subspace structure.

The "augmentation vector" added to the subspace at each step usually results from solving a correction-equation. The efficiency of the standard Davidson-type methods depends on the quality of the correction-equation used. Efficient (preconditioned) linear equation solvers are often utilized to solve the correction-equations. The original Davidson method uses the correction-equation $(\mathrm{diag}(A) - \mu I)t = -r$, where

$r = Ax - \mu x$ is the residual vector corresponding to a Ritz pair $(\mu, x)$, and $t$ is the augmentation vector to be computed. In [19] better approximations of $A$ are used to replace the diagonal of $A$ in the correction equation. However, it was noted in [19] that using the "exact preconditioner" leads to stagnation, since $t = (A - \mu I)^{-1} r = -x$ cannot augment the subspace. This led to the development of the more efficient Jacobi–Davidson (JD) algorithm [32, 14, 31]. Work in the literature has shown that the JD can be competitive with efficient Krylov subspace methods such as those in [33, 17, 36, 42, 45]. In [41, 43] other correction-equations for Davidson-type methods are derived.

The JD method can be related to the Newton method or the approximate Rayleigh-quotient iteration (RQI). As such, it has been observed that the method can be rather slow if the starting vector is far away from the desired eigenvector. We note that even though RQI is globally convergent for symmetric eigenproblems (see [22], [23, p. 81]), it may converge to an unwanted eigenpair. The global convergence can be slow when the approximate RQI is used in a subspace method and the method is required to converge to wanted eigenpairs. Global acceleration schemes for JD have been studied. For example, in [5] a nonlinearized JD correction-equation is proposed; however, the preconditioning may be difficult to apply for the nonlinearized correction-equation, and the approach can become much more expensive than the JD method when the number of desired eigenpairs is large. Another approach to achieving better global convergence, as suggested in [19, 14], is to apply an Arnoldi or Lanczos method to get a good initial vector and then apply the JD algorithm.

In this paper, we explore a different Davidson-type approach called the Chebyshev–Davidson method. There is no need to form or solve any correction-equations within this approach; instead, intervalwise filtering based on Chebyshev polynomials is utilized.

The Chebyshev–Davidson approach is very suitable for problems where solving (preconditioned) equations is expensive, e.g., when good preconditioners for correction-equations are either unknown or too expensive to construct.

Details of the Chebyshev–Davidson method are presented in sections 3–4. Comparisons with existing representative eigenvalue algorithms are in section 6. The Chebyshev–Davidson method (written in Fortran95) has been applied to solve a class of highly challenging problems with dimension over a few millions, where more than ten thousand eigenpairs need to be computed.

## 2. Advantages of polynomial filtering.

The global convergence of a Davidson-type method can be improved in a natural and systematic way via polynomial filtering. We first make the following three observations. The first is on the well-known polynomial filtering argument: For a symmetric matrix $A$ with the eigendecomposition $A = Q\Lambda Q^T$, any polynomial $\psi(s) : \mathbb{R} \to \mathbb{R}$ satisfies

$$\psi(A)v = Q\psi(\Lambda)Q^T v \quad \forall v \in \mathbb{R}^n. \tag{2.1}$$

The second observation is on the fast local convergence of JD. It is shown in [43] that the locally fast convergence of JD is mainly caused by the retention of the approximate RQI direction in the basis of the projection subspace. Assume throughout that $(\mu, x)$ denotes the current Ritz pair that best approximates a wanted eigenvalue, and the Ritz vector $x$ is of unit length, and let $r = Ax - \mu x$ denote the residual. It was observed in [43] that the JD correction equation,

$$\text{Solve for } t \perp x \text{ from } \ (I - xx^T)(A - \mu I)(I - xx^T)t = r, \tag{2.2}$$

can be simplified to

$$\text{Solve for } t \text{ from } \ (I - xx^T)(A - \mu I)t = r. \tag{2.3}$$

The right projection by $(I - xx^T)$ and the final orthogonality constraint $t \perp x$ can be omitted. It is the approximate RQI direction, which is an approximation to $(A - \mu I)^{-1}x$, that leads to the success of the JD approach. The left projector $(I - xx^T)$ in (2.2) is crucial in retaining the important approximate RQI direction in the JD direction (solution $t$ of (2.2)). This can be readily seen by writing (2.2) or (2.3) as

$$(A - \mu I)t = r + x\ \alpha, \tag{2.4}$$

where $\alpha$ is a nonzero scalar. The left projector also improves the conditioning of (2.2) and (2.3) on the $x^{\perp}$ subspace—the subspace in which a vector to augment the current projection subspace is sought, but this property is irrelevant for this paper.

Note that the exact RQI direction is $(A-\mu I)^{-1}x$, which is the current Ritz vector $x$ filtered by the rational polynomial $\varphi(s) = \frac{1}{s-\mu}$. This polynomial significantly magnifies the direction of a possibly wanted eigenvector corresponding to the Ritz value $\mu$ (the current best approximation to a wanted eigenvalue of $A$).

The third observation is that one can improve global convergence by choosing a polynomial $\psi(s)$ which magnifies not only the direction corresponding to one single point, but also directions corresponding to an interval containing wanted eigenvalues, and at the same time dampens unwanted eigenvalues. With polynomial filtering, it is unlikely that wanted eigenvalues will be missed, because when the whole interval containing wanted eigenvalues is magnified, so is each wanted eigenvalue in the interval. In contrast, standard Davidson-type methods may miss some wanted eigenvalues. This is because correction-equations often resemble certain shift-invert formulations, and the shift chosen at some step may approximate larger eigenvalues before all the wanted smaller eigenvalues are computed. Chebyshev filtering offers an alternative which can improve global convergence as well as robustness (in the sense that wanted eigenvalues are not missed) of Davidson-type methods.

Note that polynomial filters have long been exploited to accelerate Arnoldi/Lanczos algorithms; see, e.g., [26, 33]. Here we consider a natural application of Chebyshev polynomials within a Davidson-type (non-Krylov) framework. This approach combines the acceleration power of the Chebyshev filtering technique and the flexibility and robustness of the Davidson approach.

To further explain the third observation, we suppose that the eigenvalues of $A$ are ordered as $\lambda_1 \le \lambda_2 \le \cdots \le \lambda_n$, and that the wanted eigenvalues are located in $[\lambda_1, \lambda_k]$. If $\psi(s)$ is chosen to approximate the step function

$$\phi(s) = \begin{cases} 1, & \lambda_1 \le s \le \lambda_k, \\ 0, & \lambda_k < s \le \lambda_n, \end{cases} \tag{2.5}$$

then (2.1) shows that $\psi(A)v \approx \sum_{i=1}^{k} \alpha_i q_i$, where $q_i$ is the $i$th column of $Q$ and $\alpha_i = q_i^T v$. That is, $\psi(A)v$ is contained in the subspace spanned by the wanted eigenvectors $Q(:, 1 : k)$. If this $\psi(A)v$ is augmented into the basis, convergence to the wanted eigenvectors is expected to be much faster than augmenting the basis by a vector closer to unwanted eigenvectors. This claim can be verified by explicitly computing $Q$ and using $\sum_{i=1}^{k} \alpha_i q_i$ $(\alpha_i = q_i^T x$, where $x$ denotes the current Ritz vector at each iteration) as the augmentation vector in a Davidson-type method. This is equivalent to using a filter that exactly approximates (2.5). Note that this filter leads to no gap among wanted eigenvalues, but in this ideal setting it can still lead to fast convergence in a Davidson-type method. However, a low degree polynomial cannot approximate (2.5) well. In real computations, a filter that can introduce more favorable gaps for the wanted eigenvalues is far better than others that introduce no gap.

For a subspace method applied to (1.1), the essence in obtaining fast convergence is in augmenting the subspace by vectors close to the wanted invariant subspace of $A$. Therefore, a convergence acceleration scheme should construct a suitable filter $\psi$ so that the vector $\psi(A)v$ used for augmentation is contained in the wanted eigensubspace. By this filtering we obtain better global convergence.

According to observations just made, it is essential to filter the current Ritz vector $x$, not the residual vector $r$. Note that at each iteration of a Davidson-type method, $r$ is orthogonal to the projection basis, and this basis is used to approximate the wanted eigenvectors; hence $r$ can become orthogonal to the wanted eigenvectors during the iteration. The residual vector $r$ is not suitable for the filtering because, when $Q(:,1:k)^T r \approx 0$, $\psi(A)r = Q\psi(\Lambda)Q^T r$ is approximately inside the subspace spanned by unwanted eigenvectors.

We also mention that our own experiments, together with those in [13], show that the preconditioned Davidson method based on equation $(A - \mu I)t = r$ can be inefficient because of the higher possibility of stagnation if this equation is solved more accurately. An efficient correction-equation essentially should retain the approximate RQI direction in its solution. Thus, the JD method is equivalent to (2.4), but the $x$ term in the right-hand side of (2.4) may be more important than the $r$ term. However, in the case of rather inaccurate solves with a fixed preconditioner, [1] shows that $(A - \mu I)t = r$ can have better performance than other correction equations.

**3. Chebyshev polynomial filter.** The observations in section 2 suggest that polynomials which significantly magnify the lowest end of a wanted interval and dampens unwanted intervals at the same time can be used as a filter to improve global convergence. The well-known Chebyshev polynomials are a natural choice for this task. Using Chebyshev polynomials to accelerate symmetric eigenvalue computations dates back to [24, 25]. A nice discussion on Chebyshev accelerated subspace iteration can be found in [23, pp. 329–330], where it is mentioned that the Lanczos method is usually better than the Chebyshev accelerated (fixed dimension) subspace iteration algorithm. Here we integrate Chebyshev filtering into a varying dimension Davidson-type algorithm.

With Chebyshev acceleration, the subspace used in a Davidson-type method can be of much smaller dimension than that is required by a Lanczos-type method for good efficiency. Therefore the filtering approach leads to substantial savings in (re-) orthogonalization costs.

Recall that the real Chebyshev polynomials of the first kind are defined by (see, e.g., [23, p. 371], [27, p. 142])

$$C_k(t) = \begin{cases} \cos(k\, cos^{-1}(t)), & -1 \le t \le 1, \\ \cosh(k\, cosh^{-1}(t)), & |t| > 1. \end{cases}$$

Note that $C_0(t) = 1, C_1(t) = t$. Recall also the important three-term recurrence,

$$C_{k+1}(t) = 2tC_k(t) - C_{k-1}(t), \qquad t \in \mathbb{R}. \tag{3.1}$$

A remarkable property of the Chebyshev polynomial is its rapid growth outside the interval $[-1, 1]$. This property is illustrated in Figure 3.1. Here we plot only the

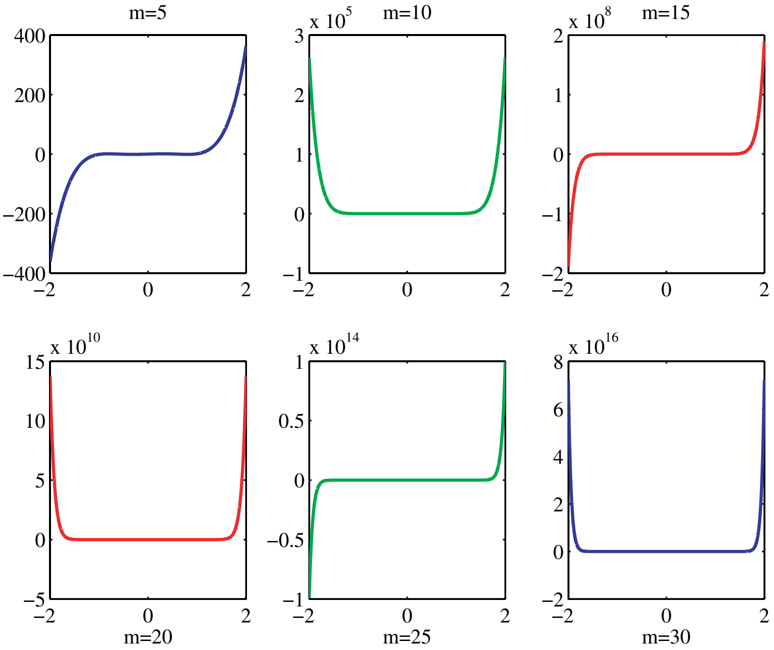

FIG. 3.1. *Rapid increase outside* $[-1, 1]$ *of Chebyshev polynomial of degree* $m$.

polynomial on the $[-2, 2]$ interval, but note that the farther away we are from $[-1, 1]$, the larger the magnitude of $C_k(t)$. Suppose that the spectrum of $A$ is contained in $[a_0, b]$ and we want to dampen the interval $[a, b]$ for $a > a_0$; then we need only to map $[a, b]$ into $[-1, 1]$ by an affine mapping. This mapping will map the wanted lower end of the spectrum, i.e., the eigenvalues closer to $a_0$, farther away from $[-1, 1]$ than the ones closer to $a$. Applying the three-term Chebyshev recurrence will then magnify eigenvalues near $a_0$ and dampen eigenvalues in $[a, b]$, which is the desired filtering.

In practice, we need the lower bound $a$ of the unwanted interval, which is easy to approximate during each iteration in a Davidson-type method. The upper bound $b$ of the eigenvalues of $A$ can by obtained by Gerschgorin's theorem. It can also be estimated by an upper-bound-estimator (Algorithm 4.3 in [47]), which applies a few steps of Lanczos iteration with a final safeguard step.

The Chebyshev iteration, which dampens values in $[a, b]$ while magnifying values in the interval to the left of $[a, b]$, is presented in Algorithm 3.1 below. Here we follow the formula derived in [26], [27, p. 223] for the complex Chebyshev iteration and adapt it to the real case. The iteration of the algorithm is equivalent to computing

$$y = p_m(A)x, \qquad \text{where} \quad p_m(t) = C_m\left(\frac{t-c}{e}\right). \tag{3.2}$$

As defined in the algorithm, $c$ is the center of the interval $[a, b]$ and $e$ its half-width; both depend on the bounds used.

In Algorithm 3.1, the $\sigma$'s are used for scaling purposes; the $a_0$ is a crude approximation of the smallest eigenvalues of $A$. The following discusses certain details of scaling. The three-term recurrence using $p_m(A)$ yields the iteration

$$x_{j+1} = \frac{2}{e}(A - cI)x_j - x_{j-1}, \quad j = 1, 2, \ldots, m-1,$$

with $x_0$ given and $x_1 = (A - cI)x_0$. This is equivalent to a power iteration of the form

$$\begin{pmatrix} x_{j+1} \\ x_j \end{pmatrix} = \underbrace{\begin{pmatrix} \frac{2}{e}(A - cI) & -I \\ I & 0 \end{pmatrix}}_{\mathcal{B}} \begin{pmatrix} x_j \\ x_{j-1} \end{pmatrix} .$$

A little analysis would show that all the eigenvalues of the nonsymmetric matrix $\mathcal{B}$ are complex and of modulus one, except that those corresponding to eigenvalues of $A$ that are less than $a$ are mapped to real eigenvalues larger than one in magnitude. Therefore, as for the standard power method, a scaling at each step is recommended. The simplest strategy, discussed in [27], is to consider the scaled sequence

$$\tilde{x}_j = \frac{C_j[\frac{2}{e}(A - cI)]}{C_j[\frac{2}{e}(a_0 - cI)]}\, x_0,$$

where $\rho_j = C_j[\frac{2}{e}(a_0 - cI)]$ is the scaling factor. This requires $a_0$, but since it is only used for scaling, a rough estimate of $a_0$ is sufficient. For the first Chebyshev–Davidson iteration, we can use a value $a_0 \leq a$; for the latter Chebyshev–Davidson steps, the smallest Ritz value from the previous step can be used. The vector sequence is not computed as shown above, because $\rho_j$ itself can be large and this would defeat the purpose of scaling. Instead, each $\tilde{x}_{j+1}$ is updated using the scaled vectors $\tilde{x}_j$ and $\tilde{x}_{j-1}$. This is discussed in [27], and Algorithm 3.1 implements this scaling (the tildes and vector subscripts are omitted).

```
ALGORITHM 3.1. [illegible] Chebyshev_filter $x, m, a, b, a_0$
[illegible] $x$ [illegible] $m$ [illegible] $[a, b]$
    $e = (b - a)/2;$   $c = (b + a)/2;$
    $\sigma = e/(a_0 - c);$   $\sigma_1 = \sigma;$
    $y = (Ax - cx)\sigma_1/e;$
    [illegible] $i = 2 : m$
        $\sigma_{new} = \frac{1}{(2/\sigma_1 - \sigma)};$
        $y_{new} = 2(Ay - cy)\sigma_{new}/e - \sigma\sigma_{new}x;$
        $x = y;$   $y = y_{new};$   $\sigma = \sigma_{new};$
    [illegible]
```

Note that the filter is intervalwise; hence no shifts such as Chebyshev zeros or Leja points are required. This is to be contrasted with pointwise filtering methods, e.g., [33, 17, 2, 3].

Clearly, polynomials other than Chebyshev can be used for filtering. Several polynomials are discussed in [34], with emphasis on approximating rational functions of the form $\varphi(s) = 1/(s - \mu)$. In contrast, we do not approximate the (shift-inverted) rational functions, but require polynomials to have the desired intervalwise filtering property, i.e., dampen an interval and significantly magnify other intervals. We choose Chebyshev polynomials because of their desirable filtering properties and ease of implementation. Note that the Chebyshev filtering used in [34] is different from Algorithm 3.1, since the former requires an additional parameter $\Delta$, which is not straightforward to specify. Another difference is that in [34] Chebyshev filtering is used in a Lanczos-type algorithm, while here we integrate Chebyshev filtering into a Davidson-type framework. The Rayleigh–Ritz step in a Davidson-type method readily provides the necessary bounds for constructing efficient Chebyshev filters. The resulting Chebyshev–Davidson method compares favorably with other methods, as shown in section 6.

Algorithm 3.1 requires no inner products, and this is another appealing feature of Chebyshev acceleration, since inner products incur a global reduction which requires additional communication costs in a parallel computing context.

## 4. Chebyshev polynomial accelerated Davidson method.

The pseudocode for the Chebyshev–Davidson method is presented in Algorithm 4.1 below. This code is very different from other Davidson-type methods in the literature (e.g., [4]). We use a natural but useful indexing scheme. The deflation of converged eigenvectors is handled by indexing the columns of the projection basis $V$. No extra storage for the converged eigenvectors is necessary. Moreover, restarting is simplified (as seen in step 8f) by the indexing. The implementation does not require extra basis updates or memory copies during the restart, since the updates in step 8g need to be performed even when restart is not necessary. We note that putting restart at step 8f is better than putting it at the end of the outer loop, because it saves operations in step 8g when restarting is necessary.

We make a few comments on Algorithm 4.1. Comments (v)–(vii) are related to the robust implementation of any Davidson-type methods.

(i) It is important that the bound `upperb` bounds all eigenvalues of $A$ from above. Otherwise the interval containing largest eigenvalues may also be magnified through filtering, and this can drastically slow convergence or even lead to wrong convergence. One inexpensive way for the bound estimation at step 5 is `upperb` $= \left|\left|A\right|\right|_1$; if $A$ is available only through a matrix-vector-product subroutine, then we can apply the upper-bound-estimator, Algorithm 4.1 in [47], to get an upper bound.

(ii) The choice of the lower bound for the unwanted interval at each iteration is one of the most critical ingredients of the method. The Chebyshev–Davidson method allows quite flexible choices for this lower bound, without any extra computations. Numerical results show that the choice at step 8l is remarkably efficient. Other choices, such as the maximum of the current Ritz values, can also be used as `lowerb`.

(iii) For the orthogonalization step 8b, we use the iterated Gram–Schmidt algorithm, often referred to as the DGKS method [10].

(iv) The refinement at step 8g is performed at each step. One can avoid this step until some eigenpair converges. But according to [23, p. 325], this refinement is necessary in order to have faster convergence for the eigenvectors.

(v) The swap at step 8j may be performed by the following pseudocode:

```
set $v_{tmp} = V(:, k_c)$;
For $(i = k_c - 1 : -1 : 1)$ Do
    If $(\mu \geq eval(i))$, exit the For loop; End If
    set $eval(i+1) = eval(i)$, $eval(i) = \mu$; set $V(:, i+1) = V(:, i)$, $V(:, i) = v_{tmp}$;
End For.
```

(Note that unnecessary memory copies in the above can be avoided with some more involved programming.)

(vi) The *noswap* flag at steps 8i–k is used to improve robustness. This flag decreases the possibility of counting converged unwanted eigenvalues as wanted ones.

(vii) At step 8j, a convergence test is performed only on the first Ritz pair among the $k_{sub} - k_c$ Ritz pairs available at each iteration. A simple loop can be added to check the convergence of more than one Ritz pair. We note that for almost all Davidson-type subspace methods, if all the $k_{sub} - k_c$ Ritz pairs are checked for convergence at each iteration step and no swap procedure is included, then there is a high possibility of missing wanted eigenvalues.

(viii) Algorithm 4.1 essentially contains a framework for Davidson-type methods based on filtering. The Chebyshev filter at step 8a can be replaced by other suitable filters. However, we mention that among the filters tried, including a least square polynomial and a different implementation of Chebyshev polynomials in [34], the filter as implemented in Algorithm 3.1 has the best numerical behavior.

**5. Analysis.** The analysis given here serves to give a preliminary understanding of the convergence for Algorithm 4.1. Therefore several simplifications of the algorithm are made.

Assume that the eigenvalues of $A$ are $\lambda_1 < \lambda_2 \le \cdots \le \lambda_n$, and denote the associated unit eigenvectors by $q_1, \dots, q_n$. According to (3.2) and the fact that the

interval of the eigenvalues to be dampened at each step is adaptively changing, we see that the matrix applied at the $j$th step is

$$p_m^{(j)}(A) = C_m^{(j)}((A - c_jI)/e_j). \tag{5.1}$$

The first simplification assumes that the interval of the eigenvalues to be dampened at each filtering step of Algorithm 4.1 is fixed. That is, the matrix involved is fixed as $p_m(A) \equiv C_m((A - cI)/e)$. The second simplification assumes that no restart is used in the algorithm.

We further assume that Algorithm 4.1 is a [illegible] version. That is, in step 8b we keep $k_{sub} \equiv 1$ and set $V(:,1) = t/||t||$, and in step 8m we set $x = V(:,1)$. Then the algorithm becomes a standard power method with the matrix $p_m(A)$. As a result, the convergence will be governed by the ratio of the two dominant eigenvalues. Note that the interval $[a, b]$ of the eigenvalues to be dampened satisfies $\lambda_1 < a$. The (unique) dominant eigenvalue of the matrix $p_m(A)$ is $C_m((\lambda_1 - c)/e)$. So, in the one-dimensional version of the algorithm, $V(:,1)$ converges to $q_1$ with the convergence factor

$$\rho = \frac{\max_{j>1} |C_m((\lambda_j - c)/e)|}{|C_m((\lambda_1 - c)/e)|} < 1.$$

Consider now the situation in which $k_{sub}$ can be increased. The simplified method turns out to have a simple Krylov interpretation. Assume that we perform two steps of the algorithm, i.e., that the dimension of the subspace is two. The first vector of the basis is $p_m(A)x$. The second is obtained as $p_m(A)x_1$, where $x_1$ is an approximate eigenvector from the one-dimensional space spanned by the first vector, which is simply a multiple of $p_m(A)x$. The subspace used in this case is

$$K_2 = \text{span}\{p_m(A)x, p_m(A)x_1\} = \text{span}\{p_m(A)x, p_m^2(A)x\} \ ,$$

which is the Krylov subspace of dimension two usually denoted by $K_2(p_m(A), x)$. Consider now the third step. The process will inject to the subspace a vector of the form

$$p_m(A)x_2 \quad \text{with} \quad x_2 \in K_2 \ .$$

The vector $x_2$ is a Ritz eigenvector computed from projecting $A$ onto the subspace $K_2$, and it is a linear combination of vectors from $K_2$, so we can write $x_2 = \alpha_1 p_m(A)x + \alpha_2 p_m^2(A)x$. The new subspace $K_3$ is again a Krylov subspace. Indeed,

$$K_3 = \text{span}\{p_m(A)x, p_m^2(A)x, p_m(A)x_2\} \equiv \text{span}\{p_m(A)x, p_m^2(A)x, p_m^3(A)x\} \ .$$

The result can be easily extended to an arbitrary step $j$ for the simplified method.

PROPOSITION 5.1. [illegible] $j$ [illegible] 4.1 [illegible] $A$ [illegible]

$$K_j\left(p_m(A), x\right).$$

In particular, this means that if one generated an orthogonal basis $V_j$ of the Krylov subspace $K_j(p_m(A), x)$ and computed the eigenvalues of $V_j^TAV_j$, these eigenvalues would be identical with those of the simplified Algorithm 4.1. This is not quite a

Krylov subspace method, because the projection uses $A$ instead of the transformed matrix $p_m(A)$. However, this simple result permits one to analyze the simplified algorithm in a complete way by considering eigenvectors. Indeed, eigenvectors of $A$ and $p_m(A)$ are identical, and there are results which establish upper bounds for the angle between the exact eigenvector and the Krylov subspace. This will be omitted, and the reader is referred to [23] for details.

Although the simplified algorithm can be viewed from the angle of Krylov subspaces, Algorithm 4.1 is not a Krylov method. There are a number of distinguishing features, related to implementation and other practical aspects. In fact, Proposition 5.1 assumes that the polynomial is fixed, but the actual Chebyshev–Davidson method adapts the filters by dynamically adjusting the bounds of the interval of eigenvalues to be dampened at each iteration. This in practice leads to significantly more efficient filters. The following presents a conservative analysis: Taking (5.1) into account, we see that

$$K_2 = \operatorname{span}\{p_m^{(1)}(A)x, p_m^{(2)}(A)p_m^{(1)}(A)x\},$$

$$K_3 = \operatorname{span}\{p_m^{(1)}(A)x,\ p_m^{(2)}(A)p_m^{(1)}(A)x,\ \alpha_1 p_m^{(3)}(A)p_m^{(1)}(A)x + \alpha_2 p_m^{(3)}(A)p_m^{(2)}(A)p_m^{(1)}(A)x\},$$

where $\alpha_2 \neq 0$ by the designed filtering (if the previous subspace can be augmented). This list easily extends to $K_j$ for any $j$. Letting

$$\Phi_k(t) = \prod_{l=1}^{k} p_m^{(l)}(t), \tag{5.2}$$

then the last term in $K_j$ contains $\Phi_j(A)x$ with a nonzero coefficient. The filtering is designed such that the subspace contains a significant direction in $\Phi_j(A)x$. Note that $\Phi_j(A)x$ corresponds to an accelerated power method applied to $x$. Because of the Rayleigh–Ritz refinement, there is a Ritz vector from $K_j$ which converges to $q_1$ at least as fast as $\Phi_j(A)x$ does, where the convergence rate for $\Phi_j(A)x$ to $q_1$ is $\frac{\max_{l>1}|\Phi_j(\lambda_l)|}{|\Phi_j(\lambda_1)|}$ under standard conditions [39, 16]. This rate can be considerably faster than the one obtained using a fixed filtering interval. The convergence for the latter eigenvectors follows from deflation; e.g., the second eigenvalue becomes dominant for the matrix $A$ restricted to the subspace orthogonal to $q_1$.

**6. Numerical results and discussion.** We compare the Chebyshev–Davidson method (denoted as ChebyD) with several other Davidson-type and Lanczos-type methods.

The first part of the comparison is done using Matlab. We compare our algorithm with the well-known JD method implemented in the publicly available Matlab code JDQR [14][1] and JDCG [20].[2] The JDCG code is for symmetric eigenproblems; the linear solver used in JDCG is (preconditioned) CG. The JDQR code can solve both symmetric and nonsymmetric problems; GMRES [28] is the default linear solver in JDQR, and it is used for the numerical tests. Since we solve symmetric eigenproblems, it is less costly to use MINRES [21] in the JD method. Moreover, since CG is usually intended for positive definite problems, JDCG does not work as efficiently for indefinite $A$ as for positive definite $A$. So for further comparisons, we implemented the JD method using the Matlab built-in MINRES as the linear solver. This code is denoted

as JDminres. JDminres is mainly based on Algorithm 4.1, except that step 8a is replaced by a linear equation solve using MINRES. The LOBPCG [15] code[3] is also used for comparison because it is a representative preconditioned eigensolver. We also compared with IRBL [2, 3], but noticed that the IRBL code becomes less competitive than other codes when $k_{want}$ becomes large. Here we report only comparisons with JDQR, JDCG, JDminres, and LOBPCG.

For the test examples listed in Tables 6.1–6.3, we compute the $k_{want}$ smallest eigenvalues and eigenvectors. The maximum subspace dimension is fixed at $2 * k_{want}$ for all methods, except that for LOBPCG it is $3 * k_{want}$. The silicon quantum dot models are available from the University of Florida Sparse Matrix Collection.[4] Figure 6.1 shows the sparsity structure of two test matrices used in Tables 6.1 and 6.2.

The accuracy is reported as $||AV - VD||/||A||_1$, where the diagonal of $D$ contains the $k_{want}$ converged eigenvalues, and $V$ contains the corresponding eigenvectors. The relative convergence tolerance is set to $10^{-10}$ for all methods. For each test problem, the computed eigenvalues are cross validated; i.e., we compute the maximum difference of the eigenvalues computed by different methods. All the differences are found to be less than order $10^{-10}$.

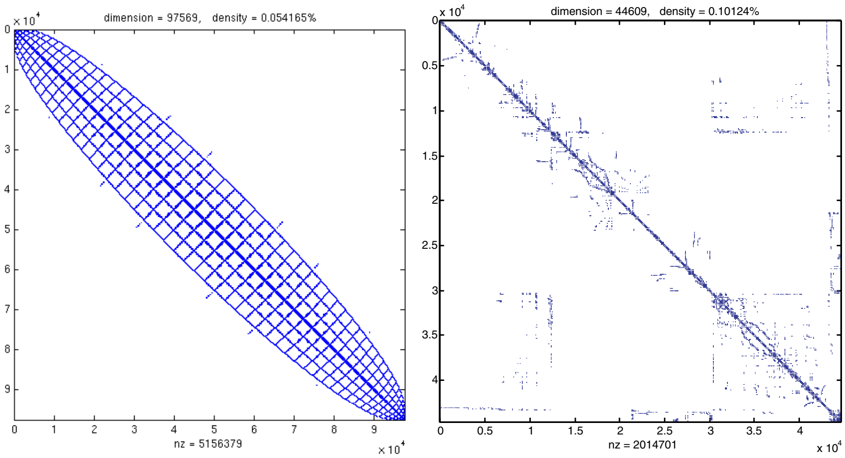

FIG. 6.1. *Structure plots of two test matrices* $Si_{34}H_{36}$ *and* `bcsstk32`.

Initial vector is set as $ones(n, 1)$ for all methods, so that the initial direction is not biased for a certain method. The LOBPCG requires additional $k_{want} - 1$ vectors for the initial block, for which random vectors are used.

In each table, "#iter" counts the total number of the outer loop, "#mvp" is the number of matrix-vector products, and "#max_le_solve" is the maximum inner iteration number for the linear equation solve by MINRES in JDminres. For JDQR, `help jdqr` indicates where #iter and #mvp are stored, but the observed output values from history(:,2) for #iter seem incompatible with the expected values. It is possible that history(:,2) stores both the outer iteration count as well as the inner iteration count, since the resulting number is often much larger than that of JDminres and JDCG. We report #iter for JDQR only for reference, and put a (-) sign to signal the difference. The #mvp for LOBPCG is reported by #iter times the block size (which is $k_{want}$ in LOBPCG).

All the Matlab numerical experiments were performed on an AMD PC with dual Opteron 2.6GHz CPU and 8GB RAM. One of the CPU was dedicated to the computation. The OS used was Red Hat EL4 Linux with kernel version 2.6.9. We used Matlab version 7.2 (R2006a) for the computations.

Note that JDCG and LOBPCG both have preconditioned CG solvers included. However, for the symmetric indefinite problems in Tables 6.1–6.3 (and other test problems not reported here), our experiments showed that both methods work better than their "preconditioned" counterparts with a standard preconditioner such as the incomplete LU. Moreover, for these indefinite problems, it is not clear what preconditioners can be used to accelerate the preconditioned CG solves. Therefore we report comparisons with JDCG and LOBPCG without preconditioned solves. The examples show that in situations where preconditioners are hard to obtain, approaches not relying on solving correction-equations have a clear advantage and can provide effective alternatives.

We recall that the "preconditioning" concept for eigenproblems is quite different from preconditioning for linear equations. The latter tries to reduce the eigenvalue gaps to make the condition number close to 1, while the former tries to introduce more favorable gaps for wanted eigenvalues. This is why in eigenvalue problems, the preconditioned linear solvers are often applied to correction equations, which leads to techniques that exploit shift-and-invert. In essence, a natural "preconditioner" for an eigenvalue problem is a filter that can transform the spectrum in a desired way so as to increase eigenvalue gaps. This "preconditioning" may not need a preconditioned linear solver. In the Chebyshev–Davidson method, we realize the "preconditioning" by dynamically constructing Chebyshev filters to filter the spectrum so that gaps among wanted eigenvalues are properly magnified.

The reported results of ChebyD are typical for the Chebyshev–Davidson method. For all the test runs, it is rather straightforward to select the polynomial degree $m$. The effect of a varying degree $m$ is illustrated in Figure 6.2. As seen from this figure, with $m$ increasing (before it becomes unnecessarily large), the number of iterations decreases, the number of matrix-vector products increases, and the CPU time decreases. Note that the CPU time difference for $m$ from 26 to 47 is not large. The test matrices are the $Si_{10}H_{16}$ and $Si_{34}H_{36}$ silicon quantum dots, but we note that similar behavior is observed for a large number of other test models. In Tables 6.1–6.3 we used $m = 20$ to see how the algorithm performs with a low degree polynomial. A better CPU time for Chebyshev–Davidson can be obtained with a larger $m$. The results in Tables 6.1–6.3 show that even without a fine-tuned $m$, the Chebyshev–Davidson method outperforms other Davidson-type methods.

The numerical results in Tables 6.1–6.3 and Figure 6.2 also show that a smaller #mvp count does not necessarily imply smaller CPU time. Eigenvalue algorithms may require substantial amounts of work not related to matrix-vector products. For example, in Figure 6.2, #mvp increases with $m$ increasing, but because #iter decreases, there is less reorthogonalization cost involved; this explains why the CPU time decreases as $m$ increases. As pointed out in [30], for large sparse eigenproblems where a large number of eigenpairs need to be computed, the total cost can be dominated by the reorthogonalization cost.

Regarding global convergence, Figure 6.3 shows one example where convergence of the Chebyshev–Davidson method is much faster than that of the standard JD approach. However, we would like to mention that for symmetric eigenproblems, a JD method often has good global convergence. For the same example as in Figure 6.3, a fine-tuned value of #max_le_solve for JDminres can make the global convergence of ChebyD and JDminres become similar.

The Chebyshev–Davidson algorithm was also implemented in Fortran95; its parallel version has been integrated into an electronic structure calculation package called PARSEC (pseudopotetial algorithm for real-space electronic calculations). PARSEC uses real-space pseudopotential implementation of density functional theory methods. The original ideas behind PARSEC date back to the early 1990s [8, 9]. Originally, PARSEC had three diagonalization methods: a preconditioned Davidson method [29, 35] called Diagla, the symmetric eigensolver from ARPACK [33, 17], and the thick-restart Lanczos method (TRLan) [40, 42]. The Chebyshev–Davidson algorithm was subsequently integrated into PARSEC (around October, 2005). Due to its efficiency and robustness, it was quickly adopted as the default eigensolver by our collaborators in material science. In the latest version of PARSEC, a true diagonalization is performed only at the first step of the self-consistent loop, after which diagonalizations are replaced by a nonlinear Chebyshev-filtered-subspace (CheFS) method [47, 46]. Nevertheless, the first diagonalization step can still be highly challenging. This is because a relatively complex material system can contain several thousand atoms, in which case the dimension of the discretized Hamiltonians can easily exceed several millions. Even more challenging is the fact that the number of eigenpairs needed

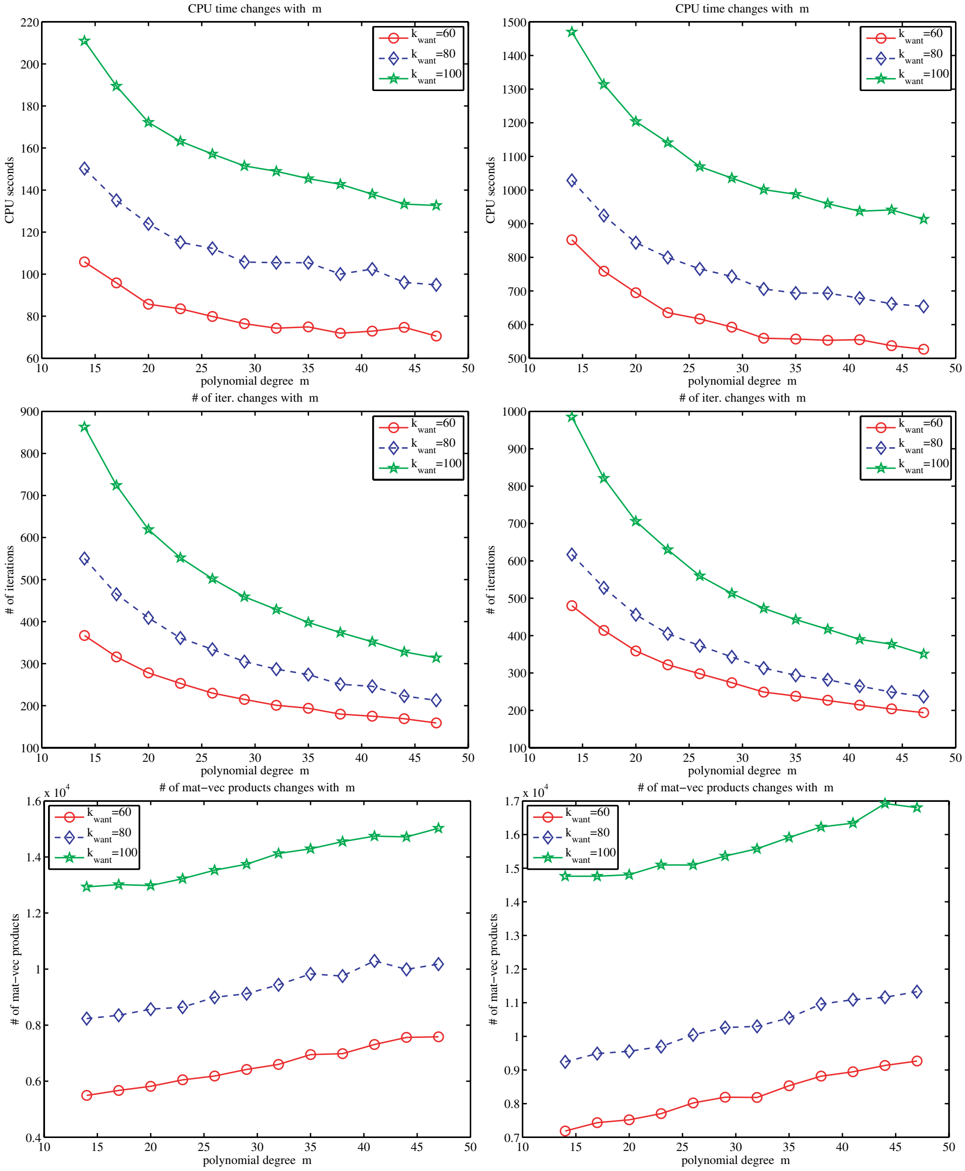

FIG. 6.2. *Changes in CPU time, number of iterations, and number of matrix-vector products with a varying polynomial degree m. Figures on the left are for quantum dot* $Si_{10}H_{16}$*, with* $n = 17077$*. Figures on the right are for quantum dot* $Si_{34}H_{36}$*, with* $n = 97569$*. The* $m$ *is varied as* $m = 14 : 3 : 47$ *in Matlab notation. For each model, the same initial vector* $ones(n, 1)$ *is used for each* $m$*. The number of vectors to keep during restart is simply set as* $k_{keep} = 60$ *for all these tests. Three cases where* $k_{want} = 60, 80, 100$ *are demonstrated.*

is proportional to the number of valence electrons in the atoms, which commonly exceed several thousand. In these cases, high memory demand is clearly a concern. Moreover, eigenvalue algorithms that are efficient for exterior eigenvalues can have problems converging for interior eigenvalues.

Table 6.4 shows the dimension of the discretized Hamiltonians and the number of needed eigenpairs for four silicon nanocrystals and two metallic (iron) clusters. The

| $Si_{9041}H_{1860}$ | 2992832 | 19015 | 48 | 102.12 |
| $Fe_{326}$ | 2985992 | 3912 | 24 | 11.62 |
| $Fe_{360}$ | 3262312 | 4320 | 24 | 16.55 |

reported CPU time is what the Chebyshev–Davidson method used to finish the first step diagonalization in the self-consistent loop.

Physical significance of the numerical results are discussed in [37, 38]. In [37] we report the largest iron-cluster first principle DFT simulations that have been published. The results are used to clarify a decade-old controversy regarding the dependence of magnetic moment on the size of iron clusters. As to first principles DFT calculations on silicon nanocrystals, previously reported results seem not have gone beyond 2000 atoms; in contrast, we were able to do first principle calculations on a sequence of silicon nanocrystals with up to 10,000 atoms [46, 7].

Although success in these challenging DFT calculations depends more on the nonlinear CheFS method, we must mention that the Chebyshev–Davidson method plays a crucial role in the computations since it provides the CheFS method with a desired initial subspace. A suitable initial subspace can substantially reduce the number of iterations required for the CheFS method to reach self-consistency (convergence).

The other three eigensolvers (Diagla, ARPACK, and TRLan) in PARSEC were also used for computing initial subspaces, but we noticed that they became impractical for the largest material systems in Table 6.4, in terms of both memory requirement and convergence speed. In comparison, Diagla is quite efficient when $n$ and $k_{want}$ are moderate, but it becomes slower than ARPACK and TRLan when $n$ and $k_{want}$ become large. TRLan is the fastest among these three solvers; it is observed in [47] to be about twice as fast as ARPACK because of the reduced reorthogonalization. But both TRLan and ARPACK require too much memory because of the requirement that the maximum subspace dimension be around $2k_{want}$.

To address the huge memory demand related to standard restart when $n$ and $k_{want}$ are large, we introduced an [illegible] technique into the Chebyshev–Davidson algorithm. The [illegible] is the same as the standard restart, but the [illegible] corresponds to a standard restart restricted to an inner subspace with dimension much smaller than $k_{want}$. This reduces the maximum dimension of the outer subspace from $2k_{want}$ to $k_{want}$. Therefore the Chebyshev–Davidson algorithm requires about half the memory required by a method with only standard restart. It did not have a memory requirement problem for all the materials reported in Table 6.4. More details about the [illegible] may be found in [44].

As to CPU time, we compared the Chebyshev–Davidson method with TRLan on the two smallest nanocrystals in Table 6.4. Using the same number of CPU nodes, TRLan spent 8.65 CPU hours on $Si_{2713}H_{828}$ and 34.99 CPU hours on $Si_{4001}H_{1012}$ for the first step diagonalization. The comparison is not completely fair since we employed an additional trick in the Chebyshev–Davidson routine, which corresponds to a subspace filtering step so that the last few basis vectors are only approximate eigenvectors. The number of these vectors not converged to full accuracy is bounded above by the dimension of the inner subspace used for inner restart. It is rather straightforward to add this subspace filtering step inside a Davidson-type iteration. Both this trick and the [illegible] are due to the remarkable flexibility of a Davidson-type method in adjusting basis vectors. A Lanczos-type method does not have this flexibility because of the need to keep a Krylov structure. In TRLan all the basis vectors are converged to the same full accuracy, which can be too costly since high accuracy is often not necessary for the last few vectors in the subspace, especially when the diagonalization is performed at the first step of the self-consistent loop to provide an initial subspace.

We also mention that the adaptive Chebyshev filter (based on [26, 27]) and the choice of bounds to achieve efficient filtering, as presented in this paper, are essential to the development of the nonlinear CheFSI method in [47, 46].

## 7. Conclusion.

A Chebyshev–Davidson algorithm has been presented for solving large symmetric eigenvalue problems. It essentially consists of filtering out the unwanted portion of the spectrum by using adaptive Chebyshev polynomials of the matrix. Comparisons with existing Davidson- and Lanczos-type methods show that the Chebyshev–Davidson method is efficient and robust.

Advantages of the Chebyshev filtering approach include not requiring correction-equations (hence no preconditioned linear solves are necessary), and robust global convergence because of the intervalwise filtering. The Chebyshev filters are easily controllable within the Davidson-type framework, and thus they can be conveniently tuned to filter the full spectrum in the desired way to accelerate global convergence.

**Acknowledgments.** We thank Professor Calvetti for her constructive comments, especially the suggestion on testing the effect of the polynomial degree in the Chebyshev–Davidson algorithm, which improved our understanding of this parameter.

# JOINT SINGULAR VALUE DISTRIBUTION OF TWO CORRELATED RECTANGULAR GAUSSIAN MATRICES AND ITS APPLICATION[*]

SHUANGQUAN WANG[†] AND ALI ABDI[†]

**Abstract.** Let $\mathbf{H} = (h_{ij})$ and $\mathbf{G} = (g_{ij})$ be two $m \times n$, $m \leq n$, *rectangular* random matrices, each with independently and identically distributed complex zero-mean unit-variance Gaussian entries, with correlation between any two elements given by $\mathbb{E}[h_{ij} g_{pq}^{\star}] = \rho\, \delta_{ip} \delta_{jq}$ such that $|\rho| < 1$, where $^{\star}$ denotes the complex conjugate and $\delta_{ij}$ is the Kronecker delta. Assume $\{s_k\}_{k=1}^{m}$ and $\{r_l\}_{l=1}^{m}$ are unordered singular values of $\mathbf{H}$ and $\mathbf{G}$, respectively, and $s$ and $r$ are randomly selected from $\{s_k\}_{k=1}^{m}$ and $\{r_l\}_{l=1}^{m}$, respectively. In this paper, exact analytical closed-form expressions are derived for the joint probability distribution function (PDF) of $\{s_k\}_{k=1}^{m}$ and $\{r_l\}_{l=1}^{m}$ using an Itzykson–Zuber-type integral as well as the joint marginal PDF of $s$ and $r$ by a biorthogonal polynomial technique. These PDFs are of interest in multiple-input multiple-output wireless communication channels and systems.

## 1. Introduction.

Random singular values have found numerous applications such as hypothesis testing and principal component analysis in statistics [14], nuclear energy levels and level spacing in nuclear physics [12], quantum chromodynamics [20], and calculation of the multiple-input multiple-output (MIMO) channel capacity in wireless communications [18]. The singular value distribution of a [illegible] Gaussian random matrix is given in [16]. For a single chiral random matrix, where a square Gaussian random matrix and its Hermitian sit on the off diagonal, the result is reported in [6]. However, the joint singular value distribution of [illegible] Gaussian random matrices has received less attention so far, although it has important applications in wireless MIMO communications, say, the second-order statistics of the [illegible] [22, Chap. 4] [25] and instantaneous mutual information [22, Chaps. 3 and 4] [23, 24, 26].

To the best of our knowledge, correlated square random matrices have been studied to some extent [4,12,13], where only Hermitian matrices were considered. Different from [4,12,13], we consider the situation where the elements, with the same indices, of the two rectangular complex Gaussian random matrices are correlated by a [illegible] number and derive exact analytical closed-form expressions for the joint probability distribution function (PDF) of their singular values.

This paper is organized as follows. Section 2 introduces the two rectangular complex Gaussian random matrices. The joint PDFs of singular values are studied in section 3 using an Itzykson–Zuber-type integral. The joint marginal PDF of singular values is derived in section 4, and its application to wireless MIMO communications is presented in section 5. Finally, concluding remarks are summarized in section 6.

The current address for the first author is NEC Laboratories America, Inc., Princeton, NJ 08540 .

[illegible] $\cdot^\dagger$ is reserved for matrix Hermitian, $\cdot^T$ for matrix transpose, $\cdot^\star$ for complex conjugate, $\mathrm{tr}[\cdot]$ for the trace of a matrix, $\jmath$ for $\sqrt{-1}$, $\mathbb{E}[\cdot]$ for mathematical expectation, $\mathbf{I}_m$ for the $m \times m$ identity matrix, $\otimes$ for the Kronecker product, and $\Re[\cdot]$ and $\Im[\cdot]$ for the real and imaginary parts of a complex number, respectively. In addition, $\mathrm{diag}(\mathbf{s})$ denotes a diagonal matrix with $\mathbf{s}$ on the main diagonal, $t \in [m, n]$ implies that $t$, $m$, and $n$ are all integers such that $m \leq t \leq n$, with $m \leq n$, and $\det|x_{kl}|$ is the determinant of the matrix, where $x_{kl}$ resides on the $k$th row and $l$th column. Moreover, lowercase bold letters represent row vectors, whereas uppercase bold letters are used for matrices. Finally $\mathcal{CN}$ means complex normal, and $\mathrm{vec}(\cdot)$ stacks all of the columns of its matrix argument into one tall column vector.

## 2. Problem description.

There are two $m \times n$ random matrices $\mathbf{H} = (h_{ij})$ and $\mathbf{G} = (g_{ij})$, $i \in [1, m]$, $j \in [1, n]$, each with independently and identically distributed (i.i.d.) complex zero-mean unit-variance Gaussian entries, i.e., $\mathbb{E}[h_{ij}] = \mathbb{E}[g_{ij}] = 0\ \forall i, j$, $\mathbb{E}[h_{ij}h_{pq}^\star] = \mathbb{E}[g_{ij}g_{pq}^\star] = \delta_{ip}\delta_{jq}$, where the Kronecker symbol $\delta_{ij}$ is 1 or 0 when $i = j$ or $i \neq j$. Therefore $\mathbf{H}, \mathbf{G} \sim \mathcal{CN}(\mathbf{0}, \mathbf{I}_{mn})$. Moreover, the correlation between the two random matrices is given by

$$\mathbb{E}[h_{ij}g_{pq}^\star] = \rho\,\delta_{ip}\delta_{jq} \quad \forall i, j, p, q, \tag{2.1}$$

where $\rho = |\rho|e^{\jmath\theta}$ is a complex number, with $|\rho| < 1$.

Without loss of generality, we assume $m \leq n$ and set $\nu = n - m$. Based on the singular value decomposition (SVD), $\mathbf{H}$ and $\mathbf{G}$ can be, respectively, diagonalized as [8]

$$\mathbf{H} = \mathbf{U}\mathbf{S}\mathbf{V}^\dagger, \tag{2.2}$$

$$\mathbf{G} = \widetilde{\mathbf{U}}\mathbf{R}\widetilde{\mathbf{V}}^\dagger, \tag{2.3}$$

where $\mathbf{S} = \big[\mathrm{diag}(\mathbf{s})\ \mathbf{0}\big]$ and $\mathbf{R} = \big[\mathrm{diag}(\mathbf{r})\ \mathbf{0}\big]$, with $\mathbf{s} = [s_1, s_2, \ldots, s_m]$ and $\mathbf{r} = [r_1, r_2, \ldots, r_m]$, respectively.

We assume that the singular values of $\mathbf{G}$, $r_1, r_2, \ldots, r_m$, are unordered and the singular values of $\mathbf{H}$, $s_1, s_2, \ldots, s_m$, are also unordered. Now we would like to know the joint PDF of $\{r_l\}_{l=1}^m$ and $\{s_l\}_{l=1}^m$. Moreover, with $r$ randomly selected from $r_1, r_2, \ldots, r_m$, and $s$ randomly selected from $s_1, s_2, \ldots, s_m$, it is of interest to derive the joint PDF of $r$ and $s$ as well. These two PDFs are derived in sections 3 and 4, respectively.

## 3. Joint PDF of $\{s_l\}_{l=1}^m$ and $\{r_l\}_{l=1}^m$.

LEMMA 3.1 (joint PDF of $\mathbf{H}$ and $\mathbf{G}$). [illegible] $\mathbf{H}, \mathbf{G} \sim \mathcal{CN}(\mathbf{0}, \mathbf{I}_{mn})$ [illegible] $\mathbf{H}$ [illegible] $\mathbf{G}$ [illegible] (2.1) [illegible] $\mathbf{H}$ [illegible] $\mathbf{G}$ [illegible]

$$p(\mathbf{H}, \mathbf{G}) = \frac{1}{\pi^{2mn}\left(1 - |\rho|^2\right)^{mn}} \exp\left[-\frac{\mathrm{tr}\big(\mathbf{H}\mathbf{H}^\dagger + \mathbf{G}\mathbf{G}^\dagger - \rho^\star\mathbf{H}\mathbf{G}^\dagger - \rho\mathbf{G}\mathbf{H}^\dagger\big)}{1 - |\rho|^2}\right]. \tag{3.1}$$

[illegible] We set $\mathbf{h} = \mathrm{vec}(\mathbf{H})$, $\mathbf{g} = \mathrm{vec}(\mathbf{G})$, and $\mathbf{x} = [\mathbf{h}^T\ \mathbf{g}^T]^T$. Based on $\mathbf{H}, \mathbf{G} \sim \mathcal{CN}(\mathbf{0}, \mathbf{I}_{mn})$ and (2.1), we have the mean and covariance matrix of $\mathbf{x}$ as $\mathbb{E}[\mathbf{x}] = \mathbf{0}$ and $\Sigma_\mathbf{x} = \Sigma_\tau \otimes \mathbf{I}_{mn}$, with $\Sigma_\tau = \left[\begin{smallmatrix} 1 & \rho \\ \rho^\star & 1 \end{smallmatrix}\right]$, respectively. Therefore the PDF of $\mathbf{x}$ is given by [11]

$$p(\mathbf{x}) = \frac{1}{\pi^{2mn}\det|\Sigma_\mathbf{x}|} \exp\left(-\mathbf{x}^\dagger\Sigma_\mathbf{x}^{-1}\mathbf{x}\right), \tag{3.2}$$

where $\det|\Sigma_\mathbf{x}| = (\det|\Sigma_\tau|)^{mn} = \left(1 - |\rho|^2\right)^{mn}$.

With $\Sigma_\tau^{-1} = \frac{1}{1-|\rho|^2}\begin{bmatrix} 1 & -\rho \\ -\rho^\star & 1 \end{bmatrix}$, we obtain $\Sigma_\mathbf{x}^{-1} = \Sigma_\tau^{-1} \otimes \mathbf{I}_{mn} = \frac{1}{1-|\rho|^2}\begin{bmatrix} \mathbf{I}_{mn} & -\rho\mathbf{I}_{mn} \\ -\rho^\star\mathbf{I}_{mn} & \mathbf{I}_{mn} \end{bmatrix}$. Therefore $\mathbf{x}^\dagger\Sigma_\mathbf{x}^{-1}\mathbf{x}$ in (3.2) can be rewritten as

(3.3)
$$\begin{aligned}\mathbf{x}^\dagger\Sigma_\mathbf{x}^{-1}\mathbf{x} &= \operatorname{tr}\left(\Sigma_\mathbf{x}^{-1}\mathbf{x}\mathbf{x}^\dagger\right) = \operatorname{tr}\left(\frac{1}{1-|\rho|^2}\begin{bmatrix} \mathbf{I}_{mn} & -\rho\mathbf{I}_{mn} \\ -\rho^\star\mathbf{I}_{mn} & \mathbf{I}_{mn} \end{bmatrix}\begin{bmatrix} \mathbf{h}\mathbf{h}^\dagger & \mathbf{h}\mathbf{g}^\dagger \\ \mathbf{g}\mathbf{h}^\dagger & \mathbf{g}\mathbf{g}^\dagger \end{bmatrix}\right), \\ &= \frac{\operatorname{tr}\left(\mathbf{h}\mathbf{h}^\dagger + \mathbf{g}\mathbf{g}^\dagger - \rho^\star\mathbf{h}\mathbf{g}^\dagger - \rho\mathbf{g}\mathbf{h}^\dagger\right)}{1-|\rho|^2} = \frac{\operatorname{tr}\left(\mathbf{H}\mathbf{H}^\dagger + \mathbf{G}\mathbf{G}^\dagger - \rho^\star\mathbf{H}\mathbf{G}^\dagger - \rho\mathbf{G}\mathbf{H}^\dagger\right)}{1-|\rho|^2},\end{aligned}$$

where $\operatorname{tr}\left(\mathbf{A}\mathbf{B}^\dagger\right) = \operatorname{vec}(\mathbf{B})^\dagger\operatorname{vec}(\mathbf{A}) = \operatorname{tr}\left[\operatorname{vec}(\mathbf{A})\operatorname{vec}(\mathbf{B})^\dagger\right]$ [7] is used in the last "=" of (3.3). Substitution of (3.3) into (3.2) leads to (3.1). □

From (2.2), we know that the unitary matrix pair $(\mathbf{U}, \mathbf{V})$ parameterizes the coset space $\mathcal{U}(m) \times \mathcal{U}(n) / [\mathcal{U}(1)]^m$, where $\mathcal{U}(p)$ is the unitary group of order $p$, and the integration measure $d[\mathbf{H}] = \prod_{i=1}^m\prod_{j=1}^n d[\Re h_{ij}]\,d[\Im h_{ij}]$ can be represented by [9]

$$d[\mathbf{H}] = \Omega J(\mathbf{s})d[\mathbf{s}]d\mu(\mathbf{U},\mathbf{V}), \tag{3.4}$$

where $J(\mathbf{s}) = \triangle^2(\mathbf{s}^2)\prod_{k=1}^m s_k^{2\nu+1}$ with the $m$-dimensional Vandermonde determinant $\triangle(\mathbf{s}^2) = \det|s_k^{2(l-1)}| = \prod_{k>l}(s_k^2 - s_l^2)$ and $\triangle^2(\cdot) = [\triangle(\cdot)]^2$, $d[\mathbf{s}] = \prod_{l=1}^m ds_l$, $d\mu(\mathbf{U},\mathbf{V})$ is the Haar measure of $\mathcal{U}(m) \times \mathcal{U}(n) / [\mathcal{U}(1)]^m$ [9], and the constant $\Omega$ is given by [9,15]

$$\Omega = \frac{2^m\pi^{mn}}{\prod_{j=1}^m j!(j+\nu-1)!} = \frac{2^m\pi^{mn}}{m!\prod_{j=0}^{m-1} j!(j+\nu)!}. \tag{3.5}$$

Similarly, we have

$$d[\mathbf{G}] = \Omega J(\mathbf{r})d[\mathbf{r}]d\mu(\widetilde{\mathbf{U}},\widetilde{\mathbf{V}}), \tag{3.6}$$

where $J(\mathbf{r}) = \triangle^2(\mathbf{r}^2)\prod_{k=1}^m r_k^{2\nu+1}$ with the $m$-dimensional Vandermonde determinant $\triangle(\mathbf{r}^2) = \det|r_k^{2(l-1)}| = \prod_{k>l}(r_k^2 - r_l^2)$ and $d[\mathbf{r}] = \prod_{l=1}^m dr_l$.

In order to obtain the joint PDF of $\{r_l\}_{l=1}^m$ and $\{s_l\}_{l=1}^m$, we need the following proposition.

Proposition 3.2 (an Itzykson–Zuber-type integral [9, equation (31)]).

$$\begin{aligned}&\int d\mu(\mathbf{U},\mathbf{V})\exp\left\{-\frac{\operatorname{tr}\left[(\mathbf{H}-\mathbf{G})(\mathbf{H}-\mathbf{G})^\dagger\right]}{t}\right\} \\ &= \frac{2^m\pi^{mn}t^{mn-m}\det\left|\exp\left(-\frac{s_k^2+r_l^2}{t}\right)I_\nu\left(\frac{2s_kr_l}{t}\right)\right|}{m!\Omega\triangle(\mathbf{s}^2)\triangle(\mathbf{r}^2)\prod_{k=1}^m(s_kr_k)^\nu},\end{aligned} \tag{3.7}$$

[illegible] $\Omega$ [illegible] (3.5) [illegible] $I_k(z) = \frac{1}{\pi}\int_0^\pi e^{z\cos\theta}\cos(k\theta)$ [illegible] $\theta$ [illegible] $k$ [illegible]

Theorem 3.3. [illegible] $\mathbf{H}$ [illegible] $\mathbf{G}$ [illegible]

$$p(\mathbf{s},\mathbf{r}) = \frac{\exp\left(-\frac{\sum_{k=1}^m s_k^2+r_k^2}{1-|\rho|^2}\right)\triangle(\mathbf{s}^2)\triangle(\mathbf{r}^2)\prod_{k=1}^m(s_kr_k)^{\nu+1}\det\left|I_\nu\left(\frac{2|\rho|s_kr_l}{1-|\rho|^2}\right)\right|}{2^{-2m}m!m!\prod_{j=0}^{m-1}j!(j+\nu)!|\rho|^{mn-m}(1-|\rho|^2)^m}. \tag{3.8}$$

[illegible] By combining (3.1) with (3.4) and (3.6), we obtain

$$p(\mathbf{s},\mathbf{r}) = \frac{\Omega^2 J(\mathbf{s})J(\mathbf{r})}{\pi^{2mn}(1-|\rho|^2)^{mn}}\Phi(\mathbf{s},\mathbf{r}), \tag{3.9}$$

where

$$
\begin{aligned}
\Phi(\mathbf{s},\mathbf{r}) &= \int d\mu(\widetilde{\mathbf{U}},\widetilde{\mathbf{V}}) \int d\mu(\mathbf{U},\mathbf{V}) \exp\left[-\frac{\operatorname{tr}\left(\mathbf{H}\mathbf{H}^\dagger + \mathbf{G}\mathbf{G}^\dagger - \rho^\star \mathbf{H}\mathbf{G}^\dagger - \rho \mathbf{G}\mathbf{H}^\dagger\right)}{1-|\rho|^2}\right] \\
&= \int d\mu(\widetilde{\mathbf{U}},\widetilde{\mathbf{V}}) \int d\mu(\mathbf{U},\mathbf{V}) \exp\left\{-\frac{\operatorname{tr}\left[(\mathbf{H}-\rho\mathbf{G})(\mathbf{H}-\rho\mathbf{G})^\dagger\right]}{1-|\rho|^2} - \operatorname{tr}(\mathbf{G}\mathbf{G}^\dagger)\right\} \\
&= \int d\mu(\widetilde{\mathbf{U}},\widetilde{\mathbf{V}})\, e^{-\operatorname{tr}(\mathbf{G}\mathbf{G}^\dagger)} \int d\mu(\mathbf{U},\mathbf{V}) \exp\left\{-\frac{\operatorname{tr}\left[(\mathbf{H}-\rho\mathbf{G})(\mathbf{H}-\rho\mathbf{G})^\dagger\right]}{1-|\rho|^2}\right\} \\
&= \int d\mu(\widetilde{\mathbf{U}},\widetilde{\mathbf{V}}) \frac{e^{-\sum_{k=1}^m r_k^2}(1-|\rho|^2)^{mn-m} \det\left| e^{-\frac{s_k^2+|\rho|^2 r_l^2}{1-|\rho|^2}} I_\nu\!\left(\frac{2|\rho| s_k r_l}{1-|\rho|^2}\right)\right|}{2^{-m} m! \pi^{-mn} \Omega \triangle(\mathbf{s}^2) \triangle(|\rho|^2 \mathbf{r}^2) \prod_{k=1}^m (|\rho| s_k r_k)^\nu} \\
&= \frac{(1-|\rho|^2)^{mn-m} \exp\left(-\frac{\sum_{k=1}^m s_k^2 + r_k^2}{1-|\rho|^2}\right) \det\left| I_\nu\!\left(\frac{2|\rho| s_k r_l}{1-|\rho|^2}\right)\right|}{2^{-m} m! \pi^{-mn} \Omega |\rho|^{mn-m} \triangle(\mathbf{s}^2) \triangle(\mathbf{r}^2) \prod_{k=1}^m (s_k r_k)^\nu}.
\end{aligned}
\tag{3.10}
$$

Derivation of the second and third lines of (3.10) are straightforward. The fourth line comes from

$$\rho\mathbf{G} = \widehat{\mathbf{U}}\widehat{\mathbf{R}}\widehat{\mathbf{V}}^\dagger, \tag{3.11}$$

with $\widehat{\mathbf{R}} = |\rho|\mathbf{R}$, and Proposition 3.2 with the replacements $t \to 1-|\rho|^2$ and $\mathbf{G} \to \rho\mathbf{G}$. The last line is based on the convention that $\int d\mu(\widetilde{\mathbf{U}},\widetilde{\mathbf{V}}) = 1$ [9]. Plugging (3.5) and the last line of (3.10) into (3.9), we obtain (3.8). $\square$

By relating the eigenvalues of $\mathbf{G}\mathbf{G}^\dagger$ to the singular values of $\mathbf{G}$ through $\alpha_l = r_l^2$, $l \in [1,m]$, and the eigenvalues of $\mathbf{H}\mathbf{H}^\dagger$ to the singular values of $\mathbf{H}$ through $\beta_l = s_l^2$, $l \in [1,m]$, we can derive the joint PDF of $\boldsymbol{\alpha} = [\alpha_1, \alpha_2, \ldots, \alpha_m]$ and $\boldsymbol{\beta} = [\beta_1, \beta_2, \ldots, \beta_m]$, presented in the following corollary.

COROLLARY 3.4. [illegible] $\mathbf{H}\mathbf{H}^\dagger$ [illegible] $\mathbf{G}\mathbf{G}^\dagger$ [illegible]

$$p(\boldsymbol{\beta},\boldsymbol{\alpha}) = \frac{\exp\left(-\frac{\sum_{k=1}^m \beta_k + \alpha_k}{1-|\rho|^2}\right) \triangle(\boldsymbol{\beta}) \triangle(\boldsymbol{\alpha}) \prod_{k=1}^m (\sqrt{\beta_k \alpha_k})^\nu \det\left| I_\nu\!\left(\frac{2|\rho|\sqrt{\beta_k \alpha_l}}{1-|\rho|^2}\right)\right|}{m! m! \prod_{j=0}^{m-1} j!(j+\nu)! |\rho|^{mn-m} (1-|\rho|^2)^m}, \tag{3.12}$$

[illegible] $m$ [illegible] $\triangle(\boldsymbol{\beta}) = \det\left|\beta_k^{l-1}\right| = \prod_{k>l}(\beta_k - \beta_l)$ [illegible] $\triangle(\boldsymbol{\alpha}) = \det\left|\alpha_k^{l-1}\right| = \prod_{k>l}(\alpha_k - \alpha_l)$

[illegible]. It is straightforward to obtain (3.12) from (3.8) by $2m$ one-to-one nonlinear mappings. $\square$

**4. Joint marginal PDF.** In this section, with $\beta = s^2$ and $\alpha = r^2$, we calculate the joint marginal PDF of $\beta$ and $\alpha$, $p(\beta,\alpha)$, using the techniques and results presented in [4,13]. Then the joint PDF of $s$ and $r$, $p(s,r)$, is easily derived.

If the polynomials $P_k(\beta)$ and $Q_l(\alpha)$ satisfy $\int w(\beta,\alpha) P_k(\beta) Q_l(\alpha) d\beta d\alpha = \delta_{kl}$, then we call $P_k(\beta)$ and $Q_l(\alpha)$ biorthogonal polynomials, associated with the weight function $w(\beta,\alpha)$ [12]. With this definition, we have the following lemma.

LEMMA 4.1. [illegible] $P_k(\beta)$ [illegible] $Q_l(\alpha)$ [illegible] $w(\beta,\alpha)$ [illegible] (3.12) [illegible]

$$p(\boldsymbol{\beta},\boldsymbol{\alpha}) = C_1 \det|P_{k-1}(\beta_l)| \det|w(\beta_k,\alpha_l)| \det|Q_{k-1}(\alpha_l)|, \tag{4.1}$$

[illegible] $C_1$ [illegible]

In this paper, $\nu$ is a nonnegative integer. Using the Hille–Hardy formula [2, p. 185, equation (46)]

$$\sum_{k=0}^{\infty}\frac{k!z^k}{(k+\nu)!}L_k^{\nu}(x)L_k^{\nu}(y)=\frac{(xyz)^{-\frac{\nu}{2}}}{1-z}\exp\left(-z\frac{x+y}{1-z}\right)I_{\nu}\left(\frac{2\sqrt{xyz}}{1-z}\right),|z|<1, \tag{4.2}$$

with $L_k^{\nu}(x)=\frac{1}{k!}e^{x}x^{-\nu}\frac{d^k}{dx^k}(e^{-x}x^{k+\nu})$ as the associated Laguerre polynomial, we can rewrite (3.12) as

$$p(\boldsymbol{\beta},\boldsymbol{\alpha})=\frac{\triangle(\boldsymbol{\beta})\triangle(\boldsymbol{\alpha})\det\left|\beta_k^{\nu}e^{-\beta_k}\alpha_l^{\nu}e^{-\alpha_l}\sum_{j=0}^{\infty}\frac{j!|\rho|^{2j}L_j^{\nu}(\beta_k)L_j^{\nu}(\alpha_l)}{(j+\nu)!}\right|}{m!m!\prod_{j=0}^{m-1}j!(j+\nu)!|\rho|^{m(m-1)}}. \tag{4.3}$$

We set the weight function $w(\beta,\alpha)$ as

$$\begin{aligned} w(\beta,\alpha)&=\beta^{\nu}\alpha^{\nu}e^{-(\beta+\alpha)}\sum_{j=0}^{\infty}\frac{j!|\rho|^{2j}L_j^{\nu}(\beta)L_j^{\nu}(\alpha)}{(j+\nu)!}\\ &=\frac{(\beta\alpha)^{\frac{\nu}{2}}e^{-\frac{\beta+\alpha}{1-|\rho|^2}}I_{\nu}\left(\frac{2|\rho|\sqrt{\beta\alpha}}{1-|\rho|^2}\right)}{(1-|\rho|^2)|\rho|^{\nu}}. \end{aligned} \tag{4.4}$$

It is easy to check that the corresponding biorthogonal polynomials are given by

$$P_k(\beta)=\sqrt{\frac{k!}{(k+\nu)!}}|\rho|^{-k}L_k^{\nu}(\beta), \tag{4.5}$$

$$Q_l(\alpha)=\sqrt{\frac{l!}{(l+\nu)!}}|\rho|^{-l}L_l^{\nu}(\alpha), \tag{4.6}$$

using the following integral equality [2, p. 267, equation 7.414.3]

$$\int_0^{\infty}e^{-x}x^{\nu}L_k^{\nu}(x)L_l^{\nu}(x)=\frac{(k+\nu)!}{k!}\delta_{kl}. \tag{4.7}$$

Moreover, by the addition of multiples of rows of lower order which do not change the determinant of the Vandermonde matrix, each of the rows can be expressed in terms of orthogonal polynomials with respect to the weight function $w(\beta,\alpha)$. Therefore two $m$-dimensional Vandermonde determinants, $\triangle(\boldsymbol{\beta})$ and $\triangle(\boldsymbol{\alpha})$, can be represented as

$$\triangle(\boldsymbol{\beta})=\det\left|\beta_k^{l-1}\right|=C_2\det\left|P_{k-1}(\beta_l)\right|, \tag{4.8}$$

$$\triangle(\boldsymbol{\alpha})=\det\left|\alpha_k^{l-1}\right|=C_3\det\left|Q_{k-1}(\alpha_l)\right|, \tag{4.9}$$

where we use the fact that the matrix transpose does not change the determinant, i.e., $\det|P_{l-1}(\beta_k)|=\det|P_{k-1}(\beta_l)|$ and $\det|Q_{l-1}(\beta_k)|=\det|Q_{k-1}(\beta_l)|$.

The coefficient of $x^k$ in $L_k^{\nu}(x)$ is $\frac{(-1)^k}{k!}$, and the coefficient of $x^k$ in $P_k(x)$ is $(-1)^k|\rho|^{-k}\frac{1}{\sqrt{k!(k+\nu)!}}$; therefore, we have $C_2=\prod_{j=0}^{m-1}(-1)^j|\rho|^j\sqrt{j!(j+\nu)!}=(-1)^{\frac{m(m-1)}{2}}$ $\times\sqrt{|\rho|^{m(m-1)}\prod_{j=0}^{m-1}j!(j+\nu)!}$, obtained by plugging (4.5) into (4.8). Similarly, substitution of (4.6) into (4.9) gives $C_3=C_2$. Now the product of (4.8) and (4.9) results in

$$\triangle(\boldsymbol{\beta})\triangle(\boldsymbol{\alpha}) = |\rho|^{m(m-1)} \prod_{j=0}^{m-1} j!(j+\nu)! \det|P_{k-1}(\beta_l)| \det|Q_{k-1}(\alpha_l)|. \tag{4.10}$$

Based on (4.4) and (4.10), one can see that (4.3) is equal to (4.1) with $C_1 = \frac{1}{m!m!}$. ☐

THEOREM 4.2. [illegible] $\beta$ [illegible] $\alpha$ [illegible]

$$\begin{aligned} p(\beta,\alpha) = {} & \frac{(\beta\alpha)^{\frac{\nu}{2}} e^{-\frac{\beta+\alpha}{1-|\rho|^2}} I_\nu\!\left(\frac{2|\rho|\sqrt{\beta\alpha}}{1-|\rho|^2}\right)}{m^2(1-|\rho|^2)|\rho|^\nu} \sum_{k=0}^{m-1} \frac{k!}{(k+\nu)!} \frac{L_k^\nu(\beta)L_k^\nu(\alpha)}{|\rho|^{2k}} \\ & + \frac{(\beta\alpha)^\nu e^{-(\beta+\alpha)}}{m^2} \sum_{0\le k<l}^{m-1} \left\{ \frac{k!l!}{(k+\nu)!(l+\nu)!} \Big\{ \left[L_k^\nu(\beta)L_l^\nu(\alpha)\right]^2 + \left[L_l^\nu(\beta)L_k^\nu(\alpha)\right]^2 \right. \\ & \left. - \left[|\rho|^{2(l-k)} + |\rho|^{2(k-l)}\right] L_k^\nu(\beta)L_l^\nu(\beta)L_k^\nu(\alpha)L_l^\nu(\alpha) \Big\} \right\}. \end{aligned} \tag{4.11}$$

[illegible]. Based on Lemma 4.1, and the results presented in [13, equation (3.7)] [4], $p(\beta,\alpha)$ can be expressed as

$$m^2\, p(\beta,\alpha) = w(\beta,\alpha) \sum_{k=0}^{m-1} P_k(\beta)Q_k(\alpha) + \sum_{0\le k<l}^{m-1} \det\begin{vmatrix} P_k(\beta) & \overline{P}_k(\alpha) \\ P_l(\beta) & \overline{P}_l(\alpha) \end{vmatrix} \det\begin{vmatrix} \overline{Q}_k(\beta) & Q_k(\alpha) \\ \overline{Q}_l(\beta) & Q_l(\alpha) \end{vmatrix}, \tag{4.12}$$

where $P_k(x)$ and $Q_k(x)$ are defined in (4.5) and (4.6), respectively, the weight function is presented in (4.4), and $\overline{P}_k(\alpha)$ and $\overline{Q}_l(\beta)$ are similarly defined as [13]

$$\overline{P}_k(\alpha) = \int P_k(\beta)w(\beta,\alpha)d\beta = \sqrt{\frac{k!}{(k+\nu)!}}\alpha^\nu e^{-\alpha}|\rho|^k L_k^\nu(\alpha), \tag{4.13}$$

$$\overline{Q}_l(\beta) = \int Q_l(\alpha)w(\beta,\alpha)d\alpha = \sqrt{\frac{l!}{(l+\nu)!}}\beta^\nu e^{-\beta}|\rho|^l L_l^\nu(\beta). \tag{4.14}$$

Plugging (4.4), (4.5), (4.6), (4.13), and (4.14) into (4.12), we arrive at (4.11). ☐

It is straightforward to obtain the joint PDF of $s$ and $r$ from (4.11), according to these one-to-one mappings $s = \sqrt{\beta}$ and $r = \sqrt{\alpha}$.

The joint PDF in (4.11) includes many existing PDFs as special cases.

- By integration over $\beta$, (4.11) reduces to the marginal PDF

  $$p(\alpha) = \frac{1}{m} \sum_{k=0}^{m-1} \frac{k!}{(k+\nu)!} \left[L_k^\nu(\alpha)\right]^2 \alpha^\nu e^{-\alpha}, \tag{4.15}$$

  which is the same as the PDF presented in [18]. When $m = 1$, (4.15) further reduces to

  $$p(\alpha) = \frac{1}{(n-1)!}\alpha^{n-1}e^{-\alpha}, \tag{4.16}$$

  which is the $\chi^2$ distribution with $2n$ degrees of freedom [17, equation (2.32)].

- With $m = 1$, (4.11) reduces to [21]

$$p(\alpha,\beta) = \frac{(\alpha\beta)^{\frac{n-1}{2}} \exp\left(-\frac{\alpha+\beta}{1-|\rho|^2}\right) I_{n-1}\left(\frac{2|\rho|\sqrt{\alpha\beta}}{1-|\rho|^2}\right)}{(n-1)!\,(1-|\rho|^2)\,|\rho|^{n-1}}. \tag{4.17}$$

Furthermore, when $n = 1$, (4.17) simplifies to

$$p(\alpha,\beta) = \frac{1}{1-|\rho|^2} \exp\left(-\frac{\alpha+\beta}{1-|\rho|^2}\right) I_0\left(\frac{2|\rho|\sqrt{\alpha\beta}}{1-|\rho|^2}\right), \tag{4.18}$$

which is identical to [3, p. 163, equation (8-103)], after two one-to-one nonlinear transformations.

For the application discussed in section 5, we need the joint marginal PDF of $\phi$ and $\varphi$, $p(\phi,\varphi)$, where $\phi$ and $\varphi$ are randomly selected from $\{\alpha_k\}_{k=1}^m$, $m \geq 2$. Using the technique in [4, 13], we have the following theorem.

THEOREM 4.3. [illegible] $\phi$ [illegible] $\varphi$ [illegible] $\{\alpha_k\}_{k=1}^m$ [illegible]

$$p(\phi,\varphi) = \frac{(\phi\varphi)^\nu e^{-(\phi+\varphi)}}{m(m-1)} \sum_{\substack{k,l=0\\k\neq l}}^{m-1} \frac{k!\,l!}{(k+\nu)!(l+\nu)!} \left\{\left[L_k^\nu(\phi)L_l^\nu(\varphi)\right]^2 - L_k^\nu(\phi)L_l^\nu(\phi)L_k^\nu(\varphi)L_l^\nu(\varphi)\right\}. \tag{4.19}$$

[illegible] According to (1.6) and (2.14) in [13] we have

$$p(\phi,\varphi) = \frac{1}{m(m-1)} \det\begin{vmatrix} K(\phi,\phi) & K(\phi,\varphi) \\ K(\varphi,\phi) & K(\varphi,\varphi) \end{vmatrix}, \tag{4.20}$$

where $K(x_1,x_2) = \sum_{k=0}^{m-1} P_k(x_1)\overline{Q}_k(x_2)$. With $P_k(x_1)$ in (4.5) and $\overline{Q}_k(x_2)$ in (4.14), we obtain (4.19) after some simple algebraic manipulations. □

## 5. Application to wireless MIMO communication systems.

For an $N_R \times N_T$ MIMO time-varying Rayleigh flat fading channel [19] with $N_T$ transmitters and $N_R$ receivers, the channel impulse response at time instant $t$ is given by

$$\mathbf{H}(t) = \begin{bmatrix} h_{1,1}(t) & \cdots & h_{1,N_T}(t) \\ \vdots & \ddots & \vdots \\ h_{N_R,1}(t) & \cdots & h_{N_R,N_T}(t) \end{bmatrix}. \tag{5.1}$$

We assume all of the $N_R N_T$ subchannels in the MIMO system $\{h_{i,j}(t)\}_{(i=1,j=1)}^{(N_R,N_T)}$ are i.i.d., with the same temporal correlation coefficient, i.e.,

$$\mathbb{E}[h_{ij}(t)h_{pq}^\star(t-\tau)] = \delta_{ip}\delta_{jq}\rho_h(\tau), \tag{5.2}$$

where $\rho_h(\tau) = J_0(2\pi f_D \tau)$ [10] in isotropic scattering environments,[1] with $J_0(x) = I_0(-\jmath x)$ [5, p. 961, equation 8.406.3], and $f_D$ is the maximum Doppler frequency shift.

---

[1] In the nonisotropic scattering environment, $\rho_h(\tau)$, in general, is a complex-value function [22,23], and $|\rho_h(\tau)|$ indicates its amplitude at the time delay $\tau$.

We set $n = \max(N_R, N_T)$ and $m = \min(N_R, N_T)$. According to (2.2), $\mathbf{H}(t)$ can be diagonalized as

$$\mathbf{H}(t) = \mathbf{U}(t)\mathbf{S}(t)\mathbf{V}^{\dagger}(t), \tag{5.3}$$

where $\mathbf{S}(t) = \left[\operatorname{diag}(\mathbf{s}(t))\ \mathbf{0}\right]$, with $\mathbf{s}(t) = [s_1(t), s_2(t), \ldots, s_m(t)]$, for $N_R \leq N_T$, and $\mathbf{S}(t) = \begin{bmatrix} \operatorname{diag}(\mathbf{s}(t)) \\ \mathbf{0} \end{bmatrix}$ for $N_R > N_T$. Therefore the MIMO channel $\mathbf{H}(t)$ is decomposed to $m$ identically distributed eigenchannels $\lambda_k(t) = s_k^2(t)$, $k \in [1, m]$, by SVD.

In wireless MIMO communication systems, we are interested in the correlation coefficient between any two eigenchannels, which is defined by

$$\rho_{k,l}(\tau) = \frac{\mathbb{E}\left[\lambda_k(t)\lambda_l(t-\tau)\right] - \mathbb{E}\left[\lambda_k(t)\right]\mathbb{E}\left[\lambda_l(t)\right]}{\sqrt{\mathbb{E}\left[\lambda_k^2(t)\right] - \left\{\mathbb{E}\left[\lambda_k(t)\right]\right\}^2}\sqrt{\mathbb{E}\left[\lambda_l^2(t)\right] - \left\{\mathbb{E}\left[\lambda_l(t)\right]\right\}^2}}. \tag{5.4}$$

For simplicity, in this paper we consider only a 2×2 MIMO system,[2] $N_R = N_T = 2$, where the correlation coefficient $\rho_{k,l}(\tau)$ can be shown to be

$$\rho_{k,l}(\tau) = \begin{cases} 1 - \frac{3}{2}\left(1 - \delta_{kl}\right), & \tau = 0, \\ \frac{|\rho_h(\tau)|^2}{4} = \frac{J_0^2(2\pi f_D \tau)}{4}, & \tau \neq 0, \end{cases} \quad k, l = 1, 2, \tag{5.5}$$

with $J_0^2(\cdot) = [J_0(\cdot)]^2$. To derive (5.5), we note that, for $\tau = 0$ and $k = l$, $\rho_{k,l}(0) = 1$ because of the definition of the correlation coefficient. Since $m = 2$, for any eigenchannel at the time instant $t$, it is easy to show that the mean value of $\lambda_k(t)$ is $\mathbb{E}\left[\lambda_k(t)\right] = 2\ \forall k$, and the second moment of $\lambda_k(t)$ is $\mathbb{E}\left[\lambda_k^2(t)\right] = 8\ \forall k$, using the PDF in (4.15). For $\tau = 0$ and $k \neq l$, we obtain $\mathbb{E}\left[\lambda_k(t)\lambda_l(t)\right] = 2$ by (4.19); hence, $\rho_{k,l}(0) = -\frac{1}{2}\ \forall k \neq l$. For $\tau \neq 0$ and $\forall k, l$, it is not difficult to get $\mathbb{E}\left[\lambda_k(t)\lambda_l(t-\tau)\right] = 4 + |\rho_h(\tau)|^2$ using (4.11); therefore, we have the second line in (5.5).

Monte Carlo simulations are performed to verify the result in (5.5). In all simulations,[3] the maximum Doppler frequency $f_D$ is set to 1 Hz, and the sampling period $T_s$ is equal to $\frac{1}{1000 f_D}$. The simulation results are shown in Figure 5.1, where the upper figure shows the channel correlation coefficient $\rho_h(\tau) = J_0\left(2\pi f_D \tau\right)$, Clarke's correlation model, whereas the lower figure presents the correlation coefficient between any two eigenchannels or for any individual eigenchannel, (5.5). Since $J_0(2\pi f_D \tau)$ is an even function of $\tau$, the correlation coefficients are plotted for $\tau \geq 0$. In the figure, "Simu." indicates the curve is obtained by Monte Carlo simulations, whereas "Theo." means theoretical. From Figure 5.1 we can conclude that the new theoretical result in (5.5) is confirmed by simulation very well.

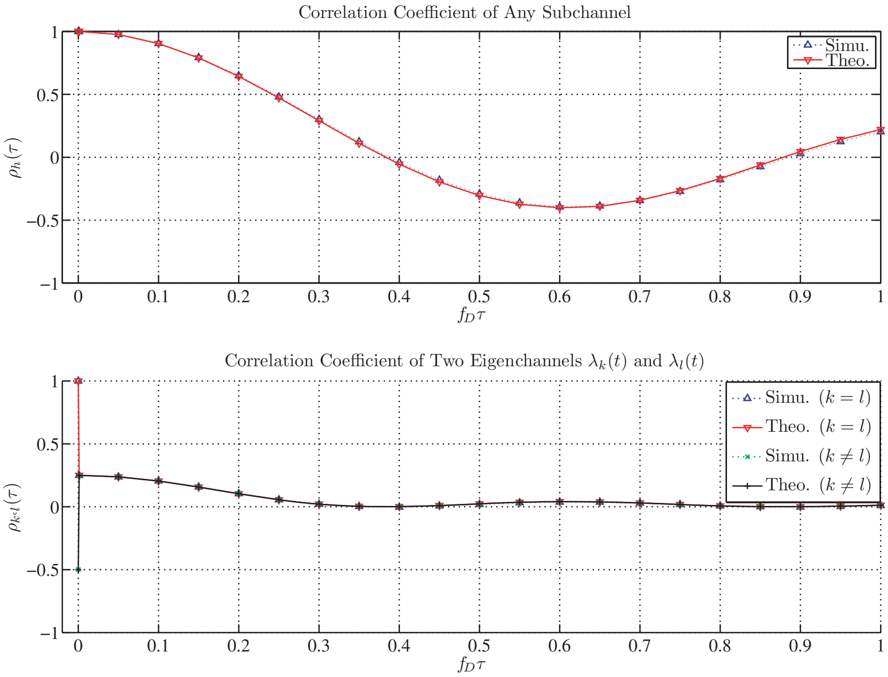
**6. Conclusion.** In this paper, the joint distribution of singular values of two correlated rectangular complex Gaussian random matrices is derived, as well as the joint marginal distribution. The derived distributions play an important role in the analysis and design of wireless MIMO communication systems. As an example, the correlation coefficient of any two eigenchannels of a 2 × 2 MIMO system is obtained and verified by the Monte Carlo simulations in this paper.

**Acknowledgment.** We thank the anonymous reviewers for bringing [6] and [20] to our attention.

---

[2] The general $N_R \times N_T$ MIMO system is considered in [22, Chap. 4].

[3] The spectral method [1] is used to generate the MIMO channels.



Correlation Coefficient of Any Subchannel

Correlation Coefficient of Two Eigenchannels $\lambda_k(t)$ and $\lambda_l(t)$

FIG. 5.1. *The channel correlation coefficient $\rho_h(\tau)$ and correlation coefficient of any two eigenchannels $\rho_{k,l}(\tau)$ in a $2 \times 2$ MIMO system with Clarke's correlation model. Note that the sampling period $T_s$ is $\frac{1}{1000 f_D}$ in Monte Carlo simulations; therefore, the first nonzero $\tau$ is $T_s$, i.e., $\frac{1}{1000 f_D}$, which corresponds to $f_D\tau = \frac{1}{1000}$ in the horizontal axis.*

# PROJECTED GENERALIZED DISCRETE-TIME PERIODIC LYAPUNOV EQUATIONS AND BALANCED REALIZATION OF PERIODIC DESCRIPTOR SYSTEMS*

ERIC KING-WAH CHU†, HUNG-YUAN FAN‡, AND WEN-WEI LIN§

**Abstract.** From the necessary and sufficient conditions for complete reachability and observability of periodic descriptor systems with time-varying dimensions, the symmetric positive semidefinite reachability/observability Gramians are defined. These Gramians can be shown to satisfy some projected generalized discrete-time periodic Lyapunov equations. We propose a numerical method for solving these projected Lyapunov equations, and give an illustrative numerical example. As an application of our results, the balanced realization of periodic descriptor systems is discussed.

**Key words.** periodic systems, descriptor systems, reachability and observability Gramians, Hankel singular values, balanced realization

## 1. Introduction.

In the second half of the last century, the development of systems and control theory, together with the achievements of digital control and signal processing, has set the stage for renewed interest in the study of periodic systems, both in continuous and discrete time; see, e.g., [11, 13, 16, 27, 42, 53] and the survey papers [3, 4]. This has been amplified by specific application demands in the aerospace realm [20, 21, 28], computer control of industrial processes [5], and communication systems [11, 40, 41, 52]. The number of contributions on linear time-varying discrete-time periodic systems has been increasing in recent times; see, e.g., [14, 19, 22, 43, 45, 47] and the references therein. This increasing interest in periodic systems has also been motivated by the large variety of processes that can be modeled through linear discrete-time periodic systems (e.g., multirate sampled-data systems, chemical processes, periodically time-varying filters and networks, and seasonal phenomena [2, 3, 6, 15, 26, 31, 51]).

We consider here a periodic descriptor system with time-varying dimensions:

$$E_k x_{k+1} = A_k x_k + B_k u_k, \quad y_k = C_k x_k, \quad k \in \mathbb{Z}, \tag{1.1}$$

where the matrices $E_k \in \mathbb{R}^{\mu_{k+1}\times n_{k+1}}$, $A_k \in \mathbb{R}^{\mu_{k+1}\times n_k}$, $B_k \in \mathbb{R}^{\mu_{k+1}\times m}$, $C_k \in \mathbb{R}^{p\times n_k}$ are periodic with period $K \geq 1$, i.e., $E_k = E_{k+K}$, $A_k = A_{k+K}$, $B_k = B_{k+K}$, $C_k = C_{k+K}$, and all system matrices $E_k$ and $A_k$ are allowed to be rectangular for all $k$. Moreover, the dimensions of matrices are also $K$-periodic, i.e., $\mu_{k+K} = \mu_k$ and $n_{k+K} = n_k$ for all $k$. Assume that $\sum_{k=0}^{K-1} \mu_k = \sum_{k=0}^{K-1} n_k \equiv N$. Recently, this class of periodic descriptor systems (1.1) has been discussed and studied extensively in the problem of solvability

and conditionability [33], the computation of $H_\infty$-norm and system zeros [49, 50], and the compensating and regularization problems for periodic descriptor systems [8, 23].

It is well known that the dynamics of the discrete-time periodic descriptor system (1.1) depend critically on the regularity and the eigenstructure of the periodic matrix pairs $\{(E_k, A_k)\}_{k=0}^{K-1}$, which satisfy the homogeneous systems of (1.1):

$$E_k x_{k+1} = A_k x_k, \quad k \in \mathbb{Z}. \tag{1.2}$$

The set of matrix pairs $\{(E_k, A_k)\}_{k=0}^{K-1}$ is said to be regular when $\det[C((\alpha_k, \beta_k)_{k=0}^{K-1})] \neq 0$, where

$$C((\alpha_k, \beta_k)_{k=0}^{K-1}) \equiv \begin{bmatrix} \alpha_0 E_0 & 0 & \cdots & 0 & -\beta_0 A_0 \\ -\beta_1 A_1 & \alpha_1 E_1 & & & 0 \\ & \ddots & \ddots & & \vdots \\ & & \ddots & \ddots & 0 \\ 0 & & 0 & -\beta_{K-1} A_{K-1} & \alpha_{K-1} E_{K-1} \end{bmatrix} \in \mathbb{R}^{N \times N}, \tag{1.3}$$

in which $\alpha_k, \beta_k$ are complex variables for $k = 0, \dots, K-1$. Note that we are considering the regularity of the [illegible] of matrix pairs $\{(E_k, A_k)\}_{k=0}^{K-1}$, rather than the regularity of the individual matrix pairs $(E_k, A_k)$.

Definition 1.1. [illegible] $\{(E_k, A_k)\}_{k=0}^{K-1}$ [illegible] $\alpha_0, \dots, \alpha_{K-1}$ $\beta_0, \dots, \beta_{K-1}$ [illegible]

$$\det[C((\alpha_k, \beta_k)_{k=0}^{K-1})] = 0, \qquad \left( \prod_{k=0}^{K-1} \alpha_k, \prod_{k=0}^{K-1} \beta_k \right) \equiv (\pi_\alpha, \pi_\beta) \neq (0, 0), \tag{1.4}$$

[illegible] $(\pi_\alpha, \pi_\beta)$ [illegible] $\{(E_k, A_k)\}_{k=0}^{K-1}$

Note that if $(\pi_\alpha, \pi_\beta)$ is an eigenvalue pair of $\{(E_k, A_k)\}_{k=0}^{K-1}$, then $(\pi_\alpha, \pi_\beta)$ and $(\tau\pi_\alpha, \tau\pi_\beta)$ represent the same eigenvalue for any nonzero $\tau$. If $\pi_\beta \neq 0$, then $\lambda = \pi_\alpha/\pi_\beta$ is a finite eigenvalue; otherwise $(\pi_\alpha, 0)$ represents an infinite eigenvalue. We shall assume throughout the paper that the set of periodic matrix pairs $\{(E_k, A_k)\}_{k=0}^{K-1}$ is regular, and use the notation $\sigma(M)$ to denote the spectrum of a square matrix $M$.

For discrete-time descriptor systems, the concepts of reachability and observability Gramians, causal and noncausal Hankel singular values, and balanced realization are well established [1, 39]. Moreover, numerical methods have been proposed in [10, 34] to solve the projected generalized Lyapunov equations for continuous-time descriptor systems. However, to the best of our knowledge, similar results have not been developed for periodic descriptor systems.

In summary, there are two main contributions in this paper. First, with the aid of the fundamental matrices $\Psi_{i,j}$ defined as in (2.15), the reachability/observability Gramians and their corresponding projected generalized discrete-time periodic Lyapunov equations (GDPLEs) are derived in terms of the original system matrices $E_k$, $A_k$, $B_k$, and $C_k$, $k = 0, 1, \dots, K-1$, respectively. These fundamental matrices play an important role here and are natural extensions of those defined for the descriptor system with period $K = 1$ [34, 39]. Second, in sections 6 and 7, Hankel singular values and balanced realization are discussed, for the first time, for completely reachable and observable periodic descriptor systems. These concepts are likely to be crucial in the model reduction problem of periodic descriptor systems.

This paper is organized as follows. Section 2 contains some notation and definitions, as well as some preliminary results. In section 3 the necessary and sufficient conditions for complete reachability and observability of periodic descriptor systems are developed from similar results for systems with constant dimensions in [10]. With these equivalent conditions, the periodic reachability and observability Gramians, which satisfy some generalized periodic Lyapunov equations, are developed in section 4. In section 5 we propose a numerical method for solving these equations under the assumption of pd-stability. A numerical example is given to illustrate its feasibility and reliability. The concept of Hankel singular values is generalized to periodic descriptor systems in section 6. The problem of balanced realization for the completely reachable and completely observable periodic descriptor systems is discussed in section 7.

**2. Preliminaries.** For period $K = 1$ and a regular matrix pair $(E, A)$, it is well known that the discrete-time descriptor system $(E, A, B, C)$ is asymptotically stable if and only if all finite eigenvalues of $(E, A)$ lie inside the unit circle [12, 35, 37]. Similarly, the stability of the periodic descriptor system (1.1) can be characterized in terms of the spectrum of the periodic matrix pairs $\{(E_k, A_k)\}_{k=0}^{K-1}$.

DEFINITION 2.1. [illegible] $\{(E_k, A_k)\}_{k=0}^{K-1}$ [illegible] $\{(E_k, A_k)\}_{k=0}^{K-1}$ [illegible] $\{(E_k, A_k)\}_{k=0}^{K-1}$ [illegible]

In a fashion similar to the Kronecker canonical form for a regular matrix pair, we can transform a regular set of periodic matrix pairs into a periodic Kronecker canonical form [48] (see also [32] for the history of the canonical form).

LEMMA 2.1. [illegible] $\{(E_k, A_k)\}_{k=0}^{K-1}$ [illegible] (1.1) [illegible] $k = 0, \ldots, K-1$ [illegible] $X_k \in \mathbb{R}^{\mu_{k+1} \times \mu_{k+1}}$ [illegible] $Y_k \in \mathbb{R}^{n_k \times n_k}$ [illegible]

$$X_k E_k Y_{k+1} = \begin{bmatrix} I_{n_{k+1}^f} & 0 \\ 0 & E_k^b \end{bmatrix}, \quad X_k A_k Y_k = \begin{bmatrix} A_k^f & 0 \\ 0 & I_{n_k^\infty} \end{bmatrix}, \tag{2.1}$$

[illegible] $Y_K \equiv Y_0$ $A_{k+K-1}^f A_{k+K-2}^f \cdots A_k^f \equiv J_k$ [illegible] $n_k^f \times n_k^f$ [illegible] $E_k^b E_{k+1}^b \cdots E_{k+K-1}^b \equiv N_k$ [illegible] $n_k^\infty \times n_k^\infty$ [illegible] $n_k = n_k^f + n_k^\infty$ [illegible] $\mu_{k+1} = n_{k+1}^f + n_k^\infty$

[illegible] Since $\{(E_k, A_k)\}_{k=0}^{K-1}$ are pd-stable, there exist orthogonal matrices $V_k \in \mathbb{R}^{\mu_{k+1} \times \mu_{k+1}}$ and $U_k \in \mathbb{R}^{n_k \times n_k}$, with $U_K \equiv U_0$ and for $k = 0, 1, \ldots, K-1$, such that

$$V_k^T E_k U_{k+1} = \begin{bmatrix} E_{k,1} & E_{k,3} \\ 0 & E_{k,2} \end{bmatrix}, \quad V_k^T A_k U_k = \begin{bmatrix} A_{k,1} & A_{k,3} \\ 0 & A_{k,2} \end{bmatrix}, \tag{2.2}$$

where the matrices $E_{k,1} \in \mathbb{R}^{n_{k+1}^f \times n_{k+1}^f}$ and $A_{k,2} \in \mathbb{R}^{n_k^\infty \times n_k^\infty}$ are nonsingular and

$$(A_{k,2})^{-1} E_{k,2} (A_{k+1,2})^{-1} E_{k+1,2} \cdots (A_{k+K-1,2})^{-1} E_{k+K-1,2}$$

are nilpotent for $k = 0, 1, \ldots, K-1$ [48]. All finite eigenvalues of the periodic matrix pairs $\{(E_{k,1}, A_{k,1})\}_{k=0}^{K-1}$ lie inside the unit circle, and the spectrum of the periodic matrix pairs $\{(E_{k,2}, A_{k,2})\}_{k=0}^{K-1}$ contains only infinite eigenvalues. We then construct

$$\begin{bmatrix} E_{k,1}^{-1} & 0 \\ 0 & A_{k,2}^{-1} \end{bmatrix} \begin{bmatrix} E_{k,1} & E_{k,3} \\ 0 & E_{k,2} \end{bmatrix} = \begin{bmatrix} I_{n_{k+1}^f} & \hat{E}_{k,3} \\ 0 & \hat{E}_k^\infty \end{bmatrix}$$

and

$$\begin{bmatrix} E_{k,1}^{-1} & 0 \\ 0 & A_{k,2}^{-1} \end{bmatrix} \begin{bmatrix} A_{k,1} & A_{k,3} \\ 0 & A_{k,2} \end{bmatrix} = \begin{bmatrix} \hat{A}_k^f & \hat{A}_{k,3} \\ 0 & I_{n_k^\infty} \end{bmatrix},$$

where $\hat{E}_{k,3} \in \mathbb{R}^{n_{k+1}^f \times n_{k+1}^\infty}$, $\hat{E}_k^\infty \in \mathbb{R}^{n_k^\infty \times n_{k+1}^\infty}$, $\hat{A}_k^f \in \mathbb{R}^{n_{k+1}^f \times n_k^f}$, and $\hat{A}_{k,3} \in \mathbb{R}^{n_{k+1}^f \times n_k^\infty}$.

We shall prove that there exist periodic matrices $P_k \in \mathbb{R}^{n_{k+1}^f \times n_k^\infty}$ and $Q_k \in \mathbb{R}^{n_k^f \times n_k^\infty}$ such that

$$\begin{bmatrix} I_{n_{k+1}^f} & P_k \\ 0 & I_{n_k^\infty} \end{bmatrix} \begin{bmatrix} I_{n_{k+1}^f} & \hat{E}_{k,3} \\ 0 & \hat{E}_k^\infty \end{bmatrix} \begin{bmatrix} I_{n_{k+1}^f} & Q_{k+1} \\ 0 & I_{n_{k+1}^\infty} \end{bmatrix} = \begin{bmatrix} I_{n_{k+1}^f} & 0 \\ 0 & \hat{E}_k^\infty \end{bmatrix} \tag{2.3}$$

and

$$\begin{bmatrix} I_{n_{k+1}^f} & P_k \\ 0 & I_{n_k^\infty} \end{bmatrix} \begin{bmatrix} \hat{A}_k^f & \hat{A}_{k,3} \\ 0 & I_{n_k^\infty} \end{bmatrix} \begin{bmatrix} I_{n_k^f} & Q_k \\ 0 & I_{n_k^\infty} \end{bmatrix} = \begin{bmatrix} \hat{A}_k^f & 0 \\ 0 & I_{n_k^\infty} \end{bmatrix}. \tag{2.4}$$

Comparing both sides of (2.3) and (2.4), we obtain, for all $k$,

$$Q_{k+1} + P_k \hat{E}_k^\infty + \hat{E}_{k,3} = 0 \tag{2.5}$$

and

$$\hat{A}_k^f Q_k + P_k + \hat{A}_{k,3} = 0. \tag{2.6}$$

Eliminating $P_k$ from (2.5) and (2.6), we arrive at, for all $k$,

$$Q_{k+1} = \hat{A}_k^f Q_k \hat{E}_k^\infty + \hat{A}_{k,3} \hat{E}_k^\infty - \hat{E}_{k,3}. \tag{2.7}$$

With $Q_K = Q_0$, (2.7) in turn implies

$$Q_0 = (\hat{A}_{K-1}^f \hat{A}_{K-2}^f \cdots \hat{A}_0^f) Q_0 (\hat{E}_0^\infty \hat{E}_1^\infty \cdots \hat{E}_{K-1}^\infty) + D_0, \tag{2.8}$$

where $D_0$ is independent of any $Q_k$. Since $\sigma(\hat{E}_0^\infty \hat{E}_1^\infty \cdots \hat{E}_{K-1}^\infty) = \{0\}$, we can uniquely determine $Q_0$ from (2.8), all the other $Q_k$ from (2.7), and all the $P_k$ from (2.6).

Finally, by the well-known Jordan decomposition, there exist nonsingular $K$-periodic matrices $G_k \in \mathbb{R}^{n_k^f \times n_k^f}$ and $Z_k \in \mathbb{R}^{n_k^\infty \times n_k^\infty}$ which produce the Jordan forms

$$J_k \equiv G_k^{-1} (\hat{A}_{k+K-1}^f \hat{A}_{k+K-2}^f \cdots \hat{A}_k^f) G_k, \tag{2.9}$$

$$N_k \equiv Z_k^{-1} (\hat{E}_k^\infty \hat{E}_{k+1}^\infty \cdots \hat{E}_{k+K-1}^\infty) Z_k. \tag{2.10}$$

Define

$$X_k \equiv \begin{bmatrix} G_{k+1}^{-1} & 0 \\ 0 & Z_k^{-1} \end{bmatrix} \begin{bmatrix} I_{n_{k+1}^f} & P_k \\ 0 & I_{n_k^\infty} \end{bmatrix} \begin{bmatrix} E_{k,1}^{-1} & 0 \\ 0 & A_{k,2}^{-1} \end{bmatrix} V_k^T,$$

$$Y_k \equiv U_k \begin{bmatrix} I_{n_k^f} & Q_k \\ 0 & I_{n_k^\infty} \end{bmatrix} \begin{bmatrix} G_k & 0 \\ 0 & Z_k \end{bmatrix}$$

and

$$E_k^b \equiv Z_k^{-1} \hat{E}_k^\infty Z_{k+1}, \quad A_k^f \equiv G_{k+1}^{-1} \hat{A}_k^f G_k;$$

then the proof is complete. □

[illegible]. (i) If $\nu_k$ is the nilpotency of the matrix $N_k$ for $k = 0, 1, \ldots, K-1$, then these $K$ values are defined as the indices of a regular set of periodic matrix pairs $\{(E_k, A_k)\}_{k=0}^{K-1}$ [23]. Hence we define the index of the periodic descriptor system (1.1) as $\nu \equiv \max\{\nu_0, \nu_1, \ldots, \nu_{K-1}\}$. We say that the periodic descriptor system (1.1) is of index at most 1 if $\nu \leq 1$, i.e., $E_k$ are all nonsingular or $N_k = 0$ for all $k$.

(ii) The technique in proving the uniqueness of the solution for (2.5) and (2.6) can be used later for similar equations in (4.7), (4.10), (5.3), (5.6), (5.11), (5.15), (5.17), and (5.21). For the special case of periodic Lyapunov equations for systems with constant dimensions, see [44].

For each $k \in \mathbb{Z}$, we let

$$x_k = Y_k \begin{bmatrix} x_k^f \\ x_k^b \end{bmatrix}\begin{matrix} \}n_k^f \\ \}n_k^\infty \end{matrix}, \quad X_k B_k = \begin{bmatrix} B_k^f \\ B_k^b \end{bmatrix}\begin{matrix} \}n_{k+1}^f \\ \}n_k^\infty \end{matrix}, \quad C_k Y_k = \begin{array}{c} \begin{bmatrix} C_k^f & C_k^b \end{bmatrix} \\ \begin{matrix} n_k^f & n_k^\infty \end{matrix} \end{array}, \tag{2.11}$$

and by using Lemma 2.1, we can decompose the original system (1.1) into forward and backward periodic subsystems, respectively:

$$x_{k+1}^f = A_k^f x_k^f + B_k^f u_k, \quad y_k^f = C_k^f x_k^f, \tag{2.12}$$

$$E_k^b x_{k+1}^b = x_k^b + B_k^b u_k, \quad y_k^b = C_k^b x_k^b, \tag{2.13}$$

with $y_k = y_k^f + y_k^b$, $k \in \mathbb{Z}$.

Notice that the state transition matrix of the forward subsystem (2.12) equals $\Phi_f(i,j) = A_{i-1}^f A_{i-2}^f \cdots A_j^f \in \mathbb{R}^{n_i^f \times n_j^f}$ when $i > j$ with $\Phi_f(i,i) := I_{n_i^f}$. The state transition matrix of the backward subsystem (2.13) is $\Phi_b(i,j) = E_i^b E_{i+1}^b \cdots E_{j-1}^b \in \mathbb{R}^{n_i^\infty \times n_j^\infty}$ when $i < j$ with $\Phi_b(i,i) := I_{n_i^\infty}$. The state transition matrix over one period $\Phi_f(\tau + K, \tau)$ is called the monodromy matrix of the forward subsystem (2.12) at time $\tau$.

For $k = 0, 1, \ldots, K-1$, the matrices

$$P_r(k) = Y_k \begin{bmatrix} I_{n_k^f} & 0 \\ 0 & 0 \end{bmatrix} Y_k^{-1} \in \mathbb{R}^{n_k \times n_k}, \qquad P_l(k) = X_k^{-1} \begin{bmatrix} I_{n_{k+1}^f} & 0 \\ 0 & 0 \end{bmatrix} X_k \in \mathbb{R}^{\mu_{k+1} \times \mu_{k+1}}, \tag{2.14}$$

are the spectral projections onto, respectively, the $k$th right and left deflating subspaces of the periodic matrix pairs $\{(E_k, A_k)\}_{k=0}^{K-1}$ corresponding to the finite eigenvalues. Moreover, the fundamental matrices $\Psi_{i,j}$ $(i, j \in \mathbb{Z})$ of the periodic descriptor system (1.1) are defined by

$$\Psi_{i,j} = \begin{cases} Y_i \begin{bmatrix} \Phi_f(i, j+1) & 0 \\ 0 & 0 \end{bmatrix} X_j & \text{if } i > j, \\ Y_i \begin{bmatrix} 0 & 0 \\ 0 & -\Phi_b(i,j) \end{bmatrix} X_j & \text{if } i \leq j. \end{cases} \tag{2.15}$$

These matrices play an essential role for the periodic discrete-time descriptor system (1.1). For the discrete-time descriptor system with period $K = 1$, these fundamental matrices coincide with the coefficient matrices of the Laurent expansion of the generalized resolvent $(\lambda E - A)^{-1}$ at infinity [25, 39].

Some of the results in this paper can be developed through the application of the results of Stykel [37], after "lifting" the periodic system into a descriptor system of higher dimension [50]. This is implicitly how we obtained the results in Theorem 4.1. However, various permutations will be involved when separating the lifted system into its forward and backward parts, diluting the simplicity we hope for. Our present approach of development without lifting is somewhat simpler and more convenient.

**3. Complete reachability and observability.** In this section, we shall give a characterization of complete reachability and observability for the periodic discrete-time descriptor systems (1.1). Proofs in [10], for similar results for systems of constant dimensions, can easily be adapted for time-variant dimensions and are omitted.

DEFINITION 3.1. (i) [illegible] (1.1) [illegible] $t$ [illegible] $\bar{x} \in \mathbb{R}^{n_t}$ [illegible] $s, \ell$ [illegible] $s < t < \ell$ [illegible] $\{u_i\}_{i=s}^{\ell}$ [illegible] $x_s = 0$ [illegible] $x_t = \bar{x}$ [illegible] (1.1) [illegible] $t$

(ii) [illegible] (2.12) [illegible] $t$ [illegible] $\bar{\xi}_1 \in \mathbb{R}^{n_t^f}$ [illegible] $s$ [illegible] $s < t$ [illegible] $\{u_i\}_{i=s}^{t-1}$ [illegible] $x_s^f = 0$ [illegible] $x_t^f = \bar{\xi}_1$ [illegible] (2.12) [illegible] $t$

(iii) [illegible] (2.13) [illegible] $t$ [illegible] $\bar{\xi}_2 \in \mathbb{R}^{n_t^\infty}$ [illegible] $\ell$ [illegible] $\ell > t$ [illegible] $\{u_i\}_{i=t}^{\ell}$ [illegible] $x_t^b = \bar{\xi}_2$ [illegible] (2.13) [illegible] $t$

[illegible] It is easily seen from Definition 3.1 that the periodic discrete-time descriptor system (1.1) is completely reachable if and only if both its forward and backward subsystems are completely reachable.

THEOREM 3.1 (forward reachability). [illegible]

(a) [illegible] (2.12) [illegible]

(b) [illegible] $t = 0, 1, 2, \ldots, K-1$ [illegible]

$$\mathcal{R}^f(t) \equiv \left[ B_{t-1}^f,\, A_{t-1}^f B_{t-2}^f, \ldots, \Phi_f(t, t - n_t^f K + 1) B_{t-n_t^f K}^f \right]$$

[illegible]

(c) [illegible] $t = 0, 1, 2, \ldots, K-1$ [illegible]

$$\mathcal{B}_t^f \equiv \left[ B_{t-1}^f,\, A_{t-1}^f B_{t-2}^f,\, A_{t-1}^f A_{t-2}^f B_{t-3}^f, \ldots, \Phi_f(t, t-K+1) B_{t-K}^f \right],$$

[illegible]

$$\left[ \mathcal{B}_t^f,\, \Phi_f(t, t-K)\mathcal{B}_t^f,\, (\Phi_f(t,t-K))^2 \mathcal{B}_t^f, \ldots, (\Phi_f(t,t-K))^{n_t^f - 1} \mathcal{B}_t^f \right]$$

[illegible]

(d) [illegible] $\prod_{i=0}^{K-1} \alpha_i \in \sigma(\Phi_f(K,0))$ [illegible] $U^f(\alpha_0, \ldots, \alpha_{K-1}) \equiv$

$$\left[ \begin{array}{ccccc|cccc} \alpha_0 I_{n_1^f} & 0 & \cdots & 0 & -A_0^f & B_0^f & & & \\ -A_1^f & \alpha_1 I_{n_2^f} & \ddots & & 0 & & B_1^f & & \\ 0 & -A_2^f & \ddots & \ddots & \vdots & & & \ddots & \\ \vdots & \ddots & \ddots & \ddots & 0 & & & & \ddots \\ 0 & \cdots & 0 & -A_{K-1}^f & \alpha_{K-1} I_{n_0^f} & & & & B_{K-1}^f \end{array} \right]$$

[illegible]

(e) [illegible] $t = 0, 1, 2, \dots, K-1$

$$y^T\Phi_f(t+K,t) = \lambda y^T,\ y^T\Phi_f(t,j)B^f_{j-1} = 0$$ [illegible] $j = t-K+1, \dots, t-1, t$

[illegible] $y = 0$

THEOREM 3.2 (backward reachability). [illegible]

(a) [illegible] (2.13) [illegible]

(b) [illegible] $t = 0, 1, 2, \dots, K-1$ [illegible]

$$\mathcal{R}^b(t) \equiv \left[B^b_t,\ E^b_tB^b_{t+1},\ \dots,\ \Phi_b(t, t+\nu K-1)B^b_{t+\nu K-1}\right]$$

[illegible]

(c) [illegible] $t = 0, 1, 2, \dots, K-1$ [illegible]

$$\mathcal{B}^b_t \equiv \left[B^b_t,\ E^b_tB^b_{t+1}, \dots, E^b_tE^b_{t+1}, \dots, E^b_{t+K-2}B^b_{t+K-1}\right],$$

[illegible] $[N_t,\ \mathcal{B}^b_t]$ [illegible]

(d) [illegible] $(\mathcal{E}_b, \mathcal{B}_b)$ [illegible]

(3.1)

$$\mathcal{E}_b \equiv \begin{bmatrix} 0 & E^b_0 & & & \\ 0 & 0 & E^b_1 & & \\ \vdots & \vdots & \ddots & \ddots & \\ 0 & 0 & & \ddots & E^b_{K-2} \\ E^b_{K-1} & 0 & \cdots & \cdots & 0 \end{bmatrix}, \quad \mathcal{B}_b \equiv \begin{bmatrix} B^b_0 & & & & \\ & B^b_1 & & & \\ & & \ddots & & \\ & & & \ddots & \\ & & & & B^b_{K-1} \end{bmatrix}.$$

DEFINITION 3.2. (i) [illegible] (1.1) [illegible] $t$ [illegible] $s, \ell$ [illegible] $s < t < \ell$ [illegible] $t$ [illegible] $\{y_i\}^{\ell}_{i=s}$ [illegible] $\{u_i\}^{\ell}_{i=s}$ [illegible] (1.1) [illegible] $t$

(ii) [illegible] (2.12) [illegible] $t$ [illegible] $\ell$ [illegible] $\ell > t$ [illegible] $t$ [illegible] $\{y_i\}^{\ell}_{i=t}$ [illegible] $\{u_i\}^{\ell}_{i=t}$ [illegible] (2.12) [illegible] $t$

(iii) [illegible] (2.13) [illegible] $t$ [illegible] $s$ [illegible] $s < t$ [illegible] $t$ [illegible] $\{y_i\}^{t}_{i=s}$ [illegible] $\{u_i\}^{t}_{i=s}$ [illegible] (2.13) [illegible] $t$

[illegible] It is easily seen from Definition 3.2 that the periodic discrete-time descriptor system (1.1) is completely observable if and only if both its forward and backward subsystems are completely observable.

THEOREM 3.3 (forward observability). [illegible]

(a) [illegible] (2.12) [illegible]

(b) [illegible] $t = 0, 1, 2, \dots, K-1$ [illegible]

$$\mathcal{O}^f(t) \equiv \begin{bmatrix} C^f_t \\ C^f_{t+1}A^f_t \\ C^f_{t+2}A^f_{t+1}A^f_t \\ \vdots \\ C^f_{t+n^f_tK-1}\Phi_f(t+n^f_tK-1, t) \end{bmatrix}$$

[illegible]

(c) [illegible] $t = 0, 1, 2, \dots, K-1$ [illegible]

$$\mathcal{C}_t^f \equiv \left[(C_t^f)^T,\, (A_t^f)^T (C_{t+1}^f)^T,\, \dots,\, \Phi_f(t+K-1,t)^T (C_{t+K-1}^f)^T\right]^T ,$$

[illegible]

$$\begin{bmatrix} \mathcal{C}_t^f \\ \mathcal{C}_t^f \Phi_f(t+K,t) \\ \mathcal{C}_t^f (\Phi_f(t+K,t))^2 \\ \vdots \\ \mathcal{C}_t^f (\Phi_f(t+K,t))^{n_t^f - 1} \end{bmatrix}$$

(d) [illegible] $\prod_{i=0}^{K-1} \alpha_i \in \sigma(\Phi_f(K,0))$ [illegible]

$$V^f(\alpha_0, \dots, \alpha_{K-1}) \equiv \left[\begin{array}{ccccc} \alpha_0 I_{n_0^f} & 0 & \cdots & 0 & -A_{K-1}^f \\ -A_0^f & \alpha_1 I_{n_1^f} & \ddots & & 0 \\ 0 & -A_1^f & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & 0 \\ 0 & \cdots & 0 & -A_{K-2}^f & \alpha_{K-1} I_{n_{K-1}^f} \\ \hline C_0^f & & & & \\ & C_1^f & & & \\ & & \ddots & & \\ & & & C_{K-2}^f & \\ & & & & C_{K-1}^f \end{array}\right]$$

(e) [illegible] $t = 0, 1, 2, \dots, K-1$

$$\Phi_f(t+K,t)x = \lambda x \text{ [illegible] } C_i^f \Phi_f(i,t)x = 0 \text{ [illegible] } i = t, t+1, \dots, t+K-1$$

[illegible] $x = 0$

THEOREM 3.4 (backward observability). [illegible]

(a) [illegible] (2.13) [illegible]

(b) [illegible] $t = 0, 1, 2, \dots, K-1$ [illegible]

$$\mathcal{O}^b(t) \equiv \begin{bmatrix} C_t^b \\ C_{t-1}^b E_{t-1}^b \\ C_{t-2}^b E_{t-2}^b E_{t-1}^b \\ \vdots \\ C_{t-\nu K+1}^b \Phi_b(t-\nu K+1,t) \end{bmatrix}$$

(c) [illegible] $t = 0, 1, 2, \dots, K-1$ [illegible]

$$\mathcal{C}_t^b \equiv \left[(C_t^b)^T,\, (E_{t-1}^b)^T (C_{t-1}^b)^T,\, \dots,\, \Phi_b(t-K+1,t)^T (C_{t-K+1}^b)^T\right]^T ,$$

[illegible]

$$\begin{bmatrix} \mathcal{C}_t^b \\ \mathcal{C}_t^b N_t \\ \mathcal{C}_t^b N_t^2 \\ \\ \mathcal{C}_t^b N_t^{\nu-1} \end{bmatrix}$$

[illegible]

(d) [illegible] $(\mathcal{E}_b, \mathcal{C}_b)$ [illegible] $\mathcal{E}_b$ [illegible] (3.1) [illegible] $\mathcal{C}_b \equiv \operatorname{diag}(C_0^b, C_1^b, \ldots, C_{K-1}^b)$

**4. Periodic reachability and observability Gramians.** It is well known that Gramians play an important role in many applications, such as the model reduction problem [17, 29, 54]. In this section, the concepts of reachability and observability Gramians are generalized to periodic discrete-time descriptor systems (1.1).

Consider the causal and noncausal reachability matrices given by

$$\mathcal{R}_+(t) \equiv \left[\Psi_{t,t-1}B_{t-1},\ \Psi_{t,t-2}B_{t-2}, \ldots,\ \Psi_{t,i}B_i, \ldots\right] \quad (t = 0, 1, \ldots, K-1)$$

and

$$\mathcal{R}_-(t) \equiv \left[\Psi_{t,t}B_t,\ \Psi_{t,t+1}B_{t+1}, \ldots,\ \Psi_{t,t+\nu K-1}B_{t+\nu K-1}\right] \quad (t = 0, 1, \ldots, K-1),$$

respectively, with $\Psi_{i,j}$ $(i, j \in \mathbb{Z})$ as defined in (2.15).

DEFINITION 4.1 (reachability Gramians). [illegible] $\{(E_k, A_k)\}_{k=0}^{K-1}$ [illegible]

(i) [illegible] (1.1) [illegible]

$$G_k^{cr} \equiv \mathcal{R}_+(k)\mathcal{R}_+(k)^T = \sum_{i=-\infty}^{k-1} \Psi_{k,i}B_iB_i^T\Psi_{k,i}^T \in \mathbb{R}^{n_k \times n_k}, \quad k = 0, 1, \ldots, K-1.$$

(ii) [illegible] (1.1) [illegible]

$$G_k^{nr} \equiv \mathcal{R}_-(k)\mathcal{R}_-(k)^T = \sum_{i=k}^{k+\nu K-1} \Psi_{k,i}B_iB_i^T\Psi_{k,i}^T \in \mathbb{R}^{n_k \times n_k}, \quad k = 0, 1, \ldots, K-1.$$

(iii) [illegible] (1.1) [illegible]

$$G_k^r \equiv G_k^{cr} + G_k^{nr}, \quad k = 0, 1, \ldots, K-1.$$

The causal and noncausal observability matrices are respectively defined by

$$\mathcal{O}_+(t) \equiv \left[\Psi_{t,t-1}^TC_t^T,\ \Psi_{t+1,t-1}^TC_{t+1}^T, \ldots, \Psi_{i,t-1}^TC_i^T, \ldots\right]^T \quad (t = 0, 1, \ldots, K-1)$$

and

$$\mathcal{O}_-(t) \equiv \left[\Psi_{t-\nu K,t-1}^TC_{t-\nu K}^T,\ \Psi_{t-\nu K+1,t-1}^TC_{t-\nu K+1}^T, \ldots,\ \Psi_{t-1,t-1}^TC_{t-1}^T\right]^T$$
$$(t = 0, 1, \ldots, K-1).$$

DEFINITION 4.2 (observability Gramians). [illegible] $\{(E_k, A_k)\}_{k=0}^{K-1}$ [illegible]

(i) [illegible] (1.1) [illegible]

$$G_k^{co} \equiv \mathcal{O}_+(k)^T\mathcal{O}_+(k) = \sum_{i=k}^{\infty} \Psi_{i,k-1}^T C_i^T C_i \Psi_{i,k-1} \in \mathbb{R}^{\mu_k \times \mu_k}, \quad k = 0, 1, \dots, K-1.$$

(ii) [illegible] (1.1) [illegible]

$$G_k^{no} \equiv \mathcal{O}_-(k)^T\mathcal{O}_-(k) = \sum_{i=k-\nu K}^{k-1} \Psi_{i,k-1}^T C_i^T C_i \Psi_{i,k-1} \in \mathbb{R}^{\mu_k \times \mu_k}, \quad k = 0, 1, \dots, K-1.$$

(iii) [illegible] (1.1) [illegible]

$$G_k^o \equiv G_k^{co} + G_k^{no}, \quad k = 0, 1, \dots, K-1.$$

[illegible] (i) From Definitions 4.1 and 4.2, the causal Gramians $G_k^{cr}$ and $G_k^{co}$ can be rewritten via (2.15) as

$$G_k^{cr} = Y_k \left( \sum_{i=-\infty}^{k-1} \Phi_f(k, i+1) B_i^f (B_i^f)^T \Phi_f(k, i+1)^T \right) Y_k^T,$$

$$G_k^{co} = X_k^T \left( \sum_{i=k}^{\infty} \Phi_f(i, k)^T (C_i^f)^T C_i^f \Phi_f(i, k) \right) X_k.$$

As mentioned in [45, 46], the infinite series in brackets above converge and are defined as reachability and observability Gramians for an asymptotically stable periodic system with $E_k = I_{n_{k+1}}$. Therefore, infinite series that appeared in the definition of Gramians $G_k^{cr}$ and $G_k^{co}$ converge because of the pd-stability of the periodic matrix pairs $\{(E_k, A_k)\}_{k=0}^{K-1}$.

(ii) The Gramians $G_k^{cr}$, $G_k^{nr}$, $G_k^{co}$, and $G_k^{no}$ are symmetric positive semidefinite matrices for all time instants $k$.

(iii) Definitions 4.1 and 4.2 are natural generalizations of the Gramians defined for descriptor systems with period $K = 1$; see, e.g., [1, 39].

(iv) In section 6, the reachability and observability Gramians $G_k^r$ and $G_k^o$ will be used to define the Hankel singular values, which are then utilized in section 7 for balancing transformations in balanced realization.

The following theorem indicates that these Gramians of the periodic descriptor system (1.1) satisfy some projected generalized discrete-time periodic Lyapunov equations with special right-hand sides.

THEOREM 4.1. [illegible] (1.1) [illegible] $\{(E_k, A_k)\}_{k=0}^{K-1}$ [illegible]

(i) [illegible] $\{G_k^{cr}\}_{k=0}^{K-1}$ [illegible] $\{G_k^{nr}\}_{k=0}^{K-1}$ [illegible]

$$\begin{aligned} E_k G_{k+1}^{cr} E_k^T - A_k G_k^{cr} A_k^T &= P_l(k) B_k B_k^T P_l(k)^T, \\ G_k^{cr} &= P_r(k) G_k^{cr} P_r(k)^T, \quad k = 0, 1, 2, \dots, K-1, \end{aligned} \tag{4.1}$$

[illegible]

$$E_kG^{nr}_{k+1}E^T_k - A_kG^{nr}_kA^T_k = -(I_{\mu_{k+1}} - P_l(k))B_kB^T_k(I_{\mu_{k+1}} - P_l(k))^T, \quad P_r(k)G^{nr}_k = 0, \quad k = 0, 1, 2, \dots, K-1, \tag{4.2}$$

[illegible] $G^{cr}_K \equiv G^{cr}_0$ [illegible] $G^{nr}_K \equiv G^{nr}_0$

(ii) [illegible] $\{G^{co}_k\}_{k=0}^{K-1}$ [illegible] $\{G^{no}_k\}_{k=0}^{K-1}$ [illegible]

$$E^T_{k-1}G^{co}_kE_{k-1} - A^T_kG^{co}_{k+1}A_k = P_r(k)^TC^T_kC_kP_r(k), \quad G^{co}_k = P_l(k-1)^TG^{co}_kP_l(k-1), \quad k = 0, 1, \dots, K-1, \tag{4.3}$$

[illegible]

$$E^T_{k-1}G^{no}_kE_{k-1} - A^T_kG^{no}_{k+1}A_k = -(I_{n_k} - P_r(k))^TC^T_kC_k(I_{n_k} - P_r(k)), \quad G^{no}_kP_l(k-1) = 0, \quad k = 0, 1, 2, \dots, K-1, \tag{4.4}$$

[illegible] $G^{co}_K \equiv G^{co}_0$ $G^{no}_K \equiv G^{no}_0$ $E_{-1} \equiv E_{K-1}$ [illegible] $P_l(-1) \equiv P_l(K-1)$

(iii) [illegible] $\{G^{r}_k\}_{k=0}^{K-1}$ [illegible] $\{G^{o}_k\}_{k=0}^{K-1}$ [illegible]

$$E_kG^{r}_{k+1}E^T_k - A_kG^{r}_kA^T_k = P_l(k)B_kB^T_kP_l(k)^T - (I_{\mu_{k+1}} - P_l(k))B_kB^T_k(I_{\mu_{k+1}} - P_l(k))^T, \quad P_r(k)G^{r}_k = G^{r}_kP_r(k)^T, \quad k = 0, 1, 2, \dots, K-1, \tag{4.5}$$

[illegible]

$$E^T_{k-1}G^{o}_kE_{k-1} - A^T_kG^{o}_{k+1}A_k = P_r(k)^TC^T_kC_kP_r(k) - (I_{n_k} - P_r(k))^TC^T_kC_k(I_{n_k} - P_r(k)), \quad P_l(k-1)^TG^{o}_k = G^{o}_kP_l(k-1), \quad k = 0, 1, 2, \dots, K-1, \tag{4.6}$$

[illegible] $G^{r}_K \equiv G^{r}_0$ $G^{o}_K \equiv G^{o}_0$ $E_{-1} \equiv E_{K-1}$ [illegible] $P_l(-1) \equiv P_l(K-1)$

[illegible] We shall verify only (4.1) here, and the other cases can be treated similarly. From (2.2) and (2.14), we can rewrite (4.1) into the following matrix equations:

$$G_{k+1,11} - A^f_kG_{k,11}(A^f_k)^T = B^f_k(B^f_k)^T, \tag{4.7}$$

$$G_{k+1,12}(E^b_k)^T - A^f_kG_{k,12} = 0, \tag{4.8}$$

$$E^b_kG_{k+1,21} - G_{k,21}(A^f_k)^T = 0, \tag{4.9}$$

$$E^b_kG_{k+1,22}(E^b_k)^T - G_{k,22} = 0, \tag{4.10}$$

where $Y_k^{-1}G^{cr}_kY_k^{-T} = \begin{bmatrix} G_{k,11} & G_{k,12} \\ G_{k,21} & G_{k,22} \end{bmatrix}$ with $G_{k,11} \in \mathbb{R}^{n^f_k \times n^f_k}$ and $G_{k,22} \in \mathbb{R}^{n^\infty_k \times n^\infty_k}$. Since $\{(E_k, A_k)\}$ are pd-stable, the matrices $J_k = A^f_{k+K-1}A^f_{k+K-2}\cdots A^f_k$ ($k = 0, 1, 2, \dots, K-1$) contain only eigenvalues lying inside the unit circle, and $N_k = E^b_kE^b_{k+1}\cdots E^b_{k+K-1}$ ($k = 0, 1, 2, \dots, K-1$) contain only zero eigenvalues. Therefore, (4.7) and (4.10) have unique symmetric solutions $G_{k,11}$ and $G_{k,22}$, respectively (see remark (ii) after Lemma 2.1). Equations (4.8) and (4.9) are solvable and have, for example, trivial solutions. It follows from $G^{cr}_k = P_r(k)G^{cr}_kP_r(k)^T$ that

$$G^{cr}_k = Y_k\begin{bmatrix} G_{k,11} & G_{k,12} \\ G_{k,21} & G_{k,22} \end{bmatrix}Y^T_k = Pr(k)G^{cr}_kP_r(k)^T = Y_k\begin{bmatrix} G_{k,11} & 0 \\ 0 & 0 \end{bmatrix}Y^T_k;$$

i.e., $G_{k,12} = G_{k,21} = G_{k,22} = 0$. Thus, the matrices

$$G_k^{cr} = Y_k \begin{bmatrix} G_{k,11} & 0 \\ 0 & 0 \end{bmatrix} Y_k^T$$

are the unique symmetric solutions of the projected GDPLEs (4.1) with $G_k^{cr} = P_r(k) G_k^{cr} P_r(k)^T$.

On the other hand, it can be shown that the causal reachability Gramians $G_k^{cr}$ satisfy the projected GDPLEs (4.1). Indeed, direct substitutions, using (2.1) and (2.15), give

$$\begin{aligned}
&E_k G_{k+1}^{cr} E_k^T - A_k G_k^{cr} A_k^T \\
&= E_k \left( \sum_{i=-\infty}^{k} \Psi_{k+1,i} B_i B_i^T \Psi_{k+1,i}^T \right) E_k^T - A_k \left( \sum_{i=-\infty}^{k-1} \Psi_{k,i} B_i B_i^T \Psi_{k,i}^T \right) A_k^T \\
&= E_k Y_{k+1} \left( \sum_{i=-\infty}^{k} \begin{bmatrix} \Phi_f(k+1,i+1) & 0 \\ 0 & 0 \end{bmatrix} X_i B_i B_i^T X_i^T \begin{bmatrix} \Phi_f(k+1,i+1)^T & 0 \\ 0 & 0 \end{bmatrix} \right) Y_{k+1}^T E_k^T \\
&\quad - A_k Y_k \left( \sum_{i=-\infty}^{k-1} \begin{bmatrix} \Phi_f(k,i+1) & 0 \\ 0 & 0 \end{bmatrix} X_i B_i B_i^T X_i^T \begin{bmatrix} \Phi_f(k,i+1)^T & 0 \\ 0 & 0 \end{bmatrix} \right) Y_k^T A_k^T \\
&= X_k^{-1} \begin{bmatrix} \sum_{-\infty}^{k} \Phi_f(k+1,i+1) B_i^f (B_i^f)^T \Phi_f(k+1,i+1)^T & 0 \\ 0 & 0 \end{bmatrix} X_k^{-T} \\
&\quad - X_k^{-1} \begin{bmatrix} \sum_{-\infty}^{k-1} \Phi_f(k+1,i+1) B_i^f (B_i^f)^T \Phi_f(k+1,i+1)^T & 0 \\ 0 & 0 \end{bmatrix} X_k^{-T} \\
&= X_k^{-1} \begin{bmatrix} B_k^f (B_k^f)^T & 0 \\ 0 & 0 \end{bmatrix} X_k^{-T} = P_l(k) B_k B_k^T P_l(k)^T
\end{aligned}$$

and

$$\begin{aligned}
&P_r(k) G_k^{cr} P_r(k)^T \\
&= Y_k \begin{bmatrix} I_{n_k^f} & 0 \\ 0 & 0 \end{bmatrix} Y_k^{-1} \left( \sum_{i=-\infty}^{k-1} \Psi_{k,i} B_i B_i^T \Psi_{k,i}^T \right) Y_k^T \begin{bmatrix} I_{n_k^f} & 0 \\ 0 & 0 \end{bmatrix} Y_k^T \\
&= Y_k \begin{bmatrix} \sum_{i=-\infty}^{k-1} \Phi_f(k,i+1) B_i^f (B_i^f)^T \Phi_f(k,i+1)^T & 0 \\ 0 & 0 \end{bmatrix} Y_k^T = G_k^{cr},
\end{aligned}$$

for $k = 0, 1, \dots, K-1$. Therefore, the causal reachability Gramians $\{G_k^{cr}\}_{k=0}^{K-1}$ are the unique symmetric positive semidefinite solutions of the projected GDPLEs (4.1). ☐

The following theorem shows that complete reachability/observability of the periodic descriptor system (1.1) can be characterized via the reachability/observability Gramians.

THEOREM 4.2. [illegible] (1.1) [illegible] $\{(E_k, A_k)\}_{k=0}^{K-1}$ [illegible]

(i) [illegible] (1.1) [illegible] $G_k^r$ [illegible] $k = 0, 1, 2, \dots, K-1$

(ii) [illegible] (1.1) [illegible] $G_k^o$ [illegible] $k = 0, 1, 2, \dots, K-1$

*Proof.* Here we shall prove only statement (i); statement (ii) can be verified similarly. For $k = 0, 1, \dots, K-1$, premultiply (4.5) by $X_k$ and postmultiply (4.5) by $X_k^T$; it follows that

(4.11)
$$X_k E_k Y_{k+1} \widehat{G}_{k+1}^r Y_{k+1}^T E_k^T X_k^T - X_k A_k Y_k \widehat{G}_k^r Y_k^T A_k^T X_k^T = \begin{bmatrix} B_k^f (B_k^f)^T & 0 \\ 0 & -B_k^b (B_k^b)^T \end{bmatrix},$$

where $\widehat{G}_k^r \equiv Y_k^{-1} G_k^r Y_k^{-T}$.

From Definition 4.1 it is easily seen, for $k = 0, 1, \dots, K-1$, that

$$\widehat{G}_k^r = Y_k^{-1} G_k^r Y_k^{-T} = \begin{bmatrix} \widehat{G}_{k,1}^{cr} & 0 \\ 0 & \widehat{G}_{k,2}^{nr} \end{bmatrix}, \tag{4.12}$$

with

$$\widehat{G}_{k,1}^{cr} \equiv \sum_{i=-\infty}^{k-1} \Phi_f(k, i+1) B_i^f (B_i^f)^T \Phi_f(k, i+1)^T,$$
$$\widehat{G}_{k,2}^{nr} \equiv \sum_{i=k}^{k+\nu K-1} \Phi_b(k, i) B_i^b (B_i^b)^T \Phi_b(k, i)^T\ .$$

Then by (2.1) and (4.12), (4.11) is decomposed into two periodic Lyapunov equations, for $k = 0, 1, 2, \dots, K-1$:

$$\widehat{G}_{k+1,1}^{cr} - A_k^f \widehat{G}_{k,1}^{cr} (A_k^f)^T = B_k^f (B_k^f)^T, \tag{4.13}$$
$$\widehat{G}_{k,2}^{nr} - E_k^b \widehat{G}_{k+1,2}^{nr} (E_k^b)^T = B_k^b (B_k^b)^T. \tag{4.14}$$

Rewrite (4.13) and (4.14) into two enlarged Lyapunov equations:

$$\mathcal{G}_{cr} - \mathcal{A}_f \mathcal{G}_{cr} \mathcal{A}_f^T = \mathcal{B}_f \mathcal{B}_f^T, \tag{4.15}$$
$$\mathcal{G}_{nr} - \mathcal{E}_b \mathcal{G}_{nr} \mathcal{E}_b^T = \mathcal{B}_b \mathcal{B}_b^T, \tag{4.16}$$

where $\mathcal{G}_{cr} = \operatorname{diag}(\widehat{G}_{k,1}^{cr}, \dots, \widehat{G}_{K-1,1}^{cr}, \widehat{G}_{0,1}^{cr})$, $\mathcal{G}_{nr} = \operatorname{diag}(\widehat{G}_{0,2}^{nr}, \widehat{G}_{1,2}^{nr}, \dots, \widehat{G}_{K-1,2}^{nr})$, $\mathcal{E}_b$, and $\mathcal{B}_b$ are as defined in (3.1), and

$$\mathcal{A}_f = \begin{bmatrix} & & & A_0^f \\ A_1^f & & & \\ & \ddots & & \\ & & A_{K-1}^f & \end{bmatrix}, \quad \mathcal{B}_f = \begin{bmatrix} B_0^f & & & \\ & B_1^f & & \\ & & \ddots & \\ & & & B_{K-1}^f \end{bmatrix}.$$

Since the periodic matrix pairs $\{(E_k, A_k)\}_{k=0}^{K-1}$ are pd-stable and the matrix $\mathcal{E}_b$ is nilpotent with index $\nu$, the pairs $(\mathcal{A}_f, \mathcal{B}_f)$ and $(\mathcal{E}_b, \mathcal{B}_b)$ are reachable if and only if the solutions $\mathcal{G}_{cr}$ and $\mathcal{G}_{nr}$ of Lyapunov equations (4.15) and (4.16) are symmetric positive definite. Equivalently, following from (4.12), all reachability Gramians $G_k^r$ $(k = 0, 1, \dots, K-1)$ are symmetric positive definite. Moreover, from Theorems 3.1–3.2 and the remark following Definition 3.1, we know that the periodic descriptor system (1.1) is completely reachable if and only if the pairs $(\mathcal{A}_f, \mathcal{B}_f)$ and $(\mathcal{E}_b, \mathcal{B}_b)$ are reachable. This completes the proof of statement (i). ☐

**5. Numerical solutions of projected GDPLEs.** In this section, a numerical method is proposed for the symmetric positive semidefinite solutions of the projected generalized discrete-time periodic Lyapunov equations (4.1) and (4.3), for pd-stable $\{(E_k, A_k)\}_{k=0}^{K-1}$. We first consider the numerical solutions of the GDPLEs (4.3).

**GDPLEs for observability Gramians $\boldsymbol{G_k^{co}}$.** As $\{(E_k, A_k)\}_{k=0}^{K-1}$ are pd-stable, there exist orthogonal matrices $V_k \in \mathbb{R}^{\mu_{k+1}\times\mu_{k+1}}$ and $U_k \in \mathbb{R}^{n_k\times n_k}$, with $U_K \equiv U_0$, such that the decompositions (2.2) of system matrices $E_k$ and $A_k$ hold.

Notice that

$$\begin{bmatrix} I_{n_{k+1}^f} & Z_k \\ 0 & I_{n_k^\infty} \end{bmatrix} \begin{bmatrix} E_{k,1} & E_{k,3} \\ 0 & E_{k,2} \end{bmatrix} \begin{bmatrix} I_{n_{k+1}^f} & -W_{k+1} \\ 0 & I_{n_{k+1}^\infty} \end{bmatrix} = \begin{bmatrix} E_{k,1} & 0 \\ 0 & E_{k,2} \end{bmatrix}, \tag{5.1}$$

$$\begin{bmatrix} I_{n_{k+1}^f} & Z_k \\ 0 & I_{n_k^\infty} \end{bmatrix} \begin{bmatrix} A_{k,1} & A_{k,3} \\ 0 & A_{k,2} \end{bmatrix} \begin{bmatrix} I_{n_k^f} & -W_k \\ 0 & I_{n_k^\infty} \end{bmatrix} = \begin{bmatrix} A_{k,1} & 0 \\ 0 & A_{k,2} \end{bmatrix} \tag{5.2}$$

if the matrices $Z_k \in \mathbb{R}^{n_{k+1}^f\times n_k^\infty}$ and $W_k \in \mathbb{R}^{n_k^f\times n_k^\infty}$, with $W_K \equiv W_0$ and for $k = 0, 1, \ldots, K-1$, satisfy the generalized periodic Sylvester equations

$$\begin{aligned} E_{k,1}W_{k+1} - Z_kE_{k,2} &= E_{k,3}, \\ A_{k,1}W_k - Z_kA_{k,2} &= A_{k,3}. \end{aligned} \tag{5.3}$$

The generalized periodic Sylvester equations (5.3) have unique solutions $Z_k$ and $W_k$ (see Remark (ii) after Lemma 2.1). Therefore, the nonsingular matrices $X_k, Y_k$ in (2.1) satisfy

$$X_k = \begin{bmatrix} I_{n_{k+1}^f} & Z_k \\ 0 & I_{n_k^\infty} \end{bmatrix} V_k^T, \quad Y_k = U_k \begin{bmatrix} I_{n_k^f} & -W_k \\ 0 & I_{n_k^\infty} \end{bmatrix},$$

and the right and left spectral projections $P_r(k)$, $P_l(k)$ are given as

$$P_l(k) = V_k \begin{bmatrix} I_{n_{k+1}^f} & Z_k \\ 0 & 0 \end{bmatrix} V_k^T, \quad P_r(k) = U_k \begin{bmatrix} I_{n_k^f} & W_k \\ 0 & 0 \end{bmatrix} U_k^T. \tag{5.4}$$

Let, for $k = 0, 1, \ldots, K-1$,

$$V_{k-1}^T G_k^{co} V_{k-1} = \begin{bmatrix} G_{k,1}^{co} & G_{k,3}^{co} \\ (G_{k,3}^{co})^T & G_{k,2}^{co} \end{bmatrix}, \quad C_kU_k = \begin{bmatrix} C_{k,1}, & C_{k,2} \end{bmatrix}. \tag{5.5}$$

Substituting (2.2), (5.4), and (5.5) into the projected GDPLEs (4.3), for $k = 0, 1, \ldots, K-1$, we have

$$E_{k-1,1}^T G_{k,1}^{co} E_{k-1,1} - A_{k,1}^T G_{k+1,1}^{co} A_{k,1} = C_{k,1}^T C_{k,1}, \tag{5.6}$$

$$\begin{aligned} &E_{k-1,1}^T G_{k,1}^{co} E_{k-1,3} + E_{k-1,1}^T G_{k,3}^{co} E_{k-1,2} - A_{k,1}^T G_{k+1,1}^{co} A_{k,3} - A_{k,1}^T G_{k+1,3}^{co} A_{k,2} \\ &\quad = C_{k,1}^T C_{k,1} W_k, \end{aligned} \tag{5.7}$$

$$\begin{aligned} &E_{k-1,3}^T G_{k,1}^{co} E_{k-1,3} + E_{k-1,3}^T G_{k,3}^{co} E_{k-1,2} + E_{k-1,2}^T (G_{k,3}^{co})^T E_{k-1,3} \\ &\quad + E_{k-1,2}^T G_{k,2}^{co} E_{k-1,2} - A_{k,3}^T G_{k+1,1}^{co} A_{k,3} - A_{k,3}^T G_{k+1,3}^{co} A_{k,2} \\ &\quad - A_{k,2}^T (G_{k+1,3}^{co})^T A_{k,3} - A_{k,2}^T G_{k+1,2}^{co} A_{k,2} = W_k^T C_{k,1}^T C_{k,1} W_k. \end{aligned} \tag{5.8}$$

Again from the pd-stability of $\{(E_{k,1}, A_{k,1})\}_{k=0}^{K-1}$, the generalized discrete-time periodic Lyapunov equations (5.6) have unique symmetric positive semidefinite solutions $G_{k,1}^{co}$. Furthermore, it follows from (5.3) that (5.7) can be rearranged as

$$E_{k-1,1}^T(G_{k,3}^{co} - G_{k,1}^{co}Z_{k-1})E_{k-1,2} - A_{k,1}^T(G_{k+1,3}^{co} - G_{k+1,1}^{co}Z_k)A_{k,2} = 0. \tag{5.9}$$

We deduce that

$$G_{k,3}^{co} = G_{k,1}^{co}Z_{k-1}, \quad k = 0, 1, \ldots, K-1. \tag{5.10}$$

From (5.3), (5.6), and (5.10), now (5.8) can be rewritten as

$$E_{k-1,2}^T(G_{k,2}^{co} - Z_{k-1}^T G_{k,1}^{co}Z_{k-1})E_{k-1,2} - A_{k,2}^T(G_{k+1,2}^{co} - Z_k^T G_{k+1,1}^{co}Z_k)A_{k,2} = 0. \tag{5.11}$$

Since the periodic matrix pairs $\{(E_{k,2}, A_{k,2})\}_{k=0}^{K-1}$ have only infinite eigenvalues, we then have

$$G_{k,2}^{co} = Z_{k-1}^T G_{k,1}^{co}Z_{k-1}, \quad k = 0, 1, \ldots, K-1. \tag{5.12}$$

Therefore, the solutions of the projected GDPLEs (4.3) have the form

$$G_k^{co} = V_{k-1}\begin{bmatrix} G_{k,1}^{co} & G_{k,1}^{co}Z_{k-1} \\ Z_{k-1}^T G_{k,1}^{co} & Z_{k-1}^T G_{k,1}^{co}Z_{k-1} \end{bmatrix} V_{k-1}^T, \quad k = 0, 1, \ldots, K-1, \tag{5.13}$$

where the matrices $G_{k,1}^{co}$ are the unique symmetric positive semidefinite solutions of the generalized periodic Lyapunov equations (5.6) (see Remark (ii) after Lemma 2.1). Moreover, from (5.4) and (5.13), they also satisfy $P_l(k-1)^T G_k^{co} P_l(k-1) = G_k^{co}$.

In many applications it is necessary to have the Cholesky factors of the solutions of the Lyapunov equations rather the solutions themselves [24]. In particular, these full-rank factors are useful for numerically computing the Hankel singular values (see the next section). If $L_{k,1}$ denotes a Cholesky factor of each matrix $G_{k,1}^{co}$, i.e., $G_{k,1}^{co} = L_{k,1}^T L_{k,1}$, then we compute the QR factorization

$$L_{k,1} = Q_{k,L}\begin{bmatrix} T_{k,L} \\ 0 \end{bmatrix},$$

where $Q_{k,L}$ is orthogonal and $T_{k,L}$ has full row rank, for $k = 0, 1, \ldots, K-1$. The full-rank factorizations of the solutions $G_k^{co}$, for $k = 0, 1, \ldots, K-1$, are given by

$$\begin{aligned} G_k^{co} &= V_{k-1}\begin{bmatrix} L_{k,1}^T \\ Z_{k-1}^T L_{k,1}^T \end{bmatrix}\begin{bmatrix} L_{k,1}, & L_{k,1}Z_{k-1} \end{bmatrix} V_{k-1}^T \\ &= V_{k-1}\begin{bmatrix} T_{k,L}^T \\ Z_{k-1}^T T_{k,L}^T \end{bmatrix}\begin{bmatrix} T_{k,L}, & T_{k,L}Z_{k-1} \end{bmatrix} V_{k-1}^T \\ &\equiv L_k^T L_k, \end{aligned}$$

where $L_k \equiv \begin{bmatrix} T_{k,L}, & T_{k,L}Z_{k-1} \end{bmatrix} V_{k-1}^T$ has full row rank.

**GDPLEs for reachability Gramians $G_k^{cr}$.** Similarly for the projected GDPLEs (4.1), for $k = 0, 1, \ldots, K-1$, we let

$$U_k^T G_k^{cr} U_k = \begin{bmatrix} G_{k,1}^{cr} & G_{k,3}^{cr} \\ (G_{k,3}^{cr})^T & G_{k,2}^{cr} \end{bmatrix}, \quad V_k^T B_k = \begin{bmatrix} B_{k,1} \\ B_{k,2} \end{bmatrix}. \tag{5.14}$$

Substituting (2.2), (5.4), and (5.14) into the projected GDPLEs (4.1), we then have

$$\begin{aligned}E_{k,1}G^{cr}_{k+1,1}E^T_{k,1} - A_{k,1}G^{cr}_{k,1}A^T_{k,1} &= -E_{k,1}G^{cr}_{k+1,3}E^T_{k,3} - E_{k,3}(G^{cr}_{k+1,3})^T E^T_{k,1} - E_{k,3}G^{cr}_{k+1,2}E^T_{k,3}\\ &\quad + A_{k,1}G^{cr}_{k,3}A^T_{k,3} + A_{k,3}(G^{cr}_{k,3})^T A^T_{k,1} + A_{k,3}G^{cr}_{k,2}A^T_{k,3}\\ &\quad + (B_{k,1} + Z_k B_{k,2})(B_{k,1} + Z_k B_{k,2})^T,\end{aligned} \tag{5.15}$$

$$E_{k,1}G^{cr}_{k+1,3}E^T_{k,2} - A_{k,1}G^{cr}_{k,3}A^T_{k,2} = -E_{k,3}G^{cr}_{k+1,2}E^T_{k,2} + A_{k,3}G^{cr}_{k,2}A^T_{k,2}, \tag{5.16}$$

$$E_{k,2}G^{cr}_{k+1,2}E^T_{k,2} - A_{k,2}G^{cr}_{k,2}A^T_{k,2} = 0, \quad k = 0, 1, \dots, K-1. \tag{5.17}$$

Since the periodic matrix pairs $\{(E_{k,2}, A_{k,2})\}_{k=0}^{K-1}$ have only infinite eigenvalues, it follows from (5.17) that

$$G^{cr}_{k,2} = 0, \quad k = 0, 1, \dots, K-1. \tag{5.18}$$

Furthermore, (5.16) can be simplified to

$$E_{k,1}G^{cr}_{k+1,3}E^T_{k,2} - A_{k,1}G^{cr}_{k,3}A^T_{k,2} = 0. \tag{5.19}$$

We then have

$$G^{cr}_{k,3} = 0, \quad k = 0, 1, \dots, K-1. \tag{5.20}$$

From (5.18) and (5.20), (5.15) can be rewritten as

$$E_{k,1}G^{cr}_{k+1,1}E^T_{k,1} - A_{k,1}G^{cr}_{k,1}A^T_{k,1} = (B_{k,1} + Z_k B_{k,2})(B_{k,1} + Z_k B_{k,2})^T. \tag{5.21}$$

Therefore, the solutions of the projected GDPLEs (4.1) have the form

$$G^{cr}_k = U_k \begin{bmatrix} G^{cr}_{k,1} & 0 \\ 0 & 0 \end{bmatrix} U^T_k, \quad k = 0, 1, \dots, K-1, \tag{5.22}$$

where the matrices $G^{cr}_{k,1}$ are the unique symmetric positive semidefinite solutions of the generalized periodic Lyapunov equations (5.21) (see Remark (ii) after Lemma 2.1). Moreover, from (5.4) and (5.22), they also satisfy $P_r(k)G^{cr}_k P_r(k)^T = G^{cr}_k$.

If $R_{k,1}$ denotes a Cholesky factor of each matrix $G^{cr}_{k,1}$, i.e., $G^{cr}_{k,1} = R_{k,1}R^T_{k,1}$, then we compute the QR factorization

$$R^T_{k,1} = Q_{k,R} \begin{bmatrix} T^T_{k,R} \\ 0 \end{bmatrix},$$

where $Q_{k,R}$ is orthogonal and $T_{k,R}$ has full column rank. The full-rank factorizations of the solutions $G^{cr}_k$ are given by

$$\begin{aligned} G^{cr}_k &= U_k \begin{bmatrix} R_{k,1} \\ 0 \end{bmatrix} \begin{bmatrix} R^T_{k,1}, & 0 \end{bmatrix} U^T_k \\ &= U_k \begin{bmatrix} T_{k,R} \\ 0 \end{bmatrix} \begin{bmatrix} T^T_{k,R}, & 0 \end{bmatrix} U^T_k \\ &\equiv R_k R^T_k, \end{aligned}$$

where $R^T_k \equiv \begin{bmatrix} T^T_{k,R}, & 0 \end{bmatrix} U^T_k$ has full row rank for $k = 0, 1, \dots, K-1$.

**Algorithm GDPLE.** We now summarize the main steps for computing the full-rank Cholesky factors of the causal Gramians, via the solution of the GDPLEs (4.1) and (4.3). For simplicity in Algorithm 5.1, we shall ignore the obvious qualification for $k$, i.e., $k = 0, 1, \dots, K-1$.

ALGORITHM 5.1 (GDPLE).

**Input:** System matrices $(E_k, A_k, B_k, C_k)$, with $\{(E_k, A_k)\}_{k=0}^{K-1}$ being pd-stable.

**Output:** Full-rank Cholesky factors $R_k$ and $L_k$ ($k = 0, 1, \dots, K-1$), where $G_k^{cr} = R_k R_k^T$ and $G_k^{co} = L_k^T L_k$.

**Step 1.** Use the algorithm [48] to compute orthogonal matrices $V_k$ and $U_k$, with $U_K \equiv U_0$, such that

$$V_k^T E_k U_{k+1} = \begin{bmatrix} E_{k,1} & E_{k,3} \\ 0 & E_{k,2} \end{bmatrix}, \quad V_k^T A_k U_k = \begin{bmatrix} A_{k,1} & A_{k,3} \\ 0 & A_{k,2} \end{bmatrix},$$

where the matrices $E_{k,1}$ and $A_{k,2}$ are nonsingular, and

$$(A_{k,2})^{-1} E_{k,2} (A_{k+1,2})^{-1} E_{k+1,2} \cdots (A_{k+K-1,2})^{-1} E_{k+K-1,2}$$

are nilpotent.

**Step 2.** Compute the solutions of the generalized periodic Sylvester equations

$$\begin{aligned} E_{k,1} W_{k+1} - Z_k E_{k,2} &= E_{k,3}, \\ A_{k,1} W_k - Z_k A_{k,2} &= A_{k,3}. \end{aligned}$$

**Step 3.** Compute the matrices

$$V_k^T B_k = \begin{bmatrix} B_{k,1} \\ B_{k,2} \end{bmatrix}, \quad C_k U_k = \begin{bmatrix} C_{k,1}, & C_{k,2} \end{bmatrix}.$$

**Step 4.** Compute the Cholesky factors $R_{k,1}$ and $L_{k,1}$ of the solutions $G_{k,1}^{cr} = R_{k,1} R_{k,1}^T$ and $G_{k,1}^{co} = L_{k,1}^T L_{k,1}$ of the generalized discrete-time periodic Lyapunov equations

$$\begin{aligned} &E_{k,1} G_{k+1,1}^{cr} E_{k,1}^T - A_{k,1} G_{k,1}^{cr} A_{k,1}^T = (B_{k,1} + Z_k B_{k,2})(B_{k,1} + Z_k B_{k,2})^T, \\ &E_{k-1,1}^T G_{k,1}^{co} E_{k-1,1} - A_{k,1}^T G_{k+1,1}^{co} A_{k,1} = C_{k,1}^T C_{k,1}. \end{aligned}$$

**Step 5.** Compute the QR factorizations

$$R_{k,1}^T = Q_{k,R} \begin{bmatrix} T_{k,R}^T \\ 0 \end{bmatrix}, \quad L_{k,1} = Q_{k,L} \begin{bmatrix} T_{k,L} \\ 0 \end{bmatrix}.$$

**Step 6.** Compute the full-rank Cholesky factors

$$R_k = U_k \begin{bmatrix} T_{k,R} \\ 0 \end{bmatrix}, \quad L_k = \begin{bmatrix} T_{k,L}, & T_{k,L} Z_{k-1} \end{bmatrix} V_{k-1}^T.$$

[illegible]. One can extend the techniques in [30], for the numerical solution of the generalized Lyapunov equations, to solve the GDPLEs given in Step 4. A thorough error analysis and practical implementation details for the algorithm extended from [30] are still under investigation. It may also be possible to generalize the Hammarling-like method proposed in [36] to our periodic discrete-time case.

For Step 2, the periodic Sylvester equations can always be solved as an expanded linear equation using Kronecker products. Without such an expansion and for systems of constant dimensions, a more efficient algorithm has been proposed in [9]. For general systems of time-varying dimensions, the proof of Lemma 2.1 provides the theoretical basis for the algorithm. The heart of the algorithm lies in the computation of the Kronecker-like canonical form in [48]. The analysis and implementation of such an algorithm will be an interesting future project.

**A numerical example.** We shall illustrate the feasibility and reliability of the proposed algorithm with an example. All computations were performed in MATLAB/ version 6.5 on a PC with an Intel Pentium-III processor at 866 MHz, with 768 MB RAM, using IEEE double-precision floating-point arithmetic. The machine precision is approximately $2.22 \times 10^{-16}$. In our example, $E_k$ and $A_k$ are $n \times n$ square matrices, where $\mu_k = n_k = n$ for all $k$. Thus, instead of using the algorithm in [48] for periodic systems of time-varying dimensions, we utilize the PQZ algorithm with eigenvalue reordering strategy [7, 19] in Step 1 of the proposed algorithm GDPLE. The other steps are the same as those for periodic systems of constant dimensions.

For approximate solutions $\widetilde{X}_k$ of the projected GDPLEs (4.1) and (4.3), we compute the relative residuals defined by

$$\gamma_k^{cr} = \frac{\|E_k \widetilde{X}_{k+1} E_k^T - A_k \widetilde{X}_k A_k^T - P_l(k) B_k B_k^T P_l(k)^T\|_2}{\|\widetilde{X}_k\|_2},$$

$$\gamma_k^{co} = \frac{\|E_{k-1}^T \widetilde{X}_k E_{k-1} - A_k^T \widetilde{X}_{k+1} A_k - P_r(k)^T C_k^T C_k P_r(k)\|_2}{\|\widetilde{X}_k\|_2}.$$

[illegible] 1. We consider a periodic discrete-time descriptor system (1.1) with $n = 10$, $m = 2$, $p = 3$ and period $K = 3$. For $k = 0, 1, 2$, we have

$$E_k^{(0)} = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & c_1 & s_1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & -s_1 & c_1 & 0 & 0 & 0 & 0 & 0 \\ 0 & c_1 & s_1 & 1 & 0 & c_2 & s_2 & 0 & 0 & 0 \\ 0 & -s_1 & c_1 & 0 & 1 & -s_2 & c_2 & 0 & 0 & 0 \\ 0 & 0 & 0 & c_2 & s_2 & 1 & 0 & c_3 & s_3 & 0 \\ 0 & 0 & 0 & -s_2 & c_2 & 0 & 1 & -s_3 & c_3 & 0 \\ 0 & 0 & 0 & 0 & 0 & c_3 & s_3 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & -s_3 & c_3 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix},$$

$$A_k^{(0)} = \operatorname{diag}(1.01, A_{01}, A_{02}, A_{03}, A_{04}, 1.001), \quad \theta_k := 2\pi k/K,$$

$$B_k^T = \begin{bmatrix} 4 & -1 & 3 & 5 & 0 & -2 & 0 & 8 & 1 & 0 \\ 1 & 1 & s_1+1 & -2 & 1 & 0 & 0 & -3 & 0 & 1 \end{bmatrix},$$

$$C_k = \begin{bmatrix} 0 & 0 & 1 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 2 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.05+c_1 & 0 & 0 \end{bmatrix},$$

where

$$
\begin{aligned}
c_1 &= \cos(\theta_k), \quad c_2 = 0.2c_1, \quad c_3 = 0.6c_1,\\
s_1 &= \sin(\theta_k), \quad s_2 = 0.2s_1, \quad s_3 = 0.6s_1,
\end{aligned}
$$

$$
A_{01} = \begin{bmatrix} r_1\cos(\pi/3) & r_1\sin(\pi/3) \\ -r_1\sin(\pi/3) & r_1\cos(\pi/3) \end{bmatrix}, \quad A_{02} = \begin{bmatrix} r_2\cos(7\pi/5) & r_2\sin(7\pi/5) \\ -r_2\sin(7\pi/5) & r_2\cos(7\pi/5) \end{bmatrix},
$$

$$
A_{03} = \begin{bmatrix} r_3\cos(\pi/4) & r_3\sin(\pi/4) \\ -r_3\sin(\pi/4) & r_3\cos(\pi/4) \end{bmatrix}, \quad A_{04} = \begin{bmatrix} r_4\cos(\pi/10) & r_4\sin(\pi/10) \\ -r_4\sin(\pi/10) & r_4\cos(\pi/10) \end{bmatrix},
$$

and

$$
r_1 = 0.5, \quad r_2 = 0.05, \quad r_3 = -0.02, \quad r_4 = 0.12.
$$

We define a Householder transformation $V = I - 2uu^T$ with $u = [1, 1, \ldots, 1, 1]^T/\sqrt{10} \in \mathbb{R}^{10}$, and the $K$-periodic system matrices $(E_k, A_k, B_k, C_k)$ are given by

$$
E_k \equiv V^T E_k^{(0)} V, \quad A_k \equiv V^T A_k^{(0)} V, \quad k = 0, 1, 2.
$$

The computed open-loop spectrum of the periodic matrix pairs $\{(E_k, A_k)\}_{k=0}^{K-1}$ consists of two infinite eigenvalues and four pairs of complex conjugate finite eigenvalues lying inside the unit circle. Thus, the periodic matrix pairs $\{(E_k, A_k)\}_{k=0}^{K-1}$ are pd-stable where $n_k^f = 8$ and $n_k^\infty = 2$ for all $k$. Accurate numerical results, indicated by small relative residuals, were produced by the proposed algorithm, as shown in Table 5.1.

TABLE 5.1
*Norms and relative residuals of causal Gramians.*

| $k$ | $\lVert G_k^{cr} \rVert_2$ | $\gamma_k^{cr}$ | $\lVert G_k^{co} \rVert_2$ | $\gamma_k^{co}$ |
|---|---|---|---|---|
| 0 | $8.30 \times 10^4$ | $2.17 \times 10^{-16}$ | $1.14 \times 10^3$ | $1.39 \times 10^{-16}$ |
| 1 | $7.11 \times 10^3$ | $3.11 \times 10^{-16}$ | $9.70 \times 10^0$ | $4.17 \times 10^{-15}$ |
| 2 | $5.82 \times 10^2$ | $6.73 \times 10^{-16}$ | $9.74 \times 10^1$ | $9.18 \times 10^{-15}$ |

## 6. Hankel singular values.

Similar to standard state space systems [17] and continuous-time descriptor systems [34, 38], the controllability and observability Gramians can be used to define Hankel singular values for the periodic descriptor systems (1.1), which are of great importance in the model reduction problem via the balanced truncation method.

For the discrete-time descriptor systems, the causal and noncausal Hankel singular values are defined via the nonnegative eigenvalues of the matrices $\mathcal{G}_{dcc}E^T\mathcal{G}_{dco}E$ and $\mathcal{G}_{dnc}A^T\mathcal{G}_{dno}A$. Here $\mathcal{G}_{dcc}$, $\mathcal{G}_{dnc}$, $\mathcal{G}_{dco}$, and $\mathcal{G}_{dno}$ denote the causal/noncausal reachability Gramians and the causal/noncausal observability Gramians, respectively [39].

LEMMA 6.1. [illegible] $\{(E_k, A_k)\}_{k=0}^{K-1}$ [illegible] $n_k \times n_k$ [illegible] $\mathbf{H}_k^c \equiv G_k^{cr}E_{k-1}^T G_k^{co} E_{k-1}$ [illegible] $\mathbf{H}_k^{nc} \equiv G_k^{nr} A_k^T G_{k+1}^{no} A_k$ $k = 0, 1, 2, \ldots, K-1$ [illegible]

[illegible] From Definitions 4.1 and 4.2 and (2.15), for $k = 0, 1, 2, \ldots, K-1$, we have

$$
\mathbf{H}_k^c = Y_k \begin{bmatrix} \widehat{G}_{k,1}^{cr}\widehat{G}_{k,1}^{co} & 0 \\ 0 & 0 \end{bmatrix} Y_k^{-1},
$$

where

$$\widehat{G}_{k,1}^{cr} \equiv \sum_{i=-\infty}^{k-1} \Phi_f(k,i+1)B_i^f(B_i^f)^T\Phi_f(k,i+1)^T,$$

$$\widehat{G}_{k,1}^{co} \equiv \sum_{i=k}^{\infty} \Phi_f(i,k)^T(C_i^f)^TC_i^f\Phi_f(i,k).$$

Since the $n_k^f \times n_k^f$ matrices $\widehat{G}_{k,1}^{cr}$ and $\widehat{G}_{k,1}^{co}$ are symmetric positive semidefinite, it follows that all $\mathbf{H}_k^c$ have real and nonnegative eigenvalues. Similarly, it can be shown that all $\mathbf{H}_k^{nc}$ also share the same property. □

Notice that, in the proof of Lemma 6.1, $\mathbf{H}_k^c$ and $\mathbf{H}_k^{nc}$ have at least $n_k^\infty$ and $n_k^f$ zero eigenvalues, respectively. Hence, we have the following definition of Hankel singular values for the periodic descriptor system (1.1).

Definition 6.1. [illegible] $\{(E_k, A_k)\}_{k=0}^{K-1}$ [illegible] $n_k^f$ $n_k^\infty$ [illegible] $\{(E_k, A_k)\}_{k=0}^{K-1}$ [illegible]

(i) [illegible] $k = 0, 1, \ldots, K-1$ [illegible] $n_k^f$ [illegible] $\mathbf{H}_k^c$ [illegible] $\zeta_{k,j}$ [illegible] (1.1)

(ii) [illegible] $k = 0, 1, \ldots, K-1$ [illegible] $n_k^\infty$ [illegible] $\mathbf{H}_k^{nc}$ [illegible] $\theta_{k,j}$ [illegible] (1.1)

[illegible] (i) When $K = 1$, the causal and noncausal Hankel singular values defined in Definition 6.1 coincide with those for discrete-time descriptor systems (see [39] and references therein). For $E_k = I$, the causal Hankel singular values are the classical Hankel singular values of linear periodic discrete-time systems [46].

(ii) As in the case of descriptor systems, the causal and noncausal Hankel singular values of the periodic descriptor system (1.1) are invariant under system equivalence transformations.

From Theorem 4.2 and Lemma 6.1, we obtain the following result.

Corollary 6.2. [illegible] (1.1) [illegible] $\{(E_k, A_k)\}_{k=0}^{K-1}$ [illegible]

(a) [illegible] (1.1) [illegible]

(b) [illegible] $k = 0, 1, 2, \ldots, K-1$ [illegible]

$$\operatorname{rank}(G_k^{cr}) = \operatorname{rank}(G_k^{co}) = \operatorname{rank}(\mathbf{H}_k^c) = n_k^f,$$
$$\operatorname{rank}(G_k^{nr}) = \operatorname{rank}(G_k^{no}) = \operatorname{rank}(\mathbf{H}_k^{nc}) = n_k^\infty.$$

(c) [illegible] (1.1) [illegible]

For pd-stable $\{(E_k, A_k)\}_{k=0}^{K-1}$, the causal and noncausal reachability and observability Gramians are symmetric and positive semidefinite. Thus, there exist full-rank factorizations

$$\begin{aligned} G_k^{cr} &= R_kR_k^T, \quad G_k^{co} = L_k^TL_k, \\ G_k^{nr} &= \widetilde{R}_k\widetilde{R}_k^T, \quad G_k^{co} = \widetilde{L}_k^T\widetilde{L}_k, \end{aligned} \tag{6.1}$$

where the matrices $R_k$, $L_k^T$, $\tilde{R}_k$, and $\tilde{L}_k^T$ are of full column rank.

The connections between the causal/noncausal Hankel singular values and the singular values of the matrices $L_kE_{k-1}R_k$ and $\widetilde{L}_{k+1}A_k\widetilde{R}_k$ are considered in the following lemma.

LEMMA 6.3. [illegible] (1.1) [illegible] $\{(E_k, A_k)\}_{k=0}^{K-1}$ [illegible] (1.1) [illegible] (6.1) [illegible] $k = 0, 1, 2, \ldots, K-1$ [illegible] $L_kE_{k-1}R_k$ [illegible] $\widetilde{L}_{k+1}A_k\widetilde{R}_k$[illegible]

[illegible] Notice that for $k = 0, 1, \ldots, K-1$, we have

$$\zeta_{k,j}^2 = \lambda_j(R_kR_k^TE_{k-1}^TL_k^TL_kE_{k-1}) = \lambda_j(R_k^TE_{k-1}^TL_k^TL_kE_{k-1}R_k) = \sigma_j^2(L_kE_{k-1}R_k),$$

$$\theta_{k,j}^2 = \lambda_j(\widetilde{R}_k\widetilde{R}_k^TA_k^T\widetilde{L}_{k+1}^T\widetilde{L}_{k+1}A_k) = \lambda_j(\widetilde{R}_k^TA_k^T\widetilde{L}_{k+1}^T\widetilde{L}_{k+1}A_k\widetilde{R}_k) = \sigma_j^2(\widetilde{L}_{k+1}A_k\widetilde{R}_k),$$

where $\lambda_j(\cdot)$ and $\sigma_j(\cdot)$ denote respectively the eigenvalues and singular values of the corresponding matrices. ☐

## 7. Balanced realization.

It is well known [17] that for any minimal realization $(A, B, C)$ of a stable continuous-time or discrete-time system there exists a transformation such that the controllability and observability Gramians for the transformed realization equal some diagonal matrix. Such a realization is called a(n) (internally) balanced realization. Recently, the issues of balanced realization and model reduction via the balanced truncation method have been discussed for continuous-time descriptor systems [34, 38] and asymptotically stable linear discrete-time periodic systems [45, 46]. In this section the problem of balanced realization is generalized for periodic descriptor systems. We shall assume that the periodic descriptor system (1.1) is completely reachable/observable, with $\{(E_k, A_k)\}_{k=0}^{K-1}$ being pd-stable.

DEFINITION 7.1. [illegible] $(E_k, A_k, B_k, C_k)$ [illegible] (1.1) [illegible]

$$G_k^{cr} = G_k^{co} = \begin{bmatrix} D_{k,1} & 0 \\ 0 & 0 \end{bmatrix} \quad [illegible] \quad G_k^{nr} = G_{k+1}^{no} = \begin{bmatrix} 0 & 0 \\ 0 & D_{k,2} \end{bmatrix},$$

[illegible] $D_{k,1}$ [illegible] $D_{k,2}$ [illegible] $k = 0, 1, \ldots, K-1$

We shall show that for a realization $(E_k, A_k, B_k, C_k)$ of the periodic descriptor system (1.1) there exist nonsingular periodic matrices $S_k \in \mathbb{R}^{\mu_{k+1}\times\mu_{k+1}}$ and $T_k \in \mathbb{R}^{n_k\times n_k}$ $(k = 0, 1, \ldots, K-1)$ with $T_K \equiv T_0$, such that the transformed realization

$$(\widehat{E}_k, \widehat{A}_k, \widehat{B}_k, \widehat{C}_k) \equiv (S_k^TE_kT_{k+1}, S_k^TA_kT_k, S_k^TB_k, C_kT_k) \tag{7.1}$$

is balanced.

Consider the full-rank factorizations (6.1) of the causal/noncausal reachability/observability Gramians. For $k = 0, 1, \ldots, K-1$, let

$$L_kE_{k-1}R_k = U_k\Sigma_kV_k^T, \quad \widetilde{L}_{k+1}A_k\widetilde{R}_k = \widetilde{U}_k\Theta_k\widetilde{V}_k^T \tag{7.2}$$

be singular value decompositions [18], where $U_k$, $V_k$, $\widetilde{U}_k$, $\widetilde{V}_k$ are orthogonal and $\Sigma_k$ and $\Theta_k$ are diagonal and nonsingular. From Corollary 6.2 and Lemma 6.3, we have $\Sigma_k = \mathrm{diag}(\zeta_{k,1}, \ldots, \zeta_{k,n_k^f}) > 0$ and $\Theta_k = \mathrm{diag}(\theta_{k,1}, \ldots, \theta_{k,n_k^\infty}) > 0$. Furthermore, it is easily seen from Theorem 4.1 and (2.14) that

$$\begin{aligned}&G_k^{cr} = P_r(k) G_k^{cr} P_r(k)^T, \quad G_k^{co} = P_l(k-1)^T G_k^{co} P_l(k-1),\\ &P_r(k) G_k^{nr} = 0, \quad G_k^{no} P_l(k-1) = 0,\\ &E_{k-1} P_r(k) = P_l(k-1) E_{k-1}, \quad A_k P_r(k) = P_l(k) A_k.\end{aligned}$$

Simple calculations then yield $G_k^{no} E_{k-1} G_k^{cr} = G_k^{co} E_{k-1} G_k^{nr} = G_{k+1}^{no} A_k G_k^{cr} = G_{k+1}^{co} A_k G_k^{nr} = 0$. Hence, for $k = 0, 1, \ldots, K-1$, we have

$$\widetilde{L}_k E_{k-1} R_k = L_k E_{k-1} \widetilde{R}_k = \widetilde{L}_{k+1} A_k R_k = L_{k+1} A_k \widetilde{R}_k = 0. \tag{7.3}$$

Now for $k = 0, 1, \ldots, K-1$, consider the $\mu_{k+1} \times \mu_{k+1}$ matrices

$$\begin{aligned}S_k &= \begin{bmatrix} L_{k+1}^T U_{k+1} \Sigma_{k+1}^{-1/2}, & \widetilde{L}_{k+1}^T \widetilde{U}_k \Theta_k^{-1/2} \end{bmatrix},\\ \check{S}_k &= \begin{bmatrix} E_k R_{k+1} V_{k+1} \Sigma_{k+1}^{-1/2}, & A_k \widetilde{R}_k \widetilde{V}_k \Theta_k^{-1/2} \end{bmatrix};\end{aligned}$$

it follows from (7.2) and (7.3) that

$$\begin{aligned}S_k^T \check{S}_k &= \begin{bmatrix} \Sigma_{k+1}^{-1/2} U_{k+1}^T L_{k+1} E_k R_{k+1} V_{k+1} \Sigma_{k+1}^{-1/2} & \Sigma_{k+1}^{-1/2} U_{k+1}^T L_{k+1} A_k \widetilde{R}_k \widetilde{V}_k \Theta_k^{-1/2} \\ \Theta_k^{-1/2} \widetilde{U}_k^T \widetilde{L}_{k+1} E_k R_{k+1} V_{k+1} \Sigma_{k+1}^{-1/2} & \Theta_k^{-1/2} \widetilde{U}_k^T \widetilde{L}_{k+1} A_k \widetilde{R}_k \widetilde{V}_k \Theta_k^{-1/2} \end{bmatrix}\\ &= I_{\mu_{k+1}},\end{aligned}$$

i.e., the matrices $S_k$ and $\check{S}_k$ are nonsingular and $S_k^{-1} = \check{S}_k^T$. Similarly, it can be shown that the $n_k \times n_k$ matrices

$$T_k = \begin{bmatrix} R_k V_k \Sigma_k^{-1/2}, & \widetilde{R}_k \widetilde{V}_k \Theta_k^{-1/2} \end{bmatrix}, \quad \check{T}_k = \begin{bmatrix} E_{k-1}^T L_k^T U_k \Sigma_k^{-1/2}, & A_k^T \widetilde{L}_{k+1}^T \widetilde{U}_k \Theta_k^{-1/2} \end{bmatrix}$$

are also nonsingular and $T_k^{-1} = \check{T}_k^T$. Therefore, with the transformation matrices $S_k$ and $T_k$ defined above and (7.3), the causal reachability and observability Gramians of the transformed periodic descriptor system (7.1) become

$$\begin{aligned}\widehat{G}_k^{cr} &\equiv T_k^{-1} G_k^{cr} T_k^{-T} = \check{T}_k^T G_k^{cr} \check{T}_k\\ &= \begin{bmatrix} \Sigma_k^{-1/2} U_k^T L_k E_{k-1} R_k R_k^T E_{k-1}^T L_k^T U_k \Sigma_k^{-1/2} & \Sigma_k^{-1/2} U_k^T L_k E_{k-1} R_k R_k^T A_k^T \widetilde{L}_{k+1}^T \widetilde{U}_k \Theta_k^{-1/2} \\ \Theta_k^{-1/2} \widetilde{U}_k^T \widetilde{L}_{k+1} A_k R_k R_k^T E_{k-1}^T L_k^T U_k \Sigma_k^{-1/2} & \Theta_k^{-1/2} \widetilde{U}_k^T \widetilde{L}_{k+1} A_k R_k R_k^T A_k^T \widetilde{L}_{k+1}^T \widetilde{U}_k \Theta_k^{-1/2} \end{bmatrix}\\ &= \begin{bmatrix} \Sigma_k & 0 \\ 0 & 0 \end{bmatrix}\end{aligned}$$

and

$$\widehat{G}_k^{co} \equiv S_{k-1}^{-1} G_k^{co} S_{k-1}^{-T} = \check{S}_{k-1}^T G_k^{cr} \check{S}_{k-1}$$

$$= \begin{bmatrix} \Sigma_k^{-1/2} V_k^T R_k^T E_{k-1}^T L_k^T L_k E_{k-1} R_k V_k \Sigma_k^{-1/2} & \Sigma_k^{-1/2} V_k^T R_k^T E_{k-1}^T L_k^T L_k A_{k-1} \widetilde{R}_{k-1} \widetilde{V}_{k-1} \Theta_{k-1}^{-1/2} \\ \Theta_{k-1}^{-1/2} \widetilde{V}_{k-1}^T \widetilde{R}_{k-1}^T A_{k-1}^T L_k^T L_k E_{k-1} R_k V_k \Sigma_k^{-1/2} & \Theta_{k-1}^{-1/2} \widetilde{V}_{k-1}^T \widetilde{R}_{k-1}^T A_{k-1}^T L_k^T L_k A_{k-1} \widetilde{R}_{k-1} \widetilde{V}_{k-1} \Theta_{k-1}^{-1/2} \end{bmatrix}$$

$$= \begin{bmatrix} \Sigma_k & 0 \\ 0 & 0 \end{bmatrix}.$$

On the other hand, one can also show that the noncausal reachability and observability Gramians of the transformed periodic descriptor system (7.1) satisfy

$$\widehat{G}_k^{nr} \equiv T_k^{-1} G_k^{nr} T_k^{-T} = \left[ \begin{array}{cc} 0 & 0 \\ 0 & \Theta_k \end{array} \right] = S_k^{-1} G_{k+1}^{no} S_k^{-T} \equiv \widehat{G}_{k+1}^{no}, \quad k = 0, 1, \ldots, K-1.$$

Consequently, $S_k$ and $T_k$ ($k = 0, 1, \ldots, K-1$) are the desired balancing transformations such that the realization (7.1) is balanced. In summary, we have the following theorem.

THEOREM 7.1. [illegible] (1.1) [illegible] $\{(E_k, A_k)\}_{k=0}^{K-1}$ [illegible] $S_k$ [illegible] $T_k$ $k = 0, 1, \ldots, K-1$ [illegible] $T_K \equiv T_0$ [illegible] (7.1) [illegible]

[illegible] As in the cases of standard state space systems [17, 29] and descriptor systems [34, 38], the balancing transformation matrices for periodic descriptor system (1.1) are not unique. Indeed, if $\{(S_k, T_k)\}_{k=0}^{K-1}$ denotes a set of balancing transformation pairs for the periodic descriptor system (1.1), then for any diagonal matrix $D$ with diagonal entries $\pm 1$, the set of matrix pairs $\{(S_k D, T_k D)\}_{k=0}^{K-1}$ are also balancing transformation matrices for the periodic descriptor system (1.1).

## 8. Concluding remarks.

In Theorem 4.1, the reachability/observability Gramians are shown to satisfy some projected GDPLEs and can be computed numerically by applying Algorithm 5.1. We have developed the concepts of reachability/observability Gramians, Hankel singular values, and balanced realization for periodic discrete-time descriptor systems, based on the necessary and sufficient conditions for complete reachability and observability. These are useful in the model reduction problem via the balanced truncation method. A numerical example was given in section 5 to illustrate the feasibility and reliability of the proposed algorithm.

The theoretical development in the paper deals with general time-varying periodic systems. Understandably, numerical algorithms are more developed for systems of constant dimensions. Development of numerical algorithms (e.g., the solution of periodic Sylvester and Lyapunov equations) needs to be investigated further.

**Acknowledgment.** We would like to thank the referees for their penetrating questions, which improved the quality of the paper tremendously.

# TOWARDS STABLE MIXED PIVOTING STRATEGIES FOR THE SEQUENTIAL AND PARALLEL SOLUTION OF SPARSE SYMMETRIC INDEFINITE SYSTEMS*

IAIN S. DUFF† AND STÉPHANE PRALET‡

**Abstract.** We consider the direct solution of sparse symmetric indefinite matrices. We develop new pivoting strategies that combine numerical pivoting and perturbation techniques. Then an iterative refinement process uses our approximate factorization to compute a solution. We show that our pivoting strategies are numerically robust, that few steps of iterative refinement are required, and that the factorization is significantly faster than with previous methods. Furthermore, we propose original approaches that are designed for parallel distributed factorization. A key point of our parallel implementation is the cheap and reliable estimation of the growth factor. This estimation is based on an approximation of the off-diagonal entries and does not require any supplementary messages.

**Key words.** direct solver for sparse symmetric indefinite matrices, Gaussian elimination, parallel multifrontal methods, static pivoting, matrix perturbation

## 1. Introduction.

We study pivoting strategies for computing the **LDL**$^{\mathbf{T}}$ factorization of a symmetric indefinite matrix, where $L$ is a lower triangular matrix and $D$ is a block diagonal matrix with $1\times1$ and $2\times2$ blocks. We consider direct methods based on a multifrontal technique, although most of our comments and analysis apply to other approaches for direct factorization.

Usually the factorization is computed in two phases. The analysis phase preprocesses the system of equations and is often based purely on matrix structure. The second phase performs the Gaussian elimination. If the numerical tests prevent the selection of some pivots chosen by the analysis, then the factorization can still proceed, but there will normally be an increase in both storage and work for the factorization compared to that required if no pivots are delayed. This effect can be particularly significant on augmented systems.

We would like to define "static pivoting" as any pivoting scheme that respects the data structures obtained from the analysis (so that static data structures can be used). However, this term is still a matter for debate within our community, so we therefore use the term [illegible] in the body of this paper. Such a scheme closely follows the pivot selection of the analysis to give generally lower fill-in and factorization times at the potential cost of worse accuracy in the factorization. In this paper we propose a new approach that is reliable in terms of numerical precision and memory estimation. Our new approach also improves the factorization time compared to approaches that perform usual numerical pivoting. The originality of our approach is to combine numerical pivoting and perturbation techniques and to propose a criterion for deciding between small $1\times1$ and small $2\times2$ pivots. When we

would select too small a pivot, we modify diagonal entries so that we compute the **LU** factorization of a perturbed matrix:

$$\mathbf{LU} = \mathbf{A} + \Delta + \mathbf{E},$$

where $\Delta$ is a diagonal matrix corresponding to the perturbed pivots and $\mathbf{E}$ corresponds to the rounding errors. We then use iterative refinement with this approximation and show that we almost always compute an accurate solution. We also find that delaying pivots is dangerous in the context of an approximate factorization. Moreover, we propose new pivoting strategies that are numerically robust on our representative test set and do not adversely affect the scalability of a parallel distributed factorization. They are based on estimations of growth factors and do not require any supplementary messages.

In our recent work [12], we developed preprocessing techniques to be used with sparse symmetric indefinite direct solvers which perform numerical pivoting:

- We showed how maximum weighted matching techniques can be used when the matrix is symmetric to effect a symmetric scaling. We have found this very beneficial over a wide range of problems. That is why we will systematically use scaling in this paper, although in some of the analysis we do not assume that the system will necessarily have been scaled.
- We also used symmetric weighted matching techniques to identify potential $2\times 2$ pivots. A major benefit of our work is that the analysis phase gives a better indication of the work and storage required by the subsequent factorization. Nevertheless the influence of our pivot preselection on the performance of the factorization depends very much on the nature of the matrix. It might increase the fill-in in the factors and the factorization time, for example. That is why we will not use this preprocessing in this paper (except in section 7, where we want to evaluate the combination of the preprocessing of [12] with the pivoting strategies presented in this paper).

Even if these preprocessing steps are sequential, they do not represent a significant overhead compared to the total analysis time and are negligible compared to the factorization time.

In section 2, we describe multifrontal solvers and parallel distributed multifrontal solvers. We also briefly describe pivoting strategies implemented in `SuperLU_DIST` [22] and PARDISO [27] and the numerical pivoting strategies that are often used in the context of sparse direct methods.

Section 3 presents our experimental environment. In section 4, we describe a new pivoting strategy that combines numerical pivoting and perturbation techniques and that is well designed for sequential factorization. We present experimental results for this strategy. In section 5, we show that combining restricted pivoting and delayed pivots severely affects the numerical quality of the factorization. Section 6 presents pivoting strategies that are particularly suited for parallel distributed solvers. In section 7, we study the influence of the preprocessings of [12] on our pivoting strategies. We present our conclusions in section 8.

### 1.1. Notation.

In the following, $s$ will be the function for the sign of a real number,

$$s(x) = \begin{cases} 1 & \text{if } x \geq 0, \\ -1 & \text{if } x < 0, \end{cases}$$

$\epsilon$ will denote the machine precision, $|| \; ||_2$ and $|| \; ||_\infty$ will denote the submultiplicative matrix norms, and $||A||_M$ will denote the norm $\max_{ij} |a_{ij}|$.

For each matrix or submatrix $A = (a_{ij})$, $|A| = (|a_{ij}|)$, $n$ will denote the order of $A$ and $nnz$ its number of nonzeros. $0 < u \leq 1$ and $\mu = \sqrt{\epsilon}$ will denote real numbers which will be used as thresholds in our pivoting strategies. In practice, we will use $u = 0.01$. $FSV$ and $PSV$ will denote fully summed variables and partially summed variables, respectively.

We summarize in Table 1.1 the main pivoting strategies that we develop in this paper.

Table 1.1

*Summary of our main pivoting strategies. The* `SEQ` *suffix means that the strategy is designed for a sequential code. The* `PAR` *suffix means that the strategy is designed for a parallel code.*

| Name | Pivoting strategy | Section |
|---|---|---|
| `numSEQ` | Numerical pivoting of Duff–Reid algorithm | 2.2 |
| `mixSEQ` | Numerical pivoting combined with perturbation techniques (restricted pivoting) | 4.1 |
| `numBPAR` | Basic restriction of Duff–Reid algorithm | 6.1 |
| `numEPAR` | Adaptation of Duff–Reid algorithm that uses estimations | 6.2 |
| `mixEPAR` | Combination of `numEPAR` and `mixSEQ` | 4.1 and 6.2 |

## 2. Symmetric indefinite multifrontal solvers and numerical pivoting.

**2.1. Multifrontal approach.** For an irreducible matrix, the [illegible] [13, 23] represents the order in which the matrix can be factorized, that is, in which the unknowns from the underlying linear system of equations can be chosen. (This tree is in the most general case a forest, but we will assume in our discussions, for the sake of clarity, that it is a connected tree. That is, the matrix is irreducible.) One central concept of the multifrontal approach [13] is to group (or [illegible]) columns with the same sparsity structure to create [illegible] or [illegible] [13, 24] in order to make use of efficient dense matrix kernels. The amalgamated elimination tree is called the [illegible].

$$
\begin{array}{rcc}
 & \text{fully summed columns} & \text{partially summed columns} \\
 & \downarrow & \downarrow \\
\text{fully summed rows} \rightarrow & F_{11} & F_{12} \\
\text{partially summed rows} \rightarrow & F_{21} & F_{22}
\end{array}
$$

Fig. 2.1. *A frontal matrix.*

When a node in the assembly tree is being processed, it assembles the contribution blocks from all its child nodes into its [illegible] (see Figure 2.1). In the symmetric case, pivots are usually chosen from the diagonal as discussed in section 2.2, and operations and storage are about half those of the general case. The pivotal variables from the [illegible] block, $F_{11}$, are eliminated, and the Schur complement matrix, $F_{22} - F_{21}F_{11}^{-1}F_{12}$, is computed. The contribution block is then sent to the parent node to be assembled. If some variables are not eliminated because of numerical issues, they are moved to the contribution block and sent to the parent node. The effect of this is that the computation $F'_{22} - F'_{21}{F'_{11}}^{-1}F'_{12}$ is performed, where $F'_{11}$ is a submatrix of $F_{11}$ of dimension the number of pivots selected at this stage. If this dimension is less than the order of $F_{11}$, then the difference represents the number of pivots [illegible] at this stage. Delayed pivots have the effect of causing extra fill-in and thus increase the memory and the number of operations for the factorization.

**2.2. Numerical pivoting.** In the unsymmetric case, at step $k$ of Gaussian elimination, the pivot $(p, q)$ is selected from the fully summed rows and columns. To limit the growth of the entries in the factors and thus to obtain a more accurate factorization, a test on the magnitude of the pivot is commonly used. $a_{pq}$ can be selected if and only if

$$|a_{pq}| \geq u \max_j |a_{pj}|, \tag{2.1}$$

where $u$ is a threshold parameter between 0 and 1. This criterion will ensure that the growth factor is limited to $1 + 1/u$.

In the symmetric indefinite case, we have to perform 1×1 and 2×2 pivoting if we want to keep the symmetry while maintaining stability. Pivot selection can be done using the Bunch–Parlett [6] or Bunch–Kaufman [5] algorithm, or a variation proposed by [4] that uses rook pivoting. In the context of sparse matrices, the criterion of the Duff–Reid algorithm that uses rook pivoting ([13], as modified in [14]) can be used to ensure a growth factor of less than $1 + 1/u$ at each step of Gaussian elimination. A $1 \times 1$ diagonal pivot can be selected if and only if it satisfies the inequality (2.1). A $2 \times 2$ pivot $P = \left(\begin{smallmatrix} a_{pp} & a_{pq} \\ a_{qp} & a_{qq} \end{smallmatrix}\right)$ can be selected if and only if it satisfies

$$|P^{-1}| \begin{pmatrix} \max_{k \neq p,q} |a_{pk}| \\ \max_{k \neq p,q} |a_{qk}| \end{pmatrix} \leq \begin{pmatrix} 1/u \\ 1/u \end{pmatrix}, \tag{2.2}$$

where $u$ is a threshold between 0 and $\frac{1}{2}$.

**2.3. Numerical pivoting and perturbation techniques.** Modifying the diagonal of the matrix instead of performing numerical pivoting was introduced by Stewart in [28]. In his approach, the magnitude of the perturbations can be quite large. Given a symmetric matrix $A$, not necessarily positive definite, approaches to compute a modified Cholesky factorization of $A + E$ with $E$ as small as possible have been developed in [7, 15, 16] (in a modified Cholesky $||E||_2 \geq -\min \lambda_i(A)$). The size of this perturbation is larger than we want, so we do not use modified Cholesky approaches. Furthermore, the approach of [7] is not adapted for sparse matrices because the pattern of $E$ can be significantly different from the pattern of $A$.

Our restricted pivoting strategy means that in our code pivoting is restricted to static data structures that have been predicted by the analysis phase. The factorization does not necessarily follow the pivot selected by the ordering exactly, and some slight variations are allowed. For example, in a multifrontal context, it is sufficient that the factorization decisions be compatible with the assembly tree (numerical pivoting is restricted to fully summed variables within a front, and delayed pivots are not allowed). A static approach was proposed by [21] in the context of **LU** factorization. The pivot order decided during the analysis is strictly followed. During Gaussian elimination when a forecast pivot is too small, [illegible]” are added to limit the growth of the factors in order to enhance the backward stability of the algorithm (see, for example, Theorem 11.4 of [20], which gives an upper bound of the residual after one iterative refinement). By [illegible]” we mean that the perturbed matrix is close enough to the original so that the factorization of the perturbed matrix is close to the factorization of the original matrix. If this is the case, then we would hope to have a cheap and sufficiently accurate solution using the computed factors.

`SuperLU_DIST` [22] adds small perturbations $\delta$ to the diagonal entries when the pivot $a_{ii}$ is too small so that $|a_{ii} + \delta| \geq \mu \; ||A||_M$. Note that the forecast large entries are permuted to the diagonal using maximum weighted matching techniques [11] and that no pivoting is performed within the supernodes.

At the same time as we were working on our pivoting algorithms (based on Duff–Reid pivoting), strategies based on the Bunch–Kaufman pivoting strategy using possible perturbations were developed in [27]. These developments are independent and give rise to different performance characteristics. The approach in [27] may degrade the precision of the solution and slow down the solution phase because of the increase in the number of iterative refinement steps [17]. Moreover, contrary to our pivoting strategies in section 6, the approach of [27] has not been designed explicitly for a parallel distributed environment. Finally, the approach in [27] does not use estimations of the growth factor to control the accuracy of the factorization [20].

**2.4. Parallel distributed approaches.** This section discusses the parallelism that is exploited by distributed multifrontal solvers, focusing on the `MUMPS` approach and using the terminology from that work [1, 2].

A pair of nodes in the assembly tree, where neither is an ancestor of the other, can be factorized independently from each other, in any order or in parallel. Consequently, independent branches of the assembly tree can be processed in parallel, and we refer to this as *tree parallelism* or *type 1 parallelism*. It is obvious that, in general, tree parallelism can be exploited more efficiently in the lower part of the assembly tree than near the root node. Additional parallelism is then created using distributed memory versions of blocked algorithms to factorize the frontal matrices (see, for example, [2, 9]).

The lower triangular part of the frontal matrix is partitioned, and each part of it is assigned to a different process. The so-called *master process* is responsible for the diagonal block of fully summed variables and also decides which processes (the so-called *slave processes*) will be involved in the parallel activity associated with this node. We refer to this as *type 2 parallelism* and call the nodes involved *type 2 nodes*. After computing its part of the contribution block, a slave will communicate with the master and the slaves of the parent node.

In order to have an efficient factorization, asynchronous schemes are used. There is no synchronization between a master and its slaves (who may be involved in another task or even be the master of another type 2 node). Hence the master has to select pivots without the knowledge of the part of fully summed columns stored on its slaves. This problem will be addressed by our pivoting strategies presented in section 6. An alternative could be to overload the master process with the work associated with the complete fully summed columns (diagonal plus off-diagonal part), but obviously this would generate workload and memory imbalances and degrade the scalability of the approach.

**3. Experimental environment.** Our experiments are conducted on one node of a COMPAQ Alpha Server SC45 at CERFACS. There are four GBytes of memory shared between four EV68 processors per node, and we disable three of the processors so that we can use all the memory of the node with the remaining single processor. We use the Fortran 90 compiler, f90 version 5.5 with the -O option. If the factorization needs more than 4 GBytes or requires more than 30 minutes CPU time, we consider that it is not successful.

We conduct our experiments on a number of challenging and sometimes badly conditioned test problems. The matrices are available from ftp.numerical.rl.ac.uk/

pub/matrices/symmetric/indef/ and most of them (all except the cvxqp3 matrix) are a subset of the matrices collected by [19] for testing symmetric sparse solvers. To select our matrices we ran our pivoting strategies on the matrices from [19] and kept the difficult matrices that illustrate the characteristics of our pivoting strategies. (We use "difficult" in the sense that they often required iterative refinement steps to get a small residual.)

Some of the matrices come from the Maros and Meszanos quadratic programming collection (M2) [25], the CUTEr optimization test set (CUTEr) [18], and the University of Florida collection (UF) [8]. Some problems were generated by Andy Wathen (AW), Mario Arioli (MA), and Miroslav Tuma (MT). These problems are described in Table 3.1. These test matrices correspond to augmented matrices of the form

$$\mathcal{K}_{H,A} = \begin{pmatrix} H & A \\ A^T & 0 \end{pmatrix}.$$

In all our experiments we use random right-hand sides. To perform an error analysis of the solution we compute the sparse componentwise backward error using the theory and measure developed by [3]. The scaled residual of the $i$th equation is

$$\Delta_i = \frac{|r_i|}{(|A||x| + |b|)_i},$$

where $r = b - Ax$ and $x$ is the computed solution, except if the denominator is too small (in our code the threshold for this is $1000 \times \epsilon$). In this case, we use

$$\Delta_i = \frac{|r_i|}{((|A||x|)_i + ||A_i||_\infty ||x||_\infty)_i},$$

where $A_i$ represents the $i$th row of $A$. We apply iterative refinement in all our approaches. At each step $k$ of the iterative refinement, we compute the current backward error $berr^{(k)} \;=\; \max_i \Delta_i$.

We also compute the normwise backward error

$$nberr \;=\; ||\mathbf{Ax} - \mathbf{b}||_\infty / (||\mathbf{A}||_\infty ||\mathbf{x}||_\infty + ||\mathbf{b}||_\infty)$$

and display it in Table 4.1 below to show that our approach is competitive with that presented in [27].

During our performance analysis, we will report the factorization time and the solution time separately because the total time really depends on the application. For example, if multiple solutions are required with the same matrix (as is often the case in optimization), the solution time may become dominant.

We will use our pivoting strategies with a symmetric multifrontal code, `MA57` Version 3.0.0 [10], on a challenging test set (see section 3). Note that `MA57` is one of the best sparse symmetric indefinite sequential direct solvers [17], and thus the advances presented here are advances on an already very competitive code. Unless otherwise stated, we use the METIS nested-dissection ordering during the analysis, and we symmetrically scale the matrix with our symmetric scaling [12]. This makes all entries smaller than 1 in magnitude, and the columns of the scaled matrix can be permuted so that it has entries of magnitude 1 on the diagonal. Thus in our experiments and in our criteria for selecting pivots we will have $||A||_M = 1$. Nevertheless, we will keep this term because in practice the matrix may be differently scaled or not scaled at all (this is an option for the user through the `MA57` interface). In these cases we observed that we obtain better solutions if we include the $||A||_M$ term in our criteria.

