# SMOOTHING-NORM PRECONDITIONING FOR REGULARIZING MINIMUM-RESIDUAL METHODS*

PER CHRISTIAN HANSEN† AND TOKE KOLDBORG JENSEN†‡

**Abstract.** When GMRES (or a similar minimum-residual algorithm such as RRGMRES, MINRES, or MR-II) is applied to a discrete ill-posed problem with a square matrix, in some cases the iterates can be considered as regularized solutions. We show how to precondition these methods in such a way that the iterations take into account a smoothing norm for the solution. This technique is well established for CGLS, but it does not immediately carry over to minimum-residual methods when the smoothing norm is a seminorm or a Sobolev norm. We develop a new technique which works for any smoothing norm of the form $\|L\,x\|_2$ and which preserves symmetry if the coefficient matrix is symmetric. We also discuss the efficient implementation of our preconditioning technique, and we demonstrate its performance with numerical examples in one and two dimensions.

**Key words.** general-form regularization, smoothing norm, regularizing iterations, GMRES, MINRES, weighted pseudoinverse

## 1. Introduction.

We are concerned with large-scale discrete ill-posed problems with a square coefficient matrix, i.e., ill-conditioned linear systems of the form $A\,x = b$ with $A \in \mathbb{R}^{n\times n}$ and $x,\, b \in \mathbb{R}^n$. These problems typically arise from discretizations of Fredholm integral equations of the first kind, e.g., in computerized tomography, geophysics, or image restoration. Due to the ill-conditioning of $A$ and the unavoidable errors in the right-hand side (coming from data), any attempt to compute the "naive" solution $A^{-1}b$ will fail to produce a meaningful solution.

Instead we must use a regularization method to compute a stabilized solution which is less sensitive to the errors. There are many such methods around, and one of the most popular is Tikhonov regularization, which amounts to computing

$$x_\lambda = \operatorname{argmin}_x \left\{ \|A\,x - b\|_2^2 + \lambda^2\,\|L\,x\|_2^2 \right\} = (A^TA + \lambda^2\,L^TL)^{-1}A^Tb, \tag{1.1}$$

where the matrix $L$ defines a [illegible] $\|L\cdot\|_2$ that acts as a regularizer and where $\lambda$ is the regularization parameter.

For large-scale problems we need iterative methods to compute regularized solutions, and there is a rich literature on CG-based methods for computing the Tikhonov solution via the least-squares formulation of (1.1). More recently we have seen an interest in methods referred to as [illegible] These are Krylov subspace methods applied directly to the problem $\min\|A\,x - b\|_2$ or $A\,x = b$ with no additional smoothing norm (such as $\lambda^2\|L\,x\|_2^2$); instead the projection of the problem onto the Krylov subspace, associated with the method, acts as a regularizer of the solution. See, e.g., [7] and [12] for details.

Probably the newest member of the family of regularizing iteration methods is the GMRES algorithm [15]. If $A$ is symmetric, then GMRES is analytically identical to the MINRES algorithm [14], the latter yielding a simpler implementation with a short recursion. Regularizing GMRES and MINRES iterations were recently studied in [1], [2], [3], and [12].

The use of a matrix $L \neq I_n$ in the Tikhonov problem (1.1) can lead to better regularized solutions than the choice $L = I_n$, the explanation being that with a proper choice of $L$ the solution $x_\lambda$ is expressed in terms of basis vectors that are better suited to the problem. The choice of $L$ is problem dependent. As demonstrated by Hanke and Hansen [8], the matrix $L$ can be incorporated into the CGLS algorithm for solving $\min \|A\,x - b\|_2$ in such a way that the modified Krylov subspace provides the desired basis for the solution.

The purpose of this paper is to give a rigorous explanation of how we can carry this idea of preconditioning over to regularizing minimum-residual methods for a general smoothing norm $\|L\,\cdot\,\|_2$. The hope is that if the minimum-residual methods produce regularized solutions similar to the Tikhonov solutions, then incorporating the smoothing norm will produce solutions comparable to the general-form Tikhonov solutions. The main difficulty is that the smoothing-norm preconditioning from [8] typically involves rectangular matrices and therefore does not immediately carry over to the methods studied here. We shall demonstrate that we can still use the underlying idea, but the practical details and the implementation are different. Our preconditioner has the additional feature that it, when used in connection with symmetric problems, preserves the symmetry of the iteration matrix, thus allowing MINRES and MR-II to be used.

Since there is no overall "best" regularization algorithm, we believe that users should preferably have access to a variety of efficient and robust regularization methods. Also, a full understanding of the theoretical properties of regularizing iterations has not emerged and is a topic of current research. The goal of this paper is therefore not to emphasize preconditioned minimum-residual methods over other regularizing iterations, but instead to demonstrate how the preconditioner should be defined for a general matrix $L$ and implemented efficiently.

Our paper is organized as follows. Section 2 describes how to incorporate the matrix $L$ into regularizing CGLS iterations via a standard-form transformation based on the $A$-weighted pseudoinverse of $L$. In section 3 we briefly summarize a method based on augmentation of $L$ to a square matrix. Our main results are given in section 4, where we introduce our rectangular preconditioning technique, and in section 5 we demonstrate how to implement the new preconditioner efficiently. Finally, we illustrate our algorithm with one- and two-dimensional examples in section 6.

Throughout the paper, $I_q$ is the identity matrix of order $q$, $A^\dagger$ is the pseudoinverse of $A$, $\mathcal{R}(\cdot)$ and $\mathcal{N}(\cdot)$ denote the range and null space of a matrix, and the Krylov subspace is denoted by $\mathcal{K}_k(A, b) = \mathrm{span}\{b, Ab, A^2b, \ldots, A^{k-1}b\}$.

## 2. Working with smoothing norms.

We first summarize the results from [8] about smoothing norms. The key idea is to transform the general-form Tikhonov problem (1.1) into a problem in standard form,

$$\min_x \left\{ \|\bar{A}\,\bar{x} - \bar{b}\|_2^2 + \lambda^2\,\|\bar{x}\|_2^2 \right\}.$$

When $L$ is invertible, the standard-form transformation is easy: set $\bar{A} = A\,L^{-1}$ and $\bar{b} = b$, and use $\bar{x} = L\,x \Leftrightarrow x = L^{-1}\bar{x}$.

Often the matrix $L$ is rectangular and therefore not invertible. For example, if the smoothing norm $\|L\,x\|_2$ represents the norm of the first or second derivative of the solution, and if $x$ represents samples of the solution on a regular grid, then as $L$ we use the matrices $L_1 \in \mathbb{R}^{(n-1)\times n}$ and $L_2 \in \mathbb{R}^{(n-2)\times n}$ given by

$$L_1 = \begin{pmatrix} -1 & 1 & & \\ & \ddots & \ddots & \\ & & -1 & 1 \end{pmatrix}, \qquad L_2 = \begin{pmatrix} 1 & -2 & 1 & & \\ & \ddots & \ddots & \ddots & \\ & & 1 & -2 & 1 \end{pmatrix}. \tag{2.1}$$

With these rectangular matrices, the smoothing norm $\|L\,x\|_2$ is a seminorm. The matrices $L_1$ and $L_2$ are chosen such that their null spaces

$$\mathcal{N}(L_1) = \operatorname{span}\left\{(1,1,\dots,1)^T\right\}, \qquad \mathcal{N}(L_2) = \operatorname{span}\left\{(1,1,\dots,1)^T, (1,2,\dots,n)^T\right\}$$

represent the null spaces of the underlying first and second derivative operators. Obviously, any component of the solution in $\mathcal{N}(L)$ is unaffected by the regularization in (1.1), but since $\mathcal{N}(L_1)$ and $\mathcal{N}(L_2)$ are spanned by very smooth vectors (representing the constant and the linear functions), there is no harm in leaving the component unregularized.

To deal with such rectangular matrices, we assume that the matrix $L \in \mathbb{R}^{p\times n}$ satisfies $\operatorname{rank}(L) = p < n$. Then it is demonstrated in [8] that the standard-form transformation takes the form

$$\bar{A} = A\,L_A^\dagger, \qquad \bar{b} = b - A\,x_0, \qquad x_\lambda = L_A^\dagger \bar{x}_\lambda + x_0,$$

where $L_A^\dagger$ is the $A$-weighted pseudoinverse of $L$ (cf. [5]) given by

$$L_A^\dagger = E\,L^\dagger, \qquad \text{with} \quad E = I_n - \bigl(A\,(I_n - L^\dagger L)\bigr)^\dagger A, \tag{2.2}$$

and $x_0$ is the component of the solution lying in the null space of $L$,

$$x_0 = \bigl(A\,(I_n - L^\dagger L)\bigr)^\dagger\, b = N\,(A\,N)^\dagger\, b,$$

in which $N$ is any matrix of full column rank such that $\mathcal{R}(N) = \mathcal{N}(L)$.

To incorporate the smoothing norm into the framework of regularizing iterations, we apply CGLS to $\|\bar{A}\,\bar{x} - \bar{b}\|_2$, and Hanke and Hansen [8] demonstrated how the CGLS algorithm can be modified in such a way that all operations with $L_A^\dagger$ act as preconditioning. To see this, following section 6.1 of [10], we note that if $\mathcal{P}_k$ is the Ritz polynomial associated with $k$ steps of CG applied to $\bar{A}^T\bar{A}\,\bar{x} = \bar{A}^T\bar{b}$, then the iterate $x^{(k)}$ after $k$ steps of the preconditioned CGLS algorithm can be written as

$$x^{(k)} = \mathcal{P}_k\bigl(L_A^\dagger L_A^{\dagger T} A^T A\bigr)\, L_A^\dagger L_A^{\dagger T} A^T b + x_0. \tag{2.3}$$

It is now obvious that $L_A^\dagger L_A^{\dagger T}$ acts like a "preconditioner," and efficient methods for implementing this kind of preconditioning for CGLS and other methods are described in [8], [9], and [10, section 2.3.2]. We refer to the preconditioned version of CGLS as P-CGLS.

In some applications we encounter $L$ matrices with more rows than columns, typically in connection with Sobolev norms such as

$$\|L\,x\|_2^2 = \|L_1\,x\|_2^2 + \|L_2\,x\|_2^2 = \left\| \begin{pmatrix} L_1 \\ L_2 \end{pmatrix} x \right\|_2^2 .$$

In this case an orthogonal factorization of $L$ can often lead to a more efficient implementation. Specifically, if $L = Q\,R$, where $Q$ has orthonormal columns and $R$ is triangular or trapezoidal and has full row rank, then $\|L\,x\|_2 = \|R\,x\|_2$, and we can thus replace $L$ with $R$. This approach can also be used in connection with P-CGLS because $L^\dagger = R^\dagger Q^T$ and $L^\dagger L = R^\dagger R$, and therefore $L_A^\dagger L_A^{\dagger T} = R_A^\dagger R_A^{\dagger T}$, showing that the underlying Krylov subspaces in (2.3) are identical.

Unfortunately, the preconditioner based on $\bar{A}$ cannot be applied to regularizing minimum-residual methods such as MINRES and GMRES because these methods require a square coefficient matrix, which is not the case for $\bar{A}$ when $L$ is noninvertible. Hence we need to develop a different kind of preconditioning for these methods.

**3. The augmented-matrix approach.** To be able to use GMRES/MINRES and the variants RRGMRES [1] and MR-II [6] (i.e., GMRES and MINRES with starting vector $Ab$ instead of $b$), the coefficient matrix must be square. When working with a rectangular $L$, such as in (2.1), it was suggested in [4] to augment it with additional rows to make it square and invertible. For $L_1$ and $L_2$, this approach leads to the augmented $n \times n$ matrices

$$\widehat{L}_1 = \begin{pmatrix} L_1 \\ w^T \end{pmatrix}, \qquad \widehat{L}_2 = \begin{pmatrix} \bar{w}^T \\ L_2 \\ w^T \end{pmatrix}. \tag{3.1}$$

If the additional rows are chosen such that the augmented matrices are invertible, then we can use the matrices $A\,\widehat{L}_1^{-1}$ and $A\,\widehat{L}_2^{-1}$ in connection with the minimum-residual methods. The use of a full-rank matrix $\widehat{L}$ in the standard-form transformation is equivalent to using $\widehat{L}^{-1}$ as a right preconditioner. We refer to [4] for more details about the choices of $w$ and $\bar{w}$.

While this augmented-matrix approach is simple to implement and use, it also has some disadvantages. For example, symmetry of the coefficient matrix $A$ does not carry over to the coefficient matrices $A\widehat{L}_1^{-1}$ and $A\widehat{L}_2^{-1}$, thus excluding the use of MINRES.[1] Moreover, any orthogonal reduction of $L$ changes the iterates because the Krylov subspace changes. For example, if $L$ is nonsingular and $L = QR$, then $\mathcal{K}_k(L^{-1}A, L^{-1}b) = \mathcal{K}_k(R^{-1}Q^TA, R^{-1}Q^Tb) \neq \mathcal{K}_k(R^{-1}A, R^{-1}b)$. This also rules out the use of any $L$ with more rows than columns.

**4. Smoothing-norm preconditioning.** As an alternative to the above technique, we now present an approach that works for any rectangular matrix $L \in \mathbb{R}^{p\times n}$ with $p < n$ and which does not require any modifications of the problem. In addition, our approach preserves symmetry, thus allowing short-recurrence implementations such as MINRES and MR-II to be used if $A$ is symmetric.

Our approach is similar in spirit to the technique described in section 2 for Tikhonov regularization and CGLS, but the details are different. We refer to the new preconditioned algorithms as SN-X, where X = GMRES, RRGMRES, MINRES, or MR-II, and SN is an abbreviation for "smoothing norm."

We start by writing the solution as the sum of the regularized component in $\mathcal{R}(L_A^\dagger)$ and the unregularized component in $\mathcal{N}(L)$,

$$x = L_A^\dagger y + x_0 = L_A^\dagger y + Nz, \tag{4.1}$$

---

[1] For symmetric $A$, one might instead consider applying MINRES to the system $\widehat{L}^{-T}A\widehat{L}^{-1}x = \widehat{L}^{-T}b$, where $\widehat{L}^{-T}A\widehat{L}^{-1}$ is symmetric.

where again $x_0 = N\,(A\,N)^\dagger\,b$ and $N$ is a matrix with full column rank whose columns span $\mathcal{N}(L)$. These columns need not be orthonormal, although this is preferable for numerical computations. The two vectors $y$ and $z = (A\,N)^\dagger b$ are uniquely determined because $L$ and $N$ both have full rank.

Our basic problem $A\,x = b$ can now be formulated as

$$A\,\left(L_A^\dagger\,,\,N\right)\begin{pmatrix} y \\ z \end{pmatrix} = b.$$

Premultiplication of this system with $\left(L_A^\dagger\,,\,N\right)^T$ leads to the $2\times 2$ block system

$$\begin{pmatrix} L_A^{\dagger T} A\,L_A^\dagger & L_A^{\dagger T} A\,N \\ N^T A\,L_A^\dagger & N^T A\,N \end{pmatrix}\begin{pmatrix} y \\ z \end{pmatrix} = \begin{pmatrix} L_A^{\dagger T} b \\ N^T b \end{pmatrix}.$$

We eliminate $z$ from this system by forming the Schur complement system $S\,y = d$ with $S$ and $d$ given by

$$S = L_A^{\dagger T} A\,L_A^\dagger - L_A^{\dagger T} A\,N(N^T A\,N)^{-1} N^T A\,L_A^\dagger = L_A^{\dagger T} P\,A\,L_A^\dagger, \tag{4.2}$$

$$d = L_A^{\dagger T} b - L_A^{\dagger T} A\,N(N^T A\,N)^{-1} N^T b = L_A^{\dagger T} P\,b, \tag{4.3}$$

where we have introduced $P = I_n - AN(N^T AN)^{-1}N^T$. We shall now study the Schur system $S\,y = d$ in more detail.

THEOREM 4.1. [illegible] $\mathcal{R}(L^T)$ [illegible] $\mathcal{R}(AN)$ [illegible][2] [illegible]

$$P = I_n - AN(N^T AN)^{-1}N^T \tag{4.4}$$

[illegible] $\mathcal{R}(L^T)$ [illegible] $\mathcal{R}(AN)$

[illegible]. The matrix $I_n - P$ is idempotent because

$$(I_n - P)^2 = AN(N^T AN)^{-1}N^T AN(N^T AN)^{-1}N^T = I_n - P,$$

and hence it is a projector. Since $I_n - P$ is nonsymmetric, it is an oblique projector, and it is easy to see that the projection is onto $\mathcal{R}(AN)$ with $\mathcal{R}(L^T)$ contained in the null space. The assumption that $\mathcal{R}(L^T)$ and $\mathcal{R}(AN)$ are complementary subspaces ensures that $P$ is an oblique projector onto $\mathcal{R}(L^T)$ along $\mathcal{R}(AN)$. ☐

Smoothing-norm preconditioning for GMRES amounts to applying GMRES to the Schur complement system $Sy = d$. We emphasize that, as for CGLS, the purpose of this preconditioning is to provide a more desirable Krylov subspace for the regularized solution.

When we apply GMRES to the Schur system $Sy = d$, there exists a polynomial $\widetilde{\mathcal{P}}_k$ such that the solution after $k$ iterations is given by

$$y^{(k)} = \widetilde{\mathcal{P}}_k\left(L_A^{\dagger T} P A\,L_A^\dagger\right) L_A^{\dagger T} P\,b.$$

The corresponding vector $x^{(k)}$ is given by $x^{(k)} = L_A^\dagger y^{(k)} + x_0$, and we therefore obtain the SN-GMRES iterate

$$\begin{aligned} x^{(k)} &= L_A^\dagger \widetilde{\mathcal{P}}_k\left(L_A^{\dagger T} P A L_A^\dagger\right) L_A^{\dagger T} P\,b + x_0 \\ &= \widetilde{\mathcal{P}}_k\left(L_A^\dagger L_A^{\dagger T} P A\right) L_A^\dagger L_A^{\dagger T} P\,b + x_0, \end{aligned} \tag{4.5}$$

---

[2] The subspaces $\mathcal{R}(L^T) \subseteq \mathbb{R}^n$ and $\mathcal{R}(AN) \subseteq \mathbb{R}^n$ are complementary if $\mathcal{R}(L^T) + \mathcal{R}(AN) = \mathbb{R}^n$ and $\mathcal{R}(L^T) \cap \mathcal{R}(AN) = \{0\}$; see, e.g., [13, section 5.9].

showing that $x^{(k)} - x_0$ lies in the Krylov subspace $\mathcal{K}_k(L_A^\dagger L_A^{\dagger T} PA, L_A^\dagger L_A^{\dagger T} Pb)$. We note that the iterates of RRGMRES take the same form as for GMRES, except that the polynomial coefficients are different, and thus RRGMRES can also be used on the Schur system.

Although the polynomial expressions for the preconditioned CGLS and GMRES methods in (2.3) and (4.5) are similar in essence, the solutions obtained from the two methods are different, due to CGLS being a Ritz–Galerkin method and GMRES being a minimum-residual method. Even when $L$ is invertible, the two approaches produce different iterates. Furthermore, the oblique projector $P$ also indicates that the SN-X algorithms do not solve the same problem as does P-CGLS. Nevertheless, as we illustrate in section 6, our preconditioned algorithms are able to produce good solutions for certain problems.

We emphasize that the two main difficulties with the augmented-matrix approach from section 3 are both satisfactorily dealt with in this new approach. For a symmetric matrix $A$, the matrix $L_A^{\dagger T} P\, A\, L_A^\dagger$ is also symmetric, which follows from the symmetry of $PA = A - AN\,(N^TA\,N)^{-1}N^TA$. This symmetry allows us to use MINRES or MR-II on the Schur system, resulting in SN-MINRES and SN-MR-II. The new approach also allows us to use any rectangular $L$, including those with more rows than columns via the orthogonal reduction $L = QR$ mentioned in section 2.

**5. Implementation issues.** In this section we consider some issues that are important for the efficient implementation of the SN-X algorithms. We start with a theorem that simplifies the Schur system.

THEOREM 5.1. [illegible] 4.1 [illegible] $S\,y = d$ [illegible] (4.2)–(4.3) [illegible]

$$L^{\dagger T} P\, A\, L^\dagger y = L^{\dagger T} P\, b, \tag{5.1}$$

[illegible] $P$ [illegible] (4.4)

[illegible]. From the relation $(A(I_n - L^\dagger L))^\dagger = (ANN^\dagger)^\dagger = N(AN)^\dagger$ it follows that the matrix $E$ in (2.2) can be written as $E = I_n - N(AN)^\dagger A$. Moreover,

$$\begin{aligned} A^T(AN)^{\dagger T}N^TP &= A^T(AN)^{\dagger T}N^T - A^T(AN)^{\dagger T}N^TAN(N^TAN)^{-1}N^T \\ &= A^T(AN)^{\dagger T}N^T - A^T(AN)^{\dagger T}N^T = 0, \end{aligned}$$

and therefore $E^TP = (I_n - A^T(AN)^{\dagger T}N^T)P = P$. We also have the relation

$$\begin{aligned} P\,A\,N(AN)^\dagger A &= \big(I_n - AN(N^TAN)^{-1}N^T\big)AN(AN)^\dagger A \\ &= AN(AN)^\dagger A - AN(AN)^\dagger A = 0, \end{aligned}$$

and thus $PAE = PA(I_n - N(AN)^\dagger A) = PA$. Inserting these relations and $L_A^\dagger = EL^\dagger$ into the Schur system, we obtain (5.1). ☐

This theorem has an important impact on the numerical implementation of our preconditioner, because the weighted pseudoinverse $L_A^\dagger$ can be replaced by the ordinary pseudoinverse $L^\dagger$ in the computations. The weighted pseudoinverse $L_A^\dagger$ is needed only in the back-transformation (4.1).

Turning to the details of the implementation, we need to compute $x_0$ efficiently. This is done via the QR factorization of the matrix $AN$, which is always "skinny" for the low-dimensional null spaces associated with the derivative operators:

$$\begin{aligned} &1.\quad AN = Q_0R_0 \text{ (skinny QR factorization)}, \\ &2.\quad x_0 \leftarrow N\,R_0^{-1}Q_0^Tb. \end{aligned} \tag{5.2}$$

We also need an efficient technique for multiplications with $P$ from (4.4), which basically amounts to a number of "skinny" matrix-vector products. Using again the QR factorization of $AN$, we obtain

$$AN\,(N^TAN)^{-1}N^T = Q_0R_0(N^TQ_0R_0)^{-1}N^T = Q_0\,(N^TQ_0)^{-1}N^T,$$

and thus the product $P\,x$ is computed as

$$P\,x = x - Q_0\,(N^TQ_0)^{-1}N^Tx,$$

where a precomputed factorization of the small square matrix $N^TQ_0$ should be used. Assuming that $N$ has orthonormal columns, the smallest singular value of $N^TQ_0$ is equal to cosine of the subspace angle between $\mathcal{N}(L)$ and $\mathcal{R}(AN)$. Our experience is that this angle is usually small (because the smooth basis vectors of the two subspaces resemble each other), and consequently $N^TQ_0$ is well conditioned—however, there is no guarantee that this is always the case.

The complete algorithm for performing the multiplication $v = L^{\dagger T}PAL^{\dagger}y$ in the SN-X algorithms thus takes the form

$$\begin{aligned} &1.\quad v_1 \leftarrow A\,(L^{\dagger}y),\\ &2.\quad v_2 \leftarrow Q_0\,(N^TQ_0)^{-1}N^Tv_1,\\ &3.\quad v \leftarrow L^{\dagger T}(v_1 - v_2). \end{aligned} \tag{5.3}$$

The cost of working with the Schur complement system is therefore for each iteration the following: one multiplication with $A$, one with $L^{\dagger}$, one with $L^{\dagger T}$, and one with the oblique projector $P$. The preconditioning technique is feasible when the computation of $L^{\dagger}y$ and $L^{\dagger T}(v_1 - v_2)$ can be implemented efficiently, and the null space $\mathcal{N}(L)$ has low dimension such that multiplication with $P$ is inexpensive. The remaining work, i.e., reorthogonalization and updating of the residual norm and the solution, etc., is identical to applying the minimum-residual method to a nonpreconditioned system. A complete SN-X algorithm thus takes the following form:

(5.4)
1. Use (5.2) to compute $Q_0$, $R_0$, and $x_0$.
2. Run $k$ steps of algorithm X on (5.1), using (5.3), to compute $y^{(k)}$.
3. Set $x^{(k)} = L_A^{\dagger}y^{(k)} + x_0$.

While not fully documented in [8], [9], [10], P-CGLS—in addition to the multiplications with $A$ and $A^T$—also requires multiplications with $L^{\dagger}$ and its transpose, as well as one multiplication with the matrix $E$ (which is also an oblique projector). Hence the overall work for preconditioning the SN-X algorithms is essentially the same as that for P-CGLS.

We use an example from two-dimensional problems to illustrate how to work with a rank-deficient $L$ with more rows than columns. Assume that $X \in \mathbb{R}^{M\times N}$ is the two-dimensional solution, and that we use the Sobolev norm $\|L_{d_2}X\|_{\mathrm{F}}^2 + \|X\,L_{d_1}^T\|_{\mathrm{F}}^2$, where $L_{d_1} \in \mathbb{R}^{(N-d_1)\times N}$ and $L_{d_2} \in \mathbb{R}^{(M-d_2)\times M}$ are the matrices in (2.1). Then $L$ takes the form

$$L = \begin{pmatrix} L_{d_1} \otimes I_M \\ I_N \otimes L_{d_2} \end{pmatrix}, \tag{5.5}$$

and we note that $L$ has more rows than columns and is rank-deficient. The following theorem shows how to proceed via the SVDs of the "small" matrices $L_{d_1}$ and $L_{d_2}$.

Theorem 5.2. [illegible] $L$ [illegible] (5.5) [illegible] $L_{d_1} = U_{d_1}\,\Sigma_{d_1}\,V_{d_1}^T$ [illegible] $L_{d_2} = U_{d_2}\,\Sigma_{d_2}\,V_{d_2}^T$ [illegible] $L_{d_1}$ [illegible] $L_{d_2}$ [illegible] $\|L\,x\|_2 = \|L_D\,x\|_2$ [illegible]

$$L_D = D\,(V_{d_1} \otimes V_{d_2})^T, \tag{5.6}$$

[illegible] $D \in \mathbb{R}^{MN\times MN}$ [illegible]

$$D^2 = \Sigma_{d_1}^T\Sigma_{d_1} \otimes I_M + I_N \otimes \Sigma_{d_2}^T\Sigma_{d_2}. \tag{5.7}$$

[illegible] $V_{d_i} = (\,\overline{V}_{d_i}\,,\,N_{d_i}\,)$ [illegible] $\mathcal{N}(L_{d_i}) = \mathcal{R}(N_{d_i})$ [illegible] $i = 1, 2$ [illegible] $\mathcal{N}(L) = \mathcal{N}(L_D)$ [illegible]

$$N = N_{d_1} \otimes N_{d_2}. \tag{5.8}$$

[illegible]. Inserting the SVDs of $L_{d_1}$ and $L_{d_2}$ and using $I_N = V_{d_1}V_{d_1}^T$ and $I_M = V_{d_2}V_{d_2}^T$, we obtain

$$\begin{aligned} L &= \begin{pmatrix} L_{d_1} \otimes I_M \\ I_N \otimes L_{d_2} \end{pmatrix} = \begin{pmatrix} (U_{d_1}\,\Sigma_{d_1}\,V_{d_1}^T) \otimes (V_{d_2}\,V_{d_2}^T) \\ (V_{d_1}\,V_{d_1}^T) \otimes (U_{d_2}\,\Sigma_{d_2}\,V_{d_2}^T) \end{pmatrix} \\ &= \begin{pmatrix} U_{d_1} \otimes V_{d_2} & 0 \\ 0 & V_{d_1} \otimes U_{d_2} \end{pmatrix} \begin{pmatrix} \Sigma_{d_1} \otimes I_M \\ I_N \otimes \Sigma_{d_2} \end{pmatrix} (V_{d_1} \otimes V_{d_2})^T. \end{aligned}$$

Since the middle matrix consists of two "stacked" diagonal matrices, we can easily determine an orthogonal matrix $Q_D$ (consisting of Givens rotations) and a diagonal matrix $D$ such that

$$Q_D^T \begin{pmatrix} \Sigma_{d_1} \otimes I_M \\ I_N \otimes \Sigma_{d_2} \end{pmatrix} = \begin{pmatrix} D \\ 0 \end{pmatrix},$$

and it is no restriction to assume that the diagonal elements of $D$ are nonnegative. Hence

$$L = \begin{pmatrix} U_{d_1} \otimes V_{d_2} & 0 \\ 0 & V_{d_1} \otimes U_{d_2} \end{pmatrix} Q_D \begin{pmatrix} D \\ 0 \end{pmatrix} (V_{d_1} \otimes V_{d_2})^T,$$

and we obtain $\|L\,x\|_2 = \|L_D\,x\|_2$. Equation (5.7) follows from the relation

$$D^2 = D^TD = \begin{pmatrix} D \\ 0 \end{pmatrix}^T \begin{pmatrix} D \\ 0 \end{pmatrix} = \begin{pmatrix} \Sigma_{d_1} \otimes I_M \\ I_N \otimes \Sigma_{d_2} \end{pmatrix}^T \begin{pmatrix} \Sigma_{d_1} \otimes I_M \\ I_N \otimes \Sigma_{d_2} \end{pmatrix}.$$

Regarding the null space $\mathcal{N}(L) = \mathcal{N}(L_D)$, it is easily seen from (5.6) that the null space vectors are given by the columns of $V_{d_1} \otimes V_{d_2}$ for which the diagonal elements of $D$ are zero. This leads directly to (5.8). □

The consequences of this theorem are that we can substitute the structured matrix $L_D$ for $L$ in the Tikhonov problem (1.1), and that we have a simple basis for $\mathcal{N}(L)$. The approach can be used in both the P-CGLS and the SN-X algorithms and leads to increased efficiency, while $L$ matrices of this form are [illegible] applicable in the augmented-matrix approach.

**6. Numerical experiments.** We include two test problems to illustrate the performance of the new preconditioning technique for regularizing minimum-residual methods. The first example is a synthetic two-dimensional problem with a symmetric coefficient matrix and an $L$ of the form (5.5); the second is a finite-element model of a steady-state heat distribution problem with a nonsymmetric coefficient matrix and a periodic solution. In both examples we calculate the relative error of the regularized solutions $x^{(k)}$ compared to the exact solution $x$, i.e.,

$$\epsilon^{(k)} = \|x^{(k)} - x\|_2 \,/\, \|x\|_2, \tag{6.1}$$

where $x^{(k)}$ is the $k$th iterate. The best regularized solution is always defined as the solution for which $\epsilon^{(k)}$ is smallest.

**6.1. Two-dimensional example.** The two-dimensional example is a synthetic problem generated from the `deriv2` test problem in Regularization Tools [9]. The coefficient matrix $A \in \mathbb{R}^{37500\times 37500}$ is generated as the Kronecker product of $A_1 \in \mathbb{R}^{250\times 250}$ and $A_2 \in \mathbb{R}^{150\times 150}$, each being a discretization of Green's function for the second derivative. The resulting coefficient matrix is symmetric, and thus MINRES and MR-II can be used.

The exact solution $X$ has size $M \times N = 150 \times 250$, and it consists of the sum of a linear function in one direction and a quadratic function in the other. The MATLAB code for generating the exact solution is

```
s = linspace(-1,1,250); t = linspace(-1,1,150);
[s,t] = meshgrid(s,t);
X = s + t.^2;
```

and then $x$ is obtained by stacking the columns of $X$. The right-hand side is computed by $b = Ax+e$, in which $e$ is white Gaussian noise scaled such that $\|e\|_2/\|Ax\|_2 = 10^{-2}$. Using the Kronecker products, all computations can be carried out without explicitly forming the large matrix $A$, instead using $A_1$ and $A_2$.

The top plots in Figure 6.1 show the exact solution and the right-hand side as two-dimensional images. Figure 6.1 also shows the best regularized solutions using MINRES, MR-II, CGLS, SN-MINRES, SN-MR-II, and P-CGLS as measured by (6.1). For the preconditioned algorithms we use the matrix $L$ in (5.5) with $d_1 = d_2 = 1$, corresponding to first derivative smoothing in both directions, and its null space is spanned by the constant image.

The six algorithms produce solutions with different properties; all the preconditioned algorithms give much better regularized solutions than the nonpreconditioned algorithms, and MINRES gives by far the most noisy solution. All the nonpreconditioned solutions tend to go to zero near the edges of the domain; this behavior comes from the fact that the bases for these solutions are the Krylov vectors, which all tend to zero at the edges. Using the matrix $L$ from (5.5) as preconditioner, the Krylov subspaces are changed to favor the particular properties of this problem, resulting in better reconstructions. The best SN-MR-II solution is similar to the best solution obtained by P-CGLS, both regarding the quality and the number of iterations. It is worth noting that even though the cost of applying the preconditioner is about the same for P-CGLS and SN-MR-II, P-CGLS needs an additional matrix-vector multiplication with $A^T$ in each iteration, which makes SN-MR-II somewhat faster.

**6.2. Steady-state heat distribution.** This test problem from [11] involves a partial differential equation that describes the steady-state heat distribution in a two-dimensional domain $\Omega$ with inner and outer boundaries $\partial\Omega_{\rm i}$ and $\partial\Omega_{\rm o}$. The forward

problem takes the form

$$\nabla^2 f(z) = 0, \quad z \in \Omega, \qquad \qquad \begin{cases} f(z) = f_{\mathrm{i}}(z), & z \in \partial\Omega_{\mathrm{i}}, \\ \frac{\partial}{\partial n} f(z) = 0, & z \in \partial\Omega_{\mathrm{o}}, \end{cases}$$

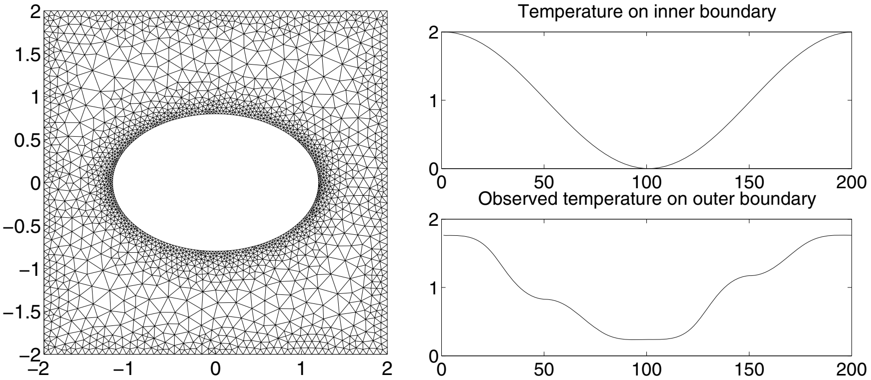

FIG. 6.2. *Test problem with steady-state heat distribution. Left: the geometry and the finite-element mesh. Right: exact temperature $f_i$ on the inner boundary (top), and measured noisy temperature $f_o$ on the outer boundary (bottom).*

where $f_{\mathrm{i}}$ is the temperature on the inner boundary and $\frac{\partial}{\partial n}$ denotes the normal derivative on the outer boundary. The inverse problem is to determine the temperature distribution on the inner boundary from measurements of the temperature on the outer boundary.

In this example, the inner boundary $\partial\Omega_{\mathrm{i}}$ is an ellipse with semiaxes of length 1.2 and 0.8, while the outer boundary $\partial\Omega_{\mathrm{o}}$ is a square with side length 4; see Figure 6.2. We use a matrix-free implementation in which $A$, the forward computation, is a finite-element model that maps the temperature $f_{\mathrm{i}}(z)$ on the inner boundary $\partial\Omega_{\mathrm{i}}$ to the temperature $f_{\mathrm{o}}(z)$ on the outer boundary $\partial\Omega_{\mathrm{o}}$.

The exact solution vector $x$ consists of values of the temperature on the inner boundary in $n = 200$ grid points. The right-hand side, consisting of the temperature in the $n$ grid points of the outer boundary, is then computed as $b = Ax + e$, where $e$ is white Gaussian noise scaled such that $\|e\|_2/\|Ax\|_2 = 10^{-3}$. Both temperature profiles are also shown in Figure 6.2.

Using $n$ points on both $\partial\Omega_i$ and $\partial\Omega_o$, the operation with the square matrix $A$ involves solving the forward problem via the finite-element model. A similar discrete model for operation with the transposed matrix is not simple to derive, and therefore P-CGLS is not directly applicable. On the other hand, GMRES and RRGMRES are natural methods of choice for solving the inverse problem.

The two top rows in Figure 6.3 show the optimal solutions obtained with GMRES and RRGMRES using $L = I_n$ and $L = L_2$. The third row shows the comparable results with $L$ equal to the augmented matrix $\widehat{L}_2$ from (3.1) with $\bar{w} = \alpha(-2, 1, 0, \ldots, 0)^T$, $w = \alpha(0, \ldots, 0, 1, -2)^T$, and $\alpha = 4.29 \cdot 10^{-4}$. The $\alpha$-parameter can be considered as a special regularization parameter for the added rows and must be chosen appropriately in addition to the number of iterations. Selecting the optimal $\alpha$ is in general not an easy problem. For this constructed test problem we compute the optimal solutions for a range of $\alpha$ values, and the chosen $\alpha$ is the one that gives rise to the overall best regularized solution. Figure 6.4 shows how the optimal GMRES solutions vary with $\alpha$—the situation is very similar for RRGMRES.

For all three choices of $L$, RRGMRES performs better than GMRES. Using a smoothing norm with $L = L_2$ or $L = \widehat{L}_2$ improves the solutions by about an order of magnitude. With these two choices of $L$, the augmented-matrix approach seems to

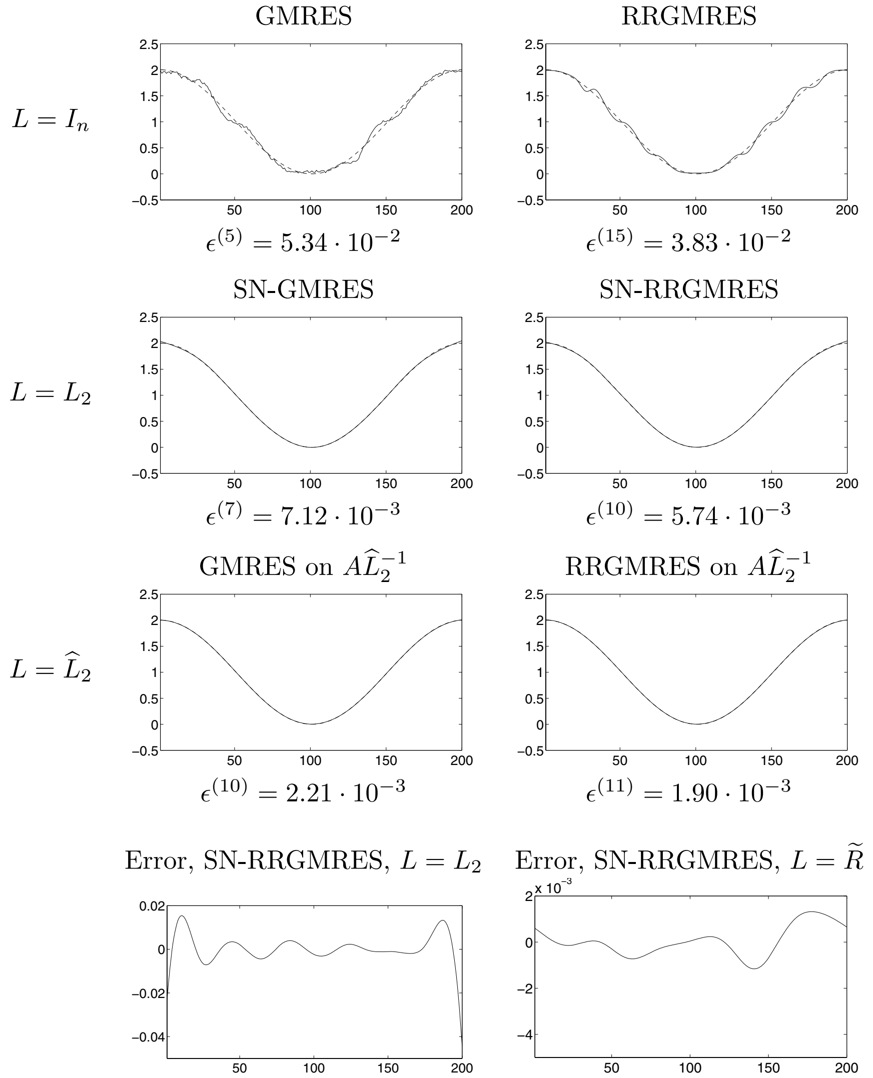

FIG. 6.3. *Three top rows: solutions to the steady-state heat distribution problem computed with standard and preconditioned GMRES and RRGMRES, and with different smoothing norms. perform better than the SN-approach. On the other hand, Figure 6.4 shows that a small change in $\alpha$ will result in worse solutions. An obvious choice of $\alpha$ would be to choose a value so small that the influence of the added rows is negligible while still keeping $\widehat{L}_2$ invertible, e.g., $\alpha = 10^{-8}$. This corresponds to the flat part of the plot in Figure 6.4, and an optimal solution with a higher relative error. The dependence on $\alpha$ illustrates the importance of choosing wise extensions to the $L$-matrices. Especially, the extension proposed in [4, Equation (13)] ($\widehat{L}_2$ with $\alpha = 1$) is seen to perform badly for this particular problem.

However, the quality of the solution can be improved further by taking into account the periodicity of the solution. A careful study shows that the errors in all the

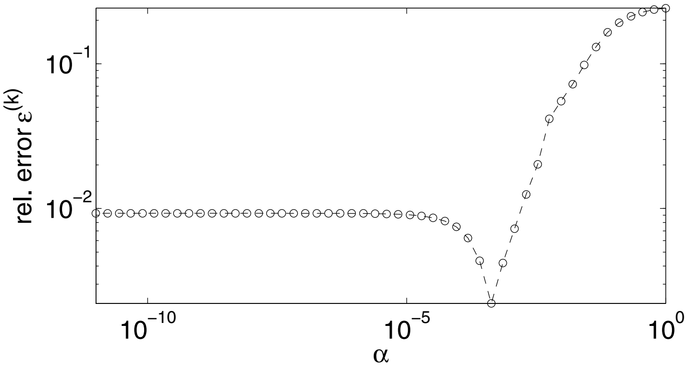

FIG. 6.4. *Best obtainable relative errors* $\epsilon^{(k)}$ *of GMRES solutions using* $\widehat{L}_2$ *with* $\bar{w} = \alpha(-2,\,1,\,0,\ldots,\,0)^T$ *and* $w = \alpha(0,\ldots,\,0,\,1,\,-2)^T$ *for a range of values of* $\alpha$.

solutions grow towards the edges; this is illustrated by the bottom left plot in Figure 6.3, which shows the error in the SN-RRGMRES solution with $L = L_2$. A natural requirement is therefore to add the constraint that the second derivative should also be minimized across the edges of the periodic solution. Hence, we use a circulant version of $L_2$ given by

$$\widetilde{L}_2 = \begin{pmatrix} -2 & 1 & & & 1 \\ 1 & -2 & 1 & & \\ & \ddots & \ddots & \ddots & \\ & & 1 & -2 & 1 \\ 1 & & & 1 & -2 \end{pmatrix} \in \mathbb{R}^{n\times n},$$

which corresponds to $L_2$ with periodic boundary conditions. This matrix is singular with $\operatorname{rank}(\widetilde{L}_2) = n-1$, and its null space is given by

$$\mathcal{N}(\widetilde{L}_2) = \operatorname{span}\left\{(1,\,1,\,\ldots,\,1)^T\right\}.$$

Since $\widetilde{L}_2$ is singular, it cannot be used in the augmented-matrix approach. In order to use the SN-approach, we compute the skinny QR-factorization $\widetilde{L}_2 = \widetilde{Q}\widetilde{R}$ with $\widetilde{R}$ trapezoidal, and use $L = \widetilde{R}$.

Using this choice of $L$, the smallest error $\epsilon^{(6)} = 6.28 \cdot 10^{-4}$ in the SN-GMRES solution is obtained after 6 iterations, while the smallest error $\epsilon^{(5)} = 5.21 \cdot 10^{-4}$ in the SN-RRGMRES solution is obtained after 5 iterations. In both cases, the relative error is reduced by an order of magnitude, compared to using $L_2$, and is also superior to the approach using the augmented $\widehat{L}_2$ with $\alpha = 4.29 \cdot 10^{-4}$. Furthermore, the number of iterations is reduced. The bottom right plot in Figure 6.3, which shows the error in the SN-RRGMRES solution with $L = \widetilde{R}$, illustrates the reduction of the error, primarily because the errors near the edges are reduced significantly.

## 7. Conclusion.

We presented a new preconditioning technique for regularizing minimum-residual methods such that it corresponds to using a smoothing norm $\|L\,x\|_2$ in the Tikhonov formulation, and the matrix $L$ is allowed to be both rank deficient and rectangular. Our algorithm preserves symmetry when the coefficient matrix is symmetric, thus allowing the use of MINRES and MR-II where appropriate. Our algorithm is computationally feasible when the dimension of $\mathcal{N}(L)$ is small and computations with $L^\dagger$ can be implemented efficiently. We showed an example of an $L$ matrix for two-dimensional problems where this is achieved. We also demonstrated how to implement the algorithm efficiently, and we gave numerical examples in one and two dimensions that illustrate the use and performance of the new preconditioner.

Our numerical examples illustrate that the proposed SN-approach can provide an improvement in the solution's accuracy compared to standard minimum-residual methods, that the SN-approach works for a larger class of smoothing norms than the augmented-matrix approach, and that preconditioned minimum-residual methods can be computationally attractive alternatives to preconditioned CGLS (e.g., when $A^T$ is not directly available).

**Acknowledgements.** We would like to thank the referees for comments, which considerably improved the presentation and the numerical examples.

# MAJORIZATION FOR CHANGES IN ANGLES BETWEEN SUBSPACES, RITZ VALUES, AND GRAPH LAPLACIAN SPECTRA*

ANDREW V. KNYAZEV[†] AND MERICO E. ARGENTATI[†]

**Abstract.** Many inequality relations between real vector quantities can be succinctly expressed as "weak (sub)majorization" relations using the symbol $\prec_w$. We explain these ideas and apply them in several areas, angles between subspaces, Ritz values, and graph Laplacian spectra, which we show are all surprisingly related. Let $\Theta(\mathcal{X},\mathcal{Y})$ be the vector of principal angles in nondecreasing order between subspaces $\mathcal{X}$ and $\mathcal{Y}$ of a finite dimensional space $\mathcal{H}$ with a scalar product. We consider the change in principal angles between subspaces $\mathcal{X}$ and $\mathcal{Z}$, where we let $\mathcal{X}$ be perturbed to give $\mathcal{Y}$. We measure the change using weak majorization. We prove that $|\cos^2\Theta(\mathcal{X},\mathcal{Z})-\cos^2\Theta(\mathcal{Y},\mathcal{Z})|\prec_w \sin\Theta(\mathcal{X},\mathcal{Y})$, and give similar results for differences of cosines, i.e., $|\cos\Theta(\mathcal{X},\mathcal{Z})-\cos\Theta(\mathcal{Y},\mathcal{Z})|\prec_w \sin\Theta(\mathcal{X},\mathcal{Y})$, and of sines and sines squared, assuming $\dim\mathcal{X}=\dim\mathcal{Y}$. We observe that $\cos^2\Theta(\mathcal{X},\mathcal{Z})$ can be interpreted as a vector of Ritz values, where the Rayleigh–Ritz method is applied to the orthogonal projector on $\mathcal{Z}$ using $\mathcal{X}$ as a trial subspace. Thus, our result for the squares of cosines can be viewed as a bound on the change in the Ritz values of an orthogonal projector. We then extend it to prove a general result for Ritz values for an arbitrary Hermitian operator $A$, not necessarily a projector: let $\Lambda\left(P_{\mathcal{X}}A|_{\mathcal{X}}\right)$ be the vector of Ritz values in nonincreasing order for $A$ on a trial subspace $\mathcal{X}$, which is perturbed to give another trial subspace $\mathcal{Y}$; then $|\Lambda\left(P_{\mathcal{X}}A|_{\mathcal{X}}\right)-\Lambda\left(P_{\mathcal{Y}}A|_{\mathcal{Y}}\right)|\prec_w(\lambda_{\max}-\lambda_{\min})\,\sin\Theta(\mathcal{X},\mathcal{Y})$, where the constant is the difference between the largest and the smallest eigenvalues of $A$. This establishes our conjecture that the root two factor in our earlier estimate may be eliminated. Our present proof is based on a classical but rarely used technique of extending a Hermitian operator in $\mathcal{H}$ to an orthogonal projector in the "double" space $\mathcal{H}^2$. An application of our Ritz values weak majorization result for Laplacian graph spectra comparison is suggested, based on the possibility of interpreting eigenvalues of the edge Laplacian of a given graph as Ritz values of the edge Laplacian of the complete graph. We prove that $\sum_k|\lambda_k^1-\lambda_k^2|\le nl$, where $\lambda_k^1$ and $\lambda_k^2$ are all ordered elements of the Laplacian spectra of two graphs with the same $n$ vertices and with $l$ equal to the number of differing edges.

## 1. Introduction.

Many inequality relations between real vector quantities can be succinctly expressed as "weak (sub)majorization" relations using the symbol $\prec_w$ that we now introduce. For a real vector $x=[x_1,\dots,x_n]$ let $x^{\downarrow}$ be the vector obtained by rearranging the entries of $x$ in an algebraically nonincreasing order. Vector $y$ weakly majorizes vector $x$; i.e., $x\prec_w y$ if $\sum_{i=1}^k x_i^{\downarrow}\le\sum_{i=1}^k y_i^{\downarrow},\ k=1,\dots,n$. The importance of weak majorization can be seen from the classical statement that the following two conditions are equivalent: $x\prec_w y$ and $\sum_{i=1}^n\phi(x_i)\le\sum_{i=1}^n\phi(y_i)$ for all nondecreasing convex functions $\phi$. Thus, a single weak majorization result implies a

great variety of inequalities. We explain these ideas and apply them in several areas, angles between subspaces, Ritz values, and graph Laplacian spectra, which we show are all surprisingly related.

The concept of principal angles, also referred to as canonical angles, between subspaces is one of the classical mathematical ideas originating from [16] with many applications. In functional analysis, the gap between subspaces, which is related to the sine of the largest principal angle, bounds the perturbation of a closed linear operator by measuring the change in its graph, while the smallest nontrivial principal angle between two subspaces determines whether the sum of the subspaces is closed. In numerical analysis, principal angles appear naturally to estimate how close an approximate eigenspace is to the true eigenspace. The chordal distance, the Frobenius norm of the sine of the principal angles, on the Grassmannian space of finite dimensional subspaces is used, e.g., for subspace packing with applications in control theory. In statistics, the cosines of principal angles are called canonical correlations and have applications in information retrieval and data visualization.

Let $\mathcal{H}$ be a real or complex $n < \infty$ dimensional vector space equipped with an inner product $(x, y)$ and a vector norm $\|x\| = (x, x)^{1/2}$. The acute angle between two nonzero vectors $x$ and $y$ is defined as

$$\theta(x, y) = \arccos \frac{|(x, y)|}{\|x\|\|y\|} \in \left[0, \frac{\pi}{2}\right].$$

For three nonzero vectors $x, y, z$, we have bounds on the change in the angle

$$|\theta(x, z) - \theta(y, z)| \leq \theta(x, y), \tag{1.1}$$

in the sine

$$|\sin(\theta(x, z)) - \sin(\theta(y, z))| \leq \sin(\theta(x, y)), \tag{1.2}$$

and in the cosine

$$|\cos(\theta(x, z)) - \cos(\theta(y, z))| \leq \sin(\theta(x, y)), \tag{1.3}$$

and a more subtle bound on the change in the sine or cosine squared:

$$\left|\cos^2(\theta(x, z)) - \cos^2(\theta(y, z))\right| = \left|\sin^2(\theta(x, z)) - \sin^2(\theta(y, z))\right| \leq \sin(\theta(x, y)). \tag{1.4}$$

Let us note that we can project the space $\mathcal{H}$ into the span$\{x, y, z\}$ without changing the angles; i.e., the inequalities above present essentially the case of a three dimensional (3D) space.

Inequality (1.1) is proved in [34, Theorem 3.2, p. 514]. We note that (1.2) follows from (1.1), since the sine function is increasing and subadditive; see [34, p. 530].

It is instructive to provide a simple proof of the sine inequality (1.2) using orthogonal projectors. Let $P_{\mathcal{X}}$, $P_{\mathcal{Y}}$, and $P_{\mathcal{Z}}$ be the orthogonal projectors onto the subspaces spanned by the vectors $x$, $y$, and $z$, respectively, and let $\|\cdot\|$ also denote the induced operator norm. When we are dealing with 1D subspaces, we have the following elementary formula: $\sin(\theta(x, y)) = \|P_{\mathcal{X}} - P_{\mathcal{Y}}\|$. (Indeed, $P_x - P_y$ has rank at most two, so it has at most two nonzero singular values, but $(P_x - P_y)^2 x = (1 - |(x, y)|^2)x$ and $(P_x - P_y)^2 y = (1 - |(x, y)|^2)y$ for unit vectors $x$ and $y$, so $1 - |(x, y)|^2 = \sin^2(\theta(x, y))$ is a double eigenvalue of $(P_x - P_y)^2$.) Then the sine inequality (1.2) is equivalent to the triangle inequality $|\,\|P_{\mathcal{X}} - P_{\mathcal{Z}}\| - \|P_{\mathcal{Y}} - P_{\mathcal{Z}}\|\,| \leq \|P_{\mathcal{X}} - P_{\mathcal{Y}}\|$.

In this paper, we replace 1D subspaces spanned by the vectors $x$, $y$, and $z$ with multidimensional subspaces $\mathcal{X}$, $\mathcal{Y}$, and $\mathcal{Z}$, and we use the concept of principal angles between subspaces. Principal angles are very well studied in the literature; however, some important gaps still remain. Here, we are interested in generalizing inequalities (1.2)–(1.4) above to multidimensional subspaces to include all principal angles, using weak majorization.

Let us denote by $\Theta(\mathcal{X},\mathcal{Y})$ the vector of principal angles in nondecreasing order between subspaces $\mathcal{X}$ and $\mathcal{Y}$. Let $\dim\mathcal{X} = \dim\mathcal{Y}$, and let another subspace $\mathcal{Z}$ be given. We prove that $|\cos^2\Theta(\mathcal{X},\mathcal{Z}) - \cos^2\Theta(\mathcal{Y},\mathcal{Z})| \prec_w \sin\Theta(\mathcal{X},\mathcal{Y})$, and give similar results for differences of cosines, i.e., $|\cos\Theta(\mathcal{X},\mathcal{Z}) - \cos\Theta(\mathcal{Y},\mathcal{Z})| \prec_w \sin\Theta(\mathcal{X},\mathcal{Y})$, and of sines and sines squared. This is the first main result of the present paper; see section 3. The proof of weak majorization for sines is a direct generalization of the 1D proof above. Our proofs of weak majorization for cosines and sines or cosines squared do not have such simple 1D analogues.

Pioneering results using angles between subspaces in the framework of unitarily invariant norms and symmetric gauge functions, equivalent to majorization, appear in [7], which introduces many of the tools that we use here. The main goal of [7] is, however, different—analyzing the perturbations of eigenvalues and eigenspaces—while in the present paper we are concerned with sensitivity of angles and Ritz values with respect to changes in subspaces.

Our second main result (see section 4) bounds the change in the Ritz values with the change of the trial subspace. We attack the problem by discovering a simple, but deep, connection between the principal angles and the Rayleigh–Ritz method.

We first give a brief definition of Ritz values. Let $A : \mathcal{H} \to \mathcal{H}$ be a Hermitian operator, and let $\mathcal{X}$ be a (so-called trial) subspace of $\mathcal{H}$. We define an operator $P_{\mathcal{X}}A|_{\mathcal{X}}$ on $\mathcal{X}$, where $P_{\mathcal{X}}$ is the orthogonal projector onto $\mathcal{X}$ and $P_{\mathcal{X}}A|_{\mathcal{X}}$ denotes the restriction of operator $P_{\mathcal{X}}A$ to its invariant subspace $\mathcal{X}$, as discussed, e.g., in [32, section 11.4, pp. 234–239]. The eigenvalues $\Lambda(P_{\mathcal{X}}A|_{\mathcal{X}})$ are called Ritz values of the operator $A$ with respect to the trial subspace $\mathcal{X}$.

We observe that the cosines squared $\cos^2\Theta(\mathcal{X},\mathcal{Z})$ of principal angles between subspaces $\mathcal{X}$ and $\mathcal{Z}$ can be interpreted as a vector of Ritz values, where the Rayleigh–Ritz method is applied to the orthogonal projector $P_{\mathcal{Z}}$ onto $\mathcal{Z}$ using $\mathcal{X}$ as a trial subspace. Let us illustrate this connection for one dimensional $\mathcal{X} = \operatorname{span}\{x\}$ and $\mathcal{Z} = \operatorname{span}\{z\}$, where it becomes trivial:

$$\cos^2(\theta(x,z)) = \frac{(x, P_{\mathcal{Z}}x)}{(x,x)}.$$

The ratio on the right is the Rayleigh quotient for $P_{\mathcal{Z}}$—the one dimensional analogue of a Ritz value. In this notation, estimate (1.4) turns into

$$\left|\frac{(x,P_z x)}{(x,x)} - \frac{(y,P_z y)}{(y,y)}\right| \leq \sin(\theta(x,y)), \tag{1.5}$$

which clearly now is a particular case of a general estimate for the Rayleigh quotient (cf. [19]),

$$\left|\frac{(x,Ax)}{(x,x)} - \frac{(y,Ay)}{(y,y)}\right| \leq (\lambda_{\max} - \lambda_{\min})\sin(\theta(x,y)), \tag{1.6}$$

where $A$ is a Hermitian operator and $\lambda_{\max} - \lambda_{\min}$ is the spread of its spectrum.

We show that the multidimensional analogue of (1.5) can be interpreted as a bound on the change in the Ritz values with the change of the trial subspace, in the particular case where the Rayleigh–Ritz method is applied to an orthogonal projector. We then extend it to prove a general result for Ritz values for an arbitrary Hermitian operator $A$, not necessarily a projector: let $\Lambda\left(P_{\mathcal{X}}A|_{\mathcal{X}}\right)$ be the vector of Ritz values in nonincreasing order for the operator $A$ on a trial subspace $\mathcal{X}$, which is perturbed to give another trial subspace $\mathcal{Y}$; then $|\Lambda\left(P_{\mathcal{X}}A|_{\mathcal{X}}\right)-\Lambda\left(P_{\mathcal{Y}}A|_{\mathcal{Y}}\right)| \prec_w (\lambda_{\max}-\lambda_{\min})\, \sin\Theta(\mathcal{X},\mathcal{Y})$, which is a multidimensional analogue of (1.6). Our present proof is based on a classical but rarely used idea of extending a Hermitian operator in $\mathcal{H}$ to an orthogonal projector in the "double" space $\mathcal{H}^2$, preserving its Ritz values.

An application of our Ritz values weak majorization result for Laplacian graph spectra comparison is suggested in section 5, based on the possibility of interpreting eigenvalues of the edge Laplacian of a given graph as Ritz values of the edge Laplacian of the complete graph. We prove that $\sum_k |\lambda_k^1-\lambda_k^2| \leq nl$, where $\lambda_k^1$ and $\lambda_k^2$ are all ordered elements of the Laplacian spectra of two graphs with the same $n$ vertices and with $l$ equal to the number of differing edges.

The rest of the paper is organized as follows. In section 2, we provide some background, definitions, and several statements concerning weak majorization, principal angles between subspaces, and extensions of Hermitian operators to projectors. In section 3, we prove in Theorems 3.2 and 3.3 that the absolute value of the change in (the squares of) the sines and cosines is weakly majorized by the sines of the angles between the original and perturbed subspaces. In section 4, we prove in Theorem 4.2 that a change in the Ritz values in the Rayleigh–Ritz method with respect to the change in the trial subspaces is weakly majorized by the sines of the principal angles between the original and perturbed trial subspaces times a constant. In section 5, we apply our Ritz values weak majorization result to Laplacian graphs spectra comparison. Section 6 gives brief conclusions.

This paper is related to several different subjects: majorization, principal angles, the Rayleigh–Ritz method, and Laplacian graph spectra. In most cases, whenever possible, we cite books rather than the original works in order to keep our already quite long list of references within a reasonable size.

## 2. Definitions and preliminaries.

In this section we introduce some definitions, basic concepts, and generally familiar results for later use.

### 2.1. Weak majorization.

Majorization is a well-known (e.g., see [14, pp. 45–49] or [24, pp. 9–14]) important mathematical concept with numerous applications.

For a real vector $x=[x_1,\ldots,x_n]$ let $x^{\downarrow}$ be the vector obtained by rearranging the entries of $x$ in an algebraically nonincreasing order, $x_1^{\downarrow}\geq\cdots\geq x_n^{\downarrow}$. We denote $[|x_1|,\ldots,|x_n|]$ by $|x|$. We say that vector $y$ weakly majorizes vector $x$, and we use the notation $[x_1,\ldots,x_n]\prec_w[y_1,\ldots,y_n]$ or $x\prec_w y$ if $\sum_{i=1}^k x_i^{\downarrow}\leq\sum_{i=1}^k y_i^{\downarrow}$ for $k=1,\ldots,n$. If in addition the sums above for $k=n$ are equal, $y$ (strongly) majorizes vector $x$, but we do not use this type of majorization in the present paper. Two vectors of different lengths may be compared by simply appending zeroes to increase the size of the smaller vector to make the vectors the same length.

Weak majorization is a powerful tool for bounds involving eigenvalues and singular values and is covered, e.g., in [10], [24], [1], and [15], which we follow here and to which we refer the reader for references to the original works and all necessary proofs. In the present paper, we use several well-known statements that we formulate for operators $\mathcal{H}\to\mathcal{H}$ and overview briefly below.

Let $S(A)$ denote the vector of all singular values of $A : \mathcal{H} \to \mathcal{H}$ in nonincreasing order, i.e., $S(A) = S^{\downarrow}(A)$, while individual singular values of $A$ enumerated in nonincreasing order are denoted by $s_i(A)$. For Hermitian $A$ let $\Lambda(A)$ denote the vector of all eigenvalues of $A$ in nonincreasing order, i.e., $\Lambda(A) = \Lambda^{\downarrow}(A)$, while individual eigenvalues of $A$ enumerated in nonincreasing order are denoted by $\lambda_i(A)$.

The starting point for weak majorization results that we use in this paper is, e.g., [24, Theorem 9.G.1, p. 241], given next.

THEOREM 2.1. $\Lambda(A+B) \prec_w \Lambda(A) + \Lambda(B)$ [illegible] $A$ [illegible] $B$

This follows easily from Ky Fan's trace maximum principle [24, Theorem 20.A.2, p. 511] and the fact that the maximum of a sum is bounded from above by the sum of the maxima. For general $A : \mathcal{H} \to \mathcal{H}$ and $B : \mathcal{H} \to \mathcal{H}$, it follows from Theorem 2.1, since the top half of the spectrum of the Hermitian 2-by-2 block operator $\left[\begin{smallmatrix} 0 & A \\ A^* & 0 \end{smallmatrix}\right]$ is nothing but $S(A)$, that (see, e.g., [15, Cor. 3.4.3, p. 196]) we have the following.

COROLLARY 2.2. $S(A \pm B) \prec_w S(A) + S(B)$

A more delicate and stronger result is the following Lidskii theorem (see, e.g., [1, Theorem III.4.1, p. 69]), which can be proved using the Wielandt maximum principle (e.g., [1, Theorem III.3.5, p. 67]).

THEOREM 2.3. [illegible] $A$ [illegible] $B$ [illegible] $1 \le i_1 < \cdots < i_k \le n = \dim\mathcal{H}$ [illegible] $\sum_{j=1}^{k} \lambda_{i_j}(A+B) \le \sum_{j=1}^{k} \lambda_{i_j}(A) + \sum_{j=1}^{k} \lambda_j(B)$, $k = 1, \ldots, n$.

By choosing an appropriate set of indices, Theorem 2.3 for Hermitian $A$ and $B$ immediately gives $\Lambda(A) - \Lambda(B) \prec_w \Lambda(A-B)$, which for singular values of arbitrary $A : \mathcal{H} \to \mathcal{H}$ and $B : \mathcal{H} \to \mathcal{H}$ is equivalent (see [1, section IV.3, pp. 98–101]) to, e.g., [15, Theorem 3.4.5, p. 198] or [1, Theorem IV.3.4, p. 100], as follows.

COROLLARY 2.4. $|S(A) - S(B)| \prec_w S(A-B)$

Applying Corollary 2.4 to properly shifted Hermitian operators, we get the next result.

COROLLARY 2.5. $|\Lambda(A) - \Lambda(B)| \prec_w S(A-B)$ [illegible] $A$ [illegible] $B$

We finally need the so-called pinching inequality (see, e.g., [10, Theorem II.5.1, p. 52] or [1, Problem II.5.5, p. 50]), which we write as follows.

THEOREM 2.6. [illegible] $P$ [illegible] $S(PAP \pm (I-P)A(I-P)) \prec_w S(A)$.

[illegible]. Indeed, $A = PAP + (I-P)A(I-P) + PA(I-P) + (I-P)AP$, so let $B = PAP + (I-P)A(I-P) - PA(I-P) - (I-P)AP$; then $(2P-I)A(2P-I) = B$, where $2P - I$ is unitary Hermitian, and thus $A^*A$ and $B^*B$ are similar and $S(A) = S(B)$. Evidently, $PAP + (I-P)A(I-P) = (A+B)/2$, and so the pinching result with the plus follows from Corollary 2.2. The pinching result with the minus is equivalent to the pinching result with the plus, since the sign does not change the singular values on the left-hand side: $S(PAP \pm (I-P)A(I-P)) = S(PAP) \cup S((I-P)A(I-P))$, since the ranges of $PAP$ and $(I-P)A(I-P)$ are disjoint. $\square$

**2.2. Principal angles between subspaces.** Let $P_{\mathcal{X}}$ and $P_{\mathcal{Y}}$ be orthogonal projectors onto the subspaces $\mathcal{X}$ and $\mathcal{Y}$, respectively, of the space $\mathcal{H}$. We define the set of cosines of principal angles between subspaces $\mathcal{X}$ and $\mathcal{Y}$ by

$$\cos\Theta(\mathcal{X},\mathcal{Y}) = [s_1(P_{\mathcal{X}}P_{\mathcal{Y}}), \ldots, s_m(P_{\mathcal{X}}P_{\mathcal{Y}})], \qquad m = \min\{\dim\mathcal{X}; \dim\mathcal{Y}\}. \tag{2.1}$$

Our definition (2.1) is evidently symmetric: $\Theta(\mathcal{X},\mathcal{Y}) = \Theta(\mathcal{Y},\mathcal{X})$. By definition, the cosines are arranged in nonincreasing order, i.e., $\cos(\Theta(\mathcal{X},\mathcal{Y})) = (\cos(\Theta(\mathcal{X},\mathcal{Y})))^{\downarrow}$, while the angles $\theta_i(\mathcal{X},\mathcal{Y}) \in [0, \pi/2]$, $i = 1, \ldots, m$, and their sines are in nondecreasing order.

The concept of principal angles is closely connected to cosine-sine (CS) decompositions of unitary operators; we refer the reader to the books [37], [38], [1] for the history and references to the original publications on principal angles and the CS decomposition. We need several simple but important statements about the angles, provided below. In the particular case $\dim\mathcal{X} = \dim\mathcal{Y}$, the standard CS decomposition can be used, and the statements are easy to derive. For the general case $\dim\mathcal{X} \neq \dim\mathcal{Y}$ that is necessary for us here, they can be obtained using the general (rectangular) form of the CS decomposition described, e.g., in [31], [30]. For completeness we provide the proofs here using ideas from [13], [7], preparing our work to be more easily extended to infinite dimensional Hilbert spaces.

In [18, Theorem 3.4, p. 2017 and Theorem 3.5, p. 2018], without proofs we formulate statements equivalent to the theorem below; see also [3, Example 1.2.6].

THEOREM 2.7. [illegible] $\pi/2$ [illegible]

$$\left[\frac{\pi}{2},\dots,\frac{\pi}{2},(\Theta(\mathcal{X},\mathcal{Y}))^{\downarrow}\right] = \left[\frac{\pi}{2}-\Theta(\mathcal{X},\mathcal{Y}^{\perp}),0,\dots,0\right], \tag{2.2}$$

[illegible] $\max\{\dim\mathcal{X}-\dim\mathcal{Y};0\}$ [illegible] $\pi/2$ [illegible]

[illegible]

$$[(\Theta(\mathcal{X},\mathcal{Y}))^{\downarrow},0,\dots,0] = [(\Theta(\mathcal{X}^{\perp},\mathcal{Y}^{\perp}))^{\downarrow},0,\dots,0], \tag{2.3}$$

[illegible] Let $\mathfrak{M}_{00} = \mathcal{X}\cap\mathcal{Y}$, $\mathfrak{M}_{01} = \mathcal{X}\cap\mathcal{Y}^{\perp}$, $\mathfrak{M}_{10} = \mathcal{X}^{\perp}\cap\mathcal{Y}$, $\mathfrak{M}_{11} = \mathcal{X}^{\perp}\cap\mathcal{Y}^{\perp}$, as suggested in [13, p. 381].

Each of the subspaces is invariant with respect to orthoprojectors $P_{\mathcal{X}}$ and $P_{\mathcal{Y}}$ and their products, and so each of the subspaces contributes independently to the set of singular values of $P_{\mathcal{X}}P_{\mathcal{Y}}$ in (2.1). Specifically, there are $\dim\mathfrak{M}_{00}$ ones, $\dim\mathfrak{M}_0$ singular values in the interval $(0,1)$ equal to $\cos\Theta(\mathfrak{M}_0,\mathcal{Y})$, where $\mathfrak{M}_0 = \mathcal{X}\cap(\mathfrak{M}_{00}\oplus\mathfrak{M}_{01})^{\perp}$, and all other singular values are zeroes; thus,

$$(\Theta(\mathcal{X},\mathcal{Y}))^{\downarrow} = \left[\frac{\pi}{2},\dots,\frac{\pi}{2},(\Theta(\mathfrak{M}_0,\mathcal{Y}))^{\downarrow},0,\dots,0\right], \tag{2.4}$$

where there are $\min\{\dim(\mathfrak{M}_{01});\dim(\mathfrak{M}_{10})\}$ values $\pi/2$ and $\dim(\mathfrak{M}_{00})$ zeroes.

The subspace $\mathfrak{M}_0$ does not change if we substitute $\mathcal{Y}^{\perp}$ for $\mathcal{Y}$ in (2.4), so we have

$$(\Theta(\mathcal{X},\mathcal{Y}^{\perp}))^{\downarrow} = \left[\frac{\pi}{2},\dots,\frac{\pi}{2},(\Theta(\mathfrak{M}_0,\mathcal{Y}^{\perp}))^{\downarrow},0,\dots,0\right],$$

where there are $\min\{\dim(\mathfrak{M}_{00});\dim(\mathfrak{M}_{11})\}$ values $\pi/2$ and $\dim(\mathfrak{M}_{01})$ zeroes. Since $\lambda$ is an eigenvalue of $(P_{\mathcal{X}}P_{\mathcal{Y}})|_{\mathfrak{M}_0}$ if and only if $1-\lambda$ is an eigenvalue of $(P_{\mathcal{X}}P_{\mathcal{Y}^{\perp}})|_{\mathfrak{M}_0}$, we have $\frac{\pi}{2}-\Theta(\mathfrak{M}_0,\mathcal{Y}^{\perp}) = (\Theta(\mathfrak{M}_0,\mathcal{Y}))^{\downarrow}$, and the latter equality turns into

$$\frac{\pi}{2}-\Theta(\mathcal{X},\mathcal{Y}^{\perp}) = \left[\frac{\pi}{2},\dots,\frac{\pi}{2},(\Theta(\mathfrak{M}_0,\mathcal{Y}))^{\downarrow},0,\dots,0\right], \tag{2.5}$$

where there are $\dim(\mathfrak{M}_{01})$ values $\pi/2$, and $\min\{\dim(\mathfrak{M}_{00});\dim(\mathfrak{M}_{11})\}$ zeroes. To obtain (2.2), we make (2.4) and (2.5) equal by adding $\max\{\dim\mathfrak{M}_{01}-\dim\mathfrak{M}_{10};0\}$ values $\pi/2$ to (2.4) and $\max\{\dim\mathfrak{M}_{00}-\dim\mathfrak{M}_{11};0\}$ zeroes to (2.5), and by noting that, since $\dim(\mathcal{X}\cap\mathcal{Y}^\perp) = \dim\mathcal{X} + \dim\mathcal{Y}^\perp - \dim(\mathcal{X}+\mathcal{Y}^\perp)$, $\mathcal{X}^\perp\cap\mathcal{Y} = (\mathcal{X}+\mathcal{Y}^\perp)^\perp$ and $\dim\mathcal{Y}^\perp - \dim((\mathcal{X}+\mathcal{Y}^\perp)^\perp) = \dim(\mathcal{X}+\mathcal{Y}^\perp) - \dim\mathcal{Y}$, we have $\dim\mathfrak{M}_{01} - \dim\mathfrak{M}_{10} = \dim(\mathcal{X}\cap\mathcal{Y}^\perp) - \dim(\mathcal{X}^\perp\cap\mathcal{Y}) = \dim\mathcal{X} + \dim\mathcal{Y}^\perp - \dim(\mathcal{X}+\mathcal{Y}^\perp) - \dim((\mathcal{X}+\mathcal{Y}^\perp)^\perp) = \dim\mathcal{X} - \dim\mathcal{Y}$.

The proof above shows that there are $\dim\mathfrak{M}_{00} = \dim(\mathcal{X}\cap\mathcal{Y})$ zeroes on the right-hand side in (2.2). To prove (2.3), we substitute $\mathcal{X}^\perp$ for $\mathcal{X}$ in (2.2) to get $\left[\frac{\pi}{2},\ldots,\frac{\pi}{2},(\Theta(\mathcal{X}^\perp,\mathcal{Y}))^\downarrow\right] = \left[\frac{\pi}{2} - \Theta(\mathcal{X}^\perp,\mathcal{Y}^\perp),0,\ldots,0\right]$ with $\dim(\mathcal{X}^\perp\cap\mathcal{Y})$ zeroes on the right, on the one hand, and exchange $\Theta(\mathcal{X},\mathcal{Y}) = \Theta(\mathcal{Y},\mathcal{X})$ in (2.2) and then substitute $\mathcal{X}^\perp$ for $\mathcal{X}$ to obtain $\left[\frac{\pi}{2},\ldots,\frac{\pi}{2},(\Theta(\mathcal{Y},\mathcal{X}^\perp))^\downarrow\right] = \left[\frac{\pi}{2} - \Theta(\mathcal{Y},\mathcal{X}),0,\ldots,0\right]$ with $\dim(\mathcal{Y}\cap\mathcal{X}^\perp)$ zeroes on the right, on the other hand. We have equal numbers of zeroes on the right in both equalities, and $\Theta(\mathcal{X}^\perp,\mathcal{Y}) = \Theta(\mathcal{Y},\mathcal{X}^\perp)$ by the symmetry of our definition (2.1), so subtracting both equalities from $\pi/2$ leads to (2.3). □

We also use the following trivial, but crucial, statement.

LEMMA 2.8. $\Lambda\left((P_\mathcal{X}P_\mathcal{Y})|_\mathcal{X}\right) = [\cos^2\Theta(\mathcal{X},\mathcal{Y}),0,\ldots,0]$, [illegible] $\max\{\dim\mathcal{X}-\dim\mathcal{Y};0\}$ [illegible]

[illegible] The operator $(P_\mathcal{X}P_\mathcal{Y})|_\mathcal{X} = \left((P_\mathcal{X}P_\mathcal{Y})(P_\mathcal{X}P_\mathcal{Y})^\star\right)|_\mathcal{X}$ is Hermitian nonnegative definite, and its spectrum can be represented using the definition of angles (2.1). The number of extra zeroes is exactly the difference between the number $\dim\mathcal{X}$ of Ritz values and the number $\min\{\dim\mathcal{X};\dim\mathcal{Y}\}$ of principal angles. □

Finally, we need the following characterization of singular values of the difference of projectors, which for $\dim\mathcal{X} = \dim\mathcal{Y}$ appears, e.g., in [38, Theorem 5.5.5, p. 43].

THEOREM 2.9.

$$[S(P_\mathcal{X} - P_\mathcal{Y}),0,\ldots,0] = [1,\ldots,1,(\sin\Theta(\mathcal{X},\mathcal{Y}),\sin\Theta(\mathcal{X},\mathcal{Y}))^\downarrow,0,\ldots,0],$$

[illegible] $|\dim\mathcal{X}-\dim\mathcal{Y}|$ [illegible] 1 [illegible] $\sin\Theta(\mathcal{X},\mathcal{Y})$ [illegible] 0 [illegible]

[illegible] The projectors $P_\mathcal{X}$ and $P_\mathcal{Y}$ are idempotent, which implies, on the one hand,

$$(P_\mathcal{X} - P_\mathcal{Y})^2 = P_\mathcal{X}(I - P_\mathcal{Y}) + P_\mathcal{Y}(I - P_\mathcal{X}) = P_\mathcal{X}P_{\mathcal{Y}^\perp} + P_\mathcal{Y}P_{\mathcal{X}^\perp},$$

so that the subspace $\mathcal{X}$ is invariant under $(P_\mathcal{X} - P_\mathcal{Y})^2$. On the other hand,

$$(P_\mathcal{X} - P_\mathcal{Y})^2 = (I - P_\mathcal{X})P_\mathcal{Y} + (I - P_\mathcal{Y})P_\mathcal{X} = P_{\mathcal{X}^\perp}P_\mathcal{Y} + P_{\mathcal{Y}^\perp}P_\mathcal{X},$$

so that the subspace $\mathcal{X}^\perp$ is also invariant under $(P_\mathcal{X} - P_\mathcal{Y})^2$. The projectors $P_\mathcal{X}$ and $P_\mathcal{Y}$ are orthogonal, and thus the operator $(P_\mathcal{X} - P_\mathcal{Y})^2$ is Hermitian, and its spectrum can be represented as a union (counting the multiplicities) of the spectra of its restrictions to the complementary invariant subspaces $\mathcal{X}$ and $\mathcal{X}^\perp$:

$$\Lambda\left((P_\mathcal{X} - P_\mathcal{Y})^2\right) = [\Lambda((P_\mathcal{X}P_{\mathcal{Y}^\perp})|_\mathcal{X}),\Lambda((P_{\mathcal{X}^\perp}P_\mathcal{Y}))|_{\mathcal{X}^\perp}]^\downarrow.$$

Using Lemma 2.8 and statement (2.2) of Theorem 2.7,

$$\begin{aligned}[\Lambda((P_\mathcal{X}P_{\mathcal{Y}^\perp})|_\mathcal{X}),0,\ldots,0] &= [\cos^2\Theta(\mathcal{X},\mathcal{Y}^\perp),0,\ldots,0]\\ &= [1,\ldots,1,(\sin^2\Theta(\mathcal{X},\mathcal{Y}))^\downarrow,0,\ldots,0],\end{aligned}$$

where there are $\max\{\dim\mathcal{X}-\dim\mathcal{Y};0\}$ leading 1's and possibly extra 0's to match the sizes, and

$$\begin{aligned}[\Lambda((P_{\mathcal{X}^\perp}P_\mathcal{Y})|_{\mathcal{X}^\perp}),0,\ldots,0] &= [\cos^2\Theta(\mathcal{X}^\perp,\mathcal{Y}),0,\ldots,0]\\ &= [1,\ldots,1,(\sin^2\Theta(\mathcal{X},\mathcal{Y}))^\downarrow,0,\ldots,0],\end{aligned}$$

where there are $\max\{\dim\mathcal{Y}-\dim\mathcal{X};0\}$ leading 1's and possibly extra 0's to match the sizes. Combining these two relations and taking the square root completes the proof. $\square$

**2.3. Extending operators to isometries and projectors.** In this subsection we present a simple and known technique (see, e.g., [12] and [35, p. 461]) for extending a Hermitian operator to a projector. We give an alternative proof based on extending an arbitrary normalized operator $B$ to an isometry $\hat{B}$ (in matrix terms, a matrix with orthonormal columns). [9, Problem X.1.26, p. 455] and [1, Problem I.3.6, p. 11] extend $B$ to a block 2-by-2 unitary operator. Our technique is similar and results in a 2-by-1 isometry operator $\hat{B}$ that coincides with the first column of the 2-by-2 unitary extension.

LEMMA 2.10. [illegible] $B:\mathcal{H}\to\mathcal{H}$ [illegible] 2 [illegible] 1 [illegible] $\hat{B}:\mathcal{H}\to\mathcal{H}^2$ [illegible] $\hat{B}$ [illegible] $B$

[illegible] $B^*B$ is Hermitian nonnegative definite, and all its eigenvalues are bounded by one, since all singular values of $B$ are bounded by one. Therefore, $I-B^*B$ is Hermitian and nonnegative definite, and thus possesses a Hermitian nonnegative definite square root. Let

$$\hat{B}=\left[\begin{array}{c} B \\ \sqrt{I-B^*B} \end{array}\right].$$

By direct calculation, $\hat{B}^*\hat{B}=B^*B+\sqrt{I-B^*B}\sqrt{I-B^*B}=I$; i.e., $\hat{B}$ is an isometry. $\square$

Now we use Lemma 2.10 to extend, in a similar sense, a shifted and normalized Hermitian operator to an orthogonal projector.

THEOREM 2.11 (see [12] and [35, p. 461]). [illegible] $A:\mathcal{H}\to\mathcal{H}$ [illegible] $[0,1]$ [illegible] 2 [illegible] 2 [illegible] $\hat{A}:\mathcal{H}^2\to\mathcal{H}^2$ [illegible] $A$

[illegible] There exists $\sqrt{A}$, which is also Hermitian and has its eigenvalues enclosed in $[0,1]$. Applying Lemma 2.10 to $B=\sqrt{A}$, we construct the isometry $\hat{B}$ and set

$$\hat{A}=\hat{B}\hat{B}^*=\left[\begin{array}{c} \sqrt{A} \\ \sqrt{I-A} \end{array}\right]\left[\begin{array}{cc} \sqrt{A} & \sqrt{I-A} \end{array}\right]=\left[\begin{array}{cc} A & \sqrt{A(I-A)} \\ \sqrt{A(I-A)} & I-A \end{array}\right].$$

We see that indeed the upper left block is equal to $A$. We can use the fact that $\hat{B}$ is an isometry to show that $\hat{A}$ is an orthogonal projector, or that can be checked directly by calculating $\hat{A}^2=\hat{A}$ and noticing that $\hat{A}$ is Hermitian by construction. $\square$

Introducing $S=\sqrt{A}$ and $C=\sqrt{I-A}$, we obtain

$$\hat{A}=\left[\begin{array}{cc} S^2 & SC \\ SC & C^2 \end{array}\right],$$

which is a well-known (see, e.g., [13], [6]) block form of an orthogonal projector that can alternatively be derived using the CS decomposition of unitary operators; see, e.g., [37], [38], [1].

The importance of Theorem 2.11 can be better seen if we reformulate it as follows.

THEOREM 2.12 (cf. [9, Example X.27, p. s455]). [illegible] $A:\mathcal{H}\to\mathcal{H}$ [illegible] $[0,1]$ [illegible] $\mathcal{X}$ [illegible] $\mathcal{Y}$ [illegible] $\mathcal{H}^2$ [illegible] $A$ [illegible] $(P_{\mathcal{X}}P_{\mathcal{Y}})|_{\mathcal{X}}$ [illegible] $P_{\mathcal{X}}$ [illegible] $P_{\mathcal{Y}}$ [illegible] $\mathcal{H}^2$ [illegible] $|_{\mathcal{X}}$ [illegible] $\mathcal{X}$

[illegible]. We use Theorem 2.11 and take $P_{\mathcal{Y}} = \hat{A}$ and $P_{\mathcal{X}} = \left[\begin{smallmatrix} I & 0 \\ 0 & 0 \end{smallmatrix}\right]$. ☐

Similar to Theorem 2.12, Lemma 2.10 implicitly states that an arbitrary normalized operator $B$ is unitarily equivalent to a product of the partial isometry $\hat{B}$ in $\mathcal{H}^2$ and the orthogonal projector in $\mathcal{H}^2$ that selects the upper block in $\hat{B}$ (called $P_{\mathcal{X}}$ in the proof of Theorem 2.12). It is instructive to compare this product to the classical polar decomposition of $B$ that is a product of a partial isometry and a Hermitian nonnegative definite operator in $\mathcal{H}$. In $\mathcal{H}^2$, we can choose the second factor to be an orthogonal projector! This statement together with Theorem 2.12 can provide interesting canonical decompositions in $\mathcal{H}^2$ that apparently are not exploited at present, but in our opinion deserve attention.

We take advantage of Theorem 2.12 in the present paper. Using Lemma 2.8 with (2.1), Theorem 2.12 implies that [illegible]. This surprising idea appears to be very powerful. It allows us, in section 4, to obtain a novel result on the sensitivity of Ritz values with respect to the trial subspace by reducing the investigation of the Rayleigh–Ritz method to the analysis of the principal angles between subspaces that we provide in the next section.

## 3. Majorization for angles.

In this section we prove the main results of the present paper involving sines and cosines and their squares of principal angles, but we start with a known statement that involves the principal angles themselves.

THEOREM 3.1 (see [34, Theorem 3.2, p. 514]). [illegible] $\mathcal{X}$ $\mathcal{Y}$ [illegible] $\mathcal{Z}$ [illegible]

$$|\Theta(\mathcal{X}, \mathcal{Z}) - \Theta(\mathcal{Y}, \mathcal{Z})| \prec_w \Theta(\mathcal{X}, \mathcal{Y}). \tag{3.1}$$

Theorem 3.1 deals with the principal angles themselves, and the obvious question is: Are there similar results for a function of these angles, in particular for sines and cosines and their squares? For one dimensional subspaces, estimate (3.1) turns into (1.1), which, as discussed in the Introduction, implies the estimate (1.2) for the sine. According to an anonymous referee, it appears to be known to some specialists that the same inference can be made for tuples of angles, but there is no good reference for this at present. Below we give easy direct proofs in a unified way for the sines and cosines and their squares.

We first prove the estimates for sine and cosine, which are straightforward generalizations of the 1D sine (1.2) and cosine (1.3) inequalities from the Introduction.

THEOREM 3.2. [illegible] $\dim\mathcal{X} = \dim\mathcal{Y}$. [illegible]

$$|\sin\Theta(\mathcal{X}, \mathcal{Z}) - \sin\Theta(\mathcal{Y}, \mathcal{Z})| \prec_w \sin\Theta(\mathcal{X}, \mathcal{Y}), \tag{3.2}$$

$$|\cos\Theta(\mathcal{X}, \mathcal{Z}) - \cos\Theta(\mathcal{Y}, \mathcal{Z})| \prec_w \sin\Theta(\mathcal{X}, \mathcal{Y}). \tag{3.3}$$

[illegible]. Let $P_{\mathcal{X}}$, $P_{\mathcal{Y}}$, and $P_{\mathcal{Z}}$ be the corresponding orthogonal projectors onto the subspaces $\mathcal{X}$, $\mathcal{Y}$, and $\mathcal{Z}$, respectively. We prove the sine estimate (3.2), using the idea of [33]. Starting with $(P_{\mathcal{X}} - P_{\mathcal{Z}}) - (P_{\mathcal{Y}} - P_{\mathcal{Z}}) = P_{\mathcal{X}} - P_{\mathcal{Y}}$, as in the proof of the 1D sine estimate (1.2), we use Corollary 2.4 to obtain

$$|S(P_{\mathcal{X}} - P_{\mathcal{Z}}) - S(P_{\mathcal{Y}} - P_{\mathcal{Z}})| \prec_w S(P_{\mathcal{X}} - P_{\mathcal{Y}}).$$

The singular values of the difference of two orthoprojectors are described by Theorem 2.9. Since $\dim\mathcal{X} = \dim\mathcal{Y}$, we have the same number of extra 1's up front in $S(P_{\mathcal{X}} - P_{\mathcal{Z}})$

and in $S(P_{\mathcal{Y}}-P_{\mathcal{Z}})$, so that the extra 1's are canceled and the set of nonzero entries of $|S(P_{\mathcal{X}}-P_{\mathcal{Z}})-S(P_{\mathcal{Y}}-P_{\mathcal{Z}})|$ consists of nonzero entries of $|\sin\Theta(\mathcal{X},\mathcal{Z})-\sin\Theta(\mathcal{Y},\mathcal{Z})|$ repeated twice. The nonzero entries of $S(P_{\mathcal{X}}-P_{\mathcal{Y}})$ are by Theorem 2.9 the nonzero entries of $\sin\Theta(\mathcal{X},\mathcal{Y})$ also repeated twice, and thus we come to (3.2).

The cosine estimate (3.3) follows directly from the sine estimate (3.2) with $\mathcal{Z}^{\perp}$ instead of $\mathcal{Z}$ because of (2.2), and utilizing the assumption $\dim\mathcal{X}=\dim\mathcal{Y}$. □

In our earlier paper [18, Lemma 5.1, p. 2023 and Lemma 5.2, p. 2025] we obtained a particular case of Theorem 3.2, only for the largest change in the sine and the cosine, but with improved constants. We are not presently able, however, to modify the proofs of [18] using weak majorization, in order to improve the estimates of Theorem 3.2 by introducing these same constants.

Our last, but not least, result in this series is the weak majorization bound for the sines or cosines squared, which provides the foundation for the rest of the paper.

THEOREM 3.3. $\dim\mathcal{X}=\dim\mathcal{Y}$.

$$|\cos^2\Theta(\mathcal{X},\mathcal{Z})-\cos^2\Theta(\mathcal{Y},\mathcal{Z})|=|\sin^2\Theta(\mathcal{X},\mathcal{Z})-\sin^2\Theta(\mathcal{Y},\mathcal{Z})|\prec_w\sin\Theta(\mathcal{X},\mathcal{Y}).$$

The equality is evident. To prove the majorization result for the sines squared, we start with the useful pinching identity

$$(P_{\mathcal{X}}-P_{\mathcal{Z}})^2-(P_{\mathcal{Y}}-P_{\mathcal{Z}})^2=P_{\mathcal{Z}^{\perp}}(P_{\mathcal{X}}-P_{\mathcal{Y}})P_{\mathcal{Z}^{\perp}}-P_{\mathcal{Z}}(P_{\mathcal{X}}-P_{\mathcal{Y}})P_{\mathcal{Z}}.$$

Applying Corollary 2.4, we obtain

$$\left|S\left((P_{\mathcal{X}}-P_{\mathcal{Z}})^2\right)-S\left((P_{\mathcal{Y}}-P_{\mathcal{Z}})^2\right)\right|\prec_w S\left(P_{\mathcal{Z}^{\perp}}(P_{\mathcal{X}}-P_{\mathcal{Y}})P_{\mathcal{Z}^{\perp}}-P_{\mathcal{Z}}(P_{\mathcal{X}}-P_{\mathcal{Y}})P_{\mathcal{Z}}\right).$$

For the left-hand side we use Theorem 2.9, as in the proof of Theorem 3.2, except that we are now working with the squares. For the right-hand side, the pinching Theorem 2.6 gives

$$S\left(P_{\mathcal{Z}^{\perp}}(P_{\mathcal{X}}-P_{\mathcal{Y}})P_{\mathcal{Z}^{\perp}}-P_{\mathcal{Z}}(P_{\mathcal{X}}-P_{\mathcal{Y}})P_{\mathcal{Z}}\right)\prec_w S\left(P_{\mathcal{X}}-P_{\mathcal{Y}}\right),$$

and we use Theorem 2.9 again to characterize $S\left(P_{\mathcal{X}}-P_{\mathcal{Y}}\right)$, as in the proof of Theorem 3.2. □

**4. Changes in the trial subspace in the Rayleigh–Ritz method.** In this section, we explore a simple, but deep, connection between the principal angles and the Rayleigh–Ritz method that we discuss in the Introduction. We demonstrate that the analysis of the influence of changes in a trial subspace in the Rayleigh–Ritz method is a natural extension of the theory concerning principal angles and the proximity of two subspaces developed in the previous section.

For the reader's convenience, let us repeat here the definition of Ritz values from the Introduction: Let $A:\mathcal{H}\to\mathcal{H}$ be a Hermitian operator and $P_{\mathcal{X}}$ be an orthogonal projector to a subspace $\mathcal{X}$ of $\mathcal{H}$. The eigenvalues $\Lambda(P_{\mathcal{X}}A|_{\mathcal{X}})$ are the Ritz values of operator $A$ with respect to $\mathcal{X}$, which is called the trial subspace.

Let $\mathcal{X}$ and $\mathcal{Y}$ both be subspaces of $\mathcal{H}$ and $\dim\mathcal{X}=\dim\mathcal{Y}$. The goal of this section is to analyze the sensitivity of Ritz values with respect to the trial subspaces, specifically to bound the change $|\Lambda\left(P_{\mathcal{X}}A|_{\mathcal{X}}\right)-\Lambda\left(P_{\mathcal{Y}}A|_{\mathcal{Y}}\right)|$ in terms of $\sin\Theta(\mathcal{X},\mathcal{Y})$ using weak majorization. Such an estimate is already obtained in Theorem 10 of our earlier paper [19] by applying Corollary 2.5 to the matrices of $P_{\mathcal{X}}A|_{\mathcal{X}}$ and $P_{\mathcal{Y}}A|_{\mathcal{Y}}$. This approach, however, leads to an extra factor $\sqrt{2}$ on the right-hand side, which is conjectured in [19] to be artificial.

We remove this $\sqrt{2}$ factor in our new Theorem 4.2 by using the entirely different and novel approach: We connect the Ritz values with extension Theorems 2.11 and 2.12, on the one hand, and with the cosine squared of principal angles in Lemma 2.8, on the other hand. We have shown in Theorem 2.11 that a Hermitian nonnegative definite contraction operator can be extended to an orthogonal projector in a larger space. The extension has an extra nice property: It preserves the Ritz values.

Corollary 4.1. [illegible] 2.11 [illegible] $A : \mathcal{H} \to \mathcal{H}$ [illegible] $\mathcal{X} \subset H$ [illegible] $\hat{A} : \mathcal{H}^2 \to \mathcal{H}^2$ [illegible]

$$\hat{\mathcal{X}} = \begin{bmatrix} \mathcal{X} \\ 0 \end{bmatrix} \subset \hat{\mathcal{H}} = \begin{bmatrix} \mathcal{H} \\ 0 \end{bmatrix} \subset \mathcal{H}^2.$$

[illegible] Let $P_{\hat{\mathcal{H}}} : \mathcal{H}^2 \to \mathcal{H}^2$ be an orthogonal projector on the subspace $\hat{\mathcal{H}}$ and $P_{\hat{\mathcal{X}}} : \mathcal{H}^2 \to \mathcal{H}^2$ be an orthogonal projector on the subspace $\hat{\mathcal{X}}$. We use the equality sign to denote the trivial isomorphism between $\mathcal{H}$ and $\hat{\mathcal{H}}$; i.e., we simply write $\mathcal{H} = \hat{\mathcal{H}}$ and $\mathcal{X} = \hat{\mathcal{X}}$.

In this notation, we first observe that $A = P_{\hat{\mathcal{H}}} \hat{A}|_{\hat{\mathcal{H}}}$; i.e., the operator $A$ itself can be viewed as a result of the Rayleigh–Ritz method applied to the operator $\hat{A}$ in the trial subspace $\hat{\mathcal{H}}$. Second, we use the fact that a recursive application of the Rayleigh–Ritz method on a system of enclosed trial subspaces is equivalent to a direct single application of the Rayleigh–Ritz method to the smallest trial subspace; indeed, in our notation, $P_{\hat{\mathcal{H}}} P_{\hat{\mathcal{X}}} = P_{\hat{\mathcal{X}}} P_{\hat{\mathcal{H}}} = P_{\hat{\mathcal{X}}}$, since $\hat{\mathcal{X}} \subset \hat{\mathcal{H}}$, and thus

$$P_{\mathcal{X}} A|_{\mathcal{X}} = \left( P_{\hat{\mathcal{X}}} P_{\hat{\mathcal{H}}} \hat{A}|_{\hat{\mathcal{H}}} \right) \Big|_{\hat{\mathcal{X}}} = P_{\hat{\mathcal{X}}} \hat{A}|_{\hat{\mathcal{X}}}. \qquad \square$$

Next we note that Lemma 2.8 states that the Rayleigh–Ritz method applied to an orthogonal projector produces Ritz values, which are essentially the cosines squared of the principal angles between the range of the projector and the trial subspace. For the reader's convenience we reformulate Lemma 2.8 here: Let the Rayleigh–Ritz method be applied to $A = P_{\mathcal{Z}}$, where $P_{\mathcal{Z}}$ is an orthogonal projector onto a subspace $\mathcal{Z}$, and let $\mathcal{X}$ be the trial subspace in the Rayleigh–Ritz method; then the set of the Ritz values is $\Lambda\left(P_{\mathcal{X}} P_{\mathcal{Z}}|_{\mathcal{X}}\right) = [\cos^2 \Theta(\mathcal{X}, \mathcal{Z}), 0, \ldots, 0]$ with $\max\{\dim\mathcal{X} - \dim\mathcal{Z}; 0\}$ extra zeroes.

Now we are ready to direct our attention to the main topic of this section: the influence of changes in a trial subspace in the Rayleigh–Ritz method on the Ritz values.

Theorem 4.2. [illegible] $A : \mathcal{H} \to \mathcal{H}$ [illegible] $\mathcal{X}$ [illegible] $\mathcal{Y}$ [illegible] $\mathcal{H}$ [illegible] $\dim\mathcal{X} = \dim\mathcal{Y}$ [illegible]

$$|\Lambda\left(P_{\mathcal{X}} A|_{\mathcal{X}}\right) - \Lambda\left(P_{\mathcal{Y}} A|_{\mathcal{Y}}\right)| \prec_w (\lambda_{\max} - \lambda_{\min}) \; \sin\Theta(\mathcal{X}, \mathcal{Y}), \tag{4.1}$$

[illegible] $\lambda_{\min}$ [illegible] $\lambda_{\max}$ [illegible] $A$ [illegible]

[illegible] We prove Theorem 4.2 in two steps. First we show that we can assume that $A$ is a nonnegative definite contraction without losing generality. Second, under these assumptions, we extend the operator $A$ to an orthogonal projector by Theorem 2.11 and use the facts that such an extension does not affect the Ritz values by Corollary 4.1 and that the Ritz values of an orthogonal projector can be interpreted as the cosines squared of principal angles between subspaces by Lemma 2.8, thus reducing the problem to the already established result on weak majorization of the cosine squared Theorem 3.3.

We observe that the statement of the theorem is invariant with respect to a shift and a scaling; indeed, for real $\alpha$ and $\beta$ if the operator $A$ is replaced with $\beta(A-\alpha)$ and $\lambda_{\min}$ and $\lambda_{\max}$ are correspondingly updated, both sides of (4.1) are just multiplied by $\beta$, and (4.1) is thus invariant with respect to $\alpha$ and $\beta$. Choosing $\alpha = \lambda_{\min}$ and $\beta = 1/(\lambda_{\max}-\lambda_{\min})$, the transformed operator $(A-\lambda_{\min})/(\lambda_{\max}-\lambda_{\min})$ is Hermitian with its eigenvalues enclosed in a segment $[0,1]$, and thus the statement (4.1) of the theorem can be equivalently rewritten as

$$|\Lambda\left(P_{\mathcal{X}}A|_{\mathcal{X}}\right) - \Lambda\left(P_{\mathcal{Y}}A|_{\mathcal{Y}}\right)| \prec_w \sin\Theta(\mathcal{X},\mathcal{Y}), \tag{4.2}$$

where we from now on assume that $A$ is a nonnegative definite contraction without losing generality.

The second step of the proof is to recast the problem into an equivalent problem for an orthogonal projector with the same Ritz values and principal angles. By Theorem 2.11 we can extend the nonnegative definite contraction $A$ to an orthogonal projector $P_{\hat{\mathcal{Z}}}$, where $\hat{\mathcal{Z}}$ is a subspace of $\mathcal{H}^2$. $P_{\hat{\mathcal{Z}}}$ has by Corollary 4.1 the same Ritz values with respect to trial subspaces,

$$\hat{\mathcal{X}} = \begin{bmatrix} \mathcal{X} \\ 0 \end{bmatrix} \subset \hat{\mathcal{H}} = \begin{bmatrix} \mathcal{H} \\ 0 \end{bmatrix} \subset \mathcal{H}^2 \quad \text{and} \quad \hat{\mathcal{Y}} = \begin{bmatrix} \mathcal{Y} \\ 0 \end{bmatrix} \subset \hat{\mathcal{H}} = \begin{bmatrix} \mathcal{H} \\ 0 \end{bmatrix} \subset \mathcal{H}^2,$$

as $A$ has with respect to the trial subspaces $\mathcal{X}$ and $\mathcal{Y}$. By Lemma 2.8, these Ritz values are equal to the cosines squared of the principal angles between $\hat{\mathcal{Z}}$ and the trial subspace $\hat{\mathcal{X}}$ or $\hat{\mathcal{Y}}$, possibly with the same number of zeroes being added. Moreover, the principal angles between $\hat{\mathcal{X}}$ and $\hat{\mathcal{Y}}$ in $\mathcal{H}^2$ are clearly the same as those between $\mathcal{X}$ and $\mathcal{Y}$ in $\mathcal{H}$ and $\dim\hat{\mathcal{X}} = \dim\mathcal{X} = \dim\mathcal{Y} = \dim\hat{\mathcal{Y}}$. Thus, (4.2) can be equivalently reformulated as

$$|\cos^2\Theta(\hat{\mathcal{X}},\hat{\mathcal{Z}}) - \cos^2\Theta(\hat{\mathcal{Y}},\hat{\mathcal{Z}})| \prec_w \sin\Theta(\hat{\mathcal{X}},\hat{\mathcal{Y}}). \tag{4.3}$$

Finally, we notice that (4.3) is already proved in Theorem 3.3. □

REMARK 4.1. [illegible] [19, Remark 7], [illegible] $\lambda_{\max}-\lambda_{\min}$ [illegible] 4.2 [illegible]

$$\max_{x\in\mathcal{X}+\mathcal{Y},\, \|x\|=1}(x,Ax) - \min_{x\in\mathcal{X}+\mathcal{Y},\, \|x\|=1}(x,Ax),$$

[illegible] $\mathcal{X}$ [illegible] $\mathcal{Y}$ [illegible]

REMARK 4.2. [illegible] 4.2 [illegible] $m = \dim\mathcal{X} = \dim\mathcal{Y}$ [illegible] $\alpha_1 \geq \cdots \geq \alpha_m$ [illegible] $A$ [illegible] $\mathcal{X}$ [illegible] $\beta_1 \geq \cdots \geq \beta_m$ [illegible] $A$ [illegible] $\mathcal{Y}$ [illegible] 4.2 [illegible]

$$\sum_{i=1}^{k} |\alpha_i - \beta_i|^{\downarrow} \leq (\lambda_{\max}-\lambda_{\min}) \sum_{i=1}^{k} \sin(\Theta_i(\mathcal{X},\mathcal{Y}))^{\downarrow}, \qquad k = 1,\ldots,m;$$

[illegible] $k = m$ [illegible]

$$\sum_{i=1}^{m} |\alpha_i - \beta_i| \leq (\lambda_{\max}-\lambda_{\min}) \sum_{i=1}^{m} \sin(\Theta_i(\mathcal{X},\mathcal{Y})), \tag{4.4}$$

[illegible] $k = 1$ [illegible]

$$\max_{j=1,\dots,m} |\alpha_j - \beta_j| \le (\lambda_{\max} - \lambda_{\min})\operatorname{gap}(\mathcal{X}, \mathcal{Y}), \tag{4.5}$$

[illegible] $\operatorname{gap}(\mathcal{X}, \mathcal{Y})$ [illegible] $\mathcal{X}$ [illegible] $\mathcal{Y}$ [illegible] $\mathcal{X}$ [illegible] $\mathcal{Y}$ [illegible] (4.5) [illegible] [19, Theorem 5].

[illegible] $x$ [illegible] $y$ [illegible] $x \prec_w y$ [illegible] $\sum_{i=1}^n \phi(x_i) \le \sum_{i=1}^n \phi(y_i)$ [illegible] $\phi$ [illegible] [24, Proposition 4.B.2., p. 109]. [illegible] $\phi(t) = t^p$ [illegible] $p \ge 1$ [illegible] 4.2 [illegible]

$$\left(\sum_{i=1}^m |\alpha_i - \beta_i|^p\right)^{\frac{1}{p}} \le (\lambda_{\max} - \lambda_{\min}) \left(\sum_{i=1}^m \sin(\Theta_i(\mathcal{X}, \mathcal{Y}))^p\right)^{\frac{1}{p}}, \quad 1 \le p < \infty.$$

We finally note that the results of Theorem 4.2 are not intended for the case where one of the subspaces $\mathcal{X}$ or $\mathcal{Y}$ is invariant with respect to operator $A$. In such a case, it is natural to expect a much better bound that involves the square of the $\sin\Theta(\mathcal{X}, \mathcal{Y})$. Majorization results of this kind are not apparently known in the literature. Without majorization, estimates are available just for the largest change in the Ritz values; e.g., see [19], [21].

## 5. Application of the majorization results to graph spectra comparison.

In this section, we show that our majorization results can be applied to compare graph spectra. The graph spectra comparison can be used for graph matching and has applications in data mining; cf. [23].

The section is divided into three subsections. In subsection 5.1, we give all necessary definitions and basic facts concerning Laplacian graph spectra. In subsection 5.2, we connect the Laplacian graph spectrum and Ritz values, by introducing the graph edge Laplacian. Finally, in subsection 5.3, we prove our main result on the Laplacian graph spectra comparison.

### 5.1. Incidence matrices and graph Laplacians.

Here, we give mostly well-known relevant definitions (see, e.g., [5], [4], [26], [27], [28], [29]), just slightly tailored for our specific needs.

Let $V$ be a finite ordered set (of vertices), with an individual element (vertex) denoted by $v_i \in V$. Let $E_c$ be the finite ordered set (of all edges), with an individual element (edge) denoted by $e_k \in E_c$ such that every $e_k = [v_i, v_j]$ for all possible $i > j$. $E_c$ can be viewed as the set of edges of a complete simple graph with vertices $V$ (without self-loops and/or multiple edges). The results of the present paper are invariant with respect to specific ordering of vertices and edges.

Let $w_c : E_c \to \mathbf{R}$ be a function describing edge weights, i.e., $w_c(e_k) \in \mathbf{R}$. If for some edge $e_k$ the weight is positive, $w_c(e_k) > 0$, we call this edge present; if $w_c(e_k) = 0$, we say that the edge is absent. In this paper we do not allow negative edge weights. For a given weight function $w_c$, we define $E \subseteq E_c$ such that $e_k \in E$ if $w_c(e_k) \neq 0$, and we define $w$ to be the restriction of $w_c$ on all present edges $E$; i.e., $w$ is made of all nonzero values of $w_c$. A pair of sets of vertices $V$ and present edges $E$ with weights $w$ is called a graph $(V, E)$ or a weighted graph $(V, E, w)$.

The vertex-edge incidence matrix $Q_c$ of a complete graph $(V, E_c)$ is a matrix which has a row for each vertex and a column for each edge, with columnwise entries determined as $q_{ik} = 1$, $q_{jk} = -1$ for every edge $e_k = [v_i, v_j]$, $i > j$, in $E_c$ and with all other entries of $Q_c$ equal to zero. The vertex-edge incidence matrix $Q$ of a graph

$(V, E)$ is determined in the same way, but only for the edges present in $E$. The vertex-edge incidence matrix can be viewed as a matrix representation of a graph analogue of the divergence operator from partial differential equations (PDE).

Extending the PDE analogy, the matrix $L = QQ^*$ is called the graph Laplacian. In the PDE context, this definition corresponds to the negative Laplacian with the natural boundary conditions; cf. [25]. Let us note that in the graph theory literature such a definition of the graph Laplacian is usually attributed to directed graphs, even though reversing any edge direction does not affect the graph Laplacian.

If we want to take into account the weights, we can work with the matrix $Q \operatorname{diag}(w(E))Q^*$, which is an analogue of an isotropic diffusion operator, or we can introduce a more general edge matrix $W$ and work with $QWQ^*$, which corresponds to a general anisotropic diffusion. It is interesting to notice the equality

$$Q_c \operatorname{diag}(w_c(E_c))Q_c^* = Q \operatorname{diag}(w(E))Q^*, \tag{5.1}$$

which shows two alternative equivalent formulas for the graph diffusion operator.

For simplicity of presentation, we assume in the rest of the paper that the weights $w_c$ take only the values zero and one. Under this assumption, we introduce the matrix $P = \operatorname{diag}(w_c(E_c))$ and notice that $P$ is the matrix of an orthogonal projector on a subspace spanned by coordinate vectors with indices corresponding to the indices of edges present in $E$, and that equality (5.1) turns into

$$Q_c P Q_c^* = QQ^* = L. \tag{5.2}$$

Let us note that our results can be easily extended to a more general case of arbitrary nonnegative weights, or even to the case of the edge matrix $W$, assuming that it is symmetric nonnegative definite, $W = W^* \geq 0$.

Fiedler's pioneering work [8] on using the eigenpairs of the graph Laplacian to determine some structural properties of the graph has attracted much attention in the past. Recent advances in large-scale eigenvalue computations using multilevel preconditioning (e.g., [17], [20], [22]) suggest novel efficient numerical methods to compute the Fiedler vector and may rejuvenate this classical approach, e.g., for graph partitioning. In this paper, we concentrate on the whole set of eigenvalues of $L$, which is called the Laplacian graph spectrum.

It is known that the Laplacian graph spectrum does not determine the graph uniquely, i.e., that there exist isospectral graphs; see, e.g., [39] and references there. However, intuition suggests that a small change in a large graph should not change the Laplacian graph spectrum very much, and attempts have been made to use the closeness of Laplacian graph spectra to judge the closeness of the graphs in applications; for alternative approaches, see [2]. The goal of this section is to back up this intuition with rigorous estimates for proximity of the Laplacian graph spectra.

**5.2. Laplacian graph spectrum and Ritz values.** In the previous section, we obtained in Theorem 4.2 a weak majorization bound for changes in Ritz values depending on a change in the trial subspace, which we would like to apply to analyze the graph spectrum. In this subsection, we present an approach that allows us to interpret the Laplacian graph spectrum as a set of Ritz values obtained by the Rayleigh–Ritz method applied to the complete graph.

A graph $(V, E)$ can evidently be obtained from the complete graph $(V, E_c)$ by removing edges; moreover, as we already discussed, we can construct the $(V, E)$ graph Laplacian by either of the terms in equality (5.2). The problem is that such a construction cannot be recast as an application of the Rayleigh–Ritz method, since the multiplication by the projector $P$ takes place inside of the product in (5.2), not outside, as required by the Rayleigh–Ritz method.

To resolve this difficulty, we use the matrix $K = Q^*Q$, which is sometimes called the matrix of the graph [illegible] Laplacian, instead of the matrix of the graph [illegible] Laplacian $L = QQ^*$, as both matrices $K$ and $L$ share the same nonzero eigenvalues. The advantage of the edge Laplacian $K$ is that it can be obtained from the edge Laplacian of the complete graph $Q_c^*Q_c$ simply by removing the rows and columns that correspond to missing edges. Mathematically, this procedure can be viewed as an instance of the classical Rayleigh–Ritz method, as follows.

LEMMA 5.1. [illegible] $w_c$ [illegible] $P = \mathrm{diag}(w_c(E_c))$ [illegible] $E$ [illegible] $Q^*Q = (PQ_c^*Q_c)|_{\mathrm{Range}(P)}$. [illegible] $Q^*Q$ [illegible] $Q_c^*Q_c$ [illegible] $\mathrm{Range}(P)$

The application of the Rayleigh–Ritz method in this case is reduced to simply crossing out rows and columns of the matrix $Q_c^*Q_c$ corresponding to absent edges, since $P$ projects onto a span of coordinate vectors with the indices of the present edges.

Lemma 5.1 is a standard tool in spectral graph theory (see, e.g., [11]) for proving that the eigenvalues are interlacing; however, the procedure is not apparently recognized in the spectral graph community as an instance of the classical Rayleigh–Ritz method. Lemma 5.1 provides us with the missing link in order to apply our Theorem 4.2 to Laplacian graph spectra comparison.

**5.3. Majorization of Ritz values for Laplacian graph spectra comparison.** Using the tools that we have presented in the previous subsections, we can now apply the particular case, (4.4), of our weak majorization result of section 4 to analyze the change in the graph spectrum when several edges are added to or removed from the graph.

THEOREM 5.2. [illegible] $(V, E^1)$ [illegible] $(V, E^2)$ [illegible] $n$ [illegible] $V$ [illegible] $n_e$ [illegible] $E^1$ [illegible] $E^2$, [illegible] $E^1$ [illegible] $E^2$ [illegible] $l$ [illegible]

$$\sum_{k=1}^{n} |\lambda_k^1 - \lambda_k^2| \leq nl, \tag{5.3}$$

[illegible] $\lambda_k^1$ [illegible] $\lambda_k^2$ [illegible] $(V, E^1)$ [illegible] $(V, E^2)$ [illegible]

[illegible] The spectra of the graph vertex $n \times n$ Laplacian $QQ^*$ and the graph edge $n_e \times n_e$ Laplacian $Q^*Q$ are the same apart from zero, which does not affect the statement of the theorem, so we redefine $\lambda_k^1$ and $\lambda_k^2$ as elements of the spectra, counting the multiplicities, of the edge Laplacians of the graphs $(V, E^1)$ and $(V, E^2)$. Then, by Theorem 5.1, $\lambda_k^1$ and $\lambda_k^2$ are the Ritz values of the edge Laplacian matrix $A = Q_c^*Q_c$ of the complete graph, corresponding to the trial subspaces $\mathcal{X} = \mathrm{Range}(P_1)$ and $\mathcal{Y} = \mathrm{Range}(P_2)$ spanned by coordinate vectors with indices of the edges present in $E^1$ and $E^2$, respectively.

Let us apply Theorem 4.2, taking the sum over all available nonzero values in the weak majorization statement as in (4.4). This already gives us the left-hand side of (5.3). To obtain the right-hand side of (5.3) from Theorem 4.2, we now show in our case that, first, $\lambda_{\max} - \lambda_{\min} = n$ and, second, the sum of sines of all angles between the trial subspaces $\mathcal{X}$ and $\mathcal{Y}$ is equal to $l$.

The first claim follows from the fact, which is easy to check by direct calculation, that the spectrum of the vertex (and thus the edge) Laplacian of the complete graph with $n$ vertices consists of only two eigenvalues $\lambda_{\max} = n$ and $\lambda_{\min} = 0$. Let us make a side note that we can interpret the Laplacian of the complete graph as a scaled projector; i.e., in this case we could have applied Theorem 3.3 directly, rather than Theorem 4.2, which would still result in (5.3).

The second claim, on the sum of sines of all angles, follows from the definitions of $\mathcal{X}$ and $\mathcal{Y}$ and the assumption that the number of differing edges in $E^1$ and $E^2$ is equal to $l$. Indeed, $\mathcal{X}$ and $\mathcal{Y}$ are spanned by coordinate vectors with indices of the edges present in $E^1$ and $E^2$. The edges that are present in both $E^1$ and $E^2$ contribute zero angles into $\Theta(\mathcal{X}, \mathcal{Y})$, while the $l$ edges that are different in $E^1$ and $E^2$ contribute $l$ right angles into $\Theta(\mathcal{X}, \mathcal{Y})$, so that the sum of all terms in $\sin \Theta(\mathcal{X}, \mathcal{Y})$ is equal to $l$. $\square$

Remark 4.1 is also applicable for Theorem 5.2—while the min term is always zero, since all graph Laplacians are degenerate, the max term can be made smaller by replacing $n$ with the largest eigenvalue of the Laplacian of the graph $(V, E^1 \cup E^2)$.

It is clear from the proof that we do not use the full force of our weak majorization results in Theorem 5.2, because it concerns angles which are zero or $\pi/2$. Nevertheless, the results of Theorem 5.2 appear to be novel in graph theory. We note that these results can easily be extended on [illegible]-partite graphs, and possibly to mixed graphs.

Let us finally mention an alternative approach to compare Laplacian graph spectra, which we do not cover in the present paper, by applying Corollary 2.5 directly to graph Laplacians and estimating the right-hand side, using the fact that the changes in $l$ edges represent a low-rank perturbation of the graph Laplacian; cf. [36].

## 6. Conclusions.

We use majorization to investigate the sensitivity of angles between subspaces and Ritz values with respect to subspaces, and to analyze changes in graph Laplacian spectra where edges are added and removed. We discover that these seemingly different areas are all surprisingly related. We establish in a unified way new results on weak majorization of the changes in the sine/cosine (squared) and in the Ritz values. The main strength of the paper in our opinion is, however, not so much in the results themselves but rather in a novel and elegant proof technique that is based on a classical but rarely used idea of extending Hermitian operators to orthogonal projectors in a larger space. We believe that this technique is very powerful and should be known to a wider audience.

**Acknowledgments.** We are indebted to Li Qiu and Yanxia Zhang, who suggested to us the idea of the proof of the sine estimate in Theorem 3.2, which also allowed us to simplify our original proof of Theorem 3.3. We also thank our Ph.D. students Ilya Lashuk, for contributing to section 2.3, and Abram Jujunashvili, for many helpful comments. Finally, we thank the anonymous referees for their numerous useful and illuminating suggestions, which dramatically improved the paper.

# SOLUTIONS OF THE PARTIALLY DESCRIBED INVERSE QUADRATIC EIGENVALUE PROBLEM*

YUEN-CHENG KUO[†], WEN-WEI LIN[‡], AND SHU-FANG XU[§]

**Abstract.** Given $k$ pairs of complex numbers and vectors (closed under conjugation), we consider the inverse quadratic eigenvalue problem of constructing $n \times n$ real symmetric matrices $M$, $C$, and $K$ (with $M$ positive definite) so that the quadratic pencil $Q(\lambda) \equiv \lambda^2 M + \lambda C + K$ has the given $k$ pairs as eigenpairs. Using various matrix decompositions, we first construct a general solution to this problem with $k \leq n$. Then, with appropriate choices of degrees of freedom in the general solution, we construct several particular solutions with additional eigeninformation or special properties. Numerical results illustrating these solutions are also presented.

**Key words.** quadratic eigenvalue problem, inverse eigenvalue problem, partially prescribed spectrum, partial eigenstructure assignment

**AMS subject classifications.** 65F15, 15A22, 65H17, 93B55

**DOI.** 10.1137/05064134X

## 1. Introduction.

This paper first constructs a general symmetric quadratic pencil

$$Q(\lambda) \equiv \lambda^2 M + \lambda C + K \tag{1.1}$$

with $M^\top = M > 0$ (being symmetric positive definite), $C^\top = C$, and $K^\top = K \in \mathbb{R}^{n\times n}$, so that $Q(\lambda)$ has $k$ given pairs of complex numbers and vectors, closed under conjugation, as its eigenpairs. Then, under appropriate choices of degrees of freedom in the general solution, we construct several particular solutions with additional eigeninformation or special properties. Here, we formulate our partially described inverse quadratic eigenvalue problem.

PD-IQEP (partially described inverse quadratic eigenvalue problem). [illegible] $(\Lambda, X) \in \mathbb{R}^{k\times k} \times \mathbb{R}^{n\times k}$ $(k \leq n)$ [illegible]

$$\Lambda = \operatorname{diag}\{\lambda_1^{[2]}, \ldots, \lambda_\ell^{[2]}; \lambda_{2\ell+1}, \ldots, \lambda_k\} \tag{1.2a}$$

[illegible]

$$\lambda_j^{[2]} = \begin{bmatrix} \alpha_j & \beta_j \\ -\beta_j & \alpha_j \end{bmatrix} \in \mathbb{R}^{2\times 2}, \quad \beta_j \neq 0, \quad [illegible] \quad j = 1, \ldots, \ell, \tag{1.2b}$$

[illegible]

$$X = [\mathbf{x}_{1R}, \mathbf{x}_{1I}, \ldots, \mathbf{x}_{\ell R}, \mathbf{x}_{\ell I}; \mathbf{x}_{2\ell+1}, \ldots, \mathbf{x}_k], \tag{1.3}$$

[illegible] $n \times n$ [illegible] $M$ [illegible] $C$ [illegible] $K$ [illegible] $M$ [illegible]

$$MX\Lambda^2 + CX\Lambda + KX = 0. \tag{1.4}$$

This problem is called "partially described" because the quadratic pencil (1.1) has part of its eigenvalues and the corresponding eigenvectors, respectively, given by

$$\begin{aligned} &\alpha_1 \pm \boldsymbol{\iota}\beta_1, \ldots, \alpha_\ell \pm \boldsymbol{\iota}\beta_\ell;\ \lambda_{2\ell+1}, \ldots, \lambda_k; \\ \text{and}\ &\mathbf{x}_{1R} \pm \boldsymbol{\iota}\mathbf{x}_{1I}, \ldots, \mathbf{x}_{\ell R} \pm \boldsymbol{\iota}\mathbf{x}_{\ell I};\ \mathbf{x}_{2\ell+1}, \ldots, \mathbf{x}_k. \end{aligned} \tag{1.5}$$

Here $\boldsymbol{\iota} = \sqrt{-1}$. We note that in a large and complicated physical system [16, 17, 19], it is often impractical or impossible to obtain complete spectral information. Thus, it is more sensible to consider a PD-IQEP where only a subset of eigenpairs is known.

In mathematical modeling, there is often a correspondence between the internal parameters and the external behavior. Finding the eigenpairs $(\lambda, \mathbf{x})$ such that $Q(\lambda)\mathbf{x} = 0$ for given $M$, $C$, and $K$ is referred to as a direct quadratic eigenvalue problem (QEP). This is part of the process to induce the dynamics behavior of a system from known physical parameters such as mass, length, elasticity, inductance, capacitance, and so on. A detailed theoretical analysis of QEPs can be found in [10]. Engineering applications, mathematical properties, and a variety of numerical methods for QEPs can be found in the recent survey paper [18]. In contrast, the inverse problem is to determine or estimate some parameters of the system from its measured or expected behavior. The concern in the direct problem is to deduce the behavior from the parameters, whereas in the inverse problem we try to recover the parameters from the behavior. The inverse problem is as important as the direct problem in application.

There is much interest in the inverse eigenvalue problem, including the pole assignment problem. Some general reviews and extensive bibliographies can be found in [5, 3]. Some previous attempts at solving the IQEP are listed as follows:

(i) In [4], special symmetric solutions $M$, $C$, and $K$ (with $M$ and $K$ being symmetric positive definite) to the standard PD-IQEP (with $k \leq n$) and the monic PD-IQEP (with $k = n + 1$) have been constructed.

(ii) In [12], symmetric solutions $M$, $C$, and $K$ (with $M$ and $K$ being symmetric positive definite, and $C$ being positive semidefinite) have been constructed when all eigenvalues are simple and nonreal, and the corresponding eigenvector matrix is of the form $X = X_R(I - \boldsymbol{\iota}\Theta)$, where $X_R$ is nonsingular and $\Theta$ is orthogonal.

(iii) In [2, 7, 6, 14, 15], a feedback control with partial eigenstructure assignment was considered. The proportional and derivative feedback controllers have been constructed to assign specific eigenpairs to the new QEP and make the closed-loop system insensitive to perturbation. However, this consideration cannot preserve the symmetry of the closed-loop system.

(iv) In [1, 13], a symmetric $Q(\lambda)$ has been constructed to partially assign some eigenvalues while retaining other eigenpairs.

(v) In [8, 9, 11], for the finite element model updating problem, a symmetric $Q(\lambda)$ which possesses partially described eigenpairs and is nearest to the original analytical model has been constructed.

(vi) Other types of IQEPs have been studied under modified conditions. For instance, in [15], a symmetric quadratic pencil $Q(\lambda) = \lambda^2 I + \lambda C + K$ has been found, so that $Q(\lambda)$ and $\hat{Q}(\lambda)$ (constructed from $Q(\lambda)$ by deleting the last row and column) have prescribed eigenvalues. In [17], nonproportional underdamped systems have been studied.

The main purpose of this paper is first to construct a general solution of the PD-IQEP. With appropriate choices of free variables in the general solution, we then construct several particular solutions to the PD-IQEP with additional eigeninformation or special structures. The particular solutions of the standard PD-IQEP and the monic PD-IQEP in [4] are just the special cases of the general solution (see section 5).

This paper is organized as follows. In section 2, we give an expression of the general solution to the PD-IQEP in terms of decompositions of some associated matrices. In section 3, we construct particular solutions with $K \geq 0$. In section 4, with $k = n$, we construct particular solutions assigning additional eigenvalues or eigenpairs. In section 5, with $k < n$, we construct particular solutions assigning one additional complex eigenpair or special structures. Numerical results, illustrating the particular solutions in section 4, are presented in section 6. A conclusion and a list of solved and unsolved PD-IQEPs are presented in section 7.

Throughout this paper, we use capital letters to denote matrices, and lowercase (bold) letters to denote scalars (vectors). For $B \in \mathbb{R}^{n\times m}$, $B^\top$, $\bar{B}$, and $B^H$ denote the transpose, conjugate, and conjugate transpose of $B$, respectively. $\mathcal{N}(B)$ denotes the null space of $B$. For a symmetric $A \in \mathbb{R}^{n\times n}$, $A > 0$ ($\geq 0$) denotes a symmetric positive definite (semidefinite) matrix. The spectrum and the spectral radius of $A$ are denoted by $\sigma(A)$ and $\rho(A)$, respectively.

For simplicity, we make the following assumptions:

(H1) The eigenvector matrix $X$ in (1.3) has full column rank, i.e., $\operatorname{rank}(X) = k$.

(H2) The eigenvalue matrix $\Lambda$ in (1.2a) has only simple eigenvalues.

**2. General solution of the PD-IQEP.** In this section, we shall solve a general solution to the PD-IQEP for a given matrix pair $(\Lambda, X) \in \mathbb{R}^{k\times k} \times \mathbb{R}^{n\times k}$ ($k \leq n$) as in (1.2) and (1.3).

THEOREM 2.1. [illegible] $(\Lambda, X) \in \mathbb{R}^{k\times k} \times \mathbb{R}^{n\times k}$ $(k \leq n)$ [illegible] (1.2) [illegible] (1.3) [illegible]

$$X = Q \begin{bmatrix} R \\ 0 \end{bmatrix} \tag{2.1}$$

[illegible] $X$ [illegible] $Q \in \mathbb{R}^{n\times n}$ [illegible] $R \in \mathbb{R}^{k\times k}$ [illegible] $S = R\Lambda R^{-1}$ [illegible] **PD-IQEP** [illegible]

$$M = Q \begin{bmatrix} M_{11} & M_{12} \\ M_{21} & M_{22} \end{bmatrix} Q^\top,\ C = Q \begin{bmatrix} C_{11} & C_{12} \\ C_{21} & C_{22} \end{bmatrix} Q^\top,\ K = Q \begin{bmatrix} K_{11} & K_{12} \\ K_{21} & K_{22} \end{bmatrix} Q^\top, \tag{2.2}$$

[illegible]

(i) $\begin{bmatrix} M_{11} & M_{12} \\ M_{21} & M_{22} \end{bmatrix} \in \mathbb{R}^{n\times n}$ [illegible],

(ii) $C_{22} = C_{22}^\top, K_{22} = K_{22}^\top \in \mathbb{R}^{(n-k)\times(n-k)}$ [illegible],

(iii) $C_{21} = C_{12}^\top \in \mathbb{R}^{(n-k)\times k}$ [illegible],

(2.3a) (iv) $C_{11} = C_{11}^\top = -(M_{11}S + S^\top M_{11} + R^{-\top} D R^{-1}) \in \mathbb{R}^{k\times k}$,

(2.3b) (v) $K_{11} = K_{11}^\top = S^\top M_{11} S + R^{-\top} D \Lambda R^{-1} \in \mathbb{R}^{k\times k}$,

(2.3c) (vi) $K_{21} = K_{12}^\top = -(M_{21}S^2 + C_{21}S) \in \mathbb{R}^{(n-k)\times k}$,

[illegible]

$$D = \operatorname{diag}\left( \begin{bmatrix} \xi_1 & \eta_1 \\ \eta_1 & -\xi_1 \end{bmatrix}, \ldots, \begin{bmatrix} \xi_\ell & \eta_\ell \\ \eta_\ell & -\xi_\ell \end{bmatrix}; \ \xi_{2\ell+1}, \ldots, \xi_k \right), \tag{2.4}$$

[illegible] $\xi_i$ [illegible] $\eta_i$ [illegible]. Substituting (2.1) and (2.2) into (1.4), we have

$$M_{11}S^2 + C_{11}S + K_{11} = 0, \tag{2.5}$$

$$M_{21}S^2 + C_{21}S + K_{21} = 0. \tag{2.6}$$

Thus, finding $M$, $C$, and $K$ which satisfy (1.4) is equivalent to finding the submatrices $M_{11}$, $M_{21}$, $C_{11}$, $C_{21}$, $K_{11}$, and $K_{21}$ which satisfy (2.5) and (2.6). Clearly, it follows from (2.6) that $K_{21}$ is determined by (2.3c), where $M_{21}$ and $C_{21}$ are arbitrary.

As $M$ and $K$ are required to be symmetric positive definite and symmetric, respectively, so are $M_{11}$ and $K_{11}$ in (2.2). From (2.5) it follows that

$$K_{11} = -(M_{11}S^2 + C_{11}S). \tag{2.7}$$

Let $M_{11}$ be an arbitrary symmetric positive definite matrix. We need to find a symmetric $C_{11}$ such that $K_{11}$ in (2.7) is symmetric. We thus need a $C_{11} = C_{11}^\top$ so that

$$(M_{11}S^2 + C_{11}S)^\top = M_{11}S^2 + C_{11}S. \tag{2.8}$$

After rearrangement, (2.8) becomes

$$C_{11}S - S^\top C_{11} = -M_{11}S^2 + (S^2)^\top M_{11}. \tag{2.9}$$

It is easily seen that (2.9) has a particular solution

$$C_{11}^0 = -(M_{11}S + S^\top M_{11}). \tag{2.10}$$

Next we consider of the homogeneous equation

$$C_{11}S - S^\top C_{11} = 0. \tag{2.11}$$

Substituting $S = R\Lambda R^{-1}$ into (2.11), we get

$$(R^\top C_{11}R)\Lambda - \Lambda^\top (R^\top C_{11}R) = 0. \tag{2.12}$$

Partitioning $R^\top C_{11}R$ compatibly with $\Lambda$, we have $s = k - \ell$ and

$$R^\top C_{11} R = \begin{bmatrix} \Gamma_{11} & \cdots & \Gamma_{1s} \\ \vdots & \ddots & \vdots \\ \Gamma_{s1} & \cdots & \Gamma_{ss} \end{bmatrix}, \tag{2.13}$$

where $\Gamma_{jj}$ is a $2 \times 2$ matrix for $1 \le j \le \ell$ and $\Gamma_{jj}$ is a $1 \times 1$ matrix for $\ell + 1 \le j \le s$. Substituting (2.13) into (2.12) and using assumption (H2), we deduce that

$$\begin{gathered} \Gamma_{ji} = 0, \qquad j \neq i, \\ \Gamma_{jj}\lambda_j^{[2]} - (\lambda_j^{[2]})^\top \Gamma_{jj} = 0, \qquad j = 1, \ldots, \ell; \end{gathered} \tag{2.14}$$

and

$$\Gamma_{\ell+j,\ell+j}\lambda_{2\ell+j} - \lambda_{2\ell+j}\Gamma_{\ell+j,\ell+j} = 0, \qquad j = 1, \ldots, s-\ell. \tag{2.15}$$

Since $\lambda_j^{[2]}$ has the form in (1.2b) with $\beta_j \neq 0$, it is easily seen that the general solution of (2.14) has the form

$$\Gamma_{jj} = \begin{bmatrix} \xi_j & \eta_j \\ \eta_j & -\xi_j \end{bmatrix}, \quad j = 1, \ldots, \ell, \tag{2.16}$$

where $\xi_j$, $\eta_j$ are arbitrary real numbers and (2.15) holds for any real numbers $\Gamma_{\ell+j,\ell+j} = \xi_{\ell+j}$. Thus, the general solution of the homogeneous equation (2.11) has the form

$$C_{11} = R^{-\top} D R^{-1}, \tag{2.17}$$

with $D$ defined in (2.4). This, together with (2.10), gives rise to the general solution of (2.9):

$$C_{11} = -R^{-\top} D R^{-1} - M_{11}S - S^{\top}M_{11}, \tag{2.18}$$

(cf. (2.3a)). Substituting (2.18) into (2.7) yields (2.3b). Note that from (2.16) and (1.2) the matrix $D\Lambda$ in (2.3b) is symmetric. This completes the proof. ☐

[illegible] 2.1. Theorem 2.1 shows that the solution to the PD-IQEP is underdetermined. Therefore, the question arises as to how these degrees of freedom could be exploited. This will be discussed in the subsequent sections.

## 3. Particular solutions with $K \geq 0$.

In practice, the matrix $K$ in the PD-IQEP is sometimes required to be symmetric positive semidefinite. In this section, we shall apply Theorem 2.1 to construct such a solution. We first prove the following two lemmas.

LEMMA 3.1. [illegible] $D$ [illegible] (2.4) [illegible] $M_{11}$ [illegible] $K_{11}$ [illegible] (2.3b) [illegible]

[illegible]. Since $S = R\Lambda R^{-1}$, it is easy to see that $K_{11}$ in (2.3b) is symmetric positive semidefinite if and only if the matrix

$$\Lambda^{\top} R^{\top} M_{11} R\Lambda + D\Lambda \tag{3.1}$$

is symmetric positive semidefinite.

Since $\Lambda$ has distinct eigenvalues, we have either $0 \notin \sigma(\Lambda)$ or 0 being a simple eigenvalue of $\Lambda$ (say, $\lambda_k = 0$). We first construct a symmetric positive definite (or a symmetric positive semidefinite when $\lambda_k = 0$) matrix $\widetilde{M}$ so that $\widetilde{M} + D\Lambda \geq 0$. Then we use $\widetilde{M}$ to construct the desired $M_{11}$.

Take

$$\widetilde{M} = \begin{cases} \widetilde{M}_1 & \text{if } 0 \notin \sigma(\Lambda), \\ \operatorname{diag}(\widetilde{M}_1,\ 0) & \text{if } 0 \in \sigma(\Lambda), \end{cases} \tag{3.2}$$

where

$$\widetilde{M}_1 = \operatorname{diag}\left( \begin{bmatrix} x_1 & z_1 \\ z_1 & y_1 \end{bmatrix}, \ldots, \begin{bmatrix} x_\ell & z_\ell \\ z_\ell & y_\ell \end{bmatrix};\ x_{2\ell+1}, \ldots, x_{k_1} \right), \tag{3.3}$$

in which $k_1 = k$ when $0 \notin \sigma(\Lambda)$ and $k_1 = k-1$ when $\lambda_k = 0$. From (2.4) and (1.2), we denote

$$D\Lambda = \operatorname{diag}\left( \begin{bmatrix} \theta_1 & \omega_1 \\ \omega_1 & -\theta_1 \end{bmatrix}, \ldots, \begin{bmatrix} \theta_\ell & \omega_\ell \\ \omega_\ell & -\theta_\ell \end{bmatrix};\ \theta_{2\ell+1}, \ldots, \theta_k \right), \tag{3.4}$$

where

$$\begin{array}{l} \theta_j = \alpha_j\xi_j - \beta_j\eta_j, \quad \omega_j = \alpha_j\eta_j + \beta_j\xi_j, \quad j = 1, \ldots, \ell, \\ \theta_j = \xi_j\lambda_j, \quad j = 2\ell+1, \ldots, k, \end{array} \tag{3.5}$$

with $\xi_j$ and $\eta_j$ being arbitrary real numbers. Using (3.4) and (3.5), if we choose $x_i$, $y_i$, and $z_i$ such that

$$\begin{cases} x_i > 0, & i = 1, \ldots, k_1, \\ x_i y_i - z_i^2 > 0, & i = 1, \ldots, \ell, \end{cases} \tag{3.6}$$

$$x_i + \theta_i \geq 0, \qquad i = 2\ell+1, \ldots, k_1, \tag{3.7}$$

$$\begin{cases} x_i + \theta_i > 0, \quad d_i \equiv (y_i - \theta_i) - \frac{(z_i+\omega_i)^2}{x_i+\theta_i} \geq 0, \\ \text{or} \quad x_i + \theta_i = z_i + \omega_i = 0, \quad y_i - \theta_i \geq 0, \end{cases} \qquad i = 1, \ldots, \ell, \tag{3.8}$$

then $\widetilde{M}_1 > 0$ and $\widetilde{M} + D\Lambda \geq 0$. Obviously, such real numbers $x_i$, $y_i$, and $z_i$ can be easily chosen. Once $\widetilde{M}_1$ is determined, the required $M_{11}$ can be chosen by

$$M_{11} = \begin{cases} R^{-\top}\Lambda^{-\top}\widetilde{M}_1\Lambda^{-1}R^{-1} & \text{if} \quad 0 \notin \sigma(\Lambda), \\ R^{-\top} \begin{bmatrix} \Lambda_1^{-\top}\widetilde{M}_1\Lambda_1^{-1} & 0 \\ 0 & 1 \end{bmatrix} R^{-1} & \text{if} \quad 0 \in \sigma(\Lambda), \end{cases} \tag{3.9}$$

where $\Lambda_1 = \Lambda(1:k-1, 1:k-1)$. $\square$

Let $K_{11}$ be constructed as in Lemma 3.1. Then from (3.2) and (3.9) it is easily seen that

$$K_{11} = R^{-\top}(\widetilde{M} + D\Lambda)R^{-1}. \tag{3.10}$$

Since $\widetilde{M} + D\Lambda \geq 0$, there exists a congruence transformation $L$ such that

$$L^\top(\widetilde{M} + D\Lambda)L = \begin{bmatrix} \widetilde{K}_1 & 0 \\ 0 & 0_q \end{bmatrix}, \tag{3.11}$$

where $\widetilde{K}_1$ is a $(k-q) \times (k-q)$ positive diagonal matrix. Since $K$ is required to be symmetric positive semidefinite, it follows that

$$\begin{bmatrix} RL & 0 \\ 0 & I \end{bmatrix}^T \begin{bmatrix} K_{11} & K_{12} \\ K_{21} & K_{22} \end{bmatrix} \begin{bmatrix} RL & 0 \\ 0 & I \end{bmatrix} = \begin{bmatrix} L^T R^T K_{11} RL & L^T R^T K_{12} \\ K_{21} RL & K_{22} \end{bmatrix} \geq 0.$$

From (3.10) and (3.11), it holds that $L^\top R^\top K_{11} RL$ has the form in (3.11), and then the last $q$ columns of $K_{21}RL$ must be zero. In the following lemma we show that $M_{21}$ and $C_{21}$ can be chosen so that this condition holds.

LEMMA 3.2. [illegible] $k \times k$ [illegible] $L$ [illegible] (3.11) [illegible] $M_{21}$ [illegible] $C_{21}$ [illegible] $q$ [illegible] $K_{21}RL$ [illegible] $K_{21}$ [illegible] (2.3c) [illegible]. We first consider the case when $0 \notin \sigma(\Lambda)$. In this case, since $R\Lambda^2 L$ and $R\Lambda L$ are nonsingular, there exist orthogonal matrices $Q_1$ and $Q_2$ such that

$$Q_1^\top R\Lambda^2 L \begin{bmatrix} 0 \\ I_q \end{bmatrix} = \begin{bmatrix} \Gamma_1 \\ 0 \end{bmatrix}, \quad Q_2^\top R\Lambda L \begin{bmatrix} 0 \\ I_q \end{bmatrix} = \begin{bmatrix} \Delta_1 \\ 0 \end{bmatrix}, \tag{3.12}$$

where $\Gamma_1, \Delta_1 \in \mathbb{R}^{q\times q}$ are nonsingular. Now let

$$M_{21}Q_1 = [M_{21}^1 \mid M_{21}^2], \qquad C_{21}Q_2 = [C_{21}^1 \mid C_{21}^2], \tag{3.13}$$

where $M_{21}^1,\ C_{21}^1 \in \mathbb{R}^{k\times q}$. It follows from (2.3c), (3.12), and (3.13) that

$$\begin{aligned} 0 &= K_{21}RL \begin{bmatrix} 0 \\ I_q \end{bmatrix} && (3.14) \\ &= -(M_{21}S^2 + C_{21}S)RL \begin{bmatrix} 0 \\ I_q \end{bmatrix} \\ &= [M_{21}^1 \mid M_{21}^2] \begin{bmatrix} \Gamma_1 \\ 0 \end{bmatrix} + [C_{21}^1 \mid C_{21}^2] \begin{bmatrix} \Delta_1 \\ 0 \end{bmatrix}. && (3.15) \end{aligned}$$

Therefore, with $C_{21}^1$ being arbitrary,

$$M_{21}^1 = -C_{21}^1 \Delta_1 \Gamma_1^{-1}. \tag{3.16}$$

Similarly, in the case when $0 \in \sigma(\Lambda)$, there exist orthogonal matrices $Q_1$ and $Q_2$ such that

$$Q_1^\top R\Lambda^2 L \begin{bmatrix} 0 \\ I_q \end{bmatrix} = \begin{bmatrix} \Gamma_1 & \boldsymbol{\gamma}_1 \\ 0 & 0 \end{bmatrix}, \qquad Q_2^\top R\Lambda L \begin{bmatrix} 0 \\ I_q \end{bmatrix} = \begin{bmatrix} \Delta_1 & \boldsymbol{\delta}_1 \\ 0 & 0 \end{bmatrix}, \tag{3.17}$$

where $\Gamma_1, \Delta_1 \in \mathbb{R}^{(q-1)\times(q-1)}$ are nonsingular and $\boldsymbol{\gamma}_1, \boldsymbol{\delta}_1 \in \mathbb{R}^{q-1}$. Let

$$M_{21}Q_1 = [M_{21}^1 \mid M_{21}^2], \qquad C_{21}Q_2 = [C_{21}^1 \mid C_{21}^2], \tag{3.18}$$

where $M_{21}^1,\ C_{21}^1 \in \mathbb{R}^{k\times(q-1)}$, and let

$$0 = K_{21}RL \begin{bmatrix} 0 \\ I_q \end{bmatrix} = -(M_{21}S^2 + C_{21}S)RL \begin{bmatrix} 0 \\ I_q \end{bmatrix}.$$

We have

$$M_{21}^1 = -C_{21}^1 \Delta_1 \Gamma_1^{-1}, \tag{3.19}$$

where $C_{21}^1$ solves $C_{21}^1(\boldsymbol{\delta}_1 - \Delta_1\Gamma_1^{-1}\boldsymbol{\gamma}_1) = 0$, which has infinite many solutions.

Thus, we have completed the proof of the lemma. □

Using Lemmas 3.1 and 3.2, we can construct a particular solution to the PD-IQEP with $K \geq 0$ as follows.

ALGORITHM 3.1. SOLVING THE PD-IQEP WITH $K \geq 0$.

[illegible] 1. Choose $D$ as in (2.4) arbitrarily and compute $D\Lambda$ by (3.4) and (3.5).

[illegible] 2. Construct a positive definite matrix $M_{11}$ by (3.2)–(3.9), compute $C_{11}$ and $K_{11}$ by (2.3a) and (2.3b), respectively, and compute $L$ as in (3.11).

[illegible] 3. Compute the decomposition (3.12) (or (3.17)), determine $M_{21}$ and $C_{21}$ by (3.13) and (3.16) (or (3.18) and (3.19)), and compute $K_{21}$ by (2.3c).

[illegible] 4. Choose an $(n-k)\times(n-k)$ positive matrix $\widehat{M}$ and an $(n-k)\times(n-k)$ semipositive matrix $\widehat{K}$ and compute $M_{22} = \widehat{M} + M_{21}M_{11}^{-1}M_{21}^T$ and $K_{22} = \widehat{K} + K_{21}K_{11}^{\dagger}K_{21}^T$. Here $K_{11}^{\dagger}$ denotes the Moore–Penrose inverse of $K_{11}$.

[illegible] 5. Choose an arbitrary symmetric $C_{22}$ and form

$$M = Q\begin{bmatrix} M_{11} & M_{21}^\top \\ M_{21} & M_{22} \end{bmatrix} Q^\top, \quad C = Q\begin{bmatrix} C_{11} & C_{21}^\top \\ C_{21} & C_{22} \end{bmatrix} Q^\top, \quad K = Q\begin{bmatrix} K_{11} & K_{21}^\top \\ K_{21} & K_{22} \end{bmatrix} Q^\top,$$

where $Q$ is given by (2.1).

**4. Particular solutions with additional eigeninformation when $k = n$.** Since there are still many degrees of freedom in the general solution of the PD-IQEP in section 3, we are motivated to satisfy additional constraints or eigeninformation so that the number of equations constructed from these additional conditions is less than or equal to the number of free variables. Consequently, such a PD-IQEP with the additional eigeninformation can be solved generically.

By Theorem 2.1, with $k = n$, the general solution of the PD-IQEP is given by

$$C = -(MS + S^\top M + R^{-\top}DR^{-1}), \tag{4.1a}$$

$$K = S^\top MS + R^{-\top}D\Lambda R^{-1}, \tag{4.1b}$$

where $M > 0$ can be arbitrarily chosen and $D$ is given by (2.4) with $k = n$. Based on the factorization of quadratic matrix pencils [10, p. 228], we then have the following theorem.

THEOREM 4.1. [illegible] $k = n$ [illegible]

$$Q(\lambda) = \lambda^2 M + \lambda C + K = (\lambda I - S^\top - R^{-\top}DR^{-1}M^{-1})M(\lambda I - S). \tag{4.2}$$

[illegible] $Q(\lambda)$ [illegible] $S$ ( [illegible] $\Lambda$) [illegible] $S + M^{-1}R^{-\top}DR^{-1}$

[illegible]. Substituting (4.1) into $Q(\lambda)$, we have

$$\begin{aligned} Q(\lambda) &= \lambda^2 M + \lambda C + K \\ &= \lambda^2 M - \lambda(MS + S^\top M + R^{-\top}DR^{-1}) + S^\top MS + R^{-\top}D\Lambda R^{-1} \\ &= (\lambda I - S)^\top M(\lambda I - S) + R^{-\top}DR^{-1}(-\lambda I + S) \\ &= \left((\lambda I - S)^\top M - R^{-\top}DR^{-1}\right)(\lambda I - S) \\ &= (\lambda I - S^\top - R^{-\top}DR^{-1}M^{-1})M(\lambda I - S). \qquad (4.3) \end{aligned}$$

Thus (4.2) holds. □

In the rest of this section, we shall present two particular solutions to the PD-IQEP with additional eigeninformation when $k = n$.

**4.1. Particular solutions with additional eigenvalues.** Our goal in this subsection is to construct a quadratic pencil $Q(\lambda)$ in (4.3) which has $n$ arbitrarily assigned eigenvalues, closed under complex conjugation, by appropriate choices of $M$ and $D$.

THEOREM 4.2. [illegible] $M$ [illegible] $D$ [illegible] (2.4) [illegible] $S + M^{-1}R^{-\top}DR^{-1}$ [illegible] (4.2) [illegible] $n$ [illegible]

Let $\widetilde{M} = (R^\top M R)^{-1}$. Then

$$S + M^{-1}R^{-\top}DR^{-1} = R(\Lambda + \widetilde{M}D)R^{-1}. \tag{4.4}$$

We need to find appropriate choices of $\widetilde{M}$ and $D$ such that $\Lambda + \widetilde{M}D$ has the $n$ given eigenvalues. We consider

$$\widetilde{M} = \operatorname{diag}\left(\begin{bmatrix} x_1 & z_1 \\ z_1 & y_1 \end{bmatrix}, \dots, \begin{bmatrix} x_s & z_s \\ z_s & y_s \end{bmatrix}\right) \tag{4.5}$$

for $n = 2s$ and

$$\widetilde{M} = \operatorname{diag}\left(\begin{bmatrix} x_1 & z_1 \\ z_1 & y_1 \end{bmatrix}, \dots, \begin{bmatrix} x_s & z_s \\ z_s & y_s \end{bmatrix}; \; x_{2s+1}\right) \tag{4.6}$$

for $n = 2s+1$. Consider the appropriate blocks in $\Lambda$, $\widetilde{M}$, and $D$ while ignoring indices; we only need to assign arbitrary (real or complex conjugate) eigenvalues to matrices of the forms

$$A_1 = \begin{bmatrix} \alpha & \beta \\ -\beta & \alpha \end{bmatrix} + \begin{bmatrix} x & z \\ z & y \end{bmatrix}\begin{bmatrix} \xi & \eta \\ \eta & -\xi \end{bmatrix} \tag{4.7}$$

and

$$A_2 = \begin{bmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{bmatrix} + \begin{bmatrix} x & z \\ z & y \end{bmatrix}\begin{bmatrix} \xi_1 & 0 \\ 0 & \xi_2 \end{bmatrix}. \tag{4.8}$$

This can be achieved via appropriate choices of $x$, $y$, $z$, $\xi$, $\eta$, $\xi_1$, and $\xi_2$. We first require $x > 0$ and $xy - z^2 > 0$ so that $\widetilde{M} > 0$ as in (4.5) and (4.6).

(i) Assume that $A_1$ is of the form found in (4.7). In this case, we first choose $z = 0$. Then we prove that for any given real numbers $\tilde{\mu}$ and $\tilde{\nu}$, there are two positive numbers $x, y$ and two real number $\xi, \eta$ such that

$$\operatorname{tr} A_1 = \tilde{\mu}, \qquad \det A_1 = \tilde{\nu}.$$

This implies

$$\xi(x - y) = \tilde{\mu} - 2\alpha \equiv \mu, \tag{4.9}$$

$$(\alpha\xi + \beta\eta)(x - y) - (\xi^2 + \eta^2)xy = \tilde{\nu} - \alpha^2 - \beta^2 \equiv \nu. \tag{4.10}$$

If $\mu = 0$, we choose $\xi = 0$; then (4.9) holds. By taking $\eta = \frac{1}{\beta}$, (4.10) becomes

$$x(\beta^2 - y) = \beta^2(\nu + y). \tag{4.11}$$

Here we use the assumption that $\beta$ is nonzero. When $\nu = -\beta^2$, we take $y = \beta^2 > 0$; then (4.11) holds automatically. When $\nu > -\beta^2$, we take $y$ satisfying $\max\{-\nu, 0\} < y < \beta^2$; when $\nu < -\beta^2$, we take $y$ satisfying $\beta^2 < y < -\nu$. In both cases, we choose

$$x = \beta^2 \frac{\nu + y}{\beta^2 - y} > 0.$$

If $\mu \neq 0$, from (4.9) it follows that

$$x - y = \frac{\mu}{\xi}. \tag{4.12}$$

Substituting (4.12) into (4.10) leads to

$$xy = \frac{1}{\xi^2+\eta^2}\left(\mu\alpha - \nu + \frac{\eta}{\xi}\mu\beta\right) \equiv c. \tag{4.13}$$

Solving $x$ in (4.12) and substituting into (4.13), we get

$$y^2 + \frac{\mu}{\xi}y - c = 0. \tag{4.14}$$

It is easy to take $\xi$ and $\eta$ so that $c$, as defined in (4.13), is positive. Thus, from (4.14), we can take

$$y = \frac{1}{2}\left(-\frac{\mu}{\xi} + \sqrt{\left(\frac{\mu}{\xi}\right)^2 + 4c}\right) > 0, \tag{4.15}$$

and then, by (4.12), we have

$$x = \frac{\mu}{\xi} + y = \frac{1}{2}\left(\frac{\mu}{\xi} + \sqrt{\left(\frac{\mu}{\xi}\right)^2 + 4c}\right) > 0. \tag{4.16}$$

(ii) Assume that $A_2$ is of the form found in (4.8). We shall prove, for any given real numbers $\tilde{\mu}$ and $\tilde{\nu}$, that there exist positive numbers $x$, $y$ and real numbers $z$, $\xi_1$, $\xi_2$ which satisfy $xy - z^2 > 0$ and

$$\mathrm{tr} A_2 = \tilde{\mu}, \qquad \det A_2 = \tilde{\nu}.$$

This implies

$$\xi_1 x + \xi_2 y = \tilde{\mu} - \lambda_1 - \lambda_2 \equiv \mu, \tag{4.17}$$

$$\xi_1\lambda_2 x + \lambda_1\xi_2 y + \xi_1\xi_2(xy - z^2) = \tilde{\nu} - \lambda_1\lambda_2 \equiv \nu. \tag{4.18}$$

From (4.17), we have $\xi_1 = (\mu - \xi_2 y)/x$. Substituting it into (4.18), we get

$$\lambda_2(\mu - \xi_2 y) + \lambda_1\xi_2 y + \frac{1}{x}\xi_2(xy - z^2)(\mu - \xi_2 y) = \nu.$$

This implies

$$-(xy - z^2)\xi_2^2 + \left[(\lambda_1 - \lambda_2) + \mu\frac{xy - z^2}{xy}\right]\xi_2 + (\lambda_2\mu - \nu) = 0. \tag{4.19}$$

It remains to show that there are real numbers $x$, $y$, $z$ with $x > 0$ and $xy - z^2 > 0$ such that the quadratic equation (4.19) has real roots. This requires the discriminant of (4.19) to be positive, i.e.,

$$\left[(\lambda_1 - \lambda_2) + \mu\frac{xy - z^2}{xy}\right]^2 + 4(xy - z^2)(\lambda_2\mu - \nu) > 0. \tag{4.20}$$

To satisfy (4.20), we can first take $xy$ sufficiently large and then take $z$ such that $xy - z^2$ is a sufficiently small positive number. ∎

With $k = n$, we have constructed a particular solution to the PD-IQEP with $n$ additional eigenvalues.

ALGORITHM 4.1. SOLVING A PD-IQEP WITH $k = n$ AND $n$ ADDITIONAL EIGENVALUES.

[illegible] 1. Choose $M > 0$ and $D$ by (i) and (ii) as in Theorem 4.2 so that $S + M^{-1}R^{-\top}DR^{-1}$ has $n$ additionally given eigenvalues.

[illegible] 2. Compute $C$ and $K$ by (4.1a) and (4.1b), respectively.

[illegible] 3. Compute $M = QMQ^\top$, $C = QCQ^\top$, $K = QKQ^\top$, where $Q$ is given by (2.1).

**4.2. Particular solutions with additional eigenpairs.** In this subsection, we are interested in solving the PD-IQEP with $k = n$ and $r$ ($r \le \sqrt{n}$) additionally given eigenpairs. Note that with these $r$ ($r \le \sqrt{n}$) additional eigenpairs, this particular solution of the PD-IQEP is generically solvable (see Remark 4.1 later). Conversely, if $r > \sqrt{n}$, the PD-IQEP, in general, has no solution.

Suppose we are additionally given $r$ ($r \le \sqrt{n}$) eigenpairs $(\mu_j, \mathbf{y}_j) \in \mathbb{C} \times \mathbb{C}^n$, where

$$\mu_j = \bar{\mu}_{j+1} \in \mathbb{C}\backslash\mathbb{R}, \quad \mathbf{y}_j = \bar{\mathbf{y}}_{j+1} \in \mathbb{C}^n\backslash\mathbb{R}^n, \quad j = 1, 3, \ldots, 2s-1, \tag{4.21a}$$

$$\mu_j \in \mathbb{R}, \quad \mathbf{y}_j \in \mathbb{R}^n, \quad j = 2s+1, \ldots, r. \tag{4.21b}$$

Furthermore, we assume that $\mu_j \notin \sigma(\Lambda)$, $j = 1, \ldots, r$, and $[\mathbf{y}_1, \ldots, \mathbf{y}_r]$ is of full column rank. Then, for $r \le \sqrt{n}$, a quadratic pencil as in (4.2) always exists and satisfies $Q(\mu_j)\mathbf{y}_j = 0$ for $j = 1, \ldots, r$. To this end, we first prove a lemma.

LEMMA 4.1. [illegible] $\boldsymbol{\zeta}_1, \ldots, \boldsymbol{\zeta}_r \in \mathbb{R}^n$ [illegible] $\boldsymbol{\delta}_1, \ldots, \boldsymbol{\delta}_r \in \mathbb{R}^n$ [illegible] $M$ [illegible]

$$M[\boldsymbol{\zeta}_1, \ldots, \boldsymbol{\zeta}_r] = [\boldsymbol{\delta}_1, \ldots, \boldsymbol{\delta}_r] \tag{4.22}$$

[illegible]

$$[\boldsymbol{\zeta}_1, \ldots, \boldsymbol{\zeta}_r]^\top [\boldsymbol{\delta}_1, \ldots, \boldsymbol{\delta}_r] \equiv Z^\top X > 0. \tag{4.23}$$

[illegible]. (Necessity.) If (4.22) holds, then

$$[\boldsymbol{\zeta}_1, \ldots, \boldsymbol{\zeta}_r]^\top [\boldsymbol{\delta}_1, \ldots, \boldsymbol{\delta}_r] = [\boldsymbol{\zeta}_1, \ldots, \boldsymbol{\zeta}_r]^\top M [\boldsymbol{\zeta}_1, \ldots, \boldsymbol{\zeta}_r] > 0$$

because $M > 0$ and $Z = [\boldsymbol{\zeta}_1, \ldots, \boldsymbol{\zeta}_r]$ is of full column rank.

(Sufficiency.) Let $V$ be an orthogonal matrix such that

$$V[\boldsymbol{\zeta}_1, \ldots, \boldsymbol{\zeta}_r] = \begin{bmatrix} R \\ 0 \end{bmatrix}, \tag{4.24}$$

where $R \in \mathbb{R}^{r \times r}$ is nonsingular and upper triangular. Let

$$V[\boldsymbol{\delta}_1, \ldots, \boldsymbol{\delta}_r] = \left[\begin{array}{c} T_1 \\ \hline T_2 \end{array}\right], \quad T_1 \in \mathbb{R}^{r \times r}. \tag{4.25}$$

It is sufficient to find an $n \times n$ $\widetilde{M} > 0$ such that

$$\widetilde{M} \begin{bmatrix} R \\ 0 \end{bmatrix} = \left[\begin{array}{c} T_1 \\ \hline T_2 \end{array}\right]. \tag{4.26}$$

Then $M = V^\top \widetilde{M} V > 0$ satisfies (4.22). Partition $\widetilde{M}$ into

$$\widetilde{M} = \begin{bmatrix} \widetilde{M}_1 & \widetilde{M}_2 \\ \widetilde{M}_2^\top & \widetilde{M}_3 \end{bmatrix}.$$

By (4.26), we have $\widetilde{M}_1 = T_1 R^{-1}$. From (4.23)–(4.25), it follows that

$$\begin{aligned} R^\top \widetilde{M}_1 R &= R^\top T_1 R^{-1} R = R^\top T_1 \\ &= [R^\top, 0] \begin{bmatrix} T_1 \\ T_2 \end{bmatrix} = [R^\top, 0] V V^\top \begin{bmatrix} T_1 \\ T_2 \end{bmatrix} \\ &= Z^\top X > 0. \end{aligned}$$

Thus, $\widetilde{M}_1 > 0$. Taking $\widetilde{M}_2^\top = T_2 R^{-1}$ and $\widetilde{M}_3 = I + \widetilde{M}_2^\top \widetilde{M}_1^{-1} \widetilde{M}_2$, we have $\widetilde{M} > 0$. ☐

From (4.2), $Q(\mu_j)\mathbf{y}_j = 0$ is equivalent to

$$\left(\mu_j I - S^\top - R^{-T} D R^{-1} M^{-1}\right) M \mathbf{z}_j = 0, \tag{4.27}$$

where $\mathbf{z}_j = (\mu_j I - S)\mathbf{y}_j$, $j = 1, \dots, r$. By letting $\mathbf{v}_j = R^{-1}\mathbf{z}_j \equiv [v_{j,1}, \dots, v_{j,n}]^\top$ and $\widetilde{M} = R^\top M R$, (4.27) is equivalent to

$$\widetilde{M}\mathbf{v}_j = (\mu_j I - \Lambda^\top)^{-1} D \mathbf{v}_j, \quad j = 1, \dots, r. \tag{4.28}$$

We now define an $n$-vector, corresponding to $D$ in (2.4), by

$$\mathbf{d} = [\xi_1,\ \eta_1; \dots ; \xi_\ell,\ \eta_\ell;\ \xi_{2\ell+1}, \dots, \xi_n]^\top. \tag{4.29}$$

Write

$$D\mathbf{v}_j = V_j \mathbf{d}, \quad j = 1, \dots, r, \tag{4.30}$$

where

$$V_j = \operatorname{diag}\left( \begin{bmatrix} v_{j,1} & v_{j,2} \\ -v_{j,2} & v_{j,1} \end{bmatrix}, \dots, \begin{bmatrix} v_{j,2\ell-1} & v_{j,2\ell} \\ -v_{j,2\ell} & v_{j,2\ell-1} \end{bmatrix}; v_{j,2\ell+1}, \dots, v_{j,n} \right).$$

Then (4.28) implies

$$\widetilde{M}\mathbf{v}_j = (\mu_j I - \Lambda^\top)^{-1} V_j \mathbf{d}, \qquad j = 1, \dots, r. \tag{4.31}$$

Let

$$\boldsymbol{\zeta}_j = \operatorname{Re}(\mathbf{v}_j), \qquad \boldsymbol{\zeta}_{j+1} = \operatorname{Im}(\mathbf{v}_j), \qquad j = 1, 3, \dots, 2s-1, \tag{4.32a}$$

$$G_j = \operatorname{Re}\left((\mu_j I - \Lambda^\top)^{-1} V_j\right), \qquad G_{j+1} = \operatorname{Im}\left((\mu_j I - \Lambda^\top)^{-1} V_j\right), \quad j = 1, 3, \dots, 2s-1, \tag{4.32b}$$

$$\boldsymbol{\zeta}_j = \mathbf{v}_j, \qquad G_j = (\mu_j I - \Lambda^\top)^{-1} V_j, \qquad j = 2s+1, \dots, r. \tag{4.32c}$$

From (4.31)–(4.32) and Lemma 4.1, we proved the following theorem.

THEOREM 4.3. [illegible] $(\mu_j, \mathbf{y}_j) \in \mathbb{C} \times \mathbb{C}^n$ $(j = 1, \dots, r)$ [illegible] (4.21) [illegible] $M$ [illegible] $D$ [illegible] (2.4) [illegible] $Q(\mu_j)\mathbf{y}_j = 0$ $(j = 1, \dots, r)$ [illegible]

$$W \equiv [\boldsymbol{\zeta}_1, \dots, \boldsymbol{\zeta}_r]^\top [G_1 \mathbf{d}, \dots, G_r \mathbf{d}] > 0, \tag{4.33}$$

[illegible] $\boldsymbol{\zeta}_j$ [illegible] $G_j$ $(j = 1, \dots, r)$ [illegible] (4.32) [illegible] $\mathbf{d}$ [illegible] (4.29) [illegible] 4.1. Suppose $r \leq \sqrt{n}$. If we set $W$ in (4.33) to be any symmetric positive definite matrix, then (4.33) can form a squared or underdetermined real linear system in $\mathbf{d} \in \mathbb{R}^n$:

$$\boldsymbol{\zeta}_i^\top G_j \mathbf{d} = w_{ij}, \quad i, j = 1, \ldots, r \leq \sqrt{n}. \tag{4.34}$$

Thus, the vector $\mathbf{d} \in \mathbb{R}^n$, and therefore $D$ in (2.4), are generically solvable.

[illegible] 4.2. The solution of the monic IQEP in [4] is a special case of Theorem 4.3 with $r = 1$.

With $k = n$, we have constructed a particular solution to the PD-IQEP with $r$ ($\leq \sqrt{n}$) additional eigenpairs.

ALGORITHM 4.2. SOLVING A PD-IQEP WITH $k = n$ AND $r$ ($r \leq \sqrt{n}$) ADDITIONAL EIGENPAIRS.

[illegible] 1. Compute $\boldsymbol{\zeta}_j$ and $G_j$ in (4.32) for $j = 1, \ldots, r$.

[illegible] 2. Choose a $W \equiv [w_{ij}]_{r \times r} > 0$; if the linear equation (4.34) for $\mathbf{d}$ is solvable, then go to Step 3; else repeat Step 2.

[illegible] 3. Compute $M > 0$ as in Lemma 4.1 by setting $\boldsymbol{\delta}_j = G_j \mathbf{d}$, $j = 1, \ldots, r$.

[illegible] 4. Compute $C$ and $K$ by (4.1a) and (4.1b), respectively.

[illegible] 5. Compute $M = QMQ^\top$, $C = QCQ^\top$, $K = QKQ^\top$, where $Q$ is given by (2.1).

**5. Particular solutions with additional eigeninformation when $\boldsymbol{k < n}$.** When $k < n$, for a given matrix pair $(\Lambda, X) \in \mathbb{R}^{k \times k} \times \mathbb{R}^{n \times k}$ as in (1.2) and (1.3) and under assumptions (H1)–(H2), Theorem 2.1 states that the general solution to the PD-IQEP is

$$M = Q \begin{bmatrix} M_{11} & M_{12} \\ M_{21} & M_{22} \end{bmatrix} Q^\top, \; C = Q \begin{bmatrix} C_{11} & C_{12} \\ C_{21} & C_{22} \end{bmatrix} Q^\top, \; K = Q \begin{bmatrix} K_{11} & K_{12} \\ K_{21} & K_{22} \end{bmatrix} Q^\top, \tag{5.1}$$

where $M$, $C_{22}$, $C_{21} = C_{12}^\top$ and $K_{22}$ can be arbitrarily chosen, while $C_{11}$, $K_{11}$, and $K_{21} = K_{12}^\top$ are given by (2.3). Furthermore, we have the following.

THEOREM 5.1. [illegible] $k < n$ [illegible]

$$\begin{aligned} &Q(\lambda) = \lambda^2 M + \lambda C + K \\ &= \begin{bmatrix} \left(\lambda I - S^\top - R^{-T} D R^{-1} M_{11}^{-1}\right) M_{11} & (\lambda I - S^\top)\left(M_{21}(\lambda I + S) + C_{21}\right)^\top \\ \left(M_{21}(\lambda I + S) + C_{21}\right) & \lambda^2 M_{22} + \lambda C_{22} + K_{22} \end{bmatrix} \begin{bmatrix} \lambda I - S & 0 \\ 0 & I \end{bmatrix}, \end{aligned} \tag{5.2}$$

[illegible] $Q(\lambda)$ [illegible] $\Lambda$

[illegible]. From (5.1) and (2.3), we have

$$\begin{aligned} \lambda^2 M_{11} + \lambda C_{11} + K_{11} &= \left(\lambda I - S^\top - R^{-T} D R^{-1} M_{11}^{-1}\right) M_{11} (\lambda I - S), \\ \lambda^2 M_{21} + \lambda C_{21} + K_{21} &= M_{21}(\lambda^2 I - S^2) + C_{21}(\lambda I - S) \\ &= [M_{21}(\lambda I + S) + C_{21}] (\lambda I - S), \end{aligned}$$

which imply (5.2). ☐

In the following subsections, we construct two particular solutions to the PD-IQEP when $k < n$, with one additional complex eigenpair (with $k = n - 1$) or positive definite property of $M$ and $K$. These solutions are equivalent to those developed in [4].

**5.1. Particular solutions with an additional complex eigenpair.** In this subsection, we shall construct the particular solution of the PD-IQEP with $k = n-1$ and an additional complex eigenpairs. We shall show that this particular solution is equivalent to the unique solution of the monic IQEP in [4] with $M = I_n$.

For a given pair $(\Lambda, X) \in \mathbb{R}^{(n-1)\times(n-1)} \times \mathbb{R}^{n\times(n-1)}$ as in (1.2) and (1.3), under assumptions (H1)–(H2), Theorem 5.1 shows that the general solution of the PD-IQEP has the decomposition (5.2), where $S = R\Lambda R^{-1}$ and $Q^\top X = [R^\top, 0]^\top$. For an additionally given complex eigenpair $(\mu, \mathbf{z})$ with $\mu \notin \sigma(\Lambda)$, we want to solve the PD-IQEP by (2.3) where $M = I_n$ and $Q(\mu)\mathbf{z} = Q(\bar{\mu})\bar{\mathbf{z}} = 0$.

Write $\mathbf{z} = \left[\begin{smallmatrix} \mathbf{r}_{12} \\ r_{22} \end{smallmatrix}\right]$, where $\mathbf{r}_{12} \in \mathbb{C}^{n-1}$ and $0 \neq r_{22} \in \mathbb{C}$, and denote $\widehat{R} = \left[\begin{smallmatrix} R & \mathbf{r}_{12} \\ 0 & r_{22} \end{smallmatrix}\right]$ and $\widehat{\Lambda} = \left[\begin{smallmatrix} \Lambda & 0 \\ 0 & \mu \end{smallmatrix}\right]$. Then we have

$$\widehat{S} \equiv \widehat{R}\widehat{\Lambda}\widehat{R}^{-1} = \begin{bmatrix} R\Lambda R^{-1} & -r_{22}^{-1} R\Lambda R^{-1}\mathbf{r}_{12} + \mu r_{22}^{-1}\mathbf{r}_{12} \\ 0 & \mu \end{bmatrix}. \tag{5.3}$$

In [4], the general solution of the Hermitian matrix $\widehat{C}$ in $Q(\lambda) \equiv \lambda^2 \widehat{M} + \lambda\widehat{C} + \widehat{K}$ is given by

$$\begin{aligned} \widehat{C} &\equiv \begin{bmatrix} \widehat{C}_{11} & \hat{\mathbf{c}}_{12} \\ \hat{\mathbf{c}}_{12}^H & \hat{c}_{22} \end{bmatrix} \\ &= -\left(\widehat{S} + \widehat{S}^H\right) - \left[\begin{array}{c} R^{-\top} \\ \hline -\bar{r}_{22}^{-1}\mathbf{r}_{12}^H R^{-\top} \end{array}\right] D \left[\begin{array}{c|c} R^{-1} & -r_{22}^{-1}R^{-1}\mathbf{r}_{12} \end{array}\right], \end{aligned} \tag{5.4}$$

where $D$ is of the form in (2.4), $\widehat{C}_{11} \in \mathbb{R}^{(n-1)\times(n-1)}$, $\hat{\mathbf{c}}_{12} \in \mathbb{C}^{n-1}$, and $\hat{c}_{22} \in \mathbb{C}$. Expanding $\widehat{C}_{11}$, $\hat{\mathbf{c}}_{12}$, and $\hat{c}_{22}$ in (5.4), we get

$$\widehat{C}_{11} = -\left(S + S^\top\right) - R^{-\top}DR^{-1}, \tag{5.5}$$

$$\hat{\mathbf{c}}_{12} = -r_{22}^{-1}\left(\mu I - S\right)\mathbf{r}_{12} + r_{22}^{-1}R^{-\top}DR^{-1}\mathbf{r}_{12}, \tag{5.6}$$

$$\hat{c}_{22} = -\mu - \bar{\mu} - |r_{22}|^{-2}\mathbf{r}_{12}^H R^{-\top}DR^{-1}\mathbf{r}_{12}. \tag{5.7}$$

On the other hand, by setting $M_{11} = I_{n-1}$ and $M_{21} = 0$ in (5.2) and relaxing $C$ to be Hermitian, we have

$$\begin{aligned} Q(\lambda) &\equiv \lambda^2 I + \lambda C + K \\ &= \begin{bmatrix} \lambda I - S^\top - R^{-\top}DR^{-1} & (\lambda I - S^\top)\mathbf{c}_{12} \\ \mathbf{c}_{12}^H & \lambda^2 + \lambda c_{22} + k_{22} \end{bmatrix} \begin{bmatrix} \lambda I - S & 0 \\ 0 & 1 \end{bmatrix}. \end{aligned} \tag{5.8}$$

Here we partition $C$ as

$$C = \begin{bmatrix} C_{11} & \mathbf{c}_{12} \\ \mathbf{c}_{12}^H & c_{22} \end{bmatrix}, \tag{5.9}$$

where $C_{11} \in \mathbb{R}^{(n-1)\times(n-1)}$, $\mathbf{c}_{12} \in \mathbb{C}^{n-1}$, $c_{22} \in \mathbb{C}$.

We want to show C $= \widehat{C}$ when $Q(\mu)\mathbf{z} = Q(\bar{\mu})\bar{\mathbf{z}} = 0$. From [4], $C$ in (5.9) satisfies $C = \bar{C} = C^H = C^\top$, and therefore $K = K^\top$.

It is easily seen that

$$C_{11} = -(S + S^\top) - R^{-\top}DR^{-1} = \widehat{C}_{11}. \tag{5.10}$$

Substituting $\lambda = \mu$ in (5.8), we compute $Q(\mu)\mathbf{z} \equiv Q(\mu)\left[\begin{smallmatrix}\mathbf{r}_{12}\\ r_{22}\end{smallmatrix}\right] = 0$ and obtain

$$(\mu I - S^\top - R^{-\top} D R^{-1})(\mu I - S)\mathbf{r}_{12} + r_{22}(\mu I - S^\top)\mathbf{c}_{12} = 0, \tag{5.11}$$

$$\mathbf{c}_{12}^H(\mu I - S)\mathbf{r}_{12} + r_{22}(\mu^2 + \mu c_{22} + k_{22}) = 0. \tag{5.12}$$

Then from $D\Lambda = \Lambda^\top D$, we have

$$\begin{aligned}\mathbf{c}_{12} &= -r_{22}^{-1}(\mu I - S^\top)^{-1}(\mu I - S^\top - R^{-\top} D R^{-1})(\mu I - S)\mathbf{r}_{12}\\ &= -r_{22}^{-1}(\mu I - S)\mathbf{r}_{12} + r_{22}^{-1} R^{-\top}(\mu I - \Lambda)^{-\top} D(\mu I - \Lambda)R^{-1}\mathbf{r}_{12}\\ &= -r_{22}^{-1}(\mu I - S - R^{-\top} D R^{-1})\mathbf{r}_{12} = \hat{\mathbf{c}}_{12}.\end{aligned} \tag{5.13}$$

Similarly, from $Q(\bar\mu)\left[\begin{smallmatrix}\bar{\mathbf{r}}_{12}\\ \bar r_{22}\end{smallmatrix}\right] = 0$, we have

$$(\bar\mu I - S^\top - R^{-\top} D R^{-1})(\bar\mu I - S)\bar{\mathbf{r}}_{12} + \bar r_{22}(\bar\mu I - S^\top)\mathbf{c}_{12} = 0, \tag{5.14}$$

$$\mathbf{c}_{12}^H(\bar\mu I - S)\bar{\mathbf{r}}_{12} + \bar r_{22}(\bar\mu^2 + \bar\mu c_{22} + k_{22}) = 0. \tag{5.15}$$

Eliminating $k_{22}$ in (5.12) using the difference of (5.12) and (5.15), we get

$$(\mu - \bar\mu)c_{22} + \mathbf{c}_{12}^H[r_{22}^{-1}(\mu I - S)\mathbf{r}_{12} - \bar r_{22}^{-1}(\bar\mu I - S)\bar{\mathbf{r}}_{12}] + \mu^2 - \bar\mu^2 = 0. \tag{5.16}$$

From (5.11) and (5.13)–(5.14), it follows that

$$\begin{aligned}(\mu - \bar\mu)c_{22} &= \mathbf{c}_{12}^H[\bar r_{22}^{-1}(\bar\mu I - S)\bar{\mathbf{r}}_{12} - r_{22}^{-1}(\mu I - S)\mathbf{r}_{12}] + \bar\mu^2 - \mu^2\\ &= -\bar r_{22}^{-1}\mathbf{r}_{12}^H(\bar\mu I - S^\top - R^{-\top} D R^{-1})[\bar r_{22}^{-1}(\bar\mu I - S)\bar{\mathbf{r}}_{12} - r_{22}^{-1}(\mu I - S)\mathbf{r}_{12}]\\ &\quad + \bar\mu^2 - \mu^2 \qquad\qquad \text{(from (4.14))}\\ &= \bar r_{22}^{-1}\mathbf{r}_{12}^H[\mu I - S^\top - R^{-\top} D R^{-1} + (\bar\mu - \mu)I]r_{22}^{-1}(\mu I - S)\mathbf{r}_{12}\\ &\quad - \bar r_{22}^{-1}\mathbf{r}_{12}^H[-(\bar\mu I - S^\top)\mathbf{c}_{12}] + \bar\mu^2 - \mu^2 \qquad\qquad \text{(from (4.11))}\\ &= -\bar r_{22}^{-1}\mathbf{r}_{12}^H[-(\bar\mu I - S^\top)\mathbf{c}_{12} + (\mu - S^\top)\mathbf{c}_{12} - (\bar\mu - \mu)r_{22}^{-1}(\mu I - S)\mathbf{r}_{12}]\\ &\quad + \bar\mu^2 - \mu^2\\ &= -\bar r_{22}^{-1}\mathbf{r}_{12}^H[(\mu - \bar\mu)(\mathbf{c}_{12} + r_{22}^{-1}(\mu I - S)\mathbf{r}_{12}] + \bar\mu^2 - \mu^2 \qquad \text{(from (4.13))}\\ &= -\bar r_{22}^{-1}\mathbf{r}_{12}^H[r_{22}^{-1}(\mu - \bar\mu)R^{-\top} D R^{-1}\mathbf{r}_{12}] + \bar\mu^2 - \mu^2\\ &= (\mu - \bar\mu)(-|r_{22}|^{-2}\mathbf{r}_{12}^H R^{-\top} D R^{-1}\mathbf{r}_{12} - \mu - \bar\mu).\end{aligned}$$

Hence $c_{22} = \hat c_{22}$. Combining with (5.10) and (5.13), we have shown that $C = \widehat{C}$.

**5.2. Particular solutions with special structures.** In this subsection, we shall construct a particular solution of the PD-IQEP with $k < n$, $M > 0$, and $K > 0$. Under suitable condition this solution is equivalent to the solution of the standard IQEP developed in [4].

We now take $D = 0$; then the decomposition (5.2) becomes

(5.17)

$$Q(\lambda) = \begin{bmatrix}\lambda I - S & 0\\ 0 & I\end{bmatrix}^\top \begin{bmatrix} M_{11} & (M_{21}(\lambda I + S) + C_{21})^\top\\ M_{21}(\lambda I + S) + C_{21} & \lambda^2 M_{22} + \lambda C_{22} + K_{22}\end{bmatrix}\begin{bmatrix}\lambda I - S & 0\\ 0 & I\end{bmatrix}.$$

Thus, we have

$$\det(Q(\lambda)) = [\det(\lambda I - S)]^2 \det(Q_2(\lambda)), \tag{5.18}$$

where

$$\begin{aligned} Q_2(\lambda) &= \lambda^2 M_{22} + \lambda C_{22} + K_{22} - [M_{21}(\lambda I + S) + C_{21}]\, M_{11}^{-1}\, [M_{21}(\lambda I + S) + C_{21}]^\top \\ &\equiv \lambda^2 \widetilde{M}_{22} + \lambda \widetilde{C}_{22} + \widetilde{K}_{22}, \end{aligned} \tag{5.19}$$

with

$$\widetilde{M}_{22} = M_{22} - M_{21} M_{11}^{-1} M_{12}^\top, \tag{5.20a}$$

$$\widetilde{C}_{22} = C_{22} - M_{21} M_{11}^{-1} (M_{21}S + C_{21})^\top - (M_{21}S + C_{21}) M_{11}^{-1} M_{21}^\top, \tag{5.20b}$$

$$\widetilde{K}_{22} = K_{22} - (M_{21}S + C_{21}) M_{11}^{-1} (M_{21}S + C_{21})^\top. \tag{5.20c}$$

On the other hand, with $m = 2n - k > n$, choose an arbitrary matrix $U \in \mathbb{R}^{m\times n}$ which is of full column rank. Partition $U = [U_1, U_2]$ with $U_1 \in \mathbb{R}^{m\times k}$. Thus, if we take

$$M = U^\top U > 0, \tag{5.21}$$

we obtain

$$M_{11} = U_1^\top U_1,\ M_{21} = U_2^\top U_1,\ M_{22} = U_2^\top U_2. \tag{5.22}$$

Substituting (5.22) into (2.3), we have

$$C_{11} = -(U_1^\top U_1 S + S^\top U_1^\top U_1), \tag{5.23a}$$

$$K_{11} = S^\top U_1^\top U_1 S, \tag{5.23b}$$

$$K_{21} = -(U_2^\top U_1 S + C_{21}) S. \tag{5.23c}$$

Let $V_1 = -U_1 S$ and $V_2$ be an arbitrary $m \times (n - k)$ matrix. Taking $C_{21} = U_2^\top V_1 + V_2^\top U_1$ and substituting it into (5.23) lead to

$$C_{11} = U_1^\top V_1 + V_1^\top U_1, \quad K_{11} = V_1^\top V_1, \tag{5.24a}$$

$$K_{21} = (U_2^\top V_1 - U_2^\top V_1 - V_2^\top U_1) S = V_2^\top V_1. \tag{5.24b}$$

If we write $V = [V_1, V_2]$ and take

$$C_{22} = U_2^\top V_2 + V_2^\top U_2, \quad K_{22} = V_2^\top V_2, \tag{5.25}$$

then from (5.24) we obtain

$$C = U^\top V + V^\top U, \quad K = V^\top V. \tag{5.26}$$

Assume without loss of generality that $X = [R^\top, 0]^\top$, and with $V_1 = -U_1 S$, we then have

$$[R^\top, \Lambda^\top R^\top] \begin{bmatrix} V_1^\top \\ U_1^\top \end{bmatrix} = [X^\top, \Lambda^\top X^\top] \begin{bmatrix} V^\top \\ U^\top \end{bmatrix} = 0. \tag{5.27}$$

If $V_2$ above is chosen so that $\left[\begin{smallmatrix} V^\top \\ U^\top \end{smallmatrix}\right]$ is of full column rank, then the quadratic pencil defined by (5.21) and (5.26) is precisely the solution of the standard IQEP in [4].

Furthermore, from (5.22)–(5.25), the matrices in (5.20) become

$$\widetilde{M}_{22} = U_2^\top B U_2, \tag{5.28a}$$

$$\widetilde{C}_{22} = U_2^\top B V_2 + V_2^\top B U_2, \tag{5.28b}$$

$$\widetilde{K}_{22} = V_2^\top B V_2, \tag{5.28c}$$

where $B = I - U_1(U_1^\top U_1)^{-1}U_1^\top$. Therefore, $Q_2(\lambda)$ in (5.18) becomes

$$\begin{aligned} Q_2(\lambda) &= \lambda^2 \widetilde{M}_{22} + \lambda \widetilde{C}_{22} + \widetilde{K}_{22} \\ &= (\lambda U_2 + V_2)^\top B (\lambda U_2 + V_2). \end{aligned} \tag{5.29}$$

Note that here $B$ is an orthogonal projector, i.e., $B^2 = B = B^\top$.

We now consider the QR-decomposition

$$U = [U_1, U_2] = P \begin{bmatrix} T_{11} & T_{12} \\ 0 & T_{22} \\ 0 & 0 \end{bmatrix}, \tag{5.30}$$

where $P$ is orthogonal, and $T_{11} \in \mathbb{R}^{k\times k}$ and $T_{22} \in \mathbb{R}^{(n-k)\times(n-k)}$ are both nonsingular and upper triangular. Then

$$V_1 = -U_1 S = -P \begin{bmatrix} T_{11}S \\ 0 \\ 0 \end{bmatrix}. \tag{5.31}$$

Let

$$P^\top V_2 = \begin{array}{c c} n-k & \\ \left[\begin{matrix} T_{13} \\ T_{23} \\ T_{33} \end{matrix}\right] & \begin{matrix} k \\ n-k \\ m-n = n-k \end{matrix} \end{array}. \tag{5.32}$$

As $\left[\begin{smallmatrix} V^\top \\ U^\top \end{smallmatrix}\right]$ is of full column rank, it follows that $T_{33}$ is nonsingular. Therefore, we have

$$B = I - U_1(U_1^\top U_1)^{-1}U_1^\top = P \begin{bmatrix} 0 & 0 \\ 0 & I_{n-k} \end{bmatrix} P^\top$$

and

$$\lambda U_2 + V_2 = P \begin{bmatrix} \lambda T_{12} + T_{13} \\ \lambda T_{22} + T_{23} \\ T_{33} \end{bmatrix},$$

implying

$$Q_2(\lambda) = (\lambda T_{22} + T_{23})^\top (\lambda T_{22} + T_{23}) + T_{33}^\top T_{33}. \tag{5.33}$$

Because $T_{33}$ is nonsingular, $\det Q_2(\lambda) > 0$ for any real number $\lambda$. Thus, $Q_2(\lambda)$ in (5.18) has only complex conjugate eigenvalues with nonzero imaginary part. Furthermore, if $\left[\begin{smallmatrix} V^\top \\ U^\top \end{smallmatrix}\right]$ is chosen to be orthogonal, then we have $T_{23} = 0$. From (5.33), we have $Q_2(\lambda) = (\lambda^2 + 1)I$ with eigenvalues $\lambda = \pm\boldsymbol{\iota}$. This also coincides with the result in [4].

Table 6.1
*Absolute errors of computed eigenvalues.*

| Eigenvalues | Absolute error $\lvert\lambda_i - \widehat{\lambda}_i\rvert$ |
|---|---|
| $\lambda_1 = \bar{\lambda}_2$ | 1.2766e-011 |
| $\lambda_3$ | 4.2322e-013 |
| $\lambda_4$ | 2.7001e-013 |
| $\lambda_5$ | 9.7161e-013 |
| $\lambda_6$ | 7.6428e-012 |
| $\lambda_7 = \bar{\lambda}_8$ | 9.9151e-012 |
| $\lambda_9 = \bar{\lambda}_{10}$ | 3.5711e-010 |
| $\lambda_{11}$ | 2.2284e-010 |
| $\lambda_{12}$ | 6.1142e-012 |

**6. Numerical examples.** The results presented in sections 4 and 5 offer a constructive way to solve the PD-IQEP with additional eigeninformation or special structures. In this section, we present two numerical examples to illustrate the particular solutions constructed in section 4. Numerical examples constructed by section 5 can be found in [4]. For presentation, we report all numbers in 5 significant digits only, though all calculations are carried out in full precision.

To generate test data, we first randomly generate the partially prescribed eigeninformation $(\Lambda, X) \in \mathbb{R}^{6\times 6} \times \mathbb{R}^{6\times 6}$ as in (1.2) and (1.3), with $\lambda_1 = 3.5121 + 8.2485\boldsymbol{\imath} = \bar{\lambda}_2$, $\lambda_3 = 1.7541$, $\lambda_4 = 1.2596$, $\lambda_5 = 0.42402$, $\lambda_6 = 6.4268$, and the corresponding eigenvectors

$$\mathbf{x}_1 = \bar{\mathbf{x}}_2 = \begin{bmatrix} 9.2963 + 1.0480\boldsymbol{\imath} \\ 2.3695 + 3.5650\boldsymbol{\imath} \\ 3.8789 + 6.5809\boldsymbol{\imath} \\ 2.8644 + 4.9742\boldsymbol{\imath} \\ 1.5007 + 1.1356\boldsymbol{\imath} \\ 1.9623 + 6.5805\boldsymbol{\imath} \end{bmatrix}, \quad \mathbf{x}_3 = \begin{bmatrix} 8.3476 \\ 8.0904 \\ 5.5542 \\ 9.2809 \\ 4.0705 \\ 2.8111 \end{bmatrix},$$

$$\mathbf{x}_4 = \begin{bmatrix} 6.6044 \\ 9.3147 \\ 2.5443 \\ 2.1294 \\ 8.1057 \\ 2.7021 \end{bmatrix}, \quad \mathbf{x}_5 = \begin{bmatrix} 3.7708 \\ 5.8997 \\ 6.7357 \\ 6.6171 \\ 3.7162 \\ 8.6814 \end{bmatrix}, \quad \mathbf{x}_6 = \begin{bmatrix} 8.5856 \\ 8.3937 \\ 3.3068 \\ 8.1301 \\ 1.8702 \\ 2.7268 \end{bmatrix}.$$

It is easy to check that the matrix pair $(\Lambda, X) \in \mathbb{R}^{6\times 6} \times \mathbb{R}^{6\times 6}$ satisfies the assumptions (H1) and (H2).

[illegible] 1. Subsection 4.1 shows that the PD-IQEP may have 6 assigned eigenvalues, closed under complex conjugation. We generate randomly 6 eigenvalues: $\lambda_7 = 4.6983 + 4.0385\boldsymbol{\imath} = \bar{\lambda}_8$, $\lambda_9 = 5.6495 + 1.5612\boldsymbol{\imath} = \bar{\lambda}_{10}$, $\lambda_{11} = 8.9227$, $\lambda_{12} = 4.1238$. We compute a real symmetric quadratic pencil

$$\widehat{Q}(\lambda) = \lambda^2 \widehat{M} + \lambda \widehat{C} + \widehat{K}$$

by using the method described in subsection 4.1. The residual $\|\widehat{M}X\Lambda^2 + \widehat{C}X\Lambda + \widehat{K}X\|_2$ and the eigenvalues of $\widehat{M}$ are, respectively, 3.6953e-011 and $\{150.52,\ 5.9347,\ 0.12706, 1.8466\text{e-}2,\ 1.2481\text{e-}2,\ 5.5983\text{e-}4\}$. In Table 6.1, we display the absolute errors $|\lambda_i - \widehat{\lambda}_i|$ $(i = 1, \ldots, 12)$, where $\widehat{\lambda}_i$ are the computed eigenvalues of $\widehat{Q}(\lambda)$.

These numerical results show that the computed quadratic pencil is satisfactory.

2. Subsection 4.2 shows the PD-IQEP may have 2 ($< \sqrt{6}$) additional assigned eigenpairs, closed under complex conjugation. We randomly generate 2 eigenpairs: $\lambda_7 = 4.6983 + 4.0385\boldsymbol{\iota} = \bar{\lambda}_8$ and

$$\mathbf{x}_7 = \bar{\mathbf{x}}_8 = \begin{bmatrix} 8.6239 + 6.7913\boldsymbol{\iota} \\ 1.2742 + 1.5386\boldsymbol{\iota} \\ 6.0538 + 9.0277\boldsymbol{\iota} \\ 5.4385 + 8.5876\boldsymbol{\iota} \\ 4.6188 + 1.0069\boldsymbol{\iota} \\ 7.9774 + 3.1084\boldsymbol{\iota} \end{bmatrix}.$$

We compute a real symmetric quadratic pencil

$$\check{Q}(\lambda) = \lambda^2 \check{M} + \lambda \check{C} + \check{K}$$

by using the method described in subsection 4.2. We have the following numerical results:

$$\begin{aligned} &\|\check{M} X \Lambda^2 + \check{C} X \Lambda + \check{K} X\|_2 = 2.0916\text{e-}013, \\ &\|\check{Q}(\lambda_7)\mathbf{x}_7\|_2 = \|\check{Q}(\lambda_8)\mathbf{x}_8\|_2 = 1.6213\text{e-}013, \\ &\sigma(\check{M}) = \{1.0144,\ 1.0081,\ 1,\ 1,\ 3.4592\text{e-}3,\ 1.1868\text{e-}3\}. \end{aligned}$$

This shows that the matrix $\check{M}$ is symmetric positive definite and the residuals are small.

**7. Conclusions.** In this paper, we use techniques involving matrix decompositions to derive an expression of the general solution to the PD-IQEP, for a set of given $k$ eigenpairs ($k \leq n$), under assumptions (H1) and (H2). With appropriate choices of degrees of freedom, we can construct a quadratic pencil $Q(\lambda) = \lambda^2 M + \lambda C + K$ with $M > 0$ and $K \geq 0$. Furthermore, we can also find solutions which satisfy various additional eigeninformation, as shown in sections 4 and 5. The problem of how to utilize the degrees of freedom in general, or under other given sets of eigeninformation, is interesting and needs further investigation. In summary, we list some of the solved and unsolved PD-IQEPs, under various constraints, in Tables 7.1 and 7.2.

For another case of $k > n$, it is rather involved and the proof technique of Theorem 2.1 seems not to be used directly to find a general solution of PD-IQEP. To our knowledge, this case has never been discussed in the literature. It might be interesting research and needs further investigation.

# THE MATRIX GOLDEN MEAN AND ITS APPLICATIONS TO RICCATI MATRIX EQUATIONS[*]

YONGDO LIM[†]

**Abstract.** In this paper we generalize the concept of the golden mean of positive numbers to the golden mean of positive definite matrices and apply it to some Riccati algebraic and differential matrix equations. We describe the unique positive definite solutions of the Riccati matrix equations $XA^{-1}X \pm X - (B - A) = 0$ with $0 < A \leq B$ in terms of geometric and golden means of positive definite matrices as well as the asymptotic behavior of the associated Riccati differential equations $\dot{X} = -XA^{-1}X \mp X + (B - A)$. We describe (apparently new) results related to matrix continued fractions, symplectic Hamiltonian matrices, and other matrix means obtained from golden mean–related inequalities via canonical iterative processes.

**Key words.** positive definite matrix, Riccati (differential) matrix equation, geometric mean, golden mean, continued fraction, symplectic Hamiltonian, Riemannian metric

**1. Introduction.** The geometric mean $A\#B = A^{1/2}(A^{-1/2}BA^{-1/2})^{1/2}A^{1/2}$ of positive definite matrices $A$ and $B$ appears in the literature with many applications in matrix inequalities (arithmetic-geometric-harmonic mean inequalities [4], [5], [6], [29]), inverse mean problems [2], [3], [20], [37], semidefinite programming (scaling point [47], [48], [22]), geometry (geodesic middle [30], [10], [11], [16], [32], [36]), statistical shape analysis (intrinsic mean [44], [45], [46]), and symmetric matrix word equations [8], [27], [25], [34]. The most important property of the geometric mean is that it has a Riccati matrix equation as the defining equation: The geometric mean $A\#B$ is the unique positive definite solution of the Riccati matrix equation $XA^{-1}X = B$. It also appears as an attracting fixed point of the associated Riccati differential equation $\dot{X} = -XA^{-1}X + B$ on the open convex cone of positive definite matrices [32, Theorem 5.1]: If $X(t)$ is a solution of the differential equation with initial point being any positive definite matrix, then $\lim_{t\to\infty} X(t) = A\#B$.

In this paper we introduce a new matrix mean having characteristics similar to the geometric mean in Riccati matrix equations. The well-known golden ratio or golden section $\frac{1}{2}(1 + \sqrt{5})$, which has been used extensively in art and architecture (cf. [23], [24], [41]), is regarded as the unique positive real solution of the quadratic equation $x^2 - x - 1 = 0$. More generally, the quadratic equations

$$\frac{x^2}{a} \mp x - (b - a) = 0, \quad 0 < a \leq b, \tag{1.1}$$

have the unique positive real solutions $a\natural b := \frac{1}{2}(a + \sqrt{4ab - 3a^2})$, $a\bar{\natural} b := \frac{1}{2}(-a + \sqrt{4ab - 3a^2})$, respectively, realizing the golden ratio as $1\natural 2 = \frac{1}{2}(1+\sqrt{5})$. We consider a

natural matrix generalization of (1.1), the Riccati matrix equations under $0 < A \leq B$,

$$XA^{-1}X - X - (B - A) = 0, \tag{1.2}$$

$$XA^{-1}X + X - (B - A) = 0, \tag{1.3}$$

and the associated Riccati matrix differential equations,

$$\dot{X} = -XA^{-1}X + X + (B - A), \tag{1.4}$$

$$\dot{X} = -XA^{-1}X - X + (B - A). \tag{1.5}$$

The classical Riccati matrix (respectively, differential) equation appearing in linear quadratic problems is of the form $XAX - MX - XM^T - B = 0$ and $\dot{X}(t) = B(t) + M(t)X(t) + X(t)M(t)^T - X(t)A(t)X(t)$, where $A \geq 0$ and $B \geq 0$ and $M$ is a square matrix [9], [15], [28]. However, the Riccati equation (1.2) is equivalent to the well-known nonlinear matrix equation $X = Q + NX^{-1}N^T, N > 0$ (see [19], [26], [40]).

In this paper we show that the matrix generalizations of $a\natural b$ and $a\bar{\natural}b$ defined by $A\natural B = \frac{1}{2}(A + A\#(4B - 3A))$ and $A\bar{\natural}B = \frac{1}{2}(-A + A\#(4B - 3A))$ are indeed unique positive definite solutions of (1.2) and (1.3), respectively. The golden mean $A\natural B$ of positive definite matrices with $A \leq B$ is studied in detail in the context of matrix means with close connections to continued fractions and symplectic Hamiltonians. We also prove that for $A < B$, $A\natural B$ and $A\bar{\natural}B$ are attracting fixed points of the differential Riccati equations of (1.4) and (1.5): If $X(t)$ and $Y(t)$ are solutions of the Riccati differential equation (1.4) and (1.5), respectively, with initial value any positive definite matrix, then $A\natural B = \lim_{t\to\infty} X(t)$, $A\bar{\natural}B = \lim_{t\to\infty} Y(t)$, and $\lim_{t\to\infty} X(t)\#Y(t) = A\#(B - A)$.

The paper is organized as follows. In section 2 we briefly review the Riemannian structure and the geometric mean operation on the positive definite convex cone. In section 3 we describe explicit solutions for nonlinear matrix equations which are uniquely equivalent to (1.2) and (1.3). Some basic properties for the golden mean $A\natural B$ of positive definite matrices $A$ and $B$ are found in section 4. The harmonic-geometric-golden mean inequalities are established and corresponding matrix means are obtained from the canonical iterative processes (Theorem 4.3). In section 5 we introduce continued fractions of positive definite matrices and then represent $A\natural B$ as a fixed point of the linear fractional action of a symplectic Hamiltonian matrix and as a limit of repeated continued fractions of positive definite matrices. This shows that for $A < B$, the differential Riccati equations (1.4) and (1.5) have attracting fixed points $A\natural B$ and $A\bar{\natural}B$, respectively. The proof depends heavily on Bougerol's contraction result on symplectic Hamiltonians for the Riemannian metric on the convex cone of positive definite matrices [14].

Throughout this paper we assume that all matrices are square matrices with real entries. Let $\mathrm{Sym}(n, \mathbb{R})$ be the vector space of all $n \times n$ symmetric matrices. For $A \in \mathrm{Sym}(n, \mathbb{R})$, we recall that $A$ is positive semidefinite, denoted by $0 \leq A$, if $\langle x, Ax\rangle \geq 0$ for all $x \in \mathbb{R}^n$, where $\langle \cdot, \cdot \rangle$ denotes the usual inner product on $\mathbb{R}^n$. Similarly, $A$ is positive definite, denoted $0 < A$, if it is positive semidefinite and invertible, or, equivalently, $\langle x, Ax\rangle > 0$ for all nonzero $x$. We denote the set of positive definite (respectively, semidefinite) matrices by $\mathrm{Sym}(n, \mathbb{R})^{++}$ (respectively, $\mathrm{Sym}(n, \mathbb{R})^{+}$).

**2. The geometric mean and invariant metrics.** The geometric mean $A\#B$ of positive semidefinite matrices $A$ and $B$ is defined (and characterized) by the maximum of all $X \geq 0$ for which $\left(\begin{smallmatrix} A & X \\ X & B \end{smallmatrix}\right)$ is positive semidefinite [4]. If $A$ is invertible, then $A\#B = A^{1/2}(A^{-1/2}BA^{-1/2})^{1/2}A^{1/2}$. Various alternative characterizations of the geometric mean can be found in matrix inequalities, semidefinite programming, geometry, statistical shape analysis, and matrix word equations. See [4], [5], [10], [11], [7], [20], [32], [36], [37], [44], [45], [46], [47], and see also [6] for multivariable geometric means.

LEMMA 2.1 (Riccati lemma). [illegible] $A$ [illegible] $B$ [illegible] $A\#B$ [illegible] $XA^{-1}X = B$. [illegible]

(i) $A\#B = B\#A$.
(ii) $(A\#B)^{-1} = A^{-1}\#B^{-1}$ [illegible] $A$ [illegible] $B$.
(iii) $M(A\#B)M^T = (MAM^T)\#(MBM^T)$ [illegible] $M$.
(iv) $2(A^{-1}+B^{-1})^{-1} \leq A\#B \leq \frac{1}{2}(A+B)$ [illegible] $A, B$.

[illegible] See [5] or [32]. □

It is known that the open convex cone $\mathrm{Sym}(n,\mathbb{R})^{++}$ of positive definite matrices admits a natural Riemannian structure induced by the trace metric $\langle X, Y\rangle_A := \mathrm{tr}(A^{-1}XA^{-1}Y), A > 0, X, Y \in \mathrm{Sym}(n,\mathbb{R})$. The Riemannian metric distance $\delta(A,B)$ is given by $\delta(A,B) = \left(\sum_{i=1}^{n} \log^2 \lambda_i(A^{-1/2}BA^{-1/2})\right)^{1/2}$, where $\lambda_i(A^{-1/2}BA^{-1/2})$ denote the eigenvalues of $A^{-1/2}BA^{-1/2}$ (see [30]). It is invariant under the matrix inversion and congruence transformations:

$$\delta(A^{-1}, B^{-1}) = \delta(A,B) = \delta(M^TAM, M^TBM), \quad M \in \mathrm{GL}(n,\mathbb{R}). \tag{2.1}$$

In particular, the geometric mean $A\#B$ of positive definite matrices $A$ and $B$ is the unique midpoint (geodesic middle) of $A$ and $B$ for the distance $\delta$ (cf. [30], [32], [11]). The nonpositive curvature property of the Riemannian manifold $\mathrm{Sym}(n,\mathbb{R})^{++}$ is known as the following (equivalent) inequality:

$$\delta(A^t, B^t) \leq t\delta(A,B), \quad 0 \leq t \leq 1. \tag{2.2}$$

In particular, the square root function $X \mapsto X^{1/2}$ is a strict contraction on $\mathrm{Sym}(n,\mathbb{R})^{++}$.

It has recently been proved by Bhatia [10] that the nonpositive curvature property (2.2) holds for metrics inherited from symmetric gauge functions: If $\Phi$ is a symmetric gauge function, for instance one of the Schatten $p$-norms $||x||_p = (\sum |x_i|^p)^{1/p}$, then it defines a natural unitary invariant norm on the complex matrices $||A||_\Phi = \Phi(s_1(A), \ldots, s_n(A))$, where $s_i(A)$ are the singular values of $A$ in nonincreasing order. The corresponding metric distance on the positive definite cone $\Omega$ is determined by $\delta_\Phi(A,B) = ||\log(A^{-1/2}BA^{-1/2})||_\Phi$. The metric $\delta_\Phi$ satisfies the nonpositive curvature property (2.2). We note that $\delta(A,B) = ||\log(A^{-1/2}BA^{-1/2})||_2$.

**3. Riccati matrix equations.** The nonlinear matrix equations $X = Q \pm A^*X^{-1}A$ are extensively studied (see [17], [18], [19], [26], [21], [40], [43]), where $Q > 0$ and $A$ is an $n \times n$ matrix. For positive definite $A$, we have an explicit formula for the positive definite solution of $X = Q + A^*X^{-1}A$.

THEOREM 3.1. [illegible] $A$ [illegible] $B$ [illegible]

$$\begin{aligned} 0 &= X^2 \pm X - A^2, \\ 0 &= BX^{-1}B - X \pm A, \\ 0 &= XA^{-1}X \pm X - B \end{aligned}$$

[illegible]

$$S_1^{\pm}(A) = \frac{1}{2}(\mp I + I\#(I + 4A^2)),$$
$$S_2^{\pm}(A,B) = \frac{1}{2}(\pm A + A\#(A + 4BA^{-1}B)),$$
$$S_3^{\pm}(A,B) = \frac{1}{2}(\mp A + A\#(A + 4B)),$$

[illegible]

[illegible] (1) It is easy to see that $S_1^{\pm}(A) = \frac{1}{2}(\mp I + I\#(I+4A^2))$ are positive definite. By direct computation, $S_1^{\pm}(A)$ are solutions of $X^2 \pm X - A^2 = 0$. Suppose that $X$ is a positive definite solution of $X^2+X-A^2 = 0$. Since $X^2+X-A^2 = (X+\frac{1}{2}I)^2 - A^2 - \frac{1}{4}I$, we have $X + \frac{1}{2}I = (A^2 + \frac{1}{4}I)^{1/2}$ and thus $X = S_1^{+}(A)$.

Next, suppose that $X$ is a positive definite solution of $X^2 - X - A^2 = 0$. Then $(X-\frac{1}{2}I)^2 = A^2 + \frac{1}{4}I$. One can see that $X$ and $A$ commute because $X^2 - X = A^2$. Then by diagonalizing $A$ and $X$, we have $X \geq I$ and $X - \frac{1}{2}I = (A^2 + \frac{1}{4}I)^{1/2}$. Therefore, $X = \frac{1}{2}I + I\#(A^2 + \frac{1}{4}I) = S_1^{-}(A)$.

(2) Consider the matrix equations $X = \pm A + BX^{-1}B$. Setting $Y = A^{-1/2}XA^{-1/2}$ and $D = A^{-1/2}BA^{-1/2}$ we have

$$Y = \pm I + DY^{-1}D, \tag{3.1}$$

respectively. By Lemma 2.1, if $Y$ is a positive definite solution of (3.1), then $Y$ satisfies $D = Y\#(Y \mp I) = (Y^2 \mp Y)^{1/2}$ or

$$Y^2 \mp Y - D^2 = 0. \tag{3.2}$$

Conversely, if $Y$ is a positive definite solution of (3.2), then $Y$ and $D$ commute and hence $Y$ satisfies (3.1). Therefore (3.2) and (3.1) are equivalent, respectively. Solving $Y$ we then have $Y = S_1^{\mp}(D)$ by (1) and therefore

$$\begin{aligned} S_2^{\pm}(A,B) &= A^{1/2}YA^{1/2} = A^{1/2}S_1^{\mp}(A^{-1/2}BA^{-1/2})A^{1/2} \\ &= A^{1/2}\Big(\frac{1}{2}(\pm I + I\#(I + 4(A^{-1/2}BA^{-1/2})^2))\Big)A^{1/2} \\ &= \frac{1}{2}(\pm A + A\#(A + 4BA^{-1}B)), \end{aligned}$$

where the last equality follows from the congruence transformation property of the geometric mean (Lemma 2.1 (iii)).

(3) We consider the matrix equations $XA^{-1}X \pm X - B = 0$. Let $Y = A^{-1/2}XA^{-1/2}$ and $D = A^{-1/2}BA^{-1/2}$. Then $Y^2 \pm Y - D = 0$ and hence $Y = S_1^{\pm}(D^{1/2})$; thus

$$\begin{aligned} S_3^{\pm}(A,B) &= A^{1/2}YA^{1/2} = A^{1/2}S_1^{\pm}(D^{1/2})A^{1/2} \\ &= A^{1/2}\Big(\frac{1}{2}(\mp I + I\#(I + 4D))\Big)A^{1/2} = \frac{1}{2}(\mp A + A\#(A + 4B)). \qquad \square \end{aligned}$$

Corollary 3.2. [illegible] $A$ [illegible] $B$ [illegible] $A \leq B$.

(i) [illegible] $XA^{-1}X - X - (B - A) = 0$ [illegible] $X = A\natural B := \frac{1}{2}(A + A\#(4B - 3A))$.

(ii) [illegible] $XA^{-1}X + X - (B - A) = 0$ [illegible] $X = A\bar{\natural}B := \frac{1}{2}(-A + A\#(4B - 3A))$.

[illegible] 3.3. The positive definite matrix $A\natural B = \frac{1}{2}(A + A\#(4B - 3A))$ is the unique positive definite fixed point of the strict contraction $f(X) = A\#(X + (B - A))$ defined on the positive definite convex cone $\mathrm{Sym}(n, \mathbb{R})^{++}$ for the Riemannian metric distance.

Indeed, the Riccati matrix equation $XA^{-1}X = X + (B - A)$ can be written as $X = A\#(X + (B - A))$ by the Riccati lemma. That is, the positive definite solution of the Riccati matrix equation is a fixed point of the function $f(X) = A\#(X + (B - A))$. Now, the square root function $X \to X^{1/2} = I\#X$ is a strict contraction for the Riemannian metric (2.2), and hence $X \mapsto A\#X$ is a strict contraction by invariance property of the metric. Furthermore, it turns out that every translation $X \mapsto X + C$, $C \geq 0$, is contracted by the Riemannian metric (Proposition 1.6 of [14]). Therefore the map $f(X) = A\#(X + (B - A))$ is a strict contraction defined on the Riemannian manifold $\mathrm{Sym}(n, \mathbb{R})^{++}$ and hence has a unique positive definite fixed point.

[illegible] 3.4. We observe that $A\bar{\natural}B = A\natural B - A$. This can be alternatively explained via a fixed point of a strict contraction. The Riccati matrix equation $XA^{-1}X + X - (B - A) = 0$ is equivalent to $X + A = A\#(X + B)$ by the Riccati lemma; $X + B = (X + A)A^{-1}(X + A) = XA^{-1}X + 2X + A$. That is, $A\bar{\natural}B$ is the unique positive solution of $X + A = A\#(X + B)$. Setting $Y = X + A$, we have $Y = X + A = A\#(X + B) = A\#(X + A + (B - A)) = A\#(Y + B - A)$. By the preceding remark, $Y = A\natural B$ and hence $A\natural B = A\bar{\natural}B + A$.

**4. The golden mean.** It is easy to see that $aA\natural bA = (a\natural b)A$ for any positive scalars $0 < a \leq b$ and, in particular, $A\natural 2A = \frac{1}{2}(1 + \sqrt{5})A$. We call $A\natural B$ the [illegible] of $A$ and $B$.

LEMMA 4.1. [illegible] $C \geq I$. [illegible] $2C^{1/2} - I \leq (4C - 3I)^{1/2} \leq 2C - I$ [illegible] $C = I$.

[illegible]. Use the spectral decomposition of $C$. □

We list some properties of the golden mean $A\natural B$.

PROPOSITION 4.2. [illegible] $A$ [illegible] $B$ [illegible] $A \leq B$.

(i) $M(A\natural B)M^T = (MAM^T)\natural(MBM^T)$ [illegible] $M(A\bar{\natural}B)M^T = (MAM^T)\bar{\natural}(MBM^T)$ [illegible] $n \times n$ [illegible] $M$.

(ii) $A\natural B = A\#B$ [illegible] $A = B$.

(iii) $A\natural B = \frac{1}{2}A^{1/2}\big(I + (4A^{-1/2}BA^{-1/2} - 3I)^{1/2}\big)A^{1/2}$.

(iv) [illegible] $A < B$, [illegible] $A\natural B = \frac{1}{2}\big(A + (B - A)\#(4A + A(B - A)^{-1}A)\big)$.

(v) ( [illegible] )

$$A \leq 2(A^{-1} + B^{-1})^{-1} \leq A\#B \leq A\natural B \leq B.$$

(vi) [illegible] $B \geq 3A$ ( [illegible] $B \leq 3A$), [illegible] $A\natural B \leq \frac{1}{2}(A + B)$ ( [illegible] $A\natural B \geq \frac{1}{2}(A + B)$)

(vii) $(A\natural B)\#(A\bar{\natural}B) = A\#(B - A)$.

(viii) $A\natural B = A\#(B + A\bar{\natural}B)$ [illegible] $A\bar{\natural}B = A\#(B - A\natural B)$.

[illegible]. (i) It follows by linearity of congruence transformations and invariance of geometric mean (Lemma 2.1 (iii)).

Set $C := A^{-1/2}BA^{-1/2}$. Then $C \geq I$ and hence we can apply Lemma 4.1.

(ii) It follows from the invariance property of the geometric and golden means that $A\#B = A\natural B$ if and only if $C^{1/2} = \frac{1}{2}(I + (4C - 3I)^{1/2})$. By Lemma 4.1, this is exactly the case $C = I$ or, equivalently, $A = B$.

(iii) It follows by (i).

(iv) Suppose that $A < B$. Then $C - I > 0$. By (iii) and Lemma 2.1 (iii),

$$\begin{aligned} A\natural B &= \frac{1}{2}A^{1/2}\Big(I + (4A^{-1/2}BA^{-1/2} - 3I)^{1/2}\Big)A^{1/2} \\ &= \frac{1}{2}A^{1/2}\Big(I + (4C - 3I)^{1/2}\Big)A^{1/2} = \frac{1}{2}A^{1/2}\Big(I + (4(C - I) + I)^{1/2}\Big)A^{1/2} \\ &= \frac{1}{2}A^{1/2}\Big(I + (C - I)\#(4I + (C - I)^{-1})\Big)A^{1/2} \\ &= \frac{1}{2}(A + (B - A)\#(4A + A(B - A)^{-1}A)). \end{aligned}$$

(v) By applying the order reversing property of the matrix inversion and the harmonic-geometric mean inequality, we get $A \leq 2(A^{-1} + B^{-1})^{-1} \leq A\#B$. The geometric and golden mean inequality follows from Lemma 4.1 and by (iii),

$$\begin{aligned} A\#B &= A^{1/2}(A^{-1/2}BA^{-1/2})^{1/2}A^{1/2} = A^{1/2}C^{1/2}A^{1/2} \\ &\overset{L(4.1)}{\leq} A^{1/2}\Big(\frac{1}{2}(I + (4C - 3I)^{1/2})\Big)A^{1/2} \overset{\text{(iii)}}{=} A\natural B \leq B. \end{aligned}$$

(vi) It follows by $C^2 - 4C + 3I = (C - 3I)(C - I)$.

(vii) It follows from $(I\natural C)(I\bar{\natural}C) = \frac{1}{4}(I + (4C - 3I)^{1/2})(-I + (4C - 3I)^{1/2}) = C - I$ and the invariance property of the golden mean (i).

(viii) By direct computation

$$\begin{aligned} (A\natural B)A^{-1}(A\natural B) &= \frac{1}{4}\Big(A + A\#(4B - 3A)\Big)A^{-1}\Big(A + A\#(4B - 3A)\Big) \\ &= \frac{1}{4}\Big(I + A\#(4B - 3A)\cdot A^{-1}\Big)\Big(A + A\#(4B - 3A)\Big) \\ &= \frac{1}{4}(A + 2\cdot A\#(4B - 3A) + 4B - 3A) \\ &= \frac{1}{2}(-A + A\#(4B - 3A)) + B = B + A\bar{\natural}B, \end{aligned}$$

where the third equality follows from the Riccati lemma $(A\#(4B-3A))A^{-1}(A\#(4B-3A)) = 4B-3A$. It then follows by the Riccati lemma $A\natural B = A\#(B+A\bar{\natural}B)$. Similarly, $A\bar{\natural}B = A\#(B - A\natural B)$. □

We denote $\mathcal{G}$ by the graph of the Löwner order $\leq$ on the positive definite cone $\mathcal{G} := \{(A,B)|\ 0 < A \leq B\}$. The functions

$$\begin{aligned} &g : \mathcal{G} \to \mathcal{G}, \quad g(A,B) = (A\#B, A\natural B), \\ &h : \mathcal{G} \to \mathcal{G}, \quad h(A,B) = (2(A^{-1} + B^{-1})^{-1}, A\natural B) \end{aligned}$$

are well-defined by the harmonic-geometric-golden mean inequalities (Proposition 4.2 (v)). We denote $g^n$ and $h^n$ by the $n$th iterate of $g$ and $h$.

THEOREM 4.3. [illegible] $(A,B) \in \mathcal{G}$ [illegible] GGM $(A,B)$ [illegible] HGM$(A,B)$ [illegible]

$$\begin{aligned} &\lim_{n\to\infty} g^n(A,B) = (\text{GGM}(A,B), \text{GGM}(A,B)), \\ &\lim_{n\to\infty} h^n(A,B) = (\text{HGM}(A,B), \text{HGM}(A,B)). \end{aligned}$$

[illegible] HGM$(A,B) \leq$ GGM$(A,B)$ [illegible]

[illegible]. Let $A, B$ be positive definite matrices such that $A \leq B$. Setting $(A_1, B_1) = (A, B), (A_{n+1}, B_{n+1}) = g^n(A, B)$, we have $A_2 = A\#B,\ B_2 = A\natural B, A_{n+1} = A_n\#B_n$, and $B_{n+1} = A_n\natural B_n$. By Proposition 4.2 (v), $A_1 = A \leq A\#B = A_2 \leq A\natural B = B_2 \leq B = B_1$. Hence $A_2 \leq B_2$. Doing this process with $(A_2, B_2)$, we get $A_1 \leq A_2 \leq A_2\#B_2 = A_3 \leq A_2\natural B_2 = B_3 \leq B_2 \leq B_1$ and by induction $A_1 \leq A_n \leq A_n\#B_n = A_{n+1} \leq A_n\natural B_n = B_{n+1} \leq B_n \leq B_1$ for all $n \in \mathbb{N}$. This implies that the sequence $A_n$ (respectively, $B_n$) is increasing (respectively, decreasing) bounded above (respectively, below). Thus they converge, say, $A_\infty = \lim_{n\to\infty} A_n, B_\infty = \lim_{n\to\infty} B_n$. Note that $A_\infty$ and $B_\infty$ are positive definite and that

$$A_\infty = \lim_{n\to\infty} A_{n+1} = \lim_{n\to\infty} A_n\#B_n = (\lim_{n\to\infty} A_n)\#(\lim_{n\to\infty} B_n) = A_\infty\#B_\infty.$$

Applying the Riccati lemma, we get $B_\infty = (A_\infty\#B_\infty)A_\infty^{-1}(A_\infty\#B_\infty) = A_\infty A_\infty^{-1} A_\infty = A_\infty$. This completes the proof for the map $g$.

Using the harmonic-golden mean inequality, one can give a similar proof for the map $h$. Furthermore, the order relation $\mathrm{HGM}(A, B) \leq \mathrm{GGM}(A, B)$ follows from the harmonic-geometric mean inequality. □

We call $\mathrm{GGM}(A, B)$ and $\mathrm{HGM}(A, B)$ the [illegible] and [illegible] of $A$ and $B$, respectively.

[illegible] 4.4. We note that the harmonic-arithmetic mean iteration $(A, B) \mapsto (2(A^{-1}+B^{-1})^{-1}, (A+B)/2)$ starting at $(A_0, B_0)$ has a (common) limit, the geometric mean $A_0\#B_0$ (cf. [32]), and that in the positive real case the limit of the arithmetic-geometric mean iteration $(a, b) \mapsto (\sqrt{ab}, (a+b)/2)$ (called the AGM) can be described in terms of complete elliptic integrals. See [12] and [13] for other mean iterations of positive real numbers. In this context, there may be interest in studying the means $\mathrm{GGM}(A, B), \mathrm{HGM}(A, B)$ and the self map of $\mathcal{G}$ defined by

$$\mathcal{G} \to \mathcal{G}, (A, B) \mapsto (\mathrm{HGM}(A, B), \mathrm{GGM}(A, B))$$

even for positive real numbers. For instance, we compute

$$\mathrm{GGM}(1, 2) = 1.58975858639889\ldots, \quad \mathrm{HGM}(1, 2) = 1.56481880877123\ldots.$$

**5. Matrix continued fractions and differential Riccati equations.** In [14] Bougerol considered the closed subsemigroup

$$\mathcal{H} := \left\{ \begin{pmatrix} A & B \\ C & D \end{pmatrix} \in \mathrm{Sp}(2n, \mathbb{R}) : A \text{ is invertible}, BA^T \geq 0, A^TC \geq 0 \right\}$$

of the symplectic Lie group $\mathrm{Sp}(2n, \mathbb{R})$. Here a symplectic matrix $T = \left(\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right)$ of order $2n$ means an invertible matrix satisfying $BA^T$ and $A^TC$ are symmetric and $A^TD - C^TB = I$. The members of $\mathcal{H}$ are called [illegible] (cf. [15]). We denote by $\mathcal{H}_0$ the subset of $\mathcal{H}$ for which $(1, 2)$ and $(2, 1)$ entries are positive definite: $BA^T, A^TC > 0$. We briefly review some results about Hamiltonian matrices. For more detail, see [31], [35], and [33]. The semigroup $\mathcal{H}$ has nonempty interior: $\mathcal{H}_0$ is the interior of $\mathcal{H}$ and is an open dense ideal of $\mathcal{H}$. Let $\mathfrak{sp}(2n, \mathbb{R})$ be the Lie algebra of the symplectic Lie group $\mathrm{Sp}(2n, \mathbb{R})$:

$$\mathfrak{sp}(2n, \mathbb{R}) = \left\{ \begin{pmatrix} A & B \\ C & -A^T \end{pmatrix} : B, C \in \mathrm{Sym}(n, \mathbb{R}), A \in \mathrm{M}(n, \mathbb{R}) \right\}.$$

The tangent Lie wedge of $\mathcal{H}$ defined by $L(\mathcal{H}) := \{X \in \mathfrak{sp}(2n,\mathbb{R}) : \exp(tX) \in \mathcal{H} \text{ for all } t \geq 0\}$ is determined by

$$L(\mathcal{H}) = \left\{ \begin{pmatrix} A & B \\ C & -A^T \end{pmatrix} \in \mathfrak{sp}(2n,\mathbb{R}) : B, C \geq 0 \right\}. \tag{5.1}$$

We further note that the interior of $L(\mathcal{H})$ is $L(\mathcal{H})_0 := \{(\begin{smallmatrix} A & B \\ C & -A^T \end{smallmatrix}) : B, C > 0\}$. It then follows by the ideal property of $\mathcal{H}_0$ and the homeomorphic property of exponential mapping near the zero matrix that

$$\exp(L(\mathcal{H})_0) \subset \mathcal{H}_0. \tag{5.2}$$

In [14] Bougerol proved that each member of $\mathcal{H}$ (respectively, $\mathcal{H}_0$) under the action of linear fractional transformations defined by

$$\begin{pmatrix} A & B \\ C & D \end{pmatrix} .X = (AX+B)(CX+D)^{-1} \text{ if } CX+D \text{ is invertible}$$

carries the convex cone $\mathrm{Sym}(n,\mathbb{R})^{++}$ into itself [14, Proposition 1.5] and is a (respectively, strict) contraction with respect to the Riemannian metric $\delta(A,B)$ [14, Theorem 1.7]. We further note that each member of $\mathcal{H}$ (respectively, $\mathcal{H}_0$) is also a (respectively, strict) contraction with respect to the Thompson part metric $d(A,B) = ||\log(A^{-1/2}BA^{-1/2})||_\infty$ induced by the spectral norm with an explicit formula (a Birkhoff contraction formula) for least contraction coefficient [38], [39], [35].

We consider the symplectic Hamiltonian matrix $(\begin{smallmatrix} I+AB & A \\ B & I \end{smallmatrix})$ for positive definite matrices $A$ and $B$. It belongs to $\mathcal{H}_0$ since $A(I+AB)^T = A + ABA > 0$ and $(I+AB)^T B = B + BAB > 0$. Now, applying Bougerol's result, the associated fractional transformation

$$\begin{aligned} \Phi_{A,B}(X) &= \begin{pmatrix} I+AB & A \\ B & I \end{pmatrix} .X = ((I+AB)X + A)(BX+I)^{-1} \\ &= (A(BX+I)+X)(BX+I)^{-1} = A + X(BX+I)^{-1} = A + (B+X^{-1})^{-1} \end{aligned}$$

is strictly contracted by the Riemannian distance, and hence it has a unique positive definite fixed point. Furthermore, the fixed point is the limit of the $n$th iterations with any initial point by the Banach fixed point theorem. We assert that the $n$th iteration $\Phi^n_{A,B}(A)$ forms a continued fraction. The continued fraction $[A_1, A_2, \ldots, A_n]$ of positive definite matrices is naturally defined by

$$[A_1] = A_1, \quad [A_1, A_2, \ldots, A_n] = A_1 + [A_2, \ldots, A_n]^{-1}.$$

Then

$$\Phi^n_{A,B}(A) = [\underbrace{A, B, A, B, \ldots, A, B, A}_{2n+1 \text{ terms}}].$$

Indeed, $\Phi_{A,B}(X) = [A, B, X]$ for any $X > 0$ and by induction

$$\begin{aligned} \Phi^n_{A,B}(A) &= \Phi_{A,B}(\Phi^{n-1}_{A,B}(A)) = [A, B, \Phi^{n-1}_{A,B}(A)] = [A, B, [\underbrace{A, B, \ldots, A}_{2n-1}]] \\ &= A + [\underbrace{B, A, B, \ldots, A}_{2n}]^{-1} = [\underbrace{A, B, A, B \ldots, A, B, A}_{2n+1}]. \end{aligned}$$

Similarly,

$$\Phi^n_{A,B}(A+B^{-1}) = [\underbrace{A, B, A, B, \ldots, A, B}_{2(n+1)\ \text{terms}}].$$

THEOREM 5.1. [illegible] $A$ [illegible] $B$ [illegible]

$$\begin{aligned} A\natural(A+B^{-1}) &= \lim_{n\to\infty}[\underbrace{A, B, A, B, \ldots, A, B, A}_{2n+1}] \\ &= \lim_{n\to\infty}[\underbrace{A, B, A, B, \ldots, A, B}_{2n}]. \end{aligned}$$

[illegible] $0 < A < B$ [illegible]

$$A\natural B = \lim_{n\to\infty}[\underbrace{A, (B-A)^{-1}, A, (B-A)^{-1}, \ldots, A}_{2n+1}]$$

[illegible]

$$A\bar{\natural}B = \lim_{n\to\infty}[\underbrace{(B-A)^{-1}, A, (B-A)^{-1}, \ldots, A}_{2n}]^{-1}.$$

[illegible] By the Banach fixed point theorem and by the above observation, the unique positive definite fixed point of $\Phi_{A,B}$ is the limit of the two $n$th iterations starting the points $A$ and $A+B^{-1}$, respectively:

$$\lim_{n\to\infty}[\underbrace{A, B, A, B, \ldots, A}_{2n+1}] = \lim_{n\to\infty}[\underbrace{A, B, A, B, \ldots, A, B}_{2n}].$$

We will show that $A\natural(A+B^{-1})$ is a fixed point of $\Phi_{A,B}$.

Let $X$ be the positive definite fixed point of $\Phi_{A,B}$. Then it satisfies the continued fraction equation $[A, B, X] = X$ and

$$\begin{aligned} X &= [A, B, X] = A + [B, X]^{-1} = A + (B + X^{-1})^{-1} \\ &= A^{1/2}\Big(I + \Big(A^{1/2}BA^{1/2} + (A^{-1/2}XA^{-1/2})^{-1}\Big)^{-1}\Big)A^{1/2} = A^{1/2}[I, C, D]A^{1/2}, \end{aligned}$$

where $C = A^{1/2}BA^{1/2}, D = A^{-1/2}XA^{-1/2}$. This implies that

$$[I, C, D] = A^{-1/2}[A, B, X]A^{-1/2} = A^{-1/2}XA^{-1/2} = D,$$

that is, $D = A^{-1/2}XA^{-1/2}$ is the unique positive definite solution of the equation of continued fraction $[I, C, Y] = Y$. Since $(C + D^{-1})^{-1} = D - D(D + C^{-1})^{-1}D$ for any positive definite matrices $C$ and $D$ (cf. [1], [49]), $[I, C, D] = D$ implies that

$$D^2 - D - C^{-1} = 0. \tag{5.3}$$

By Theorem 3.1, $D = \frac{1}{2}(I + I\#(I + 4C^{-1})) = I\natural(I + C^{-1})$. Therefore,

$$\begin{aligned} X &= A^{1/2}DA^{1/2} = A^{1/2}(I\natural(I + C^{-1}))A^{1/2} \\ &= A^{1/2}(I\natural(I + A^{-1/2}B^{-1}A^{-1/2}))A^{1/2} = A\natural(A + B^{-1}), \end{aligned}$$

where the last equality follows from the invariance property of the golden mean (Proposition 4.2).

Finally we have a similar result for $A\bar{\natural}B$:

$$\begin{aligned}A\bar{\natural}B &= (A\natural B) - A = \Big(\lim_{n\to\infty}[\underbrace{A, (B-A)^{-1}, A, (B-A)^{-1}, \dots, A}_{2n+1}]\Big) - A \\ &= \Big(A + \lim_{n\to\infty}[\underbrace{(B-A)^{-1}, A, (B-A)^{-1}, \dots, A}_{2n}]^{-1}\Big) - A \\ &= \lim_{n\to\infty}[\underbrace{(B-A)^{-1}, A, (B-A)^{-1}, \dots, A}_{2n}]^{-1}. \qquad \square\end{aligned}$$

We consider the [illegible] of the golden mean $A\natural B$, which is defined by $(B^{-1}\natural A^{-1})^{-1}$.

COROLLARY 5.2. [illegible] $0 < A < B$, [illegible] $A\natural B$ [illegible]

$$(B^{-1}\natural A^{-1})^{-1} = (A^{-1} - B^{-1})^{-1}\bar{\natural}(B + (A^{-1} - B^{-1})^{-1}).$$

[illegible] $(A\natural B)^{-1} = (B-A)^{-1}\bar{\natural}(A^{-1} + (B-A)^{-1})$.

[illegible] Let $X = (A^{-1} - B^{-1})^{-1}$ and $Y = B + (A^{-1} - B^{-1})^{-1}$. Then by Theorem 5.1,

$$(X\bar{\natural}Y)^{-1} = \lim_{n\to\infty}[B^{-1}, (A^{-1} - B^{-1})^{-1}, B^{-1}, \dots, (A^{-1} - B^{-1})^{-1}] = B^{-1}\natural A^{-1}. \qquad \square$$

We consider two Riccati differential equations

$$\dot{X} = -XA^{-1}X + X + (B - A), \tag{5.4}$$

$$\dot{X} = -XA^{-1}X - X + (B - A) \tag{5.5}$$

for positive definite matrices $A$ and $B$ with $A < B$.

Let $T = \left(\begin{smallmatrix} I/2 & B-A \\ A^{-1} & -I/2 \end{smallmatrix}\right)$ and $S = \left(\begin{smallmatrix} -I/2 & B-A \\ A^{-1} & I/2 \end{smallmatrix}\right)$. Then since $A\natural B$ is the positive definite solution of the associated matrix equations of (5.4), the graph of $A\natural B$ is $T$-invariant and hence $\exp tT$-invariant. Indeed,

$$\begin{aligned}\begin{pmatrix} I/2 & B-A \\ A^{-1} & -I/2 \end{pmatrix}\begin{pmatrix} (A\natural B)x \\ x \end{pmatrix} &= \begin{pmatrix} \frac{1}{2}(A\natural B)x + (B-A)x \\ (A^{-1}\cdot A\natural B)x - x/2 \end{pmatrix} \\ &= \begin{pmatrix} (A\natural B)y \\ y \end{pmatrix}, \quad y = (A^{-1}\cdot A\natural B)x - x/2,\end{aligned}$$

where we used the fact $(A\natural B)A^{-1}(A\natural B) = B + A\bar{\natural}B = A\natural B + (B-A)$ (Proposition 4.2 (viii)). Identifying the Möbius action of the symplectic group on symmetric matrices as the linear action on the space of isotropic subspaces of $\mathbb{R}^n \times \mathbb{R}^n$ (cf. section 5 of [32]), we have that $\exp tT.(A\natural B) = A\natural B$ for all $t \in \mathbb{R}$. Similarly, $\exp tS.(A\bar{\natural}B) = A\bar{\natural}B$.

However, from $T, S \in L(\mathcal{H})_0$ and (5.2), one sees that $\exp tT$ and $\exp tS$ belong to $\mathcal{H}_0$ for $t > 0$ and hence they are strict contractions for the Riemannian distance. This implies that $A\natural B$ and $A\bar{\natural}B$ are unique positive definite fixed points of $\exp tT$ and $\exp tS$, respectively.

Let $X_0 > 0$ be an arbitrary initial point of the Riccati differential equation (5.4). Then from a standard fact about differentiable Lie group action (cf. section 5 of [32]) one may see that $X(t) := \exp tT.X_0$ is the solution of (5.4). Putting $K := \sup_{0\le s\le 1}\delta(\exp sT.X_0, X_0)$, where $\delta(A,B) = ||\log(A^{-1/2}BA^{-1/2})||_2$ denotes the Riemannian metric on the positive definite cone $\mathrm{Sym}(n,\mathbb{R})^{++}$, we then have for $t = n + s, s \in [0,1], n = 1,2,\ldots,$

$$\begin{aligned}\delta(\exp tT.X_0, A\natural B) &= \delta(\exp(n+s)T.X_0, A\natural B)\\ &\leq \delta(\exp nT.(\exp sT.X_0), \exp nT.X_0) + \delta(\exp nT.X_0, A\natural B)\\ &\leq \alpha^n \delta(\exp sT.X_0, X_0) + \delta(\exp nT.X_0, A\natural B)\\ &\leq \alpha^n K + \alpha^n \delta(X_0, A\natural B) = \alpha^n(K + \delta(X_0, A\natural B)),\end{aligned}$$

where $\alpha$ denotes the least contraction coefficient of the strict contraction $\exp T$. We conclude that the solution $X(t)$ converges to $A\natural B$ as $t \to \infty$. A similar method can be applied for $A\bar{\natural}B$.

THEOREM 5.3. [illegible] $X(t)$ [illegible] $Y(t)$ [illegible] (5.4) [illegible] (5.5) [illegible]

$$A\natural B = \lim_{t\to\infty} X(t) \quad [illegible] \quad A\bar{\natural}B = \lim_{t\to\infty} Y(t).$$

[illegible] $\lim_{t\to\infty} X(t)\#Y(t) = (A\natural B)\#(A\bar{\natural}B) = A\#(B-A)$.

[illegible] The equality $(A\natural B)\#(A\bar{\natural}B) = A\#(B-A)$ follows from Proposition 4.2 (vii). ☐

[illegible] 5.4. The preceding result holds true under the condition $A < B$ and solutions with initial point at positive definite matrices. In the case that $A \leq B$ but not $A < B$, that is, $A^{-1/2}BA^{-1/2}$ has the eigenvalue 1, then $\exp tT$ is not a strict contraction for $t > 0$, and so it is unclear whether solutions $X(t)$ converge to $A\natural B$.

**Acknowledgment.** The author is very grateful to the referees for valuable comments.

# A FAST SOLVER FOR HSS REPRESENTATIONS VIA SPARSE MATRICES*

S. CHANDRASEKARAN[†], P. DEWILDE[‡], M. GU[§], W. LYONS[¶], AND T. PALS[†]

**Abstract.** In this paper we present a fast direct solver for certain classes of dense structured linear systems that works by first converting the given dense system to a larger system of block sparse equations and then uses standard sparse direct solvers. The kind of matrix structures that we consider are induced by numerical low rank in the off-diagonal blocks of the matrix and are related to the structures exploited by the fast multipole method (FMM) of Greengard and Rokhlin. The special structure that we exploit in this paper is captured by what we term the hierarchically semiseparable (HSS) representation of a matrix. Numerical experiments indicate that the method is probably backward stable.

**Key words.** fast multipole method, low-rank structures, fast solvers, orthogonal factorizations, hierarchically semiseparable representations, sparse matrices, direct sparse solvers

**AMS subject classifications.** 65F05, 65F50

**DOI.** 10.1137/050639028

## 1. Introduction.

Beginning with the early work of Gohberg, Kailath, and Koltracht [6] and Rokhlin [11], and the introduction of the fast multipole method (FMM) of Greengard and Rokhlin [7], it has become clear that many large matrices that arise in practice have a complex low-rank structure in their submatrices that can be exploited efficiently to speed up matrix algorithms. In particular, such structured matrices arise in the numerical solution of integral equations, as fill-in during Gaussian elimination of sparse matrices that come from the discretization of elliptic PDEs, and in many other applications. In earlier work [2] we introduced techniques to design fast and stable direct solvers for such structured matrices based on an implicit $ULV$ factorization algorithm and a matrix representation that we called hierarchically semiseparable (HSS). In this paper we show that linear systems of equations involving such dense structured matrices can be efficiently converted into a larger sparse system of equations that has an ordering of the unknowns permitting a very efficient direct Gaussian elimination solver to be used. This technique has several advantages. First, it makes it possible to exploit the highly developed sparse direct solver technology to attack dense structured problems. Second, it provides a theoretical tool to study these large dense structured matrices. However, in this paper we just concentrate on showing how this technique can be used to design a fast, stable solver for matrices in HSS form only.

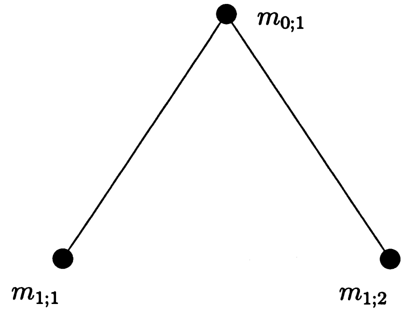

FIG. 1. *One level HSS partition tree with* $m_{0;1} = m_{1;1} + m_{1;2}$.

The idea of explicitly using sparse representations of low-rank structured matrices seems to have first originated in the use of diagonal algebras in time-varying systems theory [5]. Of course, such representations are implicit even in the original FMM papers [7].

## 2. HSS representations.

Usually an $m \times n$ matrix $A$ is represented in terms of its $mn$ entries $A_{i,j}$. The HSS representation of $A$ is another way to present the same information. It tries to exploit the presence of low- (numerical) rank submatrices in $A$. Of course this presumes that we know which submatrices are potentially of low rank. Fortunately, in the application that we have in mind, namely, the numerical solution of elliptic PDEs, this information is usually available. In particular, the HSS representation assumes that the matrix has its low-rank submatrices in the off-diagonal regions. Historically the HSS representation is just a special case of the representations commonly exploited in the FMM literature.

The HSS representation depends directly on a recursive block partitioning of the matrix. It is natural to use a tree to represent these partitions. Suppose at the first level the matrix is partitioned as follows:

$$A = \begin{array}{c} \\ m_{1;1} \\ m_{1;2} \end{array} \begin{array}{c} \begin{array}{cc} m_{1;1} & m_{1;2} \end{array} \\ \begin{pmatrix} A_{1;1,1} & A_{1;1,2} \\ A_{1;2,1} & A_{1;2,2} \end{pmatrix} \end{array}.$$

Then the corresponding HSS partition tree is shown in Figure 1 where it is assumed that $A$ is an $m_{0;1} \times m_{0;1}$ matrix.

The HSS representation tries to exploit the low (numerical) rank of the off-diagonal blocks. The one level HSS tree, for example, is based on the partitioning

$$A = \begin{array}{c} \\ m_{1;1} \\ m_{1;2} \end{array} \begin{array}{c} \begin{array}{cc} m_{1;1} & m_{1;2} \end{array} \\ \begin{pmatrix} D_{1;1} & U_{1;1} B_{1;1,2} V_{1;2}^H \\ U_{1;2} B_{1;2,1} V_{1;1}^H & D_{1;2} \end{pmatrix} \end{array},$$

where clearly the factorization of the off-diagonal blocks can be chosen to be rank-revealing. The tree is shown in Figure 2. At this stage it is not quite clear why, for example, $U_{1;1}$ is written at the first leaf node. One reason is that that particular node corresponds to the first $m_{1;1}$ rows of the matrix, and $U_{1;1}$ is associated with (a portion) of those rows. A better reason will become obvious once we get into section 3. Similarly the expansion coefficient $B_{1;1,2}$ is placed on the edge connecting

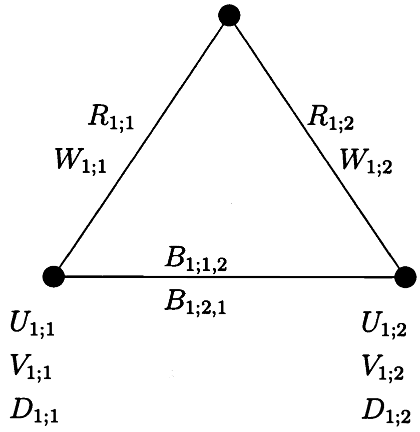

FIG. 2. *One level HSS.*

the two leaves because it sits at the intersection of the rows corresponding to the first leaf node and the columns corresponding to the second leaf node. The matrices $R_{1;i}$ and $W_{1;i}$ have no columns at all and will be explained shortly.