Although `MA57` is a sequential code, we will use it to simulate the parallel behavior of a multifrontal solver like `MUMPS` [1, 2].

## 4. Mixing numerical pivoting and perturbation techniques.

**4.1. Algorithm.** In this section, we present an approach which combines numerical checking for stability with perturbations. This approach will be referred to as [illegible]. We decided to use only $1 \times 1$ perturbations because they are easier to implement, and we want to clearly identify the impact of this mixed approach. Some promising experiments with $2 \times 2$ perturbations can be found in [26], but they were applied in a different context; the analysis fixes the 1×1 and 2×2 pivots, and appropriate perturbations were applied during the factorization. In this present paper, the pivots are dynamically chosen, and we have found that the use of $2 \times 2$ perturbations does not give a significant improvement. In our algorithm, we perturb the original entries only in extreme cases where pivots are very small in magnitude. That is why the additional use of $2 \times 2$ perturbations does not affect the precision of the solution.

Let us consider a frontal matrix from the elimination tree. It contains two kinds of variables, the $FSV$, which correspond to the pivot block that we want to eliminate, and the $PSV$, on which the Schur complement will be computed.

Our mixed approach is based on two phases. In the first phase, we perform numerical pivoting in the block of fully summed variables until no remaining variables satisfy the numerical criterion. In the second phase, we eliminate the remaining fully summed variables, adding $1 \times 1$ perturbations if necessary.

Our pivot selection is more precisely defined as follows. Using (2.1) and (2.2), we define

$$g_1(i) = \frac{\max_{k \neq i} |a_{ik}|}{|a_{ii}|}, \tag{4.1}$$

and

$$g_2(i,j) = \left\| |P^{-1}| \begin{pmatrix} \max_{k \neq i,j} |a_{ik}| \\ \max_{k \neq i,j} |a_{jk}| \end{pmatrix} \right\|_\infty . \tag{4.2}$$

During the first phase of Algorithm 1 (the usual Duff–Reid algorithm), a 1×1 pivot $a_{ii}$ is considered to be stable if and only if

$$g_1(i) \leq 1/u, \tag{4.3}$$

and a 2×2 pivot $P$ is considered to be stable if and only if

$$g_2(i,j) \leq 1/u. \tag{4.4}$$

**Algorithm 1** Numerical pivot selection combined with perturbation techniques.

```
Phase 1: Eliminate as many 1×1 and 2×2 pivots as possible which satisfy inequalities (4.3) and (4.4), respectively, using the Duff–Reid algorithm with threshold $u$.
Phase 2:
while $FSV \neq \emptyset$ do
  Let $i \in FSV$.
  if $\#FSV = 1$ then
    if $|a_{ii}| < \mu\ ||A||_M$ then $a_{ii} = s(a_{ii})\mu\ ||A||_M$
    Perform elimination using $i$ as a 1×1 pivot.
    return
  end if
  Let $j = \arg\max_{k \in FSV \setminus \{i\}} |a_{ik}|$ and $P$ be the 2×2 block associated with $i$ and $j$.
  Choose between 1×1 or 2×2 pivoting:
  if $\min\{g_1(i), g_2(i,j)\} < 1/\mu$ then /* Case 1: growth factor comparison */
    if $g_2 < g_1$ then
      Perform elimination using $(i,j)$ as a 2×2 pivot.
    else
      Perform elimination using $i$ as a 1×1 pivot.
    end if
  else if $\min\{1/|a_{ii}|, ||P^{-1}||_\infty\} < 1/(\mu\ ||A||_M)$ then /* Case 2: pivot size comparison */
    if $1/|a_{ii}| > ||P^{-1}||_\infty$ then
      Perform elimination using $(i,j)$ as a 2×2 pivot.
    else
      Perform elimination using $i$ as a 1×1 pivot.
    end if
  else /* Case 3: diagonal 1×1 perturbation */
    $a_{ii} = s(a_{ii})\mu\ ||A||_M$
    Perform elimination using $i$ as a 1×1 pivot.
  end if
end while
```

During the second phase we use the threshold $\mu$. We perturb the diagonal of the matrix if the pivot is too small with respect to the initial values in $A$ (smaller than $\mu\ ||A||_M$). We tried different thresholds for $\mu$ in [26] and compared the precision of the solution after applying iterative refinement. We remark that choosing $10^{-7} \leq \mu \leq 10^{-10}$ seems to be a good compromise between small perturbations and small growth factors (larger $\mu$ values would give a more stable factorization but at the cost of obtaining the factorization of a matrix further from the original). Moreover, we observed that different values of $\mu$ in the range $[10^{-7}, 10^{-10}]$ lead to similar behavior in terms of number of iterations and precision of the solution. In our experiments $\mu$ is fixed at $\sqrt{\epsilon} \approx 10^{-8}$.

The choice between a 1×1 and a 2×2 pivot is done in three stages. First (Case 1 of Algorithm 1), if we can eliminate a pivot and ensure a growth factor lower than $1 + 1/\mu$, then we select the one with the lower growth factor. Second (Case 2 of Algorithm 1), if we cannot ensure a growth factor lower than $1+1/\mu$, then we compare the quantities $1/|a_{ii}|$ and $||P^{-1}||_\infty$. This second comparison is guided by the growth factor that would appear if we suppose that the largest off-diagonal entry is bounded by $||A||_M$. Finally, if no pivot can be chosen, a perturbed 1×1 pivot is selected (Case 3 of Algorithm 1).

We also tried to smooth the transition between the first and the second phase. Before the second phase, we performed numerical pivoting with smaller values of $u$. More precisely we defined a parameter $u_{min}$. While $u$ is larger than $u_{min}$, we decrease the $u$ value (for example, $u = u/10$) and restart phase 1. We did not observe gains from such an approach and thus prefer to focus on the simple version of our pivoting strategies (Algorithm 1) and to keep $u$ fixed at 0.01.

**4.2. Experimental results.** In this section, we discuss the influence of the pivoting scheme described in section 4.1. It will be referred to as the `mixSEQ` algorithm because checking the stability over the partially summed rows is not well designed for existing parallel implementations (see section 2.4).

In the rest of the paper, `numSEQ` will refer to numerical pivoting strategy of Duff and Reid [13]. When we perturb a 1×1 pivot (Case 3 of Algorithm 1) this pivot is called a [illegible].

Table 4.1 compares the precision of the solution for an $\mathbf{LDL^T}$ factorization with numerical pivoting and an $\mathbf{LDL^T}$ factorization with the `mixSEQ` pivoting strategy. Because of numerical pivoting, no iterative refinement is needed for a backward error smaller than $\sqrt{\epsilon}$, whereas with `mixSEQ` the backward error without any iterative refinement is often larger than $\sqrt{\epsilon}$. Thus we advise performing one or two steps of iterative refinement when using the `mixSEQ` strategy. This slight degradation of precision is due to the tiny pivots. On average, the `mixSEQ` strategy needs one iteration more to get the same precision as the `numSEQ` strategy.

Although the number of tiny pivots can be very large (see last column of Table 4.1), our `mixSEQ` approach generally succeeds in reducing the backward error. The CONT-* matrices are the only ones for which iterative refinement does not converge to the machine precision, even with several iterations.

Columns *nberr* of Table 4.1 show that our approach is competitive with and sometimes better than the approach presented in [27] (for example, on crystk* matrices the PARDISO normwise backward error is between $10^{-13}$ and $10^{-12}$, and on stokes* matrices it is between $10^{-12}$ and $10^{-10}$). In the rest of the paper we will concentrate on sparse componentwise backward errors since they give us more information about the quality of the solution [3].

Table 4.2 shows the main advantage of using restricted pivoting: the `mixSEQ` factorization is always faster. Delaying pivots increases the number of operations

Table 4.2

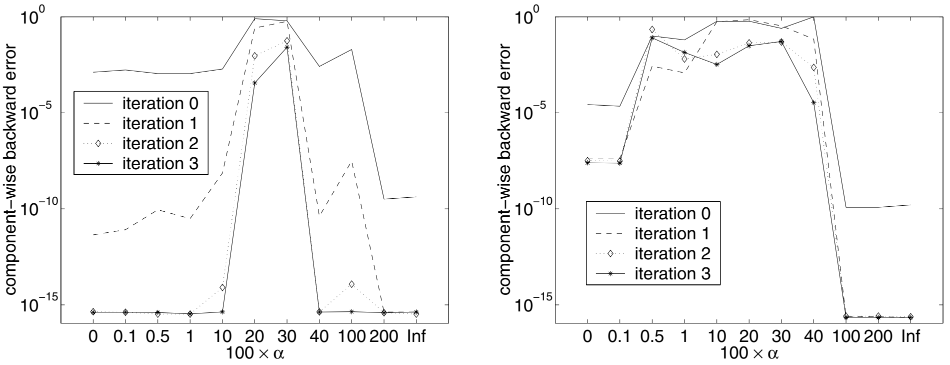
and thus tends to slow down the factorization phase. As `mixSEQ` generates sparser factors, it decreases the time for backward and forward substitution. Nevertheless the solution phase is often more costly with the `mixSEQ` strategy because it requires more iterative refinement steps and thus more backward and forward substitutions and matrix-vector multiplications.

**5. Combination of `mixSEQ` and delayed pivots.** A quite natural idea to improve the precision of the solution is to allow some delayed pivots up to a certain predetermined limit. This criterion could be based, for example, on the memory increase. We developed an approach that proceeds as follows:

- first performs pivoting using the Duff–Reid algorithm with a threshold $u$ until $\alpha \times n$ pivots have been delayed, where $\alpha$ is a real parameter (each time a pivot is delayed to its parent, one is added to the count for delayed pivots, and so there may be more than $n$ delayed pivots), and
- second uses Algorithm 1.

We show in Figure 5.1 the precision of the solution while increasing the number of delayed pivots allowed. The approach with $\alpha = 0$ is equivalent to the `mixSEQ` strategy, and $\alpha = \infty$ ($Inf$ in Figure 5.1) corresponds to the `numSEQ` strategy. We see that combining delayed pivots and `mixSEQ` pivoting may be dangerous: this combination often requires more steps of iterative refinement to obtain a small residual. We think that the poor convergence of the iterative refinement process and sometimes the degradation in the precision is due to the accumulation of both rounding errors and perturbations. When delayed pivots are not allowed, the diagonal perturbations and their influence on rounding errors are localized to the contribution blocks predicted by the analysis. If we allow delayed pivots, some pivots can be postponed, and it is possible that they remain unacceptable in ancestor nodes until we switch to `mixSEQ` mode. In that case when a delayed pivot (possibly postponed over several generations) is still small, it is perturbed. This elimination then contaminates a larger contribution block than if it had been eliminated at an earlier node.

Figure 5.1 also illustrates that it is difficult to predict the behavior of the precision. For example, there is a small window, $10 \leq 100\alpha \leq 40$, in which our algorithm does



(a) cvxqp3 (b) CONT-201

FIG. 5.1. *Influence of the number of delayed pivots on the precision of the solution.*

not return an accurate solution for cvxqp3. The failure window is completely different for CONT-201, $0.1 \leq 100\alpha \leq 100$.

Finally, let us mention that we tried more sophisticated rules (based on the topology of the assembly tree, the characteristics of the parent node, etc.) to decide how to delay the elimination of a variable, and we note that all these strategies were very unstable.

## 6. Pivoting strategies in parallel distributed environments.

**6.1. Limiting the areas for pivot checking.** The diagonal block of the fully summed part of a type 2 node is stored on a single processor, the master (see section 2.4). Furthermore, the master does not have local access to the other rows of the front, which are sent directly from the slaves of its child nodes to its own slaves. To avoid extra communications and, even worse, synchronizations we modify the quantities $g_1$ and $g_2$ of (4.1) and (4.2). Moreover, because we do not have access to all of the fully summed columns, we always suppose that the largest off-diagonal entry is greater than $\mu||A||_M$. Thus, for every type 2 node we define

$$g_1(i) = \frac{\max\{\max_{k\in FSV\setminus\{i\}} |a_{ik}|, \mu\ ||A||_M\}}{|a_{ii}|}, \tag{6.1}$$

and

$$g_2(i,j) = \left\| |P^{-1}| \begin{pmatrix} \max\{\max_{k\in FSV\setminus\{i,j\}} |a_{ik}|, \mu\ ||A||_M\} \\ \max\{\max_{k\in FSV\setminus\{i,j\}} |a_{jk}|, \mu\ ||A||_M\} \end{pmatrix} \right\|_\infty . \tag{6.2}$$

These quantities are then used to select pivots in type 2 nodes in both the Duff–Reid algorithm and in Algorithm 1. This **B**asic **PAR**allel strategy will be referred to as `BPAR`. When it is used with the Duff–Reid algorithm it will be denoted by `numBPAR`.

The `numBPAR` strategy is more friendly than `numSEQ` for the parallel distributed implementation of `MUMPS` [1] and more generally for other distributed solvers, for example, `SuperLU_DIST` [22]. Note that a similar strategy is already used in the symmetric indefinite code of `MUMPS`.

**6.2. Cheap estimation of growth factors.** We will see in section 6.3 that the `numBPAR` approach is not robust. In this section, we propose a better approximation of the off-diagonal information that does not limit the scalability and that will significantly improve the numerical robustness of the factorization. The main principle of our approach is to send information from the slaves of a node to the master of its parent when they send information related to their contribution block.

Let $c$ be a child node and $p$ be its parent. Let $i$ be a fully summed variable of node $p$. For each slave $s$ of node $c$, we define $m_i(s)$ the maximum entry (in magnitude) in row/column $i$ that is stored in the contribution block of process $s$. $s$ will send to the master of $p$ the quantities $m_i(s)$ for each fully summed variable of the node $p$. The master of node $p$ will approximate the maximum entry in each fully summed column using the maximum quantity that it has received from the slaves of its child nodes. It is only an approximation because the child contributions are not summed by the master of $p$, and no account is taken of numerical growth as the eliminations at node $p$ are performed. Hence, while receiving information about the maximum off-diagonal entries, $m_i(s)$, the master of the parent computes the quantities $M_i$:

$$M_i = \max\left\{ \max_{c \text{ child of } p} \left\{ \max_{s \text{ slave of } c} \{m_i(s)\} \right\}, \max_{k\in PSV} |a_{ik}^{(0)}| \right\}, \tag{6.3}$$

where $a^{(0)}$ denotes the original entries of $\mathbf{A}$ that are assembled at the parent node and that can be easily predicted before the factorization.

For each pivoting strategy (numerical pivoting or restricted pivoting), the $g_1$ and $g_2$ quantities of (6.1) and (6.2) are modified. For each type 2 node we define

$$g_1(i) = \frac{\max\{\max_{k\in FSV} |a_{ik}|, M_i, \mu \, ||A||_M\}}{|a_{ii}|} \tag{6.4}$$

and

$$g_2(i,j) = \left\| |P^{-1}| \begin{pmatrix} \max\{\max_{k\in FSV} |a_{ik}|, M_i, \mu \, ||A||_M\} \\ \max\{\max_{k\in FSV} |a_{ik}|, M_j, \mu \, ||A||_M\} \end{pmatrix} \right\|_\infty . \tag{6.5}$$

These quantities are then used to adapt either the Duff–Reid algorithm or Algorithm 1 on type 2 nodes to parallel distributed environments. These **E**stimations of off-diagonal entries in a **PAR**allel framework will be referred to as `EPAR`. The adaptation of Duff–Reid **NUM**erical pivoting strategy will be referred to as `numEPAR`, and the adaptation of the **MIX**ted approach of Algorithm 1 will be referred to as `mixEPAR`.

The areas checked for the computation of the $m_i(s)$ quantities are illustrated in Figure 6.1. Each slave accesses the shaded areas to compute its $m_i$ quantities for each fully summed variable of the parent node. Then it communicates them to the father while sending the black blocks of its contributions. The other parts of the contribution blocks (shaded and blank) are sent directly to the slaves of the parent node.

**6.3. Experimental results.** The precision of the solution with our parallel approaches will be affected by the choice of the type 2 nodes because of the issues discussed in section 2.4. In `MUMPS` it depends on the characteristics of the nodes in the assembly tree (front size, number of fully summed variables) and the number of MPI processes. Indeed, the number of type 2 nodes increases with the number of processes in order to have more parallelism in the upper part of the assembly tree. In our simulations, we consider that a node is a type 2 node if it is large enough (in practice, if $\#PSV > 400$) and if it is neither a leaf node nor the root node. We remark that with this choice we simulate the behavior of `MUMPS` on hundreds of processes.

### 6.3.1. Parallel adaptation of Duff–Reid algorithm.

Table 6.1 shows that the basic parallel adaptation of the Duff–Reid algorithm, `numBPAR`, is not robust. We observe numerical failures on the CONT-201, CONT-300, and BRATU3D matrices. Note that we also observe these failures with `MUMPS` with more than four processes. Furthermore, there is a significant degradation of the precision compared to the `numSEQ` approach. In contrast, `numEPAR` is robust (no numerical failures), and it returns backward errors similar to the `numSEQ` strategy.

Table 6.2 compares the size of the factors and the number of delayed pivots between the `numSEQ`, `numBPAR`, and `numEPAR` pivoting strategies. We focus on the BRATU3D and CONT-* matrices because they reveal the weaknesses of the `numBPAR` strategy.

First we observe that `numSEQ` and `numEPAR` have a similar number of entries in the factors and number of delayed pivots. This supports the idea that the `numEPAR`

$g_1$ and $g_2$ of (4.1) and (4.2) on the CONT-201 matrix. Thus the left-hand figures show the real growth factors, while the pivoting strategy may take its decision according to a different estimation. With the `numSEQ` strategy the estimation and the actual values are exactly the same. That is why we always have the actual growth factors smaller than $10^2$. With `numBPAR` and `numEPAR`, the actual value may be underestimated. That is why we observe growth factors greater than $10^2$. Figure 6.2 confirms that the `numSEQ` and `numEPAR` strategies have similar behavior in the sense that they postpone approximately the same number of pivots at each node. Furthermore the `numEPAR` strategy succeeds in bounding the growth factor by $4 \times 10^3$ at each step of Gaussian elimination on CONT-201.

The behavior of the `numBPAR` strategy is significantly different. We see, in Table 6.2, that the number of delayed pivots decreases significantly on the BRATU3D matrix. Consequences of this are a decrease in the number of nonzeros in the factors ($9.7 \times 10^6$ for `numBPAR` versus $11.5 \times 10^6$ for `numSEQ`) and a degradation of the precision, as seen in Table 6.1.

For the CONT-201 and CONT-300 matrices, `numBPAR` delays approximately the same number of variables and computes factors with a similar number of nonzeros. Figure 6.2 shows that `numBPAR` does not guarantee a reasonable growth factor on CONT-201 (growth factors nearly equal to $1/\epsilon$ for some nodes of the assembly tree). We see also that the number of delayed pivots is significantly different between the `numBPAR` strategy and the two other strategies, `numSEQ` and `numEPAR`, for some nodes of the tree.

**6.3.2. Parallel approaches combining numerical pivoting and perturbation techniques.** Table 6.3 shows that there are no significant differences between the sequential and the parallel versions of our Algorithm 1. We still need two iterations to converge to the machine precision on most of the matrices.

**7. Influence of preprocessing.** In [12] we presented preprocessing techniques to improve the quality of preselected pivots. Our preprocessing uses symmetric weighted matching and sparsity ordering techniques. Of the techniques presented, we saw that METIS combined with the `MC64SYM` scaling was the best ordering on symmetric indefinite matrices in terms of CPU factorization time, but that it sometimes caused many pivots to be delayed. We also proposed an ordering based on METIS that increases the number of nonzeros in the factors slightly but that clearly improves the

numerical stability for the preselected pivots. In this section, we study the influence of this preprocessing in the context of our new pivoting strategies. We use these two orderings for the present experiments: the MeTiS ordering and an ordering that we call MeTiS on the compressed graph (denoted by `CMP`; see [12] for more details).

Table 7.1 compares our restricted pivoting when using the above two orderings. We see that the preselection of $2 \times 2$ pivots using a symmetric weighted matching significantly decreases the number of tiny pivots and improves the precision of the solution. This influence of pivot preselection using maximum weighted matching techniques has also been observed in the context of `SuperLU_DIST` [22]. We see that, in most of the cases, the approach with an ordering on the compressed graph needs one iteration fewer than an approach based on the MeTiS ordering.

Generally the approach on the compressed graph increases the number of operations, the fill-in in the factors, and the memory needed. It also increases the factorization time (see Table 7.2). Note that the compressed approach is better on

CONT-201 and CONT-300 in terms of fill-in in the factors and factorization time, because the compression detects cliques and then improves the quality of the fill-in reducing phase (METIS).

We also compare the solution times in Table 7.2. Generally the `CMP` strategy increases the size of the factors and thus increases the time for backward and forward substitution. Nevertheless this effect is compensated by the decrease in the number of iterative refinement steps: on average, the `CMP` strategy requires one backward and forward substitution and one matrix-vector multiplication fewer than the METIS strategy to converge to a certain level of precision.

We also studied the influence of the preprocessing on parallel approaches. As in the sequential case, our preprocessing improves the numerical robustness, and we get small backward errors after one or two iterative refinement steps.

**8. Conclusions.** We have presented different pivoting strategies that combine traditional sparse pivoting strategies and perturbation techniques and have identified their main characteristics. We have implemented these within the `MA57` code. Our new pivoting strategies seem to address a large class of challenging problems and to be significantly faster than approaches with standard numerical pivoting.

We recommend checking the backward error of the computed solution. If it is too large, then one or two iterative refinement steps are enough to converge to an accurate solution. Note also that the target may not be the machine precision. For example, if we consider Newton iterations, an approximate solution of the linear system may be sufficient at the beginning. For classes of problems on which the `mixEPAR` or `mixSEQ` strategies do not compute a precise enough solution, we have proposed alternatives:

- preprocessing the matrix using a compressed graph and a maximum weighted matching,
- and/or using the numerical pivoting strategies, `numEPAR` or `numSEQ`.

Our parallel approaches can easily be generalized to the unsymmetric case. Restricted pivoting within `SuperLU_DIST` would improve its precision. Concerning the unsymmetric version of `MUMPS` it would also allow 2-dimensional partitioning of type 2 nodes (in particular, a 2-dimensional partitioning of the master task) and improve the scalability of `MUMPS`.

Even if the precision of the solution is good, further improvements can be obtained. First, there are still problems on which restricted pivoting is less accurate than approaches that perform standard threshold pivoting. Second, the number of iterative refinement steps can be decreased on some problems. This problem becomes all the more critical when we have many right-hand sides. As a much higher value for $\mu$ would result in a far more stable factorization but perhaps with a modified matrix further from the original, we intend to study the trade-off whose optimal value might well be quite different if iterative methods more sophisticated than iterative refinement (for example, MINRES, GMRES) were used.

**Acknowledgments.** We would like to thank John Reid and Jennifer Scott of the Rutherford Appleton Laboratory for their comments on a draft version of this manuscript. We are also very grateful to Serge Gratton for discussions on various aspects of this work, and to the anonymous referees for their helpful comments.

# ON THE CONVERGENCE OF A CLASS OF MULTILEVEL METHODS FOR LARGE SPARSE MARKOV CHAINS*

PETER BUCHHOLZ† AND TUĞRUL DAYAR‡

**Abstract.** This paper investigates the theory behind the steady state analysis of large sparse Markov chains with a recently proposed class of multilevel methods using concepts from algebraic multigrid and iterative aggregation-disaggregation. The motivation is to better understand the convergence characteristics of the class of multilevel methods and to have a clearer formulation that will aid their implementation. In doing this, restriction (or aggregation) and prolongation (or disaggregation) operators of multigrid are used, and the Kronecker-based approach for hierarchical Markovian models is employed, since it suggests a natural and compact definition of grids (or levels). However, the formalism used to describe the class of multilevel methods for large sparse Markov chains has no influence on the theoretical results derived.

**Key words.** Markov chains, multigrid, aggregation-disaggregation, Kronecker-based numerical techniques, multilevel methods

## 1. Introduction.

Markov chains (MCs) are a popular mathematical tool to model systems from various application areas like engineering, computer science, biology, or economics. For system analysis often one needs the steady state distribution of the MC to compute result measures for the modeled system. The problem in the continuous-time case is then to solve

$$\pi Q = 0 \quad \text{subject to} \quad \pi e = 1 \quad \text{and} \quad \pi \geq 0, \tag{1.1}$$

where $Q$ is the infinitesimal generator or generator matrix of the continuous-time Markov chain (CTMC) underlying the modeled system, $\pi$ is its (row) stationary probability vector, and $e$ is the column vector of ones of appropriate length. We assume that the state space is finite and contains $n$ states numbered starting from 0; $Q$ is irreducible, implying $\pi > 0$; and $\pi$ is also the steady state vector. The nonnegative off-diagonal elements of $Q$ represent exponential transition rates between different states, and its diagonal elements are negated row sums of its off-diagonal elements. Hence, $Q$ has row sums of zero (i.e., $Qe = 0$) and is a singular matrix of rank $(n-1)$, and (1.1) represents a homogeneous linear system subject to a normalization condition, so that its solution vector $\pi$ can be uniquely determined [29, Chap. 1]. At this level, states of the CTMC are numbered by consecutive integers. However, in almost all applications CTMCs result from some high level model like a stochastic automata network, a queueing network, or a stochastic Petri net. In all these cases, the state space is multidimensional and is mapped for solution onto a set of consecutive

integers. The multidimensional structure can be exploited in a compact representation of $Q$ and can also be exploited to develop fast solvers for the computation of $\pi$.

Practical problems arise due to the state space size of MCs resulting from applications, which often grows exponentially with the number of components in the specification. A popular way of dealing with this so-called state space explosion problem is to employ Kronecker- (or tensor)-based representations of $Q$, which remain compact even for considerably large state spaces. In the Kronecker-based approach, the system of interest is modeled so that it is formed of smaller interacting components, and its larger underlying generator matrix is neither generated nor stored but rather represented using Kronecker products of the smaller component matrices. This introduces significant storage savings at the expense of some overhead in the solution phase. In order to analyze large structured Markovian models efficiently, various algorithms for vector-Kronecker product multiplication are devised [14, 16, 17] and used as kernels in iterative solution methods. The most effective solvers known for Kronecker representations of dimension four or larger are multilevel (ML) methods [11] and block successive over relaxation (BSOR) preconditioned projection methods [12] as recently shown empirically by comparing different solvers on a large number of hierarchical Markovian models (HMMs). Unfortunately, solvers using BSOR [10, 31] are sensitive to the ordering of components, the block partitionings chosen, and the amount of fill-in in the factorized diagonal blocks, so that a robust implementation for arbitrary models is difficult to achieve.

In this paper, we investigate the theory behind the steady state analysis of large sparse MCs with the class of ML methods proposed in [11] using concepts from algebraic multigrid (AMG) [6, Chap. 8], [24] and iterative aggregation-disaggregation (IAD) [29, Chap. 6]. Our motivation is to better understand the convergence characteristics of the class of ML methods and to have a clearer formulation that will aid their implementation. Convergence analysis of a two-level IAD method for MCs and its equivalence to AMG is provided in [20]. Another paper that investigates the convergence of a two-level IAD method for MCs using concepts from multigrid is [21]. Here we consider more than two levels, different types of smoothers, different types of cycles, and different orders of aggregation. In doing this, we use restriction (or aggregation) and prolongation (or disaggregation) operators of multigrid, and employ the Kronecker-based approach for HMMs in [11]. This is for three reasons. First, the hierarchy present in the HMM description suggests a natural definition of grids (or levels). This simplifies the description of the class of ML methods. Second, with the HMM description, one can store the aggregated MC at each level during implementation compactly in Kronecker form. It is not clear how the same effect can be achieved with an MC in sparse format (see [19]). Third, Kronecker operations to define large MCs underlying structured representations are natural for many application areas since complex systems are usually composed of interacting components. Almost all MCs resulting from applications can be represented as HMMs [15], and this representation can be derived from the specification using an appropriate modeling tool [1]. Otherwise, the HMM formalism used in this paper to describe the class of ML methods for large sparse MCs has no influence on the theoretical results derived. In general, our approach can be applied for any irreducible MC with a set of nested partitions defined on its state space.

The next section introduces the Kronecker-based description of CTMCs underlying HMMs on a small example. The third section presents the proposed class of ML methods for HMMs with multiple macrostates and discusses how they work. The fourth section provides results on the convergence of ML methods. The fifth section illustrates the convergence behavior of the class of ML methods on two larger problems. The sixth section concludes the paper.

In what follows, calligraphic uppercase letters denote sets and lists, uppercase letters denote matrices, sets are defined using curly brackets, lists are defined using square brackets, matrices (and vectors) are defined using brackets, $|\cdot|$ denotes the cardinality of a set (list) when its argument is a set (list), $\emptyset$ denotes the empty set, $||\cdot||$ denotes the norm of a vector, $\cdot^T$ denotes the transpose operator, and diag$(\cdot)$ represents a diagonal matrix having its vector argument along its diagonal.

**2. Hierarchical Markovian models.** HMMs are defined using the operations of Kronecker product and Kronecker sum [32]. First we introduce these operations.

Definition 2.1. [illegible] $X \in \mathbb{R}^{r_X \times c_X}$ [illegible] $Y \in \mathbb{R}^{r_Y \times c_Y}$ [illegible] $X \otimes Y$ [illegible] $Z$ [illegible] $r_X \times c_X$ [illegible] $r_Y \times c_Y$ [illegible] $(i,j)$ [illegible] $x(i,j)Y$ [illegible] $i = 0,\ldots,r_X-1$ $j = 0,\ldots,c_X-1$ [illegible] $U \in \mathbb{R}^{r_U \times r_U}$ [illegible] $V \in \mathbb{R}^{r_V \times r_V}$ [illegible] $U \oplus V$ [illegible] $W \in \mathbb{R}^{r_U r_V \times r_U r_V}$ [illegible] $W = U \otimes I_{r_V} + I_{r_U} \otimes V$ [illegible] $I_{r_U}$ [illegible] $I_{r_V}$ [illegible] $r_U$ [illegible] $r_V$ [illegible]

Both Kronecker product and Kronecker sum are associative and defined for more than two matrices. For further properties of Kronecker operations, see [29].

HMMs consist of multiple low level models (LLMs) which can be perceived as components, and a high level model (HLM) that defines how LLMs interact. The HLM is characterized by a single matrix, whereas each LLM is characterized by multiple matrices that define its interaction with other LLMs. The order of each LLM matrix is equal to the number of states of the particular component to which the matrix belongs. A formal definition of HMMs can be found in [8, pp. 387–390]. Here we extend the definition from [12] and introduce HMMs on an example. An HMM describes a CTMC and its generator matrix $Q$. Since we consider the steady state analysis of irreducible finite CTMCs, $Q$ is sufficient to characterize the CTMC. We name the states of the HLM as [illegible], those of $Q$ as [illegible], and remark that macrostates define a partition of the microstates.

Definition 2.2. [illegible] $K$ [illegible] $\mathcal{S}^{(k)} = \{0,1,\ldots,|\mathcal{S}^{(k)}|-1\}$ [illegible] $k$ [illegible] $k = 1,2\ldots,K$ $\mathcal{S}^{(K+1)} = \{0,1,\ldots,|\mathcal{S}^{(K+1)}|-1\}$ [illegible] $\mathcal{S}_j^{(k)}$ [illegible] $k$ [illegible] $j \in \mathcal{S}^{(K+1)}$ [illegible] $\cup_j \mathcal{S}_j^{(k)} = \mathcal{S}^{(k)}$ [illegible] $\mathcal{S}_i^{(k)} \cap \mathcal{S}_j^{(k)} = \emptyset$ [illegible] $i \neq j$ $t_0$ [illegible] $\mathcal{T}_{i,j}$ [illegible] $(i,j)$ [illegible] $D_j$ [illegible] $Q$ [illegible] $j$ [illegible] $(j,j)$ [illegible] $Q$ [illegible] $(j,j)$ [illegible]

$$Q(j,j) = \bigoplus_{k=1}^{K} Q_{t_0}^{(k)}(\mathcal{S}_j^{(k)}, \mathcal{S}_j^{(k)}) + \sum_{t_e \in \mathcal{T}_{j,j}} \bigotimes_{k=1}^{K} Q_{t_e}^{(k)}(\mathcal{S}_j^{(k)}, \mathcal{S}_j^{(k)}) + D_j, \tag{2.1}$$

[illegible] $(i,j)$ [illegible] $Q$ [illegible] $(i,j)$ [illegible]

$$Q(i,j) = \sum_{t_e \in \mathcal{T}_{i,j}} \bigotimes_{k=1}^{K} Q_{t_e}^{(k)}(\mathcal{S}_i^{(k)}, \mathcal{S}_j^{(k)}), \tag{2.2}$$

[illegible] $Q_{t_e}^{(k)}(\mathcal{S}_i^{(k)}, \mathcal{S}_j^{(k)})$ [illegible] $(|\mathcal{S}_i^{(k)}| \times |\mathcal{S}_j^{(k)}|)$ [illegible][1] [illegible] $\mathcal{S}_i^{(k)}$ [illegible] $\mathcal{S}_j^{(k)}$ [illegible] $k$ [illegible] $t_e$

We remark that $D_j$ can be expressed as a sum of Kronecker products, as follows.

PROPOSITION 2.3. [illegible] $D_j$ [illegible] $Q$ [illegible] $j$ [illegible]

$$D_j = -\bigoplus_{k=1}^{K} \mathrm{diag}(Q_{t_0}^{(k)}(\mathcal{S}_j^{(k)}, \mathcal{S}_j^{(k)})e)$$

$$- \sum_{i \in \mathcal{S}^{(K+1)}} \sum_{t_e \in \mathcal{T}_{j,i}} \bigotimes_{k=1}^{K} \mathrm{diag}(Q_{t_e}^{(k)}(\mathcal{S}_j^{(k)}, \mathcal{S}_i^{(k)})e) \quad \text{[illegible]} \; j \in \mathcal{S}^{(K+1)}.$$

In order to enable the efficient implementation of numerical solvers, most of the time $D_j$ is precomputed and stored explicitly as a vector. However, the off-diagonal part of $Q$ is never stored explicitly, but is represented in memory through Definition 2.2 as sums of Kronecker products of small matrices, which are generally very sparse and therefore held in row sparse format [29, pp. 80–81].

For a definition of mapping used in the next proposition, see, for instance, [30, pp. 192–197].

PROPOSITION 2.4. [illegible] $Q$ [illegible] $(s^{(1)}, s^{(2)}, \ldots, s^{(K)}, j)$ [illegible] $s^{(k)} \in \mathcal{S}^{(k)}$ [illegible] $k$ [illegible] $k = 1, 2, \ldots, K$ [illegible] $j \in \mathcal{S}^{(K+1)}$ [illegible] $Q$ [illegible]

$$(s^{(1)}, s^{(2)}, \ldots, s^{(K)}, j) \longleftrightarrow \sum_{k=1}^{K} s^{(k)} \prod_{l=k+1}^{K} |\mathcal{S}_j^{(l)}| + \sum_{i=0}^{j-1} \prod_{k=1}^{K} |\mathcal{S}_i^{(k)}| \in \{0, 1, \ldots, n-1\},$$

[illegible] $n = \sum_{j=0}^{|\mathcal{S}^{(K+1)}|-1} \prod_{k=1}^{K} |\mathcal{S}_j^{(k)}|$.

The microstates corresponding to each macrostate result from the Cartesian (or cross) product [30, pp. 123–124] of the state space partitions of LLMs that are mapped to that particular macrostate. In contrast to other representations of CTMCs using Kronecker operators (e.g., [29, Chap. 9]), HMMs are generated in such a way that only reachable states are considered [7, 8]. Note that each macrostate in an HLM may have a different number of microstates if LLMs have partitioned state spaces. When there are multiple macrostates, $Q$ is effectively a block matrix having as many blocks in each dimension as $|\mathcal{S}^{(K+1)}|$. The diagonal and off-diagonal blocks of this partitioning are respectively the $Q_{j,j}$ and $Q_{i,j}$ matrices defined by (2.1) and (2.2). Due to the Kronecker structure suggested by Definitions 2.1 and 2.2, each of the blocks defined by the HLM matrix is also formed of blocks, and hence HMMs have nested block partitionings [10, 31].

Now, let us consider a small example HMM which gives rise to a $(5 \times 5)$ CTMC. In [13, sec. 5], we step through the ML method on this example, which is chosen deliberately to be very small. After this small example, we briefly present two larger examples which will be used in section 5 to show the convergence behavior of the class of ML methods.

---

[1] In this section, the concept of transition is used to refer to those that take place at the HMM level, except for this case, where it is used to refer to nonzeros in a matrix at the state level.

Table 2.1
*Mapping between LLM states and HLM states in Example* 1.

| LLM 1 | LLM 2 | HLM | # of microstates |
|---|---|---|---|
| {0,1} | {0,1} | {0} | 2 . 2 = 4 |
| {2} | {2} | {1} | 1 . 1 = 1 |

[illegible] 1. The HLM of two states describes the interaction among two LLMs (i.e., $K = 2$), each of which has three states. All states are numbered starting from 0. The mapping between LLM states and HLM states and the number of microstates are given in Table 2.1. In this example, $Q$ has the following states in its rows and columns: $\{0,1\} \times \{0,1\} \times \{0\} \cup \{2\} \times \{2\} \times \{1\} = \{(0,0,0),(0,1,0),(1,0,0),(1,1,0),(2,2,1)\}$. One can think of these five states written in the given order as corresponding to the integers 0 through 4.

The values of the nonzeros in $Q$ are determined by the rates of the transitions and their associated matrices. In Example 1, two transitions denoted by $t_0$ and $t_1$ take place and affect the LLMs. Transition $t_0$ covers all local transitions inside the LLMs, whereas transition $t_1$ is captured by the following $(2 \times 2)$ HLM matrix:

$$\begin{array}{c} \\ 0 \\ 1 \end{array} \begin{array}{c} \begin{array}{cc} 0 & 1 \end{array} \\ \left(\begin{array}{c|c} & t_1 \\ \hline t_1 & \end{array}\right) \end{array}. \tag{2.3}$$

To each transition in the HLM matrix corresponds a Kronecker product of two (i.e., number of LLMs, $K$) LLM matrices. The matrices associated with those LLMs that do not participate in a transition are identity. LLM 1 participates in $t_1$ with the matrix $Q_{t_1}^{(1)}$, and LLM 2 participates in $t_1$ with the matrix $Q_{t_1}^{(2)}$. In this example, the transition $t_1$ affects exactly two LLMs.

Other than Kronecker products due to the transitions in (2.3), there is a Kronecker sum implicitly associated with each diagonal element of the HLM matrix. Each Kronecker sum is formed of two (i.e., $K$) LLM matrices corresponding to [illegible] $t_0$. In the HLM matrix of (2.3), there does not exist any nonlocal transition along the diagonal. In general, this need not be so, as can be seen from Definition 2.2.

In our example, the second term in (2.1) is missing, and the matrices associated with $t_0$ and $t_1$ are given by

$$Q_{t_0}^{(1)} = \left(\begin{array}{cc|c} 0 & 1 & 0 \\ 1 & 0 & 0 \\ \hline 0 & 0 & 0 \end{array}\right), \quad Q_{t_1}^{(1)} = \left(\begin{array}{cc|c} 0 & 0 & 2 \\ 0 & 0 & 1 \\ \hline 1 & 0 & 0 \end{array}\right), \quad Q_{t_0}^{(2)} = \left(\begin{array}{cc|c} 0 & 1 & 0 \\ 1 & 0 & 0 \\ \hline 0 & 0 & 0 \end{array}\right),$$

$$Q_{t_1}^{(2)} = \left(\begin{array}{cc|c} 0 & 0 & 1 \\ 0 & 0 & 0 \\ \hline 1 & 0 & 0 \end{array}\right).$$

Then the CTMC underlying the HMM can be obtained from

$$Q = \left(\begin{array}{c|c} Q_{t_0}^{(1)}(\{0,1\},\{0,1\}) \bigoplus Q_{t_0}^{(2)}(\{0,1\},\{0,1\}) & Q_{t_1}^{(1)}(\{0,1\},\{2\}) \bigotimes Q_{t_1}^{(2)}(\{0,1\},\{2\}) \\ \hline Q_{t_1}^{(1)}(\{2\},\{0,1\}) \bigotimes Q_{t_1}^{(2)}(\{2\},\{0,1\}) & Q_{t_0}^{(1)}(\{2\},\{2\}) \bigoplus Q_{t_0}^{(2)}(\{2\},\{2\}) \end{array}\right) + D, \tag{2.4}$$

where $D$ is the diagonal correction matrix that sums the rows of $Q$ to zero; hence, written explicitly, we have

$$Q = \left(\begin{array}{rrrr|r} -4 & 1 & 1 & 0 & 2 \\ 1 & -2 & 0 & 1 & 0 \\ 1 & 0 & -3 & 1 & 1 \\ 0 & 1 & 1 & -2 & 0 \\ \hline 1 & 0 & 0 & 0 & -1 \end{array}\right). \tag{2.5}$$

If we neglect the diagonal of $Q$, which is handled separately, from Definition 2.2 it follows that each nonzero element of the HLM matrix is essentially a sum of Kronecker products, since Kronecker sums can be expressed as sums of Kronecker products. This has a very nice implication for the choice of grids in the proposed ML method when LLM aggregation is used in forming the coarse grids. LLMs 1 through $K$ and the HLM define the least coarse (in other words, the finest) grid. This grid is $Q$ and in our example has five states. Regarding the intermediate grids, let us assume that LLMs are aggregated starting from 1 up to $K$. Thus LLMs 2 through $K$ and the HLM define the first coarser grid when LLM 1 is aggregated. In our example, this grid has the states in $\{(0,0),(1,0),(2,1)\}$, where the first state in each tuple is an LLM 2 state and the second state in each tuple is the corresponding HLM state. The HLM and LLMs 3 through $K$ define the second coarser grid when LLMs 1 and 2 are aggregated. In our example, this grid is the coarsest grid corresponding to the HLM and has the states $\{(0),(1)\}$. There are no other LLMs left to be aggregated in our example; otherwise aggregation continues with the next LLM.

Now, let us concentrate on the sizes of the grids defined by the LLMs and the HLM for the assumed order in which LLMs are aggregated. In Example 1, the grids defined in this way by LLMs 1–2 and the HLM, by LLM 2 and the HLM, and by the HLM alone have respectively the sizes $(5\times 5)$, $(3\times 3)$, $(2\times 2)$ (see Table 2.1 and (2.1)–(2.2)). Clearly, we are not limited to aggregating LLMs in the order 1 through $K$, and can consider other orderings. The number of possible orderings of LLMs equals $K!$.

*Example* 2. The second example we consider is a polling system. Two servers serve customers from $K$ finite capacity queues, which are visited by the servers in cyclic order. We assume that each queue has a capacity of 3, and customers arrive according to a Poisson process with rate 1.5 and are distributed with queue specific probabilities among the queues. If a server visits a nonempty queue, it serves one customer and then moves to the next queue. A server arriving at an empty queue immediately travels to the next queue. Service and traveling times are exponentially distributed with rates 1 and 10, respectively. Each LLM describes one queue, and macrostates for this model are defined according to the number of servers serving customers at a queue or traveling to the next queue. For each LLM we obtain 20 states partitioned into three subsets. The complete model has $\binom{K+1}{K-1}$ macrostates. Table 2.2 contains the number of microstates for different values of $K$.

*Example* 3. The third example describes an availability model with $K$ LLMs. Each LLM consists of two active components and a cold spare which becomes active when a component fails. Time to failure is exponentially distributed with mean $10^k$ for the components of the $k$th LLM. With 90% probability a failure is local, requiring a local repair with an exponential duration and mean $10^{-k+1}$ for the $k$th component. With a probability of 10%, a failure has to be repaired by a global repair unit; repair times are identical to the local case. The system has one global repair unit which repairs failed components with preemptive priority such that components from the

Table 2.2
*Number of macrostates and state space sizes versus number of LLMs in Examples* 2 *and* 3.

| $K$ | Polling example $\lvert\mathcal{S}^{(K+1)}\rvert$ | Polling example $n$ | Availability example $\lvert\mathcal{S}^{(K+1)}\rvert$ | Availability example $n$ |
|---|---|---|---|---|
| 2 | – | – | 1 | 100 |
| 3 | 6 | 1,020 | 1 | 1,000 |
| 4 | 10 | 7,008 | 1 | 10,000 |
| 5 | 15 | 42,880 | 1 | 100,000 |
| 6 | 21 | 243,456 | 1 | 1,000,000 |
| 7 | 28 | 1,311,744 | 1 | 10,000,000 |

first LLM get the highest priority and components from the $K$th LLM obtain the least priority. As can be seen in Table 2.2, the system contains one macrostate and $10^K$ microstates. Note that this is an example in which different time scales occur and is therefore expected to be harder to solve by classical iterative methods.

In the next section, we introduce the class of ML methods with the grid choices suggested by the Kronecker structure of HMMs and remark that, just like $Q$, none of the grids except the coarsest is explicitly generated.

## 3. A class of ML methods.

The class of ML methods presented in this section are related to IAD for the analysis of MCs [29, sec. 6.3] and AMG for general systems of equations [24]. IAD is applied in the context of MCs to coefficient matrices with a two-level block structure, where blocks are loosely coupled. Different variants of the method exist; all combine the solution of an aggregated system, whose elements correspond to blocks in the two-level block partitioning, with iteration steps or solutions of systems of equations at the block level. The solution of the aggregated system distributes the steady state probability mass over the loosely coupled subsets of states, whereas at the block level the probability mass is distributed inside the subsets. AMG solves a system of equations by performing iterations on systems of equations of decreasing size. Our approach can be interpreted as a specific form of AMG for singular M-matrices, a class of matrices which will be defined in the next section. However, like in geometric multigrid, our grids have a physical meaning, since they are defined according to subsets of LLMs. Furthermore, the grids may change from one ML iteration to the next by varying the order in which LLMs are aggregated. Like in geometric multigrid, the goal is to achieve convergence that is independent of the size of the original problem. This means that the number of ML iterations to reach a predefined tolerance should be more or less independent of the number of LLMs for a given model structure. The proposed class of ML methods are related to IAD, since aggregation-disaggregation steps are used to realize the mapping between different levels. However, in contrast to IAD, varying and possibly more than two levels are defined, and the Kronecker structure is exploited to represent the aggregated matrix at each level. This implies that the class of ML methods are also expected to be efficient for large models where LLMs are tightly coupled.

### 3.1. Algorithms.

One iteration of AMG over a system of linear equations is referred to as a [illegible]. Throughout the text, we use [illegible] and [illegible] interchangeably. The order in which the smaller aggregated systems are visited during each AMG iteration gives rise to different cycle types. Within an AMG cycle, the iterative method used to improve the solution of each aggregated system is called a [illegible], since it is perceived to smooth the error in the solution at that level. The class of ML methods for HMMs with multiple macrostates have the capability of using (V, W, F) cycles

[33], (power, Jacobi over relaxation (JOR), successive over relaxation (SOR)) methods as smoothers, and (fixed, circular, dynamic) orders in which LLMs can be aggregated in an ML iteration. These parameters are respectively denoted by $C$ for cycle type, $S$ for smoother type, and $O$ for order of aggregating LLMs. Hence, $C \in \{V, W, F\}$, $S \in \{POWER, JOR, SOR\}$, and $O \in \{FIXED, CIRCULAR, DYNAMIC\}$. In a particular ML solver, $C$, $S$, and $O$ are fixed at the beginning and do not change.

Algorithm 1 is the driver of the ML solver. It starts executing at the finest grid involving the LLMs and the HLM, and then invokes the recursive ML function in Algorithm 2 with the order in which LLMs are to be aggregated in the list $\mathcal{C}$. Each pass through the body of the repeat-until loop in Algorithm 1 corresponds to one ML iteration (i.e., cycle). Observe that steps 3 through 8 in Algorithm 2 are almost identical to the statements between steps 3 and 4 in Algorithm 1.

Algorithm 1. [illegible]

```
main()
$\mathcal{D} = [1, 2, \ldots, K+1]$; $\tilde{Q}_{\mathcal{D}} = Q$; $x_{\mathcal{D}}$ = initial approximation; $it = 0$; $stop = FALSE$;
(step 1)
if ($C == W$ or $C == F$) then                                          (step 2)
   $\gamma = 2$;
else
   $\gamma = 1$;
repeat                                                                  (step 3)
   $x'_{\mathcal{D}} = S(\tilde{Q}_{\mathcal{D}}, x_{\mathcal{D}}, w, \nu_1)$;
   remove $\mathcal{D}_1$ from $\mathcal{D}$ by aggregation to give $\mathcal{C}$;
   $\tilde{Q}_{\mathcal{C}} = P_{x'_{\mathcal{D}}} \tilde{Q}_{\mathcal{D}} R_{\mathcal{D}}$; $x_{\mathcal{C}} = x'_{\mathcal{D}} R_{\mathcal{D}}$;
   if ($\gamma == 1$) then
      $y_{\mathcal{C}} = \mathrm{ML}(\tilde{Q}_{\mathcal{C}}, x_{\mathcal{C}}, \mathcal{C}, \gamma)$;
   else
      $y_{\mathcal{C}} = \mathrm{ML}(\tilde{Q}_{\mathcal{C}}, x_{\mathcal{C}}, \mathcal{C}, \gamma)$;
      $y_{\mathcal{C}} = \mathrm{ML}(\tilde{Q}_{\mathcal{C}}, y_{\mathcal{C}}, \mathcal{C}, \gamma)$;
   $y_{\mathcal{D}} = y_{\mathcal{C}} P_{x'_{\mathcal{D}}}$;
   $y'_{\mathcal{D}} = S(\tilde{Q}_{\mathcal{D}}, y_{\mathcal{D}}, w, \nu_2)$;
   if ($C == F$) then                                                   (step 4)
      $\gamma = 2$;
   $x_{\mathcal{D}} = y'_{\mathcal{D}}$; $it = it + 1$;                                       (step 5)
   $x_{\mathcal{D}} = x_{\mathcal{D}}/(x_{\mathcal{D}} e)$; $r = -x_{\mathcal{D}} \tilde{Q}_{\mathcal{D}}$;                                   (step 6)
   if ($it \geq MAX\_IT$ or $time \geq MAX\_TIME$ or $\|r\| \leq STOP\_TOL$) then   (step 7)
      $stop = TRUE$;
   else if ($O == DYNAMIC$) then                                        (step 8)
      sort LLM indices $\mathcal{D}_1, \mathcal{D}_2, \ldots, \mathcal{D}_K$ into increasing order of $\|r_k\|$,
      where $r_k$ is the residual associated with LLM $k$ and is computed from $r$;
   else if ($O == CIRCULAR$) then
      $\mathcal{D}_k = \mathcal{D}_{(k \bmod K)+1}$ for $k = 1, 2, \ldots, K$;
until($stop$);
take $x_{\mathcal{D}}$ as the steady state vector $\pi$ of the HMM;
```

Algorithm 2. [illegible] $\mathcal{D}$.

function ML($\tilde{Q}_{\mathcal{D}}, x_{\mathcal{D}}, \mathcal{D}, \gamma$)
if ($|\mathcal{D}| == 1$) then
   $y'_{\mathcal{D}}$ = solve($\tilde{Q}_{\mathcal{D}}, x_{\mathcal{D}}$) subject to $y'_{\mathcal{D}} e = 1$;                     (step 1)
```

```
    if ($C == F$) then                                          (step 2)
        $\gamma = 1$;
else
    $x'_{\mathcal{D}} = S(\tilde{Q}_{\mathcal{D}}, x_{\mathcal{D}}, w, \nu_1)$;          (step 3)
    remove $\mathcal{D}_1$ from $\mathcal{D}$ by aggregation to give $\mathcal{C}$;        (step 4)
    $\tilde{Q}_{\mathcal{C}} = P_{x'_{\mathcal{D}}} \tilde{Q}_{\mathcal{D}} R_{\mathcal{D}}$; $x_{\mathcal{C}} = x'_{\mathcal{D}} R_{\mathcal{D}}$;        (step 5)
    if ($\gamma == 1$) then                                     (step 6)
        $y_{\mathcal{C}} = \mathrm{ML}(\tilde{Q}_{\mathcal{C}}, x_{\mathcal{C}}, \mathcal{C}, \gamma)$;
    else
        $y_{\mathcal{C}} = \mathrm{ML}(\tilde{Q}_{\mathcal{C}}, x_{\mathcal{C}}, \mathcal{C}, \gamma)$;
        $y_{\mathcal{C}} = \mathrm{ML}(\tilde{Q}_{\mathcal{C}}, y_{\mathcal{C}}, \mathcal{C}, \gamma)$;
    $y_{\mathcal{D}} = y_{\mathcal{C}} P_{x'_{\mathcal{D}}}$;                                   (step 7)
    $y'_{\mathcal{D}} = S(\tilde{Q}_{\mathcal{D}}, y_{\mathcal{D}}, w, \nu_2)$;          (step 8)
return($y'_{\mathcal{D}}$);
```

---

The variable $\gamma$ in the two algorithms determines the number of recursive calls to the ML function. It is initialized to 2 for a W- or an F-cycle and to 1 for a V-cycle before ML starts executing for the first time. After this point, there are two places where the value of $\gamma$ changes, and these happen only for an F-cycle. Hence, for a V-cycle $\gamma$ remains 1, and for a W-cycle it remains 2, meaning for V- and W-cycles 1 and 2 recursive calls, respectively, are made to the ML function on the next coarser grid. On the other hand, for an F-cycle $\gamma$ is set to 1 at the boundary case of the recursion (see step 2 in Algorithm 2). Hence, an F-cycle can be seen as a recursive call to a W-cycle followed by a recursive call to a V-cycle. After the F-cycle is over, $\gamma$ is reset to 2 in step 4 of Algorithm 1 so as to be ready for a new ML iteration [33, pp. 174–175].

Each ML iteration starts and ends with some number of iterations using the smoother $S$. See respectively the two statements after step 3 and before step 4 in Algorithm 1. The same is true for each execution of the recursive ML function at intermediate grids, as can be seen in steps 3 and 8 of Algorithm 2. The first two arguments of the call to $S$ in both algorithms represent the grid to be used in the smoothing process and the vector to be smoothed. The parameter $\omega$ in the call to $S$ is the relaxation parameter for JOR and SOR. Although the user can be given the flexibility to change the numbers of pre- and postsmoothings in the two algorithms, depending on the residual norms (see Algorithms 1 and 2 in [13]), we consider $\nu_1$ pre- and $\nu_2$ postsmoothings at each level in order to simplify the description of the algorithms in this presentation.

The order of aggregating LLMs in each ML iteration is determined by the list $\mathcal{D}$ defined in Algorithm 1. The elements of $\mathcal{D}$ from its head to its tail are denoted respectively by $\mathcal{D}_1, \mathcal{D}_2, \ldots, \mathcal{D}_{K+1}$. The subscripts of these elements indicate their positions in $\mathcal{D}$. In each ML iteration, the HLM is always the last model to be handled due to its special position in the hierarchy. Hence, $\mathcal{D}_{K+1}$ is given the value $(K+1)$ and is associated with the HLM; the tail of $\mathcal{D}$ always has this value and does not change. Initially, LLM $k$ is associated with element $\mathcal{D}_k$, which has the value $k$ for $k = 1, 2, \ldots, K$ (see step 1 of Algorithm 1). In each ML iteration, LLMs are aggregated according to these values starting from the element at the head of the list (see the second statement in the repeat-until loop of Algorithm 1). Hence, LLM $\mathcal{D}_1$ is the first LLM to be aggregated.

In the *FIXED* order of aggregating LLMs, the initial assignment of values to the elements of $\mathcal{D}$ does not change after the ML method starts executing; this is the default order. In the *CIRCULAR* order, at the end of each ML iteration a circular shift of elements $\mathcal{D}_1$ through $\mathcal{D}_K$ in the list is performed; this ensures some kind of fairness in aggregating LLMs in the next ML iteration. On the other hand, the *DYNAMIC* order sorts the elements $\mathcal{D}_1$ through $\mathcal{D}_K$ according to the residual norms mapped (or restricted) to the corresponding LLM at the end of the ML iteration, and aggregates the LLMs in this sorted order in the next ML iteration (see step 8 of Algorithm 1). This ensures that LLMs which have smaller residual norms are aggregated earlier at finer grids. We expect small residual norms to be indicative of good approximations in those LLMs. Note that at each intermediate grid the recursive ML function is invoked for the next coarser grid with the list of LLMs in $\mathcal{C}$, which is formed by removing the LLM at the head of the incoming list $\mathcal{D}$ (i.e., $\mathcal{D}_1$) by aggregation (see step 4 in Algorithm 2). Once the list of LLMs is exhausted, that is $(K+1)$ is the only value remaining in list $\mathcal{D}$, backtracking from recursion starts by solving a linear system as large as the HLM matrix (see step 1 in Algorithm 2). This is indicated by the call to the function [illegible], which takes the coarsest grid $\tilde{Q}_{\mathcal{D}}$ as input and produces the solution $y'_{\mathcal{D}}$ up to machine precision directly (i.e., by Gaussian elimination) if $|\mathcal{S}^{(K+1)}|$ is relatively small, else iteratively using the smoother $S$ and the current approximation $x_{\mathcal{D}}$ as the starting vector.

The ML solver starts with $x_{\mathcal{D}}$, which is usually set to the uniform distribution, and $r$ as the corresponding residual vector. The repeat-until loop increments the number of ML iterations denoted by *it* and continues until *it* reaches the maximum number of iterations in *MAX_IT*, solution time reaches *MAX_TIME*, or the residual $r$ reaches the user-defined *STOP_TOL*. We remark that the smoothers of choice require two vectors of length $n$ and two vectors (three in SOR) as long as the maximum number of microstates per macrostate in the HMM. One of the vectors of length $n$ in SOR is required for the computation of residuals in the implementation of *DYNAMIC* ordering of LLMs for aggregation. Furthermore, if one turns off the call(s) in Algorithm 1 to Algorithm 2, Algorithm 1 reduces to an iterative solver in which $(\nu_1 + \nu_2)$ iterations are performed on $Q$ with the iterative method $S$ at each ML cycle. This is a useful feature for debugging.

**3.2. Operators and implementation.** Before we discuss the operation that computes the next coarser grid $\tilde{Q}_{\mathcal{C}}$ from the grid $\tilde{Q}_{\mathcal{D}}$ using the smoothed vector $x'_{\mathcal{D}}$ (see step 5 in Algorithm 2), let us define the state spaces of the grids used in the ML method for large sparse MCs in terms of a mapping [30, pp. 192–197].

DEFINITION 3.1. [illegible] $\mathcal{S}_{\mathcal{D}}$ [illegible] $\mathcal{S}_{\mathcal{C}}$ [illegible] $\tilde{Q}_{\mathcal{D}}$ [illegible] $\tilde{Q}_{\mathcal{C}}$ [illegible] $f_{\mathcal{D}} : \mathcal{S}_{\mathcal{D}} \longrightarrow \mathcal{S}_{\mathcal{C}}$ [illegible] $\mathcal{S}_{\mathcal{D}}$ [illegible] $\mathcal{S}_{\mathcal{C}}$

The mapping $f_{\mathcal{D}}$ is surjective (i.e., onto); it satisfies

$$\exists s_{\mathcal{D}} \in \mathcal{S}_{\mathcal{D}},\ f_{\mathcal{D}}(s_{\mathcal{D}}) = s_{\mathcal{C}} \quad \text{for each} \quad s_{\mathcal{C}} \in \mathcal{S}_{\mathcal{C}}$$

and $|\mathcal{S}_{\mathcal{C}}| \leq |\mathcal{S}_{\mathcal{D}}|$. When $|\mathcal{S}_{\mathcal{C}}| = |\mathcal{S}_{\mathcal{D}}|$, the mapping becomes bijective (i.e., one-to-one onto). From Definition 3.1 and [30, p. 179], we have the next proposition.

PROPOSITION 3.2. [illegible] $\tilde{f}_{\mathcal{D}}$ [illegible] $f_{\mathcal{D}}$ [illegible] $\tilde{f}_{\mathcal{D}}$ [illegible] $\mathcal{S}_{\mathcal{C}}$ [illegible] $\mathcal{S}_{\mathcal{D}}$ [illegible] $|\mathcal{S}_{\mathcal{C}}| = |\mathcal{S}_{\mathcal{D}}|$ [illegible] $f_{\mathcal{D}}$ [illegible]

Proposition 3.2 says that, if there is at least one state in $\mathcal{S}_{\mathcal{C}}$ to which multiple states from $\mathcal{S}_{\mathcal{D}}$ are mapped under $f_{\mathcal{D}}$ (i.e., $|\mathcal{S}_{\mathcal{C}}| < |\mathcal{S}_{\mathcal{D}}|$), then the converse of $f_{\mathcal{D}}$ cannot be a function; it is just a relation.

For HMMs, the Kronecker structure (see Definition 2.2 and Proposition 2.4) and the order of component aggregation determine $\mathcal{S}_{\mathcal{D}}$ and $\mathcal{S}_{\mathcal{C}}$ as in the next proposition.

PROPOSITION 3.3. [illegible] 1 [illegible] 2 [illegible] $\mathcal{D}$ [illegible] $\mathcal{C}$ [illegible] $\mathcal{S}_\mathcal{D}$ [illegible] $\mathcal{S}_\mathcal{C}$ [illegible]

$$\mathcal{S}_\mathcal{D} = \bigcup_{j \in \mathcal{S}^{(K+1)}} \times_{k=1}^{|\mathcal{D}|} \mathcal{S}_j^{(\mathcal{D}_k)} \quad [illegible] \quad \mathcal{S}_\mathcal{C} = \bigcup_{j \in \mathcal{S}^{(K+1)}} \times_{k=1}^{|\mathcal{C}|} \mathcal{S}_j^{(\mathcal{C}_k)},$$

[illegible] $\times$ [illegible]

$$|\mathcal{S}_\mathcal{D}| = \sum_{j=0}^{|\mathcal{S}^{(K+1)}|-1} \prod_{k=1}^{|\mathcal{D}|} |\mathcal{S}_j^{(\mathcal{D}_k)}| \quad [illegible] \quad |\mathcal{S}_\mathcal{C}| = \sum_{j=0}^{|\mathcal{S}^{(K+1)}|-1} \prod_{k=1}^{|\mathcal{C}|} |\mathcal{S}_j^{(\mathcal{C}_k)}|.$$

[illegible] 1 $|\mathcal{S}_\mathcal{D}| = n$

Observe from Definition 2.2 that $\mathcal{S}_\mathcal{D}$ and $\mathcal{S}_\mathcal{C}$ for HMMs given in Proposition 3.3 satisfy the mapping $f_\mathcal{D} : \mathcal{S}_\mathcal{D} \longrightarrow \mathcal{S}_\mathcal{C}$ in Definition 3.1.

Now we return to the computation of the coarser grid and the coarser approximation. For each state $s_\mathcal{C} \in \mathcal{S}_\mathcal{C}$, the columns of the grid $\tilde{Q}_\mathcal{D}$ corresponding to the states in $\mathcal{S}_\mathcal{D}$ that get mapped to the same state $s_\mathcal{C}$ are summed. The aggregation on the columns of $\tilde{Q}_\mathcal{D}$ is also performed on the columns of the smoothed row vector $x_\mathcal{D}^{'}$ yielding the vector $x_\mathcal{C}$ in step 5 of Algorithm 2. These are achieved by using the [illegible] [25] (or aggregation) operator defined next.

DEFINITION 3.4. [illegible] $(|\mathcal{S}_\mathcal{D}| \times |\mathcal{S}_\mathcal{C}|)$ [illegible] $R_\mathcal{D}$ [illegible] $f_\mathcal{D} : \mathcal{S}_\mathcal{D} \longrightarrow \mathcal{S}_\mathcal{C}$ [illegible] $(s_\mathcal{D}, s_\mathcal{C})$ [illegible]

$$r_\mathcal{D}(s_\mathcal{D}, s_\mathcal{C}) = \begin{cases} 1 & [illegible]\ f_\mathcal{D}(s_\mathcal{D}) = s_\mathcal{C}, \\ 0 & [illegible], \end{cases} \qquad [illegible]\ s_\mathcal{D} \in \mathcal{S}_\mathcal{D}\ [illegible]\ s_\mathcal{C} \in \mathcal{S}_\mathcal{C}.$$

PROPOSITION 3.5. [illegible] $R_\mathcal{D}$ [illegible] 1 [illegible] 1 [illegible] $R_\mathcal{D}$ [illegible] $\mathrm{rank}(R_\mathcal{D}) = |\mathcal{S}_\mathcal{C}|$ [illegible] $\tilde{Q}_\mathcal{D} R_\mathcal{D}$ [illegible] $\tilde{Q}_\mathcal{D}$ [illegible]

For each state $s_\mathcal{C} \in \mathcal{S}_\mathcal{C}$, the rows of $\tilde{Q}_\mathcal{D} R_\mathcal{D}$ corresponding to the states in $\mathcal{S}_\mathcal{D}$ that are mapped to the same state $s_\mathcal{C}$ are multiplied with the corresponding normalized elements of the smoothed row vector $x_\mathcal{D}^{'}$ and summed. This is achieved by using the [illegible] [25] (or disaggregation) operator defined next.

DEFINITION 3.6. [illegible] $(|\mathcal{S}_\mathcal{C}| \times |\mathcal{S}_\mathcal{D}|)$ [illegible] $P_{x_\mathcal{D}^{'}}$ [illegible] $f_\mathcal{D} : \mathcal{S}_\mathcal{D} \longrightarrow \mathcal{S}_\mathcal{C}$ [illegible] $(s_\mathcal{C}, s_\mathcal{D})$ [illegible]

$$p_{x_\mathcal{D}^{'}}(s_\mathcal{C}, s_\mathcal{D}) = \begin{cases} x_\mathcal{D}^{'}(s_\mathcal{D}) / \sum_{s_\mathcal{D} \in \mathcal{S}_\mathcal{D}, f_\mathcal{D}(s_\mathcal{D}) = s_\mathcal{C}} x_\mathcal{D}^{'}(s_\mathcal{D}) & [illegible]\ f_\mathcal{D}(s_\mathcal{D}) = s_\mathcal{C}, \\ 0 & [illegible], \end{cases}$$

$$[illegible]\ s_\mathcal{D} \in \mathcal{S}_\mathcal{D}\ [illegible]\ s_\mathcal{C} \in \mathcal{S}_\mathcal{C}.$$

PROPOSITION 3.7. [illegible] $x_\mathcal{D}^{'} > 0$ [illegible] $P_{x_\mathcal{D}^{'}}$ [illegible] $R_\mathcal{D}$ [illegible] $\mathrm{rank}(P_{x_\mathcal{D}^{'}}) = |\mathcal{S}_\mathcal{C}|$ [illegible] $x_\mathcal{D}^{'} > 0$ [illegible] $P_{x_\mathcal{D}^{'}}$ [illegible] $P_{x_\mathcal{D}^{'}}$ [illegible] 1 [illegible] $R_\mathcal{D}$ [illegible] $\tilde{Q}_\mathcal{D} R_\mathcal{D}$ [illegible] $P_{x_\mathcal{D}^{'}}$ [illegible] $(|\mathcal{S}_\mathcal{C}| \times |\mathcal{S}_\mathcal{C}|)$ [illegible] $\tilde{Q}_\mathcal{C}$ [illegible] $x_\mathcal{D}^{'}$

The prolongation operator depends not only on $\mathcal{S}_{\mathcal{D}}$ and $\mathcal{S}_{\mathcal{C}}$, but also on the smoothed vector $x'_{\mathcal{D}}$, which is indicated by using the subscript $x'_{\mathcal{D}}$ rather than $\mathcal{D}$. This implies that the elements of $\tilde{Q}_{\mathcal{C}}$ depend on $x'_{\mathcal{D}}$ and will be different in each iteration of the ML solver.

LEMMA 3.8. [illegible] $x'_{\mathcal{D}} > 0$ [illegible] $P_{x'_{\mathcal{D}}} R_{\mathcal{D}} = I_{\mathcal{C}}$ [illegible] $I_{\mathcal{C}}$ [illegible] $|\mathcal{S}_{\mathcal{C}}|$

[illegible]. The identity follows from Propositions 3.5 and 3.7 by the facts that $P_{x'_{\mathcal{D}}} \geq 0$, $R_{\mathcal{D}} \geq 0$, $P_{x'_{\mathcal{D}}}$ has the same nonzero structure as $R^T_{\mathcal{D}}$, $P_{x'_{\mathcal{D}}} e = e$, and $e^T R^T_{\mathcal{D}} = e^T$. ☐

When $x'_{\mathcal{D}} > 0$, we can state the next corollary [23, p. 387] using $R_{\mathcal{D}}(P_{x'_{\mathcal{D}}} R_{\mathcal{D}})P_{x'_{\mathcal{D}}} = R_{\mathcal{D}}(I_{\mathcal{C}})P_{x'_{\mathcal{D}}} = R_{\mathcal{D}}P_{x'_{\mathcal{D}}}$ from Lemma 3.8, $R_{\mathcal{D}} \geq 0$, $R_{\mathcal{D}}e = e$ and $P_{x'_{\mathcal{D}}} \geq 0$, $P_{x'_{\mathcal{D}}} e = e$ from Propositions 3.5 and 3.7, respectively.

COROLLARY 3.9. [illegible] $x'_{\mathcal{D}} > 0$ [illegible] $(|\mathcal{S}_{\mathcal{D}}| \times |\mathcal{S}_{\mathcal{D}}|)$ [illegible]

$$H_{x'_{\mathcal{D}}} = R_{\mathcal{D}} P_{x'_{\mathcal{D}}}$$

[illegible] $H_{x'_{\mathcal{D}}} \geq 0$ [illegible] $H^2_{x'_{\mathcal{D}}} = H_{x'_{\mathcal{D}}}$ [illegible] $H_{x'_{\mathcal{D}}} e = e$

LEMMA 3.10. [illegible] $x'_{\mathcal{D}} > 0$ [illegible] $x'_{\mathcal{D}} H_{x'_{\mathcal{D}}} = x'_{\mathcal{D}}$

[illegible]. The identity follows from the definitions of restriction and prolongation operations (see Definitions 3.4 and 3.6) and the fact that the restricted and then prolonged row vector is $x'_{\mathcal{D}}$. ☐

The analysis in section 4 is based on showing that the coarser grid $\tilde{Q}_{\mathcal{C}}$ is an irreducible CTMC and $x_{\mathcal{C}} > 0$ if the finer grid $\tilde{Q}_{\mathcal{D}}$ is an irreducible CTMC and $x'_{\mathcal{D}} > 0$. This has been done for HMMs with one macrostate in [9, p. 348]. In section 4, we show the results for the mapping $f : \mathcal{S}_{\mathcal{D}} \longrightarrow \mathcal{S}_{\mathcal{C}}$ in Definition 3.1.

Step 7 in Algorithm 2 corresponds to the opposite of what is done on $x'_{\mathcal{D}}$ in step 5; that is, it performs disaggregation using the newly computed vector $y_{\mathcal{C}}$ and the prolongation operator $P_{x'_{\mathcal{D}}}$ (which is based on the smoothed vector $x'_{\mathcal{D}}$) to obtain the vector $y_{\mathcal{D}}$. The next result follows from Proposition 3.7

PROPOSITION 3.11. [illegible] $y_{\mathcal{C}} > 0$ [illegible] $x'_{\mathcal{D}} > 0$ [illegible] $y_{\mathcal{D}} = y_{\mathcal{C}} P_{x'_{\mathcal{D}}} > 0$ [illegible] $e^T P_{x'_{\mathcal{D}}} > 0$

Similar aggregation and disaggregation operations are performed in Algorithm 1 at the finest grid $Q$.

The Kronecker representation of $\tilde{Q}_{\mathcal{C}}$ for an HMM with one macrostate is given in [9, p. 347]. Here we extend it to multiple macrostates and show that $\tilde{Q}_{\mathcal{C}}$ can be expressed as a sum of Kronecker products as in Definition 2.2 using $\sum_{i,j \in \mathcal{S}^{(K+1)}} |\mathcal{T}_{i,j}|$ vectors each of length at most $\max_{j \in \mathcal{S}^{(K+1)}} (\prod_{k=2}^{|\mathcal{C}|} |\mathcal{S}_j^{(\mathcal{C}_k)}|)$ and the matrices corresponding to the components in $\mathcal{C}$ excluding $(K+1)$, which denotes the HLM (see Proposition 3.3). More specifically, we have the next definition.

DEFINITION 3.12. [illegible] $h = \mathcal{D}_1$ [illegible] $s_{\mathcal{C}}$ [illegible] $t_e$ [illegible] $(i,j)$ [illegible] $\tilde{Q}_{\mathcal{C}}$ [illegible]

$$a_{(\mathcal{C},t_e),(i,j)}(s_{\mathcal{C}}) = \frac{\left(\sum_{s_{\mathcal{D}} \in \mathcal{S}_{\mathcal{D}}, f_{\mathcal{D}}(s_{\mathcal{D}}) = s_{\mathcal{C}}} x'_{\mathcal{D}}(s_{\mathcal{D}})\ a_{(\mathcal{D},t_e),(i,j)}(s_{\mathcal{D}})\ (e^T_{s_{\mathcal{D}}(h)} Q^{(h)}_{t_e}(\mathcal{S}^{(h)}_i, \mathcal{S}^{(h)}_j)e)\right)}{x_{\mathcal{C}}(s_{\mathcal{C}})}$$

$$[illegible]\ s_{\mathcal{C}} \in \mathcal{S}_{\mathcal{C}},\ t_e \in \mathcal{T}_{i,j},\ [illegible]\ i,j \in \mathcal{S}^{(K+1)},$$

[illegible] $a_{(\mathcal{D},t_e),(i,j)} = e$ [illegible] $\mathcal{D}$ [illegible] $s_{\mathcal{D}}(h) \in \mathcal{S}^{(h)}$ [illegible] $e_{s_{\mathcal{D}}(h)}$ [illegible] $s_{\mathcal{D}}(h)$ [illegible] $|\mathcal{S}_i^{(h)}|$

With this definition, blocks of the matrix $\tilde{Q}_{\mathcal{C}}$ become

$$\begin{aligned}
\tilde{Q}_{\mathcal{C}}(j,j) = {} & \bigoplus_{k=1}^{|\mathcal{C}|-1} Q_{t_0}^{(\mathcal{C}_k)}(\mathcal{S}_j^{(\mathcal{C}_k)}, \mathcal{S}_j^{(\mathcal{C}_k)}) + \sum_{t_e \in \mathcal{T}_{j,j}} \bigotimes_{k=1}^{|\mathcal{C}|-1} \operatorname{diag}(a_{(\mathcal{C},t_e),(j,j)}) Q_{t_e}^{(\mathcal{C}_k)}(\mathcal{S}_j^{(\mathcal{C}_k)}, \mathcal{S}_j^{(\mathcal{C}_k)}) \\
& - \bigoplus_{k=1}^{|\mathcal{C}|-1} \operatorname{diag}(Q_{t_0}^{(\mathcal{C}_k)}(\mathcal{S}_j^{(\mathcal{C}_k)}, \mathcal{S}_j^{(\mathcal{C}_k)}) e) \\
& - \sum_{i \in \mathcal{S}^{(K+1)}} \sum_{t_e \in \mathcal{T}_{j,i}} \bigotimes_{k=1}^{|\mathcal{C}|-1} \operatorname{diag}(a_{(\mathcal{C},t_e),(j,i)}) \operatorname{diag}(Q_{t_e}^{(\mathcal{C}_k)}(\mathcal{S}_j^{(\mathcal{C}_k)}, \mathcal{S}_i^{(\mathcal{C}_k)}) e) \\
& \qquad \text{for } j \in \mathcal{S}^{(K+1)}, \\
\tilde{Q}_{\mathcal{C}}(i,j) = {} & \sum_{t_e \in \mathcal{T}_{i,j}} \bigotimes_{k=1}^{|\mathcal{C}|-1} \operatorname{diag}(a_{(\mathcal{C},t_e),(i,j)}) Q_{t_e}^{(\mathcal{C}_k)}(\mathcal{S}_i^{(\mathcal{C}_k)}, \mathcal{S}_j^{(\mathcal{C}_k)}) \quad \text{for } i,j \in \mathcal{S}^{(K+1)}, i \neq j.
\end{aligned}$$

Observe from Proposition 2.3 that the last two terms of $\tilde{Q}_{\mathcal{C}}(j,j)$ return a diagonal matrix which sums the rows of $\tilde{Q}_{\mathcal{C}}(j,j)$ to zero. Furthermore, the vectors $a_{(\mathcal{D},t_e),(i,j)}$ for $t_e \in \mathcal{T}_{i,j}$ and $i,j \in \mathcal{S}^{(K+1)}$ at the finest level consist of all 1's, and therefore need not be stored. When the recursion ends at the HLM, $\tilde{Q}_{\mathcal{C}}$ is a $(|\mathcal{S}^{(K+1)}| \times |\mathcal{S}^{(K+1)}|)$ CTMC, and therefore is generated and stored explicitly in sparse format so that it can be solved either directly or iteratively, as we discussed. We remark that $a_{(\mathcal{C},t_e),(i,j)} = e$ for those $t_e$ which have all $Q_{t_e}^{(\mathcal{C}_k)}(\mathcal{S}_i^{(\mathcal{C}_k)}, \mathcal{S}_j^{(\mathcal{C}_k)})$ as diagonal matrices of size $(|\mathcal{S}_i^{(\mathcal{C}_k)}| \times |\mathcal{S}_j^{(\mathcal{C}_k)}|)$ with 1's along their diagonal for $k = 1, 2, \ldots, |\mathcal{C}| - 1$ and $i,j \in \mathcal{S}^{(K+1)}$. Since component matrices forming $\tilde{Q}_{\mathcal{C}}(i,j)$ for $i,j \in \mathcal{S}^{(K+1)}, i \neq j$, can very well be rectangular, we refrain from using $I$, and remark that such vectors need not be stored either.

The next section presents results on the convergence of the proposed class of ML methods for large sparse MCs.

## 4. Convergence of ML methods.

Convergence analysis of AMG with a post-smoother of the Richardson relaxation type (see [26, p. 412]) and a two-level grid for symmetric positive definite linear systems arising from finite element approximations to a particular differential operator appears in [18]. Therein, it is shown that the convergence rate of the method is independent of the problem size when the relaxation parameter of the smoother is chosen appropriately [18, p. 480]. On the other hand, [27] casts AMG as a special case of multi-iterative methods for positive definite linear systems in which two or more iterative techniques are successively used in each iteration to improve the error in different subspaces. When the method is AMG, one of these multi-iterative methods has an iteration matrix associated with the coarse grid correction. A convergence analysis for a two-level grid with a Richardson iteration as the presmoother and a prolongation operator with (block) antidiagonal structure is provided. Using information about the eigenvalues of the coefficient matrix together with the particular smoother, it is shown that the AMG method possesses a convergence rate independent of the problem size for banded (block) Toeplitz matrices. Although the *POWER* smoother used by the proposed class of ML methods is also a Richardson relaxation, as will be shown in this section, the methods are geared towards CTMCs, which have different characteristics. Recently, in [22] the results in

[21] are improved, and an asymptotic convergence result is provided for a two-level IAD method which uses postsmoothings of the POWER type. However, fast convergence cannot be guaranteed in a general setting even when there are only two levels [22, p. 340]. Hence, the results in the next subsections should be received as a step towards improving the formulation and understanding the convergence behavior of the proposed class of ML methods.

Let $\mathcal{D}$ represent the current level and $\mathcal{C}$ represent the next coarser level in the ML iteration, as in Algorithms 1 and 2. Let $\mathcal{S}_\mathcal{D}$ and $\mathcal{S}_\mathcal{C}$ denote respectively the state spaces of $\tilde{Q}_\mathcal{D}$ and $\tilde{Q}_\mathcal{C}$, and assume that the mapping of states from $\mathcal{S}_\mathcal{D}$ to the states in $\mathcal{S}_\mathcal{C}$ is onto and satisfies $|\mathcal{S}_\mathcal{C}| \leq |\mathcal{S}_\mathcal{D}|$ as in Definition 3.1. The results that are presented in this section for Algorithms 1 and 2 are general in that the Kronecker representation of the grids particular to HMMs is not utilized.

**4.1. Irreducibility of the coarser grids.** Recall that $R_\mathcal{D} \geq 0$, $R_\mathcal{D} e = e$, $e^T R_\mathcal{D} > 0$ from Proposition 3.5, and if $x^{'}_\mathcal{D} > 0$, then $P_{x^{'}_\mathcal{D}} \geq 0$, $P_{x^{'}_\mathcal{D}} e = e$, $e^T P_{x^{'}_\mathcal{D}} > 0$ from Proposition 3.7. Now, consider the definition of irreducibility given in [23, p. 209] and [29, p. 13]. Then the following lemma, which will be used to discuss the convergence of the ML method, can be proved.

Lemma 4.1. [illegible] $\tilde{Q}_\mathcal{C} = P_{x^{'}_\mathcal{D}} \tilde{Q}_\mathcal{D} R_\mathcal{D}$ [illegible] $x_\mathcal{C} = x^{'}_\mathcal{D} R_\mathcal{D} > 0$ [illegible] $\tilde{Q}_\mathcal{D}$ [illegible] $x^{'}_\mathcal{D} > 0$

[illegible] First, we show that $\tilde{Q}_\mathcal{C} = P_{x^{'}_\mathcal{D}} \tilde{Q}_\mathcal{D} R_\mathcal{D}$ is an irreducible CTMC. Without losing generality, consider the pair of different states $s_\mathcal{D}, s'_\mathcal{D} \in \mathcal{S}_\mathcal{D}$. Through $f : \mathcal{S}_\mathcal{D} \longrightarrow \mathcal{S}_\mathcal{C}$ in Definition 3.1, this pair of states are mapped respectively to the states $s_\mathcal{C}, s'_\mathcal{C} \in \mathcal{S}_\mathcal{C}$ (i.e., $f(s_\mathcal{D}) = s_\mathcal{C}$ and $f(s'_\mathcal{D}) = s'_\mathcal{C}$). Since $\tilde{Q}_\mathcal{D}$ is irreducible, there exists a path of transitions from $s_\mathcal{D}$ to $s'_\mathcal{D}$ in $\mathcal{S}_\mathcal{D}$ in the form $s_\mathcal{D} = s_1, s_2, \ldots, s_m = s'_\mathcal{D}$, where $m \leq |\mathcal{S}_\mathcal{D}|$, $s_k \in \mathcal{S}_\mathcal{D}$, and $\tilde{q}_D(s_k, s_{k+1}) > 0$ for $k \in \{1, 2, \ldots, m-1\}$. Mapping this path onto $\mathcal{S}_\mathcal{C}$ yields the path $s_\mathcal{C} = t_1, t_2, \ldots, t_m = s'_\mathcal{C}$, where $f(s_k) = t_k \in \mathcal{S}_\mathcal{C}$. Now, let $e_{t_k}$ denote the $t_k$th column of $I_\mathcal{C}$. Then, in the mapped path, we either have $t_k = t_{k+1}$ or $\tilde{q}_\mathcal{C}(t_k, t_{k+1}) > 0$, where the latter follows from

$$\begin{aligned}\tilde{q}_\mathcal{C}(t_k, t_{k+1}) &= e^T_{t_k} \tilde{Q}_\mathcal{C} e_{t_{k+1}} \\ &= (e^T_{t_k} P_{x^{'}_\mathcal{D}}) \tilde{Q}_\mathcal{D} (R_\mathcal{D} e_{t_{k+1}}) \geq p_{x^{'}_\mathcal{D}}(t_k, s_k) \tilde{q}_\mathcal{D}(s_k, s_{k+1}) r_\mathcal{D}(s_{k+1}, t_{k+1}),\end{aligned}$$

since $x_D(s_k) > 0$ (implying $p_{x^{'}_\mathcal{D}}(t_k, s_k) > 0$ from Definition 3.6), $\tilde{q}_\mathcal{D}(s_k, s_{k+1}) > 0$, and $f(s_{k+1}) = t_{k+1}$ (implying $r_\mathcal{D}(s_{k+1}, t_{k+1}) = 1$ from Definition 3.4). Thus we conclude that $s'_\mathcal{C}$ is reachable from $s_\mathcal{C}$.

We have effectively shown that each state in $\tilde{Q}_\mathcal{C}$ is reachable from every other state. The question that arises at this point is whether a row of $\tilde{Q}_\mathcal{C}$ can become zero after the restriction. The answer is no, as long as $\mathcal{S}_\mathcal{C}$ has multiple states (i.e., $|\mathcal{S}_\mathcal{C}| > 1$), since all states in $\mathcal{S}_\mathcal{D}$ that are mapped to a particular state in $\mathcal{S}_\mathcal{C}$ cannot have all their transitions among themselves. This would imply that $\tilde{Q}_\mathcal{D}$ is reducible, which is a contradiction. Furthermore, since the row sums of $\tilde{Q}_\mathcal{C}$ are zero (i.e., $\tilde{Q}_\mathcal{C} e = (P_{x^{'}_\mathcal{D}} \tilde{Q}_\mathcal{D} R_\mathcal{D}) e = P_{x^{'}_\mathcal{D}} \tilde{Q}_\mathcal{D} (R_\mathcal{D} e) = P_{x^{'}_\mathcal{D}} \tilde{Q}_\mathcal{D} e = 0$ because $\tilde{Q}_\mathcal{D}$ is a CTMC and $\tilde{Q}_\mathcal{D} e = 0$), its diagonal must be equal to its negated off-diagonal row sums. Hence, $\tilde{Q}_\mathcal{C}$ is an irreducible CTMC.

Now we show that $x_\mathcal{C} > 0$. Since $x_\mathcal{C} = x^{'}_\mathcal{D} R_\mathcal{D}$, $x^{'}_\mathcal{D} = e^T \mathrm{diag}(x^{'}_\mathcal{D})$, where $\mathrm{diag}(x^{'}_\mathcal{D})$ is the diagonal matrix with $x^{'}_\mathcal{D}$ along its diagonal, $\mathrm{diag}(x^{'}_\mathcal{D}) R_\mathcal{D}$ has the same nonzero structure as $R_\mathcal{D}$, and $e^T R_\mathcal{D} > 0$, we have $x_\mathcal{C} = x^{'}_\mathcal{D} R_\mathcal{D} = (e^T \mathrm{diag}(x^{'}_\mathcal{D})) R_\mathcal{D} = e^T (\mathrm{diag}(x^{'}_\mathcal{D}) R_\mathcal{D}) > 0$ when $x^{'}_\mathcal{D} > 0$. $\square$

Corollary 4.2. [illegible] $\tilde{Q}_{\mathcal{D}}$ [illegible] $x'_{\mathcal{D}} > 0$ [illegible] $x'_{\mathcal{D}}\tilde{Q}_{\mathcal{D}} = 0$ [illegible] $x_{\mathcal{C}}\tilde{Q}_{\mathcal{C}} = 0$ [illegible] $\tilde{Q}_{\mathcal{C}} = P_{x'_{\mathcal{D}}}\tilde{Q}_{\mathcal{D}}R_{\mathcal{D}}$ [illegible] $x_{\mathcal{C}} = x'_{\mathcal{D}}R_{\mathcal{D}}$

[illegible] We have $x_{\mathcal{C}}\tilde{Q}_{\mathcal{C}} = (x'_{\mathcal{D}}R_{\mathcal{D}})(P_{x'_{\mathcal{D}}}\tilde{Q}_{\mathcal{D}}R_{\mathcal{D}}) = (x'_{\mathcal{D}}R_{\mathcal{D}}P_{x'_{\mathcal{D}}})\tilde{Q}_{\mathcal{D}}R_{\mathcal{D}} = (x'_{\mathcal{D}}H_{x'_{\mathcal{D}}})$ $\tilde{Q}_{\mathcal{D}}R_{\mathcal{D}} = (x'_{\mathcal{D}})\tilde{Q}_{\mathcal{D}}R_{\mathcal{D}} = (x'_{\mathcal{D}}\tilde{Q}_{\mathcal{D}})R_{\mathcal{D}} = 0$, since $x'_{\mathcal{D}}H_{x'_{\mathcal{D}}} = x'_{\mathcal{D}}$ from Lemma 3.10 and $x'_{\mathcal{D}}\tilde{Q}_{\mathcal{D}} = 0$ by assumption. □

Proposition 4.3. [illegible] $\pi_{\mathcal{D}} = \pi > 0$ [illegible] $Q_{\mathcal{D}} = Q$ [illegible] $\mathcal{D}$ [illegible] $\mathcal{C}$ [illegible] $Q_{\mathcal{C}} = P_{\pi_{\mathcal{D}}}Q_{\mathcal{D}}R_{\mathcal{D}}$ [illegible] $\pi_{\mathcal{C}} = \pi_{\mathcal{D}}R_{\mathcal{D}} > 0$ [illegible] $\mathcal{D}$ [illegible] $\mathcal{C}$ [illegible] $\mathcal{D}$ [illegible] $Q_{\mathcal{D}}$ [illegible] $\pi_{\mathcal{D}}$ [illegible] $Q_{\mathcal{C}}$ [illegible] $\mathcal{C}$

The proposition follows from $\pi_{\mathcal{C}}Q_{\mathcal{C}} = (\pi_{\mathcal{D}}R_{\mathcal{D}})(P_{\pi_{\mathcal{D}}}Q_{\mathcal{D}}R_{\mathcal{D}}) = (\pi_{\mathcal{D}}R_{\mathcal{D}}P_{\pi_{\mathcal{D}}})$ $Q_{\mathcal{D}}R_{\mathcal{D}} = (\pi_{\mathcal{D}}H_{\pi_{\mathcal{D}}})Q_{\mathcal{D}}R_{\mathcal{D}} = (\pi_{\mathcal{D}})Q_{\mathcal{D}}R_{\mathcal{D}} = (\pi_{\mathcal{D}}Q_{\mathcal{D}})R_{\mathcal{D}} = 0$ since $\pi_{\mathcal{D}}H_{\pi_{\mathcal{D}}} = \pi_{\mathcal{D}}$ from Lemma 3.10 and $\pi_{\mathcal{D}}Q_{\mathcal{D}} = 0$ by assumption.

The next subsection specifies sufficient conditions for a converging smoother to provide improved solutions at each level.

### 4.2. Convergence of the smoothers.

By definition at the finest level in Algorithm 1 and by construction at the coarser levels in Algorithm 2, the matrix $\tilde{Q}_{\mathcal{D}}$ is an irreducible CTMC when $x'_{\mathcal{D}} > 0$ (see Lemma 4.1). Now, consider the nontransposed homogeneous singular linear system in the next definition (cf. (1.1)).

Definition 4.4. [illegible] $\mathcal{D}$ [illegible]

$$\tilde{\pi}_{\mathcal{D}}\tilde{Q}_{\mathcal{D}} = 0 \quad \text{[illegible]} \quad \tilde{\pi}_{\mathcal{D}}e = 1,$$

[illegible] $\tilde{\pi}_{\mathcal{D}} > 0$ [illegible] $\tilde{Q}_{\mathcal{D}}$

Proposition 4.5. [illegible] $\mathcal{D}$ [illegible] $\tilde{Q}_{\mathcal{D}}$ [illegible] $\tilde{\pi}_{\mathcal{D}} = \pi$ [illegible] $\tilde{Q}_{\mathcal{D}} = Q$

Now, consider the splitting of $\tilde{Q}_{\mathcal{D}}$ in the next definition.

Definition 4.6. [illegible] $\tilde{Q}_{\mathcal{D}}$ [illegible]

$$\tilde{Q}_{\mathcal{D}} = D_{\mathcal{D}} - U_{\mathcal{D}} - L_{\mathcal{D}} = M_{\mathcal{D}} - N_{\mathcal{D}},$$

[illegible] $D_{\mathcal{D}}$ $U_{\mathcal{D}}$ [illegible] $L_{\mathcal{D}}$ [illegible] $\tilde{Q}_{\mathcal{D}}$ [illegible] $M_{\mathcal{D}}$ [illegible] $M_{\mathcal{D}}^{-1}$ [illegible]

Proposition 4.7. [illegible] $\tilde{Q}_{\mathcal{D}}$ [illegible] $D_{\mathcal{D}}$ $U_{\mathcal{D}}$ [illegible] $L_{\mathcal{D}}$ [illegible] $\tilde{Q}_{\mathcal{D}}$ [illegible] $\tilde{q}_{\mathcal{D}}(s_{\mathcal{D}}, s_{\mathcal{D}}) \neq 0$ [illegible] $s_{\mathcal{D}} \in \mathcal{S}_{\mathcal{D}}$ [illegible] $D_{\mathcal{D}}^{-1}$ [illegible] $(D_{\mathcal{D}} - U_{\mathcal{D}})^{-1}$ [illegible]

The next definition involving the iteration matrices of the *POWER*, *JOR*, and *SOR* smoothers follows from [29, Chap. 3].

Proposition 4.8. [illegible] $\tilde{Q}_{\mathcal{D}}$ [illegible] $\tilde{Q}_{\mathcal{D}}$ [illegible]

$$T_{\mathcal{D}} = N_{\mathcal{D}}M_{\mathcal{D}}^{-1}$$

[illegible]

$$x_{\mathcal{D}}^{(m+1)} = x_{\mathcal{D}}^{(m)}T_{\mathcal{D}} \quad \text{[illegible]} \quad m = 0, 1, \ldots.$$

[illegible]

$$M_{\mathcal{D}}^{POWER} = -\alpha_{\mathcal{D}} I_{\mathcal{D}}, \quad N_{\mathcal{D}}^{POWER} = -\alpha_{\mathcal{D}}(I_{\mathcal{D}} + \tilde{Q}_{\mathcal{D}}/\alpha_{\mathcal{D}}),$$
$$M_{\mathcal{D}}^{JOR} = D_{\mathcal{D}}/\omega, \quad N_{\mathcal{D}}^{JOR} = (1-\omega)D_{\mathcal{D}}/\omega + L_{\mathcal{D}} + U_{\mathcal{D}},$$
$$M_{\mathcal{D}}^{SOR} = D_{\mathcal{D}}/\omega - U_{\mathcal{D}}, \quad N_{\mathcal{D}}^{SOR} = (1-\omega)D_{\mathcal{D}}/\omega + L_{\mathcal{D}},$$

[illegible] $\alpha_{\mathcal{D}} \in [\max_{s_{\mathcal{D}} \in \mathcal{S}_{\mathcal{D}}} |\tilde{q}_{\mathcal{D}}(s_{\mathcal{D}}, s_{\mathcal{D}})|, \infty)$ [illegible] $\omega \in (0,2)$ [illegible] $\omega = 1$ [illegible]

$$T_{\mathcal{D}}^{POWER} = I_{\mathcal{D}} + \tilde{Q}_{\mathcal{D}}/\alpha_{\mathcal{D}},$$
$$T_{\mathcal{D}}^{JOR} = (1-\omega)I_{\mathcal{D}} + \omega(L_{\mathcal{D}} + U_{\mathcal{D}})D_{\mathcal{D}}^{-1},$$
$$T_{\mathcal{D}}^{SOR} = ((1-\omega)D_{\mathcal{D}}/\omega + L_{\mathcal{D}})(D_{\mathcal{D}}/\omega - U_{\mathcal{D}})^{-1}.$$

Since $\tilde{Q}_{\mathcal{D}}$ is the generator matrix of an irreducible CTMC, the relation $\tilde{\pi}_{\mathcal{D}} T_{\mathcal{D}}^{S} = \tilde{\pi}_{\mathcal{D}}$ holds for $S \in \{POWER, SOR, JOR\}$ [29].

Before we state another lemma, we recall the definitions of primitivity and M-matrix from [29, pp. 352, 170] and remark that detailed information concerning M-matrices may be found in [4].

DEFINITION 4.9. [illegible] $\sigma(A)$ [illegible] $A$ [illegible] $\rho(A)$ [illegible] $A$ [illegible] $\rho(A) = \{\max |\lambda| \mid \lambda \in \sigma(A)\}$ [illegible] $B$ [illegible] $\rho(B)$

DEFINITION 4.10. [illegible] $A$ [illegible] $A = \beta I - B$ [illegible] $\beta > 0$ [illegible] $B \geq 0$ [illegible] $\beta \geq \rho(B)$ [illegible]

Hence, the negated CTMC $-\tilde{Q}_{\mathcal{D}}$ is a singular M-matrix. The next proposition follows from [23, p. 640] and [29, p. 118].

PROPOSITION 4.11. [illegible] $\tilde{Q}_{\mathcal{D}}$ [illegible] $e\tilde{\pi}_{\mathcal{D}}$ [illegible] $\tilde{Q}_{\mathcal{D}}$ [illegible] 1

COROLLARY 4.12. [illegible] $\tilde{Q}_{\mathcal{D}}$ [illegible] $|\mathcal{S}_{\mathcal{D}}| = 1$ $\tilde{Q}_{\mathcal{D}} = 0$ [illegible] $\tilde{\pi}_{\mathcal{D}} = 1$

For HMMs, Corollary 4.12 applies at the coarsest level when the HLM has one macrostate.

Now we are in a position to state and prove a lemma, which is essential in characterizing the convergence of the three smoothers.

LEMMA 4.13. [illegible] $S \in \{POWER, JOR, SOR\}$ [illegible] $\alpha_{\mathcal{D}} \in (\max_{s_{\mathcal{D}} \in \mathcal{S}_{\mathcal{D}}} |\tilde{q}_{\mathcal{D}}(s_{\mathcal{D}}, s_{\mathcal{D}})|, \infty)$ [illegible] $\omega \in (0,1)$ [illegible] $T_{\mathcal{D}}$ [illegible] $\tilde{Q}_{\mathcal{D}}$ [illegible] 1 [illegible] $T_{\mathcal{D}} = W_{\mathcal{D}} B_{\mathcal{D}} W_{\mathcal{D}}^{-1}$ [illegible] $B_{\mathcal{D}}$ [illegible] $W_{\mathcal{D}}$ [illegible] $T_{\mathcal{D}}$ [illegible] $\lim_{m\to\infty} T_{\mathcal{D}}^{m} = (W_{\mathcal{D}} e)\tilde{\pi}_{\mathcal{D}}/(\tilde{\pi}_{\mathcal{D}} W_{\mathcal{D}} e) > 0$ [illegible] 1 [illegible] $POWER$ [illegible] $W_{\mathcal{D}} = I_{\mathcal{D}}$ [illegible] $T_{\mathcal{D}}$ [illegible] $\lim_{m\to\infty} T_{\mathcal{D}}^{m} = e\tilde{\pi}_{\mathcal{D}} > 0$

[illegible] The proof follows from Theorem 17 of [29]. □

Using Lemma 4.13, the next proposition expresses the pre- and postsmoothings at level $\mathcal{D}$ concisely.

PROPOSITION 4.14. [illegible] $\tilde{Q}_{\mathcal{D}}$ [illegible] $x_{\mathcal{D}} > 0$ [illegible] $\nu > 0$ [illegible] $\mathcal{D}$ [illegible]

[illegible] $S$ [illegible] 4.13 [illegible]

$$x'_{\mathcal{D}} = x_{\mathcal{D}} T^{\nu}_{\mathcal{D}} > 0.$$

The next proposition follows from Theorem 4.4 in [28, pp. 45–46] and is introduced to aid the characterization of the nonasymptotic convergence behavior of smoothings.

PROPOSITION 4.15. [illegible] $A_{\mathcal{D}} \in \mathbb{R}^{|\mathcal{S}_{\mathcal{D}}| \times |\mathcal{S}_{\mathcal{D}}|}$ [illegible] $A_{\mathcal{D}}^{-1}$ [illegible]

$$\|w\|_{A_{\mathcal{D}}} = \|wA_{\mathcal{D}}\|_1 \quad \text{[illegible]} \quad w \in \mathbb{R}^{1 \times |\mathcal{S}_{\mathcal{D}}|}$$

[illegible][2]

The next theorem characterizes the [illegible] behavior of the smoothings through a lemma for positive stochastic matrices based on the discussion in [2, pp. 270–271] and proved in [13, appendix], and two results on nonnegative irreducible matrices similar to positive matrices [5, pp. 371 and 375]. We remark that a similar theorem may be stated for the initial approximation $y_{\mathcal{D}}$.

THEOREM 4.16. [illegible] $x_{\mathcal{D}}^{(0)} = x_{\mathcal{D}} > 0$ [illegible] $\tilde{Q}_{\mathcal{D}}$ [illegible] $S \in \{POWER, JOR, SOR\}$ [illegible] $T_{\mathcal{D}}$ [illegible] $x_{\mathcal{D}}^T \notin \text{Range}(I_{\mathcal{D}} - T_{\mathcal{D}}^T)$ [illegible] $T_{\mathcal{D}}^{\nu_1}$ [illegible]

(i) $T_{\mathcal{D}}^{\nu_1}$ [illegible]

(ii) $T_{\mathcal{D}}^{\nu_1}$ [illegible] $i_{\mathcal{D}}$ [illegible] $j_{\mathcal{D}}$

(iii) $T_{\mathcal{D}}^{\nu_1}$ [illegible] $(i_{\mathcal{D}}, j_{\mathcal{D}})$

(a) [illegible] $i_{\mathcal{D}}$ [illegible] $e_{i_{\mathcal{D}}}^T T_{\mathcal{D}}^{\nu_1} e_{i_{\mathcal{D}}} > e_{j_{\mathcal{D}}}^T T_{\mathcal{D}}^{\nu_1} e_{j_{\mathcal{D}}}$ [illegible]

(b) [illegible] $j_{\mathcal{D}}$ [illegible] $e_{i_{\mathcal{D}}}^T T_{\mathcal{D}}^{\nu_1} e_{i_{\mathcal{D}}} < e_{j_{\mathcal{D}}}^T T_{\mathcal{D}}^{\nu_1} e_{j_{\mathcal{D}}}$

[illegible]

$$\|c_{\mathcal{D}} x'_{\mathcal{D}} - \tilde{\pi}_{\mathcal{D}}\|_{A_{\mathcal{D}}} \leq \left(1 - \min_{i_{\mathcal{D}}, j_{\mathcal{D}} \in \mathcal{S}_{\mathcal{D}}} g_{\mathcal{D}}(i_{\mathcal{D}}, j_{\mathcal{D}})\right) \|c_{\mathcal{D}} x_{\mathcal{D}} - \tilde{\pi}_{\mathcal{D}}\|_{A_{\mathcal{D}}},$$

[illegible] $x'_{\mathcal{D}} = x_{\mathcal{D}} T_{\mathcal{D}}^{\nu_1}$ $G_{\mathcal{D}}$ [illegible] $G_{\mathcal{D}} = A_{\mathcal{D}}^{-1} T_{\mathcal{D}}^{\nu_1} A_{\mathcal{D}}$ [illegible] $A_{\mathcal{D}} \geq 0$ [illegible] $0 < \min_{i_{\mathcal{D}}, j_{\mathcal{D}} \in \mathcal{S}_{\mathcal{D}}} g_{\mathcal{D}}(i_{\mathcal{D}}, j_{\mathcal{D}}) \leq 1/|\mathcal{S}_{\mathcal{D}}|$ $\tilde{\pi}_{\mathcal{D}}$ [illegible] $\tilde{Q}_{\mathcal{D}}$ [illegible] $c_{\mathcal{D}} = (\tilde{\pi}_{\mathcal{D}} A_{\mathcal{D}} e)/(x_{\mathcal{D}} A_{\mathcal{D}} e)$

[illegible] From Corollary 3 and Theorem 4 in [5], if $T_{\mathcal{D}}^{\nu_1}$ is nonnegative, is irreducible, and satisfies either of the conditions (ii) or (iii), then it is similar to a positive matrix; that is, $X_{\mathcal{D}}^{-1} T_{\mathcal{D}}^{\nu_1} X_{\mathcal{D}} = H_{\mathcal{D}} > 0$ for some $(|\mathcal{S}_{\mathcal{D}}| \times |\mathcal{S}_{\mathcal{D}}|)$ nonnegative matrix $X_{\mathcal{D}}$. Condition (i) is a special case for which $X_{\mathcal{D}} = I_{\mathcal{D}}$. Since these imply $\sigma(H_{\mathcal{D}}) = \sigma(T_{\mathcal{D}}^{\nu_1})$ and we have $\rho(T_{\mathcal{D}}^{\nu_1}) = 1$ from Lemma 4.13, $H_{\mathcal{D}} > 0$ must be similar to a positive stochastic matrix $G_{\mathcal{D}}$ as in $Y_{\mathcal{D}}^{-1} H_{\mathcal{D}} Y_{\mathcal{D}} = G_{\mathcal{D}} > 0$, where $Y_{\mathcal{D}}$ is a nonnegative diagonal matrix having the positive right eigenvector of $H_{\mathcal{D}}$ along its diagonal. Now, let $A_{\mathcal{D}} = X_{\mathcal{D}} Y_{\mathcal{D}}$ to obtain $T_{\mathcal{D}}^{\nu_1} = A_{\mathcal{D}} G_{\mathcal{D}} A_{\mathcal{D}}^{-1}$, where $A_{\mathcal{D}} \geq 0$, $G_{\mathcal{D}} > 0$, and $G_{\mathcal{D}} e = e$.

For a sequence of converging approximations, one needs to ensure for the initial approximation that $x_{\mathcal{D}}^T \notin \text{Range}(I_{\mathcal{D}} - T_{\mathcal{D}}^T)$ [3, pp. 26–28]; otherwise, there will be no improvement. Furthermore, since $\tilde{\pi}_{\mathcal{D}}$ is the unique positive fixed point of $T_{\mathcal{D}}^{\nu_1}$ such that $\tilde{\pi}_{\mathcal{D}} e = 1$, the unique positive fixed point of $G_{\mathcal{D}}$ with unit 1-norm must be $\psi_{\mathcal{D}} = (\tilde{\pi}_{\mathcal{D}} A_{\mathcal{D}})/(\tilde{\pi}_{\mathcal{D}} A_{\mathcal{D}} e)$. Now, rewrite $x'_{\mathcal{D}} = x_{\mathcal{D}} T_{\mathcal{D}}^{\nu_1}$ using $T_{\mathcal{D}}^{\nu_1} = A_{\mathcal{D}} G_{\mathcal{D}} A_{\mathcal{D}}^{-1}$

---

[2] This norm should not be confused with the elliptical norm [23, p. 288] defined as $\|w\|_{A_{\mathcal{D}}} = \|wA_{\mathcal{D}}\|_2$.

to obtain $x'_{\mathcal{D}}A_{\mathcal{D}} = x_{\mathcal{D}}A_{\mathcal{D}}(G_{\mathcal{D}})$. Since $x_{\mathcal{D}} > 0$, $A_{\mathcal{D}} \geq 0$, and $A_{\mathcal{D}}$ has full rank, we have $x'_{\mathcal{D}} > 0$. Furthermore, note that $x'_{\mathcal{D}}A_{\mathcal{D}}e = x_{\mathcal{D}}A_{\mathcal{D}}(G_{\mathcal{D}}e) = x_{\mathcal{D}}A_{\mathcal{D}}e$. Letting $\overline{x}'_{\mathcal{D}} = (x'_{\mathcal{D}}A_{\mathcal{D}})/(x_{\mathcal{D}}A_{\mathcal{D}}e)$ and $\overline{x}_{\mathcal{D}} = (x_{\mathcal{D}}A_{\mathcal{D}})/(x_{\mathcal{D}}A_{\mathcal{D}}e)$, we have from Lemma A.1 in [13, appendix]

$$\|\overline{x}'_{\mathcal{D}} - \psi_{\mathcal{D}}\|_1 \leq \left(1 - \min_{i_{\mathcal{D}},j_{\mathcal{D}} \in \mathcal{S}_{\mathcal{D}}} g_{\mathcal{D}}(i_{\mathcal{D}}, j_{\mathcal{D}})\right) \|\overline{x}_{\mathcal{D}} - \psi_{\mathcal{D}}\|_1.$$

The result follows by taking each of $(\overline{x}'_{\mathcal{D}} - \psi_{\mathcal{D}})$ and $(\overline{x}_{\mathcal{D}} - \psi_{\mathcal{D}})$ into $A_{\mathcal{D}}$ parentheses, multiplying both sides of the inequality by $\tilde{\pi}_{\mathcal{D}}A_{\mathcal{D}}e$, letting $c_{\mathcal{D}} = (\tilde{\pi}_{\mathcal{D}}A_{\mathcal{D}}e)/(x_{\mathcal{D}}A_{\mathcal{D}}e)$, and using Proposition 4.15. □

Theorem 4.16 indicates that the [illegible] solution vector, $c_{\mathcal{D}}x_{\mathcal{D}}$, improves with $\nu_1$ presmoothings if $T_{\mathcal{D}}^{\nu_1}$ is positive or has a(n almost) positive row or column. Now, observe that the ordering of grids suggested by $O \in \{FIXED, CIRCULAR, DYNAMIC\}$ has no effect on the assumptions of Theorem 4.16. Note also from Lemma 4.13 that as $\nu_1$ increases, $T_{\mathcal{D}}^{\nu_1}$ converges to a positive rank 1 matrix. Hence, there is a value of $\nu_1 > 0$ for which the assumptions of Theorem 4.16 hold. We remark that $\tilde{Q}_{\mathcal{D}}$ is almost always sparse, and the iteration matrices associated with the *POWER* and *JOR* smoothers have the same off-diagonal nonzero structure as that of $\tilde{Q}_{\mathcal{D}}$. Hence, compared to *POWER* and *JOR*, the *SOR* smoother has a higher chance of satisfying the conditions of Theorem 4.16 for a smaller value of $\nu_1$, since its iteration matrix is likely to have a larger number of nonzeros, as suggested in the proof of Lemma 4.17 in [13]. Similar arguments are valid for postsmoothings. These results can be perceived as an extension of the local convergence result available in [22, sec. 2] to include the *JOR* and *SOR* smoothers and another sufficient condition (i.e., Theorem 4.16(iii)). In summary, the smoothings can always be enforced to yield improved positive approximations at each level.

**4.3. Convergence of the ML solver.** Using the results in the previous subsections, we show that under certain conditions the devised class of ML methods provide converging iterations for different choices of the cycle parameter $C \in \{V, W, F\}$.

First, we define the ML iteration matrix at level $\mathcal{D}$ in Algorithms 1 and 2 using Propositions 3.5, 3.7, 4.11, and 4.14. Note that when there are only two levels, the W- and F-cycles are not defined, and the V-cycle yields a two-level IAD solver. In order not to complicate the notation further, we refrain from introducing an index for the cycle number to the matrices and vectors at this point.

DEFINITION 4.17. [illegible] $T_{\mathcal{D}}^{ML}$ [illegible] $\mathcal{D}$ [illegible] $x_{\mathcal{D}} > 0$ [illegible] $y'_{\mathcal{D}} > 0$ [illegible] $S \in \{POWER, JOR, SOR\}$ [illegible] $T_{\mathcal{D}}$ [illegible] $\tilde{Q}_{\mathcal{D}}$ [illegible] $\alpha_{\mathcal{D}} \in (\max_{s_{\mathcal{D}} \in \mathcal{S}_{\mathcal{D}}} |\tilde{q}_{\mathcal{D}}(s_{\mathcal{D}}, s_{\mathcal{D}})|, \infty)$ [illegible] $\omega \in (0, 1)$ [illegible] $R_{\mathcal{D}}$ [illegible] $P_{x'_{\mathcal{D}}}$ [illegible] $T_{\mathcal{C}}^{ML}$ [illegible] $T_{\mathcal{B}}^{ML}$ [illegible] $\mathcal{C}$ [illegible] $\mathcal{B}$ [illegible]

$$y'_{\mathcal{D}} = x_{\mathcal{D}}T_{\mathcal{D}}^{ML},$$

[illegible]

$$T_{\mathcal{D}}^{ML} = \begin{cases} T_{\mathcal{D}}^{\nu_1} R_{\mathcal{D}} T_{\mathcal{C}}^{ML} P_{x'_{\mathcal{D}}} T_{\mathcal{D}}^{\nu_2} & [illegible]\ C = V, \\ T_{\mathcal{D}}^{\nu_1} R_{\mathcal{D}} (T_{\mathcal{C}}^{ML})^2 P_{x'_{\mathcal{D}}} T_{\mathcal{D}}^{\nu_2} & [illegible]\ C = W, \\ T_{\mathcal{D}}^{\nu_1} R_{\mathcal{D}} T_{\mathcal{C}}^{ML} T_{\mathcal{C}}^{ML'} P_{x'_{\mathcal{D}}} T_{\mathcal{D}}^{\nu_2} & [illegible]\ C = F, \end{cases}$$

$$T_{\mathcal{C}}^{ML'} = T_{\mathcal{C}}^{\nu_1} R_{\mathcal{C}} T_{\mathcal{B}}^{ML'} P_{x'_{\mathcal{C}}} T_{\mathcal{C}}^{\nu_2}, \quad x'_{\mathcal{D}} = x_{\mathcal{D}} T_{\mathcal{D}}^{\nu_1},$$

[illegible] $\tilde{Q}_{\mathcal{C}}$ [illegible] $T_{\mathcal{C}}^{ML} = T_{\mathcal{C}}^{ML'} = (ey'_{\mathcal{C}})/(x_{\mathcal{C}}e) > 0$ [illegible] $y_{\mathcal{C}} = \tilde{\pi}_{\mathcal{C}}$

COROLLARY 4.18. [illegible] $POWER$ [illegible] $x_{\mathcal{D}} > 0$ [illegible] $x_{\mathcal{D}}e = 1$ [illegible] $T_{\mathcal{D}}^{ML}$ [illegible] $C \in \{V, W, F\}$ [illegible] 1

[illegible] For the $POWER$ smoother, at the coarsest level $\mathcal{C}$ we have $T_{\mathcal{C}}^{ML} = T_{\mathcal{C}}^{ML'} = e\tilde{\pi}_{\mathcal{C}}$ from Definition 4.17 when $x_{\mathcal{D}}e = 1$, implying a positive stochastic matrix, which has a spectral radius and an eigenvalue value of 1. This forms the base case. Now, let us assume that the result is true for all levels from the coarsest up to an arbitrary level $\mathcal{C}$; this is the inductive hypothesis. We show that the result must be true for the next finer level $\mathcal{D}$. Noting that $R_{\mathcal{D}}e = e$ from Proposition 3.5, $(T_{\mathcal{C}}^{ML})e = e$ from the inductive hypothesis, $P_{x'_{\mathcal{D}}}e = e$ from Proposition 3.7, and $T_{\mathcal{D}}e = e$ from Lemma 4.13, we have $T_{\mathcal{D}}^{ML}e = T_{\mathcal{D}}^{\nu_1} R_{\mathcal{D}} T_{\mathcal{C}}^{ML} P_{x'_{\mathcal{D}}} T_{\mathcal{D}}^{\nu_2} e = T_{\mathcal{D}}^{\nu_1} R_{\mathcal{D}} T_{\mathcal{C}}^{ML} (P_{x'_{\mathcal{D}}} e) = T_{\mathcal{D}}^{\nu_1} R_{\mathcal{D}} (T_{\mathcal{C}}^{ML} e) = T_{\mathcal{D}}^{\nu_1} (R_{\mathcal{D}} e) = T_{\mathcal{D}}^{\nu_1} e = e$ for the V-cycle. The result follows similarly for W- and F-cycles. □

The interpretation of $T_{\mathcal{D}}^{ML}$ for V- and W-cycles is as follows. If the recursive call(s) to level $\mathcal{C}$ are turned off, then only $(\nu_1 + \nu_2)$ iterations are performed on $x_{\mathcal{D}}$ with the smoother $S$. Otherwise, the smoothed solution vector is restricted to level $\mathcal{C}$ (i.e., $x_{\mathcal{D}} T_{\mathcal{D}}^{\nu_1}$ is the smoothed solution vector and $x_{\mathcal{D}} T_{\mathcal{D}}^{\nu_1} R_{\mathcal{D}}$ is the restricted solution vector), the restricted solution vector is improved respectively one or two times with the iteration matrix $T_{\mathcal{C}}^{ML}$, and the improved solution vector is projected back to level $\mathcal{D}$ and smoothed. The interpretation of $T_{\mathcal{D}}^{ML}$ for an F-cycle is similar to that for V- and W-cycles with the difference that the restricted solution vector is improved with the iteration matrix $T_{\mathcal{D}}^{ML}$ once followed by the iteration matrix of the V-cycle. This is exactly what is meant with a W-cycle followed by a V-cycle at each level.

The next lemma follows from Lemma 4.1, Lemma 4.13, and Definition 4.17.

LEMMA 4.19. [illegible] $\tilde{Q}_{\mathcal{D}}$ [illegible] $x_{\mathcal{D}} > 0$ [illegible] $S \in \{POWER, JOR, SOR\}$ [illegible] $\alpha_{\mathcal{D}} \in (\max_{s_{\mathcal{D}} \in \mathcal{S}_{\mathcal{D}}} |\tilde{q}_{\mathcal{D}}(s_{\mathcal{D}}, s_{\mathcal{D}})|, \infty)$ [illegible] $\omega \in (0, 1)$ [illegible] $T_{\mathcal{D}}^{ML}$ [illegible] $C \in \{V, W, F\}$ [illegible]

[illegible] The proof is by induction. At the coarsest level $\mathcal{C}$, we have $T_{\mathcal{C}}^{ML} = T_{\mathcal{C}}^{ML'} > 0$ from Definition 4.17. This is the base case and implies $(T_{\mathcal{C}}^{ML})^2 = T_{\mathcal{C}}^{ML} T_{\mathcal{C}}^{ML'} > 0$. Now, let us assume that the statement is true for all levels from the coarsest up to an arbitrary level $\mathcal{C}$. This is the inductive hypothesis. We show that the statement must be true for the next finer level $\mathcal{D}$. Since $P_{x'_{\mathcal{D}}} \geq 0$ and each column of $P_{x'_{\mathcal{D}}}$ has one nonzero element from Proposition 3.7, the $(|\mathcal{S}_{\mathcal{C}}| \times |\mathcal{S}_{\mathcal{D}}|)$ matrices $T_{\mathcal{C}}^{ML} P_{x'_{\mathcal{D}}}$, $(T_{\mathcal{C}}^{ML})^2 P_{x'_{\mathcal{D}}}$, and $T_{\mathcal{C}}^{ML} T_{\mathcal{C}}^{ML'} P_{x'_{\mathcal{D}}}$ are positive. Furthermore, since $R_{\mathcal{D}} \geq 0$ and each row of $R_{\mathcal{D}}$ has one nonzero element from Proposition 3.5, the $(|\mathcal{S}_{\mathcal{D}}| \times |\mathcal{S}_{\mathcal{D}}|)$ matrices $R_{\mathcal{D}} T_{\mathcal{C}}^{ML} P_{x'_{\mathcal{D}}}$, $R_{\mathcal{D}} (T_{\mathcal{C}}^{ML})^2 P_{x'_{\mathcal{D}}}$, and $R_{\mathcal{D}} T_{\mathcal{C}}^{ML} T_{\mathcal{C}}^{ML'} P_{x'_{\mathcal{D}}}$ are also positive. Then the result follows from Lemma 4.13 by the fact that the iteration matrix associated with the smoother is nonnegative and irreducible, implying at least one nonzero in each row and column of $T_{\mathcal{D}}$ which pre- and postmultiplies the positive matrices $R_{\mathcal{D}} T_{\mathcal{C}}^{ML} P_{x'_{\mathcal{D}}}$, $R_{\mathcal{D}} (T_{\mathcal{C}}^{ML})^2 P_{x'_{\mathcal{D}}}$, and $R_{\mathcal{D}} T_{\mathcal{C}}^{ML} T_{\mathcal{C}}^{ML'} P_{x'_{\mathcal{D}}}$. □

The next result follows from Lemma 4.19 in that the positivity of $T_{\mathcal{D}}^{ML}$ implies its irreducibility and a positive diagonal, and hence its primitivity [4, p. 47].

COROLLARY 4.20. [illegible] $\tilde{Q}_{\mathcal{D}}$ [illegible] $x_{\mathcal{D}} > 0$ [illegible] $S \in$

$\{POWER, JOR, SOR\}$ [illegible] $\alpha_{\mathcal{D}} \in (\max_{s_{\mathcal{D}} \in \mathcal{S}_{\mathcal{D}}} |\tilde{q}_{\mathcal{D}}(s_{\mathcal{D}}, s_{\mathcal{D}})|, \infty)$ [illegible] $\omega \in (0,1)$ [illegible] $T_{\mathcal{D}}^{ML}$ [illegible] $C \in \{V, W, F\}$ [illegible]

The next lemma shows that the steady state vector, $\pi_{\mathcal{D}}$, of the exactly aggregated grid, $Q_{\mathcal{D}}$, is the unique, positive, unit 1-norm fixed point of the ML iteration matrix, $T_{\mathcal{D}}^{ML}$, at level $\mathcal{D}$ upon convergence.

LEMMA 4.21. [illegible] $\tilde{Q}_{\mathcal{D}}$ [illegible] $Q_{\mathcal{D}}$ $x_{\mathcal{D}} = \pi_{\mathcal{D}}$ [illegible] $S \in \{POWER, JOR, SOR\}$ [illegible] $\alpha_{\mathcal{D}} \in (\max_{s_{\mathcal{D}} \in \mathcal{S}_{\mathcal{D}}} |\tilde{q}_{\mathcal{D}}(s_{\mathcal{D}}, s_{\mathcal{D}})|, \infty)$ [illegible] $\omega \in (0,1)$ [illegible] $T_{\mathcal{D}}^{ML}$ [illegible] $C \in \{V, W, F\}$ [illegible] $\pi_{\mathcal{D}}$ [illegible] $\pi_{\mathcal{D}} T_{\mathcal{D}}^{ML} = \pi_{\mathcal{D}}$ [illegible] $\pi_{\mathcal{D}} e = 1$ [illegible] $\rho(T_{\mathcal{D}}^{ML}) = 1$ [illegible] $y_{\mathcal{D}}' = \pi_{\mathcal{D}}$

[illegible] The proof is by induction. At the coarsest level $\mathcal{C}$, we have $\tilde{Q}_{\mathcal{C}} = Q_{\mathcal{C}}$ and $x_{\mathcal{C}} = \pi_{\mathcal{C}} > 0$, implying $T_{\mathcal{C}}^{ML} = T_{\mathcal{C}}^{ML'} = e\pi_{\mathcal{C}} > 0$ from Definition 4.17. This positive matrix is stochastic and has the unique positive fixed point $\pi_{\mathcal{C}}$ such that $\pi_{\mathcal{C}} e = 1$. Furthermore, it has a spectral radius of 1 and $y_{\mathcal{C}}' = x_{\mathcal{C}} T_{\mathcal{C}}^{ML} = \pi_{\mathcal{C}}(e\pi_{\mathcal{C}}) = (\pi_{\mathcal{C}} e)\pi_{\mathcal{C}} = \pi_{\mathcal{C}}$. This is the base case and yields $(T_{\mathcal{C}}^{ML})^2 = T_{\mathcal{C}}^{ML} T_{\mathcal{C}}^{ML'} = (e\pi_{\mathcal{C}})(e\pi_{\mathcal{C}}) = e(\pi_{\mathcal{C}} e)\pi_{\mathcal{C}} = e\pi_{\mathcal{C}} > 0$. Now, let us assume that the statement is true for all levels from the coarsest up to an arbitrary level $\mathcal{C}$. This is the inductive hypothesis. We show that the statement must be true for the next finer level $\mathcal{D}$.

Since $x_{\mathcal{D}} = \pi_{\mathcal{D}} > 0$ is the fixed point of $T_{\mathcal{D}}$, $\pi_{\mathcal{D}} R_{\mathcal{D}} = \pi_{\mathcal{C}}$ from Definition 3.4, $\pi_{\mathcal{C}} T_{\mathcal{C}}^{ML} = \pi_{\mathcal{C}}$ by the inductive hypothesis, and $\pi_{\mathcal{C}} P_{\pi_{\mathcal{D}}} = \pi_{\mathcal{D}}$ from Definition 3.6, the result follows from Definition 4.17 for the V-cycle as $y_{\mathcal{D}}' = \pi_{\mathcal{D}} T_{ML}^{D} = (\pi_{\mathcal{D}} T_{\mathcal{D}}^{\nu_1}) R_{\mathcal{D}} T_{\mathcal{C}}^{ML} P_{\pi_{\mathcal{D}}} T_{\mathcal{D}}^{\nu_2} = (\pi_{\mathcal{D}} R_{\mathcal{D}}) T_{\mathcal{C}}^{ML} P_{\pi_{\mathcal{D}}} T_{\mathcal{D}}^{\nu_2} = (\pi_{\mathcal{C}} T_{\mathcal{C}}^{ML}) P_{\pi_{\mathcal{D}}} T_{\mathcal{D}}^{\nu_2} = (\pi_{\mathcal{C}} P_{\pi_{\mathcal{D}}}) T_{\mathcal{D}}^{\nu_2} = \pi_{\mathcal{D}} T_{\mathcal{D}}^{\nu_2} = \pi_{\mathcal{D}}$. The result follows similarly for W- and F-cycles after interchanging $T_{\mathcal{C}}^{ML}$ respectively with $(T_{\mathcal{C}}^{ML})^2$ and $T_{\mathcal{C}}^{ML} T_{\mathcal{C}}^{ML'}$. The uniqueness and positivity of the fixed point of $T_{\mathcal{D}}^{ML}$ follows from Lemma 4.19 by the fact that $T_{\mathcal{D}}^{ML}$ is positive [23, p. 666]. Clearly the spectral radius of $T_{\mathcal{D}}^{ML}$ is 1. □

The next theorem characterizes the [illegible] behavior of the ML solver with the initial approximation $x_{\mathcal{D}}$ by defining a unique, positive, unit 1-norm fixed point for the particular cycle.

THEOREM 4.22. [illegible] $T_{\mathcal{D}}^{ML}$ [illegible] $\mathcal{D}$ [illegible] $x_{\mathcal{D}} > 0$ [illegible] $x_{\mathcal{D}}^T \notin \mathrm{Range}(I_{\mathcal{D}} - T_{\mathcal{D}}^T)$ [illegible] $y_{\mathcal{D}}' > 0$ [illegible] $S \in \{POWER, JOR, SOR\}$ [illegible] $\tilde{Q}_{\mathcal{D}}$ [illegible] $\alpha_{\mathcal{D}} \in (\max_{s_{\mathcal{D}} \in \mathcal{S}_{\mathcal{D}}} |\tilde{q}_{\mathcal{D}}(s_{\mathcal{D}}, s_{\mathcal{D}})|, \infty)$ [illegible] $\omega \in (0,1)$ [illegible] $T_{\mathcal{D}}^{ML}/\rho(T_{\mathcal{D}}^{ML})$ [illegible] 1 [illegible] $\phi_{\mathcal{D}}$ [illegible] $\phi_{\mathcal{D}}(T_{\mathcal{D}}^{ML}/\rho(T_{\mathcal{D}}^{ML})) = \phi_{\mathcal{D}}$ [illegible] $\phi_{\mathcal{D}} e = 1$ [illegible] $T_{\mathcal{D}}^{ML}/\rho(T_{\mathcal{D}}^{ML}) = Z_{\mathcal{D}} H_{\mathcal{D}} Z_{\mathcal{D}}^{-1}$ [illegible] $H_{\mathcal{D}}$ [illegible] $Z_{\mathcal{D}}$ [illegible] $T_{\mathcal{D}}^{ML}/\rho(T_{\mathcal{D}}^{ML})$ [illegible] $H_{\mathcal{D}}$ [illegible] $\psi_{\mathcal{D}} = (\phi_{\mathcal{D}} Z_{\mathcal{D}})/(\phi_{\mathcal{D}} Z_{\mathcal{D}} e)$ [illegible] $\psi_{\mathcal{D}} H_{\mathcal{D}} = \psi_{\mathcal{D}}$ [illegible] $\psi_{\mathcal{D}} e = 1$ [illegible]

$$\|(b_{\mathcal{D}}/\rho(T_{\mathcal{D}}^{ML}))y_{\mathcal{D}}' - \phi_{\mathcal{D}}\|_{Z_{\mathcal{D}}} \le \left(1 - \min_{i_{\mathcal{D}}, j_{\mathcal{D}} \in \mathcal{S}_{\mathcal{D}}} h_{\mathcal{D}}(i_{\mathcal{D}}, j_{\mathcal{D}})\right) \|b_{\mathcal{D}} x_{\mathcal{D}} - \phi_{\mathcal{D}}\|_{Z_{\mathcal{D}}},$$

[illegible] $b_{\mathcal{D}} = (\phi_{\mathcal{D}} Z_{\mathcal{D}} e)/(x_{\mathcal{D}} Z_{\mathcal{D}} e)$ [illegible] $0 < \min_{i_{\mathcal{D}}, j_{\mathcal{D}} \in \mathcal{S}_{\mathcal{D}}} h_{\mathcal{D}}(i_{\mathcal{D}}, j_{\mathcal{D}}) \le 1/|\mathcal{S}_{\mathcal{D}}|$ [illegible] $\|(b_{\mathcal{D}}/\rho(T_{\mathcal{D}}^{ML}))y_{\mathcal{D}}' - \phi_{\mathcal{D}}\|_{Z_{\mathcal{D}}} = 0$ [illegible] $POWER$ [illegible] $Z_{\mathcal{D}} = I_{\mathcal{D}}$ $H_{\mathcal{D}} = T_{\mathcal{D}}^{ML}$ $\rho(T_{\mathcal{D}}^{ML}) = 1$ $\psi_{\mathcal{D}} = \phi_{\mathcal{D}}$ [illegible] $b_{\mathcal{D}} = 1$

[illegible] Recall from Lemma 4.19 that $T_{\mathcal{D}}^{ML} > 0$. Since $\rho(T_{\mathcal{D}}^{ML}) > 0$ for $T_{\mathcal{D}}^{ML} \neq 0$, the matrix $T_{\mathcal{D}}^{ML}/\rho(T_{\mathcal{D}}^{ML})$ is also positive, satisfies $\sigma(T_{\mathcal{D}}^{ML}/\rho(T_{\mathcal{D}}^{ML})) = \{\lambda/\rho(T_{\mathcal{D}}^{ML}) \mid \lambda \in \sigma(T_{\mathcal{D}}^{ML})\}$, and therefore has a spectral radius of 1. The uniqueness and positivity of the fixed point $\phi_{\mathcal{D}}$ follow from Corollary 4.20. The row vector $\phi_{\mathcal{D}} > 0$ is assumed to be normalized so as to have unit 1-norm (i.e., $\phi_{\mathcal{D}} e = 1$).

To prove the second part, recall Corollary 4.20 and the result in [4, p. 49], which is also used in the proof of Lemma 4.13. These imply that $T_{\mathcal{D}}^{ML}/\rho(T_{\mathcal{D}}^{ML})$ must have a positive right eigenvector $\zeta_{\mathcal{D}}$ for which

$$T_{\mathcal{D}}^{ML}/\rho(T_{\mathcal{D}}^{ML}) = Z_{\mathcal{D}} H_{\mathcal{D}} Z_{\mathcal{D}}^{-1},$$

where $Z_{\mathcal{D}} = \mathrm{diag}(\zeta_{\mathcal{D}})$, $H_{\mathcal{D}} > 0$, and $H_{\mathcal{D}} e = e$. In other words,

$$H_{\mathcal{D}} = Z_{\mathcal{D}}^{-1}(T_{\mathcal{D}}^{ML}/\rho(T_{\mathcal{D}}^{ML}))Z_{\mathcal{D}}$$

is a stochastic matrix similar to $T_{\mathcal{D}}^{ML}/\rho(T_{\mathcal{D}}^{ML})$, and its positivity follows from $T_{\mathcal{D}}^{ML}/\rho(T_{\mathcal{D}}^{ML}) > 0$ and $\zeta_{\mathcal{D}} > 0$. Note that it does not matter whether $\zeta_{\mathcal{D}}$ is normalized or not, since $H_{\mathcal{D}}$ is defined in terms of $Z_{\mathcal{D}}$ and $Z_{\mathcal{D}}^{-1}$. The uniqueness and positivity of the fixed point $\psi_{\mathcal{D}}$ follows from $H_{\mathcal{D}} > 0$. The row vector $\phi_{\mathcal{D}} > 0$ is assumed to be normalized so as to have unit 1-norm (i.e., $\phi_{\mathcal{D}} e = 1$), and it is given by $\psi_{\mathcal{D}} = \phi_{\mathcal{D}} Z_{\mathcal{D}}$ since $H_{\mathcal{D}}$ and $T_{\mathcal{D}}^{ML}/\rho(T_{\mathcal{D}}^{ML})$ are related by a similarity transformation, where the transformation matrix is $Z_{\mathcal{D}}$.

To prove the last part, rewrite

$$y_{\mathcal{D}}^{'} = \rho(T_{\mathcal{D}}^{ML}) x_{\mathcal{D}} (T_{\mathcal{D}}^{ML}/\rho(T_{\mathcal{D}}^{ML}))$$

using $T_{\mathcal{D}}^{ML}/\rho(T_{\mathcal{D}}^{ML}) = Z_{\mathcal{D}} H_{\mathcal{D}} Z_{\mathcal{D}}^{-1} > 0$ as

$$(y_{\mathcal{D}}^{'} Z_{\mathcal{D}})/(\rho(T_{\mathcal{D}}^{ML}) x_{\mathcal{D}} Z_{\mathcal{D}} e) = (x_{\mathcal{D}} Z_{\mathcal{D}}) H_{\mathcal{D}}/(x_{\mathcal{D}} Z_{\mathcal{D}} e),$$

which is equivalent to $\overline{y}_{\mathcal{D}}^{'} = \overline{x}_{\mathcal{D}} H_{\mathcal{D}}$. Since $x_{\mathcal{D}} > 0$, $y_{\mathcal{D}}^{'} > 0$, $\rho(T_{\mathcal{D}}^{ML}) > 0$, and $\zeta_{\mathcal{D}} > 0$, we have $\overline{x}_{\mathcal{D}} = (x_{\mathcal{D}} Z_{\mathcal{D}})/(x_{\mathcal{D}} Z_{\mathcal{D}} e) > 0$, implying $\overline{x}_{\mathcal{D}} e = 1$, and $\overline{y}_{\mathcal{D}}^{'} = (y_{\mathcal{D}}^{'} Z_{\mathcal{D}})/(\rho(T_{\mathcal{D}}^{ML}) x_{\mathcal{D}} Z_{\mathcal{D}} e) > 0$. Furthermore, since $H_{\mathcal{D}} > 0$, $H_{\mathcal{D}} e = e$, and $\overline{x}_{\mathcal{D}} e = 1$, we obtain $\overline{y}_{\mathcal{D}}^{'} e = 1$. Then, from Lemma A.1 in [13, appendix] we have

$$\|\overline{y}_{\mathcal{D}}^{'} - \psi_{\mathcal{D}}\|_1 \leq \left(1 - \min_{i_{\mathcal{D}}, j_{\mathcal{D}} \in \mathcal{S}_{\mathcal{D}}} h_{\mathcal{D}}(i_{\mathcal{D}}, j_{\mathcal{D}})\right) \|\overline{x}_{\mathcal{D}} - \psi_{\mathcal{D}}\|_1.$$

The result follows by taking each of $(\overline{y}_{\mathcal{D}}^{'} - \psi_{\mathcal{D}})$ and $(\overline{x}_{\mathcal{D}} - \psi_{\mathcal{D}})$ into $Z_{\mathcal{D}}$ parentheses, multiplying both sides of the inequality by $\phi_{\mathcal{D}} Z_{\mathcal{D}} e$, letting $b_{\mathcal{D}} = (\phi_{\mathcal{D}} Z_{\mathcal{D}} e)/(x_{\mathcal{D}} Z_{\mathcal{D}} e)$, and using Proposition 4.15. The part for the coarsest level follows from Definition 4.17 by the fact that $T_{\mathcal{D}}^{ML} = (e y_{\mathcal{D}}^{'})/(x_{\mathcal{D}} e)$ and $\rho(T_{\mathcal{D}}^{ML}) = 1/(x_{\mathcal{D}} e)$, implying $T_{\mathcal{D}}^{ML}/\rho(T_{\mathcal{D}}^{ML}) = H_{\mathcal{D}} = e y_{\mathcal{D}}^{'}$ and $Z_{\mathcal{D}} = I_{\mathcal{D}}$. For the *POWER* smoother, Corollary 4.18 implies $Z_{\mathcal{D}} = \mathrm{diag}(e) = I_{\mathcal{D}}$, and therefore, the respective results. ☐

The ML iteration matrix, $T_{\mathcal{D}}^{ML}$, changes at each cycle due to the dependence of $P_{x_{\mathcal{D}}^{'}}$ on $x_{\mathcal{D}}^{'}$, and therefore the ML iteration is nonstationary. At the end of each ML iteration, the solution vector at the finest level $\mathcal{D}$, $y_{\mathcal{D}}^{'}$, is normalized to be unit 1-norm and then assigned to $x_{\mathcal{D}}$ so as to start the next ML iteration. As long as $x_{\mathcal{D}}^{'} \neq \pi_{\mathcal{D}}$, the aggregated CTMC $\tilde{Q}_{\mathcal{C}}$ at the next coarser level can be only approximative. Theorem 4.22 indicates that the [illegible] solution vector, $b_{\mathcal{D}} x_{\mathcal{D}}$, improves with respect to the fixed point $\phi_{\mathcal{D}}$ with a converging smoother as long as $x_{\mathcal{D}} > 0$ is not in the range of $(I - T_{\mathcal{D}}^{ML})^T$. For the solution to improve with respect to steady state vector $\tilde{\pi}_{\mathcal{D}}$ at each level, one requires sufficient conditions on the smoother, as in Theorem 4.16.

Then $x_{\mathcal{D}}$ at the finest level will improve from one ML iteration to the next, implying an improvement in the aggregated CTMC at each level and thus an improved solution at each level. Then, recalling from Lemma 4.21 that $\tilde{Q}_{\mathcal{D}} = Q_{\mathcal{D}}$ and $\rho(T_{\mathcal{D}}^{ML}) = 1$ upon convergence, $\rho(T_{\mathcal{D}}^{ML})$ and $\phi_{\mathcal{D}}$ must be approaching 1 and $\pi_{\mathcal{D}}$, respectively, while the subdominant eigenvalue of $T_{\mathcal{D}}^{ML}$ in magnitude is approaching zero with an increasing number of ML iterations.

In [11], extensive numerical experiments have been conducted with the ML solver on HMMs. Therein, the values chosen for the parameters of the $POWER$, $JOR$, and $SOR$ smoothers are $\alpha_{\mathcal{D}} = \max_{s_{\mathcal{D}} \in \mathcal{S}_{\mathcal{D}}} |\tilde{q}_{\mathcal{D}}(s_{\mathcal{D}}, s_{\mathcal{D}})|/0.999$ and $\omega = 1$, and the initial approximation is the uniform distribution. Furthermore, at least one pre- and one postsmoothing is performed at each level, and the coarsest system is solved using Gaussian elimination. Hence, $POWER$ is enforced to yield a converging smoother, and the $JOR$ and $SOR$ iteration matrices are nonnegative. Although $\omega = 1$ does not guarantee converging $JOR$ and $SOR$ smoothers (see Lemma 4.8), the results indicate that convergence may still be achieved. Hence, we conclude that the conditions stated in Theorem 4.16 for the smoothers are sufficient for convergence, but not necessary.

## 5. Experimental results.

In [13, sec. 5], we step through the ML method on Example 1 in section 2. Here we consider the number of iterations and the time in seconds required to reach $\|r\|_\infty < 10^{-8}$ (see Algorithm 1) for Examples 2 and 3. We compare SOR and ML methods with $(C, S, O) \in \{(V, SOR, FIXED), (W, SOR, CIRCULAR), (F, SOR, DYNAMIC)\}$. In all cases, the relaxation parameter of $SOR$ is set to 1. All experiments are performed on PCs with AMD opteron 2.3 GHz CPU and 1 GBytes of main memory.

Table 5.1

*Number of iterations and solution times for Example* 2.

| | SOR | | ML | | | | | |
|---|---|---|---|---|---|---|---|---|
| | | | $(V, SOR, FIXED)$ | | $(W, SOR, CIRCULAR)$ | | $(F, SOR, DYNAMIC)$ | |
| $K$ | *it* | *time* | *it* | *time* | *it* | *time* | *it* | *time* |
| 3 | 180 | 0 | 90 | 0 | 44 | 0 | 46 | 0 |
| 4 | 260 | 0 | 106 | 0 | 40 | 0 | 42 | 0 |
| 5 | 290 | 2 | 92 | 1 | 34 | 1 | 36 | 1 |
| 6 | 360 | 42 | 104 | 8 | 30 | 3 | 36 | 4 |
| 7 | 420 | 123 | 114 | 57 | 30 | 19 | 32 | 20 |

Table 5.1 contains the results for Example 2. For the solution we choose SOR and three variants of ML methods. For the latter we choose $\nu_1 = \nu_2 = 1$ in all cases. It can be seen that the number of iterations of SOR increases with an increasing number of LLMs. For the ML solver with $FIXED$ aggregation of LLMs, a small increase in the number of iterations can also be observed. For the other two ML solvers with $CIRCULAR$ and $DYNAMIC$ order of aggregating LLMs, the number of ML iterations does not increase, even becomes smaller with an increasing number of LLMs, and is much smaller than that of the corresponding $FIXED$ order. This behavior can be observed for all cycle types; it depends on the order of aggregation and shows the importance of modifying the order for this example. Hence, although convergence does not depend on the order of aggregating LLMs, rate of convergence does. It should be mentioned that this example is not particularly hard to solve with SOR since LLMs are strongly coupled and the number of iterations is fairly small. Nevertheless, the use of ML steps increases convergence speed significantly, reducing the solution times for the larger configurations by almost an order of magnitude.

The third example is much harder to solve with SOR or other classical iterative

TABLE 5.2

| | SOR | | ML | | | | | |
|---|---|---|---|---|---|---|---|---|
| | | | $(V, SOR, FIXED)$ | | $(V, SOR, FIXED)$ | | $(W, SOR, CIRCULAR)$ | |
| | | | $(\nu_1 = 1,\ \nu_2 = 1)$ | | $(\nu_1 = 1,\ \nu_2 = 5)$ | | $(\nu_1 = 1,\ \nu_2 = 1)$ | |
| $K$ | *it* | *time* | *it* | *time* | *it* | *time* | *it* | *time* |
| 2 | 60 | 0 | 12 | 0 | 12 | 0 | 12 | 0 |
| 3 | 400 | 0 | 12 | 0 | 12 | 0 | 14 | 0 |
| 4 | 3,200 | 21 | 12 | 0 | 12 | 0 | 18 | 0 |
| 5 | 26,560 | 3,310 | 12 | 2 | 12 | 3 | 20 | 4 |
| 6 | | >10,000 | 18 | 45 | 12 | 42 | 14 | 38 |
| 7 | | | 16 | 492 | 12 | 554 | 14 | 529 |

methods. With the addition of a new LLM a new time scale is introduced in the model. It is known that such models are difficult to solve. Results for Example 3 are shown in Table 5.2. The results for SOR therein indicate that with an increasing number of LLMs the number of iterations grows drastically, and the system becomes practically unsolvable for $K > 5$. In the ML methods with fixed order of aggregation, at every aggregation step the fastest time scale is removed, and the system is mainly solved for the fastest remaining time scale. This implies that during a cycle each time scale is considered. Thus, we can expect fast convergence, which is confirmed by the results in Table 5.2. The number of iterations is almost independent of the number of LLMs, and even the largest configuration with $10,000,000$ states can be solved in less than 10 minutes, whereas SOR requires almost an hour to solve the system with only $10,000$ states. Since the ordering of LLMs is optimal according to the time scales, $CIRCULAR$ or $DYNAMIC$ ordering of aggregation do not help. The last two columns contain results for $CIRCULAR$ ordering and a $W$-cycle; results are similar to the $FIXED$ ordering. $DYNAMIC$ ordering gives worse results since the projected residuals which we use as a heuristic for choosing LLMs to be aggregated depend on the transition rates such that LLMs with small rates are aggregated first, resulting in a poor convergence in this example.

## 6. Conclusion.

In this paper, the convergence of a class of multilevel (ML) methods for large sparse Markov chains (MCs) has been investigated. The particular class of ML methods is inspired by algebraic multigrid and iterative aggregation-disaggregation, and has the capability of using (V, W, F) cycles, (power, Jacobi over relaxation (JOR), successive over relaxation (SOR)) methods as smoothers, and (fixed, circular, dynamic) orders in which coarser MCs can be formed by aggregation in a cycle. The conditions sufficient for convergence are an irreducible MC, a positive initial approximation from an appropriate subspace, an onto mapping of states from a finer MC to a coarser MC at each level, a uniformization parameter larger than the minimum magnitude of the diagonal elements for the power method, a relaxation parameter less than 1 for JOR and SOR, a sufficient number of pre- and postsmoothings at each level so as to ensure a smoothing matrix which is positive or has a(n almost) positive row/column, and the accurate solution of the coarsest system at each cycle. The asymptotic convergence rate of the class of ML methods across multiple levels is yet to be investigated.

# APPROXIMATE DIAGONALIZATION[*]

E. B. DAVIES[†]

**Abstract.** We describe a new method of computing functions of highly nonnormal matrices by using the concept of approximate diagonalization. We formulate a conjecture about its efficiency and provide both theoretical and numerical evidence in support of the conjecture. We apply the method to compute arbitrary real powers of highly nonnormal matrices.

**Key words.** Jordan matrices, ill-posedness, regularization, fractional powers, functional calculus, spectral theory

## 1. Introduction.

Let $A$ be a nonnormal $n \times n$ matrix and suppose that one wants to evaluate $x = f(A)b$ or solve $f(A)x = b$ for a large number of different analytic functions $f$ rapidly, without caring too much about high accuracy. If $A$ is diagonalizable, i.e., $A := SDS^{-1}$, where $D$ is diagonal, then one can solve the first problem by writing $x := Sf(D)S^{-1}b$, where $f(D)$ is evaluated by applying the function $f$ to the diagonal entries of $D$, which coincide with the eigenvalues of $A$. The second problem may be solved in a similar manner.

This procedure may not be appropriate if $A$ is highly nonnormal, because the eigenvalues of $A$ can be highly unstable under small perturbations, such as those associated with rounding errors in computation, and the matrix $S$ may have an extremely large condition number $\kappa(S) := \|S\|\,\|S^{-1}\|$. In the most extreme case, when $A$ has a nontrivial Jordan form, the method breaks down entirely.

In this paper we describe an approach which involves using an approximate diagonalization of $A$. We emphasize that this does not mean that it is close to a true diagonalization, but rather that it has many of the features of a true diagonalization, and the amount of error associated with using it can be estimated. We start by describing the idea and formulate a conjecture about its efficiency. Much of the remainder of this paper is devoted to providing theoretical and numerical evidence in support of the conjecture.

In section 5 we use the ideas developed to throw some light on the difficulties of computing fractional powers of matrices that are close to singular.

## 2. Definitions.

Throughout this paper we assume that $f$ is an analytic function defined on a neighborhood of $\mathrm{Spec}(A)$ and that $f(A)$ is defined by means of the holomorphic functional calculus as in [1, section 1.5]. In order to be able to define $f(A)$ stably for highly nonnormal $A$ one has to impose some conditions on the analytic function $f$. If $f(z) = (z-a)^{-1}$, where $a$ is not close to $\mathrm{Spec}(A)$, one may nevertheless have $a \in \mathrm{Spec}(\tilde{A})$, where $\|A - \tilde{A}\|$ is very small. In such situations $f(A)$ cannot be defined stably for reasons discussed in [11].

We assume henceforth that $\gamma$ is a simple closed curve with length $|\gamma|$ and that $\mathrm{Spec}(A) \subseteq U$, where $U$ is the region inside $\gamma$. We also assume that $f \in \mathcal{A}$, where $\mathcal{A}$ is the space of functions that are analytic on $\gamma \cup U$. We write $\|f\|_\infty$ for the maximum value of $|f(z)|$ for $z \in \gamma$, or equivalently for $z \in (\gamma \cup U)$.

LEMMA 2.1. [illegible] $R(z, A) := (zI - A)^{-1}$ [illegible] $\|R(z, A)\| \le c$ [illegible] $z \in \gamma$ [illegible] $f \in \mathcal{A}$ [illegible]

$$\|f(A)\| \le \frac{c}{2\pi} |\gamma| \, \|f\|_\infty.$$

[illegible] $\|A - \tilde{A}\| \le 1/(2c)$ [illegible] $\tilde{f} \in \mathcal{A}$ [illegible]

$$\|f(A) - \tilde{f}(\tilde{A})\| \le c^2 \pi^{-1} |\gamma| \, \|f\|_\infty \, \|A - \tilde{A}\| + c\pi^{-1} |\gamma| \, \|f - \tilde{f}\|_\infty.$$

[illegible]. The first bound depends on a routine estimate of the formula

$$f(A) = \frac{1}{2\pi i} \int_\gamma f(z) R(z, A) \, \mathrm{d}z.$$

We next assume that $z \in \gamma$ and use the bound

$$\begin{aligned} \|R(z, \tilde{A})\| &= \left\| R(z, A) \left( I - (\tilde{A} - A) R(z, A) \right)^{-1} \right\| \\ &\le \frac{\|R(z, A)\|}{1 - \|(A - \tilde{A}) R(z, A)\|} \\ &\le 2c \end{aligned}$$

to derive

$$\begin{aligned} \|R(z, \tilde{A}) - R(z, A)\| &= \|R(z, \tilde{A})(\tilde{A} - A) R(z, A)\| \\ &\le 2c^2 \|A - \tilde{A}\|. \end{aligned}$$

The second formula now follows by a routine estimate of the identity

$$\begin{aligned} f(A) - \tilde{f}(\tilde{A}) &= \frac{1}{2\pi i} \int_\gamma f(z) \left( R(z, A) - R(z, \tilde{A}) \right) \mathrm{d}z \\ &\quad + \frac{1}{2\pi i} \int_\gamma (f(z) - \tilde{f}(z)) R(z, \tilde{A}) \, \mathrm{d}z. \qquad \square \end{aligned}$$

[illegible] 2.2. There are two obvious ways of ensuring that the resolvent bound of Lemma 2.1 is satisfied. The first uses the stability of the numerical range $\mathrm{Num}(A)$ under small perturbations. If $\mathrm{Num}(A) \subseteq U$ and $\mathrm{dist}(\gamma, \mathrm{Num}(A)) \ge 1/c$, then the bound $\|R(z, A)\| \le c$ is valid for all $z \in \gamma$ by [11, Chapter 17] or [1, section 9.3].

Alternatively, given $c > 0$ one may define $\gamma$ to be the pseudospectral contour $\{z : \|R(z, A)\| = c\}$. The shape of the contour, which may have several components, can be determined numerically by using the Eigtool software; see [12].

We say that three matrices $S, D, B$ provide an approximate diagonalization of $A$ if $D$ is diagonal, $S$ is invertible, $B$ is small, and $A = SDS^{-1} + B$; we assume that $\|A\| \le 1$ whenever necessary for reasons stated below. We say that $S, B$ is a permitted pair for $A$ if $S$ is invertible and $D := S^{-1}(A - B)S$ is diagonal. The accuracy of the approximate diagonalization is measured by the quantity

$$\sigma(A, S, B, \varepsilon) := \kappa(S)\varepsilon + \|B\|,$$

where $\varepsilon \in (0, 1)$ is a preassigned degree of accuracy of the computations, for example, $\varepsilon := 10^{-16}$. Note that $1 = \|SS^{-1}\| \leq \|S\|\,\|S^{-1}\| = \kappa(S)$ for all $S$. The term $\kappa(S)\varepsilon$ measures errors associated with the condition number of $S$ and would vanish if the computations could have infinite precision, i.e., if $\varepsilon = 0$. The term $\|B\|$ represents the amount that $A$ has been perturbed with the intention of reducing the first type of error. By adding the two errors and then minimizing over all permitted pairs, one obtains the smallest overall error that is possible when diagonalizing $A$ approximately, namely

$$\underline{\sigma}(A, \varepsilon) := \inf_{B,S} \sigma(A, S, B, \varepsilon).$$

The nonzero entries of $D$ are the eigenvalues of $A - B$ and are of order 1 in all the cases considered below.

After choosing the perturbation $B$ the matrix $D$ is uniquely determined up to a permutation of its diagonal entries. However, one may replace $S$ by $SE$ where $E$ is any invertible matrix that commutes with $D$, for example, any invertible diagonal matrix. Different choices of $S$ may have very different condition numbers. Fortunately, the MATLAB algorithm `[S,D]=eig(A)` is known to choose a matrix $S$ whose condition number is within a factor $\sqrt{n}$ of the best (i.e., smallest) value possible [9, section 7.3], [10]; for the derogatory case, however, see [4].

Many of our theorems below can be viewed as providing support for the following conjecture.

[illegible] For every positive integer $n$ there exists $c_n$ such that

$$\underline{\sigma}(A, \varepsilon) \leq c_n \varepsilon^{1/2}$$

for every $n \times n$ matrix $A$ such that $\|A\| \leq 1$ and for every $\varepsilon \in (0, 1)$.

Since one can only evaluate $\underline{\sigma}(A, \varepsilon)$ exactly in simple cases, we attempt to obtain a fairly sharp upper bound on it by choosing $B, S$ appropriately. The rate of convergence of $\underline{\sigma}(A, \varepsilon)$ to 0 as $\varepsilon \to 0$ depends on whether $A$ is diagonalizable or not. Note that one obtains an approximate diagonalization for another matrix $\tilde{A}$ from that for $A$ by keeping the same $S, D$ and putting $\tilde{B} := B + (\tilde{A} - A)$. Therefore

$$|\underline{\sigma}(A, \varepsilon) - \underline{\sigma}(\tilde{A}, \varepsilon)| \leq \|A - \tilde{A}\|$$

and our definition is computationally stable. Further computational questions can be asked, for example, about the errors arising when evaluating $S^{-1}$ for a choice of $S$ that is close to singular, but the methods described here allow one to replace $S^{-1}$ by $T$ provided

$$\frac{\|T - S^{-1}\|}{\|S^{-1}\|} = O(\varepsilon).$$

We observe that

$$\underline{\sigma}(VAV^{-1}, \varepsilon) \leq \kappa(V)\underline{\sigma}(A, \varepsilon) \tag{2.1}$$

for all invertible matrices $V$; thus the order of magnitude of $\underline{\sigma}(A,\varepsilon)$ is not changed if one passes from $A$ to $VAV^{-1}$, where $\kappa(V)$ is of order 1. If $A$ is normal, then one may diagonalize it exactly with $S$ unitary and $B=0$, so $\underline{\sigma}(A,\varepsilon)=\varepsilon$.

A feature of our definitions of $\sigma$ and $\underline{\sigma}$ is that they do not scale under the map $A\to\lambda A$ when $\lambda$ is large. As $\lambda$ increases, $\mathrm{Spec}(\lambda A)$ and $\mathrm{Num}(\lambda A)$ expand, so the contour $\gamma$ and the algebra $\mathcal{A}$ must be changed. We therefore impose the condition $\|A\|\le 1$ whenever necessary.

The function $\underline{\sigma}(A,\varepsilon)$ is closely related to $\mu(A,\delta)$ defined for all $\delta>0$ by

$$\mu(A,\delta):=\inf\{\kappa(S): A=SDS^{-1}+B,\text{ where } D \text{ is diagonal and } \|B\|\le\delta\}.$$

A simple compactness argument implies that the infimum is actually attained.

LEMMA 2.3. [illegible] $c>0$ [illegible] $\alpha>0$ [illegible] $\mu(A,\delta)\le c\delta^{-\alpha}$ [illegible] $\delta\in(0,1)$ [illegible]

$$\underline{\sigma}(A,\varepsilon)\le 2(c\varepsilon)^{1/(\alpha+1)}$$

[illegible] $\varepsilon\in(0,1/c)$

[illegible]. If the infimum in the definition of $\mu(A,\delta)$ is attained for $A,S,D,B$, then

$$\underline{\sigma}(A,\varepsilon)\le\sigma(A,S,B,\varepsilon)\le\mu(A,\delta)\varepsilon+\delta\le c\varepsilon\delta^{-\alpha}+\delta$$

for all $\delta>0$. The lemma follows by applying the following general fact: If $f$ (resp., $g$) is a nonnegative, monotonically decreasing (resp., increasing) function on $(a,b)$ and $f(\xi)=g(\xi)$ for some $\xi\in(a,b)$, then

$$f(\xi)\le\inf\{f(x)+g(x):x\in(a,b)\}\le 2f(\xi).$$

THEOREM 2.4. [illegible] $\|A\|\le 1$ [illegible] $f(z)$ [illegible] $\{z:|z|\le r\}$ [illegible] $r>1$ [illegible] $\underline{\sigma}(A,\varepsilon)<(r-1)/2$ [illegible]

$$\underline{\sigma}(f(A),\varepsilon)<\underline{\sigma}(A,\varepsilon)\max\left\{1,\frac{2r\|f\|_{r,\infty}}{(r-1)^2}\right\},$$

[illegible]

$$\|f\|_{r,\infty}:=\max\{|f(z)|:|z|\le r\}.$$

[illegible]. If $\tilde{A}:=SDS^{-1}$, then $\|A-\tilde{A}\|=\|B\|\le\sigma(A,S,B,\varepsilon)$ and we can define $\tilde{B}$ by

$$f(A)=f(\tilde{A})+\tilde{B}=Sf(D)S^{-1}+\tilde{B}.$$

If $r>1$ and $\gamma$ is the circle $\{z:|z|=r\}$, then $\|R(z,A)\|\le(r-1)^{-1}$ for all $z\in\gamma$. Lemma 2.1 implies that if $\sigma(A,S,B,\varepsilon)<(r-1)/2$, then

$$\|\tilde{B}\|\le\|B\|\,\frac{2r\|f\|_{r,\infty}}{(r-1)^2}.$$

Therefore

$$\sigma(f(A),S,\tilde{B},\varepsilon)=\kappa(S)\varepsilon+\|\tilde{B}\|\le\sigma(A,S,B,\varepsilon)\max\left\{1,\frac{2r\|f\|_{r,\infty}}{(r-1)^2}\right\}.$$

The theorem now follows by taking the infimum over all permitted $S,B$.

We next establish a close connection between the above ideas and the existence of a suitable basis of (column) pseudo-eigenvectors. The results obtained are only of interest when $\|B\|$ and all $\|r_j\|$ are very small.

THEOREM 2.5. [illegible] $A = SDS^{-1} + B$ [illegible] $D$ [illegible] $\lambda_1, \dots, \lambda_n$ [illegible] $j$ [illegible] $\phi_j$ [illegible] $S$ [illegible] $j$ [illegible]

$$A\phi_j = \lambda_j \phi_j + r_j, \tag{2.2}$$

[illegible]

$$\|r_j\| \le \|B\|$$

[illegible] $j$

[illegible]. Applying the identity $AS = SD + BS$ to the standard basis elements $\{e_1, \dots, e_n\}$ of $\mathbf{C}^n$ yields (2.2) with $r_j := B\phi_j$. The bound follows immediately.

The above theorem has the following partial converse.

THEOREM 2.6. [illegible] $\{\phi_1, \dots, \phi_n\}$ [illegible] $\mathbf{C}^n$ [illegible] $\|\phi_j\| = 1$ [illegible]

$$A\phi_j = \lambda_j \phi_j + r_j \tag{2.3}$$

[illegible] $j \in \{1, \dots, n\}$ [illegible] $\lambda_j \in \mathbf{C}$ [illegible] $r_j \in \mathbf{C}^n$ [illegible] $R, S$ [illegible] $n \times n$ [illegible] $R := [r_1 \dots r_n]$ [illegible] $S := [\phi_1 \dots \phi_n]$ [illegible] $A = SDS^{-1} + B$ [illegible] $B := RS^{-1}$ [illegible] $D$ [illegible] $\lambda_1, \dots, \lambda_n$ [illegible]

$$1 \le \|S\| \le \sqrt{n}$$

[illegible]

$$\|B\| \le \|S^{-1}\| \left\{ \sum_{j=1}^{n} \|r_j\|^2 \right\}^{1/2}.$$

[illegible]. Equation (2.3) may be rewritten in the form $AS = SD + R$ by concatenating the columns. This implies $B = RS^{-1}$. We also have

$$1 \le \|S\| \le \|S\|_{\mathrm{HS}} = \sqrt{n},$$

where $\|\cdot\|_{\mathrm{HS}}$ is the Hilbert–Schmidt, or Frobenius, norm. Similarly,

$$\|B\| \le \|S^{-1}\|\,\|R\| \le \|S^{-1}\|\,\|R\|_{\mathrm{HS}} = \|S^{-1}\| \left\{ \sum_{j=1}^{n} \|r_j\|^2 \right\}^{1/2}.$$

## 3. Evidence supporting the conjecture.

We start by proving our conjecture for Jordan matrices.

LEMMA 3.1. [illegible] $J$ [illegible] $n \times n$ [illegible]

$$J_{r,s} := \begin{cases} 1 & \text{[illegible] } s = r + 1, \\ 0 & \text{[illegible]}. \end{cases} \tag{3.1}$$

[illegible]

$$1 \le \mu(J, \delta) \le \delta^{-1+1/n} \le \delta^{-1} \tag{3.2}$$

[illegible] $\delta \in (0,1)$ [illegible]

$$0 \le \underline{\sigma}(J,\varepsilon) \le 2\varepsilon^{n/(2n-1)} \le 2\varepsilon^{1/2} \tag{3.3}$$

[illegible] $\varepsilon \in (0,1)$

[illegible] We define $B$ by

$$B_{r,s} := \begin{cases} -\delta & \text{if } r = n \text{ and } s = 1, \\ 0 & \text{otherwise,} \end{cases}$$

and $T$ by

$$T_{r,s} := \begin{cases} \delta^{-r/n} & \text{if } r = s, \\ 0 & \text{otherwise.} \end{cases} \tag{3.4}$$

A direct calculation shows that

$$T(J-B)T^{-1} = \delta^{1/n}U,$$

where $U$ is the circulant and unitary matrix with entries

$$U_{r,s} := \begin{cases} 1 & \text{if } s = r+1, \\ 1 & \text{if } r = n \text{ and } s = 1, \\ 0 & \text{otherwise.} \end{cases}$$

If $F$ is the finite Fourier transform whose matrix

$$F_{r,s} := n^{-1/2}\mathrm{e}^{2\pi i rs/n}$$

is unitary, then

$$FUF^{-1} = D,$$

where $D$ is the diagonal matrix with entries $\lambda_r = \mathrm{e}^{2\pi i r/n}$, for $1 \le r \le n$. Putting $S := FT$ we finally obtain

$$J = S^{-1}(\delta^{1/n}D)S + B.$$

Since $\|T\| = \delta^{-1}$ and $\|T^{-1}\| = \delta^{1/n}$ we deduce that $\kappa(S) = \delta^{-1+1/n}$. This implies (3.2). The corresponding upper bound on $\underline{\sigma}$ is obtained by applying Lemma 2.3.

[illegible] 3.2. We compare the above theoretical result with what can be obtained numerically. We defined $J$ by (3.1) with $n = 25$ and evaluated $f(\delta) := \delta^{1-1/n}\kappa(S)$ for 200 randomly generated matrices $B$ with norms equal to $\delta$ for a range of values of $\delta$. The matrices $S$ and $D$ were defined by using the MATLAB command `[S,D]=eig(A-B)`. In Table 3.1, $\min(f(\delta))$ is the minimum value of $f(\delta)$ obtained and $\mathrm{med}(f(\delta))$ is the median value. We also took a sample of 2000 such matrices $B$ and found that all the values of $\min(f(\delta))$ remained larger than 2. The similarity of the numerical results to what was proved in Lemma 3.1 suggests that both are close to the optimal bound.

The following corollary does not prove the conjecture because the constant obtained depends on the matrix involved, not just on the dimension. It is known that finding the Jordan canonical form is an inherently unstable problem [6, p. 390], [7].

Table 3.1
*Computation of condition numbers in Example* 3.2.

| $\delta$ | $\min(f(\delta))$ | $\mathrm{med}(f(\delta))$ |
|---|---|---|
| $10^{-1}$ | 3.67 | 17.91 |
| $10^{-2}$ | 4.15 | 22.09 |
| $10^{-3}$ | 3.29 | 22.25 |
| $10^{-4}$ | 3.78 | 25.57 |
| $10^{-5}$ | 3.88 | 25.95 |
| $10^{-6}$ | 3.32 | 24.04 |
| $10^{-7}$ | 3.83 | 20.51 |
| $10^{-8}$ | 3.72 | 24.99 |

Corollary 3.3. [illegible] $n \times n$ [illegible] $A$ [illegible] $c_A$ [illegible]

$$\underline{\sigma}(A,\varepsilon) \le c_A \varepsilon^{1/2}$$

[illegible] $\varepsilon \in (0,1)$

[illegible]. If $A = V\tilde{J}V^{-1}$, where $\tilde{J}$ is a Jordan canonical form for $A$, then (2.1) implies that

$$\underline{\sigma}(A,\varepsilon) \le \kappa(V)\underline{\sigma}(\tilde{J},\varepsilon).$$

By applying the method of Lemma 3.1 to each Jordan block of $\tilde{J}$, we obtain the corollary.

We next prove the conjecture for triangular Toeplitz matrices.

Theorem 3.4. [illegible] $\alpha_0, \alpha_1, \ldots, \alpha_{n-1}$ [illegible] $\sum_{r=0}^{n-1} |\alpha_r| \le 1$ [illegible] $A$ [illegible] $n \times n$ [illegible]

$$A_{r,s} := \begin{cases} \alpha_{s-r} & \text{[illegible] } s \ge r, \\ 0 & \text{[illegible]}. \end{cases}$$

[illegible]

$$\underline{\sigma}(A,\varepsilon) \le 2\varepsilon^{n/(2n-1)} \le 2\varepsilon^{1/2}$$

[illegible] $\varepsilon \in (0,1)$

[illegible]. If we define $B$ by

$$B_{r,s} := \begin{cases} -\delta\alpha_{s-r+n} & \text{if } s < r, \\ 0 & \text{otherwise,} \end{cases}$$

where $\delta \in (0,1)$ is to be determined, then $\|B\| \le \delta$. If we define $T$ by (3.4), then a direct calculation shows that

$$C := T(A-B)T^{-1}$$

is the circulant matrix with entries

$$C_{r,s} := \alpha_{s-r}\delta^{(s-r)/n},$$

where we replace $s-r$ by $s-r+n$ if the former expression is negative. If $F$ is the finite Fourier transform, then

$$D := FCF^{-1}$$

is a diagonal matrix. Putting $S := FT$ as before we obtain $\kappa(S) = \delta^{-1+1/n}$ and

$$A = S^{-1}DS + B.$$

Putting $\delta := \varepsilon^{n/(2n-1)}$ we obtain

$$\underline{\sigma}(A, \varepsilon) < 2\varepsilon^{n/(2n-1)}.$$

We have not been able to prove the conjecture for general $n \times n$ matrices; Theorem 3.9 below is the closest that we have got to it. We originally proved it under the assumption that the eigenvalues of $A$ were collinear. The general case depends on the following theorem of Friedland [5]. Its proof depends on using the degree mod 2 of a smooth map between manifolds of equal dimension, and it would be valuable to obtain a constructive version. This may not be easy, because the number of normal "extensions" $N$ of $Q$ varies from 1 to $\infty$ (inclusive) depending on $Q$.

THEOREM 3.5 (see Friedland [5]). [illegible] $n \times n$ [illegible] $Q$ [illegible] $L$ [illegible] $N := Q + L$ [illegible]

[illegible] 3.6. A direct construction of the matrix $L$ in the theorem is not elementary even in the case of $3 \times 3$ matrices. If the eigenvalues of the upper triangular matrix $Q$ are collinear, then we may construct $L$ as follows. We first write $Q$ in the form $Q = cI + \mathrm{e}^{i\theta}(D + U)$, where $c \in \mathbf{C}$, $\theta \in \mathbf{R}$, $D$ is a real diagonal matrix, and $U$ is strictly upper triangular. If we define $L := \mathrm{e}^{i\theta}U^*$, then $Q + L = cI + \mathrm{e}^{i\theta}H$, where $H$ is self-adjoint, and this implies that $Q + L$ is normal.

LEMMA 3.7. [illegible] $N := Q + L$ [illegible] $Q$ [illegible] $L$ [illegible] $\nu(Q) = \nu(L)$ [illegible]

$$\nu(A) := \sum_{r,s} |r - s||A_{r,s}|^2.$$

[illegible] We have

$$\begin{aligned} \nu(Q) - \nu(L) &= \sum_{r,s} (s - r)|N_{r,s}|^2 \\ &= \mathrm{tr}[N^*EN] - \mathrm{tr}[N^*NE] \\ &= \mathrm{tr}[(NN^* - N^*N)E] \\ &= 0, \end{aligned}$$

where

$$E_{r,s} := \begin{cases} r & \text{if } r = s, \\ 0 & \text{otherwise.} \end{cases}$$

Further comparisons between the size of $Q$ and $L$ can be obtained by replacing $E$ by

$$E_{r,s} := \begin{cases} f(r) & \text{if } r = s, \\ 0 & \text{otherwise,} \end{cases}$$

where $f$ is any monotonic function on $\{1, \ldots, n\}$.

LEMMA 3.8. [illegible] $\nu(A) \le n^2\|A\|^2$ [illegible] $n \times n$ [illegible] $A$ [illegible] $A$ [illegible] $\|A\|^2 \le \nu(A)$

[illegible]. We have

$$\nu(A) \le n \sum_{r,s} |A_{r,s}|^2 = n \sum_{s=1}^{n} \|Ae_s\|^2 \le n^2 \|A\|^2,$$

where $\{e_s\}_{s=1}^n$ is the standard basis of $\mathbf{C}^n$.

If the diagonal entries of $A$ vanish, then the second inequality follows from

$$\|A\|^2 \le \|A\|_{\mathrm{HS}}^2 \le \nu(A).$$

Theorem 3.9. [illegible] $A$ [illegible] $n \times n$ [illegible] $\|A\| \le 1$ [illegible]

$$\underline{\sigma}(A, \varepsilon) \le (1+n)\varepsilon^{2/(n+1)}$$

[illegible] $\varepsilon \in (0,1)$ [illegible]

$$\underline{\sigma}(A, \varepsilon) < 4\varepsilon^{1/2}$$

[illegible] $3 \times 3$ [illegible] $A$ [illegible] $\|A\| \le 1$

[illegible]. By the Schur decomposition there exists a unitary matrix $U$ such that $P := U^{-1}AU$ is upper triangular. If $0 < \delta < 1$ and

$$V_{r,s} := \begin{cases} \delta^r & \text{if } r = s, \\ 0 & \text{otherwise,} \end{cases}$$

then $Q := V^{-1}PV$ is upper triangular and

$$\nu(Q) \le \delta^2 \nu(P) \le \delta^2 n^2 \|P\|^2 \le \delta^2 n^2.$$

By Friedland's theorem there exists a strictly lower triangular matrix $L$ such that $Q + L$ is normal and $\nu(L) = \nu(Q)$. A direct calculation establishes that

$$\|VLV^{-1}\|^2 \le \nu(VLV^{-1}) \le \delta^2 \nu(L) = \delta^2 \nu(Q) \le \delta^4 n^2.$$

Therefore $B := -UVLV^{-1}U^{-1}$ satisfies $\|B\| \le \delta^2 n$. Hence

$$V^{-1}U^{-1}(A - B)UV = Q + L = WDW^{-1},$$

where $D$ is diagonal and $W$ is unitary. Putting $S := UVW$ we obtain $A = SDS^{-1} + B$, where $\kappa(S) = \kappa(V) = \delta^{1-n}$. Therefore

$$\underline{\sigma}(A, \varepsilon) \le \delta^{1-n}\varepsilon + n\delta^2.$$

The result now follows by putting $\delta := \varepsilon^{1/(n+1)}$.

**4. Random perturbations.** The above methods of constructing $B$ and $S$ are too simple to prove the conjecture for $n > 3$. In this section we describe a randomized approximate diagonalization method (RADM), suggested to us by L. N. Trefethen, which provides numerical evidence in support of the conjecture. Numerically it is remarkably effective.

If the $n \times n$ matrix $A$ cannot be diagonalized or can only be diagonalized by means of a matrix $S$ whose condition number is extremely large, then one can instead diagonalize the matrix $A - B$, where $B$ is a small random perturbation. We found experimentally that for a variety of strictly upper triangular $n \times n$ matrices $A$ (none of which can be diagonalized) with $n = 100$ and $\varepsilon := 10^{-16}$ one has $\underline{\sigma}(A, \varepsilon) \le 3 \times 10^{-7}$. In each case we minimized over 100 randomly chosen $B$ such that $\|B\| = 10^{-8}$. On the other hand, for a series of 100 matrices of the form `A=rand(n)` with $n = 100$ and $B = 0$ we found that $50 \le \kappa(S) \le 1000$ in every case; our methods are not necessary for such matrices. In the computations that follow the random perturbation was of the form `B=s*randn(n)`, where $s$ is a small constant. However, we got the same results with small random perturbations `B=s*randn(n,1)*randn(1,n)` of rank one.

One can use RADM to evaluate $A^\alpha$ and other similar functions of $A$. Our conclusion from a range of such problems, some described below, is that RADM is less accurate than standard MATLAB algorithms when the matrix $A$ is quite close to being normal. If $A$ is far from normal and has a small eigenvalue, then the two methods have comparable accuracy. For many functions one cannot apply the MATLAB algorithm `funm`, described in [2], but RADM still yields a result whose accuracy can be confirmed by repeating the computation with another choice of the random perturbation.

[illegible] 4.1. We consider the $n \times n$ matrix

$$A_{r,s} := \begin{cases} r/n & \text{if } s = r+1, \\ 0 & \text{otherwise.} \end{cases} \tag{4.1}$$

We put $n := 100$ and defined

```
B1=randn(n)
B=10^(-u)*B1/norm(B1)
[S,D] = eig(A-B)
```

in the notation of MATLAB. We computed $\sigma(A, S, B, \varepsilon)$ and $\log_{10}(\kappa(S))$ for $\varepsilon = 10^{-16}$ and $1 \le u \le 15$. Table 4.1 shows that $\sigma(A, S, B, \varepsilon)$ took its minimum value for $\|B\| \sim 10^{-7}$ but that the condition number of $S$ increased steadily as $u$ increased. The minimum value of $\sigma$ is of order $\varepsilon^{1/2}$.

We also carried out a computation in which the entries $r/n$ in (4.1) were replaced by randomly chosen numbers. The conclusions were similar.

TABLE 4.1

**5. Fractional powers.** The definition of the square root of an $n \times n$ matrix $A$ is not as straightforward as it appears. If $A$ has $n$ distinct nonzero eigenvalues, then it has exactly $2^n$ square roots, which commute pairwise. On the other hand, the matrices 0 and 1 have a continuum of noncommuting square roots. If $A^n = 0$ but $A^{n-1} \neq 0$, then $A$ has no square root, but $A^2$ has a continuum of commuting square roots, namely $A + cA^{n-1}$ for any choice of $c$. If $A$ has $n$ distinct nonzero eigenvalues but two (or more) of these are approximately equal, then it may have a large number of pairwise noncommuting approximate square roots. One may avoid these ambiguities by using the holomorphic functional calculus to define $A^{1/2}$ and choosing the branch of $z^{1/2}$ that has a cut along the negative real axis.

[illegible] 5.1. Let $A$ be the $n \times n$ matrix

$$(A)_{r,s} := \begin{cases} r/n & \text{if } s = r+1, \\ c & \text{if } s = r, \\ 0 & \text{otherwise,} \end{cases} \tag{5.1}$$

where $0 < c < 1$. All such matrices satisfy $\|A\| \leq 2$ rather than $\|A\| \leq 1$ so a slight adjustment of the theory is needed. We computed $A^{1/2}$ for various values of $c$ when $n := 20$ by two methods and presented the results in Table 5.1. We compared $\|E^2 - A\|$, where $E$ is the square root computed by using RADM, with $\|F^2 - A\|$, where `F=sqrtm(A)` in the notation of MATLAB.

If one only looks at the third column of Table 5.1 one sees that the algorithm `sqrtm` is not accurate for $c < 0.1$. The situation for RADM is not as straightforward. Column 2 wrongly suggests that RADM is reasonably accurate for all values of $c$ investigated. However, column 4 shows that $\|E\|$ increases rapidly as $c$ decreases, while column 5 presents the ratio of two values of $\|E\|$ computed with two different random perturbations $B_i$, both satisfying $\|B_i\| = 10^{-8}$. One sees that the two values of $\|E\|$ obtained are quite different if $c < 0.2$, even though $\|E^2 - A\| = O(10^{-8})$ in both cases. This is possible because the map $A \to A^{1/2}$ varies very rapidly for small values of $c$ in spite of Lemma 2.1. If one only wants an approximate square root of $A$, then RADM works well for all $c$ investigated, but it does not produce a good approximation to the exact square root of $A$ for $c < 0.2$.

Our intention above was to illuminate the problems involved in computing square roots rather than to advocate the use of a particular method, but if one wishes to use RADM it is recommended that one should check that two successive applications with different random perturbations yield the same answer to within $O(10^{-8})$.

TABLE 5.1
*Computation of square roots in Example* 5.1.

| | RADM | sqrtm | | |
|---|---|---|---|---|
| $c$ | $\|E^2 - A\|$ | $\|F^2 - A\|$ | $\|E\|$ | $\|E_1\|/\|E_2\|$ |
| 0.8 | $3.0453e - 008$ | $1.8228e - 016$ | 1.2743 | 1 |

| 0.3 | $6.2193e - 008$ | $1.3148e - 014$ | 103.7 | 1.0001 |
| 0.2 | $2.6138e - 008$ | $3.2596e - 012$ | $2.0706e + 004$ | 0.97515 |
| 0.1 | $2.0012e - 008$ | $6.3565e - 008$ | $3.3292e + 006$ | 0.50668 |
| 0.05 | $2.8685e - 008$ | 0.0074873 | $3.0604e + 006$ | 0.55402 |
| 0.02 | $2.2364e - 008$ | 93768 | $9.1859e + 006$ | 0.71102 |
| 0.01 | $1.453e - 008$ | $5.5561e + 008$ | $2.2661e + 007$ | 0.89547 |

Let $A$ be an $n \times n$ matrix whose numerical range is contained in $\{z : \mathrm{Re}(z) \geq 0\}$ and contains some points very close to 0. Suppose that one wishes to compute $A^t$ for $0 \leq t \leq 1$. The formula

$$A^t = \mathrm{e}^{t \log(A)}$$

is not recommended because $\log(A)$ may have a very large norm, and it is undefined if 0 is an eigenvalue of $A$. An accuracy of $10^{-8}$ is more than sufficient for plotting the graph of $f(t) := \|A^t\|$, and RADM provides a way of doing this with a minimum of effort. Many other applications of a similar character can easily be devised.

There are four other possible methods of evaluating $A^t$. If $A = I - B$, where $\|B\| \le 1$, then

$$\mathrm{Spec}(A) \subseteq \mathrm{Num}(A) \subseteq \{z : |z-1| \le 1\}.$$

If $s > 0$, then one may define $A^s$ by

$$A^s := \frac{1}{2\pi i} \int_\gamma z^s (zI - A)^{-1} \, \mathrm{d}z,$$

where $\gamma$ is the boundary of the region

$$\{r\mathrm{e}^{i\theta} : 0 < r < 5/2 \text{ and } -3\pi/4 < \theta < 3\pi/4\}.$$

Every point on $\gamma$ except 0 is outside the numerical range of $A$, so the resolvent norm is of order 1 except near 0. The integral is norm convergent for all $s > 0$, but it may develop a singularity at $z = 0$ as $s \to 0+$, so it is not always useful for small $s$.

Alternatively, one might use the expansion

$$A^s = I - \sum_{r=1}^{\infty} c_{r,s} B^r,$$

where

$$c_{r,s} := (-1)^{r+1} s(s-1) \cdots (s-r+1)/r!.$$

The series is norm convergent for all $s \in (0,1)$ because $c_{r,s} \ge 0$ and $\sum_{r=1}^{\infty} c_{r,s} = 1$. However, the convergence of the series is very slow for small $s > 0$, so it is not numerically useful for such $s$. Both of these problems are apparent if 1 is an eigenvalue of $B$, but they also occur if the pseudospectra of $B$ are significant near 1, even if $B$ has no spectrum near 1.

We finally mention that one may also evaluate $A^s$ by using [8] if $s = 1/n$ and by the ODE method of [3].

[illegible] 5.2. We used RADM to compute the $r$th root $C_r$ of the matrix (5.1), with $c := 0.5$, $n = 20$, and $r = 1, \ldots, 10$. Other real powers may be treated in exactly the same way. In the final column of Table 5.2, $C_{r,1}$ and $C_{r,2}$ are two independent computations of $C_r$, both obtained using RADM. The small size of the entries in this column indicates that the results are all reliable to $O(10^{-8})$.

We finally remark that if greater accuracy is needed, then one may use the above procedure to obtain the starting point for a Newton-type iteration.

We used RADM to compute $\|A^t\|$ for the matrix (5.1) with $n = 100$ and $c = 0.6$. We put $t := 2^{-7}r$, where $r$ is a positive integer, $v_1 := \|A^t\|$ computed using RADM, and $v_2 := \|B^r\|$, where $B := A^{1/128}$ is computed by repeated applications of the MATLAB operator `sqrtm`. The two methods give the same answer to within 0.04 for all $t \in (0,2)$, i.e., a relative accuracy of $10^{-4}$. This may seem rather low, but it is more than enough for graph-drawing needs. Both methods computed the norm of $A$ and $A^2$ correctly. Most of the CPU time was used computing the matrix norms, but

TABLE 5.2
*Computation of* $r$*th roots in Example* 5.2.

| $r$ | $\|(C_r)^r - A\|$ | $\|C_r\|$ | $\|C_{r,1}\|/\|C_{r,2}\| - 1$ |
|---|---|---|---|
| 1 | $3.4677e - 007$ | 1.33558842 | $-2.1906e - 009$ |
| 2 | $1.4319e - 007$ | 1.35606917 | $8.9048e - 009$ |

| 4 | $1.0367e - 007$ | 1.59766857 | $4.9686e - 008$ |
| 5 | $7.8846e - 008$ | 1.55852362 | $8.1706e - 008$ |
| 6 | $4.6441e - 008$ | 1.50671663 | $2.3817e - 009$ |
| 7 | $8.0153e - 008$ | 1.45657560 | $5.0527e - 008$ |
| 8 | $7.5740e - 008$ | 1.41197706 | $-4.5141e - 008$ |
| 9 | $2.2498e - 007$ | 1.37341090 | $5.3190e - 008$ |
| 10 | $7.8768e - 008$ | 1.34032556 | $1.1992e - 007$ |

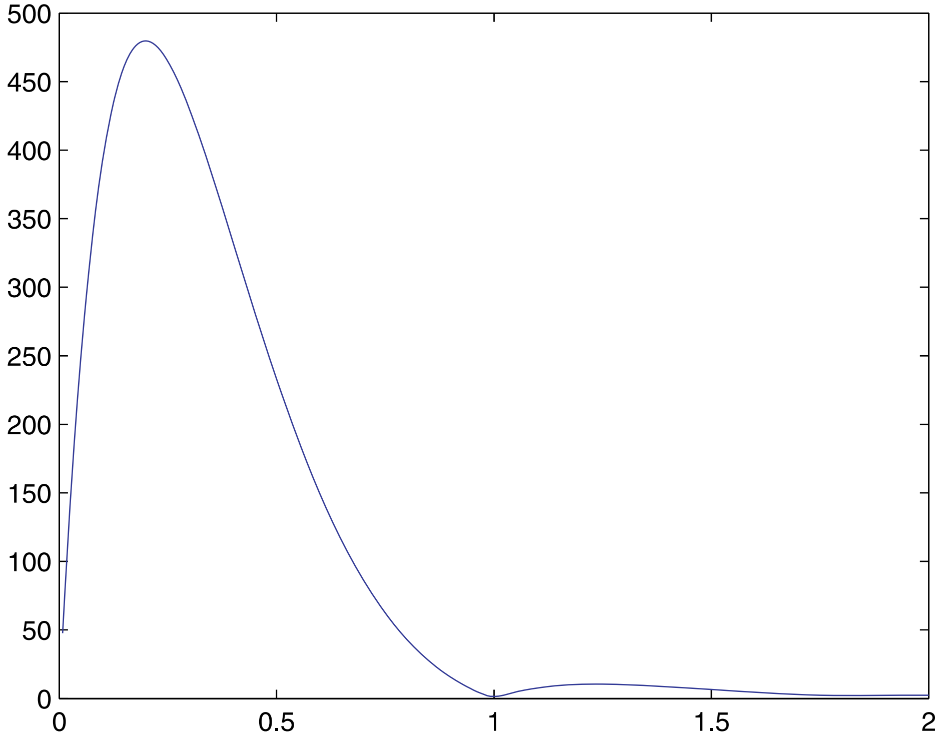

FIG. 5.1. *Graph of* $\|A^t\|$ *for* $0 < t < 2$.

excluding that RADM is substantially faster because it involves one application of `eig` as opposed to seven applications of `sqrtm`. For values of $c$ much smaller than 0.6, neither RADM nor `sqrtm` is accurate. One might also compute $B$ directly using the new algorithm of Guo and Higham [8]. Figure 5.1 shows the graph of the norm and is typical of problems in which pseudospectral behavior is important.

# ANALYSIS AND EXPLOITATION OF MATRIX STRUCTURE ARISING IN LINEARIZED OPTICAL TOMOGRAPHIC IMAGING*

DAMON HYDE†, MISHA KILMER‡, DANA H. BROOKS†, AND ERIC MILLER§

**Abstract.** We present a novel method by which the large dense forward matrix **A** involved in a linear inverse diffusion problem can be decomposed into a number of sparse easily computed matrices. We begin by introducing an errorless decomposition which is applicable to a wide array of such imaging problems. Next, we incorporate interpolation into the construction of the matrices to reduce the computational complexity involved in the matrix-vector multiplications necessary to obtain an inverse solution. Error and computational complexity analysis are provided to support these developments. We then present numerical results that illustrate the gain in computational efficiency when the approximation is used in the Tikhonov regularized inverse problem, and show that the use of the approximation has virtually no negative effect on the quality of the reconstructed images. Finally, we discuss applicability to other imaging problems.

## 1. Introduction.

In diffuse optical tomography (DOT), near-infrared light is introduced to the body from an array of sources on the surface and collected at a number of detectors as it exits [3, 7, 8, 12, 15, 17, 26, 27]. The imaging problem consists of determining images of photon absorption and/or diffusion in the body from this measured photon fluence. In this paper, we consider the problem of efficient image reconstruction from diffuse optical data. Using a linearized model of the relationship between the data and optical absorption coefficient, the specific problem we consider is the efficient solution of the Tikhonov regularized problem:

$$\min_{\mathbf{f}} \|\mathbf{A}\mathbf{f} - \mathbf{g}\|_2^2 + \lambda \|\mathbf{R}\mathbf{f}\|_2^2, \tag{1.1}$$

where the real $N_{data} \times N_{vox}$ matrix **A** is a discretization of a Born-type linearized inverse scattering operator in three dimensions (i.e., the discretization of an integral operator), **f** denotes the vectored form of the absorption image to be determined, and **g** denotes the measured data vector. The regularization term $\lambda\|\mathbf{R}\mathbf{f}\|_2^2$ is necessary to dampen the effects of noise on the quality of the reconstructions as well as to ensure uniqueness of the solution. We employ iterative algorithms as a computationally attractive means to solve (1.1). The nature of these methods is such that the matrix **A** need be utilized only for multiplications of the form $\mathbf{A}\mathbf{x}$ and $\mathbf{A}^T\mathbf{x}$ for an arbitrary

vector $\mathbf{x}$, and the problem can be solved efficiently for multiple values of $\lambda$ simultaneously. This allows us to concentrate on optimizing for matrix-vector multiplications rather than the more complicated matrix-matrix multiplications.

Though a number of different nonlinear algorithms are currently in use for DOT [6, 7, 8, 29, 25, 27], the associated data sets are generally quite small (on the order of several hundred data points). Technologically, however, sensor systems are rapidly evolving to provide greater spatial density of sources and detectors as well as finer scale sampling in time or frequency. Thus, the size of the data sets available for inversion is increasing far beyond what is typically considered in the nonlinear inversion literature. Scaling these algorithms to larger data sets, such as those considered in this paper, drastically increases the required computational power and makes application of the nonlinear inverse methods either completely infeasible or quite difficult—significant effort and new research would be required in the implementation of these methods on supercomputing-type platforms. Such efforts are indeed well beyond the capabilities of many relevant research and industrial organizations (e.g., Advanced Research Technologies (ART), who provided us with the phantom data used in this paper). In such settings the linear solution is the only feasible approach to the problem. Thus, though nonlinear methods for DOT are certainly under consideration, there remains relevance to considering the linear form of the problem as well.

Toward this end, we point to recent research using linear methods for DOT and related areas where the results presented here may prove relevant [4, 9, 14, 16, 18, 19, 30]. Moreover, we emphasize that the methods we present in this paper are really only loosely dependent upon the specific form of the Green's functions. As long as (a) the Green's functions are smooth and display some level of spatial invariance and (b) the data collection scheme is also regular, the methods detailed here will be usable. This makes our work relevant to a wide range of problems, of which DOT is but a single application. For example, the ideas here could be applicable to any large scale diffusive-type inverse problem (where data set size and voxel dimensionality prevent the use of nonlinear methods) such as diffusive-type electromagnetic induction imaging arising in geophysical applications, photothermal/photoacoustic nondestructive evaluation, bioluminescence tomography (BLT), and fluorescence molecular tomography (FMT). As a specific example, take FMT [21, 20]. When imaging fluorescence, the collected fluorescence data are approximately linearly related to the image, and using methods such as the normalized Born ratio, it is possible to minimize the effects of inhomogeneities in the background optical parameters [28]. Moreover, for this problem, the development of CCD detectors and tomographic data acquisition systems is leading to imaging problems even larger than those considered here. Thus we would anticipate that large computational gains could be achieved using the method in this paper.

The difficulty in practice with solving the Tikhonov problem is that the matrix $\mathbf{A}$ is dense and extremely large, with $N_{data}$ and $N_{vox}$ being on the order of $10^4$–$10^5$. For this work, we restricted ourselves to working with a system configuration consisting of a slab transmission geometry using time domain data collection. In this configuration, the region to be imaged is modeled as the volume contained between two parallel infinite planes. The solution volume is then a compact finite section of this infinite volume [12, 15]. Sources are located along one plane, directed into the volume, while detectors are arrayed along the other plane to collect exiting light. At each source location a picosecond laser is pulsed, and the time dependent intensity is recorded at a number of detectors for time gates of several nanoseconds. Given that each detector may collect hundreds or even thousands of time points for each source pulse, the total data set rapidly becomes extremely large. In systems of this sort, it is not uncommon to see hundreds of thousands of data points collected in a single imaging session. Thus, even with a very small number of voxels, the size of **A** rapidly becomes prohibitive. Storing such a matrix in double precision can require gigabytes of storage space and thereby renders useless any algorithm requiring the up-front computation of **A**.

Therefore, our primary goal is to represent the full matrix **A** such that both the time required for its computation and the necessary storage space are significantly reduced. In particular, we look to exploit the structure of the matrix **A** so that redundant matrix entries are not explicitly computed/stored. These redundancies arise from a combination of the regularity in the data acquisition process and the structure of the Green's functions used to compute the matrix elements. As we will show, only a relatively small amount of information is needed to implicitly represent every matrix entry, so matrix-vector products can be performed on-the-fly simply by reference to a particular source-detector pattern and the small amount of stored information. However, even with a more compact representation, a significant amount of time is still required to evaluate matrix-vector products involving these matrices. Given that these products may need to be evaluated numerous times to obtain a solution, a secondary goal of this work was the reduction of the computational complexity involved in executing matrix-vector products. To do this, we effectively replace the implicit representation of **A** by an approximation that can be applied to vectors more quickly without degradation of the reconstructed images.

To achieve the first goal, we take into account the spatial invariance of the integral equation kernel from which **A** is derived. Using a change of variables, we are able to exploit the matrix redundancies more readily. This allows us to represent **A** in terms of the product of a single small matrix and a collection of sparse, easily computed matrices. This decomposition is made possible by a regular sampling pattern and planar shift invariance in the kernel.

To achieve the second goal, we introduce an interpolation approach, applied in the aforementioned coordinate system, to further reduce the number of matrix components that must be explicitly computed. The utility of the interpolation approach arises from the smoothness of the kernel of the integral equation from which **A** is derived. In turn, this suggests applicability to other diffusing imaging problems with similarly smooth kernels. By choosing an interpolation method which is expressible in matrix form, we are then able to achieve reduction in the amount of computation required to implement the matrix vector products $\mathbf{Ax}$ and $\mathbf{A}^T\mathbf{x}$. These gains are shown to be directly proportional to the number of nodes used in the interpolation scheme, allowing for a direct tradeoff between computation time and accuracy.

Applying these two steps to the overall problem at hand, we are able to obtain a dramatic decrease in the amount of time required to obtain a solution to the problem (1.1) using an iterative algorithm. We present several sets of numerical results, both with and without the use of interpolation, to approximate **A**. Using phantom simulations, we show that while the two solutions are not identical, visually they are very similar, and mathematically they have effectively the same mean squared error with respect to the true image.

This paper is organized as follows. In section 2, we provide an overview of the physics and mathematics behind the construction of the matrix **A**. In section 3.1, we show how to represent the matrix in compact form. Section 3.2 is devoted to presenting an interpolation-based approximation to the matrix. Section 4 details the precise reductions in computational complexity. Inversion results using the algorithm in [13] on a simulated data set are presented in section 5 along with an analysis of the error introduced by the interpolation. Finally, in section 6, we summarize our results and outline potential further extensions.

**2. Problem description.** The diffusion approximation model arises as an approximation to the radiative transport equation [5], and takes the form [2]

$$\left(\nabla \cdot \gamma^2 \nabla - \mu_a - \frac{1}{v}\frac{\partial}{\partial t}\right)\Phi(\mathbf{r},t) = -q(\mathbf{r},t), \qquad \gamma^2 = \frac{1}{3[\mu_a + (1-\bar{p})\mu_s]}. \tag{2.1}$$

Here, $\Phi(\mathbf{r},t)$ represents the photon density at a location $\mathbf{r}$ and time $t$. Sources are represented by $q(\mathbf{r},t)$. The two physical parameters of interest are $\mu_a$ and $\mu_s$, the absorption and scattering parameters, respectively. Additionally, $v$ is the speed of light in the medium, and $\bar{p}$ is the mean cosine of the scattering angle.

The goal in this work is to recover $\mu_a$, assuming that $\mu_s$ is constant, given knowledge of the sources. Since it is clearly a nonlinear problem to recover $\mu_a$ from (2.1), the equation is frequently linearized by assuming that the overall system is approximately homogeneous. One can then use Green's functions for the homogeneous case to reformulate the imaging problem as one of finding the perturbation about some known background absorption level. Therefore, we let $\mu_a$, $\mu_s$ denote the known background values of absorption and scattering, and we use $\eta(\mathbf{r}')$ to denote the unknown perturbations of absorption about the known background value.

Assuming that the source term $q(\mathbf{r},t)$ is a delta function located at position $\mathbf{r}$ and time $t$, a solution $\Phi$ in the form of a Green's function can be derived. For the slab transmission geometry that we consider in this paper, the two-point time domain Green's function is [1]

$$\begin{aligned} g_{slab}^{(\Phi)}(\mathbf{r},\mathbf{r}',t,t_0) = {} & \frac{\exp\left\{-\left[\mu_a c(t-t_0) + \frac{d^2}{4\gamma^2(t-t_0)}\right]\right\}}{[4\pi\gamma^2(t-t_0)]^{3/2}} \\ & \times \sum_{n=-\infty}^{\infty}\left[\exp\left(\frac{-(z-2z_d n - z_0)^2}{4\gamma^2(t-t_0)}\right)\right. \\ & \left. - \exp\left(\frac{-(z-2z_d n + z_0)^2}{4\gamma^2(t-t_0)}\right)\right], \\ & d = \sqrt{x^2+y^2}, \quad \text{where } \mathbf{r}-\mathbf{r}' = (x,y,z), \\ & z_o = [(1-\bar{p})\mu_s]^{-1}. \end{aligned} \tag{2.2}$$

This equation models the transmission of light from point $\mathbf{r}$, leaving at time $t_0$, and arriving at point $\mathbf{r}'$ at time $t$. The constant $z_d$ represents the thickness of the slab in question and is used to generate the multiple image sources needed to satisfy the boundary conditions of the system [11, 24]. The placement of these image sources results in the Green's function taking a value of zero at the boundary of the diffusive medium. Finally, the distance $z_0$ represents the source depth; because we use a slab geometry model, all sources are located at this height. It is presumed that all light from the source travels a short distance into the medium before proceeding to scatter randomly. This is modeled by assuming the sources to be isotropic and placing them one mean scattering length into the medium.

These Green's functions are used in a model of the sensing system based on the first order Born approximation [22]. This approximation assumes that the total received signal is the sum of the signal for a homogeneous system and a perturbation due to $\eta(\mathbf{r}')$, the inhomogeneities in $\mu_a$:

$$\Gamma_{total} = \Gamma_{homog} + \Delta\Gamma(\eta(\mathbf{r}')). \tag{2.3}$$

Using the background optical properties, $\Gamma_{homog}$ can be computed and subtracted from $\Gamma_{total}$, leaving $\Delta\Gamma$. We now concentrate on obtaining a description of $\Delta\Gamma$ as a linear function of $\eta(\mathbf{r}')$.

Under the first order Born approximation, $\Delta\Gamma$ is dependent only on first order scattering; thus by integrating across $\Omega$, the volume to be imaged, an equation for $\Omega$ can be written as

$$\Delta\Gamma(\mathbf{s},\mathbf{d},t,t_0) \approx -\int_\Omega \int_{-\infty}^{\infty} [g^{(\Gamma)}_{slab}(\mathbf{s},\mathbf{r}',t',t_0)\eta(\mathbf{r}')g^{(\Phi)}_{slab}(\mathbf{r}',\mathbf{d},t-t',t_0)]dt'd\mathbf{r}'. \tag{2.4}$$

Here, $\triangle\Gamma(\mathbf{s},\mathbf{d},t,t_o)$, the change in the photon fluence measured at location $\mathbf{d}$ at time $t$ due to inhomogeneities in the background absorption for a source at location $\mathbf{s}$, is equal to the integral of all first order scattering throughout the volume. The Green's function $g^{(\Gamma)}_{slab}(\mathbf{r},\mathbf{r}',t,t_0)$ is the spatial gradient of $g^{(\Phi)}_{slab}(\mathbf{r},\mathbf{r}',t,t_0)$ with respect to a unit normal extending out of the solution volume. This gives $g^{(\Gamma)}_{slab}(\mathbf{r},\mathbf{r}',t,t_0)$ the form

$$\begin{aligned} g^{(\Gamma)}_{slab}(\mathbf{r},\mathbf{r}',t,t_0) &= \frac{\exp\left\{-\left[\mu_a c(t-t_0)+\frac{d^2}{4\gamma^2(t-t_0)}\right]\right\}}{[4\pi\gamma^2(t-t_0)]^{3/2}} \\ &\quad\times\sum_{n=-\infty}^{\infty}\left[\frac{-2\,(z-2z_d n-z_0)}{4\gamma^2(t-t_0)}\exp\left(\frac{-(z-2z_d n-z_0)^2}{4\gamma^2(t-t_0)}\right)\right. \\ &\qquad\left.+\frac{2(z-2z_d n+z_0)}{4\gamma^2(t-t_0)}\exp\left(\frac{-(z-2z_d n+z_0)^2}{4\gamma^2(t-t_0)}\right)\right], \\ d &= \sqrt{x^2+y^2}, \quad \text{where } \mathbf{r}-\mathbf{r}'=(x,y,z), \\ z_o &= [(1-\bar{\rho})\mu_s]^{-1}. \end{aligned} \tag{2.5}$$

This relationship is necessary, as the photon density is not a directly measurable quantity. By taking the gradient of the photon density, we obtain the photon fluence, the intensity of the light exiting from the boundary at the location of the detector. This fluence is a quantity which we are capable of measuring with detectors placed on the surface.

Because the system is causal, (2.2) is zero for $t < t_0$. Additionally, presuming that the timescale can be adjusted such that $t_0 = 0$, the second integral in (2.4) will have support only for $t'$ such that $0 \le t' \le t$, and the dependence upon $t_0$ can be dropped from (2.4). Discretizing (2.4) in piecewise constant fashion for each voxel converts the spatial integration into a summation. Combining these modifications results in

$$\triangle\Gamma(\mathbf{s},\mathbf{d},t) \approx -\sum_{i=1}^{Nvox} dV_i \int_0^t [g^{(\Gamma)}_{slab}(\mathbf{s},\mathbf{r}'_i,t')g^{(\Phi)}_{slab}(\mathbf{r}'_i,\mathbf{d},t-t')\eta(\mathbf{r}'_i)]dt', \tag{2.6}$$

where $dV_i$ is the volume of the $i$th voxel and the $r'_i$'s are locations of voxel centers. For simplicity and maximum computational gain, we assume that $dV_i$ is constant for all voxels and simply note it as $dV$. The above equation then serves as a basis from which to construct the discrete linear model $\mathbf{Af} \approx \mathbf{g}$, where $\mathbf{f}$ is the vector of unknown absorption values at each of the voxels in the image. This equation is ill-posed in the sense that a least-squares solution to the system would be hopelessly contaminated by noise. Therefore, we solve instead the Tikhonov regularized problem (1.1).

From (2.6), we see that the entry in the matrix $\mathbf{A}$ associated with voxel (column) $i$ and row corresponding to source $\mathbf{s}$ and detector $\mathbf{d}$ at time $t$ is

$$J_i^{(\Gamma)}(\mathbf{s}, \mathbf{d}, t) \approx -dV \left( \sum_{j=1}^{T_t} w_j \left[ g_{slab}^{(\Gamma)} \left(\mathbf{s}, \mathbf{r}'_i, t'_j\right) g_{slab}^{(\Phi)} \left(\mathbf{r}'_i, \mathbf{d}, t - t'_j\right) \right] \right), \tag{2.7}$$

where in this case the approximation notation conveys the fact that the integral was evaluated numerically using the composite trapezoid rule on a regular grid, and the $w_j$ denote the weights of the composite trapezoid rule.

As mentioned in the introduction, it is not feasible to naively construct and store each entry in $\mathbf{A}$. However, it is clear from the above Green's functions that in a slab geometry there is some degree of spatial invariance in the kernels. In the following section, we describe how to utilize the invariance to store only a minimum of information to represent every entry in $\mathbf{A}$, and to utilize the stored information to perform the matrix-vector products necessary to employ an iterative algorithm for solving (1.1).

## 3. Exploiting matrix structure.

There is a significant amount of redundancy in the forward matrix. By eliminating the excesses involved in computing the same value multiple times, we can reduce the time required to generate the matrix. We are able to store each computed value only once and reuse it as needed. This reuse takes the guise of a series of selection matrices: extremely sparse, easily formed matrices consisting entirely of ones and zeros.

### 3.1. Change of coordinates.

In (2.2), (2.5), and (2.7), the X-Y coordinates of the source-voxel and detector-voxel differences enter into the equation only as radial distances $\sqrt{x^2 + y^2}$. Because of this, the absolute X-Y locations involved are irrelevant to the computation, and it is possible to change from the original absolute Cartesian coordinates to a different coordinate system based on these radial distances. Equation (2.7) expresses each matrix component as the convolution of two Green's functions with respect to time. Given the convolution involved in obtaining the matrix components, this new coordinate system can be seen as two joined cylindrical coordinate systems, with the central axis of one lying upon the radial boundary of the other. To see this, let $(X_s, Y_s, Z_s)$ represent the absolute location of the source and $(X_r, Y_r, Z_r)$ and $(X_v, Y_v, Z_v)$ represent the absolute locations for the detector and voxel, respectively. Define the new variables:

$$\begin{aligned} D_1 &= ((X_v - X_s)^2 + (Y_v - Y_s)^2)^{1/2}, \\ Z_1 &= Z_v - Z_s, \\ D_2 &= ((X_v - X_r)^2 + (Y_v - Y_r)^2)^{1/2}, \\ Z_2 &= Z_r - Z_v. \end{aligned} \tag{3.1}$$

These four values are sufficient for computing the value of (2.7), regardless of the absolute position of the three initial sets of $(x, y, z)$ coordinates. Further, because we are modeling a slab geometry, the $z$-coordinates for the sources are fixed and known,

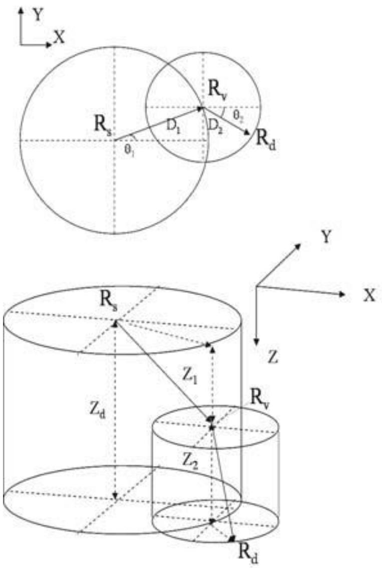

FIG. 3.1. *Dual cylindrical coordinate system. This illustration depicts visually the spatial invariance of* (2.7)*, which expresses the matrix values as the numerical convolution of two Green's functions. Here, the source is located at $R_s$, the center of the top of the larger cylinder; the voxel under consideration is at $R_v$, the top center of the smaller cylinder; and the detector is located at $R_d$, a point on the lower rim of the cylinder. Given this arrangement, the radial location of the small cylinder with respect to the larger, and the radial location of the detector with respect to the small cylinder, can both be changed arbitrarily without affecting the resulting value of* (2.7)*. Additionally, given a slab geometry of fixed thickness $Z_d$, the entire system is shift invariant to changes along the X-Y plane.*

as are the $z$-coordinates for the detectors. Therefore, the only time that $Z_1$ and $Z_2$ change is when $Z_v$ changes, and thus only one of $Z_1, Z_2, Z_v$ is needed in order to compute the other two. As the locations of the source, detector, and voxel are allowed to vary, these changes will be reflected in changes to the triple $(D_1, D_2, Z_v)$. This dual cylindrical coordinate system is shown in Figure 3.1. Note that the two radial angles $\theta_1$ and $\theta_2$ do not appear in (3.1). Clearly, (2.7) is independent of $\theta_1$ and $\theta_2$ and is therefore invariant to changes in the angles. Therefore, given fixed $t$, for each source-voxel/detector-voxel pairing in XYZ space which maps to the same $(D_1, D_2, Z_v)$ triple, the corresponding matrix entry will be the same. Note that this means that all sets of three points with the same voxel height and the same length x-y projections of the source-voxel and voxel-detector distances require identical computations.

Using this new coordinate system, we now return to the original problem, with all of the source and detector positions, and examine those positions within this dual-cylindrical system. In practice, many source-detector configurations fall into one of two categories: fixed array or raster scanned. For the fixed array case, two grids are defined, one for the sources and one for the detectors. For each source location, data are collected at all of the detectors. In a raster scanned system, a source grid is defined, along with a number of detector locations, fixed relative to the source. In both cases, high levels of redundancy in the $(D_1, D_2, Z)$ triplets will be present. This means that a large number of repeated operations are performed if each component of the matrix $\mathbf{A}$ is explicitly computed. Table 1 shows redundancy levels for several common source-detector configurations based on a raster scan and two uniform grids

Table 1

*Computational/storage improvements for a variety of source-detector configurations. This table reflects the amount of redundancy present for three examples of common source-detector geometries. The reduction is presented as the ratio of total to unique number of matrix elements. Thus, for the second example given, explicitly computing every matrix element results in each unique computation being done an average of* 690 *times. By eliminating these excess computations and simply computing each unique element once, we are able to significantly reduce the amount of time required to compute the forward matrix.*

| SD configuration | Computational/storage reduction |
|---|---|
| 7 × 7 Raster scanned | 49× |
| 5 × 5 Sources over<br>5 × 5 Detectors<br>10 × 10 × 10 Voxels | 690× |
| 10 × 10 Sources over<br>10 × 10 Detectors<br>10 × 10 × 10 Voxels | 3844× |

Table 2

*Summary of index notation. Note that* $N_{pts} \leq N_{vox} N_D N_S$.

| Symbol | Meaning |
|---|---|
| $N_z$ | No. grid pts in z-direction |
| $N_{vox}$ | No. of voxels |
| $N_{pts}$ | No. of unique $(D_1, D_2, Z)$ triples |
| $N_S$ | No. of sources |
| $N_D$ | No. of detectors |
| $N_t$ | No. of time pts |
| $N_{comp}$ | No. of interp. nodes in 3-space |

of sources and detectors.

Now we are ready to consider taking advantage of this redundancy to represent the matrix **A** (see Table 2 for definitions of the dimension notation). The matrix **A** has $N_t N_D N_S$ rows and $N_{vox}$ columns. We order the rows of **A** such that the inner loop is over time, then detectors, then sources. It will be convenient to consider the structure of $\mathbf{A}^T$ instead of **A**. Using $\mathbf{A}_{ij}$ to denote the $N_{vox} \times N_t$ submatrix holding the entries given by (2.7) for the $i$th source and the $j$th detector, the matrix $\mathbf{A}^T$ has the block structure

$$\mathbf{A}^T = [\mathbf{A}_{11} \quad \dots \quad \mathbf{A}_{1N_D} \quad \mathbf{A}_{21} \quad \dots \quad \mathbf{A}_{N_S N_D}]. \tag{3.2}$$

However, given the redundancy noted above, explicit computation of each $A_{ij}$ is unnecessary. Let us assume that there are $N_{pts}$ unique $(D_1, D_2, Z)$ coordinate triplets, given all source-voxel-detector combinations. Clearly, $N_{pts} \leq N_{vox} N_D N_S$. Each of these triplets is encountered again at each time step, for a total of $N_{pts} N_t$ unique evaluations of (2.7). Let $\mathbf{A}_s$ denote the $N_{pts} \times N_t$ matrix containing these values. Thus instead of computing and storing all $N_{vox} N_D N_S N_t$ entries in **A**, we will only need to evaluate and store the $N_{pts} N_t \leq N_{vox} N_D N_S N_t$ unique entries of $\mathbf{A}_s$.

We can represent **A** in terms of $\mathbf{A}_s$ using a series of selection matrices of size $N_{vox} \times N_{pts}$, where each row consists of all zeros, except for a single "1" to select the appropriate row from $\mathbf{A}_s$. Placing these selection matrices into the previous expression for **A** results in

$$\mathbf{A}^T = [\mathbf{S}_{11}\mathbf{A}_s \quad \dots \quad \mathbf{S}_{1N_D}\mathbf{A}_s \quad \mathbf{S}_{21}\mathbf{A}_s \quad \dots \quad \mathbf{S}_{N_S N_D}\mathbf{A}_s]. \tag{3.3}$$

It is possible to rewrite (3.3) in a form which exploits the underlying Kronecker structure of the matrix:

$$\mathbf{A}^T = [\mathbf{S}_{11} \quad \dots \quad \mathbf{S}_{1N_D} \quad \mathbf{S}_{21} \quad \dots \quad \mathbf{S}_{N_S N_D}][\mathbf{I}_{N_S * N_D} \otimes \mathbf{A}_s]. \tag{3.4}$$

We now have a compact representation of the matrix $\mathbf{A}$ that may be used inside the iterative solver to produce the necessary matrix-vector products $\mathbf{A}x$ or $\mathbf{A}^T x$. All entries of the matrix $\mathbf{A}$ need not be explicitly formed.

Furthermore, there is structure present within the selection matrices themselves. If $\mathbf{A}_s$ is arranged such that it has block structure,

$$\mathbf{A}_s = \begin{bmatrix} \mathbf{Z}_1 \\ \mathbf{Z}_2 \\ \vdots \\ \mathbf{Z}_{N_z} \end{bmatrix}, \tag{3.5}$$

where each block corresponds to the set of $(D_1, D_2, Z)$ triplets sharing a particular $Z$ value, the selection matrices themselves have a Kronecker structure. This is because, assuming a uniform grid for the voxels, the same set of $(D_1, D_2)$ values will be required from each Z-slice. Thus we have

$$\mathbf{S}_{ij} = \mathbf{I}_{N_z} \otimes \tilde{\mathbf{S}}_{ij}, \tag{3.6}$$

where the matrix $\tilde{\mathbf{S}}_{ij}$ is the selection matrix required to extract the appropriate rows from any of the $Z_k$ matrices.

**3.2. Interpolation.** While this change-of-coordinates representation provides a significant reduction in the amount of overhead required to compute and store the matrix $\mathbf{A}$, it does not provide any gains when that matrix is used in matrix-vector multiplications. While operations on $\mathbf{A}$ can be done block by block, the overall size of $\mathbf{A}$ is still exceedingly large. When used in an iterative scheme where multiple matrix-vector products are required for each iteration, the time involved in each product becomes a limiting factor. The desire to accelerate these products, as well as further reduce the required initial computation, motivates the next step in our method.

Recall that even though we have reduced the number of distinct entries that need to be computed to represent $\mathbf{A}$, each of these distinct entries requires the evaluation of the expression (2.7). These are clearly expensive to compute because of the numerous evaluations of the Green's functions and multiple summations. It is this function evaluation whose explicit calculation we hope to minimize. Therefore, we propose to use interpolation to aid in the function evaluation. Not only does this reduce the overall amount of initial computation required to approximate each matrix entry, but as we will illustrate shortly, it has the added benefit of speeding up matrix-vector products.

We utilized interpolation expressible in the linear form

$$\mathbf{A}_s \approx \mathbf{Q}\mathbf{V}. \tag{3.7}$$

Here, $\mathbf{Q}$ is of size $N_{pts} \times N_{comp}$ and is the interpolation matrix, while $\mathbf{V}$ is $N_{comp} \times N_t$, consisting of the smaller set of values which must be explicitly computed. $N_{comp}$ is the number of nodes to be computed for use in the interpolation scheme and is chosen to be significantly smaller than $N_{pts}$. While all further results, including computational complexities, will be shown with respect to the specific linear interpolation scheme

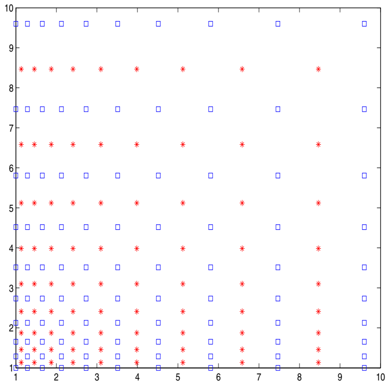

FIG. 3.2. *Graphical description of the sampling technique used with the interpolation. The sets of red and blue points (asterisks and squares, respectively) show the two grids which were used to sample $D_1 - D_2$ slices of the sample space. For each Z-value, one of the two grids was selected, alternating as the Z-value was stepped from one value to the next.*

we chose to use, this process could be used with any interpolation method that can be expressed in matrix format.

Evaluation of the function in (2.7) will occur at a set of $N_{comp}$ interpolation nodes in $(D_1, D_2, Z)$ space at each of the $N_t$ values $\{t_1, \ldots, t_{N_t}\}$. The linear interpolation we use is based on a Delaunay tessellation of the $(D_1, D_2, Z)$ space. This tessellation uses the interpolation nodes as vertices of a tetrahedral mesh. To determine the value at each point on the more dense grid to which we interpolate, we first determine inside which tetrahedron the point lies. Barycentric coordinates of the desired point are then computed with respect to the vertices of the enclosing tetrahedron, and those coordinates are used as the weights of the interpolation. For example, if the coordinates of the four interpolation nodes comprising the encircling tetrahedron are given by $(D_1^{(i)}, D_2^{(i)}, Z^{(i)})$, $i = [1, \ldots, 4]$, with corresponding function values given by $v_i$, $i = [1, \ldots, 4]$, then the barycentric coordinates of the desired point $(D_1, D_2, Z)$ can be determined as

$$\begin{bmatrix} a_1 \\ a_2 \\ a_3 \\ a_4 \end{bmatrix} = \begin{bmatrix} D_1^{(1)} & D_1^{(2)} & D_1^{(3)} & D_1^{(4)} \\ D_2^{(1)} & D_2^{(2)} & D_2^{(3)} & D_2^{(4)} \\ Z^{(1)} & Z^{(2)} & Z^{(3)} & Z^{(4)} \\ 1 & 1 & 1 & 1 \end{bmatrix}^{-1} \begin{bmatrix} D_1 \\ D_2 \\ Z \\ 1 \end{bmatrix}. \tag{3.8}$$

These barycentric coordinates become the weights of the interpolation, to give an approximate value $v$ at the point $(D_1, D_2, Z)$ of

$$v = a_1 v_1 + a_2 v_2 + a_3 v_3 + a_4 v_4. \tag{3.9}$$

Arranging the weights in $\mathbf{Q}$ and the coarse grid values in $\mathbf{V}$, the $N_{pts} \times N_{comp}$ matrix $\mathbf{Q}$ will be sparse with only four nonzero entries per row, while $\mathbf{V}$ will be dense. It remains to decide how to choose the position of the interpolation nodes.

Looking again at (2.2), there is an exponential relationship between the calculated value and the values of $D_1$ and $D_2$. Because of this, a linear sampling method is unlikely to give acceptable results when combined with a linear interpolation method. This is especially true when $D_1$ and $D_2$ are close to zero, where the value of (2.2)

Table 3

*Number of floating point operations for various matrix-vector products. This assumes that multiplication by 1 can be done at no cost. The vector $w$ is the component of $v$ corresponding to the data points from a single source-detector pair. Note that the use of $A_s$ alone does not provide computational gains when computing matrix-vector products. It is the combination of the selection and interpolation matrices (the $S_{ij}Q$ product) and the initial $Vw$ multiplication that provide the reduction in total required computation.*

| Product | Flops (in big-Oh) |
|---|---|
| $A^T v$, $A$ dense | $O(N_D N_S N_t N_{vox})$ |
| $A_s w$ | $O(N_{pts} \times N_t)$ |
| $A^T v = S(I_{N_D N_S} \otimes A_s)v$ | $O(N_D N_S N_t N_{vox})$ |
| $(S_{ij}Q)(Vw)$ | $O(4N_{vox} + N_{comp}N_t)$ |
| Approx. $A$ using $A_s w \approx QVw$ | $O(N_D N_S (4N_{vox} + N_{comp}N_t))$ |

is changing very rapidly. Initial experimentation confirmed that this held true in practice. As an alternative sampling method, a grid with exponential spacing in $D_1$ and $D_2$ was developed, as illustrated in Figure 3.2. By clustering a larger number of sample points near the origin, it was possible to achieve significantly better interpolation results for the same values of $N_{pts}$, with acceptable error levels in terms of the quality of the resulting reconstructions. To efficiently sample the space, two grids, red and blue, were established, with the nodes of one grid centered between the nodes of the other. We alternated between the two grids as we stepped down the Z-axis, as indicated by the red and blue grids in Figure 3.2. In order to ensure that the grid covered all of the necessary space, the final slice always used the blue grid, even if this meant that two adjacent slices utilized the same grid.

**4. Computational complexity.** To this point, we have been primarily concerned with the up-front costs in terms of storage and computation time for representing the matrix. We decreased the storage for the matrix by exploiting redundancy. With the interpolation approximation, we also reduced the initial time needed to represent entries in the (approximate) matrix, and the storage requirement for $\mathbf{A}_s$ has decreased from $N_{pts}N_t$ to $4N_{pts} + N_{comp}N_t$ double values stored in memory. Further, the addition of the interpolation step adds the potential to decrease the overall computational complexity of executing each matrix-vector product involved in solving the minimization problem. Because the computations in the matrix-vector product that correspond to individual source-detector pairs are independent, we will simply examine the computation required for a single source-detector pair.

As a benchmark, the number of floating point operations (i.e., multiplications and additions) required for matrix-vector products using the dense formulation and also the formulation in section 3.1 are given in Table 3. Note that the flop count is not reduced over the dense formulation when using the sparse representation in section 3.1. (Note: multiplication by the selection matrix requires no flops.)

The situation changes when utilizing interpolation. At each source-detector pair, the equation to be evaluated is

$$\mathbf{S}_{ij}\mathbf{QVx}. \tag{4.1}$$

Here, the first step is to combine the selection and interpolation matrices. Again, the product of these two matrices can be computed at no cost. The reason for taking this "product" first is that in general $N_{vox} < N_{pts}$, and thus the resulting sparse matrix will have only $4N_{vox}$ nonzeros as opposed to the $4N_{pts}$ nonzeros that are in $Q$.

Therefore, we compute $S_{ij}QVw$ in three steps:

Table 4

*The various matrices used in our approximate forward model, their sizes, and their number of nonzero values. $A_s$ is the small version of the forward matrix containing only the unique matrix elements. $S_{ij}$ are the selection matrices used to retrieve the blocks of the full matrix from $A_s$. $A$ is the full weight matrix. $Q$ is the matrix responsible for implementing the linear interpolation, and $V$ is a small dense matrix of unique values such that $A_s \simeq QV$. For descriptions of other variables used, see Table 2.*

| Matrix | Dimensions | Nonzeros |
|---|---|---|
| $A_s$ | $N_{pts} \times N_t$ | $N_{pts}N_t$ |
| $S_{ij} = I_{N_z} \otimes \tilde{S}_{ij}$ | $N_{vox} \times N_{pts}$ | $N_{vox}$ |
| $A$ | $N_D N_S N_t \times N_{vox}$ | (Sparse rep.) $N_D N_S N_{vox} + N_{pts}N_t$ |
| $Q$ | $N_{pts} \times N_{comp}$ | $4N_{pts}$ |
| $V$ | $N_{comp} \times N_t$ | $N_{comp}N_t$ |
| Approx. $A$ | | $N_D N_S N_{vox} + 4N_{pts} + N_{comp}N_t$ |

- Form the product $W_{ij} = S_{ij}Q$.
- Compute the matrix-vector product $Vw$.
- Compute the matrix-vector product $W_{ij}(Vw)$.

The first step is "free." The second step requires $O(N_{comp}N_t)$ flops. Since $W_{ij}$ is $N_{vox} \times N_{comp}$ but has only four nonzero entries per row, the product $W_{ij}(Vw)$ requires an additional $O(4N_{vox})$ flops. Thus, the cost of the product $S_{ij}QVw$ is $O(4N_{vox} + N_{comp}N_t)$ flops. There is one such product for every source-detector pair, and therefore products with the approximation to $A$ formed by using $A_s \approx QV$ cost $O(N_D N_S(4N_{vox} + N_{comp}N_t))$ flops. Comparing this to the total number of flops required for the dense formulation, we can see that the reduction in required computation is dependent upon the number of interpolation nodes $N_{comp}$ and the total number of voxels $N_{vox}$. The computational costs and storage requirements for the various steps are detailed in Tables 3 and 4.

**5. Simulation results.** For the regularization matrix $\mathbf{R}$, a first order approximation to the gradient was utilized, generated as

$$\mathbf{R} = \begin{bmatrix} R_x \\ R_y \\ R_z \end{bmatrix}, \tag{5.1}$$

where each of the three submatrices are discrete approximations to the first order derivative along the associated axis.

Rather than simply run an iterative algorithm such as LSQR [23] with an augmented matrix once for each trial value of $\lambda$ in (1.1), we used the algorithm in [13] so that the results could be run simultaneously on an array of $\lambda$'s. The number of iterations was fixed at fifty, chosen by first running the algorithm without any regularization and performing an L-curve analysis [10] across the iterations. It is reasonable to presume that a given regularized system should have sufficiently converged by several iterations past the corner of the L-curve for the unregularized problem. For the regularized problem, selection of the appropriate regularization parameter was done through the use of an L-curve analysis at the final iteration.

After some experimentation, it was found that for our first data set, where the ground truth was known, the minimum error solution was consistently at a point which would be considered underregularized according to the L-curve. Visual analysis of a second data set, provided by ART, suggested that a similar situation existed with that data. As such, the results shown for the known phantom are those at the

Table 5

*Interpolation levels, with corresponding number of computed nodes and the resulting error induced in the solution for data set* 1. *Error is computed as* $\frac{\|Computed-Actual\|_2}{\|Actual\|_2}$. *The interpolation level noted in column* 1 *denotes the initial number of interpolation nodes along each dimension of the space. To eliminate unnecessary evaluations of* (2.7), *only those nodes needed to approximate* $A_s$ *were computed.*

| Interpolation level | Number of computed points | Induced error |
|---|---|---|
| None | 11760 | 0.7336 |
| (40,40,40) | 7188 | 0.7344 |
| (30,30,30) | 4659 | 0.7352 |
| (20,20,20) | 2109 | 0.7362 |
| (15,15,15) | 1098 | 0.7409 |
| (10,10,15) | 578 | 0.7294 |
| (10,10,10) | 402 | 0.7404 |

minimum error point, while those shown for the second data set were chosen to be "underregularized" by a similar order of magnitude.

Of course, critical to determining the utility of the interpolation is evaluation of the error introduced into the reconstructions. Interpolation levels are denoted in what follows as a triplet (a,b,c), where the values define the number of grid points along each of the $(D_1, D_2, Z)$ axes, respectively. However, the rectangular grid computed using the values will contain some nodes which will not be needed during the interpolation step. Rather than compute their values and not use them, we simply eliminate these nodes. The numbers in the second column of Table 5 give the number of nodes remaining after this elimination.

We show results for two simulated data sets, each using a number of different interpolation levels. For our first data set, where ground truth was known, we present reconstruction images for two interpolation levels as well as the fully computed result. Additionally, we report error levels for a further four interpolation levels. For our second data set we present three reconstructions, two using interpolation and one without, and give an analysis of relative error levels.

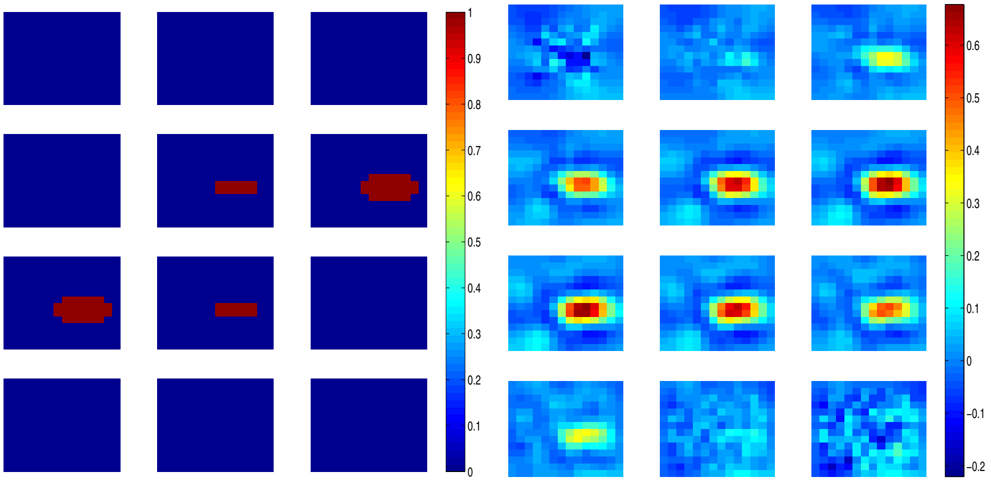
For each data set, relative error levels are computed with respect to the other reconstructions and with respect to ground truth in the case it is known. All error levels are computed as

$$E_{\mathbf{f}_b}(\mathbf{f}_a) = \frac{\|\mathbf{f}_b - \mathbf{f}_a\|_2}{\|\mathbf{f}_b\|_2}, \tag{5.2}$$

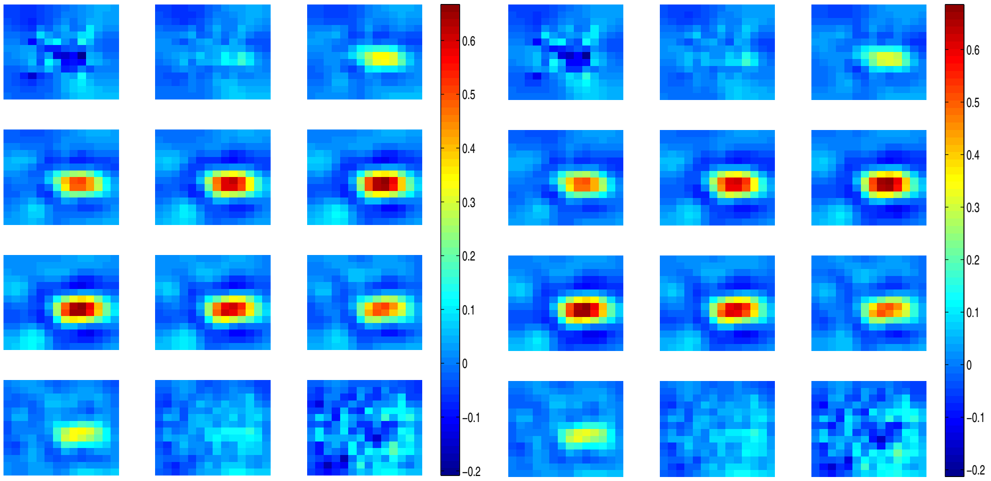
where $E_{\mathbf{f}_b}(\mathbf{f}_a)$ is the error in a reconstruction $\mathbf{f}_a$ with respect to a reconstruction $\mathbf{f}_b$, using the standard 2-norm.

**5.1. Data set 1.** In order to determine how the interpolation error affects the resulting solutions, we first used a simulated data set generated using a known phantom. The data was generated using the image in Figure 5.1(a) as $\mathbf{f}_{real}$ to get $\mathbf{g} = \mathbf{A}\mathbf{f}_{real}$, with random noise added by the Matlab awgn() function at a signal-to-noise ratio of 10dB. Inversions were then run using six different interpolation levels with a number of nodes ranging from 61% $N_{pts}$ down to 3.4% $N_{pts}$. The specific interpolation levels, and number of points computed, are shown in Table 5, along with the relative error of each solution with respect to ground truth.

Images of reconstructions obtained using the (10,10,15) and (15,15,15) interpolation levels, as well as the fully computed matrix, can be seen in Figures 5.1(b)–(d).



(a) Phantom (b) Interpolation Level (10,10,15)



(c) Interpolation Level (15,15,15) (d) Fully Computed

FIG. 5.1. *Results for data set* 1. *A known phantom was used to generate simulated data with* 10*dB white Gaussian noise. Inverse results were obtained for a number of different interpolation levels.* (a) *Phantom used to generate simulated data.* (b) *Result with (*10,10,15*) interpolation level (*578 *explicitly computed points). Absolute error of* 0.7295*, error relative to* (d) *of* 0.1128. (c) *Result with (*15,15,15*) interpolation level (*1098 *computed points). Absolute error of* 0.7406*, error relative to* (d) *of* 0.1035. (d) *Result with fully computed matrix (*11760 *computed points). Absolute error of* 0.7336*. Note that all three constructions are visually almost identical, and that while the relative error between the fully computed and interpolated reconstructions is greater than* 10*, the absolute error changes very little.*

Visual comparison of the three images reveals little if any difference. Analytic comparison results in relative error in the (10,10,15) solution with respect to the fully computed solution of 0.1128, while the (15,15,15) solution exhibits a relative error of 0.1035. Examining the errors with respect to ground truth, however, suggests that despite their differences, the solutions using interpolation are of nearly the same quality as the fully computed solution. Decreasing the number of points computed from

11760 (the full number) to 1098 (the (15,15,15) interpolation level) results in the relative error with respect to ground truth changing only 0.0070 from 0.7336 to 0.7406. Interestingly, the (10,10,15) case, with only 578 points computed, results in a relative error of 0.7295, which is actually a lower error than for the fully computed case. This suggests that, given the ill-posed nature of the problem and the regularization occurring in the inversion, the error induced by the interpolation has little consistent effect upon the absolute error in the solution.

**5.2. Data set 2.** The second data set was generated by ART using an undisclosed forward solver (background $\mu_a$ and $\mu_s$ were provided) and a proprietary noise model. Reconstruction images are shown in Figure 5.2 for the fully computed matrix, as well as (10,10,15) and (15,15,15) interpolation levels.

The results for this data set are similar to those of data set 1. Visually, the three inversion results are nearly identical. Because the ground truth is not known in this case, absolute error values cannot be computed. However, comparing the two interpolated solutions to the fully computed one yields relative differences with respect to the fully computed solution of 0.0947 and 0.0857 for the (15,15,15) and (10,10,15) solutions, respectively. These numbers are similar to those seen in the case of the known phantom, where it was shown that absolute error levels were only slightly perturbed by the use of the approximated $\mathbf{A}_s$.

## 6. Conclusions and future work.

We have presented a method by which the forward matrix $\mathbf{A}$ associated with a certain linearized diffuse optical tomography problem can be efficiently computed and then effectively approximated. Our first step utilizes a change of variables to enable us to represent $\mathbf{A}$ as a core data matrix $\mathbf{A}_s$ and a number of selection matrices $\mathbf{S}_{ij}$. While $\mathbf{A}_s$ is small and dense, the selection matrices are extremely sparse, enabling the entire representation of $\mathbf{A}$ to be stored in significantly less memory. This decomposition also allows for matrix-vector operations upon $\mathbf{A}$ to be performed in a sequential manner, drastically reducing the amount of memory required to perform such operations.

Our simulated results indicate that the use of interpolation to approximate $\mathbf{A}_s$ and thus $\mathbf{A}$ gives accurate solutions. While the solutions using interpolation result in relative errors with respect to the fully computed solution on the order of 0.10, our results indicate that these differences do not significantly affect the error with respect to ground truth.

A further test of this work would be the application of our method to experimentally collected data. Given that the mathematical models presented here are inherently an approximation of reality, there will be an increased mismatch between the data and the model. As such, the model errors introduced by our interpolation scheme should have even less of an effect than they did in the results presented here.

This method also has applications beyond diffuse optical tomography. Any system with a similar invariance to radial angle could potentially be rewritten so as to use our referencing scheme. This includes problems such as continuous wave diffusion imaging, heat transfer in solids, and other problems using omnidirectional sources.

One specific area of application is fluorescence-based optical imaging. Linear models are capable of accurately modeling such systems and have led to systems currently in use for basic in vivo research [21, 20]. Because these systems are optically based using lasers at similar wavelengths, the mathematical details of the diffusion approximation and Green's functions detailed here carry over almost unchanged.

The interpolation could also be applied to other systems, especially those which are linearizations of nonlinear systems. Presuming a reasonably smooth kernel along

(c) Fully Computed

Fig. 5.2. *Results for data set* 2*. Data set provided by ART with known background optical parameters, but unknown forward and noise models. The images compare results using different interpolation levels. Note that absolute values for the reconstructions are significantly higher, owing to a lack of information regarding source intensities. Thus the true quantitative values are all multiplied by an unknown scaling factor.* (a) *Result with (*10,10,15*) interpolation level (*578 *explicitly computed points). Error relative to* (c) *of* 0.0857. (b) *Result with (*15,15,15*) interpolation level (*1098 *computed points). Error relative to* (c) *of* 0.0947. (c) *Result with fully computed matrix (*11760 *computed points). Again, all three reconstructions are visually identical and exhibit similar degrees of relative error. The change in absolute error is likely similar to that seen with data set* 1*.*

some dimension, it is feasible that linear approximations of that kernel would result in similarly small changes to the resulting solutions. When computation of individual kernel values is prohibitively expensive, this could lead to significant reductions in required computation. This interpolation could also be investigated to determine its regularizing properties. While our results suggest empirically that any regularizing effect is minimal, a study on the regularizing effects of interpolation-smoothed kernels may be of value.

Finally, further work could seek to extend this type of optimization to the case of systems with structured inhomogeneities. Layered media offer a straightforward extension of our method, while media with more complex structure would require correspondingly more effort. Both would enable our method to be used in a wider range of systems and configurations.

# ON THE DOUBLING ALGORITHM FOR A (SHIFTED) NONSYMMETRIC ALGEBRAIC RICCATI EQUATION*

CHUN-HUA GUO†, BRUNO IANNAZZO‡, AND BEATRICE MEINI‡

**Abstract.** Nonsymmetric algebraic Riccati equations for which the four coefficient matrices form an irreducible $M$-matrix $M$ are considered. The emphasis is on the case where $M$ is an irreducible singular $M$-matrix, which arises in the study of Markov models. The doubling algorithm is considered for finding the minimal nonnegative solution, the one of practical interest. The algorithm has been recently studied by others for the case where $M$ is a nonsingular $M$-matrix. A shift technique is proposed to transform the original Riccati equation into a new Riccati equation for which the four coefficient matrices form a nonsingular matrix. The convergence of the doubling algorithm is accelerated when it is applied to the shifted Riccati equation.

**Key words.** nonsymmetric algebraic Riccati equation, minimal nonnegative solution, doubling algorithm, convergence acceleration, shift technique

## 1. Introduction.

We consider the nonsymmetric algebraic Riccati equation (or NARE)

$$XCX - XD - AX + B = 0, \tag{1.1}$$

where $A, B, C, D$ are real matrices of sizes $m \times m, m \times n, n \times m, n \times n$, respectively, and we assume throughout that

$$M = \begin{bmatrix} D & -C \\ -B & A \end{bmatrix} \tag{1.2}$$

is a nonsingular $M$-matrix or an irreducible singular $M$-matrix. As usual in algebraic Riccati equations theory one associates with (1.1) the matrix

$$H = \begin{bmatrix} D & -C \\ B & -A \end{bmatrix}. \tag{1.3}$$

Some relevant definitions are given below.

For any matrices $A, B \in \mathbb{R}^{m\times n}$, we write $A \geq B (A > B)$ if $a_{ij} \geq b_{ij} (a_{ij} > b_{ij})$ for all $i, j$. A real square matrix $A$ is called a $Z$-matrix if all its off-diagonal elements are nonpositive. Any $Z$-matrix $A$ can be written as $sI - B$ with $B \geq 0$. A $Z$-matrix $A$ is called an $M$-matrix if $s \geq \rho(B)$, where $\rho(\cdot)$ is the spectral radius; it is called a singular $M$-matrix if $s = \rho(B)$ and a nonsingular $M$-matrix if $s > \rho(B)$. Given a square matrix $A$, we will denote by $\sigma(A)$ the set of the eigenvalues of $A$.

The NARE (1.1) has applications in transport theory and Markov models [18, 23, 24]. The solution of practical interest is the minimal nonnegative solution. The equation has attracted much attention recently [2, 4, 6, 8, 9, 11, 13, 14, 15, 19, 20, 22].

Some properties of the NARE (1.1) are summarized below. See [8] and [9] for more details.

THEOREM 1.1. [illegible] (1.1) [illegible] $X$ [illegible] $M$ [illegible] $X > 0$ [illegible] $A - XC$ [illegible] $D - CX$ [illegible] $M$ [illegible] $M$ [illegible] $M$ [illegible] $A - XC$ [illegible] $D - CX$ [illegible] $M$ [illegible]

We will also need the dual equation of (1.1)

$$YBY - YA - DY + C = 0. \tag{1.4}$$

This equation has the same type as (1.1): the matrix

$$\begin{bmatrix} A & -B \\ -C & D \end{bmatrix}$$

is a nonsingular $M$-matrix or an irreducible singular $M$-matrix if and only if the matrix $M$ is so. The minimal nonnegative solution of (1.4) is denoted by $Y$.

A number of numerical methods have been studied for finding the minimal solution $X$. Recently, a doubling algorithm is studied in [15] and is shown to be efficient. The doubling algorithm itself is not new; it was studied in [1], for example. However, the presentation in [15] provides some new information about the algorithm, which makes its analysis easier for the NARE (1.1).

In [15], the discussion is limited to the case where $M$ is a nonsingular $M$-matrix. In the application of the NARE in Markov chains, however, the most important case is the one where $M$ is an irreducible singular $M$-matrix with zero row sums. So in this paper, we will assume that $M$ is an irreducible (singular or nonsingular) $M$-matrix, with the emphasis on the singular case.

We show the applicability and convergence properties of the structure preserving doubling algorithm of [15] when $M$ is singular. In particular, we show that the algorithm has quadratic convergence when 0 is a simple eigenvalue of $H$. From the numerical experiments performed so far, the doubling algorithm shows a linear convergence of rate 1/2 if 0 has algebraic multiplicity equal to 2.

We introduce an alternative approach to treat the singular case based on a shift technique. The shift consists in performing a rank-one correction of the matrix $H$ which moves one zero eigenvalue to a suitable nonzero real number. We construct a new Riccati equation associated with the shifted $H$, which has the same solution $X$ of the original one, while the coefficients of the new Riccati equation form a nonsingular matrix if 0 is a simple eigenvalue of $H$.

We analyze the structure preserving doubling algorithm for the new Riccati equation and show that its convergence is faster (when no breakdown is encountered) than the convergence of the same algorithm applied to the original equation. In particular, when 0 is a double eigenvalue of $H$, the doubling algorithm applied to the new equation is shown to have quadratic convergence.

Numerical results show the effectiveness of the shift technique.

The paper is organized as follows. In section 2 we recall some properties of the Riccati equations and nonnegative matrices. In sections 3 and 4 we show that the structure preserving doubling algorithm of [15] can also be applied to the case where $M$ is irreducible singular, and we show convergence results. In section 5 we present the shift technique. In section 6 we analyze the doubling algorithm applied to the new Riccati equation. In section 7 we show some numerical experiments.

**2. Preliminaries.** When $M$ is an irreducible singular $M$-matrix, by the Perron–Frobenius theory 0 is a simple eigenvalue and there are positive vectors $u$ and $v$ such that

$$u^TM = 0, \quad Mv = 0, \tag{2.1}$$

and the vectors $u$ and $v$ are each unique up to a scalar multiple.

For any solution $S$ of the Riccati equation (1.1), the matrix $H$ of (1.3) satisfies

$$H\begin{bmatrix} I \\ S \end{bmatrix} = \begin{bmatrix} I \\ S \end{bmatrix} R,$$

where $R = D - CS$. The eigenvalues of the matrix $R$ are a subset of the eigenvalues of $H$.

Since $H = JM$, where $J = \left[\begin{smallmatrix} I_n & 0 \\ 0 & -I_m \end{smallmatrix}\right]$, then $H$ has a one-dimensional kernel, and $u^TJ$ and $v$ are the left and right eigenvectors corresponding to the eigenvalue 0.

Writing $u^T = \left(u_1^T, u_2^T\right)$ and $v^T = \left(v_1^T, v_2^T\right)$, with $u_1, v_1 \in \mathbb{R}^n$ and $u_2, v_2 \in \mathbb{R}^m$, one can define $\mu = u_1^Tv_1 - u_2^Tv_2$.

The number $\mu$ determines some properties of the equation. Depending on the sign of $\mu$ and following a Markov chain terminology, one can classify the Riccati equations associated with an irreducible singular $M$-matrix in three categories: a Riccati equation will be called

(a) [illegible] if $\mu > 0$;

(b) [illegible] if $\mu = 0$;

(c) [illegible] if $\mu < 0$.

The [illegible] case, i.e., the case $\mu \approx 0$, deserves particular attention, since it corresponds to an ill-conditioned zero eigenvalue for the matrix $H$. In fact if $u$ and $v$ are normalized such that $\|u\|_2 = \|v\|_2 = 1$, then $1/|\mu|$ is the condition number of the zero eigenvalue for the matrix $H$ (see [7]).

In fluid queues problems, $v$ coincides with the vector of ones, which will be denoted by $e$. In general, $v$ and $u$ can be computed by performing an LU factorization of the matrix $M$ and solving two triangular linear systems.

The next results concern $\mu$ and are proved or follow easily from results shown in [8, 9, 12].

THEOREM 2.1. [illegible] $M$ [illegible] $M$ [illegible] $X$ [illegible] $Y$ [illegible] (1.1) [illegible] (1.4) [illegible]

(a) [illegible] $\mu > 0$ [illegible] $Xv_1 = v_2$ [illegible] $Yv_2 < v_1$.

(b) [illegible] $\mu = 0$ [illegible] $Xv_1 = v_2$ [illegible] $Yv_2 = v_1$.

(c) [illegible] $\mu < 0$ [illegible] $Xv_1 < v_2$ [illegible] $Yv_2 = v_1$

THEOREM 2.2. [illegible] $M$ [illegible] $M$ [illegible] $\lambda_1, \dots, \lambda_{m+n}$ [illegible] $H = \operatorname{diag}(I_n, -I_m)M$ [illegible] $\lambda_n$ [illegible] $\lambda_{n+1}$ [illegible]

$$\mathrm{Re}\lambda_{n+m} \le \cdots \le \mathrm{Re}\lambda_{n+2} < \lambda_{n+1} \le 0 \le \lambda_n < \mathrm{Re}\lambda_{n-1} \le \cdots \le \mathrm{Re}\lambda_1.$$

[illegible] $X$ [illegible] (1.1) [illegible] $Y$ [illegible] (1.4) [illegible] $\sigma(D - CX) = \{\lambda_1, \dots, \lambda_n\}$ [illegible] $\sigma(A - XC) = \sigma(A - BY) = \{-\lambda_{n+1}, \dots, -\lambda_{n+m}\}$

[illegible] $M$ [illegible] $\mu > 0$ [illegible] $\lambda_n = 0, \lambda_{n+1} < 0$. [illegible] $\mu = 0$ [illegible] $\lambda_n = \lambda_{n+1} = 0$ [illegible] $\mu < 0$ [illegible] $\lambda_n > 0, \lambda_{n+1} = 0$

In what follows, we will need some basic results about $M$-matrices. The first result can be found in [3], for example.

THEOREM 2.3. [illegible] $Z$ [illegible] $A$ [illegible]

(a) $A$ [illegible] $M$ [illegible]

(b) $A^{-1} \geq 0$

(c) $Av > 0$ [illegible] $v > 0$

(d) [illegible] $A$ [illegible]

The equivalence of (a) and (c) in Theorem 2.3 implies the next result.

LEMMA 2.4. [illegible] $A$ [illegible] $M$ [illegible] $B \geq A$ [illegible] $Z$ [illegible] $B$ [illegible] $M$ [illegible]

Most of the statements in the following result are also well known.

LEMMA 2.5. [illegible] $M$ [illegible] $M$ [illegible] $M$ [illegible] $M$ [illegible]

$$M = \begin{bmatrix} M_{11} & M_{12} \\ M_{21} & M_{22} \end{bmatrix},$$

[illegible] $M_{11}$ [illegible] $M_{22}$ [illegible] $M_{11}$ [illegible] $M_{22}$ [illegible] $M$ [illegible] $M_{11}$ ( [illegible] $M_{22}$) [illegible] $M$ [illegible] $M$ [illegible] ( [illegible] $M$) [illegible] $M$ [illegible]

[illegible] 2.6. The last statement in Lemma 2.5 follows from Theorem 2.3 of [21], where the irreducibility of the Schur complement is proved for any irreducible singular $M$-matrix of the form $I - P$ with $P$ stochastic. For a general irreducible $M$-matrix $M$, we have $M = s(I - B)$ for some scalar $s > 0$ and some irreducible $B \geq 0$ with $\rho(B) \leq 1$. Note that if we replace $B$ with a stochastic matrix with the same nonzero pattern, there will be no change of the nonzero pattern in the Schur complement. In other words, the irreducibility will not change.

## 3. The doubling algorithm.

In this section we review the structure preserving doubling algorithm (SDA) for the NARE (1.1) and show that the algorithm is well defined when $M$ is an irreducible singular $M$-matrix. When $M$ is a nonsingular $M$-matrix, the algorithm has already been shown to be well defined in [15], although the selection of a parameter in the algorithm is slightly more restrictive in [15].

For the minimal nonnegative solution $X$ of the NARE (1.1), we have

$$H \begin{bmatrix} I \\ X \end{bmatrix} = \begin{bmatrix} I \\ X \end{bmatrix} R, \tag{3.1}$$

where $H$ is defined in (1.3) and $R = D - CX$.

Using the Cayley transform

$$\mathcal{C}_\gamma : z \to \frac{z-\gamma}{z+\gamma}, \tag{3.2}$$

where $\gamma > 0$ is a positive scalar, we can transform (3.1) into

$$(H - \gamma I) \begin{bmatrix} I \\ X \end{bmatrix} = (H + \gamma I) \begin{bmatrix} I \\ X \end{bmatrix} R_\gamma, \tag{3.3}$$

where

$$R_\gamma = \mathcal{C}_\gamma(R) = (R + \gamma I)^{-1}(R - \gamma I).$$

Note that $R + \gamma I$ is nonsingular since $R$ is an $M$-matrix by Theorem 1.1. For any $\gamma > 0$, the matrix $M_\gamma = M + \gamma I$ is a nonsingular $M$-matrix. So

$$A_\gamma = A + \gamma I, \quad D_\gamma = D + \gamma I$$

are nonsingular $M$-matrices. Let

$$W_\gamma = A_\gamma - BD_\gamma^{-1}C, \quad V_\gamma = D_\gamma - CA_\gamma^{-1}B \tag{3.4}$$

be the Schur complements of $D_\gamma$ and $A_\gamma$, respectively, in $M_\gamma$. They are both nonsingular $M$-matrices by Lemma 2.5. It is shown in [15] that (3.3) can be reduced to

$$K \begin{bmatrix} I \\ X \end{bmatrix} = L \begin{bmatrix} I \\ X \end{bmatrix} R_\gamma, \tag{3.5}$$

by premultiplying both sides of (3.3) with a proper nonsingular matrix, where

$$K = \begin{bmatrix} E_\gamma & 0 \\ -H_\gamma & I \end{bmatrix}, \quad L = \begin{bmatrix} I & -G_\gamma \\ 0 & F_\gamma \end{bmatrix},$$

with

$$\begin{aligned} E_\gamma &= I - 2\gamma V_\gamma^{-1}, \quad F_\gamma = I - 2\gamma W_\gamma^{-1}, \\ G_\gamma &= 2\gamma D_\gamma^{-1} C W_\gamma^{-1}, \quad H_\gamma = 2\gamma W_\gamma^{-1} B D_\gamma^{-1}. \end{aligned} \tag{3.6}$$

Similarly, for the minimal nonnegative solution $Y$ of the NARE (1.4), we have

$$(H - \gamma I) \begin{bmatrix} Y \\ I \end{bmatrix} S_\gamma = (H + \gamma I) \begin{bmatrix} Y \\ I \end{bmatrix} \tag{3.7}$$

and then

$$K \begin{bmatrix} Y \\ I \end{bmatrix} S_\gamma = L \begin{bmatrix} Y \\ I \end{bmatrix}, \tag{3.8}$$

where $S_\gamma = (S + \gamma I)^{-1}(S - \gamma I)$ with $S = A - BY$ being an $M$-matrix.

The doubling algorithm presented in [15] is the following, where the sequences $\{H_k\}$ and $\{G_k\}$ are going to approximate $X$ and $Y$, respectively.

ALGORITHM 3.1.

$$\begin{aligned} &E_0 = E_\gamma, \quad F_0 = F_\gamma, \quad G_0 = G_\gamma, \quad H_0 = H_\gamma, \\ &E_{k+1} = E_k (I - G_k H_k)^{-1} E_k, \\ &F_{k+1} = F_k (I - H_k G_k)^{-1} F_k, \\ &G_{k+1} = G_k + E_k (I - G_k H_k)^{-1} G_k F_k, \\ &H_{k+1} = H_k + F_k (I - H_k G_k)^{-1} H_k E_k. \end{aligned}$$

In this section we show that the algorithm is well defined. The convergence behavior of the algorithm will be studied in the next section.

THEOREM 3.2. [illegible] $M$ [illegible] $M$ [illegible]

$$\gamma \geq \max\left\{ \max_{1 \leq i \leq m} a_{ii}, \max_{1 \leq i \leq n} d_{ii} \right\},$$

[illegible] $a_{ii}$ [illegible] $d_{ii}$ [illegible] $A$ [illegible] $D$ [illegible] $E_\gamma$ $F_\gamma$ $R_\gamma$ $S_\gamma < 0$ [illegible] $0 \le G_\gamma < Y, 0 \le H_\gamma < X, G_\gamma, H_\gamma \neq 0$ $I - G_\gamma H_\gamma$ [illegible] $I - H_\gamma G_\gamma$ [illegible] $M$ [illegible]

[illegible] We have

$$E_\gamma = I - 2\gamma V_\gamma^{-1} = V_\gamma^{-1}(V_\gamma - 2\gamma I).$$

Since $V_\gamma$ is the Schur complement of $A_\gamma$ in the irreducible nonsingular $M$-matrix $M_\gamma$, it is also an irreducible nonsingular $M$-matrix by Lemma 2.5. So $V_\gamma^{-1} > 0$ (see [3]). Since $\gamma \ge \max_{1\le i\le n} d_{ii}$, then $V_\gamma - 2\gamma I = -\gamma I + D - CA_\gamma^{-1}B \le 0$. Since $V_\gamma - 2\gamma I$ is irreducible, it has no zero columns, whence $E_\gamma < 0$.

Since $R = D - CX$ is an irreducible $M$-matrix by Theorem 1.1, $R + \gamma I$ is an irreducible nonsingular $M$-matrix and $(R + \gamma I)^{-1} > 0$, for any $\gamma > 0$. For $\gamma \ge \max_{1\le i\le n} d_{ii}$, one has $R - \gamma I = D - \gamma I - CX \le 0$. Since $R - \gamma I$ is irreducible and thus has no zero columns, then it follows that $R_\gamma = (R + \gamma I)^{-1}(R - \gamma I) < 0$.

Similarly, using $\gamma \ge \max_{1\le i\le m} a_{ii}$, we can prove that $F_\gamma < 0$, $S_\gamma < 0$.

It is clear that $G_\gamma, H_\gamma \ge 0$. Since $M$ is irreducible, then $B, C \neq 0$, whence it follows that $H_\gamma, G_\gamma \neq 0$. It is shown in [15] that $X - H_\gamma = F_\gamma X R_\gamma$. Since $F_\gamma X R_\gamma > 0$, we have $0 \le H_\gamma < X$. Similarly, we have $0 \le G_\gamma < Y$, so that $0 \le G_\gamma H_\gamma < YX$. By Theorem 2.1 we have $YXv_1 \le v_1$. Thus $\rho(G_\gamma H_\gamma) < \rho(YX) \le 1$ by the Perron–Frobenius theory. Therefore, $I - G_\gamma H_\gamma$ is a nonsingular $M$-matrix by Theorem 2.3. Similarly, $I - H_\gamma G_\gamma$ is a nonsingular $M$-matrix. ▯

THEOREM 3.3. [illegible] $M$ [illegible] $M$ [illegible] $k \ge 1$ $E_k, F_k > 0$ $H_{k-1} < H_k < X$ $G_{k-1} < G_k < Y$ [illegible] $I - H_k G_k, I - G_k H_k$ [illegible] $M$ [illegible]

[illegible] For any nonnegative matrices $U, V, W$ such that $UVW$ is defined, if $U, W > 0$ and $V \neq 0$, then $UVW > 0$. Since $E_0, F_0 < 0$ and $I - G_0H_0, I - H_0G_0$ are nonsingular $M$-matrices, we have

$$E_1, F_1 > 0, \quad H_1 > H_0, \quad G_1 > G_0.$$

For the doubling algorithm, it is shown in [15] that

$$X - H_1 = F_1 X R_\gamma^2, \quad Y - G_1 = E_1 Y S_\gamma^2.$$

Thus, $H_1 < X$ and $G_1 < Y$. Then, as in the proof of Theorem 3.2, $I - G_1H_1$ and $I - H_1G_1$ are nonsingular $M$-matrices. The statements in the theorem are now easily proved by induction. ▯

## 4. Convergence of the doubling algorithm.

For the doubling algorithm, we have (see [15])

$$X - H_k = F_k X R_\gamma^{2^k}, \quad Y - G_k = E_k Y S_\gamma^{2^k},$$

$$E_k = (I - G_kX)R_\gamma^{2^k} \le R_\gamma^{2^k}, \quad F_k = (I - H_kY)S_\gamma^{2^k} \le S_\gamma^{2^k} \tag{4.1}$$

for each $k \ge 1$. So

$$X - H_k = (I - H_kY)S_\gamma^{2^k} X R_\gamma^{2^k} \le S_\gamma^{2^k} X R_\gamma^{2^k}, \tag{4.2}$$

$$Y - G_k = (I - G_kX)R_\gamma^{2^k} Y S_\gamma^{2^k} \le R_\gamma^{2^k} Y S_\gamma^{2^k}. \tag{4.3}$$

When $M$ is an irreducible nonsingular $M$-matrix, we have $\rho(R_\gamma) < 1$ and $\rho(S_\gamma) < 1$. It follows that $\{H_k\}$ converges to $X$, $\{G_k\}$ converges to $Y$, $\{E_k\}$ and $\{F_k\}$ converge to 0, all quadratically. This result is shown in [15] under the assumption that $\gamma > \max\{\max a_{ii}, \max d_{ii}\}$, but without the irreducibility assumption. Here we would like to allow $\gamma = \max\{\max a_{ii}, \max d_{ii}\}$, since this $\gamma$ will be shown to be optimal in some sense. From (4.2) and (4.3), we also have

$$\limsup_{k\to\infty} \sqrt[2^k]{\|H_k - X\|} \le \rho(R_\gamma)\rho(S_\gamma), \tag{4.4}$$

$$\limsup_{k\to\infty} \sqrt[2^k]{\|G_k - Y\|} \le \rho(R_\gamma)\rho(S_\gamma). \tag{4.5}$$

THEOREM 4.1. [illegible] $M$ [illegible] $M$ [illegible]
(a) [illegible] $\mu > 0$ [illegible] $\{H_k\}$ ($\{G_k\}$) [illegible] $X$ ($Y$) [illegible]

$$\limsup_{k\to\infty} \sqrt[2^k]{\|H_k - X\|} \le \rho(S_\gamma) < 1, \quad \limsup_{k\to\infty} \sqrt[2^k]{\|G_k - Y\|} \le \rho(S_\gamma),$$

$\{F_k\}$ [illegible] 0 [illegible]

$$\limsup_{k\to\infty} \sqrt[2^k]{\|F_k\|} \le \rho(S_\gamma),$$

[illegible] $\{E_k\}$ [illegible]
(b) [illegible] $\mu < 0$ [illegible] $\{H_k\}$ ($\{G_k\}$) [illegible] $X$ ($Y$) [illegible]

$$\limsup_{k\to\infty} \sqrt[2^k]{\|H_k - X\|} \le \rho(R_\gamma) < 1, \quad \limsup_{k\to\infty} \sqrt[2^k]{\|G_k - Y\|} \le \rho(R_\gamma),$$

$\{E_k\}$ [illegible] 0 [illegible]

$$\limsup_{k\to\infty} \sqrt[2^k]{\|E_k\|} \le \rho(R_\gamma),$$

[illegible] $\{F_k\}$ [illegible]
(c) [illegible] $\mu = 0$ [illegible] $\{H_k\}$ [illegible] $X$ $\{G_k\}$ [illegible] $Y$ [illegible] $\{E_k\}, \{F_k\}$ [illegible]

[illegible] When $\mu > 0$, one has $\rho(S_\gamma) < 1$ and $\rho(R_\gamma) = 1$. Moreover, $-1$ is a simple eigenvalue of $R_\gamma$ and there are no other eigenvalues on the unit circle. When $\mu < 0$, one has $\rho(R_\gamma) < 1$ and $\rho(S_\gamma) = 1$. Moreover, $-1$ is a simple eigenvalue of $S_\gamma$ and there are no other eigenvalues on the unit circle. The statements in (a) and (b) are then valid in view of (4.1), (4.2), and (4.3).

When $\mu = 0$, one has $\rho(R_\gamma) = 1$. Moreover, $-1$ is a simple eigenvalue of $R_\gamma$ and there are no other eigenvalues on the unit circle. Also, $\rho(S_\gamma) = 1$, $-1$ is a simple eigenvalue of $S_\gamma$ and there are no other eigenvalues on the unit circle. The boundedness of $\{E_k\}$ and $\{F_k\}$ then follows immediately. However, from (4.2) and (4.3), we cannot see the convergence of $\{H_k\}$ and $\{G_k\}$ to $X$ and $Y$, respectively. So we will take a different approach.

For the minimal solution $X$ of (1.1), we have from (3.5)

$$E_\gamma = (I - G_\gamma X)R_\gamma, \quad X - H_\gamma = F_\gamma X R_\gamma. \tag{4.6}$$

Since $0 \le G_\gamma X < YX$, $I - G_\gamma X$ is a nonsingular $M$-matrix as in the proof of Theorem 3.2. Eliminating $R_\gamma$ in (4.6) gives

$$X = F_\gamma X (I - G_\gamma X)^{-1} E_\gamma + H_\gamma. \tag{4.7}$$

We now consider the basic fixed-point iteration for (4.7):

$$X_{k+1} = F_\gamma X_k (I - G_\gamma X_k)^{-1} E_\gamma + H_\gamma, \quad X_0 = 0. \tag{4.8}$$

It is easily proved by induction that $I - G_\gamma X_k$ is a nonsingular $M$-matrix and $X_k \le X_{k+1} \le X$ for all $k \ge 0$. Therefore, $\lim X_k = \widehat{X}$ with $0 \le \widehat{X} \le X$. Since $I - G_\gamma X$ is a nonsingular $M$-matrix, so is $I - G_\gamma \widehat{X}$. Thus we have

$$\widehat{X} = F_\gamma \widehat{X} (I - G_\gamma \widehat{X})^{-1} E_\gamma + H_\gamma. \tag{4.9}$$

We are going to show that $\widehat{X} = X$. Let $\widehat{R}_\gamma = (I - G_\gamma \widehat{X})^{-1} E_\gamma$, then

$$E_\gamma = (I - G_\gamma \widehat{X}) \widehat{R}_\gamma, \quad \widehat{X} - H_\gamma = F_\gamma \widehat{X} \widehat{R}_\gamma.$$

So instead of (3.5) we have

$$K \begin{bmatrix} I \\ \widehat{X} \end{bmatrix} = L \begin{bmatrix} I \\ \widehat{X} \end{bmatrix} \widehat{R}_\gamma, \tag{4.10}$$

which can be transformed back to

$$(H - \gamma I) \begin{bmatrix} I \\ \widehat{X} \end{bmatrix} = (H + \gamma I) \begin{bmatrix} I \\ \widehat{X} \end{bmatrix} \widehat{R}_\gamma. \tag{4.11}$$

If $G_\gamma \widehat{X} = G_\gamma X$, then $\widehat{R}_\gamma = R_\gamma$ and $I - \widehat{R}_\gamma$ is nonsingular. If $G_\gamma \widehat{X} \ne G_\gamma X$, then we have $0 < (I - G_\gamma \widehat{X})^{-1}(-E_\gamma) \le (I - G_\gamma X)^{-1}(-E_\gamma)$ and $(I - G_\gamma \widehat{X})^{-1}(-E_\gamma) \ne (I - G_\gamma X)^{-1}(-E_\gamma)$ since $E_\gamma < 0$. It follows from the Perron–Frobenius theory that $\rho((I - G_\gamma \widehat{X})^{-1}(-E_\gamma)) < \rho((I - G_\gamma X)^{-1}(-E_\gamma))$. Thus $\rho(\widehat{R}_\gamma) < \rho(R_\gamma) = 1$, and again $I - \widehat{R}_\gamma$ is nonsingular. Now (4.11) can be rewritten as

$$H \begin{bmatrix} I \\ \widehat{X} \end{bmatrix} = \begin{bmatrix} I \\ \widehat{X} \end{bmatrix} \gamma (I + \widehat{R}_\gamma)(I - \widehat{R}_\gamma)^{-1}. \tag{4.12}$$

Thus $\widehat{X}$ is also a nonnegative solution of (1.1). Since $X$ is minimal we have $\widehat{X} = X$ and so $\lim X_k = X$. Now, the sequence $\{H_k\}$ produced by the doubling algorithm is such that $H_k = X_{2^k}$ (see [1]). Therefore, $\lim H_k = X$, as required. The proof of $\lim G_k = Y$ is similar. □

4.2. When $\mu = 0$, the convergence of the doubling algorithm is not quadratic in general since the convergence of $\{X_k\}$ in (4.8) is sublinear in general. But the relation $H_k = X_{2^k}$ itself says that the convergence of the doubling algorithm is much faster than the basic fixed point iteration. The convergence in this case has been observed to be linear with rate 1/2.

4.3. We thank one referee for pointing out that the convergence of the doubling algorithm for the case $\mu = 0$ has recently been proved in [5] to be at least linear with rate 1/2.

In the doubling algorithm, we have the freedom to choose the parameter $\gamma$. In view of (4.4) and (4.5), the next result says that $\gamma = \max\{\max a_{ii}, \max d_{ii}\}$ is optimal, in some sense, for the doubling algorithm.

THEOREM 4.4. $\gamma \ge \max\{\max a_{ii}, \max d_{ii}\}$ $\rho(R_\gamma)$ $\rho(S_\gamma)$ $\gamma$

[illegible] Since $R = D - CX$ is an irreducible $M$-matrix, it can be written in the form $sI - N$, where $N \geq 0$ is irreducible. It follows from the Perron–Frobenius theorem that there is a positive vector $v$ such that $Rv = \lambda_n v$. Now

$$-R_\gamma v = (\gamma I + R)^{-1}(\gamma I - R)v = (\gamma + \lambda_n)^{-1}(\gamma - \lambda_n)v.$$

Since $-R_\gamma > 0$, it follows from the Perron–Frobenius theory that $\rho(R_\gamma) = \rho(-R_\gamma) = (\gamma + \lambda_n)^{-1}(\gamma - \lambda_n)$, which is a nondecreasing function of $\gamma$. Similarly, $\rho(S_\gamma)$ is a nondecreasing function of $\gamma$. ☐

**5. A shift technique.** In this section we assume that $M$ is an irreducible singular $M$-matrix. The vectors $u$ and $v$ are as in (2.1), and we have three cases: $\mu > 0$, $\mu = 0$, and $\mu < 0$. The next result shows that the case $\mu < 0$ is easily reduced to the case $\mu > 0$.

LEMMA 5.1. [illegible] $X$ [illegible] (1.1) [illegible] $Z = X^T$ [illegible]

$$ZC^TZ - ZA^T - D^TZ + B^T = 0. \tag{5.1}$$

[illegible] (1.1) [illegible] (5.1) [illegible]

[illegible] The first statement is easily shown by transposing on both sides of the equation. The $M$-matrix corresponding to (5.1) is

$$M_t = \begin{bmatrix} A^T & -C^T \\ -B^T & D^T \end{bmatrix}.$$

Since

$$\begin{bmatrix} v_2^T & v_1^T \end{bmatrix} M_t = 0, \quad M_t \begin{bmatrix} u_2 \\ u_1 \end{bmatrix} = 0,$$

the second statement follows readily. ☐

[illegible] 5.2. When $\mu \leq 0$, from the above proof and Theorem 2.1 we know that the minimal nonnegative solution $X$ of (1.1) is such that $X^Tu_2 = u_1$, or in other words, $u_2^TX = u_1^T$.

From now on, we assume that $\mu \geq 0$.

Our shift technique will be based on the following result (see also [17]).

LEMMA 5.3. [illegible] $T$ [illegible] $n \times n$ [illegible] $Tw = 0$ [illegible] $w$ [illegible] $r$ [illegible] $r^Tw = 1$ [illegible] $\eta$ [illegible]

$$\widehat{T} = T + \eta w r^T$$

[illegible] $T$ [illegible] $\widehat{T}$ [illegible] $\eta$

[illegible] We may easily verify that $(\widehat{T} - \lambda I)\lambda I = (T - \lambda I)(\lambda I - \eta w r^T)$ for any complex number $\lambda$. Taking determinants, one has that

$$\lambda^n \det(\widehat{T} - \lambda I) = \lambda^{n-1}(\lambda - \eta)\det(T - \lambda I),$$

from which the proof follows. ☐

We now construct a rank-one modification of the matrix $H$ in (1.3):

$$\widehat{H} = H + \eta v p^T, \tag{5.2}$$

where $\eta > 0$ is a scalar and $p \geq 0$ is a vector with $p^T v = 1$. Since $H$ is a singular matrix with $Hv = 0$, we know from Lemma 5.3 that the eigenvalues of $\widehat{H}$ are those of $H$ except that one zero eigenvalue of $H$ is replaced by $\eta$.

We write $p^T = \left(p_1^T, p_2^T\right)$ and

$$\widehat{H} = \begin{bmatrix} \widehat{D} & -\widehat{C} \\ \widehat{B} & -\widehat{A} \end{bmatrix}, \quad \widehat{M} = \begin{bmatrix} \widehat{D} & -\widehat{C} \\ -\widehat{B} & \widehat{A} \end{bmatrix},$$

where

$$\widehat{D} = D + \eta v_1 p_1^T, \quad \widehat{C} = C - \eta v_1 p_2^T,$$

$$\widehat{B} = B + \eta v_2 p_1^T, \quad \widehat{A} = A - \eta v_2 p_2^T.$$

Corresponding to $\widehat{M}$ we define the new NARE

$$Z\widehat{C}Z - Z\widehat{D} - \widehat{A}Z + \widehat{B} = 0. \tag{5.3}$$

We have the following important property about the NARE (5.3).

THEOREM 5.4. [illegible] $\mu \geq 0$ [illegible] $Z = X$ [illegible] (5.3) [illegible] $\sigma(\widehat{D} - \widehat{C}X) = \{\lambda_1, \ldots, \lambda_{n-1}, \eta\}$ [illegible] $X$ [illegible] (1.1)

[illegible] Observe that

$$X\widehat{C}X - X\widehat{D} - \widehat{A}X + \widehat{B} = XCX - XD - AX + B - \eta(Xv_1 - v_2)(p_2^T X + p_1^T).$$

Since $X$ is a solution of (1.1) and $Xv_1 = v_2$ by Theorem 2.1, $X$ is also a solution of the shifted equation (5.3). We have $\widehat{D} - \widehat{C}X = D - CX + \eta v_1(p_1^T + p_2^T X)$. Since $(D - CX)v_1 = Dv_1 - Cv_2 = 0$ and $(p_1^T + p_2^T X)v_1 = p^T v = 1$, the eigenvalues of $\widehat{D} - \widehat{C}X$ are $\lambda_1, \ldots, \lambda_{n-1}, \eta$ by Theorem 2.2 and Lemma 5.3. ☐

In what follows we will show that the dual equation of (5.3) has a solution $\widehat{Y}$ such that the eigenvalues of $-(\widehat{A} - \widehat{B}\widehat{Y})$ are the remaining eigenvalues of $\widehat{H}$: $\lambda_{n+1}, \ldots, \lambda_{n+m}$.

LEMMA 5.5. [illegible]

$$W = \begin{bmatrix} \eta p_1^T(v_1 - Yv_2) & \eta(p_1^T Y + p_2^T) \\ (B + \eta v_2 p_1^T)(v_1 - Yv_2) & -(A - BY - \eta v_2(p_1^T Y + p_2^T)) \end{bmatrix}$$

[illegible] $\eta, \lambda_{n+1}, \ldots, \lambda_{n+m}$

[illegible] We have

$$W = W_0 + \eta \begin{bmatrix} 1 \\ v_2 \end{bmatrix} \begin{bmatrix} p_1^T(v_1 - Yv_2) & p_1^T Y + p_2^T \end{bmatrix},$$

where

$$W_0 = \begin{bmatrix} 0 & 0 \\ B(v_1 - Yv_2) & -(A - BY) \end{bmatrix}.$$

The eigenvalues of $W_0$ are $0, \lambda_{n+1}, \ldots, \lambda_{n+m}$ by Theorem 2.2. Since

$$W_0 \begin{bmatrix} 1 \\ v_2 \end{bmatrix} = 0, \quad \begin{bmatrix} p_1^T(v_1 - Yv_2) & p_1^T Y + p_2^T \end{bmatrix} \begin{bmatrix} 1 \\ v_2 \end{bmatrix} = p^T v = 1,$$

the eigenvalues of $W$ are $\eta, \lambda_{n+1}, \ldots, \lambda_{n+m}$ by Lemma 5.3. ☐

LEMMA 5.6. [illegible] $\mu > 0$ [illegible] $f$ [illegible] $(1, f^T)$ [illegible] $W$ [illegible] $\eta$

[illegible] When $\mu > 0$, we have $Yv_2 < v_1$ by Theorem 2.1. Since $A - BY$ is an irreducible $M$-matrix, $A - BY - \eta v_2(p_1^T Y + p_2^T)$ is an irreducible $Z$-matrix. Since $\eta(p_1^T Y + p_2^T) \neq 0$ and $(B + \eta v_2 p_1^T)(v_1 - Yv_2) \neq 0$, the matrix $W$ is irreducible by a simple graph argument. It is clear that $W$ can be written in the form $N - sI$, where $N \geq 0$ is irreducible. The result then follows from the Perron–Frobenius theorem. ☐

LEMMA 5.7. [illegible] $\mu > 0$ [illegible] $\widehat{Y} = Y + (Yv_2 - v_1)f^T$ [illegible] (5.3)

[illegible] Let $\mathcal{R}(Z) = ZBZ - ZA - DZ + C$ and $\widehat{\mathcal{R}}(Z) = Z\widehat{B}Z - Z\widehat{A} - \widehat{D}Z + \widehat{C}$. We are to show $\widehat{\mathcal{R}}(\widehat{Y}) = 0$. Since $\mathcal{R}(Y) = 0$, we have

$$\widehat{\mathcal{R}}(\widehat{Y}) = (\widehat{\mathcal{R}}(\widehat{Y}) - \mathcal{R}(\widehat{Y})) + (\mathcal{R}(\widehat{Y}) - \mathcal{R}(Y)).$$

A straightforward computation shows that

$$\begin{aligned}\widehat{\mathcal{R}}(\widehat{Y}) - \mathcal{R}(\widehat{Y}) &= \eta(\widehat{Y}v_2 - v_1)(p_1^T \widehat{Y} + p_2^T) \\ &= \eta(Yv_2 - v_1)(1 + f^T v_2)(p_1^T Y + p_2^T + p_1^T(Yv_2 - v_1)f^T).\end{aligned}$$

Also, we have

$$\mathcal{R}(\widehat{Y}) - \mathcal{R}(Y) = (Yv_2 - v_1)(f^T B(Yv_2 - v_1)f^T - f^T(A - BY)),$$

where we have used the fact that

$$\begin{aligned}(D - YB)(Yv_2 - v_1) &= -Dv_1 + YBv_1 + (DY - YBY)v_2 \\ &= -Dv_1 + YBv_1 + (C - YA)v_2 = 0.\end{aligned}$$

Thus, to show $\widehat{\mathcal{R}}(\widehat{Y}) = 0$, we need only check

$$\begin{aligned}&f^T(B + \eta v_2 p_1^T)(Yv_2 - v_1)f^T + \eta p_1^T(Yv_2 - v_1)f^T \\ &\quad -f^T(A - BY - \eta v_2(p_1^T Y + p_2^T)) + \eta(p_1^T Y + p_2^T) = 0,\end{aligned}$$

which is true by the choice of $f$ in Lemma 5.6. ☐

We now show that the solution $\widehat{Y}$ has the desired spectral property.

THEOREM 5.8. [illegible] $\mu > 0$ [illegible] $\widehat{Y}$ [illegible] (5.3) [illegible] 5.7 [illegible] $\sigma(\widehat{A} - \widehat{B}\widehat{Y}) = \{-\lambda_{n+1}, \ldots, -\lambda_{n+m}\}$

[illegible] Notice that

$$\widehat{A} - \widehat{B}\widehat{Y} = A - BY - \eta v_2(p_1^T Y + p_2^T) - (B + \eta v_2 p_1^T)(Yv_2 - v_1)f^T.$$

For the matrix $W = \left[\begin{smallmatrix} W_{11} & W_{12} \\ W_{21} & W_{22}\end{smallmatrix}\right]$ in Lemma 5.5, we have

$$\begin{bmatrix} 1 & f^T \\ 0 & I \end{bmatrix} W \begin{bmatrix} 1 & f^T \\ 0 & I \end{bmatrix}^{-1} = \begin{bmatrix} 1 & f^T \\ 0 & I \end{bmatrix} W \begin{bmatrix} 1 & -f^T \\ 0 & I \end{bmatrix} = \begin{bmatrix} \eta & 0 \\ W_{21} & -(\widehat{A} - \widehat{B}\widehat{Y}) \end{bmatrix},$$

where we have used Lemma 5.6. Therefore, the eigenvalues of $\widehat{A} - \widehat{B}\widehat{Y}$ are $-\lambda_{n+1}, \ldots, -\lambda_{n+m}$ by Lemma 5.5. ☐

The case $\mu = 0$ has to be treated separately. Since $Yv_2 = v_1$, the matrix $W$ in Lemma 5.5 does not have a left eigenvector of the form $(1, f^T)$ corresponding to the eigenvalue $\eta$. In this case, we need to assume $p_1 > 0$. Actually, it is advisable in general to use a vector $p$ with $p_1 > 0$ also in the case $\mu > 0$, since this choice of $p$ guarantees that the matrix $\widehat{Y}$ is bounded independently of the nearness to null recurrence (as can be seen in the proof of the following theorem). In the next section, however, we will use a vector $p$ without this assumption for a special class of the NARE (1.1). There, the boundedness of $\widehat{Y}$ independent of the nearness to null recurrence will be guaranteed in another way.

THEOREM 5.9. [illegible] $\mu = 0$ [illegible] $p_1 > 0$ [illegible] (5.3) [illegible] $\widehat{Y}$ [illegible] $\sigma(\widehat{A} - \widehat{B}\widehat{Y}) = \{-\lambda_{n+1}, \dots, -\lambda_{n+m}\}$

[illegible]. We use a continuity argument similar to the one used in [10] when a shift technique in [16] is used for null recurrent quasi-birth-death problems. We introduce the irreducible singular $M$-matrix

$$M(k) = \begin{bmatrix} D(k) & -C(k) \\ -B(k) & A(k) \end{bmatrix} = \begin{bmatrix} D & -C \\ -(1+\frac{1}{k})B & (1+\frac{1}{k})A \end{bmatrix}$$

($k = 1, 2, \dots$). The left and right eigenvectors of $M(k)$ corresponding to the zero eigenvalue are given by

$$u_1(k) = u_1, \quad u_2(k) = \left(1 + \frac{1}{k}\right)^{-1} u_2, \quad v_1(k) = v_1, \quad v_2(k) = v_2.$$

Thus, the NARE corresponding to $M(k)$

$$ZCZ - ZD - A(k)Z + B(k) = 0 \tag{5.4}$$

is positive recurrent since $u_1(k)^T v_1(k) > u_2(k)^T v_2(k)$. Let $Y(k)$ be the minimal nonnegative solution of the dual equation of (5.4). Then $Y(k)v_2 < v_1$ and in particular the sequence $\{Y(k)\}$ is bounded. When $M$ is replaced by $M(k)$, we have a matrix $W(k)$ corresponding to the matrix $W$ in Lemma 5.5. Let $(1, f(k)^T)$ be the left eigenvector of $W(k)$ corresponding to the eigenvalue $\eta$. Now, $\widehat{Y}(k) = Y(k) + (Y(k)v_2 - v_1)f(k)^T$ is a solution of the dual equation of

$$Z\widehat{C}Z - Z\widehat{D} - \widehat{A}(k)Z + \widehat{B}(k) = 0,$$

where $\widehat{A}(k) = A(k) - \eta v_2 p_2^T$ and $\widehat{B}(k) = B(k) + \eta v_2 p_1^T$, and the eigenvalues of $\widehat{A}(k) - \widehat{B}(k)\widehat{Y}(k)$ are those of $A(k) - B(k)Y(k)$. We need to show that the sequence $\{\widehat{Y}(k)\}$ is bounded. Since $(1, f(k)^T)W(k) = \eta(1, f(k)^T)$, we have

$$\begin{aligned} \eta &= \eta p_1^T(v_1 - Y(k)v_2) + f(k)^T(B(k) + \eta v_2 p_1^T)(v_1 - Y(k)v_2) \\ &\geq f(k)^T(\eta v_2 p_1^T)(v_1 - Y(k)v_2) \end{aligned}$$

and thus

$$f(k)^T(v_2 p_1^T)(v_1 - Y(k)v_2) = p_1^T(v_1 - Y(k)v_2)f(k)^T v_2 \leq 1.$$

Since $p_1, v_2 > 0$, $\{(v_1 - Y(k)v_2)f(k)^T\}$ is bounded and thus $\{\widehat{Y}(k)\}$ is bounded. Let $\widehat{Y}$ be any limit point of the sequence $\{\widehat{Y}(k)\}$. Then the eigenvalues of $\widehat{A} - \widehat{B}\widehat{Y}$ are those of $A - BY$ since $\lim Y(k) = Y$ by Theorem 3.3 of [12]. $\square$

When $\mu = 0$, the matrix $H$ has two zero eigenvalues. The above shift technique moves one zero eigenvalue to a positive number. We may use a [illegible] to move the other zero eigenvalue to a negative number. Recall that $Hv = 0$, where $v = \left[\begin{smallmatrix} v_1 \\ v_2 \end{smallmatrix}\right]$, and $w^T H = 0$, where $w = \left[\begin{smallmatrix} u_1 \\ -u_2 \end{smallmatrix}\right]$. We define the matrix

$$\overline{H} = H + \eta v p^T + \xi q w^T, \tag{5.5}$$

where $\eta > 0$, $\xi < 0$, $p$ and $q$ are such that $p^T v = q^T w = 1$. Since $v$ and $w$ are orthogonal vectors, the double-shift moves one zero eigenvalue to $\eta$ and the other to $\xi$. Indeed, the eigenvalues of $\widetilde{H} = H + \xi q w^T$ are those of $\widetilde{H}^T = H^T + \xi w q^T$, which are the eigenvalues of $H$ except that one zero eigenvalue is replaced by $\xi$, by Lemma 5.3. Also, the eigenvalues of $\overline{H} = \widetilde{H} + \eta v p^T$ are the eigenvalues of $\widetilde{H}$ except that the remaining zero eigenvalue is replaced by $\eta$, again by Lemma 5.3.

From $\overline{H}$ we may define a new Riccati equation

$$Z\overline{C}Z - Z\overline{D} - \overline{A}Z + \overline{B} = 0. \tag{5.6}$$

As before, the minimal nonnegative solution $X$ of (1.1) is a solution of (5.6) such that $\sigma(\overline{D} - \overline{C}X) = \{\eta, \lambda_1, \dots, \lambda_{n-1}\}$. However, it seems very difficult to determine the existence of a solution $\overline{Y}$ of the dual equation of (5.6) such that $\sigma(\overline{A} - \overline{B}\,\overline{Y}) = \{-\xi, -\lambda_{n+2}, \dots, -\lambda_{n+m}\}$. We will not investigate the double-shift any further in this paper.

## 6. The doubling algorithm applied to the shifted equation.

In this section we assume that $M$ is an irreducible singular $M$-matrix and $\mu \geq 0$. We will show that the doubling algorithm applied to (5.3) converges faster (if no breakdown occurs) than the doubling algorithm applied to (1.1). The applicability of the SDA algorithm to the shifted equation (5.3) is still a work in progress, but we will prove that no breakdown occurs under suitable assumptions on the matrix $\widehat{M}$.

### 6.1. Convergence properties.

By Theorems 5.4, 5.8, and 5.9, the matrices $X$ and $\widehat{Y}$ are such that

$$\widehat{H}\begin{bmatrix} I \\ X \end{bmatrix} = \begin{bmatrix} I \\ X \end{bmatrix}(\widehat{D} - \widehat{C}X), \quad \widehat{H}\begin{bmatrix} \widehat{Y} \\ I \end{bmatrix} = \begin{bmatrix} \widehat{Y} \\ I \end{bmatrix}(-(\widehat{A} - \widehat{B}\widehat{Y})), \tag{6.1}$$

where $\sigma(\widehat{D} - \widehat{C}X) = \{\lambda_1, \dots, \lambda_{n-1}, \eta\}$, $\sigma(\widehat{A} - \widehat{B}\widehat{Y}) = \{-\lambda_{n+1} \dots, -\lambda_{n+m}\}$. Recall that we need to assume $p_1 > 0$ for the vector $p$ used in the shift technique when $\mu = 0$, to get the second equation in (6.1).

We apply the Cayley transform with $\gamma > 0$ to each of the equations in (6.1), thus obtaining

$$\begin{aligned} (\widehat{H} - \gamma I)\begin{bmatrix} I \\ X \end{bmatrix} &= (\widehat{H} + \gamma I)\begin{bmatrix} I \\ X \end{bmatrix}\mathcal{C}_\gamma(\widehat{D} - \widehat{C}X), \\ (\widehat{H} - \gamma I)\begin{bmatrix} \widehat{Y} \\ I \end{bmatrix}\mathcal{C}_\gamma(\widehat{A} - \widehat{B}\widehat{Y}) &= (\widehat{H} + \gamma I)\begin{bmatrix} \widehat{Y} \\ I \end{bmatrix}. \end{aligned} \tag{6.2}$$

We then proceed as in section 3, with (3.3) and (3.7) replaced by the equations in (6.2). Assuming that no breakdown occurs, the doubling algorithm generates the sequences of matrices $\{\widehat{E}_k\}, \{\widehat{F}_k\}, \{\widehat{G}_k\}, \{\widehat{H}_k\}$. We prove the following convergence result.

THEOREM 6.1. [illegible] $M$ [illegible] $M$ [illegible] $\mu \geq 0$ [illegible] $\{\widehat{E}_k\}, \{\widehat{F}_k\}, \{\widehat{G}_k\}, \{\widehat{H}_k\}$ [illegible] (5.3) [illegible] $\{\widehat{H}_k\}$ $(\{\widehat{G}_k\})$ [illegible] $X$ $(\widehat{Y})$ [illegible]

$$\limsup_{k\to\infty} \sqrt[2^k]{\|\widehat{H}_k - X\|} \leq \rho(\mathcal{C}_\gamma(\widehat{D} - \widehat{C}X))\rho(\mathcal{C}_\gamma(\widehat{A} - \widehat{B}\widehat{Y})), \tag{6.3}$$

$$\limsup_{k\to\infty} \sqrt[2^k]{\|\widehat{G}_k - \widehat{Y}\|} \leq \rho(\mathcal{C}_\gamma(\widehat{D} - \widehat{C}X))\rho(\mathcal{C}_\gamma(\widehat{A} - \widehat{B}\widehat{Y})). \tag{6.4}$$

[illegible] As in section 4, we have

$$X - \widehat{H}_k = (I - \widehat{H}_k\widehat{Y})(\mathcal{C}_\gamma(\widehat{A} - \widehat{B}\widehat{Y}))^{2^k} X (\mathcal{C}_\gamma(\widehat{D} - \widehat{C}X))^{2^k}, \tag{6.5}$$

$$\widehat{Y} - \widehat{G}_k = (I - \widehat{G}_k X)(\mathcal{C}_\gamma(\widehat{D} - \widehat{C}X))^{2^k} \widehat{Y} (\mathcal{C}_\gamma(\widehat{A} - \widehat{B}\widehat{Y}))^{2^k}. \tag{6.6}$$

We prove (6.3). The proof of (6.4) is similar. By writing the $\widehat{H}_k$ on the right-hand side of (6.5) as $X - (X - \widehat{H}_k)$, we find

$$\begin{aligned} &(X - \widehat{H}_k)\left(I - \widehat{Y}(\mathcal{C}_\gamma(\widehat{A} - \widehat{B}\widehat{Y}))^{2^k} X (\mathcal{C}_\gamma(\widehat{D} - \widehat{C}X))^{2^k}\right) \\ &\qquad = (I - X\widehat{Y})(\mathcal{C}_\gamma(\widehat{A} - \widehat{B}\widehat{Y}))^{2^k} X (\mathcal{C}_\gamma(\widehat{D} - \widehat{C}X))^{2^k}. \end{aligned} \tag{6.7}$$

Note that

$$\begin{aligned} &\sigma(\mathcal{C}_\gamma(\widehat{D} - \widehat{C}X)) = \{\mathcal{C}_\gamma(\lambda_1), \dots, \mathcal{C}_\gamma(\lambda_{n-1}), \mathcal{C}_\gamma(\eta)\}, \\ &\sigma(\mathcal{C}_\gamma(D - CX)) = \{\mathcal{C}_\gamma(\lambda_1), \dots, \mathcal{C}_\gamma(\lambda_{n-1}), \mathcal{C}_\gamma(0)\}, \\ &\sigma(\mathcal{C}_\gamma(\widehat{A} - \widehat{B}\widehat{Y})) = \sigma(\mathcal{C}_\gamma(A - BY)) = \{\mathcal{C}_\gamma(-\lambda_{n+1}), \dots, \mathcal{C}_\gamma(-\lambda_{m+n})\}. \end{aligned}$$

By Theorem 2.2 and the property of the Cayley transform, we have

$$\rho(\mathcal{C}_\gamma(\widehat{D} - \widehat{C}X)) < \rho(\mathcal{C}_\gamma(D - CX)) = 1, \quad \rho(\mathcal{C}_\gamma(\widehat{A} - \widehat{B}\widehat{Y})) = \rho(\mathcal{C}_\gamma(A - BY)) \leq 1. \tag{6.8}$$

Thus $I - \widehat{Y}(\mathcal{C}_\gamma(\widehat{A} - \widehat{B}\widehat{Y}))^{2^k} X (\mathcal{C}_\gamma(\widehat{D} - \widehat{C}X))^{2^k}$ converges to $I$ in (6.7), and (6.3) follows immediately. □

Recall that the sequence $\{H_k\}$ generated in section 3 is such that

$$\limsup_{k\to\infty} \sqrt[2^k]{\|H_k - X\|} \leq \rho(\mathcal{C}_\gamma(D - CX))\rho(\mathcal{C}_\gamma(A - BY)).$$

In view of (6.8), the convergence of the doubling algorithm applied to the shifted equation is faster than the convergence of the same algorithm applied to the original equation. As we will show in the numerical experiments, the number of steps necessary for convergence can decrease dramatically by using the shift technique. In particular, when $\mu = 0$, the SDA algorithm applied to the shifted equation still has quadratic convergence. According to the results in [12], the shift equation is also better conditioned than the original equation.

At this point it must be specified which is the best choice for the parameter $\eta$ in terms of the speed of convergence. In fact, the fastest convergence is expected when $\rho(\mathcal{C}_\gamma(\widehat{D} - \widehat{C}X))$ is minimal, i.e., when $|\mathcal{C}_\gamma(\eta)| \leq \max\{|\mathcal{C}_\gamma(\lambda_i)|, i = 1, \dots, n-1\}$. This happens, for instance, if $\eta = \gamma$ (i.e., $\mathcal{C}_\gamma(\eta) = 0$).

**6.2. Applicability for a special class of NARE.** We can prove the applicability of the SDA algorithm to the shifted equation for a special class of the NARE (1.1) and for proper choices of $\eta, p$, and $\gamma$.

The special class consists of equations for which either $C$ has at least one positive column or $D$ has at least one column with no zero entries.

For ease of notation, we assume without loss of generality [12] that $v = e$, the vector of ones. We define $r_1 \in \mathbb{R}^n$ and $r_2 \in \mathbb{R}^m$ by

$$(r_1)_j = \min_{1\le i\le n, i\ne j} |d_{ij}|, \quad j = 1, \ldots, n, \quad (r_2)_j = \min_{1\le i\le n} c_{ij}, \quad j = 1, \ldots, m,$$

and define $r \geq 0$ by $r^T = (r_1^T, r_2^T)$. We have $r \neq 0$ for each equation in the special class, and we use the shift (5.2) with $\eta = r^T e$ and $p = r/r^T e$.

Clearly, the matrix $\widehat{M}$ is a $Z$-matrix. It is interesting to note that $\widehat{M}$ is also an $M$-matrix. This follows from the fact that

$$\left(u_1^T, u_2^T\right) \widehat{M} = \eta \left(\mu p_1^T, \mu p_2^T\right) = \mu \left(r_1^T, r_2^T\right) \geq 0.$$

Recall that $\widehat{M}$ is nonsingular when $\mu > 0$ and is singular when $\mu = 0$. It should be noted that $\widehat{M}$ may be a [illegible] singular $M$-matrix. As a simple example, we have $\widehat{M} = \left[\begin{smallmatrix} 2 & 0 \\ -2 & 0 \end{smallmatrix}\right]$ when $M = \left[\begin{smallmatrix} 1 & -1 \\ -1 & 1 \end{smallmatrix}\right]$.

In view of the results in [15], the doubling algorithm can be applied to the NARE corresponding to $\widehat{M}$ with $\gamma > \max\{\max(a_{ii}-(r_2)_i), \max(d_{ii}+(r_1)_i)\}$, and the matrices to be inverted in the algorithm are all nonsingular $M$-matrices. The results in [15] are stated for nonsingular $M$-matrices, but are easily seen to be true also for singular $M$-matrices. By Theorem 3.2 we can also take $\gamma = \max\{\max(a_{ii}-(r_2)_i), \max(d_{ii}+(r_1)_i)\}$ when $\widehat{M}$ is irreducible.

For the convergence analysis of the doubling algorithm applied to the matrix $\widehat{M}$, we need to prove the existence of $\widehat{Y}$ with the property in (6.1). By our definition of the vector $p$, we no longer have $p_1 > 0$ unless all off-diagonal elements of $D$ are negative. Therefore, we need a different proof for the existence of $\widehat{Y}$ with the property in (6.1), for the case $\mu = 0$ (see Theorem 5.9).

For the proof, we need to assume that the $M$-matrix $\widehat{M}$ is such that $I \otimes \widehat{A} + \widehat{D}^T \otimes I$ is a nonsingular $M$-matrix, where $\otimes$ is the Kronecker product. This is an additional assumption only when $\mu = 0$ and $\widehat{M}$ is reducible, and it is guaranteed by the assumption in the next result.

LEMMA 6.2. [illegible] (1.1) [illegible] $A$ [illegible] $B$ [illegible] $I \otimes \widehat{A} + \widehat{D}^T \otimes I$ [illegible] $M$[illegible]

[illegible]. Note that

$$(D - r_2^T eI)e - (C - er_2^T)e = De - Ce = 0.$$

So $D - r_2^T eI$ is an $M$-matrix. Now,

$$\begin{aligned} I \otimes \widehat{A} + \widehat{D}^T \otimes I &\geq I \otimes (A - er_2^T) + (D - r_2^T eI)^T \otimes I + r_2^T eI \otimes I \\ &= I \otimes (A - er_2^T + r_2^T eI) + (D - r_2^T eI)^T \otimes I. \end{aligned}$$

Note that $(A - er_2^T + r_2^T eI)e = Ae = Be \geq 0$ and that $Be \neq 0$. If $A$ is irreducible, then $A - er_2^T + r_2^T eI$ is irreducible. If $B$ has no zero rows, then $Be > 0$. In either case, $A - er_2^T + r_2^T eI$ is a nonsingular $M$-matrix. Therefore, $I \otimes \widehat{A} + \widehat{D}^T \otimes I$ is also a nonsingular $M$-matrix. $\square$

We now prove the existence of $\widehat{Y}$ with the property in (6.1), assuming that $I \otimes \widehat{A} + \widehat{D}^T \otimes I$ is a nonsingular $M$-matrix for the special class of the NARE (1.1). First, we note that

$$Y\widehat{B}Y - Y\widehat{A} - \widehat{D}Y + \widehat{C} = \eta(Ye - e)(p_1^T Y + p_2^T) \le 0.$$

By Theorem 2.3 of [8], there is a minimal $\widehat{Y}$, $0 \le \widehat{Y} \le Y$, such that

$$\widehat{Y}\widehat{B}\widehat{Y} - \widehat{Y}\widehat{A} - \widehat{D}\widehat{Y} + \widehat{C} = 0.$$

Note that

$$\widehat{H}\begin{bmatrix} I & \widehat{Y} \\ X & I \end{bmatrix} = \begin{bmatrix} I & \widehat{Y} \\ X & I \end{bmatrix}\begin{bmatrix} \widehat{D} - \widehat{C}X & 0 \\ 0 & -(\widehat{A} - \widehat{B}\widehat{Y}) \end{bmatrix}.$$

When $\mu > 0$, we have $Xe = e$ and $\widehat{Y}e < e$ and the matrix

$$\begin{bmatrix} I & \widehat{Y} \\ X & I \end{bmatrix}$$

is nonsingular. So the eigenvalues of $\widehat{A} - \widehat{B}\widehat{Y}$ are $-\lambda_{n+1}, \ldots, -\lambda_{n+m}$. By a continuity argument, the eigenvalues of $\widehat{A} - \widehat{B}\widehat{Y}$ are also $-\lambda_{n+1}, \ldots, -\lambda_{n+m}$ when $\mu = 0$.

**7. Numerical experiments.** We compare the numerical behavior of the SDA algorithm applied to (1.1) and to the shifted equation (5.3), when $\mu \ge 0$. Recall that the case $\mu < 0$ is easily reduced to the case $\mu > 0$ through Lemma 5.1.

The numerical experiments are performed by using MATLAB; the stopping condition is $\min\{\|E_k\|_1, \|F_k\|_1\} < 10^{-15}$.

We take $\gamma = \max\{\max a_{ii}, \max d_{ii}\}$ for the Cayley transform, as suggested by Theorem 4.4. For the shift technique, we take $\eta = \gamma$ and $p = e/v^T e$, where $e$ is the vector (of suitable size) with all components equal to 1.

TEST 7.1 (see [8]). [illegible] $M$ [illegible] $Me = 0$. To construct $M$, we generate $R$, a $100 \times 100$ random matrix, and define $M = \mathrm{diag}(Re) - R$. The matrices $A, B, C$, and $D$ are $50 \times 50$.

We generate 5 different matrices $M$ in this way, each with $\mu > 0$. In Table 7.1 we report the number of iterations and the relative residual, defined as

$$\mathrm{res} = \frac{\|XCX - XD - AX + B\|_1}{\|XCX\|_1 + \|XD\|_1 + \|AX\|_1 + \|B\|_1}.$$

As one can see, the number of steps applied to the shifted equation is smaller, while the residual error remains roughly the same ($u \approx 2.2 \times 10^{-16}$ is the unit roundoff).

TABLE 7.1
*SDA applied to original and shifted NARE.*

| | SDA | | SDA applied to shifted NARE | |
|---|---|---|---|---|
| | iter | res/err | iter | res/err |
| Test 1 | 12–13 | res=$1.1u$–$2.1u$ | 5 | res=$1.2u$–$1.7u$ |
| Test 2 | 33 | err=$1.6 \times 10^{-9}$ | 5 | err=$2.2 \times 10^{-16}$ |
| Test 3 | 18 | err=$3.5 \times 10^{-13}$ | 4 | err=$2.3 \times 10^{-13}$ |

Test 7.2 (see [2, Example 1]). [illegible]. Let

$$M = \begin{bmatrix} 0.003 & -0.001 & -0.001 & -0.001 \\ -0.001 & 0.003 & -0.001 & -0.001 \\ -0.001 & -0.001 & 0.003 & -0.001 \\ -0.001 & -0.001 & -0.001 & 0.003 \end{bmatrix},$$

where $D$ is a $2 \times 2$ matrix. The minimal positive solution is $X = \frac{1}{2}E_{2,2}$, where $E_{m,n}$ is the $m \times n$ matrix having all entries equal to 1.

In this case the SDA algorithm shows linear convergence while the SDA applied to the shifted equation has quadratic convergence. Indeed, as reported in Table 7.1 the number of steps decreases dramatically. Since the solution is explicitly known, we have compared the absolute error, defined as the 1-norm of the difference between the exact and the computed solution, obtained with both methods. Observe that the solution computed without performing the shift is much less accurate than the one obtained by applying the shift. This phenomenon is to be expected in view of the theoretical results in [12].

Test 7.3 (see [2, Example 3]). [illegible]. In this example $A = \mathrm{diag}(0.018\, E_{2,1})$, $D = \mathrm{diag}(180.002\, E_{18,1}) - 10\, E_{18,18}$, $B = 0.001\, E_{2,18}$, and $C = B^T$. The solution is known to be $\frac{1}{18}E_{2,18}$. The results are shown in Table 7.1; the reduction of the number of iterations for the shifted equation is significant.

In all our experiments, the approximations to $X$ obtained by the SDA algorithm with the shift technique are more accurate than those obtained without the shift technique, for the same number of iterations. The approximations obtained by the shift technique converge to the positive solution $X$. However, when $X$ has very small positive elements, it is possible that at the time of termination of the algorithm the approximation obtained has some very small negative elements. We have not yet encountered such situations, but if those situations do occur, we can simply reset those small negative numbers to 0, indicating that the actual values are very small positive numbers.

# BLOCK DIAGONAL AND SCHUR COMPLEMENT PRECONDITIONERS FOR BLOCK-TOEPLITZ SYSTEMS WITH SMALL SIZE BLOCKS*

WAI-KI CHING†, MICHAEL K. NG‡, AND YOU-WEI WEN§

**Abstract.** In this paper we consider the solution of Hermitian positive definite block-Toeplitz systems with small size blocks. We propose and study block diagonal and Schur complement preconditioners for such block-Toeplitz matrices. We show that for some block-Toeplitz matrices, the spectra of the preconditioned matrices are uniformly bounded except for a fixed number of outliers where this fixed number depends only on the size of the block. Hence, conjugate gradient type methods, when applied to solving these preconditioned block-Toeplitz systems with small size blocks, converge very fast. Recursive computation of such block diagonal and Schur complement preconditioners is considered by using the nice matrix representation of the inverse of a block-Toeplitz matrix. Applications to block-Toeplitz systems arising from least squares filtering problems and queueing networks are presented. Numerical examples are given to demonstrate the effectiveness of the proposed method.

## 1. Introduction.

In this paper we consider the solution of a Hermitian positive definite block-Toeplitz (BT) system with small size blocks

$$A_{n,m}X = B, \tag{1.1}$$

where $X$ and $B$ are $mn$-by-$m$ matrices and

$$A_{n,m} = \begin{pmatrix} A_0 & A_{-1} & \cdots & A_{1-n} \\ A_1 & A_0 & \ddots & \vdots \\ \vdots & \ddots & \ddots & A_{-1} \\ A_{n-1} & \cdots & A_1 & A_0 \end{pmatrix},$$

where each $A_j$ is an $m$-by-$m$ matrix with $A_j = A_{-j}^*$ and $m$ is much smaller than $n$. Here "$*$" denotes the conjugate transpose. This kind of linear system arises from many applications such as the multichannel least squares filtering in time series [26], signal and image processing [20], and queueing system [11]. We will discuss these

applications, in particular the least squares filtering problems and queueing networks, in section 5.

Recent research on using the preconditioned conjugate gradient method as an iterative method for solving $n$-by-$n$ Toeplitz systems has received much attention.One of the more important results of this methodology is that the complexity of solving a large class of Toeplitz systems can be reduced to $O(n \log n)$ operations provided that a suitable preconditioner is chosen under certain conditions on the Toeplitz matrix [7]. Circulant preconditioners [3, 4, 8, 9, 10, 17, 25, 30, 33], banded-Toeplitz preconditioners [5], and multigrid methods [6, 12] have been proposed and analyzed. In these papers, the diagonals of the Toeplitz matrix are assumed to be the Fourier coefficients of a certain generating function.

In the literature, there are some papers [18, 21, 22, 27, 28, 29, 31] which discuss iterative BT solvers. In [21, 28, 29], the authors considered $n$-by-$n$ BT matrices with $m$-by-$m$ blocks generated by a Hermitianmatrix-valued generating function and analyzed the associated problem of preconditioning using preconditioners which generated nonnegative definite,not essentially singular, matrix-valued functions. In [18, 22, 27], the authors considered block-Toeplitz–Toeplitz-block matrices and studied block band-Toeplitz preconditioners. In [31], multigrid methods were applied to solving block-Toeplitz–Toeplitz-block systems. In the above methods, the underlying generating functions are assumed to be known in order to construct the preconditioners.

In this paper, we also consider BT matrices $A_{n,m}$ generated by a matrix-valued function

$$F_m(\theta) = [f_{u,v}(\theta)]_{1 \le u,v \le m},$$

where $f_{u,v}(\theta)$ are $2\pi$-periodic functions. Under this assumption, the block $A_j$ of $A_{n,m}$ is given by

$$A_j = \frac{1}{2\pi} \int_{-\pi}^{\pi} F_m(\theta) e^{-\mathrm{i}j\theta} d\theta.$$

When $F_m(\theta)$ is nonnegative definite and not essentially singular, the associated BT matrix $A_{n,m}$ is positive definite [21, 28]. For such BT matrices, Serra [28] has investigated BT preconditioners and studied the spectral property of these preconditioned matrices. He proved that if the BT preconditioner is generated by $G_m(\theta)$, the generalized Rayleigh quotient, related to matrix functions $F_m(\theta)$ and $G_m(\theta)$, is contained in a set of the form $(c_1, c_2)$ with $0 < c_1$ and $c_2 < \infty$, then the preconditioned conjugate gradient (PCG) method requires only a constant number of iterations in order to solve, within a preassigned accuracy, the given BT system.

In [24], Ng, Sun, and Jin proposed to using recursive-based PCG methods for solving Toeplitz systems. The idea is to use a principal submatrix of a Toeplitz matrix as a preconditioner. The inverse of the preconditioner can be constructed recursively by using the Gohberg–Semencul formula. They have shown that this method is competitive with the method of circulant preconditioners. Based on this idea, the main aim of this paper is to study block diagonal and Schur complement preconditioners for BT systems. We note that there is a natural partitioning of the BT matrix in 2-by-2 blocks as follows:

$$A_{n,m} = \begin{pmatrix} A^{(1,1)} & A^{(1,2)} \\ A^{(2,1)} & A^{(2,2)} \end{pmatrix}. \tag{1.2}$$

Here $A^{(1,1)}$ and $A^{(2,2)}$ are the principal submatrices of $A_{n,m}$. They are also BT matrices generated by the same generating function of $A_{n,m}$. Therefore it is natural and important to examine if the corresponding system

$$\begin{pmatrix} A^{(1,1)} & A^{(1,2)} \\ A^{(2,1)} & A^{(2,2)} \end{pmatrix} \begin{pmatrix} X_1 \\ X_2 \end{pmatrix} = \begin{pmatrix} B_1 \\ B_2 \end{pmatrix} \tag{1.3}$$

can be solved efficiently by exploiting this partitioning. Here we consider preconditioning $A_{n,m}$ by a block diagonal matrix

$$B_{n,m} = \begin{pmatrix} A^{(1,1)} & 0 \\ 0 & A^{(2,2)} \end{pmatrix}.$$

Since both $A^{(1,1)}$ and $A^{(2,2)}$ are BT matrices generated by the same generating function $F_m(\theta)$, we particularly consider $B_{n,m}$ in the following form:

$$B_{n,m} = \begin{pmatrix} A_{n/2,m} & 0 \\ 0 & A_{n/2,m} \end{pmatrix}. \tag{1.4}$$

Here, without loss of generality, we may assume $n$ is even. We note that if $A_{n,m}$ is positive definite, then $B_{n,m}$ is also positive definite and the eigenvalues of the preconditioned matrix $B_{n,m}^{-1}A_{n,m}$ lie in the interval $(0, 2)$.

On the other hand, the Schur complement arises when we use a block factorization of (1.2). The linear system (1.3) becomes

$$\begin{pmatrix} I & 0 \\ A^{(2,1)}(A^{(1,1)})^{-1} & I \end{pmatrix} \begin{pmatrix} A^{(1,1)} & A^{(1,2)} \\ 0 & S_{n,m} \end{pmatrix} \begin{pmatrix} X_1 \\ X_2 \end{pmatrix} = \begin{pmatrix} B_1 \\ B_2 \end{pmatrix},$$

where

$$S_{n,m} = A^{(2,2)} - A^{(2,1)}(A^{(1,1)})^{-1}A^{(1,2)}.$$

We see that the method requires the formation of the Schur complement matrix. Therefore we consider approximating $S_{n,m}$ by $A^{(2,2)} = A_{n/2,m}$ and study the preconditioner of the form

$$\begin{aligned} C_{n,m} &= \begin{pmatrix} I & 0 \\ A^{(2,1)}(A^{(1,1)})^{-1} & I \end{pmatrix} \begin{pmatrix} A^{(1,1)} & A^{(1,2)} \\ 0 & A^{(2,2)} \end{pmatrix} \\ &= \begin{pmatrix} A^{(1,1)} & A^{(1,2)} \\ A^{(2,1)} & A^{(2,2)} + A^{(2,1)}(A^{(1,1)})^{-1}A^{(1,2)} \end{pmatrix}. \end{aligned} \tag{1.5}$$

We note that if $A_{n,m}$ is positive definite, then $C_{n,m}$ is also positive definite and the eigenvalues of the preconditioned matrix $C_{n,m}^{-1}A_{n,m}$ are inside of the interval $(0, 1]$. In particular, there are at least $mn/2$ eigenvalues of the preconditioned matrix being equal to one. Our experimental results also show that the Schur-complement preconditioner is better than the block diagonal preconditioner. We remark that the main reason for discussing the block diagonal preconditioner is that it is needed for deriving the theory for the Schur-complement preconditioner.

The main result of this paper is that if the generating function $F_m(\theta)$ is Hermitian positive definite, and is spectrally equivalent to

$$G_m(\theta) = [g_{u,v}]_{1 \le u,v \le m},$$

where $g_{u,v}$ are trigonometric polynomials, then the spectra of the preconditioned matrices $B_{n,m}^{-1}A_{n,m}$ and $C_{n,m}^{-1}A_{n,m}$ are uniformly bounded except for a fixed number of outliers where the number of outliers depends only on $m$. Hence the conjugate gradient type methods, when applied to solving these preconditioned BT systems, converge very quickly, especially when $m$ is small.

The goal of this paper is to construct preconditioners that do not require matrix generating functions. We note that the construction of our preconditioners does not require the underlying matrix generating functions, while the preconditioners from [21, 28] require matrix generating functions. In the construction of our preconditioners, the inverse of BT matrix $A^{(1,1)}$ is required. Using the same idea in [24], we employ the Gohberg–Semencul formula to represent the form of the inverse of $A^{(1,1)}$ and apply a recursive method to construct the inverse of $A^{(1,1)}$. It is important to note that we do not directly use the Gohberg–Semencul formula to generate the solution of the original BT system.

We remark that the solution results are not accurate when the BT matrices are ill-conditioned. Indeed, we use the Gohberg–Semencul formula to generate an approximate inverse preconditioner and then use the PCG method with this preconditioner to compute the solution of the original system iteratively. Our numerical results indicate that the accuracy of the computed solutions using the proposed preconditioners is quite acceptable.

The outline of this paper is as follows. In section 2, we analyze the spectra of the preconditioned matrices. In section 3, we describe the recursive algorithms for block diagonal and Schur complement preconditioners. Numerical results are given in section 4 to illustrate the effectiveness of our approach. Finally, concluding remarks are given in section 5.

**2. Analysis of preconditioners.** In this section, we analyze the spectra of the preconditioned matrices $B_{m,n}^{-1}A_{n,m}$ and $C_{n,m}^{-1}A_{n,m}$.

We first note that since $A_{n,m}$ is positive definite, we have the following results, which are given in [1, pp. 374–377].

LEMMA 2.1. [illegible] $\mathbf{x}$ [illegible] $\mathbf{y}$ [illegible] $mn/2$ [illegible]

$$\gamma = \sup_{\mathbf{x},\mathbf{y}} \frac{\mathbf{x}^* A_{n/2,m}^{(1)} \mathbf{y}}{\sqrt{\mathbf{x}^* A_{n/2,m}\mathbf{x} \cdot \mathbf{y}^* A_{n/2,m}\mathbf{y}}}.$$

[illegible] $A_{n,m}$ [illegible] $\gamma < 1$ [illegible]

$$\gamma^2 = \sup_{\mathbf{y}} \frac{\mathbf{y}^* A_{n/2,m}^{2,1} A_{n/2,m}^{-1} A_{n/2,m}^{1,2} \mathbf{y}}{\mathbf{y}^* A_{n/2,m}\mathbf{y}}.$$

Using Lemma 2.1 and the assumption that $A_{n,m}$ is Hermitian and positive definite, we have the following results:

- The eigenvalues of the preconditioned matrix $B_{n,m}^{-1}A_{n,m}$ lie inside the interval $(0, 2)$. Also if $\mu$ is an eigenvalue of $B_{n,m}^{-1}A_{n,m}$, then $2-\mu$ is also an eigenvalue of $B_{n,m}^{-1}A_{n,m}$.
- The eigenvalues of $C_{n,m}^{-1}A_{n,m}$ are inside the interval $(0, 1]$. Moreover, at least $mn/2$ eigenvalues of $C_{n,m}^{-1}A_{n,m}$ are equal to 1.

We then show that the eigenvalues of $B_{n,m}^{-1}A_{n,m}$ and $C_{n,m}^{-1}A_{n,m}$ are uniformly bounded except for a fixed number of outliers for some generation functions $F_m(\theta)$. We first let

$$E_n(\theta) = [e_{u,v}(\theta)]_{1\le u,v\le n}, \quad \text{where} \quad e_{u,v}(\theta) = e^{-\mathrm{i}(u-v)\theta}.$$

The BT matrix $A_{n,m}$ can be expressed in terms of its generating function:

$$A_{n,m} = \frac{1}{2\pi}\int_{-\pi}^{\pi} E_n(\theta)\otimes F_m(\theta)d\theta. \tag{2.1}$$

Similarly, the block diagonal preconditioner can be expressed as follows:

$$B_{n,m} = \frac{1}{2\pi}\int_{-\pi}^{\pi} \begin{pmatrix} E_{n/2}(\theta) & 0 \\ 0 & E_{n/2}(\theta) \end{pmatrix} \otimes F_m(\theta)d\theta. \tag{2.2}$$

We note that there exists a permutation matrix $P_{n,m}$ such that

$$P_{n,m}^* A_{n,m} P_{n,m} = \tilde{A}_{n,m} = \frac{1}{2\pi}\int_{-\pi}^{\pi} F_m(\theta)\otimes E_n(\theta)d\theta$$

and

$$P_{n,m}^* B_{n,m} P_{n,m} = \tilde{B}_{n,m} = \frac{1}{2\pi}\int_{-\pi}^{\pi} F_m(\theta)\otimes \begin{pmatrix} E_{n/2}(\theta) & 0 \\ 0 & E_{n/2}(\theta) \end{pmatrix} d\theta.$$

It is clear that $\tilde{A}_{n,m}$ and $\tilde{B}_{n,m}$ are Toeplitz-block (TB) matrices, and the spectra of $A_{n,m}$ and $\tilde{A}_{n,m}$, and $B_{n,m}$ and $\tilde{B}_{n,m}$ are the same. Since the spectra of $B_{n,m}^{-1}A_{n,m}$ and $\tilde{B}_{n,m}^{-1}\tilde{A}_{n,m}$ are the same, it suffices to study the spectral properties of $\tilde{B}_{n,m}^{-1}\tilde{A}_{n,m}$.

We give the following two lemmas.

LEMMA 2.2. [illegible] $A = [a_{i,j}]_{1\le i,j\le m}$ [illegible] $B = [b_{i,j}]_{1\le i,j\le n}$ [illegible] $n$ [illegible] $m$ [illegible] $X = (\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_m)$ [illegible] $Y = (\mathbf{y}_1, \mathbf{y}_2, \ldots, \mathbf{y}_m)$ [illegible]

$$\operatorname{vec}(X)^*(A\otimes B)\operatorname{vec}(Y) = \sum_{u=1}^{m}\sum_{v=1}^{m} a_{u,v}\mathbf{x}_u^* B\mathbf{y}_v \tag{2.3}$$

[illegible] $\operatorname{vec}(X) = \begin{pmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \\ \vdots \\ \mathbf{x}_m \end{pmatrix}$ [illegible] $\operatorname{vec}(Y) = \begin{pmatrix} \mathbf{y}_1 \\ \mathbf{y}_2 \\ \vdots \\ \mathbf{y}_m \end{pmatrix}$

LEMMA 2.3. [illegible] $\mathbf{x} = \begin{pmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \\ \vdots \\ \mathbf{x}_m \end{pmatrix}$ [illegible] $\mathbf{x}_l = \begin{pmatrix} x_{(l-1)n+1} \\ x_{(l-1)n+2} \\ \vdots \\ x_{ln} \end{pmatrix}$ $(1 \le l \le m)$ $\mathbf{p}_1(\theta) = \begin{pmatrix} \check{\mathbf{p}}_{11}(\theta) \\ \check{\mathbf{p}}_{21}(\theta) \\ \vdots \\ \check{\mathbf{p}}_{m1}(\theta) \end{pmatrix}$ [illegible] $\check{\mathbf{p}}_{j1}(\theta) = \sum_{l=1}^{n'} x_{(j-1)n+l}e^{-\mathrm{i}(l-1)\theta}$ [illegible] $\mathbf{p}_2(\theta) = \begin{pmatrix} \check{\mathbf{p}}_{12}(\theta) \\ \check{\mathbf{p}}_{22}(\theta) \\ \vdots \\ \check{\mathbf{p}}_{m2}(\theta) \end{pmatrix}$ [illegible] $\check{\mathbf{p}}_{j2}(\theta) = e^{-\mathrm{i}n'\theta}\sum_{l=1}^{n-n'} x_{(j-1)n+n'+l}e^{-\mathrm{i}(l-1)\theta}$ [illegible] $A_{n,m}$ [illegible] $F_m(\theta)$ [illegible]

$$\mathbf{x}^*\tilde{B}_{n,m}\mathbf{x} = \frac{1}{2\pi}\int_{-\pi}^{\pi}\left[\mathbf{p}_1(\theta)^*F_m(\theta)\overline{\mathbf{p}_1(\theta)} + \mathbf{p}_2(\theta)^*F_m(\theta)\overline{\mathbf{p}_2(\theta)}\right]d\theta \tag{2.4}$$

[illegible]

$$\mathbf{x}^*\tilde{A}_{n,m}\mathbf{x} = \mathbf{x}^*\tilde{B}_{n,m}\mathbf{x} + \frac{1}{2\pi}\int_{-\pi}^{\pi}\left[\mathbf{p}_1(\theta)^*F_m(\theta)\overline{\mathbf{p}_2(\theta)} + \mathbf{p}_2(\theta)^*F_m(\theta)\overline{\mathbf{p}_1(\theta)}\right]d\theta. \tag{2.5}$$

[illegible] We construct $X = (\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_m)$, i.e., $\mathbf{x} = \mathrm{vec}(X)$. Using Lemma 2.2, we obtain

$$\mathrm{vec}(X)^* \tilde{A}_{n,m} \mathrm{vec}(X) = \frac{1}{2\pi} \int_{-\pi}^{\pi} \sum_{u=1}^{m} \sum_{v=1}^{m} f_{u,v}(\theta) \mathbf{x}_u^* E_n(\theta) \mathbf{x}_v d\theta \tag{2.6}$$

and

$$\mathrm{vec}(X)^* \tilde{B}_{n,m} \mathrm{vec}(X) = \frac{1}{2\pi} \int_{-\pi}^{\pi} \sum_{u=1}^{m} \sum_{v=1}^{m} f_{u,v}(\theta) \mathbf{x}_u^* \begin{pmatrix} E_{n/2}(\theta) & 0 \\ 0 & E_{n/2}(\theta) \end{pmatrix} \mathbf{x}_v d\theta. \tag{2.7}$$

We note that

$$\begin{aligned}
&\mathbf{x}_u^* \begin{pmatrix} E_{n/2}(\theta) & 0 \\ 0 & E_{n/2}(\theta) \end{pmatrix} \mathbf{x}_v \\
&= \sum_{j=1}^{n/2} x_{(u-1)n+j} \sum_{l=1}^{n/2} x_{(v-1)n+l} e_{jl}(\theta) + \sum_{j=n/2+1}^{n} x_{(u-1)n+j} \sum_{l=n/2+1}^{n} x_{(v-1)n+l} e_{jl}(\theta) \\
&= \sum_{j=1}^{n/2} x_{(u-1)n+j} e^{-\mathrm{i}(j-1)} \sum_{l=1}^{n/2} x_{(v-1)n+l} e^{\mathrm{i}(l-1)} \\
&\quad + \sum_{j=n/2+1}^{n} x_{(u-1)n+j} e^{-\mathrm{i}(j-1)} \sum_{l=n/2+1}^{n} x_{(v-1)n+l} e^{\mathrm{i}(l-1)} \\
&= \check{\mathbf{p}}_{u1}(\theta) \overline{\check{\mathbf{p}}_{v1}(\theta)} + \check{\mathbf{p}}_{u2}(\theta) \overline{\check{\mathbf{p}}_{v2}(\theta)}.
\end{aligned}$$

By using (2.7), one can obtain (2.4) directly. Similarly by using (2.6), (2.5) can also be derived. □

Next, we show that the eigenvalues of $B_{n,m}^{-1} A_{n,m}$ are uniformly bounded except for a fixed number of outliers when $F_m(\theta)$ is Hermitian positive definite and is spectrally equivalent to $G_m(\theta) = [g_{u,v}]_{1 \le u,v \le m}$, where $g_{u,v}$ are trigonometric polynomials. We remark that the fixed number of outliers depends on $m$.

THEOREM 2.4. [illegible] $F_m(\theta)$ [illegible] $F_m(\theta)$ [illegible] $G_m(\theta) = [g_{u,v}]_{1 \le u,v \le m}$ [illegible] $g_{u,v}$ [illegible] $s$ [illegible] $G_m(\theta)$ [illegible] $\alpha$ [illegible] $\beta$ $(\alpha < \beta)$ [illegible] $n$ [illegible] $n > 2s'$ $(s' = \lceil s/2 \rceil)$ [illegible] $2ms'$ [illegible] $\tilde{B}_{n,m}^{-1} \tilde{A}_{n,m}$ [illegible] $B_{n,m}^{-1} A_{n,m}$ [illegible] $[\alpha, \beta]$

[illegible] We note that there exist positive numbers $\gamma_1$ and $\gamma_2$ such that

$$0 < \gamma_1 \le \frac{\mathbf{y}^* F_m(\theta) \mathbf{y}}{\mathbf{y}^* G_m(\theta) \mathbf{y}} \le \gamma_2 \quad \forall \mathbf{y} \in \mathbb{R}^m, \ \forall \theta \in [0, 2\pi]. \tag{2.8}$$

We define the two sets $\Upsilon$ and $\Omega$ as follows:

$$\Upsilon = \{r : r = jn+n/2-s', jn+n/2-s'+1, \ldots, jn+n/2+s'-1 \text{ for } j = 0, 1, \ldots, m-1\}$$

and $\Omega = \left\{ \mathbf{z} = \begin{pmatrix} z_1 \\ z_2 \\ \vdots \\ z_{mn} \end{pmatrix} \mid z_k = 0 \text{ for } k \in \Upsilon \right\}$. We note that $\Omega$ is an $(mn - 2ms')$-dimensional subspace in $\mathbb{R}^{mn}$. It follows that for $\mathbf{x} \in \Omega$ and $\mathbf{p}_u(\theta)$ $(u = 1, 2)$ defined in Lemma 2.3, we have

$$\begin{aligned}
&\int_{-\pi}^{\pi} \mathbf{p}_1(\theta)^* G_m(\theta)\overline{\mathbf{p}_2(\theta)}d\theta = \int_{-\pi}^{\pi} \sum_{u=1}^{m}\sum_{v=1}^{m} \check{\mathbf{p}}_{u1}(\theta) f_{u,v}(\theta)\overline{\check{\mathbf{p}}_{v2}(\theta)}d\theta \\
&= \int_{-\pi}^{\pi} \sum_{u=1}^{m}\sum_{v=1}^{m} f_{u,v}(\theta)e^{\mathrm{i}n/2\theta}\sum_{j=1}^{n/2} x_{(u-1)n+j}e^{-\mathrm{i}(j-1)\theta}\sum_{j=1}^{n/2} x_{(v-1)n+n/2+j}e^{\mathrm{i}(j-1)\theta}d\theta \\
&= \sum_{u=1}^{m}\sum_{v=1}^{m}\int_{-\pi}^{\pi} f_{u,v}(\theta)e^{\mathrm{i}(2s'+1)\theta}\sum_{j=1}^{n/2-s'} x_{(u-1)n+j}e^{-\mathrm{i}j\theta} \\
&\cdot \sum_{j=1}^{n/2-s'} x_{(v-1)n+j+s'}e^{\mathrm{i}(n/2-s'-1+j)\theta}d\theta \;=\; 0 \qquad (2.9)
\end{aligned}$$

and

$$\begin{aligned}
&\int_{-\pi}^{\pi} \mathbf{p}_2(\theta)^* G_m(\theta)\overline{\mathbf{p}_1(\theta)}d\theta = \int_{-\pi}^{\pi} \sum_{u=1}^{m}\sum_{v=1}^{m} \check{\mathbf{p}}_{u2}(\theta)(\theta) f_{u,v}(\theta)\overline{\check{\mathbf{p}}_{v1}(\theta)(\theta)}d\theta \\
&= \int_{-\pi}^{\pi} \sum_{u=1}^{m}\sum_{v=1}^{m} f_{u,v}(\theta)e^{-\mathrm{n}/2\theta}\sum_{j=1}^{n/2} x_{(u-1)n+n/2+j}e^{-\mathrm{i}(j-1)\theta}\sum_{l=1}^{n/2} x_{(v-1)n+l}e^{\mathrm{i}(l-1)\theta}d\theta \\
&= \sum_{u=1}^{m}\sum_{v=1}^{m}\int_{-\pi}^{\pi} f_{u,v}(\theta)e^{-\mathrm{i}(2s'+1)\theta}\sum_{j=1}^{n/2-s'} x_{(u-1)n+n/2+s'+j}e^{-\mathrm{i}(n/2-s'-1+j)\theta} \\
&\cdot \sum_{l=1}^{n/2-s'} x_{(v-1)n+l}e^{\mathrm{i}j\theta}d\theta \;=\; 0. \qquad (2.10)
\end{aligned}$$

Since $F_m(\theta) - \gamma_1 G_m(\theta)$ is positive semidefinite, we have

$$\begin{aligned}
&\int_{-\pi}^{\pi} \mathbf{p}_1(\theta)^*[F_m - \gamma_1 G_m(\theta)](\theta)\overline{\mathbf{p}_1(\theta)} + \mathbf{p}_2(\theta)^*[F_m(\theta) - \gamma_1 G_m(\theta)]\overline{\mathbf{p}_2(\theta)}d\theta \\
&\geq \int_{-\pi}^{\pi} \mathbf{p}_1(\theta)^*[F_m - \gamma_1 G_m(\theta)](\theta)\overline{\mathbf{p}_2(\theta)} + \mathbf{p}_2(\theta)^*[F_m(\theta) - \gamma_1 G_m(\theta)]\overline{\mathbf{p}_1(\theta)}d\theta. \qquad (2.11)
\end{aligned}$$

By using Lemma 2.3, (2.9), (2.10), and (2.11), we get

$$\begin{aligned}
&\left|\frac{\mathbf{x}^*\tilde{T}_{n,m}\mathbf{x} - \mathbf{x}^*\tilde{B}_{n,m}\mathbf{x}}{\mathbf{x}^*\tilde{B}_{n,m}\mathbf{x}}\right| = \frac{\left|\int_{-\pi}^{\pi}(\mathbf{p}_1(\theta)F_m(\theta)\overline{\mathbf{p}_2(\theta)} + \mathbf{p}_2(\theta))F_m(\theta)\overline{(\mathbf{p}_1(\theta))}d\theta\right|}{\left|\int_{-\pi}^{\pi}(\mathbf{p}_1(\theta)F_m(\theta)\overline{\mathbf{p}_1(\theta)} + \mathbf{p}_2(\theta))F_m(\theta)\overline{(\mathbf{p}_2(\theta))}d\theta\right|} \\
&= \frac{\left|\int_{-\pi}^{\pi} \mathbf{p}_1(\theta)[F_m(\theta) - \gamma_1 G_m(\theta)]\overline{\mathbf{p}_2(\theta)} + \mathbf{p}_2(\theta)[F_m(\theta) - \gamma_1 G_m(\theta)]\overline{\mathbf{p}_1(\theta)}d\theta\right|}{\left|\int_{-\pi}^{\pi} \mathbf{p}_1(\theta)F_m(\theta)\overline{\mathbf{p}_1(\theta)} + \mathbf{p}_2(\theta)F_m(\theta)\overline{\mathbf{p}_2(\theta)}d\theta\right|}. \\
&\leq \frac{\left|\int_{-\pi}^{\pi} \mathbf{p}_1(\theta)[F_m(\theta) - \gamma_1 G_m(\theta)]\overline{\mathbf{p}_1(\theta)} + \mathbf{p}_2(\theta)[F_m(\theta) - \gamma_1 G_m(\theta)]\overline{\mathbf{p}_2(\theta)}d\theta\right|}{\left|\int_{-\pi}^{\pi} \mathbf{p}_1(\theta)F_m(\theta)\overline{\mathbf{p}_1(\theta)} + \mathbf{p}_2(\theta)F_m(\theta)\overline{\mathbf{p}_2(\theta)}d\theta\right|} \\
&\leq 1 - \frac{\gamma_1}{\gamma_2} \quad \forall \mathbf{x} \in \Omega.
\end{aligned}$$

Therefore, we have

$$\alpha \equiv \frac{\gamma_1}{\gamma_2} \le \frac{\mathbf{x}^* \tilde{A}_{n,m}\mathbf{x}}{\mathbf{x}^* \tilde{B}_{n,m}\mathbf{x}} \le 2 - \frac{\gamma_1}{\gamma_2} \equiv \beta \quad \forall \mathbf{x} \in \Omega.$$

It implies that there are at most $2ms'$ eigenvalues of $\tilde{B}_{n,m}^{-1}\tilde{A}_{n,m}$ outside the interval $[\alpha, \beta]$. ☐

In [28], Serra explicitly constructed $G_m(\theta)$ by using eigendecomposition of $F_m(\theta)$:

$$F_m(\theta) = Q(\theta)^* \Lambda(\theta) Q(\theta),$$

where $\Lambda(\theta)$ is a diagonal matrix containing the eigenvalues $\lambda_j(F_m(\theta))$ $(j = 1, \dots, m)$ of $F_m(\theta)$. Suppose $\lambda_j(F_m(\theta))$ has a zero at $\theta_j$ of even order $\nu_j$. Then $G_m(\theta)$ is constructed in the following way:

$$G_m(\theta) = \sum_{j=1}^{m} Q(\theta_j)^* \Gamma(\theta) Q(\theta_j),$$

where $\Gamma(\theta)$ is a diagonal matrix with

$$[\Gamma(\theta)]_{kk} = \begin{cases} (2 - 2\cos(\theta))^{\nu_j/2}, & k = j, \\ 1 & \text{otherwise.} \end{cases}$$

It is clear that each entry of $G_m(\theta)$ is a polynomial. The largest degree of the polynomials in $G_m(\theta)$ depends on the orders of the zeros of the eigenvalues of $F_m(\theta)$. It has been shown that $F_m(\theta)$ is spectrally equivalent to $G_m(\theta)$; see, for instance, [28].

Similarly, we show that the eigenvalues of $C_{n,m}^{-1}A_{n,m}$ are uniformly bounded except for a fixed number of outliers, where this fixed number depends on $m$.

THEOREM 2.5. [illegible] $F_m(\theta)$ [illegible] $F_m(\theta)$ [illegible] $G_m(\theta) = [g_{u,v}]_{1 \le u,v \le m}$ [illegible] $g_{u,v}$ [illegible] $s$ [illegible] $G_m(\theta)$ [illegible] $\alpha$ [illegible] $\beta$ $(\alpha < \beta)$ [illegible] $n$ [illegible] $n > 2s'$ $(s' = \lceil s/2 \rceil)$ [illegible] $ms'$ [illegible] $\tilde{C}_{n,m}^{-1}\tilde{A}_{n,m}$ [illegible] $C_{n,m}^{-1}A_{n,m}$ [illegible] $[\alpha, \beta]$

[illegible] We note from (1.4) and (1.5) that

$$\det[B_{n,m}^{-1}(A_{n,m} - B_{n,m}) - \lambda I] = \det \begin{pmatrix} -\lambda I & A_{n/2,m}^{-1}A_{n,m}^{1,2} \\ A_{n/2,m}^{-1}A_{n,m}^{2,1} & -\lambda I \end{pmatrix} = 0$$

and

$$\det[C_{n,m}^{-1}(A_{n,m} - C_{n,m}) - \lambda I] = \det(-\lambda I)\det(A_{n/2,m}^{-1}A_{n,m}^{2,1}A_{n/2,m}^{-1}A_{n,m}^{1,2} - \lambda I) = 0.$$

Therefore, when the eigenvalues of $B_{n,m}^{-1}A_{n,m}$ are equal to $1 - \lambda$, the eigenvalues of $C_{n,m}^{-1}A_{n,m}$ are given by $1 - \lambda^2$. Using Theorem 2.4, we can find two positive numbers $\alpha = (\gamma_1/\gamma_2)^2$ and $\beta = 1$ such that the result holds. ☐

## 3. Recursive computation of $B_{n,m}^{-1}$ and $C_{n,m}^{-1}$.

In the previous section, we have shown that both $B_{n,m}$ and $C_{n,m}$ are good preconditioners for $A_{n,m}$. However, the inverses of $B_{n,m}$ and $C_{n,m}$ involve the inverse of $A_{n/2,m}$. The computational cost is still expensive. In this section, we present a recursive method to construct the preconditioners $B_{n,m}$ and $C_{n,m}$ efficiently.

We remark that the inverse of a Toeplitz matrix can be reconstructed by a low number of columns. Gohberg and Semencul [13] and Trench [32] showed that if the $(1,1)$st entry of the inverse of a Toeplitz matrix is nonzero, then the first and last columns of the inverse of the Toeplitz matrix are sufficient for this purpose. A nice matrix representation of the inverse, well known as the [illegible], was presented. In [16], an inversion formula was exhibited which works for every nonsingular Toeplitz matrix and uses the solutions of two equations (the so-called fundamental equations), where the right-hand side of one of them is a shifted column of the Toeplitz matrix. Later Ben-Artzi and Shalom [2], Labahn and Shalom [19], Ng, Rost, and Wen [23], and Heinig [15] studied the representation when the (1,1)st entry of the inverse of a Toeplitz matrix is zero. In [24], Ng, Sun, and Jin used the matrix representation of the inverse of a Toeplitz matrix to construct effective preconditioners for Toeplitz matrices.

For BT matrices, Gohberg and Heinig [14] also extended the Gohberg–Semencul formula to handle this case. It was shown that if $A_{n,m}$ is nonsingular, then the following equations are solvable:

$$A_{n,m}U^{(n)} = E^{(n)} \quad \text{and} \quad A_{n,m}V^{(n)} = F^{(n)} \tag{3.1}$$

with

$$U^{(n)} = \begin{pmatrix} U_1^{(n)} \\ U_2^{(n)} \\ \vdots \\ U_n^{(n)} \end{pmatrix}, \quad V^{(n)} = \begin{pmatrix} V_1^{(n)} \\ V_2^{(n)} \\ \vdots \\ V_n^{(n)} \end{pmatrix}, \quad E^{(n)} = \begin{pmatrix} I_m \\ 0 \\ \vdots \\ 0 \end{pmatrix}, \quad F^{(n)} = \begin{pmatrix} 0 \\ \vdots \\ 0 \\ I_m \end{pmatrix}.$$

Here $U_j^{(n)}$ and $V_j^{(n)}$ are $m$-by-$m$ matrices and $I_m$ is the identity matrix. Assuming that $U_1^{(n)}$ and $V_n^{(n)}$ are nonsingular, the inverse of $A_{n,m}$ can be expressed as follows:

$$A_{n,m}^{-1} = \Psi_{n,m}W_{n,m}\Psi_{n,m}^* - \Phi_{n,m}Z_{n,m}\Phi_{n,m}^*, \tag{3.2}$$

where $\Psi_{n,m}$ and $\Phi_{n,m}$ are $mn$-by-$mn$ lower triangular BT matrices given, respectively, by

$$\Psi_{n,m} = \begin{pmatrix} U_1^{(n)} & 0 & \cdots & 0 & 0 \\ U_2^{(n)} & U_1^{(n)} & 0 & & 0 \\ \vdots & U_2^{(n)} & U_1^{(n)} & 0 & \vdots \\ U_{n-1}^{(n)} & & \ddots & \ddots & 0 \\ U_n^{(n)} & U_{n-1}^{(n)} & \cdots & U_2^{(n)} & U_1^{(n)} \end{pmatrix}$$

and

$$\Phi_{n,m} = \begin{pmatrix} 0 & 0 & \cdots & 0 & 0 \\ V_1^{(n)} & 0 & 0 & & 0 \\ \vdots & V_1^{(n)} & 0 & 0 & \vdots \\ V_{n-2}^{(n)} & & \ddots & \ddots & 0 \\ V_{n-1}^{(n)} & V_{n-2}^{(n)} & \cdots & V_1^{(n)} & 0 \end{pmatrix}.$$

Moreover, $W_{n,m}$ and $Z_{n,m}$ are block diagonal matrices:

$$W_{n,m} = \begin{pmatrix} (U_1^{(n)})^{-1} & & & 0 \\ & (U_1^{(n)})^{-1} & & \\ & & \ddots & \\ 0 & & & (U_1^{(n)})^{-1} \end{pmatrix},$$

$$Z_{n,m} = \begin{pmatrix} (V_n^{(n)})^{-1} & & & 0 \\ & (V_n^{(n)})^{-1} & & \\ & & \ddots & \\ 0 & & & (V_n^{(n)})^{-1} \end{pmatrix}.$$

For the preconditioners $B_{n,m}^{-1}$ and $C_{n,m}^{-1}$, the inverse of $A_{n/2,m}$ can be represented by the formula in (3.2). This formula can be obtained by solving the following two linear systems:

$$A_{n/2,m}U^{(n/2)} = E^{(n/2)} \quad \text{and} \quad A_{n/2,m}V^{(n/2)} = F^{(n/2)}.$$

These two systems can be solved efficiently by using the PCG method with $B_{n/2,m}$ or $C_{n/2,m}$ as preconditioners. The inverse of $A_{n/4,m}$ involved in the preconditioners $B_{n/2,m}$ and $C_{n/2,m}$ can be recursively generated by using (3.2) until the size of the linear system is sufficiently small. The procedures of recursive computation of $B_{n,m}$ and $C_{n,m}$ are described as follows:

```
Procedure    Input($A_{n,m}$, $n$)  Output($U^{(n)}$, $V^{(n)}$)
    If $k \le N$, then
        solve two linear systems
            $A_{k,m}U^{(k)} = E^{(k)}$   and   $A_{k,m}V^{(k)} = F^{(k)}$
        exactly by direct methods;
    else
        compute $U^{(k/2)}$ and $V^{(k/2)}$ by calling the procedure with the input matrix
        $A_{k/2,m}$ and the integer $k/2$; construct $A_{k/2,m}^{-1}$ by using the output $U^{(k/2)}$
        and $V^{(k/2)}$ via the formula in (3.2);
        solve the two linear systems
            $A_{k,m}U^{(k)} = E^{(k)}$   and   $A_{k,m}V^{(k)} = F^{(k)}$
        by using the PCG method with $B_{k,m}$ (or $C_{k,m}$) as the preconditioner.
```

We remark that if each block of the BT matrix $A_{n,m}$ is Hermitian, then we only need to solve one linear system $A_{n,m}U^{(n)} = E^{(n)}$ in order to represent the inverse of the BT matrix. In this case, the solution $V^{(n)}$ can be obtained by using $U^{(n)}$:

$$V^{(n)} = \begin{pmatrix} U_n^{(n)} \\ U_{n-1}^{(n)} \\ \vdots \\ U_1^{(n)} \end{pmatrix}.$$

**3.1. Computational cost.** The main computational cost of the method comes from the matrix-vector multiplications $A_{n,m}X$, $B_{n,m}^{-1}X$ (or $C_{n,m}^{-1}X$) in each PCG iteration, where $X$ is an $mn$-by-$m$ vector. We note that $A_{n,m}X$ can be computed in $2m$ $2n$-length fast Fourier transforms (FFTs) by first embedding $A_{n,m}$ into a $2mn$-by-$2mn$ block-circulant matrix and then carrying out the multiplication by using the decomposition of the block-circulant matrix. Letting $S_{n,m}$ be the circulant matrix with an $m$-by-$m$ matrix block element, one can find a permutation matrix $P_{n,m}$ such that

$$\overline{S}_{n,m} = (S_{i,j})_{m\times m} = P_{n,m}^{*} W_{n,m} P_{n,m}$$

is a circulant-block matrix, where $S_{i,j}$ is an $n$-by-$n$ circulant matrix. Let $S_{i,j}(:,1)$ denote the first column of the matrix $S_{i,j}$; it is known that $S_{i,j}$ can be diagonalized into an $n\log n$ length FFT, i.e., $S_{i,j} = F^{*}\Lambda_{i,j}F$, where $F$ and $F^{*}$ are the Fourier transform matrix and the inverse Fourier transform matrix, respectively, and $\Lambda_{i,j} = \operatorname{diag}(F\cdot S_{i,j}(:,1))$. Thus we obtain

$$\begin{aligned}\overline{S}_{n,m} &= (I\otimes F^{*})\begin{pmatrix} \Lambda_{11} & \Lambda_{11} & \cdots & \Lambda_{1m} \\ \Lambda_{21} & \Lambda_{22} & \cdots & \Lambda_{2m} \\ \vdots & \vdots & \vdots & \vdots \\ \Lambda_{m1} & \Lambda_{m2} & \cdots & \Lambda_{mm} \end{pmatrix}(I\otimes F) \\ &= (I\otimes F^{*})P^{*}DP(I\otimes F),\end{aligned}$$

where $D = \operatorname{diag}(D_1, D_2, \ldots, D_n)$ is a block diagonal matrix, and $[D_k]_{ij} = [\Lambda_{ij}]_{kk}$, i.e., the $(i,j)$th entry of $D_k$ is equal to the $(k,k)$th entry of $\Lambda_{ij}$. Therefore, the block-circulant matrix-vector multiplication can be obtained by

$$S_{n,m}X = P(I\otimes F^{*})P^{*}DP(I\otimes F)P^{*}X.$$

We note that it requires $O(m^2 n\log n)$ operations to compute the block diagonal matrix $D$, and that the block diagonal matrix-vector multiplication requires $O(m^3 n)$ operations. Thus the overall multiplication requires $O(m^2 n\log n + m^3 n)$. For the preconditioner $B_{n,m}$ or $C_{n,m}$, we need to compute matrix-vector products $A_{n/2,m}^{-1}Y$, where $Y$ is an $mn/2$-by-$m$ vector. According to (3.2), the inverse of a BT matrix can be written as the product of lower-triangular BT matrices. Therefore, the matrix-vector multiplication $A_{n/2,m}^{-1}Y$ can be computed by using FFTs by embedding such lower-triangular BT matrices into block-circulant matrices. Such matrix-vector multiplication requires $O(m^2 n\log n + m^3 n)$ operations.

Now we estimate the total cost of recursive computation for solving two linear systems

$$A_{n,m}U^{(n)} = E^{(n)} \quad \text{and} \quad A_{n,m}V^{(n)} = F^{(n)}.$$

For simplicity, we assume $n = 2^{\ell}$. Suppose the number of iterations required for convergence in solving the two $mn_j$-by-$mn_j$ linear systems

$$A_{n_j,m}U^{(n_j)} = E^{(n_j)} \quad \text{and} \quad A_{n_j,m}V^{(n_j)} = F^{(n_j)}, \quad \text{where} \quad n_j = 2^{\nu-j+1},$$

is given by $c_j$ for $j = 1, \ldots, L$. We note that the smallest size of the system is equal to $N = n/2^{\nu-L}$. Therefore the total cost of the recursive computations of $B_{n,m}$ (or $C_{n,m}$) is about $\sum_{j=1}^{L} c_j f_j$, where $f_j$ denotes the cost of each PCG iteration where the size of the system is $n_j$. Since the cost of an $n_j$-length FFT is roughly twice the cost of an $n_j m/2$-length FFT, and the cost of each PCG iteration is $O(m^2 n_j \log n_j + m^3 n_j)$ operations, hence the total cost of the recursive computation is roughly bounded by $O(\max_j\{c_j(m^2 n \log n + m^3 n)\})$.

Next, we compute the operations required for the circulant preconditioners. For the block-circulant matrix $S_{n,m}$, the solution of $S_{n,m}Z = B$ can be obtained by

$$Z = S_{n,m}^{-1}B = P(I \otimes F^*)P^* D^{-1} P(I \otimes F)P^* B.$$

In order to compute the inverse of $D$, $O(m^2 n \log n + m^3 n)$ operations are required. Moreover, the matrix-vector multiplication requires $O(m^3 n)$ operations, and thus $S_{n,m}^{-1}B$ can be computed in $O(m^2 n \log n + m^3 n)$ operations, which is the same complexity of our proposed method. In the next section, we show that our proposed method is competitive with circulant preconditioners.

## 4. Numerical results.

In this section, we test our proposed method. The initial guess is the zero vector. The stopping criterion is

$$\|r_q\|_2 / \|r_0\|_2 \leq 1 \times 10^{-7},$$

where $r_q$ is the residual vector at the $q$th iteration of the PCG method. We use MATLAB 6.1 to conduct the numerical tests. We remark that our preconditioners are constructed recursively. For instance, when we solve $A_{256,m}U^{(256)} = E^{(256)}$, the preconditioners are constructed by solving $A_{128,m}U^{(128)} = E^{(128)}$ and $A_{64,m}U^{(64)} = E^{(64)}$ using the PCG method with the stopping criterion being equal to $10^{-7}$ and using the direct solver for $A_{32,m}U^{(32)} = E^{(32)}$. In all of the tests, the coarsest level is set to be $n = 32$.

In the first test, we consider the following example of a generating function [28]:

$$\begin{pmatrix} 20\sin^2(\theta/2) & |\theta|^{5/2} \\ |\theta|^{5/2} & 20\sin^2(\theta/2) \end{pmatrix}.$$

Table 4.1 shows the corresponding numbers of iterations required for the convergence using our proposed preconditioners $B$ and $C$. As a comparison, the number of iterations from using the preconditioner $M$ studied in [28] is also listed. Our proposed preconditioners are competitive with the preconditioner studied in [28]. We also remark that the construction of our proposed preconditioners does not require the knowledge of the underlying matrix generating function of BT matrices.

TABLE 4.1

*Number of iterations required for convergence.*

| $n$ | $B$ | $C$ | $M$ |
|---|---|---|---|
| 128 | 9 | 4 | 10 |
| 256 | 9 | 5 | 10 |
| 512 | 10 | 5 | 10 |

In the second test, we consider the following four examples.

[illegible] 1.

$$F_3(\theta) = \begin{pmatrix} 2\theta^4 + 1 & |\theta|^3 & \theta^4 \\ |\theta|^3 & 3\theta^4 + 1 & |\theta| \\ \theta^4 & |\theta| & 2\theta^4 + 1 \end{pmatrix}.$$

TABLE 4.2
*Number of iterations required for convergence in Example* 1.

| $n$ | $I$ | $B$ | $C$ | S | T | $K_4$ | $K_6$ | $K_8$ |
|---|---|---|---|---|---|---|---|---|
| 64 | 111 | 13 | 6 | 13 | 12 | 12 | 12 | 12 |
| 128 | 124 | 12 | 6 | 13 | 12 | 12 | 13 | 13 |

2.

$$F_3(\theta) = \begin{pmatrix} \theta^4 + 1 & |\theta|^3 & |\theta| \\ |\theta|^3 & 2\theta^4 + 1 & \theta^2 \\ |\theta| & \theta^2 & 5|\theta| \end{pmatrix}.$$

3.

$$F_2(\theta) = \begin{pmatrix} 8\theta^2 & (\sin\theta)^4 \\ (\sin\theta)^4 & 8\theta^2 \end{pmatrix}.$$

4.

$$F_3(\theta) = \begin{pmatrix} |\theta| & (\sin\theta)^4 & 0 \\ (\sin\theta)^4 & \theta^2 & (\sin\theta)^8 \\ 0 & (\sin\theta)^8 & \theta^4 \end{pmatrix}.$$

These generating functions are Hermitian matrix-valued functions. Also the generated BT matrices are positive definite. In Example 1, the generated BT matrices are well-conditioned. For Examples 2–4, the generating functions are singular at some points and therefore the corresponding BT matrices are ill-conditioned.

In Tables 4.2–4.5, we give the number of iterations required for convergence by using $B_{n,m}$ and $C_{n,m}$ as the preconditioners. Here we set the maximum number of iterations to be 1000. If the method does not converge within 1000 iterations, we specify "$> 1000$" in the tables. According to Tables 4.2–4.5, we see that the number of iterations for the nonpreconditioned systems (the column "$I$") increases when the size $n$ increases. However, the number of iterations for the preconditioned systems (the columns "$B$" and "$C$") decreases or almost remains constant when the size $n$ increases in Examples 1–3. The performance of Schur complement preconditioner $C$ is generally better than that of block diagonal preconditioner $B$. We also compare our preconditioners with block-circulant preconditioners; the columns "S" and "T" are the number of iterations required for the Strang and the T. Chan block-circulant preconditioners, respectively. We note that the Strang block-circulant preconditioner may not be positive definite for the ill-conditioned matrix. Indeed, there are several negative eigenvalues of the Strang block-circulant preconditioners in Examples 3 and 4. Even when the Strang circulant preconditioned system converges, the solution may not be correct. We also see from Tables 4.4 and 4.5 that the T. Chan block-circulant preconditioner does not work.

Chan, Ng, and Yip [8, 9] have constructed "best" circulant preconditioners by approximating the generating function with the convolution product that matches the zeros of the generating function. They showed that these circulant preconditioners are effective for ill-conditioned Toeplitz matrices. Here we also construct such "best" block-circulant preconditioners (in the column "$K_i$" and $i$ refers to the order of the kernel that we used) and test their performance. We note from Tables 4.2–4.5 that our proposed preconditioners perform quite well. For Example 4, the method with "best" block-circulant preconditioners does not converge within 1000 iterations.

We remark that for the ill-conditioned systems, a small residual does not necessarily imply an accurate solution. For instance, the systems in Example 4 are very ill-conditioned. We check the accuracy of the solution[1] computed by using the proposed preconditioners and find that the relative errors increase from $10^{-11}$ ($n = 64$) to $10^{-4}$ ($n = 4096$). However, we reiterate that even the other preconditioners do not work.

Also we report the computational times required for convergence in Examples 1–4 in Tables 4.6–4.9, respectively. If the number of iterations is more than 1000, we specify "$**$" in the tables. We see that the computational times required by the block diagonal preconditioner and the Schur complement preconditioner are less than those of the block-circulant preconditioners, especially when $n$ is large. We also note from the tables that the performance of the Schur complement preconditioner is better

---

than that of the block diagonal preconditioner.

To illustrate the fast convergence of the proposed method, in Table 4.10, we calculate the number of eigenvalues within the small interval for $n = 128$ in Examples 1–4. We find that the spectra of the preconditioned matrices $C_{n,m}^{-1}A_{n,m}$ and $B_{n,m}^{-1}A_{n,m}$ are closer to 1 than those of circulant preconditioners and no preconditioner.

Finally, we report that the numbers of iterations are about the same even when the stopping criteria $\tau$ of the PCG method at each level in the recursive calculation of the proposed preconditioners is $1 \times 10^{-3}$, $1 \times 10^{-4}$, and $1 \times 10^{-7}$ for the proposed preconditioners.

Next, we consider an application of our algorithm to BT systems arising from

Table 4.10
*The percentages of the number of eigenvalues within the interval of* $[0.99, 1.01]$ *for* $n = 128$.

multichannel least squares filtering. Another application to queueing networks can be found in the full report at ftp://ftp.math.hkbu.edu.hk/pub/techreport/math431.pdf.

**Application I:** Multichannel least squares filtering is a data processing method that makes use of the signals from each of the $m$ channels. We represent this multichannel data by $\mathbf{x}_t$, where $\mathbf{x}_t$ is a column vector whose elements are the signals from each channel. Since we are interested in digital processing methods, we suppose that the signals are sampled at discrete, equally spaced time points which are represented by the time index $t$. Without loss of generality, we require that $t$ take on successive integer values. If we let $x_{it}$ represents the signal coming from the $i$th channel $(i = 1, 2, \ldots, m)$, the multichannel signal can be written as $\mathbf{x}_t = \begin{pmatrix} x_{1,t} \\ x_{2,t} \\ \vdots \\ x_{m,t} \end{pmatrix}$. The filter is represented by the coefficients $S_1, S_2, \ldots, S_n$, where each coefficient $S_k$ $(k = 1, 2, \ldots, n)$ is an $n$-by-$m$ matrix. The multichannel signal $\mathbf{x}_t$ received by the array system represents the input to the filter and the resulting output of the filter is a multichannel signal, which we denote by the column vector $\mathbf{y}_t = \begin{pmatrix} y_{1,t} \\ y_{2,t} \\ \vdots \\ y_{m,t} \end{pmatrix}$. The relationship between input $\mathbf{x}_t$ and output $\mathbf{y}_t$ is given by the convolution formula $\mathbf{y}_t = S_1\mathbf{x}_t + S_2\mathbf{x}_{t-1} + \cdots + S_n\mathbf{x}_{t-n+1}$. The determination of the filter coefficients is based on the concept of a desired output denoted by a column vector $\mathbf{z}_t = \begin{pmatrix} z_{1,t} \\ z_{2,t} \\ \vdots \\ z_{m,t} \end{pmatrix}$. On each channel $(i = 1, 2, \ldots, m)$, there will be an error between the desired output $\mathbf{z}_t$ and the actual output $\mathbf{y}_t$. The mean square value of this error is given by $\mathcal{E}[(\mathbf{z}_t - \mathbf{y}_t)^2]$. The sum of the mean square errors for all the channels is $\sum_{i=1}^{m} \mathcal{E}[(\mathbf{z}_t - \mathbf{y}_t)^2]$. The least squares determination of the filter coefficients requires that this sum be minimum. This minimization leads to a set of linear equations

$$\begin{pmatrix} R_0 & R_1 & \cdots & R_{n-1} \\ R_1 & R_0 & \cdots & R_{n-2} \\ \vdots & \vdots & \ddots & \vdots \\ R_{n-1} & R_{n-2} & \cdots & R_0 \end{pmatrix} \begin{pmatrix} S_1 \\ S_2 \\ \vdots \\ S_n \end{pmatrix} = \begin{pmatrix} G_1 \\ G_2 \\ \vdots \\ G_n \end{pmatrix}, \tag{4.1}$$

where

$$R_j = \mathcal{E}[\mathbf{x}_t\mathbf{x}_{t-j}^*] \quad \text{and} \quad G_j = \mathcal{E}[\mathbf{z}_t\mathbf{x}_{t-j+1}^*].$$

Here $R_j$ is an $m$-by-$m$ matrix and is the autocorrelation coefficients of the input signal $\mathbf{x}_t$, and $G_j$ is an $n$-by-$m$ matrix and is the cross-correlation coefficients between the desired output $\mathbf{z}_t$ and the input signal $\mathbf{x}_t$.

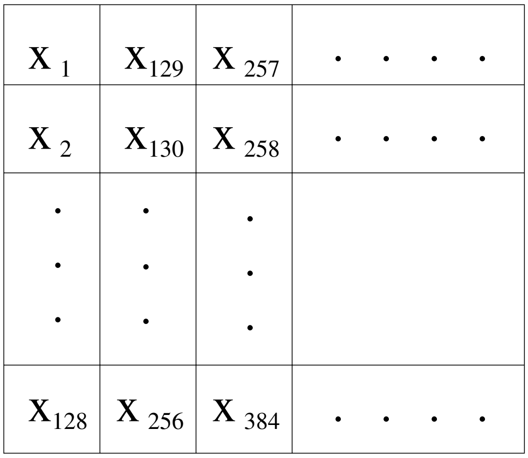

Fig. 4.1. *Color image and data vectors.*

In the test, a 128-by-128 color image is used to generate the data points. We consider the pixel value of the color image to be $\mathbf{x}_t$ $(t = 1, 2, \ldots, 128^2)$; see Figure 4.1. We remark that color can be regarded as a set of three images in their primary color components: red, green, and blue. In the least squares filtering, there are three channels, i.e., $m = 3$. Our task is to generate the multichannel least squares filters such that the sum of the mean square errors for all the channels

$$\sum_{i=1}^{m} \mathcal{E}\{\mathbf{x}_{t+1} - [S_1\mathbf{x}_t + S_2\mathbf{x}_{t-1} + \cdots + S_n\mathbf{x}_{t-n+1}]^2\}$$

is minimum. Such least squares filters have been commonly used in color image processing for coding and enhancement [20]. Table 4.11 shows the number of iterations required for convergence. Table 4.12 shows the number of iterations required for convergence when more synthetic multichannel data sets are generated to test. The stopping criteria are the same as those for Tables 4.2–4.5. Notice that the generating function of the BT matrices are unknown in this case. However, the construction of the proposed preconditioners only requires the entries of $A_{n,m}$ and does not require the explicit knowledge of the generating function $F_m(\theta)$ of $A_{n,m}$. We find that the generated BT matrices are very ill-conditioned. Therefore, the number of iterations required for convergence without preconditioning is very large, but the performance of the preconditioners $B_{n,m}$ and $C_{n,m}$ is very good. We also check the accuracy of the solution[2] computed by using the proposed preconditioners and find that the relative errors are about $10^{-9}$. These results show that our proposed preconditioner performs quite well.

We also generate more synthetic multichannel data sets to test the performance of our proposed method for larger $m$. Table 4.12 shows the number of iterations required for convergence. The stopping criteria are the same as those for Tables 4.2–4.5. The results show that our proposed preconditioner performs quite well.

---

**5. Concluding remarks.** In this paper, we proposed block diagonal and Schur complement preconditioners for BT matrices. We have proved that for some BT coefficient matrices, the spectra of the preconditioned matrices are uniformly bounded except for a fixed number of outliers, where the number of outliers depends on $m$. Therefore the conjugate gradient method will converge very quickly when applied to solving the preconditioned systems, especially when $m$ is small. Our experimental results show that the Schur-complement preconditioner is always better than the block diagonal preconditioner. Applications to BT systems arising from least squares filtering problems and queueing networks were discussed. The method can also be applied to solve other nonsymmetric problems that arise in other queueing systems [11].

**Acknowledgments.** The authors are very much indebted to Prof. Per Christian Hansen and the referees for their valuable comments and suggestions which greatly improved this paper.

# MATRIX NEARNESS PROBLEMS WITH BREGMAN DIVERGENCES*

INDERJIT S. DHILLON† AND JOEL A. TROPP‡

**Abstract.** This paper discusses a new class of matrix nearness problems that measure approximation error using a directed distance measure called a *Bregman divergence*. Bregman divergences offer an important generalization of the squared Frobenius norm and relative entropy, and they all share fundamental geometric properties. In addition, these divergences are intimately connected with exponential families of probability distributions. Therefore, it is natural to study matrix approximation problems with respect to Bregman divergences. This article proposes a framework for studying these problems, discusses some specific matrix nearness problems, and provides algorithms for solving them numerically. These algorithms apply to many classical and novel problems, and they admit a striking geometric interpretation.

**Key words.** matrix nearness problems, Bregman divergences, squared Euclidean distance, relative entropy, alternating projections

**DOI.** 10.1137/060649021

## 1. Introduction.

A recurring problem in matrix theory is to find a structured matrix that best approximates a given matrix with respect to some distance measure. For example, it may be known a priori that a certain constraint ought to hold, and yet it fails on account of measurement errors or numerical roundoff. An attractive remedy is to replace the tainted matrix by the nearest matrix that does satisfy the constraint. Matrix approximation problems typically measure the distance between matrices with a norm. The Frobenius and spectral norms are pervasive choices because they are so analytically tractable. Nevertheless, these norms are not always defensible in applications, where it may be wiser to tailor the distance measure to the context.

In this paper, we discuss a new class of matrix nearness problems that use a directed distance measure called a [illegible]. Given a differentiable, strictly convex function $\varphi$ that maps matrices to the extended real numbers, we define the Bregman divergence of the matrix $\boldsymbol{X}$ from the matrix $\boldsymbol{Y}$ as

$$D_\varphi(\boldsymbol{X};\boldsymbol{Y}) \overset{\text{def}}{=} \varphi(\boldsymbol{X}) - \varphi(\boldsymbol{Y}) - \langle \nabla\varphi(\boldsymbol{Y}), \boldsymbol{X}-\boldsymbol{Y}\rangle\,,$$

where the inner product $\langle \boldsymbol{X},\boldsymbol{Y}\rangle = \operatorname{Re}\operatorname{Tr}\boldsymbol{X}\boldsymbol{Y}^*$. The two principal examples of Bregman divergences deserve immediate mention. When $\varphi(\boldsymbol{X}) = \frac{1}{2}\|\boldsymbol{X}\|_F^2$, the associated divergence is the squared Frobenius norm $\frac{1}{2}\|\boldsymbol{X}-\boldsymbol{Y}\|_F^2$. When $\varphi$ is the negative Shannon entropy, we obtain the Kullback–Leibler divergence, which is also known as relative entropy. But these two cases are just the tip of the iceberg.

Bregman divergences are well suited for nearness problems because they share many geometric properties with the squared Frobenius norm. They also exhibit an

intimate relationship with exponential families of probability distributions, which recommends them for solving problems that arise in the statistical analysis of data. We will elaborate on these connections in what follows.

Let us begin with a formal statement of the Bregman nearness problem. Suppose that $D_\varphi$ is a Bregman divergence, and suppose that $\{C_k\}$ is a finite collection of closed, convex sets whose intersection is nonempty. Given an input matrix $\boldsymbol{Y}$, our goal is to produce a matrix $\boldsymbol{X}$ in the intersection that diverges the least from $\boldsymbol{Y}$, i.e., to solve

$$\min_{\boldsymbol{X}} \; D_\varphi(\boldsymbol{X}; \boldsymbol{Y}) \qquad \text{subject to} \qquad \boldsymbol{X} \in \bigcap\nolimits_k C_k. \tag{1.1}$$

Under mild conditions, the solution to (1.1) is unique, and it has a variational characterization analogous with the characterization of an orthogonal projection onto a convex set [10]. Minimization with respect to the second argument of the divergence enjoys rather less structure, so we refer the reader to [5] for more details. A major advantage of our problem formulation is that it admits a natural algorithm. If one possesses a method for minimizing the divergence over each of the constraint sets, then it is possible to solve (1.1) by minimizing over each constraint in turn while introducing a series of simple corrections. Several classical algorithms from the matrix literature fit into this geometric framework, but it also provides an approach to many novel problems.

We view this paper as an expository work with two central goals. First, it introduces Bregman divergences to the matrix theory literature, and it argues that they provide an important and natural class of distance measures for matrix nearness problems. Moreover, the article unifies a large class of problems into a geometrical framework, and it shows that these problems can be solved with a set of classical algorithms. Second, the paper provides specific examples of nearness problems with respect to Bregman divergences. One example is the familiar problem of producing the nearest contingency table with fixed marginals. Novel examples include computing matrix approximations using the minimum Bregman information (MBI) principle, identifying the metric graph nearest to an arbitrary graph, and determining the nearest correlation and kernel matrix with respect to matrix divergences, such as the von Neumann divergence. These applications show how Bregman divergences can be used to preserve and exploit additional structure that appears in a problem.

We must warn the reader that, in spite of the availability of some general purpose algorithms for working with Bregman divergences, they may require a substantial amount of computational effort. One basic reason is that nearness problems with respect to the Frobenius norm usually remain within the domain of linear algebra, which is a developed technology. Bregman divergences, on the other hand, transport us to the world of convex optimization, which is a rougher frontier. As outlined in section 8, there remain many unresolved research issues on the computational aspects of Bregman divergences.

Here is a brief outline of the article. Section 2 introduces Bregman divergences and Bregman projections along with their connection to exponential families of probability distributions. Matrix Bregman divergences that depend on the spectral properties of a matrix are covered in subsection 2.6. Section 3 discusses numerical methods for the basic problem of minimizing a Bregman divergence over a hyperplane. In section 4, we develop the successive projection algorithm for solving the Bregman nearness problem subject to affine constraints. Section 5 gives several examples of these problems: finding the nearest contingency table with fixed marginals, computing matrix approximations for data analysis, and determining the nearest correlation matrix with respect to the von Neumann divergence. Section 6 presents the successive projection–correction algorithm for solving the Bregman nearness problem subject to a polyhedral constraint. In section 7 we discuss two matrix nearness problems with nonaffine constraints: finding the nearest metric graph and learning a kernel matrix for data mining and machine learning applications.

## 2. Bregman divergences and Bregman projections.

This section develops the directed distance functions that were first studied by Bregman [8]. Our primary source is the superb article of Bauschke and Borwein [4], which studies a subclass of Bregman divergences that exhibits many desirable properties in connection with nearness problems like (1.1).

### 2.1. Convex analysis.

The literature on Bregman divergences involves a significant amount of convex analysis. Some standard references for this material are [35, 20]. We review some of these ideas in an effort to make this article accessible to readers who are less familiar with this field.

We will work in a finite-dimensional, real inner-product space $\mathscr{X}$. The real-linear inner product is denoted by $\langle\cdot,\cdot\rangle$ and the induced norm by $\|\cdot\|_2$. In general, the elements of $\mathscr{X}$ will be expressed with lowercase bold italic letters such as $\boldsymbol{x}$ and $\boldsymbol{y}$. We will switch to capitals, such as $\boldsymbol{X}$ and $\boldsymbol{Y}$, when it is important to view the elements of $\mathscr{X}$ as matrices.

A [illegible] is a subset $C$ of $\mathscr{X}$ that exhibits the property

$$s\,\boldsymbol{x} + (1-s)\,\boldsymbol{y} \in C \qquad \text{for all } s \in (0,1) \text{ and } \boldsymbol{x}, \boldsymbol{y} \in C.$$

In words, the line segment connecting each pair of points in a convex set falls within the set. The [illegible] of a convex set, abbreviated ri, is the interior of that set considered as a subset of the lowest-dimensional affine space that contains it.

In convex analysis, functions are defined on all of $\mathscr{X}$, and they take values in the extended real numbers, $\mathbb{R} \cup \{\pm\infty\}$. The [illegible] of a function $f$ is the set

$$\operatorname{dom} f \overset{\text{def}}{=} \{\boldsymbol{x} \in \mathscr{X} : f(\boldsymbol{x}) < +\infty\}.$$

A function $f$ is [illegible] if its domain is convex and it verifies the inequality

$$f(s\,\boldsymbol{x} + (1-s)\,\boldsymbol{y}) \le s\,f(\boldsymbol{x}) + (1-s)\,f(\boldsymbol{y}) \quad \text{for all } s \in (0,1) \text{ and } \boldsymbol{x}, \boldsymbol{y} \in \operatorname{dom} f.$$

If the inequality is strict, then $f$ is [illegible]. In words, the chord connecting each pair of points on the graph of a (strictly) convex function lies (strictly) above the graph. A convex function is [illegible] if it takes at least one finite value and never takes the value $-\infty$. A convex function $f$ is [illegible] if its lower level set $\{\boldsymbol{x} : f(\boldsymbol{x}) \le \alpha\}$ is closed for each real $\alpha$. In particular, a convex function is closed whenever its domain is closed (but not conversely).

For completeness, we also introduce some technical definitions that the casual reader may prefer to glide through. A proper convex function $f$ is called [illegible] if it is everywhere differentiable on the (nonempty) interior of its domain and if $\|\nabla f(\boldsymbol{x}_t)\|$ tends to infinity for every sequence $\{\boldsymbol{x}_t\}$ from $\operatorname{ri}(\operatorname{dom} f)$ that converges to a point on the boundary of $\operatorname{dom} f$. Roughly speaking, an essentially smooth function cannot be extended to a convex function with a larger domain. The function $f(x) = -\log(x)$ with domain $(0,+\infty)$ is an example of an essentially smooth function. In what follows, we will focus on convex functions of [illegible]. A Legendre function is a closed, proper, convex function that is essentially smooth and also strictly convex on the relative interior of its domain.

Every convex function has a dual representation in terms of its supporting hyperplanes. This idea is formalized in the *Fenchel conjugate*, which is defined as

$$f^*(\boldsymbol{\theta}) \overset{\text{def}}{=} \sup_{\boldsymbol{x}} \left\{ \langle \boldsymbol{x}, \boldsymbol{\theta} \rangle - f(\boldsymbol{x}) \right\}.$$

No confusion should arise from our usage of the symbol $^*$ for complex-conjugate transposition as well as Fenchel conjugation. The following facts are valuable. The conjugate of a convex function is always closed and convex. If $f$ is a closed, convex function, then $(f^*)^* = f$. A convex function has Legendre type if and only if its conjugate has Legendre type.

Finally, we say that a convex function $f$ is *cofinite* when

$$\lim_{\xi \to \infty} f(\xi\, \boldsymbol{x})/\xi = +\infty \qquad \text{for all nonzero } \boldsymbol{x} \text{ in } \mathscr{X}.$$

This definition means that a cofinite function grows superlinearly in every direction. For example, the function $\|\cdot\|_2^2$ is cofinite, but the function $\exp(\cdot)$ is not. It can be shown that a closed, proper, convex function $f$ is cofinite if and only if $\operatorname{dom} f^* = \mathscr{X}$.

**2.2. Divergences.** Suppose that $\varphi$ is a convex function of Legendre type. From every such seed function, we may construct a Bregman divergence[1]

$$D_\varphi : \operatorname{dom}\varphi \times \operatorname{ri}(\operatorname{dom}\varphi) \to [0, +\infty)$$

via the rule

$$D_\varphi(\boldsymbol{x}; \boldsymbol{y}) \overset{\text{def}}{=} \varphi(\boldsymbol{x}) - \varphi(\boldsymbol{y}) - \langle \nabla\varphi(\boldsymbol{y}), \boldsymbol{x} - \boldsymbol{y} \rangle .$$

Geometrically, the divergence calculates how much the supporting hyperplane to $\varphi$ at $\boldsymbol{y}$ underestimates the value of $\varphi(\boldsymbol{x})$. For an illustration, see Figure 2.1. A Bregman divergence equals zero whenever $\boldsymbol{x} = \boldsymbol{y}$, and it is positive otherwise. It is strictly convex in its first argument, and it is jointly continuous in both arguments.

As a first example, consider the seed function $\varphi(\boldsymbol{x}) = \frac{1}{2}\|\boldsymbol{x}\|_2^2$, which is a Legendre function on all of $\mathscr{X}$. The associated divergence is

$$D_\varphi(\boldsymbol{x}; \boldsymbol{y}) = \tfrac{1}{2}\|\boldsymbol{x} - \boldsymbol{y}\|_2^2 .$$

We will refer to this function as the Euclidean divergence. Observe that it is symmetric in its two arguments, but it does not satisfy the triangle inequality.

Another basic example arises from the negative Shannon entropy,

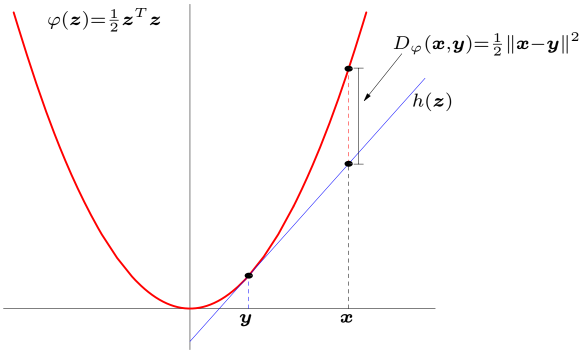
$$\varphi(\boldsymbol{x}) = \sum\nolimits_n x_n \log x_n - x_n,$$

where we place the convention that $0 \log 0 = 0$. This entropy is a Legendre function on the nonnegative orthant, and it yields the divergence

$$D_\varphi(\boldsymbol{x}; \boldsymbol{y}) = \sum\nolimits_n \left[ x_n \log \frac{x_n}{y_n} - x_n + y_n \right], \tag{2.1}$$

---

[1] It is also possible to define Bregman divergences with respect to any differentiable, strictly convex function. These divergences are not necessarily well behaved.



$\varphi(z)=\frac{1}{2}z^Tz$
$D_\varphi(x,y)=\frac{1}{2}\|x-y\|^2$
$h(z)$
$y$
$x$

FIG. 2.1. *An example of a Bregman divergence is the squared Euclidean distance. The Bregman divergence $D_\varphi(\boldsymbol{x};\boldsymbol{y})$ calculates how much the supporting hyperplane to $\varphi$ at $\boldsymbol{y}$ underestimates the value of $\varphi(\boldsymbol{x})$.*

which is variously called the [illegible], the [illegible], or the [illegible]. This divergence is not symmetric, and it does not satisfy the triangle inequality.

Bregman divergences are often referred to as [illegible], but this terminology is misleading. A Bregman divergence should not be viewed as a generalization of a metric but rather as a generalization of the preceding two examples. Like a metric, every Bregman divergence is positive except when its arguments coincide. On the other hand, divergences do not generally satisfy the triangle inequality, and they are symmetric only when the seed function $\varphi$ is quadratic. In compensation, divergences exhibit other structural properties. For every three points in the interior of dom $\varphi$, we have the relation

$$D_\varphi(\boldsymbol{x};\boldsymbol{z}) = D_\varphi(\boldsymbol{x};\boldsymbol{y}) + D_\varphi(\boldsymbol{y};\boldsymbol{z}) - \langle \nabla\varphi(\boldsymbol{z}) - \nabla\varphi(\boldsymbol{y}), \boldsymbol{x}-\boldsymbol{y}\rangle .$$

When $D_\varphi$ is the Euclidean divergence, one may identify this formula as the law of cosines. Later, we will also encounter a Pythagorean theorem.

We also note another expression for the divergence, which emphasizes that it is a sort of locally quadratic distance measure,

$$D_\varphi(\boldsymbol{x};\boldsymbol{y}) = (\boldsymbol{x}-\boldsymbol{y})^* \left\{\nabla^2\varphi(\boldsymbol{\xi})\right\} (\boldsymbol{x}-\boldsymbol{y}),$$

where $\boldsymbol{\xi}$ is an unknown vector that depends on $\boldsymbol{x}$ and $\boldsymbol{y}$. This formula can be obtained from the Taylor expansion of the seed function with an exact remainder term.

**2.3. Exponential families.** Suppose that $\psi$ is a Legendre function. A [illegible] is a parameterized family of probability distributions on $\mathscr{X}$ with density function (with respect to the Lebesgue measure on $\mathscr{X}$) of the form

$$p_\psi(\boldsymbol{x}\,|\,\boldsymbol{\theta}) = \exp\{\langle \boldsymbol{x},\boldsymbol{\theta}\rangle - \psi(\boldsymbol{\theta}) - h(\boldsymbol{x})\},$$

where the parameter $\boldsymbol{\theta}$ is drawn from the open set dom $\psi$ [3]. The function $\psi$ is called the [illegible] of the exponential family, and it completely determines the function $h$. The [illegible] of the distribution $p_\psi(\,\cdot\,|\,\boldsymbol{\theta})$ is the vector

$$\boldsymbol{\mu}(\boldsymbol{\theta}) \overset{\text{def}}{=} \int_{\mathscr{X}} \boldsymbol{x}\, p_\psi(\boldsymbol{x}\,|\,\boldsymbol{\theta})\,\mathrm{d}\boldsymbol{x},$$

where d$\boldsymbol{x}$ denotes the Lebesgue measure on $\mathscr{X}$. Many common probability distributions belong to exponential families. Prominent examples include Gaussian, Poisson, Bernoulli, and gamma distributions.

It has recently been established that there is a unique Bregman divergence that corresponds to every regular exponential family.

Theorem 1 (Banerjee et al. [2]). [illegible] $\varphi$ [illegible] $\psi$ [illegible] $D_\varphi$ [illegible] $\varphi$ [illegible] $p_\psi(\,\cdot\,|\,\boldsymbol{\theta})$ [illegible] $\psi$ [illegible]

$$p_\psi(\boldsymbol{x}\,|\,\boldsymbol{\theta}) = \exp\{-D_\varphi(\boldsymbol{x};\boldsymbol{\mu}(\boldsymbol{\theta}))\}\, g_\varphi(\boldsymbol{x}),$$

[illegible] $g_\varphi$ [illegible] $\varphi$

The spherical Gaussian distribution provides an especially interesting example of this relationship [2]. Suppose that $\boldsymbol{\mu}$ is an arbitrary vector in $\mathscr{X}$, and let $\sigma^2$ be a fixed positive number. The spherical Gaussian distributions with mean $\boldsymbol{\mu}$ and variance $\sigma^2$ form an exponential family with parameter $\boldsymbol{\theta} = \boldsymbol{\mu}/\sigma^2$ and cumulant function $\psi(\boldsymbol{\theta}) = \frac{\sigma^2}{2}\,\|\boldsymbol{\theta}\|_2^2$. The Fenchel conjugate of the cumulant function is $\varphi(\boldsymbol{x}) = \frac{1}{2\sigma^2}\,\|\boldsymbol{x}\|_2^2$, and so the Bregman divergence that appears in the bijection theorem is

$$D_\varphi(\boldsymbol{x};\boldsymbol{\mu}) = \frac{1}{2\sigma^2}\,\|\boldsymbol{x}-\boldsymbol{\mu}\|_2^2\,.$$

We see that the density of the distribution at a point $\boldsymbol{x}$ depends essentially on the Bregman divergence of $\boldsymbol{x}$ from the mean vector $\boldsymbol{\mu}$. This observation reinforces the intuition that the squared Euclidean norm enjoys a profound relationship with Gaussian random variables.

### 2.4. Bregman projections.

Suppose that $\varphi$ is a convex function of Legendre type, and let $C$ be a closed, convex set that intersects ri(dom $\varphi$). Given a point $\boldsymbol{y}$ from ri(dom $\varphi$), we may pose the minimization problem

$$\min_{\boldsymbol{x}}\; D_\varphi(\boldsymbol{x};\boldsymbol{y}) \qquad \text{subject to} \qquad \boldsymbol{x}\in C\cap \operatorname{ri}(\operatorname{dom}\varphi). \tag{2.2}$$

Since $D_\varphi(\,\cdot\,;\boldsymbol{y})$ is strictly convex, it follows from a standard argument that there exists [illegible] one minimizer. It can be shown that, when $\varphi$ is a Legendre function, there exists [illegible] one minimizer [4, Theorem 3.12]. Therefore, the problem (2.2) has a single solution, which is called the [illegible] of $\boldsymbol{y}$ onto $C$ with respect to the divergence $D_\varphi$. Denote this solution by $P_C(\boldsymbol{y})$, and observe that we have defined a map

$$P_C : \operatorname{ri}(\operatorname{dom}\varphi) \to C\cap\operatorname{ri}(\operatorname{dom}\varphi).$$

It is evident that $P_C$ acts as the identity on $C\cap\operatorname{ri}(\operatorname{dom}\varphi)$, and it can be shown that $P_C$ is continuous.

There is also a variational characterization of the Bregman projection of a point $\boldsymbol{y}$ from ri(dom $\varphi$) onto the set $C$,

$$D_\varphi(\boldsymbol{x};\boldsymbol{y}) \geq D_\varphi(\boldsymbol{x};P_C(\boldsymbol{y})) + D_\varphi(P_C(\boldsymbol{y});\boldsymbol{y}) \qquad \text{for every } \boldsymbol{x}\in C\cap\operatorname{dom}\varphi. \tag{2.3}$$

Conversely, suppose we replace $P_C(\boldsymbol{y})$ with an arbitrary point $\boldsymbol{z}$ from $C\cap\operatorname{ri}(\operatorname{dom}\varphi)$ that verifies the inequality. Then $\boldsymbol{z}$ must indeed be the Bregman projection of $\boldsymbol{y}$ onto

$C$. When the constraint $C$ is an affine space (i.e., a translated subspace), then the Bregman projection of $\boldsymbol{y}$ onto $C$ has a formally stronger characterization,

$$D_\varphi(\boldsymbol{x};\boldsymbol{y}) = D_\varphi(\boldsymbol{x};P_C(\boldsymbol{y})) + D_\varphi(P_C(\boldsymbol{y});\boldsymbol{y}) \qquad \text{for every } \boldsymbol{x} \in C \cap \operatorname{dom}\varphi. \tag{2.4}$$

When the Bregman divergence is the Euclidean divergence, formula (2.3) reduces to the criterion for identifying the orthogonal projection onto a convex set [14, Chapter 4], while formula (2.4) is usually referred to as the Pythagorean theorem. These facts justify the assertion that Bregman projections generalize orthogonal projections.

When the constraint set $C$ and the Bregman divergence are simple enough, it may be possible to determine the Bregman projection onto $C$ analytically. For example, let us define the hyperplane $C = \{\boldsymbol{x} : \langle \boldsymbol{a}, \boldsymbol{x}\rangle = \alpha\}$. When $\|\boldsymbol{a}\|_2 = 1$, the projection of $\boldsymbol{y}$ onto $C$ with respect to the Euclidean divergence is

$$P_C(\boldsymbol{y}) = \boldsymbol{y} - (\langle \boldsymbol{a}, \boldsymbol{y}\rangle - \alpha)\, \boldsymbol{a}. \tag{2.5}$$

As a second example, suppose that $C$ contains a strictly positive vector and that $\boldsymbol{y}$ is strictly positive. Using Lagrange multipliers, we check that the projection of $\boldsymbol{y}$ onto $C$ with respect to the relative entropy has components

$$(P_C(\boldsymbol{y}))_n = y_n \exp\{\xi\, a_n\}, \quad \text{where } \xi \text{ is chosen so that } P_C(\boldsymbol{y}) \in C. \tag{2.6}$$

In the case when all the components of $\boldsymbol{a}$ are identical (to one, without loss of generality), then $\xi = \log\alpha - \log\sum_n y_n$.

It is uncommon that a Bregman projection can be explicitly determined. In section 3, we describe numerical methods for computing the Bregman projection onto a hyperplane, which is the foundation for producing Bregman projections onto more complicated sets. For another example of a projection that can be computed analytically, turn to the end of subsection 3.3.

**2.5. A cornucopia of divergences.** In this subsection, we will present some important Bregman divergences. The [illegible] divergences form the most fundamental class. A separable divergence arises from a seed function of the form

$$\varphi(\boldsymbol{x}) = \sum\nolimits_n w_n\, \varphi_n(x_n) \qquad \text{for positive weights } w_n.$$

If each $\varphi_n$ is Legendre, then the weighted sum is also Legendre. In the most common situation, the weights are constant and all the $\varphi_n$ are identical. In Table 2.1 we list some important Legendre functions on $\mathbb{R}$ that may be used to build separable divergences. These examples are adapted from [4] and [2]. Several of the divergences in Table 2.1 have names. We have already discussed the Euclidean divergence and the relative entropy. The bit entropy leads to a type of logistic loss, and the Burg entropy leads to the Itakura–Saito divergence.

Many of these univariate divergences are connected with well-known exponential families of probability distributions on $\mathbb{R}$. See Table 2.2 for some key examples drawn from [2].

One fundamental divergence is genuinely multidimensional. Suppose that $\boldsymbol{Q}$ is a positive-definite operator that acts on $\mathscr{X}$. We may construct a quadratic divergence on $\mathscr{X}$ from the seed function $\varphi(\boldsymbol{x}) = \frac{1}{2}\langle \boldsymbol{Q}\,\boldsymbol{x}, \boldsymbol{x}\rangle$, resulting in

$$D_\varphi(\boldsymbol{x};\boldsymbol{y}) = \tfrac{1}{2}\left\langle \boldsymbol{Q}\,(\boldsymbol{x}-\boldsymbol{y}), \boldsymbol{x}-\boldsymbol{y}\right\rangle.$$

Table 2.1
*Common seed functions and the corresponding divergences.*

| Function name | $\varphi(x)$ | $\operatorname{dom}\varphi$ | $D_\varphi(x;y)$ |
|---|---|---|---|
| Squared norm | $\frac{1}{2}x^2$ | $(-\infty,+\infty)$ | $\frac{1}{2}(x-y)^2$ |
| Shannon entropy | $x\log x - x$ | $[0,+\infty)$ | $x\log\frac{x}{y} - x + y$ |
| Bit entropy | $x\log x + (1-x)\log(1-x)$ | $[0,1]$ | $x\log\frac{x}{y} + (1-x)\log\frac{1-x}{1-y}$ |
| Burg entropy | $-\log x$ | $(0,+\infty)$ | $\frac{x}{y} - \log\frac{x}{y} - 1$ |
| Hellinger | $-\sqrt{1-x^2}$ | $[-1,1]$ | $(1-xy)(1-y^2)^{-1/2} - (1-x^2)^{1/2}$ |
| $\ell_p$ quasi-norm | $-x^p \qquad (0<p<1)$ | $[0,+\infty)$ | $-x^p + p\,xy^{p-1} - (p-1)\,y^p$ |
| $\ell_p$ norm | $\lvert x\rvert^p \qquad (1<p<\infty)$ | $(-\infty,+\infty)$ | $\lvert x\rvert^p - p\,x\operatorname{sgn}y\,\lvert y\rvert^{p-1} + (p-1)\,\lvert y\rvert^p$ |
| Exponential | $\exp x$ | $(-\infty,+\infty)$ | $\exp x - (x-y+1)\exp y$ |
| Inverse | $1/x$ | $(0,+\infty)$ | $1/x + x/y^2 - 2/y$ |

Table 2.2
*Common exponential families and the corresponding divergences.*

| Exponential family | $\psi(\theta)$ | $\operatorname{dom}\psi$ | $\mu(\theta)$ | $\varphi(x)$ | Divergence |
|---|---|---|---|---|---|
| Gaussian ($\sigma^2$ fixed) | $\frac{1}{2}\sigma^2\theta^2$ | $(-\infty,+\infty)$ | $\sigma^2\theta$ | $\frac{1}{2\sigma^2}x^2$ | Euclidean |
| Poisson | $\exp\theta$ | $(-\infty,+\infty)$ | $\exp\theta$ | $x\log x - x$ | Relative entropy |
| Bernoulli | $\log(1+\exp\theta)$ | $(-\infty,+\infty)$ | $\frac{\exp\theta}{1+\exp\theta}$ | $x\log x + (1-x)\log(1-x)$ | Logistic loss |
| Gamma ($\alpha$ fixed) | $-\alpha\,\log(-\theta)$ | $(-\infty,0)$ | $-\alpha/\theta$ | $-\alpha\log x + \alpha\log\alpha - \alpha$ | Itakura–Saito |

This divergence is connected to the exponential family of multivariate Gaussian distributions with covariance matrix $\boldsymbol{Q}^{-1}$. In the latter context, the square root of this divergence is often referred to as the [illegible] in statistics [29]. Other multidimensional examples arise when we compose the Euclidean norm with another function. For instance, one might consider the convex function $\varphi(\boldsymbol{x}) = -\sqrt{1 - \|\boldsymbol{x}\|_2^2}$ defined on the Euclidean unit ball. It yields the Hellinger-like divergence

$$D_\varphi(\boldsymbol{x};\boldsymbol{y}) = \frac{1 - \langle \boldsymbol{x}, \boldsymbol{y}\rangle}{\sqrt{1 - \|\boldsymbol{y}\|_2^2}} - \sqrt{1 - \|\boldsymbol{x}\|_2^2}.$$

**2.6. Matrix divergences.** Hermitian matrices admit a rich variety of divergences that were first studied in [4] using the methods of Lewis [27]. Let $\mathscr{H}$ be the space of $N \times N$ Hermitian matrices equipped with the real-linear inner product $\langle \boldsymbol{X}, \boldsymbol{Y}\rangle = \operatorname{Re}\operatorname{Tr}\boldsymbol{X}\boldsymbol{Y}^*$. Define the function $\boldsymbol{\lambda} : \mathscr{H} \to \mathbb{R}^N$ that maps a Hermitian matrix to the vector listing its eigenvalues in algebraically decreasing order. Let $\varphi$ be a closed, proper, convex function on $\mathbb{R}^N$ that is invariant under coordinate permutation. That is, $\varphi(\boldsymbol{x}) = \varphi(\boldsymbol{P}\boldsymbol{x})$ for every permutation matrix $\boldsymbol{P}$.

By composing $\varphi$ with the eigenvalue map, we induce a real-valued function on Hermitian matrices. As the following theorem elaborates, the induced map has the same convexity properties as the function $\varphi$. Therefore, the induced map can be used as a seed function to define a Bregman divergence on the space of Hermitian matrices.

THEOREM 2 (Lewis [27, 26]). [illegible] $\varphi \circ \boldsymbol{\lambda}$ [illegible]

1. [illegible] $\varphi$ [illegible]
2. [illegible] $\varphi \circ \boldsymbol{\lambda}$ [illegible] $\boldsymbol{\lambda}$ [illegible] $\operatorname{dom}\varphi$
3. [illegible] $(\varphi \circ \boldsymbol{\lambda})^* = \varphi^* \circ \boldsymbol{\lambda}$
4. [illegible] $\boldsymbol{X}$ [illegible] $\varphi$ [illegible] $\boldsymbol{\lambda}(\boldsymbol{X})$ [illegible] $\boldsymbol{X}$ [illegible] $\boldsymbol{U}\{\operatorname{diag}\boldsymbol{\lambda}(\boldsymbol{X})\}\boldsymbol{U}^*$ [illegible]

$$\nabla(\varphi \circ \boldsymbol{\lambda})(\boldsymbol{X}) = \boldsymbol{U}\{\operatorname{diag}\nabla\varphi(\boldsymbol{\lambda}(\boldsymbol{X}))\}\boldsymbol{U}^*.$$

[illegible] $\varphi$ [illegible]

5. [illegible] $\varphi$ [illegible]

[illegible] $\varphi$ [illegible] $\varphi(\boldsymbol{x}) = \varphi(|\boldsymbol{x}|)$ [illegible] $\boldsymbol{x}$ [illegible] $\mathbb{R}^N$ [illegible] $|\cdot|$ [illegible]

Unitarily invariant matrix norms provide the most basic examples of induced maps. Indeed, item 3 of the last theorem generalizes von Neumann's famous result about dual norms of unitarily invariant prenorms [21, 438ff.].

An exquisite example of a matrix divergence arises from $\varphi(\boldsymbol{x}) = -\sum_n \log x_n$. The induced map is $(\varphi \circ \boldsymbol{\lambda})(\boldsymbol{X}) = -\log\det\boldsymbol{X}$, whose domain is the positive-definite cone. Since $\nabla(\varphi \circ \boldsymbol{\lambda})(\boldsymbol{X}) = -\boldsymbol{X}^{-1}$, the resulting divergence is

$$D_{\ell d}(\boldsymbol{X};\boldsymbol{Y}) = \left\langle \boldsymbol{X}, \boldsymbol{Y}^{-1}\right\rangle - \log\det\boldsymbol{X}\boldsymbol{Y}^{-1} - N. \tag{2.7}$$

Intriguingly, certain projections with respect to this divergence can be computed analytically. See subsection 3.3 for details.

Another important example arises from the negative Shannon entropy $\varphi(\boldsymbol{x}) = \sum_n x_n \log x_n - x_n$. The induced map is $(\varphi \circ \boldsymbol{\lambda})(\boldsymbol{X}) = \operatorname{Tr}(\boldsymbol{X} \log \boldsymbol{X} - \boldsymbol{X})$, whose domain is the positive-semidefinite cone. This matrix function arises in quantum mechanics, where it is referred to as the [illegible] [31]. It yields the divergence

$$D_{\mathrm{vN}}(\boldsymbol{X}; \boldsymbol{Y}) = \operatorname{Tr}[\boldsymbol{X}(\log \boldsymbol{X} - \log \boldsymbol{Y}) - \boldsymbol{X} + \boldsymbol{Y}], \tag{2.8}$$

which we will call the von Neumann divergence. In the quantum mechanics literature, this divergence is referred to as the [illegible] [31]. This formula does not literally hold if either matrix is singular, but a limit argument shows that the divergence is finite precisely when the null space of $\boldsymbol{X}$ contains the null space of $\boldsymbol{Y}$.

When the seed function $\varphi$ is separable, matrix divergences can be expressed in a way that emphasizes the distinct roles of the eigenvalues and eigenvectors. In particular, take $\varphi(\boldsymbol{x}) = \sum_n \varphi(x_n)$ and assume that $\boldsymbol{X}$ has eigenpairs $(\boldsymbol{u}_m, \mu_m)$ and that $\boldsymbol{Y}$ has eigenpairs $(\boldsymbol{v}_n, \nu_n)$. Then

$$\begin{aligned} D_{\varphi \circ \boldsymbol{\lambda}}(\boldsymbol{X}; \boldsymbol{Y}) &= \sum\nolimits_{m,n} |\langle \boldsymbol{u}_m, \boldsymbol{v}_n \rangle|^2 \left[\varphi(\mu_m) - \varphi(\nu_n) - \varphi'(\nu_n)(\mu_m - \nu_n)\right] \\ &= \sum\nolimits_{m,n} |\langle \boldsymbol{u}_m, \boldsymbol{v}_n \rangle|^2 D_\varphi(\mu_m; \nu_n). \end{aligned}$$

In words, the matrix divergence adds up the scalar divergences between pairs of eigenvalues, weighted by the squared cosine of the angle between the corresponding eigenvectors.

## 3. Computing Bregman projections.

It is not straightforward to compute the Bregman projection onto a general convex set. Unless additional structure is present, the best approach may be to apply standard convex optimization techniques. In this section, we discuss how to develop numerical methods for the basic problem of projecting onto a hyperplane or a halfspace. As we will see in sections 4 and 6, the projection onto an intersection of convex sets can be broken down into a sequence of projections onto the individual sets. Combining the two techniques, we can find the projection onto any affine space or polyhedral convex set.

### 3.1. Projection onto a hyperplane.

There is an efficient way to compute the Bregman projection onto a hyperplane. The key idea is to dualize the Bregman projection problem to obtain a nice one-dimensional problem. This approach can also be extended to produce the projection onto a halfspace because the convexity of the divergence implies that the projection lies on the boundary whenever the initial point is outside the halfspace.

We must solve the following convex program:

$$\min_{\boldsymbol{x}} D_\varphi(\boldsymbol{x}; \boldsymbol{y}) \qquad \text{subject to} \qquad \langle \boldsymbol{a}, \boldsymbol{x} \rangle = \alpha. \tag{3.1}$$

To ensure that this problem is well posed, we assume that $\operatorname{ri}(\operatorname{dom}\varphi)$ contains a feasible point. A necessary and sufficient condition on the solution $\boldsymbol{x}_\star$ of (3.1) is that the equation

$$\nabla_{\boldsymbol{x}} D_\varphi(\boldsymbol{x}; \boldsymbol{y}) = \xi \, \nabla_{\boldsymbol{x}} \left(\langle \boldsymbol{a}, \boldsymbol{x} \rangle - \alpha\right)$$

hold for a (unique) Lagrange multiplier $\xi \in \mathbb{R}$. The gradient of the divergence is $\nabla\varphi(\boldsymbol{x}) - \nabla\varphi(\boldsymbol{y})$, resulting in the equation

$$\nabla\varphi(\boldsymbol{x}_\star) = \xi \boldsymbol{a} + \nabla\varphi(\boldsymbol{y}).$$

The gradient of a Legendre function $\varphi$ is a bijection from $\operatorname{dom}\varphi$ to $\operatorname{dom}\varphi^*$, and its inverse is the gradient of the conjugate [35, Thm. 26.5]. Thus we obtain an explicit expression for the Bregman projection as a function of the unknown multiplier:

$$\boldsymbol{x}_\star = \nabla\varphi^*(\xi\boldsymbol{a} + \nabla\varphi(\boldsymbol{y})). \tag{3.2}$$

Form the inner product with $\boldsymbol{a}$ and enforce the constraint to reach

$$\langle \nabla\varphi^*(\xi\boldsymbol{a} + \nabla\varphi(\boldsymbol{y})), \boldsymbol{a}\rangle - \alpha = 0. \tag{3.3}$$

Now, the left-hand side of this equation is the derivative of the strictly convex, univariate function

$$J(\xi) = \varphi^*(\xi\boldsymbol{a} + \nabla\varphi(\boldsymbol{y})) - \alpha\xi. \tag{3.4}$$

There is an implicit constraint that the argument of $\varphi^*$ must lie within its domain. In view of (3.3), it becomes clear that the Lagrange multiplier is the unique minimizer of $J$. That is,

$$\xi_\star = \arg\min_\xi J(\xi).$$

Once we have determined the Lagrange multiplier, we introduce it into (3.2) to obtain the Bregman projection.

The best numerical method for minimizing $J$ depends strongly on the choice of the seed function $\varphi$. In some cases, the derivative(s) of $J$ may be difficult to evaluate. The second derivative may even fail to exist. To that end, we offer several observations that may be valuable.

1. The domain of $J$ contains a neighborhood of zero since $J(0) = \langle \boldsymbol{y}, \nabla\varphi(\boldsymbol{y})\rangle - \varphi(\boldsymbol{y})$.
2. Since $\varphi^*$ is a Legendre function, the first derivative of $J$ always exists. As shown in (3.3),

$$J'(\xi) = \langle \nabla\varphi^*(\xi\boldsymbol{a} + \nabla\varphi(\boldsymbol{y})), \boldsymbol{a}\rangle - \alpha.$$

3. When the Hessian of $\varphi^*$ exists, we have

$$J''(\xi) = \boldsymbol{a}^* \left\{\nabla^2\varphi^*(\xi\boldsymbol{a} + \nabla\varphi(\boldsymbol{y}))\right\} \boldsymbol{a}.$$

4. When the seed function $\varphi$ is separable, the Hessian $\nabla^2\varphi^*$ is diagonal.

The next two subsections provide examples that illustrate some of the issues involved in optimizing $J$.

**3.2. Example: Relative entropy.** Suppose that we wish to produce the Bregman projection of a nonnegative vector $\boldsymbol{y}$ onto the hyperplane $C = \{\boldsymbol{x} : \langle \boldsymbol{a}, \boldsymbol{x}\rangle = \alpha\}$ with respect to the relative entropy. This divergence arises from the seed function $\varphi(\boldsymbol{x}) = \sum_n x_n \log x_n - x_n$, whose conjugate is $\varphi^*(\boldsymbol{\theta}) = \sum_n \exp(\theta_n)$. To identify the Lagrange multiplier, we must minimize

$$J(\xi) = \sum\nolimits_n y_n \exp(\xi a_n) - \alpha\xi,$$

whose derivatives are

$$J'(\xi) = \sum\nolimits_n a_n y_n \exp(\xi a_n) - \alpha,$$

$$J''(\xi) = \sum\nolimits_n a_n^2 y_n \exp(\xi a_n).$$

These functions are all simple to evaluate, so it is best to use the Newton method preceded by a bracketing phase [32]. Once we have found the minimizer $\xi_\star$, the Bregman projection is

$$P_C(\boldsymbol{y}) = \boldsymbol{y} \cdot \exp(\xi_\star \boldsymbol{a}),$$

where $\cdot$ represents the Hadamard product and the exponential is performed componentwise.

**3.3. Example: Log-determinant divergence.** Here is a more sophisticated example that involves the log-determinant divergence. The divergence arises from the seed function $\varphi(\boldsymbol{X}) = -\log\det(\boldsymbol{X})$, whose domain is the positive-definite cone and whose gradient is $\nabla\varphi(\boldsymbol{X}) = -\boldsymbol{X}^{-1}$. The conjugate function $\varphi^*(\boldsymbol{\Theta}) = N - \log\det(-\boldsymbol{\Theta})$, whose domain is the negative-definite cone and whose gradient satisfies $\nabla\varphi^*(\boldsymbol{\Theta}) = -\boldsymbol{\Theta}^{-1}$.

Suppose we need to project the positive-definite matrix $\boldsymbol{Y}$ onto the hyperplane

$$C = \{\boldsymbol{X} : \langle \boldsymbol{A}, \boldsymbol{X}\rangle = \alpha\}, \qquad \text{where } \boldsymbol{A} = \boldsymbol{A}^*.$$

We must minimize

$$J(\xi) = N - \log\det(\boldsymbol{Y}^{-1} - \xi\boldsymbol{A}) - \alpha\xi,$$

while ensuring that $\boldsymbol{Y}^{-1} - \xi\boldsymbol{A}$ is positive definite.

Let $\boldsymbol{Y} = \boldsymbol{L}\boldsymbol{L}^*$, and abbreviate $\boldsymbol{W} = \boldsymbol{L}^*\boldsymbol{A}\boldsymbol{L}$, which is singular whenever $\boldsymbol{A}$ is rank deficient. Then the derivatives of $J$ can be expressed as

$$J'(\xi) = \operatorname{Tr}(\boldsymbol{W}(\mathbf{I} - \xi\boldsymbol{W})^{-1}) - \alpha,$$

$$J''(\xi) = \operatorname{Tr}\left( \left(\boldsymbol{W}(\mathbf{I} - \xi\boldsymbol{W})^{-1}\right)^2\right).$$

In general, $J$ and its derivatives are all costly. It appears that the most efficient way to calculate them for multiple values of the scalar $\xi$ is to preprocess $\boldsymbol{W}$ to extract its eigenvalues $\{\lambda_n\}$. It follows that

$$J'(\xi) = \left(\sum\nolimits_n \frac{\lambda_n}{1 - \lambda_n\xi}\right) - \alpha,$$

$$J''(\xi) = \sum\nolimits_n \left(\frac{\lambda_n}{1 - \lambda_n\xi}\right)^2.$$

It is worth cautioning that $\operatorname{dom} J = \{\xi : \xi < 1/\max_n \lambda_n\}$ since the matrix $\mathbf{I} - \xi\boldsymbol{W}$ must remain positive definite.

Once again, we see that a guarded or damped Newton method is the best way to optimize $J$. Given the solution $\xi_\star$, the Bregman projection is

$$P_C(\boldsymbol{Y}) = \boldsymbol{L}(\mathbf{I} - \xi_\star\boldsymbol{W})^{-1}\boldsymbol{L}^*.$$

We can reuse the eigenvalue decomposition to accelerate this final computation.

As shown in [25], these calculations simplify massively when the constraint matrix has rank one: $\boldsymbol{A} = \boldsymbol{a}\boldsymbol{a}^*$. In this case, we can find the zero of $J'$ analytically because $\boldsymbol{a}^*\boldsymbol{Y}\boldsymbol{a}$ is the only nonzero eigenvalue of $\boldsymbol{W}$. Then the Sherman–Morrison formula delivers an explicit expression for the projection:

$$P_C(\boldsymbol{Y}) = \boldsymbol{Y} + \frac{\boldsymbol{a}^*\boldsymbol{Y}\boldsymbol{a} - \alpha}{(\boldsymbol{a}^*\boldsymbol{Y}\boldsymbol{a})^2}(\boldsymbol{Y}\boldsymbol{a})(\boldsymbol{Y}\boldsymbol{a})^*.$$

The cost of performing the projection totals $O(N^2)$.

**4. The successive projection algorithm for affine constraints.** Now we describe an algorithm for solving (1.1) in the special case that the constraint sets are all [illegible]. In the next section, we will present some concrete problems to which this algorithm applies. The case of general convex constraint sets will be addressed afterward. We frame the following hypotheses.

| Assumption A.1 | |
|---|---|
| The divergence: | $\varphi$ is a convex function of Legendre type<br>$\operatorname{dom}\varphi^*$ is an open set |
| The constraints: | $C_1, C_2, \ldots, C_K$ are affine spaces with intersection $C$ |
| Constraint qualification: | $C \cap \operatorname{ri}(\operatorname{dom}\varphi)$ is nonempty |

Note that, by the results of subsection 2.3, all Bregman divergences that arise from regular exponential families satisfy Assumption A.1.

Given an input $\boldsymbol{y}_0$ from $\operatorname{ri}(\operatorname{dom}\varphi)$, we seek the Bregman projection of $\boldsymbol{y}_0$ onto the intersection $C$ of the affine constraints. In general, it may be difficult to produce $P_C(\boldsymbol{y}_0)$. Nevertheless, if the basic sets $C_1, \ldots, C_K$ are chosen well, it may be relatively straightforward to calculate the Bregman projection onto each basic set. This heuristic suggests an algorithm: Project successively onto each basic set in the hope that the sequence of iterates will converge to the Bregman projection onto the intersection. To make this approach work in general, it is clear that we must choose every set an infinite number of times, so we add one more requirement to Assumption A.1 as follows.

| Assumption A.2 | |
|---|---|
| The control mapping: | $r : \mathbb{N} \to \{1, \ldots, K\}$ is a sequence that takes each output value an infinite number of times |

Together, Assumptions A.1 and A.2 will be referred to as Assumption A. Here is a formal statement of the algorithm.

ALGORITHM A (successive projection). [illegible] A [illegible] $\boldsymbol{y}_0$ [illegible] $\operatorname{ri}(\operatorname{dom}\varphi)$ [illegible]

$$\boldsymbol{y}_t = P_{C_{r(t)}}(\boldsymbol{y}_{t-1}).$$

[illegible] $\{\boldsymbol{y}_t\}$ [illegible] $P_C(\boldsymbol{y}_0)$

We present a short proof that this algorithm is correct. We refer to the article [4] for the argument that the sequence converges, and we extend the elegant proof from [12] to show that the limit of the sequence yields the Bregman projection.

[illegible] Suppose that $\boldsymbol{a}$ is an arbitrary point in $C \cap \operatorname{dom}\varphi$. Since the seed function $\varphi$ is Legendre, Bregman projections with respect to the divergence fall in the relative interior of $\operatorname{dom}\varphi$. In particular, each iterate $\boldsymbol{y}_t$ belongs to $\operatorname{ri}(\operatorname{dom}\varphi)$. Therefore, we may apply the Pythagorean theorem (2.4) to see that

$$D_\varphi(\boldsymbol{a}; \boldsymbol{y}_{t-1}) = D_\varphi(\boldsymbol{a}; \boldsymbol{y}_t) + D_\varphi(\boldsymbol{y}_t; \boldsymbol{y}_{t-1}).$$

Observe that this equation defines a recurrence, which we may solve to obtain

$$D_\varphi(\boldsymbol{a}; \boldsymbol{y}_0) = D_\varphi(\boldsymbol{a}; \boldsymbol{y}_t) + \sum\nolimits_{i=1}^{t} D(\boldsymbol{y}_i; \boldsymbol{y}_{i-1}).$$

Under Assumption A, Theorem 8.1 of [4] shows that the sequence of iterates generated by Algorithm A converges to a point $\overline{\boldsymbol{y}}$ in $C \cap \operatorname{ri}(\operatorname{dom}\varphi)$. Since the divergence is continuous in its second argument, we may take limits to reach

$$D_\varphi(\boldsymbol{a}; \boldsymbol{y}_0) = D_\varphi(\boldsymbol{a}; \overline{\boldsymbol{y}}) + \sum\nolimits_{i=1}^{\infty} D_\varphi(\boldsymbol{y}_i; \boldsymbol{y}_{i-1}).$$

We chose $\boldsymbol{a}$ arbitrarily from $C \cap \operatorname{dom}\varphi$, so we may replace $\boldsymbol{a}$ by $\overline{\boldsymbol{y}}$ to see that the infinite sum equals $D_\varphi(\overline{\boldsymbol{y}}; \boldsymbol{y}_0)$. It follows that

$$D_\varphi(\boldsymbol{a}; \boldsymbol{y}_0) = D_\varphi(\boldsymbol{a}; \overline{\boldsymbol{y}}) + D_\varphi(\overline{\boldsymbol{y}}; \boldsymbol{y}_0).$$

This equation holds for each point $\boldsymbol{a}$ in $C \cap \operatorname{dom}\varphi$, so we see that $\overline{\boldsymbol{y}}$ meets the variational characterization (2.4) of $P_C(\boldsymbol{y}_0)$. Therefore, $\overline{\boldsymbol{y}}$ is the Bregman projection of $\boldsymbol{y}_0$ onto $C$. $\square$

If the sets $\{C_k\}$ are not affine, then Algorithm A will generally fail to produce the Bregman projection of $\boldsymbol{y}_0$ onto the intersection $C$. In section 6, we will discuss a more sophisticated iterative algorithm for solving this problem. Nevertheless, for general closed, convex constraint sets, the sequence of iterates generated by the successive projection algorithm still converges to a point in $C \cap \operatorname{ri}(\operatorname{dom}\varphi)$ [4, Theorem 8.1].

To obtain the convergence guarantee for Algorithm A, it may be necessary to work in an affine subspace of the ambient inner-product space. This point becomes important when computing the projections of nonnegative (as opposed to positive) vectors with respect to the relative entropy. It arises again when studying projections of rank-deficient matrices with respect to the von Neumann divergence. We will touch on this issue in subsections 5.1 and 5.3.

## 5. Examples with affine constraints.

This section presents three matrix nearness problems with affine constraints. The first requests the nearest contingency table with fixed marginals. A special case is to produce the nearest doubly stochastic matrix with respect to relative entropy. For this problem, the successive projection algorithm is identical to Kruithof's famous diagonal scaling algorithm [24, 13].

The second problem centers on a matrix nearness problem from data analysis, namely, that of finding matrix approximations based on the MBI principle, which is a generalization of Jaynes' maximum entropy principle [23].

The third problem shows how to construct the correlation matrix closest to a given positive-semidefinite matrix with respect to some matrix divergences. For reference, a correlation matrix is a positive-semidefinite matrix with a unit diagonal.

### 5.1. Contingency tables with fixed marginals.

A [illegible] is an array that exhibits the joint probability mass function of a collection of discrete random variables. A nonnegative rectangular matrix may be viewed as the contingency table for two discrete random variables. We will focus on this case since higher-dimensional contingency tables essentially are no more complicated.

Suppose that $p_{AB}$ is the joint probability mass function of two random variables $A$ and $B$ with sample spaces $\{1, 2, \ldots, M\}$ and $\{1, 2, \ldots, N\}$. We use $\boldsymbol{X}$ to denote the $M \times N$ contingency table whose entries are

$$x_{mn} = p_{AB}(A = m \text{ and } B = n).$$

A [illegible] of $p_{AB}$ is a linear function of $\boldsymbol{X}$. The most important marginals of $p_{AB}$ are the vector of row sums $\boldsymbol{X}\,\mathbf{e}$, which gives the distribution of $A$, and the vector of column sums $\mathbf{e}^T \boldsymbol{X}$, which gives the distribution of $B$. Here, $\mathbf{e}$ is a conformal vector of ones. The distribution of $A$ conditioned on $B = n$ is given by the $n$th column of $\boldsymbol{X}$, and the distribution of $B$ conditioned on $A = m$ is given by the $m$th row of $\boldsymbol{X}$.

However, we consider the more general case of arbitrary nonnegative matrices—we treat $\boldsymbol{X}$ as a member of the collection of $M \times N$ real matrices equipped with the inner product $\langle \boldsymbol{X}, \boldsymbol{Y} \rangle = \operatorname{Tr} \boldsymbol{X}\boldsymbol{Y}^T$. Note that, for the above probabilistic interpretation, $\boldsymbol{X}$ must be scaled so that its entries sum to 1.

A common problem is to use an initial estimate to produce a contingency table that has fixed marginals. In this setting, nearness is typically measured with relative entropy

$$D(\boldsymbol{X}; \boldsymbol{Y}) = \sum\nolimits_{m,n} \left[ x_{mn} \log \frac{x_{mn}}{y_{mn}} - x_{mn} + y_{mn} \right].$$

An important special case is to find the doubly stochastic matrix nearest to a nonnegative square matrix $\boldsymbol{Y}_0$. In this case, we have two constraint sets

$$C_1 = \{\boldsymbol{X} : \boldsymbol{X}\,\mathbf{e} = \mathbf{e}\} \qquad \text{and} \qquad C_2 = \{\boldsymbol{X} : \mathbf{e}^T \boldsymbol{X} = \mathbf{e}^T\}.$$

It is clear that the intersection $C = C_1 \cap C_2$ contains the set of doubly stochastic matrices. In fact, every nonnegative matrix in $C$ is doubly stochastic. Using (2.6), it is easy to see that Bregman projection of a matrix onto $C_1$ with respect to the relative entropy is accomplished by rescaling the rows so that each row sums to one. Likewise, Bregman projection of a matrix onto $C_2$ is accomplished by rescaling the columns. Beginning with $\boldsymbol{Y}_0$, the successive projection algorithm alternately rescales the rows and columns. This procedure, of course, is the diagonal scaling algorithm of Kruithof [24, 13], sometimes called Sinkhorn's algorithm [36]. Our approach yields a geometric interpretation of the algorithm as a method for solving a matrix nearness problem by alternating Bregman projections. It is interesting that the nonnegativity constraint is implicitly enforced by the domain of the relative entropy. This viewpoint can be traced to the work of Ireland and Kullback [22].

There is still a subtlety that requires attention. Assumption A apparently requires that $C$ contain a matrix with strictly positive entries and that the input matrix $\boldsymbol{Y}_0$ be strictly positive. In fact, we may relax these premises. A nonnegative matrix whose zero pattern does not cover the zero pattern of $\boldsymbol{Y}_0$ has an infinite divergence from $\boldsymbol{Y}_0$. Therefore, we may as well restrict our attention to the linear space of matrices whose zero pattern covers that of $\boldsymbol{Y}_0$. Now we see that the constraint qualification in Assumption A requires that $C$ contain a matrix with exactly the same zero pattern as $\boldsymbol{Y}_0$. If it does, the algorithm will still converge to the Bregman projection of $\boldsymbol{Y}_0$ onto the doubly stochastic matrices. Determining whether the constraint qualification holds will generally involve a separate investigation [30].

It is also worth noting that Algorithm A encompasses other iterative methods for scaling to doubly stochastic form. At each step, for example, one might rescale only the row or column whose sum is most inaccurate. Parlett and Landis have considered algorithms of this sort [33]. The problem of scaling to have other row and column sums also fits neatly into our framework, and it has the same geometric interpretation.

**5.2. MBI and matrix approximation.** This section discusses a novel matrix nearness problem that arises in data analysis. Given a collection of vectors $X = \{\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_N\} \subset \operatorname{dom} \varphi$, the [illegible] [2] of the collection is defined to be

$$I_\varphi(X) = \sum\nolimits_{j=1}^{N} w_j \, D_\varphi(\boldsymbol{x}_j; \boldsymbol{\mu}), \tag{5.1}$$

where $w_1, w_2, \ldots, w_N$ are nonnegative weights that sum to one, and $\boldsymbol{\mu}$ is the (weighted) arithmetic mean of the collection, i.e., $\boldsymbol{\mu} = \sum_j w_j \, \boldsymbol{x}_j$. Bregman information generalizes the notion of the [illegible], $\sigma^2 = N^{-1} \sum_j \|\boldsymbol{x}_j - \boldsymbol{\mu}\|_2^2$, of a Gaussian random variable (where each $w_j = N^{-1}$). When $D_\varphi$ is the relative entropy, the Bregman information that arises with an appropriate choice of weights is called [illegible], a fundamental quantity in information theory [11].

Bregman information exhibits an interesting connection with Jensen's inequality for a convex function $\varphi$:

$$\sum\nolimits_j w_j \, \varphi(\boldsymbol{x}_j) \geq \varphi\left(\sum\nolimits_j w_j \, \boldsymbol{x}_j\right).$$

Substituting $\boldsymbol{\mu} = \sum_j w_j \, \boldsymbol{x}_j$, we see that the difference between the two sides of the foregoing relation satisfies

$$\begin{aligned} \sum\nolimits_j w_j \, \varphi(\boldsymbol{x}_j) - \varphi(\boldsymbol{\mu}) &= \sum\nolimits_j w_j \, \varphi(\boldsymbol{x}_j) - \varphi(\boldsymbol{\mu}) - \left\langle \nabla\varphi(\boldsymbol{\mu}), \sum\nolimits_j w_j \boldsymbol{x}_j - \boldsymbol{\mu} \right\rangle \\ &= \sum\nolimits_j w_j \left[\varphi(\boldsymbol{x}_j) - \varphi(\boldsymbol{\mu}) - \langle \nabla\varphi(\boldsymbol{\mu}), \boldsymbol{x}_j - \boldsymbol{\mu}\rangle\right] \\ &= I_\varphi(X). \qquad (5.2) \end{aligned}$$

In words, the Bregman information is the disparity between the two sides of Jensen's inequality. Equation (5.2) can also be viewed as a generalization of the relationship between the variance and the arithmetic mean,

$$\sigma^2 = N^{-1} \sum\nolimits_j \|\boldsymbol{x}_j\|_2^2 - \|\boldsymbol{\mu}\|_2^2.$$

Let us describe an application of Bregman information in data analysis. In this field, matrix approximations play a central role. Unfortunately, many common approximations destroy essential structure in the data matrix. For example, consider the $k$-truncated singular value decomposition (TSVD), which provides the best rank-$k$ Frobenius-norm approximation of a matrix. In information retrieval applications, however, the matrix that describes the co-occurrence of words and documents is both sparse and nonnegative. The TSVD ruins both of these properties. In this setting, the Frobenius norm is meaningless; relative entropy is the correct divergence measure according to the unigram or multinomial language model.

We may also desire that the matrix approximation satisfy some additional constraints. For instance, it may be valuable for the approximation to preserve marginals (i.e., linear functions) of the matrix entries. Let us formalize this idea. Suppose that $\boldsymbol{Y}$ is an $M \times N$ data matrix. We seek an approximation $\widetilde{\boldsymbol{X}}$ that satisfies the constraints

$$C_k = \{\boldsymbol{X} : \langle \boldsymbol{X}, \boldsymbol{A}_k\rangle = \langle \boldsymbol{Y}, \boldsymbol{A}_k\rangle\} \qquad k = 1, \ldots, K,$$

where each $\boldsymbol{A}_k$ is a fixed constraint matrix. We will write $C = \bigcap_k C_k$. As an example, $\boldsymbol{X}$ can be required to preserve the row and/or column sums of $\boldsymbol{Y}$.

Many different matrices, including the original matrix $\boldsymbol{Y}$, may satisfy these constraints. Clearly, a good matrix approximation should involve some reduction in the number of parameters used to represent the matrix. The key question is to decide how to produce the right approximation from $C$. One rational approach invokes the principle of [illegible] (MBI) [1], which states that the approximation should be the (unique) solution of the problem

$$\min_{\boldsymbol{X} \in C} I_\varphi(\boldsymbol{X}) = \min_{\boldsymbol{X} \in C} \sum\nolimits_{m,n} w_{mn} \, D_\varphi(x_{mn}, \mu), \qquad (5.3)$$

where $w_{mn}$ are prespecified weights and $\mu = \sum_{m,n} w_{mn} x_{mn}$. If the weights $w_{mn}$ and the matrix entries $x_{mn}$ are both sets of nonnegative numbers that sum to one, and if the Bregman divergence is the relative entropy, then the MBI principle reduces to Jaynes' maximum entropy principle [23]. Thus, the MBI principle tries to obtain as uniform an approximation as possible subject to the specified constraints. Note that problem (5.3) can be readily solved by the successive projection algorithm.

Next, we consider an important and natural source of constraints. [illegible] is the problem of partitioning a set of objects into clusters, where each cluster contains "similar" objects. Data matrices often capture the relationships between two sets of objects, such as word–document matrices in information retrieval and gene-expression matrices in bioinformatics. In such applications, it is often desirable to solve the coclustering problem, i.e., to simultaneously cluster the rows and columns of a data matrix. Formally, a co-clustering $(\rho, \gamma)$ is a partition of the rows into $I$ row clusters $\rho_1, \ldots, \rho_I$ and the columns into $J$ column clusters $\gamma_1, \ldots, \gamma_J$, i.e.,

$$\bigcup_{i=1}^{I} \rho_i = \{1, 2, \ldots, M\}, \qquad \text{where} \qquad \rho_i \cap \rho_\ell = \emptyset \quad \text{for } i \neq \ell,$$

$$\bigcup_{j=1}^{J} \gamma_j = \{1, 2, \ldots, N\}, \qquad \text{where} \qquad \gamma_j \cap \gamma_\ell = \emptyset \quad \text{for } j \neq \ell.$$

Given a coclustering, the rows belonging to row cluster $\rho_1$ can be arranged first, followed by rows belonging to row cluster $\rho_2$, etc. Similarly the columns can be re-ordered. This re-ordering has the effect of dividing the matrix into $I \cdot J$ subblocks, each of which is called a [illegible].

The coclustering problem is to search for the "best" possible row and column clusters. One way to measure the quality of a coclustering is to associate it with its MBI matrix approximation. A natural constraint set $C_{(\rho,\gamma)}$ for the coclustering problem contains matrices that preserve marginals of all the $I \cdot J$ coclusters (local information) in addition to row and column marginals (global information). With this constraint set, a formal objective for the coclustering problem is to find $(\rho, \gamma)$, which corresponds to the best possible MBI approximation:

$$\min_{\rho,\gamma} D_\varphi(\boldsymbol{Y}; \boldsymbol{X}_{(\rho,\gamma)}), \qquad \text{where} \qquad \boldsymbol{X}_{(\rho,\gamma)} = \arg \min_{\boldsymbol{X} \in C_{(\rho,\gamma)}} I_\varphi(\boldsymbol{X}). \tag{5.4}$$

This formulation yields an optimal coclustering as well as its associated MBI matrix approximation. The quality of such matrix approximations is a topic for further study. Note that problem (5.4) requires a combinatorial search, and it is known to be NP-complete. The most familiar clustering formulation, namely, the $k$-means problem, is the special case of (5.4) obtained from the Euclidean divergence, the choice $J = N$, and the condition of preserving cocluster sums.

As an example, consider the nonnegative matrix

$$\boldsymbol{Y} = \begin{bmatrix} 5 & 5 & 5 & 0 & 0 & 0 \\ 5 & 5 & 5 & 0 & 0 & 0 \\ 0 & 0 & 0 & 5 & 5 & 5 \\ 0 & 0 & 0 & 5 & 5 & 5 \\ 4 & 4 & 0 & 4 & 4 & 4 \\ 4 & 4 & 4 & 0 & 4 & 4 \end{bmatrix}.$$

On using coclustering (three row clusters and two column clusters), preserving row sums, column sums, and cocluster sums, the MBI principle (with relative entropy as the Bregman divergence) yields the matrix approximation

$$\boldsymbol{X}_1 = \begin{bmatrix} 5.4 & 5.4 & 4.2 & 0 & 0 & 0 \\ 5.4 & 5.4 & 4.2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 4.2 & 5.4 & 5.4 \\ 0 & 0 & 0 & 4.2 & 5.4 & 5.4 \\ 3.6 & 3.6 & 2.8 & 2.8 & 3.6 & 3.6 \\ 3.6 & 3.6 & 2.8 & 2.8 & 3.6 & 3.6 \end{bmatrix}.$$

Note that this approximation has rank two and preserves nonnegativity as well as most of the nonzero structure of $\boldsymbol{Y}$. It can be verified that all the cocluster sums, row sums, and column sums of $\boldsymbol{X}_1$ match those of $\boldsymbol{Y}$. In contrast, the rank-two SVD approximation

$$\boldsymbol{X}_2 = \begin{bmatrix} 5.09 & 5.09 & 4.66 & -0.69 & 0.29 & 0.29 \\ 5.09 & 5.09 & 4.66 & -0.69 & 0.29 & 0.29 \\ 0.29 & 0.29 & -0.69 & 4.66 & 5.09 & 5.09 \\ 0.29 & 0.29 & -0.69 & 4.66 & 5.09 & 5.09 \\ 3.04 & 3.04 & 1.98 & 3.51 & 4.41 & 4.41 \\ 4.41 & 4.41 & 3.51 & 1.98 & 3.04 & 3.04 \end{bmatrix}$$

preserves neither the nonnegativity, the nonzero structure, nor the marginals of $\boldsymbol{Y}$.

**5.3. The nearest correlation matrix.** A [illegible] is a (real) positive-semidefinite matrix with a unit diagonal. Correlation matrices arise in statistics and applications such as finance, where they display the normalized second-order statistics (i.e., pairwise correlation coefficients) of a collection of random variables. In the deterministic setting, a correlation matrix may be viewed as the Gram matrix of a collection of unit vectors.

Higham has recently studied the nearest correlation matrix problem measuring distances using a type of weighted Frobenius norm [19]. Higham solves the problem by means of the Dykstra–Han algorithm given in section 6, alternating between the positive-semidefinite cone and the set of matrices with unit diagonal. We have observed that the nearest correlation matrix problem can be posed with Bregman divergences and, in particular, with matrix divergences.

Let us consider the problem of producing the correlation matrix closest to a given positive-semidefinite matrix with respect to the von Neumann divergence

$$D_{\mathrm{vN}}(\boldsymbol{X};\boldsymbol{Y}) = \mathrm{Tr}\,[\boldsymbol{X}(\log\boldsymbol{X} - \log\boldsymbol{Y}) - \boldsymbol{X} + \boldsymbol{Y}].$$

In case $\boldsymbol{Y}$ is singular, we must restrict our attention to the linear space of matrices whose null space contains the null space of $\boldsymbol{Y}$. After taking this step, one must interpret the formulae with care. These remarks signal our reason for employing the von Neumann divergence to measure the disparity between correlation matrices. A matrix $\boldsymbol{X}$ has an infinite divergence from $\boldsymbol{Y}$ unless the null space of $\boldsymbol{X}$ contains the null space of $\boldsymbol{Y}$. In particular, the rank of the Bregman projection of $\boldsymbol{Y}$ onto the correlation matrices cannot exceed the rank of $\boldsymbol{Y}$. See also the examples at the end of this subsection.

The correlation matrices can be viewed as the intersection of the set of unit-diagonal matrices with the positive-semidefinite cone. This cone is also the domain of the von Neumann divergence, so we do not need to explicitly enforce the positive-semidefinite constraint. In fact, we need only project onto the set $C$ of matrices whose diagonal entries all equal one. It is natural to view $C$ as the intersection of the affine constraint sets

$$C_k = \{\boldsymbol{X} : x_{kk} = 1\}.$$

There is no explicit formula for the projection of a matrix $\boldsymbol{Y}$ onto the set $C_k$, but the discussion in section 3 shows that we can solve the problem by minimizing the function (3.4), which, in this example, reads

$$J(\xi) = \operatorname{Tr} \exp\{\log \boldsymbol{Y} + \xi\, \mathbf{e}_k \mathbf{e}_k^T\} - \xi, \tag{5.5}$$

where $\mathbf{e}_k$ is the $k$th canonical basis vector. Given the minimizer $\xi_\star$, the projection of $\boldsymbol{Y}$ onto $C_k$ is

$$P_{C_k}(\boldsymbol{Y}) = \exp\{\log \boldsymbol{Y} + \xi_\star\, \mathbf{e}_k \mathbf{e}_k^T\}. \tag{5.6}$$

Beware that one cannot read these formulae literally when $\boldsymbol{Y}$ is rank deficient! In any case, the numerical calculations are not trivial to perform. In order to apply the Newton method, the second derivative of $J$ is needed, which is more involved due to the noncommutativity of matrix multiplication.

Unfortunately, treating these issues in detail is beyond the scope of this paper.

There is an interesting special case that can be treated without optimization: the von Neumann projection of a matrix with constant diagonal onto the correlation matrices can always be obtained by rescaling. In particular, the projection preserves the zero pattern of the matrix and the eigenvalue distribution. To verify this point, suppose the diagonal entries of $\boldsymbol{Y}$ equal $\alpha$, and set $\boldsymbol{X} = \alpha^{-1}\boldsymbol{Y}$. According to the Karush–Kuhn–Tucker conditions, $\boldsymbol{X}$ is the Bregman projection of $\boldsymbol{Y}$ onto the set $C$ provided that $\nabla_{\boldsymbol{X}} D_{\text{vN}}(\boldsymbol{X}; \boldsymbol{Y})$ is diagonal. The latter gradient equals $\log \boldsymbol{X} - \log \boldsymbol{Y} + \mathbf{I}$, and a short calculation completes the argument. In contrast, the Frobenius norm projection of a matrix with constant diagonal does not preserve its nonzero structure or eigenvalue distribution. As an example, let $\boldsymbol{Y}$ be the $4 \times 4$ symmetric tridiagonal Toeplitz matrix with 2's on the diagonal and $-1$'s on the off-diagonal. The nearest correlation matrix to it, in the Frobenius norm, equals (to the figures shown)

$$\begin{bmatrix} 1.0000 & -0.8084 & 0.1916 & 0.1068 \\ -0.8084 & 1.0000 & -0.6562 & 0.1916 \\ 0.1916 & -0.6562 & 1.0000 & -0.8084 \\ 0.1068 & 0.1916 & -0.8084 & 1.0000 \end{bmatrix}.$$

As a second example, draw a random orthogonal matrix $\boldsymbol{Q}$ and form the rank-deficient matrix $\boldsymbol{Y} = \boldsymbol{Q}\, \operatorname{diag}(1, 10^{-3}, 10^{-6}, 0)\, \boldsymbol{Q}^T$. For instance,

$$\boldsymbol{Y} = \begin{bmatrix} .18335 & -.15180 & .08258 & -.34620 \\ -.15180 & .12606 & -.06887 & .28655 \\ .08258 & -.06887 & .03786 & -.15582 \\ -.34620 & .28655 & -.15582 & .65373 \end{bmatrix}.$$

The correlation matrix nearest to $\boldsymbol{Y}$ in the Frobenius norm is obtained by simply shifting the diagonal:

$$\boldsymbol{X}_1 = \begin{bmatrix} 1.0000 & -.15180 & .08258 & -.34620 \\ -.15180 & 1.0000 & -.06887 & .28655 \\ .08258 & -.06887 & 1.0000 & -.15582 \\ -.34620 & .28655 & -.15582 & 1.0000 \end{bmatrix}.$$

Meanwhile, the nearest correlation matrix with respect to the von Neumann divergence has the same range space as $\boldsymbol{Y}$ and thus is also of rank 3:

$$\boldsymbol{X}_2 = \begin{bmatrix} 1.0000 & -.77271 & .59020 & -.99995 \\ -.77271 & 1.0000 & -.96847 & .77080 \\ .59020 & -.96847 & 1.0000 & -.58778 \\ -.99995 & .77080 & -.58778 & 1.0000 \end{bmatrix}.$$

Note that due to space limitations, all of the above matrices are shown only to five digits of accuracy. The eigenvalues of $\boldsymbol{X}_1$ are 0.611, 0.851, 0.951, and 1.588, while the nonzero eigenvalues of $\boldsymbol{X}_2$ are $0.457 \times 10^{-6}, 0.650 \times 10^{-2}$, and 3.350. Thus we see that the Frobenius norm solution does not preserve the small eigenvalues, while the von Neumann divergence solution preserves the rank and also tries to preserve the eigenvalue distribution.

The recent literature contains a substantial amount of work on numerical methods for calculating nearest correlation matrices with respect to the Frobenius norm. Higham describes an alternating projection method, as well as an approach via semidefinite programming [19]. Malick [28] and Boyd and Xiao [7] study efficient algorithms for solving the dual of a more general projection problem, while Qi and Sun [34] develop a generalized Newton method for the nearest correlation matrix problem.

In contrast, the problem of finding nearest correlation matrices with respect to a Bregman divergence is virtually unstudied. The main motivation for studying this problem is that it leads to correlation matrices that have a very different character, which may be more appropriate in applications. For example, as shown above, the method for solving the von Neumann nearness problem may yield low-rank correlation matrices. This type of solution has immense practical value because it explains the data using a small number of [illegible] [17]. In contrast, the Frobenius norm solution may increase the rank of the matrix. Unfortunately, to apply our technique, the initial matrix must lie in the domain of the von Neumann divergence, i.e., the positive-semidefinite cone. One remedy is to preprocess the matrix by performing a Frobenius projection onto the positive-semidefinite cone.

The broad scope of the present article limits the amount of detail we can provide, so we have been only able to sketch one algorithm for solving the nearest correlation matrix problem. It would be valuable to devise more powerful algorithms by invoking ideas from the papers cited above.

## 6. The successive projection–correction algorithm for convex constraints.

This section describes an algorithm for solving the Bregman nearness problem (1.1) in the case where the constraints are closed, convex sets. In the succeeding section, we will present some nearness problems to which this algorithm applies. We frame the following hypotheses:

| Assumption B | |
|---|---|
| The divergence: | $\varphi$ is a convex function of Legendre type<br>$\varphi$ is cofinite, i.e., $\operatorname{dom}\varphi^* = \mathscr{X}$ |
| The constraints: | $C_1, \ldots, C_K$ are closed, convex sets with intersection $C$ |
| Constraint qualification: | $\operatorname{ri}(C_1) \cap \cdots \cap \operatorname{ri}(C_K) \cap \operatorname{ri}(\operatorname{dom}\varphi)$ is nonempty |
| The control mapping: | $r : \mathbb{N} \to \{1, 2, \ldots, K\}$ is a sequence that takes each output value at least once during each $T$ consecutive input values |

Given an input $\boldsymbol{y}_0$ from $\operatorname{ri}(\operatorname{dom}\varphi)$, we seek the Bregman projection of $\boldsymbol{y}_0$ onto $C$ with respect to the divergence $D_\varphi$. As before, the algorithm projects successively onto each constraint set. Since the sets are no longer affine, it is also necessary to introduce a correction term to guide the algorithm toward the Bregman projection. This algorithm generalizes a method for the Euclidean divergence that was developed independently by Dykstra [16] and Han [18].

Algorithm B (successive projection–correction). [illegible] B [illegible] $\boldsymbol{y}_0 \in \operatorname{ri}(\operatorname{dom}\varphi)$ [illegible]

1. [illegible] $\boldsymbol{q}^k = \boldsymbol{0}$ [illegible] $k = 1, \ldots, K$
2. [illegible]

$$\boldsymbol{y}_{t+1} \leftarrow P_{C_{r(t)}}\left(\nabla\varphi^*\left(\nabla\varphi(\boldsymbol{y}_t) + \boldsymbol{q}^{r(t)}\right)\right).$$

3. [illegible]

$$\boldsymbol{q}^{r(t)} \leftarrow \boldsymbol{q}^{r(t)} + \nabla\varphi(\boldsymbol{y}_t) - \nabla\varphi(\boldsymbol{y}_{t+1}).$$

4. [illegible] 2.

[illegible] $\boldsymbol{y}_0$ [illegible] $C$ [illegible] $D_\varphi$

$$P_C(\boldsymbol{y}_0) = \lim_{t\to\infty} \boldsymbol{y}_t.$$

The proof that this algorithm succeeds is quite burdensome, and none of the arguments in the literature are especially intuitive. The correctness of the algorithm that we have presented here follows from Tseng's general framework [37]. His paper contains only the development for the Euclidean divergence; see [6, 9] for comments on the extension. The literature contains several other proofs with somewhat different hypotheses [6, 9]. We feel that the above version offers the best tradeoff between applicability and accessibility.

The following connections may help the reader understand the algorithm somewhat better. It is possible to identify this procedure as a generalization of Bregman's algorithm for minimizing strictly convex functions [10, 9]. Bregman's algorithm is a primal-dual method that maximizes with respect to one dual variable (the $\boldsymbol{q}^k$) at a time, while maintaining the Karush–Kuhn–Tucker conditions on the primal problem. It is also possible to view the algorithm as a coordinate ascent algorithm for an optimization problem that is dual to the projection problem [37]. It is for this reason that the update in step 2 closely resembles the dual function $J$ obtained in section 3.

### 6.1. Comparing the algorithms.

Let us take a moment to weigh the successive projection–correction algorithm (Algorithm B) against the successive projection algorithm (Algorithm A). It is most important to note that Algorithm A applies only to the case where the constraints are affine, while Algorithm B succeeds for general closed, convex constraints. It can be shown that the corrections in Algorithm B are unnecessary when the constraints are affine, so it reduces to Algorithm A [9].

Although it may appear that Algorithm A has a weaker constraint qualification, the difference here is purely formal. We remark that the constraint qualification in Algorithm B can be weakened when some of the constraint sets are polyhedral, i.e., can be written as a finite intersection of halfspaces. In that case, we may remove the relative interior from the polyhedral constraint sets in the constraint qualification.

The methods also place different hypotheses on the divergence; Algorithm B asks more from the seed function $\varphi$ than Algorithm A. The former requires that $\operatorname{dom} \varphi^* = \mathscr{X}$ while the latter needs only $\operatorname{dom} \varphi^*$ to be open. For example, the Burg entropy $\varphi(x) = -\log(x)$ is admissible for Algorithm A but not for Algorithm B.

Finally, the control mapping for Algorithm B is more restrictive than the control mapping for Algorithm A. The former requires that the projections be performed in almost cyclic order, while the latter requires only that each constraint set should appear an infinite number of times.

## 7. Examples with convex constraints.

This section discusses two matrix nearness problems that involve nonaffine constraints. First, we discuss the *metric nearness problem*, which elicits the closest metric graph to a given weighted graph. We have already studied this problem with respect to norms in [15]. Here, we expand our treatment to Bregman divergences.

Second, we study an important problem in data analysis, namely learning a so-called "kernel" or similarity matrix that satisfies constraints that arise from knowledge of the underlying application domain.

### 7.1. The metric nearness problem.

We recently encountered a striking new matrix nearness problem [15] while studying an application in computational biology. In this article, we extend the problem to Bregman divergences and show that it can be solved using the successive projection–correction algorithm (Algorithm B).

Suppose that $\boldsymbol{X}$ is the adjacency matrix of an undirected, weighted graph on $N$ vertices. That is, $x_{mn}$ registers the weight of the edge between vertices $m$ and $n$. Since the graph is undirected, $\boldsymbol{X}$ is a symmetric matrix. We will also assume that $\boldsymbol{X}$ is *hollow* (i.e., has a zero diagonal). If one interprets the weights as distances, it is natural to ask whether the graph can be embedded in a metric space. Indeed, the embedding is possible if and only if the triangle inequalities hold, i.e.,

$$x_{mn} \leq x_{m\ell} + x_{\ell n} \qquad \text{for each triple of distinct vertices } (\ell, m, n). \tag{7.1}$$

Note that the condition (7.1) implies that the weights are nonnegative, provided that $\boldsymbol{X}$ is symmetric. We will refer to any hollow, symmetric matrix that satisfies (7.1) as a *metric adjacency matrix*.

The *metric nearness problem* is to find the metric adjacency matrix closest to a given adjacency matrix. We view this nearness problem as an agnostic method for learning a metric from noisy distance measurements. It is entirely distinct from multidimensional scaling, which requests an ensemble of points in a [illegible] metric space (usually Euclidean) that realizes a given set of distances. In our first report on this problem [15], we used weighted matrix norms to measure the distance between adjacency matrices. In this article, we will use Bregman divergences. Note that the divergence is unrelated to the metric encoded in the entries of the adjacency matrix; the divergence is used to determine how much one adjacency matrix (i.e., graph) differs from another.

By this point, it should be clear how we propose to solve the metric nearness problem. We will work in the space of hollow, symmetric matrices. It is evident that the metric adjacency matrices from a closed, convex cone $C$. Clearly, $C$ is the intersection of $\binom{N}{3}$ halfspaces:

$$C_{\ell mn} = \{\boldsymbol{X} : x_{mn} - x_{m\ell} - x_{\ell n} \leq 0\},$$

where $\ell$, $m$, and $n$ index distinct vertices. Therefore, we may apply Algorithm B.

To be concrete, we will consider Bregman projections with respect to the relative entropy. For reference, the seed function is

$$\varphi(\boldsymbol{X}) = \sum\nolimits_{mn} \left[x_{mn} \log x_{mn} - x_{mn}\right],$$

which has Fenchel conjugate

$$\varphi^*(\boldsymbol{Y}) = \sum\nolimits_{mn} \exp y_{mn}.$$

The divergence is

$$D_\varphi(\boldsymbol{X}; \boldsymbol{Y}) = \sum\nolimits_{mn} \left[x_{mn} \log \frac{x_{mn}}{y_{mn}} - x_{mn} + y_{mn}\right].$$

This divergence has an interesting advantage over the Frobenius norm. If the original adjacency matrix does not contain zero distances, then the projection on the metric adjacency matrices will not contain any zero distances. This fact ensures that the final matrix defines a genuine metric, rather than a pseudometric.

Algorithm B requires that we compute the Bregman projection of a matrix that has the form $\boldsymbol{X} = \nabla\varphi^*(\nabla\varphi(\boldsymbol{Y}_t) + \boldsymbol{Q}^{\ell mn})$, where $\boldsymbol{Q}^{\ell mn}$ is a dual variable. It is easy to check that this expression reduces to

$$\boldsymbol{X} = \boldsymbol{Y}_t \cdot \exp\cdot(\boldsymbol{Q}^{\ell mn}),$$

where $\cdot$ is the Hadamard (i.e., componentwise) product and $\exp\cdot$ is the Hadamard exponential. We will see that the dual variable $\boldsymbol{Q}^{\ell mn}$ has at most six nonzero entries. Therefore, the matrix $\boldsymbol{X}$ differs from $\boldsymbol{Y}_t$ in at most six places.

It is straightforward to calculate the Bregman projection $\boldsymbol{Y}_{t+1}$ of the matrix $\boldsymbol{X}$ onto the constraint $C_{\ell mn}$. If $\boldsymbol{X}$ already falls in the constraint set, then the projection $\boldsymbol{Y}_{t+1} = \boldsymbol{X}$. Otherwise, set $\delta = \sqrt{(x_{m\ell} + x_{\ell n})/x_{mn}}$. The entries of the projection $\boldsymbol{Y}_{t+1}$ are identical to those of $\boldsymbol{X}$ except for the following six:

$$\begin{aligned} y_{mn} &= \delta\, x_{mn} & \qquad y_{nm} &= y_{mn} \\ y_{m\ell} &= x_{m\ell}/\delta & \qquad y_{\ell m} &= y_{m\ell} \\ y_{\ell n} &= x_{\ell n}/\delta & \qquad y_{n\ell} &= y_{\ell n}. \end{aligned}$$

In words, the projection determines how much the triangle inequality is violated, and it distributes the deficit multiplicatively among the three edges.

Finally, the algorithm updates the dual variable $\boldsymbol{Q}^{\ell mn}$ associated with the constraint using the formula

$$\boldsymbol{Q}^{\ell mn} \leftarrow \boldsymbol{Q}^{\ell mn} + \log\cdot(\boldsymbol{Y}_t) - \log\cdot(\boldsymbol{Y}_{t+1})$$

where $\log\cdot$ is the Hadamard logarithm. This update affects only six entries of $\boldsymbol{Q}^{\ell mn}$. In practice, we would store only the upper triangle of the adjacency matrices, so the update touches only three entries.

Consider the following adjacency matrix, which fails to be a metric graph,

$$\boldsymbol{Y} = \begin{bmatrix} 0 & 1 & 1 & 1 & 1 & 1 \\ 1 & 0 & 10000 & 1 & 1 & 1 \\ 1 & 10000 & 0 & 1 & 1 & 1 \\ 1 & 1 & 1 & 0 & 1 & 1 \\ 1 & 1 & 1 & 1 & 0 & 1 \\ 1 & 1 & 1 & 1 & 1 & 0 \end{bmatrix}.$$

The nearest metric adjacency matrix in relative entropy is found to be

$$\boldsymbol{X}_1 = \begin{bmatrix} 0 & 5.49 & 5.49 & 1.00 & 1.00 & 1.00 \\ 5.49 & 0 & 10.99 & 5.49 & 5.49 & 5.49 \\ 5.49 & 10.99 & 0 & 5.49 & 5.49 & 5.49 \\ 1.00 & 5.49 & 5.49 & 0 & 1.00 & 1.00 \\ 1.00 & 5.49 & 5.49 & 1.00 & 0 & 1.00 \\ 1.00 & 5.49 & 5.49 & 1.00 & 1.00 & 0 \end{bmatrix}.$$

Note that the effect of the outlier edge has dissipated, and the resulting metric graph does not have very large edge weights. On the other hand, the outlier edge leads to a significant change in edge weights when the Euclidean divergence is used:

$$\boldsymbol{X}_2 = \begin{bmatrix} 0 & 1667.33 & 1667.33 & 1.00 & 1.00 & 1.00 \\ 1667.33 & 0 & 3334.67 & 1667.33 & 1667.33 & 1667.33 \\ 1667.33 & 3334.67 & 0 & 1667.33 & 1667.33 & 1667.33 \\ 1.00 & 1667.33 & 1667.33 & 0 & 1.00 & 1.00 \\ 1.00 & 1667.33 & 1667.33 & 1.00 & 0 & 1.00 \\ 1.00 & 1667.33 & 1667.33 & 1.00 & 1.00 & 0 \end{bmatrix}.$$

**7.2. Learning a kernel matrix.** In data mining and machine learning applications, linear separators or hyperplanes are often used to cluster or classify data. However, linear separators are inadequate when the data is not linearly separable. To overcome this problem, the data can first be mapped (nonlinearly) to a higher-dimensional feature space, after which linear separators can be used in the transformed feature space.

Suppose the data belong to the set $\Omega$, and $f : \Omega \rightarrow \mathscr{X}$ maps the data to an inner-product space $\mathscr{X}$, called the [illegible]. Given data objects $\{u_1, u_2, \ldots, u_N\} \subset \Omega$, the Gram matrix $\boldsymbol{X}$ is the $N \times N$ matrix of inner products in the feature space, $x_{mn} = \langle f(u_m), f(u_n) \rangle = g(u_m, u_n)$. This Gram matrix is also called the [illegible], and it captures the similarity between the objects $u_m$ and $u_n$. When the data space $\Omega$ is an inner-product space, common kernels include the polynomial kernel $g(\boldsymbol{u}_m, \boldsymbol{u}_n) = \langle \boldsymbol{u}_m, \boldsymbol{u}_n \rangle^d$ and the Gaussian kernel $g(\boldsymbol{u}_m, \boldsymbol{u}_n) = \exp\left\{-\frac{1}{2}\|\boldsymbol{u}_m - \boldsymbol{u}_n\|_2^2/\sigma^2\right\}$. These kernels are both positive definite. Conversely, any positive-definite matrix can be thought of as a kernel matrix [38]. In general, the set $\Omega$ can be arbitrary. For example, $\Omega$ might contain nucleotide sequences of varying lengths or phylogenetic trees or arbitrary graphs.

In many such situations, the choice of the kernel matrix is unclear. There is often an approximate kernel matrix $\boldsymbol{Y}_0$ that we wish to modify based on our information about the underlying data objects. This information may take various forms:

- known values for kernel entries ($x_{mn} = \alpha$),
- known distances between objects in the feature space ($x_{mm}+x_{nn}-2x_{mn} = \beta$), or
- known bounds on kernel entries ($x_{mn} \leq x_{rs}$) or distances ($x_{mm} + x_{nn} - 2x_{mn} \leq \gamma$).

Such constraints are typically obtained from the application domain, such as information about whether a pair of genes or proteins is functionally more similar than another pair.

Suppose that we are given an approximate kernel matrix $\boldsymbol{Y}_0$. Our problem is to find the nearest positive-definite matrix to $\boldsymbol{Y}_0$ that satisfies linear equality and inequality constraints. The von Neumann divergence can be used as the nearness measure:

$$D_{\mathrm{vN}}(\boldsymbol{X};\boldsymbol{Y}) = \operatorname{Tr}\left[\boldsymbol{X}(\log \boldsymbol{X} - \log \boldsymbol{Y}) - \boldsymbol{X} + \boldsymbol{Y}\right].$$

Using the von Neumann divergence appears to be advantageous when the initial kernel matrix $\boldsymbol{Y}_0$ is of low rank and it is desired that its null space be preserved [25]. Recall that, in the low-rank case, the von Neumann divergence $D_{\mathrm{vN}}(\boldsymbol{X};\boldsymbol{Y}_0)$ is finite only when the null space of $\boldsymbol{X}$ contains the null space of $\boldsymbol{Y}_0$. Hence, both the null space constraint and positive semidefiniteness are automatically enforced by the successive projection–correction algorithm.

## 8. Open problems and conclusions.

The Bregman nearness problem is relatively unstudied, so it opens a rich vein of new questions. Here are some specific challenges that deserve attention.

1. The matrix divergences described in subsection 2.6 offer an intriguing way to compute distances between Hermitian matrices. It would be valuable to characterize different types of projections onto important sets of matrices, such as the positive-semidefinite cone, the nonnegative cone, or the set of diagonal matrices. This could lead to more efficient numerical methods for key problems.
2. The algorithms described in this paper apply only to projections onto polyhedral convex sets. Some important constraint sets—such as the positive-semidefinite cone—are not so simple. In this work, we avoided trouble by incorporating the positive-semidefinite constraint into the divergence, but this approach is not always warranted. For more general problems, a different approach is necessary.
3. A more serious problem with the successive projection approach is that it offers only linear convergence. For applications, it may be critical to develop algorithms with superlinear convergence.
4. The matrix functions that arise from the study of matrix divergences lead to another challenge. We are not aware of a sophisticated approach to calculating a function such as $\exp(\log \boldsymbol{Y} + \boldsymbol{A})$ other than to work with the corresponding eigendecompositions. Expressions of this form frequently arise in Bregman nearness problems, and we would like to have more robust,

efficient techniques for their computation. Moreover, the numerical stability of various techniques needs to be studied.

5. In applications, it is most important to determine what divergence is appropriate. This choice is likely to depend on domain expertise, coupled with a nuanced understanding of the properties of different divergences.
6. One can also imagine the problem of [illegible] a divergence from data. This method would be the ultimate way to match the distance measure with the application. The connection between divergences and exponential families even provides a theoretical justification for this approach.

In conclusion, we have offered evidence that Bregman divergences provide a powerful way to measure the distance between matrices. They can react to structure in the matrix in a way that the Frobenius norm does not. This property makes them extremely valuable for applications, although it may take some effort to determine what divergence is appropriate. Moreover, the numerical methods for computing Bregman projections are still in their infancy. These challenges must be faced before divergences can occupy their potential role in data analysis.

# A GIVENS-WEIGHT REPRESENTATION FOR RANK STRUCTURED MATRICES*

STEVEN DELVAUX† AND MARC VAN BAREL†

**Abstract.** In this paper we introduce a Givens-weight representation for rank structured matrices, where the rank structure is defined by certain submatrices starting from the bottom left or upper right matrix corner being of low rank. We proceed in two steps. First, we introduce a unitary-weight representation. This representation will be compared to the (block) quasiseparable representations introduced by P. Dewilde and A.-J. van der Veen [*Time-varying Systems and Computations*, Kluwer Academic Publishers, Boston, 1998]. More specifically, we show that our unitary-weight representations are theoretically equivalent to the so-called block quasiseparable representations in input or output normal form introduced by Dewilde and van der Veen [*Time varying Systems and Computations*, Kluwer Academic Publishers, Boston, 1998]. Next, we move from the unitary-weight to the Givens-weight representation. We then provide some basic algorithms for the unitary/Givens-weight representation, showing how to obtain such a representation for a dense matrix by means of numerical approximation. We also show how to "swap" the representation and how to reduce the number of parameters of the representation, whenever appropriate. As such, these results will become the basis for algorithms on unitary/Givens-weight representations to be described in subsequent papers.

## 1. Introduction.

In this paper we describe a way to obtain compact representations for rank structured matrices. More specifically, these will be the unitary-weight and Givens-weight representations, in increasing order of specification. The basic idea of our representations is a generalization from the so-called Givens-vector representation introduced in [17], which we generalize to the case of an arbitrary rank structure.

First, we must define the class of matrices for which our representations will be appropriate.

Definition 1 (see [3]). [illegible] $\mathcal{R}$ [illegible] $\mathbb{C}^{m\times n}$ [illegible] $\mathcal{R} = \{\mathcal{B}_k\}_k$ [illegible] $\mathcal{B}_k$ [illegible] 3 [illegible]

$$\mathcal{B}_k = (i_k, j_k, r_k),$$

[illegible] $i_k$ [illegible] $j_k$ [illegible] $r_k$ [illegible] $A \in \mathbb{C}^{m\times n}$ [illegible] $\mathcal{R}$ [illegible] $k$

$$\mathrm{Rank} A(i_k : m, 1 : j_k) \leq r_k.$$

The above definition uses the word [illegible] to distinguish from the more general rank structures that were handled in [3]. Since these more general structures do not occur in the present paper, we will simplify notation by just dropping the word [illegible] everywhere from the notation.

Note that by definition, all structure blocks have to start from the lower left matrix corner. An example of a rank structure is shown in Figure 1.1.

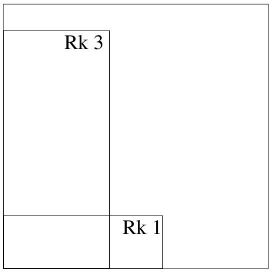

FIG. 1.1. *Example of a rank structure with two structure blocks $\mathcal{B}_1$ and $\mathcal{B}_2$. The notation "*Rk $r$*" denotes that the structure block is of rank at most $r$.*

In practice, it often happens that also the block [illegible] triangular part is rank structured, i.e., that also the matrix $A^T$ satisfies rank structure in the sense of Definition 1. By abuse of notation, we will indiscriminately use the term [illegible] also in this case.

It is easy to see that each structure block induces certain relations between the elements of the matrix. Hence it should be possible to represent a rank structured matrix using only a small number of parameters. Although one can devise several ways to obtain such a representation, there seem to be two classes of representations frequently used in the literature, which we call here $uv$ [illegible] and [illegible]. Let us give a brief survey.

The class of $uv$-representations was historically the first; see, e.g., [12]. We mention that this type of representation is possible only under certain conditions.

The different and more flexible class of block quasiseparable representations has been introduced in [7]. Starting from this book, many algorithms for these representations have been developed in the literature and appear in the work of Dewilde and van der Veen; see, e.g., [7, 8]. They were then used by Eidelman and Gohberg, who also introduced the name (block) "quasiseparable representation"; see, e.g., [9, 10, 11]. More recently, these matrices appear under the name of "sequentially semiseparable representations" in the work of Chandrasekaran, Gu et al.; see, e.g., [1]. Finally, we note that rank structured matrices appear also in a purely theoretical context in the work of Tyrtyshnikov [14], under the name of "weakly semiseparable matrices."

We are not intending to give here a complete overview of all the existing algorithms for block quasiseparable representations: this would be a task even more complicated by the sometimes varying conditions under which these algorithms are derived, most notably the fact that the underlying structure blocks must be situated just below the main diagonal, are equidistant, and so on, with the precise conditions depending sometimes from paper to paper. Instead, we will compare our own algorithms with those in the literature at the appropriate places in the remainder of this and following papers. We refer also to section 4 for a more detailed comparison with *uv*- and block quasiseparable representations.

For the special case of [illegible] matrices of semiseparability rank one, the latter defined by a collection of structure blocks $\mathcal{B}_k = (k, k, 1)$, $k = 1, \ldots, n$ on $\mathbb{C}^{n \times n}$, an alternative representation, the so-called [illegible], has been introduced in [17]. A first step in the generalization to higher semiseparability ranks was taken in [15]. In this paper, we will carry this scheme one step further, by generalizing the idea of the Givens-vector representation to be able to represent [illegible] rank structure.

Our generalization of [17] contains two layers of complication. First, we introduce the [illegible]. We show how these are theoretically equivalent to the so-called block quasiseparable representations in [illegible] or [illegible] introduced by Dewilde and van der Veen [7]. Next, we specify our representation to obtain the [illegible]. We will specify various types of such Givens-weight representations (e.g., those of type 1 and type 2), and we present several tools to deal with these representations in an efficient and stable way.

Briefly, it could be said that the present paper extends the earlier concept of the Givens-vector representation for semiseparable matrices of semiseparability rank one [17] to its natural framework, thereby significantly extending and illuminating these earlier concepts. For example, in our future work [4, 6] we use easily understandable operations like "extending and regressing the action radius" (the latter being a concept introduced in the present paper) instead of the seemingly ad hoc formulas used in [17, 16]. These methods are both stable and work under the condition of general rank structures.

One feature of our representations is that they can be used to obtain the (asymptotically) minimal number of parameters to represent the rank structured matrix part. More precisely, we show that (i) the Givens-weight representation can lead to a representation consisting of $O(rn)$ parameters, where $n$ is the matrix size and $r$ is a measure for the average rank index of the rank structure, and this for [illegible] rank structure; (ii) the unitary-weight representation (or by the same means, the block quasiseparable representations) can lead to such an $O(rn)$ representation [illegible]. The latter observation doesn't seem to be well known in the literature, in the sense that, e.g., many papers use a representation consisting of $O(r^2 n)$ parameters; see, e.g., [9], as well as many other papers by these same authors.

This paper is organized as follows. Section 2 introduces the basic ideas of the unitary-weight and Givens-weight representations. Section 3 considers the operations of approximating and reducing the representation. Section 4 contains a detailed comparison of the unitary/Givens-weight representation with the other kinds of representations in the literature. Finally, some conclusions are provided in section 5.

## 2. Givens-weight representation.

In this section, we will describe the basic ideas enabling one to obtain a compact representation for rank structured matrices. The representation will generalize the Givens-vector representation for semiseparable matrices of semiseparability rank one, which was introduced in [17].

The Givens-weight representation will be an [illegible] representation, which works strictly inside the area spanned by the structure blocks and considers the "outside world" to be inaccessible.

This section is organized as follows. In the first two subsections, we introduce the concepts of unitary-weight and Givens-weight representations, first on a special case in subsection 2.1, and later for general rank structures in subsection 2.2. In the last two subsections, we further complete the description of the representation, by specifying two directions in which it can be extended: we describe representations that are based on column instead of row operations in subsection 2.3, and for the upper instead of the lower triangular matrix part in subsection 2.4.

**2.1. Example.** In the present subsection we will try to indicate the underlying ideas of unitary-weight representations. To this end we will take the structure in Figure 2.1 as a didactical example. First, it may be noted that this figure does not show the surrounding matrix box anymore: this reflects a fact mentioned before, namely that only the area spanned by the structure blocks will be relevant for the representation and that the "outside world" will be inaccessible.

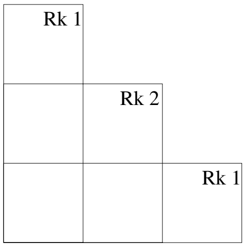

FIG. 2.1. *Example of a rank structure with three structure blocks $\mathcal{B}_1, \mathcal{B}_2$, and $\mathcal{B}_3$. We will use this example to explain the mechanism of the unitary-weight and Givens-weight representation during the following paragraphs. From now on the surrounding matrix box, as in Figure* 1.1*, will not be shown anymore.*

In what follows, we will often work with [illegible]. These are defined as unitary matrices having a block diagonal form $U = I_a \oplus Q \oplus I_b$, where $I_a, I_b$ denote identity matrices of suitable sizes. When such a unitary operation $U$ acts on the rows of a given matrix, we will represent it in a pictorial way by a vertical line segment, placed on the position of the rows on which it acts. Sometimes we will actually denote it as a vertical [illegible], instead of a line segment, as an auxiliary means for visualizing the algorithm flow; see below.

The unitary-weight representation is obtained by reducing the structure blocks into blocks of zeros, by the use of elementary unitary row transformations. First, we apply an (elementary) unitary transformation to transform the bottom Rk 1 block into a block of zeros, with one row less; see Figure 2.2.

Note that this unitary transformation acts only on the columns on the left of the vertical line which is indicated in boldface in the figure, in the present case rows $1, 2, \ldots, 9$. We say that this vertical line borders the [illegible] of the unitary transformation. Thus the action radius of the current unitary transformation is equal to 9.

Having applied this operation, note that in columns 7, 8, and 9 that we have already reached the "top" of the structure. Therefore, this is now the right moment to consider the top elements of these columns, and to store them. These elements will be called [illegible], and they are visualized on a grey background in Figure 2.2.

From now on we consider columns 7, 8, and 9 as finished, and we restrict our

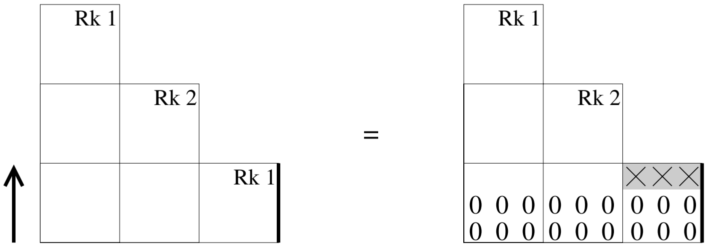

FIG. 2.2. *We apply a unitary transformation to transform the bottom two rows of the structure into zeros. This transformation acts only on the columns on the left of the vertical line which is indicated in boldface in the figure: this line borders the* action radius *of the unitary transformation. Having performed this unitary transformation, the elements indicated on a grey background are stored; they are called* weights.

perspective to the previous columns. We can then apply a unitary transformation to transform the middle Rk 2 block into a block of zeros, with two rows less; see Figure 2.3.

Note that again, this unitary operation acts only on the columns on the left of the vertical line indicated in boldface in the figure. Thus the action radius of the current unitary transformation is equal to 6.

Having applied this operation, note that also in columns 4, 5, and 6 we have reached the top of the structure. Therefore, this is now the right moment to consider the top elements of these columns and to store them. This yields us a second block of weights, which is again visualized on a grey background in Figure 2.3.

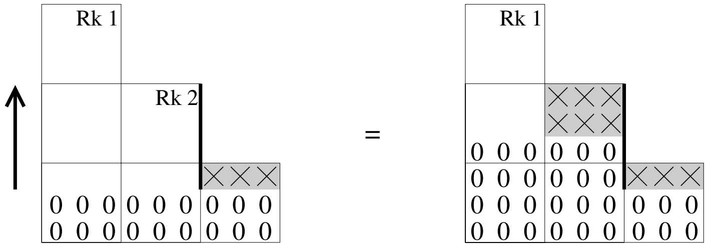

FIG. 2.3. *We apply the next unitary transformation and store the new block of weights.*

From now on we drop columns 4, 5, and 6 from our perspective. We can then apply a unitary transformation to transform the top Rk 1 block into a block of zeros, with one row less; see Figure 2.4. We conclude by storing the final block of weights.

The weights can now be collected into a single matrix, which we call the *weight matrix*. Together with the computed unitary transformations, this matrix yields us the complete *unitary-weight representation* of the given matrix; see Figure 2.5.

Of course, to be a useful representation, the unitary-weight representation should allow the possibility to restore the original matrix from which we started. This can be done by "reversing" the previous steps.

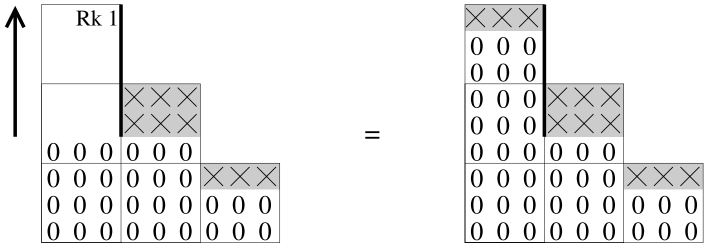

Fig. 2.4. *We apply the final unitary transformation and store the new block of weights.*

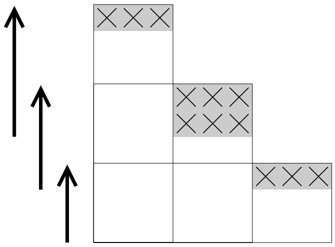

Fig. 2.5. *Schematic picture of the unitary-weight representation for the rank structure in Figure* 2.1.

This reversal process will be called [illegible] the unitary-weight representation and is shown in Figure 2.6. First, we start by spreading out the top block of weights, i.e., we multiply them with the inverse of the top unitary transformation of the unitary-weight representation; see Figure 2.6(a).

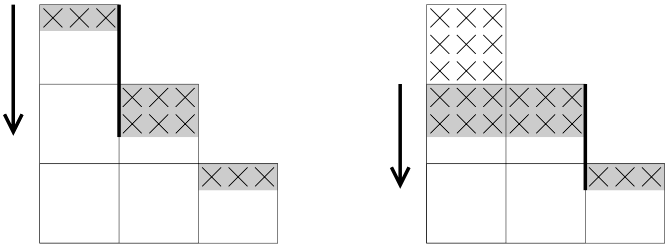
As a result of this spreading-out, the weight matrix will start to get filled-in. Moreover, since we are now at the point of entering the structure in columns 4, 5, and 6, this is now the right moment to also bring the middle block of weights into our perspective. Then we spread out all of these elements; see Figure 2.6(b).

As a result of this spreading-out, the weight matrix will get filled-in more and more. Moreover, since we are now at the point of entering the structure in columns 7, 8, and 9, this is now the right moment to also bring the last block of weights into our perspective. Then we spread out all of these elements; see Figure 2.6(c).

Finally, we then retrieve the original, full matrix which we started from; see Figure 2.6(d).

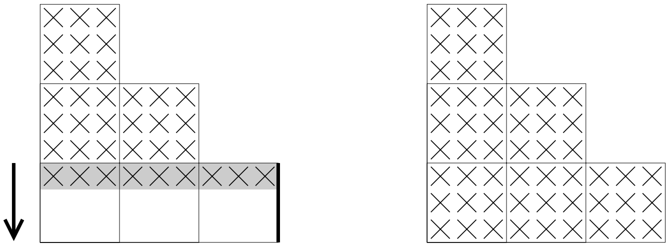
The reader will have noticed that we used a grey/white color code in Figure 2.6, as well as in the previous figures. Let us explain the meaning of this code. The grey elements are used to denote the [illegible], i.e., the elements that contain "condensed" information about the full matrix. Thus in order to see the real meaning of these elements, they first have to be spread out by the next unitary transformations of the unitary-weight representation. On the other hand, the white elements denote the [illegible], i.e., the elements that will not be further influenced by the next unitary transformations. These are actual elements of the full matrix.

This grey/white code turns out to be quite handy; therefore, it will be frequently used in what follows.



(a) Consider the first block of weights and spread out.

(b) Consider also the second block of weights and spread out.



(c) Consider also the third block of weights and spread out.

(d) We now retrieve the full matrix.

FIG. 2.6. *Spreading out the unitary-weight representation.*

**2.2. General definitions.** Now we are ready to handle the unitary-weight and Givens-weight representations in the general case. We will do this for a matrix $A$ satisfying some general rank structure $\mathcal{R} = \{\mathcal{B}_k\}$. Just as in the example of the previous subsection, we will have to assume that the structure blocks are ordered in a [illegible] way, i.e., that there is no pair of structure blocks for which the first one is completely contained in the second one. If this condition is not satisfied yet, then we first have to remove from the structure all such structure blocks which are completely contained in another structure block. (Actually, these nested structure blocks are not completely useless, in the sense that they lead to an additional sparsity pattern in the Givens-weight representation. But we will not be concerned about this here.)

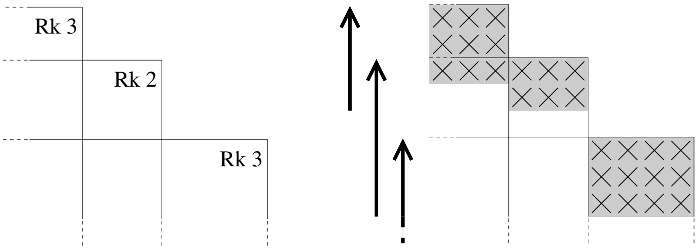
Thus we can now assume that the rank structure does not contain any nested structure blocks anymore. We can then order the remaining structure blocks in a sequential way, going from the top left to the bottom right corner of the matrix. Stated in another way, the structure blocks are ordered in such a way that both the row and column indices $i_k$ and $j_k$ of the structure blocks increase in a strictly monotonic way.

Then we can come to the general definition of unitary-weight representations.

DEFINITION 2 (index sets). [illegible] $\mathcal{R} = \{\mathcal{B}_k\}_{k=1}^{K}$ [illegible] $i_1 < \cdots < i_K$ [illegible] $j_1 < \cdots < j_K$ [illegible]

[illegible] $I_k = \{i_k, \dots, i_{k+1} - 1\}$ $I_{k,\text{top}} = \{i_k, \dots, i_k + r_k - 1\}$ [illegible] $J_k = \{j_{k-1}+1, \dots, j_k\}$ [illegible] $k = 1, \dots, K$ [illegible] $i_{K+1} := N + 1$ [illegible] $j_0 := 0$ [illegible] $r_{K+1} := 0$

Definition 3 (unitary-weight representation). [illegible] $A \in \mathbb{C}^{m \times n}$ [illegible] $\mathcal{R} = \{\mathcal{B}_k\}_{k=1}^{K}$ [illegible] $i_1 < \cdots < i_K$ [illegible] $j_1 < \cdots < j_K$ [illegible] unitary-weight representation [illegible] $A$ [illegible] $\mathcal{R}$ [illegible] $(\{U_k\}_{k=1}^{K}, W)$. [illegible] $U_k$ [illegible] $I_k \cup I_{k+1,\text{top}}$ [illegible] $\bigcup_{l=1}^{k} J_l$ [illegible] $I_{k,\text{top}}$ [illegible] $U_k$ [illegible] $k = K, \dots, 1$ [illegible] $W \in \mathbb{C}^{m \times n}$ [illegible] weight matrix [illegible] $I_{k,\text{top}}$ [illegible] $J_k$ [illegible] $U_k$ [illegible] 2.7



(a) (b)

Fig. 2.7. *For the rank structure in the left picture, the right figure shows a schematic picture of the unitary-weight representation.*

If a unitary-weight representation of a matrix is given, then we can restore the full matrix by [illegible] the representation, which we explained in the previous subsection.

Now we will add some extra constraints to the above definition of unitary-weight representation, by additionally splitting each unitary transformation $U_k$ into a product of Givens tranformations. This will lead us to the description of [illegible]

In what follows, we will use the term [illegible] to denote a unitary operation which differs from the identity matrix in only two subsequent rows $i$ and $i + 1$. This transformation will be sometimes denoted as $G_{i,i+1}$, and the index $i$ will be called the [illegible] of the Givens transformation. Similarly to our notation for elementary unitary operations, we will graphically denote the Givens transformation $G_{i,i+1}$ by means of a vertical line segment, with the height at which this line segment is standing in the figure determined by the row index $i$ (see below).

First, rather than individual Givens transformations, it will be useful to work with [illegible]: these are defined as products of the form $G_{i+k,i+k+1} \cdots G_{i,i+1}$, for some $k \geq 0$. Graphically, this can be considered as a collection of Givens transformations where each Givens transformation is situated precisely one position below the previous one; see Figure 2.8.

The number of Givens tranformations of which a Givens arrow consists will be called the [illegible] of the Givens arrow. Moreover, we define the [illegible] and the [illegible]

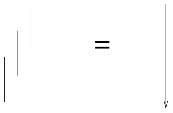


FIG. 2.8. *A Givens arrow* $G_{i+2,i+3}G_{i+1,i+2}G_{i,i+1}$ *consisting of three Givens transformations. Concerning this figure, we recall that we consider each Givens transformation as "acting" on the rows of an (invisible) matrix standing on the right of it, and hence that the Givens transformations in the figure should be evaluated from right to left, thereby explaining the downward direction of the Givens arrow.*

of the Givens arrow to be the largest and the smallest row index of the Givens transformations of which the Givens arrow consists, respectively. These notions have an obvious graphical interpretation.

Having introduced all of these notions, we can now move from unitary-weight to Givens-weight representations.

DEFINITION 4 (Givens-weight representation). [illegible] $A \in \mathbb{C}^{m\times n}$ [illegible] $\mathcal{R} = \{\mathcal{B}_k\}$ [illegible] $i_1 < \cdots < i_K$ [illegible] $j_1 < \cdots < j_K$ [illegible] Givens-weight representation [illegible] $A$ [illegible] $\mathcal{R}$ [illegible] $U_k$ [illegible]

- [illegible] $r_k$
- [illegible] $U_k$ [illegible]

[illegible] 2.9

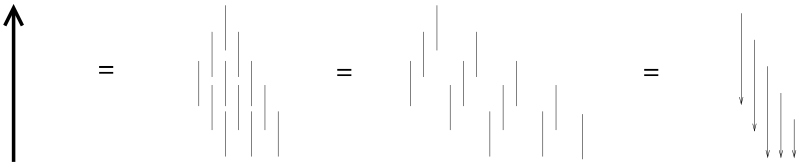

FIG. 2.9. *Suppose that the current structure block is* Rk 3 *and that the corresponding unitary transformation* $U_k$ *spans over six rows. Then we assume for this unitary transformation a decomposition into a product of Givens arrows of width at most* 3.

Let us comment on Figure 2.9. The left part of the figure denotes a unitary component $U_k$ of the Givens-weight representation. The middle and rightmost part of the figure then show the required decomposition of this unitary component $U_k$ into a product of Givens transformations. In particular, the equivalence between the two rightmost pictures in Figure 2.9 follows by repeatedly inserting Figure 2.8. On the other hand, the equivalence between the two [illegible] pictures in Figure 2.9 is purely aesthetic: these are two different ways for visualizing the same product of Givens transformations.

We should still explain why the assumption is made that each Givens arrow in the decomposition of $U_k$ has width at most $r_k$. To this end, recall that the unitary transformation $U_k$ serves to create zeros in a certain $\mathrm{Rk}(r_k)$ submatrix, except for its top $r_k$ rows. This effect can always be realized by a succession of Givens arrows as prescribed; see section 3 for more details.

It turns out that by decomposing each unitary transformation $U_k$ as specified in Definition 4, we formally obtain a decomposition into a product of [illegible] Givens transformations, in the sense that the beginning and trailing Givens transformations of two subsequent unitary transformations $U_k$ may overlap. This overlap may be especially severe when the structure is [illegible], i.e., when the vertical gaps between two subsequent structure blocks are small compared to their rank upper bounds; see Figure 2.11.

Let us comment on Figure 2.11. The figure shows a product of three subsequent unitary components $U_1U_2U_3$ of the Givens-weight representation, together with its decomposition as a product of Givens transformations. This leads to a total of $3 \times 6 = 18$ Givens transformations. However, it can be shown theoretically that the compression process for which $U_1$, $U_2$, and $U_3$ are intended can be performed using only 12 Givens transformations. More precisely, the 6 Givens transformations which are encircled in Figure 2.11 are, in principle, redundant for this compression process.

In practical situations we would like to avoid such a superfluous amount of Givens transformations. We will now describe some extreme cases where this is achieved.

Definition 5 (Givens-weight representations of type 1 and 2). [illegible] 4 [illegible] $U_k$ [illegible] of type 1 [illegible] ” [illegible] ” [illegible] of type 2[1]

It turns out that [illegible] Givens-weight representation can be brought into each of the forms of the above definition. This reduction can be achieved by means of so-called “pull-through techniques.” The following lemma is pivotal in this respect.

Lemma 6 (pull-through lemma). [illegible] 3 by 3 matrix $Q$ which is factorized as

$$Q = G'_{1,2}G_{2,3}G_{1,2},$$

then there exists a refactorization

$$Q = \tilde{G}'_{2,3}\tilde{G}_{1,2}\tilde{G}_{2,3}.$$

See Figure 2.10.

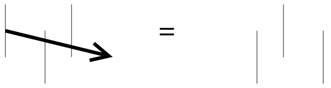

Fig. 2.10. *Pull-through lemma applied in the downward direction. One could imagine that the leftmost Givens transformation is really “pulled through” the two rightmost Givens transformations, as indicated by the bold right downward pointing arrow.*

The above version of the pull-through lemma was formulated in the downward direction. In a similar way there exists a pull-through lemma in the [illegible] direction, but we will not be concerned about this here.

---

[1] We may point out that under some additional conditions, the Givens-weight representations of type 1 and 2 have an interpretation in terms of “zero-creating” and “rank-decreasing” Givens patterns, respectively, as discussed in [6]. We should mention that the zero-creating Givens pattern has also been discussed in [5], although it was done there in a more theoretical context.

As an example, let us repeatedly apply the pull-through lemma in order to reduce the number of parameters of the representation in Figure 2.11. The resulting situation is then shown in Figure 2.12. Note that the superfluous Givens transformations have been removed by the pull-through process, and that the representation has become of type 1. Also the representation of type 2 can be obtained in this way, namely by repeatedly applying the pull-through lemma in the [illegible] direction.

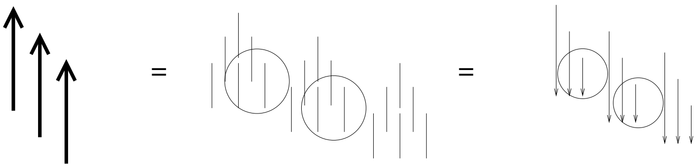

FIG. 2.11. *The leftmost picture shows a product of three subsequent unitary components* $U_1U_2U_3$ *in case of a dense rank structure* $\mathcal{R}$*. The two rightmost pictures then show the decomposition of this unitary matrix as a product of individual Givens transformations. The redundant Givens transformations are encircled.*

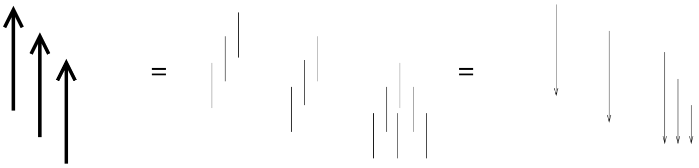

FIG. 2.12. *After removal of the superfluous Givens transformations in Figure* 2.11 *by, for example, repeatedly applying the pull-through lemma, we end up with a Givens-weight representation of type* 1.

Note that for efficiency reasons, the pull-through operations should be grouped in such a way that we move only one time from the top to bottom of the matrix. Moreover, each time we should "enlarge the action radius" of the Givens transformations which will be pulled-through, in order to give them the same action radius as the next unitary operation $U_k$; we refer to [6] for details.

In a certain sense, the representations of Definition 5 represent two extreme cases having a small amount of Givens transformations. For practical computations we can afford to work with a more general class of Givens-weight representations, which we call [illegible].

DEFINITION 7 (efficient Givens-weight representation). [illegible] 4 [illegible] $A \in \mathbb{C}^{m\times n}$ [illegible] $\mathcal{R}$ [illegible] efficient [illegible] 1 [illegible] $\mathcal{R}$ [illegible] $m \approx n$ [illegible] $rn$ [illegible] $r$ [illegible]

This definition says that a Givens-weight representation can be efficient only if the number of superfluous Givens transformations is not too high w.r.t. the "optimal" value. As an illustrative example, the reader could keep in mind the difference between Figures 2.11 and 2.12.

Summarizing, we have now completely described the Givens-weight representation induced by a rank structure $\mathcal{R}$ and some of its practical variants. For the remainder of this section, we will indicate how this entire terminology can be reformulated in two other situations.

**2.3. Row versus column operations: swapping the representation.** The unitary-weight and Givens-weight representations described previously have the feature that the elementary unitary operations $U_k$ are considered as [illegible] operations. In a completely analogous way, one could build a representation based on [illegible] operations.

We are not intending to reproduce all of the previous definitions and examples to the column case. Instead, we will focus here on an efficient [illegible] to change from a row to a column representation or vice versa, hereby generalizing the swapping algorithm for semiseparable matrices of semiseparability rank 1 introduced in [16].

The swapping algorithm will be fairly simple and, together with its generalization to "generalized swapping" described in [4, 6], it will form a key ingredient for manipulating Givens-weight representations. Moreover, in section 3 we will come to a possible application of the swapping algorithm by showing that it can be used to perform an additional compression of the representation, i.e., to approximate the matrix by one having smaller ranks in its underlying rank structure, whenever appropriate.

The swapping process is illustrated in Figure 2.13.

Let us comment on this figure. Figure 2.13(a) shows the initial weight matrix, in which we have started to spread out the Givens transformations belonging to the first unitary transformation. We would then like to go on by also spreading out the next unitary operations, so that we can finally obtain the full version of the given rank structured matrix.

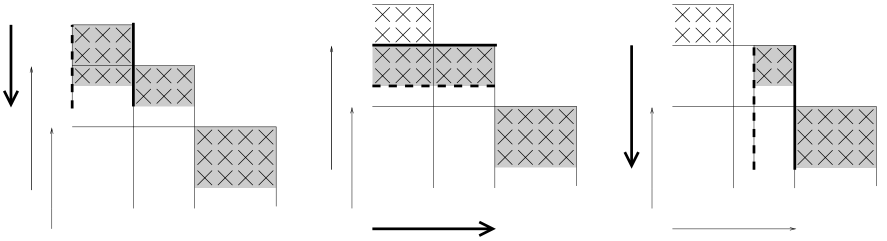
Before spreading out further, however, we apply an auxiliary column operation in order to bring the weights as much as possible to the right; see Figure 2.13(b). This auxiliary column operation serves to prevent the matrix from getting completely filled-in by the spreading-out process. It is applied only to the rows lying between the thick horizontal lines shown in Figure 2.13(b); in the present case rows $3, 4$.

Having done this, we can now go on to further spread out the rank structured matrix, while each time applying a unitary column operation to bring the weights as much as possible to the right. Figures 2.13(c), 2.13(d), 2.13(e), and 2.13(f) show the next steps in this swapping process.

In these figures, we used the following graphical code. The "active" unitary operation which is currently being applied to the rows or columns of the matrix is always shown in boldface. This may be both a unitary operation belonging already to the unitary-weight representation (for those acting on the rows), or a new unitary operation coming from outside (for those acting on the columns). On the other hand, unitary operations belonging to the unitary-weight representation, but which are not active in the current step of the algorithm, are always shown by [illegible] arrows.

The final situation in Figure 2.13(f) shows how we have completely spread out the weight matrix by annihilating the action of the original row operations, and where at the same time the weight matrix has again been compressed by the use of auxiliary column operations. In other words, we have now completely switched from a row-based to a column-based unitary-weight representation.

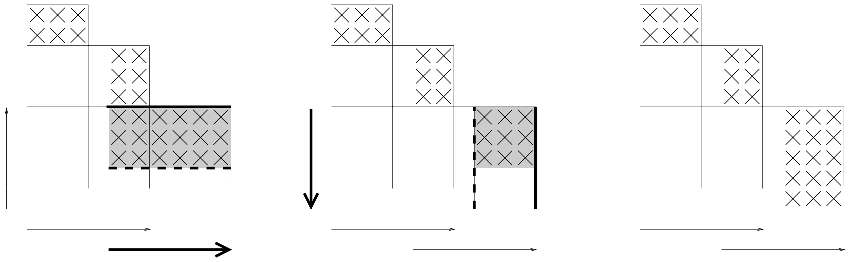
Note that also the weight blocks of the column representation can easily be read off during the swapping algorithm.



(a) Spread out the first unitary row operation.

(b) Apply a unitary column operation to bring the weights to the right.

(c) Spread out the second unitary row operation.



(d) Apply a unitary column operation to bring the weights to the right.

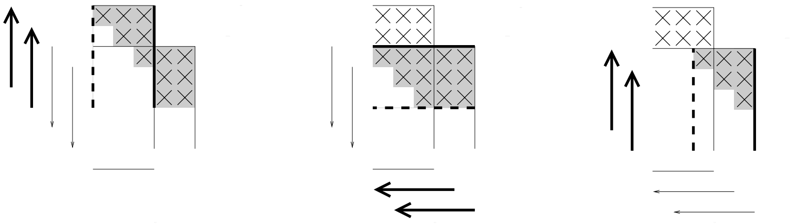
(e) Spread out the third unitary row operation.

(f) We now obtain the column-based Givens-weight representation.

FIG. 2.13. *Swapping the unitary-weight representation.*

For this algorithm, as well as for many other algorithms to be described, the algorithm was illustrated for a unitary-weight rather than a Givens-weight representation. But this is only for clarity reasons; in reality the above algorithm is capable of both exploiting and preserving the sparsity pattern satisfied by the Givens transformations. The main observation for this purpose is that by definition, the Givens transformations are organized in [illegible], each of them pointing in the opposite direction w.r.t. the algorithm flow; see Definition 4. This will guarantee that there is no superfluous fill-in during the algorithm in the sense that, loosely speaking, each Givens transformation will cause only [illegible] weight element to get filled in. The latter fact will then guarantee that the number of swapped Givens transformations is of the same order as the number of original Givens transformations; see Figure 2.14.

Let us consider the numerical complexity of the swapping algorithm. To this end we can first note that each Givens transformation on both rows and columns acts on a number of approximately $r$ weight elements, where $r$ is a measure for the average semiseparability rank of the rank structure $\mathcal{R}$. In particular, if the Givens-weight representation is efficient in the sense of Definition 7, and assuming that we work with a practical choice of rank structure, it follows that the complexity reduces to $O(r^2n)$.



(a) Starting situation. The top weight block, resulting from earlier swapping operations, will now be spread out by means of the inverses of the next Givens arrows (to be evaluated from left to right).

(b) We apply two Givens arrows (to be evaluated from top to bottom) to the columns to bring the weights to the right.

(c) We could now go on to spread out by means of the inverses of the next Givens arrows (to be evaluated from left to right) on the rows, and so on.

Fig. 2.14. *The figure shows a more detailed illustration of the swapping operation, in terms of individual Givens arrows. Note that the sparsity of the weight block in Figure* 2.14(a) *has been preserved during the algorithm, in the sense that the weight block in Figure* 2.14(c) *satisfies the same sparsity. Moreover, this sparsity allows the number of swapped Givens transformations determined in Figure* 2.14(b) *to be of the same order as the number of original Givens transformations.*

**2.4. Representation for the upper triangular part.** We will now focus on a second way to extend the definition of Givens-weight representation. Until now we have considered only rank structures in the [illegible] triangular part. But it is not difficult to generalize these notions to a Givens-weight representation for the structured [illegible] triangular part. Formally speaking, we define a rank structure in the block upper triangular part[2] as a collection $\mathcal{R}^T$ of structure blocks satisfied by the transpose matrix $A^T$. It is then straightforward to generalize the notion of Givens-weight representation to this case.

Note that if the matrix satisfies rank structure in both its block lower and block upper triangular part, we will obtain in this way a representation for the [illegible] matrix, as we describe now.

Definition 8. [illegible] $A \in \mathbb{C}^{m\times n}$ [illegible]

- [illegible] $A$
- [illegible] $A$ [illegible]
- [illegible]

[illegible] Givens-weight representation [illegible] $A$ [illegible]

---

[2] The precise meaning of the term "block upper triangular part" or its synonym "structured upper triangular part" depends of course on the underlying distribution of the structure blocks. In particular, the structure blocks are allowed to go beyond the main diagonal. The same remarks hold of course for the block *lower* triangular part.

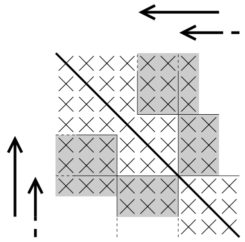


FIG. 2.15. *Schematic picture of a Givens-weight representation for a matrix A having rank structure both in its structured lower and in its structured upper triangular part. The figure shows the weight matrix as well as the unitary transformations of the representation. Note that the matrix is assumed here to be symmetric, and that the lower and upper triangular representations are based on row and column operations, respectively.*

[illegible] weight matrix [illegible] 2.15

Note that both the upper and the lower triangular part could be represented by either a row-based or a column-based Givens-weight representation, or even "hybrid" versions of this, leading to a total of at least $2\times 2 = 4$ different ways of representing the matrix $A$. The example in Figure 2.15 shows just one example of such an assignment.

Summarizing, we have now described the basic concepts of unitary/Givens-weight representations for rank structured matrices. In the remainder of this paper, as well as in the papers [4, 6], we will move to the development of practical algorithms for this representation.

## 3. Approximating and building the representation.

In this section we show how a unitary/Givens-weight representation can be built to approximate a dense matrix, and how a unitary/Givens-weight representation can be approximated to have lower ranks in its underlying rank structure. It will suffice to describe these operations for a representation of the block lower triangular part; the block upper triangular part can then be handled in a similar way.

This section is organized as follows. Subsections 3.1 and 3.2 describe how to approximate a dense matrix by a rank structured one, and how to approximate a rank structured matrix by one with smaller ranks, whenever appropriate. Subsection 3.3 discusses the complexity of the algorithms. Some comparisons with the literature are provided in subsection 3.4.

### 3.1. Approximating a dense matrix.

We start by building a unitary/Givens-weight representation to approximate the block lower triangular part of a dense matrix. The basic ideas of this process have already been given in section 2, where it was explained how the representation requires at the $k$th step the determination of an elementary unitary transformation $U_k$ that compresses a certain $\mathrm{Rk}(r_k)$ matrix, except for its top $r_k$ rows, $k = K, \ldots, 2, 1$. Moreover, it was explained there how the concept of Givens-weight representation requires this unitary operation $U_k$ to be decomposed in a certain way into a product of Givens arrows of width at most $r_k$; see Figure 2.9.

To achieve this in a practical way, we will first consider the case where the required $\mathrm{Rk}(r_k)$ matrix has been decomposed in the form of a truncated singular value decomposition, or more generally any rank-revealing factorization $GH^H$ with $G$ and $H$ both having precisely $r_k$ columns. The required unitary transformation $U_k$ can then be determined by simply applying Givens arrows to perform a QR-factorization of the generator $G$; in this way the decomposition into Givens arrows will have precisely the form required in Figure 2.9.

We may mention that this scheme can be improved to obtain a more compact form for the Givens arrows. To this end we first apply an auxiliary unitary [illegible] operation $C \in \mathbb{C}^{r_k \times r_k}$ to the generator $G$ in order to bring its bottom square submatrix into upper triangular form. Having done this, the number of Givens arrows required to perform the QR-factorization of the new generator $GC$ can be considerably lower. Having performed this QR-factorization, we can again remove the influence of the auxiliary column operation $C$ by multiplying with its inverse to the columns; the resulting generator $G$ will then still be zero except for its top $r_k$ rows, as required. We could then go on with the next structure block.

It can be shown that with a proper implementation of this scheme, each of the applied Givens arrows will [illegible] eliminate a row, which will then not be touched anymore by any of the following operations. In other words, this means that the heads of the subsequent Givens arrows will be strictly monotonically proceeding upwards, and hence that we will have obtained a Givens-weight representation of type 2.

Consider now the case where the given $\mathrm{Rk}(r_k)$ matrix is compressed by means of a rank-revealing QR-factorization [13]. We recall that this procedure consists of searching for the column with largest norm and bringing it in upper triangular form. The latter operation can be achieved, e.g., by means of a sequence of Givens transformations constituting an upward pointing Givens arrow. We can then remove the top row from our perspective and apply the same procedure to the remaining matrix. This procedure is then repeated until the remaining matrix is numerically zero, which will be the case after at most $r_k$ steps. The remaining numerically zero elements are simply truncated to zero.

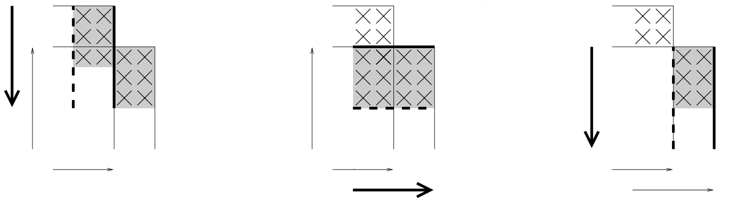
Now it is straightforward to see that the truncated rank-revealing QR-factorization will lead to a compression of the given $\mathrm{Rk}(r_k)$ matrix except for its top $r_k$ rows. The required elementary unitary transformation $U_k$ achieving this is simply the product of the applied [illegible] pointing Givens arrows of the rank-revealing QR-factorization; more precisely, it is obtained by rearranging these Givens transformations into [illegible] pointing Givens arrows of width $r_k$; see the second transition in Figure 2.9.

Just as in the previous paragraphs, it is possible to improve this scheme in order to obtain a more compact representation. This follows by remarking that the rank-revealing QR-factorization induces in a natural way a factorization $GH^H$, where $H^H$ contains the top $r_k$ rows of the compressed $\mathrm{Rk}(r_k)$ matrix, and the matrix $G$ contains the first $r_k$ columns of the (inverse of the) applied elementary unitary operation $U_k$. We can then proceed as described in the previous paragraphs to obtain a Givens-weight representation of type 2.

[illegible] 9.

1. The above discussion assumes that the exact ranks of the full matrix were known. Nevertheless, all the tools that we describe allow one to determine these ranks in a [illegible] way as the algorithm proceeds, depending on some numerical error threshold $\epsilon$. Hence we can really [illegible] the given matrix by a rank structured one.
2. Clearly, one can apply similar techniques to obtain a unitary-weight instead of a Givens-weight representation.

**3.2. Approximating a compressed matrix.** We will now show how to approximate a matrix with available unitary/Givens-weight representation by one with



(a) Starting situation. The top weight block, resulting from earlier swapping operations, will now be spread out by means of the inverse of the next unitary row operation $U_k$.

(b) Apply a unitary operation to compress the weights. Since the numerical rank is equal to two, we can compress until there are only two numerically nonzero columns left.

(c) We could now go on to spread out by means of the inverse of the next unitary row operation $U_{k+1}$, and so on.

FIG. 3.1. *Specification of Figure* 2.14 *in case the numerical ranks of the structure blocks are equal to two. We will then be able to additionally compress the representation.*

lower ranks in its underlying rank structure. Thus let us assume that the unitary/Givens-weight representation has led to an [illegible] of the numerical ranks of the underlying structure blocks, at least up to some numerical error threshold $\epsilon$. This fact will then be revealed during the swapping process, where now an additional compressing of the weight matrix can be performed; see Figure 3.1.

As can be seen, the above reduction algorithm follows by an easy application of the swapping procedure.

Let us describe here yet another closely related application of the swapping procedure, namely, the process of going from a "coarse" to a "fine" rank structure, in the sense of Figure 3.2. The corresponding algorithm is shown in Figure 3.3.

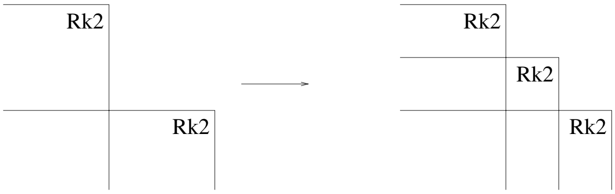


FIG. 3.2. *Going from a coarse to a fine rank structure. It is assumed here that the "intermediate" structure block is known to be numerically of rank at most two.*

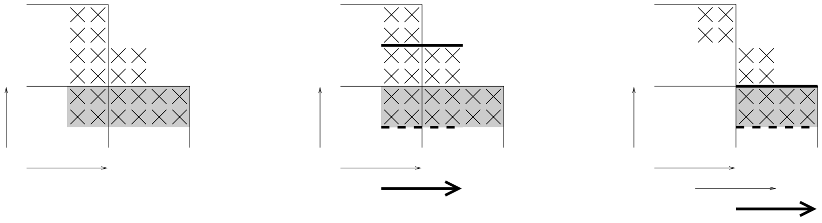
It is easy to see that the process in Figure 3.3 can be extended to deal with [illegible] intermediate structure blocks, at least when these intermediate structure blocks are treated from top left to bottom right, corresponding to the flow direction of the swapping process.

**3.3. Complexity issues.** We will now describe some complexity issues for the approximation algorithms described in the previous subsections. First, note that the illustrations in Figures 3.1 and 3.3 have been expressed in terms of a unitary-weight instead of a Givens-weight representation. We already mentioned that this is done



(a) Starting situation. We assume that the swapping process has been performed up to the indicated unitary row operation $U_k$.

(b) Compress the indicated submatrix, which is known to be numerically of rank at most two, by an auxiliary column operation.

(c) We could now go on with the swapping process, by applying the next auxiliary column operation. After that, we spread out by means of the inverse of the row operation $U_k$, and so on.

FIG. 3.3. *Going from a coarse to a fine rank structure in terms of the unitary/Givens-weight representation, for the example in Figure* 3.2. *The algorithm performs a swapping procedure, during which the intermediate structure blocks are absorbed into the structure. Although the figure shows the case of a* single *intermediate structure block, the situation is similar to the case of* several *intermediate structure blocks.*

mainly for clarity reasons, but in the present case there is also a more fundamental reason, as we explain now.

The reader should recall that for the swapping algorithm of section 2, the particular sparsity pattern of the Givens-weight representation allowed for an additional benefit, in the sense that the swapped Givens arrows could be immediately read off in terms of the original Givens transformations. This fact was reflected by the Hessenberg-like shapes of the grey weight matrices in Figure 2.14.

In contrast, these observations are [illegible] true anymore for the algorithms in the previous subsections. The reason is that we are dealing here with [illegible] algorithms, and that the additional compression of the weight blocks should be performed by means of a numerically stable method such as a truncated singular value decomposition, a pivoted QR-factorization, or a similar routine. But to the best of our knowledge, such routines are unable to exploit the given shape of the matrix, in the sense that, denoting with $r$ a number such that the number of rows, the number of columns, the original ranks, and the numerical ranks are all of order $r$, then the complexity is $O(r^3)$, even if the original matrix was given in a Hessenberg-like form.

Of course, one can always use the techniques described in subsection 3.1 (but now with the role of rows and columns reversed) in order to obtain a reduced representation of type 2 (in the sense of Definition 5).[3] Alternatively, the superfluous Givens transformations could be removed afterwards by means of the pull-through lemma. But the point that we want to make here is that these techniques cannot improve on the $O(r^3)$ complexity per step. Thus in the case of a [illegible] rank structure, i.e., when the gaps between the subsequent structure blocks are very small, the reduction

---

[3] It suffices to apply each time an auxiliary row operation to bring the left square submatrix of the generator $H^H$ in upper traingular form, and only then determine the required Givens arrows on the columns as explained in subsection 3.1.

process will be of total complexity $O(r^3 n)$, which is rather inefficient.

A solution may be to work with only $O(\frac{n}{r})$ structure blocks, i.e., to choose the gaps between the structure blocks to be of order $r$. At the rate of an $O(r^3)$ complexity per step, the total complexity reduces then to $O(r^2 n)$. This type of solution was also sometimes observed in the literature; see, e.g., [2, page 13].

Finally, we recall once more that the complexity problems described previously are really inherent to the [illegible] problems occurring in the current section. In contrast, most other algorithms to be described in this and further papers [4, 6] will be [illegible] and therefore able to both exploit and preserve the sparsity of the Givens-weight representation, disregarding the underlying distribution of structure blocks.

**3.4. Comparison to the literature.** We close this section with some references to similar algorithms in the literature. Approximation algorithms were already given in [7, Chapters 3 and 5] in a more general operator-theoretical context. In particular, algorithms were provided there to obtain a block quasiseparable representation in input or output normal form, which are the theoretical equivalents of unitary-weight (but not Givens-weight) representations; see section 5. A more recent reference about approximation algorithms can be found in [2, section 11]. See also [11].

**4. Comparison with other representations.** In this section, the unitary/Givens-weight representation will be compared with two other representations frequently encountered in the literature: block quasiseparable representations and $uv$-representations. For both representations we describe an easy algorithm to transform the representation into the unitary/Givens-weight form. Moreover, it will be shown that especially the class of [illegible] representations is tightly connected to the unitary-weight format, and the similarities and differences between these two types of representation will be emphasized.

**4.1. Quasiseparable representations.** First, we will focus on block quasiseparable representations. The idea for these representations has essentially been introduced in the book [7]. In this paper, we will follow the terminology of Eidelman and Gohberg by calling these matrices block quasiseparable [9], but the reader should be aware that they also appear under other names in the literature, such as sequentially semiseparable matrices, matrices with low Hankel rank, and so on.

We will start with the most general definition of block quasiseparable matrices. A matrix is called [illegible] w.r.t. a given block partition if it can be divided as a block matrix w.r.t. this partition, with $(i, j)$th block element given by

$$\begin{cases} A_{i,j} = P_i T_{i-1} T_{i-2} \dots T_{j+1} Q_j, & i \geq j+1, \\ A_{i,j} = D_i, & i = j, \\ A_{i,j} = G_i S_{i+1} S_{i+2} \dots S_{j-1} H_j, & i \leq j-1 \end{cases}$$

for $i, j = 0, \dots, K$. Here an empty product denotes the identity matrix. The sizes of all auxiliary matrices occurring in these formulas must be chosen to be compatible with each other. In the literature, these matrices must sometimes satisfy some additional size restrictions, such as the fact that the $D_i$ are scalar (these lead then to the usual, i.e., scalar [illegible] matrices, occurring in many papers by Eidelman and Gohberg), the fact that the $D_i$ are square, and so on. These conditions vary sometimes from paper to paper.

We will refer to the matrices $T_k$ and $S_k$ as [illegible], although this terminology is somewhat nonstandard. Moreover, we will refer to the $P_i$, $G_i$ and $Q_j$, $H_j$ as [illegible], respectively.

The block partition corresponding to a given block quasiseparable representation immediately reveals the shape of the underlying structure blocks $\mathcal{B}_k$. In what follows, we will assume that these structure blocks $\mathcal{B}_k$, $k = 1, \ldots, K$ are labeled from top left to bottom right. Note also that the block quasiseparable formulae imply a certain limitation about the relative positions of the structure blocks in the block lower versus the block upper triangular part, but this restriction is not essential.

Figure 4.1 shows the block quasiseparable representation in a schematic way.

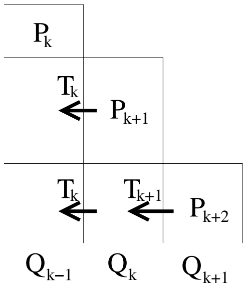


FIG. 4.1. *Schematic picture of a block quasiseparable representation. In order to obtain the* $(i, j)$*th block element, we should multiply the corresponding row shaft generator* $P_i$ *and the corresponding column shaft generator* $Q_j$*, with in between the product of all transition matrices* $T_k$ *that are needed to go from* $P_i$ *to* $Q_j$ *in the picture.*

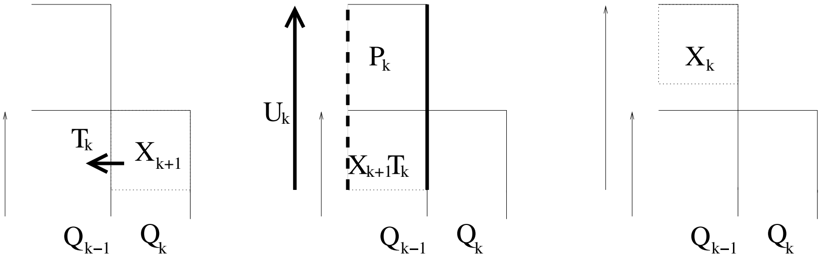
Now we consider the problem of transforming a given block quasiseparable representation into the Givens-weight format. We will restrict ourselves to the structured lower triangular part: the Givens transformations constituting the first unitary transformation $U_K$ can be derived from the QR-factorization of $P_K$. Then denoting by $X_K$ the square top part of the resulting R-factor, the Givens transformations constituting the next unitary operations $U_k$ can be derived from the QR-factorization of $\begin{bmatrix} P_k \\ X_{k+1}T_k \end{bmatrix}$, for $k = K-1, \ldots, 1$. Here we define each time the new $X_k$ to be the square top part of the resulting R-factor. During this process, the corresponding weight blocks can also be computed each time as $X_k Q_{k-1}$; see Figure 4.2.

Concerning the complexity of this algorithm, it is easy to see that the algorithm has a complexity of $O(r^3 n)$ operations in case of "dense" rank structures, and $O(r^2 n)$ operations in case the gaps between the structure blocks are of the same order as the corresponding rank indices. In fact, this should not come as a surprise, in the sense that the algorithm in Figure 4.2 has many resemblances to the process of swapping a unitary-weight representation as described in Figure 2.13. Still pursuing this similarity, note that one can use the same techniques as described in subsection 3.1 to obtain a Givens-weight representation of type 2.

Conversely, suppose now that we have given a Givens-weight representation, or more generally a unitary-weight representation, and that we want to find a quasiseparable representation for it. The reader should then revisit Definition 3: denoting with $W_k \in \mathbb{C}^{r_k \times |J_k|}$ the $k$th weight block and with $U_k$ the $k$th unitary transformation of the Givens-weight representation, we recall that the spreading-out process starts by forming

$$U_k^H \begin{bmatrix} W_k \\ 0 \end{bmatrix}.$$

Subsequently, the bottommost $r_{k+1} = |I_{k+1,\mathrm{top}}|$ rows are further spread out by the



(a) Starting situation. We are going to take into account the next transition matrix $T_k$.

(b) Compute a QR-factorization of the matrix formed by $P_k$ and $X_{k+1}T_k$.

(c) The next auxiliary matrix $X_k$ can now be read-off, and we can form the next weight block $X_kQ_{k-1}$.

FIG. 4.2. *Transition from a block quasiseparable to a Givens-weight representation.*

next unitary transformations $U_{k+1}^H, \ldots$. This suggests that we may obtain the quasiseparable parameters by subdividing

$$U_k^H = \left[\begin{array}{c|c} P_k & X \\ T_k & X \end{array}\right],$$

where the blocks $P_k$ and $T_k$ have $|I_k|$ and $|I_{k+1,\mathrm{top}}| = r_{k+1}$ rows, respectively, and $r_k$ columns. The quasiseparable generators $Q_k$ are chosen each time as $Q_k := W_{k+1}$, $k = 0, \ldots, K$.

The dynamics of this algorithm are illustrated in Figure 4.3.

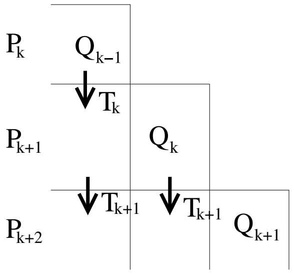


FIG. 4.3. *Schematic picture of a block quasiseparable representation constructed in a "dual" way w.r.t. Figure* 4.1.

Still concerning the algorithm to go from a unitary/Givens-weight to a block quasiseparable representation, note that the above discussion revealed that unitary-weight representations are theoretically equivalent with the matrices $\begin{bmatrix} P_k \\ T_k \end{bmatrix}$ of the quasiseparable representation having orthonormal columns, for each $k$. Thus we see that unitary-weight representations theoretically correspond to the quasiseparable representations in [illegible], following the terminology of [7].

In fact there also exists the notion of [illegible] in [7], meaning that all matrices $\begin{bmatrix} T_k & Q_k \end{bmatrix}$ must have orthonormal rows for each $k$. It can then be argued as before that this notion corresponds to unitary-weight representations that are based on [illegible], rather than row operations.

Thus we see that in a certain sense, the unitary/Givens-weight representation "breaks the symmetry" of block quasiseparable representations by assigning a preference to either row or column operations. This may seem awkward, but as we already observed, this will not prohibit the unitary-weight format from being very [illegible] for the development of algorithms. Moreover, by the fact that the representation is based on [illegible] operations, which are well known to be optimally conditioned w.r.t. the matrix 2-norm, it can be expected that an appropriate use of unitary-weight representations should lead to numerically stable algorithms.

Concerning the differences between block quasiseparable and Givens-weight representations, we should stress that

- The above discussion showed a comparison between block quasiseparable and [illegible] representations. However, the reader should not forget that we are primarily concerned with [illegible] representations, where each unitary transformation $U_k$ has an additional factorization as a sparse product of Givens transformations.[4] Although it may be observed that the Givens-weight representation may deviate by a factor of at most 4 from optimality (since the multiplication of a Givens transformation with a vector of length 2 requires essentially a number of 4 multiplications), it has the advantage that it can [illegible] be used in an efficient way. Notable exceptions where the performance of the Givens-weight representation is also sensible to the distribution of the structure blocks are the [illegible] algorithms described in section 3.

**4.2. *uv*-representations.** In this subsection we briefly consider *uv*-representations for rank structured matrices.[5] Such representations sometimes occur in solution methods for differential and integral equations. Historically, the term "semiseparable matrix" was even introduced in the context of *uv*-representations; see, e.g., [12].

First of all, we must stress that in contrast to Givens-weight and block quasiseparable representations, *uv*-representations do not exist for every rank structured matrix, but instead only for a subclass which we call the class of *uv*-representable matrices. When implementing the QR-algorithm for semiseparable matrices of semiseparability rank 1 using the *uv*-representation for such matrices, for example, this can be considered a severe weakness since the subsequent QR-iterates then converge to a limiting matrix in block upper triangular form, which in general is [illegible] *uv*-representable of rank one anymore; see [17].

Let us now give a formal definition of *uv*-representability.

DEFINITION 10. [illegible] $\mathcal{R}$ [illegible] $r_k =: r$ [illegible] $k$ [illegible] $A \in \mathbb{C}^{m\times n}$ [illegible] *uv*-representable [illegible] $\mathcal{R}$ [illegible]

$$A = uv + A_{\text{completion}}, \tag{4.1}$$

---

[4] This sparsity property constitutes an essential difference between Givens-weight and block quasiseparable representations. However, for completeness, we note that some sparse factorizations in terms of individual Givens transformations were also described in [7, Chapter 14]. But the latter discussion concerns *unitary* rank structured matrices, and we were not able to find there any indication in terms of nonunitary rank structured matrices or algorithmic exploitation.

[5] The matrices allowing such a representation are sometimes called "generator representable matrices" instead of *uv*-representable matrices [17], but we will not use this terminology here since the word "generator" could be confused with, e.g., the quasiseparable generators.

[illegible] $u \in \mathbb{C}^{m\times r}$ [illegible] $v \in \mathbb{C}^{r\times n}$ [illegible] $A_{\text{completion}}$ [illegible] " [illegible] $\mathcal{R}$ [illegible] (4.1) [illegible] $uv$-representation [illegible] $A$

The above definition states that for a matrix to be $uv$-representable, the low rank generators of the different structure blocks of $\mathcal{R}$ should be "compatible" in the sense that they can be completed to a global matrix $uv$ of rank at most $r$.

Now let us give an algorithm to transform a $uv$-representation into a Givens-weight representation. Such an algorithm is trivial and based on the QR-factorization of the matrix $u$ in (4.1). Let us partition $u$ and $v$ as block matrices according to the given distribution of the structure blocks, with block elements $u_k$ and $v_k$, for $k = 0, \dots, K$. Moreover, let us assume that in the process of forming the QR-factorization of $u$, the bottom submatrix $\begin{bmatrix} u_k \\ \vdots \\ u_K \end{bmatrix}$ has just been made upper triangular. Then denoting with $X_k$ the square top block of this upper triangular matrix, the $k$th weight block will be simply $X_k v_{k-1}$. Repeating this process for $k = K, \dots, 1$, at the end we will have obtained a Givens-weight representation for the structured lower triangular part of $A$. Moreover, assuming that the given matrix is square of size $n$, then it is easy to check that (i) the algorithm always leads to an [illegible] Givens-weight representation consisting of not more than $O(rn)$ Givens transformations, and (ii) the algorithm has complexity $O(r^2 n)$, irrespective of the precise distribution of the structure blocks. These properties should be contrasted with the reduction process for quasiseparable representations in subsection 4.1.

## 5. Conclusion.

In this paper we have introduced the notions of unitary-weight and Givens-weight representations for rank structured matrices. It was described, e.g., how the representation can be swapped and how it can be reduced to a lower complexity representation. These results provide a basis for several algorithms using unitary/Givens-weight representations such as QR-factorization, solution of linear systems [4], Hessenberg reduction [6], as well as matrix inversion, explicit and implicit QR-iteration, and so on, to be described in our future work.

# WHEN IS THE ADJOINT OF A MATRIX A LOW DEGREE RATIONAL FUNCTION IN THE MATRIX?[*]

JÖRG LIESEN[†]

**Abstract.** We show that the adjoint $A^+$ of a matrix $A$ with respect to a given inner product is a rational function in $A$, if and only if $A$ is normal with respect to the inner product. We consider such matrices and analyze the McMillan degrees of the rational functions $r$ such that $A^+ = r(A)$. We introduce the McMillan degree of $A$ as the smallest among these degrees, characterize this degree in terms of the number and distribution of the eigenvalues of $A$, and compare the McMillan degree with the normal degree of $A$, which is defined as the smallest degree of a polynomial $p$ for which $A^+ = p(A)$. We show that unless the eigenvalues of $A$ lie on a single circle in the complex plane, the ratio of the normal degree and the McMillan degree of $A$ is bounded by a small constant that depends neither on the number nor on the distribution of the eigenvalues of $A$. Our analysis is motivated by applications in the area of short recurrence Krylov subspace methods.

## 1. Introduction.

Consider a unitary matrix $A$ with $n \geq 2$ distinct eigenvalues. Since $A$ is normal, its adjoint $A^*$ is a polynomial in $A$ [9, condition 17],

$$A^* \;=\; p(A)\,. \tag{1.1}$$

It has been observed in several publications, e.g., [4, pp. 774–775], that for a unitary matrix $A$, (1.1) does not hold for a polynomial $p$ of "small" degree. In this paper we strengthen this observation by showing that the smallest degree of such polynomial is equal to $n-1$. On the other hand, the [illegible] of a rational function $r = p/q$, where $p$ and $q$ are relatively prime polynomials (i.e., their only common divisor is the constant polynomial 1), is defined as

$$\deg r \;=\; \max\,\{\deg p,\; \deg q\}\,. \tag{1.2}$$

Hence

$$A^* \;=\; r(A)\,, \tag{1.3}$$

where, since $A$ is unitary, $r(z) = 1/z$ is a rational function of McMillan degree one. In summary, the adjoint of a unitary matrix $A$ is a large degree polynomial and a small (McMillan) degree rational function in $A$. The observation that the adjoint of a normal matrix may be represented as a polynomial as well as a rational function in the matrix, and that the degrees of these representations may vastly differ, is more than a curiosity. In fact, it is of great importance for the construction of short recurrence Krylov subspace methods.

On the one hand, the fundamental theorem of Faber and Manteuffel [6] shows that if (1.1) holds for a matrix $A$ and a polynomial of degree $s$, then orthogonal Krylov subspace bases for $A$ can be generated by an $(s+2)$-term Arnoldi recurrence (this condition is not only sufficient but also necessary; see [6] or [14] for more details). For a unitary matrix $A$ with $n$ distinct eigenvalues, $A^* = p(A)$ with the smallest possible degree of $p$ being $n-1$. Thus, generating orthogonal Krylov subspace bases for unitary matrices via the Arnoldi process requires a full recurrence.

On the other hand, as shown by Barth and Manteuffel [3, 4], if (1.3) holds for a matrix $A$ and a rational function $r = p/q$, where $p$ and $q$ are relatively prime polynomials of respective degrees $\ell$ and $m$, then orthogonal Krylov subspace bases for $A$ can be generated by a recurrence containing $\ell + m + 2$ terms. The generic type of this recurrence is displayed in [4, equation (4.1)], from which it is easily seen that this recurrence is not of Arnoldi-type (partial necessary conditions for the existence of this recurrence are given in the unpublished report [5]). For stability reasons this (single) recurrence should be implemented in the form of coupled, or multiple recurrences (see [4] for details), but the actual implementation is not important for us here. The important point here is that when $\ell$ and $m$ are small, an orthogonal Krylov subspace basis can be generated by a short recurrence. For a unitary matrix $A$, $r(z) = 1/z$, hence $\ell = 0$ and $m = 1$, so that the length of this recurrence is three. In practical applications one uses coupled two-term recurrences instead of the numerically unstable three-term version. The resulting algorithm, which originally was discovered by Gragg in the context of orthogonal polynomials on the unit circle [8], is called the [illegible]. This algorithm has been used for solving unitary eigenvalue problems (see [17] for a survey) as well as for constructing a minimal residual method for solving linear systems with shifted unitary matrices [11].

For efficiency reasons we would like to use the shortest possible recurrence, and thus we would like to characterize, for a given matrix $A$, the smallest degrees of $p$ and $r$ (if any) such that (1.1) and (1.3), respectively, hold. While the smallest degree of the representation (1.1) has been characterized in the literature (we give here new proofs of some results), comparably little has been done to characterize (1.3). The only related work we are aware of is in the aforementioned papers of Barth and Manteuffel. There, for a given Hermitian positive definite (HPD) matrix $B$, a matrix $A$ is called $B$[illegible] $\ell, m$ , if $A$ is normal with respect to the inner product generated by $B$, and if its adjoint $A^+$ with respect to this inner product satisfies $A^+ = r(A)$, where $r = p/q$ for relatively prime polynomials of respective degrees $\ell$ and $m$, cf. [4, Definition 3.1]. For a given representation $A^+ = r(A)$ with known degrees $\ell$ and $m$, Barth and Manteuffel derive bounds on the maximal number of distinct eigenvalues of $A$ in terms of $\ell$ and $m$, cf. [4, Theorem 3.1], or [3, Theorem 4.1]. However, they provide no characterization of how small or large $\ell$ and $m$ may be for a given matrix $A$, which is the question of interest in this paper (see Remarks 2.4 and 3.7 for further comments on the $B$-normal$(\ell,m)$ matrices).

To allow a rigorous characterization of (1.3), we introduce here the concept of the McMillan degree of $A$, which we define as the smallest McMillan degree of a rational function $r$ such that $A^+ = r(A)$ (section 2). In section 3 we then completely answer the question raised in the title, which, as outlined above, has direct applications in the area of short recurrence Krylov subspace methods. Moreover, we show that unless the eigenvalues of $A$ lie on a single circle in the complex plane, the ratio of the smallest degree of a polynomial representation of $A^+$ (called the normal degree of $A$) and the McMillan degree of $A$ is bounded from above by a small constant (less than five), that depends neither on the number nor on the distribution of the eigenvalues of $A$. In our derivations we apply results from rational interpolation theory, which apparently have not been used in this context before.

## 2. $B$-normal matrices.

Suppose that $A$ is a square matrix and $B$ is an HPD matrix. Throughout the paper we will assume that these matrices are of the same size. The matrix $B$ generates an inner product, $\langle x, y\rangle_B = y^*Bx$, and the adjoint of $A$ with respect to this inner product, or, shortly, the $B$-adjoint of $A$, is $A^+ = B^{-1}A^*B$. If $A^+$ is a polynomial in $A$, then $A$ is said to be $B$[illegible]. This is a straightforward generalization of the common concept of normal matrices, which we here call $I$-normal. Of particular interest is the degree of the polynomial representation of the adjoint.

DEFINITION 2.1. [illegible] $A$ [illegible] $B$ [illegible]

$$A^+ \;=\; p(A)\,, \tag{2.1}$$

[illegible] $p$ [illegible] $s$ [illegible] $A$ [illegible] $s$ [illegible] $B$ [illegible] $B$ [illegible] $s$

The property that $A$ is $B$-normal($s$) is completely characterized in the following result [14, Theorem 3.1].

THEOREM 2.2. [illegible] $A$ [illegible] $B$ [illegible]

1. $A$ [illegible] $B$ [illegible] $s$
2. (a) $A$ [illegible] $A = W\Lambda W^{-1}$ [illegible] $A$ [illegible] $\Lambda$ [illegible]

   (b) [illegible] $W$ [illegible] $A$ [illegible] $B^{-1}$ [illegible] $B^{-1} = WDW^*$ [illegible] $D$ [illegible] $\Lambda$ [illegible]

   (c) [illegible] $p$ [illegible] $s$ [illegible] $p(\Lambda) = \Lambda^*$ [illegible] $s$ [illegible] $p$ [illegible]

In [14] this result is stated only for nonsingular matrices $A$, which is due to the focus of the work in that paper. It is easy to see, however, that the assertion is true also for singular matrices $A$. Using Theorem 2.2, we can characterize all $A$ and $B$ for which $A^+ = r(A)$, where $r$ is a rational function.

LEMMA 2.3. [illegible] $A$ [illegible] $B$ [illegible] $r$ [illegible] $A^+ = r(A)$ [illegible] $r(\lambda) = \overline{\lambda}$ [illegible] $\lambda$ [illegible] $A$ [illegible] $A$ [illegible] $B$ [illegible] $s$ [illegible] $s$ [illegible] $p$ [illegible] $p(\lambda) = \overline{\lambda}$ [illegible] $\lambda$ [illegible] $A$

[illegible]. We adopt the strategy of the proof of [6, Lemma 2]. Let $(\lambda, x)$ be an eigenpair of $A$, $Ax = \lambda x$. Then $A^+x = r(A)x = r(\lambda)x$, so that

$$r(\lambda)\,\langle x,x\rangle_B \;=\; \langle r(\lambda)x, x\rangle_B \;=\; \langle A^+x, x\rangle_B \;=\; \langle x, Ax\rangle_B \;=\; \langle x, \lambda x\rangle_B \;=\; \overline{\lambda}\,\langle x,x\rangle_B\,,$$

from which we receive $r(\lambda) = \overline{\lambda}$.

Now suppose that there is a nontrivial Jordan block associated with $\lambda$. Then there exists a nonzero vector $y$ such that $(A-\lambda I)y = x$. But then

$$\begin{aligned} \langle Ay, x\rangle_B = \langle \lambda y + x, x\rangle_B \;&=\; \lambda\, \langle y, x\rangle_B + \langle x, x\rangle_B\,, \\ \langle Ay, x\rangle_B = \langle y, A^+ x\rangle_B \;&=\; \langle y, \overline{\lambda} x\rangle_B \;=\; \lambda\, \langle y, x\rangle_B\,, \end{aligned}$$

which means that $\langle x, x\rangle_B = 0$. This contradiction shows that $A$ is diagonalizable, i.e., that (2a) of Theorem 2.2 holds.

If $(\eta, y)$ is another eigenpair of $A$ with $\eta \neq \lambda$, then

$$\lambda\, \langle x, y\rangle_B \;=\; \langle \lambda x, y\rangle_B \;=\; \langle Ax, y\rangle_B \;=\; \langle x, A^+ y\rangle_B \;=\; \langle x, \overline{\eta} y\rangle_B \;=\; \eta\, \langle x, y\rangle_B\,.$$

Since $\lambda \neq \eta$ we must have $\langle x, y\rangle_B = 0$, which shows that the eigenvectors of $A$ form a complete $B$-orthogonal set. In particular, when we consider the diagonalizable matrix $A$ as in (2a) of Theorem 2.2, then $W^*BW = D$, where $D$ is HPD and block diagonal, showing that $B$ is as stated in (2b) of Theorem 2.2.

Finally, the polynomial $p$ in (2c) of Theorem 2.2 is the uniquely determined interpolation polynomial of smallest degree that satisfies $p(\lambda) = \overline{\lambda}$ for all eigenvalues $\lambda$ of $A$. ☐

[illegible] 2.4. According to Lemma 2.3, the existence of a representation of the form $A^+ = r(A)$, where $r$ is a rational function, implies that $A$ is $B$-normal($s$). Therefore the assumption that $A$ be $B$-normal in the definition of the $B$-normal($\ell$,$m$) matrices of Barth and Manteuffel, cf. [3, Definition 4.2] or [4, Definition 3.1], is redundant.

The converse of Lemma 2.3 is obviously true as well: If $A$ is $B$-normal($s$), then there exists a rational function, namely $r = p$ from (2c) in Theorem 2.2, such that $A^+ = r(A)$. We therefore have the following corollary.

COROLLARY 2.5. [illegible] $A$ [illegible] $B$ [illegible] $A^+$ [illegible] $A$ [illegible] $A$ [illegible]

[illegible] $A$ [illegible] $A = W\Lambda W^{-1}$ [illegible] $B$ [illegible] $A^+$ [illegible] $A$ [illegible] (2b) [illegible] 2.2 [illegible] $B$ [illegible] $A^+ = r(A)$ [illegible] $r$ [illegible] $r(\Lambda) = \Lambda^*$

[illegible] Only the necessity part in the last sentence remains to be shown. Let $B$ be any matrix as characterized in (2b) of Theorem 2.2, i.e., $B = W^{-*}DW^{-1}$. Then

$$A^+ = B^{-1}A^*B = (WD^{-1}W^*)(W^{-*}\Lambda^*W^*)(W^{-*}DW^{-1}) = W\Lambda^*W^{-1} = r(A)\,,$$

where in the last equation we have used that $r(\Lambda) = \Lambda^*$. ☐

By Corollary 2.5, for a nondiagonalizable matrix $A$ there exists no HPD matrix $B$ such that the corresponding $A^+$ is a rational function in $A$. We therefore can restrict our attention to diagonalizable matrices. The last part of the corollary shows that if, for some HPD matrix $B$, $A^+$ is a rational function in $A$, $A^+ = r(A)$, then $r$ is completely determined by the eigenvalues of $A$. We use the following concepts in our further development.

DEFINITION 2.6. [illegible] $A$ [illegible]

1. [illegible] $p$ [illegible] $p(\lambda) = \overline{\lambda}$ [illegible] $\lambda$ [illegible] $A$ [illegible] $A$ [illegible] $d_p(A)$
2. [illegible] $r$ [illegible] $r(\lambda) = \overline{\lambda}$ [illegible] $\lambda$ [illegible] $A$ [illegible] $A$ [illegible] $d_r(A)$

We immediately observe that $d_r(A) \leq d_p(A) \leq n-1$, where $n$ is the number of distinct eigenvalues of $A$.

Let us put the degrees $d_p(A)$ and $d_r(A)$ into the picture of short recurrence Krylov subspace methods that is described in the introduction: On the one hand, if $A$ is normal with respect to an HPD matrix $B$ and $d_p(A) = s$, then $B$-orthogonal Krylov subspace bases for $A$ can be generated with an $(s+2)$-term Arnoldi recurrence [6]. On the other hand, if for an HPD matrix $B$ the $B$-adjoint of $A$ satisfies $A^+ = r(A)$, where $r = p/q$ for relatively prime polynomials $p$ and $q$ of respective degrees $\ell$ and $m$, so that $d_r(A) = \deg r = \max\{\ell, m\}$, then $B$-orthogonal Krylov subspace bases for $A$ can be generated using a nonstandard recurrence containing $\ell + m + 2 \leq 2d_r(A) + 2$ terms [4]. If $d_r(A) \ll d_p(A)$, then the nonstandard recurrence is significantly more efficient than the standard Arnoldi recurrence. It is therefore of great practical interest to characterize the (diagonalizable) matrices $A$ for which $d_r(A) \ll d_p(A)$.

**3. Characterization of the McMillan degree of $A$.** We will study the McMillan degree of a diagonalizable matrix $A$ using results from rational interpolation theory. The results we employ were originally developed by Antoulas and Anderson [2] and are summarized in Antoulas' book [1, Chapter 4.5].

Let $\lambda_1, \ldots, \lambda_n$ be the [illegible] eigenvalues of $A$. We want to determine a rational function $r = p/q$, where $p$ and $q$ are relatively prime polynomials, such that $r(\lambda_j) = \overline{\lambda}_j$, $j = 1, \ldots, n$. We assume $n \geq 2$, as otherwise the problem is trivial. If there exists such a rational function of McMillan degree $m$, then $m$ is called an [illegible]. By definition, the smallest admissible McMillan degree is equal to $d_r(A)$.

Consider the array $\mathbb{P}$ containing the interpolation points $(\lambda_j, \overline{\lambda}_j)$, $j = 1, \ldots, n$,

$$\mathbb{P} \;=\; \{(\lambda_j, \overline{\lambda}_j) \,:\, j = 1, \ldots, n\}\,. \tag{3.1}$$

We choose an integer $n_1$, $1 \leq n_1 < n$, and partition $\mathbb{P}$ into two disjoint subarrays $\mathbb{J}$ and $\mathbb{I}$,

$$\mathbb{J} \;=\; \{(\lambda_j, \overline{\lambda}_j) \,:\, j = 1, \ldots, n_1\}\,, \qquad \mathbb{I} \;=\; \{(\lambda_j, \overline{\lambda}_j) \,:\, j = n_1 + 1, \ldots, n\}\,.$$

For notational convenience, we now write $\mu_j \equiv \lambda_{j+n_1}$ for $j = 1, \ldots, n - n_1$. Then the [illegible] $L$ corresponding to the arrays $\mathbb{J}$ and $\mathbb{I}$ is defined by

$$L \;=\; [l_{i,j}]_{i=1,\ldots,n-n_1,\, j=1,\ldots,n_1}, \quad \text{where} \quad l_{i,j} \;=\; \frac{\overline{\mu}_i - \overline{\lambda}_j}{\mu_i - \lambda_j}\,. \tag{3.2}$$

Note that $L$ is of size $(n - n_1) \times n_1$. Moreover, the [illegible] $\mathbb{P}$ is defined as

$$\operatorname{rank} \mathbb{P} \;=\; \max_{L}\, \{\, \operatorname{rank} L \,\}\,, \tag{3.3}$$

where the maximum is taken over all possible Löwner matrices, which can be formed from $\mathbb{P}$ by partitioning into two subarrays as described above, cf. [1, Definition 4.51].

A similar construction can be made for any subarray of interpolation points. More precisely, we may take any $\mathbb{Q} \subset \mathbb{P}$ containing at least two points, partition $\mathbb{Q}$ into two disjoint subarrays, and form the corresponding Löwner matrix according to (3.2). In this way we can form Löwner matrices from $\mathbb{P}$ that are of size $k_1 \times k_2$ with $k_1 + k_2 < n$.

Theorem 3.1 (cf. [1, Theorem 4.55 and Corollary 4.56]). [illegible] $\mathbb{P}$ [illegible] (3.1) [illegible] $m$

(1) [illegible] $2m < n$ [illegible] $m \times m$ [illegible] $\mathbb{P}$ [illegible] $r = p/q$ [illegible] $p$ [illegible] $q$ [illegible] $m$ [illegible] $r(\lambda_j) = \overline{\lambda}_j$ $j = 1, \ldots, n$ [illegible] $m$ [illegible] $n - m$

(2) [illegible] $n - m$ [illegible] $r = p/q$ [illegible] $p$ [illegible] $q$ [illegible] $n - m$ [illegible] $r(\lambda_j) = \overline{\lambda}_j$ $j = 1, \ldots, n$

The following is a straightforward consequence.

Corollary 3.2. [illegible] $A$ [illegible] $n$ [illegible] $d_r(A) \leq \lceil n/2 \rceil$ [illegible] $n \in \{2, 3\}$ [illegible] $d_r(A) = 1$

Having characterized the cases $n = 2$ and $n = 3$, we will now focus on matrices with at least four distinct eigenvalues.

Lemma 3.3. [illegible] $\lambda_1, \ldots, \lambda_4$ [illegible] $\mathbb{P}$ [illegible] (3.1) [illegible] $\operatorname{rank} \mathbb{P} = 1$ [illegible] $\lambda_1, \ldots, \lambda_4$ [illegible]

[illegible]. We partition $\mathbb{P}$ into two subarrays $\mathbb{J}$ and $\mathbb{I}$ containing two interpolation points each. The corresponding Löwner matrix is

$$L \;=\; \left[ \frac{\overline{\mu}_i - \overline{\lambda}_j}{\mu_i - \lambda_j} \right]_{i,j=1,2},$$

giving

$$\det L \;=\; \frac{\overline{\mu}_1 - \overline{\lambda}_1}{\mu_1 - \lambda_1} \, \frac{\overline{\mu}_2 - \overline{\lambda}_2}{\mu_2 - \lambda_2} \;-\; \frac{\overline{\mu}_2 - \overline{\lambda}_1}{\mu_2 - \lambda_1} \, \frac{\overline{\mu}_1 - \overline{\lambda}_2}{\mu_1 - \lambda_2} \,.$$

Hence $\det L = 0$, if and only if

$$\frac{(\mu_1 - \lambda_1)\,(\mu_2 - \lambda_2)}{(\mu_1 - \lambda_2)\,(\mu_2 - \lambda_1)} \;\in\; \mathbb{R}\,. \tag{3.4}$$

We denote by $\widehat{\mathbb{C}}$ the extended complex plane. Recall that a circle in $\widehat{\mathbb{C}}$ is either a true circle in the complex plane or a line in the complex plane with the point at infinity adjoined. In (3.4) we replace $\mu_2$ by a variable $z$, and consider the function

$$f(z) \;=\; \frac{(\mu_1 - \lambda_1)\,(z - \lambda_2)}{(\mu_1 - \lambda_2)\,(z - \lambda_1)}\,.$$

The function $f(z)$ is the unique Moebius transformation satisfying

$$f(\lambda_1) = \infty\,, \quad f(\lambda_2) = 0\,, \quad f(\mu_1) = 1\,.$$

Now realize that through the points $\lambda_1, \lambda_2, \mu_1$ passes one and only one circle $\mathcal{C}$ in $\widehat{\mathbb{C}}$. Since the Moebius transformation $f$ conformally maps circles in $\widehat{\mathbb{C}}$ onto circles in $\widehat{\mathbb{C}}$, we see that $f(\mathcal{C}) = \mathbb{R} \cup \{\infty\}$, and, in particular, $f(\mu_2) \in \mathbb{R}$, if and only if $\mu_2 \in \mathcal{C}$ (see, e.g., [15, Chapter 3] for more on Moebius transformations). Consequently, $L$ is singular if and only if $\lambda_1, \lambda_2, \mu_1, \mu_2$ lie on the same circle in $\widehat{\mathbb{C}}$, i.e., if and only if these points in the complex plane are either collinear or concyclic, which completes the proof. $\square$

Using this lemma we can characterize the diagonalizable matrices of McMillan degree one. To do so, we recall that a matrix has rank $k$ if and only if it has a nonsingular $k \times k$ submatrix and all its $(k+1) \times (k+1)$ submatrices are singular (see, e.g., [10, pp. 12–13]).

LEMMA 3.4. [illegible] $A$ [illegible] $d_r(A) = 1$ [illegible] $A$ [illegible]

[illegible]. Let $L$ be any Löwner matrix with at least two rows and columns formed from the array $\mathbb{P}$ corresponding to the $n \geq 4$ distinct eigenvalues of $A$. Clearly, $\operatorname{rank} L \geq 1$.

If the eigenvalues of $A$ are either collinear or concyclic, then Lemma 3.3 shows that every $2 \times 2$ submatrix of $L$ is singular. Therefore, $\operatorname{rank} L = 1$, which shows that $\operatorname{rank} \mathbb{P} = 1$. Since $2 < n$, and every $1 \times 1$ Löwner matrix that can be formed from $\mathbb{P}$ is nonsingular, case (1) in Theorem 3.1 applies, showing that $d_r(A) = 1$.

On the other hand, if the eigenvalues of $A$ are neither collinear nor concyclic, then by Lemma 3.3 there exists a $2 \times 2$ submatrix of $L$ that is nonsingular. Hence $\operatorname{rank} L \geq 2$, which implies that $\operatorname{rank} \mathbb{P} \geq 2$, and hence $d_r(A) \geq 2$. ☐

If $A$ is any diagonalizable matrix with $n \geq 2$ distinct eigenvalues that all are collinear, then Corollary 3.2 and Lemma 3.4 show that $d_r(A) = 1$. These matrices are also known to be $B$-normal(1) for some HPD matrix $B$ (cf. [14, Theorem 3.3] and the references given there), and thus they satisfy $d_p(A) = 1$.

More interesting is the class of the diagonalizable matrices with $n \geq 3$ distinct eigenvalues that all are concyclic. For such matrices $A$, Corollary 3.2 and Lemma 3.4 show that $d_r(A) = 1$. Moreover, case (1) in Theorem 3.1 shows that the rational function $r$ of McMillan degree one that satisfies $r(\lambda) = \overline{\lambda}$ for all eigenvalues $\lambda$ is uniquely determined. In fact, this function can be easily computed. Suppose that the eigenvalues of $A$ are given by

$$\lambda_j \;=\; \rho e^{i\varphi_j} + \zeta\,, \quad j = 1, \ldots, n\,,$$

where $\rho \in \mathbb{R} \setminus \{0\}$ and $\zeta \in \mathbb{C}$ do not depend on $j$, while $\varphi_j \in [0, 2\pi)$. Then

$$r(z) \;=\; \frac{\overline{\zeta} z + (\rho^2 - |\zeta|^2)}{z - \zeta}$$

satisfies $r(\lambda_j) = \overline{\lambda}_j$, $j = 1, \ldots, n$. Clearly, $r$ is not a polynomial. Case (1) in Theorem 3.1 also shows that the next smallest admissible McMillan degree is $n - 1$. Apparently, a corresponding rational function is the uniquely determined (Lagrange) interpolation polynomial $p$ that satisfies $p(\lambda) = \overline{\lambda}$ for all eigenvalues $\lambda$. This means that $d_p(A) = n - 1$.

It is easy to see that, for a diagonalizable matrix $A$, $d_r(A)$ is equal to the smallest possible McMillan degree of a rational function $r$ such that the eigenvalues of $A$ are zeros of the function $r(z) - \overline{z}$. When $n \geq 4$ and the eigenvalues of $A$ are neither collinear nor concyclic, Lemma 3.4 implies that $d_r(A) \geq 2$. Hence in this case we search for a rational function $r$ of (smallest possible) $\deg r \geq 2$, such that the eigenvalues of $A$ are zeros of $r(z) - \overline{z}$. The following result summarizes what is known about the zeros of such functions.

THEOREM 3.5.

(1) [illegible] $p(z) - \overline{z}$ [illegible] $p$ [illegible] $s \geq 2$ [illegible] $3s - 2$ [illegible] $s \geq 2$ [illegible] $p$ [illegible] $s$ [illegible] $p(z) - \overline{z}$ [illegible] $3s - 2$ [illegible]

(2) [illegible] $r(z)-\overline{z}$ [illegible] $r$ [illegible] $s \geq 2$ [illegible] $5s-5$ [illegible] $s \geq 2$ [illegible] $r$ [illegible] $s$ [illegible] $r(z)-\overline{z}$ [illegible] $5s-5$ [illegible]

The bounds in (1) and (2) have been shown in [13] and [12], respectively. The corresponding sharpness results have been shown in [7] and [16]. Using these bounds we can prove the following result.

Theorem 3.6. [illegible] $A$ [illegible] $n \geq 4$ [illegible]

(1) [illegible] $d_r(A) = d_p(A) = 1$

(2) [illegible] $d_r(A) = 1$ [illegible] $d_p(A) = n-1$

(3) [illegible] $d_r(A) \geq \lfloor n/5 + 1 \rfloor$ $d_p(A) \geq \lfloor (n+2)/3 \rfloor$ [illegible]

$$1 \,\leq\, \frac{d_p(A)}{d_r(A)} \,\leq\, 5\,\frac{n-1}{n+5} \,<\, 5\,. \tag{3.5}$$

[illegible]. Cases (1) and (2) were shown above, so only case (3) needs to be proven. Here the eigenvalues are neither collinear nor concyclic, and thus by Lemma 3.4 we must have $d_r(A) \geq 2$. From case (2) in Theorem 3.5 we know that any function of the form $r(z) - \overline{z}$, where $r$ is a rational function of $\deg r \geq 2$, may have at most $5 \deg r - 5$ zeros. Since any function for which the McMillan degree of $A$ is attained must have (at least) $n$ distinct zeros, we must have $n \leq 5 d_r(A) - 5$, and thus $d_r(A) \geq \lfloor n/5 + 1 \rfloor$. The lower bound on $d_p(A)$ follows in a similar way from case (1) in Theorem 3.5. Finally, the leftmost and rightmost inequalities in (3.5) are straightforward, while the middle inequality follows from the lower bound on $d_r(A)$ and from noting that $d_p(A) \leq n-1$. □

Using Theorem 2.2, Corollary 3.2, and Theorem 3.6 we can derive the following well-known result: There exists an HPD matrix $B$ with respect to which a matrix $A$, with at least two distinct eigenvalues is normal of degree one, if and only if $A$ is diagonalizable and has collinear eigenvalues (cf. [14, Theorem 3.3] and the references given there). Here we have given a new proof of this result using rational interpolation theory and conformal mappings.

A surprising fact shown by Theorem 3.6 is that the ratio $d_p(A)/d_r(A)$ is bounded from above by five, unless the eigenvalues of $A$ are concyclic, in which case the ratio is equal to $n-1$. In this sense, the diagonalizable matrices with concyclic eigenvalues form a very special class.

Theorem 3.6 also shows that if the eigenvalues of a diagonalizable matrix $A$ are neither collinear nor concyclic, then $d_r(A)$ is small, if and only if $A$ has only a small number (at most $5d_r(A) - 5$) of distinct eigenvalues.

[illegible] 3.7. A related observation is made after the statement of [4, Theorem 3.1], but it is not fully justified from the theory presented there. According to Barth and Manteuffel, their result "says that if $A$ is $B$-normal($\ell$,$m$) and either $\ell$ or $m$ greater than 1, then $A$ has a relatively small number of distinct eigenvalues" [4, p. 775]. However, in terms of [4, Definition 3.1], any unitary matrix $A$ with $n \geq 3$ distinct eigenvalues is $I$-normal(0,1) [illegible] $I$-normal($n-1$,0). Hence, for $\ell = n-1 > 1$ and $m = 0$, $A$ is $B$-normal($\ell$,$m$), but $A$ may have arbitrarily many distinct eigenvalues. The confusion is caused by the lack of uniqueness of the "smallest degrees" $\ell$ and $m$. In general, there exist no "simultaneously smallest" $\ell$ and $m$ for which $A^+ = r(A)$ with $r = p/q$ for relatively prime polynomials of respective degrees $\ell$ and $m$.

We next show by examples that the two weak inequalities in (3.5) cannot be improved in general. First, consider the lower bound on $d_p(A)/d_r(A)$. This bound is attained if and only if a rational function $r$ of smallest possible McMillan degree, which satisfies $r(\lambda) = \overline{\lambda}$ for all eigenvalues $\lambda$ of $A$, is a polynomial (this always holds when the eigenvalues of $A$ are collinear, cf. case (1) in Theorem 3.6, where $d_r(A) = d_p(A) = 1$). Consider a diagonalizable matrix $A$ with $n = 4$ distinct eigenvalues given by

$$\lambda_1 = 1 + \sqrt{1/2}, \quad \lambda_2 = 1 - \sqrt{1/2}, \quad \lambda_3 = i\sqrt{1/2}, \quad \lambda_4 = -i\sqrt{1/2}.$$

The polynomial

$$p(z) \; = \; z^2 - z + \frac{1}{2}$$

is the unique polynomial of smallest possible degree that satisfies $p(\lambda_j) = \overline{\lambda}_j$, $j = 1, \ldots, 4$, so that $d_p(A) = 2$. On the other hand, $d_r(A) \leq 2$ by Corollary 3.2, and since the four eigenvalues are neither collinear nor concyclic, Lemma 3.4 implies that $d_r(A) = 2$, showing that the lower bound in (3.5) is attained.

To give an example that the upper bound is attained, consider any diagonalizable matrix $A$ with $n = 5$ distinct eigenvalues that are neither collinear nor concyclic. By Corollary 3.2, $d_r(A) \leq \lceil 5/2 \rceil = 2$, and by Lemma 3.4, $d_r(A) > 1$, showing that $d_r(A) = 2$. Suppose that the five eigenvalues are

$$\lambda_1 = 0, \quad \lambda_2 = 1, \quad \lambda_3 = 2, \quad \lambda_4 = i, \quad \lambda_5 = -i.$$

Obviously, these are neither collinear nor concyclic. An elementary computation (that may be performed by any computer algebra package) shows that the unique polynomial $p$ of smallest possible degree that satisfies $p(\lambda_j) = \overline{\lambda}_j$, $j = 1, \ldots, 5$, is given by

$$p(z) \; = \; \frac{3}{5}z - \frac{3}{5}z^2 + \frac{8}{5}z^3 - \frac{3}{5}z^4,$$

so that $d_p(A) = 4$. Therefore, $d_p(A)/d_r(A) = 2$, showing that the weak upper bound in (3.5) is attained.

Finally, we remark that it may be possible to extend our approach to give an alternative proof of the sharpness of the bound of [12] on the maximal number of zeros of $r(z) - \overline{z}$, where $r$ is rational with $\deg r \geq 2$ (cf. case (2) in Theorem 3.5). For example, let five distinct complex numbers be given, such that any four of them are neither collinear nor concyclic. Then, by case (1) in Theorem 3.1, there exists a unique rational function $r$ of $\deg r = 2$, so that the five complex numbers are zeros of $r(z) - \overline{z}$. This function $r$ can be explicitly computed along the lines of [1, pp. 105–107], and it attains the bound of [12].

# ON THE INDEX OF CONDITIONAL STABILITY OF STABLE INVARIANT LAGRANGIAN SUBSPACES*

ANDRÉ C. M. RAN† AND LEIBA RODMAN‡

**Abstract.** Given a nondegenerate sesquilinear inner product on a finite dimensional complex vector space, or a nondegenerate symmetric or skewsymmetric inner product on finite dimensional real vector space, subspaces that are simultaneously Lagrangian and invariant for a selfadjoint or a skewadjoint matrix with respect to the inner product are considered. The rate of conditional stability of such subspaces is studied, under small perturbations of both the inner product and the matrix. The concept of conditional stability (in contrast with unconditional stability) presupposes that one considers only those perturbed matrix and inner product for which the existence of invariant Lagrangian subspaces can be guaranteed a priori. Open problems regarding the index (= exact rate) of conditional stability are stated. Several inaccurate statements in the authors' previous works concerning the index are made precise. Finally, an application is given to conditional stability of hermitian solutions of continuous type algebraic Riccati equations.

## 1. Introduction.

Let $\mathbb{F}$ denote either the field of complex numbers $\mathbb{C}$ or the field of real numbers $\mathbb{R}$ and let $H \in \mathbb{F}^{m\times m}$ be a hermitian (symmetric in the real case) invertible matrix. Then a matrix $A \in \mathbb{F}^{m\times m}$ is called $H$-*selfadjoint* if $HA$ is hermitian, i.e., $HA = A^*H$, or $HA = A^TH$ in the real case, where the superscript $^T$, resp., $^*$, denotes the transposed, resp., conjugate transposed, matrix or vector. We consider also $H$-skewadjoint matrices $A$, i.e., such that $HA$ is skewadjoint. (Note that only in the real case the $H$-skewadjoint matrices form an essentially different class, because in the complex case $A$ is $H$-skewadjoint if and only if $iA$ is $H$-selfadjoint.) In the real case it is of interest to study the classes of matrices $A \in \mathbb{R}^{m\times m}$ with the properties that $HA = \pm A^TH$, where $H \in \mathbb{R}^{m\times m}$ is a given invertible skewsymmetric matrix ($m$ must be even for such $H$ to exist); if $HA = A^TH$, the matrix $A$ is said to be $H$-*selfadjoint*, and if $HA = -A^TH$, the matrix $A$ is said to be $H$-*skewadjoint*. (In the literature the terms $H$-Hamiltonian and $H$-skew-Hamiltonian are used as well.) The theory and applications of these classes of matrices is a well studied area of linear algebra, see, for example, books [13], [6], [7], [10], and recent expository papers [11], [12].

From now on we assume that $m = 2n$ is even, and let $H \in \mathbb{F}^{m\times m}$ be an invertible hermitian matrix (in the complex case) or invertible symmetric or skewsymmetric matrix (in the real case). We say that a subspace $\mathcal{M} \subseteq \mathbb{F}^{2n}$ is $H$-*Lagrangian* if $\dim \mathcal{M} = n$ and

$$y^*Hx = 0 \quad (y^THx = 0 \text{ in the real case}) \quad \text{for all} \quad x, y \in \mathcal{M}.$$

If $A$ is $H$-selfadjoint or $H$-skewadjoint, then $A$-invariant $H$-Lagrangian subspaces are of particular interest in many applications. Note that such subspaces do not exist for every $H$-selfadjoint or $H$-skewadjoint matrix need. Denote by $\mathcal{IL}(A, H)$ the (possibly empty) set of all $A$-invariant $H$-Lagrangian subspaces.

We now give a key definition of conditional $\alpha$-stability, a concept that was introduced and studied in various guises in [25], [22], [24], [21], [23]. A well-known notion of the [illegible] $(\mathcal{M}, \mathcal{N})$ between two subspaces $\mathcal{M}, \mathcal{N} \subseteq \mathbb{F}^{2n}$ will be used:

$$\operatorname{gap}(\mathcal{M}, \mathcal{N}) := \|P_{\mathcal{M}} - P_{\mathcal{N}}\|,$$

where $P_{\mathcal{M}}$, resp., $P_{\mathcal{N}}$, is the orthogonal projection on $\mathcal{M}$, resp., $\mathcal{N}$, and the operator norm (= the largest singular value) $\|\cdot\|$ is used throughout. See, for example, [8] for more information on the gap function.

Fix $\alpha \geq 1$, and let $A \in \mathbb{F}^{2n \times 2n}$ be an $H$-selfadjoint or $H$-skewadjoint matrix. A subspace $\mathcal{M} \in \mathcal{IL}(A, H)$ is called [illegible] $\alpha$ [illegible] if there exist $\delta > 0$ and $K > 0$ with the following properties: If $H' \in \mathbb{F}^{2n \times 2n}$ is hermitian and $A'$ is $H'$-selfadjoint or $H'$-skewadjoint as the case may be, and

$$\|A - A'\| + \|H - H'\| < \delta,$$

and if $\mathcal{IL}(A', H') \neq \emptyset$, then there exists $\mathcal{M}' \in \mathcal{IL}(A', H')$ such that

$$\operatorname{gap}(\mathcal{M}, \mathcal{M}') \leq K \left(\|A - A'\| + \|H - H'\|\right)^{1/\alpha}.$$

If in the above definition $H$ is kept fixed, i.e., the additional restriction $H' = H$ is imposed, then the definition of a conditionally $H$-$\alpha$-stable subspace $\mathcal{M} \in \mathcal{IL}(A, H)$ is obtained. One can show (we omit details) that the concept of conditional $H$-$\alpha$-stability, although formally weaker than that of conditional $\alpha$-stability, is in fact equivalent to it (compare [16], [17]). Note also that if $\mathcal{M}$ is conditionally $\alpha$-stable, then $\mathcal{M}$ is conditionally $\beta$-stable for every $\beta > \alpha$.

The concept of conditional $\alpha$-stability is one of many related notions of stability that have been studied in the literature starting with [4], [1], [2]. Although on the face of it the conditional $\alpha$-stability seems to be a rather contrived notion, it does play a role in important applications, for example, classical $H_\infty$ control. In this application, a solution to the control problem involves certain $A(\gamma)$-invariant $H$-Lagrangian subspaces, where $A(\gamma)$ is a real $H$-skewadjoint matrix parameterized by a positive parameter $\gamma$, and where $H \in \mathbb{R}^{2n \times 2n}$ is a fixed invertible skewsymmetric matrix. In some situations, the optimal solution corresponds to the minimal value $\gamma_0$ of $\gamma$ for which $A(\gamma)$-invariant $H$-Lagrangian subspaces exist (this approach to $H_\infty$ control was developed in [5] in the context of solutions of certain algebraic Riccati equations; see also [10, Chapter 20] for more details). Clearly, conditional stability is an appropriate tool for perturbation analysis in the vicinity of the optimal solution, since $\mathcal{IL}(A(\gamma), H) = \emptyset$ for $\gamma < \gamma_0$.

In the present paper we continue the investigation of conditional $\alpha$-stability initiated in [22], see also [23]. As it turns out, there are inaccuracies in several statements in [20], [22], [23] (all of them can be traced to the same source). We correct the statements, add a few additional results and applications, and formulate open problems. This theme will be further developed in [14] in the context of symplectic matrices.

**2. Conditional $\alpha$-stability: Complex case.** We state and prove here the main result on conditional $\alpha$-stability of invariant Lagrangian subspaces for $H$-selfadjoint matrices in the complex case. As before, $H \in \mathbb{C}^{2n\times 2n}$ is a fixed invertible hermitian matrix. Denote by $\mathcal{R}_\lambda(A) = \mathrm{Ker}\,(A-\lambda I)^{2n}$ the root subspace of a matrix $A \in \mathbb{C}^{2n\times 2n}$ corresponding to its eigenvalue $\lambda$.

Theorem 2.1. [illegible] $A \in \mathbb{C}^{2n\times 2n}$ [illegible] $H$ [illegible] $A$ [illegible]

$$\alpha_+ = \max\{m_1, \dots, m_r\},$$

[illegible] $m_1, \dots, m_r$ [illegible] $A$ [illegible] $\alpha_+ = 1$ [illegible] $A$ [illegible]

$$\alpha_- = \max\{2, m_1 - 1, \dots, m_r - 1\}$$

[illegible] $\alpha_- = 1$ [illegible] $A$ [illegible]

(I) [illegible] $\alpha_+$ [illegible] $A$ [illegible] $H$ [illegible] $\mathcal{M}$ [illegible] $\mathcal{M}$ [illegible]

$$\{0\} \neq \mathcal{M} \cap \mathcal{R}_\lambda(A) \neq \mathcal{R}_\lambda(A)$$

[illegible] $\lambda$ [illegible] $A$ [illegible] $\lambda$ [illegible] $1$ [illegible]

(1) [illegible] $\lambda$ [illegible] $\alpha_+$.

(2) [illegible] $\lambda$ [illegible] $\alpha_+ + 1$ [illegible]

$$k := \dim\,(\mathcal{M} \cap \mathcal{R}_\lambda(A)),$$

[illegible] $k$ [illegible] $(\alpha_+ + 1)$ [illegible]

(II) [illegible] $\beta$ [illegible] $A$ [illegible] $H$ [illegible] $\beta$ [illegible] $1 \leq \beta < \alpha_-$

Note that we always have $\alpha_- \leq \alpha_+$. Note also that the hypothesis that the geometric multiplicities of $A$ corresponding to real eigenvalues are all equal to 1 is not necessary for existence of conditionally stable $A$-invariant $H$-Lagrangian subspaces; see [17] for more information.

A particular case of Theorem 2.1 deserves special attention, namely the $A$-invariant $H$-Lagrangian subspace $\mathcal{M}_0$ with the property that the spectrum of the restriction of $A$ to $\mathcal{M}_0$ is in the closed upper half plane. Note that this subspace is unique under the hypotheses of Theorem 2.1.

Corollary 2.2. [illegible] 2.1 [illegible] $\mathcal{M}_0$ [illegible] $\alpha_+$ [illegible] $\beta$ [illegible] $1 \leq \beta < \alpha_-$

An analogous corollary holds for the $A$-invariant $H$-Lagrangian subspace with the spectrum of the restriction of $A$ to the subspace being in the closed lower half plane.

It has been claimed in [20], [22, Theorem 6.5], [23, Theorem 3.14] (in the context of $\alpha$-stability of solutions of algebraic Riccati equations) that there exist conditionally $\alpha_-$-stable $A$-invariant $H$-Lagrangian subspaces, under the hypotheses of Theorem 2.1. However, the proof given in [22], [23] falls short of proving this claim (but see Theorem 2.3). Therefore, we can state an open problem.

Problem 1. [illegible] $\alpha_-$ [illegible] $A$ [illegible] $H$ [illegible] 2.1

[illegible] 2.1. The proof of part (II) follows from [22, Lemma 6.8], using the criterion for $\beta$-stability of invariant subspaces of general complex matrices (see [24] for details).

For part (I), we first use the localization principle (see [17], [16]). Note that in [16] the localization principle is stated for the stability property of invariant Lagrangian subspaces; the same considerations yield the localization principle also in our context of conditional $\alpha$-stability. Thus, we need only to consider two cases: (a) $A$ has no real eigenvalues; (b) $A$ has only one real eigenvalue, perhaps of large multiplicity. In the case (a), we have $\alpha_+ = \alpha_- = 1$, and the spectral $A$-invariant subspace corresponding to the eigenvalues in the open upper half place (or open lower half plane) is $H$-Lagrangian and conditionally 1-stable. In the case (b), note that there is a unique $A$-invariant $H$-Lagrangian subspace $\mathcal{M}$, and its dimension is $n$. The result of [25] implies that there exist $\delta > 0$ and $K > 0$ such that every complex matrix $B$ with $\|B - A\| < \delta$ has the property that every $n$-dimensional $B$-invariant subspace $\mathcal{N}$ satisfies the inequality

$$\operatorname{gap}(\mathcal{M}, \mathcal{N}) \leq \|B - A\|^{1/\alpha_+}.$$

In particular, if $B$ is also $H'$-selfadjoint and $\mathcal{IL}(B, H') \neq \emptyset$, then one such $n$-dimensional $B$-invariant subspace will be $H'$-Lagrangian, and conditional $\alpha_+$-stability of $\mathcal{M}$ follows. $\square$

Let $A$ be as in Theorem 2.1, and let $\mathcal{M}$ be an $A$-invariant $H$-Lagrangian subspace. We say that $\alpha_0 \geq 1$ is the [illegible] of $\mathcal{M}$ if $\mathcal{M}$ is conditionally $\alpha_0$-stable but is not conditionally $\alpha$-stable for any $\alpha$ with $1 \leq \alpha < \alpha_0$. The index is obviously unique, but its existence is not obvious even when $\mathcal{M}$ is conditionally $\alpha$-stable for some $\alpha \geq 1$. Indeed, a priori it is not clear that such $\mathcal{M}$ is conditionally $\alpha_0$-stable, where $\alpha_0$ is the greatest lower bound of the (nonempty) set of all $\alpha$'s with the property that $\mathcal{M}$ is conditionally $\alpha$-stable (see Problem 2 below).

Note that generally speaking Theorem 2.1 does not provide the index of conditional stability. One particular case when the index can be obtained using the theorem is presented in the next result. It will be convenient to introduce the following notation: For a positive integer $m$, and any integer $k$, $0 \leq k \leq m$, define

$$\alpha_{\mathbb{C}}(m,k) := \begin{cases} 1 & \text{if } k = 0 \text{ or } k = m, \\ m-1 & \text{if } 1 \leq k \leq m-1 \text{ and } \exists\ k \text{ distinct } m\text{th roots of unity} \\ & \text{whose sum is 0,} \\ m & \text{in all other cases.} \end{cases}$$

THEOREM 2.3. [illegible] $A \in \mathbb{C}^{2n\times 2n}$ [illegible] $H$ [illegible] $A$ [illegible] $\alpha_0 = 1$ [illegible] $A$ [illegible] $\alpha_0 = 2$ [illegible]

[illegible] $\mathcal{M}$ [illegible] $A$ [illegible] $H$ [illegible] $\mathcal{M}$ [illegible] $\alpha$ [illegible] $\alpha$ [illegible]

[illegible]

$$\{0\} \neq \mathcal{M} \cap \mathcal{R}_\lambda(A) \neq \mathcal{R}_\lambda(A)$$

[illegible] $\lambda$ [illegible] $A$ [illegible] $\lambda$ [illegible] 1 [illegible] $\mathcal{M}$ [illegible] $\alpha_0$ [illegible]

$$\max_{j=1,2,\ldots,r} \left\{\alpha_{\mathbb{C}}\left(\dim \mathcal{R}_{\lambda}(A), \dim\left(\mathcal{R}_{\lambda}(A) \cap \mathcal{M}\right)\right)\right\}, \tag{2.1}$$

[illegible] $\lambda_1, \ldots, \lambda_r$ [illegible] $A$ [illegible] (2.1) [illegible] 1 [illegible] (2.1) $\lambda_1, \ldots, \lambda_r$ [illegible] $A$ [illegible]

[illegible] Note that $\alpha_0 = \alpha_+ = \alpha_-$, where $\alpha_\pm$ are taken from Theorem 2.1. By using the localization principle again, two cases need to be considered: (a) $A$ has only one real eigenvalue, perhaps of large multiplicity; (b) $A$ has no real eigenvalues. In case (b), we complete the proof by using a result proved in [17] (see also [23, Theorem 3.5]). The result says that (assuming the $H$-selfadjoint matrix $A$ has no real eigenvalues) an $A$-invariant $H$-Lagrangian subspace $\mathcal{M}$ is conditionally stable if and only if the intersection of $\mathcal{M}$ with the spectral invariant subspace $\mathcal{R}_+(A)$ of $A$ corresponding to the eigenvalues in the open upper half plane is stable as an $A$-invariant subspace. Moreover, the index of conditional stability of $\mathcal{M}$ coincides with the index of stability of $\mathcal{M} \cap \mathcal{R}_+(A)$, and the latter was computed in [24] leading to formula (2.1). In case (a), just use Theorem 2.1. □

It follows from Theorem 2.3 that the index of conditional stability of the $A$-invariant $H$-Lagrangian subspace with spectrum in the closed upper half (resp. lower half) plane is $\alpha_0$ under the hypotheses and the notation of Theorem 2.3.

In view of Theorem 2.3, the following open problem (a part of which is in fact a particular case of a very general and seemingly intractable problem [23, Problem 3.6]) is suggested.

PROBLEM 2. [illegible] $A$ [illegible] 2.1 [illegible] $\mathcal{M}$ [illegible] $A$ [illegible] $H$ [illegible]

$$\{0\} \neq \mathcal{M} \cap \mathcal{R}_{\lambda}(A) \neq \mathcal{R}_{\lambda}(A)$$

[illegible] $\lambda$ [illegible] $A$ [illegible] $\lambda$ [illegible] 1

(a) [illegible] $\mathcal{M}$

(b) [illegible]

**3. Conditional $\alpha$-stability: Real case.** In this section, $H$ is an invertible real symmetric or skewsymmetric $2n \times 2n$ matrix. Invariant Lagrangian subspaces of real $H$-selfadjoint and $H$-skewadjoint matrices and their various stability properties had been studied in [18], [19]. However, not much is known about conditional $\alpha$-stability, except the facts that can be derived from results on other types of stability in [18], [19]. Thus we have the following problem.

PROBLEM 3. [illegible] $A$ [illegible] $H$ [illegible] $H$ [illegible] $A$ [illegible] $H$ [illegible] $\alpha \geq 1$ [illegible] $\alpha$ [illegible] $A$ [illegible] $H$ [illegible]

In this formulation, the problem is probably intractable. We present certain analogues of Theorems 2.1 and 2.3 for $H$-skewadjoint matrices, under the basic hypothesis that pure imaginary and zero eigenvalues of $A$ have geometric multiplicity one, and state a (hopefully more tractable) particular case of Problem 3.

We need some additional notation. A finite set of complex numbers $\{\zeta_1, \ldots, \zeta_m\}$ will be called [illegible] if $\zeta_1 + \cdots + \zeta_m = 0$, and the nonreal elements of the set can be arranged in pairs of complex conjugate numbers. For two integers $k$

and $m$, with $0 \le k \le m$, $m > 0$, we define $\alpha_{\mathbb{R}}(m,\ k)$ as follows: $\alpha_{\mathbb{R}}(m,\ k) = m$ in the following three cases: (i) $0 < k < m$, $m$ is odd and there is no zero sum selfconjugate set of $k$ distinct $m$th roots of 1, (ii) $m$ is even and $k$ is odd, (iii) $m$ is even and divisible by 4, $k$ is also even but not divisible by 4, and there is no zero sum selfconjugate set of $k$ distinct $m$th roots of $-1$. We define $\alpha_{\mathbb{R}}(m,\ k) = 1$ if $k = 0$ or $k = m$. In all other cases we define $\alpha_{\mathbb{R}}(m,\ k) = m - 1$.

Denote by $\mathcal{R}_{a\pm ib}(A)$ the root subspace corresponding to a pair of nonreal complex conjugate eigenvalues $a \pm ib$, $a \in \mathbb{R}$, $b \in \mathbb{R} \setminus \{0\}$, of a real $m \times m$ matrix $A$:

$$\mathcal{R}_{a\pm ib}(A) := \operatorname{Ker}(A^2 - 2aA + (a^2 + b^2)I)^m \subseteq \mathbb{R}^m.$$

THEOREM 3.1. [illegible] $A \in \mathbb{R}^{2n\times 2n}$ [illegible] $H$ [illegible] $H \in \mathbb{R}^{2n\times 2n}$ [illegible] $A$ [illegible] $A$ [illegible]

$$\alpha_+ = \max\{m_1, \ldots, m_r\},$$

[illegible] $m_1, \ldots, m_r$ [illegible] $A$ [illegible] $\alpha_+ = 1$ [illegible] $A$ [illegible]

$$\alpha_- = \max\{2, m_1 - 1, \ldots, m_r - 1\}$$

[illegible] $\alpha_- = 1$ [illegible] $A$ [illegible]

(I) [illegible] $\alpha_+$ [illegible] $A$ [illegible] $H$ [illegible] $\mathcal{M}$ [illegible] $\mathcal{M}$ [illegible] (X) [illegible] (Y)

(X) [illegible]

$$\{0\} \ne \mathcal{M} \cap \mathcal{R}_\lambda(A) \ne \mathcal{R}_\lambda(A)$$

[illegible] $\lambda$ [illegible] $A$ [illegible] $\lambda$ [illegible] 1 [illegible]

(1) [illegible] $m$ [illegible] $\lambda$ [illegible] $\alpha_+$.

(2) [illegible] $m$ [illegible] $\lambda$ [illegible] $\alpha_+ + 1$ [illegible]

$$k := \dim\left(\mathcal{M} \cap \mathcal{R}_\lambda(A)\right),$$

[illegible] $\alpha_+ = \alpha_{\mathbb{R}}(m,\ k)$.

[illegible] $m$ [illegible] $k$

(Y) [illegible] $a \pm ib$ $(a, b \in \mathbb{R} \setminus \{0\})$ [illegible] $A$ [illegible]

$$\{0\} \ne \mathcal{R}_{a\pm ib}(A) \cap \mathcal{M} \ne \mathcal{R}_{a\pm ib}(A),$$

[illegible] $a+ib$ [illegible] $a-ib$ [illegible] $m$ [illegible]

(3) $m \le \alpha_+$.

(4) $m = \alpha_+ + 1$ [illegible] $\alpha_+ = \alpha_{\mathbb{C}}\left(m, \frac{\dim \mathcal{R}_{a\pm ib}(A)\cap\mathcal{M}}{2}\right)$.

(II) [illegible] $\beta$ [illegible] $A$ [illegible] $H$ [illegible] $\beta$ [illegible] $1 \le \beta < \alpha_-$

The proof is parallel to that of Theorem 2.1. We need a criterion for $\beta$-stability of real invariant subspaces of real matrices (without symmetries). Such a criterion was established in [21].

Analogously to Corollary 2.2 we can derive the conditional stability result for the $A$-invariant $H$-Lagrangian subspace $\mathcal{M}_\ell$ with the property that the spectrum of the restriction of $A$ to $\mathcal{M}_\ell$ is in the closed left half plane. Note that this subspace is unique under the hypotheses of Theorem 3.1.

Corollary 3.2. [illegible] 3.1 [illegible] $\mathcal{M}_\ell$ [illegible] $\alpha_+$ [illegible] $\beta$ [illegible] $1 \leq \beta < \alpha_-$

Under the additional hypothesis that $m_1 = \cdots = m_r = 2$, an analogue of Theorem 2.3 may be obtained. We leave the formulation of this analogue to the interested reader.

We state an open problem analogous to Problem 2.

Problem 4. [illegible] $A$ [illegible] 3.1 [illegible] $\mathcal{M} \subseteq \mathbb{R}^{2n}$ [illegible] $A$ [illegible] $H$ [illegible]

$$\{0\} \neq \mathcal{M} \cap \mathcal{R}_\lambda(A) \neq \mathcal{R}_\lambda(A)$$

[illegible] $\lambda$ [illegible] $A$ [illegible] $\lambda$ [illegible] 1 [illegible]

$$\{0\} \neq \mathcal{R}_{a\pm ib}(A) \cap \mathcal{M} \neq \mathcal{R}_{a\pm ib}(A)$$

[illegible] $a \pm ib$ [illegible] $A$ [illegible] $a \pm ib$ [illegible] 1

[illegible] $\mathcal{M}$ [illegible]

**4. Applications: Algebraic Riccati equations.** Theorems 2.1 and 3.1 have many important well-known applications, several of them studied in [22], [23].

We give a detailed statement for the algebraic Riccati equations application. The literature on this topic is voluminous; we mention only books [3], [10], [15], [9], where more information, applications, and references are found.

We start with the complex case. Consider the algebraic Riccati equation

$$XDX - XA - A^*X - C = 0, \tag{4.1}$$

where $A$, $D = D^*$, $C = C^*$ are given $n \times n$ complex matrices, and $X = X^*$ is to be found. The Hamiltonian matrix

$$M := i \begin{bmatrix} A & -D \\ -C & -A^* \end{bmatrix} \tag{4.2}$$

of the Riccati equation plays a key role in the theory.

For a given $\alpha \geq 1$, a (hermitian) solution $X$ of (4.1) is called [illegible] $\alpha$ [illegible] if there exist $\varepsilon > 0,\ K > 0$ such that every equation with coefficients in $\mathbb{C}^{n\times n}$

$$X\widetilde{D}X - X\widetilde{A} - \widetilde{A}^*X - \widetilde{C} = 0, \tag{4.3}$$

with $\widetilde{D} = \widetilde{D}^*,\ \widetilde{C} = \widetilde{C}^*$, and

$$\|D - \widetilde{D}\| + \|A - \widetilde{A}\| + \|C - \widetilde{C}\| < \varepsilon$$

has a (hermitian) solution $Y \in \mathbb{C}^{n\times n}$ such that

$$\|X-Y\| \le K(\|D-\widetilde{D}\| + \|A-\widetilde{A}\| + \|C-\widetilde{C}\|)^{\frac{1}{\alpha}},$$

[illegible] (4.3) [illegible]

THEOREM 4.1. [illegible] $D$ [illegible] $(A,D)$ [illegible] $\lambda$ [illegible] $A$ [illegible] $\mathcal{R}_\lambda(A)$ [illegible] $\mathcal{R}_{-\overline{\lambda}}(A)$ [illegible]

$$\text{Range}\,[D, AD, \dots, A^{n-1}D]$$

[illegible] $(A,D)$ [illegible] $\lambda_1,\dots,\lambda_r$ [illegible] $M$ [illegible] $m_1,\dots,m_r$ [illegible]

$$\alpha_+ = \max\{m_1,\dots,m_r\},$$

[illegible] $\alpha_+ = 1$ [illegible] $M$ [illegible]

$$\alpha_- = \max\{2, m_1-1,\dots,m_r-1\}$$

[illegible] $\alpha_- = 1$ [illegible] $M$ [illegible]

(I) [illegible] $\alpha_+$ [illegible] $X$ [illegible] (4.1) [illegible] 2.1 [illegible] $A$ [illegible] $M$ [illegible]

$$\mathcal{M} := \text{Range}\begin{bmatrix} I \\ X \end{bmatrix}.$$

(II) [illegible] $\beta$ [illegible] (4.1) [illegible] $\beta$ [illegible] $1 \le \beta < \alpha_-$

(III) [illegible] $X_0$ [illegible] $X_0'$ [illegible] $M$ [illegible] $\left[\begin{smallmatrix} I \\ X_0 \end{smallmatrix}\right]$ [illegible] $\left[\begin{smallmatrix} I \\ X_0' \end{smallmatrix}\right]$ [illegible] $\alpha_+$ [illegible]

The result of Theorem 4.1 follows immediately from Theorem 2.1 and Corollary 2.2, using the well-known fact (see [10], for example) that under the hypotheses of Theorem 4.1, the (hermitian) solutions $X$ of are in one-to-one correspondence with $M$-invariant $i\left[\begin{smallmatrix} 0 & I \\ -I & 0 \end{smallmatrix}\right]$-Lagrangian subspaces.

PROBLEM 5. [illegible] 4.1 [illegible] $\alpha_-$ [illegible] $X$ [illegible] (4.1)

We introduce the index of conditional stability analogously to the index for invariant Lagrangian subspaces. Namely, we say that $\alpha_0 \ge 1$ is the [illegible] of a solution $X$ if $X$ is conditionally $\alpha_0$-stable but is not conditionally $\alpha$-stable for any $\alpha$ with $1 \le \alpha < \alpha_0$. Again, we have the analogue of Theorem 2.3.

THEOREM 4.2. [illegible] 4.1 [illegible] $M$ [illegible] $\alpha_0 = 1$ [illegible] $M$ [illegible] $\alpha_0 = 2$ [illegible]

[illegible] $X$ [illegible] (4.1) [illegible] $X$ [illegible] $\alpha$ [illegible] $\alpha \ge 1$ [illegible]

[illegible]

$$\{0\} \neq \left(\text{Range}\begin{bmatrix} I \\ X \end{bmatrix}\right) \cap \mathcal{R}_\lambda(M) \neq \mathcal{R}_\lambda(M)$$

[illegible] $\lambda$ [illegible] $M$ [illegible] $\lambda$ [illegible] 1 [illegible] $\mathcal{M}$ [illegible] $\alpha_0$ [illegible]

$$\max_{j=1,2,\ldots,r}\left\{\alpha_{\mathbb{C}}\left(\dim\mathcal{R}_\lambda(M),\dim\left(\mathcal{R}_\lambda(M)\cap\left(\operatorname{Range}\begin{bmatrix} I \\ X\end{bmatrix}\right)\right)\right)\right\}, \tag{4.4}$$

[illegible] $\lambda_1,\ldots,\lambda_r$ [illegible] $M$ [illegible] (4.4) [illegible] 1

We remark that analogously to Theorems 4.1 and 4.2, the corresponding results for the real case can be obtained from Theorem 3.1 and the real analogue of Theorem 2.3 (under the additional hypothesis that $m_1 = \cdots = m_r = 2$). In the real case, one uses the matrices $\left[\begin{smallmatrix} A & D \\ C & -A^T\end{smallmatrix}\right]$ and $\left[\begin{smallmatrix} 0 & I \\ -I & 0\end{smallmatrix}\right]$ instead of $M$ (given by (4.2)) and $i\left[\begin{smallmatrix} 0 & I \\ -I & 0\end{smallmatrix}\right]$, respectively. We omit the details.

Finally, we indicate corrections that should be made in [22, Theorems 6.5 and 7.4], [23, Theorem 3.14]. Namely, in part (i) of these theorems $\alpha_0$ should be replaced with $\max\{m_1,\ldots,m_r\}$ if $M$ has real eigenvalues (or if $T$ has unimodular eigenvalues in [22, Theorem 7.4]). Also, in [22, Theorem 6.9] in the statement "there exist conditionally $\alpha_0$-stable real hermitian solutions" the number $\alpha_0$ should be replaced with $\max\{m_1,\ldots,m_r\}$ if $M_r$ has pure imaginary or zero eigenvalues; an analogous correction should be made in [20]. In the minimal factorization result of [23, Theorem 3.31], in the statement "there exists a conditionally $\alpha_0$-stable symmetric factorization of $W$" the number $\alpha_0$ should be replaced with $\max\{m_1,\ldots,m_r,n_1,\ldots,n_s\}$ provided $W$ has real poles or zeros (or both).

**Acknowledgment.** We thank C. Mehl and V. Mehrmann for useful discussions concerning the subject matter of this paper. L. Rodman gratefully acknowledges hospitality and support during his visit at the Vrije Universiteit in Amsterdam.

# RECURSIVE SOLUTION OF CERTAIN STRUCTURED LINEAR SYSTEMS*

ANDRÉ KLEIN† AND PETER SPREIJ‡

**Abstract.** We provide explicit representations of the null space $\mathcal{S}$ of adjoints of companion-related matrices and of certain rectangular generalized Vandermonde matrices of block Toeplitz type which are encountered in the Fisher information matrix of time series processes. A formula for the right-inverse of this class of matrices $A$ is provided which allows one to express the solution of the system $Ax = b$ as $x = A^{-}b + \mathcal{S}$. The formulas can be easily turned into solution algorithms.

**Key words.** linear systems, coefficient matrix, null space, generalized Vandermonde matrix, Toeplitz matrix

**AMS subject classification.** 15A06

**DOI.** 10.1137/060656115

## 1. Introduction.

The subject of this paper is concerned with a recursive solution of new linear systems of equations. The following two linear systems of equations are investigated:

$$\mathcal{K}_\nu(\sigma)X = \mathcal{E} \tag{1.1}$$

and

$$\mathcal{M}_\tau(\rho)Y = \mathcal{R}. \tag{1.2}$$

The coefficient matrices in (1.1) and (1.2) have the form

$$\mathcal{K}_\nu(\sigma) = \left(\frac{d^\nu}{dz^\nu}\left(u_q(z)u_q^{*\top}(z)\right), \frac{d^{\nu-1}}{dz^{\nu-1}}\left(u_q(z)u_q^{*\top}(z)\right), \ldots, u_q(z)u_q^{*\top}(z)\right)_{z=\sigma}$$

and

$$\mathcal{M}_\tau(\rho) = \left(\frac{d^\tau}{dz^\tau}\left(\operatorname{adj}(zI - C_p)\right), \frac{d^{\tau-1}}{dz^{\tau-1}}\left(\operatorname{adj}(zI - C_p)\right), \ldots, \operatorname{adj}(zI - C_p)\right)_{z=\rho},$$

where $\mathcal{K}_\nu(\sigma) \in \mathbb{R}^{q\times q(\nu+1)}$ and $\mathcal{M}_\tau(\rho) \in \mathbb{R}^{p\times p(\tau+1)}$. The companion matrix $C_p \in \mathbb{R}^{p\times p}$ is given by

$$C_p = \begin{pmatrix} 0 & 1 & 0 & \cdots & 0 \\ \vdots & 0 & 1 & & \vdots \\ \vdots & & \ddots & \ddots & 0 \\ 0 & & & 0 & 1 \\ -c_p & & & -c_2 & -c_1 \end{pmatrix}, \tag{1.3}$$

---

where $\rho$ is an eigenvalue of $C_p$ with algebraic multiplicity $\tau + 1$, $\top$ denotes the transpose, $\mathrm{adj}(X)$ denotes the adjoint of matrix $X$, $\sigma$, $q$, and $\nu$ are arbitrary scalar values. Further, we have

$$u_q(z) = (1, z, \ldots, z^{q-1})^\top \quad \text{and} \quad u_q^*(z) = (z^{q-1}, \ldots, 1)^\top. \tag{1.4}$$

Here $X$ and $Y$ are matrices of size $q\,(\nu + 1) \times \ell$ and $p\,(\tau + 1) \times h$, respectively, while $\mathcal{E}$ and $\mathcal{R}$ have size $q \times \ell$ and $p \times h$, respectively. The coefficient matrices in (1.1) are rectangular generalized Vandermonde matrices of block Toeplitz type and in (1.2) they are adjoints of companion-related matrices. The linear equations studied in this paper are extracted from [5], where the Fisher information matrix of a stationary time series process is interconnected with a solution to a Stein equation. The matrix $\mathcal{E}$ is the Fisher information matrix of a stationary time series process, whereas matrix $\mathcal{R}$ is a solution to a Stein equation for an extended version of $\mathcal{M}_\tau(\rho)$. The matrices $X$ and $Y$ are equal and this enables the interconnections to be successfully implemented. In this paper, stationary processes do not play any role, contrary to [5]. However, it is worth noticing that the interconnection between Toeplitz forms and stationary processes has been extensively studied in [3].

In [5], $q$ is the degree of a polynomial $d_q(z)$ in $z \in \mathbb{C}$, $\sigma$ is a root of polynomial $d_q(z)$ with algebraic multiplicity $\nu + 1$. In other words, $q$, $\sigma$, and $\nu$ are interconnected through polynomial $d_q(z)$, whereas in this paper $q$, $\sigma$, and $\nu$ are arbitrary scalar values with no link to a common polynomial and $q$, $\nu > 0$. The algorithm derived in [5] constructs a vector belonging to the null space of $\mathcal{K}_\nu(\sigma)$, which requires matrix multiplications.

A property proved in [6] is used in [5] to derive an algorithm for the kernel of $\mathcal{M}_\tau(\rho)$, it concerns an interconnection between $\mathrm{adj}(zI - C_p)$ and the basis vector $u_p(z)$, this holds for $p = q$, $\sigma = \rho$, $\nu = \tau$ and when $\rho$ is an eigenvalue of $C_p$. The vectors $y \in \mathrm{Ker}\ (\mathcal{M}_\tau(\rho))$ and $x \in \mathrm{Ker}\ (\mathcal{K}_\tau(\rho))$, where $\mathrm{Ker}(X)$ is the kernel of the matrix $X$, are then interconnected. Consequently, the algorithm of the null space of $\mathcal{M}_\tau(\rho)$ given by vector $y$ is based on the algorithm of the null space of $\mathcal{K}_\tau(\rho)$ expressed by vector $x$. The computation of the vector $y$ involves an inversion of a lower triangular and Toeplitz matrix. However, this is combined with $p\tau$ matrix multiplications of the inverted matrix with the corresponding vector $x \in \mathrm{Ker}\ (\mathcal{K}_\tau(\rho))$. This is in agreement with the dimension of the null space of $\mathcal{M}_\tau(\rho)$.

In this paper the approach is different, (1.1) and (1.2) are two different linear systems of equations without a common matrix, and we develop a new algorithm for the null space of the coefficient matrices $\mathcal{K}_\nu(\sigma)$ and $\mathcal{M}_\tau(\rho)$ independently.

A solution of the linear systems of (1.1) and (1.2) is considered when $q = \nu + 1$ and $p = \tau + 1$. In this case, the newly developed algorithms for the null spaces and right-inverses are equivalent for both coefficient matrices. The appropriate right-inverse is expressed in terms of a generalized Vandermonde matrix. A new algorithm is also developed for the kernel of $\mathcal{K}_\nu(\sigma)$ for the case $q > \nu + 1$. The newly displayed algorithms for the null space do not require matrix multiplications and matrix inversions. The main computational exercise consists of evaluating factorials and binomial coefficients, the latter can be computed by applying the Pascal triangle, combined with recursions that consist of addition of two vectors. However, the problem set forth in this paper is algebraical. The purpose is to write a solution of new linear systems of equations as a function of $z$ and the problem studied is therefore not numerical. For that purpose one will subsequently consider the coefficient matrix $\mathcal{K}_\nu(z)$. When we consider the coefficient matrix $\mathcal{M}_\tau(z)$, for technical reasons that shall be specified in section 4, we will then consider the case $z = \rho$.

When $q = \nu + 1$ and $p = \tau + 1$, the representation of the null space $\mathrm{Ker}(\mathcal{M}_\tau(\rho))$ is obtained by simply transposing certain matrices in the representation of the null space Ker $(\mathcal{K}_\nu(\sigma))$. This means that when the algorithm of Ker $(\mathcal{M}_\tau(\rho))$ needs to be evaluated one can use the algorithm for the null space Ker $(\mathcal{K}_\nu(\sigma))$. Contrary to the corresponding algorithm displayed in [5], where a matrix inversion and matrix multiplications are involved, there is no need for a computational exercise of any kind when the algorithm set forth in this paper is applied.

Another fundamental difference with the approach in [5] is that the algorithms developed in this paper cover the entire span of the null spaces of $\mathcal{K}_\nu(\sigma)$ and $\mathcal{M}_\tau(\rho)$ and not just a vector as in [5].

Consequently, we may apply these results to provide explicit expressions of the solutions to the systems (1.1) and (1.2); more specifically, for $q = \nu + 1$ and $p = \tau + 1$ we have

$$X = (\mathcal{K}_\nu(\sigma))^{-} \mathcal{E} + \mathcal{W}(\sigma) \text{ with } \mathcal{W}(\sigma) \in \text{ Ker } (\mathcal{K}_\nu(\sigma)), \tag{1.5}$$

$$Y = (\mathcal{M}_\tau(\rho))^{-} \mathcal{R} + \mathcal{L}(\rho) \text{ with } \mathcal{L}(\rho) \in \text{ Ker } (\mathcal{M}_\tau(\rho)). \tag{1.6}$$

The similarity of the null spaces of the coefficient matrices in (1.1) and (1.2) is interesting. It implies a connection between adjoints of companion-related matrices and rectangular generalized Vandermonde matrices of the block Toeplitz type.

Solutions of linear systems of equations are also presented in, e.g., [1], [2], and [4], where the coefficient matrices are Toeplitz, Hankel, Hilbert-type, Cauchy, and Vandermonde-type matrices.

The paper is organized as follows. In section 2, a right-inverse representation of the coefficient matrices $\mathcal{K}_\nu(z)$ and $\mathcal{M}_\tau(\rho)$ is introduced. In sections 3 and 4, a corresponding algorithm for the kernel of the coefficient matrices $\mathcal{K}_\nu(z)$ and $\mathcal{M}_\tau(\rho)$ is developed for the case $q = \nu + 1$, respectively, $p = \tau + 1$. The main conclusions are formulated in section 5. An algorithm for the kernel of $\mathcal{K}_\nu(z)$, when $q > \nu + 1$, is displayed in section 6.

## 2. A right-inverse: Case $q = \nu + 1$.

A right-inverse of $\mathcal{K}_\nu(z)$ is given for $q = \nu + 1$, which is a special form of the right-inverse presented in [5]. We introduce the $q \times q$ generalized Vandermonde matrix $\mathcal{T}_\nu^q(z)$ where

$$\mathcal{T}_\nu^q(z) = \left(\mathcal{T}_\nu^{(\nu)}(z), \mathcal{T}_\nu^{(\nu-1)}(z), \ldots, \mathcal{T}_\nu^{(0)}(z)\right)$$

and

$$\mathcal{T}_\nu^{(\nu-k)}(z) = \frac{\partial^{\nu-k}}{\partial z^{\nu-k}} u_q(z), \qquad k = 0, 1, \ldots, \nu.$$

The following lemma can now be formulated.

Lemma 2.1. *When $q = \nu + 1$ the relations*

$$\mathcal{K}_\nu(z)\,(I_q \otimes e_q) = \mathcal{T}_\nu^q(z),$$
$$\mathcal{K}_\nu(z)\left(\left(\mathcal{T}_\nu^q(z)\right)^{-1} \otimes e_q\right) = I_q$$

*hold true. Clearly, an appropriate right-inverse is then $(\mathcal{K}_\nu(z))_R^{-} = \left(\mathcal{T}_\nu^q(z)\right)^{-1} \otimes e_q$, where $e_q$ is the last standard basis vector in $\mathbb{R}^q$.*

*Proof.* Straightforward computation confirms the property. ☐

Consider the matrices $A$ and $B$ of size $m \times n$ and $p \times q$, respectively; then the $mp \times nq$ Kronecker product of the two matrices is defined as $A \otimes B = (a_{ij})B$ for all $i$ and $j$.

A choice for an appropriate right-inverse of $\mathcal{M}_\tau(\rho)$ when $p = \tau + 1$ is given in the following corollary.

COROLLARY 2.2. *When $p = \tau + 1$ a right-inverse of $\mathcal{M}_\tau(\rho)$ is given by*

$$\left(\mathcal{T}_\tau^p(\rho)\right)^{-1} \otimes e_p,$$

*where $e_p$ is the last standard basis vector in $\mathbb{R}^p$. We then have*

$$\mathcal{M}_\tau(\rho)\left(\left(\mathcal{T}_\tau^p(\rho)\right)^{-1} \otimes e_p\right) = I_p.$$

*Proof.* We have the property that the last column of $\operatorname{adj}(zI - C_p)$ is $u_p(z)$; this can be shown by equality (4.4), and this coincides with the last column of the matrix $u_p(z)u_p^{*\top}(z)$. This implies equality of the last column of the blocks composing $\mathcal{K}_\nu(z)$ and $\mathcal{M}_\tau(z)$. Since the construction of the right-inverse displayed in Lemma 2.1 is based on the last column of the blocks in $\mathcal{K}_\nu(z)$, the right-inverse set forth in Lemma 2.1 then also holds for $\mathcal{M}_\tau(z)$. □

In the next section an algorithm for the null space Ker $(\mathcal{K}_\nu(z))$ is displayed.

## 3. Ker $(\mathcal{K}_\nu(z))$ for the case $\nu + 1 = q$.

We shall specify the dimension of the null space Ker $(\mathcal{K}_\nu(z))$ in the next proposition.

PROPOSITION 3.1. *The null space Ker$(\mathcal{K}_\nu(z))$ has dimension equal to $q\nu$ and the rank of the coefficient matrix $\mathcal{K}_\nu(z)$ is $q$, when $\nu + 1 = q$.*

*Proof.* In Lemma 2.1, a right-inverse of the coefficient matrix $\mathcal{K}_\nu(z)$ is set forth. This implies that the $q \times q(\nu + 1)$ coefficient matrix $\mathcal{K}_\nu(z)$ is surjective or has full row rank; its rank is then $q$. By virtue of the dimension rule it can be concluded that dim Ker $(\mathcal{K}_\nu(z)) = q\nu$. □

We are going to prove that a basis of the null space Ker$(\mathcal{K}_\nu(z))$ is formed by the columns of the matrix

$$\mathcal{N} = \begin{pmatrix} \mathcal{U}(z) \\ J_{q\nu} \end{pmatrix}, \tag{3.1}$$

where $J_{q\nu}$ is the $q\nu$ rotation matrix

$$\begin{pmatrix} 0 & 0 & \dots & 0 & 1 \\ 0 & 0 & \dots & 1 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 1 & \dots & 0 & 0 \\ 1 & 0 & \dots & 0 & 0 \end{pmatrix},$$

and where the $q \times q\nu$ matrix $\mathcal{U}(z)$ will be specified later on.

Observe that $\mathcal{N}$ has full rank $q\nu$ since $J_{q\nu}$ is a nonsingular submatrix of $\mathcal{N}$. Therefore the columns of $\mathcal{N}$ form a basis of Ker$(\mathcal{K}_\nu(z))$.

The matrix $\mathcal{U}(z)$ is represented in the following form:

$$\mathcal{U}(z) = \frac{1}{\nu!}\left(\mathcal{U}_0(z), \mathcal{U}_1(z), \mathcal{U}_2(z), \dots, \mathcal{U}_{\nu-1}(z)\right). \tag{3.2}$$

The submatrices constituting (3.2) shall be specified in the next sections.

**3.1. A representation of $\mathcal{U}_0(z)$.** In Lemma 3.2 we prove that a column of the matrix $\mathcal{U}_0(z)$ which has the form

$$\mathcal{U}_0(z) = (\xi \odot u_q(z)) \otimes u_q^\top(z)), \tag{3.3}$$

and where the vector $\xi$ is given by

$$\xi = (\xi_i)\,,\ \xi_i = \left((-1)^i \binom{\nu}{i-1}\right)_{i=1,\ldots,\nu+1}, \tag{3.4}$$

belongs to the null space $\mathrm{Ker}(\mathcal{K}_\nu(z))$. The Hadamard product $\odot$ is defined by $A \odot B = (a_{ij}b_{ij})$ for $A = (a_{ij})$ and $B = (b_{ij})$ which are matrices of the same size.

Recall that the $m$th row of $\mathcal{K}_\nu(z)$ is given by

$$\frac{d^\nu}{dz^\nu}\left(z^{q-2+m}, z^{q-3+m}, \ldots, z^{m-1}\right) = \left(z^{q+m-i-\nu-1} \prod_{j=1}^{v} (n-i-j)\right)_{i=1,\ldots,q}. \tag{3.5}$$

We have the following lemma.

Lemma 3.2. *The $q\,(\nu+1)$ column vector composed of an arbitrary column of $\mathcal{U}_0(z)$ and the corresponding standard basis vector in $\mathbb{R}^{q\nu}$ belongs to the null space of the coefficient matrix $\mathcal{K}_\nu(z)$.*

*Proof.* The $k$th column of $\mathcal{U}_0(z)$ has elements

$$\frac{1}{\nu!}\left((-1)^i z^{k+i-2}\binom{\nu}{i-1}\right), \quad i = 1, \ldots, q. \tag{3.6}$$

The scalar product of (3.5) and (3.6) provides a monomial in $z^{n-\nu+k-3}$, where $n = q+m$, whose coefficient is given by

$$\begin{aligned} &\frac{1}{\nu!}\sum_{i=0}^{\nu}(-1)^{i+1}\binom{\nu}{i}(n-2-i)(n-3-i)\cdots(n-\nu-1-i) \\ &= \frac{1}{\nu!}\left\{\frac{d^\nu}{dx^\nu}\sum_{i=0}^{\nu}(-1)^{i+1}\binom{\nu}{i}x^{n-2-i}\right\}_{x=1} = -\frac{1}{\nu!}\left\{\frac{d^\nu}{dx^\nu}\left(x^{n-2-\nu}(x-1)^\nu\right)\right\}_{x=1}. \end{aligned} \tag{3.7}$$

The application of the Leibnitz rule to $\nu$-fold differentiation of a product of two functions yields the value $-\frac{1}{\nu!}\{x^{n-2-\nu}\nu!\}_{x=1} = -1$. Consequently, the scalar product of (3.5) and (3.6) is $-z^{n-\nu+k-3}$. This should be added to the product of the appropriate $z$-variable in the coefficient matrix $\mathcal{K}_\nu(z)$ by the nonzero element of the standard basis vector in the rotation matrix $J_{q\nu}$ which is $z^{n-\nu+k-3}$, so the sum is null. This completes the proof. ☐

**3.1.1. Summary of the construction of $\mathcal{U}_0(z)$.** *Step* 1. Introduce the vector $\xi$ according to (3.4).

*Step* 2. Define the columns of $\mathcal{U}_0(\sigma)$ according to (3.3).

**3.2. A representation of $\mathcal{U}_j(z)$ when $j = 1, 2, \ldots, \nu-1$.** We shall now describe the form of the matrices $\mathcal{U}_1(z), \mathcal{U}_2(z), \ldots, \mathcal{U}_{\nu-1}(z)$ that consist of the following structural representation:

$$\mathcal{U}_j(\sigma) = \left(\mathcal{U}_j^{(1)}(z)\;\mathcal{U}_j^{(2)}(z)\right),$$

for $j = 1, 2, \ldots, \nu-1$.

**3.2.1. A representation of $\boldsymbol{\mathcal{U}_j^{(1)}(z)}$.** In this section the matrix $\mathcal{U}_j^{(1)}(z)$ is displayed. It is Hankel type with the following configuration:

$$\mathcal{U}_j^{(1)}(z) = \left(\delta_j^1(z)\delta_j^2(z)\cdots\delta_j^{j+1}(z)\right), \tag{3.8}$$

where the $(\nu+1)$ basis column vector $\delta_j^{\ell+1}(z)$ has components

$$\left[\delta_j^{\ell+1}(z)\right]_i = \begin{cases} 0 & \text{for } i \leq j-\ell \text{ or } \nu+1-i \leq \ell \\ -j!(-z)^{i+\ell-j-1}\binom{\nu-j}{i+\ell-j-1} & \text{otherwise} \end{cases} \tag{3.9}$$

for $\ell = 0, 1, \ldots, j$. The following lemma is proved.

LEMMA 3.3. *The $q(\nu+1)$ column vector composed of any arbitrary column of $\mathcal{U}_j^{(1)}(z)$ and the corresponding standard basis vector in $\mathbb{R}^{q\nu}$ belongs to the null space of the coefficient matrix $\mathcal{K}_\nu(z)$.*

*Proof.* Set $j = p$ and $\ell = g$ in (3.9). As can be seen from (3.5), the appropriate nonzero elements of the scalar product of (3.9) with (3.5) provide a monomial in $z^{f-p-2-\nu}$, where $f = q+m+g$. Its coefficient is given by

(3.10)

$$\begin{aligned}
&\frac{p!}{\nu!}\sum_{i=0}^{\nu-p}(-1)^{i+1}\binom{\nu-p}{i}(f-p-2-i)(f-p-3-i)\cdots(f-p-1-i-\nu)\\
&\quad= \frac{p!}{\nu!}\left\{\frac{d^\nu}{dx^\nu}\sum_{i=0}^{\nu-p}(-1)^{i+1}\binom{\nu-p}{i}x^{f-p-2-i}\right\}_{x=1}\\
&\quad= -\frac{p!}{\nu!}\left\{\frac{d^\nu}{dx^\nu}\left[x^{f-2-\nu}\sum_{i=0}^{\nu-p}(-1)^{i}\binom{\nu-p}{i}x^{\nu-p-i}\right]\right\}_{x=1}\\
&\quad= -\frac{p!}{\nu!}\left\{\frac{d^\nu}{dx^\nu}x^{f-2-\nu}(x-1)^{\nu-p}\right\}_{x=1}\\
&\quad= -\frac{p!}{\nu!}\left\{0+0+\cdots+\binom{\nu}{\nu-p}\frac{d^p}{dx^p}x^{f-2-\nu}\frac{d^{\nu-p}}{dx^{\nu-p}}(x-1)^{\nu-p}+0+\cdots+0\right\}_{x=1}\\
&\quad= -(f-2-\nu)(f-3-\nu)\cdots(f-p-1-\nu).
\end{aligned}$$

The scalar product is then given by $-(f-2-\nu)(f-3-\nu)\cdots(f-p-1-\nu)z^{f-p-2-\nu}$. The appropriate element of the $m$th row of the coefficient matrix $\mathcal{K}_\nu(z)$ that is multiplied by the nonzero element of the corresponding standard basis vector in the rotation matrix $J_{q\nu}$ is $z^{q-w+m-1}$, where $w = \nu-g+1$, and the appropriate derivative is $p$. We therefore have

$$(d^p/dz^p)\,z^{f-\nu-2} = (f-2-\nu)(f-3-\nu)\cdots(f-p-1-\nu)\,z^{f-p-2-\nu}. \tag{3.11}$$

Adding (3.10) to (3.11) confirms that the $q(\nu+1)$ column vector composed of $\delta_j^{\ell+1}(z)$ given in (3.9) and the corresponding standard basis vector in the rotation matrix $J_{q\nu}$ belongs to the null space of the coefficient matrix $\mathcal{K}_\nu(z)$. This completes the proof. ☐

**3.2.2. Summary of construction of the matrix $\boldsymbol{\mathcal{U}_j^{(1)}(z)}$.** *Step* 1. Define vector $\delta_j^{\ell+1}(z)$ according to (3.9) for $\ell = 0, 1, \ldots, j$.

*Step* 2. Derive the columns of matrix $\mathcal{U}_j^{(1)}(z)$ according to (3.8).

**3.2.3. A representation of $\mathcal{U}_j^{(2)}(z)$.** For $j = 1, 2, 3, \ldots, \nu - 1$, the submatrix $\mathcal{U}_j^{(2)}(z)$ admits the structure

$$\mathcal{U}_j^{(2)}(z) = \left(\kappa_j^1(z)\kappa_j^2(z)\cdots\kappa_j^{\nu-j}(z)\right). \tag{3.12}$$

To specify the basis vectors $\kappa_j^1(z)\ \kappa_j^2(z)\ldots\kappa_j^{\nu-j}(z)$, we first compute recursively for $j = 1$ and $k = 2, 3, \ldots, \nu - j$ the appropriate column vectors according to

$$\kappa_1^k = \kappa_1^{k-1} + \xi, \tag{3.13}$$

where $\xi$ is given in (3.4). A solution to recursion ( 3.13) in terms of the initial vector $\kappa_j^1$ whose form shall be introduced below is

$$\kappa_1^k = \kappa_1^1 + (k-1)\xi. \tag{3.14}$$

We can now compute recursively for $j = 2, 3, \ldots, \nu - 1$, according to

$$\kappa_j^k = \kappa_j^{k-1} + j\kappa_{j-1}^k. \tag{3.15}$$

In the next proposition, an explicit solution to recursion equations (3.15) and (3.13) shall be displayed for $j = 1, 2, 3, \ldots, \nu - 1$.

PROPOSITION 3.4. *An explicit solution to the recursion equations* (3.15) *and* (3.13)*, expressed in terms of the initial vectors* $\kappa_j^1$, $\kappa_{j-1}^1, \ldots, \kappa_2^1, \kappa_1^1$ *and the known vector* $\xi$*, is given by*

$$\kappa_j^k = \sum_{i=0}^{j-1} i! \binom{j}{i} \binom{k-2+i}{k-2} \kappa_{j-i}^1 + j! \binom{k+j-2}{k-2} \xi. \tag{3.16}$$

*Proof.* The proof consists of using the recursion equations (3.15) and (3.14). Take $j = 2$, a combination of (3.15) and (3.14) yields for $k = 2, 3, 4, \ldots$

$$\begin{aligned}
\kappa_2^2 &= \kappa_2^1 + 2\kappa_1^1 + 2\xi\\
\kappa_2^3 &= \kappa_2^1 + 4\kappa_1^1 + 6\xi\\
\kappa_2^4 &= \kappa_2^1 + 6\kappa_1^1 + 12\xi\\
&\vdots\\
\kappa_2^k &= \kappa_2^1 + 2(k-1)\kappa_1^1 + k(k-1)\xi. \qquad (3.17)
\end{aligned}$$

Similarily when $j = 3, 4$, the recursion exercise yields for the $k$th column

$$\kappa_3^k = \kappa_3^1 + 3(k-1)\kappa_2^1 + 3k(k-1)\kappa_1^1 + k(k^2-1)\xi, \tag{3.18}$$

$$\kappa_4^k = \kappa_4^1 + 4(k-1)\kappa_3^1 + 6k(k-1)\kappa_2^1 + 4k(k^2-1)\kappa_1^1 + k(k^2-1)(k+2)\xi. \tag{3.19}$$

From (3.17), (3.18), and (3.19) can be concluded that for all values of $j$, the solution is then given by (3.16), where the case $j = 1$ is also included. When $j = 1$, (3.16) becomes (3.14). $\square$

The columns $\kappa_j^k$ for $k = 1, 2, \ldots, \nu - j$ and $j = 1, 2, 3, \ldots, \nu - 1$ are essential for displaying the corresponding columns of the submatrix $\mathcal{U}_j^{(2)}(z)$ set forth in (3.12) and to obtain

$$\kappa_j^k(z) = \kappa_j^k \odot z^k u_{\nu+1}(z). \tag{3.20}$$

In order to start the recursions, the $(\nu+1)$ initial column vector $\kappa_j^1$ shall be introduced. For $j = 1, 2, \dots, \nu-1$, the components of the vector $\kappa_j^1$ are given by

$$\left\{\begin{array}{c} \left[\kappa_j^1\right]_1 = (j+1)!,\ \left[\kappa_j^1\right]_2 = ((j+1)!/2)\,(2\nu - j)\,, \\ \left[\kappa_j^1\right]_i = j!\binom{\nu+1}{i} - s_i,\ i = 3, \dots, \nu - j, \\ \left[\kappa_j^1\right]_i = j!\binom{\nu+1}{i},\ i = \nu - j + 1, \dots, \nu + 1, \end{array}\right. \tag{3.21}$$

where the terms $s_\ell$, encountered if $\nu \geq 5$, are defined by

$$s_\ell = \begin{cases} j!\begin{pmatrix} \nu - j \\ \ell \end{pmatrix}, & \ell = 3, 4, \dots, \nu - j \quad \text{for } j = 1, 2, \dots, \nu - 3, \\ 0, & \qquad \alpha > \nu - 3 \qquad\quad \text{for } \kappa_\alpha^1. \end{cases} \tag{3.22}$$

From (3.22) it can be concluded that when $j = \nu - 2$ and $j = \nu - 1$, $s_\ell = 0$ for the corresponding initial vectors $\kappa_{\nu-2}^1$ and $\kappa_{\nu-1}^1$ of the submatrices $\mathcal{U}_{j=\nu-2}^{(2)}(z)$ and $\mathcal{U}_{j=\nu-1}^{(2)}(z)$, respectively. For the case $q \leq 5$, the initial vectors $\kappa_j^1$ do not contain the terms $s_\ell$ so the elements of $\kappa_j^1$ to be considered are the two first elements and then pursuing the reading upwards, starting from the last term at the bottom.

The first part of the right-hand side of (3.16) is displayed in order to better understand the development of the proof of Lemma 3.6 by setting $\vartheta = \sum_{i=0}^{j-1}\binom{k-2+i}{k-2}$,

$$j!\begin{pmatrix} \sum_{i=0}^{j-1}\binom{k-2+i}{k-2}(j-i+1) \\ \sum_{i=0}^{j-1}\binom{k-2+i}{k-2}\,((j-i+1)/2)\,(2\nu - j + i) \\ \vartheta\binom{\nu+1}{3} - \sum_{i=0}^{j-1}\binom{k-2+i}{k-2}\binom{\nu-j+i}{3} \\ \vartheta\binom{\nu+1}{4} - \sum_{i=0}^{j-1}\binom{k-2+i}{k-2}\binom{\nu-j+i}{4} \\ \vdots \\ \vartheta\binom{\nu+1}{\nu-j} - \sum_{i=0}^{j-1}\binom{k-2+i}{k-2}\binom{\nu-j+i}{\nu-j} \\ \vartheta\binom{\nu+1}{\nu-j+1} \\ \vdots \\ \vartheta\binom{\nu+1}{\nu+1} \end{pmatrix}. \tag{3.23}$$

The sign pattern of the elements in each column of $\mathcal{U}_j^{(2)}(z)$ is given by $(-1)^\ell$ with $\ell = 1, 2, \dots, \nu + 1$.

First some results which shall be used in the proof of Lemma 3.6 are set forth.

PROPOSITION 3.5. *The following equalities hold true*:

$$\sum_{i=0}^{j-1}\begin{pmatrix} k-2+i \\ k-2 \end{pmatrix} = \begin{pmatrix} k-2+j \\ k-1 \end{pmatrix}, \tag{3.24}$$

$$\sum_{i=1}^{j-1}\begin{pmatrix} k-2+i \\ k-2 \end{pmatrix} i = \frac{j(j-1)}{k}\begin{pmatrix} k-2+j \\ k-2 \end{pmatrix}, \tag{3.25}$$

$$\sum_{i=1}^{j-1}\begin{pmatrix} k-2+i \\ k-2 \end{pmatrix} i^2 = \frac{j(j-1)(1+(j-1)k)}{k(k+1)}\begin{pmatrix} k-2+j \\ k-2 \end{pmatrix}. \tag{3.26}$$

*Proof.* We shall prove the equalities (3.24), (3.25), and (3.26) by applying mathematical induction.

It is straightforward to see that the left-hand side of equality (3.24) yields the right-hand side when $j = 1$.

Assume for $j = p$ that

$$\sum_{i=0}^{p-1} \binom{k-2+i}{k-2} = \binom{k-2+p}{k-1}.$$

This implies that for $j = p + 1$,

$$\begin{aligned}\sum_{i=0}^{p} \binom{k-2+i}{k-2} &= \sum_{i=0}^{p-1} \binom{k-2+i}{k-2} + \binom{k-2+p}{k-2}\\ &= \binom{k-2+p}{k-1} + \binom{k-2+p}{k-2}\\ &= \binom{k-1+p}{k-1}.\end{aligned}$$

The last equality is based on the elementary identity for integers $n$ and $j$:

$$\binom{n}{j} + \binom{n}{j+1} = \binom{n+1}{j+1}. \tag{3.27}$$

The proof of (3.24) is completed. When $j = 2$, the left-hand side of equality (3.25) is $\binom{k-1}{k-2}$ and equals the right-hand side which becomes $\frac{2}{k}\binom{k}{k-2}$ Assume that (3.25) is true for $j = p$. Then

$$\sum_{i=0}^{p-1} \binom{k-2+i}{k-2} i = \frac{p(p-1)}{k} \binom{k-2+p}{k-2},$$

for $j = p + 1$,

$$\begin{aligned}\sum_{i=0}^{p} \binom{k-2+i}{k-2} i &= \sum_{i=0}^{p-1} \binom{k-2+i}{k-2} i + p\binom{k-2+p}{k-2}\\ &= \frac{p(p-1)}{k} \binom{k-2+p}{k-2} + p\binom{k-2+p}{k-2}\\ &= \frac{(k+p-1)!}{(k-2)!(p-1)!k} = \frac{p(p+1)}{k}\binom{k-1+p}{k-2}.\end{aligned}$$

This confirms (3.25). Finally we prove (3.26). When $j = 2$, the left-hand side of equality (3.26) is $\binom{k-1}{k-2}$ and equals the right-hand side which becomes $\frac{2}{k}\binom{k}{k-2}$ Assume for $j = p$ that

$$\sum_{i=0}^{p-1} \binom{k-2+i}{k-2} i^2 = \frac{p(p-1)(1+(p-1)k)}{k(k+1)} \binom{k-2+p}{k-2}.$$

This implies that for $j = p+1$,

$$\begin{aligned}\sum_{i=0}^{p}\binom{k-2+i}{k-2}i^2 &= \sum_{i=0}^{p-1}\binom{k-2+i}{k-2}i^2 + p^2\binom{k-2+p}{k-2}\\ &= \frac{p(p-1)(1+(p-1)k)}{k(k+1)}\binom{k-2+p}{k-2} + p^2\binom{k-2+p}{k-2}\\ &= \frac{(1+pk)\,(k+p-1)(k+p-2)!}{(k-2)!\,(p-1)!k(k+1)}\\ &= \frac{p(p+1)(1+pk)}{k(k+1)}\binom{k-1+p}{k-2}.\end{aligned}$$

This completes the proof. □

We shall now continue with the following lemma.

LEMMA 3.6. *The* $q\,(\nu+1)$ *column vector composed of* $\kappa_j^k(z)$*, described in* (3.16) *and* (3.20)*, and the corresponding standard basis vector in* $\mathbb{R}^{q\nu}$ *belongs to the null space of the coefficient matrix* $\mathcal{K}_\nu(z)$*.*

*Proof.* The scalar product of (3.20) and (3.5) provides a monomial in $z^{n+k-\nu-2}$. The $z$-variables will be reintroduced at a later stage for typographical brevity. The scalar product is first computed for the last $\nu-1$ entries of the first column of (3.23), then sets $j=p$ in (3.16) and takes (3.24) into consideration yielding

(3.28)

$$\begin{aligned}&\frac{p!}{\nu!}\binom{k-2+p}{k-1}\sum_{i=0}^{\nu-2}(-1)^{i+1}\binom{\nu+1}{3+i}(n-4-i)(n-5-i)\cdots(n-\nu-3-i)\\ &\quad= \frac{p!}{\nu!}\binom{k-2+p}{k-1}\left\{\frac{d^\nu}{dx^\nu}\sum_{i=0}^{\nu-2}(-1)^{i+1}\binom{\nu+1}{3+i}x^{n-4-i}\right\}_{x=1}\\ &\quad= -\frac{p!}{\nu!}\binom{k-2+p}{k-1}\left\{\frac{d^\nu}{dx^\nu}\left[x^{n-2-\nu}\sum_{i=0}^{\nu-2}(-1)^{i}\binom{\nu+1}{3+i}x^{\nu-2-i}\right]\right\}_{x=1}.\end{aligned}$$

Then set $j = 3+i$

$$= \frac{p!}{\nu!}\binom{k-2+p}{k-1}\left\{\frac{d^\nu}{dx^\nu}\left[x^{n-2-\nu}\left(\sum_{j=3}^{\nu+1}(-1)^{j}\binom{\nu+1}{j}x^{\nu+1-j}\right)\right]\right\}_{x=1}. \tag{3.29}$$

The following holds:

$$\sum_{j=3}^{\nu+1}(-1)^{j}\binom{\nu+1}{j}x^{\nu+1-j} = \sum_{j=0}^{\nu+1}(-1)^{j}\binom{\nu+1}{j}x^{\nu+1-j} - \sum_{j=0}^{2}(-1)^{j}\binom{\nu+1}{j}x^{\nu+1-j}.$$

Equation (3.29) becomes

(3.30)

$$\begin{aligned}&\frac{p!}{\nu!}\binom{k-2+p}{k-1}\frac{d^\nu}{dx^\nu}\left\{x^{n-2-\nu}\left((x-1)^{\nu+1} - x^{\nu+1} + (\nu+1)x^\nu - \frac{\nu(\nu+1)}{2}x^{\nu-1}\right)\right\}_{x=1}\\ &\quad= \frac{p!}{\nu!}\binom{k-2+p}{k-1}\left\{\begin{array}{c} -(n-1)(n-2)\cdots(n-\nu)\\ +(\nu+1)(n-2)(n-3)\cdots(n-\nu-1)\\ -\dfrac{\nu(\nu+1)}{2}(n-3)(n-4)\cdots(n-\nu-2)\end{array}\right\}.\end{aligned}$$

We shall now focus on the part of (3.23) that contains $s_\ell$. For that purpose an explicit representation is displayed,

$$p!\left\{\binom{k-2}{k-2}\begin{pmatrix}\binom{\nu-p}{3}\\ \binom{\nu-p}{4}\\ \vdots\\ \binom{\nu-p}{\nu-p}\end{pmatrix}+\binom{k-1}{k-2}\begin{pmatrix}\binom{\nu-p+1}{3}\\ \binom{\nu-p+1}{4}\\ \vdots\\ \binom{\nu-p+1}{\nu-p+1}\end{pmatrix}\right.$$

$$\left.+\cdots+\binom{k+p-3}{k-2}\begin{pmatrix}\binom{\nu-1}{3}\\ \binom{\nu-1}{4}\\ \vdots\\ \binom{\nu-1}{\nu-1}\end{pmatrix}\right\}.$$

The scalar product of (3.5) with each of the columns above can be expressed as follows, consider the index $\ell = 0, 1, 2, \ldots, p-1$, to obtain

$$\frac{p!}{\nu!}\binom{k+\ell-2}{k-2}\sum_{i=0}^{\nu-p+\ell-3}(-1)^i\binom{\nu-p+\ell}{3+i}(n-4-i)(n-5-i)\cdots(n-\nu-3-i)$$

$$=\frac{p!}{\nu!}\binom{k+\ell-2}{k-2}\left\{\frac{d^\nu}{dx^\nu}\sum_{i=0}^{\nu-p+\ell-3}(-1)^i\binom{\nu-p+\ell}{3+i}x^{n-4-i}\right\}_{x=1}.$$

Set $j = 3+i$; it then yields

$$\frac{p!}{\nu!}\binom{k+\ell-2}{k-2}\left\{\frac{d^\nu}{dx^\nu}\sum_{j=3}^{\nu-p+\ell}(-1)^{j-3}\binom{\nu-p+\ell}{j}x^{n-j-1}\right\}_{x=1}$$

$$=-\frac{p!}{\nu!}\binom{k+\ell-2}{k-2}\left\{\frac{d^\nu}{dx^\nu}x^{n-\nu+p-\ell-1}\left(\sum_{j=3}^{\nu-p+\ell}(-1)^j\binom{\nu-p+\ell}{j}x^{\nu-p+\ell-j}\right)\right\}_{x=1}$$

$$=-\frac{p!}{\nu!}\binom{k+\ell-2}{k-2}\left\{\frac{d^\nu}{dx^\nu}x^{n-\nu+p-\ell-1}\left(\sum_{j=0}^{\nu-p+\ell}(-1)^j\binom{\nu-p+\ell}{j}x^{\nu-p+\ell-j}\right.\right.$$

$$\left.\left.-\sum_{j=0}^{2}(-1)^j\binom{\nu-p+\ell}{j}x^{\nu-p+\ell-j}\right)\right\}_{x=1}$$

$$=-\frac{p!}{\nu!}\binom{k+\ell-2}{k-2}\left\{\frac{d^\nu}{dx^\nu}\left(x^{n-\nu+p-\ell-1}(x-1)^{\nu-p+\ell}-x^{n-1}+(\nu-p+\ell)x^{n-2}\right.\right.$$

$$\left.\left.-\frac{(\nu-p+\ell-1)(\nu-p+\ell)}{2}x^{n-3}\right)\right\}_{x=1}.$$

The first term can be expanded according to Leibnitz rule for $\nu$-fold differentiation of a product of two functions,

$$\left\{0+0+\cdots+\binom{\nu}{\nu-p+\ell}\frac{d^{p-\ell}}{dx^{p-\ell}}x^{n-\nu+p-\ell-1}\frac{d^{\nu-p+\ell}}{dx^{\nu-p+\ell}}(x-1)^{\nu-p+\ell}+0+\cdots+0\right\}_{x=1}.$$

The result is then

$$\frac{p!}{\nu!}\binom{k+\ell-2}{k-2}\left\{\begin{array}{c}(n-1)(n-2)\cdots(n-\nu)\\ -(\nu-p+\ell)(n-2)(n-3)\cdots(n-\nu-1)\\ +\dfrac{(\nu-p+\ell-1)\,(\nu-p+\ell)}{2}(n-3)(n-4)\cdots(n-\nu-2)\end{array}\right\} \tag{3.31}$$

$$-\frac{p!}{(p-\ell)!}\binom{k+\ell-2}{k-2}(n-\nu+p-\ell-1)(n-\nu+p-\ell-2)\cdots(n-\nu). \tag{3.32}$$

Since $q=\nu+1$, the terms $(n-\nu),(n-\nu-1)$, and $(n-\nu-2)$ in (3.31) are positive and $(n-\nu-2)\geq 0$.

The terms involving $\frac{p!}{\nu!}(n-1)(n-2)\cdots(n-\nu)$ appearing in (3.30) and (3.31), the latter for $\ell=0,1,2,\ldots,p-1$, when added yield

$$\begin{aligned}&-\binom{k-2+p}{k-1}+\sum_{i=0}^{p-1}\binom{k-2+i}{k-2}\\ &=-\binom{k-2+p}{k-1}+\binom{k-2+p}{k-1}=0.\end{aligned}$$

The last equality is established by virtue of (3.24). A more explicit expression for the first term in (3.23) is now considered, with the corresponding minus sign. By virtue of (3.24) and (3.25) it can be seen that

$$\begin{aligned}-\frac{p!}{\nu!}\sum_{i=0}^{p-1}\binom{k-2+i}{k-2}(p-i+1)&=-\frac{p!}{\nu!}\left\{(p+1)\binom{k-2+p}{k-1}\right.\\ &\left.-\frac{p(p-1)}{k}\binom{k-2+p}{k-2}\right\}.\end{aligned}$$

In the scalar product, the first term of (3.23) is multiplied by $(n-2)(n-3)\cdots(n-\nu-1)$. Summing up all of the terms involving this product, which also appears in (3.30) and (3.31), yields

$$\begin{aligned}&\left\{-(p+1)\binom{k-2+p}{k-1}+\frac{p(p-1)}{k}\binom{k-2+p}{k-2}+\binom{k+p-2}{k-1}(\nu+1)\right.\\ &\left.\quad-\sum_{i=0}^{p-1}\binom{k-2+i}{k-2}(\nu-p+i)\right\}\\ &=-(p+1)\binom{k-2+p}{k-1}+\frac{p(p-1)}{k}\binom{k-2+p}{k-2}+\binom{k+p-2}{k-1}(\nu+1)\\ &\quad-(\nu-p)\binom{k+p-2}{k-1}-\frac{p(p-1)}{k}\binom{k-2+p}{k-2}=0.\end{aligned}$$

The last equality is established by virtue of (3.24) and (3.25).

We focus now on an explicit form of the second term of (3.23). By virtue of (3.24), (3.25), and (3.26) we obtain

(3.33)
$$\begin{aligned}&\frac{p!}{2}\sum_{i=0}^{p-1}\binom{k-2+i}{k-2}(p-i+1)\,(2\nu-p+i)\\&\quad=\frac{p!}{2}\left\{\begin{matrix}(p+1)\,(2\nu-p)\binom{k-2+p}{k-1}+(2p-2\nu+1)\dfrac{p(p-1)}{k}\binom{k-2+p}{k-2}\\ -\dfrac{p(p-1)(1+(p-1)k)}{k(k+1)}\binom{k-2+p}{k-2}\end{matrix}\right\}.\end{aligned}$$

In the scalar product, the term (3.33) is multiplied by $(n-3)(n-4)\cdots(n-\nu-2)$. Summing up all of the terms involving this product, without $(p!/\nu!)$, which also appears in (3.30) and (3.31), yields next to (3.33),

$$\left\{-\binom{k-2+p}{k-1}\frac{\nu(\nu+1)}{2}+\frac{1}{2}\sum_{i=0}^{p-1}\binom{k-2+i}{k-2}(\nu-p+i-1)\,(\nu-p+i)\right\}. \tag{3.34}$$

We now collect all of the terms involved to obtain

$$\begin{aligned}&\frac{(p+1)\,(2\nu-p)}{2}\binom{k-2+p}{k-1}+(2p-2\nu+1)\frac{p(p-1)}{2k}\binom{k-2+p}{k-2}\\&-\frac{p(p-1)(1+(p-1)k)}{2k(k+1)}\binom{k-2+p}{k-2}-\frac{\nu(\nu+1)}{2}\binom{k-2+p}{k-1}\\&+\frac{(\nu-p-1)\,(\nu-p)}{2}\binom{k-2+p}{k-1}+(2\nu-2p-1)\frac{p(p-1)}{2k}\binom{k-2+p}{k-2}\\&+\frac{p(p-1)(1+(p-1)k)}{2k(k+1)}\binom{k-2+p}{k-2}=0;\end{aligned}$$

as in the other cases, this result is obtained by using (3.24), (3.25), and (3.26).

Consequently, the remaining terms are now collected—it concerns the term involving $\xi$ in (3.16), the appropriate scalar product is by virtue of (3.7) $-p!\binom{k-2+p}{k-2}$, and the terms derived from (3.32), for $\ell=0,1,2,\dots,p-1$, to obtain

$$-\sum_{i=0}^{p-1}\frac{p!}{(p-i)!}\binom{k+i-2}{k-2}(n-\nu+p-i-1)(n-\nu+p-i-2)\cdots(n-\nu).$$

The remaining terms can be summarized according to

$$-p!\sum_{i=0}^{p-1}\binom{k+i-2}{k-2}\binom{n-\nu+p-i-1}{n-\nu-1}-p!\binom{k-2+p}{k-2}. \tag{3.35}$$

Concerning (3.35), the following property will be proved:

$$\sum_{i=0}^{p}\binom{k+i-2}{k-2}\binom{n-\nu+p-i-1}{n-\nu-1}=\binom{n-\nu+k+p-2}{n-\nu+k-2}. \tag{3.36}$$

For proving (3.36), we consider, for all nonnegative integers $l, p$ and $n \geq p$,

$$\binom{n+l+1}{p} = \sum_{i=0}^{p} \binom{l+i}{i} \binom{n-i}{p-i}. \tag{3.37}$$

The proof is based on (3.27), which we rewrite as

$$\binom{m}{j} + \binom{m}{j+1} = \binom{m+1}{j+1}. \tag{3.38}$$

First we prove the formula for $n = p$. In this case the identity (3.37) reduces to

$$\binom{l+p+1}{p} = \sum_{i=0}^{p} \binom{l+i}{i}.$$

We use induction w.r.t. the variable $p$. The case $p = 0$ is a triviality. Assume that (3.37) holds true for a certain value of $p$. Then

$$\sum_{i=0}^{p+1} \binom{l+i}{i} = \sum_{i=0}^{p} \binom{l+i}{i} + \binom{l+p+1}{p+1}.$$

The first term on the right-hand side is equal to $\binom{l+p+1}{p}$ by hypothesis. Then adding the second term gives $\binom{l+p+2}{p+1}$ by virtue of (3.38).

The rest of the proof is by induction w.r.t. the variable $n$, $n \geq p$, since we have settled the case $n = p$. Consider the right-hand side of (3.37) with $n + 1$ instead of $n$ and compute using the induction hypothesis two times and repeatedly the identity (3.38),

$$\begin{aligned} \sum_{i=0}^{p} \binom{l+i}{i} \binom{n+1-i}{p-i} &= \sum_{i=0}^{p} \binom{l+i}{i} \binom{n-i}{p-i} + \sum_{i=0}^{p-1} \binom{l+i}{i} \binom{n-i}{p-1-i} \\ &= \binom{n+l+1}{p} + \binom{n+l+1}{p-1} \\ &= \binom{n+l+2}{p}. \end{aligned}$$

From (3.35) and (3.36) it can be concluded that the scalar product is equal to

$$-(n-\nu+k+p-2)(n-\nu+k+p-3)\cdots(n-\nu+k-1)z^{n+k-\nu-2}. \tag{3.39}$$

The corresponding nonzero element of the standard basis vector in the rotation matrix $J_{q\nu}$ is multiplied by $z^{n-w-1}$ for $w = \nu - p + 1 - k$, and the appropriate derivative is

$$(d^p/dz^p)\, z^{n-\nu+k+p-2} = (n-\nu+k+p-2)(n-\nu+k+p-3)\cdots(n-\nu+k-1)z^{n+k-\nu-2}. \tag{3.40}$$

Adding (3.39) to (3.40) confirms that the $q\,(\nu+1)$ column vector composed of vector $\kappa_j^k(z)$, described in (3.16) and (3.20), and the corresponding standard basis vector in the rotation matrix $J_{q\nu}$ belongs to the null space of the coefficient matrix $\mathcal{K}_\nu(z)$ when $s_\ell \neq 0$ in (3.21).

We now proceed with the proof when $s_\ell = 0$ in (3.21), the cases $j = \nu - 1$ and $j = \nu - 2$ are therefore considered. The initial vector (3.21) for the former case is

$$\kappa^1_{\nu-1} = (\nu-1)! \left( \nu, \binom{\nu+1}{2}, \binom{\nu+1}{3}, \dots, \binom{\nu+1}{\nu+1} \right)^\top . \tag{3.41}$$

The scalar product involving the first $\nu+1$ elements is displayed, and the last $\nu$ entries of (3.41) are first considered to obtain

$$\frac{(\nu-1)!}{\nu!} \sum_{i=0}^{\nu-1} (-1)^i \binom{\nu+1}{2+i} (n-3-i)(n-4-i)\cdots(n-\nu-2-i).$$

The same approach as we used to derive (3.29) yields

$$\frac{(\nu-1)!}{\nu!} \left\{ \begin{matrix} -(n-1)(n-2)\cdots(n-\nu) \\ +(\nu+1)(n-2)(n-3)\cdots(n-\nu-1) \end{matrix} \right\}.$$

Adding the scalar product involving the first element of (3.41) and (3.5) yields

$$\begin{aligned} &\left\{ \begin{matrix} -(n-2)(n-3)\cdots(n-\nu-1) \\ +\dfrac{(\nu-1)!\,(\nu+1)}{\nu!}(n-2)(n-3)\cdots(n-\nu-1) \\ -\dfrac{(\nu-1)!}{\nu!}(n-1)(n-2)\cdots(n-\nu) \end{matrix} \right\} \\ &= -(n-2)(n-3)\cdots(n-\nu). \end{aligned}$$

This result is obtained through straightforward calculation. It can now be concluded that the scalar product is

$$-(n-2)(n-3)\cdots(n-\nu) z^{n-\nu-1}. \tag{3.42}$$

Note for the case under study, $k = 1$ (it concerns the initial vector $\kappa^1_{\nu-1}$). The corresponding nonzero element of the standard basis vector in the rotation matrix $J_{q\nu}$ is multiplied by $z^{n-w-1}$ for $w = 2 - k$, $w = \nu - p + 1 - k$ in the general case. The appropriate derivative is then

$$\left(d^{\nu-1}/dz^{\nu-1}\right) z^{n-2} = (n-2)(n-3)\cdots(n-\nu) z^{n-\nu-1}. \tag{3.43}$$

Adding (3.42) to (3.43) confirms that when in (3.21) $s_\ell = 0$ and $j = \nu-1$, the $q\,(\nu+1)$ column vector, composed of vector $\kappa^1_{\nu-1}$, given in (3.41), and the corresponding standard basis vector in the rotation matrix $J_{q\nu}$, belongs to the null space of the coefficient matrix $\mathcal{K}_\nu(z)$.

The case $j = \nu - 2$ is considered next. The initial vector (3.21) is then

$$\kappa^1_{\nu-2} = (\nu-2)! \left( (\nu-1), ((\nu-1)/2)(\nu+2), \binom{\nu+1}{3}, \dots, \binom{\nu+1}{\nu+1} \right)^\top . \tag{3.44}$$

The scalar product involving the first $\nu+1$ elements is displayed, and the last $(\nu-1)$ entries of (3.44) are first considered to obtain

$$\frac{(\nu-2)!}{\nu!} \sum_{i=0}^{\nu-2} (-1)^{i+1} \binom{\nu+1}{3+i} (n-4-i)(n-5-i)\cdots(n-\nu-3-i).$$

According to (3.28) we have

$$\frac{(\nu-2)!}{\nu!}\left\{\begin{array}{c} -(n-1)(n-2)\cdots(n-\nu) \\ +(\nu+1)(n-2)(n-3)\cdots(n-\nu-1) \\ -\dfrac{\nu(\nu+1)}{2}(n-3)(n-4)\cdots(n-\nu-2) \end{array}\right\}.$$

The scalar product involving the first and second elements of (3.44) and (3.5) are

$$\begin{array}{l} -\dfrac{(\nu-1)!}{\nu!}(n-2)(n-3)\cdots(n-\nu-1) \\ \text{and}\quad \dfrac{((\nu-1)!/2)\,(\nu+2)}{\nu!}(n-3)(n-4)\cdots(n-\nu-2), \end{array}$$

respectively. Summing all of the terms yields

$$\begin{array}{l} \left\{\begin{array}{c} \frac{(\nu-2)!(\nu+1)-(\upsilon-1)!}{\nu!}(n-2)(n-3)\cdots(n-\nu-1) \\ +\frac{(\nu-1)!(\nu+2)-(\nu-2)!\nu(\nu+1)}{2(\nu!)}(n-3)(n-4)\cdots(n-\nu-2) \\ -\frac{(\nu-2)!}{\nu!}(n-1)(n-2)\cdots(n-\nu) \end{array}\right\} \\ = -(n-3)(n-4)\cdots(n-\nu). \end{array}$$

This result is obtained through straightforward computation. It can now be concluded that the scalar product is

$$-(n-3)(n-4)\cdots(n-\nu)z^{n-\nu-1}. \tag{3.45}$$

Note for the case under study, $k=1$ (it concerns the initial vector $\kappa_{\nu-2}^1$).

The corresponding nonzero element of the standard basis vector in the rotation matrix $J_{q\nu}$ is multiplied by $z^{n-w-1}$ for $w=3-k$ and $w=\nu-p+1-k$ in the general case. The appropriate derivative is then

$$\left(d^{\nu-2}/dz^{\nu-2}\right)z^{n-3}=(n-3)(n-4)\cdots(n-\nu)z^{n-\nu-1}. \tag{3.46}$$

Adding (3.45) to (3.46) confirms that when in (3.21) $s_\ell=0$ and $j=\nu-2$, the $q\,(\nu+1)$ column vector, composed of vector $\kappa_{\nu-2}^1$, given in (3.44), and the corresponding standard basis vector in the rotation matrix $J_{q\nu}$, belongs to the null space of the coefficient matrix $\mathcal{K}_\nu(z)$.

It can be concluded that the $q\,(\nu+1)$ column vector, composed of vector $\kappa_j^k(z)$, described in (3.16) and (3.20), and the corresponding standard basis vector in the rotation matrix $J_{q\nu}$, belongs to the null space of the coefficient matrix $\mathcal{K}_\nu(z)$. The proof of Lemma 3.6 is now complete. ☐

**3.2.4. Summary of the construction of matrix $\mathcal{U}_j^{(2)}(z)$.** *Step* 1. Define the initial vectors $\kappa_j^1$ given in (3.21) for the values of $j=1,2,3,\ldots,\nu-1$.

*Step* 2. Expand (3.16) for the corresponding values of $j=1,2,3,\ldots,\nu-1$.

*Step* 3. Compute the columns of $\mathcal{U}_j^{(2)}(z)$ according to (3.20) for the corresponding values of $j=1,2,3,\ldots,\nu-1$.

In the next section an example will illustrate the results set forth in previous sections.

**3.3. Example Ker $(\mathcal{K}_\nu(z))$ for the case $\nu + 1 = 6$.** This case will be illustrated for $q = 6$ and $\nu = 5$. The first submatrix contained in the null space of $\mathcal{K}_\nu(z)$ is then

$$\mathcal{U}_0(z) = \begin{pmatrix} -1 & -z & -z^2 & -z^3 & -z^4 & -z^5 \\ 5z & 5z^2 & 5z^3 & 5z^4 & 5z^5 & 5z^6 \\ -10z^2 & -10z^3 & -10z^4 & -10z^5 & -10z^6 & -10z^7 \\ 10z^3 & 10z^4 & 10z^5 & 10z^6 & 10z^7 & 10z^8 \\ -5z^4 & -5z^5 & -5z^6 & -5z^7 & -5z^8 & -5z^9 \\ z^5 & z^6 & z^7 & z^8 & z^9 & z^{10} \end{pmatrix}.$$

This is followed by the second class of submatrices $\mathcal{U}_j(z)$ when $j = 1, 2, 3, 4$,

$$\mathcal{U}^{(1)}_{j=1}(z) = \begin{pmatrix} 0 & -1 \\ -1 & 4z \\ 4z & -6z^2 \\ -6z^2 & 4z^3 \\ 4z^3 & -z^4 \\ -z^4 & 0 \end{pmatrix}, \quad \mathcal{U}^{(1)}_{j=2}(z) = \begin{pmatrix} 0 & 0 & -2 \\ 0 & -2 & 6z \\ -2 & 6z & -6z^2 \\ 6z & -6z^2 & 2z^3 \\ -6z^2 & 2z^3 & 0 \\ 2z^3 & 0 & 0 \end{pmatrix},$$

$$\mathcal{U}^{(1)}_{j=3}(z) = \begin{pmatrix} 0 & 0 & 0 & -6 \\ 0 & 0 & -6 & 12z \\ 0 & -6 & 12z & -6z^2 \\ -6 & 12z & -6z^2 & 0 \\ 12z & -6z^2 & 0 & 0 \\ -6z^2 & 0 & 0 & 0 \end{pmatrix},$$

and

$$\mathcal{U}^{(1)}_{j=4}(z) = \begin{pmatrix} 0 & 0 & 0 & 0 & -24 \\ 0 & 0 & 0 & -24 & 24z \\ 0 & 0 & -24 & 24z & 0 \\ 0 & -24 & 24z & 0 & 0 \\ -24 & 24z & 0 & 0 & 0 \\ 24z & 0 & 0 & 0 & 0 \end{pmatrix}.$$

This is then followed by a class of submatrices $\mathcal{U}^{(2)}_j(z)$ when $j = 1, 2, 3, 4$,

$$\mathcal{U}^{(2)}_{j=1}(z) = \begin{pmatrix} -2z & -3z^2 & -4z^3 & -5z^4 \\ 9z^2 & 14z^3 & 19z^4 & 24z^5 \\ -16z^3 & -26z^4 & -36z^5 & -46z^6 \\ 14z^4 & 24z^5 & 34z^6 & 44z^7 \\ -6z^5 & -11z^6 & -16z^7 & -21z^8 \\ z^6 & 2z^7 & 3z^8 & 4z^9 \end{pmatrix},$$

$$\mathcal{U}^{(2)}_{j=2}(z) = \begin{pmatrix} -6z & -12z^2 & -20z^3 \\ 24z^2 & 52z^3 & 90z^4 \\ -38z^3 & -90z^4 & -162z^5 \\ 30z^4 & 78z^5 & 146z^6 \\ -12z^5 & -34z^6 & -66z^7 \\ 2z^6 & 6z^7 & 12z^8 \end{pmatrix},$$

$$\mathcal{U}^{(2)}_{j=3}(z) = \begin{pmatrix} -24z & -60z^2 \\ 84z^2 & 240z^3 \\ -120z^3 & -390z^4 \\ 90z^4 & 324z^5 \\ -36z^5 & -138z^6 \\ 6z^6 & 24z^7 \end{pmatrix}, \text{ and}$$

$$\mathcal{U}^{(2)}_{j=4}(z) = \begin{pmatrix} -120z \\ 360z^2 \\ -480z^3 \\ 360z^4 \\ -144z^5 \\ 24z^6 \end{pmatrix}.$$

Insertion of $\mathcal{U}_0(z)$ and the matrices

$$\begin{aligned} \mathcal{U}_1(z) &= \left( \mathcal{U}^{(1)}_{j=1}(z)\, \mathcal{U}^{(2)}_{j=1}(z) \right), \\ \mathcal{U}_2(z) &= \left( \mathcal{U}^{(1)}_{j=2}(z)\, \mathcal{U}^{(2)}_{j=2}(z) \right), \\ \mathcal{U}_3(z) &= \left( \mathcal{U}^{(1)}_{j=3}(z)\, \mathcal{U}^{(2)}_{j=3}(z) \right), \\ \mathcal{U}_4(z) &= \left( \mathcal{U}^{(1)}_{j=4}(z)\, \mathcal{U}^{(2)}_{j=4}(z) \right), \end{aligned}$$

in (3.2) yields the form

$$\mathcal{U}(z) = \frac{1}{5!} \left( \mathcal{U}_0(z), \mathcal{U}_1(z), \mathcal{U}_2(z), \mathcal{U}_3(z), \mathcal{U}_4(z) \right).$$

The columns that compose $\binom{\mathcal{U}(z)}{J_{30}}$ span Ker $(\mathcal{K}_\nu(z))$ when $q = 6$ and $\nu = 5$.

In the next section the null space of the coefficient matrix $\mathcal{M}_\tau(\rho)$ is set forth.

## 4. A representation of Ker $(\mathcal{M}_\tau(\rho))$.

In this section a representation of the subspace Ker$(\mathcal{M}_\tau(\rho))$ is displayed for the case $\tau + 1 = p$. The coefficient matrix $\mathcal{M}_\tau(z)$ is considered for $z = \rho$, and a motivation is formulated below. We shall first focus on the dimension of the null space Ker$(\mathcal{M}_\tau(\rho))$.

PROPOSITION 4.1. *The null space Ker*$(\mathcal{M}_\tau(\rho))$ *has dimension equal to* $p\tau$ *and the rank of the coefficient matrix* $(\mathcal{M}_\tau(\rho))$ *is* $p$, *when* $\tau + 1 = p$.

*Proof.* By virtue of Corollary 2.2, a similar argument as in Proposition 3.1 holds for the coefficient matrix $\mathcal{M}_\tau(\rho)$; see also Lemma 2.4 in [5]. It can be concluded that the $p \times p(\tau + 1)$ coefficient matrix $\mathcal{M}_\tau(\rho)$ is surjective or has full row rank; its rank is then $p$. By virtue of the dimension rule, it can be concluded that dim Ker$(\mathcal{K}_\nu(z)) = p\tau$. ☐

We can essentially reduce the problem of computing the null space Ker$(\mathcal{M}_\tau(\rho))$ to the computation of the kernel of the matrix $\mathcal{K}_\tau(\rho)$. The vectors contained in

$$\mathcal{G} = \begin{pmatrix} \mathcal{Y}(\rho) \\ J_{p\tau} \end{pmatrix} \tag{4.1}$$

span the null space of $\mathcal{M}_\tau(\rho)$, where $J_{p\tau}$ is the $p\tau$ rotation matrix.

Observe that $\mathcal{G}$ has full rank $p\tau$ since $J_{p\tau}$ is a nonsingular submatrix of $\mathcal{G}$. Therefore the columns of $\mathcal{G}$ form a basis of Ker$(\mathcal{M}_\tau(\rho))$.

Write

$$\mathcal{Y}(\rho) = \frac{1}{\tau!}\left(\mathcal{Y}_0(\rho), \mathcal{Y}_1(\rho), \mathcal{Y}_2(\rho), \ldots, \mathcal{Y}_{\tau-1}(\rho)\right), \tag{4.2}$$

where

$$\mathcal{Y}_0(\rho) = \mathcal{U}_0^\top(\rho)$$

and

$$\mathcal{Y}_j(\rho) = \begin{pmatrix} \mathcal{Y}_j^{(1)}(\rho) \\ \mathcal{Y}_j^{(2)}(\rho) \end{pmatrix} = \begin{pmatrix} \left(\mathcal{U}_j^{(1)}(\rho)\right)^\top \\ \left(\mathcal{U}_j^{(2)}(\rho)\right)^\top \end{pmatrix} = \mathcal{U}_j^\top(\rho) \quad \text{for} \quad j = 1, 2, \ldots, \tau - 1.$$

The matrices $\mathcal{U}_0(\rho)$, $\mathcal{U}_j^{(1)}(\rho)$, and $\mathcal{U}_j^{(2)}(\rho)$ are given in section 3.

In section 3.2 of [5], the vector $y \in \text{Ker }(\mathcal{M}_\tau(\rho))$ is computed according to

$$y = (I_{\tau+1} \otimes S(f))^{-1} x, \tag{4.3}$$

where $x \in \text{Ker }(\mathcal{K}_\tau(\rho))$ and the $p \times p$ symmetrizer $S(f)$ is associated with a polynomial $f(z)$ of degree $p$. Consider $f(z) = z^p + a_1 z^{p-1} + a_2 z^{p-2} + \cdots + a_p$, then the $p \times p$ matrix $S(f)$ is

$$S(f) = \begin{pmatrix} 1 & 0 & 0 & \cdots & 0 \\ a_1 & 1 & 0 & & \vdots \\ \vdots & & \ddots & \ddots & 0 \\ \vdots & & & 1 & 0 \\ a_{p-1} & & & a_1 & 1 \end{pmatrix}.$$

Formula (4.3) is derived from an equality which connects the matrices $\text{adj}(zI - C_p)$ and $u_p(z) u_p^{*\top}(z)$, where $u_p(z)$ and $u_p^*(z)$ are defined in (1.4). From [6], we take Proposition 3.1 which gives the identity

$$\text{adj}\,(zI - C_p) = u_p(z) a^\top(z)\, J_p - \pi(z) \sum_{i=0}^{p-1} z^i S^{i+1}. \tag{4.4}$$

The vector $a\,(z)$ is the $p$-vector $(a_0\,(z), \ldots, a_{p-1}\,(z))$, where $a_k\,(z)$ is the Hörner polynomial defined by $a_0\,(z) = 1$ and $a_k\,(z) = z a_{k-1}\,(z) + a_k$, and $a_k$ is an entry of $C_p$. Note that $a_p\,(z)$ is the characteristic polynomial of $C_p$. We further have that the rotation matrix $J_p \in \mathbb{R}^{p \times p}$, $\pi(z)$ is the characteristic polynomial of $C_p$ and $S$ denotes the shift matrix, so $S_{ij} = \delta_{i,j+1}$. Observe that the property $a^\top(z)\, J_p = u_p^*(z)^\top S(f)$ is used in (4.4) to obtain (4.3).

If $z = \rho$, where $\rho$ is an eigenvalue of the companion matrix $C_p$, then the second term in the right-hand side of (4.4) vanishes. It is then possible to derive form (4.3) (see [5]), and this is the reason why in this section one chooses working with $z = \rho$ instead of $z$.

A relation between the submatrices $\mathcal{Y}(\rho)$ in (4.2) and $\mathcal{U}(\rho)$ in (3.2) can now be displayed through equality (4.3). For that purpose we denote the vectors $v_0(\rho)$, $v_1(\rho)$, $v_2(\rho), \ldots, v_{\tau-1}(\rho)$ as being the first columns of the submatrices $\mathcal{U}_0(\rho)$, $\mathcal{U}_1(\rho)$,

$\mathcal{U}_2(\rho), \ldots, \mathcal{U}_{\tau-1}(\rho)$, given in (3.2). Whereas the vectors $w_0(\rho)$, $w_1(\rho)$, $w_2(\rho), \ldots, w_{\tau-1}(\rho)$ represent the first rows of the same submatrices. The following property is now summarized in the lemma.

LEMMA 4.2. *By virtue of* (4.3), *the following equalities hold true for* $i = 0, 1, 2, \ldots, \tau - 1$*:*

$$y_i(\rho) = S^{-1}(f)v_i(\rho) = w_i^\top(\rho),$$

*where* $y_0(\rho)$, $y_1(\rho)$, $y_2(\rho), \ldots, y_{\tau-1}(\rho)$ *are the first columns of the submatrices* $\mathcal{Y}_0(\rho)$, $\mathcal{Y}_1(\rho), \mathcal{Y}_2(\rho), \ldots, \mathcal{Y}_{\tau-1}(\rho)$ *given in* (4.2).

*Proof.* Straightforward matrix multiplications $S^{-1}(f)v_i(\rho)$ confirm the property. ☐

This leads to the main result of this section.

COROLLARY 4.3. *For the case* $\tau + 1 = p$, *the span of the null space of* $\mathcal{M}_\tau(\rho)$ *is*

$$\begin{pmatrix} \mathcal{Y}(\rho) \\ J_{p\tau} \end{pmatrix},$$

*where* $\mathcal{Y}(\rho)$ *is given by* (4.2).

*Proof.* It can be verified through matrix multiplications that

$$\mathcal{M}_\tau(\rho) \begin{pmatrix} \mathcal{Y}(\rho) \\ J_{p\tau} \end{pmatrix} = 0$$

holds. This is in agreement with the appropriate dimensions specified above. ☐

It can be seen from (4.3) that for every vector $y \in \text{Ker}\ (\mathcal{M}_\tau(\rho))$ computed according to the approach suggested in [5], the symmetrizer $S(f)$, a lower triangular and Toeplitz matrix has to be inverted once. However, this is combined with $p\tau$ matrix multiplications by the corresponding vector $x \in \text{Ker}\ (\mathcal{K}_\tau(\rho))$. This is in agreement with the dimension of the null space of $\mathcal{M}_\tau(\rho)$. In this paper there are neither matrix multiplications nor inversions involved in the construction of the span of the null spaces of $\mathcal{K}_\tau(\rho)$ and $\mathcal{M}_\tau(\rho)$. The null space of $\mathcal{M}_\tau(\rho)$ is obtained by transposing the submatrices contained in the null space of $\mathcal{K}_\tau(\rho)$. Consequently, when the algorithm of the null space of $\mathcal{K}_\tau(\rho)$ is available, the new approach does not require any computational exercise for displaying the span of the null space of $\mathcal{M}_\tau(\rho)$. In the next section an example of the null space of $\mathcal{M}_\tau(\rho)$ is set forth so that the property emphasized in this section will be illustrated.

**4.1. Example Ker ($\mathcal{M}_\tau(\rho)$) when $\tau + 1 = 7$.** This case will be illustrated for $p = 7$ and $\tau = 6$. The first matrix is then

$$\mathcal{Y}_0(\rho) = \begin{pmatrix} -1 & 6\rho & -15\rho^2 & 20\rho^3 & -15\rho^4 & 6\rho^5 & -\rho^6 \\ -\rho & 6\rho^2 & -15\rho^3 & 20\rho^4 & -15\rho^5 & 6\rho^6 & -\rho^7 \\ -\rho^2 & 6\rho^3 & -15\rho^4 & 20\rho^5 & -15\rho^6 & 6\rho^7 & -\rho^8 \\ -\rho^3 & 6\rho^4 & -15\rho^5 & 20\rho^6 & -15\rho^7 & 6\rho^8 & -\rho^9 \\ -\rho^4 & 6\rho^5 & -15\rho^6 & 20\rho^7 & -15\rho^8 & 6\rho^9 & -\rho^{10} \\ -\rho^5 & 6\rho^6 & -15\rho^7 & 20\rho^8 & -15\rho^9 & 6\rho^{10} & -\rho^{11} \\ -\rho^6 & 6\rho^7 & -15\rho^8 & 20\ \rho^9 & -15\rho^{10} & 6\rho^{11} & -\rho^{12} \end{pmatrix}.$$

The following class of matrices are for $j = 1, 2, 3, 4, 5$:

$$\mathcal{Y}_{j=1}^{(1)}(\rho) = \begin{pmatrix} 0 & -1 & 5\rho & -10\rho^2 & 10\rho^3 & -5\rho^4 & \rho^5 \\ -1 & 5\rho & -10\rho^2 & 10\rho^3 & -5\rho^4 & \rho^5 & 0 \end{pmatrix},$$

$$\mathcal{Y}^{(1)}_{j=2}(\rho) = \begin{pmatrix} 0 & 0 & -2 & 8\rho & -12\rho^2 & 8\rho^3 & -2\rho^4 \\ 0 & -2 & 8\rho & -12\rho^2 & 8\rho^3 & -2\ \rho^4 & 0 \\ -2 & 8\rho & -12\rho^2 & 8\rho^3 & -2\rho^4 & 0 & 0 \end{pmatrix} ,$$

$$\mathcal{Y}^{(1)}_{j=3}(\rho) = \begin{pmatrix} 0 & 0 & 0 & -6 & 18\rho & -18\rho^2 & 6\rho^3 \\ 0 & 0 & -6 & 18\rho & -18\rho^2 & 6\rho^3 & 0 \\ 0 & -6 & 18\rho & -18\rho^2 & 6\rho^3 & 0 & 0 \\ -6 & 18\rho & -18\rho^2 & 6\rho^3 & 0 & 0 & 0 \end{pmatrix},$$

$$\mathcal{Y}^{(1)}_{j=4}(\rho) = \begin{pmatrix} 0 & 0 & 0 & 0 & -24 & 48\rho & -24\rho^2 \\ 0 & 0 & 0 & -24 & 48\rho & -24\rho^2 & 0 \\ 0 & 0 & -24 & 48\rho & -24\rho^2 & 0 & 0 \\ 0 & -24 & 48\rho & -24\rho^2 & 0 & 0 & 0 \\ -24 & 48\rho & -24\rho^2 & 0 & 0 & 0 & 0 \end{pmatrix},$$

$$\mathcal{Y}^{(1)}_{j=5}(\rho) = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & -120 & 120\rho \\ 0 & 0 & 0 & 0 & -120 & 120\rho & 0 \\ 0 & 0 & 0 & -120 & 120\rho & 0 & 0 \\ 0 & 0 & -120 & 120\rho & 0 & 0 & 0 \\ 0 & -120 & 120\rho & 0 & 0 & 0 & 0 \\ -120 & 120\rho & 0 & 0 & 0 & 0 & 0 \end{pmatrix}.$$

The matrices $\mathcal{Y}^{(2)}_j(\rho)$ with $j = 1, 2, 3, 4, 5$ are now displayed:

$$\mathcal{Y}^{(2)}_{j=1}(\rho) = \begin{pmatrix} -2\rho & 11\rho^2 & -25\rho^3 & 30\rho^4 & -20\rho^5 & 7\rho^6 & -\rho^7 \\ -3\rho^2 & 17\rho^3 & -40\rho^4 & 50\rho^5 & -35\rho^6 & 13\rho^7 & -2\rho^8 \\ -4\rho^3 & 23\rho^4 & -55\rho^5 & 70\rho^6 & -50\rho^7 & 19\rho^8 & -3\rho^9 \\ -5\rho^4 & 29\rho^5 & -70\rho^6 & 90\rho^7 & -65\rho^8 & 25\rho^9 & -4\rho^{10} \\ -6\rho^5 & 35\rho^6 & -85\rho^7 & 110\rho^8 & -80\rho^9 & 31\rho^{10} & -5\rho^{11} \end{pmatrix},$$

$$\mathcal{Y}^{(2)}_{j=2}(\rho) = \begin{pmatrix} -6\rho & 30\rho^2 & -62\rho^3 & 68\rho^4 & -42\rho^5 & 14\rho^6 & -2\rho^7 \\ -12\rho^2 & 64\rho^3 & -142\rho^4 & 168\rho^5 & -112\rho^6 & 40\rho^7 & -6\rho^8 \\ -20\rho^3 & 110\rho^4 & -252\rho^5 & 308\rho^6 & -212\rho^7 & 78\ \rho^8 & -12\rho^9 \\ -30\rho^4 & 168\rho^5 & -392\rho^6 & 488\rho^7 & -342\rho^8 & 128\ \rho^9 & -20\rho^{10} \end{pmatrix},$$

$$\mathcal{Y}^{(2)}_{j=3}(\rho) = \begin{pmatrix} -24\rho & 108\rho^2 & -204\rho^3 & 210\rho^4 & -126\rho^5 & 42\rho^6 & -6\rho^7 \\ -60\rho^2 & 300\rho^3 & -630\rho^4 & 714\rho^5 & -462\rho^6 & 162\ \rho^7 & -24\ \rho^8 \\ -120\rho^3 & 630\rho^4 & -1386\rho^5 & 1638\rho^6 & -1098\rho^7 & 396\ \rho^8 & -60\rho^9 \end{pmatrix},$$

$$\mathcal{Y}^{(2)}_{j=4}(\rho) = \begin{pmatrix} -120\rho & 480\rho^2 & -840\rho^3 & 840\rho^4 & -504\rho^5 & 168\rho^6 & -24\rho^7 \\ -360\rho^2 & 1680\rho^3 & -3360\rho^4 & 3696\rho^5 & -2352\rho^6 & 816\ \rho^7 & -120\rho^8 \end{pmatrix},$$

$$\mathcal{Y}^{(2)}_{j=5}(\rho) = \begin{pmatrix} -720\rho & 2520\rho^2 & -4200\rho^3 & 4200\rho^4 & -2520\rho^5 & 840\rho^6 & -120\rho^7 \end{pmatrix}.$$

Insertion of the matrix $\mathcal{Y}_0(\rho)$ in (4.2) followed by

$$\mathcal{Y}_1(\rho) = \begin{pmatrix} \mathcal{Y}^{(1)}_{j=1}(\rho) \\ \mathcal{Y}^{(2)}_{j=1}(\rho) \end{pmatrix}, \quad \mathcal{Y}_2(\rho) = \begin{pmatrix} \mathcal{Y}^{(1)}_{j=2}(\rho) \\ \mathcal{Y}^{(2)}_{j=2}(\rho) \end{pmatrix},$$

$$\mathcal{Y}_3(\rho) = \begin{pmatrix} \mathcal{Y}^{(1)}_{j=3}(\rho) \\ \mathcal{Y}^{(2)}_{j=3}(\rho) \end{pmatrix}, \quad \mathcal{Y}_4(\rho) = \begin{pmatrix} \mathcal{Y}^{(1)}_{j=4}(\rho) \\ \mathcal{Y}^{(2)}_{j=4}(\rho) \end{pmatrix}, \quad \mathcal{Y}_5(\rho) = \begin{pmatrix} \mathcal{Y}^{(1)}_{j=5}(\rho) \\ \mathcal{Y}^{(2)}_{j=5}(\rho) \end{pmatrix}$$

yields the representation

$$\mathcal{Y}(\rho) = \frac{1}{6!}\left( \mathcal{Y}_0(\rho), \mathcal{Y}_1(\rho), \mathcal{Y}_2(\rho), \mathcal{Y}_3(\rho), \mathcal{Y}_4(\rho), \mathcal{Y}_5(\rho)\right).$$

The vectors contained in $\binom{\mathcal{Y}(\rho)}{J_{42}}$ span the null space of $\mathcal{M}_\tau(\rho)$ when $p = 7$ and $\tau = 6$. It is straightforward to verify that when the matrices $\mathcal{Y}_0(\rho)$, $\mathcal{Y}_j^{(1)}(\rho)$, and $\mathcal{Y}_j^{(2)}(\rho)$, with $j = 1, 2, 3, 4, 5$, are transposed and inserted in (3.2) accordingly, one obtains the null space of $\mathcal{K}_\tau(\rho)$.

A summary of the results will be given in the next section.

**5. Main conclusions.** The results displayed in sections 2–4 allow us to present an explicit representation of the solutions to the linear systems of equations introduced in this paper. The solutions, (1.5) and (1.6), to the linear system of (1.1) and (1.2) are given by

$$\begin{aligned} X &= (\mathcal{K}_\nu(z))^- \,\mathcal{E} + \mathcal{W}(z) \text{ with } \mathcal{W}(z) \in \operatorname{Ker}(\mathcal{K}_\nu(z)),\\ Y &= (\mathcal{M}_\tau(\rho))^- \,\mathcal{R} + \mathcal{L}(\rho) \text{ with } \mathcal{L}(\rho) \in \operatorname{Ker}(\mathcal{M}_\tau(\rho)). \end{aligned}$$

An explicit expression for $(\mathcal{K}_\nu(z))^-$ and $\mathcal{W}(z)$ has been developed in sections 2 and 3, respectively, and a solution to the linear system of equations (1.1) is implementable. Analogously for the expressions $(\mathcal{M}_\tau(\rho))^-$ and $\mathcal{L}(\rho)$, constructed in sections 2 and 4, respectively, a solution to the linear system of (1.2) is implementable.

In the next section an algorithm for the null space $\operatorname{Ker}(\mathcal{K}_\nu(z))$, for the case $\nu + 1 < q$, is presented. It is a variant of the algorithm displayed in section 3.

**6. Ker ($\mathcal{K}_\nu(z)$) for the case $\nu + 1 < q$.** In this section the case $\nu + 1 < q$ is considered for the null space Ker ($\mathcal{K}_\nu(z)$). We then have $\operatorname{rank}(\mathcal{K}_\nu(z)) = \nu + 1$ so that $\dim \operatorname{Ker}(\mathcal{K}_\nu(z)) = (q - 1)(\nu + 1)$. In this case the coefficient matrix $\mathcal{K}_\nu(z)$ is not surjective, so a Moore–Penrose generalized inverse should be used when one is interested in a solution of (1.1). This can be a subject for future research. Consider the null space of the coefficient matrix $\mathcal{K}_\nu(z)$,

$$\operatorname{Ker} \mathcal{K}_\nu(z) = \operatorname{span} \begin{pmatrix} \mathcal{U}(z) \\ J_{(q-1)(\nu+1)} \end{pmatrix},$$

where $J_{(q-1)(\nu+1)}$ is the $(q - 1)(\nu + 1)$ rotation matrix. An algorithm of the matrix $\mathcal{U}(z)$ contained in $\operatorname{Ker}(\mathcal{K}_\nu(z))$ will be set forth to obtain

$$\mathcal{U}(z) = \frac{1}{\nu!}\left(\mathcal{U}_0(z), \mathcal{U}_1(z), \mathcal{U}_2(z), \ldots, \mathcal{U}_{\nu-1}(z)\right).$$

In this section no proofs are provided since they are similar to the proofs done in section 3.

**6.1. A representation for $\mathcal{U}_0(z)$.** An appropriate partition is $\mathcal{U}_0(z) = (\mathcal{U}_0^{(1)}(z)\ \mathcal{U}_0^{(2)}(z))$. For evaluating $\mathcal{U}_0^{(1)}(z)$ we introduce the $(\nu + 1) \times q$ matrix

$$\Omega = (\xi, \xi, \ldots, \xi), \tag{6.1}$$

where the vector $\xi$ is given in (3.4), and we put

$$\mathcal{U}_0^{(1)}(z) = \Omega \odot z^{-(q-\nu-1)}\left(u_{\nu+1}(z) u_q^\top(z)\right), \tag{6.2}$$

for $\nu = 1, 2, \ldots, q-2$. The signs of the elements of each column vector of $\mathcal{U}_0^{(1)}(z)$ follow the same pattern as for $\mathcal{U}_0(z)$ in section 3. The second part of $\mathcal{U}_0(z)$ is

$$\mathcal{U}_0^{(2)}(z) = \chi \odot \mathcal{U}_{1,2}^*(z), \tag{6.3}$$

where

$$\mathcal{U}_{1,2}^*(z) = \begin{cases} \mathcal{U}_1^*(z) & \text{for } \nu = 2, 3, \ldots, q-2 \\ \mathcal{U}_2^*(z) & \text{for } \nu = 1 \end{cases}$$

and

$$\begin{cases} \mathcal{U}_1^*(z) = u_{q-\nu-1}^{*\top}(z^{-1}) \otimes \begin{pmatrix} u_3^*(z^{-1}) \\ z u_{\nu-2}(z) \end{pmatrix} & \text{for } \nu = 2, 3, \ldots, q-2 \\ \mathcal{U}_2^*(z) = u_{q-\nu-1}^{*\top}(z^{-1}) \otimes z^{-1} u_2^*(z^{-1}) & \text{for } \nu = 1. \end{cases}$$

The matrix $\chi$ has the form $\chi = (\chi_{q-\nu-1}, \chi_{q-\nu-2}, \ldots, \chi_2, \chi_1)$, where the columns are computed recursively for $k = 2, 3, \ldots, q-\nu-1$:

$$\chi_k = \chi_{k-1} + \xi. \tag{6.4}$$

The $(\nu+1)$ column vector $\chi_1$ is for $\nu = 1, 2, \ldots, q-2$

$$\chi_1 = \begin{pmatrix} \binom{\nu}{0} \\ \binom{\nu}{1} + \binom{\nu-1}{0} \\ \binom{\nu}{2} + \binom{\nu-1}{1} \\ \vdots \\ \binom{\nu}{\nu} + \binom{\nu-1}{\nu-1} \end{pmatrix}. \tag{6.5}$$

The sign pattern of each column of $\mathcal{U}_0^{(2)}(z)$ is $(-1)^\ell$ with $\ell = 0, 1, \ldots, \nu$. In the next section we shall summarize the construction of $\mathcal{U}_0(z)$.

### 6.1.1. Summary of the construction of $\mathcal{U}_0(z)$.

*Step* 1. Introduce the vector $\xi$ according to (3.4).

*Step* 2. Define matrix $\Omega$ according to (6.1).

*Step* 3. Define the columns of $\mathcal{U}_0^{(1)}(z)$ according to (6.2).

*Step* 4. Introduce the vector $\chi_1$ given in (6.5).

*Step* 5. Compute the vectors $\chi_2, \chi_3, \ldots, \chi_{q-\nu-1}$ by means of the recursions (6.4).

*Step* 6. Compute the columns of $\mathcal{U}_0^{(2)}(z)$ according to (6.3).

### 6.2. Example for $\mathcal{U}_0(z)$ when $q = 6$, $\nu = 4$.

An example is chosen when $q = 6$ and $\nu = 4$ so the first matrices to consider are $\mathcal{U}_0^{(1)}(\sigma)$ and $\mathcal{U}_0^{(2)}(\sigma)$ to obtain

$$\mathcal{U}_0^{(1)}(z) = \begin{pmatrix} -\frac{1}{z} & -1 & -z & -z^2 & -z^3 & -z^4 \\ 4 & 4z & 4z^2 & 4z^3 & 4z^4 & 4z^5 \\ -6z & -6z^2 & -6z^3 & -6z^4 & -6z^5 & -6z^6 \\ 4z^2 & 4z^3 & 4z^4 & 4z^5 & 4z^6 & 4z^7 \\ -z^3 & -z^4 & -z^5 & -z^6 & -z^7 & -z^8 \end{pmatrix}$$

and

$$\mathcal{U}_0^{(2)}(z) = \begin{pmatrix} \frac{1}{z^2} \\ -\frac{5}{z} \\ 9 \\ -7z \\ 2z^2 \end{pmatrix}.$$

**6.3. A representation of $\mathcal{U}_j(z)$ when $j = 1, 2, \ldots, \nu - 1$.** The matrices $\mathcal{U}_1(z), \mathcal{U}_2(z), \ldots, \mathcal{U}_{\nu-1}(z)$ are now considered to obtain for $j = 1,\, 2, \ldots, \nu - 1$

$$\mathcal{U}_j(z) = \left(\mathcal{U}_j^{(1)}(z)\, \mathcal{U}_j^{(2)}(z) \mathcal{U}_j^{(3)}(z)\right).$$

Since the submatrices $\mathcal{U}_j^{(1)}(z)$ and $\mathcal{U}_j^{(2)}(z)$ have the same structure as the corresponding submatrices in section 3, the case $q = \nu + 1$, we therefore omit the description of $\mathcal{U}_j^{(1)}(z)$ and $\mathcal{U}_j^{(2)}(z)$.

**6.3.1. A representation of $\mathcal{U}_j^{(3)}(z)$.** We shall now focus on matrix $\mathcal{U}_j^{(3)}(z)$ and for that purpose the following matrix is considered for $j = 1,\, 2, \ldots,\, \nu - 1$:

$$\mu_j = \left(\mu_j^{q-\nu-1} \mu_j^{q-\nu-2} \cdots \mu_j^2 \mu_j^1\right). \tag{6.6}$$

The first recursion to consider is when $j = 1$ and $k = 2, 3, \ldots, q - \nu - 1$, to obtain

$$\mu_1^k = \mu_1^{k-1} + 2\chi_k. \tag{6.7}$$

The vectors $\chi_2, \chi_3, \ldots, \chi_{q-\nu-1}$ are obtained recursively for $\mathcal{U}_0^{(2)}(z)$; see (6.4). The solution to (6.4) is

$$\chi_k = \chi_1 + (k-1)\xi,$$

where $\chi_1$ is given in (6.5). A solution to (6.7) is then given by

$$\mu_1^k = \mu_1^1 + 2(k-1)\chi_1 + k(k-1)\xi.$$

A generalization can now be given for $j = 2, \ldots,\, \nu - 1$ and $k = 1, 2, 3, \ldots, q - \nu - 1$. The column vectors are computed recursively as follows:

$$\mu_j^k = \mu_j^{k-1} + (j+1)\, \mu_{j-1}^k. \tag{6.8}$$

A solution to recursion (6.8) in terms of initial vectors $\mu_j^1, \mu_{j-1}^1, \ldots, \mu_2^1, \mu_1^1$, specified in (6.10), and the known vectors $\chi_1$ and $\xi$, is given by

$$\begin{aligned}\mu_j^k = {} & \sum_{i=0}^{j-1} i! \binom{j+1}{i} \binom{k-2+i}{k-2} \mu_{j-i}^1 \\ & + (j+1)! \binom{k+j-2}{k-2} \chi_1 + (j+1)! \binom{k+j-1}{k-2} \xi.\end{aligned} \tag{6.9}$$

The explicit solution (6.10) is derived in a similar manner as in Proposition 3.4. For $j = 1, 2, \ldots, \nu - 1$, the components of the vector $\mu_j^1$ are given by

$$\begin{cases} \left[\mu_j^1\right]_i = (j+1)!\binom{\nu+1}{i}, & i = 0, 1, \ldots, j+1, \\ \left[\mu_j^1\right]_i = (j+1)!\binom{\nu+1}{i} - r_{i-j-2}, & i = j+2, \ldots, \nu - 1, \\ \left[\mu_j^1\right]_{\nu+1} = (j+2)!, & \end{cases} \tag{6.10}$$

where the terms $r_\ell$, are defined by

$$r_\ell = \begin{cases} (j+1)! \dbinom{\nu - j - 1}{\ell} & \text{for } \ell = 0, 1, \ldots, \nu - j - 3 \\ 0 & \text{for } \nu - j < 3. \end{cases}$$

The submatrix $\mathcal{U}_j^{(3)}(z)$ can now be given according to

$$\mathcal{U}_j^{(3)}(z) = \mu_j \odot z^{-j}\mathcal{U}_1^*(z) \qquad \text{for } \; j = 1, 2, \ldots, \nu - 1. \tag{6.11}$$

The matrix $\mathcal{U}_1^*(z)$ has also been used for specifying $\mathcal{U}_0^{(2)}(z)$. The sign pattern of the elements of each column of $\mathcal{U}_j^{(3)}(\sigma)$ follows the ordering $(-1)^{\ell+j}$ with $\ell = 0, 1, \ldots, \nu$.

**6.3.2. Summary of the construction of matrix $\boldsymbol{\mathcal{U}_j^{(3)}(\sigma)}$.** *Step* 1. Define the initial vector $\mu_j^1$ displayed in (6.10) for $j = 1, 2, \ldots, \nu - 1$.

*Step* 2. Compute the columns of matrix (6.6) by applying recursions (6.8) for the corresponding values of $j = 1, 2, \ldots, \nu - 1$.

*Step* 3. Compute the columns of matrix $\mathcal{U}_j^{(3)}(z)$ according to (6.11) for the corresponding values of $j = 1, 2, \ldots, \nu - 1$.

**6.4. Example $\boldsymbol{\mathcal{U}_j(z)}$ when $\boldsymbol{q = 6}$, $\boldsymbol{\nu = 4}$ and $\boldsymbol{j = 1, 2, 3}$.** The matrix $\mathcal{U}_j^{(1)}(z) = (\delta_j^1(z)\delta_j^2(z)\cdots\delta_j^{j+1}(z))$ will be illustrated for $j = 1,\ 2, 3$, to obtain

$$\mathcal{U}_{j=1}^{(1)}(z) = \begin{pmatrix} 0 & -1 \\ -1 & 3z \\ 3z & -3z^2 \\ -3z^2 & z^3 \\ z^3 & 0 \end{pmatrix}, \quad \mathcal{U}_{j=2}^{(1)}(z) = \begin{pmatrix} 0 & 0 & -2 \\ 0 & -2 & 4z \\ -2 & 4z & -2z^2 \\ 4z & -2z^2 & 0 \\ -2z^2 & 0 & 0 \end{pmatrix},$$

and

$$\mathcal{U}_{j=3}^{(1)}(z) = \begin{pmatrix} 0 & 0 & 0 & -6 \\ 0 & 0 & -6 & 6z \\ 0 & -6 & 6z & 0 \\ -6 & 6z & 0 & 0 \\ 6z & 0 & 0 & 0 \end{pmatrix}.$$

The matrix $\mathcal{U}_j^{(2)}(z)$ is, for $j = 1,\ 2, 3$,

$$\mathcal{U}_{j=1}^{(2)}(z) = \begin{pmatrix} -2z & -3z^2 & -4z^3 \\ 7z^2 & 11z^3 & 15z^4 \\ -9z^3 & -15z^4 & -21z^5 \\ 5z^4 & 9z^5 & 13z^6 \\ -z^5 & -2z^6 & -3z^7 \end{pmatrix}, \quad \mathcal{U}_{j=2}^{(2)}(z) = \begin{pmatrix} -6z & -12z^2 \\ 18z^2 & 40z^3 \\ -20z^3 & -50z^4 \\ 10z^4 & 28z^5 \\ -2z^5 & -6z^6 \end{pmatrix},$$

$$\mathcal{U}_{j=3}^{(2)}() = \begin{pmatrix} -24z \\ 60z^2 \\ -60z^3 \\ 30z^4 \\ -6z^5 \end{pmatrix}.$$

The matrix $\mathcal{U}_j^{(3)}(z)$ is, for $j = 1, 2, 3$,

$$\mathcal{U}_{j=1}^{(3)}(z) = \begin{pmatrix} -\frac{2}{z^3} \\ \frac{10}{z^2} \\ -\frac{20}{z} \\ 18 \\ -6z \end{pmatrix}, \quad \mathcal{U}_{j=2}^{(3)}(z) = \begin{pmatrix} \frac{6}{z^4} \\ -\frac{30}{z^3} \\ \frac{60}{z^2} \\ -\frac{60}{z} \\ 24 \end{pmatrix},$$

and

$$\mathcal{U}_{j=3}^{(3)}(z) = \begin{pmatrix} -\frac{24}{z^5} \\ \frac{120}{z^4} \\ -\frac{240}{z^3} \\ \frac{240}{z^2} \\ -\frac{120}{z} \end{pmatrix}.$$

Insertion in (3.2) of the matrices $\mathcal{U}_0^{(1)}(z)$ and $\mathcal{U}_0^{(2)}(z)$, followed by the matrices

$$\begin{aligned} \mathcal{U}_1(z) &= \left( \mathcal{U}_{j=1}^{(1)}(z)\, \mathcal{U}_{j=1}^{(2)}(z)\, \mathcal{U}_{j=1}^{(3)}(z) \right), \\ \mathcal{U}_2(z) &= \left( \mathcal{U}_{j=2}^{(1)}(z)\, \mathcal{U}_{j=2}^{(2)}(z)\, \mathcal{U}_{j=2}^{(3)}(z) \right), \\ \mathcal{U}_3(z) &= \left( \mathcal{U}_{j=3}^{(1)}(z)\, \mathcal{U}_{j=3}^{(2)}(z)\, \mathcal{U}_{j=3}^{(3)}(z) \right), \end{aligned}$$

results in the scheme

$$\mathcal{U}(z) = \frac{1}{4!} \left( \mathcal{U}_0^{(1)}(z), \mathcal{U}_0^{(2)}(z), \mathcal{U}_1(z), \mathcal{U}_2(z), \mathcal{U}_3(z) \right).$$

The columns that compose the matrix $\binom{\mathcal{U}(z)}{J_{25}}$ span the null space of $\mathcal{K}_\nu(z)$ when $q = 6$ and $\nu = 4$.

## 7. Conclusions.

In this paper a solution to new linear systems of equations is displayed. This is done when $q = \nu + 1$ and $p = \tau + 1$. The newly developed algorithms for the null space and right-inverse are then equivalent for both coefficient matrices. Explicit solutions to both linear system of equations can then be straightforwardly implemented by using the same algorithms. The algorithms for the null space do not require matrix multiplications and matrix inversions. The main computational exercise consists of evaluating factorials and binomial coefficients combined with recursions that consist of the addition of two vectors. The binomial coefficients can be computed by applying the Pascal triangle.

A connection between adjoints of companion-related matrices and rectangular generalized Vandermonde matrices of the block Toeplitz type is then confirmed through the corresponding null spaces.

An algorithm for the null space for $\mathcal{K}_\nu(z)$ is also set forth when $q > \nu + 1$. To compute a solution to the linear systems of (1.1) and (1.2) under these conditions can be considered for future research.

# BACKWARD ERROR OF POLYNOMIAL EIGENPROBLEMS SOLVED BY LINEARIZATION*

NICHOLAS J. HIGHAM†, REN-CANG LI‡, AND FRANÇOISE TISSEUR†

**Abstract.** The most widely used approach for solving the polynomial eigenvalue problem $P(\lambda)x = \bigl(\sum_{i=0}^{m} \lambda^i A_i\bigr)x = 0$ in $n \times n$ matrices $A_i$ is to linearize to produce a larger order pencil $L(\lambda) = \lambda X + Y$, whose eigensystem is then found by any method for generalized eigenproblems. For a given polynomial $P$, infinitely many linearizations $L$ exist and approximate eigenpairs of $P$ computed via linearization can have widely varying backward errors. We show that if a certain one-sided factorization relating $L$ to $P$ can be found then a simple formula permits recovery of right eigenvectors of $P$ from those of $L$, and the backward error of an approximate eigenpair of $P$ can be bounded in terms of the backward error for the corresponding approximate eigenpair of $L$. A similar factorization has the same implications for left eigenvectors. We use this technique to derive backward error bounds depending only on the norms of the $A_i$ for the companion pencils and for the vector space $\mathbb{DL}(P)$ of pencils recently identified by Mackey, Mackey, Mehl, and Mehrmann. In all cases, sufficient conditions are identified for an optimal backward error for $P$. These results are shown to be entirely consistent with those of Higham, Mackey, and Tisseur on the conditioning of linearizations of $P$. Other contributions of this work are a block scaling of the companion pencils that yields improved backward error bounds; a demonstration that the bounds are applicable to certain structured linearizations of structured polynomials; and backward error bounds specialized to the quadratic case, including analysis of the benefits of a scaling recently proposed by Fan, Lin, and Van Dooren. The results herein make no assumptions on the stability of the method applied to $L$ or whether the method is direct or iterative.

## 1. Introduction.

The polynomial eigenvalue problem (PEP) is to find scalars $\lambda$ and nonzero vectors $x$ and $y$ satisfying $P(\lambda)x = 0$ and $y^*P(\lambda) = 0$, where

$$P(\lambda) = \sum_{i=0}^{m} \lambda^i A_i, \qquad A_i \in \mathbb{C}^{n\times n}, \quad A_m \neq 0 \tag{1.1}$$

is a matrix polynomial of degree $m$. Here, $x$ and $y$ are right and left eigenvectors corresponding to the eigenvalue $\lambda$. We will assume throughout that $P$ is regular, that is, $\det P(\lambda) \not\equiv 0$.

The standard way of solving this problem is to convert $P$ into a linear polynomial

$$L(\lambda) = \lambda X + Y, \qquad X, Y \in \mathbb{C}^{mn\times mn}$$

with the same spectrum as $P$ and solve the eigenproblem for $L$. This generalized eigenproblem is usually solved with the QZ algorithm [20] for small to medium size problems or a projection method for large sparse problems [1]. That $L$ has the same spectrum as $P$ is assured if

$$E(\lambda)L(\lambda)F(\lambda) = \begin{bmatrix} P(\lambda) & 0 \\ 0 & I_{(m-1)n} \end{bmatrix} \tag{1.2}$$

for some unimodular $E(\lambda)$ and $F(\lambda)$. (A matrix polynomial $E(\lambda)$ is unimodular if its determinant is a nonzero constant, independent of $\lambda$.) Such an $L$ is called a *linearization* of $P(\lambda)$ [5, sec. 7.2]. As an example, the pencil

$$C_1(\lambda) = \lambda \begin{bmatrix} A_3 & 0 & 0 \\ 0 & I & 0 \\ 0 & 0 & I \end{bmatrix} + \begin{bmatrix} A_2 & A_1 & A_0 \\ -I & 0 & 0 \\ 0 & -I & 0 \end{bmatrix} \tag{1.3}$$

can be shown to be a linearization for the cubic $P(\lambda) = \lambda^3 A_3 + \lambda^2 A_2 + \lambda A_1 + A_0$; it is known as the *first companion* linearization.

Among the infinitely many linearizations $L$ of $P$ we are interested in those whose right and left eigenvectors permit easy recovery of the corresponding eigenvectors of $P$. For example, if $(x, y)$ and $(z, w)$ denote pairs of right and left eigenvectors of the cubic $P(\lambda)$ and its companion linearization $C_1(\lambda)$, respectively, associated with the simple, finite eigenvalue $\lambda$, then

$$(z, w) = \left( \begin{bmatrix} \lambda^2 x \\ \lambda x \\ x \end{bmatrix}, \begin{bmatrix} y \\ (\bar{\lambda} A_3^* + A_2^*)y \\ (\bar{\lambda}^2 A_3^* + \bar{\lambda} A_2^* + A_1^*)y \end{bmatrix} \right), \tag{1.4}$$

so that $x$ can be recovered from one of the first two blocks (if $\lambda \neq 0$) or the third block of $n$ components of $z$, and $y$ can be recovered from the first $n$ components of $w$. This correspondence extends to all eigenvalues and arbitrary $m$, as we will explain in section 3.

In practice, the eigenpairs of $L$ are not computed exactly because of rounding errors and, in the case of iterative methods, truncation errors. For a given approximate eigenpair of $L$, it is important to know how good an approximate eigenpair of $P$ will be produced. Here, "good" can have various meanings; in particular, it can refer to the relative error of the eigenvalue or the backward error of the eigenpair. The relative error question has been investigated by Higham, Mackey, and Tisseur [7], by analyzing the conditioning of both the polynomial $P$ and the linearization $L$. The purpose of the present work is to investigate the backward error for a wide variety of linearizations. Two key aspects of this task can be seen by considering the companion pencil (1.3). First, a small but arbitrary perturbation to $C_1$, such as that introduced by the QZ algorithm, does not respect the zero and identity blocks and so may not correspond to a small perturbation of $P$. Second, the block from which the approximate eigenvector is recovered will influence the backward error.

Our work builds on that of Tisseur [22], who shows that solving a quadratic eigenvalue problem (QEP) by applying a numerically stable method to the companion linearization can be backward unstable, but that stability is guaranteed if all the coefficient matrices have unit norm.

In section 2.1 we define the backward error $\eta_P$ of an approximate eigenpair and eigentriple of $P$ for the polynomial both in the $\lambda$-form (1.1) and in homogeneous $(\alpha, \beta)$-form. In section 2.2 we show that given appropriate one-sided factorizations relating a linearization $L$ to the original polynomial $P$, we can bound the backward error of an approximate eigenpair of $P$ in terms of the backward error of the approximate eigenpair of $L$ from which it was obtained. The bounds have the useful feature of separating the dependence on $L$, $P$, and $(\alpha, \beta)$ from the dependence on how the (right or left) eigenvector is recovered.

In section 3 we introduce the first and second companion linearizations and the vector spaces $\mathbb{L}_1$ and $\mathbb{L}_2$ of pencils associated with $P$. As a by-product of our analysis we obtain in section 3.1 new formulae for recovering a left (right) eigenvector of $P$ from one of a linearization in $\mathbb{L}_1$ ($\mathbb{L}_2$). In section 3.2 we obtain backward error bounds for the companion pencils and deduce sufficient conditions for a small backward error $\eta_P$. We show in section 3.3 that applying a block scaling to the companion pencils yields smaller backward error bounds when $\max_i \|A_i\|_2$ is much different from 1. The vector space $\mathbb{DL}(P) = \mathbb{L}_1(P) \cap \mathbb{L}_2(P)$ is then considered in section 3.4, where bounds of the same form as for the block-scaled companion pencils are obtained. In section 3.5 we explain how the backward error results provide essentially the same guidance on optimal choice of linearizations as the condition number bounds of Higham, Mackey, and Tisseur [7]. In section 4 we show that the results of section 3 also apply to certain structured linearizations of structured polynomials.

The special case of quadratic polynomials $\lambda^2 A + \lambda B + C$ is studied in detail in section 5, concentrating on the companion linearization and the $\mathbb{DL}(P)$ basis pencils $L_1$ and $L_m$. Bounds for $\eta_P$ are obtained and then specialized to exploit a scaling procedure recently proposed by Fan, Lin, and Van Dooren [2]. The bounds involve a growth factor $\omega$ that is shown to be bounded by $1+\tau$, where $\tau = \|B\|_2/\sqrt{\|A\|_2\|C\|_2}$. Our analysis improves upon that in [2], which contains a growth term $\max(1+\tau, 1+\tau^{-1})$. The bounds are particularly satisfactory for elliptic QEPs and, more generally, QEPs that are not too heavily damped. Numerical experiments illustrating these and other aspects of the theory are given in section 6.

Finally, we note that our results are of interest even in the case $n = 1$, although we will not consider this case specifically here. The roots of a scalar polynomial, $p$, are often found by computing the eigenvalues of a corresponding companion matrix, $C$. Our analysis provides new bounds on the backward errors of the computed roots of $p$ in terms of the backward errors of the computed eigenvalues of $C$.

## 2. Backward errors.

**2.1. Definition and notation.** The normwise backward error of an approximate (right) eigenpair $(x, \lambda)$ of $P(\lambda)$, where $\lambda$ is finite, is defined by

$$\eta_P(x,\lambda) = \min\{\, \epsilon : (P(\lambda) + \Delta P(\lambda))x = 0,\ \|\Delta A_i\|_2 \le \epsilon \|A_i\|_2,\ i = 0{:}\,m \,\}, \tag{2.1}$$

where $\Delta P(\lambda) = \sum_{i=0}^{m} \lambda^i \Delta A_i$. Tisseur [22, Thm. 1] obtained the explicit formula

$$\eta_P(x,\lambda) = \frac{\|P(\lambda)x\|_2}{\left(\sum_{i=0}^{m} |\lambda^i| \|A_i\|_2\right) \|x\|_2}. \tag{2.2}$$

Similarly, for an approximate left eigenpair $(y^*, \lambda)$, we have

$$\eta_P(y^*,\lambda) := \min\{\, \epsilon : y^*(P(\lambda) + \Delta P(\lambda)) = 0,\ \|\Delta A_i\|_2 \le \epsilon \|A_i\|_2,\ i = 0{:}\,m \,\} \tag{2.3}$$

$$= \frac{\|y^* P(\lambda)\|_2}{\left(\sum_{i=0}^{m} |\lambda^i| \|A_i\|_2\right) \|y\|_2}. \tag{2.4}$$

Also of interest is the backward error of the approximate triplet $(x, y, \lambda)$ [22, Thm. 4]:

$$\begin{aligned} (2.5)\quad \eta_P(x, y^*, \lambda) &:= \min\{\, \epsilon : (P(\lambda) + \Delta P(\lambda))x = 0,\ y^*(P(\lambda) + \Delta P(\lambda)) = 0, \\ &\qquad \|\Delta A_i\|_2 \le \epsilon \|A_i\|_2,\ i = 0\colon m \,\} \\ (2.6)\qquad\qquad &= \max\bigl(\eta_P(x, \lambda),\ \eta_P(y^*, \lambda)\bigr). \end{aligned}$$

We make two comments on notation. As an argument of $\eta$, a left eigenvector is written as a row vector to distinguish it from a right eigenvector. Symbols such as $\lambda$, $x$, and $y$ will denote both exact and (more often) approximate quantities, with the context making clear which usage is in effect. The alternative of using a tilde to denote approximate quantities leads to rather cumbersome formulae.

In order to define backward errors valid for all $\lambda$, including $\infty$, we rewrite the polynomial in the homogeneous form

$$P(\alpha, \beta) = \sum_{i=0}^{m} \alpha^i \beta^{m-i} A_i$$

and identify $\lambda$ with any pair $(\alpha, \beta) \ne (0, 0)$ for which $\lambda = \alpha/\beta$. The definitions (2.1), (2.3), and (2.5) are trivially rewritten in terms of $\alpha$ and $\beta$. Using $P(\alpha, \beta) = \beta^m P(\alpha/\beta)$ for $\beta \ne 0$, we find that in place of (2.2), (2.4), and (2.6) we have

$$\eta_P(x, \alpha, \beta) = \frac{\|P(\alpha, \beta)x\|_2}{\left(\sum_{i=0}^{m} |\alpha|^i |\beta|^{m-i} \|A_i\|_2\right) \|x\|_2}, \tag{2.7}$$

$$\eta_P(y^*, \alpha, \beta) = \frac{\|y^* P(\alpha, \beta)\|_2}{\left(\sum_{i=0}^{m} |\alpha|^i |\beta|^{m-i} \|A_i\|_2\right) \|y\|_2}, \tag{2.8}$$

$$\eta_P(x, y^*, \alpha, \beta) = \max\bigl(\eta_P(x, \alpha, \beta),\ \eta_P(y^*, \alpha, \beta)\bigr). \tag{2.9}$$

Note that these expressions are independent of the choice of $\alpha$ and $\beta$ representing the eigenvalue; that is, a scaling $\alpha \leftarrow \theta\alpha$, $\beta \leftarrow \theta\beta$ with $\theta \ne 0$ leaves the expressions unchanged.

### 2.2. Bounding the backward error for $P$ relative to that for $L$.

Let $L(\lambda) = \lambda X + Y$ be a linearization of $P(\lambda)$. For approximate right eigenvectors $z$ of $L$ and $x$ of $P$, both corresponding to an approximate eigenvalue$(\alpha, \beta)$, our aim is to compare $\eta_P(x, \alpha, \beta)$ with

$$\eta_L(z, \alpha, \beta) = \frac{\|L(\alpha, \beta)z\|_2}{(|\alpha| \|X\|_2 + |\beta| \|Y\|_2)\|z\|_2}, \tag{2.10}$$

which is obtained by applying (2.7) to $L(\alpha, \beta) = \alpha X + \beta Y$. Of course, this comparison is possible only if there is some well-defined relation between $x$ and $z$. Such a relation, and a means for bounding $\eta_P$, both follow from one key assumption: that we can find an $n \times nm$ matrix polynomial $G(\alpha, \beta)$ such that

$$G(\alpha, \beta)L(\alpha, \beta) = g^T \otimes P(\alpha, \beta) \tag{2.11}$$

for some nonzero $g \in \mathbb{C}^m$, where $\otimes$ denotes the Kronecker product [15, sec. 12.1]. Necessarily, $G(\alpha, \beta)$ will have degree $m - 1$. Note that this is a one-sided transformation as opposed to the two-sided transformation in the definition of linearization. Then we have

$$G(\alpha, \beta)L(\alpha, \beta)z = \bigl(g^T \otimes P(\alpha, \beta)\bigr)z = P(\alpha, \beta)(g^T \otimes I_n)z, \tag{2.12}$$

where the latter equation relies on $g^T$ being a row vector. Thus if $z$ is an eigenvector of $L$ then

$$x := (g^T \otimes I_n)z = \sum_{i=1}^{m} g_i z_i, \qquad z_i := z((i-1)n+1\colon in) \tag{2.13}$$

is an eigenvector of $P$, provided that $x$ is nonzero. This latter requirement is not satisfied in general but will be proved for some important classes of linearizations. As an example, for the first companion linearization $C_1(\alpha,\beta) = \beta^3 C_1(\alpha/\beta)$ in (1.3), it is easily checked that $G(\alpha,\beta) = [\,\alpha^2 I \quad -(\beta^2 A_0 + \alpha\beta A_1) \quad -\alpha\beta A_0\,]$ satisfies (2.11) with $g = e_1$, the first column of the identity matrix, and that if $z$ is a right eigenvector of $C_1$ and $\alpha \neq 0$ then $x = z_1 = z(1\colon n) \neq 0$ is a right eigenvector for $P$ (cf. (1.4)).

Suppose now that (2.11) is satisfied, an approximate right eigenvector $z$ of $L$ is given, and $x$ is given by (2.13). Then, by (2.7), (2.10), and (2.12),

$$\begin{aligned} \eta_P(x,\alpha,\beta) &\leq \frac{\|G(\alpha,\beta)\|_2 \|L(\alpha,\beta)z\|_2}{\left(\sum_{i=0}^{m} |\alpha|^i |\beta|^{m-i} \|A_i\|_2\right) \|x\|_2} \\ &\leq \frac{|\alpha|\,\|X\|_2 + |\beta|\,\|Y\|_2}{\sum_{i=0}^{m} |\alpha|^i |\beta|^{m-i} \|A_i\|_2} \cdot \frac{\|G(\alpha,\beta)\|_2 \|z\|_2}{\|x\|_2} \cdot \eta_L(z,\alpha,\beta). \end{aligned} \tag{2.14}$$

This bound largely separates the dependence on $L$, $P$, and $(\alpha,\beta)$ (in the first term) from the dependence on $G$ and $z$ (in the second term).

For left eigenvectors the appropriate analogue of the assumption (2.11) is that there exists an $mn \times n$ matrix polynomial $H(\alpha,\beta)$ such that

$$L(\alpha,\beta)H(\alpha,\beta) = h \otimes P(\alpha,\beta) \tag{2.15}$$

for some nonzero $h \in \mathbb{C}^m$. We then have, for $w \in \mathbb{C}^{mn}$,

$$w^* L(\alpha,\beta)H(\alpha,\beta) = w^*(h \otimes P(\alpha,\beta)) = w^*(h \otimes I_n)P(\alpha,\beta). \tag{2.16}$$

Hence if $w$ is a left eigenvector of $L$ then

$$y := (h^* \otimes I_n)w = \sum_{i=1}^{m} \overline{h}_i w_i, \qquad w_i := w((i-1)n+1\colon in) \tag{2.17}$$

is a left eigenvector of $P$, provided that it is nonzero. From (2.8) and (2.17) we obtain for an approximate left eigenvector $w$ of $L$ the bound

$$\eta_P(y^*,\alpha,\beta) \leq \frac{|\alpha|\|X\|_2 + |\beta|\|Y\|_2}{\sum_{i=0}^{m} |\alpha|^i |\beta|^{m-i} \|A_i\|_2} \cdot \frac{\|H(\alpha,\beta)\|_2 \|w\|_2}{\|y\|_2} \cdot \eta_L(w^*,\alpha,\beta). \tag{2.18}$$

In the rest of this paper we show that one or both of assumptions (2.11) and (2.15) are satisfied for a wide class of linearizations, and we study the upper bounds (2.14) and (2.18).

## 3. Unstructured linearizations.

We first concentrate on general, unstructured matrix polynomials, treating companion and $\mathbb{DL}(P)$ linearizations.

Associated with $P$ are two companion pencils, $C_1(\lambda) = \lambda X_1 + Y_1$ and $C_2(\lambda) = \lambda X_2 + Y_2$, called the first and second companion forms [15, sec. 14.1], respectively,

where

$$X_1 = X_2 = \operatorname{diag}(A_m, I_n, \dots, I_n),$$

$$Y_1 = \begin{bmatrix} A_{m-1} & A_{m-2} & \dots & A_0 \\ -I_n & 0 & \dots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & \dots & -I_n & 0 \end{bmatrix}, \quad Y_2 = \begin{bmatrix} A_{m-1} & -I_n & \dots & 0 \\ A_{m-2} & 0 & \ddots & \vdots \\ \vdots & \vdots & \ddots & -I_n \\ A_0 & 0 & \dots & 0 \end{bmatrix}. \tag{3.1}$$

They are widely used in practice. For example, the MATLAB function `polyeig` that solves the PEP uses the reversed first companion linearization $\operatorname{rev}C_1(\lambda)$ of the reversed matrix polynomial $\operatorname{rev}P(\lambda)$. The reversal operator is defined for $P$ in (1.1) by

$$\operatorname{rev}P(\lambda) = \lambda^m P(1/\lambda) = \sum_{i=0}^{m} \lambda^i A_{m-i}. \tag{3.2}$$

The companion forms have the important property that they are always linearizations [19, sec. 4].

$C_1(\lambda)$ and $C_2(\lambda)$ belong to large sets of potential linearizations recently identified by Mackey et al. [19] and studied in [6] and [19]. With the notation $\Lambda = [\lambda^{m-1}, \lambda^{m-2}, \dots, 1]^T$, these sets are

$$\mathbb{L}_1(P) = \{\, L(\lambda) : L(\lambda)(\Lambda \otimes I_n) = v \otimes P(\lambda),\ v \in \mathbb{C}^m \,\}, \tag{3.3}$$

$$\mathbb{L}_2(P) = \{\, L(\lambda) : (\Lambda^T \otimes I_n)L(\lambda) = \widetilde{v}^T \otimes P(\lambda),\ \widetilde{v} \in \mathbb{C}^m \,\}. \tag{3.4}$$

There are many $L(\lambda) \in \mathbb{L}_1(P)$ corresponding to a given $v$, and likewise for $\mathbb{L}_2(P)$; indeed, $\mathbb{L}_1(P)$ and $\mathbb{L}_2(P)$ both have dimension $m(m-1)n^2 + m$ [19, Cor. 3.6]. It is easy to check that $C_1(\lambda)$ and $C_2(\lambda)$ belong to $\mathbb{L}_1(P)$ and $\mathbb{L}_2(P)$, respectively, with $\widetilde{v} = v = e_1$; so the pencils in $\mathbb{L}_1$ and $\mathbb{L}_2$ can be thought of as generalizations of the first and second companion forms. It is proved in [19, Prop. 3.2, Prop. 3.12, Thm. 4.7] that $\mathbb{L}_1(P)$ and $\mathbb{L}_2(P)$ are vector spaces and that almost all pencils in these spaces are linearizations of $P$.

One of the underlying reasons for the interest in $\mathbb{L}_1$ and $\mathbb{L}_2$ is that eigenvectors of $P$ can be directly recovered from eigenvectors of linearizations in $\mathbb{L}_1$ and $\mathbb{L}_2$. As with the backward errors, it is more convenient to use the $(\alpha, \beta)$ notation, so we define

$$\Lambda_{\alpha,\beta} = [\alpha^{m-1}, \alpha^{m-2}\beta, \dots, \beta^{m-1}]^T = \beta^{m-1}\Lambda.$$

THEOREM 3.1 (eigenvector recovery from $\mathbb{L}_1$ and $\mathbb{L}_2$).

- *If $L \in \mathbb{L}_1(P)$ is a linearization of $P$ then every right eigenvector of $L$ with eigenvalue $(\alpha, \beta)$ is of the form $\Lambda_{\alpha,\beta} \otimes x$ for some right eigenvector $x$ of $P$.*
- *If $L \in \mathbb{L}_2(P)$ is a linearization of $P$ then every left eigenvector of $L$ with eigenvalue $(\alpha, \beta)$ is of the form $\overline{\Lambda}_{\alpha,\beta} \otimes y$ for some left eigenvector $y$ of $P$.*

*Proof.* See [19, Thms. 3.8, 3.14, 4.4]. ☐

Theorem 3.1 shows that from any right eigenvector $z$ of $L \in \mathbb{L}_1$ we can read off a right eigenvector of $P$ by looking at any nonzero subvector $z_i = z((i-1)n+1\colon in)$, and similarly a left eigenvector of $L \in \mathbb{L}_2$ yields a left eigenvector of $P$.

### 3.1. $\mathbb{L}_1(P)$ and $\mathbb{L}_2(P)$.

It is immediate from (3.3) and (3.4) that the pencils in $\mathbb{L}_1$ satisfy (2.15), while those in $\mathbb{L}_2$ satisfy (2.11). Therefore our backward error bounds are applicable to left eigenvectors of pencils in $\mathbb{L}_1$ and right eigenvectors of pencils in $\mathbb{L}_2$, provided that the vectors $x$ in (2.13) and $y$ in (2.17) are nonzero when $z$ and $w$ are exact eigenvectors. In fact, for $\mathbb{L}_1$ and $\mathbb{L}_2$ (2.13) and (2.17) define a bijection between eigenvectors of the pencil and of $P$ and so allow recovery of *all* the eigenvectors. The following two new results supplement the existing eigenvector recovery formulae in Theorem 3.1.

THEOREM 3.2 (left eigenvector recovery from $\mathbb{L}_1$). *Let $L \in \mathbb{L}_1(P)$ be a linearization of $P$, with vector $v$ (necessarily nonzero) in* (3.3). *If $w$ is a left eigenvector of $L$ with eigenvalue $(\alpha, \beta)$ then*

$$y = (v^* \otimes I_n)w \tag{3.5}$$

*is a left eigenvector of $P$ with eigenvalue $(\alpha, \beta)$. Moreover, any left eigenvector of $P$ corresponding to $(\alpha, \beta)$ can be recovered from one of $L$ from the formula* (3.5).

*Proof.* Assume, first, that $\mu \equiv (\alpha, \beta)$ is finite. For arbitrary $\lambda$, premultiplying the condition defining $\mathbb{L}_1$ by $w^*$ (or simply using the $\lambda$-analogue of (2.16)) gives

$$w^* L(\lambda)(\Lambda \otimes I_n) = w^*\bigl(v \otimes P(\lambda)\bigr) = w^*(v \otimes I_n)P(\lambda) =: y^* P(\lambda).$$

Since $w^* L(\mu) = 0$, it follows that $y^* P(\mu) = 0$. We therefore just have to show that $y \neq 0$. We suppose that $y = 0$ and will obtain a contradiction. If $y = 0$ then $w^* L(\lambda)(\Lambda \otimes I_n) \equiv 0$. Since $L$ is linear, we can write

$$w^* L(\lambda) = [b_1(\lambda),\ b_2(\lambda), \dots, b_m(\lambda)],$$

where $b_i(\lambda) = c_i \lambda + d_i \in \mathbb{C}^{1 \times n}$ is linear. Then

$$\begin{aligned} 0 \equiv w^* L(\lambda)(\Lambda \otimes I_n) &= [b_1(\lambda),\ b_2(\lambda), \dots,\ b_m(\lambda)] \begin{bmatrix} \lambda^{m-1} I_n \\ \lambda^{m-2} I_n \\ \vdots \\ I_n \end{bmatrix} \\ &= \lambda^{m-1} b_1(\lambda) + \lambda^{m-2} b_2(\lambda) + \cdots + b_m(\lambda) \\ &= \lambda^m c_1 + \lambda^{m-1}(d_1 + c_2) + \cdots + \lambda(d_{m-1} + c_m) + d_m. \end{aligned}$$

Hence $c_1 = 0, d_1 = -c_2, \dots, d_{m-1} = -c_m,\ d_m = 0$. Then

$$0 = w^* L(\mu) = [b_1(\mu), b_2(\mu), \dots, b_m(\mu)] = [-c_2,\ \mu c_2 - c_3, \dots, \mu c_{m-1} - c_m,\ \mu c_m],$$

which implies $c_2 = c_3 = \cdots = c_m = 0$. Hence $b_i(\lambda) \equiv 0$ for all $i$. Thus $w^* L(\lambda) \equiv 0$, which means that $L$ is a nonregular polynomial. But by [19, Thm. 4.3], $L \in \mathbb{L}_1(P)$ being nonregular implies that $L$ is not a linearization of $P$. This is a contradiction, and so $y \neq 0$, as required.

The case $\mu = \infty$ can be handled by expressing $L$ and $P$ in homogeneous $(\alpha, \beta)$-form and using $\mu \equiv (1, 0)$. The details are a minor variation on those above.

Finally, consider the map $w \mapsto (v^* \otimes I_n)w$ from $\mathcal{K}_1 = \operatorname{left\,ker} L(\alpha, \beta)$ to $\mathcal{K}_2 = \operatorname{left\,ker} P(\alpha, \beta)$, where left ker denotes the left kernel. The first part showed that this map has kernel $\{0\}$. Since $L \in \mathbb{L}_1(P)$ is a linearization and $P$ is regular, $L$ is a strong linearization[1] [19, Thm. 4.3]. Hence the geometric multiplicity of any eigenvalue (including $\infty$) is the same for $L$ and $P$ [14]; that is, $\mathcal{K}_1$ and $\mathcal{K}_2$ have the same dimension. It follows that the map is a bijection, and the result is proved. □

---

[1] $L$ is a strong linearization of $P$ if it is a linearization for $P$ and $\operatorname{rev} L$ is a linearization for $\operatorname{rev} P$.

THEOREM 3.3 (right eigenvector recovery from $\mathbb{L}_2$). *Let* $L \in \mathbb{L}_2(P)$ *be a linearization, with vector* $\widetilde{v}$ (*necessarily nonzero*) *in* (3.4). *If* $z$ *is a right eigenvector of* $L$ *with eigenvalue* $(\alpha, \beta)$ *then*

$$x = (\widetilde{v}^T \otimes I_n)z \tag{3.6}$$

*is a right eigenvector of* $P$ *with eigenvalue* $(\alpha, \beta)$. *Moreover, any right eigenvector of* $P$ *corresponding to* $(\alpha, \beta)$ *can be recovered from one of* $L$ *from the formula* (3.6).

*Proof.* The proof is entirely analogous to that of Theorem 3.2. ◻

The broader significance of Theorems 3.2 and 3.3 combined with Theorem 3.1 is that both left *and* right eigenvectors of pencils in $\mathbb{L}_1$ and $\mathbb{L}_2$ yield corresponding eigenvectors of $P$ via simple formulae.

We will not write down backward error bounds for $\mathbb{L}_1$ and $\mathbb{L}_2$, but will do so for their intersection in section 3.4.

**3.2. Companion linearizations.** It is easy to see that $C_2(P) = C_1(P^T)^T$, where $P^T$ denotes the polynomial obtained by transposing each coefficient matrix $A_i$. This property implies that any backward error results for $C_1$ have a counterpart for $C_2$, and so it suffices to concentrate on the first companion form.

Is the factorization (2.11) possible for the first companion linearization? For $C_1$ in (1.3) with $m = 3$ it is straightforward to verify that $E(\alpha, \beta)C_1(\alpha, \beta) = I_3 \otimes P(\alpha, \beta)$ with

$$E(\alpha, \beta) = \begin{bmatrix} \alpha^2 I_n & -(\beta^2 A_0 + \alpha\beta A_1) & -\alpha\beta A_0 \\ \alpha\beta I_n & \alpha\beta A_2 + \alpha^2 A_3 & -\beta^2 A_0 \\ \beta^2 I_n & \beta^2 A_2 + \alpha\beta A_3 & \beta^2 A_1 + \alpha\beta A_2 + \alpha^2 A_3 \end{bmatrix}$$

(indeed the first block row of this equation was mentioned in section 2.2), so that we have three choices for $G(\alpha, \beta)$, namely, $G_k(\alpha, \beta) := (e_k^T \otimes I_n)E(\alpha, \beta)$, $k = 1{:}3$. This result generalizes to arbitrary degrees $m$.

LEMMA 3.4. *For the first companion form* $C_1(\alpha, \beta) = \alpha X_1 + \beta Y_1$, *for any* $m$, *there exists a block* $m \times m$ *matrix* $E(\alpha, \beta) \in \mathbb{C}^{mn \times mn}$ *such that*

$$E(\alpha, \beta)C_1(\alpha, \beta) = I_m \otimes P(\alpha, \beta), \tag{3.7}$$

*where the blocks are given by*

$$[E(\alpha, \beta)]_{i1} = \alpha^{m-i}\beta^{i-1} I_n, \qquad [E(\alpha, \beta)]_{ij} = \sum_{k=0}^{m-1} s_k \alpha^k \beta^{m-k-1} A_{\ell_k} \text{ for } j > 1,$$

*where* $s_k \in \{-1, 0, 1\}$ *and the indices* $\ell_k$ *are distinct* (*our notation suppresses the dependence of* $s_k$ *and* $\ell_k$ *on* $i$ *and* $j$). *The condition* (2.11) *is satisfied for*

$$G_k(\alpha, \beta) = (e_k^T \otimes I_n)E(\alpha, \beta), \quad g = e_k, \qquad k = 1{:}m. \tag{3.8}$$

*Proof.* The proof consists of a direct verification that $E(\alpha, \beta)$ defined by

$$[E(\alpha, \beta)]_{ij} = \begin{cases} \alpha^{m-i}\beta^{i-1} I_n, & 1 \le i \le m,\ j = 1, \\ -(\alpha/\beta)^{j-i} \displaystyle\sum_{k=0}^{m-j} \alpha^{k-1}\beta^{m-k} A_k, & 1 \le i < j,\ 1 < j \le m, \\ (\alpha/\beta)^{j-i} \displaystyle\sum_{k=m-j+1}^{m} \alpha^{k-1}\beta^{m-k} A_k, & 1 < j \le i \le m, \end{cases}$$

satisfies (3.7). ◻

The next lemma will be useful when taking norms of block matrices.

LEMMA 3.5. *For any block $\ell \times m$ matrix $B$ we have $\|B\|_2 \le \sqrt{\ell m}\,\max_{i,j} \|B_{ij}\|_2$.*

*Proof.* Partitioning $x$ conformably with $B$, we have

$$\begin{aligned}\|Bx\|_2^2 &= \sum_{i=1}^{\ell} \Bigl\| \sum_{j=1}^{m} B_{ij}x_j \Bigr\|_2^2 \le \max_{i,j} \|B_{ij}\|_2^2 \sum_{i=1}^{\ell} \Bigl( \sum_{j=1}^{m} \|x_j\|_2 \Bigr)^2 \\ &\le \max_{i,j} \|B_{ij}\|_2^2 \sum_{i=1}^{\ell} m \Bigl( \sum_{j=1}^{m} \|x_j\|_2^2 \Bigr) = \ell m \max_{i,j} \|B_{ij}\|_2^2 \, \|x\|_2^2.\end{aligned}$$

The result follows. ◻

To investigate the size of the upper bound in (2.14) for $L(\alpha,\beta) = C_1(\alpha,\beta) = \alpha X_1 + \beta Y_1$ we need to bound $\|X_1\|_2$, $\|Y_1\|_2$, and the norm of the $k$th block row $G_k(\alpha,\beta)$ of $E(\alpha,\beta)$. We find that

$$\|X_1\|_2 = \max(\|A_m\|_2, 1), \quad \|Y_1\|_2 \le m \max\Bigl(1, \max_{i=0:m-1} \|A_i\|_2\Bigr), \tag{3.9}$$

where we used Lemma 3.5 for $Y_1$. From Lemma 3.4 we have, for $j > 1$,

$$\|E(\alpha,\beta)_{ij}\|_2 \le \max_{\ell} \|A_\ell\|_2 \sum_{k=0}^{m-1} |\alpha|^k |\beta|^{m-k-1} = \|\Lambda_{\alpha,\beta}\|_1 \max_{\ell} \|A_\ell\|_2,$$

so that on using Lemma 3.5,

$$\|G_k(\alpha,\beta)\|_2 \le \sqrt{m}\, \|\Lambda_{\alpha,\beta}\|_1 \max(1, \max_i \|A_i\|_2), \tag{3.10}$$

this upper bound being independent of $k$. We can now bound the ratio $\eta_P(z_k,\alpha,\beta)/\eta_L(z,\alpha,\beta)$ in terms of the approximate right eigenpair $(z,\alpha,\beta)$ and the coefficient matrices defining $P$.

THEOREM 3.6. *Let $z$ be an approximate right eigenvector of $C_1$ corresponding to the approximate eigenvalue $(\alpha,\beta)$. Then for $z_k = z((k-1)n+1\colon kn)$, $k = 1\colon m$, we have*

$$\begin{aligned}\frac{1}{m^{1/2}} \le \frac{\eta_P(z_k,\alpha,\beta)}{\eta_{C_1}(z,\alpha,\beta)} &\le m^{3/2} \frac{(|\alpha|+|\beta|)\|\Lambda_{\alpha,\beta}\|_1 \max\bigl(1, \max_i \|A_i\|_2\bigr)^2}{\sum_{i=0}^{m} |\alpha|^i |\beta|^{m-i} \|A_i\|_2} \frac{\|z\|_2}{\|z_k\|_2} \\ &\le m^{5/2} \frac{\max\bigl(1, \max_i \|A_i\|_2\bigr)^2}{\min\bigl(\|A_0\|_2, \|A_m\|_2\bigr)} \frac{\|z\|_2}{\|z_k\|_2}.\end{aligned} \tag{3.11}$$

*Proof.* The first upper bound is obtained by combining (2.14) with (3.9) and (3.10). For the second upper bound it suffices to note that

$$\begin{aligned}\frac{(|\alpha|+|\beta|)\|\Lambda_{\alpha,\beta}\|_1}{\sum_{i=0}^{m} |\alpha|^i|\beta|^{m-i}\|A_i\|_2} &\le \frac{(|\alpha|+|\beta|)(|\alpha|^{m-1} + |\alpha|^{m-2}|\beta| + \cdots + |\beta|^{m-1})}{\min\bigl(\|A_0\|_2, \|A_m\|_2\bigr)(|\alpha|^m + |\beta|^m)} \\ &\le \frac{m}{\min\bigl(\|A_0\|_2, \|A_m\|_2\bigr)}\end{aligned}$$

by [7, Lem. A.1, (A.1)]. To prove the lower bound, let $\{\Delta A_i\}$ be an optimal set of perturbations in the definition of $\eta_P$. These trivially yield feasible perturbations

$\varDelta X_1 = \operatorname{diag}(\varDelta A_m, 0, \dots, 0)$ of $X_1$ and $\varDelta Y_1$ of $Y_1$, with $\varDelta Y_1$ being zero except for the first block row $[\varDelta A_{m-1}, \dots, \varDelta A_0]$. $\|\varDelta X_1\|_2 \le \eta_P \|X_1\|_2$ is immediate. Using Lemma 3.5,

$$\|\varDelta Y_1\|_2 \le m^{1/2} \max_{i=0:m-1} \|\varDelta A_i\|_2 \le m^{1/2}\eta_P \max_{i=0:m-1} \|A_i\|_2 \le m^{1/2}\eta_P \|Y_1\|_2. \qquad \square$$

The theorem reveals two main sufficient conditions for $\eta_P$ to be not much larger than $\eta_{C_1}$. The first is that $\|z\|_2/\|z_k\|_2$ is not much larger than 1. In the context of floating point arithmetic this requirement is to be expected, because if $\|z\|_2 \gg \|z_k\|_2$ then $z_k$ is likely to have suffered damaging subtractive cancellation in its formation. The second condition is that $\min(\|A_0\|_2, \|A_m\|_2) \approx \max_i \|A_i\|_2 \approx 1$, which is certainly true if $\|A_i\|_2 \approx 1$ for all $i$. Since $C_1 \in \mathbb{L}_1(P)$, Theorem 3.1 shows that the exact eigenvector is of the form $z = \Lambda_{\alpha,\beta} \otimes x$; since the largest element of $\Lambda_{\alpha,\beta}$ is the first or the last we can achieve $\|z\|_2/\|z_k\|_2 \in [1, \sqrt{m}]$ by taking $k = 1$ if $|\alpha| \ge |\beta|$ or $k = m$ if $|\alpha| \le |\beta|$. The importance for achieving a good backward error of recovering $x$ from the largest block component of $z$ has already been noted and shown empirically for the QEP by Tisseur [22, sec. 3.2]; our analysis provides theoretical confirmation for all degrees $m$.

We now turn to the backward error for a left eigenpair. Since $C_1 \in \mathbb{L}_1(P)$ with $v = e_1$ we have $L(\alpha,\beta)(\Lambda_{\alpha,\beta} \otimes I_n) = e_1 \otimes P(\alpha,\beta)$, so that (2.15) is satisfied with $H(\alpha,\beta) = \Lambda_{\alpha,\beta} \otimes I_n$ and $h = e_1$. The ensuing eigenvector recovery property is, from (2.17) or (3.5), $y = w(1\colon n)$. Before obtaining a backward error bound we give a more complete description of the relation between $y$ and $w$, which will aid in the interpretation of the bound. The following result extends [7, Lem. 7.2], which is stated for simple, finite, nonzero eigenvalues, to an arbitrary eigenvalue expressed in $(\alpha,\beta)$-form.

LEMMA 3.7 (left eigenvector recovery for $C_1$). *The vector $y \in \mathbb{C}^n$ is a left eigenvector of $P$ corresponding to the eigenvalue $(\alpha,\beta)$ if and only if*

$$w = \left\{ \begin{array}{ll} \begin{bmatrix} [\alpha^{m-1} I_n]^* \\ -[\alpha^{m-2}\beta A_{m-2} + \cdots + \alpha\beta^{m-2}A_1 + \beta^{m-1}A_0]^* \\ -[\alpha^{m-2}\beta A_{m-3} + \cdots + \alpha^2\beta^{m-3}A_1 + \alpha\beta^{m-2}A_0]^* \\ \vdots \\ -[\alpha^{m-2}\beta A_0]^* \end{bmatrix} y, & \alpha \ne 0, \\ \begin{bmatrix} [\beta^{m-1} I_n]^* \\ [\alpha\beta^{m-2}A_m + \beta^{m-1}A_{m-1}]^* \\ \vdots \\ [\alpha^{m-1}A_m + \cdots + \alpha\beta^{m-2}A_2 + \beta^{m-1}A_1]^* \end{bmatrix} y, & \beta \ne 0, \end{array} \right. \tag{3.12}$$

*is a left eigenvector of $C_1$ corresponding to $(\alpha,\beta)$. Every left eigenvector of $C_1$ with eigenvalue $(\alpha,\beta)$ is of the form* (3.12) *for some left eigenvector $y$ of $P$. For a finite eigenvalue, an alternative representation of $w$ is*

$$w^* = y^* \,[\, I_n, \quad B_{m-2}, \quad \dots \quad B_1, \quad B_0 \,],$$

*where $(P(t) - P(\lambda))/(t-\lambda) = \sum_{i=0}^{m-1} B_i t^i$ and $B_i = B_i(\lambda)$.*

*Proof.* Note first that the two different formulae in (3.12) (either of which can be obtained from the other by multiplying through by the conjugate of $(\alpha/\beta)^{m-1}$ or its reciprocal and using $y^*P(\alpha,\beta) = 0$) are needed because when $\alpha = 0$ (and hence

$y^*A_0 = 0$), the first expression is zero, while when $\beta = 0$ (and hence $y^*A_m = 0$), the second expression is zero.

For the first part it suffices to note that for $w$ as defined by (3.12) we have

$$w^*C_1(\alpha,\beta) = \begin{cases} y^*P(\alpha,\beta)(e_1^T \otimes I_n), & \alpha \neq 0, \\ y^*P(\alpha,\beta)(e_m^T \otimes I_n), & \alpha = 0. \end{cases}$$

For the next part, since $C_1$ is a strong linearization [4] and $P$ is regular, any eigenvalue $(\alpha,\beta)$ of $C_1$ of geometric multiplicity $k$ is also an eigenvalue of $P$ of geometric multiplicity $k$. Any $k$ linearly independent eigenvectors $y$ of $P$ for $(\alpha,\beta)$ clearly yield via (3.12) $k$ linearly independent eigenvectors of $L$. Hence any eigenvector of $L$ for $(\alpha,\beta)$ has the form (3.12).

The last part generalizes the analogous formula for scalar companion matrices given by Stewart [21, sec. 2]; we omit the proof. □

Lemma 3.7 shows that even when the eigenvalue is multiple all the left eigenvectors of $P$ can be obtained from the first $n$ components of the left eigenvectors of $C_1$.

We can now obtain the desired backward error bounds.

THEOREM 3.8. *Let $w$ be an approximate left eigenvector of $C_1$ corresponding to the approximate eigenvalue $(\alpha,\beta)$. Then for $w_1 = w(1\colon n)$ we have*

$$\begin{aligned} \frac{1}{m^{1/2}} \le \frac{\eta_P(w_1^*,\alpha,\beta)}{\eta_{C_1}(w^*,\alpha,\beta)} &\le m\frac{(|\alpha|+|\beta|)\|\Lambda_{\alpha,\beta}\|_2 \max(1,\max_i\|A_i\|_2)}{\sum_{i=0}^m |\alpha|^i|\beta|^{m-i}\|A_i\|_2}\frac{\|w\|_2}{\|w_1\|_2} \\ &\le m^{3/2}\frac{\max\bigl(1,\max_i\|A_i\|_2\bigr)}{\min(\|A_0\|_2,\|A_m\|_2)}\frac{\|w\|_2}{\|w_1\|_2}. \end{aligned} \tag{3.13}$$

*Proof.* The first upper bound follows directly from (2.18), (3.9), and $\|H_1(\alpha,\beta)\|_2 = \|\Lambda_{\alpha,\beta}\otimes I_n\|_2 = \|\Lambda_{\alpha,\beta}\|_2$. For the second upper bound it suffices to note that

$$\begin{aligned} \frac{(|\alpha|+|\beta|)\|\Lambda_{\alpha,\beta}\|_2}{\sum_{i=0}^m |\alpha|^i|\beta|^{m-i}\|A_i\|_2} &\le \frac{(|\alpha|+|\beta|)(|\alpha|^{2(m-1)}+|\alpha|^{2(m-2)}|\beta^2|+\cdots+|\beta|^{2(m-1)})^{1/2}}{\min\bigl(\|A_0\|_2,\|A_m\|_2\bigr)(|\alpha|^m+|\beta|^m)} \\ &\le \frac{m^{1/2}}{\min\bigl(\|A_0\|_2,\|A_m\|_2\bigr)} \end{aligned} \tag{3.14}$$

by [7, Lem. A.1, (A.3)]. The proof of the lower bound is exactly the same as in Theorem 3.6. □

Notice that compared with the bounds in Theorem 3.6 for right eigenpairs, the factor $\max_i\|A_i\|_2$ is not squared. However, $k$ is no longer a free parameter and so the ratio $\|w\|_2/\|w_1\|_2$ is fixed. Theorem 3.8 shows that $\eta_P(w_1^*,\alpha,\beta) \approx \eta_{C_1}(w^*,\alpha,\beta)$ is guaranteed provided that $\min(\|A_0\|_2,\|A_m\|_2) \approx \max_i\|A_i\|_2 \approx 1$ and $\|w\|_2/\|w_1\|_2$ is not much larger than 1. If $\|A_i\|_2 \lesssim 1$ for all $i$ then for an exact left eigenvector $w$ the ratio $\|w\|_2/\|w_1\|_2$ is bounded by about $(m^3/3)^{1/2}$; this can be seen from the first equation in (3.12) if $|\alpha| \ge |\beta|$ and the second if $|\alpha| \le |\beta|$.

A comparison with earlier work is instructive. Tisseur [22, Thm. 7] and Van Dooren and Dewilde [24, sec. 7] both show that solving a PEP by applying a backward stable solver to the first companion pencil is backward stable for the PEP, under certain conditions on the $A_i$. Van Dooren and Dewilde measure the perturbation $\Delta P$ to $P$ by $\|[\Delta A_m,\dots,\Delta A_0]\|_F/\|[A_m,\dots,A_0]\|_F$ and show that $\|[A_m,\dots,A_0]\|_F = 1$ implies stability. Tisseur uses the more stringent measure $\max_i\|\Delta A_i\|_2/\|A_i\|_2$, as in (2.1), and proves that $\|A_i\|_2 \equiv 1$ implies stability. These analyses are carried out without reference to specific eigenpairs or eigenvector recovery formulae and so they provide much less precise information than the bounds in Theorems 3.6 and 3.8.

**3.3. Scaled companion linearizations.** When the coefficient matrices of $P$ have norms that differ widely, the companion matrices $C_i(\lambda)$, $i = 1, 2$, are badly scaled and the bounds of Theorems 3.6 and 3.8 signal that $\eta_P \gg \eta_{C_1}$ is possible. In this section we study the effect on the backward error of scaling the identity blocks of $C_i$.

Let $D = \operatorname{diag}(d) \otimes I_n$, where $d \in \mathbb{R}^m$ with $d_1 = 1$ and $d_i > 0$, $i = 2{:}\,m$. It is easily checked that $DC_1(\lambda) \in \mathbb{L}_1(P)$ with $v = e_1$, that $C_2(\lambda)D \in \mathbb{L}_2(P)$ with $\widetilde{v} = e_1$, and that both scaled companion pencils are always linearizations. Since $C_2(P)D = (DC_1(P^T))^T$ we can concentrate on $DC_1$. The condition (2.11) becomes $G_k(\alpha,\beta)D^{-1} \cdot DC_1(\alpha,\beta) = e_k^T \otimes P(\alpha,\beta)$, where $G_k$ is defined in (3.8), and we find that

$$\|DX_1\|_2 = \max\Bigl(\max_{i>1} d_i,\, \|A_m\|_2\Bigr), \tag{3.15}$$

$$\|DY_1\|_2 \le m \max\Bigl(\max_{i>1} d_i,\, \max_{i=0:m-1} \|A_i\|_2\Bigr), \tag{3.16}$$

$$\|G_k(\alpha,\beta)D^{-1}\|_2 \le \sqrt{m}\,\|\Lambda_{\alpha,\beta}\|_1 \max\Bigl(1, \frac{\max_i \|A_i\|_2}{\min_{i>1} d_i}\Bigr). \tag{3.17}$$

In particular, if we choose $d_i = \max_\ell \|A_\ell\|_2$, $i = 2{:}\,m$, then

$$\|DX_1\|_2 = \max_i \|A_i\|_2, \qquad \|DY_1\|_2 \le m \max_i \|A_i\|_2,$$
$$\|G_k(\alpha,\beta)D^{-1}\|_2 \le \sqrt{m}\,\|\Lambda_{\alpha,\beta}\|_1.$$

As we now show, this scaling yields bounds for $\eta_P/\eta_{DC_1}$ better than those for $\eta_P/\eta_{C_1}$. We introduce the quantity

$$\rho = \frac{\max_i \|A_i\|_2}{\min(\|A_0\|_2, \|A_m\|_2)}, \tag{3.18}$$

which measures the scaling of the problem.

THEOREM 3.9. *Let* $D_s = \operatorname{diag}(1, s, \dots, s) \otimes I_n \in \mathbb{R}^{mn \times mn}$ *with* $s = \max_i \|A_i\|_2$. *Let* $z$ *and* $w$ *be approximate right and left eigenvectors of* $D_sC_1$ *corresponding to the approximate eigenvalue* $(\alpha,\beta)$. *Then for* $z_k = z((k-1)n + 1{:}\,kn)$, $k = 1{:}\,m$, *we have*

$$\frac{1}{m^{1/2}} \le \frac{\eta_P(z_k,\alpha,\beta)}{\eta_{D_sC_1}(z,\alpha,\beta)} \le m^{3/2}\, \frac{(|\alpha| + |\beta|)\|\Lambda_{\alpha,\beta}\|_1 \max_i \|A_i\|_2}{\sum_{i=0}^m |\alpha|^i|\beta|^{m-i}\|A_i\|_2}\, \frac{\|z\|_2}{\|z_k\|_2} \le m^{5/2}\,\rho \frac{\|z\|_2}{\|z_k\|_2},$$

*and for* $w_1 = w(1{:}\,n)$,

$$\frac{1}{m^{1/2}} \le \frac{\eta_P(w_1^*,\alpha,\beta)}{\eta_{D_sC_1}(w^*,\alpha,\beta)} \le m\, \frac{(|\alpha| + |\beta|)\|\Lambda_{\alpha,\beta}\|_2 \max_i \|A_i\|_2}{\sum_{i=0}^m |\alpha|^i|\beta|^{m-i}\|A_i\|_2}\, \frac{\|w\|_2}{\|w_1\|_2} \le m^{3/2}\,\rho \frac{\|w\|_2}{\|w_1\|_2}.$$

*Proof.* The proof is analogous to the proofs of Theorems 3.6 and 3.8, making use of (3.15)–(3.17). □

The bounds of Theorem 3.9 for the scaled companion pencil improve upon those for the unscaled pencil in several ways.

1. For the right eigenvector, the term $\max(1, \max_i \|A_i\|_2^2)/\min(\|A_0\|_2, \|A_m\|_2)$ in (3.11) is replaced by $\rho$, which is much smaller if $\max_i \|A_i\|_2 \gg 1$ or $\max_i \|A_i\|_2 \ll 1$.
2. For the left eigenvector, the term $\max(1, \max_i \|A_i\|_2)/\min(\|A_0\|_2, \|A_m\|_2)$ in (3.13) is replaced by $\rho$, which is much smaller if $\max_i \|A_i\|_2 \ll 1$.

3. For the scaled companion pencil, $\|w\|_2/\|w_1\|_2$ is guaranteed to be $O(m^{3/2})$ for the exact eigenvector, as can be seen from the appropriate choice of formula in (3.12), bearing in mind that scaling changes $w$ in (3.12) to $D_s^{-1}w$. To draw the same conclusion for the unscaled pencil we require $\max_i \|A_i\|_2 \lesssim 1$.

Our bounds suggest that scaling the identity blocks of $C_1$ can significantly improve the backward error of the recovered eigenvectors of $P$. We can, of course, employ more sophisticated two-sided scalings, including balancing [16], [25]. However, these scalings produce a new pencil not belonging to $\mathbb{L}_1$, so our backward error bounds are not applicable to them.

**3.4. $\mathbb{DL}(P)$ linearizations.** From section 2.2 and the definition of $\mathbb{L}_1$ in (3.3), it is clear that for pencils $L \in \mathbb{L}_1$ our analysis provides upper bounds for the backward error $\eta_P$ associated with approximate *left* eigenvectors of $P$ recovered from approximate *left* eigenvectors of $L$. The same is true for $L \in \mathbb{L}_2$ and approximate *right* eigenvectors. We now concentrate on the intersection

$$\mathbb{DL}(P) = \mathbb{L}_1(P) \cap \mathbb{L}_2(P), \tag{3.19}$$

since for pencils in $\mathbb{DL}(P)$ we can obtain backward error bounds for both left *and* right eigenvectors. $\mathbb{DL}(P)$ is a much smaller space than $\mathbb{L}_1(P)$ and $\mathbb{L}_2(P)$, being just $m$-dimensional. Indeed, it is shown in [19, Thm. 5.3] and [6, Thm. 3.4] that $L \in \mathbb{DL}(P)$ if and only if $L$ satisfies the conditions in (3.3) and (3.4) with $\widetilde{v} = v$. The general form of $\mathbb{DL}(P)$ for the quadratic $P(\lambda) = \lambda^2 A_2 + \lambda A_1 + A_0$ is given by

$$\mathbb{DL}(P) = \left\{ L(\lambda) = \lambda \begin{bmatrix} v_1A_2 & v_2A_2 \\ v_2A_2 & v_2A_1 - v_1A_0 \end{bmatrix} + \begin{bmatrix} v_1A_1 - v_2A_2 & v_1A_0 \\ v_1A_0 & v_2A_0 \end{bmatrix} : \ v \in \mathbb{C}^2 \right\},$$

which illustrates the fact that the companion pencils are not contained in $\mathbb{DL}(P)$ for any $m$. Just as for $\mathbb{L}_1$ and $\mathbb{L}_2$, almost all pencils in $\mathbb{DL}(P)$ are linearizations [19, Thm. 6.8]. In fact, there is a beautiful characterization of the subset of pencils $L \in \mathbb{DL}(P)$ that are linearizations [19, Thm. 6.7]: they are those for which no eigenvalue of $P$ is a root of the polynomial $\mathsf{p}(\lambda; v) := v^T \Lambda = \sum_{i=1}^m v_i \lambda^{m-i}$, where when $v_1 = 0$ we define $\infty$ to be a root of $\mathsf{p}(\lambda; v)$. Throughout this section we assume that the pencils $L \in \mathbb{DL}(P)$ under consideration are linearizations.

For pencils $L \in \mathbb{DL}(P)$, we have, by definition,

$$L(\alpha,\beta)(\Lambda_{\alpha,\beta} \otimes I_n) = v \otimes P(\alpha,\beta), \quad (\Lambda_{\alpha,\beta}^T \otimes I_n)L(\alpha,\beta) = v^T \otimes P(\alpha,\beta),$$

so that (2.11) and (2.15) hold with $G(\alpha,\beta) = \Lambda_{\alpha,\beta}^T \otimes I_n$ and $H(\alpha,\beta) = \Lambda_{\alpha,\beta} \otimes I_n$. Moreover, $\|G(\alpha,\beta)\|_2 = \|H(\alpha,\beta)\|_2 = \|\Lambda_{\alpha,\beta}\|_2$. From [7, Lem. 4.1] we know that $L(\alpha,\beta) = \alpha X + \beta Y$ satisfies

$$\max\bigl(\|X\|_2, \|Y\|_2\bigr) \le m r^{1/2} \max_i \|A_i\|_2, \tag{3.20}$$

where $r$ is the number of nonzeros in $v$ and we assume $\|v\|_2 = 1$ without loss of generality. We now have the ingredients to obtain a backward error bound. Recall that $\rho$ is defined in (3.18).

THEOREM 3.10. *Let $L \in \mathbb{DL}(P)$ with vector $v$ in* (3.3) *be a linearization, where $v$ has unit* 2*-norm and $r$ nonzeros. Let $z$ be an approximate right eigenvector of $L$ corresponding to the approximate eigenvalue $(\alpha,\beta)$. Then for $x = \sum_{i=1}^m v_i z_i$, where $z_i = z((i-1)n+1\colon in)$, we have*

$$\frac{\eta_P(x,\alpha,\beta)}{\eta_L(z,\alpha,\beta)} \le m r^{1/2} \frac{(|\alpha|+|\beta|)\|\Lambda_{\alpha,\beta}\|_2 \max_i \|A_i\|_2}{\sum_{i=0}^m |\alpha|^i |\beta|^{m-i} \|A_i\|_2} \frac{\|z\|_2}{\|x\|_2} \le m^{3/2} r^{1/2} \rho \frac{\|z\|_2}{\|x\|_2}.$$

*Proof.* Combine (2.14), (3.20), and (3.14). ☐

Note that the exact $z$ has the form $\Lambda_{\alpha,\beta} \otimes \xi$ so that $\|z\|_2 = \|\Lambda_{\alpha,\beta}\|_2 \|\xi\|_2$, and $\|x\|_2 = \| \sum_{i=1}^m v_i z_i \|_2 = |\Lambda_{\alpha,\beta}^T v| \|\xi\|_2$. Hence $\|z\|_2 / \|x\|_2 = \|\Lambda_{\alpha,\beta}\|_2 / |\mathsf{p}(\alpha,\beta;v)|$, where $\mathsf{p}(\alpha,\beta;v) = \Lambda_{\alpha,\beta}^T v = \sum_{i=1}^m v_i \alpha^{m-i} \beta^{i-1}$. Thus $\min\{ \|z\|_2/\|x\|_2 : \|v\|_2 = 1\} = 1$, with equality attained for $v_* = \overline{\Lambda_{\alpha,\beta}} / \|\Lambda_{\alpha,\beta}\|_2$. This choice of $v$ minimizes the second upper bound of Theorem 3.10. However, simply choosing $v = e_k$ where $\|z_k\|_2 = \max_{i=1:m} \|z_i\|_2$ ensures that $\|z\|_2/\|x\|_2 \le \sqrt{m}$, which is perfectly adequate.

Intuitively, we might expect that $\eta_P(x,\alpha,\beta) \ge \eta_L(z,\alpha,\beta)$, at least to within some constant factor, but this is not necessarily the case. Consider, for example, the pencil

$$L(\lambda) = \lambda \begin{bmatrix} A & A \\ A & B - C \end{bmatrix} + \begin{bmatrix} B - A & C \\ C & C \end{bmatrix} \in \mathbb{DL}(\lambda^2 A + \lambda B + C),$$

which corresponds to $v = [1\ 1]^T$ in (3.3). Suppose $A = B = I$ and $C = \epsilon I$ with $0 < \epsilon \ll 1$, and let $\Delta A = \delta I$ and $\Delta B = \Delta C = 0$. These perturbations have relative size $\max(\|\Delta A\|_2/\|A\|_2, \|\Delta B\|_2/\|B\|_2, \|\Delta C\|_2/\|C\|_2) = \delta$, but for the pencil $\max(\|\Delta X\|_2/\|X\|_2, \|\Delta Y\|_2/\|Y\|_2) \approx \max(\delta, \delta/\epsilon) = \delta/\epsilon$. Hence a small perturbation to $P$ does not necessarily correspond to a small perturbation to $L$ and $\eta_P/\eta_L$ cannot therefore be bounded below by a positive constant. This phenomenon is not present for the pencils corresponding to $v = e_k$, which form the standard basis for $\mathbb{DL}(P)$ [6], because for these pencils each block of $X$ and $Y$ is plus or minus a single block $A_i$. We now specialize Theorem 3.10 to these pencils.

COROLLARY 3.11. *Let $L_k \in \mathbb{DL}(P)$ corresponding to $v = e_k$ in* (3.3) *be a linearization. Let $z$ be an approximate right eigenvector of $L_k$ corresponding to the approximate eigenvalue $(\alpha,\beta)$. Then for $z_k = z((k-1)n + 1{:}\,kn)$, we have*

$$\frac{1}{m} \le \frac{\eta_P(z_k,\alpha,\beta)}{\eta_{L_k}(z,\alpha,\beta)} \le m \frac{(|\alpha| + |\beta|)\|\Lambda_{\alpha,\beta}\|_2 \max_i \|A_i\|_2}{\sum_{i=0}^m |\alpha|^i |\beta|^{m-i} \|A_i\|_2} \frac{\|z\|_2}{\|z_k\|_2} \le m^{3/2} \rho \frac{\|z\|_2}{\|z_k\|_2}.$$

*Proof.* The upper bound follows from Theorem 3.10. The lower bound is proved in a similar way to the lower bound of Theorem 3.6. ☐

Analogues of Theorem 3.10 and Corollary 3.11 hold for approximate left eigenvectors $w$ of $L_k$: $z$ is simply replaced by $w$ and $x$ by $y = \sum_{i=1}^m \overline{v}_i w_i$.

With the notation in Corollary 3.11, the exact eigenvector $z$ satisfies $z = \Lambda_{\alpha,\beta} \otimes x$, and it is easy to see that $\|z\|_2/\|z_k\|_2 \approx 1$ for $k = 1$ if $|\alpha| \ge |\beta|$ and for $k = m$ if $|\alpha| \le |\beta|$. Assuming the approximate eigenvector $z$ shares the latter property, the pencils in $\mathbb{DL}(P)$ with $v = e_1$ and $v = e_m$ yield backward errors $\eta_P \approx \eta_L$ for eigenpairs with eigenvectors of modulus greater than or less than 1, respectively, provided that the measure $\rho$ of the scaling of the problem is of order 1. Two points are worth noting.

1. Although an eigenvector of $P$ can be recovered from any of the blocks $z_i = z((i-1)n + 1{:}\,in)$ of an eigenvector $z$ of $L_k$ (see Theorem 3.1), our backward error bounds in Corollary 3.11 require $i = k$.
2. The pencils $L_1$ and $L_m$ are indeed linearizations if $A_0$ and $A_m$, respectively, are nonsingular, as can be seen from the characterization mentioned at the start of this subsection.

### 3.5. Comparison with conditioning results.

Backward error and conditioning are complementary concepts. Ideally, we would like the linearization $L$ that we use to be as well conditioned as the original polynomial $P$ and for it to lead, after recovering an approximate eigenpair of $P$ from one of $L$, to a backward error $\eta_P$

of the same order of magnitude as $\eta_L$. Therefore to show that one linearization is preferable to another we need to show that it enjoys a better bound for $\eta_P/\eta_L$ as well as a better condition number bound. Remarkably, our backward error results are entirely harmonious with the results of Higham, Mackey, and Tisseur [7] concerning eigenvalue conditioning, as we now explain.

For the companion forms the analysis in [7, sec. 7] provides bounds on the ratio $\kappa_{C_1}(\lambda)/\kappa_P(\lambda)$ of appropriately defined condition numbers in the case of quadratics. That analysis is readily extended to $(\alpha,\beta)$-form and general degrees, and it shows that, like the backward error ratio in Theorem 3.6, $\kappa_{C_1}(\alpha,\beta)/\kappa_P(\alpha,\beta)$ is bounded by a multiple of $\max\bigl(1, \max_i \|A_i\|_2^2\bigr)/\min(\|A_0\|_2, \|A_m\|_2)$. Thus if $\min(\|A_0\|_2, \|A_m\|_2) \approx \max_i \|A_i\|_2 \approx 1$ and if a relatively large block is used for right eigenvector recovery then $C_1$ is an optimal linearization from the points of view of both backward error and conditioning.

For the scaled companion forms we can show that $\kappa_{D_sC_1}(\alpha,\beta)/\kappa_P(\alpha,\beta)$ is bounded by a multiple of $\rho$, just as for the backward error ratios in Theorem 3.9. So if $\rho \approx 1$ and a relatively large block is used for eigenvector recovery then $D_sC_1$ is an optimal linearization.

For the $\mathbb{DL}(P)$ pencils with $v = e_1$ (if $|\lambda| \ge 1$) or $v = e_m$ (if $|\lambda| \le 1$) it is once again the case that the factor $\rho$ in the backward error bound (in Corollary 3.11) is also the key quantity in a bound on the ratio of condition numbers $\kappa_{L_k}/\kappa_P$. We can conclude that if $\rho \approx 1$ then $L_1$ and $L_m$ are optimal with respect to both backward error and conditioning over all linearizations for $|\lambda|$ greater than 1 and less than 1, respectively, assuming $\|z_1\|_2 \approx \|z\|_2$ for $L_1$ and $\|z_m\|_2 \approx \|z\|_2$ for $L_m$ (properties that hold for the exact eigenvectors).

## 4. Structured linearizations.

We now briefly consider to what extent the results above extend to structured linearizations for structured polynomials. Our definition of backward error remains the same and so does not incorporate structure. The issue is that structure may change some key properties of a linearization and thereby may limit our freedom in choosing how to recover eigenvectors.

### 4.1. Symmetric and Hermitian structures.

If $P$ is symmetric, that is, $P(\lambda) = P(\lambda)^T$, then all the pencils in $\mathbb{DL}(P)$ are symmetric, and these comprise all the symmetric pencils in $\mathbb{L}_1(P)$ [6, Thm 5.2]. Hence Theorem 3.10 and Corollary 3.11 are both applicable with $L$ symmetric. If $P$ is Hermitian, that is, $P(\lambda) = P(\bar{\lambda})^*$, then it is precisely the pencils in $\mathbb{DL}(P)$ with a *real* vector $v$ that are Hermitian [6, Thm 6.2]. Theorem 3.10 remains applicable for Hermitian $L$ with the minor restriction that $v$ is real. Thus symmetry and Hermitian structure impose no significant limitations on the applicability of our backward error bounds.

### 4.2. Alternating and palindromic structures.

We now consider some other classes of structures for which we can identify structured linearizations. These structures are less familiar than symmetric or Hermitian structures but still important in a variety of applications [17, Chap. 7]. In what follows, the symbol $\star$ is used as an abbreviation for transpose ($T$) in the real case and either transpose or conjugate transpose ($*$) in the complex case. The $\star$-adjoint of $P$ is defined by

$$P^\star(\lambda) = \sum_{i=0}^{m} \lambda^i A_i^\star.$$

$P(\lambda)$ is said to be

$\star$-even if $P^\star(-\lambda) = P(\lambda)$, $\star$-odd if $P^\star(-\lambda) = -P(\lambda)$,
$\star$-palindromic if $\mathrm{rev}P^\star(\lambda) = P(\lambda)$, $\star$-antipalindromic if $\mathrm{rev}P^\star(\lambda) = -P(\lambda)$,
where rev is defined in (3.2). For example, the quadratic $Q(\lambda) = \lambda^2 M + \lambda G + K$ with $M$, $K$ symmetric and $G$ skew-symmetric, arising in gyroscopic systems, is $T$-even since $Q^T(-\lambda) = Q(\lambda)$. On the other hand, the quadratic $Q(\lambda) = \lambda^2 A + \lambda B + A^T$ with $B$ complex symmetric, arising in the study of vibration of rail tracks under the excitation of high speed trains [10], [11], is $T$-palindromic since $\mathrm{rev}Q^T(\lambda) = Q(\lambda)$.

Linearizations in $\mathbb{L}_1(P)$ that reflect the structure of these polynomials and therefore preserve symmetries in their spectra have recently been investigated by Mackey et al. [18]. It is shown in [18, Thms. 3.5, 3.6] that if $L(\lambda) \in \mathbb{L}_1(P)$ is $\star$-structured with vector $v$ then $(M \otimes I_n)L(\lambda)$ is in $\mathbb{DL}(P)$ with vector $Mv$, where $M$ is either a diagonal matrix of alternating signs, $M = \mathrm{diag}((-1)^{m-1}, \dots, (-1)^0)$, in the case of even/odd structures, or the reverse identity matrix, $R = (\delta_{i,n+1-i})$, in the context of palindromic structures.

Since $L$ itself is in general not in $\mathbb{DL}(P)$ we cannot apply Theorem 3.10. However, the proof of the theorem is readily adapted, and by exploiting the fact that $M \otimes I_n$ is unitary the same bound is obtained.

THEOREM 4.1. *Let $L \in \mathbb{L}_1(P)$ with vector $v$ be a $\star$-structured linearization and assume that $v$ has unit 2-norm and $r$ nonzeros. Let $z$ be an approximate right eigenvector of $L$ corresponding to the approximate eigenvalue $(\alpha, \beta)$. Then for $x = \sum_{i=1}^m v_i z_i$ we have*

$$\frac{\eta_P(x,\alpha,\beta)}{\eta_L(z,\alpha,\beta)} \le m r^{1/2} \frac{(|\alpha| + |\beta|)\|\Lambda_{\alpha,\beta}\|_2 \max_i \|A_i\|_2}{\sum_{i=0}^m |\alpha|^i |\beta|^{m-i} \|A_i\|_2} \frac{\|z\|_2}{\|x\|_2} \le m^{3/2} r^{1/2} \rho \frac{\|z\|_2}{\|x\|_2}.$$

*For approximate left eigenvectors an analogous bound holds with $z$ replaced by $w$ and $x$ by $y = \sum_{i=1}^m (M\overline{v})_i w_i$.*

Theorem 4.1 shows that $\eta_P \approx \eta_L$ as long as $\rho = O(1)$ and $\|z\|_2/\|x\|_2 \approx 1$. However, whereas for $\mathbb{DL}(P)$ $v$ can be freely chosen, in particular to minimize $\|z\|_2/\|x\|_2$, now the choice of $v$ is constrained by the requirement that $L$ be $\star$-structured. For example, for $T$-palindromic polynomials $P$, $L \in \mathbb{L}_1(P)$ with vector $v$ is $T$-palindromic if and only $Rv = v$ [18, Thm. 3.5]; in the case of a quadratic, $v = [1\ 1]/\sqrt{2}$ is forced.

## 5. Quadratic polynomials.

We now concentrate our attention on quadratic polynomials, $Q(\lambda) = \lambda^2 A + \lambda B + C$, for which we can give a more detailed analysis than in the general case, covering in particular a potentially very beneficial scaling of the polynomial. We write

$$a = \|A\|_2, \quad b = \|B\|_2, \quad c = \|C\|_2. \tag{5.1}$$

Note that $\Lambda_{\alpha,\beta} = [\alpha, \beta]^T$. We will recover eigenvectors of $Q$ from the components $z_1 = z(1\colon n)$ and $z_2 = z(n+1\colon 2n)$ (and similarly for $w$) of eigenvectors of a linearization.

The first companion form of $Q$ is given by

$$C_1(\lambda) = \lambda \begin{bmatrix} A & 0 \\ 0 & I_n \end{bmatrix} + \begin{bmatrix} B & C \\ -I_n & 0 \end{bmatrix},$$

and $D_s C_1(\lambda) = \mathrm{diag}(I_n, sI_n) C_1(\lambda)$ with $s = \max(a,b,c)$. We normalize so that $|\alpha|^2 + |\beta|^2 = 1$. Theorems 3.6 and 3.9 say that for right eigenpairs

$$\frac{\eta_Q(z_k,\alpha,\beta)}{\eta_{C_1}(z,\alpha,\beta)} \le 2^{5/2} \frac{\max\left(1,a,b,c\right)^2}{|\alpha|^2 a + |\alpha||\beta| b + |\beta|^2 c} \frac{\|z\|_2}{\|z_k\|_2}, \quad k = 1, 2, \tag{5.2}$$

$$\frac{\eta_Q(z_k,\alpha,\beta)}{\eta_{D_sC_1}(z,\alpha,\beta)} \le 2^{5/2}\frac{\max(a,b,c)}{|\alpha|^2a+|\alpha||\beta|b+|\beta|^2c}\frac{\|z\|_2}{\|z_k\|_2}, \quad k=1,2. \tag{5.3}$$

Analogous bounds hold for left eigenvectors: they have factor $2^{3/2}$ and there is no square in the numerator for the analogue of (5.2). In interpreting these bounds and those below recall that, for the exact eigenvectors of any pencil in $\mathbb{L}_1(Q)$,

$$\frac{\|z\|_2}{\|z_1\|_2} \approx 1 \quad \text{for } |\alpha| \ge |\beta|, \qquad \frac{\|z\|_2}{\|z_2\|_2} \approx 1 \quad \text{for } |\alpha| \le |\beta|. \tag{5.4}$$

The $\mathbb{DL}(Q)$ pencils with $v = e_1$ and $v = e_2$ are given by

$$L_1(\lambda) = \lambda\begin{bmatrix} A & 0 \\ 0 & -C\end{bmatrix} + \begin{bmatrix} B & C \\ C & 0\end{bmatrix}, \quad L_2(\lambda) = \lambda\begin{bmatrix} 0 & A \\ A & B\end{bmatrix} + \begin{bmatrix} -A & 0 \\ 0 & C\end{bmatrix}.$$

We know from Corollary 3.11 that

$$\frac{\eta_Q(z_1,\alpha,\beta)}{\eta_{L_1}(z,\alpha,\beta)} \le 2^{3/2}\frac{\max(a,b,c)}{|\alpha|^2a+|\alpha||\beta|b+|\beta|^2c}\frac{\|z\|_2}{\|z_1\|_2}. \tag{5.5}$$

In view of (5.4) this bound is appropriate when $|\alpha| \ge |\beta|$. If $|\alpha| \le |\beta|$ then we wish to take $z_2$ rather than $z_1$ as eigenvector of $Q$, but Theorem 3.10 does not provide a bound for $L_1$ and $z_2$. We now derive such a bound, by explicitly constructing an appropriate $G$ matrix. It is easy to check that $G_Q(\alpha,\beta) = [\,\beta I_n, \quad -(\alpha A+\beta B)C^{-1}\,]$ satisfies $G_Q(\alpha,\beta)L_1(\alpha,\beta) = e_2^T \otimes Q(\alpha,\beta)$ so that (2.11) holds, and by Lemma 3.5

$$\|G_Q(\alpha,\beta)\|_2 \le \sqrt{2}\,\|\Lambda_{\alpha,\beta}\|_\infty \max\bigl(1,(a+b)\|C^{-1}\|_2\bigr).$$

Hence (2.14) yields

$$\frac{\eta_Q(z_2,\alpha,\beta)}{\eta_{L_1}(z,\alpha,\beta)} \le 4\frac{\max(a,b,c)\max(1,(a+b)\|C^{-1}\|_2)}{|\alpha|^2a+|\alpha||\beta|b+|\beta|^2c}\frac{\|z\|_2}{\|z_2\|_2}. \tag{5.6}$$

Similarly we have for $L_2$, by an analogue of the $G_Q$ analysis and by Corollary 3.11,

$$\frac{\eta_Q(z_1,\alpha,\beta)}{\eta_{L_2}(z,\alpha,\beta)} \le 4\frac{\max(a,b,c)\max(1,(b+c)\|A^{-1}\|_2)}{|\alpha|^2a+|\alpha||\beta|b+|\beta|^2c}\frac{\|z\|_2}{\|z_1\|_2}, \tag{5.7}$$

$$\frac{\eta_Q(z_2,\alpha,\beta)}{\eta_{L_2}(z,\alpha,\beta)} \le 2^{3/2}\frac{\max(a,b,c)}{|\alpha|^2a+|\alpha||\beta|b+|\beta|^2c}\frac{\|z\|_2}{\|z_2\|_2}. \tag{5.8}$$

Essentially the same bounds (5.5)–(5.8) hold for approximate left eigenvectors: $z$ is simply replaced by $w$ and $z_i$ by $w_i$.

In Table 5.1 we summarize for unstructured quadratics the main conclusions from these bounds concerning conditions that guarantee $\eta_P \approx \eta_L$. Here, using $\rho$ from (3.18),

$$\rho = \frac{\max(a,b,c)}{\min(a,c)} \ge \frac{\max(a,b,c)}{|\alpha|^2a+|\alpha||\beta|b+|\beta|^2c}. \tag{5.9}$$

In view of the bounds, it is natural to scale the problem to try to bring the 2-norms of $A$, $B$, and $C$ close to 1. The scaling of Fan, Lin, and Van Dooren [2] has

Table 5.1

*Sufficient conditions for* $\eta_P \approx \eta_L$; $\rho$ *is defined in* (5.9).

| Linearization | Eigenvalue | Right eigenvector | Left eigenvector | Condition |
|---|---|---|---|---|
| Companion | $\lvert\alpha\rvert \ge \lvert\beta\rvert$<br>$\lvert\alpha\rvert \le \lvert\beta\rvert$ | $z_1$<br>$z_2$ | $w_1$ | $b \le a \approx c \approx 1$ |
| Scaled companion | $\lvert\alpha\rvert \ge \lvert\beta\rvert$<br>$\lvert\alpha\rvert \le \lvert\beta\rvert$ | $z_1$<br>$z_2$ | $w_1$ | $\rho \approx 1$ |
| $L_1$ | $\lvert\alpha\rvert \ge \lvert\beta\rvert$<br>$\lvert\alpha\rvert \le \lvert\beta\rvert$ | $z_1$<br>$z_2$ | $w_1$<br>$w_2$ | $\rho \approx 1$<br>$\rho \max\bigl(1, (a+b)\lVert C^{-1}\rVert_2\bigr) \approx 1$ |
| $L_2$ | $\lvert\alpha\rvert \ge \lvert\beta\rvert$<br>$\lvert\alpha\rvert \le \lvert\beta\rvert$ | $z_1$<br>$z_2$ | $w_1$<br>$w_2$ | $\rho \max\bigl(1, (b+c)\lVert A^{-1}\rVert_2\bigr) \approx 1$<br>$\rho \approx 1$ |

precisely this aim. It converts $Q(\lambda) = \lambda^2 A + \lambda B + C$ to $\widetilde{Q}(\mu) = \mu^2 \widetilde{A} + \mu \widetilde{B} + \widetilde{C}$, where

$$\lambda = \gamma\mu, \quad Q(\lambda)\delta = \mu^2(\gamma^2\delta A) + \mu(\gamma\delta B) + \delta C \equiv \widetilde{Q}(\mu), \tag{5.10a}$$

$$\gamma = \sqrt{c/a}, \quad \delta = 2/(c + b\gamma). \tag{5.10b}$$

Letting

$$\widetilde{a} = \lVert\widetilde{A}\rVert_2, \quad \widetilde{b} = \lVert\widetilde{B}\rVert_2, \quad \widetilde{c} = \lVert\widetilde{C}\rVert_2, \tag{5.11}$$

$$\tau = \frac{b}{\sqrt{ac}}, \tag{5.12}$$

we have

$$\widetilde{a} = \widetilde{c} = \frac{2}{1+\tau}, \qquad \widetilde{b} = \frac{2\tau}{1+\tau}, \qquad \frac{\widetilde{a}}{2} + \widetilde{b} + \frac{\widetilde{c}}{2} = 2,$$

so that $2/3 \le \max(\widetilde{a}, \widetilde{b}, \widetilde{c}) \le 2$. It is straightforward to show that $\widetilde{\rho} = \max(\widetilde{a}, \widetilde{b}, \widetilde{c})/\min(\widetilde{a}, \widetilde{c}) = \max(1, \tau) \le \rho$. Note that $\eta_Q(x, \lambda) = \eta_{\widetilde{Q}}(x, \mu)$, so this scaling has no effect on the backward error for the quadratic; its purpose is to improve the backward error for the linearization. For $\widetilde{Q}(\mu)$, the bounds (5.2), (5.3), and (5.5)–(5.8) can be simplified.

Theorem 5.1. *Let* $(z, w, \alpha, \beta)$ *be an approximate eigentriple of a linearization of the scaled quadratic* $\widetilde{Q}$ *in* (5.10) *with* $|\alpha|^2 + |\beta|^2 = 1$. *Define*

$$\omega = \omega(\alpha, \beta) := \frac{1+\tau}{1 + |\alpha\beta|\tau}, \tag{5.13}$$

*with* $\tau$ *as in* (5.12). *We have*

$$\frac{\eta_{\widetilde{Q}}(z_i, \alpha, \beta)}{\eta_{C_1}(z, \alpha, \beta)} \le 2^{7/2}\omega \frac{\lVert z\rVert_2}{\lVert z_i\rVert_2}, \quad i = 1, 2, \qquad \frac{\eta_{\widetilde{Q}}(w_1^*, \alpha, \beta)}{\eta_{C_1}(w^*, \alpha, \beta)} \le 2^{3/2}\omega \frac{\lVert w\rVert_2}{\lVert w_1\rVert_2}.$$

*The same bounds hold for* $D_s C_1$ *and the constant* $2^{7/2}$ *can be replaced by* $2^{5/2}$. *Furthermore,*

$$\frac{\eta_{\widetilde{Q}}(x, \alpha, \beta)}{\eta_{L_i}(z, \alpha, \beta)} \le f_i(x)\omega \frac{\lVert z\rVert_2}{\lVert x\rVert_2}, \quad i = 1, 2,$$

*with*

$$f_1(x) = \begin{cases} 2^{3/2} & \textit{if } x = z_1, \\ 8\|\widetilde{C}^{-1}\|_2 & \textit{if } x = z_2, \end{cases} \quad f_2(x) = \begin{cases} 8\|\widetilde{A}^{-1}\|_2 & \textit{if } x = z_1, \\ 2^{3/2} & \textit{if } x = z_2, \end{cases}$$

*where the nonsingularity of $C$ and $A$ is required for $f_1(z_2)$ and $f_2(z_1)$. Similar bounds hold for approximate left eigenvectors and $L_i$, $i = 1, 2$: $z$ is replaced by $w$ and $z_i$ by $w_i$.*

*Proof.* For the scaled norms in (5.11) we have

$$(5.14)\quad |\alpha|^2\widetilde{a} + |\alpha||\beta|\widetilde{b} + |\beta|^2\widetilde{c} = \frac{2}{1+\tau} + |\alpha||\beta|\frac{2\tau}{1+\tau} = \frac{2(1+|\alpha||\beta|\tau)}{1+\tau} = \frac{2}{\omega(\alpha,\beta)}$$

and the upper bounds follow from (5.2), (5.3), and (5.5)–(5.8). ☐

We can regard $\omega$ in (5.13) as a growth factor bound in the translation from backward error for $L$ to backward error for $\widetilde{Q}$. With the normalization $|\alpha|^2 + |\beta|^2 = 1$, which implies $|\alpha||\beta| \le 1/2$, this factor satisfies the bounds

$$(5.15)\qquad 1 \le \frac{1+\tau}{1+\frac{1}{2}\tau} \le \omega \le \min\left\{1+\tau, \frac{1}{|\alpha\beta|}\right\} \le 1+\tau.$$

Fan, Lin, and Van Dooren [2] identify $\max(1+\tau, 1+\tau^{-1})$ as a growth factor. Our bounds for $\omega$, which unlike in [2] are for individual eigenpairs and apply to $L_i$ as well as $C_1$, are sharper in two respects. First, they show that $\tau$ satisfying $\tau \ll 1$ are harmless, since our upper bound for $\omega$ is $O(1)$. Second, even when $\tau \gg 1$ the penultimate bound in (5.15) will still be of order 1 if $|\alpha||\beta| = |\alpha|\sqrt{1-|\alpha|^2} = O(1)$, which is the case unless $|\lambda| = |\alpha|/|\beta| = |\alpha|/\sqrt{1-|\alpha|^2}$ is small or large.

The most striking consequence of the theorem is that if

$$(5.16)\qquad \|B\|_2 \lesssim (\|A\|_2\|C\|_2)^{1/2},$$

so that $\tau = O(1)$ and hence $\omega = O(1)$, then the $\eta_{Q}/\eta_L$ ratios are 1 for the relevant choice of $z_i$, provided $\widetilde{A}^{-1}$ and $\widetilde{C}^{-1}$ have norms of order 1 in the case of two of the bounds for $L_1$ and $L_2$. In the terminology of quadratics arising from mechanical systems with damping, the condition (5.16) holds for systems that are not too heavily damped. A class of problems for which (5.16) is satisfied is the elliptic $Q$ [9], [13]: those for which $A$ is Hermitian positive definite, $B$ and $C$ are Hermitian, and $(x^*Bx)^2 < 4(x^*Ax)(x^*Cx)$ for all nonzero $x \in \mathbb{C}^n$.

Our conclusions about the benefits to the backward error of scaling $Q$ apply equally well to the condition numbers. Indeed, using (5.14) the analysis in [7] can be improved to provide bounds for $\kappa_L/\kappa_{\widetilde{Q}}$ expressed in terms of $\omega$ instead of $\rho$ for $L = C_1$, $L_1$, and $L_2$. Therefore for these three choices of $L$ both backward error (modulo the potential requirement that $\|\widetilde{A}^{-1}\|$, $\|\widetilde{C}^{-1}\| = O(1)$ for $L_1$ and $L_2$) and conditioning are essentially optimal for the scaled problem if $\omega = O(1)$.

## 6. Numerical experiments.

We illustrate the theory on three symmetric QEPs. Our experiments were performed in MATLAB 7, for which the unit roundoff is $u = 2^{-53} \approx 1.1 \times 10^{-16}$. The eigenpairs of $L(\lambda)$ were computed by MATLAB's function `qz`. Table 6.1 reports the problem sizes, the coefficient matrix norms, and the values of $\rho$ in (3.18) (or (5.9)) before and after scaling via (5.10). In our figures, the $x$-axis is the eigenvalue index and the eigenvalues are sorted in increasing order

Table 6.1

of absolute value. Throughout this section "companion" refers to the first companion linearization, $C_1$.

Our first problem comes from applying the Galerkin method to a PDE describing the wave motion of a vibrating string with clamped ends in a spatially inhomogeneous environment [3], [9]. The quadratic $Q$ is elliptic. Table 6.2 displays the smallest and largest ratios $\eta_Q(x,\alpha,\beta)/\eta_L(z,\alpha,b)$ over all computed eigenvalues for several linearizations and for the two ways of recovering the right eigenvector: $x = z_1$ and $x = z_2$. These ratios are compared with the corresponding theoretical upper bounds (5.2), (5.3), and (5.5)–(5.8) (taking the same $(\alpha,\beta)$ as for the smallest/largest backward error ratio). The upper bounds for the scaled companion linearization are smaller than those for the companion linearization, as expected by the theory since $c \gg 1$, and they also are sharper. For $\mathbb{DL}(Q)$ linearizations, the theory suggests using $L_1$ with $x = z_1$, since all the eigenvalues of $Q$ have modulus at least 1. This is reflected in Table 6.2, where the $L_1, z_1$ pairing produces smaller ratios and upper bounds than $L_2, z_1$. For the scaled quadratic $\widetilde{Q}$ in (5.10), we computed the bounds of Theorem 5.1. Since this problem is elliptic, we know from Theorem 5.1 that for the scaled problem, whose eigenvalues lie between 0.04 and 1 in modulus, the scaled and unscaled companion linearizations and the $\mathbb{DL}(\widetilde{Q})$ linearization $L_2$ will have backward errors similar to those for $\widetilde{Q}$ for every eigenvalue with the choice $x = z_2$. This is confirmed by the boldface entries in the last two columns of Table 6.2.

Our second problem is a simplified model of a nuclear power plant, as described in [12], [23]. The largest ratios $\eta_Q(x,\alpha,\beta)/\eta_L(z,\alpha,b)$ and corresponding upper bounds are displayed in Table 6.3. Similar conclusions to those for the wave problem can be drawn for this problem. Since $\rho = 7 \times 10^4$, it is not surprising that some very large ratios are obtained. This example also illustrates the advantage of scaling the companion matrix. This is even more striking in Figure 6.1, where the ratios for all the right and left eigenpairs are displayed. For the companion linearization, these ratios can be up to $10^{10}$ times as large as those for $D_sC_1$. Although the problem is not elliptic, $\|B\|_2 \le \sqrt{\|A\|_2\|C\|_2}$ holds, and so our theory says that scaling will make the scaled and unscaled companion linearizations and the $\mathbb{DL}(Q)$ linearization $L_2$ with $x = z_2$ (since the scaled eigenvalues have modulus at most 1) optimally stable. This prediction is confirmed by the boldface entries in Table 6.3. Notice that for the scaled quadratic $\widetilde{Q}$, the bounds for $L_1$ with $z_2$ and $L_2$ with $z_1$ are very weak, due to the large values of $\|\widetilde{A}^{-1}\|_2$ and $\|\widetilde{C}^{-1}\|_2$ shown in Table 6.1.

Our third problem is a standard damped mass-spring system, as described in [23,

Table 6.2

sec. 3.9]. The matrix $A = I$, $B$ is tridiagonal with super- and subdiagonal elements all $-64$ and diagonal $128, 192, 192, \dots, 192$, and $C$ is tridiagonal with super- and subdiagonal elements all $-1$ and diagonal $2, 3, \dots, 3$. The eigenvalues are all negative, with 50 eigenvalues of large modulus ranging from $-320$ to $-6.4$ and 50 small modulus eigenvalues approximately $-1.5\times 10^{-2}$. For the approximate right eigenvector, we take $x = z_1$ if $|\lambda| \geq 1$ and $x = z_2$ otherwise, as suggested by the theory. The largest ratios $\eta_Q(x, \alpha, \beta)/\eta_L(z, \alpha, b)$ and corresponding upper bounds are displayed in Table 6.4. Notice that for this problem the upper bound on the ratio $\eta_Q(x, \alpha, \beta)/\eta_{C_1}(z, \alpha, \beta)$ is nearly attained, which suggests that the factor $\max(1, a, b, c)^2$ in the bound should indeed contain the square. The largest ratio for $L = L_1$ corresponds to a small eigenvalue with $x = z_2$ and, for $L = L_2$, the largest ratio corresponds to a large eigenvalue with $x = z_1$. Hence, the reported upper bounds contain the extra factors $(a + b)\|C^{-1}\|_2$ and $(b + c)\|A^{-1}\|_2$, respectively, which explains why the bounds are larger than those for the scaled companion linearization (on the scaled and unscaled problems), which are small multiples of $\rho$. The top plot in Figure 6.2 shows that for the scaled quadratic $\widetilde{Q}$, small backward error ratios are obtained for $L = L_1$ and large eigenvalues, whereas the ratios are small with the choice $L = L_2$ for the small eigenvalues—all as the theory predicts. The bottom plot in Figure 6.2 confirms that the actual backward errors $\eta_Q$ are what we would expect, given the ratios and the fact that the computed eigenpairs of $L$ are obtained via the QZ algorithm and so necessarily have a backward error of order $u$.

Finally, we mention that further numerical illustration of the bounds developed here, on a symmetric QEP arising from a finite element model of a simply supported beam, can be found in [8].

# FURTHER RESULTS ON THE REVERSE ORDER LAW FOR GENERALIZED INVERSES*

DRAGAN S. DJORDJEVIĆ†

**Abstract.** The reverse order rule $(AB)^\dagger = B^\dagger A^\dagger$ for the Moore–Penrose inverse is established in several equivalent forms. Results related to other generalized inverses are also proved.

**Key words.** Moore–Penrose inverse, generalized inverses, reverse order law

**AMS subject classifications.** 47A05, 15A09

**DOI.** 10.1137/050638114

## 1. Introduction.

Throughout this paper $\mathcal{H}, \mathcal{K}, \mathcal{L}$ denote arbitrary Hilbert spaces. We use $\mathcal{L}(\mathcal{H}, \mathcal{K})$ to denote the set of all linear bounded operators from $\mathcal{H}$ to $\mathcal{K}$. Also, $\mathcal{L}(\mathcal{H}) = \mathcal{L}(\mathcal{H}, \mathcal{H})$. For $A \in \mathcal{L}(\mathcal{H}, \mathcal{K})$, we use $\mathcal{R}(A)$ to denote the range, and $\mathcal{N}(A)$ to denote the null-space of $A$. The Moore–Penrose inverse of $A$ is denoted by $A^\dagger$. It is well known that the Moore–Penrose inverse of $A$ exists if and only if $\mathcal{R}(A)$ is closed. We assume that the reader is familiar with the properties of the Moore–Penrose inverse (see, for example, [1], [4], [7], [10], [11], [12]). We also assume that the following classes of operators are well known: $A\{1\}$, $A\{1,3\}$, $A\{1,4\}$, $A\{1,2,3\}$, $A\{1,2,4\}$.

Some equivalent conditions of the reverse order rule

$$(AB)^\dagger = B^\dagger A^\dagger \tag{1}$$

are well known (see all references). We shall prove some new conditions, which are equivalent to (1). Also, conditions

$$\begin{aligned} B\{1,3\} \cdot A\{1,3\} &\subset (BA)\{1,3\}, \\ B\{1,4\} \cdot A\{1,3\} &\subset (BA)\{1,4\}, \\ B^\dagger A^\dagger &\in (AB)\{1,2,3\}, \\ B^\dagger A^\dagger &\in (AB)\{1,2,4\}, \\ B^\dagger A^\dagger &\in (AB)\{1,3\}, \\ B^\dagger A^\dagger &\in (AB)\{1,4\} \end{aligned}$$

will be investigated. By now, some of these conditions are investigated for complex matrices.

The aim of this paper is to prove some equivalence results for linear bounded Hilbert space operators, and thus obtain well-known results connected to the reverse order rule (1).

**2. Results.** We begin with the following auxiliary result, which can be found in [1] for complex matrices. For completeness, we give its proof.

LEMMA 2.1. *Let* $A \in \mathcal{L}(\mathcal{H},\mathcal{K})$ *have a closed range and* $B \in \mathcal{L}(\mathcal{K},\mathcal{H})$. *Then the following statements are equivalent:*

(1) $ABA = A$ *and* $(AB)^* = AB$;

(2) *there exists some* $X \in \mathcal{L}(\mathcal{K},\mathcal{H})$ *such that* $B = A^\dagger + (I - A^\dagger A)X$.

*Proof.* (2) $\Longrightarrow$ (1): Obvious. (1) $\Longrightarrow$ (2): Since $A = \begin{bmatrix} A_1 & 0 \\ 0 & 0 \end{bmatrix} : \begin{bmatrix} \mathcal{R}(A^*) \\ \mathcal{N}(A) \end{bmatrix} \to \begin{bmatrix} \mathcal{R}(A) \\ \mathcal{N}(A^*) \end{bmatrix}$, where $A_1$ is invertible, it follows that $A^\dagger = \begin{bmatrix} A_1^{-1} & 0 \\ 0 & 0 \end{bmatrix}$. An elementary calculation shows that $B = \begin{bmatrix} A_1^{-1} & 0 \\ U & V \end{bmatrix}$, where $U, V$ are arbitrary linear and bounded. Now, take $X = \begin{bmatrix} X_1 & X_2 \\ U & V \end{bmatrix}$ for arbitrary $X_1, X_2$ linear and bounded. ☐

Now, we prove the main result of this paper.

THEOREM 2.2. *Let* $A \in \mathcal{L}(\mathcal{H},\mathcal{K})$ *and* $B \in \mathcal{L}(\mathcal{K},\mathcal{L})$ *be such that* $A, B, AB$ *have closed ranges. Then the following statements are equivalent:*

(1) $\mathcal{R}(A^*AB) \subset \mathcal{R}(B)$;

(2) $B\{1,3\} \cdot A\{1,3\} \subset (AB)\{1,3\}$;

(3) $B^\dagger A^\dagger \in (AB)\{1,3\}$;

(4) $B^\dagger A^\dagger \in (AB)\{1,2,3\}$.

*Proof.* The operator $B$ has the following matrix form with respect to the orthogonal sum of subspaces: $B = \begin{bmatrix} B_1 & 0 \\ 0 & 0 \end{bmatrix} : \begin{bmatrix} \mathcal{R}(B^*) \\ \mathcal{N}(B) \end{bmatrix} \to \begin{bmatrix} \mathcal{R}(B) \\ \mathcal{N}(B^*) \end{bmatrix}$, where $B_1$ is invertible. From the proof of Lemma 2.1 it follows that any $B^{(1,3)} \in B\{1,3\}$ has the form $\begin{bmatrix} B_1^{-1} & 0 \\ U & V \end{bmatrix}$. The operator $A$ has the following form: $A = \begin{bmatrix} A_1 & A_2 \\ 0 & 0 \end{bmatrix} : \begin{bmatrix} \mathcal{R}(B) \\ \mathcal{N}(B^*) \end{bmatrix} \to \begin{bmatrix} \mathcal{R}(A) \\ \mathcal{N}(A^*) \end{bmatrix}$. Now, $A^* = \begin{bmatrix} A_1^* & 0 \\ A_2^* & 0 \end{bmatrix}$ and $AA^* = \begin{bmatrix} D & 0 \\ 0 & 0 \end{bmatrix}$, where $D = A_1A_1^* + A_2A_2^*$ is positive and invertible in $\mathcal{L}(\mathcal{R}(\mathcal{A}))$. We obtain $A^\dagger = A^*(AA^*)^\# = \begin{bmatrix} A_1^*D^{-1} & 0 \\ A_2^*D^{-1} & 0 \end{bmatrix}$. Let $A^{(1,3)} \in A\{1,3\}$. By Lemma 2.1 it follows that there exists some $X \in \mathcal{L}(\mathcal{L},\mathcal{K})$ such that $A^{(1,3)} = A^\dagger + (I - A^\dagger A)X$. Let $X$ have the form $X = \begin{bmatrix} X_{11} & X_{12} \\ X_{21} & X_{22} \end{bmatrix} : \begin{bmatrix} \mathcal{R}(A) \\ \mathcal{N}(A^*) \end{bmatrix} \to \begin{bmatrix} \mathcal{R}(B) \\ \mathcal{N}(B^*) \end{bmatrix}$. We then get the following:

$$A^{(1,3)} = \begin{bmatrix} Z_{11} & Z_{12} \\ Z_{21} & Z_{22} \end{bmatrix}$$

and

$$ABB^{(1,3)}A^{(1,3)} = \begin{bmatrix} A_1Z_{11} & A_1Z_{12} \\ 0 & 0 \end{bmatrix},$$

where

$$\begin{aligned} Z_{11} &= A_1^*D^{-1} + (I - A_1^*D^{-1}A_1)X_{11} - A_1^*D^{-1}A_2X_{21}, \\ Z_{12} &= (I - A_1^*D^{-1}A_1)X_{12} - A_1^*D^{-1}A_2X_{22}, \\ Z_{21} &= A_2^*D^{-1} - A_2^*D^{-1}A_1X_{11} + (I - A_2^*D^{-1}A_2)X_{21}, \\ Z_{22} &= -A_2^*D^{-1}A_1X_{12} + (I - A_2^*D^{-1}A_2)X_{22}. \end{aligned}$$

Notice also that $A^*AB = \begin{bmatrix} A_1^*A_1B_1 & 0 \\ A_2^*A_1B_1 & 0 \end{bmatrix}$.

(1) $\Longrightarrow$ (2): The inclusion $\mathcal{R}(A^*AB) \subset \mathcal{R}(B)$ is equivalent to $BB^\dagger A^*AB = A^*AB$. Now, $BB^\dagger A^*AB = \begin{bmatrix} A_1^*A_1B_1 & 0 \\ 0 & 0 \end{bmatrix}$. Hence, $BB^\dagger A^*AB = A^*AB$ is equivalent to

$A_2^*A_1B_1 = 0$. Since $B_1$ is invertible, we obtain $A_2^*A_1 = 0$, or, equivalently, $A_1^*A_2 = 0$. It follows that $\mathcal{R}(A_2) \subset \mathcal{N}(A_1^*)$. We have the following orthogonal decomposition: $\mathcal{R}(A) = \overline{\mathcal{R}(A_1)} \oplus \mathcal{N}(A_1^*)$. Now,

$$\begin{aligned}\mathcal{R}(A) &= \left\{\left[\begin{smallmatrix} A_1x+A_2y \\ 0 \end{smallmatrix}\right] : x \in \mathcal{R}(B), y \in \mathcal{N}(B^*)\right\} = \mathcal{R}(A_1) + \mathcal{R}(A_2)\\ &= \mathcal{R}(A_1) \oplus \mathcal{R}(A_2),\end{aligned}$$

knowing that $\mathcal{R}(A_2) \subset \mathcal{N}(A_1^*)$. Since $\mathcal{R}(A)$ is closed, we get that both $\mathcal{R}(A_1)$ and $\mathcal{R}(A_2)$ are closed. Consider the following decompositions of $A_1$ and $A_2$: $A_1 = \left[\begin{smallmatrix} A_{11} & 0 \\ 0 & 0 \end{smallmatrix}\right] : \left[\begin{smallmatrix} \mathcal{R}(A_1^*) \\ \mathcal{N}(A_1) \end{smallmatrix}\right] \to \left[\begin{smallmatrix} \mathcal{R}(A_1) \\ \mathcal{N}(A_1^*) \end{smallmatrix}\right]$, where $A_{11}$ is invertible, and $A_2 = \left[\begin{smallmatrix} 0 & 0 \\ A_{22} & 0 \end{smallmatrix}\right] : \left[\begin{smallmatrix} \mathcal{R}(A_2^*) \\ \mathcal{N}(A_2) \end{smallmatrix}\right] \to \left[\begin{smallmatrix} \mathcal{R}(A_1) \\ \mathcal{N}(A_1^*) \end{smallmatrix}\right]$. We have the following: $0 < D = A_1A_1^* + A_2A_2^* = \left[\begin{smallmatrix} A_{11}A_{11}^* & 0 \\ 0 & A_{22}A_{22}^* \end{smallmatrix}\right]$, implying that both $A_{11}A_{11}^*$ and $A_{22}A_{22}^*$ are invertible. Hence, $D^{-1} = \left[\begin{smallmatrix} (A_{11}A_{11}^*)^{-1} & 0 \\ 0 & (A_{22}A_{22}^*)^{-1} \end{smallmatrix}\right]$. Notice that $A_1^*D^{-1}A_1 = \left[\begin{smallmatrix} I & 0 \\ 0 & 0 \end{smallmatrix}\right]$, $A_1(I - A_1^*D^{-1}A_2) = 0$, and $A_1^*D^{-1}A_2 = 0$. Now, it follows that

$$A_1[(I - A_1^*D^{-1}A_1)X_{12} - A_1^*D^{-1}A_2X_{22}] = 0$$

and

$$A_1[A_1^*D^{-1} + (I - A_1^*D^{-1}A_1)X_{11} - A_1^*D^{-1}A_2X_{21}] = \begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix}$$

is selfadjoint. An elementary computation shows that $ABB^{(1,3)}A^{(1,3)}AB = AB$.

(2) $\Longrightarrow$ (3): Obvious.

(3) $\Longrightarrow$ (1): From the proof of the implication (1) $\Longrightarrow$ (2), it follows that the condition $\mathcal{R}(A^*AB) \subset \mathcal{R}(B)$ is equivalent to $A_2^*A_1 = 0$. Now, $ABB^\dagger A^\dagger = \left[\begin{smallmatrix} A_1A_1^*D^{-1} & 0 \\ 0 & 0 \end{smallmatrix}\right]$ is selfadjoint, implying that $[A_1A_1^*, D^{-1}] = 0 = [A_1A_1^*, D]$ (here $[U, V] = UV - VU$). Also, $\left[\begin{smallmatrix} A_1B_1 & 0 \\ 0 & 0 \end{smallmatrix}\right] = AB = ABB^\dagger A^\dagger AB = \left[\begin{smallmatrix} A_1A_1^*D^{-1}B_1 & 0 \\ 0 & 0 \end{smallmatrix}\right]$, implying that $A_1B_1 = A_1A_1^*D^{-1}A_1B_1 = D^{-1}A_1A_1^*A_1B_1$. Hence, we get $DA_1B_1 = A_1A_1^*A_1B_1$ and, consequently, $A_2A_2^*A_1B_1 = 0$. Since $B_1$ is invertible, we obtain $A_2A_2^*A_1 = 0$ and $\mathcal{R}(A_1) \subset \mathcal{N}(A_2A_2^*) = \mathcal{N}(A_2^*)$. It follows that $A_2^*A_1 = 0$.

(4) $\Longrightarrow$ (3): Obvious.

(1) $\Longrightarrow$ (4): If $\mathcal{R}(A^*AB) \subset \mathcal{R}(B)$, we have to prove that $B^\dagger A^\dagger ABB^\dagger A^\dagger = B^\dagger A^\dagger$. Notice that $AB = \left[\begin{smallmatrix} A_1B_1 & 0 \\ 0 & 0 \end{smallmatrix}\right]$ and $B^\dagger A^\dagger = \left[\begin{smallmatrix} B_1^{-1}A_1^*D^{-1} & 0 \\ 0 & 0 \end{smallmatrix}\right]$. By using previously proved facts, $D$ commutes with $A_1A_1^*$ (the implication (3) $\Longrightarrow$ (1)) and matrix forms of $A_1$ and $D$ (the implication (1) $\Longrightarrow$ (2)), which we compute as follows:

$$\begin{aligned}B_1^{-1}A_1^*D^{-1}A_1B_1B_1^{-1}A_1^*D^{-1} &= B_1^{-1}A_1^*A_1A_1^*D^{-2}\\ &= B_1^{-1}A_1^*\begin{bmatrix} A_{11}A_{11}^* & 0 \\ 0 & 0 \end{bmatrix}\begin{bmatrix} (A_{11}A_{11}^*)^{-2} & 0 \\ 0 & (A_{22}A_{22}^*)^{-2} \end{bmatrix} \qquad (2)\\ &= B_1^{-1}A_1^*\begin{bmatrix} (A_{11}A_{11}^*)^{-1} & 0 \\ 0 & 0 \end{bmatrix} = B_1^{-1}A_1^*D^{-1}.\end{aligned}$$

Now, it obviously follows that $B^\dagger A^\dagger ABB^\dagger A^\dagger = B^\dagger A^\dagger$ is satisfied. □

In the same manner we can prove the following result.

THEOREM 2.3. *Let $A \in \mathcal{L}(\mathcal{H}, \mathcal{K})$ and $B \in \mathcal{L}(\mathcal{K}, \mathcal{L})$ be such that $A, B, AB$ have closed ranges. Then the following statements are equivalent:*

(1) *$\mathcal{R}(BB^*A^*) \subset \mathcal{R}(A^*)$;*
(2) *$B\{1,4\} \cdot A\{1,4\} \subset (AB)\{1,4\}$;*
(3) *$B^\dagger A^\dagger \in (AB)\{1,4\}$;*
(4) *$B^\dagger A^\dagger \in (AB)\{1,2,4\}$.*

For complex matrices, see the following literature: The equivalence (1) $\Longleftrightarrow$ (4) in both Theorems 2.2 and 2.3 is proved in [15]; conditions (2) in both Theorems 2.2 and 2.3 are investigated in [16].

Now, as a corollary, we obtain the following result.

COROLLARY 2.4. *Let $A \in \mathcal{L}(\mathcal{H},\mathcal{K})$ and $B \in \mathcal{L}(\mathcal{K},\mathcal{L})$ be such that $A, B, AB$ have closed ranges. Then the following statements are equivalent:*

(1) *$\mathcal{R}(A^*AB) \subset \mathcal{R}(B)$ and $\mathcal{R}(BB^*A^*) \subset \mathcal{R}(A^*)$;*
(2) *$B\{1,3\} \cdot A\{1,3\} \subset AB\{1,3\}$ and $B\{1,4\} \cdot A\{1,4\} \subset AB\{1,4\}$;*
(3) *$B^\dagger A^\dagger \in AB\{1,3,4\}$;*
(4) *$B^\dagger A^\dagger = (AB)^\dagger$.*

It is important to mention that the equivalence (1) $\Longleftrightarrow$ (4) is a classical result, proved for complex matrices in [6], and for bounded operators on Hilbert spaces in [2], [3], and [9].

*Remark* 1. The equivalence (3) $\Longleftrightarrow$ (4) in Theorems 2.2, 2.3 and Corollary 2.4 suggests that the "{2}-property" is implied by the rest. For matrices, this follows from a rank argument. If $X$ is a $\{1\}$-inverse of $A$, then $X$ is also a $\{2\}$-inverse if and only if $\operatorname{rank} X = \operatorname{rank} A$. Since we cannot talk about "rank" here, we resolve this situation using the special partition of operators.

Results which are related to the reverse order rule for generalized inverses follow. Multiple matrix products are considered in [8] and [14]. General conditions to the reverse order rule for inner inverses are given in [18] and for outer inverses in [5]. The reverse order rule for the weighted Moore–Penrose inverse is investigated in [13].

Finally, we find that results of this paper are closely connected with the results of Werner [17]. Although in [17] the finite dimensional technique is used, the results which will be presented here are valid in arbitrary Hilbert spaces also.

In [17] the geometric approach is involved, taking the range and the null-space of the generalized inverses. Among other things, the following result is proved in [17, Theorem 5.5] (interpreted in an infinite dimensional setting).

THEOREM 2.5. *Let $B \in \mathcal{L}(\mathcal{H},\mathcal{K})$ and $A \in \mathcal{L}(\mathcal{K},\mathcal{L})$, such that $A$, $B$, and $C = AB$ have closed ranges. Let $T$ be a closed subspace of $H$ such that $T \overset{\bullet}{+} \mathcal{N}(B) = H$ (the sum is not necessarily orthogonal) and $\mathcal{R}(C^*) \subset T$. Then the following statements are equivalent:*

(1) *There exist some operators $A^-$ and $B^-$ satisfying $AA^-A = A$, $A^-A = P_{\mathcal{R}(A^*),\mathcal{N}(A)}$, $BB^-B = B$, $B^-B = P_{T,\mathcal{N}(B)}$, $BB^- = P_{\mathcal{R}(B),\mathcal{N}(B^*)}$ such that the following is satisfied: $D = B^-A^-$, $CDC = C$, and $DC = P_{\mathcal{R}(C^*),\mathcal{N}(C)}$.*
(2) *$\mathcal{R}(BB^*A) \subset \mathcal{R}(A^*)$.*
(3) *For each operator $A^-$ and $B^-$ satisfying $AA^-A = A$, $A^-A = P_{\mathcal{R}(A^*),\mathcal{N}(A)}$, $BB^-B = B$, $B^-B = P_{T,\mathcal{N}(B)}$, $BB^- = P_{\mathcal{R}(B),\mathcal{N}(B^*)}$, the following holds: $D = B^-A^-$, $CDC = C$, and $DC = P_{\mathcal{R}(C^*),\mathcal{N}(C)}$.*

We see that for $C = AB$ the condition $\mathcal{R}(C^*) \subset \mathcal{R}(B^*)$ holds. Hence, for $T = \mathcal{R}(B^*)$ we get the result closely related to our Theorem 2.3. Now, the corollary is stated according to our notations.

COROLLARY 2.6. *Let $B \in \mathcal{L}(\mathcal{H},\mathcal{K})$ and $A \in \mathcal{L}(\mathcal{K},\mathcal{L})$, such that $A$, $B$, and $C = AB$ have closed ranges. Then the following statements are equivalent:*

(1) *There exist some* $A^- \in A\{1,4\}$ *and some* $B^- \in B\{1,3,4\}$ *such that* $B^-A^- \in C\{1,4\}$.
(2) $\mathcal{R}(BB^*A^*) \subset \mathcal{R}(A^*)$.
(3) $A\{1,4\} \cdot B\{1,3,4\} \subset C\{1,4\}$.

We see that Corollary 2.6 contains a weaker result than our Theorem 2.3.

**Acknowledgments.** I am grateful to Professor Hans Joachim Werner for sending me his paper [17], and for remarks that his work in [17] is closely related to the present results. I am also grateful to the referee for helpfully pointing to Remark 1.

# A SUPERFAST ALGORITHM FOR TOEPLITZ SYSTEMS OF LINEAR EQUATIONS*

S. CHANDRASEKARAN[†], M. GU[‡], X. SUN[§], J. XIA[¶], AND J. ZHU[‡]

**Abstract.** In this paper we develop a new superfast solver for Toeplitz systems of linear equations. To solve Toeplitz systems many people use displacement equation methods. With displacement structures, Toeplitz matrices can be transformed into Cauchy-like matrices using the FFT or other trigonometric transformations. These Cauchy-like matrices have a special property, that is, their off-diagonal blocks have small numerical ranks. This low-rank property plays a central role in our superfast Toeplitz solver. It enables us to quickly approximate the Cauchy-like matrices by structured matrices called *sequentially semiseparable* (SSS) matrices. The major work of the constructions of these SSS forms can be done in precomputations (independent of the Toeplitz matrix entries). These SSS representations are compact because of the low-rank property. The SSS Cauchy-like systems can be solved in linear time with linear storage. Excluding precomputations the main operations are the FFT and SSS system solve, which are both very efficient. Our new Toeplitz solver is stable in practice. Numerical examples are presented to illustrate the efficiency and the practical stability.

## 1. Introduction.

Toeplitz systems of linear equations arise in many applications, including PDE solving, signal processing, time series analysis, orthogonal polynomials, and many others. A *Toeplitz system* is a linear system

$$Tx = b \tag{1.1}$$

with a coefficient matrix to be a *Toeplitz matrix*

$$T = \begin{pmatrix} t_0 & t_{-1} & t_{-2} & \cdots & t_{-(N-1)} \\ t_1 & t_0 & t_{-1} & \cdots & t_{-(N-2)} \\ t_2 & t_1 & t_0 & \cdots & t_{-(N-3)} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ t_{N-1} & t_{N-2} & t_{N-3} & \cdots & \cdots \end{pmatrix}, \tag{1.2}$$

that is, its entries are constant along every diagonal (a matrix whose entries are constant along every antidiagonal is called a Hankel matrix). The vector $t = (t_{-(N-1)} \ \cdots \ t_{-1} \ t_0 \ t_1 \ \cdots \ t_{N-1})$ is called the *Toeplitz-vector* that generates $T$.

There are both direct and iterative methods for solving (1.1). Direct solvers are said to be *fast* if they cost $O(N^2)$ operations; examples include Schur-type methods,

Levinson-type methods, and others [32]. An important type of direct solver is the *displacement equation–type* fast solver based on Gaussian eliminations. Some known displacement equation–type methods are the Heinig [28], GKO [22], and Gu [26] methods. Those methods have complexity $O(N^2)$. Methods with complexity less than $O(N^2)$ are called *superfast*. In this paper we will present a displacement equation–type superfast algorithm.

**1.1. Fast and superfast methods.** Many fast and superfast methods that have been developed are numerically unstable [5, 15, 16, 7, 37]. References [5] and [15] showed that the Schur algorithm and the Levinson algorithm are weakly stable in some cases, but both may be highly unstable in the case of an indefinite and nonsymmetric matrix. Stable generalized Schur algorithms [32] and look-ahead algorithms were developed in [9, 10]. High-performance look-ahead Schur algorithms were presented [20].

Many other solvers use the FFT or other trigonometric transforms to convert the Toeplitz (or even Hankel or Toeplitz-plus-Hankel) matrices into generalized Cauchy or Vandermonde matrices, which can be done stably in $O(N \log N)$ operations. This is also the approach that we will use in this paper, with the aid of a displacement structure.

The concept of displacement structure was first introduced in [31]. The Sylvester-type *displacement equation* for a matrix $\hat{C} \in \mathbf{R}^{N\times N}$ [29] is

$$\Omega\hat{C} - \hat{C}\Lambda = UV, \tag{1.3}$$

where $\Omega,\ \Lambda \in \mathbf{R}^{N\times N}$, $U \in \mathbf{R}^{N\times\alpha}$, $V \in \mathbf{R}^{\alpha\times N}$, and $\alpha \le N$ is the *displacement rank* with respect to $\Omega$ and $\Lambda$ if $\operatorname{rank}(UV) = \alpha$. The matrix $\hat{C}$ is considered to possess a *displacement structure* with respect to $\Omega$ and $\Lambda$ if $\alpha \ll N$.

With displacement structures it was shown in [19, 24, 36, 22, 28] that Toeplitz and Hankel matrices can be transformed into *Cauchy-like* matrices of the following form:

$$\hat{C} = \left(\frac{u_i^T \cdot v_j}{\eta_i - \lambda_j}\right)_{1\le i,j\le N} \qquad (u_i, v_j \in \mathbf{R}^{\alpha})\ ,$$

where we assume that $\eta_i \ne \lambda_j$ for $1 \le i, j \le N$. Equivalently, a Cauchy-like matrix is the unique solution to the displacement equation (1.3) with

$$\Omega = \operatorname{diag}(\eta_1, \ldots, \eta_n),\ \Lambda = \operatorname{diag}(\lambda_1, \ldots, \lambda_n),\ U = \begin{pmatrix} u_1^T \\ \vdots \\ u_n^T \end{pmatrix},\ \text{and } V = (v_1, \ldots, v_n)\,.$$

In particular, $\hat{C}$ is a Cauchy matrix if $u_i^T v_j = 1$ for all $i$ and $j$. The displacement rank of $\hat{C}$ is at most $\alpha$.

To solve Toeplitz systems through Cauchy-like matrices, many people have utilized matrix factorizations. Gohberg and Olshevsky [23] presented a fast variation of the straightforward Gaussian elimination with partial pivoting (GEPP) procedure to solve a Cauchy-like linear system of equations in $O(N^2)$ operations. Among other results, Gohberg, Kailath, and Olshevsky [22] developed algorithm GKO, an improved version of Heinig's algorithm [28], and demonstrated numerically that it is stable. In their algorithm, the Hankel matrix and the Toeplitz-plus-Hankel matrix are also transformed via fast trigonometric transforms into Cauchy-like matrices.

Gu presented a modified algorithm in [26] to avoid extra error growth. This algorithm is numerically stable, provided that the element growth in the computed factorization is not large. The algorithm takes $O(N^2)$ operations and is a fast stable method.

Superfast algorithms appeared in [34, 4, 6, 17, 35, 1, 2, 21] and many others. Superfast algorithms use divide-and-conquer strategies. Morf developed the first idea in [34]. These methods are unstable for nonsymmetric systems as they cannot deal with nearly singular leading principal submatrices.

Van Barel and Kravanja presented a superfast method for rational interpolation at roots of unity [39]. A similar idea was then applied to Toeplitz systems [38]. It provided an explicit formula for the inverse of a Toeplitz matrix. Additional techniques such as iterative refinement and downdating were still required to stabilize their algorithm.

### 1.2. Main results.

Our new Toeplitz solver is also of the displacement equation type. Given a Toeplitz linear system, we first use the FFT to transform the associated Toeplitz matrix into a Cauchy-like matrix. Then instead of using matrix factorizations which often cost $O(N^2)$ or more, we exploit a special *low-rank property* of Cauchy-like matrices, that is, every off-diagonal block of a Cauchy-like matrix has a low numerical rank. Using this low-rank property, we then approximate the Cauchy-like matrix by a low-rank matrix structure called the *sequentially semiseparable* (SSS) matrix proposed by Chandrasekaran et al. [12, 13]. A system with the coefficient matrix in *compact* SSS form can be solved with only $O(p^2N)$ operations, where $N$ is the matrix dimension, and $p$ is the complexity of the semiseparable description. The SSS solver is practically stable in our numerical tests and those in [12, 13].

The SSS structure was developed to capture the low-rank property of the off-diagonal blocks of a matrix and to maintain stability or practical stability in the mean time. It is a matrix analog of semiseparable integral kernels in Kailath's paper [30]. Matrix operations with compact form SSS representations are very efficient, provided that such compact representations exist or can be easily computed. This turns out to be true for our case, as the Cauchy-like matrices are transformed from Toeplitz matrices. We use a recursive compression scheme with a shifting strategy to construct compact SSS forms for those Cauchy-like matrices. The major work of the compressions can be precomputed on some Cauchy matrices which are independent of the actual Toeplitz matrix entries.

The overall algorithm thus has the following stages:

(1) Precompute compressions of off-diagonal blocks of Cauchy matrices.
(2) Transform the Toeplitz matrix into a Cauchy-like matrix in $O(N \log N)$ operations.
(3) Construct a compact SSS representation from precomputed compressions and solve the Cauchy-like matrix system $O(p^2N)$ operations.
(4) Recover the solution of the Toepliz system in $O(N \log N)$ operations.

The stages above are either stable or practically stable. Our numerical results indicate that the overall algorithm is stable in practice. The Toeplitz matrix does not have to be symmetric or positive definite, and no extra stabilizing step is necessary. After the precomputations, the total cost for the algorithm is $O(N \log N) + O(p^2N)$. This indicates that the entire algorithm is superfast.

We also point out that similar techniques are used in [33], where the low-rank property is exploited through the block columns without diagonals (called *neutered block columns* in [33]), in contrast with the off-diagonal blocks here. The compressions of either the neutered blocks or the off-diagonal blocks both give data-sparse representations which enable fast factorizations of the Cauchy-like matrices. In fact, corresponding to neutered block rows or columns, there are also matrix representations called hierarchically semiseparable (HSS) matrices [14] which are usually more complicated structures than SSS matrices.

**1.3. Overview.** We will discuss the displacement structure and the transformation from a Toeplitz problem to a Cauchy-like problem in section 2. The low-rank property of this Cauchy-like problem is then exploited. Section 3 then gives a linear complexity solver using the SSS structure. In section 4, we will present an algorithm for fast construction of SSS structures. We will then analyze the complexity in section 5 and use some numerical experiments to demonstrate the efficiency and the practical stability. All algorithms have been implemented in Fortran 90. Section 6 draws some conclusions.

## 2. Displacement structures and low-rank property.

**2.1. Cauchy-like systems.** Given a Toeplitz system (1.1), we can use a displacement structure to transform it into a Cauchy-like system. Define

$$Z_\delta = \begin{pmatrix} 0 & 0 & \cdots & 0 & \delta \\ 1 & 0 & \cdots & \cdots & 0 \\ 0 & 1 & \ddots & & \vdots \\ \vdots & & \ddots & \ddots & \vdots \\ 0 & \cdots & 0 & 1 & 0 \end{pmatrix},$$

and let $\Omega = Z_1$ and $\Lambda = Z_{-1}$ in (1.3). Kailath, Kung, and Morf [31] have shown that every Toeplitz matrix satisfies the displacement equation (1.3) with $A \cdot B$, having nonzero entries only in its first row and last column, to be a matrix of rank at most 2. Hence the displacement rank of a Toeplitz matrix is at most 2 with respect to $Z_1$ and $Z_{-1}$. The following result can be found in [28].

Proposition 2.1. *Let $\hat{C} \in \mathbf{R}^{N\times N}$ be a matrix satisfying the displacement equation*

$$Z_1\hat{C} - \hat{C}Z_{-1} = UV, \tag{2.1}$$

*where $U \in \mathbf{R}^{n\times\alpha}$ and $V \in \mathbf{R}^{\alpha\times n}$. Then $\mathcal{F}\hat{C}D_0^{-1}\mathcal{F}^H$ is a Cauchy-like matrix satisfying*

$$\mathcal{D}_1(\mathcal{F}\hat{C}D_0^{-1}\mathcal{F}^H) - (\mathcal{F}\hat{C}D_0^{-1}\mathcal{F}^H)\mathcal{D}_{-1} = (\mathcal{F}U)\left(VD_0^H\mathcal{F}^H\right), \tag{2.2}$$

*where $\mathcal{F} = \sqrt{\frac{1}{N}}(\omega^{2(k-1)(j-1)})_{1\le k,j\le N}$ is the normalized inverse discrete Fourier transform matrix, $\omega = e^{\frac{\pi i}{N}}$, and*

$$\mathcal{D}_1 = \mathrm{diag}(1, \omega^2, \ldots, \omega^{2(N-1)}), \quad \mathcal{D}_{-1} = \mathrm{diag}(\omega, \omega^3, \ldots, \omega^{2N-1}),$$
$$D_0 = \mathrm{diag}(1, \omega, \ldots, \omega^{N-1}).$$

Here $\alpha \le 2$. This proposition suggests that for a Toeplitz matrix $T$, one can convert it into the Cauchy-like matrix in (2.2). Therefore the Toeplitz system (1.1) can be readily transformed into a new system

$$C\tilde{x} = \tilde{b}, \tag{2.3}$$

where $C$ has the form

$$C = \left( \frac{u_i^T v_j}{\omega^{2i} - \omega^{2j+1}} \right)_{1 \le i,j \le N} \qquad (u_i,\ v_j \in \mathbf{R}^{\alpha}) \ . \tag{2.4}$$

In section 3 we will present a fast solver for (2.3). After obtaining $\tilde{x}$ we will then recover $x$ with an FFT again. All the stages involving FFT are stable and cost $O(N \log N)$. The solver for (2.3) has a linear complexity and turns out to be practically stable. Thus the total cost of our algorithm is bounded by $O(N \log N) + O(Np^2)$, where $p$ is some parameter that will be described below. This indicates our method is a superfast one with practical stability.

**2.2. Low-rank property of Cauchy-like matrices.** In this section, we will show a low-rank property of $C$, i.e., every off-diagonal block of $C$ has a low numerical rank. This property is the basis of the superfast SSS solver in section 3.

First, a simple numerical experiment can give us an idea of the low-rank property of $C$. To find out the numerical ranks we can use one of the following tools:

1. *$\tau$-accurate SVD*: singular values less than $\tau$ are dropped if $\tau$ is an absolute tolerance, or singular values less than $\tau$ times the largest singular value are dropped if $\tau$ is a relative tolerance.
2. *$\tau$-accurate QR*:

$$A \approx QR,\ A : m \times n,\ \ Q : m \times k,\ \ R : k \times k,\ \ k \le l \equiv \min(m, n),$$

which is obtained in the following way. Compute the exact QR factorization of matrix $A = \hat{Q}\hat{R}$, where $\hat{Q}$ is $m \times l$ and $\hat{R}$ is $l \times n$ with diagonal entries satisfying $\hat{R}_{11} \ge \hat{R}_{22} \ge \cdots \ge \hat{R}_{ll}$. Then obtain $R$ by dropping all rows of $\hat{R}$ with diagonal entries less than $\tau$ if $\tau$ is an absolute tolerance, or with diagonal entries less than $\tau\hat{R}_{11}$ if $\tau$ is a relative tolerance. Drop relevant columns of $\hat{Q}$ accordingly to obtain $Q$.

Later, by ranks we mean numerical ranks. Here we take some random Toeplitz matrices in different sizes. Then we transform them into Cauchy-like matrices $C$ and compute the numerical ranks of their off-diagonal blocks. For simplicity, we compute the ranks for blocks $C(1 : d, d+1 : N)$, $C(1 : 2d, 2d+1 : N)$, $\ldots$, $C(1 : kd, kd+1 : N), \ldots$, where $d$ is a fixed integer, and these blocks are numbered as block numbers $1, 2, \ldots, k$ as shown in Figure 2.1.

Here, $k = 8$ off-diagonal blocks for each of three $N \times N$ Cauchy-like matrices are considered. See Table 2.1 for the numerical ranks, where we use the $\tau$-accurate SVD with $\tau$ to be an absolute tolerance.

We can see that the numerical ranks are relatively small as compared to the block sizes. And when we double the dimension of the matrix, the numerical ranks do not increase much. This is more significant when a larger $\tau$ is used.

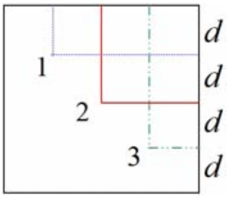

FIG. 2.1. *Off-diagonal blocks (numbered as 1, 2, 3). Upper triangular part only.*

TABLE 2.1
*Off-diagonal numerical ranks of Cauchy-like matrices transformed from some Toeplitz matrices with absolute tolerance* $\tau = 10^{-9}$.

| | $N = 640$ | | $N = 1280$ | | $N = 2560$ | |
|---|---|---|---|---|---|---|
| Block # | Block size | Rank | Block size | Rank | Block size | Rank |
| 1 | $80 \times 560$ | 37 | $160 \times 1120$ | 44 | $320 \times 2240$ | 52 |
| 2 | $160 \times 480$ | 43 | $320 \times 960$ | 50 | $640 \times 1920$ | 57 |
| 3 | $240 \times 400$ | 45 | $480 \times 800$ | 53 | $960 \times 1600$ | 60 |
| 4 | $320 \times 320$ | 46 | $640 \times 640$ | 53 | $1280 \times 1280$ | 61 |
| 5 | $400 \times 240$ | 46 | $800 \times 480$ | 52 | $1600 \times 960$ | 60 |
| 6 | $480 \times 160$ | 43 | $960 \times 320$ | 50 | $1920 \times 640$ | 58 |
| 7 | $560 \times 80$ | 37 | $1120 \times 160$ | 44 | $2240 \times 320$ | 52 |

The low-rank property can be verified theoretically in the following way. We first consider a special case of (2.4) where all $u_i^T v_j = 1$. We show that the following Cauchy matrix has low-rank off-diagonal blocks:

$$C_0 = \left( \frac{1}{\omega^{2i} - \omega^{2j+1}} \right)_{1 \le i,j \le N} \tag{2.5}$$

The central idea is similar to that in the fast multipole method [25, 8], which implies that with *well-separated* points (see, e.g., Figure 2.2) an interaction matrix is numerically low-rank.

Here we introduce two sets of points $\{\lambda_k\}_{k=1}^N \equiv \{\omega^{2k}\}_{k=1}^N$ and $\{\eta_k\}_{k=1}^N \equiv \{\omega^{2k+1}\}_{k=1}^N$ on the unit circle. When we consider an off-diagonal block of $C_0$ as follows:

$$G = \left( \frac{1}{\lambda_i - \eta_j} \right)_{1 \le i \le p,\ p+1 \le j \le N}$$

we can show $G$ is (numerically) low-rank. In fact $G$ corresponds to two well-separated sets $\{\lambda_k\}_{k=1}^p$ and $\{\eta_j\}_{k=p+1}^N$; that is, there exists a point $c \in \mathbb{C}$ such that

$$\begin{array}{rcll} |\lambda_i - c| & > & d + e, & i = 1, \ldots, p, \\ |\eta_j - c| & < & d, & j = p+1, \ldots, N, \end{array} \tag{2.6}$$

where $d, e$ are positive constants. Consider the expansion

$$\frac{1}{\lambda_i - \eta_j} = \frac{1}{\lambda_i - c} \frac{1}{1 - \frac{\eta_j - c}{\lambda_i - c}} = \sum_{k=0}^{r} \frac{(\eta_j - c)^k}{(\lambda_i - c)^{k+1}} + O\left( \left( \frac{\eta_j - c}{\lambda_i - c} \right)^{r+1} \right) \tag{2.7}$$

$$= \sum_{k=0}^{r} \frac{(\eta_j - c)^k}{(\lambda_i - c)^{k+1}} + \varepsilon, \tag{2.8}$$

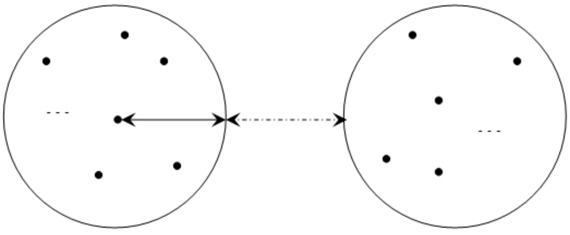

FIG. 2.2. *Well-separated sets in the plane.*

where $r$ is a number such that the error term $|\varepsilon| = |O((\frac{\eta_j - c}{\lambda_i - c})^{r+1})|$ is bounded by a given tolerance. We have the estimate

$$\left|\frac{\eta_j - c}{\lambda_i - c}\right|^{r+1} < \left(\frac{d}{d+e}\right)^{r+1},$$

which enables us to find an appropriate $r$ according to the tolerance. Thus

$$G = \left(\sum_{k=0}^{r} \frac{(\eta_j - c)^k}{(\lambda_i - c)^{k+1}}\right)_{1\le i\le p,\ p+1\le j\le N} + \hat{\varepsilon}$$

(2.9)

$$= \begin{pmatrix} \frac{1}{\lambda_1 - c} & \frac{1}{(\lambda_1 - c)^2} & \cdots & \frac{1}{(\lambda_1 - c)^{r+1}} \\ \frac{1}{\lambda_2 - c} & \frac{1}{(\lambda_2 - c)^2} & \cdots & \frac{1}{(\lambda_2 - c)^{r+1}} \\ \vdots & \vdots & \cdots & \vdots \\ \frac{1}{\lambda_p - c} & \frac{1}{(\lambda_p - c)^2} & \cdots & \frac{1}{(\lambda_p - c)^{r+1}} \end{pmatrix} \begin{pmatrix} 1 & 1 & \cdots & 1 \\ (\eta_{p+1} - c) & (\eta_{p+2} - c) & \cdots & (\eta_N - c) \\ \vdots & \vdots & \cdots & \vdots \\ (\eta_{p+1} - c)^r & (\eta_{p+2} - c)^r & \cdots & (\eta_N - c)^r \end{pmatrix} + \hat{\varepsilon}.$$

Therefore the numerical rank of $G$ is at most $r + 1$, up to an error $\hat{\varepsilon}$.

Now we can return to the Cauchy-like matrix (2.4). A similar argument shows that any off-diagonal block of $C$ satisfies

$$\hat{G} \approx \left(\sum_{k=0}^{r} (u_i^T v_j) \frac{(\eta_j - c)^k}{(\lambda_i - c)^{k+1}}\right)_{1\le i\le p,\ p+1\le j\le N}$$

$$= \begin{pmatrix} \frac{u_1^T}{\lambda_1 - c} & \frac{u_1^T}{(\lambda_1 - c)^2} & \cdots & \frac{u_1^T}{(\lambda_1 - c)^{r+1}} \\ \frac{u_2^T}{\lambda_2 - c} & \frac{u_2^T}{(\lambda_2 - c)^2} & \cdots & \frac{u_2^T}{(\lambda_2 - c)^{r+1}} \\ \vdots & \vdots & \cdots & \vdots \\ \frac{u_p^T}{\lambda_p - c} & \frac{u_p^T}{(\lambda_p - c)^2} & \cdots & \frac{u_p^T}{(\lambda_p - c)^{r+1}} \end{pmatrix} \begin{pmatrix} v_1 & v_2 & \cdots & v_q \\ (\eta_{p+1} - c)\, v_1 & (\eta_{p+2} - c)\, v_2 & \cdots & (\eta_N - c)\, v_N \\ \vdots & \vdots & \cdots & \vdots \\ (\eta_{p+1} - c)^r v_1 & (\eta_{p+2} - c)^r v_2 & \cdots & (\eta_N - c)^r v_N \end{pmatrix}.$$

That is, we replace the entries of the two matrix factors in (2.9) with appropriate vectors. Thus the numerical rank of $\hat{G}$ will be no larger than $\alpha(r + 1)$, which will be relatively small as compared to $N$.

## 3. SSS structures and superfast SSS solver.

### 3.1. SSS representations.

To take advantage of the low-rank property of the Cauchy-like matrix $C$, we can use SSS structures introduced by Chandrasekaran et al. [12, 13]. The SSS structure nicely captures the ranks of off-diagonal blocks of a matrix such as shown in Figure 2.1.

A matrix $A \in \mathbf{C}^{M\times\tilde{M}}$ satisfies the SSS structure if there exist $2n$ positive integers $m_1, \ldots, m_n$, and $\tilde{m}_1, \ldots, \tilde{m}_n$ with $M = m_1 + \cdots + m_n$ and $\tilde{M} = \tilde{m}_1 + \cdots + \tilde{m}_n$ to block-partition $A$ as $A = (A_{i,j})_{k\times k}$, where $A_{ij} \in \mathbb{C}^{m_i\times\tilde{m}_j}$ satisfies

$$A_{ij} = \begin{cases} D_i & \text{if } i = j, \\ U_i W_{i+1} \cdots W_{j-1} V_j^H & \text{if } i < j, \\ P_i R_{i-1} \cdots R_{j+1} Q_j^H & \text{if } i > j. \end{cases} \tag{3.1}$$

Here the superscript $H$ denotes the Hermitian transpose and empty products are defined to be identity matrices. The matrices $\{U_i\}_{i=1}^{n-1}$, $\{V_i\}_{i=2}^{n}$, $\{W_i\}_{i=2}^{n-1}$, $\{P_i\}_{i=2}^{n}$,

Table 3.1
*Dimensions of matrices in* (3.1).

| Matrix | $U_i$ | $V_i$ | $W_i$ | $P_i$ | $Q_i$ | $R_i$ |
|---|---|---|---|---|---|---|
| Dimensions | $m_i \times k_i$ | $\tilde{m}_i \times k_{i-1}$ | $k_{i-1} \times k_i$ | $m_i \times l_i$ | $\tilde{m}_i \times l_{i+1}$ | $l_{i+1} \times l_i$ |

$\{Q_i\}_{i=1}^{n-1}$, $\{R_i\}_{i=2}^{n-1}$, and $\{D_i\}_{i=1}^{n}$ are called *generators* for the SSS structure and their dimensions are defined in Table 3.1.

As an example, the matrix $A$ with $n = 4$ has the form

$$A = \begin{pmatrix} D_1 & U_1V_2^H & U_1W_2V_3^H & U_1W_2W_3V_4^H \\ P_2Q_1^H & D_2 & U_2V_3^H & U_2W_3V_4^H \\ P_3R_2Q_1^H & P_3Q_2^H & D_3 & U_3V_4^H \\ P_4R_3R_2Q_1^H & P_4R_3Q_2^H & P_4Q_3^H & D_4 \end{pmatrix}. \tag{3.2}$$

The SSS representation (3.2) is related to the off-diagonal blocks in Figure 2.1 in the way that the upper off-diagonal block numbers $1, 2,$ and $3$ are

$$U_1 \begin{pmatrix} V_2^H & W_2V_3^H & W_2W_3V_4^H \end{pmatrix}, \begin{pmatrix} U_1W_2 \\ U_2 \end{pmatrix} \begin{pmatrix} V_3^H & W_3V_4^H \end{pmatrix}, \begin{pmatrix} U_1W_2W_3 \\ U_2W_3 \\ U_3 \end{pmatrix} V_4^H.$$

Appropriate row and column bases of the off-diagonal blocks are clearly reflected.

The SSS structure depends on the sequences $\{m_i\}$ and $\{\tilde{m}_i\}$ and the SSS generation scheme. If $A$ is a square matrix ($M = \tilde{M}$), then we can have a simpler situation $m_i = \tilde{m}_i$, $i = 1, \ldots, n$. SSS matrices are closed under addition, multiplication, inversion, etc., although the sizes of the generators may increase.

While any matrix can be represented in this form for sufficiently large $k_i$'s and $l_i$'s, the column dimensions of $U_i$'s and $P_i$'s, respectively, our main focus will be on SSS matrices which have low-rank off-diagonal blocks and have generators with $k_i$'s and $l_i$'s to be close to those ranks. We say these SSS matrices are *compact*. Particularly true for Cauchy-like matrices, they can have compact SSS forms. Using SSS structures, we can take advantage of the superfast SSS system solver in [12, 13] to solve the Cauchy-like systems. The solver is efficient when the SSS form is compact, and is practically stable. The solver shares similar ideas with that for banded plus semiseparable systems in [11].

Here we briefly describe the main ideas of the solver in [12, 13]. We consider solving the linear system $Ax = b$, where $A \in \mathbf{C}^{N\times N}$ satisfies (3.1) and $b$ itself is an unstructured matrix. The solver computes an implicit $ULV^H$ decomposition of $A$, where $U$ and $V$ are orthogonal matrices.

Before we present the formal algorithm, we demonstrate the key ideas on a $4 \times 4$ block matrix example.

**3.2. SSS solver: $4 \times 4$ example.** Let the initial system $Ax = b$ be partitioned as follows:

(3.3)

$$\begin{pmatrix} D_1 & U_1V_2^H & U_1W_2V_3^H & U_1W_2W_3V_4^H \\ P_2Q_1^H & D_2 & U_2V_3^H & U_2W_3V_4^H \\ P_3R_2Q_1^H & P_3Q_2^H & D_3 & U_3V_4^H \\ P_4R_3R_2Q_1^H & P_4R_3Q_2^H & P_4Q_3^H & D_4 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{pmatrix} = \begin{pmatrix} b_1 \\ b_2 \\ b_3 \\ b_4 \end{pmatrix} - \begin{pmatrix} 0 \\ P_2 \\ P_3R_2 \\ P_4R_3R_2 \end{pmatrix} \xi,$$

where the dimensions of the generators follow those in Table 3.1 with $m_i = \tilde{m}_i$ and the vector $\xi = 0$. The extra zero vector $\xi$ on the right-hand side of (3.3) has been added for the purpose of a general recursive pattern.

The algorithm has two main stages, compression (or elimination) and merging, depending on the relationship between $k_i$ ($l_i$) and $m_i$ in the intermediate procedure.

**3.2.1. Compression.** At the beginning, $k_1 < m_1$ because of the low-rank property described earlier. We apply a unitary transformation $q_1^H$ to $U_1$ so that the first $m_1 - k_1$ rows of $U_1$ become zeros:

$$q_1^H U_1 = \begin{array}{cc} \begin{pmatrix} 0 \\ \hat{U}_1 \end{pmatrix} & \begin{array}{c} m_1 - k_1 \\ k_1 \end{array} \end{array}. \tag{3.4}$$

Now we multiply $q_1^H$ to the first $m_1$ equations of the system

$$\begin{pmatrix} q_1^H & 0 \\ 0 & I \end{pmatrix} Ax = \begin{pmatrix} q_1^H & 0 \\ 0 & I \end{pmatrix} b - \begin{pmatrix} 0 \\ P_2 \\ P_3R_2 \\ P_4R_3R_2 \end{pmatrix} \xi.$$

We pick another unitary transformation $w_1^H$ to lower-triangularize $q_1^H D_1$, the $(1,1)$ diagonal block $A$, i.e.,

$$\left(q_1^H D_1\right) w_1^H = \begin{array}{c} \\ m_1 - k_1 \\ k_1 \end{array} \begin{array}{c} \begin{array}{cc} m_1 - k_1 & k_1 \end{array} \\ \begin{pmatrix} D_{11} & 0 \\ D_{21} & D_{22} \end{pmatrix} \end{array}.$$

Then system (3.3) becomes

$$\begin{pmatrix} q_1^H & 0 \\ 0 & I \end{pmatrix} A \begin{pmatrix} w_1^H & 0 \\ 0 & I \end{pmatrix} \begin{pmatrix} w_1 & 0 \\ 0 & I \end{pmatrix} x = \begin{pmatrix} q_1^H & 0 \\ 0 & I \end{pmatrix} b - \begin{pmatrix} 0 \\ P_2 \\ P_3R_2 \\ P_4R_3R_2 \end{pmatrix} \xi,$$

which can be rewritten as

$$\begin{pmatrix} D_{11} & 0 & 0 & 0 & 0 \\ D_{21} & D_{22} & \hat{U}_1V_2^H & \hat{U}_1W_2V_3^H & \hat{U}_1W_2W_3V_4^H \\ P_2Q_{11}^H & P_2\hat{Q}_1^H & D_2 & U_2V_3^H & U_2W_3V_4^H \\ P_3R_2Q_{11}^H & P_3R_2\hat{Q}_1^H & P_3Q_2^H & D_3 & U_3V_4^H \\ P_4R_3R_2Q_{11}^H & P_4R_3R_2\hat{Q}_1^H & P_4R_3Q_2^H & P_4Q_3^H & D_4 \end{pmatrix} \begin{pmatrix} z_1 \\ \hat{x}_1 \\ x_2 \\ x_3 \\ x_4 \end{pmatrix}$$

$$= \begin{pmatrix} \beta_1 \\ \gamma_1 \\ b_2 \\ b_3 \\ b_4 \end{pmatrix} - \begin{pmatrix} 0 \\ 0 \\ P_2 \\ P_3R_2 \\ P_4R_3R_2 \end{pmatrix} \xi,$$

where we have used the partitions

$$w_1x_1 = \begin{array}{c} m_1 - k_1 \\ k_1 \end{array} \begin{pmatrix} z_1 \\ \hat{x}_1 \end{pmatrix}, \quad q_1^H b_1 = \begin{array}{c} m_1 - k_1 \\ k_1 \end{array} \begin{pmatrix} \beta_1 \\ \gamma_1 \end{pmatrix}, \quad \text{and} \quad w_1Q_1 = \begin{array}{c} m_1 - k_1 \\ k_1 \end{array} \begin{pmatrix} Q_{11} \\ \hat{Q}_1 \end{pmatrix}.$$

At this point, we can solve for $z_1$ from the system of equations $D_{11}z_1 = \beta_1$. We also subtract $D_{21}z_1$ from the right-hand side to obtain $\hat{b}_1 = \gamma_1 - D_{21}z_1$. Then we can discard the first $m_1 - k_1$ rows and columns of the coefficient matrix of the system to obtain

$$\begin{pmatrix} D_{22} & \hat{U}_1 V_2^H & \hat{U}_1 W_2 V_3^H & \hat{U}_1 W_2 W_3 V_4^H \\ P_2 \hat{Q}_1^H & D_2 & U_2 V_3^H & U_2 W_3 V_4^H \\ P_3 R_2 \hat{Q}_1^H & P_3 Q_2^H & D_3 & U_3 V_4^H \\ P_4 R_3 R_2 \hat{Q}_1^H & P_4 R_3 Q_2^H & P_4 Q_3^H & D_4 \end{pmatrix} \begin{pmatrix} \hat{x}_1 \\ x_2 \\ x_3 \\ x_4 \end{pmatrix} = \begin{pmatrix} \hat{b}_1 \\ b_2 \\ b_3 \\ b_4 \end{pmatrix} - \begin{pmatrix} 0 \\ P_2 \\ P_3 R_2 \\ P_4 R_3 R_2 \end{pmatrix} \hat{\xi},$$

where $\hat{\xi} = \xi + Q_{11}^H z_1$. This new system has a similar structure to the original one but with smaller dimension. We can continue to solve it by recursion, if further compressions of the blocks such as (3.4) are possible. Note the actual solution, say, $x_1$, can be recovered by

$$x_1 = w_1^H \begin{pmatrix} z_1 \\ \hat{x}_1 \end{pmatrix}.$$

**3.2.2. Merging.** During the recursive eliminations there are situations when $k_i$ is no longer smaller than $m_i$ and no further compression is possible. We are then unable to introduce more zeros into the system. Now we proceed by merging appropriate block rows and columns of the matrix. As an example we can merge the first two block rows and columns and rewrite the system of equations as follows:

$$\begin{pmatrix} \begin{pmatrix} D_1 & U_1 V_2^H \\ P_2 Q_1^H & D_2 \end{pmatrix} & \begin{pmatrix} U_1 W_2 \\ U_2 \end{pmatrix} V_3^H & \begin{pmatrix} U_1 W_2 \\ U_2 \end{pmatrix} W_3 V_4^H \\ P_3 \begin{pmatrix} Q_1 R_2^H \\ Q_2 \end{pmatrix}^H & D_3 & U_3 V_4^H \\ P_4 R_3 \begin{pmatrix} Q_1 R_2^H \\ Q_2 \end{pmatrix}^H & P_4 Q_3^H & D_4 \end{pmatrix} \begin{pmatrix} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} \\ x_3 \\ x_4 \end{pmatrix}$$

$$= \begin{pmatrix} \begin{pmatrix} b_1 \\ b_2 - P_2 \hat{\xi} \end{pmatrix} \\ b_3 \\ b_4 \end{pmatrix} - \begin{pmatrix} \begin{pmatrix} 0 \\ 0 \end{pmatrix} \\ P_3 \\ P_4 R_3 \end{pmatrix} (R_2 \hat{\xi}).$$

Hence the system becomes

$$\begin{pmatrix} \hat{D}_1 & \hat{U}_1 V_3^H & \hat{U}_1 W_3 V_4^H \\ P_3 \hat{Q}_1^H & D_3 & U_3 V_4^H \\ P_4 R_3 \hat{Q}_1^H & P_4 Q_3^H & D_4 \end{pmatrix} \begin{pmatrix} \hat{x}_1 \\ x_3 \\ x_4 \end{pmatrix} = \begin{pmatrix} \hat{b}_1 \\ b_3 \\ b_4 \end{pmatrix} - \begin{pmatrix} 0 \\ P_3 \\ P_4 R_3 \end{pmatrix} (\tilde{\xi}),$$

where

$$\hat{D}_1 = \begin{pmatrix} D_1 & U_1 V_2^H \\ P_2 Q_1^H & D_2 \end{pmatrix}, \quad \hat{U}_1 = \begin{pmatrix} U_1 W_2 \\ U_2 \end{pmatrix}, \quad \hat{Q}_1 = \begin{pmatrix} Q_1 R_2^H \\ Q_2 \end{pmatrix},$$

$$\hat{x}_1 = \begin{pmatrix} x_1 \\ x_2 \end{pmatrix}, \quad \hat{b}_1 = \begin{pmatrix} b_1 \\ b_2 - P_2 \tau \end{pmatrix}, \quad \tilde{\xi} = R_2 \hat{\xi}.$$

The number of block rows/columns is reduced by one. Further compressions become possible and we can proceed to solve the system recursively. In the case $n = 1$, we have the system $D_1 x_1 = b_1 - 0\xi$, which is solved directly.

**3.3. General solve algorithm.** We now present a short description of the general algorithm. The procedure in the $4 \times 4$ example can be directly extended to a general system. We assume that the matrix $A$ is in compact SSS form represented by the generators $\{U_i\}_{i=1}^{n-1}$, $\{V_i\}_{i=2}^{n}$, $\{W_i\}_{i=2}^{n-1}$, $\{P_i\}_{i=2}^{n}$, $\{Q_i\}_{i=1}^{n-1}$, $\{R_i\}_{i=2}^{n-1}$, and $\{D_i\}_{i=1}^{n}$ as in (3.1). We also partition $x = (x_i)$ and $b = (b_j)$ such that $x_i$ and $b_i$ have $m_i$ rows. As in the $4 \times 4$ example, there are two stages at each step of the recursion.

In the compression stage, we perform orthogonal eliminations on both sides of $A$ to create an $(m_1 - k_1) \times (m_1 - k_1)$ lower triangular submatrix at the top left corner of $A$. Then we solve a small triangular system and obtain the first few components of the solution vector. At this stage, we are left with a new system with less unknowns; hence we can carry out a recursion.

In the merging stage, we merge the first two block rows and columns of $A$ while still maintaining the SSS structure. The numbers of block rows and columns are reduced by one.

Combining these two stages, we can proceed with recursion to solve the system. When $n = 1$ we can solve the linear system directly with standard solvers.

The SSS solver has a complexity $O(Np^2)$ [12, 13], where $p$ is the maximum numerical rank of the off-diagonal blocks of $A$, as compared to the traditional $O(N^3)$ cost for a general dense $N \times N$ matrix. We use only orthogonal transformations and a single substitution in the SSS solver. Although a formal proof for the backward stability is not yet available, the solver is shown to be practically stable. The reader is referred to [12, 13] for more discussions on the stability.

**4. Fast construction of SSS representation for $C$.** According to section 3, a system in compact SSS form can be solved very efficiently. We can thus use that algorithm to solve the Cauchy-like system (2.3), provided that $C$ can be quickly written in SSS form. Therefore we try to find an efficient construction scheme. Here we provide a divide-and-conquer SSS construction scheme by using the fast merging and splitting strategy in [13]. If we know further that the matrix has low-rank off-diagonal blocks and it is easy to compress the off-diagonal blocks, then the construction can be superfast. Here we will concentrate on this situation as Cauchy-like matrices have this low-rank property.

We first present a general divide-and-conquer construction algorithm and then describe a fast shifting strategy to compress the off-diagonal blocks of $C$.

**4.1. General divide-and-conquer construction algorithm.** In this section, we discuss the construction of the SSS structure of a matrix $A$, when the partition sequence $\{m_i\}_{i=1}^{n}$ is given. The general construction methods can be applied to any unstructured matrix, thus proving that any matrix has an SSS structure. (Of course, $k_i$ and $l_i$ will usually be large in this case, precluding any speed-ups.) These methods can be viewed as specific ways to make the realization algorithm of [18] more efficient.

Suppose we are given an $N \times N$ matrix $A$ and a partition sequence $\{m_i\}_{i=1}^{n}$ with $\sum_{i=1}^{n} m_i = N$. Starting with an appropriate sequence $\{\tilde{m}_1, \tilde{m}_2\}$, where $\sum_{i=1}^{k} m_i = \tilde{m}_1$ and $\sum_{i=k+1}^{n} m_i = \tilde{m}_2$, we can first partition $A$ into a $2 \times 2$ block matrix and then construct a simple SSS form

$$A = \begin{array}{c c} & \begin{array}{cc} \tilde{m}_1 & \tilde{m}_2 \end{array} \\ \begin{array}{c} \tilde{m}_1 \\ \tilde{m}_2 \end{array} & \begin{pmatrix} D_1 & B \\ E & D_2 \end{pmatrix} \end{array} = \begin{array}{c} \begin{array}{cc} \tilde{m}_1 & \tilde{m}_2 \end{array} \\ \begin{pmatrix} D_1 & U_1 V_2^H \\ P_2 Q_1^H & D_2 \end{pmatrix} \end{array}, \tag{4.1}$$

where

$$B = U_1 V_2^H \equiv U_1 \left(\Sigma_1 F_1^H\right), \; F = P_2 Q_1^H \equiv P_2 \left(\Sigma_1 F_1^H\right) \tag{4.2}$$

are the low-rank SVDs of the off-diagonal blocks $B$ and $E$. Note if the compressions are done by $\tau$-accurate SVD approximations or rank-revealing QR decompositions, then appropriate "=" signs should be replaced by "≈" signs. We now split either the $(1,1)$ block or the $(2,2)$ block to obtain a $3\times 3$ block SSS matrix. For instance, we can split the $(1,1)$ block according to an appropriate new sequence $\{\hat{m}_1, \hat{m}_2, \hat{m}_3\}$ as follows, where $\hat{m}_1 + \hat{m}_2 = m_1,\ \hat{m}_3 = m_2$:

$$\begin{pmatrix} D_1^{\mathbf{new}} & U_1^{\mathbf{new}}(V_2^{\mathbf{new}})^H \\ P_2^{\mathbf{new}}(Q_1^{\mathbf{new}})^H & D_2^{\mathbf{new}} \end{pmatrix} = D_1,\ \begin{pmatrix} U_1^{\mathbf{new}} W_2^{\mathbf{new}} \\ U_2^{\mathbf{new}} \end{pmatrix} = U_1,\ (V_3^{\mathbf{new}})^H = V_2^H,$$

$$(R_2^{\mathbf{new}}(Q_1^{\mathbf{new}})^H (Q_2^{\mathbf{new}})^H) = Q_1^H,\ P_3^{\mathbf{new}} = P_2,\ D_3^{\mathbf{new}} = D_2,$$

where the new generators (marked by the superscript **new**) introduced based on (4.1) can be determined in the following way. First, we partition the matrices for the old first block conformally with the two new blocks as

$$\begin{pmatrix} D_1^{11} & D_1^{12} \\ D_1^{21} & D_1^{22} \end{pmatrix} = D_1,\ \begin{pmatrix} U_1^1 \\ U_1^2 \end{pmatrix} = U_1,\ ((Q_1^1)^H (Q_1^2)^H) = Q_1^H.$$

We can then identify from these and the previous equations that

$D_1^{\mathbf{new}} = D_1^{11}$, $D_2^{\mathbf{new}} = D_1^{22}$, $U_2^{\mathbf{new}} = U_1^2$, $V_3^{\mathbf{new}} = V_2$, $Q_2^{\mathbf{new}} = Q_1^2$, $P_3^{\mathbf{new}} = P_2$, $D_3^{\mathbf{new}} = D_2$.

The remaining matrices satisfy

$$(D_1^{12} U_1^1) = U_1^{\mathbf{new}}((V_2^{\mathbf{new}})^H W_2^{\mathbf{new}}),\ \begin{pmatrix} D_1^{21} \\ (Q_1^1)^H \end{pmatrix} = \begin{pmatrix} P_2^{\mathbf{new}} \\ R_2^{\mathbf{new}} \end{pmatrix} (Q_1^{\mathbf{new}})^H. \tag{4.3}$$

By factorizing the left-hand side matrices using numerical tools such as the SVD and rank-revealing QR, these two equations allow us to compute those remaining matrices for the new blocks.

$A$ is thus in the new form

$$A = \begin{array}{c} \\ \hat{m}_1 \\ \hat{m}_2 \\ \hat{m}_3 \end{array} \begin{array}{c} \begin{array}{ccc} \hat{m}_1 & \hat{m}_2 & \hat{m}_3 \end{array} \\ \begin{pmatrix} D_1^{\mathbf{new}} & U_1^{\mathbf{new}}(V_2^{\mathbf{new}})^H & U_1^{\mathbf{new}} W_2^{\mathbf{new}} (V_3^{\mathbf{new}})^H \\ P_2^{\mathbf{new}}(Q_1^{\mathbf{new}})^H & D_2^{\mathbf{new}} & U_2^{\mathbf{new}}(V_3^{\mathbf{new}})^H \\ P_2^{\mathbf{new}} R_2^{\mathbf{new}} (Q_1^{\mathbf{new}})^H & P_3^{\mathbf{new}}(Q_2^{\mathbf{new}})^H & D_3^{\mathbf{new}} \end{pmatrix} \end{array}.$$

We can use similar techniques if we want to split the second row and column of (4.1).

We can continue this by either splitting the first block row and block column or the last ones using the above techniques, or splitting any middle block row and block column similarly. Then we will be able to construct the desired SSS representation according to the given sequence $\{m_i,\ i = 1, 2, \ldots, n\}$.

The general construction can be organized with bisection. The major cost is in compressions of off-diagonal blocks of the form

$$D_i^{12} = X_i Y_i^H, \tag{4.4}$$

where $X_i$ and $Y_i$ are tall and thin, and $D_i^{12}$ is an off-diagonal block of

$$D_i = \begin{pmatrix} D_i^{11} & D_i^{12} \\ D_i^{21} & D_i^{22} \end{pmatrix}.$$

The compression (4.4) can be achieved by a $\tau$-accurate QR factorization.

The construction is also practically stable in our implementation.

**4.2. Compression of off-diagonal blocks.** For a general matrix with low-rank off-diagonal blocks, the SSS construction can cost $O(N^2p)$ as a compression such as (4.2), (4.3), and (4.4) can take $O(K^2p)$, where $K$ is the dimension of the block being compressed. However, for the Cauchy-like matrix $C$ in (2.3) the compressions can be precomputed.

THEOREM 4.1. *The compression of the off-diagonal block*

$$G = \left( \frac{u_i^T \cdot v_j}{\lambda_i - \eta_j} \right)_{1 \le i \le p,\ q \le j \le N} = XY^H \tag{4.5}$$

*of* $C$ *can be obtained by the compression of the corresponding off-diagonal block*

$$G = \left( \frac{1}{\lambda_i - \eta_j} \right)_{1 \le i \le p,\ q \le j \le N} = X_0 Y_0^H$$

*of* $C_0$*, where the column dimension of* $X$ *is no larger than twice the size of the column dimension of* $X_0$*.*

*Proof.* Assume the off-diagonal block $G_0 = (\frac{1}{\lambda_i - \eta_j})_{1 \le i \le p,\ q \le j \le N}$ is in compressed form $X_0 Y_0^H$, and the $(i,j)$ entry is $\frac{1}{\lambda_i - \eta_j} = X_{i,:} Y_{j,:}^H$, where $X_{i,:}$ $(Y_{j,:})$ denotes the $i$th row of $X$ $(Y)$. As $\alpha \le 2$ for simplicity we fix $\alpha = 2$ in (2.1). Then the corresponding off-diagonal block in $C$ is

$$\begin{aligned}
G &= \left( \frac{u_i^T \cdot v_j}{\lambda_i - \eta_j} \right)_{1 \le i \le p,\ q \le j \le N} = \left( \frac{u_{i1} v_{j1} + u_{i2} v_{j2}}{\lambda_i - \eta_j} \right)_{1 \le i \le p,\ q \le j \le N} \\
&= \left( (u_{i1} v_{j1} + u_{i2} v_{j2})\, X_{i,:} Y_{j,:}^H \right)_{1 \le i \le p,\ q \le j \le N} \\
&= \left( \begin{pmatrix} u_{i1} X_{i,:} & u_{i2} X_{i,:} \end{pmatrix} \begin{pmatrix} v_{j1} Y_{j,:}^H \\ v_{j2} Y_{j,:}^H \end{pmatrix} \right)_{1 \le i \le p,\ q \le j \le N} \\
&= \begin{pmatrix} u_{11} X_{1,:} & u_{12} X_{1,:} \\ \vdots & \vdots \\ u_{p1} X_{i,:} & u_{p2} X_{i,:} \end{pmatrix} \begin{pmatrix} v_{q1} Y_{q,:}^H & \cdots & v_{N1} Y_{N,:}^H \\ v_{q2} Y_{q,:}^H & \cdots & v_{N2} Y_{N,:}^H \end{pmatrix} \\
&\equiv XY^H.
\end{aligned}$$

That is, we get a compression of $G$. □

Theorem 4.1 indicates that we can convert the compressions of the off-diagonal blocks of $C$ to be the compressions of those of $C_0$ which is independent of the actual entries of the Toeplitz matrix $T$. This means the compressions of off-diagonal blocks of $C_0$ can be precomputed. The precomputation can be done in $O(N^2p)$ flops by a rank-revealing QR factorization such as in [27]. It is possible to reduce the cost to $O(N \log N)$ due to the fact that the compression of a large off-diagonal block can be obtained by that of small ones. This can be seen implicitly from the following subsection.

**4.3. Compressions of off-diagonal blocks in precomputation.** We further present a shifting strategy to reduce the cost of the compressions in the precomputation. The significance of this shifting strategy is to relate the compressions of large off-diagonal block of $C_0$ to those of small ones. That is, in different splitting stages of the SSS construction of $C$, the compressions of off-diagonal blocks with different sizes can be related.

For simplicity, we look at the example of partitioning $C_0$ into $4\times 4$ blocks. Assume in the first cut that we can partition $C_0$ into $2\times 2$ blocks with equal dimensions as in the following:

$$C_0 = \left(\frac{1}{\omega^{2i}-\omega^{2j+1}}\right)_{1\le i,\ j\le N} = \left(\begin{array}{c||c} C_{0;1,1} & C_{0;1,2} \\ \hline\hline C_{0;2,1} & C_{0;2,2} \end{array}\right)$$

$$= \left(\begin{array}{ccc||ccc} \frac{1}{\omega^2-\omega^3} & \cdots & \frac{1}{\omega^2-\omega^{4k+1}} & \frac{1}{\omega^2-\omega^{4k+3}} & \cdots & \frac{1}{\omega^2-\omega^{2N+1}} \\ \vdots & & \vdots & \vdots & \cdots & \vdots \\ \frac{1}{\omega^{4k}-\omega^3} & \cdots & \frac{1}{\omega^{4k}-\omega^{4k+1}} & \frac{1}{\omega^{4k}-\omega^{4k+3}} & \cdots & \frac{1}{\omega^{4k}-\omega^{2N+1}} \\ \hline\hline & & & & & \\ & C_{0;2,1} & & & C_{0;2,2} & \\ & & & & & \end{array}\right),$$

where $k=\frac{N}{4}$, and without loss of generality, we consider only the block upper triangular part. Assume that we have obtained a compression $X_1Y_1^H$ of $C_{0;1,2}$ such that

$$C_0 = \left(\begin{array}{c||c} C_{0;1,1} & X_1Y_1^H \\ \hline\hline C_{0;2,1} & C_{0;2,2} \end{array}\right),$$

where $X_1$ and $Y_1$ are tall and thin and can be computed with $\tau$-accurate SVD or rank-revealing QR factorization. Next, we split $C_{0;1,1}$, the $(1,1)$ block of $C_0$, into $2\times 2$ blocks and compress its off-diagonal block. Suppose the resulting off-diagonal block of $C_{0;1,1}$ has size $k\times(\frac{N}{2}-l)$. We will compress it by shifting certain parts of $X_1$ and $Y_1$. That is, we partition $X_1$ and $Y_1$ conformally as

$$X_1 = \begin{pmatrix} X_{1,1} \\ X_{1,2} \end{pmatrix},\ Y_1 = \begin{pmatrix} Y_{1,1} \\ Y_{1,2} \end{pmatrix},$$

and also pick a $k\times(\frac{N}{2}-l)$ block from the lower left corner of $C_{0;1,2}=X_1Y_1^H$ (that is, $X_{1,2}Y_{1,1}^H$)

$$C_0 = \left(\begin{array}{c||c} C_{0;1,1} & X_1Y_1^H \\ \hline\hline C_{0;2,1} & C_{0;2,2} \end{array}\right)$$

$$= \left(\begin{array}{c|ccc||ccc|c} & \frac{1}{\omega^2-\omega^{2l+3}} & \cdots & \frac{1}{\omega^2-\omega^{N+1}} & & & & \\ & \vdots & \cdots & \vdots & & & & \\ & \frac{1}{\omega^{2k}-\omega^{2l+3}} & \cdots & \frac{1}{\omega^{2k}-\omega^{N+1}} & & & & \\ \hline & & & & \frac{1}{\omega^{2k+2}-\omega^{N+3}} & \cdots & \frac{1}{\omega^{2k+2}-\omega^{2(N-l)+1}} & \\ & & & & \vdots & \cdots & \vdots & \\ & & & & \frac{1}{\omega^{4k}-\omega^{N+3}} & \cdots & \frac{1}{\omega^{N}-\omega^{2(N-l)+1}} & \\ \hline\hline \multicolumn{4}{c||}{} & \multicolumn{4}{c}{} \\ \multicolumn{4}{c||}{C_{0;2,1}} & \multicolumn{4}{c}{C_{0;2,2}} \\ \multicolumn{4}{c||}{} & \multicolumn{4}{c}{} \end{array}\right)$$

$$= \left(\begin{array}{c|c||c|c} & X_2Y_2^H & X_{1,1}Y_{1,1}^H & X_{1,1}Y_{1,2}^H \\ \hline & & X_{1,2}Y_{1,1}^H & X_{1,2}Y_{1,2}^H \\ \hline\hline \multicolumn{2}{c||}{C_{0;2,1}} & \multicolumn{2}{c}{C_{0;2,2}} \end{array}\right),$$

where $X_2Y_2^H$ is an unknown compression of the upper right submatrix of $C_{0;1,1}$, and the blocks that don't concern us are left blank. At this point we do not need another factorization to get $X_2Y_2^H$; instead we can directly derive the compression $X_2Y_2^H$ of $C_{0;1,1}$ from $X_{1,2}$ and $Y_{1,1}$. Clearly we have

$$\begin{aligned} X_2Y_2^H &= \begin{pmatrix} \frac{1}{\omega^2-\omega^{2l+3}} & \cdots & \frac{1}{\omega^2-\omega^{N+1}} \\ \vdots & \cdots & \vdots \\ \frac{1}{\omega^{2k}-\omega^{2l+3}} & \cdots & \frac{1}{\omega^{2k}-\omega^{N+1}} \end{pmatrix}, \\ X_{1,2}Y_{1,1}^H &= \begin{pmatrix} \frac{1}{\omega^{2k+2}-\omega^{N+3}} & \cdots & \frac{1}{\omega^{2k+2}-\omega^{2(N-l)+1}} \\ \vdots & \cdots & \vdots \\ \frac{1}{\omega^{4k}-\omega^{N+3}} & \cdots & \frac{1}{\omega^{N}-\omega^{2(N-l)+1}} \end{pmatrix} = \frac{1}{\omega^{2k}} X_2Y_2^H. \end{aligned}$$

That means we can get $X_2Y_2^H$ by shifting a subblock of $X_1Y_1^H$. A similar situation holds for the splitting of the $(2,2)$ block of $C$ after the first splitting. For the successive compressions in later splittings, a similar shifting can be used. For splitting with general block sizes the shifting is also similar.

The shifting scheme indicates that, in different levels of divide-and-conquer SSS constructions, the compressions of large blocks and small blocks are related. This can be used to further save the compression cost.

## 5. Performance and numerical experiments.

It is well known that the FFT transformation of the Toeplitz matrix $T$ to a Cauchy-like matrix $C$, and the recovery from the solution $\tilde{x}$ of the Cauchy-like system to the solution $x$ of the Toeplitz system, are stable. In addition, the fast divide-and-conquer construction and the SSS system solver in section 3 are both practically stable as we will see in our numerical results. Thus our overall algorithm is stable in practice. Here no extra steps are needed to stabilize the algorithm as required in some other superfast methods [38].

After the precomputations discussed in sections 4.2 and 4.3 are finished, the cost of each SSS construction is only $O(Np^2)$, where $p$ is the maximum of the off-diagonal ranks of the Cauchy matrix $C_0$. The SSS solver also costs $O(Np^2)$. The total cost is thus no more than $O(N \log N) + O(Np^2)$ flops. The total storage requirement is $O(Np)$. For the convenience of coding, we use an $O(N^2p)$ cost precomputation routine as discussed in subsection 4.2.

A preliminary implementation of our superfast solver in Fortran 90 is available at http://www.math.ucla.edu/˜jxia/work/toep. We did experiments on an Itanium 2 1.4 GHz SGI Altix 350 server with a 64-bit Linux operating system and Intel MKL BLAS. Our method (denoted by `NEW`) is compared to Gaussian elimination with partial pivoting (denoted by `GEPP`) (via the LAPACK linear system solver ZGESV [3]). We consider real $N \times N$ Toeplitz matrices $T$ whose entries are random and uniformly distributed in $[0, 1]$. The right-hand sides $b$ are obtained by $b = Tx$, where the exact solution $x$ has random entries uniformly distributed in $[-1, 1]$. Matrices of size $N = 2^k \times 100$, $k = 2, 3, \ldots$, are considered. These matrices are moderately ill-conditioned. For example, for $N = 2^k \times 100$ with $k = 2, \ldots, 7$, the one-norm condition numbers of the matrices increase from the order of about $10^3$ to $10^6$.

For the `NEW` solver two important parameters are involved, the SSS block size $d$ (Figure 2.1) and the tolerance $\tau$ in the compressions of off-diagonal blocks. Here we use the $\tau$-accurate QR factorization with $\tau$ as a relative tolerance (section 2.2).

Figure 5.1 shows the execution time (in seconds) for `GEPP` and our `NEW` solver with different $d$ and $\tau$. For the `NEW` solver only the time for solving the Cauchy-like

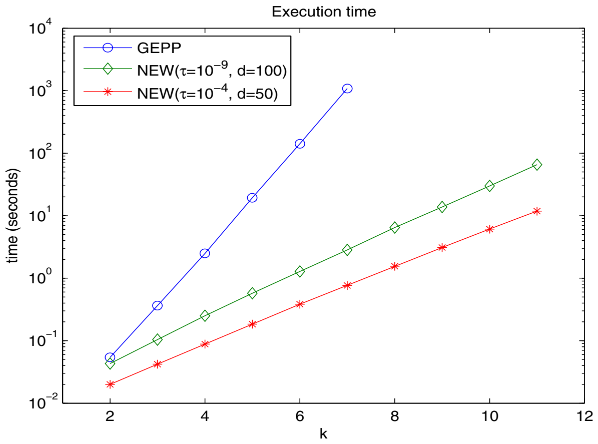

FIG. 5.1. *Computation time (in seconds) versus* $N = 2^k \times 100$*. For the* `NEW` *solver, time for the precomputation is excluded.*

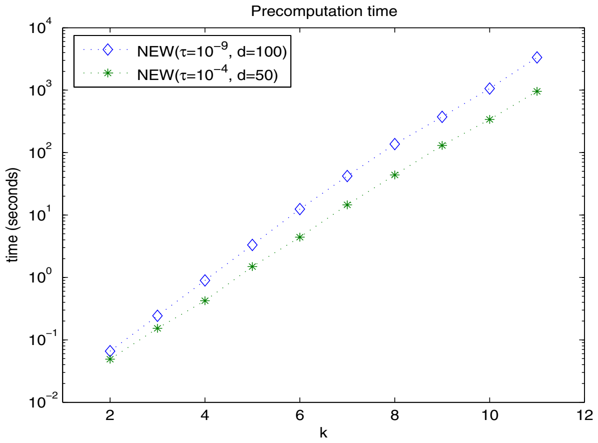

FIG. 5.2. *Time (in seconds) for precomputations in the* `NEW` *solver.*

system (2.3) is reported, as the compressions of off-diagonal blocks can be done in the precomputation, as described in section 4.3, and the SSS construction time is nearly the precomputation time. The precomputation time is shown in Figure 5.2, although the precomputation only needs to be done once for a particular matrix size $N$.

We also consider the *time scaling factor*, that is, the factor by which the time is multiplied when the matrix size doubles; see Figure 5.3. We observe that the time scaling factors for the `NEW` solver are near 2, that is to say the `NEW` solver is close to being a linear time solver.

Figures 5.4 and 5.5 present the errors $\varepsilon_1 = \frac{||\hat{x}-x||_2}{||x||_2}$ and $\varepsilon_2 = \frac{||T\hat{x}-b||_2}{|||T|\,|\hat{x}|+|b|\,||_2}$, respectively, where $\hat{x}$ denotes the numerical solution.

A significant point of the new solver is that we can use a relatively large tolerance $\tau$ in the precomputation and solving, and then use iterative refinement to improve the accuracy. A relatively large $\tau$ leads to relatively small off-diagonal ranks (and thus

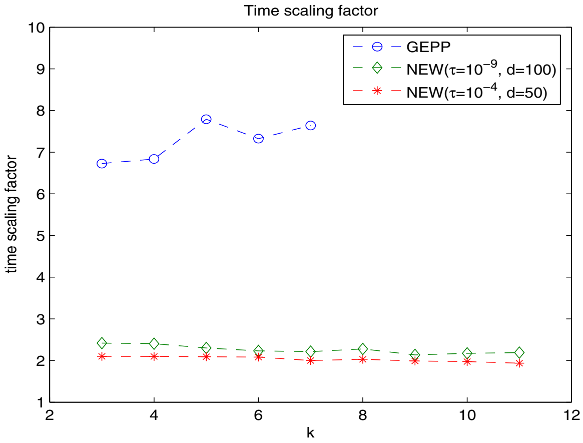

FIG. 5.3. *Time scaling factors.*

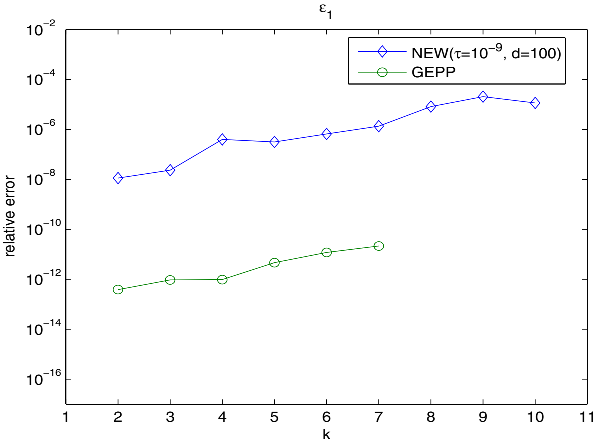

FIG. 5.4. $\varepsilon_1 = \frac{||\hat{x}-x||_2}{||x||_2}$ *versus* $N = 2^k \times 100$.

small $p$ in the operation counts above). Iterative refinements are very cheap due to the facts that no precomputation is needed and the solver itself is very fast (Figure 5.1). For $\tau = 10^{-4}$ and $d = 50$ the accuracy results after 2 to 8 steps of iterative refinement are displayed in Figure 5.6. In fact the number of iterative refinement steps required to reach $\varepsilon_2 < 10^{-13}$ is listed in Table 5.1.

Thus it is also clear that our `NEW` solver can also perform well as a preconditioner.

The block size $d$ also affects the performance. Figure 5.7 indicates that for a

| $k$ | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 |
|---|---|---|---|---|---|---|---|---|
| Number of steps | 4 | 4 | 5 | 6 | 7 | 15 | 9 | 21 |

given $N$ if $d = 2^j \times 25$ is too large or too small, then both the solver time and the precomputation time can be relatively large. In fact by counting the operations in the algorithm it is possible to determine an optimal $d$; see [12] for the derivation of the optimal choice of $d$ in the SSS solver. We can do similar derivations for both the SSS construction and the SSS solver. We just point out that when $\tau$ gets larger, the off-diagonal ranks decrease and a smaller $d$ should be chosen. In the previous experiments we used two sets of parameters: $(\tau = 10^{-9}, d = 100)$ and $(\tau = 10^{-4}, d = 50)$.

Finally, it turns out that our current preliminary implementation of the solver is slower than the implementation of the algorithm in [38], likely due to our inefficient data structure and nonoptimized codes for SSS matrices. The complicated nature of SSS matrices needs more careful coding and memory management. An improved software implementation is under construction.

## 6. Conclusions and future work.

In this paper we have presented a superfast and practically stable solver for Toeplitz systems of linear equations. A Toeplitz matrix is first transformed into a Cauchy-like matrix, which has a nice low-rank property, and then the Cauchy-like system is solved by a superfast solver. This superfast solver utilizes this low-rank property and makes use of an SSS representation of the Cauchy-like matrix. A fast construction procedure for SSS structures is presented. After a one-time precomputation the solver is very efficient ($O(N \log N) + O(Np^2)$ complexity). Also the algorithm is efficient in that only linear storage is required. In future work we hope to further reduce the precomputation cost and finish a better-designed version of the current Fortran 90 codes in both the computations and the coding.

# STEEPEST DESCENT AND CONJUGATE GRADIENT METHODS WITH VARIABLE PRECONDITIONING*

ANDREW V. KNYAZEV† AND ILYA LASHUK†

**Abstract.** We analyze the conjugate gradient (CG) method with variable preconditioning for solving a linear system with a real symmetric positive definite (SPD) matrix of coefficients $A$. We assume that the preconditioner is SPD on each step, and that the condition number of the preconditioned system matrix is bounded above by a constant independent of the step number. We show that the CG method with variable preconditioning under this assumption may not give improvement, compared to the steepest descent (SD) method. We describe the basic theory of CG methods with variable preconditioning with the emphasis on "worst case" scenarios, and provide complete proofs of all facts not available in the literature. We give a new elegant geometric proof of the SD convergence rate bound. Our numerical experiments, comparing the preconditioned SD and CG methods, not only support and illustrate our theoretical findings, but also reveal two surprising and potentially practically important effects. First, we analyze variable preconditioning in the form of inner-outer iterations. In previous such tests, the unpreconditioned CG inner iterations are applied to an artificial system with some fixed preconditioner as a matrix of coefficients. We test a different scenario, where the unpreconditioned CG inner iterations solve linear systems with the original system matrix $A$. We demonstrate that the CG-SD inner-outer iterations perform as well as the CG-CG inner-outer iterations in these tests. Second, we compare the CG methods using a two-grid preconditioning with fixed and randomly chosen coarse grids, and observe that the fixed preconditioner method is twice as slow as the method with random preconditioning.

**Key words.** Steepest descent, conjugate gradient, iterative method, inner-outer iterations, variable preconditioning, random preconditioning, preconditioner, condition number, linear systems, circular cone, Householder reflection, convergence rate bound, multigrid

## 1. Introduction.

Preconditioning, a transformation, usually implicit, of the original linear system aiming at accelerating the convergence of the approximations to the solution, is typically a necessary part of an efficient iterative technique. Modern preconditioning, e.g., based on so-called algebraic multilevel and domain decomposition methods, attempts to become as close to a "black box" ideal of direct solvers as possible. In this attempt, the mathematical structure of the preconditioner, which in the classical case is regarded as some linear transformation, may become very complex, in particular, the linearity can be easily lost, e.g., if the preconditioning itself involves "inner" iterative solvers. The fact that the preconditioner may be nonlinear, or variable, i.e., changing from iteration to iteration, may drastically affect the known theory as well as the practical behavior of preconditioned iterative methods and therefore needs special attention. Our main result is that the conjugate gradient (CG) method with variable preconditioning in certain situations may not give improvement, compared to the steepest descent (SD) method for solving a linear sys-

tem with a real symmetric positive definite (SPD) matrix of coefficients. We assume that the preconditioner is SPD on each step, and that the condition number of the preconditioned system matrix is bounded above by a constant.

Let us now introduce the notation, so that we can formulate the main result mathematically. Let $A$ be a real SPD matrix, $(x, y)$ be the standard inner product of real vectors $x$ and $y$, so that $(Ax, y) = (x, Ay)$, and let $\|x\| = \sqrt{(x, x)}$ be the corresponding vector norm. We also use $\|\cdot\|$ to denote the operator norm. The $A$-inner product and the A-norm are denoted by $(x, y)_A = (x, Ay)$ and $\|x\|_A = \sqrt{(x, x)_A}$.

We consider a family of iterative methods to obtain a sequence of approximate solutions $x_k$ of a linear system $Ax = b$ and use the $A$-norm to measure the error $e_k = x - x_k$. The SD and CG methods are well-known iterative procedures that fit into our framework. To accelerate the convergence of the error $e_k$ to zero we introduce preconditioning, i.e., on every iteration $k$ an operator $B_k$, called the preconditioner, possibly different for each iteration $k$, is applied to the residual $r_k = b - Ax_k$. A general algorithm, which includes the preconditioned SD or CG (PSD or PCG, respectively) methods as particular cases, can be presented as follows, e.g., Axelsson [1, p. 540] and Axelsson and Vassilevski [3, Algorithm 5.3]: given $A$, $b$, $\{B_k\}$, $\{m_k\}$, $x_0$, for $k = 0, 1, \ldots$: $r_k = b - Ax_k$, $s_k = B_k^{-1} r_k$, and

$$p_k = s_k - \sum_{l=k-m_k}^{k-1} \frac{(As_k, p_l)}{(Ap_l, p_l)} p_l, \quad x_{k+1} = x_k + \frac{(r_k, p_k)}{(Ap_k, p_k)} p_k, \tag{1.1}$$

where

$$0 \le m_k \le k \text{ and } m_{k+1} \le m_k + 1. \tag{1.2}$$

The latter condition is highlighted in Notay [11, p. 1447, line 1] and ensures that the formula for $p_k$ in (1.1) performs the standard Gram–Schmidt $A$-orthogonalizations to previous search directions, which are already pairwise $A$-orthogonal. The full orthogonalization that performs explicit $A$-orthogonalizations to all previous search directions corresponds to $m_k = k$. Choosing $m_k = \min\{k, 1\}$ gives the PCG method, e.g., described in Golub and Ye [6, IPCG Algorithm]. The connection of this PCG method to the commonly used PCG algorithm is discussed in section 7 following Golub and Ye [6, Remark 2.3]. The shortest recursion $m_k = 0$ leads to the standard PSD method.

It is well known, e.g., D′yakonov [4, p. 34] and Axelsson [1, section 11.1.2, p. 458] that if the preconditioner is SPD and fixed, $B_k = B = B^* > 0$, a preconditioned method, such as (1.1), using the preconditioner $B$ can be viewed as the corresponding unpreconditioned method applied to the preconditioned system $B^{-1}Ax = B^{-1}b$ in the $B$-based inner product $(x, y)_B = (x, By)$. This implies that the theory obtained for unpreconditioned methods remains valid for preconditioned methods, in particular, the $A$-orthogonalization terms with $l < k - 1$ in the sum in (1.1) vanish in exact arithmetic, e.g., Axelsson [1, section 11.2.6, Theorem 11.5]. The situation changes dramatically, however, if different preconditioners $B_k$ are used in the PCG method.

This paper concerns the behavior of method (1.1), where the preconditioner $B_k$ varies from step to step, but remains SPD on each step and the spectral condition number $\kappa\left(B_k^{-1}A\right) = \lambda_{\max}\left(B_k^{-1}A\right)/\lambda_{\min}\left(B_k^{-1}A\right)$ is bounded above by some constant $\kappa_{\max}$ independent of the step number $k$. We note that the matrix $B_k^{-1}A$ is SPD with respect to, e.g., the $B_k$ inner product, so its eigenvalues are real positive. Let us highlight that our assumption $\kappa\left(B_k^{-1}A\right) \le \kappa_{\max}$ can be equivalently written as $\|I - B_k^{-1}A\|_{B_k} \le \gamma$ with $\kappa_{\max} = (1+\gamma)/(1-\gamma)$, assuming without loss of generality that $B_k$ is scaled such that $\lambda_{\max}\left(B_k^{-1}A\right)+\lambda_{\min}\left(B_k^{-1}A\right)=2$. Here, we only deal with methods that are invariant with respect to scaling of $B_k$.

The main result of this paper is that the preconditioned method (1.1) with (1.2) turns into the PSD method with the worst possible convergence rate on every iteration, if the preconditioners $B_k$ satisfying our assumption $\kappa\left(B_k^{-1}A\right)\leq\kappa_{\max}$ are chosen in a special way. We explicitly construct a variable preconditioner that slows down the CG method to the point that the worst linear convergence rate of the SD method is recovered. Thus one can only guarantee that the convergence rate for the method (1.1) with (1.2) is just the same as for the PSD method, $m_k=0$, obtained in Kantorovich [7] and reproduced, e.g., in Kantorovich and Akilov [8, Chapter XV]:

$$\frac{\|e_{k+1}\|_A}{\|e_k\|_A}\leq\frac{\kappa_{\max}-1}{\kappa_{\max}+1}. \tag{1.3}$$

Our proof is geometric and based on the simple fact, proved in section 2, that a nonzero vector multiplied by all SPD matrices with a condition number bounded by a constant generates a pointed circular cone. We apply this fact on every iteration to the current residual vector, which becomes the center of the cone, so all points in the cone correspond to all possible preconditioned residuals. In a somewhat similar way, [6] use the angle between the exact and the perturbed preconditioned residuals. In the CG method context, this cone has a nontrivial intersection with the subspace $A$-orthogonal to all previous search directions. So on each iteration we can choose a preconditioner with the a priori chosen quality, determined by $\kappa_{\max}$, that makes enforcing $A$-orthogonality with respect to all previous search directions useless.

Basic properties of method (1.1), most importantly the local optimality, are derived in section 3. In section 4, we apply our results from section 2 about the cone to obtain a new proof of estimate (1.3). In section 5, we analyze the convergence of the PCG method with variable preconditioning and prove our main result. We assume real arithmetic everywhere in the paper, except for section 6, where we show that our main results also hold for complex Hermitian positive definite matrices. In section 7, we consider two particular PCG algorithms that are often used in practice and describe their behavior with variable preconditioning.

Our numerical experiments in section 8 comparing the preconditioned SD and CG methods support and illustrate our theoretical findings and also reveal some potentially practical important effects. In subsection 8.1, we test the widely used modification of the CG method with a simplified formula for the scalar $\beta_k$ from section 7 and demonstrate that variable preconditioning can make this modification much slower than even the SD method. In subsection 8.2, we analyze inner-outer iterations as variable preconditioning. Finally, in subsection 8.3, we demonstrate that variable preconditioning may surprisingly accelerate the SD and the CG compared to the use of fixed preconditioning in the same methods.

Different aspects of variable preconditioning are considered, e.g., in Axelsson [1] and Axelsson and Vassilevski [2, 3], where rather general nonlinear preconditioning is introduced, and in Golub and Ye [6] and Notay [11], they mainly deal with the case when the preconditioner on each iteration approximates a fixed operator. In Axelsson [1], Axelsson and Vassilevski [2], Golub and Ye [6], and Notay [11], convergence estimates for some iterative methods with variable preconditioning are proved. For recent results and other aspects of variable preconditioning, see Simoncini and Szyld [12, 13, 14] and the references therein. No attempts are apparently made in the literature to obtain a result similar to ours, even though it should appear quite natural and somewhat expected to experts in the area after reading this paper.

## 2. Pointed circular cones represent sets of SPD matrices with varying condition numbers.

For a pair of real nonzero vectors $x$ and $y$ we define the angle between $x$ and $y$ in the usual way as

$$\angle(x,y) = \arccos\left(\frac{(x,y)}{\|x\|\,\|y\|}\right) \in [0,\pi].$$

The following theorem is inspired by Neymeyr [10, Lemma 2.3].

THEOREM 2.1. *The set $\{Cx\}$, where $x$ is a fixed nonzero real vector and $C$ runs through all SPD matrices with condition number $\kappa(C)$ bounded above by some $\kappa_{\max}$, is a pointed circular cone, specifically,*

$$\{Cx : \quad C = C^* > 0,\, \kappa(C) \le \kappa_{\max}\} = \left\{y : \quad \sin\angle\,(x,y) \le \frac{\kappa_{\max}-1}{\kappa_{\max}+1}\right\}.$$

Theorem 2.1 can be proved by constructing our cone as the smallest pointed cone that includes the ball considered in Neymeyr [10, Lemma 2.3]. Preparing for section 6 that deals with the complex case, not covered in Neymeyr [10], we provide a direct proof here based on the following two lemmas. The first lemma is simple and states that the set in question cannot be larger than the cone.

LEMMA 2.2. *Let $x$ be a nonzero real vector and let $C$ be an SPD matrix with spectral condition number $\kappa\,(C)$. Then $\sin\angle\,(x,Cx) \le (\kappa\,(C)-1)/(\kappa\,(C)+1)$.*

*Proof.* Denote $y = Cx$. We have $(x,Cx) = \left(y, C^{-1}y\right) > 0$ since $C$ is SPD, so $y \ne 0$ and $\angle\,(x,y) < \pi/2$. A positive scaling of $C$ and thus of $y$ is obviously irrelevant, so let us choose $y$ to be the orthogonal projection of $x$ onto the one-dimensional subspace spanned by the original $y$. Then from elementary two-dimensional geometry it follows that $\|y-x\| = \|x\|\sin\angle\,(x,y)$. The orthogonal projection of a vector onto a subspace is the best approximation to the vector from the subspace, thus

$$\|x\|\sin\angle\,(x,y) = \|y-x\| \le \|sy-x\| = \|sCx-x\| \le \|sC-I\|\,\|x\|$$

for any scalar $s$, where $I$ is the identity. Taking $s = 2/\left(\lambda_{\max}(C)+\lambda_{\min}(C)\right)$, where $\lambda_{\min}(C)$ and $\lambda_{\max}(C)$ are the minimal and maximal eigenvalues of $C$, respectively, we get $\|sC-I\| = (\kappa\,(C)-1)/(\kappa\,(C)+1)$. ◻

The second lemma implies that every point in the cone can be represented as $Cx$ for some SPD matrix $C$ with $\kappa(C)$ determined by the opening angle of the cone.

LEMMA 2.3. *Let $x$ and $y$ be nonzero real vectors, such that $\angle\,(x,y) \in \left[0,\frac{\pi}{2}\right)$. Then there exists an SPD matrix $C$, such that $Cx = y$ and*

$$\frac{\kappa\,(C)-1}{\kappa\,(C)+1} = \sin\angle\,(x,y)\,.$$

*Proof.* Denote $\alpha = \angle\,(x,y)$. A positive scaling of vector $y$ is irrelevant, so as in the previous proof we choose $y$ to be the orthogonal projection of $x$ onto the one-dimensional subspace spanned by the original $y$, then $\|y-x\| = (\sin\alpha)\,\|x\|$, so the vectors $y-x$ and $(\sin\alpha)x$ are of the same length. This implies that there exists a Householder reflection $H$ such that $H\left((\sin\alpha)\,x\right) = y-x$, cf. Neymeyr [10, Lemma 2.3], so $(I+(\sin\alpha)\,H)\,x = y$. We define $C = I+(\sin\alpha)\,H$ to get $Cx = y$. Any Householder reflection is symmetric and has only two distinct eigenvalues $\pm 1$, so $C$ is also symmetric and has only two distinct positive eigenvalues $1 \pm \sin\alpha$, as $\alpha \in [0,\pi/2)$, and we conclude that $C > 0$ and $\kappa\,(C) = (1+\sin\alpha)/(1-\sin\alpha)$. ◻

**3. Local optimality of the method with variable preconditioning.** Here we discuss some basic properties of method (1.1) with (1.2). We derive a simple, but very useful, error propagation identity in Lemma 3.1. We prove in Lemma 3.2 that the method is well defined and has a certain local $A$-orthogonality property, formulated without a proof in Notay [11, formulas (2.1) and (2.2)] and in the important particular case $m_k = \min\{k, 1\}$ proved in Golub and Ye [6, Lemma 2.1]. Using the local $A$-orthogonality property of Lemma 3.2, we prove the local A-optimality property in Lemma 3.3 by generalizing the result of Golub and Ye [6, Proposition 2.2]. Finally, we derive a trivial Corollary 3.4 from Lemma 3.3, which uses the idea from Golub and Ye [6, p. 1309] of comparison with the PSD method, $m_k = 0$.

The material of this section is inspired by Golub and Ye [6] and may be known to experts in the field, e.g., some even more general facts can be found in Axellson [1, section 12.3.2, Lemma 12.22]. We provide straightforward and complete proofs here suitable for a general audience.

LEMMA 3.1. *Let $A$ and $\{B_k\}$ be SPD matrices. Suppose $p_k$ in method* (1.1) *is well defined and nonzero. Then*

$$e_{k+1} = e_k - \frac{(Ae_k, p_k)}{(Ap_k, p_k)} p_k. \tag{3.1}$$

*Proof.* Recall that $e_k = A^{-1}b - x_k$ and thus $r_k = Ae_k$. Then (3.1) follows immediately from the last formula in (1.1). ☐

LEMMA 3.2. *Let $A$ and $\{B_k\}$ be SPD matrices and $\{m_k\}$ satisfies* (1.2). *Then the error, the preconditioned residual, and the direction vectors generated by method* (1.1) *before the exact solution is obtained are well defined and satisfy*

$$(p_i, p_j)_A = 0,\ k - m_k \le i < j \le k, \tag{3.2}$$

$$(e_{k+1}, s_k)_A = (e_{k+1}, p_i)_A = 0,\ k - m_k \le i \le k. \tag{3.3}$$

*Proof.* We first notice that (3.1) for any $k$ obviously implies

$$(e_{k+1}, p_k)_A = 0. \tag{3.4}$$

For the rest of the proof we use an induction in $k$. Let us take $k = 0$ and suppose $x_0 \neq x$, then $r_0 \neq 0$ and $s_0 \neq 0$ since $B_0$ is SPD. By (1.2), $m_0 = 0$ and thus $p_0 = s_0 \neq 0$, so in the formula for $x_{k+1}$ we do not divide by zero, i.e., $x_{k+1}$ is well defined. There is nothing to prove in (3.2) for $k = 0$ since $m_0 = 0$. Formula (3.4) implies $(e_1, p_0)_A = (e_1, s_0)_A = 0$, i.e., (3.3) holds for $k = 0$. This provides the basis for the induction.

Suppose the statement of the lemma holds for $k - 1$, which is the induction hypothesis, i.e., up to the index $k - 1$ all quantities are well defined and

$$(p_i, p_j)_A = 0,\ k - 1 - m_{k-1} \le i < j \le k - 1, \tag{3.5}$$

$$(e_k, s_{k-1})_A = (e_k, p_i)_A = 0,\ k - 1 - m_{k-1} \le i \le k - 1. \tag{3.6}$$

We now show by contradiction that $x_k \neq x$ implies $p_k \neq 0$. Indeed, if $p_k = 0.2$ then $s_k$ is a linear combination of $p_{k-m_k}, \dots, p_{k-1}$. However, since $m_k \le m_{k-1} + 1$, it follows from (3.6) that

$$(e_k, p_i)_A = 0,\ k - m_k \le i \le k - 1. \tag{3.7}$$

Then we have $(s_k, e_k)_A = 0$. At the same time, since the matrix $B_k^{-1}A$ is $A$-SPD, $s_k = B_k^{-1}Ae_k$ cannot be $A$-orthogonal to $e_k$ unless $s_k = e_k = 0$, i.e., $x_k = x$.

Next, we prove (3.2) by showing that the formula for $p_k$ in (1.1) is a valid step of the Gram–Schmidt orthogonalization process with respect to the $A$-based inner product. If $m_k = 0$, then there is nothing to prove. If $m_k = 1$, then (3.2) gets reduced to $(p_k, p_{k-1})_A = 0$, which follows from the formula for $p_k$ in (1.1). If $m_k \geq 2$, then condition (1.2) implies that vectors $p_{k-m_k}, \ldots, p_{k-1}$ are among the vectors $p_{k-1-m_{k-1}}, \ldots, p_{k-1}$ and therefore are already $A$-orthogonal by the induction assumption (3.5). Then the formula for $p_k$ in (1.1) is indeed a valid step of the Gram–Schmidt orthogonalization process with respect to the $A$-based inner product, so (3.2) holds.

It remains to prove (3.3). We have already established (3.2), and (3.4)–(3.7). Equalities (3.2) and (3.7) imply that $p_k$ and $e_k$ are $A$-orthogonal to $p_{k-m_k}, \ldots, p_{k-1}$. Equality (3.1) implies that $e_{k+1}$ is a linear combination of $e_k$ and $p_k$. Thus, we have $(e_{k+1}, p_i)_A = 0,\ k - m_k \leq i \leq k-1$. Finally, it is enough to notice that $s_k$ is a linear combination of $p_k, p_{k-1}, \ldots, p_{k-m_k}$, so $(e_{k+1}, s_k)_A = 0$. ∎

We now use Lemma 3.2 to prove the local optimality of method (1.1) with (1.2), which generalizes the statement of Golub and Ye [6, Proposition 2.2].

LEMMA 3.3. *Under the assumptions of Lemma* 3.2,

$$\|e_{k+1}\|_A = \min_{p \in span\left\{s_k, p_{k-m_k}, \ldots, p_{k-1}\right\}} \|e_k - p\|_A.$$

*Proof.* We get $e_{k+1} \in e_k + \operatorname{span}\{s_k, p_{k-m_k}, \ldots, p_{k-1}\}$ from the formula for $p_k$ in (1.1) and (3.1). Putting this together with $A$-orthogonality relations (3.3) of the vector $e_{k+1}$ with all vectors that span the subspace finishes the proof. ∎

Two important corollaries follow immediately from Lemma 3.3 by analogy with Golub and Ye [6, Proposition 2.2].

COROLLARY 3.4. *The $A$-norm of the error $\|e_{k+1}\|_A$ in method* (1.1) *with* (1.2) *is bounded above by the $A$-norm of the error of one step of the PSD method, $m_k = 0$, using the same $x_k$ as the initial guess and $B_k$ as the preconditioner, i.e., specifically, $\|e_{k+1}\|_A \leq \min_\alpha \|e_k - \alpha s_k\|_A$.*

COROLLARY 3.5. *Let $m_k > 0$, then the $A$-norm of the error $\|e_{k+1}\|_A$ in method* (1.1) *with* (1.2) *for $k > 0$ satisfies $\|e_{k+1}\|_A \leq \min_{\alpha,\beta} \|e_k - \alpha s_k - \beta(e_k - e_{k-1})\|_A$.*

*Proof.* Under the lemma assumptions, the formula for $p_k$ in (1.1) and (3.1) imply that $e_{k+1} \in e_k + \operatorname{span}\{s_k, p_{k-1}\} = e_k + \operatorname{span}\{s_k, e_k - e_{k-1}\}$, and the $A$-orthogonality relations (3.3) turn into $(e_{k+1}, s_k)_A = 0$ and $(e_{k+1}, p_{k-1})_A = (e_{k+1}, e_k - e_{k-1})_A = 0$, so the vector $e_{k+1}$ is $A$-orthogonal to both vectors that span the subspace. As in the proof of Lemma 3.3, the local $A$-orthogonality implies the local $A$-optimality. ∎

Corollary 3.4 allows us in section 4 to estimate the convergence rate of method (1.1) with (1.2) by comparison with the PSD method, $m_k = 0$,—this idea is borrowed from Golub and Ye [6, p. 1309]. The results of Lemma 3.3 and Corollary 3.5 seem to indicate that an improved convergence rate bound of method (1.1) with (1.2) can be obtained, compared to the PSD method convergence rate bound that follows from Corollary 3.4. Our original intent has been to combine Corollary 3.5 with convergence rate bounds of the heavy ball method, in order to attempt to prove such an improved convergence rate bound. However, our results of section 5 demonstrate that this improvement is impossible under our only assumption $\kappa\left(B_k^{-1}A\right) \leq \kappa_{\max}$, since one can construct such preconditioners $B_k$ which make the minimizing value of $\beta$ in Corollary 3.5 be zero, so Corollary 3.5 gives no improvement compared to Corollary 3.4.

## 4. Convergence rate bounds for variable preconditioning.

The classical Kantorovich and Akilov [8, Chapter XV] convergence rate bound (1.3) for the PSD method is "local" in the sense that it relates the $A$-norm of the error on two subsequent iterations and does not depend on previous iterations. Thus, it remains valid when the preconditioner $B_k$ changes from iteration to iteration, while the condition number $\kappa\left(B_k^{-1}A\right)$ is bounded above by some constant $\kappa_{\max}$ independent of $k$. The goal of this section is to give an apparently new simple proof of the estimate (1.3) for the PSD method, based on our cone Theorem 2.1, and to extend this statement to cover the general method (1.1) with (1.2), using Corollary 3.4.

We denote the angle between two real nonzero vectors with respect to the $A$-based inner product by

$$\angle_A(x,y) = \arccos\left(\frac{(x,y)_A}{\|x\|_A\,\|y\|_A}\right) \in [0,\pi]$$

and express the error reduction ratio for the PSD method in terms of the angle with respect to the $A$-based inner product.

Lemma 4.1. *On every step of the PSD algorithm,* (1.1) *with* $m_k = 0$*, the error reduction factor takes the form* $\|e_{k+1}\|_A/\|e_k\|_A = \sin(\angle_A(e_k, B_k^{-1}Ae_k))$.

*Proof.* By (3.3), we have $(e_{k+1}, p_k)_A = 0$. Now, for $m_k = 0$, in addition, $p_k = s_k$, so $0 = (e_{k+1}, p_k)_A = (e_{k+1}, s_k)_A = (e_{k+1}, x_{k+1} - x_k)_A$, i.e., the triangle with vertices $x$, $x_k$, $x_{k+1}$ is right-angled in the $A$-inner product, where the hypotenuse is $e_k = x - x_k$. Therefore, $\|e_{k+1}\|_A / \|e_k\|_A = \sin(\angle_A(e_k, x_{k+1} - x_k)) = \sin(\angle_A(e_k, s_k))$, where $s_k = B_k^{-1}(b - Ax_k) = B_k^{-1}Ae_k$ by (1.1). ☐

Let us highlight that Lemma 4.1 provides an exact expression for the error reduction factor, not just a bound—we need this in the proof of Theorem 5.1 in the next section. Combining the results of Lemmas 2.2 and 4.1 together immediately leads to (1.3) for the PSD method, where $m_k = 0$. Finally, taking into account Corollary 3.4, by analogy with the arguments of Golub and Ye [6, p. 1309] and decrypting a hidden statement in Golub and Ye [6, Lemma 3.5], we get the following theorem.

Theorem 4.2. *Convergence rate bound* (1.3) *holds for method* (1.1) *with* (1.2).

## 5. The convergence rate bound is sharp.

Here we formulate and prove the main result of the paper that one can only guarantee the convergence rate described by (1.3) for method (1.1) with (1.2) with variable preconditioning if one only assumes $\kappa\left(B_k^{-1}A\right) \le \kappa_{\max}$. Let us remind the reader that (1.3) also describes the convergence rate for the PSD method, (1.1) with $m_k = 0$. We now show that adding more vectors to the PSD iterative recurrence results in no improvement in convergence, if a specially constructed set of variable preconditioners is used.

Theorem 5.1. *Let an SPD matrix $A$, vectors $b$ and $x_0$, and $\kappa_{\max} > 1$ be given. Assuming that the matrix size is larger than the number of iterations, one can choose a sequence of SPD preconditioners $B_k$, satisfying $\kappa(B_k^{-1}A) \le \kappa_{\max}$, such that method* (1.1) *with* (1.2) *turns into the PSD method,* (1.1) *with* $m_k = 0$*, and on every iteration*

$$\frac{\|e_{k+1}\|_A}{\|e_k\|_A} = \frac{\kappa_{\max} - 1}{\kappa_{\max} + 1}. \tag{5.1}$$

*Proof.* We construct the sequence $B_k$ by induction. First, we choose any vector $q_0$, such that $\sin\angle_A(q_0, e_0) = (\kappa_{\max} - 1)/(\kappa_{\max} + 1)$. According to Lemma 2.3 applied in the $A$-inner product, there exists an $A$-SPD matrix $C_0$ with condition number $\kappa(C_0) = \kappa_{\max}$, such that $C_0 e_0 = q_0$. We define the SPD $B_0 = AC_0^{-1}$, then $\kappa(B_0^{-1}A) =$

$\kappa(C_0) = \kappa_{\max}$. We have $s_k = B_k^{-1}Ae_k$, so such a choice of $B_0$ implies $s_0 = q_0$. Also, we have $p_0 = s_0$, i.e., the first step is always a PSD step; thus, by Lemma 4.1 we have proved (5.1) for $k = 0$. Note that $(e_1, p_0)_A = 0$ by (3.3).

Second, we make the induction assumption: let preconditioners $B_l$ for $l \leq k-1$ be constructed, such that $\|e_{l+1}\|_A/\|e_l\|_A = (\kappa_{\max} - 1)/(\kappa_{\max} + 1)$ and $(e_k, p_l)_A = 0$ hold for all $l \leq k-1$. The dimension of the space is greater than the total number of iterations by our assumption, so there exists a vector $u_k$, such that $(u_k, p_l)_A = 0$ for $l \leq k-1$ and $u_k$ and $e_k$ are linearly independent. Then the two-dimensional subspace spanned by $u_k$ and $e_k$ is $A$-orthogonal to $p_l$ for $l \leq k-1$.

Let us consider the boundary of the pointed circular cone made of vectors $q_k$ satisfying the condition $\sin\angle_A(q_k, e_k) = (\kappa_{\max} - 1)/(\kappa_{\max} + 1)$. This conical surface has a nontrivial intersection with the 2D subspace spanned by $u_k$ and $e_k$, since $e_k$ is the cone axis. Let us choose vector $q_k$ in the intersection, This vector will be obviously $A$-orthogonal to $p_l$, $l \leq k-1$.

Applying the same reasoning as for constructing $B_0$, we deduce that there exists an SPD $B_k$ such that $\kappa(B_k^{-1}A) \leq \kappa_{\max}$ and $B_k^{-1}Ae_k = q_k$. With such a choice of $B_k$ we have $s_k = q_k$. Since $q_k = s_k$ is $A$-orthogonal to $p_l$ for all $l \leq k-1$, it turns out that $p_k = s_k$, no matter how $\{m_k\}$ are chosen. This means that $x_{k+1}$ is obtained from $x_k$ by a steepest descent step. Then we apply Lemma 4.1 and conclude that (5.1) holds. We note, that $(e_{k+1}, p_l)_A = 0$ for all $l \leq k$. Indeed, $(e_{k+1}, p_l)_A = 0$ for all $l \leq k-1$ since $e_{k+1}$ is a linear combination of $e_k$ and $p_k = s_k = q_k$, both $A$-orthogonal to $p_l$ for $l \leq k-1$. Finally, $(e_{k+1}, p_k)_A = 0$ by (3.3). This completes the construction of $\{B_k\}$ by induction and thus the proof. □

Let us highlight that the statement of Theorem 5.1 consists of two parts: first, it is possible to have the PCG method with variable preconditioning that converges no faster than the PSD method with the same preconditioning; and second, moreover, it is possible that the PCG method with variable preconditioning converges no faster than the worst possible theoretical convergence rate for the PSD method described by (1.3). Numerical tests in section 8 show that the former possibility is more likely than the latter. Specifically, we demonstrate numerically in subsection 8.3 that the PCG and PSD methods with random preconditioning converge with the same speed, but both are much faster than what bound (1.3) predicts.

## 6. Complex Hermitian case.

In all other sections of this paper we assume for simplicity that matrices and vectors are real. However, our main results also hold when matrices $A$ and $\{B_k\}$ are complex Hermitian positive definite. Here we discuss modifications to statements and proofs in sections 2, 4, and 5 in order to cover the complex Hermitian case, assuming the scalar product be linear in its first argument and conjugate-linear in its second argument, as usual.

In section 2, the first thing to be changed is the definition of the angle between two nonzero vectors $x, y \in \mathbb{C}^n$, where an absolute value is now taken,

$$\angle(x, y) = \arccos\left|\frac{(x, y)}{\|x\|\,\|y\|}\right| \in \left[0, \frac{\pi}{2}\right],$$

that makes the angle acute and invariant with respect to complex nonzero scaling of the vectors. Lemma 2.2 remains valid in the complex case.

Lemma 6.1. *Let $x$ be a nonzero complex vector, and $C$ be a complex Hermitian positive definite matrix with the spectral condition number $\kappa(C)$, then* $\sin\angle(x, Cx) \leq (\kappa(C) - 1)/(\kappa(C) + 1)$.

*Proof.* Denote $y = Cx$ and let $\gamma = (x, y) / \|y\|^2$, then $\gamma y$ is the projection of $x$ onto span$\{y\}$, and $\angle(x, y) = \angle(x, \gamma y)$. Moreover, $(x, \gamma y) = (x, y)\bar{\gamma} = (x, y)(y, x)/\|y\|^2$ is real—we need this fact later in the proof of Lemma 6.2. We redefine $y$ to $\gamma y$. The rest of the proof is exactly the same as that of Lemma 2.2, since the identity $\|y - x\| = \|x\| \sin \angle(x, y)$, where $y$ is scaled by a complex scalar to be the orthogonal projection of $x$ onto span$\{y\}$, still holds in the complex case with the new definition of the angle. ☐

Lemma 2.3 and, thus, Theorem 2.1 do not hold in the complex case after the straightforward reformulation. A trivial counterexample is a pair of vectors $x \neq 0$ and $y = ix$—the angle between $x$ and $y$ is obviously zero, yet it is impossible that $y = Cx$ for any complex Hermitian matrix $C$, since the inner product $(x, y) = -i\|x\|^2$ is not a real number. This counterexample also gives an idea for a simple fix.

LEMMA 6.2. *Let $x$ and $y$ be nonzero complex vectors, such that $\angle(x, y) \neq \pi/2$. Then there exists a complex Hermitian positive definite matrix $C$ and a complex scalar $\gamma$, such that $Cx = \gamma y$ and $(\kappa(C) - 1)/(\kappa(C) + 1) = \sin \angle(x, y)$.*

*Proof.* We first scale the complex vector $y$ as in the proof of Lemma 6.1 to make $y$ be the projection of $x$ onto span$\{y\}$. The rest of the proof is similar to that of Lemma 2.3, but we have to be careful working with the Householder reflection in the complex case, so we provide the complete proof.

The redefined $y$ is the projection of $x$ onto span$\{y\}$, thus, $\|y - x\| = (\sin \alpha)\|x\|$, so the vectors $u = y - x$ and $v = (\sin \alpha)x$ are of the same length. Moreover, their inner product $(u, v)$ is real, since $(x, y)$ is real; see the proof of Lemma 6.1. This implies that the Householder reflection $Hz = z - 2(w, z)w$, where $w = (u - v)/\|u - v\|$, acts on $z = u$ such that $Hu = v$, i.e., $H((\sin \alpha)x) = y - x$, so $(I + (\sin \alpha)H)x = y$. We define $C = I + (\sin \alpha)H$ to get $Cx = y$.

The Householder reflection $H$ is Hermitian and has only two distinct eigenvalues $\pm 1$, so $C$ is also Hermitian and has only two distinct positive eigenvalues $1 \pm \sin \alpha$, as $\alpha \in [0, \pi/2)$, and we conclude that $C > 0$ and $\kappa(C) = (1 + \sin \alpha)/(1 - \sin \alpha)$. ☐

The same change then makes Theorem 2.1 work in the complex case.

THEOREM 6.3. *The set $\{\gamma Cx\}$, where $x$ is a fixed nonzero complex vector, $\gamma$ runs through all nonzero complex scalars, and $C$ runs through all complex Hermitian positive definite matrices with condition number $\kappa(C)$ bounded above by some $\kappa_{\max}$, is a pointed circular cone, specifically,*

$$\{\gamma\, Cx : \gamma \neq 0, C = C^* > 0,\ \kappa(C) \leq \kappa_{\max}\} = \left\{ y : \sin \angle(x, y) \leq \frac{\kappa_{\max} - 1}{\kappa_{\max} + 1} \right\}.$$

Section 3 requires no changes other then replacing "SPD" with "Hermitian positive definite." In section 4, we just change the definition of the $A$-angle to

$$\angle_A(x, y) = \arccos \left| \frac{(x, y)_A}{\|x\|_A \|y\|_A} \right| \in \left[0, \frac{\pi}{2}\right],$$

and then Lemma 4.1 holds without any further changes.

Finally, the statement of Theorem 5.1 from section 5 allows for a straightforward generalization.

THEOREM 6.4. *Let a Hermitian positive definite matrix $A$, complex vectors $b$ and $x_0$, and $\kappa_{\max} > 1$ be given. Assuming that the matrix size is larger than the number of iterations, one can choose a sequence of Hermitian positive definite preconditioners $B_k$, satisfying $\kappa(B_k^{-1}A) \leq \kappa_{\max}$, such that method* (1.1) *with* (1.2) *turns into the PSD* *method,* (1.1) *with* $m_k = 0$*, and on every iteration*

$$\frac{\|e_{k+1}\|_A}{\|e_k\|_A} = \frac{\kappa_{\max} - 1}{\kappa_{\max} + 1}. \tag{6.1}$$

*Proof.* Only a small change in the proof of Theorem 5.1 is needed. We first choose any vector $q_0'$, satisfying $\sin \angle_A(q_0, e_0) = (\kappa_{\max} - 1)/(\kappa_{\max} + 1)$. Then by Lemma 6.2 we obtain the complex Hermitian positive definite matrix $C_0$ and the complex scalar $\gamma$ such that $C_0 e_0 = \gamma q_0'$. Finally, we choose $q_0$ to be $\gamma q_0'$ and continue as in the proof of Theorem 5.1. The same modification is made in the choice of the vectors $q_k$ for $k \geq 1$ later in the proof. ☐

**7. Practical PCG algorithms.** In this section we briefly discuss two particular well-known PCG algorithms that are often used in practice. Our discussion here is motivated by and follows Golub and Ye [6, Remark 2.3]. Suppose $A$, $b$, $x_0$, $r_0 = b - Ax_0$, $\{B_k\}$ for $k = 0, 1, \ldots$ are given, and consider Algorithm 7.1 where $\beta_k$ on line 7.1 is defined either by expression

$$\beta_k = \frac{(s_k, r_k)}{(s_{k-1}, r_{k-1})}, \tag{7.1}$$

or by expression

$$\beta_k = \frac{(s_k, r_k - r_{k-1})}{(s_{k-1}, r_{k-1})}. \tag{7.2}$$

Formula (7.1) is more often used in practice compared to (7.2), since it can be implemented in such a way that does not require storing the extra vector $r_{k-1}$.

**Algorithm 7.1**