The two level HSS representation is based on the partition

$$A = \begin{array}{c} \\ \begin{pmatrix} m_{2;1} \\ m_{2;2} \end{pmatrix} \\ \begin{pmatrix} m_{2;3} \\ m_{2;4} \end{pmatrix} \end{array} \begin{array}{c} \begin{array}{cc} \begin{pmatrix} m_{2;1} & m_{2;2} \end{pmatrix} & \begin{pmatrix} m_{2;3} & m_{2;4} \end{pmatrix} \end{array} \\ \begin{pmatrix} \begin{pmatrix} A_{2;1,1} & A_{2;1,2} \\ A_{2;2,1} & A_{2;2,2} \end{pmatrix} & A_{1;1,2} \\ A_{1;2,1} & \begin{pmatrix} A_{2;3,3} & A_{2;3,4} \\ A_{2;4,3} & A_{2;4,4} \end{pmatrix} \end{pmatrix} \end{array},$$

where $m_{1;i} = m_{2;2i-1} + m_{2;2i}$ for $i = 1, 2$. The matrices that make up the two level HSS form of $A$ are in turn inferred from the equation

$$A = \begin{pmatrix} \begin{pmatrix} D_{2;1} & U_{2;1}B_{2;1,2}V_{2;2}^H \\ U_{2;2}B_{2;2,1}V_{2;1}^H & D_{2;2} \end{pmatrix} & U_{1;1}B_{1;1,2}V_{1;2}^H \\ U_{1;2}B_{1;2,1}V_{1;1}^H & \begin{pmatrix} D_{2;3} & U_{2;3}B_{2;3,4}V_{2;4}^H \\ U_{2;4}B_{2;4,3}V_{2;3}^H & D_{2;4} \end{pmatrix} \end{pmatrix}.$$

However, the matrices $U_{1;i}$ and $V_{1;i}$ are not part of the two level HSS representation. And, equally importantly, $U_{2;i}$ ($V_{2;i}$) is not chosen as a column (row) basis for $A_{2;i,j}$ ($A_{2;j,i}$). Rather we define [illegible] operators $R_{2;i}$ and $W_{2;i}$ such that

$$U_{1;i} = \begin{pmatrix} U_{2;2i-1}R_{2;2i-1} \\ U_{2;2i}R_{2;2i} \end{pmatrix}, \qquad i = 1, 2, \tag{1}$$

$$V_{1;i} = \begin{pmatrix} V_{2;2i-1}W_{2;2i-1} \\ V_{2;2i}W_{2;2i} \end{pmatrix}, \qquad i = 1, 2. \tag{2}$$

Notice that for this to be possible we must choose $U_{2;i}$ such that it forms a column basis for the submatrix

$$\begin{pmatrix} A_{2;i,1} & \cdots A_{2;i,i-1} & A_{2;i,i+1} & \cdots & A_{2;i,4} \end{pmatrix}.$$

Notice that we obtain the above matrix by taking the $i$th block row from the second level partition of $A$ and dropping the diagonal block $A_{2;i,i}$. Similarly we choose $V_{2;i}$

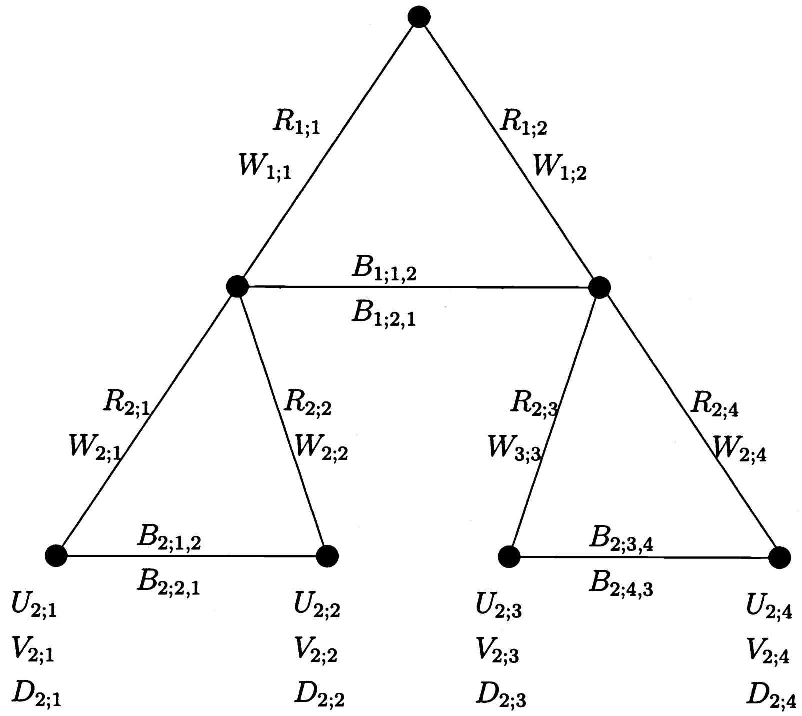

FIG. 3. *Two level HSS.*

to be a row basis for the submatrix

$$\begin{pmatrix} A_{2;1,i} \\ \vdots \\ A_{2;i-1,i} \\ A_{2;i+1,i} \\ \vdots \\ A_{2;4,i} \end{pmatrix}.$$

The two level HSS tree is shown in Figure 3. The translation operators are placed at the edges from the leaves of the second level to their parents in the first level to reflect (1) and (2). The translation operators $R_{1;i}$ and $W_{1;i}$ are not important and are usually chosen to be matrices with no columns at all.

Generally speaking, an HSS representation is a finite binary tree of the type shown in Figure 3, where the dimensions of the matrices at the nodes and leaves must be chosen according to the restrictions that these assemblies

$$\begin{pmatrix} B_{k;2i-1,2i} & R^H_{k+1;2i-1} \\ W_{k+1;2i} & 0 \end{pmatrix} \quad \text{and} \quad \begin{pmatrix} B_{k;2i,2i-1} & R^H_{k+1;2i} \\ W_{k+1;2i-1} & 0 \end{pmatrix}$$

are possible if the node $(k,i)$ is not a leaf,[1] and if it is a leaf, then the assembly

$$\begin{pmatrix} D_{k;i} & U_{k;i} \\ V^H_{k;i} & 0 \end{pmatrix}$$

---

[1] The node $(k,i)$ is the $i$th node counting from the left at level $k$ in the tree.

and the multiplications

$$U_{k;i}R_{k;i} \quad \text{and} \quad V_{k;i}W_{k;i}$$

must be possible. In this paper we always assume that $R_{1;i}$ and $W_{1;i}$ have no columns at all.

Given an arbitrary HSS tree and an arbitrary matrix $A$ with the right number of rows and columns, one can [illegible] find an HSS representation for $A$ conforming with the HSS tree. The $O(n^2)$ flops algorithm to carry this out is presented in [2].

**3. Fast multiplication.** The key to the fast inversion algorithm is the fast algorithm for multiplying a matrix in HSS form with a vector. In particular, it is the recursions for the multiplication algorithm that are the key. The recursions we present are exactly the same as those used in the FMM [7].

To be concrete assume that the HSS form of the matrix $A$ is available and that we want to multiply it rapidly with the vector $x$ to obtain $Ax = b$. Of course one method is to first get the componentwise entries $A_{i,j}$ of $A$ and to then use a conventional algorithm. However, that would not be the most efficient thing to do.

Rather, we first observe that we need to multiply submatrices of $x$ with $V_{k;i}$ for each node in the HSS tree. Of course some of these $V_{k;i}$'s are not directly available, namely, those on the nonleaf nodes, but we can get around that using the translation operators $W_{k;i}$. Before we get into the details we need some notation. We will assume that $x_{k;i}$ denotes a submatrix of $x$ partitioned according to the $k$th level of the HSS tree. That is,

$$x = \begin{array}{c} m_{1;1} \\ m_{1;2} \end{array} \begin{pmatrix} x_{1;1} \\ x_{1;2} \end{pmatrix},$$

and

$$x = \begin{array}{c} m_{2;1} \\ m_{2;2} \\ m_{2;3} \\ m_{2;4} \end{array} \begin{pmatrix} x_{2;1} \\ x_{2;2} \\ x_{2;3} \\ x_{2;4} \end{pmatrix},$$

and so on.

Now we observe that at the leaf node $(k, i)$ we can compute

$$g_{k;i} = V_{k;i}^H x_{k;i}.$$

If $(k, i)$ is not a leaf node we can infer

$$\begin{aligned} g_{k;i} &= V_{k;i}^H x_{k;i} \\ &= \begin{pmatrix} V_{k+1;2i-1}W_{k+1;2i-1} \\ V_{k+1;2i}W_{k+1;2i} \end{pmatrix}^H \begin{pmatrix} x_{k+1;2i-1} \\ x_{k+1;2i} \end{pmatrix} \\ &= W_{k+1;2i-1}^H V_{k+1;2i-1}^H x_{k+1;2i-1} + W_{k+1;2i}^H V_{k+1;2i}^H x_{k+1;2i} \\ &= W_{k+1;2i-1}^H g_{k+1;2i-1} + W_{k+1;2i}^H g_{k+1;2i}. \end{aligned}$$

We see therefore that $g_{k;i} = V_{k;i}^H x_{k;i}$ can be computed at each node of the HSS tree very efficiently via the set of equations

$$g_{k;i} = V_{k;i}^H x_{k;i} \qquad \text{at a leaf,} \tag{3}$$

$$= W_{k+1;2i-1}^H g_{k+1;2i-1} + W_{k+1;2i}^H g_{k+1;2i} \qquad \text{at a nonleaf node.} \tag{4}$$

To complete the multiplication let us look in detail at $b_{2;1}$ for a two level HSS tree

$$b_{2;1} = D_{2;1}x_{2;1} + U_{2;1}B_{2;1,2}g_{2;2} + U_{2;1}R_{2;1}B_{1;1,2}g_{1;2},$$

which we can regroup more carefully as follows:

$$b_{2;1} = D_{2;1}x_{2;1} + U_{2;1}(B_{2;1,2}g_{2;2} + R_{2;1}B_{1;1,2}g_{1;2}).$$

This suggests that we define the auxiliary variables $f_{k;i}$ such that

$$b_{k;i} = A_{k;i,i}x_{k;i} + U_{k;i}f_{k;i}.$$

Of course if $(k, i)$ is not a leaf, then we will not have access to the diagonal block $A_{k;i,i}$ or $U_{k;i}$. But in that case we see that we can split the equation using the translation operators $R_{k;i}$ as follows:

$$\begin{pmatrix} b_{k+1;2i-1} \\ b_{k+1;2i} \end{pmatrix} = \begin{pmatrix} A_{k+1;2i-1,2i-1} & U_{k+1;2i-1}B_{k+1;2i-1,2i}V_{k+1;2i}^H \\ U_{k+1;2i}B_{k+1;2i,2i-1}V_{k+1;2i-1}^H & A_{k+1;2i,2i} \end{pmatrix}$$
$$\cdot \begin{pmatrix} x_{k+1;2i-1} \\ x_{k+1;2i} \end{pmatrix} + \begin{pmatrix} U_{k+1;2i-1}R_{k+1;2i-1} \\ U_{k+1;2i}R_{k+1;2i} \end{pmatrix} f_{k;i},$$

which simplifies to the pair of equations

$$b_{k+1;2i-1} = A_{k+1;2i-1,2i-1}x_{k+1;2i-1} + U_{k+1;2i-1}\left(B_{k+1;2i-1,2i}g_{k+1;2i} + R_{k+1;2i-1}f_{k;i}\right),$$
$$b_{k+1;2i} = A_{k+1;2i,2i}x_{k+1;2i-1,2i} + U_{k+1;2i}\left(B_{k+1;2i,2i-1}g_{k+1;2i-1} + R_{k+1;2i-}f_{k;i}\right).$$

This does not seem to lead anywhere, but in fact it does tell us that the recursive equations for the auxiliary variables $f_{k;i}$ are

$$f_{k+1;2i-1} = B_{k+1;2i-1,2i}g_{k+1;2i} + R_{k+1;2i-1}f_{k;i}, \tag{5}$$

$$f_{k+1;2i} = B_{k+1;2i,2i-1}g_{k+1;2i-1} + R_{k+1;2i}f_{k;i}. \tag{6}$$

This looks good, but how do we start off the recursion? In other words, what is $f_{0;1}$? Let us look at its defining equation

$$b = Ax = b_{0;1} = A_{0;1}x_{0;1} + U_{0;1}f_{0;1},$$

which implies that

$$f_{0;1} = (\ ), \tag{7}$$

the empty matrix! Of course at the leaf level we can directly compute the outputs from

$$b_{k;i} = D_{k;i}x_{k;i} + U_{k;i}f_{k;i}. \tag{8}$$

With that we have a complete set of efficient recursions for computing $Ax = b$ given $x$ and the HSS form of $A$.

**4. Sparse representation.** We will now make the effort to write the multiplication recursions in a compact form using matrix notation, and without indices. This will turn out to be the key step that can reveal the way to the fast solver.

We first define some block diagonal matrices. Let $\mathbf{D}$ be a block diagonal matrix formed by ordering $D_{k;i}$ in, say, breadth-first order.[2] Similarly we define block diagonal matrices $\mathbf{U}$ and $\mathbf{V}$. For example, for a two level HSS form, we would have

$$\mathbf{U} = \begin{pmatrix} U_{2;1} & & & \\ & U_{2;2} & & \\ & & U_{2;3} & \\ & & & U_{2;4} \end{pmatrix}.$$

We also arrange all the translation operators $R_{k;i}$ in a block diagonal matrix $\mathbf{R}$, in breadth-first order. Note that there is one $R_{k;i}$ per parent node. So $\mathbf{R}$ will be a block diagonal matrix with a potentially different number of diagonal blocks than, say, $\mathbf{U}$. Similarly we define the block diagonal matrix $\mathbf{W}$. For example, for a two level HSS representation we would have

$$\mathbf{W} = \begin{pmatrix} W_{1;1} & & & & & \\ & W_{1;2} & & & & \\ & & W_{2;1} & & & \\ & & & W_{2;2} & & \\ & & & & W_{2;3} & \\ & & & & & W_{2;4} \end{pmatrix}.$$

We also arrange the $B_{k;i,j}$ in a block diagonal matrix $\mathbf{B}$, with the $B_{k;i,j}$ in breadth-first order, and within a node we place $B_{k+1;2i-1,2i}$ before $B_{k+1;2i,2i-1}$. So for a two level HSS form we would have

$$\mathbf{B} = \begin{pmatrix} B_{1;1,2} & & & & & \\ & B_{1;2,1} & & & & \\ & & B_{2;1,2} & & & \\ & & & B_{2;2,1} & & \\ & & & & B_{2;3,4} & \\ & & & & & B_{2;4,3} \end{pmatrix}.$$

We next define the shift-down operator $Z_{\downarrow}$ on trees. Given a binary tree with matrices on each node, the action of $Z_{\downarrow}$ on the binary tree is to produce an identical tree in which the matrix on every parent node has been moved into the children. The matrices at the leaves are dropped off. The root node acquires a zero matrix. For example for a two level HSS tree the action of $Z_{\downarrow}$ (in the depth-first order for input and output) is expressed by the following equation corresponding to Figure 4:

$$\underbrace{\begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \end{pmatrix}}_{Z_{\downarrow}} \begin{pmatrix} a \\ b \\ c \\ d \\ e \\ f \\ g \end{pmatrix} = \begin{pmatrix} 0 \\ a \\ a \\ b \\ b \\ c \\ c \end{pmatrix}. \tag{9}$$

---

[2] We are free to pick this order, but once we have chosen an order we must stick with it for the remaining diagonal matrices too.

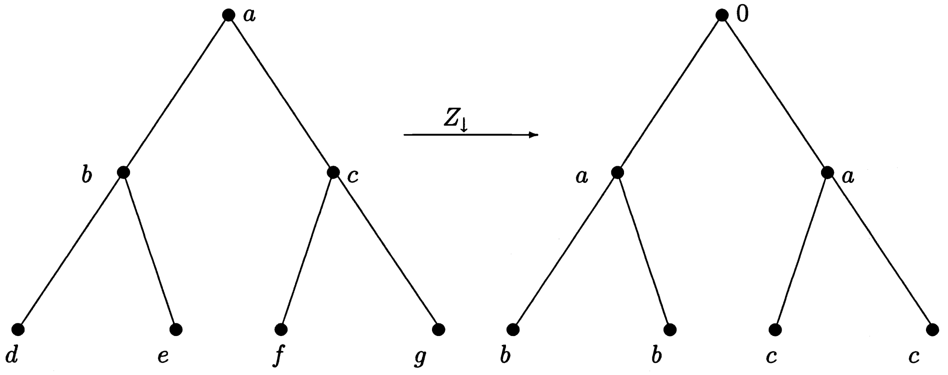

FIG. 4. *Action of $Z_\downarrow$ on a two level HSS tree.*

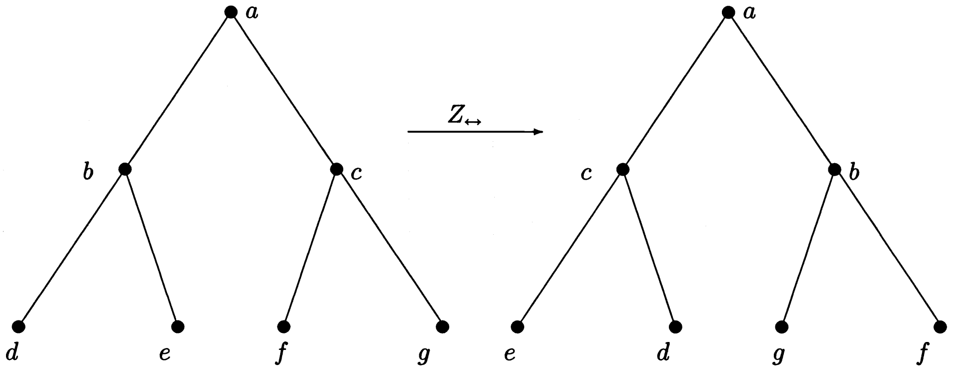

FIG. 5. *Action of $Z_\leftrightarrow$ on a two level HSS tree.*

As can be seen $Z_\downarrow$ is very sparse and noninvertible.

Now we define the twiddle operator $Z_\leftrightarrow$ on trees. When $Z_\leftrightarrow$ acts on a binary tree with matrices on each node, it exchanges the matrices on sibling nodes. The following equation gives an explicit representation for $Z_\leftrightarrow$ on a two level HSS tree (which is shown pictorially in Figure 5):

$$\underbrace{\begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 \end{pmatrix}}_{Z_\leftrightarrow} \begin{pmatrix} a \\ b \\ c \\ d \\ e \\ f \\ g \end{pmatrix} = \begin{pmatrix} a \\ c \\ b \\ e \\ d \\ g \\ f \end{pmatrix}.$$

Note that $Z_\leftrightarrow$ is a permutation matrix (which are always very sparse, of course).

Now let us assign the intermediate quantities $g_{k;i}$ and $f_{k;i}$ to the corresponding nodes on the HSS tree. Naturally we can then stack them up in breadth-first ordering in a single block vector and call them $\mathbf{g}$ and $\mathbf{f}$. For example, for the two level HSS tree we would have

$$\mathbf{f} = \begin{pmatrix} f_{0;1} \\ f_{1;1} \\ f_{1;2} \\ f_{2;1} \\ f_{2;2} \\ f_{2;3} \\ f_{2;4} \end{pmatrix}.$$

We also need to define a projection operator $\mathbf{P}_{\text{leaf}}$ that acting on a block vector like $\mathbf{f}$ would return the restriction of it to the leaf nodes. For example, for the two level HSS tree we would have

$$\underbrace{\begin{pmatrix} 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix}}_{\mathbf{P}_{\text{leaf}}} \begin{pmatrix} f_{0;1} \\ f_{1;1} \\ f_{1;2} \\ f_{2;1} \\ f_{2;2} \\ f_{2;3} \\ f_{2;4} \end{pmatrix} = \begin{pmatrix} f_{2;1} \\ f_{2;2} \\ f_{2;3} \\ f_{2;4} \end{pmatrix}. \tag{10}$$

We also define $\mathbf{x}$ and $\mathbf{b}$ as the two block vectors obtained by arranging the submatrices of $x$ and $b$ according to the leaf partitions of the HSS tree. So, for example, in the case of a two level HSS tree we would have

$$\mathbf{x} = \begin{pmatrix} x_{2;1} \\ x_{2;2} \\ x_{2;3} \\ x_{2;4} \end{pmatrix}.$$

Of course this is just $x$ in this case. But if we had ordered the tree nodes (and hence leaves) in some other order this may not have been the case.

With these new matrices we can rewrite the fast multiplication recursions in compact form. Let us start with the pair (3) and (4) which can be written together as

$$\mathbf{g} = \mathbf{P}_{\text{leaf}}^H \mathbf{V}^H \mathbf{x} + Z_{\downarrow}^H \mathbf{W}^H \mathbf{g}. \tag{11}$$

It is very important for the reader to understand why the single equation above is exactly equivalent to the pair (3) and (4). For example, let us check if (3) is captured correctly.

To do that we can apply the leaf projection operator from the left in (11) and obtain

$$\mathbf{P}_{\text{leaf}} \mathbf{g} = \mathbf{P}_{\text{leaf}} \mathbf{P}_{\text{leaf}}^H \mathbf{V}^H \mathbf{x} + \mathbf{P}_{\text{leaf}} Z_{\downarrow}^H \mathbf{W}^H \mathbf{g}. \tag{12}$$

We need to understand the significance of $\mathbf{P}_{\text{leaf}}^H$ and $Z_{\downarrow}^H$ and their relationship to $\mathbf{P}_{\text{leaf}}$.

For example, $\mathbf{P}_{\text{leaf}}^H$ is the pseudoinverse of $\mathbf{P}_{\text{leaf}}$, as $\mathbf{P}_{\text{leaf}}$ is an orthogonal projector

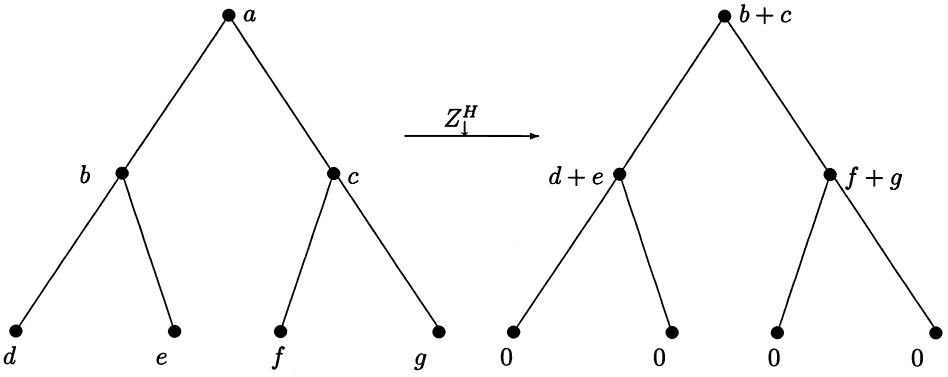

FIG. 6. *Action of $Z_{\downarrow}^{H}$ on a two level HSS tree.*

"onto the leaves of the HSS tree." So if we look at the example in (10) we have

$$\begin{pmatrix} 0 \\ 0 \\ 0 \\ f_{2;1} \\ f_{2;2} \\ f_{2;3} \\ f_{2;4} \end{pmatrix} = \mathbf{P}_{\text{leaf}}^{H} \begin{pmatrix} f_{2;1} \\ f_{2;2} \\ f_{2;3} \\ f_{2;4} \end{pmatrix}.$$

From this we can see that $\mathbf{P}_{\text{leaf}}^{H}$ [illegible] a block vector inside an HSS tree with the blocks assigned to the leaves and zeros assigned to the parent nodes. It follows that $\mathbf{P}_{\text{leaf}}\mathbf{P}_{\text{leaf}}^{H} = I$.

Next we look at $Z_{\downarrow}^{H}$. Since the action of $Z_{\downarrow}$ on an HSS tree is to move the vectors at the parent node down into the child nodes, it is not surprising to learn that $Z_{\downarrow}^{H}$ does nearly the opposite; it adds the vectors in the child nodes together and assigns them to the parent nodes, while the leaf nodes are assigned zeros. This is depicted in Figure 6. From this it follows that $\mathbf{P}_{\text{leaf}}Z_{\downarrow}^{H} = 0$.

Putting all this together we see that (12) can be simplified to

$$\mathbf{P}_{\text{leaf}}\mathbf{g} = \mathbf{V}^{H}\mathbf{x},$$

which is exactly (3) written using block matrices.

Next we quickly describe how (4) is embedded in (11). For this we need to consider the nonleaf nodes on both sides of (11). We can do so, for example, by multiplying both sides by $I - \mathbf{P}_{\text{leaf}}^{H}\mathbf{P}_{\text{leaf}}$. The latter acts on an HSS tree by setting all the vectors at the leaf nodes to zero. From this, and our earlier description of $\mathbf{P}_{\text{leaf}}^{H}$ and $Z_{\downarrow}^{H}$, it is easy to verify that $(I - \mathbf{P}_{\text{leaf}}^{H}\mathbf{P}_{\text{leaf}})\mathbf{P}_{\text{leaf}}^{H} = 0$ and $(I - \mathbf{P}_{\text{leaf}}^{H}\mathbf{P}_{\text{leaf}})Z_{\downarrow}^{H} = Z_{\downarrow}^{H}$. Therefore when we multiply both sides of (11) by $(I - \mathbf{P}_{\text{leaf}}^{H}\mathbf{P}_{\text{leaf}})$ we obtain

$$(I - \mathbf{P}_{\text{leaf}}^{H}\mathbf{P}_{\text{leaf}})\mathbf{g} = Z_{\downarrow}^{H}\mathbf{W}^{H}\mathbf{g},$$

which when written out componentwise for each nonleaf node yields (4).

Next we observe that (7), (5), and (6) can be combined and written as the single equation

$$\mathbf{f} = \mathbf{R}Z_{\downarrow}\mathbf{f} + \mathbf{B}Z_{\leftrightarrow}\mathbf{g}. \tag{13}$$

Finally, we can write the output (8) as

$$\mathbf{b} = \mathbf{D}\mathbf{x} + \mathbf{U}\mathbf{P}_{\text{leaf}}\mathbf{f}. \tag{14}$$

It is more convenient to combine the three equations (11), (13), and (14) into the single equation

$$\underbrace{\begin{pmatrix} \mathbf{D} & 0 & \mathbf{U}\mathbf{P}_{\text{leaf}} \\ 0 & \mathbf{B}Z_{\leftrightarrow} & \mathbf{R}Z_{\downarrow} - I \\ \mathbf{P}_{\text{leaf}}^{H}\mathbf{V}^{H} & Z_{\downarrow}^{H}\mathbf{W}^{H} - I & 0 \end{pmatrix}}_{\mathbf{S}} \begin{pmatrix} \mathbf{x} \\ \mathbf{g} \\ \mathbf{f} \end{pmatrix} = \begin{pmatrix} \mathbf{b} \\ 0 \\ 0 \end{pmatrix}. \tag{15}$$

We first observe that the matrix $\mathbf{S}$ is extremely sparse. In particular, $\mathbf{S}$ is a block matrix with at most three nonzero blocks in every block row. For example, the first block row of (15) reads

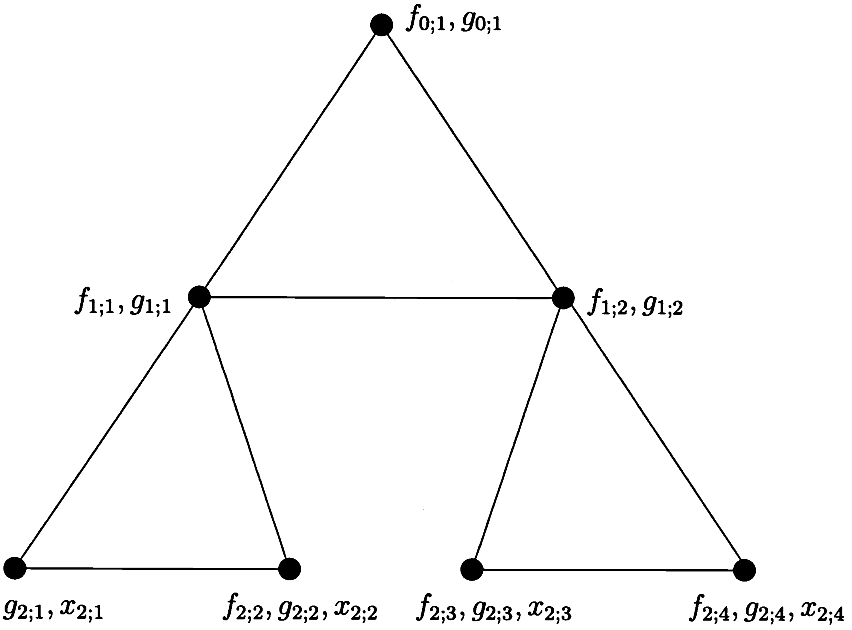
$$D_{2;1}x_{2;1} + U_{2;1}f_{2;1} = b_{2;1},$$

and it shows that $\mathbf{S}$ has only two nonzero blocks, $D_{2;1}$ and $U_{2;1}$, in its first block row. The general observation, that $\mathbf{S}$ has at most three nonzero blocks in any block row, follows from the recursions for the fast multiplication algorithm, (3) to (7).

It is now convenient to look at a graph representation of $\mathbf{S}$. We will use the standard one from text books (see [1, section 6.4.2]). Usually sparse matrices are viewed elementwise and the corresponding graphs have elements on the edges. In our case it is best to view $\mathbf{S}$ as a block sparse matrix and to look at the corresponding graph instead. First we observe that even though $\mathbf{S}$ is not a Hermitian matrix, its nonzero blocks form a structurally symmetric matrix; that is, if the $(i, j)$ block of $\mathbf{S}$ is a structural nonzero block, then the $(j, i)$ block is also a structural nonzero block. Therefore, we can use an undirected graph to represent the block sparsity of $\mathbf{S}$. An example of the graph we will use for a two level HSS form is shown in Figure 7. The graph is set up as follows. First certain block rows and columns are assigned (or associated) with a node of the graph. For example, in Figure 7, the block column corresponding to the unknowns $f_{0;1}$ and $g_{0;1}$ is assigned to the topmost node in the figure. Similarly the block column corresponding to the unknowns $f_{2;1}$, $g_{2;1}$, and $x_{2;1}$ is assigned to the bottom leftmost leaf node. Once a block column has been associated with a node of the graph the corresponding block row is also associated with the same node. Note that the nodes for the graph representation of $\mathbf{S}$ are exactly the nodes of the HSS tree. This is not a coincidence. Once the nodes have been assigned the edges for the graph are picked according to the structural nonzero blocks of $\mathbf{S}$. For example, the equation

$$g_{1;2} - W_{2;3}^{H}g_{2;3} - W_{2;4}^{H}g_{2;4} = 0$$

is one of the rows of the equation expressed by (15). Since this equation connects the block variable $g_{2;3}$ with the block variable $g_{1;2}$ there is an edge in the graph of Figure 7 between the two nodes connecting these two variables. We do a similar thing for every block row equation of (15), drawing an edge between two nodes of the graph if there is a block equation connecting unknowns in the two nodes. The resulting graph representation for $\mathbf{S}$ for a two level HSS form is shown in Figure 7. The assignment of block rows and columns in this figure might seem arbitrary but the intention will become clear soon. Definitely one of the reasons was to make clear that



$f_{0;1}, g_{0;1}$
$f_{1;1}, g_{1;1}$
$f_{1;2}, g_{1;2}$
$f_{2;1}, g_{2;1}, x_{2;1}$
$f_{2;2}, g_{2;2}, x_{2;2}$
$f_{2;3}, g_{2;3}, x_{2;3}$
$f_{2;4}, g_{2;4}, x_{2;4}$

FIG. 7. *Block sparse graph of* **S** *arising from two level HSS form.*

the graph representing the sparsity of **S** is closely related to the graph representing the HSS form of $A$.

Since **S** is very sparse it naturally raises the idea that we could solve the sparse system of equations (15) for $x$ efficiently using a [illegible] sparse solver. However, to establish that we must first establish that the system is invertible (if the original matrix $A$ is) and that we will not incur too much fill-in during Gaussian elimination on **S**.

We begin with the first issue: does $\mathbf{S}^{-1}$ exist whenever $A^{-1}$ exists? While resolving this question we will discover a remarkable diagonal formula for HSS representations. First, observe that the bottom $2 \times 2$ principal submatrix of **S** is invertible with an inverse given by the explicit formula

$$\begin{pmatrix} \mathbf{B}Z_{\leftrightarrow} & \mathbf{R}Z_{\downarrow} - I \\ Z_{\downarrow}^{H}\mathbf{W}^{H} - I & 0 \end{pmatrix}^{-1} = \begin{pmatrix} 0 & (Z_{\downarrow}^{H}\mathbf{W}^{H} - I)^{-1} \\ (\mathbf{R}Z_{\downarrow} - I)^{-1} & -(\mathbf{R}Z_{\downarrow} - I)^{-1}\mathbf{B}Z_{\leftrightarrow}(Z_{\downarrow}^{H}\mathbf{W}^{H} - I)^{-1} \end{pmatrix}.$$

Of course the validity of this formula hinges upon the existence of the two inverses

$$(\mathbf{W}Z_{\downarrow} - I)^{-1} \quad \text{and} \quad (\mathbf{R}Z_{\downarrow} - I)^{-1}.$$

But these two inverses always exist. The reasoning is as follows. We see from (9) that $Z_{\downarrow}$ is nilpotent. Since **W** and **R** are block diagonal matrices with block sizes chosen to be compatible with the block identities in $Z_{\downarrow}$, it follows that $\mathbf{W}Z_{\downarrow}$ and $\mathbf{R}Z_{\downarrow}$ are also nilpotent matrices. From this it follows that the above two inverses always exist. This proves our assertion.

Now we can [illegible] solve (15) for **x** and obtain

$$\left(\mathbf{D} + \mathbf{U}\mathbf{P}_{\text{leaf}}(I - \mathbf{R}Z_{\downarrow})^{-1}\mathbf{B}Z_{\leftrightarrow}(I - Z_{\downarrow}^{H}\mathbf{W}^{H})^{-1}\mathbf{P}_{\text{leaf}}^{H}\mathbf{V}^{H}\right)\mathbf{x} = \mathbf{b}. \tag{16}$$

Since this is true for all $x$, it follows that

$$A = \mathbf{D} + \mathbf{U}\mathbf{P}_{\text{leaf}}(I - \mathbf{R}Z_{\downarrow})^{-1}\mathbf{B}Z_{\leftrightarrow}(I - Z_{\downarrow}^{H}\mathbf{W}^{H})^{-1}\mathbf{P}_{\text{leaf}}^{H}\mathbf{V}^{H}. \tag{17}$$

This is a compact diagonal representation of the HSS form of $A$. It therefore follows that if $A$ is invertible then the sparse matrix $\mathbf{S}$ in (15) is also invertible, since $A$ is just the $(1,1)$ Schur complement of $\mathbf{S}$.

So it is clear that to solve $Ax = b$ for $x$ we could solve the sparse system of equations (15) instead. But to establish that there is a computational advantage in doing so, we must show that the sparse system (15) has an ordering that will not fill in during Gaussian elimination. Of course if we first eliminate $\mathbf{f}$ and then $\mathbf{g}$, we will get exactly $A$, which is the original matrix and completely filled in!

To find a better ordering we look at the block sparse graph for the system of which an example for the two level HSS representation is shown in Figure 7. From that figure it is obvious that there will be no block fill-in for the nested dissection ordering of the unknowns, that is, if we eliminate in the following block order: $(\, f_{2;1} \quad g_{2;1} \quad x_{2;1}\,)$, $(\, f_{2;2} \quad g_{2;2} \quad x_{2;2}\,)$, $(\, f_{2;3} \quad g_{2;3} \quad x_{2;3}\,)$, $(\, f_{2;4} \quad g_{2;4} \quad x_{2;4}\,)$, $(\, f_{1;1} \quad g_{1;1}\,)$, $(\, f_{1;2} \quad g_{1;2}\,)$, $(\, f_{0;1} \quad g_{0;1}\,)$. To see why this is so, note that after eliminating the variables $f_{2;1}$, $g_{2;1}$, and $x_{2;1}$, for example, the remaining equations will have no new nonzero blocks (see [1, sections 6.4.4 and 6.5.3] for further explanations on how determine fill-in during Gaussian elimination from the graph representation).

In general, in the nested dissection ordering all the variables on the left subtree are ordered before all the variables in the right subtree, with the variables on the root node coming last. Of course, the variables in the left and right subtrees are themselves ordered recursively in nested dissection order.

The bottom line is that there [illegible] a no fill-in Gaussian elimination order. But what about pivoting to ensure numerical stability? That is a more complicated question, and we do not answer it here. Rather, we just observe that the block sparse graph also shows that we can get an efficient sparse $QR$ factorization in the nested dissection ordering.

To see this let us follow through the first step of a block Givens $QR$ factorization algorithm on the two level HSS form shown in Figure 7. We first try to eliminate the node containing $f_{2;1}$, $g_{2;1}$, and $x_{2;1}$. We have to first apply a block Givens rotation involving the pivot row and the row corresponding to the variables $f_{2;2}$, $g_{2;2}$, and $x_{2;2}$. We note that the only possible fill-in in this row and the pivot row must correspond to the variables $f_{1;1}$ and $g_{1;1}$. But both these positions are already nonzero, so no fill-in edges have to be added to the graph. If we now proceed with the nested dissection ordering, we can argue similarly that no fill-in edges at all will be added to the block sparse graph (see [1, section 6.6.4]).

Hence, to avoid numerical instabilities, we can just use a sparse $QR$ factorization method. Since there is essentially no fill-in, we obtain a solver that is numerically stable and is linear in the dimension of the matrix $A$, with a constant that depends on the size of the $B_{k;i,j}$ matrices. In particular, the number of flops is a constant times the sum of the cube of the sizes of the $B_{k;i,j}$'s. This can be inferred as follows.

First note that every block equation has at most three block terms. Therefore, every stage of the block $QR$ factorization involves a constant number of matrix multiplications. For the sake of simplicity, let us consider the case when every matrix in the HSS form is no bigger than $p \times p$ for some integer $p$. Then, it is clear that at every stage of the block $QR$ algorithm, the number of flops will not exceed some constant times $p^3$. Since there is no fill-in during the $QR$ factorization, it also follows that the total number of flops will not exceed the number of nodes in the HSS tree times $p^3$ times some constant. But the number of nodes in the HSS tree cannot exceed $n/p$ times some constant, where $n$ is the dimension of the matrix $A$. Therefore, in this case, the number of flops is $O(np^2)$.

We caution that to construct an HSS representation from a dense matrix will in general require $O(n^2)$ flops (using the algorithm presented in [2], for example). The same paper [2] also describes examples where the HSS representation can be computed in $O(n)$ flops. Similarly, the entire FMM literature can be viewed as a repository of examples where the FMM representation can be computed in $O(n)$ flops, and from which the HSS representation in turn can be computed in $O(n)$ flops.

**5. Numerical experiments.** We now describe some numerical experiments that exhibit the efficiency and the stability of the sparse solver approach. All experiments were carried out on a 1GHz PowerPC G4 machine with 1.5GB RAM and a 167MHz bus. We used the vendor supplied BLAS.

The $n \times n$ matrix $A$ was chosen according to the formula $A_{i,j} = \sqrt{|x_i^{(n)} - x_j^{(n)}|}$, with the points $x_i^{(n)} = \cos(\pi(2i+1)/2n)$ as the zeros of the $n$th Chebyshev polynomial. The HSS tree was decided by a standard dyadic division of the interval $[-1, 1]$. The intervals were repeatedly divided in half until there were less than $p$ points left. The value of $p$ was chosen according to the matrix size to enable better memory behavior. Since the zeros of the Chebyshev polynomial cluster at the end points the resulting HSS tree was not uniform. We measure the skewness of the HSS tree as the ratio of the longest path (shortest distance) from a root to a leaf to the shortest path from a root to a leaf. The HSS form of the matrix was computed beforehand using the algorithm in the earlier paper [2] to eight digits of accuracy. It is well known that for matrices of the form we are considering in this experiment the ranks of the $B_{k;i,j}$'s are essentially proportional to the logarithm of the accuracy. Therefore, in this experiment the sizes of the $B_{k;i,j}$'s were essentially constant, independent of the matrix size. Therefore, we should expect the CPU time of the solver to scale linearly in the matrix size.

The experimental data are reported in Table 1. The first column shows that we tried matrices that varied in size from $256 \times 256$ to $131072 \times 131072$. The second column shows the factor $p$ that decides the maximum number of rows (and columns) in a leaf node. The skewness of the HSS tree of the various matrices that we tried is shown in column three. The fourth column shows the CPU time required by the sparse solver.

The sparse solver we used was a custom built block $QR$ solver. We ordered the sparse matrix in (15) in nested dissection order. As can be seen from column four of the table the solver is essentially a linear time solver as predicted by the theory, and that it is not affected adversely by the skewness of the HSS tree.

In column five we show the backward error for each solve. The backward error for solving the system $Ax = b$ with computed solution $\hat{x}$ is defined to be the ratio of the smallest 2-norm of any matrix $E$ that satisfies the equation $(A+E)\hat{x} = b$, and the 2-norm of $A$ (see [1, section 1.4.6]). As can be seen from column five, the backward error for our method is essentially machine precision. This shows that the method behaved in a backward stable manner in this set of experiments.

**6. Conclusion.** We have shown that a fast direct solver for linear systems of equations with the coefficient matrix in HSS form can be easily constructed from a sparse solver. The resulting algorithm is fast and stable.

It is easy to see that this idea can easily be extended to handle more complex

TABLE 1

*Speed and stability of sparse solver for HSS forms.*

| Matrix size | Leaf block size | Skewness of tree | CPU time in seconds | Backward error |
|---|---|---|---|---|
| 256 | 13 | 2 | 0.07 | 9.90765e-17 |
| 512 | 14 | 1.8 | 0.15 | 1.01727e-16 |
| 1024 | 15 | 1.83333 | 0.32 | 2.86709e-16 |
| 2048 | 16 | 1.85714 | 0.68 | 5.5083e-17 |
| 4096 | 17 | 1.875 | 1.43 | 8.24819e-17 |
| 8192 | 18 | 1.88889 | 2.87 | 4.0822e-17 |
| 16384 | 19 | 1.9 | 5.57 | 5.32472e-17 |
| 32768 | 20 | 2 | 11.29 | 4.96643e-17 |
| 65536 | 21 | 2 | 25.43 | 8.64522e-17 |
| 131072 | 22 | 2 | 53.88 | 8.51812e-17 |

partitions of the matrix than the one used in the HSS representation. In particular, the method can easily be extended to handle a full FMM representation of the matrix (see [10]), the hierarchical matrix representation (see [8, 9]), and the sequentially semiseparable representation (see [3, 4]). These matters will be presented in a companion paper.

# MINIMIZING THE CONDITION NUMBER FOR SMALL RANK MODIFICATIONS*

CHEN GREIF† AND JAMES M. VARAH†

**Abstract.** We consider the problem of minimizing the condition number of a low rank modification of a matrix. Analytical results show that the minimum, which is not necessarily unique, can be obtained and expressed by a small number of eigenpairs or singular pairs. The symmetric and the nonsymmetric cases are analyzed, and numerical experiments illustrate the analytical observations.

**Key words.** condition number, low rank modifications, minimization, interlacing

**AMS subject classifications.** 65F35, 15A12

**DOI.** 10.1137/050647554

## 1. Introduction.

Let $A \in \mathbb{R}^{n\times n}$ be a general matrix, and consider the problem

$$\min_{U,V} \kappa_2(A + UV^T), \tag{1.1}$$

where $\kappa_2$ denotes the spectral condition number, and $U, V \in \mathbb{R}^{n\times k}$, so that $UV^T$ is a rank-$k$ matrix. The parameter $k$ is prescribed along with the matrix $A$.

The problem of minimizing the condition number of a matrix has been studied often, but not, as far as we know, very systematically. This is in contrast with the problem of minimizing the spectral norm, or the maximum eigenvalue of a symmetric matrix, over given parameterizations. These are much easier problems because the 2-norm is a convex function on the matrix space, as is the maximum eigenvalue on the space of real symmetric matrices, making them amenable to convex optimization techniques (specifically, semidefinite programming); see [1]. By contrast, the condition number is not convex on matrix space. In the case of symmetric positive definite matrices, it is possible to transform a linearly parameterized condition number optimization problem to a convex optimization problem in the semidefinite programming framework (see [1, p. 203]), but when the matrices are symmetric indefinite or nonsymmetric, the problem is more difficult. See [5, 8] for relatively early work on optimizing preconditioners with specified sparsity patterns via eigenvalue optimization. A thorough eigenvalue analysis of low rank perturbations of symmetric matrices is given in the classic [9] and in other places. A recent paper [2] provides necessary and sufficient conditions on when the singular values of a rectangular matrix can be reassigned, using low rank modifications. Low rank perturbations are used, for example, for stable computation of eigenvalues of symmetric tridiagonal matrices using the divide and conquer method [6].

In this paper we provide an analysis of the problem, discuss uniqueness and existence, and derive results for minimizers in a variety of cases, including symmetric semidefinite, symmetric indefinite, and general nonsymmetric matrices, for rank-1, rank-2, and higher rank modifications.

There are many reasons for studying condition number optimization, and the recent availability of new approaches and code for solving nonsmooth optimization problems may allow for a comprehensive experimental and theoretical study. Our own original motivation arose from a search for effective preconditioners for symmetric indefinite systems. Of course, the condition number is only one factor in the convergence of iterative solvers, and in fact low rank perturbations by their nature have a limited effect on the spectrum due to the interlacing property which we discuss in detail throughout the paper. Nevertheless, when the spectrum of a matrix does not have an obvious structure, it may be useful to consider whether an approach of condition number minimization is effective, at least for symmetric, or nonsymmetric but normal, matrices.

The rest of the paper is structured as follows. In sections 2–5 we discuss the symmetric problem. First, in section 2 we introduce the interlacing property for rank-$k$ modifications and show how it can be proved using the Courant–Fischer min/max representation. In section 3 we present our analytic results for semidefinite matrices and show that a solution (not necessarily unique) can be obtained by using the eigenvectors corresponding to the smallest eigenvalues. In section 4 we extend our analysis to the symmetric indefinite case and show that a solution can be obtained using the eigenvectors that correspond to the largest and smallest eigenvalues in magnitude. In section 5 we show that even if those eigenvectors are not known exactly, their approximations may yield a nearly optimal solution. In section 6 we show that, using similar techniques, we can deal with the nonsymmetric problem as well. In section 7 we give an example of an application: preconditioning a saddle point system using condition number minimization. We conclude with a short summary of our main observations.

## 2. The interlacing property.

This section and sections 3–5 are devoted to the symmetric version of problem (1.1):

$$\min_{V} \kappa_2(A + VV^T), \tag{2.1}$$

with $A$ symmetric. We will assume throughout that the spectral decomposition of $A$ is given by

$$Q^T A Q = D,$$

with the columns of $Q$ containing the eigenvectors of $A$:

$$Q = [q^{(1)} \quad q^{(2)} \quad \dots \quad q^{(n)}], \qquad i = 1, \dots, n.$$

First consider the rank-1 case. We can write the modified matrix as $(A + \gamma vv^T)$ with $\|v\|_2 = 1$. The following separation theorem, or interlacing property, is well known (see, e.g., [3, p. 442]). Below we provide a proof based on the Courant–Fischer result.

Theorem 2.1. [illegible] $A$ [illegible] $\lambda_n \le \lambda_{n-1} \le \cdots \le \lambda_1$ [illegible] $(A + \gamma vv^T)$ [illegible] $\mu_n \le \mu_{n-1} \le \cdots \le \mu_1$, [illegible] $\gamma \ge 0$

$$\lambda_n \le \mu_n \le \lambda_{n-1} \le \mu_{n-1} \le \cdots \le \lambda_1 \le \mu_1.$$

[illegible] For $\gamma \ge 0$, clearly $\mu_i \ge \lambda_i$ for $1 \le i \le n$. To show $\mu_n \le \lambda_{n-1}$, use the Courant–Fischer min/max representation (see [3, p. 394] or [9, p. 101])

$$\lambda_{n-1} = \max_{y \ne 0} \min_{\substack{x^T x = 1 \\ x^T y = 0}} (x^T A x).$$

We have

$$\begin{aligned}\mu_n = \min_{x^Tx=1} x^T(A+\gamma vv^T)x &\le \min_{\substack{x^Tx=1\\ x^Tv=0}} x^T(A+\gamma vv^T)x \\ = \min_{\substack{x^Tx=1\\ x^Tv=0}} (x^TAx) &\le \max_{y\neq 0} \min_{\substack{x^Tx=1\\ x^Ty=0}} (x^TAx) = \lambda_{n-1}.\end{aligned}$$

A similar argument works for the other eigenvalues, using $Y$ with $k$ columns and

$$\lambda_{n-k} = \max_{Y\neq 0} \min_{\substack{x^Tx=1\\ x^TY=0}} (x^TAx).$$

This completes the proof. $\square$

A similar result holds for $\gamma \le 0$. Next, the rank-$k$ case can be handled as a succession of rank-1 modifications:

$$A + VV^T = A + \sum_{j=1}^{k} v^{(j)}{v^{(j)}}^T,$$

where $\{v^{(j)}\}$ are the columns of $V$. Applying the separation theorem successively gives, for example, $\lambda_n \le \mu_n \le \lambda_{n-k}$.

More generally, when $A$ is indefinite, one would like to treat indefinite rank-$k$ modifications

$$A + VEV^T = A + \sum_{j=1}^{k} e_j v^{(j)}{v^{(j)}}^T,$$

where $E = \text{diag}(\pm 1)$. This can also be handled as a succession of rank-1 modifications. Suppose $A_1 = A + v^{(1)}{v^{(1)}}^T$. Then its eigenvalues $\{\mu_j\}$ satisfy

$$\lambda_n \le \mu_n \le \lambda_{n-1} \le \cdots \le \mu_2 \le \lambda_1 \le \mu_1.$$

Now let $A_2 = A_1 - v^{(2)}{v^{(2)}}^T$. Its eigenvalues $\{\tau_j\}$ satisfy

$$\tau_n \le \mu_n \le \tau_{n-1} \le \cdots \le \tau_2 \le \mu_2 \le \tau_1 \le \mu_1.$$

Hence we have

$$\begin{cases} \tau_n \le \lambda_{n-1}, \\ \lambda_n \le \tau_{n-1} \le \lambda_{n-2} \le \cdots \le \lambda_3 \le \tau_2 \le \lambda_1, \\ \lambda_2 \le \tau_1. \end{cases}$$

Similar inequalities hold in the general rank-$k$ case: if $E$ has $p$ positive and $m$ negative coefficients, then in general the eigenvalues $\{\tau_j\}$ of $(A + VEV^T)$ satisfy

$$\lambda_{j+m} \le \tau_j \le \lambda_{j-p}.$$

The proof is a straightforward extension of the above argument and is omitted for the sake of brevity.

The above results provide natural bounds on the eigenvalues of small rank modifications, which we exploit in the following sections.

## 3. The symmetric positive semidefinite case.

Having introduced interlacing results, we now move on to focus on the problem of minimizing the condition number.

### 3.1. Rank-1 modifications.

Consider the problem of minimizing the spectral condition number of a rank-1 modification of a positive semidefinite matrix $A$:

$$\min_v \kappa_2(A + vv^T) = \min_v \frac{\mu_1(v)}{\mu_n(v)}.$$

By scaling $v$, we can express this alternatively as

$$\min_{\substack{\|v\|_2=1\\ \gamma\geq 0}} \kappa_2(A + \gamma vv^T).$$

The case $\gamma \leq 0$ can be handled analogously.

Theorem 3.1. [illegible] $A$ [illegible] $0 \leq \lambda_n \leq \cdots \leq \lambda_1$ [illegible]

$$\min_{\substack{\|v\|_2=1\\ \gamma\geq 0}} \kappa_2(A + \gamma vv^T) = \frac{\lambda_1}{\lambda_{n-1}}$$

[illegible] $v = q^{(n)}$ [illegible] $\lambda_n$ [illegible] $\gamma$ [illegible] $\lambda_{n-1} - \lambda_n \leq \gamma \leq \lambda_1 - \lambda_n$.

[illegible] We can easily see that $\lambda_1/\lambda_{n-1}$ is a lower bound using the interlacing property: we can do no better than keep $\mu_1 = \lambda_1$ and increase $\mu_n$ to $\lambda_{n-1}$, giving $\kappa_2 \geq \frac{\lambda_1}{\lambda_{n-1}}$.

Since $A$ is symmetric, its eigenvectors $\{q^{(i)}\}$ are orthonormal. Hence $(A+\gamma q^{(n)}{q^{(n)}}^T)$ has eigenvalues $\lambda_n + \gamma, \lambda_{n-1}, \ldots, \lambda_2$ and $\lambda_1$. Thus, as long as $\lambda_{n-1} \leq \lambda_n + \gamma \leq \lambda_1$, the extreme eigenvalues are $\lambda_1$ and $\lambda_{n-1}$, so we have equality. ☐

[illegible] The eigenvalues of the modified matrix $(A+\gamma vv^T)$ are generally denoted in [illegible] form as $\mu_n \leq \mu_{n-1} \leq \cdots \leq \mu_1$. However, when $v = q^{(n)}$ as in the proof above, only one of these eigenvalues differs from the original set $\lambda_n \leq \cdots \leq \lambda_1$. In this case it is convenient to refer to that eigenvalue $\lambda_n + \gamma$ as $\mu_n$ (and hence $\mu_i = \lambda_i$ for $i \neq n$) even though the resulting set $\{\mu_n, \ldots, \mu_1\}$ may not be ordered. The interlacing property holds, of course, but since $\gamma$ is such that $\lambda_n + \gamma$ could be larger than $\lambda_{n-1}$, the $\{\mu_i\}$ would have to be renumbered to be properly ordered. We make use of this slight abuse of notation later in section 4.

Finally, note that $\kappa_2(\gamma) \equiv \kappa_2(A + \gamma vv^T)$ has a "flat spot" at its minimum. Of course, one could also consider $\gamma < 0$, which may reduce the condition number further.

### 3.2. Rank-*k* modifications.

For the rank-$k$ case, we consider $\min_V \kappa_2(A + VV^T)$ over all $n \times k$ matrices $V$. If we again scale the columns of $V$, we can express this as

$$\min_{\|v_j\|_2=1} \kappa_2(A + VEV^T) = \min_{\substack{\|v_j\|_2=1\\ \gamma_j\geq 0}} \kappa_2(A + \gamma_1 v_1 v_1^T + \cdots + \gamma_k v_k v_k^T). \tag{3.1}$$

THEOREM 3.2. [illegible] $A$ [illegible] $0 \le \lambda_n \le \cdots \le \lambda_1$ [illegible] $k$ [illegible]

$$\min_V \kappa_2(A + VEV^T) = \frac{\lambda_1}{\lambda_{n-k}}.$$

[illegible] $V = [q^{(n)} \cdots q^{(n-k+1)}]$ [illegible] $E = \mathrm{diag}(\gamma_1, \ldots, \gamma_k)$ [illegible]

$$\left\{ \begin{array}{l} \lambda_{n-k} - \lambda_n \le \gamma_1 \le \lambda_1 - \lambda_n \ ; \\ \\ \lambda_{n-k} - \lambda_{n-k+1} \le \gamma_k \le \lambda_1 - \lambda_{n-k+1}. \end{array} \right. \tag{3.2}$$

[illegible] Again from the interlacing property, $\lambda_1/\lambda_{n-k}$ is a lower bound. Then for $V$ as above, the eigenvalues of $(A+VEV^T)$ are $\lambda_n+\gamma_1, \ldots, \lambda_{n-k+1}+\gamma_k, \lambda_{n-k}, \ldots, \lambda_1$. Thus we must ensure that each transformed eigenvalue is in the closed interval $[\lambda_{n-k}, \lambda_1]$, which is equivalent to requiring (3.2). □

We remark that in this rank-$k$ case, one might also consider instead of (3.1),

$$\min_{\substack{\|v_j\|_2=1 \\ \gamma \ge 0}} \kappa_2(A + \gamma VV^T),$$

with only one scaling factor $\gamma$. Then the above result again applies, but the range of $\gamma$ is more restrictive. For the transformed eigenvalues to lie in $[\lambda_{n-k}, \lambda_1]$, we need $\lambda_n + \gamma \ge \lambda_{n-k}$ [illegible] $\lambda_{n-k+1} + \gamma \le \lambda_1$, or $\lambda_{n-k} - \lambda_n \le \gamma \le \lambda_1 - \lambda_{n-k+1}$. This range is nonempty only if $\lambda_{n-k+1} - \lambda_n \le \lambda_1 - \lambda_{n-k}$, which will certainly be true for $k$ small enough.

These results show that to optimize the condition number of a rank-$k$ modification, one should choose vectors $\{v_j\}$ close to the eigenvectors of $A$ associated with the smallest eigenvalues. In section 5 we will consider the effect of using approximations to these eigenvectors. Note also that solutions to the minimization problem are not necessarily unique: there is a range of values for which the minimum is obtained.

**4. The symmetric indefinite case.** When $A$ is indefinite, we first consider the rank-1 case:

$$\min_{\substack{\|v\|_2=1 \\ \gamma}} \kappa_2(A + \gamma vv^T). \tag{4.1}$$

Here $\gamma$ may be positive or negative. We will keep the ordering of the eigenvalues the same as before (even though some may now be negative) and make the following definitions and assumptions:

- D1. We will assume throughout that $n > 2$. (The case $n = 2$ is trivial.)
- D2. Denote by $\{\sigma_j\}$ the singular values of $A$, $\sigma_1 \ge \cdots \ge \sigma_n \ge 0$. Of course these are simply the moduli of the eigenvalues.
- D3. Let $|\lambda_m| = \min_j |\lambda_j|$. That is, $m$ denotes the index of the smallest eigenvalue in magnitude. Thus $\sigma_n = |\lambda_m|$.
- D4. Assume without loss of generality that the largest eigenvalue in magnitude is $\lambda_n$, so that $\sigma_n = -\lambda_n \ge \lambda_1$. (If not, we can use $-A$ in place of $A$.)
- D5. Finally, since $\kappa_2(A) = \frac{\sigma_1}{\sigma_n} = \frac{|\lambda_n|}{|\lambda_m|}$, we call $\lambda_n$ and $\lambda_m$ the [illegible] eigenvalues of $A$.

The following lemma presents a lower bound for the condition number. Later (in Theorem 4.3) we will show that this bound can actually be attained.

LEMMA 4.1. [illegible] $A$ [illegible]

$$\min_{\substack{\|v\|_2=1\\ \gamma\geq 0}} \kappa_2(A+\gamma vv^T) \geq \frac{\sigma_2}{\sigma_{n-1}}.$$

[illegible] The mapping $A \to (A+\gamma vv^T)$ transforms the eigenvalues from $\{\lambda_i\}$ to $\{\mu_i\}$. Since $\gamma \geq 0$ we have $\mu_i \geq \lambda_i$ for each $i$. In trying to minimize the resulting condition number, we must take into account the interlacing property. Thus, we can do no better than the following:

(i) transform $\lambda_n$ to $\mu_n = -\sigma_2 = \min(\lambda_{n-1}, -\lambda_1)$;
(ii) transform $\lambda_m$ to $\mu_m = \lambda_{m-1}$ (whether $\lambda_m$ is positive or negative);
(iii) leave the other eigenvalues unchanged, i.e., $\mu_i = \lambda_i, i \neq n, m$.

The resulting matrix will have condition number

$$\frac{\max(\lambda_1, |\lambda_{n-1}|)}{\min(|\lambda_{m+1}|, |\lambda_{m-1}|)} = \frac{\sigma_2}{\sigma_{n-1}}, \tag{4.2}$$

which completes the proof. □

[illegible] The case $\gamma \leq 0$ does not change the result, since a similar argument gives a lower bound of $\frac{\max(|\lambda_n|,\lambda_2)}{\min(|\lambda_{m+1}|,|\lambda_{m-1}|)}$. It is worse (greater) than that above, since by one of our assumptions $-\lambda_n \geq \lambda_1$.

We now wish to show that we can actually attain the lower bound by appropriate choice of $v$ (and $\gamma$). We have $\gamma \geq 0$ and thus we can incorporate it into $v$, so that (4.1) becomes

$$\min_v \kappa_2(A+vv^T). \tag{4.3}$$

First consider $A$ diagonal, $A = \mathrm{diag}(d_i)$, $d_n \leq \cdots \leq 0 \leq \cdots \leq d_1$, with active eigenvalues $d_n$ and $d_m$. Now take a vector $v$ with nonzero components only in positions $n$ and $m$. Denote them by $v_n$ and $v_m$. Then $(A+vv^T)$ is identical to $A$ except for the $2\times 2$ block formed by rows and columns $m$ and $n$. This block is

$$\begin{pmatrix} d_m + v_m^2 & v_n v_m \\ v_n v_m & d_n + v_n^2 \end{pmatrix},$$

and its eigenvalues $\mu$ are the roots of

$$\mu^2 - (d_n + d_m + v_m^2 + v_n^2)\mu + d_n d_m + d_n v_m^2 + d_m v_n^2 = 0. \tag{4.4}$$

So the eigenvalues of $(A+vv^T)$ are $\mu_i = d_i$ if $i \neq n, m$ and the roots of (4.4) if $i = n, m$. Let us denote the latter by $\mu_n$ and $\mu_m$, so that $d_n$ is transformed to $\mu_n$ and $d_m$ to $\mu_m$. Although $\mu_n \geq d_n$ and $\mu_m \geq d_m$, they can otherwise be chosen anywhere without violating the interlacing theorem, as again the $\{\mu_i\}$ here are not necessarily ordered.

Evaluating the quadratic equation (4.4) gives two [illegible] equations for the two unknowns $v_m^2$ and $v_n^2$. Fortunately, this linearity, which does not hold in general for cases where $v$ has more than two nonzero components, allows us to make a few useful analytical observations. The linear equations are

$$\begin{pmatrix} d_n-\mu_n & d_m-\mu_n \\ d_n-\mu_m & d_m-\mu_m \end{pmatrix} \begin{pmatrix} v_m^2 \\ v_n^2 \end{pmatrix} = \begin{pmatrix} (\mu_n-d_n)(d_m-\mu_n) \\ (\mu_m-d_n)(d_m-\mu_m) \end{pmatrix}. \tag{4.5}$$

We denote the linear system (4.5) by

$$Bw = c$$

and note that the solution $w$ must have nonnegative components, which restricts the possible choices for $\mu_n$ and $\mu_m$. The case of a homogeneous linear system is trivial, since it implies that $\mu_n = d_n$ and $\mu_m = d_m$, which means none of the eigenvalues change. We therefore have the following result.

LEMMA 4.2. [illegible] $\mu_n$ [illegible] $\mu_m$ [illegible] $\mu_n \le d_m \le \mu_m$ [illegible] $w$ [illegible] $Bw = c$ [illegible]

[illegible] From (4.5) it is easy to see that $\det(B) = (d_m - d_n)(\mu_m - \mu_n) \neq 0$ if $d_m \neq d_n$ and $\mu_m \neq \mu_n$. It is sufficient to consider $d_n < d_m < d_1$, since nonsharp inequalities can be trivially handled separately. By D1–D5 we have $d_n \le -d_1$. Direct computation gives

$$w = B^{-1}c = \frac{1}{d_m - d_n} \begin{pmatrix} (\mu_m-d_m)(d_m-\mu_n) \\ (d_n-\mu_m)(d_n-\mu_n) \end{pmatrix}.$$

Thus $w_1 \ge 0$ if $\mu_n \le d_m \le \mu_m$. Moreover, $w_2 \ge 0$ if $d_n \le \mu_n$ and $d_n \le \mu_m$, but this is ensured since by interlacing the mapping $A \to (A + \gamma vv^T)$ transforms the $\{d_i\}$ into algebraically equal or larger eigenvalues, $\{\mu_i\}$. □

We can therefore choose $\mu_n$ and $\mu_m$ anywhere, subject to the above stated restriction, and are now ready to show that the lower bound presented in Lemma 4.1 can actually be attained.

THEOREM 4.3. [illegible] $A$ [illegible] D1–D5 [illegible]

$$\min_{\substack{\|v\|_2=1 \\ \gamma}} \kappa_2(A+\gamma vv^T) = \min_v \kappa_2(A+vv^T) = \frac{\sigma_2}{\sigma_{n-1}}.$$

[illegible] Since $A$ is symmetric, it can be diagonalized, and so it is reasonable to start by considering a diagonal $A$ as above. In this case we have $\max_{i\neq n}|d_i| = \sigma_2 = \max(d_1, |d_{n-1}|)$, and $\min_{i\neq m}|d_i| = \sigma_{n-1} = \min(|d_{m-1}|, |d_{m+1}|)$. Thus, by Lemma 4.2 we need only ensure that $\mu_n$ and $\mu_m$ do not become active. We must have $\sigma_{n-1} \le |\mu_n|, |\mu_m| \le \sigma_2$, and $\mu_n \le d_m \le \mu_m$. To ensure both of these, choose $\mu_n$ negative, $-\sigma_2 \le \mu_n \le -\sigma_{n-1}$, and $\mu_m$ positive, $\sigma_{n-1} \le \mu_m \le \sigma_2$. Indeed any such choice will result in $\kappa_2(A + vv^T) = \sigma_2/\sigma_{n-1}$, giving a two-parameter family of solutions.

Now, for nondiagonal $A$, suppose $Q^TAQ = D$, diagonal. Then, defining $u = Q^Tv$ we have

$$\begin{aligned} Q^T(A+vv^T)Q &= D + (Q^Tv)(v^TQ) \\ &= D + uu^T. \end{aligned}$$

So, we first solve for $u$ using the above described procedure, giving $u_n$ and $u_m$. We then form

$$v = Qu = u_m q^{(m)} + u_n q^{(n)}.$$

The similarity transformation does not change the 2-norm, and hence not the condition number. It follows that minimizing $\kappa_2(A + vv^T)$ is equivalent to minimizing $\kappa_2(D + uu^T)$, and the proof is complete. □

There are many reasonable choices for $\mu_n$ and $\mu_m$ so that $\mu_n \le d_m \le \mu_m$ and $\sigma_{n-1} \le |\mu_n|, |\mu_m| \le \sigma_2$. For example, one could choose the median singular value $\sigma_* = \sigma_{n/2}$ or $\sigma_{(n+1)/2}$ and pick

$$\mu_n = -\sigma_*, \;\; \mu_m = \sigma_*.$$

It is also worth mentioning that Theorem 4.3 applies to $A$ positive definite, with the resulting modified matrix indefinite.

For the indefinite rank-$k$ case, that is,

$$A + VEV^T = A + \sum_{j=1}^{k} e_j v^{(j)} {v^{(j)}}^T, \tag{4.6}$$

where $E = \text{diag}(e_j) = \text{diag}(\pm 1)$, we first extend the lower bound of Lemma 4.1 as follows.

LEMMA 4.4. [illegible] $A$ [illegible] $VEV^T$ [illegible] $k$ [illegible]

$$\min_{V,E} \kappa_2(A + VEV^T) \ge \frac{\sigma_{k+1}}{\sigma_{n-k}}.$$

[illegible]. Using (4.6) to express $A + VEV^T$ as a sequence of $k$ rank-1 modifications, we apply Lemma 4.1 at each step. Notice that each step can be positive or negative, and the result "peels off" the top and bottom singular values at each step. □

Now, to show that the bound can again be attained, we choose a particular sequence of rank-1 modifications with appropriate sign.

THEOREM 4.5. [illegible] $A$ [illegible] $VEV^T$ [illegible] $k$ [illegible]

$$\min_{V,E} \kappa_2(A + VEV^T) = \frac{\sigma_{k+1}}{\sigma_{n-k}}.$$

[illegible]. For $A$ diagonal, we apply a sequence of $2 \times 2$ rank-1 modifications as in Theorem 4.3, choosing $e_j = +1$ if the largest eigenvalue at that step is negative (and thus transforming eigenvalues into algebraically equal or larger eigenvalues), and $e_j = -1$ if the largest eigenvalue is positive (and thus the eigenvalues are mapped into algebraically equal or smaller eigenvalues). To ensure that we "peel off" the top and bottom singular values at each step, we need only choose the transformed eigenvalues $\mu_n$ and $\mu_m$ so that $\sigma_{n-k} \le |\mu_n|, |\mu_m| \le \sigma_{k+1}$. For a nondiagonal $A$, we again have to multiply by the eigenvector matrix $Q$. □

[illegible] 4.6. Take $A = \text{diag}(-9, -5, -1, 0, 1, 5, 9)$ and ask for the best rank-1 and rank-2 modifications. For the first step, the active eigenvalues can be taken to be $-9$ and $0$. Lemma 4.2 gives ${v^{(1)}}^T = (2.49, 0, 0, 1.67, 0, 0, 0)$ and $e_1 = 1$. The resulting matrix $A_1 = A + v^{(1)}{v^{(1)}}^T$ has eigenvalues $(-5, -5, -1, 1, 5, 5, 9)$, and $\kappa_2(A_1) = 9$. Notice for this example that in this first step, we could choose $\mu_n$ and $\mu_m$ anywhere in the range $1 = \sigma_{n-1} \le |\mu_n|, |\mu_m| \le \sigma_2 = 9$.

For the second step, we take active eigenvalues 9 and $-1$. We get $e_2 = -1$ and ${v^{(2)}}^T = (0, 0, 1.55, 0, 0, 0, 0, 2.37)$. The resulting matrix $A_2 = A_1 - v^{(2)}{v^{(2)}}^T$ has eigenvalues $(-5, -5, -5, 1, 5, 5, 5)$, and $\kappa_2(A_2) = 5$. Notice that we do not have to rediagonalize $A_1$ since the second set of active eigenvalues is distinct from the first.

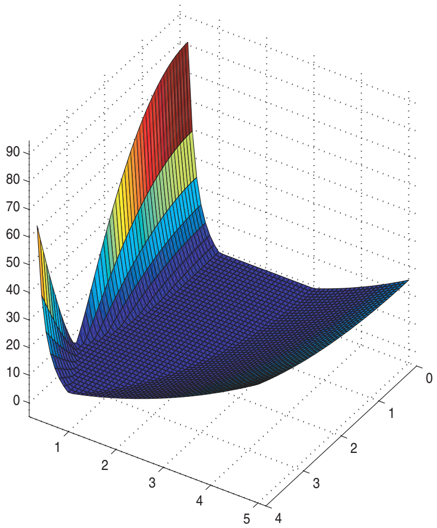

FIG. 4.1. *The condition number of the modified matrix for a range of values of $v_n$ and $v_m$.*

In Figure 4.1 we plot $\kappa_2(A + vv^T)$ for $0 \leq v_m, v_n \leq 4$ . Notice the "flat spot" in this graph, where $\kappa_2 = 9$, that is, a two-dimensional range where the minimum condition is attained. Finally, the solution $V = [v^{(1)} \;\; v^{(2)}]$ is by no means unique. However, it does have the minimum number of nonzero components.

**5. The effect of perturbations.** From the analysis so far, it is clear that to minimize the condition number of the modified matrix, one needs to know particular eigenvectors. Of course, for a large matrix, these are not known explicitly and are often expensive to compute. This raises the question of approximations: what effect will inexact knowledge of the eigenvectors have on the condition number of the modified matrix?

We consider here only the simple case of a semidefinite $A$ (with eigenvalues $\{\lambda_i\}$ and eigenvectors $\{q^{(j)}\}$) modified by a rank-1 matrix. Following Theorem 3.1, we choose the modification $v = q^{(n)}$ and consider

$$C(\gamma) = A + \gamma q^{(n)} {q^{(n)}}^T. \tag{5.1}$$

If $G$ is defined as the interval $\lambda_{n-1} - \lambda_n \leq \gamma \leq \lambda_1 - \lambda_n$, then for $\gamma \in G$, $\lambda_{\min}(C) = \lambda_{n-1}$ and $\lambda_{\max}(C) = \lambda_1$, so $\kappa_2(C)$ is minimized.

Now suppose we allow perturbations in $q^{(n)}$, caused, for example, by inexact approximation. Then we have the following result.

THEOREM 5.1. [illegible] $\gamma \in G$ [illegible]

$$A + \gamma uu^T, \;\; u = q^{(n)} + \varepsilon w,$$

[illegible] $\varepsilon \ll 1$ [illegible] $\|w\|_2 = 1$ [illegible]

$$\kappa_2(A + \gamma uu^T) = \kappa_2(C) + \mathcal{O}(\varepsilon^2), \tag{5.2}$$

[illegible] $C = C(\gamma)$ [illegible] (5.1).

[illegible] Define $F = \gamma(q^{(n)} w^T + w {q^{(n)}}^T)$. Then we have

$$\begin{aligned} A + \gamma u u^T &= A + \gamma(q^{(n)} + \varepsilon w)(q^{(n)} + \varepsilon w)^T \\ &= C(\gamma) + \varepsilon\gamma(q^{(n)} w^T + w {q^{(n)}}^T) + \varepsilon^2 w w^T \\ &= C + \varepsilon F + \varepsilon^2 w w^T. \end{aligned} \tag{5.3}$$

The eigenvalues of $C = C(\gamma)$ are $\lambda_1, \ldots, \lambda_{n-1}$, and $\lambda_n + \gamma$. Now let $\gamma$ be fixed and consider the eigenvalues of the first-order perturbation $C + \varepsilon F$. For any specific eigenvalue $\lambda_j(C)$, let

$$\lambda_j(\varepsilon) = \lambda_j(C + \varepsilon F) = \lambda_j(C) + \varepsilon \lambda_j' + \mathcal{O}(\varepsilon^2).$$

Assuming each eigenvalue is simple, recall that (see, e.g., [9, Chap. 2])

$$\lambda_j' = \frac{{q^{(j)}}^T F q^{(j)}}{{q^{(j)}}^T q^{(j)}}.$$

We have two cases:

(i) $j = n$: $\lambda_n' = \gamma {q^{(n)}}^T (q^{(n)} w^T + w {q^{(n)}}^T) q^{(n)} = 2\gamma w^T q^{(n)}$.

(ii) $j \neq n$: $\lambda_j' = \gamma {q^{(j)}}^T (q^{(n)} w^T + w {q^{(n)}}^T) q^{(j)} = 0$.

Hence

$$\lambda_n(\varepsilon) = \lambda_n(C) + \mathcal{O}(\varepsilon), \quad \lambda_j(\varepsilon) = \lambda_j(C) + \mathcal{O}(\varepsilon^2) \ \text{ for } j \neq n.$$

Thus from (5.3) the same is true for the full perturbation $A + \gamma u u^T$.

Finally then, if $\gamma$ is chosen [illegible] $G$, so that the extreme eigenvalues of $C$ are $\lambda_1$ and $\lambda_{n-1}$, then under perturbation in the vector $u = q^{(n)} + \varepsilon w$, (5.2) follows. □

Theorem 5.1 shows, then, that the effect of a first-order perturbation in the eigenvector is only second-order in the condition number. Thus, an approximation to the eigenvector that can be computed rapidly can be useful for the purpose of obtaining a nearly optimal condition number.

[illegible] 5.2. Consider the discrete Laplace operator using finite difference discretizations on a uniform, two-dimensional grid. It is well known that if Neumann boundary conditions are employed, the matrix has nullity 1 with a vector of constants as its null-space. We set a grid of 32 points in each direction; the resulting matrix is $1024 \times 1024$. The Lanczos algorithm (without reorthogonalization) is applied using four dimension sizes: $k = 4, 8, 16, 32$. The initial guess is random. We compute approximations to the null vector of the matrix using the Ritz vector associated with the smallest Ritz value. As is evident from Table 5.1, the condition number of the modified matrix using the approximation to the null vector is close to that of the modified matrix using the exact null vector, with the relative error decreasing as $\varepsilon$ decreases. A precise assessment of the error is more involved and would require the evaluation of the magnitude of the term multiplied by $\varepsilon^2$ in Theorem 5.1. Nevertheless, for $n$ large enough examining the relative error, $\frac{|\kappa_2(A + q^{(n)} {q^{(n)}}^T) - \kappa_2(A + u u^T)|}{\kappa_2(A + q^{(n)} {q^{(n)}}^T)}$ (given in the last column of the table) illustrates the quadratic dependence on $\varepsilon$, as predicted by Theorem 5.1. For example, between $k = 16$ and $k = 32$ the value of $\varepsilon$ goes down by a factor of approximately 3.43 while the relative error decreases by a factor of approximately 17.5.

Table 5.1

*Effect of perturbations for a discrete Laplace operator with Neumann boundary conditions. The approximations to the null vector are generated using the Lanczos algorithm. In the table, $q^{(n)}$ is a normalized vector of constants (i.e., a null vector of $A$) and $u$ is the approximation to it generated by the Lanczos procedure.*

| $k$ | $\lambda_n$ | $\|Au\|_2$ | $\varepsilon \equiv \|u - q^{(n)}\|_2$ | $\kappa_2(A + q^{(n)}q^{(n)^T})$ | $\kappa_2(A + uu^T)$ | Rel. error |

## 6. Extension to nonsymmetric matrices.

We now move to consider the nonsymmetric case. For rank-1 modifications, the nonsymmetric case could be transformed into a problem of minimizing the condition number of a [illegible]-2 modification of the $2n \times 2n$ [illegible] matrix

$$G = \begin{pmatrix} 0 & A \\ A^T & 0 \end{pmatrix}.$$

But in fact much can be said about the nonsymmetric problem by working on it directly. Consider a nonsymmetric matrix $A$, with singular values $\sigma_1 \geq \cdots \geq \sigma_n \geq 0$, and its unsymmetric rank-1 modification $A + uv^T$, with singular values $\tau_1 \geq \cdots \geq \tau_n \geq 0$. Using the interlacing result for symmetric matrices given in section 2, one can formulate a separation theorem for these singular values as well.

Theorem 6.1. [illegible] $\{\tau_j\}$ [illegible] $A + uv^T$ [illegible] $\{\sigma_j\}$ [illegible] $A$ [illegible]

$$\begin{cases} \sigma_2 \leq \tau_1, & \\ \sigma_{k+1} \leq \tau_k \leq \sigma_k, & 1 < k < n, \\ 0 \leq \tau_n \leq \sigma_{n-1}. & \end{cases} \tag{6.1}$$

[illegible] $\kappa_2(A + uv^T)$ [illegible]

$$\kappa_2(A + uv^T) = \frac{\tau_1}{\tau_n} \geq \frac{\sigma_2}{\sigma_{n-1}}. \tag{6.2}$$

[illegible] Using the Courant–Fischer min/max result for $A^TA$,

$$\sigma_{n-k}^2 = \max_{Y \neq 0} \min_{\substack{x^Tx=1 \\ x^TY=0}} (x^TA^TAx)$$

for $Y$ an $n \times k$ matrix. Consider, for example, $\tau_{n-1}$:

$$\begin{aligned} \tau_{n-1}^2 &= \max_{y \neq 0} \min_{\substack{x^Tx=1 \\ x^Ty=0}} x^T(A + uv^T)^T(A + uv^T)x \\ &= \max_{y \neq 0} \min_{\substack{x^Tx=1 \\ x^Ty=0}} x^T\left(A^TA + A^Tuv^T + vu^TA + v(u^Tu)v^T\right)x. \end{aligned}$$

Thus, taking $y = v$,

$$\tau_{n-1}^2 \geq \min_{\substack{x^Tx=1 \\ x^Tv=0}} (x^TA^TAx) \geq \min_{x^Tx=1} (x^TA^TAx) = \sigma_n^2.$$

Moreover,

$$\tau_{n-1}^2 \le \max_{v,y\neq 0} \min_{\substack{x^Tx=1\\ x^Ty=0\\ x^Tv=0}} (x^TA^TAx) \le \max_{\substack{y\neq 0\\ z\neq 0}} \min_{\substack{x^Tx=1\\ x^Ty=0\\ x^Tz=0}} (x^TA^TAx) = \sigma_{n-2}^2.$$

A similar result holds for each intermediate singular value $\tau_k$, $1 < k < n$. For the extreme values $\tau_1$ and $\tau_n$, one achieves only one-sided inequalities; thus $\tau_1 \ge \sigma_2$ and $0 \le \tau_n \le \sigma_{n-1}$. Using these last two inequalities gives (6.2). $\square$

Now we show that this bound can be attained. For $A = D = \operatorname{diag}(\sigma_1, \ldots, \sigma_n)$, we proceed as in section 4: consider $(D + uv^T)$ with $u$ and $v$ having nonzero components only in the first and last places, corresponding to the extreme singular values $\sigma_1, \sigma_n$. Then $(D + uv^T)$ is diagonal, with singular values $\sigma_2, \ldots, \sigma_{n-1}$, except for the $2 \times 2$ block

$$\begin{pmatrix} d_1 + u_1v_1 & u_1v_n \\ u_nv_1 & d_n + u_nv_n \end{pmatrix}.$$

Notice that we want to choose $u$ and $v$ so the singular values of this $2\times 2$ block are well inside the interval $[d_n, d_1]$. Choosing $u = v$ does not work, as a positive solution of the analogue of (4.5) results in singular values outside this interval. Thus we need to make the block nonsymmetric but simple enough that the singular values are readily calculated. One approach is to make the block look like $\begin{pmatrix} a & b \\ -b & a \end{pmatrix}$, whose (double) singular values are $(a^2 + b^2)^{1/2}$. For this to happen, we must have

$$\left\{ \begin{array}{l} u_nv_1 = -u_1v_n, \\ d_1 + u_1v_1 = d_n + u_nv_n. \end{array} \right. \tag{6.3}$$

We have two constraints for four unknowns. One way to proceed is to let $u_1, u_n$ be arbitrary, and then (6.3) gives

$$v_1 = \frac{-u_1}{u_1^2 + u_n^2} \cdot (d_1 - d_n), \quad v_n = \frac{u_n}{u_1^2 + u_n^2} \cdot (d_1 - d_n) \tag{6.4}$$

and

$$a = \frac{u_1^2 d_n + u_n^2 d_1}{u_1^2 + u_n^2}, \quad b = \frac{u_1u_n}{u_1^2 + u_n^2} \cdot (d_1 - d_n). \tag{6.5}$$

Notice that the expression for $a$ is a weighted average of $d_1$ and $d_n$ and thus can be made to equal any value in $[d_n, d_1]$ by appropriate choice of $u_1, u_n$.

THEOREM 6.2. [illegible] $A$ [illegible] $n \times n$ [illegible] $(n > 2)$ [illegible] $\sigma_1 \ge \cdots \ge \sigma_n \ge 0$ [illegible]

$$\min_{u,v} \kappa_2(A + uv^T) = \frac{\sigma_2}{\sigma_{n-1}}.$$

[illegible] To show that the bound (6.2) can be attained, use $A$'s singular value decomposition $A = UDV^T$, $D = \operatorname{diag}(\sigma_1, \ldots, \sigma_n)$. Then apply the above technique for some value of $\tau^*$, $\sigma_{n-1} \le \tau^* \le \sigma_2$. From (6.5) we have

$$u_1^2 = \frac{d_1^2 - (\tau^*)^2}{d_1^2 - d_n^2}\ , \quad u_n^2 = \frac{(\tau^*)^2 - d_n^2}{d_1^2 - d_n^2}\ , \tag{6.6}$$

and $v_1, v_n$ are given by (6.4). Notice that $u_1^2 + u_n^2 = 1$.

This gives $(D + uv^T)$ with singular values $\sigma_2, \ldots, \sigma_{n-1}$, and $\tau^*$ (twice). Finally,

$$U(D + uv^T)V^T = A + (Uu)(Vv)^T = A + \tilde{u}\tilde{v}^T$$

has minimal condition. Since the 2-norm is invariant under orthogonal transformations, the condition numbers of $D + uv^T$ and $A + \tilde{u}\tilde{v}^T$ are minimized at the same time. $\square$

Notice that $\tilde{u}$ and $\tilde{v}$ are linear combinations of the extreme singular vectors of $A$. In our code we use $\tau^* = \sigma_{n/2}$ or $\sigma_{(n+1)/2}$, the median singular value. Again the solution is *not* unique. The rank-$k$ case can be handled as a sequence of rank-1 modifications, as in previous sections.

*Example* 6.3. The $5 \times 5$ matrix

$$A = \begin{pmatrix} -0.1693 & 0.9417 & -0.5721 & -0.1761 & 0.3667 \\ -0.3900 & 0.9802 & 0.2870 & 0.4891 & -0.5749 \\ 0.7487 & 0.5777 & -0.3599 & -0.4641 & 0.6785 \\ -0.9700 & -0.1227 & 0.9202 & -0.1202 & 0.2576 \\ 0.5359 & -0.0034 & 0.4533 & 0.8668 & -0.7325 \end{pmatrix}$$

was generated randomly, and we sought to minimize the condition number of a rank-1 modification. The singular values of $A$ are $1.8910, 1.5398, 1.4567, 0.6648, 0.1610$. Using our analytical observations and our strategy for choosing $\tau^*$ to be the median singular value, the resulting modified matrix has singular values $1.5398, 1.4567, 1.4567, 1.4567, 0.6648$. By construction, then, we obtain three equal singular values. The optimal condition number is 2.3163. Next, we use the MATLAB command `fminsearch` to find a solution, and get the same minimal value, now with singular values $1.5446, 1.5446, 1.1185, 0.6648, 0.6647$. Thus, the solution is indeed nonunique.

**7. Example: Saddle point system preconditioning.** Consider the numerical solution of a large and sparse saddle point linear system whose associated matrix is

$$\mathcal{K} = \begin{pmatrix} A & B \\ B^T & 0 \end{pmatrix},$$

where $A$ is $n \times n$ and $B$ is $n \times m$, with $m < n$. Popular preconditioners have a $2 \times 2$ block diagonal structure, with their (1,1) block approximating the (1,1) block of the original saddle point matrix, and their (2,2) block approximating the Schur complement. Motivated by this, let us make a connection to the analysis presented in the previous sections by considering the preconditioner

$$\mathcal{M} = \begin{pmatrix} A + VV^T & 0 \\ 0 & \pm B^T(A + VV^T)^{-1}B \end{pmatrix},$$

where $V$ is $n \times k$. The $\pm$ signs in front of the $(2,2)$ block suggest two options. It makes sense to consider such a preconditioner if solving a system with $A + VV^T$, a rank-$k$ modification of $A$, is significantly easier than solving for $A$. (Notice that $A$ could be singular even if $\mathcal{K}$ is not.) Thus, we could aim to select a rank-$k$ matrix $V$ that minimizes the condition number of $A + VV^T$.

This approach is computationally delicate for the following reasons. First, $V$ is dense in general, whereas the original saddle point matrix is assumed sparse. In terms of storage, if we are to store $V$ explicitly it will require $nk$ entries. Note that $A + VV^T$

need not be stored explicitly when iterative solvers are used. If $A$ has $\ell$ nonzero entries per row on average, then the storage requirements for the $(1,1)$ block increase from $n\ell$ for $A$ to $n(\ell+k)$ for $A+VV^T$. In terms of computational cost, since a decisive cost factor in the (implicit) inversion of the (1,1) block are matrix-vector products, the overhead for the cost of multiplying a vector by $A+VV^T$ compared to multiplying by $A$ is the addition of two matrix-vector products with $n \times k$ matrices. In other words, the overhead here is $\mathcal{O}(nk)$ floating point operations per iteration. Another potential difficulty is the computation of $V$, which may be expensive to the extent of dominating the cost of solution of the linear system. Here the observations in section 5 come to our aid, since Theorem 5.1 implies that computing $V$ can be done inexactly (likely at a substantially lower cost), while still obtaining a nearly optimal condition number. Finally, to make this approach more practical, inexact inner iterations for solving $A+VV^T$ could be applied throughout the iteration.

The sign in front of the $(2,2)$ block affects the structure of the preconditioned eigenvalues as follows. If it is a positive sign, then the preconditioner is positive definite. In this case the eigenvalues of the preconditioned matrix are real, and a minimum residual solver employing short recurrence relations (such as MINRES) can be applied. If, on the other hand, the sign in front of the $(1,1)$ block is negative, then the preconditioner is no longer positive definite but its inertia is closer to the inertia of the original saddle point matrix. Furthermore, it can be shown that at least $m+n-k$ of the eigenvalues of the preconditioned matrix are complex with unit norm.

Let $\nu$ be an eigenvalue of the preconditioned matrix $\mathcal{M}^{-1}\mathcal{K}$, with associated eigenvector $(x,y)$, and denote

$$M = A + VV^T.$$

Then

$$\begin{pmatrix} A & B \\ B^T & 0 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \nu \begin{pmatrix} M & 0 \\ 0 & \pm B^T M^{-1} B \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix}.$$

Since we are assuming that $\mathcal{M}^{-1}\mathcal{K}$ is nonsingular, we must have $\nu \neq 0$. Observing that

$$\begin{aligned} &\begin{pmatrix} M & 0 \\ 0 & \pm B^T M^{-1} B \end{pmatrix}^{-1} \begin{pmatrix} A & B \\ B^T & 0 \end{pmatrix} \\ &\quad = \begin{pmatrix} M & 0 \\ 0 & \pm B^T M^{-1} B \end{pmatrix}^{-1} \left[ \begin{pmatrix} M & B \\ B^T & 0 \end{pmatrix} - \begin{pmatrix} VV^T & 0 \\ 0 & 0 \end{pmatrix} \right], \end{aligned}$$

we now proceed as follows. If the positive sign in front of the $(2,2)$ block of $\mathcal{M}$ is selected, it follows that the preconditioned matrix is a rank-$k$ modification of a matrix which by [7] has precisely three distinct nonzero eigenvalues: 1 and $(1 \pm \sqrt{5})/2$, with algebraic multiplicities $n-m$, $m$, and $m$, respectively. Thus, for $k < \min(m, n-m)$, $\mathcal{M}^{-1}\mathcal{K}$ has eigenvalues 1, $(1 \pm \sqrt{5})/2$ of algebraic multiplicities at least $n-m-k$, $m-k$, and $m-k$, respectively. If, on the other hand, the negative sign is chosen, the preconditioned matrix is a rank-$k$ modification of a matrix with eigenvalues 1 and $\frac{1 \pm \imath\sqrt{3}}{2}$, with the same algebraic multiplicities as above. Here $\imath = \sqrt{-1}$.

Substituting $y = \frac{1}{\nu}(B^T M^{-1} B)^{-1} B^T x$ and defining $\tilde{x} = M^{1/2}x$, we have $(\nu^2 I - \nu K - P)\tilde{x} = 0$, where $K = M^{-1/2} A M^{-1/2}$, $P = P^2 = M^{-1/2} B (B^T M^{-1} B)^{-1} B^T M^{-1/2}$ is an orthogonal projector. In our case

$$K = M^{-1/2} A M^{-1/2} = M^{-1/2}(M - VV^T) M^{-1/2} = I - M^{-1/2} V V^T M^{-1/2} = I - \tilde{V}\tilde{V}^T,$$

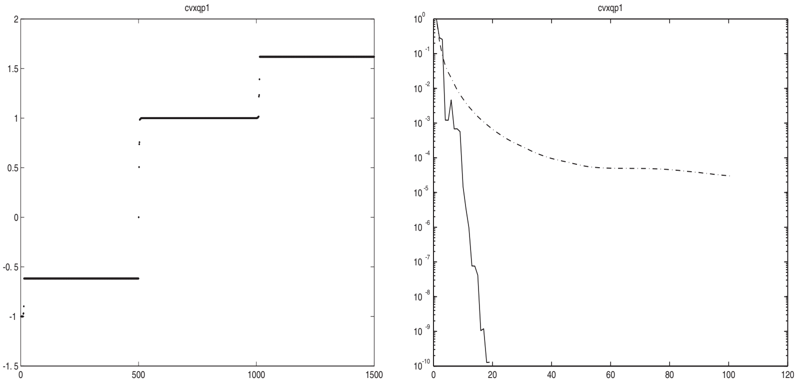

FIG. 7.1. *Eigenvalues of the preconditioned matrix for* `cvxqp1` *(on the left) and convergence of preconditioned MINRES (on the right). The right-hand side vector $b$ was generated by setting the solution as a vector of constants, such that $\|b\|_2 = 1$.*

where $\tilde{V} = M^{-1/2}V$, and we can rewrite our quadratic eigenvalue problem as

$$((\nu^2 - \nu)I + \nu\tilde{V}\tilde{V}^T \mp P)\tilde{x} = 0. \tag{7.1}$$

We can say more if $A$ is symmetric positive semidefinite with nullity $k$. Let $V$ be an $n \times k$ orthogonal matrix representing the null-space of $A$. Since $MV = (A + VV^T)V = V$, it follows that the columns of $V$ are eigenvectors of $M$ with multiple eigenvalues 1. By the analysis of section 3, $V$ is a minimizer for problem (2.1). Since $MV = V$ we have $M^{1/2}V = V$, and hence $\tilde{V} = V$. Thus, (7.1) takes the form

$$((\nu^2 - \nu)I + \nu VV^T \mp P)\tilde{x} = 0.$$

We can thus express the eigenvalue problem in terms of an orthogonal projector onto a space related to the range of $B$ and the null vectors of $A$.

[illegible] 7.1. We used the `cvxqp1` matrix from the CUTEr test collection [4] in its "raw" form, i.e., without taking into account the constraint settings in the context of an optimization problem, for testing the preconditioning approach suggested in this section. The matrix has a $1000 \times 1000$ (1,1) block, whose rank is 986. The size of $B$ is $1000 \times 500$. For this experiment, the matrix $V$ contains the 14 eigenvectors corresponding to the zero eigenvalues. We have applied the preconditioner with a positive sign selected for its $(2, 2)$ block. The eigenvalues of the preconditioned matrix are given in Figure 7.1 on the left and validate the eigenvalue analysis of this section and the algebraic multiplicities of the three clusters of eigenvalues. Convergence graphs for MINRES are given in Figure 7.1 on the right.

Computing the null vectors exactly in this case would be costly and storing all of them would require more storage than that required for the matrix of the linear system. In practice adjustments such as inexpensive approximation of the null vectors and inexact inversion of $A + VV^T$ have to be made. Nevertheless, the substantial savings in iteration counts may indicate the viability of this approach.

**8. Conclusions.** We have considered the problem of minimizing the condition number of a matrix that is subject to low rank modifications. For symmetric matrices, the standard interlacing property of eigenvalues can be applied and for the nonsymmetric case an analogous property of the singular values can be used. There is nonuniqueness, but a solution can be obtained using [illegible] eigenvectors or singular vectors of the matrices, which correspond to extremal eigenvalues (in the symmetric case) or singular values (nonsymmetric case). There is a large "flat spot" of values that can be used to obtain the minimum. In the symmetric indefinite case the two equations that need to be solved to find a possible minimizer are linear, even though the general setting of the problem is nonlinear. For the nonsymmetric case there are more degrees of freedom, and in fact we have four equations with two unknowns. We exploited this freedom by computing the vectors using a particular shifted skew-symmetric matrix for which the singular values are available analytically.

**Acknowledgments.** We are indebted to Michael Overton for many enjoyable and fruitful discussions of the problem—before, after, and while he visited the University of British Columbia in summer 2005. Michael's insightful comments and suggestions for improving this manuscript are gratefully acknowledged. We are also grateful to two very thorough referees for many constructive comments which helped improve this manuscript.

# SCHWARZ ITERATIONS FOR SYMMETRIC POSITIVE SEMIDEFINITE PROBLEMS*

REINHARD NABBEN† AND DANIEL B. SZYLD‡

**Abstract.** Convergence properties of additive and multiplicative Schwarz iterations for solving linear systems of equations with a symmetric positive semidefinite matrix are analyzed. The analysis presented applies to matrices whose principal submatrices are nonsingular, i.e., positive definite. These matrices appear in discretizations of some elliptic partial differential equations, e.g., those with Neumann or periodic boundary conditions.

**Key words.** linear systems, additive Schwarz, multiplicative Schwarz, domain decomposition methods, symmetric positive semidefinite systems, singular matrices, comparison theorems, overlap, coarse grid correction

**DOI.** 10.1137/050644203

## 1. Introduction.

Domain decomposition methods, including additive and multiplicative Schwarz, are widely used for the numerical solution of partial differential equations; see, e.g., [38], [41], [44]. Advantages of these methods include enhancement of parallelism and a localized treatment. One can find algebraic descriptions of them, e.g., in [14], [20], [47], especially for symmetric positive definite problems.

In this paper, we adopt the algebraic representation of additive and multiplicative Schwarz developed in a series of papers [1], [18], [19], [34], [35], where analysis of convergence and properties for several variants of the methods are provided, both for symmetric positive definite and for nonsingular $M$-matrices. Recently, convergence properties were studied for singular systems arising in the solution of Markov chains, i.e., singular $M$-matrices with all principal submatrices being nonsingular [7], [32]. In particular, this theory applies to singular matrices with a one-dimensional null-space, and to those representing irreducible Markov chains; see, e.g., [42]. We also mention the recent work on multiplicative Schwarz iterations for positive semidefinite operators [26], [28].

In this paper, we extend the theory to the symmetric positive semidefinite case, with particular emphasis on the singular case (the analysis of the symmetric positive definite case is known; see, e.g., [1], [21, Ch. 11], [41], [44]). We study in particular the case when all principal submatrices are nonsingular, i.e., positive definite. This situation arises in practice, e.g., in the discretization of certain elliptic differential equations such as $-\Delta u + u = f$ with Neumann or periodic boundary conditions; see, e.g., [5]. We show that in this case, the additive and multiplicative Schwarz iterations are convergent and we characterize the convergence factor $\gamma$ for such methods (sections 4 and 5). We use the theory of matrix splittings (see section 3) to obtain these convergence properties. We remark that we do not use splittings to produce new

stationary iterative methods. What we do is recast the Schwarz iteration matrices as coming from specific splittings, and we use this setup as an analytical tool to obtain convergence results.

The convergence theory we develop implies that the corresponding preconditioned matrices have zero as an isolated point in the spectrum. The rest of the spectrum is contained in a circle centered at one with radius $\gamma < 1$. When considering additive and multiplicative Schwarz preconditioners for singular systems, one needs to use Krylov subspace methods which are sometimes tailored for this case; see, e.g., [17], [23], [39], and the references given therein.

We believe that our purely algebraic approach is much simpler than that of [26], [28], and in addition, it can be applied to problems which may not have a variational formulation. Of course our approach is only valid for the finite dimensional case. We also consider the case of inexact local solvers (section 6), and the influence of the amount of overlap and the number of blocks in the convergence rate (sections 7 and 8). Finally, we study the convergence of two-level methods, i.e., methods where a coarse grid correction is considered as well (section 9).

**2. The algebraic representation and notation.** We first briefly describe the additive and multiplicative Schwarz methods and give some auxiliary results. Additional notation and background are also given in the next section.

Let $\mathcal{R}(A)$ be the range of $A$. Consider the linear system in $\mathbb{R}^n$ of the form

$$Ax = b, \quad b \in \mathcal{R}(A). \tag{2.1}$$

In this paper we consider the case where $A$ is symmetric positive semidefinite, and we denote this by $A \succeq O$. We assume that every principal submatrix of $A$ is nonsingular, i.e., a symmetric positive definite matrix, and if $A_i$ is such a submatrix, we denote this by $A_i \succ O$. This situation occurs, for instance, when the null-space of $A$, $\mathcal{N}(A)$, is unidimensional and any generator of it has no zero entries; cf. [5].

We consider $p$ subspaces $V_i$, with $\dim V_i = n_i, i = 1, \dots, p$, which are spanned by columns of the identity $I$ over $\mathbb{R}^n$ and such that

$$\sum_{i=1}^{n} V_i = \mathbb{R}^n =: V. \tag{2.2}$$

Note that the subspaces $V_i$ may overlap. Between the subspaces $V_i$ and the space $V$ we consider the following mappings:

$$R_i : V \to V_i, \qquad R_i^T : V_i \to V,$$

where $\operatorname{rank}(R_i^T) = n_i$. $R_i$ is called the restriction operator while $R_i^T$ is called the prolongation operator. We also use the matrices

$$P_i = R_i^T A_i^{-1} R_i A = R_i^T (R_i A R_i^T)^{-1} R_i A,$$

where $A_i := R_i A R_i^T$ is a permutation of a principal submatrix of $A$, which because of our assumption is nonsingular. Note that $P_i$ is a projection.

With these projections the damped additive Schwarz method used as an iterative method to solve (2.1) can be described as

$$\begin{aligned} x^{k+1} &= x^k + \theta \sum_{i=1}^{p} R_i^T A_i^{-1} R_i (b - Ax^k) \\ &= \left( I - \theta \sum_{i=1}^{p} R_i^T A_i^{-1} R_i A \right) x^k + \left( \theta \sum_{i=1}^{p} R_i^T A_i^{-1} R_i \right) b, \end{aligned} \tag{2.3}$$

where $0 < \theta \leq 1$ is a damping parameter; see [8], [11], [12], [13], [20], [21, Ch. 11], [41], [44]. The iteration matrix is then given by

$$T_{AS,\theta} = I - \theta \sum_{i=1}^{p} R_i^T A_i^{-1} R_i A = I - \theta \sum_{i=1}^{p} P_i, \tag{2.4}$$

or, using the notation

$$M_{AS}^{-1} = \sum_{i=1}^{p} R_i^T A_i^{-1} R_i, \tag{2.5}$$

then, the iteration matrix (2.4) can be written as

$$T_{AS,\theta} = I - \theta M_{AS}^{-1} A.$$

Later on, in Theorem 4.2, we show that the matrix on the right-hand side in (2.5) is nonsingular, and therefore it makes sense to denote it as $M_{AS}^{-1}$. Furthermore, for each $\theta > 0$ one can define a splitting of $A$ for which the iteration matrix is precisely (2.4). One such splitting is $A = \frac{1}{\theta} M_{AS} - (\frac{1}{\theta} M_{AS} - A)$. When $A$ is singular, such splitting however is not unique; see [2].

Very often in practice the additive Schwarz method is used for preconditioning a Krylov subspace method. In the symmetric cases considered here the method of choice is the conjugate gradient method; for a study of this method for singular systems, see [23]. While the matrix $A$ may be singular, the preconditioning matrix $M$ is usually assumed to be symmetric positive definite. The additive Schwarz preconditioner is $M_{AS}^{-1}$ and the preconditioned matrix is then

$$M_{AS}^{-1} A = \sum_{i=1}^{p} P_i = I - T_{AS,1}.$$

The multiplicative Schwarz method can be written as the iteration

$$x^{k+1} = T_{MS} x^k + c, \qquad k = 0, 1, \ldots, \tag{2.6}$$

with the iteration matrix

$$T_{MS} = (I - P_p)(I - P_{p-1}) \cdots (I - P_1) = \prod_{i=p}^{1} (I - P_i), \tag{2.7}$$

and a certain vector $c$. The corresponding preconditioned matrix in this case is $I - T_{MS}$.

[illegible] 2.1. Observe that for any vector $y \in \mathcal{N}(A)$, i.e., such that $Ay = 0$, one has $Ty = y$ for both iteration matrices $T = T_{AS,\theta}$ of (2.4), or $T = T_{MS}$ of (2.7). This implies in particular that we need to require in our iterations, such as (2.3), that $x_0 \notin \mathcal{N}(A)$.

We outline our strategy to prove the convergence of the iterations (2.3) and (2.6). We need to show that the powers of the iteration matrices (2.4) and (2.7) converge to a limit; see Definition 3.1 below. One sufficient condition for this to hold is that there is a splitting of $A$ of the form $A = M - N$ with $M$ nonsingular such that $M^{-1}N$ is the iteration matrix, and we show that this splitting is $P$-regular (see

Definition 3.3 below), which implies convergence; see Theorem 3.2 below. We also use certain comparison theorems to relate the convergence of different versions of these iterations. We present a context for these analytical tools in section 3. In the rest of this section, we repeat the algebraic characterization of the Schwarz methods used, e.g., in [1], which is the basis to produce the above-mentioned splittings.

As already mentioned, we assume that the rows of $R_i$ are rows of the $n \times n$ identity matrix $I$, e.g., of the form

$$R_i = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \end{bmatrix}.$$

This restriction operator is often called a Boolean gather operator, while its transpose $R_i^T$ is called a Boolean scatter operator. Formally, such a matrix $R_i$ can be expressed as

$$R_i = [I_i | O]\, \pi_i \tag{2.8}$$

with $I_i$ the identity on $\mathbb{R}^{n_i}$ and $\pi_i$ a permutation matrix on $\mathbb{R}^n$. Then $A_i$ is a symmetric permutation of an $n_i \times n_i$ principal submatrix of $A$. In fact, we can write

$$\pi_i A \pi_i^T = \begin{bmatrix} A_i & K_i \\ K_i^T & A_{\neg i} \end{bmatrix}, \tag{2.9}$$

where $A_{\neg i}$ is the principal submatrix of $A$ "complementary" to $A_i$, i.e.,

$$A_{\neg i} = [O | I_{\neg i}] \cdot \pi_i \cdot A \cdot \pi_i^T \cdot [O | I_{\neg i}]^T$$

with $I_{\neg i}$ the identity on $\mathbb{R}^{n-n_i}$.

For each $i = 1, \ldots, p$, we define

$$E_i := R_i^T R_i \in \mathbb{R}^{n \times n}. \tag{2.10}$$

These diagonal matrices have ones on the diagonal in every row where $R_i^T$ has nonzeros. We further need sets $S_i$ defined by

$$S_i := \{ j \in \{1, \ldots, n\} : (E_i)_{j,j} = 1 \}.$$

Then

$$\bigcup_{i=1}^{p} S_i = S = \{1, 2, \ldots, n\}; \tag{2.11}$$

i.e., each index is in at least one set $S_i$. This is equivalent to saying that $\sum_{i=1}^{p} E_i \geq I$, with equality if and only if there is no overlap. In other words, in the case of overlapping subspaces, we have here that each diagonal entry of $\sum_{i=1}^{p} E_i$ is greater than or equal to one, which implies nonsingularity. Only in the rows corresponding to overlap this matrix has an entry different from one.

For each $i = 1, \ldots, p$, we construct a second set of matrices $M_i \in \mathbb{R}^{n \times n}$ associated with $R_i$ from (2.8) as

$$M_i = \pi_i^T \begin{bmatrix} A_i & O \\ O & D_{\neg i} \end{bmatrix} \pi_i, \tag{2.12}$$

where under our assumptions on $A \succeq O$, we have that $D_{\neg i} = \text{diag}(A_{\neg i}) \succ O$, and thus $M_i$ is invertible.

With the definitions (2.10) and (2.12) we obtain the following equality which we will use throughout the paper:

$$E_i M_i^{-1} A = R_i^T A_i^{-1} R_i A = P_i, \quad i = 1, \ldots, p. \tag{2.13}$$

**3. Convergent matrices, splittings, and comparison theorems.** In this section we present some more definitions and results which we use in the rest of the paper.

Definition 3.1. [illegible] $T$ [illegible] $\lim_{k\to\infty} T^k$ [illegible]

(1) $\rho(T) \le 1$
(2) $\text{rank}(I-T) = \text{rank}(I-T)^2$
(3) [illegible] $|\lambda| = 1$ [illegible] $\lambda$ [illegible] $T$ [illegible] $\lambda = 1$

Condition 2 states that the index of the matrix $I - T$ is one, or in this case that $ind_1 T = 1$ [3]. Several equivalent conditions can be found in [43]. One of them is the following:

$$ind_1 T = 1 \Leftrightarrow \mathcal{R}(I-T) \cap \mathcal{N}(I-T) = \{0\}, \tag{3.1}$$

i.e., that the intersection of the range and the null-space of $I - T$ is trivial.

If $\rho(T) = 1$ for a convergent matrix then the asymptotic rate of convergence is given by

$$\gamma(T) := \max\{|\lambda| \ : \ \lambda \in \sigma(T), |\lambda| < 1\}. \tag{3.2}$$

When $A$ is singular, and we have a nonsingular matrix $M$, and a convergent matrix $T$ such that $A = M(I-T)$, then $P = \lim_{k\to\infty} T^k$ is a projection onto $\mathcal{N}(A) = \mathcal{N}(I-T)$. In fact $P = I-(I-T)(I-T)^D$, where $(I-T)^D$ denote the Drazin inverse of $(I-T)$. Furthermore, if we let $c = M^{-1}b$, and consider the iteration $x^{k+1} = Tx^k + c$, $x_0 \notin \mathcal{N}(A)$ (cf. (2.3)), then $\lim_{k\to\infty} x^k = (I-T)^D c + (I-P)x^0$; see, e.g., [3, Ch. 7.6].

A useful result in the analysis of convergent iteration matrices is the following, due to Keller [24].

Theorem 3.2. [illegible] $A$ [illegible] $M$ [illegible] $M + M^T - A$ [illegible] $T = I - M^{-1}A$ [illegible] $A$ [illegible]

Note than when $M$ is symmetric this theorem says that if $2M - A \succ O$, then $T$ is convergent if and only if $A \succeq O$.

Definition 3.3. [illegible] $A = M - N$ [illegible] $P$-regular [illegible] $M + M^T - A \succ O$ [36] [illegible] strong $P$-regular [illegible] $N \succ O$ [33]

With this definition, Theorem 3.2 indicates that a sufficient condition for convergence of $T$ is that $A = M - N$ is a $P$-regular splitting of a positive semidefinite matrix. Weaker sufficient conditions, and also necessary conditions not requiring the nonsingularity of $M$, can be found in the recent paper [27].

The following result is a new sufficient condition for convergence, which we use later in the paper.

Lemma 3.4. [illegible] $A$ [illegible] $A = M - N$ [illegible] $M$ [illegible]

$$A^{\frac{1}{2}} M^{-1} A^{\frac{1}{2}} \prec 2I,$$

[illegible] $T = I - M^{-1}A$ [illegible] $A = M - N$ [illegible] $P$ [illegible]

We have $A^{\frac{1}{2}}M^{-1}A^{\frac{1}{2}} \prec 2I$. Thus

$$\sigma(A^{\frac{1}{2}}M^{-1}A^{\frac{1}{2}}) \subset [0,2).$$

Since

$$\sigma(A^{\frac{1}{2}}M^{-1}A^{\frac{1}{2}}) = \sigma(M^{-1}A) = \sigma(AM^{-1}) = \sigma(AM^{-\frac{1}{2}}M^{-\frac{1}{2}}) = \sigma(M^{-\frac{1}{2}}AM^{-\frac{1}{2}}),$$

we have that

$$2I - M^{-\frac{1}{2}}AM^{-\frac{1}{2}} \succ 0.$$

Hence,

$$M^{\frac{1}{2}}(2I - M^{-\frac{1}{2}}AM^{-\frac{1}{2}})M^{\frac{1}{2}} \succ 0$$

and therefore,

$$2M - A \succ 0;$$

i.e., we have a $P$-regular splitting. Using Theorem 3.2 we obtain that $T = I - M^{-1}A$ is convergent. □

The use of $P$-regular splittings as sufficient conditions for convergence of classical stationary iterative methods for symmetric matrices mimics the use of regular or weak regular splittings as sufficient conditions for the convergence of classical stationary iterative methods for monotone matrices; see, e.g., the classic books [3], [37], [45]. In this case, the rate of convergence of the iterative method is given by the spectral radius of the iteration matrix. Thus, the rate of convergence of two iterative methods for monotone matrices can be compared by looking at the corresponding spectral radii. Many comparison theorems using different hypothesis on the splittings have appeared in the literature; see, e.g., [9], [10], [16], [29], [33], [45], [46], and other references therein. When the iteration matrices have spectral radius equal to one, as is usually the case for singular linear systems, the convergence rate is given by (3.2). Comparison theorems for these can be found in [30], [31]. Here we present a new comparison theorem, which we use in our context.

We first present the following result due to Weyl; see [22, Theorem 4.3.7]. Let $M \succeq O$, and denote its eigenvalues by $\lambda_1(M) \ge \lambda_2(M), \ldots, \lambda_n(M) \ge 0$.

PROPOSITION 3.5. $M_1$ $M_2$ $M_1 \succeq M_2$ $\lambda_i(M_1) \ge \lambda_i(M_2)$ $i$

Of course, this proposition is valid when $M$ is positive definite as well.

THEOREM 3.6. $A$ $M_1$ $M_2$ $N_1 := M_1 - A$ $N_2 := M_2 - A$

$$M_1^{-1} \succeq M_2^{-1},$$

$$\lambda_i(M_1^{-1}N_1) \le \lambda_i(M_2^{-1}N_2)$$

$i$ $N_1$ $N_2$

$$\gamma(M_1^{-1}N_1) \le \gamma(M_2^{-1}N_2).$$

[illegible] We first note that

$$\sigma(M_k^{-1}A) = \sigma(M_k^{-1}A^{\frac{1}{2}}A^{\frac{1}{2}}) = \sigma(A^{\frac{1}{2}}M_k^{-1}A^{\frac{1}{2}}), \quad k = 1, 2.$$

With Proposition 3.5 we obtain for each $i$ that

$$\lambda_i(M_1^{-1}A) = \lambda_i(A^{\frac{1}{2}}M_1^{-1}A^{\frac{1}{2}}) \geq \lambda_i(A^{\frac{1}{2}}M_2^{-1}A^{\frac{1}{2}}) = \lambda_i(M_2^{-1}A). \tag{3.3}$$

Since $M_k^{-1}N_k = I - M_k^{-1}A$, $k = 1, 2$, (3.3) indicates that for each $i$,

$$\lambda_i(M_1^{-1}N_1) \leq \lambda_i(M_2^{-1}N_2).$$

If $N_1$ and $N_2$ are positive semidefinite then all eigenvalues of $M_1^{-1}N_1$ and $M_2^{-1}N_2$ are nonnegative, and therefore

$$\gamma(M_1^{-1}N_1) \leq \gamma(M_2^{-1}N_2). \qquad \square$$

## 4. Convergence of additive Schwarz.

We begin with an auxiliary result, the proof of which follows by a straightforward calculation.

LEMMA 4.1. [illegible] $A$ [illegible]

$$A^{\frac{1}{2}}R_i^T(R_iAR_i^T)^{-1}R_iA^{\frac{1}{2}}$$

[illegible] $I - A^{\frac{1}{2}}R_i^T(R_iAR_i^T)^{-1}R_iA^{\frac{1}{2}}$ [illegible]

$$A^{\frac{1}{2}}R_i^T(R_iAR_i^T)^{-1}R_iA^{\frac{1}{2}} \preceq I, \tag{4.1}$$

[illegible]

$$\sigma(A^{\frac{1}{2}}R_i^T(R_iAR_i^T)^{-1}R_iA^{\frac{1}{2}}) = \{0, 1\}.$$

THEOREM 4.2. [illegible] $A$ [illegible] $b \in \mathcal{R}(A)$ [illegible] $x_0 \notin \mathcal{N}(A)$ [illegible] $0 < \theta < 2/p$ [illegible] (2.4) [illegible] $M = \frac{1}{\theta}M_{AS}$ [illegible] $P$ [illegible]

[illegible] First, as is done in [21] for the nonsingular case, we prove that the matrix

$$\sum_{i=1}^{p} R_i^T(R_iAR_i^T)^{-1}R_i$$

is nonsingular. To that end, let the vector $x$ be such that

$$\sum_{i=1}^{p} R_i^T(R_iAR_i^T)^{-1}R_ix = 0.$$

Hence

$$x^T\sum_{i=1}^{p} R_i^T(R_iAR_i^T)^{-1}R_ix = 0,$$

and thus

$$\sum_{i=1}^{p}(A_i^{-\frac{1}{2}}R_ix)^TA_i^{-\frac{1}{2}}R_ix = \sum_{i=1}^{p}||A_i^{-\frac{1}{2}}R_ix||_2^2 = 0,$$

which implies $R_i x = 0$ for $i = 1, \ldots, p$. By our assumption (2.2) this implies that $x = 0$.

Using Lemma 4.1 we have that (4.1) holds. Summing up, we have

$$A^{\frac{1}{2}} \left( \sum_{i=1}^{p} R_i^T (R_i A R_i^T)^{-1} R_i \right) A^{\frac{1}{2}} \preceq pI, \tag{4.2}$$

and since $\theta < 2/p$, we have $A^{\frac{1}{2}} \theta M_{AS}^{-1} A^{\frac{1}{2}} \prec 2I$. We can now use Lemma 3.4, and this completes the proof. □

As is done in [21, Ch. 11.2.4] in the symmetric positive definite case, a careful look at the sum in (4.2) indicates that we can replace the number of subdomains $p$ with the number of colors $q$ of the graph of $A$. Thus $A^{\frac{1}{2}} M_{AS}^{-1} A^{\frac{1}{2}} \prec qI$, and if $\theta < 2/q$, we have convergence.

[illegible] 4.3. If we further restrict the value of the damping parameter to $\theta < 1/p$ (or $\theta < 1/q$), we have that the splitting defined by $\frac{1}{\theta} M_{AS}$ is strong $P$-regular. This follows since in this case $A^{\frac{1}{2}} \theta M_{AS}^{-1} A^{\frac{1}{2}} \prec I$, which implies $\frac{1}{\theta} M_{AS} \succ A$.

We note that the result in Theorem 4.2 applies in particular to the symmetric positive definite case. Thus, in our formulation we have doubled the interval of admissible damping factors for convergence of the damped additive Schwarz method, since the usual restriction is that $\theta < 1/q$; see [18], [21, Ch. 11.2.4]. We mention also that simple examples show that this method may not be convergent for $\theta = 1$.

From Theorem 4.2 it follows that the only eigenvalue of $T$ in the unit circle is $\lambda = 1$, and since we showed that $M_{AS}$ is nonsingular, the corresponding eigenvector is a generator of the one-dimensional $\mathcal{N}(A)$. It follows then (see, e.g., [22, section 4.2]), that the convergence factor (3.2) of the additive Schwarz iteration can be characterized as

$$\begin{aligned} \gamma(T_{AS,\theta}) &= \max_{\substack{z \perp \mathcal{N}(A) \\ z^T z = 1}} z^T T_{AS,\theta} z \\ &= \max_{\substack{z \perp \mathcal{N}(A) \\ (z,z) = 1}} \left( 1 - \theta \sum_{i=1}^{p} (R_i^T A_i^{-1} R_i z, Az) \right) \\ &= 1 - \theta \left( \min_{\substack{z \perp \mathcal{N}(A) \\ (z,z) = 1}} \sum_{i=1}^{p} (R_i^T A_i^{-1} R_i z, Az) \right). \end{aligned} \tag{4.3}$$

We note that on the subspace $\mathcal{N}(A)^{\perp}$, the matrix $A$ is positive definite. Let us call $\hat{A} = A|_{\mathcal{N}(A)^{\perp}}$, and we can thus replace $A$ with $\hat{A}$ in (4.3). Furthermore, since $\hat{A}^{1/2}$ is invertible, we can write $w = \hat{A}^{1/2} z$, and write (4.3) as

$$\gamma(T_{AS,\theta}) = 1 - \theta \left( \min_{\substack{\hat{A}^{-1/2} w \perp \mathcal{N}(A) \\ (w, \hat{A}^{-1} w) = 1}} \sum_{i=1}^{p} w^T \hat{A}^{-1/2} R_i^T A_i^{-1} R_i \hat{A}^{1/2} w \right). \tag{4.4}$$

We point out that the characterization (4.4) is also valid for the case of $A$ symmetric positive definite, in which case we have $\hat{A} = A$.

**5. Convergence of multiplicative Schwarz.** We begin with an important auxiliary result.

LEMMA 5.1. [illegible] $A$ [illegible] $x,\ y \in \mathbb{R}^n$ [illegible]

$$y = (I - E_i M_i^{-1} A)x, \tag{5.1}$$

[illegible] $E_i$ [illegible] (2.10) [illegible] $M_i$ [illegible] (2.12) [illegible]

$$y^TAy - x^TAx = -(y-x)^TE_iAE_i(y-x) \le 0. \tag{5.2}$$

[illegible] Consider $x = \pi_i^T(x_1^T, x_2^T)^T$ and $y = \pi_i^T(y_1^T, y_2^T)^T$, with $x_1,\ y_1 \in \mathbb{R}^{n_i}$. Further, from (2.10) and (2.8) we have that

$$E_i = \pi_i^T \begin{bmatrix} I_i & O \\ O & O \end{bmatrix} \pi_i. \tag{5.3}$$

Consider now (5.1), whence we immediately have that

$$y_2 = x_2, \tag{5.4}$$

and using (2.12) and (2.9), we also get

$$A_iy_1 = -A_{12}x_2, \tag{5.5}$$

where here we use the notation $A_{12} = K_i$, and similarly $A_{21} = K_i^T = A_{12}^T$. Using these identities we write

$$\begin{aligned} y^TAy - x^TAx &= (y_1^T, y_2^T)\pi_iA\pi_i^T(y_1^T, y_2^T)^T - (x_1^T, x_2^T)\pi_iA\pi_i^T(x_1^T, x_2^T)^T \\ &= y_1^TA_iy_1 + y_2^TA_{21}y_1 + y_1^TA_{12}y_2 - x_1^TA_ix_1 - x_2^TA_{21}x_1 - x_1^TA_{12}x_2 \\ &= x_2^TA_{21}(y_1 - x_1) + (y_1^T - x_1^T)A_{12}x_2 + y_1^TA_iy_1 - x_1^TA_ix_1 \\ &= -y_1^TA_i(y_1 - x_1) - (y_1^T - x_1^T)A_iy_1 + y_1^TA_iy_1 - x_1^TA_ix_1 \\ &= -(y_1^T - x_1^T)A_i(y_1 - x_1) = -(y-x)^TE_iAE_i(y-x), \end{aligned}$$

where the last equality follows from the identity

$$E_iAE_i = \pi_i^T \begin{bmatrix} A_i & O \\ O & O \end{bmatrix} \pi_i.$$

Since $A \succeq O$, $E_iAE_i$ is semidefinite as well, and the right-hand side of (5.2) is nonpositive. ◻

THEOREM 5.2. [illegible] $A$ [illegible] $b \in \mathcal{R}(A)$ [illegible] $x_0 \notin \mathcal{N}(A)$ [illegible] (2.6) [illegible]

[illegible] We need to prove that the iteration matrix $T = T_{MS}$ is convergent; i.e., we need to prove conditions (1), (2), and (3) of Definition 3.1.

(1) Starting with $z = x^{(1)} \notin \mathcal{N}(A)$, let $x^{(i+1)} = (I - P_i)x^{(i)}$. Thus $x^{(p+1)} = Tx^{(1)}$. Using (5.2) repeatedly, and canceling terms, we obtain

$$\begin{aligned} z^TT^TATz - z^TAz &= -\sum_{i=1}^{p}(x^{(i+1)} - x^{(i)})^TE_iAE_i(x^{(i+1)} - x^{(i)}) \\ &= -\sum_{i=1}^{p}((x^{(i+1)} - x^{(i)})^TE_i)E_iAE_i(E_i(x^{(i+1)} - x^{(i)})). \end{aligned} \tag{5.6}$$

Since $E_iAE_i$ is positive definite it follows that the right-hand side of (5.6) is nonpositive. However, the right-hand side is zero if and only if

$$E_i(x^{(i+1)} - x^{(i)}) = 0 \qquad \text{for all } i,\ i = 1, \ldots, p.$$

The other $n - n_i$ components of $x^{(i+1)} - x^{(i)}$ are also zero using the same argument as in Lemma 5.1 to obtain (5.4). But this implies $x^{(p+1)} = x^{(i+1)} = x^{(i)} = x^{(1)}$, $i = 1, \ldots, p$. Thus $x^{(1)}$ must be a common fixed point of $(I - P_i)$ for all $i = 1, \ldots, p$. However, the fixed points of the projections $(I - P_i)$ are just the vectors $z \in \mathbb{R}^n$ with $E_i z = 0$. Since $\sum_{i=1}^{p} E_i \geq I$ there is no such common nonzero fixed point. Hence the right-hand side of (5.6) must be negative, and we obtain

$$z^T T^T A T z - z^T A z < 0.$$

Thus we have that for all $\lambda \in \sigma(T)$ with corresponding eigenvector $y \notin \mathcal{N}(A)$

$$\lambda^2 y^T A y - y^T A y < 0. \tag{5.7}$$

Hence $\lambda^2 - 1 < 0$. Thus

$$|\lambda| < 1.$$

If $\lambda \in \sigma(T)$ but the corresponding eigenvector $y \in \mathcal{N}(A)$, we easily obtain from the definition of $T$ that $\lambda = 1$. Hence, $\rho(T) \leq 1$.

(2) By (3.1), it suffices to prove that $\mathcal{N}(I - T) \cap \mathcal{R}(I - T) = \{0\}$. Here we have that $\mathcal{N}(A) = \mathcal{N}(I - T)$. This holds since $y \notin \mathcal{N}(A)$ implies $Ty \neq y$ by part (1), i.e., $y \notin \mathcal{N}(I - T)$. On the other hand $y \in \mathcal{N}(A)$ implies $y \in \mathcal{N}(I - T)$, using the definition of $T$; cf. Remark 2.1. Hence, we need to prove that

$$\mathcal{N}(A) \cap \mathcal{R}(I - T) = \{0\}. \tag{5.8}$$

Let $x \in \mathcal{N}(A) \cap \mathcal{R}(I - T)$. Then there exists a $y$ with $(I - T)y = x$, i.e., $y = Ty + x$. Since $x \in \mathcal{N}(A)$ we obtain

$$A(I - T)y = Ax = 0, \quad \text{and thus} \quad y^T A y - y^T A T y = 0.$$

Using $y = Ty + x$ we get

$$y^T A y - y^T T^T A T y + x^T A T y = y^T A y - y^T T^T A T y = 0.$$

Part (1) of this proof now implies $y \in \mathcal{N}(A)$; cf. (5.7). Therefore, by Remark 2.1, $x = (I - T)y = 0$, which completes this part of the proof.

(3) As proved above we have $\lambda < 1$ for all $\lambda \in \sigma(T)$ with corresponding eigenvector $y \notin \mathcal{N}(A)$. Thus if $|\lambda| = 1$ for some eigenvalue $\lambda$ of $T$ then the corresponding eigenvector $y$ must be in the null-space of $A$. Hence $Ay = 0$. But then $Ty = y$ and thus $\lambda = 1$. ☐

We mention that we need to prove explicitly (5.8) since we do not have an explicit representation of a nonsingular matrix $M_{MS}$ such that $M_{MS}^{-1} A = I - T_{MS}$. The existence of such a matrix, i.e., of a splitting induced by $T_{MS}$ [2] is only obtained after the theorem is proved. Any splitting induced by such a matrix $M_{MS}$ is thus $P$-regular.

We also comment on the fact that in some cases one may want to have a symmetric operator, and in such a case, the natural multiplicative operator is

$$T_{SMS} = (I - P_1)(I - P_2) \cdots (I - P_{p-1})(I - P_p)(I - P_{p-1}) \cdots (I - P_1). \tag{5.9}$$

It follows that Theorem 6.1 applies to this case as well, and that a posteriori, there exists a nonsingular matrix $M_{SMS}$ such that $M_{SMS}^{-1} A = I - T_{SMS}$. We can characterize the convergence factor (3.2) of this symmetric multiplicative Schwarz iteration as

$$\gamma = \gamma(T_{SMS}) = \max_{\substack{z \perp \mathcal{N}(A) \\ z^T z = 1}} (z, T_{SMS} z). \tag{5.10}$$

**6. Inexact local solvers.** In this section we study the effect of varying how exactly (or inexactly) the local problems are solved. The convergence of these very practical versions of the methods is based on the same ideas used to prove that of the standard Schwarz iterations in sections 4 and 5. The influence of different levels of inexactness is analyzed using our comparison theorem, Theorem 3.6.

Very often in practice, instead of solving the local problems $A_i y_i = z_i$ exactly, such linear systems are approximated by $\tilde{A}_i^{-1} z_i$, where $\tilde{A}_i$ is an approximation of $A_i$; see, e.g., [6], [41], [44]. The expression $\tilde{A}_i^{-1} z_i$ often represents an approximation to the solution of the system $A_i z_i = v_i$ using some steps of an (inner) iterative method. By replacing $A_i$ with $\tilde{A}_i$ in (2.4) one obtains the damped additive Schwarz iterations with inexact local solvers, and its iteration matrix is then

$$\tilde{T}_{AS,\theta} = I - \theta \sum_{i=1}^{p} R_i^T \tilde{A}_i^{-1} R_i A. \tag{6.1}$$

The iteration matrices $T_{AS,\theta}$ and $\tilde{T}_{AS,\theta}$ in (2.4) and (6.1) are induced by splittings $A = M_\theta - N_\theta$ and $A = \tilde{M}_\theta - \tilde{N}_\theta$ where

$$M_\theta^{-1} = \theta \sum_{i=1}^{p} R_i^T A_i^{-1} R_i = \theta \sum_{i=1}^{p} E_i M_i^{-1} \succ O, \tag{6.2}$$

$$\tilde{M}_\theta^{-1} = \theta \sum_{i=1}^{p} R_i^T \tilde{A}_i^{-1} R_i = \theta \sum_{i=1}^{p} E_i \tilde{M}_i^{-1} \succ O. \tag{6.3}$$

Here

$$\tilde{M}_i = \pi_i^T \begin{bmatrix} \tilde{A}_i & O \\ O & D_{\neg i} \end{bmatrix} \pi_i, \quad \text{and thus} \quad \tilde{M}_i^{-1} = \pi_i^T \begin{bmatrix} \tilde{A}_i^{-1} & O \\ O & D_{\neg i}^{-1} \end{bmatrix} \pi_i. \tag{6.4}$$

The fact that the matrix (6.3) is nonsingular follows in the same manner as in the proof that (6.2) is nonsingular in Theorem 4.2.

In the case considered in this paper we assume, as is generally done (see, e.g., [21, Ch. 11.2.4]), that the inexact local solvers correspond to symmetric positive definite matrices and satisfy

$$\tilde{A}_i \succeq A_i. \tag{6.5}$$

For examples of splittings for which the inequality (6.5) holds, see, e.g., [33]. A situation worth mentioning where (6.5) holds is when $A_i$ is semidefinite and the inexact local solver is definite. This process is usually called regularization; see, e.g., [15], [25].

Theorem 6.1. [illegible] $A$ [illegible] $b \in \mathcal{R}(A)$ [illegible] $x_0 \notin \mathcal{N}(A)$ [illegible] $\tilde{A}_i$ [illegible] $\bar{A}_i$ [illegible] $A_i$ [illegible] $\tilde{A}_i \succeq \bar{A}_i \succeq A_i$ [illegible] $\bar{T}_{AS,\theta}$ [illegible] $\tilde{A}_i$ [illegible] $\bar{A}_i$ [illegible] (6.1) $i = 1, \ldots, p$ [illegible] $0 < \theta < 2/p$ [illegible] (6.1) [illegible] $\bar{T}_{AS,\theta}$ [illegible] $P$ [illegible] $0 < \theta < 1/p$ [illegible] $\gamma(T_{AS,\theta}) \le \gamma(\bar{T}_{AS,\theta}) \le \gamma(\tilde{T}_{AS,\theta})$ [illegible] $P$ [illegible]

[illegible] Since $\tilde{A}_i \succeq A_i$ we have

$$\tilde{A}_i^{-1} \preceq A_i^{-1}, \tag{6.6}$$

and thus, using Lemma 4.1

$$A^{\frac{1}{2}} R_i^T \tilde{A}_i^{-1} R_i A^{\frac{1}{2}} \preceq A^{\frac{1}{2}} R_i^T A_i^{-1} R_i A^{\frac{1}{2}} \preceq I.$$

Similar inequalities are obtained with $\bar{A}_i$. The rest of the convergence proof proceeds in the same manner as that of Theorem 4.2.

Consider the matrices (6.2) and (6.3) which are symmetric positive definite using $M_i$ as in (2.12) and $\tilde{M}_i$ as in (6.4). From (6.6), we have that $M_\theta^{-1} \succeq \tilde{M}_\theta^{-1} \succ O$. This implies $M_\theta \preceq \tilde{M}_\theta$ and $N_\theta \preceq \tilde{N}_\theta$. By Remark 4.3, we have that $N_\theta \succ O$, i.e., that the splittings are strong $P$-regular. The same results are obtained in the case of $\bar{A}_i$. The theorem follows from Theorem 3.6. $\square$

As was the case with Theorem 4.2, we can replace $p$ in the restriction on the damping parameter with $q$, the number of colors; i.e., we guarantee convergence of additive Schwarz with inexact local solvers for $\theta < 2/q$. Since Theorem 6.1 applies in particular to the symmetric positive definite case, we have again double the interval of admissible damping factors for the additive Schwarz iteration with inexact local solvers; cf. [1].

*Remark* 6.2. An alternative proof of the second part of Theorem 6.1 can be obtained by considering the two convergence factors, $\gamma(T_{AS,\theta})$ given by (4.4) for the exact case, and the second given by

$$\gamma(\tilde{T}_{AS,\theta}) = 1 - \theta \left( \min_{\substack{\hat{A}^{-1/2} w \perp \mathcal{N}(A) \\ (w, \hat{A}^{-1} w) = 1}} \sum_{0=1}^{p} w^T \hat{A}^{-1/2} R_i^T \tilde{A}_i^{-1} R_i \hat{A}^{1/2} w \right) \tag{6.7}$$

for the inexact case. Since $\sigma(\hat{A}^{-1/2} R_i^T A_i^{-1} R_i \hat{A}^{1/2}) = \{0\} \cup \sigma(A_i^{-1})$ and $\sigma(\hat{A}^{-1/2} R_i^T \tilde{A}_i^{-1} R_i \hat{A}^{1/2}) = \{0\} \cup \sigma(\tilde{A}_i^{-1})$, and since $-\tilde{A}_i^{-1} \succeq -A_i^{-1}$, we have that

$$-w^T \hat{A}^{-1/2} R_i^T \tilde{A}_i^{-1} R_i \hat{A}^{1/2} w \ \geq \ - w^T \hat{A}^{-1/2} R_i^T A_i^{-1} R_i \hat{A}^{1/2} w, \quad i = 1, \ldots, p,$$

which implies that $\gamma(\tilde{T}_{AS,\theta}) \geq \gamma(T_{AS,\theta})$.

For simplicity, in Theorem 6.1, we assumed that the inexact versions use the same damping parameter $\theta$. It is evident from the proofs that if the damping parameter for the inexact version is smaller, say, $\tilde{\theta} < \theta$, the same conclusions hold.

The implication of Theorem 6.1 is that by replacing the local solvers $A_i$ with the approximate counterparts $\tilde{A}_i$, the additive Schwarz iteration is expected to take more iterations. In practice, a solve with $\tilde{A}_i$ should be sufficiently less expensive so that the overall method is cheaper.

Next we consider the multiplicative Schwarz method with inexact local solvers on the subdomains. Here we assume that the approximations $\tilde{A}_i$ satisfy

$$\tilde{A}_i + \tilde{A}_i^T - A_i \succ 0. \tag{6.8}$$

This assumption implies that

$$A_i = \tilde{A}_i - (\tilde{A}_i - A_i) \quad \text{are } P\text{-regular splittings.}$$

Using (6.4), the inexact multiplicative Schwarz iteration matrix is given by

$$\tilde{T} = (I - E_p \tilde{M}_p^{-1} A)(I - E_{p-1} \tilde{M}_{p-1}^{-1} A) \cdots (I - E_1 \tilde{M}_1^{-1} A). \tag{6.9}$$

LEMMA 6.3. [illegible] $A$ [illegible] $x,\ y \in \mathbb{R}^n$ [illegible] $y = (I - E_i\tilde{M}_i^{-1}A)x$ [illegible] $\tilde{M}_i$ [illegible] (6.4) [illegible] $\tilde{A}_i$ [illegible] (6.8) [illegible]

$$-(y-x)^T E_i(\tilde{M}_i^T + \tilde{M}_i - A)E_i(y-x) \le 0. \tag{6.10}$$

[illegible] The proof proceeds as that of Lemma 5.1. We have that (5.4) holds, but instead of (5.5) we have $\tilde{A}_i y_1 = (\tilde{A}_i - A_i)x_1 - A_{12}x_2$. We then obtain

$$\begin{aligned} y^TAy - x^TAx &= x_2^TA_{21}(y_1-x_1) + (y_1^T - x_1^T)A_{12}x_2 + y_1^TA_iy_1 - x_1^TA_ix_1 \\ &= (x_1^T(\tilde{A}_i - A_i)^T - y_1^T\tilde{A}_i^T)(y_1-x_1) \\ &\quad + (y_1^T - x_1^T)((\tilde{A}_i - A_i)x_1 - \tilde{A}_iy_1) + y_1^TA_iy_1 - x_1^TA_ix_1 \\ &= (-x_1^TA_i - (y_1^T - x_1^T)\tilde{A}_i^T)(y_1 - x_1) \\ &\quad + (y_1^T - x_1^T)(-A_ix_1 - \tilde{A}_i(y_1 - x_1)) + y_1^TA_iy_1 - x_1^TA_ix_1 \\ &= -(y_1^T - x_1^T)(\tilde{A}_i + \tilde{A}_i^T - A_i)(y_1 - x_1) \\ &= -(y-x)^TE_i(\tilde{M}_i^T + \tilde{M}_i - A)E_i(y-x) \le 0, \end{aligned}$$

where the last inequality follows from (6.8) and the form of the matrices $\tilde{M}_i$ in (6.4). □

THEOREM 6.4. [illegible] $A$ [illegible] $b \in \mathcal{R}(A)$ [illegible] $x_0 \notin \mathcal{N}(A)$ [illegible] (6.9) [illegible] $\tilde{M}_i$ [illegible] (6.4) [illegible] (6.8) [illegible] $Ax = b$

[illegible] We need to prove that the iteration matrix $T$ is convergent; i.e., we need to prove conditions (1), (2), and (3) of Definition 3.1. The proof is similar to the proof of Theorem 5.2. The only difference appears in proving condition (1). Here we use Lemma 6.3 and obtain

$$z^T\tilde{T}^TA\tilde{T}z - z^TAz < 0$$

for all $z \notin \mathcal{N}(A)$, and the rest of the proof follows. □

A symmetric version of multiplicative Schwarz with inexact local solvers can also be constructed in a way similar to (5.9), and its convergence factor can be characterized in a way similar to (5.10).

We mention that a comparison analogous to that of the second part of Theorem 6.1 is not valid for multiplicative Schwarz, not even in the definite case. A counterexample can be found in [40].

## 7. Varying the amount of overlap.

We study here how varying the amount of overlap between subblocks (subdomains) influences the convergence rate of additive Schwarz.

Let us consider two sets of subblocks (subdomains) of the matrix $A$, as defined by the sets (2.11), such that one has more overlap than the other; i.e., let

$$\hat{S}_i \supseteq S_i, \quad i = 1, \ldots, p, \tag{7.1}$$

with $\bigcup_{i=1}^p \hat{S}_i = \bigcup_{i=1}^p S_i = S$. Of course, each set $\hat{S}_i$ defines an $\hat{n}_i \times n$ matrix $\hat{R}_i$, where $\hat{n}_i$ is the cardinality of $\hat{S}_i$, and the corresponding $n \times n$ matrix $\hat{E}_i = \hat{R}_i^T\hat{R}_i$, as in (2.10). The relation (7.1) implies that

$$I \succeq \hat{E}_i \succeq E_i \succeq O. \tag{7.2}$$

Similarly, if $\hat{\pi}_i$ is such that $\hat{R}_i = [I_i|O]\,\hat{\pi}_i$, with $I_i$ the identity in $\mathbb{R}^{\hat{n}_i}$, we denote by $\hat{A}_i$ the corresponding principal submatrix of $A$, i.e.,

$$\hat{A}_i = \hat{R}_i A \hat{R}_i^T = [I_i|O] \cdot \hat{\pi}_i \cdot A \cdot \hat{\pi}_i^T \cdot [I_i|O]^T,$$

and, as in (2.12) define

$$\hat{M}_i = \hat{\pi}_i^T \begin{bmatrix} \hat{A}_i & O \\ O & \hat{D}_{\neg i} \end{bmatrix} \hat{\pi}_i, \tag{7.3}$$

where $\hat{D}_{\neg i} = \operatorname{diag}(\hat{A}_{\neg i}) \succ O$, and $\hat{A}_{\neg i}$ is the $(n - \hat{n}_i) \times (n - \hat{n}_i)$ complementary principal submatrix of $A$ as in (2.9). As in (2.13), we have here also the fundamental identity

$$\hat{E}_i \hat{M}_i^{-1} = \hat{R}_i^T \hat{A}_i^{-1} \hat{R}_i, \quad i = 1, \ldots, n.$$

We want to compare $\hat{M}_i$ with $M_i$, although $\hat{A}_i$ and $A_i$ are of different size. Without loss of generality, we can assume that the permutations $\pi_i$ and $\hat{\pi}_i$ coincide on the set $S_i$, and that the indexes in $S_i$ are the first $n_i$ elements in $\hat{S}_i$. In fact, we can assume that $\hat{\pi}_i = \pi_i$. Thus, $A_i$ is a principal submatrix of $\hat{A}_i$, and $\hat{M}_i$ has the same diagonal as $M_i$.

We will apply to these the following result for symmetric positive definite matrices which can be found, e.g., in [21].

LEMMA 7.1. [illegible] $A$ [illegible] $\tilde{M}_i$ [illegible] (6.4) [illegible] $A$ [illegible] $A_i = R_i A R_i^T$ $R_i$ [illegible] $A_i$ [illegible] $A$ [illegible] $R_i^T A_i^{-1} R_i \preceq A^{-1}$

We consider the case of damped additive Schwarz with iteration matrix (2.4), and the iteration matrix corresponding to the larger overlap is

$$\hat{T}_{AS,\theta} = I - \theta \sum_{i=1}^{p} \hat{R}_i^T \hat{A}_i^{-1} \hat{R}_i A. \tag{7.4}$$

THEOREM 7.2. [illegible] $A$ [illegible] $b \in \mathcal{R}(A)$ [illegible] $x_0 \notin \mathcal{N}(A)$ [illegible] $A$ [illegible] (7.1) [illegible] (2.4) [illegible] (7.4) [illegible] $\theta \leq 1/p$ [illegible] $\gamma(\hat{T}_\theta) \leq \gamma(T_\theta)$

[illegible] As mentioned above assume that all the principal submatrices of $A$ of order less than $n$ are nonsingular. Let $Q_i = E_i M_i^{-1} = R_i^T A_i^{-1} R_i$ and $\hat{Q}_i = \hat{E}_i \hat{M}_i^{-1} = \hat{R}_i^T \hat{A}_i^{-1} \hat{R}_i$. Since $A_i$ is a principal submatrix of $\hat{A}_i$, by Lemma 7.1 we have that $\hat{Q}_i \succeq Q_i$. Therefore,

$$\hat{M}_\theta^{-1} = \theta \sum_{i=1}^{p} \hat{Q}_i \succeq \theta \sum_{i=1}^{p} Q_i = M_\theta^{-1} \succ O.$$

As shown in Remark 4.3, these splittings are strong $P$-regular, and the theorem follows from Theorem 3.6. □

We note that an alternative proof similar to that in Remark 6.2 can be applied here, using the relation $\hat{R}_i^T \hat{A}_i^{-1} \hat{R}_i = \hat{Q}_i \succeq Q_i = R_i^T A_i^{-1} R_i$ just proved.

Theorem 7.2 indicates that the more overlap there is, the faster the convergence of the algebraic additive Schwarz method. As a special case, we have that overlap is better than no overlap. This is consistent with the analysis for grid-based methods; see, e.g., [4], [41]. Of course, the faster convergence rate brings an associated increased cost of the local solvers, since now they have matrices of larger dimension and more nonzeros. In the cited references a small amount of overlap is recommended, and the increase in cost is usually offset by faster convergence.

We should mention that with an increase of overlap, the number of colors of the graph may decrease, so that the damping factor may need to be revised. In all cases, the maximum restriction is $\theta < 1/p$.

A comparison analogous to that of Theorem 7.2 is not valid for multiplicative Schwarz, not even in the definite case. A counterexample can be found in [40].

## 8. Varying the number of blocks.

We address here the following question: If we partition a block into smaller blocks, how is the convergence of the Schwarz method affected? We show that for the additive Schwarz method the more subblocks (subdomains), the slower the convergence. In a limiting case, if we have a single variable in each block and there is no overlap, this is the classic Jacobi method, and our results indicate that this has asymptotically slower convergence than any sets of blocks for additive Schwarz.

As in the situations described in sections 6 and 7, the slower convergence may be partially compensated by less expensive local solvers, since they are of smaller dimension.

Formally, consider each block of variables $S_i$ partitioned into $k_i$ subblocks; i.e., we have

$$S_{i_j} \subset S_i, \quad j = 1, \dots, k_i, \tag{8.1}$$

$\bigcup_{j=1}^{k_i} S_{i_j} = S_i$, and $S_{i_j} \cap S_{i_k} = \emptyset$ if $j \neq k$. Each set $S_{i_j}$ has associated matrices $R_{i_j}$ and $E_{i_j} = R_{i_j}^T R_{i_j}$. Since we have a partition,

$$E_{i_j} \preceq E_i, \quad j = 1, \dots, k_i, \quad \text{and} \quad \sum_{j=1}^{k_i} E_{i_j} = E_i, \ i = 1, \dots, p. \tag{8.2}$$

We define the matrices $A_{i_j} = R_{i_j} A R_{i_j}^T$, and $M_{i_j}$ corresponding to the set $S_{i_j}$ in the manner already familiar to the reader (see, e.g., (7.3)), so that

$$E_{i_j} M_{i_j}^{-1} = R_{i_j}^T A_{i_j}^{-1} R_{i_j}, \ j = 1, \dots, k_i, \ i = 1, \dots, p.$$

Given a fixed damping parameter $\theta$, the iteration matrix of the refined partition is then

$$\bar{T}_\theta = I - \theta \sum_{i=1}^{p} \sum_{j=1}^{k_i} E_{i_j} M_{i_j}^{-1} A \tag{8.3}$$

(cf. (2.4)), and an induced strong $P$-splitting (assuming the proper restriction on $\theta$) $A = \bar{M}_\theta - \bar{N}_\theta$ is given by

$$\bar{M}_\theta^{-1} = \theta \sum_{i=1}^{p} \sum_{j=1}^{k_i} E_{i_j} M_{i_j}^{-1}.$$

THEOREM 8.1. [illegible] $A$ [illegible] $b \in \mathcal{R}(A)$ [illegible] $x_0 \notin \mathcal{N}(A)$ [illegible] $A$ [illegible] (2.11) [illegible] (8.1) [illegible] (2.4) [illegible] (8.3) [illegible] $k = \max_i k_i$ [illegible] $\theta \leq 1/p$ [illegible] $\bar{\theta} = \theta/k \leq 1/(kp)$ [illegible] $\gamma(T_\theta) \leq \gamma(\bar{T}_{\bar{\theta}})$

[illegible]. As in the proof of Theorem 7.2 we have, using Lemma 7.1, that

$$Q_{i_j} = E_{i_j} M_{i_j}^{-1} \preceq Q_i = E_i M_i^{-1}.$$

Therefore, $\sum_{j=1}^{k_i} Q_{i_j} \preceq k_i Q_i$, and

$$\bar{M}_\theta^{-1} = \theta \sum_{i=1}^{p} \sum_{j=1}^{k_i} Q_{i_j} \preceq k\theta \sum_{i=1}^{p} Q_i = k M_\theta^{-1},$$

which is equivalent to $\bar{M}_{\bar{\theta}}^{-1} = (1/k)\bar{M}_\theta^{-1} \preceq M_\theta^{-1}$. The theorem now follows using Theorem 3.6 and the fact that these are strong $P$-regular splittings, as shown in Remark 4.3. ☐

As in the previous sections a comparison analogous to that of Theorem 8.1 is not valid for multiplicative Schwarz, not even in the definite case. Again, a counterexample can be found in [40].

**9. Two-level schemes.** We consider now two-level schemes, i.e., those in which an additional step is taken, corresponding to a coarse grid correction. In the nonsingular case, this additional step makes Schwarz methods optimal in the sense that the condition number of the preconditioned matrix $M^{-1}A$ is independent of the mesh size; see, e.g., [38], [41], [44]. In our setting, for the coarse grid correction consider an additional subspace $V_0$ of $V$, and the corresponding projection $P_0 = R_0^T A_0^{-1} R_0 A = R_0^T (R_0 A R_0^T)^{-1} R_0 A$. There are several cases we consider here: additive Schwarz with coarse grid correction, with iteration matrix given by

$$T_{ASc,\theta} = T_{AS,\theta} - \theta R_0^T A_0^{-1} R_0 A = I - \theta \sum_{i=0}^{p} R_i^T A_i^{-1} R_i A = I - \theta \sum_{i=0}^{p} P_i; \tag{9.1}$$

multiplicative Schwarz with coarse grid correction, with iteration matrix given by

$$T_{MSc} = T_{MS}(I - P_0) = \prod_{i=p}^{0} (I - P_i),$$

or in the symmetrized case by $T_{SMSc} = (I - P_0) T_{SMS} (I - P_0)$; multiplicative Schwarz additively corrected, known as the two-level hybrid I Schwarz method, with iteration matrix given by

$$H_{I,\theta} = I - \theta P_0 - \theta(I - T_{MS}) = I - \theta(G_0 + M_{MS}^{-1})A,$$

where $G_0 = R_0^T A_0^{-1} R_0$; and the two-level hybrid II Schwarz method, which is additive Schwarz multiplicatively corrected, with iteration matrix given by

$$H_{II,\theta} = T_{AS,\theta}(I - P_0).$$

We begin our analysis with the additive Schwarz iteration with coarse grid correction. By comparing the iteration matrices in (9.1) and (2.4), one can see that

Theorem 4.2 is valid in this case as well, with the exception that the damping factor $\theta$ needs to be less than $2/(p+1)$. Therefore we have that the matrix $T_{ASc,\theta}$ is a convergent matrix, and that the induced splitting defined by $M_{ASc,\theta}^{-1} = \theta \sum_{i=0}^{p} R_i^T A_i^{-1} R_i$ is $P$-regular. We can also show that coarse grid correction does not increase (and may decrease) the convergence factor of the iterations.

THEOREM 9.1. [illegible] $A$ [illegible] $\gamma(T_{ASc,\theta}) \leq \gamma(T_{AS,\theta})$

[illegible]. We use the fact that $G_0 = R_0^T A_0^{-1} R_0 \succeq 0$ to conclude that

$$M_{ASc,\theta}^{-1} = \theta(M_{AS}^{-1} + G_0) \succeq \theta M_{AS}^{-1} \; .$$

The theorem now follows by the application of Theorem 3.6. ☐

A characterization similar to (4.4) applies to this two-level method, with one more term in the sum. Thus, an alternative proof of this theorem using this characterization can be done in a manner similar to that in Remark 6.2.

Next, we consider the multiplicative Schwarz iterations with coarse grid correction. It is not hard to see that Theorem 5.2 applies to this case as well, so that $T_{MSc}$ and $T_{SMSc}$ are convergent.

We conclude by mentioning that the coarse grid corrections can be applied to the methods with inexact solvers described in section 6 as well, and since the analysis is very similar, we do not repeat it.

**Acknowledgments.** We thank Michele Benzi and the referees for their comments on an earlier version of this paper, which helped improve our presentation.

# MATRIX MEASURES AND RANDOM WALKS WITH A BLOCK TRIDIAGONAL TRANSITION MATRIX[*]

HOLGER DETTE[†], BETTINA REUTHER[†], W. J. STUDDEN[‡], AND M. ZYGMUNT[§]

**Abstract.** In this paper we study the connection between matrix measures and random walks with a block tridiagonal transition matrix. We derive sufficient conditions such that the blocks of the $n$-step block tridiagonal transition matrix of the Markov chain can be represented as integrals with respect to a matrix valued spectral measure. Several stochastic properties of the processes are characterized by means of this matrix measure. In many cases this measure is supported in the interval $[-1, 1]$. The results are illustrated by several examples including random walks on a grid and the embedded chain of a queuing system.

**Key words.** Markov chain, block tridiagonal transition matrix, spectral measure, matrix measure, quasi-birth-and-death process, canonical moments, Chebyshev matrix polynomials

**AMS subject classifications.** 60J10, 42C05

## 1. Introduction.

Consider a homogeneous Markov chain with state space

$$\mathcal{C}_d = \{(i, j) \in \mathbb{N}_0 \times \mathbb{N} \mid 1 \leq j \leq d\} \tag{1.1}$$

and block tridiagonal transition matrix

$$P = \begin{pmatrix} B_0 & A_0 & & & 0 \\ C_1^T & B_1 & A_1 & & \\ & C_2^T & B_2 & A_2 & \\ 0 & & \ddots & \ddots & \ddots \end{pmatrix}, \tag{1.2}$$

where $d \in \mathbb{N}$ is finite, and $A_0, A_1, \ldots, B_0, B_1, \ldots, C_1, C_2, \ldots$ are $d \times d$ matrices containing the probabilities of one-step transitions (here and throughout this paper $C^T$ denotes the transpose of the matrix $C$). If the one-step block tridiagonal transition matrix is represented by

$$P = (P_{ii'})_{i,i'=0,1,\ldots} \tag{1.3}$$

with $d \times d$ block matrices $P_{ii'}$, the probability of going in one step from state $(i, j)$ to $(i', j')$ is given by the element in the position $(j, j')$ of the matrix $P_{ii'}$. In the state $(i, j)$, $i$ is usually referred to as the level of the state and $j$ is referred to as the phase

of the state. Some illustrative examples will be given below. Block tridiagonal transition matrices of the form (1.2) naturally appear in the analysis of the embedded Markov chains of continuous-time Markov processes with state space (1.1) and block tridiagonal infinitesimal generator (see, e.g., the monographs of Neuts (1981) and Neuts (1989) or the recent work of Marek (2003) and Dayar and Quessette (2002) among many others) and these models have significant applications in the performance evalutation of communication systems (see, e.g., Ost (2001)). Markov chains with transition matrix (1.2) are known in the literature as level dependent quasi-birth-and-death processes and several authors have contributed to the analysis of such processes (see Hajek (1982), Gaver, Jacobs, and Latouche (1984), Ramaswami and Taylor (1996), Bright and Taylor (1995), Latouche, Pearce, and Taylor (1998), Bean, Pollett, and Taylor (2000), and Li and Cao (2004) among many others). Bright and Taylor (1995) considered the problem of calculating the equilibrium distribution of a quasi-birth-and-death process for finite dimensional block matrices, while Ramaswami and Taylor (1996) investigated level dependent processes with infinite dimensional blocks. Quasistationary distributions of these processes were considered by Bean, Pollett, and Taylor (2000). Latouche, Pearce, and Taylor (1998) discussed the existence and the form of invariant measures for quasi-birth-and-death processes. In the present paper we propose an alternative methodology for analyzing some level dependent quasi-birth-and-death processes which is based on some spectral analysis of the transition matrix.

For this we note that matrices of the form (1.2) are also closely related to a sequence of matrix polynomials recursively defined by

$$xQ_n(x) = A_nQ_{n+1}(x) + B_nQ_n(x) + C_n^TQ_{n-1}(x),\ n \in \mathbb{N}_0, \tag{1.4}$$

where $Q_{-1}(x) = 0$ and $Q_0(x) = I_d$ denotes the $d \times d$ identity matrix. If $A_n = C_{n+1}$ and $B_n$ is symmetric it follows that there exists a matrix measure $\Sigma = \{\sigma_{ij}\}_{i,j=1,\dots,d}$ on the real line (here $\sigma_{ij}$ are signed measures such that for any Borel set $A \subset \mathbb{R}$ the matrix $\Sigma(A)$ is nonnegative definite) such that the polynomials $Q_j(x)$ are orthonormal with respect to a left inner product, i.e.,

$$\langle Q_i, Q_j\rangle = \int_{\mathbb{R}} Q_i(x)d\Sigma(x)Q_j^T(x) = \delta_{ij}I_d \tag{1.5}$$

(see, e.g., Sinap and Van Assche (1996), or Duran (1995)). In recent years several authors have studied properties of matrix orthonormal polynomials (see, e.g., Rodman (1990), Duran and Van Assche (1995), Duran (1996, 1999), and Dette and Studden (2001) among many others).

In the present paper we are interested in the relation between Markov chains with state space $\mathcal{C}_d$ defined in (1.1) and block tridiagonal transition matrix (1.2) and the polynomials $Q_j(x)$ defined by the recursive relation (1.4). In the case $d = 1$ this problem has been studied extensively in the literature (see Karlin and McGregor (1959), Whitehurst (1982), Woess (1985), Van Doorn and Schrijner (1993, 1995), and Dette (1996) among many others), but the case $d > 1$ is more difficult, because in this case a system of matrix polynomials $\{Q_j(x)\}_{j\geq 0}$ satisfying a recurrence relation of the form (1.4) is not necessarily orthogonal with respect to an inner product induced by a matrix measure. In section 2 we characterize the transition matrices of the form (1.2) such that there exists an integral representation for the corresponding $n$-step transition probabilities in terms of the matrix measure and corresponding orthogonal matrix polynomials, i.e.,

$$P_{ij}^n\left(\int Q_j(x)d\Sigma(x)Q_j^T(x)\right)=\left(\int x^nQ_i(x)d\Sigma(x)Q_j^T(x)\right),$$

where $P_{ij}^n$ denotes the $d\times d$ block of the $n$-step block tridiagonal transition matrix $P^n$ in the position $(i,j)$. In other words, the element in the position $(k,l)$ of $P_{ij}^n$ is the probability of going in $n$ steps from state $(i,k)$ to $(j,l)$ and admitting an integral representation. We also derive a sufficient condition such that the spectral (matrix) measure $\Sigma$ (if it exists) is supported on the interval $[-1,1]$. In section 3 we discuss several illustrative examples where this condition is satisfied including some examples from queuing theory. Section 4 continues our more theoretical discussion and some consequences of the integral representation are derived. We present a characterization of recurrence by properties of the blocks of the transition matrix, which generalizes the classical characterization of recurrence of a birth-and-death chain (see Karlin and Taylor (1975)). Finally, in section 5 we present some applications of our results, which demonstrate the potential of our approach. In particular we derive a very simple necessary condition for positive recurrence of a quasi-birth-and-death process and a new representation of the equilibrium distribution in terms of the random walk measure $\Sigma$ and the orthogonal polynomials $Q_j(x)$.

## 2. Random walk matrix polynomials.

A matrix measure $\Sigma$ is a $d\times d$ matrix $\Sigma=\{\sigma_{ij}\}_{i,j=1,\dots,d}$ of finite signed measures $\sigma_{ij}$ on the Borel field of the real line $\mathbb{R}$ or of an appropriate subset. It will be assumed here that for each Borel set $A\subset\mathbb{R}$ the matrix $\Sigma(A)=\{\sigma_{ij}(A)\}_{i,j=1,\dots,d}$ is symmetric and nonnegative definite, i.e., $\Sigma(A)\geq 0$. The moments of the matrix measure $\Sigma$ are given by the $d\times d$ matrices

$$S_k=\int t^k d\Sigma(t),\quad k=0,1,\dots, \tag{2.1}$$

and only measures for which all relevant moments exist will be considered throughout this paper. Let $G_i$ $(i=0,\dots,n)$ denote $d\times d$ matrices; then a matrix polynomial is defined by $P(t)=\sum_{i=0}^n G_it^i$. The inner product of two matrix polynomials, say, $P$ and $Q$, is defined by

$$\langle P,Q\rangle \;=\; \int P(t)\Sigma(dt)Q^T(t), \tag{2.2}$$

where $Q^T(t)$ denotes the transpose of the matrix $Q(t)$. Sinap and Van Assche (1996) call this the "left" inner product. Orthogonal polynomials are defined by orthogonalizing the sequence $I_p, tI_p, t^2I_p,\dots$ with respect to the above inner product. If $S_0,S_1,\dots$ is a given sequence of matrices such that the block Hankel matrices

$$\underline{H}_{2m}=\begin{pmatrix} S_0 & \cdots & S_m\\ \vdots & & \vdots\\ S_m & \dots & S_{2m}\end{pmatrix} \tag{2.3}$$

are positive definite, it is well known (see, e.g., Marcellán and Sansigre (1993)) that a matrix measure $\Sigma$ with moments $S_j$ $(j\in\mathbb{N}_0)$ and a corresponding infinite sequence of orthogonal matrix polynomials with respect to $d\Sigma(x)$ exist. Moreover, these matrix polynomials satisfy a three term recurrence relation.

Let $\{Q_j(x)\}_{j\geq 0}$ denote a sequence of matrix polynomials defined by the recurrence relationship (1.4), where the matrices $C_j$ $(j \in \mathbb{N})$ and $A_j$ $(j \in \mathbb{N}_0)$ in (1.2) are assumed to be nonsingular. The following results characterize the existence of a matrix measure $\Sigma$ such that the polynomials $Q_j(x)$ are orthogonal with respect to $d\Sigma(x)$ in the sense of (2.2).

THEOREM 2.1. [illegible] $A_n$ $(n \in \mathbb{N}_0)$[illegible] $C_n$ $(n \in \mathbb{N})$[illegible] (1.2)[illegible] $\Sigma$ [illegible] $\underline{H}_{2m}$ $(m \in \mathbb{N}_0)$ [illegible] $\{Q_n(x)\}_{n\in\mathbb{N}_0}$ [illegible] (1.4)[illegible] $d\Sigma(x)$[illegible] $\{R_n\}_{n\in\mathbb{N}_0}$ [illegible]

$$
\begin{aligned}
&R_nB_nR_n^{-1} \text{ [illegible] } \quad \forall\ n \in \mathbb{N}_0, \\
(2.4) \qquad & \\
&R_n^TR_n = C_n^{-1}\cdots C_1^{-1}(R_0^TR_0)A_0\cdots A_{n-1} \quad \forall\ n \in \mathbb{N}.
\end{aligned}
$$

[illegible] Assume that the polynomials $\{Q_n(x)\}_{n\in\mathbb{N}_0}$ are orthogonal with respect to the measure $d\Sigma(x)$, that is,

$$
\int_{\mathbb{R}} Q_i(x)d\Sigma(x)Q_j^T(x) = 0, \tag{2.5}
$$

whenever $i \neq j$ and

$$
\int_{\mathbb{R}} Q_i(x)d\Sigma(x)Q_i^T(x) = F_i > 0 \quad (i \in \mathbb{N}_0), \tag{2.6}
$$

where we use the notation $F_i > 0$ for a positive definite matrix $F_i \in \mathbb{R}^{d\times d}$ (the fact that the matrix $F_i$ is positive definite follows from a straightforward calculation using the assumption that $\underline{H}_{2m}$ is positive definite for all $m \in \mathbb{N}_0$). Define $R_n = F_n^{-1/2}$ and $\tilde{Q}_n(x) = R_nQ_n(x)$; then it is easy to see that the polynomials $\{\tilde{Q}_n(x)\}_{n\in\mathbb{N}_0}$ are orthonormal with respect to the measure $d\Sigma(x)$. Therefore it follows from Sinap and Van Assche (1996) that there exist $d\times d$ nonsingular matrices $\{D_n\}_{n\in\mathbb{N}}$ and symmetric matrices $\{E_n\}_{n\in\mathbb{N}_0}$ such that the recurrence relation

$$
x\tilde{Q}_n(x) = D_{n+1}\tilde{Q}_{n+1}(x) + E_n\tilde{Q}_n(x) + D_n^T\tilde{Q}_{n-1}(x) \tag{2.7}
$$

is satisfied for all $n \in \mathbb{N}_0$, $(\tilde{Q}_{-1}(x) = 0,\ \tilde{Q}_0(x) = R_0)$. On the other hand, we obtain from (1.4) and the representation $\tilde{Q}_n(x) = R_nQ_n(x)$ the recurrence relation

(2.8)
$$
x\tilde{Q}_n(x) = R_nA_nR_{n+1}^{-1}\tilde{Q}_{n+1}(x) + R_nB_nR_n^{-1}\tilde{Q}_n(x) + R_nC_n^TR_{n-1}^{-1}\tilde{Q}_{n-1}(x),
$$

and a comparison of (2.7) and (2.8) yields

$$
D_{n+1} = R_nA_nR_{n+1}^{-1}, \quad E_n = R_nB_nR_n^{-1}\ , \quad D_n^T = R_nC_n^TR_{n-1}^{-1}, \tag{2.9}
$$

where the matrix $E_n$ is symmetric. Now a straightforward calculation gives

$$R_n A_n R_{n+1}^{-1} = (R_{n+1} C_{n+1}^T R_n^{-1})^T = (R_n^T)^{-1} C_{n+1} R_{n+1}^T,$$

or equivalently

$$R_{n+1}^T R_{n+1} = C_{n+1}^{-1} (R_n^T R_n) A_n.$$

This yields by an induction argument

$$R_n^T R_n = C_n^{-1} \cdots C_1^{-1} R_0^T R_0 A_0 \cdots A_{n-1}, \;\; n \in \mathbb{N},$$

and proves the first part of Theorem 2.1.

For the converse assume that the relations in (2.4) are satisfied and consider the polynomials $\tilde{Q}_n(x) = R_n Q_n(x)$. These polynomials satisfy the recurrence relation (2.8) and from (2.4) it follows that the matrices

$$E_n = R_n B_n R_n^{-1}$$

are symmetric ($n \in \mathbb{N}_0$), while

$$D_{n+1} = R_n A_n R_{n+1}^{-1} = (R_{n+1} C_{n+1}^T R_n^{-1})^T$$

by the second assumption in (2.4). Therefore the recurrence relation for the polynomials $\tilde{Q}_n(x)$ is of the form (2.7) and by the discussion following Theorem 3.1 in Sinap and van Assche (1996) these polynomials are orthonormal with respect to a matrix measure $d\Sigma(x)$. This also implies the orthogonality of the polynomials $Q_n(x) = R_n^{-1}\tilde{Q}_n(x)$ with respect to the measure $d\Sigma(x)$.

Because the polynomials $\underline{Q}_n(t) = R_0^{-1} D_1 \cdots D_n \tilde{Q}_n(t)$ have leading coefficient $I_d$ we obtain that the matrix

$$\langle \underline{Q}_n, \underline{Q}_n \rangle = \int \underline{Q}_n(t) d\Sigma(t) \underline{Q}_n^T(t) = R_0^{-1} D_1 \cdots D_n D_n^T \cdots D_1^T (R_0^T)^{-1} \tag{2.10}$$

is nonsingular. On the other hand it follows from Dette and Studden (2001) that the left-hand side of (2.10) is equal to the Schur complement, say, $S_{2n} - S_{2n}^-$, of $S_{2n}$ in $\underline{H}_{2n}$. Because the matrix $\underline{H}_{2n}$ is positive definite if and only if $\underline{H}_{2n-2}$ and the Schur complement of $S_{2n}$ in $\underline{H}_{2n}$ are positive definite it follows by an induction argument that all Hankel matrices obtained from the moments of the matrix measure $\Sigma$ are positive definite. $\square$

2.2. Throughout this paper a matrix measure $\Sigma$ with corresponding orthogonal matrix polynomials $Q_i(x)$ is called a random walk matrix measure or spectral measure and the polynomials $Q_i(x)$ will be called random walk matrix polynomials if the assumptions of Theorem 2.1 are satisfied. Because the polynomials $\tilde{Q}_i(x) = R_i Q_i(x)$ defined in the proof of Theorem 2.1 are orthonormal with respect to the measure $d\Sigma(x)$ it follows that

$$I_d = \langle \tilde{Q}_0, \tilde{Q}_0 \rangle = \int \tilde{Q}_0(x) d\Sigma(x) \tilde{Q}_0^T = R_0 S_0 R_0^T, \tag{2.11}$$

or equivalently

$$R_0^{-1}((R_0^T)^{-1}) = (R_0^T R_0)^{-1} = S_0, \tag{2.12}$$

where $S_0$ is the 0th moment of the matrix measure $\Sigma$ (see (2.1)). We finally note that the matrices $R_n$ in Theorem 2.1 are not unique. If $\{R_n\}_{n\in\mathbb{N}_0}$ is a sequence of matrices satisfying (2.4), these relations are also fulfilled for the sequence $\{\tilde{R}_n\}_{n\in\mathbb{N}_0} = \{U_nR_n\}_{n\in\mathbb{N}_0}$, where $U_n$ $(n \in \mathbb{N}_0)$ are arbitrary orthogonal matrices.

Before we present some examples, where the conditions of Theorem 2.1 are satisfied we derive some consequences of the existence of a random walk measure. For this let $Q(x) = (Q_0^T(x), Q_1^T(x), \dots)^T$ denote the vector of matrix polynomials defined by the recursive relation (1.4); then it is easy to see that the recurrence relation (1.4) is equivalent to

$$xQ(x) = PQ(x), \tag{2.13}$$

which gives (by iteration)

$$x^nQ(x) = P^nQ(x). \tag{2.14}$$

Therefore

$$\int x^nQ(x)d\Sigma(x)Q_j^T(x) = P^n\int Q(x)d\Sigma(x)Q_j^T(x), \tag{2.15}$$

and from the orthogonality of the random walk polynomials we obtain the representation

$$P_{ij}^n = \left(\int x^nQ_i(x)d\Sigma(x)Q_j^T(x)\right)\left(\int Q_j(x)d\Sigma(x)Q_j^T(x)\right)^{-1} \tag{2.16}$$

for the block in the position $(i,j)$ of the $n$-step block tridiagonal transition matrix $P^n$.

THEOREM 2.3. [illegible] 2.1 [illegible] $P_{ij}^n$ [illegible] $(i,j)$ [illegible] $n$ [illegible] $P^n$ [illegible] (2.16) [illegible] $\Sigma$ [illegible] $P$ [illegible]

[illegible] 2.4. Note that the random walk measure is not necessarily uniquely determined by the random walk on the grid $\mathcal{C}_d$. However, using the case $i = j = 0$ in (2.16) it follows for the moments of the random walk measure

$$P_{00}^n = S_nS_0^{-1} \quad (n \in \mathbb{N}_0), \tag{2.17}$$

where $P_{00}^n$ is the first block in the $n$-step transition matrix of the random walk. Therefore the moments of a random walk measure are essentially uniquely determined. In the following we will derive a sufficient condition such that the random walk measure (if it exists) is supported on the interval $[-1, 1]$. In this case the measure is determined by its moments.

THEOREM 2.5. [illegible] 2.1 [illegible] $R = \operatorname{diag}(R_0, R_1, R_2, \dots)$. [illegible] $R$ [illegible]

$$\tilde{P} = R^TPR^{-1} \tag{2.18}$$

[illegible] $\Sigma = \{\sigma_{ij}\}_{i,j=1,\dots,d}$ [illegible] (1.4) [illegible] $[-1,1]$, [illegible]

$$\operatorname{supp}(\sigma_{ij}) \subset [-1,1] \quad \forall\, i,j = 1,\dots,d.$$

[illegible] Note that the matrix in (2.18) is symmetric (because the assumptions of Theorem 2.1 are satisfied) and that the entries of $\tilde{P}$ are nonnegative, by the assumptions of the theorem. According to Schur's test (see Halmos and Sunder (1978), Theorem 5.2) it follows that

$$\|\tilde{P}\|_2 \le 1 \tag{2.19}$$

if we can find two vectors, say, $v, w$, with positive components such that

$$\tilde{P}v \le w \quad \text{and} \quad \tilde{P}w \le v$$

(where the symbol $\le$ means here inequality in each component). If $v = w = R1$ (here 1 denotes the infinite dimensional vector with all elements equal to one), then the representation (2.18) implies that

$$\tilde{P}v = \tilde{P}R1 = R^T P1 \le R^T 1,$$

which shows that (2.19) is indeed satisfied. Now let

$$\Pi_j = C_j^{-1} \dots C_1^{-1} R_0^T R_0 A_0 \dots A_{j-1} = R_j^T R_j, \tag{2.20}$$

and consider the inner product

$$\langle x, y\rangle_\Pi = \sum_{j=0}^{\infty} x_j^T \Pi_j y_j \tag{2.21}$$

(with $x = (x_0^T, x_1^T, \dots); y = (y_0^T, y_1^T, \dots); x_j \in \mathbb{R}^d, y_j \in \mathbb{R}^d$) and its corresponding norm, say, $\|\cdot\|_\Pi$. Define

$$\ell^2(\mathbb{R}^d) = \{x = (x_0^T, x_1^T, \dots) \mid x_j \in \mathbb{R}^d\ (j \in \mathbb{N}_0); \|x\|_\Pi^2 < \infty\}. \tag{2.22}$$

From the definition of $P$ and $\Pi_j$ it is easy to see that $\Pi_i P_{ij} = P_{ji}^T \Pi_j$ (for all $i, j \in \mathbb{N}_0$), which implies that $P$ is a selfadjoint operator with respect to the inner product $\langle\cdot,\cdot\rangle_\Pi$. Moreover, we have for any $x$

$$\begin{aligned} \|Px\|_\Pi &= x^T P^T \Pi P x = x^T R^T \tilde{P}^T \tilde{P} R x = \|\tilde{P} R x\|_2 \\ &\le \|\tilde{P}\|_2 \|Rx\|_2 \le x^T R^T R x = x^T \Pi x = \|x\|_\Pi, \end{aligned}$$

where we used the representation $\Pi = R^T R$ and (2.19). Consequently, $\|P\|_\Pi \le 1$, which proves the theorem. □

We note that there are many examples where the assumptions of Theorem 2.5 are satisfied and we conjecture, in fact, that a random walk measure is always supported in the interval $[-1,1]$. In the case $d = 1$ this property holds because in this case the assumptions of Theorems 2.1 and 2.5 are obviously satisfied. This was shown before by Karlin and McGregor (1959), and an alternative proof can be found in Dette and Studden (1997), Chapter 8.

Our next result gives a relation between the Stieltjes transforms of two random walk measures, say, $\Sigma$ and $\tilde{\Sigma}$, where only the matrices $B_0$ and $\tilde{B}_0$ differ in the corresponding one-step block tridiagonal transition matrices $P$ and $\tilde{P}$.

THEOREM 2.6. [illegible] $P$ [illegible] (1.2) [illegible]

$$\tilde{P} = \begin{pmatrix} \tilde{B}_0 & A_0 & & & 0 \\ C_1^T & B_1 & A_1 & & \\ & C_2^T & B_2 & A_2 & \\ & & & & \\ 0 & & & & \end{pmatrix}, \tag{2.23}$$

[illegible] $\Sigma$ [illegible] $P$ [illegible] $R_0\tilde{B}_0R_0^{-1}$ [illegible] $R_0$ [illegible] (2.4) [illegible] $\tilde{\Sigma}$ [illegible] $\tilde{P}$. [illegible] $\Sigma$ [illegible] $\tilde{\Sigma}$ [illegible]

$$\int \frac{d\Sigma(t)}{z-t} = \left\{ \left( \int \frac{d\tilde{\Sigma}(t)}{z-t} \right)^{-1} - S_0^{-1}(B_0 - \tilde{B}_0) \right\}^{-1}. \tag{2.24}$$

[illegible]. Because the matrix $R_0\tilde{B}_0R_0^{-1}$ is symmetric and the matrices $P$ and $\tilde{P}$ differ only by the element in the first block, the sequence of matrices $R_0, R_1, \dots$ can be used to symmetrize the matrices $P$ and $\tilde{P}$ simultaneously (see the proof of Theorem 2.1). Consequently, there exists a random walk measure corresponding to the random walk with one-step block tridiagonal transition matrix $\tilde{P}$. Let $\{Q_n(x)\}_{n\in\mathbb{N}_0}$ denote the system of matrix orthogonal polynomials defined by the recursive relation (1.4) and define $\{\tilde{Q}_n(x)\}_{n\in\mathbb{N}_0}$ by the same recursion, where the matrix $B_0$ has been replaced by $\tilde{B}_0$. A straightforward calculation shows that the difference polynomials

$$R_j(x) = \tilde{Q}_j(x) - Q_j(x)$$

also satisfy the recursion (1.4) with initial conditions $R_0(x) = 0$, $R_1(x) = A_0^{-1}(B_0 - \tilde{B}_0)$. In particular, these polynomials are "proportional" to the first associated orthogonal matrix polynomials

$$Q_n^{(1)}(x) = \int \frac{Q_n(x) - Q_n(t)}{x-t} d\Sigma(t) \quad (n \in \mathbb{N}_0), \tag{2.25}$$

that is,

$$R_n(x) = Q_n^{(1)}(x) R_0^T R_0 (B_0 - \tilde{B}_0). \tag{2.26}$$

Recall from the proof of Theorem 2.1 that the systems $\{R_nQ_n(x)R_0^{-1}\}_{n\in\mathbb{N}_0}$ and $\{R_n\tilde{Q}_n(x)R_0^{-1}\}_{n\in\mathbb{N}_0}$ are orthonormal with respect to the random walk measures $d\mu(x) = R_0 d\Sigma(x) R_0^T$ and $d\tilde{\mu} = R_0 d\tilde{\Sigma}(x) R_0^T$, respectively, and that $\mu$ and $\tilde{\mu}$ are determinate. Therefore we obtain from Markov's theorem for matrix orthogonal polynomials (see Duran (1996)) that

$$
\begin{aligned}
(2.27) \qquad \int \frac{d\tilde{\Sigma}(t)}{z-t} &= R_0^{-1} \int \frac{d\tilde{\mu}(t)}{z-t} (R_0^T)^{-1} \\
&= \lim_{n\to\infty} R_0^{-1} (R_n \tilde{Q}_n(z) R_0^{-1})^{-1} (R_n \tilde{Q}_n^{(1)}(z) R_0^T)(R_0^T)^{-1} \\
&= \lim_{n\to\infty} (\tilde{Q}_n(z))^{-1} \tilde{Q}_n^{(1)}(z) \\
&= \lim_{n\to\infty} \{Q_n(z) + Q_n^{(1)}(z) R_0^T R_0 (B_0 - \tilde{B}_0)\}^{-1} Q_n^{(1)}(z) \\
&= \lim_{n\to\infty} \{\{(Q_n(z))^{-1} Q_n^{(1)}(z)\}^{-1} + R_0^T R_0 (B_0 - \tilde{B}_0)\}^{-1} \\
&= \lim_{n\to\infty} \{R_0^T \{(R_n Q_n(z) R_0^{-1})^{-1} R_n Q_n^{(1)}(z) R_0^T\}^{-1} R_0 \\
&\qquad\qquad + R_0^T R_0 (B - \tilde{B}_0)\}^{-1} \\
&= \left\{ R_0^T \left( \int \frac{d\mu(t)}{z-t} \right)^{-1} R_0 + R_0^T R_0 (B_0 - \tilde{B}_0) \right\}^{-1} \\
&= \left\{ \left( \int \frac{d\Sigma(t)}{z-t} \right)^{-1} + R_0^T R_0 (B_0 - \tilde{B}_0) \right\}^{-1} \\
&= \left\{ \left( \int \frac{d\Sigma(t)}{z-t} \right)^{-1} + S_0^{-1} (B_0 - \tilde{B}_0) \right\}^{-1},
\end{aligned}
$$

where $\tilde{Q}_n^{(1)}(x)$ denotes the first associated orthogonal matrix polynomial obtained by the analogue of (2.25) from $\tilde{Q}_n(x)$ and we have used the fact that $\tilde{Q}_n^{(1)}(x) = Q_n^{(1)}(x)$ for the third equality (note that this identity is obvious from the definition of $P$ and $\tilde{P}$ in (1.2) and (2.23), respectively). ☐

[illegible] 2.7. Note that Theorem 2.1 and some of its consequences are derived under the assumption of nonsingular matrices $A_n$ and $C_n$. As pointed out by a referee there are several applications in queuing theory where these matrices do not have full rank (see Latouche and Ramaswami (1999)). In this remark we indicate how the nonsingularity assumptions regarding the matrices $C_n$ can be relaxed (note that this covers most of the commonly used queuing models). For this purpose we rewrite the conditions in Theorem 2.1 as

$$
(2.28) \qquad C_{n+1} R_{n+1}^T R_{n+1} = R_n^T R_n A_n \quad \forall\, n \in \mathbb{N}_0
$$

and

$$
(2.29) \qquad R_n B_n = E_n R_n \quad \forall\, n \in \mathbb{N}_0,
$$

for some sequence of symmetric matrices $(E_n)_{n\in\mathbb{N}_0}$. Note that the conditions (2.28) and (2.29) were derived in the proof of Theorem 2.1 (under the assumptions of Theorem 2.1 they are in fact equivalent to (2.4)). We will now demonstrate that these conditions are in fact sufficient for the proof of the existence of a random walk measure using some spectral theory of selfadjoint operators (see, e.g., Berezanskii (1968)). In the following we indicate how such a measure can be derived; further details can be found in Berezanskii (1968), pages 501–607.

For this purpose define

$$\Pi_j = R_j^T R_j \quad (j \in \mathbb{N}_0)$$

and consider the space $L(\mathbb{R}^d, L(\mathbb{R}^d, \mathbb{R}^d))$ which can be identified with

$$\ell^2(\mathbb{R}^{d\times d}) := \left\{ X = \left(X_0^T, X_1^T, \dots\right)^T \mid X_j \in \mathbb{R}^{d\times d}, \langle\langle X, X\rangle\rangle < \infty \right\},$$

where the matrix valued pseudo inner product is defined by ($Y = \left(Y_0^T, Y_1^T, \dots\right)^T$)

$$\langle\langle X, Y\rangle\rangle := \sum_{j=1}^{\infty} X_j^T \Pi_j Y_j.$$

Note that the space $\ell^2(\mathbb{R}^{d\times d})$ equipped with the inner product

$$\langle X, Y\rangle = \frac{1}{d}\,\mathrm{trace}\langle\langle X, Y\rangle\rangle$$

is a Hilbert space and isometric isomorph to the space $\ell^2(\mathbb{R}^d)$ defined in (2.22). Moreover, the matrix $P$ in (1.2) defines an operator acting on $\ell^2(\mathbb{R}^{d\times d})$ and $\ell^2(\mathbb{R}^d)$, denoted by $P$ and $J$, respectively; that is,

$$\begin{aligned} (PX)_n &= A_n X_{n+1} + B_n X_n + C_n^T X_{n-1} \quad (n \in \mathbb{N}_0, X_{-1} = 0), \\ (Jx)_n &= A_n x_{n+1} + B_n x_n + C_n^T x_{n-1} \quad (n \in \mathbb{N}_0, x_{-1} = 0). \end{aligned}$$

Note that (2.28) and (2.29) imply the symmetry conditions

$$P_{ij}^T \Pi_i = \Pi_j P_{ji} \tag{2.30}$$

(this follows by an elementary calculation), and recalling the definition of the inner product $\langle\cdot,\cdot\rangle_\Pi$ in (2.21) we obtain

$$\langle Jx, y\rangle_\Pi = \sum_{i=0}^{\infty}\sum_{j=0}^{\infty} (P_{ij} x_j)^T \Pi_i y_i = \sum_{i=0}^{\infty}\sum_{j=0}^{\infty} x_j^T \Pi_j P_{ji} y_i = \langle x, Jy\rangle_\Pi.$$

In other words, $J$ is a selfadjoint operator acting on $\ell^2(\mathbb{R}^d)$. Let $(E_\lambda)_\lambda$ denote the corresponding resolution of the identity (i.e., $J = \int \lambda E_\lambda$); then $(E_\lambda)_\lambda$ induces a resolution of the identity, say, $(\mathcal{E}_\lambda)_\lambda$, corresponding to the operator $P$ on $\ell^2(\mathbb{R}^{d\times d})$ in the following way:

$$(\mathcal{E}_\lambda U)x := E_\lambda(Ux), \ U \in \ell^2(\mathbb{R}^{d\times d}), \ x \in \mathbb{R}^d.$$

Now define $E^{(j)} = (0_d, \dots, 0_d, I_d, 0_d, \dots)^T \in \ell^2(\mathbb{R}^{d\times d})$ as the $j$th "unit" vector (here $0_d$ is the $d \times d$ matrix with all entries equal to 0) and the spectral measure by

$$\Sigma(\lambda) = \langle\langle E^{(0)}, \mathcal{E}_\lambda E^{(0)}\rangle\rangle \ \in \mathbb{R}^{d\times d};$$

then it follows by similiar arguments as in Berezanskii (1968), pages 562–565, that

$$\int Q_i(x)d\Sigma(x)Q_j^T(x) = \langle\langle E^{(i)}, E^{(j)}\rangle\rangle = \delta_{ij}\Pi_j,$$

where $\delta_{ij}$ denotes Kronecker's symbol. The same arguments as used in the derivation of Theorem 2.3 now imply

$$P_{ij}^n\Pi_j = \int x^n Q_i(x)d\Sigma(x)Q_j^T(x),$$

which is the statement of Theorem 2.3. Other results of this paper can be generalized in a similiar way. For example, Theorem 2.5 remains valid if there exists a matrix $\tilde{P}$ with nonnegative entries such that $\tilde{P}R = R^TP$. The details are omitted for the sake of brevity.

**3. Examples.** In this section we present several examples where the conditions of Theorem 2.1 are satisfied.

**3.1. Random walks on the integers.** Consider the classical random walk on $\mathbb{Z}$ (see, e.g., Feller (1950)) with one-step up, down, and holding transition probabilities $p_i$, $q_i$, and $r_i$ (respectively), where $p_i + q_i + r_i \le 1$, $i \in \mathbb{Z}$, where the strict inequality $p_i + q_i + r_i < 1$ is interpreted as a permanent absorbing state $i^*$, which can be reached from the state $i$ with probability $1 - p_i - q_i - r_i$. By the one-to-one mapping

$$\psi : \begin{cases} \mathbb{Z} \to \mathcal{C}_2, \\ i \to \begin{cases} (i,1) & \text{if } i \in \mathbb{N}_0, \\ (-i-1,2) & \text{else}, \end{cases} \end{cases}$$

this process can be interpreted as a process on the grid $\mathcal{C}_2$, where transitions from the first to the second row are only possible if the process is in state $(0,1)$. The transition matrix of this process is given by (1.2) with $2 \times 2$ blocks

$$B_0 = \begin{pmatrix} r_0 & q_0 \\ p_{-1} & r_{-1} \end{pmatrix}; \quad B_n = \begin{pmatrix} r_n & 0 \\ 0 & r_{-n-1} \end{pmatrix}; \tag{3.1}$$

$$A_n = \begin{pmatrix} p_n & 0 \\ 0 & q_{-n-1} \end{pmatrix}; \quad C_n^T = \begin{pmatrix} q_n & 0 \\ 0 & p_{-n-1} \end{pmatrix}. \tag{3.2}$$

It is easy to see that the conditions of Theorem 2.1 are satisfied with the matrices

$$R_0 = \begin{pmatrix} 1 & 0 \\ 0 & \sqrt{\frac{q_0}{p_{-1}}} \end{pmatrix}, \quad R_n = \begin{pmatrix} \sqrt{\frac{p_0 \cdots p_{n-1}}{q_1 \cdots q_n}} & 0 \\ 0 & \sqrt{\frac{q_0 q_{-1} \cdots q_{-n}}{p_{-1} p_{-2} \cdots p_{-n-1}}} \end{pmatrix}, \tag{3.3}$$

and consequently, there exists a random walk matrix measure corresponding to this process, say, $\Sigma$, which is supported in the interval $[-1,1]$ (see Theorem 2.5). For the calculation of the Stieltjes transform of this measure we use Theorem 2.6 and obtain

$$\Phi(z) = \int \frac{d\Sigma(t)}{z-t} = \left\{\tilde{\Phi}^{-1}(z) - R_0^T R_0(B_0 - \tilde{B}_0)\right\}^{-1}. \tag{3.4}$$

Here $\tilde{\Phi}$ is the Stieltjes transform of a random walk measure $\tilde{\Sigma}$ with transition matrix (1.2), where the matrix $B_0$ in (3.1) has been replaced by

$$\tilde{B}_0 = \begin{pmatrix} r_0 & 0 \\ 0 & r_{-1} \end{pmatrix},$$

and the matrix $B_0 - \tilde{B}_0$ is given by

$$B_0 - \tilde{B}_0 = \begin{pmatrix} 0 & q_0 \\ p_{-1} & 0 \end{pmatrix}.$$

Note that the matrix $\tilde{\Phi}$ is diagonal and if $\tilde{\Phi}^+$ and $\tilde{\Phi}^-$ denote the corresponding diagonal elements, we obtain from (3.4) the representation

$$\begin{aligned} \Phi(z) = \int \frac{d\Sigma(t)}{z-t} &= \begin{pmatrix} 1/\tilde{\Phi}^+(z) & -q_0 \\ -q_0 & 1/\tilde{\Phi}^-(z) \end{pmatrix}^{-1} \\ &= \frac{1}{1-q_0^2\tilde{\Phi}^+(z)\tilde{\Phi}^-(z)} \begin{pmatrix} \tilde{\Phi}^+(z) & q_0\tilde{\Phi}^-(z)\tilde{\Phi}^+(z) \\ q_0\Phi^-(z)\tilde{\Phi}^+(z) & \tilde{\Phi}^-(z) \end{pmatrix}. \end{aligned}$$

In particular, for the classical random walk ($p_i = p,\ q_i = q,\ r_i = 0$ for all $i \in \mathbb{Z}$) we have

$$\tilde{\Phi}^+(z) = -\frac{z-\sqrt{z^2-4pq}}{2pq}, \quad \tilde{\Phi}^-(z) = \frac{p}{q}\Phi^+(z),$$

and a straightforward calculation gives the result

$$\Phi(z) = \begin{pmatrix} \frac{-1}{\sqrt{z^2-4pq}} & \frac{1}{2q}\left(1-\frac{z}{\sqrt{z^2-4pq}}\right) \\ \frac{1}{2q}\left(1-\frac{z}{\sqrt{z^2-4pq}}\right) & \frac{p}{q}\frac{-1}{\sqrt{z^2-4pq}} \end{pmatrix},$$

which was also obtained by Karlin and McGregor (1959) by a probabilistic argument.

**3.2. An example from queuing theory.** In a recent paper Dayar and Quessette (2002) considered a system of two independent queues, where queue 1 is an $M/M/1$ and queue 2 is an $M/M/1/d-1$. Both queues have a Poisson arrival process with rate $\lambda_i$ $(i = 1, 2)$ and exponential service distributions with rates $\mu_i$ $(i = 1, 2)$. It is easy to see that the embedded random walk corresponding to the quasi-birth-and-death process representing the length of queue 1 (which is unbounded) and the length of queue 2 (which varies between $0, 1, \ldots, d-1$) has a one-step transition matrix of the form (1.2), where the blocks $B_i, A_i$, and $C_i$ are given by

$$B_0 = \begin{pmatrix} 0 & \frac{\lambda_2}{\lambda_1+\lambda_2} & & & \\ \frac{\mu_2}{\gamma-\mu_1} & 0 & \frac{\lambda_2}{\gamma-\mu_1} & & \\ & \ddots & \ddots & \ddots & \\ & & \frac{\mu_2}{\gamma-\mu_1} & 0 & \frac{\lambda_2}{\gamma-\mu_1} \\ & & & \frac{\mu_2}{\lambda_1+\mu_2} & 0 \end{pmatrix}, \tag{3.5}$$

$$B_i = \begin{pmatrix} 0 & \frac{\lambda_2}{\gamma-\mu_2} & & & \\ \frac{\mu_2}{\gamma} & 0 & \frac{\lambda_2}{\gamma} & & \\ & \ddots & \ddots & \ddots & \\ & & \frac{\mu_2}{\gamma} & 0 & \frac{\lambda_2}{\gamma} \\ & & & \frac{\mu_2}{\gamma-\lambda_2} & 0 \end{pmatrix}, \ i \geq 1, \tag{3.6}$$

$$A_0 = \begin{pmatrix} \frac{\lambda_1}{\lambda_1+\lambda_2} & & & & \\ & \frac{\lambda_1}{\gamma-\mu_1} & & & \\ & & \ddots & & \\ & & & \frac{\lambda_1}{\gamma-\mu_1} & \\ & & & & \frac{\lambda_1}{\lambda_1+\mu_2} \end{pmatrix}, \tag{3.7}$$

$$A_i = \begin{pmatrix} \frac{\lambda_1}{\gamma-\mu_2} & & & & \\ & \frac{\lambda_1}{\gamma} & & & \\ & & \ddots & & \\ & & & \frac{\lambda_1}{\gamma} & \\ & & & & \frac{\lambda_1}{\gamma-\lambda_2} \end{pmatrix}, \; i \geq 1, \tag{3.8}$$

and

$$C_i = \begin{pmatrix} \frac{\mu_1}{\gamma-\mu_2} & & & & \\ & \frac{\mu_1}{\gamma} & & & \\ & & \ddots & & \\ & & & \frac{\mu_1}{\gamma} & \\ & & & & \frac{\mu_1}{\gamma-\lambda_2} \end{pmatrix}, \; i \geq 1, \tag{3.9}$$

respectively, and $\gamma = \lambda_1 + \lambda_2 + \mu_1 + \mu_2$, $\lambda_1 < \mu_1$. A straightforward calculation shows that the assumptions of Theorem 2.1 are satisfied, where the matrices $R_n$ are diagonal and given by

$$R_0 = \operatorname{diag}\left( \frac{\sqrt{(\lambda_1+\lambda_2)\mu_2}}{\sqrt{(\gamma-\mu_1)\lambda_2}}, 1, \frac{\sqrt{\lambda_2}}{\sqrt{\mu_2}}, \frac{\lambda_2}{\mu_2}, \dots, \left(\frac{\sqrt{\lambda_2}}{\sqrt{\mu_2}}\right)^{d-3}, \frac{\sqrt{(\lambda_1+\mu_2)\lambda_2^{d-2}}}{\sqrt{(\gamma-\mu_1)\mu_2^{d-2}}} \right),$$

$$R_1 = \operatorname{diag}\left( \frac{\sqrt{\lambda_1(\gamma-\mu_2)\mu_2}}{\sqrt{\lambda_2(\gamma-\mu_1)\mu_1}}, \frac{\sqrt{\gamma\lambda_1}}{\sqrt{(\gamma-\mu_1)\mu_1}}, \dots, \frac{\sqrt{\gamma\lambda_1\lambda_2^{d-3}}}{\sqrt{(\gamma-\mu_1)\mu_1\mu_2^{d-3}}}, \frac{\sqrt{\lambda_1(\gamma-\lambda_2)\lambda_2^{d-2}}}{\sqrt{(\gamma-\mu_1)\mu_1\mu_2^{d-2}}} \right),$$

$$R_i = \left(\sqrt{\frac{\lambda_1}{\mu_1}}\right)^{i-1} R_1, \; i \geq 2.$$

It also follows from Theorem 2.5 that the corresponding random walk matrix measure is supported in the interval $[-1, 1]$.

**3.3. The simple random walk on the grid.** Consider the random walk on the grid $\mathcal{C}_d$, where the probabilities of going from state $(i,j)$ to $(i,j+1), (i,j-1), (i-1,j), (i+1,j)$ are given by $u, v, \ell, r$, respectively, where $u+v+\ell+r = 1$. In this case it follows that $A_i = rI_d$ $(i \geq 0)$, $C_i = \ell I_d$ $(i \geq 1)$,

$$B_i = \begin{pmatrix} 0 & u & & & & \\ v & 0 & u & & & \\ & v & 0 & u & & \\ & & \ddots & \ddots & \ddots & \\ & & & v & 0 & u \\ & & & & v & 0 \end{pmatrix}, \; i \geq 0, \tag{3.10}$$

and it is easy to see that the conditions of Theorem 2.1 are satisfied with

$$R_0 = \operatorname{diag}\left(1, \sqrt{\frac{u}{v}}, \sqrt{\frac{u^2}{v^2}}, \dots, \sqrt{\frac{u^{d-1}}{v^{d-1}}}\right), \ R_i = \left(\sqrt{\frac{r}{\ell}}\right)^i R_0, \ i \geq 1.$$

It now follows from Theorem 2.5 that the corresponding random walk matrix measure is supported in the interval $[-1, 1]$. For the identification of the Stieltjes transform of the spectral measure we note that the orthonormal polynomials defined by (2.7) have constant coefficients given by $D = D_n = \sqrt{r\ell} I_d$,

$$E = E_n = \begin{pmatrix} 0 & \sqrt{vu} & & & & \\ \sqrt{vu} & 0 & \sqrt{vu} & & & \\ & \sqrt{vu} & 0 & \sqrt{vu} & & \\ & & \ddots & \ddots & \ddots & \\ & & & \sqrt{vu} & 0 & \sqrt{vu} \\ & & & & \sqrt{vu} & 0 \end{pmatrix}. \tag{3.11}$$

Therefore it follows from the work of Duran (1999) that the Stieltjes transform of the random walk measure is given by

$$\int \frac{d\Sigma(t)}{z-t} = \frac{1}{2r\ell}\Big\{zI_d - E - \Big\{(zI_d - E)^2 - 4r\ell I_d\Big\}^{1/2}\Big\}.$$

From the same reference we obtain that the support of the random walk measure is given by the set

$$\operatorname{supp}(\Sigma) = \{x \in \mathbb{R} \mid xI_d - E \text{ has an eigenvalue in } [-2\sqrt{r\ell}, 2\sqrt{r\ell}]\}. \tag{3.12}$$

It is well known (see Basilevsky (1983)) that the eigenvalues of the matrix $E$ in (3.11) are given by

$$2\sqrt{uv}\cos\left(\frac{j\pi}{d+1}\right), \quad j = 1, \dots, d,$$

with corresponding normalized eigenvectors

$$x_j = \sqrt{\frac{2}{d+1}}\left(\sin\left(\ell\frac{\pi j}{d+1}\right)\right)_{\ell=1}^d.$$

Therefore it follows from (3.12) that

$$\operatorname{supp}(\Sigma) = \left[-2\sqrt{r\ell} + 2\sqrt{uv}\cos\left(\frac{\pi d}{d+1}\right), 2\sqrt{r\ell} + 2\sqrt{uv}\cos\left(\frac{\pi}{d+1}\right)\right]$$

(note that $\operatorname{supp}(\Sigma) \subset [-1, 1]$). For the calculation of the random walk measure we determine the spectral decomposition of the matrix

$$\begin{aligned} -H(x) &= 4I_d - D^{-1/2}(xI_d - E)D^{-1}(xI_d - E)D^{-1/2} \\ &= \frac{1}{r\ell}\Big\{4r\ell I_d - (xI_d - E)^2\Big\}. \end{aligned}$$

The eigenvalues of this matrix are given by

$$\lambda_j(x) = \frac{1}{r\ell}\left\{4r\ell - \left(x - 2\sqrt{vu}\cos\left(\frac{\pi j}{d+1}\right)\right)^2\right\},$$

and by the results in Duran (1999) the weight of the matrix measure is given by

$$d\Sigma(x) = \frac{1}{2\pi\sqrt{r\ell}} U\Lambda(x)U^T dx,$$

where the matrix $\Lambda(x)$ is defined by

$$\Lambda(x) = \Big\{ \mathrm{diag}(\max(\lambda_1(x), 0), \ldots, \max(\lambda_d(x), 0)) \Big\}^{1/2},$$

and the elements of the matrix $U = \{u_{j\ell}\}_{j,\ell=1,\ldots,d}$ are given by

$$u_{j\ell} = \sqrt{\frac{2}{d+1}} \sin\left(\ell \frac{j\pi}{d+1}\right).$$

**3.4. Finite state spaces.** The assertions of section 2 remain correct for random walks on a finite grid, where the corresponding random walk measure has a finite support. As an example consider a random walk on the finite grid

$$\mathcal{C} = \mathcal{C}_{d,N} = \{(i,j) \in \mathbb{N}_0 \times \mathbb{N} \,|\, 0 \le i \le N-1, 1 \le j \le d\},$$

where the probabilities of going from state $(i,j)$ to $(i,j+1), (i,j-1), (i-1,j), (i+1,j)$ are given by $u, v, \ell$, and $r$, respectively, where $u+v+\ell+r = 1$. Then the transition matrix $P$ is given by the finite dimensional block tridiagonal matrix

$$P = \begin{pmatrix} B_0 & A_0 & & & 0 \\ C_1^T & B_1 & A_1 & & \\ & \ddots & \ddots & \ddots & \\ & & C_{N-2}^T & B_{N-2} & A_{N-2} \\ 0 & & & C_{N-1}^T & B_{N-1} \end{pmatrix}$$

with $A_i = rI_d,\ 0 \le i \le N-2,\ C_i = \ell I_d,\ 1 \le i \le N-1$, and matrices $B_i$ defined by (3.10). A straightforward calculation shows that the corresponding random walk matrix polynomials are given by

$$Q_n(x) = \left(\sqrt{\frac{\ell}{r}}\right)^n U_n\left(\frac{1}{2}\sqrt{\frac{r}{\ell}}A\right),$$

$n = 0, \ldots, N-1$, where $U_n(z)$ denotes the Chebyshev polynomial of the second kind and the matrix $A$ is given by

$$A = \frac{1}{r} \begin{pmatrix} x & -u & & & & \\ -v & x & -u & & & \\ & -v & x & -u & & \\ & & \ddots & \ddots & \ddots & \\ & & & -v & x & -u \\ & & & & -v & x \end{pmatrix}.$$

Moreover, observing the representations

$$U_N\left(\frac{z}{2}\right) = \prod_{j=1}^{N} \left(z - 2\cos\left(\frac{j\pi}{N+1}\right)\right), \quad \det A = \left(\frac{\sqrt{uv}}{r}\right)^d U_d\left(\frac{1}{2\sqrt{uv}}x\right),$$

we obtain that the zeros of the polynomials $Q_N(x)$ are given by

$$\lambda_{ij} = 2\left(\sqrt{uv}\cos\left(\frac{i\pi}{d+1}\right) + \sqrt{\ell r}\cos\left(\frac{j\pi}{N+1}\right)\right), \quad i = 1,\dots,d; j = 1,\dots,N.$$

In particular, it follows for the rate of convergence of the probability of no absorption that

$$P(X_n \in \mathcal{C}_{d,N} \mid X_0 = x) = O\left(2^n\left(\sqrt{uv}\cos\left(\frac{\pi}{d+1}\right) + \sqrt{\ell r}\cos\left(\frac{\pi}{N+1}\right)\right)^n\right).$$

**3.5. A random walk on a tree.** Consider a graph with $d$ rays which are connected at one point, the origin. On each ray the probability of moving away from the origin is $p$ and moving in one step toward the origin is $q$, where $p + q = 1$. From the origin the probability of going to the $i$th ray is $d_i > 0\,(i = 1,\dots,d)$ (see Figure 1, where the case $d = 4$ is illustrated). It is easy to see that this process corresponds to a random walk on the grid $\mathcal{C}_d$ with block tridiagonal transition matrix $P$ in (1.2), where $B_i = 0$ if $i \geq 1$, $C_i = qI_d$ for all $i \geq 1$, $A_0 = \operatorname{diag}(d_1, p, \dots, p)$, $A_i = pI_d$ for all $i \geq 1$, and

$$B_0 = \begin{pmatrix} 0 & d_2 & \cdots & \cdots & d_d \\ q & 0 & \cdots & \cdots & 0 \\ \vdots & \vdots & & & \vdots \\ q & 0 & \cdots & \cdots & 0 \end{pmatrix},$$

where $\sum_{i=1}^d d_i = 1$. Moreover, this matrix clearly satisfies the assumptions of Theorem 2.1 with

$$R_0 = \operatorname{diag}\left(1, \sqrt{\frac{d_2}{q}}, \dots, \sqrt{\frac{d_d}{q}}\right), \quad R_1 = \operatorname{diag}\left(\sqrt{\frac{d_1}{q}}, \sqrt{\frac{d_2 p}{q^2}}, \dots, \sqrt{\frac{d_d p}{q^2}}\right),$$

and

$$R_i = \left(\sqrt{\frac{p}{q}}\right)^{i-1} R_1, \; i \geq 2.$$

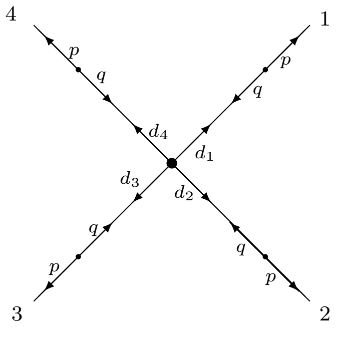

FIG. 1. *A random walk on a tree.*

By an application of Theorem 2.6 and the inversion formula for Stieltjes transforms we obtain for the corresponding random walk measure

$$d\Sigma(x) = \begin{bmatrix} a(x) & b_2(x) & b_3(x) & \dots & b_d(x) \\ b_2(x) & f_2(x) & e_{2,3}(x) & \dots & e_{2,d}(x) \\ b_3(x) & e_{2,3}(x) & f_3(x) & \dots & e_{3,d}(x) \\ \vdots & \vdots & \vdots & & \vdots \\ b_{d-1}(x) & e_{2,d-1}(x) & e_{3,d-1}(x) & \dots & e_{d-1,d}(x) \\ b_d(x) & e_{2,d}(x) & e_{3,d}(x) & \dots & f_d(x) \end{bmatrix} dx,$$

where the functions $a, b_i, e_{k,\ell}$, and $f_k$ are given by

$$a(x) = \frac{(\sum_{i=2}^d d_i^2 d_1 + d_1^2 q - (d_1 - p)x^2)\sqrt{4pq - x^2}}{2p\pi((\sum_{i=2}^d d_i^2 + d_1 q)^2 - (\sum_{i=2}^d d_i^2 + (d_1 - p)q)x^2)},$$

$$b_k(x) = -\frac{d_k x\sqrt{4pq - x^2}}{2\pi((\sum_{i=2}^d d_i^2 + d_1 q)^2 - (\sum_{i=2}^d d_i^2 + (d_1 - p)q)x^2)}, \quad k = 2, \dots, d,$$

$$e_{k,\ell}(x) = \frac{d_k d_\ell \sqrt{4pq - x^2}(px^2 - \sum_{i=2}^d d_j^2 d_1 - d_1^2 q)}{2\pi(d_1^2 q - (d_1 - p)x^2)((\sum_{i=2}^d d_i^2 + d_1 q)^2 - (\sum_{i=2}^d d_i^2 + (d_1 - p)q)x^2)},$$

$$k = 2, \dots, d-1,\ \ell = 3, \dots, d,$$

$$f_k(x) = \frac{d_1(\sum_{i=2}^d d_i^2 + d_1 q)(\sum_{i=2, i\neq k}^d d_i^2 + d_1 q)\sqrt{4pq - x^2}}{2\pi(d_1^2 q - (d_1 - p)x^2)((\sum_{i=2}^d d_i^2 + d_1 q)^2 - (\sum_{i=2}^d d_i^2 + (d_1 - p)q)x^2)}$$

$$+ \frac{-((\sum_{i=2}^d d_i^2 (d_1 - p) + \sum_{i=2, i\neq k}^d d_i^2 p + d_1(d_1 - p)q)x^2)\sqrt{4pq - x^2}}{2\pi(d_1^2 q - (d_1 - p)x^2)((\sum_{i=2}^d d_i^2 + d_1 q)^2 - (\sum_{i=2}^d d_i^2 + (d_1 - p)q)x^2)},$$

$$k = 2, \dots, d.$$

Note that the random walk measure is supported in the interval $[-2\sqrt{pq}, 2\sqrt{pq}]$.

## 4. Further discussion.

In the present section we derive further consequences of the existence of a random walk measure corresponding to the block tridiagonal transition matrix (1.2). Throughout this section we assume that the conditions of Theorem 2.1 are satisfied and that the corresponding random walk measure is supported in the interval $[-1, 1]$.

### 4.1. Recurrence.

We denote by

$$H_{ij}(z) = \sum_{n=0}^{\infty} (P_{ij}^n) z^n = \left( \int \frac{Q_i(x) d\Sigma(x) Q_j^T(x)}{1 - xz} \right) \left( \int Q_j(x) d\Sigma(x) Q_j^T(x) \right)^{-1} \tag{4.1}$$

the (matrix) generating function of the block $(i, j)$, where the last identity follows from Theorem 2.3 and Lebesgue's theorem. Therefore we obtain that a state $(i, \ell) \in \mathcal{C}_d$ is recurrent if and only if

$$\sum_{n=0}^{\infty} e_\ell^T P_{ii}^n e_\ell = \lim_{z\to 1} e_\ell^T H_{ii}(z) e_\ell = e_\ell^T \left(\int \frac{Q_i(x)d\Sigma(x)Q_i^T(x)}{1-x}\right)\left(\int Q_i(x)d\Sigma(x)Q_i^T(x)\right)^{-1} e_\ell = \infty, \tag{4.2}$$

where $e_\ell^T = (0,\dots,0,1,0,\dots,0)^T$ denotes the $\ell$th unit vector in $\mathbb{R}^d$. We summarize this observation in the following corollary.

Corollary 4.1. [illegible] 2.1 [illegible] $P$ [illegible] (1.2) [illegible] $\mathcal{C}_d$ [illegible] $[-1,1]$. [illegible] $(i,\ell)\in\mathcal{C}_d$ [illegible] (4.2) [illegible]

$$e_j^T \int_{-1}^{1} \frac{d\Sigma(x)}{1-x} S_0^{-1} e_j = \infty \tag{4.3}$$

[illegible] $j\in\{1,\dots,d\}$ [illegible] $j\in\{1,\dots,d\}$

Corollary 4.2. [illegible] 2.1 [illegible] $P$ [illegible] (1.2) [illegible] $\mathcal{C}_d$ [illegible] $[-1,1]$. [illegible] $d\tau_\ell(x) = e_\ell^T d\Sigma(x) S_0^{-1} e_\ell$ $(\ell = 1,\dots,d)$ [illegible] 1. [illegible] $d\tau_\ell(x)$ $(\ell = 1,\dots,d)$ [illegible] 1

[illegible]. Let $d\tau_\ell(x) = e_\ell^T d\Sigma(x) S_0^{-1} e_\ell$; then the probability of returning from state $(0,\ell)$ to $(0,\ell)$ in $k$ steps is given by

$$\alpha_k = e_\ell^T (P_{00}^k) e_\ell = e_\ell^T \int_{-1}^{1} x^k d\Sigma(x) S_0^{-1} e_\ell = \int_{-1}^{1} x^k d\tau_\ell(x).$$

The random walk is positive recurrent if and only if $\alpha = \lim_{k\to\infty}\alpha_k$ exists and is positive. Considering the sequence $\alpha_{2n}$ it follows by the dominated convergence theorem that this is the case if and only if $\tau_\ell$ has a jump at $x=-1$ or $x=1$. If $\tau_\ell$ has no jump at $x=1$ we obtain

$$\begin{aligned}\tau_\ell(-1) &= \lim_{n\to\infty}\left\{-\int_{-1}^{1} x^{2n+1} d\tau_\ell(x) + \int_{-1^-}^{1} x^{2n+1} d\tau_\ell(x)\right\}\\ &= -\lim_{n\to\infty} P_{00}^{2n+1} \le 0,\end{aligned}$$

and consequently $\tau_\ell$ has no jump at $x=-1$. Therefore the random walk is positive recurrent if and only if $\tau_\ell$ has a jump at $x=1$. □

[illegible] 4.3. For an irreducible random walk with a random walk measure $\Sigma$ satisfying $S_0 = I_d$ the properties of recurrence and positive recurrence are characterized by the diagonal elements of the corresponding random walk measure $\Sigma$.

**4.2. Canonical moments and random walk measures.** In this section we will represent the Stieltjes transform of a random walk matrix measure $\Sigma$ which is supported in the interval $[-1,1]$ in terms of its canonical moments, which were recently introduced by Dette and Studden (2001) in the context of matrix measures. We will use this representation to derive a characterization of recurrence of the process in terms of blocks of the matrix $P$.

THEOREM 4.4. [illegible] $\Sigma$, [illegible] $[-1,1]$ [illegible]

$$\int \frac{d\Sigma(x)}{z-x} = \lim_{n\to\infty} S_0^{1/2}\Big\{zI_d + I_d - 2\zeta_1^T - \Big\{zI_d + I_d - 2\zeta_2^T - 2\zeta_3^T - \Big\{zI_d + I_d - 2\zeta_4^T -2\zeta_5^T - \cdots - \Big\{zI_d + I_d - 2\zeta_{2n}^T - 2\zeta_{2n+1}^T\Big\}^{-1} 4\zeta_{2n}^T\zeta_{2n-1}^T\Big\}^{-1} \cdot \cdots 4\zeta_4^T\zeta_3^T\Big\}^{-1} 4\zeta_2^T\zeta_1^T\Big\}^{-1} S_0^{1/2}$$

$$= \lim_{n\to\infty} S_0^{1/2}\Big\{(z+1)I_d - \Big\{I_d - \Big\{(z+1)I_d - \cdots - \Big\{(z+1)I_d - 2\zeta_{2n+1}^T\Big\}^{-1} 2\zeta_{2n}^T\Big\}^{-1} \ldots 2\zeta_2^T\Big\}^{-1} 2\zeta_1^T\Big\}^{-1} S_0^{1/2},$$

[illegible] $\zeta_j \in \mathbb{R}^{d\times d}$ [illegible] $\zeta_0 = 0$ $\zeta_1 = U_1$, $\zeta_j = V_{j-1}U_j$ [illegible] $j \geq 2$ [illegible] $\{U_j\}$ [illegible] $\{V_j\}$ [illegible] $\Sigma$. [illegible] $\mathbb{C}$ [illegible] $[-1,1]$. [illegible]

$$\int \frac{d\Sigma(x)}{1-x} = \frac{1}{2} S_0^{1/2} \left[ I_d + \sum_{l=1}^{\infty} (V_1^T)^{-1} \ldots (V_l^T)^{-1} U_l^T \ldots U_1^T \right] S_0^{1/2}. \tag{4.4}$$

[illegible]. Let $\underline{P}_n(t)$ denote the $n$th monic orthogonal polynomial with respect to the matrix measure $d\Sigma(t)$; then it follows from Dette and Studden (2001) that $\underline{P}_n(t)$ can be calculated recursively as

$$\underline{P}_{n+1}(t) = \Big\{(t+1)I_d - 2\zeta_{2n+1}^T - 2\zeta_{2n}^T\Big\}\underline{P}_n(t) - 4\zeta_{2n}^T\zeta_{2n-1}^T\underline{P}_{n-1}(t), \tag{4.5}$$

where $\underline{P}_0(t) = I_d, \underline{P}_{-1}(t) = 0$, the quantities $\zeta_j \in \mathbb{R}^{d\times d}$ are defined by $\zeta_0 = 0$, $\zeta_1 = U_1$, $\zeta_j = V_{j-1}U_j$ if $j \geq 2$, and the sequences $\{U_j\}$ and $\{V_j\}$ are the canonical moments of the random walk measure $\Sigma$. Note that Dette and Studden (2001) define the canonical moments for matrix measures on the interval $[0,1]$, but the canonical moments are invariant with respect to transformations of the measure. More precisely, it can be shown that measures related by an affine transformation $t \to a + (b-a)t$ ($a, b \in \mathbb{R}$, $a < b$) have the same canonical moments. The results for the corresponding orthogonal polynomials can also easily be extended to matrix measures on the interval $[-1,1]$. The quantities

$$\Delta_{2n} := \langle \underline{P}_n, \underline{P}_n \rangle = 2^{2n}(S_0\zeta_1 \ldots \zeta_{2n})^T \tag{4.6}$$

are positive definite (see Dette and Studden (2001)) and consequently the polynomials

$$P_n(z) = \Delta_{2n}^{-1/2}\underline{P}_n(z)$$

are orthonormal with respect to the measure $d\Sigma(x)$. Now a straightforward calculation shows that these polynomials satisfy the recurrence relation

$$tP_k(t) = A_{k+1}P_{k+1}(t) + B_kP_k(t) + A_k^TP_{k-1}(t), \quad k = 0, 1, \ldots, \tag{4.7}$$

with initial conditions

$$P_{-1}(t) = 0,\ P_0(t) = S_0^{-1/2} \tag{4.8}$$

and coefficients

$$\begin{aligned} A_{n+1} &= \Delta_{2n}^{-1/2}\Delta_{2n+2}^{1/2}, && (4.9)\\ B_n &= -\Delta_{2n}^{-1/2}(I_d - 2\zeta_{2n}^T - 2\zeta_{2n+1}^T)\Delta_{2n}^{1/2}, && (4.10)\\ A_n^T &= 4\Delta_{2n}^{-1/2}\zeta_{2n}^T\zeta_{2n-1}^T\Delta_{2n-2}^{1/2} && (4.11) \end{aligned}$$

(note that the matrix $\Delta_{2n} = 4\Delta_{2n-2}\zeta_{2n-1}\zeta_{2n}$ is symmetric and therefore the two representations in (4.9) and (4.11) for the matrix $A_n$ are in fact identical). If $P_n^{(1)}(z)$ denotes the first associated orthogonal polynomial corresponding to $P_n(z)$ we obtain from Zygmunt (2002) the representation

$$\begin{aligned} F_n(z) &= (P_{n+1}(z))^{-1}P_{n+1}^{(1)}(z)\\ &= S_0\{zI_d - B_0 - A_1\{zI_d - B_1 - A_2\{zI_d - B_2 -\\ &\qquad \cdots - A_n\{zI_d - B_n\}^{-1}A_n^T\}^{-1}\ldots A_2^T\}^{-1}A_1^T\}^{-1}. \end{aligned} \tag{4.12}$$

Now a straightforward application of (4.9)–(4.11) yields

$$\begin{aligned} F_n(z) = S_0^{1/2}\{&zI_d + I_d - 2\zeta_1^T - \{zI_d + I_d - 2\zeta_2^T - 2\zeta_3^T - \{zI_d + I_d - 2\zeta_4^T\\ &-2\zeta_5^T - \cdots - \{zI_d + I_d - 2\zeta_{2n}^T - 2\zeta_{2n+1}^T\}^{-1}4\zeta_{2n}^T\zeta_{2n-1}^T\}^{-1}\cdot\\ &\cdots\cdot 4\zeta_4^T\zeta_3^T\}^{-1}4\zeta_2^T\zeta_1^T\}^{-1}S_0^{1/2}, \end{aligned} \tag{4.13}$$

and an iterative application of the matrix identity

$$I_d + A^{-1}B = (I_d - (B + A)^{-1}B)^{-1}$$

and Markov's theorem (see Duran (1996)) gives

$$\begin{aligned} \int \frac{d\Sigma(x)}{z - x} = \lim_{n\to\infty} S_0^{1/2}\Big\{&(z+1)I_d - \Big\{I_d - \Big\{(z+1)I_d -\\ &\cdots - \Big\{(z+1)I_d - 2\zeta_{2n+1}^T\Big\}^{-1}2\zeta_{2n}^T\Big\}^{-1}\ldots 2\zeta_2^T\Big\}^{-1}2\zeta_1^T\Big\}^{-1}S_0^{1/2} \end{aligned}$$

(note that this transformation is essentially a contraction). This proves the first part of the theorem. For the second part we put $z = 1$ and use formula (1.3) in Fair (1971) to obtain

$$\begin{aligned} \int \frac{d\Sigma(x)}{1 - x} &= \lim_{n\to\infty} \frac{1}{2}S_0^{1/2}\Big\{I_d - \Big\{I_d - \Big\{I_d -\\ &\qquad \cdots - \Big\{I_d - \zeta_{2n+1}^T\Big\}^{-1}\zeta_{2n}^T\Big\}^{-1}\ldots\Big\}^{-1}\zeta_1^T\Big\}^{-1}S_0^{1/2}\\ &= \lim_{n\to\infty} \frac{1}{2}S_0^{1/2}\sum_{j=0}^{n+1} X_{j+1}^{-1}\zeta_j^T X_{j-1}X_j^{-1}\zeta_{j-1}^T X_{j-2}X_{j-1}^{-1}\ldots X_1X_2^{-1}\zeta_1^T S_0^{1/2}, \end{aligned} \tag{4.14}$$

where $X_0 = I_d, X_1 = I_d$,

$$X_{n+1} = X_n - \zeta_n^T X_{n-1} \quad (n \geq 1).$$

Now a straightforward induction argument shows that $X_{n+1} = V_n^T \dots V_1^T$ and (4.14) reduces to (4.4), which proves the remaining assertion of the theorem. □

Our next result generalizes the famous characterization of recurrence in an irreducible birth-and-death chain to the matrix case.

THEOREM 4.5. [illegible] 2.1 [illegible] $[-1,1]$. [illegible] $(0,\ell)$ [illegible]

$$e_\ell^T S_0^{1/2} \sum_{i=0}^{\infty} T_{i+1}^{-1} A_i^{-1} C_i^T T_{i-1} T_i^{-1} A_{i-1}^{-1} C_{i-1}^T T_{i-2} T_{i-1}^{-1} \cdot \\ \cdots T_1 T_2^{-1} A_1^{-1} C_1^T T_0 T_1^{-1} A_0^{-1} T_0 S_0^{-1/2} e_\ell = \infty,$$

[illegible] $T_i = Q_i(1)$ $(i \in \mathbb{N}_0)$ $T_{-2} = T_{-1} = I_d$ [illegible] $Q_i(x)$ [illegible] $i$ [illegible] (1.4) [illegible] $\mathcal{C}_d$ [illegible]

$$S_0^{1/2} \sum_{i=0}^{\infty} T_{i+1}^{-1} A_i^{-1} C_i^T T_{i-1} T_i^{-1} A_{i-1}^{-1} C_{i-1}^T T_{i-2} T_{i-1}^{-1} \dots T_1 T_2^{-1} A_1^{-1} C_1^T T_0 T_1^{-1} A_0^{-1} T_0 S_0^{-1/2}$$

[illegible]

[illegible] A combination of Corollary 4.1 and Theorem 4.4 shows that the state $(0,\ell)$ is recurrent if and only if

$$(4.15) \qquad t = \frac{1}{2} e_\ell^T S_0^{1/2} \left[ I_d + \sum_{j=1}^{\infty} (V_j^T)^{-1} \dots (V_l^T)^{-1} U_j^T \dots U_1^T \right] S_0^{-1/2} e_\ell = \infty,$$

where $U_1, U_2, \dots$ are the canonical moments of the random walk measure $\Sigma$ and $V_j = I_d - U_j$ $(j \geq 1)$. In the following we express the right-hand side in terms of the blocks of the one-step block tridiagonal transition matrix $P$ corresponding to the random walk. For this consider the recurrence relation (1.4) and define $T_n = Q_n(1)$. Note that the polynomials $\underline{Q}_n(t) = A_0 \dots A_{n-1} Q_n(t)$ are monic and satisfy the recurrence relation

$$\underline{Q}_{n+1}(t) = t\underline{Q}_n(t) - A_0 \dots A_{n-1} B_n A_{n-1}^{-1} \dots A_0^{-1} \underline{Q}_n(t) \\ - A_0 \dots A_{n-1} C_n^T A_{n-2}^{-1} \dots A_0^{-1} \underline{Q}_{n-1}(t).$$

Therefore a comparison with (4.5) yields

$$(4.16) \qquad \begin{aligned} A_0 \dots A_{n-1} B_n A_{n-1}^{-1} \dots A_0^{-1} &= -I_d + 2\zeta_{2n}^T + 2\zeta_{2n+1}^T, \\ A_0 \dots A_{n-1} C_n^T A_{n-2}^{-1} \dots A_0^{-1} &= 4\zeta_{2n}^T \zeta_{2n-1}^T. \end{aligned}$$

Using these representations and the fact that $U_k V_k = V_k U_k$ (see Dette and Studden (2001), Theorem 2.7) it is easy to see that

$$T_n = Q_n(1) = 2^n A_{n-1}^{-1} \dots A_0^{-1} V_{2n-1}^T V_{2n-2}^T \dots V_1^T,$$

and it follows from the same reference that these matrices are nonsingular for all $n \in \mathbb{N}_0$. Therefore we can define

$$(4.17) \qquad \hat{Q}_n(x) = T_n^{-1} Q_n(x),$$

and it is easy to see that these polynomials satisfy the recurrence relation

$$x\hat{Q}_n(x) = \hat{A}_n\hat{Q}_{n+1}(x) + \hat{B}_n\hat{Q}_n(x) + \hat{C}_n^T\hat{Q}_{n-1}(x), \tag{4.18}$$

where

$$\hat{A}_n = T_n^{-1}A_nT_{n+1}, \quad \hat{B}_n = T_n^{-1}B_nT_n, \quad \hat{C}_n^T = T_n^{-1}C_n^TT_{n-1} \tag{4.19}$$

(note that $\hat{A}_n + \hat{B}_n + \hat{C}_n^T = I_d$). Combining (4.16) with (4.19) we obtain

$$\begin{aligned}\hat{A}_0\dots\hat{A}_{n-1}\hat{B}_n\hat{A}_{n-1}^{-1}\dots\hat{A}_0^{-1} &= -I_d + 2\zeta_{2n}^T + 2\zeta_{2n+1}^T,\\ \hat{A}_0\dots\hat{A}_{n-1}\hat{C}_n^T\hat{A}_{n-2}^{-1}\dots\hat{A}_0^{-1} &= 4\zeta_{2n}^T\zeta_{2n-1}^T,\end{aligned}$$

and by an induction argument (noting that $\hat{A}_n + \hat{B}_n + \hat{C}_n^T = I_d$) it follows that

$$\begin{aligned}2U_{2n}^TU_{2n-1}^T &= \hat{A}_0\dots\hat{A}_{n-1}\hat{C}_n^T\hat{A}_{n-1}^{-1}\dots\hat{A}_0^{-1},\\ 2V_{2n+1}^TV_{2n}^T &= \hat{A}_0\dots\hat{A}_{n-1}\hat{A}_n\hat{A}_{n-1}^{-1}\dots\hat{A}_0^{-1}.\end{aligned}$$

Finally, we obtain for the left-hand side of (4.15)

$$\begin{aligned}t &= \frac{1}{2}e_\ell^TS_0^{1/2}\sum_{j=0}^{\infty}\Big\{(V_1^T)^{-1}\dots(V_{2j}^T)^{-1}U_{2j}^T\dots U_1^T\\ &\qquad\qquad + (V_1^T)^{-1}\dots(V_{2j+1}^T)^{-1}U_{2j+1}^T\dots U_1^T\Big\}S_0^{-1/2}e_\ell\\ &= e_\ell^TS_0^{1/2}\sum_{j=0}^{\infty}\hat{A}_j^{-1}\hat{C}_j^T\hat{A}_{j-1}^{-1}\dots\hat{A}_1^{-1}\hat{C}_1^T\hat{A}_0^{-1}S_0^{-1/2}e_\ell\\ &= e_\ell^TS_0^{1/2}\sum_{j=0}^{\infty}T_{j+1}^{-1}A_j^{-1}C_j^TT_{j-1}T_j^{-1}A_{j-1}^{-1}C_{j-1}^TT_{j-2}T_{j-1}^{-1}\cdot\\ &\qquad\qquad \cdots T_1T_2^{-1}A_1^{-1}C_1^TT_0T_1^{-1}A_0^{-1}T_0S_0^{-1/2}e_\ell\end{aligned}$$

with $T_i = Q_i(1)$ $(i \in \mathbb{N}_0)$, which proves the assertion of the theorem. □

4.6. It is interesting to note that the condition in Theorem 4.5 simplifies substantially if all the matrices $T_i, A_i, C_i$ are commuting. In this case an irreducible random walk is recurrent if and only if

$$e_\ell^TS_0^{1/2}\sum_{i=0}^{\infty}T_{i+1}^{-1}T_i^{-1}(C_1\dots C_i)^T(A_0\dots A_i)^{-1}S_0^{-1/2}e_\ell = \infty$$

for some $\ell \in \{1,\dots,d\}$.

4.7. Consider the random walk on the tree introduced in section 3.5. By Corollary 4.1 the state $(0,1)$ (which corresponds to the origin) is recurrent if and only if

$$\infty = e_1^T\left(\int\frac{d\Sigma(x)}{1-x}\right)\left(\int d\Sigma(x)\right)^{-1}e_1 = \int_{2\sqrt{pq}}^{2\sqrt{pq}}\frac{a(x)}{1-x}dx,$$

where the function $a$ is defined in section 3.5 and we have used the fact that $\int d\Sigma(x) = S_0 = (R_0^TR_0)^{-1}$ (see Remark 2.2). Because the support of the spectral measure is given by the interval $[-\sqrt{4pq}, -\sqrt{4pq}]$ it follows that the condition $p = q = \frac{1}{2}$ is necessary for the recurrence of the random walk. Now a straightforward calculation shows that the state $(0,1)$ (i.e., the center of the graph) is recurrent if and only if the condition $2\sum_{i=2}^d d_i^2 = \sum_{i=2}^d d_i$ is satisfied (in all other cases the integral is finite).

## 5. Applications.

In this section we briefly discuss some applications of our approach.

### 5.1. Representations of the invariant measure.

Note that an irreducible quasi-birth-and-death process always has an invariant measure with a matrix product form (see Latouche, Pearce, and Taylor (1998)). In particular, if the process is positive recurrent, the invariant measure coincides with the stationary distribution $x = (x_0^T, x_1^T, \dots)$, which can be represented as

$$x_k^T = x_0^T \prod_{\ell=0}^{k-1} \tilde{R}_\ell, \tag{5.1}$$

where the set $\{\tilde{R}_\ell\}_{\ell=0}^\infty$ is the minimal nonnegative solution of the equations

$$R_k = A_k + R_k B_{k+1} + R_k R_{k+1} C_{k+2}^T \quad (k \geq 0) \tag{5.2}$$

and $x_0$ satisfies

$$x_0^T (B_0 + \tilde{R}_0 C_1^T) = x_0^T, \tag{5.3}$$

normalized so that $x^T e = 1$, where $e$ denotes a vector with all entries equal to one. We will now investigate these properties from the viewpoint derived in this paper and suppose that the assumptions of Theorem 2.5 are satisfied for an irreducible aperiodic Markov chain on the grid $\mathcal{C}_d$. Note that the limits

$$L_{i'} = \lim_{n\to\infty} P_{ii'}^n$$

exist and do not depend on $i$. By the Theorem of dominated convergence and (2.16) it follows that

$$L_{i'} = \lim_{n\to\infty} \left\{ Q_i(1)\Sigma(1)Q_{i'}^T(1) + (-1)^n Q_i(-1)\Sigma(-1)Q_{i'}^T(-1) \right\} Z_{i'}^{-1}, \tag{5.4}$$

where $Z_{i'} = \int Q_{i'}(x) d\Sigma(x) Q_{i'}^T(x)$ and $\Sigma(1)$ and $\Sigma(-1)$ denote the mass of the random walk matrix measure at the points 1 and $-1$, respectively. Considering the subsequence of odd positive integers it follows that $\Sigma$ has no mass at $-1$ and (5.4) reduces to

$$L_{i'} = \lim_{n\to\infty} P_{ii'}^n = Q_i(1)\Sigma(1)Q_{i'}^T(1) Z_{i'}^{-1}. \tag{5.5}$$

Note that the left-hand side of this equation does not depend on $i$ and therefore (5.5) provides several representations for the same quantity (by using different values of $i$). For example, if we put $i = 0$ and note that the rank of the matrices $L_{i'}$ is 1 we obtain from the identity $L_0 = \Sigma(1) Z_0^{-1}$ that the rank of the weight $\Sigma(1)$ is 1. Moreover, if the random walk is positive recurrent, the stationary distribution is given by

$$x = (x_0^T, x_1^T, \dots) = e_0^T (L_0, L_1, \dots),$$

and it follows that

$$x_k^T = e_0^T L_k = e_0^T \Sigma(1) Q_k^T(1) Z_k^{-1} \quad (k \geq 0),$$

which is an alternative representation for the stationary distribution. In particular, we have for the vector $x_0$ in (5.1)

$$x_0^T = e_0^T \Sigma(1) S_0^{-1}.$$

Moreover, if the matrices $Q_k(1)$ are nonsingular, we obtain by straightforward calculation that the representation (5.1) holds with

$$\tilde{R}_j = Z_j (Q_j^T(1))^{-1} Q_{j+1}^T(1) Z_{j+1}^{-1}. \tag{5.6}$$

Using the relations (2.4) it follows by straightforward algebra that the sequence $\{\tilde{R}_j\}_{j\in\mathbb{N}_0}$ is in fact a solution of the system (5.2) and (5.3), which yield to the stationary distribution. We finally note that the proof of Theorem 2.1 shows that the matrix $Z_j^{-1} = R_j^T R_j$ can be expressed in terms of the blocks $A_j, C_j$ and the matrix $S_0$.

**5.2. A necessary condition for positive recurrence.** As a second application we use the identity (5.5) for two values $i, k$ and obtain

$$Q_i(1)\Sigma(1)Q_{i'}^T(1) = Q_k(1)\Sigma(1)Q_{i'}^T(1) = L_{i'}$$

which reduces for $i' = 0$ to

$$(Q_i(1) - Q_k(1))\Sigma(1) = 0 \quad (i, k \geq 0). \tag{5.7}$$

Recall that by Corollary 4.2 the irreducible random walk is positive recurrent if and only if all measures $e_\ell^T d\Sigma(x) S_0^{-1} e_\ell$ have a jump at the point 1. In this case it follows from (5.7) that all matrices $Q_i(1) - Q_k(1)$ are singular (otherwise $\Sigma(1)$ would be the null matrix). Consequently we obtain the following result.

THEOREM 5.1. [illegible] 2.5 [illegible]

$$Q_i(1) - Q_k(1)$$

[illegible] $i, k \in \mathbb{N}_0$.

[illegible] 5.2. Consider the random walk on the tree presented in section 3.5. In Example 4.7 it is demonstrated that the random walk is recurrent if and only if $p = q = \frac{1}{2}$ and

$$\sum_{i=2}^{d} d_i = 2\sum_{i=2}^{d} d_i^2,$$

which will be assumed in the following discussion. A straightforward calculation shows that $Q_0(1) = I_d$,

$$Q_1(1) = \begin{pmatrix} 2 & -2d_2 & -2d_3 & \dots & -2d_d \\ -1 & 2 & 0 & \dots & 0 \\ -1 & 0 & 2 & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ -1 & 0 & 0 & \dots & 2 \end{pmatrix},$$

and consequently we obtain

$$|Q_1(1) - Q_0(1)| = |I_d - 2B_0| = 1 - 2d_2 - \cdots - 2d_d = 2d_1 - 1.$$

Therefore, if the random walk would be positive recurrent it follows that $d_1 = \frac{1}{2}$. Because the tree corresponding to the random walk is symmetric we conclude that the role of $d_1$ and $d_2$ can be interchanged. Consequently the random walk can only be positive recurrent if two of the probabilities $d_j$ are equal to $1/2$ and the others vanish. However, this corresponds to the symmetric random walk on $\mathbb{Z}$, which is not positive recurrent. In other words: the random walk considered in section 3.5 is recurrent if $p = q = \frac{1}{2}$ and $\sum_{i=2}^{d} d_i = 2\sum_{i=2}^{d} d_i^2$ but never positive recurrent.

# SYMMETRIC LINEARIZATIONS FOR MATRIX POLYNOMIALS*

NICHOLAS J. HIGHAM[†], D. STEVEN MACKEY[†], NILOUFER MACKEY[‡], AND FRANÇOISE TISSEUR[†]

**Abstract.** A standard way of treating the polynomial eigenvalue problem $P(\lambda)x = 0$ is to convert it into an equivalent matrix pencil—a process known as linearization. Two vector spaces of pencils $\mathbb{L}_1(P)$ and $\mathbb{L}_2(P)$, and their intersection $\mathbb{DL}(P)$, have recently been defined and studied by Mackey, Mackey, Mehl, and Mehrmann. The aim of our work is to gain new insight into these spaces and the extent to which their constituent pencils inherit structure from $P$. For arbitrary polynomials we show that every pencil in $\mathbb{DL}(P)$ is block symmetric and we obtain a convenient basis for $\mathbb{DL}(P)$ built from block Hankel matrices. This basis is then exploited to prove that the first $\deg(P)$ pencils in a sequence constructed by Lancaster in the 1960s generate $\mathbb{DL}(P)$. When $P$ is symmetric, we show that the symmetric pencils in $\mathbb{L}_1(P)$ comprise $\mathbb{DL}(P)$, while for Hermitian $P$ the Hermitian pencils in $\mathbb{L}_1(P)$ form a proper subset of $\mathbb{DL}(P)$ that we explicitly characterize. Almost all pencils in each of these subsets are shown to be linearizations. In addition to obtaining new results, this work provides a self-contained treatment of some of the key properties of $\mathbb{DL}(P)$ together with some new, more concise proofs.

**Key words.** matrix polynomial, matrix pencil, linearization, companion form, quadratic eigenvalue problem, vector space, block symmetry, Hermitian, Hankel

## 1. Introduction.

The polynomial eigenvalue problem $P(\lambda)x = 0$, where

$$P(\lambda) = \sum_{i=0}^{k} \lambda^i A_i, \qquad A_i \in \mathbb{C}^{n\times n}, \quad A_k \neq 0, \tag{1.1}$$

arises in many applications and is an active topic of study. The quadratic case ($k = 2$) is the most important in practice [25], but higher degree polynomials also arise [5], [13], [19], [24]. We continue the practice stemming from Lancaster [15] of developing theory for general $k$ where possible, in order to gain the most insight and understanding.

The standard way of solving the polynomial eigenvalue problem is to linearize $P(\lambda)$ into $L(\lambda) = \lambda X + Y \in \mathbb{C}^{kn\times kn}$, solve the generalized eigenproblem $L(\lambda)z = 0$, and recover eigenvectors of $P$ from those of $L$. Formally, $L$ is a linearization of $P$ if there exist unimodular $E(\lambda)$ and $F(\lambda)$ (that is, $\det(E(\lambda))$ and $\det(F(\lambda))$ are nonzero constants) such that

$$E(\lambda)L(\lambda)F(\lambda) = \begin{bmatrix} P(\lambda) & 0 \\ 0 & I_{(k-1)n} \end{bmatrix}.$$

Hence $\det(L(\lambda))$ agrees with $\det(P(\lambda))$ up to a nonzero constant multiplier, so that $L$ and $P$ have the same eigenvalues. The linearizations used in practice are almost

invariably one of $C_1(\lambda) = \lambda X_1 + Y_1$ and $C_2(\lambda) = \lambda X_2 + Y_2$, called the first and second companion forms [16, sect. 14.1], respectively, where

$$X_1 = X_2 = \mathrm{diag}(A_k, I_n, \ldots, I_n), \tag{1.2a}$$

$$Y_1 = \begin{bmatrix} A_{k-1} & A_{k-2} & \ldots & A_0 \\ -I_n & 0 & \ldots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & \ldots & -I_n & 0 \end{bmatrix}, \quad Y_2 = \begin{bmatrix} A_{k-1} & -I_n & \ldots & 0 \\ A_{k-2} & 0 & \ddots & \vdots \\ \vdots & \vdots & \ddots & -I_n \\ A_0 & 0 & \ldots & 0 \end{bmatrix}. \tag{1.2b}$$

Yet many linearizations exist, and other than the convenience of their construction, there is no apparent reason for preferring the companion forms. Indeed one obvious disadvantage of the companion forms is their lack of preservation of certain structural properties of $P$, most obviously symmetry.

Four recent papers have systematically addressed the task of broadening the menu of available linearizations and providing criteria to guide the choice. Mackey et al. [17] construct two vector spaces of pencils generalizing the companion forms and prove many interesting properties, including that almost all of these pencils are linearizations. In [18], the same authors identify linearizations within these vector spaces that respect palindromic and odd-even structures. Higham, D. S. Mackey, and Tisseur [10] analyze the conditioning of some of the linearizations introduced in [17], looking for a best conditioned linearization and comparing its condition number with that of the original polynomial. Most recently, Higham, Li, and Tisseur [9] investigate the backward error of approximate eigenpairs recovered from a linearization, obtaining results complementary to, but entirely consistent with, those of [10].

Before discussing our aims, we recall some definitions and results from [17]. Let $\mathbb{F}$ denote $\mathbb{C}$ or $\mathbb{R}$. With the notation

$$\Lambda = [\lambda^{k-1}, \lambda^{k-2}, \ldots, 1]^T \in \mathbb{F}^k, \quad \text{where} \quad k = \deg(P),$$

define two vector spaces of $kn \times kn$ pencils $L(\lambda) = \lambda X + Y$:

$$\mathbb{L}_1(P) = \left\{ L(\lambda) : L(\lambda)(\Lambda \otimes I_n) = v \otimes P(\lambda),\ v \in \mathbb{F}^k \right\}, \tag{1.3}$$

$$\mathbb{L}_2(P) = \left\{ L(\lambda) : (\Lambda^T \otimes I_n)L(\lambda) = w^T \otimes P(\lambda),\ w \in \mathbb{F}^k \right\}. \tag{1.4}$$

The vectors $v$ and $w$ are referred to as "right ansatz" and "left ansatz" vectors, respectively. It is easily checked that for the companion forms in (1.2), $C_1(\lambda) \in \mathbb{L}_1(P)$ with $v = e_1$ and $C_2(\lambda) \in \mathbb{L}_2(P)$ with $w = e_1$, where $e_i$ denotes the $i$th column of $I_k$. The dimensions of $\mathbb{L}_1(P)$ and $\mathbb{L}_2(P)$ are both $k(k-1)n^2 + k$ [17, Cor. 3.6]. For any regular $P$ (that is, any $P$ for which $\det(P(\lambda)) \not\equiv 0$), almost all pencils in $\mathbb{L}_1(P)$ and $\mathbb{L}_2(P)$ are linearizations of $P$ [17, Thm. 4.7].

A crucial property of $\mathbb{L}_1$ and $\mathbb{L}_2$ is that eigenvectors of $P$ can be directly recovered from eigenvectors of linearizations in $\mathbb{L}_1$ and $\mathbb{L}_2$. Specifically, for any pencil $L \in \mathbb{L}_1(P)$ with nonzero right ansatz vector $v$, $x$ is a right eigenvector of $P$ with eigenvalue $\lambda$ if and only if $\Lambda \otimes x$ (if $\lambda$ is finite) or $e_1 \otimes x$ (if $\lambda = \infty$) is a right eigenvector for $L$ with eigenvalue $\lambda$. Moreover, if this $L \in \mathbb{L}_1(P)$ is a linearization for $P$, then right eigenvector of $L$ has one of these two Kronecker product forms; hence some right eigenvector of $P$ can be recovered from every right eigenvector of $L$. A similar recovery property holds for left eigenvectors and pencils in $\mathbb{L}_2(P)$. For more details, see [17, Thms. 3.8, 3.14, and 4.4].

The subspace

$$\mathbb{DL}(P) = \mathbb{L}_1(P) \cap \mathbb{L}_2(P) \tag{1.5}$$

of "double ansatz" pencils is of particular interest, because there is a simultaneous correspondence via Kronecker products between left [illegible] right eigenvectors of $P$ and those of pencils in $\mathbb{DL}(P)$. Two key facts are that $L \in \mathbb{DL}(P)$ if and only if $L$ satisfies the conditions in (1.3) and (1.4) with $w = v$, and that every $v \in \mathbb{F}^k$ uniquely determines $X$ and $Y$ such that $L(\lambda) = \lambda X + Y$ is in $\mathbb{DL}(P)$ [17, Thm. 5.3]. Thus $\mathbb{DL}(P)$ is a $k$-dimensional space of pencils associated with $P$. Just as for $\mathbb{L}_1(P)$ and $\mathbb{L}_2(P)$, almost all pencils in $\mathbb{DL}(P)$ are linearizations [17, Thm. 6.8].

Our contributions are now summarized. We show in section 3 that the set of block symmetric pencils in $\mathbb{L}_1(P)$ is precisely $\mathbb{DL}(P)$. That $\mathbb{DL}(P)$ should comprise only block symmetric pencils is perhaps surprising, as $P$ is arbitrary. We show that the pencils corresponding to $v = e_i$, $i = 1\colon k$, form a basis for $\mathbb{DL}(P)$ built from block diagonal matrices with block Hankel blocks. This basis is used in section 4 to prove that the first $k = \deg(P)$ pencils in a sequence constructed by Lancaster [14], [15], generate $\mathbb{DL}(P)$. In sections 5 and 6 we show that when $P$ is symmetric the set of symmetric pencils in $\mathbb{L}_1(P)$ is the same as $\mathbb{DL}(P)$, while for Hermitian $P$ the Hermitian pencils in $\mathbb{L}_1(P)$ form a proper subset of $\mathbb{DL}(P)$ corresponding to real ansatz vectors. In section 7 we summarize the known "almost all pencils are linearizations" results and prove such a result for the Hermitian pencils in $\mathbb{L}_1(P)$.