```
1: for $k = 0, 1, \ldots$ do
2:    $s_k = B_k^{-1} r_k$
3:    if $k = 0$ then
4:       $p_0 = s_0$
5:    else
6:       $p_k = s_k + \beta_k p_{k-1}$ (where $\beta_k$ is defined by either (7.2) or (7.1) for all iterations)
7:    end if
8:    $\alpha_k = \frac{(s_k, r_k)}{(p_k, Ap_k)}$
9:    $x_{k+1} = x_k + \alpha_k p_k$
10:   $r_{k+1} = r_k - \alpha_k A p_k$
11: end for
```

If the preconditioner is SPD and fixed, it is well known, e.g., Golub and Ye [6, Remark 2.3], that $(s_k, r_{k-1}) = 0$, so formula (7.2) coincides with (7.1) and Algorithm 7.1 is described by (1.1) with $m_k = \min(k, 1)$. Of course, in this case the choice $m_k = \min(k, 1)$ is enough to keep *all* search directions $A$-orthogonal in exact arithmetic.

Things become different when variable preconditioning is used. It is well known, e.g., Golub and Ye [6, Remark 2.3] and Notay [11, Table 2], that using formula (7.1) for $\beta_k$ can significantly slow down the convergence, and we provide our own numerical evidence of that in section 8. At the same time, comparing Lemma 3.2

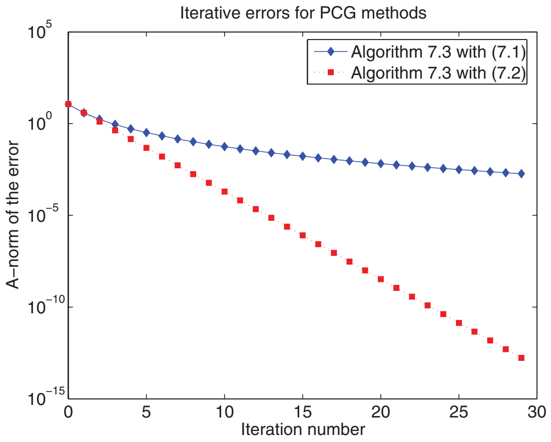

FIG. 8.1. *Algorithm* 7.1 *with* (7.1) *fails to provide the PSD convergence rate.*

with Lemma 2.1 from Golub and Ye [6], we can show, see Knyazev and Lashuk [9, v1], that Algorithm 7.1 with $\beta_k$ defined by (7.2), which is exactly as stated by Golub and Ye [6, IPCG Algorithm], is equivalent to the particular case of (1.1), namely with $m_k = \min(k, 1)$, and therefore is guaranteed by Theorem 4.2 to converge with at least the same speed as the PSD method.

## 8. Numerical experiments.

We first illustrate the main theoretical results of the paper numerically for a model problem. We numerically investigate the influence of the choice for $\beta_k$ between formulas (7.1) and (7.2) in Algorithm 7.1 and observe that (7.2) leads to the theoretically predicted convergence rate, while (7.1) may significantly slow down the convergence. Second, we test the convergence of inner-outer iteration schemes, where the inner iterations play the role of the variable preconditioning in the outer PCG iteration, and we illustrate our main conclusion that variable preconditioning may effectively reduce the convergence speed of the PCG method to the speed of the PSD method. Third, and last, we test the PSD and PCG methods with preconditioners of the same quality chosen randomly. We observe a surprising acceleration of the PCG method compared to the use of only one fixed preconditioner; at the same time, we show that the PSD method with random preconditioners works as well as the PCG method, which explains the PCG acceleration and again supports our main conclusion.

### 8.1. Numerical illustration of the main results.

Here, we use the standard 3-point approximation of the one-dimensional Laplacian of the size 200 as the matrix $A$ of the system. To simulate the application of the variable preconditioner, we essentially repeat the steps described in the proof of Theorem 5.1, i.e., we fix the condition number $\kappa\left(B_k^{-1}A\right) = 2$ and on each iteration we generate a pseudorandom vector $s_k$, which is $A$-orthogonal to previous search directions and such that the $A$-angle between $s_k$ and $e_k$ satisfies $\sin\left(\angle_A\left(s_k, e_k\right)\right) = (\kappa - 1)/(\kappa + 1)$.

We summarize the numerical results of this subsection on Figure 8.1, where the horizontal axis represents the number of iterations and the vertical axis represents the $A$-norm of the error. The iteration count actually starts from 1, so the $A$-norm of the error on the 0th iteration $\|e_0\|_A$ is just the $A$-norm of the initial error. The straight dotted (red in the electronic version) line marked with squares on Figure 8.1

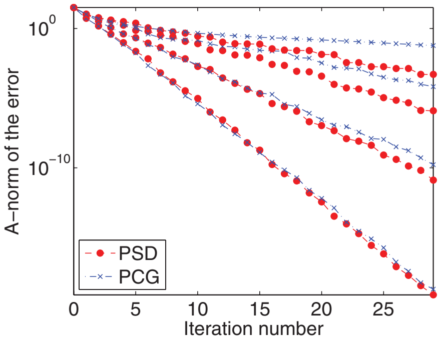

FIG. 8.2. *The PSD and PCG methods with preconditioning by inner CG with different stopping criteria* $\eta = 0.2, 0.4, 0.6,$ *and* $0.8$ *(from the bottom to the top).*

represents the PSD theoretical bound (1.3) and at the same time it perfectly coincides, which illustrates the statements of Theorem 5.1, with the change of the $A$-norm of the error in the case where the complete $A$-orthogonalization is performed, i.e., $m_k = k$ in method (1.1), as well as in the case where Algorithm 7.1 with $\beta_k$ defined by (7.2) is used. The curved solid (blue) line marked with diamonds represents the convergence of Algorithm 7.1 with $\beta_k$ defined by (7.1), which visibly performs much worse in this test compared to Algorithm 7.1 with (7.2). Notay's paper [11, section 5.2] contains analogous results comparing the change in the convergence rate using formulas (7.1) and (7.2), but it misses a comparison with the PSD method. To check our results of section 6, we repeat the tests in the complex arithmetic. The figure generated is similar to Figure 8.1, so we do not reproduce it here.

**8.2. Inner-outer iterations as variable preconditioning.** Inner-outer iterative schemes, where the inner iterations play the role of the variable preconditioner in the outer PCG iteration is a traditional example of variable preconditioning; see, e.g., Golub and Ye [6] and Notay [11]. Previously published tests analyze an approximation of some fixed preconditioner, $B_k \approx B$, different from $A$, by inner iterations, typically using the PCG method. The quality of the approximation is determined by the stopping criteria of the inner PCG method. A typical conclusion is that the performance of the outer PCG method improves and starts behaving like the PCG method with the fixed preconditioner $B$ when $B_k$ approximates $B$ more accurately by performing more inner iterations.

The idea of our tests in this subsection is different: we approximate $B_k \approx B = A$. The specific setup is the following. We take a diagonal matrix $A$ with all integer entries from 1 to 2000, with the right-hand side zero and a random normally distributed zero mean initial guess; we do the same for the PSD and PCG methods. For preconditioning on the $k$th step, applied to the residual $r_k$, we run the standard CG method without preconditioning as inner iterations, using the zero initial approximation, and for the stopping criteria we compute the norm of the true residual at every inner iteration and iterate until it gets smaller than $\eta\|r_k\|$ for a given constant $\eta$. On Figure 8.2, we demonstrate the performance of the PSD and PCG methods for four values of $\eta = 0.2, 0.4, 0.6,$ and $0.8$ (from the bottom to the top). We observe that the PSD, displayed using dashed (red in the electronic version) lines marked with circles and PCG shown as dash-dot (blue) lines with x-marks methods both converge with a similar rate, for each tested value of $\eta$. We notice here that the PSD method is even

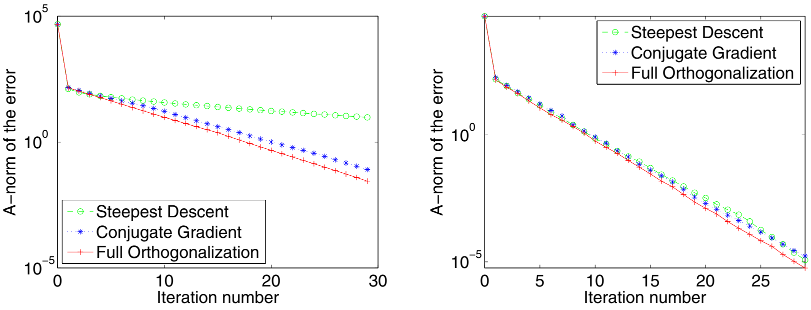

FIG. 8.3. *Two-grid preconditioning with fixed (left) and random (left) coarse grids.*

a bit faster than the PCG method. This does not contradict our Corollary 3.4, since the preconditioners $B_k$ here are evidently different in the PSD and PCG methods even though they are constructed using the same principle.

**8.3. Random vs. fixed preconditioning.** In this subsection, we numerically investigate a situation where random preconditioners of a similar quality are used in the course of iterations. The system matrix is the standard 3-point finite-difference approximation of the one-dimensional Laplacian using 3000 uniform mesh points and the Dirichlet boundary conditions. We test the simplest multigrid preconditioning using two grids, where the number of coarse grid points is 600. We set the interpolation to be linear, the restriction to be the transpose of the interpolation, the coarse-grid operator to be defined by the Galerkin condition, and the smoother to be the Richardson iteration. On Figure 8.3 (left), we once choose (pseudo-)randomly 600 coarse mesh points and build the fixed two-grid preconditioner, based on this choice. On Figure 8.3 (right), we choose 600 new random coarse mesh points and rebuild the two-grid preconditioner on each iteration. We note that in the algebraic multigrid the geometric information about the actual position of the coarse grid points is not available, so the random choice of the coarse grids may be an interesting alternative to traditional approaches.

Figure 8.3 displays the convergence history for the PSD (top), PCG (middle), and PCG with the full orthogonalization (bottom) with the same random initial guess using the fixed (left) and variable (right) two-grid preconditioners. On Figure 8.3 (left), for a fixed preconditioner, we observe the expected convergence behavior, with the PSD being noticeably the slowest and the PCG with the full orthogonalization being slightly faster than the standard PCG. Figure 8.3 (right) demonstrates that all three methods with the variable random preconditioner converge with essentially the same rate, which again illustrates the main result of the paper that the PCG method with variable preconditioning may just converge with the same speed as the PSD method.

Figure 8.3 reveals a surprising fact that the methods with random preconditioning converge twice as fast as the methods with fixed preconditioning! We highlight that Figure 8.3 shows a typical case, not a random outlier, as we confirm by repeating the fixed preconditioner test in the left panel for *every* random preconditioner used in the right panel of Figure 8.3 and by running the tests multiple times with different seeds. Our informal explanation for the fast convergence of the PSD method with random preconditioning is based on Lemma 4.1 that provides the exact expression for the error reduction factor as $\sin(\angle_A(e_k, B_k^{-1}Ae_k))$. It takes its largest value only if $e_k$ is one of specific linear combination of the eigenvectors of $B_k^{-1}Ae$ corresponding to the two extreme eigenvalues. If $B_k$ is fixed, the error $e_k$ in the PSD method after several first iterations approaches these magic linear combinations, e.g., Forsythe [5], and the convergence rate reaches its upper bound. If $B_k$ changes randomly, as in our test, the average "effective" angle is smaller, i.e., the convergence is faster.

**Conclusions.** We use geometric arguments to investigate the behavior of the PCG methods with variable preconditioning under a rather weak assumption that the quality of the preconditioner is fixed. Our main result is negative in its nature: We show that under this assumption the PCG method with variable preconditioning may converge as slow as the PSD method, moreover, as the PSD method with the slowest rate guaranteed by the classical convergence rate bound. In particular, which gives the negative answer, under our assumption, to the question asked in Golub and Ye [6, section 6, Conclusion] whether better bounds for the steepest descent reduction factor may exist for Algorithm 7.1 with (7.2).

Stronger assumptions on variable preconditioning, e.g., such as made in Golub and Ye [6] and Notay [11] that the variable preconditioners are all small perturbations of some fixed preconditioner, are necessary in order to hope to prove a convergence rate bound of the PCG method with variable preconditioning resembling the standard convergence rate bound of the PCG method with fixed preconditioning. Such stronger assumptions hold in many presently known real life applications of the PCG methods with variable preconditioning, but often require extra computational work, e.g., more inner iterations in the inner-outer iterative methods.

# PAGERANK COMPUTATION, WITH SPECIAL ATTENTION TO DANGLING NODES*

ILSE C. F. IPSEN† AND TERESA M. SELEE†

**Abstract.** We present a simple algorithm for computing the PageRank (stationary distribution) of the stochastic Google matrix $G$. The algorithm lumps all dangling nodes into a single node. We express lumping as a similarity transformation of $G$ and show that the PageRank of the nondangling nodes can be computed separately from that of the dangling nodes. The algorithm applies the power method only to the smaller lumped matrix, but the convergence rate is the same as that of the power method applied to the full matrix $G$. The efficiency of the algorithm increases as the number of dangling nodes increases. We also extend the expression for PageRank and the algorithm to more general Google matrices that have several different dangling node vectors, when it is required to distinguish among different classes of dangling nodes. We also analyze the effect of the dangling node vector on the PageRank and show that the PageRank of the dangling nodes depends strongly on that of the nondangling nodes but not vice versa. Last we present a Jordan decomposition of the Google matrix for the (theoretical) extreme case when all Web pages are dangling nodes.

## 1. Introduction.

The order in which the search engine Google displays the Web pages is determined, to a large extent, by the *PageRank* vector [7, 33]. The PageRank vector contains, for every Web page, a ranking that reflects the importance of the Web page. Mathematically, the PageRank vector $\pi$ is the stationary distribution of the so-called *Google matrix*, a sparse stochastic matrix whose dimension exceeds 11.5 billion [16]. The Google matrix $G$ is a convex combination of two stochastic matrices

$$G = \alpha S + (1-\alpha)E, \qquad 0 \leq \alpha < 1,$$

where the matrix $S$ represents the link structure of the Web, and the primary purpose of the rank-one matrix $E$ is to force uniqueness for $\pi$. In particular, element $(i, j)$ of $S$ is nonzero if Web page $i$ contains a link pointing to Web page $j$.

However, not all Web pages contain links to other pages. Image files or pdf files, and uncrawled or protected pages have no links to other pages. These pages are called *dangling nodes*, and their number may exceed the number of nondangling pages [11, section 2]. The rows in the matrix $S$ corresponding to dangling nodes would be zero if left untreated. Several ideas have been proposed to deal with the zero rows and force $S$ to be stochastic [11]. The most popular approach adds artificial links to the dangling nodes, by replacing zero rows in the matrix with the same vector, $w$, so that the matrix $S$ is stochastic.

It is natural as well as efficient to exclude the dangling nodes with their artificial links from the PageRank computation. This can be done, for instance, by

"lumping" all the dangling nodes into a single node [32]. In section 3, we provide a rigorous justification for lumping the dangling nodes in the Google matrix $G$, by expressing lumping as a similarity transformation of $G$ (Theorem 3.1). We show that the PageRank of the nondangling nodes can be computed separately from that of the dangling nodes (Theorem 3.2), and we present an efficient algorithm for computing PageRank by applying the power method only to the much smaller, lumped matrix (section 3.3). Because the dangling nodes are excluded from most of the computations, the operation count depends, to a large extent, on only the number of nondangling nodes, as opposed to the total number of Web pages. The algorithm has the same convergence rate as the power method applied to $G$, but is much faster because it operates on a much smaller matrix. The efficiency of the algorithm increases as the number of dangling nodes increases.

Many other algorithms have been proposed for computing PageRank, including classical iterative methods [1, 4, 30], Krylov subspace methods [13, 14], extrapolation methods [5, 6, 20, 26, 25], and aggregation/disaggregation methods [8, 22, 31]; see also the survey papers [2, 28] and the book [29]. Our algorithm is faster than the power method applied to the full Google matrix $G$, but retains all the advantages of the power method: It is simple to implement and requires minimal storage. Unlike Krylov subspace methods, our algorithm exhibits predictable convergence behavior and is insensitive to changes in the matrix [13]. Moreover, our algorithm should become more competitive as the Web frontier expands and the number of dangling nodes increases. The algorithms in [30, 32] are special cases of our algorithm because our algorithm allows the dangling node and personalization vectors to be different, and thereby facilitates the implementation of TrustRank [18]. TrustRank is designed to diminish the harm done by link spamming and was patented by Google in March 2005 [35]. Moreover, our algorithm can be extended to a more general Google matrix that contains several different dangling node vectors (section 3.4).

In section 4 we examine how the PageRanks of the dangling and nondangling nodes influence each other, as well as the effect of the dangling node vector $w$ on the PageRanks of dangling and nondangling nodes. In particular we show (Theorem 4.1) that the PageRanks of the dangling nodes depend strongly on the PageRanks of the nondangling nodes but not vice versa. Finally, in section 5, we consider a (theoretical) extreme case, where the Web consists solely of dangling nodes. We present a Jordan decomposition for general rank-one matrices (Theorems 5.1 and 5.2) and deduce from it a Jordan decomposition for a Google matrix of rank one (Corollary 5.3).

## 2. The ingredients.

Let $n$ be the number of Web pages and $k$ the number of nondangling nodes among the Web pages, $1 \leq k < n$. We model the link structure of the Web by the $n \times n$ matrix

$$H \equiv \begin{bmatrix} H_{11} & H_{12} \\ 0 & 0 \end{bmatrix},$$

where the $k \times k$ matrix $H_{11}$ represents the links among the nondangling nodes, and $H_{12}$ represents the links from nondangling to dangling nodes; see Figure 2.1. The $n-k$ zero rows in $H$ are associated with the *dangling nodes.*

The elements in the nonzero rows of $H$ are nonnegative and sum to one,

$$H_{11} \geq 0, \qquad H_{12} \geq 0, \qquad H_{11}e + H_{12}e = e, \qquad \text{where} \quad e \equiv \begin{bmatrix} 1 \\ \vdots \\ 1 \end{bmatrix},$$

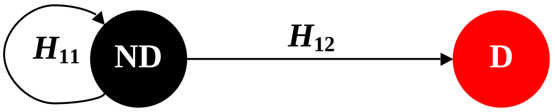

FIG. 2.1. *A simple model of the link structure of the Web. The sphere ND represents the set of nondangling nodes, and D represents the set of dangling nodes. The submatrix $H_{11}$ represents all the links from nondangling nodes to nondangling nodes, while the submatrix $H_{12}$ represents links from nondangling to dangling nodes.*

and the inequalities are to be interpreted elementwise. To obtain a stochastic matrix, we add artificial links to the dangling nodes. That is, we replace each zero row in $H$ by the same *dangling node vector*

$$w = \begin{bmatrix} w_1 \\ w_2 \end{bmatrix}, \qquad w \geq 0, \qquad \|w\| \equiv w^T e = 1.$$

Here $w_1$ is $k \times 1$, $w_2$ is $(n-k) \times 1$, $\|\cdot\|$ denotes the one norm (maximal column sum), and the superscript $T$ denotes the transpose. The resulting matrix

$$S \equiv H + dw^T = \begin{bmatrix} H_{11} & H_{12} \\ ew_1^T & ew_2^T \end{bmatrix}, \qquad \text{where} \quad d \equiv \begin{bmatrix} 0 \\ e \end{bmatrix},$$

is stochastic, that is, $S \geq 0$ and $Se = e$.

Finally, so as to work with a stochastic matrix that has a unique stationary distribution, one selects a *personalization vector*

$$v = \begin{bmatrix} v_1 \\ v_2 \end{bmatrix}, \qquad v \geq 0, \qquad \|v\| = 1,$$

where $v_1$ is $k \times 1$ and $v_2$ is $(n-k) \times 1$, and defines the Google matrix as the convex combination

$$G \equiv \alpha S + (1-\alpha) ev^T, \qquad 0 \leq \alpha < 1.$$

Although the stochastic matrix $G$ may not be primitive or irreducible, its eigenvalue 1 is distinct and the magnitude of all other eigenvalues is bounded by $\alpha$ [12, 19, 25, 26, 34]. Therefore $G$ has a unique stationary distribution,

$$\pi^T G = \pi^T, \qquad \pi \geq 0, \qquad \|\pi\| = 1.$$

The stationary distribution $\pi$ is called *PageRank*. Element $i$ of $\pi$ represents the PageRank for Web page $i$.

If we partition the PageRank conformally with $G$,

$$\pi = \begin{bmatrix} \pi_1 \\ \pi_2 \end{bmatrix},$$

then $\pi_1$ represents the PageRank associated with the nondangling nodes and $\pi_2$ represents the PageRank of the dangling nodes.

The identity matrix of order $n$ will be denoted by $I_n \equiv [e_1 \cdots e_n]$, or simply by $I$.

**3. Lumping.** We show that lumping can be viewed as a similarity transformation of the Google matrix; we derive an expression for PageRank in terms of the stationary distribution of the lumped matrix; we present an algorithm for computing PageRank that is based on lumping; and we extend everything to a Google matrix that has several different dangling node vectors, when it is required to distinguish among different classes of dangling nodes.

It was observed in [32] that the Google matrix represents a lumpable Markov chain. The concept of *lumping* was originally introduced for general Markov matrices, to speed up the computation of the stationary distribution or to obtain bounds [9, 17, 24, 27]. Below we paraphrase lumpability [27, Theorem 6.3.2] in matrix terms: Let $P$ be a permutation matrix and

$$PMP^T = \begin{bmatrix} M_{11} & \cdots & M_{1,k+1} \\ \vdots & & \vdots \\ M_{k+1,1} & \cdots & M_{k+1,k+1} \end{bmatrix}$$

be a partition of a stochastic matrix $M$. Then $M$ is *lumpable* with respect to this partition if each vector $M_{ij}e$ is a multiple of the all-ones vector $e$, $i \neq j$, $1 \leq i, j \leq k+1$.

The Google matrix $G$ is lumpable if all dangling nodes are lumped into a single node [32, Proposition 1]. We condense the notation in section 2 and write the Google matrix as

$$G = \begin{bmatrix} G_{11} & G_{12} \\ eu_1^T & eu_2^T \end{bmatrix}, \qquad \text{where} \quad u = \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} \equiv \alpha w + (1-\alpha)v, \tag{3.1}$$

$G_{11}$ is $k \times k$, and $G_{12}$ is $(n-k) \times k$. Here element $(i, j)$ of $G_{11}$ corresponds to block $M_{ij}$, $1 \leq i, j \leq k$; row $i$ of $G_{12}$ corresponds to block $M_{i,k+1}$, $1 \leq i \leq k$; column $i$ of $eu_1^T$ corresponds to $M_{k+1,i}$, $1 \leq i \leq k$; and $eu_2^T$ corresponds to $M_{k+1,k+1}$.

### 3.1. Similarity transformation.

We show that lumping the dangling nodes in the Google matrix can be accomplished by a similarity transformation that reduces $G$ to block upper triangular form.

THEOREM 3.1. *With the notation in section* 2 *and the matrix* $G$ *as partitioned in* (3.1)*, let*

$$X \equiv \begin{bmatrix} I_k & 0 \\ 0 & L \end{bmatrix}, \qquad \textit{where} \quad L \equiv I_{n-k} - \frac{1}{n-k}\hat{e}e^T \quad \textit{and} \quad \hat{e} \equiv e - e_1 = \begin{bmatrix} 0 \\ 1 \\ \vdots \\ 1 \end{bmatrix}.$$

*Then*

$$XGX^{-1} = \begin{bmatrix} G^{(1)} & * \\ 0 & 0 \end{bmatrix}, \qquad \textit{where} \quad G^{(1)} \equiv \begin{bmatrix} G_{11} & G_{12}e \\ u_1^T & u_2^T e \end{bmatrix}.$$

*The matrix* $G^{(1)}$ *is stochastic of order* $k+1$ *with the same nonzero eigenvalues as* $G$.

*Proof.* From

$$X^{-1} = \begin{bmatrix} I_k & 0 \\ 0 & L^{-1} \end{bmatrix}, \qquad L^{-1} = I_{n-k} + \hat{e}e^T,$$

it follows that

$$XGX^{-1} = \begin{bmatrix} G_{11} & G_{12}(I + \hat{e}e^T) \\ e_1 u_1^T & e_1 u_2^T (I + \hat{e}e^T) \end{bmatrix}$$

has the same eigenvalues as $G$. In order to reveal the eigenvalues, we choose a different partitioning and separate the leading $k+1$ rows and columns, and observe that

$$G_{12}(I + \hat{e}e^T)e_1 = G_{12}e, \qquad u_2^T(I + \hat{e}e^T)e_1 = u_2^T e$$

to obtain the block triangular matrix

$$XGX^{-1} = \begin{bmatrix} G^{(1)} & * \\ 0 & 0 \end{bmatrix}$$

with at least $n-k-1$ zero eigenvalues. □

**3.2. Expression for PageRank.** We give an expression for the PageRank $\pi$ in terms of the stationary distribution $\sigma$ of the small matrix $G^{(1)}$.

Theorem 3.2. *With the notation in section* 2 *and the matrix $G$ as partitioned in* (3.1)*, let*

$$\sigma^T \begin{bmatrix} G_{11} & G_{12}e \\ u_1^T & u_2^T e \end{bmatrix} = \sigma^T, \qquad \sigma \geq 0, \qquad \|\sigma\| = 1$$

*and partition $\sigma^T = \begin{bmatrix} \sigma_{1:k}^T & \sigma_{k+1} \end{bmatrix}$, where $\sigma_{k+1}$ is a scalar. Then the PageRank equals*

$$\pi^T = \begin{bmatrix} \sigma_{1:k}^T & \sigma^T \begin{pmatrix} G_{12} \\ u_2^T \end{pmatrix} \end{bmatrix}.$$

*Proof.* As in the proof of Theorem 3.1, we write

$$XGX^{-1} = \begin{bmatrix} G^{(1)} & G^{(2)} \\ 0 & 0 \end{bmatrix},$$

where

$$G^{(2)} \equiv \begin{bmatrix} G_{12} \\ u_2^T \end{bmatrix} (I + \hat{e}e^T)[e_2 \cdots e_{n-k}].$$

The vector $\begin{bmatrix} \sigma^T & \sigma^T G^{(2)} \end{bmatrix}$ is an eigenvector for $XGX^{-1}$ associated with the eigenvalue $\lambda = 1$. Hence

$$\hat{\pi} \equiv \begin{bmatrix} \sigma^T & \sigma^T G^{(2)} \end{bmatrix} X$$

is an eigenvector of $G$ associated with $\lambda = 1$ and a multiple of the stationary distribution $\pi$ of $G$. Since $G^{(1)}$ has the same nonzero eigenvalues as $G$, and the dominant eigenvalue 1 of $G$ is distinct [12, 19, 25, 26, 34], the stationary distribution $\sigma$ of $G^{(1)}$ is unique.

Next we express $\hat{\pi}$ in terms of quantities in the matrix $G$. We return to the original partitioning which separates the leading $k$ elements,

$$\hat{\pi}^T = \begin{bmatrix} \sigma_{1:k}^T & \begin{pmatrix} \sigma_{k+1} & \sigma^T G^{(2)} \end{pmatrix} \end{bmatrix} \begin{bmatrix} I_k & 0 \\ 0 & L \end{bmatrix}.$$

Multiplying out

$$\hat{\pi}^T = \begin{bmatrix} \sigma_{1:k}^T & \begin{pmatrix} \sigma_{k+1} & \sigma^T G^{(2)} \end{pmatrix} L \end{bmatrix}$$

shows that $\hat{\pi}$ has the same leading $k$ elements as $\sigma$.

We now examine the trailing $n-k$ components of $\hat{\pi}^T$. To this end we partition the matrix $L = I_{n-k} - \frac{1}{n-k}\hat{e}e$ and distinguish the first row and column,

$$L = \begin{bmatrix} 1 & 0 \\ -\frac{1}{n-k}e & I - \frac{1}{n-k}ee^T \end{bmatrix}.$$

Then the eigenvector part associated with the dangling nodes is

$$z^T \equiv \begin{bmatrix} \sigma_{k+1} & \sigma^T G^{(2)} \end{bmatrix} L = \begin{bmatrix} \sigma_{k+1} - \frac{1}{n-k}\sigma^T G^{(2)} e & \sigma^T G^{(2)} \left( I - \frac{1}{n-k}ee^T \right) \end{bmatrix}.$$

To remove the terms containing $G^{(2)}$ in $z$, we simplify

$$(I + \hat{e}e^T)[e_2 \cdots e_{n-k}]e = (I + \hat{e}e^T)\hat{e} = (n-k)\hat{e}.$$

Hence

$$G^{(2)} e = (n-k) \begin{bmatrix} G_{12} \\ u_2^T \end{bmatrix} \hat{e} \tag{3.2}$$

and

$$\begin{aligned} \frac{1}{n-k}\sigma^T G^{(2)} e &= \sigma^T \begin{bmatrix} G_{12} \\ u_2^T \end{bmatrix} \hat{e} = \sigma^T \begin{bmatrix} G_{12} \\ u_2^T \end{bmatrix} e - \sigma^T \begin{bmatrix} G_{12} \\ u_2^T \end{bmatrix} e_1 \\ &= \sigma_{k+1} - \sigma^T \begin{bmatrix} G_{12} \\ u_2^T \end{bmatrix} e_1, \end{aligned}$$

where we used $\hat{e} = e - e_1$, and the fact that $\sigma$ is the stationary distribution of $G^{(1)}$, so

$$\sigma_{k+1} = \sigma^T \begin{bmatrix} G_{12} \\ u_2^T \end{bmatrix} e.$$

Therefore the leading element of $z$ equals

$$z_1 = \sigma_{k+1} - \frac{1}{n-k}\sigma^T G^{(2)} e = \sigma^T \begin{bmatrix} G_{12} \\ u_2^T \end{bmatrix} e_1.$$

For the remaining elements of $z$, we use (3.2) to simplify

$$G^{(2)} \left( I - \frac{1}{n-k}ee^T \right) = G^{(2)} - \frac{1}{n-k}G^{(2)}ee^T = G^{(2)} - \begin{bmatrix} G_{12} \\ u_2^T \end{bmatrix} \hat{e}e^T.$$

Replacing

$$(I + \hat{e}e^T)[e_2 \cdots e_{n-k}] = [e_2 \cdots e_{n-k}] + \hat{e}e^T$$

in $G^{(2)}$ yields

$$z_{2:n-k}^T = \sigma^T G^{(2)} \left( I - \frac{1}{n-k}ee^T \right) = \sigma^T \begin{bmatrix} G_{12} \\ u_2^T \end{bmatrix} [e_2 \cdots e_{n-k}].$$

Therefore the eigenvector part associated with the dangling nodes is

$$z = \begin{bmatrix} z_1 & z_{2:n-k}^T \end{bmatrix} = \sigma^T \begin{bmatrix} G_{12} \\ u_2^T \end{bmatrix}$$

and

$$\hat{\pi} = \begin{bmatrix} \sigma_{1:k}^T & \sigma^T \begin{pmatrix} G_{12} \\ u_2^T \end{pmatrix} \end{bmatrix}.$$

Since $\pi$ is unique, as discussed in section 2, we conclude that $\hat{\pi} = \pi$ if $\hat{\pi}^T e = 1$. This follows, again, from the fact that $\sigma$ is the stationary distribution of $G^{(1)}$ and $\sigma^T \left[ \begin{smallmatrix} G_{12} \\ u_2^T \end{smallmatrix} \right] e = \sigma_{k+1}$. □

**3.3. Algorithm.** We present an algorithm, based on Theorem 3.2, for computing the PageRank $\pi$ from the stationary distribution $\sigma$ of the lumped matrix

$$G^{(1)} \equiv \begin{bmatrix} G_{11} & G_{12}e \\ u_1^T & u_2^T e \end{bmatrix}.$$

The input to the algorithm consists of the nonzero elements of the hyperlink matrix $H$, the personalization vector $v$, the dangling node vector $w$, and the amplification factor $\alpha$. The output of the algorithm is an approximation $\hat{\pi}$ to the PageRank $\pi$, which is computed from an approximation $\hat{\sigma}$ of $\sigma$.

Algorithm 3.1.

```
% Inputs: $H$, $v$, $w$, $\alpha$        Output: $\hat{\pi}$
% Power method applied to $G^{(1)}$:
Choose a starting vector $\hat{\sigma}^T = [\hat{\sigma}_{1:k}^T \quad \hat{\sigma}_{k+1}]$ with $\hat{\sigma} \geq 0$, $\|\hat{\sigma}\| = 1$.
While not converged
    $\hat{\sigma}_{1:k}^T = \alpha\hat{\sigma}_{1:k}^T H_{11} + (1-\alpha)v_1^T + \alpha\hat{\sigma}_{k+1}w_1^T$
    $\hat{\sigma}_{k+1} = 1 - \hat{\sigma}_{1:k}^T e$
end while
% Recover PageRank:
$\hat{\pi}^T = [\hat{\sigma}_{1:k}^T \quad \alpha\hat{\sigma}_{1:k}^T H_{12} + (1-\alpha)v_2^T + \alpha\hat{\sigma}_{k+1}w_2^T]$.
```

Each iteration of the power method applied to $G^{(1)}$ involves a sparse matrix vector multiply with the $k \times k$ matrix $H_{11}$ as well as several vector operations. Thus the dangling nodes are excluded from the power method computation. The convergence rate of the power method applied to $G$ is $\alpha$ [23]. Algorithm 3.1 has the same convergence rate, because $G^{(1)}$ has the same nonzero eigenvalues as $G$ (see Theorem 3.1), but is much faster because it operates on a smaller matrix whose dimension does not depend on the number of dangling nodes. The final step in Algorithm 3.1 recovers $\pi$ via a single sparse matrix vector multiply with the $k \times (n-k)$ matrix $H_{12}$, as well as several vector operations.

Algorithm 3.1 is significantly faster than the power method applied to the full Google matrix $G$, but it retains all advantages of the power method: It is simple to implement and requires minimal storage. Unlike Krylov subspace methods, Algorithm 3.1 exhibits predictable convergence behavior and is insensitive to changes in the matrix [13]. The methods in [30, 32] are special cases of Algorithm 3.1 because they allow the dangling node vector to be different from the personalization vector, thereby facilitating the implementation of TrustRank [18]. TrustRank allows zero elements in the personalization vector $v$ in order to diminish the harm done by link spamming. Algorithm 3.1 can also be extended to the situation when the Google matrix has several different dangling node vectors; see section 3.4.

The power method in Algorithm 3.1 corresponds to Stage 1 of the algorithm in [32]. However, Stage 2 of that algorithm involves the power method on a rank-two matrix of order $n - k + 1$. In contrast, Algorithm 3.1 simply performs a single matrix vector multiply with the $k \times (n-k)$ matrix $H_{12}$. There is no proof that the two-stage algorithm in [32] does compute the PageRank.

**3.4. Several dangling node vectors.** So far we have treated all dangling nodes in the same way, by assigning them the same dangling node vector $w$. However, one dangling node vector may be inadequate for an advanced Web search. For instance, one may want to distinguish different types of dangling node pages based on their functions (e.g., text files, image files, videos, etc.); or one may want to personalize a Web search and assign different vectors to dangling node pages pertaining to different topics, different languages, or different domains; see the discussion in [32, section 8.2].

To facilitate such a model for an advanced Web search, we extend the single class of dangling nodes to $m \geq 1$ different classes, by assigning a different dangling node vector $w_i$ to each class, $1 \leq i \leq m$. As a consequence we need to extend lumping to a more general Google matrix that is obtained by replacing the $n-k$ zero rows in the hyperlink matrix $H$ by $m \geq 1$ possibly different dangling node vectors $w_1, \ldots, w_m$. The more general Google matrix is

$$F \equiv \begin{array}{c} \\ k \\ k_1 \\ \vdots \\ k_m \end{array} \begin{array}{c} \begin{array}{cccc} k & k_1 & \ldots & k_m \end{array} \\ \begin{pmatrix} F_{11} & F_{12} & \cdots & F_{1,m+1} \\ eu_{11}^T & eu_{12}^T & \cdots & eu_{1,m+1}^T \\ \vdots & \vdots & & \vdots \\ eu_{m1}^T & eu_{m2}^T & \cdots & eu_{m,m+1}^T \end{pmatrix} \end{array},$$

where

$$u_i \equiv \begin{bmatrix} u_{i1} \\ \vdots \\ u_{i,m+1} \end{bmatrix} \equiv \alpha w_i + (1-\alpha)v.$$

Let $\tilde{\pi}$ be the PageRank associated with $F$,

$$\tilde{\pi}^T F = \tilde{\pi}^T, \qquad \tilde{\pi} \geq 0, \qquad \|\tilde{\pi}\| = 1.$$

We explain our approach for the case when $F$ has two types of dangling nodes,

$$F = \begin{array}{c} \\ k \\ k_1 \\ k_2 \end{array} \begin{array}{c} \begin{array}{ccc} k & k_1 & k_2 \end{array} \\ \begin{pmatrix} F_{11} & F_{12} & F_{13} \\ eu_{11}^T & eu_{12}^T & eu_{13}^T \\ eu_{21}^T & eu_{22}^T & eu_{23}^T \end{pmatrix} \end{array}.$$

We perform the lumping by a sequence of similarity transformations that starts at the bottom of the matrix. The first similarity transformation lumps the dangling nodes represented by $u_2$ and leaves the leading block of order $k + k_1$ unchanged,

$$X_1 \equiv \begin{array}{c} \\ k+k_1 \\ k_2 \end{array} \begin{array}{c} \begin{array}{cc} k+k_1 & k_2 \end{array} \\ \begin{pmatrix} I & 0 \\ 0 & L_1 \end{pmatrix} \end{array},$$

where $L_1$ lumps the $k_2$ trailing rows and columns of $F$,

$$L_1 \equiv I - \frac{1}{k_2}\hat{e}e^T, \quad L_1^{-1} \equiv I + \hat{e}e^T, \qquad \hat{e} = e - e_1 = \begin{bmatrix} 0 \\ 1 \\ \vdots \\ 1 \end{bmatrix}.$$

Applying the similarity transformation to $F$ gives

$$X_1FX_1^{-1}=\begin{array}{cc} & \begin{array}{cccc} k & k_1 & 1 & k_2-1\end{array}\\ \begin{array}{c} k\\ k_1\\ 1\\ k_2-1\end{array} & \begin{pmatrix} F_{11} & F_{12} & F_{13}e & \tilde{F}_{13}\\ eu_{11}^T & eu_{12}^T & (u_{13}^Te)e & e\tilde{u}_{13}^T\\ u_{21}^T & u_{22}^T & u_{23}^Te & \tilde{u}_{23}^T\\ 0 & 0 & 0 & 0 \end{pmatrix}\end{array}$$

with

$$\tilde{F}_{13}\equiv F_{13}L_1^{-1}\begin{bmatrix}e_2 & \cdots & e_{k_2}\end{bmatrix}, \qquad \tilde{u}_{j3}^T\equiv u_{j3}^TL_1^{-1}\begin{bmatrix}e_2 & \cdots & e_{k_2}\end{bmatrix}, \quad j=1,2.$$

The leading diagonal block of order $k+k_1+1$ is a stochastic matrix with the same nonzero eigenvalues as $F$. Before applying the second similarity transformation that lumps the dangling nodes represented by $u_1$, we move the rows with $u_1$ (and corresponding columns) to the bottom of the nonzero matrix, merely to keep the notation simple. The move is accomplished by the permutation matrix

$$P_1\equiv[e_1\cdots e_k \quad e_{k+k_1+1} \quad e_{k+1}\cdots e_{k+k_1} \quad e_{k+k_1+2}\cdots e_n].$$

The symmetrically permuted matrix

$$P_1X_1FX_1^{-1}P_1^T=\left[\begin{array}{ccc|c} F_{11} & F_{13}e & F_{12} & \tilde{F}_{13}\\ u_{21}^T & u_{23}^Te & u_{22}^T & \tilde{u}_{23}^T\\ eu_{11}^T & (u_{13}^Te)e & eu_{12}^T & e\tilde{u}_{13}^T\\ \hline 0 & 0 & 0 & 0 \end{array}\right]$$

retains a leading diagonal block that is stochastic. Now we repeat the lumping on dangling nodes represented by $u_1$, by means of the similarity transformation

$$X_2\equiv\begin{array}{cc} & \begin{array}{ccc} k+1 & k_1 & k_2-1\end{array}\\ \begin{array}{c} k+1\\ k_1\\ k_2-1\end{array} & \begin{pmatrix} I & 0 & 0\\ 0 & L_2 & 0\\ 0 & 0 & I \end{pmatrix}\end{array},$$

where $L_2$ lumps the trailing $k_1$ nonzero rows,

$$L_2\equiv I-\frac{1}{k_1}\hat{e}e^T, \qquad L_2^{-1}\equiv I+\hat{e}e^T.$$

The similarity transformation produces the lumped matrix

$$X_2P_1X_1FX_1^{-1}P_1^TX_2^{-1}=\begin{array}{cc} & \begin{array}{ccccc} k & 1 & 1 & k_1-1 & k_2-1\end{array}\\ \begin{array}{c} k\\ 1\\ 1\\ k_1-1\\ k_2-1\end{array} & \begin{pmatrix} F_{11} & F_{13}e & F_{12}e & \tilde{F}_{12} & \tilde{F}_{13}\\ u_{21}^T & u_{23}^Te & u_{22}^Te & \tilde{u}_{22}^T & \tilde{u}_{23}^T\\ u_{11}^T & u_{13}^Te & u_{12}^Te & \tilde{u}_{12}^T & \tilde{u}_{13}^T\\ 0 & 0 & 0 & 0 & 0\\ 0 & 0 & 0 & 0 & 0 \end{pmatrix}\end{array}.$$

Finally, for notational purposes, we restore the original ordering of dangling nodes by permuting rows and columns $k+1$ and $k+2$,

$$P_2\equiv[e_1\cdots e_k \quad e_{k+2} \quad e_{k+1} \quad e_{k+3}\cdots e_n].$$

The final lumped matrix is

$$P_2X_2P_1X_1FX_1^{-1}P_1^TX_2^{-1}P_2^T = \begin{bmatrix} F_{11} & F_{12}e & F_{13}e & * \\ u_{11}^T & u_{12}^Te & u_{13}^Te & * \\ u_{21}^Te & u_{22}^Te & u_{23}^Te & * \\ 0 & 0 & 0 & 0 \end{bmatrix} = \begin{bmatrix} F^{(1)} & * \\ 0 & 0 \end{bmatrix}.$$

The above discussion for $m = 2$ illustrates how to extend Theorems 3.1 and 3.2 to any number $m$ of dangling node vectors.

THEOREM 3.3. *Define* $X_i$ *as*

$$\begin{array}{ll} & \begin{array}{ccc} k+(i-1)+\sum_{j=1}^{m-i}k_j & k_{m-i+1} & 1-i+\sum_{j=m-i+2}^{m}k_j \end{array} \\ \begin{array}{l} k+(i-1)+\sum_{j=1}^{m-i}k_j \\ k_{m-i+1} \\ 1-i+\sum_{j=m-i+2}^{m}k_j \end{array} & \left(\begin{array}{ccc} I & 0 & 0 \\ 0 & L_i & 0 \\ 0 & 0 & I \end{array}\right) \end{array}$$

*and*

$$P_i \equiv [e_1 \cdots e_k \quad e_{r+i} \quad e_{k+1} \cdots e_{r+i-1} \quad e_{r+i+1} \cdots e_n], \qquad r = k + \sum_{j=1}^{m-i} k_j.$$

*Then*

$$P_mX_mP_{m-1}X_{m-1} \cdots P_1X_1FX_1^{-1}P_1^T \cdots X_m^{-1}P_m^T = \begin{bmatrix} F^{(1)} & * \\ 0 & 0 \end{bmatrix},$$

*where the lumped matrix*

$$F^{(1)} \equiv \begin{bmatrix} F_{11} & F_{12}e & \cdots & F_{1,m+1}e \\ u_{11}^T & u_{12}^Te & \cdots & u_{1,m+1}^Te \\ \vdots & \vdots & & \vdots \\ u_{m1}^T & u_{m2}^Te & \cdots & u_{m,m+1}^Te \end{bmatrix}$$

*is stochastic of order* $k+m$ *with the same nonzero eigenvalues as* $F$.

THEOREM 3.4. *Let* $\rho$ *be the stationary distribution of the lumped matrix*

$$F^{(1)} \equiv \begin{bmatrix} F_{11} & F_{12}e & \cdots & F_{1,m+1}e \\ u_{11}^T & u_{12}^Te & \cdots & u_{1,m+1}^Te \\ \vdots & \vdots & & \vdots \\ u_{m1}^T & u_{m2}^Te & \cdots & u_{m,m+1}^Te \end{bmatrix}; \tag{3.3}$$

*that is,*

$$\rho^TF^{(1)} = \rho^T, \qquad \rho \geq 0, \qquad \|\rho\| = 1.$$

*With the partition* $\rho^T = \begin{bmatrix} \rho_{1:k}^T & \rho_{k+1:k+m}^T \end{bmatrix}$, *where* $\rho_{k+1:k+m}$ *is* $m \times 1$, *the PageRank of* $F$ *equals*

$$\tilde{\pi}^T = \left[ \rho_{1:k}^T \quad \rho^T \begin{pmatrix} F_{12} & \cdots & F_{1,m+1} \\ u_{12}^T & \cdots & u_{1,m+1}^T \\ \vdots & & \vdots \\ u_{m2}^T & \cdots & u_{m,m+1}^T \end{pmatrix} \right].$$

**4. PageRanks of dangling versus nondangling nodes.** We examine how the PageRanks of dangling and nondangling nodes influence each other, as well as the effect of the dangling node vector on the PageRanks.

From Theorem 3.2 and Algorithm 3.1, we see that the PageRank $\pi_1$ of the nondangling nodes can be computed separately from the PageRank $\pi_2$ of the dangling nodes, and that $\pi_2$ depends directly on $\pi_1$. The expressions below make this even clearer.

Theorem 4.1. *With the notation in section* 2*,*

$$\begin{aligned}\pi_1^T &= \left((1-\alpha)v_1^T + \rho w_1^T\right)(I-\alpha H_{11})^{-1},\\ \pi_2^T &= \alpha\pi_1^T H_{12} + (1-\alpha)v_2^T + \alpha(1-\|\pi_1\|)w_2^T,\end{aligned}$$

*where*

$$\rho \equiv \alpha\frac{1-(1-\alpha)v_1^T(I-\alpha H_{11})^{-1}e}{1+\alpha w_1^T(I-\alpha H_{11})^{-1}e} \geq 0.$$

*Proof.* Rather than using Theorem 3.2 we found it easier just to start from scratch. From $G = \alpha(H+dw^T)+(1-\alpha)v^T$ and the fact that $\pi^T e = 1$, it follows that $\pi$ is the solution to the linear system

$$\pi^T = (1-\alpha)v^T\left(I-\alpha H-\alpha dw^T\right)^{-1},$$

whose coefficient matrix is a strictly row diagonally dominant M-matrix [1, equation (5)], [4, equation (2), Proposition 2.4]. Since $R \equiv I-\alpha H$ is also an M-matrix, it is nonsingular, and the elements of $R^{-1}$ are nonnegative [3, section 6]. The Sherman–Morrison formula [15, section 2.1.3] implies that

$$\left(R-\alpha dw^T\right)^{-1} = R^{-1} + \frac{\alpha R^{-1}dw^TR^{-1}}{1-\alpha w^TR^{-1}d}.$$

Substituting this into the expression for $\pi$ gives

$$\pi^T = (1-\alpha)v^TR^{-1} + \frac{\alpha(1-\alpha)v^TR^{-1}d}{1-\alpha w^TR^{-1}d}w^TR^{-1}. \tag{4.1}$$

We now show that the denominator $1-\alpha w^TR^{-1}d > 0$. Using the partition

$$R^{-1} = (I-\alpha H)^{-1} = \begin{bmatrix}(I-\alpha H_{11})^{-1} & \alpha(I-\alpha H_{11})^{-1}H_{12}\\ 0 & I\end{bmatrix}$$

yields

$$1-\alpha w^TR^{-1}d = 1-\alpha\left(\alpha w_1^T(I-\alpha H_{11})^{-1}H_{12}e + w_2^Te\right). \tag{4.2}$$

Rewrite the term involving $H_{12}$ by observing that $H_{11}e+H_{12}e = e$ and that $I-\alpha H_{11}$ is an M-matrix, so

$$0 \leq \alpha(I-\alpha H_{11})^{-1}H_{12}e = e-(1-\alpha)(I-\alpha H_{11})^{-1}e. \tag{4.3}$$

Substituting this into (4.2) and using $1 = w^Te = w_1^Te + w_2^Te$ shows that the denominator in the Sherman–Morrison formula is positive,

$$1-\alpha w^TR^{-1}d = (1-\alpha)\left(1+\alpha w_1^T(I-\alpha H_{11})^{-1}e\right) > 0.$$

Furthermore, $0 \le \alpha < 1$ implies $1 - \alpha w^T R^{-1} d > 1 - \alpha$.

Substituting the simplified denominator into the expression (4.1) for $\pi$ yields

$$\pi^T = (1-\alpha) v^T R^{-1} + \alpha \frac{v^T R^{-1} d}{1 + \alpha w_1^T (I - \alpha H_{11})^{-1} e} w^T R^{-1}. \tag{4.4}$$

We obtain for $\pi_1$

$$\pi_1^T = \left( (1-\alpha) v_1^T + \alpha \frac{v^T R^{-1} d}{1 + \alpha w_1^T (I - \alpha H_{11})^{-1} e} w_1^T \right) (I - \alpha H_{11})^{-1}.$$

Combining the partitioning of $R^{-1}$, (4.3), and $v_1^T e + v_2^T e = 1$ gives

$$\begin{aligned} 0 \le v^T R^{-1} d &= \begin{bmatrix} v_1^T & v_2^T \end{bmatrix} \begin{bmatrix} (I - \alpha H_{11})^{-1} & \alpha (I - \alpha H_{11})^{-1} H_{12} \\ 0 & I \end{bmatrix} \begin{bmatrix} 0 \\ e \end{bmatrix} \\ &= \alpha v_1^T (I - \alpha H_{11})^{-1} H_{12} e + v_2^T e \\ &= 1 - (1-\alpha) v_1^T (I - \alpha H_{11})^{-1} e. \end{aligned}$$

Hence $\pi_1^T = \left( (1-\alpha) v_1^T + \rho w_1^T \right) (I - \alpha H_{11})^{-1}$ with $\rho > 0$.

To obtain the expression for $\pi_2$, observe that the second block element in

$$\pi^T (I - \alpha H - \alpha d w^T) = (1-\alpha) v^T$$

equals

$$-\alpha \pi_1^T H_{12} + \pi_2^T - \alpha \pi_2^T e w_2^T = (1-\alpha) v_2^T.$$

The result follows from $\pi_1^T e + \pi_2^T e = 1$. $\square$

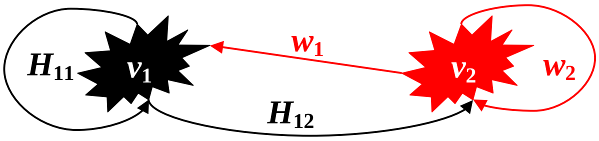

Fig. 4.1. *Sources of PageRank. Nondangling nodes receive their PageRank from $v_1$ and $w_1$, distributed through the links $H_{11}$. In contrast, the PageRank of the dangling nodes comes from $v_2$, $w_2$, and the PageRank of the nondangling nodes through the links $H_{12}$.*

*Remark* 4.1. We draw the following conclusions from Theorem 4.1 with regard to how dangling and nondangling nodes accumulate PageRank; see Figure 4.1.

- The PageRank $\pi_1$ of the nondangling nodes does *not* depend on the connectivity among the dangling nodes (elements of $w_2$), the personalization vector for the dangling nodes (elements of $v_2$), or the links from nondangling to dangling nodes (elements of $H_{12}$).
  To be specific, $\pi_1$ does not depend on individual elements of $w_2$, $v_2$, and $H_{12}$. Rather, the dependence is on the norms, through $\|v_2\| = 1 - \|v_1\|$, $\|w_2\| = 1 - \|w_1\|$, and $H_{12} e = e - H_{11} e$.
- The PageRank $\pi_1$ of the nondangling nodes does not depend on the PageRank $\pi_2$ of the dangling nodes or their number, because $\pi_1$ can be computed without knowledge of $\pi_2$.

- The nondangling nodes receive their PageRank $\pi_1$ from their personalization vector $v_1$ and the dangling node vector $w_1$, both of which are distributed through the links $H_{11}$.
- The dangling nodes receive their PageRank $\pi_2$ from three sources: the associated part $v_2$ of the personalization vector; the associated part $w_2$ of the dangling node vector; and the PageRank $\pi_1$ of the nondangling nodes filtered through the connecting links $H_{12}$.

  The links $H_{12}$ determine how much PageRank flows from nondangling to dangling nodes.
- The influence of the associated dangling node vector $w_2$ on the PageRank $\pi_2$ of the dangling nodes diminishes as the combined PageRank $\|\pi_1\|$ of the nondangling nodes increases.

Taking norms in Theorem 4.1 gives a bound on the combined PageRank of the nondangling nodes. As in section 2, the norm is $\|z\| \equiv z^T e$ for $z \geq 0$.

Corollary 4.2. *With the assumptions of Theorem* 4.1,

$$\|\pi_1\| = \frac{(1-\alpha)\|v_1\|_H + \alpha\|w_1\|_H}{1+\alpha\|w_1\|_H},$$

*where* $\|z\|_H \equiv z^T(I-\alpha H_{11})^{-1}e$ *for any* $z \geq 0$ *and*

$$(1-\alpha)\|z\| \leq \|z\|_H \leq \frac{1}{1-\alpha}\|z\|.$$

*Proof.* Since $(I-\alpha H_{11})^{-1}$ is nonsingular with nonnegative elements, $\|\cdot\|_H$ is a norm. Let $\|\cdot\|_\infty$ be the infinity norm (maximal row sum). Then the Hölder inequality [15, section 2.2.2] implies for any $z \geq 0$,

$$\|z\|_H \leq \|z\| \, \|(I-\alpha H_{11})^{-1}\|_\infty \leq \frac{1}{1-\alpha}\|z\|.$$

As for the lower bound,

$$\|z\|_H \geq \|z\| - \alpha z^T H_{11} e \geq (1-\alpha)\|z\|. \qquad \square$$

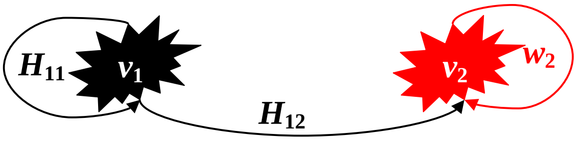

Fig. 4.2. *Sources of PageRank when* $w_1 = 0$. *The nondangling nodes receive their PageRank only from* $v_1$. *The dangling nodes, in contrast, receive their PageRank from* $v_2$ *and* $w_2$, *as well as from the PageRank of the nondangling nodes filtered through the links* $H_{12}$.

Corollary 4.2 implies that the combined PageRank $\|\pi_1\|$ of the nondangling nodes is an increasing function of $\|w_1\|$. In particular, when $w_1 = 0$, the combined PageRank $\|\pi_1\|$ is minimal among all $w$ and the dangling vector $w_2$ has a stronger influence on the PageRank $\pi_2$ of the dangling nodes. The dangling nodes act like a sink and absorb more PageRank because there are no links back to the nondangling nodes; see Figure 4.2. When $w_1 = 0$ we get

$$\begin{aligned} \pi_1^T &= (1-\alpha)v_1^T(I-\alpha H_{11})^{-1}, \\ \pi_2^T &= \alpha\pi_1^T H_{12} + (1-\alpha)v_2^T + \alpha(1-\|\pi_1\|)w_2^T. \end{aligned} \tag{4.5}$$

In the other extreme case when $w_2 = 0$, the dangling nodes are not connected to each other; see Figure 4.3:

$$\begin{aligned} \pi_1^T &= \left((1-\alpha)v_1^T + \rho w_1^T\right)(I - \alpha H_{11})^{-1}, \\ \pi_2^T &= \alpha \pi_1^T H_{12} + (1-\alpha) v_2^T. \end{aligned} \tag{4.6}$$

In this case the PageRank $\pi_1$ of the nondangling nodes has only a positive influence on the PageRank of the dangling nodes.

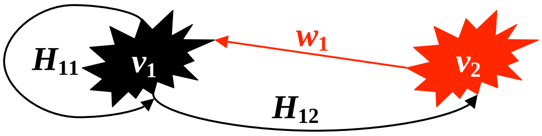

FIG. 4.3. *Sources of PageRank when $w_2 = 0$. The dangling nodes receive their PageRank only from $v_2$, and from the PageRank of the nondangling nodes filtered through the links $H_{12}$.*

An expression for $\pi$ when dangling node and personalization vectors are the same, i.e., $w = v$, was given in [10],

$$\pi^T = (1-\alpha)\left(1 + \frac{\alpha v^T R^{-1} d}{1 - \alpha v^T R^{-1} d}\right) v^T R^{-1}, \qquad \text{where} \quad R \equiv I - \alpha H.$$

In this case the PageRank vector $\pi$ is a multiple of the vector $v^T(I - \alpha H)^{-1}$.

## 5. Only dangling nodes.

We examine the (theoretical) extreme case when all Web pages are dangling nodes. In this case the matrices $S$ and $G$ have rank one. We first derive a Jordan decomposition for general matrices of rank one, before we present a Jordan form for a Google matrix of rank one.

We start with rank-one matrices that are diagonalizable. The vector $e_j$ denotes the $j$th column of the identity matrix $I$.

THEOREM 5.1 (eigenvalue decomposition). *Let $A = yz^T \neq 0$ be a real square matrix with $\lambda \equiv z^T y \neq 0$. If $z$ has an element $z_j \neq 0$, then $X^{-1}AX = \lambda\, e_j e_j^T$, where*

$$X \equiv I + y e_j^T - \frac{1}{z_j} e_j z^T, \qquad X^{-1} = I - e_j e_j^T - \frac{1}{\lambda} y z^T + \frac{1 + y_j}{\lambda} e_j z^T.$$

*Proof.* The matrix $A$ has a repeated eigenvalue zero and a distinct nonzero eigenvalue $\lambda$ with right eigenvector $y$ and left eigenvector $z$. From $\lambda y e_j^T = AX = \lambda X e_j e_j^T$ and $X^{-1}A = e_j z^T$ it follows that $X^{-1}X = I$ and $X^{-1}AX = \lambda e_j e_j^T$. □

Now we consider rank-one matrices that are not diagonalizable. In this case all eigenvalues are zero, and the matrix has a Jordan block of order two.

THEOREM 5.2 (Jordan decomposition). *Let $A = yz^T \neq 0$ be a real square matrix with $z^T y = 0$. Then $y$ and $z$ have elements $y_j z_j \neq 0 \neq y_k z_k$, $j < k$. Define a symmetric permutation matrix $P$ so that $Pe_k = e_{j+1}$ and $Pe_j = e_j$. Set $\hat{y} \equiv Py$ and $\hat{u} \equiv Pz - e_{j+1}$. Then $X^{-1}AX = e_j e_{j+1}^T$ with*

$$X \equiv P\left(I + \hat{y} e_j^T - \frac{1}{\hat{u}_j} e_j \hat{u}^T\right), \qquad X^{-1} = \left(I - e_j e_j^T + \frac{1}{\hat{y}_k} \hat{y} \hat{u}^T - \frac{1 + \hat{y}_j}{\hat{y}_k} e_j \hat{u}^T\right) P.$$

*Proof.* To satisfy $z^T y = 0$ for $y \neq 0$ and $z \neq 0$, we must have $y_j z_j \neq 0$ and $y_k z_k \neq 0$ for some $j < k$.

Since $A$ is a rank-one matrix with all eigenvalues equal to zero, it must have a Jordan block of the form $\left[\begin{smallmatrix}0&1\\0&0\end{smallmatrix}\right]$. To reveal this Jordan block, set $\hat{z} \equiv Pz$,

$$\hat{X} \equiv \left(I + \hat{y}e_j^T - \frac{1}{\hat{u}_j}e_j\hat{u}^T\right), \qquad \hat{X}^{-1} = \left(I - e_je_j^T + \frac{1}{\hat{y}_k}\hat{y}\hat{u}^T - \frac{1+\hat{y}_j}{\hat{y}_k}e_j\hat{u}^T\right).$$

Then the matrix $\hat{A} \equiv \hat{y}\hat{z}^T$ has a Jordan decomposition $\hat{X}^{-1}\hat{A}\hat{X} = e_je_{j+1}^T$. This follows from $u_j = z_j$, $\hat{y}e_{j+1}^T = \hat{A}\hat{X} = \hat{X}e_je_{j+1}^T$, and $\hat{X}^{-1}\hat{A} = e_j\hat{z}^T$.

Finally, we undo the permutation by means of $X \equiv P\hat{X}$, $X^{-1} = \hat{X}^{-1}P$, so that $X^{-1}X = I$ and $X^{-1}AX = e_je_{j+1}^T$. ☐

Theorems 5.1 and 5.2 can also be derived from [21, Theorem 1.4].

In the (theoretical) extreme case when all Web pages are dangling nodes, the Google matrix is diagonalizable of rank one.

Corollary 5.3 (rank-one Google matrix). *With the notation in section* 2 *and* (3.1), *let* $G = eu^T$. *Let* $u_j \neq 0$ *be a nonzero element of* $u$. *Then* $X^{-1}GX = e_je_j^T$ *with*

$$X = I + ee_j^T - \frac{1}{v_j}e_ju^T$$

*and*

$$X^{-1} = I - e_je_j^T - eu^T + 2e_ju^T.$$

*In particular,* $\pi^T = e_j^TX^{-1} = u^T$.

*Proof.* Since $1 = u^Te \neq 0$, the Google matrix is diagonalizable, and the expression in Theorem 5.1 applies. ☐

Corollary 5.3 can also be derived from [34, Theorems 2.1, 2.3].

# MAXIMUM ATTAINABLE ACCURACY OF INEXACT SADDLE POINT SOLVERS*

PAVEL JIRÁNEK[†] AND MIROSLAV ROZLOŽNÍK[‡]

**Abstract.** In this paper we study numerical behavior of several iterative Krylov subspace solvers applied to the solution of large-scale saddle point problems. Two main representatives of segregated solution approach are analyzed: the Schur complement reduction method based on the elimination of primary unknowns and the null-space projection method, which relies on a basis for the subspace described by the constraints. We show that the choice of the back-substitution formula may considerably influence the maximum attainable accuracy of approximate solutions computed in finite precision arithmetic.

**Key words.** saddle point problems, Schur complement reduction method, null-space projection method, rounding error analysis

**AMS subject classifications.** 65F10, 65F20, 65F35

**DOI.** 10.1137/060659727

## 1. Introduction.

We want to solve a saddle point system which is in fact the symmetric indefinite system with $2 \times 2$ block structure

$$\begin{pmatrix} A & B \\ B^T & 0 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} f \\ 0 \end{pmatrix}, \tag{1.1}$$

where the diagonal $n \times n$ block $A$ is symmetric positive definite and the $n \times m$ off-diagonal block $B$ has full column rank. Saddle point problems have recently attracted a lot of attention and appear to be a time-critical component in the solution of large-scale problems in many applications of computational science and engineering. A large amount of work has been devoted to a wide selection of solution techniques varying from the fully direct approach, through the use of iterative stationary or Krylov subspace methods, up to the combination of direct and iterative techniques including preconditioned iterative schemes. For an excellent survey on applications, methods, and results on numerical solution of saddle point problems, we refer to [5] and numerous references therein (relevant references will be given later in the text). Significantly less attention, however, has been paid so far to the numerical stability aspects. In this paper we concentrate on the numerical behavior of schemes which compute separately the unknown vectors $x$ and $y$: one of them is first obtained from a reduced system of a smaller dimension and, once it has been computed, the other unknown is obtained by back-substitution solving exactly or inexactly another reduced problem. The main representatives of such a segregated approach are the Schur

complement reduction method and the null-space projection method. In this paper we analyze such algorithms which can be interpreted as iterations for the reduced system but compute the approximate solutions $x_k$ and $y_k$ to both unknown vectors $x$ and $y$ simultaneously.

The Schur complement reduction method uses the block factorization in the form

$$\begin{pmatrix} A & B \\ B^T & 0 \end{pmatrix} = \begin{pmatrix} I & 0 \\ B^T A^{-1} & I \end{pmatrix} \begin{pmatrix} A & B \\ 0 & -B^T A^{-1} B \end{pmatrix},$$

where the matrix $-B^T A^{-1} B$ is the Schur complement of $A$ in (1.1). Such decomposition leads to solving the resulting block triangular system

$$\begin{pmatrix} A & B \\ 0 & -B^T A^{-1} B \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} f \\ -B^T A^{-1} f \end{pmatrix}, \tag{1.2}$$

which is nothing but a block Gaussian elimination applied to the original system (1.1). The block triangular system (1.2) is solved by computing the unknown $y$ from the symmetric positive definite Schur complement system of order $m$ and then by computing the unknown $x$ from a system of order $n$ with the symmetric positive definite matrix $A$. This approach leads to the explicit formula for the unknown vector $x = A^{-1}(f - By)$. The system (1.1) can be seen as two block equations and we refer to them as the "first block equation in (1.1)" and the "second block equation in (1.1)." The null-space projection method is based on the projection of the first block equation in (1.1) onto the null-space $N(B^T)$ and onto its orthogonal complement $R(B)$, respectively. According to the second block equation of (1.1) the unknown $x$ belongs to $N(B^T)$ and therefore we get the block triangular system

$$\begin{pmatrix} (I - \Pi)A(I - \Pi) & 0 \\ B^T A & B^T B \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} (I - \Pi)f \\ B^T f \end{pmatrix}, \tag{1.3}$$

where $\Pi \equiv B(B^T B)^{-1} B^T$ denotes the orthogonal projector onto $R(B)$. This triangular system is solved by back substitution, where we first compute the unknown $x$ from the projected system of order $n$ with the symmetric positive semidefinite matrix $(I - \Pi)A(I - \Pi)$. Once it has been computed, the unknown $y$ is obtained as $y = B^\dagger(f - Ax)$ by solving the least squares problem

$$\|f - Ax - By\| = \min_{v \in \mathbb{R}^m} \|f - Ax - Bv\|, \tag{1.4}$$

where $B^\dagger$ denotes the Moore–Penrose pseudoinverse of $B$. The success of algorithms for solving the block triangular system (1.2) or (1.3) depends on the availability of good approximations to the inverse of the block $A$ or to the pseudoinverse of $B$, respectively. More precisely, one looks for a cheap approximate solution to the inner systems with the matrix $A$ and/or to the associated least squares problems with the matrix $B$. Numerous inexact schemes have been used and analyzed (see, e.g., the analysis of inexact Uzawa algorithms [15, 11, 12, 4, 37], inexact null-space methods [28, 35, 36], multilevel or multigrid methods [10, 9, 36], domain decomposition methods [8], two-stage iterative processes [27, 16], and inner-outer iterations [19]). These works contain mainly the analysis of a convergence delay caused by the inexact solution of inner systems or least squares problems.

In this paper we concentrate on the question of what is the best accuracy we can get from inexact schemes solving either (1.2) or (1.3) when implemented in finite precision arithmetic. The fact that the inner solution tolerance strongly influences the accuracy of computed iterates is known and was studied in several contexts. The general framework for understanding inexact Krylov subspace methods has been developed in [31] and [33]. Assuming exact arithmetic, Simoncini and Szyld [31] and van den Eshof and Sleijpen [33] investigated the effect of an approximately computed matrix-vector product in every iteration on the ultimate accuracy of several solvers and explained the success of relaxation strategies for the inner accuracy tolerance from [7, 8, 18]. The developed theory strongly exploits the particular properties of an iterative method used for solving the associated system. In the context of saddle point problems, this requires a deep analysis of the outer iteration scheme for solving the reduced Schur complement or projected system (in particular, we refer to [31, section 8]).

The effects of rounding errors in the Schur complement reduction method and the null-space projection method have been studied, e.g., in [1, 2, 14, 26], where the maximum attainable accuracy of computed approximate solutions by means of residuals and errors is estimated depending on the user tolerance specified in the outer iteration. In this paper we analyze the influence of the inexact solution of inner systems/least squares problems on the same quantities. Our approach is based on a standard backward analysis which allows us to take into account both the inexactness of the inner iteration loops as well as the accompanying rounding errors that occur in finite precision arithmetic.

The theory developed for the outer iteration process is similar to the analysis of Greenbaum in [22, 21] who estimated the gap between the true and recursively updated residual for a general class of iterative methods using coupled two-term recursions. The difference here is that every computed approximate solution of an inner problem is interpreted as an exact solution of a perturbed problem induced by the actual stopping criterion, while the theory of [22] considered only the rounding errors associated with a fixed matrix-vector multiplication. In contrast to the theory of inexact Krylov methods [31, 33], the bounds for the true residual in the outer iteration loop are obtained without specifying the solver used for solving the Schur complement or the projected Hessian system. It appears that the maximum attainable accuracy level in the outer process is mainly given by the inexactness of solving the inner problems and it is not further magnified by the associated rounding errors. These results are thus similar to ones which can be obtained in exact arithmetic.

The situation is different when looking at the numerical behavior of residuals associated with the original saddle point system, which describe how accurately the two block equations in (1.1) are satisfied. It is shown that the attainable accuracy of computed approximate solutions then depends significantly on the back-substitution formula used for computing the remaining unknowns. Our results show that, independent of the fact that the inner systems are solved inexactly, some back-substitution schemes lead ultimately to residuals on the roundoff unit level. Indeed, our results confirm that, depending on which back-substitution formula is used, the computed iterates may satisfy either the first or the second block equation to the working accuracy. We believe that such results cannot be obtained using the exact arithmetic considerations and are of importance in applications requiring accurate approximations (see, e.g., [20, 17, 13]). On the other hand, we agree that in many applications the saddle point system comes from a discretization of certain partial differential equa-

tions and much lower accuracy is sufficient. In any case, our paper gives a theoretical explanation for the behavior which was probably observed or is already implicitly known. However, we have not found any explicit references to this issue. The implementations that we point out as optimal are actually those which are widely used and suggested in applications.

The organization of the paper is as follows. Sections 2 and 3 are devoted to the rounding error analysis of the Schur complement reduction method and the null-space projection method, respectively. Each section is divided into five subsections (see the flow-chart in Figure 1.1). In subsections 2.1 and 3.1 we analyze the influence of inexact solution of inner systems or least squares on the maximum attainable accuracy in the outer iteration process for solving (1.2) or (1.3), and we estimate the ultimate norms of the true residuals $-B^T A^{-1} f + B^T A^{-1} B \bar{y}_k$ and $(I - \Pi) f - (I - \Pi) A (I - \Pi) \bar{x}_k$. In the consequent three subsections of sections 2 and 3, we give bounds for the ultimate norm of the true residuals $f - A\bar{x}_k - B\bar{y}_k$ and $-B^T \bar{x}_k$. As we will see in subsections 2.2–2.4 and 3.2–3.4, the limiting accuracy of these residuals may significantly differ for various back-substitution formulas for computing $x_k$ or $y_k$, respectively. Subsections 2.5 and 3.5 contain forward analysis with the bounds for the errors $x - \bar{x}_k$ and $y - \bar{y}_k$. Throughout this paper our theoretical results are illustrated on the model example taken from [30]: we put $n = 100$, $m = 20$, and

$$A = \mathrm{tridiag}(1, 4, 1) \in \mathbb{R}^{n \times n}, \quad B = \mathrm{rand}(n, m), \quad f = \mathrm{rand}(n, 1).$$

The spectrum of $A$ and singular values of $B$ lie in the interval $[2.0010, 5.9990]$ and $[2.1727, 7.1695]$, respectively. Therefore the conditioning of $A$ or $B$ does not play an important role in our experiments. For further discussion, we refer to subsections 2.5 and 3.5.

For distinction, we denote quantities computed in finite precision arithmetic by bars. We assume that the usual rules of a well-designed floating-point arithmetic hold and use occasionally the notation $\mathrm{fl}(\cdot)$ for a computed result of an expression. The roundoff unit is denoted by $u$. In particular, for a matrix-vector multiplication the bound $\|\mathrm{fl}(Ax)-Ax\| \leq O(u)\|A\|\|x\|$ is used and $\|x\|$ denotes the 2-norm of the vector $x$; for a general matrix $A$ we make use of the spectral norm $\|A\|$ and the corresponding condition number $\kappa(A) = \|A\|/\sigma_{min}(A)$, where $\sigma_{min}(A)$ is the minimal singular value of $A$. For a symmetric positive definite matrix $A$, $\|x\|_A$ denotes the $A$-norm of the vector $x$. Finally, we apply the $O$-notation when suitable.

**2. Schur complement reduction method.** In this section we will discuss algorithms which compute simultaneously approximations $x_k$ and $y_k$ to the unknowns $x$ and $y$ and ideally fulfill the first block equation in (1.1)

$$Ax_k + By_k = f. \tag{2.1}$$

Our goal here is not to survey all existing schemes based on (2.1) but to analyze the numerical behavior of three implementations which use different back-substitution formulas for computing the approximate solution $x_k$. More precisely, without specifying any particular method, we assume that we have computed the approximate solution $y_{k+1}$ and the residual vector $r_{k+1}^{(y)}$ using the recursions

$$y_{k+1} = y_k + \alpha_k p_k^{(y)}, \tag{2.2}$$

$$r_{k+1}^{(y)} = r_k^{(y)} + \alpha_k B^T A^{-1} B p_k^{(y)} \tag{2.3}$$

with $r_0^{(y)} = -B^T A^{-1}(f - By_0)$. We will distinguish between the following three mathematically equivalent formulas:

$$x_{k+1} = x_k + \alpha_k(-A^{-1}Bp_k^{(y)}), \tag{2.4}$$

$$x_{k+1} = A^{-1}(f - By_{k+1}), \tag{2.5}$$

$$x_{k+1} = x_k + A^{-1}(f - Ax_k - By_{k+1}). \tag{2.6}$$

The resulting schemes are summarized in Figure 2.1. These schemes have been used and studied in the context of many applications, including various classical Uzawa algorithms, the two-level pressure correction approach, and the inner-outer iteration method for solving (1.1); see, e.g., the schemes with (2.4) in [29, 3], (2.5) in [15], or (2.6) in [11, 12, 4, 37], respectively. Because the solves with matrix $A$ in formulas (2.4)–(2.6) are expensive, these systems are in practice solved only approximately. Our analysis is based on the assumption that every solution of a symmetric positive definite system with the matrix $A$ is replaced by an approximate solution produced by an arbitrary method. The resulting vector is then interpreted as an exact solution of the system with the same right-hand side vector but with a perturbed matrix $A + \Delta A$. We always require that the relative norm of the perturbation is bounded as $\|\Delta A\| \leq \tau\|A\|$, where $\tau$ represents a backward error associated with the computed solution vector. We will always assume that the perturbation $\Delta A$ does not exceed the limitation given by the distance of $A$ to the nearest singular matrix and put restriction in the form $\tau\kappa(A) \ll 1$. It follows then from the standard perturbation analysis (see, e.g., [23, 6]) that

$$\|(A + \Delta A)^{-1} - A^{-1}\| \leq \frac{\tau\kappa(A)}{1 - \tau\kappa(A)}\|A^{-1}\|.$$

FIG. 2.1. *Schur complement reduction: Three different schemes for computing the approximate solution* $x_{k+1}$ *(called in the text the updated approximate solution* (A), *the approximate solution computed by a direct substitution* (B), *and the approximate solution computed by a corrected direct substitution* (C), *respectively).*

Note that if $\tau = O(u)$, then we have a backward stable method for solving the positive definite system with $A$. In our numerical experiments, we solve the systems with $A$ inexactly using the conjugate gradient method or with the Cholesky factorization as indicated by the notation $\tau = O(u)$.

**2.1. The attainable accuracy in the Schur complement system.** In this subsection we look at the ultimate accuracy in the outer iteration process by means of the true residual $-B^TA^{-1}f + B^TA^{-1}B\bar{y}_k$. It is clear that if we perturb the Schur complement system $-B^TA^{-1}By = -B^TA^{-1}f$ to $-B^T(A+\Delta A)^{-1}B\hat{y} = -B^TA^{-1}f$, where $\|\Delta A\| \leq \tau\|A\|$, then the residual associated with $\hat{y}$ can be bounded as

$$\| - B^TA^{-1}f + B^TA^{-1}B\hat{y}\| \leq \frac{\tau\kappa(A)}{1-\tau\kappa(A)}\|A^{-1}\|\|B\|^2\|\hat{y}\|. \tag{2.7}$$

We see from (2.7) that there is a limitation to the accuracy of the residual obtained directly from $\hat{y}$ and its bound is proportional to $\tau$. Note that these considerations were made assuming exact arithmetic. The effects of rounding errors on the same quantity have been studied by Greenbaum [22], who considered a general class of methods for solving the fixed system of linear equations using two-term recursions given by (2.2) and (2.3). Using a similar approach we can extend these results and formulate the following theorem.

THEOREM 2.1. *The gap between the true residual* $-B^TA^{-1}f + B^TA^{-1}B\bar{y}_k$ *and the updated residual* $\bar{r}_k^{(y)}$ *can be bounded as*

$$\|-B^TA^{-1}f + B^TA^{-1}B\bar{y}_k - \bar{r}_k^{(y)}\| \leq \frac{[(2k+1)\tau + O(u)]\kappa(A)}{1-\tau\kappa(A)}\|A^{-1}\|\|B\|(\|f\|+\|B\|\bar{Y}_k),$$

*where* $\bar{Y}_k$ *is defined as a maximum norm over all computed approximate solutions* $\bar{Y}_k \equiv \max_{i=0,\dots,k} \|\bar{y}_i\|$.

*Proof.* The initial residual $\bar{r}_0^{(y)}$ is computed as $\bar{r}_0^{(y)} = -\mathrm{fl}(B^T\bar{x}_0)$, where $(A + \Delta A_0)\bar{x}_0 = \mathrm{fl}(f - By_0)$, $\|\Delta A_0\| \le \tau\|A\|$. It is easy to see that the statement holds for $k = 0$. The computed approximate solution $\bar{y}_{k+1}$ and the residual $\bar{r}_{k+1}^{(y)}$ satisfy

$$\bar{y}_{k+1} = \bar{y}_k + \bar{\alpha}_k\bar{p}_k^{(y)} + \Delta y_{k+1},\ \|\Delta y_{k+1}\| \le u\|\bar{y}_k\| + (2u+u^2)\|\bar{\alpha}_k\bar{p}_k^{(y)}\|, \tag{2.8}$$

$$\bar{r}_{k+1}^{(y)} = \bar{r}_k^{(y)} - \bar{\alpha}_k B^T\bar{p}_k^{(x)} + \Delta r_{k+1}^{(y)},\ \|\Delta r_{k+1}^{(y)}\| \le u\|\bar{r}_k^{(y)}\| + O(u)\|B\|\|\bar{\alpha}_k\bar{p}_k^{(x)}\|, \tag{2.9}$$

where $\bar{p}_k^{(x)}$ is the exact solution of the perturbed system

$$(A + \Delta A_k)\bar{p}_k^{(x)} = -\mathrm{fl}(B\bar{p}_k^{(y)}),\ \|\Delta A_k\| \le \tau\|A\|. \tag{2.10}$$

Multiplying (2.8) by $B^TA^{-1}B$, substituting (2.10) into the recurrence (2.9), and subtracting these two equations we get the recurrence

$$\begin{aligned} -B^TA^{-1}f + B^TA^{-1}B\bar{y}_{k+1} - \bar{r}_{k+1}^{(y)} &= -B^TA^{-1}f + B^TA^{-1}B\bar{y}_k - \bar{r}_k^{(y)} \\ &\quad -\bar{\alpha}_k(B^T\bar{p}_k^{(x)} + B^TA^{-1}B\bar{p}_k^{(y)}) + B^TA^{-1}B\Delta y_k - \Delta r_k^{(y)}. \end{aligned}$$

The norm of the vector $\bar{\alpha}_k\bar{p}_k^{(y)}$ can be bounded as $\|\bar{\alpha}_k\bar{p}_k^{(y)}\| \le \|\bar{y}_{k+1}\| + \|\bar{y}_k\| + \|\Delta y_{k+1}\|$. This bound in combination with (2.8) gives $\|\Delta y_{k+1}\| \le O(u)\bar{Y}_{k+1}$ and $\|\bar{\alpha}_k\bar{p}_k^{(y)}\| \le 3\bar{Y}_{k+1}$ which also implies

$$\|\bar{\alpha}_k\bar{p}_k^{(x)}\| \le \frac{3\|A^{-1}\|}{1 - \tau\kappa(A)}\|B\|\bar{Y}_{k+1}. \tag{2.11}$$

Using (2.10), the bound on $\|\bar{\alpha}_k\bar{p}_k^{(y)}\|$, and some elementary manipulation, we can estimate the term $\bar{\alpha}_k(B^T\bar{p}_k^{(x)} + B^TA^{-1}B\bar{p}_k^{(y)})$

$$\begin{aligned} \|\bar{\alpha}_k(B^T\bar{p}_k^{(x)} + B^TA^{-1}B\bar{p}_k^{(y)})\| &\le \|\bar{\alpha}_k B^T[(A+\Delta A_k)^{-1} - A^{-1}]\mathrm{fl}(B\bar{p}_k^{(y)})\| \\ +\|\bar{\alpha}_k B^TA^{-1}[\mathrm{fl}(B\bar{p}_k^{(y)}) - B\bar{p}_k^{(y)}]\| &\le \frac{[\tau + O(u)]\kappa(A)}{1 - \tau\kappa(A)}\|A^{-1}\|\|B\|^2\bar{Y}_{k+1}. \end{aligned}$$

Considering (2.9), (2.11), and the induction assumption on $-B^TA^{-1}f + B^TA^{-1}B\bar{y}_k - \bar{r}_k^{(y)}$ (similar to the one used in [22]), we obtain the bound for the error vector $\Delta r_{k+1}^{(y)}$ in the form

$$\|\Delta r_{k+1}^{(y)}\| \le \frac{O(u)\kappa(A)}{1 - \tau\kappa(A)}\|A^{-1}\|\|B\|(\|f\| + \|B\|\bar{Y}_{k+1})$$

which proves the statement of the theorem. □

It is a well-known fact that the residual $\bar{r}_k^{(y)}$ computed recursively via (2.3) usually converges far below $O(u)$. Using this assumption we can obtain from the estimate for the gap $-B^TA^{-1}f + B^TA^{-1}B\bar{y}_k - \bar{r}_k^{(y)}$ the estimate for the maximum attainable accuracy of the true residual $-B^TA^{-1}f + B^TA^{-1}B\bar{y}_k$ itself. Summarizing, while the updated residual $\bar{r}_k^{(y)}$ converges to zero the true residual stagnates at the level proportional to $\tau$. This is also illustrated in our numerical example, where the Schur complement system $-B^TA^{-1}By = -B^TA^{-1}f$ is solved using the steepest descent method with the initial approximation $y_0$ set to zero. In Figure 2.2(a) we show the relative norms of the true residual $-B^TA^{-1}f + B^TA^{-1}B\bar{y}_k$ (solid lines) and the updated residual $\bar{r}_k^{(y)}$ (dashed lines).

Similar to Greenbaum [22], we have shown that the gap between the true and updated residual is proportional to the maximum norm of approximate solutions computed during the whole iteration process. Since the Schur complement system is symmetric negative definite, the norm of the error or residual converges monotonically for the most iterative methods like the steepest descent, the conjugate gradient, the conjugate residual method, or other error/residual minimizing methods or at least becomes orders of magnitude smaller than the initial error/residual without exceeding this limit. In such cases, the quantity $\bar{Y}_k$ does not play an important role in the bound, and it can usually be replaced by $\|y_0\|$ or a small multiple of $\|y\|$. The situation is more complicated when $A$ is nonsingular and nonsymmetric; see [24].

As we already noted, the main difference with respect to the analysis of Greenbaum is that the floating-point multiplication with the fixed $A^{-1}$ is replaced by the step-dependent inexact solution of the system with $A$ such that it can be interpreted as the exact application of the matrix $(A+\Delta A_k)^{-1}$, where the perturbation matrix $\Delta A_k$ changes at every step $k$. This concept is very similar to the notion of inexact Krylov subspace methods (see [31] or [33]), which, on the other hand, do not take into account the effects of rounding errors. The theory of Greenbaum [22] could be directly applied if we only have at each iteration $\|\mathrm{fl}(B^TA^{-1}Bx) - B^TA^{-1}Bx\| \le O(u)\|A^{-1}\|\|B\|^2\|x\|$. Since in our idealized case $\mathrm{fl}(B^TA^{-1}Bx) = B^T(A+\Delta A_k)^{-1}Bx$ with $\|\Delta A_k\| \le \tau\|A\|$, we have only

$$\|\mathrm{fl}(B^TA^{-1}Bx) - B^TA^{-1}Bx\| \le \frac{\tau\kappa(A)}{1-\tau\kappa(A)}\|A^{-1}\|\|B\|^2\|x\|.$$

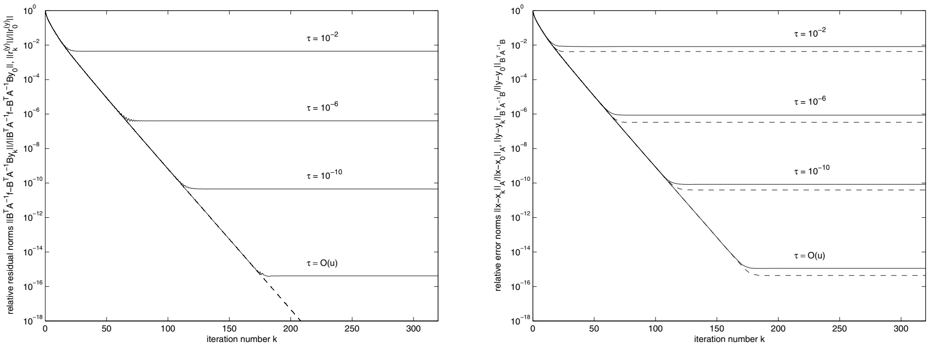
This bound could be improved if we make a restriction and use a variable tolerance for inner systems. If we require that every inner system is solved so that the relative residual of its computed solution needs the tolerance $\tau$, then every inexact application of the matrix $B^TA^{-1}B$ would satisfy the inequality

$$\|\mathrm{fl}(B^TA^{-1}Bx) - B^TA^{-1}Bx\| \le \tau\|A^{-1}\|\|B\|^2\|x\|. \tag{2.12}$$

Then the whole outer process (2.2) and (2.3) together with (2.12) could be interpreted as a floating-point iteration with the roundoff unit equal to $\tau$. The computation in this "extended" arithmetic would lead to

$$\| - B^TA^{-1}f + B^TA^{-1}B\bar{y}_k - \bar{r}_k^{(y)}\| \le \frac{O(\tau)}{1-\tau\kappa(A)}\|A^{-1}\|\|B\|^2(\|y\| + \bar{Y}_k).$$

A thorough rounding analysis of the block LU factorization has been given in [14] and further developed in the saddle point context in [26]. The approach was quite converse to the one used in our paper. It is assumed that all inner systems are solved in a backward stable way and the accuracy of computed approximate solutions is estimated in terms of the user prescribed tolerance for the outer Schur complement system. Roughly speaking, the higher tolerance $\eta$ leads to the higher level of attainable accuracy of the true residuals $f - A\bar{x}_k - B\bar{y}_k$ and $-B^T\bar{x}_k$. This level is magnified by the quantities that play a similar role as the growth factor in the Gaussian elimination with partial pivoting (see, e.g., [23]). On the other hand, the parameter $\eta$ giving the threshold for the backward error cannot be infinitely small. Theorem 2.1 actually



(a) (b)

FIG. 2.2. *Schur complement reduction method:* (a) *the relative norms of the true residual* $-B^TA^{-1}f + B^TA^{-1}\bar{y}_k$ *(solid lines) and the updated residual* $\bar{r}_k^{(y)}$ *(dashed lines)—the updated solution scheme* (2.4); (b) *the relative error norms* $\|x - \bar{x}_k\|_A/\|x - \bar{x}_0\|_A$ *(solid lines) and* $\|y - \bar{y}_k\|_{B^TA^{-1}B}/\|y - y_0\|_{B^TA^{-1}B}$ *(dashed lines)—the updated solution scheme* (2.4).

gives its lower bound. Dividing the right-hand side by $\|A^{-1}\|\|B\|^2\|\bar{y}\|$ we end up with $\eta \geq O(u)\kappa(A)/(1 - O(u)\kappa(A))$.

In the following we will estimate the residuals $f - A\bar{x}_k - B\bar{y}_k$ and $-B^T\bar{x}_k$. We will show that these quantities depend on the actual implementation of the back-substitution formula for $x_k$ and distinguish between three schemes (2.4), (2.5), and (2.6). No matter how we compute the approximations $\bar{x}_k$ and $\bar{y}_k$ it holds that

$$-B^TA^{-1}f + B^TA^{-1}B\bar{y}_k = -B^T\bar{x}_k - B^TA^{-1}(f - A\bar{x}_k - B\bar{y}_k), \tag{2.13}$$

which gives the mutual relation between the residual $-B^TA^{-1}f + B^TA^{-1}B\bar{y}_k$ in the Schur complement system and the residuals $f - A\bar{x}_k - B\bar{y}_k$ and $-B^T\bar{x}_k$ associated with the saddle point system (1.1). According to Theorem 2.1, $\|-B^TA^{-1}f + B^TA^{-1}B\bar{y}_k\|$ is ultimately $O(\tau)$. Then it is clear from (2.13) that both $f - A\bar{x}_k - B\bar{y}_k$ and $-B^T\bar{x}_k$ cannot be proportional to the roundoff unit $u$. We will show that, depending on the chosen back-substitution scheme, we can ensure either that $f - A\bar{x}_k - B\bar{y}_k = O(\tau)$ with $-B^T\bar{x}_k = O(u)$ (scheme A (2.4)), or that $f - A\bar{x}_k - B\bar{y}_k = O(u)$ with $-B^T\bar{x}_k = O(\tau)$ (scheme C (2.6)), while the most straightforward scheme B (2.5) leads to both $f - A\bar{x}_k - B\bar{y}_k = O(\tau)$ and $-B^T\bar{x}_k = O(\tau)$.

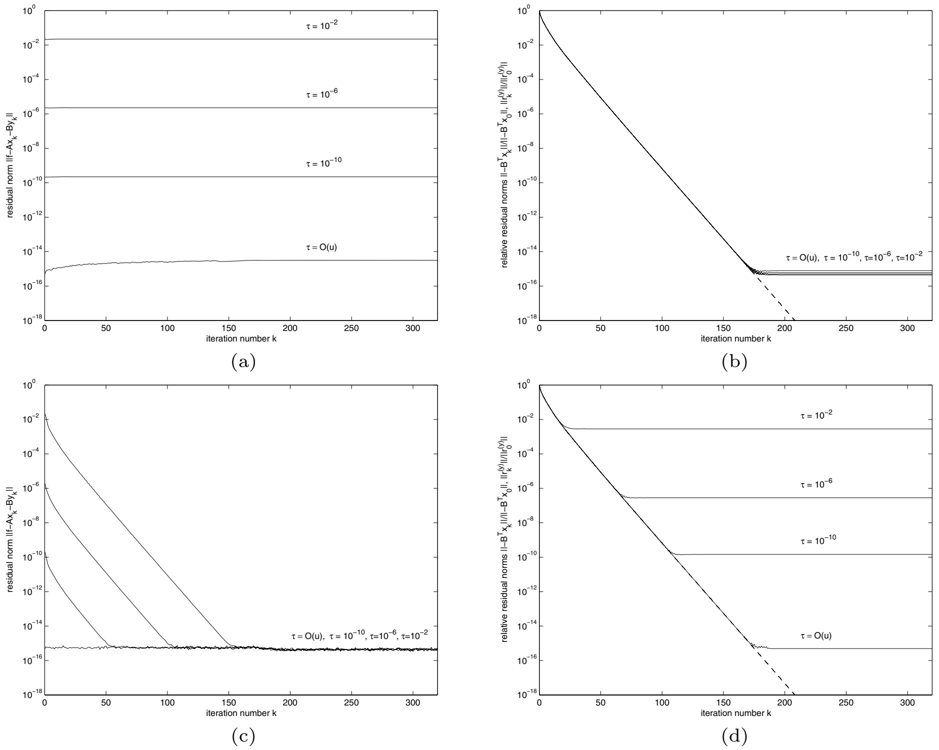
**2.2. Scheme A: The updated approximate solution.** In this subsection we analyze the generic update (2.4). It is clear that this scheme requires only one system solve with $A$ per iteration. Indeed, we compute only the direction vector $p_k^{(x)} = -A^{-1}Bp_k^{(y)}$, which appears in the recurrence $r_{k+1}^{(y)} = r_k^{(y)} - \alpha_k B^T p_k^{(x)}$ anyway. As we will see, in finite precision arithmetic this algorithm guarantees that $-B^T\bar{x}_k$ will ultimately reach $O(u)$. This happens despite the fact that the systems with the matrix block $A$ are computed inexactly with the parameter $\tau$ frequently much larger than $O(u)$.

THEOREM 2.2. *The true residual* $f - A\bar{x}_k - B\bar{y}_k$ *satisfies the bound*

$$\|f - A\bar{x}_k - B\bar{y}_k\| \leq O(u)(\|f\| + \|B\|\bar{Y}_k) + [(k+1)\tau + O(u)]\|A\|\bar{X}_k. \tag{2.14}$$

*The gap between the residuals* $-B^T\bar{x}_k$ *and* $\bar{r}_k^{(y)}$ *can be estimated as*

$$\|-B^T\bar{x}_k - \bar{r}_k^{(y)}\| \leq O(u)\|A^{-1}\|\|B\|(\|f\| + \|A\|\bar{X}_k + \|B\|\bar{Y}_k),$$



(a) (b)

(c) (d)

FIG. 2.3. *Schur complement reduction method:* (a) *the norms of the true residual* $f - A\bar{x}_k - B\bar{y}_k$ *and* (b) *the relative norms of the true residual* $-B^T\bar{x}_k$ *(solid lines) and the recursively computed residual* $\bar{r}_k^{(y)}$ *(dashed lines)—the updated solution scheme* (2.4); (c) *the norms of the true residual* $f - A\bar{x}_k - B\bar{y}_k$*—the corrected direct substitution scheme* (2.6); (d) *the relative norms of the true residual* $-B^T\bar{x}_k$ *(solid lines) and the recursively computed residual* $\bar{r}_k^{(y)}$ *(dashed lines)—the direct substitution scheme* (2.5).

*where* $\bar{X}_k$ *is now defined as a maximum norm over all computed approximate solutions* $\bar{X}_k \equiv \max_{i=0,\dots,k} \|\bar{x}_i\|$.

*Proof.* The computed approximate solution $\bar{x}_{k+1}$ satisfies

$$\bar{x}_{k+1} = \bar{x}_k + \bar{\alpha}_k \bar{p}_k^{(x)} + \Delta x_{k+1}, \ \|\Delta x_{k+1}\| \le u\|\bar{x}_k\| + (2u+u^2)\|\bar{\alpha}_k \bar{p}_k^{(x)}\|. \tag{2.15}$$

Substituting recurrently (2.15) and (2.8) into the residual

$$f - A\bar{x}_{k+1} - B\bar{y}_{k+1} = f - A\bar{x}_k - B\bar{y}_k - \bar{\alpha}_k(A\bar{p}_k^{(x)} + B\bar{p}_k^{(y)}) - A\Delta x_{k+1} - B\Delta y_{k+1},$$

we obtain the following bound:

$$\begin{aligned}\|f - A\bar{x}_k - B\bar{y}_k\| &\le \|f - A\bar{x}_0 - By_0\| \\ &+ \sum_{i=0}^{k-1} \left( \|\bar{\alpha}_i(A\bar{p}_i^{(x)} + B\bar{p}_i^{(y)})\| + \|A\|\|\Delta x_{i+1}\| + \|B\|\|\Delta y_{i+1}\| \right).\end{aligned}$$

Here we, in fact, reformulate the main result of Greenbaum [22, Theorem 2.2] and heavily use the fact that the vectors $\bar{p}_k^{(x)}$ satisfy the perturbed system (2.10). From Theorem 2.1 we have bounds $\|\Delta y_{k+1}\| \le O(u)\bar{Y}_{k+1}$ and $\|\bar{\alpha}_k \bar{p}_k^{(y)}\| \le 3\bar{Y}_{k+1}$ which also imply the bound (2.11). Using all of these results we get

$$\|\bar{\alpha}_k(A\bar{p}_k^{(x)} + B\bar{p}_k^{(y)})\| \le \|\bar{\alpha}_k[\mathrm{fl}(B\bar{p}_k^{(y)}) - B\bar{p}_k^{(y)}]\| + \|\Delta A_k\|\|\bar{\alpha}_k\bar{p}_k^{(x)}\|.$$

Further we use $\|\Delta x_{k+1}\| \le O(u)\bar{X}_{k+1}$ and $\|\bar{\alpha}_k\bar{p}_k^{(x)}\| \le 3\bar{X}_{k+1}$. Summarizing, we get the first result. The gap between $-B^T\bar{x}_{k+1}$ and $\bar{r}_{k+1}^{(y)}$ is equal to

$$-B^T\bar{x}_{k+1} - \bar{r}_{k+1}^{(y)} = -B^T\bar{x}_k - \bar{r}_k^{(y)} - B^T\Delta x_{k+1} - \Delta r_{k+1}^{(y)}$$

and it leads to the expansion containing just the local errors $\Delta x_{i+1}$, $\Delta y_{i+1}$ and the initial gap $-B^T\bar{x}_0 - \bar{r}_0^{(y)}$

$$-B^T\bar{x}_k - \bar{r}_k^{(y)} = -B^T\bar{x}_0 - \bar{r}_0^{(y)} - \sum_{i=0}^{k-1} B^T\Delta x_{i+1} - \sum_{i=0}^{k-1} \Delta r_{k+1}^{(y)}.$$

Taking norms, considering the bounds on $\|\Delta x_{k+1}\|$, $\|\Delta y_{k+1}\|$, (2.9), and the relation $\bar{r}_0^{(y)} = -\mathrm{fl}(B^T\bar{x}_0)$, we get the second result. □

As we will see in the next subsection, the bound for the gap $-B^T\bar{x}_k - \bar{r}_k^{(y)}$ is considerably better than for the scheme (2.5). In contrast to (2.18), it does not depend on $\tau$. Provided that $\bar{r}_k^{(y)}$ converges to zero, the true residual $-B^T\bar{x}_k$ will stagnate at the level proportional to $u$ and the second block equation in (1.1) will be satisfied to working accuracy.

Figures 2.3(a), (b) show the norms of the true residual $f - A\bar{x}_k - B\bar{y}_k$ and $-B^T\bar{x}_k$ (solid lines), respectively, including the norms of the updated residual $\bar{r}_k^{(y)}$ (dashed lines). The numerical results are in good agreement with Theorem 2.2. The residual $f - A\bar{x}_k - B\bar{y}_k$ is growing slightly due to the accumulation of errors in inner systems $Ap_k^{(x)} = -Bp_k^{(y)}$ but it essentially remains on the level proportional to $\tau$. The residual $-B^T\bar{x}_k$ ultimately stagnates at $O(u)$. The formula (2.4) is suitable whenever the second block equation in (1.1) must be satisfied accurately, no matter how small or big the inner tolerance $\tau$ is.

### 2.3. Scheme B: The approximate solution computed by a direct substitution.

In this subsection we assume that $x_k$ is computed by the direct substitution (2.5). The computed $\bar{x}_k$ then satisfies the equality

$$(A + \Delta A_k)\bar{x}_k = \mathrm{fl}(f - B\bar{y}_k), \ \|\Delta A_k\| \le \tau\|A\|. \tag{2.16}$$

The perturbation matrices $\Delta A_k$ are different from those defined in subsection 2.1, but for simplicity we will keep the same notation. In the following we will show that the residual $\bar{r}_k^{(y)}$ is a good approximation for the residual $-B^T\bar{x}_k$, provided that they are above the level given by the bound for $-B^T\bar{x}_k - \bar{r}_k^{(y)}$. This quantity is now, however, proportional to $\tau$.

Theorem 2.3. *The true residual $f - A\bar{x}_k - B\bar{y}_k$ satisfies the bound*

$$\|f - A\bar{x}_k - B\bar{y}_k\| \le O(u)(\|f\| + \|B\|\|\bar{y}_k\|) + \tau\|A\|\|\bar{x}_k\|. \tag{2.17}$$

*The gap between the residuals $-B^T\bar{x}_k$ and $\bar{r}_k^{(y)}$ can be bounded as follows:*

$$\begin{aligned} \| - B^T\bar{x}_k - \bar{r}_k^{(y)}\| &\le O(u)\|A^{-1}\|\|B\|(\|f\| + \|B\|\bar{Y}_k) \\ &\quad + [(k+3)\tau + O(u)]\kappa(A)\|B\|\bar{X}_k, \end{aligned} \tag{2.18}$$

*where* $\bar{X}_k$ *is defined as* $\bar{X}_k \equiv \max_{i=0,\dots,k-1}\{\|\bar{x}_0\|, \|\bar{x}_k\|, \|\bar{\alpha}_i\bar{p}_i^{(x)}\|\}$.

*Proof.* The first result follows from (2.16) and the relation for the true residual

$$f - A\bar{x}_k - B\bar{y}_k = f - B\bar{y}_k - \mathrm{fl}(f - B\bar{y}_k) - \Delta A_k\bar{x}_k.$$

For the gap between $-B^T\bar{x}_k$ and $\bar{r}_k^{(y)}$ we have the identity

$$\begin{aligned}-B^T\bar{x}_k - \bar{r}_k^{(y)} = {}& -B^TA^{-1}f + B^TA^{-1}B\bar{y}_k - \bar{r}_k^{(y)} + B^TA^{-1}\Delta A_k\bar{x}_k\\ &+ B^TA^{-1}[\mathrm{fl}(f - B\bar{y}_k) - (f - B\bar{y}_k)].\end{aligned} \tag{2.19}$$

The statement of Theorem 2.1 together with (2.19) gives the second result (2.18). ☐

Indeed, while the residual $\bar{r}_k^{(y)}$ converges ultimately below $O(u)$, the residual $-B^T\bar{x}_k$ will remain proportional to $\tau$. The norm of $f - A\bar{x}_k - B\bar{y}_k$ is unconditionally bounded by the term proportional to $\tau$ dominating other terms in (2.17).

Figure 2.3(d) shows the norms of $-B^T\bar{x}_k$ (solid lines) and $\bar{r}_k^{(y)}$ (dashed lines). The residual $f - A\bar{x}_k - B\bar{y}_k$ behaves similarly to that of the scheme (2.4) shown in plot (a). The residual $f - A\bar{x}_k - B\bar{y}_k$ remains almost constant since it is nothing but the residual of the system $Ax_k = f - By_k$ solved in each iteration with the uniform accuracy.

### 2.4. Scheme C: The approximate solution computed with a corrected direct substitution.

The third back-substitution formula (2.6) can be derived by a correction of the scheme (2.5) and requires two system solves with $A$. In this subsection we show that its numerical behavior is very similar to the behavior of classical nonstationary iterative methods described and analyzed by Higham [23]. We prove that under certain conditions the true residual $f - A\bar{x}_k - B\bar{y}_k$ ultimately converges to the level proportional to $u$, which is significantly smaller than those residuals for the previous two schemes.

THEOREM 2.4. *Assume for sufficiently large* $k$ *with* $\|\bar{y}_{k+1} - \bar{y}_k\| \le O(u)\bar{Y}_{k+1}$ *that there exists a step* $k_0$ *such that the true residual* $f - A\bar{x}_k - B\bar{y}_k$ *is bounded by*

$$\|f - A\bar{x}_k - B\bar{y}_k\| \le O(u)(\|f\| + \|A\|\bar{X}_k + \|B\|\bar{Y}_k) \tag{2.20}$$

*for all steps* $k \ge k_0$. *The gap between* $-B^T\bar{x}_k$ *and* $\bar{r}_k^{(y)}$ *can be estimated as follows*:

$$\|-B^T\bar{x}_k - \bar{r}_k^{(y)}\| \le O(u)\|A^{-1}\|\|B\|(\|f\| + \|B\|\bar{Y}_k) + [(k+3)\tau + O(u)]\kappa(A)\|B\|\bar{X}_k.$$

*The quantity* $\bar{X}_k$ *is here defined as* $\bar{X}_k \equiv \max_{i=0,\dots,k-1}\{\|\bar{x}_0\|, \|\bar{x}_k\|, \|\bar{\alpha}_i\bar{p}_i^{(x)}\|\}$.

*Proof.* The computed approximate solution $\bar{x}_{k+1}$ satisfies

$$\bar{x}_{k+1} = \bar{x}_k + \bar{u}_k + \Delta x_{k+1}, \quad \|\Delta x_{k+1}\| \le u(\|\bar{x}_k\| + \|\bar{u}_k\|), \tag{2.21}$$

where the vector $\bar{u}_k$ is the exact solution of the system

$$(A + \Delta A_{k+1})\bar{u}_k = \mathrm{fl}(f - A\bar{x}_k - B\bar{y}_{k+1}), \quad \|\Delta A_{k+1}\| \le \tau\|A\|. \tag{2.22}$$

The residual $f - A\bar{x}_{k+1} - B\bar{y}_{k+1}$ can be expressed using (2.21) and (2.22) as

$$\begin{aligned}f - A\bar{x}_{k+1} - B\bar{y}_{k+1} &= \Delta A_{k+1}\bar{u}_k - A\Delta x_{k+1}\\ &\quad + \mathrm{fl}(f - A\bar{x}_k - B\bar{y}_{k+1}) - (f - A\bar{x}_k - B\bar{y}_{k+1})\\ &= G_{k+1}(f - A\bar{x}_k - B\bar{y}_k) - G_{k+1}B(\bar{\alpha}_k\bar{p}_k^{(y)}) + h_{k+1},\end{aligned} \tag{2.23}$$

where the matrix $G_{k+1}$ and the vector $h_{k+1}$ are defined as $G_{k+1} \equiv \Delta A_{k+1}(A + \Delta A_{k+1})^{-1}$ and $h_{k+1} \equiv (I + G_{k+1})[\mathrm{fl}(f - A\bar{x}_k - B\bar{y}_{k+1}) - (f - A\bar{x}_k - B\bar{y}_{k+1})] - A\Delta x_{k+1} - G_{k+1}B\Delta y_{k+1}$. From a recursive use of the formula (2.23) we obtain

$$f - A\bar{x}_k - B\bar{y}_k = G_k \cdots G_1(f - A\bar{x}_0 - By_0) - \sum_{i=0}^{k-1} G_k \cdots G_{i+2}(G_{i+1}B\bar{\alpha}_i\bar{p}_i^{(y)} - h_{i+1}).$$

Taking norms, using the relation $\|\bar{\alpha}_i\bar{p}_i^{(y)}\| \le \|\bar{y}_{i+1} - \bar{y}_i\| + \|\Delta y_{i+1}\|$ and $\|\Delta A_i\| \le \tau\|A\|$ we obtain the uniform bound $\|G_i\| \le \tau\kappa(A)[1 - \tau\kappa(A)]^{-1} < 1$. This leads to the inequality

$$\begin{aligned}\text{(2.24)}\qquad \|f - A\bar{x}_k - B\bar{y}_k\| \le{}& \left(\frac{\tau\kappa(A)}{1 - \tau\kappa(A)}\right)^k \|f - A\bar{x}_0 - By_0\| \\ &+ \sum_{i=0}^{k-1}\left(\frac{\tau\kappa(A)}{1 - \tau\kappa(A)}\right)^{k-i} \|B\|\|\bar{y}_{i+1} - \bar{y}_i\| \\ &+ k \max_{i=0,\ldots,k-1} \|h_{i+1}\| + k \max_{i=0,\ldots,k-1} \|B\|\|\Delta y_{i+1}\|.\end{aligned}$$

For the vector $h_{k+1}$ it further follows that

$$\|h_{k+1}\| \le O(u)[\|f\| + \|A\|(\|\bar{x}_{k+1}\| + \|\bar{x}_k\|) + \|B\|\bar{Y}_{k+1}].$$

It is easy to see that for sufficiently large $k$ the first term on the right-hand side of (2.24) will decrease far below $O(u)$, while the second term will be at most $O(u)\|B\|\bar{Y}_{k+1}$ for all steps $k$ starting from some index $k_0$. Summarizing, for sufficiently large $k \ge k_0$ we have the bound

$$\|f - A\bar{x}_k - B\bar{y}_k\| \le O(u)[\|f\| + \|A\|(\|\bar{x}_{k+1}\| + \|\bar{x}_k\|) + \|B\|\bar{Y}_k].$$

The second statement can be proved considering

$$\begin{aligned}-B^T\bar{x}_{k+1} - \bar{r}_{k+1}^{(y)} ={}& -B^TA^{-1}f + B^TA^{-1}B\bar{y}_{k+1} - \bar{r}_{k+1}^{(y)} \\ &- B^T[(A + \Delta A_{k+1})^{-1} - A^{-1}]\mathrm{fl}(f - A\bar{x}_k - B\bar{y}_{k+1}) \\ &- B^TA^{-1}[\mathrm{fl}(f - A\bar{x}_k - B\bar{y}_{k+1}) - (f - A\bar{x}_k - B\bar{y}_{k+1})].\end{aligned}$$

The first term on the right-hand side can be estimated using Theorem 2.1. Based on (2.22) we have

$$\|[(A + \Delta A_{k+1})^{-1} - A^{-1}]\mathrm{fl}(f - A\bar{x}_k - B\bar{y}_{k+1})\| \le \frac{\tau\kappa(A)}{1 - \tau\kappa(A)}\|\bar{u}_k\|,$$

which together with the bound on $\|\bar{u}_k\|$ completes the proof. □

In Theorem 2.4 we assume that $\bar{y}_k$ ultimately stagnates so that $\|\bar{y}_{k+1} - \bar{y}_k\| \le O(u)\bar{Y}_{k+1}$ for sufficiently large $k \ge k_0$. It appears that this condition does not represent a serious restriction. Using (2.8) we have $\|\bar{y}_{k+1} - \bar{y}_k\| \le \|\bar{\alpha}_k\bar{p}_k^{(y)}\| + O(u)\bar{Y}_{k+1}$. We will show that the norm of $\bar{\alpha}_k\bar{p}_k^{(y)}$ is much smaller than $u$ for large $k$, i.e., we can absorb it into the term $O(u)\bar{Y}_{k+1}$. Denoting $\hat{S}_k \equiv B^T(A + \Delta A_k)^{-1}B$, using (2.9) and (2.10) we have the bound

$$\|\bar{\alpha}_k\bar{p}_k^{(y)}\| \le 2\|\hat{S}_k^{-1}\|(\|\bar{r}_{k+1}^{(y)}\| + \|\bar{r}_k^{(y)}\|) + O(u)\|\hat{S}_k^{-1}\|\|(A + \Delta A_k)^{-1}\|\|B\|^2\|\bar{\alpha}_k\bar{p}_k^{(y)}\|.$$

Provided that $O(u)\|\hat{S}_k^{-1}\|\|(A+\Delta A_k)^{-1}\|\|B\|^2 < 1$, we obtain

$$\|\bar{\alpha}_k \bar{p}_k^{(y)}\| \leq \frac{2\|\hat{S}_k^{-1}\|(\|\bar{r}_{k+1}^{(y)}\| + \|\bar{r}_k^{(y)}\|)}{1 - O(u)\|\hat{S}_k^{-1}\|\|(A+\Delta A_k)^{-1}\|\|B\|^2}.$$

Since the norms of updated residuals decrease far below the roundoff unit, the assumption on $\|\bar{y}_{k+1} - \bar{y}_k\|$ will be true for sufficiently large $k$. Note that $O(u)\|\hat{S}_k^{-1}\|\|(A+\Delta A_k)^{-1}\|\|B\|^2 < 1$ is nothing but the restricted assumption of numerical nonsingularity of the Schur complement matrix $B^T A^{-1} B$.

The bound (2.20) is significantly better than its counterparts (2.14) and (2.17). Theorem 2.4 describes that the residual $f - A\bar{x}_k - B\bar{y}_k$ will ultimately reach the roundoff unit level provided that the matrix $G_k G_{k-1} \cdots G_1$ converges to zero for $k \to \infty$. As soon as iterates $\bar{y}_k$ start to stagnate at their limiting accuracy level, the rate of convergence of this nonstationary iteration process is bounded by the factor $\tau\kappa(A)[1-\tau\kappa(A)]^{-1}$. The behavior of $-B^T\bar{x}_k$ is similar to that of scheme (2.5). Indeed, when $\bar{r}_k^{(y)}$ converges ultimately below $O(u)$, the residual $-B^T\bar{x}_k$ remains proportional to $\tau$. Figure 2.3(c) shows the norms of the residual $f - A\bar{x}_k - B\bar{y}_k$. The plot for $-B^T\bar{x}_k$ (not reported) is similar to the plot (d) for the scheme (2.5). It is clear that in our well-conditioned case the stationary method converges very fast and the rate of decrease of $f - A\bar{x}_k - B\bar{y}_k$ is essentially comparable to the convergence rate of the outer iteration.

**2.5. Forward error analysis.** In this subsection we estimate the maximum attainable accuracy in terms of the errors $x - \bar{x}_k$ and $y - \bar{y}_k$. First we formulate the bounds in the 2-norm, then in the $A$-norm of the error $x - \bar{x}_k$, and then in the $B^T A^{-1} B$-norm of the error $y - \bar{y}_k$. The errors $x - \bar{x}_k$ and $y - \bar{y}_k$, and the residuals $f - A\bar{x}_k - B\bar{y}_k$ and $-B^T\bar{x}_k$, satisfy

$$\begin{pmatrix} A & B \\ B^T & 0 \end{pmatrix} \begin{pmatrix} x - \bar{x}_k \\ y - \bar{y}_k \end{pmatrix} = \begin{pmatrix} f - A\bar{x}_k - B\bar{y}_k \\ -B^T\bar{x}_k \end{pmatrix}. \tag{2.25}$$

We have the explicit expression for the inverse of the saddle point matrix

$$\begin{pmatrix} A & B \\ B^T & 0 \end{pmatrix}^{-1} = \begin{pmatrix} (I-\Pi)A^{-1} & -\Pi B(B^T B)^{-1} \\ -(B^T B)^{-1} B^T \Pi^T & -(B^T A^{-1} B)^{-1} \end{pmatrix},$$

where $\Pi \equiv A^{-1}B(B^T A^{-1} B)^{-1} B^T$ represents the oblique projector onto a range of $R(B)$ along $N(B^T)$. Considering (2.25), the inequalities $\|(I-\Pi)A^{-1}\| \leq \|A^{-1}\|$, and $\|A^{-1}B(B^T A^{-1}B)^{-1}\| = \|\Pi B(B^T B)^{-1}\| \leq \|(B^T B)^{-1}\|^{1/2}$ we obtain the bounds

$$\|x - \bar{x}_k\| \leq \gamma_1 \|f - A\bar{x}_k - B\bar{y}_k\| + \gamma_2 \| - B^T\bar{x}_k\|, \tag{2.26}$$

$$\|y - \bar{y}_k\| \leq \gamma_2 \|f - A\bar{x}_k - B\bar{y}_k\| + \gamma_3 \| - B^T\bar{x}_k\|, \tag{2.27}$$

where $\gamma_1 \equiv \sigma_{min}^{-1}(A)$, $\gamma_2 \equiv \sigma_{min}^{-1}(B)$, and $\gamma_3 \equiv \sigma_{min}^{-1}(B^T A^{-1} B)$ are constants independent of the iteration step $k$. It is clear from (2.26), (2.27) and Theorems 2.2, 2.3, and 2.4 that $\|x - \bar{x}_k\|$ and $\|y - \bar{y}_k\|$ will be $O(\tau)$ for all back-substitution schemes. In contrast to our numerical example, the saddle point systems that arise in practice can be ill-conditioned. In such cases the constants $\gamma_1$, $\gamma_2$, and $\gamma_3$ may play an important role.

In exact arithmetic we have $\|x-x_k\|_A = \|y-y_k\|_{B^TA^{-1}B}$. Since in finite precision arithmetic the residual $f - A\bar{x}_k - B\bar{y}_k$ is no longer zero, instead of this identity we get

$$\big|\|x-\bar{x}_k\|_A - \|y-\bar{y}_k\|_{B^TA^{-1}B}\big| \le \gamma_1^{1/2}\|f - A\bar{x}_k - B\bar{y}_k\|. \tag{2.28}$$

We can also formulate the proposition, which gives bounds for the errors in terms of the residuals $f - A\bar{x}_k - B\bar{y}_k$ and $-B^TA^{-1}f + B^TA^{-1}B\bar{y}_k$.

Theorem 2.5. *The $A$-norm of the error $x-\bar{x}_k$ and the $B^TA^{-1}B$-norm of the error $y-\bar{y}_k$ can be bounded as*

$$\|x-\bar{x}_k\|_A \le \gamma_1^{1/2}\|f - A\bar{x}_k - B\bar{y}_k\| + \gamma_3^{1/2}\|-B^TA^{-1}f + B^TA^{-1}B\bar{y}_k\|, \tag{2.29}$$

$$\|y-\bar{y}_k\|_{B^TA^{-1}B} \le \gamma_3^{1/2}\|-B^TA^{-1}f + B^TA^{-1}B\bar{y}_k\|. \tag{2.30}$$

*Proof.* It follows from (2.28) that

$$\begin{aligned} \|x-\bar{x}_k\|_A &\le \|y-\bar{y}_k\|_{B^TA^{-1}B} + \big|\|x-\bar{x}_k\|_A - \|y-\bar{y}_k\|_{B^TA^{-1}B}\big| \\ &\le \|y-\bar{y}_k\|_{B^TA^{-1}B} + \sigma_{min}^{-1/2}(A)\|f - A\bar{x}_k - B\bar{y}_k\|. \end{aligned} \tag{2.31}$$

For the $B^TA^{-1}B$-norm of the error $y-\bar{y}_k$ we have

$$\|y-\bar{y}_k\|_{B^TA^{-1}B} = \|B^TA^{-1}f - B^TA^{-1}B\bar{y}_k\|_{(B^TA^{-1}B)^{-1}}, \tag{2.32}$$

which completes the proof. □

The first term on the right-hand side of (2.29) should be zero in exact arithmetic and it describes how well the computed $\bar{x}_k$ and $\bar{y}_k$ satisfy (2.1). The second term is related to the Schur complement residual which in exact arithmetic should converge to zero. The recursively computed residual $\bar{r}_k^{(y)}$ is a good approximation to $-B^TA^{-1}f + B^TA^{-1}B\bar{y}_k$, provided they are above the level given by Theorem 2.1. Therefore its norm represents an easily computable quantity for the second term on the right-hand side of (2.29). The residual $f - A\bar{x}_k - B\bar{y}_k$ depends on the computed $\bar{x}_k$ and we distinguish between three schemes with (2.4), (2.5), and (2.6), respectively. We can see that, no matter which implementation we use, $-B^TA^{-1}f + B^TA^{-1}B\bar{y}_k$ is a dominating quantity in (2.29). Therefore, $\|x-\bar{x}_k\|_A$ can be thus well approximated during the convergence by the quantity $\gamma_3^{1/2}\|\bar{r}_k^{(y)}\|$ or its estimate. Similar can be said also for $\|y-\bar{y}_k\|_{B^TA^{-1}B}$; see (2.30).

The errors $x-\bar{x}_k$ and $y-\bar{y}_k$ can be estimated with more sophisticated but easily computable bounds (without explicit use of residuals and conditioning). As an example we refer to the rounding error analysis of the conjugate gradient method and various mathematically equivalent formulas for estimating $\|x-\bar{x}_k\|_A$ [32]. It appears that although many existing bounds were developed using exact arithmetic considerations, they estimate successfully the energy error using computed quantities which can be orders of magnitude different from their exact precision counterparts. Therefore, despite that we assume that $A^{-1}$ is performed inexactly, it is feasible to estimate the $B^TA^{-1}B$-norm of the error $y-\bar{y}_k$.

In Figure 2.2(b) we report the relative error norms $\|x-\bar{x}_k\|_A/\|x-\bar{x}_0\|_A$ and $\|y-\bar{y}_k\|_{B^TA^{-1}B}/\|y-y_0\|_{B^TA^{-1}B}$. The inverse of $A$ in the computation of the $B^TA^{-1}B$-norm is computed by a direct solver. In agreement with (2.29) and (2.30) and Theorems 2.2, 2.3, and 2.4 (see also Figure 2.3), the relative $A$-norm of the error $x-\bar{x}_k$ and also the relative $B^TA^{-1}B$-norm of the error $y-\bar{y}_k$ begin to stagnate at the level proportional to $\tau$. Since the behavior of these quantities for all implementations is similar, we present only the results for the scheme (2.5). The slight difference is visible only in the gap between both error norms given by the estimate (2.28).

## 3. Null-space projection method.

In this section we deal with algorithms which compute approximations $x_k$ and $y_k$ such that $x_k$ satisfies $B^T x_k = 0$ and $y_k$ solves the least squares problem minimizing the residual $f - Ax_k - By_k$, i.e.,

$$\|f - Ax_k - By_k\| = \min_{v \in \mathbb{R}^m} \|f - Ax_k - Bv\|. \tag{3.1}$$

We will denote (3.1) by $By_k \approx f - Ax_k$ and assume that the approximate solution $x_{k+1}$ and the residual vector $r_{k+1}^{(x)}$ are computed using

$$x_{k+1} = x_k + \alpha_k p_k^{(x)}, \tag{3.2}$$

$$r_{k+1}^{(x)} = r_k^{(x)} - \alpha_k A p_k^{(x)} - B p_k^{(y)}, \tag{3.3}$$

where $r_0^{(x)} = B^\dagger (f - Ax_0)$. The vectors $x_0$ and $p_k^{(x)}$ belong to $N(B^T)$ and $p_k^{(y)}$ solves the problem $Bp_k^{(y)} \approx r_k^{(x)} - \alpha_k A p_k^{(x)}$ minimizing the residual

$$\|r_k^{(x)} - \alpha_k A p_k^{(x)} - B p_k^{(y)}\| = \min_{p \in \mathbb{R}^m} \|r_k^{(x)} - \alpha_k A p_k^{(x)} - Bp\|.$$

This residual update strategy was proposed in [20] (see also [10, 9]) and is used to reduce the roundoff errors in the projection onto $N(B^T)$. Note that the vectors $p_k^{(y)}$ can be, with no additional cost, used as direction vectors for computing the approximate solution $y_{k+1}$. Again we will distinguish between three back-substitution formulas (the resulting schemes are described in Figure 3.1)

$$y_{k+1} = y_k + p_k^{(y)}, \; p_k^{(y)} = B^\dagger (r_k^{(x)} - \alpha_k A p_k^{(x)}), \tag{3.4}$$

$$y_{k+1} = B^\dagger (f - Ax_{k+1}), \tag{3.5}$$

$$y_{k+1} = y_k + B^\dagger (f - Ax_{k+1} - By_k). \tag{3.6}$$

The pseudoinverse $B^\dagger$ in (3.4)–(3.6) is applied by solving the least squares with the matrix $B$. These problems are solved inexactly. In our considerations we will assume that the computed solution $\bar{v}$ of the least squares problem $Bv \approx c$ is an exact solution of a perturbed problem $(B + \Delta B)\bar{v} \approx c + \Delta c$ with $\|\Delta B\|/\|B\| \leq \tau$ and $\|\Delta c\|/\|c\| \leq \tau$. The parameter $\tau$ again represents the measure for the inexact solution of the least squares with $B$ and actually describes the backward error. This can be achieved in many different ways considering the inner iteration loop solving the associated system of normal equations, the augmented system formulation, or solving it directly. Similar inexact schemes have been considered for solving quadratic programming problems [1, 2], multigrid methods [9, 10], or constraint preconditioners [25, 30, 28]. We assume $\tau\kappa(B) \ll 1$ which guarantees $B + \Delta B$ to have a full column rank. This allows the use of the perturbation theory (see [34] or [23, Lemma 19.8]), in particular the inequalities

$$\|(B + \Delta B)^\dagger\| \leq \frac{\|B^\dagger\|}{1 - \tau\kappa(B)}, \quad \|BB^\dagger - B(B + \Delta B)^\dagger\| \leq \frac{2\tau\kappa(B)}{1 - \tau\kappa(B)}.$$

Note that if $\tau = O(u)$, then we have a backward stable method for solving the least squares problem with $B$. In our experiments we applied the conjugate gradient least squares (CGLS) method [6] with the stopping criterion based on the corresponding backward error. Notation $\tau = O(u)$ stands for the Householder QR factorization.

FIG. 3.1. *Null-space projection method: Three different schemes for computing the approximate solution* $y_{k+1}$ *(called in the text the updated approximate solution* (A), *the approximate solution computed by a direct substitution* (B), *and the approximate solution computed by a corrected direct substitution* (C), *respectively).*

**3.1. The attainable accuracy in the projected system.** In this subsection we look at the accuracy in the outer iteration for solving the projected system $(I - \Pi)A(I - \Pi)x = (I - \Pi)f$. We can consider the perturbed system

$$(I - \hat{\Pi})A(I - \hat{\Pi})\hat{x} = (I - \hat{\Pi})f, \tag{3.7}$$

where $\hat{\Pi} = (B + \Delta B)(B + \Delta B)^\dagger$ such that $\|\Delta B\| \leq \tau \|B\|$. The residual associated with the solution of (3.7) can be written as

$$(I - \Pi)f - (I - \Pi)A(I - \Pi)\hat{x} = (\hat{\Pi} - \Pi)f + (I - \hat{\Pi})A(\Pi - \hat{\Pi})\hat{x} + (\Pi - \hat{\Pi})A(I - \Pi)\hat{x}$$

and due to $\|\hat{\Pi} - \Pi\| \leq \|\Delta B\| \min\{\|B^\dagger\|, \|(B + \Delta B)^\dagger\|\}$ [23, Lemma 19.8], we have

$$\|(I - \Pi)f - (I - \Pi)A(I - \Pi)\hat{x}\| \leq \frac{2\tau\kappa(B)}{1 - \tau\kappa(B)}(\|f\| + \|A\|\|\hat{x}\|).$$

Indeed, even if we assume exact arithmetic, the residual obtained directly from $\hat{x}$ is proportional to the parameter $\tau$. In addition, we ideally have $(B + \Delta B)^T\hat{x} = 0$ which implies $\|-B^T\hat{x}\| \leq \tau\|B\|\|\hat{x}\|$. Therefore we can expect that also the residual $-B^T\bar{x}_k$ associated with the computed approximate solution $\bar{x}_k$ will be proportional to $\tau$. Such analysis is dependent on the choice of a particular method with the recurrences (3.2) and (3.3), and therefore we do not give it here. In accordance with [22] it seems reasonable that the bound for $-B^T\bar{x}_k$ is proportional to the factor $\bar{X}_k$. Moreover, the error in the projection of an arbitrary vector is represented in the bounds by $\tau\kappa(B)/[1 - \tau\kappa(B)]$. Therefore $-B^T\bar{x}_k$ and $\Pi\bar{x}_k$ can be expected to have the form

$$\|-B^T\bar{x}_k\| \leq \frac{O(\tau)\|B\|}{1 - \tau\kappa(B)}\bar{X}_k, \quad \|\Pi\bar{x}_k\| \leq \frac{O(\tau)\kappa(B)}{1 - \tau\kappa(B)}\bar{X}_k. \tag{3.8}$$

Theorem 3.1 shows that the true residual $(I-\Pi)f-(I-\Pi)A(I-\Pi)\bar{x}_k$ is ultimately proportional to $\tau$, while its projection onto $N(B^T)$ will finally reach the level $O(u)$ provided that the updated residual $\bar{r}_k^{(x)}$ converges far below that level.

THEOREM 3.1. *The gap between the true residual* $(I-\Pi)f-(I-\Pi)A(I-\Pi)\bar{x}_k$ *and the projection of the updated residual* $(I-\Pi)\bar{r}_k^{(x)}$ *can be bounded by*

$$\|(I-\Pi)f-(I-\Pi)A(I-\Pi)\bar{x}_k-(I-\Pi)\bar{r}_k^{(x)}\| \le \frac{O(\tau)\kappa(B)}{1-\tau\kappa(B)}(\|f\|+\|A\|\bar{X}_k),$$

*where* $\bar{X}_k \equiv \max_{i=0,\dots,k}\|\bar{x}_i\|$.

*Proof.* The computed approximation $\bar{x}_{k+1}$ satisfies the relations

$$\bar{x}_{k+1}=\bar{x}_k+\bar{\alpha}_k\bar{p}_k^{(x)}+\Delta x_{k+1},\ \|\Delta x_{k+1}\|\le u\|\bar{x}_k\|+(2u+u^2)\|\bar{\alpha}_k\bar{p}_k^{(x)}\|. \tag{3.9}$$

The inequality $\|\bar{\alpha}_k\bar{p}_k^{(x)}\|\le\|\bar{x}_{k+1}\|+\|\bar{x}_k\|+\|\Delta x_{k+1}\|$ gives $\|\bar{\alpha}_k\bar{p}_k^{(x)}\|\le 3\bar{X}_{k+1}$ and $\|\Delta x_{k+1}\|\le O(u)\bar{X}_{k+1}$. The vectors $\bar{y}_0$ and $\bar{p}_k^{(y)}$ satisfy $(B+\Delta B_0)\bar{y}_0\approx \mathrm{fl}(f-Ax_0)+\Delta c_0$ with $\|\Delta B_0\|\le\tau\|B\|$, $\|\Delta c_0\|\le\tau\|\mathrm{fl}(f-Ax_0)\|$, and

$$(B+\Delta B_k)\bar{p}_k^{(y)}\approx \mathrm{fl}(\bar{r}_k^{(x)}-\bar{\alpha}_kA\bar{p}_k^{(x)})+\Delta c_k, \tag{3.10}$$

$$\|\Delta B_k\|\le\tau\|B\|,\ \|\Delta c_k\|\le\tau\|\mathrm{fl}(\bar{r}_k^{(x)}-\bar{\alpha}_kA\bar{p}_k^{(x)})\|. \tag{3.11}$$

For updated residuals we have $\bar{r}_0^{(x)}=\mathrm{fl}(f-Ax_0-B\bar{y}_0)$ and

$$\bar{r}_{k+1}^{(x)}=\bar{r}_k^{(x)}-\bar{\alpha}_kA\bar{p}_k^{(x)}-B\bar{p}_k^{(y)}+\Delta r_{k+1}^{(x)}, \tag{3.12}$$

$$\|\Delta r_{k+1}^{(x)}\|\le O(u)(\|\bar{r}_k^{(x)}\|+\|A\|\|\bar{\alpha}_k\bar{p}_k^{(x)}\|+\|B\|\|\bar{p}_k^{(y)}\|). \tag{3.13}$$

The recursive use of (3.9) and (3.12) leads to the expression for the gap between the projections of $f-A\bar{x}_k$ and $\bar{r}_k^{(x)}$

$$(I-\Pi)(f-A\bar{x}_k-\bar{r}_k^{(x)})=(I-\Pi)(f-A\bar{x}_0-\bar{r}_0^{(x)})-\sum_{i=0}^{k-1}(I-\Pi)(A\Delta x_{i+1}+\Delta r_{i+1}^{(x)}).$$

Taking norms and corresponding bounds we get the following after some manipulation:

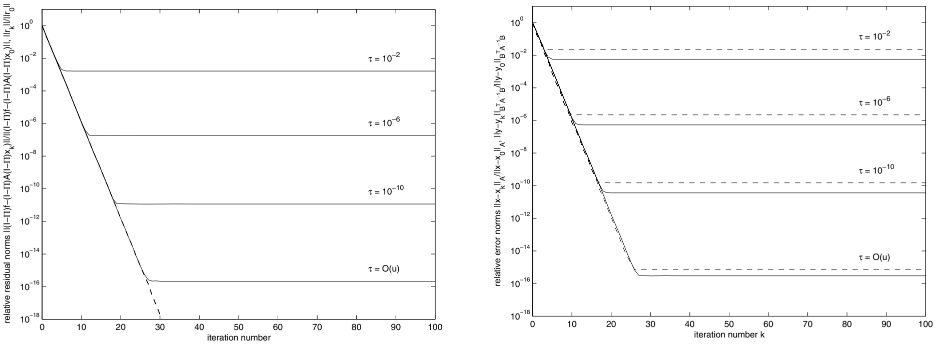
$$\|(I-\Pi)(f-A\bar{x}_k-\bar{r}_k^{(x)})\|\le\frac{O(u)\kappa(B)}{1-\tau\kappa(B)}\left(\|f\|+\|A\|\bar{X}_k\right). \tag{3.14}$$

Here we have used that $\|\bar{r}_k^{(x)}\|\le\|\bar{r}_0^{(x)}\|$ for $k=0,1,\dots$ which seems reasonable when solving the positive semidefinite problem. For the gap between $(I-\Pi)f-(I-\Pi)A(I-\Pi)\bar{x}_k$ and $(I-\Pi)\bar{r}_k^{(x)}$, we can write

$$\|(I-\Pi)f-(I-\Pi)A(I-\Pi)\bar{x}_k-(I-\Pi)\bar{r}_k^{(x)}\|\le\|(I-\Pi)(f-A\bar{x}_k-\bar{r}_k^{(x)})\|+\|(I-\Pi)A\Pi\bar{x}_k\|.$$

Considering (3.14) and (3.8) we can conclude the proof. □

In Figure 3.2(a) we report the relative norms of the true residual $(I-\Pi)f-(I-\Pi)A(I-\Pi)\bar{x}_k$ (solid lines) and the updated residual $\bar{r}_k^{(x)}$ (dashed lines). The numerical results confirm that the residual $f-A\bar{x}_k$ is within $N(B^T)$ approximated by $\bar{r}_k^{(x)}$ to the working precision $u$. However, this is not true for the residual $(I-\Pi)f-(I-\Pi)A(I-\Pi)\bar{x}_k$ which is ultimately $O(\tau)$ as it follows from Theorem 3.1.



(a) (b)

FIG. 3.2. *Null-space projection method:* (a) *the relative norms of the true residual* $(I-\Pi)f-(I-\Pi)A(I-\Pi)\bar{x}_k$ *of the projected system (solid lines) and the updated residual* $\bar{r}_k^{(x)}$ *(dashed lines)—the updated solution scheme* (3.4); *the relative norms of the errors* $\|x-\bar{x}_k\|_A/\|x-x_0\|_A$ *(solid lines) and* $\|y-\bar{y}_k\|_{B^TA^{-1}B}/\|y-\bar{y}_0\|_{B^TA^{-1}B}$ *(dashed lines)—the updated solution scheme* (3.4).

The residual $-B^T\bar{x}_k$ obviously does not depend on the back-substitution scheme; see Figure 3.3(d).

In contrast to the Schur complement reduction method, the inexactness is connected with the matrix $B$ instead of $A$. In practice, the sequential application of the matrix $(I-\Pi)A(I-\Pi)$ does not represent a symmetric operator. This is also reflected in the fact that we assume a general framework for computing the vector $x_k$ and analyze another projection of residuals $f-A\bar{x}_k-B\bar{y}_k$ and $\bar{r}_k^{(x)}$. Ideally at every iteration step we apply the matrix-vector product with the matrix $(I-\hat{\Pi})A(I-\hat{\Pi})$, where $\hat{\Pi}$ represents the orthogonal projector $\hat{\Pi}=(B+\Delta B)(B+\Delta B)^\dagger$ with $\|\Delta B\|\leq\tau\|B\|$. A question similar to one in subsection 2.1 arises as to whether we can apply the results of [22] directly to the system $(I-\hat{\Pi})A(I-\hat{\Pi})\hat{x}=(I-\hat{\Pi})f$. Theorem 3.1 shows that in finite precision arithmetic the residual $(I-\Pi)f-(I-\Pi)A(I-\Pi)\bar{x}_k$ will remain proportional to the parameter $\tau$. The theory of Greenbaum can be directly applied only if the multiplication by $(I-\Pi)A(I-\Pi)$ satisfies $\|\mathrm{fl}[(I-\Pi)A(I-\Pi)x]-(I-\Pi)A(I-\Pi)x\|\leq O(u)\|(I-\Pi)A(I-\Pi)\|\|x\|$ which is obviously not the case here. In the idealized case we have $\mathrm{fl}[(I-\Pi)A(I-\Pi)x]=(I-\hat{\Pi})A(I-\hat{\Pi})x$ and hence

$$\|\mathrm{fl}[(I-\Pi)A(I-\Pi)x]-(I-\Pi)A(I-\Pi)x\|\leq\frac{O(\tau)\kappa(B)}{1-\tau\kappa(B)}\|A\|\|x\|.$$

If we could improve this bound to satisfy $\|\mathrm{fl}[(I-\Pi)A(I-\Pi)x]-(I-\Pi)A(I-\Pi)x\|\leq\tau\|A\|\|x\|$, the outer iteration process could be viewed as an iteration in finite precision arithmetic with the roundoff unit equal to $\tau$ and the theory of Greenbaum would lead to the estimate

$$\|(I-\Pi)f-(I-\Pi)A(I-\Pi)\bar{x}_k-\bar{r}_k^{(x)}\|\leq\frac{O(\tau)}{1-\tau\kappa(B)}\|A\|(\|x\|+\bar{X}_k).$$

The numerical behavior of the null-space projection method was studied also in [1, 2], where the inner least squares are solved by the QR or LU factorization with $\tau=O(u)$ and the projected system is solved inexactly with the parameter $\eta$. Our Theorem 3.1 thus gives an answer to the question of how small the parameter $\eta$ can be in the outer iteration. Roughly speaking, when using the error or residual minimizing

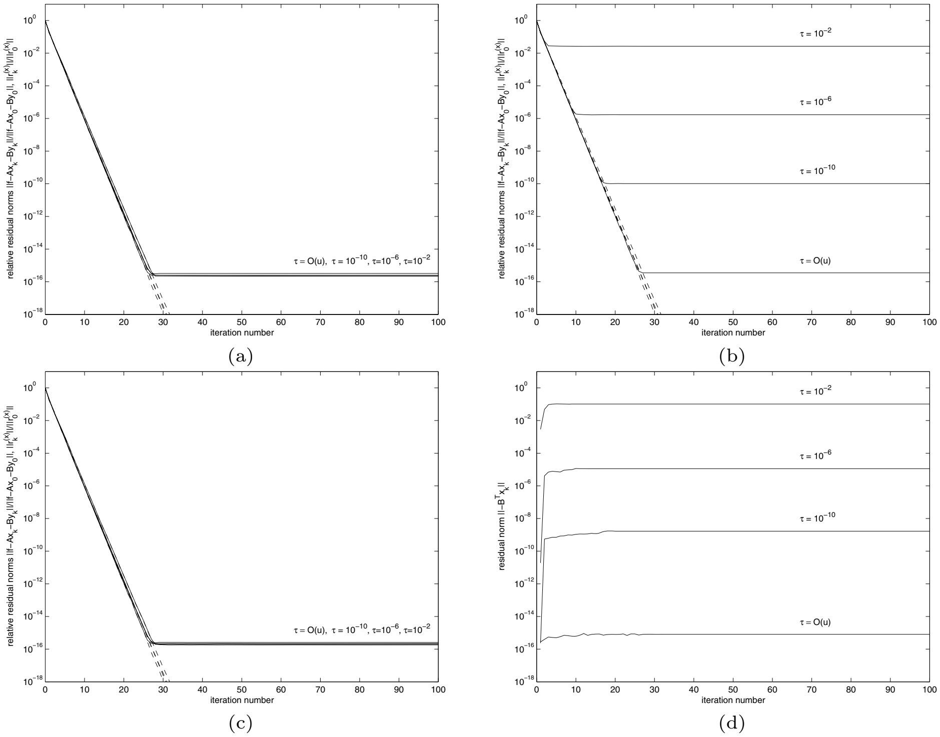


FIG. 3.3. *Null-space projection method: The relative norms of the true residual* $f - A\bar{x}_k - B\bar{y}_k$ *and the updated residual* $\bar{r}_k^{(x)}$ *(plots* (a), (b), *and* (c) *for the updated solution scheme* (3.4), *the direct substitution scheme* (3.5), *and the corrected direct substitution scheme* (3.6), *respectively);* (d) *the norms of the residual* $-B^T\bar{x}_k$*—the updated solution scheme* (3.4).

method for solving the projected Hessian system the backward error associated with the iterate $\bar{x}_k$ cannot be smaller than $O(u)\kappa(B)/[1 - O(u)\kappa(B)]$.

It is clear that no matter how we compute $\bar{x}_k$ and $\bar{y}_k$ we have the following relation between $(I - \Pi)f - (I - \Pi)A(I - \Pi)\bar{x}_k$, $f - A\bar{x}_k - B\bar{y}_k$, and $-B^T\bar{x}_k$:

$$(I - \Pi)f - (I - \Pi)A(I - \Pi)\bar{x}_k = (I - \Pi)(f - A\bar{x}_k - B\bar{y}_k) + (I - \Pi)A\Pi\bar{x}_k. \tag{3.15}$$

Owing to (3.8), $\Pi\bar{x}_k$ (and thus also $-B^T\bar{x}_k$) is $O(\tau)$. From Theorem 3.1 we have that $\|(I - \Pi)f - (I - \Pi)A(I - \Pi)\bar{x}_k\|$ is ultimately $O(\tau)$. Since $(I - \Pi)(f - A\bar{x}_k) = (I - \Pi)(f - A\bar{x}_k - B\bar{y}_k)$ for any $\bar{y}_k$ it also follows from Theorem 3.1 that the projection of $f - A\bar{x}_k - B\bar{y}_k$ onto $N(B^T)$ will ultimately reach $O(u)$. It is not clear from (3.15) whether the whole residual $f - A\bar{x}_k - B\bar{y}_k$ will be ultimately $O(\tau)$ or $O(u)$. It strongly depends on the back-substitution scheme used for computing the approximate solutions $y_{k+1}$. The following subsections show that the residual $f - A\bar{x}_k - B\bar{y}_k$ for the schemes with (3.4) (scheme A) and with (3.6) (scheme C) will finally reach $O(u)$, while the scheme B using (3.5) leads to the accuracy that is proportional only to $\tau$.

### 3.2. Scheme A: The updated approximate solution.

In this subsection we analyze the generic scheme with the update (3.4). This implementation does not require any additional solution of a least squares problem with the matrix $B$. Indeed, the computed direction vector $p_k^{(y)}$ is used to update both the iterate $y_k$ and the residual $\bar{r}_k^{(x)}$. As we will see, this algorithm computes the residual $f - A\bar{x}_k - B\bar{y}_k$

which will ultimately reach the level of roundoff unit $u$ independently of the fact that the inner least squares are solved with the accuracy determined by the parameter $\tau$.

THEOREM 3.2. *The gap between the residuals* $f - A\bar{x}_k - B\bar{y}_k$ *and* $\bar{r}_k^{(x)}$ *can be bounded as follows*:

$$\|f - A\bar{x}_k - B\bar{y}_k - \bar{r}_k^{(x)}\| \leq O(u)(\|f\| + \|A\|\bar{X}_k + \|B\|\bar{Y}_k),$$

*where* $\bar{Y}_k \equiv \max_{i=0,\dots,k} \|\bar{y}_i\|$. *The statement of the theorem remains true if we replace* $\bar{Y}_k$ *by* $\max\{\|y_0\|, \|p_i^{(y)}\|,\ i = 0, 1, \dots, k-1\}$.

*Proof.* The vector $\bar{x}_{k+1}$ satisfies (3.9) with $\|\Delta x_{k+1}\| \leq O(u)\bar{X}_{k+1}$, and similarly for $\bar{y}_{k+1}$ we have

$$\bar{y}_{k+1} = \bar{y}_k + \bar{p}_k^{(y)} + \Delta y_{k+1},\ \|\Delta y_{k+1}\| \leq u\|\bar{y}_k\| + (2u + u^2)\|\bar{p}_k^{(y)}\|$$

with $\|\Delta y_{k+1}\| \leq O(u)\bar{Y}_{k+1}$. The residual $\bar{r}_{k+1}^{(x)}$ satisfies (3.12) and thus $\|\Delta r_{k+1}^{(x)}\| \leq O(u)(\|\bar{r}_k^{(x)}\| + \|A\|\bar{X}_{k+1} + \|B\|\bar{Y}_{k+1})$. Using the above relations we obtain the recursive formula

$$f - A\bar{x}_{k+1} - B\bar{y}_{k+1} - \bar{r}_{k+1}^{(x)} = f - A\bar{x}_k - B\bar{y}_k - \bar{r}_k^{(x)} - A\Delta x_{k+1} - B\Delta y_{k+1} - \Delta r_{k+1}^{(x)}.$$

Taking the norms we get the following after some manipulation:

$$\|f - A\bar{x}_k - B\bar{y}_k - \bar{r}_k^{(x)}\| \leq O(u)\left(\|f\| + \|A\|\bar{X}_k + \|B\|\bar{Y}_k + \sum_{i=0}^{k-1}\|\bar{r}_i^{(x)}\|\right).$$

The statement can now be proved by induction on $k$. □

We have shown that $\bar{r}_k^{(x)}$ is a good approximation to $f - A\bar{x}_k - B\bar{y}_k$ independent of the fact that $\bar{p}_k^{(y)}$ are computed inexactly. Note that Theorem 3.1 can be derived using Theorem 3.2 due to $\|(I - \Pi)(f - A\bar{x}_k - \bar{r}_k^{(x)})\| = \|(I - \Pi)(f - A\bar{x}_k - B\bar{y}_k - \bar{r}_k^{(x)})\| \leq \|f - A\bar{x}_k - B\bar{y}_k - \bar{r}_k^{(x)}\|$. In Figure 3.3(a) we show the relative norms of $f - A\bar{x}_k - B\bar{y}_k$ (solid lines) and $\bar{r}_k^{(x)}$ (dashed lines). The results of our numerical experiment are in a good agreement with Theorem 3.2.

### 3.3. Scheme B: The approximate solution computed by a direct substitution.

In this subsection we analyze the scheme (3.5), which uses the directly computed right-hand side vector $f - Ax_k$. The computed $\bar{y}_k$ is then a solution of the perturbed problem

$$(B + \Delta B_k)\bar{y}_k \approx \mathrm{fl}(f - A\bar{x}_k) + \Delta c_k \tag{3.16}$$

with $\|\Delta B_k\| \leq \tau\|B\|$ and $\|\Delta c_k\| \leq \tau\|\mathrm{fl}(f - A\bar{x}_k)\|$. We will show that $(I - \Pi)\bar{r}_k^{(x)}$ is a good approximation of $f - A\bar{x}_k - B\bar{y}_k$ provided that both are above their level of maximum attainable accuracy.

THEOREM 3.3. *The gap between the residuals* $f - A\bar{x}_k - B\bar{y}_k$ *and* $(I - \Pi)\bar{r}_k^{(x)}$ *can be bounded by*

$$\begin{aligned}\|f - A\bar{x}_k - B\bar{y}_k - (I - \Pi)\bar{r}_k^{(x)}\| \leq{}& \tfrac{5\tau\kappa(B)}{1-\tau\kappa(B)}(\|f\| + \|A\|\|\bar{x}_k\|)\\ &+ O(u)(\|f\| + \|A\|\bar{X}_k + \|B\|\bar{Y}_k).\end{aligned}$$

*Proof.* Considering (3.16) it follows for the true residual that

$$\begin{aligned} f - A\bar{x}_k - B\bar{y}_k &= f - A\bar{x}_k - B(B+\Delta B_k)^\dagger[\mathrm{fl}(f - A\bar{x}_k) + \Delta c_k] \\ &= (I-\Pi)(f - A\bar{x}_k) + B[B^\dagger - (B+\Delta B_k)^\dagger]\mathrm{fl}(f - A\bar{x}_k) \\ &\quad + BB^\dagger[\mathrm{fl}(f - A\bar{x}_k) - (f - A\bar{x}_k)] - B(B+\Delta B_k)^\dagger\Delta c_k. \end{aligned}$$

Taking (3.16), the bounds on $B[B^\dagger - (B+\Delta B_k)^\dagger]$, $(B+\Delta B_k)^\dagger$, and Theorem 3.1 we get the desired result. ☐

When using the formula (3.5) the residual $f - A\bar{x}_k - B\bar{y}_k$ will not decrease below a level proportional to $\tau$, while $(I-\Pi)\bar{r}_k^{(x)}$ converges beyond the level $O(u)$. This result is illustrated by our numerical experiment. In Figure 3.3(b) we plotted the relative norms of $f - A\bar{x}_k - B\bar{y}_k$ (solid lines) and $\bar{r}_k^{(x)}$ (dashed lines).

**3.4. Scheme C: The approximate solution computed with a corrected direct substitution.** In this subsection we analyze the scheme (3.6) requiring a solution of two least squares problems with $B$. We show that its behavior is similar to the algorithm using the update (3.4). We prove that under certain assumptions the true residual $f - A\bar{x}_k - B\bar{y}_k$ converges ultimately to the $O(u)$ level. The difference is that while Theorem 3.2 holds without any additional conditions, here we have a situation analogous to the behavior of nonstationary iterative methods (see [23, Chapter 16]).

THEOREM 3.4. *Provided that for sufficiently large step $k$ the computed vector $\bar{x}_k$ stagnates, i.e., we have $\|\bar{x}_{k+1} - \bar{x}_k\| \le O(u)\bar{X}_{k+1}$, there exists some iteration step $k_0$ such that*

$$\|f - A\bar{x}_k - B\bar{y}_k - (I-\Pi)\bar{r}_k^{(x)}\| \le O(u)(\|f\| + \|A\|\bar{X}_k + \|B\|\bar{Y}_k) \tag{3.17}$$

*holds for all $k \ge k_0$.*

*Proof.* The vector $\bar{y}_{k+1}$ satisfies $\bar{y}_{k+1} = \bar{y}_k + \bar{q}_k^{(y)} + \Delta y_{k+1}$ and $\|\Delta y_{k+1}\| \le O(u)\bar{Y}_{k+1}$, where $\bar{q}_k^{(y)}$ is the solution of the problem $(B+\Delta B_k)\bar{q}_k^{(y)} \approx \mathrm{fl}(f - A\bar{x}_{k+1} - B\bar{y}_k) + \Delta c_k$ with $\|\Delta B_k\| \le \tau\|B\|$ and $\|\Delta c_k\| \le \tau\|\mathrm{fl}(f - A\bar{x}_{k+1} - B\bar{y}_k)\|$. For $f - A\bar{x}_{k+1} - B\bar{y}_{k+1}$ we can then write

$$\begin{aligned} f - A\bar{x}_{k+1} - B\bar{y}_{k+1} &= (I-\Pi)(f - A\bar{x}_{k+1}) + G_k(f - A\bar{x}_{k+1} - B\bar{y}_k) \\ &\quad - B(B+\Delta B_k)^\dagger\Delta c_k + h_k, \end{aligned}$$

where $G_k = B[B^\dagger - (B+\Delta B_k)^\dagger]$ and $h_k = -B(B+\Delta B_k)^\dagger[\mathrm{fl}(f - A\bar{x}_{k+1} - B\bar{y}_k) - (f - A\bar{x}_{k+1} - B\bar{y}_k)] - B\Delta y_{k+1}$. Projecting $f - A\bar{x}_{k+1} - B\bar{y}_{k+1}$ onto $R(B)$ and taking norms, we obtain

$$\begin{aligned} \|\Pi(f - A\bar{x}_{k+1} - B\bar{y}_{k+1})\| &\le \left[\|G_k\| + \tau\|B(B+\Delta B_k)^\dagger\|\right]\|f - A\bar{x}_{k+1} - B\bar{y}_k\| \\ &\quad + \tau\|B(B+\Delta B_k)^\dagger\|\|\mathrm{fl}(f - A\bar{x}_{k+1} - B\bar{y}_k) - (f - A\bar{x}_{k+1} - B\bar{y}_k)\| + \|h_k\|. \end{aligned}$$

The term $\|f - A\bar{x}_{k+1} - B\bar{y}_k\|$ can be further bounded by

$$\|f - A\bar{x}_{k+1} - B\bar{y}_k\| \le \|(I-\Pi)(f - A\bar{x}_{k+1})\| + \|\Pi(f - A\bar{x}_k - B\bar{y}_k)\| + \|A(\bar{x}_{k+1} - \bar{x}_k)\|$$

which together with the bound on $\|G_k\|$, $\|h_k\| \le O(u)(\|f\| + \|A\|\bar{X}_{k+1} + \|B\|\bar{Y}_{k+1})$, and $\tau\|B(B+\Delta B_k)^\dagger\| \le \tau\kappa(B)[1-\tau\kappa(B)]^{-1} < 1$ leads to

$$\begin{aligned}
&\|\Pi(f - A\bar{x}_{k+1} - B\bar{y}_{k+1})\| \\
&\quad \le \frac{3\tau\kappa(B)}{1-\tau\kappa(B)} \left[\|\Pi(f - A\bar{x}_k - B\bar{y}_k)\| + \|(I-\Pi)(f - A\bar{x}_{k+1})\| + \|A\|\|\bar{x}_{k+1} - \bar{x}_k\|\right] \\
&\qquad + O(u)(\|f\| + \|A\|\bar{X}_{k+1} + \|B\|\bar{Y}_{k+1}).
\end{aligned}$$

After the recursive use of the previous inequality we obtain

$$\begin{aligned}
(3.18)\qquad \|\Pi(f - A\bar{x}_k - B\bar{y}_k)\| &\le \left(\frac{3\tau\kappa(B)}{1-\tau\kappa(B)}\right)^k \|f - A\bar{x}_0 - B\bar{y}_0\| \\
&+ \sum_{i=0}^{k-1} \left(\frac{3\tau\kappa(B)}{1-\tau\kappa(B)}\right)^{k-i} \left[\|(I-\Pi)(f - A\bar{x}_{i+1})\| + \|A\|\|\bar{x}_{i+1} - \bar{x}_i\|\right] \\
&+ O(u)(\|f\| + \|A\|\bar{X}_k + \|B\|\bar{Y}_k).
\end{aligned}$$

Under the assumption on the stagnation of iterates there exist some index $k_0$ such that the second term on the right-hand side of (3.18) will be of order $O(u)(\|f\| + \|A\|\bar{X}_k + \|B\|\bar{Y}_k)$ for all iteration steps $k \ge k_0$. Finally, from Theorem 3.2 we have $\|(I-\Pi)(f - A\bar{x}_k) - (I-\Pi)\bar{r}_k^{(x)}\| \le O(u)(\|f\| + \|A\|\bar{X}_k + \|B\|\bar{Y}_k)$. ☐

Theorem 3.4 shows that $f - A\bar{x}_k - B\bar{y}_k$ will ultimately reach the $O(u)$ level. As soon as the approximate solutions $\bar{x}_k$ stagnate with $\|\bar{x}_{k+1} - \bar{x}_k\| \le O(u)\bar{X}_{k+1}$, the rate of convergence of this process is roughly given by the factor $3\tau\kappa(B)[1-\tau\kappa(B)]^{-1}$. Note that similar to subsection 2.4 the assumption on the stagnation is not restrictive. The numerical results on a model example are shown in Figure 3.3(c), which reports the relative norms of $f - A\bar{x}_k - B\bar{y}_k$ (solid lines) and $\bar{r}_k^{(x)}$ (dashed lines), and are in good agreement with Theorem 3.4.

### 3.5. Forward error analysis.

In this subsection we look at the maximum attainable accuracy measured by errors $x - \bar{x}_k$ and $y - \bar{y}_k$. The analysis is very similar to the Schur complement reduction method and therefore we focus only on issues particular to the null-space projection method. We recall that relation (2.25) gives the universal bounds (2.26), (2.27), and (2.28). Independent of the back-substitution scheme used for computing $\bar{y}_k$, the terms $\gamma_2\| - B^T\bar{x}_k\|$ and $\gamma_3\| - B^T\bar{x}_k\|$ on the right-hand side of (2.26) and (2.27), respectively, are always proportional to $\tau$. The terms with $f - A\bar{x}_k - B\bar{y}_k$ depend on the back-substitution formula and their final magnitude will be at most $O(\tau)$, leading to similar conclusions on errors as in subsection 2.5. The estimate for $\|x - \bar{x}_k\|_A$ is given in the following theorem.

Theorem 3.5. *The A-norm of the error $x - \bar{x}_k$ can be bounded as*

$$(3.19)\qquad \|x - \bar{x}_k\|_A \le \delta_1\| - B^T\bar{x}_k\| + \delta_2\|(I-\Pi)(f - A\bar{x}_k)\|,$$

*where $\delta_1 \equiv \|A\|^{1/2}/\sigma_{min}(B)$ and $\delta_2 \equiv \sigma_{min}^{-1/2}(A)$ are constants independent of the iteration step $k$.*

*Proof.* Since $(I-\Pi)A(x - \bar{x}_k) = (I-\Pi)(f - A\bar{x}_k)$, $B^Tx = 0$ and $\|B(B^TB)^{-1}\| = \sigma_{min}^{-1}(B)$, $\|x - \bar{x}_k\|_A^2$ can be written as

$$\begin{aligned}
(3.20)\quad \|x - \bar{x}_k\|_A^2 &= (\Pi(x - \bar{x}_k), A(x - \bar{x}_k)) + ((I-\Pi)A(x - \bar{x}_k), x - \bar{x}_k) \\
&\le \|A^{1/2}\|\|x - \bar{x}_k\|_A(\|B(B^TB)^{-1}\|\|B^T(x - \bar{x}_k)\| + \|(I-\Pi)(f - A\bar{x}_k)\|).
\end{aligned}$$

Dividing both sides by $\|x - \bar{x}_k\|_A$ gives the statement (3.19). $\square$

The first term on the right-hand side of (3.19) should be zero in exact arithmetic. The computed $\bar{x}_k$, however, does not fulfill $-B^T\bar{x}_k = 0$ and its departure from $N(B^T)$ was discussed in (3.8). The second term converges to zero in exact arithmetic and it is related to the projected residual $(I - \Pi)(f - A\bar{x}_k)$; see Theorem 3.14. The result for $y - \bar{y}_k$ can be obtained from (3.19) using (2.28). Provided that $\bar{r}_k^{(x)}$ is larger than $O(\tau)$, $\|x - \bar{x}_k\|_A$ is then well approximated by $\delta_2\|(I - \Pi)\bar{r}_k^{(x)}\|$.

**4. Conclusions.** In this paper we have looked at the numerical behavior of certain inexact saddle point solvers. In particular, for several mathematically equivalent implementations we studied the influence of inexact solving of the inner systems and estimated their maximum attainable accuracy. When considering the outer iteration process our rounding error analysis has led to results similar to ones which can be obtained assuming exact arithmetic. The situation was different when we looked at the residuals in the saddle point system. We have shown that some implementations lead ultimately to residuals on the roundoff unit level independently of the fact that the inner systems were solved inexactly on a much higher level $\tau$. Indeed, our results confirmed that the generic and actually the cheapest implementations deliver the approximate solutions which satisfy either the second or the first block equation to the working accuracy. In addition, the schemes with the corrected direct substitution are also very attractive. We gave a theoretical explanation for the behavior which was probably observed or is already tacitly known. The implementations that we pointed out as optimal are actually those which are widely used and suggested in applications. It appears that, when measured in terms of the errors, the maximum attainable accuracy level is similar for all considered implementations and is proportional to the parameter which measures the inexactness in solving the inner systems.

**Acknowledgments.** The authors would like to thank the anonymous referees for their valuable comments and suggestions and Volker Mehrmann for his discussion during the MAT-TRIAD 2005 meeting, which actually stimulated this work.

# NEW FAST AND ACCURATE JACOBI SVD ALGORITHM. I*

ZLATKO DRMAČ† AND KREŠIMIR VESELIĆ‡

*Dedicated to the memory of Patricia J. Eberlein, whose enthusiasm and belief in the powers of the Jacobi methods were a constant inspiration*

**Abstract.** This paper is the result of concerted efforts to break the barrier between numerical accuracy and run-time efficiency in computing the fundamental decomposition of numerical linear algebra—the singular value decomposition (SVD) of general dense matrices. It is an unfortunate fact that the numerically most accurate one-sided Jacobi SVD algorithm is several times slower than generally less accurate bidiagonalization-based methods such as the QR or the divide-and-conquer algorithm. Our quest for a highly accurate and efficient SVD algorithm has led us to a new, superior variant of the Jacobi algorithm. The new algorithm has inherited all good high accuracy properties of the Jacobi algorithm, and it can outperform the QR algorithm.

**Key words.** Jacobi method, singular value decomposition, eigenvalues

## 1. Introduction.

In 1846, Jacobi [25] introduced a new simple and accurate algorithm for diagonalization of symmetric matrices. The algorithm starts with symmetric matrix $H^{(0)} = H \in \mathbb{R}^{n\times n}$ and then generates a sequence of congruences, $H^{(k+1)} = (V^{(k)})^T H^{(k)} V^{(k)}$, where $V^{(k)}$ is plane rotation; i.e., $V^{(k)}$ differs from the identity only at the cleverly chosen positions $(p_k, p_k)$, $(p_k, q_k)$, $(q_k, p_k)$, $(q_k, q_k)$, where

$$\begin{pmatrix} V^{(k)}_{p_k,p_k} & V^{(k)}_{p_k,q_k} \\ V^{(k)}_{q_k,p_k} & V^{(k)}_{q_k,q_k} \end{pmatrix} = \begin{pmatrix} \cos\phi_k & \sin\phi_k \\ -\sin\phi_k & \cos\phi_k \end{pmatrix}.$$

The angle $\phi_k$ is determined to annihilate the $(p_k, q_k)$ and $(q_k, p_k)$ positions in $H^{(k)}$. Simple trigonometry reveals that in the nontrivial case ($H^{(k)}_{p_kq_k} \neq 0$) we can take

$$\cot 2\phi_k = \frac{H^{(k)}_{q_kq_k} - H^{(k)}_{p_kp_k}}{2H^{(k)}_{p_kq_k}} \quad\text{and}\quad \tan\phi_k = \frac{\operatorname{sign}(\cot 2\phi_k)}{|\cot 2\phi_k| + \sqrt{1+\cot^2 2\phi_k}} \in \left(-\frac{\pi}{4}, \frac{\pi}{4}\right],$$

where $\phi_k$ is the smaller of two angles satisfying the requirements. (If $H^{(k)}_{p_kq_k} = 0$, then $V^{(k)} = I$, the identity.) Under suitable pivot strategies $k \mapsto (p_k, q_k)$, the sequence $(H^{(k)})_{k=0}^{\infty}$ converges to diagonal matrix $\Lambda$, and the product $V^{(0)}V^{(1)}\cdots V^{(k)}\cdots$ converges to the orthogonal matrix $V$ of eigenvectors of $H$, $HV = V\Lambda$. The convergence is monitored using the off-norm, $\Omega(H) = \sqrt{\sum_{i\neq j} H_{ij}^2}$, for which one easily shows the monotonicity $\Omega^2(H^{(k+1)}) = \Omega^2(H^{(k)}) - 2(H^{(k)})^2_{p_k,q_k} \leq \Omega^2(H^{(k)})$.

Hestenes [23] noted that the Jacobi method can be used to compute the SVD of general matrices. If $A$ is of full column rank[1] and if we define $H = A^T A$, then the application of the method to $H$, $H^{(k+1)} = (V^{(k)})^T H^{(k)} V^{(k)}$, can be represented by the sequence $A^{(k+1)} = A^{(k)} V^{(k)}$. To determine the parameters of $V^{(k)}$ we only need the four pivot elements of $H^{(k)}$, that is, the $2 \times 2$ Gram matrix of the $p_k$th and the $q_k$th column of $A^{(k)}$. The limit matrix of $(A^{(k)})_{k=0}^{\infty}$ is $U\Sigma$, where the columns of orthonormal $U$ are the left singular vectors and the diagonal matrix $\Sigma$ carries the singular values along its diagonal. The accumulated product of Jacobi rotations is orthogonal matrix $V$ of the eigenvectors of $H$. The SVD of $A$ is $A = U\Sigma V^T$.

The development of fast methods based on reduction of $A$ to bidiagonal form shifted interest away from the Jacobi SVD method—bidiagonalization-based routines xGESVD [11] and xGESDD [21] from LAPACK [1] can in some cases be ten or even fifteen times faster than the Jacobi SVD. However, Demmel and Veselić [12] showed that the Jacobi algorithm is more accurate than any other algorithm that first reduces the matrix to bidiagonal form. Some classes of matrices that appear ill-conditioned with respect to SVD computation in fact define the SVD perfectly well, and the ill-conditioning is artificial. For instance, if $A \in \mathbb{R}^{m\times n}$ is such that $\min_{D=\mathrm{diag}} \kappa_2(AD)$ is moderate, then the Jacobi SVD algorithm computes all singular values $\sigma_1 \geq \cdots \geq \sigma_n$ with guaranteed number of correct digits independent of the size of $\kappa_2(A) = \sigma_{\max}(A)/\sigma_{\min}(A) \equiv \sigma_1/\sigma_n$. The Jacobi method correctly deals with artificial ill-conditioning (e.g., grading), while the bidiagonalization-based methods do not.

In this paper we present a new preconditioned Jacobi SVD algorithm which provides higher accuracy with efficiency comparable to the bidiagonalization-based methods. In section 2 we show that rank revealing QR factorization can be used as an efficient preconditioner for the Jacobi SVD algorithm, and we reduce the problem to SVD computation of structured triangular matrices. Important detail of choosing $A$ or $A^T$ as input to the new algorithm is discussed in section 3. The dilemma "$A$ or $A^T$" generates interesting mathematical questions leading us to study entropy of the set of normalized diagonals of the adjoint orbit of a positive definite matrix. The basic structure of the new Jacobi SVD algorithm is developed in section 4. Numerical properties are analyzed in section 5. It is shown that the backward perturbation has structure which allows scaling invariance of the condition number for the forward error. Implementation details of a new Jacobi SVD for triangular matrices and results of numerical testing of the preconditioned Jacobi SVD are given in the second part of this paper [18], where we demonstrate the potential of the new approach.

## 2. QR factorization as preconditioner for the Jacobi SVD algorithm.

In the case $m \gg n$, the QR factorization $A = Q \begin{pmatrix} R^T & 0 \end{pmatrix}^T$ is an attractive preprocessor for the Jacobi SVD algorithm, because Jacobi rotations can be applied to $R \in \mathbb{R}^{n\times n}$ instead of $A \in \mathbb{R}^{m\times n}$. If the QR factorization is computed with a rank revealing column pivoting, $A\Pi = Q \begin{pmatrix} R^T & 0 \end{pmatrix}^T$, then the additional structure of $R$ opens quite a few possibilities for more efficient SVD computation by the Jacobi algorithm.

### 2.1. Faster convergence.

Veselić and Hari [34] noted that the eigenvalues of symmetric positive definite $H$ can be computed more efficiently if the Jacobi SVD method is applied to the lower triangular factor $L$ from the pivoted Cholesky factorization $P^T H P = LL^T$. If $H = A^T A$, $\mathrm{rank}(A) = n$, then Cholesky factorization with pivoting of $H$ corresponds to the QR factorization with column pivoting

---

[1] This is only a temporary assumption for the sake of simplicity.

$A\Pi = Q\begin{pmatrix} R^T & 0 \end{pmatrix}^T$, $L = R^T$. Hence, the Jacobi SVD on $R^T$ should have better convergence than if applied to $R$, and the preconditioning is performed simply by taking $R^T$ instead of $R$ as input. Implicitly, this is one step of the Rutishauser [31] LR diagonalization method $R^TR \rightsquigarrow RR^T$, which has a nontrivial diagonalizing effect.

Let $R = \left(\begin{smallmatrix} R_{[11]} & R_{[12]} \\ 0 & R_{[22]} \end{smallmatrix}\right)$, where the diagonal blocks are $k \times k$ and $(n-k) \times (n-k)$, and consider the corresponding block partitions of $H = R^TR$ and $M = RR^T$:

$$H = \begin{pmatrix} H_{[11]} & H_{[12]} \\ H_{[21]} & H_{[22]} \end{pmatrix} = \left(\begin{array}{c|c} R_{[11]}^T R_{[11]} & R_{[11]}^T R_{[12]} \\ \hline R_{[12]}^T R_{[11]} & R_{[12]}^T R_{[12]} + R_{[22]}^T R_{[22]} \end{array}\right),$$

$$M = \begin{pmatrix} M_{[11]} & M_{[12]} \\ M_{[21]} & M_{[22]} \end{pmatrix} = \left(\begin{array}{c|c} R_{[11]} R_{[11]}^T + R_{[12]} R_{[12]}^T & R_{[12]} R_{[22]}^T \\ \hline R_{[22]} R_{[12]}^T & R_{[22]} R_{[22]}^T \end{array}\right). \tag{2.1}$$

Note that the $(1,1)$ block in $M$ is increased, and the $(2,2)$ block is decreased, i.e., $\mathrm{Trace}(M_{[11]}) = \mathrm{Trace}(H_{[11]}) + \|R_{[12]}\|_F^2$, $\mathrm{Trace}(M_{[22]}) = \mathrm{Trace}(H_{[22]}) - \|R_{[12]}\|_F^2$.

This redistribution of the mass of the diagonal blocks makes the gap between the dominant and subdominant parts of the spectrum more visible on the diagonal. Using the monotonicity of the spectrum, we also conclude that properly ordered eigenvalues $\lambda_i(\cdot)$ of the diagonal blocks satisfy $\lambda_i(M_{[11]}) \geq \lambda_i(H_{[11]})$, $\lambda_j(M_{[22]}) \leq \lambda_j(H_{[22]})$, $1 \leq i \leq k$, $1 \leq j \leq n-k$. With suitable pivot strategy, this has positive impact on the structure of Jacobi rotations (smaller angles) in the off-diagonal blocks in (2.1). Moreover, the off-diagonal blocks of $M$ are expected to be smaller than those in $H$.

PROPOSITION 2.1. *With the partition of* $R$ *and* (2.1) *define* $R_{[1:]} = \begin{pmatrix} R_{[11]} & R_{[12]} \end{pmatrix}$, $R_{[:2]} = \left(\begin{smallmatrix} R_{[12]} \\ R_{[22]} \end{smallmatrix}\right)$, $\cos\Phi = H_{[11]}^{-1/2} H_{[12]} H_{[22]}^{-1/2}$, *and* $\cos\Psi = M_{[11]}^{-1/2} M_{[12]} M_{[22]}^{-1/2}$. *Then, with* $\|\cdot\| \in \{\|\cdot\|_2 \equiv \sigma_{\max}(\cdot), \|\cdot\|_F\}$,

$$\text{(i)} \quad \|M_{[12]}\| \leq \frac{\sigma_{\max}(R_{[22]})}{\sigma_{\min}(R_{[11]})}\|H_{[12]}\|\ ; \quad \text{(ii)} \quad \|\cos\Psi\| \leq \frac{\sigma_{\max}(R_{[:2]})}{\sigma_{\min}(R_{[1:]})}\|\cos\Phi\|. \tag{2.2}$$

*Proof.* To prove the well-known relation (i), one notes that $M_{[12]} = R_{[11]}^{-T} H_{[12]} R_{[22]}^T$. For the new estimate (ii), we use the connections between the LQ factorization, Cholesky factorization and the positive definite matrix square root to conclude that there exist orthogonal matrices $S_1$, $S_2$ such that

$$\cos\Psi = (R_{[1:]}R_{[1:]}^T)^{-1/2}\ S_1\ \cos\Phi\ (R_{[:2]}^T R_{[:2]})^{1/2}\ S_2.$$

Taking the norm completes the proof. □

Let $\xi = \xi(R,k) = \sigma_{\max}(R_{[22]})/\sigma_{\min}(R_{[11]})$. If $\xi < 1$, then $\|M_{[12]}\|_F \leq \xi\|H_{[12]}\|_F < \|H_{[12]}\|_F$. Thus, a smaller value of $\xi$ implies more block diagonal structure in $M$ than in $H$. Now, it is the task of the rank revealing pivoting in the QR factorization to find index $k$ for which $\xi \ll 1$. If the pivoting is done right, and if the singular values of $R$ are distributed so that $\sigma_k \gg \sigma_{k+1}$ for some $k$, then $\xi$ will be much smaller than one. See [7], [8] for a detailed analysis related to (2.2(i)).

Note that (2.2(ii)) estimates scaled off-diagonal blocks, which is relevant for the convergence of the Jacobi algorithm. Relevant separation is given by $\zeta = \zeta(R,k) = \sigma_{\max}(R_{[:2]})/\sigma_{\min}(R_{[1:]})$. In general, $\xi < 1$ does not imply $\zeta < 1$, but an additional factorization will provide that stronger separation.

THEOREM 2.2. *Let* $R = LQ_L$ *be the LQ factorization of* $R$,

$$\begin{pmatrix} R_{[11]} & R_{[12]} \\ 0 & R_{[22]} \end{pmatrix} = \begin{pmatrix} L_{[11]} & 0 \\ L_{[21]} & L_{[22]} \end{pmatrix} Q_L = LQ_L.$$

*Then we have the following monotonicity relations*:

$$\sigma_i\left(\begin{pmatrix} L_{[11]} \\ L_{[21]} \end{pmatrix}\right) \geq \sigma_i(L_{[11]}) = \sigma_i(R_{[1:]}) \geq \sigma_i(R_{[11]}),\quad i = 1,\ldots,k; \tag{2.3}$$

$$\sigma_j(L_{[22]}) \leq \sigma_j(\begin{pmatrix} L_{[21]} & L_{[22]} \end{pmatrix}) = \sigma_j(R_{[22]}) \leq \sigma_j(R_{[:2]}),\quad j = 1,\ldots,n-k. \tag{2.4}$$

*In particular, if* $\sigma_{\min}(R_{[1:]}) > \sigma_{\max}(R_{[22]})$, *then* $\xi(L^T,k) < 1$, $\zeta(L^T,k) < 1$, *and* $\|L_{[21]}\| < \|R_{[12]}\|$. *In that case,* $M = RR^T$ *is a shifted quasi-definite matrix.*

*Proof.* The inequalities (2.3) and (2.4) are obtained by an application of the monotonicity principle to the corresponding eigenvalues. Combination of the inequalities with the assumption $\sigma_{\min}(R_{[1:]}) > \sigma_{\max}(R_{[22]})$ gives the bounds on $\xi$ and $\zeta$. Since $L_{[21]} = R_{[22]}R_{[12]}^T L_{[11]}^{-T}$ we have, for $\|\cdot\| \in \{\|\cdot\|_2, \|\cdot\|_F\}$, $\|L_{[21]}\| \leq \frac{\sigma_{\max}(R_{[22]})}{\sigma_{\min}(R_{[1:]})}\|R_{[12]}\| < \|R_{[12]}\|$. Finally, note that $M - s^2 I$ is quasi-definite for any $s \in (\sigma_{\max}(R_{[22]}), \sigma_{\min}(R_{[1:]}))$. $\square$

*Remark* 2.1. Theorem 2.2 introduces gap $\gamma(R,k) = \sigma_{\max}(R_{[22]})/\sigma_{\min}(R_{[1:]})$, which from the pivoted QR factorization requires less than the condition $\sigma_{\max}(R_{[22]}) < \sigma_{\min}(R_{[11]})$. If $\gamma < 1$, then the off-diagonal block in $M^{(1)} = L^T L$ satisfies $\|M^{(1)}_{[21]}\| \leq (\sigma_{\max}(L_{[22]})/\sigma_{\min}(L_{[11]}))(\sigma_{\max}(R_{[22]})/\sigma_{\min}(R_{[11]}))\|H_{21}\|$.

Now, it is reasonable to expect that the one-sided Jacobi SVD algorithm applied to $L$ runs quite differently than if applied to the initial $A$. The structure of $L$ calls for modifications, and the result is a new Jacobi-type algorithm designed for triangular matrices. Its complete description is in the second part of this report [18].

*Remark* 2.2. It is well known that repeated application of the step "do QR factorization and transpose $R$" is actually a simple way to approximate the SVD; see [29], [20], [32]. Fernando and Parlett [20] first realized that "the use of a preconditioner for cyclic Jacobi is not a futile effort." Here we stress the term *preconditioner* and use of the implicit Cholesky SVD as preconditioner for Jacobi iterations.

**2.2. Rank deficient cases.** Consider the case of $A$ with low numerical rank. The task is to compute the singular values with standard error bound. In a rank revealing QR factorization, the computed $\tilde{R}$, $\tilde{Q}$ satisfy backward stability relations

$$(A + \delta A)\Pi = \hat{Q}\begin{pmatrix} \tilde{R} \\ 0 \end{pmatrix},\quad \|\delta A(:,i)\|_2 \leq \varepsilon_{qr}\|A(:,i)\|_2,\quad i = 1,\ldots,n;\quad \|\tilde{Q} - \hat{Q}\|_F \leq \varepsilon_{qr},$$

where $\hat{Q}$ is orthogonal and $\varepsilon_{qr}$ is bounded by a moderate $f(m,n)$ times the round-off $\boldsymbol{\varepsilon}$. Suppose there is an index $k \in \{1,\ldots,n\}$ such that $\tilde{R}$ can be partitioned as

$$\tilde{R} = \begin{pmatrix} \tilde{R}_{[11]} & \tilde{R}_{[12]} \\ 0 & \tilde{R}_{[22]} \end{pmatrix},\quad \text{where } \tilde{R}_{[22]} \in \mathbb{R}^{(n-k)\times(n-k)} \text{ is sufficiently small.} \tag{2.5}$$

If we set $\tilde{R}_{[22]}$ to zero, then we will implicitly continue working with the matrix

$$\hat{Q}\begin{pmatrix} \tilde{R}_{[11]} & \tilde{R}_{[12]} \\ 0 & 0 \\ 0 & 0 \end{pmatrix} = \left(A + \delta A - \hat{Q}\begin{pmatrix} 0 & 0 \\ 0 & \tilde{R}_{[22]} \\ 0 & 0 \end{pmatrix}\Pi^T\right)\Pi \equiv (A + \Delta A)\Pi. \tag{2.6}$$

If $\|\tilde{R}_{[22]}\|_2/\|A\|_2$ is of the order of $\varepsilon_{qr}$, then replacing $\tilde{R}_{[22]}$ with zero is in the matrix norm a backward stable operation for singular value computation with classical error bound—the perturbation in each singular value is small compared to $\|A\|_2 = \sigma_{\max}(A)$.

Further, (2.6) is the QR factorization of $(A+\Delta A)\Pi$, where for the computed orthogonal factor we can keep $\tilde{Q}$. If we compute the LQ factorization of the $k \times n$ matrix, $\hat{R} \equiv (\,\tilde{R}_{[11]} \quad \tilde{R}_{[12]}\,) = LQ_1$, then the Jacobi iterations work on substantially smaller $k \times k$ lower triangular matrix $L$. Thus, a rank revealing ULV decomposition is in this case an excellent preprocessor for the Jacobi SVD algorithm.

Theorem 2.3. *Let the block $\tilde{R}_{[11]}$ in* (2.6) *be nonsingular and let $\tilde{R}_{[11]} = DT$, where $D$ is diagonal with $\sigma_{\min}(D) = |\tilde{r}_{kk}|$. Further, let the truncated block $\tilde{R}_{[22]}$ satisfy $\|\tilde{R}_{[22]}\|_2 \le \tau|\tilde{r}_{kk}|$. If $\tilde{\sigma}_1 \ge \cdots \ge \tilde{\sigma}_k$ and $\hat{\sigma}_1 \ge \cdots \ge \hat{\sigma}_k$ are the nonzero singular values of $\tilde{R}$ and $\hat{R}$, respectively, then for $i = 1, \ldots, k$*

$$0 \le \frac{\tilde{\sigma}_i - \hat{\sigma}_i}{\tilde{\sigma}_i} \le \left(\frac{\hat{\sigma}_k}{\tilde{\sigma}_i}\right) \tau \|T^{-1}\|_2.$$

*Proof.* We first note that $\max_{i=1:k} |\tilde{\sigma}_i - \hat{\sigma}_i| \le \|\tilde{R}_{[22]}\|_2 \le \tau|\tilde{r}_{kk}| \le \tau\tilde{\sigma}_1$, which estimates truncation error relative to the matrix norm. This bound actually contains better estimate because $|\tilde{r}_{kk}|$ is related to $\tilde{\sigma}_k$. From the Courant–Fisher minimax theorem we conclude $|\tilde{r}_{kk}| \le \|T^{-1}\|_2 \sigma_k(\tilde{R}_{[11]})$, where $\sigma_k(\tilde{R}_{[11]})$ is the $k$th largest singular value of $\tilde{R}_{[11]}$. The proof is completed by the Cauchy interlacing theorem, which yields $\sigma_k(\tilde{R}_{[11]}) \le \hat{\sigma}_k \le \tilde{\sigma}_k$. ☐

Consider, for example, the classical Businger–Golub pivoting [6],

$$A\Pi = Q\begin{pmatrix} R \\ 0 \end{pmatrix}, \quad |r_{ii}| \ge \sum_{k=i}^{j} r_{kj}^2, \quad 1 \le i < j \le n. \tag{2.7}$$

With careful implementation [16], the computed $\tilde{R}$ has the structure (2.7) up to small round-off. The index $k$ can be determined, for example, by looking for a gap between two consecutive diagonals of $\tilde{R}$, i.e., $|\tilde{r}_{k+1,k+1}| \le \epsilon|\tilde{r}_{kk}|$. In that case, $\|\tilde{R}_{[22]}\|_2 \le \sqrt{n-k}\epsilon|\tilde{r}_{kk}|$. Further, with $D = \operatorname{diag}(\|\tilde{R}_{[11]}(i,:)\|_2)_{i=1}^k$, the condition number $\|T^{-1}\|_2$ in Theorem 2.3 is usually smaller than $O(k)$. (Its theoretical upper bound contains $2^k$ factor, and it is attained at the Kahan matrix.) We refer to [14] for more details.

To conclude, in cases of low numerical rank, we can always use best available rank revealing QR factorization to reduce the dimension, if necessary with an additional LQ factorization, as described above.

## 3. $A$ or $A^T$?

If $A \in \mathbb{R}^{m\times n}$ with $m > n$, then the QR factorization of $A$ is an efficient preprocessor and preconditioner for the Jacobi algorithm. If $m < n$, then we start with the QR factorization of $A^T$. But what if $A$ is a square nonsingular $n \times n$ matrix? For example, let $A = DQ$, where $D$ is diagonal and $Q$ is orthogonal. In that case working with $A$ is implicit diagonalization of $A^TA = Q^TD^2Q$, while taking $A^T$ implicitly diagonalizes diagonal matrix $AA^T = D^2$. For a nonnormal $A$, a better choice between $A^TA$ and $AA^T$ has a smaller off-diagonal part and the diagonals reveal the spectrum in the sense that their distribution reveals the distribution of the spectrum as closely as possible. This desirable spectrum revealing property implies that we prefer $A$ with less equilibrated column norms. Otherwise, the effect of preconditioning is weaker, and larger angles of Jacobi rotations are more likely to appear during the process, thus causing slower convergence. In an efficient computation, the decision "$A$ or $A^T$" has to be based on at most $O(n^2)$ flops. This complexity corresponds to computing the diagonal entries of $H = A^TA$ and $M = AA^T$.

Let $s^2(H) = \sum_{i=1}^n h_{ii}^2 = \operatorname{Trace}(H \circ H)$, $s^2(M) = \operatorname{Trace}(M \circ M)$. (Here $\circ$ denotes the Hadamard matrix product.) Since $H$ and $M$ are orthogonally similar,

$\|H\|_F = \|M\|_F$, a larger value ($s^2(H)$ or $s^2(M)$) implies smaller corresponding off-norm $\Omega(H)$ or $\Omega(M)$. In fact, $s^2(\cdot)$ attains its maximum over the set of matrices orthogonally similar to $H$ only at diagonal matrices. In the standard symmetric Jacobi algorithm the value of $\frac{\Omega^2(H)}{\|H\|_F^2} = 1 - \frac{\mathrm{Trace}(H \circ H)}{\mathrm{Trace}(HH)} = 1 - \frac{s^2(H)}{\|H\|_F^2}$ is used to measure numerical convergence. Hence, $s^2(\cdot)$ is one possible choice for the decision between $A$ and $A^T$, but with respect to the standard matrix off-norm. Note, however, that in floating point computation $s^2(\cdot)$ may ignore tiny diagonal entries, and that it does not provide any information about the distributions of the diagonal entries of $H$ and $M$. The latter is crucial for the success of both the preconditioner and the Jacobi iterations. In the next section we address that issue by a novel application of well-known tools.[2]

### 3.1. Entropy of the diagonal of the adjoint orbit.

Let $H = H^T$ be positive semidefinite. From the spectral decomposition $H = U\Lambda U^T$, $h_{ii} = \sum_{j=1}^n |u_{ij}|^2 \lambda_j$, $i = 1, \ldots, n$. If we define vectors $d(H) = (\, h_{11}, \ldots, h_{nn}\,)^T$, $\lambda(H) = (\, \lambda_1, \ldots, \lambda_n\,)^T$, then $d(H) = (U \circ U)\lambda(H)$, where the matrix $S = U \circ U$ is doubly stochastic, in fact, orthostochastic. Thus, $d(H)$ is majorized by $\lambda(H)$ ($d(H) \prec \lambda(H)$), which is known as the Schur theorem; see, e.g., [3]. If we use normalization[3] by the trace,

$$\frac{d(H)}{\mathrm{Trace}(H)} = S\frac{\lambda(H)}{\mathrm{Trace}(H)}, \quad \text{and define } d'(H) = \frac{d(H)}{\mathrm{Trace}(H)}, \quad \lambda'(H) = \frac{\lambda(H)}{\mathrm{Trace}(H)},$$

then $d'(H)$ and $\lambda'(H)$ are two finite probability distributions connected by the doubly stochastic matrix $S$. Thus, $d'(H)$ has larger entropy than $\lambda'(H)$. Recall that for a probability distribution $p = (\, p_1, \ldots, p_n\,)^T$ ($p_i \geq 0$, $\sum_i p_i = 1$) the entropy of $p$ is $\eta(p) = -\frac{1}{\log n}\sum_{i=1}^n p_i \log p_i \in [0,1]$. For any doubly stochastic matrix $S$ we have $\eta(Sp) \geq \eta(p)$ with the equality if and only if $S$ is a permutation matrix. The entropy is a symmetric concave function on the compact and convex set of finite probability distributions. It is maximal, $\eta(p) = 1$, if and only if $p_i = 1/n$ for all $i$. Also, $\eta(p) = 0$ if and only if the probability distribution degenerates to $p_k = 1$, $p_i = 0$, $i \neq k$.

Definition 3.1. *The d-entropy of positive semidefinite $H$ is defined as the entropy of its diagonal normalized by the trace, $\eta_d(H) \equiv \eta(d'(H))$.*

Proposition 3.2. *The d-entropy $\eta_d$ is strictly positive on the open cone of positive definite matrices. It always attains its maximum* 1 *on the real adjoint orbit $\mathcal{O}(H) = \{W^T H W : W \text{ orthogonal}\}$. Further, it holds $\eta_d(\mathcal{O}(H)) = \{1\}$ if and only if $H$ is a scalar ($H = \mathrm{scalar} \cdot I$). If $H$ has $s$ different eigenvalues with multiplicities $n_1, \ldots, n_s$, then $\eta_d$ attains its minimal value on $\mathcal{O}(H)$ at each of $\frac{n!}{\prod_{i=1}^s n_i!}$ different diagonal matrices in $\mathcal{O}(H)$, and nowhere else.*

*Proof.* There always exists an orthogonal $W$ such that $W^T H W$ has constant diagonal. The fact that the entropy $\eta_d(\cdot)$ of the diagonal of $H$ is larger than the entropy of the vector of the eigenvalues holds for any symmetric concave function. To see that, recall the relation $d'(H) = S\lambda'(H)$, where $S$ is doubly stochastic. By the Birkhoff theorem [3, Theorem II.2.3], $S$ is from the convex hull of permutation matrices, thus $S = \sum_k \alpha_k P_k$, where the $P_k$'s are permutation matrices and the $\alpha_k$'s are nonnegative with sum one. Thus, $d'(H)$ belongs to the convex polyhedral set spanned by permutations of the vector $\lambda'(H)$. Hence, a concave function on $d'(H)$

---

[2] For the sake of brevity, we will just illustrate the main idea and leave the details for a forthcoming paper.

[3] By definition, $0/0 = 0$ and $0 \log 0 = 0$.

cannot have smaller value than its minimal value on the vectors $P_k\lambda'(H)$. Note that the number of minimal points represents the number of possible affiliations of $n$ diagonal entries with $s$ different eigenvalues. $\square$

*Example* 3.1. The following example illustrates the preceding discussion on the relation between the entropy and the spectral information along the diagonal of the matrix. Let $A$ be the upper triangular factor from the QR factorization of the $4\times 4$ Hilbert matrix, and let $H = A^TA$, $M = AA^T$. The $d(H)$, $\lambda(H)$, and $d(M)$ are

$$\begin{array}{llll} h_{11}\approx 1.4236e{+}00, & h_{22}\approx 4.6361e{-}01, & h_{33}\approx 2.4138e{-}01, & h_{44}\approx 1.5068e{-}01,\\ \lambda_1\approx 2.2506e{+}00, & \lambda_2\approx 2.8608e{-}02, & \lambda_3\approx 4.5404e{-}05, & \lambda_4\approx 9.3513e{-}09,\\ m_{11}\approx 2.2355e{+}00, & m_{22}\approx 4.3655e{-}02, & m_{33}\approx 1.3022e{-}04, & m_{44}\approx 3.5308e{-}08. \end{array}$$

If we look at only the diagonal entries of the matrix, we cannot say how close the diagonal is to the spectrum. After all, the matrix can be diagonal, that is, with minimum entropy in its orbit, and we cannot detect that. But if we have the diagonals of two orthogonally similar matrices, then we see the difference between the two diagonals. If we compute the entropies, $\eta_d(H)\approx 7.788e-001 > \eta_d(M)\approx 8.678e-002$.

*Remark* 3.1. Just looking at $d(H)$ and $d(M)$ in Example 3.1 and knowing that they are diagonals of unitarily similar matrices is enough to choose $d(M)$ as a better approximation of the spectrum since if $H$ were close to diagonal, then $\kappa_2(H)$ would be $O(1)$, while $\kappa_2(M)\geq 10^8$. In other words, orthogonal similarity can hide the high spectral condition number of diagonal matrix (so that it is not seen on the diagonal of the similar matrix), but it cannot produce it starting from a well-conditioned, almost diagonal matrix. In some sense, with respect to the problem of guessing the spectrum, the diagonal of $M$ has less uncertainty than the diagonal of $H$. Our algorithm can better utilize diagonals with a smaller entropy.

## 4. The algorithm.

We now describe the new preconditioned Jacobi SVD algorithm with rank revealing QR factorization as preconditioner. At this point we do not consider the details of the application of the one-sided Jacobi rotations to triangular matrix. Instead, we use triangular Jacobi SVD as a black box and give the details in [18]. On input to the black box we have triangular nonsingular matrix $X$, and the box computes $X_\infty = XV_x$, where $X_\infty = U_x\Sigma$, $X = U_x\Sigma V_x^T$ is the SVD of $X$, and $V_x$ is the product of the Jacobi rotations. If $V_x$ is not computed, we write $X_\infty = X\langle V_x\rangle$. We keep this notation in other situations as well. If in a relation some matrix is enclosed in $\langle\cdot\rangle$, then that matrix is not computed and no information about it is stored. For example, $A = \langle Q\rangle \begin{pmatrix} R^T & 0\end{pmatrix}^T$ means computing only $R$ in the QR factorization of $A$.

### 4.1. Computing only $\Sigma$.

We first describe the algorithm for computing only the singular values of $A$. In Algorithm 1 we use two QR factorizations with pivoting and then apply the one-sided Jacobi SVD algorithm. We do not specify which rank revealing QR factorization is used—the rule is to use the best available; see, e.g., [5], [4]. In some cases, the rows of $A$ can be sorted to get more structured backward error; see section 5.3.

*Remark* 4.1. The pivoting in the second QR factorization is optional, and $P_1 = I$ works well. If efficient QR factorization with local pivoting is available, it can be used to compute $R_1$. If $\max_{i=2:n}\|R(1:i-1,i)\|_2/|r_{ii}|\leq O(n)\varepsilon$, then the columns of $A$ are nearly orthogonal, and the second QR factorization is unnecessary, $X = R^T$.

**Algorithm 1** $\sigma = SVD(A)$.