Initially, our main motivation for this investigation was the problem of systematically generating symmetric linearizations for symmetric matrix polynomials. However, the analysis has led, via the study of [illegible] pencils, to new derivations of some of the general properties of $\mathbb{DL}(P)$. Therefore this paper should be useful as a self-contained introduction to $\mathbb{DL}(P)$ with proofs that are conceptually clearer and more concise than the original derivations in [17].

Finally, we motivate our interest in the preservation of symmetry. A matrix polynomial that is real symmetric or Hermitian has a spectrum that is symmetric with respect to the real axis, and the sets of left and right eigenvectors coincide. These properties are preserved in a symmetric (Hermitian) linearization by virtue of its structure—not just through the numerical entries of the pencil. A symmetry-preserving pencil has the practical advantages that storage and computational cost are reduced if a method that exploits symmetry is applied. The eigenvalues of a symmetric (Hermitian) pencil $L(\lambda) = \lambda X + Y$ can be computed, for small to medium size problems, by first reducing the matrix pair $(Y, X)$ to tridiagonal-diagonal form [23] and then using the HR [4], [6] or LR [21] algorithms or the Ehrlich–Aberth iterations [3]. For large problems, a symmetry-preserving pseudo-Lanczos algorithm of Parlett and Chen [20], [2, sect. 8.6], based on an indefinite inner product, can be used. For a quadratic polynomial $Q(\lambda)$ that is hyperbolic, or in particular overdamped, a linearization that is a symmetric definite pencil can be identified [11, Thm. 3.6]; this pencil is amenable to structure-preserving methods that exploit both the symmetry and the definiteness [27] and guarantee real computed eigenvalues for $Q(\lambda)$ not too close to being nonhyperbolic.

**2. Block symmetry and shifted sum.** We begin with some notation and results concerning block transpose and block symmetry. Our aim is to investigate the existence and uniqueness of solutions in block symmetric matrices of the equation $X \boxplus\!\!\rightarrow Y = Z$, where $\boxplus\!\!\rightarrow$ is a "shifted sum" operation and $Z$ is a given arbitrary matrix. For the purposes of this paper we consider only block matrices in which all the blocks have the same size.

Definition 2.1 (block transpose). [illegible] $A = (A_{ij})$ [illegible] $k \times \ell$ [illegible] $m \times n$ [illegible] $A_{ij}$ [illegible] $A$ [illegible] $\ell \times k$ [illegible] $A^{\mathcal{B}}$ [illegible] $m \times n$ [illegible] $(A^{\mathcal{B}})_{ij} = A_{ji}$

Recall that all pencils in $\mathbb{L}_1(P)$ and $\mathbb{L}_2(P)$ are of size $kn \times kn$, where $k$ is the degree of the $n \times n$ matrix polynomial $P(\lambda)$. Throughout this paper we regard these pencils as block $k \times k$ matrices with $n \times n$ blocks. The block transpose operation, performed relative to this partitioning, establishes an intimate link between $\mathbb{L}_1(P)$ and $\mathbb{L}_2(P)$.

Theorem 2.2. [illegible] $P(\lambda)$ [illegible]

$$\mathbb{L}_1(P) \longrightarrow \mathbb{L}_2(P),$$

$$L(\lambda) \longmapsto L(\lambda)^{\mathcal{B}}$$

[illegible] $\mathbb{L}_1(P)$ [illegible] $\mathbb{L}_2(P)$ [illegible] $L(\lambda) \in \mathbb{L}_1(P)$ [illegible] $v$ [illegible] $L(\lambda)^{\mathcal{B}} \in \mathbb{L}_2(P)$ [illegible] $w = v$

[illegible] It is straightforward to check that $\big(L(\lambda)(\Lambda \otimes I_n)\big)^{\mathcal{B}} = (\Lambda \otimes I_n)^{\mathcal{B}} L(\lambda)^{\mathcal{B}} = (\Lambda^T \otimes I_n) L(\lambda)^{\mathcal{B}}$ and $\big(v \otimes P(\lambda)\big)^{\mathcal{B}} = v^T \otimes P(\lambda)$. Hence if $L(\lambda) \in \mathbb{L}_1(P)$ with right ansatz vector $v$, then block transposing the defining condition in (1.3) yields $(\Lambda^T \otimes I_n) L(\lambda)^{\mathcal{B}} = v^T \otimes P(\lambda)$. Thus $L(\lambda)^{\mathcal{B}} \in \mathbb{L}_2(P)$ with left ansatz vector $v$, and so block transpose gives a well-defined map from $\mathbb{L}_1(P)$ to $\mathbb{L}_2(P)$. Clearly this map is linear and the kernel is just the zero pencil, since $L(\lambda)^{\mathcal{B}} = 0 \Rightarrow L(\lambda) = 0$. Since $\dim \mathbb{L}_1(P) = \dim \mathbb{L}_2(P)$, the proof is complete. ☐

The companion forms give a nice illustration of Theorem 2.2. By inspection, $C_2(\lambda) = \big(C_1(\lambda)\big)^{\mathcal{B}}$ and, as noted earlier, $C_1(\lambda) \in \mathbb{L}_1(P)$ with right ansatz vector $v = e_1$ while $C_2(\lambda) \in \mathbb{L}_2(P)$ with left ansatz vector $w = v = e_1$.

Given the notion of block transpose, it is natural to consider block symmetric matrices, which will play a central role in our development. A block $k \times k$ matrix $A$ with $m \times n$ blocks is [illegible] if $A^{\mathcal{B}} = A$. For example, a block $2 \times 2$ block symmetric matrix has the form $\left[\begin{smallmatrix} A_{11} & A_{12} \\ A_{12} & A_{22} \end{smallmatrix}\right]$. Note that if each block $A_{ij} \in \mathbb{F}^{n \times n}$ in a block symmetric matrix $A$ is symmetric, then $A$ is symmetric.

The [illegible] introduced in [17] is a simple operation on block matrices that enables us both to easily construct pencils in $\mathbb{L}_1(P)$ and to conveniently test when a given pencil is in $\mathbb{L}_1(P)$.

Definition 2.3 (column-shifted sum). [illegible] $X$ [illegible] $Y$ [illegible] $k \times k$ [illegible] $n \times n$ [illegible] $X_{ij}$ [illegible] $Y_{ij}$ [illegible] $X \boxplus\!\!\rightarrow Y$ [illegible] $X$ [illegible] $Y$ [illegible]

$$X \boxplus\!\!\rightarrow Y := \begin{bmatrix} X_{11} & \dots & X_{1k} & 0 \\ & & & \\ X_{k1} & \dots & X_{kk} & 0 \end{bmatrix} + \begin{bmatrix} 0 & Y_{11} & \dots & Y_{1k} \\ & & & \\ 0 & Y_{k1} & \dots & Y_{kk} \end{bmatrix} \in \mathbb{F}^{kn \times k(n+1)},$$

[illegible] $n \times n$

The significance of this shifted sum operation is revealed by the following result [17, Lem. 3.4], which shows how membership in $\mathbb{L}_1(P)$ is equivalent to a specific Kronecker product form in the shifted sum.

LEMMA 2.4. $P(\lambda) = \sum_{i=0}^{k} \lambda^i A_i$ $n \times n$ $k$ $L(\lambda) = \lambda X + Y$ $kn \times kn$ $v \in \mathbb{F}^k$

$$L(\lambda) \in \mathbb{L}_1(P) \quad v \iff X \boxplus\!\!\rightarrow Y = v \otimes [A_k \; A_{k-1} \; \dots \; A_0].$$

We now show that the equation $X \boxplus\!\!\rightarrow Y = Z$ with an arbitrary $Z$ may always be solved with block symmetric $X$ and $Y$. To this end we introduce the mapping

$$(X, Y) \overset{\mathcal{S}}{\longmapsto} X \boxplus\!\!\rightarrow Y$$

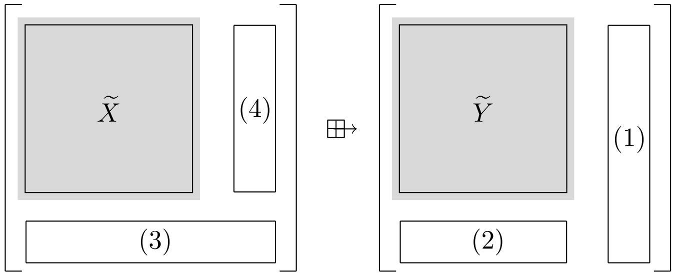
between the space of all pairs of block symmetric block $k \times k$ matrices $(X, Y)$ and the space of all block $k \times (k+1)$ matrices $Z$.

LEMMA 2.5. $\mathcal{S}$

The linearity of $\mathcal{S}$ follows easily from the definition of column-shifted sum in Definition 2.3. Since $\mathcal{S}$ is linear and its domain and codomain have the same dimension $n^2k(k+1)$, it suffices to establish either the injectivity or the surjectivity of $\mathcal{S}$; we show here the injectivity.

Suppose $X$ and $Y$ are block symmetric and $X \boxplus\!\!\rightarrow Y = 0$. We will show by induction that $X = Y = 0$. If $k = 1$ then $X \boxplus\!\!\rightarrow Y = [X \; Y]$ and $X = Y = 0$ is immediate. Let $k \geq 2$ and let $X$ and $Y$ be partitioned as indicated in the following diagram, with the last block row and last block column labeled:

$X \boxplus\!\!\rightarrow Y =$



The last block column of $X \boxplus\!\!\rightarrow Y = 0$ implies that (1) is zero. The block symmetry of $Y$ then implies that (2) is zero. The last block row of $X \boxplus\!\!\rightarrow Y = 0$ now shows that (3) is zero, and (4) is then zero by the block symmetry of $X$. We now have that

$$X \boxplus\!\!\rightarrow Y = \begin{bmatrix} \widetilde{X} & 0 \\ 0 & 0 \end{bmatrix} \boxplus\!\!\rightarrow \begin{bmatrix} \widetilde{Y} & 0 \\ 0 & 0 \end{bmatrix} = \begin{bmatrix} \widetilde{X} \boxplus\!\!\rightarrow \widetilde{Y} & 0 \\ 0 & 0 \end{bmatrix} = 0.$$

Since $\widetilde{X} \boxplus\!\!\rightarrow \widetilde{Y} = 0$, the inductive hypothesis implies $\widetilde{X} = \widetilde{Y} = 0$, and consequently that $X = Y = 0$. ☐

Although Lemma 2.5 implies that $X \boxplus\!\!\rightarrow Y = Z$ can always be solved with block symmetric $X$ and $Y$, it gives no information about the form of the solution or how to construct it. Knowing the structure of $X$ and $Y$ is crucial to the later developments in sections 3 and 4, so we close this section with a procedure for explicitly constructing these solutions.

First we define three special types of block symmetric matrix that play a central role in the construction. Let

$$R_\ell = \begin{bmatrix} & & 1 \\ & \iddots & \\ 1 & & \end{bmatrix}_{\ell\times\ell} \quad \text{and} \quad N_\ell = \begin{bmatrix} 0 & 1 & & \\ & 0 & \ddots & \\ & & \ddots & 1 \\ & & & 0 \end{bmatrix}_{\ell\times\ell}. \quad \text{(Note that } N_1 = 0.\text{)} \tag{2.1}$$

For an arbitrary $n\times n$ block $M$, we define three block Hankel, block symmetric, block $\ell\times\ell$ matrices:

$$\mathcal{H}_\ell^{(0)}(M) := \begin{bmatrix} & & M \\ & \iddots & \\ M & & \end{bmatrix} = R_\ell \otimes M,$$

$$\mathcal{H}_\ell^{(1)}(M) := \begin{bmatrix} & & M & 0 \\ & \iddots & \iddots & \\ M & \iddots & & \\ 0 & & & \end{bmatrix} = (N_\ell R_\ell)\otimes M = \begin{bmatrix} & & 1 & 0 \\ & \iddots & \iddots & \\ 1 & \iddots & & \\ 0 & & & \end{bmatrix} \otimes M,$$

$$\mathcal{H}_\ell^{(-1)}(M) := \begin{bmatrix} & & & 0 \\ & & \iddots & M \\ & \iddots & \iddots & \\ 0 & M & & \end{bmatrix} = (R_\ell N_\ell)\otimes M = \begin{bmatrix} & & & 0 \\ & & \iddots & 1 \\ & \iddots & \iddots & \\ 0 & 1 & & \end{bmatrix} \otimes M.$$

The superscript (0), (1), or (−1) denotes that the blocks $M$ are on, above, or below the antidiagonal, respectively. Note that all three of these block Hankel matrices are symmetric if $M$ is.

Now let $E_{ij}^\ell \in \mathbb{F}^{\ell\times(\ell+1)}$ denote the matrix that is everywhere zero except for a 1 in the $(i,j)$ entry. Our construction is based on the observation that for arbitrary $M, P \in \mathbb{F}^{n\times n}$, the shifted sums

$$\mathcal{H}_\ell^{(0)}(M) \boxplus\!\!\rightarrow (-\mathcal{H}_\ell^{(1)}(M)) = \begin{bmatrix} 0 & \dots & \dots & 0 & 0 \\ \vdots & & \iddots & \iddots & \vdots \\ 0 & 0 & \iddots & & \vdots \\ M & 0 & \dots & \dots & 0 \end{bmatrix} = E_{\ell 1}^\ell \otimes M, \tag{2.2}$$

$$-\mathcal{H}_\ell^{(-1)}(P) \boxplus\!\!\rightarrow \mathcal{H}_\ell^{(0)}(P) = \begin{bmatrix} 0 & \dots & \dots & 0 & P \\ \vdots & & \iddots & 0 & 0 \\ \vdots & \iddots & \iddots & & \vdots \\ 0 & 0 & \dots & \dots & 0 \end{bmatrix} = E_{1,\ell+1}^\ell \otimes P \tag{2.3}$$

place $M$ and $P$ at the bottom left corner and top right corner of a block $\ell\times(\ell+1)$ matrix, respectively.

Inherent in the linearity of the map $\mathcal{S}$ is the compatibility of the shifted sum $\boxplus\!\!\rightarrow$ with ordinary sums, i.e.,

$$\Big(\sum X_i\Big) \boxplus\!\!\rightarrow \Big(\sum Y_i\Big) = \sum (X_i \boxplus\!\!\rightarrow Y_i).$$

Hence if we can show how to construct block symmetric $X$ and $Y$ that place an arbitrary $n\times n$ block into an arbitrary $(i,j)$ block location in $Z$, then sums of such examples will achieve the desired result for an arbitrary $Z$.

For indices $i, j$ such that $1 \leq i \leq j \leq k$, let $\ell = j - i + 1$ and embed $\mathcal{H}^{(0)}_{\ell}(M)$ and $-\mathcal{H}^{(1)}_{\ell}(M)$ as principal submatrices in block rows and block columns $i$ through $j$ of block $k \times k$ zero matrices to get

$$(2.4)\qquad \widehat{X}_{ij} \boxplus\!\!\!\rightarrow \widehat{Y}_{ij} := \begin{array}{cc} & \begin{array}{cc} i & j \end{array} \\ \begin{array}{c} i \\ j \end{array} & \left[\begin{array}{c} \\ \boxed{\mathcal{H}^{(0)}_{\ell}(M)} \\ \\ \end{array}\right] \end{array} \boxplus\!\!\!\rightarrow \begin{array}{cc} & \begin{array}{cc} i & j \end{array} \\ \begin{array}{c} i \\ j \end{array} & \left[\begin{array}{c} \\ \boxed{-\mathcal{H}^{(1)}_{\ell}(M)} \\ \\ \end{array}\right] \end{array}$$

$$= \begin{array}{cc} & \begin{array}{cc} i & j+1 \end{array} \\ \begin{array}{c} i \\ j \end{array} & \left[\begin{array}{c} \\ \boxed{\mathcal{H}^{(0)}_{\ell}(M) \boxplus\!\!\!\rightarrow (-\mathcal{H}^{(1)}_{\ell}(M))} \\ \\ \end{array}\right] \end{array}$$

$$= E_{ji} \otimes M \quad (i \leq j).$$

Note that embedding $\mathcal{H}^{(0)}_{\ell}(M)$ and $-\mathcal{H}^{(1)}_{\ell}(M)$ as [illegible] block submatrices guarantees that $\widehat{X}_{ij}$ and $\widehat{Y}_{ij}$ are block symmetric. Similarly, defining the block symmetric matrices

$$(2.5)\qquad \widetilde{X}_{ij} = \begin{array}{cc} & \begin{array}{cc} i & j \end{array} \\ \begin{array}{c} i \\ j \end{array} & \left[\begin{array}{c} \\ \boxed{-\mathcal{H}^{(-1)}_{\ell}(P)} \\ \\ \end{array}\right] \end{array}, \quad \widetilde{Y}_{ij} = \begin{array}{cc} & \begin{array}{cc} i & j \end{array} \\ \begin{array}{c} i \\ j \end{array} & \left[\begin{array}{c} \\ \boxed{\mathcal{H}^{(0)}_{\ell}(P)} \\ \\ \end{array}\right] \end{array},$$

we have

$$(2.6)\qquad \widetilde{X}_{ij} \boxplus\!\!\!\rightarrow \widetilde{Y}_{ij} = E_{i,j+1} \otimes P \qquad (i \leq j).$$

Thus sums of these principally embedded versions of (2.2) and (2.3) can produce an arbitrary block $k \times (k+1)$ matrix $Z$ as the column-shifted sum of block symmetric $X$ and $Y$.

## 3. Block symmetric pencils and $\mathbb{DL}(P)$ for general $P$.

We now study the subspace of block symmetric pencils in $\mathbb{L}_1(P)$, which turns out to be the same as the space $\mathbb{DL}(P)$. This way of characterizing $\mathbb{DL}(P)$ leads to short proofs of some of its properties, as well as the identification of a useful basis.

### 3.1. Block symmetric pencils in $\mathbb{L}_1(P)$.

For a general polynomial $P$ we can use the results of section 2 to analyze the subspace

$$(3.1)\qquad \mathbb{B}(P) := \left\{\lambda X + Y \in \mathbb{L}_1(P) : X^{\mathcal{B}} = X,\ Y^{\mathcal{B}} = Y\right\}$$

of all block symmetric pencils in $\mathbb{L}_1(P)$. We will see in section 7 that almost all of these pencils are indeed linearizations for $P$.

Theorem 3.1. [illegible] $P(\lambda)$ [illegible] $k$ $\dim \mathbb{B}(P) = k$ [illegible] $v \in \mathbb{F}^k$ [illegible] $\mathbb{B}(P)$

[illegible]. Recalling that $\mathbb{L}_1$ is defined by (1.3), the theorem is proved if we can show that the map

$$
\begin{aligned}
\text{(3.2)}\qquad \mathbb{B}(P) &\xrightarrow{\mathcal{M}} \mathcal{V}_P := \{v \otimes P(\lambda) : v \in \mathbb{F}^k\},\\
L(\lambda) &\longmapsto L(\lambda)\,(\Lambda \otimes I_n)
\end{aligned}
$$

is a linear isomorphism.

First, recall from Lemma 2.4 that for any pencil $\lambda X + Y \in \mathbb{L}_1(P)$,

$$
(\lambda X + Y)(\Lambda \otimes I_n) = v \otimes P(\lambda) \iff X \boxplus\!\!\!\rightarrow Y = v \otimes [A_k\ A_{k-1}, \dots, A_0]. \tag{3.3}
$$

Thus $\lambda X + Y$ is in $\ker \mathcal{M}$ if and only if $X \boxplus\!\!\!\rightarrow Y = 0$. But $X$ and $Y$ are block symmetric, so by Lemma 2.5 we see that $\ker \mathcal{M} = \{0\}$, and hence $\mathcal{M}$ is 1-1.

To see that $\mathcal{M}$ is onto, let $v \otimes P(\lambda)$ with $v \in \mathbb{F}^k$ be an arbitrary element of $\mathcal{V}_P$. With $Z = v \otimes [A_k\ A_{k-1}, \dots, A_0]$, Lemma 2.5 shows that there exist block symmetric $X$ and $Y$ such that $X \boxplus\!\!\!\rightarrow Y = v \otimes [A_k\ A_{k-1}, \dots, A_0]$. Then by (3.3) we have $\mathcal{M}(\lambda X + Y) = v \otimes P(\lambda)$, showing that $\mathcal{M}$ is onto. □

### 3.2. Double ansatz pencils.

Our goal is now to show that $\mathbb{DL}(P) := \mathbb{L}_1(P) \cap \mathbb{L}_2(P) = \mathbb{B}(P)$. The inclusion $\mathbb{DL}(P) \subseteq \mathbb{B}(P)$, which says that all pencils $\lambda X + Y$ in $\mathbb{DL}(P)$ are block symmetric, can be deduced immediately from the following formulae for the blocks of $X$ and $Y$ in terms of the right ansatz vector $v$ [17, Thm. 5.3]:

$$
X_{ij} = v_{\max(i,j)} A_{k+1-\min(i,j)} + \sum_{\mu=1}^{\min(i-1,j-1)} \left(v_{j+i-\mu} A_{k+1-\mu} - v_\mu A_{k+1-j-i+\mu}\right),
$$

$$
Y_{ij} = \sum_{\mu=1}^{\min(i,j)} \left(v_\mu A_{k-j-i+\mu} - v_{j+i+1-\mu} A_{k+1-\mu}\right), \qquad i,j = 1\colon k.
$$

However, the derivation of these formulas is long and tedious. We present a shorter proof, based on first principles, of the stronger result $\mathbb{DL}(P) = \mathbb{B}(P)$.

LEMMA 3.2. [illegible] $P(\lambda)$ $\mathbb{B}(P) \subseteq \mathbb{DL}(P)$ [illegible] $L(\lambda) \in \mathbb{B}(P)$ [illegible]

[illegible]. For $L(\lambda) \in \mathbb{B}(P) \subset \mathbb{L}_1(P)$ with right ansatz vector $v$, we know from Theorem 2.2 that $L(\lambda)^{\mathcal{B}} = L(\lambda)$ is in $\mathbb{L}_2(P)$ with left ansatz vector $w = v$, and so $L(\lambda) \in \mathbb{DL}(P)$. □

Now we consider the special case of $\mathbb{DL}(P)$-pencils with $v = 0$, showing that in this case the left ansatz vector $w$ is forced to be 0 and the pencil is unique. Note that the definition of $\mathbb{DL}(P)$ does not require that $X$ and $Y$ are block symmetric, so we cannot appeal to Lemma 2.5 here.

LEMMA 3.3. [illegible] $L(\lambda) = \lambda X + Y \in \mathbb{DL}(P)$ [illegible] $v$ [illegible] $w$ [illegible] $v = 0$ [illegible] $w$ [illegible] 0 [illegible] $X = Y = 0$

[illegible]. We first show that the $\ell$th block column of $X$ and the $\ell$th coordinate of $w$ is zero for $\ell = 1\colon k$, by an induction on $\ell$.

Suppose that $\ell = 1$. From Lemma 2.4 we know that $X \boxplus\!\!\!\rightarrow Y = v \otimes [A_k\ A_{k-1}, \dots, A_0]$. Since $v = 0$ we have $X \boxplus\!\!\!\rightarrow Y = 0$, and hence the first block column of $X$ is zero. Now from Theorem 2.2, $L(\lambda)$ being in $\mathbb{L}_2(P)$ with left ansatz vector $w$ implies that $L(\lambda)^{\mathcal{B}} \in \mathbb{L}_1(P)$ with right ansatz vector $w$, which can be written in terms of the shifted sum as

$$X^{\mathcal{B}} \boxplus\!\!\rightarrow Y^{\mathcal{B}} = w \otimes [A_k\ A_{k-1}, \dots, A_0]. \tag{3.4}$$

The $(1,1)$-block of the right-hand side of (3.4) is $w_1 A_k$, while on the left-hand side the $(1,1)$-block of $X^{\mathcal{B}} \boxplus\!\!\rightarrow Y^{\mathcal{B}}$ is the same as the $(1,1)$-block of $X$. Hence $w_1 A_k = 0$. But the leading coefficient $A_k$ of $P(\lambda)$ is nonzero by assumption, so $w_1 = 0$.

Now suppose that the $\ell$th block column of $X$ is zero and that $w_\ell = 0$. Then by (3.4) the $\ell$th block row of $X^{\mathcal{B}} \boxplus\!\!\rightarrow Y^{\mathcal{B}}$ is zero. Since the $\ell$th block row of $X^{\mathcal{B}}$ is zero, the $\ell$th block row of $Y^{\mathcal{B}}$, or, equivalently, the $\ell$th block column of $Y$, must also be zero. Combining this with $X \boxplus\!\!\rightarrow Y = 0$ implies that the $(\ell+1)$st block column of $X$ is zero. Now equating the $(\ell+1, 1)$-blocks of both sides of (3.4) gives $w_{\ell+1} A_k = 0$, and hence $w_{\ell+1} = 0$. This concludes the induction, and shows that $X = 0$ and $w = 0$.

Finally, $X = 0$ and $X \boxplus\!\!\rightarrow Y = 0$ implies $Y = 0$, completing the proof. □

We can now characterize $\mathbb{DL}(P)$ and give a precise description of all right/left ansatz vector pairs $(v, w)$ that can be realized by some $\mathbb{DL}(P)$-pencil. The latter has already been done in [17, Thm. 5.3], but with a much longer derivation.

THEOREM 3.4. [illegible] $P(\lambda)$ [illegible] $k$ $\mathbb{DL}(P) = \mathbb{B}(P)$ [illegible] $L(\lambda) \in \mathbb{DL}(P)$ [illegible] $v$ [illegible] $w$ [illegible] $v = w$ [illegible] $L$ [illegible] $\dim \mathbb{DL}(P) = k$ [illegible] $v \in \mathbb{F}^k$ [illegible] $\mathbb{DL}(P)$

[illegible] Consider the linear map $\mathbb{DL}(P) \longrightarrow \mathbb{F}^k$ that associates to any pencil $L(\lambda) \in \mathbb{DL}(P)$ its right ansatz vector $v \in \mathbb{F}^k$. By Lemma 3.3 this map is injective, so that $\dim \mathbb{DL}(P) \le k$. But $\mathbb{B}(P) \subseteq \mathbb{DL}(P)$ by Lemma 3.2, and $\dim \mathbb{B}(P) = k$ by Theorem 3.1, so $\mathbb{B}(P) = \mathbb{DL}(P)$. The rest of the theorem follows from the properties of $\mathbb{B}(P)$ in Theorem 3.1 and Lemma 3.2. □

The equality $\mathbb{DL}(P) = \mathbb{B}(P)$ can be thought of as saying that the pencils in $\mathbb{DL}(P)$ are [illegible] structured: they have block symmetry as well as the eigenvector recovery properties that were the original motivation for their definition.

**3.3. The standard basis for $\mathbb{B}(P)$.** The isomorphism established in the proof of Theorem 3.1 immediately suggests the possibility that the basis for $\mathbb{B}(P)$ corresponding (via the map $\mathcal{M}$ in (3.2)) to the standard basis $\{e_1, \dots, e_k\}$ for $\mathbb{F}^k$ may be especially simple and useful. In this section we derive a general formula for these "standard basis pencils" in $\mathbb{B}(P)$ as a corollary of the shifted sum construction used in section 2 to build block symmetric solutions of the equation $X \boxplus\!\!\rightarrow Y = Z$. These pencils are of course also a basis for $\mathbb{DL}(P)$, since $\mathbb{DL}(P) = \mathbb{B}(P)$.

In light of Lemma 2.4, then, our goal is to construct for each $1 \le m \le k$ a block symmetric pencil $\lambda X_m + Y_m$ such that

$$X_m \boxplus\!\!\rightarrow Y_m \;=\; e_m \otimes [\, A_k\ A_{k-1}, \dots, A_0 \,]. \tag{3.5}$$

This is most easily done in two steps. First we show how to achieve the first $m$ block columns in the desired shifted sum, i.e., how to get $e_m \otimes [\, A_k, \dots, A_{k-m+1}\ \ 0, \dots, 0 \,]$. Then the last $k-m+1$ block columns $e_m \otimes [\, 0, \dots, 0\ A_{k-m}, \dots, A_1\ A_0 \,]$ are produced by a related but slightly different construction. We use the following notation for principal block submatrices, adapted from [12]: for a block $k \times k$ matrix $X$ and index set $\alpha \subseteq \{1, 2, \dots, k\}$, $X(\alpha)$ will denote the principal block submatrix lying in the block rows and block columns with indices in $\alpha$.

To get the first $m$ block columns in the desired shifted sum we repeatedly use the construction in (2.4) to build block $k \times k$ matrices $\widehat{X}_m$ and $\widehat{Y}_m$, embedding once in each of the principal block submatrices $\widehat{X}_m(\alpha_i)$ and $\widehat{Y}_m(\alpha_i)$ for the index sets $\alpha_i = \{i, i+1, \dots, m\}$, $i = 1\colon m$. Accumulating these embedded submatrices, we obtain

$$
\widehat{X}_m = \begin{array}{cl}
\begin{array}{ccccc} & & & m & \phantom{0} \end{array} & \\
\left[\begin{array}{cccc|c}
 & & & A_k & \\
 & & \iddots & A_{k-1} & \\
 & \iddots & \iddots & \vdots & 0 \\
\iddots & \iddots & & \vdots & \\
A_k & A_{k-1} & \cdots\cdots & A_{k-m+1} & \\ \hline
 & & & & \\
 & 0 & & & 0 \\
 & & & &
\end{array}\right] & \begin{array}{l} \\ \\ \\ \\ m, \\ \\ \\ \\ \end{array}
\end{array}
$$

$$
\widehat{Y}_m = -\begin{array}{cl}
\begin{array}{ccccc} & & & & m \end{array} & \\
\left[\begin{array}{ccccc|c}
 & & & A_k & 0 & \\
 & & \iddots & A_{k-1} & 0 & \\
 & \iddots & \iddots & \vdots & \vdots & 0 \\
A_k & A_{k-1} & \cdots & A_{k-m+2} & 0 & \\
0 & \cdots & \cdots & 0 & 0 & \\ \hline
 & & & & & \\
 & & 0 & & & 0 \\
 & & & & &
\end{array}\right] & \begin{array}{l} \\ \\ \\ \\ \\ m, \\ \\ \\ \\ \end{array}
\end{array}
$$

with the property that $\widehat{X}_m \boxplus\!\!\!\rightarrow \widehat{Y}_m = e_m \otimes [\, A_k, \dots, A_{k-m+1} \;\; 0, \dots, 0 \,]$.

To obtain the last $k-m+1$ columns we use the construction outlined in (2.5) and (2.6) $k-m+1$ times to build block $k \times k$ matrices $\widetilde{X}_m$ and $\widetilde{Y}_m$ , embedding once in each of the principal block submatrices $\widetilde{X}_m(\beta_j)$ and $\widetilde{Y}_m(\beta_j)$ for the index sets $\beta_j = \{m, m+1, \dots, j\}$, $j = m\colon k$, which yields

$$
\widetilde{X}_m = -\begin{array}{cl}
\begin{array}{cccccc} \phantom{0} & m & & & & k \end{array} & \\
\left[\begin{array}{c|ccccc}
0 & & & 0 & & \\ \hline
 & 0 & 0 & \cdots\cdots & & 0 \\
 & 0 & A_{k-m-1} & \iddots & A_1 & A_0 \\
0 & \vdots & \vdots & \iddots & \iddots & \\
 & \vdots & A_1 & \iddots & & \\
 & 0 & A_0 & & &
\end{array}\right] & \begin{array}{l} \\ \\ m, \\ \\ \\ \\ k \end{array}
\end{array}
$$

$$
\widetilde{Y}_m = \begin{array}{cl}
\begin{array}{ccccc} \phantom{0} & m & & & k \end{array} & \\
\left[\begin{array}{c|cccc}
0 & & & 0 & \\ \hline
 & A_{k-m} & \cdots\cdots & A_1 & A_0 \\
 & \vdots & & \iddots & A_0 \\
0 & \vdots & \iddots & \iddots & \\
 & A_1 & \iddots & & \\
 & A_0 & & &
\end{array}\right] & \begin{array}{l} \\ \\ m, \\ \\ \\ \\ k \end{array}
\end{array}
$$

satisfying $\widetilde{X}_m \boxplus\!\!\rightarrow \widetilde{Y}_m = e_m \otimes [\,0, \dots, 0\ A_{k-m}, \dots, A_1\ A_0\,]$. With $X_m := \widehat{X}_m + \widetilde{X}_m$ and $Y_m := \widehat{Y}_m + \widetilde{Y}_m$ we have $X_m \boxplus\!\!\rightarrow Y_m = e_m \otimes [\,A_k\ A_{k-1}, \dots, A_1\ A_0\,]$, so $\lambda X_m + Y_m$ is the $m$th standard basis pencil for $\mathbb{B}(P)$.

A more concise way to express the $m$th standard basis pencil uses the following block Hankel matrices. Let $\mathcal{L}_j(P(\lambda))$ denote the lower block antitriangular, block Hankel, block $j \times j$ matrix

$$\mathcal{L}_j(P(\lambda)) := \begin{bmatrix} & & & A_k \\ & & \cdot^{\cdot^{\cdot}} & A_{k-1} \\ & \cdot^{\cdot^{\cdot}} & \cdot^{\cdot^{\cdot}} & \vdots \\ A_k & A_{k-1} & \dots & A_{k-j+1} \end{bmatrix} \tag{3.6}$$

formed from the first $j$ matrix coefficients $A_k, A_{k-1}, \dots, A_{k-j+1}$ of $P(\lambda)$. Similarly, let $\mathcal{U}_j(P(\lambda))$ denote the upper block antitriangular, block Hankel, block $j \times j$ matrix

$$\mathcal{U}_j(P(\lambda)) := \begin{bmatrix} A_{j-1} & \dots & A_1 & A_0 \\ \vdots & \cdot^{\cdot^{\cdot}} & \cdot^{\cdot^{\cdot}} & \\ A_1 & \cdot^{\cdot^{\cdot}} & & \\ A_0 & & & \end{bmatrix} \tag{3.7}$$

formed from the last $j$ matrix coefficients $A_{j-1}, A_{j-2}, \dots, A_1, A_0$ of $P(\lambda)$. Then the block symmetric matrices $X_m$ and $Y_m$ in the $m$th standard basis pencil ($m = 1\colon k$) can be neatly expressed as direct sums of block Hankel matrices:

$$X_m = X_m(P(\lambda)) = \begin{bmatrix} \mathcal{L}_m(P(\lambda)) & 0 \\ 0 & -\mathcal{U}_{k-m}(P(\lambda)) \end{bmatrix}, \tag{3.8a}$$

$$Y_m = Y_m(P(\lambda)) = \begin{bmatrix} -\mathcal{L}_{m-1}(P(\lambda)) & 0 \\ 0 & \mathcal{U}_{k-m+1}(P(\lambda)) \end{bmatrix}. \tag{3.8b}$$

($\mathcal{L}_j$ and $\mathcal{U}_j$ are taken to be void when $j = 0$.) From (3.8) it now becomes obvious that the coefficient matrices in successive standard basis pencils are closely related:

$$Y_m(P(\lambda)) \;=\; -X_{m-1}(P(\lambda)), \qquad m = 1\colon k. \tag{3.9}$$

Thus we have the following explicit formula for the standard basis pencils in $\mathbb{B}(P)$.

THEOREM 3.5. [illegible] $P(\lambda)$ [illegible] $k$ [illegible] $m = 1\colon k$ [illegible] $\mathbb{B}(P)$ [illegible] $e_m$ [illegible] $\lambda X_m - X_{m-1}$ [illegible] $X_m$ [illegible] (3.8a)

The standard basis pencils in $\mathbb{B}(P)$ for general polynomials of degree 2 and 3 are listed in Tables 3.1 and 3.2, where the partitioning from (3.8) is shown in each

TABLE 3.1

case. As an immediate consequence we have, for the important case of quadratics $P(\lambda) = \lambda^2 A + \lambda B + C$, the following description of all block symmetric pencils in $\mathbb{L}_1(P)$:

$$\mathbb{B}(P) = \left\{ L(\lambda) = \lambda \begin{bmatrix} v_1 A & v_2 A \\ v_2 A & v_2 B - v_1 C \end{bmatrix} + \begin{bmatrix} v_1 B - v_2 A & v_1 C \\ v_1 C & v_2 C \end{bmatrix} \; : \; v \in \mathbb{C}^2 \right\}.$$

## 4. Other constructions of block symmetric linearizations.

Several other methods for constructing block symmetric linearizations of matrix polynomials have appeared previously in the literature.

Antoniou and Vologiannidis [1] have recently found new companion-like linearizations for general matrix polynomials $P$ by generalizing Fiedler's results [7] on a factorization of the companion matrix of a scalar polynomial and certain of its permutations. From this finite family of $\frac{1}{6}(2 + \deg P)!$ pencils, all of which are linearizations, they identify one distinguished pencil that is Hermitian whenever $P$ is Hermitian. But this example has structure even for general $P$: it is block symmetric. Indeed, it provides a simple example of a block symmetric linearization for $P(\lambda)$ that is not in $\mathbb{B}(P)$. In the case of a cubic polynomial $P(\lambda) = \lambda^3 A + \lambda^2 B + \lambda C + D$, the pencil is

$$L(\lambda) = \lambda \begin{bmatrix} A & 0 & 0 \\ 0 & 0 & I \\ 0 & I & C \end{bmatrix} + \begin{bmatrix} B & -I & 0 \\ -I & 0 & 0 \\ 0 & 0 & D \end{bmatrix}. \tag{4.1}$$

Using the column-shifted sum it is easy to see that $L(\lambda)$ is not in $\mathbb{L}_1(P)$, and hence not in $\mathbb{B}(P)$.

Contrasting with the "permuted factors" approach of [1], [7] and the additive construction used in this paper, is a third "multiplicative" method for generating block symmetric linearizations described by Lancaster in [14], [15]. In [14] only scalar polynomials $p(\lambda) = a_k\lambda^k + \cdots + a_1\lambda + a_0$ are considered; the starting point is the companion matrix of $p(\lambda)$,

$$C = \begin{bmatrix} -a_k^{-1} & & & \\ & 1 & & \\ & & \ddots & \\ & & & 1 \end{bmatrix} \begin{bmatrix} a_{k-1} & a_{k-2} & \dots & a_0 \\ 1 & 0 & \dots & 0 \\ & \ddots & \ddots & \vdots \\ 0 & & 1 & 0 \end{bmatrix}, \tag{4.2}$$

and the associated pencil $\lambda I - C$. Lancaster's idea is to seek a nonsingular symmetric matrix $B$ such that $BC$ is symmetric, thus providing a symmetric linearization $B(\lambda I - C) = \lambda B - BC$ for $p(\lambda)$. That such a $B$ can always be found follows from a standard result in matrix theory [12, Cor. 4.4.11]. Lancaster shows further that $B$ and $BC$ symmetric imply $BC^j$ is symmetric for all $j \geq 1$; thus $BC^{j-1}(\lambda I - C) = \lambda BC^{j-1} - BC^j$ is a symmetric pencil for any $j \geq 1$, and for $j \geq 2$ it is a linearization of $p(\lambda)$ if $a_0 \neq 0$. This strategy is realized in [14] with the particular choice of symmetric (Hankel) matrix

$$B = \begin{bmatrix} & & & a_k \\ & & \iddots & a_{k-1} \\ & \iddots & \iddots & \vdots \\ a_k & a_{k-1} & \dots & a_1 \end{bmatrix}, \tag{4.3}$$

which is nonsingular since $a_k \neq 0$, and it is observed that this particular $B$ gives symmetric pencils $\lambda BC^{j-1} - BC^j$ with an especially simple form for $1 \leq j \leq k$, though apparently with a much more complicated form for $j > k$.

It is easy to see that these symmetric pencils, constructed for scalar polynomials $p(\lambda)$, can be immediately extended to block symmetric pencils for general matrix polynomials $P(\lambda)$ simply by formally replacing the scalar coefficients of $p(\lambda)$ in $B, BC, BC^2, \dots$ by the matrix coefficients of $P(\lambda)$. This has been done in [15, sect. 4.2] and [8]. Garvey et al. [8] go even further with these block symmetric pencils, using them as a foundation for defining a new class of isospectral transformations on matrix polynomials.

Since Lancaster's construction of pencils is so different from ours there is no a priori reason to expect any connection between his pencils and the pencils in $\mathbb{DL}(P)$. The next result shows, rather surprisingly, that the first $k$ pencils in Lancaster's sequence generate $\mathbb{DL}(P)$.

THEOREM 4.1. [illegible] $P(\lambda)$ [illegible] $k$ [illegible] $\lambda BC^{k-m} - BC^{k-m+1}$ [illegible] $B$ [illegible] $C$ [illegible] (4.2) [illegible] (4.3) [illegible] $\lambda X_m - X_{m-1}$ [illegible] $m$ [illegible] $\mathbb{DL}(P)$ [illegible] $m = 1\colon k$

[illegible]. We have to show that $X_m = BC^{k-m}$, $m = 0\colon k$, where $X_m$ is given by (3.8a). For notational simplicity we will carry out the proof for a scalar polynomial; the same proof applies to a matrix polynomial with only minor changes in notation. The $m = k$ case, $X_k(p(\lambda)) = \mathcal{L}_k(p(\lambda)) = B$, is immediate from (3.6), (3.8), and (4.3). The rest follow inductively (downward) from the relation $X_{m-1}(p(\lambda)) = X_m(p(\lambda)) \cdot C$, which we now proceed to show holds for $m = 1\colon k$.

To see that $X_m C = X_{m-1}$, or equivalently that

$$\begin{bmatrix} \mathcal{L}_m(p(\lambda)) & 0 \\ 0 & -\mathcal{U}_{k-m}(p(\lambda)) \end{bmatrix} C = \begin{bmatrix} \mathcal{L}_{m-1}(p(\lambda)) & 0 \\ 0 & -\mathcal{U}_{k-m+1}(p(\lambda)) \end{bmatrix}$$

holds for $1 \leq m \leq k$, it will be convenient to rewrite the companion matrix (4.2) in the form

$$C = N_k^T - a_k^{-1} \begin{bmatrix} a_{k-1} & a_{k-2} & \dots & a_0 \\ 0 & 0 & \dots & 0 \\ \vdots & \vdots & & \vdots \\ 0 & 0 & \dots & 0 \end{bmatrix} = N_k^T - a_k^{-1} e_1 \begin{bmatrix} a_{k-1} & a_{k-2} & \dots & a_0 \end{bmatrix},$$

where $N_k$ is defined in (2.1). Then

$$\begin{aligned} X_m(p(\lambda))C &= X_m(p(\lambda))N_k^T - a_k^{-1}X_m(p(\lambda))\, e_1 \begin{bmatrix} a_{k-1} & a_{k-2} & \dots & a_0 \end{bmatrix} \\ &= \begin{bmatrix} \mathcal{L}_m(p(\lambda)) & 0 \\ 0 & -\mathcal{U}_{k-m}(p(\lambda)) \end{bmatrix} N_k^T - e_m \begin{bmatrix} a_{k-1} & a_{k-2} & \dots & a_0 \end{bmatrix}. \end{aligned}$$

In the first term, postmultiplication by $N_k^T$ has the effect of shifting the columns to the left by one (and losing the first column), thus giving

$$\begin{aligned} X_m(p(\lambda))C &= \begin{bmatrix} \mathcal{L}_{m-1}(p(\lambda)) & 0 & 0 \\ a_{k-1} \dots a_{k-m+1} & 0 & 0 \\ 0 & -\mathcal{U}_{k-m}(p(\lambda)) & 0 \end{bmatrix} \\ &\quad - \begin{bmatrix} 0 & 0 & 0 \\ a_{k-1} \dots a_{k-m+1} & a_{k-m} \dots a_1 & a_0 \\ 0 & 0 & 0 \end{bmatrix} \\ &= \left[\begin{array}{c|cc} \mathcal{L}_{m-1}(p(\lambda)) & 0 & 0 \\ \hline 0 & -a_{k-m} \dots -a_1 & -a_0 \\ 0 & -\mathcal{U}_{k-m}(p(\lambda)) & 0 \end{array}\right] \\ &= \begin{bmatrix} \mathcal{L}_{m-1}(p(\lambda)) & 0 \\ 0 & -\mathcal{U}_{k-m+1}(p(\lambda)) \end{bmatrix} = X_{m-1}(p(\lambda)). \end{aligned}$$

This completes the inductive step of the proof. □

**5. Symmetric pencils in $\mathbb{L}_1(P)$ for symmetric $P$.** We now return to the problem that originally motivated the investigation in this paper, that of systematically finding large sets of symmetric linearizations for symmetric polynomials, $P(\lambda) = P(\lambda)^T$. Our strategy is first to characterize the set

$$\mathbb{S}(P) := \left\{ \lambda X + Y \in \mathbb{L}_1(P) : X^T = X,\, Y^T = Y \right\} \tag{5.1}$$

of all symmetric pencils in $\mathbb{L}_1(P)$ when $P$ is symmetric, and then later in section 7 to show that almost all of these symmetric pencils are indeed linearizations for $P$.

We begin with a result for symmetric polynomials reminiscent of Theorem 2.2, but using transpose rather than block transpose.

Lemma 5.1. [illegible] $P(\lambda)$ [illegible] $L(\lambda) \in \mathbb{L}_1(P)$ [illegible] $v$ [illegible] $L^T(\lambda) \in \mathbb{L}_2(P)$ [illegible] $w = v$ [illegible] $L(\lambda) \in \mathbb{L}_2(P)$ [illegible] $v$ [illegible] $L^T(\lambda) \in \mathbb{L}_1(P)$ [illegible] $v$

[illegible]. Suppose $L(\lambda) \in \mathbb{L}_1(P)$ with right ansatz vector $v$. Then

$$\big(L(\lambda)(\varLambda \otimes I)\big)^T = \big(v \otimes P(\lambda)\big)^T \Longrightarrow (\varLambda^T \otimes I)L^T(\lambda) = v^T \otimes P(\lambda).$$

Thus $L^T(\lambda) \in \mathbb{L}_2(P)$ with left ansatz vector $v$. The proof of the second statement is analogous. □

We characterize the space $\mathbb{S}(P)$ in the next result by relating it to the previously developed space $\mathbb{DL}(P)$, which we already know equals $\mathbb{B}(P)$.

Theorem 5.2. [illegible] $P(\lambda)$ $\mathbb{S}(P) = \mathbb{DL}(P)$

[illegible] Suppose $L(\lambda) \in \mathbb{S}(P) \subseteq \mathbb{L}_1(P)$ with right ansatz vector $v$. Then by Lemma 5.1 we know that $L^T(\lambda) = L(\lambda)$ is in $\mathbb{L}_2(P)$ with left ansatz vector $v$, and so $L(\lambda) \in \mathbb{DL}(P)$. Thus $\mathbb{S}(P) \subseteq \mathbb{DL}(P)$.

By Lemma 5.1, $L(\lambda) \in \mathbb{DL}(P)$ with right/left ansatz vector $v$ implies that $L^T(\lambda) \in \mathbb{DL}(P)$ with left/right ansatz vector $v$. But by Theorem 3.4 pencils in $\mathbb{DL}(P)$ are uniquely determined by their ansatz vector, so $L(\lambda) \equiv L^T(\lambda)$, and hence $\mathbb{DL}(P) \subseteq \mathbb{S}(P)$. Therefore $\mathbb{DL}(P) = \mathbb{S}(P)$. ☐

Once again one may refer to Tables 3.1 and 3.2 for examples of what are in effect [illegible] structured pencils whenever $P$ is symmetric. Recall, however, that there are symmetric linearizations for $P$ that are not in $\mathbb{S}(P)$: $L$ in (4.1) is not in $\mathbb{S}(P)$, but is a symmetric linearization for any symmetric cubic $P$.

## 6. Hermitian pencils in $\mathbb{L}_1(P)$ for Hermitian $P$.

For a Hermitian matrix polynomial $P(\lambda)$ of degree $k$, that is, $P(\lambda)^* = P(\overline{\lambda})$, let

$$\mathbb{H}(P) := \left\{ \lambda X + Y \in \mathbb{L}_1(P) : X^* = X,\ Y^* = Y \right\} \tag{6.1}$$

denote the set of all Hermitian pencils in $\mathbb{L}_1(P)$. A priori the right ansatz vector $v$ of a pencil in $\mathbb{H}(P)$ might be any vector in $\mathbb{C}^k$, since $P$ is a complex polynomial. However, we will see that any such $v$ must in fact be real, and furthermore that any Hermitian pencil in $\mathbb{L}_1(P)$ must be in $\mathbb{DL}(P)$.

THEOREM 6.1. [illegible] $P(\lambda)$ [illegible] $\mathbb{H}(P)$ [illegible] $\mathbb{DL}(P)$ [illegible] $v \in \mathbb{R}^k$ [illegible] $\mathbb{H}(P)$

[illegible] Suppose $L(\lambda) \in \mathbb{H}(P) \subset \mathbb{L}_1(P)$ with right ansatz vector $v$, so that $L(\lambda)(\Lambda \otimes I) = v \otimes P(\lambda)$. Then, since $P$ and $L$ are Hermitian,

$$\big(L(\lambda)(\Lambda \otimes I)\big)^* = \big(v \otimes P(\lambda)\big)^* \Longrightarrow (\overline{\Lambda}^T \otimes I)L(\overline{\lambda}) \;=\; \overline{v}^T \otimes P(\overline{\lambda}).$$

This last equation holds for all $\lambda$, so we may replace $\overline{\lambda}$ by $\lambda$ to get $(\Lambda^T \otimes I)L(\lambda) = \overline{v}^T \otimes P(\lambda)$, so that $L(\lambda) \in \mathbb{L}_2(P)$ with left ansatz vector $w = \overline{v}$. Thus $L(\lambda) \in \mathbb{DL}(P)$ and $\mathbb{H}(P) \subseteq \mathbb{DL}(P)$. But by Theorem 3.4 the right and left ansatz vectors of any $\mathbb{DL}(P)$-pencil must be equal. So $v = \overline{v}$, which means $v \in \mathbb{R}^k$.

Conversely, for an arbitrary $v \in \mathbb{R}^k$ let $H(\lambda)$ be the unique pencil in $\mathbb{DL}(P)$ with right/left ansatz vector $v$. By arguments analogous to those used in Lemma 5.1 it is straightforward to show that for Hermitian $P$, $L(\lambda) \in \mathbb{DL}(P)$ with any right/left ansatz vector $v \in \mathbb{C}^k$ implies that $L^*(\lambda) := \lambda X^* + Y^* \in \mathbb{DL}(P)$ with left/right ansatz vector $\overline{v}$. But $H(\lambda)$ has a real ansatz vector $v$, so $H^*(\lambda) \in \mathbb{DL}(P)$ with exactly the same ansatz vector $v$. Thus the uniqueness of $\mathbb{DL}(P)$-pencils established in Theorem 3.4 implies that $H(\lambda) \equiv H^*(\lambda)$, i.e., $H(\lambda) \in \mathbb{H}(P)$. ☐

## 7. Almost all pencils in $\mathbb{B}(P)$, $\mathbb{DL}(P)$, $\mathbb{S}(P)$, and $\mathbb{H}(P)$ are linearizations.

The remaining fundamental issue is the question of which pencils in the subspaces $\mathbb{B}(P)$, $\mathbb{DL}(P)$, $\mathbb{S}(P)$, and $\mathbb{H}(P)$ are actually linearizations for $P$ when $P$ is regular. Some answers to this question are already known. First, a pencil $L$ in $\mathbb{L}_1(P)$ or $\mathbb{L}_2(P)$ is a linearization precisely when $L$ is a regular pencil [17, Thm. 4.3]. Second, for each of $\mathbb{L}_1(P)$, $\mathbb{L}_2(P)$, and $\mathbb{DL}(P)$ it is known that almost all pencils are linearizations, where "almost all" means all except for a closed, nowhere dense set of measure zero [17, Thms. 4.7, 6.8]. Because of Theorems 3.4 and 5.2, the same conclusion follows immediately for $\mathbb{B}(P)$, and for $\mathbb{S}(P)$ when $P$ is symmetric. However, for $\mathbb{H}(P)$ the possible ansatz vectors lie in $\mathbb{R}^k$, a closed, nowhere dense set of measure zero in $\mathbb{C}^k$

(the ansatz vector set of $\mathbb{DL}(P)$ when $P$ is Hermitian), so we cannot immediately deduce an "almost all" result for $\mathbb{H}(P)$. Some further analysis is therefore needed.

To a vector $v = [v_1, v_2, \dots, v_k]^T \in \mathbb{F}^k$ associate the scalar polynomial

$$\mathsf{p}(x; v) = v_1 x^{k-1} + v_2 x^{k-2} + \cdots + v_{k-1} x + v_k,$$

referred to as the "$\mathsf{v}$-polynomial" of the vector $v$. We adopt the convention that $\mathsf{p}(x; v)$ has a root at $\infty$ whenever $v_1 = 0$. The following result provides a condition that $L \in \mathbb{DL}(P)$ be a linearization of $P$.

Theorem 7.1 (eigenvalue exclusion theorem [17, Thm. 6.7]). [illegible] $P(\lambda)$ [illegible] $L(\lambda) \in \mathbb{DL}(P)$ [illegible] $v$ [illegible] $L(\lambda)$ [illegible] $P(\lambda)$ [illegible] $\mathsf{v}$ [illegible] $\mathsf{p}(x; v)$ [illegible] $P(\lambda)$

With the aid of this result we can establish the desired genericity statement.

Theorem 7.2 (linearizations are generic in $\mathbb{H}(P)$). [illegible] $P(\lambda)$ [illegible] $v \in \mathbb{R}^k$ [illegible] $\mathbb{H}(P)$ [illegible]

[illegible] Recall that the resultant $\operatorname{res}(f, g)$ of two polynomials $f(x)$ and $g(x)$ is a polynomial in the coefficients of $f$ and $g$ with the property that $\operatorname{res}(f, g) = 0$ if and only if $f(x)$ and $g(x)$ have a common (finite) root [22, p. 248], [26]. Now consider $r = \operatorname{res}\bigl(\mathsf{p}(x; v), \det P(x)\bigr)$, which, because $P$ is Hermitian and fixed, can be viewed as a real polynomial $r(v_1, v_2, \dots, v_k)$ in the components of $v \in \mathbb{R}^k$. The zero set $\mathcal{Z}(r) = \bigl\{ v \in \mathbb{R}^k : r(v_1, v_2, \dots, v_k) = 0 \bigr\}$, then, is exactly the set of all $v \in \mathbb{R}^k$ for which some finite root of $\mathsf{p}(x; v)$ is an eigenvalue of $P(\lambda)$. Recall that by our convention the $\mathsf{v}$-polynomial $\mathsf{p}(x; v)$ has $\infty$ as a root exactly for $v \in \mathbb{R}^k$ lying in the hyperplane $v_1 = 0$. Thus by Theorem 7.1 the set of vectors $v \in \mathbb{R}^k$ for which the corresponding pencil $L(\lambda) \in \mathbb{H}(P) \subset \mathbb{DL}(P)$ is [illegible] a linearization of $P(\lambda)$ is either the proper (real) algebraic set $\mathcal{Z}(r)$, or the union of two proper (real) algebraic sets, $\mathcal{Z}(r)$ and the hyperplane $v_1 = 0$. But the union of any finite number of proper (real) algebraic sets is always a closed, nowhere dense set of measure zero in $\mathbb{R}^k$. ☐

## 8. Conclusions.

We have revisited $\mathbb{DL}(P)$, the space of double ansatz pencils introduced in [17], proving that it is the same as the set of block symmetric pencils in the right ansatz space $\mathbb{L}_1(P)$. Our alternative characterization of $\mathbb{DL}(P)$ shows that even unstructured matrix polynomials admit linearizations that are symmetric at the block level, while simultaneously possessing the $\mathbb{DL}(P)$ property of revealing both left and right eigenvectors of $P$.

Our analysis shows how to find all the symmetric pencils in $\mathbb{L}_1(P)$ for a symmetric matrix polynomial $P$: these are precisely the pencils in $\mathbb{DL}(P)$. For Hermitian $P$, the Hermitian pencils in $\mathbb{L}_1(P)$ correspond to the double ansatz pencils that have a real ansatz vector. Almost all pencils in each of these vector spaces have been shown to be linearizations.

**Acknowledgment.** We thank the referees for perceptive comments that led to an improvement in the presentation.

# A NEW ITERATIVE CRITERION FOR *H*-MATRICES*

M. ALANELLI† AND A. HADJIDIMOS†

**Abstract.** *H*-matrices appear in many areas of science and engineering, e.g., in the solution of the linear complementarity problem (LPC) in optimization theory and in the solution of large systems for real time changes of data in fluid analysis in the car industry. Classical (stationary) iterative methods used for the solution of linear systems have been shown to converge for this class of matrices. Several authors have proposed direct and iterative criteria to identify whether a certain matrix $A \in \mathbb{C}^{n,n}$ is an *H*-matrix. Based on previous and new ideas we propose a new iterative algorithm for irreducible matrices $A$ that, except in a "very special" case, decides whether $A$ is an *H*- or a non *H*-matrix. A MATLAB subroutine is given and numerical examples are provided in support of the theory developed.

**Key words.** *M*- and *H*-matrices, (generalized) strictly diagonally dominant matrices, criteria for *H*-matrices

## 1. Introduction.

In numerical linear algebra, the theory of *M*- and *H*-matrices is very important for the solution of linear systems of algebraic equations by iterative methods (see, e.g., [2], [12], [24], and [26]). For example, (a) in the linear complementarity problem (LCP) [1] (see also section 10.1 of [2] for specific applications), where we are interested in finding a $z \in \mathbb{R}^n$ such that $z \geq 0$, $Mz + q \geq 0$, $z^T(Mz+q) = 0$, with $M \in \mathbb{R}^{n,n}$ and $q \in \mathbb{R}^n$ given, a sufficient condition for a solution to exist, and to be found by a modification of an iterative method, especially of SOR, is that $M$ is an *H*-matrix, with $m_{ii} > 0$, $i = 1(1)n$ [1]; (b) in fluid analysis, in the car modeling design [23], [18], it was observed that large linear systems with an *H*-matrix coefficient $A$ are solved iteratively much faster if $A$ is postmultiplied by a suitable diagonal matrix $D$, with $d_{ii} > 0$, $i = 1(1)n$, so that $AD$ is [illegible]. Although an *H*-matrix can be defined via the definition for an *M*-matrix, which will be given later on, in what follows and in the algorithms that will be presented we mostly use the following definition.

DEFINITION 1.1. [illegible] $A \in \mathbb{C}^{n,n}$ [illegible] $H$ [illegible] $D$, [illegible] $AD$ [illegible] row-wise strictly diagonally dominant

[illegible] (i) If there exists a diagonal matrix $D$ satisfying Definition 1.1 for a given $A$, there exist infinitely many $D$'s and their set is denoted by $\mathfrak{D}_A$. (ii) An *H*-matrix is also called a [illegible]. (iii) Note that Definition 1.1 for an *H*-matrix $A$ implies that $A$ is nonsingular; this is consistent with the original definition by Ostrowski [20] (see also [24]).

We remind the reader of the following definition.

DEFINITION 1.2. [illegible] $X \in \mathbb{C}^{n,n}$ [illegible] (row-wise) strictly diagonally

dominant [illegible]

$$|x_{ii}| > \sum_{j=1,\ j\neq i}^{n} |x_{ij}|,\ i = 1(1)n. \tag{1.1}$$

In what follows we are to use for a matrix the terms [illegible] and [illegible]. For these terms we give the following definition.

DEFINITION 1.3. [illegible] $A \in \mathbb{C}^{n,n}$ [illegible] reducible [illegible] $P \in \mathbb{R}^{n,n}$ [illegible]

$$PAP^T = \begin{bmatrix} A_{11} & A_{12} \\ O & A_{22} \end{bmatrix},$$

[illegible] $A_{11} \in \mathbb{C}^{r,r},\ 1 \le r \le n-1,$ [illegible] $O \in \mathbb{C}^{n-r,r}$ [illegible] not [illegible] $A$ [illegible] irreducible

Knowing that a matrix $A \in \mathbb{C}^{n,n}$ is an $H$-matrix guarantees that many iterative methods applied for the solution of the linear system $Ax = b,\ b \in \mathbb{C}^n$, possess nice convergence properties. The majority of the proposed identification criteria are iterative (see, e.g., [10], [16], [15], [17], [19], and [9]) because direct ones (see, e.g., [7], [13], [8], [6], and [4]) have high computational complexities. For example, one may argue that for this identification of $A \in \mathbb{C}^{n,n}$ a simple direct criterion would be "find the inverse of its [illegible] matrix and check if its entries are nonnegative." However, such a criterion requires $\mathcal{O}(n^3)$ floating point operations for a large dense matrix compared to $\mathcal{O}(n^2)$ per iteration for an iterative method, while for a large sparse matrix, e.g., a tridiagonal whose inverse of its [illegible], as is known, is dense, the cost is $\mathcal{O}(n^2)$ compared to $\mathcal{O}(n)$ per iteration. By the way, the only iterative criterion that takes advantage of the sparsity of $A$, as this is the case in almost all applications, is the one proposed in [9], where an extension of the compact profile technique of [14] was developed. This criterion is much cheaper compared to any of the direct or even iterative criteria.

In this work we focus on the three algorithms in [16], [17], and [19] denoted by $\mathbb{H}$, $\mathbb{L}$, and $\mathbb{B}$, respectively. In section 2, some introductory notation is given, the three algorithms are presented, and we show, by giving a number of examples, that there are cases where Algorithms $\mathbb{L}$ and $\mathbb{B}$ [illegible] converge as it was claimed. In section 3, a number of statements needed in what follows are given and some of them are proved. In section 4, by using the theory in section 3, we propose a new Jacobi-type iterative criterion for identifying $H$-matrices in pseudocode (Algorithm $\mathbb{AH}$). The convergence of the new algorithm is proved mainly for [illegible] matrices. Finally, in section 5, we implement it to a MATLAB function, present a number of numerical examples, and conclude with a couple of points.

## 2. Preliminaries, the three algorithms, and comments.

In this section we present some introductory notation, the two mathematically documented algorithms $\mathbb{H}$ in [16] and $\mathbb{L}$ in [17] and also $\mathbb{B}$ in [19], and make some comments regarding the convergence of the last two. Each of the algorithms has been slightly modified, as regards the notation, so that their similarities and differences are readily distinguished.

For the aforementioned algorithms the following matrices are defined: First, the sequence of positive diagonal matrices

$$D^{(k)},\ k = 0, 1, 2, \ldots,\quad D^{(0)} = I, \tag{2.1}$$

and also the matrices

$$A^{(k)} = A^{(k-1)}D^{(k-1)},\ k = 1, 2, 3, \ldots,\quad A^{(0)} = A, \tag{2.2}$$

for Algorithms $\mathbb{H}$ and $\mathbb{L}$, while

$$A^{(k)} = \left(D^{(k-1)}\right)^{-1} A^{(k-1)}D^{(k-1)},\ k = 1, 2, 3, \ldots,\quad A^{(0)} = (\operatorname{diag}(A))^{-1} A, \tag{2.3}$$

for Algorithm $\mathbb{B}$. From the definitions in (2.1) and (2.3), it is concluded that for Algorithm $\mathbb{B}$ there holds

$$a_{ii}^{(k)} = 1,\ i = 1(1)n,\ k = 0, 1, 2, \ldots. \tag{2.4}$$

Let $\mathbb{N} := \{1, 2, \ldots, n\}$ and

$$s_i^{(k)} = \sum_{j=1,\ j\neq i}^{n} |a_{ij}^{(k)}|,\ i = 1(1)n,\ k = 0, 1, 2, \ldots. \tag{2.5}$$

Let also

$$\mathbb{N}_1^{(k)} \equiv \mathbb{N}_1(A^{(k)}) := \left\{ i \in \mathbb{N} : |a_{ii}^{(k)}| > s_i^{(k)} \right\},$$

and $n_1^{(k)} \equiv n_1(A^{(k)})$ be its cardinality.

```
ALGORITHM ℍ.
INPUT: A matrix $A := [a_{ij}] \in \mathbb{C}^{n,n}$ and any $\varepsilon > 0$.
OUTPUT: $D = D^{(0)}D^{(1)} \cdots D^{(k)} \in \mathfrak{D}_A$ if $A$ an $H$-matrix.
1. If $\mathbb{N}_1(A) = \emptyset$ or $a_{ii} = 0$ for some $i \in \mathbb{N}$, "$A$ is an $H$-matrix," STOP; Otherwise
2. Set $A^{(0)} = A,\ D^{(0)} = I,\ k = 1$
3. Compute $A^{(k)} = A^{(k-1)}D^{(k-1)} = [a_{ij}^{(k)}]$
4. Compute $s_i^{(k)} = \sum_{j=1,\ j\neq i}^{n} |a_{ij}^{(k)}|,\ i = 1(1)n$, Update $\mathbb{N}_1^{(k)}$ and $n_1^{(k)}$
5. If $n_1^{(k)} = n$, "$A$ an $H$-matrix," STOP; Otherwise
6. Set $d = [d_i]$, where
       $d_i = \begin{cases} \frac{s_i^{(k)}+\varepsilon}{|a_{ii}^{(k)}|+\varepsilon} & \text{if } i \in \mathbb{N}_1^{(k)}, \\ 1 & \text{if } i \notin \mathbb{N}_1^{(k)} \end{cases}$
7. Set $D^{(k)} = \operatorname{diag}(d),\ k = k + 1$; Go to Step 3.
```

ALGORITHM 𝕃.
INPUT: A matrix $A := [a_{ij}] \in \mathbb{C}^{n,n}$ and any $\varepsilon > 0$.
OUTPUT: $D = D^{(0)}D^{(1)} \cdots D^{(k)} \in \mathfrak{D}_A$ or $\notin \mathfrak{D}_A$ if $A$ or is an $H$-matrix, respectively.
1. If $a_{ii} = 0$ for some $i \in \mathbb{N}$, "$A$ is an $H$-matrix," STOP; Otherwise
2. Set $A^{(0)} = A,\ D^{(0)} = I,\ k = 1$
3. Compute $A^{(k)} = A^{(k-1)}D^{(k-1)} = [a_{ij}^{(k)}]$
4. Compute $s_i^{(k)} = \sum_{j=1,\ j\neq i}^{n} |a_{ij}^{(k)}|,\ i = 1(1)n$, Set $n_1^{(k)} = 0$
5. If $|a_{ii}^{(k)}| > s_i^{(k)}$, $n_1^{(k)} = n_1^{(k)} + 1,\ i = 1(1)n$
6. If $n_1^{(k)} = n$, "$A$ an $H$-matrix," STOP; Otherwise
```

7. If $n_1^{(k)} = 0$, "$A$ is [illegible] an $H$-matrix," STOP; Otherwise
8. Set $d = [d_i]$, where

$$d_i \;=\; \frac{s_i^{(k)} + \varepsilon}{|a_{ii}^{(k)}| + \varepsilon},\ i = 1(1)n$$

9. Set $D^{(k)} =$ diag$(d)$, $k = k + 1$; Go to Step 3.

ALGORITHM $\mathbb{B}$.

INPUT: A matrix $A := [a_{ij}] \in \mathbb{C}^{n,n}$.
OUTPUT: $D = D^{(0)}D^{(1)} \cdots D^{(k)} \in \mathfrak{D}_{D^{-1}A} \equiv \mathfrak{D}_A$ or $\notin \mathfrak{D}_A$ if $A$ [illegible] or is [illegible] an $H$-matrix, respectively
1. If $\mathbb{N}_1(A) = \emptyset$ or $a_{ii} = 0$ for some $i \in \mathbb{N}$, "$A$ is [illegible] an $H$-matrix," STOP; Otherwise
2. Compute $s_i \;=\; \sum_{j=1,=\ j\neq i}^{n} |a_{ij}|,\ i = 1(1)n$
3. If $s_i \;= 0,\ i = 1(1)n$, "$A$ [illegible] an $H$-matrix," STOP; Otherwise
4. Set $A^{(0)} = (\text{diag}(A))^{-1} A,\ D^{(0)} = I,\ k = 1$
5. Compute $A^{(k)} \;=\; \left(D^{(k-1)}\right)^{-1} A^{(k-1)} D^{(k-1)} \;=\; [a_{ij}^{(k)}]$
6. Compute $s_i^{(k)} \;=\; \sum_{j=1,\ j\neq i}^{n} |a_{ij}^{(k)}|,\ i = 1(1)n$
7. If $s_i^{(k)} \;\leq\; 1,\ i = 1(1)n$, and $s_i^{(k)} < 1$ for at least one $i \in \mathbb{N}$, "$A$ [illegible] an $H$-matrix," STOP; Otherwise
8. If $s_i^{(k)} \;\geq\; 1,\ i = 1(1)n$, "$A$ is [illegible] an $H$-matrix," STOP; Otherwise
9. Determine $m$ such that $s_m^{(k)} \;=\; \min_{i=1(1)n} s_i^{(k)}$ for $s_i^{(k)} \neq 0$
10. Set $d = [d_i]$, where

$$d_i \;=\; \begin{cases} s_m^{(k)} & \text{if } i = m, \\ 1 & \text{if } i \neq m \end{cases}$$

11. Set $D^{(k)} = \text{diag}(d),\ k = k + 1$; Go to Step 5.

We proceed with some observations on the three algorithms.

According to the theory in [16, Theorem 2.1] or [17, Theorems 1, 2, 3, and 4] if $A$ is an $H$-matrix either Algorithm $\mathbb{H}$ or Algorithm $\mathbb{L}$ converges. On the other hand, if Algorithm $\mathbb{H}$ converges, $A$ is an $H$-matrix, while if Algorithm $\mathbb{L}$ converges, then $A$ may or may not be an $H$-matrix depending on the algorithm's output.

Regarding Algorithm $\mathbb{L}$, one can find out that in the case of a non $H$-matrix, convergence of the algorithm [illegible] always be guaranteed. When $A$ is [illegible] there may be problems as the following example shows. Let

$$A \;=\; \begin{bmatrix} 1 & -2 & 0 & -0.5 \\ -2 & 1 & 0 & 0 \\ 0 & 0 & 2 & -1 \\ 0 & 0 & -1 & 2 \end{bmatrix}, \tag{2.6}$$

which is [illegible] an $H$-matrix. If one applies Algorithm $\mathbb{L}$ to $A$, where initially it is $n_1(A) = 2$, it is found that the algorithm [illegible] converge. No matter what $\varepsilon > 0$ is used, it is always $n_1(A^{(k)}) = 2,\ k = 0, 1, 2, \ldots$. This is because, for any $A^{(k)}$ strict diagonal dominance holds for its last two rows and (strict) nondiagonal dominance holds for the first two.

Let us now consider the irreducible matrices

$$A_1 \;=\; \begin{bmatrix} 1 & 0 & -0.5 \\ -0.5 & 1 & 0 \\ 0 & -2 & 1 \end{bmatrix},\quad A_2 \;=\; \begin{bmatrix} 1 & 0 & -0.5 \\ -2 & 1 & 0 \\ 0 & -2 & 1 \end{bmatrix}, \tag{2.7}$$

where $A_1$ is an $H$-matrix while $A_2$ is not. In the proof of Theorem 2 in [17] it is assumed that $\varepsilon = 0$; therefore we make the same assumption here. Applying Algorithm $\mathbb{L}$, we obtain

$$A_1^{(2)} = \begin{bmatrix} 0.5 & 0 & -1 \\ -0.25 & 0.5 & 0 \\ 0 & -1 & 2 \end{bmatrix}, \quad A_2^{(2)} = \begin{bmatrix} 0.5 & 0 & -1 \\ -1 & 2 & 0 \\ 0 & -4 & 2 \end{bmatrix}, \tag{2.8}$$

$$A_1^{(3)} = \begin{bmatrix} 1 & 0 & -0.5 \\ -0.5 & 0.25 & 0 \\ 0 & -0.5 & 1 \end{bmatrix}, \quad A_2^{(3)} = \begin{bmatrix} 1 & 0 & -2 \\ -2 & 1 & 0 \\ 0 & -2 & 4 \end{bmatrix}, \tag{2.9}$$

$$A_1^{(4)} = \begin{bmatrix} 0.5 & 0 & -0.25 \\ -0.25 & 0.5 & 0 \\ 0 & -1 & 0.5 \end{bmatrix}, \quad A_2^{(4)} = \begin{bmatrix} 2 & 0 & -1 \\ -4 & 2 & 0 \\ 0 & -4 & 2 \end{bmatrix}, \tag{2.10}$$

etc. So, for the $A_1^{(k)}$ sequence we have $d_1^{(1)} = d_2^{(1)} = 0.5$, $d_3^{(1)} = 2$ and after three iterations we have again $d_1^{(4)} = d_2^{(4)} = 0.5$, $d_3^{(4)} = 2$. Obviously, this three-cyclic pattern is repeated ad infinitum. For the sequence of $A_2^{(k)}$'s a similar situation arises since then $d_1^{(1)} = 0.5$, $d_2^{(1)} = d_3^{(1)} = 2$ and $d_1^{(4)} = 0.5$, $d_2^{(4)} = d_3^{(4)} = 2$. Hence neither of the two sequences converges. This is most probably due to the assumption made in [17], that $\lim_{\varepsilon \to 0^+} \left( \lim_{k\to\infty} D^{(k)} \right) = \lim_{k\to\infty} \left( \lim_{\varepsilon\to 0^+} D^{(k)} \right)$, which may not be valid and so $\varepsilon$ [illegible] be taken to be zero. There is one more crucial point in the same theorem. It is proved that any two consecutive Jacobi matrices $B^{(k)},\ k = 0, 1, 2, \ldots$, associated with the [illegible] of the $A^{(k)}$'s (see Definition 3.2) satisfy

$$B^{(k+1)} = \left( D^{(k)} \right)^{-1} B^{(k)} D^{(k)}, \quad k = 0, 1, 2, \ldots. \tag{2.11}$$

During each iteration a similarity permutation on $D^{(k)}$ (which has to be applied also on $A^{(k)}$ and $B^{(k)}$) sets the diagonal elements $d_i^{(k)}$ in a nondecreasing order. It is then proved that for any $b_{ij}^{(k)}$ $(i < j)$, $b_{ij}^{(k)} \le b_{ij}^{(k+1)}$, while for any $b_{ij}^{(k)}$ $(i > j)$, $b_{ij}^{(k)} \ge b_{ij}^{(k+1)}$. However, in the next iteration the $d_i^{(k+1)}$'s may be in a different order as a result of which $b_{ij}^{(k+1)}$ $(i < j)$ may be found at a different position $(l, m)$, $l > m$, and the new $b_{ij}^{(k+1)}$ may not be greater than $b_{ij}^{(k)}$. Hence the sequence of $b_{ij}^{(k)}$'s may [illegible] be a monotone one as a result of which convergence [illegible] be guaranteed. For example, for $A_1$ in (2.7) it is

$$B^{(1)} = \begin{bmatrix} 0 & 0 & 0.5 \\ 0.5 & 0 & 0 \\ 0 & 2 & 0 \end{bmatrix} \quad \text{and} \quad D^{(1)} = \operatorname{diag}(0.5, 0.5, 2).$$

Since the elements of $D^{(1)}$ are already in a nondecreasing order, the permutation matrix to be used is $P^{(1)} = I_3$ and (2.11) gives

$$B^{(2)} = \begin{bmatrix} 0 & 0 & 2 \\ 0.5 & 0 & 0 \\ 0 & 0.5 & 0 \end{bmatrix} \quad \text{and} \quad D^{(2)} = \operatorname{diag}(2, 0.5, 0.5).$$

This time $P^{(2)} = [e^2 e^3 e^1]$, with $e^i,\ i = 1, 2, 3$, the columns of the identity matrix, so by permuting and using the same symbol $B^{(2)}$ for $(P^{(2)})^{-1} B^{(2)} P^{(2)}$ we have that

$B^{(2)} \equiv B^{(1)}$. This pattern repeats itself ad infinitum. Observe that the sequence of differences

$$\max_{i=1,2,3} d_i^{(k)} - \min_{i=1,2,3} d_i^{(k)} = 2 - 0.5 = 1.5, \;\; k = 1, 2, 3, \ldots,$$

[illegible] tend to zero as $k \to \infty$ as is claimed in [17]. Note, in view of (2.11), that $b_{13}^{(1)} = 0.5$ becomes $b_{13}^{(2)} = 2$ but after the similarity permutation takes place the new $b_{13}^{(2)}$ is again 0.5.

So, even in the case of irreducible matrices, for Algorithm $\mathbb{L}$ to be valid, a proof of Theorem 2 in [17] has to be provided in which the quantity $\varepsilon > 0$ should be used throughout the proof, and this is because the value $\varepsilon = 0$ leads to erroneous conclusions.

Let us now come to Algorithm $\mathbb{B}$ in [19]. Besides the conclusion which follows the restriction in Step 7 which holds if and only if $A$ is irreducible, one can make similar observations as in the case of Algorithm $\mathbb{L}$. Consider the following two matrices, where the first one is reducible and the second irreducible.

$$A_3 = \begin{bmatrix} 1 & -2 & 0 & 0 \\ -2 & 1 & 0 & 0 \\ 0 & -\frac{1}{4} & 1 & -\frac{1}{2} \\ -\frac{1}{4} & 0 & -\frac{1}{2} & 1 \end{bmatrix}, \quad A_4 = \begin{bmatrix} 1 & -2 & -1 & 0 \\ -2 & 1 & 0 & -1 \\ 0 & -\frac{1}{4} & 1 & -\frac{1}{2} \\ -\frac{1}{4} & 0 & -\frac{1}{2} & 1 \end{bmatrix}. \tag{2.12}$$

For both matrices $s_3^{(1)} = s_4^{(1)} = \min_{i=1(1)4} s_i^{(1)} = \frac{3}{4}$; let us take $m = 3$. After the first iteration we have

$$A_3^{(2)} = \begin{bmatrix} 1 & -2 & 0 & 0 \\ -2 & 1 & 0 & 0 \\ 0 & -\frac{1}{3} & 1 & -\frac{2}{3} \\ -\frac{1}{2} & 0 & -\frac{3}{8} & 2 \end{bmatrix}, \quad A_4^{(2)} = \begin{bmatrix} 1 & -2 & -\frac{3}{4} & 0 \\ -2 & 1 & 0 & -1 \\ 0 & -\frac{1}{3} & 1 & -\frac{2}{3} \\ -\frac{1}{4} & 0 & -\frac{3}{8} & 1 \end{bmatrix}. \tag{2.13}$$

For the second iteration $s_m^{(2)} = s_4^{(2)} = \frac{5}{8}$ and therefore

$$A_3^{(3)} = \begin{bmatrix} 1 & -2 & 0 & 0 \\ -2 & 1 & 0 & 0 \\ 0 & -\frac{1}{3} & 1 & -\frac{5}{12} \\ -\frac{2}{5} & 0 & -\frac{3}{5} & 1 \end{bmatrix}, \quad A_4^{(3)} = \begin{bmatrix} 1 & -2 & -\frac{3}{4} & 0 \\ -2 & 1 & 0 & -\frac{5}{8} \\ 0 & -\frac{1}{3} & 1 & -\frac{5}{12} \\ -\frac{2}{5} & 0 & -\frac{3}{5} & 1 \end{bmatrix}, \tag{2.14}$$

and then the sequence of $s_m$'s is $s_3^{(3)} = \frac{3}{4}$, $s_4^{(4)} = \frac{17}{20}$, $s_3^{(5)} = \frac{33}{36}$, and so on. Obviously, for either example, the algorithm does [illegible] converge.

Based on all previous examples it is realized that one must distinguish the reducible from the irreducible case. However, because in the case of a large matrix with an unstructured pattern of nonzero elements checking for irreducibility may be of prohibitive computational complexity, we leave aside this issue.

**3. Preliminaries and background material.** For the analysis that will follow, we have to recall some definitions and give a number of useful statements, most of which can be found in [2], [12], and [24].

DEFINITION 3.1. [illegible] $A \in \mathbb{R}^{n,n}$ [illegible] $M$ matrix [illegible] $A = sI - B$, [illegible] $B \geq 0$ [illegible] $\rho(B) < s$, [illegible] $\rho(.)$ [illegible]

[illegible] In Definition 3.1 and in this context an $M$-matrix is assumed to be nonsingular.

Lemma 3.1. [illegible] $A \in \mathbb{R}^{n,n}$ [illegible] $M$ [illegible] $PAP^T$ [illegible] $P$ [illegible]

Definition 3.2. [illegible] comparison [illegible] $A \in \mathbb{C}^{n,n}$ [illegible] $\mathcal{M}(A)$ [illegible]

$$m_{ij} = \begin{cases} |a_{ii}| & \text{[illegible]}\ i = j = 1(1)n, \\ -|a_{ij}| & \text{[illegible]}\ i,j = 1(1)n,\ i \neq j. \end{cases}$$

Lemma 3.2. [illegible] $A \in \mathbb{C}^{n,n}$ [illegible] $H$ [illegible] $M$ [illegible]

Lemma 3.3. [illegible] $A \in \mathbb{C}^{n,n}$ [illegible] $H$ [illegible]

[illegible] Lemmas 3.2 and 3.3 can be used as alternative and equivalent definitions to Definition 1.1 for an $H$-matrix.

Lemma 3.4. [illegible] $A \in \mathbb{C}^{n,n}$, [illegible] $a_{ii} \neq 0$, $i = 1(1)n$, [illegible] $B = EA$ [illegible] $E = \mathrm{diag}(e_1, e_2, \ldots, e_n) \in \mathbb{C}^{n,n}$ [illegible] $J_A$ [illegible] $J_B$ [illegible] $A$ [illegible] $B$ [illegible] $J_A$ [illegible] $J_B$ [illegible]

Based on the last two lemmas, our objective would be that of approximating the spectral radius of the Jacobi iteration matrix $B = J_{\mathcal{M}(A)}$ associated with the comparison matrix of a given $A \in \mathbb{C}^{n,n}$. In fact we will be able to prove that if $A$ is irreducible and $\rho(B) < 1$ ($A$ [illegible] an $H$-matrix) or $\rho(B) > 1$ ($A$ is [illegible] an $H$-matrix), there exists an algorithm that converges. Also, the same algorithm converges in case $A$ [illegible] a reducible $H$-matrix. In case $A$ is [illegible] an $H$-matrix the algorithm may [illegible] converge.

The algorithm we are to propose is based on a modification of the well-known [illegible] (see, e.g., [25] and, more specifically, [5] and [11]), which all iterative criteria for $H$-matrices use indirectly as a starting point. The [illegible] is stated below.

Theorem 3.1 (the Power Method). [illegible] $A \in \mathbb{C}^{n,n}$ [illegible] $\lambda_i$, $i = 1(1)n$ [illegible]

$$|\lambda_1| > |\lambda_j|,\ j = 2(1)n.$$

[illegible]

$$x^{(k)} = Ax^{(k-1)},\ k = 1, 2, 3, \ldots,\ \text{[illegible]}\ x^{(0)} \in \mathbb{C}^n \backslash \{0\}. \tag{3.1}$$

[illegible] $x^{(0)}$ [illegible] $\lambda_1$ [illegible]

$$\lambda_1 = \lim_{k \to \infty} \frac{(Ax^{(k)})_i}{x_i^{(k)}} \quad \text{[illegible]}\ x_i^{(k)} \neq 0, \quad i = 1(1)n. \tag{3.2}$$

Since, from now on, we are to deal with nonnegative irreducible matrices we give a number of statements that will be used later on and can be found in either [2] or [24].

Theorem 3.2 (see [24]). [illegible] $A \in \mathbb{R}^{n,n}$ $A \geq 0$ [illegible] $\rho(A)$ [illegible]

Definition 3.3 (see [24]). [illegible] $A \in \mathbb{R}^{n,n}$ $A \geq 0$ [illegible] $k$ [illegible] $\rho(A)$ [illegible] $k = 1$ [illegible] $A$ [illegible] primitive [illegible] $k > 1$ [illegible] $A$ [illegible] cyclic of index $k$

Lemma 3.5 (see [2]). [illegible] $A \in \mathbb{R}^{n,n}$ $A \geq 0$ [illegible] $\sum_{i=1}^{n} a_{ii} > 0$ [illegible]

Theorem 3.3 (see [24]). [illegible] $A \in \mathbb{R}^{n,n}$, $A \geq 0$ [illegible] $P^*$ [illegible] hyperoctant [illegible] $x > 0$ [illegible] $x \in P^*$ [illegible]

$$\min_{i=1(1)n} \left\{ \frac{\sum_{j=1}^{n} a_{ij} x_j}{x_i} \right\} < \rho(A) < \max_{i=1(1)n} \left\{ \frac{\sum_{j=1}^{n} a_{ij} x_j}{x_i} \right\}$$

[illegible]

$$\frac{\sum_{j=1}^{n} a_{ij} x_j}{x_i} = \rho(A), \ i = 1(1)n.$$

[illegible] 3.1. A fixed vector $x \in P^*$ in Theorem 3.3 can be considered as representing all of its positive multiples ($cx$, $c \in \mathbb{R}_+$). Obviously, for any positive multiple $cx$, the theorem holds true and the three ratios in it remain unchanged.

Below we prove a key statement needed for the application of the Power Method (3.1) to an irreducible, nonnegative, primitive matrix $A \in \mathbb{R}^{n,n}$. In passing we mention that for reducible, nonnegative, and primitive matrices, an issue outside this work and on which we have been working, references [3], [21], and [22] may be of great help since they refer, among other issues, to the eigenspaces of nonnegative matrices, the nonnegative Jordan bases, and the orthogonality of some eigenspaces involved.

Theorem 3.4. [illegible] $A \in \mathbb{R}^{n,n}$, $A \geq 0$ [illegible] $\lambda_1 = \rho(A)$ [illegible] $A = SJS^{-1}$ [illegible] $J = \operatorname{diag}(J_1, J_2, \ldots, J_p)$, $J_i \in \mathbb{C}^{n_i,n_i}$, $i = 1(1)p$, $\sum_{i=1}^{p} n_i = n$, [illegible] $S = [s_1\, s_2\, s_3 \, \ldots \, s_n]$ [illegible] $A$ [illegible] $x \in P^*$, [illegible] $s_i$, $i = 1(1)n$, [illegible] $s_1$ [illegible] $\lambda_1$

[illegible] Due to its properties, $A$ has a unique positive eigenvalue $\lambda_1$ ([illegible]) equal to its spectral radius and a positive eigenvector $s_1$ ([illegible]) associated with it. Let $x \in P^*$ be written as $x = \sum_{i=1}^{n} \eta_i s_i$. Since $A^T$ and $A$ have identical eigenvalue spectra, and $A^T$ is also nonnegative, irreducible, and primitive, its [illegible] is $\lambda_1$; let $z\,(>0)$ be its [illegible]. Consequently,

$$0 \ < \ z^T x \ = \ \sum_{i=1}^{n} \eta_i z^T s_i. \tag{3.3}$$

Noting that $z$ is also the left eigenvector of $A$ corresponding to $\lambda_1$, consider any of the Jordan blocks $J_m \in \mathbb{C}^{n_m,n_m}$, $m = 2(1)p$, of $J$ and let $m = 2$ for the sake of convenience. From the Jordan canonical form of $A$ we have $AS = SJ$ and so

$$As_1 \ = \ \lambda_1 s_1, \ As_2 \ = \ \lambda_2 s_2, \ \text{and } As_i \ = \ s_{i-1} + \lambda_2 s_i, \ i = 3(1)n_2 + 1. \tag{3.4}$$

Recalling that $z$ is a left eigenvector and $s_2$ is a (right) eigenvector of $A$ corresponding to different eigenvalues $\lambda_1$ and $\lambda_2$, respectively, there will hold that $z^T s_2 = 0$ (see, e.g., Theorem 1.1.7 of [11]). From the third set of relations in (3.4) we have for $i = 3$, $z^T A s_3 = z^T(s_2 + \lambda_2 s_3)$, from which $z^T A s_3 - \lambda_2 z^T s_3 = 0$ or $(\lambda_1 - \lambda_2) z^T s_3 = 0$ and $z^T s_3 = 0$. Inductively, it is found that $z^T s_i = 0$, $i = 3(1)n_2 + 1$. What we have just proved for $J_2$ applies to every Jordan block $J_m$, $m = 2(1)p$; consequently

$$z^T s_i \ = \ 0, \ \ i = 2(1)n. \tag{3.5}$$

In view of (3.5), (3.3) becomes $z^T x = \eta_1 z^T s_1 > 0$; hence the positivity of $z$, $x$, and $s_1$ implies directly that $\eta_1 > 0$ and the theorem has been proved. □

In the next section, using some ideas from Algorithms $\mathbb{H}$, $\mathbb{L}$, and $\mathbb{B}$, as well as some new ones, Definition 1.1, or one of its equivalents in Lemmas 3.2 and 3.3, we mainly exploit Theorems 3.1, 3.3, and 3.4 and propose a new algorithm (Algorithm $\mathbb{AH}$) which, in case of an [illegible] matrix $A \in \mathbb{C}^{n,n}$, converges.

For our algorithm to identify if an irreducible matrix $A \in \mathbb{C}^{n,n}$, with $a_{ii} \neq 0$, $i = 1(1)n$, is an $H$-matrix or not we apply the Power Method (3.1) to the irreducible and primitive nonnegative matrix $|A^{(0)}|$, where $A^{(0)} = (\text{diag}(A))^{-1}A$, with $x^{(0)} = e (\in P^*)$ and $e$ the vector of ones. Considering $|A^{(k)}| = I + B^{(k)}$, $k = 0, 1, 2, \ldots$, and noting that $B^{(0)}$ is the Jacobi matrix associated with the comparison matrix of $A$, $J_{\mathcal{M}(A)}$, we stop iterating as soon as one of the following three possibilities occurs: all the components of the vector $(I - B^{(k)})e$ are positive, negative, or zero. It is understood that the similar to $A^{(0)}$ matrix $A^{(k)}$ is given by $A^{(k)} = (\text{diag}(x_1^{(k-1)}, x_2^{(k-1)}, \ldots, x_n^{(k-1)}))^{-1} A^{(k-1)} \text{diag}(x_1^{(k-1)}, x_2^{(k-1)}, \ldots, x_n^{(k-1)})$, with $x^{(0)} = e$. Then, according to Theorem 3.3, $[\min_{i=1(1)n} s_i^{(k)}, \max_{i=1(1)n} s_i^{(k)}]$, $s_i^{(k)} = \sum_{j=1(1)n} |b_{ij}^{(k)}|$, $i = 1(1)n$, is an interval in which the [illegible] $\rho(B^{(0)}) = \rho(|A^{(0)}|) - 1$ of $J_{\mathcal{M}(A)}$ lies and also the vector $\text{diag}(x^{(0)})\text{diag}(x^{(1)}) \cdots \text{diag}(x^{(k)})e$ is an approximation to the [illegible] of $|A^{(0)}|$ or of $B^{(0)}$. As is clear, it is [illegible] necessary to go through all the iterations of the Power Method (3.1) since it suffices to go as far as one of the aforementioned stopping criteria is satisfied. Hence, our algorithm will converge at a much earlier stage than the Power Method.

**4. The new algorithm.** In our algorithm we follow Algorithms $\mathbb{L}$, [illegible] the need of a parameter $\varepsilon$ in the definition of the $d_i$'s, and adopt a more general normalization than that of Algorithm $\mathbb{B}$ so that at each stage $A^{(k)}$, $k = 0, 1, 2, \ldots$, has diagonal elements $a_{ii}^{(k)} = 1$, $i = 1(1)n$, $k = 0, 1, 2, \ldots$. The proofs of our main claims will be given analytically after the presentation of the new algorithm below.

ALGORITHM $\mathbb{AH}$.

```
INPUT: An irreducible matrix $A := [a_{ij}] \in \mathbb{C}^{n,n}$.
OUTPUT: $D = D^{(0)} D^{(1)} \cdots D^{(k)} \in \mathfrak{D}_{D^{-1}A} \equiv \mathfrak{D}_A$ or $\notin \mathfrak{D}_A$ if $A$ [illegible] or is [illegible] an $H$-matrix, respectively
1. If $a_{ii} = 0$ for some $i \in \mathbb{N}$, "$A$ is [illegible] an $H$-matrix," STOP; Otherwise
2. Set $D = I$, $A^{(0)} = (\text{diag}(A))^{-1} A$, $D^{(0)} = I$, $k = 1$
3. Compute $D = DD^{(k-1)}$, $A^{(k)} = \left(D^{(k-1)}\right)^{-1} A^{(k-1)} D^{(k-1)} = [a_{ij}^{(k)}]$
4. Compute $s_i^{(k)} = \sum_{j=1,\ j\neq i}^{n} |a_{ij}^{(k)}|$, $i = 1(1)n$, $s^{(k)} = \min_{i=1(1)n} s_i^{(k)}$, $S^{(k)} = \max_{i=1(1)n} s_i^{(k)}$
5. If $s^{(k)} > 1$, "$A$ is [illegible] an $H$-matrix," STOP; Otherwise
6. If $S^{(k)} < 1$, "$A$ [illegible] an $H$-matrix," STOP; Otherwise
7. If $S^{(k)} = s^{(k)}$, "$\mathcal{M}(A)$ is [illegible]," STOP; Otherwise
8. Set $d = [d_i]$, where

       $d_i = \frac{1 + s_i^{(k)}}{1 + S^{(k)}}, \ i = 1(1)n$

9. Set $D^{(k)} = \text{diag}(d)$, $k = k + 1$; Go to Step 3.
```

THEOREM 4.1. [illegible] $A \in \mathbb{C}^{n,n}$ [illegible] $\mathbb{AH}$ [illegible] $\det(\mathcal{M}(A)) = 0$

[illegible]. If any $a_{ii}$, $i = 1(1)n$, is zero the algorithm terminates (Step 1). Assuming $a_{ii} \neq 0$, $i = 1(1)n$, then by Lemma 3.4, $A^{(0)}$ and $A$ have the same Jacobi iteration matrices. Therefore, $A^{(0)}$ is an $H$-matrix if and only if $A$ is (Step 2). Since $A$ is irreducible so are $A^{(0)}$ and $|A^{(0)}|$. Also, by Lemma 3.5, $|A^{(0)}|$ is primitive. At the $k$th iteration step we form $A^{(k)}$ and indirectly the comparison matrix $\mathcal{M}(A^{(k)})$. Note that the Jacobi iteration matrix $B^{(k)} = |A^{(k)}| - I$, associated with $\mathcal{M}(A^{(k)})$, will be

$$J_{\mathcal{M}(A^{(k)})} = B^{(k)} = I - \mathcal{M}(A^{(k)}) = \begin{bmatrix} 0 & |a_{12}^{(k)}| & \dots & |a_{1n}^{(k)}| \\ |a_{21}^{(k)}| & 0 & \dots & |a_{2n}^{(k)}| \\ \vdots & \vdots & \ddots & \vdots \\ |a_{n1}^{(k)}| & |a_{n2}^{(k)}| & \dots & 0 \end{bmatrix} = [b_{ij}^{(k)}]. \tag{4.1}$$

Because of the similarity transformation (Step 3), we have by induction that $|A^{(k)}| = I + B^{(k)}$ is nonnegative, irreducible, and primitive. Observe that (Step 4)

$$s_i^{(k)} = \sum_{j=1}^{n} b_{ij}^{(k)} = \sum_{j=1,\, j\neq i}^{n} |a_{ij}^{(k)}|, \ i = 1(1)n,$$

are the row sums of the off-diagonal elements of $-\mathcal{M}(A^{(k)})$. Furthermore, $B^{(k)} = \left(D^{(k-1)}\right)^{-1} B^{(k-1)} D^{(k-1)}$, so $B^{(k)}$ and $B^{(k-1)}$ are similar and inductively so are $B^{(k)}$ and $B^{(0)}$. Hence all $B^{(k)}$'s, $k = 0, 1, 2, \dots$, have the same eigenvalue spectra and the same spectral radii. If any of the criteria in Steps 5–7 are satisfied, then according to the discussion in the last paragraph of the previous section the algorithm terminates. By choosing $d^{(0)} = e \in P^*$, we define

$$d^{(k)} = |A^{(0)}| d^{(k-1)} = \cdots = |A^{(0)}|^k d^{(0)}, \ k = 1, 2, \dots,$$

and by induction we have $d^{(k)} \in P^*$. By the definition of $D$ and $D^{(k)}$'s in the algorithm (Steps 8–9, 2), $d^{(k)} = [d_1 \ d_2 \ \dots \ d_n]^T$, where the $d_i$'s refer to the current matrix $D$ after Step 2 of the algorithm is executed, is an approximation to the [illegible] of $|A^{(0)}|$; the presence of the denominators in Step 8 aims at the avoidance of the uncontrollable increase of the components of $d^{(k)}$. Forming now the ratios $\frac{d_i^{(k)}}{d_i^{(k-1)}}$, $i = 1(1)n$, where $d_i^{(k-1)} \neq 0$, $i = 1(1)n$, $\forall\, k = 1, 2, \dots$, since $d^{(k-1)} \in P^*$, by (4.1) we obtain that

$$\frac{d_i^{(k)}}{d_i^{(k-1)}} = \frac{\left(|A^{(k-1)}| d^{(k-1)}\right)_i}{d_i^{(k-1)}} = \frac{\sum_{j=1}^n |a_{ij}^{(k-1)}|(1 + s_j^{(k-1)})}{1 + s_i^{(k-1)}} = 1 + s_i^{(k)}, \tag{4.2}$$

$$\text{with } s_i^{(0)} = 0, \ i = 1(1)n.$$

By virtue of Theorem 3.4, the requirement of having a nonzero component of $d^{(0)}$ $(> 0)$ along the Perron vector of $|A^{(0)}|$ is satisfied. Since then all the assumptions of Theorem 3.1 hold, there will be $\lim_{k\to\infty} s_i^{(k)} = \rho(B^{(0)})$, $i = 1(1)n$. Therefore, by Theorem 3.3 (and also by Lemma 4.1 and Theorem 4.3 below) we have that

$$1 + s^{(1)} \leq 1 + s^{(2)} \leq \cdots \leq 1 + \rho(B^{(0)}) \leq \cdots \leq 1 + S^{(2)} \leq 1 + S^{(1)}, \tag{4.3}$$

where $s^{(k)} = \min_{i=1(1)n} s_i^{(k)}$ and $S^{(k)} = \max_{i=1(1)n} s_i^{(k)}$, and that

$$\lim_{k\to\infty} s^{(k)} = \lim_{k\to\infty} S^{(k)} = \rho(B^{(0)}).$$

All elements the of the two monotonically convergent sequences $s^{(k)}$ and $S^{(k)}$, $k = 1, 2, \dots$ (nondecreasing and nonincreasing, respectively), except for a finite number of them, will belong to $\big(\rho(B^{(0)}) - \varepsilon, \rho(B^{(0)}) + \varepsilon\big)$ for every $\varepsilon > 0$. This, in turn, guarantees convergence of the algorithm. To prove our claim we have to distinguish the following three cases.

(i) If $\rho(B^{(0)}) < 1$, then setting $\varepsilon = 1 - \rho(B^{(0)})$, all the terms of $S^{(k)}$, $k = 1, 2, \dots$, but a finite number of them belong to $(2\rho(B^{(0)}) - 1, 1)$. Consequently, there will exist an integer $k_S$ such that for all $k \geq k_S$ it will be $S^{(k)} < 1$, and so by Lemma 3.3 $A$ [illegible] an $H$-matrix.

(ii) If $\rho(B^{(0)}) > 1$, we set $\varepsilon = \rho(B^{(0)}) - 1$; hence analogously only a finite number of the terms of $s^{(k)}$, $k = 1, 2, \dots$, will lie outside $(1, 2\rho(B^{(0)}) - 1)$, and by Lemma 3.3, as before, $A$ is [illegible] an $H$-matrix.

(iii) If $\rho(B^{(0)}) = 1$, the algorithm, theoretically, may converge or not. Computationally, it is inconclusive. □

The converse of Theorem 4.1 is easy to prove. More specifically, we have the following theorem.

THEOREM 4.2. [illegible] $A \in \mathbb{C}^{n,n}$ [illegible] $\mathbb{AH}$ [illegible]

[illegible]. Assume that the algorithm converges. Then, we have to distinguish cases based on the algorithm's output and on the step from which the algorithm exited.

(i) Suppose that the output is "$A$ [illegible] an $H$-matrix." The only possible exit is from Step 6. In such a case, $S^{(k)} < 1$. By Theorem 3.3, there holds

$$s^{(k)} \leq \rho(B^{(0)}) \leq S^{(k)} < 1 \Longrightarrow \rho(B^{(0)}) < 1.$$

Thus by Lemma 3.3, $A^{(k)}$ is an $H$-matrix and so are $A^{(0)}$ and $A$.

(ii) Suppose that the output is "$A$ is [illegible] an $H$-matrix." Possible exits are from Steps 1 and 5.

(a) If the exit is from Step 1, then $a_{ii} = 0$ for some $i \in \mathbb{N}$, meaning that $A$ is [illegible] an $H$-matrix.

(b) If the exit is from Step 5, then by an analogous argument to that in (i) previously, there holds $\rho(B^{(0)}) > 1$; hence $A$ is [illegible] an $H$-matrix.

(iii) If the exit is from Step 7, then since the algorithm has just passed from Steps 5 and 6 it is implied that $s^{(k)} \leq 1$ and $S^{(k)} \geq 1$, respectively. Therefore $s^{(k)} = S^{(k)} = 1$; hence, by Theorem 3.3, $\rho(B^{(k)}) = 1$ and as a consequence of the matrix similarities we have from Lemmas 3.1 and 3.2 (or 3.3) that $\rho(B^{(0)}) = 1$. By virtue of Lemma 3.4 it follows that $A$ is [illegible] an $H$-matrix. If the aforementioned equality in Step 7 has been produced computationally, then $\rho(B^{(0)})$ may be very close to unity and therefore [illegible] conclusion whether $A$ is an $H$-matrix or not can be drawn. □

[illegible] 4.1. Practically, each iteration of Algorithm $\mathbb{AH}$, excluding initializations, substitutions, and comparisons, consists of the following three major steps which show the total cost per iteration step.

1. Compute $I + B^{(k)} = (\mathrm{diag}(d_1^{(k-1)}, \dots, d_n^{(k-1)}))^{-1}(I + B^{(k-1)})\mathrm{diag}(d_1^{(k-1)}, \dots, d_n^{(k-1)})$.

2. Compute $s_i^{(k)} = \frac{\left(B^{(k-1)}d^{(k-1)}\right)_i}{d_i^{(k-1)}}, \quad i = 1(1)n$.

3. Compute $d_i^{(k)} = \frac{1+s_i^{(k)}}{1+S^{(k)}}, \quad i = 1(1)n$.

To conclude this section we present a theorem based on the assumptions and notation of Theorems 4.1 and 4.2 which guarantees that after at most $l$ iterations $(l \leq [\frac{n}{2}])$ it will be $[s^{(k+l)}, S^{(k+l)}] \subset [s^{(k)}, S^{(k)}]$ while after at most $m$ iterations

$(l \leq m \leq n-1)$ there will hold $s^{(k)} < s^{(k+m)} \leq \rho(B^{(0)}) \leq S^{(k+m)} < S^{(k)}$. This theorem is based on the following lemma.

LEMMA 4.1. [illegible] 4.1 [illegible]

$$s^{(k)} \leq s_i^{(k+1)} = \frac{\sum_{j=1}^{n} b_{ij}^{(k)}(1+s_j^{(k)})}{1+s_i^{(k)}} \leq S^{(k)},\ i = 1(1)n, \tag{4.4}$$

$a_{ii} \neq 0$, $i = 1(1)n$ [illegible] $S^{(k)}$, [illegible] $s^{(k)}$ [illegible]

[illegible]. The first part of the lemma is an immediate consequence of relationships (4.2) and (4.3), where at least one of the two inequalities is strict for otherwise the algorithm would terminate. For the second part suppose that there are $n_1^{(k)} (< n)$ rows of $B^{(k)}$ that have the maximum row sum $S^{(k)}$, $n_3^{(k)}$ $(\leq n - n_1^{(k)})$ rows that have the minimum row sum $s^{(k)}$ and that for the remaining $n_2^{(k)}$ $(= n - n_1^{(k)} - n_3^{(k)} \geq 0)$ rows, the above inequalities are strict. Suppose also that by a similarity permutation with permutation matrix $P^{(k)}$, we bring the aforementioned $n_1^{(k)}$ rows first, the $n_2^{(k)}$ rows next, and the $n_3^{(k)}$ rows last, by keeping the same symbol $B^{(k)}$ for $P^{(k)}B^{(k)}(P^{(k)})^T$. So, the following three series of relationships hold:

$$\begin{aligned} S^{(k)} = \max\nolimits_{i=1(1)n_1^{(k)}} s_i^{(k)},\ \ s^{(k)} < s_i^{(k)} < S^{(k)},\ i = n_1^{(k)} + 1(1)n_1^{(k)} + n_2^{(k)}, \\ s^{(k)} = \min\nolimits_{i=n_1^{(k)}+n_2^{(k)}+1(1)n} s_i^{(k)}, \end{aligned} \tag{4.5}$$

and, in agreement with (4.5), $B^{(k)}$ will have the block partitioned form

$$B^{(k)} = \left[\begin{array}{c|c|c} B_{11}^{(k)} & B_{12}^{(k)} & B_{13}^{(k)} \\ \hline B_{21}^{(k)} & B_{22}^{(k)} & B_{23}^{(k)} \\ \hline B_{31}^{(k)} & B_{32}^{(k)} & B_{33}^{(k)} \end{array}\right]. \tag{4.6}$$

From the irreducibility of $A$, and therefore of $B^{(k)}$, submatrix $\left[\ B_{12}^{(k)}\ \middle|\ B_{13}^{(k)}\ \right]$ will have at least one nonzero element $b_{ij}^{(k)}$, for otherwise $B^{(k)}$ would be reducible. The same is true for submatrix $\left[\ B_{31}^{(k)}\ \middle|\ B_{32}^{(k)}\ \right]$ and also for at least one of $B_{21}^{(k)}$ and $B_{23}^{(k)}$. As we have already seen $B^{(k+1)} = (D^{(k)})^{-1}B^{(k)}D^{(k)}$; therefore, by summing up all the elements in each row of $I + B^{(k+1)}$, one can find out that for at least one row $i \in \{1, 2, \ldots, n_1^{(k)}\}$ there will hold

$$1 + s^{(k)} < 1 + s_i^{(k+1)} = 1 + \sum_{j=1}^{n} b_{ij}^{(k+1)} < 1 + S^{(k)}. \tag{4.7}$$

To prove this, suppose that $b_{i_1 j_1}^{(k)} \neq 0$ for some $i_1 \in \{1, \ldots, n_1^{(k)}\}$ and $j_1 \in \{n_1^{(k)} + 1, \ldots, n\}$; then we may see that the second inequality of (4.7) is proved as follows:

$$\begin{aligned} s_{i_1}^{(k+1)} = \frac{\sum_{j=1,\, j\neq i_1}^{n} b_{i_1 j}^{(k)}(1+s_j^{(k)})}{1+s_{i_1}^{(k)}} < S^{(k)} \iff \sum_{j=1,\, j\neq i_1}^{n} b_{i_1 j}^{(k)} + \sum_{j=1,\, j\neq i_1}^{n} b_{i_1 j}^{(k)} s_j^{(k)} \\ < S^{(k)} + s_{i_1}^{(k)} S^{(k)} \iff \end{aligned}$$

$$\sum_{j=1,\, j\neq i_1}^{n} b_{i_1 j}^{(k)} s_j^{(k)} < s_{i_1}^{(k)} S^{(k)} \ (s_{i_1}^{(k)} = S^{(k)}) \Longleftrightarrow \sum_{j=1,\, j\neq i_1}^{n} b_{i_1 j}^{(k)} s_j^{(k)} < \sum_{j=1,\, j\neq i_1}^{n} b_{i_1 j}^{(k)} S^{(k)}.$$

Obviously, $s_j^{(k)} \leq S^{(k)},\ j = 1(1)n,\, j \neq i_1$. But since $b_{i_1 j_1}^{(k)} \neq 0$, $b_{i_1 j_1} s_{j_1}^{(k)} < b_{i_1 j_1} S^{(k)}$, because $s_{j_1}^{(k)} < S^{(k)}$, $j_1 = n_1^{(k)} + 1(1)n$. Therefore the last strict inequality in the equivalences is true and so is the very first one. In an analogous way it is proved that the minimum row sum in the last $n_3^{(k)}$ rows is increased in at least one row. Finally, in a similar way, it can be proved that any of the new row sums in $B^{(k+1)}$, $i = n_1^{(k)} + 1(1)n_1^{(k)} + n_2^{(k)}$, can become neither as big as $S^{(k)}$ nor as small as $s^{(k)}$. ☐

THEOREM 4.3. [illegible] 4.1 [illegible] 4.1 [illegible] $k$ [illegible] $l(\leq [\frac{n}{2}])$ [illegible] $m(l \leq m \leq n-1)$ [illegible]

$$[s^{(k+q)}, S^{(k+q)}] \subset [s^{(k)}, S^{(k)}], \quad q = l, m; \tag{4.8}$$

[illegible] $q = m$ [illegible]

$$s^{(k)} < s^{(k+m)} \leq \rho(B^{(0)}) \leq S^{(k+m)} < S^{(k)}. \tag{4.9}$$

[illegible]. For the inclusion (4.8) to hold for $q = l$, and hence for $q = m$, there must be either $s^{(k)} < s^{(k+l)}$ for the minimum row sum or $S^{(k+l)} < S^{(k)}$ for the maximum row sum. Using the notation of Lemma 4.1, it is obvious that the "worst" case we could have is $n_2^{(k)} = 0$, and (i) for $n$ even $n_1^{(k)} = n_3^{(k)} = \frac{n}{2}$, while (ii) for $n$ odd either $n_1^{(k)} = \frac{n-1}{2}$ and $n_3^{(k)} = \frac{n+1}{2}$ or $n_1^{(k)} = \frac{n+1}{2}$ and $n_3^{(k)} = \frac{n-1}{2}$. Lemma 4.1 implies that in either case, $n$ even or odd, the maximum number of iterations needed to have one of the two inequalities strict is $l = [\frac{n}{2}]$. Finally, for the set of strict inequalities in (4.9) to be satisfied the "worst" case is again to have $n_2^{(k)} = 0$ and either $n_1^{(k)} = n - 1$ or $n_3^{(k)} = n - 1$. So, combining it with the result of Lemma 4.1 we have that inequalities (4.9) are both satisfied after at most $m = n - 1$ iterations. ☐

**5. A MATLAB function, examples, and comments.** We begin this section by giving a MATLAB function that implements our $\mathbb{AH}$ Algorithm. The MATLAB function has as a guide Algorithm $\mathbb{H}$ of [16].

```
function [s_min, s_max, k, dd]=ahalgo(n, a, maxit)
% INPUT: n = dimension of a square (complex) matrix,
%        a = an n-by-n (complex) matrix,
%        maxit = maximum number of iterations allowed
% OUTPUT: dd = diagonal matrix D (if "A IS an H-matrix" or if "A is NOT an
H-matrix"),
%             = [] (if "A is NOT an H-matrix; it has at least one zero diagonal
element"
%             or if "M(A) IS SINGULAR"),
%        s_min = smallest row sum of moduli of the Jacobi matrix of M(A(k)),
%        s_max = largest row sum of moduli of the Jacobi matrix of M(A(k)),
%        k = number of iterations performed
finish=0; k=1; dd=eye(n);
if (1-all(diag(a)))
    "A is NOT an H-matrix; It has at least one zero diagonal element"
    finish=1; s_min=0; s_max=Inf; k=k-1; dd=[];
```

```
end
if (finish == 0)
    for i=1:n
        a(i,1:n)=abs(a(i,1:n));
    end
    a=inv(diag(diag(a)))*a;
    for i=1:n
        a(i,i)=1;
    end
end

A number of numerical examples, where the matrix considered is irreducible, run with the given MATLAB function are presented.

First we consider the irreducible matrices that played the roles of counterexamples in section 2 for which Algorithm $\mathbb{L}$, with $\varepsilon = 0$, enters a loop and thus fails to converge.

1. $A_1$ in (2.7):

: "$A$ is an $H$-matrix," $\max_{i=1(1)3} s_i^{(4)} = 0.8750 < 1$, $D = \operatorname{diag}(0.5000, 0.3125, 0.8750)$.

2. $A_2$ in (2.7):
: "$A$ is NOT an $H$-matrix," $\min_{i=1(1)3} s_i^{(4)} = 1.1429 > 1$,
$D = \text{diag}(0.3333,\ 0.5333,\ 0.9333)$.

Next, the counterexample in (2.12), where Algorithm $\mathbb{B}$ fails to converge, is presented.

3. $A_4$ in (2.12):
: "$A$ is NOT an $H$-matrix," $\min_{i=1(1)4} s_i^{(2)} = 1.0714 > 1$,
$D = \text{diag}(1.0000,\ 1.0000,\ 0.4375,\ 0.4375)$.

The following two examples, taken from [17], verify the conclusion, although not in the same number of steps.

4. $A$ in [17, Example 1]:

$$A = \begin{bmatrix} 1 & -0.2 & -0.1 & -0.2 & -0.1 \\ -0.4 & 1 & -0.2 & -0.1 & -0.1 \\ -0.9 & -0.2 & 1 & -0.1 & -0.1 \\ -0.3 & -0.7 & -0.3 & 1 & -0.1 \\ -1 & -0.3 & -0.2 & -0.4 & 1 \end{bmatrix}.$$

: "$A$ IS an $H$-matrix," $\max_{i=1(1)5} s_i^{(6)} = 0.9989 < 1$,
$D = \text{diag}(0.4178,\ 0.4802,\ 0.6560,\ 0.7648,\ 1)$.

5. $A$ in [17, Example 2]:

$$A = \begin{bmatrix} 1 & -0.8 & -0.1 \\ -0.5 & 1 & \mathrm{c} \\ -0.8 & -0.6 & 1 \end{bmatrix}.$$

For $c = -0.3951$:
: "$A$ IS an $H$-matrix," $\max_{i=1(1)3} s_i^{(8)} = 0.99999417061559 < 1$,
$D = \text{diag}(0.69344055479302,\ 0.74176649875408,\ 0.99985294182613)$.
For $c = -0.3952$:
: "$A$ is NOT an $H$-matrix," $\min_{i=1(1)3} s_i^{(9)} = 1.00001588177980 > 1$,
$D = \text{diag}(0.69343749916264,\ 0.74183369108397,\ 0.99983433483175)$.

Obviously, to the accuracy of four decimal places we consider $c$, it is clear that for all $|c| \leq 0.3951$ $A$ IS an $H$-matrix, while for $|c| \geq 0.3952$ $A$ is NOT an $H$-matrix.

The example below verifies the conclusion drawn by a Gauss–Seidel-type modification of Algorithm $\mathbb{H}$ of [16] given in an extended compact profile technique in [9]. In addition the case of inconclusiveness we had in [9] is now removed.

6. $A$ in the example of [9],

$$A = \begin{bmatrix} -1 & a_{12} & 0 & 0 & 0 \\ 0.5 & -1 & 0 & -0.6 & 0 \\ 0 & -0.1 & 1 & 0 & 0.5 \\ 0 & 0.5 & 0 & 1 & -0.5 \\ -0.2 & 0.1 & 0.3 & 0 & -1 \end{bmatrix}.$$

For $a_{12} = 1.146391$:
: "$A$ IS an $H$-matrix," $\max_{i=1(1)5} s_i^{(32)} = 0.99999993216569 < 1$,
$D = \text{diag}(1,\ 0.87230267174610,\ 0.27158312363400,\ 0.62050421587928,\ 0.36870533832715)$.
For $a_{12} = 1.146392$:

: "$A$ is NOT an $H$-matrix," $\min_{i=1(1)5} s_i^{(37)} = 1.00000002036218 > 1$, $D = \mathrm{diag}(1,\ 0.87230203336695,\ 0.27158269490209,\ 0.62050348290098,\ 0.36870499419081)$.

A similar note to the one in Example 6 is made. To the accuracy of six decimal places for $a_{12}$, for all $|a_{12}| \leq 1.146391$ $A$ IS an $H$-matrix, while for $|a_{12}| \geq 1.146392$ $A$ is NOT an $H$-matrix.

In the following two examples the given irreducible matrices, one of which is complex, are singular. Even in the first example this is indirectly spotted by our MATLAB function despite the fact that the output is "$A$ IS an $H$-matrix."

7. $A$ is the following matrix:

$$A = \begin{bmatrix} 2 & -1 & -0.5 \\ -1 & 2 & -1 \\ -0.5 & -1 & \frac{7}{6} \end{bmatrix}.$$

: "$A$ IS an $H$-matrix,"
$\min_{i=1(1)3} s_i^{(33)} = \max_{i=1(1)3} s_i^{(33)} = 1.0000$,
$D = \mathrm{diag}(0.6667,\ 0.8333,\ 1.0000)$.

8. $A$ is the following matrix:

$$A = \begin{bmatrix} \frac{1+\mathrm{i}\sqrt{3}}{4} & 2\sqrt{2}(1+\mathrm{i}) \\ \frac{\sqrt{2}(1-\mathrm{i})}{8} & 2(1-\mathrm{i}\sqrt{3}) \end{bmatrix}.$$

: "$\mathcal{M}(A)$ (to the MATLAB precision) IS SINGULAR,"
$\min_{i=1(1)2} s_i^{(3)} = \max_{i=1(1)2} s_i^{(3)} = 1$, $D = \mathrm{diag}(1.0000,\ 0.1250)$.

The last example is the one in Example 6 with $a_{12} = 1.146391$ except that $a_{33}$ was set to zero to check whether our MATLAB function can spot the presence of zero element(s) in the diagonal of the input matrix $A$.

9. $A_4$ in (2.12) except that $a_{33}$ is set to zero:

: "$A$ is NOT an $H$-matrix; It has at least one zero diagonal element,"
$\min_{i=1(1)4} s_i^{(0)} = 0$, $\max_{i=1(1)4} s_i^{(0)} = \infty$, $D = []$.

To conclude our work we make the following two points.

(i) Our algorithm (and MATLAB function), with a slight modification, works in case we want to find a good approximation to the spectral radius of an irreducible matrix with diagonal elements of the same sign and nonpositive (or nonnegative) off-diagonal elements. It can also find the spectral radius of the Jacobi matrix associated with a nonnegative (or nonpositive) irreducible matrix. In any of these cases a criterion like, e.g., $S^{(k)} - s^{(k)} < \eta$, where $\eta$ is the accuracy required for the spectral radius, should be set.

(ii) Our algorithm (and MATLAB function) works as is in case the matrix $A$ IS an $H$-matrix regardless of $A$ being irreducible or reducible. A possible extension of our present algorithm to also fully cover the reducible case is under investigation.

**Acknowledgments.** The authors would like to express their sincere thanks to the two unknown referees for their very constructive criticism, to the associate editor, Prof. Daniel Szyld, for the discussions the second author had with him on a first version of the paper as well as for various suggestions on later versions, to Prof. Volker Mehrmann for suggesting [22], and also to Prof. Michael Neumann for some useful comments. To all who contributed to the improvement of the quality of the presentation of this work the authors are most indebted.

# SOLVING REAL LINEAR SYSTEMS WITH THE COMPLEX SCHUR DECOMPOSITION*

CARLA D. MORAVITZ MARTIN[†] AND CHARLES F. VAN LOAN[‡]

**Abstract.** If the complex Schur decomposition is used to solve a real linear system, then the computed solution generally has a complex component because of roundoff error. We show that the real part of the computed solution that is obtained in this way solves a nearby *real* linear system. Thus, it is "numerically safe" to obtain real solutions to real linear systems via the complex Schur decomposition. This result is useful in certain Kronecker product situations where fast linear equation solving is made possible by reducing the involved matrices to their complex Schur form. This is critical because in these applications one cannot work with the real Schur form without greatly increasing the volume of work.

**Key words.** linear systems, Schur decomposition, back-substitution, Kronecker products

**AMS subject classifications.** 15A06, 65F05, 65G50

**DOI.** 10.1137/050631690

**1. Introduction.** The [illegible] states that if $A \in \mathbb{R}^{n\times n}$, then there exists a unitary $Q \in \mathbb{C}^{n\times n}$ so that $Q^HAQ = T$ is upper triangular. The eigenvalues that appear along the diagonal of $T$ can be arbitrarily ordered. See [3, p. 313].

This decomposition, coupled with back-substitution and matrix-vector multiplication, can be used to solve a real linear system $Ax = b$. Indeed, since $Q^Hb = (Q^HAQ)(Q^Hx) = T(Q^Hx)$ we have the following algorithm.

```
Algorithm SchurSolve
    Step 1. Compute the Schur decomposition $Q^HAQ = T$.
    Step 2. Form $c = Q^Hb$.
    Step 3. Solve $Ty = c$ by back-substitution.
    Step 4. Set $x = Qy$.
```

Ordinarily, it is preferred to work with the $LU$ factorization because it is much cheaper. However, there are settings involving Kronecker products when this is not the case. For example, the [illegible]

$$FX + XG^T = B, \qquad F \in \mathbb{R}^{m\times m},\ G \in \mathbb{R}^{n\times n},\ B \in \mathbb{R}^{m\times n},$$

can be reshaped as $Ax = b$, where $A = I_n \otimes F + G \otimes I_m$, $x = \mathrm{vec}(X)$, and $b = \mathrm{vec}(B)$. (Here, $\mathrm{vec}(\cdot)$ makes a column vector out of a matrix by stacking its columns.) The $LU$ factorization of $A$ involves $O(m^3n^3)$ flops. But if we compute the Schur decompositions $Q_F^HFQ_F = R$ and $Q_G^HGQ_G = S$ and set $Q = Q_F \otimes Q_G$, then $Q^HAQ = I_n \otimes R + S \otimes I_m$ is the Schur decomposition of $A$ and `SchurSolve` requires $O(n^3 + m^3)$ flops if the Kronecker structure is exploited. See [3, p. 367].

A problem with `SchurSolve` is that complex arithmetic arises whenever $A$ has complex eigenvalues. This increases the volume of work. Moreover, the computed solution vector $x$ will inevitably have a complex component because of roundoff error. These problems can be avoided by working with the [illegible] Schur decomposition. In this factorization we find a real orthogonal $Q$ so that $Q^TAQ = T$ is upper quasi-triangular, i.e., block triangular with 1-by-1 and 2-by-2 diagonal blocks. Because $T$ is "almost" triangular, the `SchurSolve` philosophy essentially applies, except that a quasi-triangular system is solved in Step 3 of `SchurSolve`, rather than a (complex) triangular system.

Therefore, an algorithm to solve a linear system using the real Schur decomposition appears to involve a simple modification of `SchurSolve`. However, there are situations where the real Schur decomposition is much more expensive to compute than the (complex) Schur decomposition. Consider (again) the Sylvester equation problem. If we have computed the real Schur decompositions $Q_F^TFQ_F{=}R$ and $Q_G^TGQ_G = S$ and set $Q = Q_F \otimes Q_G$, then $Q^TAQ = I_n \otimes R + S \otimes I_m$ is [illegible] the real Schur decomposition of $A$. Attempting to compute the canonical form would destroy the Kronecker structure and would greatly increase the volume of work. Fortunately, there is a way of handling the subdiagonal blocks of $I_n \otimes R + S \otimes I_m$ using clever permutations so that the overall procedure remains $O(m^3 + n^3)$. See [3, p. 367].

However, in [4] we describe another Kronecker product situation where the permutation "device" does not work—specifically, the shifted Kronecker product system

$$\left(A^{(p)} \otimes \cdots \otimes A^{(1)} - \lambda I_N\right) x = b, \qquad \lambda \in \mathbb{R},\ b \in \mathbb{R}^N,\ N = n_1 \cdots n_p\ , \tag{1.1}$$

where $A^{(i)} \in \mathbb{R}^{n_i \times n_i}$ for $i = 1, \ldots, p$. After computing the real Schur decompositions of the $A^{(i)}$, a fast recursive procedure exists to solve for $x$ if the $A^{(i)}$ have real eigenvalues. However, if the $A^{(i)}$ have complex eigenvalues, the resulting $p$-fold Kronecker product of quasi-triangular matrices has a complicated and very problematic block structure below the diagonal, thus increasing the volume of work needed by the recursive procedure. This impasse brings us back to `SchurSolve` and the main contribution of this paper. In particular, we examine the properties of the real part of the computed solution $\hat{x}$.

The analysis to determine if a computed solution of a system solves a nearby system of the same form is illustrative of recent work in the general area of "structured" perturbations and error analysis. For example, in [5, 6] the conditioning of structured linear systems is examined where the structure includes symmetric, Toeplitz, circulant, and Hankel matrices. In addition, [1] analyzes the stability of algorithms for solutions of symmetric indefinite systems. In our paper, we show that the real part of the computed solution solves a nearby [illegible] system, a type of structured perturbation. We are not the first to examine complex algorithms for real problems. For example, [2] compares the condition of a complex eigenvalue of a real matrix under real and complex perturbations in order to analyze the accuracy of real algorithms versus complex algorithms. Our work is in this spirit, expanding what we know about structured perturbations for the case when "structure" means real data.

In section 2 we show that `SchurSolve` produces a complex solution that solves a nearby, but complex, linear system. This result is not new but is included for the sake of completeness. We then proceed to prove a perturbation theorem in section 3. It shows that when a real linear system is subjected to complex perturbations, then the real part of the solution to the perturbed system solves a nearby real linear system. This is followed by a brief summary in section 4.

Throughout this paper we use the 2-norm. The 2-norm condition of a matrix $M$ is denoted by $\kappa(M)$. The unit roundoff is designated by $\mathbf{u}$. We repeatedly use the fact that if $M \in \mathbb{C}^{m\times n}$, then both $\|\operatorname{Re}(M)\|$ and $\|\operatorname{Im}(M)\|$ are bounded by $\|M\|$.

**2. Backward error analysis.** We show that if $\hat{x}$ is the solution produced by `SchurSolve` when floating point arithmetic is used, then

$$(A+\Delta A)\,\hat{x} = b+\Delta b, \tag{2.1}$$

$$\|\Delta A\| \le \delta_A \|A\|, \tag{2.2}$$

$$\|\Delta b\| \le \delta_b \|b\|, \tag{2.3}$$

where the $\delta$'s are modest multiples of the unit roundoff $\mathbf{u}$. To present an uncluttered but sufficiently rigorous analysis, we adopt the convention that all the $\delta$'s below are $O(\mathbf{u})$ in magnitude. The floating point result of a matrix calculation is indicated by $\mathrm{fl}(\cdot)$. The floating point properties associated with the Schur decomposition, back-substitution, and other basic computations can be found in [3].

In Step 1 the computed Schur decomposition of $A \in \mathbb{R}^{n\times n}$ produces a "nearly" unitary $\hat{Q} \in \mathbb{C}^{n\times n}$. That is, there is an exactly unitary $Q \in \mathbb{C}^{n\times n}$ such that

$$Q = \hat{Q} + \Delta Q, \qquad \|\Delta Q\| \le \delta_1\ . \tag{2.4}$$

The computed Schur form $\hat{T}$ satisfies

$$\hat{T} = Q^H(A+H)Q, \qquad \|H\| \le \delta_2\|A\|\ , \tag{2.5}$$

where $H \in \mathbb{C}^{n\times n}$. Accounting for the roundoff error in Step 2, there exists $\Delta b \in \mathbb{C}^n$ such that

$$\hat{c} = \mathrm{fl}(\hat{Q}^H b) = Q^H(b+\Delta b), \qquad \|\Delta b\| \le \delta_b\|b\|, \tag{2.6}$$

while in Step 3 the computed solution to the triangular system satisfies

$$(\hat{T}+G)\hat{y} \;=\; \hat{c}, \qquad \|G\| \le \delta_3\|\hat{T}\| \le \delta_4\|A\|\ . \tag{2.7}$$

In the last step the computed solution $\hat{x}$ can be related to $\hat{y}$ as follows:

$$\hat{x} = \mathrm{fl}(\hat{Q}\hat{y}) \;=\; Q(\hat{y}+g), \qquad \|g\| \le \delta_5\|\hat{y}\| \le \delta_6\|\hat{x}\|\ . \tag{2.8}$$

Now let us combine these results. From (2.6) and (2.7) we have

$$(\hat{T}+G)\hat{y} \;=\; Q^H(b+\Delta b),$$

and so by (2.5) and (2.8)

$$b+\Delta b \;=\; Q\left(\hat{T}+G\right)Q^HQ\hat{y} \;=\; \left(A+H+QGQ^H\right)(\hat{x}-Qg)\,.$$

If $M = A+H+QGQ^H$, then

$$\begin{aligned} b+\Delta b = M(\hat{x}-Qg) \;&=\; \left(M - \frac{MQg\hat{x}^H}{\hat{x}^H\hat{x}}\right)\hat{x} \\ &= \left(A+H+QGQ^H - \frac{MQg\hat{x}^H}{\hat{x}^H\hat{x}}\right)\hat{x}, \end{aligned}$$

and so if we define

$$\Delta A = H + QGQ^H - \frac{MQg\hat{x}^H}{\hat{x}^H\hat{x}}, \tag{2.9}$$

then $(A + \Delta A)\,\hat{x} = b + \Delta b$, i.e., $\hat{x}$ solves a perturbed system. From (2.6) we know that $\Delta b$ satisfies (2.3). Thus, the verification of (2.1)–(2.3) is complete once we show that $\|\, \Delta A \,\|$ is sufficiently small. Toward that end we note that

$$\begin{aligned} \|\, M \,\| = \|\, A + H + QGQ^H \,\| &\le \|\, A \,\| + \|\, H \,\| + \|\, G \,\| \\ &\le (1 + \delta_2 + \delta_4)\|\, A \,\| = (1 + \delta_7)\|\, A \,\|. \end{aligned}$$

It follows from (2.5), (2.7), (2.8), and (2.9) that

$$\begin{aligned} \|\, \Delta A \,\| &\le \|\, H \,\| + \|\, G \,\| + \|\, M \,\| \frac{\|\, g \,\|}{\|\, \hat{x} \,\|} \\ &\le \delta_2\|\, A \,\| + \delta_4\|\, A \,\| + \delta_6(1 + \delta_7)\|\, A \,\|. \end{aligned}$$

The inequality (2.2) is established by setting $\delta_A = \delta_2 + \delta_4 + \delta_6(1 + \delta_7)$.

## 3. A perturbation theorem.

In this section we prove a result that will enable us to say something very favorable about the real part of the computed `SchurSolve` solution.

THEOREM 3.1. [illegible] $0 < \epsilon \le 1/6$, [illegible] $A \in \mathbb{R}^{n\times n}$, [illegible] $b \in \mathbb{R}^n$ [illegible] $\epsilon \cdot \kappa(A) \le 1/2$ [illegible]

$$(A + E)z = b + f, \tag{3.1}$$

[illegible]

$$\begin{array}{lll} E = E_1 + iE_2, & E_1,\, E_2 \in \mathbb{R}^{n\times n}, & \|\, E \,\| \le \epsilon\|\, A \,\|, \\ f = f_1 + if_2, & f_1,\, f_2 \in \mathbb{R}^n, & \|\, f \,\| \le \epsilon\|\, b \,\|, \\ z = z_1 + iz_2, & z_1,\, z_2 \in \mathbb{R}^n, & \end{array}$$

[illegible] $\tilde{E} \in \mathbb{R}^{n\times n}$ [illegible]

$$\left(A + \tilde{E}\right) z_1 = b + f_1 \tag{3.2}$$

[illegible]

$$\|\, \tilde{E} \,\| \le 4\epsilon\|\, A \,\|, \tag{3.3}$$

$$\|\, f_1 \,\| \le \epsilon\|\, b \,\| \,. \tag{3.4}$$

[illegible] Since

$$\|\, f_1 \,\| \le \|\, f_1 + if_2 \,\| = \|\, f \,\| \le \epsilon\|\, b \,\|,$$

the inequality (3.4) holds. Note that if $b = 0$ then $\|\, f \,\| = 0$ and so $\|\, f_1 \,\| = 0$. Expanding (3.1) we get

$$(A + E_1 + iE_2)(z_1 + iz_2) = b + f_1 + if_2$$

from which follows

$$(A+E_1)z_1 - E_2 z_2 = b + f_1, \tag{3.5}$$

$$(A+E_1)z_2 + E_2 z_1 = f_2. \tag{3.6}$$

If $b = 0$ and $z_1 = 0$, then any such $\tilde{E}$ such that $\| \tilde{E} \| \leq 4\epsilon \| A \|$ completes the proof. If $z_1 \neq 0$, (3.5) can be rewritten as

$$\left( A + E_1 - \frac{E_2 z_2 z_1^T}{z_1^T z_1} \right) z_1 = b + f_1,$$

and so (3.2) holds with

$$\tilde{E} = E_1 - \frac{E_2 z_2 z_1^T}{z_1^T z_1}. \tag{3.7}$$

Now to establish (3.3), we start by taking norms in (3.7):

$$\| \tilde{E} \| \leq \| E_1 \| + \| E_2 \| \frac{\| z_2 \|}{\| z_1 \|} \leq \epsilon \| A \| \left( 1 + \frac{\| z_2 \|}{\| z_1 \|} \right) . \tag{3.8}$$

Looking at (3.3), we must confirm that $\| z_2 \|$ is not too much bigger than $\| z_1 \|$. From (3.6) we have

$$z_2 = (A+E_1)^{-1} (f_2 - E_2 z_1) = (I + A^{-1}E_1)^{-1} A^{-1} (f_2 - E_2 z_1),$$

and so

$$\| z_2 \| \leq \| (I + A^{-1}E_1)^{-1} \| \| A^{-1} \| (\| f_2 \| + \| E_2 \| \| z_1 \|) .$$

The assumption $\epsilon \cdot \kappa(A) < 1/2$ implies

$$\| (I + A^{-1}E_1)^{-1} \| \leq \frac{1}{1 - \| A^{-1}E_1 \|} \leq \frac{1}{1 - \epsilon \cdot \| A \| \| A^{-1} \|} \leq 2,$$

and thus

$$\| z_2 \| \leq 2\epsilon \| A^{-1} \| (\| b \| + \| A \| \| z_1 \|) . \tag{3.9}$$

By rearranging (3.5) we see that $b = (A+E_1)z_1 - E_2 z_2 - f_1$ and therefore

$$\begin{aligned} \| b \| &\leq (\| A \| + \| E_1 \|) \| z_1 \| + \| E_2 \| \| z_2 \| + \| f_1 \| \\ &\leq (1+\epsilon) \| A \| \| z_1 \| + \epsilon \| A \| \| z_2 \| + \epsilon \| b \| \\ &\leq \frac{1+\epsilon}{1-\epsilon} \| A \| \| z_1 \| + \frac{\epsilon}{1-\epsilon} \| A \| \| z_2 \|. \end{aligned}$$

By substituting this inequality into (3.10) and using the assumption that $\epsilon \leq 1/6$ we get

$$\begin{aligned}
\| z_2 \| &\leq 2\epsilon \| A^{-1} \| \left( \frac{1+\epsilon}{1-\epsilon} \| A \| \| z_1 \| + \frac{\epsilon}{1-\epsilon} \| A \| \| z_2 \| \; + \; \| A \| \| z_1 \| \right) \\
&= 2\epsilon\kappa(A) \left( \frac{2}{1-\epsilon} \| z_1 \| \; + \; \frac{\epsilon}{1-\epsilon} \| z_2 \| \right) \\
&\leq \left( \frac{2}{1-\epsilon} \| z_1 \| \; + \; \frac{\epsilon}{1-\epsilon} \| z_2 \| \right) \\
&\leq \frac{2}{1-2\epsilon} \| z_1 \| \; \leq \; 3 \| z_1 \|.
\end{aligned}$$

The inequality (3.3) follows from this and (3.9).

The proof will be complete after we address whether $z_1$ can be zero. By way of contradiction, assume $z_1 = 0$. Then (3.5) and (3.6) become $-E_2 z_2 = b + f_1$ and $(A + E_1) z_2 = f_2$, respectively. So

$$\begin{aligned}
b &= -f_1 - E_2 z_2 \\
&= -f_1 - E_2 (A + E_1)^{-1} f_2.
\end{aligned}$$

This implies that

$$\begin{aligned}
\| b \| &\leq \| f_1 \| + \| E_2 \| \| (A + E_1)^{-1} \| \| f_2 \| \\
&\leq \epsilon \| b \| + 2\epsilon \| A \| \| A^{-1} \| (\epsilon \| b \|) \\
&\leq 2\epsilon \| b \|,
\end{aligned}$$

and therefore $1 \leq 2\epsilon$, which is a contradiction. Since $z_1$ is nonzero, the proof is now complete. □

In section 2 we showed that SchurSolve produces a computed solution $\hat{x}$ that exactly solves a ( ) linear system that is “within roundoff” of the original. Thus,

$$\frac{\| \hat{x} - x \|}{\| x \|} \; \approx \; \mathbf{u}\kappa(A)\,.$$

Since $\| \mathrm{Re}(\hat{x}) - x \| \leq \| \hat{x} - x \|$ it follows that

$$\frac{\| \mathrm{Re}(\hat{x}) - x \|}{\| x \|} \; \approx \; \mathbf{u}\kappa(A),$$

which is what we would expect from a stable linear equation solving process. But we can say more in light of Theorem 3.1. The following corollary to Theorem 3.1 shows that using the complex Schur decomposition to solve a real problem results in a computed solution whose real part solves a nearby real system.

COROLLARY 3.2. $A \in \mathbb{R}^{n \times n}$ $b \in \mathbb{R}^n$ $\hat{x}$ $Ax = b$ SchurSolve $\epsilon = \max(\delta_A, \delta_b) \leq 1/6$ $\Delta A \in \mathbb{R}^{n \times n}$ $\delta b \in \mathbb{R}^n$

$$(A + \Delta A)\mathrm{Re}(\hat{x}) = b + \delta b, \tag{3.10}$$

[illegible]

$$\| \Delta A \| \leq \delta_A \| A \|, \tag{3.11}$$

$$\| \delta B \| \leq \delta_b \| b \|. \tag{3.12}$$

**4. Summary.** We have illustrated certain situations where the complex Schur decomposition is preferred to using the real Schur decomposition when solving a real system. Thus, we show that it is numerically safe to obtain solutions to the real system by introducing complex arithmetic. In particular, Theorem 3.1 and Corollary 3.2 show that the real part of the computed solution obtained using `SchurSolve` solves a nearby [illegible] linear system.

# SHIFTED KRONECKER PRODUCT SYSTEMS*

CARLA D. MORAVITZ MARTIN[†] AND CHARLES F. VAN LOAN[‡]

**Abstract.** A fast method for solving a linear system of the form $(A^{(p)} \otimes \cdots \otimes A^{(1)} - \lambda I)x = b$ is given where each $A^{(i)}$ is an $n_i$-by-$n_i$ matrix. The first step is to convert the problem to triangular form $(T^{(p)} \otimes \cdots \otimes T^{(1)} - \lambda I)y = c$ by computing the (complex) Schur decompositions of the $A^{(i)}$. This is followed by a recursive back-substitution process that fully exploits the Kronecker structure and requires just $O(N(n_1 + \cdots + n_p))$ flops where $N = n_1 \cdots n_p$. A similar method is employed when the real Schur decomposition is used to convert each $A^{(i)}$ to quasi-triangular form. The numerical properties of these new methods are the same as if we explicitly formed $(T^{(p)} \otimes \cdots \otimes T^{(1)} - \lambda I)$ and used conventional back-substitution to solve for $y$.

## 1. Introduction.

Matrix problems with replicated block structure abound in signal and image processing, semidefinite programming, control theory, and many other application areas. In these venues fast algorithms have emerged that exploit the rich algebra of the Kronecker product. Perhaps the best example of this is the fast Fourier transform which can be described using the "language" of sparse matrix factorizations and the Kronecker product. This operation is surfacing more and more as cheap memory prompts the assembly of huge, multidimensional datasets. When techniques for problems of low dimension are generalized or "tensored" together to address a high-dimensional, multilinear problem, then one typically finds a computational challenge that involves the Kronecker product.

It is in the spirit of bringing the fruits of numerical linear algebra to the realm of numerical multilinear algebra that we present the current paper. Our goal is to present a methodology for solving a shifted linear system when the matrix of coefficients is a Kronecker product. Specifically, the question we address is how to solve a shifted Kronecker product system of the form

$$\left(A^{(p)} \otimes \cdots \otimes A^{(1)} - \lambda I_N\right) x = b, \qquad b \in \mathbb{R}^N, \tag{1.1}$$

where $A^{(i)} \in \mathbb{R}^{n_i \times n_i}$, $i = 1{:}p$, are given and $N = n_1 \cdots n_p$. A reshaped special case of this problem is the discrete-time Sylvester equation $A^{(1)} X {A^{(2)}}^T - X = B$. As with many matrix equations of this variety, the first step is to convert $A^{(1)}$ and $A^{(2)}$ to triangular form via the Schur decompoistion. The resulting system can then be solved via a back-substitution process. Jonsson and Kågström [2] have developed block

recursive methods for these kinds of problems and they are very effective in high-performance computing environments. The method we present is also recursive and can be regarded as a generalization of their technique. However, we do not generate the subproblems by splitting at the block level.

There are other well-known settings where linear equation solving via the Schur, real Schur, or Hessenberg decompositions is preferred over Gaussian elimination and the $LU$ factorization. For example, suppose $A \in \mathbb{R}^{N\times N}$, $b \in \mathbb{R}^N$, $d \in \mathbb{R}^N$, and that we want to explore the behavior of the function

$$f(\lambda) = d^T(A - \lambda I_N)^{-1}b,$$

where $\lambda$ is a scalar. Note that for each $\lambda$ we must solve a system of linear equations

$$(A - \lambda I_N)x = b. \tag{1.2}$$

If one proceeds to use Gaussian elimination, then each $f$-evaluation requires $\mathrm{O}(N^3)$ flops because the underlying $LU$ factorization must be recomputed from scratch for each $\lambda$.

If many $f$-evaluations are required, then a better approach is to rely on a similarity transformation such as the Schur or Hessenberg decomposition:

$$Q^H A Q = T. \tag{1.3}$$

Here $Q \in \mathbb{C}^{N\times N}$ is unitary, and $T \in \mathbb{C}^{N\times N}$ is upper triangular, quasi-triangular, or Hessenberg, depending on whether $A$ has complex eigenvalues and depending on whether the real or complex Schur (or Hessenberg) decomposition is used. Once this $O(N^3)$ "investment" is performed, then

$$f(\lambda) = \tilde{d}^T(T - \lambda I_N)^{-1}\tilde{b}, \qquad \tilde{b} = Q^T b,\ \tilde{d} = Q^T d,$$

can be evaluated in just $O(N^2)$ flops. In practice, one typically invokes the Hessenberg decomposition because it is cheaper, or the real Schur decomposition because it permits the handling of the complex eigenvalue case with real arithmetic.

Applying these ideas to (1.1) we first compute the Schur decompositions

$$Q^{(i)H} A^{(i)} Q^{(i)} \;=\; T^{(i)}, \qquad i = 1{:}p, \tag{1.4}$$

a calculation that requires $O(n_1^3 + \cdots + n_p^3)$ flops. If

$$Q = Q^{(p)} \otimes \cdots \otimes Q^{(1)},$$

then $Q$ is unitary and

$$Q^H\left(A^{(p)} \otimes \cdots \otimes A^{(1)}\right)Q \;=\; T^{(p)} \otimes \cdots \otimes T^{(1)}.$$

Thus, (1.1) transforms to

$$\left(T^{(p)} \otimes \cdots \otimes T^{(1)} - \lambda I_N\right) y = c, \tag{1.5}$$

where $y \in \mathbb{R}^N$ and $c \in \mathbb{R}^N$ are defined by

$$x \;=\; \left(Q^{(p)} \otimes \cdots \otimes Q^{(1)}\right) y \tag{1.6}$$

and

$$c = \left(Q^{(p)} \otimes \cdots \otimes Q^{(1)}\right)^H b. \tag{1.7}$$

If the Kronecker structure is exploited, then the computations for $x$ and $c$ require $O(N(n_1 + \cdots + n_p))$ flops. If the complex Schur decomposition is used, then the resulting system (1.5) is triangular, and we show that it can also be solved in $O(N(n_1 + \cdots + n_p))$ flops. If the real Schur decomposition is used, then the Kronecker product in (1.5) has a complicated structure. In this case, we invoke the complex Schur decomposition to deal with the 2-by-2 bumps in each of the $T^{(i)}$. Regardless, the system (1.5) is an example where introducing complex arithmetic to solve a real problem is more advantageous. Our main contribution is to show that we can solve (1.5) "just as fast" where the $T^{(i)}$ are either upper triangular or upper quasi-triangular. In both cases, complex operations are used to solve the problem.

Thus, with our new method in place, the overall solution process (1.4)–(1.7) requires just $O(N(n_1 + \cdots + n_p))$ flops to execute. To put this in perspective, $O(N^2)$ flops are typically needed for $N$-by-$N$ triangular system solving and $O(N^3)$ flops for the preliminary factorization. Note that we are assuming that the Schur decompositions in (1.4) are insignificant. Exceptions occur, for example, when $p = 2$ and $n_1 \gg n_2$.

We stress that it is the presence of the shift $\lambda$ in (1.5) that creates the problem. If $\lambda = 0$, then we have an easy factorization of the matrix of coefficients. Indeed, if the $T^{(i)}$ are upper triangular,

$$\left(T^{(p)} \otimes \cdots \otimes T^{(1)}\right) = \prod_{i=1}^{p} \left(I_{\rho_i} \otimes T^{(i)} \otimes I_{\mu_i}\right),$$

where $\rho_i = n_{i+1} \cdots n_p$ and $\mu_i = n_1 \cdots n_{i-1}$ for $i = 1{:}p$. A sequence of triangular system solves can then be used to obtain $y$:

(1.8)
```
$y \leftarrow c$
for $i = 1{:}p$
    $y \leftarrow \left(I_{\rho_i} \otimes T^{(i)} \otimes I_{\mu_i}\right)^{-1} y$
end
```

This implementation of back-substitution requires $N(n_1 + \cdots + n_p)$ flops.

Unfortunately, if $\lambda \neq 0$ then we are stranded without a "Kronecker-friendly" factorization for $\left(T^{(p)} \otimes \cdots \otimes T^{(1)} - \lambda I_N\right)$. However, we can implement a recursive back-substitution procedure involving the Schur decomposition so that (1.5) can be solved as fast as (1.8).

Our presentation is structured as follows. In section 2 we review relevant properties of the Kronecker product. To motivate our general procedure for both the triangular and quasi-triangular case, we consider the $p = 2$ case in section 3. In section 4 we present the algorithm for general $p$ using both the complex Schur decomposition and the real Schur decomposition. Numerical behavior and various performance and implementation issues are discussed at the end in section 5. Finally, the error analysis is presented in the appendix.

## 2. Some properties of the Kronecker product.

We review a few essential facts about the Kronecker product. Details and proofs can be found in [4].

Matrix computations that involve the Kronecker product require an understanding of the `vec` and `reshape` operators. If $Z \in \mathbb{R}^{m\times n}$, then the `vec` operator is defined by

$$\texttt{vec}(Z) = \begin{bmatrix} Z(:,1) \\ \vdots \\ Z(:,n) \end{bmatrix} \in \mathbb{R}^{mn}.$$

In other words, $\texttt{vec}(Z)$ is a vector obtained by stacking the columns of $Z$.

The `reshape` operator is a more general way of rearranging the entries in a matrix. (It is also a built-in MATLAB function.) If $z \in \mathbb{R}^{mn}$ then $Z = \texttt{reshape}(z, m, n)$ is the $m$-by-$n$ matrix defined by

$$Z(:,j) = z(1 + (j-1)m{:}jm), \qquad j = 1{:}n.$$

For example, if $m = 3$ and $n = 5$, then

$$\texttt{reshape}(z,3,5) = \begin{bmatrix} z_1 & z_4 & z_7 & z_{10} & z_{13} \\ z_2 & z_5 & z_8 & z_{11} & z_{14} \\ z_3 & z_6 & z_9 & z_{12} & z_{15} \end{bmatrix} = Z.$$

Thus, $\texttt{reshape}(z, m, n)$ makes a matrix out of $z$ by using its components to "fill up" an $m$-by-$n$ array in column-major order. We also use `reshape` to build new matrices from the components of a given matrix. If $Z \in \mathbb{R}^{m_1\times n_1}$ and $m_2 n_2 = m_1 n_1$, then $\texttt{reshape}(Z, m_2, n_2)$ is the $m_2$-by-$n_2$ matrix $\texttt{reshape}(\texttt{vec}(Z), m_2, n_2)$.

If $F$, $G$, $H$, and $K$ are matrices and the multiplications $FH$ and $GK$ are defined, then $(F \otimes G)(H \otimes K) = FH \otimes GK$. Moreover, $(F \otimes G)^{-1} = (F^{-1} \otimes G^{-1})$ and $(F \otimes G)^T = F^T \otimes G^T$, assuming in the former case that $F$ and $G$ are nonsingular.

In general, if $F \in \mathbb{R}^{m\times m}$ and $G \in \mathbb{R}^{n\times n}$ then $F \otimes G \neq G \otimes F$. However, if we define the permutation matrix $\Pi_{n,nm} \in \mathbb{R}^{mn\times mn}$ by

$$\Pi^T_{n,nm} x = \begin{bmatrix} x(1{:}n{:}nm) \\ x(2{:}n{:}nm) \\ \vdots \\ x(n-1{:}n{:}nm) \end{bmatrix},$$

then it can be shown that

$$\Pi^T_{n,nm}(F \otimes G)\Pi_{n,nm} = G \otimes F.$$

The matrix $\Pi_{n,nm}$ is called the [illegible] and its action on a vector is very neatly described in terms of the `reshape` operation:

$$y = \Pi^T_{n,mn} x \quad \Leftrightarrow \quad \texttt{reshape}(y, m, n) = \texttt{reshape}(x, n, m)^T, \tag{2.1}$$

$$y = \Pi_{n,mn} x \quad \Leftrightarrow \quad \texttt{reshape}(y, n, m) = \texttt{reshape}(x, m, n)^T. \tag{2.2}$$

Note that $y = \Pi_{2,52} x$ is the perfect shuffle of the "card deck" $x \in \mathbb{R}^{52}$. We mention that if $x$ (and $y$) are complex, then (2.1) and (2.2) apply exactly as they are specified; the transpose is [illegible] replaced by a conjugate transpose.

The `vec` operator enables us to identify certain matrix-vector products as matrix-matrix products. In particular, if $F \in \mathbb{R}^{m\times m}$, $G \in \mathbb{R}^{n\times n}$, and $X \in \mathbb{R}^{n\times m}$, then it can be shown that

$$Y = GXF^T \qquad \Leftrightarrow \qquad \texttt{vec}(Y) = (F \otimes G)\,\texttt{vec}(X). \tag{2.3}$$

For matrix-vector products of the form

$$y = (F_p \otimes \cdots \otimes F_1)\, x, \qquad F_i \in \mathbb{R}^{n_i\times n_i}, \tag{2.4}$$

it is convenient to make use of the factorization

$$F_p \otimes \cdots \otimes F_1 \;=\; M_p \cdots M_1, \tag{2.5}$$

where

$$M_i = \Pi^T_{n_i,N}\left(I_{N/n_i} \otimes F_i\right) \tag{2.6}$$

and $N = n_1 \cdots n_p$. This result can be found in [4, p. 153] where it is exploited in connection with high-dimensional fast Fourier transforms. In practice, here is how one typically computes the vector $y$ in (2.4):

(2.7)

```
$Z \leftarrow x$
for $i = 1{:}p$
    $Z \leftarrow (F_i \cdot \texttt{reshape}(Z, n_i, N/n_i))^T$
end
$y \leftarrow \texttt{reshape}(Z, N, 1)$
```

The $i$th pass through the loop requires $(2n_i^2)(N/n_i) = 2Nn_i$ flops so the overall computation involves $2N(n_1 + \cdots n_p)$ flops.

We mention that a similar process can be used to solve

$$(F_p \otimes \cdots \otimes F_1)\, x = d.$$

From (2.5) and (2.6) it follows that

$$(F_p \otimes \cdots \otimes F_1)^{-1} \;=\; F_p^{-1} \otimes \cdots \otimes F_1^{-1} \;=\; M_1^{-1} \cdots M_p^{-1},$$

where

$$M_i^{-1} = \left(I_{N/n_i} \otimes F_i^{-1}\right)\Pi_{n_i,N},$$

and so we obtain

(2.8)

```
$B \leftarrow d$
for $i = p{:} - 1{:}1$
    $B \leftarrow F_i^{-1}\, \texttt{reshape}(B, N/n_i, n_i)^T$
end
$x \leftarrow \texttt{reshape}(B, N, 1)$
```

If the $F_i$ are triangular, then the $i$th pass through the loop requires $n_i^2(N/n_i) = Nn_i$ flops.

**3. The $p = 2$ case.** To motivate the proposed new method for (1.5) for the triangular and quasi-triangular case, we first consider the special case when $p = 2$. That is, for $F \in \mathbb{R}^{m\times m}$ and $G \in \mathbb{R}^{n\times n}$,

$$(F \otimes G - \lambda I)y = c. \tag{3.1}$$

Using (2.3), one can rewrite (3.1) as the real discrete-time Sylvester matrix equation

$$GYF^T - \lambda Y = C,$$

where $Y = \texttt{reshape}(y, n, m)$ and $C = \texttt{reshape}(c, n, m)$. As we mentioned earlier, a block procedure for solving the real discrete-time Sylvester matrix equation is described in [2]. In this section, we describe the details of solving (3.1) in a way that facilitates the presentation of the general $p > 2$ algorithm. We begin with a small particular problem, $(F \otimes G - \lambda I_{3n})\, y = c$, where

$$F = \begin{bmatrix} f_{11} & f_{12} & f_{13} \\ 0 & f_{22} & f_{23} \\ 0 & 0 & f_{33} \end{bmatrix}$$

and $G \in \mathbb{R}^{n\times n}$ is upper triangular. The shifted Kronecker system has the form

$$\begin{bmatrix} f_{11}G - \lambda I_n & f_{12}G & f_{13}G \\ 0 & f_{22}G - \lambda I_n & f_{23}G \\ 0 & 0 & f_{33}G - \lambda I_n \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \\ y_3 \end{bmatrix} = \begin{bmatrix} c_1 \\ c_2 \\ c_3 \end{bmatrix},$$

where $y_i \in \mathbb{R}^n$ and $c_i \in \mathbb{R}^n$ for $i = 1{:}3$. Assume that the system is nonsingular. The first step is to solve the $n$-by-$n$ triangular system

$$(f_{33}G - \lambda I_n)\, y_3 = c_3$$

for $y_3$. By substituting $y_3$ into the first two equations we obtain

$$\begin{bmatrix} f_{11}G - \lambda I_n & f_{12}G \\ 0 & f_{22}G - \lambda I_n \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} \tilde{c}_1 \\ \tilde{c}_2 \end{bmatrix}, \tag{3.2}$$

where $\tilde{c}_i = c_i - f_{i3}Gy_3$, $i = 1{:}2$. The vectors $y_3$ and $Gy_3$ require $O(n^2)$ flops. This process is then repeated to render $y_2$, and $y_1$ in turn.

Note from the example that if $G$ is quasi-triangular (or even Hessenberg), then the systems involving the $(f_{ii}G - \lambda I_n)$ still just require $O(n^2)$ flops to solve. However, if $F$ is upper quasi-triangular, then there is a more serious complication. To illustrate let us examine the system $(F \otimes G - \lambda I_{4n})\, y = c$, where

$$F = \begin{bmatrix} f_{11} & f_{12} & f_{13} & f_{14} \\ 0 & f_{22} & f_{23} & f_{24} \\ 0 & f_{32} & f_{33} & f_{34} \\ 0 & 0 & 0 & f_{44} \end{bmatrix}$$

and $G \in \mathbb{R}^{n\times n}$ is upper quasi-triangular. In this case the shifted Kronecker system has the form

$$\begin{bmatrix} f_{11}G - \lambda I_n & f_{12}G & f_{13}G & f_{14}G \\ 0 & f_{22}G - \lambda I_n & f_{23}G & f_{24}G \\ 0 & f_{32}G & f_{33}G - \lambda I_n & f_{34}G \\ 0 & 0 & 0 & f_{44}G - \lambda I_n \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \end{bmatrix} = \begin{bmatrix} c_1 \\ c_2 \\ c_3 \\ c_4 \end{bmatrix},$$

where $y_i \in \mathbb{R}^n$ and $c_i \in \mathbb{R}^n$ for $i = 1{:}4$. Assume that the system is nonsingular. The first step is to solve the $n$-by-$n$ quasi-triangular system

$$(f_{44}G - \lambda I_n)\, y_4 = c_4$$

for $y_4$. Substituting this into the above system reduces it to

$$\begin{bmatrix} f_{11}G - \lambda I_n & f_{12}G & f_{13}G \\ 0 & f_{22}G - \lambda I_n & f_{23}G \\ 0 & f_{32}G & f_{33}G - \lambda I_n \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \\ y_3 \end{bmatrix} = \begin{bmatrix} \tilde{c}_1 \\ \tilde{c}_2 \\ \tilde{c}_3 \end{bmatrix}, \tag{3.3}$$

where $\tilde{c}_i = c_i - f_{i4}Gy_4$. The vectors $y_4$ and $Gy_4$ require $O(n^2)$ flops. Next we solve the block 2-by-2 system

$$\begin{bmatrix} f_{22}G - \lambda I_n & f_{23}G \\ f_{32}G & f_{33}G - \lambda I_n \end{bmatrix} \begin{bmatrix} y_2 \\ y_3 \end{bmatrix} = \begin{bmatrix} \tilde{c}_2 \\ \tilde{c}_3 \end{bmatrix} \tag{3.4}$$

for $y_2$ and $y_3$. We are then left with a single system for $y_1$:

$$(f_{11}G - \lambda I_n)y_1 = \tilde{c}_1 - f_{12}Gy_2 - f_{13}Gy_3.$$

From this example the general plan is clear. At each stage we solve either an $n$-by-$n$ system for a single $y_i$ or a $2n$-by-$2n$ block system for a pair of $y_i$'s. The results are then substituted into the remaining equations.

Now let us consider how to solve a system of the form (3.4). For concreteness, suppose

$$G = \begin{bmatrix} \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \\ 0 & 0 & \times & \times & \times \\ 0 & 0 & 0 & \times & \times \\ 0 & 0 & 0 & \times & \times \end{bmatrix}.$$

It is easy to verify that the 2-by-2 block matrix of coefficients in (3.4) has the form

$$\left[\begin{array}{ccccc|ccccc} \times & \times & \times & \times & \times & \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times & \times & \times & \times & \times & \times \\ 0 & 0 & \times & \times & \times & 0 & 0 & \times & \times & \times \\ 0 & 0 & 0 & \times & \times & 0 & 0 & 0 & \times & \times \\ 0 & 0 & 0 & \times & \times & 0 & 0 & 0 & \times & \times \\ \hline \times & \times & \times & \times & \times & \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times & \times & \times & \times & \times & \times \\ 0 & 0 & \times & \times & \times & 0 & 0 & \times & \times & \times \\ 0 & 0 & 0 & \times & \times & 0 & 0 & 0 & \times & \times \\ 0 & 0 & 0 & \times & \times & 0 & 0 & 0 & \times & \times \end{array}\right] = S. \tag{3.5}$$

Since $S = F(2{:}3, 2{:}3) \otimes G - \lambda I_{10}$, we can reverse the order of the Kronecker factors via a permutation as discussed in section 2:

$$\Pi_{5,10}^T S \Pi_{5,10} = G \otimes F(2{:}3, 2{:}3) - \lambda I_{10} = \left[\begin{array}{cccc|cc|cccc} \times & \times & \times & \times & \times & \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times & \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times & \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times & \times & \times & \times & \times & \times \\ \hline 0 & 0 & 0 & 0 & \times & \times & \times & \times & \times & \times \\ 0 & 0 & 0 & 0 & \times & \times & \times & \times & \times & \times \\ \hline 0 & 0 & 0 & 0 & 0 & 0 & \times & \times & \times & \times \\ 0 & 0 & 0 & 0 & 0 & 0 & \times & \times & \times & \times \\ 0 & 0 & 0 & 0 & 0 & 0 & \times & \times & \times & \times \\ 0 & 0 & 0 & 0 & 0 & 0 & \times & \times & \times & \times \end{array}\right].$$

Extrapolating from this example it is clear that a block system like (3.4) can be solved in $O(n^2)$ flops by permuting it into a block triangular system with diagonal blocks that are either 2-by-2 or 4-by-4.

We are now in a position to formulate a complete algorithm for the problem $(F \otimes G - \lambda I_{mn})y = c$ when $F \in \mathbb{R}^{m\times m}$ and $G \in \mathbb{R}^{n\times n}$ are upper quasi-triangular. If

$$F = \begin{bmatrix} F_{11} & F_{12} & \cdots & F_{1r} \\ 0 & F_{22} & \cdots & F_{2r} \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & F_{rr} \end{bmatrix}$$

with 1-by-1 and 2-by-2 diagonal blocks, then $(F \otimes G - \lambda I_{mn})y = c$ has the form

$$\begin{bmatrix} F_{11} \otimes G - \lambda I_\ell & F_{12} \otimes G & \cdots & F_{1r} \otimes G \\ 0 & F_{22} \otimes G - \lambda I_\ell & \cdots & F_{2r} \otimes G \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & F_{rr} \otimes G - \lambda I_\ell \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ y_r \end{bmatrix} = \begin{bmatrix} c_1 \\ c_2 \\ \vdots \\ c_r \end{bmatrix},$$

where $\ell = n$ if $F_{ii}$ is 1-by-1 and $\ell = 2n$ if $F_{ii}$ is 2-by-2 for $i = 1{:}r$. The overall back-substitution process then looks like this:

```
(3.6)
for $k = r{:}-1{:}1$
    if $F_{kk}$ is 1-by-1
        Solve $(F_{kk}G - \lambda I_n)y_k = c_k$ for $y_k \in \mathbb{R}^n$
        $z \leftarrow Gy_k$
        $c_i \leftarrow c_i - F_{ik}z,\ \ i = 1{:}k-1$
    else
        Solve $(F_{kk} \otimes G - \lambda I_{2n})y_k = c_k$ for $y_k \in \mathbb{R}^{2n}$
        $z \leftarrow (I_2 \otimes G)y_k$
        $c_i \leftarrow c_i - (F_{ik} \otimes I_n)z,\ \ i = 1{:}k-1$
    end
end
```

Thus, on each pass through the loop we solve an $n$-by-$n$ quasi-triangular system or a $2n$-by-$2n$ block triangular system obtained via permutation. The exact flop count depends upon the number of 2-by-2 blocks along the diagonals of $F$ and $G$, i.e., the number of complex conjugate eigenvalue pairs that these matrices have. But regardless, the volume of computation is $O(mn(m+n))$.

**4. The general algorithm.** Observe that algorithm (3.6) could be a solution framework for the general $(T^{(p)} \otimes \cdots \otimes T^{(1)})y = c$ problem if we set

$$\begin{aligned} F &= T^{(p)}, \\ G &= T^{(p-1)} \otimes \cdots \otimes T^{(1)}, \\ m &= n_p, \\ n &= n_1 \cdots n_{p-1}. \end{aligned}$$

The "solve" steps in (3.6) become recursive calls. If the $T^{(i)}$ are all upper triangular, then $F_{kk}$ is 1-by-1 and algorithm (3.6) can be easily extended for general $p$. However, if the $T^{(i)}$ are quasi-triangular, then $F_{kk}$ is 2-by-2 and the system $(F_{kk} \otimes G - \lambda I_{2n})y_k = c_k$ has the form

$$\left(F_{kk} \otimes T^{(p-1)} \otimes \cdots \otimes T^{(1)} - \lambda I_m\right) y_k = c_k.$$

If we use the methods of the previous section, we can permute this system to obtain

$$\left(T^{(p-1)} \otimes \cdots \otimes T^{(1)} \otimes F_{kk} - \lambda I_m\right) \tilde{y}_k = \tilde{c}_k. \tag{4.1}$$

However, the permute-to-block-triangular-form approach that we illustrated in section 3 is much less appealing when we consider the general $p$ case. If $G$ is itself a Kronecker product, e.g., $T^{(p-1)} \otimes \cdots \otimes T^{(1)}$, then its structure is adversely scrambled when we permute $S$ in (3.5).

For this reason, if we are confronted with a system of the form

$$(\alpha \otimes G - \lambda I)\, y = c, \tag{4.2}$$

where

$$\alpha = \begin{bmatrix} \alpha_{11} & \alpha_{12} \\ \alpha_{21} & \alpha_{22} \end{bmatrix}$$

has complex eigenvalues, then we compute the [illegible] 2-by-2 Schur decomposition

$$Q^H \alpha Q = \begin{bmatrix} s_{11} & s_{12} \\ 0 & s_{22} \end{bmatrix}.$$

Equation (4.2) transforms to

$$\left(\begin{bmatrix} s_{11} & s_{12} \\ 0 & s_{22} \end{bmatrix} \otimes G - \lambda I\right) z = d,$$

where $z = (Q^H \otimes I)y$ and $d = (Q^H \otimes I)c$. This can be solved recursively when $G$ is a Kronecker product. The (real) solution to the original system is then prescribed by $y = (Q \otimes I)z$.

Therefore, if the $T^{(i)}$ are upper quasi-triangular, extending algorithm (3.6) for general $p$ involves creating an input parameter, $\alpha$, that can be either a 1-by-1 or a 2-by-2 matrix. If $\alpha$ is 2-by-2 we compute its complex Schur decomposition and solve

$$\left(\begin{bmatrix} \alpha_{11} & \alpha_{12} \\ \alpha_{21} & \alpha_{22} \end{bmatrix} \otimes T^{(p-1)} \otimes \cdots \otimes T^{(1)} - \lambda I\right) y = c$$

recursively.

Of course, the hassle associated with the 2-by-2 bumps can be avoided altogether if the complex Schur decompositions $Q^{(i)H}AQ^{(i)} = T^{(i)}$ are computed right at the start. However, the proposed strategy is preferred because it restricts complex arithmetic to diagonal block subproblems. In pseudo-MATLAB our algorithm, `KPShiftSolve`, is given in Figure 1.

To assess the volume of the computation, let $\nu_p$ be the number of flops required by a call to `KPShiftSolve` when the matrix of coefficients involves a $p$-fold Kronecker product. Ignoring low-order terms,

$$\nu_p = \begin{cases} 1.5n_1^2 & \text{if } p = 1, \\ \\ n_p\nu_{p-1} + n_1 \cdots n_p(n_1 + \cdots + n_p) & \text{if } p > 1. \end{cases} \tag{4.3}$$

Of course, the exact flop count depends on the number of complex eigenvalues of the $T^{(i)}$. We mentioned that an alternative, but more costly, algorithm involves computing the complex Schur decompositions of the $T^{(i)}$ from the start. If $p = 1$, then solving $(T_1 - \lambda I)y = c$ in complex arithmetic requires $6.5n_1^2$ as compared with (4.3). When $p > 1$, the cost of the update (2.7) also increases by a factor of 6 using complex arithmetic. Hence, the exact flop count of `KPShiftSolve` lies between what is specified in (4.3) and the bounds given above when complex arithmetic is used for the entire process.

If $n_1 = \cdots = n_p \equiv n$ in (4.3), then it can be shown that

$$\nu_p = \frac{1 + p + p^2}{2} n^{p+1} = \frac{1 + p + p^2}{2} Nn.$$

Things are even more complicated if the $n_i$ vary. For example, if the $T^{(i)}$ are triangular and real, then having $n_1 \leq \cdots \leq n_p$ is more advantageous than having $n_1 \geq \cdots \geq n_p$ to reduce the number of recursive calls. For quasi-triangular $T^{(i)}$, the flop count, vectorization properties, and recursion overheads depend upon the size ordering and the number of 2-by-2 bumps in each $T^{(i)}$.

**5. Implementation issues and performance.** `KPShiftSolve` can be made more efficient in two ways. First, the $T^{(i)}$ should be sorted so that $T^{(i+1)}$ has fewer 2-by-2 bumps than $T^{(i)}$, $i = 1{:}p - 1$, so there are fewer recursive calls. This can be accomplished via the perfect shuffle explained in section 2 and reduces the overall flop count. Second, instead of computing the real Schur form of $T^{(1)}$, we need only compute the cheaper Hessenberg decomposition. To appreciate why this is sufficient consider the $p = 2$ example at the start of section 3. If $G$ is upper Hessenberg then the linear systems with coefficient matrices $f_{ii}G - \lambda I$ that arise during the back-substitution process (3.2) are also upper Hessenberg. Hessenberg systems can be solved as quickly as quasi-triangular systems [1, p. 155].

MATLAB codes for the algorithms discussed in this paper are available at

http://www.math.jmu.edu/∼carlam/.

The reader interested in details, especially as they concern the recursion, should study the codes directly.

With respect to the roundoff properties of the algorithm, the computed solution $\hat{x}$ can be shown to solve

$$\left(A^{(p)} \otimes \cdots \otimes A^{(1)} - \lambda I_N + E\right) \hat{x} = b, \tag{5.1}$$

```
function $y = \texttt{KPShiftSolve}(T, n, c, \lambda, \alpha)$
% $T$ is a length $p$ cell array and $n = (n_1, \ldots, n_p)$. Assume that the
% $i$th element of $T$ is the upper quasi-triangular matrix $T_i$.

FIG. 1. *Pseudo*-MATLAB *code for* `KPShiftSolve`.

where for any $p$-norm

$$\| E \| \approx \mathbf{u}\Big(\| A^{(p)} \| \cdots \| A^{(1)} \| + |\lambda|\Big) = \mathbf{u}\Big(\| A^{(p)} \otimes \cdots \otimes A^{(1)} \| + |\lambda|\Big) \tag{5.2}$$

and $\mathbf{u}$ is the unit roundoff. See the appendix for details.

We make a three comments related to (5.2). First, the explicit formation of the coefficient matrix involves rounding errors of the same magnitude as $\| E \|$. Second, as with any shifted, nonsymmetric linear system, there is not much we can say about the forward stability in $\hat{x}$ because the connection between the condition and the shift parameter is nontrivial. Finally, if $\kappa_p(\cdot)$ denotes the $p$-norm condition, then $\kappa_p(A^{(p)} \otimes \cdots \otimes A^{(1)}) = \kappa_p(A^{(p)}) \cdots \kappa_p(A^{(1)})$. Thus, modest ill-conditioning among the $A^{(i)}$ compounds to severe ill-conditioning in the Kronecker product.

## 6. Conclusion.

We have presented an algorithm that solves the shifted system

$$\Big(A^{(p)} \otimes \cdots \otimes A^{(1)} - \lambda I_N\Big)\, x = b,$$

where $A^{(i)} \in \mathbb{R}^{n_i \times n_i}$ for $i = 1{:}p$ and $N = n_1 \cdots n_p$. Our algorithm involves taking the real Schur decompositions to convert this system to a quasi-triangular system and uses a recursive block back-substitution procedure (`KPShiftSolve`). When a 2-by-2 bump is encountered in the leading coefficient matrix, the complex Schur decomposition is computed by the 2-by-2 matrix. This is faster than computing the complex Schur decompositions from the start. The error associated with our algorithm is no worse than the method of actually forming the Kronecker product and using standard back-substitution.

## Appendix. Error analysis.

In this appendix, we establish (5.1) and (5.2). Recall that the first step in our algorithm is to compute the (real) Schur decompositions of each $A^{(i)}$. Because of the results in [3], it suffices to show that if $\hat{y}$ is produced by `KPShiftSolve` then

$$(T^{(p)} \otimes \cdots \otimes T^{(1)} - \lambda I + \Delta T)\hat{y} = c, \tag{A.1}$$

$$\| \Delta T \| \le \delta_T(||T^{(p)}|| \cdots ||T^{(1)}|| + |\lambda|), \tag{A.2}$$

where $\delta_T$ is a modest multiple of the unit roundoff $\mathbf{u}$ and $T^{(i)}$ is either triangular or quasi-triangular for $i = 1{:}p$. To establish these results we first say something about the case $p = 2$. As in [3], we adopt the convention that all the $\delta$'s below are $O(\mathbf{u})$ in magnitude. In addition, the floating point result of a matrix calculation is indicated by fl$(\cdot)$ and we use "hat" notation to represent computed quantities.

Lemma A.1. [illegible] $F \in \mathbb{R}^{m\times m}$ [illegible] $G \in \mathbb{R}^{n\times n}$ [illegible] $c \in \mathbb{R}^{mn}$ [illegible] $\lambda \in \mathbb{R}$ [illegible] $\hat{y}$ [illegible] `KPShiftSolve` [illegible] $(F \otimes G - \lambda I)y = c$ [illegible] $E \in \mathbb{R}^{mn\times mn}$ [illegible]

$$(F \otimes G - \lambda I + E)\hat{y} = c, \tag{A.3}$$

$$\| E \| \le \delta_E(\| F \| \| G \| + |\lambda|). \tag{A.4}$$

[illegible] The proof is by induction on the dimension of $F$. If $m = 1$ then we solve $(f_{11}G - \lambda I_n)y = c$. This involves first forming $M = f_{11}G - \lambda I_n$ and then solving

$My = c$ using back-substitution. Accounting for the rounding error associated with forming $M$, there exists $H_1$ such that

$$\hat{M} = \mathrm{fl}(M) = f_{11}G - \lambda I + H_1, \qquad \| H_1 \| \le \delta_1(|f_{11}| \cdot \| G \| + |\lambda|). \tag{A.5}$$

Next, the computed solution to the triangular system satisfies

$$(\hat{M} + H_2)\hat{y} = c, \tag{A.6}$$

$$\| H_2 \| \le \delta_2 \| \hat{M} \| \le \delta_3(|f_{11}| \cdot \| G \| + |\lambda|), \tag{A.7}$$

where $\delta_3 = \delta_1 + \delta_2$ (see [1, p. 89]). Combining (A.5)–(A.7) and setting $E = H_1 + H_2$ complete the proof when $m = 1$.

Now suppose (A.3), (A.4) hold for all $k < m$. Partition the system as

$$\begin{bmatrix} f_{11}G - \lambda I & F_{12} \otimes G \\ 0 & F_{22} \otimes G - \lambda I \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} c_1 \\ c_2 \end{bmatrix},$$

where $F_{12} = F(1, 2{:}m)$, $F_{22} = F(2{:}m, 2{:}m)$, and $y_1, y_2, c_1, c_2$ are appropriate blockings of $y$ and $c$, respectively. By induction, $\hat{y}_2$ solves

$$(F_{22} \otimes G - \lambda I + E_{22})\hat{y}_2 = c_2$$

with

$$\| E_{22} \| \le \delta_4(\| F_{22} \| \| G \| + |\lambda|). \tag{A.8}$$

The next step is to solve for $y_1$ with

$$(f_{11}G - \lambda I)y_1 = \mathrm{fl}(c_1 - (F_{12} \otimes G)\hat{y}_2).$$

The computations associated with the update $d_1 = c_1 - (F_{12} \otimes G)\hat{y}_2$ satisfy

$$\hat{d}_1 = \mathrm{fl}(d_1) = c_1 - (F_{12} \otimes G + E_{12})\hat{y}_2 + \Delta c,$$

where

$$\| E_{12} \| \le \delta_5 \| F_{12} \| \| G \|, \tag{A.9}$$

$$\| \Delta c \| \le \delta_6(\| c_1 \| + \| F_{12} \| \| G \| \| \hat{y}_2 \|). \tag{A.10}$$

Finally, we form $M = f_{11}G - \lambda I$ and solve $My_1 = d_1$ using back-substitution. Forming $M$ gives

$$\hat{M} = \mathrm{fl}(M) = f_{11}G - \lambda I + \Delta_1, \tag{A.11}$$

$$\| \Delta_1 \| \le \delta_7(|f_{11}| \cdot \| G \| + |\lambda|). \tag{A.12}$$

Then the computed solution to the triangular system $\hat{M}y_1 = \hat{d}_1$ satisfies

$$(\hat{M} + \Delta_2)\hat{y}_1 = \hat{d}_1$$

with

$$\| \Delta_2 \| \le \delta_8 \| \hat{M} \| \le \delta_9(|f_{11} \cdot \| G \| + |\lambda|). \tag{A.13}$$

Let $E_{11} = \Delta_1 + \Delta_2$ and set

$$E = \begin{bmatrix} E_{11} & E_{12} \\ 0 & E_{22} \end{bmatrix}.$$

The proof follows from (A.8), (A.9), (A.12), (A.13), and by setting $\delta_E = \delta_4 + \delta_5 + \delta_7 + \delta_9$. □

Next, we address the error associated with computations when a 2-by-2 bump is encountered. For simplicity, we show this for $p = 2$.

Lemma A.2. [illegible] $\alpha$ [illegible] $2 \times 2$ [illegible] $T$ [illegible] $n \times n$ [illegible] $m = n\dim(\alpha)$ $c \in \mathbb{R}^m$ [illegible] $\lambda \in \mathbb{R}$ [illegible] $\hat{y}$ [illegible] `KPShiftSolve` [illegible] $(\alpha \otimes T - \lambda I)y = c$ [illegible] $E \in \mathbb{R}^{m\times m}$ [illegible]

$$(\alpha \otimes T - \lambda I_m + E)\hat{y} = c, \tag{A.14}$$

$$\| E \| \leq \delta_E(\| \alpha \| \| T \| + |\lambda|). \tag{A.15}$$

[illegible]. If $\alpha$ is $1\times 1$, then the proof is completed by using Lemma A.1. If $\alpha$ is $2\times 2$, then `KPShiftSolve` computes the complex Schur decomposition of $\alpha$ and then solves a block upper triangular system. Specifically, `KPShiftSolve` performs the following four steps:

1. Compute the complex Schur decomposition $Q^H \alpha Q = S$.
2. Form $d = (Q^H \otimes I)c$.
3. Solve the system $(S \otimes T - \lambda I)z = d$ for $z$ using `KPShiftSolve`.
4. Set $y = (Q \otimes I)z$.

These steps are analogous to solving a linear system using the complex Schur decomposition. The Kronecker product structure does not affect the result and can be shown using the methods found in [3] and Lemma A.1. □

Now that we have dealt with the error associated with solving the system when a 2-by-2 bump is encountered, we are ready to establish the error results for a Kronecker product of quasi-triangular matrices. In the next lemma, we present the results for $p = 2$.

Lemma A.3. [illegible] $F$ [illegible] $G$ [illegible] $m \times m$ [illegible] $n \times n$ [illegible] $\lambda \in \mathbb{R}$ [illegible] $b \in \mathbb{R}^{mn}$ [illegible] `KPShiftSolve` [illegible] $(F \otimes G - \lambda I_{mn})y = c$ [illegible] $E \in \mathbb{R}^{mn\times mn}$ [illegible] $\hat{y}$ [illegible]

$$(F \otimes G - \lambda I + E)\hat{y} = c, \tag{A.16}$$

$$\| E \| \leq \delta_E(\| F \| \| G \| + |\lambda|). \tag{A.17}$$

[illegible]. The proof is similar to the proof of Lemma A.1 and is completed by induction on the dimension of $F$. Lemma A.2 is used when a 2-by-2 bump is encountered in $F$. □

We are now ready to establish the final result for general $p$. The following lemma establishes (A.1) and (A.2).

Lemma A.4. [illegible] $T^{(1)}, \ldots, T^{(p)}$ [illegible] $n_i \times n_i$ [illegible] $i = 1, \ldots, p$ [illegible] $\lambda \in \mathbb{R}$ [illegible] $b \in \mathbb{R}^{n_1 \cdots n_p}$ [illegible] `KPShiftSolve` [illegible] $(T^{(p)} \otimes \cdots \otimes T^{(1)} - \lambda I)y = c$ [illegible] $\Delta T \in \mathbb{R}^{N\times N}$ [illegible] $N = n_1 \cdots n_p$ [illegible]

[illegible] $\hat{y}$ [illegible]

$$(T^{(p)} \otimes \cdots \otimes T^{(1)} - \lambda I + \Delta T)\hat{y} = c,$$

$$\| \Delta T \| \leq \delta_T(||T^{(p)}|| \cdots ||T^{(1)}|| + |\lambda|).$$

[illegible]. We prove this by induction on $p$. Lemma A.3 proves the base case when $p = 2$. Now assume Lemma A.4 holds for $p - 1$. To show this is true for $p$, we use induction on $\dim(A^{(p)})$. The proof follows by following the methods similar to the proof of Lemma A.1 when $p = 2$. The proof now easily follows from Lemma A.3 by setting $G = T^{(p-1)} \otimes \cdots \otimes T^{(1)}$. ☐

# MULTISHIFT VARIANTS OF THE QZ ALGORITHM WITH AGGRESSIVE EARLY DEFLATION[*]

BO KÅGSTRÖM[†] AND DANIEL KRESSNER[†‡]

**Abstract.** New variants of the QZ algorithm for solving the generalized eigenvalue problem are proposed. An extension of the small-bulge multishift QR algorithm is developed, which chases chains of many small bulges instead of only one bulge in each QZ iteration. This allows the effective use of level 3 BLAS operations, which in turn can provide efficient utilization of high performance computing systems with deep memory hierarchies. Moreover, an extension of the aggressive early deflation strategy is proposed, which can identify and deflate converged eigenvalues long before classic deflation strategies would. Consequently, the number of overall QZ iterations needed until convergence is considerably reduced. As a third ingredient, we reconsider the deflation of infinite eigenvalues and present a new deflation algorithm, which is particularly effective in the presence of a large number of infinite eigenvalues. Combining all these developments, our implementation significantly improves existing implementations of the QZ algorithm. This is demonstrated by numerical experiments with random matrix pairs as well as with matrix pairs arising from various applications.

## 1. Introduction.

The QZ algorithm is a numerically backward stable method for computing generalized eigenvalues and deflating subspaces of small- to medium-sized regular matrix pairs $(A, B)$ with $A, B \in \mathbb{R}^{n\times n}$. It goes back to Moler and Stewart in 1973 [37] and underwent only a few modifications during the following 25 years, notably through works by Ward [47, 48], Kaufman [29], and Dackland and Kågström [12]. Nonorthogonal variants of the QZ algorithm include the LZ algorithm by Kaufman [28] and the AB algorithm for pencils by Kublanovskaya [34].

The purpose of the QZ algorithm is to compute a [illegible] of $(A, B)$, i.e., orthogonal matrices $Q$ and $Z$ so that $S = Q^TAZ$ is quasi-upper triangular with $1 \times 1$ and $2 \times 2$ blocks on the diagonal, while the matrix $T = Q^TBZ$ is upper triangular. This decomposition provides almost everything needed to solve the generalized nonsymmetric eigenvalue problem (GNEP). [illegible], defined as root pairs $(\alpha, \beta)$ of the bivariate polynomial $\det(\beta A - \alpha B)$, can be directly computed from the diagonal blocks of $S$ and $T$, although some care must be taken to implement this computation in a safe manner; see [37, 45]. Moreover, the leading $k$ columns of the orthogonal matrices $Z$ and $Q$ span a pair of [illegible] [40] if the $(k+1, k)$ subdiagonal entry of the matrix $S$ vanishes. A reordering of the diagonal blocks of $S$ and $T$ can be used to compute other deflating subspaces; see [26, 25, 44].

The eigenvalues of $(A, B)$ are read off from $(S, T)$ as follows. The $2 \times 2$ diagonal blocks correspond to pairs of complex conjugate eigenvalues. The real eigenvalues

are given in pairs $(s_{ii}, t_{ii})$ corresponding to the $1 \times 1$ diagonal blocks of $(S, T)$. The finite eigenvalues are $s_{ii}/t_{ii}$, where $t_{ii} \neq 0$. An infinite eigenvalue is represented as $(s_{ii}, 0)$ with $s_{ii} \neq 0$. If $(s_{ii}, t_{ii}) \neq (0, 0)$ for all $i$, then $(A, B)$ is a [illegible], or equivalently $\beta A - \alpha B$ is a regular matrix pencil. Otherwise, the matrix pair is [illegible] and at least one $(s_{ii}, t_{ii})$ equals $(0, 0)$. These situations need extra caution, and so-called staircase-type algorithms can be used for identifying singular cases by computing a generalized upper triangular (GUPTRI) form of $(A, B)$ (e.g., see Demmel and Kågström [13, 14]).

Three ingredients make the QZ algorithm work effectively. First, the matrix pair $(A, B)$ is reduced to Hessenberg-triangular form; i.e., orthogonal matrices $Q$ and $Z$ are computed so that $H = Q^T AZ$ is upper Hessenberg and $T = Q^T BZ$ is upper triangular. Second, a sequence of so-called implicit shifted QZ iterations is applied to $(H, T)$ in order to bring $H$ closer to (block) upper triangular form while preserving the Hessenberg-triangular form of $(H, T)$. Each of these iterations can be seen as chasing a pair of bulges from the top left to the bottom right corners along the subdiagonals of $H$ and $T$, a point of view that has been emphasized by Watkins and Elsner [49]. The third ingredient is deflation, which aims at splitting the computation of the generalized Schur form $(S, T)$ into smaller subproblems. This paper describes improvements for the latter two ingredients, QZ iterations, and deflations.

Inspired by the works of Braman, Byers, and Mathias [7] and Lang [36] for the QR algorithm, we propose multishift QZ iterations that chase a tightly coupled chain of bulge pairs instead of only one bulge pair per iteration. This allows the effective use of level 3 BLAS operations [15, 23, 24] during the bulge chasing process, which in turn can provide efficient utilization of today's high performance computing systems with deep memory hierarchies. Tightly coupled bulge chasing has also successfully been used in the reduction of a matrix pair $(H_r, T)$ in block Hessenberg-triangular form, where $H_r$ has $r$ subdiagonals, to Hessenberg-triangular form $(H, T)$ [12].

Recently, Braman, Byers, and Mathias [6] also presented a new, advanced deflation strategy, the so-called aggressive early deflation. Combining this deflation strategy with multishift QR iterations leads to a variant of the QR algorithm, which may, for sufficiently large matrices, require less than 10% of the computing time needed by the LAPACK [2] implementation. We will show that this deflation strategy can be extended to the QZ algorithm, resulting in similar time savings.

A (nearly) singular matrix $B$ often implies that the triangular matrix $T$ of the corresponding Hessenberg-triangular form has one or more diagonal entries close to zero. Each of these diagonal entries admits the deflation of an infinite eigenvalue. Some applications, such as semidiscretized Stokes equations [42], lead to matrix pairs that have a large number of infinite eigenvalues. Consequently, a substantial amount of computational work in the QZ algorithm is spent deflating these eigenvalues. We will provide a discussion on this matter including preprocessing techniques, and we propose windowing techniques that lead to more efficient algorithms for deflating infinite eigenvalues within the QZ algorithm. This approach is conceptually close to blocked algorithms for reordering eigenvalues in standard and generalized Schur forms [32].

The rest of this paper is organized as follows. In section 2, we review and extend conventional multishift QZ iterations and provide some new insight into their numerical backward stability. Multishift variants that are based on chasing a tightly coupled chain of bulge pairs are described in section 3. In section 4, a thorough discussion on dealing with infinite eigenvalues is presented that includes preprocessing and efficient methods for deflating such eigenvalues within the QZ algorithm. Aggressive early deflation for the QZ algorithm and its connection to the distance of uncontrollability for descriptor systems are studied in section 6. Computational experiments, presented in section 7, demonstrate the effectiveness of our newly developed multishift QZ algorithm with advanced deflation techniques. Finally, some concluding remarks are summarized in section 8.

**2. Conventional multishift QZ iterations.** Throughout the rest of this paper we assume that the matrix pair under consideration, which will be denoted by $(H, T)$, is already in Hessenberg-triangular form. Efficient algorithms for reducing a given matrix pair to this form can be found in [12, 31]. For the moment, we also assume that $(H, T)$ is an [illegible]; i.e., all subdiagonal entries of $H$ as well as all diagonal entries of $T$ are different from zero. The latter condition implies that only finite eigenvalues are considered.

A QZ iteration relies on a fortunate choice of $m$ shifts (or shift pairs) $(\mu_1, \nu_1)$, $(\mu_2, \nu_2), \dots, (\mu_m, \nu_m)$ with $\mu_i \in \mathbb{C}$ and $\nu_i \in \mathbb{R}$, giving rise to the [illegible]

$$p(HT^{-1}) = (\nu_1 HT^{-1} - \mu_1 I_n)(\nu_2 HT^{-1} - \mu_2 I_n) \cdots (\nu_m HT^{-1} - \mu_m I_n). \tag{2.1}$$

If $x$ denotes the first column of this matrix polynomial, then the first step of an implicit shifted QZ iteration consists of choosing an orthogonal matrix $Q_1$ such that $Q_1^T x$ is a multiple of the first unit vector $e_1$. The rest of the QZ iteration consists of reducing the updated matrix pair $(Q_1^T H, Q_1^T T)$ back to Hessenberg-triangular form, without modifying the first rows of $Q_1^T H$ and $Q_1^T T$ by transformations from the left.

In the original formulation of the QZ algorithm [37], this reduction to Hessenberg-triangular form was described for $m \leq 2$, based on combinations of Givens rotations and Householder matrices. This approach has the negative side-effect that one QZ iteration with $m = 2$ shifts requires more [illegible] (floating point operations) than two QZ iterations with $m = 1$ shift. Partly avoiding this increase of flops, Ward [47] proposed the so-called [illegible] which uses $m = 1$ for real shifts and $m = 2$ for complex conjugate pairs of shifts. Later on, Watkins and Elsner [49] proposed a variant solely based on Householder matrices which requires roughly 27% fewer flops than the original formulation and may employ an arbitrary number $m$ of shifts. This variant is currently implemented in the LAPACK subroutine `DHGEQZ`. A curiosity of this subroutine is that it still uses Ward's combination shift strategy despite the fact that two single shift QZ iterations now require roughly 9% more flops than one double shift iteration.

**2.1. Householder-based variants.** In the following, we describe the Householder-based variant by Watkins and Elsner in more detail. To simplify the notation, we make use of the following convention.

DEFINITION 2.1. [illegible] $n - j$ [illegible] $x \in \mathbb{R}^n$ [illegible] $j - 1$ [illegible] $\mathcal{H}_j(x)$

Let us illustrate the first few steps of an implicit QZ iteration for $n = 6, m = 2$. First, a Householder matrix $\mathcal{H}_1(x)$ is used to map $x$, the first column of the shift polynomial defined in (2.1), to a multiple of $e_1$. Note that only the leading three elements of $x$ are nonzero. Hence, if $\mathcal{H}_1(x)$ is applied from the left to $H$ and $T$, only the first three rows (denoted by the symbols $\hat{h}$ and $\hat{t}$ below) are affected while the remaining rows stay unchanged (denoted by $h$ and $t$):

$$(H,T) \leftarrow \left( \begin{bmatrix} \hat h & \hat h & \hat h & \hat h & \hat h & \hat h \\ \hat h & \hat h & \hat h & \hat h & \hat h & \hat h \\ \hat h & \hat h & \hat h & \hat h & \hat h & \hat h \\ 0 & 0 & h & h & h & h \\ 0 & 0 & 0 & h & h & h \\ 0 & 0 & 0 & 0 & h & h \end{bmatrix}, \begin{bmatrix} \hat t & \hat t & \hat t & \hat t & \hat t & \hat t \\ \hat t & \hat t & \hat t & \hat t & \hat t & \hat t \\ \hat t & \hat t & \hat t & \hat t & \hat t & \hat t \\ 0 & 0 & 0 & t & t & t \\ 0 & 0 & 0 & 0 & t & t \\ 0 & 0 & 0 & 0 & 0 & t \end{bmatrix} \right). \tag{2.2}$$

Next, to avoid further fill-in in the factor $T$, the newly introduced entries $(2,1)$ and $(3,1)$ must be eliminated. Recall that we are not allowed to change the first row of $T$ by applying a transformation from the left. However, it is still possible to achieve these eliminations by applying a Householder matrix using the following simple fact.

LEMMA 2.2 (see [49]). [illegible] $T \in \mathbb{R}^{n\times n}$ [illegible] $T\mathcal{H}_1(T^{-1}e_1)$ [illegible] $e_1$

Applying a Householder matrix from the [illegible] to eliminate several elements in one [illegible] (instead of one row) is somewhat opposite to their standard use. This motivates us to call such a matrix an [illegible]. Applying $\mathcal{H}_1(T^{-1}e_1)$ from the right yields the following diagram:

$$(H,T) \leftarrow \left( \begin{bmatrix} \hat h & \hat h & \hat h & h & h & h \\ \hat h_b & \hat h_b & \hat h_b & h & h & h \\ \hat h_b & \hat h_b & \hat h_b & h & h & h \\ \hat h_b & \hat h_b & \hat h_b & h & h & h \\ 0 & 0 & 0 & h & h & h \\ 0 & 0 & 0 & 0 & h & h \end{bmatrix}, \begin{bmatrix} \hat t & \hat t & \hat t & t & t & t \\ \hat 0_b & \hat t_b & \hat t_b & t & t & t \\ \hat 0_b & \hat t_b & \hat t_b & t & t & t \\ 0_b & 0_b & 0_b & t & t & t \\ 0 & 0 & 0 & 0 & t & t \\ 0 & 0 & 0 & 0 & 0 & t \end{bmatrix} \right). \tag{2.3}$$

Here, we have used the subscript $b$ to designate entries that belong to the so-called [illegible]. The rest of the QZ iteration can be seen as pushing this bulge pair along the subdiagonals down to the bottom right corners until it vanishes. The next two steps consist of applying the Householder matrix $\mathcal{H}_2(He_1)$ from the left and the opposite Householder matrix $\mathcal{H}_2(T^{-1}e_2)$ from the right:

$$(H,T) \leftarrow \left( \begin{bmatrix} h & h & h & h & h & h \\ \hat h & \hat h & \hat h & \hat h & \hat h & \hat h \\ \hat 0 & \hat h & \hat h & \hat h & \hat h & \hat h \\ \hat 0 & \hat h & \hat h & \hat h & \hat h & \hat h \\ 0 & 0 & 0 & h & h & h \\ 0 & 0 & 0 & 0 & h & h \end{bmatrix}, \begin{bmatrix} t & t & t & t & t & t \\ 0 & \hat t & \hat t & \hat t & \hat t & \hat t \\ 0 & \hat t & \hat t & \hat t & \hat t & \hat t \\ 0 & \hat t & \hat t & \hat t & \hat t & \hat t \\ 0 & 0 & 0 & 0 & t & t \\ 0 & 0 & 0 & 0 & 0 & t \end{bmatrix} \right),$$

$$(H,T) \leftarrow \left( \begin{bmatrix} h & \hat h & \hat h & \hat h & h & h \\ h & \hat h & \hat h & \hat h & h & h \\ 0 & \hat h_b & \hat h_b & \hat h_b & h & h \\ 0 & \hat h_b & \hat h_b & \hat h_b & h & h \\ 0 & \hat h_b & \hat h_b & \hat h_b & h & h \\ 0 & 0 & 0 & 0 & h & h \end{bmatrix}, \begin{bmatrix} t & \hat t & \hat t & \hat t & t & t \\ 0 & \hat t & \hat t & \hat t & t & t \\ 0 & \hat 0_b & \hat t_b & \hat t_b & t & t \\ 0 & \hat 0_b & \hat t_b & \hat t_b & t & t \\ 0 & 0_b & 0_b & 0_b & t & t \\ 0 & 0 & 0 & 0 & 0 & t \end{bmatrix} \right). \tag{2.4}$$

For general $m$ and $n$, the implicit shifted QZ iteration based on (opposite) Householder matrices is described in Algorithm 1. Here, the [illegible] $A(i_1 : i_2, j_1 : j_2)$ is used to designate the submatrix of a matrix $A$ defined by rows $i_1$ through $i_2$ and columns $j_1$ through $j_2$.

Note that the shifts employed in Algorithm 1 are based on the generalized eigenvalues of the bottom right $m \times m$ submatrix pair, a choice which is sometimes called [illegible] and which ensures quadratic local convergence [49]. If $m \ll n$, a proper implementation of this algorithm requires $2(4m+3)n^2 + \mathcal{O}(n)$ flops for updating $H$ and $T$. In addition, $(4m+3)n^2 + \mathcal{O}(n)$ flops are required for updating each of the orthogonal factors $Q$ and $Z$.

**Algorithm 1** Implicit shifted QZ iteration based on Householder matrices

**Input:** An $n \times n$ matrix pair $(H, T)$ in unreduced Hessenberg-triangular form, an integer $m \in [2, n]$.

**Output:** Orthogonal matrices $Q, Z \in \mathbb{R}^{n\times n}$ so that $Q^T(H,T)Z$ is the Hessenberg-triangular matrix pair obtained after applying a QZ iteration with $m$ shifts. The matrix pair $(H, T)$ is overwritten by $Q^T(H,T)Z$.

```
Compute $(\mu_1,\nu_1), (\mu_2,\nu_2), \dots, (\mu_m,\nu_m)$ as generalized eigenvalues of the matrix pair
    $(H(n-m+1:n, n-m+1:n), T(n-m+1:n, n-m+1:n))$.
Set $x = ((\nu_1 HT^{-1} - \mu_1 I_n)(\nu_2 HT^{-1} - \mu_2 I_n)\cdots(\nu_m HT^{-1} - \mu_m I_n))e_1$.
$(H,T) \leftarrow \mathcal{H}_1(x)\cdot(H,T)$
$Q \leftarrow \mathcal{H}_1(x)$,    $Z \leftarrow \mathcal{H}_1(T^{-1}e_1)$
$(H,T) \leftarrow (H,T)\cdot Z$
for $j \leftarrow 1,2,\dots,n-2$ do
  $\tilde{Q} \leftarrow \mathcal{H}_{j+1}(He_j)$
  $(H,T) \leftarrow \tilde{Q}\cdot(H,T)$
  $Q \leftarrow Q\tilde{Q}$
  $\tilde{Z} \leftarrow \mathcal{H}_{j+1}(T^{-1}e_{j+1})$
  $(H,T) \leftarrow (H,T)\cdot\tilde{Z}$
  $Z \leftarrow Z\tilde{Z}$
end for
```

**2.2. Error analysis of opposite Householder matrices.** Some authors have raised concerns that the use of opposite Householder matrices could introduce numerical instabilities in the QZ algorithm; see, e.g., [12, p. 444]. Such instabilities could arise if some entries that should be zero after the application of an opposite Householder matrix are nonnegligible in finite-precision arithmetic. In the following, we provide a brief error analysis showing that such an event may not occur if some care is taken.

Without loss of generality, we can restrict the analysis to an opposite Householder matrix of the form $\mathcal{H}_1(T^{-1}e_1)$ for some nonsingular matrix $T \in \mathbb{R}^{n\times n}$. Although an ill-conditioned $T$ may severely affect the data representing $\mathcal{H}_1(T^{-1}e_1)$, it has almost no effect on the purpose of $\mathcal{H}_1(T^{-1}e_1)$, which is the introduction of zero entries. To explain this, assume that a numerically backward stable method is employed to solve the linear system $Tx = e_1$, yielding a computed solution $\hat{x}$. This implies that $\hat{x}$ is the exact solution of a slightly perturbed system

$$(T+F)\hat{x} = e_1, \quad \|F\|_2 \le c_T\|T\|_2, \tag{2.5}$$

where $c_T$ is not much larger than the unit roundoff $\mathbf{u}$ [21]. Now, consider the Householder matrix $\mathcal{H}_1(\hat{x}) = I - \tilde{\beta}\tilde{v}\tilde{v}^T$, where $\tilde{\beta} \in \mathbb{R}, \tilde{v} \in \mathbb{R}^n$, such that $(I - \tilde{\beta}\tilde{v}\tilde{v}^T)\hat{x} = \tilde{\gamma}e_1$ for some scalar $\tilde{\gamma}$. The computation of the quantities $\tilde{\beta}, \tilde{v}$ defining $\mathcal{H}_1(\hat{x})$ is also subject to roundoff errors. Using standard computational methods, the computed quantities $\hat{v}, \hat{\beta}$ satisfy

$$|\hat{\beta} - \tilde{\beta}| \le c_\beta|\tilde{\beta}| \approx (4n+8)\mathbf{u}|\tilde{\beta}|, \quad \|\hat{v} - \tilde{v}\|_2 \le c_v\|\tilde{v}\|_2 \approx (n+2)\mathbf{u}\|\tilde{v}\|_2;$$

see [21, p. 365]. It follows that

$$\begin{aligned}\|T\cdot(I - \hat{\beta}\hat{v}\hat{v}^T)e_1 - 1/\tilde{\gamma}\cdot e_1\|_2 &\le \|T\cdot(I - \tilde{\beta}\tilde{v}\tilde{v}^T)e_1 - 1/\tilde{\gamma}\cdot e_1\|_2 \\ &\quad + (2c_\beta + 4c_v)\|T\|_2 + \mathcal{O}(\mathbf{u}^2) \\ &\le (c_T + 2c_\beta + 4c_v)\|T\|_2 + \mathcal{O}(\mathbf{u}^2).\end{aligned}$$

This shows that if $\hat{x}$ is computed by a backward stable method, then the last $n-1$ elements in the first column of $T(I - \beta\hat{v}\hat{v}^T)$ can be set to zero without spoiling the backward stability of the QZ algorithm.

In this paper, we favor the following method for constructing opposite Householder matrices. Let $T = RQ$ be an RQ decomposition; i.e., the matrix $R \in \mathbb{R}^{n\times n}$ is upper triangular and $Q \in \mathbb{R}^{n\times n}$ is orthogonal. If $T$ is invertible, then $Q^T e_1$ is a scalar multiple of $T^{-1}e_1$ implying that $\mathcal{H}_1(Q^T e_1)$ is an opposite Householder matrix. Even if $T$ is singular, it can be shown that the first column of $T \cdot \mathcal{H}_1(Q^T e_1)$ is mapped to a multiple of $e_1$:

$$\begin{aligned} T \cdot \mathcal{H}_1(Q^T e_1) = R \cdot [Q \cdot \mathcal{H}_1(Q^T e_1)] &= \begin{bmatrix} r_{11} & R_{12} \\ 0 & R_{22} \end{bmatrix} \begin{bmatrix} \tilde{q}_{11} & 0 \\ 0 & \tilde{Q}_{22} \end{bmatrix} \\ &= \begin{bmatrix} r_{11}\tilde{q}_{11} & R_{12}\tilde{Q}_{22} \\ 0 & R_{22}\tilde{Q}_{22} \end{bmatrix}. \end{aligned}$$

RQ decompositions enjoy a favorable backward error analysis, and the constant $c_T$ in (2.5) can be bounded by roughly $n^2\mathbf{u}$; see, e.g., [21, Thm. 18.4].

**2.3. Bulge pairs and shift blurring.** Convergence in the implicit shifted QZ iteration typically becomes manifest in the bottom right corner of the matrix pair; often the $m$th-last subdiagonal entry of $H$ converges to zero. As a QZ iteration can be interpreted as chasing a bulge pair from the top left corner to the bottom right corner of $(H, T)$, the question arises how the information contained in the shifts is passed during this chasing process. Watkins [53] discovered a surprisingly simple relationship; the intended shifts are the finite eigenvalues of the bulge pairs.

To explain this in more detail, suppose that the implicit shifted QZ iteration with $m$ shifts, Algorithm 1, is applied to $(H, T) \in \mathbb{R}^{n\times n} \times \mathbb{R}^{n\times n}$ with $n > m$. As before, we assume that $(H, T)$ is in unreduced Hessenberg-triangular form but we do not assume that $T$ is nonsingular; only the part used for the shift computation (the trailing $m \times m$ principal submatrix of $T$) and the part involved in the introduction of the bulge pair (the leading $m \times m$ principal submatrix of $T$) are required to be nonsingular. Let $x$ be a multiple of the first column of the shift polynomial defined in (2.1). The [illegible] is the matrix pair $\big(B_0^{(H)}, B_0^{(T)}\big)$, where

$$B_0^{(H)} = [x(1:m+1), H(1:m+1:1:m)] = \begin{bmatrix} x_1 & h_{11} & \cdots & h_{1m} \\ x_2 & h_{21} & \ddots & \vdots \\ \vdots & & \ddots & h_{mm} \\ x_{m+1} & 0 & & h_{m+1,m} \end{bmatrix},$$

$$B_0^{(T)} = [0, T(1:m+1:1:m)] = \begin{bmatrix} 0 & t_{11} & \cdots & t_{1m} \\ 0 & 0 & \ddots & \vdots \\ \vdots & & \ddots & t_{mm} \\ 0 & 0 & \cdots & 0 \end{bmatrix}.$$

THEOREM 2.3 (see [53]). [illegible] $m \times m$ [illegible] $T$ [illegible] $(\sigma_1, 1), \dots, (\sigma_m, 1)$ [illegible] $\big(B_0^{(H)}, B_0^{(T)}\big)$

During the course of a QZ iteration, a bulge pair is first created at the top left corners and then chased down to the bottom right corners. Let $\big(H^{(j)}, T^{(j)}\big)$ denote the updated matrix pair $(H, T)$ obtained after the bulge pair has been chased $j-1$ steps, which amounts to applying $j-1$ loops of Algorithm 1. Then, the $j$[illegible] $\big(B_j^{(H)}, B_j^{(T)}\big)$ is given by

$$
\begin{array}{rcl}
B_j^{(H)} & = & H^{(j)}(j+1:j+m+1, j:j+m+1), \\
B_j^{(T)} & = & T^{(j)}(j+1:j+m+1, j:j+m+1),
\end{array}
\tag{2.6}
$$

which corresponds to the submatrices designated by the subscript $b$ in (2.3)–(2.4).

THEOREM 2.4 (see [53]). [illegible] $m$[illegible] $T$ [illegible] $\sigma_1, \ldots, \sigma_m$ [illegible] $j$[illegible] $\big(B_j^{(H)}, B_j^{(T)}\big)$

Note that the definition of a bulge pair is only possible for $j \leq n-m-1$, since otherwise (2.6) refers to entries outside of $H^{(j)}$ and $T^{(j)}$. This issue can be resolved by adding virtual rows and columns to the matrix pair $(H^{(j)}, T^{(j)})$; see [53]. Theorem 2.4 can be extended to the case $j > n-m-1$.

Early attempts to improve the performance of the QR algorithm focused on using shift polynomials of high degree [4], leading to medium-order Householder matrices during the QR iteration and enabling the efficient use of WY representations. This approach, however, has proved disappointing due to the fact that the convergence of such a large-bulge multishift QR algorithm is severely affected by roundoff errors [16]. This effect is caused by [illegible]: with increasing $m$ the eigenvalues of the bulge pairs, which should represent the shifts in exact arithmetic, often become extremely sensitive to perturbations [51, 52, 33]. Already for moderate $m$, say, $m \geq 15$, the shifts may be completely contaminated by roundoff errors during the bulge chasing process. Not surprisingly, we made similar observations in numerical experiments with implicit shifted QZ iterations, which also suffer from shift blurring.

## 3. Multishift QZ iterations based on tightly coupled tiny bulge pairs.

The trouble with shift blurring can be avoided by developing variants of the implicit shifted QZ algorithm that still rely on a large number of simultaneous shifts but chase several tiny bulge pairs instead of one large bulge pair. Such ideas have already been successfully applied to the QR algorithm; see, e.g., [7, 36] and the references therein. In this section, we describe an extension of the work by Braman, Byers, and Mathias [7] to the QZ algorithm.

For the purpose of describing this new tiny-bulge multishift QZ algorithm, let $m$ denote the number of simultaneous shifts to be used in each QZ iteration and let $n_s$ denote the number of shifts contained in each bulge pair. It is assumed that $m$ is an integer multiple of $n_s$. To avoid shift blurring phenomena we use tiny values for $n_s$, say, $n_s = 2$ or $n_s = 4$.

Our algorithm performs an implicit shifted QZ iteration with $m$ generalized Francis shifts to a Hessenberg-triangular matrix pair $(H, T)$ and consists of three stages, which are described in more detail below. First, a tightly coupled chain of $m/n_s$ bulge pairs is bulge-by-bulge introduced in the top left corners of $H$ and $T$. Second, the whole chain at once is chased down along the subdiagonal until the bottom bulge pair reaches the bottom right corners of $H$ and $T$. Finally, all bulge pairs are bulge-by-bulge chased off this corner.

### 3.1. Introducing a chain of bulge pairs.

The tiny-bulge multishift QZ algorithm begins with introducing $m/n_s$ bulge pairs in the top left corner of the matrix pair $(H, T)$. Every bulge pair contains a set of $n_s$ shifts. It is assumed that the $((m/n_s)(n_s+1)-1)$th leading principal submatrix of $T$ is nonsingular. The first

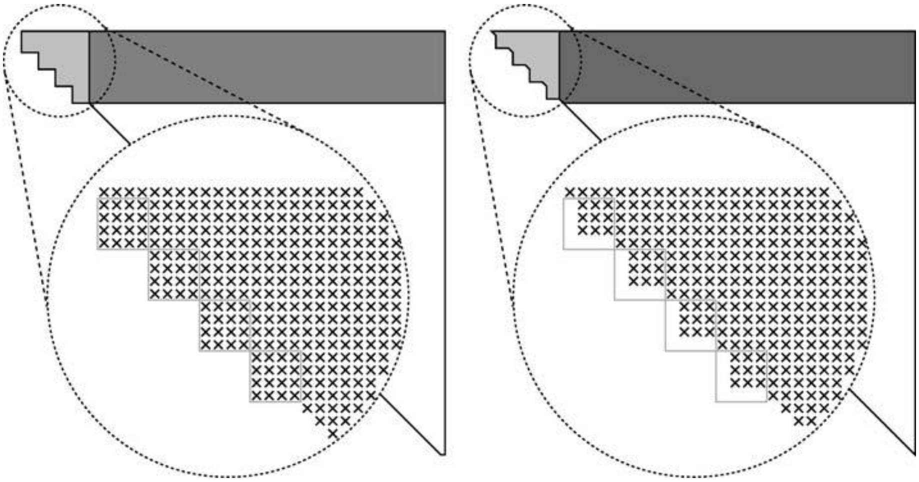

FIG. 3.1. *Introducing a chain of $m/n_s = 4$ tightly coupled bulge pairs, each of which contains $n_s = 3$ shifts.*

bulge pair is introduced by applying an implicit QZ iteration with $n_s$ shifts and interrupting the bulge chasing process as soon as the bottom right corner of the bulge in $H$ touches the $(p_h - 1, p_h)$ subdiagonal entry of $H$, where $p_h = (m/n_s)(n_s + 1) + 1$. The next bulge pair is chased until the bottom right corner of the bulge in $H$ touches the $(p_h - n_s - 2, p_h - n_s - 1)$ subdiagonal entry. This process is continued until all $m/n_s$ bulge pairs are introduced; see Figure 3.1. Note that only the submatrices marked light gray in Figure 3.1 must be updated during the bulge chasing process. To update the remaining parts (marked dark gray), all orthogonal transformations from the left are accumulated into a $p_h \times p_h$ matrix $U$ and applied in terms of general matrix-matrix multiply (GEMM) operations:

$$\begin{aligned} H(1 : p_h, (p_h + 1) : n) &\leftarrow U^T \cdot H(1 : p_h, (p_h + 1) : n), \\ T(1 : p_h, (p_h + 1) : n) &\leftarrow U^T \cdot T(1 : p_h, (p_h + 1) : n). \end{aligned}$$

**3.2. Chasing a chain of bulge pairs.** In each step of the tiny-bulge multishift QZ algorithm, the chain of bulge pairs is chased $k$ steps downward. Before the first step, this chain resides in columns/rows $p_l : p_h$ with $p_l = 1, p_h = (m/n_s)(n_s + 1) + 1$ as above. Before the next step, we have $p_l = 1 + k, p_h = (m/n_s)(n_s + 1) + 1 + k$, and so on.

The whole chain is chased in a bulge-by-bulge and bottom-to-top fashion. One such step is illustrated in Figure 3.2. Again, only the principal submatrices marked light gray in Figure 3.2 must be updated during the bulge chasing process. All transformations from the left and from the right are accumulated into orthogonal matrices $U$ and $V$, respectively. Then, GEMM operations can be used to update the rest of the matrix pair (marked dark gray in Figure 3.2):

$$\begin{aligned} H(p_l : p_h + k, (p_h + 1) : n) &\leftarrow U^T \cdot H(p_l : p_h + k, (p_h + 1) : n), \\ T(p_l : p_h + k, (p_h + 1) : n) &\leftarrow U^T \cdot T(p_l : p_h + k, (p_h + 1) : n), \\ H(1 : p_l - 1, p_l : p_h + k) &\leftarrow H(1 : p_l - 1, p_l : p_h + k) \cdot V, \\ T(1 : p_l - 1, p_l : p_h + k) &\leftarrow T(1 : p_l - 1, p_l : p_h + k) \cdot V. \end{aligned}$$

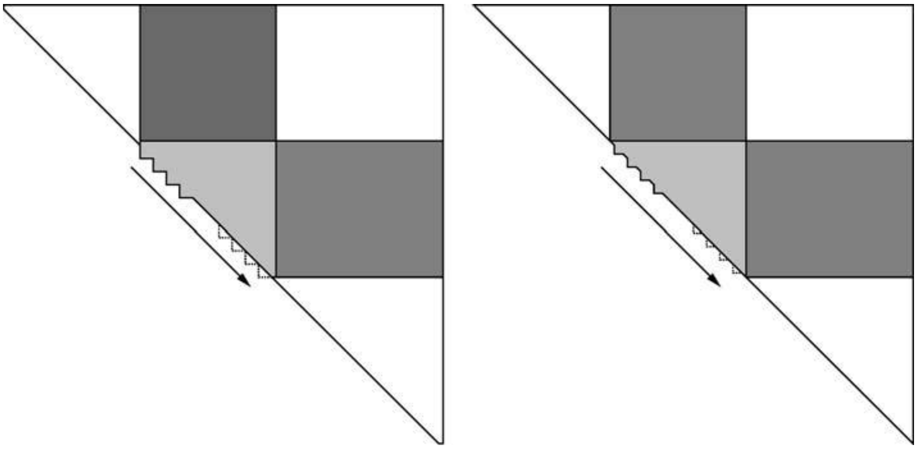

FIG. 3.2. *Chasing a chain of $m/n_s = 4$ tightly coupled bulge pairs.*

Note that both matrices, $U$ and $V$, have the following block structure:

$$\begin{array}{c} \\ 1 \\ l_1 \\ l_2 \end{array}\begin{array}{c} \begin{array}{ccc} 1 & l_2 & l_1 \end{array} \\ \left[\begin{array}{ccc} 1 & 0 & 0 \\ 0 & \square & \text{◺} \\ 0 & \text{◹} & \square \end{array}\right] \end{array}, \tag{3.1}$$

where $l_1 = (m/n_s)(n_s + 1) - n_s$ and $l_2 = k + n_s$. If this structure is largely ignored, applying $U$ or $V$ amounts to a single GEMM with one of the factors being an $(l_1 + l_2) \times (l_1 + l_2)$ matrix. If, on the other hand, the triangular block structure is fully exploited, applying $U$ or $V$ amounts to two triangular matrix-matrix multiplies (TRMMs), one with an $l_1 \times l_1$ factor and the other with an $l_2 \times l_2$ factor, as well as two rectangular GEMMs, one with an $l_1 \times l_2$ factor and the other with an $l_2 \times l_1$ factor. The ratio between the flops needed by these two options is $1+(l_1^2+l_2^2)/(l_1^2+l_2^2+4l_1l_2)$. Following the suggestion in [7], we set the number of steps the bulge chain is chased to $k = 3/2m$, leading to $l_2 \approx 3/2l_1$. In this case, exploiting the triangular block structure reduces the number of flops by 26%. Whether this reduction leads to an actual saving of execution time depends on the performance of TRMM relative to GEMM, which may vary depending on BLAS implementations used for the target architecture and actual matrix sizes (e.g., see [23, 24]). A recent report [19] has identified computing environments for which TRMM performs significantly worse than GEMM, especially for the matrix dimensions arising in our application. In such a setting, it is more favorable to apply $U$ or $V$ with a single GEMM. However, many BLAS implementations, including the one proposed in [19], contain TRMM operations that perform well in comparison to GEMM. In this case, it is often possible to turn the flop reduction offered by the block triangular structure into an actual decrease of execution time.

As for the tiny-bulge multishift QR algorithm, we have to be aware of so-called [illegible] [7, 50], i.e., zero or tiny subdiagonal elements in $H$ that arise during the chasing process. In order to preserve the information contained in the bulge pairs, the chain of bulge pairs must be reintroduced in the row in which the zero appears. Fortunately, we do not have to be aware of zero or tiny subdiagonal elements in $T$, since the bulge pairs are properly passed through infinite eigenvalues; see section 4.4.

After a certain number of steps, the bottom bulge pair of the chain reaches the bottom right corners of the matrix pair. As soon as this happens, the whole chain is bulge-by-bulge chased off this corner, similarly to the introduction of bulge pairs.

**3.3. Classic deflation of finite eigenvalues.** The goal of (multishift) QZ iterations is to drive the subdiagonal entries of the Hessenberg matrix in $(H, T)$ to zero while preserving the upper triangular shape of $T$. Once a subdiagonal entry $h_{k+1,k}$ is considered zero, the problem is deflated into two smaller problems:

$$\left( \begin{bmatrix} H_{11} & H_{12} \\ 0 & H_{22} \end{bmatrix}, \begin{bmatrix} T_{11} & T_{12} \\ 0 & T_{22} \end{bmatrix} \right).$$

Afterward, the (multishift) QZ iteration is applied separately to the $k \times k$ and $(n-k) \times (n-k)$ matrix pairs $(H_{11}, T_{11})$ and $(H_{22}, T_{22})$, respectively.

In the original formulation of the QZ algorithm [37] and the current implementation in LAPACK, a subdiagonal entry $h_{k+1,k}$ is considered zero if

$$|h_{k+1,k}| \le \mathbf{u}\, \|H\|_F. \tag{3.2}$$

A more conservative criterion, in the spirit of the LAPACK implementation of the QR algorithm, is to consider $h_{k+1,k}$ zero if

$$|h_{k+1,k}| \le \mathbf{u}\,(|h_{k,k}| + |h_{k+1,k+1}|). \tag{3.3}$$

It is known for standard eigenvalue problems that, especially in the presence of graded matrices, the use of the criterion (3.3) gives higher accuracy in the computed eigenvalues [41]. We have observed similar accuracy improvements for the QZ algorithm when using (3.3) in favor of (3.2). We have also encountered examples where both criteria give similar accuracy but with slightly shorter execution times for (3.2) due to earlier deflations.

**4. Dealing with infinite eigenvalues.** If the degree $p$ of the polynomial det $(\beta A - \alpha B)$ is less than $n$ then the matrix pair $(A, B)$ is said to have $n - p$ infinite eigenvalues. The relationship between infinite eigenvalues and the QZ algorithm is subtle and calls for caution. In finite-precision arithmetic, the QZ algorithm may utterly fail to correctly identify infinite eigenvalues, especially if the [illegible] of the matrix pair, defined as the size of the largest Jordan block associated with an infinite eigenvalue [17], is larger than one [37]. In the context of differential-algebraic equations (DAEs), the index of $(A, B)$ corresponds to the index of the DAE $B\dot{x} = Ax + f$. Many applications, such as multibody systems and electrical circuits, lead to DAEs with index at least two; see, e.g., [8, 39, 43].

If the matrix pair $(A, B)$ has an infinite eigenvalue then the matrix $B$ is singular. This implies that at least one of the diagonal entries in the upper triangular matrix $T$ in the Hessenberg-triangular form $(H, T)$ and in the generalized Schur form $(S, T)$ is zero, and vice versa. In finite-precision arithmetic, zero diagonal entries are spoiled by roundoff errors. While a tiny zero diagonal entry of $T$ implies that $T$ is numerically singular, the converse is generally [illegible] true. There are well-known examples of upper triangular matrices that are numerically singular but have diagonal entries that are not significantly smaller than the norm of the matrix [18, Ex. 5.5.1].

In such cases, much more reliable decisions on the nature of infinite eigenvalues can be met using algorithms that reveal Kronecker structures, such as GUPTRI [13, 14]. In some cases, infinite eigenvalues can be cheaply and reliably deflated by exploiting the structure of $A$ and $B$.

**4.1. Preprocessing deflation of infinite eigenvalues.** Given a regular matrix pair $(A, B)$ with infinite eigenvalues corresponding to several Jordan blocks, the QZ algorithm will typically compute eigenvalue pairs $(\alpha_i, \beta_i)$ with $\beta_i$ nonzero. Moreover, otherwise well-conditioned eigenvalues can be affected by perturbations from these defective infinite eigenvalues; e.g., they may coincide or appear in clusters of eigenvalues corresponding to computed infinite as well as finite eigenvalues. In the following, we briefly describe two preprocessing techniques for handling such situations.

**Exploiting staircase algorithms.** Without having any knowledge of the Jordan structure of the infinite eigenvalue, in principle, the only reliable and robust way to identify all infinite eigenvalues is to apply a preprocessing step with a staircase-type algorithm.

By applying the GUPTRI algorithm [13, 14, 27] to a regular pair $(A, B)$ with infinite eigenvalues, we get

$$U^T(A,B)V = \left( \begin{bmatrix} A_{11} & A_{12} \\ 0 & A_{\text{inf}} \end{bmatrix}, \begin{bmatrix} B_{11} & B_{12} \\ 0 & B_{\text{inf}} \end{bmatrix} \right), \tag{4.1}$$

where $U$ and $V$ are orthogonal transformation matrices, $(A_{\text{inf}}, B_{\text{inf}})$ reveals the Jordan structure of the infinite eigenvalue, and $(A_{11}, B_{11})$ is a matrix pair with only finite eigenvalues.

Let us illustrate the GUPTRI form (4.1) with a small example. We consider a 7×7 pair $(A, B)$ with three finite eigenvalues and an infinite eigenvalue of multiplicity four corresponding to two nilpotent Jordan blocks $N_1$ and $N_3$. The infinite eigenvalue is both [illegible] and [illegible], since it has more than one eigenvector (two Jordan blocks) but lacks a full setting of eigenvectors (four Jordan blocks). Then $(A_{\text{inf}}, B_{\text{inf}})$ has the following schematic staircase form:

$$(A_{\text{inf}}, B_{\text{inf}}) = \left( \left[ \begin{array}{c|c|cc} \mathbf{z} & y & x & x \\ \hline 0 & \mathbf{y} & x & x \\ \hline 0 & 0 & \mathbf{x} & \mathbf{x} \\ 0 & 0 & 0 & \mathbf{x} \end{array} \right], \left[ \begin{array}{c|c|cc} 0 & \mathbf{y} & x & x \\ \hline 0 & 0 & \mathbf{x} & \mathbf{x} \\ \hline 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{array} \right] \right).$$

The bold numbers $\mathbf{x}$, $\mathbf{y}$, $\mathbf{z}$ in $A_{\text{inf}}$ represent diagonal blocks of full rank, and the $\mathbf{x}$ and $\mathbf{y}$ in $B_{\text{inf}}$ represent superdiagonal blocks of full row rank. Outgoing from the bottom right corner of $B_{\text{inf}}$, the sizes of the diagonal blocks (stairs) $w = (2, 1, 1)$ are the [illegible] of the infinite eigenvalue. These indices relate to the dimensions of the nullspaces $\mathcal{N}(B^j)$ such that $\sum_{k=1}^{j} w_k = \dim \mathcal{N}(B^j)$ for $j = 1, 2, 3$. In other words, $w_j$ is the number of Jordan blocks of size $\geq j$. Now, the infinite Jordan structure can be read off from $w$ giving the [illegible] $s = (3, 1)$, where $s_1$ is the size of the largest Jordan block, $s_2$ is the size of the second largest block, and so on. Both $w$ and $s$ sum up to the [illegible] and $w_1$ is the [illegible] of the infinite eigenvalue.

After such a preprocessing deflation of the infinite eigenvalues of $(A, B)$, we apply the QZ algorithm to the matrix pair $(A_{11}, B_{11})$ in (4.1). For more introductory material on singular matrix pairs and the GUPTRI form see [27] and the references therein.

**Exploiting knowledge of structure.** In some cases, infinite eigenvalues can be reliably deflated by taking into account knowledge on the structure of the matrices $A$ and $B$. If this is feasible by orthogonal transformations, this is the recommended way of dealing with infinite eigenvalues, as the decision which eigenvalues are considered infinite is not affected by roundoff error. In the context of DAEs, several frameworks have been developed that can help identify and exploit such structures; see, e.g., [20, 35]. The following example is closely related to work by Stykel [42], in which $(A, B)$ arises from a semidiscretized Stokes equation.

[illegible] 4.1. Consider $A = \left[\begin{smallmatrix} K & L \\ L^T & 0 \end{smallmatrix}\right]$ and $B = \left[\begin{smallmatrix} M & 0 \\ 0 & 0 \end{smallmatrix}\right]$, where $L$ is an $m \times (n-m)$ matrix of full column rank ($n \le 2m$) and $M$ is an $m \times m$ symmetric positive definite matrix. By a QR decomposition of $L$ we may transform the matrix pair $(A, B)$ to

$$(A, B) \leftarrow \left( \begin{bmatrix} K_{11} & K_{12} & L_1 \\ K_{21} & K_{22} & 0 \\ L_1^T & 0 & 0 \end{bmatrix}, \begin{bmatrix} M_{11} & M_{12} & 0 \\ M_{21} & M_{22} & 0 \\ 0 & 0 & 0 \end{bmatrix} \right),$$

where $L_1$ is an $m \times m$ invertible matrix. The submatrix $M_{22}$ is again symmetric positive definite, which in particular yields its invertibility. By a simple block permutation, $A$ and $B$ can be transformed to block upper triangular form,

$$(A, B) \leftarrow \left( \begin{bmatrix} L_1 & K_{12} & K_{11} \\ 0 & K_{22} & K_{21} \\ 0 & 0 & L_1^T \end{bmatrix}, \begin{bmatrix} 0 & M_{12} & M_{11} \\ 0 & M_{22} & M_{21} \\ 0 & 0 & 0 \end{bmatrix} \right).$$

Thus, the eigenvalues of the matrix pair $(K_{22}, M_{22})$ constitute the finite eigenvalues of $(A, B)$.

**4.2. Deflation of infinite eigenvalues within the QZ algorithm.** Although preprocessing is the preferable way of dealing with infinite eigenvalues, there can be good reasons to let the QZ algorithm do this job, particularly if the reliable detection of infinite eigenvalues is not a major concern. One reason is that computing a GUPTRI form is quite a costly procedure [14]. This and the following two subsections are concerned with existing and new approaches to deflate infinite eigenvalues that are signaled by tiny diagonal entries of the matrix $T$ in a Hessenberg-triangular matrix pair $(H, T)$.

For testing the smallness of a diagonal entry $t_{jj}$ we may, similar to (3.2)–(3.3), either use the norm-wise criterion

$$|t_{jj}| \le \mathbf{u} \cdot \|T\|_F, \tag{4.2}$$

as implemented in the LAPACK routine `DHGEQZ`, or the neighbor-wise criterion $|t_{jj}| \le \mathbf{u} \cdot (|t_{j-1,j}| + |t_{j,j+1}|)$. The latter criterion might help avoid artificial infinite eigenvalues caused by a poor scaling of the matrix pair. Let us briefly sketch the procedure developed by Moler and Stewart [37] for deflating an infinite eigenvalue after $t_{jj}$ has been set to zero, for the case $n = 5$ and $j = 3$:

$$(H, T) = \left( \begin{bmatrix} h & h & h & h & h \\ h & h & h & h & h \\ 0 & h & h & h & h \\ 0 & 0 & h & h & h \\ 0 & 0 & 0 & h & h \end{bmatrix}, \begin{bmatrix} t & t & t & t & t \\ 0 & t & t & t & t \\ 0 & 0 & 0 & t & t \\ 0 & 0 & 0 & t & t \\ 0 & 0 & 0 & 0 & t \end{bmatrix} \right).$$

First, a Givens rotation is applied to columns 2 and 3 to annihilate $t_{22}$, followed by a Givens rotation acting on rows 3 and 4 to annihilate the newly introduced nonzero entry $h_{42}$:

$$(H, T) \leftarrow \left( \begin{bmatrix} h & \hat{h} & \hat{h} & h & h \\ h & \hat{h} & \hat{h} & h & h \\ 0 & \hat{h} & \hat{h} & \hat{h} & \hat{h} \\ 0 & \hat{0} & \hat{h} & \hat{h} & \hat{h} \\ 0 & 0 & 0 & h & h \end{bmatrix}, \begin{bmatrix} t & \hat{t} & \hat{t} & t & t \\ 0 & \hat{0} & \hat{t} & t & t \\ 0 & 0 & 0 & \hat{t} & \hat{t} \\ 0 & 0 & 0 & \hat{t} & \hat{t} \\ 0 & 0 & 0 & 0 & t \end{bmatrix} \right).$$

In a similar manner, the two zero diagonal entries in $T$ are pushed one step upward:

$$(H,T) \leftarrow \left( \begin{bmatrix} \hat{h} & \hat{h} & h & h & h \\ \hat{h} & \hat{h} & \hat{h} & \hat{h} & \hat{h} \\ \hat{0} & \hat{h} & \hat{h} & \hat{h} & \hat{h} \\ 0 & 0 & h & h & h \\ 0 & 0 & 0 & h & h \end{bmatrix}, \begin{bmatrix} \hat{0} & \hat{t} & t & t & t \\ 0 & 0 & \hat{t} & \hat{t} & \hat{t} \\ 0 & 0 & \hat{t} & \hat{t} & \hat{t} \\ 0 & 0 & 0 & t & t \\ 0 & 0 & 0 & 0 & t \end{bmatrix} \right).$$

Finally, a Givens rotation acting on rows 1 and 2 is used to deflate the infinite eigenvalue at the top left corner:

$$(H,T) \leftarrow \left( \left[ \begin{array}{c|cccc} \hat{h} & \hat{h} & \hat{h} & \hat{h} & \hat{h} \\ \hline \hat{0} & \hat{h} & \hat{h} & \hat{h} & \hat{h} \\ 0 & h & h & h & h \\ 0 & 0 & h & h & h \\ 0 & 0 & 0 & h & h \end{array} \right], \left[ \begin{array}{c|cccc} 0 & \hat{t} & \hat{t} & \hat{t} & \hat{t} \\ \hline 0 & \hat{t} & \hat{t} & \hat{t} & \hat{t} \\ 0 & 0 & t & t & t \\ 0 & 0 & 0 & t & t \\ 0 & 0 & 0 & 0 & t \end{array} \right] \right).$$

The outlined procedure requires roughly $6jn$ flops for updating each of the factors $H, T, Q$, and $Z$. If $j > n/2$, it is cheaper to push the infinite eigenvalue to the bottom right corner.

**4.3. Windowing techniques for deflating infinite eigenvalues.** The algorithm described in the previous subsection performs $\mathcal{O}(jn)$ flops while accessing $\mathcal{O}(jn)$ memory, making it costly in terms of execution time on computing systems with deep memory hierarchies. If the dimension of the matrix pair is large and many infinite eigenvalues are to be deflated, this degrades the overall performance of the multishift QZ algorithm. A higher computation/communication ratio can be attained by using windowing techniques similar to those proposed in [5, 12, 32]. In the following, we illustrate such an algorithm, conceptually close to a recently presented block algorithm for reordering standard and generalized Schur forms [32].

Consider a matrix pair $(H,T)$ in Hessenberg-triangular form, where the 9th and the 16th diagonal entries of $T$ are zero; see Figure 4.1(a). Both zero entries will be pushed simultaneously in a window-by-window fashion to the top left corner. The first step consists of pushing the lower zero diagonal entry to the top left corner of the 8-by-8 window marked by the light gray area in Figure 4.1(b). This creates zero diagonal entries at positions 11 and 12. Note that it makes little sense to push one step further; the leading zero at position 10 would be destroyed when pushing the zero diagonal entry at position 9. During this procedure, only the entries of $H$ and $T$ that reside within the window are updated and the data representing the performed Givens rotations is pipelined; see [32] for more details. Afterward, the pipelined transformations are applied to the parts outside the window marked by dark gray areas in Figure 4.1(b) as well as to the corresponding parts of the transformation matrices $Q$ and $Z$. To maintain locality of the memory reference pattern, rows are updated in stripes of $n_b$ columns (in the computational environments we considered, choosing $n_b = 32$ was nearly optimal). The next window contains the diagonal positions $5, \ldots, 12$; see Figure 4.1(c). The zeros at positions 9 and 11 are subsequently pushed to positions 5 and 7, respectively. Again, the update of parts outside the window as well as the update of the transformation matrices are delayed as described above. The last 8-by-8 window resides in the top left corner and yields the deflation of two infinite eigenvalues; see Figure 4.1(d).

Note that we have only provided the generic picture; pushing a zero diagonal entry in $T$ may leave "traces" in the form of additional zero diagonal entries. A proper implementation of the windowing algorithm has to take care of such events.

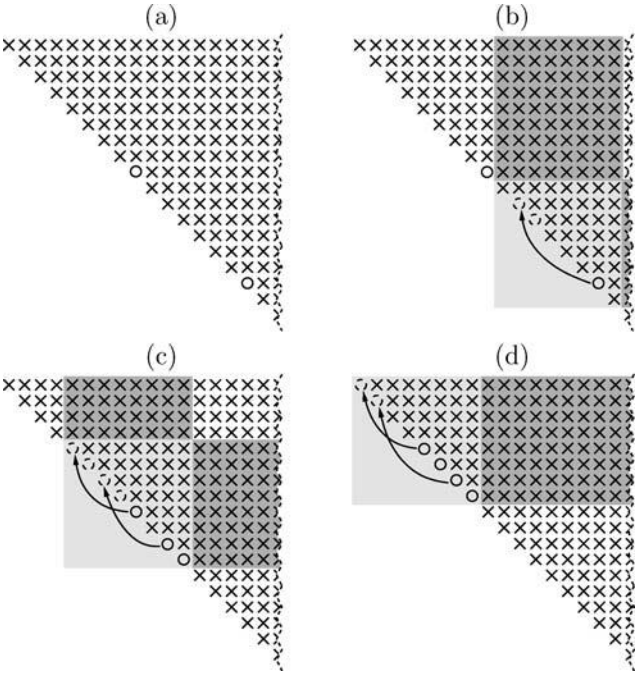

FIG. 4.1. *Illustration of windowing algorithm for deflating two infinite eigenvalues. Only the $T$-matrix of $(H,T)$ is shown.*

Moreover, to achieve optimal performance, the number of zero diagonal entries to be simultaneously pushed and the window size should be significantly larger than those chosen in the descriptive example; see section 7.2.

**4.4. Infinite eigenvalues and multishift QZ iterations.** An important observation made in [53] is that the shift transmission mechanism works even if $T$ is singular, provided that this singularity does not affect the generalized Francis shifts or the definition of the first column of the shift polynomial. In fact, Theorem 2.4 assumes only that the intended shifts are finite and that the $m$th leading principal submatrix of $T$ is nonsingular.

Hence, zero diagonal entries at positions $m+1,\dots,n-m$ in $T$ do not affect the information contained in the bulge pairs and consequently do not affect the convergence of the QZ iteration. What happens to such a zero diagonal entry if a bulge pair passes through it? This question has been addressed by Ward [46, 47] for $m \leq 2$, and by Watkins for general $m$ [53]. The answer is that the zero diagonal entry moves $m$ positions upward along the diagonal. Note that although it is assumed in [53] that the multishift QZ iteration is based on Givens rotations, the same answer holds for a QZ iteration based on (opposite) Householder matrices; see [31].

These results imply that infinite eigenvalues need only be deflated if they correspond to zero diagonal entries at positions $1,\dots,m$ and $n-m+1,\dots,n$ of $T$. Other zero diagonal entries will be automatically moved upward in the course of the QZ algorithm to the top diagonal positions, where they then can be deflated. Note, however, that this "transport" of zero diagonal elements holds only under the assumption of exact arithmetic; it can be severely affected by roundoff error.

[illegible] 4.2. Consider the $10 \times 10$ matrix pair

$$(H,T) = \left( \begin{bmatrix} 3 & 3 & \cdots & \cdots & 3 \\ 1 & 3 & \ddots & & \vdots \\ & \ddots & \ddots & \ddots & \vdots \\ & & \ddots & 3 & 3 \\ & & & 1 & 3 \end{bmatrix}, \begin{bmatrix} 1 & 1 & \cdots & \cdots & 1 \\ & 0 & \ddots & & \vdots \\ & & \ddots & \ddots & \vdots \\ & & & 0 & 1 \\ & & & & 1 \end{bmatrix} \right)$$

in Hessenberg-triangular form. It can be shown that this matrix pair has four infinite eigenvalues. Applying a single-shift QZ iteration, Algorithm 1 with $m = 1$, once to $(H,T)$ leads to an updated triangular matrix $T$ with the leading diagonal entry being exactly zero. None of the other diagonal entries, however, satisfies the deflation criterion (4.2). Also in the course of further QZ iterations applied to the deflated matrix pair no other infinite eigenvalue can be detected. After convergence, the three remaining infinite eigenvalues of $(H,T)$ have been perturbed to finite eigenvalues of magnitude $\approx 1.9 \times 10^5$. On the other hand, if all entries of $T$ satisfying (4.2) are subsequently deflated [illegible] any QZ iteration, then all four infinite eigenvalues are detected.

Example 4.2 reveals that not taking care of all (nearly) zero diagonal entries in $T$ increases the chances that infinite eigenvalues go undetected. Besides the obvious disadvantages, failing to detect infinite eigenvalues may have an adverse effect on the convergence of the QZ algorithm [29, 53]. There is no simple cure for the effects observed in Example 4.2. Setting a diagonal entry, which is known to be zero in exact arithmetic but does not satisfy (4.2), explicitly to zero would spoil the backward stability of the QZ algorithm. We therefore recommend taking care of [illegible] nearly zero diagonal entries in $T$ before applying a QZ iteration. Small or—in rare circumstances—even zero diagonal entries in $T$ may still appear during a multishift QZ iteration. In particular, we may encounter such a situation when having chased some but not all of the bulge pairs from a chain of bulge pairs. Then the small diagonal entry resides between two smaller chains and from the point of view of Example 4.2 it would be desirable to deflate the corresponding (nearly) infinite eigenvalue. However, with the existing deflation techniques, this can only be achieved by chasing off at least one of the smaller chains.

**5. Singular and nearly singular pencils.** For a moment, let us consider a square singular pencil $\beta A - \alpha B$. Then the generalized Schur form $(S,T)$ of $(A,B)$ must (in theory) have at least one pair $(s_{ii}, t_{ii})$ with $s_{ii} = t_{ii} = 0$. This situation appears, for example, when $A$ and $B$ have a common column (or row) null space. On the other hand, given a singular pair $(S,T)$ in generalized Schur form with a regular part, an equivalence transformation of $(S,T)$ that produces upper triangular matrices may give no information about the regular part by inspection of the diagonal elements. For example, the pair

$$(S,T) = \left( \left[\begin{array}{cc|c|c} 3 & 1 & 0 & 0 \\ 0 & 3 & 0 & 0 \\ \hline 0 & 0 & 2 & 0 \\ \hline 0 & 0 & 0 & 0 \end{array}\right], \left[\begin{array}{cc|c|c} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ \hline 0 & 0 & 1 & 0 \\ \hline 0 & 0 & 0 & 0 \end{array}\right] \right)$$

has the finite eigenvalues 3/1, 3/1, and 2/1, besides the singular part (0/0). The equivalent matrix pair

$$(SQ,TQ) = \left( \left[\begin{array}{c|cc|c} 0 & 3 & 1 & 0 \\ 0 & 0 & 3 & 0 \\ \hline 0 & 0 & 0 & 2 \\ \hline 0 & 0 & 0 & 0 \end{array}\right], \left[\begin{array}{c|cc|c} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ \hline 0 & 0 & 0 & 1 \\ \hline 0 & 0 & 0 & 0 \end{array}\right] \right), \text{ with } Q = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \end{bmatrix},$$

has all diagonal elements equal to zero (0/0). So examination of the diagonal elements only gives no indication of the well-defined regular part of $(S, T)$.

In practice, the QZ algorithm will in general not detect the above-mentioned singularities reliably and otherwise well-conditioned eigenvalues can change drastically, meaning that the values of the computed pairs $(s_{ii}, t_{ii})$ cannot be trusted (e.g., see Wilkinson [54] for several illustrative examples.) Moreover, it is impossible to decide just by inspection whether $s_{ii} = \epsilon_1$ and $t_{ii} = \epsilon_2$, with $\epsilon_1$ and $\epsilon_2$ tiny, correspond to a finite eigenvalue $\epsilon_1/\epsilon_2$ or to a true singular pencil. Anyhow, with this information we know that $\beta A - \alpha B$ is close to a singular pencil. (Note that the converse of this statement is not true [9, 27].)

Although the QZ algorithm delivers erratic results for singular or almost singular cases, the computed results are still exact for small perturbations of the original matrix pair $(A, B)$. To robustly deal with such cases, it is recommended to first identify any singularity and deflate the associated Kronecker structure of $(A, B)$ in a preprocessing step before the QZ algorithm is applied. As with infinite eigenvalues, this can be done by exploiting staircase-type algorithms like GUPTRI [13, 14].

## 6. Aggressive early deflation applied to the QZ algorithm.

The idea behind the aggressive early deflation strategy in the QZ algorithm is to enhance the deflation strategy described in section 3.3 by taking advantage of perturbations outside the subdiagonal entries of the Hessenberg matrix, as in the QR algorithm [6]. This gives the possibility to identify and deflate converged eigenvalues much earlier than either of the deflation criteria (3.2) and (3.3) would do, which results in fewer QZ iterations and thereby has the potential to save both floating point operations and execution time.

### 6.1. Pairs of reducing perturbations.

For simplicity, we consider an $n \times n$ [illegible] unreduced Hessenberg-triangular matrix pair $(H, T)$. Let $P_H$ and $P_T$ be complex perturbation matrices. Suppose there exist a unitary matrix $Q$ of the form $Q = \begin{bmatrix} 1 & 0 \\ 0 & \tilde{Q} \end{bmatrix}$ and a unitary matrix $Z$ such that the transformed perturbed matrix pair,

$$(\hat{H}, \hat{T}) \equiv Q^H (H + P_H, T + P_T) Z, \tag{6.1}$$

is in reduced Hessenberg-triangular form:

$$\hat{H} = \begin{bmatrix} \hat{H}_{11} & \hat{H}_{12} \\ 0 & \hat{H}_{22} \end{bmatrix}, \qquad \hat{T} = \begin{bmatrix} \hat{T}_{11} & \hat{T}_{12} \\ 0 & \hat{T}_{22} \end{bmatrix}. \tag{6.2}$$

Then, in analogy to the matrix case, $(P_H, P_T)$ is called a [illegible]. If the norm of $(P_H, P_T)$ is tiny, the equivalence transformation above has split the problem of computing the eigenvalues of $(H, T)$ in two (or more) subproblems of smaller size without affecting the backward stability of the QZ algorithm.

In the following, we derive results that characterize and identify pairs of reducing perturbations, which are extensions of similar results for the matrix case [6].

LEMMA 6.1. [illegible] $(H, T)$ [illegible] $H, T \in \mathbb{C}^{n \times n}$ [illegible] $P_H, P_T \in \mathbb{C}^{n \times n}$ [illegible] $T + P_T$ [illegible] $(P_H, P_T)$ [illegible] reducing perturbation pair [illegible] $(H, T)$ if and only if [illegible] $(H + P_H, T + P_T)$ [illegible] $y \in \mathbb{C}^n$ [illegible] $y_1 = 0$

[illegible] Assume $(P_H, P_T)$ is a reducing perturbation pair for $(H, T)$; i.e., there exist a unitary matrix $Q = \begin{bmatrix} 1 & 0 \\ 0 & \tilde{Q} \end{bmatrix}$ and a unitary matrix $Z$ such that $(\hat{H}, \hat{T})$ defined by (6.1) is in reduced block-triangular form (6.2). This implies that $(\hat{H}, \hat{T})$ has a left (generalized) eigenvector $\hat{y}$ with $\hat{y}_1 = 0$; indeed, the first $\dim(\hat{H}_{11})$ components equal to zero. Since $Q$ has block diagonal structure, it follows that $y = Q\hat{y}$ is a left eigenvector of $(H + P_H, T + P_T)$ with $y_1 = \hat{y}_1 = 0$.

In the opposite direction, assume that $(H + P_H, T + P_T)$ has a left (generalized) eigenvector $y \in \mathbb{C}^n$ with a zero first component, $y_1 = 0$, associated with the eigenvalue pair $(\alpha, \beta) \in \mathbb{C}^2$, i.e., $\beta y^H(H + P_H) = \alpha y^H(T + P_T)$. By replacing the initial QR factorization of $B$ in the standard algorithm for reducing a matrix pair $(A, B)$ to Hessenberg-triangular form [18, Alg. 7.7.1] by an RQ factorization of $B$, we construct unitary matrices $Q = \left[\begin{smallmatrix} 1 & 0 \\ 0 & Q \end{smallmatrix}\right]$ and $Z$ such that $Q^H(H + P_H, T + P_T)Z = (\hat{H}, \hat{T})$ is in Hessenberg-triangular form. It follows that $\hat{y} = Q^H y$ is a left (generalized) eigenvector of $(\hat{H}, \hat{T})$ and $\hat{y}_1 = y_1 = 0$ due to the fact that $Q$ is block diagonal. Let $k$ be the smallest index for which $\hat{y}_k \neq 0$ and partition $\hat{y}^H = [0, z]^H$ with $z \in \mathbb{C}^{n-k+1}$. If $\hat{H}$ and $\hat{T}$ are conformably partitioned,

$$\hat{H} = \begin{bmatrix} \hat{H}_{11} & \hat{H}_{12} \\ h_{k,k-1} e_1 e_{k-1}^T & \hat{H}_{22} \end{bmatrix}, \qquad \hat{T} = \begin{bmatrix} \hat{T}_{11} & \hat{T}_{12} \\ 0 & \hat{T}_{22} \end{bmatrix},$$

then $\beta\, \hat{y}^H \hat{H} = \alpha\, \hat{y}^H \hat{T}$ yields

$$\beta\, [\hat{h}_{k,k-1} \hat{y}_k e_{k-1}^T, z^H \hat{H}_{22}] = \alpha\, [0, z^H \hat{T}_{22}].$$

The nonsingularity of $T + P_T$ implies $\beta \neq 0$, which in turn gives $\hat{h}_{k,k-1} = 0$; i.e., $\hat{H}$ is in reduced Hessenberg form. □

Note that the second part of the proof of Lemma 6.1 also shows how orthogonal matrices $Q$ and $Z$ yielding a deflated matrix pair (6.2) can be obtained by a slightly modified form of Hessenberg-triangular reduction. In the context of aggressive deflation, a useful reducing perturbation pair $(P_H, P_T)$ must have enough zero structure so that relatively little work is needed to retransform $(H + P_H, T + P_T)$ to Hessenberg-triangular form. By restricting $P_H$ and $P_T$ to Hessenberg and triangular matrices, respectively, there will be no extra work.

LEMMA 6.2. $(P_H, P_T)$ [illegible] reducing perturbation pair [illegible] $(H, T)$ [illegible] if and only if $P_T$ [illegible] $P_H$ [illegible]

[illegible] Let $(P_H, P_T)$ be a reducing perturbation pair in Hessenberg-triangular form. Decompose $P_H = P_H^{(s)} + P_H^{(u)}$ in its subdiagonal part $P_H^{(s)}$ and its upper triangular part $P_H^{(u)}$. Then $(P_H^{(s)}, 0)$ is a reducing perturbation pair of smaller norm. □

This choice leads to the small-subdiagonal deflation strategy for the QZ algorithm described in section 3.3.

In order to reach a more aggressive deflation strategy, we must allow more general perturbations, where $(P_H, P_T)$ is not necessarily in Hessenberg-triangular form. Extending the matrix case, we consider small perturbations $P_H$ and $P_T$ that are nonzero only in the last $k$ rows and $k + 1$ columns. Now, if $k \ll n$, the cost is small (compared to a QZ iteration) to retransform the perturbed matrix pair to Hessenberg-triangular form; see also section 6.2.

Let the matrix pair $(H,T)$ be in unreduced Hessenberg-triangular form with $H,T \in \mathbb{C}^{n\times n}$ and partitioned as follows:

$$H = \begin{bmatrix} H_{11} & H_{12} & H_{13} \\ H_{21} & H_{22} & H_{23} \\ 0 & H_{32} & H_{33} \end{bmatrix}, \qquad T = \begin{bmatrix} T_{11} & T_{12} & T_{13} \\ 0 & T_{22} & T_{23} \\ 0 & 0 & T_{33} \end{bmatrix}, \tag{6.3}$$

where the block rows from top to bottom (and block columns from left to right) have $n-n_w-1, 1$, and $n_w$ rows (columns), respectively. Let the perturbation pair $(P_H,P_T)$ be partitioned conformably with $(H,T)$, but with the following nonzero structure:

$$P_H = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & P_{32}^{(H)} & P_{33}^{(H)} \end{bmatrix}, \qquad P_T = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & P_{33}^{(T)} \end{bmatrix}. \tag{6.4}$$

A special choice of such perturbations is given in the following lemma.

LEMMA 6.3. [illegible] $(\alpha,\beta)$ [illegible] $(H_{33},T_{33})$ [illegible] $y$ [illegible] $\|y\|_2 = 1$ [illegible] $(P_H,P_T)$ [illegible] (6.4) [illegible] $P_{32}^{(H)} = -(y^H H_{32})y$ [illegible] $P_{33}^{(H)} = 0$ [illegible] $P_T = 0$ [illegible].

[illegible] We have

$$\beta\,[0,0,y^H](H+P_H) = \beta\,[0,0,y^H H_{33}] = \alpha\,[0,0,y^H T_{33}] = \alpha\,[0,0,y^H]T.$$

This shows that $[0,0,y^H]^H$ is a left eigenvector of the perturbed matrix pair $(H+P_H, T+P_T)$ with $P_T = 0$, which together with Lemma 6.1 concludes the proof. ☐

To search for reducing perturbation pairs, we can choose from all, generically $n_w$, possible perturbations in the sense of Lemma 6.3. Although this strategy will generally yield only a reducing perturbation of [illegible] minimal Frobenius norm among all pairs of the form (6.4), the perturbations of Lemma 6.3 have the major advantage of being effectively computed and tested. Finding the minimum among all reducing perturbations of the form (6.4) is closely related to finding the distance to uncontrollability of a descriptor system [10]. This connection along with numerical methods for computing the distance to uncontrollability will be studied in a forthcoming paper. However, in preliminary numerical experiments with the multishift QR algorithm we observed that rarely can any extra deflations be gained from using perturbations more general than those of Lemma 6.3.

To illustrate the effectiveness of Lemma 6.3, let us consider the following matrix pair, which has been considered in [1] as an extension of the motivating example in [6]:

$$(H,T) = \left( \begin{bmatrix} 6 & 5 & 4 & 3 & 2 & 1 \\ 0.001 & 1 & 0 & 0 & 0 & 0 \\ & 0.001 & 2 & 0 & 0 & 0 \\ & & 0.001 & 3 & 0 & 0 \\ & & & 0.001 & 4 & 0 \\ & & & & 0.001 & 5 \end{bmatrix}, \begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 \\ & 1 & 0 & 0 & 0 & 0 \\ & & 1 & 0 & 0 & 0 \\ & & & 1 & 0 & 0 \\ & & & & 1 & 0 \\ & & & & & 1 \end{bmatrix} \right). \tag{6.5}$$

Let us consider a partitioning of the form (6.3) for $n_w = 5$. Then the eigenvalues of $(H_{33},T_{33})$ are given by the $(\alpha,\beta)$ pairs $(1,1),(2,1),\ldots,(5,1)$ with $\lambda = \alpha/\beta$. Each of these eigenvalues yields a reducing perturbation pair in the sense of Lemma 6.3. The respective norms of $\|P_{32}^{(H)}\|$ are as follows:

$$1:\ 1.0\times 10^{-3},\ 2:\ 1.0\times 10^{-6},\ 3:\ 5.0\times 10^{-10},\ 4: 1.7\times 10^{-13},\ 5: 4.2\times 10^{-17}.$$

In double precision, the eigenvalue 5 can thus be safely deflated. In single precision, even three eigenvalues (3, 4, and 5) correspond to a reducing perturbation of norm below machine precision. See also section 7.3, where this example is studied for larger matrices.

**6.2. Implementation aspects.** In the following, we describe an efficient method which puts the aggressive early deflation motivated by Lemma 6.3 into practice. For this purpose, we consider a partition of $(H, T)$ of the form (6.3) and focus on the $n_w \times (n_w + 1)$ submatrix pair $([H_{32},\ H_{33}], [0,\ T_{33}])$, which defines the [illegible]

First, by means of the QZ algorithm, orthogonal matrices $Q_1$ and $Z_1$ resulting in a generalized Schur decomposition of $(H_{33}, T_{33})$ are computed. This admits the following partitioning:

$$Q_1^T([H_{32},\ H_{33}], [0,\ T_{33}]) \begin{bmatrix} 1 & 0 \\ 0 & Z_1 \end{bmatrix} = \left( \begin{bmatrix} s_3 & \tilde{H}_{33} & \tilde{H}_{34} \\ s_4 & 0 & \tilde{H}_{44} \end{bmatrix}, \begin{bmatrix} 0 & \tilde{T}_{33} & \tilde{T}_{34} \\ 0 & 0 & \tilde{T}_{44} \end{bmatrix} \right),$$

where $s_3, s_4$ are column vectors of appropriate size, and $(\tilde{H}_{44}, \tilde{T}_{44})$ is either $1 \times 1$, representing a real eigenvalue of $(H_{33}, T_{33})$, or $2 \times 2$, representing a complex conjugate pair of eigenvalues. If $(\tilde{H}_{44}, \tilde{T}_{44})$ represents a real eigenvalue, then the corresponding reducing perturbation in the sense of Lemma 6.3 is obtained by setting the scalar $s_4$ to zero. Similarly, if $(\tilde{H}_{44}, \tilde{T}_{44})$ is $2 \times 2$, a reducing perturbation is obtained by setting the two entries of $s_4$ to zero. This is, strictly speaking, not a perturbation in the sense of Lemma 6.3 and it may happen that one of the two complex conjugate eigenvalues of $(\tilde{H}_{44}, \tilde{T}_{44})$ considered individually yields a reducing perturbation which is significantly smaller than $\|s_4\|_2$. However, deflating this eigenvalue alone is not possible without leaving the realm of real matrices.

There are several possible choices for criteria under which $\|s_4\|_2$, the norm of the reducing perturbation described above, can be considered negligible. A liberal deflation criterion, which just preserves numerical backward stability, is given by

$$\|s_4\|_2 \leq \mathbf{u}\|H\|_F. \tag{6.6}$$

A more conservative criterion in the spirit of (3.3) is given by

$$\|s_4\|_2 \leq \begin{cases} \mathbf{u}|\tilde{H}_{44}| & \text{if } \tilde{H}_{44} \text{ is } 1 \times 1, \\ \mathbf{u}\sqrt{|\det(\tilde{H}_{44})|} & \text{otherwise.} \end{cases} \tag{6.7}$$

This is preferred for reasons explained in section 3.3. A range of other criteria can be found in [6, sec. 2.4].

If $\|s_4\|_2$ satisfies the chosen deflation criterion, we mark $(\tilde{H}_{44}, \tilde{T}_{44})$ as deflatable and apply the described process again to the reduced matrix pair $([s_3,\ \tilde{H}_{33}], \tilde{T}_{33}])$. Otherwise, we mark $(\tilde{H}_{44}, \tilde{T}_{44})$ as undeflatable and reorder the generalized Schur decomposition of $(H_{33}, T_{33})$ to construct orthogonal matrices $Q_2$ and $Z_2$ such that

$$(Q_1 Q_2)^T([H_{32},\ H_{33}], [0,\ T_{33}]) \begin{bmatrix} 1 & 0 \\ 0 & Z_1 Z_2 \end{bmatrix} = \left( \begin{bmatrix} \bar{s}_3 & \bar{H}_{33} & \bar{H}_{34} \\ \bar{s}_4 & 0 & \bar{H}_{44} \end{bmatrix}, \begin{bmatrix} 0 & \bar{T}_{33} & \bar{T}_{34} \\ 0 & 0 & \bar{T}_{44} \end{bmatrix} \right),$$

where $(\bar{H}_{33}, \bar{T}_{33})$ is of the same order and has the same eigenvalues as $(\tilde{H}_{44}, \tilde{T}_{44})$. In this case, the described process is applied again to the matrix pair $([\bar{s}_4,\ \bar{H}_{44}], \bar{T}_{44}])$. The whole procedure is repeated until the matrix pair vanishes, i.e., $n_w - k$ undeflatable and $k$ deflatable eigenvalues have been found yielding a decomposition of the form

$$Q^T([H_{32},\ H_{33}], [0,\ T_{33}]) \begin{bmatrix} 1 & 0 \\ 0 & Z \end{bmatrix} = \left( \begin{bmatrix} \check{s}_3 & \check{H}_{33} & \check{H}_{34} \\ \check{s}_4 & 0 & \check{H}_{44} \end{bmatrix}, \begin{bmatrix} 0 & \check{T}_{33} & \check{T}_{34} \\ 0 & 0 & \check{T}_{44} \end{bmatrix} \right),$$

where $(\check{H}_{44}, \check{T}_{44})$ is $k \times k$ and contains all deflatable eigenvalues. Moreover, we have $\|\check{s}_4\|_2 \leq \sqrt{k}\mathbf{u}\|H\|_F$ no matter whether (6.6) or (6.7) is used. Hence, $\check{s}_4$ can be safely set to zero and the QZ algorithm is continued with the $(n-k) \times (n-k)$ matrix pair

$$(\tilde{H}, \tilde{T}) = \left( \begin{bmatrix} H_{11} & H_{12} & H_{13}Z \\ H_{21} & H_{22} & H_{23}Z \\ 0 & \check{s}_3 & \check{H}_{33} \end{bmatrix}, \begin{bmatrix} T_{11} & T_{12} & T_{13}Z \\ 0 & T_{22} & T_{23}Z \\ 0 & 0 & \check{T}_{33} \end{bmatrix} \right).$$

Note that the matrix pair $(\tilde{H}, \tilde{T})$ is not in Hessenberg-triangular form due to the "spike" $\check{s}_3$. If we apply a Householder matrix $\mathcal{H}_1(\check{s}_3) = I - \beta vv^T$ to the last $n_w - k$ rows of $(\tilde{H}, \tilde{T})$, we have

$$\mathcal{H}_1(\check{s}_3)\check{T}_{33} = \check{T}_{33} - \beta v(\check{T}_{33}^T v)^T.$$

Hence, $\mathcal{H}_1(\check{s}_3)\check{T}_{33}$ is a rank-one update of a triangular matrix. Similar to updating algorithms for the QR decomposition [18, sec. 12.5], we can construct an orthogonal matrix $Z_3$ as a sequence of $n_w - k - 1$ Givens rotations such that $Z_3^T \check{T}_{33}^T v = \gamma e_n$ for some $\gamma \in \mathbb{R}$. Consequently,

$$\mathcal{H}_1(\check{s}_3)\check{T}_{33}Z_3 = \check{T}_{33}Z_3 - \beta\gamma v e_n^T$$

is an upper Hessenberg matrix. By another sequence of $n_w - k - 1$ Givens rotations the subdiagonal elements of $\mathcal{H}_1(\check{s}_3)\check{T}_{33}Z_3$ can be eliminated so that $\mathcal{H}_1(\check{s}_3)\check{T}_{33}Z_3Z_4$ becomes upper triangular. The described algorithm requires $\mathcal{O}((n_w - k)^2)$ flops which is favorable compared to the $\mathcal{O}((n_w - k)^3)$ flops needed for computing an RQ factorization of $\mathcal{H}_1(\check{s}_3)\check{T}_{33}$ from scratch. Finally, the standard reduction algorithm [18, Alg. 7.7.1] without the initial QR factorization is applied to the matrix pair $\mathcal{H}_1(\check{s}_3)(\check{H}_{33}, \check{T}_{33})Z_3Z_4$ in order to compute orthogonal matrices $Q_3 = \left[\begin{smallmatrix} 1 & 0 \\ 0 & \tilde{Q}_3 \end{smallmatrix}\right]$ and $Z_5$ such that $Q_3^T \mathcal{H}_1(\check{s}_3)(\check{H}_{33}, \check{T}_{33})Z_3Z_4Z_5$ is Hessenberg-triangular. Setting

$$\tilde{Q} = \begin{bmatrix} I_{n-n_w} & 0 \\ 0 & \mathcal{H}_1(\check{s}_3)Q_3 \end{bmatrix}, \quad \tilde{Z} = \begin{bmatrix} I_{n-n_w} & 0 \\ 0 & Z_3Z_4Z_5 \end{bmatrix}$$

yields a Hessenberg-triangular matrix pair $\tilde{Q}^T(\tilde{H}, \tilde{T})\tilde{Z}$ from which the multishift QZ algorithm can be continued. Note that before continuing with a multishift QZ iteration it can be beneficial to apply aggressive early deflation again if sufficiently many eigenvalues have been deflated, i.e., if the ratio $k/n_w$ is above a certain threshold, which has been set to 40% in our experiments (parameter #3 in Table 7.1).

## 7. Computational experiments.

To assess their performance and robustness, we have implemented the newly developed variants of the QZ algorithm in FORTRAN 77 and performed several experiments to be described in the following subsections.

### 7.1. Computational platform(s).

The experiments are carried out on one processor of two of the HPC2N clusters, `seth` and `sarek`, which have advanced memory systems with different characteristics.

The cluster `seth` consists of 120 nodes, dual Athlon MP2000+ (1.667Ghz) with 1 GB memory per node. Athlon MP2000+ has a 64 kB instruction, a 64 kB data L1 Cache, and 256 kB of integrated L2 cache. Software used: Debian GNU/Linux 3.0, Portland F90 6.0, ATLAS BLAS 3.5.9.

The cluster `sarek` consists of 190 HP DL145 nodes, with dual AMD Opteron 248 (2.2GHz) and 8 GB memory per node. AMD Opteron 248 has a 64 kB instruction

Table 7.1
*Default values for some parameters of the multishift QZ algorithm with aggressive early deflation.*

| | | `seth` | `sarek` |
|---|---|---|---|
| #1 | Minimal (sub)matrix pair dimension for multishift QZ iterations | 300 | 300 |
| #2 | Minimal (sub)matrix pair dimension for aggressive early deflation | 300 | 300 |
| #3 | Minimal success rate for repeated aggressive early deflation | 40% | 40% |
| #4 | Window size for simultaneous deflation of infinite eigenvalues | 60 | 84 |
| #5 | Number of infinite eigenvalues to be deflated simultaneously | 20 | 28 |

and 64 kB data L1 Cache (2-way associative) and a 1024 kB unified L2 Cache (16-way associative). Software used: Debian GNU/Linux 3.1, Portland F90 6.0, Goto BLAS 0.94.

All results reported are run in double precision real arithmetic ($\epsilon_{mach} \approx 2.2 \times 10^{-16}$).

**7.2. Random matrix pairs.** The described multishift QZ iterations and deflation algorithms depend on various parameters, which all have some influence on the overall execution time of the QZ algorithm. We have performed numerical experiments with randomly generated matrix pairs and numerous sets of parameters to measure the influence of each individual parameter. In the following, we focus on the three parameters that have been observed to have the largest impact on the execution time and therefore require particular attention:

$m$: number of simultaneous shifts used in each multishift QZ iteration (integer multiple of $n_s$),
$n_s$: number of shifts contained in each bulge during multishift QZ iterations,
$n_w$: aggressive early deflation window size.

All other parameters turned out to have less influence on the performance and have been set in a heuristic manner. The default values displayed in Table 7.1 yielded good performance for matrix pairs of size $500, \dots, 3000$. If the order of an active submatrix pair in the course of the multishift QZ algorithm described in section 3 becomes smaller than parameter #1, it is more efficient to resort to double-shift QZ iterations. Similarly, if the order is smaller than parameter #2, aggressive early deflation is turned off. It is best to choose #1 not smaller than #2. If aggressive early deflation yielded the deflation of $k$ eigenvalues and the ratio $k/n_w$ exceeds parameter #3, another search for early deflations is immediately performed on the deflated matrix pair before applying a (multishift) QZ iteration. Finally, the parameters #4 and #5 represent the window size and the maximal number of infinite eigenvalues to be pushed simultaneously in the block algorithm for deflating infinite eigenvalues described in section 4.3. It is necessary to choose #4 larger than two times #5; we found choosing #4 three times larger nearly optimal.

To make the new implementation better comparable to the LAPACK version 3.0 implementation, we used throughout all experiments the liberal deflation criteria (3.2), (4.2), and (6.6). The use of the more conservative deflation criteria (3.3) and (6.7) may result in more accurate eigenvalues but may also lead to slightly more QZ iterations.

**7.2.1. Influence of $\boldsymbol{m}$ and $\boldsymbol{n_s}$.** To measure the influence of the parameters $m$ and $n_s$ on the performance of the multishift QZ algorithm [illegible] aggressive early deflation, we generated $n \times n$ matrices $A$ and $B$ having pseudorandom entries uniformly distributed in the interval $[-1, 1]$ and reduced them to Hessenberg-triangular form by applying the LAPACK version 3.0 routine `DGGHRD`. Figures 7.1 and 7.2 display

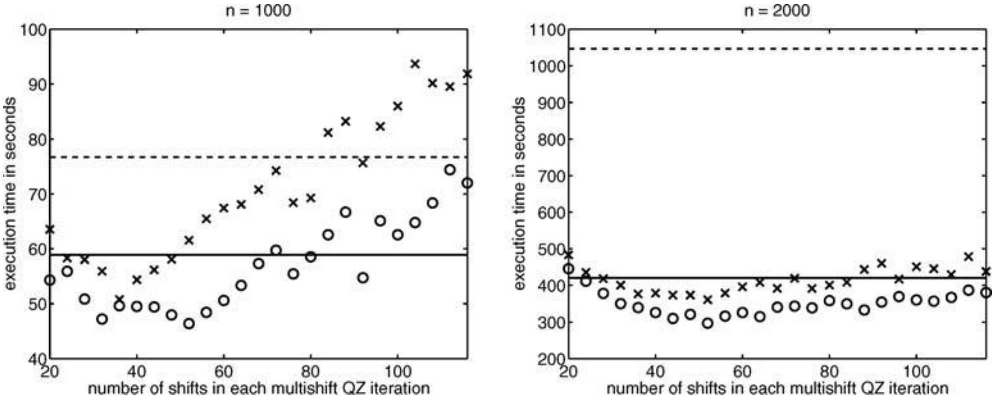

FIG. 7.1. *Random matrix pairs: Execution times on* `seth` *of* `DHGEQZ` *(dashed line),* `KDHGEQZ` *(solid line), and* `MULTIQZ` without *aggressive early deflation for* $n_s = 2$ *(crosses) and* $n_s = 4$ *(circles).*

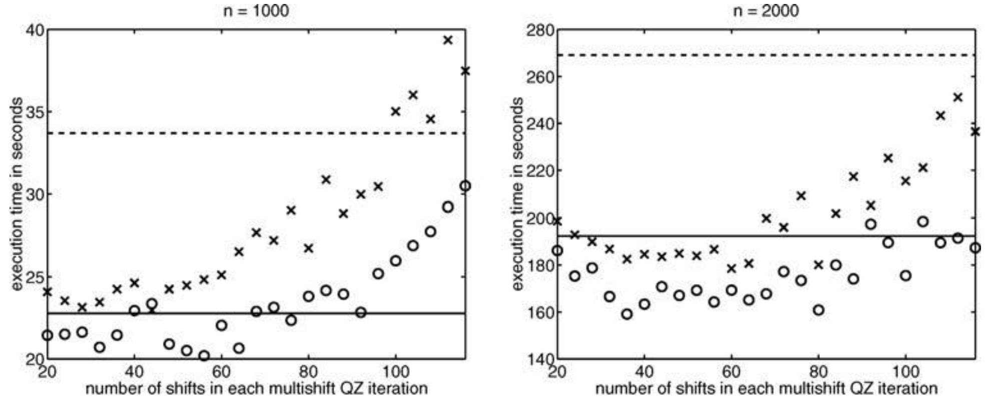

FIG. 7.2. *Random matrix pairs: Execution times on* `sarek` *of* `DHGEQZ` *(dashed line),* `KDHGEQZ` *(solid line), and* `MULTIQZ` without *aggressive early deflation for* $n_s = 2$ *(crosses) and* $n_s = 4$ *(circles).*

the measured execution times for the following implementations of the QZ algorithm:

| | |
|---|---|
| `DHGEQZ`: | LAPACK version 3.0 implementation as described in the original paper by Moler and Stewart [37] with some of the modifications proposed in [29, 47, 49]; see also section 2.1. |
| `KDHGEQZ`: | Blocked variant of `DHGEQZ`, developed by Dackland and Kågström [12]. |
| `MULTIQZ`: | Multishift QZ algorithm based on tightly coupled chains of tight bulges as described in section 3. |

The graphs in Figures 7.1 and 7.2 show the sensitivity of the measured execution times for $n = 1000$ and $n = 2000$ as a function of $m$, the degree of the multishift polynomial used in `MULTIQZ`, where $m$ is varying between 20 and 116 with step size 4. Note that in these and the following figures all results for a fixed value of $n$ are observations from a single random matrix pair. On `seth` it can be observed that the optimal time for `MULTIQZ` is significantly lower for both $n_s = 2$ and $n_s = 4$ than the time needed by `DHGEQZ` and `KDHGEQZ`. On `sarek` the gained savings are less substantial. In fact, for $n_s = 2$ and $n = 1000$ even with the optimal $m$, `MULTIQZ` requires slightly more execution time than `KDHGEQZ`.

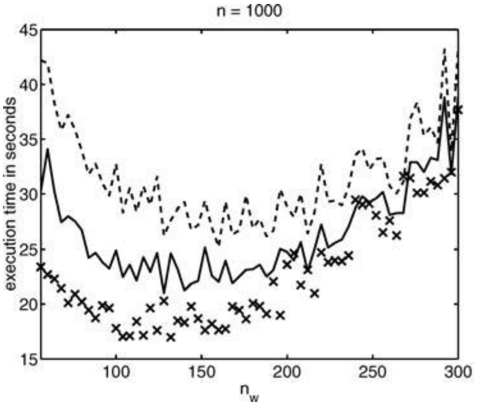

FIG. 7.3. *Random matrix pairs: Execution times on* `seth` *of* `DHGEQZ` with *aggressive early deflation (dashed line),* `KDHGEQZ` with *aggressive early deflation (solid line), and* `MULTIQZ` with *aggressive early deflation (crosses).*

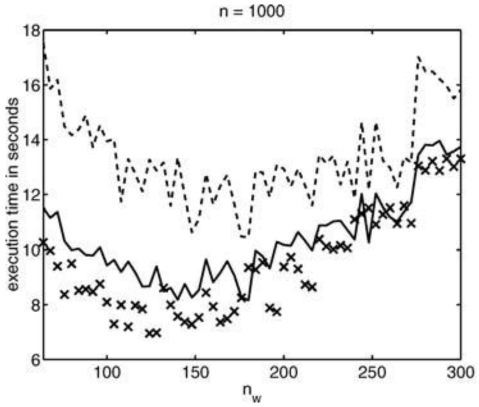

FIG. 7.4. *Random matrix pairs: Execution times on* `sarek` *of* `DHGEQZ` with *aggressive early deflation (dashed line),* `KDHGEQZ` with *aggressive early deflation (solid line), and* `MULTIQZ` with *aggressive early deflation (crosses).*

**7.2.2. Influence of $n_w$.** Similar results for the three implementations of the QZ algorithm with aggressive early deflation are displayed in Figures 7.3 and 7.4. The graphs show the sensitivity of the measured execution times with respect to $n_w$, the size of the deflation window, for $n = 1000$ and $n = 2000$. For `DHGEQZ` and `KDHGEQZ` aggressive early deflation has not been performed after each QZ iteration but only after every $m/2$ (double-shift) QZ iterations, meaning that an overall number of $m$ shifts is applied before each search for early deflations. For all three implementations, we have chosen the optimal value for $m$ in the set $\{20, 24, \dots, 116\}$. Moreover, we have set $n_s = 4$ for `MULTIQZ`. Again, it can be seen that `MULTIQZ` outperforms LAPACK's `DHGEQZ`, but is also faster than `KDHGEQZ`.

**7.2.3. Infinite eigenvalues.** To generate matrix pairs having large numbers of infinite eigenvalues, we generated Hessenberg-triangular matrix pairs $(H, T)$ in the same manner as in the previous two subsections and set each diagonal element of $T$ with probability 0.5 to zero. For $n = 2000$, this resulted in a matrix pair $(H, T)$ with roughly 1000 zero entries on the diagonal of $T$. Either implementation of the

The numbers shown in brackets correspond to the part (number between* 0 *and* 1*) of the execution time that was spent for deflating infinite eigenvalues.*

| Deflation strategy | `seth` | `sarek` |
|---|---|---|
| All $\infty$ eigenvalues at top left corner (unblocked) | 204.8 (0.70) | 71.6 (0.66) |
| All $\infty$ eigenvalues at top left corner (blocked) | 142.1 (0.56) | 59.8 (0.54) |
| All $\infty$ eigenvalues at nearest corner (unblocked) | 137.0 (0.60) | 43.5 (0.55) |
| All $\infty$ eigenvalues at nearest corner (blocked) | 91.6 (0.45) | 37.1 (0.44) |
| Necessary $\infty$ eigenvalues at nearest corner (unblocked) | 99.6 (0.11) | 43.9 (0.13) |
| Necessary $\infty$ eigenvalues at nearest corner (blocked) | 94.1 (0.05) | 42.8 (0.11) |

QZ algorithm detected 656 infinite eigenvalues. If only those infinite eigenvalues that correspond to nearly zero diagonal entries at the top left and bottom right corners of $T$ are deflated in the course of the QZ algorithm (see section 4.4), then a significant portion remains undetected. For example, when using this strategy together with `DHGEQZ` only 399 infinite eigenvalues were detected, which confirms the findings of Example 4.2. On the other hand, this strategy significantly lowers the time spent for dealing with infinite eigenvalues. This can be seen in the last two rows of Table 7.2, which lists execution times for various strategies used in `MULTIQZ` with $n_s = 4$ and the optimal values for $m$ and $n_w$ obtained from section 7.2.2. Note, however, that failing to detect infinite eigenvalues adversely affects the convergence of the QZ algorithm; the time spent for QZ iterations increases from 61 to 89 seconds on `seth`. We remark that the use of the windowing technique described in section 4.3 is denoted by "(blocked)" in Table 7.2. There are other interesting observations in the figures of this table. Deflating infinite eigenvalues at the nearest corner of the matrix $T$ (and not at only one corner as it is done in `DHGEQZ`) is a simple means to significantly lower the execution time. Roughly the same portion of time can be saved by using the windowing technique. The most efficient strategy, which detects all 656 infinite eigenvalues, is a combination of both techniques, deflation at the nearest corner combined with windowing.

**7.3. Aggressive early deflation at its best.** In exceptional cases, aggressive early deflation can have a dramatic positive effect on the computational time. Such a case are matrix pairs of the form (6.5), for which rarely any QZ iterations are needed to deflate eigenvalues. The graphs in Figure 7.5 show the measured execution times of the three implementations of the QZ algorithm with and without aggressive early deflation for $n = 600$ to 3000 (`seth`) or 4000 (`sarek`) with step size 200. For all examples we used $n_w = n - 1$.

We remark that since aggressive early deflation works so well, the time spent for (multishift) QZ iterations is negligible compared to the overall time. In fact, the timings for `DHGEQZ`, `KDHGEQZ`, and `MULTIQZ` with aggressive early deflation are virtually identical and orders of magnitude better than without early deflation. For example, for $n = 4000$ the time of `DHGEQZ` is reduced from nearly one hour to less than 7 seconds.

**7.4. Examples from applications.** The purpose of this section is to summarize the performance of the multishift QZ algorithm with aggressive early deflation for matrix pairs that arise from practically relevant applications. We have selected 16 matrix pairs from the Matrix Market collection [3], 6 matrix pairs from model reduction benchmark collections [11, 30], and 4 matrix pairs arising from the com-

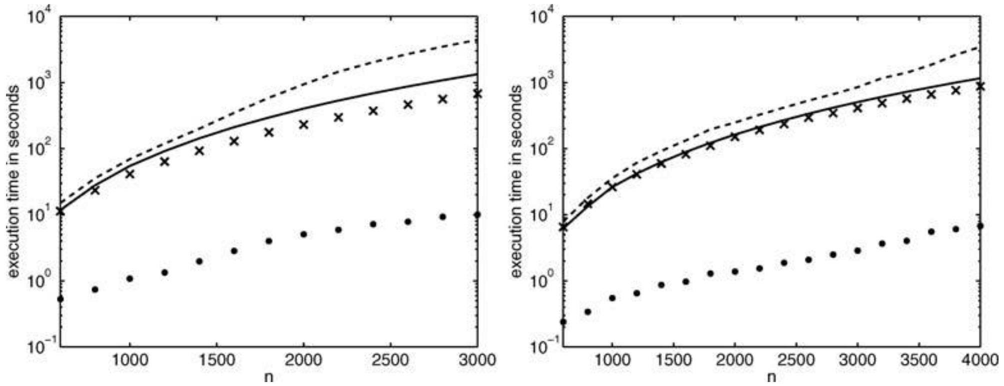

FIG. 7.5. *BBM/ADK example* [1, 6]*: Execution times (in logarithmic scale) on* `seth` *(left figure) and* `sarek` *(right figure) of* `DHGEQZ` *(dashed line),* `KDHGEQZ` *(solid line),* `MULTIQZ` *(crosses)* without *aggressive early deflation, and* `DHGEQZ/KDHGEQZ/MULTIQZ` with *aggressive early deflation (dots).*

putation of corner singularities of elliptic PDEs [38]. A more detailed description of the selected matrix pairs along with individual performance results can be found in Appendix A of the technical report version [22] of this paper. In the following, we summarize these results and sort the matrix pairs into groups according to their order $n$ as shown in the following table.

| Group | G1 | G2 | G3 | G4 |
|---|---|---|---|---|
| order | $n \in [485, 1000]$ | $n \in [1001, 1500]$ | $n \in [1501, 2000]$ | $n \in [2001, 3600]$ |
| #pairs | 6 | 8 | 5 | 7 |

Matrix pairs arising from applications differ in many aspects from random matrix pairs. An aspect which can particularly affect the performance of the QZ algorithm is that the matrix entries in most of the pairs from the Matrix Market collection differ wildly in magnitude. Bad scaling makes the performance of the QZ algorithm erratic and much less predictive than for random matrix pairs. For example, LAPACK's `DHGEQZ` requires 338 seconds for a $1900 \times 1900$ matrix pair arising from the discretized heat equation (see section A.19 in [22]) but less than 25 seconds for the $1922 \times 1922$ matrix pair consisting of the matrices BCSSTK26 and BCSSTM26 from the Matrix Market collection (see section A.12 in [22]). Balancing can remedy bad scaling but we have decided not to make use of it since this preprocessing step is by default turned off in most major software environments such as MATLAB.

We have tested `DHGEQZ`, `KDHGEQZ`, and `MULTIQZ` for all possible combinations of the parameters $n_w$ (aggressive early deflation window size), $m$ (number of shifts before each aggressive early deflation) and $n_s$ (number of shifts per bulge) satisfying $n_w \in \{40, 60, 80, \ldots, 400\}$, $m \in \{24, 32, 40, \ldots, 160\}$, and $n_s \in \{2, 4\}$. Due to the memory limitations of `seth`, all numerical experiments described in the following have only been performed on `sarek`. Also, to limit the variety of parameters, we have turned off the blocked algorithms for deflating infinite eigenvalues. Column 3 of Table 7.3 shows for each of the four groups the average times in seconds of `DHGEQZ` and `KDHGEQZ` without aggressive early deflation. The fourth column displays the average computing times for all three implementations with aggressive early deflation obtained by choosing $m$ and $n_w$ optimally for [illegible] matrix pair in the group. The fifth column displays similar times obtained by choosing $m$ and $n_w$ optimally to yield the best average performance for [illegible] matrix pairs together in each group. The corresponding choices

Table 7.3

*Application examples: Summary of measured execution times and choice of parameters $m$ and $n_w$ that give optimal average performance.*

| Group | Implementation | W/o agg. | Optimal | Ave. opt. | $m$ | $n_w$ |
|---|---|---|---|---|---|---|
| G1 | `DHGEQZ+AGG` | 8.86 | 4.61 | 5.03 | 24 | 120 |
| | `KDHGEQZ+AGG` | 7.07 | 3.62 | 3.78 | 24 | 100 |

| | `MULTIQZ(`$n_s=4$`)+AGG` | – | 3.40 | 3.56 | 24 | 40 |
| G2 | `DHGEQZ+AGG` | 55.5 | 23.7 | 26.5 | 56 | 180 |
| | `KDHGEQZ+AGG` | 41.4 | 17.2 | 18.9 | 40 | 140 |
| | `MULTIQZ(`$n_s=2$`)+AGG` | – | 15.3 | 16.5 | 72 | 160 |
| | `MULTIQZ(`$n_s=4$`)+AGG` | – | 15.1 | 16.3 | 88 | 180 |
| G3 | `DHGEQZ+AGG` | 130.3 | 53.6 | 56.4 | 48 | 220 |
| | `KDHGEQZ+AGG` | 89.9 | 36.5 | 38.8 | 72 | 200 |
| | `MULTIQZ(`$n_s=2$`)+AGG` | – | 30.3 | 30.7 | 56 | 200 |
| | `MULTIQZ(`$n_s=4$`)+AGG` | – | 27.5 | 30.0 | 88 | 200 |
| G4 | `DHGEQZ+AGG` | 479 | 157 | 170 | 48 | 340 |
| | `KDHGEQZ+AGG` | 271 | 97 | 104 | 40 | 220 |
| | `MULTIQZ(`$n_s=2$`)+AGG` | – | 80 | 85 | 72 | 220 |
| | `MULTIQZ(`$n_s=4$`)+AGG` | – | 115 | 124 | 80 | 220 |

of $m$ and $n_w$ are listed in columns 6 and 7, respectively. The difference between the figures of columns 4 and 5 is roughly 10%, which demonstrates that nearly optimal average performance can be obtained without having to optimize $m$ and $n_w$ for each matrix pair individually. Ideally, $m$ and $n_w$ should be chosen adaptively within the QZ algorithm, but it is not clear how such a strategy can be effectively realized.

On average, the multishift QZ algorithm with aggressive early deflation (`MULTIQZ +AGG`, $n_s = 2$) is between 2.6 and 6 times faster than the original LAPACK implementation (`DHGEQZ`). Surprisingly, the block version of Dackland and Kågström is, when equipped with aggressive early deflation (`KDHGEQZ+AGG`), only 10% to 20% slower than the multishift QZ algorithm. There is little justification for setting $n_s$, the number of shifts per bulge, to $n_s = 4$ in favor of $n_s = 2$, in contrast to the results for random matrix pairs.

We have also tested the backward stability of the new variants of the QZ algorithm by measuring the residual $\|(\hat{Q}^T A\hat{Z} - \hat{S}, \hat{Q}^T B\hat{Z} - \hat{T})\|_F$ of the computed Schur decomposition $(\hat{S}, \hat{T})$ as well as the orthogonality $\|\hat{Q}^T\hat{Q} - I\|_F, \|\hat{Z}^T\hat{Z} - I\|_F$ of the computed transformation matrices $\hat{Q}$ and $\hat{Z}$. The obtained results are of the same order as those obtained using the LAPACK implementation.

**8. Conclusions.** In this paper, we have developed new multishift variants of the QZ algorithm using advanced deflation techniques which significantly improve upon the performance compared to all existing implementations. It is planned that an implementation of our multishift QZ algorithm with aggressive early deflation is included in a coming release of LAPACK. The ideas presented here are currently applied to the development of a distributed memory QZ algorithm. Future work also includes the investigation of extending the described results to even more general versions of the QR algorithm, such as the periodic QR and QZ algorithms.

**9. Final remarks and acknowledgments.** The work presented in this article is based on preliminary results derived in [1, 31]. The authors are greatly indebted to Ralph Byers and David Watkins for several discussions on the odds and ends of multishift QR and QZ algorithms. The computational experiments in section 7 were

performed using facilities of the High Performance Computing Center North (HPC2N) in Umeå.

# DIAGONAL MARKOWITZ SCHEME WITH LOCAL SYMMETRIZATION*

PATRICK R. AMESTOY†, XIAOYE S. LI‡, AND ESMOND G. NG‡

**Abstract.** We describe a fill-reducing ordering algorithm for sparse, nonsymmetric LU factorizations, where the pivots are restricted to the diagonal and are selected greedily. The ordering algorithm uses only the structural information. Most of the existing methods are based on some type of symmetrization of the original matrix. Our algorithm exploits the nonsymmetric structure of the given matrix as much as possible. The new algorithm is thus more complex than classical symmetric orderings, but we show that our algorithm can be implemented in space bounded by the number of nonzero entries in the original matrix, and has the same time complexity as the analogous algorithms for symmetric matrices. We provide numerical experiments to demonstrate the ordering quality and the runtime of the new ordering algorithm.

## 1. Introduction.

We consider the direct solution of sparse linear equations $\mathbf{Ax} = \mathbf{b}$ using Gaussian elimination, where $\mathbf{A}$ is an $n \times n$ nonsymmetric sparse matrix. A major difficulty with nonsymmetric matrices is that they are rarely diagonally dominant, which means that during numerical factorization one must compromise fill-in reduction with numerical stability. Many nonsymmetric solvers deal with this situation using the [illegible], which includes an [illegible] phase, a [illegible] phase, and a [illegible] phase [2, 6, 16]. Iterative refinements may be included in the triangular solution. The analysis phase includes a (numerical) preprocessing of the matrix and a symbolic phase that builds the computational graph for the numerical factorization phase. An advantage of the three-phase approach lies in its ability to anticipate the choice of the next pivot, which decouples the analysis from factorization and makes parallelization of numerical factorization easier. Therefore, it is a very important class of methods on high performance computers. In this context, it has been observed in [3] that it is critical to put numerically large entries on the diagonal during the preprocessing phase to limit the scope of numerical pivoting during numerical factorization. One may then want to preserve this diagonal during sparsity reordering. That is, only a symmetric permutation is allowed afterward. One common practice to obtain such an ordering is to apply a symmetric ordering algorithm, either minimum-degree or nested-dissection variant, to the symmetrized pattern of $A + A^T$. Such reordering algorithms do not exploit the fact that during factorization the solvers can exploit the asymmetry of the permuted matrix.

In this article, we propose a new symmetric ordering algorithm, working directly on $A$ and exploiting the nonsymmetric structure of $A$, to compute a "good" symmetric permutation of $A$. It is based on greedy heuristics that preserve the large diagonal entries and at the same time take into account the asymmetry of the matrix. In the symmetric case, the minimum-degree algorithm is a very effective greedy heuristic for fill-in reduction. By using the quotient graph elimination model [12, 13] and the approximate degree updates [1], the minimum-degree algorithm can be implemented very efficiently both in time and space. The nonsymmetric variant of minimum-degree was actually discovered earlier and was named after Markowitz [19], in which the "degree" of a vertex is the product of the row count and column count (known as the Markowitz count). But the original Markowitz algorithm is asymptotically slower than the minimum-degree algorithm, mainly due to the lack of a concise quotient graph model. A theoretical advancement was made by Pagallo and Maulino [22], who extended the quotient graph idea for symmetric matrices to the nonsymmetric case by introducing the [illegible] and showed that the bipartite quotient graph model can be implemented in space bounded by the size of **A**. But timewise, using only the quotient graph model does not lead to an ordering algorithm that is as fast as the minimum-degree algorithm. This is because the lengths of the reachable paths to be searched when updating the Markowitz counts are not bounded. One main contribution of our work is the introduction of a [illegible] mechanism that bounds the lengths of the reachable paths as in the symmetric case while capturing most of the asymmetry in the matrix. A secondary contribution is to adapt and extend the metrics to select pivots based on approximate degree [1] to metrics based on approximate Markowitz count and deficiency [24, 20]. Indeed, in our context all metrics have to anticipate the effect that local symmetrization would have on the pivot to be selected. Our algorithm has the same asymptotic complexity as the minimum-degree algorithm, both in space and in time.

The remainder of the paper is organized as follows. In section 2, we first briefly introduce the bipartite quotient graph notation and properties. We then present the local symmetrization technique and describe our new ordering algorithm. In particular, we discuss how to update the quotient graph and how to compute metrics to select pivots within this framework. Section 3 describes the numerical experiments we have performed and analyzes the effect of the new ordering algorithm on the multifrontal code `MA41_UNS` [2, 6]. Section 4 provides a summary of this research.

## 2. Diagonal Markowitz with local symmetrization.

This section presents the algorithmic ingredients of our new Markowitz ordering framework. We show that the Markowitz algorithm can be implemented as efficiently as the approximate minimum-degree algorithm by using bipartite quotient graphs, the local symmetrization scheme, and the metrics based on approximate row and column degrees.

### 2.1. The Markowitz criterion.

The Markowitz ordering algorithm [19] has been used successfully in general-purpose solvers [11]. This local greedy strategy can be described succinctly as follows. After $k$ steps of Gaussian elimination, let $r_i^k$ (resp., $c_j^k$) denote the number of nonzero entries in row $i$ (resp., column $j$) of the remaining $(n-k) \times (n-k)$ submatrix. The (structural) Markowitz criterion is to select, as the next pivot, a nonzero entry $a_{ij}^k$ from the remaining submatrix that has the minimum Markowitz count $(r_i^k - 1) \times (c_j^k - 1)$. This attempts to minimize an upper bound on the amount of fill-in generated at step $k+1$. Note that, in our context, we want to restrict the pivot selection to the diagonal of the remaining submatrix. This restriction of the

Markowitz scheme will be referred to as the [illegible] scheme.

The simple rule above for choosing the next pivot does not immediately render an efficient implementation, because it requires updating the sparsity pattern of the remaining submatrix at each step, which may generate fill-in. From the development of the minimum-degree algorithm, which can be considered as a symmetric variant of Markowitz algorithm, we learned that by using the quotient graph elimination model [13], the algorithm can be implemented in space bounded by the size of the original matrix rather than that of the filled matrix. This is the so-called [illegible] property and is very much desirable in an efficient ordering algorithm. Pagallo and Maulino [22] extended the quotient graph model by using [illegible] to model the nonsymmetric elimination and showed that this model indeed has the in-place property. Now we briefly review this concept and illustrate how we can use and modify this model to design our ordering algorithm.

**2.2. Bipartite quotient graphs.** Let $\mathbf{A}$ be a nonsymmetric $n \times n$ matrix. The nonzero pattern of $\mathbf{A}$ can be represented by a bipartite graph $G = (V_r, V_c, E)$, where $V_r$ and $V_c$ are the sets of row and column vertices, respectively. For a row vertex $r_i \in V_r$ and a column vertex $c_j \in V_c$, an edge $(r_i, c_j) \in E$ exists if and only if $a_{ij} \neq 0$. Let $G^0 = (V_r^0, V_c^0, E^0)$ be the same as $G$. We use a bipartite graph $G^k = (V_r^k, V_c^k, E^k)$ to represent the nonzero pattern of the remaining submatrix after $k$ steps of Gaussian elimination. Assuming pivots are chosen from the main diagonal, at step $k$, the transformation from $G^{k-1}$ to $G^k$ is based on the following elimination rule. Suppose the $k$th pivot node $(r_p, c_p)$, $p \geq k$, is selected for elimination. The vertex sets become $V_r^k = V_r^{k-1} \backslash \{r_p\}$ and $V_c^k = V_c^{k-1} \backslash \{c_p\}$. The edge set $E^k$ is derived from $E^{k-1}$ by deleting the edges incident on $c_p$ and $r_p$ and adding edges $(r_i, c_j)$ for all $r_i$ and $c_j$ that are adjacent to $c_p$ and $r_p$, respectively. This creates a fully connected bipartite subgraph (a [illegible] in the symmetric analogue). We may refer to this as a [illegible], or [illegible] in short.

We now briefly review the symmetric quotient graph elimination model. The main idea is to use a compact representation to implicitly store the subgraph induced by the vertices that have been eliminated. Suppose $G_s$ is a undirected graph corresponding to a sparse symmetric matrix. Let $S$ denote the subset of vertices in $G_s$ that have been eliminated. Consider the subgraph $G_s(S)$ induced by $S$ in $G_s$. In the quotient graph model, each [illegible][1] in $G(S)$ will be represented by a single "supervertex." As a result, any path in $G_s$ from a vertex $i \notin S$ to a vertex $j \notin S$ through $S$ corresponds to a path through at most one supervertex in $S$. The set of vertices adjacent to $i$ in the remaining filled subgraph is given precisely by the reachable set of $i$ through $S$. See [13] for details.

We now describe the nonsymmetric elimination process using the bipartite quotient graph model. We will use calligraphic letters to denote the sets associated with the bipartite quotient graph. Let $\mathcal{G}^k$ denote the bipartite quotient graph which represents the structure of the reduced submatrix after $k$ steps of Gaussian elimination, and define $\mathcal{G}^0 = G^0$. When there is no ambiguity, we will omit superscript $k$. Both row and column vertices are partitioned into two sets: the set of uneliminated vertices referred to as [illegible] and the set of eliminated vertices referred to as [illegible]. That is, $\mathcal{G} = (\mathcal{V}_r \cup \bar{\mathcal{V}}_r, \mathcal{V}_c \cup \bar{\mathcal{V}}_c, \mathcal{E} \cup \bar{\mathcal{E}})$. Members of $\mathcal{V}_r$ ($\mathcal{V}_c$) will be referred to as [illegible] (to distinguish them from the row vertices in $V_r$ ($V_c$)), while members of $\bar{\mathcal{V}}_r$ ($\bar{\mathcal{V}}_c$) will be referred to as [illegible]. The edge set $\mathcal{E}$ contains the

---

[1] A connected component is a graph in which there is a path between every pair of vertices.

edges between row (column) and column (row) variables. The edge set $\bar{\mathcal{E}}$ contains the edges between row (column) variables and column (row) elements, as well as the edges between row elements and column elements. An eliminated pivot $e = (r_e, c_e)$ has two vertices $r_e \in \bar{\mathcal{V}}_r$ and $c_e \in \bar{\mathcal{V}}_c$ referred to as a [illegible]. Similarly an uneliminated pivot entry (a diagonal entry in the reduced matrix) $i = (r_i, c_i)$ will be referred to as a [illegible]. A nonzero entry $(r_i, c_j)$ exists in the factors if and only if there exists a path of the form $r_i \to c_{e_1} \to r_{e_1} \ldots \to c_{e_l} \to r_{e_l} \to c_j$, where $e_i = (r_{e_i}, c_{e_i}), 1 \le i \le l$, are the coupled elements associated with the pivots already eliminated [23]. Therefore, following such paths, we can determine the nonzero entries of any row $i$ or column $j$ in the reduced submatrix.

Let $\mathcal{A}_{i*}$ be the set of column variables adjacent to row variable $r_i$ in $\mathcal{G}$ which have never been modified after $k$ steps of elimination. $\mathcal{A}_{*j}$ is defined similarly for column variable $c_j$. For each row variable $r_i$ and column variable $c_j$, define the element adjacency lists:

$$\mathcal{R}_i \equiv \{e = (r_e, c_e) \,:\, (r_i, c_e) \in \bar{\mathcal{E}}\} \subseteq \bar{\mathcal{V}}_c, \text{ the set of coupled elements adjacent to } r_i\,,$$
$$\mathcal{C}_j \equiv \{e = (r_e, c_e) \,:\, (r_e, c_j) \in \bar{\mathcal{E}}\} \subseteq \bar{\mathcal{V}}_r, \text{ the set of coupled elements adjacent to } c_j\,.$$

The adjacency lists of variables in the current bipartite quotient graph are then defined as

$$\mathcal{U}_i \equiv Adj^{row}_{\mathcal{G}}(r_i) = \mathcal{A}_{i*} \cup \mathcal{R}_i\,, \tag{1}$$
$$\mathcal{L}_j \equiv Adj^{col}_{\mathcal{G}}(c_j) = \mathcal{A}_{*j} \cup \mathcal{C}_j\,. \tag{2}$$

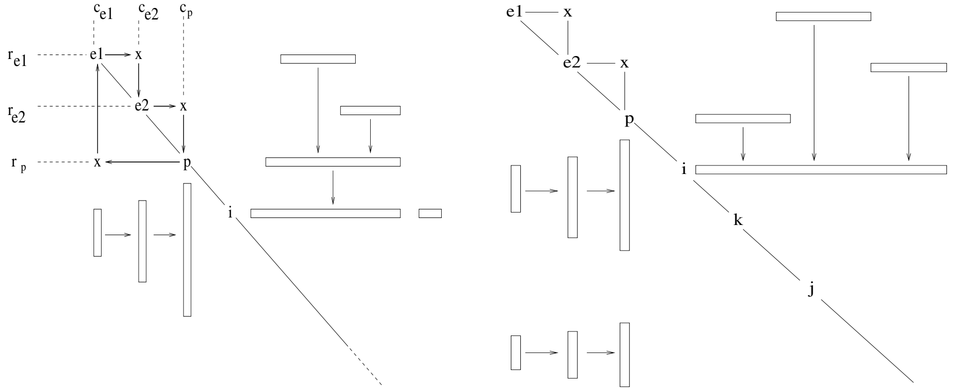
For each coupled element $e = (r_e, c_e)$ define the variable adjacency lists:

$$\mathcal{L}_e \equiv \{r_i \,:\, (r_i, c_e) \in \bar{\mathcal{E}}\} \subseteq \mathcal{V}_r, \text{ the set of row variables adjacent to } c_e\,,$$
$$\mathcal{U}_e \equiv \{c_j \,:\, (r_e, c_j) \in \bar{\mathcal{E}}\} \subseteq \mathcal{V}_c, \text{ the set of column variables adjacent to } r_e\,.$$

In other words, $\mathcal{L}_e$ and $\mathcal{U}_e$ are, respectively, the sets of row and column vertices in the biclique induced after elimination of the coupled element $e$.

Now, suppose a pivot $p = (r_p, c_p)$, $p \ge k$, is chosen to be eliminated next. If there exists a cycle of the form $r_p \to c_{e_1} \to r_{e_1} \ldots \to c_{e_l} \to r_{e_l} \to c_p \to r_p$ $(e_i \le k, 1 \le i \le l)$ (referred to as a [illegible] in [22]), then $\mathcal{L}_{e_i} \subseteq \mathcal{L}_p$ and $\mathcal{U}_{e_i} \subseteq \mathcal{U}_p$ for all $i$. Hence, except for $(r_p, c_p)$, the other coupled elements in the cycle are no longer needed. See Figure 1(a) for an illustration. When updating the quotient graph, we can coalesce the coupled elements in the cycle into a single "supervertex," using the last element $p$ as the representative vertex and removing the other elements and the incident edges. This process will be referred to as [illegible].

The transformation from bipartite quotient graph $\mathcal{G}^{k-1}$ to $\mathcal{G}^k$ at step $k$ is carried out as follows. We search in the subgraph of $\mathcal{G}^{k-1}$ induced by $\bar{\mathcal{V}}_r^{k-1} \cup \bar{\mathcal{V}}_c^{k-1}$ for cycles that include the pivot $(r_p, c_p)$. We then perform the element absorptions and form the new adjacency lists $\mathcal{L}_p$ and $\mathcal{U}_p$. The structure of a column $k$ in the reduced submatrix, $\mathbf{L}_{*k}$, can be determined very easily using $\mathcal{G}^{k-1}$: $\ell_{ik} \ne 0$ if and only if $r_i$ is reachable from $c_k$ through the coupled elements in $\mathcal{G}^{k-1}$. The structure of $\mathbf{U}_{k*}$ can be determined in a similar way. The biclique introduced by the current pivot is then used to prune the edges in $\mathcal{E}^k$. This process will be referred to as [illegible]. From the variable pruning process it results that $(r_i, c_j) \in \mathcal{E}^k$ if and only if $(r_i, c_j) \in E$ and entry $a_{i,j}$ of the original matrix has not been modified during steps 1 through $k$ of the elimination. It was proved that using this scheme, the in-place property is maintained



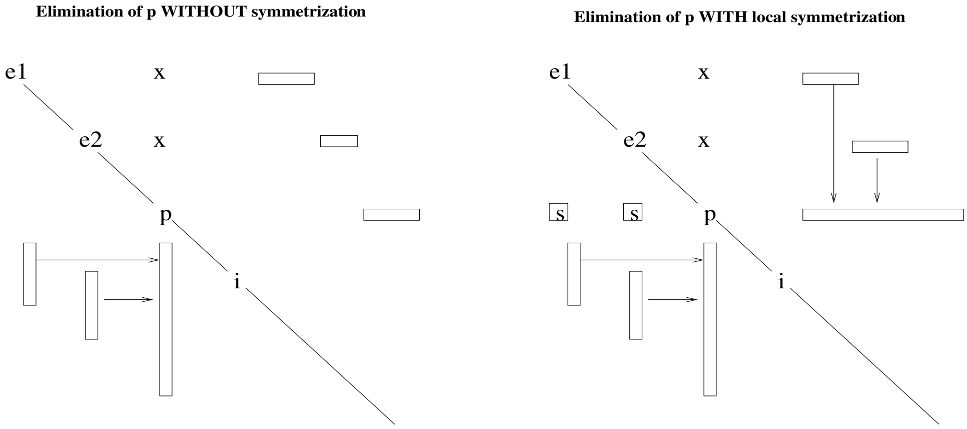
(a) Quotient graph with a cycle. (b) Quotient graph without cycle.

FIG. 1. (a) *Quotient graph with a cycle:* $r_p \rightarrow c_{e_1} \rightarrow r_{e_1} \rightarrow c_{e_2} \rightarrow r_{e_2} \rightarrow c_p$. (b) *Quotient graph without cycle.*

for each $\mathcal{G}^k$ [22]. But unlike the symmetric case, here, computing the reachable sets can be very expensive, because the length of the search path is not bounded by two. (In fact, it can be as long as $|\bar{\mathcal{V}}_r \cup \bar{\mathcal{V}}_c| + 1$ if no cycle is found.) This is illustrated by the example in Figure 1(b). There is only a simple path between $p$ and elements $e_1$ and $e_2$, which results in $\mathcal{L}_{e_1} \subseteq \mathcal{L}_{e_2} \subseteq \mathcal{L}_p$. However, $\mathcal{U}_{e_1} \nsubseteq \mathcal{U}_p$ and $\mathcal{U}_{e_2} \nsubseteq \mathcal{U}_p$. For an uneliminated variable $i$ such that $r_i \in \mathcal{L}_p \cap \mathcal{L}_{e_1} \cap \mathcal{L}_{e_2}$, all the column variables in $\mathcal{U}_p \cup \mathcal{U}_{e_2} \cup \mathcal{U}_{e_1}$ need to be included in $\mathbf{U}_{i*}$. In an in-place algorithm, one must store $r_i$ only in $\mathcal{L}_{e_1}$, and then via the path $c_{e_1} \rightarrow r_{e_1} \rightarrow c_{e_2} \rightarrow r_{e_2} \rightarrow c_p$ one can deduct that $\mathbf{U}_{i*}$ should contain the union $\mathcal{U}_p \cup \mathcal{U}_{e_2} \cup \mathcal{U}_{e_1}$. We also note that, although $\mathcal{L}_{e_1} \subseteq \mathcal{L}_{e_2} \subseteq \mathcal{L}_p$, $\mathcal{L}_{e_1}$ alone may be required to build $\mathbf{L}_{*j}$ for any $j$ such that $c_j \in \mathcal{U}_{e_1}$ and $c_j \notin \mathcal{U}_{e_2} \cup \mathcal{U}_p$. This means that $\mathcal{L}_{e_1}$ should not be absorbed into $\mathcal{L}_p$. Furthermore, if one considers a variable $k$ such that $c_k \in \mathcal{U}_p$ but $c_k \notin \mathcal{U}_{e_1} \cup \mathcal{U}_{e_2}$, then $\mathcal{L}_p$ will need to be included in $\mathcal{L}_k$. If we maintain the in-place property, the entries belonging to both $\mathcal{L}_{e_i}$, $i = 1, 2$, and $\mathcal{L}_p$ are stored only in $\mathcal{L}_{e_i}$, then we must be able to reach $e_i$, $i = 1, 2$, through a path starting at $p$: $c_p \rightarrow r_{e_2} \rightarrow c_{e_2} \rightarrow r_{e_1}$.

**2.3. Local symmetrization.** To avoid the long search path in a truly nonsymmetric algorithm, we have designed a relaxed diagonal Markowitz scheme. Figure 2 illustrates such a relaxation. The entry marked $\boxed{\text{s}}$ shows an artificial nonzero introduced to symmetrize only a [illegible] part of the matrix. In the example, we assume that $(r_p, c_p)$ is the current pivot, and $\mathcal{R}_p = \emptyset$ and $\mathcal{C}_p = \{e_1, e_2\}$. We also assume that $\mathcal{U}_{e_1} \nsubseteq \mathcal{U}_p$ and $\mathcal{U}_{e_2} \nsubseteq \mathcal{U}_p$. For the sake of clearness, we have assumed that $\mathcal{U}_{e_1} \cap \mathcal{U}_p = \emptyset$ and $\mathcal{U}_{e_2} \cap \mathcal{U}_p = \emptyset$. In order to obtain the row structure $\mathbf{U}_{i*}$, where $r_i \in \mathcal{L}_{e_1} \cap \mathcal{L}_{e_1} \cap \mathcal{L}_p$, $\mathcal{R}_i$ must contain elements $e_1$, $e_2$, and $p$. In other words, all the variables in $\mathcal{U}_{e_1} \cup \mathcal{U}_{e_2} \cup \mathcal{U}_p$ should be included in $\mathbf{U}_{i*}$. With symmetrization (shown on the right part of Figure 2), we pretend that $\mathcal{R}_p = \{e_1, e_2\}$ and $\mathcal{C}_p = \{e_1, e_2\}$. Therefore, $\mathcal{U}_{e_1} \subseteq \mathcal{U}_p$ and $\mathcal{U}_{e_2} \subseteq \mathcal{U}_p$. Hence, the coupled element $p$ can absorb the coupled elements $e_1$ and $e_2$. As a result, we now need only the adjacency lists of $r_p$ and $c_p$ to get the adjacency lists of $r_i$ and $c_i$. This eliminates the need to keep the adjacency lists of $r_{e_1}$, $r_{e_2}$, $c_{e_1}$, and $c_{e_2}$.

In summary, the local symmetrization works as follows. Suppose the current pivot



**Elimination of p WITHOUT symmetrization**

**Elimination of p WITH local symmetrization**

FIG. 2. *Illustration of local symmetrization.*

is $(r_p, c_p)$. The adjacency lists $\mathcal{U}_p$ and $\mathcal{L}_p$ are computed by

$$\mathcal{U}_p = \left( \mathcal{A}_{p*} \cup \bigcup_{e \in \mathcal{R}_p} \mathcal{U}_e \cup \bigcup_{e \in \mathcal{C}_p} \mathcal{U}_e \right) \setminus \{c_p\}, \tag{3}$$

$$\mathcal{L}_p = \left( \mathcal{A}_{*p} \cup \bigcup_{e \in \mathcal{C}_p} \mathcal{L}_e \cup \bigcup_{e \in \mathcal{R}_p} \mathcal{L}_e \right) \setminus \{r_p\}. \tag{4}$$

The third terms in the unions result from the local symmetrization. The adjacency lists in the bipartite quotient graph (see (1) and (2)) of all the row (column) variables in the adjacency lists of the newly formed coupled element $p$ should then be updated. All the row and column elements in $\mathcal{R}_p \cup \mathcal{C}_p$ are absorbed by the coupled element $p$. Therefore, if $(r_e, c_e)$ is such an absorbed element, then $r_e$ $(c_e)$ will be replaced by $r_p$ $(c_p)$ each time it appears in an edge of $\bar{\mathcal{E}}$ and will be excluded from the quotient graph together with $\mathcal{L}_e$ $(\mathcal{U}_e)$. Furthermore, because of local symmetrization, more variable pruning can be performed. Let $i = (r_i, c_i)$ be a coupled variable (diagonal entry in the reduced matrix) such that $r_i \in \mathcal{L}_p$ and $c_i \notin \mathcal{U}_p$. We can anticipate local symmetrization between $i$ and the coupled element $p$ to prune all the row variables in $\mathcal{A}_{*i}$ that belong to $\mathcal{L}_p$. Entries in $\mathcal{A}_{i*}$ can also be pruned in a similar way (even if $r_i \notin \mathcal{L}_p$).

Our relaxation mechanism will be referred to as [illegible], because the symmetrization is applied to only the local part of the graph involving only those row and column elements adjacent to $c_p$ and $r_p$. Globally, the nonzero structure generally still remains nonsymmetric (the index sets $\{k : r_k \in \mathbf{L}_{*i}\}$ and $\{k : c_k \in \mathbf{U}_{i*}\}$ are different). By construction, the length of a search path is bounded by three. In essence, we trade off some amount of asymmetry and space (because some zero entries may be stored) with a much faster search algorithm. We show in Theorem 2.1 that although the local symmetrization may introduce extra (zero) entries in the factors with respect to a pure nonsymmetric scheme (see Figure 2), it leads to an in-place algorithm.

THEOREM 2.1. [illegible] $v$ [illegible] $\mathcal{G}^k$ [illegible] $\mathcal{A}^k_{v*}$ [illegible] $\mathcal{A}^k_{*v}$ [illegible] $v$ [illegible]

[illegible] $k$ [illegible] $2 \leq k \leq n$ $|\mathcal{A}^k_{v*}| + |\mathcal{R}^k_v| \leq |\mathcal{A}^{k-1}_{v*}| + |\mathcal{R}^{k-1}_v| \leq |\mathcal{A}^0_{v*}|$ [illegible] $|\mathcal{A}^k_{*v}| + |\mathcal{C}^k_v| \leq |\mathcal{A}^{k-1}_{*v}| + |\mathcal{C}^{k-1}_v| \leq |\mathcal{A}^0_{*v}|$

[illegible]. We focus on the row structures in this proof. The proof for the column structures is similar. We prove this theorem by induction. By construction, $\mathcal{R}^0_i = \emptyset$, so $|\mathcal{A}^0_{i*}| + |\mathcal{R}^0_i| = |\mathcal{A}^0_{i*}|$. Suppose at the $k$th step of elimination that $(r_p, c_p)$ is selected as the pivot. We first build $\mathcal{U}^k_p$ using (3). The entries in $\mathcal{U}^k_p$ either come from the original matrix $\mathcal{A}_{p*}$ or from the entries in $\mathcal{U}_e$ such that $e \in \mathcal{R}_p \cup \mathcal{C}_p$. Because of local symmetrization, the coupled element $e$ will be absorbed by $p$, and the space of $\mathcal{U}_e$ can be used by $\mathcal{U}^k_p$ to store the new entries from $\mathcal{U}_e$. To take into account the fill-in we have to update the adjacency lists of all variables adjacent to the pivot. We focus on the row structures and thus consider the updating of $\mathcal{U}^k_i$ for $r_i \in \mathcal{L}^k_p$ using (1). By construction, all the entries in $\mathcal{U}^k_p \cap \mathcal{A}^{k-1}_{i*}$ are pruned from $\mathcal{A}^{k-1}_{i*}$, showing that $|\mathcal{A}^k_{i*}| \leq |\mathcal{A}^{k-1}_{i*}|$, and $c_p$ is added to $\mathcal{R}^k_i$. Now we consider the size of $\mathcal{R}^k_i$. If $r_i \in \mathcal{L}^k_p$, then there exists a coupled element $e_j = (r_j, c_j)$ in the supervertex $p = (r_p, c_p)$ such that $(r_i, c_j)$ is in the original graph. Since $(r_i, c_j)$ has been pruned and $c_j$ cannot belong to any other supervertex, then we have $|\mathcal{A}^k_{i*}| + |\mathcal{R}^k_i| \leq |\mathcal{A}^{k-1}_{i*}| + |\mathcal{R}^{k-1}_i|$. This concludes our proof of the in-place property of the algorithm. ☐

COROLLARY 2.2. [illegible] $\mathcal{G}^k$ [illegible] $\mathcal{G}^0$ [illegible] $|\mathcal{E}^k \cup \bar{\mathcal{E}}^k| \leq |\mathcal{E}^{k-1} \cup \bar{\mathcal{E}}^{k-1}| \leq |\mathcal{E}^0|$, [illegible] $2 \leq k \leq n$

Theorem 2.1 implies that the in-place property holds for the row adjacency lists and for the column adjacency lists so that we could have an in-place implementation while keeping two separate lists to store entries in rows and in columns at each step of the elimination.

We will call our relaxed scheme [illegible] (`DMLS`). We now illustrate its main properties with an example. In Figure 3, we apply the `DMLS` algorithm assuming that pivots are in the natural ordering. The matrix on the right is the structure of the LU factors. The elimination tree [18] built by the `DMLS` algorithm is shown in Figure 4. Each node of the tree corresponds to the elimination of a pivot. The nonsymmetric frontal matrix of each node corresponds to the structure of $\mathcal{U}_p$ and $\mathcal{L}_p$ as defined by (3) and (4). The dark area corresponds to the entries in the reduced matrix updated during the node elimination (i.e., the nonsymmetric contribution block sent by one node to its parent).

FIG. 3. *Illustration of the fill-ins introduced by the* `DMLS` *algorithm.* **F** *corresponds to the normal fill-in when eliminating pivot* $(1,1)$*.* **S** *corresponds to the fill-in due to the local symmetrization when eliminating pivot* $(2,2)$*.*

At the first step, pivot $(1,1)$ is eliminated resulting in two fill-ins (**F** in positions $(4,2)$ and $(4,3)$). In the quotient graph $\mathcal{G}^1$, these fill-ins are implicitly represented by removing $r_1$ from $\mathcal{A}_{*2}$ and $\mathcal{A}_{*3}$ and adding $r_1$ to $\mathcal{C}_2$ and $\mathcal{C}_3$. Note that at this step there is no symmetrization of the column and row adjacency lists of $r_1$ and $c_1$, which otherwise would result in a completely full reduced matrix. When eliminating

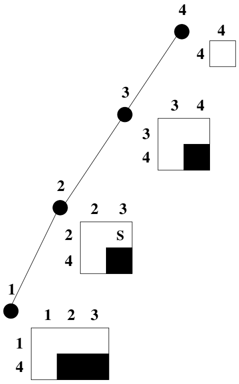

FIG. 4. *Elimination tree built by the* `DMLS` *algorithm applied to the matrix of Figure* 3.

pivot $(2,2)$, since $r_1 \in \mathcal{C}_2$ and $c_1 \notin \mathcal{R}_2$, local symmetrization is applied, and when computing $\mathcal{U}_2$ by (3) entry $\mathbf{S}$ in position $(2,3)$ is added to the quotient graph $\mathcal{G}^2$ (i.e., the coupled element 1 is absorbed by 2, and $r_2$ is added to $\mathcal{C}_3$). One should note that entry $(2,1)$ is only [illegible] considered as nonzero and is never added in the LU factors. Similarly, when eliminating pivot $(3,3)$ at the next step, only the effect of adding entry $(3,2)$, by symmetrization of $(2,3)$, on the structure of the column $\mathcal{L}_3$ is considered (it happens to have no effect in our example). Even if entry $(3,2)$ is not effectively stored and has no effect on the size of the factors, it still has an effect on the structure of the dependency graph, as shown in Figure 4. The fact that pivot 3 can absorb the coupled element 2 because of the artificial $(3,2)$ nonzero entry also means that node 3 in Figure 4 becomes the unique parent of node 2 in the dependency graph, which in turn becomes a tree (or forest when the matrix is reducible). It is also interesting to note that, since entry $(2,3)$ ($\mathbf{S}$ in the figure) is considered nonzero, column 3 is added to the frontal matrix of node 2. But entry $(4,3)$ will not be modified during elimination of pivot $(2,2)$, because entry $(2,3)$ is structurally zero. Entry $(4,3)$ is a contribution resulting only from elimination of pivot $(1,1)$, and it is needed only when eliminating pivot $(3,3)$. Because of this newly added column, the frontal matrix of node 2 has the minimum structure to carry all the contributions of node 1 to all of its ancestral nodes 2 and 3. The edge between nodes 1 and 3 can be removed, which corresponds to the coupled element 2 absorbing the coupled element 1 in the quotient graph.

We have shown that even if local symmetrization may result in extra fill-ins, it does not symmetrize the adjacency lists of the pivot; it builds at each elimination step the minimal nonsymmetric structure capable of absorbing all the nonsymmetric contributions from all the elements adjacent to the pivot. This nonsymmetric structure is called the [illegible], similar to the symmetric case. By doing so, node $p$ becomes the [illegible] parent of all the nodes $e$ such that $c_e \in \mathcal{R}_p$ or $r_e \in \mathcal{C}_p$ in a tree rooted with the last pivot. The `DMLS` algorithm thus explicitly builds an elimination tree in which each node corresponds to the processing of a nonsymmetric frontal matrix whose structure is defined by $\mathcal{L}_p$ and $\mathcal{U}_p$. This elimination tree is identical to the dependency graph that `MA41_UNS` [6] would build if the same ordering were provided. In fact, the `DMLS` ordering is searching for an ordering that provides a good nonsymmetric elimination tree with respect to some local criterion/metric. The `DMLS` ordering also provides a good estimation of the size of the factors and all the working space required during numerical factorization using the `MA41_UNS` approach. This estimation is exact if the diagonal pivots are numerically stable.

**2.4. The DMLS algorithm.** To design the `DMLS` algorithm, we have exploited many algorithmic techniques from the `AMD` approach [1] and have extended them to the nonsymmetric case. The main difficulty is handling local symmetrization during degree calculation. We first explain how to adapt the symmetric algorithms, then describe the modifications needed for local symmetrization, and conclude this section with a description of the metrics used in pivot selection.

Exploiting identical structures in the graph can greatly speed up the degree update at each elimination step. Two coupled variables $i = (r_i, c_i)$ and $j = (r_j, c_j)$ are said to be [illegible] in $\mathcal{G}$ if they have the same row adjacency structure [illegible] the same column adjacency structure in $\mathcal{G}$ (although the row structure may be different from the column structure). Indistinguishable coupled variables can then be merged into a single so-called [illegible]. We use a boldface letter to denote a supervariable. Thus, $\mathbf{i} = (\mathbf{r}_i, \mathbf{c}_i)$, with $\mathbf{r}_i \equiv \{r_i, r_j\}$, and $\mathbf{c}_i \equiv \{c_i, c_j\}$.

For each row supervariable $\mathbf{r}_i$, let $d_{r_i}$ denote its external row degree [1, 17]. Similarly, for each column supervariable $\mathbf{c}_i$, let $d_{c_i}$ denote its external column degree. The external degrees are defined as

$$d_{r_i} = |\mathcal{A}_{i*} \backslash \mathbf{c}_i| + \left| \left( \bigcup_{e \in \mathcal{R}_i \cup \mathcal{C}_i} \mathcal{U}_e \right) \backslash \mathbf{c}_i \right|, \tag{5}$$

$$d_{c_i} = |\mathcal{A}_{*i} \backslash \mathbf{r}_i| + \left| \left( \bigcup_{e \in \mathcal{C}_i \cup \mathcal{R}_i} \mathcal{L}_e \right) \backslash \mathbf{r}_i \right|. \tag{6}$$

Note that we should consider [illegible] the elements in [illegible] $\mathcal{R}_i$ and $\mathcal{C}_i$ contributing to the row degree and column degree. Indeed, because of local symmetrization, when $(r_i, c_i)$ is selected as the pivot at a later step, those elements will contribute to the structure of both $\mathcal{U}_i$ and $\mathcal{L}_i$ (see (3) and (4)). Therefore, we must ensure that the computed degrees are also consistent with the local symmetrization scheme. This does not mean that we symmetrize all the edges in $\bar{\mathcal{E}}$. It means only that our degree evaluation must anticipate what would happen if $(r_i, c_i)$ were selected as the pivot. That is, during the degree calculation of the uneliminated variables, we need to simulate the effect of local symmetrization. The local symmetrization actually takes place only when a variable is selected as the pivot. This has been illustrated in Figure 3.

Following the symmetric `AMD` algorithm [1], we can approximate the true degrees by their upper bounds, $\bar{d}_{r_i}$ and $\bar{d}_{c_i}$, which, at step $k$, can be computed by

$$\bar{d}_{r_i}^{\,k} = \min \begin{cases} n - k, \\ \bar{d}_{r_i}^{\,k-1} + |\mathcal{U}_p \backslash \mathbf{c}_i|, \\ |\mathcal{A}_{i*} \backslash \mathbf{c}_i| + |\mathcal{U}_p \backslash \mathbf{c}_i| + \displaystyle\sum_{e \in \mathcal{R}_i \cup \mathcal{C}_i} |\mathcal{U}_e \backslash \mathcal{U}_p| - \alpha_i, \end{cases} \tag{7}$$

$$\bar{d}_{c_i}^{\,k} = \min \begin{cases} n - k, \\ \bar{d}_{c_i}^{\,k-1} + |\mathcal{L}_p \backslash \mathbf{r}_i|, \\ |\mathcal{A}_{*i} \backslash \mathbf{r}_i| + |\mathcal{L}_p \backslash \mathbf{r}_i| + \displaystyle\sum_{e \in \mathcal{C}_i \cup \mathcal{R}_i} |\mathcal{L}_e \backslash \mathcal{L}_p| - \beta_i. \end{cases} \tag{8}$$

Note that, unlike the symmetric case, two correction terms $\alpha_i$ and $\beta_i$ have been introduced to improve the accuracy of the approximation to the external degree. Let us justify the $\alpha_i$ term in (7). In the nonsymmetric case, it may happen that $\mathbf{c}_i \notin \mathcal{U}_p$, whereas for an accurate prediction of $\bar{d}_{r_i}$ in the context of local symmetrization, we need to pretend that $\mathbf{c}_i \in \mathcal{U}_p$. In this case, $|\mathbf{c}_i|$ was mistakenly counted in every $|\mathcal{U}_e \backslash \mathcal{U}_p|$ for $e \in \mathcal{C}_i$ and should thus be deducted. The total amount that should be deducted is $\alpha_i = |\mathcal{C}_i| \times |\mathbf{c}_i|$; see [4] for details.

Once $\bar{d}_{r_i}$ and $\bar{d}_{c_i}$ are computed, we have many choices of minimization criteria to select the next pivot. Each choice will lead to a different ordering. One set of criteria or metrics is degree-based, which is a direct function of the degrees (e.g., $\text{Min}(\bar{d}_{r_i} \times \bar{d}_{c_i})$, $\text{Min}(\bar{d}_{r_i} + \bar{d}_{c_i})$, $\text{Min}(\text{Min}(\bar{d}_{r_i}, \bar{d}_{c_i}))$, $\text{Min}(\text{Max}(\bar{d}_{r_i}, \bar{d}_{c_i})))$. Another set is deficiency-based, which is based on estimates of the amount of new fill-in generated at each step. We have experimented several variants of the approximations of the deficiency. Most of the heuristics in [20, 24] can be adapted easily to the nonsymmetric case. Moreover, we have considered a deficiency heuristic that results from discussions with T. Davis and I. S. Duff while working on the approximate minimum degree ordering for symmetric matrices `AMD`. This approximation of the deficiency (referred to as `AMDF` in the symmetric context) is based on the following observation. Suppose $\{r_p, c_p\}$ is the current pivot and the two column elements $e_1$ and $e_2$ are adjacent to $r_i \in \mathcal{L}_p$. In our approximate degree $\bar{d}_{c_i}$ we count twice the row variables that belong to $(\mathcal{L}_{e_1} \backslash \mathcal{L}_p) \cap (\mathcal{L}_{e_2} \backslash \mathcal{L}_p)$. This property can be exploited to improve the estimation of the deficiency, since, in this context, we try to deduct from the degree product the cliques of all the elements adjacent to the current variable. We can consider that $(\mathcal{L}_{e_1} \backslash \mathcal{L}_p) \cap (\mathcal{L}_{e_2} \backslash \mathcal{L}_p) = \emptyset$, because this overlapped term also occurs in the degree product, which is cancelled after subtraction. Thus, for each $r_i \in \mathcal{L}_p$, we can deduct both the area relative to the current clique $p$ (i.e., $|L_p| \times |U_p|$) and the sum of the "external areas" of all the elements adjacent to $(r_i, c_i)$ (i.e., $\sum_{e \in \mathcal{C}_i \cup \mathcal{R}_i} |\mathcal{L}_e \backslash \mathcal{L}_p| \times |\mathcal{U}_p|$). The external area is readily available, since $|\mathcal{L}_e \backslash \mathcal{L}_p|$ has already been computed during the approximate degree calculation. This leads to a more accurate approximation of the deficiency than the approximations introduced in [20, 24] when used in an approximate minimum degree code. This approximation of the deficiency can be easily adapted to our nonsymmetric ordering and will be referred to as `DMLS-MF`. Note that using `AMDF` on symmetric matrices, the amounts of reduction in fill-in and flop count relative to `AMD` have been found to be similar to those reported in [20, 24].

## 3. Numerical experiments.

We now evaluate the `DMLS` ordering algorithm and compare its ordering quality with that obtained by applying both approximate minimum degree and minimum deficiency algorithms on $\mathbf{A} + \mathbf{A}^T$.

### 3.1. Testing environment.

To experiment with our ordering algorithm, we will consider the unsymmetrized multifrontal code `MA41_UNS` [2, 6], which automatically detects and exploits the structural asymmetry of the submatrices involved when processing the elimination tree associated with the pattern of the symmetric matrix $\mathbf{A} + \mathbf{A}^{\mathrm{T}}$. In [7], `MA41_UNS` with `AMD` ordering was shown to be very competitive with `SuperLU` and `UMFPACK` on a large class of matrices including very nonsymmetric ones. We will show in this section that using `DMLS` ordering can significantly improve the speed of `MA41_UNS`. `MA41_UNS` is a tree-based multifrontal algorithm, in which some steps of Gaussian elimination are performed on a dense frontal matrix at each node of the assembly tree, and the Schur complement (or the contribution block) that remains is passed for assembly at the parent node.

`MA41_UNS` can benefit from a numerical scaling of the matrix followed by a numerical preordering (row or column permutations) to maximize the magnitude of the diagonal entries. After numerical pivoting and scaling, a sparsity preserving ordering (symmetric permutation of $\mathbf{A}$) based on an analysis of the pattern of $\mathbf{A} + \mathbf{A}^T$ can be used. The computational graph of the factorization is then computed assuming that diagonal pivots are numerically stable. Since this assumption may not be entirely true during numerical factorization, the solver uses partial pivoting with a threshold value to select numerically stable pivots. It is thus possible that some variables cannot be eliminated from a frontal matrix. The rows and columns containing the noneliminated variables of a frontal matrix are then added to the contribution block and passed to the parent node. Those [illegible] eliminations will result in an increase in the size of the LU factors estimated in the analysis and an increase in the number of operations. In practice, it has been observed that using `MC64` [21, 9, 10] from HSL [15] as preordering can significantly reduce the number of delayed pivots during factorization [3]. This preordering will thus be applied on all our test matrices.

Our test matrices are from the forthcoming Rutherford-Boeing Sparse Matrix Collection [8], the industrial partners of the PARASOL Project,[2] Tim Davis's collection[3], and SPARSEKIT2.[4] Only matrices with structural symmetry less than 0.5 and dimension greater than 1000 were chosen. We define the structural symmetry as the fraction of the nonzeros matched by nonzeros in symmetric locations. Thus, a symmetric matrix has a value of 1, and a highly nonsymmetric matrix has a value close to 0. When there were many similar matrices from the same application domain, we used only a subset with the largest dimensions. Altogether, there were 61 structurally nonsymmetric matrices in our study.

Our computer platform comprises a 2.8 GHz Pentium 4 processor, 2 GBytes of memory, and 1 MByte of cache, with a Linux operating system. We used `gcc -O` to compile the `DMLS` code and `pgf90 -O` to compile all the FORTRAN routines. We also used Goto's BLAS library `libgoto_p4_512-r0.94.so` [14].

We systematically applied random row and column permutations to each matrix. Eleven different permutations were applied to each matrix, and the run that provided the median value of the LU factor size was used in the report.

**3.2. Results.** We first evaluated the quality of the `DMLS` ordering when using different minimization metrics and heuristics mentioned in section 2.4 (min-prod, min-sum, min-min, min-max, and minimum deficiency). Our study showed that `DMLS-MF` (i.e., `DMLS` with approximate minimum deficiency) gives the best quality in terms of fill-in and flop reductions. Therefore, we used `DMLS-MF` in the rest of the experiments. To illustrate the gain in quality we compared `DMLS-MF` with the standard approximate minimum degree algorithm `AMD` as well as `AMDF` (our best local heuristic to approximate the deficiency for the symmetrized matrix $\mathbf{A} + \mathbf{A}^T$).

We observed that for five highly reducible matrices (raefsky5.rua, raefsky6.rua, meg1.rua, bayer05.rua and bayer07.rua) `DMLS-MF` significantly outperformed both `AMD` and `AMDF`—the factor sizes were reduced by 4 to 10 times. Although this is a nice property of `DMLS` it not the scope of our work, since on highly reducible matrices one could consider preprocessing the matrices to first permute them to a block triangular form (BTF) and then search for a symmetric permutation within the diagonal blocks of the BTF format. We have thus excluded these five matrices when reporting the

[4] http://math.nist.gov/MatrixMarket/data/SPARSKIT.

results, because they will skew the statistics. For the other 56 matrices, we compare in Figure 5 the actual size of the factors (including the extra fill-ins due to numerical pivoting) of the `DMLS-MF`, `AMD`, and `AMDF` orderings. For a relatively large number of matrices (23 with respect to `AMD` and 18 with respect to `AMDF`), the `DMLS-MF` ordering leads to ratios greater than 1.20. Sometimes `DMLS-MF` may give worse ordering than `AMD` or `AMDF`, but it is never less than a ratio of 0.70. Note that there are eight matrices which have structural symmetry less than 0.5 initially but larger than 0.5 after preordering with `MC64`. As expected, for these matrices, relatively smaller gains are obtained from `DMLS`.

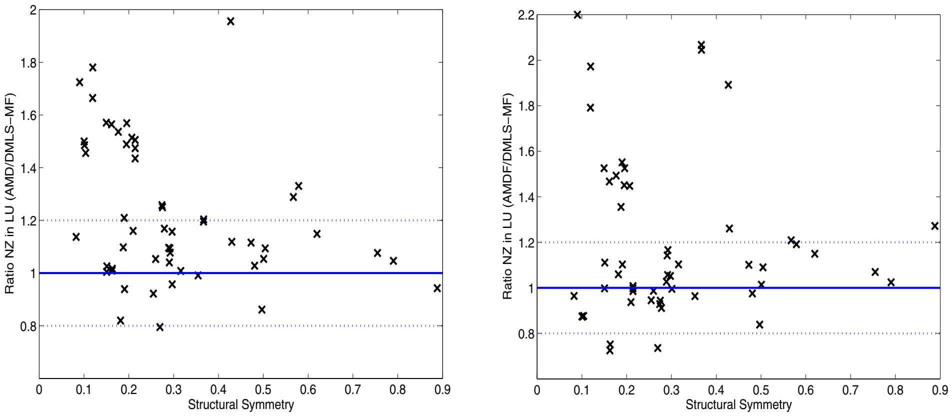

FIG. 5. *Actual fill-in ratios. The x-axis shows the structural symmetry after preprocessing. Left:* `AMD/DMLS-MF`*, mean ratio is* 1.22*, median ratio is* 1.14*; right:* `AMDF/DMLS-MF`*, mean ratio is* 1.20*, median ratio is* 1.6.

In Figure 6, we compare the number of floating-point operations performed during factorization (including numerical pivoting) using the three orderings. For a large number of matrices, the `DMLS-MF` ordering leads to ratios greater than 1.30 for the flop reduction compared to `AMD` (34 matrices) and `AMDF` (23 matrices).

We now focus on 19 large matrices of dimension larger than 10000 and having initial structural symmetry smaller than 0.5 (except for Sandia/mult_dcop_03 and Zhao/Zhao2). This is a subset of the 61 matrices studied above. For this subset, we perform a more detailed quantitative comparison of the `AMDF` and `DMLS-MF` algorithms. These matrices are listed in Table 1 and are sorted in increasing symmetry after the matrices are randomly permuted and reordered using the maximum transversal given by `MC64`. Here, among the 11 symmetry numbers from the 11 initial random permutations, we report the one corresponding to the permutation that gives the mean fill ratio of `AMDF` over `DMLS-MF`.

In Table 2 we report both the estimated factor size given by the analysis phase (columns 2 and 3) and the actual factor size computed during factorization using `MA41_UNS` (columns 5 and 6). Since the pruned frontal matrix structures appeared in factorization are exactly those on which the `DMLS` algorithm is based, the estimation given by `DMLS-MF` is correct modulo small variation due to numerical pivoting. In fact, in addition to an ordering, `DMLS` also gives an assembly tree with the correct frontal size that `MA41_UNS` can use. It is important to note that numerical pivoting has little effect on the structural changes. But this is not the case with `AMDF`, which is based on the graph of the symmetrized matrix $\mathbf{A} + \mathbf{A}^T$. We see that the difference between

estimation and actual size is significant, and the estimation is often much larger than the actual size. This is because the `MA41_UNS` factorization algorithm can dynamically exploit a more precise frontal matrix structure at each pivot, which can be rectangular and smaller than the frontal matrix structure predicted by `AMDF`. (The frontal matrix predicted by `AMDF` is always square due to initial, global symmetrization $\mathbf{A} + \mathbf{A}^T$.) Furthermore, it has been observed in [6] that an even larger difference can occur in the size of the stack memory. Therefore, after `AMDF` (or `AMD`) ordering and before numerical factorization, one should run a nonsymmetric symbolic factorization algorithm to identify the nonsymmetric structures needed to perform numerical factorization. In our context this extra cost should thus be added to the analysis time when an ordering based on $\mathbf{A} + \mathbf{A}^T$ is used.

In addition to the actual factor size and the floating-point operations, we also report the peak memory (labeled “Real memory” in Table 2) needed to factorize the matrix, which is measured in the number of double precision words. For some classes of matrices (ATandT, Mallya, Norris, Sandia) the `DMLS-MF` ordering leads to much less memory usage than that of `AMDF`. For some other classes of matrices (Grund, Vavasis, Shen), the results are comparable. We found that the Hollinger matrices are very sensitive to the initial random permutations. For example, the number of operations varies between $6.5 \times 10^8$ and $8.3 \times 10^8$ using `AMDF`, between $12.7 \times 10^8$ and $18.4 \times 10^8$ using `DMLS-MF`, and between $17.1 \times 10^8$ and $20.7 \times 10^8$ using `AMD`. Moreover, for this class of matrices, `MA41_UNS` combined with the `AMD` ordering applied to $\mathbf{A} + \mathbf{A}^{\mathrm{T}}$ significantly outperforms all the nonsymmetric solvers considered in [7]. Using `AMDF` thus further reduced the number of operations, and the attempt to exploit the asymmetry of the original matrix did not improve the ordering quality (as shown by the `UMPFPACK` code which attempts to exploit all the asymmetry [7]).

For smaller matrices in the same classes, which are among the complete set of 61 matrices but not shown in Table 2, we have observed a similar behavior. One should point out that on reducible matrices it is always beneficial to first permute to BTF and then apply the ordering to the diagonal block. Furthermore, it has been observed (private communication with Stan Einsenstat) that if one compares the orderings on the largest diagonal block of the BTF, the gains of `DMLS` relative to `AMDF` as reported in this paper are reduced. We feel that this can be only partially explained by the fact that the diagonal blocks of the BTF permuted reducible matrices tend to be structurally more symmetric than the original matrices.

Finally, we report in Table 2 the runtimes of the ordering algorithms. Since both `AMDF` and `DMLS-MF` exploit approximate degree calculations, the complexity of these two codes is directly related to that of the `AMD` ordering. For `DMLS`, since we need to maintain the adjacency structures and the approximate degrees both rowwise and columnwise, we expect `DMLS-MF` to be twice as slow as `AMDF`. This is in general true except for Hohn and Norris classes of matrices, for which `DMLS-MF` is much slower. For Hohn/Sinc* matrices, large dense off-diagonal blocks lead to larger supervariables in the graph of $\mathbf{A} + \mathbf{A}^T$ than in the graph of $\mathbf{A}$. In this case, the asymmetry prevents `DMLS-MF` from selecting larger supervariables, whereas it is not sufficiently nonsymmetric to lead to better ordering. For the matrix Norris/Torso1, the situation is different for at least two reasons. First, taking into account the asymmmetry of the matrix significantly improves the quality of the ordering. Second, it has been shown in our recent work [5] (generalization of the `DMLS` approach to allow off-diagonal and numerical-based pivot selection) that using separate row and column supervariables, one can significantly decrease the ordering time on this class of matrices, and this is true even when pivot selection is restricted to the diagonal as in `DMLS`. However, considering separate row and column supervariables is not at all natural in the `DMLS` context; it would require significant modifications of the data structures used in `DMLS` code and is out of the scope of this work.

In this section, we have focused on the comparison among the local heuristic-based orderings. We believe that improving local heuristics will also benefit the global heuristic orderings that often combine global and local heuristics. Furthermore, we also observed (experiments not reported in this paper) that `DMLS-MF` ordering is at least as good as a nested dissection ordering in preserving sparsity of the factors for most matrices from our set of 19 large matrices.

## 4. Summary.

In this paper, we have considered the ordering problem for the triangular factorization of a sparse nonsymmetric matrix when pivots can be chosen on the main diagonal. We have described a bipartite quotient graph model for nonsymmetric elimination and have used it as a compact way to represent the elimination graph. The model was first proposed by Pagallo and Maulino [22], but to our knowledge, its implementation did not appear in any literature. Using this model, an ordering algorithm can be implemented in space bounded by the size of the original matrix. This is the so-called in-place property. However, we have found that a straightforward implementation may lead to an algorithm with much higher complexity than an `AMD` type of algorithm applied to the graph of $\mathbf{A} + \mathbf{A}^T$. In order to speed up the ordering algorithm itself, we have introduced the local symmetrization mechanism in the diagonal Markowitz scheme, which allows us to reduce the amount of backtracking needed to update the Schur complement structure at each step. As a result, we have obtained an efficient ordering algorithm both in space and in time—it has the in-place property and the same time complexity as the `AMD` type of algorithms.

We have performed numerical experiments on large numbers of matrices (61) that come from a wide range of applications. The results have showed that our modified diagonal Markowitz scheme indeed can produce better orderings. Compared to the best local greedy algorithms that cannot exploit asymmetry, our algorithm has achieved average gain ratios of 1.22 in factor size and 1.56 in flop count.

**Acknowledgment.** We owe a great deal to the anonymous referees whose careful reading of the initial manuscript and valuable comments have helped us significantly improved the presentation.

# COMBINATORIAL ANALYSIS OF SINGULAR MATRIX PENCILS*

SATORU IWATA[†] AND RYO SHIMIZU[‡]

**Abstract.** This paper investigates the Kronecker canonical form of matrix pencils under the genericity assumption that the set of nonzero entries is algebraically independent. We provide a combinatorial characterization of the sums of the row/column indices supported by efficient bipartite matching algorithms. We also give a simple alternative proof for a theorem of Poljak on the generic ranks of matrix powers.

**Key words.** Kronecker canonical form, matrix pencil, combinatorial matrix theory, bipartite matching, Dulmage–Mendelsohn decomposition

**DOI.** 10.1137/S0895479804442450

## 1. Introduction.

A matrix pencil is a pair of matrices of the same size. It is often treated as a polynomial matrix whose nonzero entries are of degree at most one. Based on the theory of elementary divisors, Weierstrass established a criterion for strict equivalence, as well as a canonical form, of regular matrix pencils. Somewhat later, Kronecker investigated singular pencils to obtain a canonical form for matrix pencils in general under strict equivalence transformations, which is now called the Kronecker canonical form [12].

The Kronecker canonical form finds a variety of applications in control theory of linear dynamical systems [2, 22, 31, 32]. It is also closely related to the index of differential algebraic equations [13, 14, 29].

Numerically stable algorithms are already available for computing the Kronecker canonical form [1, 3, 8, 19, 20, 35, 36]. Nevertheless, these algorithms are not very accurate in the presence of round-off errors. The numerical difficulty is inherent in the problem as the Kronecker canonical form is highly sensitive to perturbation, which has motivated extensive research on perturbation of matrix pencils [9, 10].

On the other side, matrix pencils arising in applications are often very sparse. It is then desirable to predict the structure of the Kronecker canonical form efficiently from combinatorial information such as the zero/nonzero pattern without numerical computation. Of course, one cannot always obtain exact prediction of the Kronecker canonical form without numerical information. The zero/nonzero pattern, however, determines the indices in the Kronecker canonical form under a genericity assumption that there is no algebraic relation among nonzero entries. One may hope to devise an efficient method for computing them.

Such a structural approach has been developed for regular matrix pencils by Duff and Gear [5] and Pantelides [29] in the context of differential algebraic equations. Murota [26] described a complete characterization of the Kronecker canonical form of regular matrix pencils in terms of the maximum degree of minors, which is tantamount to the maximum weight of bipartite matchings under the genericity assumption. A recent paper of van der Woude [34] provides another combinatorial characterization based on the Smith normal form [25].

In this paper, we extend the structural approach to the analysis of singular matrix pencils. The possible existence of the minimal row/column indices (rectangular blocks in the canonical form) makes this problem much more complicated than the regular case. In fact, it remains open to design an efficient algorithm for determining the row/column indices. The main result of this paper, however, provides a combinatorial characterization of the sums of the minimal row/column indices using the Dulmage–Mendelsohn decomposition and weighted bipartite matchings. Thus our combinatorial characterization is supported by efficient algorithms.

The structure of the Kronecker canonical form is closely related to the ranks of certain sequences of embedded matrices, called the expanded matrices. We investigate those expanded matrices to show that their ranks are equal to the term-ranks in most cases. As a byproduct, we give a simple alternative proof for a theorem of Poljak [30] on the generic ranks of matrix powers.

The genericity assumption certainly needs some refinement to deal with practical situations. In the description of dynamical systems such as electric circuits, entries that come from conservation laws are exact integers, while other entries that represent physical characteristics of devices are not precise in value because of noises. It should be reasonable to assume the algebraic independence only among the latter types of entries. Based on such an observation, Murota [24, 28] introduced the concept of mixed matrices and investigated their fundamental properties with the aid of matroid theory. In particular, a complete characterization of the Kronecker canonical form of regular mixed matrix pencils is presented in [27]. With a view towards applications, our ultimate target is an extension of this result to singular mixed matrix pencils. Such an investigation, however, requires a solution on generic matrix pencils as the first step.

The outline of this paper is as follows. Section 2 recapitulates the Kronecker canonical form. In section 3, we introduce generic matrix pencils. In section 4, we explain the Dulmage–Mendelsohn decomposition, which plays an essential role in our result on the minimal row/column indices presented in section 5. Sections 6 and 7 are devoted to the analysis of expanded matrices. The simple proof for the theorem of Poljak is shown in section 8. Sections 6 and 8 are independent of sections 4 and 5. Finally, in section 9, we briefly discuss how to use results of combinatorial analysis in the context of numerical computation.

## 2. The Kronecker canonical form of matrix pencils.

Let $D(s) = A + sB$ be an $m \times n$ matrix pencil with the row set $R$ and the column set $C$. We denote by $D(s)[X, Y]$ the submatrix of $D(s)$ determined by $X \subseteq R$ and $Y \subseteq C$. A matrix pencil $D(s) = A + sB$ is said to be regular if $\det D(s) \neq 0$ as a polynomial in $s$. It is strictly regular if both $A$ and $B$ are nonsingular matrices. The rank of $D(s)$ is the maximum size of its submatrix that is a regular matrix pencil. A matrix pencil $\bar{D}(s)$ is said to be strictly equivalent to $D(s)$ if there exists a pair of nonsingular constant matrices $U$ and $V$ such that $\bar{D}(s) = UD(s)V$.

For a positive integer $\mu$, we consider $\mu \times \mu$ matrix pencils $K_\mu$ and $N_\mu$ defined by

$$K_\mu = \begin{pmatrix} s & 1 & 0 & \cdots & 0 \\ 0 & s & 1 & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & 0 \\ \vdots & & \ddots & s & 1 \\ 0 & \cdots & \cdots & 0 & s \end{pmatrix}, \qquad N_\mu = \begin{pmatrix} 1 & s & 0 & \cdots & 0 \\ 0 & 1 & s & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & 0 \\ \vdots & & \ddots & 1 & s \\ 0 & \cdots & \cdots & 0 & 1 \end{pmatrix}.$$

For a positive integer $\varepsilon$, we further denote by $L_\varepsilon$ an $\varepsilon \times (\varepsilon + 1)$ matrix pencil

$$L_\varepsilon = \begin{pmatrix} s & 1 & 0 & \cdots & 0 \\ 0 & s & 1 & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & 0 \\ 0 & \cdots & 0 & s & 1 \end{pmatrix}.$$

We also denote by $L_\eta^\top$ the transpose matrix of $L_\eta$.

The following theorem establishes the Kronecker canonical form of matrix pencils under strict equivalence transformations. We denote by block-diag$(D_1, \ldots, D_b)$ the block-diagonal matrix pencil with diagonal blocks $D_1, \ldots, D_b$.

THEOREM 2.1 (Kronecker, Weierstrass). [illegible] $D(s)$ [illegible] $U$ [illegible] $V$ [illegible] $\bar{D}(s) = UD(s)V$ [illegible]

$$\bar{D}(s) = \text{block-diag}(H_\nu, K_{\rho_1}, \ldots, K_{\rho_c}, N_{\mu_1}, \ldots, N_{\mu_d}, L_{\varepsilon_1}, \ldots, L_{\varepsilon_p}, L_{\eta_1}^\top, \ldots, L_{\eta_q}^\top, O),$$

[illegible] $\rho_1 \geq \cdots \geq \rho_c > 0$ $\mu_1 \geq \cdots \geq \mu_d > 0$ $\varepsilon_1 \geq \cdots \geq \varepsilon_p > 0$ $\eta_1 \geq \cdots \geq \eta_q > 0$ [illegible] $H_\nu$ [illegible] $\nu$ [illegible] $c$ $d$ $p$ $q$ $\nu$ $\rho_1, \ldots, \rho_c$ $\mu_1, \ldots, \mu_d$ $\varepsilon_1, \ldots, \varepsilon_p$ $\eta_1, \ldots, \eta_q$ [illegible]

The block-diagonal matrix pencil $\bar{D}(s)$ in Theorem 2.1 is often referred to as the Kronecker canonical form of $D(s)$. The numbers $\mu_1, \ldots, \mu_d$ are called the indices of nilpotency. The numbers $\varepsilon_1, \ldots, \varepsilon_p$ and $\eta_1, \ldots, \eta_q$ are the minimal column and row indices, respectively. These numbers together with $\nu, \rho_1, \ldots, \rho_c$ are collectively called the structural indices of $D(s)$.

For a polynomial $g(s)$ in $s$, let $\deg g(s)$ and $\operatorname{ord} g(s)$ denote the highest and lowest degrees of nonvanishing terms of $g(s)$, respectively. By convention, we put $\deg 0 = -\infty$ and $\operatorname{ord} 0 = \infty$. Let $r$ be the rank of $D(s)$. For each $k = 1, \ldots, r$, we denote

$$\delta_k(D) = \max\{\deg \det D(s)[X, Y] \mid |X| = |Y| = k, X \subseteq R, Y \subseteq C\},$$

$$\zeta_k(D) = \min\{\operatorname{ord} \det D(s)[X, Y] \mid |X| = |Y| = k, X \subseteq R, Y \subseteq C\}.$$

The following well-known lemma asserts that $\delta_k$ and $\zeta_k$ are invariant under strict equivalence transformations.

LEMMA 2.2. [illegible] $\bar{D}(s)$ [illegible] $D(s)$ [illegible] $\delta_k(\bar{D}) = \delta_k(D)$ [illegible] $\zeta_k(\bar{D}) = \zeta_k(D)$ [illegible]

[illegible] Since any nonsingular matrix is a product of elementary matrices, it suffices to show that $\delta_k$ and $\zeta_k$ are invariant under strict equivalence transformations by elementary matrices. In particular, we consider a row transformation $\bar{D}(s) = UD(s)$

by an elementary matrix $U$ that is identical with the unit matrix except for the $(v,u)$-component $U_{vu} = \lambda$. This corresponds to adding a multiple of a row $u$ to another row $v$. Let $D(s)[X,Y]$ be an arbitrary submatrix with $|X| = |Y| = k$. Note that $D(s)[X,Y] = \bar{D}(s)[X,Y]$ unless $u \in R \setminus X$ and $v \in X$. If $u \in R \setminus X$ and $v \in X$, then we have

$$\det \bar{D}(s)[X,Y] = \det D(s)[X,Y] + \lambda \det D(s)[X \setminus \{v\} \cup \{v\}, Y],$$

which implies $\deg\det \bar{D}(s)[X,Y] \leq \delta_k(D)$. If, in addition, $\det D(s)[X,Y]$ attains the maximum degree for $\delta_k(D)$, either $\deg\det \bar{D}(s)[X,Y] = \deg\det D(s)[X,Y]$ or $\deg\det \bar{D}(s)[X,Y] < \deg\det D(s)[X,Y] = \deg\det D(s)[X \setminus \{v\} \cup \{u\}, Y]$ holds. Since $\bar{D}(s)[X \setminus \{v\} \cup \{u\}, Y] = D(s)[X \setminus \{v\} \cup \{u\}, Y]$, we have $\deg\det \bar{D}(s)[X \setminus \{v\} \cup \{u\}, Y] = \delta_k(D)$ in the latter case. Thus we obtain $\delta_k(\bar{D}) = \delta_k(D)$.

The same argument applies to an elementary column transformation. Moreover, the invariance of $\zeta_k$ can be shown in a similar manner. □

For the Kronecker canonical form $\bar{D}(s)$ of $D(s)$, we have

$$\zeta_k(D) = \zeta_k(\bar{D}) = \sum_{i=r-k+1}^{c} \rho_i, \qquad \delta_k(D) = \delta_k(\bar{D}) = k - \sum_{i=r-k+1}^{d} \mu_i. \tag{2.1}$$

In particular, $\zeta_k(D) = 0$ for $k = 1, \ldots, r-c$, and $\delta_k(D) = k$ for $k = 1, \ldots, r-d$. Hence, $c = r - \max\{k \mid \zeta_k(D) = 0\}$ and $d = r - \max\{k \mid \delta_k(D) = k\}$ hold. Note that $\delta_k(D)$ is concave in $k$ and $\zeta_k(D)$ is convex in $k$. Moreover, we have $\rho_i = \zeta_{r-i+1}(D) - \zeta_{r-i}(D)$ for $i = 1, \ldots, c$ and $\mu_i = \delta_{r-i}(D) - \delta_{r-i+1}(D) + 1$ for $i = 1, \ldots, d$. Since the sum of the structural indices is equal to the rank of $D(s)$, the equalities in (2.1) for $k = r$ imply that

$$\nu + \sum_{i=1}^{p} \varepsilon_i + \sum_{i=1}^{q} \eta_i = r - \sum_{i=1}^{d} \mu_i - \sum_{i=1}^{c} \rho_i = \delta_r(D) - \zeta_r(D). \tag{2.2}$$

For an $m \times n$ matrix pencil $D(s) = A + sB$, we construct a pair of $km \times kn$ matrices $\Theta_k(D)$ and $\Omega_k(D)$ defined by

$$\Theta_k(D) = \begin{pmatrix} A & O & \cdots & \cdots & O \\ B & A & \ddots & & \vdots \\ O & B & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & A & O \\ O & \cdots & O & B & A \end{pmatrix}, \qquad \Omega_k(D) = \begin{pmatrix} B & O & \cdots & \cdots & O \\ A & B & \ddots & & \vdots \\ O & A & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & B & O \\ O & \cdots & O & A & B \end{pmatrix}.$$

We denote $\theta_k(D) = \operatorname{rank} \Theta_k(D)$ and $\omega_k(D) = \operatorname{rank} \Omega_k(D)$. We also construct a $(k+1)m \times kn$ matrix $\Psi_k(D)$ and a $km \times (k+1)n$ matrix $\Phi_k(D)$ defined by

$$\Psi_k(D) = \begin{pmatrix} A & O & \cdots & O \\ B & A & \ddots & \vdots \\ O & B & \ddots & O \\ \vdots & \ddots & \ddots & A \\ O & \cdots & O & B \end{pmatrix}, \qquad \Phi_k(D) = \begin{pmatrix} A & B & O & \cdots & O \\ O & A & B & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & O \\ O & \cdots & O & A & B \end{pmatrix}.$$

We denote $\psi_k(D) = \operatorname{rank} \Psi_k(D)$ and $\varphi_k(D) = \operatorname{rank} \Phi_k(D)$. Then it is easy to see that the ranks of these expanded matrices are expressed by the structural indices as follows.

THEOREM 2.3. [illegible] $D(s)$ [illegible] $r$ [illegible] $(\nu, \rho_1, \dots, \rho_c, \mu_1, \dots, \mu_d, \varepsilon_1, \dots, \varepsilon_p, \eta_1, \dots, \eta_q)$ [illegible]

$$\theta_k(D) = rk - \sum_{i=1}^{c} \min\{k, \rho_i\}, \qquad \omega_k(D) = rk - \sum_{i=1}^{d} \min\{k, \mu_i\},$$

$$\psi_k(D) = rk + \sum_{i=1}^{p} \min\{k, \varepsilon_i\}, \qquad \varphi_k(D) = rk + \sum_{i=1}^{q} \min\{k, \eta_i\}.$$

[illegible] $\psi_1(D) = r + p$ [illegible] $\varphi_1(D) = r + q$

[illegible] For the matrix pencils $K_\rho$, $N_\mu$, $L_\varepsilon$, $L_\eta^\top$, we have

$$\theta_k(K_\rho) = \mu k - \min\{\rho, k\}, \quad \theta_k(N_\mu) = \mu k, \quad \theta_k(L_\varepsilon) = \varepsilon k, \quad \theta_k(L_\eta^\top) = \eta k,$$

$$\omega_k(K_\rho) = \rho k, \quad \omega_k(N_\mu) = \mu k - \min\{\mu, k\}, \quad \omega_k(L_\varepsilon) = \varepsilon k, \quad \omega_k(L_\eta^\top) = \eta k,$$

$$\psi_k(K_\rho) = \rho k, \quad \psi_k(N_\mu) = \mu k, \quad \psi_k(L_\varepsilon) = \varepsilon k + \min\{\varepsilon, k\}, \quad \psi_k(L_\eta^\top) = \eta k,$$

$$\varphi_k(K_\rho) = \rho k, \quad \varphi_k(K_\mu) = \mu k, \quad \varphi_k(L_\varepsilon) = \varepsilon k, \quad \varphi_k(L_\eta^\top) = \eta k + \min\{\eta, k\}.$$

Summing up these equalities for the blocks in the Kronecker canonical form, we obtain the above formulas. □

COROLLARY 2.4. [illegible] $D(s)$ [illegible] $\Psi_k(D)$ [illegible] $k$ [illegible] $D(s)$ [illegible] $\Phi_k(D)$ [illegible] $k$

[illegible] If $D(s)$ is of column-full rank, the Kronecker canonical form has no minimal column indices. Hence Theorem 2.3 implies $\psi_k(D) = rk$. Similarly, if $D(s)$ is of row-full rank, the Kronecker canonical form has no minimal row indices, which together with Theorem 2.3 implies $\varphi_k(D) = rk$. □

Theorem 2.3 together with (2.1) implies the following corollary.

COROLLARY 2.5. [illegible] $D(s)$ [illegible] $r$ [illegible] $k \geq r$ [illegible] $\theta_k(D) = rk - \zeta_r(D)$ [illegible] $\omega_k(D) = r(k-1) + \delta_r(D)$

[illegible] For $k \geq r$, we have $\theta_k(D) = rk - \sum_{i=1}^{c} \rho_i$ and $\omega_k(D) = rk - \sum_{i=1}^{d} \mu_i$ by Theorem 2.3. Then it follows from (2.1) that $\theta_k(D) = rk - \zeta_k(D)$ and $\omega_k(D) = r(k-1) + \delta_r(D)$ hold for $k \geq r$. □

**3. Generic matrix pencils.** Given a matrix $A$ with the row set $R$ and the column set $C$, we construct a bipartite graph $G(A) = (R, C; E)$ with the vertex sets $R$ and $C$ and the edge set $E$ that consists of nonzero entries of $A$. A subset $M \subseteq E$ is called a matching if no two edges in $M$ share an end-vertex. The term-rank of $A$, denoted by $\operatorname{t-rank} A$, is the maximum size of a matching in $G(A)$. The term-rank provides an upper bound on the rank of $A$. Under the genericity assumption that the set of nonzero entries is algebraically independent, this upper bound is tight. That is, $\operatorname{rank} A = \operatorname{t-rank} A$ holds for a generic matrix. The set function $\tau$ defined by $\tau(X) = \operatorname{t-rank} A[X, C]$ for $X \subseteq R$ is submodular; i.e.,

$$\tau(X) + \tau(Z) \geq \tau(X \cup Z) + \tau(X \cap Z)$$

holds for any $X, Z \subseteq R$. This submodularity will be used in section 7.

A matrix pencil $D(s) = A + sB$ is called a generic matrix pencil if the nonzero entries in $A$ and $B$ are indeterminates (independent parameters). To be more precise, suppose $D(s)$ is a matrix pencil over a field $\mathbf{F}$. That is, $A$ and $B$ are matrices over the field $\mathbf{F}$. Let $\mathbf{K}$ be the prime field of $\mathbf{F}$. A finite set $\mathcal{T} = \{\xi_1, \ldots, \xi_t\} \subseteq \mathbf{F}$ is said to be algebraically independent over $\mathbf{K}$ if there is no nontrivial polynomial $g(x_1, \ldots, x_t)$ over $\mathbf{K}$ such that $g(\xi_1, \ldots, \xi_t) = 0$. A matrix pencil $D(s)$ is generic if the set $\mathcal{T}$ of nonzero entries in $A$ and $B$ is algebraically independent over the prime field $\mathbf{K}$. A typical setting in practice is $\mathbf{F} = \mathbf{R}$ and $\mathbf{K} = \mathbf{Q}$.

For a matrix pencil $D(s) = A + sB$ with the row set $R$ and the column set $C$, let $E$ and $F$ be the sets of edges that correspond to the positions of nonzero entries in $A$ and $B$, respectively. Thus we construct a bipartite graph $G(D) = (R, C; E \cup F)$ with the vertex sets $R$ and $C$ and the edge set $E \cup F$. Since the edges in $E$ and $F$ are distinguished, there may be parallel edges in $G(D)$. Each edge $e$ has a weight $w(e)$ defined by $w(e) = 1$ for $e \in E$ and $w(e) = 0$ for $e \in F$. A subset $M$ of $E \cup F$ is called a matching if no two edges in $M$ share an end-vertex. The maximum size of a matching in $G(D)$ is the term-rank, denoted by $\text{t-rank}\, D(s)$. The weight $w(M) = \sum_{e \in M} w(e)$ of a matching $M$ is equal to the number of edges in $M \cap E$. We denote by $\widehat{\delta}_k(D)$ the maximum weight of a matching of size $k$. We also denote by $\widehat{\zeta}_k(D)$ the minimum weight of a matching of size $k$.

The following two lemmas demonstrate that fundamental quantities of a generic matrix pencil coincide with their combinatorial counterparts; see [28, Theorem 6.2.2] for the proof of Lemma 3.2. It should be emphasized here that these combinatorial counterparts are easy to compute with efficient combinatorial algorithms for bipartite matchings [11, 15, 16, 21, 23, 33].

Lemma 3.1. [illegible] $D(s)$ [illegible] $\operatorname{rank} D(s) = \text{t-rank}\, D(s)$

Lemma 3.2. [illegible] $D(s)$ [illegible] $\delta_k(D) = \widehat{\delta}_k(D)$ [illegible] $\zeta_k(D) = \widehat{\zeta}_k(D)$

It should be remarked that the above definition of genericity is different from that in the previous works [9, 10], where the Kronecker canonical form of a "generic" matrix pencil is known to have a very simple structure with at most two types of blocks [9, section 3.3].

**4. Dulmage–Mendelsohn decomposition.** In this section, we recapitulate the Dulmage–Mendelsohn decomposition of bipartite graphs [6, 7, 8] following the exposition in [28, section 2.2.3].

For a generic matrix pencil $D(s)$ with the row set $R$ and the column set $C$, let $(R_0; R_1; R_\infty)$ and $(C_0; C_1; C_\infty)$ be partitions of $R$ and $C$ such that $|R_0| < |C_0|$ (unless $R_0 = C_0 = \emptyset$), $|R_1| = |C_1|$, and $|R_\infty| > |C_\infty|$ (unless $R_\infty = C_\infty = \emptyset$). Then $D(s)$ is said to be in a block-triangular form with respect to these partitions if it satisfies $D(s)[R_1, C_0] = O$, $D(s)[R_\infty, C_0] = O$, and $D(s)[R_\infty, C_1] = O$. If, in addition, $\operatorname{rank} D(s)[R_j, C_j] = \min(|R_j|, |C_j|)$ holds for $j = 0, 1, \infty$, then $D(s)$ is in a proper block-triangular form. The Dulmage–Mendelsohn decomposition (DM-decomposition) is such a pair of partitions with largest $|R_1| = |C_1|$ that gives a proper block-triangular form. The existence and uniqueness of the DM-decomposition can be verified through the construction below.

Let $\Gamma(Y) \subseteq R$ denote the set of vertices adjacent to $Y \subseteq C$ in $G(D)$. Then the function $f$ defined by

$$f(Y) = |\Gamma(Y)| - |Y| \qquad (Y \subseteq C)$$

is submodular, i.e.,

$$f(Y) + f(Z) \geq f(Y \cup Z) + f(Y \cap Z)$$

holds for any $Y, Z \subseteq C$. The term-rank of the matrix pencil $D(s)$ is characterized by the minimum value of this submodular function $f$, i.e.,

$$\text{t-rank}\, D(s) = \min\{f(Y) \mid Y \subseteq C\} + |C|,$$

which follows from the Hall–Ore theorem for bipartite graphs. Note that the set of minimizers of a submodular function forms a distributive lattice.

Let $Y_0$ denote the unique minimal minimizer of $f$, and $Y_1$ the unique maximal minimizer of $f$. We put

$$\begin{aligned} C_0 &= Y_0, & R_0 &= \Gamma(Y_0), \\ C_1 &= Y_1 \setminus Y_0, & R_1 &= \Gamma(Y_1) \setminus \Gamma(Y_0), \\ C_\infty &= C \setminus Y_1, & R_\infty &= R \setminus \Gamma(Y_1). \end{aligned}$$

Since $f(Y_0) \leq f(\emptyset) = 0$, we have $|R_0| \leq |C_0|$, where the equality holds only if $C_0 = \emptyset$. It follows from $f(Y_0) = f(Y_1)$ that $|R_1| = |C_1|$. Moreover, $f(Y_1) \leq f(C)$ implies $|R_\infty| \geq |C_\infty|$, where the equality holds only if $R_\infty = \emptyset$. The resulting partition $(R_0; R_1; R_\infty)$ and $(C_0; C_1; C_\infty)$ provides the DM-decomposition of $D(s)$. We call $D_0(s) = D(s)[R_0, C_0]$ the horizontal tail and denote its rank by $r_0 = |R_0|$. We also call $D_\infty(s) = D(s)[R_\infty, C_\infty]$ the vertical tail and denote its rank by $r_\infty = |C_\infty|$. The DM-decomposition can be computed efficiently with the aid of bipartite matching algorithms.

**5. The Kronecker canonical form via DM-decomposition.** In this section, we investigate the Kronecker canonical form of a generic matrix pencil $D(s)$ via the DM-decomposition.

LEMMA 5.1. [illegible] $D_0$ [illegible] $D(s)$ [illegible] $\psi_k(D) = \psi_k(D_0) + k(r - r_0)$

[illegible]. Recall $r = |R_0| + |C \setminus C_0|$ and $r_0 = |R_0|$. Since $D_*(s) = D(s)[R \setminus R_0, C \setminus C_0]$ is of column-full rank, so is $\Psi_k(D_*)$ by Corollary 2.4, namely, $\psi_k(D_*) = k(r - r_0)$. Then it follows from $D(s)[R \setminus R_0, C_0] = O$ that $\psi_k(D) = \psi_k(D_0) + k(r - r_0)$. □

Lemma 5.1 together with Theorem 2.3 implies that the minimal column indices of $D(s)$ coincide with those of $D_0(s)$. We now investigate the Kronecker canonical form of the horizontal tail $D_0$.

Let $g_0(s)$ be the monic determinantal divisor

$$g_0(s) = \gcd\{\det D(s)[R_0, Y] \mid |Y| = r_0, Y \subseteq C_0\},$$

where gcd designates the greatest common divisor whose leading coefficient is equal to one. The following lemma is a special case of a theorem of Murota [25] (see also [28, Theorem 6.3.8]). We describe its proof here for completeness.

LEMMA 5.2. [illegible] $g_0(s)$ [illegible] $s$

[illegible]. We first claim that $g_0(s)$ belongs to $\mathbf{K}[s]$. For any column $j \in C_0$, there exists a column subset $Y \subseteq C_0 \setminus \{j\}$ such that $|Y| = r_0$ and $\det D(s)[R_0, Y] \neq 0$. Therefore, for any independent parameter $\xi \in \mathcal{T}$, the monic determinantal divisor $g_0(s)$ is free from $\xi$. Thus $g_0(s)$ is a polynomial over $\mathbf{K}$.

We now suppose that $g_0(s)$ is not a monomial in $s$. Let $\overline{\mathbf{K}}$ be the algebraic closure of $\mathbf{K}$. Then $\mathcal{T}$ is algebraically independent over $\overline{\mathbf{K}}$. On the other hand, there exists a root $\sigma \in \overline{\mathbf{K}} \setminus \{0\}$ that satisfies $g_0(\sigma) = 0$. For a regular submatrix $D(s)[R_0, Y]$, we have $\det D(\sigma)[R_0, Y] = 0$. Since $\det D(\sigma)[R_0, Y]$ is a polynomial in $\mathcal{T}$, this contradicts the algebraic independence of $\mathcal{T}$ over $\overline{\mathbf{K}}$. □

The determinantal divisor is invariant under strict equivalence transformations. Hence $g_0(s)$ is equal to the determinantal divisor of the Kronecker canonical form $\bar{D}_0$ of $D_0$. Then Lemma 5.2 implies that $\bar{D}_0$ does not contain a strictly regular block.

THEOREM 5.3. [illegible]

$$\sum_{i=1}^{p} \varepsilon_i = \widehat{\delta}_{r_0}(D_0) - \widehat{\zeta}_{r_0}(D_0), \tag{5.1}$$

[illegible] $\widehat{\delta}_{r_0}(D_0)$ [illegible] $\widehat{\zeta}_{r_0}(D_0)$ [illegible] $r_0$ [illegible] $G(D_0)$ [illegible]

[illegible]. Since the Kronecker canonical form $\bar{D}_0$ of $D_0$ does not contain a strictly regular block or a rectangular block $L_\eta^\top$, it follows from (2.2) and Lemma 3.2 that $\sum_{i=1}^{p} \varepsilon_i = \delta_{r_0}(D_0) - \zeta_{r_0}(D_0) = \widehat{\delta}_{r_0}(D_0) - \widehat{\zeta}_{r_0}(D_0)$. □

A similar argument applied to the vertical tail $D_\infty$ leads to the following results. Lemma 5.4 together with Theorem 2.3 implies that the minimal row indices of $D(s)$ coincide with those of $D_\infty(s)$. Lemma 5.5 shows that the Kronecker canonical form $\bar{D}_\infty(s)$ of $D_\infty(s)$ does not contain a strictly regular block.

LEMMA 5.4. [illegible] $D_\infty$ [illegible] $D(s)$ [illegible] $\varphi_k(D) = \varphi_k(D_\infty) + k(r - r_\infty)$

LEMMA 5.5. [illegible]

$$g_\infty(s) = \gcd\{\det D(s)[X, C_\infty] \mid X \subseteq R_\infty, |X| = r_\infty\}$$

[illegible] $s$

THEOREM 5.6. [illegible]

$$\sum_{i=1}^{q} \eta_i = \widehat{\delta}_{r_\infty}(D_\infty) - \widehat{\zeta}_{r_\infty}(D_\infty), \tag{5.2}$$

[illegible] $\widehat{\delta}_{r_\infty}(D_\infty)$ [illegible] $\widehat{\zeta}_{r_\infty}(D_\infty)$ [illegible] $r_\infty$ [illegible] $G(D_\infty)$ [illegible]

As an immediate consequence of Theorems 5.3 and 5.6, we have the following theorem implied by (2.2).

THEOREM 5.7. [illegible] $\nu$ [illegible] $\bar{D}(s)$ [illegible] $D(s)$ [illegible]

$$\nu = \widehat{\delta}_r(D) - \widehat{\zeta}_r(D) - \widehat{\delta}_{r_0}(D_0) + \widehat{\zeta}_{r_0}(D_0) - \widehat{\delta}_{r_\infty}(D_\infty) + \widehat{\zeta}_{r_\infty}(D_\infty). \tag{5.3}$$

Note that all these right-hand sides of (5.1), (5.2), and (5.3) can be computed efficiently by the DM-decomposition and weighted bipartite matching algorithms. We have thus obtained a useful combinatorial characterization of the sums of the minimal row/column indices as well as the size of the strictly regular block in the Kronecker canonical form.

Among the structural indices of a generic matrix pencil, $\mu_1, \ldots, \mu_d$ and $\rho_1, \ldots, \rho_c$ are known to be efficiently computable by weighted bipartite matching algorithms.

The results in this section enable us to compute $\nu$, $\sum_{i=1}^{p} \varepsilon_i$ and $\sum_{i=1}^{q} \eta_i$ as well. It still remains open to determine the values of the minimal row/column indices. The obtained partial results, however, provide sufficient information to discern if the Kronecker canonical form contains vertical/horizontal rectangular blocks.

**6. Expanded matrices for indices of nilpotency.** We now turn to the ranks of the expanded matrices, which are in close relation to the structural indices as shown in Theorem 2.3, for a generic matrix pencil $D(s) = A + sB$. Even though the set of nonzero entries in $A$ and $B$ are algebraically independent, the expanded matrices are not generic matrices. It will be shown, however, that the ranks of the expanded matrices are equal to their term-ranks in most cases. In this section, we deal with the expanded matrices $\Theta_k(D)$ and $\Omega_k(D)$, which are particularly related to $\mu_1, \dots, \mu_d$ and $\rho_1, \dots, \rho_c$. The other expanded matrices $\Psi_k(D)$ and $\Phi_k(D)$ will be investigated in section 7.

In order to examine the ranks of $\Theta_k(D)$ and $\Omega_k(D)$, we consider the bipartite graphs $G(\Theta_k(D))$ and $G(\Omega_k(D))$ associated with the expanded matrices. It will turn out that these bipartite graphs allow maximum matchings with periodic structures. As a consequence, the ranks of these expanded matrices are equal to their term-ranks denoted by $\widehat{\theta}_k(D)$ and $\widehat{\omega}_k(D)$.

We first investigate $\Theta_k(D)$. Let $\bar{R}$ and $\bar{C}$ be the row set and the column set of $\Theta_k(D)$. Then $\bar{R} = R^1 \cup \cdots \cup R^k$ and $\bar{C} = C^1 \cup \cdots \cup C^k$, where $R^h$ and $C^h$ are the copies of the row set $R$ and the column set $C$ of $D$ for $h = 1, \dots, k$. For vertices $u \in R$ and $v \in C$, we denote by $u^h$ and $v^h$ the corresponding vertices in $R^h$ and $C^h$. The edge set of the bipartite graph $G(\Theta_k(D))$ consists of $\bar{E} = E^1 \cup \cdots \cup E^k$ and $\bar{F} = F^1 \cup \cdots \cup F^{k-1}$, where $E^h$ and $F^h$ are the copies of $E$ and $F$. The edges in $E^h$ connect $R^h$ and $C^h$, whereas the edges in $F^h$ connect $R^h$ and $C^{h+1}$. In other words, $E^h = \{(u^h, v^h) \mid (u, v) \in E\}$ and $F^h = \{(u^h, v^{h+1}) \mid (u, v) \in F\}$.

For a matching $M$ in $G(D)$, let $M^\circ$ be the set of edges $(u^h, v^h)$ with $(u, v) \in E \cap M$ for $h = 1, \dots, k$ and $(u^h, v^{h+1})$ with $(u, v) \in F \cap M$ for $h = 1, \dots, k-1$. Then $M^\circ$ forms a matching in $G(\Theta_k(D))$. A matching in $G(\Theta_k(D))$ is called a periodic matching if it can be represented as $M^\circ$ with a certain matching $M$ in $G(D)$.

We now introduce the weight $w_k$ on the edge set of $G(D)$ by $w_k(e) = k$ for $e \in E$ and $w_k(e) = k - 1$ for $e \in F$. For a matching $M$ in $G(D)$, we consider the weight of $M$ by $w_k(M) = \sum_{e \in M} w_k(e)$.

LEMMA 6.1. [illegible] $M$ [illegible] $w_k(M)$ [illegible] $G(D)$ [illegible] $M^\circ$ [illegible] $G(\Theta_k(D))$

[illegible]. Suppose to the contrary that $M^\circ$ is not a maximum matching in $G(\Theta_k(D))$. Then there exists an augmenting path with respect to $M^\circ$ in $G(\Theta_k(D))$. Let $P^\circ$ be such an augmenting path with a minimum number of edges. The corresponding set of edges in $G(D)$ forms an augmenting path $P$ with respect to $M$ in $G(D)$. Then we analyze the weight of a matching $M' = M \triangle P$, which is the symmetric difference of $M$ and $P$, i.e., $M \triangle P = (M \cup P) \setminus (M \cap P)$. Suppose that the end-vertices of $P^\circ$ are $u^h \in R^h$ and $v^l \in C^l$. If $h < l$, then the weight of $M'$ satisfies $w_k(M') - w_k(M) = (l - h)(k - 1) - k(l - h - 1) = k - l + h$. On the other hand, if $h \geq l$, then we have $w_k(M') - w_k(M) = (h - l + 1)k - (h - l)(k - 1) = k + h - l$. Thus, in either case, we have $w_k(M') = w_k(M) + k + h - l > w_k(M)$, which contradicts the maximality of $w_k(M)$. $\square$

Let $M^\circ$ be a maximum periodic matching in $G(\Theta_k(D))$ corresponding to the maximum-weight matching $M$ in $G(D)$. We denote by $\partial M^\circ$ the set of end-vertices of the edges in $M^\circ$. Consider the submatrix $\Theta_k(D)[X, Y]$ determined by $X = \bar{R} \cap \partial M$

and $Y = \bar{C} \cap \partial M$. Then the expansion of $\det \Theta_k(D)[X, Y]$ contains a nonzero term

$$\prod_{(u,v)\in M\cap E} {A_{uv}}^{k} \prod_{(u,v)\in M\cap F} {B_{uv}}^{k-1},$$

where $A_{uv}$ and $B_{uv}$ denote the $(u, v)$-components of $A$ and $B$. Each $A_{uv}$ appears exactly $k$ times in $\Theta_k(D)$ and $B_{uv}$ appears exactly $k-1$ times in $\Theta_k(D)$. Hence no other matching cancels this term in the expansion. Thus $\Theta_k(D)[X, Y]$ is a nonsingular submatrix of size $|M^\circ|$, which implies $\theta_k(D) = \widehat{\theta}_k(D)$ by Lemma 6.1.

By interchanging the roles of $A$ and $B$, essentially the same argument leads to $\omega_k(D) = \widehat{\omega}_k(D)$. Thus we obtain the following theorem.

THEOREM 6.2. [illegible] $D(s)$ [illegible] $\theta_k(D) = \widehat{\theta}_k(D)$ [illegible] $\omega_k(D) = \widehat{\omega}_k(D)$

**7. Expanded matrices for column/row indices.** This section is devoted to a combinatorial analysis of the ranks of the expanded matrices $\Psi_k(D)$ and $\Phi_k(D)$ for a generic matrix pencil $D(s)$. Let $\widehat{\psi}_k(D)$ and $\widehat{\varphi}_k(D)$ denote the term-ranks of these matrices.

For $k = 1$, the expanded matrices $\Psi_1(D)$ and $\Phi_1(D)$ are generic matrices and hence their ranks are equal to the term-ranks. This together with Theorem 2.3 enables us to compute $p$ and $q$, the numbers of horizontal and vertical blocks in the Kronecker canonical form, by efficient bipartite matching algorithms.

For general $k$, however, it is not immediately clear that the ranks are equal to the term-ranks. This is because the expanded matrices admit the same entries to appear in different places. In fact, the ranks of the expanded matrices may be less than their term-ranks. For instance, consider a generic matrix pencil

$$D(s) = A + sB = \begin{pmatrix} \alpha_1 & s\beta_1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & \alpha_2 & s\beta_2 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & s\beta_3 & \alpha_3 & 0 & 0 & 0 \\ 0 & 0 & \alpha_4 & 0 & s\beta_4 & \alpha_5 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & \alpha_6 + s\beta_5 & s\beta_6 & \alpha_7 \\ 0 & 0 & 0 & 0 & 0 & 0 & \alpha_8 & s\beta_7 \end{pmatrix}.$$

The Kronecker canonical form of $D(s)$ is $\bar{D}(s) = \text{block-diag}(L_4, L_2)$, which implies

$$\psi_k(D) = \begin{cases} 8k & (k \le 2), \\ 7k + 2 & (2 \le k \le 4), \\ 6k + 6 & (k \ge 4), \end{cases}$$

whereas

$$\widehat{\psi}_k(D) = \begin{cases} 8k & (k \le 3), \\ 6k + 6 & (k \ge 3). \end{cases}$$

Thus $\psi_k(D) = \widehat{\psi}_k(D)$ holds for $k \ne 3$. For $k = 3$, however, we have $\psi_3(D) = 23$ and $\widehat{\psi}_3(D) = 24$.

For $k = 2$, in contrast, the ranks of the expanded matrices coincide with their term-ranks.

THEOREM 7.1. [illegible] $D(s)$ [illegible] $\psi_2(D) = \widehat{\psi}_2(D)$ [illegible] $\varphi_2(D) = \widehat{\varphi}_2(D)$

[illegible]. Let $M^*$ be a maximum matching in $G(\Psi_2(D))$. The row set $\bar{R}$ and the column set $\bar{C}$ are given by $\bar{R} = R_1 \cup R_2 \cup R_3$ and $\bar{C} = C_1 \cup C_2$, where $R_h$ and $C_h$ are copies of $R$ and $C$. For $u \in R$ and $v \in C$, we denote their copies by $u_h \in R_h$ and $v_h \in C_h$. We also denote $X = \bar{R} \cap \partial M^*$ and $Y = \bar{C} \cap \partial M^*$. Then it suffices to show that $W = \Psi_2(D)[X, Y]$ is nonsingular.

Let $M_1^*$ and $M_2^*$ be the sets of edges in $M^*$ incident to $C_1$ and $C_2$, respectively. We denote $X_1 = X \cap \partial M_1^*$, $X_2 = X \cap \partial M_2^*$, $Y_1 = C_1 \cap \partial M^*$, and $Y_2 = C_2 \cap \partial M^*$.

Let $\mathcal{P}$ denote the family of perfect matchings in $G(W)$. For each matching $M \in \mathcal{P}$, we denote $\pi(M) = \prod_{(u,v)\in M} W_{uv}$, where $W_{uv}$ is the $(u, v)$-component of $W$. Recall that

$$\det W = \sum_{M\in\mathcal{P}} \sigma_M \pi(M),$$

where $\sigma_M$ takes 1 or $-1$. We also denote by $\mathcal{P}^\bullet$ the family of perfect matchings $M = M_1 \cup M_2$ such that $\partial M_1 = \partial M_1^*$ and $\partial M_2 = \partial M_2^*$.

We now claim that $\pi(M^\bullet) \neq \pi(M')$ for any pair of $M^\bullet \in \mathcal{P}^\bullet$ and $M' \in \mathcal{P} \setminus \mathcal{P}^\bullet$. Suppose to the contrary that $\pi(M^\bullet) = \pi(M')$. The matching $M'$ contains an edge $(u_2, v_2)$ with $u_2 \in X_1$. Then we have $(u_1, v_1) \in M^\bullet \setminus M'$, and hence $(u_1, z_1) \in M'$ for some $z \in C \setminus \{v\}$, which implies $(u_2, z_2) \in M^\bullet$. This is a contradiction to $u_2 \in X_1$.

Since both $W[X_1, Y_1]$ and $W[X_2, Y_2]$ are generic matrices, we have

$$\sum_{M\in\mathcal{P}^\bullet} \sigma_M \pi(M) = \det W[X_1, Y_1] \cdot \det W[X_2, Y_2] \neq 0.$$

Then the claim above implies $\det W \neq 0$, which means $W$ is nonsingular. □

Furthermore, our analysis on the Kronecker canonical form implies that the ranks of the expanded matrices are equal to their term-ranks for sufficiently large $k$ as follows.

THEOREM 7.2. [illegible] $D(s)$ [illegible] $r$ [illegible] $r_0$ [illegible] $D_0$ [illegible] $k \geq r_0$ [illegible]

$$\psi_k(D) = \widehat{\psi}_k(D) = kr + \widehat{\delta}_{r_0}(D_0) - \widehat{\zeta}_{r_0}(D_0).$$

[illegible]. Due to the submodularity of the term-rank, we have

$$\widehat{\psi}_k(D_0) + \widehat{\varphi}_{k-1}(D_0) \leq \widehat{\theta}_k(D_0) + \widehat{\omega}_k(D_0).$$

Since $D_0$ is of row-full rank, Corollary 2.4 implies $\widehat{\varphi}_{k-1}(D_0) = (k-1)r_0$. It follows from Corollary 2.5 and Theorem 6.2 that $\widehat{\theta}_k(D_0) = \theta_k(D_0) = r_0(k-1) - \delta_{r_0}(D_0)$ and $\widehat{\omega}_k(D_0) = \omega_k(D_0) = r_0 k - \zeta_{r_0}(D_0)$ hold for $k \geq r_0$ Thus, we obtain

$$\widehat{\psi}_k(D_0) \leq kr_0 + \delta_{r_0}(D_0) - \zeta_{r_0}(D_0).$$

Since $\widehat{\psi}_k(D) \leq \widehat{\psi}_k(D_0) + k(r - r_0)$, we have

$$\widehat{\psi}_k(D) \leq kr + \widehat{\delta}_{r_0}(D_0) - \widehat{\zeta}_{r_0}(D_0).$$

On the other hand, Theorems 2.3 and 5.3 imply $\psi_k(D) = rk + \widehat{\delta}_{r_0}(D_0) - \widehat{\zeta}_{r_0}(D_0)$ for $k \geq r_0$. Since $\psi_k(D_0) \leq \widehat{\psi}_k(D_0)$, we have $\psi_k(D) = \widehat{\psi}_k(D) = kr + \widehat{\delta}_{r_0}(D_0) - \widehat{\zeta}_{r_0}(D_0)$ for $k \geq r_0$. □

A similar argument applied to the vertical tail $D_\infty$ leads to the following theorem.

THEOREM 7.3. [illegible] $D(s)$ [illegible] $r$ [illegible] $r_\infty$ [illegible] $D_\infty$ [illegible] $k \geq r_\infty$ [illegible]

$$\varphi_k(D) = \widehat{\varphi}_k(D) = kr + \widehat{\delta}_{r_\infty}(D_\infty) - \widehat{\zeta}_{r_\infty}(D_\infty).$$

**8. Generic matrix powers.** As a byproduct of our combinatorial analysis in section 6, we give a simple alternative proof for a theorem of Poljak [30] on the ranks of powers of generic square matrices.

Let $A$ be an $n \times n$ generic matrix. We associate a directed graph $\vec{G}(A) = (R, \vec{E})$ with the vertex set $R$ identical with the row/column set of $A$. The arc set $\vec{E}$ is the set of nonzero entries of $A$, namely $\vec{E} = \{(u, v) \mid A_{uv} \neq 0\}$. A $k$-walk in $\vec{G}(A)$ is an alternating sequence $(v_0, e_1, v_1, \ldots, e_k, v_k)$ of vertices $v_h \in R$ and $e_h \in \vec{E}$ such that $e_h = (v_{h-1}, v_h)$ for $h = 1, \ldots, k$. A pair of $k$-walks $(v_0, e_1, v_1, \ldots, e_k, v_k)$ and $(v_0', e_1', v_1', \ldots, e_k', v_k')$ is called independent if $v_h \neq v_h'$ holds for $h = 0, 1, \ldots, k$. The following theorem characterizes the rank of $A^k$ in terms of independent $k$-walks.

THEOREM 8.1 (Poljak [30]). [illegible] $A$ [illegible] $A^k$ [illegible] $k$ [illegible] $\vec{G}(A)$

Consider a regular matrix pencil $D(s) = A + sI$, where $I$ denotes the unit matrix. Then a $k$-walk naturally corresponds to a path $P$ in $G(\Theta_k(D))$ from $C^1$ to $R^k$. To be more specific, the path $P$ is given by

$$P = \{({v_{h-1}}^h, {\bar{v_h}}^h) \mid h = 1, \ldots, k\} \cup \{({v_h}^h, {\bar{v_h}}^h) \mid h = 1, \ldots, k\},$$

where $\bar{v_h}$ denotes the column that is identical to the row $v_h \in R$. Then a pair of independent $k$-walks correspond to a pair of vertex-disjoint paths in $G(\Theta_k(D))$. Let $\bar{P} = P_1 \cup \cdots \cup P_\ell$ denote the edge set of $\ell$ such vertex-disjoint paths that come from $\ell$ independent $k$-walks. Then the symmetric difference $\bar{P} \triangle \bar{F}$ forms a matching of size $\ell + n(k-1)$. Conversely, any periodic matching $M^\circ$ can be obtained in this way from a set of independent $k$ walks. Therefore, Lemma 6.1 implies that the maximum number of independent $k$-walks is equal to $\widehat{\theta}_k(D) - (k-1)n$.

On the other hand, we have

$$\operatorname{rank} A^k = \theta_k(D) - (k-1)n.$$

Therefore, in order to prove Theorem 8.1, it suffices to show that $\theta_k(D) = \widehat{\theta}_k(D)$. Since $D(s)$ is not a generic matrix, we cannot directly apply Theorem 6.2. However, we can use essentially the same argument.

Let $M^\circ$ be a maximum periodic matching in $G(\Theta_k(D))$ that corresponds to a matching $M$ in $G(D)$. Consider the submatrix $\Theta_k(D)[X, Y]$ with $X = \bar{R} \cap \partial M$ and $Y = \bar{C} \cap \partial M$. Then the expansion of $\det \Theta_k(D)[X, Y]$ contains a nonzero term

$$\prod_{(u,v) \in M \cap E} {A_{uv}}^k,$$

where $A_{uv}$ denotes the $(u, v)$-component of $A$. Since each $A_{uv}$ appears exactly $k$ times in $\Theta_k(D)$, no other matching cancels this term in the expansion. Thus $\Theta_k(D)[X, Y]$ is a nonsingular submatrix of size $|M^\circ|$, which implies $\theta_k(D) = \widehat{\theta}_k(D)$ by Lemma 6.1.

**9. Discussions.** This paper has investigated the Kronecker canonical form of generic matrix pencils. Even if the genericity assumption is not valid, we can efficiently compute the combinatorial estimates of the sums of the minimal row/column indices as well as the size of the strictly regular block. These estimates may differ from the exact values. However, we can use them for checking if the result of a numerical computation is consistent with the combinatorial information.

For instance, consider a real matrix pencil

$$D(s) = A + sB = \begin{pmatrix} 1 & s & 0 & 30 & 0 & 0 \\ 60 & 0 & s\beta & 0 & 1 & s \\ 0 & 5 & 0 & s & 0 & 0 \\ 0 & 0 & 1 & 0 & s & 1 \\ 0 & 0 & 0 & s & 0 & 0 \end{pmatrix}$$

with a parameter $\beta$. The DM-decomposition provides a pair of permutations of the rows and the columns that transforms $D(s)$ into a block-triangular matrix

$$\widetilde{D}(s) = \begin{pmatrix} s & 1 & 1 & 0 & 0 & 0 \\ 1 & s & s\beta & 60 & 0 & 0 \\ 0 & 0 & 0 & 1 & s & 30 \\ 0 & 0 & 0 & 0 & 5 & s \\ 0 & 0 & 0 & 0 & 0 & s \end{pmatrix}.$$

The Kronecker canonical form of $D(s)$ is $\bar{D}(s) = \text{block-diag}(K_1, N_2, L_2)$ unless $\beta = 1$. If $\beta = 1$, then $\bar{D}(s) = \text{block-diag}(H_2, K_1, N_2, O)$, where $H_2$ is a strictly regular matrix pencil of size 2. This is consistent with the combinatorial estimates obtained as follows.

Let $D'(s)$ be the generic matrix pencil having the same zero/nonzero pattern as $D(s)$. Finding maximum weight bipartite matchings in $G(D')$, we obtain $\delta_1(D') = 1$, $\delta_2(D') = 2$, $\delta_3(D') = 3$, $\delta_4(D') = 4$, and $\delta_5(D') = 3$, which imply that the Kronecker canonical form of $D'(s)$ contains $N_2$. Similarly, we obtain $\zeta_1(D') = 0$, $\zeta_2(D') = 0$, $\zeta_3(D') = 0$, $\zeta_4(D') = 0$, and $\zeta_5(D') = 1$, which imply that the Kronecker canonical form contains $K_1$. The horizontal tail $D'_0$ is of size $2 \times 3$, which means $r_0 = 2$. Furthermore, we have $\delta_2(D'_0) = 2$ and $\zeta_2(D'_0) = 0$. It follows from Theorem 5.3 that the sum of the column indices is equal to 2. Since the DM-decomposition of $D(s)$ does not have a vertical tail, Theorem 5.7 implies $\nu = 0$. Therefore, the Kronecker canonical form of $D'(s)$ is block-diag$(K_1, N_2, L_2)$, which coincides with that of $D(s)$ unless $\beta = 1$.

On the other hand, computer software `guptri` [3, 4] that implements a staircase algorithm may fail to return the correct answer in its default setting of the deflation tolerance `EPSU` $= 10^{-8}$. For example, if we assign $\beta = 40$, then `guptri` returns block-diag$(K_2, N_2, L_1)$ as the Kronecker canonical form. If we assign $\beta = 4$, then the output is block-diag$(K_2, N_1, L_2)$, which is still different from the solution. These phenomena reflect computational difficulty inherent in the problem. In the latter case, however, we are able to detect an error with the aid of combinatorial estimates. In fact, if the Kronecker canonical form is block-diag$(K_2, N_1, L_2)$, we must have $\delta_5(D) = 4$, which contradicts $\delta_5(D) \leq \delta_5(D')$. Then one can obtain the correct answer by trying smaller `EPSU`. Thus, combinatorial analysis may help us to make numerical solutions more reliable.

Another way to use the combinatorial estimates is to design a numerical algorithm that exploits the combinatorial information. If one had an easier way to check the correctness of the estimates, it would lead to a new algorithm particularly efficient for sparse matrices. In fact, such algorithms of combinatorial relaxation type have been developed for the maximum degree of subdeterminants [17, 18, 26, 28]. It would be interesting to devise the same type of algorithms for minimal row/column indices.

# SPECTRAL ANALYSIS OF A PRECONDITIONED ITERATIVE METHOD FOR THE CONVECTION-DIFFUSION EQUATION*

DANIELE BERTACCINI†, GENE H. GOLUB‡, AND STEFANO SERRA-CAPIZZANO§

**Abstract.** The convergence features of a preconditioned algorithm for the convection-diffusion equation based on its diffusion part are considered. Analyses of the distribution of the eigenvalues of the preconditioned matrix in arbitrary dimensions and of the fundamental parameters of convergence are provided, showing the existence of a proper cluster of eigenvalues. The structure of the cluster is not influenced by the discretization. An upper bound on the condition number of the eigenvector matrix under some assumptions is provided as well. The overall cost of the algorithm is $O(n)$, where $n$ is the size of the underlying matrices.

**Key words.** finite differences discretization, preconditioning, multilevel structures, convection-diffusion equation

**AMS subject classifications.** 65F10, 65N22, 15A18, 15A12, 47B65

**DOI.** 10.1137/050627381

## 1. Introduction.

The aim of this work is to study the convergence behavior of a preconditioned algorithm to solve the linear systems generated by the discretization of the convection-diffusion equation

$$-\nu\ \nabla\cdot(a(x)\nabla u)+q(x)\cdot\nabla u = f,\quad x\in\Omega, \tag{1.1}$$

$$u = g,\quad x\in\partial\Omega, \tag{1.2}$$

where $\Omega$ is an open region of $\mathbb{R}^d$ with $a(x)$ a uniformly positive function, $q(x)\in\mathbb{R}^d$ a convective velocity field (the wind), $\nabla=(\frac{\partial}{\partial x_1},\dots,\frac{\partial}{\partial x_d})^T$, and $\nu$ the viscosity (or diffusion) coefficient. We stress that models based on similar equations, whose domains can be of dimension $d>3$, arise, e.g., in finance, where each spatial dimension is related to an asset in a basket.

Discretizing problem (1.1) by using centered or upwinding finite differences on equispaced meshes, we reduce the approximate solution of the above problem to the solution of the linear system

$$Ay=b,$$

where the matrix $A$ is nonsymmetric and positive definite and $n$ is the size of $A$; see section 2.2 for more details. If $\Omega$ coincides with $(0,1)^d$ and the stepsizes are given by $(N_j+1)^{-1}$, $N_j\in\mathbb{N}$, $j=1,\dots,d$, $N=(N_1,\dots,N_d)^T$, then the dimension of $A$ is

$n = N_1 \cdot N_2 \cdots N_d$. In the case when $\Omega \subset (0,1)^d$ is a connected domain formed by a finite union of $d$-dimensional rectangles (e.g., L, T, U-shaped domains, etc.), the discretization of the diffusion part of (1.1) is symmetric and positive definite, and the size $n$ will be approximately equal to $m(\Omega) \cdot N_1 \cdot N_2 \cdots N_d$, with $m(\cdot)$ being the usual Lebesgue measure ($m(\Omega) = 1$ for $\Omega = (0,1)^d$). Therefore, when the number of the mesh points in the domain $\Omega$ is large enough, $A$ is large and sparse.

Let us emphasize the dependence of the matrix $A$ on the parameters $a$ and $q$ in (1.1) by writing $A = A(a,q)$ or $A = A(a,q,\Omega)$, where $\Omega$ is the domain. The preconditioner we consider is defined as

$$P = P(a) := D^{1/2}(a)A(1,0)D^{1/2}(a), \tag{1.3}$$

where $D(a)$ is a suitably scaled main diagonal of $A(a,0)$, and $A(1,0)$ denotes the discrete Laplacian ($a = 1$). Preconditioning with a scaled discrete Laplacian operator for nonself-adjoint and nonseparable elliptic boundary value problems was considered in [12] and [15]. Moreover, in [15] the independence of preconditioned iterations from the mesh was observed. The eigenvalue distribution for the diffusive part of the latter problem was investigated in [23, 26, 25].

In this paper we focus our attention on the case when $q$ is nonzero and $\Omega$ is a connected finite union of $d$-dimensional rectangles (a plurirectangle) so that $A(1,0)$ (and consequently the whole preconditioner $P(a)$) is symmetric and positive definite as proven in [26]. In particular, the authors of [23, 26] found that, if $a(x)$ is positive and regular enough and $q(x) \equiv 0$, then the preconditioned sequence shows a proper eigenvalue clustering at the unity (for the notion of proper eigenvalue and singular value clustering, see Definition 2.2), and we prove here that the same holds true in the complex field for problem (1.1) as well. Moreover, under mild assumptions on the coefficients of the problem, we prove that all the eigenvalues of the preconditioned system belong in a complex rectangle $\{z \in \mathbb{C} : \ \mathrm{Re}(z) \in [c, C], \mathrm{Im}(z) \in [-\hat{c}, \hat{c}]\}$ with $c, C > 0$, $\hat{c} \geq 0$ independent of the dimension $n$. Note that the existence of a proper eigenvalue cluster and the aforementioned localization results in the preconditioned spectrum can be very important for fast convergence of preconditioned iterations (see, e.g., [4]): here we will use and generalize to the case of nonnormal preconditioners a recent general tool devised in [24] for deducing the eigenvalue clustering from the singular value clustering, the latter being much easier to check.

In previous works [1, 5] solvers based on the symmetric/skew-symmetric splittings of $A$ were considered. We stress that symmetric/skew-symmetric splittings can be used successfully as preconditioners; see [2].

Indeed, beside the spectral theoretical analysis of the preconditioned structures, the idea is to propose a technique that can be easily used. In fact, the ingredients are a Krylov method (e.g., GMRES, BiCGSTAB, etc.), a matrix vector routine (for sparse or even diagonal matrices), and a solver for the related diffusion equation with a constant coefficient (a method based, e.g., on the cyclic reduction approach [9, 14] or on multigrid methods [27, 19] for which professional software is available). Of course, if the convection part is dominating, then the considered approach can be enriched by approximating the related discrete operator. We stress that convection-dominated problems require appropriate upwind discretization to avoid spurious oscillations.

### 1.1. Outline.

The paper is organized as follows. In section 2 some tools and definitions from structured linear algebra are introduced, while in section 3 the preconditioner and some of its basic properties are introduced. In sections 4 and 5 we first derive specific tools for dealing with eigenvalue clusters and then we study the spectral properties of the preconditioned matrix sequences, with special emphasis on the eigenvalue and singular value clusterings. Section 6 is devoted to the convergence analysis of GMRES. Moreover, some numerical experiments in both two dimensions and three dimensions, and their computational aspects, are presented and discussed. Section 7 concludes the paper with some final comments and remarks.

## 2. Preliminaries.

We start by stating a few results from the spectral theory of Toeplitz matrix sequences (subsection 2.1) and then we briefly analyze the structure of the coefficient matrix $A$ (subsection 2.2).

### 2.1. Definitions and tools for sequences of Toeplitz matrices.

Let $f$ be a $d$-variate Lebesgue integrable function defined over the hypercube $\mathcal{T}^d$, with $\mathcal{T} = (-\pi, \pi]$ and $d \geq 1$. From the Fourier coefficients of $f$ (called a symbol or generating function)

$$a_j = \frac{1}{(2\pi)^d} \int_{\mathcal{T}^d} f(z) e^{-\mathrm{i}(j,z)}\, dz, \qquad \mathrm{i}^2 = -1, \quad j = (j_1, \ldots, j_d) \in \mathbb{Z}^d, \tag{2.1}$$

with $(j,z) = \sum_{r=1}^{d} j_r z_r$, one can build the sequence of Toeplitz matrices $\{T_N(f)\}_N$, $N = (N_1, \ldots, N_d)$, where $T_N(f) \in \mathbb{C}^{n \times n}$ and $n = \prod_{r=1}^{d} N_r$. The matrix $T_N(f)$ is said to be the Toeplitz matrix of order $N$ generated by $f$ (see, e.g., [8] for more details).

For example, if $d = 1$ we have that $a_j$, $j = -(N_1 - 1), \ldots, 0, \ldots, (N_1 - 1)$, is the value on the $j$th diagonal of the $N_1 \times N_1$ Toeplitz matrix $T_{N_1}$. The Fourier coefficients $a_j$ are equal to zero (for $|j|$ large enough) if $f$ is a (multivariate) trigonometric polynomial. Therefore, the corresponding Toeplitz matrix is multilevel and banded. A typical example is the case of the classical $d$-level Laplacian with Dirichlet boundary conditions, discretized by equispaced finite difference formulas over a square region. For instance, the generating function of the (negative) Laplacian (discretized by centered differences of accuracy order 2 and minimal bandwidth) is expressed by

$$\sum_{j=1}^{d} (2 - 2\cos(z_j)).$$

For $d = 1$ the corresponding matrix is the symmetric tridiagonal matrix $T_{N_1} = \text{Toeplitz}(-1, 2, -1)$ while, in the general case, it corresponds to $\sum_{j=1}^{d} P_j$ with

$$P_j = I_{N_1} \otimes \cdots \otimes I_{N_{j-1}} \otimes T_{N_j} \otimes I_{N_{j+1}} \otimes \cdots \otimes I_{N_d}.$$

The spectral properties of the sequence $\{T_N(f)\}_N$ and of related preconditioned sequences are completely understood and characterized in terms of the underlying generating functions. For instance, $T_N(f) = T_N^*(f)$ ($^*$ is the transpose conjugate operator) for every $N$ if and only if $f$ is real valued: more results are given in Theorem 2.1 following. Before stating it we clarify some notation that we will use throughout the paper.

We consider two nonnegative function $\alpha(\cdot)$ and $\beta(\cdot)$ defined over a domain $D$ with accumulation point $\bar{x}$ (if $D = \mathbb{N}$, then $\bar{x} = \infty$; if $D = \mathcal{T}^d$, then $\bar{x}$ can be any point of $D$). We write

- $\alpha(\cdot) = O(\beta(\cdot))$ if and only if there exists a pure positive constant $K$, such that $\alpha(x) \leq K\beta(x)$, for every (or for almost every) $x \in D$ (here and in the following, by pure or universal constant we mean a quantity not depending on the variable $x \in D$);

- $\alpha(\cdot) = o(\beta(\cdot))$ if and only if $\alpha(\cdot) = O(\beta(\cdot))$ and $\lim_{x\to\bar{x}} \alpha(x)/\beta(x) = 0$ with $\bar{x}$ a given accumulation point of $D$, which will be clear from the context;
- $\alpha(\cdot) \sim \beta(\cdot)$ if and only if $\alpha(\cdot) = O(\beta(\cdot))$ and $\beta(\cdot) = O(\alpha(\cdot))$;
- $\alpha(\cdot) \approx \beta(\cdot)$ if and only if $\alpha(\cdot) \sim \beta(\cdot)$ and $\lim_{x\to\bar{x}} \alpha(x)/\beta(x) = 1$ with $\bar{x}$ a given accumulation point of $D$ (the latter can be rewritten as $\alpha(x) = \beta(x)(1+o(1))$ with $1+o(1)$ uniformly positive in $D$).

**2.2. The discrete problem and splitting the contribution of convection and diffusion.** We denote with $\mathrm{Re}(G)$ the symmetric and with $\mathrm{i}\,\mathrm{Im}(G)$ the skew-symmetric part of a real coefficient matrix $G$, i.e., $\mathrm{Re}(G) = (G+G^*)/2$ and $\mathrm{Im}(G) = (G-G^*)/(2\mathrm{i})$, respectively.

The analysis is performed without restrictions on the dimension $d$ of problem (1.1), provided that $a(x) > 0$ and that the domain is a hypercube (by exploiting the analysis in [26], the same can be extended to the case when the domain is a connected finite union of $d$-dimensional rectangles by using the same arguments as in [5]). Conversely, we emphasize that here the numerical tests are performed mainly on two-dimensional problems with $a(x) > 0$.

Note that we can always write

$$A = \Theta(a) + \Psi(q),$$

where the matrix $\Theta(a) = A(a,0)$ is the discretization of the diffusion term, and the matrix $\Psi(q)$ is the discretization of the convection term. We observe that when $q(x) = (w_1, w_2, \ldots, w_d)^T$ is a constant vector and a centered difference discretization is used, the matrix $\Psi(q)$ is skew-symmetric and coincides with the $d$-level Toeplitz structure that, for $d=2$, is given by

$$S_{N_1} \otimes I_{N_2} + I_{N_1} \otimes S_{N_2},$$

where $S_{N_k}$, $k=1,2$, is the Toeplitz matrix generated by $f(z) = (-2\mathrm{i}w_k/(2h_k))\sin(z)$, i.e.,

$$S_{N_k} = \frac{w_k}{2h_k} \begin{pmatrix} 0 & 1 & & & \\ -1 & & & & \\ & \ddots & \ddots & \ddots & \\ & & & & 1 \\ & & & -1 & 0 \end{pmatrix}_{N_k \times N_k} . \tag{2.2}$$

On the other hand, $\Theta(a)$ is a $d$-level Toeplitz matrix which, for $d=2$, is given by

$$T_{N_1} \otimes I_{N_2} + I_{N_1} \otimes T_{N_2},$$

where, if $a(x)=1$, $T_{N_k}$ is the usual one-dimensional discrete Laplacian with generating function given by $(\nu/h_k^2)(2-2\cos(z))$, i.e., the tridiagonal Toeplitz matrix

$$T_{N_k} = \frac{\nu}{h_k^2} \begin{pmatrix} 2 & -1 & & & \\ -1 & & & & \\ & \ddots & \ddots & \ddots & \\ & & & & -1 \\ & & & -1 & 2 \end{pmatrix}_{N_k \times N_k} .$$

For the upwind scheme we consider here, if $q(x)$ is a constant vector, the matrix $A$ is as before with the exception of $S_{N_k}$ as in (2.2), which is now the following bidiagonal matrix:

$$S'_{N_k} = \frac{w_k}{h_k} \begin{pmatrix} 1 & 0 & & & \\ -1 & & & & \\ & \ddots & \ddots & \ddots & \\ & & & & 0 \\ & & & -1 & 1 \end{pmatrix}_{N_k \times N_k} . \tag{2.3}$$

For simplicity, from here on we consider $h_k = h$, $k = 1, \dots, d$, and we normalize the underlying linear systems by multiplying the left and right sides by $h^2$.

As in the case of the upwind scheme considered above, the symmetric part of $A$ cannot be exactly the discretization of the diffusion term $\Theta(a)$, and the skew-symmetric part of $A$ cannot be exactly the discretization of the convection term $\Psi(q)$. Indeed, we observed (see [5, Theorem 3.5, p. 466] and Remark 3.2 in [5]) the following property for a centered difference discretization of (1.1).

THEOREM 2.3. [illegible] $\nabla \cdot q(x)$ [illegible] (1.1) [illegible] (1.1) [illegible] 2 [illegible]

$$\mathrm{Re}(A(a,q)) = \Theta(a) + E,$$

$$\mathrm{iIm}(A(a,q)) = \Psi(q) - E,$$

$$E = \frac{\Psi(q) + \Psi^*(q)}{2} \tag{2.4}$$

$$\|E\|_2 \leq c_d\, h^2 \tag{2.5}$$

$$c_d = \alpha_d \|\nabla \cdot q\|_\infty$$

$\alpha_d = 2d$ $d = 2$ $d = 3$ $\Omega = (0,1)^d$

For the upwind scheme based on (2.3), we have that

$$||E||_2 \leq h\, \alpha_d' \max_{x \in \overline{\Omega}} |q(x)|,$$

where $\alpha_d'$ is a constant of the order of unity which depends only on $d$ and the discretization.

Under the assumption that $\|\nabla \cdot q\|_\infty$ is smaller than a suitable positive constant, by using the same arguments as in [5], we can prove that $\mathrm{Re}(A)$ is real symmetric positive definite but ill-conditioned with a condition number asymptotic to $h^{-2}$.

## 3. The preconditioner.

Here we focus on certain Krylov methods (e.g., GMRES; see [20] and [10]) preconditioned by

$$P := P(a, \Omega) = D^{1/2}(a)\Theta(1)D^{1/2}(a), \quad \Theta(1) = A(1, 0), \tag{3.1}$$

where $D(a)$ is a diagonal matrix which, in MATLAB notation, is given by

$$D(a) = \frac{1}{\gamma}\mathrm{diag}\left(\mathrm{diag}\left(\Theta(a)\right)\right), \qquad \gamma = \Theta(1)_{j,j}.$$

For example, if we consider the centered difference approximation of the Laplacian $\Theta(1)$, we have $\gamma = 4$ for $d = 2$ and $\gamma = 6$ for $d = 3$, where $d$ is the dimension of the domain of the problem. Note that $P$ in (3.1) is an approximation of the matrix generated by the discretization of the diffusive part of (1.1). Similar strategies were used in [11], in [15], and in [23, 25] for the purely diffusive equation, or, in other words, with $q$ as a null vector in (1.1).

The resolution of linear systems with matrices as in (3.1) can be performed within a linear arithmetic cost by means of fast Poisson solvers, and this is important for an efficient implementation of (3.1). Classical (direct) Poisson solvers are mainly based on cyclic reduction or on multigrid algorithms (see [9, 14] and, e.g., [27, 19]). From Theorem 2.3, we infer that $A$ is certainly positive definite if the norm of $E$ is smaller than the minimum (positive) eigenvalue of $\Theta(a)$. More specifically

$$\min_j(\lambda_j(\Theta(a))) \geq \nu h^2\, m(\Omega)\beta_d \min_{\overline{\Omega}} a,$$

with $m(\cdot)$ denoting the Lebesgue measure. Therefore, by using again the bound in Theorem 2.3 and by following the same arguments as in [5, Theorems 3.6 and 3.7], it is easy to prove the following two results, which are important in order to gain insight into the convergence of preconditioned iterations. From here on, where not otherwise stated, we will consider the centered differences discretization of precision order 2 and minimal bandwidth for (1.1).

THEOREM 3.1. [illegible] $A \in \mathbb{R}^{n\times n}$ [illegible] (1.1) [illegible]

$$\|\nabla \cdot q\|_\infty < \nu \frac{\beta_d}{\alpha_d} m(\Omega) \min_{\overline{\Omega}} a$$

[illegible] $a(x)$ [illegible] $\mathbf{C}^2(\overline{\Omega})$ [illegible] $\{P^{-1}\mathrm{Re}(A)\}_n$ [illegible] 1 [illegible] $[c, C]$ [illegible]

THEOREM 3.2. [illegible] 3.1 [illegible] $\{P^{-1}\mathrm{Im}(A)\}_n$ [illegible] 0 [illegible] $[-\hat{c}, \hat{c}]$ $\hat{c} > 0$

In reference to Theorem 3.1 we have $\beta_3 = 3\pi^2$ (i.e., for $d = 3$) and $\beta_2 = 2\pi^2$ if centered differences are used in (1.1). Therefore, for $d = 3$, $\Omega = (0,1)^d$ (three dimensions), the hypothesis on $q$ in Theorem 3.1 reads $||\nabla \cdot q||_\infty < \nu\pi^2/2$, which can be quite restrictive. However, if the latter is not satisfied, then everything in Theorems 3.1 and 3.2 can be stated identically, except for the fact that the interval $[c, C]$ (only in Theorem 3.1), with $c, C$ still independent of $n$, may include 0. The same can be stated for the subsequent and more important Theorem 4.3. In conclusion, the eigenvalue spectral clustering is not affected by the considered assumption, while the localization is affected only partially. However, we stress that we experienced the existence of good localization results even with weaker hypotheses than those in Theorems 3.1 and 3.2.

**4. The cluster.** To understand the behavior of preconditioned iterations, we analyze the spectrum of the coefficient matrix associated with (1.1) after preconditioning and the related matrix of eigenvectors; see, e.g., [10, 4]. First, we prove the existence of a proper cluster of the singular values through the decomposition of the preconditioned matrices as identity plus low-norm plus low-rank (Theorem 4.1). Second, we derive a general result (Theorem 4.3) on the relationships between proper eigenvalue and singular value clusters. From the latter result and from Theorems 3.1 and 3.2, we deduce the eigenvalue uniform boundedness and proper eigenvalue clustering in Corollary 4.4 and, in section 5, we provide some inequalities for the eigenvalues. Finally, we give a bound for the condition number of the matrix of the eigenvectors and discuss the convergence of GMRES in section 6.

THEOREM 4.1. [illegible] 3.1 [illegible] $\epsilon > 0$ [illegible] $\bar{N} = (\bar{N}_1, \ldots, \bar{N}_d)$ ([illegible] $\mathbb{N}^d$) $\bar{N} = \bar{N}(\epsilon)$ $r = r(\epsilon) < n$ [illegible]

$$N = (N_1, \ldots, N_d) > \bar{N}(\epsilon) = (\bar{N}_1, \ldots, \bar{N}_d),$$

[illegible]

$$P^{-1/2}AP^{-1/2} = I + R^{(1)} + R^{(2)}, \tag{4.1}$$

[illegible] $||R^{(1)}||_2 \leq \epsilon$ [illegible] $\mathrm{rank}(R^{(2)}) \leq r$ [illegible] $\{P^{-1/2}AP^{-1/2}\}_n$ [illegible] 1 [illegible]. We can write

$$P^{-1/2}AP^{-1/2} = P^{-1/2}(\mathrm{Re}(A) + \mathrm{i}\mathrm{Im}(A))P^{-1/2}$$
$$= P^{-1/2}(\Theta(a) + E)P^{-1/2} + P^{-1/2}(\Psi(q) - E)P^{-1/2},$$

and, from Theorem 3.1, we have that, with fixed $\epsilon_1 > 0$ small enough, there exist $\tilde{N} = (\tilde{N}_1, \ldots, \tilde{N}_d)$ and a constant $r_1$ such that for $N > \tilde{N}$ (to be intended componentwise), $n - r_1$ eigenvalues of the matrix $P^{-1/2}\mathrm{Re}(A)P^{-1/2}$ belong to the interval $(1-\epsilon_1, 1+\epsilon_1)$, and all the eigenvalues of $P^{-1/2}\mathrm{Re}(A)P^{-1/2}$ belong to an interval $[c, C]$, $0 < c < C$; i.e., we can write

$$P^{-1/2}\mathrm{Re}(A)P^{-1/2} = I + R_1^{(1)} + R_1^{(2)}, \tag{4.2}$$

where $||R_1^{(1)}||_2 \le \epsilon_1$ and $\mathrm{rank}(R_1^{(2)}) \le r_1$.

Moreover, from Theorem 3.2, we infer that the matrix sequence

$$\{P^{-1/2}\mathrm{Im}(A)P^{-1/2}\}_n$$

is spectrally bounded and clustered at zero; i.e., for $N$ large enough,

$$\mathrm{i}P^{-1/2}\mathrm{Im}(A)P^{-1/2}$$

is a skew-symmetric matrix whose eigenvalues are in $[-\mathrm{i}\hat{c}, \mathrm{i}\hat{c}]$. Therefore, there exist $\hat{N} = (\hat{N}_1, \ldots, \hat{N}_d)$ and a constant $r_2$ such that for $N > \hat{N}$, $n - r_2$ eigenvalues of $P^{-1/2}\mathrm{Im}(A)P^{-1/2}$ belong to $(-\epsilon_2, \epsilon_2)$ and all the eigenvalues of $P^{-1/2}\mathrm{Im}(A)P^{-1/2}$ belong to $[-\hat{c}, \hat{c}]$. Then, we can write

$$P^{-1/2}\mathrm{Im}(A)P^{-1/2} = R_2^{(1)} + R_2^{(2)}, \tag{4.3}$$

where $||R_2^{(1)}||_2 \le \epsilon_2$ and $\mathrm{rank}(R_2^{(2)}) \le r_2$, $||P^{-1/2}\mathrm{Im}(A)P^{-1/2}||_2 = \hat{c}$. The claimed results follow by taking

$$R^{(1)} = R_1^{(1)} + R_2^{(1)}, \quad \epsilon = \epsilon_1 + \epsilon_2; \quad r = r_1 + r_2, \quad \bar{N} = \max\{\hat{N}, \tilde{N}\}, \tag{4.4}$$

where the condition for $\bar{N}$ is to be intended componentwise. Finally, the existence of a proper singular value cluster at 1 of the sequence $\{P^{-1/2}AP^{-1/2}\}_n$ is a direct consequence of (4.1) and of the singular value decomposition [17]. □

Note that $r$ in (4.4) does not depend on $N$ for $N > \overline{N}$ because of the existence of a proper cluster for the spectrum of

$$\{P^{-1/2}\mathrm{Re}(A)P^{-1/2}\}_n$$

and of

$$\{P^{-1/2}\mathrm{Im}(A)P^{-1/2}\}_n.$$

Now we introduce a general tool, i.e., Theorem 4.3, for analyzing eigenvalue clusters of a preconditioned matrix sequence. We will take recourse to the following result (Theorem 4.2) essentially based on the majorization theory (see, e.g., [7]).

Theorem 4.2 (see [24]). [illegible] $\{A_n\}_n$ [illegible] $n$ [illegible] $\{A_n\}_n$ [illegible]

Theorem 4.3. [illegible] $\{A_n\}_n$ [illegible] $\{P_n\}_n$ [illegible] $P_n$ [illegible] $B_n$ $C_n$ [illegible] $U_n$ [illegible] $U_n$ [illegible] $A_n = B_n + C_n$ [illegible]

1. [illegible] $V_n = U_nP_n^{-1}B_nU_n^{-1}$ $W_n = U_nP_n^{-1}C_nU_n^{-1}$ [illegible]
2. $\{P_n^{-1}B_n\}_n$ [illegible] $r \in \mathbb{C}$ [illegible] $\rho(P_n^{-1}B_n)$ [illegible] $b$ [illegible] $b \geq 0$ [illegible] $n$.
3. $\{P_n^{-1}C_n\}_n$ [illegible] $s \in \mathbb{C}$ [illegible] $\rho(P_n^{-1}C_n)$ [illegible] $c$ [illegible] $c \geq 0$ [illegible] $n$

[illegible] $\{P_n^{-1}A_n\}_n$ [illegible] $r + s$ [illegible] $\rho(P_n^{-1}A_n)$ [illegible] $b + c$

[illegible] Since we are interested in the eigenvalues of $P_n^{-1}A_n$, it is natural to consider $U_nP_n^{-1}A_nU_n^{-1}$ which is similar to the original matrix. Moreover,

$$U_nP_n^{-1}A_nU_n^{-1} = V_n + W_n = (r+s)I_n + (V_n - rI_n) + (W_n - sI_n), \quad I_n \text{ identity matrix.}$$

By items 2 and 3 it is evident that $\{V_n - rI_n\}_n$ and $\{W_n - sI_n\}_n$ are both properly clustered at zero in the eigenvalue sense. Moreover, $V_n$ and $W_n$ are normal (item 1) and so are $V_n - rI_n$ and $W_n - sI_n$: as a consequence, $\{V_n - rI_n\}_n$ and $\{W_n - sI_n\}_n$ are also both properly clustered at zero in the singular value sense (the singular values are the moduli of the eigenvalues). Moreover, by the triangle inequality and from the assumption on the spectral radii, we have

$$\|V_n - rI_n\|_2 \leq |r| + \|V_n\|_2 = |r| + \rho(P_n^{-1}B_n) \leq |r| + b$$

and

$$\|W_n - sI_n\|_2 \leq |r| + \|W_n\|_2 = |s| + \rho(P_n^{-1}C_n) \leq |s| + c.$$

Finally, the matrix sequence

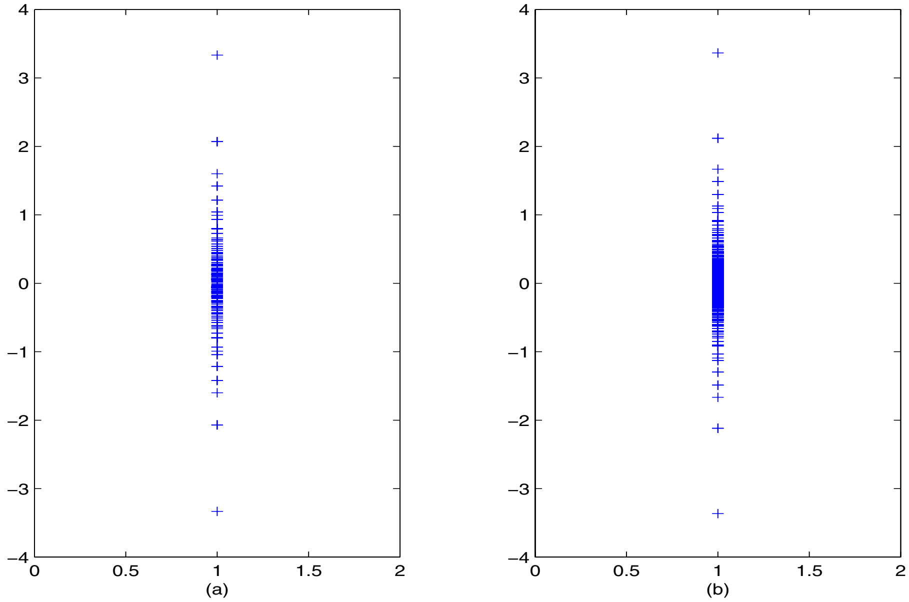
$$\{Z_n = V_n - rI_n + W_n - sI_n\}_n$$

is properly clustered at zero in the singular value sense (by the singular value decomposition) and its spectral norm is bounded, by the triangle inequality, by $|r| + b + |s| + c$ which is independent of $n$. Therefore, by Theorem 4.2, the sequence $\{Z_n\}_n$ is properly clustered at zero in the eigenvalue sense and $\{P_n^{-1}A_n\}_n$ is properly clustered at $r + s$ in the eigenvalue sense with $\rho(P_n^{-1}A_n) \leq |r + s| + |r| + b + |s| + c$. However, by exploiting again similarity and normality, the latter estimate can be substantially improved (leading to a more natural estimate) by observing that

$$\begin{aligned}\rho(P_n^{-1}A_n) = \rho(V_n + W_n) &\leq \|V_n + W_n\|_2 \leq \|V_n\|_2 + \|W_n\|_2 \\ &= \rho(P_n^{-1}B_n) + \rho(P_n^{-1}C_n) \leq b + c. \qquad \square\end{aligned}$$

It is worth mentioning that the latter result is an extension (potentially for nonsymmetric preconditioners) of Proposition 2.1 in [24]. Moreover, Theorem 4.3 works unchanged if the assumption of normality of $X_n \in \{V_n, W_n\}$ is replaced with a weaker one such as the existence of a pure constant $d \geq 1$ (independent of $n$) such that for all $j$ and uniformly with respect to $n$ it holds that $\sigma_j \leq d|\lambda_j|$, where the values $\lambda_j$ and $\sigma_j$ are the eigenvalues and the singular values of $X_n$, respectively, arranged by nondecreasing moduli.

Corollary 4.4. [illegible] 4.1 [illegible] $\{P^{-1}A\}_n$ [illegible] $1 \in \mathbb{C}^+$ $\mathbb{C}^+$ [illegible]



(a)

(b)

FIG. 4.1. *Eigenvalues for the preconditioned problem with* $\nu = 1/30$, $a = 1$, *discretization in two dimensions using centered differences and* $q = [-\sqrt{2}/2 \quad \sqrt{2}/2]^T$. (a) $h = 1/16$; (b) $h = 1/32$, *h stepsize.*

[illegible]

[illegible] The localization result simply follows from Bendixson (see, e.g., [17]): indeed, it is clear that any eigenvalue of $P^{-1}A$ has to belong to the field of values

$$\mathcal{F} = \left\{ z \in \mathbb{C} : \, z = \frac{x^*\mathrm{Re}(A)x}{x^*Px} + \mathrm{i}\frac{x^*\mathrm{Im}(A)x}{x^*Px}, \ x \in \mathbb{C}^n \backslash \{0\} \right\} \tag{4.5}$$

and that any eigenvalue of $P^{-1}\mathrm{Re}(A)$ and any eigenvalue of $P^{-1}\mathrm{Im}(A)$ must stay in

$$\left\{ z \in \mathbb{C} : \, z = \frac{x^*\mathrm{Re}(A)x}{x^*Px}, x \in \mathbb{C}^n \backslash \{0\} \right\} \text{ and } \left\{ z \in \mathbb{C} : \, z = \frac{x^*\mathrm{Im}(A)x}{x^*Px}, x \in \mathbb{C}^n \backslash \{0\} \right\},$$

respectively. Therefore, from Theorems 3.1 and 3.2 we deduce that all the eigenvalues of $P^{-1}A$ belong to $\{z \in \mathbb{C} : \ \mathrm{Re}(z) \in [c, C], \mathrm{Im}(z) \in [-\hat{c}, \hat{c}]\}$ with $c, C > 0$, $\hat{c} \geq 0$ independent of the dimension $n$, as in Theorems 3.1 and 3.2.

Now setting $U_n = P^{1/2}$, $P_n = P$, and $A_n = A$ we have (a) the eigenvalues of $\{P^{-1}\mathrm{Re}(A)\}_n$ are properly clustered to 1 and all lie in a uniformly bounded interval (Theorem 3.1), and $V_n = P^{-1/2}\mathrm{Re}(A)P^{-1/2}$ is symmetric and therefore normal; (b) the eigenvalues of $\{P^{-1}\mathrm{Im}(A)\}_n$ are properly clustered to 0 and all lie in a uniformly bounded interval (Theorem 3.2), and $W_n = \mathrm{i}P^{-1/2}\mathrm{Im}(A)P^{-1/2}$ is skew-symmetric and therefore normal.

Statements (a) and (b) are the assumptions of Theorem 4.3 from which we deduce that the eigenvalues of $\{P^{-1}A\}_n$ are properly clustered at $1 \in \mathbb{C}^+$. $\square$

Figures 4.1 and 4.2 report some examples of the spectrum of the coefficient matrix associated with equation (1.1) in two dimensions after preconditioning. Note the presence of the cluster in 1 in the complex field.

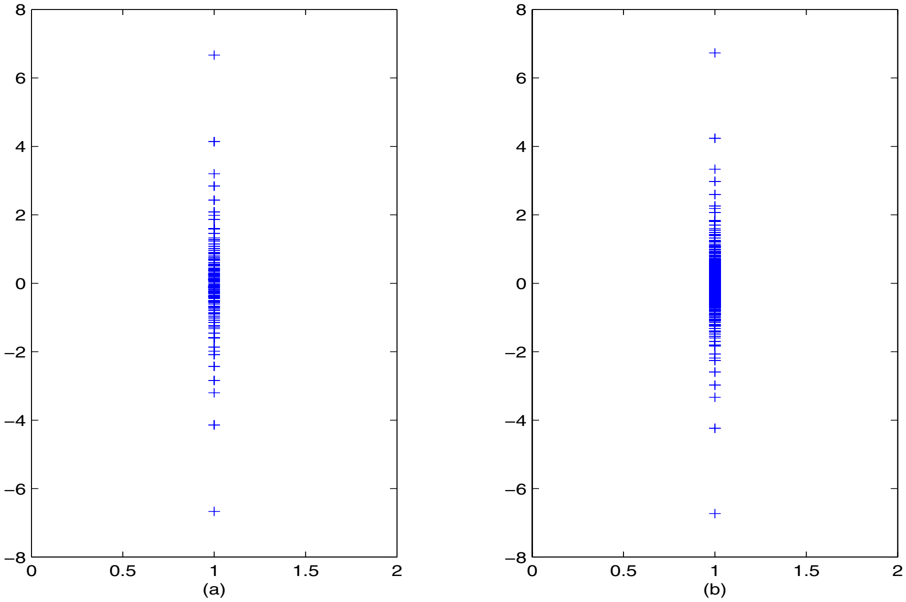


FIG. 4.2. *Eigenvalues for the preconditioned matrix with* $\nu = 1/60$*,* $a = 1$*, discretization in two dimensions using centered differences and* $q = [-\sqrt{2}/2 \quad \sqrt{2}/2]^T$. (a) $h = 1/16$*;* (b) $h = 1/32$*,* $h$ *stepsize.*

## 5. Spectrum of the preconditioned matrix.

We state here some a-priori bounds on the spectrum of the underlying preconditioned matrix.

In what follows, the numbers $\gamma_j$, $j \in \mathbb{N}$, denote constants of the order of unity, and $\alpha_d$ is defined as in section 2 (see Theorem 2.3). All these constants, in general, depend on the discretization and on the dimension $d$ of the considered domain $\Omega$. To simplify the notation, here we will focus on the two-dimensional case, where $\Omega$ is the rectangle $[0,1] \times [0,1]$. The extension to any connected finite union of rectangles in any $d$ dimension and therefore for the three-dimensional case (by just changing some constants) can be performed with the same arguments. In the result below, $d = 2$ and centered differences are used for (1.1), $\gamma_1 \to 2$ for $n \to \infty$, and $\gamma_j \to 1$ $j = 2, 3$. As usual, with $\lambda_j(X)$ we denote the generic eigenvalue of a square matrix $X$.

THEOREM 5.1. [illegible] 4.1 $\lambda_j\left(P^{-1}\mathrm{Re}(A)\right)$ [illegible]

[illegible]

$$\left[\frac{\min_{x\in\overline{\Omega}}(a)}{\max_{x\in\overline{\Omega}}(a)} - \frac{1}{\nu}\frac{\alpha_d}{2\gamma_2\pi^2}\frac{\|\nabla\cdot q\|_\infty}{\min_{x\in\overline{\Omega}}(a)}, \frac{\max_{x\in\overline{\Omega}}(a)}{\min_{x\in\overline{\Omega}}(a)} + \frac{1}{\nu}\frac{\alpha_d}{2\gamma_2\pi^2}\frac{\|\nabla\cdot q\|_\infty}{\min_{x\in\overline{\Omega}}(a)}\right]. \tag{5.1}$$

[illegible]

$$\left|\lambda_j\left(P^{-1}\mathrm{Im}(A)\right)\right| \in \left[0, \left(1+\pi^{-3}\right)\frac{\alpha_d}{\nu}\gamma_1\|q\|_\infty\frac{\max_{x\in\overline{\Omega}}(a)}{[\min_{x\in\overline{\Omega}}(a)]^2}\right]. \tag{5.2}$$

[illegible] By (4.5) and the properties of the field of values, we have

$$\mathrm{Re}\left(\lambda_j\left(P^{-1}A\right)\right) \in \left[\min_{x\in\mathbb{C}^n\setminus\{0\}}\frac{x^*\mathrm{Re}(A)x}{x^*Px}, \max_{x\in\mathbb{C}^n\setminus\{0\}}\frac{x^*\mathrm{Re}(A)x}{x^*Px}\right] \tag{5.3}$$

and

$$\operatorname{Im}\left(\lambda_j\left(P^{-1}A\right)\right) \in \left[\min_{x\in\mathbb{C}^n\setminus\{0\}} \frac{x^*\operatorname{Im}(A)x}{x^*Px}, \max_{x\in\mathbb{C}^n\setminus\{0\}} \frac{x^*\operatorname{Im}(A)x}{x^*Px}\right]. \tag{5.4}$$

For the sake of clarity, we prove the statements through three progressive steps.

- Let $a \in \mathbb{R}$ and $q \in \mathbb{R}^d$ be constants in (1.1). Then, $P \equiv \operatorname{Re}(A)$ and

  $$P^{-1}A = I + \mathrm{i}P^{-1}\operatorname{Im}(A).$$

  Therefore, the real part of the eigenvalues of the preconditioned matrix is equal to 1. Moreover, by using similar arguments as in [5, Theorem 3.2], we have the following bound for $\lambda_j(P^{-1}\operatorname{Im}(A))$:

  $$\left|\lambda_j\left(P^{-1}\operatorname{Im}(A)\right)\right| \in \left[0,\ \frac{1}{\nu}\|q\|_\infty \cdot \left(1+\pi^{-3}\right)\gamma_1\right].$$

- Let $q(x) = q$ be constant and $a(x) > 0$ in (1.1). The discretization of the diffusive part $\Theta(a)$ is exactly $\operatorname{Re}(A)$. Therefore, by [23, Theorem 8.1],

  $$\lambda_j\left(P^{-1}\operatorname{Re}(A)\right) \in \left[\frac{\min_{x\in\overline{\Omega}}(a)}{\max_{x\in\overline{\Omega}}(a)},\ \frac{\max_{x\in\overline{\Omega}}(a)}{\min_{x\in\overline{\Omega}}(a)}\right]. \tag{5.5}$$

  Moreover, $\Psi(q) \equiv \mathrm{i}\operatorname{Im}(A)$ (i.e., the discretization of the convective part is exactly $\mathrm{i}\operatorname{Im}(A)$). As a consequence, by [5, Theorem 3.2, 3.3, and 3.4], we have

  $$\left|\lambda_j\left(P^{-1}\operatorname{Im}(A)\right)\right| \in \left[0, \frac{1}{\nu}\|q\|_\infty \cdot \frac{\max_{x\in\overline{\Omega}}(a)}{[\min_{x\in\overline{\Omega}}(a)]^2}\left(1+\pi^{-3}\right)\gamma_1\right]. \tag{5.6}$$

- Finally, let us consider the general case, i.e., $a(x) : \Omega \to \mathbb{R}^+$ and $q(x) : \Omega \to \mathbb{R}^d$. Recalling Theorem 2.3, we deduce

  $$\operatorname{Re}(A(a,q)) = \Theta(a) + E, \quad \mathrm{i}\operatorname{Im}(A(a,q)) = \Psi(q) - E,$$

  $$\frac{x^*\operatorname{Re}(A)x}{x^*P\,x} = \frac{x^*\Theta(a)x}{x^*P\,x} + \frac{x^*Ex}{x^*P\,x}, \tag{5.7}$$

  $$\frac{x^*\operatorname{Im}(A)x}{x^*P\,x} = \frac{x^*\Psi(q)x}{x^*P\,x} - \frac{x^*Ex}{x^*P\,x}. \tag{5.8}$$

  By (3.1), we observe that

  $$\min\lambda_j(P) \geq 2\gamma_2\pi^2h^2\min_{x\in\overline{\Omega}}(a), \quad \max\lambda_j(P) \leq 8\gamma_3\max_{x\in\overline{\Omega}}(a),$$

  and invoking Theorem 2.3 (i.e., $\|E\|_2 \leq h^2\alpha_d\|\nabla\cdot q\|_\infty$), that

  $$\left|\frac{x^*Ex}{x^*Px}\right| \leq \frac{1}{\nu}\frac{\alpha_d}{2\gamma_2\pi^2}\frac{\|\nabla\cdot q\|_\infty}{\min_{x\in\overline{\Omega}}(a)}.$$

  Therefore, from (5.5), (5.7), and Theorem 2.3, we have (5.1). On the other hand,

  $$P^{-1}\operatorname{Im}(A) = -\frac{\mathrm{i}}{2}P^{-1}\left(\Psi(q) - \Psi(q)^*\right), \tag{5.9}$$

and hence, by the same arguments as in [5, Theorem 3.4], we deduce

$$\frac{\min_{x\in\overline{\Omega}}(a)}{[\max_{x\in\overline{\Omega}}(a)]^2}Z \le P^{-1/2}\mathrm{Im}(A)P^{-1/2} \le \frac{\max_{x\in\overline{\Omega}}(a)}{[\min_{x\in\overline{\Omega}}(a)]^2}Z, \tag{5.10}$$

with

$$Z = [A(1,\Omega)]^{-1/2}\mathrm{Im}(A)[A(1,\Omega)]^{-1/2}.$$

Finally, by the similarity of the two sequences of matrices

$$\left\{P^{-1}\mathrm{Im}(A)\right\}_n \text{ and } \left\{P^{-1/2}\mathrm{Im}(A)P^{-1/2}\right\}_n,$$

and considering expressions (5.9), (5.10), and (5.8), Theorems 3.2 and 2.3, and [5, Theorem 3.2], we infer (5.2), i.e., the desired result. □

If $q(x)$ is not a constant function, we note that the eigenvalues of the spectrum of the preconditioned matrix can have negative real part if $||\nabla\cdot q||_\infty$ is huge and/or $\nu$ is small. This may slow down the initial phase of the convergence process of the Krylov subspace projection method used to solve the underlying preconditioned linear system. However, if the convection is overly dominant, a preconditioning strategy based on a suitable upwind discretization can be used. The related eigenvalue analysis can be adapted by using tools similar to those considered here.

## 6. Notes on the convergence of iterative methods.

**6.1. The condition number of the eigenvector matrix.** Here we will focus on the case

$$q = [\cos(\phi) \quad \sin(\phi)]^T, \quad 0 \le \phi < \pi,$$

where $\phi$ is a constant angle; i.e., the wind is constant. In this case, the following result holds true. For simplicity, here we focus on the case when $N_1 = N_2 = \cdots = N_d = n^{1/d}$, where $n$ is the size of $A$ (uniform grid).

LEMMA 6.1. [illegible] $q(x)$ [illegible] $a(x)$ [illegible] (1.1) [illegible] (1.1) [illegible] $P^{-1}A$ [illegible] $n$ [illegible] $V$ [illegible] $P^{-1}A$ $V$ [illegible] $\kappa_2(V) \sim n^{1/d}$ [illegible] $N_i \approx \alpha_{i,j}N_j$ [illegible] $i, j$, [illegible] $\alpha_{i,j}$ [illegible] $\kappa_2(V) \approx cn^{1/d}$ [illegible] $c$ [illegible]

[illegible] Under our assumptions, since $q(x)$ and $a(x)$ in (1.1) are constant, then $P \equiv \Theta(1)$ and $\Psi(q)$ is a skew-symmetric matrix. Moreover, the preconditioned matrix $P^{-1}A$ can be written as

$$P^{-1}A = (\Theta(1))^{-1}\cdot(\Theta(1) + \Psi(q)) = I + (\Theta(1))^{-1}\Psi(q) = I + (\Theta(1))^{-1/2}S(\Theta(1))^{1/2},$$

where $\Theta(1)$ and $\Psi(q)$ are the matrices generated by the discretization of the diffusive and convective parts of (1.1), respectively. However, by construction $S = (\Theta(1))^{-1/2}\,\Psi(q)\,(\Theta(1))^{-1/2}$ is a skew-symmetric matrix since $(\Theta(1))^{-1/2}$ is a symmetric positive definite matrix and $\Psi(q)$ is a skew-symmetric matrix. Therefore, $I+S$ is normal because

$$(I+S)^*\cdot(I+S) = (I-S)(I+S) = I - S^2,$$

which is the same matrix obtained as $(I+S)\cdot(I+S)^*$. Consequently,

$$\begin{aligned} P^{-1}A &= (\Theta(1))^{-1/2}(I+S)(\Theta(1))^{1/2} \\ &= (\Theta(1))^{-1/2}QDQ^*(\Theta(1))^{1/2}, \end{aligned}$$

where $D$ is diagonal (the eigenvalue matrix), $Q$ is unitary, and $V=(\Theta(1))^{-1/2}Q$ is the eigenvector matrix. Since $\kappa_2(P^{-1})=\kappa_2((\Theta(1))^{-1})\sim n^{2/d}$ (it is a classical result on the discrete Laplacian; refer, e.g., to part 3 of Theorem 2.1), it directly follows that $\kappa_2(V)=\kappa_2((\Theta(1))^{-1/2}Q)=\kappa_2((\Theta(1))^{-1/2})\sim n^{1/d}$. Moreover, if $N_i\approx\alpha_{i,j}N_j$ for every $i,j$ and $\alpha_{i,j}$ are universal constants, then $\kappa_2((\Theta(1))^{-1})\approx c^2n^{2/d}$, where $c$ is a pure positive constant, and therefore $\kappa_2(V)=\kappa_2((\Theta(1))^{-1/2}Q)=\kappa_2((\Theta(1))^{-1/2})\approx cn^{1/d}$. □

Note that if we could use $P^{-1/2}$ as a split preconditioner instead of $P$ as a left (or right) preconditioner, then $\kappa_2(V)=1$ because $P^{-1/2}AP^{-1/2}=I+S$ is normal. This, in theory, could have some relevance for the convergence (see the next section); in practice we observed no changes.

**6.2. Analysis of the convergence.** To study the convergence of GMRES, we report a few tools based on polynomials related to the minimal polynomial of the matrix $K$ of the underlying linear system, which have been introduced in [10].

Recall the bound on the convergence of GMRES (see [20, sections 6.11.2, 6.11.4]):

$$||r_j||_2 \le \kappa_2(V)\cdot \min_{p_j(0)=1}\max_{\lambda\in\lambda(K)}|p_j(\lambda)|\cdot\|r_0\|_2, \tag{6.1}$$

where $\lambda(K)$ is the set of all the eigenvalues of the matrix $K$, $\kappa_2(V)$ is the spectral condition number of the matrix of the eigenvectors of $K$, $V$ is chosen to minimize $\kappa_2(V)$, is and $p_j(z)$ is a polynomial of degree at most $j$. Note that, under the assumptions of Lemma 6.1, we have $\kappa_2(V)=cn^{1/d}$, with $c$ a universal constant.

Let us consider the preconditioned sequence $\{K=P^{-1}A\}_n$ whose spectrum $\{\lambda(K)\}_n$ is clustered (recall Corollary 4.4) and partition $\lambda(K)$ as in [4]:

$$\lambda(K)=\lambda^{(c)}(K)\cup\lambda^{(0)}(K)\cup\lambda^{(1)}(K),$$

where $\lambda^{(c)}(K)$ denotes the clustered set of eigenvalues of $K$ and $\lambda^{(0)}(K)\cup\lambda^{(1)}(K)$ denotes the set of the (distinct) outliers. We assume that the clustered set $\lambda^{(c)}(K)$ of eigenvalues is contained in a convex set $\mathcal{C}$ whose closure must not contain the origin.

The sets

$$\lambda^{(0)}(K)=\{\hat\lambda_1,\hat\lambda_2,\ldots,\hat\lambda_{j_0}\}\quad\text{and}\quad\lambda^{(1)}(K)=\{\tilde\lambda_1,\tilde\lambda_2,\ldots,\tilde\lambda_{j_1}\}$$

denoting two sets of $j_0$ and $j_1$ outliers, respectively, are defined as in [4]; i.e., if $\hat\lambda_j\in\lambda^{(0)}(K)$, we have

$$1<\left|1-\frac{z}{\hat\lambda_j}\right|\le c_j\quad\forall z\in\mathcal{C},$$

while, for $\tilde\lambda_j\in\lambda^{(1)}(K)$,

$$0<\left|1-\frac{z}{\tilde\lambda_j}\right|<1\quad\forall z\in\mathcal{C},$$

respectively.

From (6.1) and the above definitions, we have

$$\min_{p_j(0)=1} \max_{z\in\lambda(K)} |p_j(z)| \leq \max_{z\in\lambda(K)} |\hat{p}(z)\cdot q(z)\cdot \tilde{p}(z)|, \tag{6.2}$$

where

$$\hat{p}(z) = \left(1-\frac{z}{\hat{\lambda}_1}\right)\cdots\left(1-\frac{z}{\hat{\lambda}_{j_0}}\right), \quad \tilde{p}(z) = \left(1-\frac{z}{\tilde{\lambda}_1}\right)\cdots\left(1-\frac{z}{\tilde{\lambda}_{j_1}}\right)$$

are the polynomials whose roots are the (distinct) outlying eigenvalues in $\lambda^{(0)}(K) \cup \lambda^{(1)}(K)$ and $q(z)$ is a polynomial of degree at most $j - j_0 - j_1 \geq 0$ such that $q(0) = 1$. The polynomial $q(z)$ can be chosen to be the shifted and scaled complex Chebyshev polynomial $q(z) = C_k((c-z)/d)/C_k(c/d)$ which is small on the set containing $\lambda^{(c)}(K)$; see [20, sections 6.11.2, 6.11.4]. Therefore, by using the same arguments as in [4], we have the following.

THEOREM 6.2. [illegible] $j$ [illegible] $\epsilon$ [illegible] $2$ [illegible] $||r_j||_2/||r_0||_2$ [illegible] $Kx = b$ $K$ [illegible]

$$\min\left\{ j_0 + j_1 + \left\lceil \frac{\log(\epsilon) - \log(\kappa_2(V))}{\log(\rho)} - \sum_{\ell=1}^{j_0} \frac{\log(c_\ell)}{\log(\rho)} \right\rceil, n \right\}, \tag{6.3}$$

[illegible]

$$\rho^k = \frac{\left(a/d + \sqrt{(a/d)^2-1}\right)^k + \left(a/d + \sqrt{(a/d)^2-1}\right)^{-k}}{\left(c/d + \sqrt{(c/d)^2-1}\right)^k + \left(c/d + \sqrt{(c/d)^2-1}\right)^{-k}}, \tag{6.4}$$

[illegible] $\mathcal{C} \in \mathbb{C}^+$ [illegible] $c$ [illegible] $d$ [illegible] $a$

The bound (6.3) suggests that there will be a latency of $j_0 + j_1$ steps before the asymptotic behavior is observed. If $j_0 > 0$, then there may be some additional delay proportional to $(\sum_l \log c_l)^{-1}$. In practice, the asymptotic convergence behavior will not be manifested until the expression

$$\max_{z\in\lambda^{(c)}(K)} |\hat{p}(z)\cdot\tilde{p}(z)|\rho^k$$

is less than 1, where $k$ is the degree of the shifted and scaled Chebyshev polynomial. Of course, these are theoretical arguments because $||p_j||$ can be arbitrarily large, and then no general statements can be made about how much larger the delay in convergence can be in practice or when superlinear convergence sets in.

### 6.3. Examples and comments.

In this section we report on a few experiments with a centered difference discretization and constant coefficients for problem (1.1) in order to compare the theoretical results and notes above. The preconditioner $P$ is implemented here in MATLAB by using a fast Poisson solver. Performances (timings) can be improved with a multigrid-based fast Poisson solver, but this will be considered in a future work together with more general test problems. Experiments are performed with GMRES but we include also two-dimensional tests and (total) timings with preconditioned and nonpreconditioned BiCGSTAB. In three or more dimensions,

fair timings require a more efficient implementation. For memory limitations, we provide large tests for BiCGSTAB only. A dagger † in the tables means that the solver does not converge after 1000 iterations (i.e., 1000 matrix-vector products for GMRES and 2000 for BiCGSTAB).

Our experiments are performed under the assumptions of Lemma 6.1. By Theorem 5.1, we have $j_0 = 0$. Therefore, the delay for asymptotic convergence behavior is mainly related to the number of distinct outlying eigenvalues. However, if $\epsilon$ is large enough, GMRES may treat as multiple eigenvalues those which belong to $\lambda^{(1)}$, are nondefective, and form small satellite clusters, as observed in [10]. In this case, the above mentioned delay can be less than $j_1$ iterations.

We stress that the presence of a proper cluster of eigenvalues means also that the number of the outliers does not increase with $N$, provided that it is large enough, and that their influence is limited to an initial delay for the asymptotic phase of convergence.

In Tables 6.1, 6.2, and 6.3, we report the number of preconditioned and nonpreconditioned GMRES iterations for the underlying two-dimensional problem with

$$q = [-\sqrt{(}2)/2 \ \sqrt{(}2)/2]^T,$$

$a = 1$, $\epsilon = 10^{-6}$ for $h = 1/16$ to $h = 1/128$, and $\nu = 1/10$ to $\nu = 1/80$, and similarly for BiCGSTAB. The boundary conditions in (1.1) are

$$u(0, y) = u(1, y) = 1, \quad 0 < y < 1; \quad u(x, 0) = u(x, 1) = 0, \quad 0 < x < 1.$$

Table 6.4

*Preconditioned GMRES iterations for centered differences discretization of* (1.1)*, three-dimensional problem with* $q = [1/\sqrt{3} \quad 1/\sqrt{3} \quad 1/\sqrt{3}]^T$*,* $a = 1$*,* $\epsilon = 10^{-6}$*. In parentheses: non-preconditioned (full) GMRES iterations.*

| $h \setminus \nu$ | 1/10 | 1/20 | 1/30 | 1/40 | 1/60 | 1/80 |
|---|---|---|---|---|---|---|
| 1/8 | 12 (25) | 17 (23) | 22 (21) | 26 (25) | 33 (31) | 40 (37) |
| 1/16 | 12 (51) | 18 (50) | 24 (48) | 29 (47) | 38 (45) | 49 (50) |
| 1/32 | 11 (93) | 17 (97) | 23 (97) | 28 (97) | 38 (95) | 49 (94) |

In Table 6.4 we report similar tests with the three-dimensional problem using GMRES but with

$$q = [1/\sqrt{3} \quad 1/\sqrt{3} \quad 1/\sqrt{3}]^T,$$

and the boundary conditions are $u(0,0,0) = 1$ and zero elsewhere. Similar results are obtained with other Dirichlet boundary conditions.

We note that halving the stepsize means that the sizes of matrices are multiplied by four. The theoretical computational cost is $O(N)$, where the mesh is equispaced, and thus $N = n^d$, with $d$ the dimension of the domain. However, we can see that when we halve the stepzise, timings for preconditioned iterations (see Table 6.3, where $d = 2$) are always less than quadruple.

**6.4. Convergence and the viscosity parameter.** In the analysis performed in section 5 we observed that, if $q$ in (1.1) is constant, then the imaginary parts of the eigenvalues of the preconditioned matrix are proportional to $\nu^{-1}$; see Theorem 5.1. Moreover, the number of the distinct outliers does not depend on $\nu$ or on the mesh, but it does depend on the choice of the function $q$; see the results on the existence of a proper cluster in the previous sections. For example, if $a(x)$ is also constant, we have

$$\beta = \max_j \{ \left| \operatorname{Im} \left( \lambda_j (P^{-1}A) \right) \right| \} = \frac{c}{\nu},$$

where $c$ is a universal positive constant. Another evidence of this can be found in Figures 4.1 and 4.2.

Moreover, by denoting with $\beta$ the radius of the cluster and provided that $\beta > 0$, with the notation of Theorem 6.2, the contribution to the number of the iterations of the eigenvalues in the cluster is bounded from above by

$$\frac{\log(\epsilon)}{\log(\rho)} = c' \frac{\log(\epsilon)}{\frac{-1}{1+\beta}} = c'(1+\beta)\log(\epsilon^{-1}). \tag{6.5}$$

Here, $c'$ is a pure positive constant which takes into account that $\rho$ is approximated by

$$\tilde{\rho} = \frac{\beta}{1 + \sqrt{1+\beta^2}} < \frac{\beta}{1+\beta} = 1 - \frac{1}{1+\beta}$$

and that, provided that $\beta > 0$, $\log(\rho)$ is approximated by the Taylor expansion of $\log(\tilde{\rho})$, with $\tilde{\rho}$ being defined as above. Again, note that we are in the hypotheses of Lemma 6.1, and then the convergence is dictated by the distribution of the eigenvalues. Therefore, the number of iterations is expected to grow with $\nu^{-1}$. However, in practice, the number of iterations seems to be proportional to $\sqrt{\nu^{-1}}$ (see Tables 6.1

and 6.4), and this behavior is confirmed for various functions $a(x)$ and $q(x)$; see also the numerical experiments in [6].

The above discussion was done under restrictive hypotheses. However, the experience of several different choices of functions $a(x)$ and $q(x)$ and values of the viscosity parameter $\nu$ (always such that the hypotheses of Theorem 4.1 are satisfied) suggests that the number of the iterations depends on a function of $\nu^{-1}$, even under more general assumptions, but it is independent of the mesh and of the dimension $d$ of problem (1.1).

## 7. Conclusions.

The purpose of this work was to explore some properties of the preconditioned operator $P^{-1}A$, where $P$ is defined in (3.1) and $A$ is the matrix generated by a finite difference discretization (using centered differences or upwind) of the convection-diffusion equation (1.1). In particular, we proved the existence of a cluster in the spectrum of $\{P^{-1}A\}_n$ and gave a bound for the condition number of the matrix of the eigenvector. Moreover, we found that eigenvalue distribution and convergence rates are independent of the discretization mesh size and of the dimension of the problem but do depend (weakly) on $\nu^{-1}$.

Indeed, beside the spectral theoretical analysis of the preconditioned structures, we stress that our technique can be easily implemented. In fact, the ingredients are constituted by the following blocks: a Krylov method (e.g., GMRES, BiCGSTAB, etc.), a matrix vector routine (for sparse or even diagonal matrices), and a solver for the related diffusion equation with a constant coefficient (a method based, e.g., on the cyclic reduction approach [9, 14] or on multigrid methods [27, 19] for which professional software is available). Of course, if the convection part is dominating, then the considered approach can be enriched by alternating the discussed diffusion-based preconditioning with a preconditioner for an upwind discretization. At this point, we recall that the idea of using, e.g., a multigrid (for a simpler differential problem) as a preconditioner in a Krylov-type method is quite classical, as it emerges in [18, 27]. In this direction, we must quote the following statements from Greenbaum [18, subsection 12.1.5, p. 197]:

> Some multigrid aficionados will argue that if one has used the proper restriction, prolongation, and relaxation operators, then the multigrid algorithm will require so few cycles ... that it is almost pointless to try to accelerate it with CG-like methods. This may be true, but unfortunately such restriction, prolongation, and relaxation schemes are not always known. In such cases, CG, GMRES QMR, or BiCGSTAB acceleration may help.
>
> Equivalently, one can consider multigrid as a preconditioner for one of these Krylov subspace methods.

A future work will be in the direction of combining different iterative solvers (the multi-iterative idea [21]) and more specifically we would like (A) to use the preconditioner considered in this paper as one of the smoothers for a V-cycle directly in the original problem; (B) to make a comparison between the present approach and the one in (A); and (C) to enrich the analysis in the case of convection-dominated problems in order to achieve more robustness.

**Acknowledgments.** We are grateful to the referees for useful comments which have improved this presentation.

# INVERSE SPECTRAL PROBLEMS FOR SEMISIMPLE DAMPED VIBRATING SYSTEMS*

PETER LANCASTER†

*This paper is dedicated to the memory of Miron Tismenetsky, a good friend and colleague*

**Abstract.** Computational schemes are investigated for the solution of inverse spectral problems for $n \times n$ real systems of the form $L(\lambda) = M\lambda^2 + D\lambda + K$. Thus, admissible sets of data concerning systems of eigenvalues and eigenvectors are examined, and procedures for generating associated (isospectral) families of systems are developed. The analysis includes symmetric systems, systems with mixed real/nonreal spectrum, systems with positive definite coefficients, and hyperbolic systems (with real spectrum). A one-to-one correspondence between Jordan pairs and structure preserving similarities is clarified. An examination of complex symmetric matrices is included.

**Key words.** inverse problems, vibrating systems, structure preserving transformations

**AMS subject classifications.** Primary, 74A15; Secondary, 15A29

**DOI.** 10.1137/050640187

## 1. Introduction.

Inverse eigenvalue problems are addressed here in the context of vibrating systems which, for our present purposes, are defined as follows.

DEFINITION 1. (vibrating) system [illegible] $n \times n$ real [illegible] $\{M, D, K\}$ [illegible] $M$ [illegible]

Many problems of physical interest also require that some or all of the coefficients $M$, $D$, $K$ be symmetric and positive definite or semidefinite (see [2] and [16], for example).

In this paper, an idea introduced in [10] is extended from the restriction to systems with purely nonreal spectrum to the full range of real and nonreal spectrum, but with the continuing limitation (seen as nonrestrictive by many in the field) to semisimple eigenvalues; i.e., an eigenvalue of multiplicity $m \geq 1$ has $m$ associated linearly independent eigenvectors. This hypothesis has the added advantage that analysis is simplified considerably. The generation of real systems, real symmetric systems, and systems with positive semidefinite or positive definite coefficients will be considered, in this order.

First, it is necessary to summarize the spectral properties admitted in this analysis. Since the systems of interest have real coefficients, the eigenvalues may be real or may appear in complex conjugate pairs. All eigenvalues are required to be semisimple for both real and nonreal eigenvalues. The set of all the eigenvalues, both real and complex, is denoted by $\sigma$.

The central problem considered here is, given an admissible set of spectral data (real and complex eigenvalues and, where required, a sign characteristic), to construct a family of systems consistent with this data. Another closely related problem is,

---

given a real system (with spectral data implicitly defined), to construct a family of systems consistent with [illegible] data. In both cases the objective is the construction of [illegible] families of systems; i.e., each member of the family has spectrum $\sigma$ and it is semisimple.

For the second formulation, in particular, it is natural to reformulate the problem in terms of the well-known [illegible], in which case all eigenvalues, at least, are preserved by similarity transformations. This, in turn, leads to the notion of [illegible], which have been discussed elsewhere (in [10] and [15], for example) and which are developed further in sections 2 and 3. In section 4 these ideas are re-examined in terms of Jordan pairs (see Theorem 3), and this leads to constructions for families of real systems in section 5.

The study of [illegible] systems (in which $M$, $D$, $K$ are real and symmetric) is taken up in sections 6 and 7. A strategy is adopted in which the real eigenvectors are assigned (subject to some necessary constraints) and then the eigenvectors for [illegible] eigenvalues are determined from them. This requires the symmetric factorization of a complex symmetric matrix and is accomplished with the aid of [illegible] (section 7 and Appendix A). This also requires some detailed knowledge of the rank of complex symmetric matrices which is presented in Appendix C.

Hypotheses that ensure the positivity conditions of $M$, $D$, $K$ are the subject of section 8, where Theorem 5 is the central (new) result. Systems with all eigenvalues real (quasi hyperbolic or overdamped, for instance) are the subject of section 9, where Corollary 6 is the main contribution.

**2. Massaging the spectrum.** If the system is $n \times n$, then $2r$ real eigenvalues are admitted ($0 \le r \le n$). The nonreal eigenvalues in the upper half of the complex plane are determined by a complex diagonal matrix $\Lambda = U_1 + iW$ of size $(n-r)\times(n-r)$ with $W > 0$. Their complex conjugates are also eigenvalues and make up the diagonal entries of $\bar{\Lambda}$. Then there are $2r$ real eigenvalues which are distributed between the diagonal entries of two $r \times r$ real diagonal matrices $U_2$ and $U_3$. The way in which these two matrices are formed will be discussed in what follows.

A complex (canonical) diagonal $2n \times 2n$ matrix including all the eigenvalues is now

$$J = \begin{bmatrix} \Lambda & 0 & 0 & 0 \\ 0 & U_2 & 0 & 0 \\ 0 & 0 & U_3 & 0 \\ 0 & 0 & 0 & \bar{\Lambda} \end{bmatrix} = \begin{bmatrix} U_1 + iW & 0 & 0 & 0 \\ 0 & U_2 & 0 & 0 \\ 0 & 0 & U_3 & 0 \\ 0 & 0 & 0 & U_1 - iW \end{bmatrix}. \tag{1}$$

Defining $\Omega_1^2 = U_1^2 + W^2$, it is easily seen that there is an associated (diagonal, real symmetric) vibrating system:

$$L_0(\lambda) := \lambda^2 I_n - 2\lambda \begin{bmatrix} U_1 & 0 \\ 0 & \frac{1}{2}(U_2 + U_3) \end{bmatrix} + \begin{bmatrix} \Omega_1^2 & 0 \\ 0 & U_2 U_3 \end{bmatrix}. \tag{2}$$

It is simply a direct sum of the two diagonal systems

$$\lambda^2 I_{n-r} - 2\lambda U_1 + \Omega_1^2 = (\lambda I_{n-r} - \Lambda)(\lambda I_{n-r} - \overline{\Lambda})$$

and

$$\lambda^2 I_{2r} - \lambda(U_2 + U_3) + U_2 U_3 = (\lambda I_r - U_2)(\lambda I_r - U_3)$$

with nonreal and real eigenvalues, respectively.

Construct the abbreviations

$$U = \begin{bmatrix} U_1 & 0 \\ 0 & \frac{1}{2}(U_2+U_3) \end{bmatrix} \quad \text{and} \quad \Omega^2 = \begin{bmatrix} \Omega_1^2 & 0 \\ 0 & U_2U_3 \end{bmatrix} \tag{3}$$

so that (2) takes the form

$$L_0(\lambda) = \lambda^2 I - 2\lambda U + \Omega^2.$$

Now a particular linearization of $L_0(\lambda)$ is $\lambda I_{2n} - C_0$, where $C_0$ is the associated [illegible]:

$$C_0 := \begin{bmatrix} 0 & I_n \\ -\Omega^2 & 2U \end{bmatrix}. \tag{4}$$

Our objective is to generate vibrating systems whose companion matrices are similar to $C_0$, and which, consequently, are isospectral.

A first step in the analysis is to show that, under a weak assumption on the distribution of the [illegible] eigenvalues, an explicit similarity can be formulated which transforms the companion matrix $C_0$ into the diagonal matrix, $J$, of its eigenvalues. First, define a $2n \times 2n$ block matrix in terms of the blocks of $J$:

$$Z = \begin{bmatrix} \bar{\Lambda} & 0 & 0 & -I_{n-r} \\ 0 & -U_3 & I_r & 0 \\ 0 & -U_2 & -I_r & 0 \\ \Lambda & 0 & 0 & -I_{n-r} \end{bmatrix}. \tag{5}$$

LEMMA 1. [illegible]

$$\det(U_2 - U_3) \neq 0. \tag{6}$$

[illegible] $Z$ [illegible] $J$ [illegible] (1)

$$ZC_0Z^{-1} = J. \tag{7}$$

[illegible]. Elementary block operations can be applied to $Z$ to reduce it to the block triangular form

$$\begin{bmatrix} -2iW & 0 & I_{n-r} & 0 \\ 0 & U_2 - U_3 & 0 & I_r \\ 0 & 0 & -I_{n-r} & 0 \\ 0 & 0 & 0 & I_r \end{bmatrix}.$$

Since $W > 0$, it is apparent that $Z$ is nonsingular if and only if condition (6) is satisfied.

Then write $C_0$ in partitioned form consistent with that of $Z$:

$$C_0 = \begin{bmatrix} 0 & 0 & I_{n-r} & 0 \\ 0 & 0 & 0 & I_r \\ -\Omega_1^2 & 0 & 2U_1 & 0 \\ 0 & -U_2U_3 & 0 & U_2+U_3 \end{bmatrix}.$$

Now a simple calculation with block matrices shows that $ZC_0 = JZ$. Thus, when (6) holds, $Z$ is nonsingular and $ZC_0Z^{-1} = J$. □

Notice that condition (6), together with our standing hypotheses, ensures that the systems investigated here are [illegible] in the sense of Definition 8 of [15]. These conditions also appear in Theorem 7 of [14].

**3. Structure preserving similarities.** The following two-part definition reflects a definition introduced in the paper [10]. The underlying idea concerns similarity transformations of $C_0$ which preserve the companion matrix structure (and, necessarily, the spectrum, $\sigma$). For brevity, the term "SPS" (for structure preserving similarity) is introduced.

DEFINITION 2. [illegible] $V \in \mathbb{R}^{2n\times 2n}$ [illegible] $C_0$ [illegible]

$$C := VC_0V^{-1} = V \begin{bmatrix} 0 & I_n \\ -\Omega^2 & 2U \end{bmatrix} V^{-1} \tag{8}$$

[illegible] $C$ [illegible] $n \times n$ [illegible]

$$C = \begin{bmatrix} 0 & I_n \\ C_{21} & C_{22} \end{bmatrix}.$$

It is clear that all matrices $C$ of (8) determined by an SPS are isospectral with spectrum $\sigma$. Furthermore, the corresponding vibrating systems are isospectral [illegible] have real coefficients.

A simple lemma from [10] will be useful.

LEMMA 2 (see [10]). [illegible] $V \in \mathbb{R}^{2n\times 2n}$ [illegible] $n \times n$ [illegible] $V_{ij}$ [illegible] $C_0$ [illegible]

$$V_{21} = -V_{12}\Omega^2 \quad \text{[illegible]} \quad V_{22} = V_{11} + 2V_{12}U. \tag{9}$$

[illegible] With $V$ nonsingular, (8) is equivalent to

$$CV = V \begin{bmatrix} 0 & I_n \\ -\Omega^2 & 2U \end{bmatrix}.$$

Comparing blocks, it is found that $C_{11} = 0$ and $C_{12} = I_n$ if and only if (9) holds. □

[illegible] 1. A simple class of SPS is defined by matrices

$$V = \begin{bmatrix} A & 0 \\ 0 & A \end{bmatrix},$$

where $A$ is nonsingular. These transformations generate a narrow class of systems which are similar to the canonical system and for which the coefficients $M$, $D$, $K$ commute.

[illegible] 2. Another class of SPS is generated by nonsingular matrices $V$ which commute with $C_0$. They could be described as "automorphisms" because they satisfy $VC_0V^{-1} = C_0$; they transform $C_0$ into itself. Our interest is in transformations for which the greatest possible freedom in the coefficients is achieved (consistent with preservation of the spectrum).

**4. Jordan pairs and SPS.** A right eigenvector (say, $x_j \neq 0$) can be associated with each diagonal entry of $J$ (each eigenvalue), and these form the columns of an associated $n \times 2n$ matrix of eigenvectors, say, $X$. More generally, if $X \in \mathbb{C}^{n\times 2n}$, the pair $(X, J)$ (with $J$ as in (1)) forms a [illegible] if $\left[\begin{smallmatrix} X \\ XJ \end{smallmatrix}\right]$ is nonsingular.[1] It is well known (see [4], [9], or Chapter 14 of [12], for example) that a Jordan pair, together with a mass matrix $M$, defines a system completely.

---

[1] This guarantees, in particular, that every column of $X$ (every eigenvector) is nonzero.

Here, with our hypotheses on the spectrum, we may define an $n \times 2n$ matrix of eigenvectors of $L(\lambda)$ in the form

$$X = \left[\begin{array}{cccc} X_c & X_{R1} & X_{R2} & \overline{X_c} \end{array}\right], \tag{10}$$

where $X_c$ is an $n \times (n-r)$ matrix of (generally) nonreal eigenvectors corresponding to the eigenvalues in $\Lambda_1$, and matrices $X_{R1}$ and $X_{R2}$ are $n \times r$ real matrices of eigenvectors corresponding to the real eigenvalues in $U_2$ and $U_3$, respectively. Note that the structure of $X$ is consistent with that of $J$ in (1).

The following theorem establishes a one-to-one connection between Jordan pairs constructed in this way and matrices $V$ which define SPS transformations of $C_0$ as defined in Definition 2.

THEOREM 3. [illegible] $J$ [illegible] (1) [illegible] $\det(U_2 - U_3) \neq 0$

(a) [illegible] $X$ [illegible] (10) [illegible] $(X, J)$ [illegible] $Z$ [illegible] (5)

$$V = \left[\begin{array}{c} X \\ XJ \end{array}\right] Z \tag{11}$$

[illegible] $C_0$

(b) [illegible] $V$ [illegible] $C_0$ [illegible] $Z$ [illegible] (5) [illegible] $X$ [illegible] (10) [illegible] (11) [illegible] $(X, J)$ [illegible]

[illegible] By definition of a Jordan pair and using Lemma 1, it is found that $V$ of (11) is nonsingular. Then compute with block matrices to find

$$V_{21} = \left[\begin{array}{cc} (X_c + \overline{X_c})\Omega_1^2 & -(X_{R1} + X_{R2})U_2U_3 \end{array}\right],$$

$$V_{12} = \left[\begin{array}{cc} -(X_c + \overline{X_c}) & X_{R1} + X_{R2} \end{array}\right],$$

and it can be checked that $V_{21} = -V_{12}\Omega^2$. Similarly, it is found that

$$V_{11} = \left[\begin{array}{cc} X_c\overline{\Lambda} + \overline{X_c}\Lambda & -X_{R1}U_3 - X_{R2}U_2 \end{array}\right],$$

$$V_{22} = \left[\begin{array}{cc} -(X_c\Lambda + \overline{X_c\Lambda}) & X_{R1}U_2 + X_{R2}U_3 \end{array}\right],$$

and, finally, that $V_{22} = V_{11} + 2V_{12}U$. Now part (a) follows from Lemma 2, provided that $V$ is a real matrix.

However, using (5), it follows that

$$\begin{aligned} V &= \left[\begin{array}{cccc} X_c & X_{R1} & X_{R2} & \overline{X_c} \\ X_c\Lambda_1 & X_{R1}U_2 & X_{R2}U_3 & \overline{X_c\Lambda} \end{array}\right] Z \\ &= \left[\begin{array}{cccc} X_c\overline{\Lambda} + \overline{X_c}\Lambda & -X_{R1}U_3 - X_{R2}U_2 & X_{R1} + X_{R2} & -(X_c + \overline{X_c}) \\ (X_c + \overline{X_c})\Omega_1^2 & -(X_{R1} + X_{R2})U_2U_3 & X_{R1}U_2 + X_{R2}U_3 & -(X_c\Lambda_1 + \overline{X_c\Lambda_1}) \end{array}\right] \end{aligned} \tag{12}$$

and is clearly a real matrix (as Definition 2 requires).

For the converse, observe first that, under condition (6), $C_0Z^{-1} = Z^{-1}J$, and it follows from this equation that the columns of $Z^{-1}$ are right eigenvectors of $C_0$. If $V$ defines an SPS of $C_0$, then using the defining equation (8),

$$C = VZ^{-1}J(VZ^{-1})^{-1}. \tag{13}$$

Thus, the columns of $VZ^{-1}$ are eigenvectors of $C$. Since $C$ has the same spectrum as $C_0$ (and $J$), this matrix of eigenvectors can be written in the form

$$VZ^{-1} = \begin{bmatrix} X \\ XJ \end{bmatrix} = \begin{bmatrix} X_c & X_{R1} & X_{R2} & \overline{X_c} \\ X_c\Lambda & X_{R1}U_2 & X_{R2}U_3 & \overline{X_c\Lambda} \end{bmatrix}. \tag{14}$$

Thus, $X$ has the required form and, since $VZ^{-1}$ is nonsingular, $(X,\, J)$ form a Jordan pair. □

**5. Generating real isospectral systems.** Computational procedures for generating isospectral families of real systems can be formulated from the preceding analysis. This is done first in the language of SPS, and then in terms of Jordan pairs.

1. Fix the diagonal matrix of eigenvalues, $J$, with the form (1). Form matrices $Z$ of (5) and $C_0$ of (4).
2. Assign the $n \times 2n$ matrix of eigenvectors, $X$ with the form (10), in such a way that $(X,\, J)$ form a Jordan pair. (Clearly, this can be done in many ways.)
3. Compute $V = [{X \atop XJ}]Z$.
4. Compute $C = VC_0V^{-1}$ and read off the submatrices $M^{-1}K = -C_{21}$ and $M^{-1}D = -C_{22}$.
5. Assign a nonsingular real mass matrix $M$ and compute $K = -MC_{21}$, $D = -MC_{22}$.

The alternative procedure is based on the notion of a Jordan triple. Thus, given the Jordan pair of item 2 above, [illegible] a real nonsingular mass matrix $M$ and determine a $2n \times n$ matrix $Y$ satisfying

$$\begin{bmatrix} X \\ XJ \end{bmatrix} Y = \begin{bmatrix} 0 \\ M^{-1} \end{bmatrix}, \tag{15}$$

and $(X,\, J,\, Y)$ is known as a [illegible].

When $Y$ has been determined, the [illegible]

$$\Gamma_j = XJ^jY, \qquad j = 0, 1, 2, 3, \tag{16}$$

can be formed, and the system coefficients can be defined recursively in terms of the moments (see Theorem 2 of [9], for example):

$$M = \Gamma_1^{-1}, \qquad D = -M\Gamma_2M, \qquad K = -M\Gamma_3M + D\Gamma_1D. \tag{17}$$

The alternative procedure for generating an isospectral family of real systems is now as follows:

1. Fix the diagonal matrix of eigenvalues, $J$, with the form (1).
2. Assign the $n \times 2n$ matrix of eigenvectors, $X$ with the form (10), in such a way that $(X,\, J)$ form a Jordan pair. (Clearly, this can be done in many ways.)
3. Assign a nonsingular real mass matrix $M$ and solve (15) for $Y$.
4. Compute the moments (16) and hence the coefficients $D$ and $K$ from (17).

Consider first an obvious construction of isospectral systems. Given a set of eigenvalues with self-conjugate symmetry (as in (1)), the diagonal system $L_0(\lambda)$ of (2) has this spectrum. Then a class of real isospectral systems is obtained by applying a real strict equivalence transformation to $L_0(\lambda)$. Indeed, a class of real symmetric (resp., Hermitian) systems can be generated by applying a real (resp., complex) congruence. However, it is easily seen that with any of these constructions, each pair of eigenvalues determined by a diagonal entry of $L_0(\lambda)$ has a common eigenspace of dimension at least one. This property is generally unnatural for systems of physical origin, and our interest is in more general constructions.

3. We will construct a $4 \times 4$ real system with 4 real eigenvalues and 4 nonreal eigenvalues. Take a Jordan matrix of the form (1) with blocks

$$\Lambda = \operatorname{diag}[-1+i,\ -4+i], \quad U_2 = \operatorname{diag}[-0.5,\ -1], \quad U_3 = \operatorname{diag}[-3, -4].$$

Then take a matrix $X$ of the form (10) with blocks

$$X_c = \begin{bmatrix} 0.0625(1-i) & (0.6)(1-0.1i) \\ 0.2500(1-i) & (0.6)(1-0.1i) \\ 0.5625(1-i) & 0 \\ 1.0000(1-i) & (-1)(1-0.1i) \end{bmatrix},$$

$$X_{R1} = \begin{bmatrix} 1 & 1 \\ 1 & -1 \\ 1 & 1 \\ 1 & -1 \end{bmatrix}, \quad X_{R2} = \begin{bmatrix} 1 & 1 \\ 1 & 1 \\ -1 & 1 \\ -1 & -1 \end{bmatrix}.$$

It is found that this data generate the real monic system with

$$D = \begin{bmatrix} -6.0008 & 6.5981 & 5.8527 & -4.4416 \\ -8.4540 & 8.7557 & 6.1483 & -4.6190 \\ 7.2668 & -8.8863 & 6.8695 & -0.9717 \\ 22.9877 & -21.5283 & -5.2094 & 8.8756 \end{bmatrix},$$

$$K = \begin{bmatrix} -20.7791 & 15.4356 & 19.5039 & -13.4062 \\ -22.8678 & 16.8592 & 20.4793 & -13.8052 \\ 1.2225 & -7.0538 & 11.2192 & -3.4988 \\ 35.3128 & -32.9667 & -18.4409 & 18.4076 \end{bmatrix}.$$

These calculations can then be checked by showing that the eigenvalues of this monic system are, indeed, those specified in $J$.

**6. Symmetric systems, part 1.** The next objective is, of course, to determine the matrices $V$ defining an SPS of $C_0$, and which also generate systems. The question of when these coefficients satisfy positivity conditions will be considered later.

At this point it is necessary to introduce the rather subtle notion of the [2] associated with the real eigenvalues. (The reader is referred to the references listed in the footnote for formal definitions, but for the uninitiated, Appendix B gives an intuitive introduction to this important notion.) For systems with symmetries it is not enough to allocate arbitrary real eigenvalues; the invariants of the sign characteristic must also be specified. With our hypotheses on the spectrum, this can be accomplished by introducing the matrix

$$P = \begin{bmatrix} 0 & 0 & 0 & I_{n-r} \\ 0 & I_r & 0 & 0 \\ 0 & 0 & -I_r & 0 \\ I_{n-r} & 0 & 0 & 0 \end{bmatrix}. \tag{18}$$

---

[2] See [3], [4], [9], and the expository Appendix B to this paper.

Notice that, with $J$ of the form (1), $(PJ)^* = PJ$. Thus, although $J$ is generally not Hermitian, $PJ$ is so.

Symmetry of the coefficients of the system follows if a symmetric $M$ is chosen and, also, if $Y = PX^*$ is the only solution of (15). For then the $\Gamma$'s are Hermitian and, using (17), so are $D$ and $K$ (and when this is the case, $(X, J, PX^*)$ is said to be a [illegible]). If, in addition, $X$ has the block structure of (10), then the moments and the system coefficients will be real and symmetric.

Thus, if a self-adjoint triple is to be constructed, then (see (15)) $XY = XPX^* = 0$. Thus, once admissible matrices $J$ and $P$ have been assigned, the crux of the problem is to find an $X$ such that $XPX^* = 0$ and $X(PJ)X^*$ is nonsingular. In [9] a geometric approach is taken for the determination of such matrices $X$. Here, attention is focused on [illegible] systems so that the structure of (10) is also to be imposed on $X$. In this case, $XPX^* = 0$ can be written in the form

$$X_c X_c^T + \overline{X_c X_c^T} = -X_{R1} X_{R1}^T + X_{R2} X_{R2}^T. \tag{19}$$

Now this equation simply says that the real part of the matrix $X_c X_c^T$ takes the value $\frac{1}{2}(-X_{R1} X_{R1}^T + X_{R2} X_{R2}^T)$ and does not constrain the imaginary part.

Consequently, it follows from (19) that

$$X_c X_c^T = R_1 - iR, \tag{20}$$

where

$$R_1 := \frac{1}{2}(-X_{R1} X_{R1}^T + X_{R2} X_{R2}^T) = \begin{bmatrix} X_{R1} & X_{R2} \end{bmatrix} \begin{bmatrix} -I_r & 0 \\ 0 & I_r \end{bmatrix} \begin{bmatrix} X_{R1}^T \\ X_{R2}^T \end{bmatrix} \tag{21}$$

and $R$ is a real symmetric matrix.

Notice also that, if $R_1 - iR$ is designed to have rank $n - r$, then $\operatorname{rank}(X_c) \geq n - r$. (To see that equality need not be the case, consider the product $A_0 A_0^T$ where $A_0 = \begin{bmatrix} 1 & i \\ i & -1 \end{bmatrix}$.)

The broad strategy suggested here is to assign all the real eigenvectors, and hence the matrix $R_1$. Generically, it can be expected that the eigenvectors associated with the eigenvalues in the upper half-plane will be linearly independent. Thus, the matrix $X_c \in \mathbb{C}^{n \times (n-r)}$ of (10) will have full rank, $n - r$. Now there is a standard method for finding a symmetric factorization of a complex symmetrix matrix (as required in (20)), in which the rank of the factors is equal to that of the given right-hand side. So the problem reduces to the following: Given $R_1$, with rank determined by the choice of real eigenvectors, find an $R$ such that $R_1 - iR$ has rank $n - r$.

The "standard method" for symmetric factorization referred to above was developed by Takagi in the 1920s. A quick introduction, based on the exposition and algorithm of [1], is given in Appendix A of this paper.

It is instructive to consider a simple example at this stage.

[illegible] 4. We construct a $2 \times 2$ system with two real eigenvalues and one complex pair. The spectral data are

$$J = \begin{bmatrix} -2+i & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -2 & 0 \\ 0 & 0 & 0 & -2-i \end{bmatrix}, \quad P = \begin{bmatrix} 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 1 & 0 & 0 & 0 \end{bmatrix}.$$

(a) We first prescribe the [illegible] eigenvectors:

$$X_{R1} = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \qquad X_{R2} = \begin{bmatrix} 0 \\ 1 \end{bmatrix}.$$

Then calculate to find

$$R_1 = \frac{1}{2}(-X_{R1}X_{R1}^T + X_{R2}X_{R2}^T) = \begin{bmatrix} -\frac{1}{2} & 0 \\ 0 & \frac{1}{2} \end{bmatrix}.$$

Choosing

$$R = \begin{bmatrix} 0 & \frac{1}{2} \\ \frac{1}{2} & 0 \end{bmatrix}$$

yields the rank one matrix

$$R_1 - iR = \frac{1}{2}\begin{bmatrix} -1 & -i \\ -i & 1 \end{bmatrix},$$

and this has the factorization (cf. (20)) $R_1 - iR = X_c X_c^T$, where

$$X_c = \frac{1}{\sqrt{2}}\begin{bmatrix} -i \\ 1 \end{bmatrix}.$$

Now compute with (16) and (17) to find the real symmetric system

$$M = \begin{bmatrix} 0 & 1 \\ 1 & -1 \end{bmatrix}, \quad D = \begin{bmatrix} 1 & 3 \\ 3 & -5 \end{bmatrix}, \quad K = \begin{bmatrix} 1 & 2 \\ 2 & -6 \end{bmatrix},$$

and it can be checked that the spectrum is, indeed, that prescribed.

(b) In contrast to (a), if $X_{R1} = X_{R2} = \left[\begin{smallmatrix} 1 \\ 0 \end{smallmatrix}\right]$, then $R_1 = 0$ and $R$ is chosen so that $R_1 - iR$ has rank one, say $R = \begin{bmatrix} 0 & 0 \\ 0 & -1 \end{bmatrix}$, so that $R_1 - iR = \begin{bmatrix} 0 & 0 \\ 0 & i \end{bmatrix}$, in which case we take

$$X_c = \begin{bmatrix} 0 \\ e^{i\pi/4} \end{bmatrix} = \begin{bmatrix} 0 \\ \frac{1}{\sqrt{2}}(1+i) \end{bmatrix}$$

and

$$X = \begin{bmatrix} 0 & 1 & 1 & 0 \\ \frac{1}{\sqrt{2}}(1+i) & 0 & 0 & \frac{1}{\sqrt{2}}(1-i) \end{bmatrix}.$$

Following the steps above, it is found that this determines the [illegible] system,

$$M = \begin{bmatrix} 1 & 0 \\ 0 & -\frac{1}{2} \end{bmatrix}, \quad D = \begin{bmatrix} 3 & 0 \\ 0 & -2 \end{bmatrix}, \quad K = \begin{bmatrix} 2 & 0 \\ 0 & \frac{-5}{2} \end{bmatrix}.$$

The fact that the system is diagonal can be attributed to the choice of linearly dependent real eigenvectors (see the discussion before Example 3).

An interesting feature of Example 4 is the fact that $R$ is first chosen to [illegible] the rank of $R_1 - iR$ relative to that of $R_1$. Clearly, this was necessary, as $X_c$ must have rank one. In the second case, $R$ is chosen to augment the rank of $R_1$. Features of this kind are a major difficulty in the design of a general strategy for finding solutions to (19). Notice also that the necessary condition that $X$ have full rank was guaranteed by our choice of the real eigenvectors the first time around, but not the second.

Another approach to the determination of solutions of (19) begins with assigning a [illegible] matrix of eigenvectors $X_c$ and then solving (19) for real matrices $X_{R1}$ and $X_{R2}$. This line of attack is postponed to a future investigation.

**7. Symmetric systems, part 2.** The problem of finding matrices $X$ of the form (10) which also satisfy $XPX^* = 0$ has been reformulated in the form of (20), where $R_1$ is given by (21). This matrix is to be assigned, and then a real symmetric matrix $R$ is to be chosen in such a way that $R_1 - iR$ has rank $n - r$. To ensure that both real and nonreal eigenvalues appear, it is assumed that $1 \leq r \leq n - 1$.

It appears that the rank of $R_1$ can take any value between zero (when $X_{R2} = X_{R1}$) and $n$ (when the real eigenvectors span the whole space). A complete understanding of our problem seems to require knowledge of the connections between

$$\operatorname{rank}(R_1), \quad \operatorname{rank}(R), \quad \text{and} \quad \operatorname{rank}(R_1 - iR).$$

As this seems not to be well known, the details are provided in Appendix C. In particular, Theorem 9 shows that, to achieve

$$n - r = \operatorname{rank}(R_1 - iR) < \operatorname{rank}(R_1),$$

which can certainly be physically reasonable, $R$ must be chosen so that $\pm i$ become eigenvalues of the real symmetric pencil $R_1 - \lambda R$. Now this phenomenon arose in Example 4, apparently fortuitously! But, in fact, Theorem 9 shows that this choice of $R$ was essentially unique.

More generally, notice that although the factor

$$\begin{bmatrix} -I_r & 0 \\ 0 & I_r \end{bmatrix}$$

in (21) has rank $2r$, the "modified" matrix

$$\begin{bmatrix} -I_r & iI_r \\ iI_r & I_r \end{bmatrix}$$

has rank $r$ with eigenvalues $\pm i$ repeated $r$ times. Thus, by choosing

$$R = \begin{bmatrix} X_{R1} & X_{R2} \end{bmatrix} \begin{bmatrix} 0 & I_r \\ I_r & 0 \end{bmatrix} \begin{bmatrix} X_{R1}^T \\ X_{R2}^T \end{bmatrix}, \tag{22}$$

$$R_1 - iR = \begin{bmatrix} X_{R1} & X_{R2} \end{bmatrix} \begin{bmatrix} -I_r & iI_r \\ iI_r & I_r \end{bmatrix} \begin{bmatrix} X_{R1}^T \\ X_{R2}^T \end{bmatrix},$$

we introduce eigenvalues $\pm i$ of multiplicity $r$ into the pencil $R_1 - iR$. Modifications of this definition for $R$ are easily devised to generate real symmetric matrices $R_1 - iR$ with rank $\rho$, where $r \leq \rho \leq 2r$.

If $R_1$ has rank $n - r$, then by choosing an $R$ with the same range as $R_1$, an $R_1 + iR$ can be constructed with the same rank, $n - r$. However, with this construction, the necessary condition that the range of $X$ have dimension $n$ cannot be satisfied. Indeed, there seems to be a difficult problem here when the rank of $R_1$ is low. There may be a deep property that is not fully understood to the effect that, although linear dependencies among the real eigenvectors are known to be possible, the dimension of the span of the real eigenvectors cannot be "too low." The parameters used in Theorem 9 of Appendix C will probably play a role in any resolution of this problem. Indeed, the sets of admissible parameters can be analyzed using the canonical forms found in Theorem 9.2 of [11] and described in Appendix C.

These techniques are not investigated more deeply here, and we conclude the present discussion with a numerical illustration.

5. The program here is to take the data from Example 3, which were used in the design of a real (nonsymmetric) system, augment it with a sign characteristic, and design a real system. Thus, as in Example 3, we take $n = 4$, $r = 2$, and

$$\Lambda = \operatorname{diag}[-1+i,\ -4+i], \quad U_2 = \operatorname{diag}[-0.5,\ -1], \quad U_3 = \operatorname{diag}[-3, -4].$$

Now consider (20). Since there are two pairs of nonreal eigenvalues, $X_c$ is to be constructed with rank 2. Following the strategy leading to (22) results in

$$A = R_1 + iR = \begin{bmatrix} 2i & 1+i & -1+i & -1-i \\ & 0 & 0 & -2 \\ & & 0 & -2i \\ & & & 0 \end{bmatrix}.$$

Notice that $R_1$ is defined by the data of Example 3 and $R$ is chosen as in (22). Using the Takagi algorithm, we obtain

$$X_c = \begin{bmatrix} -1.0082(1+i) & 0.1281(-1+i) \\ -0.8801 & (-0.8801)i \\ (-0.8801)i & 0.8801 \\ 1.1362 & (-1.1362)i \end{bmatrix},$$

and construction of the $4 \times 8$ matrix $X$ is complete.

The Jordan matrix is now $\operatorname{diag}[-1+i,\ -4+i,\ -0.5,\ -1,\ -3,\ -4,\ -1-i,\ -4-i]$, and (see (18))

$$P = \begin{bmatrix} 0 & 0 & 0 & I_2 \\ 0 & I_2 & 0 & 0 \\ 0 & 0 & -I_2 & 0 \\ I_2 & 0 & 0 & 0 \end{bmatrix}.$$

It can be verified that $XPX^* = 0$, and the formulae of (16) and (17) are applied to produce the real symmetric system:

$$M = \begin{bmatrix} 0.4496 & -0.3267 & 1.6481 & -0.2840 \\ & 0.2748 & -0.6290 & 0.0519 \\ & & 0.8991 & 0.2533 \\ & & & -0.0696 \end{bmatrix},$$

$$D = \begin{bmatrix} -8.4914 & 4.2104 & 4.9463 & -4.5620 \\ & -1.6488 & -0.6350 & 1.7465 \\ & & 6.5591 & -1.7314 \\ & & & -0.3876 \end{bmatrix},$$

$$K = \begin{bmatrix} 0.4612 & -3.0335 & -4.5721 & 4.8244 \\ & 3.8425 & 6.4105 & -5.2257 \\ & & 12.0600 & -9.8717 \\ & & & 7.8178 \end{bmatrix}.$$

As usual, it can be verified that this system has the spectrum determined by $J$. It is interesting that, in spite of the location of all the eigenvalues in the left half-plane, [illegible] coefficients are indefinite.

Of course, the analysis simplifies if there are to be [illegible] real eigenvalues (as in [10]), for then $X_c$ is nonsingular and it is necessary only to assign a nonsingular real symmetric $R$. On the other hand, if $X_c$ is a solution of (19), so is $X_c\Theta$ for any real orthogonal matrix $\Theta$. Thus, for a fixed right-hand side of (19), a family of solutions $X$ is obtained depending on $\frac{1}{2}(n-r)(n-r-1)$ real parameters. This is consistent with results obtained in [10] for the case $r = 0$.

The situation in which there are no [illegible] eigenvalues is also of great interest and includes the so-called overdamped, hyperbolic, and quasi-hyperbolic systems. They are the topics of section 10 below.

**8. Positivity of $M$, $D$, and $K$.** In this section it is assumed that the spectral data are consistent with real and symmetric systems, and we examine the further conditions required to ensure positive definite (or possibly semidefinite) coefficients $M$, $D$, $K$. It will be convenient to make a further simplifying hypothesis, namely, that systems are to be designed which are [illegible]. This is equivalent to the hypothesis that $K$ is nonsingular. This can be justified here on the grounds that, in this section, our major interest is in [illegible] systems, i.e., those with all eigenvalues in the open left half of the complex plane. In other words, $J$ of (1) is to be a stable matrix.

In this case there is a nice alternative to the formula

$$K = -M\Gamma_3 M + D\Gamma_1 D$$

of (17) (see Theorem 2 of [10], for example). Thus, given a self-adjoint triple ($X$, $J$, $PX^*$), we have

$$\Gamma_{-1} := X(J^{-1}P)X^* = -K^{-1}. \tag{23}$$

This follows immediately from the [illegible] for $L(\lambda)$ expressed here in terms of any Jordan triple:

$$L(\lambda)^{-1} = X(\lambda I_{2n} - J)^{-1}Y.$$

LEMMA 4. [illegible] $J$ [illegible] $\Gamma_1$ [illegible] $M$, $D$, $K$ [illegible] $\Gamma_1$ $-\Gamma_2$ [illegible] $-\Gamma_{-1}$ [illegible]

[illegible]. Observe that, if 0 is not an eigenvalue of $J$, then $\Gamma_{-1}$ is well defined, and the lemma follows from the first two relations of (17) together with (23). □

Since the moments are readily computed from a Jordan triple, this immediately suggests that the positivity of $M$, $D$, $K$ could be checked by trial and error. However, a more precise result can be proved, which generalizes Theorem 9 of [10]. Notice the important role played by positivity of the [illegible] moment in this result.

THEOREM 5. [illegible] $J$ [illegible] $\Gamma_2 \leq 0$ [illegible] $\Gamma_1, \Gamma_{-1}$ [illegible] $M > 0$ $D \geq 0$, [illegible] $K > 0$

[illegible]. Since $\Gamma_1$ and $\Gamma_{-1}$ are nonsingular, $M$ and $K$ are well defined by (17) and (23). Then the stability of $J$, together with Theorem 7 of [13], implies that $M > 0$ and $K > 0$. Then $D \geq 0$ follows from $\Gamma_2 \leq 0$ and (17). □

Note that there is, of course, a classical converse statement for Theorem 5: If $M > 0$, $D \geq 0$, and $K > 0$, then all eigenvalues are in the (possibly closed) left half-plane.

In general, it will be difficult to apply the last result numerically ab initio. A major open question (to which partial contributions are made here) is the following.

[illegible] 1. Given that the spectrum is stable, what further conditions on $X$ (the matrix of [illegible]) will ensure that the coefficients of the system are positive definite?

A closely connected question arising in section 7 is as follows.

[illegible] 2. What are the constraints linking the dimensions of the ranges of the matrices $\begin{bmatrix} X_{R1} & X_{R2} \end{bmatrix}$ and $\begin{bmatrix} X_c & \overline{X_c} \end{bmatrix}$?

[illegible] 6. Reconsider Example 4. Modify the data and take $X_{R1} = X_{R2} = \begin{bmatrix} 1 \\ 0 \end{bmatrix}$, and retain the same matrices $J$ and $P$. Now $R_1 = 0$ and we choose $R = \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}$. It is found that a diagonal system with positive definite coefficients is generated:

$$M = \begin{bmatrix} 1 & 0 \\ 0 & 0.5 \end{bmatrix}, \quad D = \begin{bmatrix} 3 & 0 \\ 0 & 2 \end{bmatrix}, \quad K = \begin{bmatrix} 2 & 0 \\ 0 & 2.5 \end{bmatrix}.$$

**9. Hyperbolic and overdamped systems.** For the purpose of this discussion, consider systems with a positive definite leading coefficient, $M$. It is well known that there are symmetric vibrating systems of practical interest for which all eigenvalues are real. An early and influential paper on this subject was that of Duffin [2] concerning overdamped systems. Subsequently, it has been realized that systems with real spectrum arise more generally. Thus, systems with all $2n$ eigenvalues real with $n$ of positive type (with a $+1$ in the sign characteristic) and $n$ of negative type (with a $-1$ in the sign characteristic) are said to be [illegible]. If, furthermore, the sets of eigenvalues of the two types are separated (all positive-type eigenvalues greater than all negative-type eigenvalues), then the system is [illegible]. Finally, a system which is hyperbolic and in which $D > 0$, $K \geq 0$ is said to be [illegible]. Given these inequalities it is equivalent to say that a hyperbolic system is overdamped if all eigenvalues are negative. (Numerical methods for such problems are the topic of [7] and [6], for example.)

The distinction between these classes of systems is quite clear in our context of inverse problems. Let us begin with hyperbolic systems. Thus, all eigenvalues are real, and the data for the inverse problem consist of diagonal matrices

$$J = \begin{bmatrix} U_2 & 0 \\ 0 & U_3 \end{bmatrix}, \quad P = \begin{bmatrix} I_n & 0 \\ 0 & -I_n \end{bmatrix} \tag{24}$$

(cf. (1) and (18)). Furthermore, the smallest eigenvalue of $U_2$ (having positive type) exceeds the largest eigenvalue of $U_3$ (having negative type). Thus,

$$\max_{u_j \in U_3}(u_j) < \min_{u_k \in U_2}(u_k). \tag{25}$$

Then the necessary condition (6) of Lemma 1 is satisfied.

For the more general quasi-hyperbolic systems, $U_2$ and $U_3$ are simply specified in such a way that (6) holds but (25) does not necessarily hold.

Now an isospectral family of quasi-hyperbolic systems with spectrum defined by $U_2$ and $U_3$ is determined by full rank eigenvector matrices

$$X = \begin{bmatrix} X_{R1} & X_{R2} \end{bmatrix},$$

where $X_{R1}, X_{R2} \in \mathbb{R}^{n \times n}$ and

$$XPX^* = X_{R1}X_{R1}^T - X_{R2}X_{R2}^T = 0$$

(cf. (10), (19)). This condition is easily satisfied: Since $X$ has full rank, both $X_{R1}$ and $X_{R2}$ must be nonsingular, so we may take an arbitrary $A > 0$ in $\mathbb{R}^{n\times n}$ and then choose $X_{R1}$ and $X_{R2}$ so that

$$X_{R1}X_{R1}^T = X_{R2}X_{R2}^T = A. \tag{26}$$

Natural choices for $X_{R1}$ and $X_{R2}$ are then $A^{1/2}$, or a lower triangular matrix generated by a Cholesky factorization of $A$ (see [5], for example). Having made a first choice of $X_{R1}$ and $X_{R2}$, infinitely many more candidates are generated by multiplying on the right with a real orthogonal matrix. In particular, once a nonsingular $X_{R1}$ is chosen, one may take

$$X_{R2} = X_{R1}\Theta,$$

where $\Theta$ is real orthogonal. We adopt this strategy.

Then it is easily verified that the following formulae hold: For the moments,

$$\begin{aligned} \Gamma_1 &= X_{R1}(U_2 - \Theta U_3\Theta^T)X_{R1}^T, \\ \Gamma_2 &= X_{R1}(U_2^2 - \Theta U_3^2\Theta^T)X_{R1}^T, \\ \Gamma_{-1} &= X_{R1}(U_2^{-1} - \Theta U_3^{-1}\Theta^T)X_{R1}^T, \end{aligned} \tag{27}$$

and for the coefficients,

$$\begin{aligned} M &= X_{R1}^{-T}(U_2 - \Theta U_3\Theta^T)^{-1}X_{R1}^{-1}, \\ D &= -X_{R1}^{-T}(U_2 - \Theta U_3\Theta^T)^{-1}(U_2^2 - \Theta U_3^2\Theta^T)(U_2 - \Theta U_3\Theta^T)^{-1}X_{R1}^{-1}, \\ K &= -X_{R1}^{-T}(U_2^{-1} - \Theta U_3^{-1}\Theta^T)^{-1}X_{R1}^{-1}. \end{aligned} \tag{28}$$

It is immediately apparent that $X_{R1}$ merely determines a simultaneous congruence applied to the three system coefficients. Once the spectrum is specified in the form of $U_2$ and $U_3$, the coefficients are determined (to within this simultaneous congruence) by the choice of $\Theta$. Thus, the [illegible] of $M$, $D$, $K$ do not depend on $X_{R1}$. (A similar phenomenon arises in the case when all eigenvalues are [illegible]; see (34)–(36) and Theorem 13 of [10].)

Theorem 5 now provides criteria for generating families of real hyperbolic systems.

Corollary 6. [illegible] $\Lambda$ [illegible] $W$ [illegible] (1) [illegible] $U_2 < 0$ $U_3 < 0$ [illegible] $\det(U_2 - U_3) \neq 0$ [illegible]

(a) $X_{R1} \in R^{n\times n}$ [illegible]

(b) $\Theta$ [illegible]

$$U_2^2 \leq \Theta U_3^2\Theta^T \tag{29}$$

[illegible] $U_2 - \Theta U_3\Theta^T$ $U_2^{-1} - \Theta U_3^{-1}\Theta^T$ [illegible]

[illegible] (28)) $M > 0$ $D \geq 0$ $K > 0$ [illegible] $M\lambda^2 + D\lambda + K$ [illegible]

[illegible] (25) [illegible]

[illegible]. Condition (29) and the equation for $\Gamma_2$ in (27) ensure that $\Gamma_2 \geq 0$. Also, from (27), $\Gamma_1$ and $\Gamma_{-1}$ are nonsingular. So the result follows from Theorem 5. ☐

7. Clearly, given the hypotheses of the corollary on $U_2$ and $U_3$, $X_{R1} = I_n$ and $\Theta = I_n$ are admissible choices. If we write

$$U_2 = \operatorname{diag}[\mu_1^{(2)}, \mu_2^{(2)}, \dots, \mu_n^{(2)}], \quad U_3 = \operatorname{diag}[\mu_1^{(3)}, \mu_2^{(3)}, \dots, \mu_n^{(3)}],$$

(28) determines the diagonal system with diagonal entries

$$\frac{\lambda^2 - (\mu_j^{(2)} + \mu_j^{(3)})\lambda + \mu_j^{(2)}\mu_j^{(3)}}{\mu_j^{(2)} - \mu_j^{(3)}} = \frac{(\lambda - \mu_j^{(2)})(\lambda - \mu_j^{(3)})}{\mu_j^{(2)} - \mu_j^{(3)}}.$$

8. Take $X_{R1} = I_4$ and

$$U_2 = \operatorname{diag}[-1,\ -2,\ -3,\ -4], \qquad U_3 = \operatorname{diag}[-5,\ -6,\ -7,\ -8].$$

Consider the orthogonal matrix

$$\Theta = \frac{1}{10}\begin{bmatrix} 2 & -8 & 4 & -4 \\ 8 & -2 & -4 & 4 \\ 4 & 4 & -3 & -8 \\ 4 & 4 & 8 & 2 \end{bmatrix}$$

and verify that the hypotheses of the corollary are satisfied. Apply the formulae of (28) to generate the overdamped system (with truncated decimal form)

$$M = \begin{bmatrix} 0.1886 & 0.0269 & -0.0168 & -0.0051 \\ & 0.2896 & 0.0690 & 0.0707 \\ & & 0.2694 & 0.0808 \\ & & & 0.42342 \end{bmatrix},$$

$$D = \begin{bmatrix} 1.3771 & 0.0808 & -0.0673 & -0.0253 \\ & 2.1582 & 0.3451 & 0.4242 \\ & & 2.6162 & 0.5657 \\ & & & 4.3939 \end{bmatrix},$$

$$K = \begin{bmatrix} 1.1886 & 0.0539 & -0.0505 & -0.0202 \\ & 3.1582 & 0.4141 & 0.5657 \\ & & 5.4242 & 0.9697 \\ & & & 10.7879 \end{bmatrix},$$

with eigenvalues $-1$, $-2$, $-3$, $-4$ of positive type, and $-5$, $-6$, $-7$, $-8$ of negative type. An associated matrix of eigenvectors has the form

$$X = [\ I \quad \Theta\ ] = \begin{bmatrix} 1 & 0 & 0 & 0 & 0.2 & -0.8 & 0.4 & -0.4 \\ 0 & 1 & 0 & 0 & 0.8 & -0.2 & -0.4 & 0.4 \\ 0 & 0 & 1 & 0 & 0.4 & 0.4 & -0.2 & -0.8 \\ 0 & 0 & 0 & 1 & 0.4 & 0.4 & 0.8 & 0.2 \end{bmatrix}.$$

**10. Conclusions.** Real damped vibrating systems defined by $n \times n$ coefficient matrices $M$, $D$, and $K$ have been studied, with the simplifying hypothesis of semi-simple Jordan structure, i.e., associated $2n \times 2n$ Jordan canonical forms, $J$, are diagonal. A corresponding primitive companion matrix, $C_0$, is formulated (equation (4)) and plays a significant role. The equivalence between "structure preserving similarities" of $C_0$ and Jordan pairs for the system has been established in Theorem 3.

These constructions have been used to find solutions to the following inverse problem: Given $J$, find consistent real vibrating systems (see section 5). The corresponding problem for consistent [illegible] real systems (with mixed real and nonreal spectrum) is more complicated. A partial solution for this problem (taking advantage of Takagi's factorization of symmetric complex matrices) is the subject of sections 6 and 7. To ensure that coefficient matrices $M$, $D$, $K$ have definiteness properties is more difficult again, but significant insight is provided in section 8 in terms of "moments" of the system.

Similar methods applied to systems having [illegible] real eigenvalues are more tractable (and include systems of hyperbolic and overdamped types). They are developed in section 9, where parametrizations of isospectral systems by real orthogonal matrices arise naturally. This compares nicely with similar results of [10] for systems at the other (elliptic) extreme with [illegible] real eigenvalues.

The analysis developed here requires knowledge of the relationship between the ranks of a complex symmetric matrix and its real and imaginary parts. This is clarified in Theorem 9 of Appendix C. The result seems to be new and may be of more general interest.

**Appendix A. Takagi's factorization.** A method for making the factorization needed in sections 6 and 7 is attributed to Takagi and dates from the 1920s. For a given complex symmetric matrix $A \in \mathbb{C}^{n\times n}$ of rank $n-r$, a factorization $A = X_c X_c^T$ is produced in which $X_c$ also has rank $n-r$. Computer programs are now available for this task (see Bunse-Gerstner and Gragg [1]). There is also a careful discussion of this in section 4.4.4 of Horn and Johnson [8]. Here, an introduction is made to the relatively simple case in which nonzero singular values of the right-hand side of (20) (i.e., when $A = R_1 - iR$) are distinct. It is based on the presentation of [1].

1. Let $A$ denote the (given) complex symmetric right-hand side of (20) and assume that $\operatorname{rank}(A) = n-r$. Form the singular value decomposition $A = U\Sigma V^*$, where $U$ and $V$ are unitary matrices and
$$\Sigma = \operatorname{diag}\begin{bmatrix} \sigma_1 & \sigma_2 & \cdots & \sigma_n \end{bmatrix}$$
with $\sigma_1 > \sigma_2 > \cdots > \sigma_{n-r} > 0$ and $\sigma_{n-r+1} = \ldots = \sigma_n = 0$ (see [5] for further details).
2. Let $u_j$ and $v_j$ denote the columns of $U$ and $V$, respectively, and compute $q_j^2 := u_j^T v_j$, $j = 1, 2, \ldots, n-r$ (note that $q_j^2$ will generally be complex).
3. Form $\Sigma_1 := \operatorname{diag}\begin{bmatrix} \sigma_1 & \sigma_2 & \cdots & \sigma_{n-r} \end{bmatrix}$ of size $(n-r)\times(n-r)$ and form the $n\times(n-r)$ matrix $U_0 = \begin{bmatrix} u_1 & u_2 & \cdots & u_{n-r} \end{bmatrix}$.
4. Compute a matrix $Q = \operatorname{diag}\begin{bmatrix} q_1 & q_2 & \cdots & q_{n-r} \end{bmatrix}$.
5. Compute $X_c = U_0 \bar{Q} \Sigma_1^{1/2}$ (of size $n\times(n-r)$).

Let us quickly confirm that this produces the required symmetric factorization. Since $A$ is symmetric,

$$A = U\Sigma V^* = \overline{V}\Sigma U^T.$$

But the singular vectors for the (distinct) nonzero singular values are unique to within a scalar multiplier of modulus one. Thus, there are numbers $\omega_1, \ldots, \omega_{n-r}$ such that

$$v_j = \omega_j \overline{u_j}, \quad |\omega_j| = 1, \quad j = 1, 2, \ldots, n-r.$$

Defining $U_0$ as in item 3, $V_0 = \begin{bmatrix} v_1 & \cdots & v_{n-r} \end{bmatrix}$ and $\Omega = \operatorname{diag}\begin{bmatrix} \omega_1 & \ldots & \omega_{n-r} \end{bmatrix}$, we have $V_0 = \overline{U_0}\Omega$, or

$$V_0^* = \overline{\Omega} U_0^T.$$

Furthermore, $u_j^T v_j = \omega_j (u_j^T \overline{u_j}) = \omega_j$ for $j = 1, 2, \ldots, n-r$, so that (see item 4) $\Omega = Q^2$.

Now compute

$$\begin{aligned} X_c X_c^T &= (U_0 \overline{Q} \Sigma^{\frac{1}{2}})(\Sigma^{\frac{1}{2}} \overline{Q} U_0^T) \\ &= U_0 \Sigma \overline{Q}^2 U_0^T = U_0 \Sigma (\overline{\Omega} U_0^T) \\ &= U_0 \Sigma V_0^* = U \Sigma V^* = A. \end{aligned}$$

The purpose of the next example is simply to illustrate this scheme. Calculations are completed in MATLAB.

[illegible] 9. Let $A = \begin{bmatrix} i & i \\ i & 0 \end{bmatrix}$ and note that $n = 2$, $r = 0$ (so no singular values are equal to zero). The MATLAB singular value decomposition yields (with truncated numbers)

$$U = \begin{bmatrix} -0.8507 & -0.5257 \\ -0.5257 & 0.8507 \end{bmatrix} i, \qquad V = \begin{bmatrix} -0.8507 & 0.5257 \\ -0.5257 & -0.8507 \end{bmatrix}.$$

Also, $\sigma_1^2 = (1 + \sqrt{5})/2$, and $\sigma_2^2 = (1 - \sqrt{5})/2$. It is found that $q_1^2 = i$ and $q_2^2 = -i$, and then $q_1 = \frac{\sqrt{2}}{2}(1 + i)$, $q_2 = \frac{\sqrt{2}}{2}(1 - i)$. Finally,

$$X_c = U \bar{Q} \Sigma^{1/2} = \begin{bmatrix} -0.7651(1+i) & 0.2923(1-i) \\ -0.4729(1+i) & -0.4729(1-i) \end{bmatrix}.$$

It can be verified that, indeed, $X_c X_c^T = A$.

**Appendix B. The sign characteristic and an expository example.** We first indicate that the sign characteristic is an intrinsic property of the matrix function $L(\lambda) := \lambda^2 M + \lambda D + K$, where $M$, $D$, $K$ are Hermitian and $M$ is nonsingular. For simplicity, and in the spirit of this exposition, it is assumed that all eigenvalues of $L(\lambda)$ are semisimple. The following theorem is a special case of Theorem 3.7 of [3].

Theorem 7. [illegible] $L(\lambda)$ [illegible] $\mu_1(\lambda), \ldots, \mu_n(\lambda)$ [illegible] $\lambda$ [illegible]

$$\det(\mu_j(\lambda) I - L(\lambda)) = 0, \quad j = 1, 2, \ldots, n.$$

[illegible] $\lambda_1, \ldots, \lambda_r$ [illegible] $L(\lambda)$ [illegible] $i$ $1 \le i \le r$ [illegible]

$$\mu_j(\lambda) = (\lambda - \lambda_i) \nu_{ij}(\lambda), \quad \nu_{ij}(\lambda_i) \neq 0. \tag{30}$$

[illegible] $(\nu_{ij}(\lambda_i))$ [illegible] $\lambda_i$ [illegible]

For each real eigenvalue $\lambda_i$ of $L(\lambda)$ there must be at least one function $\mu_j(\lambda)$ which vanishes at $\lambda = \lambda_i$. Thus, implicitly, (30) determines a function $\mu_j(\lambda)$ of the matrix function $L(\lambda)$ which vanishes at $\lambda_i$. Since $\mu_j'(\lambda_i) = \nu_{ij}(\lambda_i)$, the sign characteristic tells us whether this particular function has a positive or negative slope at $\lambda_i$.

Now, for illustration, consider the problem of constructing 2×2 symmetric systems with the simple (mixed) spectrum: 1, −1, i, −i. One such system is obvious, namely, the monic system

$$L(\lambda) = \begin{bmatrix} \lambda^2 - 1 & 0 \\ 0 & \lambda^2 + 1 \end{bmatrix}. \tag{31}$$

Let us first examine the [illegible] problem for this system. Using the theorem above, it is easily seen that the sign characteristic associated with the real eigenvalues $\{1,\ -1\}$ of this system is $\{+1,\ -1\}$. Then observe that this system has associated matrices

$$X = \begin{bmatrix} 0 & 1 & 1 & 0 \\ 1 & 0 & 0 & 1 \end{bmatrix}, \quad J = \begin{bmatrix} i & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -i \end{bmatrix}, \quad P = \begin{bmatrix} 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 1 & 0 & 0 & 0 \end{bmatrix}. \tag{32}$$

Since $\det\left[\begin{smallmatrix} X \\ XJ \end{smallmatrix}\right] \neq 0$, $(X,\ J)$ form a Jordan pair. However,

$$Y := \begin{bmatrix} X \\ XJ \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ M \end{bmatrix} \neq PX^*,$$

so $(X,\ J)$ is not part of a [illegible]. The eigenvectors must be renormalized to achieve this. (Such a renormalization leaves the moments and the coefficients invariant.) It is found that if we set $\kappa = e^{-i\pi/4}$ and define

$$X = \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 1 & 1 & 0 \\ \kappa & 0 & 0 & \overline{\kappa} \end{bmatrix},$$

then $Y = PX^*$. It is now a matter of computation to verify that (16) and (17) lead back to the coefficients of system (31).

Now consider the inverse problem in which the data consist of matrices $J$ and $P$ of (32). Observe first that $X_{R1}$ and $X_{R2}$ will be $2 \times 1$ vectors and, to find an $X_c$ of rank one, it is convenient to assume that $X_{R1}$ and $X_{R2}$ are linearly dependent (see section 6). Indeed, with $\alpha, \beta \in \mathbb{R}$ let us take $X_{R1} = X_{R2} = \left[\begin{smallmatrix} \alpha \\ \beta \end{smallmatrix}\right]$. Then $R_1 = 0$ in (20) and we may choose $R = \left[\begin{smallmatrix} 0 & 0 \\ 0 & \gamma \end{smallmatrix}\right]$, where $\gamma \in \mathbb{R}$, so that the equation for $X_c$ becomes $X_c X_c^T = \left[\begin{smallmatrix} 0 & 0 \\ 0 & -i\gamma \end{smallmatrix}\right]$.

It is easily verified that

$$X_c = \begin{bmatrix} 0 \\ \gamma^{\frac{1}{2}} \kappa \end{bmatrix}$$

is a solution of this equation. Thus, a complete eigenvector matrix $X$ is

$$X = \begin{bmatrix} 0 & \alpha & \alpha & 0 \\ \gamma^{\frac{1}{2}} \kappa & \beta & \beta & \overline{\gamma^{\frac{1}{2}} \kappa} \end{bmatrix}. \tag{33}$$

Now compute to find $\Gamma_0 = 0$ and

$$\Gamma_1 = 2 \begin{bmatrix} \alpha^2 & \alpha\beta \\ \alpha\beta & \beta^2 + \gamma \end{bmatrix}, \quad \Gamma_2 = 0, \quad \Gamma_3 = 2 \begin{bmatrix} \alpha^2 & \alpha\beta \\ \alpha\beta & \beta^2 - \gamma \end{bmatrix},$$

and then, assuming $\alpha\gamma \neq 0$,

$$M = \Gamma_1^{-1} = (2\alpha^2\gamma)^{-1} \begin{bmatrix} \beta^2+\gamma & -\alpha\beta \\ -\alpha\beta & \alpha^2 \end{bmatrix}, \quad D = 0,$$

$$K = (2\alpha^2\gamma)^{-1} \begin{bmatrix} \beta^2-\gamma & -\alpha\beta \\ -\alpha\beta & \alpha^2 \end{bmatrix}.$$

Thus, a three-parameter family of isospectral systems is obtained. The system (31), with which this discussion began, is obtained by taking $\alpha = 1/\sqrt{2}$, $\beta = 0$, $\gamma = 1/2$. In contrast with matrix $X$ of (32), (33) evaluated at these parameter values is a member of a [illegible] triple.

To illustrate the role played by the sign characteristic, consider the following special cases:

[illegible] 1. $\alpha = 1 \;\; \beta = 0 \;\; \gamma = 1.$

$$M_1\lambda^2 + K_1 = \frac{1}{2}\begin{bmatrix} \lambda^2-1 & 0 \\ 0 & \lambda^2+1 \end{bmatrix}.$$

[illegible] 2. $\alpha = 1 \;\; \beta = -1 \;\; \gamma = 1.$

$$M_2\lambda^2 + K_2 = \frac{1}{2}\begin{bmatrix} 2\lambda^2 & \lambda^2+1 \\ \lambda^2+1 & \lambda^2+1 \end{bmatrix}.$$

[illegible] 3. $\alpha = 1 \;\; \beta = 0 \;\; \gamma = -1.$

$$M_3\lambda^2 + K_3 = \frac{1}{2}\begin{bmatrix} \lambda^2-1 & 0 \\ 0 & -(\lambda^2+1) \end{bmatrix}.$$

Theorem 7 tells us that the sign characteristic determines the derivatives of the eigenvalue functions $\mu_1(\lambda)$, $\mu_2(\lambda)$ of the matrix function $L(\lambda)$ at the points where they cross the real axis. Obviously, in Case 1, the nature of these eigenvalue functions corresponds to the left side of Figure 1, and the eigenvalue functions are $\mu_1(\lambda) = \frac{1}{2}(\lambda^2-1)$, $\mu_2(\lambda) = \frac{1}{2}(\lambda^2+1)$. The sign characteristic $\{-1,\ +1\}$ corresponds to the sign of the derivative of $\mu_1(\lambda)$ at the points $\lambda = -1$ and $\lambda = +1$, respectively.

The system of Case 2 has a similar structure (the matrix polynomials are congruent) but now $\mu_1(\lambda) = \frac{1}{2}(\lambda^2-1)$, $\mu_2(\lambda) = \lambda^2+1$.

In contrast, Case 3 has $\mu_1(\lambda) = \frac{1}{2}(\lambda^2-1)$, $\mu_2(\lambda) = -\frac{1}{2}(\lambda^2+1)$, and $M$ is indefinite (right side of Figure 1). However, it is clear from both sides of the figure that both the real spectrum of $L(\lambda)$ and the sign characteristic are the same in every case.

**Appendix C. The rank of complex symmetric matrices.** Let $M$ be a complex symmetric matrix in $\mathbb{C}^{n\times n}$. Thus, there are real symmetric matrices $A$ and $B$ such that $X = A + iB$. Our objective is to show how the ranks of matrices $X$, $A$, and $B$ are connected. Notice that there are no other hypotheses on $A$ and $B$, such as invertibility or positivity.

The rank of a square matrix is invariant under congruence transformations so, if $S \in \mathbb{R}^{n\times n}$ is nonsingular, then $\operatorname{rank} X = \operatorname{rank}(SXS^T)$. Our problem will be resolved by applying a congruence with matrix $S$ which simultaneously reduces $A$ and $B$ to a canonical form. The canonical forms in question can be found in the recent work [11] and are described here. It is convenient to use the language of spectral analysis and consider our problem in the context of the reduction of the [illegible] $A + \lambda B$ by real congruence.

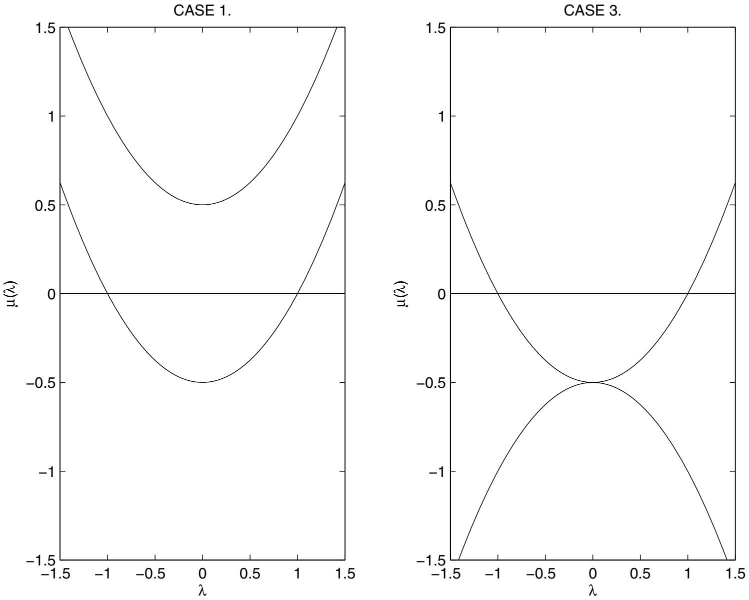

Fig. 1. *Eigenvalue functions* $\mu_j(\lambda)$.

The general canonical forms are quite complicated. They are block diagonal with blocks of several different types as follows.

- Square matrices $F_m$ of size $m$ with ones on the NE–SW diagonal and zeros elsewhere (also known as the [illegible] matrices).
- Matrices $G_m$:

$$G_m = \begin{bmatrix} 0 & \cdots & \cdots & 1 & 0 \\ \vdots & & & 0 & 0 \\ \vdots & & & & \vdots \\ 1 & 0 & & & \vdots \\ 0 & 0 & \cdots & \cdots & 0 \end{bmatrix} = \begin{bmatrix} F_{m-1} & 0 \\ 0 & 0 \end{bmatrix}.$$

- Matrices $H_{2m}$:

$$H_{2m} = \begin{bmatrix} 0 & 0 & & \cdots & & 1 & 0 \\ 0 & & & & & 0 & -1 \\ \vdots & & & 1 & 0 & & \\ & & & 0 & -1 & & \\ & & \cdot & & & & \vdots \\ 1 & 0 & & & & & 0 \\ 0 & -1 & & & \cdots & 0 & 0 \end{bmatrix}.$$

Then the canonical form for $A$ is a direct sum of blocks of (up to) five distinct types, say,

$$A = A_1 \oplus A_2 \oplus A_3 \oplus A_4 \oplus A_5,$$

and similarly for $B$. The blocks $A_r$ and $B_r$ will have the same size for each $r$ and are as follows:

1. $A_1 = B_1 = 0$ (a square zero matrix).
2. $A_2 = \sum_j \oplus G_{2\varepsilon_j+1}$,
$$B_2 = \sum_j \oplus \begin{bmatrix} 0 & 0 & F_{\varepsilon_j} \\ 0 & 0 & 0 \\ F_{\varepsilon_j} & 0 & 0 \end{bmatrix}.$$
3. $A_3 = \sum_j \oplus \delta_j F_{k_j}$, $B_3 = \sum_j \oplus \delta_j G_{k_j}$, where each $\delta_j$ is $\pm 1$ and, together, they define the sign characteristic of the eigenvalue of $A + \lambda B$ at infinity (if any).
4. $A_4 = \sum_j \oplus(\eta_j \alpha_j F_{l_j} + G_{l_j})$, $B_4 = \sum_j \oplus \eta_j F_{l_j}$, where each $\eta_j$ is $\pm 1$ and, together, they define the sign characteristic associated with the real eigenvalues (if any).
5. $$A_5 = \sum_j \oplus \left( \mu_j F_{2m_j} + \nu_j H_{2m_j} + \begin{bmatrix} F_{2m_j - 2} & 0 \\ 0 & 0_2 \end{bmatrix} \right), \qquad B_5 = \sum_j \oplus F_{2m_j},$$
where $\mu_j \pm i\nu_j$ with $\nu_j \neq 0$ are the complex eigenvalues (if any), and $0_2$ is the $2 \times 2$ zero matrix.

It is clear that $\operatorname{rank}(A) = \sum_{r=1}^{5} \operatorname{rank}(A_r)$, $\operatorname{rank}(B) = \sum_{r=1}^{5} \operatorname{rank}(B_r)$, and $\operatorname{rank}(A + iB) = \sum_{r=1}^{5} \operatorname{rank}(A_r + iB_r)$. However, the ranks of these component matrices are easily obtained from those of the $F$'s, $G$'s, and $H$'s. Notice, in particular, that for the first four types the component diagonal blocks are triangular, and the rank can be read off by observation. For the fifth type, the structures will be clear if we just examine the case $m_j = 3$ more closely. It is easily seen that, if we define

$$\Delta_j := \begin{bmatrix} \nu_j & \mu_j \\ \mu_j & -\nu_j \end{bmatrix},$$

then, in this case,

$$A_5 = \begin{bmatrix} 0_2 & F_2 & \Delta_j + iF_2 \\ F_2 & \Delta_j + iF_2 & 0_2 \\ \Delta_j + iF_2 & 0_2 & 0_2 \end{bmatrix},$$

so that $\det(A_5) = 0$ if and only if $\det(\Delta_j + iF_2) = 0$ (and this is the case whatever the value of $m_j$). However,

$$\det(\Delta_j + iF_2) = -(\mu_j^2 + \nu_j^2) - 2i\mu_j + 1,$$

and this vanishes if and only if $\mu_j = 0$ and $\nu_j = \pm 1$; i.e., the corresponding complex eigenvalue pair is $\pm i$.

Notice also that, when $\mu_j + i\nu_j = i$, then

$$\Delta_j + iF_2 = \begin{bmatrix} 1 & i \\ i & -1 \end{bmatrix},$$

a matrix of rank one.

The important conclusion of this argument is the following.

PROPOSITION 8.

$$\operatorname{rank}(A_5) = 2\sum_j m_j, \tag{34}$$

[illegible] $j$ [illegible] $\pm i$

[illegible] $A_5$ [illegible] (34) [illegible] $i$ [illegible] $-i$

It will be convenient to denote the algebraic multiplicity of the eigenvalue $i$ by $a(i)$ so that, in general,

$$\operatorname{rank}(A_5) = 2\sum_j m_j - a(i).$$

Now it can be seen that

1. $\operatorname{rank}(A_1) = \operatorname{rank}(B_1) = \operatorname{rank}(A_1 + iB_1) = 0$;
2. $\operatorname{rank}(A_2) = \operatorname{rank}(B_2) = \operatorname{rank}(A_2 + iB_2) = \sum_j 2\varepsilon_j$;
3. $\operatorname{rank}(A_3) = \sum_j k_j$, $\operatorname{rank} B_3 = \sum_j (k_j - 1)$, $\operatorname{rank}(A_3 + iB_3) = \sum_j k_j$;
4. $\operatorname{rank}(A_4) = \sum_{j:\alpha_j \neq 0} l_j + \sum_{j:\alpha_j = 0}(l_j - 1)$, $\operatorname{rank}(B_4) = \sum_j l_j$, $\operatorname{rank}(A_4 + iB_4) = \sum_j l_j$;
5. $\operatorname{rank}(A_5) = 2\sum_j m_j - a(i)$, $\operatorname{rank}(B_5) = 2\sum_j m_j$, $\operatorname{rank}(A_5 + iB_5) = 2\sum_j m_j$.

Now consider how the ranks of $A$ and $B$ can differ from that of $A + iB$. Items 1 and 2 produce no differences. Due to item 3, however, the rank of $B_3$ (and hence $B$) is less than the other two ranks by one for [illegible] associated with the eigenvalue at infinity (if there is such an eigenvalue), i.e., the geometric multiplicity of the eigenvalue at infinity, say $g(\infty)$.

Similarly, it can be deduced from item 4 that $\operatorname{rank}(A_4)$ is less than $\operatorname{rank}(B_4)$ and $\operatorname{rank}(A_4 + iB_4)$ by the geometric multiplicity of the zero eigenvalue, say, $g(0)$. The case of blocks of the fifth type is covered by Proposition 8.

Since $\operatorname{rank}(A) = \sum_{r=1}^{5} \operatorname{rank}(A_r)$ and $\operatorname{rank}(B) = \sum_{r=1}^{5} \operatorname{rank}(B_r)$, the results can be brought together in the following form (and we keep in mind that $a(i)$, $g(o)$, and $g(\infty)$ refer to eigenvalues of the pencil $A + \lambda B$).

THEOREM 9.

$$\operatorname{rank}(A + iB) = \operatorname{rank}(A) - a(i) + g(0) = \operatorname{rank}(B) - a(i) + g(\infty).$$

[illegible] Let us illustrate with Example 4 of the main text. The first case arising there is

$$A + iB = \frac{1}{2}\begin{bmatrix} -1 & -i \\ -i & 1 \end{bmatrix},$$

so that

$$A + \lambda B = \frac{1}{2}\begin{bmatrix} -1 & -\lambda \\ -\lambda & 1 \end{bmatrix}.$$

We have $a(i) = 1$, $g(0) = g(\infty) = 0$, and $\operatorname{rank}(A + iB) = 1$.

The second case is

$$A + iB = \begin{bmatrix} 0 & 0 \\ 0 & i \end{bmatrix},$$

so that

$$A + \lambda B = \begin{bmatrix} 0 & 0 \\ 0 & \lambda \end{bmatrix}.$$

Notice first that, in this case, $A_1 = B_1 = [0]$. Then $a(i) = 0$, $g(0) = 1$, $g(\infty) = 0$, and $\operatorname{rank}(A + iB) = 1$. ◻

# UNSYMMETRIC ORDERING USING A CONSTRAINED MARKOWITZ SCHEME*

PATRICK R. AMESTOY†, XIAOYE S. LI‡, AND STÉPHANE PRALET†

**Abstract.** We present a family of ordering algorithms that can be used as a preprocessing step prior to performing sparse **LU** factorization. The ordering algorithms simultaneously achieve the objectives of selecting numerically good pivots and preserving the sparsity. We describe the algorithmic properties and challenges in their implementation. By mixing the two objectives we show that we can reduce the amount of fill-in in the factors and reduce the number of numerical problems during factorization. On a set of large unsymmetric real problems, we obtained the median reductions of 12% in the factorization time, of 13% in the size of the **LU** factors, of 20% in the number of operations performed during the factorization phase, and of 11% in the memory needed by the multifrontal solver `MA41_UNS`. A byproduct of this ordering strategy is an incomplete **LU**-factored matrix that can be used as a preconditioner in an iterative solver.

**Key words.** sparse unsymmetric matrices, greedy heuristics, ordering methods, bipartite quotient graph

## 1. Introduction.

Direct methods for sparse unsymmetric linear systems usually involve an analysis phase preceding the effective **LU** factorization [2, 10, 14, 20, 21]. The analysis phase transforms $\mathbf{A}$ into $\tilde{\mathbf{A}}$ with better properties for sparse factorization. It exploits the structural information to reduce the amount of fill-in in the **LU** factors and exploits the numerical information to reduce the need for numerical pivoting during factorization.

Two separate steps can be used in sequence for these two objectives:

1. Scaling and maximum transversal algorithms are used to transform $\mathbf{A}$ into $\mathbf{A}_1$ with large entries in magnitude on the diagonal.
2. A symmetric fill-reducing ordering, which preserves the large diagonal, is used to permute $\mathbf{A}_1$ into $\tilde{\mathbf{A}}$ so that the factors of $\tilde{\mathbf{A}}$ are sparser than those of $\mathbf{A}_1$.

Thus, the ultimate factorization is

$$\mathbf{LU} = \mathbf{P}_3\mathbf{P}_2\mathbf{D}_r\mathbf{A}\mathbf{D}_c\mathbf{Q}_1\mathbf{P}_2^T\mathbf{Q}_3, \tag{1.1}$$

where $\mathbf{D}_r$ and $\mathbf{D}_c$ are diagonal scaling matrices, $\mathbf{Q}_1$ is a permutation obtained from the maximum transversal algorithm, $\mathbf{P}_2$ corresponds to the fill-reducing permutation, and $\mathbf{P}_3$ and $\mathbf{Q}_3$ are permutations corresponding to numerical pivoting during factorization.

It has been observed in [4] that permuting large entries on the diagonal (computing $\mathbf{Q}_1$ based on [17]) can significantly reduce the number of numerical problems

during factorization. A standard way to find $\mathbf{P}_2$ is to apply a symmetric ordering algorithm (e.g., `AMD` [1]) to the structure of $\mathbf{A}_1 + \mathbf{A}_1^T$, where $\mathbf{A}_1 = \mathbf{D}_r\mathbf{A}\mathbf{D}_c\mathbf{Q}_1$. A better algorithm, called [illegible] (or `DMLS`), was developed in [5], which could exploit the unsymmetric structure of $\mathbf{A}_1$ and was shown to give sparser factors than with `AMD`.

The above two-step approach has two drawbacks:

- The numerical treatment forces the fill-reducing ordering to restrict pivot selection on the diagonal of $\mathbf{A}_1$, and so to compute a symmetric permutation.
- The ordering phase does not have numerical information to select pivots.

To improve sparsity preservation and numerical quality of the preselected pivots, we describe in this paper a family of orderings that can select off-diagonal pivots using a combination of structural and numerical criteria. Based on a numerical preprocessing of the matrix we build a set of numerically acceptable pivots, referred to as matrix $\mathbf{C}$, that may contain off-diagonal entries. We then compute an unsymmetric ordering taking into account both the structure of $\mathbf{A}$ and the numerical information in $\mathbf{C}$. The $\mathbf{C}$ matrix serves as a [illegible] for the pivot selection, and nontrivial floating point operations can be performed on this matrix to update the characteristics of the pivots. The new algorithm is referred to as [illegible] (or `CMLS`).

In summary, this work extended and generalized the `DMLS` work in several ways:

1. We do not limit our choice of pivots to the maximum transversal of $\mathbf{D}_r\mathbf{A}\mathbf{D}_c$. Our pivots can be chosen from a constraint matrix $\mathbf{C}$ that includes a transversal but is not limited to this transversal.
2. The constraint matrix $\mathbf{C}$ is updated [illegible] after each step of elimination. The final $\mathbf{C}$ is an incomplete $\mathbf{LU}$ factor of $\mathbf{D}_r\mathbf{A}\mathbf{D}_c$.

Thus, instead of computing the permutations $\mathbf{Q}_1$ and $\mathbf{P}_2$ of (1.1) in two separate steps, `CMLS` simultaneously computes row and column permutations $\mathbf{P}_2$ and $\mathbf{Q}_2$, and the final factorization is

$$\mathbf{LU} = \mathbf{P}_3\mathbf{P}_2\mathbf{D}_r\mathbf{A}\mathbf{D}_c\mathbf{Q}_2^T\mathbf{Q}_3. \tag{1.2}$$

We evaluated the new ordering algorithms using two state-of-the-art direct solvers: the multifrontal code `MA41_UNS` [2, 7] and the supernodal code `SuperLU_DIST` [27, 28]. In `MA41_UNS`, standard partial pivoting with a threshold value is applied to locally select numerically stable pivots within a so-called frontal matrix. It is possible that some variables cannot be locally eliminated and are postponed for later eliminations, which may result in an increase in the size of the $\mathbf{LU}$ factors and the number of operations compared with those predicted during analysis. In `SuperLU_DIST`, a static pivoting strategy is used and the pivotal sequence chosen during analysis is kept the same (i.e., $\mathbf{P}_3$ and $\mathbf{Q}_3$ are the identity matrices in (1.1) and (1.2)). Iterative refinement may be needed to improve the solution.

The rest of the paper is organized as follows. Section 2 introduces the main components of our algorithm. Section 3 defines the graph-theoretic notation and describes the use of local symmetrization in our context. Section 4 describes the algorithmic contributions of the proposed `CMLS` method. A full detailed presentation of our implementation is given in [32]. Section 5 analyzes the results of the newly implemented `CMLS` algorithm when applied to real-life unsymmetric test cases.

**2. Components of our unsymmetric ordering.** Given a matrix $\mathbf{A}$, let $\mathcal{P}attern(\mathbf{A})$ be the set of nonzero entries of $\mathbf{A}$: $\mathcal{P}attern(\mathbf{A}) = \{(i, j) \text{ such that } a_{ij} \neq 0\}$. Our unsymmetric ordering consists of two main steps:

- *Step* 1. Based on a numerical pretreatment of the matrix $\mathbf{A}$, we extract a set of numerically acceptable pivots, referred to as the *constraint matrix* $\mathbf{C}$. We have $\mathcal{P}attern(\mathbf{C}) \subseteq \mathcal{P}attern(\mathbf{A})$, and if $c_{ij} \neq 0$ then $c_{ij} = a_{ij}$.
- *Step* 2. Constrained unsymmetric ordering: the constraint matrix is used at each step of the symbolic Gaussian elimination to control the set of eligible pivots (possibly with respect to both numerical and structural criteria).

Before describing these two steps more precisely, we introduce definitions and notation that will be used to describe our algorithms.

Let $\mathbf{M} = (m_{ij})$ be a matrix of order $n$. If $\mathbf{M}$ can be permuted to have $n$ nonzeros on the diagonal then $\mathbf{M}$ is *structurally nonsingular*. Let $G_M = (V_r, V_c, E)$ be the bipartite graph associated with the matrix $\mathbf{M}$. $V_r$ is the set of row vertices and $V_c$ is the set of column vertices. Let $(i, j) \in V_r \times V_c$; then $(i, j) \in E$ if and only if $m_{ij} \neq 0$. A *matching* is a subset of edges $\mathcal{M} \subseteq E$ such that for all vertices $v \in V_r \cup V_c$, at most one edge of $\mathcal{M}$ is incident on $v$. If $\mathbf{M}$ is structurally nonsingular, then there exists a matching $\mathcal{M}$ with $n$ edges and $\mathcal{M}$ is said to be a *perfect matching*. We will also say that $\mathcal{M}$ is a *perfect transversal*.

For the sake of clarity, in the remainder of this paper we assume that $\mathbf{A}$ is structurally nonsingular. The adaptation of our algorithms to structurally singular matrices is straightforward but would have severely complicated our notation and comments.

### 2.1. Step 1: Numerical preprocessing.

The objective of this preprocessing step is to extract the most significant (structurally and numerically) entries of the matrix $\mathbf{A}$ and to use them to build the constraint matrix $\mathbf{C}$.

First, we scale the matrix $\mathbf{A}$ with the diagonal matrices $\mathbf{D}_r$ and $\mathbf{D}_c$, resulting in $\mathbf{A} \leftarrow \mathbf{D}_r\mathbf{A}\mathbf{D}_c$. The objective of this scaling is to homogenize the magnitude of the entries of the matrix. In particular, it helps us to compare the magnitude of entries belonging to different rows and columns and thus to decide which entries will be selected in our *constraint matrix* $\mathbf{C}$. In this paper we use the scaling computed with the maximum weighted matching algorithm [17]. All entries in our scaled matrix then have entries lower than 1 in magnitude with a perfect transversal with entries of magnitude equal to 1.

Second, a *constraint matrix* $\mathbf{C}$ can be constructed from $\mathbf{A}$ such that $\mathcal{P}attern(\mathbf{C}) \subseteq \mathcal{P}attern(\mathbf{A})$ and $\mathbf{C}$ satisfies certain numerical and/or structural properties. Since the entries in $\mathbf{C}$ correspond to the potential pivots for the subsequent step, we keep only a subset of bounded size (typically less than $3n$) of the largest entries in the scaled matrix. Furthermore, we want $\mathbf{C}$ to be structurally nonsingular, and thus we add entries from $\mathbf{A}$ to guarantee that $\mathbf{C}$ includes a perfect transversal $\mathcal{M}$.

### 2.2. Step 2: Constrained unsymmetric ordering.

Let $\mathbf{A}^1 = \mathbf{A}$ be the original matrix of order $n$ and $\mathbf{A}^k$ be the reduced matrix after eliminating the first $k-1$ pivots (not necessarily on the diagonal). Let $\mathbf{C}^1 = \mathbf{C}$ be such that $\mathcal{P}attern(\mathbf{C}^1) \subseteq \mathcal{P}attern(\mathbf{A}^1)$. At each step $k$, a pivot $p^k$ such that $p^k \in \mathcal{P}attern(\mathbf{C}^k)$ is selected. This selection may combine structural heuristics based on the structure of $\mathbf{A}^k$ (e.g., approximate Markowitz count, approximate minimum fill, etc.) and numerical heuristics carried by the $\mathbf{C}^k$ matrix. Matrix $\mathbf{A}^k$ is updated (remove the row and the column of the pivot and add fill-ins in the Schur complement). Matrix $\mathbf{C}^k$ is updated such that $\mathbf{C}^{k+1}$ remains structurally nonsingular and $\mathcal{P}attern(\mathbf{C}^{k+1})$ is included in $\mathcal{P}attern(\bar{\mathbf{C}}^k)$, where $\bar{\mathbf{C}}^k$ is defined as the reduced matrix after the elimination of pivot $p^k$ in $\mathbf{C}^k$. The structure of $\mathbf{A}^{k+1}$ contains the structure of $\bar{\mathbf{C}}^k$. This implies that $\mathcal{P}attern(\mathbf{C}^{k+1}) \subseteq \mathcal{P}attern(\mathbf{A}^{k+1})$. To keep $\mathbf{C}^k$ structurally nonsingular, a perfect matching in $\mathbf{C}^k$ is maintained at each step. When there is no ambiguity, we will omit the superscript $k$ from the matrix notation.

The following two considerations influence the update that will be performed on $\mathbf{C}$:

- Which metric do we use to select a pivot?
- Which entries and/or values are added/updated in $\mathbf{C}$ at each step of the elimination?

Note that if we consider the magnitude of $\mathbf{C}$'s entries to select a pivot, both the pattern of $\mathbf{C}$ and the numerical values need to be stored and updated. Furthermore, any structural information about each entry $(i, j)$ in $\mathbf{C}$ should carry information on the reduced matrix associated with the complete matrix $\mathbf{A}$.

The ordering algorithm also depends on how $\mathbf{C}$ is updated at each step. As mentioned before in the description of Step 2, we want at each step to guarantee that

$$\mathbf{C} \text{ must remain structurally nonsingular, and} \tag{2.1}$$

$$\mathcal{P}attern(\mathbf{C}^{k+1}) \subseteq \mathcal{P}attern(\bar{\mathbf{C}}^k). \tag{2.2}$$

## 3. Notation and definitions.

Before giving the algorithmic details of the proposed `CMLS` method, we introduce the graph structures and notation that will be used in this paper. We first describe the main properties of bipartite graphs and bipartite quotient graphs and their relationship with Gaussian elimination. We then introduce the notation that will be used to describe our algorithms and define local symmetrization [5], a technique that simplifies the bipartite quotient graph implementation. Note that we use calligraphic font for notation related to quotient graphs and Roman font for other graphs.

### 3.1. Bipartite graph.

Let $\mathbf{M} = (m_{ij})$ be a matrix and $G_M = (V_r, V_c, E)$ be its associated bipartite graph. Let $R_i$ denote the structure of row $i$; i.e., $R_i = \{j \in V_c \text{ s.t. } (i, j) \in E\}$. Let $C_j$ denote the structure of column $j$; i.e., $C_j = \{i \in V_r \text{ s.t. } (i, j) \in E\}$.

In Gaussian elimination, when a pivot $p = (r_p, c_p)$ is eliminated, a new matrix, referred to as the reduced matrix $\bar{\mathbf{M}}$, is computed. $\bar{\mathbf{M}}$ is obtained from $\mathbf{M}$ by removing row $r_p$ and column $c_p$ and by adding the Schur complement entries. In terms of graph manipulations, this elimination adds edges in the bipartite graph of $\mathbf{M}$ to connect all the rows adjacent to $c_p$ to all the columns adjacent to $r_p$. This set of connected rows and columns is referred to as a *biclique*.

The symbolic factorization of $\mathbf{M}$ is done by building $\mathbf{M}^k$ for $k = 1$ to $n$, with $\mathbf{M}^1 = \mathbf{M}$. After eliminating the $k$th pivot, we compute $\mathbf{M}^{k+1} = \bar{\mathbf{M}}^k$.

### 3.2. Bipartite quotient graph.

In the previous section we have shown that to update the bipartite graph we must add, at each elimination step, entries to the Schur complement matrix which may be costly to update and to store. It has been shown that quotient graphs can be used to efficiently model the factorization of symmetric matrices [20, 24]. The main idea is to use a compact representation of the cliques associated with the eliminated vertices. This concept can be extended (see [31]) to model the $\mathbf{LU}$ factorization. In this case, a bipartite quotient graph can be used to represent the edges in a biclique. It has then been shown in [31] that doing so the elimination can be modeled in space bounded by the size of the original matrix $\mathbf{A}$.

In this section, we first explain why the quotient graph model leads to more complex algorithms on unsymmetric matrices than on symmetric matrices. We then briefly define element absorption and explain the use of local symmetrization to reduce the quotient graph complexity. Finally, we introduce notation that will be used to describe our algorithms.

Let $\mathcal{P}_r \subseteq 2^{V_r}$ and $\mathcal{P}_c \subseteq 2^{V_c}$ be two partitions of $V_r$ and $V_c$, respectively. We define the bipartite quotient graph $\mathcal{G}_A = (\mathcal{P}_r, \mathcal{P}_c, \xi)$ of $\mathbf{A}$ such that an edge $(\mathcal{I}, \mathcal{J})$ belongs to $\xi \subseteq \mathcal{P}_r \times \mathcal{P}_c$ if and only if there exists an edge in $G$ between a node of $\mathcal{I}$ and a node of $\mathcal{J}$.

Let $\mathcal{G}_A^k$ be the bipartite quotient graph used to represent the structure of the reduced submatrix $\mathbf{A}^k$ after $k$ steps of elimination. Initially the bipartite quotient graph $\mathcal{G}_A^1$ is initialized with the partitions $\mathcal{P}_r = \{\{i\}$ such that $i \in V_r\}$ and $\mathcal{P}_c = \{\{j\}$ such that $j \in V_c\}$. Thus it is equivalent to the bipartite graph $G^1$. At step $k$ of Gaussian elimination, any eliminated pivot $e = (r_e, c_e)$ will be referred to as a [illegible]. All the row and column vertices that are not coupled elements are referred to as the row and column [illegible] of $\mathcal{G}_A^k$. Both row and column vertices of the graph are thus partitioned into two sets composed of variables (uneliminated vertices) and [illegible] (eliminated vertices). We then define $\mathcal{G}_A^k = (\mathcal{V}_r^k \cup \overline{\mathcal{V}}_r^k, \mathcal{V}_c^k \cup \overline{\mathcal{V}}_c^k, \mathcal{E}^k \cup \overline{\mathcal{E}}^k)$. When it is clear from the context, we will omit the superscript $k$. The vertices in $\mathcal{V}_r$ (resp., $\mathcal{V}_c$) correspond to the row (resp., column) variables. The vertices in $\overline{\mathcal{V}}_r$ (resp., $\overline{\mathcal{V}}_c$) correspond to the row (resp., column) elements. The edge set $\mathcal{E}$ is such that $\mathcal{E} \subseteq (\mathcal{V}_r \times \mathcal{V}_c)$, whereas $\overline{\mathcal{E}}$ is such that $\overline{\mathcal{E}} \subseteq (\mathcal{V}_r \times \overline{\mathcal{V}}_c) \cup (\overline{\mathcal{V}}_r \times \mathcal{V}_c) \cup (\overline{\mathcal{V}}_r \times \overline{\mathcal{V}}_c)$. With our definitions $(i, j)$ is a nonzero entry in the reduced matrix at step $k$ if and only if there exists a path joining $i$ and $j$ which visits only the elements and for which all the edges in the even positions correspond to already eliminated pivots. In other words, the structure of a row $i$ at step $k$ is the set of reachable columns $j$ through all the paths of the form $i \to c_{e_1} \to r_{e_1} \cdots \to c_{e_l} \to r_{e_l} \to j$, where $e_t = (r_{e_t}, c_{e_t}), 1 \leq t \leq l$, are coupled elements. Similarly, the structure of a column $j$ at step $k$ is the set of reachable rows $i$ through all the paths of the form $j \to r_{e_1} \to c_{e_1} \cdots \to r_{e_l} \to c_{e_l} \to i$. This process may involve paths of arbitrary length in $\mathcal{G}_A^k$ [31] and in particular through more than one coupled element. For example, in Figure 3.1, we assume that the entry $(r_p, c_{e_2})$ is initially zero and corresponds to fill-in due to the elimination of element $e_1$. Because of the path $r_p \to c_{e_1} \to r_{e_1}$, we know that the row structure of $r_p$ contains the row structure of $e_1$ and in particular the entry $(r_p, c_{e_2})$. We know also that the row structure of $r_p$ contains the row structure of $e_2$ because of the path $r_p \to c_{e_1} \to r_{e_1} \to c_{e_2} \to r_{e_2}$.

In the context of sparse Cholesky factorization, an undirected quotient graph (the row and column vertices are merged) is preferred and commonly used to compute an ordering for symmetric matrices (e.g., multiple minimum degree [29] and approximate minimum degree [1]). The structure of the factors can be computed following the paths of length at most two in this quotient graph. There are no edges between the elements.

In the unsymmetric case, when a pivot $p = (r_p, c_p)$ is selected, if there exists a cycle of the form $r_p \to c_{e_1} \to r_{e_1} \cdots \to c_{e_l} \to r_{e_l} \to c_p \to r_p$, then, except for $r_p$ and $c_p$, the row and column elements in the cycle are no longer needed to retrieve the structure of the remaining variables. This process will be called [illegible] and is illustrated in Figure 3.1. This absorption can be explained by the two following remarks (see [31] for further details):

- The row and the column of $p$ contain the structures of, respectively, the row

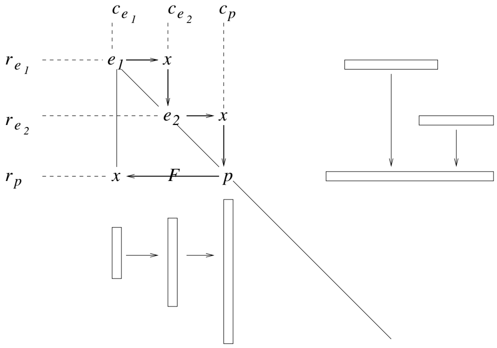

FIG. 3.1. *Illustration of a cycle* ($r_p \rightarrow c_{e_1} \rightarrow r_{e_1} \rightarrow c_{e_2} \rightarrow r_{e_2} \rightarrow c_p \rightarrow r_p$ ).

elements and the column elements in the cycle.

- If one of the elements is reachable from a variable $i$, then the other elements in the cycle are also reachable from $i$ (in particular $p$).

During the absorption, each path from $i$ to an element in the cycle is thus replaced by an edge from $i$ to the current pivot.

To avoid long search paths when we compute the structure of the row and the column of a pivot we decided to relax the element absorption rule as done in [5]. A row (resp., column) element is absorbed by the current row (resp., column) pivot if either it is adjacent to the column (resp., row) pivot or its associated column (resp., row) element is adjacent to the row (resp., column) pivot. This is referred to as [illegible] in [5]. It implies that the resulting quotient graph $\mathcal{G}_A^k$ at step $k$ models only an approximation of the structure of the reduced submatrix. It has been shown in [5] that the exploitation of element absorption combined with local symmetrization results in an in-place algorithm: at each step of the Gaussian elimination, the size of the quotient graph is bounded by the size of $\mathcal{G}_A^1$. Note that because of local symmetrization, an approximation of the symbolic factors can be computed following the paths of length at most three of the form $i \rightarrow c_e \rightarrow r_e \rightarrow j$, where $(r_e, c_e)$ denotes a coupled row and column element. Note that applying local symmetrization is significantly different from symmetrization of the complete matrix. In fact we add at most $n-1$ virtual entries (at most one per absorbed element), and thus the structure of the factors computed with local symmetrization is equal to the real structure of the factors of a matrix $\mathbf{A}+\mathbf{D}$ where $\mathbf{D}$ has fewer than $n$ entries.

To simplify the description of how the bipartite quotient graph is modified at each elimination step, we define $\overline{\mathcal{V}} \subseteq (\overline{\mathcal{V}}_r \times \overline{\mathcal{V}}_c)$ to be the set of coupled row and column elements corresponding to already eliminated pivots. Entries of the set $\overline{\mathcal{V}}$ will also be referred to as [illegible] or [illegible] when it is clear from the context. Let $\mathcal{U}_p$ (resp., $\mathcal{L}_p$) be the column (resp., row) variables adjacent in $\mathcal{G}_A^k$ to the row (resp., column) element of a pivot $p = (r_p, c_p)$. Thanks to local symmetrization, the concept of absorption can be extended to coupled elements: an element $e = (r_e, c_e)$ such that $(r_p, c_e) \in \overline{\mathcal{E}}$ [illegible] $(r_e, c_p) \in \overline{\mathcal{E}}$ can be absorbed by $p$ when $p$ is selected as a pivot. A consequence of this absorption is that our ordering also generates a dependency graph between elements that is in fact a forest. This forest will be fully exploited by the unsymmetrized multifrontal approach [7].

For each row variable $i \in \mathcal{V}_r$ and column variable $j \in \mathcal{V}_c$, we define the element lists $\mathcal{R}_i$ and $\mathcal{C}_j$ as follows:

$$\mathcal{R}_i = \{e = (r_e, c_e) \in \overline{\mathcal{V}} \text{ s.t. } (i, c_e) \in \overline{\mathcal{E}}\}$$

and

$$\mathcal{C}_j = \{e = (r_e, c_e) \in \overline{\mathcal{V}} \text{ s.t. } (r_e, j) \in \overline{\mathcal{E}}\}.$$

Let $e = (r_e, c_e)$ be an element; if $e \in \mathcal{R}_i$ then we will say that [illegible] $e$ [illegible] $i$. Similarly, if $e \in \mathcal{C}_j$ we will say that [illegible] $e$ [illegible] $j$.

Using this notation, the adjacency of a row variable $i$ (resp., column $j$) in $\mathcal{G}_A$ consists of a list of column variables denoted as $\mathcal{A}_{i*}$ (resp., a list of row variables $\mathcal{A}_{*j}$) and a list of elements $\mathcal{R}_i$ (resp., $\mathcal{C}_j$). Initially $\mathcal{R}_i = \mathcal{C}_j = \emptyset$ and $\mathcal{A}_{i*}$ and $\mathcal{A}_{*j}$ correspond to the original entries of $\mathbf{A}$. Each step of Gaussian elimination involves changes in the sets $\mathcal{R}_i$ and $\mathcal{C}_j$ as well as the computation of the structure of a current pivot $p$. The variable lists $\mathcal{A}_{i*}$ and $\mathcal{A}_{*j}$ can also be pruned. Indeed, the edges in $\mathcal{G}_A$ between the variables and the elements implicitly represent the biclique of the element and can thus be used to remove the redundant entries in $\mathcal{A}_{i*}$ and $\mathcal{A}_{*j}$. This important point will be further discussed in detail in section 4.3.

When $(r_p, c_p) \in \mathcal{V}_r \times \mathcal{V}_c$ is selected as the next pivot we build the element $p$ such that

$$\mathcal{U}_p = \mathcal{A}_{r_p*} \cup \bigcup_{e \in \mathcal{R}_{r_p}} \mathcal{U}_e \cup \bigcup_{e \in \mathcal{C}_{c_p}} \mathcal{U}_e \tag{3.1}$$

and

$$\mathcal{L}_p = \mathcal{A}_{*r_p} \cup \bigcup_{e \in \mathcal{C}_{c_p}} \mathcal{L}_e \cup \bigcup_{e \in \mathcal{R}_{r_p}} \mathcal{L}_e. \tag{3.2}$$

The third term in each equation results from local symmetrization and will enable the current pivot to absorb all the elements which it was adjacent to. For example, let us assume that the entry $p1$ is selected as pivot in Figure 3.2. Since $c_{p1}$ is adjacent to $e_1$, local symmetrization adds the virtual $S_{p1}$ entry so that the row structure of $p1$ contains $\mathcal{U}_{e_1}$.

Let $\mathcal{F}_p = \mathcal{C}_{c_p} \cup \mathcal{R}_{r_p}$ be the set of elements adjacent to the current pivot. The elements in $\mathcal{F}_p$ are absorbed by $p$ and the adjacency of each column variable $j$ in $\mathcal{U}_p$ (resp., $i$ in $\mathcal{L}_p$) is updated so that $\mathcal{C}_j \leftarrow (\mathcal{C}_j \setminus \mathcal{F}_p) \cup \{p\}$ (resp., $\mathcal{R}_i \leftarrow (\mathcal{R}_i \setminus \mathcal{F}_p) \cup \{p\}$). The structure of column $j$ of the factors in the reduced matrix is then given by $\mathcal{A}_{*j} \cup \bigcup_{e \in \mathcal{C}_j} \mathcal{L}_e$. The structure of row $i$ of the factors is $\mathcal{A}_{i*} \cup \bigcup_{e \in \mathcal{R}_i} \mathcal{U}_e$.

Note that, although the above structural changes of the reduced submatrix are correct, they should not be used to estimate the structure of the factors. Indeed, if $(i, j)$ were selected as the next pivot, then the correctly computed structure of the reduced matrix should include the local symmetrization terms (similar to (3.1) and (3.2)). In Figure 3.2, we illustrate the effect of local symmetrization on the structure of the selected pivot. Let us consider two candidate pivots belonging to the same row $r_p$, $p1 = (r_p, c_{p1})$ and $p2 = (r_p, c_{p2})$. We assume that all the elements in $\mathcal{G}_A$ adjacent to $p1$ and $p2$ are indicated in the figure. The structure of row $r_p$ is then given by $\mathcal{A}_{r_p*} \cup \mathcal{U}_{e_3}$. This, however, does not give enough information on the structure of row $r_p$ if either $p1$ or $p2$ were selected as the next pivot. If $p1$ were the next pivot

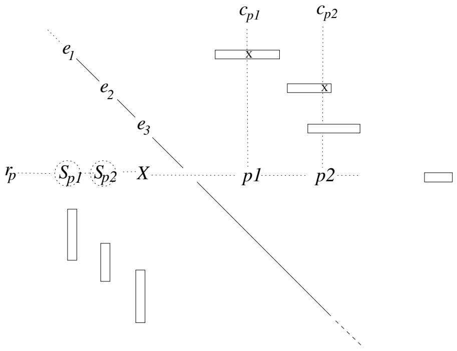

FIG. 3.2. *Influence of local symmetrization on the pivot structure.*

then the structure of row $r_p$ would be given by $\mathcal{U}_{p1} = \mathcal{A}_{r_p*} \cup \mathcal{U}_{e_3} \cup \mathcal{U}_{e_1}$ because of the locally symmetrized entry $S_{p1}$. If $p2$ were the next pivot then the structure of row $r_p$ would be given by $\mathcal{U}_{p2} = \mathcal{A}_{r_p*} \cup \mathcal{U}_{e_3} \cup \mathcal{U}_{e_2}$ because of the locally symmetrized entry $S_{p2}$. This shows that, even if we cannot anticipate the effect of local symmetrization on the quotient graph $\mathcal{G}_A$ before the pivot selection, we should anticipate its effect on the metrics used to select the best pivot between $p1$ and $p2$.

## 4. CMLS algorithm.

In this section, we describe the main features and properties of the `CMLS` algorithm. At each step of the algorithm, we need to know the exact structure of each row and column in $\mathbf{C}$. Moreover, we need to compute a metric that reflects the quality of each nonzero entry in $\mathbf{C}$. It is thus natural to use a bipartite graph (with possibly weighted edges) for $\mathbf{C}$. Each edge corresponding to a nonzero entry may have one or more weights that will be used to select a pivot. For example, a numerical value that approximates the magnitude of the entries and a structural metric that approximates the Markowitz cost (i.e., the product of the row and column degree) can be used. On the other hand, in order to have a fast computation of a structural metric based on the pattern of $\mathbf{A}$ and to have an in-place algorithm, $\mathbf{A}$ is represented by its quotient graph and local symmetrization is employed. The notation used to represent the quotient graph at each step of the algorithm is summarized in Table 4.1.

In section 4.1, we first describe the pivot selection algorithms. Updating the graphs $G_C$ and $\mathcal{G}_A$ associated with $\mathbf{C}$ and $\mathbf{A}$, respectively, is discussed in sections 4.2 and 4.3. In section 4.4 we describe how to compute, at each step $k$ and for each entry in the constraint matrix $\mathbf{C}^k$, structural metrics relative to $\mathcal{G}_A^k$. Section 4.5 finally explains how supervariables are defined and used in our context.

### 4.1. Pivot selection.

At each step, the best pivot according to a given metric is selected. The metric choice determines the underlying algorithmic strategy. We say that we use [illegible] in our algorithms when the entries are selected with respect to only information about the structure of the factors. In that case we will say that we use a [illegible]. When we combine a [illegible] metric and a [illegible] metric to select the pivot we will say that we use a [illegible].

Moreover, in sparse matrix factorization, we also want to preserve the sparsity of the factors while controlling the numerical growth in the factors. Numerical thresholds are introduced to give freedom for the pivot selection to balance numerical precision with sparsity preservation. An entry $(i, j) \in \mathbf{C}^k$ is said to be [illegible]

TABLE 4.1

*Notation used for bipartite quotient graph.*

| Bipartite quotient graph of **A**: $\mathcal{G}_A = (\mathcal{V}_r \cup \overline{\mathcal{V}}_r, \mathcal{V}_c \cup \overline{\mathcal{V}}_c, \mathcal{E} \cup \overline{\mathcal{E}})$ | |
|---|---|
| $\mathcal{R}_i$<br>$\mathcal{A}_{i*}$ | elements adjacent to row $i$<br>variables adjacent to row $i$ |
| $\mathcal{C}_j$<br>$\mathcal{A}_{*j}$ | elements adjacent to column $j$<br>variables adjacent to column $j$ |
| $\mathcal{U}_p$ | row structure of pivot $p$ after its elimination. |
| $\mathcal{L}_p$ | column structure of the pivot $p$ after its elimination. |
| $\mathcal{F}_p$ | elements that are adjacent to the row $r_p$ or the column $c_p$ of a noneliminated pivot $p$ ($\mathcal{F} = \mathcal{R}_{r_p} \cup \mathcal{C}_{c_p}$) |
| $\mathcal{F}$ | elements that are adjacent to row $i$ or column $j$ where $i$ and $j$ will depend on the context ($\mathcal{F} = \mathcal{R}_i \cup \mathcal{C}_j$) |

(or acceptable) according to a threshold $\tau$ if and only if $|c_{ij}| \geq \tau \times ||c_{.j}||_\infty$, where $\tau \in [0, 1]$. To reduce the complexity of the algorithms, it is also common to limit the pivot search to a set of candidate pivots. For example, in [13] the authors proposed to visit the entries of a fixed number of columns using the Zlatev-style search [37]. A similar strategy is used in [34] to find a pivot set in the context of parallel sparse **LU** factorization.

We use a slightly different algorithm: our pivot search is not restricted to columns but to a more complex set of entries in order to achieve a better fill-in reduction. At each step of the ordering, we look for the best entry $p = (r_p, c_p)$ within a subset (say, $S$) of the entries in the bipartite graph $G_C$. The subset $S$ is defined by two threshold parameters `MS` $> 0$ and `ncol` $\geq 0$ as follows. First, the `MS` entries with the smallest structural metric $m_0$ are added to $S$. Second, those `MS` entries may belong to several columns. We then add in $S$ all the other nonzero entries of those columns, but restricted to at most the first `ncol` columns. The set $S$ is thus composed of a first set of `MS` entries, the so-called `MS`-set, and a second set, the so-called `ncol`-set $= S \backslash$`MS`-set.

We now explain how we select the entry of minimum structural metric in $S$ among the numerically acceptable pivots. We first visit the `MS`-set sorted in increasing order of the structural metric $m_0$. The first numerically acceptable entry found corresponds to the minimum with respect to our hybrid strategy and we stop the search. Otherwise, none of the values in the `MS`-set entries is numerically acceptable. However, if `ncol` $> 0$ then we are sure that at least `ncol` entries will be numerically acceptable since $\tau \leq 1$. Finally, if `ncol` $= 0$ and none of the entries in the `MS`-set is numerically acceptable then the first entry of the `MS`-set is selected even if it is not numerically acceptable. (In our experiments `MS` $= 100$ and `ncol` $= 10$ are used.)

### 4.2. Update of the bipartite graph $G_C$.

A bipartite graph is used to represent **C**. At each step $k$, we need to add new entries in $G_{C^{k+1}}$ corresponding to the fill-ins in $\mathbf{C}^{k+1}$. Since $G_C$ holds the set of candidate pivots, we need to guarantee that properties (2.1) and (2.2) hold.

Let $\mathcal{M}$ be a matching in $\mathbf{C}^k$. The following two extreme strategies preserve these two properties:

- `MATCH_UPDATE` will refer to the strategy that performs incomplete Gaussian elimination on **C** to preserve only the perfect matching property (2.1). Let $p = (r_p, c_p)$ be the current pivot. Let ($r_p$, `match_col`) and (`match_row`, $c_p$) be the matched entries of **C** in row $r_p$ and column $c_p$, respectively. That is, ($r_p$, `match_col`) $\in \mathcal{M}$ and (`match_row`, $c_p$) $\in \mathcal{M}$. If these entries are the same (i.e., $(r_p, c_p)$ is a matched entry), nothing needs to be done to maintain

property (2.1). Otherwise, entry (`match_row`, `match_col`) is added to $\mathbf{C}$ and $\mathcal{M}$ to maintain property (2.1). Note that this entry corresponds to an entry in $\mathcal{P}attern(\bar{\mathbf{C}}^k)$, so that property (2.2) remains true.
- `TOTAL_UPDATE` will refer to the strategy which performs all the updates in $\mathbf{C}$ (i.e., $\mathbf{C}^{k+1} = \bar{\mathbf{C}}^k$). Note that even if this strategy naturally preserves property (2.2), our perfect matching on $\mathbf{C}^{k+1}$ may have to be updated as in the `MATCH_UPDATE` strategy.

In practice, a mixed strategy, exploiting both `MATCH_UPDATE` and `TOTAL_UPDATE`, will be used for the experiments. (The decision is based on memory and cost estimations of the algorithm.)

**4.3. Update of the bipartite quotient graph $\mathcal{G}_A$.** In Algorithm 4.1 we describe how the bipartite quotient graph associated with the reduced matrix is updated.

**Algorithm 4.1** `CMLS` update of the bipartite quotient graph $\mathcal{G}_A^k$