```
$(P_r A)P = \langle Q \rangle \begin{pmatrix} R \\ 0 \end{pmatrix}$ ; $\rho = \mathrm{rank}(R)$ ; [optional deflation, section 2.2][optional $P_r$, section 5.3]
$R(1:\rho, 1:n)^T P_1 = \langle Q_1 \rangle R_1$ ; $X = R_1^T$ ; [optional pivoting $P_1$]
$X_\infty = X \langle V_x \rangle$ ; {Use section 5.4 for sharp stopping criterion.}
$\sigma_i = \|X_\infty(:, i)\|_2, \quad i = 1, \dots, \rho$ ; $\boxed{\sigma = (\sigma_1, \dots, \sigma_\rho, 0, \dots, 0)}$ .
```

**Algorithm 2** $(\sigma, V) = SVD(A)$.

```
$(P_r A)P = \langle Q \rangle \begin{pmatrix} R \\ 0 \end{pmatrix}$; $\rho = \mathrm{rank}(R)$ ; [optional deflation, section 2.2][optional $P_r$, section 5.3]
$X = R(1:\rho, 1:n)^T$ ; $X_\infty = X \langle V_x \rangle$ ;
$\sigma_i = \|X_\infty(:, i)\|_2, \quad i = 1, \dots, \rho$ ; $\boxed{\sigma = (\sigma_1, \dots, \sigma_\rho, 0, \dots, 0)}$ ;
$U_x(:, i) = \frac{1}{\sigma_i} X_\infty(:, i), \quad i = 1, \dots, \rho$ ; $\boxed{V = PU_x}$ .
```

**4.2. Computing $\boldsymbol{\Sigma}$ and $\boldsymbol{V}$.** If we need the singular values and the right singular vectors, a direct application of Jacobi rotations to $A$ or $R$ requires the accumulated product of rotations to construct the right singular vector matrix $V$. To avoid the explicit multiplication of Jacobi rotations, in this case we use Algorithm 2. The beauty of the preconditioning $R \rightsquigarrow R^T$ in Algorithm 2 is in the fact that the set of the right singular vectors is computed without the product of the Jacobi rotations, and at the same time, due to preconditioning, fewer rotations are needed to reach the numerical convergence. If $\rho \ll n$, an additional LQ factorization of $R(1:\rho, 1:n)$ is advisable. In that case, the accumulation of rotations can be avoided, as described in section 4.4.2.

**4.3. Computing $\boldsymbol{\Sigma}$ and $\boldsymbol{U}$.** If $\Sigma$ and $U$ are needed and if we apply the Jacobi SVD on $X = A$ or $X = R$, then we do not need the product of Jacobi rotations. The problem is that in the case $m \gg n$ the rotations on $A$ are too expensive, and that in both cases ($A$ or $R$) the convergence is slower than in the case $X = R^T$.

In the case $X = R^T$, we need the accumulated product of the Jacobi rotations, and the cost of the product of only one sweep of fast rotations is $2n\rho(\rho - 1) = 2n\rho^2 - 2n\rho$. To this we should also add the cost of heavier memory traffic and increased cache miss probability because two square arrays are transformed. All this is avoided by an extra QR factorization followed by transposition of the triangular factor, which is computed in $2n\rho^2 - 2\rho^3/3$ flops on BLAS 3 level.

In some cases $X = A$ is the perfect choice. For instance, if $H$ is a symmetric positive definite matrix and $P^T H P = AA^T$ its pivoted Cholesky factorization with lower triangular matrix $A$, then $A^T$ has the same properties as $R$ in (2.7). Thus $A \langle V \rangle = U\Sigma$ will be an efficient Jacobi SVD and, since $H = (PU)\Sigma^2(PU)^T$, we obtain the spectral decomposition of $H$ without computing $V$.

In Algorithm 3 we define for a matrix $M$ its property $\tau(M)$ to be *true* if $M$ is of full column rank and the Jacobi SVD algorithm applied to $M$ converges quickly. For instance, if $A$ is the Cholesky factor of positive definite matrix, computed with pivoting, then $\tau(A) = \mathit{true}$. If evaluation of $\tau(A)$ requires more than $O(mn)$ flops, or if we do not know how to judge $A$, then by definition $\tau(A) = \mathit{false}$.

**Algorithm 3** $(\sigma, U) = SVD(A)$.

```
if $\tau(A)$ then {e.g., $A$ computed by pivoted Cholesky factorization, $P^T H P = AA^T$}
    $X = A$; $X_\infty = X \langle V_x \rangle$ ;
    $\sigma_i = \|X_\infty(:,i)\|_2, \quad i = 1, \ldots, n$ ; $\boxed{\sigma = (\sigma_1, \ldots, \sigma_n)}$ ;
    $\boxed{U(:,i) = \frac{1}{\sigma_i} X_\infty(:,i), \quad i = 1, \ldots, n}$ ;
else
    $(P_r A)P = Q \begin{pmatrix} R \\ 0 \end{pmatrix}$; $\rho = \mathrm{rank}(R)$ ; [optional deflation, section 2.2][optional $P_r$, section 5.3]
    if $\tau(R)$ then {e.g., $\max_{i=2:n} \|R(1:i-1,i)\|_2/|r_{ii}|$ small}
        $X = R$ ; $X_\infty = X \langle V_x \rangle$ ;
        $\sigma_i = \|X_\infty(:,i)\|_2, \quad i = 1, \ldots, \rho$ ; $\boxed{\sigma = (\sigma_1, \ldots, \sigma_\rho, 0, \ldots, 0)}$ ;
        $U_x(:,i) = \frac{1}{\sigma_i} X_\infty(:,i), \quad i = 1, \ldots, \rho$; $\boxed{U = P_r^T Q \begin{pmatrix} U_x \\ 0_{(m-\rho)\times\rho} \end{pmatrix}}$ ;
    else
        $R(1:\rho, 1:n)^T P_1 = \langle Q_1 \rangle R_1$ ; [optional pivoting $P_1$]
        $X = R_1^T$ ; $X_\infty = X \langle V_x \rangle$ ;
        $\sigma_i = \|X_\infty(:,i)\|_2, \quad i = 1, \ldots, \rho$ ; $\boxed{\sigma = (\sigma_1, \ldots, \sigma_\rho, 0, \ldots, 0)}$ ;
        $U_x(:,i) = \frac{1}{\sigma_i} X_\infty(:,i), \quad i = 1, \ldots, \rho$; $\boxed{U = P_r^T Q \begin{pmatrix} P_1 U_x \\ 0_{(m-\rho)\times\rho} \end{pmatrix}}$ ;
    end if
end if
```

### 4.4. Computation of $U$, $\Sigma$, and $V$.

In this section we describe an efficient implementation of the preconditioned Jacobi SVD algorithm for computing the full SVD. The classical implementation of the Jacobi SVD algorithm transforms two matrices, one approaching the matrix of the left singular vectors scaled by the corresponding singular values ($U\Sigma$), and the second being the accumulated product of the Jacobi rotations ($V$). We extend an idea from [14] and compute the product of Jacobi rotations a posteriori from a well-conditioned matrix equation. In this way, the expensive iterative part has fewer flops and needs less cache space. The rotations are explicitly accumulated only if none of four candidate matrix equations can guarantee an accurate solution.

#### 4.4.1. Classical computation of $V$ by accumulation.

Let the Jacobi iterations stop at index $\overline{k}$ and let $\tilde{X}_\infty = \tilde{X}^{(\overline{k})}$. Let $\tilde{V}_x$ be the computed accumulated product of Jacobi rotations used to compute $\tilde{X}_\infty$. Rowwise backward stability implies that $\tilde{X}_\infty = (X + \delta X)\hat{V}_x$, where $\hat{V}_x$ is orthogonal, and $\|\delta X(i,:)\|_2 \leq \epsilon_J \|X(i,:)\|_2$, $\epsilon_J \leq O(n\varepsilon)$; see [13]. The matrix $\tilde{V}_x$ can be written as $\tilde{V}_x = (I + E_0)\hat{V}_x$, where $\|E_0\|_2$ is small. In fact, $\max_i \|E_0(i,:)\|_2 \leq \varepsilon_J$. Note that the matrix $\hat{V}_x$ is a purely theoretical entity—it exists only in the proof of the backward stability. If we want to recover $\hat{V}_x$, the best we can do is to compute

$$X^{-1}\tilde{X}_\infty = (I + E_1)\hat{V}_x, \quad E_1 = X^{-1}\delta X, \tag{4.1}$$

since we do not have $\delta X$. Thus, we can come $\|E_1\|_2$ close to $\hat{V}_x$. To estimate $E_1$, we write $X = DY$, where $D$ is diagonal scaling, $D_{ii} = \|X(i,:)\|_2$, and $Y$ has unit rows in the Euclidean norm. We obtain for $\|\cdot\| \in \{\|\cdot\|_2, \|\cdot\|_F\}$

$$\|E_1\| \le \|Y^{-1}\|_2 \|D^{-1}\delta X\| \le \|Y^{-1}\|_2 \sqrt{n}\epsilon_J \le \|Y^{-1}\|_2 O(n^{3/2})\boldsymbol{\varepsilon}. \tag{4.2}$$

Finally, the matrix $\tilde{X}_\infty$ is written as $\tilde{U}_x\tilde{\Sigma}$. The diagonal entries of $\tilde{\Sigma}$ are computed as $\tilde{\Sigma}_{ii} = \tilde{\sigma}_i = \mathit{computed}(\|\tilde{X}_\infty(:,i)\|_2) = \|\tilde{X}_\infty(:,i)\|_2(1+\nu_i)$, $|\nu_i| \le O(n\boldsymbol{\varepsilon})$, and then $\tilde{U}_x(:,i)$ is computed by dividing $\tilde{X}_\infty(:,i)$ by $\tilde{\sigma}_i$. Thus,

$$\tilde{U}_x\tilde{\Sigma} = \tilde{X}_\infty + \delta\tilde{X}_\infty, \quad |\delta\tilde{X}_\infty| \le \boldsymbol{\varepsilon}|\tilde{X}_\infty|. \tag{4.3}$$

If $\tilde{\sigma}_i$ is computed using a double accumulated dot product, then $|\nu_i| \le O(\boldsymbol{\varepsilon})$ and the columns of $\tilde{U}_x$ are of unit norm up to $O(\boldsymbol{\varepsilon})$. The following proposition explains how well the computed SVD resembles the matrix $X$.

PROPOSITION 4.1. *The matrices* $\tilde{U}_x$, $\tilde{\Sigma}$, $\tilde{V}_x$, $\hat{V}_x$ *satisfy residual relations*

$$\text{(i)}\quad \tilde{U}_x\tilde{\Sigma}\hat{V}_x^T = X + F = X(I + X^{-1}F); \quad \text{(ii)}\quad \tilde{U}_x\tilde{\Sigma}\tilde{V}_x^T = (X+F)(I+E_0^T),$$

*where for all* $i$, $\|F(i,:)\|_2 \le \overline{\varepsilon_J}\|X(i,:)\|_2$, $\overline{\varepsilon_J} = \varepsilon_J + \boldsymbol{\varepsilon}(1+\varepsilon_J)$. *Further,* $\|E_0\|_2 \le \sqrt{n}\varepsilon_J \le O(n^{3/2}\boldsymbol{\varepsilon})$, *and* $\|X^{-1}F\|_2 \le \|Y^{-1}\|_2\sqrt{n}\overline{\varepsilon_J}$.

*Proof.* From the relations $\tilde{X}_\infty = (X+\delta X)\hat{V}_x$ and (4.3) we obtain $\tilde{U}_x\tilde{\Sigma}\hat{V}_x^T = X+F$, $F = \delta X + \delta\tilde{X}_\infty\hat{V}_x^T$, and for (ii) we use $\tilde{V}_x = (I+E_0)\hat{V}_x$. ☐

**4.4.2. Computation of $V$ from matrix equation.** Suppose that, instead of $\tilde{V}_x$, we decide to use some other approximation of $\hat{V}_x$. The matrix $X^{-1}\tilde{X}_\infty$ is a good candidate (it gets $\|E_1\|_2$ close to $\hat{V}_x$), but we cannot have the exact value of $X^{-1}\tilde{X}_\infty$. We can solve the matrix equation and take $\breve{V}_x = \mathit{computed}(X^{-1}\tilde{X}_\infty)$. Since $X$ is triangular, the residual bound for $\breve{V}_x$ is

$$E_2 = X\breve{V}_x - \tilde{X}_\infty, \quad |E_2| \le \epsilon_T|X||\breve{V}_x|, \quad \epsilon_T \le \frac{n\boldsymbol{\varepsilon}}{1-n\boldsymbol{\varepsilon}}. \tag{4.4}$$

From (4.1) and (4.4) we conclude that

$$\breve{V}_x = (I+E_3)\hat{V}_x = \hat{V}_x(I + \hat{V}_x^T E_3 \hat{V}_x), \quad E_3 = E_1 + X^{-1}E_2\hat{V}_x^T, \tag{4.5}$$

where only the symmetric part $Sym(E_3) = 0.5(E_3 + E_3^T)$ contributes to the first order departure from orthogonality of $\breve{V}_x$, $\|\breve{V}_x^T\breve{V}_x - I\|_2 \le 2\|Sym(E_3)\|_2 + \|E_3\|_2^2$.

The following proposition shows that we have also computed a rank revealing decomposition of $X$ (in the sense of [10]).

PROPOSITION 4.2. *The matrices* $\tilde{U}_x$, $\tilde{\Sigma}$, $\breve{V}_x$ *satisfy the residual relations*

$$\tilde{U}_x\tilde{\Sigma}\breve{V}_x^T = (X+F)(I+E_3^T), \quad E_3 = E_1 + X^{-1}E_2\hat{V}_x^T; \tag{4.6}$$

$$\tilde{U}_x\tilde{\Sigma}\breve{V}_x^{-1} = X + F_1, \quad F_1 = E_2\breve{V}_x^{-1} + \delta\tilde{X}_\infty\breve{V}_x^{-1}, \tag{4.7}$$

*where* $F$ *is as in Proposition* 4.1, $\|E_3\|_2 \le \|Y^{-1}\|_2(\sqrt{n}\varepsilon_J + n\epsilon_T)$, *and it holds for all* $i$ *that* $\|F_1(i,:)\|_2 \le (\varepsilon_T\||\breve{V}_x|\|_2 + \boldsymbol{\varepsilon}(1+\varepsilon_J))\|\breve{V}_x^{-1}\|_2\|X(i,:)\|_2$.

This analysis shows that the quality of the computed right singular vector matrix $\breve{V}_x$ depends on the condition number $\|Y^{-1}\|_2$, where $X = DY$. Hence, the rows of the triangular matrix $X$ must be well-conditioned in the scaled sense. If $X$ is computed from the initial $A$ using the QR factorization with column pivoting, $AP = Q\begin{pmatrix} R^T & 0 \end{pmatrix}^T$, then $X = R$ can be written as $X = DY$ with well-conditioned $Y$.

Thus, we expect that $\check{V}_x$ can be computed accurately, but immediately notice a drawback. The Jacobi rotations implicitly transform the matrix $P^T(A^TA)P$, which means that we do not have the preconditioning effect—for that the input matrix to Jacobi procedure should be $X^T = Y^TD$.

We conclude that the initial matrix should be of the form $X = DY = ZC$, where $D$, $C$ are diagonal and both $Y$ and $Z$ are well-conditioned. Well-conditioned $Z$ implies fast convergence, while well-conditioned $Y$ ensures stable a posteriori computation of the right singular vectors. Therefore, we define $X$ in the following way:

(i) $AP = Q\begin{pmatrix} R^T & 0 \end{pmatrix}^T$;
(ii) $R^TP_1 = Q_1R_1$;
(iii) $X = R_1^T$.

The matrix $R$ can be written as $R = D_rR_r$ with well-conditioned $R_r$, and if we write $R_1 = (R_1)_c(D_1)_c$, then $\kappa((R_1)_c) = \kappa(R_r)$; thus $X = DY$ with $D = (D_1)_c$, $Y = (R_1)_c^T$. Further, $R_1 = (D_1)_r(R_1)_r$ with the expected value of $\kappa((R_1)_r)$ smaller than $\kappa((R_1)_c)$, and thus $X = ZD_c$ with well-conditioned $Z$. In fact, $Z^TZ$ is very strongly diagonally dominant. We have strong numerical evidence that the pivoting in the second QR factorization is not worth the overhead. If we have an efficient QR factorization with local pivoting, such overhead is negligible. Note that $X = R_1$ also has the required properties. Without column pivoting in the second QR factorization ($P_1 = I$) we cannot give any theoretical bound on the condition number of $Y$, and condition estimators must be used. Putting all of this together, we obtain Algorithm 4.

Since the key matrices in the algorithm are all triangular, condition estimators can be used to control the program flow. We can decide which matrix is the best input to the one-sided Jacobi algorithm, or which matrix equation to solve. For instance, in the case $\rho = n$ and small $\kappa_1$, the SVD $R_1^T = U_x\Sigma V_x^T$ implies $V_x = R_1^{-T}(U_x\Sigma)$, but we also note that $R(Q_1V_x) = (U_x\Sigma)$. It can be shown (as in section 4.4.2) that computing $W = Q_1V_x$ very efficiently as $R^{-1}X_\infty$ is numerically as accurate as first computing $V_x = R_1^{-T}X_\infty$ and then multiplying $Q_1V_x$. (Similar situations occur in the case of well-conditioned $Y$ and $X = L_2$, where $Q_2^TV_x$ is computed directly as $R_1^{-1}X_\infty$.) Since in each major step we have estimates of relevant condition number (of scaled matrices), the algorithm can be authorized (an input option) to drop some small singular values if the condition number test shows that they are highly sensitive.

The last line of defense in Algorithm 4 computes with explicit accumulation of Jacobi rotations. So far, we know of no example in which accumulation of Jacobi rotation is needed, because the previous three preconditioning steps failed to produce $X$, which is structured as $X = DY$ with moderate $\|Y^{-1}\|_2$. In fact, we never had the case that required $X = L_2^T$. The worst-case example, which probably already has crossed the reader's mind, is Kahan's matrix [26].

*Example* 4.1. It is instructive to see how our algorithm deals with the upper triangular Kahan's matrix $K = K(m,c)$ with $K_{ii} = s^{i-1}$ and $K_{ij} = -c\cdot s^{i-1}$ for $i < j$, where $s^2 + c^2 = 1$. Using MATLAB, we generate $K(100, 0.9998)$. It is estimated that $\kappa_1 \approx \|R_r^{-1}\|$ is bigger than $10^{16}$. Now, the trick here is that our entropy test will transpose the matrix automatically and take $A = K^T$ instead of $A = K$. In that case the estimated $\kappa_1$ is around one. Suppose now that the transposing mechanism is switched off, or that, e.g., $A = K(1:m, 1:n)$, $n < m$, so that no transposition is allowed. Let $A$ be equal to the first 90 columns of $K$. Again, $\kappa_1 > 10^{16}$, but $\kappa_Y \approx 1$.

## 5. Assessing the accuracy of the computed SVD.

In this section we analyze numerical properties of the new algorithm. To simplify the notation, we drop the permutation matrices, thus assuming that $A$ is replaced with the permuted matrix

**Algorithm 4** $(U, \sigma, V) = \mathrm{SVD}(A)$.

$P_rAP$. The computed matrices are marked by *tildes*, and by *hats* we denote matrices whose existence is obtained during backward error analysis (they are usually close to the corresponding matrices marked with tildes). We note that detailed analysis is given without the details of the triangular SVD computation $X_\infty = XV_x$. We only need the fact that the computed $\tilde{X}_\infty$, $\tilde{V}_x$ satisfy $\tilde{X}_\infty = (X + \delta X)\hat{V}_x$, where for all $i$ $\|\delta X(i,:)\|_2 \leq \varepsilon_J \|X(i,:)\|_2$, $\varepsilon_J \leq O(n\boldsymbol{\varepsilon})$, and $\hat{V}_x$ is exactly orthogonal, close to $\tilde{V}_x$. This is independent of the pivot strategy. For the sake of brevity we will not analyze all variants of algorithms given in section 4.

### 5.1. Backward error analysis.

The following proposition is central to the analysis of Algorithms 1 and 2. It gives backward stability with a rather strong columnwise estimate of the relative backward error.

PROPOSITION 5.1. *Let the SVD of the real $m \times n$ matrix $A$ be computed by reducing $A$ to triangular form, $A = Q\begin{pmatrix} R^T & 0\end{pmatrix}^T$, and then applying the Jacobi SVD algorithm to $X = R^T$. If only the singular values or singular values and the right singular vectors are needed (Algorithms 1 or 2), then the backward stability of the computation can be described as follows:*

(i) *Let $X \approx \tilde{U}_x \tilde{\Sigma} \langle \tilde{V}_x^T \rangle$ be the computed SVD of the computed matrix $X$. Then there exist a columnwise small perturbation $\Delta A$ and orthogonal matrices $\hat{Q}$, $\hat{V}_x$ such that*

$$A + \Delta A = \hat{Q}\begin{pmatrix} \hat{V}_x & 0 \\ 0 & I \end{pmatrix}\begin{pmatrix} \tilde{\Sigma} \\ 0 \end{pmatrix}\tilde{U}_x^T, \quad \textit{where} \tag{5.1}$$

$$\|\Delta A(:,i)\|_2 \leq \tilde{\eta}\|A(:,i)\|_2, \;\; i = 1, \ldots, n, \;\; \tilde{\eta} = \varepsilon_{qr} + \overline{\varepsilon_J} + \varepsilon_{qr}\overline{\varepsilon_J}. \tag{5.2}$$

(ii) *Furthermore, let $\varepsilon_u \equiv \|\tilde{U}_x^T\tilde{U}_x - I\|_F < 1/2$. There exist a backward perturbation $\mathcal{E}$ and orthogonal matrix $\hat{U}$ such that $\|\tilde{U}_x - \hat{U}\|_F \leq \sqrt{2}\varepsilon_u$ and the SVD of $A + \mathcal{E}$ is*

$$A + \mathcal{E} = \hat{Q}\begin{pmatrix} \hat{V}_x & 0 \\ 0 & I \end{pmatrix}\begin{pmatrix} \tilde{\Sigma} \\ 0 \end{pmatrix}\hat{U} \equiv \hat{U}_a\begin{pmatrix} \tilde{\Sigma} \\ 0 \end{pmatrix}\hat{V}_a^T, \quad \textit{where} \tag{5.3}$$

$$\|\mathcal{E}(:,i)\|_2 \leq \hat{\eta}\|A(:,i)\|_2, \;\; \hat{\eta} = \tilde{\eta} + \sqrt{2n}\varepsilon_u + O(\boldsymbol{\varepsilon}^2) \quad \textit{for all } i. \tag{5.4}$$

*Proof.* Let $\tilde{Q}$ and $\tilde{R}$ be the computed numerically orthogonal and the triangular factor of $A$, respectively. Then there exist an orthogonal matrix $\hat{Q}$ and backward perturbation $\delta A$ such that $A + \delta A = \hat{Q}\begin{pmatrix} \tilde{R}^T & 0 \end{pmatrix}^T$, where for all column indices $\|\delta A(:,i)\|_2 \leq \varepsilon_{qr}\|A(:,i)\|_2$. Let the one-sided Jacobi SVD be applied to $X = \tilde{R}^T$. By Proposition 4.1, $X + F = \tilde{U}_x\tilde{\Sigma}\hat{V}_x^T$, $\|F(i,:)\|_2 \leq \overline{\varepsilon_J}\|X(i,:)\|_2$, and therefore

$$A + \delta A + \hat{Q}\begin{pmatrix} F^T \\ 0 \end{pmatrix} = \hat{Q}\begin{pmatrix} \hat{V}_x & 0 \\ 0 & I \end{pmatrix}\begin{pmatrix} \tilde{\Sigma} \\ 0 \end{pmatrix}\tilde{U}_x^T, \;\; \Delta A = \delta A + \hat{Q}\begin{pmatrix} F^T \\ 0 \end{pmatrix}, \tag{5.5}$$

where $\|\Delta A(:,i)\|_2 \leq \varepsilon_{qr}\|A(:,i)\|_2 + \overline{\varepsilon_J}\|\tilde{R}(:,i)\|_2$, $\|\tilde{R}(:,i)\|_2 \leq (1 + \varepsilon_{qr})\|A(:,i)\|_2$, and (5.1), (5.2) follow. Note that the right-hand side of relation (5.1) is not an SVD. To obtain a relation with the SVD of a matrix in the vicinity of $A$, we need to replace $\tilde{U}_x$ with a nearby orthogonal matrix. However, since the backward error $\Delta A$ is columnwise small, we need to do this carefully and preserve this fine structure of the backward error. Since $\tilde{U}_x$ is on the right-hand side, correcting its departure from orthogonality implies certain linear combinations of the columns of $A + \Delta A$. If $A$ has very large and very small columns, then such linear combinations may introduce large perturbations into the small ones. This is why we cannot use the orthogonal polar factor of $\tilde{U}_x$ as the closest orthogonal matrix. We proceed with the following thought experiment.

Let $\Pi$ be a permutation matrix such that the columns of $A\Pi$ have decreasing Euclidean lengths.[4] Let $\Pi^T\tilde{U}_x = (I + G_0^T)\hat{U}_x$ be the RQ factorization of $\Pi^T\tilde{U}_x$, with lower triangular $G_0$ and orthogonal $\hat{U}_x$. Since $\tilde{U}_x$ is numerically orthogonal, we can nicely estimate $G_0$. First, $I + G_0$ is regular.

From the Cholesky factorization $(I + G_0)(I + G_0)^T = I + \hat{U}_x(\tilde{U}_x^T\tilde{U}_x - I)\hat{U}_x^T$, we conclude, using [17], that $\|G_0\|_F \leq \sqrt{2}\varepsilon_u$. Let $I + G = (I + G_0)^{-1}$. Obviously, $G$ is lower triangular. Since $G = -G_0 + G_0^2(I + G_0)^{-1}$, it holds that $\|G\|_1 \leq \|G_0\|_1 + \|G_0\|_1^2/(1 - \|G_0\|_1)$. From (5.5) we obtain the SVD

$$(A + \Delta A)(I + \Pi G\Pi^T) = \hat{Q}\begin{pmatrix}\hat{V}_x & 0\\ 0 & I\end{pmatrix}\begin{pmatrix}\tilde{\Sigma}\\ 0\end{pmatrix}(\Pi\hat{U}_x)^T. \tag{5.6}$$

Note that small $\|\Pi G\Pi^T\|_1 = \|G\|_1 \approx \|G_0\|_1$ does not automatically mean columnwise small backward perturbation in $A$. Let us estimate the columns of $A\Pi G\Pi^T$. Note that in the multiplication $A\Pi G$ each column of $A$ gets a contribution only from columns that are smaller in norm, i.e., $A\Pi G(:,i) = \sum_{k=i}^{n} g_{ki}(A\Pi)(:,k)$, and thus $\|A\Pi G(:,i)\|_2 \leq \|G\|_1\|(A\Pi)(:,i)\|_2$. Since $\Pi^T$ redistributes the columns back to the original order, we have $\|(A\Pi G\Pi^T)(:,i)\|_2 \leq \|G\|_1\|A(:,i)\|_2$.

Similarly, $\|(\Delta A\Pi G\Pi^T)(:,i)\|_2 \leq \tilde{\eta}\|G\|_1\|A(:,i)\|_2$. Note that from the relation $\tilde{U}_x = (I + \Pi G_0^T\Pi^T)(\Pi\hat{U}_x)$ we easily find that the matrix $\hat{U} = \Pi\hat{U}_x$ satisfies $\|\hat{U} - \tilde{U}_x\|_F \leq \|G_0\|_F$. Finally, note that (5.6) defines $\mathcal{E}$ in relation (5.3). ☐

Consider now the computation of the full SVD with a single preconditioning step.

PROPOSITION 5.2. *Let* $A \approx \tilde{Q}\binom{\tilde{R}}{0}$ *be the computed QR factorization of* $A$. *Let the computed SVD of* $X = \tilde{R}^T$ *be* $X \approx \tilde{U}_x\tilde{\Sigma}\overline{V}_x$, *where the following hold.*

(a) $\overline{V}_x = \tilde{V}_x$ *if* $\overline{V}_x$ *is computed as the accumulated product of Jacobi rotations (Proposition* 4.1*). In that case* $\|\overline{V}_x - \hat{V}_x\|_F \leq \sqrt{n}\varepsilon_J$.

(b) $\overline{V}_x = \breve{V}_x$ *if* $\overline{V}_x$ *is computed from the triangular matrix equation (Proposition* 4.2*). In that case* $\|\overline{V}_x - \hat{V}_x\|_F \leq \|Y^{-1}\|_2(\sqrt{n}\varepsilon_J + n\varepsilon_T)$, *where* $Y = \mathrm{diag}(1/\|X(i,:)\|_2)X$.

*Let* $\tilde{V}_a = \tilde{U}_x$, $\hat{V}_a = \hat{U}$, *where* $\hat{U}$ *is as in Proposition* 5.1 *and let*

$$\hat{U}_a = \hat{Q}\begin{pmatrix}\hat{V}_x & 0\\ 0 & I\end{pmatrix}, \quad \tilde{U}_a = computed\left(\tilde{Q}\begin{pmatrix}\overline{V}_x & 0\\ 0 & I\end{pmatrix}\right).$$

*Then* $\|\tilde{U}_a - \hat{U}_a\|_2 \leq \sqrt{m}\varepsilon_{qr} + \|\overline{V}_x - \hat{V}_x\|_2 + O(\varepsilon^2)$, $\|\tilde{V}_a - \hat{V}_a\|_F \leq \sqrt{2}\varepsilon_u$, *and the residual (that is, the backward error)*

$$\Delta' A = \tilde{U}_a\begin{pmatrix}\tilde{\Sigma}\\ 0\end{pmatrix}\tilde{V}_a^T - A = (I + (\tilde{U}_a - \hat{U}_a)\hat{U}_a^T)(A + \Delta A) - A \tag{5.7}$$

*satisfies* $\|\Delta' A(:,i)\|_2 \leq \tilde{\eta}'\|A(:,i)\|_2$, $\quad \tilde{\eta}' = \tilde{\eta} + \|\tilde{U}_a - \hat{U}_a\|_2 + \tilde{\eta}\|\tilde{U}_a - \hat{U}_a\|_2$.

*Proof.* In addition to the proof of Proposition 5.1, we need an estimate for $\tilde{U}_a - \hat{U}_a$. Note that $\tilde{U}_a$ is computed using Householder vectors computed in the QR factorization, and then replace $\overline{V}_x$ with $\hat{V}_x + (\overline{V}_x - \hat{V}_x)$. ☐

---

[4] One should keep in mind that $\Pi$ is an object in our thought experiment, unrelated to actual pivoting in the algorithm.

**5.2. Backward errors for two preconditionings.** In the case $X = R^T$ all transformations are applied to $A$ from the same side, $\binom{\Sigma}{0}U_x^T = (V_x^T \oplus I)Q^T A$. This fact is the key for columnwise small backward error. In the case of two QR factorizations in the preconditioning phase, where $X = R_1^T$, columnwise small backward error in $A$ is not obvious, because in that case we compute ULV decomposition by transforming $A$ from both sides.

THEOREM 5.3. *For the computed matrix* $\tilde{X}_\infty \approx \tilde{U}_x\tilde{\Sigma}$, *there exist backward perturbation* $\Delta A$, *permutation* $\tilde{P}_1$, *and orthogonal* $\hat{Q}$, $\hat{Q}_1$, $\hat{V}_x$, $S$ *such that*

$$\begin{pmatrix} \tilde{U}_x\tilde{\Sigma} \\ 0 \end{pmatrix} \approx \begin{pmatrix} \tilde{X}_\infty \\ 0 \end{pmatrix} = \begin{pmatrix} \tilde{P}_1^T & 0 \\ 0 & I_{m-n} \end{pmatrix} \hat{Q}^T (A + \Delta A) S \hat{Q}_1 \hat{V}_x^T. \tag{5.8}$$

*For each* $i$, $\Delta A(:,i)$ *is a small relative perturbation of* $A(:,i)$, *and* $S$ *is close to identity.*

*Proof.* The second factorization $R^T P_1 = Q_1 R_1$ is computed as $(\tilde{R}^T + \delta\tilde{R}^T)\tilde{P}_1 = \hat{Q}_1\tilde{R}_1$, where $\|\delta\tilde{R}(i,:)\|_2 \le \varepsilon_{qr}\|\tilde{R}(i,:)\|_2$. Jacobi rotations are applied to $X = \tilde{R}_1^T$, which yields $\tilde{X}_\infty = (X + \delta X)\hat{V}_x$, $\|\delta X(i,:)\|_2 \le \varepsilon_J\|X(i,:)\|_2$. This means that $\tilde{R}_1$ is changed backward to $\tilde{R}_1 + \delta\tilde{R}_1$ with columnwise bound $\|\delta\tilde{R}_1(:,i)\|_2 \le \varepsilon_J\|\tilde{R}_1(:,i)\|_2$. To push $\delta\tilde{R}_1$ further backward we have to change $\tilde{R}$. It is easy to check that $\Delta\tilde{R} = \delta\tilde{R} + \tilde{P}_1\delta\tilde{R}_1^T\hat{Q}_1^T$ is a rowwise small perturbation of $\tilde{R}$ with the property

$$(\tilde{R}^T + \Delta\tilde{R}^T)\tilde{P}_1 = \hat{Q}_1(\tilde{R}_1 + \delta\tilde{R}_1). \tag{5.9}$$

Write $\tilde{R} + \Delta\tilde{R} = \tilde{R}(I + E)$ with $E = \tilde{R}^{-1}\Delta\tilde{R}$, and let $\tilde{R} = D_r\tilde{R}_r$ with $D_r = \mathrm{diag}(\|\tilde{R}(i,:)\|_2)_{i=1}^n$. It is easily shown that $\|E\|_F \le \sqrt{n}(\varepsilon_{qr} + \varepsilon_J(1 + \varepsilon_{qr}))\|\tilde{R}_r^{-1}\|_2$. Note that this bound depends on $\|\tilde{R}_r^{-1}\|_2$, which in our case is at most $O(n)$.

Let $\Delta A_0 = \delta A + \hat{Q}\left( (\Delta\tilde{R})^T \quad 0 \right)^T$. Then we almost have the explicit backward relationship (5.8) with columnwise bound. The backward perturbed matrix is

$$A + \Delta_0 A = (A + \delta A)(I + E) \quad (= (I + \delta A A^\dagger)A(I + E) \text{ if } \mathrm{rank}(A) = n). \tag{5.10}$$

Note that $I + E$ represents multiplicative backward perturbation, which immediately and cleanly exposes its corresponding forward error. However, additive backward perturbation might be more desirable and interpretable. Therefore, we are going to transform the multiplicative part into an additive one. If the columns of $A + \delta A$ are not ordered from large to small in the Euclidean norm, then we order them using permutation $\Pi$ and write $(A + \delta A)(I + E) = (A + \delta A)\Pi(I + \Pi^T E \Pi)\Pi^T$.

If $I + \Pi^T E \Pi = L S_0$ is the LQ factorization, then we can write $L = I + F$ with lower triangular $F$ and $\|F\|_F \le O(1)\|E\|_F$. The orthogonal matrix $S_0$ is close to identity. Then we have

$$(A + \delta A)(I + E) = (A + \delta A)\Pi(I + F)S_0\Pi^T = ((A + \delta A)\Pi + (A + \delta A)\Pi F)S_0\Pi^T,$$

where $\|((A + \delta A)\Pi F)(:,i)\|_2 \le \|F\|_1\|((A + \delta A)\Pi)(:,i)\|_2$. If we permute the columns of $A + \delta A$ back to the original order, we obtain

$$A + \Delta A_0 = (A + \delta A)(I + E) = (A + \delta A + \delta_1 A)\Pi S_0 \Pi^T, \tag{5.11}$$

where $\|\delta_1 A(:,i)\|_2 \le (1 + \varepsilon_{qr}(A))\|F\|_1\|A(:,i)\|_2$, $i = 1, \ldots, n$. Using this in (5.8), we conclude that $\tilde{U}_x\tilde{\Sigma}$ is computed by orthogonal transformations on $A + \delta A + \delta_1 A$, where the perturbation $\Delta A = \delta A + \delta_1 A$ is columnwise small, and $S = \Pi S_0 \Pi^T$. ☐

The practical value of this is that no matter how the columns of $A$ are scaled, the algorithm computes the SVD of $A$ with columnwise small backward relative error.

**5.3. Complete pivoting and two-sided scaling.** In [14], we recommended that the rows of $A$ be sorted before the first QR factorization with column pivoting, thus having the effect of complete pivoting suggested by Powell and Reid [30]. The reason was more structured backward error, as shown in [9]. It is important that the whole algorithm preserves this structured perturbation.

THEOREM 5.4. *Let $A = D_1 C D_2$, where $D_1$, $D_2$ are diagonal matrices, be prepivoted so that the computed QR factorization satisfies*

$$D_1(C + \delta C)D_2 = \hat{Q}\begin{pmatrix} \tilde{R} \\ 0 \end{pmatrix}, \quad \hat{Q}^T\hat{Q} = I_m. \tag{5.12}$$

*Let $q = \max_{i\geq j} |(D_2)_{ii}/(D_2)_{jj}|$. There exists an orthogonal matrix $S$, close to identity, such that the backward perturbation in Theorem* 5.3 *can be written as*

$$\begin{pmatrix} \tilde{U}_x\tilde{\Sigma} \\ 0 \end{pmatrix} \approx \begin{pmatrix} \tilde{X}_\infty \\ 0 \end{pmatrix} = \begin{pmatrix} \tilde{P}_1^T & 0 \\ 0 & I_{m-n} \end{pmatrix} \hat{Q}^T D_1(C + \Delta C)D_2 S\hat{Q}_1\hat{V}_x^T. \tag{5.13}$$

*It holds that $\|\Delta C\|_F \leq \|\delta C\|_F + q\sqrt{8}\|E\|_F(\|C\|_2 + \|\delta C\|_2) + O(\|E\|_F^2)$.*

*Proof.* We go back to relation (5.10) and rewrite it as

$$A + \Delta A = (A + \delta A)(I + E) = D_1(C + \delta C)D_2(I + E). \tag{5.14}$$

If $I + E = (I + F)S$ is the LQ factorization, then $\|F\|_F \leq \sqrt{8}\|E\|_F + \sqrt{2}\|E\|_F^2$, provided that $\|E\|_F \leq 1/5$; see [17]. Further, $\|I - S\|_2 \leq \|E\|_2 + \|F\|_2$, and

$$A + \Delta A = D_1(C + \delta C)(I + F_1)D_2 S, \quad F_1 = D_2 F D_2^{-1}, \quad \|F_1\|_F \leq q\|F\|_F. \tag{5.15}$$

If we let $\Delta C = \delta C + CF_1 + \delta CF_1$, then using (5.8) we obtain (5.13). ☐

For SVD perturbation under this backward error with two-sided scaling we refer to [33], [9], [14], [10], [15], [24].

**5.4. Forward relative errors in the computed SVD.** Since the Jacobi SVD algorithm has columnwise small backward error, the condition number for the errors in the singular values of $A+\delta A = (I+\delta AA^\dagger)A$ is up to a $\sqrt{n}$ factor $\min_{D=\mathrm{diag}} \kappa_2(AD)$. This is in sharp contrast with bidiagonalization-based methods where the backward error has no columnwise structure and the condition number is $\kappa_2(A)$.

THEOREM 5.5. *Consider $A \in \mathbb{R}^{m\times n}$ with the SVD $A = U\binom{\Sigma}{0}V^T$ and singular values $\sigma_1 \geq \cdots \geq \sigma_n > 0$. Let $\tilde{\sigma}_1 \geq \cdots \geq \tilde{\sigma}_n$ be the singular values of the perturbed matrix $\tilde{A} = A + \delta A = (I + \Gamma)A$, $\Gamma = \delta AA^\dagger$, and let $\|\Gamma\|_2 < 1$.*

(i) *It holds that*

$$\max_{j=1:n} \frac{|\tilde{\sigma}_j - \sigma_j|}{\sqrt{\tilde{\sigma}_j\sigma_j}} \leq \|Sym(\Gamma)\|_2 + \frac{1}{2}\frac{\|\Gamma\|_2^2}{1 - \|\Gamma\|_2} \leq \|\Gamma\|_2 + O(\|\Gamma\|_2^2). \tag{5.16}$$

(ii) *Let $I+\Xi = \mathrm{diag}(\|(I+\Gamma)U(:,i)\|_2)_{i=1}^n$, $\breve{U} = (I+\Gamma)U(I+\Xi)^{-1}$, $\breve{U}^T\breve{U} = I+\Omega$, and $\hat{\Omega} = \Omega(1:n, 1:n)$. Let the singular values of $\tilde{A}$ be written with multiplicities as*

$$\tilde{\sigma}_1 = \cdots = \tilde{\sigma}_{\tilde{s}_1} > \tilde{\sigma}_{\tilde{s}_1+1} = \cdots = \tilde{\sigma}_{\tilde{s}_2} > \cdots > \tilde{\sigma}_{\tilde{s}_{\tilde{\ell}-1}+1} = \cdots = \tilde{\sigma}_{\tilde{s}_{\tilde{\ell}}}, \quad \tilde{s}_{\tilde{\ell}} = n, \quad \tilde{s}_0 \equiv 0,$$

*and let the relative gaps be defined by $\tilde{\gamma}_i = \min_{j\neq i} \frac{|\tilde{\sigma}_{\tilde{s}_i}^2 - \tilde{\sigma}_{\tilde{s}_j}^2|}{\tilde{\sigma}_{\tilde{s}_i}^2 + \tilde{\sigma}_{\tilde{s}_j}^2}$, $i = 1, \ldots, \tilde{\ell}$, $\tilde{\gamma} = \min_i \tilde{\gamma}_i$. If $\|\hat{\Omega}\|_2 < \tilde{\gamma}/3$, then for all $i$ and $\breve{\sigma}_j = \sigma_j\|(I + \Gamma)U(:,j)\|_2 = \sigma_j(1 + \Xi_{jj})$*

$$\sqrt{\sum_{j=\tilde{s}_{i-1}+1}^{\tilde{s}_i} \left|\frac{\tilde{\sigma}_{\tilde{s}_i} - \breve{\sigma}_j}{\breve{\sigma}_j}\right|^2} \leq \sqrt{\sum_{j=\tilde{s}_{i-1}+1}^{\tilde{s}_i} \left|1 - \frac{\tilde{\sigma}_{\tilde{s}_i}^2}{\breve{\sigma}_j^2}\right|^2} \leq \frac{2}{\tilde{\gamma}_i}\|\hat{\Omega}\|_2^2.$$

*In particular,* $\max_{j=1:n} \frac{|\tilde{\sigma}_j - \breve{\sigma}_j|}{\breve{\sigma}_j} \leq \frac{2}{\tilde{\gamma}} \|\hat{\Omega}\|_2^2$.

(iii) *For columnwise small* $\delta A$, $\|\Gamma\|_F \leq \sqrt{n} \max_{i=1:n}(\|\delta A(:,i)\|_2 / \|A(:,i)\|_2) \|A_c^{\dagger}\|_2$, *where* $A_c$ *is obtained by scaling the columns of* $A$ *to have unit norm.*

*Proof.* Since $I + \Gamma$ is nonsingular, we can use [27] and relation $(I+\Gamma)^{-1} = (I - \Gamma) + \Gamma^2 (I+\Gamma)^{-1}$ to conclude that

$$\max_{1 \leq j \leq n} \frac{|\tilde{\sigma}_j - \sigma_j|}{\sqrt{\tilde{\sigma}_j \sigma_j}} \leq \frac{1}{2} \|(I+\Gamma)^{-1} - (I+\Gamma)^T\|_2 = \frac{1}{2} \| - 2 Sym(\Gamma) + \Gamma^2 (I+\Gamma)^{-1}\|_2.$$

Relation (5.16) follows using the fact that $\|\Gamma\|_2 < 1$. Write

$$\tilde{A} = (I+\Gamma) U \begin{pmatrix} \Sigma \\ 0 \end{pmatrix} V^T = \breve{U}(I + \Xi) \begin{pmatrix} \Sigma \\ 0 \end{pmatrix} V^T, \tag{5.17}$$

where $(I+\Gamma)U = \breve{U}(I+\Xi)$ with diagonal matrix $\Xi$ determined so that $\breve{U}$ has unit columns. Obviously, $|\Xi_{ii}| \leq \|\Gamma U(:,i)\|_2$ for all $i$, and $\|\Xi\|_2 \leq \|\Gamma\|_2$. Write $\tilde{A}$ as

$$\tilde{A} = \breve{U} \begin{pmatrix} \breve{\Sigma} \\ 0 \end{pmatrix} V^T, \quad \begin{pmatrix} \breve{\Sigma} \\ 0 \end{pmatrix} = (I + \Xi) \begin{pmatrix} \Sigma \\ 0 \end{pmatrix}, \quad \breve{\Sigma} = \mathrm{diag}(\breve{\sigma}_j)_{j=1}^n, \tag{5.18}$$

and note that $\breve{U}^T \breve{U} = I + \Omega$ with $\Omega_{ii} = 0$ for all $i$. Now,

$$\tilde{A}^T \tilde{A} = V \begin{pmatrix} \breve{\Sigma} & 0 \end{pmatrix} (I + \Omega) \begin{pmatrix} \breve{\Sigma} \\ 0 \end{pmatrix} V^T = V \breve{\Sigma} (I_n + \hat{\Omega}) \breve{\Sigma} V^T, \tag{5.19}$$

where $\hat{\Omega} = \Omega(1:n, 1:n)$. Using the orthogonal similarity in the last relation, we can compare the eigenvalues of $\tilde{A}^T \tilde{A}$ and the corresponding eigenvalues of the matrix $M \equiv \breve{\Sigma}(I_n + \hat{\Omega})\breve{\Sigma}$. A second look at the relations (5.17)–(5.19) reveals the transformation of the multiplicative perturbation $I + \Gamma$ of $A$ into the nonorthogonality of the left singular vector matrix $U$ and then the splitting of the nonorthogonality of $(I+\Gamma)U$ into the column length changes and angle changes. The changes of the unit lengths of the columns of $U$ are then taken as perturbation of $\Sigma$, thus defining $\breve{\Sigma}$.

Note that the matrix $M$ is $\|\hat{\Omega}\|_2$—scaled diagonally dominant (s.d.d.) [2] with eigenvalues $\tilde{\sigma}_1^2 \geq \cdots \geq \tilde{\sigma}_n^2$ and diagonal entries $\breve{\sigma}_1^2 \geq \cdots \geq \breve{\sigma}_n^2$. Using [22, Corollary 3.2] we conclude that

$$\sum_{j=\tilde{s}_{i-1}+1}^{\tilde{s}_i} \left| 1 - \frac{\tilde{\sigma}_{\tilde{s}_i}^2}{(\breve{\sigma}_j)^2} \right|^2 + \sum_{j=\tilde{s}_{i-1}+1}^{\tilde{s}_i} \sum_{k=\tilde{s}_{i-1}+1}^{\tilde{s}_i} \hat{\Omega}_{jk}^2$$
$$\leq \frac{4}{\tilde{\gamma}_i^2} \left( \sum_{j=\tilde{s}_{i-1}+1}^{\tilde{s}_i} \Big( \sum_{k=1}^{\tilde{s}_{i-1}} \hat{\Omega}_{jk}^2 + \sum_{k=\tilde{s}_i+1}^{n} \hat{\Omega}_{jk}^2 \Big) \right)^2 . \qquad \square$$

*Remark* 5.1. Consider the right-handed Jacobi SVD algorithm on $X \in \mathbb{R}^{n \times n}$. Let $\tilde{X}_\infty \equiv \tilde{X}^{(\overline{k})} = (X + \delta X)\hat{V}$ be the computed matrix and $\tilde{X}_\infty + \delta \tilde{X}_\infty = \tilde{U}\tilde{\Sigma}$ as in relation (4.3). Let $\max_{i \neq j} \left|(\tilde{U}^T \tilde{U})_{ij}\right| \leq \tau$, $\max_i \left|1 - \|\tilde{U}(:,i)\|_2\right| \leq \nu$. We wish to know how the sizes of $\tau$ and $\nu$ influence the relative distance between the $\tilde{\sigma}_i = \tilde{\Sigma}_{ii}$ and the corresponding exact singular value $\hat{\sigma}_i$ of $\tilde{U}\tilde{\Sigma}$. As in the proof of Theorem 5.5, we split the perturbation (the departure from orthogonality of $\tilde{U}$) into two parts. Let $\tilde{U} = \breve{U}(I + \Xi)$, where $\breve{U}$ has unit columns and $\Xi$ is a diagonal matrix with

$\|\Xi\|_2 \le \nu$. Write $\tilde{U}\tilde{\Sigma}$ as $\breve{U}\breve{\Sigma}$, where $\breve{\Sigma}$ is the diagonal matrix with diagonal entries $\breve{\sigma}_i = \tilde{\sigma}_i(1 + \Xi_{ii})$. Note that $\nu$ can be as small as $O(\varepsilon)$ with the cost of doubly accumulated dot products, and $O(n\varepsilon)$ if no extra precision is used. The potentially larger and harder to control value $\tau$ enters the estimate quadratically, and that opens a possibility for better stopping criteria. As in Theorem 5.5, we note that $\breve{\Sigma}\breve{U}^T\breve{U}\breve{\Sigma}$ has diagonal entries $\breve{\sigma}_i^2$ and eigenvalues $\hat{\sigma}_i^2$, $i = 1, \ldots, n$. Further, $\Omega = \breve{U}^T\breve{U} - I$ satisfies $\max_{ij} |\Omega_{ij}| \le \tau/(1-\nu)^2$. Let $\|\Omega\|_2 < \hat{\gamma}/3$, where the gap $\hat{\gamma}$ between the $\hat{\sigma}_i^2$'s is analogous to $\tilde{\gamma}$ in Theorem 5.5. Then, if $\hat{k}_i$ is the multiplicity of $\hat{\sigma}_i$, it holds that

$$\frac{|\hat{\sigma}_i - \breve{\sigma}_i|}{\breve{\sigma}_i} \le \frac{2}{\hat{\gamma}_i}\hat{k}_i(n - \hat{k}_i)\frac{\tau^2}{(1-\nu)^4} \le \frac{1}{\hat{\gamma}_i}\frac{n^2\tau^2}{2(1-\nu)^4}. \tag{5.20}$$

*Example* 5.1. We illustrate the application of the relation (5.20) in stopping the Jacobi SVD algorithm. Let $\varepsilon \approx 2.22 \cdot 10^{-16}$, $n = 1000$, and $\tau = 10^{-8}$. Since we do not have the $\hat{\sigma}_i$'s, the relative gaps will be estimated using the computed $\tilde{\sigma}_i$'s. Let $\tilde{U}^T\tilde{U} = I + \tilde{\Omega}$. Then $\|\tilde{\Omega}\|_F \le \omega \equiv \sqrt{n(n-1)\tau^2 + n\nu^2} < 9.9950 \cdot 10^{-6}$ and

$$\max_{i=1:n} \frac{|\hat{\sigma}_i - \tilde{\sigma}_i|}{\sqrt{\hat{\sigma}_i\tilde{\sigma}_i}} \le \|(I + \tilde{\Omega})^{-1/2} - (I + \tilde{\Omega})^{1/2}\|_2 \le \omega_1 \equiv \frac{\omega}{\sqrt{1-\omega}} < 9.9951 \cdot 10^{-6}.$$

From this we conclude that for all $i$

$$\frac{|\hat{\sigma}_i - \tilde{\sigma}_i|}{\min\{\hat{\sigma}_i, \tilde{\sigma}_i\}} \le \omega_2 \equiv \frac{\omega_1}{1-\omega_1} < 9.996 \cdot 10^{-6}, \quad \frac{|\hat{\sigma}_i - \tilde{\sigma}_i|}{\hat{\sigma}_i + \tilde{\sigma}_i} \le \frac{\omega_1}{2} < 4.998 \cdot 10^{-6}.$$

Suppose that we have $n$ different values $\tilde{\sigma}_1 > \cdots > \tilde{\sigma}_n > 0$ and that they are well separated relative to their uncertainty in approximating the $\hat{\sigma}_i$'s, i.e., let

$$\max_{i \ne j} \frac{|\tilde{\sigma}_i - \tilde{\sigma}_j|}{\tilde{\sigma}_i + \tilde{\sigma}_j} > 5\omega > 4.997 \cdot 10^{-5}. \text{ Then } \tilde{\gamma}_i \equiv \min_{j \ne i} \frac{|\tilde{\sigma}_i^2 - \tilde{\sigma}_j^2|}{\tilde{\sigma}_i^2 + \tilde{\sigma}_j^2} > 5\omega.$$

Since the $\hat{\sigma}_i$'s are $O(\omega)$ close to the $\tilde{\sigma}_i$'s, we know that the $\hat{\sigma}_i$'s are simple and that $\hat{\gamma}_i \equiv \min_{j \ne i} \frac{|\hat{\sigma}_i^2 - \hat{\sigma}_j^2|}{\hat{\sigma}_i^2 + \hat{\sigma}_j^2} \ge \tilde{\gamma}_i\big(1 - \frac{\omega_2}{5\omega}\big)\frac{1-\omega_2}{(1+\omega_2)^2} > 0.7999\tilde{\gamma}_i > 3.999\omega > 3\|\Omega\|_2$. Since $\breve{\sigma}_i = \tilde{\sigma}_i(1 + O(10^{-13}))$, we have $\breve{\sigma}_1 > \cdots > \breve{\sigma}_i > \breve{\sigma}_{i+1} > \cdots > \breve{\sigma}_n > 0$. We can now apply the quadratic bound, which yields for each $i$

$$\frac{|\hat{\sigma}_i - \breve{\sigma}_i|}{\breve{\sigma}_i} \le \frac{2}{0.7999}\frac{1}{\tilde{\gamma}_i}(n-1)\frac{\tau^2}{(1-\nu)^4} \le \frac{1}{\tilde{\gamma}_i}2.498 \cdot 10^{-13}. \tag{5.21}$$

Thus, if for instance $\tilde{\gamma}_i > 10^{-3}$, we can claim that $\tilde{\sigma}_i$ coincides with the corresponding $\hat{\sigma}_i$ to about ten decimal places, which actually doubles the previous number by about five known correct digits.

**5.5. Accuracy of the singular vectors.** The structure of the backward error in our algorithm is such that we can use well-developed and sharp perturbation theory [19], [28]. Our starting point is the relation (5.3) in Proposition 5.1, which is the SVD of $A+\mathcal{E}$ with the computed singular values in diagonal $\tilde{\Sigma}$, and exactly orthogonal matrices $\hat{Q}$, $\hat{V}_x$, $\hat{U}$ which are close to the corresponding computed approximations $\tilde{Q}$, $\overline{V}_x$, $\tilde{U}_x$, respectively. We first deal with the singular vector perturbations in the case of simple well-separated singular values. If $\sigma_1 \ge \cdots \ge \sigma_n$ are the singular values of $A = U\big(\begin{smallmatrix}\Sigma \\ 0\end{smallmatrix}\big)V^T$, then the relative separation is defined as $\rho_i = \min\big\{2, \min_{j \ne i} \frac{|\sigma_j - \sigma_i|}{\sigma_i}\big\}$, $i = 1, \ldots, n$. If the singular values are simple, then each $\rho_i$ is positive and the singular vectors define one-dimensional singular subspaces. If the perturbed matrix also has only simple singular values, then we can use the angles between the original and the perturbed subspaces as a natural error measure. Let $\theta_i$ and $\vartheta_i$ denote the error angles in the $i$th left and right singular vector, respectively. In the case of the perturbation from relation (5.3), $\theta_i = \angle(U(:,i), \hat{U}_a(:,i))$, $\vartheta_i = \angle(V(:,i), \hat{V}_a(:,i))$.

Proposition 5.6. *Let* $A = U\binom{\Sigma}{0}V^T$ *be the SVD of* $A$ *and let* (5.3) *be the SVD of a perturbed matrix with* $\|\mathcal{E}(:,i)\|_2 \leq \hat{\eta}\|A(:,i)\|_2$, $i = 1, \ldots, n$ *(cf. Proposition* 5.1*). Let* $\Phi = \mathcal{E}A^\dagger$, $\phi = \|\Phi + \Phi^T + \Phi\Phi^T\|_2$, $\phi \leq 2\|Sym(\Phi)\|_2 + \|\Phi\|_2^2$. *If* $\phi < \rho_i$, *then*

$$\max\{\sin\theta_i, \sin\vartheta_i\} \leq \sqrt{2}\left\{\frac{\xi}{\rho_i - \phi} + \|\Phi\|_2\right\}, \tag{5.22}$$

*where* $\xi \leq 2\|Sym(\Phi)\|_2 + O(\|\Phi\|_2^2)$ *and* $\|\Phi\|_2 \leq \sqrt{n}\hat{\eta}\|A_c^\dagger\|_2$.

*Proof.* We obtain the proof by applying [19, Theorem 3.3]. □

Application of the above estimates to the actually computed matrices $\tilde{U}_a$, $\tilde{V}_a$ follows by combining Propositions 5.6 and 5.2, since the angles $\angle(\tilde{U}_a(:,i), \hat{U}_a(:,i))$ and $\angle(\tilde{V}_a(:,i), \hat{V}_a(:,i))$ are small, with bounds sharper than those in (5.22).

In cases of clustered or multiple singular values, the singular vectors are not the right objects to be approximated numerically. Instead, we try to compute well-defined singular subspaces, belonging to multiple or tightly grouped singular values. The structure of the backward perturbation in the Jacobi SVD algorithm fits nicely into the perturbation estimates. For the sake of simplicity, we will give only one perturbation result, following [28]. Other interesting bounds can be derived from the fact that $A + \mathcal{E} = (I + \Phi)A$, where $\|\Phi\|$ is independent of the column scaling of $A$.

Proposition 5.7. *Let* $\Sigma = \Sigma_1 \oplus \Sigma_2$, $\tilde{\Sigma} = \tilde{\Sigma}_1 \oplus \tilde{\Sigma}_2$ *with* $\Sigma_1 = \mathrm{diag}(\sigma_1, \ldots, \sigma_k)$, $\Sigma_2 = \mathrm{diag}(\sigma_{k+1}, \ldots, \sigma_n)$, $\tilde{\Sigma}_1 = \mathrm{diag}(\tilde{\sigma}_1, \ldots, \tilde{\sigma}_k)$, $\tilde{\Sigma}_2 = \mathrm{diag}(\tilde{\sigma}_{k+1}, \ldots, \tilde{\sigma}_n)$. *Let* $\varrho = \min_{i=1:k;j=1:n-k} |\sigma_i - \tilde{\sigma}_{k+j}|/\sqrt{\sigma_i^2 + \tilde{\sigma}_{k+j}^2}$. *In the rectangular case,* $m > n$, *replace* $\varrho$ *with* $\min\{\varrho, 1\}$. *Let* $\mathcal{U}_1$, $\hat{\mathcal{U}}_1$, $\mathcal{V}_1$, $\hat{\mathcal{V}}_1$ *be the subspaces spanned by the columns of* $U_1 \equiv U(:,1:k)$, $\hat{U}_a(:,1:k)$, $V(:,1:k)$, $\hat{V}_a(:,1:k)$, *respectively. If* $\varrho > 0$, *then*

$$\left\|\begin{pmatrix} \|\sin\Theta(\mathcal{U}_1, \hat{\mathcal{U}}_1)\|_F \\ \|\sin\Theta(\mathcal{V}_1, \hat{\mathcal{V}}_1)\|_F \end{pmatrix}\right\|_F \leq \frac{\sqrt{\|\Phi^T U_1\|_F^2 + \|-\Phi U_1 + \Phi^2(I-\Phi)^{-1}U_1\|_F^2}}{\varrho}. \tag{5.23}$$

*Thus, the error angles are bounded by* $O(\|\Phi\|_F/\varrho)$.

This concludes the first part of our report. We have defined the global structure of a new preconditioned Jacobi SVD algorithm, which uses pivoted QR factorization as the preconditioner and reduces the computation to the SVD of structured triangular matrices. We have shown that the new algorithm computes the SVD with columnwise small backward error and with condition number independent of column scaling. Reliable implementation of the preconditioner is given in [16]. The new implementation of the Jacobi SVD on triangular matrices and the results of numerical testing are presented in [18], where we show that the new method can reach the efficiency of less accurate bidiagonalization-based methods (SGESVD and SGESDD from LAPACK). The speedup over the equally accurate standard one-sided Jacobi SVD can be a factor of ten or more.

# NEW FAST AND ACCURATE JACOBI SVD ALGORITHM. II*

ZLATKO DRMAČ† AND KREŠIMIR VESELIĆ‡

**Abstract.** This paper presents a new one-sided Jacobi SVD algorithm for triangular matrices computed by revealing QR factorizations. If used in the preconditioned Jacobi SVD algorithm, described in part one of this paper, it delivers superior performance leading to the currently fastest method for computing SVD decomposition with high relative accuracy. Furthermore, the efficiency of the new algorithm is comparable to the less accurate bidiagonalization-based methods. The paper also discusses underflow issues in floating point implementation and shows how to use perturbation theory to fix the imperfectness of the machine arithmetic.

**Key words.** Jacobi method, singular value decomposition, eigenvalues

**AMS subject classifications.** 15A09, 15A12, 15A18, 15A23, 65F15, 65F22, 65F35

## 1. Introduction.

Jacobi iteration is one of the time-honored methods for computing the spectral decomposition $H = V\Lambda V^T$ of a real symmetric matrix $H$. The early discovery in 1846 is certainly due to the simplicity and the elegance of the method as well as to the geniality of C. G. J. Jacobi, who called it "ein leichtes Verfahren" and applied it to compute the secular perturbations of the planets. Jacobi's original article [25] is a masterpiece of applied mathematics and may even today be read with profit by both students and scientists. The simplicity of the Jacobi method is not only theoretical but also computational, and in this respect it may well be compared with Gaussian elimination. Thus, with coming of automatic computation, the Jacobi method was soon rediscovered by Goldstine, Murray, and von Neumann [17], who provided the first detailed implementation and error analysis.

In our recent work [14] we introduced a preconditioner for the Hestenes variant [24] of the Jacobi method for SVD computation of general matrices. We have shown that rank revealing QR factorization can serve as a versatile preconditioner which enables efficient execution of Jacobi iterations on the triangular factor. The idea of QR iterations as preconditioner for SVD computation is well known (see [33], [27], [15]), but thus far it has not been fully exploited in the context of the Jacobi method. It is both simple and powerful: If $AP = Q(R^T \; 0)^T$ is the Businger–Golub QR factorization of $A$, then the Hestenes one-sided Jacobi algorithm applied to $X = R^T$ converges much faster than if applied to $A$. (If $R$ is singular, then the second QR factorization $R^T P_1 = Q_1 \left( R_1^T \quad 0 \right)^T$ provides nonsingular $X = R_1^T$.) In [14] Jacobi iterations on triangular matrices are used as a *black-box* procedure: starting with $X^{(0)} = X$, the sequence $X^{(k+1)} = X^{(k)} V^{(k)}$ converges to $X_\infty = U\Sigma$ and the product of Jacobi rotations $V^{(0)}V^{(1)}\cdots$ converges to $V$. The SVD of $X$ is $X = U\Sigma V^T$, where the matrix

$V$ is obtained not from the accumulated product of Jacobi rotations but rather in an a posteriori manner, using the relation $V = X^{-1}X_{\infty}$. Assembling the SVD of $A$ from the SVD of $X$ is straightforward.

In this report we unwrap the black box and present a new one-sided Jacobi SVD method for triangular matrices. A new pivot strategy is introduced in section 2. We use the triangular structure to reduce the flop count and memory traffic. At the same time, faster convergence is achieved using the knowledge of the asymptotic behavior of Jacobi iterations. We also use the structure of the SVD of triangular matrices, obtained from the theory of symmetric quasi-definite matrices. A new ordering of rotations is also designed to improve the use of fast cache memory. Underflow problems in floating point implementation of the algorithm are solved using perturbation theory in section 3. Numerical testing of the new preconditioned Jacobi SVD algorithm (cf. [14, Algorithm 4] with the new triangular SVD method from this paper) is presented in section 4. The results presented in section 4.3 carry the main message of [8], [14], and this paper: *Our new Jacobi SVD algorithm is more accurate than the bidiagonalization-based QR (SGESVD) and divide-and-conquer (SGESDD) algorithms from LAPACK* [1]. *Moreover, the new algorithm can compute the SVD faster than SGESVD, and it is not much slower than SGESDD.* Concluding remarks and discussion of future work are given in section 5.

## 2. One-sided Jacobi SVD on $n \times n$ preconditioned triangular matrices.

The Jacobi transformation $X^{(k+1)} = X^{(k)}V^{(k)}$ transforms pivot columns $p_k$, $q_k$ chosen by pivot strategy (ordering) $k \mapsto (p_k, q_k)$. An example is the row-cyclic strategy, which is periodic, and in one full sweep of $n(n-1)/2$ rotations it rotates at the pivot positions $(1,2), (1,3), \ldots, (1,n);\ (2,3), \ldots, (2,n);\ (3,4), \ldots, (3,n); \ldots, (n-2,n);\ (n-1,n)$. The convergence of $X^{(k)}$ is studied in terms of the convergence of $H^{(k)} = (X^{(k)})^T X^{(k)}$ towards the diagonal form, and its rate is usually measured using the off-norm, $\boldsymbol{\Omega}(H^{(k)}) = \|H^{(k)} - \mathrm{diag}(H^{(k)})\|_F$. In the case of the row-cyclic strategy the convergence is asymptotically quadratic [20]: If $\boldsymbol{\Omega}(H^{(0)})$ is sufficiently small and if the diagonal entries of $H^{(0)}$ are sorted, then $\boldsymbol{\Omega}(H^{(n(n-1)/2)}) \leq \mathrm{const} \cdot \boldsymbol{\Omega}(H^{(0)})^2$.

In practice, the Jacobi rotation $V^{(k)}$ is executed only if the cosine of the angle between $X^{(k)}(:,p_k)$ and $X^{(k)}(:,q_k)$ is greater than a tolerance which is usually $n$ times the round-off $\boldsymbol{\varepsilon}$. Otherwise, the rotation is skipped. If $n(n-1)/2$ consecutive rotations with all possible pivot pairs are skipped, i.e.,

$$\max_{i \neq j} \frac{|X(:,i)^T X(:,j)|}{\|X(:,i)\|_2 \|X(:,j)\|_2} \leq n\boldsymbol{\varepsilon}, \tag{2.1}$$

then the iterations are stopped and numerical convergence is declared. Demmel and Veselić [8] showed that (2.1) is important for high relative accuracy. If the floating point Jacobi rotation is implemented as in [11], then the procedure can compute the singular values in the full range of machine numbers.

Our new pivot strategy is based on the fact that the initial matrix $X = X^{(0)}$ is triangular, nonsingular, and with additional structure implied by the Businger–Golub column pivoting. In this section, we outline the key ingredients of the new approach.

### 2.1. SVD of lower triangular matrix.

As discussed in [14], the preconditioned Jacobi SVD algorithm computes a rank revealing QR factorization $AP = Q\binom{R}{0}$, and then it applies one-sided Jacobi SVD to $X = R^T$. (In some cases, it uses second QR factorization $R^T = Q_1 \begin{pmatrix} R_1^T & 0 \end{pmatrix}^T$ and then $X = R_1^T$.) The reason is that $RR^T$ is more diagonal than $R^T R$. In addition to the arguments in [14], we give an illustration by simple MATLAB example and show that the gap revealing property of the pivoted QR factorization (cf. [31], [32]) opens a connection to the theory of symmetric quasi-definite matrices.

*Example* 2.1. We generate in MATLAB $A \in \mathbb{R}^{50\times 50}$ with entries uniformly distributed over $[0,1]$, and compare the column norms of $A$ and $X = R^T$. Further, we compare the diagonality of the Gram matrices $H_s = R_c^T R_c$ and $M_s = X_c^T X_c$, where $R_c$, $X_c$ are obtained by column equilibration, e.g., $X_c = X\mathrm{diag}(\|X(:,i)\|_2^{-1})$. The results shown in Figure 2.1 strongly suggest that the Jacobi method should diagonalize $X^TX$ faster than $R^TR$. In the case of graded $A$ (column norms vary in length) the positive effect of using $X$ instead of $R$ is even stronger. (See the second row in Figure 2.1.) An analysis of perfect behavior of the column norms of $X$ can be found in [12].

It appears that the Jacobi iterations $X^{(k+1)} = X^{(k)}V^{(k)}$ in general work better if the initial $X$ is lower triangular. An explanation is given in the following theorem.

THEOREM 2.1. *Let $X \in \mathbb{R}^{n\times n}$ be a lower triangular matrix with the partition*

$$X = \begin{pmatrix} X_{11} & 0 \\ X_{21} & X_{22} \end{pmatrix}, X_{11} \in \mathbb{R}^{k\times k}, \quad \text{and let } \sigma_{\min}\left(\begin{pmatrix} X_{11} \\ X_{21}\end{pmatrix}\right) > \sigma_{\max}(X_{22}). \tag{2.2}$$

*Let the SVD of $X$ be given with the partition*

$$X = U\Sigma V^T = \begin{pmatrix} U_{11} & U_{12} \\ U_{21} & U_{22} \end{pmatrix}\begin{pmatrix} \Sigma_1 & 0 \\ 0 & \Sigma_2 \end{pmatrix}\begin{pmatrix} V_{11} & V_{12} \\ V_{21} & V_{22} \end{pmatrix}^T. \tag{2.3}$$

*Then the matrix $V$ is more block diagonal than $U$ in the following sense:*

- (i) *In the Löwner partial order $V_{11}^TV_{11} \succ V_{21}^TV_{21}$, $V_{22}^TV_{22} \succ V_{12}^TV_{12}$. (For symmetric matrices $S_1$ and $S_2$, $S_1 \succ S_2$ if and only if $S_1 - S_2$ is positive definite.) As a consequence, $\sigma_{\min}(V_{11}) > 1/\sqrt{2}$ and $\sigma_{\min}(V_{22}) > 1/\sqrt{2}$.*
- (ii) *Let $\mathcal{U}_k$, $\mathcal{V}_k$, $\mathcal{I}_k$ be the subspaces spanned by the first $k$ columns of $U$, $V$, and the identity matrix $I$, respectively. If the angles $\psi_k$, $\theta_k$ are defined as $\psi_k = \angle(\mathcal{V}_k, \mathcal{I}_k)$, $\theta_k = \angle(\mathcal{U}_k, \mathcal{I}_k)$, then $\psi_k < \pi/4$ and*

$$\tan\psi_k \le \frac{\sigma_{k+1}}{\sigma_k}\tan\theta_k.$$

*Proof.* Consider the block partition of the cross product matrix $H = X^TX$,

$$X^TX = \begin{pmatrix} X_{11}^TX_{11} + X_{21}^TX_{21} & X_{21}^TX_{22} \\ X_{22}^TX_{21} & X_{22}^TX_{22} \end{pmatrix} = \begin{pmatrix} H_{11} & H_{12} \\ H_{21} & H_{22} \end{pmatrix}.$$

The gap assumption (2.2) implies that for any shift $\xi \in \mathcal{S} = (\lambda_{\max}(H_{22}), \lambda_{\min}(H_{11}))$ both $H_{11} - \xi I$ and $\xi I - H_{22}$ are positive definite. Therefore, the matrix $H - \xi I$ is symmetric quasi-definite, and the matrix $V$ must have the special structure of the eigenvector matrix of quasi-definite matrices [16]. In particular, $V_{11}^TV_{11} \succ V_{21}^TV_{21}$, $V_{22}^TV_{22} \succ V_{12}^TV_{12}$, yielding $\sigma_{\min}(V_{11}) > 1/\sqrt{2}$, $\sigma_{\min}(V_{22}) > 1/\sqrt{2}$. From this and $X_{11}V_{11} = U_{11}\Sigma_1$ it follows that $U_{11}$ is nonsingular. Further, from the SVD of $X$ it follows that

$$V_{11}^{-1}V_{12} = -(V_{22}^{-1}V_{21})^T = \Sigma_1^{-1}U_{11}^{-1}U_{12}\Sigma_2 \quad \text{and} \quad \|V_{11}^{-1}V_{12}\|_2 \le \frac{\sigma_{k+1}}{\sigma_k}\|U_{11}^{-1}U_{12}\|_2.$$

Finally, from the CS decomposition of partitioned $V$ we have $\|V_{11}^{-1}V_{12}\|_2 = \tan\psi_k$. ☐

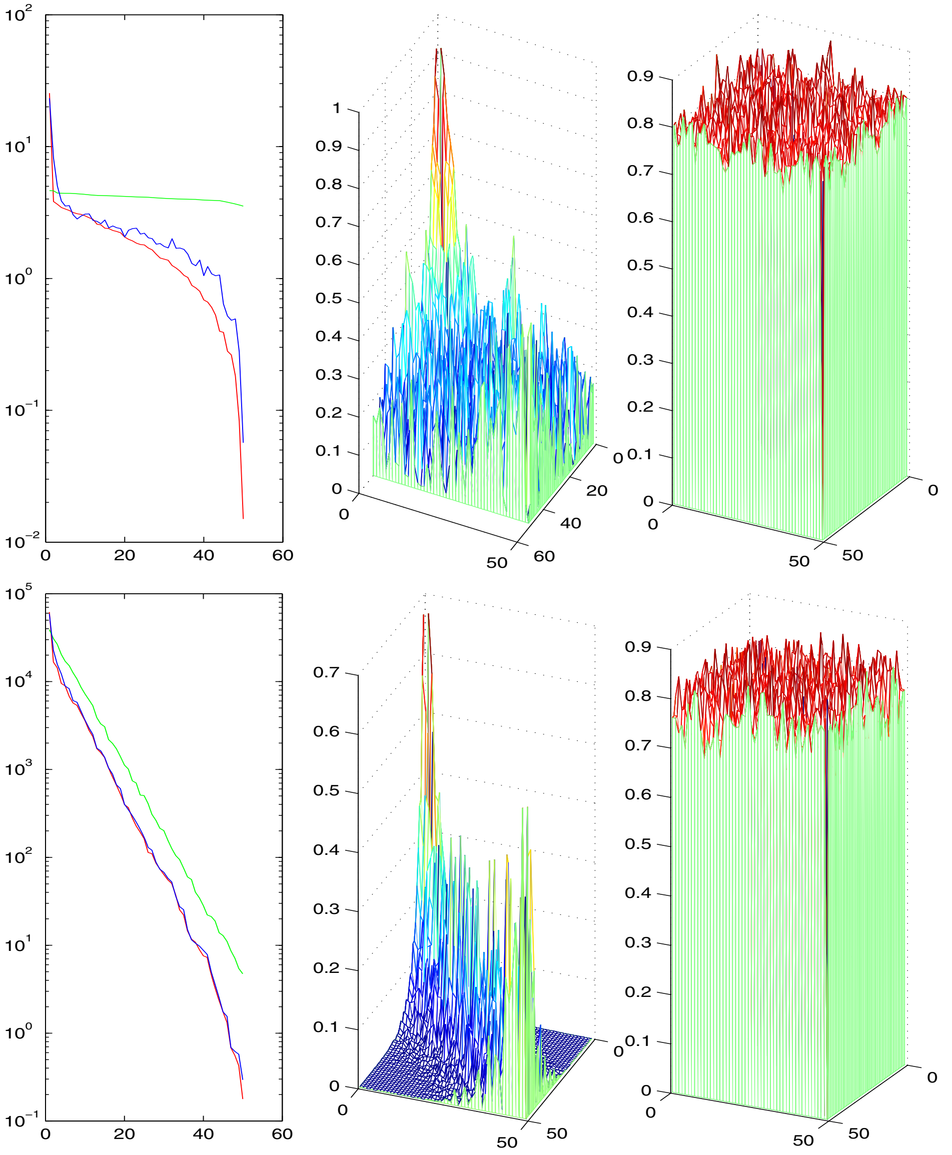

FIG. 2.1. *Example* 2.1*: In the first plot, the top line denotes* sorted *column norms of $A$, the middle line denotes the column norms of $X = R^T$, and lowest line denotes the singular values. The next two plots are obtained by meshz$(abs(M_s - \mathrm{diag}(M_s)))$ and meshz$(abs(H_s - \mathrm{diag}(H_s)))$, respectively. In the second row of the figure, the plots correspond to matrix $A$ with graded columns.*

*Remark* 2.1. Part (ii) of Theorem 2.1 is due to Chandrasekaran and Ipsen [6] but under the assumption that $X$ and one of the matrices $U_{11}$, $V_{11}$ is nonsingular. The contribution of (ii) is in establishing a connection between the separation condition (2.2) and the theory of symmetric quasi-definite matrices to conclude (i), which yields nonsingularity of $V_{11}$. Further, our "weak separation" condition (2.2) is weaker than the usual condition $\sigma_{\min}(X_{11}) > \sigma_{\max}(X_{22})$.

*Remark* 2.2. Comparing $X^TX$ with $XX^T = \begin{pmatrix} X_{11}X_{11}^T & X_{11}X_{21}^T \\ X_{21}X_{11}^T & X_{22}X_{22}^T + X_{21}X_{21}^T \end{pmatrix}$ we see that one important difference is that the monotonicity principle acts inside different diagonal blocks. Thus, it can increase or decrease the initial separation gap. Also note that in the case of "strong separation" $\sigma_{\min}(X_{11}) > \sigma_{\max}((X_{21}\ X_{22}))$, even the matrix $U$ has the property (i). However, property (ii) implies that $V$ is more block diagonal. Hence, we prefer $V$ to be the product of Jacobi rotations.

In the Jacobi SVD algorithm applied to $X = R^T$, the matrix $V$ is built as the accumulated product of Jacobi rotations. The structure of $V$ (more block diagonal than $U$) is an additional argument to apply Jacobi rotations to the columns of $X$.

**2.2. How to exploit the triangular form.** Classical pivot strategies in the one-sided Jacobi method are not designed to preserve any zero pattern of the input matrix. In fact, the incapability to preserve created zeros was the main reason for the poor performance, as compared with bidiagonalization-based methods.

However, if the initial matrix is triangular, quite a few rotations in the first sweep can use and partially preserve the zero structure. Let $X$ denote the array in the memory occupied by the iterates in the Jacobi SVD algorithm. Initially, $X$ is lower triangular; see (2.4). Let the columns of $X$ be partitioned into four blocks, $X_{[1]}$, $X_{[2]}$, $X_{[3]}$, $X_{[4]}$, of dimensions $n \times n_i$, respectively, where each $n_i$ is approximately $n/4$. Further, let $X^{[1]} = \big(X_{[1]}, X_{[2]}\big)$, $X^{[2]} = \big(X_{[3]}, X_{[4]}\big)$.

$$X = \left(\begin{array}{cc|cc||cc|cc}
\blacksquare & o & 0 & 0 & 0 & 0 & 0 & 0 \\
\blacksquare & \blacksquare & 0 & 0 & 0 & 0 & 0 & 0 \\
\hline
\blacksquare & \blacksquare & \blacksquare & o & 0 & 0 & 0 & 0 \\
\blacksquare & \blacksquare & \blacksquare & \blacksquare & 0 & 0 & 0 & 0 \\
\hline\hline
\blacksquare & \blacksquare & \blacksquare & \blacksquare & \blacksquare & o & 0 & 0 \\
\blacksquare & \blacksquare & \blacksquare & \blacksquare & \blacksquare & \blacksquare & 0 & 0 \\
\hline
\blacksquare & \blacksquare & \blacksquare & \blacksquare & \blacksquare & \blacksquare & \blacksquare & o \\
\blacksquare & \blacksquare & \blacksquare & \blacksquare & \blacksquare & \blacksquare & \blacksquare & \blacksquare
\end{array}\right) \equiv \big(X_{[1]}, X_{[2]}, X_{[3]}, X_{[4]}\big) \equiv \big(X^{[1]}, X^{[2]}\big). \tag{2.4}$$

We will say that rotations are applied in $X_{[i]}^{\circlearrowright}$ ($X_{\circlearrowright}^{[i]}$) if we implicitly transform $X_{[i]}^T X_{[i]}$ ($(X^{[i]})^T X^{[i]}$) by following one full sweep of some pivot strategy. Further, for two blocks $X_{[i]}$ and $X_{[j]}$ ($X^{[i]}$ and $X^{[j]}$) of $X$, rotating in $X_{[i]} \leftrightarrow X_{[j]}$ ($X^{[i]} \leftrightarrow X^{[j]}$) means choosing, in some order, all pivot pairs with the first pivot column from $X_{[i]}$ ($X^{[i]}$) and the second one from $X_{[j]}$ ($X^{[j]}$).

Consider the most natural greedy approach. Rotating in $X_{[4]}$ is efficient because all columns are, and remain during rotations, in a canonical subspace of dimension $n_4 \approx n/4$. Thus, only the submatrix $X_{[4]}(n_1 + n_2 + n_3 + 1 : n, 1 : n_4)$ is transformed. This reduces the operation count of rotations applied in $X_{[4]}^{\circlearrowright}$ by a factor of four. In the same way, transformations of the columns of $X_{[3]}$ by any strategy is computed in a subspace of dimension $n_3 + n_4 \approx n/2$. The same holds for the transformations of the columns of $X^{[2]}$. Repeated transformations of the columns of $X_{[3]}$ (and independently $X_{[4]}$) are still in a lower-dimensional subspace, and thus very efficient. Savings in the transformations of the columns of $X_{[2]}$ are modest, but not worthless. Note that this strategy in the first sweep transforms more often closer to the diagonal, which seems reasonable given the structure of the initial matrix (see Example 2.1).

DEFINITION 2.2. *The greedy triangular sweep for the partition* (2.4) *of lower triangular matrix is defined as the following ordering of Jacobi rotations:*

$$X_{[3]}^{\circlearrowright},\ X_{[4]}^{\circlearrowright},\ X_{[3]} \leftrightarrow X_{[4]},\ X_{[3]}^{\circlearrowright},\ X_{[4]}^{\circlearrowright};\ X_{[1]}^{\circlearrowright},\ X_{[2]}^{\circlearrowright},\ X_{[1]} \leftrightarrow X_{[2]},\ X_{[1]}^{\circlearrowright},\ X_{[2]}^{\circlearrowright};\ X^{[1]} \leftrightarrow X^{[2]}. \tag{2.5}$$

*In each bulk of rotations (*$X_{[i]}^{\circlearrowleft}$, $X_{[j]}\leftrightarrow X_{[k]}$, $X^{[j]}\leftrightarrow X^{[k]}$*) pivot ordering is arbitrary and implemented to transform only the nontrivial parts of the corresponding submatrices.*

Thus, in the greedy triangular sweep, the blocks of zeros denoted by "0" in (2.4) are at some point used to reduce the complexity (number of operations and memory traffic), as discussed above. This is particularly important because the first sweep is the busiest one. The positions denoted by "$o$" are treated as nonzero entries, i.e., they are not used to save operations.

This technique can be applied recursively by refining the partition (2.4).

**2.3. Cubic convergence.** Mascarenhas [26] observed that in the row-cyclic strategy the off-diagonal entries converge to zero at different rates and showed that by using special quasi-cyclic strategies the Jacobi method can attain cubic asymptotic convergence. Here the term quasi-cyclic refers to a modified row-cyclic strategy in which slowly convergent positions are visited more often. To motivate quasi-cyclic strategy, assume that $H = X^T X$ is almost diagonal, $\boldsymbol{\Omega}(H) = O(\epsilon)$, and introduce the following block partitions:

$$H = \left(\begin{array}{c||c} H^{[11]} & H^{[12]} \\ \hline\hline H^{[21]} & H^{[22]} \end{array}\right) = \left(\begin{array}{c|c||c|c} H_{[11]} & H_{[12]} & H_{[13]} & H_{[14]} \\ \hline H_{[21]} & H_{[22]} & H_{[23]} & H_{[24]} \\ \hline\hline H_{[31]} & H_{[32]} & H_{[33]} & H_{[34]} \\ \hline H_{[41]} & H_{[42]} & H_{[43]} & H_{[44]} \end{array}\right). \tag{2.6}$$

For simplicity, assume that the eigenvalues of $H$ are well separated. If the row-cyclic strategy is first applied to the diagonal blocks $H^{[11]}$ and then to $H^{[22]}$, their off-diagonal norms will be reduced from $O(\epsilon)$ to $O(\epsilon^2)$. Rotating in the row-cyclic fashion inside the block $H^{[12]}$ reduces its norm to the order of $O(\epsilon^3)$. Visiting the diagonal blocks $H^{[11]}$ and $H^{[22]}$ once more will reduce their off-norms to $O(\epsilon^4)$. Repeating this pattern recursively on a finer partition of $H$, we obtain the quasi-cyclic ordering which visits all pivot pairs from

$$H_{[33]}, H_{[44]}, H_{[34]}, H_{[33]}, H_{[44]}, H_{[11]}, H_{[22]}, H_{[12]}, H_{[11]}, H_{[22]}, H^{[12]}, \tag{2.7}$$

respectively. The pivot positions inside each block are visited using a row-cyclic strategy.

THEOREM 2.3 (see Rhee and Hari [28]). *Let the diagonal entries of $H$ in* (2.6) *be ordered from large to small, and let no two diagonal entries from different blocks $H_{[ii]}$, $H_{[jj]}$ be affiliated with the same eigenvalue. Let* $\boldsymbol{\delta} = \min_{\lambda_i\neq\lambda_j}|\lambda_i-\lambda_j|$ *and*

$$\Gamma_1 = \frac{\sqrt{\boldsymbol{\Omega}(H^{[11]})^2 + \boldsymbol{\Omega}(H^{[22]})^2}}{\boldsymbol{\delta}/3},\quad \Gamma_2 = \left(\frac{\|H^{[12]}\|_F}{\boldsymbol{\delta}/3}\right)^{2/3},\quad \Gamma \equiv \Gamma(H) = \max\{\Gamma_1, \Gamma_2\}.$$

*Let $H'$ be the matrix computed after the quasi-cycle* (2.7). *If* $\Gamma(H) < 1/4$, *then* $\Gamma(H') < (49/25)\Gamma(H)^3$. *Further, if* $\Gamma(H) = \Gamma_1 < 1/4$, *then* $\boldsymbol{\Omega}(H') \le (18/\boldsymbol{\delta}^2)\boldsymbol{\Omega}(H)^3$.

Rhee and Hari pointed out that the reduction of $\boldsymbol{\Omega}(H)$ is only quadratic if $\Gamma_2$ dominates $\Gamma_1$. One of the key points in our new preconditioned algorithm is that preconditioning makes the dominance of $\Gamma_2$ over $\Gamma_1$ very unlikely; see Example 2.1. Intuitively, it is then a reasonable strategy to take care of $\Gamma_1$ first and then follow the strategy (2.7) in its implicit form (2.5). We expect positive effects of the cubic convergence mechanism even in the first sweep, before the conditions for the cubic convergence are fulfilled.

Let us summarize the elements of the first sweep and the benefits of working on $X = R^T$, as compared to the classical application of the Hestenes Jacobi SVD on $A$:

$$X^TX = \left(\begin{array}{cccc||cccc}
\blacksquare & \boxplus & \boxminus & \boxminus & \otimes & \otimes & \otimes & \otimes \\
 & \blacksquare & \boxminus & \boxplus & \boxminus & \boxminus & \otimes & \otimes \\
 & & \blacksquare & \boxminus & \boxminus & \otimes & \otimes & \otimes \\
 & & & \blacksquare & \boxplus & \boxminus & \boxminus & \otimes \\
\hline\hline
 & & & & \blacksquare & \boxplus & \boxminus & \boxplus \\
 & & & & & \blacksquare & \boxplus & \boxminus \\
 & & & & & & \blacksquare & \boxplus \\
 & & & & & & & \blacksquare
\end{array}\right)$$

$\boxplus$ rotated
$\boxminus$ rotation skipped after test
$\otimes$ dot product test abandoned

FIG. 2.2. *Example of modified row-cyclic strategy: if two consecutive rotations in a row are skipped, then the remaining pivot positions in that row are not even tested against the threshold.*

(i) $R$ is computed efficiently by BLAS 3 operation; smaller dimension in the case $m > n$;

(ii) preconditioning effect ($X^TX$ closer to diagonal than $A^TA$; see Example 2.1);

(iii) a priori known structure of $X^TX$ and of Jacobi rotations (Theorem 2.1);

(iv) greedy sweep (2.5) exploits triangular structure to save flops and reduce memory traffic; it transforms more often where most needed, and at the same time it follows cubically convergent strategy (2.7).

**2.4. How to adapt to the nearly band structure.** Upon completion of the first sweep, the array $X$ is dense. However, $X$ is the result of the preconditioning by a rank revealing QR factorization, followed by a greedy sweep. Hence, $X$ must have structure that can be exploited. We expect that $H = X^TX$ is a scaled diagonally dominant (s.d.d.) matrix in the sense of [2] and that its off-diagonal mass is distributed close to the diagonal. This is a typical nonpathological situation. The pathological case occurs in the presence of multiple or tightly clustered singular values.

It is known that the convergence of Jacobi iterations is improved if the threshold for the rotation is set higher at the beginning of the process and then gradually reduced to the final level. Such a strategy is not suitable for the implicit Jacobi SVD algorithm because $O(n)$ flops are required to compute a single pivot element. Further, in the nonpathological case we may expect that many rotations with pivot positions far from diagonal will be skipped. In fact, in each row of the row-cyclic pivoting, each skipped rotation increases the probability that the next rotation in that row will be skipped as well. Hence, it is reasonable to have a pivot strategy which will dynamically adapt to the structure of the matrix and anticipate small pivots. This strategy saves many unnecessary dot products, and it can be applied inside the blocks of the quasi-cyclic strategy (2.5) as well as globally on $X$.

The scheme on Figure 2.2 gives the main idea. The basic strategy is row-cyclic with de Rijk's pivoting[1] [9], but if in a row $i$ a certain number of consecutive rotations is skipped (because the pivot elements are sufficiently small), the control of the row-cycling moves to the next row—the remaining pivot positions of the $i$th row are not visited. This strategy is motivated by the following reasons. First, it is very likely that the $\otimes$-positions in Figure 2.2 will pass the tolerance check, so we save unnecessary dot products. Second, even if the $\otimes$-positions do not satisfy the tolerance criterion, they are expected to be much smaller than the pivot positions closer to the diagonal, and it is more useful for the overall convergence to reduce those positions close to the diagonal.

---

[1] Due to preconditioning and monotonicity of Jacobi rotation (it increases larger and decreases smaller diagonal pivots), de Rijk's pivoting is identity most of the time.

Certainly, this modification of the row-cyclic strategy may bring no savings in the pathological case. However, it does no harm—in that case it simply reduces to the classical strategy. Also, this modification is in general not convergent, so an additional switch turns it off after at most 3 or 4 modified sweeps. After that, the classical full sweep does the final cleanup. Numerical evidence shows that in a nonpathological case the expected total number of rotations in 3 or 4 sweeps of this predict-and-skip strategy is much smaller than in one classical full sweep.

**2.5. Cache-aware pivot strategy.** In sections 2.1–2.4 we considered modifications to reduce the number of operations and to improve the convergence rate of the Jacobi SVD algorithm. Numerical evidence shows that those modifications, combined with the preconditioning, substantially improve the one-sided Jacobi SVD algorithm. However, the algorithm still transforms a full square array, where the basic operations (dot product and plane rotation) both have $O(n)$ operations per $O(n)$ memory references. Pivot strategies in Jacobi methods are usually not designed to enhance temporal and spatial data locality, which results in numerous cache misses, thus degrading the performance. Fortunately, a well-known tiling technique fits very nicely into our previous modifications and considerably improves data locality.

Introduce a parameter $b$ (block size expressed in number of columns) and partition the columns of $X$ in $\lceil n/b \rceil$ blocks (the first $\lceil n/b \rceil - 1$ blocks with $b$ columns each, the last block with the remaining $n - b(\lceil n/b \rceil - 1)$ columns). This introduces a $\lceil n/b \rceil \times \lceil n/b \rceil$ block partition in $H = X^T X$ and the new strategy is to visit all blocks in the usual row-cyclic fashion (on the block-level), where at the beginning of the $r$th block row, after rotating in the diagonal block $(r, r)$, we allow the possibility of transforming the next $k$ diagonal blocks (and, optionally, to repeat transformations in the block $(r, r)$) before entering the block $(r, r + 1)$. The parameter $k$ is a small integer (typically $0, 1, 2$) depending on $X$, $n$, $b$ and cache parameters. It influences the convergence rate (this is easily seen by taking, for example, $k = 1$) and memory access patterns. Inside each block all positions are visited row by row. We call this strategy "tiled row-cyclic." Its detailed description is shown in Algorithm 1.

Proposition 2.4. *The tiled row-cyclic strategy with $k = 0$ is equivalent to the row-cyclic strategy: both strategies compute the same matrix after the full cycle of $n(n-1)/2$ rotations. Thus, it is convergent.*

The proof is straightforward. The proof of global convergence for $k > 0$ is only a technical matter [22]. The tiled row-cycling can be immediately deployed inside the blocks of (2.5), and it can be modified following the lines of section 2.4.

## 3. Underflow and overflow—problems and solutions by perturbation theory.

Reliable software implementation of an SVD algorithm must take care of underflow and overflow exceptions. This is particularly important for our new preconditioned Jacobi SVD algorithm (cf. [14, Algorithm 4] with the triangular Jacobi SVD as described in previous sections), because it is designed to compute the singular values in the full range of floating point numbers. For example, if $\sigma_{\max}(A) \approx 10^{30}$, $\sigma_{\min}(A) \approx 10^{-30}$, but $\min_{D=\mathrm{diag}} \kappa_2(AD)$ is moderate, then we can approximate all singular values to high relative accuracy even in single precision arithmetic (with round-off unit $\varepsilon \approx 10^{-8}$). (For comparison, bidiagonalization-based methods cannot guarantee any correct digit in the singular values below $\varepsilon\sigma_{\max}$, which is in this case approximately $10^{22}$.) Jacobi SVD computation in the full range of floating point numbers requires nonstandard implementation of Jacobi rotation because it can get denormalized or flushed to identity, even in cases where its action is nontrivial [11].

In this section we discuss some other problems related to underflow and overflow.

**Algorithm 1** Tiled row-cyclic strategy with tile size $b$.

The underflow and overflow thresholds are denoted by $\boldsymbol{\nu}$ and $\boldsymbol{\omega}$, respectively. The round-off unit of the working precision is denoted by $\boldsymbol{\varepsilon}$.

**3.1. Scaling against overflow.** Overflow issues are resolved simply by multiplying the matrix by a suitable scalar factor. However, even this simple operation can introduce unacceptably large errors. For instance, LAPACK's driver routine xGESVD computes $\alpha = \max_{i,j} |A_{ij}|$ and scales the input matrix $A$ with $(1/\alpha)\sqrt{\boldsymbol{\nu}}/\boldsymbol{\varepsilon}$ (if $\alpha < \sqrt{\boldsymbol{\nu}}/\boldsymbol{\varepsilon}$) or with $(1/\alpha)\boldsymbol{\varepsilon}\sqrt{\boldsymbol{\omega}}$ (if $\alpha > \boldsymbol{\varepsilon}\sqrt{\boldsymbol{\omega}}$).

*Example* 3.1. Take in MATLAB $A = \left(\begin{smallmatrix} 1.0e250 & 0 \\ 0 & 1.0e{-201} \end{smallmatrix}\right)$, $d = \mathrm{diag}(A)$, $\sigma = \mathrm{svd}(A)$. $A$ is (bi)diagonal, and its singular values are on the diagonal. However,

$$d = \begin{pmatrix} 9.999999999999999e+249 \\ 1.000000000000000e-201 \end{pmatrix}, \quad \sigma = \begin{pmatrix} 9.999999999999999e+249 \\ 1.0000000000\underline{16167}e-201 \end{pmatrix}.$$

To explain this, let $\alpha = \max_{i,j} |A_{ij}|$, $\boldsymbol{\varepsilon} = eps/2$, $\boldsymbol{\omega} = realmax$, $\boldsymbol{\nu} = realmin$, $s = \boldsymbol{\varepsilon}\sqrt{\boldsymbol{\omega}}/\alpha$, and scale $A$ with $s$. The singular values of $sA$ are on its diagonal; scaling the diagonal of $sA$ with $1/s$ changes the $(2,2)$ entry precisely to $1.000000000016167e$–$201$. Five digits in the second singular value of a $2 \times 2$ diagonal matrix are lost due to scaling $\sigma = (1/s) * (s * d)$. (In MATLAB, $\boldsymbol{\omega} \approx 1.79 \cdot 10^{308}$, $\boldsymbol{\nu} \approx 2.22 \cdot 10^{-308}$.) The problem is not removed if $s$ is changed to the closest integer power of 2. Note that in this example $\lambda = \mathrm{eig}(A)$ returns $\lambda = d$.

Our implementation of fast scaled Jacobi rotations uses the column norms and the cosines of the angles between the columns (cf. [11]); i.e., we can compute the singular values of $X$ even if $\sigma_{\min}(X) \approx \boldsymbol{\nu}$, $\sigma_{\max}(X) \approx \boldsymbol{\omega}$. Since the largest singular value of an $n \times n$ $X$ is bounded by $\sqrt{n} \max_j \|X(:,j)\|_2$, it is enough to have initial $X$ scaled so that its maximal column is not larger than $\boldsymbol{\omega}/\sqrt{n}$. Since the largest value of any column norm of $X$ is $\sqrt{n}\boldsymbol{\omega}$, even in the most extreme case, the scaling factor against overflow does not have to be smaller than $1/n$. In the nonextreme case $(\max_j \|X(:,j)\|_2/\min_j \|X(:,j)\|_2 < \boldsymbol{\omega}\boldsymbol{\varepsilon}/\sqrt{n})$ we scale $X$ to have maximal column norm at $\sqrt{\boldsymbol{\omega}}/\sqrt{n}$.

*Remark* 3.1. A concrete implementation of BLAS and LAPACK may contain computational routines which are optimized for speed at the cost of reduced computational range. For instance, xNRM2() is sometimes implemented as SQRT(xDOT()), which works correctly for vector norms in the range $(\sqrt{\boldsymbol{\nu}}, \sqrt{\boldsymbol{\omega}})$. In such cases, scaling of $A$ must ensure that the maximal column is not larger than $\sqrt{\boldsymbol{\omega}}/\sqrt{n}$ in the Euclidean norm. If the spectrum of singular values spreads over the full range of normalized numbers and if all of them are wanted to high relative accuracy, then enforcing $\sqrt{\boldsymbol{\omega}}/\sqrt{n}$ as the maximum column norm may damage smallest singular values.

*Remark* 3.2. The one-sided Jacobi SVD can be adapted to work even beyond the range of working precision. Let $A = A_0 D_0$ with diagonal $D_0$, where $A$ cannot be stored because of underflow/overflow, but both $A_0$ and $D_0$ can. Fast scaled Jacobi rotations work on the pair $A_0, D_0$ and deliver the result in factored form. The only required modification is that the array of scaling factors for fast rotations be initialized to $\mathrm{diag}(D_0)$ instead of a vector of ones.

**3.2. An unusual underflow problem.** Preliminary tests of software implementation of the preconditioned Jacobi SVD algorithm showed undesirable behavior in some cases of strongly graded matrices: the convergence of the Jacobi iterations was swift, the total number of rotations was very small, but the run time was unacceptably long. This called for detailed step-by-step analysis. Recall that the algorithm first computes[2] $AP = Q_0\binom{R}{0}$, then it computes the QR factorization $L = QT$ of $L = R^T$, and finally it applies our new Jacobi SVD algorithm to the lower triangular matrix $X = T^T$.

To our surprise, in some examples the second QR factorization without pivoting was considerably slower than the QR factorization with column pivoting. In these examples, $L$ was structured, strongly graded, with deep gap in the spectrum:

$$L = \begin{pmatrix} L_{11} & 0 \\ L_{21} & L_{22} \end{pmatrix}, \quad \text{with } \|L_{11}^{-1}\|_2^{-1} \gg \|L_{22}\|_2 \text{ and } \|L_{21}\|_2 \ll \|L_{11}\|_2.$$

We traced the problem to computation with many denormalized floating point numbers during the computation of the factorization $L = QT$. From the block-partitioned QR factorization $L = \left(\begin{smallmatrix} Q_{11} & Q_{12} \\ Q_{21} & Q_{22} \end{smallmatrix}\right)\left(\begin{smallmatrix} T_{11} & T_{12} \\ 0 & T_{22} \end{smallmatrix}\right)$ we have $T_{12} = Q_{11}^T L_{11}^{-T} L_{21}^T L_{22}$ and $\|T_{12}\|_2 \leq \|Q_{11}\|_2 \|L_{11}^{-1}\|_2 \|L_{22}\|_2 \|L_{21}\|_2$. This is the well-known QR mechanism that eventually forces the $(1,2)$ block to zero, and it is clearly seen in Example 3.2.

*Example* 3.2. This example illustrates how denormalized numbers appear in the QR factorization. Using SGEQRF from LAPACK we compute

$$L = \begin{pmatrix} 1.0e{+}20 & 0 & 0 \\ 1.0e{-}15 & 1.0e{-}06 & 0 \\ 1.0e{-}20 & 1.0e{-}25 & 1.0e{-}21 \end{pmatrix}, \quad T = \begin{pmatrix} -0.10e{+}21 & -0.99e{-}41 & 0.00e{+}00 \\ 0 & -0.10e{-}05 & -0.99e{-}40 \\ 0 & 0 & 0.99e{-}21 \end{pmatrix}.$$

From the point of view of numerical accuracy, these denormalized numbers in the upper triangle of $T$ are as good as zeros—backward stability and the forward errors are given with respect to column norms, and these are well preserved if the entries

---

[2] For simplicity, we give only one branch of the algorithm.

of the initial $A$ are normalized numbers. Unfortunately, if the denormals are created and transformed inside an optimized black-box routine, they can cause considerable slowdown (take, e.g., $n > 1000$).

The performance of Jacobi rotations applied to a lower triangular matrix can also be degraded by the denormalized numbers. The dot products needed to compute the rotation angles can be extremely slow (many of the summands can be denormalized and are as good as zeros in the final result), and rotations with small angles during the first greedy sweep may generate additional denormalized entries where there are zeros in the upper triangle.

**3.2.1. Solution by artificial perturbation.** How do we deal with this problem? We can ignore it, because it is automatically solved with proper implementation of the machine arithmetic or with the *set to zero* underflow. However, it is very instructive to solve it in the framework of the imperfect arithmetic. The first natural idea is to set small off-diagonal matrix entries to zero. This has to be done by inspection after each transformation in QR factorization (or in the Jacobi iterations). This may kill the performance of highly optimized blocked code, and the underflows may still appear because they actually grow in places of zero entries. Furthermore, setting an entry to zero means perturbing the data, which may not be allowed because it causes unacceptably large perturbation. (For instance setting in Example 3.2 the element $L_{31}$ to zero introduces large perturbation in the third row of $L$. In some cases this may be unacceptable.)

Now consider the opposite approach—using artificial perturbation we destroy all zeros and increase small entries. Let $X$ be an $n \times n$ lower triangular and nonsingular matrix. The goal is to replace $X$ with $X + \delta X$, where the perturbation $\delta X$ is (i) small enough so that it does not introduce errors larger than the initial uncertainty of the SVD caused by computing $X$; (ii) big enough to prevent underflows in the next QR factorization or in Jacobi iterations; (iii) small enough so that it does not interfere with the convergence and that it does not prevent the use of the lower triangular structure; and (iv) small enough so that it does not preclude stable a posteriori computation of the right singular vectors.

This means that the perturbation $\delta X$ has to be columnwise and also rowwise small. We use $\zeta$ to denote an appropriate threshold value used in the construction of $\delta X \equiv \delta X_\zeta$, for instance, $\zeta = \sqrt{\boldsymbol{\nu}}$, $\zeta = \sqrt{\boldsymbol{\nu}/\boldsymbol{\varepsilon}}$, or $\zeta = \boldsymbol{\varepsilon}/n$. The choice of $\zeta$ depends on $\kappa_2(X)$, from smallest values in the nonextreme case, $\kappa_2(X) < \boldsymbol{\omega\varepsilon}$, to largest in the case[3] $\kappa(X) \approx \omega^2\boldsymbol{\varepsilon}$.

Definition 3.1. *For lower triangular matrix $X$ and small positive parameter $\zeta$, define $\delta X_\zeta$ as follows:*

$$(\delta X_\zeta)_{ij} = \left\{ \begin{array}{cc} 0 & \text{if } |X_{ij}| \geq \zeta \min\{|X_{ii}|, |X_{jj}|\} \\ -X_{ij} + \operatorname{sign}(X_{ij})\zeta \min\{|X_{ii}|, |X_{jj}|\} & \text{else} \end{array} \right\} \text{ for } i \geq j; \tag{3.1}$$

$$(\delta X_\zeta)_{ij} = -\operatorname{sign}(X_{ji})\zeta \min\{|X_{ii}|, |X_{jj}|\} \text{ for } i < j. \tag{3.2}$$

The perturbed matrix $\tilde{X} = X + \delta X_\zeta$ is not triangular. On the other hand, efficient implementation of the first sweep of the quasi-cyclic strategy (section 2.2) is based on the triangular form. We now show that in application of the pivoting (2.5) to $\tilde{X}$ we can use the same technique as in section 2.2 and treat $\tilde{X}$ as triangular. More

---

[3] Extreme cases are relevant only if the singular values are well determined by the data and all wanted to high relative accuracy. Of course, such extreme cases are difficult if the machine arithmetic is not well implemented.

precisely, in the first bulk of rotations $\tilde{X}_{[3]}^{\circlearrowleft}$ we transform only $\tilde{X}_{[3]}(n_1+n_2+1:n,:)$, thus ignoring the perturbation added to $X_{[3]}(1:n_1+n_2,:)$. The perturbed zeros inside the block $\tilde{X}_{[3]}(1:n_1+n_2,:)$ are used to drown denormalized numbers during the phase $X^{[1]} \leftrightarrow X^{[2]}$. The same strategy is applied to $\tilde{X}_{[4]}^{\circlearrowleft}$, where in particular $\tilde{X}_{[4]}(1:n_1+n_2+n_3, 1:n_4)$ is treated as zero and not transformed. In other words, we ignore the perturbation $\delta X_\zeta$ whenever we need a triangular structure to apply (2.5) as described in section 2.2.

Proposition 3.2. *The application of the first sweep of the quasi-cyclic strategy* (2.5) *to* $\tilde{X}$ *(as described above) is rowwise backward stable. Further, the perturbation of the upper triangle can be ignored in the a posteriori computation of the right singular vectors.*

*Proof.* To justify this manipulation with $\delta X_\zeta$, we first note that it contains tiny rowwise relative perturbations $X$. Indeed, for $i<j$ we have

$$\frac{|(\delta X_\zeta)_{ij}|}{\|X(i,:)\|_2} = \zeta \frac{\min\{|X_{ii}|,|X_{jj}|\}}{\|X(i,:)\|_2} \leq \zeta, \text{ where in case of a graded matrix } \frac{|X_{jj}|}{\|X(i,:)\|_2} \ll 1.$$

The key argument is shown for the simplest $(n_1,n_2)$ block partition of $\tilde{X}$,

$$\tilde{X} = \begin{pmatrix} \tilde{X}_{11} & \tilde{X}_{12} \\ \tilde{X}_{21} & \tilde{X}_{22} \end{pmatrix} = \begin{pmatrix} \tilde{X}_{11} & 0 \\ \tilde{X}_{21} & \tilde{X}_{22} \end{pmatrix} + \begin{pmatrix} 0 & \tilde{X}_{12} \\ 0 & 0 \end{pmatrix} \equiv \tilde{X}_{\text{L}} + \delta\tilde{X}_{\text{L}}.$$

Obviously, $\|\tilde{X}_{12}(i,:)\|_2 \leq \sqrt{n_2}\zeta\|X(i,:)\|_2$ for all $i=1,\ldots,n_1$. Suppose we transform the last $n_2$ columns of $\tilde{X}$, following some pivot strategy, but we simply do not reference $\tilde{X}_{12}$ (that is, we work on $\tilde{X}_{\text{L}}$ and use its triangular structure). The computed matrix is represented by the backward perturbation analysis as

$$\begin{aligned} \tilde{X}' &= \begin{pmatrix} \tilde{X}_{11} & 0 \\ \tilde{X}_{21} & \tilde{X}_{22}+\delta\tilde{X}_{22} \end{pmatrix} \begin{pmatrix} I & 0 \\ 0 & \hat{W} \end{pmatrix} + \begin{pmatrix} 0 & \tilde{X}_{12} \\ 0 & 0 \end{pmatrix} \\ &= \begin{pmatrix} \tilde{X}_{11} & \tilde{X}_{12}\hat{W}^T \\ \tilde{X}_{21} & \tilde{X}_{22}+\delta\tilde{X}_{22} \end{pmatrix} \begin{pmatrix} I & 0 \\ 0 & \hat{W} \end{pmatrix}, \quad \hat{W}^T\hat{W} = I, \end{aligned}$$

where $\|\delta\tilde{X}_{22}(i,:)\|_2 \leq O(n)\varepsilon\|\tilde{X}_{22}(i,:)\|_2$, $i=1,\ldots,n_2$, which means that ignoring $\tilde{X}_{12}$ is equivalent to replacing it with $\tilde{X}_{12}\hat{W}^T$ and then applying $\hat{W}$. Since right-handed orthogonal transformation does not change the row-norms of the involved matrices, the rowwise backward stability is preserved. ☐

If we need only to compute the QR factorization of $X$, or to compute only the singular values, then we can allow even bigger $\delta X_\zeta$. Each $X_{ij}$ in the lower triangle with the property $|X_{ij}| < \zeta|X_{jj}|$ is replaced with $\text{sign}(X_{ij})\zeta|X_{jj}|$, and thus $(\delta X_\zeta)_{ij} = -X_{ij} + \text{sign}(X_{ij})\zeta|X_{jj}|$ for all $i>j$. Simultaneously, the position $X_{ji}$ in the upper triangle is set to $(\delta X_\zeta)_{ji} = -\text{sign}(X_{ij})\zeta|X_{ii}|$. Note that $\|\delta X_\zeta(:,j)\|_2 \leq \sqrt{n}\zeta|X_{jj}|$, i.e., the perturbation is columnwise small. Since the matrix $X$ is computed in the QR factorization with pivoting, the condition number of column scaled $X$ is moderate, which means that computations with $X$ and $X+\delta X_\zeta$ will give equally good singular value approximations.

## 4. Numerical testing.

In this section we present software implementation of the new algorithm described in [14, Algorithm 4] and in this report. We give the results of preliminary testing of the algorithm with respect to numerical accuracy and efficiency (run times compared with those of existing algorithms). Our goal is numerically reliable software implemented to reach a reasonable fraction of the efficiency of the less accurate bidiagonalization-based methods. In other words, we want to make the high accuracy of the Jacobi SVD algorithm so affordable that the new algorithm becomes attractive as one of the methods of choice for dense full SVD computation.

Carefully designed testing of the software is also a test of the theory. It shows how sharp the theoretical bounds are and also gives new insights into the cases of input matrices which are on the boundaries of the theoretical assumptions. Good test cases give insights into the behavior of the algorithm and may induce modifications which improve the efficiency of the algorithm. The feedback loop created in this way is part of the research process. In fact, the material of section 3 is the result of numerical tests of an early version of the code. Further, during the tests of our code we found serious problem in the LAPACK implementations xGEQPF and xGEQP3 of the QR factorization with column pivoting; see [13] for a provably stable implementation.

We test single precision (32-bit representation, $\varepsilon \approx 5.3 \cdot 10^{-8}$) implementation. It is always assumed that the nonzero entries of input matrix are normalized floating point numbers.

**4.1. Measuring error—distance to what?** One difficulty in testing a new SVD software on a large set of pseudorandom matrices is how to provide reference (exact) values of $\Sigma$, $U$, and $V$, which are used to estimate the accuracy of the computed approximations $\tilde{\Sigma}$, $\tilde{U}$, $\tilde{V}$. One could start by generating pseudorandom numerically orthogonal $\overline{U}$, diagonal $\overline{\Sigma}$, and numerically orthogonal $\overline{V}$ and then define $A = \mathit{computed}(\overline{U}\ \overline{\Sigma}\ \overline{V}^T)$. However, the numerical SVD of $A$ may be very much different from $\overline{U}\ \overline{\Sigma}\ \overline{V}^T$. Using the same algorithm in higher precision is useful but not always—depending on the matrix, it is possible that both procedures compute with large errors. The alternative is to use existing, tested(!), and trusted double precision software to compute the SVD of a given test matrix $A$. In our case, this means DGESVD and/or DGESDD[4] from LAPACK, but this will be useful only as long these procedures guarantee at least eight digits of accuracy, that is, for (roughly) $\kappa(A) < 1/\varepsilon \approx 10^8$. Our choice of the reference procedure is the classical one-sided Jacobi SVD with de Rijk's [9] pivoting, implemented in double precision.

If $\tilde{\sigma}_1 \geq \cdots \geq \tilde{\sigma}_n$ and $\hat{\sigma}_1 \geq \cdots \geq \hat{\sigma}_n$ are the computed and the reference singular values computed in higher precision, then the forward errors of interest are[5]

$$\mathbf{e}_i = \frac{|\tilde{\sigma}_i - \hat{\sigma}_i|}{\hat{\sigma}_i}, \quad i = 1, \ldots, n, \quad \mathbf{e} = \max_{i=1:n} \mathbf{e}_i. \tag{4.1}$$

**4.2. Test matrices.** Our primary targets are the matrices of the form $A = BD$, where $D$ is diagonal and $B$ is well conditioned with equilibrated (unit in Euclidean norm) columns. In that case the relative error in the output is governed by the condition number $\kappa(B)$ independent of $D$. To illustrate this property we need to generate test matrices $A = BD$, where $B$ has given $\kappa(B)$ and unit columns. Moreover, the matrices should be generated so systematically that the maximal measured forward errors attain the predicted theoretical bounds, and that experimental data show that no accuracy can be guaranteed if the assumptions of the theory are not satisfied. In

---

[4] During the testing we accidentally found an example of serious failure of the DGESDD procedure from the SUN performance library—a ghost singular value of the size of the largest one appeared in the dominant part of the spectrum.

[5] Here by definition $0/0 = 0$.

that case we will have experimental evidence that both the theory and the numerical testing are done properly.

We use the algorithm of Stewart [29] to generate random orthogonal matrices distributed uniformly with respect to the Haar measure over the orthogonal group $\mathcal{O}(n)$. If $W_1$ and $W_2$ are two such matrices, and if $S$ is diagonal with given condition number $\kappa(S)$, we compute $C = W_1 S W_2$. Then we use the fact that for the matrix $C^T C$ there always exists an orthogonal $W_3$ such that the diagonal entries of $W_3^T(C^T C)W_3$ are all equal to $\mathrm{Trace}(C^T C)/n$. Then the matrix $B = CW_3$ has equilibrated columns and condition number $\kappa$. If we generate diagonal $D$, then $A = BD$. There are several ways to generate the matrix $W_3$; see, e.g., [5], [7]. The distributions of the diagonal entries of $S$ and $D$ can be chosen in different ways. We use the modes provided in the LAPACK test matrix generators (parameter MODE in DLATM1), and the chosen modes are denoted by $\mu(S)$ and $\mu(D)$. Thus, each generated matrix $A$ has four parameters, $p(A) = (\kappa(S), \mu(S), \kappa(D), \mu(D))$. For each fixed $p(A)$, we use three different random number generators provided in the LAPACK testing library (LAPACK/TESTING/MATGEN/), and with each of them we generate a certain number of samples (test matrices). In this way, we have an automated generator of pseudorandom matrices with certain relevant parameters varying systematically in a given range; for instance, $\kappa(S)(= \kappa(B))$ is set to take the values 10, $10^2$, $10^3, \ldots, 10^8$.

**4.3. Test results.** Our new algorithm is implemented in a LAPACK-style routine SGEPVD, which is in an early stage of development. We have done no serious profiling in order to optimize it for a particular architecture. The bulk of the code (rotations) is still on BLAS 1 level, and we have plans to change this in near future. Nevertheless, the obtained results are surprisingly good and encouraging. The results presented in this report were obtained on an HP X2100 workstation (1.9GHz Pentium 4, 1Gb RAM, 8 Kb L1 cache, 256 Kb L2 cache), using GNU FORTRAN compiler F77 3.3.1 under SuSE Linux. The LAPACK library is compiled from the source code and linked with the BLAS library from Intel's MKL 6.1.

**4.3.1. Computing the full SVD.** The test matrices of the form $A = BD$ are generated as follows. We take $A = ((W_1 S W_2) W_3) D$ as described in section 4.2, and $\kappa(S) = 10^i$, $i = 1, \ldots, 8$, and $\kappa(D) = 10^{2j}$, $j = 0, \ldots, 7$. For each fixed pair $(i, j)$ we generate diagonal $S$ and $D$ each with four different distributions of the diagonal entries (as specified by the parameter MODE). This gives for each fixed $(\kappa(S) = 10^i, \kappa(D) = 10^{2j})$ 16 different types of matrices, giving a total of $64 \cdot 16 = 1024$ classes. The matrices are generated in four nested loops; the outer loop controls $\kappa(B) = \kappa(S)$. Hence, the matrices are divided into eight groups with fixed $\kappa(B)$.[6] Finally, we choose the row and the column dimensions, $m$ and $n$, and the test procedure is ready.

Once we compute $A \approx \tilde{U}\tilde{\Sigma}\tilde{V}^T$, $\tilde{\Sigma} = \mathrm{diag}(\tilde{\sigma}_1, \ldots, \tilde{\sigma}_n)$, we can immediately estimate the quality of the computed decomposition using the following computed quantities:

$$\mathbf{r} = \mathit{computed}\left(\frac{\|A - \tilde{U}\tilde{\Sigma}\tilde{V}^T\|_F}{\|A\|_F}\right) \quad \text{(should be at most } f(m,n)\boldsymbol{\varepsilon},\ f \text{ moderate);}$$

$$\mathbf{o}_U = \mathit{computed}\left(\max_{i,j} |(\tilde{U}^T\tilde{U})_{ij} - \delta_{ij}|\right) \quad \text{(should be at most } O(m\boldsymbol{\varepsilon})\text{);}$$

$$\mathbf{o}_V = \mathit{computed}\left(\max_{i,j} |(\tilde{V}^T\tilde{V})_{ij} - \delta_{ij}|\right) \quad \text{(should be at most } O(n\boldsymbol{\varepsilon})\text{).}$$

---

[6] This helps in the interpretation of the results of the experiments and explains the shapes of the graphs on the figures given here.

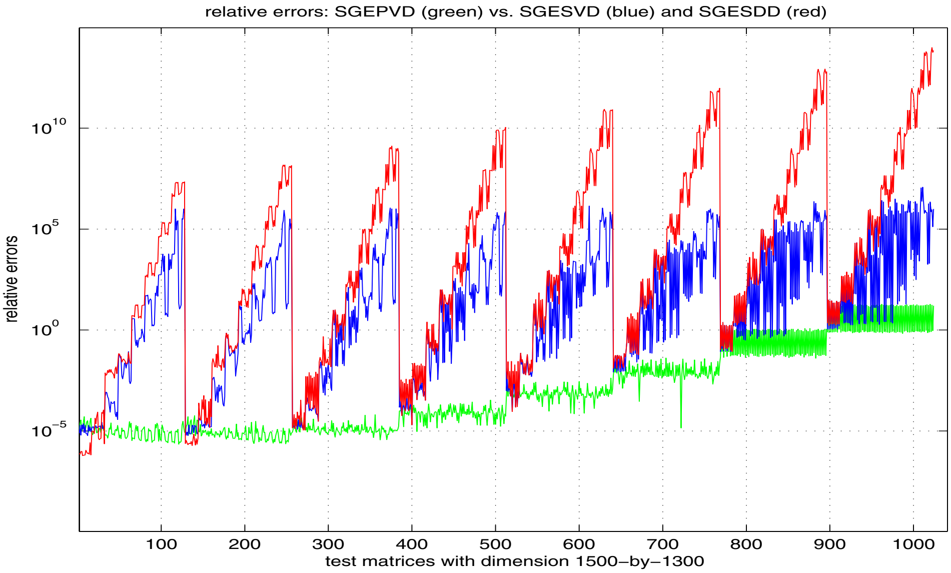

FIG. 4.1. *Maximal relative errors in the computed singular values for* $1500 \times 1300$ *matrices. The top curve (worst case) describes the accuracy of SGESDD. The middle curve represents the errors of SGESVD, and the lowest curve (smallest relative errors) belongs to SGEPVD.*

These measures are useful to test the correctness of the code and backward stability in the matrix norm sense. It is easy to show that $\mathbf{r}$, $\mathbf{o}_U$, and $\mathbf{o}_V$ can be computed sufficiently accurately (best using higher precision) to be used as relevant measures of the quality of the computed decomposition. Thus, the standard error bound can be a posteriori numerically checked. Our procedure, called SGEPVD,[7] has successfully passed all three tests; $\mathbf{r}$, $\mathbf{o}_U$, $\mathbf{o}_V$ were in the allowed ranges. Note that SGEPVD returns the singular vectors numerically orthogonal up to the theoretical bound $m\varepsilon$ ($n\varepsilon$), which, as in other algorithms dealing with numerical orthogonality, for large $m$ and $n$ may not look satisfactory in single precision ($\varepsilon \approx 10^{-7}$ and, e.g., $m = n = 4000$).

Before we go over to the comparison of SGEPVD with SGESVD and SGESDD from LAPACK, we should point out that SGEPVD computes the SVD to higher accuracy and also provides an estimate of the maximal relative error by computing an approximation of $\|B^\dagger\|_2$.

We show only two out of the many tests performed during code development. Or first test ran with $m = 1500$, $n = 1300$, and with one pseudorandom matrix in each class. Compare the maximal relative errors in computed singular values for all 1024 test cases, shown on Figure 4.1. It is clearly seen that the accuracy of SGEPVD depends on $\kappa(B)$, while the other two methods depend on $\kappa(A)$. Any SVD algorithm that starts with bidiagonalization is at risk to have error behaving like the SGESVD and SGESDD errors in Figure 4.1. The best caption for this figure is the title of [8]. Note that SGESVD returns much better results than SGESDD. To the best of our knowledge, this fact is not mentioned elsewhere in the literature. Also, note the considerable upward bias in the relative errors of the bidiagonalization-based procedures (cf. [30]).

The timings for this example are shown on Figure 4.2. We immediately note that the new Jacobi SVD algorithm is not that much slower than the bidiagonalization-

---

[7] PVD is the acronym for principal value decomposition, an old name for SVD.

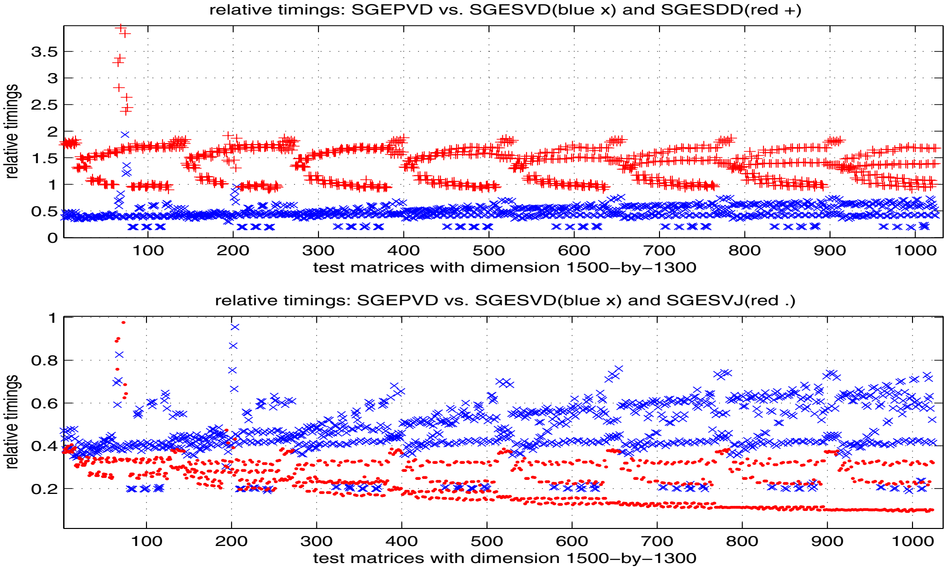

FIG. 4.2. *Computing full SVD: Relative timings for* $1500 \times 1300$ *matrices on a Pentium* 4 *machine with Intel MKL* 6.1 *library. In the first plot, the crosses denote* $time_{\mathrm{SGEPVD}}/time_{\mathrm{SGESVD}}$ *and the pluses* $time_{\mathrm{SGEPVD}}/time_{\mathrm{SGESDD}}$. *The second plot shows* $time_{\mathrm{SGEPVD}}/time_{\mathrm{SGESVD}}$ *(crosses) and* $time_{\mathrm{SGEPVD}}/time_{\mathrm{SGESVJ}}$ *(dots). See Remark* 4.1.

based fast methods. In fact, it outperforms the QR algorithm and is on average less than twice as slow as the divide-and-conquer algorithm. The worst-case performance for SGEPVD is on matrices with weak column scaling and a singular spectrum composed of many tight clusters (examples above the 1.5 mark on Figure 4.2). In all other cases the time of SGEPVD is on average 1.5 times the time of SGESDD. Here, again, we stress the fact that the results obtained by SGEPVD enjoy much better numerical properties and that the time of SGEPVD includes computed error bound—better results and additional information are computed in reasonable time. Thus, for a fair comparison one should consider both Figures 4.1 and 4.2 before deciding which algorithm is the better choice for a particular application. The second plot on Figure 4.2 shows $time_{\mathrm{SGEPVD}}/time_{\mathrm{SGESVD}}$ and $time_{\mathrm{SGEPVD}}/time_{\mathrm{SGESVJ}}$, where SGESVJ denotes our careful implementation (cf. [11]) of de Rijk's [9] one-sided Jacobi SVD. (De Rijk's one-sided Jacobi SVD is much more efficient than other classical cyclic Jacobi algorithms.) It is interesting that de Rijk reported superior performance of his Jacobi SVD code over the SSVDC routine from LINPACK (Golub–Reinsch SVD) on CYBER 205. Note that our code SGEPVD runs up to ten times faster than SGESVJ.

In the second test we have $500 \times 350$ matrices, with two examples in each of 1024 classes. The results are given in Figure 4.3.

*Remark* 4.1. Note the few outliers above mark 2 on Figures 4.2 and 4.3. They correspond to matrices on which SGEPVD actually performed very well, with a low number of rotations and swift convergence. (We checked this by inspecting the details of those particular runs. In fact, on these matrices even the classical one-sided Jacobi, usually much slower, comes close to our new method.) However, since our threshold for perturbation used to trap denormals was set to $\zeta = \sqrt{\boldsymbol{\nu}} \approx 10^{-19}$, some of them were

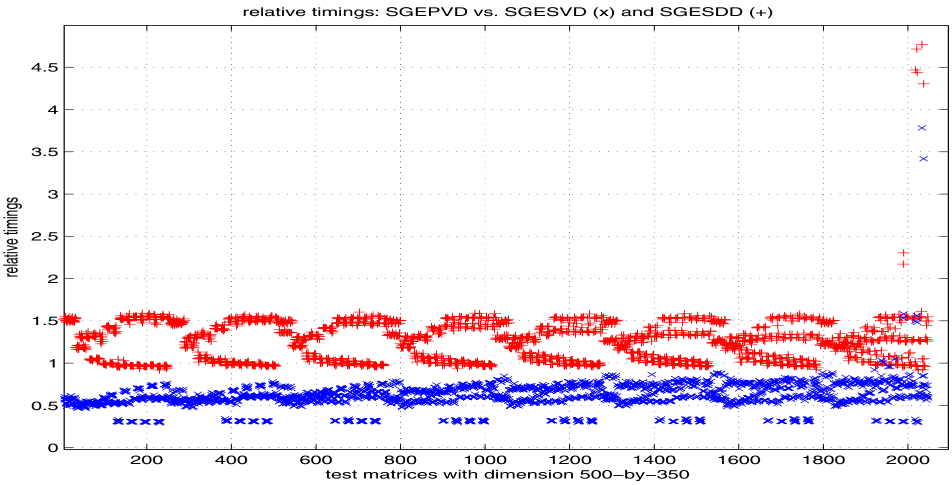

FIG. 4.3. *Computing full SVD: Relative timings for* $500 \times 350$ *matrices on a Pentium* 4 *machine with Intel MKL* 6.1 *library. The crosses denote* $time_{\mathrm{SGEPVD}}/time_{\mathrm{SGESVD}}$ *and the pluses are* $time_{\mathrm{SGEPVD}}/time_{\mathrm{SGESDD}}$.

not captured, and imperfect denormalized arithmetic caused considerable slowdown. We used this value of $\zeta$ to illustrate the problem. In practice the threshold can be set higher; e.g., if in those cases $\zeta = \varepsilon/n$, or if *set to zero* underflow is in function, then the run time reflects the actual flop count and the outliers disappear.

*Remark* 4.2. We have noted that using a double accumulated dot product in preparation of Jacobi rotation reduces the total number of rotations, especially in cases of multiple or tightly clustered singular values. Unfortunately, in the MKL BLAS library DSDOT performs poorly in comparison to SDOT, and the savings in number of rotations do not reduce the total run time.

*Remark* 4.3. The results may vary on the same machine with different BLAS libraries. We note that with the GOTO BLAS [18], [19] all routines run faster (as compared to the MKL library), but the relative speedup is smallest in our algorithm. This is because GOTO BLAS 3 outperforms MKL 6.1 BLAS 3, but GOTO BLAS 1 is no match for really efficient MKL 6.1 BLAS 1. Since our code still depends on BLAS 1 (dot products and plane rotations), switching to GOTO BLAS has mixed consequences. A hybrid of the two libraries would be much better for our algorithm.

**4.3.2. Computing only Σ.** We have established that the singular values are computed by the new algorithm as predicted by the theory—our variant of the Jacobi SVD complies with [8], [10]. In the previous section we showed that it computes the full SVD with efficiency comparable to fast bidiagonalization-based approaches. If only the singular values are needed, reaching a similar level of relative efficiency seems to be mission impossible, for we would need a Jacobi-based algorithm that computes $\Sigma$ in time comparable to the time needed to bidiagonalize the matrix! However, the results of [14, Algorithm 1] with the rank revealing QR factorization [4], [3] are encouraging.

The test matrices of the form $A = BD$ are generated as in section 4.3.1, with 2048 examples in each test run. We show the results of two tests; in the first the matrices were $500 \times 350$ and in the second $m = 1000$, $n = 700$. The maximal measured relative errors $\mathbf{e}$ are not shown because they behave as shown in section 4.3.1. In Figure 4.4

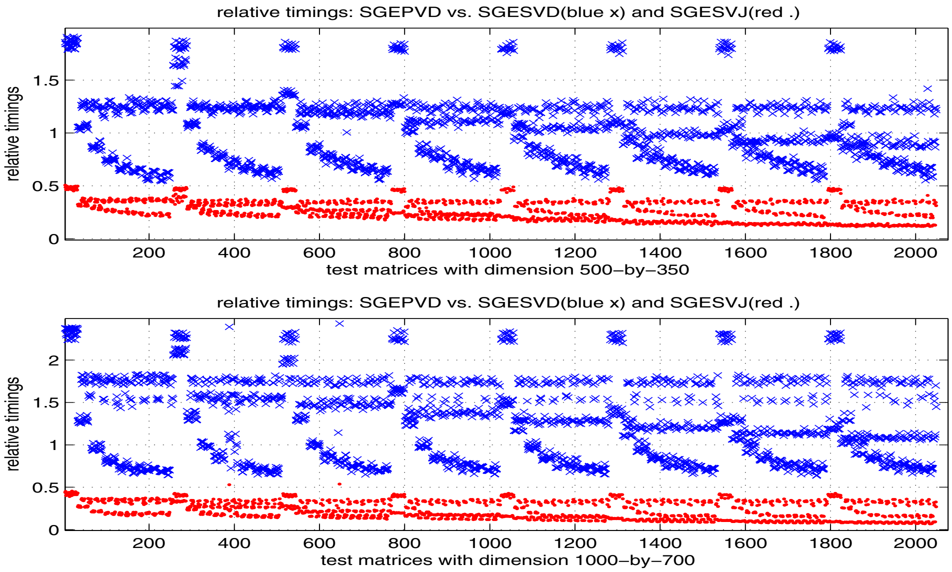

FIG. 4.4. *Computing only* $\Sigma$*: Relative timings for* $500 \times 350$ *and* $1000 \times 700$ *matrices on a Pentium* 4 *machine with Intel MKL* 6.1 *library. The crosses denote* $time_{\mathrm{SGEPVD}}/time_{\mathrm{SGESVD}}$ *and the dots are* $time_{\mathrm{SGEPVD}}/time_{\mathrm{SGESVJ}}$.

we display the relative timings and compare SGEPVD with SGESDD (or SGESVD) and with the classical one-sided Jacobi SVD with de Rijk's pivoting (SGESVJ). The speedup of the new algorithm over SGESVJ ranges from a factor of 2 up to a factor of 15. (We note that SGEPVD computes $\Sigma$ and also an estimate of the scaled condition number.) It is interesting to note that in cases of well separated singular values (especially in cases of badly scaled matrices) the new method computes all singular values faster than bidiagonalization-based methods. In less favorable cases of clustered singular values the new method is slower with a factor of up to 2.43, depending on the input matrix.

## 5. Conclusion and future work.

The most important message of [14] and this paper is that the question of the ultimate dense nonstructured full SVD method is still open. What is desired is the most efficient algorithm capable of computing the SVD to optimal (numerically feasible) accuracy warranted by the data. Because the one-sided Jacobi SVD is more accurate than any other algorithm that first bidiagonalizes the matrix, in our quest for the ultimate dense nonstructured SVD algorithm we follow the Jacobi idea. We have enhanced the basic Jacobi SVD algorithm with a preconditioning stage and new iterative scheme for preconditioned triangular matrices.

Our results show that the new preconditioned Jacobi-type SVD algorithm can be competitive in efficiency with fast bidiagonalization-based methods (QR and divide-and-conquer algorithms) without trading accuracy for speed. *In fact, the new algorithm computes the SVD more accurately and almost twice as fast as the SGESVD from LAPACK, and the speedup factor over the equally accurate standard one-sided Jacobi SVD (enhanced with de Rijk's pivoting) typically ranges between three and ten.* (See Figures 4.1 and 4.2.) The new Jacobi SVD algorithm remains slower (with factors ranging from 1 to 1.75) than the less accurate divide-and-conquer SVD (SGESDD from LAPACK). If only the singular values are computed, our method can be up to fifteen times faster than the standard one-sided Jacobi SVD, and it is up to twice as slow as bidiagonalization-based singular value computation. (In our tests with dimensions up to 1000 the efficiency was within factors 0.63–2.43 of SGESVD and SGESDD.)

The new algorithm has an advantage over bidiagonalization-based methods in cases of matrices with low numerical rank, because it starts with a rank revealing factorization (cf. [23]). (Bidiagonalization is not rank revealing unless enhanced with pivoting, which would make it more expensive.) In fact, in cases of low numerical rank, we can even outperform SGESDD. If $m \gg n$, both methods start with the QR factorization, which is the most expensive part of the computation, and in that case the efficiency of all three methods is about the same. Also, if only the standard absolute accuracy is required, then Jacobi iterations can be controlled by a loosened stopping criterion, thus allowing satisfactory approximation with less computational effort.

However, our algorithm is not yet fully optimized and several issues are the subject of our current and future work. The most expensive part of our method are BLAS 1 Jacobi rotations, which means that there is more potential for optimization. One simple improvement will be possible once optimized combinations of AXPY and DOT, and combination of two linked AXPY operations are available in single calls.

Nontrivial improvement will be obtained by using block rotations. We expect that the fast scaled block rotations designed by Hari [21] will fully exploit the potential of our approach and considerably improve the performance, especially in difficult cases of tightly clustered singular values. Namely, in such cases the preconditioner does not perform well, which means that one or two full sweeps of rotations are needed to compensate the lack of proper preconditioning. Such heavy computation on a BLAS 1 level is clearly seen in the numerical results presented in section 4 (see, e.g., the crosses above 1.5 and 2 on Figure 4.4).

Further, the overhead of column pivoting in BLAS 3 optimized QR factorization (SGEQP3 from LAPACK) is still too big. Any future improvement of the column-pivoted QR factorization contributes to the efficiency of our algorithm. Other issues include new rank revealing QR factorization and using shifts in the second QR (and third in some cases) factorization if only classical absolute error bounds are required. Our ultimate goal is high performance LAPACK-style software. The question is whether or not we will be able to reach the efficiency of SGESDD. Time will tell.

# ALGORITHMIC ASPECTS OF ELIMINATION TREES FOR SPARSE UNSYMMETRIC MATRICES*

STANLEY C. EISENSTAT† AND JOSEPH W. H. LIU‡

**Abstract.** The elimination tree of a symmetric matrix plays an important role in sparse elimination. We recently defined a generalization of this structure to the unsymmetric case that retains many of its properties. Here we present an algorithm for constructing the elimination tree of an unsymmetric matrix and show how it can be used to find a symmetric reordering of the matrix into a recursive, bordered block triangular form. We also present two symbolic factorization algorithms that use the elimination tree to determine the nonzero structures of the triangular factors of such matrices. Numerical experiments demonstrate that these algorithms are efficient and compare the new symbolic factorization schemes with existing ones.

**Key words.** elimination tree, symbolic factorization, sparse matrix factorization

**DOI.** 10.1137/050643581

## 1. Introduction.

The elimination tree of a symmetric matrix plays many important roles in sparse factorization [20]. By using paths instead of edges to define the tree, we recently generalized this structure to unsymmetric matrices while retaining many of its properties [15]. In this paper we consider several algorithmic aspects of elimination trees. The outline of the paper is as follows.

In section 2 we introduce some graph notation and review the elimination tree of an unsymmetric matrix and tree-based, bordered block triangular (BBT) orderings [15]. In section 3 we present algorithms for constructing the elimination tree and for finding a BBT ordering. The basic algorithm repeatedly finds strongly connected components of subgraphs. Quotient graphs and path-preserving edge reduction are used to improve its efficiency.

In section 4 we review existing algorithms for symbolic $LU$ factorization, which use either symmetric pruning [13] or the elimination dags (directed acyclic graphs) [18] to improve performance. We describe a tree-based pruning scheme that is the first practical implementation of path-symmetric reduction [13]. We also present two symbolic factorization algorithms for matrices that are in BBT form. Both are based on special structural properties of the triangular factors of BBT ordered matrices and this tree-based pruning scheme.

In section 5 we give experimental results from running these algorithms on a set of test problems. We also compare the performance of the new symbolic factorization codes with existing ones. In section 6 we offer some concluding remarks and suggest possible applications of elimination trees to other aspects of sparse factorization.

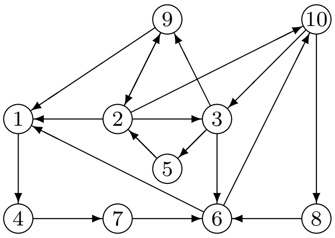

FIG. 1. *A sparse matrix and its directed graph.*

## 2. Background.

The authors introduced the elimination tree of a sparse unsymmetric matrix and studied tree-based, BBT orderings in [15]. We briefly review these ideas here.

### 2.1. Graph notation.

The *directed graph* $G(M)$ of a sparse unsymmetric $n \times n$ matrix $M$ is defined as follows: the vertex set is $X(M) = \{1, 2, \ldots, n\}$; and for distinct vertices $r$ and $c$, there is a *directed edge* $r \xmapsto{M} c$ from $r$ to $c$ if and only if the entry $m_{rc} \neq 0$. We shall use the notation $r \overset{M}{\Longrightarrow} c$ to indicate a *directed path*[1] from $r$ to $c$. If the matrix $M$ is clear from context, we shall sometimes use the abbreviated forms $r \mapsto c$ and $r \Rightarrow c$.

At times we shall consider composite paths such as $r \xmapsto{M} u \overset{M'}{\Longrightarrow} c$. If there is no restriction on the intermediate vertex $u$, we shall use the abbreviated form[2] $r \xmapsto{M} \overset{M'}{\Longrightarrow} c$.

A set of vertices $S \subseteq X(M)$ induces a *subgraph* of $G(M)$ consisting of the vertices in $S$ and all edges $u \mapsto v$ with $u, v \in S$. To simplify the presentation we shall not distinguish between a set of vertices and the subgraph of $G(M)$ that it induces; that is, we shall use $S$ as a subset of $X(M)$ and as a subgraph of $G(M)$ interchangeably. It should be clear from context which use is intended. We shall use the notation $G_m(M)$ to denote the subgraph $\{1, 2, \ldots, m\}$ of $G(M)$ for $0 \leq m \leq n$.

A subgraph $S$ of $G(M)$ is *strongly connected* if, for any pair of distinct vertices $u, v \in S$, there is a cycle $u \Rightarrow v \Rightarrow u$ in the subgraph $S$. If $S$ is a *maximal* strongly connected subgraph, then it is a (strongly connected) *component* of $G(M)$.

Figure 1 contains a $10 \times 10$ unsymmetric matrix that will be used as an example throughout the paper. The diagonal entries are the vertices; each $\bullet$ represents an off-diagonal nonzero. The subgraph $\{1, 4, 6, 7\}$ is strongly connected (since $1 \mapsto 4 \mapsto 7 \mapsto 6 \mapsto 1$ is a cycle), but is not a component (since the entire graph is strongly connected).

### 2.2. Quotient graphs and matrices.

Let $\{S_1, S_2, \ldots, S_q\}$ be a partition of the vertex set $X(M)$. The *quotient graph* of $G(M)$ induced by this partition has the vertices $S_1$, $S_2$, $\ldots$, $S_q$ and a directed edge from $S_i$ to $S_j$ if and only if there are vertices $u \in S_i$ and $v \in S_j$ with $u \xmapsto{M} v$. We can represent the quotient graph as $G(Q)$ by defining a $q \times q$ *quotient matrix* $Q$ with $q_{ij} = 1$ if there is an edge from $S_i$ to $S_j$ and $q_{ij} = 0$ otherwise.

---

[1] Paths and cycles must contain at least one edge, but need not be *simple*; that is, they may visit a vertex or edge more than once.

[2] This notation is due to John Gilbert.

$$Q = \begin{pmatrix} S_1 & \bullet & & \bullet & \bullet \\ & S_2 & & & \bullet \\ & \bullet & S_3 & & \\ \bullet & \bullet & & S_4 & \\ \bullet & & \bullet & & S_5 \end{pmatrix}$$

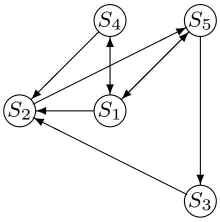

FIG. 2. *A quotient graph of the matrix in Figure* 1.

$$A^+ = \begin{pmatrix} 1 & & & \bullet & & & & & & \\ \bullet & 2 & \bullet & \circ & & & & & \bullet & \bullet \\ & & 3 & & \bullet & \bullet & & & \bullet & \\ & & & 4 & & & \bullet & & & \\ & \bullet & \circ & \circ & 5 & \circ & \circ & & \circ & \circ \\ \bullet & & & \circ & & 6 & \circ & & & \bullet \\ & & & & & \bullet & 7 & & & \circ \\ & & & & & \bullet & \circ & 8 & & \circ \\ \bullet & \bullet & \circ & \circ & \circ & \circ & \circ & & 9 & \circ \\ & & \bullet & & \circ & \circ & \circ & \bullet & \circ & 10 \end{pmatrix}$$

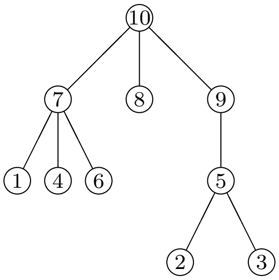

FIG. 3. *The filled matrix and elimination tree for the matrix of Figure* 1.

Figure 2 contains the quotient graph $G(Q)$ of the directed graph in Figure 1 for the partition

$$S_1 = \{2,3,5\}, \quad S_2 = \{1,4,6,7\}, \quad S_3 = \{8\}, \quad S_4 = \{9\}, \quad S_5 = \{10\}.$$

Note that there is an edge from $S_3$ to $S_2$ since there is an edge $8 \mapsto 6$ in the original graph. Also, there is a directed edge from $S_1$ to $S_2$ since there is an edge $2 \mapsto 1$ (or an edge $3 \mapsto 6$).

### 2.3. The elimination tree of an unsymmetric matrix.

Let $A$ be a nonsingular sparse unsymmetric $n \times n$ matrix with a nonzero diagonal and the factorization $A = LU$, where $L$ is unit lower triangular and $U$ is upper triangular; and let $A^+ = L + U - I$ denote its *filled matrix.*

We define the *elimination tree* $T(A)$ of $A$ using the parent function

$$\textsc{fpnz}(k) = \min\{x \mid x > k \text{ and } x \overset{L}{\Longrightarrow} k \overset{U}{\Longrightarrow} x\},$$

where the minimum over the empty set is taken to be $\infty$. Vertex $p = \textsc{fpnz}(k)$ is the parent of vertex $k$ if $\textsc{fpnz}(k) < \infty$. By definition we have $\textsc{fpnz}(n) = \infty$, so that vertex $n$ is a root. In general $T(A)$ consists of one or more trees, and each vertex $k$ with $\textsc{fpnz}(k) = \infty$ is a root. However, there is only one tree when $A$ is irreducible [15, Corollary 3.7].

For example, the filled matrix and elimination tree for the matrix in Figure 1 is given in Figure 3. The diagonal entries are the vertices; each $\circ$ represents an off-diagonal nonzero in $A^+$ that is zero in $A$.

We shall use the notation $\mathcal{T}_k$ to denote both the subtree of $T(A)$ rooted at vertex $k$ and the set of vertices in this subtree.

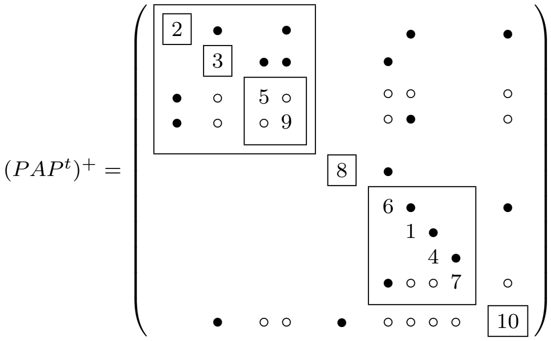

FIG. 4. *The filled matrix of an upper BBT postordering of the matrix in Figure* 1.

**2.4. BBT postorderings.** A matrix $M$ is said to be upper *bordered block triangular* (BBT) if it can be written in the form

$$\begin{pmatrix} M_{1,1} & M_{1,2} & \cdots & M_{1,s} & M_{1,s+1} \\ 0 & M_{2,2} & \cdots & M_{2,s} & M_{2,s+1} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & M_{s,s} & M_{s,s+1} \\ M_{s+1,1} & M_{s+1,2} & \cdots & M_{s+1,s} & M_{s+1,s+1} \end{pmatrix}$$

for some symmetric blocking of the rows and columns. If we can find a permutation matrix $P$ such that the reordered matrix $PAP^t$ is in BBT form for some $s > 1$, we can take advantage of this structure by working with $PAP^t$ instead of $A$.

Let $c_1, \ldots, c_t$ be the children of a vertex $k$ in the elimination tree $T(A)$. In a *postordering* of $T(A)$ the vertices within each subtree $\mathcal{T}_{c_i}$ are numbered consecutively, and $k$ is numbered immediately after its descendants. Postordering preserves[3] the structure of $T(A)$.

To achieve a (recursive) BBT form, an *upper BBT* (resp., *lower BBT*) postordering imposes a further condition on the order in which the subtrees $\mathcal{T}_{c_1}, \ldots, \mathcal{T}_{c_t}$ are numbered: an edge in $G(A)$ from a vertex in one subtree to a vertex in another must always be directed from the lower-numbered vertex to the higher-numbered one (resp., higher to lower). A BBT postordering need not be unique and need not preserve the filled graph.[4] However, it does preserve the set of values on the diagonal of $U$ (see [15, Theorem 5.2]) and thus is arguably just as stable numerically.

For example, the ordering $2, 3, 5, 9, 8, 6, 1, 4, 7, 10$ is an upper BBT postordering of the elimination tree in Figure 3 and gives rise to the permuted matrix $PAP^t$ in Figure 4. The boxes emphasize the recursive nature of BBT form.

We shall say that a matrix $A$ is upper (resp., lower) *BBT ordered* if the natural ordering is an upper (resp., lower) BBT postordering of $T(A)$.

## 3. Constructing the elimination tree.

**3.1. The basic algorithm.** In this section we consider effective ways to construct the elimination tree $T(A)$. All are based on the following result, which is a

---

[3] That is, letting $P$ denote the corresponding permutation matrix, the elimination tree $T(PAP^t)$ is identical to $T(A)$ up to the numbering of the vertices [15, Theorem 5.1].

[4] Indeed, it may increase the amount of fill.

FIG. 5. *Basic algorithm for constructing the elimination tree.*

more usable characterization of the parent function FPNZ($*$) than the definition given in section 2.3.

THEOREM 3.1 (see [15, Corollary 3.4]). *Vertex $k$ is the parent of vertex $x$ in the elimination tree $T(A)$ if and only if $k$ is the first vertex after $x$ such that $k$ and $x$ belong to the same strongly connected component of the subgraph $G_k(A)$ of $G(A)$.*

For example, Table 1 gives the strongly connected components in $G_k(A)$ for the matrix in Figure 1, with the component containing $k$ listed last. From this it is easy to verify that the elimination tree is as shown in Figure 3. For example, vertex 5 is the parent of vertex 2 because $G_5(A)$ is the first subgraph $G_k(A)$ with a component containing vertices 2 and $k$.

Theorem 3.1 leads immediately to Algorithm ETREE in Figure 5, which sets FPNZ($x$) equal to the first $k$ for which $x$ and $k$ belong to the same component of $G_k(A)$.

There are many algorithms for finding strongly connected components (e.g., [7, p. 489], [17], and [23]). When adapted to find the component containing $k$, all take time proportional to the number of vertices and edges in $G_k(A)$ reachable from $k$. Thus Algorithm ETREE runs in time $O(mn)$, where $m$ is the number of nonzero entries in $A$.

There is still benefit to reducing both the number of these vertices (see section 3.2) and the number of these edges (see section 3.3) in such a way that strong connectivity is preserved.

**3.2. Using quotients of strongly connected components.** The strongly connected components of a graph form a partition of its vertex set, and by definition the quotient graph they induce has the following property:

> Let distinct vertices $x$ and $y$ belong to strongly connected components $\mathcal{X}$ and $\mathcal{Y}$, respectively. Then there exists a path $x \Rightarrow y$ in the graph if and only if either $\mathcal{X} = \mathcal{Y}$ or there exists a path $\mathcal{X} \Rightarrow \mathcal{Y}$ in the quotient graph.

Moreover, the quotient graph is *acyclic* (i.e., cycle-free). In this section we use this succinct representation of the connectivity of a graph [21] to improve Algorithm eTree. We begin with a characterization of the components of the graph $G_k(A)$.

Theorem 3.2. *Let $\mathcal{K}$ be a component of $G_k(A)$, and let $m$ be the highest-numbered vertex in $\mathcal{K}$. Then $\mathcal{K} = \mathcal{T}_m$, the subtree of the elimination tree $T(A)$ rooted at $m$.*

*Proof.* ($\mathcal{K} \subseteq \mathcal{T}_m$) Assume that $\mathcal{K} \not\subseteq \mathcal{T}_m$, and let $x$ be the highest-numbered vertex in $\mathcal{K} \setminus \mathcal{T}_m$. Since $\mathcal{K}$ is a component of $G_k(A)$ and $m$ is the highest-numbered vertex in $\mathcal{K}$, it follows that $\mathcal{K}$ is a component of $G_m(A)$. Since in addition both $x$ and $m$ belong to $\mathcal{K}$, by Theorem 3.1 vertex $x$ has a parent $p$ in $T(A)$, both $x$ and $p$ belong to the same component of $G_p(A)$, and $x < p \leq m$. Thus both $x$ and $p$ belong to the same component of $G_m(A)$, namely, $\mathcal{K}$. On the other hand, since $x \notin \mathcal{T}_m$, we have $p \notin \mathcal{T}_m$ so that $p \in \mathcal{K} \setminus \mathcal{T}_m$, which contradicts the definition of $x$.

($\mathcal{T}_m \subseteq \mathcal{K}$) Since $\mathcal{T}_m$ is the subtree of $T(A)$ rooted at $m$ and $m \in \mathcal{K}$, it suffices to show that if vertex $p \in \mathcal{K}$ and vertex $c$ is a child of $p$ in $T(A)$, then $c \in \mathcal{K}$. By Theorem 3.1 both $p$ and $c$ belong to the same component of $G_p(A)$, which is a subgraph of $G_k(A)$ since $p \leq k$. Thus $c$ and $p$ must also belong to the same component of $G_k(A)$, namely, $\mathcal{K}$. ☐

For example, the subgraph $G_7(A)$ of the graph in Figure 1 has two strongly connected components $\{2, 3, 5\}$ and $\{1, 4, 6, 7\}$ (see Table 1) corresponding to the subtrees $\mathcal{T}_5$ and $\mathcal{T}_7$ of the elimination tree in Figure 3.

Let $G(Q_k)$ denote the quotient graph of $G_k(A)$ induced by its strongly connected components, where $Q_k$ is the quotient matrix. Then each vertex in $G(Q_k)$ is a subtree $\mathcal{T}_u$ of $T(A)$ for some vertex $u$ with $u \leq k$; and for distinct vertices $\mathcal{T}_u$ and $\mathcal{T}_v$ in $G(Q_k)$, there is an edge $\mathcal{T}_u \mapsto \mathcal{T}_v$ if and only if there exist vertices $x \in \mathcal{T}_u$ and $y \in \mathcal{T}_v$ such that $x \overset{A}{\longmapsto} y$.

The graph $G_k(A)$ is obtained from the graph $G_{k-1}(A)$ (the empty graph if $k = 1$) by adding vertex $k$ and all edges $x \overset{A}{\longmapsto} k$ and $k \overset{A}{\longmapsto} x$ with $1 \leq x < k$. Similarly, $G(Q_k)$ can be obtained from $G(Q_{k-1})$ (the empty graph if $k = 1$) in two steps:

1. Form the intermediate graph $G(Q'_k)$ from $G(Q_{k-1})$ by
   - adding vertex $k$;
   - for each vertex $\mathcal{T}_u$, adding the edge $\mathcal{T}_u \mapsto k$ if there is an edge $x \overset{A}{\longmapsto} k$ with $x \in \mathcal{T}_u$; and
   - for each vertex $\mathcal{T}_v$, adding the edge $k \mapsto \mathcal{T}_v$ if there is an edge $k \overset{A}{\longmapsto} y$ with $y \in \mathcal{T}_v$.
2. Form $G(Q_k)$ from $G(Q'_k)$ by coalescing $k$ and all vertices in the strongly connected component of $G(Q'_k)$ that contains it into the new vertex $\mathcal{T}_k$.

Figure 6 gives the intermediate quotient graphs $G(Q'_7)$, $G(Q'_8)$, $G(Q'_9)$, and $G(Q'_{10})$ for the matrix in Figure 1. For example, the four components of $G_6(A)$,

$$\mathcal{T}_1 = \{1\}, \qquad \mathcal{T}_4 = \{4\}, \qquad \mathcal{T}_5 = \{2, 3, 5\}, \qquad \mathcal{T}_6 = \{6\},$$

are used to form $G(Q'_7)$.

Let $\mathcal{T}_c$ be a vertex of $G(Q'_k)$ that is coalesced into $\mathcal{T}_k$, and let vertex $p$ be the parent of vertex $c$ in $T(A)$. Then $c$ and $k$ belong to the same component of $G_k(A)$, and $p \leq k$ by Theorem 3.1. But if $p < k$, then $\mathcal{T}_c$ could not have been a component of $G_{k-1}(A)$ or a vertex of $G(Q_{k-1})$ by Theorem 3.2. Thus $p = k$, and $c$ is a child of $k$. This leads immediately to Algorithm eTreeQ in Figure 7.

$$Q'_7 = \left(\begin{array}{cccc|c} \mathcal{T}_1 & \bullet & & & \\ & \mathcal{T}_4 & & & \bullet \\ \bullet & & \mathcal{T}_5 & \bullet & \\ \bullet & & & \mathcal{T}_6 & \\ \hline & & & \bullet & 7 \end{array}\right)$$

$$Q'_8 = \left(\begin{array}{cc|c} \mathcal{T}_5 & \bullet & \\ & \mathcal{T}_7 & \\ \hline & \bullet & 8 \end{array}\right)$$

$$Q'_9 = \left(\begin{array}{ccc|c} \mathcal{T}_5 & \bullet & & \bullet \\ & \mathcal{T}_7 & & \\ & \bullet & \mathcal{T}_8 & \\ \hline \bullet & \bullet & & 9 \end{array}\right)$$

$$Q'_{10} = \left(\begin{array}{ccc|c} \mathcal{T}_7 & & & \bullet \\ \bullet & \mathcal{T}_8 & & \\ \bullet & & \mathcal{T}_9 & \bullet \\ \hline & \bullet & \bullet & 10 \end{array}\right)$$

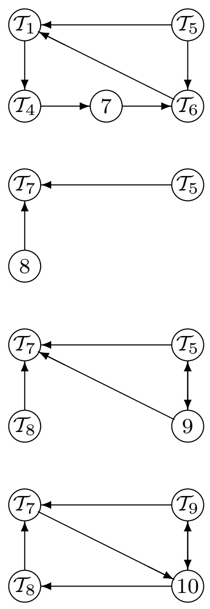

Fig. 6. *Some of the intermediate quotient graphs for the matrix in Figure* 1. *The leading diagonal block of* $Q'_k$ *is* $Q_{k-1}$.