```
   Let $p = (r_p, c_p)$ be the current pivot at step $k$ and $\mathcal{F}_p = \mathcal{R}_{r_p} \cup \mathcal{C}_{c_p}$.
   if $\mathcal{U}_p \neq \emptyset$ and $\mathcal{L}_p \neq \emptyset$ then
     for each row $i \in \mathcal{L}_p$ do
1      $\mathcal{A}_{i*} = (\mathcal{A}_{i*} \setminus \mathcal{U}_p) \setminus \{c_p\}$ /* variable elimination in row direction */
2      $\mathcal{R}_i = (\mathcal{R}_i \setminus \mathcal{F}_p) \cup p$
     end for
     for each column $j \in \mathcal{U}_p$ do
3      $\mathcal{A}_{*j} = (\mathcal{A}_{*j} \setminus \mathcal{L}_p) \setminus \{r_p\}$ /* variable elimination in column direction */
4      $\mathcal{C}_j = (\mathcal{C}_j \setminus \mathcal{F}_p) \cup p$
     end for
   else /* pivot pruning: delete all that is related to $p$, if $\mathcal{U}_p = \emptyset$ or $\mathcal{L}_p = \emptyset$ */
     for each row $i \in \mathcal{L}_p$ do
       $\mathcal{R}_i = (\mathcal{R}_i \setminus \mathcal{F}_p)$
       $\mathcal{A}_{i*} = \mathcal{A}_{i*} \setminus \{c_p\}$
     end for
     for each column $j \in \mathcal{U}_p$ do
       $\mathcal{C}_j = (\mathcal{C}_j \setminus \mathcal{F}_p)$
       $\mathcal{A}_{*j} = \mathcal{A}_{*j} \setminus \{r_p\}$
     end for
   end if
```

The "if" block of Algorithm 4.1 shows how the elements and variables are pruned. The element pruning performed at lines 2 and 4 includes pruning due to local symmetrization. The variable pruning performed at lines 1 and 3 removes the intersection of the adjacency structures. For each row $i$ in $\mathcal{L}_p$, variables of $\mathcal{A}_{i*}$ that appear in $\mathcal{U}_p$ are removed and we say that we perform [illegible]. For each column $j$ in $\mathcal{U}_p$, variables of $\mathcal{A}_{*j}$ that appear in $\mathcal{L}_p$ are removed. This will be referred to as [illegible]. We then say that our algorithm performs [illegible]. Note that if, at a given step, variables are removed from both row $i$ and column $i$, it means that $i \in \mathcal{L}_p$ and $i \in \mathcal{U}_p$. In section 4.3.1, we will prove that under additional assumptions more pruning of the variables could have been introduced. We then however comment in section 4.3.2 that doing so makes impossible the detection of the reducibility as done in the "else" block of Algorithm 4.1. We will also explain why it is correlated with the strategy used to prune variables. Note that this additional pruning would have improved the accuracy of our structural metrics as explained in section 4.4.

**4.3.1. Two-way variable elimination.** Property 4.1 shows that under additional assumptions the structure of the quotient graph can be further pruned.

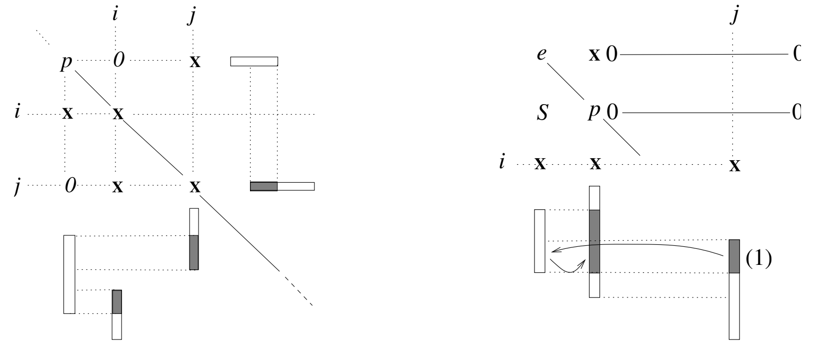
PROPERTY 4.1. [illegible] $k$ [illegible] $(i,j)$ [illegible] $i$ [illegible] $j$ [illegible] $\mathbf{C}^k$ [illegible]

(1) [illegible] $i \in \mathcal{L}_p$ [illegible] $\mathcal{L}_p$ [illegible] $\mathcal{A}_{*j}$ [illegible] $j \notin \mathcal{U}_p$

(2) [illegible] $j \in \mathcal{U}_p$ [illegible] $\mathcal{U}_p$ [illegible] $\mathcal{A}_{i*}$ [illegible] $i \notin \mathcal{L}_p$

[illegible]. From (2.2), we have $\mathcal{P}attern(\mathbf{C}^{k+1}) \subseteq \mathcal{P}attern(\bar{\mathbf{C}}^k)$. Therefore, if at step $k$, $(i,j)$ is the only entry in row $i$ and column $j$ of $\mathbf{C}^k$, it will remain the only entry in its row and column for all subsequent $\mathbf{C}^l$ for $l > k$. Thus $(i,j)$ will be selected as a pivot in a future step, and we can anticipate where local symmetrization will occur. So the entries in $\mathcal{A}_{*j} \cap \mathcal{L}_p$ for Property 4.1(1) (or in $\mathcal{A}_{i*} \cap \mathcal{U}_p$ for Property 4.1(2)) can be pruned and will be retrieved from $\mathcal{L}_p$ (or $\mathcal{U}_p$) when $(i,j)$ is eliminated. ☐

When we apply Property 4.1, we say that the algorithm performs elimination in both row and column directions. This process will be referred to as [illegible]. For example, when the pivot choice is limited to a transversal, the two-way variable elimination can be performed at each step of the elimination, as in the `DMLS` algorithm [5]. This is illustrated in Figure 4.1(a). We assume, for the sake of clarity, that the input matrix has been permuted to have all the candidate pivots on the diagonal. The shaded areas correspond to the variables that can be removed from the variable adjacency lists because they are implicitly stored through the adjacency lists of element $p$.



(a) Illustration of two-way variable elimination.

(b) Effect of variable elimination in both directions on reducibility detection (S indicates the position of local symmetrization).

FIG. 4.1. *Variable elimination and reducibility detection.*

If the hypothesis of Property 4.1 is not true, the two-way variable elimination cannot be applied because we do not know whether local symmetrization will be performed or not. Let us consider Figure 4.1(a) again. If all three entries $(i,i)$, $(j,j)$, and $(j,i)$ belong to $\mathbf{C}$, then we cannot prune all the shaded areas. This is because both $(i,i)$ and $(j,i)$ are potential pivots from column $i$. If $(i,i)$ were chosen as the pivot from column $i$, then the shaded area in column $i$ could have been pruned during the elimination of $p$ thanks to local symmetrization relative to entry $i$ in column $\mathcal{L}_p$. However, if $(j,i)$ were selected as the pivot from column $i$, then since $j \notin \mathcal{L}_p$ and $i \notin \mathcal{U}_p$, the element $p$ would not be used to build the row and column adjacency of $(j,i)$. In this case the shaded area in column $i$ should not be pruned during the elimination of $p$ since it would be impossible to retrieve those variables. Note that the shaded area in column $j$ can be pruned, because the entry $(p, j)$ is [illegible], and so the variable elimination in the column direction can be applied.

**4.3.2. Reducibility detection.** If the input matrix is reducible, we may encounter a pivot $p$ such that either (1) both $\mathcal{L}_p = \emptyset$ and $\mathcal{U}_p = \emptyset$ (referred to as [illegible]) or (2) $\mathcal{L}_p = \emptyset$ or $\mathcal{U}_p = \emptyset$ (referred to as [illegible]). Ideally, we would like to remove $p$ from the quotient graph $\mathcal{G}_A$ in both reducible cases. (In our context [illegible] from $\mathcal{G}_A$ means that both the pivot and its adjacency structure can be suppressed without any further update of the graph.) However, we will show that whether $p$ can be removed or not depends on whether we use only one-way variable elimination or we use two-way variable elimination as well.

PROPERTY 4.2. [illegible] $p$ [illegible]

Property 4.2 comes from the fact that the pruning of the structures due to local symmetrization has not been anticipated. Thus, none of the entries in $\mathcal{L}_p$ (if $\mathcal{U}_p = \emptyset$) or $\mathcal{U}_p$ (if $\mathcal{L}_p = \emptyset$) will be needed by the other variables to represent their adjacency structure in $\mathcal{G}_A$. Therefore, pivot $p$ can be removed from $\mathcal{G}_A$.

PROPERTY 4.3. [illegible] $p$ [illegible]

[illegible]. First, when $\mathcal{U}_p = \emptyset$ and $\mathcal{L}_p = \emptyset$, $p$ becomes a singleton element and can certainly be removed from the quotient graph. Second, let us suppose that two-way variable elimination has been performed at least once. We now build a counterexample to show that we cannot safely (in all possible cases) remove a weakly reducible pivot $p$. Let us assume without loss of generality that $\mathcal{U}_p = \emptyset$ and $\mathcal{L}_p \neq \emptyset$. Let us assume that there exists a variable $i \in \mathcal{L}_p$ and that there is an entry $(i, j)$ that is the only entry in row $i$ and column $j$ in $\mathbf{C}$. We also assume that variables in $\mathcal{A}_{*j}$ have been pruned under two-way variable elimination. Therefore, $p$ must be used to retrieve those entries and cannot be removed from $\mathcal{G}_A$. This is illustrated in Figure 4.1(b) where the shaded area (1) in column $j$ is first stored through element $e$ and then stored through element $p$ (after pivot $p$ absorbs element $e$). ☐

Property 4.3 indicates a drawback of the two-way variable elimination: we can only prune the pivot in the strongly reducible case. The algorithm may be very inefficient if the matrix is very reducible in the weak sense.

When the matrix is reducible to block triangular form (BTF), the reducibility detection may have a significant impact on the ordering quality [15]. In that case many instances in which an element is strongly or weakly reducible can appear. Property 4.2 can then be used to show that thanks to one-way variable elimination `CMLS` will better detect and exploit the BTF of a matrix (see [6, 32] for further details).

**4.4. Update of the structural metric.** In this section, we describe heuristics to estimate the structural quality of a pivot.

In the preamble section, we first describe how we approximate the row and column degrees. In section 4.4.2, we describe a metric based on an upper bound on the fill-ins introduced at each step of elimination. This approximation of the fill-ins has been studied by the authors of `AMD` [1] for symmetric matrices. We provide a generalization of this approximation to unsymmetric matrices and prove that it is a tighter upper bound on the fill-ins than the approximations proposed for symmetric matrices in [33]. Note that concerning the deficiency approximation in [30], there is no guarantee that it is an upper bound of the fill-in. Our approximate minimum fill-in heuristic will be referred to as `AMFI`.

**4.4.1. Preamble.** Let us assume that the $k$th pivot $p = (r_p, c_p)$ has been selected. All the entries in $(\mathcal{L}_p \times V_c \;\cup\; V_r \times \mathcal{U}_p) \cap \mathcal{P}attern(\mathbf{C})$ are involved in the structural metric updates. The size of this area is thus larger than the area involved in the update of the structure of $\mathbf{C}$. The algorithm to update the structural metrics is one of the most costly steps of our algorithm.

We want the metrics to reflect the structural quality of an entry if it were selected as the next pivot. That is why we compute metrics which are related to the structure of our quotient graph and for which local symmetrization is anticipated. In the following, the degrees, approximate degrees, fill-ins, and approximate fill-ins are all related to this quotient graph structure.

Let $d_r(i,j)$ and $d_c(i,j)$ denote, respectively, the external row and the external column degrees of entry $(i,j)$. Similarly to the `AMD` [1] and `DMLS` [5] algorithms, approximate row and column external degrees are computed. The `AMD`-like approximate external row and column degrees, $amd_r(i,j) > d_r(i,j)$ and $amd_c(i,j) > d_c(i,j)$, respectively, are then defined by the following two equations:

$$\begin{aligned} amd_r(i,j) = \;& |\mathcal{A}_{i*} \setminus \mathcal{U}_p| + |\mathcal{U}_p \setminus j| + \textstyle\sum_{e \in \mathcal{R}_i \cup \mathcal{C}_j} (|\mathcal{U}_e \setminus \mathcal{U}_p|) - \alpha_j, \\ & \text{with } \alpha_j = \max(|\mathcal{C}_j|, 1) \text{ if } j \notin \mathcal{U}_p \text{ else } \alpha_j = 0. \end{aligned} \tag{4.1}$$

$$\begin{aligned} amd_c(i,j) = \;& |\mathcal{A}_{*j} \setminus \mathcal{L}_p| + |\mathcal{L}_p \setminus i| + \textstyle\sum_{e \in \mathcal{C}_j \cup \mathcal{R}_i} (|\mathcal{L}_e \setminus \mathcal{L}_p|) - \beta_i, \\ & \text{with } \beta_i = \max(|\mathcal{R}_i|, 1) \text{ if } i \notin \mathcal{L}_p \text{ else } \beta_i = 0. \end{aligned} \tag{4.2}$$

As was done in [5], degree corrections ($\alpha_j$ and $\beta_i$ in (4.1) and (4.2)) are introduced to improve the approximations of the row and column external degrees in the presence of local symmetrization. To justify these correction terms, one can observe that if $j \notin \mathcal{U}_p$ then $j$ is counted in every $\mathcal{U}_e \setminus \mathcal{U}_p$ for $e$ that is adjacent to column $j$ ($e \in \mathcal{C}_j$). Furthermore, if $\mathcal{C}_j$ is empty and $j \notin \mathcal{U}_p$ then column $j$ has been counted in $\mathcal{A}_{i*} \setminus \mathcal{U}_p$ and should then be subtracted. This explains the use of $\alpha_j$ in the correction. $\beta_i$ can be justified in a similar way. The $|\mathcal{U}_e \setminus \mathcal{U}_p|$ and $|\mathcal{L}_e \setminus \mathcal{L}_p|$ quantities are computed similarly in the `AMD` algorithm.

Note that since only one-way variable elimination is employed, the computation of the metric is less accurate than with two-way variable elimination. This is because in the latter case, for any element $e$, row index $i \in \mathcal{U}_p$, and column index $j \in \mathcal{L}_p$, we have $\mathcal{A}_{i*} \cap \mathcal{U}_e = \emptyset$ and $\mathcal{A}_{*j} \cap \mathcal{L}_e = \emptyset$. This is no longer true when one-way variable elimination is used (see Algorithm 4.1). But as was explained in section 4.3, the benefit of one-way variable elimination is to better exploit the BTF of the matrix.

After eliminating the $k$th pivot, we approximate the row and column degree by

$$\overline{amd}_r(i,j) = \min(amd_r(i,j), n-k-1) \tag{4.3}$$

and

$$\overline{amd}_c(i,j) = \min(amd_c(i,j), n-k-1). \tag{4.4}$$

Note that these approximations do not use the values of the previous approximate row and column degrees because it would be costly to store these quantities for each entry in $\mathbf{C}$.

**4.4.2. Approximation of the fill-in.** We want to estimate the amount of new fill-in that would occur in the reduced matrix if an entry were selected as the next pivot. A coarse upper bound of the fill-in that would occur can be obtained by removing the area corresponding to $\mathcal{L}_p \times \mathcal{U}_p$ from the Markowitz cost or the area corresponding to the largest adjacent clique [33]. A tighter approximation of the fill-in in the factors can be obtained by removing all the areas already filled during the elimination of the previous elements.

Suppose that $i \in \mathcal{L}_p$ or $j \in \mathcal{U}_p$. Let $\mathcal{F} = \mathcal{R}_i \cup \mathcal{C}_j$. Let $e$ be an element that belongs to $\mathcal{F}$. Let $S(i, j)$ denote the union of the areas associated with all the elements adjacent to entry $(i, j)$:

$$S(i,j) = \left| \bigcup_{e \in \mathcal{F}} (\mathcal{L}_e \setminus \{i\}) \times (\mathcal{U}_e \setminus \{j\}) \setminus (\mathcal{L}_p \times \mathcal{U}_p) \right| .$$

Ideally one might want to subtract both $\mid (\mathcal{L}_p \setminus \{i\}) \times (\mathcal{U}_p \setminus \{j\}) \mid$ and $S(i, j)$ from the Markowitz cost $d_r(i, j) \times d_c(i, j)$. An upper bound of the fill-in that would occur (including local symmetrization) if an entry $(i, j)$ were eliminated is

$$d_r(i,j) d_c(i,j) - \mid (\mathcal{U}_p \setminus \{j\}) \mid \mid (\mathcal{L}_p \setminus \{i\}) \mid - S(i,j).$$

The authors of [33] have observed that instead of using the exact external degrees one could use the approximate (in the sense of the `AMD` algorithm) external degrees since both produce results of comparable quality and since `AMD`-based metrics are significantly faster to compute. In this context, the corresponding upper bound of the fill-in metric becomes

$$amd_r(i,j) amd_c(i,j) - \mid (\mathcal{U}_p \setminus \{j\}) \mid \mid (\mathcal{L}_p \setminus \{i\}) \mid - S(i,j). \tag{4.5}$$

Let $AS$ be an overestimation of area $S$,

$$AS(i,j) = \sum_{e \in \mathcal{F}} \mid (\mathcal{L}_e \setminus \{i\}) \times (\mathcal{U}_e \setminus \{j\}) \setminus (\mathcal{L}_p \times \mathcal{U}_p)|. \tag{4.6}$$

Property 4.4 proves that one can in fact subtract area $AS(i, j)$, instead of $S(i, j)$, to obtain a more accurate upper bound of the fill-in metric than expression (4.5).

PROPERTY 4.4. $amd_r(i,j) amd_c(i,j) - \mid (\mathcal{U}_p \setminus \{j\}) \mid \mid (\mathcal{L}_p \setminus \{i\}) \mid - AS(i,j)$ [illegible] $(i, j)$ [illegible]

An intuitive proof of Property 4.4 is that, during the computation of the approximate degree, the submatrix is expanded in such a way that the intersections between all $(\mathcal{U}_e \setminus \mathcal{U}_p \setminus \{j\})$ and between all $(\mathcal{L}_e \setminus \mathcal{L}_p \setminus \{i\})$ for $e \in \mathcal{F}$ are empty. The area $AS$ corresponds to a real surface in the expanded matrix and can be removed from the area $amd_r(i, j) amd_c(i, j)$ to compute the fill-in that would occur in the expanded matrix. Moreover, this fill-in in the expanded matrix is an upper bound of the exact fill-in in the quotient graph. A formal proof of Property 4.4 is given in [32].

In practice we use $\overline{amd}_r(i, j)$ and $\overline{amd}_c(i, j)$ as defined in (4.3) and (4.4) instead of $amd_r(i, j)$ and $amd_c(i, j)$. Because of that it may happen that $\overline{amd}_r(i,j) \overline{amd}_c(i,j) - |\mathcal{U}_p \setminus j| |\mathcal{L}_p \setminus i| - AS(i,j)$ becomes negative, meaning that either $\overline{amd}_r(i,j) < amd_r(i,j)$ or $\overline{amd}_c(i,j) < amd_c(i,j)$. In such cases, as it is done in `AMD` and `DMLS`, one can artificially set the metric to 0. We propose here an alternative that could also be applied to these approaches to limit the tie-breaking. We introduce row and column scaling terms

$$\texttt{rowscale} = \frac{\overline{amd}_r(i,j) - |\mathcal{U}_p \setminus j|}{amd_r(i,j) - |\mathcal{U}_p \setminus j|} \text{ and } \texttt{colscale} = \frac{\overline{amd}_c(i,j) - |\mathcal{L}_p \setminus i|}{amd_c(i,j) - |\mathcal{L}_p \setminus i|}.$$

If one systematically scales the area $AS$ by `rowscale` × `colscale`, then we ensure a positive metric and avoid tie-breaking problems due to metrics equal to 0. Our final `AMFI` metric is then defined as follows:

$$metric^{(k+1)}(i,j) = \min \left\{ \begin{array}{ll} \multicolumn{2}{l}{\overline{amd}_r(i,j)\overline{amd}_c(i,j) - |\mathcal{U}_p \setminus j||\mathcal{L}_p \setminus i|} \\ \multicolumn{2}{l}{\quad - \texttt{rowscale} \times \texttt{colscale} \times AS(i,j)} \\ metric^{(k)}(i,j) & +|\mathcal{U}_p \setminus j| \times \overline{amd}_r(i,j) \\ & +|\mathcal{L}_p \setminus i| \times \overline{amd}_c(i,j) \\ & -2 \times |\mathcal{U}_p \setminus j| \times |\mathcal{L}_p \setminus i|. \end{array} \right. \tag{4.7}$$

**4.5. Supervariables and mass elimination.** For the sake of clarity, the algorithms described in the previous section did not include supervariables. In this section, we first define our generalization of [illegible] and [illegible] to bipartite quotient graphs with off-diagonal pivots. We then revisit the previous algorithms and explain what has to be modified to detect and exploit supervariables.

In our context, we want supervariables to exploit identical adjacency structures in the graph at each step of the elimination. Supervariables are thus defined on the bipartite quotient graph of **A**, whereas on the bipartite graph of **C** we use only simple variables. With the `CMLS` algorithm we cannot use exactly the same kinds of supervariables as in [1, 5, 19, 23] because they assume that pivots are on the diagonal so that a row can be associated with a column before being selected as a pivot. That is why our concept of supervariable is closer to the one used in [22]: we define [illegible] (resp., [illegible]) as row variables (resp., columns variables) which have the same adjacency in $\mathcal{G}_A$. To limit the cost of supervariable detection, two hash functions (see, for example, [9]) are then used for each row and column direction.

If $i$ and $j$ are two indistinguishable row variables, they are replaced in $\mathcal{G}_A$ by a [illegible] containing both $i$ and $j$, labeled by its [illegible] ($i$, say) [18, 19, 20]. The notation $\mathbf{i}$ is used to denote this row supervariable and $\mathbf{i} = \{i, j\}$. $i$ and $j$ are said to be [illegible] of the row supervariable $\mathbf{i}$ and the notations $i \in \mathbf{i}$ and $j \in \mathbf{i}$ are then used. At the beginning of Gaussian elimination, the row variables are said to be [illegible]. Each simple row variable $i$ can also be seen as a row supervariable $\mathbf{i} = \{i\}$. For each row supervariable $\mathbf{i}$, $|\mathbf{i}|$ corresponds to its size, i.e., its number of constituent variables. Similar definitions and notation can be introduced for the [illegible], the [illegible], the [illegible], and the [illegible]. When it is clear from the context, we do not differentiate between a column or a row supervariable. Furthermore, let $r_1$ and $r_2$ be two row variables which belong to the same row supervariable $\mathbf{r}$ and $c_1$ and $c_2$ be two column variables which belong to the same column supervariable $\mathbf{c}$. After the elimination of pivot $p_1 = (r_1, c_1)$, $p_2 = (r_2, c_2)$ can be eliminated in $\mathcal{G}_A$ without causing extra fill-in. This process, commonly referred to as [illegible] [25], creates a new (super)element $e = (\mathbf{r}_e, \mathbf{c}_e)$ in the quotient graph with $\mathbf{r}_e = \{r_1, r_2\}$ and $\mathbf{c}_e = \{c_1, c_2\}$. In the following, we comment on the algorithmic modifications due to the introduction of supervariables.

Let $p$ be the current pivot. The first modification of the algorithm concerns the introduction of a scaling of the structural metric as defined by (4.7). The structural metric of an entry $(\mathbf{i},\mathbf{j})$ adjacent to $p$ either in the row or in the column direction is divided by $\min(|\mathbf{i}|,|\mathbf{j}|)$. Indeed, $\min(|\mathbf{i}|,|\mathbf{j}|)$ corresponds to the size of the largest pivot block which could be eliminated if a pivot at the intersection of these row and column supervariables were selected.

The second modification of the algorithm concerns the elimination process which is performed in the following three main steps. During the first step, the scaled metric is used to select a pivot in $\mathbf{C}$. During the second step, we retrieve its associated row $\mathbf{r}_p$ and column $\mathbf{c}_p$ supervariables in $\mathbf{A}$. During the third step, we eliminate "as many as possible" variables belonging to $(\mathbf{r}_p \times \mathbf{c}_p) \cap \mathbf{C}$. Note that the meaning of "as many as possible" will depend on the context. If a hybrid strategy is used then pivot entries might be rejected because of numerical criteria. Furthermore, since the $\mathbf{C}$ matrix is updated when eliminating a pivot, the new nonzero entries that might be at the intersection of the pattern of $\mathbf{C}$ and the supervariables need also be considered. The same modified three steps are also applied when the mass elimination process of supervariables adjacent to the current pivot is involved. Finally, if some constituent variables of a supervariable have not been eliminated, then they are used to build a new supervariable and are reinserted in $\mathcal{G}_A$.

The final modification concerns the update of the structural metric. After the elimination of a pivot $p$, the approximate external row and column degrees as defined by (4.1) and (4.2) become

$$\begin{aligned} amd_r(i,j) = \; & |\mathcal{A}_{\mathbf{i}*} \setminus \mathcal{U}_p| + |\mathcal{U}_p \setminus \{\mathbf{j}\}| + \textstyle\sum_{e\in\mathcal{R}_{\mathbf{i}}\cup\mathcal{C}_{\mathbf{j}}}(|\mathcal{U}_e \setminus \mathcal{U}_p|) - \alpha_{\mathbf{j}}\,|\mathbf{j}|, \\ & \text{with } \alpha_{\mathbf{j}} = \max(|\mathcal{C}_{\mathbf{j}}|,1) \text{ if } \mathbf{j} \notin \mathcal{U}_p \text{ else } \alpha_{\mathbf{j}} = 0, \end{aligned} \tag{4.8}$$

$$\begin{aligned} amd_c(i,j) = \; & |\mathcal{A}_{*\mathbf{j}} \setminus \mathcal{L}_p| + |\mathcal{L}_p \setminus \{\mathbf{i}\}| + \textstyle\sum_{e\in\mathcal{R}_{\mathbf{i}}\cup\mathcal{C}_{\mathbf{j}}}(|\mathcal{L}_e \setminus \mathcal{L}_p|) - \beta_{\mathbf{i}}\,|\mathbf{i}|, \\ & \text{with } \beta_{\mathbf{i}} = \max(|\mathcal{R}_{\mathbf{i}}|,1) \text{ if } \mathbf{i} \notin \mathcal{L}_p \text{ else } \beta_{\mathbf{i}} = 0. \end{aligned} \tag{4.9}$$

**5. Experiments.** In this section we analyze the effect of the `CMLS` ordering on the performance of sparse solvers. Our new ordering will be compared to the combination of `DMLS` ordering and `MC64` [16, 17] because it is the most robust in-place local heuristic (better than the combination of `AMD` and `MC64`; see [5]) in terms of numerical stability and fill-in reduction in the factors. `DMLS` takes into account the asymmetry of the matrices, selects pivots on the diagonal, and applies local symmetrization and two-way variable elimination. Thus it can be considered a restricted `CMLS`. We recall that `MC64` permutes the matrix such that the product of the diagonal elements is maximized.

With the `CMLS` ordering, our pivot sequence results from a combination of structural and numerical information (even when only structural metrics are used to select the pivots, the initialization of our constraint matrix is based on numerical considerations). Therefore it is important to analyze the numerical quality of the proposed sequence of pivots. In this context, for very different motivations, we may want to experiment with both an approach that performs partial pivoting to preserve numerical stability and an approach based on static pivoting. In the first case, the numerical quality of the proposed sequence of pivots is not so critical to obtaining a backward stable factorization, and we expect to improve the sparsity of the factors because of the freedom to select entries in the constraint matrix $\mathbf{C}$. In the case of a static pivoting, we expect that the capacity of `CMLS` to select pivots according to numerical criteria can be used to better control the numerical quality of the sequence while still offering more freedom than a diagonal Markowitz algorithm. In fact with the `CMLS` algorithm we can define a family of orderings and expect that two probably different members of this family can be used in these two cases: a `CMLS` ordering in which $\mathbf{C}$ offers a lot of freedom to choose the pivots, and a `CMLS` ordering in which the selection of the pivots is strongly guided by the numerical values in $\mathbf{C}$.

To represent each class of solver techniques, we consider the multifrontal code `MA41_UNS` [2, 7] which performs numerical pivoting during the factorization and the supernodal code `SuperLU_DIST` [28] which performs static pivoting. Both codes are run in sequential mode. As shown in [4, 7, 12, 26] the approaches used to factorize the matrix in `MA41_UNS` and `SuperLU_DIST` are very competitive in shared/sequential and distributed memory environments, respectively. Note that because of the important algorithmic similarities between `MA41_UNS` and the distributed memory code `MUMPS` [3], this work also will be very beneficial to the distributed memory multifrontal code.

In section 5.1, we present our experimental environment. In section 5.2, we discuss the case where the pivot choice in `CMLS` is restricted to the matching provided by `MC64`. In section 5.3, we analyze the behavior of our ordering when a structural strategy is used to select the pivots. We report performance obtained with `MA41_UNS` in terms of time and memory used during factorization. In section 5.4, we illustrate the benefits resulting from the use of hybrid strategies for pivot selection in `SuperLU_DIST` and focus on the numerical effects.

### 5.1. Experimental environment.

**5.1.1. Test matrices and computing environment.** Consider a matrix $\mathbf{A} = (a_{ij})$ and let $nnz(\mathbf{A})$ be its number of nonzero entries. We define the [illegible] [illegible] $s(\mathbf{A})$ as

$$s(\mathbf{A}) = \frac{|\{(i,j) \text{ s.t. } a_{ij} \neq 0 \text{ and } a_{ji} \neq 0\}|}{nnz(\mathbf{A})}.$$

If $\mathbf{A}$ is symmetric, then $s(\mathbf{A}) = 1$, and if $\mathbf{A}$ is strictly triangular, then $s(\mathbf{A}) = 0$. In the remainder of this section, the symmetry of a matrix always refers to the structural symmetry after the `MC64` permutation has been applied (see column sym of Table 5.1).

A representative set of 19 large unsymmetric matrices has been selected from Davis's collection [11]; see Table 5.1. Only matrices with a structural symmetry lower than 0.5 and of order greater than 10000 were chosen. Moreover, we limited the number of similar matrices from the same family to two in order to avoid the class effects. We also added to our test set four matrices (mixtank, invextr1, fidapm11, and cavity16) from the PARASOL test data[1] and Matrix Market,[2] because we have observed that for these matrices `SuperLU_DIST` needs iterative refinement to improve the accuracy of the solution [4]. These four matrices will be used in section 5.4 to illustrate that using the `CMLS` ordering improves the numerical behavior of `SuperLU_DIST`.

All our results were obtained on a Linux PC computer (Pentium 4, 2.8 GHz, 2 GBytes of memory, and 1 MByte of cache). We used the Portland Fortran 90 compiler `pgf90`, C compiler `gcc` (both with -O3 option), and ATLAS BLAS [35, 36].

We systematically applied random row and column permutations to our initial matrix so that the ordering algorithms were less sensitive to the effects of tie-breaking. We ran each problem with eleven random permutations and selected the run whose

ordering returns the median fill-in in the factors. We did not observe large variations of the amount of fill-in in the factors from these random permutations except for matrix bbmat. (In general variations are smaller than 10%.)

**5.1.2. CMLS and DMLS testing environment.** The initialization of $\mathbf{C}$ is done using a scaled matrix and the maximum weighted matching returned by `MC64`. To limit the size of $\mathbf{C}$ and the complexity (cost and memory) of the ordering phase, the initial number of entries in $\mathbf{C}^0$ is set between $n$ and $4n$ (computation based on a function that depends on both $n$ and $nnz(\mathbf{A})$). We then drop the entries that are smaller than 0.1 in magnitude and the entries whose structural metrics are too large. While dropping, we still maintain the nonsingularity property (2.1). In our test set, we observed that the size of $\mathbf{C}^0$ is between $n$ and $3n$ after this last dropping phase.

We use the metric `AMFI` of section 4.4.2 since it is the most efficient metric for both `CMLS` and `DMLS` orderings. In the `CMLS` implementation, we use `rowscale` and `colscale` coefficients (see end of section 4.4.2) to reduce the amount of tie-breaking between variables that would have a negative metric (reset to 0) with `DMLS`. This algorithmic modification has also been implemented in the `DMLS` code to simplify our discussions in this section.

**5.2. Preliminary remarks about diagonal constraint matrix.** When $\mathbf{C}^0$ contains only the entries from the `MC64` matching and thus the set of candidate pivots for `CMLS` and `DMLS` is identical, one should expect a comparable behavior of the two algorithms in terms of fill-in in the factors. However, we have noticed that `CMLS` ordering tends to produce sparser factors (see [32] for detailed results) even if `DMLS` uses two-way variable elimination which leads to more accurate structural metrics, as explained in section 4.4.1. This can be explained by the following algorithmic differences:

Table 5.2

- Thanks to the one-way variable elimination, `CMLS` can eliminate all the elements in both the strongly reducible and the weakly reducible situations. This is well illustrated by the mult_dcop_3 matrix, which has 7448 irreducible components. `DMLS` and `CMLS` detect 875 singletons during a common preprocessing step. Then during ordering, `DMLS` detects 95 additional blocks versus 229 blocks for `CMLS`.
- `CMLS` can create a row (column) supervariable if two rows (columns) have the same structure. `DMLS` can create a supervariable only if both rows and columns have the same structure. Thus, on the same quotient graph `CMLS` will detect more supervariables than `DMLS`. Note that the use of supervariables improves the accuracy of the structural metric. For example, if we consider that variables $i$ and $j$ belong to the same row supervariable, then the entries in $\mathcal{A}_{i*}$ and $\mathcal{A}_{j*}$ will not be counted as fill-in.

We should stress that these algorithmic differences were justified because `CMLS` is designed to handle more general and complex situations than `DMLS`. What was not at all predicted is that even a `DMLS`-like algorithm—pivot choice limited to the diagonal—could benefit from the more general framework of the `CMLS` ordering.

### 5.3. Structural strategy.

**5.3.1. Structure of the factors.** In this section, we analyze the effect of the ordering on the size of the factors and compare the predicted size and the actual size of the factors. When there are no off-diagonal pivoting and node amalgamation, the actual size would be the same as the predicted size.

Table 5.2 compares `CMLS` with `DMLS` for both the estimated and the real size of the factors, using the `MA41_UNS` solver. For most matrices, the `CMLS` ordering results in sparser factors. The gains in sparsity vary from −22% to 56%, with gains very much comparable for both the estimated and the real size of the factors. On all matrices `CMLS` is either comparable or significantly better than `DMLS` except for lhr34c and lhr71c for which `DMLS` performs better. For the two matrices `CMLS` performs many mass eliminations (approximatively 25% of the variables are eliminated during mass elimination). Instead of dividing our minimum fill-in estimation by the minimum of the sizes of the column and row supervariables, one could anticipate the number of mass eliminations and divide the `AMFI` estimation by the maximum of the sizes of the column and row supervariables. With this modification, we observed similar results in terms of fill-in between `CMLS` and `DMLS` for these two matrices.

As expected, the fact that more flexibility has been offered to select off-diagonal pivots in the constraint matrix helps `CMLS` to preserve the sparsity of the factors. However, in doing so we have allowed `CMLS` to select pivots that do not belong to the maximum weighted matching. Since a structural metric is then used by `CMLS` to select pivots, it is thus critical to evaluate the numerical quality of this pivot sequence with `MA41_UNS`. We recall that, thanks to partial threshold pivoting, the factorization phase of `MA41_UNS` (the default value of the threshold is used in all experiments) will modify the pivot sequence to control the growth of the size of the factors. This may result in an increase in the estimated factor size and number of operations. We thus also provide in Table 5.2 the ratio between the number of nonzeros in the factors and the forecast number of nonzeros in the factors. Note that from a software point of view it is also critical for the estimation to reflect reality. Clearly an accurate estimation is important for algorithms that are implemented without dynamic memory allocation. Even for C, C++, or Fortran 90 based implementations that allow dynamic memory allocations, their cost may be not negligible. Finally, the accuracy of the memory estimation is even more critical in a distributed memory environment. For example, the buffers used for communications need to be well estimated. We see in Table 5.2 that the increase in the size of the factors is reasonable.

**5.3.2. Run-time and memory usage.** In this section, we examine the number of operations, run-time, and memory usage of `MA41_UNS`. The extra cost due to numerical pivoting during factorization is always included in the number of operations. Note that the timings for the factorization and the solution phases have to be interpreted carefully because they strongly depend on the basic linear algebra kernels used.

We see in Table 5.3 that on almost all the matrices, the `CMLS` ordering reduces the amount of memory used, with an average reduction around 11%. The reduction in the number of operations is even larger (median value of 20%) and will contribute to the reduction in the factorization time.

Table 5.4 then compares the time of the three main steps of the solution process. Note that the ordering time of both orderings depends on two opposite effects that are difficult to assess. The better we preserve sparsity, the smaller might be the quotient graph, and the faster we can process it. On the other hand, the better we preserve sparsity, the fewer elements are absorbed, the fewer supervariables are detected, and the higher the complexity might be. However, our new ordering is a real unsymmetric ordering that selects off-diagonal pivots and updates a constraint matrix. One should thus expect the time spent in the ordering to be higher with `CMLS` than with `DMLS`. Indeed, `CMLS` performs more metric computations and has to explicitly store and manipulate the constraint matrix $\mathbf{C}$. The metric update is the most costly step of the ordering so that the complexity of the ordering is tightly linked to the size of $\mathbf{C}$. Considering that the size of $\mathbf{C}^0$ is typically between $2n$ and $3n$, we see in Table 5.4 that `CMLS` is quite competitive with respect to `DMLS` (we observe that the cost of `CMLS`

does not linearly increase with the size of $\mathbf{C}^0$). Two algorithmic differences might explain the good behavior of the `CMLS` ordering (see, for example, torso1 matrix).

- Since `CMLS` has the flexibility to select pivots in the constraint matrix it may not be critical to know the metric of the entries that belong to a fairly dense row or column. That is why our CMLS implementation can easily avoid metric updates of such entries in the **C** matrix.

- Furthermore, supervariables have been generalized in our context resulting in separated row and column supervariables. This feature helps CMLS exploit the unsymmetric structure of the matrix in a more efficient way.

We then see in Table 5.3 that the decrease in fill-in and in the number of operations performed during the factorization phase leads to a decrease in the factorization time. The reductions in factorization time are slightly smaller than those in the number of operations (the average reduction in the number of operations is around 20%). This is because sparser factors often lead to smaller full blocks for which basic linear algebra kernels are slower. We observed that the flop rate of MA41_UNS tends to be smaller with CMLS than with DMLS: the average flop rate is nearly 1.02 GFlops with the DMLS ordering, whereas it is around 0.99 GFlops with the CMLS ordering.

### 5.4. Impact of the hybrid strategies on SuperLU_DIST.

We now study the numerical behavior of SuperLU_DIST using CMLS ordering. Because of the static pivoting strategy used during factorization, SuperLU_DIST is expected to be numerically more sensitive than MA41_UNS to the use of hybrid strategies in pivot selection, and iterative refinement may be required to obtain an accurate solution, as was observed in [4]. We thus analyze the componentwise backward error of the solution [8] during iterative refinement. Note that one step of iterative refinement costs at least as much as one forward and backward substitution. The cost of the solution phase is closely related to the number of steps of iterative refinement. In the hybrid strategy (see section 4.1), a relative threshold is set to avoid the selection of small pivots in **C**. This was chosen to be 0.01 in all our experiments.

Table 5.5 shows that SuperLU_DIST often does not compute an accurate solution if the CMLS ordering is obtained with a structural metric (compare the number of entries with $\star$ in columns STR and HYB). With the hybrid strategy to select pivots, some more pivots are postponed by CMLS because of their numerical values. We observe that this often results in an increase in the fill-in in the factor with respect to a structural metric (compare columns STR and HYB) but improves the numerical reliability of the CMLS pivot sequence. Note that we report only the median values because large variations of gains perturb the average statistics.

Figure 5.1 compares the componentwise backward errors during iterative refinement with the CMLS and DMLS orderings (results after two and four steps). In each plot, a data point above the diagonal corresponds to a matrix for which CMLS performs better in terms of componentwise backward error. Is it clear that using the CMLS ordering improves the numerical behavior of SuperLU_DIST. There are still two matrices (av41092 and Zhao2) for which, with either CMLS or DMLS ordering, iterative refinement does not converge to an accurate solution (upper right corner). The torso1 matrix is the only one for which the DMLS approach succeeds, whereas the CMLS approach fails (bottom right corner). There are four matrices in the upper left corner (lhr34c, lhr71c, mult_dcop3, and fidapm11) for which the backward error of SuperLU_DIST combined with DMLS remains larger than $10^{-8}$, whereas SuperLU_DIST combined with CMLS converges in less than four iterations. It is interesting to observe that the only matrices for which CMLS with the hybrid strategy leads to significantly more fill-in in the factors are the lhr34c, lhr71c, and mult_dcop3 matrices on which DMLS did not converge after iterative refinement (and independently of the number of steps). Note finally that, with CMLS, on all problems except three we obtain an accurate solution (backward error smaller than $10^{-8}$) with four steps of iterative refinement, whereas,

with `DMLS`, iterative refinement did not converge on six matrices.

**6. Concluding remarks.** The originality of the `CMLS` algorithm relies on its ability to compute an unsymmetric permutation with the following goals in mind: to reduce the fill-in in the factors and to preselect numerically good pivots for the factorization. It is based on a constraint matrix which contains the candidate pivots and a quotient graph that is used to compute the structural metrics. The `CMLS` algorithm can be used to design a family of orderings that can address a large class of problems. The main results and the properties of the algorithm are summarized as follows:

- Significant reductions in terms of fill-in (13%) and flops (20%) have been obtained with the structural strategy to select the pivots.
- Using structural metrics to select the pivots does not affect the numerical behavior of the `MA41_UNS` solver.
- On numerically difficult problems, `CMLS` can be used to improve the accuracy of `SuperLU_DIST` and reduce the number of steps of iterative refinement during the solution phase.
- Our generalized supervariables could be used in the context of `DMLS` to also improve the metric computation.

One indirect but important consequence of our work is that we do not need to limit our pivot choice to a maximum weighted transversal of the original matrix. Preliminary experiments have shown that the maximum weighted matching can in fact be replaced by a simpler structural maximum transversal during the preprocessing phase (Step 1 as defined in section 2). One possible direction for future work could then be to design a parallel version of the preprocessing phase.

Furthermore, the constraint matrix $\mathbf{C}$ contains the information of an incomplete factorization. We intend to use it as a preconditioner and to compare its quality and cost with existing incomplete $\mathbf{LU}$ factorizations.

Finally, in our paper we have focused on local strategies and on very unsymmetric matrices. We also did experiments to compare our algorithms with global strategies such as nested dissection and observed that our approach was generally better on this set of test matrices. Combining our numerically based local heuristics with structurally based global strategies is another interesting direction for future work.

# GEOMETRIC MEANS IN A NOVEL VECTOR SPACE STRUCTURE ON SYMMETRIC POSITIVE-DEFINITE MATRICES*

VINCENT ARSIGNY†, PIERRE FILLARD†, XAVIER PENNEC†, AND NICHOLAS AYACHE†

**Abstract.** In this work we present a new generalization of the geometric mean of positive numbers on symmetric positive-definite matrices, called Log-Euclidean. The approach is based on two novel algebraic structures on symmetric positive-definite matrices: first, a lie group structure which is compatible with the usual algebraic properties of this matrix space; second, a new scalar multiplication that smoothly extends the Lie group structure into a vector space structure. From bi-invariant metrics on the Lie group structure, we define the Log-Euclidean mean from a Riemannian point of view. This notion coincides with the usual Euclidean mean associated with the novel vector space structure. Furthermore, this means corresponds to an arithmetic mean in the domain of matrix logarithms. We detail the invariance properties of this novel geometric mean and compare it to the recently introduced affine-invariant mean. The two means have the same determinant and are equal in a number of cases, yet they are not identical in general. Indeed, the Log-Euclidean mean has a larger trace whenever they are not equal. Last but not least, the Log-Euclidean mean is much easier to compute.

**Key words.** geometric mean, symmetric positive-definite matrices, Lie groups, bi-invariant metrics, geodesics

## 1. Introduction.

Symmetric positive-definite (SPD) matrices of real numbers appear in many contexts. In medical imaging, their use has become common during the last 10 years with the growing interest in diffusion tensor magnetic resonance imaging (DT-MRI, or simply DTI) [3]. In this imaging technique, based on nuclear magnetic resonance (NMR), the assumption is made that the random diffusion of water molecules at a given position in a biological tissue is Gaussian. As a consequence, a diffusion tensor image is an SPD matrix-valued image in which the SPD matrix associated with the current volume element (or voxel) is the covariance matrix of the local diffusion process. SPD matrices also provide a powerful framework for modeling the anatomical variability of the brain, as shown in [15]. More generally, they are widely used in image analysis, especially for segmentation, grouping, motion analysis, and texture segmentation [16]. They are also used intensively in mechanics, for example, with strain or stress tensors [4]. Last, but not least, SPD matrices are becoming a common tool in numerical analysis for generating adapted meshes to reduce the computational cost of solving partial differential equations (PDEs) in three dimensions [17].

As a consequence, there has been a growing need to carry out computations with these objects, for instance to interpolate, restore, and enhance images SPD matrices. To this end, one needs to define a complete operational framework. This

is necessary to fully generalize to the SPD case the usual statistical tools or PDEs on vector-valued images. The framework of Riemannian geometry [8] is particularly adapted to this task, since many statistical tools [18] and PDEs can be generalized to this framework.

To evaluate the relevance of a given Riemannian metric, the properties of the associated notion of [illegible] are of great importance. Indeed, most computations useful in practice involve averaging procedures. This is the case in particular for the interpolation, regularization, and extrapolation of SPD matrices, where mean values are implicitly computed to generate new data. For instance, the classical regularization technique based on the heat equation is equivalent to the convolution of the original data with Gaussian kernels.

Let $\mathcal{M}$ be an abstract manifold endowed with a Riemannian metric, whose associated distance is $d(.,.)$. Then the classical generalization of the Euclidean mean is given by the [illegible] (also called the [illegible]) [18, 19]. Let $(x_i)_{i=1}^N$ be $N$ points of $\mathcal{M}$. Their Fréchet mean $\mathbb{E}(x_i)$ (possibly not uniquely defined) is defined as the point minimizing the following [illegible]:

$$\mathbb{E}(x_i) = \arg\min_x \sum_{i=1}^{N} d^2(x, x_i). \tag{1.1}$$

One can directly use a Euclidean structure on square matrices to define a metric on the space of SPD matrices. This is straightforward, and in this setting, the Riemannian mean of a system of SPD matrices is their [illegible] mean, which is an SPD matrix since SPD matrices form a convex set. However, this mean is [illegible] adequate in many situations, for two main reasons. First, symmetric matrices with nonpositive eigenvalues are at a finite distance from any SPD matrix in this framework. In the case of DT-MRI, this is not physically acceptable, since this amounts to assuming that small diffusions (i.e., small eigenvalues) are much more likely than large diffusions (i.e., large eigenvalues). A priori, large and small diffusions are equally unlikely in DT-MRI, and a [illegible] should be respected. In particular, a matrix and its inverse should be at the same distance from the identity. Therefore, the use of a generalization to SPD matrices of the [illegible] mean of positive numbers would be preferable, since such a mean is precisely invariant with respect to inversion.

Second, an SPD matrix corresponds typically to a [illegible]. The value of its determinant is a direct measure of the dispersion of the associated multivariate Gaussian. The reason is that the volumes of associated trust regions are proportional to the square root of this determinant. But the Euclidean averaging of SPD matrices often leads to a [illegible]: the determinant of the Euclidean mean can be strictly larger than the original determinants. The reason is that the induced interpolation of determinants is polynomial and [illegible] monotonic in general. In DTI, diffusion tensors are assumed to be covariance matrices of the local Brownian motion of water molecules. Introducing more dispersion in computations amounts to introducing more diffusion, which is physically unacceptable. For illustrations of this effect, see [20, 21]. As a consequence, the determinant of a mean of SPD matrices should remain bounded by the values of the determinants of the averaged matrices.

To fully circumvent these difficulties, other metrics have been recently proposed for SPD matrices. With the affine-invariant metrics proposed in [12, 22, 23, 19], symmetric matrices with negative and null eigenvalues are at an infinite distance from any SPD matrix. The swelling effect has disappeared, and the symmetry with respect to inversion is respected. These new metrics provide an affine-invariant generalization of the geometric mean of positive numbers on SPD matrices. But the price paid for this success is a high computational burden in practice, essentially due to the curvature induced on the space of SPD matrices. This leads in many cases to slow and hard-to-implement algorithms (especially for PDEs) [12].

We propose here a new Riemannian framework on SPD matrices, which gives rise to a novel generalization of the geometric mean to SPD matrices. It fully overcomes the computational limitations of the affine-invariant framework, while conserving excellent theoretical properties. This is obtained with a new family of metrics named [illegible]. Such metrics are particularly simple to use. They result in classical Euclidean computations in the domain of matrix logarithms. As a consequence, there is a closed form for the Log-Euclidean mean, contrary to the affine-invariant case. It results in a drastic reduction in computation time: the Log-Euclidean mean can be computed approximately 20 times faster.

The remainder of this article is organized as follows. In section 2, we recall a number of elementary properties of the space of SPD matrices. Then we proceed in section 3 to the theory of Log-Euclidean metrics which is based on two novel algebraic structures on SPD matrices: a Lie group structure and a new scalar multiplication which complements the new multiplication to obtain a new vector space structure. The definition of the Log-Euclidean mean is deduced from these new structures. Contrary to the affine-invariant mean, there is a closed form for the Log-Euclidean mean and it is simple to compute. In section 4 we highlight the resemblances and differences between affine-invariant and Log-Euclidean means. They are quite similar, since they have the same determinant, which is the classical geometric mean of the determinants of the averaged SPD matrices. They even coincide in a number of cases, and yet are different in general. We prove that Log-Euclidean means are strictly more anisotropic when averaged SPD matrices are isotropic enough.

## 2. Preliminaries.

We begin with a description of the fundamental properties and tools used in this work. First, we recall the elementary properties of the matrix exponential. Then we examine the general properties of SPD matrices. These properties are of two types: algebraic and differential. On the one hand, SPD matrices have algebraic properties because they are a special kind of invertible matrices, and on the other hand they can be considered globally as a smooth manifold and therefore have differential geometry properties. These properties are not independent: on the contrary, they are compatible in a profound way. This compatibility is the core of the approach developed here.

### 2.1. Notation.

We will use the following definitions and notation:

- $Sym_\star^+(n)$ is the space of SPD real $n \times n$ matrices.
- $Sym(n)$ is the vector space of real $n \times n$ symmetric matrices.
- $GL(n)$ is the group of real invertible $n \times n$ matrices.
- $M(n)$ is the space of real $n \times n$ square matrices.
- $\mathrm{Diag}(\lambda_1, \ldots, \lambda_n)$ is the diagonal matrix constructed with the real values $(\lambda_i)_{i \in 1 \ldots n}$ in its diagonal.
- For any square matrix $M$, $Sp(M)$ is the [illegible] of $M$, i.e., the set of its eigenvalues.
- $\phi : E \rightarrow F$ is differentiable mapping between two smooth manifolds. Its differential at a point $M \in E$ acting on a infinitesimal displacement $dM$ in the tangent space to $E$ at $M$ is written as $D_M \phi . dM$.

**2.2. Matrix exponential.** The exponential plays a central role in [illegible] (see [11, 5, 8]). We will consider here only the matrix version of the exponential, which is a tool that we extensively use in the next sections. We recall its definition and give its elementary properties. Last but not least, we give the Baker–Campbell–Hausdorff formula. It is a powerful tool that provides fine information on the structure of Lie groups around the identity. We will see in section 4 how it can be used to compare Log-Euclidean means to affine-invariant means in terms of anisotropy.

DEFINITION 2.1. [illegible] $\exp(M)$ [illegible] $M$ [illegible] $\exp(M) = \sum_{n=0}^{\infty} \frac{M^k}{k!}$ [illegible] $G \in GL(n)$ [illegible] $M \in M(n)$ [illegible] $G = \exp(M)$ [illegible] $M$ [illegible] $N$

In general, the logarithm of a real invertible matrix may not exist, and if it exists it may not be unique. The lack of existence is a general phenomenon in connected Lie groups. One generally needs [illegible] exponentials to reach every element [10]. The lack of uniqueness is essentially due to the influence of rotations: rotating of an angle $\alpha$ is the same as rotating of an angle $\alpha + 2k\pi$, where $k$ is an integer. Since the logarithm of a rotation matrix directly depends on its rotation angles (one angle suffices in three dimensions, but several angles are necessary when $n > 3$), it is not unique. However, when a real invertible matrix has no (complex) eigenvalue on the (closed) negative real line, then it has a unique real logarithm whose (complex) eigenvalues have an imaginary part in $]-\pi, \pi[$ [2]. This particular logarithm is called [illegible]. We will write $\log(M)$ for the principal logarithm of a matrix $M$ whenever it is defined.

THEOREM 2.2. $\exp : M(n) \rightarrow GL(n)$ [illegible] $\mathcal{C}^{\infty}$ [illegible] $M \in M(n)$ [illegible] $dM \in M(n)$ [illegible]

$$D_M \exp .dM = \sum_{k=1}^{\infty} \frac{1}{k!} \left( \sum_{l=0}^{k-1} M^{k-l-1}.dM.M^l \right). \tag{2.1}$$

[illegible]. The smoothness of exp is simply a consequence of the uniform absolute convergence of its series expansion in any compact set of $M(n)$. The differential is obtained classically by a term by term derivation of the series defining the exponential. □

We see here that the noncommutativity of the matrix multiplication seriously complicates the differentiation of the exponential, which is much simpler in the scalar case. However, taking the trace in (2.1) yields the following.

COROLLARY 2.3. [illegible]

$$\text{Trace}(D_M \exp .dM) = \text{Trace}(\exp(M).dM). \tag{2.2}$$

In the following we will also use this property on determinants.

PROPOSITION 2.4. [illegible] $M \in M(n)$ [illegible] $\det(\exp(M)) = \exp(\text{Trace}(M))$

[illegible]. This is easily seen in terms of eigenvalues of $M$. The Jordan decomposition of $M$ [1] ensures that Trace($M$) is the sum of its eigenvalues. But the exponential of a triangular matrix transforms the diagonal values of this matrix into their scalar exponential. The determinant of $\exp(M)$ is simply the product of its eigenvalues, which is precisely the exponential of the trace of $M$. □

THEOREM 2.5 (Baker–Campbell–Hausdorff formula [9] (matrix case)). [illegible] $M, N \in M(n)$ [illegible] $t \in \mathbb{R}$ [illegible] $t$ [illegible]

[illegible]

$$\begin{aligned}\log(\exp(t.M).\exp(t.N)) &= t.(M+N) + t^2/2([M,N]) \\ &\quad + t^3/12([M,[M,N]] + [N,[N,M]]) \\ &\quad + t^4/24([[M,[M,N]],N]) + O(t^5). \end{aligned} \tag{2.3}$$

[illegible] $[M,N] = MN - NM$ [illegible] $M$ [illegible] $N$

The Baker–Campbell–Hausdorff formula shows how much $\exp(\log(M).\log(N))$ deviates from $M+N$ due to the noncommutativity of the matrix product. Remarkably, this deviation can be expressed only in terms of Lie brackets between $M$ and $N$ [14].

**2.3. Algebraic properties.** SPD matrices have remarkable algebraic properties. First, there always exists a unique real and [illegible] logarithm for any SPD matrix, which is its principal logarithm. Second, if the space of SPD matrices is not a subgroup of $GL(n)$, it is stable with respect to inversion. Moreover, its spectral decomposition is particularly simple.[1]

THEOREM 2.6. [illegible] $S \in Sym(n)$ [illegible] $S$ [illegible] $Sym_\star^+(n)$ [illegible] $GL(n)$ [illegible] $\exp : Sym(n) \rightarrow Sym_\star^+(n)$ [illegible]

[illegible]. For a proof of the first assertion, see elementary linear algebra manuals, or [1]. For the second assertion, we see from section 2.2 that SPD matrices have a unique real logarithm whose eigenvalues have an imaginary part between $-\pi$ and $+\pi$, since the eigenvalues of SPD matrices are real and always positive. The principal logarithm of an SPD matrix can be obtained simply by replacing its eigenvalues with their natural logarithms, which shows that this logarithm is symmetric. $\square$

Thanks to the existence of an orthonormal basis in which an SPD matrix (resp., a symmetric matrix) is diagonal, the logarithm (resp., the exponential) has a particularly simple expression. In such a basis, taking the log (resp., the exp) is simply done by applying its scalar version to eigenvalues:

$$\begin{cases} \log(R.\mathrm{Diag}(\lambda_1,\ldots,\lambda_N).R^T) = R.\mathrm{Diag}(\log(\lambda_1),\ldots,\log(\lambda_N)).R^T, \\ \exp(R.\mathrm{Diag}(\lambda_1,\ldots,\lambda_N).R^T) = R.\mathrm{Diag}(\exp(\lambda_1),\ldots,\exp(\lambda_N)).R^T. \end{cases}$$

These formulae provide a particularly efficient method to calculate the logarithms and exponentials of symmetric matrices, whenever the cost of a diagonalization is less than that of the many matrix multiplications (in the case of the exponential) and inversions (in the case of the logarithm) used in the general matrix case by classical algorithms [13, 24]. For small values of $n$, and in particular $n = 3$, we found such formulae to be extremely useful.

**2.4. Differential properties.** From the point of view of topology and differential geometry, the space of SPD matrices also has many particularities. The properties recalled here are elementary and will not be detailed. See [25] for complete proofs.

PROPOSITION 2.7. $Sym_\star^+(n)$ [illegible] $Sym(n)$ [illegible] $Sym(n)$ [illegible] $n(n+1)/2$

**2.5. Compatibility between algebraic and differential properties.** We have seen that exp is a smooth bijection. We show here that the logarithm, i.e.,

---

[1] This is due to the fact that SPD matrices are *normal operators*, like rotations and antisymmetric matrices [1].

its inverse, is also smooth. As a consequence, all the algebraic operations on SPD matrices presented before are also smooth, in particular the inversion. Thus, the two structures are fully compatible.

THEOREM 2.8. $\log : Sym^+_\star(n) \to Sym(n)$ [illegible] $\mathcal{C}^\infty$ [illegible] exp [illegible] log [illegible] exp [illegible]

[illegible]. In fact, we need only prove the last assertion. If it is true, the implicit function theorem [6] applies and ensures that log is also smooth. Since the differential of exp at 0 is simply given by the identity, it is invertible by continuity in a neighborhood of 0. We now show that this propagates to the entire space $Sym(n)$. Indeed, let us then suppose that for a point $M$, the differential $D_{M/2}\exp$ is invertible. We claim that then $D_M \exp$ is also invertible, which suffices to prove the point. To show this, let us take $dM \in Sym(n)$ such that $D_M \exp .dM = 0$. If $D_M \exp$ is invertible, we should have $dM = 0$. To see this, remark that $\exp(M) = \exp(M/2).\exp(M/2)$. By differentiation and applying to $dM$, we get

$$D_M \exp .dM = 1/2((D_{M/2}\exp .dM).\exp(M/2) + \exp(M/2).(D_{M/2}\exp .dM)) = 0.$$

This implies by multiplication by $\exp(-M/2)$:

$$\exp(-M/2)(D_{M/2}\exp .dM).\exp(M/2) + (D_{M/2}\exp .dM) = 0.$$

Since

$$A^{-1}.\exp(B).A = \exp(A^{-1}.B.A)$$

we have also by differentiation

$$A^{-1}.D_B \exp(dB).A = D_B \exp(A^{-1}.dB.A).$$

Using this simplification and the hypothesis that $D_{M/2}\exp$ is invertible, we obtain

$$\exp(-M/2).dM.\exp(M/2) + dM = 0.$$

Let us rewrite this equation in an orthonormal basis in which $M$ is diagonal with a rotation matrix $R$. Let $(\lambda_i)$ be the eigenvalues of $M$ and let $dN := R.dM.R^T$. Then we have

$$dN = -\mathrm{Diag}(\exp(-\lambda_1/2), \ldots, \exp(-\lambda_N/2)).dN.\mathrm{Diag}(\exp(\lambda_1/2), \ldots, \exp(\lambda_N/2)).$$

Coordinate by coordinate, this is written as:

$$\forall i, j : dN_{i,j}(1 + \exp(-\lambda_i/2 + \lambda_j/2)) = 0.$$

Hence for all $i, j$ : $dN_{i,j} = 0$ which is equivalent to $dM = 0$. We are done. □

COROLLARY 2.9. [illegible] $\alpha \in \mathbb{R}$ [illegible] $S \mapsto S^\alpha$ [illegible] $\alpha = -1$

[illegible]. We have $S^\alpha = \exp(\alpha \log(S))$. The composition of smooth mappings is smooth. □

## 3. Log-Euclidean means.

In this section we focus on the construction of Log-Euclidean means. They are derived from two new structures on SPD matrices.

The first is a Lie group structure [11], i.e., an algebraic group structure that is [illegible] with the differential structure of the Space of SPD matrices. The second structure is a [illegible]. Indeed, one can define a [illegible] that complements the Lie group structure to form a vector space structure on the space of SPD matrices. In this context, Log-Euclidean metrics are defined as bi-invariant metrics on the Lie group of SPD matrices. The Log-Euclidean mean is the Fréchet mean associated with these metrics. It is particularly simple to compute.

### 3.1. Multiplication of SPD matrices.

It is not a priori obvious how one could define a multiplication on the space of SPD matrices compatible with classical algebraic and differential properties. How can one combine smoothly two SPD matrices to make a third one, in such a way that Id is still the identity and the usual inverse remains its inverse? Moreover, if we obtain a new Lie group structure, we would also like the matrix exponential to be the exponential associated with the Lie group structure which, a priori, can be different.

The first idea that comes to mind is to directly use matrix multiplication. But then the noncommutativity of matrix multiplication between SPD matrices stops the attempt: if $S_1, S_2 \in Sym_\star^+(n)$, $S_1.S_2$ is an SPD matrix (or equivalently, is symmetric) if and only if $S_1$ and $S_2$ commute. To overcome the possible asymmetry of the matrix product of two SPD matrices, one can simply take the [illegible] (i.e., the closest symmetric matrix in the sense of the Frobenius norm [7]) of the product and define the new product $\diamond$:

$$S_1 \diamond S_2 := \frac{1}{2}(S_1.S_2 + S_2.S_1).$$

This multiplication is smooth and conserves the identity and the inverse. But $S_1 \diamond S_2$ is not necessarily positive! Also, since the set of SPD matrices is not closed, one cannot define in general a closest SPD matrix, but only a closest symmetric [illegible] matrix [7].

In [12], affine-invariant distances between two SPD matrices $S_1, S_2$ are of the form

$$d(S_1, S_2) = \| \log(S_1^{-1/2}.S_2.S_1^{-1/2}) \|, \tag{3.1}$$

where $\|.\|$ is a Euclidean norm defined on $Sym(n)$. Let us define the following multiplication $\circledcirc$:

$$S_1 \circledcirc S_2 := S_1^{1/2}.S_2.S_1^{1/2}.$$

With this multiplication, the affine-invariant metric constructed in [12] can be interpreted then as a left-invariant metric. Moreover, this multiplication is smooth and compatible with matrix inversion and matrix exponential, and the product truly defines an SPD matrix. Everything works fine, except that it is not [illegible]. This makes everything fail, because associativity is an essential requirement of group structure. Without it, many fundamental properties disappear. For Lie groups, the notion of adjoint representation no longer exists without associativity.

Theorem 2.8 points to an important fact: $Sym_\star^+(n)$ is diffeomorphic to its tangent space at the identity, $Sym(n)$. But $Sym(n)$ has an additive group structure, and to obtain a group structure on the space of SPD matrices, one can simply transport the additive structure of $Sym(n)$ to $Sym_\star^+(n)$ with the exponential. More precisely, we have the following.

DEFINITION 3.1. [illegible] $S_1, S_2 \in Sym_\star^+(n)$ [illegible] $S_1 \odot S_2$ [illegible]

$$S_1 \odot S_2 := \exp(\log(S_1) + \log(S_2)). \tag{3.2}$$

PROPOSITION 3.2. $(Sym_\star^+(n), \odot)$ [illegible]

[illegible] The multiplication is defined by addition on logarithms. It is therefore associative and commutative. Since $\log(\mathrm{Id}) = 0$, the neutral element is Id, and since $\log(S^{-1}) = -\log(S)$, the new inverse is the matrix inverse. Finally, we have $\exp(\log(S_1) + \log(S_2)) = \exp(\log(S_1)).\exp(\log(S_2)) = S_1.S_2$ when $[S_1, S_2] = 0$. □

THEOREM 3.3. [illegible] $\odot$ [illegible] $Sym_\star^+(n)$ [illegible] $(S_1, S_2) \mapsto S_1 \odot S_2^{-1}$ [illegible] $\mathcal{C}^\infty$ [illegible] $Sym_\star^+(n)$ [illegible] $\odot$

[illegible] $(S_1, S_2) \mapsto S_1 \odot S_2^{-1} = \exp(\log(S_1) - \log(S_2))$. But since exp and log and the addition are smooth, their composition is also smooth. By definition (see [8, page 29]), $Sym_\star^+(n)$ is a Lie group. □

PROPOSITION 3.4. $\exp : (Sym(n), +) \rightarrow (Sym_\star^+(n), \odot)$ [illegible] $Sym_\star^+(n)$ [illegible] $Sym(n)$ [illegible] $(t.V)_{t\in\mathbb{R}}$ [illegible] $V \in Sym(n)$ [illegible] $Sym_\star^+(n)$ [illegible] $Sym(n)$

[illegible] We have explicitly transported the group structure of $Sym(n)$ into $Sym_\star^+(n)$ so exp is a morphism. It is also a bijection, and thus an isomorphism. The smoothness of exp then ensures its compatibility with the differential structure.

Let us recall the definition of one-parameter subgroups. $(S(t))_{t\in\mathbb{R}}$ is such a subgroup if and only if we have for all $t, s$: $S(t + s) = S(t) \odot S(s) = S(s) \odot S(t)$. But then $\log(S(t+s) = \log(S(t) \odot S(s)) = \log(S(t)) + \log(S(s))$ by definition of $\odot$. Therefore $\log S(t)$ is also a one-parameter subgroup of $(Sym(n), +)$, which is necessarily of the form $t.V$, where $V \in Sym(n)$. $V$ is the [illegible] of $S(t)$. Finally, the exponential is obtained from one-parameter subgroups, which are all of the form $(\exp(t.V))_{t\in\mathbb{R}}$ (see [5, Chap. V]). □

Thus, we have given the space of SPD matrices a structure of Lie group that leaves unchanged the classical matrix notions of inverse and exponential. The new multiplication used, i.e., the logarithmic multiplication, generalizes the matrix multiplication when two SPD matrices do not commute in the matrix sense.

The associated Lie algebra is the space of symmetric matrices, which is diffeomorphic and isomorphic to the group itself. The associated Lie bracket is the null bracket: $[S_1, S_2] = 0$ for all $S_1, S_2 \in Sym(n)$.

The reader should note that this Lie group structure is, to our knowledge, new in the literature. For a space as commonly used as SPD matrices, this is quite surprising. The probable reason is that the Lie group of SPD matrices is [illegible] a multiplicative matrix group, contrary to most Lie groups.

**3.2. Log-Euclidean metrics on the Lie group of SPD matrices.** Now that we have given $Sym_\star^+(n)$ a Lie group structure, we turn to the task of exploring metrics compatible with this new structure. Among Riemannian metrics in Lie groups, [illegible] metrics are the most convenient. We have the following definition.

DEFINITION 3.5. [illegible] $\langle , \rangle$ [illegible] $G$ [illegible] $m \in G$ [illegible] $m$ [illegible]

THEOREM 3.6. [illegible] [5, [illegible] V], [illegible]

1. [illegible]
2. [illegible] $m \in G$, $Ad(m)$ [illegible] $\mathfrak{g}$ [illegible] $Ad(m)$ [illegible] $m$
3. [illegible] $G$ [illegible]

COROLLARY 3.7. [illegible] $\langle , \rangle$ [illegible] $T_{Id}Sym_\star^+(n) = Sym(n)$ [illegible] $Sym_\star^+(n)$ [illegible]

[illegible]. The commutativity of the multiplication implies that $Ad(Sym_\star^+(n)) = \{\mathrm{Id}\}$, which is trivially an isometry group. ◻

This result is striking. In general Lie groups, the existence of bi-invariant metrics is not guaranteed. More precisely, it is guaranteed if and only if the adjoint representation $Ad(G)$ is relatively compact, i.e., (the dimension is assumed finite) if the group of matrices given by $Ad(G)$ is [illegible] (see [5, Theorem V.5.3]). This is trivially the case when the group is commutative, as here, since $Ad(G) = \{e\}$, which is obviously bounded. Other remarkable cases where $Ad(G)$ is bounded are compact groups, such as rotations. But for noncompact noncommutative groups, there is in general [illegible] bi-invariant metric, as in the case of rigid transformations.

DEFINITION 3.8. [illegible] 3.9

COROLLARY 3.9. [illegible] $\langle , \rangle$ [illegible] $Sym_\star^+(n)$ [illegible]

$$(\exp(V_1 + t.V_2))_{t\in\mathbb{R}}, \quad [illegible] \quad V_1,\ V_2 \in Sym(n). \tag{3.3}$$

[illegible]

$$\begin{cases} \log_{S_1}(S_2) = D_{\log(S_1)} \exp .(\log(S_2) - \log(S_1)), \\ \exp_{S_1}(L) = \exp(\log(S_1) + D_{S_1} \log .L). \end{cases} \tag{3.4}$$

[illegible] $V_1$, $V_2$ [illegible] $S$ [illegible]

$$\langle V_1, V_2 \rangle_S = \langle D_S \log .V_1, D_S \log .V_2 \rangle_{Id}. \tag{3.5}$$

[illegible]

$$d(S_1, S_2) = \| \log_{S_1}(S_2) \|_{S_1} = \| \log(S_2) - \log(S_1) \|_{Id}, \tag{3.6}$$

[illegible] $\|.\|$ [illegible]

[illegible]. Theorem 3.6 states that geodesics are obtained by translating one-parameter subgroups, and Proposition 3.4 gives the form of these subgroups in terms of the matrix exponential. By definition, the metric exponential $\exp_{S_1} : T_{S_1}Sym_\star^+(n) \to Sym_\star^+(n)$ is the mapping that associates with a tangent vector $L$ the value at time 1 of the geodesic starting at time 0 from $S_1$ with an initial speed vector $L$. Differentiating the geodesic equation (3.3) at time 0 yields an initial vector speed equal to

$D_{V_1}\exp.V_2$. As a consequence, $\exp_{S_1}(L) = \exp(\log(S_1) + (D_{\log(S_1)}\exp)^{-1}.L)$. The differentiation of the equality $\log\circ\exp = \mathrm{Id}$ yields $(D_{\log(S_1)}\exp)^{-1} = D_{S_1}\log$. Hence we have the formula for $\exp_{S_1}(L)$. Solving in $L$ the equation $\exp_{S_1}(L) = S_2$ provides the formula for $\log_{S_1}(S_2)$.

The metric at a point $S$ is obtained by propagating by translation the scalar product on the tangent space at the identity. Let $L_S : Sym_\star^+(n) \to Sym_\star^+(n)$ be the logarithmic multiplication by $S$. We have $\langle V_1, V_2\rangle_S = \langle D_S L_{S^{-1}}.V_1, D_S L_{S^{-1}}.V_2\rangle$. But simple computations show that $D_S L_{S^{-1}} = D_S\log$. Hence we have (3.5). Finally, we combine (3.4) and (3.5) to obtain the (simple this time!) formula for the distance. □

COROLLARY 3.10. [illegible] ( [8, [illegible] 107]) [illegible] $Sym(n)$ [illegible]

In [12], the metric defined on the space of SPD matrices is affine invariant. The action act$(A)$ of an invertible matrix $A$ on the space of SPD matrices is defined by

$$\forall S,\ \mathrm{act}(A)(S) = A.S.A^T.$$

Affine-invariance means that for all invertible matrices $A$, the mapping $\mathrm{act}(A) : Sym_\star^+(n) \to Sym_\star^+(n)$ is an isometry. This group action describes how an SPD matrix, assimilated to a covariance matrix, is affected by a general affine change of coordinates.

Here, the Log-Euclidean Riemannian framework will not yield full affine-invariance. However, it is not far from it, because we can obtain invariance by similarity (isometry plus scaling).

PROPOSITION 3.11. [illegible] $Sym_\star^+(n)$ [illegible] $\langle V_1, V_2\rangle :=$ [illegible] $(V_1.V_2)$ [illegible] $V_1, V_2 \in Sym(n)$

[illegible] Let $R \in SO(n)$ be a rotation and $s > 0$ be a scaling factor. Let $S$ be an SPD matrix. $V$ is transformed by the action of $s.R$ into $\mathrm{act}(sR)(S) = s^2.R.S.R^T$. From (3.6), the distance between two SPD matrices $S_1$ and $S_2$ transformed by $sR$ is

$$d(\mathrm{act}(sR)(S_1), \mathrm{act}(sR)(S_2)) = \mathrm{Trace}(\{\log(\mathrm{act}(sR)(S_1)) - \log(\mathrm{act}(sR)(S_2))\}^2).$$

A scaling by a positive factor $\lambda$ on an SPD matrix corresponds to a translation by $\log(\lambda).\mathrm{Id}$ in the domain of logarithms. Furthermore, we have $\log(R.S.R^T) = R.\log(S).R^T$ for any SPD matrix $S$ and any rotation $R$. Consequently, the scaling zeros out in the previous formula and we have

$$\begin{aligned} d(\mathrm{act}(sR)(S_1), \mathrm{act}(sR)(S_2)) &= \mathrm{Trace}(\{R.(\log(S_1) - \log(S_2)).R^T\}^2) \\ &= \mathrm{Trace}(\{\log(S_1) - \log(S_2)\}^2) \\ &= d(S_1, S_2). \end{aligned}$$

Hence we have the result. □

Thus, we see that the Lie group of SPD matrices with an appropriate Log-Euclidean metric has many [illegible]: Lie group bi-invariance and similarity-invariance. Moreover, Theorem 3.6 shows that the inversion mapping $S \mapsto S^{-1}$ is an isometry.

**3.3. A vector space structure on SPD matrices.** We have already seen that the Lie group of SPD matrices is isomorphic and diffeomorphic to the additive group of symmetric matrices. We have also seen that with a Log-Euclidean metric, the Lie group of SPD matrices is also isometric to the space of symmetric matrices endowed with the associated Euclidean metric. There is more: the Lie group isomorphism exp from the Lie algebra of symmetric matrices to the space of SPD matrices can be smoothly extended into an isomorphism of vector spaces. Indeed, let us define the following operation.

DEFINITION 3.12. [illegible] $\circledast$ [illegible] $\lambda \in \mathbb{R}$ [illegible]

$$\lambda \circledast S = \exp(\lambda . \log(S)) = S^{\lambda}. \tag{3.7}$$

When we assimilate the logarithmic multiplication to an addition and the logarithmic scalar multiplication to a usual scalar multiplication, we have all the properties of a vector space. By construction, the mapping $\exp : (Sym(N), +, .) \to (Sym_{\star}^{+}(n), \odot, \circledast)$ is a vector space isomorphism. Since all algebraic operations on this vector space are smooth, this defines what could be called a "Lie vector space structure" on SPD matrices.

Of course, this result does not imply that the space of SPD matrices is a vector subspace of the vector space of square matrices. But it shows that we can view this space as a vector space when we identify an SPD matrix with its logarithm. The question of whether or not the SPD matrix space is a vector space depends on the vector space structure we are considering, and [illegible] on the space itself.

From this point of view, bi-invariant metrics on the Lie group of SPD matrices are simply the classical Euclidean metrics on the vector space $(Sym(n), +, .)$. Thus, we have in fact defined a new Euclidean structure on the space of SPD matrices by transporting that of its Lie algebra $Sym(n)$ on SPD matrices. But this Euclidean structure does not have the defects mentioned in the introduction of this article: matrices with null eigenvalues are at infinite distance and the symmetry principle is respected. Last but not least, with an appropriate metric, similarity-invariance is also guaranteed.

**3.4. Log-Euclidean mean.** We present here the definition of the Log-Euclidean mean of SPD matrices and its invariance properties.

THEOREM 3.13. [illegible] $(S_i)_1^N$ [illegible]

$$\mathbb{E}_{LE}(S_1, \ldots, S_N) = \exp\left(\frac{1}{N}\sum_{i=1}^{N}\log(S_i)\right). \tag{3.8}$$

[illegible]

[illegible]. When one expresses distances in the logarithm domain, one is faced with the classical computation of an Euclidean mean. Hence we have the formula by mapping back the results with exp in the domain of SPD matrices. Now, this mean does not depend on the chosen Log-Euclidean metric, and since there exist similarity-invariant metrics among Log-Euclidean metrics, this property propagates to the mean. The three last invariance properties are reformulations in the domain of SPD matrices of classical properties of the arithmetic mean in the domain of logarithms. ☐

Table 4.1

*Comparison between affine-invariant and Log-Euclidean metrics. Note on the one hand the important simplifications in terms of distance and geodesics in the Log-Euclidean case. On the other hand, this results in the use of the differentials of the matrix exponential and logarithm in the exponential and logarithm maps.*

| Affine-invariant metrics | Log-Euclidean metrics |
|---|---|
| Exponential map: $\exp_{S_1}(L) =$ | |
| $S_1^{1/2}.\exp(S_1^{-1/2}.L.S_1^{-1/2}).S_1^{1/2}$ | $\exp(\log(S_1) + D_{S_1}\log .L)$ |
| Logarithm map: $\log_{S_1}(S_2) =$ | |
| $S_1^{1/2}.\log(S_1^{-1/2}.S_2.S_1^{-1/2}).S_1^{1/2}$ | $D_{\log(S_1)}\exp .(\log(S_2) - \log(S_1))$ |
| Dot product: $\langle L_1, L_2\rangle_S =$ | |
| $\langle S^{-1/2}.L_1.S^{-1/2}, S^{-1/2}.L_2.S^{-1/2}\rangle_{\mathrm{Id}}$ | $\langle D_S\log .L_1, D_S\log .L_2\rangle_{\mathrm{Id}}$ |
| Distance: $d(S_1, S_2) =$ | |
| $\lVert \log(S_1^{-1/2}.S_2.S_1^{-1/2})\rVert$ | $\lVert \log(S_2) - \log(S_1)\rVert$ |
| Geodesic between $S_1$ and $S_2$: | |
| $S_1^{1/2}.\exp(tW).S_1^{1/2}$<br>with $W = \log\left(S_1^{-1/2}.L.S_1^{-1/2}\right)$ | $\exp\left((1-t)\log(S_1) + t\log(S_2)\right)$ |
| Invariance properties | |
| Affine-invariance | Lie group bi-invariance,<br>Similarity-invariance |

**4. Comparison with the affine-invariant mean.** In this section we compare the Log-Euclidean mean to the recently introduced affine-invariant mean [12, 19, 23, 22]. To this end, we first recall the differences between affine-invariant metrics and Log-Euclidean metrics in terms of elementary operators, distance, and geodesics. Then we turn to a study of the algebraic properties of Fréchet means in the Log-Euclidean and affine-invariant cases.

**4.1. Elementary metric operations and invariance.** Distances, geodesics, and Riemannian means take a much simpler form in the Log-Euclidean than in the affine-invariant case. Invariance properties are comparable: some Log-Euclidean metrics are not only bi-invariant but also similarity invariant. These properties are summarized in Table 4.1. However, we see in this table that the exponential and logarithmic mappings are complicated in the Log-Euclidean case by the use of the differentials of the matrix exponential and logarithm. This is the price to pay to obtain simple distances and geodesics. Interestingly, using spectral properties of symmetric matrices, one can obtain a closed form for the differential of both matrix logarithm and exponential and it is possible compute them very efficiently. See [26] for more details.

**4.2. Affine-invariant means.** Let $(S_i)_{i=1}^N$ be a system of SPD matrices. Contrary to the Log-Euclidean case, there is in general no closed form for the affine-invariant Fréchet mean $E_{Aff}(S_1, \dots, S_N)$ associated with affine-invariant metrics. The affine-invariant mean is defined [illegible] by a [illegible], which is the following:

$$\sum_{i=1}^{N} \log(\mathbb{E}_{Aff}(S_1, \dots, S_N)^{-1/2}.S_i.\mathbb{E}_{Aff}(S_1, \dots, S_N)^{-1/2}) = 0. \tag{4.1}$$

This equation is equivalent to the following other barycentric equation, given in [19]:

$$\sum_{i=1}^{N} \log(\mathbb{E}_{Aff}(S_1, \ldots, S_N)^{-1}.S_i) = 0. \tag{4.2}$$

The two equations are equivalent simply because for all $i$,

$$\mathbb{E}_{Aff}(S_1, \ldots, S_N)^{-1/2}.S_i.\mathbb{E}_{Aff}(S_1, \ldots, S_N)^{-1/2} = A.\mathbb{E}_{Aff}(S_1, \ldots, S_N)^{-1}.S_i.A^{-1}$$

with $A = \mathbb{E}_{Aff}(S_1, \ldots, S_N)^{-1/2}$. The fact that $\log(A.S.A^{-1}) = A.\log(S).A^{-1}$ suffices to conclude.

To solve (4.1), the only known strategy is to resort to an iterative numerical procedure, such as the Gauss–Newton gradient descent method described in [12].

**4.3. Geometric interpolation of determinants.** The definition of the Log-Euclidean mean given by (3.8) is extremely similar to that of the classical scalar geometrical mean. We have the following classical definition.

DEFINITION 4.1. [illegible] $d_1, \ldots, d_N$ [illegible]

$$\mathbb{E}(d_1, \ldots, d_N) = \exp\left(\frac{1}{N}\sum_{i=1}^{N} \log(d_i)\right).$$

The Log-Euclidean and affine-invariant Fréchet means can [illegible] be considered as generalizations of the geometric mean. Indeed, their determinants are both equal to the scalar geometric mean of the determinants of the original SPD matrices. This fundamental property can be thought of as the [illegible] to SPD matrices.

THEOREM 4.2. [illegible] $(S_i)_{i=1}^{N}$ [illegible] $N$ [illegible]

[illegible] From Proposition 2.4 we know that $\det(\exp(M)) = \exp(\text{Trace}(M))$ for any square matrix $M$. Then for the geometric mean, we get

$$\begin{aligned}
\det(\mathbb{E}_{LE}(S_1, \ldots, S_N)) &= \exp(\text{Trace}(\log(\mathbb{E}_{LE}(S_1, \ldots, S_N)))) \\
&= \exp\left(\text{Trace}\left(\frac{1}{N}\sum_{i=1}^{N} \log(S_i)\right)\right) \\
&= \exp\left(\frac{1}{N}\sum_{i=1}^{N} \log(\det(S_i))\right) \\
&= \exp\left(\mathbb{E}(\log(\det(S_1, \ldots, S_N)))\right).
\end{aligned}$$

For affine-invariant means, there is no closed form for the mean. [illegible] there is the barycentric equation given by (4.1). By applying the same formula as before after having taken the exponential and using $\det(S.T) = \det(S).\det(T)$ we obtain the result. □

Theorem 4.2 shows that the Log-Euclidean and affine-invariant means of SPD matrices are quite similar. In terms of interpolation, this result is satisfactory, since it implies that the interpolated determinant, i.e., the volume of the associated interpolated ellipsoids, will vary between the values of the determinants of the source SPD matrices. Indeed, we have the following.

Corollary 4.3. [illegible] $(S_i)_{i=1}^N$ [illegible] $N$ [illegible]

$$\left[\inf_{i\in 1\dots N}(S_i),\ \sup_{i\in 1\dots N}(S_i)\right].$$

[illegible]. This is simply a consequence of the monotonicity of the scalar exponential and of the scalar integral. □

Corollary 4.4. [illegible] $S_1$ [illegible] $S_2$ [illegible]

[illegible]. Indeed, in both cases, the interpolated determinant $\mathrm{Det}(t)$ is the geometric mean of the two determinants, i.e., at $t \in [0,1]$: $\mathrm{Det}(t) = \exp((1-t)\log(\det(S_1)) + t\log(\det(S_2)))$. This interpolation is monotonic, since the differentiation yields

$$\frac{d}{dt}\mathrm{Det}(t) = \mathrm{Det}(t)\log(\det(S_2.S_1^{-1})).$$

As a consequence, $\mathrm{Det}(t)$ is equal to $\det(S_1).\exp(t.\log(\det(S_2.S_1^{-1})))$, and the sign of $\frac{d}{dt}\mathrm{Det}(t)$ is constant and given by $\log(\det(S_2.S_1^{-1}))$. □

**4.4. Criterion for the equality of the two means.** In general, Log-Euclidean and affine-invariant means are similar, yet they are [illegible] identical. Nonetheless, there are a number of cases where they are identical, for example, when the logarithms of averaged SPD matrices all commute with one another. In fact, we have more as follows.

Proposition 4.5. [illegible] $(S_i)_{i=1}^N$ [illegible] $N$ [illegible] $\log(S_i)$ [illegible]

[illegible]. Let $\bar{L} := \frac{1}{N}\sum_{i=1}^N \log(S_i)$. The hypothesis is that $[\bar{L}, \log(S_i)] = 0$ for all $i$. This implies that $\log(\exp(-\frac{1}{2}\bar{L}).S_i.\exp(-\frac{1}{2}\bar{L})) = \log(S_i) - \bar{L}$ for all $i$. We see then that $\exp\bar{L}$, i.e., the Log-Euclidean mean, is the solution of (4.1), i.e., is the affine-invariant mean. □

So far, we have not been able to prove the converse part of this proposition. However, the next subsection provides a partial proof, valid when SPD matrices are isotropic enough, i.e., close to a scaled version of the identity. The intensive numerical experiments we have carried out strongly suggest that the result given in the next section is true in general. The full proof of this assertion will be the subject of future work.

**4.5. Larger anisotropy in Log-Euclidean means.** In section 4.6, we will verify experimentally that affine-invariant means tend to be less anisotropic than Log-Euclidean means. The following theorem accounts for this phenomenon when SPD matrices are isotropic enough.

Theorem 4.6. [illegible] $(S_i)_{i=1}^N$ [illegible] 2 [illegible] $\log(S_i)$ [illegible]

$$\text{[illegible]}\,(\mathbb{E}_{Aff}(S_1,\dots,S_N)) < \text{[illegible]}\,(\mathbb{E}_{LE}(S_1,\dots,S_N)). \tag{4.3}$$

[illegible]. The idea is to see how the two means differ close to the identity. To this end, we introduce a small scaling factor $t$ and see how the two means vary when $t$ is close to zero. For all $i$, let $S_{i,t}$ be the version of $S_i$ scaled by $t$ in the logarithmic domain. Around the identity, we can use the Baker–Campbell–Hausdorff formula to simplify the barycentric equation (4.1). Let us denote both Riemannian cases as $\mathbb{E}(S_t) = \mathbb{E}(S_{1,t}, \ldots, S_{N,t})$ and $\mathbb{E}(S) := \mathbb{E}(S_1, \ldots, S_N)$. We will also use the following notation: $\log(S_i) := L_i$, $\bar{L}_{t;Aff} := \log(\mathbb{E}_{Aff}(S_t))$ and $\bar{L}_{LE} := \log(\mathbb{E}_{LE}(S))$.

%pagebreak

First, we use twice the Baker–Campbell–Hausdorff formula to obtain the following approximation:

$$\begin{aligned}\log(\mathbb{E}_{Aff}(S_t)^{-1/2}.S_{i,t}.\mathbb{E}_{Aff}(S_t)^{-1/2}) = \;& tL_i - \bar{L}_{t;Aff} - t^3\tfrac{1}{12}[L_i,[L_i,\bar{L}_{t;Aff}]] \\ & + t^3\tfrac{1}{24}[\bar{L}_{t;Aff},[\bar{L}_{t;Aff},L_i]] + O(t^5).\end{aligned} \tag{4.4}$$

Then we average over $i$ to obtain the following approximation lemma.

Lemma 4.7. [illegible] $t$ [illegible]

$$\bar{L}_{t;Aff} = t\bar{L}_{LE} + \frac{t^3}{12.N}\sum_{i=1}^{N}[L_i,[\bar{L}_{LE},L_i]] + O(t^5). \tag{4.5}$$

[illegible]. To obtain the approximation, note that the second factor $t^3\frac{1}{24}[\bar{L}_{t;Aff}, [\bar{L}_{t;Aff}, L_i]]$ in (4.4) becomes an $O(t^5)$. Indeed, when the sum over $i$ is done, $L_i$ becomes $\bar{L}_{LE}$. But we can replace $\bar{L}_{LE}$ with its value in term of the affine-invariance mean by using (4.4). Then, using the fact that $[\bar{L}_{t;Aff}, \bar{L}_{t;Aff}] = 0$ we see that we obtain an $O(t^5)$.

Note also that, thanks to the symmetry with respect to inversion, $\bar{L}_{t;Aff}$ becomes $-\bar{L}_{t;Aff}$ when $t$ is changed into $-t$, i.e., $t \mapsto \bar{L}_{t;Aff}$ is odd. As a consequence, only odd terms appear in the development in powers of $t$. ☐

Next, we take the exponential of (4.5) and differentiate the exponential to obtain

$$\mathbb{E}_{Aff}(S_t) = \mathbb{E}_{LE}(S_t) + D_{t\bar{L}_{LE}}\exp.\left(\frac{t^3}{12.N}\sum_{i=1}^{N}[L_i,[\bar{L}_{LE},L_i]]\right) + O(t^5).$$

Then we use several properties to approximate the trace of affine-invariant means. First, we use Corollary 2.3 to simplify the use of the differential of the exponential. Then we approximate the exponential by the first two terms of its series expansion. We obtain

$$\mathrm{Trace}(\mathbb{E}_{Aff}(S_t)) = \mathrm{Trace}(\mathbb{E}_{LE}(S_t)) + t^3.F(t,L_i,\bar{L}_{LE}) + O(t^5),$$

with $F(t,L_i,\bar{L}_{LE}) = \mathrm{Trace}(\exp(t\bar{L}_{LE}).\frac{1}{12.N}\sum_{i=1}^{N}[L_i,[\bar{L}_{LE},L_i]])$. This expression can be simplified as follows:

$$\begin{aligned}F(t,L_i,\bar{L}_{LE}) &= \mathrm{Trace}\left((\mathrm{Id}+t\bar{L}_{LE}).\frac{1}{12.N}\sum_{i=1}^{N}[L_i,[\bar{L}_{LE},L_i]]\right) + O(t^2) \\ &= \frac{t}{12.N}\sum_{i=1}^{N}\mathrm{Trace}\left(\bar{L}_{LE}.[L_i,[\bar{L}_{LE},L_i]]\right) + O(t^2) \\ &= -\frac{t}{12.N}\sum_{i=1}^{N}\mathrm{Trace}\left(L_i^2.\bar{L}_{LE}^2 - (L_i.\bar{L}_{LE})^2\right) + O(t^2).\end{aligned}$$

As a consequence, the difference between the two traces can be written as

$$\mathrm{Trace}(\mathbb{E}_{Aff}(S_t)) - \mathrm{Trace}(\mathbb{E}_{LE}(S_t)) = -\frac{t^4}{12.N}\sum_{i=1}^{N} \mathrm{Trace}\left(L_i^2.\bar{L}_{LE}^2 - (L_i.\bar{L}_{LE})^2\right) + O(t^5).$$

To conclude, we use the following lemma.

LEMMA 4.8. [illegible] $A$, $B \in Sym(n)$ [illegible] $(A^2.B^2 - (A.B)^2) \geq 0$ [illegible] $A$ [illegible] $B$ [illegible]

[illegible]. Let $(A_i)$ (resp., $(B_i)$) be the column vectors of $A$ (resp., $B$). Let $\langle , \rangle$ be the usual scalar product. Then we have

$$\begin{cases} \mathrm{Trace}(A^2.B^2) = \sum_{i,j}\langle A_i, A_j\rangle\langle B_i, B_j\rangle, \\ \mathrm{Trace}((A.B)^2) = \sum_{i,j}\langle A_i, B_j\rangle\langle B_i, A_j\rangle. \end{cases}$$

Let us now chose a rotation matrix $R$ that makes $A$ diagonal: $\mathrm{R.A.R^T} = Diag(\lambda_1, \dots, \lambda_n) =: D$. Let us define $C := R.B.R^T$ and use the notation $(C_i)$ and $(D_i)$ for the column vectors of $C$ and $D$. We have

$$\begin{cases} \mathrm{Trace}(A^2.B^2) = \sum_{i,j}\langle D_i, D_j\rangle\langle C_i, C_j\rangle = \sum_i \lambda_i^2\langle C_i, C_i\rangle, \\ \mathrm{Trace}((A.B)^2) = \sum_{i,j}\langle D_i, C_j\rangle\langle C_i, D_j\rangle = \sum_{i,j}\lambda_i.\lambda_j\langle C_i, C_j\rangle. \end{cases}$$

Then the Cauchy–Schwarz inequality yields

$$\left|\sum_{i,j}\lambda_i.\lambda_j\langle C_i, C_j\rangle\right| \leq \sum_i \lambda_i^2\langle C_i, C_i\rangle,$$

which proves the first point. But the Cauchy–Schwarz inequality is an equality if and only if there is a constant $\mu$ such that $D.C = \mu C.D$. But only $\mu = 1$ allows the inequality of the lemma to be an equality. This is equivalent to $C.D = D.C$, which is equivalent in turn to $A.B = B.A$. Hence we have the result. □

[illegible] 4.6 When we apply Lemma 4.8 to the obtained estimation for the trace, we see that for a $t \neq 0$ small enough, the trace of the affine-invariant mean is indeed strictly inferior to the trace of the Log-Euclidean mean whenever the mean logarithm does not commute with all logarithms $\log(S_i)$. □

COROLLARY 4.9. [illegible] 4.6 [illegible] $\lambda$ [illegible] $\lambda > 0$

COROLLARY 4.10. [illegible] 2 [illegible]

[illegible]. In this case, there are only two eigenvalues for each mean. Their products are equal and we have a strict inequality between their sums. Consequently, the largest eigenvalue of the Log-Euclidean mean is strictly larger than the affine-invariant one, and we have the opposite result for the smallest eigenvalue. □

**4.6. Linear and bilinear interpolation of SPD matrices.** Volume elements (or [illegible]) in clinical DT images are often spatially anisotropic. Yet, in many practical situations where DT images are used, it is recommended (see [27]) to work with isotropic voxels to avoid spatial biases. A preliminary resampling step with an adequate interpolation method is therefore important in many cases. Proper interpolation methods are also required to generalize to the SPD case usual registration

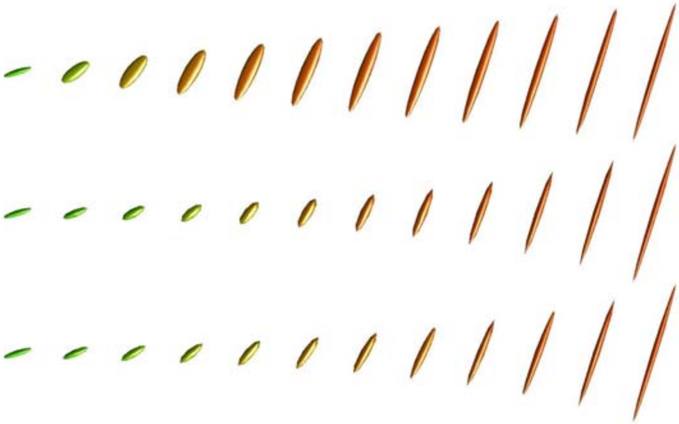

FIG. 4.1. *Linear interpolation of two SPD matrices. Top: linear interpolation on coefficients. Middle: affine-invariant interpolation. Bottom: Log-Euclidean interpolation. The shading of ellipsoids is based on the direction of dominant eigenvectors. Note the characteristic swelling effect observed in the Euclidean case, which is not present in both Riemannian frameworks. Note also that Log-Euclidean means are slightly more anisotropic their affine-invariant counterparts.*

techniques used on scalar or vector images. The framework of Riemannian metrics allows a direct generalization to SPD matrices of classical resampling methods with the use of associated Fréchet means instead of the Euclidean (i.e., arithmetic) mean.

In the Riemannian case, the equivalent of linear interpolation is [illegible]. To interpolate between two SPD matrices, intermediate values are taken along the shortest path joining the two matrices. Figure 4.1 presents a typical result of linear interpolation between two SPD matrices. The Euclidean, affine-invariant, and Log-Euclidean results are given. The "swelling effect" is clearly visible in the Euclidean case: the volume of associated ellipsoids is parabolically interpolated and reaches a global maximum between the two extremities! This effect disappears in both Riemannian cases, where volumes are interpolated geometrically. As expected, Log-Euclidean means are a little more anisotropic than their affine-invariant counterparts.

To resample images, bilinear (resp., trilinear) interpolation generalizes in two dimensions (resp., in three dimensions) the linear interpolation and offers an efficient compromise between simplicity and accuracy in the scalar and vector cases. With this technique, the value at any given point is inferred from known values measured at the vertices of a regular grid whose elementary cells are rectangles in two dimensions (resp., right parallelepipeds in three dimensions), which is usually the case with MR images. More precisely, the interpolated value at a given point is given by the weighted mean of the values at the vertices of the current cell. The weights are the [illegible] of the current point with respect to the vertices of the current cell.

Figure 4.2 presents the results of the bilinear interpolation of four SPD matrices placed at the extremities of a rectangle. Again, a large swelling effect is present in Euclidean results and not in both Riemannian results, and Log-Euclidean means are slightly more anisotropic than their affine-invariant equivalents. One should note that the computation of the affine-invariant mean here is iterative, since the number of averaged matrices is larger than 2 (we use the Gauss–Newton method described in [12]), whereas the closed form given by 3.8 is used directly in the Log-Euclidean case. This has a large impact on computation times: $0.003s$ (Euclidean), $0.009s$

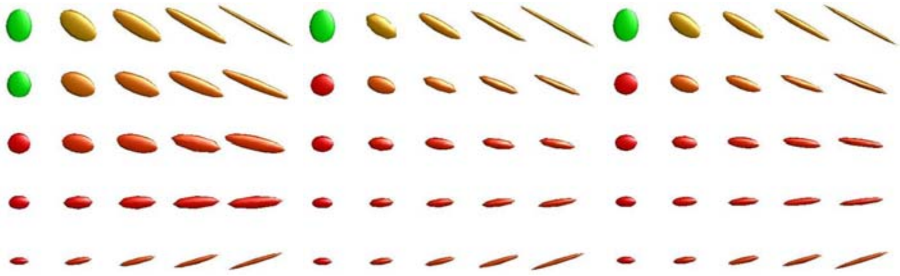

Fig. 4.2. *Bilinear interpolation of four SPD matrices at the corners of a regular grid. Left: Euclidean interpolation. Middle: affine-invariant interpolation. Right: Log-Euclidean interpolation. Again, a characteristic swelling effect is observed in the Euclidean case and not in both Riemannian frameworks. As expected, Log-Euclidean means are slightly more anisotropic than their affine-invariant counterparts.*

(Log-Euclidean), and $1s$ (affine-invariant) for a $5 \times 5$ grid on a Pentium M 2 GHz. Computations were carried out with MATLAB, which explains the poor computational performance. Here, Log-Euclidean means were calculated approximately 100 times faster than affine-invariant means because the logarithms of the four interpolated tensors were computed only once, instead of being computing each time a new barycenter is calculated. When only one mean is computed, the typical ratio is closer to 20, since between 15 and 20 iterations are typically needed (for $3 \times 3$ SPD matrices) to obtain the affine-invariant mean with a precision of the order of $10^{-12}$.

One should note that from a numerical point of view the computation of Log-Euclidean means is not only much faster but also more [illegible] than in the affine-invariant case. On synthetic examples, as soon as SPD matrices are quite anisotropic (for instance, with the dominant eigenvalue larger than 500 times the smallest), numerical instabilities appear, essentially due to limited numerical precision (even with double precision). This can greatly complicate the computation of affine-invariant means. On the contrary, the computation of Log-Euclidean means is more stable since the logarithm and exponential are taken only once and thus even very large anisotropies can be dealt with. In applications where very high anisotropies are present, such as the generation of adapted meshes [17], this phenomenon could severely limit the use of affine-invariant means, whereas no such limitation exists in the Log-Euclidean case.

**5. Conclusion and perspectives.** In this work, we have presented a particularly simple and efficient generalization of the geometric mean to SPD matrices, called Log-Euclidean. It is simply an arithmetic mean in the domain of matrix logarithms. This mean corresponds to a bi-invariant mean in our novel Lie group structure on SPD matrices, or equivalently to a Euclidean mean when this structure is smoothly extended into a vector space by a novel scalar multiplication.

The Log-Euclidean mean is similar to the recently introduced affine-invariant mean, which is another generalization of the geometric mean to SPD matrices. Indeed, the Log-Euclidean mean is similarity invariant, and two means have the same determinant, which is the geometric mean of the determinants of averaged SPD matrices. However, they are not equal: the Log-Euclidean trace is larger when the two means differ. The most striking difference between the two means resides in their computational cost: the Log-Euclidean mean can be calculated approximately 20 times faster than the affine-invariant mean. This property can be crucial in applications where large amounts of data are processed. This is especially the case in medical imaging with DTI and in numerical analysis with the generation of adapted meshes.

We have shown in this work that there are indeed several generalizations of the geometric mean to SPD matrices. Other variants may exist, and we will investigate other possible generalizations in future work. This is important, since situations in applied mathematics, mechanics, medical imaging, etc., where SPD matrices need to be processed, are highly varied. As a consequence, the relevance of each generalization of the geometric mean and of the associated metric framework may depend on the application considered. We have already begun to compare the Log-Euclidean and affine-invariant frameworks in the case of DT-MRI processing [28]. In future work, we will proceed to variability tensors, which we began to use in [15] to model and analyze the variability of brain anatomy.

# CONVERGENCE OF A BLOCK-ORIENTED QUASI-CYCLIC JACOBI METHOD*

VJERAN HARI†

**Abstract.** This paper proves the global convergence of a block-oriented, quasi-cyclic Jacobi method for symmetric matrices. The result applies to the new fast one-sided Jacobi method, proposed by Drmač and Veselić, for computing the singular value decomposition. There is no restriction on the matrix block-partition which defines the pivot strategy.

**Key words.** eigenvalues, Jacobi method, global convergence

**AMS subject classification.** 65F15

**DOI.** 10.1137/05064552X

## 1. Introduction.

Recently, Drmač and Veselić [5, 6] have proposed an improved modification of the one-sided Jacobi method for computing the singular value decomposition (SVD) of rectangular matrices. It is fast (somewhat faster than QR and somewhat slower than divide and conquer (DC); see [6]) and is accurate in a relative sense (which cannot be said for QR and DC; see [1]). It also requires less workspace and applies to a wider class of matrices (the matrix elements can vary in a wider range of magnitudes) than its competitors. The modified Jacobi method first prepares the initial matrix for the iteration by applying to it one or two QR factorizations (cf. [19, 4, 5]). In the iterative part, many ideas from [3] have been implemented. In addition, to better exploit the computer resources, like the cache memory, it uses a new block-oriented, quasi-cyclic pivot strategy. This strategy mimics the BLAS blocking, thus exploiting contiguous memory benefits. It also takes into account the fact that after QR factorization, the larger elements typically lie in the vicinity of the diagonal, so more work has to be done within the diagonal blocks.

Still lacking are the global and the asymptotic convergence proofs of the modification of [5, 6]. The latter is less critical, since it is well known that Jacobi methods are quadratically convergent per sweep under usual cyclic strategies (see [20, 11]), and therefore, the quasi-cyclic methods should be (at least; see [17]) quadratically convergent per quasi sweep.

The aim of this paper is to fill the missing gap, i.e., to prove the global convergence of the Jacobi method, defined by the pivot strategy proposed in [6]. The proof presented here covers the main algorithm from [6, Algorithm 1, case $k = 1$]. The other cases ($k = 0$, which is trivial, and $k = 2$, which is even more complicated) can be proved by the same technique.

Note that the global convergence of a one-sided SVD Jacobi method for the matrix $G$ actually means the global convergence of the corresponding two-sided Jacobi method for the nonnegative definite Gram matrix $G^T G$. For this reason, we consider here the two-sided Jacobi method for general symmetric matrices, under the special quasi-cyclic pivot strategy which has been used in [6].

For any quadratic matrix $X = (x_{ij})$, the function $\mathrm{Off}(X) = \|X - \mathrm{diag}(X)\|_F$, where $\mathrm{diag}(X)$ is the diagonal part of $X$ and $\|\cdot\|_F$ is the Frobenius norm, is referred

to as [illegible] of $X$. Then, for any symmetric $A$, a useful measure of almost diagonality is

$$S(A) = \mathrm{Off}(A)/\sqrt{2} = \sqrt{\sum_{i=1}^{n-1} \sum_{j=i+1}^{n} |a_{ij}|^2}.$$

In [15] Mascarenhas has proved that the diagonal elements of the iterated symmetric matrix $A^{(k)}$, obtained by the Jacobi method under any pivot strategy, converge. Therefore, it is sufficient to prove that for any initial symmetric matrix $A$, $S(A^{(k)}) \to 0$ as $k \to \infty$. Actually, we shall prove that under the pivot strategy used in [6],

$$S^2(A^{(M)}) \le t_n S^2(A), \quad 0 \le t_n < 1. \tag{1.1}$$

Here $A^{(M)}$ is obtained from $A$ after one quasi sweep, and $t_n$ depends just on $n$. This is sufficient for the proof since the sequence $S(A^{(k)})$ is nonincreasing.

The paper is divided into three sections. In section 2 we introduce notation and the quasi-cyclic strategy, and we formulate the main theorem. In section 3 we prove the theorem.

**2. The quasi-cyclic Jacobi method $J_{\mathcal{M}}$.** Although the method and the proof can be considered for complex Hermitian matrices, for simplicity we restrict our considerations to real symmetric matrices.

**2.1. Simple symmetric quasi-cyclic Jacobi methods.** A (two-sided) Jacobi method for diagonalizing a symmetric $n \times n$ matrix $A$ performs a sequence of similarity transformations

$$A^{(k+1)} = [R^{(k)}]^T A^{(k)} R^{(k)}, \quad V^{(k+1)} = V^{(k)} R^{(k)}, \quad k \ge 0\,, \tag{2.1}$$

where $A^{(0)} = A$, $V^{(0)} = I_n$, and $R^{(0)}, R^{(1)}, \dots$ are plane rotations. For each $k$, $R^{(k)}$ is defined by a pair of indices $(p,q) = (p(k), q(k))$ called a [illegible] and by four essential elements $R_{pp}^{(k)} = R_{qq}^{(k)} = \cos\phi_k$, $R_{pq}^{(k)} = -R_{qp}^{(k)} = \sin\phi_k$. All other elements of $R^{(k)}$ are as in the identity matrix $I_n$. The process (2.1) is defined by a rule for computing the elements of $R^{(k)}$ and by a way of selecting pivot pairs ([illegible]). We assume the standard angle choice

$$\tan 2\phi_k = \frac{2a_{pq}^{(k)}}{a_{qq}^{(k)} - a_{pp}^{(k)}}, \quad \phi_k \in \left[\frac{-\pi}{4}, \frac{\pi}{4}\right]\,, \tag{2.2}$$

which makes the [illegible] $a_{pq}^{(k)}$ zero; i.e., $a_{p(k)q(k)}^{(k+1)} = 0$, $k \ge 0$, holds. Consequently, we have

$$S^2(A^{(k+1)}) = S^2(A^{(k)}) \; - \; \left(a_{p(k)q(k)}^{(k)}\right)^2, \quad k \ge 0,$$

and $\lim_{k\to\infty} a_{p(k)q(k)}^{(k)} = 0$. Here we have assumed $A^{(k)} = (a_{ij}^{(k)})$.

If $A$ is a $1 \times 1$ matrix, we set $S(A) = 0$, and if $A$ is $2 \times 2$, the process is completed for $k = 1$ since $S(A^{(1)}) = 0$. So, we assume $n \ge 3$.

Let $N = n(n-1)/2$, $\mathbf{P}_n = \{(i,j) : 1 \le i < j \le n\}$ and $\mathbf{N}_0 = \{0, 1, 2, \dots\}$. Each pivot strategy can be identified with a function $\mathcal{I}$ from $\mathbf{N}_0$ to $\mathbf{P}_n$, defined by $\mathcal{I}(k) = (p(k), q(k))$, $k \ge 0$. If $\mathcal{I}$ is periodic, then $\mathcal{I}$ is called a [illegible]. Let $\mathcal{I}$

be a periodic strategy with period $M$. If $\{\mathcal{I}(k) : 0 \le k \le M-1\} = \mathbf{P}_n$ and $M > N$ ($M = N$), then $\mathcal{I}$ is called a *quasi-cyclic* (*cyclic*) *strategy*.

Let $\mathbf{S}$ be a subset of $\mathbf{P}_n$ and let $\nu(\mathbf{S})$ denote its cardinality. By $\mathbf{O}(\mathbf{S})$ we mean a collection of all finite sequences made of the elements from $\mathbf{S}$. If $O \in \mathbf{O}(\mathbf{S})$, we assume that each element of $\mathbf{S}$ appears at least once in $O$ (otherwise $\mathbf{S}$ is replaced with some of its proper subsets). Thus, each sequence from $\mathbf{O}(\mathbf{S})$ contains at least $\nu(\mathbf{S})$ terms. If $\mathbf{S}$ is an empty set, $\nu(\mathbf{S}) = 0$ and $\mathbf{O}(\mathbf{S})$ consists of a singleton, which is an empty sequence.

A cyclic or a quasi-cyclic strategy can be specified in the following way. For any $O = \{(i_r, j_r)\}_{r=0}^{M-1} \in \mathbf{O}(\mathbf{P}_n)$, the cyclic or the quasi-cyclic strategy $\mathcal{I}_O$, generated by $O$, is given by

$$\mathcal{I}_O(k) \equiv (p(k), q(k)) = (i_r, j_r), \quad 0 \le r \le M-1, \quad k \ge 0,$$

provided that $k \equiv r \pmod{M}$. Thus,

$$\begin{aligned}
&(p(0), q(0)) = (i_0, j_0), \ (p(1), q(1)) = (i_1, j_1), \ldots, \\
&(p(M-1), q(M-1)) = (i_{M-1}, j_{M-1}), \ (p(M), q(M)) = (i_0, j_0), \\
&(p(M+1), q(M+1)) = (i_1, j_1), \ldots .
\end{aligned}$$

We denote the Jacobi method, which defines $\phi_k$ by (2.2) and uses the pivot strategy $\mathcal{I}$ by $J(\mathcal{I})$. $J(\mathcal{I})$ is called a quasi-cyclic/cyclic (Jacobi) method if $\mathcal{I}$ is the quasi-cyclic/cyclic strategy. Since $n$ is fixed, in what follows we write $\mathbf{P}$ for $\mathbf{P}_n$.

Let $\mathbf{S}$ be any subset of $\mathbf{P}$. By $O_R(\mathbf{S})$ we denote the "rowwise ordering" of $\mathbf{S}$, that is, the sequence satisfying the following two conditions: (i) Each element $(i,j) \in \mathbf{S}$ appears exactly once in $O_R(\mathbf{S})$; (ii) for any two terms $(i_1, j_1)$ and $(i_2, j_2)$ in $O_R(\mathbf{S})$, $(i_1, j_1)$ precedes $(i_2, j_2)$ if $i_1 < i_2$ or $i_1 = i_2$ and $j_1 < j_2$. In an obvious manner we can define the "columnwise" ordering of $\mathbf{S}$ denoted by $O_C(\mathbf{S})$.

Let $\mathbf{S}_i$, $1 \le i \le \sigma$, be subsets of $\mathbf{P}$ and let $O_i \in \mathbf{O}(\mathbf{S}_i)$, $1 \le i \le \sigma$, be arbitrary sequences. By $[O_1, O_2, \ldots, O_\sigma]$, we mean the sequence which is obtained by the concatenation of the sequences $O_1, O_2, \ldots, O_\sigma$. Often, we shall omit the brackets.

**2.2. Quasi-cyclic strategies.** To prove the convergence theorem (Theorem 2.1 below), we need the notion of equivalent strategies. This notion is extended from cyclic [8, 9, 18] to quasi-cyclic strategies, as it has been done in [17]. In what follows, *strategy* means *quasi-cyclic* or *cyclic strategy*.

Let $\mathbf{S}$ be a subset of $\mathbf{P}$. Let $O = \{(i_r, j_r)\}_{r=0}^{s} \in \mathbf{O}(\mathbf{S})$. An admissible transposition on $O$ is any transposition of two adjacent terms $(i_r, j_r), (i_{r+1}, j_{r+1}) \to (i_{r+1}, j_{r+1}), (i_r, j_r)$, provided that the sets $\{i_r, j_r\}$ and $\{i_{r+1}, j_{r+1}\}$ are disjoint. Such pairs will also be called *commuting* or *disjoint*.

The sequences $O, O' \in \mathbf{O}(\mathbf{S})$ are *equivalent* if one can be obtained from the other by a finite number of admissible transpositions. In this case we write $O \sim O'$. For example, if $\mathbf{S} = \{(1,2), (2,3), (1,4)\}$, then $O = (1,2), (1,2), (1,4), (2,3), (2,3) \in \mathbf{O}(\mathbf{S})$ and $O' = (1,2), (1,2), (2,3), (2,3), (1,4) \in \mathbf{O}(\mathbf{S})$ are equivalent.

Let $\mathcal{I}$ be a strategy with period $M$. By $O_{\mathcal{I}}$ we mean the sequence $\{\mathcal{I}(k)\}_{k=0}^{M-1}$. If $\mathcal{I}$ and $\mathcal{I}'$ are two strategies with the same period $M$, then $\mathcal{I}$ and $\mathcal{I}'$ are equivalent if $O_{\mathcal{I}} \sim O_{\mathcal{I}'}$. In such a case we write $\mathcal{I} \sim \mathcal{I}'$.

For a given symmetric matrix $A$ and a given strategy $\mathcal{I}$, the sequence $\{R^{(k)}\}$ is well defined. Let $T_{\mathcal{I}(k)}(X)$ mean $[R^{(k)}]^T X R^{(k)}$. Then the recursion in (2.1) can be written $A^{(k+1)} = T_{\mathcal{I}(k)}(A^{(k)})$, implying

$$A^{(k+1)} = T_{\mathcal{I}(k)} T_{\mathcal{I}(k-1)} \cdots T_{\mathcal{I}(0)}(A), \quad k \ge 0,$$

where $T_{\mathcal{I}(k)}T_{\mathcal{I}(k-1)}\cdots T_{\mathcal{I}(0)}$ denotes the composition of the underlying linear operators. Let

$$T_k^{\mathcal{I}} = T_{\mathcal{I}(k-1)}T_{\mathcal{I}(k-2)}\cdots T_{\mathcal{I}(0)}, \quad k \geq 1; \qquad T_0^{\mathcal{I}} = E,$$

where $E$ is the identity operator. Note that $T_{\mathcal{I}(k)}$ commutes with $T_{\mathcal{I}(k+1)}$ if $(p(k), q(k))$ and $(p(k+1),\ q(k+1))$ are commuting. Hence using the same argument as in [11, Lemma 1.1], we obtain the following implication (see also [8]):

$$\text{If } \mathcal{I} \sim \mathcal{I}', \text{ then } T_{kM}^{\mathcal{I}}(A) = T_{kM}^{\mathcal{I}'}(A), \ k \geq 0. \tag{2.3}$$

That is, equivalent strategies give the same matrices at the end of each quasi sweep consisting of $M$ iterations of the form (2.1). Since $\{S(A^{(k)})\}_{k=0}^{\infty}$ makes a nonincreasing sequence, (2.3) implies that $J(\mathcal{I})$ is convergent iff $J(\mathcal{I}')$ is convergent, provided that $\mathcal{I} \sim \mathcal{I}'$. In particular, if the relation (1.1) holds for $\mathcal{I}'$ and $\mathcal{I} \sim \mathcal{I}'$, then it holds for $\mathcal{I}$.

**2.3. The special quasi-cyclic block-oriented method.** Let $A = (a_{rs})$ be a real symmetric matrix of order $n$. The starting point in describing the method is the following block-partition of $A$:

$$A = \left[\begin{array}{cccc} A_{11} & A_{12} & \cdots & A_{1m} \\ A_{21} & A_{22} & \cdots & A_{2m} \\ \vdots & \vdots & \ddots & \vdots \\ A_{m1} & A_{m2} & \cdots & A_{mm} \end{array}\right] \begin{array}{l} \}\, n_1 \\ \}\, n_2 \\ \vdots \\ \}\, n_m \end{array},$$

where $A_{ij}$ is an $n_i \times n_j$ block of $A$. Since $n_1 + \cdots + n_m = n$, $\mathcal{M} = (n_1, n_2, \ldots, n_m)$ is a partition of $n$. In practical computations, it is desirable that no $n_i$ exceeds some $n_0$ which depends on the machine and its available fast (cache) memory. The cache memory is several times faster than the main computer memory (according to [2, section 1.3.2] 5 to 10 times faster).

With each submatrix $B$ contained in the uppertriangle of $A$ (or with each principal submatrix $B$ of $A$) one can associate the set $\mathbf{S}(B) \subseteq \mathbf{P}$ of those pairs which are subscripts of the elements of $B$ (and of the upper triangle of $B$). By abuse of notation, the row- and columnwise orderings of $\mathbf{S}(B)$ are denoted by $O_R(B)$ $(= O_R(\mathbf{S}(B)))$ and $O_C(B)$ $(= O_C(\mathbf{S}(B)))$, respectively. We shall also use $\mathbf{S}_{ij} = \mathbf{S}(A_{ij})$ and $\mathcal{R}_{ij} = O_R(A_{ij})$ $(= O_R(\mathbf{S}_{ij}))$, $\mathcal{C}_{ij} = O_C(A_{ij})$ $(= O_C(\mathbf{S}_{ij}))$ for $i \leq j$.

Let $\mathcal{O}_{\mathcal{M}}$ denote the sequence of pairs which defines one quasi sweep of the method from [6]. It is defined as follows.

First, define sequences

$$\mathcal{R}_i = [\mathcal{R}_{i+1,i+1}, \mathcal{R}_{ii}, \mathcal{R}_{i,i+1}, \mathcal{R}_{i,i+2}, \ldots, \mathcal{R}_{im}], \quad 1 \leq i \leq m-1.$$

Then,

$$\mathcal{O}_{\mathcal{M}} = [\mathcal{R}_{11}, \mathcal{R}_1, \mathcal{R}_2, \ldots, \mathcal{R}_{m-1}, \mathcal{R}_{mm}]. \tag{2.4}$$

The quasi-cyclic Jacobi method from [6] is defined by the strategy $\mathcal{I}_{\mathcal{M}} = \mathcal{I}_{\mathcal{O}_{\mathcal{M}}}$ and we denote it by $J_{\mathcal{M}}$. Its pivot strategy $\mathcal{I}_{\mathcal{M}}$ uses the rowwise ordering within each block $A_{ij}$. $\mathcal{I}_{\mathcal{M}}$ fetches the blocks in a rowwise fashion, and all the diagonal blocks $A_{ii}$ are operated twice. Therefore, we call it the [illegible]. The quasi sweep contains $M$ ordinary Jacobi steps, where $M$ is the number of pairs in the sequence $\mathcal{O}_{\mathcal{M}}$ from (2.4). The aim of this paper is to prove the global convergence of $J_{\mathcal{M}}$. In particular, we shall prove the following.

THEOREM 2.1. [illegible] $m \geq 1$ [illegible] $n \geq \max\{m, 2\}$ [illegible]

[illegible] $\mathcal{M} = (n_1, \ldots, n_m)$ [illegible] $n$ [illegible] $m$ [illegible] $A$ [illegible] $n$ [illegible] $(A_{ij})$ [illegible] $A$ [illegible] $m$ [illegible] $m$ [illegible] $A_{ii}$ [illegible] $n_i \times n_i$ $1 \leq i \leq m$ [illegible] $J_{\mathcal{M}}$ [illegible] $A$ [illegible] $A^{(0)} = A$, $A^{(1)}$, $A^{(2)}, \ldots$ [illegible]

$$M = n(n-1)/2 + \sum_{i=1}^{m} n_i(n_i - 1)/2$$

[illegible]

$$S^2(A^{(M)}) \leq t_n^{(\mathcal{M})}\, S^2(A), \quad 0 \leq t_n^{(\mathcal{M})} < 1, \tag{2.5}$$

[illegible] $\mathcal{M}$ [illegible] $t_n^{(\mathcal{M})}$ [illegible] $n$

**3. Proof of Theorem 2.1.** To prove Theorem 2.1, it is sufficient to prove (2.5) for some strategy $\mathcal{I}$ which is equivalent to $\mathcal{I}_{\mathcal{M}}$. We shall find such an $\mathcal{I}$ with the special property that it fetches the matrix elements by block-columns, and within each block-column by columns, plus some extra work within the diagonal blocks.

**3.1. Obtaining $\mathcal{I}$.** We call two sets $\mathbf{S}_1$ and $\mathbf{S}_2$ from $\mathbf{P}$ commuting if each pair from $\mathbf{S}_1$ commutes with all the pairs from $\mathbf{S}_2$. In the same way we define two commuting sequences made of the elements from $\mathbf{P}$. Obviously, if $\mathbf{S}_1$ and $\mathbf{S}_2$ are commuting, then each sequence made of the elements from $\mathbf{S}_1$ commutes with all the sequences made of the elements from $\mathbf{S}_2$ and vice versa. If the two commuting subsequences take adjacent positions in the sequence which defines some pivot strategy, then we can interchange the positions of these two subsequences, obtaining an equivalent (sequence and) pivot strategy.

To define $\mathcal{I}$, we start with the sequence $\mathcal{O}_{\mathcal{M}}$ and transform it using admissible transpositions. We divide the process into several stages. In the first stage, we transform $\mathcal{O}_{\mathcal{M}}$ into $\mathcal{O}_1$; in the second stage we transform $\mathcal{O}_1$ into $\mathcal{O}_2$; and finally, we transform $\mathcal{O}_2$ into $\mathcal{O}$ which defines $\mathcal{I}$.

We shall illustrate the transitions for the case $m = 5$. After this illustration, we shall provide the result which holds for general $m$. Except for the first line, we shall omit writing [ ] which denotes the concatenation of sequences. Vertical bars | are used only to better recognize the obtained subsequences. We have

$$\begin{aligned}\mathcal{O}_{\mathcal{M}} &= [\mathcal{R}_{11}, \mathcal{R}_1, \mathcal{R}_2, \mathcal{R}_3, \mathcal{R}_4, \mathcal{R}_{55}] \\ &= \mathcal{R}_{11}, |\, \mathcal{R}_{22}, \mathcal{R}_{11}, \mathcal{R}_{12}, \mathcal{R}_{13}, \mathcal{R}_{14}, \mathcal{R}_{15}, |\, \mathcal{R}_{33}, \mathcal{R}_{22}, \mathcal{R}_{23}, \mathcal{R}_{24}, \mathcal{R}_{25}, | \\ &\quad\ \mathcal{R}_{44}, \mathcal{R}_{33}, \mathcal{R}_{34}, \mathcal{R}_{35} |\, \mathcal{R}_{55}, \mathcal{R}_{44}, \mathcal{R}_{45}, |\, \mathcal{R}_{55}\,.\end{aligned}$$

Note that $\mathcal{R}_{ii}$ commutes with $\mathcal{R}_{i+1,i+1}$ and that $\mathcal{R}_{ij}$ commutes with $\mathcal{R}_{pq}$ provided that $(i, j)$ and $(p, q)$ are commuting. Using these facts, we can "move left" the subsequence $\mathcal{R}_{22}$ from the ninth position to the fifth position, just behind $\mathcal{R}_{12}$, and we can "move right" $\mathcal{R}_{22}$ from the second position to the third position. Continuing this process, we obtain the following equivalent sequences:

$$\begin{aligned}\mathcal{O}_{\mathcal{M}} \sim\ & \mathcal{R}_{11}, | \,\mathcal{R}_{11}, | \,\mathcal{R}_{22}, \mathcal{R}_{12}, \mathcal{R}_{22}, | \,\mathcal{R}_{13}, \mathcal{R}_{14}, \mathcal{R}_{15}, \mathcal{R}_{33}, \mathcal{R}_{23}, \mathcal{R}_{24}, \mathcal{R}_{25},\\ & \quad \mathcal{R}_{44}, \mathcal{R}_{33}, \mathcal{R}_{34}, \mathcal{R}_{35}, | \,\mathcal{R}_{55}, \mathcal{R}_{44}, \mathcal{R}_{45}, | \,\mathcal{R}_{55}\\ \sim\ & \mathcal{R}_{11},\ \mathcal{R}_{11}, | \,\mathcal{R}_{22}, \mathcal{R}_{12}, \mathcal{R}_{22}, | \,\mathcal{R}_{13}, \mathcal{R}_{33}, \mathcal{R}_{23}, \mathcal{R}_{33}, | \,\mathcal{R}_{14}, \mathcal{R}_{15}, \mathcal{R}_{24}, \mathcal{R}_{25},\\ & \mathcal{R}_{44}, \mathcal{R}_{34}, \mathcal{R}_{35}, \mathcal{R}_{55}, \mathcal{R}_{44}, \mathcal{R}_{45}, | \,\mathcal{R}_{55}\\ \sim\ & \mathcal{R}_{11},\ \mathcal{R}_{11}, | \,\mathcal{R}_{22}, \mathcal{R}_{12}, \mathcal{R}_{22}, | \,\mathcal{R}_{13}, \mathcal{R}_{33}, \mathcal{R}_{23}, \mathcal{R}_{33}, | \,\mathcal{R}_{14}, \mathcal{R}_{24}, \mathcal{R}_{44}, \mathcal{R}_{34}, |\\ & \quad \mathcal{R}_{15}, \mathcal{R}_{25}, \mathcal{R}_{35}, \mathcal{R}_{55}, \mathcal{R}_{44}, \mathcal{R}_{45}, | \,\mathcal{R}_{55}\\ \sim\ & \mathcal{R}_{11},\ \mathcal{R}_{11}, | \,\mathcal{R}_{22}, \mathcal{R}_{12}, \mathcal{R}_{22}, | \,\mathcal{R}_{13}, \mathcal{R}_{33}, \mathcal{R}_{23}, \mathcal{R}_{33}, |\\ & \quad \mathcal{R}_{14}, \mathcal{R}_{24}, \mathcal{R}_{44}, \mathcal{R}_{34}, \mathcal{R}_{44}, | \,\mathcal{R}_{15}, \mathcal{R}_{25}, \mathcal{R}_{35}, \mathcal{R}_{55}, \mathcal{R}_{45},\ \mathcal{R}_{55}\,.\end{aligned}$$

Using the same technique, we can conclude that for general $m$, $\mathcal{O}_{\mathcal{M}} \sim \mathcal{O}_1$, where

$$\begin{aligned}\mathcal{O}_1 = \mathcal{R}_{11},\ & \mathcal{R}_{11}, | \,\mathcal{R}_{22}, \mathcal{R}_{12}, \mathcal{R}_{22}, | \,\mathcal{R}_{13}, \mathcal{R}_{33}, \mathcal{R}_{23}, \mathcal{R}_{33}, | \dots\\ & | \,\mathcal{R}_{1m}, \mathcal{R}_{2m}, \mathcal{R}_{3m}, \dots, \mathcal{R}_{m-2,m}, \mathcal{R}_{mm}, \mathcal{R}_{m-1,m}, \mathcal{R}_{mm}.\end{aligned}$$

We see that $\mathcal{O}_1$ is obtained by the concatenation of $m$ subsequences, the $j$th one having the form

$$\mathcal{R}_{1j}, \mathcal{R}_{2j}, \mathcal{R}_{3j}, \dots, \mathcal{R}_{j-2,j}, \mathcal{R}_{jj}, \mathcal{R}_{j-1,j}\mathcal{R}_{jj}, \quad 3 \le j \le m.$$

Note that the first subsequence $\mathcal{R}_{11}, \mathcal{R}_{11}$ and the second one $\mathcal{R}_{22}, \mathcal{R}_{12}, \mathcal{R}_{22}$ also fit into this pattern. Therefore, we can write

$$\mathcal{O}_{\mathcal{M}} \sim \square_{j=1}^{m}\ \mathcal{R}_{1j}, \mathcal{R}_{2j}, \mathcal{R}_{3j}, \dots, \mathcal{R}_{j-2,j}, \mathcal{R}_{j,j}, \mathcal{R}_{j-1,j}\mathcal{R}_{j,j}, \tag{3.1}$$

where $\square$ stands for the concatenation. Now, remember that (see [8, 9]) the row-cyclic and the column-cyclic orderings are equivalent. This means that we can replace each $\mathcal{R}_{ii}$ with $\mathcal{C}_{ii}$. Furthermore, the rowwise ordering of each rectangular block is equivalent to the columnwise ordering of that block. Hence, for $3 \le j \le m$, we have

$$\mathcal{R}_{1j}, \mathcal{R}_{2j}, \mathcal{R}_{3j}, \dots, \mathcal{R}_{j-2,j} \sim O_R(B_j) \sim O_C(B_j) \equiv \mathsf{C}_j\,, \text{ where } B_j = \begin{bmatrix} A_{1j} \\ A_{2j} \\ \vdots \\ A_{j-2,j} \end{bmatrix}.$$

Note that $B_j \in \mathbf{R}^{s_{j-2} \times n_j}$, where

$$s_j = n_1 + n_2 + \cdots + n_j, \quad 1 \le j \le m, \quad s_0 = 0.$$

Let

$$\mathsf{c}_{jk} = O_C(B_j e_k) = (1, s_{j-1}+k), (2, s_{j-1}+k), \dots, (s_{j-2}, s_{j-1}+k), \quad 1 \le k \le n_j,$$

where $e_k$ is the $k$th column of the identity matrix, so that $B_j e_k$ is the $k$th column of $B_j$. Then

$$\mathsf{C}_j = \mathsf{c}_{j1}, \mathsf{c}_{j2}, \dots, \mathsf{c}_{jn_j}, \quad 3 \le j \le m\,.$$

Furthermore, we can write

$$\mathcal{R}_{1j}, \mathcal{R}_{2j}, \mathcal{R}_{3j}, \dots, \mathcal{R}_{j-2,j}, \mathcal{R}_{jj}, \mathcal{R}_{j-1,j}\mathcal{R}_{jj} \sim \mathsf{C}_j, \mathcal{C}_{jj}, \mathcal{C}_{j-1,j}, \mathcal{C}_{jj} \equiv \mathbf{C}_j\,. \tag{3.2}$$

If we set

$$\begin{aligned} \mathsf{c}'_{jk} &= O_C(A_{j-1,j}e_k), \quad 1 \le k \le n_j, \quad \text{and} \\ \mathsf{c}''_{jk} &= O_C([e_1,\dots,e_{k-1}]^T A_{jj}e_k), \quad 2 \le k \le n_j, \end{aligned}$$

then

$$\mathcal{C}_{j-1,j} = \mathsf{c}'_{j1},\mathsf{c}'_{j2},\dots,\mathsf{c}'_{jn_j} \quad \text{and} \quad \mathcal{C}_{jj} = \mathsf{c}''_{j2},\mathsf{c}''_{j3},\dots,\mathsf{c}''_{jn_j}.$$

Hence we can write for $3 \le j \le m$,

$$\mathbf{C}_j = \mathsf{c}_{j1},\mathsf{c}_{j2},\dots,\mathsf{c}_{jn_j},\mathsf{c}''_{j2},\dots,\mathsf{c}''_{jn_j},\mathsf{c}'_{j1},\mathsf{c}'_{j2},\dots,\mathsf{c}'_{jn_j},\mathsf{c}''_{j2},\dots,\mathsf{c}''_{jn_j}. \tag{3.3}$$

For $j = 1$ the above formula reduces to $\mathsf{c}''_{12},\dots,\mathsf{c}''_{1n_1},\mathsf{c}''_{12},\dots,\mathsf{c}''_{1n_1}$ and for $j = 2$ to $\mathsf{c}''_{22},\dots,\mathsf{c}''_{2n_2},\mathsf{c}'_{21},\mathsf{c}'_{22},\dots,\mathsf{c}'_{2n_2},\mathsf{c}''_{22},\dots,\mathsf{c}''_{2n_2}$.

LEMMA 3.1. [illegible]

(i) $\mathbf{C}_j \sim \mathcal{C}_j = \mathsf{c}_{j1},\mathsf{c}_{j2},\mathsf{c}''_{j2},\mathsf{c}_{j3},\mathsf{c}''_{j3},\dots,\mathsf{c}_{jn_j},\mathsf{c}''_{jn_j},\mathsf{c}'_{j1},\mathsf{c}'_{j2},\mathsf{c}''_{j2},\dots,\mathsf{c}'_{jn_j},\mathsf{c}''_{jn_j}$ $3 \le j \le m$

(ii) [illegible] $\mathcal{C}_1 = \mathcal{C}_{11},\mathcal{C}_{11}$ $\mathcal{C}_2 = \mathcal{C}_{22},\mathsf{c}'_{21},\mathsf{c}'_{22},\mathsf{c}''_{22},\dots,\mathsf{c}'_{2n_2},\mathsf{c}''_{2n_2}$ [illegible]

$$\mathcal{O}_{\mathcal{M}} \sim \mathcal{O} = \Box_{j=1}^{m} \mathcal{C}_j\,. \tag{3.4}$$

[illegible] (i) We start from the sequence $\mathbf{C}_j$ in the relation (3.3) and transform it by admissible transformations into $\mathcal{C}_j$. Since $\mathsf{c}''_{j2}$ commutes with the subsequence $\mathsf{c}_{j3},\dots,\mathsf{c}_{jn_j}$, we can move it left to the position just behind $\mathsf{c}_{j2}$. In a similar fashion, we move $\mathsf{c}''_{j3}$ just behind $\mathsf{c}_{j3}$ and so on. Note that, $\mathsf{c}'_{j1},\dots,\mathsf{c}'_{jn_j},\mathsf{c}''_{j2},\dots,\mathsf{c}''_{jn_j}$, can be replaced with $\mathsf{c}'_{j1},\mathsf{c}'_{j2},\mathsf{c}''_{j2},\dots,\mathsf{c}'_{jn_j},\mathsf{c}''_{jn_j}$, which is the columnwise ordering of $[A^T_{j-1,j},A^T_{jj}]^T$.

(ii) As has been shown in the lines after the relation (3.3),

$$\begin{aligned} \mathcal{R}_{11}\mathcal{R}_{11} &\sim \mathbf{C}_1 = \mathcal{C}_{11}\mathcal{C}_{11} = \mathcal{C}_1, \\ \mathcal{R}_{22}\mathcal{R}_{12}\mathcal{R}_{22} &\sim \mathbf{C}_2 = \mathcal{C}_{22}\mathcal{C}_{12}\mathcal{C}_{22} \sim \mathcal{C}_2\,. \end{aligned}$$

Using (3.1), (3.2), (3.3), and (i), we obtain (3.4). □

Thus, in considering the off-norm reduction after one quasi sweep of the original method $J_{\mathcal{M}}$, we can replace the initial pivot strategy defined by $\mathcal{O}_{\mathcal{M}}$ with the pivot strategy defined by $\mathcal{O}$.

To prove Theorem 2.1, we use mathematical induction with respect to $m$.

**The induction basis.** For $m = 1$, $\mathcal{O}_{\mathcal{M}} = \mathcal{R}_{11}\mathcal{R}_{11} \sim \mathcal{C}_{11}\mathcal{C}_{11} = \mathcal{O}$ and by the well-known result of Henrici and Zimmermann [14], we have

$$S^2(A^{(M)}) \le \left(1 - 2^{-\frac{(n_1-1)(n_1-2)}{2}}\right)^2 S^2(A)\,.$$

Since for $m = 1$, $n = n_1$, we can take $t_n^{(\mathcal{M})} = (1 - 2^{-\frac{n^2}{2}})^2$, which is smaller than 1 for all $n \ge 2$.

For $m = 2$, $\mathcal{O}_{\mathcal{M}} = \mathcal{R}_{11}\mathcal{R}_{22}\mathcal{R}_{11}\mathcal{R}_{12}\mathcal{R}_{22} \sim \mathcal{O}$, and hence by the same result,

$$S^2(A^{(M)}) \le \left(1 - 2^{-\frac{(n-1)(n-2)}{2}}\right) S^2(A^{(\frac{n_1(n_1-1)}{2}+\frac{n_2(n_2-1)}{2})}) \le \left(1 - 2^{-\frac{(n-1)(n-2)}{2}}\right) S^2(A)\,,$$

so we can take $t_n^{(\mathcal{M})} = 1 - 2^{-\frac{n^2}{2}}$, $n \ge 2$.

**The induction hypothesis.** Let us assume that the assertion of Theorem 2.1 holds for $m' = m-1$. This means that (2.5) holds for any partition $\mathcal{M}' = (n'_1, \ldots, n'_{m'})$ of $n'$, $n' \geq \max\{2, m'\}$, and for any symmetric matrix $A'$ of order $n'$ such that

(a) $A'$ is partitioned into $m'$ block-rows and block-columns, according to the partition $\mathcal{M}'$.

(b) the sequence $A^{(0)} = A'$, $A^{(1)}$,… is generated by the Jacobi method, which is defined by the quasi-cyclic strategy $\mathcal{I}_{\mathcal{O}_{\mathcal{M}'}}$, and $\mathcal{O}_{\mathcal{M}'}$ is defined by (2.4), provided that $m$ and $\mathcal{M}$ are replaced with $m'$ and $\mathcal{M}'$, respectively.

Since $\mathcal{O}_{\mathcal{M}'} \sim \mathcal{O}'$, where $\mathcal{O}'$ is defined as in (3.4), the induction hypothesis implies that (2.5) holds for the strategy defined by $\mathcal{O}'$.

**3.2. The induction step.** To prove the induction step, we assume that $\mathcal{M} = (n_1, \ldots, n_m)$ is an arbitrary partition of $n$, $n \geq m \geq 3$, and $A = (A_{ij})$ is an arbitrary symmetric matrix of order $n$, partitioned into $m$ block-rows and $m$ block-columns, according to the partition $\mathcal{M}$. We have to prove Theorem 2.1 for $A$ and $J_{\mathcal{M}}$ defined by $\mathcal{O}_{\mathcal{M}}$, provided the induction hypothesis holds.

Since $\mathcal{O}_{\mathcal{M}} \sim \mathcal{O}$, the same matrix $A^{(M)}$ is obtained if the quasi-cyclic Jacobi method $J_{\mathcal{M}}$ is replaced with $J$, which is defined by $\mathcal{O}$. So, from here on, we assume that $A = A^{(0)}$, $A^{(1)}$,…,$A^{(M)}$ are generated by $J$.

**Notation.** Let $I_n = [e_1, \ldots, e_n]$ be the column-partition of the identity matrix. Using the coordinate vectors $e_j$, we define

$$E_j = [e_1, \ldots, e_j], \ 1 \leq j \leq n,$$

so that $E_n = I_n$. Let

$$\begin{aligned} \tilde{n} &= s_{m-1} = n_1 + n_2 + \cdots + n_{m-1}, \\ \tilde{M} &= \frac{\tilde{n}(\tilde{n}-1)}{2} + \sum_{i=1}^{m-1} \frac{n_i(n_i-1)}{2}, \\ \tilde{A} &= A^{(\tilde{M})}, \quad B = E_{\tilde{n}}^T A E_{\tilde{n}}, \quad \tilde{B} = E_{\tilde{n}}^T \tilde{A} E_{\tilde{n}}, \\ \Sigma^2 &= S^2(A)\,, \quad S^2(B) = \varepsilon\Sigma^2\,, \quad 0 \leq \varepsilon \leq 1\,. \end{aligned}$$

Note that after $\tilde{M}$ steps, one full quasi sweep is performed on $B$. The underlying strategy is defined by $\tilde{\mathcal{O}}$, which is defined via $\tilde{\mathcal{M}} = (n_1, \ldots, n_{m-1})$. This $\tilde{\mathcal{O}}$ is one of those $\mathcal{O}'$ described above, and the induction hypothesis can be applied to $B$. We obtain

$$S^2(\tilde{B}) \leq t_{\tilde{n}}^{(\tilde{\mathcal{M}})} S^2(B) = t_{\tilde{n}}^{(\tilde{\mathcal{M}})} \varepsilon \Sigma^2, \quad 0 \leq t_{\tilde{n}}^{(\tilde{\mathcal{M}})} < 1\,.$$

Hence

$$S^2(\tilde{A}) = S^2(\tilde{B}) + (1-\varepsilon)\Sigma^2 \leq t_{\tilde{n}}^{(\tilde{\mathcal{M}})} \varepsilon \Sigma^2 + (1-\varepsilon)\Sigma^2 = [1 - \varepsilon(1 - t_{\tilde{n}}^{(\tilde{\mathcal{M}})})]\Sigma^2\,.$$

Although $S^2(A^{(M)}) \leq S^2(\tilde{A})$, we cannot set $t_n^{(\mathcal{M})} = 1 - \varepsilon(1 - t_{\tilde{n}}^{(\tilde{\mathcal{M}})})$, since $\varepsilon$ can be arbitrarily small or even zero. Therefore, we have to estimate the contribution to the further off-norm reduction coming from the last $M - \tilde{M}$ steps.

Let

$$\begin{aligned} \varepsilon_1 \Sigma^2 &= S^2(E_{\tilde{n}-n_{m-1}}^T \tilde{A} E_{\tilde{n}-n_{m-1}}), \\ \varepsilon_2 \Sigma^2 &= \textstyle\sum_{i=1}^{m-2} \|\tilde{A}_{i,m-1}\|_F^2, \\ \varepsilon_3 \Sigma^2 &= S^2(\tilde{A}_{m-1,m-1})\,. \end{aligned} \tag{3.5}$$

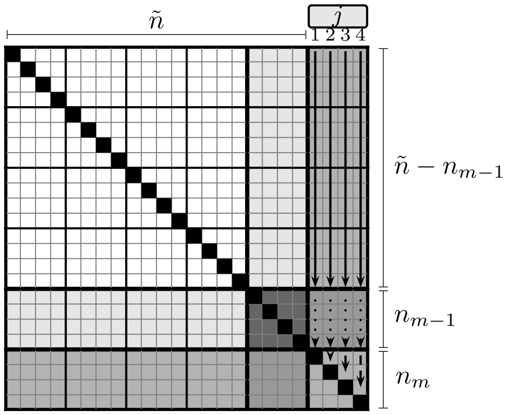

FIG. 1. *Matrices $\tilde{A}$ and $\tilde{B}$ for the case $n_i = 4$, $1 \le i \le m$, $m = 6$.*

Then

$$\varepsilon_1 + \varepsilon_2 + \varepsilon_3 \le t_{\tilde{n}}^{(\tilde{\mathcal{M}})}\varepsilon \le \varepsilon\,. \tag{3.6}$$

In Figure 1, the areas of $\tilde{A}$ which have contributed to $\varepsilon_1\Sigma^2$, $\varepsilon_2\Sigma^2$, and $\varepsilon_3\Sigma^2$ are shaded □, ▨, and ■, respectively.

**3.2.1. The case $n_m = 1$.** In this case, the proof of the induction step immediately follows from the third assertion of the following proposition. One just has to set $\Gamma = \Sigma$ $(= S(A^{(0)}))$ and $\mu = t_{\tilde{n}}^{(\tilde{\mathcal{M}})}$.

The first and third assertions of this proposition are modifications of a similar result from [12].

PROPOSITION 3.2. [illegible] $A = (a_{pq})$ [illegible] $n \ge 3$, [illegible] $B = E_{n-1}^T A E_{n-1}$ [illegible] $r$ $1 \le r \le n-1$ [illegible] $A$ [illegible] $(1,n), (2,n), \ldots, (r,n)$ [illegible] $A^{(0)} = A, A^{(1)}, \ldots, A^{(n-1)}$ [illegible]

(i) $\left[\sum_{i=1}^{r} |a_{in}^{(i-1)}|^2\right]^{1/2} \ge \left[\frac{2^{1-r}}{r}\sum_{i=1}^{r}|a_{in}|^2\right]^{1/2} - \left[\frac{r-1}{4}\sum_{i=1}^{r}\sum_{k=1}^{i-1}|a_{ik}|^2\right]^{1/2}, r \le n-1.$

(ii) $\left[\sum_{i=r+1}^{t} |a_{in}^{(r)}|^2\right]^{1/2} \ge \left[\frac{2^{-r}}{t-r}\sum_{i=r+1}^{t}|a_{in}|^2\right]^{1/2} - \left[\frac{r}{2}\sum_{i=r+1}^{t}\sum_{k=1}^{r}|a_{ik}|^2\right]^{1/2}, t > r.$

(iii) [illegible] $0 \le \mu < 1$ $0 \le \alpha \le 1$ [illegible] $\Gamma$ [illegible]

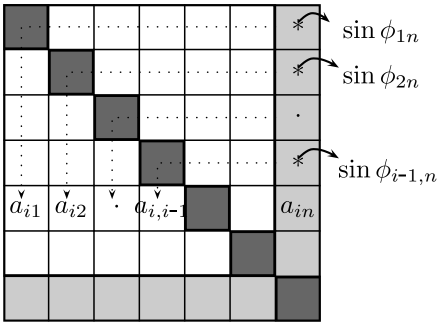
$$S^2(B) \le \mu(\alpha\Gamma^2) \quad [illegible] \quad \sum_{i=1}^{n-1}|a_{in}|^2 = (1-\alpha)\Gamma^2\,. \tag{3.7}$$

[illegible] $\mu'$ $0 \le \mu' < 1$ [illegible] $n$ [illegible] $\mu$ [illegible]

$$S^2(A^{(n-1)}) \le \mu'\,\Gamma^2\,.$$

[illegible] (i) Let us denote the rotation angle which is used to annihilate the element at position $(k,n)$ by $\phi_{kn}$. Consider the history of the element at position $(i,n)$, $i > 1$, up to its annihilation. We have

$$
\begin{aligned}
a_{in}^{(1)} &= \cos\phi_{1n}\, a_{in} + \sin\phi_{1n}\, a_{i1} \\
a_{in}^{(2)} &= \cos\phi_{2n}\, a_{in}^{(1)} + \sin\phi_{2n}\, a_{i2} \\
&\ \ \vdots \\
a_{in}^{(i-1)} &= \cos\phi_{i-1,n}\, a_{in}^{(i-2)} \\
&\qquad + \sin\phi_{i\text{-}1,n}\, a_{i,i-1}
\end{aligned}
$$



These relations imply

$$
\begin{aligned}
a_{in}^{(i-1)} &= a_{in}\cos\phi_{1n}\cos\phi_{2n}\cdots\cos\phi_{i-1,n} + a_{i,i-1}\sin\phi_{i-1,n} \\
&\quad + a_{i,i-2}\sin\phi_{i-2,n}\cos\phi_{i-1,n} + \cdots + a_{i1}\sin\phi_{1n}\cos\phi_{2n}\cdots\cos\phi_{i-1,n}\,.
\end{aligned}
$$

Note that $z = x + y$ implies $|z| \geq |x| - |y|$. Applying this to the above relation, one obtains

$$
\begin{aligned}
|a_{in}^{(i-1)}| &\geq \cos\phi_{1n}\cos\phi_{2n}\cdots\cos\phi_{i-1,n}|a_{in}| \\
&\qquad - \sum_{k=1}^{i-1} |a_{ik}|\,|\sin\phi_{kn}|\,\cos\phi_{k+1,n}\cdots\cos\phi_{i-1,n} \\
&\geq |a_{in}|\cdot(2^{-\frac{1}{2}})^{i-1} - \sum_{k=1}^{i-1} |a_{ik}|\,|\sin\phi_{kn}|\,.
\end{aligned}
$$

This inequality holds for $i = 1$ provided that an empty sum is defined as zero.

Summing up over $1 \leq i \leq r$ and using the Cauchy–Schwarz inequality, we obtain

$$
\begin{aligned}
\sum_{i=1}^{r} |a_{in}^{(i-1)}| &\geq \sum_{i=1}^{r} 2^{-\frac{i-1}{2}}|a_{in}| \;-\; \sum_{i=1}^{r}\sum_{k=1}^{i-1} |a_{ik}|\,|\sin\phi_{kn}| \\
&\geq 2^{-\frac{r-1}{2}} \sum_{i=1}^{r} |a_{in}| - \left[\sum_{i=1}^{r}\sum_{k=1}^{i-1} |a_{ik}|^2\right]^{1/2} \left[\frac{1}{2}\frac{r(r-1)}{2}\right]^{1/2} \\
&\geq \sqrt{2^{1-r}}\left[\sum_{i=1}^{r} |a_{in}|^2\right]^{1/2} - \frac{\sqrt{r(r-1)}}{2}\left[\sum_{i=1}^{r}\sum_{k=1}^{i-1} |a_{ik}|^2\right]^{1/2}.
\end{aligned}
$$

Since by the Cauchy–Schwarz inequality

$$
\sum_{i=1}^{r} |a_{in}^{(i-1)}| \leq \sqrt{r}\left[\sum_{i=1}^{r} |a_{in}^{(i-1)}|^2\right]^{1/2},
$$

the first assertion easily follows.

(ii) In this case we have for $r + 1 \leq i \leq t$, $t \leq n - 1$,

$$
\begin{aligned}
a_{in}^{(r)} &= a_{in}\cos\phi_{1n}\cos\phi_{2n}\cdots\cos\phi_{rn} + \ a_{ir}\sin\phi_{rn} + a_{i,r-1}\sin\phi_{r-1,n}\cos\phi_{rn} \\
&\quad + \cdots + a_{i1}\sin\phi_{1n}\cos\phi_{2n}\cdots\cos\phi_{rn}
\end{aligned}
$$

and

$$|a_{in}^{(r)}| \geq \cos\phi_{1n}\cdots\cos\phi_{rn}|a_{in}| - \sum_{k=1}^{r}|a_{ik}|\,|\sin\phi_{kn}|\,\cos\phi_{k+1,n}\cdots\cos\phi_{rn}$$

$$\geq |a_{in}|\cdot(2^{-\frac{1}{2}})^r - \sum_{k=1}^{r}|a_{ik}|\,|\sin\phi_{kn}|\,.$$

Hence

$$\sum_{i=r+1}^{t}|a_{in}^{(r)}| \geq \sum_{i=r+1}^{t}2^{-\frac{r}{2}}|a_{in}| \;-\; \sum_{i=r+1}^{t}\sum_{k=1}^{r}|a_{ik}|\,|\sin\phi_{kn}|$$

$$\geq 2^{-\frac{r}{2}}\left[\sum_{i=r+1}^{t}|a_{in}|^2\right]^{1/2} - \left[\sum_{i=r+1}^{t}\sum_{k=1}^{r}|a_{ik}|^2\right]^{1/2}\left[\frac{r(t-r)}{2}\right]^{1/2},$$

and an application of the Cauchy–Schwarz inequality yields (ii).

(iii) Using (i) with $r = n-1$ and the assumption (3.7), we obtain

$$\left[\sum_{i=1}^{n-1}|a_{in}^{(i-1)}|^2\right]^{1/2} \geq \left\{\left[\frac{2^{2-n}}{n-1}\right]^{1/2}\sqrt{1-\alpha} - \frac{\sqrt{n-2}}{2}\sqrt{\alpha}\right\}\Gamma\,. \tag{3.8}$$

The function

$$f_n(\alpha) = \left[\frac{2^{2-n}}{n-1}\right]^{1/2}\sqrt{1-\alpha} - \frac{\sqrt{n-2}}{2}\sqrt{\alpha}$$

is continuous and decreasing on the segment $[0,1]$ with the only root

$$\xi_n = \frac{1}{1+2^{n-4}(n-1)(n-2)}\,.$$

In the above relation, note that $n \geq 3$. If we take

$$\zeta_n = \frac{\xi_n}{2} = \frac{1}{2+2^{n-3}(n-1)(n-2)}\,,$$

we obtain from the relation (3.8)

$$\sum_{i=1}^{n-1}|a_{in}^{(i-1)}|^2 \geq \eta_n\Gamma^2\,, \quad \eta_n = [f_n(\zeta_n)]^2 > 0, \quad \alpha \in [0,\zeta_n]\,.$$

Thus, during the last $n-1$ steps, $S^2(A) = S^2(B) + (1-\alpha)\Gamma^2 \leq \mu(\alpha\Gamma^2) + (1-\alpha)\Gamma^2 = [1-\alpha(1-\mu)]\Gamma^2 \leq \Gamma^2$ has decreased by an amount not smaller than $\eta_n\Gamma^2$, $\eta_n > 0$. Hence

$$S^2(A^{(n-1)}) \leq \begin{cases} (1-\eta_n)\Gamma^2 & \text{if } \alpha \in [0,\zeta_n], \\ [1-\alpha(1-\mu)]\Gamma^2 & \text{if } \alpha \in [\zeta_n\,,\,1]. \end{cases}$$

So, we can complete the proof by setting

$$\mu' = \max\{1-\zeta_n(1-\mu)\,,\,1-\eta_n\}\,.$$

Note that $\mu'$ depends only on $n$ and $\mu$. □

3.3. Proposition 3.2(iii) provides a basis for the simplest proof of global convergence of the serial symmetric Jacobi method. Indeed, the proof uses induction with respect to $n$. The induction basis takes advantage of the fact that for $n = 2$, $S(A^{(1)}) = 0$. The induction hypothesis assumes that $S(A^{(\frac{(n-1)(n-2)}{2})}) \leq \mu S(A)$ for any initial symmetric matrix of order $n-1$, where $0 \leq \mu < 1$ depends only on $n-1$ (that is, on $n$). The induction step is then proved by Proposition 3.2(iii) and the assumption that $\Gamma = S(A)$.

However, the proof presented here can easily be generalized for strategies slightly more general than the column-cyclic strategy. We can consider any strategy which annihilates the elements in columnwise fashion so that in the $j$th column, $2 \leq j \leq n$, the annihilation ordering is $(\pi_{j-1}(1), j), (\pi_{j-1}(2), j), \ldots, (\pi_{j-1}(j-1), j)$ for any permutation $\pi_{j-1}$ of the set $\{1, 2, \ldots, j-1\}$. The proof of the induction step is almost the same as that of Proposition 3.2. Just consider the history of the element at position $(\pi_{n-1}(i), n)$, $i > 1$, up to its annihilation. This means that at step $i-1$ (of the last $n-1$ steps) the element at position $(\pi_{n-1}(i), n)$ is annihilated. Now, follow the proof of Proposition 3.2(iii) and replace all the subscripts $i$ and $k$ (but not the superscript $i$) with $\pi(i)$ and $\pi(k)$, respectively.

3.4. The first proof of global convergence of the serial methods is given by Forsythe and Henrici [13] and the first estimate of the form $S(A^{(N)}) \leq t_n S(A)$ by Henrici and Zimmermann [14] who obtained the known estimate

$$t_n = \left[ 1 - \prod_{i=1}^{n-2} \prod_{j=i+2}^{n} \cos\phi_{ij}^2 \right]^{1/2}.$$

See also similar results in [16, 10, 7].

### 3.2.2. The case $n_m \geq 2$.

Note that $m \geq 3$, $n \geq m$, and $n_m \geq 2$; hence $n \geq 4$. We assume $\Sigma > 0$, since otherwise there is nothing to prove. According to the pivot strategy, during the subsequent

$$\mu = n_m(\tilde{n} - n_{m-1}) + n_m(n_m - 1)/2 \tag{3.9}$$

Jacobi steps defined by the pivot pairs sequence $\mathsf{c}_{m1}, \mathsf{c}_{m2}, \mathsf{c}''_{m2}, \ldots, \mathsf{c}_{m,n_m}, \mathsf{c}''_{m,n_m}$, we have

$$\|A_{m-1,m}^{(\tilde{M}+k)}\|_F^2 + \sum_{i=1}^{m-2} \|A_{i,m-1}^{(\tilde{M}+k)}\|_F^2 = \|\tilde{A}_{m-1,m}\|_F^2 + \varepsilon_2 \Sigma^2, \quad 0 \leq k \leq \mu.$$

Therefore, for $0 \leq k \leq \mu$, we split $A^{(\tilde{M}+k)}$ into

$$A^{(\tilde{M}+k)} = H^{(\tilde{M}+k)} + T^{(\tilde{M}+k)},$$

where

$$H^{(\tilde{M}+k)} = \begin{bmatrix} B_{\tilde{n}-n_{m-1}}^{(\tilde{M}+k)} & 0 & \Gamma^{(\tilde{M}+k)} \\ 0 & 0 & 0 \\ [\Gamma^{(\tilde{M}+k)}]^T & 0 & A_{mm}^{(\tilde{M}+k)} \end{bmatrix}, \quad \Gamma^{(\tilde{M}+k)} = \begin{bmatrix} A_{1m}^{(\tilde{M}+k)} \\ \vdots \\ A_{m-2,m}^{(\tilde{M}+k)} \end{bmatrix}, \quad 0 \leq k \leq \mu.$$

Since the off-norm of $T^{(\tilde{M}+k)}$ is invariant under Jacobi transformations during all these $\mu$ steps, we shall use the matrix

$$W^{(\tilde{M}+k)} = \begin{bmatrix} B_{\tilde{n}-n_{m-1}}^{(\tilde{M}+k)} & \Gamma^{(\tilde{M}+k)} \\ [\Gamma^{(\tilde{M}+k)}]^T & A_{mm}^{(\tilde{M}+k)} \end{bmatrix}, \quad 0 \le k \le \mu . \tag{3.10}$$

Since the annihilations advance in a block-columnwise fashion, we have

$$(1-\varepsilon)\Sigma^2 = S^2(A_{mm}) + \sum_{i=1}^{m-1} \|A_{im}\|_F^2 = S^2(\tilde{A}_{mm}) + \sum_{i=1}^{m-1} \|\tilde{A}_{im}\|_F^2 . \tag{3.11}$$

This follows from the fact that the Frobenius norm is invariant under orthogonal transformations. Recall that $\varepsilon$ can be arbitrarily small. Because of (3.11), we consider the following two cases:

$$\text{(a) } S^2(\tilde{A}_{mm}) + \sum_{i=1}^{m-2} \|\tilde{A}_{im}\|_F^2 \ge \frac{2^{-n}}{1-2^{-2n}}\Sigma^2,$$

$$\text{(b) } \|\tilde{A}_{m-1,m}\|_F^2 > \left(1 - \varepsilon - \frac{2^{-n}}{1-2^{-2n}}\right)\Sigma^2.$$

We start with case (a).

(a) In this case, there exists $\jmath$, $1 \le \jmath \le n_m$, such that

$$\sum_{i\in\mathcal{N}_\jmath} |\tilde{a}_{i,\tilde{n}+\jmath}|^2 \ge 2^{-(2(n_m-\jmath)+1)n} \cdot \Sigma^2, \tag{3.12}$$

where

$$\mathcal{N}_j = \{1, 2, \dots, \tilde{n}+j-1\} \setminus \{\tilde{n}-n_{m-1}+1, \dots, \tilde{n}\}, \quad 1 \le j \le n_m ,$$

and $\tilde{A} = (\tilde{a}_{ij})$. Indeed, if (3.12) were false, then we would have

$$\begin{aligned} S^2(\tilde{A}_{mm}) + \sum_{i=1}^{m-2} \|\tilde{A}_{im}\|_F^2 &= \sum_{j=1}^{n_m} \sum_{i\in\mathcal{N}_j} |\tilde{a}_{i,\tilde{n}+j}|^2 < \sum_{j=1}^{n_m} 2^{-(2(n_m-j)+1)n}\Sigma^2 \\ &= \left(2^{-n} + 2^{-3n} + \cdots + 2^{-(2n_m-1)n}\right)\Sigma^2 = \frac{2^{-n}}{1-2^{-2n}}(1-2^{-2n_m n})\,\Sigma^2 \\ &< \frac{2^{-n}}{1-2^{-2n}}\,\Sigma^2 , \end{aligned}$$

which contradicts (a). If there are more than one $\jmath$ satisfying (3.12), we define $\jmath$ as the [illegible].

Let $\hat{A} = (\hat{a}_{ij})$, $\hat{A} = A^{(\hat{M})}$, $\hat{W} = W^{(\hat{M})}$, where $W^{(\hat{M})}$ is given by (3.10), and

$$\hat{M} = \tilde{M} + (\tilde{n}-n_{m-1}) + (\tilde{n}-n_{m-1}+1) + \cdots + (\tilde{n}-n_{m-1}+\jmath-2) .$$

In other words, $\hat{A}$ is the matrix iterate at the stage just before the annihilations in column $\jmath$ of the $m$th block-column have begun. Thus, $\hat{A}$ is obtained from $\tilde{A}$ by applying

$$\mu_\jmath = (\jmath-1)(\tilde{n}-n_{m-1}) + (\jmath-2)(\jmath-1)/2$$

additional Jacobi steps. They are defined by the sequence of pivot pairs $\mathsf{c}_{m1}, \mathsf{c}_{m2}, \mathsf{c}''_{m2}, \ldots, \mathsf{c}_{m,\jmath-1}, \mathsf{c}''_{m,\jmath-1}$. Now, consider the matrices $\hat{W}_{\tilde{n}-n_{m-1}+\jmath}$ and $W^{(k)}_{\tilde{n}-n_{m-1}+\jmath}$, where

$$\hat{W}_i = E_i^T \hat{W} E_i \quad \text{and} \quad W_i^{(k)} = E_i^T A^{(k)} E_i, \quad k \geq \tilde{M}\,.$$

Since all the Jacobi steps involved in the transition from $\tilde{A}$ to $\hat{A}$ cannot increase the off-norm of any $W^{(k)}_{\tilde{n}-n_{m-1}+\jmath-1}$, $\tilde{M} \leq k \leq \hat{M}$, we have

$$\begin{aligned} S^2(\hat{W}_{\tilde{n}-n_{m-1}+\jmath-1}) &\leq S^2(W^{(\tilde{M})}_{\tilde{n}-n_{m-1}+\jmath-1}) \leq S^2(\tilde{B}_{\tilde{n}-n_{m-1}}) + \sum_{j=1}^{\jmath-1} \sum_{i\in\mathcal{N}_j} |\tilde{a}_{i,\tilde{n}+j}|^2 \\ &\leq \varepsilon_1 \Sigma^2 + \left(2^{-(2n_m-1)n} + 2^{-(2n_m-3)n} + \cdots + 2^{-(2(n_m-\jmath)+3)n}\right)\Sigma^2 \\ &\leq \left(\varepsilon_1 + \frac{2^{(-2n_m+2\jmath-3)n}}{1-2^{-2n}}\right)\Sigma^2\,. \end{aligned} \tag{3.13}$$

We also know that none of these $\mu_\jmath$ Jacobi steps has changed the sum of squares of the affected elements in the last column of $W^{(\tilde{M}+k)}_{\tilde{n}-n_{m-1}+\jmath}$, $\tilde{M} \leq k \leq \hat{M}$. Therefore,

$$\sum_{i\in\mathcal{N}_\jmath} |\hat{a}_{i,\tilde{n}+\jmath}|^2 = \sum_{i\in\mathcal{N}_\jmath} |\tilde{a}_{i,\tilde{n}+\jmath}|^2\,. \tag{3.14}$$

In order to estimate the contribution to the off-norm reduction, coming from the annihilations in the $(\tilde{n}-n_{m-1}+\jmath)$th column, we apply Proposition 3.2(i) to $\hat{W}_{\tilde{n}-n_{m-1}+\jmath}$ with $r = \tilde{n} - n_{m-1} + \jmath - 1$. This, together with (3.12), (3.13), and (3.14), implies

$$\begin{aligned} \left[\sum_{i\in\mathcal{N}_\jmath} |\hat{a}^{(\hat{M}+i-1)}_{i,\tilde{n}+\jmath}|^2\right]^{1/2} &\geq \frac{2}{\sqrt{(\tilde{n}-n_{m-1}+\jmath-1)2^{\tilde{n}-n_{m-1}+\jmath}}} \left[\sum_{i\in\mathcal{N}_\jmath} |\hat{a}_{i,\tilde{n}+\jmath}|^2\right]^{1/2} \\ &\quad - \frac{\sqrt{\tilde{n}-n_{m-1}+\jmath-2}}{2}\left[\varepsilon_1 + \frac{2^{(-2n_m+2\jmath-3)n}}{1-2^{-2n}}\right]^{1/2} \Sigma \\ \geq \frac{2\cdot\; 2^{-(n_m-\jmath)n-\frac{n}{2}} \cdot 2^{-\frac{n-n_{m-1}}{2}}}{\sqrt{n-n_{m-1}-1}}\Sigma &- \frac{\sqrt{n-n_{m-1}-2}}{2}\left[\varepsilon_1 + \frac{2^{(-2n_m+2\jmath-3)n}}{1-2^{-2n}}\right]^{1/2} \Sigma \\ \geq \left\{\frac{2\sqrt{2}\cdot 2^{-(n_m-\jmath+1)n}}{\sqrt{n-n_{m-1}}} \right. &\left. - \frac{\sqrt{n-n_{m-1}}}{2}\left[\varepsilon_1 + \frac{2^{(-2n_m+2\jmath-3)n}}{1-2^{-2n}}\right]^{1/2}\right\}\Sigma\,. \end{aligned}$$

We can write

$$\left[\sum_{i\in\mathcal{N}_\jmath} |\hat{a}^{(\hat{M}+i-1)}_{i,\tilde{n}+\jmath}|^2\right]^{1/2} \geq g_{n,n_m,n_{m-1},\jmath}(\varepsilon_1)\Sigma,$$

where

$$g_{n,n_m,n_{m-1},\jmath}(x) = \frac{\sqrt{n-n_{m-1}}}{2}\left\{\frac{4\sqrt{2}\cdot 2^{-(n_m-\jmath+1)n}}{n-n_{m-1}} - \left[x + \frac{2^{(-2n_m+2\jmath-3)n}}{1-2^{-2n}}\right]^{1/2}\right\}.$$

The function $g_{n,n_m,n_{m-1},\jmath}$ is decreasing and convex for $0 \le x \le 1$,

$$g_{n,n_m,n_{m-1},\jmath}(0) = \frac{\sqrt{n-n_{m-1}}}{2} 2^{-(n_m-\jmath+1)n} \left[ \frac{4\sqrt{2}}{n-n_{m-1}} - \frac{2^{-\frac{n}{2}}}{\sqrt{1-2^{-2n}}} \right]$$
$$> \frac{\sqrt{3}}{2} 2^{-(n-2)n} \left[ \frac{4\sqrt{2}}{n-1} - 2^{-\frac{n}{2}} \right] > \frac{4}{n} 2^{-(n-2)n} ,$$

and with the positive root

$$\eta_{n,n_m,n_{m-1},\jmath} = 2^{(-2n_m+2\jmath-2)n} \left( \frac{32}{(n-n_{m-1})^2} - \frac{2^{-n}}{1-2^{-2n}} \right) .$$

Let

$$\zeta_{n,n_m,\jmath} = \frac{16}{n^2} \cdot 2^{-2(n_m-\jmath+1)n} .$$

Then

$$\frac{1}{2} \eta_{n,n_m,n_{m-1},\jmath} > \zeta_{n,n_m,\jmath} > \frac{16}{n^2}\, 2^{-2(n-2)n} \equiv \xi_n ,$$

and we have

$$\sum_{i\in\mathcal{N}_\jmath} |\hat{a}^{(\hat{M}+i-1)}_{i,\tilde{n}+\jmath}|^2 \ge [g_{n,n_m,n_{m-1}}(\zeta_{n,n_m,\jmath})]^2 \Sigma^2 \quad \text{whenever} \quad 0 \le \varepsilon_1 \le \zeta_{n,n_m,\jmath} .$$

Note that

$$[g_{n,n_m,n_{m-1}}(\zeta_{n,n_m,\jmath})]^2 = \frac{n-n_{m-1}}{4} 2^{-2(n_m-\jmath+1)n}$$
$$\times \left\{ \frac{2\sqrt{2}}{n-n_{m-1}} - \frac{4}{n} \left[ 1 - \frac{n^2}{16} \frac{2^{-n}}{1-2^{-2n}} \right]^{1/2} \right\}^2$$
$$> \frac{1}{2}\, 2^{-2(n-2)n} \left\{ \frac{2\sqrt{2}}{n-n_{m-1}} - \frac{4}{n} \left[ 1 - \frac{n^2}{16} \frac{2^{-n}}{1-2^{-2n}} \right]^{1/2} \right\}^2 .$$

Hence if $0 \le \varepsilon_1 \le \zeta_{n,n_m,\jmath}$, we have

$$\sum_{i\in\mathcal{N}_\jmath} |\hat{a}^{(\hat{M}+i-1)}_{i,\tilde{n}+\jmath}|^2 > \varrho_n \Sigma^2, \qquad \rho_n = \frac{8}{n^2} \left\{ \sqrt{2} - \left[ 1 - \frac{n^2}{16} \frac{2^{-n}}{1-2^{-2n}} \right]^{1/2} \right\}^2 2^{-2(n-2)n} .$$

This inequality certainly holds for $0 \le \varepsilon_1 \le \xi_n$. Thus, during the last $M - \tilde{M}$ Jacobi steps, $S^2(\tilde{A}) = S^2(\tilde{B}) + (1-\varepsilon)\Sigma^2$ has decreased by an amount not smaller than $\varrho_n \Sigma^2$, $\varrho_n > 0$, provided that $\varepsilon \le \xi_n$. Hence

$$S^2(A^{(M)}) \le \begin{cases} (1-\varrho_n)\Sigma^2 & \text{if } \ \varepsilon \in [0, \xi_n], \\ [1 - \varepsilon(1 - t_{\tilde{n}}^{(\tilde{\mathcal{M}})})]\Sigma^2 & \text{if } \ \varepsilon \in [\xi_n \, , \, 1]. \end{cases}$$

So, we can complete the proof of the theorem by setting

$$t_n^{(\mathcal{M})} = \max\{[1 - \xi_n(1 - t_{\tilde{n}}^{(\tilde{\mathcal{M}})}) \, , \, 1 - \varrho_n\} .$$

(b) In this case we begin the proof by assuming

$$\varepsilon < \frac{2^{-n}}{1-2^{-4n}}\,. \tag{3.15}$$

This implies

$$\|\tilde{A}_{m-1,m}\|_F^2 > \left(1-\frac{2^{-n}}{1-2^{-4n}}-\frac{2^{-n}}{1-2^{-2n}}\right)\Sigma^2 > \left(1-\frac{2^{-n+1}}{1-2^{-2n}}\right)\Sigma^2\,. \tag{3.16}$$

Let $\tilde{F}=[\tilde{A}_{m-1,1},\tilde{A}_{m-1,2},\ldots,\tilde{A}_{m-1,m}]$, and let $[\tilde{f}_1,\tilde{f}_2,\ldots,\tilde{f}_n]$ be the column-partition of $\tilde{F}$. We claim that there exists $\jmath$, $1\le \jmath\le n_m$, not necessarily the same as above, such that

$$\|\tilde{f}_{\tilde{n}+\jmath}\| > \begin{cases} 2^{-2(n_m-\jmath)n}\,\Sigma & \text{if } 1\le \jmath\le n_m-1,\\ (1-2^{-n+1})\,\Sigma & \text{if } \jmath=n_m\,. \end{cases} \tag{3.17}$$

In fact, if (3.17) were false, we would have

$$\begin{aligned} \|\tilde{A}_{m-1,m}\|_F^2 &= \sum_{j=1}^{n_m}\|\tilde{f}_{\tilde{n}+j}\|^2 \le \left[2^{-4(n_m-1)n}+2^{-4(n_m-2)n}+\cdots+2^{-4n}\right]\Sigma^2\\ &+\left(1-2^{-n+2}+2^{-2n+2}\right)\Sigma^2 = \frac{1-2^{-4n_mn}}{1-2^{-4n}}\Sigma^2-(2^{-n+2}+2^{-2n+2})\Sigma^2\\ &=\left[1-2^{-n+2}\left(1-2^{-n}-\frac{2^{-3n-2}-2^{-4n_mn+n-2}}{1-2^{-4n}}\right)\right]\Sigma^2 < \left(1-\frac{2^{-n+1}}{1-2^{-2n}}\right)\Sigma^2\,, \end{aligned}$$

which contradicts (3.16).

Recall that $\mathsf{c}_{m1},\mathsf{c}_{m2},\mathsf{c}''_{m2},\mathsf{c}_{m3},\mathsf{c}''_{m3},\ldots,\mathsf{c}_{mn_m},\mathsf{c}''_{mn_m} \sim \mathsf{c}_{m1},\mathsf{c}_{m2},\mathsf{c}_{m3},\ldots,\mathsf{c}_{mn_m},$ $\mathsf{c}''_{m2},\mathsf{c}''_{m3},\ldots,\mathsf{c}''_{mn_m}$. Hence the same matrix $A^{(\tilde{M}+\mu)}$ (thus, the same block $A^{(\tilde{M}+\mu)}_{m-1,m}$, where $\mu$ is given by (3.9)) is obtained if we assume that the annihilation ordering is defined by $\mathsf{c}_{m1},\mathsf{c}_{m2},\mathsf{c}_{m3},\ldots,\mathsf{c}_{mn_m},\mathsf{c}''_{m2},\mathsf{c}''_{m3},\ldots,\mathsf{c}''_{mn_m}$. Accepting that, note that the rotations which annihilate the elements in the diagonal block $A^{(k)}_{mm}$ do not change the Frobenius norm of $A^{(k)}_{m-1,m}$.

Therefore, we divide the proof into two stages. In Stage I we estimate the weight remaining in $A^{(k)}_{m-1,m}$ after all Jacobi steps defined by the sequence $\mathsf{c}_{m1},\mathsf{c}_{m2},\ldots,\mathsf{c}_{mn_m}$ are completed. Actually, we shall compute a lower bound of $\|A^{(\tilde{M}+n_m(\tilde{n}-n_{m-1}))}_{m-1,m}\|_F = \|A^{(\tilde{M}+\mu)}_{m-1,m}\|_F$.

In Stage II, we use a similar proof as in case (a), but we apply it only to the part of the $m$th block-column consisting of the blocks $A^{(k)}_{m-1,m}$ and $A^{(k)}_{mm}$. In this stage, the annihilation ordering is defined by the sequence of pairs $\mathsf{c}'_{\jmath 1},\mathsf{c}'_{\jmath 2},\mathsf{c}''_{\jmath 2}\ldots,\mathsf{c}'_{\jmath n_\jmath},\mathsf{c}''_{\jmath n_\jmath}$.

Stage I. Let $\jmath$ be the first (smallest) index for which (3.17) holds. Let $\hat{A}=(\hat{a}_{ij})$ be the matrix $A^{(\hat{M})}$, where

$$\hat{M}=\tilde{M}+\tilde{\mu}_\jmath,\quad \tilde{\mu}_\jmath=(\tilde{n}-n_{m-1})(\jmath-1)\,.$$

Thus, $\hat{A}$ is obtained from $\tilde{A}$ by applying additional $\tilde{\mu}_\jmath$ Jacobi steps according to the sequence of pivot pairs $\mathsf{c}_{m1},\mathsf{c}_{m2},\ldots,\mathsf{c}_{m,\jmath-1}$. Let $\hat{F}=[\hat{A}_{m-1,1},\hat{A}_{m-1,2},\ldots,\hat{A}_{m-1,m}]$

and let $\hat F = [\hat f_1, \hat f_2, \dots, \hat f_n]$ be its column-partition. More generally, for $0 \le k \le \tilde\mu_\jmath$, let

$$\tilde F^{(k)} = [A_{m-1,1}^{(\tilde M+k)}, A_{m-1,2}^{(\tilde M+k)}, \dots, A_{m-1,m}^{(\tilde M+k)}] = [\tilde f_1^{(k)}, \tilde f_2^{(k)}, \dots, \tilde f_n^{(k)}].$$

The Jacobi transformations involved in the transition from $\tilde F$ to $\hat F$ do not change the Frobenius norm of any $\tilde F^{(k)} E_{\tilde n+\jmath-1}$, $0 \le k \le \tilde\mu_\jmath$, and they do not transform any element of $\tilde A_{m-1,m-1}$. Therefore, we have

$$\begin{aligned} &\sum_{j=1}^{\tilde n - n_{m-1}} \|\hat f_j\|^2 + \sum_{j=\tilde n+1}^{\tilde n+\jmath-1} \|\hat f_j\|^2 = \sum_{j=1}^{\tilde n - n_{m-1}} \|\tilde f_j\|^2 + \sum_{j=\tilde n+1}^{\tilde n+\jmath-1} \|\tilde f_j\|^2 \\ (3.18)\quad &+ \left(2^{-4(n_m-1)n} + \cdots + 2^{-(4(n_m-\jmath+1)n}\right)\Sigma^2 \le \left(\varepsilon_2 + \frac{2^{-4(n_m-\jmath+1)n}}{1-2^{-4n}}\right)\Sigma^2 .\end{aligned}$$

We know that none of these $\tilde\mu_\jmath$ Jacobi transformations has affected any of the elements of $\tilde f_{\tilde n+\jmath}^{(k)}$. Therefore,

$$\hat f_{\tilde n+\jmath} = \tilde f_{\tilde n+\jmath} . \tag{3.19}$$

We also know that the later transformations, defined by $\mathsf{c}_{m,\jmath+1}, \dots, \mathsf{c}_{m,n_m}$, will not affect the $\jmath$th column of $A_{m-1,m}^{(\hat M+\tilde n-n_{m-1})}$.

So, let us consider the transformations which do affect $\hat f_{\tilde n+\jmath}$, i.e., those which annihilate the elements at positions given in $\mathsf{c}_{m,\jmath}$.

For $1 \le k \le \tilde n - n_{m-1}$, let

$$\hat F^{(k)} = [A_{m-1,1}^{(\hat M+k)}, A_{m-1,2}^{(\hat M+k)}, \dots, A_{m-1,m}^{(\hat M+k)}] = [\hat f_1^{(k)}, \hat f_2^{(k)}, \dots, \hat f_n^{(k)}].$$

We can apply Proposition 3.2(ii) to $E_{\tilde n+\jmath}^T \hat A E_{\tilde n+\jmath}$, with $r = \tilde n - n_{m-1}$, to obtain

$$\begin{aligned} \|\hat f_{\tilde n+\jmath}^{(\tilde n-n_{m-1})}\| &\ge \left[\frac{2^{-(\tilde n-n_{m-1})}}{n_{m-1}}\right]^{1/2} \|\hat f_{\tilde n+\jmath}\| - \left[\frac{\tilde n-n_{m-1}}{2}\right]^{1/2} \left[\sum_{i=1}^{\tilde n-n_{m-1}} \|\hat f_i\|^2\right]^{1/2} \\ &\ge \frac{2^{-\frac{n-3}{2}}}{\sqrt{n_{m-1}}} \|\tilde f_{\tilde n+\jmath}\| - \left[\frac{\tilde n-n_{m-1}}{2}\right]^{1/2} \left[\varepsilon_2 + \frac{2^{-4(n_m+1-\jmath)n}}{1-2^{-4n}}\right]^{1/2} \Sigma .\end{aligned}$$

Here we have used (3.19), (3.18), and $\tilde n - n_{m-1} = n - n_m - n_{m-1} \le n-2-1$. If we require

$$\varepsilon_2 + \frac{2^{-4(n_m+1-\jmath)n}}{1-2^{-4n}} \le 2 \cdot 2^{-4(n_m+1-\jmath)n}, \tag{3.20}$$

we obtain

$$\|\hat f_{\tilde n+\jmath}^{(\tilde n-n_{m-1})}\| \ge \frac{2^{-\frac{n-3}{2}}}{\sqrt{n_{m-1}}} \|\tilde f_{\tilde n+\jmath}\| - \sqrt{\tilde n - n_{m-1}}\, 2^{-2(n_m+1-\jmath)n}\, \Sigma .$$

Now, we consider the two possible cases $\jmath < n_m$ and $\jmath = n_m$.

If $\jmath < n_m$, then (3.17) implies

$$\|\hat f_{\tilde n+\jmath}^{(\tilde n-n_{m-1})}\| \ge \frac{2^{-2(n_m+1-\jmath)n}}{\sqrt{n_{m-1}}} \left[2^{-\frac{n-3}{2}} 2^{2n} - \frac{\tilde n}{2}\right]\Sigma \ge \frac{2^{-2(n_m+1-\jmath)n}}{\sqrt{n_{m-1}}} \left[2^{\frac{3}{2}n+\frac{3}{2}} - \frac{n-2}{2}\right]\Sigma .$$

Here we have used the fact that $n_{m-1}(\tilde{n}-n_{m-1}) \leq \tilde{n}^2/4$ and $\tilde{n} \leq n-2$.

If $\jmath = n_m$, then (3.17) implies

$$\begin{aligned} \|\hat{f}_{\tilde{n}+\jmath}^{(\tilde{n}-n_{m-1})}\| &\geq \frac{2^{-\frac{n-3}{2}}(1-2^{-n+1})}{\sqrt{n_{m-1}}}\Sigma - \sqrt{\tilde{n}-n_{m-1}}\,2^{-2n}\Sigma \\ &\geq \frac{2^{-2n}}{\sqrt{n_{m-1}}}\left[\frac{7}{8}2^{\frac{3}{2}n+\frac{3}{2}} - \frac{n-2}{2}\right]\Sigma\,. \end{aligned}$$

Here we have used the inequality $2^{-n+1} \leq 1/8$ since $n \geq 4$.

Taking into account (3.20), we can conclude that, if

$$\varepsilon_2 \leq \frac{1-2^{-4n+1}}{1-2^{-4n}}2^{-4n_m n}, \tag{3.21}$$

then

$$\|\hat{f}_{\tilde{n}+\jmath}^{(\tilde{n}-n_{m-1})}\| \geq \alpha_{n,n_m,n_{m-1}}\Sigma\,, \quad \alpha_{n,n_m,n_{m-1}} = \frac{2^{-2n_m n}}{\sqrt{n_{m-1}}}\left[\frac{7\sqrt{2}}{4}2^{\frac{3}{2}n} - \frac{n-2}{2}\right]$$

holds for all possible choices of $\jmath$.

As we have noted, the later transformations, defined by $\mathsf{c}_{m,\jmath+1},\ldots,\mathsf{c}_{m,n_m}$, do not affect the $\jmath$th column of $A_{m-1,m}^{(\hat{M}+\tilde{n}-n_{m-1})}$, so $\tilde{f}_{\tilde{n}+\jmath}^{((\tilde{n}-n_{m-1})n_m)} = \hat{f}_{\tilde{n}+\jmath}^{(\tilde{n}-n_{m-1})}$. The subsequent $n_m(n_m-1)/2$ rotations which annihilate the off-diagonal elements of $A_{mm}^{(k)}$ do not change the Frobenius norm of $\tilde{A}^{((\tilde{n}-n_{m-1})n_m)}$. Therefore, if (3.21) holds, then

$$\|A_{m-1,m}^{(\bar{M})}\|_F \geq \alpha_{n,n_m,n_{m-1}}\Sigma\,, \tag{3.22}$$

where

$$\bar{M} = M - n_{m-1}n_m - \frac{n_m(n_m-1)}{2}\,.$$

We complete the considerations in Stage I by making some preparations for Stage II.

Let $r$ be the smallest positive integer such that

$$\alpha_{n,n_m,n_{m-1}}^2 \geq \frac{2^{-rn}}{1-2^{-2n}}\,.$$

Obviously, $r$ depends on $n_{m-1}$ and $n_m$. Since $n_m \leq n-2$, we have

$$\alpha_{n,n_m,n_{m-1}} \geq \frac{2^{-2(n-2)n}}{\sqrt{n-2}}\left[\frac{7\sqrt{2}}{4}\cdot 2^{\frac{3}{2}n} - \frac{n-2}{2}\right].$$

Running the following simple program (m-file) in MATLAB, one finds out that all `y-z` are positive. Since for larger $n$, $(n-2)/2$ is negligible compared to $2^{(3/2)n}$, we have shown that $r \leq 4n-10$.