```

        Create $G(Q'_k)$ from $G(Q_{k-1})$ by adding $k$ and
            its incident edges
        Find the component $\mathcal{K}$ of $G(Q'_k)$ that contains $k$
        for each vertex $\mathcal{T}_c \in \mathcal{K} \setminus \{k\}$ do
            FPNZ($c$) = $k$
        end for
        Create $G(Q_k)$ from $G(Q'_k)$ by coalescing
            the vertices in $\mathcal{K}$ into the new vertex $\mathcal{T}_k$
        FPNZ($k$) = $\infty$
    end for
```

Fig. 7. *Constructing the elimination tree using quotient graphs.*

To find the component of $G(Q'_k)$ containing $k$ we could adapt any of the standard algorithms for finding strongly connected components. However, $G(Q'_k)$ has the property that, when $k$ and its incident edges are deleted, the subgraph $G(Q_{k-1})$ remaining is acyclic. Algorithm SCC of Figure 8 is a new, special-purpose algorithm that takes advantage of this property. As a result it is much simpler than the other algorithms, which work for general graphs. The following result proves its correctness.

Theorem 3.3. *Algorithm* SCC *returns the strongly connected component of* $G(Q'_k)$ *that contains vertex* $k$.

*Proof.* Since there is a path $k \Rightarrow v$ in $G(Q'_k)$ for each vertex $v$ visited during the depth-first search DFS($k$), it suffices to prove that INSC$[v]$ = **true** when DFS($v$) returns if and only if there is a path $v \Rightarrow k$. We use induction on the order in which DFS($v$) returns.

From the algorithm we see that for any $v \neq k$, we have INSC$[v]$ = **true** if and only if INSC$[w]$ = **true** for some neighbor $w$ of $v$. Since either $w = k$ or DFS($w$)

```
Algorithm SCC (vertex $k$)
    for each vertex $v$ in $G(Q'_k)$ do
        VISITED[$v$] = INSC[$v$] = false
    end for
    INSC[$k$] = true;   SC = {$k$}
    DFS($k$)
    return SC

    procedure DFS (vertex $v$)
        VISITED[$v$] = true
        for each vertex $w$ adjacent to $v$ in $G(Q'_k)$ do
            if not VISITED[$w$] then DFS($w$)
            if INSC[$w$] then INSC[$v$] = true
        end for
        if INSC[$v$] then SC = SC ∪ {$v$}
    end procedure
```

FIG. 8. *Finding the strongly connected component of $G(Q'_k)$ that contains vertex $k$.*

returns before DFS($v$), by induction the latter is true if and only if either $w = k$ or there is a path $w \Rightarrow k$; i.e., there is a path $v \Rightarrow k$. ☐

The time to initialize the arrays VISITED[∗] and INSC[∗] at the start of Algorithm SCC need not be proportional to the number of vertices and edges reached during the depth-first search. However, suppose that we set all elements in these arrays to 0 at the start of Algorithm ETREEQ and adopt the convention that **true** means "equal to $k$" during the call to SCC($k$). Since none of these elements can have that value before the call, they all have a value equivalent to **false**, and no further initialization is necessary.

While in practice Algorithm ETREEQ is much faster than Algorithm ETREE, its worst-case run-time is still $O(mn)$.

### 3.3. Using path-preserving edge reductions.

Let $u$ and $v$ be distinct vertices in $G(Q_k)$ for which there is both an edge $u \mapsto v$ and a path $u \mapsto\Rightarrow v$ of length at least two. Then the edge $u \mapsto v$ can be deleted without changing the connectivity.[5] Pruning such edges while transforming $G(Q_{k-1})$ into $G(Q_k)$ will improve the performance of Algorithm ETREEQ during subsequent iterations since there will be fewer edges to examine. However, it is not necessary to delete all redundant edges; indeed, it can be more efficient to prune only an easily identifiable subset of them [13].

In this section we shall describe two forms of such *path-preserving edge pruning* that are easily incorporated into Algorithm SCC. We need the following result to justify this approach.

THEOREM 3.4. *Let $W$ be a set of edges in the graph $G(Q'_k)$ with the property that, for each edge $u \mapsto v$ in $W$, there is a corresponding path $u \mapsto\Rightarrow v$ of length at least two that does not contain an edge of the form $x \mapsto k$. Then we can prune all of the edges in $W$ without changing the connectivity.*

*Proof.* Let $G(Q''_k)$ be the graph obtained from $G(Q'_k)$ by deleting every edge in $W$. It suffices to show that for each edge $u \mapsto v$ deleted, there is a path $u \Rightarrow v$ in $G(Q''_k)$. By assumption there is such a path in $G(Q'_k)$. If no edge on this path is in $W$, we are done. Otherwise replace the first such edge $x \mapsto y$ by the corresponding path $x \Rightarrow y$ in $G(Q'_k)$ and repeat. Since no replacement path contains an edge of the

---

[5] These transformations were used in [14] to define effective implicit representations of the nonzero structure of the Schur complement of a sparse matrix.

form $x \mapsto k$ and every cycle in $G(Q'_k)$ must contain such an edge, none of the paths created can contain a cycle and this process must eventually halt. $\square$

For example, in the graph $G(Q'_7)$ of Figure 6 the set with the single edge $\mathcal{T}_5 \mapsto \mathcal{T}_1$ satisfies the condition in the theorem since there is a path $\mathcal{T}_5 \mapsto \mathcal{T}_6 \mapsto \mathcal{T}_1$ of length two, but the set with the single edge $\mathcal{T}_5 \mapsto \mathcal{T}_6$ does not since the only path $\mathcal{T}_5 \mapsto \Rightarrow \mathcal{T}_6$ of length at least two contains the edge $\mathcal{T}_4 \mapsto 7$.

The first form of pruning applies to edges emanating from $k$. Let $\text{ISPATH}[w] =$ **true** if and only if there is a path $k \Rightarrow v \mapsto w$ in $G(Q'_k)$ for some vertex $v \neq k$. Then the set of edges

$$W_1 = \{k \mapsto w \mid \text{ISPATH}[w]\}$$

is redundant. We can compute the $\text{ISPATH}[*]$ array by initializing it to **false** and inserting the statement

$$\textbf{if } v \neq k \textbf{ then } \text{ISPATH}[w] = \textbf{true}$$

into the **for each** loop in function $\text{DFS}(*)$.

The second form of pruning applies to *forward* edges. Let $\text{PRE}[u] = i$ if $u$ is the $i$th vertex visited during the depth-first search. Assume that the call $\text{DFS}(v)$ finds a vertex $w$ adjacent to $v$ that has already been visited (i.e., $\text{VISITED}[w] =$ **true**). By definition, if $\text{PRE}[w] > \text{PRE}[v]$, then $w$ must have been visited after the call $\text{DFS}(v)$ began. Moreover, that visit must have been the result of a call $\text{DFS}(x)$ for some other vertex $x$ that is adjacent to $v$; i.e., $w$ must be on a path $v \mapsto x \Rightarrow w$ of length of least two. Thus the set of forward edges

$$W_2 = \{v \mapsto w \mid \text{PRE}[w] > \text{PRE}[v] \text{ but } w \text{ was not visited from } v\}$$

is redundant. We can compute the $\text{PRE}[*]$ array by initializing an integer value $\text{DFSNO}$ to 0 and inserting the statements

$$\text{PRE}[v] = \text{DFSNO}; \quad \text{DFSNO} = \text{DFSNO} + 1$$

at the start of function $\text{DFS}(*)$.

A version of Algorithm SCC that incorporates both forms of pruning is shown in Figure 9. It runs somewhat faster but has the same worst-case complexity.

### 3.4. Finding a BBT postordering.

Once we have constructed the elimination tree we can find a postordering using a depth-first search where each vertex $k$ is numbered after all of its children have been visited. However, a BBT postordering imposes an additional constraint on the *order* in which the children are visited. In this section we show that Algorithm SCC provides this order.

Let vertices $c_1, \ldots, c_t$ be the children of $k$ in $T(A)$. By Theorem 3.2 the subtrees $\mathcal{T}_{c_1}, \ldots, \mathcal{T}_{c_t}$ of $T(A)$ are the strongly connected components of $G_{k-1}(A)$ that are coalesced into the component $\mathcal{T}_k$ of $G_k(A)$ during the formation of $G(Q_k)$. The additional condition for a lower BBT postordering is that $c_i$ must be numbered after $c_j$ if there is an edge $x \mapsto y$ with $x \in \mathcal{T}_{c_i}$ and $y \in \mathcal{T}_{c_j}$. In terms of the quotient graph $G(Q'_k)$, this means that $c_i$ must be numbered after $c_j$ if there is an edge $\mathcal{T}_{c_i} \mapsto \mathcal{T}_{c_j}$.

Consider the order in which vertices are added to $\mathcal{K}$ in Algorithm SCC. Vertex $k$ is added first; and if there is an edge $\mathcal{T}_{c_i} \mapsto \mathcal{T}_{c_j}$ in $G(Q'_k)$, then vertex $\mathcal{T}_{c_i}$ is added to $\mathcal{K}$ after vertex $\mathcal{T}_{c_j}$. That is, ignoring vertex $k$, this order satisfies the condition for a lower BBT postordering. Similarly, the reverse of this order satisfies the condition for an upper BBT postordering.

```
Algorithm sccP (vertex $k$)
    for each vertex $v$ in $G(Q'_k)$ do
        visited[$v$] = inSC[$v$] = isPath[$v$] = false
    end for
    inSC[$k$] = true;   SC = $\{k\}$;   dfsNo = 0
    dfsP($k$)
    for each vertex $v$ adjacent to $k$ do
        if isPath[$v$] then prune $k \mapsto v$
    end for
    return SC

    procedure dfsP (vertex $v$)
        visited[$v$] = true
        pre[$v$] = dfsNo;   dfsNo = dfsNo + 1
        for each vertex $w$ adjacent to $v$ in $G(Q'_k)$ do
            if not visited[$w$] then dfsP($w$)
            else if pre[$w$] > pre[$v$] then prune $v \mapsto w$
            if $v \neq k$ then isPath[$w$] = true
            if inSC[$w$] then inSC[$v$] = true
        end for
        if inSC[$v$] then SC = SC $\cup \{v\}$
    end procedure
```

FIG. 9. *Finding the strongly connected component using edge pruning.*

## 4. Symbolic *LU* factorization.

Symbolic factorization is the process of determining the nonzero structure of the triangular factors $L$ and $U$. We can find the structure of $L$ either by rows or by columns and the structure of $U$ either by rows or by columns. In this section we shall discuss the by-row variants. We assume that no pivoting is required for numerical stability.

Let $\mathrm{Struct}(M_{r*})$ denote the nonzero structure of the $r$th row of the matrix $M$, that is, the vertex set $\{j \mid m_{rj} \neq 0\}$. We can characterize $\mathrm{Struct}(L_{r*})$ and $\mathrm{Struct}(U_{r*})$ using the nonzero structure of the original matrix and paths in the graphs $G(L)$ and $G(U)$ of the factor matrices:

$$\mathrm{Struct}(L_{r*}) = \{\, j \mid j \leq r \text{ and either } r \xmapsto{A} j \text{ or } r \xmapsto{A} \xRightarrow{U_{RR}} j\},$$

where $U_{RR}$ denotes the $r \times r$ leading principal submatrix of $U$ (see [22, Theorem 6]), and

$$\mathrm{Struct}(U_{r*}) = \left( \mathrm{Struct}(A_{r*}) \cup \bigcup_{k \in \mathrm{Struct}(L_{r*}) \setminus \{r\}} \mathrm{Struct}(U_{k*}) \right) \setminus \{1, \dots, r-1\}$$

(see [6]).

### 4.1. Pruning.

Reducing the number of edges in $G(U_{RR})$ that must be traversed to find $\mathrm{Struct}(L_{r*})$ and the number of vertices $k \in \mathrm{Struct}(L_{r*}) \setminus \{r\}$ for which $\mathrm{Struct}(U_{k*})$ contributes to $\mathrm{Struct}(U_{r*})$ will speed up symbolic factorization. We can do both by using path-preserving edge pruning as discussed in section 3.3.

Let $G(\bar{U})$ be the subgraph of $G(U)$ obtained by pruning some set of redundant edges, that is, edges $x \xmapsto{U} y$ for which there is a path $x \xmapsto{U} \xRightarrow{U} y$. Here $\bar{U}$ is the matrix obtained from $U$ by setting the entries associated with these edges to zero. The graph $G(\bar{L})$ and the matrix $\bar{L}$ are defined similarly.

THEOREM 4.1 (see [13, Observations 3.1 and 3.2]). *The row structure of* $L_{r*}$ *is given by*

$$\mathrm{Struct}(L_{r*}) = \{\, j \mid j \le r \textit{ and either } r \xmapsto{A} j \textit{ or } r \xmapsto{A} \overset{U^{-}_{RR}}{\Longrightarrow} j\};$$

*and the row structure of* $U_{r*}$ *is given by*

$$\mathrm{Struct}(U_{r*}) = \left(\mathrm{Struct}(A_{r*}) \;\cup \bigcup_{k \in \mathrm{Struct}(L^{-}_{r*})\setminus\{r\}} \mathrm{Struct}(U_{k*})\right) \setminus \{1, \ldots, r-1\}.$$

The minimal pruned graphs that can be used in Theorem 4.1 are the *transitive reductions*[6] of $G(L)$ and $G(U)$, also known as the *elimination dags* $G(L^o)$ and $G(U^o)$, respectively [18]. However, the expense[7] of computing these dags could outweigh the savings [13].

A practical compromise is to prune only an easily identifiable subset of edges. Let the function $\rho(k)$ have the property that all edges $i \xmapsto{L} k$ and $k \xmapsto{U} i$ with $i > \rho(k)$ are redundant. Given $\rho(k)$, these edges are easily pruned from $G(L)$ and $G(U)$. Several such *symmetric pruning* functions have been proposed:

- *Symmetric reduction* [13, Theorem 3.3]:

  $$\rho_s(k) = \min\{i \mid i > k \text{ and } i \xmapsto{L} k \xmapsto{U} i\}.$$

  This usually gave the best performance for the matrices considered in [13].
- *Path-symmetric reduction* [13, Theorem 5.1]:

  $$\rho_p(k) = \min\{i \mid i \overset{L}{\Longrightarrow} k \overset{U}{\Longrightarrow} i\}.$$

  This is a generalization of symmetric reduction where the symmetric edges can be paths. No implementation is given in [13]. However, since $\rho_p(k) \equiv$ FPNZ($k$), we can easily evaluate $\rho_p(k)$ by constructing the elimination tree. We shall use $L^\theta$ and $U^\theta$ to represent the reduced factors.
- *Partial path-symmetric reduction* [13, Corollaries 5.2 and 5.3]:

  $$\rho_\pi(k) = \min\{i \mid i \xmapsto{L} k \overset{U}{\Longrightarrow} i \text{ or } i \overset{L}{\Longrightarrow} k \xmapsto{U} i\}.$$

  This is a special case of path-symmetric reduction where one of the symmetric paths must be an edge. It was introduced in [13] as an easily implemented approximation.

Figure 10 gives the factors $L$ and $U$ for the matrix in Figure 1 with the entries pruned by symmetric reduction, partial path-symmetric reduction, path-symmetric reduction, and the elimination dag marked.

**4.2. BBT ordered matrices.** In this section we consider the case where $A$ is upper BBT ordered. The elimination dag $G(L^o)$ is the same as the elimination tree $T(A)$ with edges directed from parent to child [15, Theorem 6.3]. Together with Theorem 4.1, this gives the following result.

---

[6] The *transitive reduction* of a directed graph $G(M)$ is a subgraph $G(M^o)$ such that $u \overset{M}{\Longrightarrow} v$ if and only if $u \overset{M^o}{\Longrightarrow} v$, and that no subgraph with fewer edges has this property. The transitive reduction of a *directed acyclic graph* (dag) is unique [1].

[7] Using supernodes reduces the cost somewhat [19], but the same savings accrue from using pruning as described in what follows.

$$A^+ = \left(\begin{array}{cccccccccc}

\end{array}\right)$$

FIG. 10. *The pruned filled matrix of the matrix in Figure* 1*, where $s$ denotes entries pruned by symmetric reduction; $\pi$ denotes entries pruned by partial path-symmetric reduction; $p$ denotes entries pruned by path-symmetric reduction; $d$ denotes entries pruned using the elimination dag, and a bar denotes entries not pruned by a lesser form of pruning.*

COROLLARY 4.2. *Let $A$ be upper BBT ordered. The row structure of $L_{r*}$ is given by*

$$\mathrm{Struct}(L_{r*}) = \{\, j \mid j \le r \textit{ and either } r \xmapsto{A} j \textit{ or } r \xmapsto{A} \xRightarrow{\bar{U}_{RR}} j \}.$$

*The row structure of $U_{r*}$ is given by*

$$\mathrm{Struct}(U_{r*}) = \left( \mathrm{Struct}(A_{r*}) \;\cup \bigcup_{k\,:\,\mathrm{FPNZ}(k)=r} \mathrm{Struct}(U_{k*}) \right) \setminus \{1, \ldots, r-1\}.$$

The expression for $\mathrm{Struct}(U_{r*})$ is the same as in the symmetric case [20, Theorem 8.1], where it is the key to efficient symbolic factorization.

**4.2.1. Pruning using the elimination tree.** Corollary 4.2 leads immediately to Algorithm ETREESYMBOLIC in Figure 11. The pruning strategy is based on the elimination tree and thus is equivalent to path-symmetric reduction as discussed in section 4.1.

However, there is another interpretation. Let $p = \mathrm{FPNZ}(r)$ be the parent of vertex $r$ in $T(A)$. By definition there is a cycle $p \xRightarrow{L} r \xRightarrow{U} p$. Since $A$ is upper BBT ordered, there is an edge $p \xmapsto{L} r$ (see [15, Theorem 6.5]). Thus there is a cycle $p \xmapsto{L} r \xRightarrow{U} p$; and path-symmetric reduction is the same as partial path-symmetric reduction. Algorithm ETREESYMBOLIC can be viewed as an implementation of either.

**4.2.2. Pruning using the elimination dags.** When the elimination dags are used in a symbolic factorization algorithm, they are usually constructed in parallel with the row structures of the factors [18, section 5.2]. That is, during the $r$th step,

```
Algorithm eTreeSymbolic
    Use Algorithm eTreeQ to construct the elimination tree
    for $r = 1$ to $n$ do
        $\text{Struct}(U_{r*}) = \text{Struct}(A_{r*}) \setminus \{1, \ldots, r-1\}$
        for each child $s$ of $r$ in $T(A)$ do
            $\text{Struct}(U_{r*}) = \text{Struct}(U_{r*}) \cup (\text{Struct}(U_{s*}) \setminus \{1, \ldots, r-1\})$
        end for
        $\text{Struct}(U^\theta_{r*}) = \text{Struct}(U_{r*}) \setminus \{\textsc{fpnz}(r)+1, \ldots, n\}$
        $\text{Struct}(L_{r*}) = \phi$
        for each vertex $i$ in $\text{Struct}(A_{r*}) \setminus \{1, \ldots, r-1\}$ do
            Add to $\text{Struct}(L_{r*})$ every vertex reachable from $i$
                through a path in $G(U^\theta_{RR})$
        end for
    end for
```

FIG. 11. *Symbolic factorization using the elimination tree (i.e., path-symmetric reduction) for an upper BBT ordered matrix.*

after computing $\text{Struct}(L_{r*})$ we use depth-first search to prune the row $L_{r*}$ to $L^o_{r*}$; and after computing $\text{Struct}(U_{r*})$ we use depth-first search to prune the column $U_{*r}$ to $U^o_{*r}$. (Pruning the row $U_{r*}$ to $U^o_{r*}$ would require the structures of higher-numbered rows of $U$.)

However, the situation is quite different when the matrix is upper BBT ordered. First, we need not construct the dag $G(L^o)$, which as noted earlier is the elimination tree with edges directed from parent to child [15, Theorem 6.3]. Second, we can use FPNZ$(r)$ to prune $U_{r*}$ to $U^\theta_{r*}$ as soon as we compute $\text{Struct}(U_{r*})$ so that there will be fewer edges to consider during transitive reduction.

Third, we can prune the *rows* of $U^\theta$ rather than the columns. Let vertex $s$ be a child of vertex $r$ in $T(A)$. Since $\ell_{rs}$ is the first off-diagonal nonzero in the $s$th column of $L$ (see [16, section 5.1]), we will not need $U^o_{s*}$ to compute the structure of any row of $L$ until we are ready to compute $\text{Struct}(L_{r*})$. Since the nonzero entries in $U^o_{s*}$ are in columns $s+1, \ldots, r = \textsc{fpnz}(s)$, pruning $U^\theta_{s*}$ to $U^o_{s*}$ requires only the corresponding rows of $U^o$. These rows will always be available if we transitively reduce the rows of $U^\theta$ corresponding to the children of $r$ in *descending* order when we are ready to compute the structure of $L_{r*}$.

Finally, we do not have to prune $U^\theta_{t*}$ to $U^o_{t*}$ if vertex $t$ is the last child of vertex $r$ in $T(A)$. By the definition of FPNZ$(t)$ we have $r \overset{L}{\Longrightarrow} t \overset{U}{\Longrightarrow} r$. Since the natural ordering of a BBT ordered matrix is a postordering and $t$ is the last child of $r$, we have $r = t + 1$. Thus the path $t \overset{U}{\Longrightarrow} r$ must be an edge in $U$; that is, $u_{tr} \neq 0$. Since $u_{tr}$ is the first nonzero in row $t$ of $U$, it must be retained in the elimination dag $G(U^o)$. On the other hand, since $r = \textsc{fpnz}(t)$, it is the only off-diagonal nonzero in row $t$ of $U^\theta$. Therefore $U^o_{t*} = U^\theta_{t*}$.

These observations lead to Algorithm EDAGSYMBOLIC in Figure 12.

**5. Experimental results.** In this section we demonstrate the efficiency of the algorithms to construct the elimination tree and to find a BBT postordering of an unsymmetric sparse matrix. We also compare the performance of Algorithms ETREESYMBOLIC and EDAGSYMBOLIC with existing codes for symbolic factorization. All of these algorithms were implemented in Fortran, and the experiments were performed on a dual 2.8 GHz Intel Xeon processor with 2 GB of RAM.

We started with 21 matrices from the University of Florida Sparse Matrix Collection [8] (see Table 2). Most are reducible, and for such matrices a block factorization (i.e., permute the rows and columns so that the matrix is in block upper triangular form and factor only the irreducible diagonal blocks) leads to less fill and work.

```
Algorithm edagSymbolic
  Use Algorithm eTreeQ to construct the elimination tree
  for $r = 1$ to $n$ do
    $\mathrm{Struct}(U_{r*}) = \mathrm{Struct}(A_{r*}) \setminus \{1, \ldots, r-1\}$
    for each child $s$ of $r$ in $T(A)$ do
      $\mathrm{Struct}(U_{r*}) = \mathrm{Struct}(U_{r*}) \cup (\mathrm{Struct}(U_{s*}) \setminus \{1, \ldots, r-1\})$
    end for
    $\mathrm{Struct}(U^{\theta}_{r*}) = \mathrm{Struct}(U_{r*}) \setminus \{\textsc{fpnz}(r)+1, \ldots, n\}$
    for each child $s$ of $r$ in $T(A)$, in descending order, do
      if $s$ is not the last child of $r$ then
        Prune $U^{\theta}_{s*}$ to obtain $U^{o}_{s*}$
    end for
    $\mathrm{Struct}(L_{r*}) = \phi$
    for each vertex $i$ in $\mathrm{Struct}(A_{r*}) \setminus \{1, \ldots, r-1\}$ do
      Add to $\mathrm{Struct}(L_{r*})$ every vertex reachable from $i$
        through a path in $G(U^{\theta}_{RR})$
    end for
  end for
```

FIG. 12. *Symbolic factorization using the elimination dags for an upper BBT ordered matrix.*

Thus we "preprocessed" each as follows:

1. Use the Dulmage–Mendelsohn decomposition [12] (`dmperm` in MATLAB) to identify the rows and columns in each irreducible diagonal block and delete all entries that lie in off-diagonal blocks.
2. Apply a random permutation symmetrically to the rows and columns to randomize the tie-breaking strategy in the next step.
3. Run the analysis phase of the multifrontal code `MA41_UNS` [3] (with `ICNTL(6) = 5`, `ICNTL(7) = 2`, and `ICNTL(8) = 7`) to find a transversal [10] (i.e., a column permutation that puts large entries on the diagonal) and a DMLS ordering [2] (i.e., a symmetric row and column permutation that preserves the large entries on the diagonal but reduces the off-diagonal fill).
4. Symmetrically permute the rows and columns to put the matrix in block diagonal form while preserving the (relative) DMLS ordering within each block.

We refer to the resulting matrix as $A$. Each problem was preprocessed eleven times (with different symmetric random permutations), and all numbers reported are medians over the corresponding set of eleven matrices.

Table 2 gives the basic statistics for the preprocessed problems. Here $n(A)$ is the size of $A$; $nz(A)/n(A)$ is the average number of nonzeros per row; $symm(A)$ is the percentage of nonzero off-diagonal elements $a_{ij}$ for which $a_{ij}$ and $a_{ji}$ are both nonzero; $fill(A)$ and $work(A)$ are the fill and work (in multiply-adds) when factoring $A$; and $t_s(A)$ is the time (in milliseconds) to perform a symbolic factorization of $A$ using symmetric reduction.

Table 3 gives the statistics for finding the elimination tree. Here $h(A)$ is the height of the elimination tree $T(A)$; $h(M)$ is the height of $T(M)$, the elimination tree for the symmetrized matrix $M = A + A^t$; $w_i(A)$ is the number of redundant edges in the set $W_i$, where an edge that can be pruned by both heuristics is included in both counts (see section 3.3); $t_e(A)$ is the time to find $T(A)$; $t_u(A)$ is the time to find $T(A)$ and an upper BBT reordering of that tree; and $t_p(A)$ is the time to perform a symbolic factorization of $A$ using path-symmetric reduction, *given* $T(A)$. Note the following:

- We must have $h(A) \leq h(M)$ since the parent of any node in $T(A)$ is an ancestor of that node in $T(M)$ (see [16, Theorem 7.1]).

- The number of edges in the sets $W_1$ and $W_2$ is small, most likely because of the pruning implicit in working with the quotient graph.
- The time to find $T(A)$ is never appreciably larger than the time for symbolic factorization, and the time to find an upper BBT ordering as well is only slightly larger.
- As expected, path-symmetric reduction is faster than symmetric reduction. However, the improvement is less than the cost of finding $T(A)$. Thus symmetric reduction remain the preferred approach unless the elimination tree is needed for other reasons.

Table 4 gives the fill and work for the upper BBT reordered matrix $A_u$ of $A$ and the symbolic factorization times $t_s(A_u)$, $t_p(A_u)$, and $t_d(A_u)$ using symmetric reduction, Algorithm eTreeSymbolic, and Algorithm edagSymbolic, respectively. Note the following:

- BBT reordering generally increases both the fill and the work (by medians of 59% and 32%, respectively), which offsets some of the advantages of BBT ordered matrices [16].
- Again path-symmetric reduction (Algorithm eTreeSymbolic) is faster than symmetric reduction; but while the improvement is usually less than the cost of finding $T(A_u)$, that should not be necessary in this case.
- Algorithm edagSymbolic is faster than symmetric reduction more often than not; but again the improvement is usually less than the cost of finding $T(A_u)$.

Thus path-symmetric reduction is the preferred approach.

$$A = \begin{pmatrix} 1 & \bullet & & & & & \bullet & \bullet & \bullet & & & \\ & 2 & \bullet & & & & \bullet & \bullet & \bullet & & & \\ & & 3 & \bullet & & & \bullet & \bullet & \bullet & & & \\ & & & 4 & \bullet & & \bullet & \bullet & \bullet & & & \\ & & & & 5 & \bullet & \bullet & \bullet & \bullet & & & \\ \bullet & \bullet & \bullet & \bullet & \bullet & 6 & \bullet & \bullet & \bullet & \bullet & \bullet & \bullet \\ & & & & & \bullet & 7 & \bullet & \circ & \circ & \circ & \circ \\ & & & & & \bullet & \circ & 8 & \bullet & \circ & \circ & \circ \\ & & & & & \bullet & \circ & \circ & 9 & \bullet & \circ & \circ \\ \bullet & \circ & \circ & \circ & \circ & \bullet & \circ & \circ & \circ & 10 & \bullet & \circ \\ \bullet & \circ & \circ & \circ & \circ & \bullet & \circ & \circ & \circ & \circ & 11 & \bullet \\ \bullet & \circ & \circ & \circ & \circ & \bullet & \circ & \circ & \circ & \circ & \circ & 12 \end{pmatrix}$$

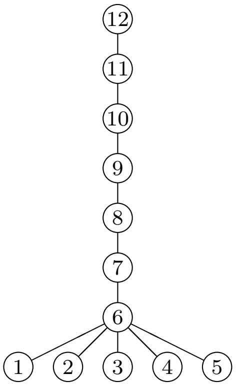

Fig. 13. *A contrived matrix and its elimination tree.*

Table 5
*Times for the* 1000 × 1000 *version of the matrix in Figure* 13.

| Algorithm | Time (ms) |
|---|---|
| Algorithm eTreeQ | 5.62 |
| Symbolic factorization by | |
| Symmetric reduction | 82.34 |
| Path-symmetric reduction | 8.14 |
| Algorithm eTreeSymbolic | 7.60 |
| Algorithm edagSymbolic | 7.46 |

The upper BBT matrix in Figure 13 demonstrates the advantage that the algorithms considered here can have over symmetric reduction. Table 5 gives the times for a larger version of that matrix.

## 6. Concluding remarks.

In this paper we have presented algorithms for constructing the elimination tree and finding a BBT postordering of an unsymmetric matrix. Experiments indicate that the run-times of these algorithms are comparable with those for symbolic factorization. We have also shown how the elimination tree and BBT postorderings can be used to improve the performance of a symbolic factorization algorithm. However, for the problems considered here path-symmetric reduction, the best of the new algorithms, is only better than symmetric reduction if the elimination tree is available.

These ideas also have been applied with great effect in the unsymmetric multifrontal method [16]. Here we suggest two other applications.

### 6.1. Unsymmetric supernodes.

By grouping together adjacent rows and/or columns with the same nonzero structure in $A^+$ and treating them as a dense matrix for storage and computation, we can improve the efficiency of symmetric [5] and unsymmetric [9] sparse numerical factorization. These groupings of row/column indices are called *supernodes*.

There are several ways to define an unsymmetric supernode [9], including the following:

- A $T_1$ supernode is a range[8] $r:s$ of columns of $L$ and rows of $U$, such that the diagonal block $A^+(r:s, r:s)$ is full and each row of $L(s+1:n, r:s)$ and each column of $U(r:s, s+1:n)$ is either full or zero.

---

[8] We use the MATLAB notations $p:q$, denoting the sequence $p, p+1, \ldots, q$, and $M(P,Q)$, denoting the submatrix of $M$ defined by the row sequence $P$ and the column sequence $Q$.

- A $T_3$ supernode is a range $r\!:\!s$ of columns of $L$ and $U$, such that the diagonal block $A^+(r\!:\!s, r\!:\!s)$ is full and each row of $L(s{+}1\!:\!n, r\!:\!s)$ is either full or zero.

Since the diagonal block $A^+(r\!:\!s, r\!:\!s)$ is dense, necessary (but not sufficient) conditions for $r\!:\!s$ to be a $T_1$ or $T_3$ supernode are that the nodes $r, \ldots, s$ lie on an upward path in the elimination tree $T(A)$ and that only node $r$ has more than one child. This simplifies the identification of supernodes and suggests how to relax the definitions to increase their number and/or sizes (see [4, 11] for the symmetric case). Moreover, since the nodes in a supernode are numbered sequentially during a BBT ordering, such an ordering may also reveal more or larger supernodes.

**6.2. Diagonal Markowitz ordering.** Suppose that we want to minimize the work required to factor an unsymmetric matrix by symmetrically reordering the rows and columns (i.e., the same permutation is applied to both rows and columns). A greedy algorithm selects at each stage the pivot $i$ in the reduced matrix for which the product $r_i c_i$ is smallest. This is the diagonal Markowitz ordering [2].

To implement this algorithm we need an efficient scheme to maintain the nonzero structure of the reduced matrix (i.e., the connectivity in the Schur complement). One approach is to use quotient graphs [21, 2]. The techniques used to speed construction of the elimination tree in section 3 seem to have immediate application to making the maintenance of these quotient graphs more efficient.

**Acknowledgments.** We thank Patrick Amestoy, who provided us with a version of `MA41_UNS` that includes the DMLS ordering; and the referees, whose insightful comments helped us to improve the presentation.

# ON THE CONVERGENCE OF GENERAL STATIONARY LINEAR ITERATIVE METHODS FOR SINGULAR LINEAR SYSTEMS*

ZHI-HAO CAO†

**Abstract.** Recently, Lee et al. have published an interesting paper [*SIAM J. Matrix Anal. Appl.*, 28 (2006), pp. 634–641] concerning the energy norm convergence of general stationary linear iterative methods for semidefinite linear systems. In this paper, we first consider the convergence of general stationary linear iterative methods for general singular consistent linear systems and show that the convergence and the quotient convergence are equivalent. Then we consider the convergence of general stationary iterative methods for the semidefinite systems and clarify some issues in Lee et al.'s paper.

**Key words.** iterative methods, singular linear systems, matrix splitting, convergence, quotient convergence, energy norm convergence

## 1. Introduction.

We consider the problem of finding a solution $x \in \mathcal{R}^n$ to

$$Ax = b, \tag{1.1}$$

where $A \in \mathcal{R}^{n,n}$ is a given singular matrix and $b \in \mathcal{R}^n$ is a given vector in the range of $A$. A classical stationary linear iterative method to solve (1.1) can be obtained by using a splitting [2, 3, 7, 12] of $A$: $A = M - N$,

$$Mx^{(k)} = Nx^{(k-1)} + b, \quad k = 1, 2, \dots,$$

which is equivalent to the following iterative scheme:

$$x^{(k)} = x^{(k-1)} - M^{-1}(Ax^{(k-1)} - b), \quad k = 1, 2, \dots. \tag{1.2}$$

The matrix $T = I - M^{-1}A \equiv M^{-1}N$ determined by the splitting $A = M - N$ is called the iteration matrix and the splitting is called induced by the iteration matrix $T$ [7]. When $A$ is nonsingular, an iteration matrix $T$ induces an unique splitting of $A$. Thus, constructing a classical stationary iterative scheme is equivalent to making a splitting of $A$. However, when $A$ is singular, there are infinitely many splittings of $A$ induced by the same iteration matrix $T$ (cf. [2, 5]). Therefore, we extend the classical stationary linear iterative method to the general stationary linear iterative method by replacement of $M^{-1}$ in (1.2) with $M^\dagger$ in a straightforward manner

$$x^{(k)} = x^{(k-1)} - M^\dagger(Ax^{(k-1)} - b), \quad k = 1, 2, \dots, \tag{1.3}$$

where $M^\dagger$ is the Moore–Penrose generalized inverse of $M$ (see [1]). The iteration matrix is

$$T = I - M^\dagger A. \tag{1.4}$$

---

†School of Mathematical Sciences and Laboratory of Mathematics for Nonlinear Sciences, Fudan University, Shanghai 200433, People's Republic of China (zcao@fudan.edu.cn; zhcao@cableplus.com.cn).

We emphasize that (1.3) is not proposed as a computational scheme but rather as useful for theoretical analysis.

Definition 1.1. *We say that the iterative scheme* (1.3) *is convergent if, for any initial guess* $x^{(0)} \in \mathcal{R}^n$*, the iteration sequence* $\{x^{(k)}\}$ *produced by the iterative scheme converges to a solution* $x_*$ *of* (1.1) *as* $k \to \infty$.

Let $A^\dagger$ be the Moore–Penrose inverse of $A$, and then $P \equiv A^\dagger A$ is an orthogonal projection onto $\mathcal{N}(A)^\perp$, the orthogonal complement of the null space $\mathcal{N}(A)$. Then $x_{**} \equiv A^\dagger b$ is the unique solution of (1.1) with the least 2-norm (see [1, 3]).

Definition 1.2. *We say that the iterative scheme* (1.3) *is quotient convergent if, for any initial guess* $x^{(0)} \in \mathcal{R}^n$*, the iteration sequence* $\{x^{(k)}\}$ *produced by the iterative scheme is such that the sequence* $\{Px^{(k)}\}$ *converges to the least* 2*-norm solution* $x_{**}$ *of* (1.1) *as* $k \to \infty$.

**2. General singular systems.** For any matrix $B \in \mathcal{R}^{n,n}$ let $\gamma(B)$ denote the pseudospectral radius of $B$, i.e.

$$\gamma(B) = \max\{|\lambda| : \lambda \in \sigma(B) \setminus \{1\}\}, \tag{2.1}$$

where $\sigma(B)$ is the set of the eigenvalues of $B$.

We now consider the convergence of the iterative method (1.3). Let $e^{(k)} = x^{(k)} - x_{**}$ be the iteration error of $x^{(k)}$, and then from (1.3) we have

$$e^{(k)} = (I - M^\dagger A)e^{(k-1)} = Te^{(k-1)} = T^k e^{(0)}. \tag{2.2}$$

Thus, the fact that $e^{(k)} \to x_* - x_{**} \in \mathcal{N}(A)(k \to \infty)$; i.e., the iterative scheme (1.3) is convergent if and only if $T$ is semiconvergent [3]; i.e.,

$$T^k \to T_\infty(k \to \infty), \tag{2.3}$$

and $T_\infty$ is a projection onto the null space $\mathcal{N}(A)$.

It is well known (see [10]) that a matrix $T$ is semiconvergent if and only if there is a nonsingular matrix $S$ such that

$$S^{-1}TS = \begin{pmatrix} I & \\ & \widetilde{T} \end{pmatrix}, \tag{2.4}$$

where the spectral radius $\rho(\widetilde{T})$ of $\widetilde{T}$ satisfies $\rho(\widetilde{T}) < 1$, i.e., $\widetilde{T}$ is a convergent matrix. Therefore, $T$ is semiconvergent if and only if the following two conditions are satisfied:

(a) The pseudospectral radius $\gamma(T) \equiv \rho(\widetilde{T}) < 1$.

(b) $\operatorname{rank}(I - T) = \operatorname{rank}((I - T)^2)$ or, equivalently, $index_1(T) \equiv index(I - T) = 1$ (cf. [3] for the definitions of $index_\lambda(B)$ and $index(B)$ for a square matrix $B$).

From (1.4) and (2.4) we have

$$M^\dagger A = S \begin{pmatrix} 0 & \\ & I - \widetilde{T} \end{pmatrix} S^{-1} \tag{2.5}$$

and

$$T_\infty = S \begin{pmatrix} I & \\ & 0 \end{pmatrix} S^{-1}. \tag{2.6}$$

Let $S = [S_1, S_2]$, (2.5) and (2.6) imply that $T_\infty$ is a projection, and

$$Span(S_1) = \mathcal{R}(T_\infty) = \mathcal{N}(M^\dagger A), \tag{2.7}$$

$$Span(S_2) = \mathcal{N}(T_\infty) = \mathcal{R}(M^\dagger A). \tag{2.8}$$

From (2.7) we know that $T_\infty$ is a projection onto $\mathcal{N}(M^\dagger A)$. Therefore, the condition

$$\mathcal{N}(M^\dagger A) = \mathcal{N}(A) \tag{2.9}$$

is a necessary and sufficient condition for the projection $T_\infty$ being a projection onto $\mathcal{N}(A)$.

From the discussion above we can obtain the following convergence theorem (see [9]).

THEOREM 2.1. *The general stationary linear iterative scheme*

$$x^{(k)} = x^{(k-1)} - M^\dagger(Ax^{(k-1)} - b), \quad k = 1, 2, \ldots,$$

*is convergent if and only if the following three conditions are fulfilled:*

(a) $\gamma(T) < 1$, *where* $T \equiv I - M^\dagger A$ *is the iteration matrix,*

(b) $index_1(T) \equiv index(I - T) = 1$,

(c) $\mathcal{N}(M^\dagger A) = \mathcal{N}(A)$.

We now consider the relationship between the convergence and the quotient convergence. We obtain the following theorem, which extends the corresponding result in [4], and it is the one of the main results in this paper.

THEOREM 2.2. *For the general stationary linear iterative scheme* (1.3)

$$x^{(k)} = x^{(k-1)} - M^\dagger(Ax^{(k-1)} - b), \quad k = 1, 2, \ldots,$$

*the convergence and the quotient convergence are equivalent.*

*Proof.* We need only to show that the quotient convergence implies the convergence, since the latter is obviously implies the former.

The iterative scheme can be written as

$$x^{(k)} = x^{(k-1)} - M^\dagger A(x^{(k-1)} - x_{**}), \quad k = 1, 2, \ldots .$$

If $\mathcal{N}(M^\dagger A) \neq \mathcal{N}(A)$, then there exists an initial guess $x^{(0)}$ such that $e^{(0)} \equiv x^{(0)} - x_{**} \in \mathcal{N}(M^\dagger A)$ and $e^{(0)} \notin \mathcal{N}(A)$. With this $x^{(0)}$, the iterative scheme (1.3) produces an iteration sequence $\{x^{(k)}\} : x^{(k)} = x^{(0)}, k = 1, 2, \ldots$. Obviously, $Px^{(0)} - x_{**} \equiv Pe^{(0)} \neq 0$, since $A(Pe^{(0)}) = Ae^{(0)} \neq 0$. Therefore, the quotient convergence implies

$$\mathcal{N}(M^\dagger A) = \mathcal{N}(A). \tag{2.10}$$

From (2.2) we have

$$Pe^{(k)} = PT^k e^{(0)}.$$

Thus, the iterative scheme (1.3) is quotient convergent if and only if

$$PT^k \to 0 (k \to \infty), \tag{2.11}$$

since $PT^k e^{(0)} \to 0 (k \to \infty)$ for all $e^{(0)} \in \mathcal{R}^n$. Since $P \equiv A^\dagger A$ is an orthogonal projection onto $\mathcal{N}(A)^\perp$, there exists an orthogonal matrix $\widehat{S}$ such that

$$\widehat{S}^T P \widehat{S} = \begin{pmatrix} 0 & \\ & I \end{pmatrix}. \tag{2.12}$$

Let $\widehat{S} = [\widehat{S}_1, \widehat{S}_2]$, where (using (2.10))

$$Span(\widehat{S}_1) = \mathcal{N}(A) = \mathcal{N}(M^\dagger A) \quad \text{and} \quad Span(\widehat{S}_2) = \mathcal{N}(A)^\perp = \mathcal{N}(M^\dagger A)^\perp. \tag{2.13}$$

Since $T = I - M^\dagger A$, we have $T\widehat{S}_1 = \widehat{S}_1$. Thus, the matrix $\widehat{S}^T T \widehat{S}$ can be expressed as the following form:

$$\widehat{S}^T T \widehat{S} = \begin{pmatrix} I & R_{12} \\ & R_{22} \end{pmatrix}.$$

If $index_1(T) \equiv index(I - T) > 1$, then $1 \in \sigma(R_{22})$. In this case, we have

$$PT^k = \widehat{S} \begin{pmatrix} 0 & \\ & R_{22}^k \end{pmatrix} \widehat{S}^T \not\to 0 (k \to \infty).$$

This means that $index_1(T) \equiv index(I - T) = 1$ is the necessary condition for the quotient convergence.

Since $index_1(T) = 1$, there exists a nonsingular matrix $S$ such that

$$T = S \begin{pmatrix} I & \\ & \widetilde{T} \end{pmatrix} S^{-1}, \quad \text{and hence} \quad M^\dagger A = S \begin{pmatrix} 0 & \\ & I - \widetilde{T} \end{pmatrix} S^{-1}, \tag{2.14}$$

where $1 \notin \sigma(\widetilde{T})$ and $\rho(\widetilde{T}) = \gamma(T)$. Let $S = [S_1, S_2]$, where (using (2.10))

$$Span(S_1) = \mathcal{N}(M^\dagger A) = \mathcal{N}(A) \quad \text{and} \quad Span(S_2) = \mathcal{R}(M^\dagger A). \tag{2.15}$$

Then the matrix $S = [S_1, S_2]$ can be expressed as

$$[S_1, S_2] = [\widehat{S}_1, \widehat{S}_2] \begin{pmatrix} G_{11} & G_{12} \\ & G_{22} \end{pmatrix}, \tag{2.16}$$

where $G_{11}$ and $G_{22}$ are nonsingular. From (2.16) we have

$$S^{-1} = \begin{pmatrix} G_{11}^{-1} & \widehat{G}_{12} \\ & G_{22}^{-1} \end{pmatrix} \widehat{S}^T. \tag{2.17}$$

From (2.12), (2.14), (2.16), and (2.17) we have

$$\begin{aligned} PT^k &= \widehat{S} \begin{pmatrix} 0 & \\ & I \end{pmatrix} \widehat{S}^T S \begin{pmatrix} I & \\ & \widetilde{T}^k \end{pmatrix} S^{-1} \\ &= [0, \widehat{S}_2] \begin{pmatrix} G_{11} & G_{12} \\ & G_{22} \end{pmatrix} \begin{pmatrix} I & \\ & \widetilde{T}^k \end{pmatrix} \begin{pmatrix} G_{11}^{-1} & \widehat{G}_{12} \\ & G_{22}^{-1} \end{pmatrix} \widehat{S}^T \\ &= [0, \widehat{S}_2 G_{22} \widetilde{T}^k G_{22}^{-1}] \widehat{S}^T. \end{aligned}$$

Thus, the fact that $PT^k \to 0 (k \to \infty)$ implies $\widetilde{T}^k \to 0 (k \to \infty)$, which is equivalent to $\gamma(T) = \rho(\widetilde{T}) < 1$.

In summary, we have showed that the quotient convergence of the iterative scheme (1.3) implies that all three conditions (a), (b), and (c) in Theorem 2.1 are satisfied. Thus, the quotient convergence implies the convergence. ☐

By applying Theorem 2.2 we obtain the following result.

THEOREM 2.3. *The general stationary linear iterative scheme*

$$x^{(k)} = x^{(k-1)} - M^\dagger (A x^{(k-1)} - b), \quad k = 1, 2, \ldots,$$

*is convergent if and only if*

$$r^{(k)} \equiv A x^{(k)} - b \to 0 (k \to \infty) \quad \forall x^{(0)} \in \mathcal{R}^n. \tag{2.18}$$

*Proof.* Equation (2.18) is equivalent to

$$Ae^{(k)} \to 0 (k \to \infty) \quad \forall e^{(0)} \in \mathcal{R}^n, \tag{2.19}$$

since $e^{(k)} = x^{(k)} - x_{**}$. (2.19) implies

$$Pe^{(k)} \to 0 (k \to \infty) \quad \forall e^{(0)} \in \mathcal{R}^n, \tag{2.20}$$

since $P = A^{\dagger}A$. Inversely, (2.20) implies (2.19), since $AP = AA^{\dagger}A = A$. Thus, (2.19) and (2.20) are equivalent to each other. Now (2.20) is equivalent to the quotient convergence. Applying Theorem 2.2 (2.18) is also equivalent to the convergence. ☐

Theorem 2.3 shows that (2.18) can be used as the definition of convergence (cf. Definition 1.1) of the general stationary iterative scheme (1.3).

## 3. Semidefinite systems.

Now we consider the symmetric positive semidefinite systems; i.e., we assume the matrix $A \in \mathcal{R}^{n,n}$ in (1.1) is symmetric positive semidefinite. Lee et al. [8] call the iterative scheme (1.3) being energy norm convergent if and only if

$$|I - M^{\dagger}A|_A < 1. \tag{3.1}$$

Obviously, (3.1) implies (2.18). Thus, from Theorem 2.3 the energy norm convergence implies the convergence.

For symmetric positive definite systems and the classical stationary linear iterative scheme, i.e., in the case that $A$ is symmetric positive definite and $M$ is invertible, we have the following well known theorem (see [11, 6]).

THEOREM 3.1. *For symmetric positive definite systems $Ax = b$, the classical stationary linear iterative scheme*

$$x^{(k)} = x^{(k-1)} - M^{-1}(Ax^{(k-1} - b), \quad k = 1, 2, \dots,$$

*is energy norm convergent if and only if $M^T + M - A$ is symmetric positive definite.*

This convergence result can easily be extended to positive semidefinite systems.

THEOREM 3.2. *For symmetric positive semidefinite systems $Ax = b$, the classical stationary linear iterative scheme*

$$x^{(k)} = x^{(k-1)} - M^{-1}(Ax^{(k-1} - b), \quad k = 1, 2, \dots,$$

*is energy norm convergent if and only if $M^T + M - A$ is symmetric positive definite on $\mathcal{R}(M^{-1}A)$.*

*Proof.* It is easy to see that (cf. [5])

$$A - (I - M^{-1}A)^T A(I - M^{-1}A) = (M^{-1}A)^T(M^T + M - A)(M^{-1}A). \tag{3.2}$$

From (3.2) we immediately obtain the conclusion of the theorem. ☐

Lee et al. [8] have further extended these convergence results to the case of the general stationary linear iterative scheme and obtain the following necessary and sufficient conditions for the energy norm convergence (see Theorem 4.4 in [8]):

(A1) $\mathcal{R}(A) \subset \mathcal{R}(M)$ or, equivalently, $\mathcal{N}(M^T) \subset \mathcal{N}(A)$,
(A2) $M^T + M - A$ is symmetric positive definite on $\mathcal{R}(M^{\dagger}A)$,

or, equivalently,

(A1) $\mathcal{R}(A) \subset \mathcal{R}(M)$ or, equivalently, $\mathcal{N}(M^T) \subset \mathcal{N}(A)$,
(A2a) there exists $\omega \in (0, 1)$ such that $(M^{\dagger}Ax, M^{\dagger}Ax)_A \le \omega(M^{\dagger}Ax, Ax)$ for all $x \in \mathcal{R}^n$,
(A2b) there exists $\alpha > 0$ such that $(M^{\dagger}Ax, M^{\dagger}Ax)_A \ge \alpha(M^{\dagger}Ax, M^{\dagger}Ax)$ for all $x \in \mathcal{R}^n$.

However, this result has some problems to clarify.

First we compare the condition (A1) with the condition $\mathcal{N}(M^\dagger A) = \mathcal{N}(A)$, which is necessary for the convergence.

THEOREM 3.3. *Let* $A \in \mathcal{R}^{n,n}$ *be a symmetric matrix, and* $M \in \mathcal{R}^{n,n}$*. Then the condition* (A1) *implies the condition* $\mathcal{N}(M^\dagger A) = \mathcal{N}(A)$*.*

*Proof.* It is easy to see that the condition $\mathcal{N}(M^\dagger A) = \mathcal{N}(A)$ is equivalent to the condition $\mathcal{N}(M^\dagger) \bigcap \mathcal{R}(A) = \{0\}$.

Now if $\mathcal{N}(M^T) \subset \mathcal{N}(A)$, then $\mathcal{N}(M^T) \bigcap \mathcal{R}(A) = \{0\}$, since $A$ is symmetric. Noting that $\mathcal{N}(M^\dagger) = \mathcal{N}(M^T)$ the conclusion of the theorem follows. ☐

Now we give a semidefinite system and a general stationary linear iterative scheme which is energy norm convergent, but the conditions (A1) and (A2) are not satisfied.

*Example.* We take the semidefinite matrix $A$ and the vector $b \in \mathcal{R}(A)$ as

$$A = \begin{pmatrix} 0 & \\ & 1 \end{pmatrix} \quad \text{and} \quad b = \begin{pmatrix} 0 \\ 1 \end{pmatrix},$$

respectively. The matrix $M$ is

$$M = \frac{1}{2}\begin{pmatrix} 0 & -1 \\ 0 & 1 \end{pmatrix},$$

and hence, the matrix $M^\dagger$ is

$$\begin{pmatrix} 0 & 0 \\ -1 & 1 \end{pmatrix}.$$

Obviously, the least 2-norm solution of $Ax = b$ is $x_{**} = \binom{0}{1}$, and the iteration matrix $T$ is

$$T = I - M^\dagger A = \begin{pmatrix} 1 & \\ & 0 \end{pmatrix}.$$

Since

$$(I - M^\dagger A)^T A (I - M^\dagger A) = T^T A T = 0,$$

$|I - M^\dagger A|_A = 0$. Thus, the general stationary linear iterative scheme is energy norm convergent. Now we have

$$\mathcal{N}(M^T) = Span\left\{\begin{pmatrix} 1 \\ 1 \end{pmatrix}\right\} \quad \text{and} \quad \mathcal{N}(A) = Span\left\{\begin{pmatrix} 1 \\ 0 \end{pmatrix}\right\},$$

and, thus, the condition (A1) is not satisfied. We note that the condition $\mathcal{N}(M^\dagger A) = \mathcal{N}(A)$ is satisfied, since $M^\dagger A = \left(\begin{smallmatrix} 0 & \\ & 1 \end{smallmatrix}\right) = A$.

Now we consider the condition (A2). We have

$$M^T + M - A = \frac{1}{2}\begin{pmatrix} 0 & -1 \\ -1 & 0 \end{pmatrix},$$

and

$$(M^\dagger A)^T (M^T + M - A)(M^\dagger A) = 0.$$

Thus, condition (A2) is also not satisfied.

Finally, we point out that the key problem in Theorem 4.4 of [8] is that (A1) is not a necessary condition for energy norm convergence (cf. Theorem 3.3). It is easy to show that if the condition (A1) is assumed to be satisfied, then the condition (A2) is sufficient and necessary for energy norm convergence. Therefore, Theorem 4.4 of [8] can be revised or correctly formulated as follows.

THEOREM 3.4. *Let* (A1) *be satisfied. Then the iterative scheme* (1.3) *is energy norm convergent if and only if* (A2) *is satisfied or, equivalently, if and only if* (A2a) *and* (A2b) *are satisfied.*

*Proof.* By (A1) and the fact that $MM^\dagger M = M$ it is easy to see that (cf. Lemma 4.1 in [8])

$$MM^\dagger A = A, \tag{3.3}$$

and we have showed that (A1) implies (cf. Theorem 3.3)

$$\mathcal{N}(M^\dagger A) = \mathcal{N}(A). \tag{3.4}$$

By using (3.3) we have (cf. (3.2))

$$\begin{aligned} A - (I - M^\dagger A)^T A(I - M^\dagger A) &= (M^\dagger A)^T A + AM^\dagger A - (M^\dagger A)^T A(M^\dagger A) \\ &= (M^\dagger A)^T M(M^\dagger A) + A(M^\dagger)^T M^T(M^\dagger A) - (M^\dagger A)^T A(M^\dagger A) \\ &= (M^\dagger A)^T (M + M^T - A)(M^\dagger A). \end{aligned} \tag{3.5}$$

From (3.5) and (3.4) we obtain that the iterative scheme (1.3) is energy norm convergent if and only if (A2) is satisfied.

By Lemma 4.3 in [8] (A2) is equivalent to (A2a) and (A2b). ☐

We note that Theorem 3.4 is still an extension of Theorem 3.2 to general stationary linear iterative schemes for positive semidefinite linear systems.

# STRUCTURED MAPPING PROBLEMS FOR MATRICES ASSOCIATED WITH SCALAR PRODUCTS. PART I: LIE AND JORDAN ALGEBRAS*

D. STEVEN MACKEY†, NILOUFER MACKEY†, AND FRANÇOISE TISSEUR‡

**Abstract.** Given a class of structured matrices $\mathbb{S}$, we identify pairs of vectors $x, b$ for which there exists a matrix $A \in \mathbb{S}$ such that $Ax = b$, and we also characterize the set of all matrices $A \in \mathbb{S}$ mapping $x$ to $b$. The structured classes we consider are the Lie and Jordan algebras associated with orthosymmetric scalar products. These include (skew-)symmetric, (skew-)Hamiltonian, pseudo(skew-)Hermitian, persymmetric, and perskew-symmetric matrices. Structured mappings with extremal properties are also investigated. In particular, structured mappings of minimal rank are identified and shown to be unique when rank one is achieved. The structured mapping of minimal Frobenius norm is always unique, and explicit formulas for it and its norm are obtained. Finally the set of all structured mappings of minimal 2-norm is characterized. Our results generalize and unify existing work, answer a number of open questions, and provide useful tools for structured backward error investigations.

**Key words.** Lie algebra, Jordan algebra, scalar product, bilinear form, sesquilinear form, orthosymmetric, adjoint, structured matrix, backward error, Hamiltonian, skew-Hamiltonian, Hermitian, complex symmetric, skew-symmetric, persymmetric, perskew-symmetric, minimal rank, minimal Frobenius norm, minimal 2-norm

## 1. Introduction.

The problem of finding all matrices $A$ that map a given nonzero vector $x \in \mathbb{K}^n$ to a given vector $b \in \mathbb{K}^m$, where $\mathbb{K}$ is a fixed field, can be solved using elementary means [10]. Trenkler [21] recently revisited this problem, giving a solution using generalized inverses:

$$A = bx^{\dagger} + Z(I_n - xx^{\dagger}), \tag{1.1}$$

where $I_n$ is the $n \times n$ identity matrix, $Z \in \mathbb{K}^{m\times n}$ is arbitrary, and $x^{\dagger}$ is any generalized inverse of $x$. In this work we restrict the permissible transformations to a class of structured matrices $\mathbb{S} \subset \mathbb{K}^{n\times n}$ and consider the following *structured mapping problems.*

EXISTENCE. *For which vectors $x, b$ does there exist some $A \in \mathbb{S}$ such that $Ax = b$?*

CHARACTERIZATION. *Determine the set $\mathcal{S} = \{\, A \in \mathbb{S} : \ Ax = b \,\}$ of all structured mappings taking $x$ to $b$.*

We present a complete, unified solution for these two problems when $\mathbb{S}$ is the Lie or Jordan algebra associated with an orthosymmetric scalar product. These $\mathbb{S}$ include, for example, symmetric and skew-symmetric, Hermitian, pseudo-Hermitian and skew-Hermitian, Hamiltonian, persymmetric, and perskew-symmetric matrices.

We will assume that $x \neq 0$ throughout, since both problems have trivial solutions if $x = 0$.

Answers to some particular instances of these structured mapping problems can be found in the literature. Liu and Leake [9, Lem. 1] show that for $x, b \in \mathbb{R}^n$, $x$ can be mapped to $b$ by a real skew-symmetric matrix if and only if $x$ and $b$ are orthogonal. Khatri and Mitra [8] and later Sun [17] address the existence and characterization problems for the matrix equation $AX = B$, where $X$, $B$ are matrices and the unknown $A$ is Hermitian; the skew-Hermitian and complex symmetric cases are covered in [19]. Restricting the results of [8], [17], and [19] to the case when $X$ and $B$ are vectors yields one among the many representations of the set $\mathcal{S}$ identified in this paper. Structured mapping problems for double structures, for structures that do not arise in the context of a scalar product, and for some specific nonlinear structures have also been investigated (see [5], [6], [15], [18], and [22] for examples).

One of our motivations for studying these problems stems from the analysis of structured backward errors in the solutions to structured linear systems and structured eigenproblems [7], [19], [20]. Recall that a backward error of an approximate solution $y$ to a linear system $Ax = b$ is a measure of the smallest perturbation $E$ such that $(A + E)y = b$. When $A$ is in some linearly structured class $\mathbb{S}$ one may want to require $E$ to have the same structure; the structured backward error is then a measure of the smallest structured perturbation $E$ such that $Ey = r := b - Ay$. Hence solving the structured mapping problem is the first step towards obtaining explicit expressions for structured backward errors.

For any linear matrix structure $\mathbb{S}$ it is possible to obtain a characterization of the structured mapping set $\mathcal{S}$ using the Kronecker product approach of [4], which we briefly outline here. The equation $Ax = b$ is first rewritten as $(x^T \otimes I_n)\operatorname{vec}(A) = b$, where $\otimes$ denotes the Kronecker product and vec is the operator that stacks the columns of a matrix into one long vector. The linear nature of the matrix structure is then encoded by $\operatorname{vec}(A) = \Pi_{\mathbb{S}} p$, where $\Pi_{\mathbb{S}}$ is an $n^2 \times m$ pattern matrix giving (in essence) a basis for the structured class $\mathbb{S}$, and $p$ is an $m$-dimensional vector of parameters ($m = \dim \mathbb{S} \leq n^2$). Hence

$$\mathcal{S} = \{\, A \in \mathbb{K}^{n \times n} : \ (x^T \otimes I_n)\Pi_{\mathbb{S}} p = b, \ \operatorname{vec}(A) = \Pi_{\mathbb{S}} p \,\}. \tag{1.2}$$

Note that there may be no solution to the system $(x^T \otimes I_n)\Pi_{\mathbb{S}} p = b$ if $(x^T \otimes I_n)\Pi_{\mathbb{S}}$ is rank deficient or if the system is overdetermined ($n > m$). When they exist, solutions can be obtained from the singular value decomposition of $(x^T \otimes I_n)\Pi_{\mathbb{S}}$. In particular, if the system is underdetermined and consistent, and if the pattern matrix $\Pi_{\mathbb{S}}$ is chosen so that $\|p\|_2 = \|A\|_F$ for all $A \in \mathbb{S}$ (i.e., $\Pi_{\mathbb{S}}$ contains an orthonormal basis for $\mathbb{S}$ in the Frobenius inner product), then the solution $A \in \mathbb{S}$ with minimal Frobenius norm is given in terms of the pseudoinverse by $p = \big((x^T \otimes I_n)\Pi_{\mathbb{S}}\big)^{+} b$. As a result a computable expression for the structured backward error is obtained:

$$\eta_F(y) = \min\{\, \|E\|_F : (A + E)y = b, \ E \in \mathbb{S} \,\} = \big\|\big((y^T \otimes I_n)\Pi_{\mathbb{S}}\big)^{+}(b - Ay)\big\|_2. \tag{1.3}$$

There are several disadvantages associated with this Kronecker product approach. The existence of structured solutions to $Ax = b$ may not be easy to check. In addition, the set $\mathcal{S}$ of all structured mappings is given only implicitly by (1.2). Also, among all solutions in $\mathcal{S}$, it is difficult to distinguish ones with special properties, other than that of minimal Frobenius norm. The structured backward error expression in (1.3) is expensive to evaluate and difficult to compare with its unstructured counterpart $\|b - Ay\|_2$.

By contrast, the approach presented in this paper gives easy-to-check conditions for the existence problem and an *explicit* solution for the characterization problem when $\mathbb{S}$ is the Lie or Jordan algebra of a scalar product. The set $\mathcal{S}$ is rewritten as

$$\mathcal{S} = B + \{\, A \in \mathbb{S} : \ Ax = 0 \,\}, \tag{1.4}$$

where $B$ is any particular solution of the nonhomogeneous mapping problem. We provide a set of possible particular solutions $B$ for a given class $\mathbb{S}$ and given vectors $x$ and $b$, thus giving multiple ways of representing $\mathcal{S}$. This enables one to more easily identify structured mappings with minimal rank or minimal Frobenius norm and to readily derive bounds for the ratio between the structured and unstructured backward errors. A multiplicative representation, by contrast with the additive representation in (1.4), is used to characterize the set of all minimal 2-norm structured mappings in $\mathcal{S}$. From this characterization, minimal 2-norm mappings of minimal rank and minimal 2-norm mappings of minimal Frobenius norm can be identified.

To give an idea of the scope of the paper, we give here an illustration of what is obtained by applying our general results to a particular structure $\mathbb{S}$, in this case the Lie algebra of complex skew-symmetric matrices. For given $x, b \in \mathbb{C}^n$ our results imply that

$$\mathcal{S} := \{\, A \in \mathbb{C}^{n\times n} : \ Ax = b, \ A^T = -A \,\} \ \text{is nonempty} \quad \Longleftrightarrow \quad x^T b = 0\,,$$

and that

$$\mathcal{S} \ = \ \{\, bw^T - wb^T + (I - vx^T)L(I - xv^T) : \ L \in \mathbb{C}^{n\times n}, \ L^T = -L \,\}\,, \tag{1.5}$$

where $w, v \in \mathbb{C}^n$ are any fixed but arbitrary vectors chosen such that $w^T x = v^T x = 1$. All mappings in $\mathcal{S}$ of the form $bw^T - wb^T$ (corresponding to setting $L = 0$ in (1.5)) have minimal rank two, and the choice $w = \bar{x}/\|x\|_2^2$, $L = 0$ gives the unique mapping $A_{\text{opt}}$ of minimal Frobenius norm:

$$A_{\text{opt}} = (b\bar{x}^T - \bar{x}b^T)/\|x\|_2^2\,, \quad \|A_{\text{opt}}\|_F = \min_{A\in\mathcal{S}} \|A\|_F = \sqrt{2}\|b\|_2/\|x\|_2\,. \tag{1.6}$$

The set $\mathcal{M} := \{\ A \in \mathcal{S} : \ \|A\|_2 = \min_{B\in\mathcal{S}} \|B\|_2 \ \}$ of all minimal 2-norm mappings can be characterized by

$$\mathcal{M} = \frac{\|b\|_2}{\|x\|_2}\left\{ U^T \operatorname{diag}\left( \left[\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right], S \right) U : \ S \in \mathbb{C}^{(n-2)\times(n-2)}, \ S^T = -S, \ \|S\|_2 \le 1 \right\},$$

where $U^*[\,x\ \bar{b}\,] = [\,\|x\|_2 e_1\ \ \|b\|_2 e_2\,]$; i.e., $U$ is the unitary factor of the QR factorization of $[\,x\ \bar{b}\,]$ with $R$ forced to have positive entries. For this structure $\mathbb{S}$ it turns out that $A_{\text{opt}} \in \mathcal{M}$, so $A_{\text{opt}}$ is simultaneously a mapping of minimal rank, minimal Frobenius norm, and minimal 2-norm. As a consequence of (1.6) an explicit formula for the structured backward error in (1.3) for this class $\mathbb{S}$ is given for the Frobenius norm by

$$\eta_F(y) = \sqrt{2}\,\frac{\|Ay - b\|_2}{\|y\|_2}\,,$$

which is immediately seen to differ from its unstructured counterpart by a factor of only $\sqrt{2}$. For the 2-norm the structured and unstructured backward errors are equal.

In summary, the results here generalize and unify existing work, answer a number of open questions, and provide useful tools for the investigation of structured backward errors. After some preliminaries in section 2, a complete solution to the existence and characterization problems is presented in sections 3 and 4. In section 5 we identify structured mappings of minimal rank, minimal Frobenius norm, and minimal 2-norm, and investigate their uniqueness. Some technical proofs are given in the appendix.

## 2. Preliminaries.

**2.1. Scalar products.** A *bilinear form* on $\mathbb{K}^n$ ($\mathbb{K} = \mathbb{R}, \mathbb{C}$) is a map $(x, y) \mapsto \langle x, y\rangle$ from $\mathbb{K}^n \times \mathbb{K}^n$ to $\mathbb{K}$, which is linear in each argument. If $\mathbb{K} = \mathbb{C}$, the map $(x, y) \mapsto \langle x, y\rangle$ is a *sesquilinear form* if it is conjugate linear in the first argument and linear in the second. To a bilinear form on $\mathbb{K}^n$ is associated a unique $M \in \mathbb{K}^{n\times n}$ such that $\langle x, y\rangle = x^T My$ for all $x, y \in \mathbb{K}^n$; if the form is sesquilinear, $\langle x, y\rangle = x^*My$ for all $x, y \in \mathbb{C}^n$, where the superscript $*$ denotes the conjugate transpose. The form is said to be *nondegenerate* when $M$ is nonsingular.

A bilinear form is symmetric if $\langle x, y\rangle = \langle y, x\rangle$ or, equivalently, if $M^T = M$, and skew-symmetric if $\langle x, y\rangle = -\langle y, x\rangle$ or, equivalently, if $M^T = -M$. A sesquilinear form is Hermitian if $\langle x, y\rangle = \overline{\langle y, x\rangle}$ and skew-Hermitian if $\langle x, y\rangle = -\overline{\langle y, x\rangle}$. The matrices associated with such forms are Hermitian and skew-Hermitian, respectively.

We will use the term *scalar product* to mean a nondegenerate bilinear or sesquilinear form on $\mathbb{K}^n$. When we have more than one scalar product under consideration, we will denote $\langle x, y\rangle$ by $\langle x, y\rangle_{\mathrm{M}}$, using the matrix $M$ defining the form as a subscript to distinguish the forms under discussion.

**2.2. Adjoints.** The *adjoint* of $A$ with respect to the scalar product $\langle\cdot,\cdot\rangle_{\mathrm{M}}$, denoted by $A^\star$, is uniquely defined by the property $\langle Ax, y\rangle_{\mathrm{M}} = \langle x, A^\star y\rangle_{\mathrm{M}}$ for all $x, y \in \mathbb{K}^n$. It can be shown that the adjoint is given explicitly by

$$A^\star = \begin{cases} M^{-1}A^TM & \text{for bilinear forms,} \\ M^{-1}A^*M & \text{for sesquilinear forms.} \end{cases}$$

The following properties of adjoint, all analogous to properties of transpose (or conjugate transpose), follow easily and hold for all scalar products.

LEMMA 2.1. *$(A + B)^\star = A^\star + B^\star$, $(AB)^\star = B^\star A^\star$, $(A^{-1})^\star = (A^\star)^{-1}$ and*

$$(\alpha A)^\star = \begin{cases} \alpha A^\star & \textit{for bilinear forms,} \\ \overline{\alpha} A^\star & \textit{for sesquilinear forms.} \end{cases}$$

The involutory property $(A^\star)^\star = A$ does not hold for all scalar products; this issue is discussed in section 2.4.

**2.3. Lie and Jordan algebras.** Associated with $\langle\cdot,\cdot\rangle_{\mathrm{M}}$ is a Lie algebra $\mathbb{L}$ and a Jordan algebra $\mathbb{J}$, defined by

$$\mathbb{L} := \left\{A \in \mathbb{K}^{n\times n} : \langle Ax, y\rangle_{\mathrm{M}} = -\langle x, Ay\rangle_{\mathrm{M}}\ \forall x, y \in \mathbb{K}^n\right\} = \left\{A \in \mathbb{K}^{n\times n} : A^\star = -A\right\},$$

$$\mathbb{J} := \left\{A \in \mathbb{K}^{n\times n} : \langle Ax, y\rangle_{\mathrm{M}} = \langle x, Ay\rangle_{\mathrm{M}}\ \forall x, y \in \mathbb{K}^n\right\} = \left\{A \in \mathbb{K}^{n\times n} : A^\star = A\right\}.$$

All the structured matrices considered in this paper belong to one of these two classes. Note that $\mathbb{L}$ and $\mathbb{J}$ are linear subspaces of $\mathbb{K}^{n\times n}$. Table 2.1 shows a sample of well-known structured matrices in some $\mathbb{L}$ or $\mathbb{J}$ associated with a scalar product.

**2.4. Orthosymmetric and unitary scalar products.** Scalar products for which vector orthogonality is a symmetric relation, i.e.,

$$\langle x, y\rangle_{\mathrm{M}} = 0 \Leftrightarrow \langle y, x\rangle_{\mathrm{M}} = 0\ \forall x, y \in \mathbb{K}^n,$$

will be referred to as *orthosymmetric scalar products* [12], [13]. One can show that $\langle\cdot,\cdot\rangle_{\mathrm{M}}$ is orthosymmetric if and only if it satisfies any one (and hence all) of the following equivalent properties:

Table 2.1

*Structured matrices associated with some orthosymmetric scalar products.*

$$R = \begin{bmatrix} & & 1 \\ & \iddots & \\ 1 & & \end{bmatrix},\ J = \begin{bmatrix} 0 & I_n \\ -I_n & 0 \end{bmatrix},\ \Sigma_{p,q} = \begin{bmatrix} I_p & 0 \\ 0 & -I_q \end{bmatrix} \text{ with } p+q=n.$$

| Space | $M$ | Adjoint<br>$A^\star$ | Jordan algebra<br>$\mathbb{J} = \{A : A^\star = A\}$ | Lie algebra<br>$\mathbb{L} = \{A : A^\star = -A\}$ |

| $\mathbb{C}^{2n}$ | $J$ | $-JA^*J$ | $J$-skew-Hermitian | $J$-Hermitian |

1. The adjoint with respect to $\langle\cdot,\cdot\rangle_{\mathrm{M}}$ is involutory, i.e., $(A^\star)^\star = A$ for all $A \in \mathbb{K}^{n\times n}$.
2. $M = \alpha M^T$ with $\alpha = \pm 1$ for bilinear forms; $M = \alpha M^*$ with $\alpha \in \mathbb{C}$, $|\alpha| = 1$ for sesquilinear forms.
3. $\mathbb{K}^{n\times n} = \mathbb{L} \oplus \mathbb{J}$.

See [12, Thm. A.4] or [13, Thm. 1.6] for a proof of this equivalence along with a list of additional equivalent properties. The second property says that orthosymmetric bilinear forms are always either symmetric or skew-symmetric. On the other hand, an orthosymmetric sesquilinear form $\langle x, y\rangle_{\mathrm{M}} = x^*My$, where $M = \alpha M^*$, $|\alpha| = 1$, $\alpha \in \mathbb{C}$, is always closely tied to a Hermitian form: defining the Hermitian matrix $H = \bar{\alpha}^{1/2} M$ gives $\langle x, y\rangle_{\mathrm{H}} = \bar{\alpha}^{1/2} \langle x, y\rangle_{\mathrm{M}}$ for all $x, y \in \mathbb{C}^n$. Consequently, the Jordan algebra of $\langle\cdot,\cdot\rangle_{\mathrm{H}}$ is identical to the Jordan algebra of $\langle\cdot,\cdot\rangle_{\mathrm{M}}$:

$$\langle Ax, y\rangle_{\mathrm{H}} = \langle x, Ay\rangle_{\mathrm{H}} \quad\Leftrightarrow\quad \bar{\alpha}^{1/2} \langle Ax, y\rangle_{\mathrm{M}} = \bar{\alpha}^{1/2} \langle x, Ay\rangle_{\mathrm{M}} \quad\Leftrightarrow\quad \langle Ax, y\rangle_{\mathrm{M}} = \langle x, Ay\rangle_{\mathrm{M}} \ .$$

Similarly, the Lie algebras of $\langle\cdot,\cdot\rangle_{\mathrm{H}}$ and $\langle\cdot,\cdot\rangle_{\mathrm{M}}$ are also identical. Thus a result established for Hermitian sesquilinear forms immediately translates into a corresponding result for orthosymmetric sesquilinear forms. Up to a scalar multiple, then, there are really only three distinct types of orthosymmetric scalar products: symmetric bilinear, skew-symmetric bilinear, and Hermitian sesquilinear. We will, however, continue to include separately stated results (without separate proofs) for skew-Hermitian forms for convenience, as this is a commonly occurring special case.

The results in this paper hold only for orthosymmetric scalar products, which as just mentioned are those for which the useful and simplifying property $(A^\star)^\star = A$

holds for all matrices [12], [13]. For these scalar products, adjoints of rank-one matrices will often be needed,

$$
\begin{aligned}
&(yz^TM)^\star = zy^TM^T && \text{for orthosymmetric bilinear forms,}\\
&(yz^*M)^\star = zy^*M^* && \text{for orthosymmetric sesquilinear forms.}
\end{aligned}
\tag{2.1}
$$

Some of our results will require the extra property that the scalar product $\langle\cdot,\cdot\rangle_{\mathrm{M}}$ is also *unitary*, that is, $\beta M$ is unitary for some $\beta > 0$ [12]. One can show that in unitary scalar products, "the stars commute," i.e., $(A^*)^\star = (A^\star)^*$ for all $A \in \mathbb{K}^{n\times n}$ and that for every unitarily invariant norm $\|\cdot\|$, $\|A^\star\| = \|A\|$ for all $A \in \mathbb{K}^{n\times n}$ [13, Thm. 1.8]. Finally, note that important classes of structured matrices arise in the context of scalar products that are both orthosymmetric and unitary, as witnessed by the entries in Table 2.1 (for all of which $\alpha = \pm 1$ and $\beta = 1$). The results in this paper are not confined to just the examples in the table, however.

### 2.5. Projections.

Projections that map $x$ to the zero vector form a key part in our solution to the structured mapping problems.

Since the matrix $M$ of the scalar product is nonsingular, given a nonzero $x \in \mathbb{K}^n$ one can always construct many $w \in \mathbb{K}^n$ such that $\langle w, x\rangle_{\mathrm{M}} = 1$. For example, when $x$ is nonisotropic (i.e., $\langle x, x\rangle_{\mathrm{M}} \neq 0$), $w = x/\langle x, x\rangle_{\mathrm{M}}$ will work for bilinear forms, and $w = x/\overline{\langle x, x\rangle_{\mathrm{M}}}$ can be used for sesquilinear forms. If $x$ is isotropic (i.e., $\langle x, x\rangle_{\mathrm{M}} = 0$), choose $k$ so that $x_k \neq 0$; then $w = M^{-T}e_k/x_k$ will have the desired property for bilinear forms, and $w = M^{-*}e_k/\overline{x}_k$ will work for sesquilinear forms.

With $w$ chosen so that $\langle w, x\rangle_{\mathrm{M}} = 1$, it is easy to show that for bilinear forms, $xw^TM$ is idempotent and hence a projection with range span$\{x\}$. Replacing $^T$ by $^*$ gives a similar result for sesquilinear forms. The complementary projections $P_w$ defined by

$$
P_w := \begin{cases} I - xw^TM, & \langle w, x\rangle_{\mathrm{M}} = 1 \quad \text{for bilinear forms,}\\ I - xw^*M, & \langle w, x\rangle_{\mathrm{M}} = 1 \quad \text{for sesquilinear forms}\end{cases}
\tag{2.2}
$$

have kernel span$\{x\}$, and in particular map $x$ to the zero vector.

## 3. The existence problem.

Throughout the rest of the paper we assume that $x, b \in \mathbb{K}^n$ with $x \neq 0$, but that any $b$ is allowed unless otherwise stated. For a scalar product $\langle\cdot,\cdot\rangle_{\mathrm{M}}$ we will denote by $\mathbb{S}$ the corresponding Jordan algebra $\mathbb{J}$ or Lie algebra $\mathbb{L}$ and will write

$$
\mathcal{S} := \{\, A \in \mathbb{S} : \ Ax = b \,\},\ \mathcal{J} := \{\, A \in \mathbb{J} : \ Ax = b \,\},\ \mathcal{L} = \{\, A \in \mathbb{L} : \ Ax = b \,\}
\tag{3.1}
$$

for the associated structured mapping sets. Note that $\mathcal{S} = \mathcal{J}$ when $\mathbb{S} = \mathbb{J}$ and $\mathcal{S} = \mathcal{L}$ when $\mathbb{S} = \mathbb{L}$.

As a preliminary step towards solving the existence problem, we show that the projections given in (2.2) can be used to construct maps that send $x$ to $b$.

LEMMA 3.1. *Let $x \neq 0$, and let $w \in \mathbb{K}^n$ be chosen so that $\langle w, x\rangle_{\mathrm{M}} = 1$ with $\langle\cdot,\cdot\rangle_{\mathrm{M}}$ orthosymmetric. Then ${}^{\pm}B_w x = b$, where ${}^{\pm}B_w$ is defined by*

$$
{}^{\pm}B_w := \begin{cases} bw^TM \pm (bw^TM)^\star P_w & \text{for bilinear forms,}\\ bw^*M \pm (bw^*M)^\star P_w & \text{for sesquilinear forms.}\end{cases}
\tag{3.2}
$$

*Note that ${}^{+}B_w$ and ${}^{-}B_w$ have rank at most two.*

*Proof.* Since $P_w x = 0$ and $\langle w, x\rangle_{\mathrm{M}} = 1$, we immediately conclude ${}^{\pm}B_w x = b$. Next, by (2.1) we see that in the bilinear case, $(bw^T M)^{\star} P_w = wb^T M^T P_w$, which is a rank-one matrix, and hence ${}^{+}B_w$, ${}^{-}B_w$ are the sum of two matrices of rank one. The proof in the sesquilinear case is similar. ☐

Thus, since ${}^{+}B_w$, ${}^{-}B_w$ are always solutions to the unstructured mapping problem, they should be consistent with (1.1), which captures all solutions. Now $\langle w, x\rangle_{\mathrm{M}} = 1$ implies $w^T M x = 1$ in the bilinear case. Since any row vector $u^T$ with the property $u^T x = 1$ is a generalized inverse $x^{\dagger}$ for the map $x : \mathbb{R} \to \mathbb{R}^n$, we can take $x^{\dagger}$ to be $w^T M$. Rewriting (3.2) for the bilinear case we get

$$
{}^{\pm}B_w = bx^{\dagger} \pm wb^T M^T (I - xx^{\dagger}), \tag{3.3}
$$

which is of the form given by Trenkler in (1.1) with $Z = \pm wb^T M^T$. The argument for the sesquilinear case is similar, with the role of $x^{\dagger}$ being played by $w^* M$. It is worth observing that once the parameter $w^T$ is chosen, both $x^{\dagger}$ and $Z$ in (3.3) are determined, and thus we are confining our attention to a constrained subset of the maps given by (1.1).

We still have to determine when a structured mapping exists, and what role ${}^{+}B_w$, ${}^{-}B_w$ play in such a mapping. The next theorem characterizes pairs of vectors $x$, $b$ for which there exists $A \in \mathbb{L}$ or $A \in \mathbb{J}$ such that $Ax = b$. When a structured mapping exists, we show that either ${}^{-}B_w$ or ${}^{+}B_w$ will be in the Lie or Jordan algebra, thus yielding a constructive proof of existence.

THEOREM 3.2 (existence for $\mathbb{L}$, $\mathbb{J}$). *Let $\langle \cdot, \cdot\rangle_{\mathrm{M}}$ be an orthosymmetric scalar product. Then for any given pair of vectors $x, b \in \mathbb{K}^n$ with $x \neq 0$ and associated structured mapping sets $\mathcal{J}$ and $\mathcal{L}$ in* (3.1),

$$
\mathcal{J} \neq \emptyset \iff \langle b, x\rangle_{\mathrm{M}} = \langle x, b\rangle_{\mathrm{M}}, \tag{3.4}
$$

$$
\mathcal{L} \neq \emptyset \iff \langle b, x\rangle_{\mathrm{M}} = -\langle x, b\rangle_{\mathrm{M}}. \tag{3.5}
$$

*In particular, when $\langle b, x\rangle_{\mathrm{M}} = \langle x, b\rangle_{\mathrm{M}}$ then ${}^{+}B_w \in \mathcal{J}$, and when $\langle b, x\rangle_{\mathrm{M}} = -\langle x, b\rangle_{\mathrm{M}}$, ${}^{-}B_w \in \mathcal{L}$.*

*Proof.* ($\Rightarrow$) Since $Ax = b$, in all cases we have

$$
A \in \mathbb{J} \Rightarrow \langle b, x\rangle_{\mathrm{M}} = \langle Ax, x\rangle_{\mathrm{M}} = \langle x, Ax\rangle_{\mathrm{M}} = \langle x, b\rangle_{\mathrm{M}},
$$

$$
A \in \mathbb{L} \Rightarrow \langle b, x\rangle_{\mathrm{M}} = \langle Ax, x\rangle_{\mathrm{M}} = \langle x, -Ax\rangle_{\mathrm{M}} = -\langle x, b\rangle_{\mathrm{M}}.
$$

($\Leftarrow$) By Lemma 3.1 we know that ${}^{+}B_w$, ${}^{-}B_w$ as defined in (3.2) map $x$ to $b$. It suffices to prove that when $\langle b, x\rangle_{M} = \langle x, b\rangle_{M}$, ${}^{+}B_w \in \mathbb{J}$, and when $\langle b, x\rangle_{M} = -\langle x, b\rangle_{M}$, ${}^{-}B_w \in \mathbb{L}$. Using Lemma 2.1 and the expressions for the adjoints given in (2.1), we have for bilinear forms

$$
\begin{aligned}
{}^{\pm}B_w &= bw^T M \pm (bw^T M)^{\star}(I - xw^T M) \\
&= bw^T M \pm (bw^T M)^{\star} \mp w(b^T M^T x) w^T M \\
&= bw^T M \pm (bw^T M)^{\star} \mp \langle x, b\rangle_{\mathrm{M}} ww^T M,
\end{aligned}
$$

and on the other hand,

$$
\begin{aligned}
{}^{\pm}B_w^{\star} &= (bw^T M)^{\star} \pm (I - wx^T M^T) bw^T M \\
&= (bw^T M)^{\star} \pm bw^T M \mp w(x^T M^T b) w^T M \\
&= (bw^T M)^{\star} \pm bw^T M \mp \langle b, x\rangle_{\mathrm{M}} ww^T M.
\end{aligned}
$$

If $\langle b, x\rangle_M = \langle x, b\rangle_M$, then clearly ${}^+B_w = {}^+B_w^\star$ so that ${}^+B_w \in \mathbb{J}$. If $\langle b, x\rangle_M = -\langle x, b\rangle_M$, then ${}^-B_w^\star = (bw^TM)^\star - bw^TM - \langle x, b\rangle_{\mathrm{M}} ww^TM = -{}^-B_w$ so that ${}^-B_w \in \mathbb{L}$. The proof in the sesquilinear case is similar. □

The existence conditions in (3.4)–(3.5) are made more explicit in Corollary 3.3 for the main types of orthosymmetric scalar products. Observe that sometimes a condition on $\langle b, x\rangle_{\mathrm{M}}$ is needed, while in other cases a structured mapping exists with no restrictions at all on $x$ and $b$.

COROLLARY 3.3. *Let* $\langle\cdot,\cdot\rangle_{\mathrm{M}}$ *be any orthosymmetric scalar product for which*

$$M = \begin{cases} \pm M^T & \text{for bilinear forms,} \\ \pm M^* & \text{for sesquilinear forms.} \end{cases}$$

*Then for any given pair of vectors* $x,\ b \in \mathbb{K}^n$ *with* $x \neq 0$*, let* $\mathcal{S}$ *denote either* $\mathcal{J}$ *or* $\mathcal{L}$ *as in* (3.1)*. Then* $\mathcal{S} \neq \emptyset$ *if and only if the conditions given in the following table hold:*

| *Scalar product* | $\mathcal{J} \neq \emptyset$ | $\mathcal{L} \neq \emptyset$ |
|---|---|---|
| *Symmetric bilinear* | *always* | $\langle b, x\rangle_{\mathrm{M}} = 0$ |
| *Skew-symmetric bilinear* | $\langle b, x\rangle_{\mathrm{M}} = 0$ | *always* |
| *Hermitian sesquilinear* | $\langle b, x\rangle_{\mathrm{M}} \in \mathbb{R}$ | $\langle b, x\rangle_{\mathrm{M}} \in i\mathbb{R}$ |
| *Skew-Hermitian sesquilinear* | $\langle b, x\rangle_{\mathrm{M}} \in i\mathbb{R}$ | $\langle b, x\rangle_{\mathrm{M}} \in \mathbb{R}$ |

*Proof.* The conditions in the table follow from Theorem 3.2 and the definitions of symmetric and skew-symmetric bilinear forms and of Hermitian and skew-Hermitian sesquilinear forms. □

Theorem 3.2 and Corollary 3.3 unify and generalize existence results in [9] for real skew-symmetric matrices, in [8] and [17] for symmetric and Hermitian matrices, in [19] for complex symmetric and skew-Hermitian structures, and in [16, Lem. 5.1] for real persymmetric matrices, which are particular instances of Lie and Jordan algebras associated with different bilinear and sesquilinear forms on $\mathbb{R}^n$ and $\mathbb{C}^n$ (see Table 2.1).

## 4. The characterization problem.

We turn now to the task of determining the set of *all* matrices that map $x$ to $b$ and belong to a Lie or Jordan algebra.

LEMMA 4.1. *Let* $\mathbb{S}$ *denote the Lie or Jordan algebra of any orthosymmetric scalar product. Then*

(a) $A \in \mathbb{S} \Rightarrow Q^\star A Q \in \mathbb{S}$ *for all* $Q$*; that is,* $\star$*-congruence preserves* $\mathbb{L}$ *and* $\mathbb{J}$ *structures;*

(b) $\{P_w^\star S P_w : S \in \mathbb{S}\} \subseteq \{A \in \mathbb{S} : Ax = 0\}$*, where* $P_w$ *is any particular one of the projection matrices defined in* (2.2)*;*

(c) *for any* $w \in \mathbb{K}^n$ *such that* $\langle w, x\rangle_M = 1$, $A \in \mathbb{S}$, $Ax = 0 \Longrightarrow A = P_w^\star A\, P_w$.

*Proof.* (a) This is a direct consequence of adjoint being involutory in orthosymmetric scalar products.

(b) Follows immediately from the fact that $P_w x = 0$, together with (a).

(c) For any bilinear form, $A \in \mathbb{S} \Longrightarrow A = \pm A^\star = \pm M^{-1}A^TM \Longrightarrow MA = \pm A^TM \Longrightarrow x^TMA = \pm x^TA^TM = \pm(Ax)^TM$. But $Ax = 0$. Hence $x^TMA = 0$. From (2.2), we have $P_w = I - xw^TM$. Hence $AP_w = A - Axw^TM = A$, since $Ax = 0$. Using (2.1) and $x^TMA = 0$ we now obtain

$$P_w^\star A\, P_w = P_w^\star A = (I - wx^TM^T)A = A,$$

since for orthosymmetric bilinear forms $M^T = \pm M$. The proof for sesquilinear forms follows along the same lines. ◻

The complete solution to the *homogeneous mapping problem* can now be described.

THEOREM 4.2 (characterization for $\mathbb{J}$ and $\mathbb{L}$: homogeneous case). *Let $\mathbb{S}$ denote the Lie or Jordan algebra of any orthosymmetric scalar product space. Given $x \in \mathbb{K}^n$ with $x \neq 0$, and $w \in \mathbb{K}^n$ such that $\langle w, x\rangle_{\mathrm{M}} = 1$,*

$$\{A \in \mathbb{S} : Ax = 0\} = \{P_w^\star S P_w : S \in \mathbb{S}\}$$

*where $P_w$ is defined in* (2.2)*.*

*Proof.* The proof follows immediately by combining (b) and (c) of Lemma 4.1. ◻

COROLLARY 4.3. *If $v$, $w \in \mathbb{K}^n$, with $\langle v, x\rangle_{\mathrm{M}} = \langle w, x\rangle_{\mathrm{M}} = 1$, then*

$$\{P_v^\star S P_v : S \in \mathbb{S}\} = \{P_w^\star S P_w : S \in \mathbb{S}\}.$$

Thus we have several representations of the set of solutions to the homogeneous mapping problem. Now if $A$, $B \in \mathbb{S}$ are such that $Ax = Bx = b$, then $(A - B)x = 0$. By Theorem 4.2, $A - B = P_w^\star S P_w$, or equivalently, $A = B + P_w^\star S P_w$ for some $S \in \mathbb{S}$. Hence,

$$\{A \in \mathbb{S} : Ax = b\} = B + \{A \in \mathbb{S} : Ax = 0\}, \tag{4.1}$$

where $B$ is any particular solution of the nonhomogeneous mapping problem. By combining Theorems 3.2 and 4.2 together with (4.1) we now have the complete solution of the characterization part of the mapping problem for $\mathbb{J}$ and $\mathbb{L}$.

THEOREM 4.4 (characterization for $\mathbb{J}$ and $\mathbb{L}$: nonhomogeneous case). *Let $\mathbb{J}$ and $\mathbb{L}$ be the Jordan and Lie algebras of any orthosymmetric scalar product on $\mathbb{K}^n$. Let $x, b \in \mathbb{K}^n$ with $x \neq 0$ and let $\mathcal{J}$ and $\mathcal{L}$ be the structured mapping sets as in* (3.1)*. Choose any $v, w \in \mathbb{K}^n$ such that $\langle v, x\rangle_{\mathrm{M}} = \langle w, x\rangle_{\mathrm{M}} = 1$, and use $v$ and $w$ to define $P_v$, ${}^{\pm}B_w$ as in* (2.2) *and* (3.2)*, respectively. Consider the following sets:*

$$\mathcal{J}_+ = \{{}^{+}B_w + P_v^\star S P_v : S \in \mathbb{J}\}, \qquad \mathcal{L}_- = \{{}^{-}B_w + P_v^\star L P_v : L \in \mathbb{L}\}.$$

*Then*

$$\mathcal{J} = \begin{cases} \mathcal{J}_+ & \text{if } \langle x, b\rangle_{\mathrm{M}} = \langle b, x\rangle_{\mathrm{M}}, \\ \emptyset & \text{otherwise,} \end{cases} \qquad \mathcal{L} = \begin{cases} \mathcal{L}_- & \text{if } \langle x, b\rangle_{\mathrm{M}} = -\langle b, x\rangle_{\mathrm{M}}, \\ \emptyset & \text{otherwise.} \end{cases}$$

A more general problem for Hermitian, and real symmetric matrices in particular, was considered by Sun [17, Lem. 1.4]. For given matrices $X, B \in \mathbb{K}^{n\times \ell}$, Sun gave a characterization of the set

$$\mathcal{H} = \{A \in \mathbb{K}^{n\times n} : A^* = A \text{ and } AX = B\}$$

in terms of the pseudoinverse $X^+$ of $X$, and the complementary orthogonal projections $\Pi_X = XX^+$ and $\Pi_{X^\perp} = I - \Pi_X$. He proved that $\mathcal{H} \neq \emptyset$ if and only if two conditions are satisfied: $B\Pi_{X^*} = B$ and $\Pi_X B X^+$ is Hermitian. In this case $\mathcal{H}$ can be expressed as

$$\mathcal{H} = \{BX^+ + (BX^+)^*\Pi_{X^\perp} + \Pi_{X^\perp} S \Pi_{X^\perp} : \quad S^* = S,\ S \in \mathbb{K}^{n\times n}\}. \tag{4.2}$$

When $\ell = 1$, writing $X$, $B$ as $x$, $b$, respectively, we get $\Pi_x = xx^*/(x^*x)$, and $x^+ = x^*/(x^*x)$. Since $\Pi_{x^*} = 1$, the conditions for $\mathcal{H}$ to be nonempty reduce to requiring that

$\Pi_x b x^+$ be Hermitian. A simple calculation shows that this happens if and only if $x^*b$ is real, which is in agreement with the condition in Corollary 3.3. Sun's characterization of $\mathcal{H}$ becomes

$$\mathcal{H} = \left\{ \frac{bx^*}{x^*x} + \frac{x^*b}{x^*x}\Pi_x + \Pi_x S \Pi_x,\ S^* = S \right\},$$

which corresponds to $\mathcal{J}_+$ in Theorem 4.4 with $M = I$ and the special choice $v = w = x/(x^*x)$. This choice of $w$ corresponds to using an orthogonal projection in the representation for $\mathcal{J}_+$, since $P_v$ is now $I - xx^*/(x^*x)$. Thus Sun's characterization is one among many given by Theorem 4.4.

A similar analysis of the real symmetric case shows that the results of Corollary 3.3 and Theorem 4.4 are compatible with Sun's solution for the case $\ell = 1$, and due to the freedom in the choice of $v$ and $w$, give a more flexible description of the set of real symmetric matrices mapping $x$ to $b$.

## 5. Structured mappings with extremal properties.

Let $\mathcal{J}$ and $\mathcal{L}$ be the sets of all structured solutions to the mapping problem as in (3.1). We now show how to find matrices in $\mathcal{J}$ or $\mathcal{L}$ with the extremal properties of minimal rank, minimal Frobenius norm, or minimal 2-norm, and we investigate their uniqueness.

### 5.1. Structured mappings of minimal rank.

In what follows, we assume $b \neq 0$.

THEOREM 5.1 (rank-one structured mappings). *Let* $\langle\cdot,\cdot\rangle_{\mathrm{M}}$ *be an orthosymmetric scalar product, and let* $\mathcal{S}$ *denote either* $\mathcal{J}$ *or* $\mathcal{L}$ *as in* (3.1). *Assume* $b \neq 0$. *A necessary condition for the existence of a rank-one matrix in* $\mathcal{S}$ *is* $\langle b, x\rangle_{\mathrm{M}} \neq 0$. *Whenever this rank-one matrix exists, it is unique and given by*

$$A = \begin{cases} bb^TM/\langle b,x\rangle_{\mathrm{M}} & \textit{for bilinear forms,} \\ bb^*M/\langle b,x\rangle_{\mathrm{M}} & \textit{for sesquilinear forms.} \end{cases}$$

*Proof.* Consider any rank-one matrix $A = uv^T$ such that $Ax = b$ with $b \neq 0$. Since $b \in \operatorname{range}(A)$, $u$ is a multiple of $b$, so without loss of generality we can take $u = b$.

Now suppose the orthosymmetric scalar product is bilinear, so $M = \pm M^T$. Since $M$ is nonsingular, there exists $z \in \mathbb{K}^n$ such that $v^T = z^TM$, and so $A = uv^T = bz^TM$. For $A \in \mathbb{S}$ we have $A^\star = \epsilon A$ with $\epsilon = \pm 1$. Hence by (2.1) we have $\pm zb^TM = \epsilon bz^TM$ and so $zb^T = \pm\epsilon bz^T$. Thus $z = \mu b$ and $A = \mu bb^TM$ with $\mu$ a scalar. But $Ax = b \Rightarrow \mu b(b^TMx) = b \Rightarrow \mu\langle b,x\rangle_{\mathrm{M}} = 1$, thus forcing $\langle b,x\rangle_{\mathrm{M}}$ to be nonzero, and uniquely determining $A$ by $A = bb^TM/\langle b,x\rangle_{\mathrm{M}}$. Similar reasoning applies for the sesquilinear case, leading to the formula $A = bb^*M/\langle b,x\rangle_{\mathrm{M}}$. ☐

COROLLARY 5.2. *Let* $b \neq 0$. *If* $\langle b,x\rangle_{\mathrm{M}} \neq 0$, *then either* $\mathcal{S}$ *is empty or there is a unique* $A \in \mathcal{S}$ *with* $\operatorname{rank}(A) = 1$.

*Proof.* When $\mathcal{S} \neq \emptyset$, we know from Theorem 3.2 that ${}^+B_w \in \mathcal{J}$ and ${}^-B_w \in \mathcal{L}$ for any $w$ such that $\langle w,x\rangle_{\mathrm{M}} = 1$. Since $\langle b,x\rangle_{\mathrm{M}} \neq 0$, choose $w = w_*$, where

$$w_* := \begin{cases} b/\langle b,x\rangle_{\mathrm{M}} & \text{for bilinear forms,} \\ b/\overline{\langle b,x\rangle}_{\mathrm{M}} & \text{for sesquilinear forms} \end{cases} \tag{5.1}$$

so that $\langle w_*,x\rangle_{\mathrm{M}} = 1$. Substituting this choice of $w$ into the formulas for ${}^+B_w$, ${}^-B_w$ given in (3.2) yields the unique rank-one mapping specified in Theorem 5.1. ☐

TABLE 5.1

*Rank-one structured mappings when* $\langle b, x\rangle_{\mathrm{M}} \neq 0$ *with* $w_*$ *as in* (5.1).

| Scalar product | $\mathcal{J}$ | $\mathcal{L}$ |
|---|---|---|
| Symmetric bilinear | ${}^{+}B_{w_*}$ | $\mathcal{L}$ is empty |
| Skew-symmetric bilinear | $\mathcal{J}$ is empty | ${}^{-}B_{w_*}$ |
| Hermitian sesquilinear | ${}^{+}B_{w_*}$ if $0 \neq \langle b, x\rangle_{\mathrm{M}} \in \mathbb{R}$.<br>Otherwise $\mathcal{J}$ is empty. | ${}^{-}B_{w_*}$ if $0 \neq \langle b, x\rangle_{\mathrm{M}} \in i\mathbb{R}$.<br>Otherwise $\mathcal{L}$ is empty. |
| Skew-Hermitian sesquilinear | ${}^{+}B_{w_*}$ if $0 \neq \langle b, x\rangle_{\mathrm{M}} \in i\mathbb{R}$.<br>Otherwise $\mathcal{J}$ is empty. | ${}^{-}B_{w_*}$ if $0 \neq \langle b, x\rangle_{\mathrm{M}} \in \mathbb{R}$.<br>Otherwise $\mathcal{L}$ is empty. |

Particular cases of Corollary 5.2 are summarized in Table 5.1. The extra conditions in the sesquilinear cases come from the results in Corollary 3.3.

For nonzero $b$ we have seen that the condition $\langle b, x\rangle_{\mathrm{M}} \neq 0$, while necessary for the existence of structured rank-one mappings, is precisely the condition that precludes the existence of *any* structured mappings in certain cases (see Theorem 3.2). On the other hand, Theorem 3.2 also shows that structured mapping sets $\mathcal{S}$ are never empty when the condition $\langle b, x\rangle_{\mathrm{M}} = 0$ is met. We turn to the question of determining what the minimal achievable rank is in this case.

THEOREM 5.3 (rank-two structured mappings). *Let* $\langle \cdot, \cdot\rangle_{\mathrm{M}}$ *be an orthosymmetric scalar product, and let* $\mathcal{S}$ *denote either* $\mathcal{J}$ *or* $\mathcal{L}$ *as in* (3.1)*. Consider any nonzero* $x$*,* $b \in \mathbb{K}^n$*. If* $\langle b, x\rangle_{\mathrm{M}} = 0$*, then*

$$\min_{A \in \mathcal{S}} \operatorname{rank}(A) = 2.$$

*There are always infinitely many matrices in* $\mathcal{S}$ *attaining this minimal rank. Among these are* ${}^{-}B_w \in \mathcal{L}$ *and* ${}^{+}B_w \in \mathcal{J}$*, where* ${}^{-}B_w$*,* ${}^{+}B_w$ *are given by* (3.2)*, with any choice of* $w \in \mathbb{K}^n$ *such that* $\langle w, x\rangle_{\mathrm{M}} = 1$*.*

*Proof.* If $\langle b, x\rangle_{\mathrm{M}} = 0$, then by Theorem 5.1, the minimum possible rank for matrices in $\mathcal{S}$ is 2. We know ${}^{+}B_w$, ${}^{-}B_w$ map $x$ to $b$ for all $w \in \mathbb{K}^n$ such that $\langle w, x\rangle_{\mathrm{M}} = 1$, and from Theorem 3.2 it follows that ${}^{+}B_w \in \mathbb{J}$ and ${}^{-}B_w \in \mathbb{L}$ for all such $w$. Since ${}^{+}B_w$, ${}^{-}B_w$ are at most rank two, and since they cannot be rank one, they are structured mappings of rank two. ◻

**5.2. Structured mappings of minimal Frobenius norm.** Another important special property is minimal norm, since this is directly related to structured backward errors for linear systems and eigenvalue problems [19], [20] as well as to the derivation of quasi-Newton methods [3]. We first consider minimal Frobenius norm; the minimal 2-norm case will be treated in the next section. For real symmetric or Hermitian matrices, it is well known [2], [3] that minimal Frobenius norm is achieved by

$$A_{\mathrm{opt}} = \frac{bx^* + xb^*}{x^*x} - \frac{(b^*x)}{(x^*x)^2}xx^*.$$

We show how to generalize this result to all Lie and Jordan algebras associated with scalar products that are both orthosymmetric and unitary. To prove the uniqueness of the structured mapping of minimal Frobenius norm, we will need the next two lemmas.

LEMMA 5.4. *In any real or complex inner product space, the associated norm* $\|\cdot\|$ *is strictly convex on independent vectors, that is,*

$$\|tu + (1-t)v\| \;<\; t\|u\| + (1-t)\|v\|\,, \quad 0 < t < 1\,,$$

*for any linearly independent* $u$ *and* $v$.

*Proof.* The Cauchy–Schwarz inequality implies that $\langle u, v\rangle + \langle v, u\rangle < 2\|u\|\|v\|$ for linearly independent $u, v$. A straightforward calculation then establishes the result. □

LEMMA 5.5. *For* $b \neq 0$, *the Frobenius norm is strictly convex on* $\mathcal{S}$ ($\mathcal{S} = \mathcal{J}, \mathcal{L}$).

*Proof.* Assuming $b \neq 0$, distinct $A, B \in \mathcal{S}$ are linearly independent. Since the Frobenius norm arises from the inner product $\langle A, B\rangle = \mathrm{tr}(A^*B)$, the result is immediate from Lemma 5.4. □

As Lemma 3.1 and Theorem 3.2 show, whenever the set of structured mappings $\mathcal{S}$ is nonempty, we can construct a parametrized set of structured maps ${}^{+}B_w$ or ${}^{-}B_w$ that take $x$ to $b$. The next theorem shows how this latitude in the choice of the parameter $w \in \mathbb{K}^n$, $\langle w, x\rangle_{\mathrm{M}} = 1$, can be exploited to identify the unique map of minimal Frobenius norm.

THEOREM 5.6 (minimal Frobenius norm structured mapping). *Let* $\langle\cdot,\cdot\rangle_{\mathrm{M}}$ *be a scalar product that is both orthosymmetric and unitary. Let* $\mathcal{S}$ *denote either* $\mathcal{J}$ *or* $\mathcal{L}$ *as in* (3.1). *If* $\mathcal{S} \neq \emptyset$, *the problem*

$$\min_{A\in\mathcal{S}} \|A\|_F$$

*has a unique solution given by*

$$A_{\mathrm{opt}} = \frac{bx^*}{x^*x} + \epsilon\left(\frac{bx^*}{x^*x}\right)^{\star}\left(I - \frac{xx^*}{x^*x}\right), \qquad \epsilon = \begin{cases} 1 & \text{if } \mathcal{S} = \mathcal{J}, \\ -1 & \text{if } \mathcal{S} = \mathcal{L}. \end{cases} \tag{5.2}$$

*Moreover,*

$$\|A_{\mathrm{opt}}\|_F^2 = 2\frac{\|b\|_2^2}{\|x\|_2^2} - \beta^2\frac{|\langle b, x\rangle_{\mathrm{M}}|^2}{\|x\|_2^4}, \tag{5.3}$$

*where* $\beta > 0$ *is such that* $\beta M$ *is unitary.*

*Proof.* Since $\mathcal{S} \neq \emptyset$, we know from Theorem 3.2 that ${}^{+}B_w \in \mathcal{J}$ and ${}^{-}B_w \in \mathcal{L}$ for any $w \in \mathbb{K}^n$ such that $\langle w, x\rangle_{\mathrm{M}} = 1$. Choose $w = w_0$, where

$$w_0 = \begin{cases} M^{-T}\overline{x}/(x^*x) & \text{for bilinear forms,} \\ M^{-*}x/(x^*x) & \text{for sesquilinear forms.} \end{cases} \tag{5.4}$$

Then $\langle w_0, x\rangle_{\mathrm{M}} = 1$, and the expressions for the structured maps ${}^{\pm}B_{w_0}$ in (3.2) and the projection $P_{w_0}$ in (2.2) become

$${}^{\pm}B_{w_0} = \frac{bx^*}{x^*x} \pm \left(\frac{bx^*}{x^*x}\right)^{\star} P_{w_0}, \qquad P_{w_0} = I - \frac{xx^*}{x^*x}. \tag{5.5}$$

For brevity, let $A_0$ denote ${}^{\pm}B_{w_0}$, and let $P_0$ denote the orthogonal projection $P_{w_0}$. We now show that $A_0$ is the unique map of minimal Frobenius norm in $\mathcal{S}$.

Complete $\{\,x/\|x\|_2\}$ to an orthonormal basis $\{\,x/\|x\|_2, u_2, \ldots, u_n\}$ with respect to the standard inner product on $\mathbb{K}^n$. We first observe that for all $A \in \mathcal{S}$,

$$\|Ax\|_F = \|b\|_F = \|A_0x\|_F.$$

The characterization theorem, Theorem 4.4, with $v = w = w_0$ tells us that any $A \in \mathcal{S}$ can be written as $A = A_0 + P_0^\star S P_0$ for some $S \in \mathbb{S}$. Premultiplying $u_i$ by $A$ and taking the norm yields

$$\|Au_i\|_2^2 = \|A_0u_i\|_2^2 + \|P_0^\star SP_0u_i\|_2^2 + 2\,\mathrm{Re}\Big((A_0u_i)^*P_0^\star SP_0u_i\Big), \quad 2 \le i \le n. \tag{5.6}$$

When $\langle\cdot,\cdot\rangle_{\mathrm{M}}$ is unitary, the last term on the right-hand side of (5.6) always vanishes. To see this, first consider the case when the form is bilinear. Since the stars commute in a unitary scalar product and $x^*u_i = 0$, $i = 2\colon n$, we have

$$(A_0u_i)^* = \pm u_i^*\left(\left(\frac{bx^*}{x^*x}\right)^\star\right)^* = \pm u_i^*\left(\frac{xb^*}{x^*x}\right)^\star = \pm\left(\frac{u_i^*M^{-1}\bar{b}}{x^*x}\right)x^TM =: \alpha_i x^TM$$

and

$$(A_0u_i)^*P_0^\star SP_0u_i = \alpha_i x^TM\Big(M^{-1}\Big(I - \frac{\bar{x}x^T}{x^*x}\Big)M\Big)Su_i = \alpha_i(x^T - x^T)MSu_i = 0.$$

Similarly, for sesquilinear forms, $(A_0u_i)^* = \alpha_i x^*M$ with $\alpha_i = \pm(u_i^*M^{-1}b)/(x^*x)$ and

$$(A_0u_i)^*P_0^\star SP_0u_i = \alpha_i x^*M\Big(M^{-1}\Big(I - \frac{xx^*}{x^*x}\Big)M\Big)Su_i = \alpha_i(x^* - x^*)MSu_i = 0.$$

Therefore from (5.6), $\|Au_i\|_2 \ge \|A_0u_i\|_2$, $2 \le i \le n$. Recall that the Frobenius norm is unitarily invariant; since $\{\,x/\|x\|_2, u_2, \dots, u_n\}$ forms an orthonormal basis for $\mathbb{K}^n$,

$$\|A\|_F^2 = \frac{\|Ax\|_2^2}{\|x\|_2^2} + \sum_{i=2}^n \|Au_i\|_2^2 \ge \frac{\|A_0x\|_2^2}{\|x\|_2^2} + \sum_{i=2}^n \|A_0u_i\|_2^2 = \|A_0\|_F^2 \quad \forall A \in \mathcal{S},$$

showing that $A_0$ has minimal Frobenius norm.

It is well known that strictly convex functions have at most one minimizer [1, p. 4]. Therefore Lemma 5.5 implies that $A_0$ is unique for $b \ne 0$. When $b = 0$, $A_0 \equiv 0$ is clearly unique. Thus $A_{\mathrm{opt}}$, the unique structured map of minimal Frobenius norm, is $A_0$, defined by (5.2).

Finally, for the Frobenius norm of $A_{\mathrm{opt}}$ we have

$$\|A_{\mathrm{opt}}\|_F^2 = \Big(\|bx^*\|_F^2 + \|(bx^*)^\star P_0\|_F^2 + 2\epsilon\,\mathrm{Re}\,\big(\mathrm{tr}[xb^*(bx^*)^\star P_0]\big)\Big)/\|x\|_2^4. \tag{5.7}$$

Now $P_0x = 0$ implies

$$\mathrm{tr}[xb^*(bx^*)^\star P_0] = \mathrm{tr}[P_0xb^*(bx^*)^\star] = \mathrm{tr}(0) = 0. \tag{5.8}$$

Since $P_0$ is an orthogonal projection, $P_0^2 = P_0 = P_0^*$. Hence

$$\begin{aligned}\|(bx^*)^\star P_0\|_F^2 = \mathrm{tr}\left[(bx^*)^\star P_0\big((bx^*)^\star\big)^*\right] &= \|(bx^*)^\star\|_F^2 - \|(bx^*)^\star x\|_2^2/(x^*x)\\ &= \|(bx^*)\|_F^2 - x^*(bb^*)^\star x.\end{aligned} \tag{5.9}$$

For the last equality we have used the fact that $\|X^\star\|_F = \|X\|_F$ for any unitary scalar product.[1] Recall that $\beta M$ is unitary for some $\beta > 0$. Thus $M^{-1} = \beta^2M^*$ and

$$x^*(bb^*)^\star x = \beta^2\left\{\begin{array}{ll} x^*M^*\bar{b}b^TMx & \text{(bilinear forms)}\\ x^*M^*bb^*Mx & \text{(sesquilinear forms)}\end{array}\right\} = \beta^2|\langle b,x\rangle_{\mathrm{M}}|^2. \tag{5.10}$$

Now combining (5.8)–(5.10) into (5.7) gives the desired formula for $\|A_{\mathrm{opt}}\|_F^2$. $\square$

---

[1] Surprisingly, this property characterizes unitary scalar products [13].

**5.3. Structured mappings of minimal 2-norm.** From $Ax = b$ it is clear that $\|b\|_2/\|x\|_2$ is always a lower bound for $\|A\|_2$. For a large class of scalar products Theorem 5.6 also yields an upper bound:

$$\frac{\|b\|_2}{\|x\|_2} \le \min_{A\in\mathcal{S}} \|A\|_2 \le \min_{A\in\mathcal{S}} \|A\|_F \le \sqrt{2}\,\frac{\|b\|_2}{\|x\|_2}\,, \tag{5.11}$$

where $\mathcal{S}$ denotes either $\mathcal{J}$ or $\mathcal{L}$ as in (3.1). In this section we show that the lower bound is actually attained in any Lie or Jordan algebra of a scalar product that is both orthosymmetric and unitary.

Unlike the structured mapping of minimal Frobenius norm, mappings of minimal 2-norm in $\mathcal{S}$ are almost never unique. For example, consider the Jordan algebra of $n \times n$ symmetric matrices with $n \ge 3$, and take $x = e_1$ and $b = e_2$ to be the first and second columns of the identity matrix, respectively. Then all matrices of the form $A = \operatorname{diag}\left(\left[\begin{smallmatrix}0&1\\1&0\end{smallmatrix}\right], S\right)$ with $S$ symmetric and $\|S\|_2 \le 1$ satisfy $A^T = A$, $Ax = b$ and have $\|A\|_2 = \|b\|_2/\|x\|_2 = 1$. Indeed, this formula captures *all* symmetric matrices mapping $e_1$ to $e_2$ that have minimal 2-norm. We develop similar characterizations of the sets of structured mappings of minimal 2-norm for large classes of Lie and Jordan algebras by reducing to the characterization problem for the following special structures:

$$\begin{aligned} \operatorname{Sym}(n,\mathbb{K}) &= \{A \in \mathbb{K}^{n\times n} : A^T = A\},\\ \operatorname{Skew}(n,\mathbb{K}) &= \{A \in \mathbb{K}^{n\times n} : A^T = -A\},\\ \operatorname{Herm}(n,\mathbb{C}) &= \{A \in \mathbb{C}^{n\times n} : A^* = A\}. \end{aligned} \tag{5.12}$$

We will use the simplified notation $\operatorname{Sym}(\mathbb{K})$, etc., when the size of the matrices is clear from the context. The technical details for these special structures can be found in the appendix. Recall that for nonzero $\mu \in \mathbb{K}$,

$$\operatorname{sign}(\mu) := \overline{\mu}/|\mu|.$$

THEOREM 5.7 (minimal 2-norm structured mappings: general case). *Let $\mathbb{S}_n$ be the Lie algebra $\mathbb{L}$ or Jordan algebra $\mathbb{J}$ of a scalar product $\langle\cdot,\cdot\rangle_{\mathrm{M}}$ on $\mathbb{K}^n$ that is both orthosymmetric and unitary, so that $M \cdot \mathbb{S}_n$ is either* $\operatorname{Sym}(n,\mathbb{K})$, $\operatorname{Skew}(n,\mathbb{K})$, *or* $\gamma\operatorname{Herm}(n,\mathbb{C})$ *for some $|\gamma| = 1$. Also let $x, b \in \mathbb{K}^n \setminus \{0\}$ be vectors such that $\mathcal{S} = \{A \in \mathbb{S}_n : Ax = b\}$ is nonempty. Then*

$$\min_{A\in\mathcal{S}} \|A\|_2 = \frac{\|b\|_2}{\|x\|_2}.$$

*Furthermore, with $\mathcal{M} := \big\{A \in \mathcal{S} : \|A\|_2 = \|b\|_2/\|x\|_2\big\}$, there exists a unitary matrix $U$ such that*

$$\mathcal{M} = \left\{ \frac{\|b\|_2}{\|x\|_2} U^{\star}(\beta M)^{-1} \begin{bmatrix} R & 0 \\ 0 & S \end{bmatrix} U : S \in \widetilde{\mathbb{S}}_{n-r}, \|S\|_2 \le 1 \right\}, \tag{5.13}$$

*where $\beta > 0$ is a real constant such that $\beta M$ is unitary and $\star$ denotes the adjoint of the scalar product $\langle\cdot,\cdot\rangle_{\mathrm{M}}$. The number $r$, the structured class $\widetilde{\mathbb{S}}_{n-r}$, and $R \in \mathbb{K}^{r\times r}$ are given in each case by the following:*

(i) $M\cdot\mathbb{S}_n = \mathrm{Sym}(n,\mathbb{K})$: *$r = 1$ ($r = 2$) if $x$ and $\overline{Mb}$ are linearly dependent (independent), $\widetilde{\mathbb{S}}_{n-r} = \mathrm{Sym}(n-r,\mathbb{K})$, and*

$$R = \begin{cases} \mathrm{sign}(\mu) & \textit{if } \beta\overline{Mb} = \mu x \textit{ for some } \mu \in \mathbb{K}, \\ \left[\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right] & \textit{otherwise.} \end{cases}$$

(ii) $M\cdot\mathbb{S}_n = \mathrm{Skew}(n,\mathbb{K})$: *$r = 2$, $\widetilde{\mathbb{S}}_{n-r} = \mathrm{Skew}(n-2,\mathbb{K})$, and $R = \left[\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right]$.*

(iii) $M\cdot\mathbb{S}_n = \gamma\mathrm{Herm}(n,\mathbb{C})$ *for some $|\gamma| = 1$: $r = 1$ ($r = 2$) if $x$ and $Mb$ are linearly dependent (independent), $\widetilde{\mathbb{S}}_{n-r} = \gamma\mathrm{Herm}(n-r,\mathbb{C})$, and*

$$R = \begin{cases} \gamma\,\mathrm{sign}(\mu) & \textit{if } \gamma^{-1}\beta Mb = \mu x \textit{ for some } \mu \in \mathbb{R}, \\ \gamma\left[\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right] & \textit{otherwise.} \end{cases}$$

*The matrix $U$ can be taken as the product of at most two unitary Householder reflectors; when $\mathbb{K} = \mathbb{R}$, $U$ is real orthogonal.*

*Proof.* For orthosymmetric $\langle\cdot,\cdot\rangle_{\mathrm{M}}$ it is shown in [12, Thm. 8.4] that left multiplication by the matrix $M$ defining the scalar product is a bijection from $\mathbb{K}^{n\times n}$ to $\mathbb{K}^{n\times n}$ that maps $\mathbb{L}$ and $\mathbb{J}$ to Skew($\mathbb{K}$) and Sym($\mathbb{K}$) for bilinear forms, and to unit scalar multiples of Herm($\mathbb{C}$) for sesquilinear forms. Furthermore $\beta M$ being unitary implies that the map $\mathbb{S} \longmapsto \beta M\cdot\mathbb{S}$ is a 2-norm-preserving bijection. For bilinear forms, the equivalence of the equations $Ax = b$ and $\widetilde{A}x := (\beta MA)x = (\beta Mb) =: \widetilde{b}$ thus reduces the structured mapping problem for $\mathcal{S} = \{A \in \mathbb{S}_n : Ax = b\}$ in a 2-norm-preserving way to the structured mapping problem for finding $\widetilde{A}$ in Skew$(n,\mathbb{K})$ or Sym$(n,\mathbb{K})$ such that $\widetilde{A}x = \widetilde{b}$. Similarly for sesquilinear forms, the equivalence of $Ax = b$ and $\widetilde{A}x := (\gamma^{-1}\beta MA)x = (\gamma^{-1}\beta Mb) =: \widetilde{b}$ gives a 2-norm-preserving reduction of the structured mapping problem for $\mathcal{S}$ to that of finding $\widetilde{A}$ in Herm$(n,\mathbb{C})$ such that $\widetilde{A}x = \widetilde{b}$.

The value of $\min_{A\in\mathcal{S}} \|A\|_2$ and the formula for $\mathcal{M}$ in (5.13) now follow by applying Theorem A.2 to the minimal 2-norm structured mapping problem for $\widetilde{A}x = \widetilde{b}$, and then using the correspondence between $\widetilde{A}$ and $A$. ☐

Note the structure of formula (5.13) and how it automatically produces matrices in $\mathbb{S}_n$. In all cases, $\frac{\|b\|_2}{\|x\|_2}(\beta M)^{-1}\,\mathrm{diag}(R,S)$ is in $\mathbb{S}_n$, since the scalar product is orthosymmetric and $\|b\|_2/\|x\|_2$ and $\beta$ are real. Lemma 4.1(a) shows that $\star$-congruence preserves $\mathbb{L}$ and $\mathbb{J}$ structure, so $U^\star\frac{\|b\|_2}{\|x\|_2}(\beta M)^{-1}\,\mathrm{diag}(R,S)U$ is again in $\mathbb{S}_n$.

### 5.4. Comparison of the various "minimal" structured mappings.

We conclude section 5 by exploring the relationships between the three types of extremal mappings—minimal rank, Frobenius norm, and 2-norm—under the assumption that the scalar product $\langle\cdot,\cdot\rangle_{\mathrm{M}}$ is both unitary and orthosymmetric.

In general the minimal Frobenius norm solution $A_{\mathrm{opt}}$ differs from the minimal rank solution. The latter is usually rank one, whereas $A_{\mathrm{opt}}$ is generally rank two. From (5.2) we see that $A_{\mathrm{opt}}$ is rank one if and only if $M^{-1}\bar{x} \in \mathrm{span}\{b\}$ for bilinear forms or $M^{-1}x \in \mathrm{span}\{b\}$ for sesquilinear forms.

For structured mappings of the minimal 2-norm, the following corollary of Theorem 5.7 singles out the unique matrix of minimal rank as well as that of minimal Frobenius norm.

Corollary 5.8. *Under the hypotheses of Theorem 5.7, let $\mathcal{M}$ denote the set of all minimal 2-norm mappings in $\mathcal{S} = \{A \in \mathbb{S} : Ax = b\}$. Assume further that $x, b$ are* *vectors such that $\mathcal{S}$ is nonempty. Consider the particular mapping*

$$A_2 := \frac{\|b\|_2}{\|x\|_2} U^\star (\beta M)^{-1} \begin{bmatrix} R & 0 \\ 0 & 0 \end{bmatrix} U \in \mathcal{M}\,, \tag{5.14}$$

*obtained by setting $S$ equal to* 0 *in* (5.13). *Then $A_2$ is the unique solution of both the minimal rank problem $\min_{A\in\mathcal{M}} \operatorname{rank}(A)$ and the minimal Frobenius norm problem $\min_{A\in\mathcal{M}} \|A\|_F$. Moreover, either*

(1) *$A_2$ has rank one and $\|A_2\|_F = \|b\|_2/\|x\|_2$, or*

(2) *$A_2$ has rank two and $\|A_2\|_F = \sqrt{2}\,\|b\|_2/\|x\|_2$.*

*Case* (1) *occurs when $x$ and $\overline{Mb}$ ($x$ and $Mb$) are linearly dependent and the scalar product is bilinear* (*sesquilinear*). (*Note that if $M\cdot\mathbb{S} = \operatorname{Skew}(n,\mathbb{K})$, then this linear dependence implies that $\mathcal{S}$ is empty.*) *Otherwise case* (2) *holds.*

Are there any conditions under which there is a structured mapping in $\mathcal{S}$ that simultaneously has all three extremal properties? The next result provides a complete answer to this question.

THEOREM 5.9. *Let $\mathbb{S}$ be the Lie or Jordan algebra of a scalar product $\langle\cdot,\cdot\rangle_{\mathrm{M}}$ that is both unitary and orthosymmetric. Assume that $x, b \in \mathbb{K}^n \setminus \{0\}$ are vectors such that $\mathcal{S} = \{A \in \mathbb{S} :\ Ax = b\}$ is nonempty and $A_2$ is the matrix defined* (5.14). *Then the unique minimal Frobenius norm mapping $A_{\mathrm{opt}} \in \mathcal{S}$ has both minimal* 2*-norm and minimal rank in $\mathcal{S}$ if and only if the pair of vectors $(x, b)$ satisfies either property* (a) *or property* (b) *below.*

(a) *$M^{-1}\bar{x} \in \operatorname{span}\{b\}$ for bilinear forms or $M^{-1}x \in \operatorname{span}\{b\}$ for sesquilinear forms. In this case*

$$A_{opt} = A_2 = \begin{cases} bb^T M/\langle b, x\rangle_{\mathrm{M}} & \textit{for bilinear forms,} \\ bb^* M/\langle b, x\rangle_{\mathrm{M}} & \textit{for sesquilinear forms} \end{cases}$$

*is the unique rank-one mapping in $\mathcal{S}$.*

(b) *$\langle b, x\rangle_{\mathrm{M}} = 0$. In this case*

$$A_{\mathrm{opt}} = A_2 = \frac{bx^*}{x^*x} + \epsilon \left(\frac{bx^*}{x^*x}\right)^\star, \quad \epsilon = \begin{cases} 1 & \textit{if } \mathbb{S} = \mathbb{J}, \\ -1 & \textit{if } \mathbb{S} = \mathbb{L}, \end{cases}$$

*is the unique rank-two mapping in $\mathcal{M} = \{A \in \mathcal{S} :\ \|A\|_2 = \min_{B\in\mathcal{S}} \|B\|_2\}$.*

*Proof.* ($\Rightarrow$) $A_{\mathrm{opt}}$ having minimal 2-norm in $\mathcal{S}$ means that $A_{\mathrm{opt}} \in \mathcal{M}$, with minimal Frobenius norm in $\mathcal{M}$; thus $A_{\mathrm{opt}} = A_2$ by Corollary 5.8. But $A_2$ is either rank one or rank two. $A_2$ with rank one means $A_{\mathrm{opt}}$ has rank one, and therefore property (a) holds by the remarks preceding the corollary. On the other hand $A_2$ with rank two implies $\|A_{\mathrm{opt}}\|_F = \|A_2\|_F = \sqrt{2}\,\|b\|_2/\|x\|_2$, which by (5.3) implies that property (b) holds.

($\Leftarrow$) Property (a) implies that $A_{\mathrm{opt}}$ is rank one by the remarks preceding the corollary. But property (a) is equivalent to the linear dependence of $x$ and $\overline{Mb}$ ($x$ and $Mb$) for bilinear (sesquilinear) forms, which are precisely the conditions in Corollary 5.8 which guarantee that $A_2$ is rank one. The uniqueness of rank-one mappings in $\mathcal{S}$ from Theorem 5.1 now implies that $A_{\mathrm{opt}} = A_2$ has all three minimality properties.

Property (b) implies that $\|A_{\mathrm{opt}}\|_F = \sqrt{2}\,\|b\|_2/\|x\|_2$ by (5.3), and that the minimal rank in $\mathcal{S}$ is two by Theorem 5.3. By Corollary 5.8 we know that $\|A_2\|_F \le \sqrt{2}\,\|b\|_2/\|x\|_2$, so the uniqueness of minimal Frobenius norm mappings implies that $A_{\mathrm{opt}} = A_2$. This map has minimal rank two by case (2) of Corollary 5.8. $\square$

## 6. Concluding remarks.

In this paper we have presented complete, unified, and explicit solutions of the existence and characterization problems for structured mappings coming from Lie and Jordan algebras associated with orthosymmetric scalar products. In addition, in the set $\{ A \in \mathbb{S} : \; Ax = b \}$ we have identified and characterized the structured mappings of minimal rank, minimal Frobenius norm, and minimal 2-norm. These results have already found application in the analysis of structured condition numbers and backward errors [7], [20], and constitute the first step towards characterizing the set $\{ A \in \mathbb{S} : \; AX = B \}$, where $X$ and $B$ are given matrices.

In part II of this paper [14] we consider the same structured mapping problems for a third class of structured matrices $\mathbb{S}$ associated with a scalar product: the automorphism group $\mathbb{G}$ defined by

$$\mathbb{G} = \left\{ A \in \mathbb{K}^{n\times n} : \langle Ax, Ay \rangle_{\mathrm{M}} = \langle x, y \rangle_{\mathrm{M}} \; \forall x, y \in \mathbb{K}^n \right\} = \left\{ A \in \mathbb{K}^{n\times n} : A^\star = A^{-1} \right\}.$$

Unlike the corresponding Lie and Jordan algebras, the group $\mathbb{G}$ is a *nonlinear* subset of $\mathbb{K}^{n\times n}$; hence different (and somewhat more elaborate) techniques are needed to solve the structured mapping problems for $\mathbb{G}$. There are, however, some ways in which the results for groups $\mathbb{G}$ are actually simpler than the ones developed in this paper for $\mathbb{L}$ and $\mathbb{J}$. Consider, for example, the solution of the existence problem given in [14]: for any orthosymmetric scalar product $\langle \cdot, \cdot \rangle_{\mathrm{M}}$, there exists $A \in \mathbb{G}$ such that $Ax = b$ if and only if $\langle x, x \rangle_{\mathrm{M}} = \langle b, b \rangle_{\mathrm{M}}$. A clean, unified, and simply stated result. Examples of groups $\mathbb{G}$ covered by this theorem include the orthogonal, symplectic, and pseudounitary groups. Two types of characterization of the set $\{A \in \mathbb{G} : \; Ax = b\}$ are also given in [14], both of which are expected to be useful in structured backward error investigations.

## Appendix. Structured mappings of minimal 2-norm for symmetric, skew-symmetric, and Hermitian structures.

Our goal in this appendix is to characterize the complete set of all minimal 2-norm mappings for each of the five key structures in (5.12). For example, for real symmetric matrices it is already well known that $A = (\|b\|_2/\|x\|_2)H$, where $H$ is a Householder reflector mapping $x/\|x\|_2$ to $b/\|b\|_2$, provides a minimal 2-norm solution. However, the set of *all* minimal 2-norm symmetric matrices taking $x$ to $b$ has not previously been explicitly described.

First we consider the $2 \times 2$ case for a special type of $(x, b)$ vector pair and for symmetric and Hermitian structures.

LEMMA A.1. *Let* $\mathbb{S}$ *be either* $\mathrm{Sym}(2, \mathbb{K})$ *or* $\mathrm{Herm}(2, \mathbb{C})$ *and let*

$$\mathcal{S} = \left\{ A \in \mathbb{S} : \; A \begin{bmatrix} \alpha \\ \beta \end{bmatrix} = \begin{bmatrix} \alpha \\ -\beta \end{bmatrix} \right\},$$

*where* $\alpha, \beta \in \mathbb{C}$ *with* $\mathrm{Re}(\alpha) \neq 0$ *and* $\beta \neq 0$ *when* $\mathbb{S} = \mathrm{Sym}(2, \mathbb{C})$*, and* $\alpha, \beta \in \mathbb{R} \setminus \{0\}$ *otherwise. Then*

$$\min_{A \in \mathcal{S}} \|A\|_2 = 1,$$

*with* $A = \left[\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right]$ *being the* unique *matrix in* $\mathcal{S}$ *of minimal* 2*-norm.*

*Proof.* Note that from (5.11) any $A \in \mathcal{S}$ satisfies $\|A\|_2 \geq 1$, and since $\left[\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right] \in \mathcal{S}$ has unit 2-norm we have $\min_{A \in \mathcal{S}} \|A\|_2 = 1$. The rest of the proof consists of showing that $\left[\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right]$ is the unique minimizer of the 2-norm for $\mathcal{S}$.

We start by parameterizing $\mathcal{S}$ using (4.1):

$$\mathcal{S} = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} + \left\{ A \in \mathbb{S} : \; A \begin{bmatrix} \alpha \\ \beta \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \right\},$$

where $\left[\begin{smallmatrix}1 & 0\\ 0 & -1\end{smallmatrix}\right]$ is a particular mapping in $\mathcal{S}$. Any $A \in \mathrm{Sym}(2,\mathbb{K})$ has the form $\left[\begin{smallmatrix}a & z\\ z & c\end{smallmatrix}\right]$ with $a, c, z \in \mathbb{K}$, so $A\left[\begin{smallmatrix}\alpha\\ \beta\end{smallmatrix}\right] = \left[\begin{smallmatrix}0\\ 0\end{smallmatrix}\right]$ implies $\left[\begin{smallmatrix}a & z\\ z & c\end{smallmatrix}\right] = z\left[\begin{smallmatrix}-\beta/\alpha & 1\\ 1 & -\alpha/\beta\end{smallmatrix}\right]$. Similarly any $A \in \mathrm{Herm}(2,\mathbb{C})$ has the form $\left[\begin{smallmatrix}a & z\\ \bar{z} & c\end{smallmatrix}\right]$ with $a, c \in \mathbb{R}$; then $\alpha, \beta \in \mathbb{R}$ together with $A\left[\begin{smallmatrix}\alpha\\ \beta\end{smallmatrix}\right] = \left[\begin{smallmatrix}0\\ 0\end{smallmatrix}\right]$ implies that $z \in \mathbb{R}$, and so $A$ can once again be expressed in the form $z\left[\begin{smallmatrix}-\beta/\alpha & 1\\ 1 & -\alpha/\beta\end{smallmatrix}\right]$. Hence writing

$$P(z) = \begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix} + z\begin{bmatrix}-\frac{\beta}{\alpha} & 1\\ 1 & -\frac{\alpha}{\beta}\end{bmatrix} = \begin{bmatrix}1 - \frac{\beta}{\alpha}z & z\\ z & -1 - \frac{\alpha}{\beta}z\end{bmatrix},$$

we have $\mathcal{S} = \{P(z) : \ z \in \mathbb{K}\}$ if $\mathbb{S} = \mathrm{Sym}(2,\mathbb{K})$, and $\mathcal{S} = \{P(z) : \ z \in \mathbb{R}\}$ when $\mathbb{S} = \mathrm{Herm}(2,\mathbb{C})$ and $\alpha, \beta \in \mathbb{R}$.

We can now calculate the 2-norm of $P(z)$ by computing the largest eigenvalue of

$$P^*P(z) = \begin{bmatrix}1 - \left(\frac{\beta}{\bar{\alpha}}\bar{z} + \frac{\beta}{\alpha}z\right) + \left(1 + \frac{\beta^2}{|\alpha|^2}\right)|z|^2 & (z - \bar{z}) - \gamma|z|^2\\ (\bar{z} - z) - \bar{\gamma}|z|^2 & 1 + \left(\frac{\bar{\alpha}}{\beta}\bar{z} + \frac{\alpha}{\beta}z\right) + \left(1 + \frac{|\alpha|^2}{\beta^2}\right)|z|^2\end{bmatrix},$$

where $\gamma := (\alpha/\beta) + (\beta/\overline{\alpha})$. Much calculation and simplification yields

$$\operatorname{tr} P^*P(z) = 2 + 2q(z), \qquad \det P^*P(z) = 1 + 2q(z) - 2\Big(1 + \operatorname{Re}\frac{\alpha^2}{|\alpha|^2}\Big)|z|^2,$$

where $q(z) := \operatorname{Re}\left[\left(\frac{\alpha}{\beta} - \frac{\beta}{\alpha}\right)z\right] + |\gamma|^2|z|^2/2 \in \mathbb{R}$. Since the characteristic polynomial of $P^*P(z)$ is $\lambda^2 - \operatorname{tr} P^*P(z)\lambda + \det P^*P(z)$, we get

$$\begin{aligned}\lambda_{\pm}(z) &= \frac{1}{2}\left(\operatorname{tr} P^*P(z) \pm \sqrt{\Big(\operatorname{tr} P^*P(z)\Big)^2 - 4\det P^*P(z)}\ \right)\\ &= 1 + q(z) \pm \sqrt{q(z)^2 + 2\Big(1 + \operatorname{Re}\frac{\alpha^2}{|\alpha|^2}\Big)|z|^2}\ .\end{aligned}$$

Since $q(z) \in \mathbb{R}$, clearly the largest eigenvalue of $P^*P(z)$ is $\lambda_+(z)$. But the hypothesis $\operatorname{Re}(\alpha) \neq 0$ means that $\operatorname{Re}\frac{\alpha^2}{|\alpha|^2} > -1$, so the second term under the square root is strictly bigger than 0 for all nonzero $z$. Hence $\lambda_+(z)$ satisfies $\lambda_+(0) = 1$ and $\lambda_+(z) > 1$ for all nonzero $z$. Thus $z = 0$ is the unique minimizer of $\lambda_+(z)$, and hence $P(0) = \left[\begin{smallmatrix}1 & 0\\ 0 & -1\end{smallmatrix}\right]$ is the unique minimizer of the 2-norm for $\mathcal{S}$. $\square$

We are now in a position to give a complete description of the set of all minimal 2-norm structured mappings for symmetric, skew-symmetric, and Hermitian matrices.

THEOREM A.2 (minimal 2-norm structured mappings: special cases). *Let* $\mathbb{S}_n$ *be either* $\mathrm{Sym}(n,\mathbb{K})$, $\mathrm{Skew}(n,\mathbb{K})$, *or* $\mathrm{Herm}(n,\mathbb{C})$, *and let* $x, b \in \mathbb{K}^n \setminus \{0\}$ *be vectors such that* $\mathcal{S} = \{A \in \mathbb{S}_n : Ax = b\}$ *is nonempty. Then*

$$\min_{A \in \mathcal{S}} \|A\|_2 = \frac{\|b\|_2}{\|x\|_2}.$$

*Furthermore with* $\mathcal{M} := \big\{A \in \mathcal{S} : \|A\|_2 = \|b\|_2/\|x\|_2\big\}$, *there exists an* $n \times n$ *unitary matrix* $U$ *such that*

$$\mathcal{M} = \left\{\frac{\|b\|_2}{\|x\|_2}U^{\star}\operatorname{diag}(R, S)U : \ S \in \mathbb{S}_{n-r}, \ \|S\|_2 \le 1\right\},$$

*where the adjoint* $\star$, *the number* $r$, *and* $R \in \mathbb{S}_r$ *are given by the following:*

(i) $\mathbb{S}_n = \mathrm{Sym}(n, \mathbb{K})$: $\star = T$ *and* $r = 1$ $(r = 2)$ *if* $x$ *and* $\overline{b}$ *are linearly dependent* (*independent*)*, with*

$$R = \begin{cases} \mathrm{sign}(\mu) & \textit{if } \overline{b} = \mu x \textit{ for some } \mu \in \mathbb{K}, \\ \left[\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right] & \textit{otherwise.} \end{cases}$$

(ii) $\mathbb{S}_n = \mathrm{Skew}(n, \mathbb{K})$: $\star = T$ *and* $r = 2$*, with* $R = \left[\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right]$.

(iii) $\mathbb{S}_n = \mathrm{Herm}(n, \mathbb{C})$: $\star = *$ *and* $r = 1$ $(r = 2)$ *if* $x$ *and* $b$ *are linearly dependent* (*independent*)*, with*

$$R = \begin{cases} \mathrm{sign}(\mu) & \textit{if } b = \mu x \textit{ for some } \mu \in \mathbb{R}, \\ \left[\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right] & \textit{otherwise.} \end{cases}$$

*The matrix* $U$ *can be taken as the product of at most two unitary*[2] *Householder reflectors; when* $\mathbb{K} = \mathbb{R}$, $U$ *is real orthogonal.*

*Proof.* For any $A \in \mathbb{S}_n$ such that $Ax = b$, observe that the matrix $B = \frac{\|x\|_2}{\|b\|_2} A$ is also in $\mathbb{S}_n$ and maps $\frac{x}{\|x\|_2}$ to $\frac{b}{\|b\|_2}$; also note that $\overline{b} = \mu x$ (resp., $b = \mu x$) in the theorem is equivalent to $\frac{\overline{b}}{\|b\|_2} = \mathrm{sign}(\overline{\mu}) \frac{x}{\|x\|_2}$ $\big($resp., $\frac{b}{\|b\|_2} = \mathrm{sign}(\overline{\mu}) \frac{x}{\|x\|_2}\big)$. Thus it suffices to prove the theorem for $x, b \in \mathbb{K}^n$ with $\|x\|_2 = \|b\|_2 = 1$ and the condition $\overline{b} = \mu x$ (resp., $b = \mu x$) replaced by $\overline{b} = \mathrm{sign}(\overline{\mu}) x$ $\big($resp., $b = \mathrm{sign}(\overline{\mu}) x\big)$; we make these assumptions throughout the rest of the argument.

The proof proceeds by first developing a unitary $U$ and accompanying $R$ for each of the five structures in (5.12). Then these $U$ and $R$ matrices are used to build explicit families of matrices in the structured mapping set $\mathcal{S}$ that realize the lower bound in (5.11), and thus are of minimal 2-norm. Finally we show that for each structure these families account for all of $\mathcal{M}$.

We begin by constructing for each case of the theorem a unitary matrix $U$ such that

$$Ux = \begin{bmatrix} y \\ 0 \end{bmatrix}, \quad (U^\star)^{-1} b = \begin{bmatrix} c \\ 0 \end{bmatrix}, \tag{A.1}$$

with $y, c \in \mathbb{K}^r$ satisfying $Ry = c$, where $R \in \mathbb{S}_r$ is as defined in the theorem.

(i) First, suppose that $\mathbb{S}_n = \mathrm{Sym}(n, \mathbb{K})$. If $\overline{b} = \mathrm{sign}(\overline{\mu}) x$ for some $\mu \in \mathbb{K}$, then let $U$ be the unitary Householder reflector mapping $x$ to $e_1$, so that $y = 1$. Then $(U^\star)^{-1} b = \overline{U} b = \mathrm{sign}(\mu) e_1$, so $c = \mathrm{sign}(\mu)$. Clearly with $R := \mathrm{sign}(\mu) \in \mathbb{S}_1$ we have $Ry = c$.

When $x$ and $\overline{b}$ are linearly independent then $U$ can be taken as the product of two unitary Householder reflectors, $U = H_2 H_1$. The first reflector $H_1$ takes $x + \overline{b}$ to $\pm\| x + \overline{b} \|_2 e_1$; with $H_1 x = \left[\begin{smallmatrix} \alpha \\ v \end{smallmatrix}\right]$ and $H_1 \overline{b} = \left[\begin{smallmatrix} \gamma \\ w \end{smallmatrix}\right]$ we see that $w = -v$ with $v \neq 0$ because of the linear independence of $x$ and $\overline{b}$, and $\alpha + \gamma = \pm\| x + \overline{b} \|_2 \in \mathbb{R} \setminus \{0\}$. Then $\|x\|_2 = \| \overline{b} \|_2 \Rightarrow \|H_1 x\|_2 = \|H_1 \overline{b} \|_2 \Rightarrow |\alpha| = |\gamma|$, which together with $\alpha + \gamma \in \mathbb{R}$ implies that $\gamma = \overline{\alpha}$, and hence $H_1 \overline{b} = \left[\begin{smallmatrix} \overline{\alpha} \\ -v \end{smallmatrix}\right]$. Note also that $2 \,\mathrm{Re}\, \alpha = \alpha + \overline{\alpha} = \pm\| x + \overline{b} \|_2 \neq 0$. For the second reflector pick $H_2 = \left[\begin{smallmatrix} 1 & 0 \\ 0 & \widetilde{H}_2 \end{smallmatrix}\right]$ so that $\widetilde{H}_2 v = \beta e_1$ with $\beta = \pm\|v\|_2 \neq 0$.

---

[2] But not necessarily Hermitian; see [11].

Hence

$$U\,[\,x \quad \overline{b}\,] = \begin{bmatrix} \alpha & \overline{\alpha} \\ \beta & -\beta \\ 0 & 0 \\ \vdots & \vdots \\ 0 & 0 \end{bmatrix}, \quad \operatorname{Re}\alpha \neq 0,\ 0 \neq \beta \in \mathbb{R}, \tag{A.2}$$

and therefore $y = \left[\begin{smallmatrix}\alpha\\ \beta\end{smallmatrix}\right]$ and $c = \left[\begin{smallmatrix}\alpha\\ -\beta\end{smallmatrix}\right]$ satisfy $Ry = c$ with $R = \left[\begin{smallmatrix}1 & 0\\ 0 & -1\end{smallmatrix}\right] \in \mathbb{S}_2$. Note that $U$ can be taken to be real orthogonal when $\mathbb{K} = \mathbb{R}$.

(ii) For $\mathbb{S}_n = \operatorname{Skew}(n, \mathbb{K})$, Theorem 3.2 says that $\mathcal{S}$ is nonempty if and only if $b^T x = 0$. In this situation $U$ can be taken as the product of two unitary Householder reflectors, $U = H_2 H_1$. The first reflector $H_1$ is defined to take $x$ to $e_1$; then $H_1 \overline{b} = \left[\begin{smallmatrix}\alpha\\ v\end{smallmatrix}\right]$ for some $v \in \mathbb{K}^{n-1}$. The fact that $b^T x = 0$ implies $\alpha = 0$, since $b^T x = [\,\overline{\alpha} \quad v^*\,] H_1 H_1^* e_1 = \overline{\alpha}$. For the second reflector pick $H_2 = \left[\begin{smallmatrix}1 & 0\\ 0 & \widetilde{H}_2\end{smallmatrix}\right]$ so that $\widetilde{H}_2 v = e_1 \in \mathbb{K}^{n-1}$. Then $U\,[\,x \quad \overline{b}\,] = [\,e_1 \quad e_2\,] \in \mathbb{K}^{n\times 2}$, giving $y = \left[\begin{smallmatrix}1\\ 0\end{smallmatrix}\right]$ and $c = \left[\begin{smallmatrix}0\\ 1\end{smallmatrix}\right]$ in $\mathbb{K}^2$ satisfying $Ry = c$ for $R = \left[\begin{smallmatrix}0 & -1\\ 1 & 0\end{smallmatrix}\right] \in \mathbb{S}_2$. Note once again that $U$ can be taken to be real orthogonal when $\mathbb{K} = \mathbb{R}$.

(iii) Finally suppose that $\mathbb{S}_n = \operatorname{Herm}(n, \mathbb{C})$. Theorem 3.2 says that $\mathcal{S}$ is nonempty if and only if $b^* x \in \mathbb{R}$. If $x$ and $b$ are linearly dependent, then $b = \operatorname{sign}(\overline{\mu})x$ for some $\mu \in \mathbb{C}$, and $b^* x \in \mathbb{R}$ implies that $\mu \in \mathbb{R}$. In this case $U$ can be taken as the unitary Householder reflector mapping $x$ to $e_1$ so that $(U^\star)^{-1} b = Ub = \operatorname{sign}(\mu) e_1$ since $\mu$ is real. Hence $[\,y \ \ c\,] = [\,1 \ \ \operatorname{sign}(\mu)\,]$ and $Ry = c$ with $R = \operatorname{sign}(\mu) \in \mathbb{S}_1$.

On the other hand if $x$ and $b$ are linearly independent, then $U$ can be taken as the product of two unitary Householder reflectors $U = H_2 H_1$ in a manner analogous to that described above in (i) for $\operatorname{Sym}(n, \mathbb{K})$; the only difference is that $H_1$ now takes $x + b$ to $\pm\|x + b\|_2 e_1$. In this case (A.2) holds with $\overline{b}$ replaced by $b$. Also $b^* x = (H_1 b)^*(H_1 x) = \alpha^2 - v^* v \in \mathbb{R}$ so that $\alpha^2 \in \mathbb{R}$. This together with $\operatorname{Re}\alpha \neq 0$ implies that $\alpha \in \mathbb{R}$. Hence we have $y = \left[\begin{smallmatrix}\alpha\\ \beta\end{smallmatrix}\right]$ and $c = \left[\begin{smallmatrix}\alpha\\ -\beta\end{smallmatrix}\right]$ with $\alpha, \beta \in \mathbb{R} \setminus \{0\}$, satisfying $Ry = c$ with $R = \left[\begin{smallmatrix}1 & 0\\ 0 & -1\end{smallmatrix}\right] \in \mathbb{S}_2$.

Using the unitary $U$ and $R \in \mathbb{S}_r$ constructed above for each $\mathbb{S}_n$, we can now show that the lower bound $1 = \|b\|_2 / \|x\|_2 \leq \min_{A \in \mathcal{S}} \|A\|_2$ from (5.11) is actually attained by a whole family of $A \in \mathcal{S}$. For any $S \in \mathbb{S}_{n-r}$ with $\|S\|_2 \leq 1$, consider $A = U^\star \operatorname{diag}(R, S) U$. Then $A \in \mathbb{S}_n$, since $\mathbb{S}_n$ is preserved by any $\star$-congruence (see Lemma 4.1(a)) and $\operatorname{diag}(R, S) \in \mathbb{S}_n$. Also $Ax = b$ because of the properties of $U$ in (A.1), and $\|A\|_2 = \|\operatorname{diag}(R, S)\|_2 = \|R\|_2 = 1$. Thus

$$\Big\{ U^\star \operatorname{diag}(R, S) U : \ S \in \mathbb{S}_{n-r}\,, \ \|S\|_2 \leq 1 \Big\} \subseteq \mathcal{M}\,.$$

Finally, we complete the characterization of $\mathcal{M}$ by showing that this containment is actually an equality. Consider an arbitrary $A \in \mathcal{M}$. Then $Ax = b \ \Rightarrow\ ((U^\star)^{-1} A U^{-1})(Ux) = (U^\star)^{-1} b$, so the matrix $B := (U^\star)^{-1} A U^{-1} = (U^{-1})^\star A U^{-1}$ is in $\mathbb{S}_n$ and maps the vector $Ux = \left[\begin{smallmatrix}y\\ 0\end{smallmatrix}\right]$ to $(U^\star)^{-1} b = \left[\begin{smallmatrix}c\\ 0\end{smallmatrix}\right]$. Let $B_{11} \in \mathbb{S}_r$ be the leading principal $r \times r$ submatrix of $B$, so $\|B_{11}\|_2 \leq \|B\|_2 = \|A\|_2 = 1$. The form of the two vectors $\left[\begin{smallmatrix}y\\ 0\end{smallmatrix}\right]$ and $\left[\begin{smallmatrix}c\\ 0\end{smallmatrix}\right]$ implies that $B_{11}$ maps $y$ to $c$; since $\|y\|_2 = \|c\|_2 = 1$ we have $\|B_{11}\|_2 \geq 1$, and hence $\|B_{11}\|_2 = 1$. Using Lemma A.1 we can now show that $B_{11} = R$ in all cases.

(i) Suppose $\mathbb{S}_n = \operatorname{Sym}(n, \mathbb{K})$ and $B_{11} \in \mathbb{S}_r$. Then $\overline{b} = \operatorname{sign}(\overline{\mu})x$ for some $\mu \in \mathbb{K}$ implies $[\,y \ c\,] = [\,1 \ \operatorname{sign}(\mu)\,]$, so $B_{11} y = c$ implies $B_{11} = \operatorname{sign}(\mu) = R$. On the other hand if $\bar{b}$ and $x$ are linearly independent, then $[\,y\ c\,] = \left[\begin{smallmatrix} \alpha & \alpha \\ \beta & -\beta \end{smallmatrix}\right]$ with $\mathrm{Re}(\alpha) \neq 0$ and $0 \neq \beta \in \mathbb{R}$. Since $B_{11}y = c$ with $\|B_{11}\|_2 = 1$, Lemma A.1 implies that $B_{11} = \left[\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right] = R$.

(ii) $B_{11} \in \mathrm{Skew}(2, \mathbb{K})$ must have the form $\left[\begin{smallmatrix} 0 & -\sigma \\ \sigma & 0 \end{smallmatrix}\right]$ for some $\sigma \in \mathbb{K}$. So $B_{11}y = c$ with $y = e_1$ and $c = e_2$ implies $\sigma = 1$, and hence $B_{11} = \left[\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right] = R$.

(iii) Finally consider $\mathbb{S}_n = \mathrm{Herm}(n, \mathbb{C})$ and $B_{11} \in \mathbb{S}_r$. If $b = \mathrm{sign}(\mu)x$ for some $\mu \in \mathbb{R}$, then $[\,y\ c\,] = [\,1\ \ \mathrm{sign}(\mu)\,]$, so $B_{11}y = c$ implies $B_{11} = \mathrm{sign}(\mu) = R$. If $b$ and $x$ are linearly independent, then $[\,y\ c\,] = \left[\begin{smallmatrix} \alpha & \alpha \\ \beta & -\beta \end{smallmatrix}\right]$ with $\alpha, \beta$ both real and nonzero. Since $B_{11}y = c$ with $\|B_{11}\|_2 = 1$, Lemma A.1 implies that $B_{11} = \left[\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right] = R$.

The condition $\|B\|_2 = 1$ now forces the rest of the first $r$ columns of $B$ to be all zeros; since $B \in \mathbb{S}_n$, the rest of the first $r$ rows of $B$ must also be all zeros. Thus $B$ has the form $B = \mathrm{diag}(R, S)$, with $S \in \mathbb{S}_{n-r}$. Finally, $\|B\|_2 = 1$ and $\|R\|_2 = 1$ implies that $\|S\|_2 \leq 1$. Thus we have $B := (U^\star)^{-1}AU^{-1} = \mathrm{diag}(R, S)$, so $A = U^\star \,\mathrm{diag}(R, S)U$ and hence $\mathcal{M} \subseteq \big\{U^\star \,\mathrm{diag}(R, S)U : S \in \mathbb{S}_{n-r}\,,\ \|S\|_2 \leq 1\big\}$. $\square$

Note that when $\mathbb{S}_n$ is the class of real symmetric matrices and if $x, y \in \mathbb{R}^n$ are linearly independent, then choosing $S = I_n$ in Theorem A.2 yields the Householder reflector $I - 2U^T e_2 e_2^T U$ mapping $x$ to $b$.