```
format long e;
  for n=4:100
  x=2^(n);
  y=((7/4)*sqrt(2/(n-2))*x*sqrt(x)-sqrt(n-2)/2);
  z=x^(1.46)/sqrt(1-x^(-2));
  display([n,y,z,y-z])
end
```

Now, we can conclude that there is some $\jmath$, not necessarily the same as earlier, such that

$$\|\bar{f}_{\tilde{n}+\jmath}\|^2 \geq 2^{-(2(n_m-\jmath)+r)n}\,\Sigma^2\,. \tag{3.23}$$

Indeed, on the contrary we would have

$$\begin{aligned}\|A^{(\bar{M})}_{m-1,m}\|_F^2 &= \sum_{j=1}^{n_m}\|\bar{f}_{\tilde{n}+j}\|^2 < \sum_{j=1}^{n_m} 2^{-(2(n_m-\jmath)+r)n}\cdot\Sigma^2\\ &= 2^{-rn}\left[2^{-2(n_m-1)n}+2^{-2(n_m-2)n}+\cdots+1\right]\Sigma^2\\ &= 2^{-rn}\frac{1-2^{-2n_m n}}{1-2^{-2n}}\Sigma^2 < \frac{2^{-rn}}{1-2^{-2n}}\Sigma^2 \leq \alpha^2_{n,n_m,n_{m-1}}\Sigma^2\,,\end{aligned}$$

which contradicts (3.22). Let $\jmath$ be the smallest index satisfying (3.23).

For $1 \leq k \leq M-\bar{M}$, let $\bar{A}^{(k)} = (A_{ij}^{(\bar{M}+k)})$. Then $\bar{A} = \bar{A}^{(0)}$ is the matrix appearing at the beginning of Stage II.

[illegible] II Note that the rotations applied to $A^{(k)}$ for $\tilde{M} \leq k \leq \bar{M}$ have not changed any element of $A^{(k)}_{m-1,m-1}$, so $S^2(\bar{A}_{m-1,m-1}) = \varepsilon_3\Sigma^2$. Let $G^{(k)} = (g^{(k)}_{pq})$ with $1 \leq p, q \leq n_{m-1}+n_m$, be defined by

$$G^{(k)} = \begin{bmatrix} G^{(k)}_{11} & G^{(k)}_{12}\\ G^{(k)}_{21} & G^{(k)}_{22}\end{bmatrix} = \begin{bmatrix} \bar{A}^{(k)}_{m-1,m-1} & \bar{A}^{(k)}_{m-1,m}\\ \bar{A}^{(k)}_{m,m-1} & \bar{A}^{(k)}_{mm}\end{bmatrix}, \quad 0 \leq k \leq M-\bar{M},$$

and let $G = G^{(0)}$. We shall now estimate the contribution to the off-norm reduction coming from the last $M-\bar{M}$ Jacobi steps. We can restrict our attention to the matrices $G^{(k)}$, since the sum of squares of other off-diagonal elements of $\bar{A}^{(k)}$ remains invariant during these transformations.

The method applies Jacobi rotations in a columnwise fashion, following the ordering defined by $\mathsf{c}'_{j1}, \mathsf{c}'_{j2}, \mathsf{c}''_{j2}, \ldots, \mathsf{c}'_{jn_j}, \mathsf{c}''_{jn_j}$. Let

$$\nu_j = \nu_{j-1} + n_{m-1} + j - 1, \quad 1 \leq j \leq n_m, \quad \nu_0 = 0,$$

and let $G^{(k)}_j$ be the leading $j \times j$ submatrix of $G^{(k)}$. Let $g^{(k)}_2, g^{(k)}_3, \ldots, g^{(k)}_{n_{m-1}+n_m}$ be the columns of the strict uppertriangle of $G^{(k)}$, i.e. $g^{(k)}_j = [g^{(k)}_{1j}, g^{(k)}_{2j}, \ldots, g^{(k)}_{j-1,j}]^T$ and let $g_j = g^{(0)}_j$. Because of (3.23), it is obvious that

$$\|g_{n_{m-1}+\jmath}\|^2 \geq \|\bar{f}_{\tilde{n}+\jmath}\|^2 \geq 2^{-(2(n_m-\jmath)+r)n}\Sigma^2$$

holds. Note that $\jmath$ is the smallest integer satisfying the second inequality. Let us redefine $\jmath$ to be the smallest of the numbers in the set $\{1, 2, \ldots, n_m\}$, satisfying

$$\|g_{n_{m-1}+\jmath}\|^2 \geq 2^{-(2(n_m-\jmath)+r)n}\Sigma^2\,.$$

Since the Jacobi rotations cannot increase the off-norm, this assumption yields

$$S^2(G^{(\nu_{\jmath-1})}_{n_{m-1}+\jmath-1}) \leq S^2(G^{(0)}_{11}) + \sum_{j=1}^{\jmath-1}\|g_{n_{m-1}+j}\|^2 \leq \varepsilon_3\Sigma^2 + \frac{2^{-(2(n_m-\jmath+1)+r)n}}{1-2^{-2n}}\Sigma^2\,.$$

Here, the empty sum is considered zero.

Now, consider the contribution to the off-norm reduction coming from the annihilations in the vector $g_{n_{m-1}+\jmath}^{(\nu_\jmath-1)}$. Applying Proposition 3.2(i) to $G_{n_{m-1}+\jmath}^{(\nu_\jmath-1)}$, we obtain

$$\left[\sum_{i=1}^{n_{m-1}+\jmath-1} |g_{i,n_{m-1}+\jmath}^{(\nu_{\jmath-1}+i-1)}|^2\right]^{1/2} \geq \left\{\left[\frac{2^{-(n_{m-1}+\jmath-2)}}{n_{m-1}+\jmath-1} 2^{-(2(n_m-\jmath)+r)n}\right]^{1/2}\right.$$
$$\left. - \left[\frac{n_{m-1}+\jmath-2}{4}\left(\varepsilon_3 + \frac{2^{-(2(n_m-\jmath+1)+r)n}}{1-2^{-2n}}\right)\right]^{1/2}\right\}\Sigma \geq \frac{2^{-(n_m-\jmath+1+\frac{r}{2})n}}{\sqrt{n_{m-1}+n_m-1}}$$
$$\times\left\{2^{n+1-\frac{n_{m-1}+n_m}{2}} - \frac{n_{m-1}+n_m\text{-}1}{2}\left[2^{(2(n_m-\jmath+1)+r)n}\varepsilon_3 + \frac{1}{1-2^{-2n}}\right]^{1/2}\right\}\Sigma\,.$$

To simplify the expression under the square root, we can require

$$\varepsilon_3 \leq \frac{1-2^{-2n+1}}{1-2^{-2n}} 2^{-(2n_m+r)n}\,. \tag{3.24}$$

Then the expression under the square root is not larger than 2 and we have

$$\left[\sum_{i=1}^{n_{m-1}+\jmath-1} |g_{i,n_{m-1}+\jmath}^{(\nu_\jmath+i-1)}|^2\right]^{1/2} \geq \frac{2^{-(n_m-\jmath+1+\frac{r}{2})n}}{\sqrt{n_{m-1}+n_m}}\left[2^{\frac{n}{2}+1} - \frac{n_{m-1}+n_m}{\sqrt{2}}\right]\Sigma$$
$$\geq \frac{2^{-(n_m+\frac{r}{2})n}}{\sqrt{n_{m-1}+n_m}}\left[2^{\frac{n}{2}+1} - \frac{n_{m-1}+n_m}{\sqrt{2}}\right]\Sigma \equiv \sqrt{\theta_{n_{m-1},n_m}(n)}\,\Sigma > 0\,, \tag{3.25}$$

with $\theta_{n_{m-1},n_m}(n) > 0$. Looking back at the relations (3.5), (3.6), (3.15), (3.21), and (3.24), we can conclude that (3.25) holds, provided that

$$\varepsilon \leq 2^{-(2n_m+r+1)n}\,.$$

Thus, during the last $M - \bar{M}$ Jacobi steps, $S^2(\bar{A})$ has decreased by the amount not smaller than $\theta_{n_{m-1},n_m}(n)\Sigma^2$. Hence

$$S^2(A^{(M)}) \leq \begin{cases} [1-\theta_{n_{m-1},n_m}(n)]\,\Sigma^2 & \text{if } \varepsilon \in [0, 2^{(-2n_m+r+1)n}], \\ [1-\varepsilon(1-t_{\tilde{n}}^{(\tilde{\mathcal{M}})})]\,\Sigma^2 & \text{if } \varepsilon \in [2^{(-2n_m+r+1)n}\,,\, 1]. \end{cases}$$

Since $r < 4n - 10$, we can complete the proof by setting

$$t_n^{(\mathcal{M})} = \max\{[1 - 2^{-(4n+2n_m-9)n}(1 - t_{\tilde{n}}^{(\tilde{\mathcal{M}})})\,,\, 1 - \theta_{n_{m-1},n_m}(n)\}\,.$$

[illegible] 3.5. Theorem 2.1 holds even if in [6, Algorithm 1] one dynamically combines the cases $k = 0$ and $k = 1$, that is to say if some diagonal blocks are operated twice and some are operated once. Indeed, the proof can use the same induction per block-columns. If $A_{rr}$ is operated once, then the appropriate equivalent pivot strategy within this block-column is simply the columnwise one and the proof of the induction step is similar to case (a).

# PATH PRODUCT MATRICES AND EVENTUALLY INVERSE $M$-MATRICES*

CHARLES R. JOHNSON† AND RONALD L. SMITH‡

**Abstract.** Those nonnegative matrices, some Hadamard power of which are inverse $M$-matrices, are characterized. This requires a refinement of the strict path product necessary condition [C. R. Johnson and R. L. Smith, *Linear Multilinear Algebra*, 46 (1999), pp. 177–191] for an inverse $M$-matrix. The smallest such Hadamard power may be arbitrarily large. It is also shown that, beyond some threshold, *all* continuous Hadamard powers of an inverse $M$-matrix are inverse $M$. In the process, several new results about inverse $M$-matrices are given.

**Key words.** $M$-matrices, inverse $M$-matrices, path product matrices

**AMS subject classifications.** 15A48, 15A45

## 1. Path product matrices and eventually inverse $M$-matrices.

An *inverse* $M$ ($IM$) matrix is an invertible $n$-by-$n$ nonnegative matrix whose inverse has nonpositive off-diagonal entries [2, 8, 9]. The $M$-matrices (those square matrices with positive principal minors and nonpositive off-diagonal entries) comprise the inverse class of $IM$ matrices and have a wide variety of applications. For example, $M$-matrices arise in various aspects of numerical linear algebra, in cost model matrices in economics, and in the numerical solution of certain types of differential equations. In addition to their obvious application to inverse problems involving $M$-matrices, $IM$ matrices themselves arise in a number of applications such as numerical integration [15], the Ising model of ferromagnetism [15], taxonomy [1], and random energy models in statistical physics [6]. Many applications of $IM$ matrices involve the subclass of strictly ultrametric matrices. Consequently, there has been a great deal of work on this particular type of $IM$ matrix (see, for example, [4, 5, 7, 13]). However, other special types of $IM$ matrices have also been considered (see [12, 14]).

An $n$-by-$n$ entry wise nonnegative matrix $A = (a_{ij})$ is called a *strict path product* ($SPP$) *matrix* if, for any triple of indices $i, j, k \in N = \{1, 2, \ldots, n\}$,

$$\frac{a_{ij}a_{jk}}{a_{jj}} \leq a_{ik} \tag{1}$$

with strict inequality whenever $i \neq j$ and $k = i$ [10]. We say that a nonnegative matrix is *normalized* if it has ones on the diagonal and off-diagonal entries less than 1. In the event that $A$ is a normalized $SPP$ matrix, the basic path product inequalities become

$$a_{ij}a_{jk} \leq a_{ik} \tag{2}$$

(with strict inequality whenever $i \neq j$ and $k = i$).

In [10], it was noted that any $IM$ matrix is $SPP$ and that for $n \leq 3$ (but not greater) the two classes are the same. See also [15]. Our interest here lay in further relating these two classes via consideration of Hadamard powers: by the $p$th Hadamard power $A^{(p)}$ of $A$ we mean the matrix $(a_{ij}^p)$ for a real number $p$. We were motivated, in part, by the main result of a recent paper [3] in which it was shown that if $A$ is $IM$, then $A^{(k)}$ is $IM$ for any positive integer $k \geq 1$. If $A$ is $SPP$ and $p > 0$, it is clear that $A^{(p)}$ remains $SPP$. (In fact, a Hadamard product of any two $SPP$ matrices is again $SPP$, and this remains so for the variants of $SPP$ to be mentioned in the following.) This raises the question as to whether $A^{(p)}$ eventually becomes $IM$ as $p$ increases without bound. If there is a $P > 0$ such that $A^{(p)}$ is $IM$ for all $p > P$, we call $A$ an . Our question, then, is: which nonnegative matrices are $EIM$? It is clear that it is necessary that an $EIM$ matrix be $SPP$, but it is not sufficient.

1. Consider the normalized $SPP$ matrix

$$\mathbf{A} = \begin{bmatrix} 1 & 0.5 & 0.7 & 0.4 \\ 0.5 & 1 & 0.5 & 0.25 \\ 0.7 & 0.5 & 1 & 0.5 \\ 0.4 & 0.25 & 0.5 & 1 \end{bmatrix}.$$

Since the $2,4$ cofactor of $A^{(p)}$ is $c_{24}^{(p)} = [(0.5)^p - (0.35)^p][(0.4)^p - (0.35)^p]$, which is positive for all $p > 0$, we see that $A$ is not $EIM$.

We also address the question of whether there is some converse to the statement that $IM$ implies (some kind of) $SPP$.

In order to answer these questions, we refine further the path product conditions for $IM$ matrices and identify the appropriate additional necessary conditions. These involve the arrangement of occurrences of equality in the path product inequalities (1). We say that $(i, j, k)$ is a (for the $SPP$ matrix $A$) if equality occurs in (1). For instance, $(2, 3, 4)$ is a path product equality triple in Example 1. Note that the path product equality triples of $A$ and a normalized version of $A$ are the same. When $n \geq 4$, we will see that path product equalities in an $IM$ matrix (which can occur) necessarily imply others. In view of previous work [11], this is not surprising, as a path product equality implies that a 2-by-2 almost principal minor is 0, so that a certain 3-by-3 principal submatrix has a 0 in its inverse. By [11] this implies further 0's in the inverse of the full matrix (though it is not necessary that all inverse 0's stem from path product equalities).

2. Consider the $IM$ matrix

$$\mathbf{A} = \begin{bmatrix} 1 & 0.4 & 0.4 & 0.3 \\ 0.4 & 1 & 0.5 & 0.5 \\ 0.4 & 0.4 & 1 & 0.6 \\ 0.4 & 0.4 & 0.4 & 1 \end{bmatrix}.$$

Matrix $A$ contains no path product equalities. However, $A^{-1}$ has a 0 in the $1,4$ position.

It was noted in [10, Corollary 2.6] that if $A$ is an $n$-by-$n$ $SPP$ matrix, then there exist positive diagonal matrices $D$ and $E$ such that $B = DAE$, in which $B$ is a normalized $SPP$ matrix. Thus, $B^{(p)} = D^p A^{(p)} E^p$ for $p \geq 0$ and, since it is apparent that $SPP$ matrices are closed under positive diagonal equivalence, $A^{(p)}$ is $SPP$ if and only if $B^{(p)}$ is. Therefore, it suffices to consider normalized $SPP$ matrices when studying (positive) Hadamard powers of $SPP$ matrices. In that $IM$ matrices are closed under positive diagonal equivalence, the same can be said for $IM$ matrices.

First, we identify the case in which no path product equalities occur, i.e., all inequalities (1) are strict, and call such $SPP$ matrices *totally strict path product* (*totally* $SPP$). Observe that totally $SPP$ matrices are necessarily positive. Totally $SPP$ is not necessary for $EIM$ (just consider the $IM$ matrix $B = A[\{2,3,4\}]$ of Example 1), but we will see (Theorem 3) that totally $SPP$ is sufficient for $EIM$.

Consider the following condition (3) on the collection of path product inequalities: for all distinct indices $i, j, k \in N$ and for all $m \in N - \{i, j, k\}$,

$$a_{ik} = \frac{a_{ij}a_{jk}}{a_{jj}} \quad \text{implies that either} \quad a_{im} = \frac{a_{ij}a_{jm}}{a_{jj}} \quad \text{or} \quad a_{mk} = \frac{a_{mj}a_{jk}}{a_{jj}}. \tag{3}$$

If (3) is satisfied by an $SPP$ matrix, we say that $A$ is *purely strict path product* (*purely* $SPP$). We will see (Lemma 1) that, in purely $SPP$ matrices, path product equalities force certain cofactors to vanish. Notice that condition (3) does not hold for Example 1 since $a_{24} = 0.25 = (0.5)(0.5) = a_{23}a_{34}$ while $a_{14} = 0.4 > (0.7)(0.5) = a_{13}a_{34}$ and $a_{21} = 0.5 > (0.5)(0.7) = a_{23}a_{31}$. We show that any $IM$ matrix is purely $SPP$ (Theorem 1) and that $EIM$ is equivalent to purely $SPP$ (Theorem 4).We note that purely $SPP$ and $SPP$ coincide (vacuously) when $n \leq 3$ and that generally the totally $SPP$ matrices are contained in the purely $SPP$ matrices (vacuously). Lastly, but importantly, observe that, if $A$ is totally (purely) $SPP$, then so is any normalization of $A$. Thus, in trying to show that a totally (purely) $SPP$ matrix is $IM$, by positive diagonal equivalence, we may, and do, assume that $A$ is normalized.

Below is our first key result. We follow traditional submatrix notation: for $\phi \neq \alpha, \beta \subseteq N$, $A[\alpha, \beta]$ $(A(\alpha, \beta))$ denotes the submatrix of $A$ with rows indexed by $\alpha$ $(\alpha^c)$ and columns by $\beta$ $(\beta^c)$. For brevity, we denote $A[\alpha, \alpha]$ $(A(\alpha, \alpha))$ by $A[\alpha]$ $(A(\alpha))$.

THEOREM 1. *Every* $IM$ *matrix is purely* $SPP$

*Proof*. Without loss of generality, let $A = (a_{ij})$ be a normalized $IM$ matrix. If $n \leq 3$, then $A$ is purely $SPP$ vacuously. So we may assume that $n \geq 4$. Assume that $a_{ik} = a_{ij}a_{jk}$ for the distinct indices $i, j, k$ of $N$ and let $m \in N - \{i, j, k\}$. Consider the principal submatrix

$$A[\{m, j, k, i\}] = \begin{bmatrix} 1 & a_{mj} & a_{mk} & a_{mi} \\ a_{jm} & 1 & a_{jk} & a_{ji} \\ a_{km} & a_{kj} & 1 & a_{ki} \\ a_{im} & a_{ij} & a_{ik} & 1 \end{bmatrix}$$

of $A$. This submatrix is $IM$ by inheritance. So (via, for instance, the special case of Sylvester's identity for determinants given in [11]) the $k$, $i$ cofactor $c_{ki} = (a_{mk} - a_{mj}a_{jk})(a_{im} - a_{ij}a_{jm}) \leq 0$. Hence, by condition (2), either $a_{mk} = a_{mj}a_{jk}$ or $a_{im} = a_{ij}a_{jm}$. Thus, $A$ is purely $SPP$. ☐

A graph may be constructed on the path product equality triples with an edge corresponding to coincidence of the first two or last two indices. This can be informative about the structure of path product equalities, but all we need here is the following lemma. The important idea is that the occurrence of path product *equalities* ensure that certain submatrices have rank 1 and, moreover, these rank 1 submatrices are large enough to guarantee that certain almost principal minors vanish. We make use of the well-known fact that an $n$-by-$n$ matrix is singular if it contains an $s$-by-$t$ submatrix of rank $r$ such that $s + t \geq n + r + 1$.

LEMMA 1. [illegible] $(i,j,k)$ [illegible] $n$ [illegible] $n$ [illegible] $SPP$ [illegible] $A$ [illegible] $n \geq 4$ [illegible] $\det A(\{k\},\{i\}) = 0$. [illegible] $(k,i)$ [illegible] $A$ [illegible] $p$ $\det A^{(p)}(\{k\},\{i\}) = 0$

[illegible]. Without loss of generality, assume that $A$ is an $n$-by-$n$ normalized purely $SPP$ matrix, $n \geq 4$, and that $(i,j,k)$ is a path product equality for $A$. By permutation similarity, we may assume that $(i,j,k) = (1,2,3)$ so that $a_{13} = a_{12}a_{23}$. Then, since $A$ is purely $SPP$, for each $c \in N - \{1,2,3\}$, either $a_{1c} = a_{12}a_{2c}$ or $a_{c3} = a_{c2}a_{23}$. Without loss of generality, assume that $\{\, c \mid c \in N - \{1,2,3\} \;\text{ and }\; a_{1c} = a_{12}a_{2c}\} \neq \phi$. By permutation similarity, we may assume, again without loss of generality, that, for some $q \in N - \{1,2,3\}$,

(i) $a_{1c} = a_{12}a_{2c}, c = 3, \ldots, q$;

(ii) $a_{1c} \neq a_{12}a_{2c}, c = q+1, \ldots, n$.

Note that, for $c \in \{3, \ldots, q\}$ and $r \in \{q+1, \ldots, n\} \subseteq N - \{1,2,c\}$, (i) implies (by condition (3)) that either $a_{1r} = a_{12}a_{2r}$ or $a_{rc} = a_{r2}a_{2c}$. Hence, by (ii), we have

iii) $a_{rc} = a_{r2}a_{2c}, r = q+1, \ldots, n, c = 3, \ldots, q$.

If $q = n$ and $B = A[\{1,2\},\{2,\ldots,q\}]$, then (i) implies that $[a_{12}\, a_{13}\, \ldots\, a_{1q}]$, the first row of $B$, is $a_{12}$ times $[1\, a_{23}\, a_{24}\, \ldots\, a_{2q}]$, the second row of $B$. Thus, $B$ is a 2-by-$(n-1)$ rank 1 submatrix of $A(\{3\},\{1\})$. Since $2+(n-1) = n+1 \geq n+1 = (n-1)+1+1$, $A(\{3\},\{1\})$ is singular.

On the other hand, if $3 \leq q < n$, let $C = A[\{1,2,q+1,\ldots,n\},\{2,\ldots,q\}]$. Then, (i) implies that $[a_{12}\, a_{13}\, \ldots\, a_{1q}]$, the first row of $C$, is $a_{12}$ times $[1\, a_{23}\, a_{24}\, \ldots\, a_{2q}]$, the second row of $C$. Now consider $[a_{r2}\, a_{r3}\, \ldots\, a_{rq}]$, the $r$th row of $C$, $r = q+1, \ldots, n$. It follows from (iii) that the $r$th row of $C$ is $a_{r2}$ times the second row of $C$, $r = q+1, \ldots, n$. Hence, $C$ is an $(n-q+2)$-by-$(q-1)$ rank 1 submatrix of $A(\{3\},\{1\})$. Since $(n-q+2)+(q-1) = n+1 \geq n+1 = (n-1)+1+1$, $A(\{3\},\{1\})$ is singular in this case also. Thus, $\det A(\{3\},\{1\}) = 0$ in either case, completing the proof of the first part.

The second part follows by the same argument, since condition (3) holds for $A$ if and only if it holds for $A^{(p)}$ for any real number $p$. $\square$

Now using Theorem 1, we have the following.

COROLLARY 1. [illegible] $(i,j,k)$ [illegible] $n$ [illegible] $n$ $IM$ [illegible] $A$ $n \geq 4$ [illegible] $(A^{-1})_{ki} = 0$

THEOREM 2. [illegible] $A$ [illegible] $n$ [illegible] $n$ $SPP$ [illegible] $P > 0$ [illegible] $\det A^{(p)} > 0$ [illegible] $p > P$

[illegible]. Without loss of generality, let $A$ be an $n$-by-$n$ normalized $SPP$ matrix and let $\max_{i \neq j} a_{ij} = M < 1$. Denote the set of permutations of $N$ by $S_n$ and the identity permutation by [illegible]. Then,

$$\begin{aligned}
det\, A^{(p)} &= \sum_{\tau \in S_n} sgn(\tau) a^p_{1,\tau(1)} a^p_{2,\tau(2)} \cdots a^p_{n,\tau(n)} \\
&= 1 + \sum_{\substack{\tau \in S_n \\ \tau \neq id}} sgn(\tau) a^p_{1,\tau(1)} a^p_{2,\tau(2)} \cdots a^p_{n,\tau(n)} \\
&> 1 - \sum_{\substack{\tau \in S_n \\ \tau \neq id}} a^p_{1,\tau(1)} a^p_{2,\tau(2)} \cdots a^p_{n,\tau(n)} \\
&> 1 - (n! - 1)M^p.
\end{aligned}$$

It is clear that there exists $P > 0$ such that for all $p > P$, $1 - (n!-1)M^p > 0$, completing the proof. $\square$

THEOREM 3. [illegible] $A$ [illegible] $n$ [illegible] $n$ [illegible] $SPP$ [illegible] $P > 0$ [illegible] $A^{(p)} \in IM$ [illegible] $p > P$

[illegible]. Without loss of generality, let $A$ be an $n$-by-$n$ normalized, totally $SPP$ matrix. As in the proof of Theorem 2, let $\max_{i \neq j} a_{ij} = M < 1$, let $S_n$ denote the set of permutations of $N$, and let [illegible] denote the identity permutation. Then, it follows from Theorem 2 that there exists $P_1 > 0$ such that, for all $p > P_1$, $\det A^{(p)} > 0$.

Now let $i, j \in N$ with $i \neq j$, and let $N_1 = N - \{i, j\}$. Consider $c_{ij}^{(p)}$, the $i, j$ cofactor of $A^{(p)}$. Without loss of generality, assume that $i < j$. Then, if $B = \begin{bmatrix} A^{(p)}[N_1] & A^{(p)}[N_1, i] \\ A^{(p)}[j, N_1] & a_{ji}^p \end{bmatrix}$,

$$\begin{aligned} c_{ij}^{(p)} &= (-1)^{i+j} \det A^{(p)}(\{i, j\}) \\ &= (-1)^{i+j}(-1)^{n-i-1}(-1)^{n-j} \det B \\ &= (-1) \det B \\ &= -\sum_{\tau \in S_{n-1}} sgn(\tau) b_{1,\tau(1)} b_{2,\tau(2)} \dots b_{n-1,\tau(n-1)} \\ &= -a_{ji}^p - \sum_{\substack{\tau \in S_{n-1} \\ \tau \neq id}} sgn(\tau) b_{1,\tau(1)} b_{2,\tau(2)} \dots b_{n-1,\tau(n-1)} \\ &\leq -a_{ji}^p + \sum_{\substack{\tau \in S_{n-1} \\ \tau \neq id}} b_{1,\tau(1)} b_{2,\tau(2)} \dots b_{n-1,\tau(n-1)}. \end{aligned}$$

Now let

$$\begin{aligned} \Lambda_1 &= \{ \tau \in S_{n-1} \mid \tau \neq id \text{ and } \tau(n-1) = n-1 \} \\ &= \{ \tau \in S_{n-1} \mid \tau \neq id \text{ and } b_{n-1,\tau(n-1)} = a_{ji}^p \} \end{aligned}$$

and

$$\begin{aligned} \Lambda_2 &= \{ \tau \in S_{n-1} \mid \tau(n-1) \neq n-1 \} \\ &= \{ \tau \in S_{n-1} \mid b_{n-1,\tau(n-1)} \neq a_{ji}^p \}, \end{aligned}$$

so that $\{id\}$, $\Lambda_1$, and $\Lambda_2$ form a partition of $S_{n-1}$. Thus,

$$\begin{aligned} \sum_{\substack{\tau \in S_{n-1} \\ \tau \neq id}} b_{1,\tau(1)} b_{2,\tau(2)} \dots b_{n-1,\tau(n-1)} &= \sum_{\tau \in \Lambda_1} b_{1,\tau(1)} b_{2,\tau(2)} \dots b_{n-1,\tau(n-1)} \\ &\quad + \sum_{\tau \in \Lambda_2} b_{1,\tau(1)} b_{2,\tau(2)} \dots b_{n-1,\tau(n-1)}. \end{aligned} \tag{4}$$

Each term of the first summation on the right-hand side of (4) is the product of $b_{n-1,\tau(n-1)} = a_{ji}^p$ and a "nonidentity" term of the expansion of $\det A[N_1]$ (since $\tau \neq id$). Hence, each term in this summation has a factor of the form

$$a_{ji}^p a_{si_1}^p a_{i_1 i_2}^p \dots a_{i_{k-1} i_k}^p a_{i_k s}^p \tag{5}$$

in which $s, i_1, \dots, i_k$ are distinct indices in $N_1$ and $k \geq 1$. Therefore, the cycle product (5) has at least three terms. Since the factors of this term distinct from $a_{ji}^p$ are $< 1$, each term in the first summation is $< a_{ji}^p M^{2p}$, and there are $|S_{n-2}| - 1 = (n-2)! - 1$ such terms.

On the other hand, each term of the second summation on the right-hand side of (4) has a factor of the form

$$a^p_{ji_1} a^p_{i_1 i_2} a^p_{i_2 i_3} \cdots a^p_{i_{k-1} i_k} a^p_{i_k i} \tag{6}$$

in which $i_1, \ldots, i_k$ are distinct indices in $N_1$ with $k \geq 1$. Hence, the path product (6) has at least two terms. Let $m_{ji}$ denote the maximum $(j,i)$ path product given by (6). Therefore, each term in the second summation is $\leq m_{ji}$, and there are $(n-1)! - (n-2)! = (n-2)((n-2)!)$ such terms. Notice that, since $A$ is totally $SPP$, $m_{ji} < a_{ji}$. Thus,

$$\begin{aligned} c^{(p)}_{ij} &\leq -a^p_{ji} + ((n-2)! - 1)\, a^p_{ji} M^{2p} + (n-2)((n-2)!)\, m^p_{ji} \\ &= -a^p_{ji} \left(1 - ((n-2)! - 1)\, M^{2p} - (n-2)((n-2)!)\, (\tfrac{m_{ji}}{a_{ji}})^p\right). \end{aligned} \tag{7}$$

Since $M < 1$ and $m_{ji} < a_{ji}$, there exists $P_{ij} > 0$ such that, for all $p > P_{ij}$, $c^{(p)}_{ij} \leq 0$. Let $P_2 = \max_{i \neq j} P_{ij}$. Then, for all $p > \max(P_1, P_2) = P$, the inverse of $A^{(p)}$ has non-positive off-diagonal entries and, hence, $A^{(p)} \in IM$, completing the proof. $\square$

Our main result characterizes $EIM$ matrices and, in a certain sense, provides a converse to the statement that $IM$ implies (some kind of) $SPP$.

THEOREM 4. [illegible] $A$ [illegible] $n$ [illegible] $n$ [illegible] $A$ [illegible] $SPP$ [illegible] $A \in EIM$

[illegible]. We observe that, for either of the two properties in question, purely $SPP$ or $EIM$, we may assume that $A$ is an $n$-by-$n$ normalized $SPP$ matrix. Necessity of the condition purely $SPP$ then follows from Theorem 1 and the previously noted fact that the path product inequalities (and equalities) are preserved for any positive Hadamard power $p$.

For sufficiency, let $A$ be an $n$-by-$n$ normalized purely $SPP$ matrix. It follows from Theorem 2 that there exists $P_1 > 0$ such that $\det A^{(p)} > 0$ for all $p > P_1$. So we are left to show that, for some $P > 0$, the off-diagonal entries of $(A^{(p)})^{-1}$ are nonpositive for all $p > P$. To this end, let $i, j \in N$ with $i \neq j$, and $N_1 = N - \{i, j\}$. If $a_{ji} = a_{jk} a_{ki}$ for some $k \in N_1$, then it follows from Lemma 1 that $c^{(p)}_{ij}$, the $i,j$ cofactor of $A^{(p)}$, vanishes for all positive $p$. Let $P_{ij} = 1$ in this case. On the other hand, suppose that

$$a_{ji} > a_{jk} a_{ki} \tag{8}$$

for all $k \in N_1$. Following the proof of Theorem 3, let $\max_{i \neq j} a_{ij} = M < 1$ and let $m_{ji}$ denote the maximum $(j,i)$ path product given by (6). That $m_{ji} < a_{ji}$ follows from (8). Hence, (7) implies that there is a positive constant $P_{ij}$ such that, for all $p > P_{ij}$, $c^{(p)}_{ij}$, the $i,j$ cofactor of $A^{(p)}$, is $\leq 0$. Letting $P_2 = \max_{i \neq j} P_{ij}$ and $P = \max(P_1, P_2)$, we see that for all $p > P$, $A^{(p)}$ is invertible, and its inverse has nonpositive off-diagonal entries; that is, $A^{(p)}$ is $IM$. So $A$ is $EIM$, completing the proof. $\square$

[illegible] Suppose that we have a totally (purely) $SPP$ matrix that is not $IM$. Since the totally (purely) $SPP$ matrices are closed under any positive Hadamard power, extraction of a small enough Hadamard root will produce a totally (purely) $SPP$ matrix in which $P$ must be arbitrarily large, while raising the matrix to a large enough Hadamard power will produce a totally (purely) $SPP$ matrix in which $P$ may be taken to be an arbitrarily small positive number. In fact, $P$ can be 0.

Immediately from Theorem 1, we have the following result.

COROLLARY 2. [illegible] $A$ [illegible] $IM$ [illegible] $P > 0$ [illegible] $A^{(p)} \in IM$ [illegible] $p > P$

# A SUBSPACE-BASED METHOD FOR SOLVING LAGRANGE–SYLVESTER INTERPOLATION PROBLEMS*

HÜSEYIN AKÇAY† AND SEMIHA TÜRKAY†

**Abstract.** In this paper, we study the Lagrange–Sylvester interpolation of rational matrix functions which are analytic at infinity, and propose a new interpolation algorithm based on the recent subspace-based identification methods. The proposed algorithm is numerically efficient and delivers a minimal interpolant in state-space form. The solvability condition for the subspace-based algorithm is particularly simple and depends only on the total multiplicity of the interpolation nodes. As an application, we consider subspace-based system identification with interpolation constraints, which arises, for example, in the identification of continuous-time systems with a given relative degree.

**Key words.** rational interpolation, Lagrange–Sylvester, identification, subspace-based

## 1. Introduction.

Many problems in control, circuit theory, and signal processing can be reduced to the solution of matrix rational interpolation problems which have been widely studied (see, for example, [14, 15, 2, 19, 21, 3, 4, 1, 5, 6, 7, 31, 30, 11, 10] and the references therein). Applications arise, for example, in robust controller synthesis [19, 21], in the $Q$-parameterization of stabilizing controllers for unstable plants [18], in the problem of model validation [32], in circuit theory [34], in spectral estimation [12], and in adaptive filtering and control [31, 26].

In the simplest form, given complex numbers $z_k$ and $w_k$ for $k = 1, \ldots, N$, an interpolation problem asks for scalar rational functions $G(z)$ which meet the interpolation conditions

$$G(z_k) = w_k, \qquad k = 1, \ldots, N.$$

The interpolants can further be required to have minimal complexity in terms of their McMillan degree. Let **R** and **C** denote the fields of the real and complex numbers, respectively. An extension of this problem to the matrix case is as follows.

[illegible] a subset $\vartheta \subset \mathbf{C}$, points $z_1, \ldots, z_L$ in $\vartheta$, rational $1 \times p$ row vector functions $v_1(z), \ldots, v_L(z)$ with $v_k(z_k) \neq 0$ for all $k$, and rational $1 \times m$ row vectors $w_1(z), \ldots, w_L(z)$.

[illegible] (at least one or all) $p \times m$ rational matrix functions $G(z)$ with no poles in $\vartheta$ which satisfy the [illegible] interpolation conditions

$$\frac{d^j}{dz^j}\{v_k(z)G(z)\}\bigg|_{z=z_k} = \frac{d^j}{dz^j} w_k(z)\bigg|_{z=z_k} \tag{1.1}$$

for $0 \leq j \leq N_k$, $1 \leq k \leq L$.

This problem is known as the tangential [illegible] rational interpolation problem. One approach to finding a solution is to reduce the problem to a system of

independent scalar problems, which is not interesting from the viewpoint of matrix interpolation theory. In addition, a minimal realization can be obtained only after the elimination of unobservable or/and uncontrollable modes. The contour integral version of this problem is treated in the comprehensive work [6]. The [illegible] or [illegible] version is studied, for example, in [14, 15, 7, 4]. Related problems are the nonhomogenous interpolation problem with metric constraints, as in the various types of Nevanlinna–Pick interpolation and its generalizations [10, 20], and the partial realization problem, that is, finding a rational matrix function analytic at infinity of the smallest possible McMillan degree with prescribed values of itself and a few of its derivatives at infinity [17, 1, 6, 27, 28]. Further applications of interpolation theory to control and systems theory and estimation are presented in [6, 13, 29].

Prior work on the unconstrained tangential interpolation problem has been largely carried out by Ball, Gohberg, and Rodman [6, 7]. The solvability issues of the interpolation problem, i.e., the existence and the uniqueness of the solutions, have been analyzed in [8] by using a [illegible] framework. A more direct algebraic approach in [11] shows that solving a tangential interpolation problem is equivalent to solving a matrix Padé approximation problem with Taylor coefficients obeying a set of linear constraints. In [1, 2, 3, 4], the tangential interpolation problem above was studied using a tool called the Löwner matrix. In [4], the problem of finding admissible degrees of complexity of the solutions to the above interpolation problem, that is, finding all positive integers $n$ for which there exits an interpolant with McMillan degree $n$, and the problem of parameterizing all solutions for a given admissible degree of complexity were investigated. Clearly, the solutions of minimal complexity are of special interest.

The main result in [7] states that the family of rational matrix functions satisfying (1.1) can be parameterized in terms of a certain [illegible]. First, the interpolation data is translated into a so-called [illegible] that describes the zero structure of a $(p+m) \times (p+m)$ [illegible]. The computation of the resolvent matrix requires that the solution of a particular Sylvester equation be invertible. The details can be found in [6]. In [11], a recursive method for computing the resolvent matrix as a product of elementary first-order rational matrix functions is presented. This scheme allows recursive updating of the resolvent matrix whenever a new interpolation point is added to the input data. In the special case when the resolvent matrix is in [illegible] form, it is possible to extract the admissible degrees of complexity as well as the minimal degree of complexity from the linear fractional parameterization formula. The resolvent matrix obtained by an unconstrained algorithm can be transformed into column-reduced form via a sequence of elementary unimodular transformations [16]. A detailed algorithm for the construction of a column-reduced rational matrix function from a given [illegible] is given in [9]. This algorithm is not recursive, whereas in [11] a column-reduced transfer function is recursively obtained.

In this paper, we present a numerically efficient algorithm for solving the unconstrained tangential interpolation problem formulated above. This algorithm is inspired by the recent work on the frequency domain subspace-based identification [23, 24, 25, 33]. The solvability conditions for the proposed algorithm are simple, and depend only on the total multiplicities of the interpolation points. The resulting interpolating function is in the minimal state-space form. To this date, interpolation properties of the subspace-based methods have not been investigated in the generality of this paper. Only in [24] was an interpolation result obtained for uniformly spaced data on the unit circle of the complex plane. The problem of curve fitting is also closely related to the interpolation problem. The use of the frequency domain subspace-based methods for curve fitting is briefly described in [22].

Let us reformulate the tangential interpolation problem described above in terms of system properties. More precisely, let us consider a multi-input/multi-output, linear-time invariant, discrete-time system represented by the state-space equations

$$\begin{aligned} x(k+1) &= Ax(k) + Bu(k), \\ y(k) &= Cx(k) + Du(k), \end{aligned} \tag{1.2}$$

where $x(k) \in \mathbf{R}^n$ is the state and $u(k) \in \mathbf{R}^m$ and $y(k) \in \mathbf{R}^p$ are, respectively, the input and the output of the system. The transfer function of the system (1.2) denoted by $G(z)$ is computed as

$$G(z) = D + C(zI_n - A)^{-1}B, \tag{1.3}$$

where $I_n$ is the $n \times n$ identity matrix. We assume that that the system (1.2) is stable and the pairs $(A, B)$ and $(C, A)$ are [illegible] and [illegible], respectively. The stability of (1.2) means that $G(z)$ is a [illegible] matrix that is analytic and bounded in the region $\vartheta = \{z \in \mathbf{C} : |z| \geq 1\}$, and both the controllability and the observability of the pairs $(A, B)$ and $(C, A)$ mean that the quadruplet $(A, B, C, D)$ is a [illegible] of $G(z)$.

The interpolation problem studied in this paper can be stated as follows.

[illegible] noise-free samples of $G(z)$ and its derivatives at $L$ distinct points $z_k \in \vartheta$,

$$\left. \frac{d^j}{dz^j} G(z) \right|_{z=z_k} = w_{kj}, \qquad j = 0, 1, \ldots, N_k, \quad k = 1, 2, \ldots, L. \tag{1.4}$$

[illegible] a quadruplet $(\widehat{A}, \widehat{B}, \widehat{C}, \widehat{D})$ that is a minimal realization of $G(z)$.

Clearly, (1.4) is a special case of (1.1) with suitably selected left vectors $v_k(z)$ and nodes $z_k$. A subspace-based algorithm handling the tangential-type constraints (1.1) as well can be derived along the same lines of the proposed algorithm. The minimality and the uniqueness of the interpolant are the parts of the problem formulation. What is left unanswered is a condition on the number of the interpolation nodes, counting multiplicities. It is also clear that, if it exists, the subspace-based solution is a minimal interpolating function in the set of all possible solutions.

The proposed interpolation scheme is particularly useful when the samples of $G(z)$ and its derivatives are corrupted by noise and the amount of data is large with respect to $n$. In the noisy case, most interpolation schemes deliver state-space realizations with McMillan degrees tending to infinity as the amount of data grows unboundedly; thus such schemes are sensitive to inaccuracies in the interpolation data. Since our algorithm is subspace-based, it inherits robustness properties of the subspace-based identification algorithms. In particular, there is no need for explicit model parameterization, and this algorithm is computationally efficient since it uses numerically robust QR factorization and the singular value decomposition. In the paper, we also consider subspace-based system identification with interpolation constraints.

Note that a given interpolation problem on the right half complex plane can be converted to an interpolation problem on the unit disk by using the Möbius transformation:

$$s = \psi(z) \triangleq \lambda \frac{z-1}{z+1} \qquad (\lambda > 0). \tag{1.5}$$

We omit the details.

**2. Subspace-based interpolation algorithm.** We begin by taking the $z$-transform of (1.2),

$$\begin{aligned} zX(z) &= AX(z) + BU(z), \\ Y(z) &= CX(z) + DU(z), \end{aligned} \tag{2.1}$$

assuming $x(0) = 0$, where $X(z)$, $Y(z)$, and $U(z)$ denote respectively the $z$-transforms of $x(k)$, $y(k)$, and $u(k)$ defined by

$$U(z) \triangleq \sum_{k=0}^{\infty} u(k)\, z^{-k}. \tag{2.2}$$

Let $X_j(x)$ be the resulting state $z$-transform when

$$u(k) = \begin{cases} e_j, & k = 0, \\ 0, & \text{otherwise}, \end{cases}$$

where $e_j$ denotes the unit vector in $\mathbf{R}^m$ with 1 on the $j$th position and 0 elsewhere. By defining the compound state $z$-transform matrix,

$$X_{\mathrm{C}}(z) \triangleq \left[X_1(z) \;\; X_2(z) \;\; \cdots \;\; X_m(z)\right], \tag{2.3}$$

$G(z)$ can implicitly be described as

$$G(z) = CX_{\mathrm{C}}(z) + D \tag{2.4}$$

with

$$zX_{\mathrm{C}}(z) = AX_{\mathrm{C}}(z) + B. \tag{2.5}$$

By recursive use of (2.5), we obtain the relation

$$z^k X_{\mathrm{C}}(z) = A^k X_{\mathrm{C}}(z) + \sum_{j=0}^{k-1} A^{k-1-j} B z^j, \qquad k \geq 1. \tag{2.6}$$

Multiplying both sides of (2.6) with $C$ and using (2.4), we get

$$z^k G(z) = CA^k X_{\mathrm{C}}(z) + Dz^k + \sum_{j=0}^{k-1} CA^{k-1-j} B z^j, \qquad k \geq 1. \tag{2.7}$$

Now, recall that the impulse response coefficients of $G(z)$ are given by

$$g_k = \begin{cases} D, & k = 0, \\ CA^{k-1}B, & k \geq 1. \end{cases} \tag{2.8}$$

Thus, from (2.4), (2.7), and (2.8),

$$z^k G(z) = CA^k X_{\mathrm{C}}(z) + \sum_{j=0}^{k} g_{k-j}\, z^j, \qquad k \geq 0. \tag{2.9}$$

Hence from (2.9),

$$\begin{bmatrix} G(z) \\ zG(z) \\ \vdots \\ z^{q-1}G(z) \end{bmatrix} = \mathcal{O}_q X_{\mathrm{C}}(z) + \Gamma_q \begin{bmatrix} I_m \\ zI_m \\ \vdots \\ z^{q-1}I_m \end{bmatrix}, \tag{2.10}$$

where

$$\mathcal{O}_q \triangleq \begin{bmatrix} C \\ CA \\ \vdots \\ CA^{q-1} \end{bmatrix}, \tag{2.11}$$

$$\Gamma_q \triangleq \begin{bmatrix} g_0 & 0 & \cdots & 0 \\ g_1 & g_0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ g_{q-1} & g_{q-2} & \cdots & g_0 \end{bmatrix}. \tag{2.12}$$

For later use, let us write (2.10) in a compact form. The matrix $\mathcal{O}_q$ is known as the [illegible] and has full rank $n$ if $(A, C)$ is an observable pair and $q \geq n$. We define the [illegible] of two matrices $E \in \mathbf{C}^{m\times n}$ and $F \in \mathbf{C}^{p\times q}$ by

$$E \otimes F \triangleq \begin{bmatrix} E_{11}F & E_{12}F & \cdots & E_{1n}B \\ E_{21}F & E_{22}F & \cdots & E_{2n}F \\ \vdots & \vdots & \ddots & \vdots \\ E_{m1}F & E_{m2}F & \cdots & E_{mn}F \end{bmatrix} \in \mathbf{C}^{mp\times nq}. \tag{2.13}$$

Let

$$\mathcal{Z}_q(z) \triangleq \begin{bmatrix} 1 \\ z \\ \vdots \\ z^{q-1} \end{bmatrix}, \tag{2.14}$$

$$\mathcal{J}_{q,2} \triangleq \begin{bmatrix} 0 & & \cdots & & 0 \\ 1 & 0 & & & \\ 0 & 1 & 0 & & \\ \vdots & & & \ddots & \vdots \\ 0 & & \cdots & 1 & 0 \end{bmatrix} \in \mathrm{R}^{q\times q}. \tag{2.15}$$

By a slight abuse of notation, let $\mathcal{J}_{q,1}$ denote the $q \times q$ identity matrix $I_q$. Observe that $\mathcal{J}_{q,2}$ is obtained by shifting the elements of $\mathcal{J}_{q,1}$ one row down and filling its first row with zeros. Let $\mathcal{J}_{q,j}$ denote the matrix obtained by $j-1$ repeated applications of this process to $\mathcal{J}_{q,1}$ and $J_{q,2}^0 = I_q$. Note the following relations:

$$\mathcal{J}_{q,j} = \begin{cases} \mathcal{J}_{q,2}^{j-1}, & j \leq q \\ 0, & j > q. \end{cases} \tag{2.16}$$

Thus, the lower triangular block Toeplitz matrix in (2.12) can be written as

$$\Gamma_q = \sum_{j=0}^{q-1} \mathcal{J}_{q,1+j} \otimes g_j . \tag{2.17}$$

Hence, from (2.11)–(2.17) we arrive at the following compact expression for (2.10):

$$\mathcal{Z}_q(z) \otimes G(z) = \mathcal{O}_q X_{\mathrm{C}}(z) + \sum_{j=0}^{q-1} [\mathcal{J}_{q,2}^{j} \otimes g_j] \; [\mathcal{Z}_q(z) \otimes I_m] \, . \tag{2.18}$$

This equation forms the basis of the frequency domain subspace-based identification algorithms [24, 23]. In subspace-based identification algorithms, $\mathcal{Z}_q(z) \otimes G(z)$ and the right-hand side of (2.18) are evaluated at a set of distinct points on the unit circle and then stacked into columns of long matrices. This procedure yields a matrix equation [illegible] in $\mathcal{O}_q$. From this equation, the range space of $\mathcal{O}_q$ is recovered by a projection. Once the observability range space is recovered, a realization of $G(z)$ is derived in a routine manner. We will adapt the same strategy.

First, we differentiate both sides of (2.18) $l$ times with respect to $z$:

$$\begin{aligned} \frac{d^l}{dz^l} H_q(z) &= \sum_{j=0}^{l} \begin{pmatrix} l \\ j \end{pmatrix} \frac{d^j}{dz^j} \mathcal{Z}_q(z) \otimes \frac{d^{l-j}}{dz^{l-j}} G(z) \\ &= \mathcal{O}_q \, \frac{d^l}{dz^l} X_{\mathrm{C}}(z) + \sum_{j=0}^{q-1} [\mathcal{J}_{q,2}^{j} \otimes g_j] \left[ \frac{d^l}{dz^l} \mathcal{Z}_q(z) \otimes I_m \right], \qquad l \geq 0, \end{aligned} \tag{2.19}$$

where

$$H_q(z) \triangleq \mathcal{Z}_q(z) \otimes G(z). \tag{2.20}$$

Then, we augment $H_q(z_k)$ and the first $N_k$ derivatives of $H_q(z)$ at $z_k$ in a data matrix:

$$\mathcal{H}_k \triangleq \left[ H_q(z) \;\; \frac{d}{dz} H_q(z) \;\; \cdots \;\; \frac{d^{N_k}}{dz^{N_k}} H_q(z) \right]_{z=z_k} , \qquad k = 1, \ldots, L. \tag{2.21}$$

Using the right-hand side of the first equality in (2.19), let us derive a compact expression for $\mathcal{H}_k$ in terms of the elementary matrices

$$\mathcal{D}_k \triangleq \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ & 0 & 2 & & \\ & & 0 & \cdots & \\ \vdots & & & \ddots & N_k \\ 0 & & & \cdots & 0 \end{bmatrix} \in \mathbf{R}^{(N_k+1) \times (N_k+1)} \tag{2.22}$$

and

$$\mathcal{W}_k \triangleq \left[ \mathcal{Z}_q(z) \;\; \frac{d}{dz} \mathcal{Z}_q(z) \;\; \cdots \;\; \frac{d^{N_k}}{dz^{N_k}} \mathcal{Z}_q(z) \right]_{z=z_k} , \qquad k = 1, \ldots, L, \tag{2.23}$$

as follows:

$$\begin{aligned}
\mathcal{H}_k = {} & \left[\mathcal{Z}_q(z)\ \frac{\mathrm{d}}{dz}\mathcal{Z}_q(z)\ \frac{d^2}{dz^2}\mathcal{Z}_q(z)\ \cdots\ \frac{d^{N_k}}{dz^{N_k}}\mathcal{Z}_q(z)\right]_{z=z_k} \otimes G(z_k) \\
& + \left[0\ \ \mathcal{Z}_q(z)\ \ 2\frac{d}{\mathrm{d}z}\mathcal{Z}_q(z)\ \ \cdots\ \ \begin{pmatrix} N_k \\ 1 \end{pmatrix} \frac{d^{N_k-1}}{dz^{N_k-1}}\mathcal{Z}_q(z)\right]_{z=z_k} \otimes \frac{d}{dz}G(z_k) \\
& + \left[0\ \ 0\ \ \mathcal{Z}_q(z)\ \ \cdots\ \ \begin{pmatrix} N_k \\ 2 \end{pmatrix} \frac{d^{N_k-2}}{dz^{N_k-2}}\mathcal{Z}_q(z)\right]_{z=z_k} \otimes \frac{d^2}{dz^2}G(z_k) + \cdots \\
& + \left[0\ \ 0\ \ 0\ \ \cdots\ \ \mathcal{Z}_q(z)\right]_{z=z_k} \otimes \frac{d^{N_k}}{dz^{N_k}}G(z_k) \\
= {} & \mathcal{W}_k \otimes G(z_k) + [\mathcal{W}_k\mathcal{D}_k] \otimes \frac{d}{dz}G(z_k) + \frac{1}{2!}\,[\mathcal{W}_k\mathcal{D}_k^2] \otimes \frac{d^2}{dz^2}G(z_k) \\
& + \frac{1}{N_k!}\,[\mathcal{W}_k\mathcal{D}_k^{N_k}] \otimes \frac{d^{N_k}}{dz^{N_k}}G(z_k).
\end{aligned}$$

Note that $\mathcal{D}_k^j = 0$ for all $j > N_k$. Hence,

$$\mathcal{H}_k = \sum_{j=0}^{N_k} \frac{1}{j!}\,[\mathcal{W}_k\,\mathcal{D}_k^j] \otimes w_{kj}, \qquad k = 1, \ldots, L. \tag{2.24}$$

It remains to compute the derivatives of $\mathcal{Z}_q(z)$. To this end, let

$$\mathcal{T}_q \triangleq \begin{bmatrix} 0! & 0 & \cdots & 0 \\ 0 & 1! & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & (q-1)! \end{bmatrix} \in \mathbf{R}^{q\times q}. \tag{2.25}$$

Then, it is easy to verify that

$$\frac{d^l}{dz^l}\mathcal{Z}_q(z) = \mathcal{T}_q\mathcal{J}_{q,2}^l\mathcal{T}_q^{-1}\mathcal{Z}_q(z), \qquad l \geq 0. \tag{2.26}$$

Hence from (2.23) and (2.26),

$$\mathcal{W}_k = \mathcal{T}_q\left[I_q\ \ \mathcal{J}_{q,2}\ \ \cdots\ \ \mathcal{J}_{q,2}^{N_k}\right]\left[I_{N_k+1} \otimes \mathcal{T}_q^{-1}\mathcal{Z}_q(z_k)\right], \qquad k = 1, \ldots, L. \tag{2.27}$$

An alternative compact expression for $\mathcal{H}_k$ is obtained by evaluating the right-hand side of the second equality in (2.19) for $l = 0, \ldots, N_k$, $k = 1, \ldots, L$, and augmenting the similar terms in compound matrices as follows:

$$\mathcal{H}_k = \mathcal{O}_q\,\mathcal{X}_k + \sum_{j=0}^{q-1}[\mathcal{J}_{q,2}^j \otimes g_j]\,[\mathcal{W}_k \otimes I_m], \qquad k = 1, \ldots, L, \tag{2.28}$$

where

$$\mathcal{X}_k \triangleq \left[X_{\mathrm{C}}(z)\ \ \frac{d}{dz}X_{\mathrm{C}}(z)\ \ \cdots\ \ \frac{d^{N_k}}{dz^{N_k}}X_{\mathrm{C}}(z)\right]_{z=z_k}, \qquad k = 1, \ldots, L. \tag{2.29}$$

Now, we collect $\mathcal{H}_k$, $\mathcal{X}_k$, and $\mathcal{W}_k$, $k = 1, \ldots, L$, in the compound matrices

$$\mathcal{H} \triangleq [\mathcal{H}_1\ \mathcal{H}_2\ \cdots\ \mathcal{H}_L]\,, \tag{2.30}$$

$$\mathcal{X} \triangleq [\mathcal{X}_1\ \mathcal{X}_2\ \cdots\ \mathcal{X}_L]\,, \tag{2.31}$$

$$\mathcal{W} \triangleq [\mathcal{W}_1\ \mathcal{W}_2\ \cdots\ \mathcal{W}_L]\,. \tag{2.32}$$

Hence,

$$\mathcal{H} = \mathcal{O}_q\,\mathcal{X} + \sum_{j=0}^{q-1}[\mathcal{J}_{q,2}^{j} \otimes g_j]\,[\mathcal{W} \otimes I_m], \tag{2.33}$$

where $\mathcal{H}$ and $\mathcal{W}$ are computed from the problem data $\{z_k, \{w_{kj}\}_{j=0}^{N_k}\}_{k=1}^{L}$ by the formulae (2.30), (2.32), (2.27), (2.24), (2.22), (2.14), (2.15), (2.25). This completes the first stage of our subspace-based interpolation algorithm. Observe that $\mathcal{H}$ is affine in $\mathcal{O}_q$ as advertised.

Since $\mathcal{O}_q$ is a real matrix and we are interested in the real range space, we can convert (2.33) into a relation involving only real valued matrices:

$$\widehat{\mathcal{H}} = \mathcal{O}_q\,\widehat{\mathcal{X}} + \sum_{j=0}^{q-1}[\mathcal{J}_{q,2}^{j} \otimes g_j]\,\mathcal{F}, \tag{2.34}$$

where

$$\widehat{\mathcal{H}} \triangleq [\mathrm{Re}\mathcal{H}\ \ \mathrm{Im}\mathcal{H}]\,, \tag{2.35}$$

$$\mathcal{F} \triangleq [\mathrm{Re}\mathcal{W}\ \ \mathrm{Im}\mathcal{W}] \otimes I_m, \tag{2.36}$$

$$\widehat{\mathcal{X}} \triangleq [\mathrm{Re}\mathcal{X}\ \ \mathrm{Im}\mathcal{X}]\,. \tag{2.37}$$

Let $z^*$ denote the complex conjugate of $z$. When $z_k \in \mathbf{R}$, from (2.14) we have $\mathcal{Z}_q(z_k) \in \mathbf{R}^q$. This, by (2.27), implies that $\mathcal{W}_k \in \mathbf{R}^{q\times(N_k+1)}$. From (2.5),

$$X_{\mathrm{C}}(z) = (zI_n - A)^{-1}B. \tag{2.38}$$

Then, from (2.4), (2.38), and (2.29), it follows that $\mathcal{X}_k \in \mathbf{R}^{n\times m(N_k+1)}$ and, for all $j = 0, \ldots, N_k$, $w_{kj} \in \mathbf{R}^{p\times m}$ whenever $z_k \in \mathbf{R}$. Thus, whenever $z_k \in \mathbf{R}$ from (2.24) we have $\mathcal{H}_k \in \mathbf{R}^{pq\times m(N_k+1)}$. Hence, the imaginary parts of $\mathcal{H}_k$, $\mathcal{F}$, and $\mathcal{X}_k$ are all zero, and they need not be included in (2.35)–(2.37) if $z_k \in \mathbf{R}$; without loss of generality, we will assume this in what follows. Let

$$N \triangleq \sum_{k:z_k\in\mathbf{R}}(N_k+1) + \sum_{k:z_k\in\mathbf{C}-\mathbf{R}} 2(N_k+1). \tag{2.39}$$

Then, $\widehat{\mathcal{H}} \in \mathbf{R}^{pq\times mN}$, $\mathcal{F} \in \mathbf{R}^{mq\times mN}$, and $\widehat{\mathcal{X}} \in \mathbf{R}^{n\times mN}$.

**2.1. Projection onto the observability range space.** Let $\mathcal{F}^{\perp}$ be the projection matrix onto the null space of $\mathcal{F}$ given by

$$\mathcal{F}^{\perp} \triangleq I_{mN} - \mathcal{F}^T(\mathcal{F}\mathcal{F}^T)^{-1}\mathcal{F}, \tag{2.40}$$

where $\mathcal{F}^T$ denotes the transpose of $\mathcal{F}$. The summand in (2.34) is cancelled for all $j$ when multiplied from right by $\mathcal{F}^{\perp}$. Thus,

$$\widehat{\mathcal{H}}\mathcal{F}^{\perp} = \mathcal{O}_q\,\widehat{\mathcal{X}}\mathcal{F}^{\perp}. \tag{2.41}$$

A numerically efficient way of forming $\widehat{\mathcal{H}}\mathcal{F}^{\perp}$ is to use the QR-factorization

$$\begin{bmatrix} \mathcal{F} \\ \widehat{\mathcal{H}} \end{bmatrix} = \begin{bmatrix} R_{11} & 0 \\ R_{21} & R_{22} \end{bmatrix} \begin{bmatrix} Q_1^T \\ Q_2^T \end{bmatrix}. \tag{2.42}$$

A simple derivation yields

$$\widehat{\mathcal{H}}\mathcal{F}^{\perp} = R_{22}Q_2^T, \tag{2.43}$$

and it suffices to use $R_{22} \in \mathbf{R}^{pq\times m(N-q)}$ in the extraction of the observability range space since $Q_2^T$ is a matrix of full rank.

The range space of $\widehat{\mathcal{H}}\mathcal{F}^{\perp}$ equals the range space of $\mathcal{O}_q$ unless rank cancellations occur. A sufficient condition for the range spaces to be equal is that the intersection of the row spaces of $\mathcal{F}$ and $\widehat{\mathcal{X}}$ be empty. In the following, we present sufficient conditions in terms of the data and the system.

LEMMA 2.1. [illegible] $\widehat{\mathcal{X}}$ $\mathcal{F}$ [illegible] $N$ [illegible] (2.37) (2.36) [illegible] (2.39) [illegible] $N \geq q+n$ [illegible] $A$ [illegible] $z_k$ [illegible]

$$\operatorname{rank}\begin{bmatrix} \mathcal{F} \\ \widehat{\mathcal{X}} \end{bmatrix} = qm+n \qquad \Longleftrightarrow \qquad (A,B) \text{ controllable pair.} \tag{2.44}$$

[illegible] The matrix $\begin{bmatrix} \mathcal{W}\otimes I_m \\ \mathcal{X} \end{bmatrix}$ is rank deficient if and only if there exists a row vector

$$[\alpha_0 \ \cdots \ \alpha_{q-1} \ \beta] \neq 0 \tag{2.45}$$

with $\alpha_k^T \in \mathrm{R}^m,\ k=0,\dots,q-1$, and $\beta^T \in \mathrm{R}^n$ such that

$$[\alpha_0 \ \cdots \ \alpha_{q-1} \ \beta]\begin{bmatrix} \mathcal{W}\otimes I_m \\ \mathcal{X} \end{bmatrix} = 0. \tag{2.46}$$

From (2.32), (2.23), and (2.31), (2.29), equation (2.46) holds if and only if

$$[\alpha_0 \ \cdots \ \alpha_{q-1} \ \beta]\frac{d^j}{dz^j}\begin{bmatrix} \mathcal{Z}_q(z)\otimes I_m \\ \mathcal{X}_{\mathrm{C}}(z) \end{bmatrix}_{z=z_k} = 0, \quad 0 \leq j \leq N_k,\ k=1,\dots,L,$$

$$\Updownarrow$$

$$\left.\frac{d^j}{dz^j}E(z)\right|_{z=z_k} = 0, \quad 0 \leq j \leq N_k,\ k=1,\dots,L, \tag{2.47}$$

where

$$E(z) \triangleq \sum_{k=0}^{q-1}\alpha_k z^k + \beta(zI_n - A)^{-1}B.$$

Equation (2.47) implies that for each $k$ the elements of the rational vector $E(z)$ have common zeros at $z_k$ with multiplicity $N_k+1$. Since $E(z)$ is real-rational, $z_k$ is a zero of $E(z)$ if and only if $z_k^*$ is also a zero of $E(z)$. Therefore, $E(z)$ happens to have a total number of $N$ zeros counting multiplicities. However, the elements of $E(z)$ have numerator degrees not exceeding $n+q-1$. Hence, any element of $E(z)$ cannot have $N$ zeros. Thus, $E(z) \equiv 0$. This implies that $\alpha_k = 0$ for all $k$ and $\beta(zI_n - A)^{-1}B \equiv 0$. The latter result follows from the fact that $\beta(zI_n - A)^{-1}B$ is analytic and has a zero at $z=\infty$; hence it is orthogonal to $\sum_{k=0}^{q-1}\alpha_k z^k$. Recall that $(A,B)$ is an uncontrollable pair if and only if it is possible to find a vector $\beta \neq 0$ such that $\beta(zI_n - A)^{-1}B \equiv 0$. Finally, note that $\begin{bmatrix} \mathcal{F} \\ \widehat{\mathcal{X}} \end{bmatrix}$ is rank deficient if and only if $\begin{bmatrix} \mathcal{W} \otimes I_m \\ \mathcal{X} \end{bmatrix}$ is rank deficient. The last assertion is due to the fact that, for any complex matrix $Z$ and real vector $x$,

$$x^T Z = 0 \Longleftrightarrow x\,[\mathrm{Re}Z \ \mathrm{Im}Z] = 0. \qquad \square$$

Since all the eigenvalues of $A$ are inside the unit circle, none of them coincide with any of $z_k$. Thus, by applying Lemma 2.1, we conclude that the two row spaces of $\widehat{\mathcal{X}}$ and $\mathcal{F}$ do not intersect and the range space of $\widehat{\mathcal{H}}\mathcal{F}^\perp$ coincides with the range space of $\mathcal{O}_q$. Then, using the singular value factorization of $\widehat{\mathcal{H}}\mathcal{F}^\perp$,

$$\begin{aligned} \widehat{\mathcal{H}}\mathcal{F}^\perp &= \widehat{U}\widehat{\Sigma}\widehat{V}^T \\ &= \begin{bmatrix} \widehat{U}_s & \widehat{U}_o \end{bmatrix} \begin{bmatrix} \widehat{\Sigma}_s & 0 \\ 0 & \widehat{\Sigma}_o \end{bmatrix} \begin{bmatrix} \widehat{V}_s^T \\ \widehat{V}_o^T \end{bmatrix}, \end{aligned} \tag{2.48}$$

where $\widehat{\Sigma}_s \in \mathbf{R}^{n\times n}$, we determine the system matrices $\widehat{A}$ and $\widehat{C}$ as

$$\begin{aligned} \widehat{A} &= (J_1\widehat{U}_s)^\dagger J_2\widehat{U}_s, \\ \widehat{C} &= J_3\widehat{U}_s, \end{aligned} \tag{2.49}$$

where

$$J_1 = \begin{bmatrix} I_{(q-1)p} & 0_{(q-1)p\times p} \end{bmatrix}, \tag{2.50}$$

$$J_2 = \begin{bmatrix} 0_{(q-1)p\times p} & I_{(q-1)p} \end{bmatrix}, \tag{2.51}$$

$$J_3 = \begin{bmatrix} I_p & 0_{p\times(q-1)p} \end{bmatrix}, \tag{2.52}$$

$0_{i\times j}$ is the $i \times j$ zero matrix, and $X^\dagger = (X^TX)^{-1}X^T$ is the Moore–Penrose pseudoinverse of the full column rank matrix $X$. Provided that $(C, A)$ is an observable pair, the pseudoinverse in (2.49) exists if and only if $q > n$. Therefore, in order to apply the lemma it suffices to let $q = n + 1$. In this case, we have the sole requirement $N > 2n$ with $N$ defined by (2.39). From Lemma 2.1, it follows that $\widehat{A}$ and $\widehat{C}$ defined in (2.49) are related to $A$ and $C$ in (1.2) by

$$\begin{aligned} \widehat{A} &= T^{-1}AT, \\ \widehat{C} &= CT \end{aligned} \tag{2.53}$$

for some $T \in \mathbf{R}^{n\times n}$.

As noted before, in (2.48) $\widehat{\mathcal{H}}\mathcal{F}^\perp$ can be replaced with $R_{22}$.

**2.2. Extracting *B* and *D* from the data.** We will now determine $B$ and $D$ matrices in the realization using the given frequency domain data. Repeated application of the differentiation formula

$$\frac{d}{dz}X^{-1} = -X^{-1}\frac{dX}{dz}X^{-1}$$

to $X_{\mathrm{C}}(z) = (zI_n - A)^{-1}B$ yields the derivatives of $G(z)$ as follows:

$$\frac{d^j}{dz^j}G(z) = \delta_{0j}\, D + (-1)^j j!\, C(zI_n - A)^{-j-1}B, \qquad j \geq 0, \tag{2.54}$$

where $\delta_{ks}$ is the Kronecker delta. Now, let

$$\mathcal{G}_k \triangleq \begin{bmatrix} w_{k0} \\ w_{k1} \\ \vdots \\ w_{kN_k} \end{bmatrix}, \qquad k = 1, \ldots, L, \tag{2.55}$$

and

$$\mathcal{G} \triangleq \begin{bmatrix} \mathcal{G}_1 \\ \mathcal{G}_2 \\ \vdots \\ \mathcal{G}_L \end{bmatrix}. \tag{2.56}$$

Observe from (2.54) that, for fixed $A$ and $C$, the matrices $B$ and $D$ appear linearly in $\mathcal{G}$. Hence, we can uniquely determine $B$ and $D$ by solving the following linear least-squares problem

$$\widehat{B}, \widehat{D} = \arg\min_{B,D} \left\| \widehat{\mathcal{G}} - \widehat{\mathcal{Y}} \begin{bmatrix} B \\ D \end{bmatrix} \right\|_F^2, \tag{2.57}$$

where

$$\|X\|_F \triangleq \left[ \sum_k \sum_s |x_{ks}|^2 \right]^{1/2}$$

is the [illegible],

$$\widehat{\mathcal{G}} \triangleq \begin{bmatrix} \mathrm{Re}\mathcal{G} \\ \mathrm{Im}\mathcal{G} \end{bmatrix} \in \mathbf{R}^{pN \times m}, \tag{2.58}$$

$$\widehat{\mathcal{Y}} \triangleq \begin{bmatrix} \mathrm{Re}\mathcal{Y} \\ \mathrm{Im}\mathcal{Y} \end{bmatrix} \in \mathbf{R}^{pN \times (n+p)}, \tag{2.59}$$

and

$$\mathcal{Y}_k \triangleq \begin{bmatrix} C(z_k I_n - A)^{-1} & I_p \\ -C(z_k I_n - A)^{-2} & 0 \\ \vdots & \\ (-1)^{N_k} N_k!\, C(z_k I_n - A)^{-N_k - 1} & 0 \end{bmatrix}, \tag{2.60}$$

$$\mathcal{Y} \triangleq \begin{bmatrix} \mathcal{Y}_1 \\ \mathcal{Y}_2 \\ \vdots \\ \mathcal{Y}_L \end{bmatrix}, \tag{2.61}$$

provided that $\widehat{\mathcal{Y}}$ is not rank deficient. For the last requirement, a sufficient condition is presented next.

LEMMA 2.2. [illegible] $N$, [illegible] $\widehat{\mathcal{Y}}$ [illegible] (2.39), [illegible] (2.59) [illegible] $N > n$, [illegible] $A$ [illegible] $z_k$ [illegible]

$$\mathrm{rank}\widehat{\mathcal{Y}} = p + n \qquad \Longleftrightarrow \qquad (C, A) \text{ observable pair}. \tag{2.62}$$

The matrix $\mathcal{Y}$ is rank deficient if and only if there exists $\begin{bmatrix} B \\ D \end{bmatrix} \neq 0$ such that

$$\mathcal{Y}\begin{bmatrix} B \\ D \end{bmatrix} = 0 \iff \frac{d^j}{dz^j}G(z)\bigg|_{z=z_k} = 0, \quad 0 \leq j \leq N_k,\ k = 1, \dots, L.$$

As in the proof of Lemma 2.1, this equation implies that every element of $G(z)$ has a total number of $N$ zeros counting multiplicities, a contradiction if $G(z)$ is not identically zero unless $N \leq n$. ☐

Thus, from (2.53) and Lemma 2.2, if $N \geq q + n$ and $q > n$, we have

$$\widehat{B} = T^{-1}B, \qquad \widehat{D} = D. \tag{2.63}$$

Moreover,

$$\widehat{G}(z) \triangleq \widehat{C}(zI_n - \widehat{A})^{-1}\widehat{B} + \widehat{D} = G(z). \tag{2.64}$$

**2.3. Solvability conditions.** By picking $q = n + 1$ in the subspace-based algorithm developed above, we obtain a sufficient condition for the interpolation of $G(z)$ from its noise-free samples and derivatives evaluated at $L$ distinct points in $\vartheta$ as $N \geq 2n + 1$, where $N$ is defined by (2.39). This condition turns out to be a necessary condition for the interpolation of $G(z)$, as demonstrated next by a simple example.

Consider an $n$th-order stable single-input/single-output system represented by the transfer function

$$G(z) = \frac{b_0 z^n + b_1 z + \cdots + b_n}{z^n + a_1 z + \cdots + a_n}. \tag{2.65}$$

We are to determine $2n + 1$ unknown real coefficients $a_1, \dots, a_n, b_0, \dots, b_n$ from the evaluations of $G(z)$ and its derivatives at a given set of distinct frequencies $z_k \in \vartheta$. Let $N$ be as in (2.39).

Let us first assume in (1.4) that $N_k = 0$ and $z_k \in \mathbf{C} - \mathbf{R}$ for all $k$; i.e., the interpolation nodes are simple and purely complex numbers. Then, $N = 2L$. With $q = n + 1$, the subspace-based algorithm delivers a minimal realization of $G(z)$, provided that $2L \geq 2n + 1$. This condition is satisfied by choosing $L = n + 1$. Clearly, this is the least amount of data one could use to interpolate an arbitrary $n$th-order system, as can directly be verified by writing $2L$-linear equations down from (1.4) and (2.65) to determine the unknowns $a_1, \dots, a_n, b_0, \dots, b_n$. Notice that if some interpolation nodes have multiplicities, then the resulting equations become nonlinear in $a_1, \dots, a_n, b_0, \dots, b_n$.

Now, as a special case, let us consider the situation that all $z_k$ are on the unit circle excluding the points $\pm 1$. Thus, Algorithm 2.1 recovers $n$th-order stable systems from $n + 1$ noise-free frequency response measurements, excluding the frequencies 0 and $\pi$. If the frequencies contain 0, from (2.39) we then have $N = 2L - 1$. Hence, with $q = n + 1$ selected, we must have $2L - 1 \geq 2n + 1$, which is fulfilled by letting $L = n + 1$. If, in addition, the frequencies contain $\pi$ as well, we end up with the interpolation condition $L = n + 2$. The last conclusion extends an interpolation result in [24] derived for the uniformly spaced frequencies case to the nonuniformly spaced frequencies case.

It is easy to see, for example, by the partial fraction expansion or similar techniques, that these results hold for multi-input/multi-output systems with multiple interpolation nodes as well. Therefore, Algorithm 2.1 is capable of using a minimum amount of the frequency domain data for the Lagrange–Sylvester interpolation of stable systems.

**2.4. Summary of the subspace-based interpolation algorithm.** Let us summarize the interpolation algorithm in the following.

ALGORITHM 2.1.

1. (1.4) $\mathcal{H}$ $\mathcal{F}$ (2.35) (2.36) (2.30) (2.32) (2.24) (2.27) (2.22) (2.25) (2.15) (2.14)
2. (2.42)
3. (2.48) $\widehat{\mathcal{H}}\mathcal{F}^{\perp}$ $R_{22}$ (2.42)
4. $\widehat{\Sigma}_s$ $n$
5. $J_1$ $J_2$ $J_3$ (2.50)–(2.52) $\widehat{A}$ $\widehat{C}$ (2.49)
6. (2.57) $\widehat{B}$ $\widehat{D}$ $\widehat{\mathcal{G}}$ $\widehat{\mathcal{Y}}$ (2.58) (2.59) (2.60)–(2.61) (2.55)–(2.56)

Clearly, $\widehat{\Sigma}_o = 0$ in (2.48) when the data are not corrupted by noise, the system that has generated the data is of McMillan degree $n$, $N \geq q + n$, and $q > n$. As we stated earlier, Algorithm 2.1 produces a minimal stable realization of the interpolant, given that the latter exits. In most interpolation problems, the existence and the uniqueness questions are easily settled, and the construction of a solution (or all solutions) with certain properties such as the McMillan degree constraints, in particular minimality, remains a difficult one. The algorithm outlined above is straightforward to implement. In the implementation of the algorithm, it suffices to let $q = n + 1$ and $N = 2n + 1$, where $N$ is defined by (2.39). The system order, if unknown a priori, can be determined in step 4 of Algorithm 2.1 from the inspection of the singular values. This process also reveals redundancies in the data. Numerically, the most expensive step in the algorithm is the singular value decomposition of $R_{22}$. Notice with $q = n + 1$ and $N = 2n + 1$ selected, that $R_{22} \in \mathbf{R}^{p(n+1)\times mn}$.

The main result of this paper is captured in the following.

THEOREM 2.3. 2.1 (1.4) $n$ $N$ (2.39) $N \geq q + n$ $q > n$ $(\widehat{A}, \widehat{B}, \widehat{C}, \widehat{D})$ $G(z)$

**2.5. Discussion.** In the rest of this section, we will briefly comment on the similarities and the differences between Algorithm 2.1 and the Löwner matrix–based approach [1].

The most striking difference between the methods appears to be the formation of data matrices. In [1], elements of a Löwner matrix are computed by taking partial derivatives of the divided differences $[G(z) - G(s)]/(z - s)$ evaluated at $z = z_k$ and $s = z_l$, where the number of the derivatives is determined by the particular choice of the (block) row and column sets and the multiplicities of the nodes. If $z_k$ equals $z_l$, a limiting process has to be used to define that particular element. It is required that the numbers of the chosen block rows and columns add up to $N$. The elements of $\mathcal{H}$ in the proposed algorithm, on the other hand, consist of linear combinations of the derivatives of the products $z^l G(z)$ evaluated at $z = z_k$, where for each $k$, $l$ satisfies $0 \leq l \leq N_k$. A simple transformation that relates $\mathcal{H}$ to a Löwner matrix does not seem possible unless all the $z_k$ are the same, in which case the problem solved reduces to a conventional partial realization problem. In the latter case, notice that this link is provided by the bilinear map (1.5).

Both algorithms rely on the factorization of the data matrices discussed above as a product of two matrices which are directly related to the observability and controllability concepts. In [1], the Löwner matrix is expressed as a product of the so-called generalized observability and the controllability matrices, whereas in the proposed algorithm this relation is recovered after some projections. In fact, the proofs of Lemmas 2.1, 2.2, and 3.1R in [1] use the same ideas.

The most striking similarity between the algorithms is the condition $N > 2n$. It should be noted that the stability assumption is not essential in the formulation of the interpolation problem, since the data are already assumed to originate from a finite-dimensional dynamical system with a complexity bounded above and the number of the nodes is finite. This assumption is necessary in an identification setup. Without the knowledge that the data have originated from a dynamical system with a complexity bounded above, the condition $N > 2n$ is precisely one of the requirements for the existence of a unique minimal-order interpolating rational matrix [1]. In addition to this requirement, there is also a more stringent rank condition captured in Assumption 4.1 in [1]. Thus, both algorithms operate under the same conditions which assure the existence of a unique minimal interpolating rational matrix. We have not addressed the properness issue in this paper due to our standing assumption on the origins of the data. Again, without the knowledge of the origins of the data, one has to secure that the solution of the interpolation problem is a proper transfer function. The properness is guaranteed by Assumption 4.2 in [1]. It is also noted there that this assumption can be eliminated by means of a suitably chosen bilinear transformation.

The Löwner matrix–based and proposed algorithms cannot be directly applied when there does not exist a unique minimal interpolating function and the data are not scalar. This may happen either in the presence of noise which corrupts transfer function evaluations or when the true dynamics is of higher dimension. The problem is then to find the admissible degrees of complexity, i.e., those positive integers $n$ for which there exist solutions $G(z)$ to the interpolation problem (1.4) with $deg\, G = n$, and to construct all corresponding solutions for a given admissible degree $n$. This problem is known as the partial realization problem. If the original data do not satisfy the criterion for the existence of a unique minimal interpolating function, one needs to add interpolation data until the criterion becomes satisfied. The fact that the data can be found so that the increase in degree is finite is nontrivial. The added data will necessarily drive up the degree of the interpolating transfer function. In the scalar case, dealt with in [2], the way this can be done is set out and is rather complicated. The multivariable case is studied in [4] using the generating system approach. While [4] gives the theory behind the determination of the minimal McMillan degree and all admissible degrees, the current paper and [1] provide the theory behind the construction in state-space terms of the solution of admissible degrees.

A departure of Algorithm 2.1 from the Löwner matrix–based approach is the determination of the minimal order. Under the stated conditions, in Algorithm 2.1 the minimal order and the observability range space are extracted by a singular value decomposition, while in the Löwner matrix–based approach the minimal order is determined by checking ranks of several (generalized) Löwner matrices. The singular value decomposition is not sensitive to random inaccuracies in data; that is, the true singular values and the observability range space are consistently estimated as $N$ increases unboundedly, provided that $n$ is finite or increases more slowly than $N$ [24, 25]. To our best knowledge, an asymptotic error analysis for randomly corrupted transfer function evaluations has not been performed for any of the interpolation algorithms in the literature.

Deficiencies of the proposed interpolation algorithm and the Löwner matrix–based approach are the same. As pointed out in [1], a parameterization of solutions when the original data have to be added and derivation of recursive formulae for allowing update of a realization when one or more interpolation data become available are absent. It would be interesting to develop connections between the constrained interpolation problems such as the Nevanlinna–Pick and the positive-real interpolation and Algorithm 2.1. It is worth mentioning that the Nevanlinna–Pick interpolation can be transformed into an interpolation problem without norm constraint by adding the mirror image interpolation points to the original data [3].

**3. Subspace-based identification with interpolation constraints.** In this section, we will consider identification of an $n$th-order stable system with transfer function $G(z)$ from noisy samples of the frequency response,

$$w_l = G(e^{i\theta_l}) + \eta_l, \qquad l = 1, \dots, M, \tag{3.1}$$

with the interpolation constraints

$$\left.\frac{d^j}{dz^j} G(z)\right|_{z=z_k} = E_{kj}, \qquad j = 0, 1, \dots, N_k, \quad k = 1, \dots, L, \tag{3.2}$$

where $0 \leq \theta_l \leq \pi$, $l = 1, \dots, M$, denote the discrete-time frequencies and $\eta_l$ is a sequence of independent zero-mean complex random variables with a known covariance function that is uniformly bounded. The number of the constraints defined in (2.39) satisfies $N < n$. The interpolation constraints (3.2) reflect the prior knowledge on $G(z)$. For example, by taking $E_{kj} = 0$ for all $j \leq N_k$, we enforce a zero with multiplicity $N_k + 1$ at $z_k$. These constraints may also be used as design variables to focus on a frequency band of interest.

We would like to find an identification algorithm which maps the data $\{w_l, \theta_l\}_{l=1}^{M}$ to an $n$th-order model $\widehat{G}_M(z)$ that satisfies the interpolation constraints in (3.2) such that, with probability one,

$$\lim_{M\to\infty} \|\widehat{G}_M - G\|_\infty = 0,$$

where

$$\|X\|_\infty \triangleq \sup_\omega \sigma_1(X(e^{i\omega}))$$

and $\sigma_1$ denotes the largest singular value. Algorithms with this property are called [illegible]. This identification setup except for the constraints in (3.2) can be found, for example, in [24].

A motivating example for the constraints in (3.2) is as follows. Suppose that the system to be identified is $n$th order stable single-input/single-output continuous-time system represented by the transfer function

$$G^c(s) = \frac{b_0 s^m + b_1 s + \cdots + b_m}{s^n + a_1 s + \cdots + a_n}, \tag{3.3}$$

where the denominator degree $n$ is greater than the numerator degree $m$, and we are given $M$ noise corrupted frequency response measurements

$$w_l = G(i\omega_l) + \eta_l, \qquad l = 1, \dots, M. \tag{3.4}$$

Assuming $b_0 \neq 0$, the [illegible] of $G^c(s)$ is defined as $\tau \triangleq n - m$.

A direct use of the Möbius transform technique (1.5) targets identifying the discrete-time equivalent of $G^c(s)$ defined by

$$G^d(z) \triangleq G^c(\psi(z)), \tag{3.5}$$

using $w_l$, $l = 1, \ldots, M$, at the transformed discrete-time frequencies

$$\theta_k = 2 \arctan\left(\frac{\omega_k}{\lambda}\right), \qquad k = 1, \ldots, M. \tag{3.6}$$

Then, the continuous-time identified transfer function denoted by $\widehat{G}^c_M(s)$ is obtained from the discrete-time identified transfer function denoted by $\widehat{G}^d_M(z)$ by using the inverse Möbius map $z = \psi^{-1}(s)$; i.e., $\widehat{G}^c_M(s) = \widehat{G}^d_M(\psi^{-1}(s))$. Due to noise and unmodeled dynamics, the former is only a proper transfer function.

If maintaining the relative degree is a concern, we then high-pass filter $\widehat{G}^c_M(s)$ as follows:

$$\widehat{G}_M(s) = \frac{\widehat{G}^c_M(s)}{(s+\mu)^\tau},$$

where $\mu > 0$ is chosen sufficiently outside the bandwidth of $\widehat{G}^c_M(s)$. This filtering increases the order of the identified model by $\tau$. This problem can be circumvented by including the constraints

$$\left.\frac{d^j}{dz^j} G^d(z)\right|_{z=-1} = 0, \qquad j = 1, \ldots, \tau,$$

in the problem formulation. Observe that when applied to (3.3), the Möbius map (1.5) introduces a zero of $G^d(z)$ at $z = -1$ with multiplicity $\tau$.

Now, the solution of the constrained identification problem (3.1)–(3.2) is particularly simple if one notes from (2.54) the following set of equations:

$$\delta_{0j}\, D + (-1)^j j!\, C(z_k I_n - A)^{-j-1} B = E_{kj}, \;\; j = 0, \ldots, N_k, \;\; k = 1, \ldots, L, \tag{3.7}$$

which describe $N$ hyperplanes in the parameter space of $B$ and $D$ for fixed $C$ and $A$. Hence, it suffices to solve the linear least-squares problem (2.57) with the linear constraints (3.7). With this modification, the frequency domain subspace-based identification algorithm presented in [24] is strongly consistent. The inclusion of the noise covariance information in the algorithm is straightforward and can be found in [24]. This extension can be viewed as the tangential version of the Lagrange–Sylvester interpolation problem (1.1).

**4. Example.** The purpose of this section is to illustrate Algorithm 2.1 with a step-by-step numerical example. Suppose that the system to be found by interpolation has the following state-space representation:

$$A = \begin{bmatrix} -0.5 & 0.5 & 0 & 0 \\ -0.5 & -0.5 & 0 & 0 \\ 0 & 0 & 0.5 & 0 \\ 0 & 0 & 0 & -0.25 \end{bmatrix}, \qquad B = \begin{bmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ 0 & -1 & 0 \\ 1 & 1 & 1 \end{bmatrix},$$

$$C = \begin{bmatrix} 1 & 1 & 1 & 0 \\ 0 & 1 & 0 & 1 \end{bmatrix}, \qquad D = \begin{bmatrix} 1 & -1 & 0 \\ 0 & 1 & 1 \end{bmatrix}.$$

Thus, $n = 4$, $p = 2$, and $m = 3$. This system has the transfer function

$$G(z) = \begin{bmatrix} \dfrac{z^2 + 3z + 1.5}{z^2 + z + 0.5} & -\dfrac{z^3 + 0.5z^2 + 0.5z + 0.75}{z^3 + 0.5z^2 - 0.25} & 0 \\ \dfrac{2z^2 + 1.25z + 0.5}{z^3 + 1.25z^2 + 0.75z + 0.125} & \dfrac{z^3 + 3.25z^2 + 2.5z + 0.75}{z^3 + 1.25z^2 + 0.75z + 0.125} & \dfrac{z + 1.25}{z + 0.25} \end{bmatrix}.$$

Let us assume that the interpolation data are as follows:

$$z_1 = 1 + i,\ N_1 = 0,\ z_2 = 1 - i,\ N_2 = 0,\ z_3 = 2,\ N_3 = 4$$

and

$$w_{10} = \begin{bmatrix} 1.9333 - 0.5333i & -0.8667 + 0.4000i & 0 \\ 0.8878 - 0.5236i & 1.9545 - 0.6569i & 1.4878 - 0.3902i \end{bmatrix},$$

$$w_{20} = \begin{bmatrix} 1.9333 + 0.5333i & -0.8667 - 0.4000i & 0 \\ 0.8878 + 0.5236i & 1.9545 + 0.6569i & 1.4878 + 0.3902i \end{bmatrix},$$

$$w_{30} = \begin{bmatrix} 1.7692 & -1.2051 & 0 \\ 0.7521 & 1.8291 & 1.4444 \end{bmatrix}, \quad w_{31} = \begin{bmatrix} -0.2840 & 0.2433 & 0 \\ -0.2804 & -0.3395 & -0.1975 \end{bmatrix},$$

$$w_{32} = \begin{bmatrix} 0.2003 & -0.4251 & 0 \\ 0.2084 & 0.2757 & 0.1756 \end{bmatrix}, \quad w_{33} = \begin{bmatrix} -0.2000 & 0.9844 & 0 \\ -0.2333 & -0.3341 & -0.2341 \end{bmatrix},$$

$$w_{34} = \begin{bmatrix} 0.2456 & -2.8518 & 0 \\ 0.3531 & 0.5390 & 0.4162 \end{bmatrix}.$$

Then we set $q = 5$ and compute $N = 9$. Therefore, the inequalities $N \geq q + n$ and $q > n$ are both satisfied. In step 1, we compute the matrices $\widehat{\mathcal{H}} \in \mathbf{R}^{10\times 27}$ and $\mathcal{F} \in \mathbf{R}^{15\times 27}$. The QR-factorization in step 2 results in $R_{22} \in \mathbf{R}^{10\times 12}$ given by

$$R_{22} = \left[\begin{array}{rrrrccc} -0.4622 & 0 & 0 & 0 & 0 & \cdots & 0 \\ 0.0381 & -0.0518 & 0 & 0 & \vdots & \ddots & \vdots \\ -0.2544 & 0.0203 & -0.0240 & 0 & & & \\ -0.0176 & 0.0194 & -0.0075 & -0.0009 & & & \\ -0.1144 & -0.0070 & 0.0091 & -0.0089 & & & \\ 0.0094 & -0.0110 & 0.0094 & -0.0025 & & & \\ -0.0583 & 0.0035 & -0.0045 & 0.0045 & & & \\ -0.0033 & 0.0057 & -0.0061 & 0.0037 & & & \\ -0.0344 & 0.0033 & -0.0037 & -0.0022 & \vdots & \ddots & \vdots \\ -0.0007 & -0.0013 & 0.0015 & -0.0027 & 0 & \cdots & 0 \end{array}\right],$$

which is not unexpected since $n = 4$. In step 3, we compute the nonzero singular values 0.5460, 0.0609, 0.0249, and 0.0098. The matrices $\widehat{A}$ and $\widehat{C}$ computed in step 5 are

$$\widehat{A} = \begin{bmatrix} 0.5204 & -0.1361 & 0.3199 & 0.5352 \\ 0.0882 & -0.4983 & 0.4848 & -0.1035 \\ 0.0052 & 0.0820 & -0.4810 & 0.7195 \\ -0.0295 & 0.1919 & -0.3546 & -0.2911 \end{bmatrix},$$

$$\widehat{C} = \begin{bmatrix} 0.8460 & 0.2123 & -0.2149 & -0.3233 \\ -0.0721 & 0.8069 & 0.5289 & 0.1046 \end{bmatrix}.$$

In step 6, we compute $\widehat{\mathcal{G}} \in \mathbf{R}^{18\times 3}$ and $\widehat{\mathcal{Y}} \in \mathbf{R}^{18\times 6}$ matrices, and the solution of the least-squares problem is

$$\widehat{B} = \begin{bmatrix} 1.0502 & -0.5390 & -0.0816 \\ 2.8626 & 1.8321 & 0.9041 \\ -0.1545 & 1.0984 & 0.4896 \\ -1.4555 & -0.9375 & 0.0547 \end{bmatrix},$$

$$\widehat{D} = \begin{bmatrix} 1.0000 & -1.0000 & -0.0000 \\ -0.0000 & 1.0000 & 1.0000 \end{bmatrix}.$$

The realization $(\widehat{A}, \widehat{B}, \widehat{C}, \widehat{D})$ is similar to $(A, B, C, D)$. In fact, the estimates of the interpolation data computed from the former has a maximum error $5.9746 \times 10^{-14}$.

**5. Conclusions.** In this paper, we presented a new algorithm for the Lagrange–Sylvester interpolation of rational matrix functions that are analytic at infinity. This algorithm is related to the recent frequency domain subspace-based identification methods and is not sensitive to inaccuracies in data. A necessary and sufficient condition for the existence and the uniqueness of a minimal interpolant was formulated in terms of the total multiplicity of the interpolation nodes. The purpose of this contribution was to pinpoint the kinship between the frequency domain subspace-based identification of stable linear systems and the minimal rational interpolation of stable systems.

# ITERATIVE SOLUTION OF A NONSYMMETRIC ALGEBRAIC RICCATI EQUATION*

CHUN-HUA GUO† AND NICHOLAS J. HIGHAM‡

**Abstract.** We study the nonsymmetric algebraic Riccati equation whose four coefficient matrices are the blocks of a nonsingular $M$-matrix or an irreducible singular $M$-matrix $M$. The solution of practical interest is the minimal nonnegative solution. We show that Newton's method with zero initial guess can be used to find this solution without any further assumptions. We also present a qualitative perturbation analysis for the minimal solution, which is instructive in designing algorithms for finding more accurate approximations. For the most practically important case, in which $M$ is an irreducible singular $M$-matrix with zero row sums, the minimal solution is either stochastic or substochastic and the Riccati equation can be transformed into a unilateral matrix equation by a procedure of Ramaswami. The minimal solution of the Riccati equation can then be found by computing the minimal nonnegative solution of the unilateral equation using the Latouche–Ramaswami algorithm. When the minimal solution of the Riccati equation is stochastic, we show that the Latouche–Ramaswami algorithm, combined with a shift technique suggested by He, Meini, and Rhee, is breakdown-free and is able to find the minimal solution more efficiently and more accurately than the algorithm without a shift. When the minimal solution of the Riccati equation is substochastic, we show how the substochastic minimal solution can be found by computing the stochastic minimal solution of a related Riccati equation of the same type.

## 1. Introduction.

We consider the nonsymmetric algebraic Riccati equation (or NARE)

$$\mathcal{R}(X) = XCX - XD - AX + B = 0, \tag{1.1}$$

where $A, B, C, D$ are real matrices of sizes $m \times m, m \times n, n \times m, n \times n$, respectively, and we assume throughout that

$$M = \begin{bmatrix} D & -C \\ -B & A \end{bmatrix} \tag{1.2}$$

is a nonsingular $M$-matrix or an irreducible singular $M$-matrix. Some relevant definitions are as follows. For any matrices $A, B \in \mathbb{R}^{m\times n}$, we write $A \geq B$ ($A > B$) if $a_{ij} \geq b_{ij} (a_{ij} > b_{ij})$ for all $i, j$. A real square matrix $A$ is called a $Z$-matrix if all its off-diagonal elements are nonpositive. It is clear that any $Z$-matrix $A$ can be written as $sI - B$ with $B \geq 0$. A $Z$-matrix $A$ is called an $M$-matrix if $s \geq \rho(B)$, where $\rho(\cdot)$ is the spectral radius; it is a singular $M$-matrix if $s = \rho(B)$ and a nonsingular $M$-matrix if $s > \rho(B)$.

The NARE (1.1) has applications in transport theory and Markov models [20, 27, 28]. The solution of practical interest is the minimal nonnegative solution. The equation has attracted much attention recently [1, 4, 10, 11, 14, 16, 17, 18, 21, 24, 26].

For application to Markov models, the case of primary interest is the one where $M$ is an irreducible singular $M$-matrix with zero row sums. When $M$ is an irreducible singular $M$-matrix, we have $M = \rho(N)I - N$ for some irreducible nonnegative matrix $N$. Thus, by applying the Perron–Frobenius theorem to $N$, there are positive vectors $u_1, v_1 \in \mathbb{R}^n$ and $u_2, v_2 \in \mathbb{R}^m$ such that

$$M(v_1^T \;\, v_2^T)^T = 0, \quad (u_1^T \;\, u_2^T)M = 0, \tag{1.3}$$

and the vectors $(v_1^T \;\, v_2^T)$ and $(u_1^T \;\, u_2^T)$ are each unique up to a scalar multiple.

Since $M$ is a nonsingular $M$-matrix or an irreducible singular $M$-matrix, we have $B, C \geq 0$, and $A$ and $D$ are nonsingular $M$-matrices (see [10], for example). Therefore, the matrix $I \otimes A + D^T \otimes I$ is also a nonsingular $M$-matrix, where $\otimes$ is the Kronecker product. Some properties of the NARE (1.1) are summarized below. See [10, 11, 13] for more details.

THEOREM 1.1. [illegible] $M$ [illegible] $M$[illegible] [illegible] [illegible] $M$[illegible] [illegible] (1.1) [illegible] $S$[illegible] $M$ [illegible] $S > 0$ [illegible] $A - SC$ [illegible] $D - CS$ [illegible] $M$[illegible] [illegible] $M$ [illegible] $M$[illegible] [illegible] $A - SC$ [illegible] $D - CS$ [illegible] $M$[illegible] [illegible] $M$ [illegible] $M$[illegible] [illegible] $M$[illegible] [illegible] $u_1^T v_1 \neq u_2^T v_2$ [illegible]

$$M_S = I \otimes (A - SC) + (D - CS)^T \otimes I$$

[illegible] $M$[illegible] [illegible] $M$ [illegible] $M$[illegible] [illegible] $u_1^T v_1 = u_2^T v_2$ [illegible] $M_S$ [illegible] $M$[illegible]

We will also need the dual equation of (1.1):

$$YBY - YA - DY + C = 0. \tag{1.4}$$

This equation has the same type as (1.1): the matrix

$$\begin{bmatrix} A & -B \\ -C & D \end{bmatrix}$$

is a nonsingular $M$-matrix or an irreducible singular $M$-matrix if and only if the matrix $M$ has the same property. The minimal nonnegative solution of (1.4) is denoted by $\widehat{S}$.

A number of numerical methods have been studied for finding the minimal solution $S$, some of which require additional assumptions on the NARE (1.1). In particular, a class of basic fixed-point iterations has been studied in [10] and [16]. The Schur method has been studied in [10] and a modified Schur method is given in [14]. These methods are applicable without further assumptions on (1.1). Newton's method has also been studied in [10] and [16], where convergence of the Newton sequence $\{X_k\}$, with $X_0 = 0$, to the minimal solution $S$ has been established under the additional assumption that

$$B, C \neq 0, \quad (I \otimes A + D^T \otimes I)^{-1}\text{vec}B > 0. \tag{1.5}$$

Here, the vec operator stacks the columns of a matrix into one long vector. When $M$ is irreducible, we have $B, C \neq 0$. However, the condition $(I \otimes A + D^T \otimes I)^{-1}\text{vec}B > 0$

is not guaranteed by the irreducibility of $M$, as is shown in [10]. The question then arises as to whether (1.5) is necessary for the convergence of the Newton iteration. Our first contribution in this paper is a proof of convergence without this additional condition.

When $M$ is an irreducible singular $M$-matrix and $u_1^T v_1 = u_2^T v_2$, the matrix $M_S$ is a singular $M$-matrix. In this case, Newton's method has a singular Jacobian at the solution, and thus we cannot expect to find an accurate solution by the Newton iteration in finite precision arithmetic. A modified Schur method has been proposed in [14] to find a more accurate solution when $u_1^T v_1 \approx u_2^T v_2$. Another approach is to transform the bilateral equation (1.1) into a unilateral equation and use methods based on cyclic reduction, including the Latouche–Ramaswami (LR) algorithm [23], in combination with a shift technique proposed in [19].

The design of numerical methods for finding the minimal solution with higher accuracy is related to the perturbation behavior of the minimal solution. The minimal solution $S$ is a function of $M$ in (1.2). If the matrix $M$ is perturbed to $\widetilde{M}$, which is always assumed to be again a nonsingular $M$-matrix or an irreducible singular $M$-matrix, and $\widetilde{S}$ is the new minimal solution, we would like to know the relation between $\|\widetilde{S} - S\|$ and $\|\widetilde{M} - M\|$, where $\|\cdot\|$ is any matrix norm. Our second contribution is to prove the following.

- If $M$ is a nonsingular $M$-matrix or an irreducible singular $M$-matrix with $u_1^T v_1 \neq u_2^T v_2$, then there exist constants $\gamma > 0$ and $\epsilon > 0$ such that $\|\widetilde{S} - S\| \leq \gamma \|\widetilde{M} - M\|$ for all $\widetilde{M}$ with $\|\widetilde{M} - M\| < \epsilon$.
- If $M$ is an irreducible singular $M$-matrix with $u_1^T v_1 = u_2^T v_2$, then there exist constants $\gamma > 0$ and $\epsilon > 0$ such that
  - (a) $\|\widetilde{S} - S\| \leq \gamma \|\widetilde{M} - M\|^{1/2}$ for all $\widetilde{M}$ with $\|\widetilde{M} - M\| < \epsilon$;
  - (b) $\|\widetilde{S} - S\| \leq \gamma \|\widetilde{M} - M\|$ for all singular $\widetilde{M}$ with $\|\widetilde{M} - M\| < \epsilon$.

This result tells us that to achieve high accuracy for $S$ when $M$ is an irreducible singular $M$-matrix with $u_1^T v_1 \approx u_2^T v_2$, it is necessary to use the singularity of $M$ in the design of algorithms. Otherwise, we can only expect to achieve an accuracy of $O(\epsilon_m^{1/2})$, where $\epsilon_m$ is the machine epsilon. The modified Schur method in [14] and the methods using a shift technique in [4] and [14] all use the singularity of $M$. However, the use of the shift technique creates a new problem: it is not clear whether the resulting algorithm may break down, although quadratic convergence is guaranteed if no breakdown occurs. Our third contribution is to show that the (simplified) LR algorithm with a shift technique, presented in [14], is breakdown-free.

## 2. Convergence of Newton's method.

The Riccati function $\mathcal{R}$ is a mapping from $\mathbb{R}^{m\times n}$ into itself. The Fréchet derivative of $\mathcal{R}$ at a matrix $X$ is a linear map $\mathcal{R}'_X : \mathbb{R}^{m\times n} \to \mathbb{R}^{m\times n}$ given by

$$\mathcal{R}'_X(Z) = -\big((A - XC)Z + Z(D - CX)\big). \tag{2.1}$$

The Newton method for the solution of (1.1) is

$$X_{i+1} = X_i - (\mathcal{R}'_{X_i})^{-1}\mathcal{R}(X_i), \quad i = 0, 1, \ldots, \tag{2.2}$$

where the maps $\mathcal{R}'_{X_i}$ all need to be nonsingular. In view of (2.1), the iteration (2.2) is equivalent to

$$(A - X_i C)X_{i+1} + X_{i+1}(D - CX_i) = B - X_i C X_i, \quad i = 0, 1, \ldots . \tag{2.3}$$

We will need the following well-known result (see [2], for example).

THEOREM 2.1. [illegible] $Z$ [illegible] $A$ [illegible]

(a) $A$ [illegible] $M$ [illegible]

(b) $A^{-1} \geq 0$

(c) $Av > 0$ [illegible] $v > 0$

(d) [illegible] $A$ [illegible]

The equivalence of (a) and (c) in Theorem 2.1 implies the next result.

LEMMA 2.2. [illegible] $A$ [illegible] $M$ [illegible] $B \geq A$ [illegible] $Z$ [illegible] $B$ [illegible] $M$ [illegible]

We can now give a proof of convergence of the Newton iteration that does not require the assumption (1.5) made in [10].

THEOREM 2.3. [illegible] $S$ [illegible] (1.1) [illegible] (2.3) [illegible] $X_0 = 0$ [illegible] $\{X_i\}$ [illegible] $X_k \leq X_{k+1} \leq S$ [illegible] $k \geq 0$ [illegible] $\lim_{i\to\infty} X_i = S$

[illegible] Throughout the proof, we use the notation

$$M_X = I \otimes (A - XC) + (D - CX)^T \otimes I$$

for a given matrix $X$ (this notation is consistent with the notation $M_S$ already used in Theorem 1.1). Since $S$ is a solution of (1.1),

$$SCS - SD - AS + B = 0. \tag{2.4}$$

For the Newton iteration (2.3) with $X_0 = 0$, we have $AX_1 + X_1D = B$, which is equivalent to

$$(I \otimes A + D^T \otimes I)\mathrm{vec}X_1 = \mathrm{vec}B. \tag{2.5}$$

Since $I \otimes A + D^T \otimes I$ is a nonsingular $M$-matrix, Theorem 2.1(b) and (2.5) imply $\mathrm{vec}X_1 \geq 0$, i.e., $X_1 \geq 0$.

We first assume that $M$ is a nonsingular $M$-matrix, and we will prove by induction that

$$X_k \leq X_{k+1}, \quad X_k \leq S, \quad M_{X_k} \text{ is a nonsingular } M\text{-matrix} \tag{2.6}$$

for $k \geq 0$. It is clear that (2.6) is true for $k = 0$. We now assume that (2.6) is true for $k = i \geq 0$. By (2.3) and (2.4) we have

$$\begin{aligned}(A - X_iC)(X_{i+1} - S) + (X_{i+1} - S)(D - CX_i) \\ &= B - X_iCX_i - AS + X_iCS - SD + SCX_i \\ &= -(S - X_i)C(S - X_i).\end{aligned} \tag{2.7}$$

Since $X_i \leq S$ and $M_{X_i}$ is a nonsingular $M$-matrix, it follows from Theorem 2.1(b) and (2.7) that $X_{i+1} \leq S$. Since $M_S$ is a nonsingular $M$-matrix by Theorem 1.1, it follows from Lemma 2.2 that $M_{X_{i+1}}$ is a nonsingular $M$-matrix. By (2.3),

$$\begin{aligned}&(A - X_{i+1}C)X_{i+1} + X_{i+1}(D - CX_{i+1}) \\ &= \big(A - X_iC - (X_{i+1} - X_i)C\big)X_{i+1} + X_{i+1}\big(D - CX_i - C(X_{i+1} - X_i)\big) \\ &= B - X_iCX_i - (X_{i+1} - X_i)CX_{i+1} - (X_i + X_{i+1} - X_i)C(X_{i+1} - X_i) \\ &= B - X_{i+1}CX_{i+1} - (X_{i+1} - X_i)C(X_{i+1} - X_i).\end{aligned} \tag{2.8}$$

By (2.8) and (2.3),

$$\begin{aligned}&(A - X_{i+1}C)(X_{i+1} - X_{i+2}) + (X_{i+1} - X_{i+2})(D - CX_{i+1})\\ &\qquad = -(X_{i+1} - X_i)C(X_{i+1} - X_i) \le 0.\end{aligned}$$

Therefore, $X_{i+1} \le X_{i+2}$. We have thus proved that (2.6) is true for $k = i + 1$. Hence (2.6) is true for all $k \ge 0$ by induction.

We now assume that $M$ is an irreducible singular $M$-matrix. Then $S > 0$ by Theorem 1.1. Thus, the statement

$$X_k \le X_{k+1}, \quad X_k < S, \quad M_{X_k} \text{ is a nonsingular } M\text{-matrix} \tag{2.9}$$

is true for $k = 0$. Assume that (2.9) is true for $k = i \ge 0$. Then, by (2.7) we get $X_{i+1} < S$. It follows from (2.8) and (2.4) that

$$\begin{aligned}&(A - X_{i+1}C)(X_{i+1} - S) + (X_{i+1} - S)(D - CX_{i+1})\\ &\qquad = -(X_{i+1} - X_i)C(X_{i+1} - X_i) - (X_{i+1} - S)C(X_{i+1} - S) < 0.\end{aligned}$$

Therefore, $M_{X_{i+1}}\mathrm{vec}(S - X_{i+1}) > 0$. Thus $M_{X_{i+1}}$ is a nonsingular $M$-matrix by Theorem 2.1(c). It follows as before that $X_{i+1} \le X_{i+2}$. So (2.9) is true for $k = i + 1$, and hence for all $k \ge 0$ by induction.

Therefore, in both cases, the Newton sequence $X_k$ is well defined, monotonically increasing, and bounded above by $S$. Let $\lim_{k\to\infty} X_k = X_*$. Then $X_*$ is a nonnegative solution of (1.1) by (2.3). Since $X_* \le S$ and $S$ is minimal, we have $X_* = S$. ☐

**3. Perturbation analysis for the minimal solution.** In this section we are interested in a qualitative description of the perturbation of the minimal nonnegative solution $S$ of (1.1) as a function of $M$. The perturbation analysis of the minimal solution will be carried out through the perturbation analysis of a proper invariant subspace of the matrix

$$L = \begin{bmatrix} D & -C \\ B & -A \end{bmatrix} = \begin{bmatrix} I & 0 \\ 0 & -I \end{bmatrix} M. \tag{3.1}$$

Let all eigenvalues of $L$ be arranged in descending order of their real parts and be denoted by $\lambda_1, \ldots, \lambda_n, \lambda_{n+1}, \ldots, \lambda_{n+m}$. Then (see [10])

$$\sigma(D - CS) = \{\lambda_1, \ldots, \lambda_n\}$$

and

$$\sigma(A - SC) = \sigma(A - B\widehat{S}) = \{-\lambda_{n+1}, \ldots, -\lambda_{n+m}\}, \tag{3.2}$$

where $\widehat{S}$ is the minimal nonnegative solution of the dual equation (1.4). If $M$ is a nonsingular $M$-matrix, then $\lambda_1, \ldots, \lambda_n \in \mathbb{C}^+$ (the open right half plane) and $\lambda_{n+1}, \ldots, \lambda_{n+m} \in \mathbb{C}^-$ (the open left half plane). If $M$ is an irreducible singular $M$-matrix, then $\lambda_1, \ldots, \lambda_{n-1} \in \mathbb{C}^+$, $\lambda_{n+2}, \ldots, \lambda_{n+m} \in \mathbb{C}^-$. Moreover,

- if $u_1^T v_1 > u_2^T v_2$, then $\lambda_n = 0$ and $\lambda_{n+1} < 0$ are simple eigenvalues;
- if $u_1^T v_1 < u_2^T v_2$, then $\lambda_n > 0$ and $\lambda_{n+1} = 0$ are simple eigenvalues;
- if $u_1^T v_1 = u_2^T v_2$, then $\lambda_n = \lambda_{n+1} = 0$ is a double eigenvalue with only one linearly independent eigenvector.

Therefore, in all cases, there is a unique invariant subspace of $L$ corresponding to the eigenvalues $\lambda_1, \ldots, \lambda_n$. Let the invariant subspace be Im $[U_1^T\ U_2^T]^T$, where $U_1 \in \mathbb{C}^{n\times n}$, $U_2 \in \mathbb{C}^{m\times n}$ and Im $U$ denotes the image (or range) of the matrix $U$. Then $U_1$ is nonsingular and $S = U_2U_1^{-1}$ (see [10]).

When $M$ is an irreducible $M$-matrix, the matrices $D - CS$ and $A - SC$ are also irreducible $M$-matrices by Theorem 1.1. Since $A - SC$ and $(D - CS)^T$ can be written in the form $sI - N$, where $N \geq 0$ is irreducible, it follows from the Perron–Frobenius theorem that there exist unique positive vectors $a$ and $b$ with unit 1-norm such that

$$(A - SC)a = -\lambda_{n+1}a, \quad b^T(D - CS) = \lambda_n b^T. \tag{3.3}$$

Since $M$ is irreducible, we have $C \neq 0$ and thus $b^TCa > 0$. We will need the following result [7] in the perturbation analysis below.

THEOREM 3.1. [illegible] $M$ [illegible] $M$ [illegible] $M$ [illegible] $u_1^Tv_1 \neq u_2^Tv_2$ [illegible] $S_+$ [illegible] (1.1) [illegible]

$$S_+ = S + \delta ab^T, \tag{3.4}$$

[illegible] $a, b$ [illegible] (3.3) [illegible] $\delta = (\lambda_n - \lambda_{n+1})/b^TCa$ [illegible]

$$\sigma(D - CS_+) = \{\lambda_1, \ldots, \lambda_{n-1}, \lambda_{n+1}\}. \tag{3.5}$$

Let $\mathcal{M}$ and $\mathcal{N}$ be any invariant subspaces of $L$. For any fixed norm $\|\cdot\|$ (for definiteness we use the spectral norm), let $\theta(\mathcal{M}, \mathcal{N})$ be the gap between $\mathcal{M}$ and $\mathcal{N}$, defined by

$$\theta(\mathcal{M}, \mathcal{N}) = \|P_{\mathcal{M}} - P_{\mathcal{N}}\|,$$

where $P_M$ and $P_{\mathcal{N}}$ are the orthogonal projectors on $\mathcal{M}$ and $\mathcal{N}$, respectively, with orthogonality defined by the standard scalar product on $\mathbb{C}^{m+n}$. See [8] or [22] for properties of the gap metric.

We first consider the case where $M$ is a nonsingular $M$-matrix or an irreducible singular $M$-matrix with $u_1^Tv_1 \neq u_2^Tv_2$. In this case, since the eigenvalues $\lambda_1, \ldots, \lambda_n$ are disjoint from the eigenvalues $\lambda_{n+1}, \ldots, \lambda_{n+m}$, the invariant subspace corresponding to the eigenvalues $\lambda_1, \ldots, \lambda_n$,

$$\mathcal{M} = \text{Im}\begin{bmatrix} U_1 \\ U_2 \end{bmatrix} = \text{Im}\begin{bmatrix} I \\ S \end{bmatrix},$$

is known to be Lipschitz stable [8], i.e., there exist constants $\gamma_1, \epsilon > 0$ such that every matrix $K$ satisfying $\|K - L\| < \epsilon$ has an invariant subspace $\mathcal{N}$ for which $\theta(\mathcal{M}, \mathcal{N}) \leq \gamma_1\|K - L\|$. In particular, every $\widetilde{L} = \text{diag}(I, -I)\widetilde{M}$ with $\|\widetilde{L} - L\| < \epsilon$ has an invariant subspace $\mathcal{N}$ for which $\theta(\mathcal{M}, \mathcal{N}) \leq \gamma_1\|\widetilde{L} - L\|$. Let $\mathcal{N} = \text{Im}[V_1^T\ V_2^T]^T$. Then for $\epsilon$ small enough, $V_1$ is nonsingular and we let $T = V_2V_1^{-1}$. Then for $\|\widetilde{M} - M\| = \|\widetilde{L} - L\| < \epsilon$

$$\theta\left(\text{Im}\begin{bmatrix} I \\ S \end{bmatrix}, \text{Im}\begin{bmatrix} I \\ T \end{bmatrix}\right) \leq \gamma_1\|\widetilde{M} - M\|.$$

Note that there is a constant $\gamma_2 > 0$ such that [8]

$$\gamma_2^{-1}\|T - S\| \leq \theta\left(\text{Im}\begin{bmatrix} I \\ S \end{bmatrix}, \text{Im}\begin{bmatrix} I \\ T \end{bmatrix}\right) \leq \gamma_2\|T - S\|.$$

Thus

$$\|T - S\| \le \gamma_1\gamma_2\|\widetilde{M} - M\|.$$

For $\epsilon$ small enough, we know that the eigenvalues of $\widetilde{D} - \widetilde{C}T$ are individually close to the eigenvalues of $D - CS$, and hence they are the $n$ eigenvalues of $\widetilde{L}$ with the largest real parts. It follows that $T = \widetilde{S}$, the minimal nonnegative solution of (1.1) with $M$ replaced by $\widetilde{M}$.

We have thus proved the following result.

THEOREM 3.2. [illegible] $M$ [illegible] $M$ [illegible] $M$ [illegible] $u_1^T v_1 \neq u_2^T v_2$ [illegible] $\gamma > 0$ [illegible] $\epsilon > 0$ [illegible] $\|\widetilde{S} - S\| \le \gamma\|\widetilde{M} - M\|$ [illegible] $\widetilde{M}$ [illegible] $\|\widetilde{M} - M\| < \epsilon$

We now consider the case where $M$ is an irreducible singular $M$-matrix with $u_1^T v_1 = u_2^T v_2$. Let $q_1, q_2, \ldots, q_{n-1}$ be the eigenvectors and generalized eigenvectors corresponding to the eigenvalues $\lambda_1, \ldots, \lambda_{n-1}$ and let $v$ be the eigenvector corresponding to the zero eigenvalue. Now,

$$\mathrm{Im}\begin{bmatrix} I \\ S \end{bmatrix} = \mathrm{Im}[q_1\ q_2\ \ldots\ q_{n-1}] \dotplus \mathrm{Im}[v].$$

As in the previous case, there exist constants $\gamma_1, \epsilon > 0$ such that for any $\widetilde{M}$ with $\|\widetilde{M} - M\| < \epsilon$, $\widetilde{L}$ has an invariant subspace $\mathcal{N}_1$ for which

$$\theta(\mathrm{Im}[q_1\ q_2\ \ldots\ q_{n-1}], \mathcal{N}_1) \le \gamma_1\|\widetilde{M} - M\|.$$

We assume that $\epsilon$ is small enough such that the eigenvalues of $\widetilde{L}$ corresponding to $\mathcal{N}_1$ are the $n-1$ eigenvalues of $\widetilde{L}$ with the largest real parts. Note that when $\widetilde{M}$ is close enough to $M$, $\widetilde{M}$ is also irreducible. We consider two cases: (a) $\widetilde{M}$ is nonsingular and (b) $\widetilde{M}$ is singular.

For case (a), $\widetilde{L}$ has an eigenvalue $\widetilde{\lambda}_n > 0$ that is a perturbation of the zero eigenvalue (with index two) of $L$. The eigenvector $\widetilde{v}$ corresponding to $\widetilde{\lambda}_n$ is such that

$$\theta(\mathrm{Im}[v], \mathrm{Im}[\widetilde{v}]) \le \gamma_2\|\widetilde{M} - M\|^{1/2}$$

for some $\gamma_2 > 0$ (see section 16.5 of [8] or section 5 of [9]). Now, there are constants $\gamma_3, \gamma_4 > 0$ such that [8]

$$\begin{aligned}
&\theta(\mathrm{Im}[q_1\ q_2\ \ldots\ q_{n-1}] \dotplus \mathrm{Im}[v], \mathcal{N}_1 \dotplus \mathrm{Im}[\widetilde{v}]) \\
&\quad \le \gamma_3[\theta(\mathrm{Im}[q_1\ q_2\ \ldots\ q_{n-1}], \mathcal{N}_1) + \theta(\mathrm{Im}[v], \mathrm{Im}[\widetilde{v}])] \\
&\quad \le \gamma_4\|\widetilde{M} - M\|^{1/2}.
\end{aligned}$$

It then follows as before that $\|\widetilde{S} - S\| \le \gamma\|\widetilde{M} - M\|^{1/2}$ for some $\gamma > 0$.

For case (b), let $\widetilde{v}$ be the eigenvector corresponding to the zero eigenvalue of $\widetilde{L}$. Then $v$ and $\widetilde{v}$ are also eigenvectors of $M$ and $\widetilde{M}$ corresponding to its simple zero eigenvalue. It is known that

$$\theta(\mathrm{Im}[v], \mathrm{Im}[\widetilde{v}]) \le \gamma_2\|\widetilde{M} - M\|$$

for some $\gamma_2 > 0$. If $0 = \widetilde{\lambda}_n \geq \widetilde{\lambda}_{n+1}$ then as before $\|\widetilde{S} - S\| \leq \gamma \|\widetilde{M} - M\|$ for some $\gamma > 0$. If $0 = \widetilde{\lambda}_{n+1} < \widetilde{\lambda}_n$ then we use Theorem 3.1 with $M$ replaced by $\widetilde{M}$ (so accordingly we have $\widetilde{S}, \widetilde{S}_+, \widetilde{a}, \widetilde{b}$, etc.) to get

$$\|\widetilde{S}_+ - S\| \leq \gamma_3 \|\widetilde{M} - M\|$$

for some $\gamma_3 > 0$. Note that $\|\widetilde{S}_+ - \widetilde{S}\| \leq \|\widetilde{\delta}\ \widetilde{a}\ \widetilde{b}^T\| \leq \gamma_4 |\widetilde{\lambda}_n|$ for some $\gamma_4 > 0$. The eigenvalues of $\widetilde{A} - \widetilde{S}_+\widetilde{C}$ are $-\widetilde{\lambda}_n, -\widetilde{\lambda}_{n+2}, \ldots, -\widetilde{\lambda}_{n+m}$. The simple eigenvalue $-\widetilde{\lambda}_n$ of $\widetilde{A} - \widetilde{S}_+\widetilde{C}$ is a perturbation of the simple eigenvalue $-\lambda_{n+1} = 0$ of $A - SC$. Thus $|\widetilde{\lambda}_n| \leq \gamma_5 \|(\widetilde{A} - \widetilde{S}_+\widetilde{C}) - (A - SC)\| \leq \gamma_6 \|\widetilde{M} - M\|$ for some $\gamma_5, \gamma_6 > 0$. Therefore $\|\widetilde{S} - S\| \leq \|\widetilde{S}_+ - S\| + \|\widetilde{S}_+ - \widetilde{S}\| \leq \gamma \|\widetilde{M} - M\|$ for some $\gamma > 0$.

In summary, we have shown the following.

THEOREM 3.3. [illegible] $M$ [illegible] $M$ [illegible] $u_1^T v_1 = u_2^T v_2$ [illegible] $\gamma > 0$ [illegible] $\epsilon > 0$ [illegible]

(a) $\|\widetilde{S} - S\| \leq \gamma \|\widetilde{M} - M\|^{1/2}$ [illegible] $\widetilde{M}$ [illegible] $\|\widetilde{M} - M\| < \epsilon$.

(b) $\|\widetilde{S} - S\| \leq \gamma \|\widetilde{M} - M\|$ [illegible] singular $\widetilde{M}$ [illegible] $\|\widetilde{M} - M\| < \epsilon$

We illustrate the results in Theorem 3.3 with a simple example.

Consider the matrix

$$M = \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix}$$

and its three different perturbations

$$M_1 = \begin{bmatrix} 1+\epsilon & -1 \\ -1 & 1 \end{bmatrix}, \quad M_2 = \begin{bmatrix} 1 & -(1+\epsilon) \\ -1 & 1+\epsilon \end{bmatrix}, \quad M_3 = \begin{bmatrix} 1 & -1 \\ -(1+\epsilon) & 1 \end{bmatrix},$$

where $0 < \epsilon < 1$. Note that $M$ satisfies the condition in Theorem 3.3, and that $S = 1$ for the corresponding NARE (1.1). $M_1$ is a nonsingular $M$-matrix and the corresponding minimal solution is $S_1 = \frac{1}{2}(2 + \epsilon - \sqrt{4\epsilon + \epsilon^2}) \sim 1 - \epsilon^{1/2}$, which is the situation in Theorem 3.3(a). $M_2$ is an irreducible singular $M$-matrix and the corresponding minimal solution is $S_2 = 1/(1+\epsilon) \sim 1 - \epsilon$, which is the situation in Theorem 3.3(b). $M_3$ is not an $M$-matrix and the corresponding NARE does not have real solutions.

The continuity of the minimal solution shown in Theorem 3.3 can be used to prove the next result, where the statements are stronger than those given in [10, Thm. 4.8]. The result will be needed in section 4.

THEOREM 3.4. [illegible] $M$ [illegible] $M$ [illegible]

(a) [illegible] $u_1^T v_1 = u_2^T v_2$ [illegible] $Sv_1 = v_2$ [illegible] $\widehat{S}v_2 = v_1$

(b) [illegible] $u_1^T v_1 > u_2^T v_2$ [illegible] $Sv_1 = v_2$ [illegible] $\widehat{S}v_2 < v_1$

(c) [illegible] $u_1^T v_1 < u_2^T v_2$ [illegible] $Sv_1 < v_2$ [illegible] $\widehat{S}v_2 = v_1$

[illegible] We only need to prove the result for $S$ since the result for $\widehat{S}$ follows immediately by duality. So we need to show $Sv_1 = v_2$ when $u_1^T v_1 \geq u_2^T v_2$ and $Sv_1 < v_2$ when $u_1^T v_1 < u_2^T v_2$. In fact,

$$\begin{aligned}(A - SC)(v_2 - Sv_1) &= Av_2 - SCv_2 + (SCS - AS)v_1 \\ &= Bv_1 - SDv_1 + (SD - B)v_1 = 0.\end{aligned}$$

If $u_1^T v_1 > u_2^T v_2$, then $A - SC$ is nonsingular and so $Sv_1 = v_2$. If $u_1^T v_1 < u_2^T v_2$, then $A - SC$ is an irreducible singular $M$-matrix and $v_2 - Sv_1 \geq 0$ is an eigenvector corresponding to the zero eigenvalue (it is already proved in [10] that $Sv_1 \le v_2$ and $Sv_1 \ne v_2$). By the Perron–Frobenius theorem, $v_2 - Sv_1 > 0$ and so $Sv_1 < v_2$. If $u_1^T v_1 = u_2^T v_2$, then for

$$M(\alpha) = \begin{bmatrix} D & -C \\ -\alpha B & \alpha A \end{bmatrix}$$

with $\alpha > 1$, we have

$$u_1(\alpha) = u_1, \quad u_2(\alpha) = \alpha^{-1} u_2, \quad v_1(\alpha) = v_1, \quad v_2(\alpha) = v_2.$$

So we have $u_1(\alpha)^T v_1(\alpha) > u_2(\alpha)^T v_2(\alpha)$. It follows that $S(\alpha)v_1(\alpha) = v_2(\alpha)$. However, $\lim_{\alpha\to 1^+} S(\alpha) = S$ by Theorem 3.3 and so $Sv_1 = v_2$. ☐

## 4. Applicability of the shifted LR algorithm.

In this section we assume that $M$ is an irreducible singular $M$-matrix. For the NARE (1.1) arising in the study of Markov models, we have $Me = 0$, where $e$ is the vector of ones. In that case, we may take $v_1 = e \in \mathbb{R}^n$ and $v_2 = e \in \mathbb{R}^m$ in (1.3).

If $M$ is a general irreducible singular $M$-matrix, we can transform (1.1) into a new equation for which $v_1 = e$ and $v_2 = e$. More precisely, (1.1) can be rewritten as

$$W(V_1^{-1}CV_2)W - W(V_1^{-1}DV_1) - (V_2^{-1}AV_2)W + V_2^{-1}BV_1 = 0 \tag{4.1}$$

with $V_1 = \operatorname{diag}(v_1)$, $V_2 = \operatorname{diag}(v_2)$, and $W = V_2^{-1}XV_1$. Note that the minimal nonnegative solution of (4.1) is $\overline{S} = V_2^{-1}SV_1$ and that

$$\begin{bmatrix} V_1^{-1}DV_1 & -V_1^{-1}CV_2 \\ -V_2^{-1}BV_1 & V_2^{-1}AV_2 \end{bmatrix} \begin{bmatrix} e \\ e \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}. \tag{4.2}$$

It is clear that the leftmost matrix in (4.2) is still an irreducible singular $M$-matrix. From now on, we assume that $M$ is an irreducible singular $M$-matrix with $Me = 0$.

Ramaswami [26] made the interesting observation that the matrix equation (1.1) is closely related to a quadratic matrix equation arising in quasi-birth-death processes. To see this connection, let

$$a_* = \max_{1\le i\le m} a_{ii}, \quad d_* = \max_{1\le i\le n} d_{ii}, \quad \theta_* = \max(a_*, d_*). \tag{4.3}$$

Choose a number $\theta \ge \theta_*$ and let $P = I - \frac{1}{\theta}M$. Then $P$ is nonnegative with $Pe = e$, i.e., $P$ is a stochastic matrix. Let

$$P = \begin{bmatrix} P_{11} & P_{12} \\ P_{21} & P_{22} \end{bmatrix},$$

where the partitioning is conformable with that for the matrix $M$. Thus

$$P_{11} = I - \frac{1}{\theta}D, \quad P_{12} = \frac{1}{\theta}C, \quad P_{21} = \frac{1}{\theta}B, \quad P_{22} = I - \frac{1}{\theta}A. \tag{4.4}$$

Ramaswami [26] constructed three nonnegative matrices from $P$:

$$A_0 = \begin{bmatrix} P_{11} & 0 \\ \frac{1}{2}P_{21} & 0 \end{bmatrix}, \quad A_1 = \begin{bmatrix} 0 & P_{12} \\ 0 & \frac{1}{2}P_{22} \end{bmatrix}, \quad A_2 = \begin{bmatrix} 0 & 0 \\ 0 & \frac{1}{2}I \end{bmatrix}. \tag{4.5}$$

Associated with the matrices $A_0, A_1, A_2$ are the matrix equation

$$G = A_0 + A_1 G + A_2 G^2 \tag{4.6}$$

and its dual equation

$$F = A_2 + A_1 F + A_0 F^2. \tag{4.7}$$

We let $G$ and $F$ be the minimal nonnegative solutions of (4.6) and (4.7), respectively.

The next two results are known (see [26, Thm. 4.1] and [14]).

Proposition 4.1. [illegible] (4.6) [illegible]

$$G = \begin{bmatrix} P_{11} + P_{12}S & 0 \\ S & 0 \end{bmatrix},$$

[illegible] $S$ [illegible] (1.1)

Proposition 4.2. [illegible] (4.7) [illegible]

$$F = \begin{bmatrix} 0 & \widehat{S} \\ 0 & (2I - P_{22} - P_{21}\widehat{S})^{-1} \end{bmatrix},$$

[illegible] $\widehat{S}$ [illegible] (1.4)

Since $(2I - P_{22} - P_{21}\widehat{S})^{-1} = (I + \frac{1}{\theta}(A - B\widehat{S}))^{-1}$ is a nonnegative matrix, $\rho(F) = \rho((2I - P_{22} - P_{21}\widehat{S})^{-1})$ is the largest positive eigenvalue of $(I + \frac{1}{\theta}(A - B\widehat{S}))^{-1}$, which is $1/(1 - \frac{1}{\theta}\lambda_{n+1})$. Similarly, $\rho(G) = \rho(P_{11} + P_{12}S) = \rho(I - \frac{1}{\theta}(D - CS)) = 1 - \frac{1}{\theta}\lambda_n$.

The solution $G$ can be computed by the LR algorithm [23], which is essentially the cyclic reduction algorithm combined with block-diagonal scaling (see [12]).

Algorithm 4.3. [illegible]

$$L^{(0)} = (I - A_1)^{-1} A_0,$$
$$H^{(0)} = (I - A_1)^{-1} A_2,$$
$$G^{(0)} = L^{(0)},$$
$$T^{(0)} = H^{(0)}.$$

[illegible] $k = 0, 1, \ldots$ [illegible]

$$U^{(k)} = H^{(k)} L^{(k)} + L^{(k)} H^{(k)},$$
$$L^{(k+1)} = (I - U^{(k)})^{-1} (L^{(k)})^2,$$
$$H^{(k+1)} = (I - U^{(k)})^{-1} (H^{(k)})^2,$$
$$G^{(k+1)} = G^{(k)} + T^{(k)} L^{(k+1)},$$
$$T^{(k+1)} = T^{(k)} H^{(k+1)}.$$

It is shown in [23] that the matrices $H^{(k)}$ and $L^{(k)}$ are well defined and nonnegative and that the sequence $\{G^{(k)}\}$ converges quadratically to the matrix $G$, except for a critical case which corresponds to the case $u_1^T e = u_2^T e$ in the NARE (1.1). In the latter case, the convergence is expected to be linear with rate $1/2$ (see [12] and [14]).

When $m = n$, the LR algorithm needs about $\frac{400}{3}n^3$ flops each iteration. Using the special structure of the matrices $A_0, A_1, A_2$, we can simplify the LR algorithm and the simplified algorithm requires about $\frac{124}{3}n^3$ flops each iteration [14]. The simplified LR algorithm is less expensive than Newton's method, which requires roughly $60n^3$ flops each iteration when $m = n$. However, there are examples [1] for which the (simplified) LR algorithm requires many more iterations than Newton's method, even though they both have quadratic convergence.

The matrix $G^{(k)}$ from Algorithm 4.3 has the form

$$G^{(k)} = \begin{bmatrix} G_1^{(k)} & 0 \\ G_2^{(k)} & 0 \end{bmatrix},$$

and the solution $S$ is approximated by the matrices $S_k = G_2^{(k)}$. It is shown in [14] that

$$\limsup_{k\to\infty} \sqrt[2^{k+1}]{\|S_k - S\|} \le \rho(F)\rho(G), \tag{4.8}$$

so $S_k$ converges to $S$ quadratically when $\rho(F)\rho(G) < 1$ and the convergence will be fast if $\rho(F)\rho(G)$ is not close to 1.

Since

$$\rho(F) = 1/\left(1 - \frac{1}{\theta}\lambda_{n+1}\right), \quad \rho(G) = 1 - \frac{1}{\theta}\lambda_n$$

are nondecreasing functions of $\theta$ for $\theta \ge \theta_*$, we should take $\theta = \theta_*$ in (4.4) to have faster convergence for the (simplified) LR algorithm.

Note that when $u_1^T e = u_2^T e$, $Se = e$ and $\widehat{S}e = e$ by Theorem 3.4. So $Fe = Ge = e$, $\rho(F) = \rho(G) = 1$ and the convergence is expected to be linear with rate 1/2. To have faster convergence when $u_1^T e \ge u_2^T e$, we need to use a shift technique [19] for the (simplified) LR algorithm. The case $u_1^T e < u_2^T e$ for the NARE will be reduced to the case $u_1^T e > u_2^T e$ for a new NARE of the same type.

**4.1. Case $u_1^T e \ge u_2^T e$.** In this subsection we assume $u_1^T e \ge u_2^T e$. In this case $Se = e$ and so $G$ is stochastic. It is shown in [14] that the only eigenvalue of $G$ on the unit circle is the simple eigenvalue 1.

The shift technique introduced in [19] is $H = G - ev^T$, where $v > 0$ and $v^T e = 1$. For our purposes here, we only require that $v \ge 0$ and $v^T e = 1$. Then the eigenvalues of $H$ are those of $G$ except that the eigenvalue 1 of $G$ is replaced by 0, and $H$ is a solution of the new equation

$$H = B_0 + B_1 H + B_2 H^2, \tag{4.9}$$

where

$$B_0 = A_0(I - ev^T), \quad B_1 = A_1 + A_2 ev^T, \quad B_2 = A_2. \tag{4.10}$$

It is shown in [14] that there is a matrix $K$ with $\rho(K) = \rho(F)$ such that

$$K = B_2 + B_1 K + B_0 K^2. \tag{4.11}$$

To find the solution $H$ of (4.9), we can apply Algorithm 4.3 with the triple $(A_0, A_1, A_2)$ replaced by the triple $(B_0, B_1, B_2)$. To avoid confusion, we will put a "hat" on each sequence generated. We take

$$v = \begin{bmatrix} p \\ 0 \end{bmatrix}, \tag{4.12}$$

where $p \in \mathbb{R}^n$ is positive and $p^T e = 1$. In this way we can get a simplified LR algorithm as before, with no increase in computational work for each iteration. Note that $S$ is now approximated by $\widehat{S}_k = \widehat{G}_2^{(k)} + ep^T$.

It is shown in [14] that when Algorithm 4.3 is applied with $(A_0, A_1, A_2)$ replaced by $(B_0, B_1, B_2)$, the matrix $I - B_1$ in the initialization step is always invertible. Assuming that $I - \widehat{U}^{(k)}$ is invertible for each $k \geq 0$, it is shown in [14] that

$$\limsup_{k\to\infty} \sqrt[2^{k+1}]{\|\widehat{S}^{(k)} - S\|} \leq \rho(K)\rho(H) = \rho(F)\rho(H) < 1. \tag{4.13}$$

Since $\rho(H) < \rho(G)$, the shift technique has improved the speed of convergence. In particular, $\widehat{S}^{(k)}$ converges to $S$ quadratically whenever $u_1^T e \geq u_2^T e$. It is also shown in [14] that $I - \widehat{U}^{(k)}$ converges to $I$ quadratically, assuming that $I - \widehat{U}^{(k)}$ is nonsingular for all $k \geq 0$.

The problem as to whether the matrices $I - \widehat{U}^{(k)}$ could be singular for small $k$ was unsolved in [14]. We will now solve this problem.

We proceed as in [6] but depart from [6] at some point. Let

$$T_k = \begin{bmatrix} I - A_1 & -A_2 & & \\ -A_0 & I - A_1 & \ddots & \\ & \ddots & \ddots & -A_2 \\ & & -A_0 & I - A_1 \end{bmatrix}$$

and

$$\widehat{T}_k = \begin{bmatrix} I - B_1 & -B_2 & & \\ -B_0 & I - B_1 & \ddots & \\ & \ddots & \ddots & -B_2 \\ & & -B_0 & I - B_1 \end{bmatrix}$$

be block $k \times k$ Toeplitz matrices. Since the LR algorithm is well defined if and only if the cyclic reduction (CR) algorithm is well defined [5], it follows from Theorem 13 of [3] that the matrices $T_{2^j-1}$ are nonsingular for all $j \geq 1$ and that $I - \widehat{U}^{(k)}$ are nonsingular for all $k \geq 0$ if $\widehat{T}_{2^j-1}$ are nonsingular for all $j \geq 2$. The relation between $T_k$ and $\widehat{T}_k$ (for $k \geq 3$) has been obtained in [6] as

$$\widehat{T}_k = T_k \begin{bmatrix} I & & & \\ V & I & & \\ \vdots & \ddots & \ddots & \\ V & \dots & V & I \end{bmatrix} + \begin{bmatrix} 0 \\ \vdots \\ 0 \\ -A_2 \end{bmatrix} \begin{bmatrix} V & V & \dots & V \end{bmatrix}, \tag{4.14}$$

where $V = ev^T$. Note that this relation can be obtained directly from (4.10). Let $Q_k$ and $P_k$ be the $(k, 1)$ block and $(k, k)$ block of $T_k^{-1}$, respectively. From (4.14), it is shown in [6] that $\widehat{T}_k$ is nonsingular if and only if $v^T P_k A_2 e \neq 1$. From the proof of Theorem 9 in [6] we also know that

$$v^T Q_k A_0 e + v^T P_k A_2 e = 1. \tag{4.15}$$

In the case where $v$ is taken to be positive and $u_1^T e > u_2^T e$, it has been shown in [6] that $v^T P_k A_2 e \neq 1$, using, among other things, the canonical factorizations of matrix polynomials and the so-called asymptotic applicability of the SCR (CR with a shift technique). So, the argument in [6] is very involved and it does not cover the case $u_1^T e = u_2^T e$. Suppose SCR were to break down for the case $u_1^T e = u_2^T e$. Then near-breakdown would happen to SCR with $u_1^T e > u_2^T e$, but $u_1^T e \approx u_2^T e$. Moreover, as we mentioned earlier, we need to take the vector $v$ in the form (4.12) to avoid an increase in computational work when using the shift technique. Fortunately, we can prove the applicability of the LR algorithm, with a shift given by (4.12), for all cases with $u_1^T e \geq u_2^T e$ and $\theta > \theta_*$. Moreover, the proof is very simple.

In fact, what we need to prove is $v^T Q_k A_0 e > 0$, which implies $v^T P_k A_2 e \neq 1$ by (4.15). Note that

$$T_k^{-1} \geq \begin{bmatrix} I & & & \\ -A_0 & I & & \\ & \ddots & \ddots & \\ & & -A_0 & I \end{bmatrix}^{-1} = \begin{bmatrix} I & & & \\ A_0 & I & & \\ \vdots & \ddots & \ddots & \\ A_0^{k-1} & \cdots & A_0 & I \end{bmatrix}. \tag{4.16}$$

So $Q_k \geq A_0^{k-1}$ and hence $v^T Q_k A_0 e \geq v^T A_0^k e$. For $A_0$ given by (4.5), we have

$$A_0^k = \begin{bmatrix} P_{11}^k & 0 \\ \frac{1}{2} P_{21} P_{11}^{k-1} & 0 \end{bmatrix}.$$

Therefore, $v^T Q_k A_0 e \geq p^T P_{11}^k e$, by (4.12). Recall that the nonnegative matrix $P_{11}$ is given by $P_{11} = I - \frac{1}{\theta} D$. If the diagonal elements $d_{ii}$ of $D$ are not all equal or $a_*$ and $d_*$ defined in (4.3) satisfy $d_* < a_*$, then $P_{11}$ has at least one nonzero diagonal element and hence $p^T P_{11}^k e > 0$ for all $k \geq 1$ and for all $\theta \geq \theta_*$. If the elements $d_{ii}$ are all equal and $d_* \geq a_*$, then $p^T P_{11}^k e > 0$ for all $k \geq 1$ and all $\theta > \theta_* = d_*$.

THEOREM 4.4. [illegible] 4.3 [illegible] $A_0, A_1, A_2$ [illegible] (4.5) [illegible] $B_0, B_1, B_2$ [illegible] (4.10) [illegible] $\theta \geq \theta_*$ [illegible] $d_{ii}$ [illegible] $D$ [illegible] $d_* < a_*$ [illegible] $\theta > \theta_*$ [illegible] $d_{ii}$ [illegible] $d_* \geq a_*$

When the elements $d_{ii}$ of $D$ are all equal, it is possible for $P_{11}$ to be nilpotent if we take $\theta = \theta_*$. One simple example is

$$M = \begin{bmatrix} 1 & -1 & 0 & 0 \\ 0 & 1 & -1 & 0 \\ 0 & 0 & 1 & -1 \\ -1 & 0 & 0 & 1 \end{bmatrix}. \tag{4.17}$$

For this example with $\theta = 1$, $p^T P_{11}^k e = 0$ for $k \geq 2$. However, it is very likely that we still have $v^T Q_k A_0 e > 0$ since the lower bound in (4.16) is not tight.

For the LR algorithm without a shift, the number $\rho(F)\rho(G)$ in (4.8) in minimized for $\theta = \theta_*$. So $\theta = \theta_*$ is optimal in this sense and should be recommended. For the LR algorithm with a shift, however, the optimal $\theta$ should minimize $\rho(F)\rho(H)$ in (4.13).

When $u_1^Te = u_2^Te$, we have $\lambda_{n+1} = 0$ and $\rho(F) = 1$ for any $\theta$. When $u_1^Te > u_2^Te$ but $u_1^Te \approx u_2^Te$, we have $\lambda_{n+1} \approx 0$ and hence the effect of $\theta$ on $\rho(F)$ is very limited. So one should try to minimize $\rho(H)$. Note that $\rho(H) = \max_{1\le i\le n-1} |1-\frac{1}{\theta}\lambda_i|$. For the matrix $M$ given by (4.17), the corresponding matrix $L$ has eigenvalues $\sqrt{2}, 0, 0, -\sqrt{2}$. So $\rho(F) = 1$ and $\rho(H)$ is minimized for $\theta = \sqrt{2}$ and the minimum is 0. This example shows that $\theta = \theta_*$ is not necessarily optimal when the shift technique is used. We can also give a necessary and sufficient condition for $\theta_*$ to be optimal. Let $D = \{z \in \mathbb{C} : |z-1| < 1\}$. Then $\lambda_i/\theta_* \in D$ for $i = 1, \ldots, n-1$ since $\rho(H) < 1$. Let $D_1 = \{z \in \mathbb{C} : |z-1/2| \le 1/2\}$, $D_2 = D \setminus D_1$, $I_1 = \{1 \le i \le n-1 : \lambda_i/\theta_* \in D_1\}$, and $I_2 = \{1 \le i \le n-1 : \lambda_i/\theta_* \in D_2\}$. Then we have the following result.

PROPOSITION 4.5. [illegible] $\theta \in [\theta_*, \infty)$ $\rho(H)$ [illegible] $\theta = \theta_*$ [illegible]

$$\max_{i\in I_1} |1-\lambda_i/\theta_*| \ge \max_{i\in I_2} |1-\lambda_i/\theta_*|,$$

[illegible]

[illegible]. Note that for any point (other than 0) on the circle $|z-1/2| = 1/2$, the boundary of $D_1$, the line passing through $z$ and 0 is perpendicular to the line passing through $z$ and 1. If $\max_{i\in I_1} |1-\lambda_i/\theta_*| \ge \max_{i\in I_2} |1-\lambda_i/\theta_*|$, then for any $\theta > \theta_*$ and $i \in I_1$, which is nonempty, $|1-\lambda_i/\theta| > |1-\lambda_i/\theta_*|$ and thus $\rho(H)$ is minimized at $\theta_*$. On the other hand, if $\max_{i\in I_1} |1-\lambda_i/\theta_*| < \max_{i\in I_2} |1-\lambda_i/\theta_*|$, we can take $\theta > \theta_*$ such that

$$\max_{i\in I_1} |1-\lambda_i/\theta| < \max_{i\in I_2} |1-\lambda_i/\theta| < \max_{i\in I_2} |1-\lambda_i/\theta_*|.$$

(The first inequality holds when $\theta-\theta_*$ is small enough and the second inequality holds when $\theta-\theta_*$ is small enough so that $\lambda_i/\theta \in D_2$ for $i \in I_2$.) Thus $\rho(H)$ does not attain its minimum at $\theta_*$. $\square$

In practice, we would not compute the eigenvalues $\lambda_1, \ldots, \lambda_{n-1}$ when we use the LR algorithm. However, the above result shows that $\theta = \theta_*$ is often not optimal when the shift technique is used. Therefore, when the diagonal elements $d_{ii}$ of $D$ are all equal and $d_* \ge a_*$, we can simply take $\theta > \theta_* = d_*$ (say $\theta = 1.1\theta_*$) to ensure the applicability of the LR algorithm with a shift.

**4.2. Case $u_1^Te < u_2^Te$.** We now assume $u_1^Te < u_2^Te$. Then $Se < e$ by Theorem 3.4. We will reduce this case to the case $u_1^Te > u_2^Te$ for a new NARE of the same type, and the substochastic minimal solution $S$ of the original NARE will be obtained from the stochastic minimal solution of the new NARE. This reduction process is in essence similar to the one given in [25]. The difference is that the reduction here is given directly on the Riccati equation, rather than on the unilateral matrix equation obtained through the Ramaswami construction.

As in [15, Lem. 5.1] we note that the minimal nonnegative solution $S$ of the NARE (1.1) is such that $S = Z^T$, where $Z$ is the minimal nonnegative solution of the new NARE

$$ZC^TZ - ZA^T - D^TZ + B^T = 0. \tag{4.18}$$

As at the beginning of section 4, (4.18) can be rewritten as

$$W(U_2^{-1}C^TU_1)W - W(U_2^{-1}A^TU_2) - (U_1^{-1}D^TU_1)W + U_1^{-1}B^TU_2 = 0, \tag{4.19}$$

with $U_1 = \operatorname{diag}(u_1), U_2 = \operatorname{diag}(u_2)$, and $W = U_1^{-1} Z U_2$. Now the irreducible singular $M$-matrix corresponding to (4.19) is

$$\widehat{M} = \begin{bmatrix} U_2^{-1} A^T U_2 & -U_2^{-1} C^T U_1 \\ -U_1^{-1} B^T U_2 & U_1^{-1} D^T U_1 \end{bmatrix}.$$

It is easy to see that $(u_2^T \ u_1^T)\widehat{M} = 0$ and $\widehat{M}e = 0$. Since $u_2^T e > u_1^T e$, the new NARE (4.19) has a stochastic minimal solution $W$ and it can be computed as in section 4.1. The substochastic minimal solution $S$ of the original NARE is obtained through $S = U_2^{-1} W^T U_1$.

For the above procedure, we need to compute the vector $(u_1^T \ u_2^T)^T$ accurately since it determines the coefficient matrices of the NARE (4.19). This can be done by using the LU factorization of the irreducible singular $M$-matrix $M^T$, and the computational work is very minor compared with that required by each iteration for the simplified LR algorithm. So the shift technique is worthwhile as long as we can save one iteration. Moreover, as our perturbation analysis in section 3 suggests, the minimal solution computed by the LR algorithm without a shift is much more vulnerable to rounding errors when $u_1^T e \approx u_2^T e$.

We use one example to illustrate the usefulness of the above procedure. Consider the NARE (1.1) with $m = n = 100$ and

$$A = \begin{bmatrix} 3 & -1 & & \\ & \ddots & \ddots & \\ & & 3 & -1 \\ -1 & & & 1.9 \end{bmatrix}, \quad B = \begin{bmatrix} 1 & 1 & & \\ & \ddots & \ddots & \\ & & 1 & 1 \\ & & & 0.9 \end{bmatrix},$$

$$C = \begin{bmatrix} 1 & & & \\ 1 & 1 & & \\ & \ddots & \ddots & \\ & & 1 & 1 \end{bmatrix}, \quad D = \begin{bmatrix} 2 & -1 & & \\ & 3 & \ddots & \\ & & \ddots & -1 \\ -1 & & & 3 \end{bmatrix}.$$

It is easily verified that $Me = 0$ and $u_1^T e < u_2^T e$. We apply the (simplified) LR algorithm with a shift to the NARE (4.19) (so the matrices $A, B, C, D$ in (4.4) are replaced accordingly), with $\theta = 3$ in (4.4) and $p = m^{-1}e$ in (4.12). After 6 iterations we find an approximation $\widetilde{W}$ to $W$ with $\|\mathcal{R}(\widetilde{W})\|_\infty = 4.4 \times 10^{-11}$. We then use $\widetilde{W}$ to get an approximation $\widetilde{S}$ to $S$ with $\|\mathcal{R}(\widetilde{S})\|_\infty = 6.1 \times 10^{-11}$. A very accurate approximation to $S$ (with residual $2.3 \times 10^{-14}$) can be obtained by performing 7 iterations instead and we take it as the "exact" solution $S$. We now apply the (simplified) LR algorithm without a shift to the NARE (1.1), with $\theta = 3$ in (4.4). We find after 13 iterations an approximation $\widetilde{S}'$ to $S$, with $\|\mathcal{R}(\widetilde{S}')\|_\infty = 6.0 \times 10^{-10}$. However, the accuracy in this case is much lower than the residual suggests. Indeed, we find $\|\widetilde{S} - S\|_\infty = 1.4 \times 10^{-10}$ but $\|\widetilde{S}' - S\|_\infty = 4.2 \times 10^{-7}$. So the (simplified) LR algorithm with a shift is more efficient and more accurate.

**5. Conclusions.** In this further study of a class of NAREs, we have been able to relax the condition for the convergence of Newton's method to the minimal solution. The qualitative perturbation analysis for the minimal solution, while of independent interest, is instructive in designing algorithms for finding more accurate approximations. For the NAREs arising in Markov models, we have shown that the LR algorithm, combined with a shift technique, is breakdown-free in all cases and therefore is guaranteed to find the minimal solution more efficiently and more accurately.

**Acknowledgments.** This work was carried out while the first author visited MIMS in the School of Mathematics at the University of Manchester; he thanks the School for its hospitality. Both authors thank the referees for their helpful comments. In particular, comments from one referee led to a significant improvement of section 4.2.

# A PARTIAL CONDITION NUMBER FOR LINEAR LEAST SQUARES PROBLEMS*

MARIO ARIOLI[†], MARC BABOULIN[‡], AND SERGE GRATTON[‡]

**Abstract.** We consider here the linear least squares problem $\min_{y\in\mathbb{R}^n} \|Ay-b\|_2$, where $b\in\mathbb{R}^m$ and $A\in\mathbb{R}^{m\times n}$ is a matrix of full column rank $n$, and we denote $x$ its solution. We assume that both $A$ and $b$ can be perturbed and that these perturbations are measured using the Frobenius or the spectral norm for $A$ and the Euclidean norm for $b$. In this paper, we are concerned with the condition number of a linear function of $x$ ($L^Tx$, where $L\in\mathbb{R}^{n\times k}$) for which we provide a sharp estimate that lies within a factor $\sqrt{3}$ of the true condition number. Provided the triangular $R$ factor of $A$ from $A^TA=R^TR$ is available, this estimate can be computed in $2kn^2$ flops. We also propose a statistical method that estimates the partial condition number by using the exact condition numbers in random orthogonal directions. If $R$ is available, this statistical approach enables us to obtain a condition estimate at a lower computational cost. In the case of the Frobenius norm, we derive a closed formula for the partial condition number that is based on the singular values and the right singular vectors of the matrix $A$.

**Key words.** linear least squares, normwise condition number, statistical condition estimate, parameter estimation

## 1. Introduction.

Perturbation theory has been applied to many problems of linear algebra such as linear systems, linear least squares, or eigenvalue problems [1, 4, 11, 18]. In this paper we consider the problem of calculating the quantity $L^Tx$, where $x$ is the solution of the linear least squares problem (LLSP) $\min_{x\in\mathbb{R}^n} \|Ax-b\|_2$, where $b\in\mathbb{R}^m$ and $A\in\mathbb{R}^{m\times n}$ is a matrix of full column rank $n$. This estimation is a fundamental problem of parameter estimation in the framework of the Gauss–Markov model [17, p. 137]. More precisely, we focus here on the evaluation of the sensitivity of $L^Tx$ to small perturbations of the matrix $A$ and/or the right-hand side $b$, where $L\in\mathbb{R}^{n\times k}$ and $x$ is the solution of the LLSP.

The interest for this question stems, for instance, from parameter estimation where the parameters of the model can often be divided into two parts: the variables of physical significance and a set of ancillary variables involved in the models. For example, this situation occurs in the determination of positions using the GPS system, where the three-dimensional coordinates are the quantities of interest, but the statistical model involves other parameters such as clock drift and GPS ambiguities [12] that are generally estimated during the solution process. It is then crucial to ensure that the solution components of interest can be computed with satisfactory accuracy. The main goal of this paper is to formalize this problem in terms of a condition number and to describe practical methods to compute or estimate this quantity. Note that as far as the sensitivity of a subset of the solution components is concerned, the matrix $L$ is a projection whose columns consist of vectors of the canonical basis of $\mathbb{R}^n$.

The condition number of a map $g : \mathbb{R}^m \mapsto \mathbb{R}^n$ at $y_0$ measures the sensitivity of $g(y_0)$ to perturbations of $y_0$. If we assume that the data space $\mathbb{R}^m$ and the solution space $\mathbb{R}^n$ are equipped, respectively, with the norms $\|.\|_{\mathcal{D}}$ and $\|.\|_{\mathcal{S}}$, the condition number $K(y_0)$ is defined by

$$K(y_0) = \lim_{\delta \to 0} \sup_{0 < \|y_0 - y\|_{\mathcal{D}} \leq \delta} \frac{\|g(y_0) - g(y)\|_{\mathcal{S}}}{\|y_0 - y\|_{\mathcal{D}}}, \tag{1.1}$$

whereas the relative condition number is defined by $K^{(rel)}(y_0) = K(y_0)\|y_0\|_{\mathcal{D}} / \|g(y_0)\|_{\mathcal{S}}$. This definition shows that $K(y_0)$ measures an asymptotic sensitivity and that this quantity depends on the chosen norms for the data and solution spaces. If $g$ is a Fréchet-differentiable (F-differentiable) function at $y_0$, then $K(y_0)$ is the norm of the F-derivative $|||g'(y_0)|||$) (see [6]), where $|||.|||$ is the operator norm induced by the choice of the norms on the data and solution spaces.

For the full rank LLSP, we have $g(A,b) = (A^TA)^{-1}A^Tb$. If we consider the product norm $\|(A,b)\|_F = \sqrt{\|A\|_{\mathrm{F}}^2 + \|b\|_2^2}$ for the data space and $\|x\|_2$ for the solution space, then [8] gives an explicit formula for the relative condition number $K^{(rel)}(A,b)$:

$$K^{(rel)}(A,b) = \left\|A^\dagger\right\|_2 \left(\left\|A^\dagger\right\|_2^2 \|r\|_2^2 + \|x\|_2^2 + 1\right)^{\frac{1}{2}} \frac{\|(A,b)\|_F}{\|x\|_2},$$

where $A^\dagger$ denotes the pseudoinverse of $A$, $r = b - Ax$ is the residual vector, and $\|.\|_{\mathrm{F}}$ and $\|.\|_2$ are, respectively, the Frobenius and Euclidean norms. But does the value of $K^{(rel)}(A,b)$ give us useful information about the sensitivity of $L^Tx$? Can it in some cases overestimate the error in components or on the contrary be too optimistic?

Let us consider the following example:

$$A = \begin{pmatrix} 1 & 1 & \epsilon^2 \\ \epsilon & 0 & \epsilon^2 \\ 0 & \epsilon & \epsilon^2 \\ \epsilon^2 & \epsilon^2 & 2 \end{pmatrix}, \quad x = \begin{pmatrix} \epsilon \\ \epsilon \\ \frac{1}{\epsilon} \end{pmatrix}, \quad \text{and} \quad b = \begin{pmatrix} 3\epsilon \\ \epsilon^2 + \epsilon \\ \epsilon^2 + \epsilon \\ 2\epsilon^3 + \frac{2}{\epsilon} \end{pmatrix},$$

where $x$ is the exact solution of the LLSP $\min_{x \in \mathbb{R}^3} \|Ax - b\|_2$. If we take $\epsilon = 10^{-8}$, then we have $x = (10^{-8}, 10^{-8}, 10^8)^T$ and the solution computed in MATLAB using a machine precision $2.22 \cdot 10^{-16}$ is $\tilde{x} = (1.5 \cdot 10^{-8}, 1.5 \cdot 10^{-8}, 10^8)^T$. The LLSP condition number is $K^{(rel)}(A,b) = 2.4 \cdot 10^8$ and the relative errors on the components of $x$ are

$$\frac{|x_1 - \tilde{x}_1|}{|x_1|} = \frac{|x_2 - \tilde{x}_2|}{|x_2|} = 0.5 \quad \text{and} \quad \frac{|x_3 - \tilde{x}_3|}{|x_3|} = 0.$$

Then, if $L = \left(\begin{smallmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)$, we expect a large value for the condition number of $L^Tx$ because there is a 50% relative error on $x_1$ and $x_2$. If now $L = (0,0,1)^T$, then we expect that the condition number of $L^Tx$ would be close to 1 because $\tilde{x}_3 = x_3$. For these two values of $L$, the LLSP condition number is far from giving a good idea of the sensitivity of $L^Tx$. Note in this case that the perturbations are due to roundoff errors.

Let us now consider a simple example in the framework of parameter estimation where, in addition to roundoff errors, random errors are involved. Let $b = \{b_i\}_{i=1,\ldots,10}$ be a series of observed values depending on data $s = \{s_i\}$, where $s_i = 10 + i, i = 1, \ldots, 10$. We determine a 3-degree polynomial that approximates $b$ in the least squares sense, and we suppose that the following relationship holds:

$$b = x_1 + x_2 \frac{1}{s} + x_3 \frac{1}{s^2} + x_4 \frac{1}{s^3} \quad \text{with } x_1 = x_2 = x_3 = x_4 = 1.$$

We assume that the perturbation on each $b_i$ is $10^{-8}$ multiplied by a normally distributed random number and denote by $\tilde{b} = \{\tilde{b_i}\}_{i=1,\ldots,10}$ the perturbed quantity. This corresponds to the LLSP $\min_{x\in\mathbb{R}^4} \|Ax - \tilde{b}\|_2$, where $A$ is the Vandermonde matrix defined by $A_{ij} = \frac{1}{s_i^{j-1}}$. Let $\tilde{x}$ and $\tilde{y}$ be the computed solutions corresponding to two perturbed right-hand sides. Then we obtain the following relative errors on each component:

$$\frac{|\tilde{x}_1 - \tilde{y}_1|}{|\tilde{x}_1|} = 2 \cdot 10^{-7}, \frac{|\tilde{x}_2 - \tilde{y}_2|}{|\tilde{x}_2|} = 6 \cdot 10^{-6}, \frac{|\tilde{x}_3 - \tilde{y}_3|}{|\tilde{x}_3|} = 6 \cdot 10^{-5}, \text{ and } \frac{|\tilde{x}_4 - \tilde{y}_4|}{|\tilde{x}_4|} = 10^{-4}.$$

We have $K^{(rel)}(A, b) = 3.1 \cdot 10^5$. Regarding the disparity between the sensitivity of each component, we need a quantity that evaluates more precisely the sensitivity of each solution component of the LLSP.

The idea of analyzing the accuracy of some solution components in linear algebra is by no means new. For linear systems $Ax = b$, $A \in \mathbb{R}^n$ and for LLSP, [3] defines so-called componentwise condition numbers that correspond to amplification factors of the relative errors in solution components due to perturbations of data $A$ or $b$ and explains how to estimate them. In our formalism, these quantities are upper bounds of the condition number of $L^T x$, where $L$ is a column of the identity matrix. We also emphasize that the term "componentwise" refers here to the solution components and must be distinguished from the metric used for matrices and for which [21] provides a condition number for generalized inversion and linear least squares.

For LLSP, [14] provides a statistical estimate for componentwise condition numbers due to either relative or structured perturbations. In the case of linear systems, [2] proposes a statistical approach, based on [13] that enables one to compute the condition number of $L^T x$ in $\mathcal{O}(n^2)$.

Our approach differs from the previous studies in the following aspects:

1. We are interested in the condition of $L^T x$, where $L$ is a general matrix and not only a canonical vector of $\mathbb{R}^n$.
2. We are looking for a condition number based on the F-derivative, and not only for an upper bound of this quantity.

We present in this paper three ways to obtain information on the condition of $L^T x$. The first one uses an explicit formula based on the singular value decomposition (SVD) of $A$. The second is at the same time an upper bound of this condition number and a sharp estimate of it. The third method supplies a statistical estimate. The choice between these three methods will depend on the size of the problem (computational cost) and on the accuracy desired for this quantity.

This paper is organized as follows. In section 2, we define the notion of a partial condition number. Then, when perturbations on $A$ are measured using a Frobenius norm, we give a closed formula for this condition number in the general case where $L \in \mathbb{R}^{n\times k}$ and in the particular case when $L \in \mathbb{R}^n$. In section 3, we establish bounds of the partial condition number in Frobenius as well as in spectral norm, and we show that these bounds can be considered as sharp estimates of it. In section 4 we describe a statistical method that enables us to estimate the partial condition number. In section 5 we present numerical results in order to compare the statistical estimate and the exact condition number on sample matrices $A$ and $L$. In section 6 we give a summary comparing the three ways to compute the condition of $L^T x$ as well as a numerical illustration. Finally some concluding remarks are given in section 7.

Throughout this paper we will use the following notation. We use the Frobenius norm $\|.\|_F$ and the spectral norm $\|.\|_2$ on matrices and the usual Euclidean $\|.\|_2$ on vectors. The matrix $I$ is the identity matrix and $e_i$ is the $i$th canonical vector. We also denote by $\mathrm{Im}(A)$ the space spanned by the columns of $A$ and by $\mathrm{Ker}(A)$ the null space of $A$.

**2. The partial condition number of an LLSP.** Let $L$ be an $n \times k$ matrix, with $k \leq n$. We consider the function

$$\begin{array}{rccl} g : & \mathbb{R}^{m\times n} \times \mathbb{R}^m & \longrightarrow & \mathbb{R}^k, \\ & A, b & \longmapsto & g(A,b) = L^T x(A,b) = L^T(A^TA)^{-1}A^Tb. \end{array} \tag{2.1}$$

Since $A$ has full rank $n$, $g$ is continuously F-differentiable in a neighborhood of $(A,b)$ and we denote by $g'$ its F-derivative. Let $\alpha$ and $\beta$ be two positive real numbers. In the present paper we consider the Euclidean norm for the solution space $\mathbb{R}^k$. For the data space $\mathbb{R}^{m\times n} \times \mathbb{R}^m$, we use the product norms defined by

$$\|(A,b)\|_F = \sqrt{\alpha^2 \|A\|_F^2 + \beta^2 \|b\|_2^2}, \quad \alpha, \beta > 0,$$

and

$$\|(A,b)\|_2 = \sqrt{\alpha^2 \|A\|_2^2 + \beta^2 \|b\|_2^2}, \quad \alpha, \beta > 0.$$

These norms are very flexible since they allow us to monitor the perturbations on $A$ and $b$. For instance, large values of $\alpha$ (resp., $\beta$ ) enable us to obtain condition number problems where mainly $b$ (resp., $A$) are perturbed. A more general weighted Frobenius norm $\|(AT, \beta b)\|_{\mathrm{F}}$, where T is a positive diagonal matrix, is sometimes chosen. This is the case, for instance, in [20], which gives an explicit expression for the condition number of rank deficient linear least squares using this norm.

According to [6], the absolute condition numbers of $g$ at the point $(A,b)$ using the two product norms defined above is given by

$$\kappa_{g,F}(A,b) = \max_{(\Delta A, \Delta b)} \frac{\|g'(A,b).(\Delta A, \Delta b)\|_2}{\|(\Delta A, \Delta b)\|_F}$$

and

$$\kappa_{g,2}(A,b) = \max_{(\Delta A, \Delta b)} \frac{\|g'(A,b).(\Delta A, \Delta b)\|_2}{\|(\Delta A, \Delta b)\|_2}.$$

The corresponding relative condition numbers of $g$ at $(A,b)$ are expressed by

$$\kappa_{g,F}^{(rel)}(A,b) = \frac{\kappa_{g,F}(A,b) \ \ \|(A,b)\|_F}{\|g(A,b)\|_2}$$

and

$$\kappa_{g,2}^{(rel)}(A,b) = \frac{\kappa_{g,2}(A,b) \ \ \|(A,b)\|_2}{\|g(A,b)\|_2}.$$

We call the condition numbers related to $L^T x(A,b)$ [illegible] of the LLSP with respect to the linear operator $L$. The partial condition number defined using the product norm $\|(.,.)\|_F$ is given by the following theorem.

THEOREM 1. [illegible] $A = U\Sigma V^T$ [illegible] $A$ [illegible] [7] [illegible] $\Sigma = \mathrm{diag}(\sigma_i)$ [illegible] $\sigma_1 \geq \sigma_2 \cdots \geq \sigma_n > 0$ [illegible] $g(A,b) = L^T x(A,b)$ [illegible]

$$\kappa_{g,F}(A,b) = \left\|SV^T L\right\|_2,$$

[illegible] $S \in \mathbb{R}^{n\times n}$ [illegible] $S_{ii} = {\sigma_i}^{-1}\sqrt{\frac{{\sigma_i}^{-2}\|r\|_2^2 + \|x\|_2^2}{\alpha^2} + \frac{1}{\beta^2}}$

[illegible] The demonstration is divided into three parts. In Part 1, we establish an explicit formula of $g'(A,b).(\Delta A,\Delta b)$. In Part 2, we derive an upper bound for $\frac{\left\|g'(A,b).(\Delta A,\Delta b)\right\|_2}{\|(\Delta A,\Delta b)\|_F}$. In Part 3, we show that this bound is reached for a particular $(\Delta A,\Delta b)$.

[illegible] 1. Let $\Delta A \in \mathbb{R}^{m\times n}$ and $\Delta b \in \mathbb{R}^m$. Using the chain rules of composition of derivatives, we get

$$\begin{aligned} g'(A,b).(\Delta A,\Delta b) = {} & L^T(A^TA)^{-1}\Delta A^T(b - A(A^TA)^{-1}A^Tb) \\ & - L^T(A^TA)^{-1}A^T\Delta A(A^TA)^{-1}A^Tb + L^TA^\dagger\Delta b, \end{aligned}$$

i.e.,

$$g'(A,b).(\Delta A,\Delta b) = L^T(A^TA)^{-1}\Delta A^T r - L^TA^\dagger\Delta A x + L^TA^\dagger\Delta b. \tag{2.2}$$

We write $\Delta A = \Delta A_1 + \Delta A_2$ by defining $\Delta A_1 = AA^\dagger\Delta A$ (projection of $\Delta A$ onto $\mathrm{Im}(A)$) and $\Delta A_2 = (I - AA^\dagger)\Delta A$ (projection of $\Delta A$ onto $\mathrm{Im}(A)^\perp$). We have $\Delta A_1^T r = 0$ (because $r \in \mathrm{Im}(A)^\perp$) and $A^\dagger\Delta A_2 = 0$. Then we obtain

$$g'(A,b).(\Delta A,\Delta b) = L^T(A^TA)^{-1}\Delta A_2^T r - L^TA^\dagger\Delta A_1 x + L^TA^\dagger\Delta b. \tag{2.3}$$

[illegible] 2. We now prove that $\kappa_{g,F}(A,b) \leq \left\|SV^TL\right\|_2$. Let $u_i$ and $v_i$ be the $i$th column of $U$ and $V$, respectively.

From $A^\dagger = V\Sigma^{-1}U^T$, we get $AA^\dagger = UU^T = \sum_{i=1}^n u_iu_i^T$ and since $\sum_{i=1}^n v_iv_i^T = I$, we have $\Delta A_1 = \sum_{i=1}^n u_iu_i^T\Delta A$ and $\Delta A_2 = (I - AA^\dagger)\Delta A\sum_{i=1}^n v_iv_i^T$. Moreover, still using the thin SVD of $A$ and $A^\dagger$, it follows that

$$(A^TA)^{-1}v_i = \frac{v_i}{\sigma_i^2}, \quad A^\dagger u_i = \frac{v_i}{\sigma_i}, \quad \text{and} \quad A^\dagger\Delta b = \sum_{i=1}^n v_iu_i^T\frac{\Delta b}{\sigma_i}. \tag{2.4}$$

Thus (2.3) becomes

$$\begin{aligned} g'(A,b).(\Delta A,\Delta b) &= \sum_{i=1}^n L^Tv_i\left[v_i^T\Delta A^T(I - AA^\dagger)\frac{r}{\sigma_i^2} - u_i^T\Delta A\frac{x}{\sigma_i} + u_i^T\frac{\Delta b}{\sigma_i}\right] \\ &= L^T\sum_{i=1}^n v_iy_i, \end{aligned}$$

where we set $y_i = v_i^T\Delta A^T(I - AA^\dagger)\frac{r}{\sigma_i^2} - u_i^T\Delta A\frac{x}{\sigma_i} + u_i^T\frac{\Delta b}{\sigma_i} \in \mathbb{R}$.

Thus if $Y = (y_1, y_2, \ldots, y_n)^T$, we get $\|g'(A,b).(\Delta A,\Delta b)\|_2 = \left\|L^TVY\right\|_2$ and then

$$\|g'(A,b).(\Delta A,\Delta b)\|_2 = \left\|L^TVSS^{-1}Y\right\|_2 \leq \left\|SV^TL\right\|_2\left\|S^{-1}Y\right\|_2.$$

We denote by $w_i = \frac{v_i^T \Delta A^T (I - AA^\dagger) r}{S_{ii}\sigma_i^2} - \frac{u_i^T \Delta A x}{S_{ii}\sigma_i} + \frac{u_i^T \Delta b}{S_{ii}\sigma_i}$ the $i$th component of $S^{-1}Y$. Then we have

$$\begin{aligned}
|w_i| &\leq \alpha \left\| v_i^T \Delta A^T (I - AA^\dagger)^T \right\|_2 \frac{\|r\|_2}{\alpha S_{ii}\sigma_i^2} + \alpha \left\| u_i^T \Delta A \right\|_2 \frac{\|x\|_2}{\alpha S_{ii}\sigma_i} + \beta |u_i^T \Delta b| \frac{1}{\beta S_{ii}\sigma_i} \\
&\leq \left( \frac{\|r\|_2^2}{\alpha^2 S_{ii}^2 \sigma_i^4} + \frac{\|x\|_2^2}{\alpha^2 S_{ii}^2 \sigma_i^2} + \frac{1}{\beta^2 S_{ii}^2 \sigma_i^2} \right)^{\frac{1}{2}} \\
&\quad \times (\alpha^2 \left\| (I - AA^\dagger) \Delta A v_i \right\|_2^2 + \alpha^2 \left\| u_i^T \Delta A \right\|_2^2 + \beta^2 |u_i^T \Delta b|^2)^{\frac{1}{2}} \\
&= \frac{S_{ii}}{S_{ii}} (\alpha^2 \left\| (I - AA^\dagger) \Delta A v_i \right\|_2^2 + \alpha^2 \left\| u_i^T \Delta A \right\|_2^2 + \beta^2 |u_i^T \Delta b|^2)^{\frac{1}{2}}.
\end{aligned}$$

Hence

$$\begin{aligned}
\left\| S^{-1} Y \right\|_2^2 &\leq \sum_{i=1}^{n} \alpha^2 \left\| (I - AA^\dagger) \Delta A v_i \right\|_2^2 + \alpha^2 \left\| u_i^T \Delta A \right\|_2^2 + \beta^2 |u_i^T \Delta b|^2 \\
&= \alpha^2 \left\| (I - AA^\dagger) \Delta A V \right\|_F^2 + \alpha^2 \left\| U^T \Delta A \right\|_F^2 + \beta^2 \left\| U^T \Delta b \right\|_2^2 \\
&= \alpha^2 \left\| (I - AA^\dagger) \Delta A \right\|_F^2 + \alpha^2 \left\| U^T \Delta A \right\|_F^2 + \beta^2 \left\| U^T \Delta b \right\|_2^2 .
\end{aligned}$$

Since $\left\| U^T \Delta A \right\|_F = \left\| U U^T \Delta A \right\|_F = \left\| AA^\dagger \Delta A \right\|_F$ and $\left\| U^T \Delta b \right\|_2 = \left\| U U^T \Delta b \right\|_2 \leq \|\Delta b\|_2$, we get

$$\left\| S^{-1} Y \right\|_2^2 \leq \alpha^2 \left\| \Delta A_1 \right\|_F^2 + \alpha^2 \left\| \Delta A_2 \right\|_F^2 + \beta^2 \left\| \Delta b \right\|_2^2 .$$

From $\|\Delta A\|_F^2 = \|\Delta A_1\|_F^2 + \|\Delta A_2\|_F^2$, we get $\left\| S^{-1} Y \right\|_2^2 \leq \|(\Delta A, \Delta b)\|_F^2$ and thus

$$\|g'(A,b).(\Delta A, \Delta b)\|_2 \leq \left\| S V^T L \right\|_2 \|(\Delta A, \Delta b)\|_F .$$

So we have shown that $\left\| S V^T L \right\|_2$ is an upper bound for $\kappa_{g,F}(A,b)$.

*Part* 3. We now prove that this upper bound can be reached, i.e., that $\left\| S V^T L \right\|_2 = \frac{\left\| g'(A,b).(\Delta A, \Delta b) \right\|_2}{\|(\Delta A, \Delta b)\|_F}$ holds for some $(\Delta A, \Delta b) \in \mathbb{R}^{m \times n} \times \mathbb{R}^m$.

Let us consider the particular choice of $(\Delta A, \Delta b)$ defined by

$$(\Delta A, \Delta b) = (\Delta A_2 + \Delta A_1, \Delta b) = \left( \sum_{i=1}^{n} \frac{\alpha_i}{\alpha} \frac{r}{\|r\|_2} v_i^T + \sum_{i=1}^{n} \frac{\beta_i}{\alpha} u_i \frac{x^T}{\|x\|_2}, \sum_{i=1}^{n} \frac{\gamma_i}{\beta} u_i \right),$$

where $\alpha_i$, $\beta_i$, $\gamma_i$ are real constants to be chosen in order to achieve the upper bound obtained in Part 2.

Since $\Delta A_1^T r = 0$ and $A^\dagger \Delta A_2 = 0$, it follows from (2.3) and (2.4) that

$$\begin{aligned} g'(A,b).(\Delta A, \Delta b) &= L^T (A^T A)^{-1} \sum_{i=1}^n \frac{\alpha_i}{\alpha} \|r\|_2 v_i^T - L^T A^\dagger \sum_{i=1}^n \frac{\beta_i}{\alpha} u_i \|x\|_2 \\ &\quad + L^T A^\dagger \sum_{i=1}^n \frac{\gamma_i}{\beta} u_i \\ &= L^T \sum_{i=1}^n \frac{\alpha_i}{\alpha \sigma_i^2} v_i \|r\|_2 - L^T \sum_{i=1}^n \frac{\beta_i}{\alpha \sigma_i} v_i \|x\|_2 + L^T \sum_{i=1}^n \frac{\gamma_i}{\beta \sigma_i} v_i \\ &= \sum_{i=1}^n L^T v_i \left( \frac{\alpha_i}{\alpha \sigma_i^2} \|r\|_2 - \frac{\beta_i}{\alpha \sigma_i} \|x\|_2 + \frac{\gamma_i}{\beta \sigma_i} \right). \end{aligned}$$

Thus by denoting $\xi_i = [L^T v_i \frac{\|r\|_2}{\alpha \sigma_i^2}, -L^T v_i \frac{\|x\|_2}{\alpha \sigma_i}, \frac{L^T v_i}{\beta \sigma_i}] \in \mathbb{R}^{k \times 3}$, $\Gamma = [\xi_1, \ldots, \xi_n] \in \mathbb{R}^{k \times 3n}$, and $X = (\alpha_1, \beta_1, \gamma_1, \ldots, \alpha_n, \beta_n, \gamma_n)^T \in \mathbb{R}^{3n \times 1}$ we get

$$g'(A,b).(\Delta A, \Delta b) = \Gamma X. \tag{2.5}$$

Since $\forall i, j$ $\mathrm{trace}((\frac{r}{\|r\|_2} v_i^T)^T (\frac{r}{\|r\|_2} v_i^T)) = \mathrm{trace}((u_i \frac{x^T}{\|x\|_2})^T (u_i \frac{x^T}{\|x\|_2})) = \delta_{ij}$, where $\delta_{ij}$ is the Kronecker symbol and $\mathrm{trace}((\frac{r}{\|r\|_2} v_i^T)^T (u_i \frac{x^T}{\|x\|_2})) = 0$, then $\{\frac{r}{\|r\|_2} v_i^T\}_{i=1,\ldots,n}$ and $\{u_i \frac{x^T}{\|x\|_2}\}_{i=1,\ldots,n}$ form an orthonormal set of matrices for the Frobenius norm and we get $\|\Delta A\|_F = \sum_{i=1}^n (\alpha_i^2 + \beta_i^2)$. It follows that

$$\|(\Delta A, \Delta b)\|_F^2 = \sum_{i=1}^n \alpha_i^2 + \sum_{i=1}^n \beta_i^2 + \sum_{i=1}^n \gamma_i^2 = \|X\|_2^2,$$

and (2.5) yields

$$\frac{\|g'(A,b).(\Delta A, \Delta b)\|_2}{\|(\Delta A, \Delta b)\|_F} = \frac{\|\Gamma X\|_2}{\|X\|_2}.$$

We know that $\|\Gamma\|_2 = \max_X \frac{\|\Gamma X\|_2}{\|X\|_2}$ is reached for some $X = (\alpha_1, \beta_1, \gamma_1, \ldots, \alpha_n, \beta_n, \gamma_n)^T$. Then for the $(\Delta A, \Delta b)$ corresponding to this $X$, we have $\frac{\|g'(A,b).(\Delta A, \Delta b)\|_2}{\|(\Delta A, \Delta b)\|_F} = \|\Gamma\|_2$.

Furthermore we have

$$\begin{aligned} \Gamma \Gamma^T &= L^T v_1 \left( \frac{\|r\|_2^2}{\alpha^2 \sigma_1^4} + \frac{\|x\|_2^2}{\alpha^2 \sigma_1^2} + \frac{1}{\beta^2 \sigma_1^2} \right) v_1^T L + \cdots + L^T v_n \left( \frac{\|r\|_2^2}{\alpha^2 \sigma_n^4} + \frac{\|x\|_2^2}{\alpha^2 \sigma_n^2} + \frac{1}{\beta^2 \sigma_n^2} \right) v_n^T L \\ &= L^T v_1 S_{11}^2 v_1^T L + \cdots + L^T v_n S_{nn}^2 v_n^T L \\ &= (L^T V S)(S V^T L). \end{aligned}$$

Hence

$$\|\Gamma\|_2 = \sqrt{\|\Gamma \Gamma^T\|_2} = \left\| S V^T L \right\|_2$$

and $\alpha_1, \beta_1, \gamma_1, \ldots, \alpha_n, \beta_n, \gamma_n$ are such that $\frac{\left\|g'(A,b).(\Delta A, \Delta b)\right\|_2}{\|(\Delta A, \Delta b)\|_F} = \left\|SV^T L\right\|_2$.

Thus $\left\|SV^T L\right\|_2 \leq \kappa_{g,F}(A,b)$, which concludes the proof. ☐

1. Let $l_j$ be the $j$th column of $L$, $j = 1, \ldots, k$. From

$$SV^T L = \begin{pmatrix} S_{11}{v_1}^T \\ \vdots \\ S_{nn}{v_n}^T \end{pmatrix} (l_1, \ldots, l_k) = \begin{pmatrix} S_{11}{v_1}^T l_1 & \cdots & S_{11}{v_1}^T l_k \\ \vdots & & \vdots \\ S_{nn}{v_n}^T l_1 & \cdots & S_{nn}{v_n}^T l_k \end{pmatrix},$$

it follows that $\left\|SV^T L\right\|_2$ is large when there exist at least one large $S_{ii}$ and an $l_j$ such that ${v_i}^T l_j \neq 0$. In particular, the condition number of $L^T x(A,b)$ is large when $A$ has small singular values and $L$ has components in the corresponding right singular vectors or when $\|r\|_2$ is large.

2. In the general case where $L$ is an $n \times k$ matrix, the computation of $\kappa_{g,F}(A,b)$ via the exact formula given in Theorem 1 requires the computation of the singular values and the right singular vectors of $A$, which might be expensive in practice since it involves $2mn^2$ operations if we use an R-SVD algorithm and if $m \gg n$ (see [7, p. 254]). If the LLSP is solved using a direct method, the $R$ factor of the QR decomposition of $A$ (or equivalently, in exact arithmetic, the Cholesky factor of $A^T A$) might be available. Since the right singular vectors of $A$ are also those of $R$, the condition number can be computed in about $12n^3$ flops (using the Golub–Reinsch SVD [7, p. 254]).

Using $R$ is even more interesting when $L \in \mathbb{R}^n$, since from

$$\left\|L^T A^\dagger\right\|_2 = \left\|R^{-T} L\right\|_2 \text{ and } \left\|L^T (A^T A)^{-1}\right\|_2 = \left\|R^{-1}(R^{-T} L)\right\|_2, \tag{2.6}$$

it follows that the computation of $\kappa_{g,F}(A,b)$ can be done by solving two successive $n \times n$ triangular systems which involve about $2n^2$ flops.

### 2.1. Special cases and GSVD.

In this section, we analyze some special cases of practical relevance. Moreover, we relate the formula given in Theorem 1 for

$$\kappa_{g,F}(A,b)$$

to the generalized singular value decomposition (GSVD) (see [1, p. 157], [7, p. 466], and [15, 19]). Using the GSVD of $A$ and $L^T$, there exist $U_A \in \mathbb{R}^{m \times m}, U_L \in \mathbb{R}^{k \times k}$ orthogonal matrices and $Z \in \mathbb{R}^{n \times n}$ invertible such that

$$U_A^T A = \begin{pmatrix} D_A \\ 0 \end{pmatrix} Z \quad \text{and} \quad U_L^T L^T = \begin{pmatrix} D_L & 0 \end{pmatrix} Z$$

with

$$D_A = \mathrm{diag}(\alpha_1, \ldots, \alpha_n), \qquad D_L = \mathrm{diag}(\beta_1, \ldots, \beta_k),$$

$$\alpha_i^2 + \beta_i^2 = 1, \quad i = 1, \ldots, k, \qquad \alpha_i = 1, \quad i = k+1, \ldots, n.$$

The diagonal matrix $S$ can be decomposed in the product of two diagonal matrices

$$S = \Sigma^{-1} D$$

with

$$D_{ii} = \sqrt{\frac{{\sigma_i}^{-2} \|r\|_2^2 + \|x\|_2^2}{\alpha^2} + \frac{1}{\beta^2}}.$$

Then, taking into account the relations

$$\left\|SV^TL\right\|_2 = \left\|L^TVS\right\|_2 = \left\|L^TV\Sigma^{-1}U^TUD\right\|_2 = \left\|L^TA^\dagger UD\right\|_2,$$

$$L^TA^\dagger = U_L \begin{pmatrix} D_L & 0 \end{pmatrix} ZZ^{-1} \begin{pmatrix} D_A^{-1} & 0 \end{pmatrix} U_A^T,$$

we can represent $\kappa_{g,F}(A,b)$ as

$$\kappa_{g,F}(A,b) = \left\|T\widetilde{H}D\right\|_2,$$

where $T \in \mathbb{R}^{k\times k}$ is a diagonal matrix with $T_{ii} = \beta_i/\alpha_i$, $i = 1,\ldots,k$, and $\widetilde{H} \in \mathbb{R}^{k\times n}$ is

$$\widetilde{H} = \begin{pmatrix} I & 0 \end{pmatrix} U_A^T U.$$

Note that $\left\|L^TA^\dagger\right\|_2 = \|T\|_2$.

We also point out that the diagonal entries of $T$ are the nonzero generalized eigenvalues of

$$\lambda A^TAz = LL^Tz.$$

There are two interesting special cases where the expression of $\kappa_{g,F}(A,b)$ is simpler.

First, when $r = 0$, i.e., the LLSP problem is consistent, we have

$$D = \sqrt{\frac{\|x\|_2^2}{\alpha^2} + \frac{1}{\beta^2}}\; I$$

and

$$\kappa_{g,F}(A,b) = \left\|T\widetilde{H}\right\|_2 \sqrt{\frac{\|x\|_2^2}{\alpha^2} + \frac{1}{\beta^2}}.$$

Second, if we allow only perturbations on $b$ and if we use the expression (2.2) of the derivative of $g(A,b)$, we get

$$\kappa_{g,F}(A,b) = \frac{\left\|L^TA^\dagger\right\|_2}{\beta} = \frac{\|T\|_2}{\beta}$$

(see Remark 4 in section 3).

Other relevant cases where the expression for $\kappa_{g,F}(A,b)$ has a special interest are $L = I$ and $L$ is a column vector.

In the special case where $L = I$, the formula given by Theorem 1 becomes

$$\kappa_{g,F}(A,b) = \left\|SV^TL\right\|_2 = \|S\|_2 = \max_i S_{ii} = {\sigma_n}^{-1}\sqrt{\frac{{\sigma_n}^{-2}\,\|r\|_2^2 + \|x\|_2^2}{\alpha^2} + \frac{1}{\beta^2}}.$$

Since $\left\|A^\dagger\right\|_2 = {\sigma_n}^{-1}$, we obtain that

$$\kappa_{g,F}(A,b) = \left\|A^\dagger\right\|_2 \sqrt{\frac{\|A^\dagger\|_2^2\,\|r\|_2^2 + \|x\|_2^2}{\alpha^2} + \frac{1}{\beta^2}}.$$

This corresponds to the result known from [8] and also to a generalization of the formula of the condition number in the Frobenius norm given in [6, p. 92] (where only $A$ was perturbed).

Finally, let us study the particular case where $L$ is a column vector, i.e., when $g$ is a scalar derived function.

COROLLARY 1. [illegible] $L$ [illegible] $L \in \mathbb{R}^n$ [illegible] $g(A, b) = L^T x(A, b)$ [illegible]

$$\kappa_{g,F}(A, b) = \left( \left\|L^T (A^T A)^{-1}\right\|_2^2 \frac{\|r\|_2^2}{\alpha^2} + \left\|L^T A^\dagger\right\|_2^2 \left( \frac{\|x\|_2^2}{\alpha^2} + \frac{1}{\beta^2} \right) \right)^{\frac{1}{2}}.$$

[illegible] By replacing $(A^T A)^{-1} = V\Sigma^{-2}V^T$ and $A^\dagger = V\Sigma^{-1}U^T$ in the expression of $K = (\left\|L^T(A^TA)^{-1}\right\|_2^2 \|r\|_2^2 + \left\|L^T A^\dagger\right\|_2^2 (\|x\|_2^2 + 1))^{\frac{1}{2}}$ we get

$$\begin{aligned} K^2 &= \left\|L^T V\Sigma^{-2}V^T\right\|_2^2 \frac{\|r\|_2^2}{\alpha^2} + \left\|L^T V\Sigma^{-1}U^T\right\|_2^2 \left( \frac{\|x\|_2^2}{\alpha^2} + \frac{1}{\beta^2} \right) \\ &= \left\|L^T V\Sigma^{-2}\right\|_2^2 \frac{\|r\|_2^2}{\alpha^2} + \left\|L^T V\Sigma^{-1}\right\|_2^2 \left( \frac{\|x\|_2^2}{\alpha^2} + \frac{1}{\beta^2} \right) \\ &= \left\|\Sigma^{-2}V^T L\right\|_2^2 \frac{\|r\|_2^2}{\alpha^2} + \left\|\Sigma^{-1}V^T L\right\|_2^2 \left( \frac{\|x\|_2^2}{\alpha^2} + \frac{1}{\beta^2} \right). \end{aligned}$$

By writing $z = V^T L$, where $z = (z_1, \ldots, z_n)^T \in \mathbb{R}^n$, we obtain

$$\begin{aligned} K^2 &= \sum_{i=1}^{n} \frac{z_i^2}{\sigma_i^4} \frac{\|r\|_2^2}{\alpha^2} + \sum_{i=1}^{n} \frac{z_i^2}{\sigma_i^2} \left( \frac{\|x\|_2^2}{\alpha^2} + \frac{1}{\beta^2} \right) \\ &= \sum_{i=1}^{n} \frac{z_i^2}{\sigma_i^2} \left( \frac{\sigma_i^{-2}\|r\|_2^2 + \|x\|_2^2}{\alpha^2} + \frac{1}{\beta^2} \right) \\ &= \sum_{i=1}^{n} S_{ii}^2 z_i^2 \\ &= \left\|SV^T L\right\|_2^2, \end{aligned}$$

and Theorem 1 gives the result. ☐

## 3. Sharp estimate of the partial condition number in Frobenius and spectral norms.

In many cases, obtaining a lower and/or an upper bound of $\kappa_{g,F}(A, b)$ is satisfactory when these bounds are tight enough and significantly cheaper to compute than the exact formula. Moreover, many applications use condition numbers expressed in the spectral norm. In the following theorem, we give sharp bounds for the partial condition numbers in the Frobenius and spectral norms.

THEOREM 2. [illegible] $g(A, b) = L^T x(A, b)$ $(L \in \mathbb{R}^{n\times k})$ [illegible]

$$\frac{f(A, b)}{\sqrt{3}} \leq \kappa_{g,F}(A, b) \leq f(A, b),$$

$$\frac{f(A,b)}{\sqrt{3}} \leq \kappa_{g,2}(A,b) \leq \sqrt{2} f(A,b),$$

[illegible]

$$f(A,b) = \left( \left\| L^T(A^TA)^{-1} \right\|_2^2 \frac{\|r\|_2^2}{\alpha^2} + \left\| L^TA^\dagger \right\|_2^2 \left( \frac{\|x\|_2^2}{\alpha^2} + \frac{1}{\beta^2} \right) \right)^{\frac{1}{2}}.$$

[illegible] 1. We start by establishing the lower bounds. Let $w_1$ and $w_1'$ (resp., $a_1$ and $a_1'$) be the right (resp., the left) singular vectors corresponding to the largest singular values of $L^T(A^TA)^{-1}$ and $L^TA^\dagger$, respectively. We use a particular perturbation $(\Delta A, \Delta b)$ expressed as

$$(\Delta A, \Delta b) = \left( \frac{r}{\alpha \|r\|_2} w_1^T + \epsilon w_1' \frac{x^T}{\alpha \|x\|_2}, -\epsilon \frac{w_1'}{\beta} \right),$$

where $\epsilon = \pm 1$.

By replacing this value of $(\Delta A, \Delta b)$ in (2.2) we get

$$\begin{aligned} g'(A,b).(\Delta A, \Delta b) = {} & \frac{\|r\|_2}{\alpha} L^T(A^TA)^{-1} w_1 + \frac{\epsilon}{\alpha \|x\|_2} L^T(A^TA)^{-1} x {w_1'}^T r \\ & - L^TA^\dagger r \frac{w_1^T x}{\alpha \|r\|_2} - \frac{\epsilon \|x\|_2}{\alpha} L^TA^\dagger w_1' - \frac{\epsilon}{\beta} L^TA^\dagger w_1'. \end{aligned}$$

Since $r \in \operatorname{Im}(A)^\perp$ we have $A^\dagger r = 0$. Moreover we have $w_1' \in \operatorname{Ker}(L^TA^\dagger)^\perp$ and thus $w_1' \in \operatorname{Im}(A^{\dagger T} L)$, which can be written $w_1' = A^{\dagger T} L \delta$ for some $\delta \in \mathbb{R}^k$. Then ${w_1'}^T r = \delta^T L^T A^\dagger r = 0$. It follows that

$$g'(A,b).(\Delta A, \Delta b) = \frac{\|r\|_2}{\alpha} L^T(A^TA)^{-1} w_1 - \frac{\epsilon \|x\|_2}{\alpha} L^TA^\dagger w_1' - \frac{\epsilon}{\beta} L^TA^\dagger w_1'.$$

From $L^T(A^TA)^{-1} w_1 = \left\| L^T(A^TA)^{-1} \right\|_2 a_1$ and $L^TA^\dagger w_1' = \left\| L^TA^\dagger \right\|_2 a_1'$, we obtain

$$g'(A,b).(\Delta A, \Delta b) = \left\| L^T(A^TA)^{-1} \right\|_2 \frac{\|r\|_2}{\alpha} a_1 - \epsilon \left( \frac{\|x\|_2}{\alpha} + \frac{1}{\beta} \right) \left\| L^TA^\dagger \right\|_2 a_1'.$$

Since $a_1$ and $a_1'$ are unit vectors, $\|g'(A,b).(\Delta A, \Delta b)\|_2$ can be developed as

$$\begin{aligned} \|g'(A,b).(\Delta A, \Delta b)\|_2^2 = {} & \left\| L^T(A^TA)^{-1} \right\|_2^2 \frac{\|r\|_2^2}{\alpha^2} + \left\| L^TA^\dagger \right\|_2^2 \left( \frac{\|x\|_2}{\alpha} + \frac{1}{\beta} \right)^2 \\ & - 2\epsilon \left\| L^T(A^TA)^{-1} \right\|_2 \frac{\|r\|_2}{\alpha} \left( \frac{\|x\|_2}{\alpha} + \frac{1}{\beta} \right) \left\| L^TA^\dagger \right\|_2 \cos(a_1, a_1'). \end{aligned}$$

By choosing $\epsilon = -sign(\cos(a_1, a_1'))$ the third term of the above expression becomes positive. Furthermore we have $(\frac{\|x\|_2}{\alpha} + \frac{1}{\beta})^2 \geq \frac{\|x\|_2^2}{\alpha^2} + \frac{1}{\beta^2}$. Then we obtain

$$\|g'(A,b).(\Delta A, \Delta b)\|_2 \geq \left( \left\| L^T(A^TA)^{-1} \right\|_2^2 \frac{\|r\|_2^2}{\alpha^2} + \left\| L^TA^\dagger \right\|_2^2 \left( \frac{\|x\|_2^2}{\alpha^2} + \frac{1}{\beta^2} \right) \right)^{\frac{1}{2}},$$

i.e.,

$$\|g'(A,b).(\Delta A,\Delta b)\|_2 \geq f(A,b).$$

On the other hand, we have

$$\|\Delta A\|_F^2 = \left\|\frac{r}{\alpha\,\|r\|_2} w_1^T\right\|_F^2 + \left\|w_1' \frac{x^T}{\alpha\,\|x\|_2}\right\|_F^2 + 2\ \epsilon \ \text{trace}\left(\left(\frac{r}{\alpha\,\|r\|_2} w_1^T\right)^T \left(w_1' \frac{x^T}{\alpha\,\|x\|_2}\right)\right)$$

and

$$\left\|\frac{w_1'}{\beta}\right\|_2^2 = \frac{1}{\beta^2}$$

with

$$\left\|\frac{r}{\alpha\,\|r\|_2} w_1^T\right\|_F^2 = \left\|w_1' \frac{x^T}{\alpha\,\|x\|_2}\right\|_F^2 = \frac{1}{\alpha^2}, \qquad \text{trace}\left(\left(\frac{r}{\alpha\,\|r\|_2} w_1^T\right)^T \left(w_1' \frac{x^T}{\alpha\,\|x\|_2}\right)\right) = 0.$$

Then $\|(\Delta A,\Delta b)\|_F = \sqrt{3}$ and thus we have $\frac{\|g'(A,b).(\Delta A,\Delta b)\|_2}{\|(\Delta A,\Delta b)\|_F} \geq \frac{f(A,b)}{\sqrt{3}}$ for a particular value of $(\Delta A,\Delta b)$. Furthermore, from $\|(\Delta A,\Delta b)\|_2 \leq \|(\Delta A,\Delta b)\|_F$ we get $\frac{\|g'(A,b).(\Delta A,\Delta b)\|_2}{\|(\Delta A,\Delta b)\|_2} \geq \frac{f(A,b)}{\sqrt{3}}$ (for the same particular value of $(\Delta A,\Delta b)$). Then we obtain $\kappa_{g,F}(A,b) \geq \frac{f(A,b)}{\sqrt{3}}$ and $\kappa_{g,2}(A,b) \geq \frac{f(A,b)}{\sqrt{3}}$.

[illegible] 2. Let us now establish the upper bound for $\kappa_{g,F}(A,b)$ and $\kappa_{g,2}(A,b)$.

If $\Delta A_1 = AA^\dagger\Delta A$ and $\Delta A_2 = (I - AA^\dagger)\Delta A$, then it comes from (2.3) that $\forall(\Delta A,\Delta b) \in \mathbb{R}^{m\times n} \times \mathbb{R}^m$

$$\begin{aligned}\|g'(A,b).(\Delta A,\Delta b)\|_2 &\leq \left\|L^T(A^TA)^{-1}\right\|_2 \|\Delta A_2\|_2 \|r\|_2 \\ &\qquad + \left\|L^TA^\dagger\right\|_2 \|\Delta A_1\|_2 \|x\|_2 + \left\|L^TA^\dagger\right\|_2 \|\Delta b\|_2 \\ &= YX,\end{aligned}$$

where

$$Y = \left(\frac{\|L^T(A^TA)^{-1}\|_2 \|r\|_2}{\alpha}, \frac{\|L^TA^\dagger\|_2 \|x\|_2}{\alpha}, \frac{\|L^TA^\dagger\|_2}{\beta}\right)$$

and

$$X = (\alpha\,\|\Delta A_2\|_2\,, \alpha\,\|\Delta A_1\|_2\,, \beta\,\|\Delta b\|_2)^T.$$

Hence, from the Cauchy–Schwarz inequality we get

$$\|g'(A,b).(\Delta A,\Delta b)\|_2 \leq \|Y\|_2\,\|X\|_2\,, \tag{3.1}$$

with

$$\|X\|_2^2 = \alpha^2\,\|\Delta A_1\|_2^2 + \alpha^2\,\|\Delta A_2\|_2^2 + \beta^2\,\|\Delta b\|_2^2 \leq \alpha^2\,\|\Delta A_1\|_F^2 + \alpha^2\,\|\Delta A_2\|_F^2 + \beta^2\,\|\Delta b\|_2^2$$

and

$$\|Y\|_2 = f(A,b).$$

Then, since $\|\Delta A\|_F^2 = \|\Delta A_1\|_F^2 + \|\Delta A_2\|_F^2$, we have $\|X\|_2 \leq \|(\Delta A, \Delta b)\|_F$ and (3.1) yields

$$\|g'(A,b).(\Delta A, \Delta b)\|_2 \leq \|(\Delta A, \Delta b)\|_F \, \|Y\|_2 \, ,$$

which implies that

$$\kappa_{g,F}(A,b) \leq f(A,b).$$

An upper bound of $\kappa_{g,2}(A,b)$ can be computed in a similar manner: we get from (2.2) that

$$\begin{aligned} \|g'(A,b).(\Delta A, \Delta b)\|_2 &\leq (\left\|L^T(A^TA)^{-1}\right\|_2 \|r\|_2 + \left\|L^T A^\dagger\right\|_2 \|x\|_2) \, \|\Delta A\|_2 \\ &\quad + \left\|L^T A^\dagger\right\|_2 \|\Delta b\|_2 \\ &= Y'X', \end{aligned}$$

where

$$Y' = \left( \frac{\left\|L^T(A^TA)^{-1}\right\|_2 \|r\|_2 + \left\|L^T A^\dagger\right\|_2 \|x\|_2}{\alpha}, \frac{\left\|L^T A^\dagger\right\|_2}{\beta} \right)$$

and

$$X' = (\alpha \, \|\Delta A\|_2 \, , \beta \, \|\Delta b\|_2)^T.$$

Since $\|X'\|_2 = \|(\Delta A, \Delta b)\|_2$ we have $\kappa_{g,2}(A,b) \leq \|Y'\|_2$. Then using the inequality

$$\left(\left\|L^T(A^TA)^{-1}\right\|_2 \|r\|_2 + \left\|L^T A^\dagger\right\|_2 \|x\|_2\right)^2 \leq 2\left(\left\|L^T(A^TA)^{-1}\right\|_2^2 \|r\|_2^2 + \left\|L^T A^\dagger\right\|_2^2 \|x\|_2^2\right)$$

we get $\|Y'\|_2 \leq \sqrt{2} \, \|Y\|_2$ and finally obtain $\kappa_{g,2}(A,b) \leq \sqrt{2} f(A,b)$, which concludes the proof. □

Theorem 2 shows that $f(A,b)$ can be considered as a very sharp estimate of the partial condition number expressed either in Frobenius or spectral norm. Indeed, it lies within a factor $\sqrt{3}$ of $\kappa_{g,F}(A,b)$ or $\kappa_{g,2}(A,b)$.

Another observation is that we have

$$\frac{1}{\sqrt{6}} \leq \frac{\kappa_{g,F}(A,b)}{\kappa_{g,2}(A,b)} \leq \sqrt{3}.$$

Thus even if the Frobenius and spectral norms of a given matrix can be very different (for $X \in \mathbb{R}^{m \times n}$, we have $\|X\|_2 \leq \|X\|_F \leq \sqrt{n} \, \|X\|_2$), the condition numbers expressed in both norms are of the same order. The result is that a good estimate of $\kappa_{g,F}(A,b)$ is also a good estimate of $\kappa_{g,2}(A,b)$.

Moreover (2.6) shows that if the $R$ factor of $A$ is available, $f(A,b)$ can be computed by solving two $n \times n$ triangular systems with $k$ right-hand sides and thus the computational cost is $2kn^2$.

[illegible] 3. We can check in the following example that $\kappa_{g,F}(A,b)$ is not equal to $f(A,b)$. Let us consider

$$A = \begin{pmatrix} 2 & 0 \\ 0 & 1 \\ 0 & 0 \end{pmatrix}, \; L = \begin{pmatrix} 3 & 0 \\ 0 & 1 \end{pmatrix}, \text{ and } \; b = \begin{pmatrix} 2/\sqrt{2} \\ 1/\sqrt{2} \\ 1 \end{pmatrix}.$$

We have

$$x = (1/\sqrt{2}, 1/\sqrt{2})^T \quad \text{and} \quad \|x\|_2 = \|r\|_2 = 1,$$

and we get

$$\kappa_{g,F}(A, b) = \frac{\sqrt{45}}{4} \; < \; f(A, b) = \frac{\sqrt{13}}{2}.$$

4. Using the definition of the condition number and of the product norms, we can obtain tight estimates for the partial condition number for perturbations of $A$ only (resp., $b$ only) by taking $\alpha > 0$ and $\beta = +\infty$ (resp., $\beta > 0$ and $\alpha = +\infty$) in Theorem 2. In particular, when we perturb only $b$ we have, with the notation of section 2.1,

$$f(A, b) = \frac{\|L^T A^\dagger\|_2}{\beta} = \frac{\|T\|_2}{\beta} = \kappa_{g,F}(A, b).$$

Moreover, when $r = 0$ we have

$$f(A, b) = \|L^T A^\dagger\|_2 \left( \frac{\|x\|_2^2}{\alpha^2} + \frac{1}{\beta^2} \right)^{\frac{1}{2}} = \|T\|_2 \left( \frac{\|x\|_2^2}{\alpha^2} + \frac{1}{\beta^2} \right)^{\frac{1}{2}}.$$

5. In the special case where $L = I$, we have

$$f(A, b) = \left( \|(A^T A)^{-1}\|_2^2 \frac{\|r\|_2^2}{\alpha^2} + \|A^\dagger\|_2^2 \left( \frac{\|x\|_2^2}{\alpha^2} + \frac{1}{\beta^2} \right) \right)^{\frac{1}{2}}.$$

Since $\|(A^T A)^{-1}\|_2 = \|A^\dagger\|_2^2$ we obtain that

$$f(A, b) = \|A^\dagger\|_2 \sqrt{\frac{\|A^\dagger\|_2^2 \|r\|_2^2 + \|x\|_2^2}{\alpha^2} + \frac{1}{\beta^2}}.$$

In that case $\kappa_{g,F}(A, b)$ is exactly equal to $f(A, b)$ due to [8].

Regarding the condition number in the spectral norm, since we have $\|(\Delta A, \Delta b)\|_2 \leq \|(\Delta A, \Delta b)\|_F$ we get $\kappa_{g,2}(A, b) \geq f(A, b)$. This lower bound is similar to that obtained in [6] (where only $A$ is perturbed). As mentioned in [6], an upper bound of $\kappa_{g,2}(A)$ is $\kappa_{g,2}^u(A) = \|A^\dagger\|_2^2 \|r\|_2 + \|A^\dagger\|_2 \|x\|_2$. If we take $\alpha = 1$ and $\beta = +\infty$, we notice that $f(A, b) \leq \kappa_{g,2}^u(A) \leq \sqrt{2} f(A, b)$, showing thus that our upper bound and $\kappa_{g,2}^u(A)$ are essentially the same.

6. Generalization to other product norms:

Other product norms may have been used for the data space $\mathbb{R}^{m \times n} \times \mathbb{R}^m$.

If we consider a norm $\nu$ on $\mathbb{R}^2$ such that $c_1 \nu(x, y) \leq \sqrt{x^2 + y^2} \leq c_2 \nu(x, y)$, then we can define a product norm $\|(A, b)\|_{F,\nu} = \nu(\alpha \|\Delta A\|_F, \beta \|\Delta b\|_2)$. For instance, in [9], $\nu$ corresponds to $\|.\|_\infty$. Note that the product norm $\|(.,.)\|_F$ used throughout this paper corresponds to $\nu = \|.\|_2$ and that with the above notation we have $\|(A, b)\|_{F,2} = \|(A, b)\|_F$. Then the following inequality holds:

$$c_1 \|(\Delta A, \Delta b)\|_{F,\nu} \leq \|(\Delta A, \Delta b)\|_F \leq c_2 \|(\Delta A, \Delta b)\|_{F,\nu}.$$

If we denote $\kappa_{g,F,\nu}(A,b) = \max_{(\Delta A,\Delta b)} \frac{\left\|g'(A,b).(\Delta A,\Delta b)\right\|_2}{\|(\Delta A,\Delta b)\|_{F,\nu}}$, we obtain

$$\frac{\kappa_{g,F,\nu}(A,b)}{c_2} \leq \kappa_{g,F}(A,b) \leq \frac{\kappa_{g,F,\nu}(A,b)}{c_1}.$$

Using the bounds for $\kappa_{g,F}$ given in Theorem 2 we can obtain tight bounds for the partial condition number expressed using the product norm based on $\nu$ and when the perturbations on matrices are measured with the Frobenius norm:

$$\frac{c_1}{\sqrt{3}} f(A,b) \leq \kappa_{g,F,\nu}(A,b) \leq c_2 f(A,b).$$

Similarly, if the perturbations on matrices are measured with the spectral norm, we get

$$\frac{c_1}{\sqrt{3}} f(A,b) \leq \kappa_{g,F,\nu}(A,b) \leq c_2 \sqrt{2} f(A,b).$$

The bounds obtained for three possible product norms ($\nu = \|.\|_\infty$, $\nu = \|.\|_2$, and $\nu = \|.\|_1$) are given in Table 3.1 when using the Frobenius norm for matrices and in Table 3.2 when using the spectral norm for matrices.

Table 3.1
*Bounds for partial condition number (Frobenius norm on matrices).*

| Product norm | $\nu$, $c_1$, $c_2$ | Lower bound (factor of $f(A,b)$) | Upper bound (factor of $f(A,b)$) |

## 4. Statistical estimation of the partial condition number.

In this section we compute a statistical estimate of the partial condition number. We have seen in section 3 that using the Frobenius or the spectral norm for the matrices gives condition numbers that are of the same order of magnitude. For the sake of simplicity, we compute here a statistical estimate of $\kappa_{g,F}(A,b)$.

Let $(z_1, z_2, \ldots, z_q)$ be an orthonormal basis for a subspace of dimension $q$ ($q \leq k$) that has been randomly and uniformly selected from the space of all $q$-dimensional subspaces of $\mathbb{R}^k$ (this can be done by choosing $q$ random vectors and then orthogonalizing). Let us denote $g_i(A,b) = (Lz_i)^T x(A,b)$.

Since $Lz_i \in \mathbb{R}^n$, the absolute condition number of $g_i$ can be computed via the exact formula given in Corollary 1, i.e.,

$$\kappa_{g_i,F}(A,b) = \left( \left\| (Lz_i)^T (A^TA)^{-1} \right\|_2^2 \frac{\|r\|_2^2}{\alpha^2} + \left\| (Lz_i)^T A^\dagger \right\|_2^2 \left( \frac{\|x\|_2^2}{\alpha^2} + \frac{1}{\beta^2} \right) \right)^{\frac{1}{2}}. \tag{4.1}$$

We define the random variable $\phi(q)$ by

$$\phi(q) = \left( \frac{k}{q} \sum_{i=1}^{q} \kappa_{g_i,F}(A,b)^2 \right)^{\frac{1}{2}}.$$

Let the operator $E(.)$ denote the expected value. The following proposition shows that the root mean square of $\phi(q)$, defined by $R(\phi(q)) = \sqrt{E(\phi(q)^2)}$, can be considered as an estimate for the condition number of $g(A,b) = L^T x(A,b)$.

Proposition 1. [illegible]

$$\frac{R(\phi(q))}{\sqrt{k}} \leq \kappa_{g,F}(A,b) \leq R(\phi(q)). \tag{4.2}$$

[illegible]. Let *vec* be the operator that stacks the columns of a matrix into a long vector and let $M$ be the $k \times m(n+1)$ matrix such that $vec(g'(A,b).(\Delta A, \Delta b)) = M\binom{vec(\alpha\Delta A)}{vec(\beta\Delta b)}$. Note that $M$ depends on $A$, $b$, $L$ and not on the $z_i$.

Then we have

$$\begin{aligned}\kappa_{g,F}(A,b) &= \max_{(\Delta A,\Delta b)} \frac{\|g'(A,b).(\Delta A,\Delta b)\|_2}{\|(\Delta A,\Delta b)\|_F} = \max_{(\Delta A,\Delta b)} \frac{\|vec(g'(A,b).(\Delta A,\Delta b))\|_2}{\left\| \begin{pmatrix} vec(\alpha\Delta A) \\ vec(\beta\Delta b) \end{pmatrix} \right\|_2} \\ &= \max_{z \in \mathbb{R}^{m(n+1)}, z \neq 0} \frac{\|M\, z\|_2}{\|z\|_2} = \|M\|_2 = \left\|M^T\right\|_2.\end{aligned}$$

Let $Z = [z_1, z_2, \ldots, z_q]$ be the $k \times q$ random matrix with orthonormal columns $z_i$. From [10] it follows that $\frac{k}{q}\left\|M^T Z\right\|_F^2$ is an unbiased estimator of the Frobenius norm of the $m(n+1) \times k$ matrix $M^T$, i.e., we have $E(\frac{k}{q}\left\|M^TZ\right\|_F^2) = \left\|M^T\right\|_F^2$.

From

$$\begin{aligned}\left\|M^TZ\right\|_F^2 &= \left\|Z^TM\right\|_F^2 \\ &= \left\| \begin{pmatrix} z_1^TM \\ \vdots \\ z_q^TM \end{pmatrix} \right\|_F^2\end{aligned}$$

we get, since $z_i^TM$ is a row vector,

$$\left\|M^TZ\right\|_F^2 = \sum_{i=1}^{q} \left\|z_i^TM\right\|_2^2.$$

We notice that for every vector $u \in \mathbb{R}^k$, if we consider the function $g_u(A,b) = u^Tg(A,b)$, then we have $\left\|u^TM\right\|_F = \|g_u'(A,b)\| = \kappa_{g_u,F}(A,b)$ and therefore

$$\left\|z_i^TM\right\|_F = \kappa_{g_i,F}(A,b).$$

Eventually we obtain

$$\left\|M^T\right\|_F^2 = E\left(\frac{k}{q}\sum_{i=1}^{q}\kappa_{g_i,F}(A,b)^2\right) = E(\phi(q)^2).$$

Moreover, considering that $M^T \in \mathbb{R}^{m(n+1)\times k}$ and using the well-known inequality

$$\frac{\left\|M^T\right\|_F}{\sqrt{k}} \leq \left\|M^T\right\|_2 \leq \left\|M^T\right\|_F,$$

we get the result (4.2). Then we will consider $\phi(q)\frac{\|(A,b)\|_F}{\|L^T\tilde{x}\|_2}$ as an estimator of $\kappa_{g,F}^{(rel)}(A,b)$. □

The root mean square of $\phi(q)$ is an upper bound of $\kappa_g(A,b)$, and estimates $\kappa_{g,F}(A,b)$ within a factor $\sqrt{k}$. Proposition 1 involves the computation of the condition number of each $g_i(A,b), i = 1,\dots,q$. From Remark 2, it follows that the computational cost of each $\kappa_{g_i,F}(A,b)$ is $2n^2$ (if the $R$ factor of the QR decomposition of $A$ is available). Hence, for a given sample of vectors $z_i$, $i = 1,\dots,q$, computing $\phi(q)$ requires about $2qn^2$ flops.

However, Proposition 1 is mostly of theoretical interest, since it relies on the computation of the root mean square of a random variable, without providing a practical method to obtain it. In the next proposition, the use of the small sample estimate theory developed by Gudmundsson, Kenney, and Laub [10] gives a first answer to this question by showing that the evaluation of $\phi(q)$ using only one sample of $q$ vectors $z_1, z_2, \dots, z_q$ in the unit sphere may provide an acceptable estimate.

PROPOSITION 2. [illegible] [10, p. 781] [illegible] $\alpha > 10$

$$\Pr\left(\frac{\phi(q)}{\alpha\sqrt{k}} \leq \kappa_{g,F}(A,b) \leq \alpha\phi(q)\right) \geq 1-\alpha^{-q}.$$

[illegible] 1 [illegible] $q$ [illegible] $\alpha = 11$ [illegible] $q = 3$ [illegible] $\phi(q)$ [illegible] $\kappa_{g,F}(A,b)$ [illegible] $11\sqrt{k}$ [illegible] 99.9%

[illegible]. We define as in the proof of Proposition 1 the matrix $M$ as the matrix related to the *vec* operation representing the linear operator $g'(A,b)$. From [10, eq. (4), p. 781 and eq. (9), p. 783] we get

$$\Pr\left(\frac{\left\|M^T\right\|_F}{\alpha} \leq \phi(q) \leq \alpha\left\|M^T\right\|_F\right) \geq 1-\alpha^{-q}. \tag{4.3}$$

We have seen in the proof of Proposition 1 that $\kappa_{g,F}(A,b) = \left\|M^T\right\|_2$. Then we have

$$\kappa_{g,F}(A,b) \leq \left\|M^T\right\|_F \leq \kappa_{g,F}(A,b)\,\sqrt{k}.$$

It follows that, for the random variable $\phi(q)$, we have

$$\Pr\left(\frac{\kappa_{g,F}(A,b)}{\alpha} \leq \phi(q) \leq \alpha\kappa_{g,F}(A,b)\,\sqrt{k}\right) \geq \Pr\left(\frac{\left\|M^T\right\|_F}{\alpha} \leq \phi(q) \leq \alpha\left\|M^T\right\|_F\right).$$

Then we obtain the result from

$$\Pr\left(\frac{\kappa_{g,F}(A,b)}{\alpha} \leq \phi(q) \leq \alpha\kappa_{g,F}(A,b)\,\sqrt{k}\right) = \Pr\left(\frac{\phi(q)}{\alpha\sqrt{k}} \leq \kappa_{g,F}(A,b) \leq \alpha\phi(q)\right). \quad \square$$

We see from this proposition that it may not be necessary to estimate the root mean square of $\phi(q)$ using sophisticated algorithms. Indeed only one sample of $\phi(q)$ obtained for $q = 3$ provides an estimate of $\kappa_{g,F}(A, b)$ within a factor $\alpha\sqrt{k}$.

[illegible] 7. If $k = 1$, then $Z = 1$ and the problem is reduced to computing $\kappa_{g_1}(A, b)$. In this case, $\phi(1)$ is exactly the partial condition number of $L^T x(A, b)$.

[illegible] 8. Concerning the computation of the statistical estimate in the presence of roundoff errors, the numerical reliability of the statistical estimate relies on an accurate computation of the $\kappa_{g_i,F}(A, b)$ for a given $z_i$. Let $A$ be a $17\times13$ Vandermonde matrix, $b$ a random vector, and $L \in \mathbb{R}^n$ the right singular vector $v_n$.

Using the [illegible] software that computes in exact arithmetic, we obtained $\kappa_{g,F}^{(rel)}(A, b) \approx 5 \cdot 10^8$. If the triangular factor $R$ form $A^T A = R^T R$ is obtained by the QR decomposition of $A$, we get $\kappa_{g,F}^{(rel)}(A, b) \approx 5 \cdot 10^8$. If $R$ is computed via a classical Cholesky factorization, we get $\kappa_{g,F}(A, b)^{(rel)} \approx 10^{10}$.

Corollary 1 and Remark 2 show that the computation of $\kappa_{g,F}(A, b)^{(rel)}$ involves linear systems of the type $A^T Ax = d$, which differs from the usual normal equation for least squares in their right-hand side. Our observation that for this kind of ill-conditioned systems, a QR factorization is more accurate than a Cholesky factorization is in agreement with [5].

## 5. Numerical experiments.

All experiments were performed in MATLAB 6.5 using a machine precision of $2.22 \cdot 10^{-16}$.

### 5.1. Examples.

For the examples of section 1, we compute the partial condition number using the formula given in Theorem 1.

In the first example we have

$$A = \begin{pmatrix} 1 & 1 & \epsilon^2 \\ \epsilon & 0 & \epsilon^2 \\ 0 & \epsilon & \epsilon^2 \\ \epsilon^2 & \epsilon^2 & 2 \end{pmatrix},$$

and we assume that only $A$ is perturbed. If we consider the values for $L$ that are $\left(\begin{smallmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)$ and $L = (0, 0, 1)^T$, then we obtain partial condition numbers $\kappa_{g,F}^{(rel)}(A)$ that are, respectively, $10^{24}$ and 1.22, as expected since there is 50% relative error on $x_1$ and $x_2$ and there is no error on $x_3$.

In the second example where $A$ is the $10 \times 4$ Vandermonde matrix defined by $A_{ij} = \frac{1}{(10+i)^{j-1}}$ and only $b$ is perturbed, the partial condition numbers $\kappa_{g,F}^{(rel)}(b)$ with respect to each component $x_1, x_2, x_3, x_4$ are, respectively, $4.5 \cdot 10^2, 2 \cdot 10^4, 3 \cdot 10^5, 1.4 \cdot 10^6$, which is consistent with the error variation given in section 1 for each component.

### 5.2. Average behavior of the statistical estimate.

We compare here the statistical estimate described in the previous section with the partial condition number obtained via the exact formula given in Theorem 1. We suppose that only $A$ is perturbed and then the partial condition number can be expressed as $\kappa_{g,F}^{(rel)}(A)$. We use the method described in [16] in order to construct test problems $[A, x, r, b] = P(m, n, n_r, l)$ with

$$A = Y \begin{pmatrix} D \\ 0 \end{pmatrix} Z^T \in \mathbb{R}^{m\times n}, \quad Y = I - 2yy^T, \; Z = I - 2zz^T,$$

where $y \in \mathbb{R}^m$ and $z \in \mathbb{R}^n$ are random unit vectors and where $D = n^{-l} \operatorname{diag}(n^l, (n-1)^l, \ldots, 1)$.

$x = (1, 2^2, \ldots, n^2)^T$ is given and $r = Y\binom{0}{c} \in \mathbb{R}^m$ is computed with $c \in \mathbb{R}^{m-n}$ random vector of norm $n_r$. The right-hand side is $b = Y\binom{DZx}{c}$. By construction, the condition number of $A$ and $D$ is $n^l$.

In our experiments, we consider the matrices

$$A = \begin{pmatrix} A_1 & E' \\ E & A_2 \end{pmatrix} \quad \text{and} \quad L = \begin{pmatrix} I \\ 0 \end{pmatrix},$$

where $A_1 \in \mathbb{R}^{m_1 \times n_1}$, $A_2 \in \mathbb{R}^{m_2 \times n_2}$, $L \in \mathbb{R}^{n \times n_1}$, $m_1 + m_2 = m$, $n_1 + n_2 = n$, and $E$ and $E'$ contain the same element $e_p$ which defines the coupling between $A_1$ and $A_2$. The matrices $A_1$ and $A_2$ are randomly generated using, respectively, $P(m_1, n_1, n_{r_1}, l_1)$ and $P(m_2, n_2, n_{r_2}, l_2)$.

For each sample matrix, we compute in MATLAB

1. the partial condition number $\kappa_{g,F}^{(rel)}(A)$ using the exact formula given in Theorem 1 and based on the singular value decomposition of $A$;
2. the statistical estimate $\phi(3)$ using three random orthogonal vectors and computing each $\kappa_{g_i,F}(A, b), i = 1, 3$, with the $R$ factor of the QR decomposition of $A$.

These data are then compared by computing the ratio

$$\gamma = \frac{\phi(3)}{\kappa_{g,F}^{(rel)}(A)}.$$

Table 5.1 contains the mean $\overline{\gamma}$ and the standard deviation $s$ of $\gamma$ obtained on 1000 random matrices with $m_1 = 12, n_1 = 10, m_2 = 17, n_2 = 13$ by varying the condition numbers ${n_1}^{l_1}$ and ${n_2}^{l_2}$ of, respectively, $A_1$ and $A_2$ and the coupling coefficient $e_p$. The residual norms are set to $n_{r_1} = n_{r_2} = 1$. In all cases, $\overline{\gamma}$ is close to 1 and $s$ is about 0.3. The statistical estimate $\phi(3)$ lies within a factor 1.22 of $\kappa_{g,F}^{(rel)}(A)$, which is very accurate in condition number estimation. We notice that in two cases $\phi(3)$ is lower than 1. This is possible because Proposition 1 shows that $E(\phi(3)^2)$ is an upper bound of $\kappa_{g,F}(A)^2$ but not necessarily $\phi(3)^2$.

TABLE 5.1
*Ratio between statistical and exact condition numbers of $L^T x$.*

| Condition | | $e_p = 10^{-5}$ | | $e_p = 1$ | | $e_p = 10^5$ | |
|---|---|---|---|---|---|---|---|
| $l_1$ | $l_2$ | $\overline{\gamma}$ | $s$ | $\overline{\gamma}$ | $s$ | $\overline{\gamma}$ | $s$ |
| 1 | 1 | 1.22 | $2.28 \cdot 10^{-1}$ | 1.15 | $2.99 \cdot 10^{-1}$ | 1.07 | $3.60 \cdot 10^{-1}$ |
| 1 | 8 | 1.02 | $3.19 \cdot 10^{-1}$ | 1.22 | $3.05 \cdot 10^{-1}$ | 1.21 | $3.35 \cdot 10^{-1}$ |
| 8 | 1 | $9 \cdot 10^{-1}$ | $3 \cdot 10^{-1}$ | 1.13 | $3 \cdot 10^{-1}$ | 1.06 | $3.45 \cdot 10^{-1}$ |
| 8 | 8 | $9.23 \cdot 10^{-1}$ | $2.89 \cdot 10^{-1}$ | 1.22 | $2.95 \cdot 10^{-1}$ | 1.18 | $3.33 \cdot 10^{-1}$ |

## 6. Estimates versus exact formula.

We assume that the $R$ factor of the QR decomposition of $A$ is known. We gather in Table 6.1 the results obtained in this paper in terms of accuracy and flop counts for the estimation of the partial condition number for the LLSP. Table 6.2 gives the estimates and flop counts in the particular situation where

$$m = 1500, \; n = 1000, \; k = 50,$$

$$A_1 = \begin{pmatrix} 2 & 0 \\ 0 & 1 \end{pmatrix}, \; L_1 = \begin{pmatrix} 3 & 0 \\ 0 & 1 \end{pmatrix},$$

Table 6.1
*Comparison between exact formula and estimates for $\kappa_{g,F}(A,b)$.*

| $\kappa_{g,F}(A,b)$ | Flops | Accuracy |
|---|---|---|
| Exact formula<br>$n \ll m$ | $12n^3$ | Exact |
| Sharp estimate $f(A,b)$<br>$k \ll n$ | $2kn^2$ | $\frac{f(A,b)}{\sqrt{3}} \leq \kappa_{g,F}(A,b) \leq f(A,b)$ |
| Stat. estimate $\phi(q)$<br>$q \ll k$ | $2qn^2$ | $\frac{\phi(q)}{\alpha\sqrt{k}} \leq \kappa_{g,F}(A,b) \leq \alpha\phi(q)$<br>$Pr \geq 1-\alpha^{-q}$ for $\alpha > 10$ |

Table 6.2
*Flops and accuracy: exact formula versus estimates.*

| $\kappa_{g,F}^{(rel)}(A,b)$ | $f(A,b)\frac{\Vert(A,b)\Vert_F}{\Vert L^T\tilde{x}\Vert_2}$ | $\phi(q)\frac{\Vert(A,b)\Vert_F}{\Vert L^T\tilde{x}\Vert_2}$ |
|---|---|---|
| $2.09 \cdot 10^2$<br>12 Gflops | $2.18 \cdot 10^2$<br>100 Mflops | $11.44 \cdot 10^2$<br>6 Mflops |

$$A = \begin{pmatrix} A_1 & 0 \\ 0 & I_{n-2} \\ 0 & 0 \end{pmatrix} \text{ and } b = \frac{1}{\sqrt{2}}(2,1,\ldots,1)^T,\ L = \begin{pmatrix} L_1 & 0 \\ 0 & I_{k-2} \\ 0 & 0 \end{pmatrix}.$$

We see here that the statistical estimates may provide information on the condition number using a very small amount of floating point operations compared with the other two methods.

**7. Conclusion.** We have shown the relevance of the partial condition number for test cases from parameter estimation. This partial condition number evaluates the sensitivity of $L^T x$, where $x$ is the solution of an LLSP when $A$ and/or $b$ are perturbed. It can be computed via a closed formula, a sharp estimate, or a statistical estimate. The choice will depend on the size of the LLSP and on the needed accuracy. The closed formula requires $\mathcal{O}(n^3)$ flops and is affordable for small problems only. The sharp estimate and the statistical estimate will be preferred for larger problems especially if $k \ll n$ since their computational cost is in $\mathcal{O}(n^2)$.

# DYNAMICAL LOW-RANK APPROXIMATION*

OTHMAR KOCH† AND CHRISTIAN LUBICH†

**Abstract.** For the low-rank approximation of time-dependent data matrices and of solutions to matrix differential equations, an increment-based computational approach is proposed and analyzed. In this method, the derivative is projected onto the tangent space of the manifold of rank-$r$ matrices at the current approximation. With an appropriate decomposition of rank-$r$ matrices and their tangent matrices, this yields nonlinear differential equations that are well suited for numerical integration. The error analysis compares the result with the pointwise best approximation in the Frobenius norm. It is shown that the approach gives locally quasi-optimal low-rank approximations. Numerical experiments illustrate the theoretical results.

## 1. Introduction.

Low-rank approximation of unbearably large system matrices is a basic model reduction technique in many application areas, such as image compression, linear dynamical systems, regularization methods for ill-posed problems, and latent semantic indexing in information retrieval. In the present paper, we consider the task of computing low-rank approximations to matrices $A(t) \in \mathbb{R}^{m\times n}$ depending smoothly on a real parameter, henceforth referred to as time $t$. At any time $t$, a best approximation to $A(t)$ of rank $r$ is a matrix $X(t)$ in the manifold $\mathcal{M}_r = \mathcal{M}_r^{m\times n}$ of rank-$r$ matrices that satisfies

$$X(t) \in \mathcal{M}_r \quad \text{such that} \quad \|X(t) - A(t)\| = \min! \tag{1.1}$$

This is formulated for a matrix norm, which we choose as the Frobenius norm in the following. The problem is solved by a singular value decomposition (SVD) of $A(t)$, truncating all singular values after the $r$ largest ones. When the matrix is so large that a complete SVD is not feasible, a standard approach to obtaining an approximate solution is based on the Lanczos bidiagonalization process with $A(t)$ [15].

Here, we consider instead the low-rank approximation $Y(t) \in \mathcal{M}_r$ determined from the condition that for every $t$ the derivative $\dot{Y}(t)$, which is in the tangent space $\mathcal{T}_{Y(t)}\mathcal{M}_r$, be chosen as

$$\dot{Y}(t) \in \mathcal{T}_{Y(t)}\mathcal{M}_r \quad \text{such that} \quad \|\dot{Y}(t) - \dot{A}(t)\| = \min! \tag{1.2}$$

This is complemented with an initial condition, ideally $Y(t_0) = X(t_0)$. For given $Y(t)$, the derivative $\dot{Y}(t)$ is obtained by a [illegible] projection, though onto a solution-dependent vector space. Problem (1.2) yields an initial value problem of nonlinear ordinary differential equations on $\mathcal{M}_r$, which becomes numerically efficiently accessible after choosing a suitable factorization of rank-$r$ matrices.

There are several independent reasons that make the approach to low-rank approximation via (1.2) attractive:

(a) Problem (1.2) and its solution algorithm depend on the increments $\dot{A}(t)$ instead of the complete data matrix $A(t)$. This appears to be an essential benefit in processes where $\dot{A}(t)$ is much [illegible] than $A(t)$, e.g., in series of moving images or in time-varying term-document matrices in information retrieval (updates are usually small compared to the whole encyclopedia).

(b) Solving the differential equations corresponding to (1.2) requires only multiplications of $\dot{A}(t)$ with matrices having few $(r)$ columns, but [illegible] of matrices of the size of $A$, except for the low-rank approximation to the initial data $A(t_0)$.

(c) The differential equations for $Y(t)$ yield a [illegible] low-rank approximation. This is not assured when computing a pointwise best approximation, which is not unique in general.

(d) Since the problem (1.2) of determining $\dot{Y}(t)$ for given $Y(t)$ is linear, the approach extends more easily than (1.1) to [illegible] low-rank approximation, where $\mathcal{M}_r$ is replaced by some submanifold.

(e) In contrast to (1.1), the approach (1.2) extends to the situation where $A(t)$ is not a given matrix but the unknown solution of a [illegible], a matrix differential equation $\dot{A} = F(A)$. In this case, $\dot{A}(t)$ in (1.2) is simply replaced by the approximation $F(Y(t))$, so that the defect in the differential equation is minimized:

$$\dot{Y}(t) \in \mathcal{T}_{Y(t)}\mathcal{M}_r \quad \text{such that} \quad \|\dot{Y}(t) - F(Y((t))\| = \min! \tag{1.3}$$

Some comments and references to these aspects are in order: (a) and (b) are related to updating problems for low-rank approximations [3, 17], and item (c) to smooth decompositions of matrices, in particular to smooth SVD and the corresponding differential equations [1, 4, 7, 13, 16]. Item (d) refers to structured low-rank approximation as considered in [5, 6] for time-independent matrices. Item (e) and its generalization to low-rank approximation of tensors have a surprisingly long history in quantum mechanics: in 1930, Dirac [8] proposed to approximate the solution of the time-dependent Schrödinger equation, the multivariate wave function $\psi(x_1, \ldots, x_d, t)$, by a rank-1 approximation, namely an (antisymmetrized) tensor product $\phi_1(x_1, t) \ldots \phi_d(x_d, t)$, and derived differential equations for the functions $\phi_k$ from a variational principle analogous to (1.3), which is now known as the [illegible] in the chemical physics literature; see the historical references [8, 9] and, e.g., [2, 12]. Since the 1990s, the numerical approach of approximating the wave function by linear combinations of tensor products obeying differential equations derived from the Dirac–Frenkel principle (the multiconfiguration time-dependent Hartree or MCTDH method) has been used with great success for computations in quantum molecular dynamics [2]. It was, in fact, our work on variational approximations in quantum dynamics that led us to consider the dynamical low-rank matrix approximation (1.2), which does not appear to have been used or studied previously.

In the present paper we formulate the differential equations determining the solution of (1.2) and study the approximation properties of this approach, comparing the deviation from the best approximation, $Y(t) - X(t)$, with the best-approximation error $X(t) - A(t)$.

In section 2, we describe decompositions of rank-$r$ matrices and their tangent matrices, and we derive differential equations for the factors that define the rank-$r$

approximation $Y(t)$. These differential equations are used for the numerical solution of the problem. In section 3 we illustrate the approach and the behavior of the dynamical low-rank approximation (1.2) by numerical experiments.

The analysis of the approximation properties of (1.2) turns out to be more demanding than the formal similarity of (1.1) and (1.2) would suggest. In section 4 we give a preparatory result on orthogonal projections onto tangent spaces of $\mathcal{M}_r$. The approximation properties of (1.2) are then studied in section 5 under the assumption that $A(t)$ is a perturbation to a matrix of rank $\le r$. We first give near-optimality results when the effective rank of $A(t)$ is equal to $r$ (Theorems 5.1 and 5.2), and then extend the result to the case where $r$ in (1.2) is larger than the effective rank (Theorem 5.3). A further approximation result concerns systems without gaps in the distribution of the singular values (Theorem 5.5). Before turning to these approximation results, however, it should be noted that $Y(t)$ cannot always be expected to remain close to $X(t)$. This is already seen from the example of finding a rank-1 approximation to $\operatorname{diag}(e^{-t}, e^{t})$, where starting from $t_0 < 0$ yields $X(t) = Y(t) = \operatorname{diag}(e^{-t}, 0)$ for $t < 0$, but $Y(t) = \operatorname{diag}(e^{-t}, 0)$ and $X(t) = \operatorname{diag}(0, e^{t})$ for $t > 0$. The best approximation $X(t)$ here has a discontinuity at $t = 0$, caused by a crossing of singular values of which one is inside and the other outside the approximation. Our results show, however, that $Y(t)$ yields a near-optimal approximation on intervals where a good smooth approximation exists.

In section 6 we consider the following extensions of the basic approach:

- Regularization: the inverses of ill-conditioned matrices in the differential equations are replaced by regularized inverses.
- Stabilization: the differential equations are stabilized in order to drive the dynamical approximation toward the best approximation.
- Structured low-rank approximation: as an example we consider the problem of approximation by rank-$r$ orthogonal projections.
- Matrix differential equations: we extend the method and the approximation results to the low-rank approximation (1.3) to solutions of matrix differential equations $\dot{A} = F(A)$.

The present paper deals with theoretical aspects of the dynamical low-rank approximation. Our very promising first experiences in using this technique for applications ranging from the compression of time-varying term-document matrices and of series of images to the computation of blow-up in reaction-diffusion equations are reported in [14].

Throughout the paper, $\|\cdot\|$ is the Frobenius norm,

$$\|A\| = \left( \sum_{i,j} a_{ij}^2 \right)^{1/2},$$

and $\langle \cdot, \cdot \rangle$ denotes the corresponding inner product, $\langle A, B \rangle = \operatorname{tr}(A^T B) = \sum_{i,j} a_{ij} b_{ij}$. We make frequent use of the inequality $\|AB\| \le \|A\|_2 \cdot \|B\|$ and occasionally of $\|A\|_2 \le \|A\|$, where $\|\cdot\|_2$ is the spectral norm.

## 2. Differential equations for low-rank approximation.

### 2.1. Decompositions of rank-$r$ matrices and of their tangent matrices.

Every real rank-$r$ matrix of dimension $m \times n$ can be written in the form

$$Y = USV^T, \tag{2.1}$$

where $U \in \mathbb{R}^{m\times r}$ and $V \in \mathbb{R}^{n\times r}$ have orthonormal columns, i.e.,

$$U^TU = I_r, \qquad V^TV = I_r \tag{2.2}$$

(with the identity matrix $I_r$ of dimension $r$), and $S \in \mathbb{R}^{r\times r}$ is nonsingular. The SVD yields $S$ diagonal, but here we will not assume a special form of $S$. The representation (2.1) is not unique: replacing $U$ by $\widetilde{U} = UP$ and $V$ by $\widetilde{V} = VQ$ with orthogonal matrices $P, Q \in \mathbb{R}^{r\times r}$, and correspondingly $S$ by $\widetilde{S} = P^TSQ$, yields the same matrix $Y = USV^T = \widetilde{U}\widetilde{S}\widetilde{V}^T$.

As a substitute for the nonuniqueness in the decomposition (2.1), we will use a [illegible]. Let $\mathcal{V}_{m,r}$ denote the Stiefel manifold of real $m \times r$ matrices with orthonormal columns. The tangent space at $U \in \mathcal{V}_{m,r}$ is

$$\mathcal{T}_U\mathcal{V}_{m,r} = \{\delta U \in \mathbb{R}^{m\times r} :\ \delta U^TU + U^T\delta U = 0\} = \{\delta U \in \mathbb{R}^{m\times r} :\ U^T\delta U \in \mathrm{so}(r)\},$$

where so$(r)$ denotes the space of skew-symmetric real $r \times r$ matrices. Consider the extended tangent map of $(S, U, V) \mapsto Y = USV^T$,

$$\begin{aligned} \mathbb{R}^{r\times r} \times \mathcal{T}_U\mathcal{V}_{m,r} \times \mathcal{T}_V\mathcal{V}_{n,r} &\to \mathcal{T}_Y\mathcal{M}_r \times \mathrm{so}(r) \times \mathrm{so}(r), \\ (\delta S, \delta U, \delta V) &\mapsto (\delta USV^T + U\delta SV^T + US\delta V^T, U^T\delta U, V^T\delta V). \end{aligned}$$

This linear map is an isomorphism, since it is readily seen to have zero null-space, and since the dimensions of the vector spaces on both sides agree.

Hence, every tangent matrix $\delta Y \in \mathcal{T}_Y\mathcal{M}_r$ is of the form

$$\delta Y = \delta USV^T + U\delta SV^T + US\delta V^T, \tag{2.3}$$

where $\delta S \in \mathbb{R}^{r\times r}$, and $\delta U \in \mathcal{T}_U\mathcal{V}_{m,r}$ and $\delta V \in \mathcal{T}_V\mathcal{V}_{n,r}$. Moreover, $\delta S, \delta U, \delta V$ are uniquely determined by $\delta Y$ if we impose the orthogonality constraints

$$U^T\delta U = 0, \qquad V^T\delta V = 0. \tag{2.4}$$

With the identity matrices $I_m$, $I_n$ of dimensions $m$ and $n$, respectively, we define by

$$P_U = UU^T, \quad P_V = VV^T, \quad P_U^{\perp} = I_m - P_U, \quad P_V^{\perp} = I_n - P_V \tag{2.5}$$

the orthogonal projections onto the spaces spanned by the columns of $U$ and $V$, and onto their orthogonal complements, respectively. Now, (2.3) and (2.4) yield

$$\begin{aligned} \delta S &= U^T\delta YV, \\ \delta U &= P_U^{\perp}\delta YVS^{-1}, \\ \delta V &= P_V^{\perp}\delta Y^TUS^{-T}. \end{aligned} \tag{2.6}$$

Formulas (2.3) and (2.6) establish an isomorphism between the subspace

$$\{(\delta S, \delta U, \delta V) \in \mathbb{R}^{r\times r} \times \mathbb{R}^{m\times r} \times \mathbb{R}^{n\times r} : U^T\delta U = 0,\ V^T\delta V = 0\}$$

and the tangent space $\mathcal{T}_Y\mathcal{M}_r$.

**2.2. The differential equations for the factors.** The minimization condition (1.2) on the tangent space is equivalent to an orthogonal projection: find $\dot{Y} \in \mathcal{T}_Y\mathcal{M}_r$ (we omit the argument $t$) satisfying

$$\langle \dot{Y} - \dot{A}, \delta Y \rangle = 0 \quad \text{for all} \;\; \delta Y \in \mathcal{T}_Y\mathcal{M}_r. \tag{2.7}$$

From the viewpoint of numerical analysis, this is a Galerkin condition on the tangent space $\mathcal{T}_Y\mathcal{M}_r$. With this formulation we derive differential equations for the factors in the representation (2.1).

PROPOSITION 2.1. [illegible] $Y = USV^T \in \mathcal{M}_r$ [illegible] $S \in \mathbb{R}^{r\times r}$ [illegible] $U \in \mathbb{R}^{m\times r}$ [illegible] $V \in \mathbb{R}^{n\times r}$ [illegible] (1.2) [illegible] (2.7) [illegible] $\dot{Y} = \dot{U}SV^T + U\dot{S}V^T + US\dot{V}^T$, [illegible]

$$\begin{aligned} \dot{S} &= U^T\dot{A}V, \\ \dot{U} &= P_U^\perp \dot{A}VS^{-1}, \\ \dot{V} &= P_V^\perp \dot{A}^T US^{-T}, \end{aligned} \tag{2.8}$$

[illegible] $P_U^\perp = I_m - UU^T$ [illegible] $P_V^\perp = I_n - VV^T$

[illegible]. For $u \in \mathbb{R}^m$, $v \in \mathbb{R}^n$, and $B \in \mathbb{R}^{m\times n}$, we use the identity

$$\langle uv^T, B\rangle = u^T Bv.$$

In view of (2.4) we require $U^T\dot{U} = V^T\dot{V} = 0$ along the solution trajectory in order to define a unique representation of $\dot{Y}$. We first substitute $\delta Y = u_i v_j^T$, for $i,\ j = 1, \dots, r$, into (2.7), where $u_i, v_j$ denote the columns of $U,\ V$, respectively. This is of the form (2.3) with $\delta U = \delta V = 0$ and one nonzero element in $\delta S$. In this way we find $\dot{S} = U^T\dot{A}V$. Similarly, choosing $\delta Y = \sum_{j=1}^r \delta u\, s_{ij} v_j^T,\ i = 1, \dots, r$, where $\delta u \in \mathbb{R}^m$ is arbitrary with $U^T\delta u = 0$, we obtain the stated differential equation for $U$, and likewise for $\delta Y = \sum_{j=1}^r u_j s_{ji} \delta v^T$ with $V^T\delta v = 0$ the differential equation for $V$. ☐

Note that with $\Lambda = U^T\dot{A}V$, the differential equations can be rewritten as

$$\begin{aligned} \dot{S} &= \Lambda, \\ \dot{U}S &= \dot{A}V - U\Lambda, \\ \dot{V}S^T &= \dot{A}^T U - V\Lambda^T. \end{aligned} \tag{2.9}$$

The matrices $U$ and $V$ retain orthonormal columns when the initial values have this property: since $U^T\dot{U} = 0$, we have $\frac{d}{dt}U^TU = \dot{U}^TU + U^T\dot{U} = 0$, and similarly for $V$.

The differential equations (2.8) are related to differential equations for other smooth matrix decompositions, in particular the smooth SVD; see [7, 16]. Unlike the differential equations for singular values given there, no singularities appear in (2.8) at points where singular values of $Y(t)$ coalesce. Equations (2.8) are in close relationship with the MCTDH equations [2], specialized to matrices instead of multivariate functions and stripped of the Schrödinger equation context.

In the numerical integration of (2.8), the step size control should be based on the local error in the low-rank approximation $Y = USV^T$, not on the local error in its factors (this makes a marked difference when $S$ has small singular values). The orthogonality of the columns of $U$ and $V$ can be preserved in the numerical integration by the methods described, e.g., in [10, Chapter IV].

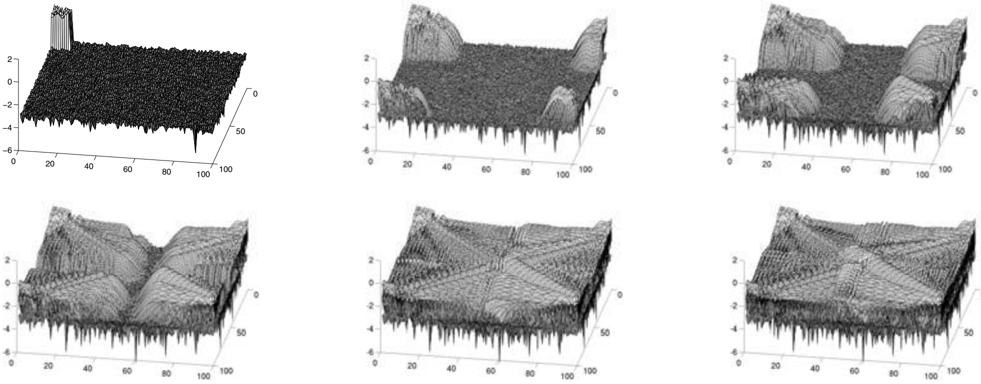

FIG. 3.1. *Size of the matrix elements for $t = 0, 0.2, \dots, 1$, first example, $\varepsilon = 1e - 3$.*

**3. Numerical experiments.** In this section we illustrate the behavior of the dynamical low-rank approximation method by three numerical examples. In all experiments, we have chosen the step sizes in the numerical integration of the differential equations (2.8) small enough that the error of the numerical integration is negligible as compared with the error of the low-rank approximation.

[illegible] We consider a model problem which was constructed in the following way: first, a $10 \times 10$ matrix of random numbers between 0 and 0.5 was added to the unit matrix of the same size, giving a matrix with singular values of magnitude $\approx 1$. Subsequently, this matrix was added as the leading $10 \times 10$ block to a $100 \times 100$ matrix with random entries between 0 and 1 multiplied by a perturbation parameter $\varepsilon$, yielding a matrix $A_1$. Another matrix $A_2$ built in the same way, multiplied by $\exp(t)$, was added for $t \in [0, 1]$. Finally, to eliminate the possibility that this particular structure of the matrix might have an influence on our results, we applied a time-dependent transformation by orthogonal matrices (which does not alter the singular values, but the left and right singular vectors), which were created by solving initial value problems $\dot{Q}_i = T_i Q_i$ $(i = 1, 2)$ with skew-symmetric $T_i$ and initial values equal to identity. To illustrate the structure of the resulting matrices,

$$A(t) = Q_1(t)(A_1 + e^t A_2)Q_2(t)^T,$$

we show, in Figure 3.1, the size of the matrix entries for values $t = 0, 0.2, 0.4, 0.6, 0.8, 1$, with the perturbation parameter $\varepsilon = 1e - 3$. At $t = 0$ the large entries are located in a corner according to the construction of the test example, and afterwards the orthogonal transformations spread these large matrix elements such that the size of matrix entries is approximately the same all over.

Figure 3.2 shows the time evolution of the errors $\|Y - X\|$, $\|Y - A\|$ and the best-approximation error $\|X - A\|$ over the interval $[0, 1]$ for $\varepsilon = 1e - 3$. When we vary the order of magnitude of the perturbation $\varepsilon$, we observe that the size of the error of the approximation $Y$ defined by (1.2) as compared with the best approximation $X$ from (1.1) is proportional to the error of the best approximation. In Table 3.1, the results are given for $\varepsilon = 1e - 1, \dots, 1e - 5$ at time $t = 1$, where the maximum errors on the interval $[0, 1]$ occur. When the parameter $\varepsilon$ is decreased by an order of magnitude, $\|X - A\|$ decreases proportionally, and $\|Y - X\|$ and $\|Y - A\|$ show the same behavior. We show the errors in the Frobenius norm, and additionally the norm of $S^{-1}$. We observe that for an approximation of rank $r = 10$, $\|S^{-1}\|$ does not increase significantly when $\varepsilon$ decreases.

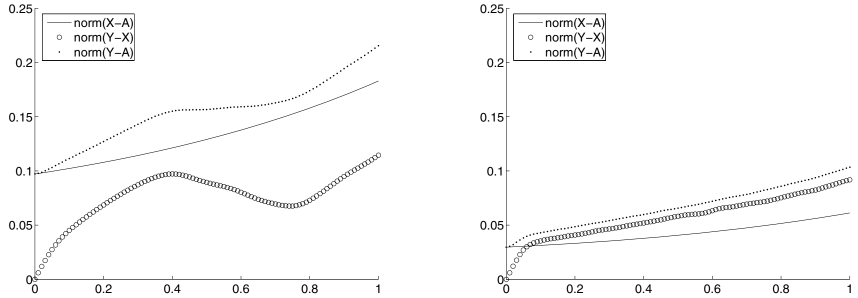

FIG. 3.2. *Errors as a function of $t$, for $r = 10$ (left) and $r = 20$ (right).*

TABLE 3.1
*First example, $r = 10$.*

| 1e−4 | 6.1282e−03 | 9.0416e−03 | 1.0298e−02 | 1.2940e+03 |

We repeat the same experiments with $r = 20$, which is larger than the effective rank 10 of the matrices that are to be approximated; see Table 3.2. We observe that $\|S^{-1}\|$ grows rapidly with $\varepsilon$ in this case. However, the approximation quality is not negatively affected. Rather, the approximation error is smaller than in the case $r = 10$, especially for larger $\varepsilon$, since more singular values are taken into account. The approximation of the dominant singular values and vectors does not suffer from the bad overall conditioning introduced by the small, insignificant contributions. For small $\varepsilon$, a similar error behavior as in the case $r = 10$ is observed. We have not included the values for still smaller $\varepsilon$, because there the numerical integrator is forced to take very small step sizes. In this way the large norm of $S^{-1}$ does have an influence on the numerical solution. This unfavorable effect can be avoided by using the regularization of section 6.

[illegible] This example demonstrates a scenario which may cause a failure of the dynamical low-rank approximation because of a discontinuous best approximation. If the approximation rank $r$ is chosen too small, then singular values which are initially small may in the course of time become larger than the singular values that are actually approximated by the algorithm. Thus, a rather large error compared to the (then discontinuous) best approximation may result when $r$ is too small and the parameter $t$ varies in an unfavorably large interval without a restart of the algorithm by recomputing a best approximation. Figure 3.3 shows such a situation for an exam-

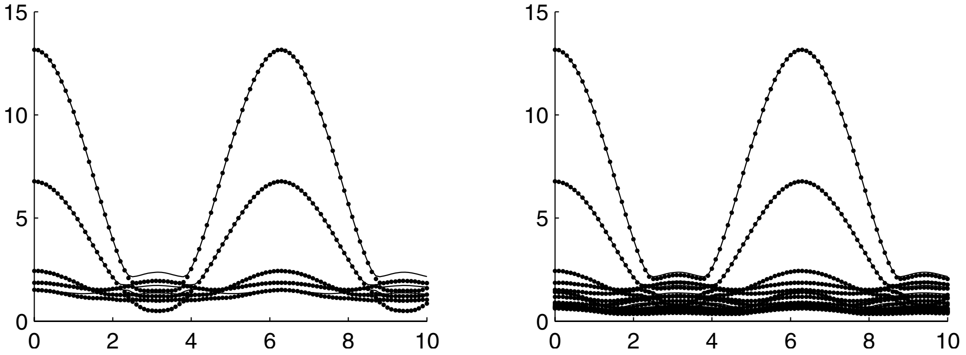

FIG. 3.3. *Second example, singular values for $r = 5$ and $r = 20$.*

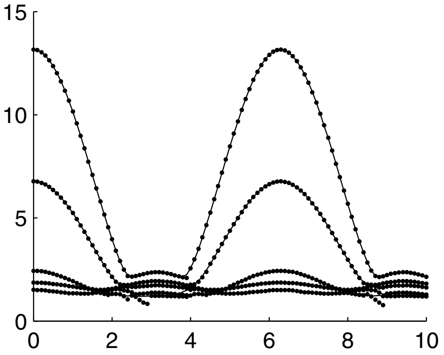

FIG. 3.4. *Second example, singular values for $r = 5$, algorithm restarted at* 20 *points.*

ple constructed by the same principles as for the example discussed above, yet with a time-dependence of the form $\cos(t)$ for $t \in [0, 10]$ and with $\varepsilon = 1e-1$. In both figures, we compare the $r$ largest singular values of $A(t)$ (computed by SVD in every point considered) with the singular values of the rank-$r$ approximation matrix $Y(t)$. In all the figures, the largest singular values computed for the exact matrix are given by a solid line, while those of the dynamical low-rank approximation (at equidistant output points) are represented by dots. If we choose $r = 5$, then the algorithm does not approximate the $r$ largest singular values for all $t$. Rather, for $t \approx 3$, one of the singular values not included in the approximation becomes largest; see Figure 3.3(left). However, if we choose $r = 20$, then all the dominant singular values and vectors are included in the approximation; see Figure 3.3(right). The correct behavior is captured with $r = 5$ if the algorithm is restarted 20 times in the interval (Figure 3.4).

[illegible] This example is again constructed similarly to the first example, $A(t) = Q_1(t)e^t DQ_2(t)^T \in \mathbb{R}^{100\times 100}$, where $D$ is a diagonal matrix with entries $2^{-i/10}$, $i = 1, \ldots, 100$, in descending order. In contrast to the first example, however, there is no distinguishable gap in the set of singular values of $A(t)$. Nonetheless, the dynamical low-rank approximation yields satisfactory results. In Figure 3.5, the errors at $t = 1$ are given for a sequence of approximations of increasing rank $r$, where $r = 3(3)99$. We observe that $\|Y - X\|$ tends to zero at the same rate as $\|X - A\|$.

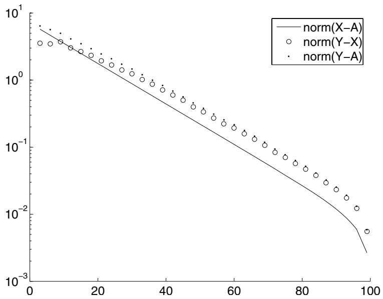

FIG. 3.5. *Third example, errors at $t = 1$ as a function of the rank $r$ of the approximation.*

**4. Tangent space projection and curvature bounds.** In the following two sections we give an analysis that explains the error behavior observed in the numerical experiments. We begin with some preparation.

Condition (2.7) can be written as the differential equation on $\mathcal{M}_r$,

$$\dot{Y} = P(Y)\dot{A}, \tag{4.1}$$

where $P(Y)$ is the orthogonal projection onto the tangent space $\mathcal{T}_Y\mathcal{M}_r$. Basic properties of this projection are formulated in the following two lemmas.

LEMMA 4.1. [illegible] $\mathcal{T}_Y\mathcal{M}_r$ [illegible] $Y = USV^T \in \mathcal{M}_r$ [illegible]

$$P(Y) = I - P^{\perp}(Y) \quad \text{[illegible]} \quad P^{\perp}(Y)B = P_U^{\perp} B P_V^{\perp} \tag{4.2}$$

[illegible] $B \in \mathbb{R}^{m\times n}$

[illegible] Proposition 2.1 yields $\dot{Y} = \dot{A} - P_U^{\perp}\dot{A}P_V^{\perp}$ for $\dot{Y}$ of (2.7) or equivalently of (4.1). Since this holds for every matrix $\dot{A}$, the result follows. □

LEMMA 4.2. [illegible] $r$ [illegible] $X \in \mathcal{M}_r$ [illegible] $\sigma_r(X) \geq \rho > 0$ [illegible] $Y \in \mathcal{M}_r$ [illegible] $\|Y - X\| \leq \frac{1}{8}\rho$ [illegible] $B \in \mathbb{R}^{m\times n}$

$$\|\big(P(Y) - P(X)\big)B\| \leq 8\rho^{-1}\,\|Y - X\| \cdot \|B\|_2, \tag{4.3}$$

$$\|P^{\perp}(Y)(Y - X)\| \leq 4\rho^{-1}\,\|Y - X\|^2. \tag{4.4}$$

[illegible] (a) For $X = U_0S_0V_0^T \in \mathcal{M}_r$ we have the bound $\|S_0^{-1}\|_2 \leq \rho^{-1}$. Since we have, by [11, p. 448],

$$|\sigma_r(Y) - \sigma_r(X)| \leq \|Y - X\|_2 \leq \|Y - X\|,$$

we obtain for $\|Y - X\| \leq \frac{1}{8}\rho$ that

$$\sigma_r(Y) \geq \sigma_r(X) - |\sigma_r(Y) - \sigma_r(X)| \geq \tfrac{7}{8}\rho,$$

and hence $Y = U_1S_1V_1^T$ with $\|S_1^{-1}\|_2 \leq \frac{8}{7}\rho^{-1}$.

(b) We decompose the matrices on the straight line connecting $X$ and $Y$ as

$$X + \tau(Y - X) = M(\tau) + N(\tau) \qquad \text{with} \qquad M(\tau) \in \mathcal{M}_r,\ N(\tau) \perp \mathcal{T}_X\mathcal{M}_r.$$

A smooth such decomposition exists at least for small $\tau$, but the arguments below show that it exists in fact for $0 \leq \tau \leq 1$. We denote

$$\Delta = P(X)(Y - X) \in \mathcal{T}_X\mathcal{M}_r, \qquad \text{with } \|\Delta\| \leq \delta := \|Y - X\|.$$

We then have $P(X)(M(\tau) - X) = \tau\Delta$, which yields

$$P(X)\dot{M}(\tau) = \Delta.$$

Since (4.2) gives $P(X)\dot{M} = \dot{M} - P_{U_0}^{\perp}\dot{M}P_{V_0}^{\perp}$, we obtain $P_{U_0}\dot{M} = P_{U_0}\Delta$ and $\dot{M}P_{V_0} = \Delta P_{V_0}$, which implies

$$U_0^T\dot{M}(\tau) = U_0^T\Delta, \quad \dot{M}(\tau)V_0 = \Delta V_0. \tag{4.5}$$

(c) Using Proposition 2.1 with $M(\tau) \in \mathcal{M}_r$ in the role of $A(\tau)$ and $Y(\tau)$, we get

$$M(\tau) = U(\tau)S(\tau)V(\tau)^T,$$

where $S, U, V$ satisfy the differential equations

$$\begin{aligned} \dot{S} &= U^T\dot{M}V = U^T\Delta V + (U-U_0)^T P_{U_0}^{\perp}\dot{M}P_{V_0}^{\perp}(V-V_0), \\ \dot{U} &= P_U^{\perp}\dot{M}VS^{-1} = P_U^{\perp}\Delta V_0 S^{-1} + P_U^{\perp}\dot{M}(V-V_0)S^{-1}, \\ \dot{V} &= P_V^{\perp}\dot{M}^T U S^{-T} = P_V^{\perp}\Delta^T U_0 S^{-T} + P_V^{\perp}\dot{M}^T(U-U_0)S^{-T}. \end{aligned} \tag{4.6}$$

In the second equalities we have used $\dot{M} = \Delta + P_{U_0}^{\perp}\dot{M}P_{V_0}^{\perp}$ and (4.5), and the fact that $P_{U_0}^{\perp}U_0 = 0$ and $P_{V_0}^{\perp}V_0 = 0$. In addition, we have $\dot{M} = U\dot{S}V^T + (\dot{U}S)V^T + U(\dot{V}S^T)^T$, and hence

$$\dot{M} = \Delta + P_{U_0}^{\perp}\big((U-U_0)\dot{S}(V-V_0)^T + (\dot{U}S)(V-V_0)^T + (U-U_0)(\dot{V}S^T)^T\big)P_{V_0}^{\perp}. \tag{4.7}$$

We will show that these differential equations have a solution up to $\tau = 1$. As long as $\|U - U_0\| \le \frac{1}{4}$ and $\|V - V_0\| \le \frac{1}{4}$, they give the bounds

$$\|\dot{S}\| \le \delta + \tfrac{1}{16}\|\dot{M}\|, \quad \|\dot{U}S\| \le \delta + \tfrac{1}{4}\|\dot{M}\|, \quad \|\dot{V}S^T\| \le \delta + \tfrac{1}{4}\|\dot{M}\|,$$

which inserted into the equation for $\dot{M}$ yield

$$\|\dot{M}\| \le 2\delta \quad \text{and} \quad \|\dot{S}\| \le \tfrac{9}{8}\delta, \quad \|\dot{U}S\| \le \tfrac{3}{2}\delta, \quad \|\dot{V}S^T\| \le \tfrac{3}{2}\delta. \tag{4.8}$$

The bound for $\dot{S}$ yields $\|S(\tau) - S_0\| \le \frac{9}{8}\delta$ for $\tau \le 1$. By the assumption $\delta \le \frac{1}{8}\rho$ and the argument in part (a), we thus obtain $\|S(\tau)^{-1}\|_2 \le \frac{4}{3}\rho^{-1}$ for $\tau \le 1$. From the bound for $\dot{U}S$ we then have

$$\|\dot{U}\| \le \|\dot{U}S\| \cdot \|S^{-1}\|_2 \le \tfrac{3}{2}\delta \cdot \tfrac{4}{3}\rho^{-1} = 2\rho^{-1}\delta \le \tfrac{1}{4}. \tag{4.9}$$

The same bound holds for $\dot{V}$. These bounds show that the differential equation has a solution on the whole interval $0 \le \tau \le 1$ with

$$\|S_1 - S_0\| \le \tfrac{9}{8}\,\delta, \quad \|U_1 - U_0\| \le 2\rho^{-1}\delta, \quad \|V_1 - V_0\| \le 2\rho^{-1}\delta. \tag{4.10}$$

(d) The above bounds give immediately

$$\|P_{U_1}^{\perp} - P_{U_0}^{\perp}\| \le 4\rho^{-1}\delta, \quad \|P_{V_1}^{\perp} - P_{V_0}^{\perp}\| \le 4\rho^{-1}\delta. \tag{4.11}$$

Formula (4.2) shows

$$\big(P(Y) - P(X)\big)B = P_{U_0}^{\perp}BP_{V_0}^{\perp} - P_{U_1}^{\perp}BP_{V_1}^{\perp},$$

which together with (4.11) yields the bound (4.3).

(e) With $P_U^\perp U = 0$ and $P_V^\perp V = 0$ we obtain

$$\begin{aligned} P^\perp(Y)(Y-X) &= P_{U_1}^\perp (U_1 S_1 V_1^T - U_0 S_0 V_0^T) P_{V_1}^\perp = -P_{U_1}^\perp U_0 S_0 V_0^T P_{V_1}^\perp \\ &= -P_{U_1}^\perp (U_1 - U_0) S_0 (V_1 - V_0)^T P_{V_1}^\perp . \end{aligned} \tag{4.12}$$

We write

$$(U_1 - U_0) S_0 = \int_0^1 \dot U(\tau) S_0 \, d\tau = \int_0^1 \dot U(\tau) S(\tau)\, d\tau - \int_0^1 \dot U(\tau)(S(\tau) - S_0)\, d\tau,$$

and hence (4.8) and (4.9) yield

$$\|(U_1 - U_0) S_0\| \le 2\delta.$$

Using this bound and (4.10) in (4.12) finally gives the bound for $P^\perp(Y)(Y-X)$. ☐

## 5. Approximation properties.

We give four results that illustrate different aspects of the dynamical low-rank approximation problem.

### 5.1. Local quasi optimality.

If the low-rank approximation problem (1.1) has a continuously differentiable best approximation $X(t) \in \mathcal{M}_r$, then the error of (1.2) can be bounded in terms of the best-approximation error $\|X(t) - A(t)\|$. The result involves a bound on $\dot A(t)$:

$$\|\dot A(t)\|_2 \le \mu \qquad \text{for } \ 0 \le t \le \bar t. \tag{5.1}$$

(For convenience we choose the initial time $t_0 = 0$.)

THEOREM 5.1. [illegible] $X(t) \in \mathcal{M}_r$ [illegible] $A(t)$ [illegible] $0 \le t \le \bar t$ [illegible] $r$ [illegible] $X(t)$ [illegible] $\sigma_r(X(t)) \ge \rho > 0$ [illegible] $\|X(t) - A(t)\| \le \frac{1}{16}\rho$ [illegible] $0 \le t \le \bar t$ [illegible] (1.2) [illegible] $Y(0) = X(0)$ [illegible]

$$\|Y(t) - X(t)\| \le 2\beta\, e^{\beta t} \int_0^t \|X(s) - A(s)\|\, ds \qquad [illegible] \quad \beta = 8\mu\rho^{-1}$$

[illegible] $t \le \bar t$ [illegible] $\frac{1}{8}\rho$

[illegible]. For the best approximation it must hold that $X - A$ is orthogonal to the tangent space $\mathcal{T}_X\mathcal{M}_r$, or equivalently,

$$P(X)(X - A) = 0.$$

We differentiate this relation with respect to $t$ and denote $(P'(X)\cdot B)\dot X = \frac{d}{dt} P(X(t))B$ to obtain

$$P(X)(\dot X - \dot A) + \big(P'(X)\cdot (X - A)\big)\dot X = 0.$$

Since $\dot X \in \mathcal{T}_X\mathcal{M}_r$, we have $P(X)\dot X = \dot X$, and the equation becomes

$$\big(I - P'(X)\cdot (X - A)\big)\dot X = P(X)\dot A. \tag{5.2}$$

Lemma 4.2 and the condition $d := \|X - A\| \le \frac{1}{16}\rho$ yield

$$\|P'(X)\cdot (X - A)\| \le 8\rho^{-1} d \le \tfrac{1}{2},$$

and hence (5.2) can be solved for $\dot{X}$ to yield

$$\dot{X} = P(X)\dot{A} + D \qquad \text{with} \quad \|D\| \le 16\rho^{-1} d\mu = 2\beta d.$$

We subtract this equation from (4.1), that is, $\dot{Y} = P(Y)\dot{A}$, and integrate from 0 to $t$. As long as $e := \|Y - X\| \le \frac{1}{8}\rho$, Lemma 4.2 yields

$$\|\big(P(Y) - P(X)\big)\dot{A}\| \le 8\rho^{-1} e\mu = \beta e,$$

and hence we obtain

$$e(t) \le \beta \int_0^t e(s)\, ds + 2\beta \int_0^t d(s)\, ds.$$

The result now follows with the Gronwall inequality. □

**5.2. A farther-reaching error bound.** Smaller errors over longer time intervals are obtained if not only $X - A$ but also its derivative is small. We assume that $A(t)$ is of the form

$$A(t) = X(t) + E(t), \qquad 0 \le t \le \bar{t}, \tag{5.3}$$

where $X(t) \in \mathcal{M}_r$ (now this need not necessarily be the best approximation) with

$$\|\dot{X}(t)\|_2 \le \mu, \tag{5.4}$$

and the derivative of the remainder term is bounded by

$$\|\dot{E}(t)\| \le \varepsilon \tag{5.5}$$

with a small $\varepsilon > 0$. We assume $\varepsilon \le \frac{1}{8}\mu$.

Theorem 5.2. [illegible] $r$ [illegible] $X(t)$ [illegible] $\sigma_r(X(t)) \ge \rho > 0$ [illegible] (1.2) [illegible] $Y(0) = X(0)$ [illegible]

$$\|Y(t) - X(t)\| \le 2t\varepsilon \qquad \text{for} \quad t \le \min\left(\bar{t}, \frac{\rho}{4\sqrt{2\mu\varepsilon}}\right).$$

[illegible]. We note $\dot{X} = P(X)\dot{X}$, rewrite (4.1) as $\dot{Y} = P(Y)\dot{X} + P(Y)\dot{E}$, and subtract the two equations. We observe

$$\big(P(Y) - P(X)\big)\dot{X} = -\big(P^\perp(Y) - P^\perp(X)\big)\dot{X} = -P^\perp(Y)\dot{X} = -P^\perp(Y)^2\dot{X}.$$

We take the inner product with $Y - X$ to obtain

$$\begin{aligned} \langle Y - X, \big(P(Y) - P(X)\big)\dot{X}\rangle &= -\langle Y - X, P^\perp(Y)\dot{X}\rangle = -\langle P^\perp(Y)(Y - X), P^\perp(Y)\dot{X}\rangle \\ &= \langle P^\perp(Y)(Y - X), \big(P(Y) - P(X)\big)\dot{X}\rangle. \end{aligned}$$

With Lemma 4.2 and (5.4), (5.5) this yields

$$\begin{aligned} \langle Y - X, \dot{Y} - \dot{X}\rangle &= \langle P^\perp(Y)(Y - X), \big(P(Y) - P(X)\big)\dot{X}\rangle + \langle Y - X, P(Y)\dot{E}\rangle \\ &\le 32\,\mu\rho^{-2}\|Y - X\|^3 + \|Y - X\| \cdot \varepsilon, \end{aligned}$$

and, on the other hand, we have

$$\langle Y-X,\dot Y-\dot X\rangle=\frac{1}{2}\frac{d}{dt}\|Y-X\|^2=\|Y-X\|\,\frac{d}{dt}\|Y-X\|.$$

Taken together, we obtain for $e(t)=\|Y(t)-X(t)\|$ the differential inequality

$$\dot e\le\gamma e^2+\varepsilon,\qquad e(0)=0,$$

with $\gamma=32\,\mu\rho^{-2}$. Hence, $e(t)$ is majorized by the solution of

$$\dot y=\gamma y^2+\varepsilon,\qquad y(0)=0,$$

which equals $y(t)=\sqrt{\varepsilon/\gamma}\,\tan(t\sqrt{\gamma\varepsilon})$ and is bounded by $2t\varepsilon$ for $t\sqrt{\gamma\varepsilon}\le 1$. Lemma 4.2 remains applicable as long as $2t\varepsilon\le\frac{1}{8}\rho$, which is satisfied on the given interval under the assumption $\varepsilon\le\frac{1}{8}\mu$. ☐

**5.3. The case of overapproximation.** The time interval in Theorem 5.2 becomes tiny when $\rho\le\varepsilon$. In that case, the effective rank ($\varepsilon$-pseudorank) of $A(t)$ is $q<r$, but the approximation is done by a rank-$r$ matrix $Y(t)$. It is not clear a priori that $Y(t)$ preserves an effective rank $q$ over longer times. Even if it does, the matrix $S(t)$ in (2.1) is ill-conditioned, and since its inverse appears in the differential equations (2.8), one might expect a severe adverse effect on the approximation properties. Remarkably, this does not happen, as is shown by the following result.

THEOREM 5.3. [illegible] (5.3)–(5.5) [illegible] $X(t)\in\mathcal{M}_q$ [illegible] $q<r$ [illegible] $q$ [illegible] $X(t)$ [illegible] $\sigma_q(X(t))\ge\rho>0$ [illegible] $Y(0)\in\mathcal{M}_r$ [illegible] $Y(0)=X(0)+E_0$ [illegible] $\operatorname{Im}E_0\perp\operatorname{Im}X(0)$ [illegible] $\operatorname{Im}E_0^T\perp\operatorname{Im}X(0)^T$ [illegible] $\|E_0\|\le\varepsilon_0\le\frac{1}{16}\rho\mu^{-1}\varepsilon$ [illegible] (2.8) [illegible] $0\le t\le t^*$ [illegible] (1.2) [illegible]

$$\|Y(t)-X(t)\|\le\varepsilon_0+6t\varepsilon\qquad\text{for}\qquad t\le\min\left(\bar t,t^*,\frac{\rho}{16\mu}\right).$$

The existence of the solution of the differential equation (2.8) is not ensured over the whole interval, since $S(t)$ might become singular. The orthogonality condition on $E_0$ is satisfied if the best rank-$r$ approximation is taken as initial value. However, this orthogonality condition is not essential. A similar, but less clear-cut estimate holds whenever $Y(0)\in\mathcal{M}_r$ is sufficiently close to $X(0)\in\mathcal{M}_q$.

The proof of Theorem 5.3 is based on combining the previous proof with the following two-scale lemma.

LEMMA 5.4. [illegible] $Y\in\mathcal{M}_r$ [illegible]

$$Y=U\begin{pmatrix}S_1&0\\0&S_2\end{pmatrix}V^T=U_1S_1V_1^T+U_2S_2V_2^T,\tag{5.6}$$

[illegible] $U=(U_1,U_2)$ [illegible] $V=(V_1,V_2)$ [illegible] $S_1\in\mathbb{R}^{q\times q}$ [illegible] $S_2\in\mathbb{R}^{(r-q)\times(r-q)}$ [illegible]

$$\sigma_{\min}(S_1)\ge\rho,\qquad\sigma_{\max}(S_2)\le\delta\qquad[\text{illegible}]\ \rho\ge 2\delta\tag{5.7}$$

[illegible] (2.7) [illegible]

$$\dot{Y} = \sum_{i=1}^{2} \Big( \dot{U}_i S_i V_i^T + U_i \dot{S}_i V_i^T + U_i S_i \dot{V}_i^T \Big), \tag{5.8}$$

[illegible]

$$\begin{aligned} \dot{S}_1 &= U_1^T \dot{A} V_1, \qquad \dot{S}_2 = U_2^T \dot{A} V_2, \\ \dot{U}_1 S_1 &= P_{U_1}^{\perp} \dot{A} V_1 + E_U, \\ \dot{V}_1 S_1^T &= P_{V_1}^{\perp} \dot{A}^T U_1 + E_V, \end{aligned} \tag{5.9}$$

[illegible] $\|E_U\| \le 2\delta\rho^{-1}\|\dot{A}\|$ [illegible] $\|E_V\| \le 2\delta\rho^{-1}\|\dot{A}\|$

The point of the lemma is that for $\delta \ll \rho$ the equations for $\dot{S}_1, \dot{U}_1, \dot{V}_1$ are, up to the small perturbations $E_U$ and $E_V$, the same as those for solving the corresponding rank-$q$ problem for $Y_q = U_1 S_1 V_1^T \in \mathcal{M}_q$; see Proposition 2.1. Under conditions (5.3)–(5.5) with $X \in \mathcal{M}_q$, the equation for $\dot{S}_2$ has a small right-hand side as long as $Y$ is close to $A$ or $X$, and hence $S_2$ remains small. The term $U_2 S_2 V_2^T$ then gives only a small contribution to $Y$, no matter what the derivatives of $U_2$ and $V_2$ are. The equations for $\dot{U}_2$ and $\dot{V}_2$, which have not been stated explicitly, contain in fact $S_2^{-1}$, which may have an arbitrarily large norm.

[illegible] 5.4. We begin by showing that $\dot{S}_i, \dot{U}_i, \dot{V}_i$ in (5.8) are uniquely determined if, instead of (2.4), we impose the constraints (cf. [7])

$$U^T \dot{U} = H, \qquad V^T \dot{V} = K,$$

with $r \times r$ matrices of the block form

$$H = \begin{pmatrix} 0 & H_{12} \\ H_{21} & 0 \end{pmatrix}, \qquad K = \begin{pmatrix} 0 & K_{12} \\ K_{21} & 0 \end{pmatrix},$$

which are skew-symmetric: $H_{12} = -H_{21}^T$ and $K_{12} = -K_{21}^T$. As in the proof of Proposition 2.1 we then obtain, instead of (2.8), the equation

$$U^T \dot{A} V = HS + \dot{S} + SK^T, \tag{5.10}$$

which yields $\dot{S}$ as the block diagonal of $\Lambda := U^T \dot{A} V$:

$$\dot{S}_1 = U_1^T \dot{A} V_1, \qquad \dot{S}_2 = U_2^T \dot{A} V_2.$$

We multiply (5.10) with $S^{-1}$ from the right and take the symmetric part. Then $H$ drops out, and we obtain

$$SK^T S^{-1} + S^{-T} K S^T = \begin{pmatrix} 0 & B_{12} S_2^{-1} \\ S_2^{-T} B_{21} & 0 \end{pmatrix},$$

where $B_{21} = B_{12}^T = \Lambda_{12}^T + S_2^T \Lambda_{21} S_1^{-1}$ is bounded by

$$\|B_{21}\| \le (1 + \delta\rho^{-1}) \, \|\dot{A}\| \le \tfrac{3}{2} \|\dot{A}\|.$$

We multiply the (2,1) block of the above equation with $S_2^T$ from the left and with $S_1^{-T}$ from the right to obtain

$$K_{21} - (S_2^T S_2) K_{21} (S_1^T S_1)^{-1} = B_{21} S_1^{-T}.$$

By condition (5.7), this equation can be uniquely solved for $K_{21}$ by fixed-point iteration, and

$$\|K_{21}\| \le \tfrac{4}{3}\rho^{-1}\|B_{21}\| \le 2\rho^{-1}\|\dot{A}\|.$$

As in (2.8), we derive

$$\dot{U}S = \dot{A}V - U\dot{S} - USK^T.$$

For the first component of $\dot{U} = (\dot{U}_1, \dot{U}_2)$ this becomes

$$\dot{U}_1 S_1 = \dot{A}V_1 - U_1\dot{S}_1 + E_U = P_{U_1}^{\perp}\dot{A}V_1 + E_U$$

with $E_U = U_2 S_2 K_{21}$, which is bounded by $\|E_U\| \le \delta \cdot 2\rho^{-1}\|\dot{A}\|$. The equation and estimate for $\dot{V}_1$ are obtained in the same way. □

In the proof of Theorem 5.3 we will actually use a variant of the above result, which is proved in the same way: if condition (5.7) is replaced by

$$\sigma_{\min}(S_1) \ge \rho, \qquad \|S_2\| \le \delta, \tag{5.11}$$

then Lemma 5.4 holds with the modified bounds

$$\|E_U\| \le 2\delta\rho^{-1}\|\dot{A}\|_2, \qquad \|E_V\| \le 2\delta\rho^{-1}\|\dot{A}\|_2. \tag{5.12}$$

*Proof of Theorem* 5.3. We write $Y$ in the form (5.6) as

$$Y = Y_1 + Y_2 \equiv U_1 S_1 V_1^T + U_2 S_2 V_2^T.$$

We will estimate $e_1 = \|Y_1 - X\|$ and $e_2 = \|Y_2\|$.

(a) By Lemma 5.4 and (5.3), $Y_1$ satisfies the differential equation

$$\dot{Y}_1 = P_q(Y_1)\dot{X} + P_q(Y_1)\dot{E} + E_U V_1^T + U_1 E_V^T,$$

where $P_q(Y_1)$ denotes the orthogonal projection onto $\mathcal{T}_{Y_1}\mathcal{M}_q$. Comparing this equation with $\dot{X} = P_q(X)\dot{X}$ as in the proof of Theorem 5.2, we obtain

$$e_1(t) \le 2t\eta, \tag{5.13}$$

provided that, up to time $t$,

$$d := \|P_q(Y_1)\dot{E} + E_U V_1^T + U_1 E_V^T\| \le \eta.$$

By (5.5) and (5.12) together with (5.4) we have

$$d(t) \le \varepsilon + 5\rho^{-1}\mu\, e_2(t). \tag{5.14}$$

(The factor 5 instead of 4 takes into account that $\|\dot{A}\| \le \mu + \varepsilon$ may be slightly larger than $\mu$ of (5.4), and $\rho$ in (5.11) may differ slightly from $\rho$ in the formulation of the theorem. The bound holds as long as $e_1$ is sufficiently small.)

(b) We have

$$e_2(t) = \|S_2(t)\| \le \varepsilon_0 + \int_0^t \|\dot{S}_2(s)\|\, ds.$$

Now,

$$\begin{aligned}\|\dot S_2\| &= \|U_2^T \dot A V_2\| = \|P_{U_2}\dot A P_{V_2}\| \le \|P_{U_1}^{\perp}\dot A P_{V_1}^{\perp}\|\\ &= \|P_q^{\perp}(Y_1)\dot A\| \le \|P_q^{\perp}(Y_1)\dot X\| + \varepsilon = \|\big(P_q^{\perp}(Y_1) - P_q^{\perp}(X)\big)\dot X\| + \varepsilon\\ &= \|\big(P_q(Y_1) - P_q(X)\big)\dot X\| + \varepsilon \le 8\rho^{-1}\mu\, e_1 + \varepsilon,\end{aligned}$$

where we have used Lemma 4.2 and (5.4) in the last inequality. Hence,

$$e_2(t) \le \varepsilon_0 + 8\rho^{-1}\mu \int_0^t e_1(s)\, ds + t\varepsilon. \tag{5.15}$$

(c) With the bound (5.13) this inequality yields

$$e_2(t) \le \varepsilon_0 + 8\rho^{-1}\mu\, t^2\eta + t\varepsilon.$$

In view of (5.14), we thus need to choose $\eta$ and the maximum value of $t$ such that

$$\eta \ge \varepsilon + 5\rho^{-1}\mu\varepsilon_0 + 5(\rho^{-1}\mu t)\varepsilon + 40(\rho^{-1}\mu t)^2\eta.$$

For $\rho^{-1}\mu\varepsilon_0 \le \frac{1}{16}\varepsilon$ and $\rho^{-1}\mu t \le \frac{1}{16}$ this is satisfied for $\eta = 2\varepsilon$. This yields

$$e_1(t) \le 4t\varepsilon, \qquad e_2(t) \le \varepsilon_0 + 2t\varepsilon,$$

which implies the result. ☐

**5.4. Systems without gaps between the singular values.** The results of the preceding subsections give satisfactory error bounds when there is a gap in the distribution of the singular values so that essential and inessential singular values are widely separated. We now consider a situation where such a gap need not exist, as in the third numerical example. We make the assumptions of Theorem 5.2 and further that $X(t) \in \mathcal{M}_r$ with $\sigma_r(X(t)) \ge \rho > 0$ has a decomposition

$$X(t) = U_0(t)S_0(t)V_0(t)^T \qquad \text{for } \ 0 \le t \le \bar t, \tag{5.16}$$

with nonsingular $S_0(t) \in \mathbb{R}^{r\times r}$, and with $U_0(t) \in \mathbb{R}^{m\times r}$ and $V_0(t) \in \mathbb{R}^{n\times r}$ having orthogonal columns, such that the following bounds hold for $0 \le t \le \bar t$:

$$\Big\|\frac{d}{dt}S_0^{-1}(t)\Big\|_2 \le c_1\rho^{-1}, \qquad \|\dot U_0(t)\|_2 \le c_2, \quad \|\dot V_0(t)\|_2 \le c_2. \tag{5.17}$$

Under these conditions we can show an $O(\varepsilon)$ error over times $O(1)$ even with $\rho \sim \varepsilon$.

THEOREM 5.5. [illegible] 5.2 [illegible] (5.16) (5.17) [illegible] (1.2) [illegible] $Y(0) = X(0)$ [illegible]

$$\|Y(t) - X(t)\| \le 2t\varepsilon \qquad \text{for} \quad t \le \min\Big(\bar t,\ \frac{1}{16c_2^{1/2}}\Big(\frac{\rho}{\varepsilon}\Big)^{1/2},\ \frac{1}{8c_1^{1/3}}\Big(\frac{\rho}{\varepsilon}\Big)^{2/3},\ \frac{1}{16}\frac{\rho}{\varepsilon}\Big).$$

[illegible] From the proof of Theorem 5.2 we have the equation

$$\langle Y - X, \dot Y - \dot X\rangle = -\langle P^{\perp}(Y)(Y - X), P^{\perp}(Y)\dot X\rangle + \langle Y - X, P(Y)\dot E\rangle. \tag{5.18}$$

For $e = \|Y - X\| \le \frac{1}{8}\rho$, the proof of Lemma 4.2 shows that $Y$ can be decomposed as $Y = U_1S_1V_1^T$ with

$$\|(U_1 - U_0)S_0\| \le 2e, \qquad \|S_0(V_1 - V_0)^T\| \le 2e.$$

By Lemma 4.1 we can write

$$\begin{aligned} P^\perp(Y)\dot X &= P_{U_1}^\perp\big(\dot U_0 S_0 V_0^T + U_0 \dot S_0 V_0^T + U_0 S_0 \dot V_0^T\big)P_{V_1}^\perp \\ &= P_{U_1}^\perp\big(-\dot U_0 S_0 (V_1 - V_0)^T + (U_1 - U_0)S_0 \cdot S_0^{-1}\dot S_0 S_0^{-1} \cdot S_0 (V_1 - V_0)^T \\ &\qquad - (U_1 - U_0) S_0 \dot V_0^T\big)P_{V_1}^\perp . \end{aligned}$$

With (4.4), (5.17), and the above estimate, (5.18) gives the differential inequality, as long as $e \le \frac{1}{8}\rho$:

$$\dot e \le 4\rho^{-1} e\big(2c_2 e + 4c_1\rho^{-1}e^2 + 2c_2 e\big) + \varepsilon. \tag{5.19}$$

The error is bounded by $2t\varepsilon$ as long as the first term on the right-hand side is bounded by $\varepsilon$, which is thus satisfied for $16c_2\rho^{-1}(2t\varepsilon)^2 \le \frac{1}{2}\varepsilon$ and $16c_1\rho^{-2}(2t\varepsilon)^3 \le \frac{1}{2}\varepsilon$. This holds under the stated bounds for $t$. ◻

## 6. Extensions of the basic approach.

**6.1. Regularization.** Though Theorem 5.3 shows that overapproximation has no disastrous effect on the approximation properties, it is in fact harmful to the numerical solution of the differential equations (2.8). Near-singularity of $S$ enforces very small step sizes in numerical integrators, and rounding errors may become important. The situation is alleviated by replacing $S^{-1}$ by a [illegible], e.g., obtained from computing an SVD of $S \in \mathbb{R}^{r\times r}$ and replacing the $i$th singular value $\sigma_i$ by $\sqrt{\sigma_i^2 + \epsilon^2}$. The approximation result of Theorem 5.3 remains valid (with modified constants), since transformation to the block form (5.8) yields only an $O(\epsilon)$ perturbation in (5.9).

**6.2. Stabilization.** In order to drive the solution toward the best approximation, we replace (2.7) by

$$\langle \dot Y - \dot A, \delta Y\rangle + \alpha\langle Y - A, \delta Y\rangle = 0 \qquad \text{for all} \quad \delta Y \in \mathcal{T}_Y\mathcal{M}_r \tag{6.1}$$

with a positive parameter $\alpha$. This amounts to replacing $\dot A$ by $\dot A - \alpha(Y - A)$ in the differential equations (2.8) determining $Y = USV^T$. (This approach requires knowledge of both $\dot A$ and $A$ and can therefore not be extended to the low-rank approximation of matrix differential equations as in section 6.4 below.)

The effect of the parameter $\alpha$ is easily seen in the framework of the proof of Theorem 5.1. With the notation used there, we have the differential equations

$$\begin{aligned} \dot Y &= P(Y)(\dot A - \alpha(Y - A)), \\ \dot X &= P(X)(\dot A - \alpha(X - A)) + D. \end{aligned}$$

Subtracting the equations yields

$$\begin{aligned} \dot Y - \dot X = \big(P(Y) - P(X)\big)\dot A - D \\ - \alpha(Y - X) + \alpha P^\perp(Y)(Y - X) - \alpha\big(P(Y) - P(X)\big)(X - A). \end{aligned}$$

Taking the inner product with $Y - X$ and using Lemma 4.2 yields the following differential inequality for $e = \|Y - X\|$: with $d = \|X - A\|$ and $\beta = 8\mu\rho^{-1}$,

$$\dot e \le \beta e + 2\beta d - \alpha e(1 - \tfrac{1}{2}\beta e - \beta d). \tag{6.2}$$

The last term is stabilizing, provided that $d$ and $e$ are small enough.

**6.3. An example of structured low-rank approximation: Approximation on Grassmann manifolds.** We now approximate $A(t) \in \mathbb{R}^{n\times n}$ not just by arbitrary rank-$r$ matrices, but by orthogonal projections onto $r$-dimensional subspaces. We thus replace the manifold $\mathcal{M}_r^{n\times n}$ in (1.2) by the submanifold (known as a Grassmann manifold)

$$\mathcal{G} = \mathcal{G}_{n,r} = \{Y \in \mathcal{M}_r^{n\times n} :\ Y^2 = Y,\ Y^T = Y\}.$$

A projection $Y \in \mathcal{G}$ can be written, in a nonunique way, as

$$Y = UU^T \qquad \text{with} \quad U \in \mathcal{V}_{n,r};$$

that is, $U \in \mathbb{R}^{n\times r}$ has orthonormal columns. $U$ is unique up to right-multiplication with an $r \times r$ orthogonal matrix. Tangent matrices in $\mathcal{T}_Y\mathcal{G}$ are of the form

$$\delta Y = \delta U U^T + U\delta U^T \qquad \text{with} \quad \delta U \in \mathcal{T}_U\mathcal{V}_{n,r}. \tag{6.3}$$

This representation is unique if we impose the condition $U^T\delta U = 0$, which yields $\delta U^T = U^T\delta Y$. The Galerkin condition (2.7) for the manifold $\mathcal{G}$ determines $\dot{Y} \in \mathcal{T}_Y\mathcal{G}$ such that

$$\langle \dot{Y} - \dot{A}, \delta Y\rangle = 0 \qquad \text{for all} \ \ \delta Y \in \mathcal{T}_Y\mathcal{G}.$$

Substituting (6.3) and using the rules $\langle A, B\rangle = \langle A^T, B^T\rangle$ and $\langle A, BC^T\rangle = \langle AC, B\rangle$, this condition becomes, with the condition $U^T\dot{U} = 0$,

$$\langle \dot{U} - \tfrac{1}{2}(\dot{A} + \dot{A}^T)U,\ \delta U\rangle = 0 \quad \text{ for all } \delta U \in \mathbb{R}^{n\times r} \text{ with } U^T\delta U = 0.$$

This gives the differential equation

$$\dot{U} = P_U^{\perp}\tfrac{1}{2}(\dot{A} + \dot{A}^T)U. \tag{6.4}$$

With the appropriate version of Lemma 4.2 for the orthogonal projection $P(Y)$ onto the submanifold $\mathcal{G}$, the approximation estimates corresponding to Theorems 5.1 and 5.2 follow without further ado.

**6.4. Minimum defect approximation of matrix differential equations.** For the low-rank approximation to a solution of the matrix differential equation

$$\dot{A} = F(A), \tag{6.5}$$

condition (1.2) is replaced, at every time $t$, by

$$\dot{Y} \in \mathcal{T}_Y\mathcal{M}_r \quad \text{ such that } \quad \|\dot{Y} - F(Y)\| = \min! \tag{6.6}$$

Equivalently, condition (2.7) is replaced by the Galerkin condition

$$\langle \dot{Y} - F(Y),\ \delta Y\rangle = 0 \quad \text{for all} \ \ \delta Y \in \mathcal{T}_Y\mathcal{M}_r, \tag{6.7}$$

and correspondingly, the expression $\dot{A}$ is replaced by $F(Y)$ for $Y = USV^T$ in the differential equations (2.8) for $S, U, V$.

Theorems 5.1–5.3 extend to the low-rank approximation of matrix differential equations (6.5). We assume that $F$ has a moderate bound along the approximations,

$$\|F(X(t))\| \le \mu, \qquad \|F(Y(t))\| \le \mu \qquad \text{for} \ \ 0 \le t \le \bar{t}, \tag{6.8}$$

and satisfies a one-sided Lipschitz condition: there is a real $\lambda$ (positive or negative or zero) such that

$$\langle F(Y) - F(X), Y - X \rangle \le \lambda \, \|Y - X\|^2 \tag{6.9}$$

for all matrices $X, Y \in \mathcal{M}_r$. We further assume that for the best approximation $X(t)$,

$$\|F(X(t)) - F(A(t))\| \le L \, \|X(t) - A(t)\| \qquad \text{for } \ 0 \le t \le \bar{t}, \tag{6.10}$$

which is in particular satisfied if $F$ is Lipschitz continuous with Lipschitz constant $L$. We then have the following extension of the quasi-optimality result of Theorem 5.1.

THEOREM 6.1. [illegible] $X(t) \in \mathcal{M}_r$ [illegible] $A(t)$ [illegible] (6.5) [illegible] $0 \le t \le \bar{t}$ [illegible] (6.8) [illegible] (6.10) [illegible] $r$ [illegible] $X(t)$ [illegible] $\sigma_r(X(t)) \ge \rho > 0$ [illegible] $\|X(t) - A(t)\| \le \frac{1}{16}\rho$ [illegible] $0 \le t \le \bar{t}$ [illegible] (1.2) [illegible] $Y(0) = X(0)$ [illegible]

$$\|Y(t) - X(t)\| \le (2\beta + L)\, e^{(2\beta+\lambda)t} \int_0^t \|X(s) - A(s)\| \, ds \qquad \text{[illegible]} \quad \beta = 8\mu\rho^{-1}$$

[illegible] $t \le \bar{t}$ [illegible] $\frac{1}{8}\rho$

[illegible]. Equation (6.7) rewritten as in (4.1) reads

$$\dot{Y} = P(Y)F(Y). \tag{6.11}$$

As in the proof of Theorem 5.1, we have the equation

$$\dot{X} = P(X)F(A) + D \qquad \text{with} \quad \|D\| \le 2\beta d$$

for $d = \|X - A\|$. We subtract the two equations, write

$$\begin{aligned} P(Y)F(Y) - P(X)F(A) - D = {} & (P(Y) - P(X))F(X) + P(X)(F(X) - F(A)) \\ & + (F(Y) - F(X)) - P^{\perp}(Y)(F(Y) - F(X)) - D, \end{aligned}$$

and take the inner product with $Y - X$. With Lemma 4.2 we obtain

$$\begin{aligned} \langle \dot{Y} - \dot{X}, Y - X \rangle \le {} & \beta \, \|Y - X\|^2 + Ld \, \|Y - X\| \\ & + \lambda \, \|Y - X\|^2 + \beta \, \|Y - X\|^2 + 2\beta d \, \|Y - X\|. \end{aligned}$$

For $e = \|Y - X\|$ this gives the differential inequality

$$\dot{e} \le (2\beta + \lambda)e + (2\beta + L)d, \qquad e(0) = 0, \tag{6.12}$$

which yields the result. □

We refer to [12, Theorem 4.1] for a related quasi-optimality result in a situation of a linear differential equation with an unbounded operator.

In the differential equation analogue of Theorem 5.2 with the splitting (5.3), we start from the equations $\dot{Y} - \dot{X} = P(Y)F(Y) - P(X)\dot{X}$ and $\dot{X} = F(A) - \dot{E}$, yielding

$$\begin{aligned} \dot{Y} - \dot{X} = {} & (P(Y) - P(X))\dot{X} - P^{\perp}(Y)(F(Y) - F(X)) \\ & + (F(Y) - F(X)) + P(Y)(F(X) - F(A)) + P(Y)\dot{E}, \end{aligned}$$

where we now take the inner product with $Y - X$. If it is additionally assumed that $F$ has Lipschitz constant $L$, then this leads to the differential inequality

$$\dot{e} \leq 4\rho^{-1}(\beta + L)e^2 + \lambda e + Ld + \varepsilon, \qquad e(0) = 0. \tag{6.13}$$

With $\widehat{\gamma} = 4\rho^{-1}(\beta + L)$ and $\widehat{\varepsilon} = \varepsilon + L \max_{0 \leq t \leq \bar{t}} d(t)$, and with $\varphi(x) = (e^x - 1)/x$, this yields the error bound

$$\|Y(t) - X(t)\| \leq 2t\,\varphi(\lambda t)\,\widehat{\varepsilon} \qquad \text{for} \quad t\varphi(\lambda t) \leq \tfrac{1}{2}(\widehat{\gamma}\widehat{\varepsilon})^{-1/2} \tag{6.14}$$

and as long as $t \leq \bar{t}$ and $2t\varphi(\lambda t)\widehat{\varepsilon} \leq \frac{1}{8}\rho$.

Theorems 5.3 and 5.5 are extended similarly.

**6.5. The special case of linear matrix differential equations.** Systems

$$\dot{A} = LA + AR \tag{6.15}$$

with possibly time-dependent matrices $L(t)$ and $R(t)$ have the solution $A(t) \in \mathcal{M}_r$ for initial data $A_0 = Y_0 \in \mathcal{M}_r$. This is seen immediately from Lemma 4.1 and (6.11), which yield $\dot{Y} = LY + YR$ and hence $A(t) = Y(t) \in \mathcal{M}_r$. From the differential equations (2.8), we thus obtain a decomposition of the solution $A = USV^T$ with $U$ and $V$ having orthonormal columns and with the factors satisfying the differential equations

$$\begin{aligned} \dot{S} &= U^T LUS + SV^T RV, \\ \dot{U} &= P_U^{\perp} LU, \\ \dot{V} &= P_V^{\perp} R^T V. \end{aligned} \tag{6.16}$$

A different situation arises for linear problems of the type

$$\dot{A} = LA + AR + B \bullet A, \tag{6.17}$$

where $\bullet$ denotes the Hadamard (or entrywise) product of matrices. The differential equations (2.8), with $\dot{A}$ replaced by the right-hand side of (6.17) evaluated at $Y = USV^T$ instead of $A$, determine a low-rank approximation, but the entrywise multiplication with $B(t)$ in general requires the explicit computation of the entries of $Y$. The situation simplifies if $B$ is itself a low-rank matrix $B = \sum_{j=1}^{k} \beta_j c_j d_j^T$. Writing $Y = \sum_{i=1}^{r} \sigma_i \widehat{u}_i \widehat{v}_i^T$ (obtained from an SVD of the matrix $S$ of $Y = USV^T$), we can use $B \bullet Y$ in the differential equations for $S, U, V$ in the decomposed form

$$B \bullet Y = \sum_{j=1}^{k} \sum_{i=1}^{r} \beta_j \sigma_i (c_j \bullet \widehat{u}_i)(d_j \bullet \widehat{v}_i)^T;$$

cf. [2] for an analogous observation for the potential in the Schrödinger equation. The dynamical low-rank approximation $Y(t)$ to $A(t)$ of (6.17) can thus be computed inexpensively if $B(t)$ is of low rank or otherwise approximated by a matrix of low rank, and in the present paper we have seen how this can be computed.

**7. Conclusions and outlook.** The dynamical low-rank approximation (1.2), or equivalently (2.7) or (4.1), becomes an attractive computational approach via the differential equations (2.8) that determine the factors in the representation (2.1) of the approximation. The method yields a near-optimal smooth low-rank approximation, as is shown in Theorems 5.1, 5.2, 5.3, and 5.5 and observed in numerical experiments. A direct but very noteworthy extension is the minimum-defect low-rank approximation (1.3) to solutions of matrix differential equations. Our first numerical experience in compressing time-varying term-document matrices and series of images, and in approximating time-dependent PDEs whose solutions are essentially of low rank (e.g., smooth with the exception of a few pulses or spikes, as in blow-up problems in reaction-diffusion equations), is very promising, as reported in [14]. It will be interesting to see the dynamical low-rank approximation used for large-scale problems in applications, well beyond the already important area of quantum dynamics, where basic ideas for this approach originated 75 years ago as a physical model reduction technique.

# HERMITE INDICES AND JORDAN STRUCTURE OF A PERTURBED LINEAR SYSTEM[*]

I. BARAGAÑA[†], V. FERNÁNDEZ[†], AND I. ZABALLA[‡]

**Abstract.** The aim of this work is to characterize the Hermite indices and the Jordan structure of a pair of matrices $(A, B)$ under small perturbations. The proofs of the sufficiency give us a constructive method to obtain a pair as close as we want to $(A, B)$ and with prescribed structure.

**Key words.** similarity, Hermite indices, invariant factors, Segre characteristic

**DOI.** 10.1137/060650726

## 1. Introduction.

Consider the following system of differential equations with control:

$$\dot{x}(t) = Ax(t) + Bu(t), \tag{1.1}$$

where $A \in \mathbb{F}^{n\times n}$ and $B \in \mathbb{F}^{n\times m}$, with $\mathbb{F}$ the field of real or complex numbers. We will identify the system with the matrix pair $(A, B)$.

A change of bases in the state space, $y = Px$, yields the new system $\dot{y}(t) = PAP^{-1}y(t) + PBu(t)$. Pairs $(A, B)$ and $(PAP^{-1}, PB)$ are said to be similar. For controllable systems there may be many complete systems of invariants (see [15, 19]), all of them consisting of two sequences of numbers: a sequence of real or complex numbers and a, possibly nonordered, sequence of positive integers whose sum is $n$, the order of the system (i.e., a partition of $n$). The elements of these partitions are indices of nice bases [1] taken from the controllability matrix of the system and appear as the size of prominent blocks in the corresponding canonical form of $(A, B)$. Following [11] these invariants can be called invariants of structure of the system. For noncontrollable systems there are, in addition, other invariants of structure: the partial multiplicities of the eigenvalues of $(A, B)$, i.e., the sizes of the blocks in the Jordan canonical form of the noncontrollable part of the system.

The aim of this paper is to study the change of some invariants of structure of $(A, B)$ under small additive perturbations. This can be seen as a continuation of the results in [3, 6, 12, 16]. In [3, 12] the authors solved the problem posed in [5] on the possible partial multiplicities of the eigenvalues of all square matrices that are close enough to a given square matrix over $\mathbb{C}$. Also they proved that the obtained conditions are necessary and sufficient for the existence of matrices, as close as one may desire to a given matrix. In [2] the problem of characterizing the closure of similarity orbits of a square matrix was solved. One can easily see that these two problems are closely related. In fact, all matrices in the same similarity orbit have the

same eigenvalues and partial multiplicities, and every matrix in the closure of that orbit is the limit of matrices in the given orbit. Thus the eigenvalues of such a matrix must be the same as the eigenvalues of the matrices in the orbit (continuity of the eigenvalues w.r.t. the matrix), and it is "close enough" to some matrix in the orbit. So, the difference between the two problems is that in the first one the eigenvalues of the near matrices may change, but the conditions on the partial multiplicities in both problems are the same. The point is that in the problem of the closure, since the eigenvalues do not change, the conditions on the partial multiplicities can be translated into divisibility conditions among the invariant factors (see Lemma 4.1). In [6] the result of [3, 12] was generalized to square matrices over $\mathbb{R}$, and a similar question was addressed for the feedback invariants of matrix pairs, i.e., to say, for the controllability indices and Jordan structure of the noncontrollable part (see Lemma 3.1). This result was generalized in [16] to singular pencils of matrices. The controllability indices are one of the many possible invariants of structure of a matrix pair for similarity. Another system of invariants of structure is the one formed by the Hermite indices. These indices appear in several places in the literature. They were first mentioned, with no specific name, in [9, p. 426] and associated to the degrees of the diagonal elements of the denominator of a matrix fraction description of the system. Such a denominator turns to be a polynomial matrix in Hermite form [9, p. 476]. These indices were used in [8] to study the strict system equivalence. And, above all, in [7] the Hermite indices were shown to play a central role in the study of the topological properties of the orbit space of controllable systems under similarity. Actually, in [7] the possible Hermite indices that can be attained by small additive perturbation of a given complex controllable system were characterized. Also, it was shown that such a characterization is not enough, in the real case, to guarantee the existence of a controllable matrix pair as close to a given system as one may want with those Hermite indices. In this paper we provide a new characterization that works for both the real and complex case. In addition, we also consider the other type of invariants of structure for the similarity of matrix pairs: the partial multiplicities of the noncontrollable part of the system.

**2. Notation and preliminary results.** As already stated, $\mathbb{F}$ will denote either the field of real or complex numbers. $\mathbb{F}[s]$ is the ring of polynomials in the indeterminate $s$ with coefficients in $\mathbb{F}$. We will use $\mathbb{F}^{n\times m}$ and $\mathbb{F}[s]^{n\times m}$ to denote the set of $n\times m$ matrices over $\mathbb{F}$ and $\mathbb{F}[s]$, respectively. $Gl_n(\mathbb{F})$ denotes the linear group of order $n$ over $\mathbb{F}$.

We will use Greek letters to denote polynomials. If $\alpha \in \mathbb{F}[s]$ we will write $d(\alpha)$ for the degree of $\alpha$ and $\Lambda(\alpha)$ for the set of roots in $\mathbb{C}$ of the polynomial $\alpha$. If $\alpha \in \mathbb{R}[s]$ we will denote by $r(\alpha)$ the sum of the multiplicities of the real roots of the polynomial $\alpha$. If $\alpha, \beta \in \mathbb{F}[s]$ we will use $\alpha|\beta$ to mean divides.

As usual, we will say that $(A,B)$ is [illegible] if $\operatorname{rank} \mathcal{C}(A,B) = n$, where

$$\mathcal{C}(A,B) := \begin{bmatrix} B & AB & \cdots & A^{n-1}B \end{bmatrix} \in \mathbb{F}^{n\times nm}$$

is the [illegible] of $(A,B)$.

We will use the [illegible] as introduced in [19]. Given a matrix pair $(A,B) \in \mathbb{F}^{n\times n} \times \mathbb{F}^{n\times m}$, the matrix

$$\mathcal{H}(A,B) := [b_1 \ Ab_1 \ \cdots \ A^{n-1}b_1 \ \cdots \ b_m \ Ab_m \ \cdots \ A^{n-1}b_m],$$

where $b_i \in \mathbb{F}^{n\times 1}$ is the $i$th column of $B$, will be called the [illegible] of $(A,B)$.

If rank $\mathcal{H}(A,B)=r$ and we select from left to right the first $r$ linearly independent columns in $\mathcal{H}(A,B)$ and we write them as

$$b_1,\dots,A^{h_1-1}b_1,\dots,b_m,\dots,A^{h_m-1}b_m,$$

then $h_1,\dots,h_m$ are the [illegible] of the pair (we agree that $h_i=0$ if the column $b_i$ has not been selected).

Two matrix pairs $(A,B),(\overline{A},\overline{B})\in\mathbb{F}^{n\times n}\times\mathbb{F}^{n\times m}$ are [illegible], $(A,B)\overset{s}{\sim}(\overline{A},\overline{B})$, if there exists $P\in Gl_n(\mathbb{F})$ such that $\overline{A}=PAP^{-1}$ and $\overline{B}=PB$.

In the following lemma we give a canonical form for similarity associated to the Hermite indices (see [19, 8, 14]).

LEMMA 2.1. [illegible] $(A,B)\in\mathbb{F}^{n\times n}\times\mathbb{F}^{n\times m}$ [illegible] $h_1,\dots,h_m$ [illegible] $P\in GL_n(\mathbb{F})$ [illegible]

$$(PAP^{-1},PB)=\left(\begin{bmatrix}A_{11}&A_{12}&\cdots&A_{1m}\\0&A_{22}&\cdots&A_{2m}\\\vdots&\vdots&\ddots&\vdots\\0&0&\cdots&A_{mm}\end{bmatrix},\begin{bmatrix}B_{11}&B_{12}&\cdots&B_{1m}\\0&B_{22}&\cdots&B_{2m}\\\vdots&\vdots&\ddots&\vdots\\0&0&\cdots&B_{mm}\end{bmatrix}\right),$$

[illegible] $i=1,\dots,m$ [illegible] $j=i,\dots,m$

(i)

$$A_{ii}=\begin{bmatrix}0&0&\cdots&0&x_{ii0}\\1&0&\cdots&0&x_{ii1}\\0&1&\cdots&0&x_{ii2}\\\vdots&\vdots&\ddots&\vdots&\vdots\\0&0&\cdots&1&x_{iih_i-1}\end{bmatrix}\in\mathbb{F}^{h_i\times h_i},$$

$$A_{ij}=\begin{bmatrix}0&0&\cdots&0&x_{ji0}\\0&0&\cdots&0&x_{ji1}\\0&0&\cdots&0&x_{ji2}\\\vdots&\vdots&\ddots&\vdots&\vdots\\0&0&\cdots&0&x_{jih_i-1}\end{bmatrix}\in\mathbb{F}^{h_i\times h_j},\quad i<j,$$

(ii)

$$\begin{aligned}&B_{ii}=[1\ 0\ \cdots\ 0]^T\in\mathbb{F}^{h_i\times 1} && \text{[illegible]}\ h_i>0,\\&B_{ij}=0\in\mathbb{F}^{h_i\times 1} && \text{[illegible]}\ h_j>0,\quad i<j,\\&B_{ij}=[x_{ji0}\ x_{ji1}\ \cdots\ x_{jih_i-1}]^T\in\mathbb{F}^{h_i\times 1} && \text{[illegible]}\ h_j=0,\quad i\le j,\end{aligned}$$

[illegible] 0 [illegible] 0 [illegible]

If the pair $(A,B)$ is not controllable, then the Hermite indices are also invariant under similarity. Furthermore, if we call invariant factors of $(A,B)$ those of the polynomial matrix $[sI-A\ B]$, then these polynomials are also invariant under similarity. Notice that the invariant factors of $(A,B)$ are equal to 1 if and only if the pair $(A,B)$ is controllable [17].

Throughout this paper, for a given polynomial $\alpha = s^h - a_{h-1}s^{h-1} - \cdots - a_1 s - a_0$, we will say that

$$\begin{bmatrix} 0 & 0 & \cdots & 0 & a_0 \\ 1 & 0 & \cdots & 0 & a_1 \\ 0 & 1 & \cdots & 0 & a_2 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & a_{h-1} \end{bmatrix}$$

is [illegible] of $\alpha$. Thus, in Lemma 2.1, block $A_{ii}$ is the companion matrix of $\theta_i = s^{h_i} - x_{iih_i-1}s^{h_i-1} \cdots - x_{ii1}s - x_{ii0}$, $i = 1, \ldots, m$. These polynomials will be called the [illegible] of $(A, B)$. Actually, as pointed out in [9, p. 476], they are the polynomials appearing on the diagonal of the Hermite normal form of the denominator of any right coprime factorization of the matrix transfer function $(sI_n - A)^{-1}B$.

For noncontrollable pairs we will use the well-known [illegible] (see, for example [9, p. 361]).

Lemma 2.2 (Zaballa [20]). [illegible] $(A, B) \in \mathbb{F}^{n\times n} \times \mathbb{F}^{n\times m}$. [illegible]

$$\left( \begin{bmatrix} A_1 & A_2 \\ 0 & A_3 \end{bmatrix}, \begin{bmatrix} B_1 \\ 0 \end{bmatrix} \right) \quad [illegible] \quad \left( \begin{bmatrix} \overline{A}_1 & \overline{A}_2 \\ 0 & \overline{A}_3 \end{bmatrix}, \begin{bmatrix} \overline{B}_1 \\ 0 \end{bmatrix} \right)$$

[illegible] $(A, B)$ [illegible]

$$(A_1, B_1) \overset{s}{\sim} (\overline{A}_1, \overline{B}_1) \quad [illegible] \quad A_3 \overset{s}{\sim} \overline{A}_3.$$

Then, given any Kalman decomposition of a pair $(A, B)$, the controllable part $(A_1, B_1)$ and the square block $A_3$ are determined up to similarity by $(A, B)$. Therefore, the diagonal Hermite polynomials of $(A_1, B_1)$ are invariant under similarity and, in this paper, will be called diagonal Hermite polynomials of $(A, B)$. On the other hand, the invariant factors different from 1 of $(A, B)$ and those of $A_3$ coincide (see [18]). This means, among other things, that if $r = \operatorname{rank} \mathcal{C}(A, B)$ and $\alpha_n \mid \cdots \mid \alpha_1$ are the invariant factors of $(A, B)$, then $\alpha_{n-r+1} = \cdots = \alpha_n = 1$.

Let $(A, B) \in \mathbb{F}^{n\times n} \times \mathbb{F}^{n\times m}$; a complex number $\lambda$ is said to be an eigenvalue of $(A, B)$ if $\lambda$ is an eigenvalue of $A_3$ in a Kalman decomposition of $(A, B)$. We will denote by $\Lambda(A, B)$ the set of the eigenvalues of $(A, B)$. Similarly we define the characteristic polynomial of $(A, B)$, the Segre characteristic, and the algebraic multiplicity of $\lambda \in \Lambda(A, B)$. This algebraic multiplicity will be denoted by $m_{(A,B)}(\lambda)$. That is to say, if $\alpha_n | \cdots | \alpha_1$ are the invariant factors of $(A, B)$ and

$$\alpha_j = \prod_{i=1}^{p} (s - \lambda_i)^{s_{ij}}, \quad 1 \le j \le n,$$

then $(s_{i1}, \ldots, s_{in})$ is the Segre characteristic corresponding to $\lambda_i$ and $m_{(A,B)}(\lambda_i) = \sum_{j=1}^{n} s_{ij}$. We agree that if $\lambda \notin \Lambda(A, B)$, then $m_{(A,B)}(\lambda) = 0$ and $(0, 0, \ldots)$ is the partition corresponding to the Segre characteristic of $\lambda$.

Let $(A, [B_1\ B_2]) \in \mathbb{F}^{n\times n} \times \mathbb{F}^{n\times(m_1+m_2)}$. Let $\theta_1, \ldots, \theta_{m_1}, \theta_{m_1+1}, \ldots, \theta_{m_1+m_2}$ be the diagonal Hermite polynomials of $(A, [B_1\ B_2])$, and let $\vartheta$ be the characteristic polynomial of $(A, [B_1\ B_2])$. It is easy to prove that $\theta_1, \ldots, \theta_{m_1}$ are the diagonal Hermite polynomials and $\theta = \vartheta \prod_{i=1}^{m_2} \theta_{m_1+i}$ is the characteristic polynomial of $(A, B_1)$.

Given $A = (a_{ij}) \in \mathbb{F}^{n\times m}$ we are going to consider the following matrix norm:

$$\| A \| = \sum_{i,j} |a_{ij}|.$$

The set $\mathbb{F}^{n\times m}$ is a metric space with the distance associated to this norm. For a given $n$ and a polynomial $\theta = c_n s^n + c_{n-1}s^{n-1} + \cdots + c_1 s + c_0 \in \mathbb{F}[s]$, we will denote

$$\| \theta \| = \sum_{i=0}^{n} |c_i|$$

which is a norm on the vector space of polynomials of degree less than or equal to $n$.

If $z \in \mathbb{C}$ and $r$ is a positive real number, the open ball of $\mathbb{C}$ centered in $\alpha$ and radius $r$ is denoted by $B(z, r)$.

Let $(A, B) \in \mathbb{F}^{n\times n} \times \mathbb{F}^{n\times m}$, let $\Lambda(A, B) = \{\lambda_1, \ldots, \lambda_u\}$, and let $\eta$ be a positive real number. We define the $\eta$-neighborhood of the spectrum of $(A, B)$ as the set

$$\mathcal{V}_\eta(A, B) := \dot{\cup}_{i=1}^{u} B(\lambda_i, \eta)$$

whenever the balls $B(\lambda_i, \eta)$, $i = 1, \ldots, u$, are pairwise disjoint.

From now on $\eta$ will always mean a positive real number small enough for the expresion $\eta$-neighborhood of the spectrum of $(A, B)$, or of $A$, to make sense.

Let $a = (a_1, \ldots, a_n)$ and $b = (b_1, \ldots, b_n)$ be two partitions of nonnegative integers with its components arranged in nonincreasing order. Following [13], we will say that $a$ is majorized by $b$, $a \prec b$, if

$$\sum_{j=1}^{k} a_j \le \sum_{j=1}^{k} b_j, \quad k = 1, \ldots, n-1, \text{ and } \sum_{j=1}^{n} a_j = \sum_{j=1}^{n} b_j.$$

Moreover, $a + b$ is the partition whose $i$th component is $a_i + b_i$.

We finish this section with two relevant results of [7] with the terminology of [6].

LEMMA 2.3 (see [7, proof of Thm. 4.2]). $(A, B) \in \mathbb{F}^{n\times n} \times \mathbb{F}^{n\times m}$ $h_1, \ldots, h_m$ $\epsilon > 0$ $\| [A\ B] - [A'\ B'] \| < \epsilon$ $h'_1, \ldots, h'_m$ $(A', B')$

$$\sum_{j=1}^{i} h_j \le \sum_{j=1}^{i} h'_j, \qquad i = 1, \ldots, m. \tag{2.1}$$

$(A, B)$ $(A', B')$

$$\sum_{j=1}^{m} h_j = \sum_{j=1}^{m} h'_j. \tag{2.2}$$

LEMMA 2.4 (see [7, Thm. 4.2]). $(A, B) \in \mathbb{C}^{n\times n} \times \mathbb{C}^{n\times m}$ $h_1, \ldots, h_m$ $h'_1, \ldots, h'_m$ $\epsilon > 0$ $(A', B') \in \mathbb{C}^{n\times n} \times \mathbb{C}^{n\times m}$

(i) $\| [A\ B] - [A'\ B'] \| < \epsilon$,

(ii) $h'_1, \ldots, h'_m$ $(A', B')$,

(2.1) (2.2)

In the present work we generalize the above results for $\mathbb{F} = \mathbb{R}$ or $\mathbb{C}$ and for noncontrollable systems. In section 3 we establish conditions that must necessarily satisfy the Hermite indices and the Jordan part of all systems that are close enough to a given system. Then Lemma 2.3 will follow as a particular case. In section 4 we generalize Lemma 2.4 by giving necessary and sufficient conditions for the existence of matrix pairs as close to a given pair as desired and having prescribed its Hermite indices and invariant factors.

**3. Necessary conditions.** First of all we give Theorem 4.3 of [6] in a different form.

LEMMA 3.1. [illegible] $(A,B) \in \mathbb{F}^{n\times n} \times \mathbb{F}^{n\times m}$[illegible] $\eta > 0$ [illegible] $\lambda \in \Lambda(A,B)$[illegible] $s$ [illegible] $\lambda$[illegible] $(A,B)$ [illegible] $\epsilon > 0$ [illegible] $\| [A \ B] - [A' \ B'] \| < \epsilon$ [illegible]

(i) $\Lambda(A',B') \subset \mathcal{V}_\eta(A,B)$[illegible]

(ii) [illegible] $\mu_1,\dots,\mu_t$[illegible] $(A',B')$[illegible] $\mathcal{B}(\lambda,\eta)$[illegible] $s'_i$[illegible] $\mu_i$[illegible] $(A',B')$, $i = 1,\dots,t$ [illegible] $q \geq 0$ [illegible]

$$s \prec \sum_{j=1}^{t} s'_i + (q,0,\dots).$$

[illegible] 3.2. Condition (ii) implies

$$\sum_{\mu\in\mathcal{B}(\lambda,\eta)\cap\Lambda(A',B')} m_{(A',B')}(\mu) \leq m_{(A,B)}(\lambda).$$

Moreover, if $(A,B) \in \mathbb{R}^{n\times n} \times \mathbb{R}^{n\times m}$ and $\lambda \in \mathbb{C} \setminus \mathbb{R}$, then $\overline{\mu}_1,\dots,\overline{\mu}_t$ are the eigenvalues of $(A',B')$ in $\mathcal{B}(\overline{\lambda},\eta)$, and $s'_i$ is the partition corresponding to $\overline{\mu}_i$ in the Segre characteristic of $(A',B')$, $i = 1,\dots,t$.

THEOREM 3.3. [illegible] $(A,B) \in \mathbb{F}^{n\times n} \times \mathbb{F}^{n\times m}$ $\eta > 0$[illegible] $\theta_1,\dots,\theta_m$ [illegible] $(A,B)$ [illegible] $\Lambda(A,B) = \{\lambda_1,\dots,\lambda_p\}$[illegible] $s_i$ [illegible] $\lambda_i$, $i = 1,\dots,p$ [illegible] $(A,B)$ [illegible] $\epsilon > 0$ [illegible] $\| [A \ B] - [A' \ B'] \| < \epsilon$ [illegible]

(i) $\Lambda(A',B') \subset \mathcal{V}_\eta(A,B)$

(ii) [illegible] $\mu_{i1},\dots,\mu_{it_i}$[illegible] $(A',B')$[illegible] $\mathcal{B}(\lambda_i,\eta)$, $i = 1,\dots,p$[illegible] $s'_{ij}$ [illegible] $\mu_{ij}$, $i = 1,\dots,p$, $j = 1,\dots,t_i$ [illegible] $(A',B')$ [illegible] $q_i \geq 0$, $i = 1,\dots,p$ [illegible]

$$s_i \prec \sum_{j=1}^{t_i} s'_{ij} + (q_i,0,\dots), \quad i = 1,\dots,p,$$

(iii) [illegible] $h'_1,\dots,h'_m$[illegible] $(A',B')$ [illegible] $\beta_1,\dots,\beta_m \in \mathbb{F}[s]$ [illegible] $d(\beta_i) = h'_i$, $i = 1,\dots,m$[illegible]

$$\beta_j \cdots \beta_m \mid \theta_j \cdots \theta_m \omega, \quad j = 2,\dots,m,$$

$$\beta_1 \cdots \beta_m = \theta_1 \cdots \theta_m \omega,$$

[illegible] $\omega := \prod_{i=1}^{p} (s-\lambda_i)^{q_i}$.

*Proof.* Let $B = [b_1 \;\cdots\; b_m]$. For $j = 1, \ldots, m$, put $B_j := [b_1 \;\cdots\; b_j]$ and $(A, B_0) := A$.

Let $\theta_{m+1}$ be the characteristic polynomial of $(A, B)$. Then $\Lambda(A, B_j) = \Lambda(\theta_{j+1} \ldots \theta_m \theta_{m+1})$ for $j = 0, \ldots, m$.

Suppose that $\Lambda(A) = \{\lambda_1, \ldots, \lambda_p, \lambda_{p+1}, \ldots, \lambda_{p+q}\},\ q \geq 0$.

For $j = 0, \ldots, m$, $i = 1, \ldots, p+q$, let $m_i^j := m_{(A,B_j)}(\lambda_i)$. Notice that $m_i^j = 0$ if $\lambda_i \notin \Lambda(A, B_j)$. Therefore

$$\theta_{j+1} \cdots \theta_m \theta_{m+1} = \prod_{i=1}^{p+q} (s - \lambda_i)^{m_i^j}, \qquad j = 0, \ldots, m. \tag{3.1}$$

By Lemma 3.1, for $j = 0, \ldots, m$ there exists $\varepsilon_j > 0$ such that if $(A', B_j')$ satisfies $\| [A, B_j] - [A', B_j'] \| < \varepsilon_j$, then

$$\Lambda(A', B_j') \subset \mathcal{V}_\eta(A, B_j), \tag{3.2}$$

$$\sum_{\mu \in \mathcal{B}(\lambda_i, \eta) \cap \Lambda(A', B_j')} m_{(A', B_j')}(\mu) \leq m_i^j, \quad i = 1, \ldots, p+q. \tag{3.3}$$

Moreover, if $\mu_{i1}, \ldots, \mu_{it_i}$ are the eigenvalues of $(A', B_m')$ in $\mathcal{B}(\lambda_i, \eta),\ i = 1, \ldots, p$, and $s_{ij}'$ is the partition corresponding to $\mu_{ij},\ i = 1, \ldots, p,\ j = 1, \ldots, t_i$, in the Segre characteristic of $(A', B_m')$, then there exist nonnegative integers $q_i \geq 0,\ i = 1, \ldots, p$, such that

$$s_i \prec \sum_{j=1}^{t_i} s_{ij}' + (q_i, 0, \ldots), \quad i = 1, \ldots, p.$$

Let $\varepsilon = \min_{0 \leq j \leq m}(\varepsilon_j)$, and let $(A', B')$ be such that $\| [A' \; B'] - [A \; B] \| < \varepsilon$. Then $(A', B')$ satisfies conditions (i) and (ii) of theorem.

Let $B' = [b_1' \;\cdots\; b_m']$, and for $j = 1, \ldots, m$, put $B_j' := [b_1' \;\cdots\; b_j']$ and $(A', B_0') := A'$.

Then, for $j = 0, \ldots, m$, $\| [A \; B_j] - [A' \; B_j'] \| < \varepsilon \leq \varepsilon_j$ and therefore (3.2) and (3.3) hold.

Let $h_1', \ldots, h_m'$ be the Hermite indices, let $\theta_1', \ldots, \theta_m'$ be the diagonal Hermite polynomials and let $\theta_{m+1}'$ be the characteristic polynomial of $(A', B')$. Then $h_j' = d(\theta_j')$, $j = 1, \ldots, m$, and

$$\Lambda(A', B_j') = \Lambda(\theta_{j+1}' \cdots \theta_m' \theta_{m+1}'), \quad j = 0, \ldots, m. \tag{3.4}$$

Let

$$n_i^j := \sum_{\mu \in \mathcal{B}(\lambda_i, \eta) \cap \Lambda(A', B_j')} m_{(A', B_j')}(\mu), \quad i = 1, \ldots, p+q;\ j = 0, \ldots, m.$$

For $j = 1, \ldots, m+1$, we define

$$\delta_j := \prod_{i=1}^{p+q} (s - \lambda_i)^{n_i^{j-1}}.$$

Notice that $\delta_j \in \mathbb{F}[s]$. In fact, if $\mathbb{F} = \mathbb{R}$ and $\lambda_i \in \Lambda(A, B_{j-1}) \setminus \mathbb{R}$, then $\lambda_k = \overline{\lambda}_i \in \Lambda(A, B_{j-1})$, and by Remark 3.2, $n_i^{j-1} = n_k^{j-1}$. Moreover,

$$d(\delta_j) = d(\theta_j' \cdots \theta_{m+1}'),$$

and from (3.1) and (3.3) we have that

$$\delta_j \mid \theta_j \cdots \theta_m \theta_{m+1}, \qquad j = 1, \ldots, m+1.$$

Recall that $n_i^m = 0$ for $i = p+1, \ldots, p+q$ and

$$q_i = m_{(A,B)}(\lambda_i) - \sum_{\mu \in \mathcal{B}(\lambda_i,\eta) \cap \Lambda(A',B')} m_{(A',B')}(\mu) = m_i^m - n_i^m, \qquad i = 1, \ldots, p.$$

This implies that $\omega = \prod_{i=1}^{p} (s - \lambda_i)^{q_i} = \frac{\theta_{m+1}}{\delta_{m+1}}$.

From (3.4) we have that $n_i^j \leq n_i^{j-1}$, $i = 1, \ldots, p+q$; $j = 1, \ldots, m$. Therefore $\delta_{j+1} \mid \delta_j$, $j = 1, \ldots, m$. Let

$$\beta_j := \frac{\delta_j}{\delta_{j+1}}, \quad j = 1, \ldots, m.$$

Then $\beta_j \in \mathbb{F}[s]$, $j = 1, \ldots, m$, and

$$\beta_j \cdots \beta_m = \frac{\delta_j}{\delta_{m+1}} \mid \theta_j \cdots \theta_m \frac{\theta_{m+1}}{\delta_{m+1}} = \theta_j \cdots \theta_m \omega, \qquad j = 1, \ldots, m.$$

We have to prove only that $d(\beta_j) = h'_j$, $j = 1, \ldots, m$, and $\beta_1 \cdots \beta_m = \theta_1 \cdots \theta_m \omega$. In fact,

$$\sum_{i=j}^{m} h'_i = d(\theta'_j \cdots \theta'_m) = d(\delta_j) - d(\theta'_{m+1}) = d(\delta_j) - d(\delta_{m+1}) = \sum_{i=j}^{m} d(\beta_i), \quad j = 1, \ldots, m.$$

As a consequence $d(\beta_j) = h'_j$, $j = 1, \ldots, m$.

Finally,

$$d(\beta_1 \cdots \beta_m) = \sum_{i=1}^{m} h'_i = n - d(\theta'_{m+1}) = \sum_{i=1}^{m} h_i + d(\theta_{m+1}) - d(\delta_{m+1}) = d(\theta_1 \theta_2 \cdots \theta_m) + d(\omega).$$

Since $\beta_1 \cdots \beta_m \mid \theta_1 \cdots \theta_m \omega$ we conclude that

$$\beta_1 \cdots \beta_m = \theta_1 \cdots \theta_m \omega$$

as desired. ☐

For the controllable case we have the following corollary.

COROLLARY 3.4. [illegible] $(A, B) \in \mathbb{F}^{n \times n} \times \mathbb{F}^{n \times m}$ [illegible] $\theta_1, \ldots, \theta_m$ [illegible] $\epsilon > 0$ [illegible] $\| [A\ B] - [A'\ B'] \| < \epsilon$ [illegible] $h'_1, \ldots, h'_m$ [illegible] $(A', B')$ [illegible] $\beta_1, \ldots, \beta_m$ [illegible] $d(\beta_i) = h'_i$, $i = 1, \ldots, m$ [illegible]

$$\beta_j \cdots \beta_m \mid \theta_j \cdots \theta_m, \quad j = 2, \ldots, m,$$

$$\beta_1 \cdots \beta_m = \theta_1 \cdots \theta_m.$$

[illegible] 3.5. It is easily seen that, if $\mathbb{F} = \mathbb{C}$, the condition of the previous corollary is equivalent to those of Lemma 2.3.

**4. Sufficient conditions.** This section is devoted to proving the near-converse of Theorem 3.3. The proof is constructive and it gives us a general method to obtain a pair as close to a given pair as desired and with prescribed structure.

Before going into formal proofs let us describe the perturbation process for the controllable case. Given a pair $(A, B)$ with diagonal Hermite polynomials $\theta_1, \ldots, \theta_m$ and given $m$ nonnegative integers $h'_1, \ldots, h'_m$, we have to prove that the condition of the Corollary 3.4 is sufficient for the existence of a controllable pair $(A', B')$ as close as we want to $(A, B)$ and with Hermite indices $h'_1, \ldots, h'_m$. Observe that this condition implies (2.1) and (2.2).

Without loss of generality, we can assume that $(A, B)$ is in the canonical form shown in Lemma 2.1:

$$(A,B) = \left( \begin{bmatrix} A_{11} & A_{12} & \cdots & A_{1m} \\ 0 & A_{22} & \cdots & A_{2m} \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & A_{mm} \end{bmatrix}, \begin{bmatrix} B_{11} & B_{12} & \cdots & B_{1m} \\ 0 & B_{22} & \cdots & B_{2m} \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & B_{mm} \end{bmatrix} \right).$$

The proof is inductive, and the first step is to decrease the index $h_m$ by increasing $h_{m-1}$ in order to obtain a pair $(A_1, B_1)$ with $h_1, \ldots, h_{m-2}, h_{m-1} + h_m - h'_m, h'_m$ as Hermite indices. This will be done by putting the coefficients of the polynomial $\beta_m$ multiplied by an appropriate scalar in the last column of the $(m, m-1)$ block:

$$(A_1,B_1) = \left( \begin{bmatrix} A_{11} & \cdots & A_{1,m-1} & A_{1m} \\ 0 & \cdots & A_{2,m-1} & A_{2m} \\ \vdots & \ddots & \vdots & \vdots \\ 0 & \cdots & A_{m-1,m-1} & A_{m-1,m} \\ 0 & \cdots & C & A_{mm} \end{bmatrix}, \begin{bmatrix} B_{11} & \cdots & B_{1m} \\ 0 & \cdots & B_{2m} \\ \vdots & \ddots & \vdots \\ 0 & \cdots & B_{m-1,m} \\ 0 & \ldots & B_{mm} \end{bmatrix} \right).$$

This pair is similar to

$$\left( \begin{bmatrix} A_{11} & \cdots & \overline{A}_{1,m-1} & \overline{A}_{1m} \\ 0 & \cdots & \overline{A}_{2,m-1} & \overline{A}_{2m} \\ \vdots & \ddots & \vdots & \vdots \\ 0 & \cdots & \overline{A}_{m-1,m-1} & \overline{A}_{m-1,m} \\ 0 & \cdots & 0 & \overline{A}_{mm} \end{bmatrix}, \begin{bmatrix} B_{11} & \cdots & B_{1,m-1} & B_{1m} \\ 0 & \cdots & B_{2,m-1} & B_{2m} \\ \vdots & \ddots & \vdots & \vdots \\ 0 & \cdots & \overline{B}_{m-1,m-1} & \overline{B}_{m-1,m} \\ 0 & \ldots & 0 & \overline{B}_{mm} \end{bmatrix} \right),$$

where $\overline{A}_{m-1,m-1} \in \mathbb{F}^{(h_{m-1}+h_m-h'_m)\times(h_{m-1}+h_m-h'_m)}$ and $\overline{A}_{m,m} \in \mathbb{F}^{h_m \times h_m}$.

Now, if we are perturbing in $\mathbb{C}$, as $h'_{m-1} \leq h_{m-1} + h_m - h'_m$, we can continue with the induction process and obtain a pair $(A_2, B_2)$ with Hermite indices $h_1, \ldots, h_{m-3}, h_{m-2} + h_{m-1} + h_m - h'_m - h'_{m-1}, h'_{m-1}, h'_m$ and so on.

But, if we are perturbing in $\mathbb{R}$ and $\theta_1, \ldots, \theta_{m-2}, \bar{\theta}_{m-1}, \bar{\theta}_m$ are the diagonal Hermite polynomials of $(A_1, B_1)$, in order to continue with the induction process we need to guarantee the existence of a polynomial $\bar{\beta}_{m-1} \in \mathbb{R}[s]$ such that $d(\bar{\beta}_{m-1}) = h'_{m-1}$ and $\bar{\beta}_{m-1} \mid \bar{\theta}_{m-1}$. As divisibility conditions are involved, we will have to take into account the sum of the multiplicities of the roots of $\bar{\theta}_{m-1}$ in $\mathbb{R}$, $r(\bar{\theta}_{m-1})$.

On the one hand, notice that $\bar{\theta}_m = \beta_m$, and as $\beta_{m-1}\beta_m \mid \theta_{m-1}\theta_m$, we have that there exists a polynomial $\nu$ such that $\frac{\theta_{m-1}\theta_m}{\beta_m} = \beta_{m-1}\nu$.

On the other hand, $\bar{\theta}_{m-1} = \frac{\theta_{m-1}\theta_m - \beta_m\psi}{\beta_m}$, where $\psi$ is a polynomial such that $d(\psi) < d(\theta_{m-1})$. Then, $\bar{\theta}_{m-1} = \beta_{m-1}\nu - \psi$.

Now, if $r(\bar{\theta}_{m-1}) = r(\beta_{m-1}\nu)$, we can guarantee the existence of $\bar{\beta}_{m-1}$ such that $\bar{\beta}_{m-1} \mid \bar{\theta}_{m-1}$ and $d(\bar{\beta}_{m-1}) = d(\beta_{m-1})$. If $\psi \neq 0$, i.e., if the block $A_{m-1,m} \neq 0$, the mentioned equality cannot be assured.

Therefore, we first perturb in the block $A_{m-1,m-1}$ for the spectrum of this block and that of $A_{m,m}$ to be disjoint and to put a zero in the block $(m-1,m)$ by similarity.

In the noncontrollable case our first goal is to modify the Hermite indices but prescribing the spectrum of $(A',B')$. This will be done in Theorem 4.11. In this case we start by modifying the last Hermite index to obtain a pair $(\bar{A},\bar{B})$ with the prescribed invariant factors, Hermite indices $h_1,\dots,h_{m-1},h_m+d(\omega)$, and diagonal Hermite polynomials $\theta_1,\dots,\theta_{m-1},\bar{\theta}_m$. As in the controllable case, when $\mathbb{F}=\mathbb{R}$ we can continue with the process if $r(\bar{\theta}_m) = r(\theta_m\omega)$.

In the following example we will explain the steps for the controllable case.

1. Let

$$(A,B) = \left( \left[ \begin{array}{cc|c|cc} 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 \\ \hline 0 & 0 & 0 & 0 & -1 \\ \hline 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \end{array} \right] \left[ \begin{array}{ccc} 1 & 0 & 0 \\ 0 & 0 & 0 \\ \hline 0 & 1 & 0 \\ \hline 0 & 0 & 1 \\ 0 & 0 & 0 \end{array} \right] \right).$$

This pair has $h_1 = 2, h_2 = 1, h_3 = 2$ as Hermite indices and $\theta_1 = s^2, \theta_2 = s$, $\theta_3 = s^2$ as diagonal Hermite polynomials.

Our goal is to obtain a pair $(A',B')$ as close to $(A,B)$ as desired and with Hermite indices $h_1' = 3, h_2' = 1, h_3' = 1$. If we chose $\beta_3 = s$, $\beta_2 = s$, and $\beta_1 = s^3$, we can verify that the conditions of Corollary 3.4 are satisfied:

$$\beta_3 \mid \theta_3, \ \beta_2\beta_3 \mid \theta_2\theta_3 \text{ and } \beta_1\beta_2\beta_3 = \theta_1\theta_2\theta_3.$$

As we have said, we first modify the last Hermite index to obtain a pair with $h_3' = 1$ putting in the last column of the block $A_{32}$ the coefficients of $\beta_3$ multiplied by a convenient $\epsilon_1$:

$$\left( \left[ \begin{array}{cc|c|cc} 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 \\ \hline 0 & 0 & 0 & 0 & -1 \\ \hline 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & \epsilon_1 & 1 & 0 \end{array} \right] \left[ \begin{array}{ccc} 1 & 0 & 0 \\ 0 & 0 & 0 \\ \hline 0 & 1 & 0 \\ \hline 0 & 0 & 1 \\ 0 & 0 & 0 \end{array} \right] \right).$$

This pair has Hermite indices $2,2,1$ and diagonal Hermite polynomials $\overline{\theta}_1 = s^2, \overline{\theta}_2 = s^2 + \epsilon_1$, $\overline{\theta}_3 = s$, and it is similar to

$$(\overline{A},\overline{B}) = \left( \left[ \begin{array}{cc|cc|c} 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 \\ \hline 0 & 0 & 0 & -\epsilon_1 & 0 \\ 0 & 0 & 1 & 0 & \frac{1}{\epsilon_1} \\ \hline 0 & 0 & 0 & 0 & 0 \end{array} \right] \left[ \begin{array}{ccc} 1 & 0 & 0 \\ 0 & 0 & 0 \\ \hline 0 & 1 & 0 \\ 0 & 0 & 0 \\ \hline 0 & 0 & 1 \end{array} \right] \right).$$

To continue with the process we consider the polynomial $\overline{\beta}_2 = s - \sqrt{\epsilon_1} i$ of degree $h_2'$ that divides $\overline{\theta}_2$, and we put in the last column of the block $A_{22}$ its coefficients multiplied by a convenient $\epsilon_2 > 0$:

$$(\overline{A}', \overline{B}') = \left( \left[ \begin{array}{cc|cc|c} 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 \\ \hline 0 & -\sqrt{\epsilon_1} i \epsilon_2 & 0 & -\epsilon_1 & 0 \\ 0 & \epsilon_2 & 1 & 0 & \frac{1}{\epsilon_1} \\ \hline 0 & 0 & 0 & 0 & 0 \end{array} \right] \left[ \begin{array}{ccc} 1 & 0 & 0 \\ 0 & 0 & 0 \\ \hline 0 & 1 & 0 \\ 0 & 0 & 0 \\ \hline 0 & 0 & 1 \end{array} \right] \right).$$

This pair has Hermite indices $h'_1 = 3, h'_2 = 1, h'_3 = 1$, but notice that it is not a real pair. In this case $\overline{\theta}_2$ has no real roots, and therefore, there is no $\overline{\beta}_2 \in \mathbb{R}[s]$ of degree 1 such that $\overline{\beta}_2 | \overline{\theta}_2$. That is because $r(\overline{\theta}_2) \neq r(\frac{\theta_2 \theta_3}{\beta_3})$.

Then, in the real case we first perturb matrix $A$ for the spectrum of blocks $A_{22}$ and $A_{33}$ to be disjoint, and by similarity transformations we can put a zero in the block $A_{23}$:

$$\left( \left[ \begin{array}{cc|c|cc} 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 \\ \hline 0 & 0 & \epsilon_0 & 0 & -1 \\ \hline 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \end{array} \right] \left[ \begin{array}{ccc} 1 & 0 & 0 \\ 0 & 0 & 0 \\ \hline 0 & 1 & 0 \\ \hline 0 & 0 & 1 \\ 0 & 0 & 0 \end{array} \right] \right).$$

This pair is similar to

$$(\overline{A}, \overline{B}) = \left( \left[ \begin{array}{cc|c|cc} 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 \\ \hline 0 & 0 & \epsilon_0 & 0 & 0 \\ \hline 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \end{array} \right] \left[ \begin{array}{ccc} 1 & 0 & 0 \\ 0 & 0 & 0 \\ \hline 0 & 1 & -\frac{1}{\epsilon_0^2} \\ \hline 0 & 0 & 1 \\ 0 & 0 & 0 \end{array} \right] \right).$$

Now we proceed as before. First we obtain $h'_3$ by perturbing in the block $A_{32}$:

$$\left( \left[ \begin{array}{cc|c|cc} 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 \\ \hline 0 & 0 & \epsilon_0 & 0 & 0 \\ \hline 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & \epsilon_1 & 1 & 0 \end{array} \right] \left[ \begin{array}{ccc} 1 & 0 & 0 \\ 0 & 0 & 0 \\ \hline 0 & 1 & -\frac{1}{\epsilon_0^2} \\ \hline 0 & 0 & 1 \\ 0 & 0 & 0 \end{array} \right] \right).$$

This pair has $2, 2, 1$ as Hermite indices and $\overline{\overline{\theta}}_1 = s^2, \overline{\overline{\theta}}_2 = s^2 - \epsilon_0 s$, and $\overline{\overline{\theta}}_3 = s$ as diagonal Hermite polynomials, and it is similar to

$$(\overline{\overline{A}}, \overline{\overline{B}}) = \left( \left[ \begin{array}{cc|cc|c} 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 \\ \hline 0 & 0 & 0 & 0 & -\frac{\epsilon_0}{\epsilon_1} \\ 0 & 0 & 1 & \epsilon_0 & -\frac{1}{\epsilon_0^2} + \frac{1}{\epsilon_1} \\ \hline 0 & 0 & 0 & 0 & 0 \end{array} \right] \left[ \begin{array}{ccc} 1 & 0 & 0 \\ 0 & 0 & 0 \\ \hline 0 & 1 & 0 \\ 0 & 0 & 0 \\ \hline 0 & 0 & 1 \end{array} \right] \right).$$

Now $r(\overline{\overline{\theta}}_2) = r(\frac{\theta_2 \theta_3}{\beta_3})$. Then, we can choose $\overline{\overline{\beta}}_2 = s \in \mathbb{R}[s]$ of degree $h'_2$ to put its coefficients multiplied by a convenient $\epsilon_2 > 0$ in the last column of the block $\overline{\overline{A}}_{21}$:

$$(\overline{\overline{A}}', \overline{\overline{B}}') = \left( \left[ \begin{array}{cc|cc|c} 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 \\ \hline 0 & 0 & 0 & 0 & -\frac{\epsilon_0}{\epsilon_1} \\ 0 & \epsilon_2 & 1 & \epsilon_0 & -\frac{1}{\epsilon_0^2} + \frac{1}{\epsilon_1} \\ \hline 0 & 0 & 0 & 0 & 0 \end{array} \right] \left[ \begin{array}{ccc} 1 & 0 & 0 \\ 0 & 0 & 0 \\ \hline 0 & 1 & 0 \\ 0 & 0 & 0 \\ \hline 0 & 0 & 1 \end{array} \right] \right).$$

To finish we must undo the two similarity transformations that we have done throughout the process to obtain

$$(A',B')=\left(\left[\begin{array}{cc|c|cc} 0 & 0 & 0 & 0 & 0\\ 1 & 0 & 0 & 0 & 0\\ \hline 0 & \frac{\epsilon_2(\epsilon_0^2+\epsilon_1)}{\epsilon_0} & \frac{\epsilon_0^2+\epsilon_1}{\epsilon_0} & -\frac{\epsilon_1}{\epsilon_0^3} & -1-\frac{\epsilon_1}{\epsilon_0^2}\\ \hline 0 & 0 & 0 & 0 & 0\\ 0 & \epsilon_1\epsilon_2 & \epsilon_1 & 1-\frac{\epsilon_1}{\epsilon_0^2} & -\frac{\epsilon_1}{\epsilon_0} \end{array}\right]\left[\begin{array}{ccc} 1 & 0 & 0\\ 0 & 0 & 0\\ \hline 0 & 1 & 0\\ \hline 0 & 0 & 1\\ 0 & 0 & 0 \end{array}\right]\right).$$

This pair is a real pair and has the prescribed Hermite indices.

Now, if we choose $\epsilon_2=\epsilon_0$ and $\epsilon_1=\epsilon_0^4$ it is easy to verify that

$$\parallel [A\ B]-[A'\ B'] \parallel = \epsilon_0^5+2\epsilon_0^4+2\epsilon_0^3+3\epsilon_0^2+2\epsilon_0.$$

By choosing $\epsilon_0$ small enough, $(A',B')$ can be as close as we want to $(A,B)$.

Lemma 4.1 (see [2]). [illegible] $A\in\mathbb{F}^{n\times n}$ [illegible] $\alpha_n\mid\dots\mid\alpha_1$[illegible] $\alpha'_1,\dots,\alpha'_n\in\mathbb{F}[s]$ [illegible] $\alpha'_n\mid\dots\mid\alpha'_1$ [illegible] $\epsilon>0$ [illegible] $A'\in\mathbb{F}^{n\times n}$ [illegible]

(i) $\parallel A'-A\parallel<\epsilon$

(ii) $\alpha'_1,\dots,\alpha'_n$[illegible] $A'$ [illegible]

$$\alpha_1\cdots\alpha_k\mid\alpha'_1\cdots\alpha'_k,\qquad k=1,\dots,n-1,$$

$$\alpha_1\cdots\alpha_n=\alpha'_1\cdots\alpha'_n.$$

The aim of the next lemma, whose proof is straightforward, is to show that the pair $(A,B)$ can be replaced by any pair in its similarity class.

Lemma 4.2. [illegible] $(A,B),(\overline{A},\overline{B})\in\mathbb{F}^{n\times n}\times\mathbb{F}^{n\times m}$ [illegible] $(A,B)\overset{s}{\sim}(\overline{A},\overline{B})$[illegible] $\mathcal{C}_s$ [illegible] $\mathbb{F}^{n\times n}\times\mathbb{F}^{n\times m}$. [illegible]

(1) [illegible] $\epsilon>0$ [illegible] $(A',B')\in\mathcal{C}_s$ [illegible]

$$\parallel [A\ B]-[A'\ B'] \parallel<\epsilon.$$

(2) [illegible] $\epsilon'>0$ [illegible] $(\overline{A}',\overline{B}')\in\mathcal{C}_s$ [illegible]

$$\parallel [\overline{A}\ \overline{B}]-[\overline{A}'\ \overline{B}'] \parallel<\epsilon'.$$

[illegible] 4.3. A similar lemma can be made if we prescribe some of the invariants for similarity instead of the whole similarity class.

Lemma 4.4. [illegible]

$$(A,b)=\left(\begin{bmatrix} A_1 & 0\\ 0 & J\end{bmatrix},\begin{bmatrix} b_1\\ 0\end{bmatrix}\right)\in\mathbb{F}^{n\times n}\times\mathbb{F}^{n\times 1},$$

[illegible] $(A_1,b_1)\in\mathbb{F}^{h\times h}\times\mathbb{F}^{h\times 1}$[illegible] $\theta$[illegible] $d(\theta)=h$[illegible] $J$[illegible] $\alpha$

[illegible] $\alpha',\omega\in\mathbb{F}[s]$ [illegible] $\alpha=\alpha'\omega$

[illegible] $\epsilon>0$ [illegible] $(A',b')\in\mathbb{F}^{n\times n}\times\mathbb{F}^{n\times 1}$ [illegible]

(i) $\parallel [A'\ b']-[A\ b] \parallel<\epsilon$

(ii) [illegible] $(A',b')$[illegible] $\theta'=\theta\omega$

(iii) [illegible] $(A', b')$ [illegible] $\alpha'$ [illegible] $\alpha' = 1$ [illegible] $(A', b')$ [illegible]

[illegible]. Let $\epsilon > 0$. If $\alpha' = \alpha$, we put $(A', b') := (A, b)$.

If $\alpha' = s^d - a_{d-1}s^{d-1} - \cdots - a_1 s - a_0$ with $d < n - h = d(\alpha)$, we define

$$c := \epsilon_1 \left[ \begin{array}{cccccccc} a_0 & a_1 & \cdots & a_{d-1} & -1 & 0 & \cdots & 0 \end{array} \right]^T \in \mathbb{F}^{(n-h)\times 1},$$

$0 < \epsilon_1 < \epsilon / \sum_{i=0}^{d-1} |a_i| + 1$.

[illegible] 1. If $h = 0$, (i.e., $(A_1, b_1)$ is absent), then we put

$$(A', b') := (J, c) \in \mathbb{F}^{n\times n} \times \mathbb{F}^{n\times 1}.$$

[illegible] 2. If $h > 0$, then we put $C := \left[ \begin{array}{cc} 0 & c \end{array} \right] \in \mathbb{F}^{(n-h)\times h}$ and

$$(A', b') := \left( \left[ \begin{array}{cc} A_1 & 0 \\ C & J \end{array} \right], \left[ \begin{array}{c} b_1 \\ 0 \end{array} \right] \right) \in \mathbb{F}^{n\times n} \times \mathbb{F}^{n\times 1}.$$

It is easily seen that the only nontrivial invariant factor of $(A', b')$ is $\alpha'$.

The characteristic polynomial of $A'$ is $\theta\alpha$. If the diagonal Hermite polynomial of $(A', b')$ is $\theta'$, then $\theta\alpha = \theta'\alpha'$, and so $\theta' = \theta\omega$. □

The following lemma can be easily proved (see [4, p. 225] or [10, p. 422]).

LEMMA 4.5. [illegible]

$$(A, B) = \left( \left[ \begin{array}{cc} A_1 & X \\ 0 & J \end{array} \right], \left[ \begin{array}{c} B_1 \\ 0 \end{array} \right] \right) \in \mathbb{F}^{n\times n} \times \mathbb{F}^{n\times m}.$$

[illegible] $\Lambda(A_1) \cap \Lambda(J) = \emptyset$ [illegible]

$$(A, B) \overset{s}{\sim} \left( \left[ \begin{array}{cc} A_1 & 0 \\ 0 & J \end{array} \right], \left[ \begin{array}{c} B_1 \\ 0 \end{array} \right] \right).$$

LEMMA 4.6. [illegible] $\theta \in \mathbb{R}[s]$ [illegible] $S = \{\lambda_1, \ldots, \lambda_p\} \subset \mathbb{C}$ [illegible] $\epsilon > 0$ [illegible] $\vartheta \in \mathbb{R}[s]$ [illegible]

$$\| \vartheta - \theta \| < \epsilon, \quad d(\vartheta) = d(\theta), \quad \Lambda(\vartheta) \cap S = \emptyset, \quad r(\vartheta) = r(\theta),$$

[illegible] $r(\theta)$ [illegible] $\theta$

[illegible]. If $\theta = \prod_{i=1}^{n}(s - \mu_i)$, let $\vartheta := \prod_{i=1}^{n}(s - \mu_i - r)$, $r \in \mathbb{R}$. For any $r \in \mathbb{R}$ we have that $\vartheta$ is a monic polynomial, $\vartheta \in \mathbb{R}[s]$, $d(\vartheta) = n$, and $r(\vartheta) = r(\theta)$. By the continuity of the coefficients of a polynomial w.r.t. its roots it is easily seen that it is possible to choose $r$ such that conditions $\| \vartheta - \theta \| < \epsilon$ and $\Lambda(\vartheta) \cap S = \emptyset$ hold. □

LEMMA 4.7. [illegible] $(A, b) \in \mathbb{R}^{n\times n} \times \mathbb{R}^{n\times 1}$ [illegible] $\theta$ [illegible] $\alpha_n \mid \cdots \mid \alpha_1$ [illegible] $\alpha'_1, \ldots, \alpha'_n, \omega \in \mathbb{R}[s]$ [illegible] $\alpha'_n \mid \cdots \mid \alpha'_1$ [illegible]

$$\alpha_1 \cdots \alpha_k \mid \alpha'_1 \cdots \alpha'_k \omega, \qquad k = 1, \ldots, n-1,$$

$$\alpha_1 \cdots \alpha_n = \alpha'_1 \cdots \alpha'_n \omega,$$

[illegible] $\epsilon > 0$ [illegible] $(A', b') \in \mathbb{R}^{n\times n} \times \mathbb{R}^{n\times 1}$ [illegible] $\vartheta$ [illegible] $r(\vartheta) = r(\theta)$ [illegible] $d(\vartheta) = d(\theta)$ [illegible]

(i) $\| [A' \; b'] - [A \; b] \| < \epsilon$,

(ii) [illegible] $(A', b')$ [illegible] $\vartheta\omega$

(iii) [illegible] $(A', b')$ [illegible] $\alpha'_1, \ldots, \alpha'_n$.

[illegible] Let $h := d(\theta)$. Then $\alpha_i = \alpha'_i = 1$, $i = n-h+1, \dots, n$.

By Lemma 4.2 we can assume that the pair $(A, b)$ is in Kalman form

$$(A,b) = \left( \begin{bmatrix} A_{11} & X \\ 0 & J \end{bmatrix}, \begin{bmatrix} B_{11} \\ 0 \end{bmatrix} \right),$$

where $(A_{11}, B_{11}) \in \mathbb{R}^{h \times h} \times \mathbb{R}^{h \times 1}$ with $\theta$ as diagonal Hermite polynomial, $d(\theta) = h$, $A_{11}$ is the companion matrix of the polynomial $\theta$, and $\alpha_{n-h} \mid \cdots \mid \alpha_1$ are the invariant factors of $J$. Remember that if $h = 0$, then $(A_{11}, B_{11})$ and $X$ vanish.

Let $\alpha''_k := \alpha'_k$, $k = 2, \dots, n-h$, and $\alpha''_1 := \alpha'_1\omega$, then

$$\alpha_1 \cdots \alpha_k \mid \alpha''_1 \cdots \alpha''_k, \qquad k = 1, \dots, n-h,$$

$$\alpha_1 \cdots \alpha_{n-h} = \alpha''_1 \cdots \alpha''_{n-h}.$$

Let $\epsilon > 0$. By Lemma 4.1 there exists a matrix $\overline{J} \in \mathbb{R}^{(n-h)\times(n-h)}$ such that $\| \overline{J} - J \| < \frac{\epsilon}{3}$ and $\alpha''_1, \dots, \alpha''_{n-h}$ are the invariant factors of $\overline{J}$. Then

$$\overline{J} \overset{s}{\sim} \begin{bmatrix} J_1 & 0 \\ 0 & J_2 \end{bmatrix}, \tag{4.1}$$

where $J_1$ is the companion matrix of $\alpha''_1 = \alpha'_1\omega$.

On the other hand, by Lemma 4.6, there exists a monic polynomial $\vartheta \in \mathbb{R}[s]$ such that $\| \vartheta - \theta \| < \frac{\epsilon}{3}$, $r(\vartheta) = r(\theta)$, $d(\vartheta) = d(\theta)$, and $\Lambda(\vartheta) \cap \Lambda(J) = \emptyset$.

Let $\overline{A}_{11}$ be the companion matrix of $\vartheta$. Then $\| \overline{A}_{11} - A_{11} \| < \frac{\epsilon}{3}$. Put

$$\overline{A} := \begin{bmatrix} \overline{A}_{11} & X \\ 0 & \overline{J} \end{bmatrix}.$$

Then by (4.1) and Lemma 4.5,

$$(\overline{A}, b) \overset{s}{\sim} \left( \begin{bmatrix} \overline{A}_{11} & 0 & 0 \\ 0 & J_1 & 0 \\ 0 & 0 & J_2 \end{bmatrix}, \begin{bmatrix} B_{11} \\ 0 \\ 0 \end{bmatrix} \right).$$

By Lemmas 4.2 and 4.4 there exists a matrix pair $(A', b') \in \mathbb{R}^{n \times n} \times \mathbb{R}^{n \times 1}$ such that $\| [A' \ b'] - [\overline{A} \ b] \| < \frac{\epsilon}{3}$, the diagonal Hermite polynomial of $(A', b')$ is $\vartheta\omega$, and $\alpha'_1, \dots, \alpha'_n$ are the invariant factors of $(A', b')$. ☐

COROLLARY 4.8. [illegible] $(A, B) \in \mathbb{R}^{n \times n} \times \mathbb{R}^{n \times m}$ [illegible] $\theta_1, \dots, \theta_m$ [illegible] $\alpha_n \mid \cdots \mid \alpha_1$ [illegible] $\alpha'_1, \dots, \alpha'_n, \omega \in \mathbb{R}[s]$ [illegible] $\alpha'_n \mid \cdots \mid \alpha'_1$ [illegible]

$$\alpha_1 \cdots \alpha_k \mid \alpha'_1 \cdots \alpha'_k\omega, \qquad k = 1, \dots, n-1,$$

$$\alpha_1 \cdots \alpha_n = \alpha'_1 \cdots \alpha'_n\omega,$$

[illegible] $\epsilon > 0$ [illegible] $(A', B') \in \mathbb{R}^{n \times n} \times \mathbb{R}^{n \times m}$ [illegible] $\vartheta_m$ [illegible] $r(\vartheta_m) = r(\theta_m)$ [illegible] $d(\vartheta_m) = d(\theta_m)$ [illegible]

(i) $\| [A' \ B'] - [A \ B] \| < \epsilon$,

(ii) [illegible] $(A', B')$ [illegible] $\theta_1, \dots, \theta_{m-1}, \vartheta_m\omega$

(iii) [illegible] $(A', B')$ [illegible] $\alpha'_1, \dots, \alpha'_n$.

In the next theorem we solve the controllable case.

THEOREM 4.9. [illegible] $(A,B) \in \mathbb{R}^{n\times n} \times \mathbb{R}^{n\times m}$ [illegible] $\theta_1,\dots,\theta_m$ [illegible] $(A,B)$ [illegible] $h'_1,\dots,h'_m$ [illegible]

[illegible] $\epsilon > 0$ [illegible] $(A',B') \in \mathbb{R}^{n\times n} \times \mathbb{R}^{n\times m}$ [illegible]

(i) $\| \, [A \ B] - [A' \ B'] \, \| < \epsilon$

(ii) $(A',B')$ [illegible] $h'_1,\dots,h'_m$ [illegible] $\beta_1,\dots,\beta_m \in \mathbb{R}[s]$ [illegible] $d(\beta_i) = h'_i, \ i = 1,\dots,m$ [illegible]

$$\beta_i \cdots \beta_m \mid \theta_i \cdots \theta_m, \quad i = 2,\dots,m,$$
$$\beta_1 \cdots \beta_m = \theta_1 \cdots \theta_m.$$

[illegible]. The necessity is a consequence of Corollary 3.4.

We will prove the sufficiency by induction on $m$. If $m = 1$ the theorem is trivially true with $(A',B') := (A,B)$.

Suppose that the theorem is true up to $m-1$.

By Lemma 2.3 there exists $\epsilon_0 > 0$ such that if $\| \, [A' \ B'] - [A \ B] \, \| < \epsilon_0$, then $(A',B')$ is controllable.

If $B = [b_1 \ \dots \ b_{m-1} \ b_m]$ and $B_{m-1} = [b_1 \ \dots \ b_{m-1}]$ then the matrix pair $(A, B_{m-1})$ has $\theta_1,\dots,\theta_{m-1}$ as diagonal Hermite polynomials and $\alpha_1 = \theta_m, \alpha_2 = \cdots = \alpha_n = 1$ as invariant factors.

Given $\epsilon > 0$, let $\epsilon_1 = \min\{\frac{\epsilon}{2}, \epsilon_0\}$, $\alpha'_n = \cdots = \alpha'_2 := 1$, $\alpha'_1 := \beta_m$, and $\omega := \frac{\theta_m}{\beta_m}$. Then we have that

$$\alpha_1 \cdots \alpha_k = \alpha'_1 \cdots \alpha'_k \omega, \qquad k = 1,\dots,n$$

By Corollary 4.8 there exists a matrix pair $(\overline{A}, \overline{B}_{m-1}) \in \mathbb{F}^{n\times n} \times \mathbb{F}^{n\times(m-1)}$ and a polynomial $\vartheta_{m-1}$ satisfying $r(\vartheta_{m-1}) = r(\theta_{m-1})$ and $d(\vartheta_{m-1}) = d(\theta_{m-1})$ such that $\| \, [\overline{A} \ \overline{B}_{m-1}] - [A \ B_{m-1}] \, \| < \epsilon_1$, $\alpha'_1,\dots,\alpha'_n$ are the invariant factors of $(\overline{A}, \overline{B}_{m-1})$ and its diagonal Hermite polynomials are $\theta_1,\dots,\theta_{m-2}, \vartheta_{m-1}\omega$. Notice that the characteristic polynomial of $(\overline{A}, \overline{B}_{m-1})$ is $\beta_m$.

Put $\bar{\theta}_i := \theta_i$, $i = 1,\dots,m-2$, $\bar{\theta}_{m-1} =: \vartheta_{m-1}\omega$, and $\bar{\theta}_m =: \beta_m$, and let $(\overline{A}, \overline{B}) =: (\overline{A}, [\overline{B}_{m-1} \ b_m])$. Then $(\overline{A}, \overline{B})$ is controllable, and $\bar{\theta}_1,\dots,\bar{\theta}_m$ are its diagonal Hermite polynomials.

By Lemma 2.1, we can write

$$(\overline{A}, \overline{B}) \sim \left( \begin{bmatrix} \overline{A}_1 & X \\ 0 & A'_{mm} \end{bmatrix}, \begin{bmatrix} \overline{B}_1 & Y \\ 0 & B'_{mm} \end{bmatrix} \right),$$

where $(\overline{A}_1, \overline{B}_1) \in \mathbb{R}^{(n-h'_m)\times(n-h'_m)} \times \mathbb{R}^{(n-h'_m)\times(m-1)}$ is a controllable pair with diagonal Hermite polynomials $\bar{\theta}_1,\dots,\bar{\theta}_{m-2},\bar{\theta}_{m-1}$ and $(A'_{mm}, B'_{mm}) \in \mathbb{R}^{h'_m\times h'_m} \times \mathbb{R}^{h'_m\times 1}$ is a controllable pair with $\beta_m$ as diagonal Hermite polynomial.

Bearing in mind that

$$\beta_i \cdots \beta_{m-1} \mid \theta_i \cdots \theta_{m-1}\omega, \quad i = 2,\dots,m-1,$$
$$\beta_1 \cdots \beta_{m-1} = \theta_1 \cdots \theta_{m-1}\omega$$

and that $d(\bar{\theta}_{m-1}) = d(\theta_{m-1}\omega)$ and $r(\bar{\theta}_{m-1}) = r(\theta_{m-1}\omega)$, it is easily seen that there exist $\beta'_i \in \mathbb{R}[s]$, $i = 1,\dots,m-1$, such that $d(\beta'_i) = h'_i, i = 1,\dots,m-1$, and

$$\beta'_i \cdots \beta'_{m-1} \mid \bar{\theta}_i \cdots \bar{\theta}_{m-1}, \quad i = 2,\dots,m,$$
$$\beta'_1 \cdots \beta'_{m-1} = \bar{\theta}_1 \cdots \bar{\theta}_{m-1}.$$

By the induction hypothesis, in any neighborhood of $(\overline{A}_1, \overline{B}_1)$ there exists a controllable matrix pair $(A'_1, B'_1) \in \mathbb{R}^{(n-h'_m)\times(n-h'_m)} \times \mathbb{R}^{(n-h'_m)\times(m-1)}$ with Hermite indices $h'_1, \dots, h'_{m-1}$. Then

$$\left( \begin{bmatrix} A'_1 & X \\ 0 & A'_{mm} \end{bmatrix}, \begin{bmatrix} B'_1 & Y \\ 0 & B'_{mm} \end{bmatrix} \right)$$

has $h'_1, \dots, h'_m$ as Hermite indices. By Lemma 4.2, there exists a matrix pair $(A', B') \in \mathbb{R}^{n\times n} \times \mathbb{R}^{n\times m}$ such that $\| \, [A' \; B'] - [\overline{A} \; \overline{B}] \, \| < \frac{\epsilon}{2}$ with Hermite indices $h'_1, \dots, h'_m$. ☐

[illegible] 4.10. In the complex case, the divisibility condition of the previous theorem is equivalent to conditions (2.1) and (2.2). Thus, for $\mathbb{F} = \mathbb{C}$ the above theorem and Lemma 2.4 coincide.

THEOREM 4.11. [illegible] $(A, B) \in \mathbb{R}^{n\times n} \times \mathbb{R}^{n\times m}$ [illegible] $\theta_1, \dots, \theta_m$, [illegible] $\alpha_n \mid \cdots \mid \alpha_1$ [illegible] $\alpha'_1, \dots, \alpha'_n, \omega \in \mathbb{R}[s]$ [illegible] $\alpha'_n \mid \cdots \mid \alpha'_1$ [illegible] $h'_1, \dots, h'_m$ [illegible]

[illegible] $\epsilon$ [illegible] $(A', B') \in \mathbb{R}^{n\times n} \times \mathbb{R}^{n\times n}$ [illegible]

(i) $\| \, [A' \; B'] - [A \; B] \, \| < \epsilon$

(ii) $h'_1, \dots, h'_m$ [illegible] $(A', B')$

(iii) $\alpha'_1, \dots, \alpha'_n$ [illegible] $(A', B')$

[illegible]

(a)

$$\alpha_1 \cdots \alpha_k \mid \alpha'_1 \cdots \alpha'_k \omega, \qquad k = 1, \dots, n-1,$$
$$\alpha_1 \cdots \alpha_n = \alpha'_1 \cdots \alpha'_n \omega;$$

(b) [illegible] $\beta_1, \dots, \beta_m \in \mathbb{R}[s]$ [illegible] $d(\beta_j) = h'_j$, $j = 1, \dots, m$ [illegible]

$$\beta_k \cdots \beta_m \mid \theta_k \cdots \theta_m \omega, \quad k = 2, \dots, m,$$
$$\beta_1 \cdots \beta_m = \theta_1 \cdots \theta_m \omega.$$

[illegible]. Conditions (a) and (b) are necessary by Theorem 3.3.

To prove the sufficiency let $n_1 := \sum_{i=1}^{m} d(\theta_i)$ and $n_2 := \sum_{i=1}^{n} d(\alpha_i)$. Then

$$\alpha_i = \alpha'_i = 1, \quad i = n_2 + 1, \dots, n. \tag{4.2}$$

By Lemmas 4.2 and 2.1 we can assume that

$$(A, B) = \left( \begin{bmatrix} A_1 & A_3 \\ 0 & A_2 \end{bmatrix}, \begin{bmatrix} B_1 & Y \\ 0 & B_2 \end{bmatrix} \right),$$

where

$$(A_1, B_1) \in \mathbb{R}^{(n_1 - d(\theta_m))\times(n_1 - d(\theta_m))} \times \mathbb{R}^{(n_1 - d(\theta_m))\times(m-1)}$$

has $\theta_1, \dots, \theta_{m-1}$ as diagonal Hermite polynomials and

$$(A_2, B_2) \in \mathbb{R}^{(n_2 + d(\theta_m))\times(n_2 + d(\theta_m))} \times \mathbb{R}^{(n_2 + d(\theta_m))\times 1}$$

has $\theta_m$ as the diagonal Hermite polynomial and $\alpha_1, \dots, \alpha_{n_2 + d(\theta_m)}$ as invariant factors.

From (a) and (4.2), we have that

$$\alpha_1 \cdots \alpha_k \mid \alpha'_1 \cdots \alpha'_k \omega, \qquad k = 1, \dots, n_2 + d(\theta_m),$$
$$\alpha_1 \cdots \alpha_{n_2 + d(\theta_m)} = \alpha'_1 \cdots \alpha'_{n_2 + d(\theta_m)} \omega.$$

Let $\epsilon > 0$. By Corollary 4.8, there exists a matrix pair

$$(A'_2, B'_2) \in \mathbb{R}^{(n_2 + d(\theta_m))\times(n_2 + d(\theta_m))} \times \mathbb{R}^{(n_2 + d(\theta_m))\times 1}$$

such that $\| \, [A_2' \; B_2'] - [A_2 \; B_2] \, \| < \frac{\epsilon}{2}$, the invariant factors of $(A_2', B_2')$ are $\alpha_1', \ldots, \alpha_{n_2+d(\theta_m)}'$, and the diagonal Hermite polinomial of $(A_2', B_2')$ is $\theta_m' = \vartheta_m \omega$, where $r(\vartheta_m) = r(\theta_m)$ and $d(\vartheta_m) = d(\theta_m)$.

Let $(\overline{A}, \overline{B}) := \left( \begin{bmatrix} A_1 & A_3 \\ 0 & A_2' \end{bmatrix}, \begin{bmatrix} B_1 & Y \\ 0 & B_2' \end{bmatrix} \right)$. This matrix pair has $\alpha_1', \ldots, \alpha_n'$ as invariant factors and $\theta_1, \ldots, \theta_{m-1}, \theta_m'$ as diagonal Hermite polynomials.

Bearing in mind the Kalman decomposition we have

$$(\overline{A}, \overline{B}) \overset{s}{\sim} \left( \begin{bmatrix} \overline{A}_1 & \overline{A}_3 \\ 0 & \overline{A}_2 \end{bmatrix}, \begin{bmatrix} \overline{B}_1 \\ 0 \end{bmatrix} \right),$$

where $(\overline{A}_1, \overline{B}_1) \in \mathbb{R}^{(n_1+d(\omega)) \times (n_1+d(\omega))} \times \mathbb{R}^{(n_1+d(\omega)) \times m}$ is a controllable pair with $\theta_1, \ldots, \theta_{m-1}, \theta_m'$ as the diagonal Hermite polynomials and $\overline{A}_2 \in \mathbb{R}^{(n_2-d(\omega)) \times (n_2-d(\omega))}$ has the same nontrivial invariant factors as $(\overline{A}, \overline{B})$.

Since $d(\theta_m') = d(\theta_m \omega)$ and $r(\theta_m') = r(\theta_m \omega)$ and bearing in mind (b), it is easily seen that there exist monic polynomials $\beta_i' \in \mathbb{R}[s]$, $1 \le i \le m$, $d(\beta_i') = d(\beta_i)$, $1 \le i \le m$, such that

$$\beta_j' \cdots \beta_m' \mid \theta_j \cdots \theta_{m-1} \theta_m', \qquad j = 1, \ldots, m,$$

$$\beta_1' \cdots \beta_m' = \theta_1 \cdots \theta_{m-1} \theta_m'.$$

Now the theorem follows by applying Theorem 4.9 to $(\overline{A}_1, \overline{B}_1)$. $\square$

[illegible] 4.12. By using the results of [12] and [6], condition (a) of Theorem 4.11 can be written in terms of the Segre characteristic of the eigenvalues of $(A, B)$ as in Theorem 3.3.

# SEMICIRCLE LAW FOR HADAMARD PRODUCTS*

Z. D. BAI† AND L. X. ZHANG‡

**Abstract.** In this paper, assuming $p/n \to 0$ as $n \to \infty$, we will prove the weak and strong convergence to the semicircle law of the empirical spectral distribution of the Hadamard product of a normalized sample covariance matrix and a sparsing matrix, which is of the form $A_p = \frac{1}{\sqrt{np}}(X_{m,n}X_{m,n}^* - \sigma^2 n I_m) \circ D_m$, where the matrices $X_{m,n}$ and $D_m$ are independent and the entries of $X_{m,n}$ $(m \times n)$ are independent, the matrix $D_m$ $(m \times m)$ is Hermitian with independent entries above and on the diagonal, $p$ is the sum of the second moments of the row (and column) entries of $D_m$, and "$\circ$" denotes the Hadamard product of matrices.

## 1. Introduction.

The study of large random matrices started in the 1950s in the field of theoretical nuclear physics and from then on has attracted considerable interest of both theoretical physicists and statisticians. Initially, in theoretical nuclear physics, random matrices are constructed to model the interactions between a huge body of interacting atomic nuclei. Then the energy levels of these particles can be interpreted by the eigenvalues of the random matrices. The study of the eigenvalue behavior of large random matrices has been called the spectral theory of large random matrices.

Suppose $A_m$ is an $m \times m$ random matrix whose eigenvalues are denoted by $\{\lambda_j^{(m)} : 1 \le j \le m\}$. Then by putting suitable assumptions on $A_m$, such as $A_m$ being Hermitian, these eigenvalues are real numbers, and it is possible to define the following empirical distribution:

$$F^{A_m}(x) = \frac{1}{m}\#\{j : \lambda_j^{(m)} \le x\},$$

which is called the empirical spectral distribution (ESD) of $A_m$. Here #{...} denotes the number of elements contained in the set {...}. The spectral theory of large random matrices involves the limiting distribution of these ESDs. The first rigorous theoretical result in this field is considered to be the work of Wigner [25], in which it is proved that if $A_m$ is a Gaussian matrix, namely, $A_m$ is symmetric and its diagonal entries and those above the diagonal are independent normal variables with mean 0, and the variance of the diagonal elements is $2\sigma^2$ while that of the off-diagonal elements is $\sigma^2$, then the expected ESD, i.e., $EF^{\frac{1}{\sqrt{m}}A_m}$ of $\frac{1}{\sqrt{m}}A_m$, converges to the semicircle law with

‡Department of Statistics and Applied Probability, National University of Singapore, Singapore 117546 (scip1379@nus.edu.sg).

scale parameter $\sigma$ $F_{sc}(x)$, which is given by

$$\frac{d}{dx}F_{sc}(x) = \begin{cases} \frac{1}{2\pi\sigma^2}\sqrt{4\sigma^2 - x^2} & \text{if } |x| \le 2\sigma, \\ 0 & \text{otherwise.} \end{cases}$$

This theorem was later extended to the general Wigner matrix $A_m = [a_{ij}]$, which is a Hermitian matrix with independent complex entries above and on the diagonal satisfying the following:

(1) The means of all entries are 0 and the variance of the off-diagonal entries is $\sigma^2$ (the variance of the diagonal elements is allowed to be different from that of the off-diagonal entries).

(2) For any $\eta > 0$,

$$\frac{1}{m^2}\sum_{i,j=1}^{m} E|a_{ij}^2|I[|a_{ij}| > \eta\sqrt{m}] \to 0.$$

Another class of important random matrices are the sample covariance ones, which are defined as

$$S_n = \frac{1}{n}\sum_{i=1}^{n} \mathbf{x}_i\mathbf{x}_i^*,$$

where $\mathbf{x}_i = (x_{1i}, \dots, x_{mi})'$ and $\{x_{ij}\}$ are i.i.d. with mean zero and variance $\sigma^2$, and $(.)^*$ denotes the complex conjugate of vectors or matrices. It is known that the ESD of $S_n$ a.s. tends to the Marcĕnko–Pastur law (see Marcĕnko and Pastur [17]) with density

$$\frac{d}{dx}F_y(x) = \begin{cases} \frac{1}{2\pi\sigma^2 xy}\sqrt{(b-x)(x-a)} & \text{if } a < x < b, \\ 0 & \text{otherwise,} \end{cases}$$

where $y = \lim m/n$ and $a = \sigma^2(1-\sqrt{y})^2$, $b = \sigma^2(1+\sqrt{y})^2$, with an additional point mass of $1 - 1/y$ at 0 when $y > 1$. Their law was later extended under the following condition:

$$\frac{1}{mn}\sum_{ij} E|x_{ij}^2|I[|x_{ij}| > \eta\sqrt{n}] \to 0.$$

Some properties of the extreme eigenvalues of Wigner matrices and sample covariance matrices can be found in Bai and Yin [5, 6] and Bai and Silverstein [2, 3]. For more references, the reader is referred to Bai [1].

These two types of matrices are asymptotically connected. Indeed, when $E|x_{11}|^4 < \infty$ and $m$ is fixed, the normalized sample covariance matrix $\sqrt{n}(S_n - \sigma^2 I_m)$ will tend to a Gaussian matrix. Therefore, it is conceivable that the ESD of $\sqrt{n/m}(S_n - \sigma^2 I_m)$ would tend to the semicircle law if $m \to \infty$ and $m/n \to 0$. This was confirmed in Bai and Yin [4].

In nuclear physics, since the particles move in a very high velocity in a small range, many exciting states in very short time cannot be observed. Generally, if a real physical system is not of full connectivity, the random matrix describing the interactions between the particles in the system will have a large proportion of zero elements. In this case, a sparse random matrix provides a more natural and relevant description of the system. Indeed, in neural network theory, the number of neurons in one person's brain is probably of several orders of magnitude larger than that of the dendrites connected with one individual neuron (see Grenander and Silverstein [12]). Sparse random matrices are adopted in modelling these partially connected systems in neural network theory. A sparse or dilute matrix is a random matrix in which some entries will be replaced by 0 if not observed. Sometimes a large portion of the entries of the interesting random matrix can be 0's. Due to its special application background, the sparse matrix has received special attention in quantum mechanics, atomic physics, neural networks, and many other areas. Some recent works on large sparse matrices and their applications to various areas can be found in, among others, [7, 9] for linear algebra, [8, 12] for neural networks, [10, 11, 13, 15, 16, 21, 23, 24] for algorithms and computing, [18] for finance modeling, [19, 26] for electrical engineering, [20] for bio-interactions, and [22] for theoretical physics.

A sparse matrix can be expressed by a Hadamard product. If $B_m = [b_{ij}]$ and $D_m = [d_{ij}]$ are two $m \times m$ matrices, then the Hadamard product $A_p = (A_{ij})$ with $A_{ij} = b_{ij} d_{ij}$ is denoted by

$$A_p = B_m \circ D_m.$$

The matrix $A_p$ is sparse if the elements $d_{ij}$ of $D_m$ take values 0 and 1 with $\sum_{i=1}^m P(d_{ij} = 1) = p = o(m)$. The index $p$ usually stands for the level of sparseness; i.e., after performing the Hadamard product, the resulting matrix will have $p$ nonzero elements per row on the average.

It is commonly assumed that the matrix $D_m$ is symmetric and its entries $\{d_{ij} : i \leq j\}$ are independent Bernoulli trials with $P(d_{ij} = 1) = p_{ij}$ and independent of the entries of the matrix $B_m$. In Kohrunzhy and Rodgers [14, 15], it is assumed that

$$p_{ij} = \frac{\alpha}{m^\beta},$$

with $0 \leq \beta \leq 1$, $0 < \frac{\alpha}{m^\beta} < 1$, and the entries of $B_m$ are centralized elements of a sample covariance matrix. More precisely, suppose $X_{m,n} = [x_{ij} : i = 1, 2, \ldots, m, j = 1, 2, \ldots, n]$ is an $m \times n$ matrix with independent entries of mean 0 and variance $\sigma^2$. Let the sample covariance matrix of $X_{m,n}$ be defined as $S_n = \frac{1}{n} X_{m,n} X_{m,n}^*$. Then, define $B_m = \sqrt{n/p}(S_n - \sigma^2 I_m)$ and $A_p = B_m \circ D_m$.

In the present paper, we shall consider a kind of Hadamard product of a normalized sample covariance matrix with a sparsing matrix (whose entries are not necessarily Bernoulli trials) and show the weak and strong convergence to the semicircle law of the ESD of this kind of Hadamard product. To this end, we make the following assumptions. In what follows, the entries of $D_m$ and $X_{m,n}$ are allowed to depend on $n$. For brevity, the dependence on $n$ is suppressed.

[illegible] $D_m$

(D1) $D_m = [d_{ij}]$ is $m \times m$ Hermitian with $\{d_{ij} : i \leq j\}$ independent complex random variables.

(D2) $\max_j \left| \sum_{i=1}^m p_{ij} - p \right| = o(p)$, where $p_{ij} = E|d_{ij}^2|$.

(D3.1) For some $\delta \in [0, 1/2]$, there exists a constant $C_1 > 0$ such that $\max_j \sum_i E|d_{ij}| \leq C_1 m^\delta p^{1-\delta}$.

(D3.2) For each $k > 2$ there is a constant $C_k$ such that

$$E|d_{ij}|^k \leq C_k p_{ij}. \tag{1.1}$$

We remark here that condition (D3.2) implies that $p_{ij}$ are uniformly bounded. In fact, $p_{ij} = E|d_{ij}|^2 \leq (E|d_{ij}|^4)^{1/2} \leq C_4$. Combining this fact with condition (D2), we indeed have $p \leq Km$, for some constant $K > 0$. In view of this relation between $p$ and $m$, we notice that if condition (D3.1) holds for some $\delta_0 \in [0, 1/2]$, then it must hold for every $\delta \geq \delta_0$, $\delta \in [0, 1/2]$. Therefore, we clarify here and in what follows that when we say condition (D3.1) holds for some $\delta^* \in [0, 1/2]$ we are referring to $\delta^*$ as the smallest value in $[0, 1/2]$ for which condition (D3.1) holds. In this sense, for any $0 \leq \delta_1 \leq \delta_2 \leq 1/2$, we say we have a stronger sparseness in the case when condition (D3.1) holds for $\delta_1$ than in the case when condition (D3.1) holds for $\delta_2$. Also note that in the case of the weakest sparseness, i.e., $\delta = 1/2$, condition (D3.1) is a direct consequence of Hölder's inequality and condition (D2); that is, no additional assumption is imposed on the first moments of the sparsing factors in this case.

[illegible] $X_{m,n}$

(X1) $X_{m,n} = [x_{ij}]$ is $m \times n$ consisting of independent random variables with $Ex_{ij} = 0$, $E|x_{ij}|^2 = \sigma^2$.

(X2.1) For any $\eta > 0$,

$$\frac{1}{mn}\sum_{ij} E|x_{ij}^2|I[|x_{ij}| > \eta\sqrt[4]{np}] \to 0.$$

(X2.2) For any $\eta > 0$,

$$\sum_{u=1}^{\infty} \frac{1}{mn}\sum_{ij} E|x_{ij}^2|I[|x_{ij}| > \eta\sqrt[4]{np}] < \infty,$$

where $u$ may take $[p]$, $m$, or $n$.

(X3) For any $\eta > 0$,

$$\frac{1}{m}\sum_{i=1}^{m} P\left(\left|\sum_{k=1}^{n}(|x_{ik}|^2 - \sigma^2)d_{ii}\right| > \eta\sqrt{np}\right) \to 0. \tag{1.2}$$

We shall prove the following theorem.

THEOREM 1.1. (i) [illegible] (1.1) [illegible] (1.2) [illegible]
(ii) [illegible] $D_m$ [illegible] $X_{m,n}$
(iii) $p/n \to 0$ [illegible] $p \to \infty$
(iv) [illegible] (D3.1) [illegible] $\delta = 1/2$ [illegible] $m/n \to 0$ [illegible] (D3.1) [illegible] $\delta \in (0, 1/2)$ [illegible] $m \leq Kn$ [illegible] $K$ [illegible] (D3.1) [illegible] $\delta = 0$ [illegible] $m$ [illegible] $n$

[illegible] $F^{A_p}$ [illegible] $\sigma^2$ [illegible] $[p] \to \infty$ [illegible] $A_p = \frac{1}{\sqrt{np}}(X_{m,n}X_{m,n}^* - \sigma^2 nI_m) \circ D_m$ [illegible] (X2.1) [illegible] $[p] \to \infty$ [illegible] $m \to \infty$ [illegible] (X2.2) [illegible] $u = [p]$ [illegible] $u = m$ [illegible]

[illegible] 1.1. Theorem 1.1 covers all well-known results on sparse matrices, since the Bernoulli trials satisfy conditions (D3.1) (with $\delta = 0$) and (D3.2) obviously. The new contribution of Theorem 1.1 is to allow the sparsing factors $d_{ij}$ to be very nonhomogenous. Consider the following example. Let $D_m = [d_{ij}]$ be symmetric. Let $m = kL$ with $L$ fixed, and let for all $(\ell - 1)k < i, j \leq \ell k$ with $\ell \leq L$,

$$P(d_{ij} = 1) = p/k = 1 - P(d_{ij} = 0),$$

and for all other indices $i, j$, $d_{ij} \equiv 0$. Then conditions (D1), (D2), (D3.1), and (D3.2) are true whenever $p \le k$.

1.2. In the case of the strongest sparseness, condition (D3.1) seems not to allow the $d_{ij}$'s to take large values. In fact, it is not the case. For example, consider that

$$d_{ij} = c_n^{-1}|z_{ij}|I(|z_{ij}| > c_n),$$

where $z_{ij}$ are i.i.d. $N(0, 1)$ subject to the condition $d_{ij} = d_{ji}$ and $c_n$ is a positive constant uniquely solving the equation $Ez_{ij}^2 I(|z_{ij}| > c_n) = c_n^2 p/m$. Then obviously $d_{ij}$ can take very large values, and $D_m$ is symmetric with

$$\sum_{i=1}^{m} p_{ij} = c_n^{-2} \sum_{i=1}^{m} Ez_{ij}^2 I(|z_{ij}| > c_n) = p;$$

i.e., conditions (D1) and (D2) are satisfied.

Now we show that condition (D3.1) holds for $\delta = 0$ if $p/m \to 0$. In fact, we can see that if $p/m \to 0$, then $c_n \to \infty$ and consequently

$$Ez_{ij}^2 I(|z_{ij}| > c_n) \simeq 2c_n \varphi(c_n),$$

which implies that

$$\frac{p}{m} \simeq \frac{2}{c_n}\varphi(c_n),$$

where the notation "$\simeq$" is used to represent the relation that the two quantities on its two sides have a ratio which tends to 1 as $n \to \infty$, while $\varphi(\cdot)$ is the density function of standard normal variables.

Therefore, we get

$$\sum_{i=1}^{m} E|d_{ij}| = mc_n^{-1} E|z_{ij}|I(|z_{ij}| > c_n) \simeq 2mc_n^{-1}\phi(c_n) \simeq p,$$

and

$$\begin{aligned} E|d_{ij}|^k &= c_n^{-k} E|z_{ij}|^k I(|z_{ij}| > c_n) \\ &\simeq 2c_n^{-k} c_n^{k-1} \phi(c_n) = 2c_n^{-1}\phi(c_n) \\ &\simeq p/m = E|d_{ij}|^2, \end{aligned}$$

which implies that condition (D3.1) holds for $\delta = 0$, and that condition (D3.2) holds.

1.3. However, if condition (D3.1) is assumed for $\delta = 0$, then sometimes it may happen that the $d_{ij}$'s are not allowed to take small values with large probabilities. For example,

$$d_{ij} = \sqrt{p/m} \text{ with probability 1.}$$

Then obviously (D3.1) holds for and only for $\delta = 1/2$, i.e., the weakest sparseness. For this case, condition (D3.1) holds automatically when condition (D3.2) is assumed. Condition (D3.2), assuming that higher moments of the $d_{ij}$'s are not larger than a multiple of their second moments, is not seriously restrictive because the $d_{ij}$'s are usually small random variables.

Nonetheless, if condition (D3.1) is assumed for $\delta = 1/2$, the condition does allow the first moments of $d_{ij}$'s to be much larger than their second moments, e.g., $d_{ij} = c\sqrt{p/m}|z_{ij}|$, where $z_{ij}$ are i.i.d. random variables subject to the restriction $d_{ij} = d_{ji}$ and $c$ makes $Ed_{ij}^2 = p/m$. As a price, however, we need to require $m$ to have a smaller order than that of $n$, that is, $m/n \to 0$. The requirement is necessary in some sense. In section 3, we will present a counterexample showing that the semicircle law fails to hold if this requirement is not satisfied.

[illegible] 1.4. Note that $p$ may not be an integer, and it may increase very slowly as $n$ increases. Thus, the limit for $p \to \infty$ may not be true for almost sure convergence. So, we consider the limit when the integer part of $p$ tends to infinity. However, if we consider the convergence in probability, Theorem 1.1 is true for $p \to \infty$.

[illegible] 1.5. Conditions (D2) and (D3.2) imply that $p \le Km$; that is, the order of $p$ cannot be larger than that of $m$. In the theorem, it is assumed that $p/n \to 0$; that is, $p$ also has a lower order than $n$. This is essential. However, the relation between $m$ and $n$ can be arbitrary if condition (D3.1) holds for $\delta = 0$. It is important to remind the readers that the statement "the relation between $m$ and $n$ can be arbitrary" only says that there are examples with $m/n \to \infty$ as well as examples with $m/n \to 0$, for which the results in Theorem 1.1 are applicable equally well once condition (D3.1) is satisfied with $\delta = 0$. For example, if the $d_{ij}$'s (subject to the condition $d_{ij} = d_{ji}$) are the Bernoulli trials defined by $P(d_{ij} = 1) = p/m = 1 - P(d_{ij} = 0)$ for any $i$, $j$, then $E|d_{ij}| = E|d_{ij}|^2 = E|d_{ij}|^k$ for any $k > 2$. This implies conditions (D1), (D2), (D3.1) (with $\delta = 0$), and (D3.2) always hold. But no matter $m/n \to 0$, $m/n \le K < \infty$, or $m/n \to \infty$, Theorem 1.1 always holds, provided that $p/n \to 0$.

[illegible] 1.6. From the proof given in the next sections, one can see that the almost sure convergence is true for $m \to \infty$ in all places except the part of the truncation on the entries of $X_{m,n}$ which was guaranteed by condition (X2.2). Thus, if condition (X2.2) holds for $u = m$, then the almost sure convergence is true in the sense of $m \to \infty$. Sometimes, it may be of interest to consider the almost sure convergence in the sense of $n \to \infty$. Examining the proof given in the next sections, one can find that to guarantee the almost sure convergence for $n \to \infty$, the removal of the diagonal elements of the matrix requires $m/\log n \to \infty$; the truncation on the entries of $X_{m,n}$ requires condition (X2.2) to be true for $u = n$. As for Proposition 3.1, as remarked in section 3, one may modify the conclusion of (II) on page 11 as

$$E|M_k - EM_k|^{2\mu} = O(m^{-\mu})$$

for any fixed integer $\mu$. Thus, if $m \ge n^{\varepsilon}$ for some positive constant $\varepsilon$, then the almost sure convergence of the ESD of the matrix after the truncation and centralization is true for $n \to \infty$. We therefore see that the conclusion of Theorem 1.1 can be strengthened to the almost sure convergence as $n \to \infty$ under the additional assumptions that, for some small positive constant $\varepsilon$, $m \ge n^{\varepsilon}$ and condition (X2.2) holds for $u = n$.

[illegible] 1.7. In Theorem 1.1, if $p = m$ and $d_{ij} \equiv 1$ for all $i$ and $j$ and the entries of $X_{m,n}$ are i.i.d., then the model considered in Theorem 1.1 reduces to that of Bai and Yin [4], where it is assumed that the fourth moment of $x_{ij}$ is finite. It can be easily verified that the conditions of Theorem 1.1 are satisfied under Bai and Yin's assumption. Thus, Theorem 1.1 contains Bai and Yin's result as a special case.

[illegible] 1.8. If there is a positive and increasing function $\varphi(x)$ defined on $\mathbb{R}^+$ such that

$$Q_n \equiv \frac{1}{mn}\sum_{ij} E|x_{ij}^2|\varphi(|x_{ij}|)I[|x_{ij}| > \eta\sqrt[4]{np}] \to 0, \tag{1.3}$$

then condition (X2.1) holds. Letting $\varphi(x) = x^{4(2\nu-1)}$ with $\frac{1}{2} \le \nu < 1$, (1.3) reduces to condition (2.4) of Kohrunzhy and Rodgers [14], if we change their notation to $p_{ij} = P(d_{ij} = 1) = p/m$ with $p = n^{2\nu-1}$ and $m/n \to c \in (0,\infty)$. It can be verified easily that all other assumptions of Theorem 1.1 are satisfied under their conditions; condition (X3) is automatically true since $P(d_{ii} \ne 0) = 0$ was assumed in their paper. Thus Theorem 1.1 covers Kohrunzhy and Rodgers [14] as a special case for all $\nu$'s in the interval $[1/2, 1)$.

Furthermore, it can be seen that if $Q_n \to 0$ with a suitable rate such that

$$\sum_{u=1}^{\infty} Q_n/\varphi(\eta\sqrt[4]{np}) < \infty, \tag{1.4}$$

then condition (X2.2) is satisfied. Indeed, $\varphi(x) = x^{4(2\nu-1)}$, with $(1+\sqrt{5})/4 < \nu < 1$, makes (1.4) hold. Then for these $\nu$'s Theorem 1.1 states the almost sure convergence holds and hence is stronger than the conclusion of i.p. convergence proven by Kohrunzhy and Rodgers [14].

[illegible] 1.9. The most important contribution of Theorem 1.1 to the random matrix theory is to allow nonhomogeneous and nonzero-one sparseness and for the case of the strongest sparseness to allow an arbitrary relation between $m$ and $n$. The conditions on the entries of $X_{m,n}$ are to require some homogeneity on the $X_{m,n}$ matrix. We conjecture that the homogeneity on the $X_{m,n}$ matrix can be relaxed if we require the entries of the $D_m$ matrix to have certain homogeneity. This problem is under investigation.

The organization of this paper is as follows. In section 2, we apply the truncation and centralization technique to the matrix $A_p$ so that the proof of Theorem 1.1 can proceed under more convenient conditions and hence can be simplified. Then in section 3, for the matrix resulting from the truncation and centralization treatment, we prove the convergence of the moments of their ESDs, and from the result we infer the validity of Theorem 1.1.

## 2. Truncation and centralization.

In this section, we apply the truncation and centralization techniques to $A_p$. However, we first need to present some preliminary results useful in subsequent proofs. These results consist of several inequalities concerning the difference between two ESDs.

Lemma 2.1 (difference inequality). [illegible] $n \times n$ [illegible] $A$ [illegible] $B$ [illegible]

$$L^3(F^A, F^B) \le \frac{1}{n} tr(A-B)^2,$$

[illegible] $L(\cdot,\cdot)$ [illegible] é [illegible] $F$ [illegible] $G$ [illegible]

$$L(F,G) = \inf\{\varepsilon > 0 : F(x-\varepsilon) - \varepsilon < G(x) < F(x+\varepsilon) + \varepsilon \quad \forall x \in \mathbb{R}\}.$$

Lemma 2.2 (rank inequality). [illegible] $A$ [illegible] $B$ [illegible] $n \times n$ [illegible]

$$\|F^A - F^B\| \le \frac{1}{n}\text{rank}(A-B),$$

[illegible] $\|\cdot\|$ [illegible] $f(\cdot)$ [illegible] $\|f\| = \sup_{x\in\mathbb{R}}|f(x)|$

LEMMA 2.3 (Bernstein's inequality). $\{X_n\}$ 0 $M$ $S_n = \sum_{i=1}^n X_i$ $\eta_n = ES_n^2$

$$P(|S_n| > \varepsilon) \le 2\exp\left\{-\frac{\varepsilon^2}{2(M\varepsilon + \eta_n)}\right\}.$$

The proofs for the first two lemmas can be found in Bai [1]. With the aid of these lemmas, we can now develop the following results on applying the truncation and centralization techniques.

**2.1. Removal of the diagonal elements of $\boldsymbol{A_p}$.** For any $\varepsilon > 0$, denote by $\widehat{A}_p$ the matrix obtained from $A_p$ by replacing its diagonal elements whose absolute values are greater than $\varepsilon$ by 0 and denote by $\widetilde{A}_p$ the matrix obtained from $A_p$ by replacing all its diagonal elements by 0.

PROPOSITION 2.4. 1.1

$$\|F^{\widehat{A}_p} - F^{A_p}\| \to 0, \ a.s.$$

$$L^3(F^{\widehat{A}_p}, F^{\widetilde{A}_p}) \le \varepsilon^2.$$

The second conclusion of the proposition is a trivial consequence of Lemma 2.1. As for the first conclusion, by the rank inequality,

$$\|F^{\widehat{A}_p} - F^{A_p}\| \le \frac{1}{m}\sum_{i=1}^m I\left[\left|\frac{1}{\sqrt{np}}\sum_{k=1}^n (|x_{ik}|^2 - \sigma^2)d_{ii}\right| > \varepsilon\right].$$

By condition (X3) in (1.2), we have

$$\sum_{i=1}^m P\left(\left|\frac{1}{\sqrt{np}}\sum_{k=1}^n (|x_{ik}|^2 - \sigma^2)d_{ii}\right| > \varepsilon\right) = o(m).$$

By Bernstein's inequality, it follows that for any constant $\eta > 0$,

$$\begin{aligned} P(\|F^{\widehat{A}_p} - F^{A_p}\| \ge \eta) &\le P\left(\sum_{i=1}^m I\left[\left|\frac{1}{\sqrt{np}}\sum_{k=1}^n (|x_{ik}|^2 - \sigma^2)d_{ii}\right| > \varepsilon\right] \ge \eta m\right) \\ &\le 2e^{-bm}, \end{aligned}$$

for some constant $b > 0$. By the Borel–Cantelli lemma, we conclude that

$$\|F^{\widehat{A}_p} - F^{A_p}\| \to 0, \ \text{a.s.}$$

Combining the two conclusions in Proposition 2.4, we have shown that

$$L(F^{A_p}, F^{\widetilde{A}_p}) \to 0, \ \text{a.s.}$$

Hence, in what follows, we can assume that the diagonal elements are 0; i.e., assume $d_{ii} = 0$ for all $i = 1, \ldots, m$.

**2.2. Truncation and centralization of the entries of $X_{m,n}$.** Note that condition (X2.1) in (1.2) guarantees the existence of $\eta_n \downarrow 0$ such that

$$\frac{1}{mn\eta_n^2}\sum_{ij} E|x_{ij}|^2 I(|x_{ij}| > \eta_n \sqrt[4]{np}) \to 0.$$

Similarly, if condition (X2.2) holds, there exists $\eta_n \downarrow 0$ such that

$$\sum_{u=1}^{\infty} \frac{1}{mn\eta_n^2}\sum_{ij} E|x_{ij}|^2 I[|x_{ij}| > \eta_n \sqrt[4]{np}] < \infty,$$

for $u$ takes $[p]$, $m$, or $n$. In the subsequent truncation procedure, we shall not distinguish under whichever condition the sequence $\{\eta_n\}$ is defined. The reader should remember that whatever condition is used, the $\{\eta_n\}$ is defined by that condition.

Define $\tilde{x}_{ij} = x_{ij}I[|x_{ij}| \le \eta_n \sqrt[4]{np}] - Ex_{ij}I[|x_{ij}| \le \eta_n \sqrt[4]{np}]$ and $\hat{x}_{ij} = x_{ij} - \tilde{x}_{ij}$. Also, define $\widetilde{B}_m$ with $\widetilde{B}_{ij} = \frac{1}{\sqrt{np}}\sum_{k=1}^{n} \tilde{x}_{ik}\bar{\tilde{x}}_{jk}$ $(i \neq j)$, and denote its Hadamard product with $D_m$ by $\widetilde{A}_p$. Then we have the following proposition.

Proposition 2.5. [illegible] (X2.1) [illegible] (1.2) [illegible] 1.1

$$L(F^{\widetilde{A}_p},\ F^{A_p}) \to 0,\ i.p.$$

[illegible] (X2.1) [illegible] (X2.2) [illegible]

$$L(F^{\widetilde{A}_p},\ F^{A_p}) \to 0,\ a.s. \text{ as }\ u \to \infty,$$

[illegible] $u = [p]$, $m$ [illegible] $n$ [illegible] $u$ [illegible] (X2.2) [illegible] By the difference inequality,

$$\begin{aligned} L^3(F^{\widetilde{A}_p},\ F^{A_p}) &\le \frac{1}{m}\mathrm{tr}[(B_m - \widetilde{B}_m)\circ D_m]^2 \\ &= \frac{1}{mnp}\sum_{i\neq j}\Big|\sum_{k=1}^{n}(x_{ik}\bar{x}_{jk} - \tilde{x}_{ik}\bar{\tilde{x}}_{jk})d_{ij}\Big|^2. \end{aligned}$$

We have

$$\begin{aligned} &E\left(\frac{1}{mnp}\sum_{i\neq j}\Big|\sum_{k=1}^{n}(x_{ik}\bar{x}_{jk} - \tilde{x}_{ik}\bar{\tilde{x}}_{jk})d_{ij}\Big|^2\right) \\ &= \frac{1}{mnp}\sum_{i\neq j}\sum_{k=1}^{n} E|x_{ik}\bar{x}_{jk} - \tilde{x}_{ik}\bar{\tilde{x}}_{jk}|^2 E|d_{ij}^2| \\ &\le \frac{8\sigma^2}{mnp}\sum_{j=1}^{m}\sum_{k=1}^{n} E|\hat{x}_{jk}|^2 \sum_{i=1}^{m} p_{ij} \\ &\le \frac{16\sigma^2}{mn}\sum_{j=1}^{m}\sum_{k=1}^{n} E|x_{jk}|^2 I[|x_{jk}| > \eta_n \sqrt[4]{np}], \end{aligned}$$

where in the last step we have used condition (D2), which can be easily shown to remain true after the removal of the diagonal elements of $D_m$. Thus we can see that if condition (X2.1) in (1.2) is assumed, then the right-hand side of the above inequality converges to 0 and hence the first conclusion follows.

However, if condition (X2.2) holds, then we have

$$\sum_{u=1}^{\infty}\frac{16\sigma^2}{mn}\sum_{ij}E|x_{ij}|^2 I(|x_{ij}|>\eta_n\sqrt[4]{np})<\infty,$$

and it follows that

$$L^3(F^{\widetilde{A}_p},\ F^{A_p})\to 0,\ \text{a.s.}$$

as $u\to\infty$, where $u$ takes $[p]$, $m$, or $n$ in accordance with the choice of $u$ in (X2.2). The proof of this proposition is complete.

From the above two propositions, we are allowed to make the following additional assumptions:

$$\text{(i) } d_{ii}=0.$$

$$\text{(ii) } Ex_{ij}=0,\quad |x_{ij}|\le\eta_n\sqrt[4]{np}. \tag{2.1}$$

Note that, we shall no longer have $E|x_{ij}|^2=\sigma^2$ after the truncation and centralization on the $X_{m,n}$ entries. Write $E|x_{ij}|^2=\sigma_{ij}^2$. We shall have the following proposition.

PROPOSITION 2.6. 1.1

(a) $\max_j|\sum_i E|d_{ij}|^2-p|=o(p)$,

(b) $i$ $j$ $\sigma_{ij}^2\le\sigma^2$ $\frac{1}{mn}\sum_{ij}\sigma_{ij}^2\to\sigma^2$

It is trivial to check the truth of (a) and the first part in (b). While the second part of (b) follows from condition (X2.1) and the following fact:

$$\begin{aligned}0&\le\sigma^2-\frac{1}{mn}\sum_{ij}\sigma_{ij}^2\\&\le\frac{2}{mn}\sum_{ij}E|x_{ij}|^2 I(|x_{ij}|>\eta_n\sqrt[4]{np})\to 0.\end{aligned}$$

**3. Proof of the theorem by the moment approach.** In the last section, we have shown that to prove Theorem 1.1, it suffices to do it under the additional conditions (i), (ii) in (2.1) and (a), (b) in Proposition 2.6. In the present section, we shall prove the following proposition.

PROPOSITION 3.1. 1.1 (i), (ii) (2.1) (a), (b) 2.6 $m\to\infty$ $F^{A_p}(x)$ $A_p$ $\sigma^2$

To prove the proposition, we employ the moment method. That is, based on the moment convergence theorem, by denoting $M_k$ and $m_k$ the $k$th moment of $F^{A_p}$ and the semicircle law $F_{sc,\sigma^2}(x)$ with scale parameter $\sigma^2$, we prove that $M_k\to m_k$ a.s. and that the sequence $\{m_k\}$ satisfies the Carleman condition $\sum_{k=1}^{\infty}m_{2k}^{-1/2k}=\infty$. It is easy to calculate that

$$m_k=\begin{cases}\frac{\sigma^{4s}(2s)!}{s!(s+1)!} & \text{if } k=2s,\\ 0 & \text{if } k=2s+1.\end{cases}$$

By noting that $m_{2k} \leq \sigma^{4k} 2^{2k}$, it is easy to see that the Carleman condition holds. Thus, to complete the proof of the proposition, by using the Borel–Cantelli lemma, we only need to prove

$$(\mathrm{I}) : E(M_k) = m_k + o(1),$$

and

$$(\mathrm{II}) : E|M_k - EM_k|^4 = O\left(\frac{1}{m^2}\right).$$

Now, we begin to proceed in the proof of (I) and (II) under conditions of Proposition 3.1. Write $\mathbf{i} = (i_1, \ldots, i_k)$, $\mathbf{j} = (j_1, \ldots, j_k)$, and by defining $i_{k+1} \equiv i_1$,

$$\begin{aligned} \mathcal{I} = \{(\mathbf{i}, \mathbf{j}) : 1 \leq i_v \leq m, 1 \leq j_v \leq n, \\ \text{with } i_v \neq i_{v+1} \text{ for each } 1 \leq v \leq k\}. \end{aligned} \tag{3.1}$$

Then, by definition we have

$$M_k = \frac{1}{mn^{k/2}p^{k/2}} \sum_{(\mathbf{i},\mathbf{j}) \in \mathcal{I}} d_{(\mathbf{i},\mathbf{j})} X_{(\mathbf{i},\mathbf{j})},$$

where

$$d_{(\mathbf{i},\mathbf{j})} = d_{i_1 i_2} \cdots d_{i_k i_1},$$

$$X_{(\mathbf{i},\mathbf{j})} = x_{i_1 j_1} \overline{x}_{i_2 j_1} x_{i_2 j_2} \overline{x}_{i_3 j_2} \cdots \overline{x}_{i_k j_{k-1}} x_{i_k j_k} \overline{x}_{i_1 j_k}.$$

For each pair $(\mathbf{i}, \mathbf{j}) = ((i_1, \ldots, i_k), (j_1, \ldots, j_k)) \in \mathcal{I}$, construct a graph $G(\mathbf{i}, \mathbf{j})$ by plotting the $i_v$'s and $j_v$'s on two parallel straight lines, respectively, and then drawing $k$ down edges $(i_v, j_v)$ from $i_v$ to $j_v$, $k$ up edges $(j_v, i_{v+1})$ from $j_v$ to $i_{v+1}$, and another $k$ horizontal edges $(i_v, i_{v+1})$ from $i_v$ to $i_{v+1}$. A down edge $(i_v, j_v)$ corresponds to the variable $x_{i_v j_v}$, an up edge $(j_v, i_{v+1})$ corresponds to the variable $\overline{x}_{i_{v+1} j_v}$, and a horizontal edge $(i_v, i_{v+1})$ corresponds to the variable $d_{i_v i_{v+1}}$. A graph corresponds to the product of the variables corresponding to the edges making up this graph. We shall call the subgraph of horizontal edges and their vertices of $G(\mathbf{i}, \mathbf{j})$ the roof of $G(\mathbf{i}, \mathbf{j})$ and denote it as $\overline{G}(\mathbf{i}, \mathbf{j})$, and call the subgraph of vertical edges and their vertices of $G(\mathbf{i}, \mathbf{j})$ the base of $G(\mathbf{i}, \mathbf{j})$ and denote it as $\underline{G}(\mathbf{i}, \mathbf{j})$. By noting that the roof of $G(\mathbf{i}, \mathbf{j})$ depends on $\mathbf{i}$ only, we may simplify the notation of roofs as $\overline{G}(\mathbf{i})$.

Two graphs $G(\mathbf{i}_1, \mathbf{j}_1)$ and $G(\mathbf{i}_2, \mathbf{j}_2)$ are said to be isomorphic if one can be converted to the other by a permutation on $(1, \ldots, m)$ and a permutation on $(1, \ldots, n)$. All graphs are classified into isomorphic classes. An isomorphic class is denoted by $\mathcal{G}$. Similarly, two roofs $\overline{G}(\mathbf{i}_1)$ and $\overline{G}(\mathbf{i}_2)$ are said to be isomorphic if one can be converted to the other by a permutation on $(1, \ldots, m)$. An isomorphic roof class is denoted by $\overline{\mathcal{G}}$. For a given $\mathbf{i}$, two graphs $G(\mathbf{i}, \mathbf{j}_1)$ and $G(\mathbf{i}, \mathbf{j}_2)$ are said to be isomorphic given $\mathbf{i}$ if one can be converted to the other by a permutation on $(1, \ldots, n)$. An isomorphic class given $\mathbf{i}$ is denoted by $\underline{\mathcal{G}}(\mathbf{i})$.

Then, we may rewrite

$$\begin{aligned} M_k &= \frac{1}{mn^{k/2}p^{k/2}} \sum_{\mathbf{i},\mathbf{j}} d_{\overline{G}(\mathbf{i})} X_{\underline{G}(\mathbf{i},\mathbf{j})} \\ &= \frac{1}{mn^{k/2}p^{k/2}} \sum_{\mathcal{G}} \sum_{G(\mathbf{i},\mathbf{j}) \in \mathcal{G}} d_{\overline{G}(\mathbf{i})} X_{\underline{G}(\mathbf{i},\mathbf{j})}. \end{aligned} \tag{3.2}$$

(I) 11 By the notation introduced above,

$$E(M_k) = \frac{1}{mn^{k/2}p^{k/2}} \sum_{\mathcal{G}} \sum_{G(\mathbf{i},\mathbf{j})\in\mathcal{G}} Ed_{\overline{G}(\mathbf{i})} EX_{\underline{G}(\mathbf{i},\mathbf{j})}. \tag{3.3}$$

Note that when $G(\mathbf{i},\mathbf{j})$ contains a single vertical edge, $EX_{\underline{G}(\mathbf{i},\mathbf{j})} = 0$. Thus we may assume in the following that each graph appearing in the summation of $EM_k$ does not contain single vertical edges. Also note that, from the definition of the set $\mathcal{I}$, each graph also does not contain any loops of horizontal edges.

Let us denote by $l$, $r$, $s$ the numbers of noncoincident vertical edges, noncoincident $i_v$ vertices, and noncoincident $j_v$ vertices, respectively. It is obvious that these numbers must be the same for isomorphic graphs. Further, notice that for each isomorphic class $\mathcal{G}$, there is a unique graph $G(\mathbf{i},\mathbf{j})$ satisfying

$$i_1 = 1, i_{v+1} \le \max\{i_1, \ldots, i_v\} + 1,$$

$$j_1 = 1, j_{v+1} \le \max\{j_1, \ldots, j_v\} + 1,$$

which will be called the canonical (or representative) graph of $\mathcal{G}$. We can further define a number $q$ as follows. Suppose that $\mathcal{G}$ is an isomorphic class having the index $r$, the number of noncoincident $i$-vertices in its canonical graph $G(\mathbf{i},\mathbf{j})$. Then since $\overline{G}(\mathbf{i})$, the roof of $G(\mathbf{i},\mathbf{j})$, is a connected graph, we can select a tree which contains all the $r$ vertices of $\overline{G}(\mathbf{i})$ and exactly $r-1$ edges. Excluding the $r-1$ edges in $\overline{G}_1(\mathbf{i})$, we have $k-(r-1)$ edges left in $\overline{G}(\mathbf{i})$. Then the remaining $k-(r-1)$ edges together with all of the vertices of $\overline{G}(\mathbf{i})$ form another subgraph of $\overline{G}(\mathbf{i})$, which will be denoted by $\overline{G}_2(\mathbf{i})$. The remainder subgraph $\overline{G}_2(\mathbf{i})$ may not be connected. Suppose that $\overline{G}_2(\mathbf{i})$ consists of $q$ connected blocks with the understanding that each isolated vertex is considered as a connected block. Then by permutations of the $i$-vertices and $j$-vertices, we may use the same number $q$ for all the other graphs in this isomorphic class. Therefore, we may denote by $\mathcal{G}(l,r,s,q)$ the collection of isomorphic classes with the indices $l$, $r$, $s$, and $q$. We then have the following two propositions for estimating the terms involved in $EM_k$.

PROPOSITION 3.2. 3.1 $\mathcal{G} \in \mathcal{G}(l,r,s,q)$ $K$

$$\sum_{\overline{G}(\mathbf{i})\in\overline{\mathcal{G}}} E|d_{\overline{G}(\mathbf{i})}| \le Km^{1+\delta(q-1)}p^{r-1-\delta(q-1)} \tag{3.4}$$

$$\sum_{\substack{\overline{G}(\mathbf{i})\in\overline{\mathcal{G}} \\ I\,fixed}} E|d_{\overline{G}(\mathbf{i})}| \le Km^{\delta(q-1)}p^{r-1-\delta(q-1)}, \tag{3.5}$$

$I$ $i$ $\overline{G}(\mathbf{i})$. $K$ $I$

It is straightforward to see that (3.4) is a consequence of (3.5). We thus need only prove (3.5). Since $\overline{G}(\mathbf{i})$ is connected, there must exist $q-1$ edges in $\overline{G}_1(\mathbf{i})$ which make the $q$ blocks of $\overline{G}_2(\mathbf{i})$ connected. From the definition of $\overline{G}_1(\mathbf{i})$, these $q-1$ edges are single in $\overline{G}(\mathbf{i})$ and, together with their vertices, cannot form any cycles. We shall call them bridge edges. Suppose the $(q-1)$ bridge edges are

$$(i_{b_1}, i_{b_1+1}), (i_{b_2}, i_{b_2+1}), \ldots, (i_{b_{q-1}}, i_{b_{q-1}+1});$$

the other $r-q$ edges in $\overline{G}_1(\mathbf{i})$ are

$$(i_{a_1}, i_{a_1+1}), (i_{a_2}, i_{a_2+1}), \dots, (i_{a_{r-q}}, i_{a_{r-q}+1});$$

the $k-r+1$ edges in $\overline{G}_2(\mathbf{i})$ are

$$(i_{c_1}, i_{c_1+1}), (i_{c_2}, i_{c_2+1}), \dots, (i_{c_{k-r+1}}, i_{c_{k-r+1}+1}).$$

(Note that $q$ may be equal to 1 so that there are no bridge edges at all, but it is easy to see that the proof that follows is still valid.) Then by Hölder's inequality, we have

$$\begin{aligned}
&\sum_{\substack{\overline{G}(\mathbf{i})\in\overline{\mathcal{G}}\\ I fixed}} E|d_{\overline{G}(\mathbf{i})}| \\
&= E \sum_{\substack{\overline{G}(\mathbf{i})\in\overline{\mathcal{G}}\\ I fixed}} \prod_{u=1}^{q-1} |d_{i_{b_u} i_{b_u+1}}| \prod_{v=1}^{r-q} |d_{i_{a_v} i_{a_v+1}}| \prod_{w=1}^{k-r+1} |d_{i_{c_w} i_{c_w+1}}| \\
&\le \left( E \sum_{\substack{\overline{G}(\mathbf{i})\in\overline{\mathcal{G}}\\ I fixed}} \prod_{u=1}^{q-1} |d_{i_{b_u} i_{b_u+1}}| \prod_{v=1}^{r-q} |d_{i_{a_v} i_{a_v+1}}|^2 \right)^{1/2} \\
&\quad \left( E \sum_{\substack{\overline{G}(\mathbf{i})\in\overline{\mathcal{G}}\\ I fixed}} \prod_{u=1}^{q-1} |d_{i_{b_u} i_{b_u+1}}| \prod_{w=1}^{k-r+1} |d_{i_{c_w} i_{c_w+1}}|^2 \right)^{1/2} \\
&\le K m^{\delta(q-1)} p^{r-1-\delta(q-1)}.
\end{aligned}$$

To get this inequality, we used the following two results namely, by conditions (D2), (D3.1), and (D3.2),

$$\begin{aligned}
&E \sum_{\substack{\overline{G}(\mathbf{i})\in\overline{\mathcal{G}}\\ I fixed}} \prod_{u=1}^{q-1} |d_{i_{b_u} i_{b_u+1}}| \prod_{v=1}^{r-q} |d_{i_{a_v} i_{a_v+1}}|^2 \\
&= \sum_{\substack{\overline{G}(\mathbf{i})\in\overline{\mathcal{G}}\\ I fixed}} \prod_{u=1}^{q-1} E|d_{i_{b_u} i_{b_u+1}}| \prod_{v=1}^{r-q} E|d_{i_{a_v} i_{a_v+1}}|^2 \\
&\le K(m^\delta p^{1-\delta})^{q-1} p^{r-q} \\
&= K m^{\delta(q-1)} p^{r-1-\delta(q-1)},
\end{aligned}$$

and further by the fact that the $p_{ij}$'s are uniformly bounded,

$$\begin{aligned}
&E \sum_{\substack{\overline{G}(\mathbf{i})\in\overline{\mathcal{G}}\\ I fixed}} \prod_{u=1}^{q-1} |d_{i_{b_u} i_{b_u+1}}| \prod_{w=1}^{k-r+1} |d_{i_{c_w} i_{c_w+1}}|^2 \\
&= \sum_{\substack{\overline{G}(\mathbf{i})\in\overline{\mathcal{G}}\\ I fixed}} \prod_{u=1}^{q-1} E|d_{i_{b_u} i_{b_u+1}}| E \prod_{w=1}^{k-r+1} |d_{i_{c_w} i_{c_w+1}}|^2 \\
&\le K m^{\delta(q-1)} p^{r-1-\delta(q-1)}.
\end{aligned}$$

This completes the proof of the proposition.

Note that since each graph does not contain a single vertical edge, we have $l \leq k$. Since each graph does not contain any loops of horizontal edges, we further have $l \geq 2s$. And as a basic property of connected graph, we have $r + s \leq l + 1$. To estimate the integer $q$, we need the following proposition.

PROPOSITION 3.3. [illegible] $l$ $s$ $q$ [illegible]

$$l - 2s \geq q - 1. \tag{3.6}$$

[illegible] Since $\overline{G}(\mathbf{i})$ contains no loops, it follows that each $j$-vertex is connected with at least two noncoincident vertical edges and hence that $l - 2s \geq 0$, which implies (3.6) for the case of $q = 1$. Now assume $q > 1$. Then we have $q - 1$ bridge edges. If $(i_v, i_{v+1})$ is a bridge edge, then we call the vertex $j_v$ its supporting vertex, while the edges $(i_v, j_v)$, $(j_v, i_{v+1})$ are its supporting edges.

Denote the $s$ noncoincident $j$-vertices by $J_1, J_2, \ldots, J_s$. For each $1 \leq a \leq s$, denote by $l_a$ the number of noncoincident vertical edges connected with $J_a$. Then obviously $l = l_1 + l_2 + \cdots + l_s$. Note that each noncoincident $j$-vertex is composed of at least two $j$-vertices coincident with each other. For each $1 \leq a \leq s$, denote by $t_a$ the number of bridge edges supported by $J_a$. Here, of course, $t_a$ is the total number of bridge edges whose supporting $j$-vertex is from those coincident $j$-vertices constituting $J_a$. Then $q - 1 = t_1 + t_2 + \cdots + t_s$. To prove $l - 2s \geq q - 1$, it is sufficient to prove for each $1 \leq a \leq s$, $l_a \geq t_a + 2$.

If $t_a = 0$, then $l_a \geq t_a + 2$ follows simply from the previously stated fact that each $j$-vertex is connected with at least two noncoincident vertical edges. Now assume $t_a \geq 1$. In view of the property that bridge edges together with their vertices do not form any cycles and may be disconnected among themselves, we shall consider two cases, when the $t_a$ bridge edges (together with their vertices) form exactly one tree and when they form more than one tree disjoint with each other. For the first case, since each supporting edge connected with $J_a$ must take one vertex of the tree, there are exactly $t_a + 1$ noncoincident supporting edges connected with $J_a$. The same reasoning shows that for the second case, there are at least $t_a + 2$ noncoincident supporting edges connected with $J_a$, and hence $l_a \geq t_a + 2$.

To complete the proof of the proposition, we need only proceed with the proof of the first case. In this case, the tree formed by the $t_a$ bridge edges possesses $(t_a + 1)$ vertices. Arbitrarily select two vertices of the tree. Then these two vertices are joined by one path composed of only bridge edges from the tree. We assert that there cannot be any edge of $\overline{G}(\mathbf{i})$ which does not belong to the tree, taking the two vertices as its two endpoints. To see this, by the way of contradiction, we suppose that one such edge exists. Then this edge and the prescribed path form a cycle, and consequently we see that this edge must not belong to $\overline{G}_1(\mathbf{i})$ and that the cycle belongs to the graph consisting of $\overline{G}_2(\mathbf{i})$ and all bridge edges. Denote this later mentioned graph by $\overline{G}_3(\mathbf{i})$. It follows that removing any edge of the path from $\overline{G}_3(\mathbf{i})$ does not cause the graph to be disconnected, and so any edge arbitrarily selected from the bridge edges forming the path is not cutting in $\overline{G}_3(\mathbf{i})$. However, by the definition of bridge edges, $\overline{G}_3(\mathbf{i})$ is a connected graph and each of the $(q - 1)$ bridge edges should be cutting in the graph. Thus we reach a contradiction and conclude that our assertion is true.

Now arbitrarily select one vertex of degree one in the tree. Then the supporting edge connecting this vertex and $J_a$ must be single among supporting edges and must be coincident with one nonsupporting vertical edge. Note that this nonsupporting vertical edge may be a down edge and also may be an up edge. We first consider the case when this vertical edge is a down edge, say $(i_v, j_v)$. Then $i_v$ is coincident with the vertex we selected which has degree one in the tree, and $j_v$ is one of the coincident $j$-vertices constituting $J_a$. Note that since $(i_v, j_v)$ is nonsupporting, $(i_v, i_{v+1})$ is not a bridge edge. Recall that by (3.1), $i_v \neq i_{v+1}$. By the preceding argument, $i_{v+1}$ cannot be coincident with any of the other $t_a$ vertices of the tree either. This implies that the up vertical edge $(j_v, i_{v+1})$ cannot be coincident with any of the $(t_a + 1)$ noncoincident supporting edges connected with $J_a$. Therefore it follows that $l_a \geq t_a + 2$. For the other case when the vertical edge is an up edge, say $(j_v, i_{v+1})$, a similar argument can be used to conclude that the anterior down edge $(i_v, j_v)$ cannot be coincident with any of the $(t_a + 1)$ noncoincident supporting edges connected with $J_a$ (see Figure 3.1). The proof of the proposition is now complete.

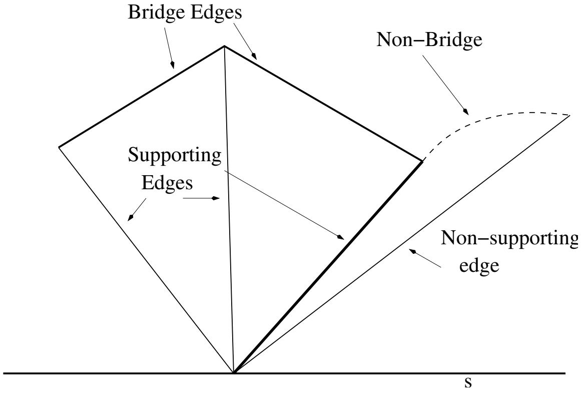

FIG. 3.1. *The definition of bridge edges.*

From Proposition 3.2, it follows for each $\mathcal{G} \in \mathcal{G}(l, r, s, q)$,

$$\begin{aligned}
&\frac{1}{mn^{k/2}p^{k/2}} \left| \sum_{G(\mathbf{i},\mathbf{j})\in\mathcal{G}} Ed_{\overline{G}(\mathbf{i})} EX_{\underline{G}(\mathbf{i},\mathbf{j})} \right| \\
&\leq \frac{1}{mn^{k/2}p^{k/2}} \sum_{\overline{G}(\mathbf{i})\in\overline{\mathcal{G}}} |Ed_{\overline{G}(\mathbf{i})}| \sum_{\underline{G}(\mathbf{i},\mathbf{j})\in\underline{\mathcal{G}}(\mathbf{i})} |EX_{\underline{G}(\mathbf{i},\mathbf{j})}| \\
&\leq \frac{1}{mn^{k/2}p^{k/2}} K m^{1+\delta(q-1)} p^{r-1-\delta(q-1)} n^{s} (\eta_n \sqrt[4]{np})^{2k-2l} \\
&= K\eta_n^{2(k-l)} m^{\delta(q-1)} n^{s-l/2} p^{r-l/2-1-\delta(q-1)} \\
&= K\eta_n^{2(k-l)} (m/n)^{\delta(q-1)} (p/n)^{\frac{l}{2}-s-\delta(q-1)} p^{r+s-l-1}. \qquad (3.7)
\end{aligned}$$

Based on this relation, we separate the terms involved in $EM_k$ into three parts; i.e., let $S_1$ be the sum of terms with $l < k$, $S_2$ be the sum of terms with $l = k$, but either $r + s < l + 1$ or $l > 2s$, and $S_3$ be the sum of terms with $l = k$, $r + s = l + 1$, $l = 2s$, and hence from Proposition 3.3, $q = 1$. Noting the relations between the numbers $l$, $r$, $s$ analyzed previously, we have

$$EM_k = S_1 + S_2 + S_3.$$

We first prove $S_1 \to 0$ and $S_2 \to 0$. Note that under the assumptions of Theorem 1.1, $(m/n)^{\delta(q-1)}$ is bounded. From Proposition 3.3, $l/2 - s \geq \delta(q-1)$ always holds.

Thus we get

$$|S_1| = o((m/n)^{\delta(q-1)}(p/n)^{\frac{l}{2}-s-\delta(q-1)}p^{r+s-l-1}) = o(1).$$

If $\delta(q-1) = 0$, then

$$|S_2| = O((p/n)^{\frac{k}{2}-s}p^{r+s-k-1}) = o(1),$$

since either $k > 2s$ or $r + s < k + 1$. If $\delta \in (0, 1/2)$ and $q > 1$, then

$$|S_2| = O((p/n)^{\frac{k}{2}-s-\delta(q-1)}) = o(1),$$

since $k/2 - s > \delta(q-1)$. If $\delta = 1/2$ and $q > 1$, then since $m/n \to 0$,

$$|S_2| = O((m/n)^{\frac{1}{2}(q-1)}) = o(1).$$

Note that when $k$ is odd, no terms involved in the summation of $EM_k$ belong to $S_3$ and hence we must have

$$EM_k \to 0.$$

In the following we only need to evaluate $S_3$ for when the case $k$ is even, by definition of $S_3$, $k = 2s$.

We first note that $r+s = k+1$ implies that there cannot be cycles of noncoincident vertical edges in the base of the graph. Also note that $l = k$ implies that each noncoincident vertical edge must consist of exactly two vertical edges. It follows that each down edge must coincide with one and only one up edge because the coincidence of a down edge (an up edge) with another down edge (up edge) would imply that the noncoincident edges of the base contain a cycle. Therefore, if we denote the noncoincident vertical edges by $\{(u_1, v_1), \ldots, (u_k, v_k)\}$, then

$$EX_{\underline{G}(\mathbf{i},\mathbf{j})} = \prod_{j=1}^{k} \sigma^2_{u_j v_j},$$

and hence for each isomorphic class $\mathcal{G} \in \mathcal{G}(2s, s+1, s, 1)$ (all isomorphic classes involved in $S_3$ constitute $\mathcal{G}(2s, s+1, s, 1)$), we have

$$\sum_{G(\mathbf{i},\mathbf{j})\in\mathcal{G}} Ed_{\overline{G}(\mathbf{i})} EX_{\underline{G}(\mathbf{i},\mathbf{j})} = \sum_{G(\mathbf{i},\mathbf{j})\in\mathcal{G}} Ed_{\overline{G}(\mathbf{i})} \prod_{j=1}^{k} \sigma^2_{u_j v_j}.$$

Now we show that

$$\frac{1}{m(np)^s} \sum_{G(\mathbf{i},\mathbf{j})\in\mathcal{G}} Ed_{\overline{G}(\mathbf{i})} \prod_{j=1}^{k} \sigma^2_{u_j v_j} = \frac{1}{m(np)^s} \sum_{G(\mathbf{i},\mathbf{j})\in\mathcal{G}} Ed_{\overline{G}(\mathbf{i})} \sigma^{2k} + o(1). \tag{3.8}$$

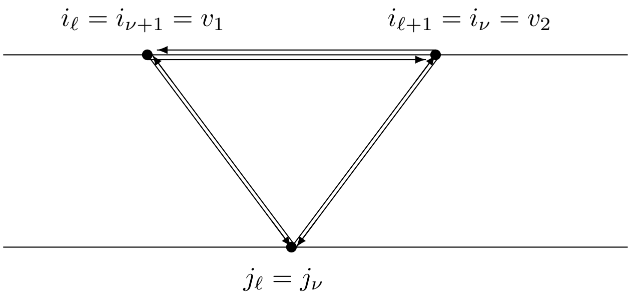

FIG. 3.2. $(v_1, v_2)$ *coincides with* $(v_2, v_1)$.

By (b) of Proposition 2.6 and (3.5) of Proposition 3.2 for the case $q = 1$, we have

$$\begin{aligned}
0 &\le \frac{1}{m(np)^s} \sum_{G(\mathbf{i},\mathbf{j})\in\mathcal{G}} |Ed_{\overline{G}(\mathbf{i})}| \left[\sigma^{2k} - \prod_{j=1}^{k} \sigma^2_{u_j v_j}\right] \\
&\le \frac{1}{m(np)^s} \sum_{G(\mathbf{i},\mathbf{j})\in\mathcal{G}} |Ed_{\overline{G}(\mathbf{i})}| \sum_{\ell=1}^{k} \left[\sigma^{2(k-\ell)}(\sigma^2 - \sigma^2_{u_\ell v_\ell}) \prod_{j=1}^{\ell-1} \sigma^2_{u_j v_j}\right] \\
&\le \frac{1}{m(np)^s} \sum_{G(\mathbf{i},\mathbf{j})\in\mathcal{G}} |Ed_{\overline{G}(\mathbf{i})}| \sum_{\ell=1}^{k} [\sigma^{2(k-1)}(\sigma^2 - \sigma^2_{u_\ell v_\ell})] \\
&\le \frac{\sigma^{2(k-1)}}{mnp^s} \sum_{\overline{G}(\mathbf{i})\in\overline{\mathcal{G}}} |Ed_{\overline{G}(\mathbf{i})}| \sum_{\ell=1}^{k} \sum_{v_\ell} (\sigma^2 - \sigma^2_{u_\ell v_\ell}) \\
&\le \sum_{\ell=1}^{k} \frac{K\sigma^{2(k-1)}}{mn} \sum_{v_\ell} \sum_{u_\ell} (\sigma^2 - \sigma^2_{u_\ell v_\ell}) \to 0,
\end{aligned}$$

from which (3.8) follows.

For a graph corresponding to a term in $S_3$, we claim that each horizontal edge $(v_1, v_2)$ must coincide with a horizontal edge $(v_2, v_1)$. In fact, suppose that $(i_\ell, i_{\ell+1})$ is the first appearance of $(v_1, v_2)$; i.e., $i_\ell = v_1$, $i_{\ell+1} = v_2$ and $v_2$ is not in $\{i_1, \ldots, i_\ell\}$. We claim that $j_\ell$ is not in $\{j_1, \ldots, j_{\ell-1}\}$. Otherwise, assuming $j_\ell$ is coincident with $j_a$ with $a < \ell$, then because of (3.1) and the definition of $i_{\ell+1}$, $i_a$, $i_{a+1}$, and $i_{\ell+1}$ are three noncoincident $i$-vertices so that $(i_a, j_a)$, $(j_a, i_{a+1})$, and $(j_\ell, i_{\ell+1})$ are three noncoincident vertical edges. It follows that there are at least three noncoincident vertical edges connected with the noncoincident $j$-vertex which contains $j_a$, $j_\ell$. This obviously violates the assumption $k = 2s$. As a consequence of the assertion, both of the two vertical edges $(i_\ell, j_\ell)$ and $(j_\ell, i_{\ell+1})$ are single up to the vertex $i_{\ell+1}$. In the future development of the graph, there must be one down edge $(i_\nu, j_\nu)$ coincident with the single upedge $(j_\ell, i_{\ell+1})$; that is, $i_\nu = i_{\ell+1} = v_2$ and $j_\nu = j_\ell$. Then the next up edge $(j_\nu, i_{\nu+1})$ must coincide with $(i_\ell, j_\ell)$ since, otherwise, the vertex $j_\nu = j_\ell$ will be connected with at least three noncoincident vertical edges. Thus $i_{\nu+1} = i_\ell = v_1$, and so the horizontal edge $(i_\ell, i_{\ell+1}) = (v_1, v_2)$ coincides with the horizontal edge

$(i_\nu, i_{\nu+1}) = (v_2, v_1)$ (see Figure 3.2). In view of the total number of noncoincident $i$-vertices contained in $\overline{G}(\mathbf{i})$ is $r = s+1$, we conclude that the noncoincident horizontal edges of $\overline{G}(\mathbf{i})$ form a tree of $s$ edges, each edge consisting of exactly two horizontal edges of converse directions.

It follows that

$$Ed_{\overline{G}(\mathbf{i})} = \prod_{\ell=1}^{s} p_{a_\ell, b_\ell},$$

where $(a_\ell, b_\ell)$, $1 \le \ell \le s$, denote the edges of the tree of noncoincident horizontal edges. By (3.8) and condition (D2), we have

$$\begin{aligned}
&\frac{1}{m(np)^s} \sum_{G(\mathbf{i},\mathbf{j}) \in \mathcal{G}} Ed_{\overline{G}(\mathbf{i})} EX_{\underline{G}(\mathbf{i},\mathbf{j})} \\
&= \frac{\sigma^{2k}}{mp^s} \sum_{\overline{G}(\mathbf{i}) \in \overline{\mathcal{G}}} \prod_{\ell=1}^{s} p_{a_\ell, b_\ell} + o(1) \\
&= \sigma^{2k} + o(1).
\end{aligned}$$

Therefore, to evaluate $EM_k$, what remains is to count the number of isomorphic classes in $\mathcal{G}(2s, s+1, s, 1)$. Note that for the graphs defined earlier, one only needs to arrange the vertical edges, since the positions of the horizontal edges will then be automatically determined by the positions of the $i$-vertices. When one draws the graph edge by edge, starting from $i_1$, an edge is called an innovation if it is the first appearance of a noncoincident edge and called a Type 3 edge otherwise. As we have shown in the previous paragraph, for a graph corresponding to a term in $S_3$, a down innovation must be followed by an up innovation, and a down edge of Type 3 must be followed by an up edge of Type 3. Thus, we only need to arrange the $s$ down innovations and the $s$ down edges of Type 3. Define $a_\ell = 1$ if the $\ell$th down edge is an innovation and $= -1$ otherwise. Before any Type 3 edge, there must be a single innovation. That is, for every $\ell \le k$, we should have

$$a_1 + \cdots + a_\ell \ge 0.$$

Thus, the number of isomorphic classes in $\mathcal{G}(2s, s+1, s, 1)$ is the number of sequences of $s$ ones and $s$ minus ones subject to the nonnegative partial sum requirement. By the reflection theorem, it is easy to show the number of such sequences is

$$\binom{2s}{s} - \binom{2s}{s-1} = \frac{(2s)!}{s!(s+1)!}.$$

Conclusion (I) on page 11 is proved.

[illegible] (II) [illegible] 11 Since $M_k$ is real, we consider

$$\begin{aligned}
&E(M_k - EM_k)^4 \\
&= \frac{1}{m^4 n^{2k} p^{2k}} \sum_{\substack{\mathbf{i}_\ell, \mathbf{j}_\ell \\ 1 \le \ell \le 4}} E\left( \prod_{\ell=1}^{4} [d_{\overline{G}(\mathbf{i}_\ell)} X_{\underline{G}(\mathbf{i}_\ell, \mathbf{j}_\ell)} - Ed_{\overline{G}(\mathbf{i}_\ell)} EX_{\underline{G}(\mathbf{i}_\ell, \mathbf{j}_\ell)}] \right),
\end{aligned}$$

where $G(\mathbf{i}_\ell, \mathbf{j}_\ell)$ is the graph defined by $(\mathbf{i}_\ell, \mathbf{j}_\ell)$ in the way given in the proof of (I) on page 11.

If $G(\mathbf{i}_\ell, \mathbf{j}_\ell)$ has no edges coincident with edges of the other three, then the corresponding term in the summation is 0 by independence. Furthermore, the term is also 0 if $\bigcup_{\ell=1}^4 G(\mathbf{i}_\ell, \mathbf{j}_\ell)$ contains a single vertical edge. Hence we need to consider only the following two cases:

(1) The four graphs are connected together through edges.

(2) $\bigcup_{\ell=1}^4 G(\mathbf{i}_\ell, \mathbf{j}_\ell)$ consists of two separated pieces, each of which is composed of two graphs connected together.

Split $E|M_k - EM_k|^4 = S_I + S_{II}$ according to the two cases. Denote the collection of graphs in case (1) by $\mathcal{C}_1$ and similar to the notation $\mathcal{C}_2$.

In case (1), the graph $G = \bigcup_{\ell=1}^4 G(\mathbf{i}_\ell, \mathbf{j}_\ell)$ has a connected roof. Let $r$, $s$, and $l$ be, respectively, the numbers of noncoincident $i$-vertices, noncoincident $j$-vertices, and noncoincident vertical edges contained in $G$. Similarly, we can define the number $q$. Then, similar to the estimation of $EM_k$, under the assumptions of Proposition 3.1, we have

$$
\begin{aligned}
|S_I| &\leq \frac{16}{m^4 n^{2k} p^{2k}} \sum_{G \in \mathcal{C}_1} E\left(\prod_{\ell=1}^4 |d_{\overline{G}(\mathbf{i}_\ell)}||X_{\underline{G}(\mathbf{i}_\ell, \mathbf{j}_\ell)}|\right) \\
&\leq \frac{K}{m^4 n^{2k} p^{2k}} \sum_{r,s,l,q} m^{1+\delta(q-1)} p^{r-1-\delta(q-1)} (\eta_n \sqrt[4]{np})^{(8k-2l)} n^s \\
&\leq K m^{-3} \sum_{r,s,l,q} \eta_n^{8k-2l} (m/n)^{\delta(q-1)} (p/n)^{\frac{l}{2}-s-\delta(q-1)} p^{r+s-l-1} \\
&= O(m^{-3}),
\end{aligned}
$$

where we have used Proposition 3.2 and the facts $l \leq 4k$, $r+s \leq l+1$, and $l-2s \geq q-1$.

To estimate $S_{II}$, one only needs to note that for each piece of the roof subgraph, there is one factor $m$ obtained and so totally there is one more factor $m$ obtained. Thus under the assumptions of Proposition 3.1, one gets that

$$S_{II} = O(m^{-2}).$$

Combining the above gives (II) on page 11. Consequently, we have completed the proof of Proposition 3.1 and Theorem 1.1.

[illegible] 3.1. Using the same approach as we prove (II) on page 11, one can easily show that

$$E|M_k - EM_k|^{2\mu} = O(m^{-\mu}), \tag{3.9}$$

for any fixed integer $\mu$. This result will be useful when the almost sure convergence is considered for $n \to \infty$.

At the end, we present two examples. The first example is to show, when condition (D3.1) is assumed for $\delta = 1/2$, to ensure the convergence of the semicircle law of $F^{A_p}$, it is necessary to require $m/n \to 0$.

[illegible] 3.1. Let $D_m = [d_{ij}]$ consist of $d_{ii} = 0$ and $d_{ij} = \sqrt{p/m}$ for $i \neq j$. Let $X_{m,n} = [x_{ij}]$ consist of i.i.d. standard normal random variables. Now assume $m/n \to c > 0$ and $p/n \to 0$. Then conditions (D2), (D3.1), and (D3.2) hold. Specifically, 1/2 is the smallest parameter in $[0, 1/2]$ such that condition (D3.1) is satisfied by $A_p$.

Consider the $k$th moment of $F^{A_p}$. Using the definitions we gave in proving Proposition 3.1, for any isomorphic class $\mathcal{G}$ whose canonical graph possesses $r$ noncoincident $i$-vertices and $s$ noncoincident $j$-vertices and does not contain loops of horizontal edges, we have

$$\begin{aligned} S_{\mathcal{G}} &= \frac{1}{mn^{k/2}p^{k/2}} \sum_{G(\mathbf{i},\mathbf{j})\in\mathcal{G}} Ed_{\overline{G}(\mathbf{i})} EX_{\underline{G}(\mathbf{i},\mathbf{j})} \\ &= K_{\mathcal{G}} m^{-1} n^{-k/2} p^{-k/2} (p/m)^{k/2} m^r n^s + o(1) \\ &= K_{\mathcal{G}} m^{r+s-k-1} (n/m)^{s-k/2} + o(1), \end{aligned}$$

where $K_{\mathcal{G}} = EX_{\underline{G}(\mathbf{i},\mathbf{j})}$. It is easy to see that

$$S_{\mathcal{G}} \to \begin{cases} 0 & \text{if } r+s < k+1, \\ K_{\mathcal{G}} c^{k/2-s} & \text{if } r+s = k+1. \end{cases}$$

Note that when $r+s = k+1$, since $r+s \le l+1$, where $l$ is the number of noncoincident vertical edges contained in the canonical graph of $\mathcal{G}$, it follows that $l \ge k$. If $l > k$, then there must exist a single vertical edge and hence $K_{\mathcal{G}} = 0$. Otherwise, $l = k$; then every noncoincident vertical edge is composed of exactly two vertical edges of opposite directions and hence $K_{\mathcal{G}} = 1$. Therefore, noticing the restriction that, since there are no loops of horizontal edges, every noncoincident $j$-vertex must be connected with at least two noncoincident vertical edges, we get

$$EM_k \to m_k = \sum_{s=1}^{[\frac{k}{2}]} c^{k/2-s} \mu_s,$$

where $\mu_s$ is the number of isomorphic classes whose canonical graphs satisfy the following condition:

(1) Each canonical graph contains exactly $s$ noncoincident $j$-vertices and $(k+1-s)$ noncoincident $i$-vertices.

(2) Each canonical graph contains exactly $k$ noncoincident vertical edges, each of which consists of two edges, of opposite directions.

(3) Each canonical graph possesses the property that, supposing one person starts a walk along its edges, then whenever a down edge leads to a new noncoincident $j$-vertex the next up edge must lead to a new $i$-vertex.

To estimate the limit $m_k$, let us observe further that

$$\begin{aligned} &\left(\frac{m}{n}\right)^{k/2} \times EM_k \\ &= m^{-1} n^{-k} \sum_{i_1,\dots,i_k}^{res} \sum_{j_1,\dots,j_k} E(x_{i_1 j_1} x_{i_2 j_1} x_{i_2 j_2} x_{i_3,j_2} \cdots x_{i_k j_k} x_{i_1 j_k}), \quad (3.10) \\ &\le E m^{-1} tr \left(\frac{1}{n} X_{m,n} X_{m,n}^*\right)^k, \quad (3.11) \end{aligned}$$

where the summation $\sum_{i_1,\dots,i_k}^{res}$ is taken over all possible values of $i_1,\dots,i_k$ satisfying the restriction that $i_1 \ne i_2$, $i_2 \ne i_3, \dots, i_k \ne i_1$. Thus it follows, by Theorem 2.5 of Bai [1], that $c^{k/2} m_k$ is bounded by the $k$th moment of the Marcĕnko–Pastur law with ratio index $c$ and scale index 1. Thus $\{m_k\}_{k=1}^{\infty}$ satisfies the Carleman condition.[1]

---

[1] Note that there is a one-to-one correspondence between $\mathcal{G}$ and its base and that the base of $\mathcal{G}$ must be a canonical graph defined in deriving the Marcĕnko–Pastur law. Thus, we indeed have

$$\mu_s \le \frac{1}{k+1-s}\binom{k}{s}\binom{k-1}{s-1}.$$

Using (3.10), one can easily show that

$$E(M_k - EM_k)^{2\mu} = O(m^{-2\mu}).$$

Therefore, with probability one, $F^{A_p}$ converges to a nonrandom limiting distribution, say $F$. It is easy to verify that when $k = 3$, we have $s = 1$ and $r = 3$ so that $i_1 \neq i_2 \neq i_3$ and $j_1 = j_2 = j_3$; i.e., there is exactly one contributing isomorphic class $\mathcal{G}$. Thus,

$$m_3 = \sqrt{c}.$$

Since the third moment of $F$ is not 0, $F$ is not the semicircle law. That is, we have shown with probability one that $F^{A_p}$ converges weakly but the limiting spectral distribution is not the semicircle law.

The next example is to show for the case when condition (D3.1) is assumed for $\delta \in (0, 1/2)$ that the condition $m/n$ is bounded and also necessary for the convergence to the semicircle law.

Example 3.2. Let $D_m = [d_{ij}]$ be defined as in Example 3.1. We assume the same conditions $m/n \to c > 0$ and $p/n \to 0$. Now we define $\tilde{D}_h = D_m \otimes I_h$ and $\tilde{B}_h = \frac{1}{\sqrt{np}}(X_{mh,n}X^*_{mh,n} - \sigma^2 n I_{mh})$, where "$\otimes$" denotes the Kronecker product of matrices, $h = [m^\eta]$ with $\eta > 0$, and $X_{mh,n}$ is $mh \times n$ consisting of i.i.d. standard normal random variables.

Let $\tilde{A}_p = \tilde{B}_h \circ \tilde{D}_h$. Then $\tilde{A}_p = \operatorname{diag}[A_{1,m}, \ldots, A_{h,m}]$, where

$$A_{i,m} = B_{ii} \circ D_m,\ i = 1, \ldots, h,$$

and $B_{ii}$ is the $i$th $m \times m$ major submatrix of $\tilde{B}_h$.

Note that $A_{1,m}, \ldots, A_{h,m}$ are independent with the same distribution as $A_p$ defined in Example 3.1. Denote by $\tilde{M}_k$, $M_{i,k}$, and $M_k$, respectively, the $k$th moment of $\tilde{A}_p$, the $k$th moment of $A_{i,m}$, and the $k$th moment of $A_p$. Then it follows that $EM_{i,k} = EM_k$ and $E(M_{i,k} - EM_{i,k})^{2\mu} = E(M_k - EM_k)^{2\mu}$. Since $F^{\tilde{A}_p} = \frac{1}{h}\sum_{i=1}^h F^{A_{i,m}}$ so that $\tilde{M}_k = \frac{1}{h}\sum_{i=1}^h M_{i,k}$, we get $E\tilde{M}_k = EM_k$ and $E(\tilde{M}_k - E\tilde{M}_k)^{2\mu} \le E(M_k - EM_k)^{2\mu}$. By the results we proved in Example 3.1, it follows with probability one that $F^{\tilde{A}_p}$ converges weakly but the limiting spectral distribution is not the semicircle law.

Let us now check the validity of the assumptions of Theorem 1.1 for $\tilde{A}_p$. Conditions (D1), (D2), and (D3.2) hold for $\tilde{A}_p$ automatically by definition. We now show that for any $\delta \in (0, 1/2)$ by choosing $\eta > 0$ such that $2\delta(1 + \eta) = 1$, condition (D3.1) is satisfied by $\tilde{A}_p$ for the given $\delta$. To see this, note that the dimension of $\tilde{A}_p$ is $mh$, and so we have

$$\sum_i Ed_{ij} \le \sqrt{mp} \le \frac{\sqrt{m}}{(mh)^\delta}(mh)^\delta p^{1-\delta} \le C_1 (mh)^\delta p^{1-\delta}.$$

By requiring $p = O(\log m)$, we can further see for any $\delta_0 < \delta$ that

$$\left(\sum_i Ed_{ij}\right) / \left((mh)^{\delta_0} p^{1-\delta_0}\right) \ge \frac{1}{2} m^{\frac{1}{2}(1-\delta_0/\delta)} p^{\delta_0 - \frac{1}{2}} \to \infty,$$

which confirms that $\delta$ is the smallest parameter in $(0, 1/2)$ such that condition (D3.1) is satisfied by $\tilde{A}_p$. Noticing that $mh/n \to \infty$, we see that $\tilde{A}_p$ satisfies all assumptions of Theorem 1.1 except only the condition that in case of $\delta \in (0, 1/2)$ the ratio between the vector dimension and the sample size should be bounded. We achieved our target.

# LOW RANK PERTURBATION OF KRONECKER STRUCTURES WITHOUT FULL RANK*

FERNANDO DE TERÁN[†] AND FROILÁN M. DOPICO[†]

**Abstract.** Let $P(\lambda) = A_0 + \lambda A_1$ be a singular $m \times n$ matrix pencil without full rank whose Kronecker canonical form (KCF) is given. Let $\rho$ be a positive integer such that $\rho \leq \min\{m, n\} - \operatorname{rank}(P)$ and $\rho \leq \operatorname{rank}(P)$. We study the change of the KCF of $P(\lambda)$ due to perturbation pencils $Q(\lambda)$ with $\operatorname{rank}(Q) = \rho$. We focus on the generic behavior of the KCF of $(P + Q)(\lambda)$, i.e., the behavior appearing for perturbations $Q(\lambda)$ in a dense open subset of the pencils with rank $\rho$. The most remarkable generic properties of the KCF of the perturbed pencil $(P + Q)(\lambda)$ are (i) if $\lambda_0$ is an eigenvalue of $P(\lambda)$, finite or infinite, then $\lambda_0$ is an eigenvalue of $(P + Q)(\lambda)$; (ii) if $\lambda_0$ is an eigenvalue of $P(\lambda)$, then the number of Jordan blocks associated with $\lambda_0$ in the KCF of $(P + Q)(\lambda)$ is equal to or greater than the number of Jordan blocks associated with $\lambda_0$ in the KCF of $P(\lambda)$; (iii) if $\lambda_0$ is an eigenvalue of $P(\lambda)$, then the dimensions of the Jordan blocks associated with $\lambda_0$ in $(P + Q)(\lambda)$ are equal to or greater than the dimensions of the Jordan blocks associated with $\lambda_0$ in $P(\lambda)$; (iv) the row (column) minimal indices of $(P + Q)(\lambda)$ are equal to or greater than the largest row (column) minimal indices of $P(\lambda)$. Moreover, if the sum of the row (column) minimal indices of the perturbations $Q(\lambda)$ is known, apart from their rank, then the whole set of the row (column) minimal indices of $(P + Q)(\lambda)$ is generically obtained, and in the case $\rho < \min\{m, n\} - \operatorname{rank}(P)$ the whole KCF of $(P + Q)(\lambda)$ is generically determined.

## 1. Introduction.

Matrix spectral canonical forms are very important both in theory and in applications like the behavior of dynamical systems near bifurcations. Spectral canonical forms are mathematical structures that are very fragile under perturbations. For instance, it is well known that, although the *Jordan* canonical form of a matrix $A$ has blocks of dimension larger than one, all the blocks in the Jordan form of the perturbed matrix $A + E$ have dimension one and correspond to eigenvalues different from those of $A$, for almost all perturbations $E$. The same can be said on the behavior of the *Weierstrass* canonical form of a regular matrix pencil $A_0 + \lambda A_1$, and on the *Kronecker* canonical form (KCF) of singular matrix pencils. In this latter case, in fact, the perturbed pencil has full rank for almost all perturbations. However, there are perturbations that allow us to guarantee that some part of the spectral canonical form of the original pencil is also a part of the spectral canonical form of the perturbed pencil. One example of perturbations of this kind is *low rank perturbations*, i.e., perturbations with a fixed rank that is small in some way specified by a property of the unperturbed matrix or pencil.

Low rank perturbations of spectral canonical forms have received attention since the 1980s. At least two kinds of contributions can be considered in this area. Given an

$m \times n$ pencil (or matrix) $P(\lambda)$ and perturbations $Q(\lambda)$ with fixed rank, the first class of works tries to classify all the spectral canonical forms of $(P+Q)(\lambda)$ compatible with the canonical form of $P(\lambda)$ and the rank of the perturbations $Q(\lambda)$. As far as we know, this has only been done for rank one perturbations; see [1] and [18] in this context. A second class of papers in this area characterizes generic properties of the spectral canonical form of $(P+Q)(\lambda)$, i.e., properties that hold for perturbations in a dense open subset of the matrices or pencils with a fixed rank; for this problem, see the references [4, 10, 13, 16, 17]. Generic properties have been considered only for the Jordan canonical form of matrices and for the Weierstrass canonical form of regular matrix pencils, and the study of explicit necessary and sufficient conditions for the generic behaviors to hold has been performed only in [4, 13]. The purpose of this paper is to determine generic properties of the KCF of singular matrix pencils without full rank under certain low rank perturbations, and to provide sufficient conditions for these properties to hold.

Throughout this work the term *generic* will frequently be used. This word appears in many mathematical works, but it is not a well-defined technical term, and its precise meaning is not always the same in the literature. In this paper, we use *generic* in the following sense: *[illegible] $\mathcal{C}$ [illegible] $\mathcal{C}$.* In our context, $\mathcal{C}$ will be the set of allowable perturbations, and we identify the set of $m \times n$ complex matrix pencils, $A_0 + \lambda A_1$, with $\mathbb{C}^{2mn}$, where the usual topology is considered. Therefore every subset $\mathcal{C}$ of pencils can be seen as a subset of $\mathbb{C}^{2mn}$. In this setting, we have that a set $\mathcal{G} \subset \mathcal{C}$ is dense in $\mathcal{C}$ if and only if every element in $\mathcal{C}$ is the limit of a sequence of elements in $\mathcal{G}$, and we will say that $\mathcal{G}$ is open in $\mathcal{C}$ if $\mathcal{G}$ is the intersection of $\mathcal{C}$ with an open subset of $\mathbb{C}^{2mn}$; i.e., we consider in $\mathcal{C}$ the *relative topology* induced by the usual topology of $\mathbb{C}^{2mn}$. To finish these comments on the term *generic*, let us remark that it will not be used in the statement of most theorems, where precise assumptions will be included. Discussions on the genericity of these assumptions will be separately addressed.

We will consider as unperturbed pencil a singular $m \times n$ matrix pencil $P(\lambda)$ without full rank, i.e., $\operatorname{rank}(P) < \min\{m, n\}$. Given an integer number $\rho$ such that

$$0 < \rho \leq \min\{m, n\} - \operatorname{rank}(P), \tag{1}$$

and $\rho \leq \operatorname{rank}(P)$, the set of perturbations is restricted to pencils $Q(\lambda)$ with $\operatorname{rank}(Q) = \rho$. Notice that (1) and $\rho \leq \operatorname{rank}(P)$ are both low rank conditions imposed on the perturbations. Here, the rank has to be understood as the rank of matrix polynomials, which is also known as the *normal rank* of a pencil.

For the set of perturbations defined in the previous paragraph the first problem we deal with is to get information on the generic regular part of the perturbed pencil $(P+Q)(\lambda)$. This is addressed in section 4, where it is proved that, generically, if $\lambda_0$ is an eigenvalue of $P(\lambda)$, finite or infinite, then $\lambda_0$ is also an eigenvalue of $(P+Q)(\lambda)$ with partial multiplicities greater than or equal to the corresponding partial multiplicities of $\lambda_0$ relative to $P(\lambda)$. These results are consequences of Theorem 4.4, *[illegible]*. The second problem we deal with is to get information on the generic minimal indices of $(P+Q)(\lambda)$. For the sake of brevity, let us summarize the results only for the column or right minimal indices. Similar results hold for the row minimal indices. It is known that the number of column minimal indices of $P(\lambda)$ is $n - \operatorname{rank}(P)$. The initial result we present is that, generically, $P + Q$ has $n - \operatorname{rank}(P) - \rho$ column minimal indices. This implies, in particular, that if $\rho = n - \operatorname{rank}(P)$, then $P + Q$ has no column minimal indices; i.e., it has full column rank. These results follow from Theorem 3.1 and its direct consequence, Corollary 3.2. The case $\rho < n - \operatorname{rank}(P)$ is much more difficult, and it is addressed in Theorem 5.8, where all the column minimal indices of $P + Q$ are generically determined if, apart from the rank, the sum of the column minimal indices of the perturbations $Q(\lambda)$ is known. As a corollary, Theorem 5.10 presents generic partial information on the column minimal indices of $P + Q$ when $\rho = \operatorname{rank}(Q)$ is the only property known on the perturbations. Loosely speaking, one can say that the generic column minimal indices of $P + Q$ are equal to or greater than the $n - \operatorname{rank}(P) - \rho$ largest column minimal indices of $P$. Theorems 5.8 and 5.10 constitute [illegible]. All the results previously described remain valid in the limit case

$$\rho = \min\{m, n\} - \operatorname{rank}(P).$$

If the strict inequality is assumed in (1), i.e., $\operatorname{rank}(P) + \operatorname{rank}(Q) < \min\{m, n\}$, it is possible to fully determine the generic KCF of $(P + Q)(\lambda)$ in terms of the sums of the column and row minimal indices and of the regular part of the KCF of $Q(\lambda)$. In the case that $\operatorname{rank}(Q)$ is the only information available on the perturbations, the generic KCF of $(P + Q)(\lambda)$ can only be partially determined. These results appear in Theorems 6.2 and 6.3, which are [illegible]. It should be stressed that all the generic results on the KCF of $(P + Q)(\lambda)$ that we present are very easy to describe, although to prove that they occur under certain generic sufficient conditions is a hard task that requires techniques very different from those used in [4, 13].

The class of low rank perturbations considered in this work includes very interesting problems. To cite one of them: the study of the generic variation of the minimal indices of a square pencil ($m = n$) under low rank perturbations requires necessarily the assumptions $\operatorname{rank}(P) < n$ (because otherwise $P(\lambda)$ has no minimal indices) and $\operatorname{rank}(P) + \operatorname{rank}(Q) < n$ (because otherwise generically $\operatorname{rank}(P + Q) = n$ and $P + Q$ has no minimal indices). However, this class of perturbations does not cover all the relevant situations. There are still open problems in the area of generic low rank perturbations of spectral canonical forms. Some of them will be discussed in section 7, where we will explain why the results obtained in this paper are, apart from being relevant by themselves, an essential step towards the solution of new open problems.

The perturbations considered in this work are not of small norm. The change of KCF of matrix pencils under small normwise perturbations was studied in [14], where the set of Kronecker structures nearby to a given one was characterized in terms of some majorization conditions on the sequences of column and row minimal indices and on the regular structure. Further results of this kind were obtained in [2] and [5].

Low rank perturbations of spectral properties have appeared in several applied problems. For instance, in the area of structural modifications of dynamical systems, it is of particular relevance to study how a system must be modified in order to fix certain eigenvalues in the new system. This is known generically as the "pole-zero assignment" problem [15]. In [7], low rank perturbations of the damping matrices of vibrating systems are considered in order to obtain defective systems.

The paper is organized as follows. In section 2 the notation and some preliminary results are introduced. In section 3 the meaning and genericity of the low rank assumptions used in different sections of this work are discussed, and, as a consequence, the generic number of row and column minimal indices of the perturbed pencil is determined. In section 4 generic properties of the regular structure of the perturbed pencil $(P + Q)(\lambda)$ are established. Section 5 deals with the minimal indices of $(P + Q)(\lambda)$. Section 6 describes the whole generic KCF of $(P + Q)(\lambda)$, assuming that the strict inequality $\rho < \min\{m, n\} - \operatorname{rank}(P)$ holds. Finally, in section 7 the conclusions and some open profblems are presented.

**2. Notation, definitions, and preliminary results.** Several basic definitions and results are presented in this section. Some of them are well known and are stated just to establish the notation used throughout the paper. In addition, some other definitions and elementary results are presented.

**2.1. Kronecker canonical form and rank of a pencil.** We begin by introducing the concepts of singular pencil, rank or normal rank of a pencil, and eigenvalue of a pencil.

[illegible] singular [illegible] $m \neq n$ [illegible] $m = n$ [illegible] $\det(P(\lambda))$ [illegible] $\lambda$ [illegible] regular

DEFINITION 2.2. [illegible] $P(\lambda)$ [illegible] $\lambda$ [illegible] $P(\lambda)$ [illegible] $\operatorname{rank}(P)$ [illegible] $\lambda$

The [illegible] of a pencil is also called its [illegible] [2, 5]. However, we prefer the classical name [illegible], because this concept corresponds to the usual rank of matrices whose entries are rational functions of $\lambda$.

DEFINITION 2.3. [illegible] $\mu$ [illegible] $P(\lambda)$ [illegible] $P(\mu)$ [illegible] $\operatorname{rank}(P)$ [illegible] $P(\lambda) = A_0 + \lambda A_1$ [illegible] infinite [illegible] dual pencil $A_1 + \lambda A_0$

For every pencil $P(\lambda)$ there exist two nonsingular matrices $R \in \mathbb{C}^{m\times m}$ and $S \in \mathbb{C}^{n\times n}$ such that $R\,P(\lambda)\,S = \mathcal{K}_P(\lambda)$ is the KCF of $P(\lambda)$ (see [8, Chapter XII]). The KCF is a block diagonal matrix and is unique up to permutations of the diagonal blocks. To be more precise,

$$\mathcal{K}_P(\lambda) = \operatorname{diag}(L_{\varepsilon_1}, \ldots, L_{\varepsilon_p}, L^T_{\eta_1}, \ldots, L^T_{\eta_q}, \mathcal{J}_P), \tag{3}$$

where $L_{\varepsilon_i}$ is the $\varepsilon_i \times (\varepsilon_i + 1)$ matrix pencil

$$L_{\varepsilon_i} = \begin{bmatrix} \lambda & 1 & & & \\ & \lambda & 1 & & \\ & & \ddots & \ddots & \\ & & & \lambda & 1 \end{bmatrix},$$

the superscript $T$ means transposition, and $\mathcal{J}_P$ is a square pencil that constitutes the [illegible] of the KCF of $P(\lambda)$. The matrix pencil $\mathcal{J}_P$ contains the spectral information on the eigenvalues of $P(\lambda)$. This means that $\mathcal{J}_P$ is a direct sum of Jordan blocks

$$J_k(\lambda_i) = \begin{bmatrix} \lambda-\lambda_i & 1 & & \\ & \lambda-\lambda_i & \ddots & \\ & & \ddots & 1 \\ & & & \lambda-\lambda_i \end{bmatrix}_{k\times k},$$

associated with certain finite eigenvalues $\lambda_i \in \mathbb{C}$ of $P(\lambda)$, and, eventually, of Jordan blocks associated with the infinite eigenvalue

$$J_k(\infty) = \begin{bmatrix} 1 & \lambda & & \\ & 1 & \ddots & \\ & & \ddots & \lambda \\ & & & 1 \end{bmatrix}_{k\times k}.$$

The numbers $\varepsilon_1, \ldots, \varepsilon_p$ are called the *column minimal indices of* $P(\lambda)$, and $\eta_1, \ldots, \eta_q$ are called the *row minimal indices of* $P(\lambda)$ [8, Chapter XII]. Notice that the row minimal indices of $P(\lambda)$ are the column minimal indices of $P(\lambda)^T$ and vice versa. We will assume that they are indexed in nondecreasing order, i.e.,

$$0 \le \varepsilon_1 \le \varepsilon_2 \le \cdots \le \varepsilon_p \quad \text{and} \quad 0 \le \eta_1 \le \eta_2 \le \cdots \le \eta_q.$$

Analogously the matrix pencils $L_{\varepsilon_i}$ ($L_{\eta_j}^T$) are called the column or right (row or left) singular blocks of the KCF of $P(\lambda)$. These blocks reveal the *singular structure* of $P(\lambda)$.

Observe that, if the KCF of $P(\lambda)$ is given by (3), then

$$\operatorname{rank}(P) = n - p = m - q; \tag{4}$$

i.e., the rank of a pencil is related to the number of column and row singular blocks in its KCF. Notice also that if $\mathcal{J}_P$ is a $j \times j$ pencil, then

$$\operatorname{rank}(P) = j + \varepsilon_1 + \cdots + \varepsilon_p + \eta_1 + \cdots + \eta_q. \tag{5}$$

**2.2. The vector space of $n$-tuples of rational functions. Minimal bases.** The entries of an $m \times n$ pencil $P(\lambda) = A_0 + \lambda A_1$ are polynomials of degree one over $\mathbb{C}$. Moreover, it is well known that the column (row) minimal indices of $P(\lambda)$ are related to the degrees of certain polynomial solutions of $(A_0 + \lambda A_1)x(\lambda) = 0$ ($(A_0 + \lambda A_1)^T y(\lambda) = 0$) [8, Chapter XII], where $x(\lambda)$ ($y(\lambda)$) is an $n$-tuple ($m$-tuple) whose entries are polynomials. The vector $x(\lambda)$ will be called a *vector polynomial*. Previous comments make clear that vector polynomials can naturally arise in dealing with singular pencils. The set of polynomials with complex coefficients is a *ring* but not a *field*. This means that to extend many elementary ideas of linear algebra to vector polynomials one has to consider the field of all rational functions with complex coefficients. For instance, let $v_1 = [1+\lambda, 1+\lambda]^T$ and $v_2 = [1+\lambda^2, 1+\lambda^2]^T$ be two vector polynomials. The determinant of the matrix $[v_1|v_2]$ is obviously zero, but a rational function has to be necessarily used as a coefficient to express $v_2$ as a linear combination of $v_1$: $v_2 = \frac{1+\lambda^2}{1+\lambda} v_1$. The *field of rational functions* with complex coefficients will be denoted by $\mathbb{C}(\lambda)$, and the *vector space* over $\mathbb{C}(\lambda)$ *of* $n$-*tuples of rational functions* will be denoted by $\mathbb{C}^n(\lambda)$.

The following definitions are taken from [6] (see also [11]). The *degree*, $\deg(x)$, *of a vector polynomial* $x(\lambda)$ is the greatest degree of its components. Every vector subspace $\mathcal{V}$ of $\mathbb{C}^n(\lambda)$ always has a basis consisting of vector polynomials. It can be obtained from a general basis simply by multiplying each vector by the denominators of its entries. The *order* of such a polynomial basis is defined as the sum of the degrees of its vectors. A *minimal basis* of $\mathcal{V}$ is a polynomial basis of $\mathcal{V}$ that has least order among all polynomial bases of $\mathcal{V}$.

Let us introduce some additional concepts that we will use very often. Given an $m \times n$ matrix pencil $P(\lambda) = A_0 + \lambda A_1$, the [illegible] $P(\lambda)$ is the subspace of $\mathbb{C}^n(\lambda)$ ($\mathbb{C}^m(\lambda)$), $\mathcal{N}(P) = \{x(\lambda) \in \mathbb{C}^n(\lambda) : P(\lambda)x(\lambda) = 0\}$ ($\mathcal{N}(P^T) = \{y(\lambda) \in \mathbb{C}^m(\lambda) : P^T(\lambda)y(\lambda) = 0\}$). A [illegible] of $P(\lambda)$ is a [illegible] contained in $\mathcal{N}(P)$ ($\mathcal{N}(P^T)$). A [illegible] $P(\lambda)$ [illegible] is a minimal basis, $\{x_1(\lambda), \dots, x_p(\lambda)\}$, of $\mathcal{N}(P)$ with $\deg(x_1) \leq \deg(x_2) \leq \cdots \leq \deg(x_p)$. A [illegible] $P(\lambda)$ [illegible] is a minimal basis, $\{y_1(\lambda), \dots, y_q(\lambda)\}$, of $\mathcal{N}(P^T)$ with $\deg(y_1) \leq \deg(y_2) \leq \cdots \leq \deg(y_q)$.

Lemma 2.4 shows that the degrees of the vectors in an ROMB (LOMB) of $P(\lambda)$ are equal to the column (row) minimal indices of $P(\lambda)$.

Lemma 2.4. [illegible] $\varepsilon_1 \leq \cdots \leq \varepsilon_p$ [illegible] $\eta_1 \leq \cdots \leq \eta_q$ [illegible] $P(\lambda)$ [illegible] $\{x_1(\lambda), \dots, x_p(\lambda)\}$ [illegible] $\{y_1(\lambda), \dots, y_q(\lambda)\}$ [illegible] $P(\lambda)$ [illegible] $\deg(x_i)$ [illegible] $\varepsilon_i$ [illegible] $i = 1, \dots, p$ [illegible] $\deg(y_j)$ [illegible] $\eta_j$ [illegible] $j = 1, \dots, q$

[illegible]. We prove the result for the column minimal indices. For the row minimal indices simply use $P^T(\lambda)$ and invoke the result for column minimal indices. Let us recall [8, Chapter XII, p. 38] the relationship between the column minimal indices of $P(\lambda)$ and the polynomial solutions of $P(\lambda)x(\lambda) = 0$. Among all the polynomial solutions of this system of equations we choose a nonzero solution $z_1(\lambda)$ of least degree. This degree is $\varepsilon_1$. Among all the polynomial solutions that are linearly independent of $z_1(\lambda)$ we take a solution $z_2(\lambda)$ of least degree. This degree is $\varepsilon_2$. We continue this process until we get a [illegible] $\{z_1(\lambda), \dots, z_p(\lambda)\}$, i.e., $p = \dim \mathcal{N}(P)$ linearly independent polynomial solutions of $P(\lambda)x(\lambda) = 0$ of degrees $\varepsilon_1 \leq \cdots \leq \varepsilon_p$. A fundamental series of solutions is not uniquely determined, but the degrees of its vectors are, and, as we prove in the next paragraph, every fundamental series of solutions is an ROMB and vice versa.

Let us assume that there exists some index $j$ such that $\deg(x_j) < \varepsilon_j$. Let $j_0$ be the least of these indices, i.e., $\deg(x_{j_0}) < \varepsilon_{j_0}$ and $\deg(x_k) \geq \varepsilon_k$ for $k = 1, \dots, j_0 - 1$. Obviously $j_0 > 1$. Therefore, $\varepsilon_{j_0-1} \leq \deg(x_{j_0-1}) \leq \deg(x_{j_0}) < \varepsilon_{j_0}$. The definition of the minimal indices implies that the linearly independent vectors $\{x_1(\lambda), \dots, x_{j_0}(\lambda)\}$ are linear combinations of $\{z_1(\lambda), \dots, z_{j_0-1}(\lambda)\}$. This is impossible. Then $\deg(x_j) \geq \varepsilon_j$ for all $j = 1, \dots, p$, and, in fact, $\deg(x_j) = \varepsilon_j$ for all $j$, because $\{x_1(\lambda), \dots, x_p(\lambda)\}$ is an ROMB. $\square$

We will also use the following related lemma.

Lemma 2.5. [illegible] $P(\lambda)$ [illegible] (3) [illegible] $\{x_1(\lambda), \dots, x_p(\lambda)\}$ [illegible] $P(\lambda)$ [illegible] $P(\lambda)$ [illegible] $\varepsilon_i$ [illegible] $\{x_1(\lambda), \dots, x_j(\lambda)\}$ [illegible] polynomial coefficients [illegible] $j$ [illegible] $\deg(x_j) \leq \varepsilon_i$ [illegible] $P(\lambda)$ [illegible] $\{x_1(\lambda), \dots, x_p(\lambda)\}$ [illegible] polynomial coefficients [illegible]

[illegible]. The fact that every right null space vector is a linear combination of the mentioned vectors is a straightforward consequence of the definition of minimal indices. The fact that the coefficients are polynomials follows from [6, Main Theorem, p. 495]. $\square$

We will need to ascertain the linear independence of some sets of vector polynomials of $\mathbb{C}^n(\lambda)$. In some situations, this problem can be solved through a standard linear independence problem in $\mathbb{C}^n$. This is shown by Lemma 2.6.

Lemma 2.6. [illegible] $\{v_1(\lambda), \dots, v_r(\lambda)\}$ [illegible] $\mathbb{C}^n(\lambda)$ [illegible]

[illegible]

$$v_i(\lambda) = v_{i0} + \lambda\, v_{i1} + \cdots + \lambda^{d_i}\, v_{id_i} \quad \text{for } 1 \leq i \leq r,$$

[illegible] $v_{ij} \in \mathbb{C}^n$ [illegible] $i, j$ [illegible] $d_i = \deg(v_i(\lambda))$

1. [illegible] $\{v_{10}, \dots, v_{r0}\}$ [illegible] $\mathbb{C}^n$ [illegible] $\{v_1(\lambda), \dots, v_r(\lambda)\}$ [illegible] $\mathbb{C}^n(\lambda)$
2. [illegible] $\{v_{1d_1}, \dots, v_{rd_r}\}$ [illegible] $\mathbb{C}^n$ [illegible] $\{v_1(\lambda), \dots, v_r(\lambda)\}$ [illegible] $\mathbb{C}^n(\lambda)$

[illegible] To prove the first item, the linear combination

$$\alpha_1(\lambda)\, v_1(\lambda) + \cdots + \alpha_r(\lambda) v_r(\lambda) = 0 \tag{6}$$

is considered, where $\alpha_i(\lambda)$, $1 \leq i \leq r$, can be chosen to be polynomials, because if they were rational functions, one could multiply by their denominators. Let us express these polynomials as

$$\alpha_i(\lambda) = \alpha_{i0} + \lambda\, \alpha_{i1} + \cdots + \lambda^{t_i}\, \alpha_{it_i} \quad \text{for } 1 \leq i \leq r,$$

where $\alpha_{ij} \in \mathbb{C}$ for all $i, j$. Therefore, the coefficient vector of the term of degree zero in (6) is

$$\sum_{i=1}^{r} \alpha_{i0} v_{i0} = 0.$$

If $\{v_{10}, \dots, v_{r0}\}$ is a linearly independent set in $\mathbb{C}^n$, then $\alpha_{10} = \alpha_{20} = \cdots = \alpha_{r0} = 0$. Thus, the coefficient vector of the term of degree one in (6) is $\sum_{i=1}^{r} \alpha_{i1} v_{i0} = 0$; this implies $\alpha_{11} = \alpha_{21} = \cdots = \alpha_{r1} = 0$. A simple inductive argument completes the proof of the first item. To prove the second item one simply begins with the coefficient of the term with greatest degree, and performs downward the inductive step. ☐

We finish this section with another technical result on the linear independence of vector polynomials.

LEMMA 2.7. [illegible] $\{z_1(\lambda), \dots, z_k(\lambda)\}$ $k < n$ [illegible] $\mathbb{C}^n(\lambda)$ [illegible] $\{z_1'(\lambda), \dots, z_l'(\lambda)\}$ [illegible] $\mathbb{C}^n(\lambda)$ [illegible] $k + l \leq n$ [illegible] $\operatorname{rank}[z_1(\lambda)| \dots |z_k(\lambda)|z_1'(\lambda)| \dots |z_l'(\lambda)] = k$ [illegible] $\{u_1, \dots, u_n\}$ [illegible] $\mathbb{C}^n$ [illegible] $(u_i)_j = \delta_{ij}$ [illegible] $l$ [illegible] $u_{j_1}, \dots, u_{j_l}$ [illegible] $\{z_1(\lambda), \dots, z_k(\lambda), z_1'(\lambda) + \alpha_1 u_{j_1}, \dots, z_l'(\lambda) + \alpha_l u_{j_l}\}$ [illegible] $\mathbb{C}^n(\lambda)$ [illegible] $\alpha_1, \dots, \alpha_l$

[illegible] There exists at least one $u_{j_1}$ such that $\{z_1(\lambda), \dots, z_k(\lambda), u_{j_1}\}$ is linearly independent because, otherwise, all the vectors in $\{u_1, \dots, u_n\}$ would be linear combinations of $\{z_1(\lambda), \dots, z_k(\lambda)\}$. This is impossible because $\{u_1, \dots, u_n\}$ is also a basis of $\mathbb{C}^n(\lambda)$ and $k < n$. This argument can be successively applied to prove that there exist $u_{j_1}, \dots, u_{j_l}$ vectors of the canonical basis such that $\{z_1(\lambda), \dots, z_k(\lambda), u_{j_1}, \dots, u_{j_l}\}$ is linearly independent. Thus $\{z_1(\lambda), \dots, z_k(\lambda), \alpha_1 u_{j_1}, \dots, \alpha_l u_{j_l}\}$ is linearly independent for all nonzero complex numbers $\alpha_1, \dots, \alpha_l$. Notice that the assumption $\operatorname{rank}[z_1(\lambda)| \dots |z_k(\lambda)|z_1'(\lambda)| \dots |z_l'(\lambda)] = k$ implies that the vectors $z_i'(\lambda)$ are linear combinations of $\{z_1(\lambda), \dots, z_k(\lambda)\}$ with coefficients in $\mathbb{C}(\lambda)$. Therefore, elementary column operations can be used to transform the matrix $[z_1(\lambda)| \dots |z_k(\lambda)|\alpha_1 u_{j_1}| \dots |\alpha_l u_{j_l}]$ into $[z_1(\lambda)| \dots |z_k(\lambda)|z_1'(\lambda) + \alpha_1 u_{j_1}| \dots |z_l'(\lambda) + \alpha_l u_{j_l}]$. This does not change the rank of the matrix, which proves the result. ☐

**2.3. Expansion of a pencil as sum of rank-one pencils.** The expansion presented in Lemma 2.8 will play a key role in this paper.

LEMMA 2.8. [illegible] $Q(\lambda)$ [illegible] $m \times n$ [illegible] $\rho$ [illegible] $\widetilde{\varepsilon}$ [illegible] $Q(\lambda)$ [illegible]

$$Q(\lambda) = v_1(\lambda)w_1(\lambda)^T + \cdots + v_\rho(\lambda)w_\rho(\lambda)^T, \tag{7}$$

[illegible]

(i) $\{v_1(\lambda), \dots, v_\rho(\lambda)\}$ [illegible] $\mathbb{C}^m(\lambda)$ [illegible]

(ii) $\{w_1(\lambda), \dots, w_\rho(\lambda)\}$ [illegible] $\mathbb{C}^n(\lambda)$ [illegible]

(iii) [illegible] $v_i(\lambda)w_i(\lambda)^T$ $1 \le i \le \rho$ [illegible] $m \times n$ [illegible] $v_i(\lambda)$ [illegible] $w_i(\lambda)$ [illegible]

(iv) [illegible] $\widetilde{\varepsilon}$ [illegible] $w_1(\lambda), \dots, w_\rho(\lambda)$ [illegible] $w_i(\lambda)$ [illegible]

[illegible] (7) [illegible] right decomposition of $Q(\lambda)$ [illegible] $Q(\lambda)$ [illegible] $\rho$ [illegible] $\widetilde{\varepsilon}$ [illegible] $w_1(\lambda), \dots, w_\rho(\lambda)$ [illegible]

[illegible]. The result is a direct consequence of the KCF. Let the KCF of $Q$ be

$$\mathcal{K}_Q(\lambda) = \operatorname{diag}(L_{\widetilde{\varepsilon}_1}, \dots, L_{\widetilde{\varepsilon}_h}, L_{\widetilde{\eta}_1}^T, \dots, L_{\widetilde{\eta}_l}^T, \mathcal{J}_Q),$$

where $\mathcal{J}_Q$ is the regular structure of $Q(\lambda)$ and there exist two nonsingular matrices, $X$ and $Y$, such that $Q(\lambda) = X\mathcal{K}_Q(\lambda)Y$. Now, notice that a block $L_{\widetilde{\varepsilon}_i}$ can be expanded as a sum of $\widetilde{\varepsilon}_i$ rank-one pencils,

$$\begin{bmatrix} \lambda & 1 & & & \\ & \lambda & 1 & & \\ & & \ddots & \ddots & \\ & & & \lambda & 1 \end{bmatrix} = \begin{bmatrix} 1 \\ 0 \\ \vdots \\ 0 \end{bmatrix} \begin{bmatrix} \lambda & 1 & \dots & 0 \end{bmatrix} + \cdots + \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 1 \end{bmatrix} \begin{bmatrix} 0 & \dots & \lambda & 1 \end{bmatrix},$$

where the row (column) vectors have degree equal to one (zero). An expansion for a block $L_{\widetilde{\eta}_j}^T$ is obtained by transposition, but now the column (row) vectors have degree equal to one (zero). For the Jordan blocks in $\mathcal{J}_Q$, corresponding to finite or infinite eigenvalues, similar expansions with row vectors of degree zero are possible. All these expansions can be combined with $Q(\lambda) = X\mathcal{K}_Q(\lambda)Y$ to prove straightforwardly the four items of the lemma.

Let us prove now the fact that any other decomposition of $Q(\lambda)$ as a sum of $\rho$ rank-one matrix pencils contains at least $\widetilde{\varepsilon}$ vectors among $w_1(\lambda), \dots, w_\rho(\lambda)$ with degree exactly one. Notice that the set of solutions of $Q(\lambda)x(\lambda) = 0$ is equal to the set of solutions of $[w_1(\lambda), \dots, w_\rho(\lambda)]^T x(\lambda) = 0$, and therefore the column minimal indices of the pencils $Q(\lambda)$ and $D_0 + \lambda D_1 \equiv [w_1(\lambda), \dots, w_\rho(\lambda)]^T$ are equal. If there were less than $\widetilde{\varepsilon}$ vectors among $w_1(\lambda), \dots, w_\rho(\lambda)$ with degree exactly one, then $\operatorname{rank}(D_1) < \widetilde{\varepsilon}$. This implies that the matrix coefficient of $\lambda$ in the KCF of $[w_1(\lambda), \dots, w_\rho(\lambda)]^T$ has also rank smaller than $\widetilde{\varepsilon}$. This is in contradiction with $\widetilde{\varepsilon}$ being the sum of its column minimal indices. □

[illegible] 1. A result similar to that in Lemma 2.8 can be obtained by considering the sum of the row (or left) minimal indices, $\widetilde{\eta}$, of $Q(\lambda)$ and choosing the column vectors of the expansions of the Jordan blocks in $\mathcal{J}_Q$ to be of degree zero. In this case, we will consider a [illegible] of $Q(\lambda)$:

$$Q(\lambda) = \widehat{v}_1(\lambda)\widehat{w}_1(\lambda)^T + \cdots + \widehat{v}_\rho(\lambda)\widehat{w}_\rho(\lambda)^T, \tag{8}$$

where the vectors $\{\widehat{v}_1(\lambda), \ldots, \widehat{v}_\rho(\lambda)\}$ and $\{\widehat{w}_1(\lambda), \ldots, \widehat{w}_\rho(\lambda)\}$ have the properties appearing in items (i), (ii), and (iii) of Lemma 2.8, but (iv) is replaced by "there are $\widetilde{\eta}$ vectors among $\{\widehat{v}_i(\lambda), \ldots, \widehat{v}_\rho(\lambda)\}$ with degree exactly one, and the remaining vectors are of degree zero." Notice that left and right decompositions are not unique. Besides, a left decomposition of $Q(\lambda)$ may not be simultaneously a right decomposition.

[illegible] 1. Let us show right and left decompositions of a pencil with $\widetilde{\varepsilon} = 1$, $\widetilde{\eta} = 0$, and $\rho = 2$:

$$\begin{bmatrix} \lambda & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & \lambda \end{bmatrix} = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} \begin{bmatrix} \lambda & 1 & 0 \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ \lambda \end{bmatrix} \begin{bmatrix} 0 & 0 & 1 \end{bmatrix},$$

$$\begin{bmatrix} \lambda & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & \lambda \end{bmatrix} = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} \begin{bmatrix} \lambda & 1 & 0 \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} \begin{bmatrix} 0 & 0 & \lambda \end{bmatrix}.$$

### 2.4. Jordan blocks, invariant polynomials, elementary divisors, and dual pencils.

Given an arbitrary $m \times n$ complex matrix pencil $P(\lambda)$ with rank $r$, there exist two matrix polynomials $U(\lambda)$ and $V(\lambda)$ with dimensions $m \times m$ and $n \times n$, respectively, and nonzero constant determinants, such that

$$U(\lambda)P(\lambda)V(\lambda) = \operatorname{diag}(h_1(P), \ldots, h_r(P), 0, \ldots, 0), \tag{9}$$

where $h_i(P)$ are nonzero monic polynomials in $\lambda$ satisfying $h_i(P) | h_{i+1}(P)$; i.e., $h_i(P)$ divides $h_{i+1}(P)$ for $i = 1, \ldots, r-1$ [8, Chapter VI]. These polynomials are called the [illegible] of $P(\lambda)$, and the diagonal matrix in the right-hand side of (9) is called the [illegible] of $P(\lambda)$. This form is unique and, in fact, [illegible] and not only for pencils. If each

$$h_i(P) = (\lambda - \lambda_1)^{\nu_{i1}} \cdot \cdots \cdot (\lambda - \lambda_d)^{\nu_{id}} \quad \text{for } i = 1, \ldots, r \tag{10}$$

is decomposed in powers of different irreducible factors, then those factors among $(\lambda-\lambda_1)^{\nu_{11}}, \ldots, (\lambda-\lambda_d)^{\nu_{1d}}, \ldots, (\lambda-\lambda_1)^{\nu_{r1}}, \ldots, (\lambda-\lambda_d)^{\nu_{rd}}$ with $\nu_{ij} > 0$ are called the [illegible] $P(\lambda)$. There exists a close relationship between the elementary divisors and the dimensions of the Jordan blocks associated with the finite eigenvalues in the regular structure of the KCF of the pencil $P(\lambda)$. This is revealed by the following result. It is a simple consequence of the theory developed in [8, Chapter VI].

LEMMA 2.9. [illegible] $P(\lambda)$ [illegible] $m \times n$ [illegible] $(\lambda-\lambda_j)^{\nu_{ij}}$ [illegible] $P(\lambda)$ [illegible] $\nu_{ij}$ [illegible] $\lambda_j$ [illegible] $P(\lambda)$ [illegible] $\nu_{ij}$ [illegible] $\lambda_j$ [illegible] $P(\lambda)$ [illegible] $(\lambda - \lambda_j)^{\nu_{ij}}$

The reader should notice that Lemma 2.9 gives no information for the infinite eigenvalue of the pencil $P(\lambda)$. This information can be obtained from the zero eigenvalue of the [illegible] through Lemma 2.10, whose trivial proof is omitted.

LEMMA 2.10. [illegible] $A$ [illegible] $B$ [illegible] $m \times n$ [illegible] $A + \lambda B$ [illegible] $B + \lambda A$ [illegible] $A + \lambda B$ [illegible] $B + \lambda A$ [illegible]

Given an eigenvalue $\lambda_j$ of the pencil $P(\lambda)$, the exponents $0 \leq \nu_{1j} \leq \nu_{2j} \leq \cdots \leq \nu_{rj}$ in (10) are called the [illegible] of $\lambda_j$ relative to $P$, and if a number $\mu$ [illegible] an eigenvalue of $P(\lambda)$, then all its partial multiplicities relative to $P$ are defined as zero [9, p. 331]. Anyway, for any number $\lambda_0$ its partial multiplicities relative to $P$ coincide with the dimensions of the Jordan blocks associated with $\lambda_0$ in the regular structure of the KCF of $P(\lambda)$, whenever Jordan blocks of zero dimension are admitted as nonexisting blocks. This also holds for the infinite eigenvalue. The partial multiplicities of an eigenvalue $\lambda_0$, [illegible], of $P(\lambda)$ with $g$ associated Jordan blocks in the KCF are usually arranged in an infinite sequence called [illegible] of $\lambda_0$ relative to $P(\lambda)$. This sequence is

$$\mathcal{S}_P(\lambda_0) = (n_g(\lambda_0), n_{g-1}(\lambda_0), \ldots, n_1(\lambda_0), 0, \ldots),$$

where $n_g(\lambda_0) \geq n_{g-1}(\lambda_0) \geq \cdots \geq n_1(\lambda_0)$ are the dimensions of the Jordan blocks associated with $\lambda_0$ in the KCF of $P(\lambda)$. Notice that in the case when $\lambda_0$ [illegible] $P(\lambda)$, all the terms in $\mathcal{S}_P(\lambda_0)$ are equal to zero.

The concepts of partial multiplicities and Segre characteristics are also valid for [illegible]. The eigenvalues of a matrix polynomial can be defined as the roots of its invariant polynomials. Given two matrix polynomials $P(\lambda)$ and $Q(\lambda)$, we write

$$\mathcal{S}_P(\lambda_0) \geq \mathcal{S}_Q(\lambda_0) \quad \text{if} \quad (\mathcal{S}_P(\lambda_0))_i \geq (\mathcal{S}_Q(\lambda_0))_i \quad \text{for all } i > 0;$$

i.e., the inequality holds for each entry in the Segre characteristics.

The Smith canonical form (9) allows us to express every matrix polynomial $P(\lambda)$ of rank $r$ as

$$P(\lambda) = h_1(P)\, a_1(\lambda) z_1^T(\lambda) + \cdots + h_r(P)\, a_r(\lambda) z_r^T(\lambda), \tag{11}$$

where $h_1(P), \ldots, h_r(P)$ are its invariant polynomials and $a_i(\lambda)$ and $z_i(\lambda)$ are vector polynomials. Besides, according to (9), the vectors $a_i(\lambda)$ and $z_i(\lambda)$ are, respectively, the columns of $U^{-1}(\lambda)$ and $V^{-T}(\lambda)$. This implies that neither $a_i(\lambda)$ nor $z_i(\lambda)$ can be written as the product of a scalar polynomial of degree greater than zero times a vector polynomial, because the matrices $U^{-1}(\lambda)$ and $V^{-T}(\lambda)$ are matrix polynomials with constant nonzero determinants. Notice that in the case when $P(\lambda)$ [illegible] (11) [illegible] (7), in general, because the summands $h_i(P)\, a_i(\lambda) z_i^T(\lambda)$ have, in general, degree larger than one.

The KCF of the direct sum, $P(\lambda) \oplus Q(\lambda)$, of two pencils $P(\lambda)$ and $Q(\lambda)$ is the direct sum of the KCFs of $P(\lambda)$ and $Q(\lambda)$, up to some permutations of the diagonal blocks. Therefore, the Segre characteristic of $\lambda_0$ relative to $P(\lambda) \oplus Q(\lambda)$ is obtained simply by putting together the Segre characteristics of $\lambda_0$ relative to $P(\lambda)$ and to $Q(\lambda)$, and then reordering the resulting sequence. The same holds in the case when $P(\lambda)$and $Q(\lambda)$ are general matrix polynomials. This follows from [8, Chapter VI, Theorem 5].

**3. Low rank assumptions: Meaning and genericity.** Throughout this work we will deal with three $m \times n$ complex pencils: the fixed [illegible] pencil $P(\lambda)$, the [illegible] pencil $Q(\lambda)$, and the [illegible] pencil $(P+Q)(\lambda)$. The pencil $P(\lambda)$ does not have full rank, and its KCF will always be assumed to be known; it will be denoted by (3). We will frequently omit the variable $\lambda$ when there is no risk of confusion.

As announced in the Introduction, the set of perturbations we considered is the set of pencils

$$\mathcal{C} = \{Q(\lambda) \, : \, \operatorname{rank}(Q) = \rho\}, \tag{12}$$

where $\rho > 0$ is an integer such that

$$\operatorname{rank}(P) + \rho \leq \min\{m, n\} \tag{13}$$

and $\rho \leq \operatorname{rank}(P)$. These are the two low rank conditions imposed on the set of perturbations. Notice also that $\rho > 0$, and (13) implies that $\operatorname{rank}(P) < \min\{m, n\}$, i.e., that $P(\lambda)$ does not have full rank.

A key result in this work is that the property

$$\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q) \tag{14}$$

is generic in the set $\mathcal{C}$. This is rigorously proved in Theorem 3.1 below. By combining this result with the identity (4), one can say that, for perturbations in the set $\mathcal{C}$, the perturbed pencils $(P+Q)(\lambda)$ have generically $n - \operatorname{rank}(P) - \rho$ column minimal indices and $m - \operatorname{rank}(P) - \rho$ row minimal indices. See Corollary 3.2 below on this point.

Notice that, taking into account that $P+Q$ is an $m \times n$ pencil, the condition (14) implies $\operatorname{rank}(P) + \operatorname{rank}(Q) \leq \min\{m, n\}$, i.e., the assumption (13), and that $P(\lambda)$ does not have full rank for $Q(\lambda) \neq 0$, i.e., for nontrivial perturbations. These facts and the genericity of (14) in $\mathcal{C}$ lead us to impose $\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q)$ in most of the lemmas and theorems we prove, without explicitly mentioning the initial low rank condition (13).

Section 5 is devoted to studying the generic column minimal indices of $(P+Q)(\lambda)$. In section 5

$$\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q) < n \tag{15}$$

is assumed as a hypothesis in most of the results. Notice that (15) is implied by (14) only if $\min\{m, n\} = m < n$; otherwise (15) is an additional assumption. The reason for assuming (15) in section 5 is that, according to (4), the number of column minimal indices of $P+Q$ is $n - \operatorname{rank}(P+Q)$, which is zero if $\operatorname{rank}(P+Q) = n$. Therefore the study of the generic column minimal indices of $P+Q$ makes sense only if (15) holds. In the case of the row minimal indices, $m$ instead of $n$ has to be used in (15).

Finally, let us comment on the additional low rank assumption,

$$\rho = \operatorname{rank}(Q) \leq \operatorname{rank}(P).$$

This assumption is very natural for considering $Q(\lambda)$ as a low rank perturbation of $P(\lambda)$, and it is essential to guarantee that other hypotheses used in the study of the minimal indices of $P+Q$ are really [illegible]. This will be discussed in subsection 5.5.

### 3.1. Genericity of the assumption $\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q)$. Number of minimal indices of $P+Q$.

The purpose of this section is to present a rigorous proof of the genericity of the most pervasive and crucial assumption in this work. This assumption determines the generic number of row and column minimal indices of the perturbed pencil $(P+Q)(\lambda)$.

THEOREM 3.1. [illegible] $P(\lambda)$ [illegible] $m \times n$ [illegible] $\rho$ [illegible] $\operatorname{rank}(P) + \rho \leq \min\{m,n\}$ [illegible] $m \times n$ [illegible]

$$\mathcal{G} = \{Q(\lambda)\ m \times n \text{ [illegible]} : \operatorname{rank}(Q) = \rho \text{ [illegible]} \quad \operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q)\}$$

[illegible] $m \times n$ [illegible] $\rho$

[illegible]. First, let us prove that $\mathcal{G}$ is dense in the set of pencils with rank $\rho$. Notice that $\operatorname{rank}(P+E) \leq \operatorname{rank}(P) + \operatorname{rank}(E)$ for every pencil $E(\lambda)$. Therefore, we have to prove that for every pencil $E(\lambda)$ with rank $\rho$ and $\operatorname{rank}(P+E) < \operatorname{rank}(P) + \operatorname{rank}(E)$ there exists a sequence $\{Q^{(t)}(\lambda)\}_{t=1}^{\infty} \subset \mathcal{G}$ whose limit is $E(\lambda)$. Let $r \equiv \operatorname{rank}(P)$. According to (7), we can write

$$\begin{aligned} P(\lambda) &= v_1(\lambda)w_1(\lambda)^T + \cdots + v_r(\lambda)w_r(\lambda)^T, \\ E(\lambda) &= a_1(\lambda)b_1(\lambda)^T + \cdots + a_\rho(\lambda)b_\rho(\lambda)^T, \end{aligned}$$

and

$$(P+E)(\lambda) = [v_1|\dots|v_r|a_1|\dots|a_\rho]\ [w_1|\dots|w_r|b_1|\dots|b_\rho]^T,$$

where we have omitted some $\lambda$'s for simplicity. Elementary arguments show that $\operatorname{rank}(P+E) < \operatorname{rank}(P) + \operatorname{rank}(E) = r + \rho$ if and only if $\operatorname{rank}[v_1|\dots|v_r|a_1|\dots|a_\rho] < r+\rho$ or $\operatorname{rank}[w_1|\dots|w_r|b_1|\dots|b_\rho] < r+\rho$. Suppose that $\operatorname{rank}[v_1|\dots|v_r|a_1|\dots|a_\rho] < r+\rho$. This implies, due to the fact that the set $\{v_1,\dots,v_r\}$ is linearly independent, that

(i) $\operatorname{rank}[v_1|\dots|v_r|a_1|\dots|a_\rho] = r + \widehat{\rho}$ with $0 \leq \widehat{\rho} < \rho$; and

(ii) the vectors $a_1,\dots,a_\rho$ can be reordered as $a_{i_1},\dots,a_{i_{\widehat{\rho}}}, a_{k_1},\dots,a_{k_{\rho-\widehat{\rho}}}$, where $\{v_1,\dots,v_r,a_{i_1},\dots,a_{i_{\widehat{\rho}}}\}$ is a linearly independent set.

Now, Lemma 2.7 is used to show that there exist $\rho - \widehat{\rho}$ vectors, $u_{j_1},\dots,u_{j_{\rho-\widehat{\rho}}}$, of the canonical bases of $\mathbb{C}^m$ such that, for every $t = 1,2,\dots$,

$$\operatorname{rank}\left[v_1|\dots|v_r|a_{i_1}|\dots|a_{i_{\widehat{\rho}}}|a_{k_1} + \frac{1}{t}u_{j_1}|\dots|a_{k_{\rho-\widehat{\rho}}} + \frac{1}{t}u_{j_{\rho-\widehat{\rho}}}\right] = r + \rho.$$

Let $\{a_1^{(t)},\dots,a_\rho^{(t)}\}$ be the set of vectors that is obtained from $\{a_1,\dots,a_\rho\}$ by replacing $a_{k_1},\dots,a_{k_{\rho-\widehat{\rho}}}$ by $a_{k_1} + \frac{1}{t}u_{j_1},\dots,a_{k_{\rho-\widehat{\rho}}} + \frac{1}{t}u_{j_{\rho-\widehat{\rho}}}$. If $\operatorname{rank}[w_1|\dots|w_r|b_1|\dots|b_\rho] < r+\rho$, we proceed in a similar way to produce a set of vectors $\{b_1^{(t)},\dots,b_\rho^{(t)}\}$. Finally, let us define the sequence of pencils

$$Q^{(t)}(\lambda) = a_1^{(t)}(\lambda)(b_1^{(t)}(\lambda))^T + \cdots + a_\rho^{(t)}(\lambda)(b_\rho^{(t)}(\lambda))^T, \quad t = 1,2,\dots.$$

It is trivial to check that (i) $\lim_{t\to\infty} Q^{(t)}(\lambda) = E(\lambda)$; (ii) $\operatorname{rank}(Q^{(t)}) = \rho$ for all $t$; and (iii) $\operatorname{rank}(P+Q^{(t)}) = \operatorname{rank}(P) + \operatorname{rank}(Q^{(t)})$ for all $t$. This proves that $\mathcal{G}$ is dense.

Now, we will prove that $\mathcal{G}$ is open in the set of matrix pencils with rank $\rho$. To this purpose, let us proceed as follows: as explained in the Introduction, the set of $m \times n$ complex matrix pencils is identified with $\mathbb{C}^{2mn}$, and the set of matrix pencils with rank $\rho$ is a subset $\mathcal{C}$ of $\mathbb{C}^{2mn}$. Thus $\mathcal{G} \subset \mathcal{C} \subset \mathbb{C}^{2mn}$. We consider in $\mathcal{C}$ the [illegible] induced by the usual topology of $\mathbb{C}^{2mn}$, as we explained in the Introduction. Therefore, for proving that $\mathcal{G}$ is open in $\mathcal{C}$, it is sufficient to prove that every $Q(\lambda) \in \mathcal{G}$ is included in an open subset $\mathcal{X}_Q$ of $\mathbb{C}^{2mn}$ such that

$$\operatorname{rank}(P+E) \geq \operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q) \quad \text{for all } E \in \mathcal{X}_Q.$$

The reason is that in this case the following hold:

1. $\mathcal{X}_Q \cap \mathcal{C}$ is open in $\mathcal{C}$; and
2. the fact that $\operatorname{rank}(P) + \operatorname{rank}(Q) \leq \operatorname{rank}(P+E) \leq \operatorname{rank}(P) + \operatorname{rank}(E)$ for all $E \in \mathcal{X}_Q$ implies that $\operatorname{rank}(P+E) = \operatorname{rank}(P) + \operatorname{rank}(E)$ for all $E \in \mathcal{X}_Q \cap \mathcal{C}$. This means that $\mathcal{X}_Q \cap \mathcal{C} \subset \mathcal{G}$ and that $Q$ is an interior point of $\mathcal{G}$.

Let us see how $\mathcal{X}_Q \subset \mathbb{C}^{2mn}$ is constructed. Given $Q \in \mathcal{G}$, the equation $\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \rho \equiv r + \rho$ implies that the pencil $(P+Q)(\lambda)$ has a $(r+\rho)\times(r+\rho)$ minor that is a polynomial in $\lambda$ with at least one nonzero coefficient. Let $\det(P+Q)(\alpha,\beta)$ be this minor, where the sets $\alpha \subseteq \{1,\ldots,m\}$ and $\beta \subseteq \{1,\ldots,n\}$ denote, respectively, the rows and columns that define the minor. By identifying every pencil $E(\lambda) = E_0 + \lambda E_1$ with an element of $\mathbb{C}^{2mn}$, the coefficients of $\det(P+E)(\alpha,\beta)$ define a continuous function $f(E)$, $f : \mathbb{C}^{2mn} \longrightarrow \mathbb{C}^{r+\rho+1}$, because these coefficients are polynomials in the entries of the complex matrices $E_0$ and $E_1$. Taking into account that $f(Q) \neq 0$, there exists an open ball, $\mathcal{B}$, in $\mathbb{C}^{r+\rho+1}$ whose center is $f(Q)$ and such that $0 \notin \mathcal{B}$. Then we can take $\mathcal{X}_Q = f^{-1}(\mathcal{B})$, because it is open, $f(E) \neq 0$ for all $E \in \mathcal{X}_Q$, and, therefore, $\operatorname{rank}(P+E) \geq r+\rho$ for all $E \in \mathcal{X}_Q$. ☐

As a consequence of Theorem 3.1 and (4) the generic number of row and column minimal indices of $P+Q$ is determined.

Corollary 3.2. [illegible] $P(\lambda)$ [illegible] $m \times n$ [illegible] $p$ [illegible] $q$ [illegible] $\rho$ [illegible] $\operatorname{rank}(P) + \rho \leq \min\{m,n\}$ [illegible] $Q(\lambda)$ [illegible] $\operatorname{rank}(Q) = \rho$ [illegible] $P+Q$ [illegible] $p-\rho$ [illegible] $q-\rho$ [illegible] $m \times n$ [illegible] $\rho$

## 4. The regular structure of the perturbed pencil.

In this section we get information on the regular structure of the KCF of the perturbed pencil $(P+Q)(\lambda)$ in terms of the regular structures of $P(\lambda)$ and $Q(\lambda)$, i.e., $\mathcal{J}_P$ and $\mathcal{J}_Q$. With only the hypothesis $\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q)$, we prove that for every eigenvalue of $P$ or $Q$, the regular structure of $P+Q$ has as least as many blocks as $\mathcal{J}_P \oplus \mathcal{J}_Q$, with dimensions larger than or equal to the dimensions of the blocks in $\mathcal{J}_P \oplus \mathcal{J}_Q$. Besides, other blocks may be present. This is presented in Theorem 4.4, and it is our first major contribution. In section 6, we will see that the generic regular structure of $P+Q$ is precisely $\mathcal{J}_P \oplus \mathcal{J}_Q$ if $\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q) < \min\{m,n\}$.

In this section, the auxiliary lemma, Lemma 4.1, will be used. It appears without proof in [12]. The proof is elementary.

Lemma 4.1 (see [12, p. 799]). [illegible] $D = \operatorname{diag}(z_1,\ldots,z_k)$ [illegible] $k \times k$ [illegible]

$$\det(D+G) = \det G + \sum z_{\nu_1} \ldots z_{\nu_j} \cdot \det \breve{G}(\nu_1,\ldots,\nu_j),$$

[illegible] $j \in \{1,\ldots,k\}$ [illegible] $\nu_1,\ldots,\nu_j$ [illegible] $1 \leq \nu_1 < \cdots < \nu_j \leq k$ [illegible] $\breve{G}(\nu_1,\ldots,\nu_j)$ [illegible] $G$ [illegible] $\nu_1,\ldots,\nu_j$ [illegible] $\det \breve{G}(1,\ldots,k) \equiv 1$

Lemma 4.2 extends [18, Theorem 1] under more stringent assumptions.

Lemma 4.2. [illegible] $\mathcal{L}(\lambda)$ [illegible] $m \times n$ [illegible] $r$ [illegible] $e_1 \leq \cdots \leq e_r$ [illegible] $\lambda_0$ [illegible] $\mathcal{L}(\lambda)$ [illegible] $\mathcal{M}(\lambda)$ [illegible] $e$ [illegible] $\lambda_0$ [illegible] $\mathcal{M}(\lambda)$ [illegible] $\operatorname{rank}(\mathcal{L}+\mathcal{M}) = \operatorname{rank}(\mathcal{L}) + \operatorname{rank}(\mathcal{M})$ [illegible] $e_i < e \leq e_{i+1}$ [illegible] $i \in \{0, 1, \ldots, r\}$ [illegible] $e_0 \equiv -1$ [illegible] $e_{r+1} \equiv \infty$ [illegible] $f_1 \leq \cdots \leq f_{r+1}$ [illegible] $\lambda_0$ [illegible] $(\mathcal{L}+\mathcal{M})(\lambda)$ [illegible]

$$f_1 = e_1\,, \ldots, \, f_i = e_i, \quad e \leq f_{i+1}, \quad e_{i+1} \leq f_{i+2}\,, \ldots\,, \, e_r \leq f_{r+1}.$$

[illegible] 2. Notice that in Lemma 4.2 it is possible that $e_1 = \cdots = e_r = 0$ or that $e = 0$; i.e., $\lambda_0$ may not be an eigenvalue of $\mathcal{L}(\lambda)$ or of $\mathcal{M}(\lambda)$.

[illegible] 4.2 Theorem 1 in [18] implies that

$$e_1 \leq f_2\,, \, e_2 \leq f_3\,, \, \ldots\,, \, e_r \leq f_{r+1}.$$

So, we only need to prove that $f_1 = e_1, \ldots, f_i = e_i, e \leq f_{i+1}$. Let $U(\lambda)$ and $V(\lambda)$ be the matrix polynomials, with nonzero constant determinants, that transform $\mathcal{L}$ into its Smith normal form, i.e., $U(\lambda)\mathcal{L}(\lambda)V(\lambda) = \operatorname{diag}((\lambda-\lambda_0)^{e_1}p_1(\lambda), \ldots, (\lambda-\lambda_0)^{e_r}p_r(\lambda), 0, \ldots, 0)$, with the polynomials $p_1(\lambda), \ldots, p_r(\lambda)$ such that $p_j(\lambda_0) \neq 0$, for $j = 1, \ldots, r$. Invariant polynomials and partial multiplicities remain unchanged under multiplication by $U(\lambda)$ and $V(\lambda)$; therefore we can focus on the partial multiplicities of the matrix polynomial:

$$\begin{aligned} U(\lambda)(\mathcal{L}+\mathcal{M})(\lambda)V(\lambda) = {} & \operatorname{diag}((\lambda-\lambda_0)^{e_1}p_1(\lambda), \ldots, (\lambda-\lambda_0)^{e_r}p_r(\lambda), 0, \ldots, 0) \\ & + (\lambda-\lambda_0)^{e}x(\lambda)y(\lambda)^T, \end{aligned} \tag{16}$$

where the second term of the right-hand side is $U(\lambda)\mathcal{M}(\lambda)V(\lambda)$ (see (11)).

In the case $e_0 < e \leq e_1$, i.e., $i = 0$, the exponent of the factor $(\lambda - \lambda_0)$ of the greatest common divisor of all $1 \times 1$ minors in (16) is greater than or equal to $e$; thus $e \leq f_1$ by the definition of invariant polynomials [8, Chapter VI, section 3], and the result is proven. Let us assume from now on that $i \geq 1$. In the rest of the proof, we will prove that if $c_k$, $k = 1, \ldots, r+1$, denotes the exponent of the factor $(\lambda - \lambda_0)$ of the greatest common divisor of all $k \times k$ minors in (16), then

$$c_1 = e_1, \quad c_2 = e_1 + e_2\,, \ldots, \quad c_i = e_1 + \cdots + e_i, \quad c_{i+1} \geq e_1 + \cdots + e_i + e. \tag{17}$$

This and the definition of invariant polynomials imply $f_1 = e_1\,, \ldots, \, f_i = e_i\,, \, e \leq f_{i+1}$.

The lowest power of $(\lambda - \lambda_0)$ in a $1 \times 1$ minor of (16) is easily seen to be $e_1$, so $c_1 = e_1$. For $k \geq 2$, let us notice that all the nonzero $k \times k$ minors of (16) must contain at least $k-1$ of the $(1,1), \ldots, (r,r)$ diagonal entries. Then, a nonzero $k \times k$ minor of (16) must be of one of these two types:

(i)

$$\begin{aligned} \det \big( & \operatorname{diag}(\,(\lambda-\lambda_0)^{e_{i_1}}p_{i_1}(\lambda), \ldots, 0, \ldots, (\lambda-\lambda_0)^{e_{i_{k-1}}}p_{i_{k-1}}(\lambda)\,) \\ & + (\lambda-\lambda_0)^{e}[x(\lambda)y(\lambda)^T]_k \big)\,, \end{aligned}$$

(ii)

$$\det \big(\operatorname{diag}((\lambda-\lambda_0)^{e_{i_1}}p_{i_1}(\lambda), \ldots, (\lambda-\lambda_0)^{e_{i_k}}p_{i_k}(\lambda)) + (\lambda-\lambda_0)^{e}[x(\lambda)y(\lambda)^T]_k\big)\,, \tag{18}$$

where $[x(\lambda)y(\lambda)^T]_k$ is some $k \times k$ submatrix of $x(\lambda)y(\lambda)^T$. If we apply Lemma 4.1 to these minors, we see that

(i) every minor of type (i) may be written as

$$(\lambda-\lambda_0)^{e_1+\cdots+e_{k-1}+e}\,q(\lambda), \tag{19}$$

where $q(\lambda)$ is a polynomial;

(ii) every minor of type (ii) may be written as

$$(\lambda-\lambda_0)^{e_1+\cdots+e_{k-1}+\min\{e,e_k\}}\,t(\lambda), \tag{20}$$

where $t(\lambda)$ is a polynomial.

In the case $k=i+1$, these results directly imply that $c_{i+1}\geq e_1+\cdots+e_i+e$. In the case $k\leq i$, (19) and (20) imply $c_k\geq e_1+\cdots+e_k$. Moreover, the equality follows by taking $i_1=1,i_2=2,\ldots,i_k=k$, in (18) and applying Lemma 4.1. ☐

Next we prove a corollary of Lemma 4.2.

Corollary 4.3. [illegible] $\mathcal{L}(\lambda)$ [illegible] $\mathcal{M}(\lambda)$ [illegible] $m\times n$ [illegible] $\operatorname{rank}(\mathcal{M})=1$ [illegible] $\operatorname{rank}(\mathcal{L}+\mathcal{M})=\operatorname{rank}(\mathcal{L})+\operatorname{rank}(\mathcal{M})$ [illegible] $h(\mathcal{M})$ [illegible] $\mathcal{M}(\lambda)$ [illegible]

$$\mathcal{S}_{\mathcal{L}+\mathcal{M}}(\lambda_0)\geq\mathcal{S}_{\mathcal{L}\oplus h(\mathcal{M})}(\lambda_0)=\mathcal{S}_{\mathcal{L}\oplus\mathcal{M}}(\lambda_0)\quad\text{for any complex number }\ \lambda_0.$$

[illegible] Let us use the notation in Lemma 4.2 for the partial multiplicities of $\lambda_0$. The partial multiplicities of $\lambda_0$ relative to $\mathcal{L}\oplus h(\mathcal{M})$ are $e_1\leq\cdots\leq e_i<e\leq e_{i+1}\leq\cdots\leq e_r$, by Theorem 5 in [8, Chapter VI, p. 142]. These are also the partial multiplicities of $\lambda_0$ relative to $\mathcal{L}\oplus\mathcal{M}$, by the same argument. Lemma 4.2 implies the inequality $\mathcal{S}_{\mathcal{L}+\mathcal{M}}(\lambda_0)\geq\mathcal{S}_{\mathcal{L}\oplus h(\mathcal{M})}(\lambda_0)$. ☐

Now we prove the main theorem in this section.

Theorem 4.4. [illegible] $P(\lambda)$ [illegible] $Q(\lambda)$ [illegible] $m\times n$ [illegible] $\operatorname{rank}(P+Q)=\operatorname{rank}(P)+\operatorname{rank}(Q)$ [illegible] $\lambda_0$ [illegible] $\mathcal{S}_{P+Q}(\lambda_0)\geq\mathcal{S}_{P\oplus Q}(\lambda_0)$ [illegible] $\lambda_0$ [illegible] $P(\lambda)$ [illegible] $\lambda_0$ [illegible] $Q(\lambda)$ [illegible] $\lambda_0$ [illegible] $(P+Q)(\lambda)$

[illegible] We consider only finite numbers $\lambda_0$. The result for the infinite eigenvalue follows from considering the zero eigenvalue in the dual pencils of $P(\lambda)$ and $Q(\lambda)$. According to (11), $Q(\lambda)$ can be expressed as

$$Q(\lambda)=h_1(Q)\,b_1(\lambda)c_1^T(\lambda)+\cdots+h_\rho(Q)\,b_\rho(\lambda)c_\rho^T(\lambda),$$

where $\rho\equiv\operatorname{rank}(Q)$ and where $h_1(Q),\ldots,h_\rho(Q)$ are the invariant polynomials of $Q(\lambda)$. The property $\operatorname{rank}(P+Q)=\operatorname{rank}(P)+\operatorname{rank}(Q)$ implies that

$$\begin{aligned}&\operatorname{rank}(P+h_1(Q)\,b_1c_1^T+\cdots+h_k(Q)\,b_kc_k^T)\\&\quad=\operatorname{rank}(P+h_1(Q)\,b_1c_1^T+\cdots+h_{k-1}(Q)\,b_{k-1}c_{k-1}^T)+\operatorname{rank}(h_k(Q)\,b_kc_k^T),\end{aligned}\tag{21}$$

for $k=1,\ldots,\rho$. We have omitted the variable $\lambda$ for the sake of simplicity. Therefore, Corollary 4.3 can be applied $\rho$ times to prove

$$\begin{aligned}\mathcal{S}_{P+Q}(\lambda_0)&\geq\mathcal{S}_{(P+h_1(Q)b_1c_1^T+\cdots+h_{\rho-1}(Q)b_{\rho-1}c_{\rho-1}^T)\oplus h_\rho(Q)}(\lambda_0)\geq\cdots\\&\geq\mathcal{S}_{P\oplus h_1(Q)\oplus\cdots\oplus h_\rho(Q)}(\lambda_0),\end{aligned}$$

where we have used $(A+B)\oplus C=(A\oplus C)+(B\oplus 0)$. Finally, Theorem 5 in [8, Chapter VI, p. 142] implies $\mathcal{S}_{P\oplus h_1(Q)\oplus\cdots\oplus h_\rho(Q)}(\lambda_0)=\mathcal{S}_{P\oplus Q}(\lambda_0)$. ☐

**5. The minimal indices of the perturbed pencil.** The purpose of this section is to determine the minimal indices of the perturbed pencil $(P+Q)(\lambda)$ in terms of data of $P(\lambda)$ and $Q(\lambda)$. For the sake of brevity, we will develop the results only for the column minimal indices. A set of counterpart results for the row minimal indices can be obtained just by considering the column minimal indices of the transpose pencil $(P+Q)^T(\lambda)$.

The main result in this section is Theorem 5.8, where the whole set of column minimal indices of $P+Q$ is found for most perturbations $Q$ having a given rank and a given sum of its column minimal indices. The genericity of the hypotheses of Theorem 5.8 is discussed in subsection 5.5. Theorem 5.10 presents some generic information on the column minimal indices of $P+Q$ when only the rank of the perturbation is available.

According to Lemma 2.4, determining the column minimal indices of $P+Q$ is equivalent to finding the degrees of an ROMB of $P+Q$. This ROMB will not be explicitly constructed, but the degrees of its vectors will be precisely determined. Lemma 5.1 is the key result for this task. It allows us to delimit the search for this basis.

LEMMA 5.1. [illegible] $P(\lambda)$ [illegible] $Q(\lambda)$ [illegible] $\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q)$ [illegible] $x(\lambda)$ [illegible] $P+Q$ [illegible] $x(\lambda)$ [illegible] $P(\lambda)$ [illegible] $Q(\lambda)$ [illegible] $\mathcal{N}(P+Q) = \mathcal{N}(P) \cap \mathcal{N}(Q)$

[illegible] Let $\operatorname{col}(P)$ be the column space of $P(\lambda)$ in $\mathbb{C}^m(\lambda)$. Then,

$$\dim(\operatorname{col}(P+Q)) \leq \dim(\operatorname{col}[P\ Q]) = \dim(\operatorname{col}(P)) + \dim(\operatorname{col}(Q)) - \dim(\operatorname{col}(P) \cap \operatorname{col}(Q)).$$

The assumption $\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q)$ implies that $\operatorname{col}(P) \cap \operatorname{col}(Q) = \{0\}$. If $x(\lambda)$ is a right null space vector of $P+Q$, then $P(\lambda)x(\lambda) = -Q(\lambda)x(\lambda)$. Notice that the vector $z(\lambda) \equiv P(\lambda)x(\lambda) = -Q(\lambda)x(\lambda)$ is a vector in $\operatorname{col}(P) \cap \operatorname{col}(Q)$, and thus $z(\lambda) = 0$ and $P(\lambda)x(\lambda) = Q(\lambda)x(\lambda) = 0$. The converse is trivial. □

We have already remarked in section 3 that if $\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q) = n$, then the pencil $(P+Q)(\lambda)$ does not have column minimal indices. Therefore, in the rest of this section, it will be assumed $\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q) < n$. This implies that $\operatorname{rank}(Q) < p$, where $p$ is the number of column minimal indices of $P$.

### 5.1. Connection polynomials and associated mosaic Toeplitz matrices.

From Lemma 5.1, it is possible to obtain a more specific characterization of the right null space vectors of $P+Q$.

LEMMA 5.2. [illegible] $P(\lambda)$ [illegible] $Q(\lambda)$ [illegible] $m \times n$ [illegible] $\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q) < n$ $\widetilde{\varepsilon}$ [illegible] $Q(\lambda)$ [illegible] $\{x_1(\lambda), \ldots, x_p(\lambda)\}$ [illegible] $P(\lambda)$ [illegible] $Q(\lambda)$ [illegible] (7) [illegible] $\widetilde{\varepsilon}$ [illegible] $\{w_1(\lambda), \ldots, w_\rho(\lambda)\}$ [illegible] $(P+Q)(\lambda)$ [illegible] $\{x_1(\lambda), \ldots, x_p(\lambda)\}$ [illegible]

$$x(\lambda) = \alpha_1(\lambda)x_1(\lambda) + \cdots + \alpha_p(\lambda)x_p(\lambda) \tag{22}$$

[illegible] $(P+Q)(\lambda)$ [illegible] $\alpha_1(\lambda),\dots,\alpha_p(\lambda)$ [illegible] $\mathbb{C}^p(\lambda)$

$$\begin{aligned} a_{11}(\lambda)\alpha_1(\lambda)+\cdots+a_{1p}(\lambda)\alpha_p(\lambda) &= 0 \\ a_{\rho 1}(\lambda)\alpha_1(\lambda)+\cdots+a_{\rho p}(\lambda)\alpha_p(\lambda) &= 0, \end{aligned} \tag{23}$$

[illegible]

$$a_{ij}(\lambda)=w_i(\lambda)^T x_j(\lambda), \quad i=1,\dots,\rho,\ j=1,\dots,p. \tag{24}$$

[illegible]. A vector polynomial, $x(\lambda)$, is a right null space vector of $P+Q$ if and only if it is a right null space vector of $P$ and $Q$, by Lemma 5.1. $P(\lambda)x(\lambda)=0$ is equivalent to the fact that $x(\lambda)$ is a linear combination of $\{x_1(\lambda),\dots,x_p(\lambda)\}$ with polynomial coefficients, by Lemma 2.5. $Q(\lambda)x(\lambda)=0$ is equivalent, taking into account (7), to $w_1(\lambda)^T x(\lambda)=\cdots=w_\rho(\lambda)^T x(\lambda)=0$, and this is the system of equations (23). ☐

The system of equations (23) is of capital importance in this work, because the set of its solutions allows us to obtain the right null space of $P+Q$ through (22), and we are looking for the degrees of an ROMB of $\mathcal{N}(P+Q)$. Thus, the coefficients $a_{ij}(\lambda)$ of the system (23) play an essential role. They are polynomials in $\lambda$ and link the pencils $P$ and $Q$. They are used so often that we introduce the following definition.

DEFINITION 5.3. [illegible] $\{a_{ij}(\lambda) : i=1,\dots,\rho\ ,\ j=1,\dots,p\}$ [illegible] (24) [illegible] complete set of right connection polynomials [illegible] $P(\lambda)$ [illegible] $Q(\lambda)$

Since neither an ROMB of $P$ nor a right decomposition (7) of $Q$ is unique, a complete set of right connection polynomials of $P$ and $Q$ is not necessarily unique.

[illegible] 3. A left decomposition (8) of $Q(\lambda)$ and an LOMB $\{y_1(\lambda),\dots,y_q(\lambda)\}$ of $P(\lambda)$ can be considered to define a [illegible] $P(\lambda)$ [illegible] $Q(\lambda)$. These are the polynomials

$$b_{ij}(\lambda)=\widehat{v}_i(\lambda)^T y_j(\lambda), \quad i=1,\dots,\rho\ ,\ j=1,\dots,q.$$

These polynomials are needed to obtain the row minimal indices of $(P+Q)(\lambda)$.

Let us denote by $\varepsilon_1\leq\cdots\leq\varepsilon_p$ the column minimal indices of the unperturbed pencil $P(\lambda)$, and by $\widetilde{\varepsilon}$ the sum of the column minimal indices of the perturbation pencil $Q(\lambda)$, as in section 2. Then the degrees of the right connection polynomials of $P$ and $Q$ are bounded as follows:

$$\deg(a_{ij}(\lambda))\leq\begin{cases}\varepsilon_j+1, & i=1,\dots,\widetilde{\varepsilon},\\ \varepsilon_j, & i=\widetilde{\varepsilon}+1,\dots,\rho.\end{cases} \tag{25}$$

For most perturbations $Q(\lambda)$ these inequalities are, in fact, equalities, but this will not be assumed in the subsequent developments. Nevertheless, the generic behavior for the minimal indices of the perturbed pencil $P+Q$ holds under certain conditions that limit the number of right connection polynomials with degrees strictly less than the right-hand side of (25). These generic conditions involve some of the mosaic Toeplitz matrices appearing in the following definition.

DEFINITION 5.4. [illegible] $\varepsilon_1\leq\cdots\leq\varepsilon_p$ [illegible] $P(\lambda)$ $\widetilde{\varepsilon}$ [illegible] $Q(\lambda)$ [illegible] $\{a_{ij}(\lambda) : i=1,\dots,\rho\ ,\ j=1,\dots,p\}$ [illegible] $P$ [illegible]

$Q$ [illegible][1]

$$a_{ij}(\lambda) = a_{ij}^0 + \lambda\, a_{ij}^1 + \cdots + \lambda^{\epsilon_{ij}} a_{ij}^{\epsilon_{ij}}, \quad \text{where} \quad \epsilon_{ij} = \begin{cases} \varepsilon_j + 1, & i = 1, \dots, \widetilde{\varepsilon}, \\ \varepsilon_j, & i = \widetilde{\varepsilon} + 1, \dots, \rho. \end{cases}$$

[illegible] $k$ [illegible] $d$ [illegible] $1 \le k \le p$ [illegible] $d \ge \varepsilon_k - 1$ [illegible] $d$ [illegible] $a_{ij}(\lambda)$ [illegible] $A_k(d)$ [illegible] $\rho$ [illegible] $k$ [illegible] $(s,t)$ [illegible] $s = 1, \dots, \rho$, $t = 1, \dots, k$ [illegible]

$$(A_k(d))_{st} = \underbrace{\begin{bmatrix} a_{st}^0 & & \\ \vdots & \ddots & \\ a_{st}^{\epsilon_{st}} & & a_{st}^0 \\ & \ddots & \vdots \\ & & a_{st}^{\epsilon_{st}} \end{bmatrix}}_{d - \varepsilon_t + 1},$$

[illegible] $d - \varepsilon_t + 1$ [illegible]

$$\epsilon_{st} + 1 + d - \varepsilon_t = \begin{cases} d + 2, & s = 1, \dots, \widetilde{\varepsilon}, \\ d + 1, & s = \widetilde{\varepsilon} + 1, \dots, \rho. \end{cases}$$

[illegible] 4. Notice that in the case $d = \varepsilon_k - 1$ the [illegible]th column of blocks of $A_k(d)$ is formed by matrices having a "number of columns equal to zero," i.e., by empty matrices. This also happens for those columns whose index $j$ satisfies $d = \varepsilon_j - 1$. We understand in this case that $A_k(d)$ has less than $k$ columns of blocks. This convention will simplify the notation and the statements of our results.

The importance of the family of mosaic Toeplitz matrices $A_k(d)$ is made clear by the next lemma, Lemma 5.5. This result extends and complements Lemma 5.2, characterizing right null space vectors of $P + Q$ of a given degree through systems of constant linear equations, i.e., systems of equations in $\mathbb{C}^n$ and not in $\mathbb{C}^n(\lambda)$ as (23). Degrees are the fundamental quantities in this section, because our goal is to get the degrees of the vectors of an ROMB of $P + Q$, i.e., the column minimal indices of $P + Q$. According to Lemma 5.2 all the right null space vectors, $x(\lambda)$, of $P + Q$ are of the form (22), and they have $\deg(x) = \max_{1 \le i \le p} \{\varepsilon_i + \deg(\alpha_i) : \alpha_i(\lambda) \neq 0\}$ [6, Main Theorem, p. 495]. This implies that if $j$ is the largest index such that $\alpha_j(\lambda) \neq 0$, then $\deg(x) \ge \varepsilon_j$. To look for smaller degrees, one has to consider necessarily linear combinations $x(\lambda) = \alpha_1(\lambda) x_1(\lambda) + \cdots + \alpha_k(\lambda) x_k(\lambda)$, with $k < j$. See also Lemma 2.5.

LEMMA 5.5. [illegible] $P(\lambda)$ [illegible] $Q(\lambda)$ [illegible] $m \times n$ [illegible] $\operatorname{rank}(P + Q) = \operatorname{rank}(P) + \operatorname{rank}(Q) < n$ $\{x_1(\lambda), \dots, x_p(\lambda)\}$ [illegible] $P$ [illegible] $\varepsilon_1 \le \cdots \le \varepsilon_p$ [illegible] $P$ [illegible] $\deg(x_i) = \varepsilon_i$ [illegible]

1. [illegible] $x(\lambda)$ [illegible] $(P + Q)(\lambda)$ [illegible] $d$ [illegible] $x(\lambda) = \alpha_1(\lambda) x_1(\lambda) + \cdots + \alpha_k(\lambda) x_k(\lambda)$ [illegible] $k$ [illegible] $1 \le k \le p$ [illegible] $d \ge \varepsilon_k$ [illegible] $\{\alpha_1(\lambda), \dots, \alpha_k(\lambda)\}$

---

[1] The reader should notice that the superscript notation $a_{ij}^k$ *does not mean* $a_{ij}$ to the $k$th power.

2. [illegible]

$$x(\lambda) = \alpha_1(\lambda)x_1(\lambda) + \cdots + \alpha_k(\lambda)x_k(\lambda) \tag{26}$$

[illegible] $(P+Q)(\lambda)$ [illegible] $d \geq \varepsilon_k$ [illegible] $\alpha_1(\lambda), \dots, \alpha_k(\lambda)$ [illegible]

(i) [illegible] $\alpha_i(\lambda)$ [illegible]

$$\alpha_i(\lambda) = \alpha_{i0} + \lambda\,\alpha_{i1} + \cdots + \lambda^{d-\varepsilon_i}\,\alpha_{i,d-\varepsilon_i} \tag{27}$$

[illegible] $i = 1, \dots, k$ [illegible] $\alpha_{j,d-\varepsilon_j} \neq 0$ [illegible] $j$

(ii) [illegible] $A_k(d)$ [illegible] $d$ [illegible] $P$ [illegible] $Q$ [illegible] $\{x_1(\lambda), \dots, x_p(\lambda)\}$ [illegible] $\alpha_{il}$ [illegible] constant [illegible]

$$A_k(d) \left[\begin{array}{c} \alpha_{10} \\ \\ \alpha_{1,d-\varepsilon_1} \\ \hline \\ \\ \hline \alpha_{k0} \\ \\ \alpha_{k,d-\varepsilon_k} \end{array}\right] = 0. \tag{28}$$

[illegible] (28) [illegible] $\alpha_{1,d-\varepsilon_1} = \cdots = \alpha_{k,d-\varepsilon_k} = 0$ [illegible] $P+Q$ [illegible] (26) [illegible] $d$

[illegible] The proof of the first item is a direct consequence of Lemma 5.2 and the fact that in (22) $\deg(x) = \max_{1\leq i\leq p}\{\varepsilon_i + \deg(\alpha_i) : \alpha_i(\lambda) \neq 0\}$ according to [6, Main Theorem, p. 495]. Once the index $k$ is chosen, the uniqueness of $\{\alpha_1(\lambda), \dots, \alpha_k(\lambda)\}$ follows from the linear independence of $\{x_1(\lambda), \dots, x_k(\lambda)\}$.

The second item follows from (22) and (23) by setting $\alpha_{k+1}(\lambda) = \cdots = \alpha_p(\lambda) = 0$. Notice that (27) simply states that there are no indices $i$, $1 \leq i \leq k$, such that $\deg(\alpha_i) > d - \varepsilon_i$, because this would imply $\deg(x) > d$. The condition $\alpha_{j,d-\varepsilon_j} \neq 0$ for at least one index $j$ guarantees that $\deg(x) = d$. On the other hand, the linear system (28) is the system obtained from (23) by expanding products and sums of polynomials and equating the coefficients to zero. With these remarks in mind, the proof is trivial. ☐

### 5.2. Properties of mosaic Toeplitz matrices.

Lemma 5.6 gathers the properties of mosaic Toeplitz matrices that we will use to deduce the generic minimal indices of the pencil $P+Q$.

Lemma 5.6. [illegible] $\mathcal{T} = \{A_k(d) : 1 \leq k \leq p, d \geq \varepsilon_k - 1\}$ [illegible] 5.4 [illegible]

1. [illegible] $A_k(d)$ [illegible] $\rho(d+1) + \widetilde{\varepsilon}$
2. [illegible] $A_k(d)$ [illegible] $k(d+1) - \sum_{j=1}^{k} \varepsilon_j$
3. $A_k(d)$ [illegible]

$$k > \rho \quad \text{and} \quad d > \frac{\sum_{i=1}^{k} \varepsilon_i + \widetilde{\varepsilon}}{k - \rho} - 1.$$

4. $A_k(d)$ $A_k(d)$ $A_{k'}(d')$ $\mathcal{T}$ $k' \leq k$ $d' \leq d$

5. $A_k(d)$ $A_k(d)$ $A_{k'}(d')$ $\mathcal{T}$ $k' \geq k$ $d' \geq d$

6. $A_k(d)$

$$\text{rank}\begin{bmatrix} a_{11}(\lambda) & a_{12}(\lambda) & \dots & a_{1j}(\lambda) \\ & & & \\ a_{\rho 1}(\lambda) & a_{\rho 2}(\lambda) & \dots & a_{\rho j}(\lambda) \end{bmatrix} = \rho \quad \text{for} \quad j \geq k. \tag{29}$$

The first three items are direct consequences of the number of rows and columns of the blocks appearing in Definition 5.4.

Item 4. Notice that $A_{k-1}(d)$ is obtained from $A_k(d)$ just by erasing the last column of blocks. As a consequence, the columns of $A_{k-1}(d)$ are a subset of the columns of $A_k(d)$. Then, $A_{k-1}(d)$ has full column rank if $A_k(d)$ has full column rank, and, by induction, $A_{k'}(d)$ has full column rank whenever $k' \leq k$.

If $d-1 \geq \varepsilon_k - 1$, then $A_k(d-1)$ is an element of $\mathcal{T}$, and it is obtained from $A_k(d)$ by erasing the last column of each block of $A_k(d)$ to get a certain matrix $A'_k(d)$ and, after that, erasing the last row of each block of $A'_k(d)$ to get $A_k(d-1)$. However, notice that $A'_k(d)$ is of full column rank, and that the last rows of the blocks of $A'_k(d)$ are zero rows; then $A_k(d-1)$ also has full column rank.

If $d-1 < \varepsilon_k - 1$, then $A_k(d-1)$ is not in $\mathcal{T}$. Let $k' < k$ be the largest index such that $d-1 \geq \varepsilon_{k'} - 1$. Then $A_{k'}(d-1)$ is an element of $\mathcal{T}$, and $A_{k'}(d)$ has full column rank. The argument in the paragraph above is applied to prove that $A_{k'}(d-1)$ has full column rank.

Finally, the results above can be combined inductively to prove item 4.

Item 5. Let $k' \geq k$. Then the submatrix of $A_{k'}(d)$ that lies in the first $k(d+1) - \sum_{j=1}^{k} \varepsilon_j$ columns is precisely $A_k(d)$. Therefore, if $A_k(d)$ has full row rank, then $A_{k'}(d)$ also has full row rank. To complete the proof, let us prove that $A_k(d+t)$ has full row rank for any integer $t > 0$ whenever $A_k(d)$ has full row rank. It is enough to prove this statement for $t = 1$ and then to apply an inductive argument. Notice that the submatrix of $A_k(d)$ that contains the last row of each of the row blocks of $A_k(d)$ has linearly independent rows. This means that for the matrix

$$B \equiv \begin{bmatrix} a_{11}^{\epsilon_{11}} & \dots & a_{1k}^{\epsilon_{1k}} \\ \vdots & & \vdots \\ a_{\rho 1}^{\epsilon_{\rho 1}} & \dots & a_{\rho k}^{\epsilon_{\rho k}} \end{bmatrix},$$

$\text{rank}(B) = \rho$. Observe that the matrix $B$ is also the $\rho \times k$ submatrix of $A_k(d+1)$ that lies in the last rows and columns of the blocks of $A_k(d+1)$. If the last rows and columns of the blocks of $A_k(d+1)$ are moved down and back by permutations to the last positions, the rank does not change, and the matrix we get has the structure

$$\begin{bmatrix} A_k(d) & * \\ 0 & B \end{bmatrix}.$$

The rank of this matrix is clearly $\text{rank}(A_k(d)) + \rho = \rho(d+2) + \widetilde{\varepsilon}$, i.e., the number of rows of $A_k(d+1)$. Therefore $A_k(d+1)$ has full row rank.

Item 6. It is enough to prove this property for $j = k$. If the rows of $A_k(d)$ are linearly independent, then the submatrix of $A_k(d)$ that contains the first row of each of the row blocks of $A_k(d)$ has linearly independent rows. This means that

$$\operatorname{rank}\begin{bmatrix} a_{11}^0 & \cdots & a_{1k}^0 \\ \vdots & & \vdots \\ a_{\rho 1}^0 & \cdots & a_{\rho k}^0 \end{bmatrix} = \rho.$$

The result follows by applying Lemma 2.6.1 to the rows of the matrix (29) for $j = k$. ☐

According to [8, Chapter XII, p. 38] (see also the proof of Lemma 2.4 in this paper), the smallest column minimal index of $P + Q$ is the least degree among the degrees of nonzero right null space vectors of $P+Q$. Taking into account Lemma 5.5.2, this smallest minimal index corresponds to the smallest $d$ for which a linear system of the family (28) ($1 \leq k \leq p$) has nonzero solutions with $\alpha_{j,d-\varepsilon_j} \neq 0$ for at least one index $j$. Our intuition here is that solutions of this kind do not exist, generically, if $A_k(d)$ has a number of rows larger than or equal to the number of columns, and they do exist, generically, in the opposite case. This intuition is based on the idea that if the coefficients of the connection polynomials are random for random perturbations pencils $Q$, then the columns of $A_k(d)$ should be linearly independent if $A_k(d)$ has more rows than columns or the same number of rows and columns. Based on this intuition, one can tentatively think that the most likely value of the smallest minimal index of $P + Q$ for random perturbations $Q$ is the smallest $d$ such that some of the $A_k(d)$ has more columns than rows. Of course, these naive arguments have to be supported with rigorous assumptions, but they, together with Lemma 5.6.3, make it natural to consider the following sequence of integer numbers:

$$d_k = \left\lfloor \frac{\sum_{i=1}^{k} \varepsilon_i + \widetilde{\varepsilon}}{k-\rho} \right\rfloor \quad \text{for} \quad k = \rho+1, \ldots, p,$$

where $\lfloor x \rfloor$ denotes the floor function of $x$, i.e., the largest integer that is less than or equal to $x$. Notice that $A_k(d_k)$ exists only if $d_k \geq \varepsilon_k - 1$; in this case Lemma 5.6.3 guarantees that $A_k(d_k)$ has more columns than rows. However, it is not difficult to devise examples for which $d_k < \varepsilon_k - 1$ for some $k$. The natural candidate for the smallest column minimal index of $P + Q$ is $\min_{\rho+1 \leq k \leq p} d_k$. To prove that this is the case under certain generic assumptions, and also to find the rest of the column minimal indices, it is necessary to study the properties of the sequence $\{d_k\}$.

LEMMA 5.7. $0 \leq \varepsilon_1 \leq \cdots \leq \varepsilon_p$ $p$ $\rho$ $\widetilde{\varepsilon}$ $0 < \rho < p$ $0 \leq \widetilde{\varepsilon} \leq \rho$

$$d_k = \left\lfloor \frac{\sum_{i=1}^{k} \varepsilon_i + \widetilde{\varepsilon}}{k-\rho} \right\rfloor \qquad k = \rho+1, \ldots, p. \tag{30}$$

1. $d_{\rho+1} \geq \varepsilon_{\rho+1} \geq \cdots \geq \varepsilon_1$
2. $d_k < d_{k-1}$ $d_k \geq \varepsilon_k \geq \cdots \geq \varepsilon_1$
3. $d_k < d_{k+1}$ $d_k < d_{k+1} \leq d_{k+2} \leq \cdots \leq d_p$
4. $d_k < d_{k+1}$ $d_i < \varepsilon_i$ $i \geq (k+1)$
5.

$$d_{\min} \equiv \min_{\rho+1 \leq k \leq p} d_k.$$

[illegible] $j$ [illegible] $d_j = d_{\min}$, [illegible] $d_j = d_{\min}$ [illegible] $j_1 < j_2$ [illegible]

$$d_j = d_{\min} \quad [illegible] \quad j_1 \leq j \leq j_2 \quad [illegible] \quad d_j > d_{\min} \quad [illegible] \quad j < j_1 \quad [illegible] \quad j_2 < j.$$

[illegible] $d_{j_1} \geq \varepsilon_{j_1}$

6. [illegible] $s$ [illegible] $d_s = d_{\min}$, [illegible] $d_s \geq \varepsilon_s$ [illegible]

$$\varepsilon_k > d_k \geq d_s \quad [illegible] \quad k > s.$$

7. [illegible] $s$ [illegible] $A_s(d_{\min})$, [illegible] $A_s(d_{\min}-1)$ [illegible] 5.4 [illegible]
   (i) $A_s(d_{\min})$ [illegible] $s$ [illegible]
   (ii) $A_s(d_{\min}-1)$ [illegible]
   (iii) [illegible] $k > s$ $A_k(d_{\min})$ [illegible] $A_k(d_{\min}) = A_s(d_{\min})$

Before proving this lemma, we would like to point out that the index $s$ appearing in item 6 will play an essential role in determining the generic column minimal indices of $P + Q$.

[illegible] 5.7. The first item is trivial.

Item 2. Let us consider the integer divisions

$$\sum_{i=1}^{k} \varepsilon_i + \widetilde{\varepsilon} = (k-\rho)d_k + r_k, \quad \text{where} \quad 0 \leq r_k < k - \rho, \tag{31}$$

$$\sum_{i=1}^{k-1} \varepsilon_i + \widetilde{\varepsilon} = (k-1-\rho)d_{k-1} + r_{k-1}, \quad \text{where} \quad 0 \leq r_{k-1} < k - 1 - \rho. \tag{32}$$

Let us subtract (32) from (31) to get

$$\varepsilon_k = (k-\rho-1)(d_k - d_{k-1}) + d_k + r_k - r_{k-1} \leq (k-\rho-1)(d_k - d_{k-1}) + d_k + k - \rho - 1.$$

Thus, $\varepsilon_k \leq (k-\rho-1)(d_k - d_{k-1} + 1) + d_k \leq d_k$. The last step is a consequence of $(d_k - d_{k-1} + 1) \leq 0$ and $(k-1) > \rho$.

Item 3. Let us consider the integer division

$$\sum_{i=1}^{k+1} \varepsilon_i + \widetilde{\varepsilon} = (k+1-\rho)d_{k+1} + r_{k+1}, \quad \text{where} \quad 0 \leq r_{k+1} < k + 1 - \rho. \tag{33}$$

Let us subtract (31) from (33) to get

$$\varepsilon_{k+1} = (k-\rho)(d_{k+1} - d_k) + d_{k+1} + r_{k+1} - r_k \geq (k-\rho) + d_{k+1} + r_{k+1} - r_k > d_{k+1},$$

where we have used that $r_{k+1} - r_k > -(k-\rho)$. Therefore, we have proved that

$$d_k < d_{k+1} \quad \text{implies} \quad \varepsilon_{k+1} > d_{k+1}. \tag{34}$$

Let us consider now an index $l$ such that $l \geq (k+2)$, and the integer division

$$\sum_{i=1}^{l} \varepsilon_i + \widetilde{\varepsilon} = (l-\rho)d_l + r_l, \quad \text{where} \quad 0 \leq r_l < l - \rho. \tag{35}$$

Let us subtract (33) from (35) to get

$$\varepsilon_l + \varepsilon_{l-1} + \cdots + \varepsilon_{k+2} = (d_l - d_{k+1})(l - \rho) + d_{k+1}(l - (k+1)) + r_l - r_{k+1},$$

and then,

$$(\varepsilon_l - d_{k+1}) + (\varepsilon_{l-1} - d_{k+1}) + \cdots + (\varepsilon_{k+2} - d_{k+1}) = (d_l - d_{k+1})(l - \rho) + r_l - r_{k+1}.$$

The inequality (34) implies $(d_l - d_{k+1})(l - \rho) + r_l - r_{k+1} > 0$, and therefore $(d_l - d_{k+1} + 1)(l - \rho) > 0$. Thus, we have proven that

$$d_k < d_{k+1} \quad \text{implies} \quad d_l \geq d_{k+1} \quad \text{for all } l \geq (k+2). \tag{36}$$

This result allows us to prove the more general result appearing in item 3. Let us proceed by contradiction. Assume that $d_{k+1} \leq d_{k+2} \leq \cdots \leq d_p$ is false. This means that there exists an index $l \geq (k+2)$ such that $d_{k+1} \leq d_{k+2} \leq \cdots \leq d_{l-1} > d_l$. Let $j$ be the smallest integer such that $(k+1) \leq j \leq (l-1)$ and $d_j = d_{j+1} = \cdots = d_{l-1}$. Notice that this integer is at least $k+1$, because $d_k < d_{l-1}$ by (36). Then $d_{j-1} < d_j$, and (36) can be applied with $k = j-1$ to see that $d_j \leq d_l$; on the other hand, $d_j = d_{l-1} > d_l$. This is absurd.

Item 4. Let us prove the result by induction. In (34), we have already proven the base case of the induction: $d_{k+1} < \varepsilon_{k+1}$. Let us assume that $d_i < \varepsilon_i$ for some $i \geq (k+1)$. On the other hand, $d_i \leq d_{i+1}$ due to the result in item 3. If $d_i < d_{i+1}$, one can apply (34) with $k = i$ to see that $d_{i+1} < \varepsilon_{i+1}$. Otherwise, $d_i = d_{i+1}$ and $d_{i+1} < \varepsilon_i \leq \varepsilon_{i+1}$.

Item 5. The fact that the indices are consecutive is a direct consequence of item 3. The fact that $d_{j_1} \geq \varepsilon_{j_1}$ is a consequence of items 1 and 2.

Item 6. If there is only one index $s$ such that $d_s = d_{\min}$, the result is a simple consequence of items 4 and 5. Otherwise, let $j_1$ and $j_2$ be the two indices appearing in item 5. If $s = j_2 \leq p$, the result follows again from item 4. If $s < j_2$, then, by definition, $d_s = d_{s+1} < \varepsilon_{s+1} \leq \cdots \leq \varepsilon_{j_2}$. Therefore, $d_k < \varepsilon_k$ for $s+1 \leq k \leq j_2$. Also, by definition, $d_{j_2} < d_{j_2+1}$, and item 4 implies $d_k < \varepsilon_k$ for $k \geq (j_2+1)$.

Item 7. The assertions on the number of rows and columns of $A_s(d_{\min})$ and $A_s(d_{\min}-1)$ follow from Lemma 5.6.3. Let us remember that the $j$th column of blocks of $A_s(d_{\min})$ has $d_{\min} - \varepsilon_j + 1$ columns; therefore, $d_{\min} \geq \varepsilon_s$ guarantees that all the blocks of $A_s(d_{\min})$ have at least one column. Notice that $d_{\min} \geq \varepsilon_s$ also implies that $d_{\min} - 1 \geq \varepsilon_s - 1$; thus $A_s(d_{\min}-1)$ is defined, but some (or all) of its blocks may be empty. Finally, for $j > s$ we know that $\varepsilon_j > d_{\min}$, i.e., $\varepsilon_j - 1 \geq d_{\min}$. This means that $A_k(d_{\min})$, with $k > s$, is not defined unless $\varepsilon_j - 1 = d_{\min}$ for $s+1 \leq j \leq k$, but in this case the $j$th blocks $(A_k(d_{\min}))_{ij}$ are empty matrices. □

**5.3. Generic column minimal indices of $P+Q$.** Now we are in position to find out which are the generic column minimal indices of the perturbed pencil $(P+Q)(\lambda)$, assuming that, apart from the rank, the sum of the column minimal indices of the perturbation is known. This is done in Theorem 5.8, our second major contribution.

THEOREM 5.8. $P(\lambda)$ $Q(\lambda)$ $m \times n$ $\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q) < n$ $\rho \equiv \operatorname{rank}(Q)$ $\varepsilon_1 \leq \cdots \leq \varepsilon_p$ $P$ $\widetilde{\varepsilon}$ $Q$ $\{d_{\rho+1}, \ldots, d_p\}$ (30) $d_{\min}$ $s$ $d_s = d_{\min}$ $d_s \geq \varepsilon_s$ $A_s(d_{\min}-1)$ $A_s(d_{\min})$ $s$ $d_{\min} - 1$

[illegible] $d_{\min}$ [illegible] $P$ [illegible] $Q$ [illegible]

$$A_s(d_{\min}-1) \quad \text{[illegible]} \tag{37}$$

$$A_s(d_{\min}) \quad \text{[illegible]} \tag{38}$$

[illegible] $(P+Q)(\lambda)$ [illegible] $p-\rho$ [illegible]

$$\underbrace{d_{\min} = \cdots = d_{\min}}_{s-\rho-\gamma_s} < \underbrace{(d_{\min}+1) = \cdots = (d_{\min}+1)}_{\gamma_s} \leq \varepsilon_{s+1} \leq \cdots \leq \varepsilon_p, \tag{39}$$

[illegible] $\gamma_s$ [illegible] $\sum_{i=1}^{s} \varepsilon_i + \widetilde{\varepsilon}$ [illegible] $s-\rho$

[illegible] In the first place, let us notice that the ordering appearing in (39) is a consequence of Lemma 5.7.6. Also notice that the number of column minimal indices of $P+Q$ is $p-\rho$; this is a simple consequence of (4) and $\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q)$. For the rest of the proof, it is convenient to bear in mind Lemma 2.4 applied to $P+Q$, and the way ROMBs of $P+Q$ are constructed (see the first paragraph in the proof of Lemma 2.4).

Let us begin by proving that there are no column minimal indices of $P+Q$ smaller than $d_{\min}$. Lemma 5.5.1 and Lemma 5.7.6 guarantee that every right null space vector of $P+Q$ with degree $d < d_{\min}$ is a linear combination of the type $x(\lambda) = \alpha_1(\lambda)x_1(\lambda) + \cdots + \alpha_k(\lambda)x_k(\lambda)$ for some $k \leq s$. In this situation, the matrix $A_k(d)$ appearing in (28) has full column rank in the case $A_s(d_{\min}-1)$ has full column rank, by Lemma 5.6.4. The system (28) has only the zero solution and $x(\lambda) = 0$. In the case $A_s(d_{\min}-1)$ is the empty matrix $d_{\min} = \varepsilon_k$ whenever $1 \leq k \leq s$, and there are no nonzero linear combinations of $\{x_1(\lambda), \ldots, x_p(\lambda)\}$ of degree smaller than $\varepsilon_1 = d_{\min}$, because otherwise the smallest column minimal index of $P$ would be less than $\varepsilon_1$.

Our next step is to prove that $d_{\min}$ is a column minimal index of $P+Q$. The system (28) with coefficient matrix $A_s(d_{\min})$ necessarily has nonzero solutions because $A_s(d_{\min})$ has more columns than rows by Lemma 5.7.7. Besides, there are no nonzero solutions with $\alpha_{1,d_{\min}-\varepsilon_1} = \cdots = \alpha_{s,d_{\min}-\varepsilon_s} = 0$, because otherwise the solutions of (28) correspond to right null space vectors of $P+Q$ of degree less than $d_{\min}$, and we already know that they do not exist. This proves that $d_{\min}$ is the smallest column minimal index of $P+Q$.

To see that there are precisely $s-\rho-\gamma_s$ column minimal indices of $P+Q$ equal to $d_{\min}$, we need to find $s-\rho-\gamma_s$ linearly independent right null space vectors of $P+Q$ of degree $d_{\min}$, and to prove that there are no more. Again, Lemma 5.5.1 and Lemma 5.7.6 guarantee that every right null space vector of $P+Q$ with degree $d_{\min}$ is a linear combination of the type

$$x(\lambda) = \alpha_1(\lambda)x_1(\lambda) + \cdots + \alpha_s(\lambda)x_s(\lambda). \tag{40}$$

Notice that the set of solutions of (28) with $A_s(d_{\min})$ as coefficient matrix can be described in terms of a number of free parameters equal to the difference between the number of columns and the number of rows of $A_s(d_{\min})$, i.e.,

$$s(d_{\min}+1) - \sum_{i=1}^{s} \varepsilon_i - \rho(d_{\min}+1) - \widetilde{\varepsilon} = s - \rho - \gamma_s,$$

where Lemma 5.6.1 and Lemma 5.6.2 have been used. This means that the system of linear equations (28) with $A_s(d_{\min})$ has $s-\rho-\gamma_s$ linearly independent solutions, and, by Lemma 5.5, that they correspond to $s-\rho-\gamma_s$ right null space vectors of $P+Q$ of the form (40) of degree $d_{\min}$. Let us denote these vectors by

$$\{z_1(\lambda), z_2(\lambda), \dots, z_{\beta_s}(\lambda)\}, \quad \text{with } \beta_s \equiv s-\rho-\gamma_s. \tag{41}$$

It is clear that any other solution of (28) corresponds to right null space vectors of degree $d_{\min}$ that are linear combinations of (41) with constant coefficients; however, we still need to prove that the vectors $\{z_1(\lambda), z_2(\lambda), \dots, z_{\beta_s}(\lambda)\}$ can be chosen to be linearly independent in $\mathbb{C}^n(\lambda)$. To see this, notice that the $\beta_s$ free parameters of (28) with $A_s(d_{\min})$ may be taken among the $\alpha_{1,d_{\min}-\varepsilon_1}, \dots, \alpha_{s,d_{\min}-\varepsilon_s}$ variables, because the columns of $A_s(d_{\min})$ that do not correspond to these variables are linearly independent, as we have already seen in the paragraph proving that $d_{\min}$ is the smallest minimal index of $P+Q$. By setting the $l$th of these $\beta_s$ variables equal to 1 and the rest equal to 0, and repeating this process for $l=1,\dots,\beta_s$, a set $\mathcal{S}$ of $\beta_s$ linearly independent solutions of (28) may be obtained. Let us denote by

$$a_l = [\alpha^l_{1,d_{\min}-\varepsilon_1}, \dots, \alpha^l_{s,d_{\min}-\varepsilon_s}]^T, \quad l=1,\dots,\beta_s, \tag{42}$$

a vector containing the shown entries of the $l$th solution of (28) in $\mathcal{S}$. The vectors $\{a_1,\dots,a_{\beta_s}\}$ are obviously linearly independent. If (27) and (40) are recalled, the coefficients of the highest degree terms of the vectors (41) corresponding to the $\beta_s$ solutions of (28) in $\mathcal{S}$ are

$$z_{l,d_{\min}} = \alpha^l_{1,d_{\min}-\varepsilon_1} x_{1,\varepsilon_1} + \dots + \alpha^l_{s,d_{\min}-\varepsilon_s} x_{s,\varepsilon_s}, \qquad \text{for } l=1,\dots,\beta_s, \tag{43}$$

where $x_{i,\varepsilon_i}$ is the highest degree coefficient of $x_i(\lambda)$. The vectors $\{x_{1,\varepsilon_1},\dots,x_{s,\varepsilon_s}\}$ are linearly independent in $\mathbb{C}^n$, because $x_1(\lambda),\dots,x_s(\lambda)$ are part of an ROMB and [6, Main Theorem, Item 2, p. 495] can be applied. Therefore, $\{z_{1,d_{\min}},\dots,z_{\beta_s,d_{\min}}\}$ is a linearly independent set, because $[z_{1,d_{\min}},\dots,z_{\beta_s,d_{\min}}] = [x_{1,\varepsilon_1},\dots,x_{s,\varepsilon_s}][a_1,\dots,a_{\beta_s}]$ and the two matrices in the right-hand side have full column rank. Finally, Lemma 2.6.2 implies that $\{z_1(\lambda), z_2(\lambda), \dots, z_{\beta_s}(\lambda)\}$ are linearly independent, and that there are precisely $\beta_s \equiv s-\rho-\gamma_s$ column minimal indices of $P+Q$ equal to $d_{\min}$.

In this paragraph, we prove that there are $\gamma_s$ column minimal indices of $P+Q$ equal to $d_{\min}+1$. At present, we have found a set $\mathcal{C}_1 = \{z_1(\lambda), z_2(\lambda), \dots, z_{\beta_s}(\lambda)\}$ of $s-\rho-\gamma_s$ linearly independent right null space vectors of $P+Q$ of the form (40) and degree $d_{\min}$. However, the fact that $A_s(d_{\min})$ has full row rank, Lemma 5.6.6 with $j=s$, and Lemma 5.2 imply that a maximal linearly independent set of right null space vectors of $P+Q$ of the form (40) has $s-\rho$ vectors. We will prove that the remaining $\gamma_s$ vectors can be chosen to be of degree $d_{\min}+1$. Let us consider the system (28) with coefficient matrix $A_s(d_{\min}+1)$. The matrix $A_s(d_{\min}+1)$ has full row rank because $A_s(d_{\min})$ has full row rank, and Lemma 5.6.5 can be applied. This means that $\operatorname{rank}(A_s(d_{\min}+1)) = \operatorname{rank}(A_s(d_{\min}))+\rho$. Remember that $A_s(d_{\min}+1)$ can be obtained from $A_s(d_{\min})$ by adding one row and one column in the last positions of each block. Therefore, among the $s$ columns of $A_s(d_{\min}+1)$ that are in the last positions of the column blocks, $s-\rho$ are linear combinations of the remaining columns of $A_s(d_{\min}+1)$. Thus, the corresponding variables in the system (28) with $A_s(d_{\min}+1)$ can be taken as some of the free parameters to solve this system.[2] This

---

[2] The reader should notice that the difference between the number of columns and rows of $A_s(d_{\min}+1)$ is $2(s-\rho)-\gamma_s$. Therefore, the system (28) with matrix $A_s(d_{\min}+1)$ has $2(s-\rho)-\gamma_s$ linearly independent solutions, while there are only $s-\rho$ linearly independent right null space vectors of the form (40). This means that linearly independent solutions of (28) do not always correspond to linearly independent right null space vectors (26).

implies that $s-\rho$ free parameters to solve (28) with $A_s(d_{\min}+1)$ may be taken among the $\alpha_{1,(d_{\min}+1)-\varepsilon_1}, \dots, \alpha_{s,(d_{\min}+1)-\varepsilon_s}$ variables. If we proceed with these parameters as in the previous paragraph (arguments around (41)–(43)), we can find a set $\mathcal{C}_2$ of $(s-\rho)$ linearly independent right null space vectors of $P+Q$ of degree exactly $d_{\min}+1$, and of the form (40). Therefore, we can join the set $\mathcal{C}_1$ of $s-\rho-\gamma_s$ vectors of degree $d_{\min}$ with some $\gamma_s$ vectors of $\mathcal{C}_2$, to get a maximal linearly independent set of right null space vectors of $P+Q$ of the form (40). This proves that there exist $\gamma_s$ column minimal indices of $P+Q$ equal to $d_{\min}+1$.

Our last task in proving Theorem 5.8 is to show that the remaining column minimal indices of $P+Q$ are $\varepsilon_{s+1} \leq \cdots \leq \varepsilon_p$. The right null space vectors of $P+Q$ that we have already found, corresponding to minimal indices equal to $d_{\min}$ and to $d_{\min}+1$, constitute a maximal linearly independent set of right null space vectors of $P+Q$ of the form (40). This fact implies that any right null space vector $x(\lambda)$ of $P+Q$ corresponding to the next smallest minimal index has to be necessarily of the form (22) with at least one of the coefficients $\alpha_{s+1}(\lambda), \dots, \alpha_p(\lambda)$ different from zero. Otherwise, it would depend linearly on the right null space vectors corresponding to the minimal indices $d_{\min}$ and $d_{\min}+1$. Thus, according to [6, Main Theorem, p. 495], $\deg(x) = \max_{1\leq i\leq p}\{\varepsilon_i + \deg(\alpha_i) : \alpha_i(\lambda) \neq 0\} \geq \varepsilon_{s+1} \geq d_{\min}+1$, where the last inequality is a consequence of Lemma 5.7.6. Then, the least candidate to the next minimal index is $\varepsilon_{s+1}$. To show that, in fact, $\varepsilon_{s+1}$ is the next column minimal index, we will prove that there is a right null space vector of $P+Q$ of the form

$$x(\lambda) = \alpha_1(\lambda)x_1(\lambda) + \cdots + \alpha_{s+1}(\lambda)x_{s+1}(\lambda), \tag{44}$$

with $\alpha_{s+1}(\lambda) \neq 0$ and $\deg(x) = \varepsilon_{s+1}$, i.e., with $\alpha_{s+1}(\lambda)$ a nonzero constant. This is equivalent to proving that the linear system (28) with coefficient matrix $A_{s+1}(\varepsilon_{s+1})$ has solutions with the last entry different from zero. Notice that $A_{s+1}(\varepsilon_{s+1})$ has full row rank because $A_s(d_{\min})$ has full row rank, $\varepsilon_{s+1} > d_{\min}$ by Lemma 5.7.6, and Lemma 5.6.5 can be applied. Besides, the matrices in the last columns of blocks of $A_{s+1}(\varepsilon_{s+1})$ have only one column. Therefore, if the last column of $A_{s+1}(\varepsilon_{s+1})$ is removed, then $A_s(\varepsilon_{s+1})$ is obtained. However,

$$\text{number of rows of } A_{s+1}(\varepsilon_{s+1}) = \text{number of rows of } A_s(\varepsilon_{s+1}), \tag{45}$$

and $A_s(\varepsilon_{s+1})$ has also full row rank by the same argument; then

$$\operatorname{rank}(A_{s+1}(\varepsilon_{s+1})) = \operatorname{rank}(A_s(\varepsilon_{s+1})). \tag{46}$$

This implies that the last column of $A_{s+1}(\varepsilon_{s+1})$ is a linear combination of its remaining columns. As a consequence the last variable in the linear system (28) with coefficient matrix $A_{s+1}(\varepsilon_{s+1})$ may be considered as free parameter, and therefore it may be different from zero. This proves that the $\varepsilon_{s+1}$ is the next minimal index.

Notice that assumption (38) and Lemma 5.6.6 imply that a maximal linearly independent set of right null space vectors of $P+Q$ of the form (44) has $s+1-\rho$ vectors. Therefore, a maximal linearly independent set of this type has already been found in the previous paragraphs. With this remark in mind, the proof that $\varepsilon_{s+2}$ is the next smallest column minimal index follows step-by-step the proof presented in the previous paragraph for $\varepsilon_{s+1}$ with the corresponding changes of indices. The same holds for proving that $\varepsilon_{s+3}, \dots, \varepsilon_p$ are the remaining column minimal indices of $P+Q$. ☐

**5.4. Application of Theorem 5.8 to an example.** Let us show with an example how to apply Theorem 5.8. Let $P(\lambda)$ be the $5 \times 5$ matrix pencil

$$P(\lambda) = \operatorname{diag}(L_0,\, L_1,\, L_1, L_0^T,\, L_0^T,\, L_0^T) = \begin{bmatrix} 0 & \lambda & 1 & 0 & 0 \\ 0 & 0 & 0 & \lambda & 1 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix},$$

with $\varepsilon_1 = 0$, $\varepsilon_2 = \varepsilon_3 = 1$. An ROMB of $P$ is given by

$$x_1 = \begin{bmatrix} 1 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}, \qquad x_2 = \begin{bmatrix} 0 \\ 1 \\ -\lambda \\ 0 \\ 0 \end{bmatrix}, \qquad x_3 = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \\ -\lambda \end{bmatrix}.$$

Consider an arbitrary perturbation $Q$ of $P$ with $\rho = 2$ and $\widetilde{\varepsilon} = 1$. This means that a right decomposition of $Q$ (see (7)) is of the form

$$Q(\lambda) = v_1 w_1^T + v_2 w_2^T,$$

where

$$w_1 = \begin{bmatrix} b_1 + \lambda c_1 \\ b_2 + \lambda c_2 \\ b_3 + \lambda c_3 \\ b_4 + \lambda c_4 \\ b_5 + \lambda c_5 \end{bmatrix}, \qquad w_2 = \begin{bmatrix} d_1 \\ d_2 \\ d_3 \\ d_4 \\ d_5 \end{bmatrix},$$

and $b_i$, $c_i$, $d_i \in \mathbb{C}$ for $i = 1, \ldots, 5$. In addition, $\deg(v_1) = 0$ and $\deg(v_2) \leq 1$. Notice that in this example $p - \rho = 3 - 2 = 1$, and so the sequence $\{d_{\rho+1}, \ldots, d_p\}$ has only the element $d_3$. This means that in the conditions of Theorem 5.8 [illegible] $P + Q$ [illegible]

$$d_{\min} = d_3 = \left\lfloor \frac{0+1+1+1}{3-2} \right\rfloor = 3.$$

The matrices $A_s(d_{\min} - 1)$ and $A_s(d_{\min})$ are in this case $A_3(2)$ and $A_3(3)$, respectively. The right connection polynomials associated with the previous data are given by

$$\begin{aligned} a_{11}(\lambda) &= w_1(\lambda)^T x_1 = b_1 + \lambda c_1, & a_{21}(\lambda) &= w_2^T x_1 = d_1, \\ a_{12}(\lambda) &= w_1(\lambda)^T x_2 = b_2 + \lambda(c_2 - b_3) - \lambda^2 c_3, & a_{22}(\lambda) &= w_2^T x_2 = d_2 - \lambda d_3, \\ a_{13}(\lambda) &= w_1(\lambda)^T x_3 = b_4 + \lambda(c_4 - b_5) - \lambda^2 c_5, & a_{23}(\lambda) &= w_2^T x_3 = d_4 - \lambda d_5, \end{aligned}$$

and then the mosaic Toeplitz matrix $A_3(3)$ is the $9 \times 10$ matrix

$$A_3(3) = \left[\begin{array}{cccc|ccc|ccc} b_1 & 0 & 0 & 0 & b_2 & 0 & 0 & b_4 & 0 & 0 \\ c_1 & b_1 & 0 & 0 & c_2 - b_3 & b_2 & 0 & c_4 - b_5 & b_4 & 0 \\ 0 & c_1 & b_1 & 0 & -c_3 & c_2 - b_3 & b_2 & -c_5 & c_4 - b_5 & b_4 \\ 0 & 0 & c_1 & b_1 & 0 & -c_3 & c_2 - b_3 & 0 & -c_5 & c_4 - b_5 \\ 0 & 0 & 0 & c_1 & 0 & 0 & -c_3 & 0 & 0 & -c_5 \\ \hline d_1 & 0 & 0 & 0 & d_2 & 0 & 0 & d_4 & 0 & 0 \\ 0 & d_1 & 0 & 0 & -d_3 & d_2 & 0 & -d_5 & d_4 & 0 \\ 0 & 0 & d_1 & 0 & 0 & -d_3 & d_2 & 0 & -d_5 & d_4 \\ 0 & 0 & 0 & d_1 & 0 & 0 & -d_3 & 0 & 0 & -d_5 \end{array}\right].$$

It can be numerically checked using MATLAB that this matrix has full row rank for random values of $b_i, c_i$, and $d_i$. The $7 \times 7$ matrix $A_3(2)$ is constructed in a similar way, and it can be numerically checked that $A_3(2)$ has full column rank.

**5.5. On the genericity of the assumptions of Theorem 5.8.** The relevance of Theorem 5.8 depends on the [illegible] of its hypotheses, i.e., whether they are satisfied in a dense open subset of the considered set of perturbations. The meaning and genericity of the condition $\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q) < n$ was discussed in depth in section 3. The other two essential hypotheses in Theorem 5.8 are (37)–(38). We have checked numerically with MATLAB on a sample of more than 50000 mosaic Toeplitz matrices (Definition 5.4), constructed on random polynomials, that these matrices have full rank. We have run experiments with matrices with more rows than columns, and vice versa. Then to see that (37)–(38) are indeed generic assumptions that hold for almost all perturbations, it remains only to justify that the connection polynomials of $P$ and $Q$ are [illegible] for random perturbations $Q$. In this process the natural assumption

$$\operatorname{rank}(Q) \leq \operatorname{rank}(P), \tag{47}$$

noted in section 3, plays a relevant role. Let us remember Definition 5.3. We can assume in the following argument, without loss of generality, that $P$ is given in KCF. Taking into account that the right null space vector of a column singular block $L_\varepsilon$ can be chosen to be $[1, -\lambda, \lambda^2, \ldots, (-\lambda)^\varepsilon]^T$, the vectors $\{x_1(\lambda), \ldots, x_p(\lambda)\}$ of the ROMB of $P$ can be chosen with the following property: if $(x_j(\lambda))_k \neq 0$ for some $j$, then $(x_{j'}(\lambda))_k = 0$ for $j' \neq j$; i.e., the nonzero entries of every vector correspond to zero entries of the remaining vectors. With this in mind, it seems at a first glance that the coefficients of the connection polynomials (24) are random, because $Q$ being a random perturbation, the vectors $\{w_1(\lambda), \ldots, w_\rho(\lambda)\}$ should be also random. But, according to (7), the vectors $w_i(\lambda)$ are of degree at most one. This means that, putting together the zero and first order coefficients of each $w_i(\lambda)$, we get a set $\mathcal{W}$ with $\rho + \widetilde{\varepsilon}$ vectors of $\mathbb{C}^n$. Notice that $\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q) \leq \min\{m, n\}$ and (47) imply that $\rho + \widetilde{\varepsilon} \leq n$, and then the vectors in $\mathcal{W}$ are linearly independent for almost all $Q$, and the coefficients of the connection polynomials are really random. But, if $\rho + \widetilde{\varepsilon} > n$, then the set $\mathcal{W}$ is linearly dependent, and some linear dependence may appear among the coefficients of the connection polynomials.[3]

**5.6. When the only information available on the perturbation is its rank.** Theorem 5.8 determines the generic whole set of column minimal indices of the perturbed pencil $(P+Q)(\lambda)$. This set depends on $\widetilde{\varepsilon}$, i.e., the sum of the column minimal indices of the perturbation $Q(\lambda)$. The reason for this dependence can be traced back to the expansion (7), because the properties of (7) depend on $\widetilde{\varepsilon}$. This fact is related to a deeper mathematical result: the set of singular matrix pencils of rank $\rho$ has exactly $\rho + 1$ maximal irreducible components, each of them corresponding to a value of $\widetilde{\varepsilon}$, for $\widetilde{\varepsilon} = 0, \ldots, \rho$ [3]. However, one may want to get some partial information if only the rank of the perturbation $Q(\lambda)$ is known. This partial information is presented in Theorem 5.10. To prove this theorem the following lemma is needed.

LEMMA 5.9. [illegible] $0 \leq \varepsilon_1 \leq \cdots \leq \varepsilon_p$ [illegible] $p$ [illegible] $\rho$ [illegible] $\widetilde{\varepsilon}$ [illegible] $0 < \rho < p$ [illegible] $0 \leq \widetilde{\varepsilon} \leq \rho$ [illegible] $\widetilde{\varepsilon}$ [illegible]

---

[3] Notice that the argument of this paragraph holds if the assumption (47) is replaced by $\rho + \widetilde{\varepsilon} \leq n$, which is fulfilled by a wider set of perturbations. However, this condition is not natural and requires knowing $\widetilde{\varepsilon}$ apart from the rank of the perturbation.

[illegible]

$$d_k(\widetilde{\varepsilon}) = \left\lfloor \frac{\sum_{i=1}^{k} \varepsilon_i + \widetilde{\varepsilon}}{k-\rho} \right\rfloor \qquad k = \rho+1,\dots,p. \tag{48}$$

[illegible] $d_{\min}(\widetilde{\varepsilon}) \equiv \min_{\rho+1\le k\le p} d_k(\widetilde{\varepsilon})$ [illegible] $s(\widetilde{\varepsilon})$ [illegible] $d_{s(\widetilde{\varepsilon})}(\widetilde{\varepsilon}) = d_{\min}(\widetilde{\varepsilon})$ [illegible] $d_{s(\widetilde{\varepsilon})}(\widetilde{\varepsilon}) \ge \varepsilon_{s(\widetilde{\varepsilon})}$ [illegible]

$$d_{\min}(\rho) \ge d_{\min}(\rho-1) \ge \cdots \ge d_{\min}(0) \quad \text{and} \quad s(\rho) \ge s(\rho-1) \ge \cdots \ge s(0).$$

[illegible] Let us prove that $d_{\min}(\widetilde{\varepsilon}') \ge d_{\min}(\widetilde{\varepsilon})$ and $s(\widetilde{\varepsilon}') \ge s(\widetilde{\varepsilon})$, whenever $\widetilde{\varepsilon}' > \widetilde{\varepsilon}$. Notice that $d_k(\widetilde{\varepsilon}') \ge d_k(\widetilde{\varepsilon})$ for $k = \rho+1,\dots,p$. Therefore $d_{\min}(\widetilde{\varepsilon}') \ge d_{\min}(\widetilde{\varepsilon})$. According to Lemma 5.7.6, $\varepsilon_{s(\widetilde{\varepsilon}')+1} > d_{s(\widetilde{\varepsilon}')}(\widetilde{\varepsilon}') \ge d_{s(\widetilde{\varepsilon})}(\widetilde{\varepsilon}) \ge \varepsilon_{s(\widetilde{\varepsilon})}$. This means that $s(\widetilde{\varepsilon}') + 1 > s(\widetilde{\varepsilon})$. ☐

By combining Theorem 5.8 and Lemma 5.9, we can state the generic theorem, Theorem 5.10. We name Theorem 5.10 as generic, because the precise assumptions needed in the theorem are (37)–(38), and they depend on the sum of the column minimal indices of the perturbation $Q$, information that is not available. The only requirement for proving Theorem 5.10 is to notice that if $\rho$ is the rank of $Q$ and $\widetilde{\varepsilon}$ is the sum of the column minimal indices of $Q$, then $0 \le \widetilde{\varepsilon} \le \rho$.

THEOREM 5.10. [illegible] $P(\lambda)$ [illegible] $Q(\lambda)$ [illegible] $m \times n$ [illegible] $\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q) < n$ [illegible] $\operatorname{rank}(Q) \le \operatorname{rank}(P)$ [illegible] $\rho \equiv \operatorname{rank}(Q)$ [illegible] $\varepsilon_1 \le \cdots \le \varepsilon_p$ [illegible] $P$ [illegible]

$$d_k' = \left\lfloor \frac{\sum_{i=1}^{k} \varepsilon_i + \rho}{k-\rho} \right\rfloor \qquad k = \rho+1,\dots,p. \tag{49}$$

[illegible] $d_{\min}'$ [illegible] $\{d_k'\}$ [illegible] $s'$ [illegible] $d_{s'}' = d_{\min}'$ [illegible] $d_{s'}' \ge \varepsilon_{s'}$ [illegible] $Q(\lambda)$ [illegible] $\rho$ $(P+Q)(\lambda)$ [illegible] $p-\rho$ [illegible]

1. [illegible] $p-s'$ [illegible] $(P+Q)(\lambda)$ [illegible] $\varepsilon_{s'+1} \le \cdots \le \varepsilon_p$.
2. [illegible] $s'-\rho$ [illegible] $(P+Q)(\lambda)$ $\hat{\varepsilon}_1 \le \cdots \le \hat{\varepsilon}_{s'-\rho}$ [illegible] $\varepsilon_{\rho+j} \le \hat{\varepsilon}_j$ [illegible] $j = 1,\dots,s'-\rho$ [illegible] $\hat{\varepsilon}_1 \le d_{min}'$

## 6. The Kronecker canonical form of perturbed pencils without full rank.

The results presented so far remain valid whenever $\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q) \le \min\{m,n\}$. This assumption includes the limit case $\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q) = \min\{m,n\}$, i.e., the case of perturbed pencils $(P+Q)(\lambda)$ with full rank. In this full rank case $P+Q$ does not have row minimal indices if $\operatorname{rank}(P+Q) = m$, and $P+Q$ does not have column minimal indices if $\operatorname{rank}(P+Q) = n$, according to (4). If $\operatorname{rank}(P+Q) = m < n$, the generic column minimal indices of $P+Q$ are described by Theorem 5.8, and if $\operatorname{rank}(P+Q) = n < m$, the generic row minimal indices of $P+Q$ are described by Theorem 5.8 applied on $(P+Q)^T$. Theorem 4.4 also holds in the full rank case and gives partial information on the regular part of $P+Q$.

The purpose of this section is to show that complete information on the generic KCF of $P+Q$ can be obtained for perturbed pencils without full rank, i.e.,

$$\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q) < \min\{m,n\}.$$

We will gather the information obtained in Theorems 4.4 and 5.8, together with the counterpart version of Theorem 5.8 for row minimal indices, to fully describe the generic KCF of $(P+Q)(\lambda)$, in terms of the sums of the row and column minimal indices and of the regular structure of the perturbation $Q(\lambda)$. This KCF will be presented in Theorem 6.2. In addition, Theorem 6.3 presents some generic partial information on the KCF of $P+Q$ when $\operatorname{rank}(Q)$ is the only information available on the perturbation.

Lemma 6.1 will allow us to avoid certain redundancy in the hypotheses.

LEMMA 6.1. [illegible] $P(\lambda)$ [illegible] $Q(\lambda)$ [illegible] $m \times n$ [illegible] $\operatorname{rank}(P) + \operatorname{rank}(Q) < \min\{m,n\}$ [illegible] $A_s(d_{\min})$ [illegible] $P$ [illegible] $Q$ [illegible] 5.8 [illegible] $B_t(h_{\min})$ [illegible] 5.8 [illegible] $P^T$ [illegible] $Q^T$ [illegible] $A_s(d_{\min})$ [illegible] $B_t(h_{\min})$ [illegible] $\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q)$

[illegible] From elementary linear algebra we know $\operatorname{rank}(P+Q) \leq \operatorname{rank}(P) + \operatorname{rank}(Q)$. Let us consider right decompositions of $P$ and $Q$ of the kind appearing in (7):

$$P(\lambda) = v_1'(\lambda)w_1'(\lambda)^T + \cdots + v_r'(\lambda)w_r'(\lambda)^T,$$
$$Q(\lambda) = v_1(\lambda)w_1(\lambda)^T + \cdots + v_\rho(\lambda)w_\rho(\lambda)^T,$$

where $r \equiv \operatorname{rank}(P)$ and $\rho \equiv \operatorname{rank}(Q)$. Therefore

$$P + Q = [v_1', \dots, v_r', v_1, \dots, v_\rho]\,[w_1', \dots, w_r', w_1, \dots, w_\rho]^T,$$

where the dependence on $\lambda$ has been omitted. This means that $P+Q$ is the product of an $m \times (r+\rho)$ matrix times an $(r+\rho) \times n$ matrix, with $(r+\rho) < \min\{m,n\}$. Therefore $\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q)$ if and only if

$$\operatorname{rank}[v_1', \dots, v_r', v_1, \dots, v_\rho] = r + \rho \quad \text{and} \quad \operatorname{rank}[w_1', \dots, w_r', w_1, \dots, w_\rho] = r + \rho.$$

Let us prove that if $A_s(d_{\min})$ has full row rank, then $\operatorname{rank}[w_1', \dots, w_r', w_1, \dots, w_\rho] = r + \rho$. If $\operatorname{rank}[w_1', \dots, w_r', w_1, \dots, w_\rho] < r + \rho$, there exists an index $i$ such that $w_i(\lambda)$ is a linear combination of $\{w_1'(\lambda), \dots, w_r'(\lambda), w_1(\lambda), \dots, w_{i-1}(\lambda)\}$ in $\mathbb{C}^n(\lambda)$, i.e.,

$$w_i(\lambda) = \beta_1'(\lambda)w_1'(\lambda) + \cdots + \beta_r'(\lambda)w_r'(\lambda) + \beta_1(\lambda)w_1(\lambda) + \cdots + \beta_{i-1}(\lambda)w_{i-1}(\lambda),$$

for some rational functions $\beta_1'(\lambda), \dots, \beta_{i-1}(\lambda)$. Let us recall (24) and $P(\lambda)x_j(\lambda) = 0$, i.e., $w_k'(\lambda)^T x_j(\lambda) = 0$ for all $k$. Then the right connection polynomials of $P$ and $Q$ satisfy

$$a_{ij}(\lambda) = \beta_1(\lambda)a_{1j}(\lambda) + \cdots + \beta_{i-1}(\lambda)a_{i-1,j}(\lambda) \quad \text{for} \quad j = 1, \dots, p,$$

and the matrix $[a_{kl}(\lambda)]_{1 \leq k \leq \rho}^{1 \leq l \leq p}$ does not have full row rank. But the fact that $A_s(d_{\min})$ has full row rank implies that $\operatorname{rank}[a_{kl}(\lambda)]_{1 \leq k \leq \rho}^{1 \leq l \leq p} = \rho$, by Lemma 5.6.6.

An analogous argument shows that if $B_t(h_{\min})$ has full row rank, then $\operatorname{rank}[v_1', \dots, v_r', v_1, \dots, v_\rho] = r + \rho$. $\square$

We do not explicitly impose $\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q)$ in Theorem 6.2 because of Lemma 6.1.

THEOREM 6.2. [illegible] $P(\lambda)$ [illegible] $Q(\lambda)$ [illegible] $m \times n$ [illegible] $\operatorname{rank}(P) + \operatorname{rank}(Q) < \min\{m,n\}$ [illegible] $\rho \equiv \operatorname{rank}(Q)$ [illegible] $\varepsilon_1 \leq \cdots \leq \varepsilon_p$ [illegible] $\eta_1 \leq \cdots \leq \eta_q$ [illegible] $P$ [illegible] $\mathcal{J}_P$ [illegible] $P$ [illegible] $\widetilde{\varepsilon}$ [illegible] $\widetilde{\eta}$ [illegible]

[illegible] $Q$ [illegible] $\mathcal{J}_Q$ [illegible] $Q$ [illegible]

$$d_k = \left\lfloor \frac{\sum_{i=1}^{k} \varepsilon_i + \widetilde{\varepsilon}}{k-\rho} \right\rfloor \quad \text{[illegible]} \quad k = \rho+1,\dots,p \quad \text{[illegible]}$$

$$h_l = \left\lfloor \frac{\sum_{i=1}^{l} \eta_i + \widetilde{\eta}}{l-\rho} \right\rfloor \quad \text{[illegible]} \quad l = \rho+1,\dots,q.$$

[illegible] $d_{\min} = \min_{\rho+1\le k\le p}\{d_k\}$ [illegible] $s$ [illegible] $d_s = d_{\min}$ [illegible] $d_s \ge \varepsilon_s$ [illegible] $h_{\min} = \min_{\rho+1\le l\le q}\{h_l\}$ [illegible] $t$ [illegible] $h_t = h_{\min}$ [illegible] $h_t \ge \eta_t$ [illegible] $A_s(d_{\min}-1)$ [illegible] $A_s(d_{\min})$ $B_t(h_{\min}-1)$ [illegible] $B_t(h_{\min})$ [illegible] $s$ [illegible] $t$ [illegible] $d_{\min}-1$ [illegible] $d_{\min}$ $h_{\min}-1$ [illegible] $h_{\min}$ [illegible] $P$ [illegible] $Q$ [illegible]

$A_s(d_{\min}-1)$ [illegible] $B_t(h_{\min}-1)$ [illegible] $A_s(d_{\min})$ [illegible] $B_t(h_{\min})$ [illegible]

[illegible]

1. $(P+Q)(\lambda)$ [illegible] $p-\rho$ [illegible]

$$d_{\min} = \cdots = d_{\min} \tag{50}$$

$$\underbrace{d_{\min} = \cdots = d_{\min}}_{s-\rho-\gamma_s} < \underbrace{(d_{\min}+1) = \cdots = (d_{\min}+1)}_{\gamma_s} \le \varepsilon_{s+1} \le \cdots \le \varepsilon_p, \tag{50}$$

[illegible] $\gamma_s$ [illegible] $\sum_{i=1}^{s} \varepsilon_i + \widetilde{\varepsilon}$ [illegible] $s-\rho$.

2. $(P+Q)(\lambda)$ [illegible] $q-\rho$ [illegible]

$$\underbrace{h_{\min} = \cdots = h_{\min}}_{t-\rho-\mu_t} < \underbrace{(h_{\min}+1) = \cdots = (h_{\min}+1)}_{\mu_t} \le \eta_{t+1} \le \cdots \le \eta_q, \tag{51}$$

[illegible] $\mu_t$ [illegible] $\sum_{i=1}^{t} \eta_i + \widetilde{\eta}$ [illegible] $t-\rho$ [illegible]

3. $\mathcal{J}_P \oplus \mathcal{J}_Q$ [illegible] $(P+Q)(\lambda)$ [illegible] $(P+Q)(\lambda)$

[illegible] 5. We noted in subsection 5.5 that the additional assumption $\operatorname{rank}(Q) \le \operatorname{rank}(P)$ is sufficient for considering that the KCF of $(P+Q)(\lambda)$ found in Theorem 6.2 is generic.

[illegible] 6.2. Theorem 5.8 applied to $P$ and $Q$ proves (50) and applied to $P^T$ and $Q^T$ proves (51). Theorem 4.4 proves that for every complex number $\lambda_0$, including the infinite, $\mathcal{S}_{P+Q}(\lambda_0) \ge \mathcal{S}_{P\oplus Q}(\lambda_0)$. To prove that, in fact, $\mathcal{S}_{P+Q}(\lambda_0) = \mathcal{S}_{P\oplus Q}(\lambda_0)$, we will simply show that the direct sum of $\mathcal{J}_P \oplus \mathcal{J}_Q$ plus the column and row singular blocks corresponding to (50) and to (51) is an $m \times n$ pencil. Let us call this direct sum $Z(\lambda)$.

Let the matrix $\mathcal{J}_P$ be $r_1 \times r_1$, and $\mathcal{J}_Q$ be $r_2 \times r_2$. Notice that, in this situation, the following identities hold:

$$\varepsilon + \eta + q + r_1 = m, \quad \varepsilon + p + \eta + r_1 = n, \quad \widetilde{\varepsilon} + \widetilde{\eta} + r_2 = \rho,$$

where $\varepsilon$ $(\eta)$ is the sum of the column (row) minimal indices of $P$. Thus, the number of rows of $Z(\lambda)$ is

$$\begin{aligned}
&[d_{\min}(s-\rho-\gamma_s) + (d_{\min}+1)\gamma_s + \varepsilon_{s+1} + \cdots + \varepsilon_p] \\
&+ [(h_{\min}+1)(t-\rho-\mu_t) + (h_{\min}+2)\mu_t + (\eta_{t+1}+1) + \cdots + (\eta_q+1)] + r_1 + r_2 \\
&= [\varepsilon + \widetilde{\varepsilon}\,] + [\eta + q + \widetilde{\eta} - \rho\,] + r_1 + r_2 = m + \widetilde{\varepsilon} + \widetilde{\eta} + r_2 - \rho = m.
\end{aligned}$$

An analogous computation shows that the number of columns of $Z(\lambda)$ is $n$, and, therefore, that $Z(\lambda)$ is the KCF of $(P+Q)(\lambda)$. ☐

[illegible] 2. Let us apply Theorem 6.2 to the pencil $P(\lambda)$ of the example in subsection 5.4. In that subsection, we considered a perturbation $Q(\lambda)$ with $\rho = 2$ and $\widetilde{\varepsilon} = 1$. Now, let us assume also that $\widetilde{\eta} = 0$ and that $Q$ has a simple eigenvalue $\mu = 1$. The generic column minimal index of $P+Q$ predicted by Theorem 6.2 was computed in subsection 5.4 and is 3. Let us compute the generic row minimal indices of $P+Q$. In this example $\eta_1 = \eta_2 = \eta_3 = 0$. Thus, the number of row minimal indices of $P+Q$ is $q - \rho = 3 - 2 = 1$. Therefore, $h_{\min} = h_3 = 0$ is the generic row minimal index of $P+Q$. The generic KCF of $P+Q$ is

$$\begin{bmatrix} \lambda & 1 & 0 & 0 & 0 \\ 0 & \lambda & 1 & 0 & 0 \\ 0 & 0 & \lambda & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & \lambda - 1 \end{bmatrix}.$$

In the case that the only information available on the perturbation $Q(\lambda)$ is its rank, Theorem 4.4 can be combined with Theorem 5.10, and the corresponding counterpart version for row minimal indices, to produce Theorem 6.3, that gives partial information of the KCF of $(P+Q)(\lambda)$.

THEOREM 6.3. [illegible] $P(\lambda)$ [illegible] $Q(\lambda)$ [illegible] $m \times n$ [illegible] $\mathrm{rank}(P) + \mathrm{rank}(Q) < \min\{m, n\}$ [illegible] $\mathrm{rank}(Q) \leq \mathrm{rank}(P)$ [illegible] $\rho \equiv \mathrm{rank}(Q)$ [illegible] $\varepsilon_1 \leq \cdots \leq \varepsilon_p$ [illegible] $\eta_1 \leq \cdots \leq \eta_q$ [illegible] $P$ [illegible] $\mathcal{J}_P$ [illegible] $P$ [illegible]

$$d'_k = \left\lfloor \frac{\sum_{i=1}^{k} \varepsilon_i + \rho}{k - \rho} \right\rfloor \quad [illegible] \quad k = \rho + 1, \ldots, p \; [illegible]$$

$$h'_l = \left\lfloor \frac{\sum_{i=1}^{l} \eta_i + \rho}{l - \rho} \right\rfloor \quad [illegible] \quad l = \rho + 1, \ldots, q.$$

[illegible] $d'_{\min}$ $h'_{\min}$ [illegible] $\{d'_k\}$ $\{h'_l\}$ [illegible] $s'$ $t'$ [illegible] $d'_{s'} = d'_{\min}$ $h'_{t'} = h'_{\min}$ [illegible] $d'_{s'} \geq \varepsilon_{s'}$ $h'_{t'} \geq \eta_{t'}$ [illegible] $Q(\lambda)$ [illegible] $\rho$ $(P+Q)(\lambda)$ [illegible] $p - \rho$ [illegible] $q - \rho$ [illegible]

1. [illegible] $p - s'$ [illegible] $(P+Q)(\lambda)$ [illegible] $\varepsilon_{s'+1} \leq \cdots \leq \varepsilon_p$
2. [illegible] $s' - \rho$ [illegible] $(P+Q)(\lambda)$ $\hat{\varepsilon}_1 \leq \cdots \leq \hat{\varepsilon}_{s'-\rho}$ [illegible] $\varepsilon_{\rho+j} \leq \hat{\varepsilon}_j$ [illegible] $j = 1, \ldots, s' - \rho$ [illegible] $\hat{\varepsilon}_1 \leq d'_{min}$
3. [illegible] $q - t'$ [illegible] $(P+Q)(\lambda)$ [illegible] $\eta_{t'+1} \leq \cdots \leq \eta_q$
4. [illegible] $t' - \rho$ [illegible] $(P+Q)(\lambda)$ $\hat{\eta}_1 \leq \cdots \leq \hat{\eta}_{t'-\rho}$ [illegible] $\eta_{\rho+j} \leq \hat{\eta}_j$ [illegible] $j = 1, \ldots, t' - \rho$ [illegible] $\hat{\eta}_1 \leq h'_{min}$
5. [illegible] $(P+Q)(\lambda)$ [illegible] $\mathcal{J}_P$

**7. Conclusions and open problems.** The results presented in this paper are, as far as we know, the first contribution in the area of [illegible] low rank perturbations of singular matrix pencils, but they do not solve all the problems of this kind.

A first interesting problem is to consider unperturbed pencils $P(\lambda)$ [illegible], i.e., $\mathrm{rank}(P) = \min\{m, n\}$. The full rank square case, $m = n$, corresponds to unperturbed regular pencils. In this case the KCF of $P(\lambda)$ does not have singular blocks, and it is called the Weierstrass canonical form. This problem has been solved in [4]. The full rank rectangular case, $m \neq n$, is an open problem. In this case the KCF of $P(\lambda)$ has only one type of singular blocks: $n-m$ column or right singular blocks if $m < n$, and $m-n$ row or left singular blocks if $m > n$. Generically the same holds for the perturbed pencil $(P+Q)(\lambda)$, but the dimensions of the singular blocks may change. A first important task in this setting is to define the precise meaning of [illegible].

A second open problem is to consider unperturbed pencils $P(\lambda)$ without full rank, but [illegible] (1). For instance, if $P(\lambda)$ is a $100 \times 200$ pencil with $\operatorname{rank}(P) = 98$ and the rank of the perturbations is $\rho \equiv \operatorname{rank}(Q) = 3$, then the perturbations $Q(\lambda)$ are, intuitively, low rank perturbations of $P(\lambda)$. The solution of this kind of problem is naturally connected with the results presented in this work and with the first open problem we have discussed in the previous paragraph. In our specific example, the right decomposition of $Q$ in (7) allows us to write $Q(\lambda) = Q_1(\lambda) + Q_2(\lambda)$, where $\operatorname{rank}(Q_1) = 2$ and $\operatorname{rank}(Q_2) = 1$. Thus, we can split the original perturbation problem, $P+Q = P+Q_1+Q_2$, into two perturbation problems of smaller rank, $P+Q_1$ and $(P+Q_1)+Q_2$. The first one is of the type considered in this work, and in the second one the unperturbed pencil $P+Q_1$ has generically full rank.

A final open problem has to do with the fact that in some situations the information given by the results presented in this paper for the [illegible], i.e., $\operatorname{rank}(P+Q) = \operatorname{rank}(P) + \operatorname{rank}(Q) = \min\{m, n\}$, [illegible] is irrelevant. Notice that in the rectangular case—let us assume $m < n$ without loss of generality—our results say that $P+Q$ does not have row minimal indices, and Theorems 5.8 and 5.10 determine the generic column minimal indices. Additionally, Theorem 4.4 gives information on the regular part of $P+Q$. However, in the square case, although our results are still true, they may produce irrelevant information. Let us illustrate this with two examples. The first example is

$$\underbrace{\begin{bmatrix} \lambda & 1 & 0 \\ 0 & \lambda & 1 \\ 0 & 0 & 0 \end{bmatrix}}_{P} + \underbrace{\begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & \lambda \end{bmatrix}}_{Q} = \underbrace{\begin{bmatrix} \lambda & 1 & 0 \\ 0 & \lambda & 2 \\ 0 & 0 & \lambda \end{bmatrix}}_{P+Q}. \tag{52}$$

Notice that $P$ has $\operatorname{rank}(P) = 2$, minimal indices $\varepsilon_1 = 2$ and $\eta_1 = 0$, and no eigenvalues because its rank is 2 for all the values of $\lambda$. The same holds for the dual pencil. Thus, $P$ has no regular part. The pencil $Q$ has $\operatorname{rank}(Q) = 1$, minimal indices $\varepsilon_1 = \varepsilon_2 = 0$ and $\eta_1 = 0, \eta_2 = 1$, and no eigenvalues. However, $P+Q$ has $\operatorname{rank}(P+Q) = 3$; i.e., it is a regular pencil and does not have minimal indices, neither row nor column minimal indices. This is predicted by our theory; see Corollary 3.2. In addition, $P+Q$ has $\mu = 0$ as a triple eigenvalue with only one associated Jordan block. Notice that the information given by Theorem 4.4 is true—$\mathcal{S}_{P+Q}(0) = (3, 0, \dots)$, while $\mathcal{S}_{P \oplus Q}(0) = (0, 0, \dots)$—but irrelevant, because [illegible] $P$ [illegible] $Q$ [illegible] $P+Q$. This first example illustrates a type of perturbation that destroys all the singular information of the unperturbed pencil and creates a regular part in $P+Q$ that does not exist at all in $P$. Therefore the [illegible] of $P+Q$ is created from [illegible] of $P$ and $Q$. Notice that this example is not particular, because once $P$ is fixed and the rank of the perturbations is fixed to be one, it is generic that $\operatorname{rank}(P+Q) = 3$ (see Theorem 3.1), and $P+Q$ has no minimal indices but only a regular part. The second example is the following:

$$\underbrace{\begin{bmatrix} \lambda-1 & 0 \\ 0 & 0 \end{bmatrix}}_{P} + \underbrace{\begin{bmatrix} \lambda & 1+2\lambda \\ 2\lambda & 2+4\lambda \end{bmatrix}}_{Q} = \underbrace{\begin{bmatrix} 2\lambda-1 & 1+2\lambda \\ 2\lambda & 2+4\lambda \end{bmatrix}}_{P+Q}. \tag{53}$$

In this example, the pencil $P$ has $\operatorname{rank}(P)=1$, minimal indices $\varepsilon_1=0$ and $\eta_1=0$, and one simple eigenvalue equal to 1. The pencil $Q$ has $\operatorname{rank}(Q)=1$, minimal indices $\varepsilon_1=1$ and $\eta_1=0$, and no regular part. The pencil $P+Q$ is regular with determinant $\det(P+Q)=2(1+2\lambda)(\lambda-1)$; this means that $P+Q$ has two simple eigenvalues equal to $-1/2$ and 1. Notice that in this case, $\mu=1$ is an eigenvalue of $P$ and also of $P+Q$. This is guaranteed by Theorem 4.4, and it is not a coincidence. But the new eigenvalue appearing in $P+Q$, i.e., $-1/2$, is not related to the regular structure of $P$. In both examples, (52) and (53), it seems difficult to say something generic on the regular part of $P+Q$ beyond Theorem 4.4, except that the new eigenvalues appearing in $P+Q$ will be [illegible] different from those of $P$. However, to find precise conditions for this behavior to hold needs delicate algebraic work and still remains as an open problem.

**Acknowledgments.** The authors thank the editor of this paper, Prof. Ilse Ipsen, and two anonymous referees for many helpful suggestions which have resulted in a great improvement of the presentation.

# STABILITY AND FAST ALGORITHMS OF INCOMPLETE LU FACTORIZATION WITH ZERO-FILL FOR NINE-DIAGONAL MATRICES*

ZHENYUE ZHANG†, MIN FANG†, AND JING WANG†

**Abstract.** Stability and fast algorithms of zero-fill incomplete LU factorization for nonsymmetric nine-diagonal matrices are considered. Based on a convergence analysis of the diagonal sequences in the LU factors of a monotone nine-diagonal matrix, we give necessary and sufficient conditions for stably computing the ILU factorization in terms of an extreme solution to a system of nonlinear equations. Furthermore, the extreme solution is used to construct a fast ILU factorization with much less cost in flops and storage. Basically we use the standard ILU recursions up to a certain point and then replace the remaining terms of the recursive sequences by their limit values that can be determined by the extreme solution. Two strategies, preconditioning the nonlinear system to suit for Newton iterations and estimating the solution to get a good initial for the iterations, are discussed for computing the extreme solution efficiently. We also generalize the stability analysis and propose fast algorithms for nine-diagonal matrices with periodically monotone diagonals or other nonconstant diagonals. Numerical examples show the efficiency of the proposed fast algorithms.

## 1. Introduction.

Solving a large sparse system of linear equations continues to be a major research task in widespread applications. In general, preconditioning is thought of as a necessary technique for solving a linear system in large scale iteratively. One line of research in preconditioning is based upon incomplete LU factorization (ILU) [2, 12, 16, 17, 21].

The stability of factorization plays an important role in the performance of ILU preconditioning. For symmetric M-matrices or positive definite matrices, ILU factorizations exit and are stable; see [15, 16, 24] for discussions. However, standard ILU factorizations often fail for highly indefinite and nonsymmetric sparse matrices because of the instability [5, 9]. It is known that a small pivot can lead to an unstable ILU process or inaccurate factorization, and the ILU recursions may even break down. In [6], instabilities involved in the incomplete factorizations were discussed in detail. In general, a preprocessing on the coefficient matrix is required before or during factorization to guarantee a stable factorization for the resulting matrix. Such preprocessing strategies include nonsymmetrical permutation and scaling [19, 7, 3], or diagonal compensation [2, 18].

Stability of ILU is generally matrix-dependent. For simple two-dimensional partial differential equations (PDE), five-point difference operators are commonly involved and lead to five-diagonal matrices. In [9], stability analysis of ILU with zero fill-in was given for five-diagonal matrices with constant diagonals that are discretized

from a simple two-dimensional non-self-adjoint elliptic problem. The stability was characterized by a positive root of a quadratic equation. This analysis was extended to cover the zero fill-in relaxed ILU denoted by RILU($\omega$) in [10] and the 1-level of fill-in RILU($1, \omega$) in [11] for constant five-diagonal matrices. For some PDE such as Fokker–Planck equations [14], cross-derivative terms play an important role. In that case, a nine-point difference operator is more stable and has better convergence than a five-point difference method [20]. Some discussions for preconditioning nine-point approximation to a convection-diffusion equation were given in [4].

This paper deals with a class of nonsymmetric nine-diagonal matrices that are generally obtained by nine-point difference approximations for two-dimensional PDE. We focus our attention on both the stability and related fast algorithms for (approximate) ILU factorization of a nine-diagonal matrix. For a matrix with infinite size, the stability of ILU of a principal submatrix clearly depends on its matrix size. By [illegible], we mean that the ILU of the principal submatrix is still stable when its matrix size increases infinitely. This makes sense since the number of grids of the considered domain may be increased to achieve a higher accuracy, though the matrix size is always finite in practice. Interestingly, the uniform stability is associated with the convergence of nonlinear recursive scheme of the zero-fill ILU factorization. Indeed, a convergence analysis of the nonlinear recursions touches on two important issues: conditions for uniformly stable ILU and fast algorithms for (approximate) ILU factorizations. These two issues are closely related to each other. In fact, if the limit values can be predetermined, and the iterations have achieved to their limits within an acceptable accuracy, then the recursive process can be terminated duly and the remaining terms of the recursive sequences can be simply replaced by their limit values. This idea leads to a fast ILU factorization with much less cost in flops and storage.

We will start our discussion on the uniform stability of ILU of diagonally monotone matrices (nine-diagonal matrices with monotone diagonal sequences in each diagonal). We will give a detailed analysis of the equivalence between uniform stability and recursive convergence of ILU. The convergence analysis of ILU recursions for a diagonally monotone matrix leads to a nonlinear system of equations with multiple variables. We will show that the uniform stability of ILU is equivalent to the existence of positive solutions to the nonlinear equations. Furthermore, an [illegible] determines the limit values of the ILU recursion sequences. For numerical computation, we will give some discussions related to Newton iterations for solving the nonlinear equations: estimation of the extreme solution and preconditioning the nonlinear equations. An important property is that the different sequences converge at [illegible] convergence rates. This gives an easy way to check the convergence of ILU recursions.

The discussion for uniformly stable ILU will be generalized to nine-diagonal matrices with periodically monotone matrices, which also yields a fast ILU factorization in block form. For a matrix which has nonconstant diagonals, an approximate ILU factorization can also be constructed by applying the fast algorithm to a diagonally monotone or periodic matrix which is an approximation to this matrix. Our stability analysis is also true for the zero-fill relaxed ILU (RILU) [2] since the added terms in RILU do not affect the convergence analysis. It can be generalized to RILU with level of fill-in. For simplicity, we focus our discussion on the RILU factorization. The question of selecting the relaxation parameter of RILU is important in applications, but that is beyond the scope of this paper.

The rest of this paper is organized as follows. In section 2, we give a detailed analysis to show the equivalence of uniform stability of RILU factorization and con-

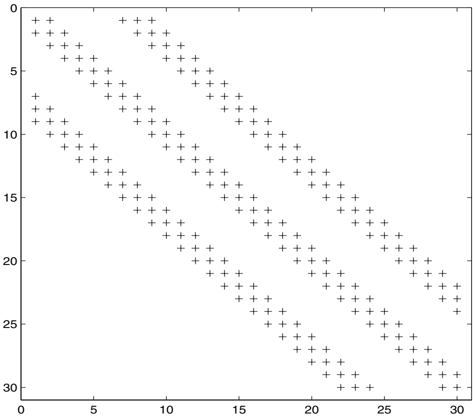

FIG. 1. *The structure of a nine-diagonal matrix of order $N = 30$ with $m = 7$.*

vergence of RILU recursions for diagonally monotone matrices. Some computational issues related to solving the resulting nonlinear system are discussed in section 3. We expand the discussions to more general nine-diagonal matrices such as diagonally periodic matrices in section 4. In section 5, we give fast algorithms for computing the RILU factorization. Some numerical results are reported in section 6.

## 2. The uniform stability of RILU for diagonally monotone matrices.

When a nine-point difference method is applied to a linear non-self-adjoint PDE, the resulting coefficient matrix is a nine-diagonal matrix with the main diagonal and the first, $(m-1)$th, $m$th, and $(m+1)$th upper and lower diagonal lines, where $m \geq 2$ depends on the grid size. Figure 1 illustrates the structure of a nine-diagonal matrix. For simplicity, we write the entries $a_{ij}$ of a nine-diagonal matrix $A = (a_{ij})$ as

$$\begin{array}{lll} a_{i,i} = a_i, & a_{i,i+1} = -b_i, & a_{i+1,i} = -\bar{b}_i, \\ a_{i,i+m-1} = -c_i, & a_{i,i+m} = -d_i, & a_{i,i+m+1} = -e_i, \\ a_{i+m-1,i} = -\bar{c}_i, & a_{i+m,i} = -\bar{d}_i, & a_{i+m+1,i} = -\bar{e}_i, \end{array}$$

and denote the nine-diagonal matrix by

$$A = \{-\bar{e}_i, -\bar{d}_i, -\bar{c}_i, -\bar{b}_i, a_i, -b_i, -c_i, -d_i, -e_i\}.$$

For an elliptic PDE, we may assume that $a_i > 0$ and the rest are nonnegative.

An incomplete LU factorization of $A$ may be written in the form $A = LD^{-1}U - R$ with residual matrix $R$, where $D$ is a diagonal matrix, $L$ is lower triangular and $U$ upper triangular, and the diagonal vectors of $L$, $U$, and $D$ are equal to each other. In the case of zero fill-in, $L$ and $U$ have the same sparse structures as the lower and upper parts of $A$, respectively. For a nine-diagonal matrix $A$, the RILU factorization with zero level of fill-in produces a lower five-diagonal matrix $L$ and an upper five-diagonal $U$ with

$$L = \{-\bar{e}_i, -\bar{\lambda}_i, -\bar{\gamma}_i, -\bar{\beta}_i, \alpha_i, 0, 0, 0, 0\},$$

$$U = \{0, 0, 0, 0, \alpha_i, -\beta_i, -\gamma_i, -\lambda_i, -e_i\},$$

$$D = \mathrm{diag}(\alpha_1, \alpha_2, \ldots, \alpha_N),$$

where $N$ is the size of $A$. The residual matrix $R = LD^{-1}U - A$ is a five-diagonal matrix with zero entries outside of the five diagonals: the main diagonal and the second and $(m-2)$th upper and lower diagonals. It is easy to verify that the RILU factorization can be executed by the following nonlinear recursions:

$$\beta_i = b_i + \frac{\bar\gamma_{i-m+1}\lambda_{i-m+1}}{\alpha_{i-m+1}} + \frac{e_{i-m}\bar\lambda_{i-m}}{\alpha_{i-m}}, \quad \bar\beta_i = \bar b_i + \frac{\gamma_{i-m+1}\bar\lambda_{i-m+1}}{\alpha_{i-m+1}} + \frac{\bar e_{i-m}\lambda_{i-m}}{\alpha_{i-m}}, \tag{2.1}$$

$$\gamma_i = c_i + \lambda_{i-1}\frac{\bar\beta_{i-1}}{\alpha_{i-1}}, \quad \bar\gamma_i = \bar c_i + \bar\lambda_{i-1}\frac{\beta_{i-1}}{\alpha_{i-1}}, \tag{2.2}$$

$$\lambda_i = d_i + e_{i-1}\frac{\bar\beta_{i-1}}{\alpha_{i-1}}, \quad \bar\lambda_i = \bar d_i + \bar e_{i-1}\frac{\beta_{i-1}}{\alpha_{i-1}}, \tag{2.3}$$

$$\begin{aligned}\alpha_i = a_i &- \frac{\big(\beta_{i-1} + \omega\gamma_{i-1}\big)\bar\beta_{i-1}}{\alpha_{i-1}} - \frac{\big(\gamma_{i-m+1} + \omega(e_{i-m+1} + \beta_{i-m+1})\big)\bar\gamma_{i-m+1}}{\alpha_{i-m+1}} \\ &- \frac{\lambda_{i-m}\bar\lambda_{i-m}}{\alpha_{i-m}} - \frac{\big(e_{i-m-1} + \omega\gamma_{i-m-1}\big)\bar e_{i-m-1}}{\alpha_{i-m-1}}.\end{aligned} \tag{2.4}$$

Here we assume $\alpha_1 = a_1$ and

$$\beta_i = \bar\beta_i = \lambda_i = \bar\lambda_i = \gamma_i = \bar\gamma_i = 0$$

if $i \le 0$. Note that if $A$ has a finite size $N$, the terms $e_{N-m}$, $\bar e_{N-m}$, $e_{N-m+1}$, $\bar e_{N-m+1}$, $\gamma_i$, $\bar\gamma_i$ $(i \ge N-m+2)$, $\lambda_i$, $\bar\lambda_i$ $(i \ge N-m+1)$ are not involved in the RILU recursions because they are not in the matrix. So we set $\gamma_i = \bar\gamma_i = 0$ for $i \ge N-m+2$ and $\lambda_i = \bar\lambda_i = 0$ for $i \ge N-m+1$ in (2.4); see Algorithm RILU for details.

The RILU recursions result in the seven sequences $\{\alpha_i\}$, $\{\beta_i\}$, $\{\bar\beta_i\}$, $\{\lambda_i\}$, $\{\bar\lambda_i\}$, $\{\gamma_i\}$, and $\{\bar\gamma_i\}$. For convenience, we call $\{a_i\}$, $\{b_i\}$, $\{c_i\}$, $\{d_i\}$, $\{e_i\}$, $\{\bar b_i\}$, $\{\bar c_i\}$, $\{\bar d_i\}$, and $\{\bar e_i\}$ the input sequences and $\{\alpha_i\}$, $\{\beta_i\}$, $\{\bar\beta_i\}$, $\{\lambda_i\}$, $\{\bar\lambda_i\}$, $\{\gamma_i\}$, and $\{\bar\gamma_i\}$ the output sequences. That ILU of $A$ is uniformly stable implies that $\{\alpha_i\}$ has a positive lower bound. By the recursive formulae (2.2)–(2.4), we have the following obvious observations.

Lemma 2.1. [illegible] $\{\alpha_i\}$ [illegible]

$$\alpha_i \le a_i,\ \beta_i \ge b_i,\ \bar\beta_i \ge \bar b_i,\ \gamma_i \ge c_i,\ \bar\gamma_i \ge \bar c_i,\ \lambda_i \ge d_i,\ \bar\lambda_i \ge \bar d_i. \tag{2.5}$$

[illegible] $\{a_i\}$ [illegible]

[illegible]. Since $\alpha_i > 0$ for all $i$ and all the inputs are nonnegative, by the recursions (2.2)–(2.3), it is obviously true that the outputs except for $\{\alpha_i\}$ are nonnegative at least. So the first assertion is true by (2.2)–(2.4). The second assertion follows from (2.4). In fact, by the assumed properties of the input sequences and (2.5), $\{\alpha_i\}$ is bounded above while the other output sequences have positive lower bounds. Notice that all the sequences are nonnegative. We have by (2.4) that

$$0 < \alpha_i \le a_i - \frac{\beta_{i-1}\bar\beta_{i-1}}{\alpha_{i-1}}, \quad a_i - \frac{\gamma_{i-m+1}\bar\gamma_{i-m+1}}{\alpha_{i-m+1}}, \quad a_i - \frac{\lambda_{i-m}\bar\lambda_{i-m}}{\alpha_{i-m}}.$$

Hence $\beta_i\bar\beta_i \le a_{i+1}a_i$, $\gamma_i\bar\gamma_i \le a_{m+i-1}a_i$, and $\lambda_i\bar\lambda_i \le a_{m+i}a_i$ since $\alpha_i \le a_i$. It follows immediately that $\{\beta_i\}$, $\{\bar\beta_i\}$, $\{\gamma_i\}$, $\{\bar\gamma_i\}$, $\{\lambda_i\}$, and $\{\bar\lambda_i\}$ are bounded above since

Algorithm RILU (relaxed incomplete LU factorization).

```

they have positive lower bounds. Finally, $\{\alpha_i\}$ has a positive bound because $\alpha_i > \beta_i\bar\beta_i/a_{i+1}$. $\square$

We say $A$ is [illegible] if the input sequences are positive. We also say $A$ is [illegible] if $\{a_i\}$ is decreasing and the other input sequences are increasing. Furthermore, $A$ is said to be [illegible] if its diagonal sequences are convergent. For a diagonally positive and monotone $A$, if $\{\alpha_i\}$ is positive, we can conclude that the outputs are monotone; i.e., $\{\alpha_i\}$ is decreasing and the other output sequences are increasing. This assertion can be easily verified due to the initial monotonicity

$$\alpha_2 \le \alpha_1,\ \beta_2 \ge \beta_1,\ \gamma_2 \ge \gamma_1,\ \lambda_2 \ge \lambda_1,\ \bar\beta_2 \ge \bar\beta_1,\ \bar\gamma_2 \ge \bar\gamma_1,\ \bar\lambda_2 \ge \bar\lambda_1,$$

and the monotone recursions (2.2)–(2.4) of the respective terms. Thus, Lemma 2.1 ensures the convergence of the output sequences. Notice that, by the first assertion of Lemma 2.1, the input sequences are also bounded and hence convergent. Therefore the following theorem is true.

THEOREM 2.2. $A$ $A$ $A$ $\{\alpha_i\}$ $\{\beta_i\}$ $\{\bar\beta_i\}$ $\{\lambda_i\}$ $\{\bar\lambda_i\}$ $\{\gamma_i\}$ $\{\bar\gamma_i\}$

As a necessary condition for uniformly stable RILU, all the input sequences are assumed to be convergent. We denote the limit values by $a$, $b$, $c$, $d$, $\bar a$, $\bar b$, $\bar c$, and $\bar d$, respectively. The limits of the output sequences are denoted by $\alpha^*$, $\beta^*$, $\gamma^*$, $\lambda^*$, $\bar\beta^*$, $\bar\gamma^*$, and $\bar\lambda^*$. By (2.2)–(2.4), we obviously have

$$\beta^* = b + \frac{\lambda^*\bar\gamma^* + e\bar\lambda^*}{\alpha^*}, \qquad \bar\beta^* = \bar b + \frac{\bar\lambda^*\gamma^* + \bar e\lambda^*}{\alpha^*}, \tag{2.6}$$

$$\gamma^* = c + \frac{\lambda^*\bar\beta^*}{\alpha^*}, \qquad \bar\gamma^* = \bar c + \frac{\bar\lambda^*\beta^*}{\alpha^*}, \tag{2.7}$$

$$\lambda^* = d + \frac{e\bar\beta^*}{\alpha^*}, \qquad \bar\lambda^* = \bar d + \frac{\bar e\beta^*}{\alpha^*}, \tag{2.8}$$

and

$$\alpha^* = a - \frac{1}{\alpha^*}\Big(\beta^*\bar\beta^* + \gamma^*\bar\gamma^* + \lambda^*\bar\lambda^* + e\bar e + \omega\big((\bar e + \bar\beta^*)\gamma^* + (e + \beta^*)\bar\gamma^*\big)\Big). \tag{2.9}$$

We will modify the equalities (2.6)–(2.9) equivalently and yield a compact form by introducing $t^* = \beta^*/\alpha^*$ and $\bar t^* = \bar\beta^*/\alpha^*$, the limit values of sequences $\{t_i\}$ and $\{\bar t_i\}$ with $t_i = \beta_i/\alpha_i$ and $\bar t_i = \bar\beta_i/\alpha_i$. To this end, we substitute (2.7) and (2.8) into (2.6) and (2.9). By simple calculations, it is easy to verify that $(\alpha^*, t^*, \bar t^*)$ is a positive solution to the following nonlinear system with variables $\alpha$, $t$, and $\bar t$:

$$(b - t\alpha)\alpha + \lambda\bar\gamma + e\bar\lambda = 0, \tag{2.10}$$

$$(\bar b - \bar t\alpha)\alpha + \bar\lambda\gamma + \bar e\lambda = 0, \tag{2.11}$$

$$(\alpha - a)\alpha + \beta\bar\beta + \gamma\bar\gamma + \lambda\bar\lambda + e\bar e + \omega\big((\bar e + \bar\beta)\gamma + (e + \beta)\bar\gamma\big) = 0, \tag{2.12}$$

where $\lambda = \lambda(\bar t)$, $\gamma = \gamma(\bar t)$, $\bar\lambda = \bar\lambda(t)$, $\bar\gamma = \bar\gamma(t)$, $\beta = \beta(\alpha, t)$, and $\bar\beta = \bar\beta(\alpha, \bar t)$ are simply defined by

$$\lambda = d + e\bar t, \quad \gamma = c + \lambda\bar t, \quad \bar\lambda = \bar d + \bar e t, \quad \bar\gamma = \bar c + \bar\lambda t, \quad \beta = t\alpha, \quad \bar\beta = \bar t\alpha. \tag{2.13}$$

Conversely, if the nonlinear system has a positive solution, the RILU of $A$ is also uniformly stable.

THEOREM 2.3. $A$ $A$ (2.10)–(2.12) $(\alpha, t, \bar t)$

The necessity has been proven. To show the sufficiency, assume that the nonlinear equations (2.10)–(2.12) have a positive solution $(\alpha, t, \bar t)$. It follows from (2.13) that $\beta$, $\bar\beta$, $\lambda$, $\bar\lambda$, $\gamma$, and $\bar\gamma$ are positive. Thus the first terms in each of the three equalities (2.10)–(2.12) must be negative. Hence

$$\beta > b, \quad \bar\beta > \bar b, \quad \alpha < a. \tag{2.14}$$

We use the inequalities above to prove the monotonicity of the outputs

$$\begin{cases} \alpha_{i-1} \ge \alpha_i > \alpha, \\ 0 \le \beta_{i-1} \le \beta_i < \beta, \quad 0 \le \bar\beta_{i-1} \le \bar\beta_i < \bar\beta, \\ 0 \le \gamma_{i-1} \le \gamma_i < \gamma, \quad 0 \le \bar\gamma_{i-1} \le \bar\gamma_i < \bar\gamma, \\ 0 \le \lambda_{i-1} \le \lambda_i < \lambda, \quad 0 \le \bar\lambda_{i-1} \le \bar\lambda_i < \bar\lambda \end{cases} \tag{2.15}$$

by induction. From (2.2)–(2.4), (2.9), and (2.14), we see that

$$\beta_2 = \beta_1 = b < \beta, \quad \bar\beta_2 = \bar\beta_1 = \bar b < \bar\beta, \quad \alpha_1 \ge \alpha_2 = a - \frac{\beta_1\bar\beta_1}{a} > a - \frac{\beta\bar\beta}{\alpha} > \alpha$$

and

$$\lambda_1 \le \lambda_2 = d + e\frac{\bar\beta_1}{\alpha_1} < d + e\frac{\bar\beta}{\alpha} = \lambda, \quad \bar\lambda_1 \le \bar\lambda_2 = \bar d + e\frac{\beta_1}{\alpha_1} < \bar d + e\frac{\beta}{\alpha} = \bar\lambda,$$

$$\gamma_1 \le \gamma_2 = c + \lambda_1\frac{\beta_1}{\alpha_1} < c + \lambda\frac{\beta}{\alpha} = \gamma, \quad \bar\gamma_1 \le \bar\gamma_2 = \bar c + \bar\lambda_1\frac{\beta_1}{\alpha_1} < \bar c + \bar\lambda\frac{\beta}{\alpha} = \bar\gamma.$$

Hence (2.15) is true for $i = 2$.

Assume (2.15) holds for all $i \le k$. Then

$$\lambda_k = d + e\frac{\bar\beta_{k-1}}{\alpha_{k-1}} \le d + e\frac{\bar\beta_k}{\alpha_k} = \lambda_{k+1} \quad \text{and} \quad \lambda_{k+1} = d + e\frac{\bar\beta_k}{\alpha_k} < d + e\frac{\bar\beta}{\alpha} = \lambda.$$

Similarly we have

$$\bar\lambda_k \le \bar\lambda_{k+1} < \bar\lambda, \quad \beta_k \le \beta_{k+1} < \beta, \quad \bar\beta_k \le \bar\beta_{k+1} < \bar\beta,$$

$$\gamma_k \le \gamma_{k+1} < \gamma, \quad \bar\gamma_k \le \bar\gamma_{k+1} < \bar\gamma, \quad \alpha_k < \alpha_{k+1}.$$

It follows from (2.4) that

$$\alpha_{k+1} > a - \frac{1}{\alpha}\Big(\bar\beta\beta + \bar\gamma\gamma + \bar\lambda\lambda + \bar e e - \omega(\bar e\gamma + e\bar\gamma + \bar\gamma\beta + \gamma\bar\beta)\Big) = \alpha.$$

Thus (2.15) also holds for $i = k+1$. We conclude that $\alpha_i > \alpha > 0$ holds for all $i$; i.e., the RILU factorization is uniformly stable. □

The nonlinear system (2.10)–(2.12) may have multiple positive solutions. However, the solution $(\alpha^*, t^*, \bar t^*)$ has the following extreme properties: for any positive solution $(\alpha,\ t,\ \bar t)$ of (2.10)–(2.12),

$$\alpha^* \ge \alpha, \quad t^* \le t, \quad \bar t^* \le \bar t. \tag{2.16}$$

From the proof in the sufficiency part above, $\alpha_i \ge \alpha$ for all $i$ implies $\alpha^* \ge \alpha$. The last two inequalities follow from $t^*\alpha^* = \beta^* = t\alpha$ and $\bar t^*\alpha^* = \bar\beta^* = \bar t\alpha$. Obviously, $(\alpha^*, t^*, \bar t^*)$ is unique. We call it an [illegible] solution of (2.10)–(2.12).

Clearly, $\{\alpha_i\}$, $\{t_i\}$, and $\{\bar t_i\}$ determine the convergence behaviors of the other output sequences. The following theorem shows that all the output sequences converge at equivalent rates. This is an important property for constructing a fast RILU factorization which will be discussed in the next section.

THEOREM 2.4. [illegible] $A$ [illegible] $A$ [illegible]

(a) $$\frac{\bar\gamma^*\lambda^* + e\bar\lambda^*}{(\alpha^*)^2\alpha_1} \le \frac{t^* - t_i}{\alpha_i - \alpha^*} \le \frac{1}{\bar\beta^*}, \quad \frac{\gamma^*\bar\lambda^* + \bar e\lambda^*}{(\alpha^*)^2\alpha_1} \le \frac{\bar t^* - \bar t_i}{\alpha_i - \alpha^*} \le \frac{1}{\beta^*},$$

(b) $$\frac{\bar\gamma^*\lambda^* + e\bar\lambda^*}{\alpha^*\alpha_1} \le \frac{\beta^* - \beta_i}{\alpha_i - \alpha^*} \le \frac{\alpha^*}{\bar\beta^*}, \quad \frac{\gamma^*\bar\lambda^* + \bar e\lambda^*}{\alpha^*\alpha_1} \le \frac{\bar\beta^* - \bar\beta_i}{\alpha_i - \alpha^*} \le \frac{\alpha^*}{\beta^*},$$

(c) $$\lambda^* - \lambda_{i+1} = e(\bar t^* - \bar t_i), \quad \bar\lambda^* - \bar\lambda_{i+1} = \bar e(t^* - t_i),$$

(d) $$\frac{\lambda^*(\bar\gamma^*\lambda^* + e\bar\lambda^*)}{(\alpha^*)^2\alpha_1} \le \frac{\gamma^* - \gamma_{i+2}}{\alpha_i - \alpha^*} \le \frac{e\bar t^* + \lambda^*}{\beta^*}, \quad \frac{\bar\lambda^*(\gamma^*\bar\lambda^* + \bar e\lambda^*)}{(\alpha^*)^2\alpha_1} \le \frac{\bar\gamma^* - \bar\gamma_{i+2}}{\alpha_i - \alpha^*} \le \frac{\bar e t^* + \bar\lambda^*}{\bar\beta^*}.$$

[illegible]. The monotonicity of the sequences will be repeatedly used without comment. Substituting all terms in (2.4) except for the second one by their limit values, we have

$$\alpha_i \geq a^* - \bar{\beta}^* t_{i-1} - \frac{\omega\gamma^*\bar{\beta}^*}{\alpha^*} - \frac{\big(\gamma^* + \omega(e+\beta^*)\big)\bar{\gamma}^*}{\alpha^*} - \frac{\lambda^*\bar{\lambda}^*}{\alpha^*} - \frac{\big(e+\omega\gamma^*\big)\bar{e}}{\alpha^*} = \alpha^* + \bar{\beta}^*(t^* - t_{i-1}).$$

The equality on the right follows from (2.9). So $t^* - t_i \leq t^* - t_{i-1} \leq \frac{\alpha_i - \alpha^*}{\bar{\beta}^*}$. Again, by $\alpha_i \geq \alpha^*$, we get

$$\beta^* - \beta_i = \alpha^* t^* - \alpha_i t_i \leq \alpha^*(t^* - t_i) \leq \frac{\alpha^*}{\bar{\beta}^*}(\alpha_i - \alpha^*).$$

On the other hand, by (2.2) and (2.6),

$$\beta^* - \beta_i \geq (\bar{\gamma}^*\lambda^* + e\bar{\lambda}^*)\left(\frac{1}{\alpha^*} - \frac{1}{\alpha_i}\right) = \frac{\bar{\gamma}^*\lambda^* + e\bar{\lambda}^*}{\alpha^*\alpha_i}(\alpha_i - \alpha^*) \geq \frac{\bar{\gamma}^*\lambda^* + e\bar{\lambda}^*}{\alpha^*\alpha_1}(\alpha_i - \alpha^*)$$

and

$$t^* - t_i = \frac{\beta^*}{\alpha^*} - \frac{\beta_i}{\alpha_i} \geq \frac{\beta^* - \beta_i}{\alpha^*} \geq \frac{\bar{\gamma}^*\lambda^* + e\bar{\lambda}^*}{(\alpha^*)^2\alpha_1}(\alpha_i - \alpha^*).$$

Thus, the bounds of $\frac{t^* - t_i}{\alpha_i - \alpha_i^*}$ and $\frac{\beta^* - \beta_i}{\alpha_i - \alpha_i^*}$ in (a) and (b) hold. Similarly, we can prove (a) and (b) for $\frac{\bar{t}^* - \bar{t}_i}{\alpha_i - \alpha_i^*}$ and $\frac{\bar{\beta}^* - \bar{\beta}_i}{\alpha_i - \alpha_i^*}$. The equalities in (c) follow directly from the definition. Finally, the recursions (2.2) and (2.8) give

$$\gamma^* - \gamma_{i+2} = \lambda^*\bar{t}^* - \lambda_{i+1}\bar{t}_{i+1} = (\lambda^* - \lambda_{i+1})\bar{t}^* + \lambda_{i+1}(\bar{t}^* - \bar{t}_{i+1}) = e\bar{t}^*(\bar{t}^* - \bar{t}_i) + \lambda_{i+1}(\bar{t}^* - \bar{t}_{i+1}).$$

By the inequalities $\bar{t}^* - \bar{t}_{i+1} \leq \bar{t}^* - \bar{t}_i$, $d \leq \lambda_{i+1} \leq \lambda^*$, we have

$$\lambda^*(\bar{t}^* - \bar{t}_{i+1}) = (e\bar{t}^* + d)\,(\bar{t}^* - \bar{t}_{i+1}) \leq \gamma^* - \gamma_{i+2} \leq (e\bar{t}^* + \lambda^*)\,(\bar{t}^* - \bar{t}_i).$$

Therefore (d) follows immediately from the bounds given in (a). $\square$

It is convenient to check the convergence of the RILU recursions using the uniform properties shown in Theorem 2.4, meaning that we only have to check the convergence of $\{\alpha_i\}$, provided that the limit $\alpha^*$ can be predetermined.

## 3. Computing the extreme solution.

It is difficult to formulate solutions of the nonlinear system (2.10)–(2.12). The common method is to use Newton iterations, and that is what we are going to do. However, to improve efficiency, the system of equations (2.10)–(2.12) will be preconditioned such that the resulting nonlinear system also has the extreme solution and can be computed by the Newton method applied on the new system. We also give an estimation of the extreme solution to find an initial guess for the Newton iterations.

### 3.1. Estimation of the extreme solution.

The following lower bounds of $\lambda^*$, $\bar{\lambda}^*$, $\gamma^*$, and $\bar{\gamma}^*$ come directly from (2.13):

$$\lambda^* \geq d, \quad \gamma^* \geq c, \quad \bar{\lambda}^* \geq \bar{d}, \quad \bar{\gamma}^* \geq \bar{c}.$$

By (2.6) we have lower bounds

$$\beta^* \geq b + (\bar{c}d + e\bar{d})/\alpha^*, \quad \bar{\beta}^* \geq \bar{b} + (c\bar{d} + \bar{e}d)/\alpha^* \tag{3.1}$$

of $\beta^*$ and $\bar{\beta}^*$. For convenience, we will use the simple lower bounds $b$ and $\bar{b}$ for $\beta^*$ and $\bar{\beta}^*$. Substituting these bounds into (2.12) and by simple calculations, we obtain

$$(\alpha^*)^2 - a\alpha^* + (b\bar{b} + c\bar{c} + d\bar{d} + e\bar{e}) + \omega\big((\bar{e} + \bar{b})c + (e + b)\bar{c}\big) \le 0,$$

an inequality quadratic in $\alpha^*$. It implies the necessary condition

$$a^2 \ge 4\Big(b\bar{b} + c\bar{c} + d\bar{d} + e\bar{e} + \omega(\bar{e}c + \bar{c}b + e\bar{c} + c\bar{b})\Big)$$

for uniformly stable RILU, and $\alpha^*$ is bounded by the two roots,

$$\frac{a - \sqrt{\Delta}}{2} \le \alpha^* \le \frac{a + \sqrt{\Delta}}{2}, \tag{3.2}$$

where $\Delta = a^2 - 4(b\bar{b} + c\bar{c} + d\bar{d} + e\bar{e} + \omega(\bar{e}c + \bar{c}b + e\bar{c} + c\bar{b}))$. Thus, (3.1) and (3.2) yield the lower bounds

$$t^* \ge \frac{2b}{a + \sqrt{\Delta}} + \frac{4(\bar{c}d + e\bar{d})}{(a + \sqrt{\Delta})^2}, \quad \bar{t}^* \ge \frac{2\bar{b}}{a + \sqrt{\Delta}} + \frac{4(c\bar{d} + \bar{e}d)}{(a + \sqrt{\Delta})^2} \tag{3.3}$$

for $t^* = \beta^*/\alpha^*$ and $\bar{t}^* = \bar{\beta}^*/\alpha^*$. We summarize these results in the following theorem.

THEOREM 3.1. [illegible] $A$ [illegible] $A$ [illegible] $(\alpha^*, t^*, \bar{t}^*)$ [illegible] (2.10)–(2.12) [illegible] (3.2) [illegible] (3.3)

**3.2. Preconditioning (2.10)–(2.12) for the extreme solution.** We will precondition (2.10)–(2.12) and establish an equivalent system of two nonlinear equations that involve $t$ and $\bar{t}$ only. It is obvious that (2.10) and (2.11) are equivalent to

$$\begin{aligned} \alpha &= \tfrac{1}{2t}\Big(b + \sqrt{b^2 + 4t(\lambda\bar{\gamma} + e\bar{\lambda})}\Big) \equiv \phi(t, \bar{t}), \\ \alpha &= \tfrac{1}{2\bar{t}}\Big(\bar{b} + \sqrt{\bar{b}^2 + 4\bar{t}(\bar{\lambda}\gamma + \bar{e}\lambda)}\Big) \equiv \bar{\phi}(t, \bar{t}), \end{aligned} \tag{3.4}$$

respectively. This leads to the first equation $\phi(t, \bar{t}) = \bar{\phi}(t, \bar{t})$.

There are many approaches to derive equivalent representations of $\alpha$ in terms of $t$ and $\bar{t}$ to get the second equation. For example, eliminating the square term of $\alpha$ in (2.10) and (2.12) yields

$$\alpha = \frac{t\Big(\gamma\bar{\gamma} + \lambda\bar{\lambda} + e\bar{e} + \omega(\bar{e}\gamma + e\bar{\gamma})\Big) + (1 + t\bar{t})(\lambda\bar{\gamma} + e\bar{\lambda})}{t\Big(a - \omega(\bar{\gamma}t + \gamma\bar{t})\Big) - b(1 + t\bar{t})} \equiv \eta(t, \bar{t}).$$

Likewise, from (2.11) and (2.12) we obtain

$$\alpha = \frac{\bar{t}\Big(\gamma\bar{\gamma} + \lambda\bar{\lambda} + e\bar{e} + \omega(\bar{e}\gamma + e\bar{\gamma})\Big) + (1 + t\bar{t})(\bar{\lambda}\gamma + \bar{e}\lambda)}{\bar{t}\Big(a - \omega(\bar{\gamma}t + \gamma\bar{t})\Big) - \bar{b}(1 + t\bar{t})} \equiv \bar{\eta}(t, \bar{t}).$$

One can prove that (2.10)–(2.12) have positive solutions if and only if

$$\eta(t, \bar{t}) = \phi(t, \bar{t}) = \bar{\phi}(t, \bar{t}) \tag{3.5}$$

have positive solutions and that $(t^*, \bar{t}^*)$ with $t^* = \frac{\beta^*}{\alpha^*}$ and $\bar{t}^* = \frac{\bar{\beta}^*}{\alpha^*}$ is the smallest positive solution of (3.5).

However, we do not want to let $\eta(t, \bar{t}) = \phi(t, \bar{t})$ be the second equation for determining the extreme solution $(t^*, \bar{t}^*)$ because $\eta(t, \bar{t})$ has relative large partial derivatives nearby $(t^*, \bar{t}^*)$. Newton-like iterative methods converge slowly if partial derivatives are large in a neighborhood of a solution. Fortunately, a flatter function is available and can be derived as follows.

Substitute $\beta = t\alpha$ and $\bar{\beta} = \bar{t}\alpha$ into (2.12), and denoting

$$\zeta = \gamma\bar{\gamma} + \lambda\bar{\lambda} + e\bar{e}, +\omega(\bar{e}\gamma + e\bar{\gamma}),$$

we obtain

$$(1 + t\bar{t})\alpha^2 + (\omega(\bar{\gamma}t + \gamma\bar{t}) - a)\alpha + \zeta = 0. \tag{3.6}$$

Then we have $\alpha = \psi_+(t, \bar{t})$, where

$$\psi_+(t, \bar{t}) = \frac{a - \omega(\bar{\gamma}t + \gamma\bar{t}) + \sqrt{(a - \omega(\bar{\gamma}t + \gamma\bar{t}))^2 - 4(1 + t\bar{t})\zeta}}{2(1 + t\bar{t})} \tag{3.7}$$

is the largest root of the quadratic equation (3.6). We will use $\phi(t, \bar{t}) = \psi_+(t, \bar{t})$ as the second equation to determine the extreme solution $(t^*, \bar{t}^*)$, together with $\phi(t, \bar{t}) = \bar{\phi}(t, \bar{t})$. Theorem 3.3 below shows the equivalence between the system of these two equations and the system (2.10)–(2.12). We remark that the smallest root $\psi_-(t, \bar{t})$ of the quadratic equation (3.6) cannot be chosen to compute $(t^*, \bar{t}^*)$, due to its increasing property shown in the following lemma. This lemma is also used in the proof of Theorem 3.3.

Lemma 3.2. [illegible] $\psi_-(t, \bar{t})$ [illegible] (3.6) [illegible] $t > 0$ [illegible] $\bar{t} > 0$

$$\frac{\partial \psi_-(t, \bar{t})}{\partial t} > 0, \quad \frac{\partial \psi_-(t, \bar{t})}{\partial \bar{t}} > 0.$$

[illegible] Let

$$h(t, \bar{t}) = \omega(\bar{\gamma}t + \gamma\bar{t}) - a, \quad g(t, \bar{t}) = \gamma\bar{\gamma} + \lambda\bar{\lambda} + e\bar{e} + \omega(\bar{e}\gamma + e\bar{\gamma}).$$

We have

$$(1 + t\bar{t})\psi_-^2(t, \bar{t}) + h(t, \bar{t})\psi_-(t, \bar{t}) + g(t, \bar{t}) \equiv 0.$$

Taking the partial derivative with respect to $t$ yields

$$(2(1 + t\bar{t})\psi_- + h)\frac{\partial \psi_-}{\partial t} + F(t, \bar{t}) = 0,$$

where $F(t, \bar{t}) = \bar{t}\psi_-^2 + \frac{\partial h}{\partial t}\psi_- + \frac{\partial g}{\partial t} > 0$ for positive $t$ and $\bar{t}$, since $\frac{\partial h}{\partial t} > 0$ and $\frac{\partial g}{\partial t} > 0$. On the other hand,

$$\psi_- < \frac{\psi_- + \psi_+}{2} = -\frac{h}{2(1 + t\bar{t})}.$$

Hence $2(1 + t\bar{t})\psi_- + h < 0$. Therefore, $\frac{\partial \psi_-}{\partial t} = -\frac{F}{2(1+t\bar{t})\psi_- + h} > 0$. Similarly, one can prove that the partial derivative of $\psi_-$ with respective to $\bar{t}$ is also positive. ☐

THEOREM 3.3. [illegible] (2.10)–(2.12) [illegible]

$$\psi_+(t,\bar t) = \phi(t,\bar t) = \bar\phi(t,\bar t) \tag{3.8}$$

[illegible] $(t^*,\bar t^*)$ [illegible] $\{(t_i,\bar t_i)\}$ [illegible] (3.8)

[illegible]. The proof for sufficiency is simple. If (3.8) has a positive solution $(t,\bar t)$, then the value $\alpha = \psi_+(t,\bar t) = \phi(t,\bar t) = \bar\phi(t,\bar t)$ is positive and hence $(\alpha, t, \bar t)$ satisfies (2.10)–(2.12) by (3.4) and (3.7).

Conversely, if (2.10)–(2.12) has positive solutions, then for the extreme solution $(\alpha^*, t^*, \bar t^*)$, $\alpha^* = \phi(t^*,\bar t^*) = \bar\phi(t^*,\bar t^*)$. So $(t^*,\bar t^*)$ solves (3.8) if we can prove $\alpha^* = \psi_+(t^*,\bar t^*)$. To this end, we consider the RILU of the diagonally constant matrix

$$A = \{-\bar e, -\bar d, -\bar c, -\bar b, a, -b, -c, -d, -e\}.$$

By Theorem 2.3, the RILU factorization is uniformly stable and hence, by Theorem 2.2, the output sequences are positive and monotone convergent: $\{\alpha_i\}$ is decreasing and the others are increasing. Therefore,

$$\alpha_i \ge \alpha_{i+1} \ge a - t_i\bar t_i\alpha_i - \frac{\bar\gamma_{i+1}\gamma_{i+1} + \bar\lambda_{i+1}\lambda_{i+1} + \bar e e}{\alpha_i} - \omega\Big(\frac{\bar e\gamma_{i+1} + e\bar\gamma_{i+1}}{\alpha_i} + \bar\gamma_{i+1}t_i + \gamma_{i+1}\bar t_i\Big).$$

Notice that $\lambda_{i+1} = \lambda(\bar t_i)$ and $\bar\lambda_{i+1} = \bar\lambda(t_i)$ as defined in (2.13). We also have $\gamma_{i+1} \ge \gamma(\bar t_i)$ and $\bar\gamma_{i+1} \ge \bar\gamma(t_i)$. Substituting them into the inequality for $\alpha_i$ above yields the quadratic inequality

$$\begin{aligned}(1 + t_i\bar t_i)\alpha_i^2 &+ \Big(\omega\big(\bar\gamma(t_i)t_i + \gamma(\bar t_i)\bar t_i\big) - a\Big)\alpha_i \\ &+ \gamma(\bar t_i)\bar\gamma(t_i) + \lambda(\bar t_i)\bar\lambda(t_i) + e\bar e + \omega\Big(\bar e\gamma(\bar t_i) + e\bar\gamma(t_i)\Big) \ge 0\end{aligned}$$

for $\alpha_i$. Thus, $\alpha_i \le \psi_-(t_i,\bar t_i)$ or $\alpha_i \ge \psi_+(t_i,\bar t_i)$, where $\psi_-(t_i,\bar t_i)$ and $\psi_+(t_i,\bar t_i)$ are the two roots of the quadratic function. Notice that $(\alpha_i, t_i, \bar t_i) \to (\alpha^*, t^*, \bar t^*)$. So $\alpha^*$ is a root of the quadratic equation (3.6) with $t = t^*$ and $\bar t = \bar t^*$, and the limit $\psi_-(t^*,\bar t^*)$ of $\{\psi_-(t_i,\bar t_i)\}$ is the smallest root. We conclude that $\alpha_i \ge \psi_+(t_i,\bar t_i)$ for all $i$ because $\{\alpha_i\}$ is monotonic decreasing and $\{\psi_-(t_i,\bar t_i)\}$ is increasing by Lemma 3.2. Therefore $\alpha^* = \psi_+(t^*,\bar t^*)$, completing the proof. □

Notice that the equation $\phi = \psi_-$ may give unwanted solutions, and $\psi_+$ has a much smaller derivative than $\eta$ in a neighborhood of the smallest solution $(t^*,\bar t^*)$. We illustrate these phenomena by two symmetric examples with different values of $b = \bar b$, $c = \bar c$, $d = \bar d$, $e = \bar e$. Obviously, $t = \bar t$ and $\phi = \bar\phi$, and we simply write $\phi(t,\bar t)$ as $\phi(t)$ and do the same for other functions. In Figure 2, we plot the four curves of $\phi$, $\eta$, $\psi_+$, and $\psi_-$ of two examples. Obviously, the nonlinear equation $\phi = \psi_-$ does not take $t^*$ as a solution. Meanwhile, $\eta = \psi_-$ may have no solutions, as shown in the diagraph on the left, or an unwanted solution, in the diagraph on the right. Compared with $\eta$, $\psi_+$ has a much smaller derivative than $\eta$ nearby the smallest solution. As we mentioned, this property makes the Newton method converge quickly if we use $\phi = \psi_+$ rather than $\phi = \eta$.

We also illustrate the equivalence between the convergence of the Newton iterations and the uniform stability of the RILU factorization. The matrix used in each testing is

$$A = \{-\bar e, -\bar d, -\bar c, -\bar b,\ a, -b, -c, -d, -e\}$$

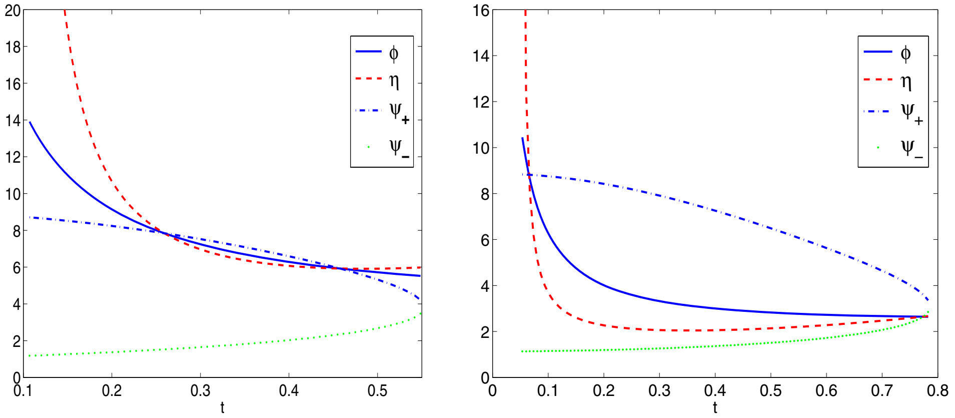

FIG. 2. *Plots of the curves $\phi(t)$, $\eta(t)$, $\psi_+(t)$, and $\psi_-(t)$ for symmetric $A$. The equation $\phi = \psi_-$ gives an unwanted solution. $\psi_+$ is flatter than $\eta$ nearby the smallest solution $t^*$ of $\phi = \psi_+$.*

with fixed $b = 2$, $\bar{b} = 3$, $c = 3$, $\bar{c} = 2$, $d = 2$, $\bar{d} = 3$, $e = 2$, $\bar{e} = 1$ and one of eight values of $a$ from 13.25 to 13.4. Half of the eight values yield uniformly stable ILU, and the other half yield unstable ILU. In each testing, we also compute the extreme solution of (2.10)–(2.12) by Newton iterations, using the lower bounds

$$t_0 = \frac{2b}{a + \sqrt{\Delta}} + \frac{4(\bar{c}d + e\bar{d})}{(a + \sqrt{\Delta})^2}, \quad \bar{t}_0 = \frac{2\bar{b}}{a + \sqrt{\Delta}} + \frac{4(c\bar{d} + \bar{e}d)}{(a + \sqrt{\Delta})^2} \tag{3.9}$$

given by Theorem 3.1 as the initial guess. The convergence of the Newton method conforms to the uniform stability of ILU completely. See Table 1 for the computed results, where "div.," "conv.," "unstab.," and "u.stab." stand for "divergent," "convergent," "unstable," and "uniformly stable," respectively.

TABLE 1

## 4. Generalization for diagonally variable matrices.

For the general case when $A$ is diagonally variable, it is quite difficult to give a detailed analysis for the uniform stability of RILU factorization. In this section, we will generalize the stability analysis in two cases: (1) nine-diagonal matrices [illegible] by diagonally constant matrices and (2) periodically monotone matrices.

DEFINITION 4.1. [illegible]

$$A = \{-\bar{e}_i, -\bar{d}_i, -\bar{c}_i, -\bar{b}_i, a_i, -b_i, -c_i, -d_i, -e_i\},$$
$$A^* = \{-\bar{e}_i^*, -\bar{d}_i^*, -\bar{c}_i^*, -\bar{b}_i^*, a_i^*, -b_i^*, -c_i^*, -d_i^*, -e_i^*\}$$

[illegible] $A$ [illegible] $A^*$ [illegible] $a_i \geq a_i^*$ [illegible]

$$e_i \leq e_i^*, \quad d_i \leq d_i^*, \quad c_i \leq c_i^*, \quad b_i \leq b_i^*,$$
$$\bar{e}_i \leq \bar{e}_i^*, \quad \bar{d}_i \leq \bar{d}_i^*, \quad \bar{c}_i \leq \bar{c}_i^*, \quad \bar{b}_i \leq \bar{b}_i^*.$$

There are many ways to construct a diagonally constant or monotone matrix that dominates $A$. For example, defining

$$a^* = \inf_k a_k, \quad b^* = \sup_k b_k, \quad c^* = \sup_k c_k, \quad d^* = \sup_k d_k, \quad e^* = \sup_k e_k \tag{4.1}$$

yields a diagonally constant matrix $A^*$, while setting

$$a_i^* = \min_{k\le i} a_k, \quad b_i^* = \max_{k\le i} b_k, \quad c_i^* = \max_{k\le i} c_k, \quad d_i^* = \max_{k\le i} d_k, \quad e_i^* = \max_{k\le i} e_k \tag{4.2}$$

produces a diagonally monotone matrix $A^*$. Clearly, the two matrices defined by (4.1) or (4.2) dominate $A$.

Let $A^* = L^*(D^*)^{-1}U^* - R^*$ be the RILU factorization of a dominant matrix $A^*$ of $A$, where

$$L^* = \{-\bar{e}_i^*, -\bar{\lambda}_i^*, -\bar{\gamma}_i^*, -\bar{\beta}_i^*, \alpha_i^*, 0, 0, 0, 0\}, \quad U^* = \{0, 0, 0, 0, \alpha_i^*, -\beta_i^*, -\gamma_i^*, -\lambda_i^*, -e_i^*\},$$

and $D^* = \mathrm{diag}(\ldots, \alpha_i^*, \ldots)$.

THEOREM 4.2. [illegible] $A$ [illegible] $A^*$ [illegible] $A^*$ [illegible] $A$ [illegible] $L$ $D$ [illegible] $U$ [illegible] $L^*$ $D^*$ [illegible] $U^*$ [illegible]

$$\alpha_i^* \le \alpha_i, \tag{4.3}$$

$$\beta_i^* \ge \beta_i, \quad \gamma_i^* \ge \gamma_i, \quad \lambda_i^* \ge \lambda_i, \quad \bar{\beta}_i^* \ge \bar{\beta}_i, \quad \bar{\gamma}_i^* \ge \bar{\gamma}_i, \quad \bar{\lambda}_i^* \ge \bar{\lambda}_i. \tag{4.4}$$

[illegible] We prove the theorem by induction. Obviously (4.3) and (4.4) hold for $i = 1$ since $\alpha_1 = a_1 \ge a_1^* = \alpha_1^*$ and $\beta_1 = b_1 \le b_1^* = \beta_1^*$.

Assume that (4.3) and (4.4) hold for $i \le k-1$. Since $A$ is dominated by $A^*$, it follows from (2.3) that

$$\lambda_k = d_k + e_k \frac{\beta_{k-1}}{\alpha_{k-1}} \le d_k^* + e_k^* \frac{\beta_{k-1}^*}{\alpha_{k-1}^*} = \lambda_k^*.$$

Similarly, by (2.2)–(2.3), one can prove the other inequalities in (4.4) for $i = k$. Then (4.3) with $i = k$ follows from (2.4) and (4.4) immediately, completing the proof. □

For a diagonally positive, monotone, and convergent nine-diagonal matrix $A$, we denote by

$$A_* = \{-\bar{e}, -\bar{d}, -\bar{c}, -\bar{b}, a, -b, -c, -d, -e\}$$

the diagonally constant matrix consisting of the limit values of the input sequences. Obviously, $A$ is dominated by $A_*$. Using Theorem 2.3, the following equivalence between $A$ and $A_*$ can be proven easily.

THEOREM 4.3. [illegible] $A$ [illegible] $A$ [illegible] $A_*$ [illegible]

**4.1. Block-convergence for periodically monotone matrices.** In general, matrices obtained from two-dimensional PDE by a nine-point difference scheme are not diagonally constant or monotone. Because of the block-tridiagonal form of the resulting matrices, the off-diagonals are periodically zero with period $m$. These periodic zeros can be simply replaced by constants to construct a dominate matrix $A^*$

as in (4.1) or (4.2), if $A$ is diagonally monotone except for the periodic zeros. However, the conditions of uniformly stable RILU of $A$ in terms of the parameters in $A^*$ may be unnecessarily strict. In this subsection, we consider a more general case for nine-diagonal matrices with periodically monotone properties without involving a dominant matrix of $A$.

For a sequence $\{x_i\}$, let

$$x^{(k)} = (x_{km+1}, x_{km+2}, \ldots, x_{km+m})$$

be the $k$th periodic section of $\{x_i\}$ with period $m$, where $m$ is the same as before. Obviously, $\{x^{(k)}\}$ is increasing (convergent) if and only if for any (fixed) $i$, $1 \le i \le m$, the subsequence $\{x_{km+i}\}_{k=1}^{\infty}$ is increasing (convergent).

DEFINITION 4.4. [illegible] $A = \{-\bar{e}_i, -\bar{d}_i, -\bar{c}_i, -\bar{b}_i, a_i, -b_i, -c_i, -d_i, -e_i\}$ [illegible] $m$ [illegible] $\{a^{(k)}\}$ [illegible] $\{b^{(k)}\}$ [illegible]

THEOREM 4.5. [illegible] $A = \{-\bar{e}_i, -\bar{d}_i, -\bar{c}_i, -\bar{b}_i, a_i, -b_i, -c_i, -d_i, -e_i\}$ [illegible] $m$ [illegible] $\{a_i\}$ [illegible] $\{b_i\}$ $\{c_i\}$ $\{d_i\}$ $\{e_i\}$ $\{\bar{b}_i\}$ $\{\bar{c}_i\}$ $\{\bar{d}_i\}$ [illegible] $\{\bar{e}_i\}$ [illegible] $A$ [illegible] $\{\alpha^{(k)}\}$ $\{\beta^{(k)}\}$ $\{\bar{\beta}^{(k)}\}$ $\{\lambda^{(k)}\}$ $\{\bar{\lambda}^{(k)}\}$ $\{\gamma^{(k)}\}$ $\{\bar{\gamma}^{(k)}\}$ [illegible]

[illegible] We first prove that $\{\alpha^{(k)}\}$ is decreasing and $\{\beta^{(k)}\}$ and the others are increasing; i.e.,

$$\begin{aligned}
&\alpha_{i+km} \ge \alpha_{i+(k+1)m}, \\
&\beta_{i+km} \le \beta_{i+(k+1)m}, \quad \lambda_{i+km} \le \lambda_{i+(k+1)m}, \quad \gamma_{i+km} \le \gamma_{i+(k+1)m}, \\
&\bar{\beta}_{i+km} \le \bar{\beta}_{i+(k+1)m}, \quad \bar{\lambda}_{i+km} \le \bar{\lambda}_{i+(k+1)m}, \quad \bar{\gamma}_{i+km} \le \bar{\gamma}_{i+(k+1)m}
\end{aligned} \tag{4.5}$$

for $i = 1, \ldots, m$ and $k \ge 0$.

Consider the initial case when $k = 0$. Since $\alpha_i > 0$ for all $i$, all the output sequences are nonnegative (see Lemma 2.1). It follows immediately that (4.5) holds for $i = 1$. Note that for $i \le m-1$, $\beta_{m+i} \ge b_{m+i} = b_i = \beta_i$ and $\bar{\beta}_{m+i} \ge \bar{\beta}_i$. Assume that (4.5) is true for $i < j$ with fixed $j \le m$. Then for $i = j$,

$$\gamma_{m+i} = c_{m+i} + \lambda_{m+i-1}\frac{\bar{\beta}_{m+i-1}}{\alpha_{m+i-1}} \ge c_i + \lambda_{i-1}\frac{\bar{\beta}_{i-1}}{\alpha_{i-1}} = \gamma_i,$$

and also $\bar{\gamma}_{m+i} \ge \bar{\gamma}_i$, $\lambda_{m+i} \ge \lambda_i$, and $\bar{\lambda}_{m+i} \ge \bar{\lambda}_i$. If $i = j < m$, by (2.4) we have

$$\begin{aligned}
\alpha_{m+i} &= a_{m+i} - \frac{\big(\beta_{m+i-1} + \omega\gamma_{m+i-1}\big)\bar{\beta}_{m+i-1}}{\alpha_{m+i-1}} \\
&\quad - \frac{\big(\gamma_{i+1} + \omega(e_{i+1} + \beta_{i+1})\big)\bar{\gamma}_{i+1}}{\alpha_{i+1}} - \frac{\omega\bar{e}_{i-1}\gamma_{i-1}}{\alpha_{i-1}} \\
&\le a_{m+i} - \frac{\big(\beta_{m+i-1} + \omega\gamma_{m+i-1}\big)\bar{\beta}_{m+i-1}}{\alpha_{m+i-1}} \\
&\le a_i - \frac{\big(\beta_{i-1} + \omega\gamma_{i-1}\big)\bar{\beta}_{i-1}}{\alpha_{i-1}} = \alpha_i.
\end{aligned}$$

If $i = j = m$, we also have

$$\alpha_{m+i} \le a_{m+i} - \frac{\big(\beta_{m+i-1} + \omega\gamma_{m+i-1}\big)\bar{\beta}_{m+i-1}}{\alpha_{m+i-1}} - \frac{\big(\gamma_{i+1} + \omega(e_{i+1} + \beta_{i+1})\big)\bar{\gamma}_{i+1}}{\alpha_{i+1}} = \alpha_i.$$

So (4.5) holds for $i \le m$ when $k = 0$.

Because of the periodicity assumption of $A$, (4.5) holds for all $k \ge 0$ and $i \le m$. For example, if (4.5) is true for $k = j - 1$, then for $k = j$,

$$\begin{aligned}\beta_{km+i} &= b_{km+i} + \frac{\bar{\gamma}_{(k-1)m+i+1}\lambda_{(k-1)m+i+1}}{\alpha_{(k-1)m+i+1}} + \frac{e_{(k-1)m+i}\bar{\lambda}_{(k-1)m+i}}{\alpha_{(k-1)m+i}} \\ &\le b_{(k+1)m+i} + \frac{\bar{\gamma}_{km+i+1}\lambda_{km+i+1}}{\alpha_{km+i+1}} + \frac{e_{km+i}\bar{\lambda}_{km+i}}{\alpha_{km+i}} = \beta_{(k+1)m+i}.\end{aligned}$$

The $m$-block convergence of the output sequences follows from the boundedness of $\{\alpha_i\}$. In fact,

$$0 < \alpha_{i+1} \le a_{i+1} - \frac{\beta_i\bar{\beta}_i}{\alpha_i} \le a_{i+1} - \frac{b\bar{b}}{\alpha_i} \le a_1 - \frac{b\bar{b}}{\alpha_i},$$

giving $\alpha_i > \frac{b\bar{b}}{a_1}$. Similar to Lemma 2.1, using the $m$-block monotonicity in (4.5), we conclude that $\{\beta_i\}$, $\{\bar{\beta}_i\}$, $\{\lambda_i\}$, $\{\bar{\lambda}_i\}$, $\{\gamma_i\}$, and $\{\bar{\gamma}_i\}$ are bounded above. Therefore, all these sequences are $m$-block convergent, and $\{\alpha^{(k)}\}$ converges to a positive vector. ☐

Let $\alpha^* = (\alpha_1^*, \dots, \alpha_m^*)$ be the limit vector of the vector sequence $\{\alpha^{(k)}\}$, and we similarly define $\beta^*$, $\gamma^*$, $\lambda^*$, $\bar{\beta}^*$, $\bar{\gamma}^*$, and $\bar{\lambda}^*$. Also let $A_*$ be the diagonally periodic matrix consisting of these limit vectors. Similar to Theorem 4.3, one can prove that the RILU of a diagonally $m$-monotone matrix $A$ is uniformly stable if and only if the RILU of $A_*$ is uniformly stable.

These limit vectors can be obtained by solving nonlinear equations that are constructed as follows. Let $t_i^* = \beta_i^*/\alpha_i^*$ and $\bar{t}_i^* = \bar{\beta}_i^*/\alpha_i^*$. For $i = 1, \dots, m$, we have

$$\alpha_i^* t_i^* = b_i + \frac{\bar{\gamma}_{i+1}^*\lambda_{i+1}^*}{\alpha_{i+1}^*} + \frac{e_i\bar{\lambda}_i^*}{\alpha_i^*}, \quad \alpha_i^*\bar{t}_i^* = \bar{b}_i + \frac{\gamma_{i+1}^*\bar{\lambda}_{i+1}^*}{\alpha_{i+1}^*} + \frac{\bar{e}_i\lambda_i^*}{\alpha_i^*}, \tag{4.6}$$

$$\gamma_i^* = c_i + \lambda_{i-1}^*\bar{t}_{i-1}^*, \quad \bar{\gamma}_i^* = \bar{c}_i + \bar{\lambda}_{i-1}^* t_{i-1}^*, \tag{4.7}$$

$$\lambda_i^* = d_i + e_{i-1}\bar{t}_{i-1}^*, \quad \bar{\lambda}_i^* = \bar{d}_i + \bar{e}_{i-1} t_{i-1}^*, \tag{4.8}$$

$$\begin{aligned}\alpha_i^* = a_i \quad &- \alpha_{i-1}^* t_{i-1}^*\bar{t}_{i-1}^* - \tfrac{(\gamma_{i+1}^*+\omega e_{i+1})\bar{\gamma}_{i+1}^*}{\alpha_{i+1}^*} - \tfrac{\bar{\lambda}_i^*\lambda_i^*}{\alpha_i^*} \\ &- \tfrac{(e_{i-1}+\omega\gamma_{i-1}^*)\bar{e}_{i-1}}{\alpha_{i-1}^*} - \omega(\bar{t}_{i-1}^*\gamma_{i-1}^* + t_{i+1}^*\bar{\gamma}_{i+1}^*),\end{aligned} \tag{4.9}$$

where $e_0 = e_m$, $e_{m+1} = e_1$, $\bar{e}_0 = \bar{e}_m$, and $\bar{e}_{m+1} = \bar{e}_1$. In the same vein, $\alpha_0^* = \alpha_m^*$ and $\alpha_{m+1}^* = \alpha_1^*$. It is similar for other limit values. Let

$$\lambda_i(t) = d_i + e_{i-1}t, \quad \bar{\lambda}_i(t) = \bar{d}_i + \bar{e}_{i-1}t, \quad \gamma_i(t,s) = c_i + \lambda_{i-1}(s)t, \quad \bar{\gamma}_i(t,s) = \bar{c}_i + \bar{\lambda}_{i-1}(s)t$$

with the periodicity constraints: $\alpha_i = \alpha_j$, $t_i = t_j$, and $\bar{t}_i = \bar{t}_j$, if $|i - j| = m$. Then $\lambda_i^* = \lambda_i(\bar{t}_{i-1}^*)$, $\bar{\lambda}_i^* = \bar{\lambda}_i(t_{i-1}^*)$, $\gamma_i^* = \gamma_i(\bar{t}_{i-1}^*, \bar{t}_{i-2}^*)$, and $\bar{\gamma}_i^* = \bar{\gamma}_i(t_{i-1}^*, t_{i-2}^*)$. Substituting these equalities into (4.6) and (4.9) yields

$$f(\alpha, t, \bar{t}) = 0, \quad \bar{f}(\alpha, t, \bar{t}) = 0, \quad g(\alpha, t, \bar{t}) = 0, \tag{4.10}$$

in the variables $\alpha = (\alpha_1, \dots, \alpha_m)^T$, $t = (t_1, \dots, t_m)^T$, and $\bar{t} = (\bar{t}_1, \dots, \bar{t}_m)^T$, where $f$, $\bar{f}$, and $g$ are $m$-dimensional vector functions with components

$$f_i(\alpha, t, \bar{t}) = b_i - \alpha_i t_i + \frac{\bar{\gamma}_{i+1}(t_i, t_{i-1})\lambda_{i+1}(\bar{t}_i)}{\alpha_{i+1}} + \frac{e_i\bar{\lambda}_i(t_{i-1})}{\alpha_i},$$

$$\begin{aligned}
\bar{f}_i(\alpha, t, \bar{t}) &= \bar{b}_i - \alpha_i \bar{t}_i + \frac{\gamma_{i+1}(\bar{t}_i, \bar{t}_{i-1}) \bar{\lambda}_{i+1}(t_i)}{\alpha_{i+1}} + \frac{\bar{e}_i \lambda_i(\bar{t}_{i-1})}{\alpha_i}, \\
g_i(\alpha, t, \bar{t}) &= \alpha_i - a_i + \alpha_{i-1} t_{i-1} \bar{t}_{i-1} + \frac{\big(\gamma_{i+1}(\bar{t}_i, \bar{t}_{i-1}) + \omega e_{i+1}\big) \bar{\gamma}_{i+1}(t_i, t_{i-1})}{\alpha_{i+1}} \\
&\qquad + \frac{\bar{\lambda}_i(t_{i-1}) \lambda_i(\bar{t}_{i-1})}{\alpha_i} + \frac{\big(e_{i-1} + \omega \gamma_{i-1}(\bar{t}_{i-2}, \bar{t}_{i-3})\big) \bar{e}_{i-1}}{\alpha_{i-1}} \\
&\qquad + \omega \Big( \bar{t}_{i-1} \gamma_{i-1}(\bar{t}_{i-2}, \bar{t}_{i-3}) + t_{i+1} \bar{\gamma}_{i+1}(t_i, t_{i-1}) \Big).
\end{aligned}$$

As shown in the last section, the limit vectors $\alpha^* = (\alpha_1^*, \ldots, \alpha_m^*)$, $t^* = (t_1^*, \ldots, t_m^*)$, and $\bar{t}^* = (\bar{t}_1^*, \ldots, \bar{t}_m^*)$ are the extreme solutions to the nonlinear system (4.10). Newton-like iterations can solve (4.10) if we first run the RILU for several steps to get a good initial guess for the extreme solutions.

**5. Fast algorithms of approximate RILU.** In this section, we give two fast algorithms for computing RILU factorization, one for diagonally monotone matrices and the other for diagonally $m$-monotone matrices. Basically, we first run the standard RILU recursions until the output diagonal sequences are convergent or block-convergent within a given accuracy, and then replace the remaining terms in the recursions by their limit values, except for the last few components of $\{\alpha_i\}$.

**5.1. Fast RILU for diagonally monotone matrices.** For a given diagonally monotone nine-diagonal matrix $A$ of order $N$, we set the parameters in the definitions (3.4) and (3.7) of $\phi(t, \bar{t})$, $\bar{\phi}(t, \bar{t})$, and $\psi_+(t, \bar{t})$ by the last components of the input sequences. For example, set $a = a_N$, $b = b_{N-1}$, $c = c_{N-m+1}$, $d = d_{N-m}$, and $e = e_{N-m-1}$. We solve the nonlinear equations (3.8) for the smallest solution $(t^*, \bar{t}^*)$ by Newton iterations, starting at the initial guess shown in (3.9). (One can also run several steps of RILU recursions first and take the last $(t_i, \bar{t}_i)$ as an initial guess for the Newton iteration.) The stopping criterion is

$$\left\| \begin{pmatrix} t^{(k+1)} - t^{(k)} \\ \bar{t}^{(k+1)} - \bar{t}^{(k)} \end{pmatrix} \right\| < \tau \tag{5.1}$$

with accuracy parameter $\tau$. As soon as $t^*$ and $\bar{t}^*$ are computed, we set $\alpha^* = \psi_+(t^*, \bar{t}^*)$, $\beta^* = \alpha^* t^*$, $\bar{\beta}^* = \alpha^* \bar{t}^*$, and $\gamma^*$, $\bar{\gamma}$, $\lambda^*$, $\bar{\lambda}^*$ as defined in (2.7)–(2.8). We use

$$|\alpha_k - \alpha^*| < \varepsilon \alpha^* \tag{5.2}$$

as the stopping criterion of the RILU recursions with accuracy parameter $\varepsilon$. Because the matrix size is always finite in applications, the terms $\gamma_i$, $\bar{\gamma}_i$ $(i \geq N-m+2)$ and $\lambda_i$, $\bar{\lambda}_i$ $(i \geq N-m+1)$, including $\beta_N$, $\bar{\beta}_N$, and $e_{N-m}$, are not in the matrix. Therefore, for $\max(k+1, N-m+3) \leq i \leq N$, the last several terms $\alpha_i$ are evaluated by

$$\begin{aligned}
\alpha_i \;=\; a_i &- \tfrac{\beta_{i-1} \bar{\beta}_{i-1}}{\alpha_{i-1}} - \tfrac{\big(\gamma_{i-m+1} + \omega(e_{i-m+1} + \beta_{i-m+1})\big) \bar{\gamma}_{i-m+1}}{\alpha_{i-m+1}} \\
&- \tfrac{\lambda_{i-m} \bar{\lambda}_{i-m}}{\alpha_{i-m}} - \tfrac{\big(e_{i-m-1} + \omega \gamma_{i-m-1}\big) \bar{e}_{i-m-1}}{\alpha_{i-m-1}}, \quad i \leq N-2,
\end{aligned} \tag{5.3}$$

$$\begin{aligned}
\alpha_i \;=\; a_i &- \tfrac{\beta_{i-1} \bar{\beta}_{i-1}}{\alpha_{i-1}} - \tfrac{\big(\gamma_{i-m+1} + \omega \beta_{i-m+1}\big) \bar{\gamma}_{i-m+1}}{\alpha_{i-m+1}} \\
&- \tfrac{\lambda_{i-m} \bar{\lambda}_{i-m}}{\alpha_{i-m}} - \tfrac{\big(e_{i-m-1} + \omega \gamma_{i-m-1}\big) \bar{e}_{i-m-1}}{\alpha_{i-m-1}}, \quad i = N-1, N.
\end{aligned} \tag{5.4}$$

Note that if $k \leq N - 2m + 2$, all the terms on the right of (5.3) and (5.4) can be replaced by their limit values.

Now we are ready to present the fast algorithm FRILU for computing RILU factorization of a diagonally monotone matrix.

```
ALGORITHM FRILU-I (FAST RILU FOR DIAGONALLY MONOTONE MATRICES).
Step 0. Initialization.
        (0) Set $a = a_N,\ b = b_{N-1},\ c = c_{N-m+1},\ d = d_{N-m},\ e = e_{N-m-1},$
            $\bar{b} = \bar{b}_{N-1},\ \bar{c} = \bar{c}_{N-m+1},\ \bar{d} = \bar{d}_{N-m},\ \bar{e} = \bar{e}_{N-m-1}.$
        (1) Determine the thresholds $\tau$ for Newton iteration and $\varepsilon$ for RILU.
Step 1. Compute the limits of the output sequences of RILU.
        (2) Solve (3.8) for the smallest positive $(t^*, \bar{t}^*)$ by Newton method with the
            stopping criterion (5.1).
        (3) If the computed $(t^*, \bar{t}^*)$ is not positive (no stable RILU), terminate.
            Otherwise set $\alpha^* = \psi(t^*, \bar{t}^*)$, $\beta^* = \alpha^* t^*$, $\bar{\beta}^* = \alpha^* \bar{t}^*$, and $\gamma^*$, $\bar{\gamma}$, $\lambda^*$, $\bar{\lambda}^*$
            as in (2.7)–(2.8).
Step 2. Partial RILU recursions.
        (4) Run the algorithm RILU until $\alpha_k$ satisfies $|\alpha_k - \alpha^*| < \varepsilon\alpha^*$ or $k = N$.
Step 3. Set the remaining outputs.
        (5) Set $\beta_i = \beta^*,\ \gamma_i = \gamma^*,\ \lambda_i = \lambda^*,\ \bar{\beta}_i = \bar{\beta}^*,\ \bar{\gamma}_i = \bar{\gamma}^*,\ \bar{\lambda}_i = \bar{\lambda}^*$ for $i > k$.
        (6) Set $\alpha_i = \alpha^*$ for $k < i \le N - m + 2$, and compute $\alpha_i$ by (5.3)–(5.4) for
            $i > \max(k, N - m + 2)$.
```

**5.2. Fast RILU for *m*-periodically monotone matrices.** We use the stopping criteria

$$\|\alpha^{(k)} - \alpha^{(k-1)}\| < \varepsilon \|\alpha^{(k)}\|$$

for the RILU recursions when $A$ is $m$-periodically monotone. The index $k$ here should not be larger than $(N - 2m + 2)/m$ since the $\alpha_i$'s are not periodic for $i > N - m + 2$. As soon as this criterion is satisfied, we set the remaining entries of the factor matrices in RILU by the periodical terms

$$\begin{aligned}
&\beta_{jm+i} = \beta_{km+i}, \quad &&\bar{\beta}_{jm+i} = \bar{\beta}_{km+i}, \quad &&j > k,\ jm + i \le n - 1,\\
&\gamma_{jm+i} = \gamma_{km+i}, \quad &&\bar{\gamma}_{jm+i} = \bar{\gamma}_{km+i}, \quad &&j > k,\ jm + i \le n - m + 1,\\
&\lambda_{jm+i} = \lambda_{km+i}, \quad &&\bar{\lambda}_{jm+i} = \bar{\lambda}_{km+i}, \quad &&j > k,\ jm + i \le n - m.
\end{aligned}$$

The substitution of the $\alpha_i$'s is restricted to the range $jm + i \le N - m + 2$; i.e., $\alpha_{jm+i} = \alpha_{km+i}$ for $jm + i \le N - m + 2$. The others are computed as in (5.3)–(5.4). If $mk > N - 2m - 2$, we complete the standard RILU recursions without the substitution.

```
ALGORITHM FRILU-II (FAST RILU FOR $m$-PERIODICALLY MONOTONE MATRICES).
Step 1. Partial RILU factorization.
        (1) Run the algorithm RILU until $\|\alpha^{(k)} - \alpha^{(k-1)}\| < \varepsilon\|\alpha^{(k)}\|$.
        (2) If $k > [(N-2m+2)/m]$, complete the RILU factorization and terminate.
Step 2. Periodically substituting.
            $\beta_{jm+i} = \beta_{km+i},\quad \bar{\beta}_{jm+i} = \bar{\beta}_{km+i},\quad j > k,\ jm + i \le n - 1,$
            $\lambda_{jm+i} = \lambda_{km+i},\quad \bar{\lambda}_{jm+i} = \bar{\lambda}_{km+i},\quad j > k,\ jm + i \le n - m,$
            $\gamma_{jm+i} = \gamma_{km+i},\quad \bar{\gamma}_{jm+i} = \bar{\gamma}_{km+i},\quad j > k,\ jm + i \le n - m + 1,$
            $\alpha_{jm+i} = \alpha_{km+i},\quad j > k,\ jm + i \le N - m + 2.$
Step 3. Compute $\alpha_i$ by (5.3)−(5.4) for $N - m + 3 \le i \le N$.
```

**6. Numerical results.** In this section, we give three numerical examples to illustrate the effectiveness of our fast algorithms for constructing RILU factorization. The examples are a constructed nine-diagonal matrix with diagonal constants, a real data coming from a bioengineering problem, and a nine-diagonal matrix from finite-difference PDE that is not diagonally monotone or periodically monotone. We check the uniform stability by the Newton iterations for the nonlinear system (3.8) with the initial guesses given in (3.9). The convergence criterion is (5.1)

$$\left\| \begin{pmatrix} t^{(k+1)} - t^{(k)} \\ \bar{t}^{(k+1)} - \bar{t}^{(k)} \end{pmatrix} \right\| < \tau,$$

where $(t^{(k)}, \bar{t}^{(k)})^T$ is the $k$th approximation computed by the Newton method. We use the stopping criteria

$$|\alpha_k - \alpha^*| < \varepsilon\alpha^*, \quad \|\alpha^{(k)} - \alpha^{(k-1)}\| < \varepsilon\|\alpha^{(k)}\|$$

with the accuracy parameter $\varepsilon$ for FRILU-I and FRILU-II, respectively.

[illegible] 1. The test matrix is a diagonally constant matrix

$$A = \{-\bar{e},\, -\bar{d},\, -\bar{c},\, -\bar{b},\, a,\, -b,\, -c,\, -d,\, -e\}$$

with

$$a = 13.9,\ b = 1,\ c = 2,\ d = 1,\ e = 1,\ \bar{e} = 2,\ \bar{d} = 2,\ \bar{c} = 3,\ \bar{b} = 2,$$

$m = 100$ and $N = 100,000$. The RILU factorization of $A$ is stable, sufficiently guaranteed by the uniform stability that can be checked by the Newton iterations. Starting with the initial guess shown in (3.9), the Newton method converges quickly for this matrix. For example, if $\omega = 0.5$, we obtain $t^* = 0.2268$, $\bar{t}^* = 0.1317$, and $\alpha^* = 11.687249$ approximately in the relative accuracy $\tau < 10^{-7}$ within 4 Newton iterations. The convergence slightly depends on the relaxation parameter $\omega$. In Table 2, we list the numbers of Newton iterations for different values of $\omega$ and the convergence accuracy $\tau$.

TABLE 2
*Numbers of Newton iterations for Example* 1.

| $\omega$ | log($\tau$) = -4 | -5 | -6 | -7 | -8 | -9 | -10 | -11 | -12 | -13 | -14 | -15 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| 0 | 3 | 4 | 4 | 4 | 4 | 5 | 5 | 5 | 5 | 5 | 5 | 5 |
| 0.2 | 3 | 4 | 4 | 4 | 4 | 5 | 5 | 5 | 5 | 5 | 5 | 5 |
| 0.4 | 3 | 4 | 4 | 4 | 5 | 5 | 5 | 5 | 5 | 5 | 5 | 6 |
| 0.6 | 4 | 4 | 4 | 5 | 5 | 5 | 5 | 5 | 5 | 6 | 6 | 6 |
| 0.8 | 4 | 4 | 5 | 5 | 5 | 5 | 5 | 6 | 6 | 6 | 6 | 6 |
| 1.0 | 4 | 5 | 5 | 5 | 6 | 6 | 6 | 6 | 6 | 6 | 6 | 7 |

The recursive sequences of RILU converge fast for this example. In the right-hand panel of Figure 3, we plot the approximate errors of the first 2000 terms of the output sequence $\{\alpha_i\}$, $\{\beta_i\}$, $\{\gamma_i\}$, $\{\lambda_i\}$ of RILU with $\omega = 0$ to their limit values. The other output sequences have similar properties. It illustrates the consistent convergence behaviors in Theorem 2.4. In general, the convergence monotonically depends on the value of the relaxation $\omega$. See the left-hand panel of Figure 3 for the required iteration number $k$ of RILU($\omega$) with the relative accuracy $\epsilon = 10^{-12}$ for variant $\omega$.

This fast convergence implies that one can obtain the factorization at low computational cost. In Table 3, we list the number $k$ of the partial recursive steps of

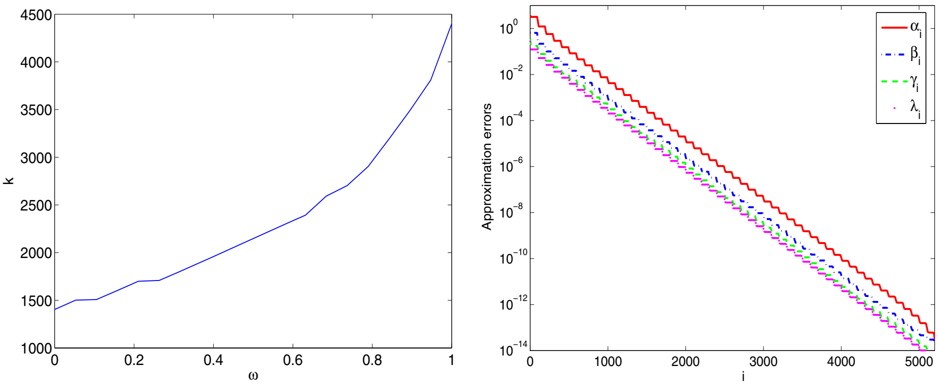

FIG. 3. *Left: convergence of RILU($\omega$) recursions. The required iteration number $k$ ($\epsilon = 10^{-12}$) monotonically depends on $\omega$. Right: consistent convergence of outputs. The approximation errors of the first* 5000 *terms of* $\{\alpha_i\}$, $\{\beta_i\}$, $\{\gamma_i\}$, $\{\lambda_i\}$ *to their limit values are plotted* ($\omega = 0$).

MILU (RILU with $\omega = 1$), flops, and CPU times (including the cost of the Newton iterations), and the total errors of FRILU-I for different values of $\varepsilon$, where the total error is defined by

$$Error = \|(\alpha, \beta, \gamma, \lambda, \bar{\beta}, \bar{\gamma}, \bar{\lambda}) - (\alpha^I, \beta^I, \gamma^I, \lambda^I, \bar{\beta}^I, \bar{\gamma}^I, \bar{\lambda}^I)\|,$$

where $\alpha$ and $\alpha^I$ are the sequences computed by the RILU and FRILU-I, respectively. Similar notations are used here for other outputs. The computational results show that the total error is proportional to the accuracy parameter $\varepsilon$. Notice that the storage cost is proportional to $k$. Compared with the costs of classical RILU listed in the right two columns of Table 3, FRILU is quite efficient for this example. It needs only about 1% of the cost of ILU in storage and flops, and 2% of CPU time. FRILU-I has similar convergence behavior for other values of $\omega$. Notice that the cost of FRILU is constant, while the CPU time of the standard RILU increases when $N$ is enlarged.

TABLE 3
*Computational costs of FRILU-I and MILU.*

| FRILU-I | | | | | MILU | |
|---|---|---|---|---|---|---|
| $\varepsilon$ | $k$ | Flops | CPU (s) | Error | Flops | CPU (s) |
| $10^{-3}$ | 901 | 41948 | 0.80 | $9.6 \times 10^{-2}$ | 43997013 | 10.98 |
| $10^{-4}$ | 1300 | 59903 | 0.80 | $9.0 \times 10^{-3}$ | | |

*Example* 2. The test matrix comes from a bioengineering problem.[1] It is a nine-point matrix of order $N = 9604$ and $m = 98$ with constant entries in the diagonal lines except for the periodic zeros $b_{km} = \bar{b}_{km} = 0$ $(1 \le k \le m-1)$, $c_{km+1} = \bar{c}_{km+1} = 0$ $(0 \le k \le m-1)$, and $e_{km} = \bar{e}_{km} = 0$ $(1 \le k \le m-2)$. So $A$ is a diagonally periodic

---

[1] This matrix, code name fv1, can be found at http://www.cise.ufl.edu/research/sparse/HBformat/Norris/.

matrix. Note that although $A$ is almost diagonally constant, all the output sequences are $m$-periodically monotone.

FRILU-II is also very efficient for this diagonally periodic matrix, due to the fast block-convergence of the output sequences. For example, within $k = 14$ block-iterations, $\{\alpha_i\}$ reaches the relative accuracy $\varepsilon = 10^{-10}$ when $\omega = 0.5$: $\|\alpha^{(k)} - \alpha^{(k-1)}\| < \varepsilon\|\alpha^{(k)}\|$, and the costs of FRILU-II in flops, CPU time, and storage are about 15% of those of RILU. In Table 4 we list the numbers $k$ of the block-iteration steps required to achieve the given relative accuracy $\varepsilon$ for different values of the relaxation parameter $\omega$. The number $k$ increases slightly as $\omega$ increases. Note that the number of componentwise recursive steps of FRILU-II is about $km$.

TABLE 4

Now we consider the efficiency of the incomplete LU factorization obtained by FRILU-II applied on the preconditioned GMRES algorithm for solving the linear system $Ax = f$. We randomly select a right-hand-side vector $f$ with components uniformly distributed in the interval $[-1, 1]$. The computational cost of FRILU-II can be ignored in this experiment. Its CPU time is only 0.06 seconds. The preconditioned GMRES algorithm starting at $x_0 = 0$ converges and achieves the accuracy $\|Ax - f\| < \epsilon$ with $\epsilon = 10^{-10}$ after 9 iterations and 0.25 seconds. We remark that the iteration number of GMRES with the preconditioner RILU($\omega$) is almost unchanged when the relaxation parameter $\omega$ varies in the interval $[0, 1]$. If the standard RILU is used in the preconditioned GMRES, the cost of the standard RILU is dominative in the entry computation. The CPU time of the standard RILU is 0.41 seconds. About half of the time is reduced by using FRILU-II, compared with the standard RILU preconditioning. We report that for this example the factorization ILUT$(p, \tau)$ [21, 22] costs much more than FILU-II or standard RILU, where $\tau$ is a dropping threshold of small components and $p$ the largest number of nonzero elements in each row of the factors $L$ or $U$. Table 5 summarizes the results for $p = 3, 5$ and $\tau = 0.01, 0.02, 0.03, 0.04, 0.05$. The column "ILUT sparsity" stands for the ratio $\frac{\mathrm{nnz}(L)+\mathrm{nnz}(U)-n}{\mathrm{nnz}(A)}$ of the total number of nonzero elements in both factors $L$ and $U$ and that in $A$. As $\tau$ increases, ILUT$(p, \tau)$ time decreases quickly. Meanwhile the preconditioning loses its efficiency gradually. Note that GMRES converges with 33 iterations without preconditioning.

[illegible] 3. This example shows the effectiveness of our fast algorithms for a more general matrix. Consider the convection-diffusion equation

$$-\Delta u + \sigma(xu_x + yu_y) - \rho u = f \quad \text{in} \quad \Omega = (0, 1) \times (0, 10)$$

with homogeneous Dirichlet boundary condition. Here $\sigma$ and $\rho$ are two positive constants. We discretize the PDE by a nine-point difference scheme with mesh size

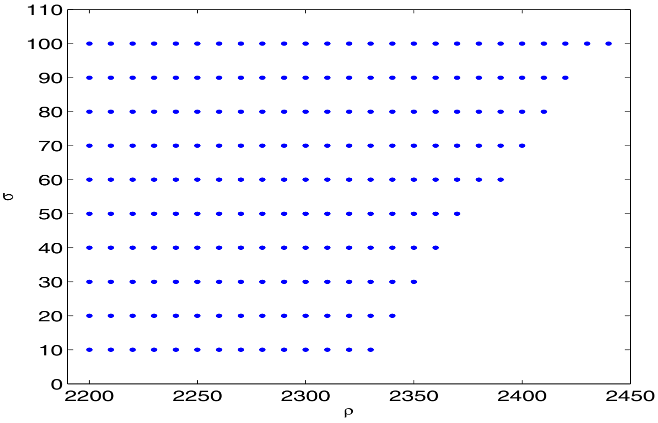

FIG. 4. *Stable region of the RILU factorization of $A(\rho,\sigma)$ in Example 3.*

$h = 1/(m+1)$. Let $\lceil x \rceil$ denote the smallest integer not less than $x$. The resulting nine-diagonal matrix $A = A(\rho,\sigma)$ of order $N = 10m^2$ has entries

$$a_i = 20 - 6\rho h^2, \quad d_i = 4 - 3\sigma h^2 \left\lceil \frac{i}{m} \right\rceil, \quad \bar{d}_i = 4 + 3\sigma h^2 \left\lceil \frac{i}{m} + 1 \right\rceil,$$
$$b_i = 4 - 3\sigma h^2 \mathrm{mod}(i,m), \quad \bar{b}_i = 4 + 3\sigma h^2(\mathrm{mod}(i,m) + 1),$$
$$c_i = 1, \quad \bar{c}_i = 1, \quad e_i = 1, \quad \bar{e}_i = 1,$$

except for the periodic zeros $b_{km} = \bar{b}_{km} = 0$ $(1 \le k \le m-1)$, $c_{km+1} = \bar{c}_{km+1} = 0$ $(0 \le k \le m-1)$, and $e_{km} = \bar{e}_{km} = 0$ $(1 \le k \le m-2)$. We set $m = 100$. The stability of the RILU factorization of $A(\rho,\sigma)$ depends on the parameters $\rho$ and $\sigma$. In Figure 4, we show a part of the stable region (marked by dots) in the $(\rho,\sigma)$-plane in which the matrix $A(\rho,\sigma)$ has stable RILU factorization with $\omega = 0.5$. All the $(\rho,\sigma)$ parameters used in this example are chosen in the stable region, and some of them are close to the boundary.

The matrix $A$ in this example is not diagonally periodically monotone. Ignoring the zeros appearing in the diagonals periodically, $\{d_i\}$ is piecewise monotone decreasing, while $\{\bar{d}_i\}$ is piecewise increasing for positive $\sigma$, though both $\{b_i\}$ and $\{\bar{b}_i\}$ are periodically constant. However, if $\rho$ is not large enough, the components change very slightly and the convergence of the output sequences is close to being periodical. We can apply algorithm FRILU-II on $A$ directly to compute an approximate RILU factorization. In Table 6 we show the pairs $(k,\, \epsilon_\alpha)$ for different parameters $(\rho, \sigma)$ chosen in the convergence region, where $k$ is the iteration number such that $\{\alpha^{(k)}\}$ achieves the given accuracy, and $\epsilon_\alpha = \|\alpha - \alpha^{II}\|_2/\|\alpha\|_2$ is the relative error of $\alpha^{II} = \alpha^{(k)}$ computed by FRILU-II with $\omega = 0.5$ and accuracy $\varepsilon = 10^{-4}$. $\{\beta_i^{II}\}$ has the same relative error as $\{\alpha_i^{II}\}$ in magnitude, while the accuracy of $\{\lambda_i^{II}\}$ and $\{\gamma_i^{II}\}$ are lower than the accuracy of $\{\alpha_i^{II}\}$ in general. We remark that the block approximation also depends on the parameters. If $(\rho, \sigma)$ tends to the boundary of the convergence region, then the approximate error $\|\alpha - \alpha^{II}\|_2$ increases, and the approximate block-convergence may no longer be maintained, though those parameters $\rho$ and $\sigma$ are chosen in the stable region. The loss of block-convergence within the given accuracy is indicated by "–" in Table 6.

TABLE 6
*Block-convergence* $(k,\, \epsilon_\alpha)$ *for Example* 3 *with* $\varepsilon = 10^{-4}$, $\omega = 0.5$.

| 2300 | (33, 2.7e-3) | (28, 9.8e-3) | – | – | – |
| 2320 | (41, 3.2e-3) | – | – | – | – |
| 2330 | (57, 3.3e-3) | – | – | – | – |

However, we can obtain an approximate RILU factorization with a higher accuracy by applying FRILU-II on a true diagonally periodic matrix $A_c$. Such a matrix $A_c$ can be obtained from $A$ by replacing $\{d_i\}$ and $\{\bar{d}_i\}$ by the constant $d_1 = 4 - 3\sigma h^2$ and $\bar{d}_1 = 4 + 6\sigma h^2$, respectively. Let $\{\alpha_i^c\}$ and the other outputs with subscript $c$ be the computed sequences by FRILU-II for $A_c$. Since there are input errors $d_i - d_1$ and $\bar{d}_i - \bar{d}_1$ in $\{d_i^c\}$ and $\{\bar{d}_i{}^c\}$, $\{\lambda_i^c\}$ and $\{\gamma_i^c\}$ have relatively large errors to $\{\lambda_i\}$ and $\{\gamma_i\}$. However $\{\alpha_i^c\}$, $\{\beta_i^c\}$, and $\{\bar{\beta}_i^c\}$ still have acceptable accuracy if $\sigma$ is not large. In that case, we can improve $\lambda_i^c$ and $\gamma_i^c$ by adding back the input errors to the outputs $\lambda_i^c$ and $\gamma_i^c$ with the refinement

$$\lambda_i^R = \lambda_i^c + (d_i - d_1), \quad \bar{\lambda}_i^R = \bar{\lambda}_i^c + (\bar{d}_i - \bar{d}_1),$$

$$\gamma_i^R = \gamma_i^c + (d_{i-1} - d_1)\frac{\bar{\beta}_{i-1}^c}{\alpha_{i-1}^c}, \quad \bar{\gamma}_i^R = \bar{\gamma}_i^c + (\bar{d}_{i-1} - \bar{d}_1)\frac{\beta_{i-1}^c}{\alpha_{i-1}^c}.$$

This refinement gives acceptable accuracy of the approximate RILU factorization. Table 7 shows the accuracy of the computed $\{\lambda_i\}$ and $\{\gamma_i\}$ by applying the algorithm FRILU-II to $A$ or the approximation $A_c$, and the refinement discussed above, marked by I, II, and III in the second column of Table 7, respectively. Note that for some values of $\rho$ and $\sigma$, FRILU-II fails if it is applied on $A$ directly.

# SIGN PATTERNS THAT ALLOW A POSITIVE OR NONNEGATIVE LEFT INVERSE*

IN-JAE KIM†, D. D. OLESKY‡, B. L. SHADER§, AND P. VAN DEN DRIESSCHE¶

**Abstract.** An $m$ by $n$ sign pattern $\mathcal{S}$ is an $m$ by $n$ matrix with entries in $\{+, -, 0\}$. Such a sign pattern allows a positive (resp., nonnegative) left inverse, provided that there exist an $m$ by $n$ matrix $A$ with the sign pattern $\mathcal{S}$ and an $n$ by $m$ matrix $B$ with only positive (resp., nonnegative) entries satisfying $BA = I_n$, where $I_n$ is the $n$ by $n$ identity matrix. For $m > n \geq 2$, a characterization of $m$ by $n$ sign patterns with no rows of zeros that allow a positive left inverse is given. This leads to a characterization of all $m$ by $n$ sign patterns with $m \geq n \geq 2$ that allow a positive left inverse, giving a generalization of the known result for the square case, which involves a related bipartite digraph. For $m \geq n$, $m$ by $n$ sign patterns with all entries in $\{+, 0\}$ and $m$ by 2 sign patterns with $m \geq 2$ that allow a nonnegative left inverse are characterized, and some necessary or sufficient conditions for a general $m$ by $n$ sign pattern to allow a nonnegative left inverse are presented.

**Key words.** bipartite digraph, nonnegative left inverse, positive left inverse, positive left nullvector, sign pattern, strong Hall

## 1. Introduction.

An $m$ by $n$ *sign pattern* $\mathcal{S} = [s_{ij}]$ is an $m$ by $n$ matrix with entries in $\{+, -, 0\}$. If a sign pattern $\mathcal{S}$ has all entries in $\{+, 0\}$, then $\mathcal{S}$ is a *nonnegative* sign pattern. A *subpattern* of $\mathcal{S}$ is an $m$ by $n$ sign pattern $\mathcal{U} = [u_{ij}]$ such that $u_{ij} = 0$ whenever $s_{ij} = 0$. If $\mathcal{U}$ is a subpattern of $\mathcal{S}$, then $\mathcal{S}$ is a *superpattern* of $\mathcal{U}$. The *sign pattern class* $Q(\mathcal{S})$ of an $m$ by $n$ sign pattern $\mathcal{S}$ is the set of $m$ by $n$ matrices $A = [a_{ij}]$ such that $\text{sgn}(a_{ij}) = s_{ij}$ for all $i, j$. If $A \in Q(\mathcal{S})$, then $A$ is a *realization* of $\mathcal{S}$.

Let $A = [a_{ij}]$ be an $m$ by $n$ matrix. If each entry of $A$ is positive (resp., nonnegative), then $A$ is *positive* (resp., *nonnegative*), written $A > 0$ (resp., $A \geq 0$). A *left inverse* of an $m$ by $n$ matrix $A$ is an $n$ by $m$ matrix $B$ such that $BA = I_n$, where $I_n$ denotes the $n$ by $n$ identity matrix. If $B > 0$, then $B$ is a *positive* left inverse (abbreviated as *PLI*) of $A$. If $B \geq 0$, then $B$ is a *nonnegative* left inverse (abbreviated as *NLI*) of $A$. In general, neither a PLI nor an NLI of $A$ is unique. It is easily verified that $A$ has a left inverse if and only if $\operatorname{rank} A = n$; thus, if $A$ has a left inverse, then necessarily $m \geq n$. An $m$ by $n$ sign pattern $\mathcal{S}$ *allows a positive* (resp., *nonnegative*) *left inverse*, provided there exist $A \in Q(\mathcal{S})$ and a matrix $B > 0$ (resp., $B \geq 0$) such that $BA = I_n$. Note that if $P_1$ and $P_2$ are permutation matrices, then $\mathcal{S}$ allows a PLI (resp., an NLI) if and only if $P_1 \mathcal{S} P_2$ allows a PLI (resp., an NLI).

---

A motivation for studying PLIs and NLIs comes from determining the qualitative behavior of solutions of $A^T x = b$ with $A$ an $m$ by $n$ matrix; see, for example, [2, Chapter 1] and [5] for applications in economics. Specifically, $A$ has a PLI (resp., an NLI) if and only if for each $n$ by 1 nonzero vector $b \geq 0$ there exists an $m$ by 1 vector $x > 0$ (resp., $x \geq 0$) satisfying $A^T x = b$ or equivalently $x^T A = b^T$; see Proposition 4.1 for a proof.

Square sign patterns with entries in $\{+, -\}$ that allow a positive (left) inverse are characterized in [6], and this characterization is extended to arbitrary square sign patterns in [4]. These results are summarized in [2, section 9.2]. In section 2, we characterize nonsquare sign patterns that allow a PLI, and combine the square and nonsquare characterizations. In section 3, we discuss sign patterns that allow an NLI. More specifically, we characterize nonnegative sign patterns and $m$ by 2 sign patterns with $m \geq 2$ that allow an NLI, and present some necessary or sufficient conditions for general $m$ by $n$ sign patterns with $m \geq n$ to allow an NLI. We conclude with some remarks in section 4.

**2. Positive left inverses.** We begin this section with a necessary and sufficient condition for a column sign pattern to allow a PLI or an NLI.

PROPOSITION 2.1. [illegible] $\mathcal{S} = (s_1, s_2, \ldots, s_m)^T$ [illegible] $m$ [illegible] 1 [illegible]

(i) $\mathcal{S}$ [illegible] $+$ [illegible]
(ii) $\mathcal{S}$ [illegible]
(iii) $\mathcal{S}$ [illegible]

[illegible]. Suppose there is an index $i \in \{1, 2, \ldots, m\}$ with $s_i = +$. For $j \in \{1, \ldots, m\}$, set

$$a_j = \begin{cases} 1 & \text{if } j \neq i \text{ and } s_j = +, \\ -1 & \text{if } j \neq i \text{ and } s_j = -, \\ 0 & \text{if } j \neq i \text{ and } s_j = 0, \\ 1 + \sum_{k \neq i} |a_k| & \text{if } j = i. \end{cases}$$

Then $A = (a_1, \ldots, a_m)^T \in Q(\mathcal{S})$, and $(1, 1, \ldots, 1)A = 1 + \sum_{k \neq i} (|a_k| + a_k) = c > 0$. This implies that $\frac{1}{c}(1, 1, \ldots, 1)$ is a PLI of $A$. Thus, $\mathcal{S}$ allows a PLI.

It is clear that (ii) implies (iii). Next, suppose that the sign pattern $\mathcal{S}$ allows an NLI. Then there exist $A = (a_1, \ldots, a_m)^T \in Q(\mathcal{S})$ and $B = (b_1, \ldots, b_m) \geq 0$ such that $BA = 1$, i.e., $\sum_{j=1}^m b_j a_j = 1 > 0$. This implies that there exists an $i$ with $b_i a_i > 0$. Since $b_i \geq 0$, it follows that $b_i > 0$; hence $a_i > 0$ and thus $s_i = +$. $\square$

We now consider $m \geq n \geq 2$. The following two lemmas give necessary conditions for a sign pattern to allow a PLI.

LEMMA 2.2. [illegible] $\mathcal{S}$ [illegible] $m$ [illegible] $n$ [illegible] $n \geq 2$ [illegible] $\mathcal{S}$ [illegible] $\mathcal{S}$ [illegible] $+$ [illegible] $-$ [illegible]

[illegible]. Suppose that there exist $A \in Q(\mathcal{S})$ and an $n$ by $m$ positive matrix $B$ such that $BA = I_n$. Let $i \in \{1, 2, \ldots, n\}$. Since the $(i, i)$-entry of $BA$ is 1 and each entry of $B$ is positive, it follows that some entry in column $i$ of $A$ is positive. Hence, column $i$ of $\mathcal{S}$ has a $+$ entry.

Since $n \geq 2$, there exists $j \in \{1, \ldots, n\}$ with $j \neq i$. The $(j, i)$-entry of $BA$ is 0, so since $B > 0$ and at least one entry of column $i$ of $A$ is positive, it follows that at least one entry of column $i$ of $A$ must be negative. Thus, column $i$ of $\mathcal{S}$ has a $-$ entry. $\square$

An $m$ by $n$ sign pattern $\mathcal{S}$ with $n \geq 2$ is [illegible], provided that for every nonempty proper subset $\gamma$ of $\{1, 2, \ldots, n\}$ the submatrix of $\mathcal{S}$ consisting of the columns indexed by $\gamma$ has nonzero entries in at least $|\gamma|+1$ rows (see [3]). Note that if $\mathcal{S}$ is strong Hall, then necessarily $m \geq n$. Also, for $m \geq n$, $\mathcal{S}$ is not strong Hall if and only if there exist permutation matrices $P_1$ and $P_2$ such that

$$P_1 \mathcal{S} P_2 = \begin{bmatrix} \mathcal{S}_{11} & \mathcal{S}_{12} \\ O & \mathcal{S}_{22} \end{bmatrix}, \tag{2.1}$$

where $\mathcal{S}_{11}$ is a $k$ by $\ell$ sign pattern for some integers $k$, $\ell$ with $n > \ell \geq 1$ and $k \leq \ell$.

LEMMA 2.3. [illegible] $\mathcal{S}$ [illegible] $m$ [illegible] $n$ [illegible] $n \geq 2$ [illegible] $\mathcal{S}$ [illegible] $\mathcal{S}$ [illegible]

[illegible]. To prove the contrapositive, assume that $\mathcal{S}$ is not strong Hall. If $m < n$, then it is clear that $\mathcal{S}$ does not allow a PLI. Otherwise, without loss of generality, we may assume that $\mathcal{S}$ has the form (2.1). If $k < \ell$, then the first $\ell$ columns of each realization of $\mathcal{S}$ are linearly dependent, and hence $\mathcal{S}$ does not allow a PLI.

Otherwise, $k = \ell < n$. Suppose that there exists a matrix $A = \left[\begin{smallmatrix} A_{11} & A_{12} \\ O & A_{22} \end{smallmatrix}\right] \in Q(\mathcal{S})$ with a left inverse $B = \left[\begin{smallmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{smallmatrix}\right]$, where $B_{11}$ is an $\ell$ by $\ell$ matrix. Clearly, the $\ell$ by $\ell$ matrix $A_{11}$ is invertible, and by $BA = I_n$, it follows that $\left[\begin{smallmatrix} B_{21} & B_{22} \end{smallmatrix}\right] \left[\begin{smallmatrix} A_{11} \\ O \end{smallmatrix}\right] = O$. Thus, $B_{21}A_{11} = O$, and since $A_{11}$ is invertible, the $(n-\ell)$ by $\ell$ matrix $B_{21} = O$. Since $n - \ell \geq 1$ and $\ell \geq 1$, every left inverse of a matrix in $Q(\mathcal{S})$ has a zero entry, and hence $\mathcal{S}$ does not allow a PLI. $\square$

Note that if $\mathcal{S}$ is a square sign pattern of order $n \geq 2$, then $\mathcal{S}$ is strong Hall if and only if $\mathcal{S}$ is fully indecomposable (see [3]), and $\mathcal{S}$ allows a PLI if and only if $\mathcal{S}$ allows a positive inverse. The next theorem, first proved in [4], provides a characterization of square sign patterns that allow a positive inverse. In order to recall this characterization, we use the following definition as in [1] and [2]. Let $\mathcal{S} = [s_{ij}]$ be an $m$ by $n$ sign pattern. The [illegible] $D(\mathcal{S})$ of $\mathcal{S}$ is the digraph with row vertices $u_1, \ldots, u_m$, column vertices $v_1, \ldots, v_n$, an arc $u_i \to v_j$ if $s_{ij} = +$, and an arc $v_j \to u_i$ if $s_{ij} = -$. Note that there exists at most one arc between $u_i$ and $v_j$.

THEOREM 2.4 (see [2, Theorem 9.2.1]). [illegible] $n$ [illegible] $n$ [illegible] $\mathcal{S}$ [illegible] $n \geq 2$ [illegible] ( [illegible] ) [illegible] $\mathcal{S}$ [illegible] $D(\mathcal{S})$ [illegible] $\mathcal{S}$ [illegible]

Let $\mathcal{S}$ be an $m$ by $n$ sign pattern and let $D(\mathcal{S})$ be its bipartite digraph. A [illegible] of $D(\mathcal{S})$ is a maximal strongly connected subdigraph of $D(\mathcal{S})$. If $\alpha$ is a strong component of $D(\mathcal{S})$, then $|\alpha|$ denotes the number of vertices in $\alpha$.

[illegible] 2.5. Let $\alpha$ be a strong component of $D(\mathcal{S})$. Since $D(\mathcal{S})$ is a bipartite digraph with no cycles of length 2, it follows that if $|\alpha| \geq 2$, then $\alpha$ has at least two row vertices and at least two column vertices.

Let $\alpha_1, \alpha_2, \ldots, \alpha_t$ be the strong components of $D(\mathcal{S})$. The [illegible] digraph $CD(\mathcal{S})$ of $\mathcal{S}$ has vertices $\alpha_1, \alpha_2, \ldots, \alpha_t$ and an arc $\alpha_i \to \alpha_j$ if and only if $i \neq j$ and $D(\mathcal{S})$ has at least one arc from a vertex in $\alpha_i$ to a vertex in $\alpha_j$. A strong component $\alpha_i$ of $D(\mathcal{S})$ is a [illegible] if there is no arc coming into $\alpha_i$ in $CD(\mathcal{S})$ and there is at least one arc coming out of $\alpha_i$ in $CD(\mathcal{S})$; $\alpha_i$ is a [illegible] if there is no arc coming out of $\alpha_i$ in $CD(\mathcal{S})$ and there is at least one arc coming into $\alpha_i$ in $CD(\mathcal{S})$; and $\alpha_i$ is [illegible] if there are no arcs coming into or out of $\alpha_i$ in $CD(\mathcal{S})$.

LEMMA 2.6. [illegible] $\mathcal{S}$ [illegible] $m$ [illegible] $n$ [illegible] $+$ [illegible] $-$ [illegible] $D(\mathcal{S})$:

(i) [illegible] $D(\mathcal{S})$ [illegible]

(ii) [illegible]

[illegible]. (i) Let $\alpha$ be a sink or source strong component. If $|\alpha| = 1$, then since each column of $\mathcal{S}$ has a $+$ and a $-$ entry, it follows that no sink or source strong component consists of exactly one column vertex. Hence, $\alpha$ is a row vertex. If $|\alpha| \geq 2$, then Remark 2.5 implies that $\alpha$ has at least one row vertex.

(ii) By the assumptions on the rows and columns of $\mathcal{S}$, there is no isolated strong component with exactly one vertex. Hence, by Remark 2.5, each isolated strong component has at least two row vertices. $\square$

Let $A$ be an $m$ by $n$ matrix with $m \geq n$. If there exists an $m$ by 1 vector $y > 0$ satisfying $y^T A = 0$, then $y^T$ is a [illegible] nullvector of $A$. The following theorem gives a characterization of nonsquare sign patterns with no rows of zeros that allow a PLI. Note that conditions for such a sign pattern to allow a PLI are weaker than those for square sign patterns (Theorem 2.4), although the bipartite digraph is used in our proof for a nonsquare sign pattern.

THEOREM 2.7. [illegible] $m > n \geq 2$ [illegible] $\mathcal{S}$ [illegible] $m$ [illegible] $n$ [illegible]

(i) [illegible] $A \in Q(\mathcal{S})$ [illegible]

(ii) $\mathcal{S}$ [illegible]

(iii) [illegible] $\mathcal{S}$ [illegible] $+$ [illegible] $-$ [illegible] $\mathcal{S}$ [illegible]

[illegible]. Clearly, (i) implies (ii). By Lemmas 2.2 and 2.3, (ii) implies (iii).

To prove that (iii) implies (i), assume that $\mathcal{S}$ is strong Hall and that $\mathcal{S}$ has a $+$ and a $-$ entry in each column. We claim that it suffices to show that there exists an $m$ by $(m-n)$ sign pattern $\mathcal{C}$ so that the $m$ by $m$ sign pattern $[\mathcal{S} \mid \mathcal{C}]$ allows a positive (left) inverse. To prove this claim, suppose there exists an $m$ by $m$ matrix $[A \mid C] \in Q([\mathcal{S} \mid \mathcal{C}])$ with a positive (left) inverse $\left[\begin{smallmatrix} B_1 \\ B_2 \end{smallmatrix}\right]$ where $B_1$ is an $n$ by $m$ positive matrix and $B_2$ is an $(m-n)$ by $m$ positive matrix. Then $B_1 A = I_n$ and hence $B_1$ is a PLI of $A$, implying that $\mathcal{S}$ allows a PLI. In addition, since $B_2 A = O$ and $B_2$ has at least one positive row, $A$ has a positive left nullvector. Therefore, by Theorem 2.4, it suffices to find an $m$ by $(m-n)$ sign pattern $\mathcal{C}$ such that the $m$ by $m$ sign pattern $[\mathcal{S} \mid \mathcal{C}]$ is strong Hall and its bipartite digraph $D([\mathcal{S} \mid \mathcal{C}])$ is strongly connected.

Consider the bipartite digraph $D(\mathcal{S})$ of $\mathcal{S}$. Let $\alpha_1, \alpha_2, \ldots, \alpha_t$ be its strong components, where $\alpha_1, \ldots, \alpha_k$ are sinks, $\alpha_{k+1}, \ldots, \alpha_{k+\ell}$ are sources, $\alpha_{k+\ell+1}, \ldots, \alpha_{k+\ell+r}$ are isolated, and $\alpha_{k+\ell+r+1}, \ldots, \alpha_t$ are neither sinks, sources, nor isolated strong components. By Lemma 2.6 (i), each sink and source strong component has a row vertex. Let $r_i$ be a fixed row vertex of $\alpha_i$ for each $i \in \{1, \ldots, k+\ell\}$. Also, by Lemma 2.6 (ii), each isolated strong component has at least two row vertices. Let $r_i^+, r_i^-$ be distinct fixed row vertices of $\alpha_i$ for each $i \in \{k+\ell+1, \ldots, k+\ell+r\}$. Let $\mathcal{C}_{n+1}$ be the $m$ by 1 column sign pattern with nonzero $j$th coordinate:

$$\begin{cases} + & \text{if } u_j \in \{r_1, \ldots, r_k\} \cup \{r_{k+\ell+1}^-, \ldots, r_{k+\ell+r}^-\}, \\ - & \text{if } u_j \in \{r_{k+1}, \ldots, r_{k+\ell}\} \cup \{r_{k+\ell+1}^+, \ldots, r_{k+\ell+r}^+\}, \\ + & \text{otherwise.} \end{cases} \tag{2.2}$$

Then $D([\mathcal{S} \mid \mathcal{C}_{n+1}])$ is obtained from $D(\mathcal{S})$ by appending a new column vertex $c_{n+1}$, and arcs $r_j \to c_{n+1}$ if $r_j$ is in a sink component; $c_{n+1} \to r_j$ if $r_j$ is in a source component; $r_j^- \to c_{n+1}$ and $c_{n+1} \to r_j^+$ if $r_j^-$ and $r_j^+$ are in the same isolated component; as well as some additional arcs coming into vertex $c_{n+1}$.

To prove that $D([\mathcal{S} \mid \mathcal{C}_{n+1}])$ is strongly connected, we show that for each vertex $w$ of $D(\mathcal{S})$ there exists in $D([\mathcal{S} \mid \mathcal{C}_{n+1}])$ a walk from $c_{n+1}$ to $w$ and a walk from $w$ to $c_{n+1}$. Note that if $w$ is not in an isolated strong component of $D(\mathcal{S})$, then there is a walk from $w$ to a vertex in a sink strong component $\alpha_i$ of $D(\mathcal{S})$ $(i \in \{1, \ldots, k\})$. Since $\alpha_i$ is strongly connected, this walk from $w$ can be extended to the fixed row vertex $r_i$ of $\alpha_i$. By (2.2), there is an arc $r_i \to c_{n+1}$ in $D([\mathcal{S} \mid \mathcal{C}_{n+1}])$. Hence, there is a walk from $w$ to $c_{n+1}$. Similarly, there is a walk from $c_{n+1}$ to $w$.

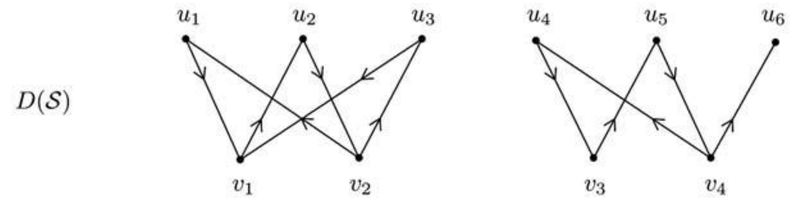
Next, suppose that $w$ is a vertex in an isolated strong component $\alpha_i$ in $D(\mathcal{S})$ ($i \in \{k+\ell+1,\ldots,k+\ell+r\}$). Since $\alpha_i$ is strongly connected, there is a walk from $w$ to the fixed row vertex $r_i^-$ of $\alpha_i$. By (2.2), there are arcs $r_i^- \to c_{n+1}$ and $c_{n+1} \to r_i^+$ in $D([\mathcal{S} \mid \mathcal{C}_{n+1}])$. Since $\alpha_i$ is strongly connected, there is a walk from $r_i^+$ to $w$. Thus, there exist a walk from $w$ to $c_{n+1}$ and a walk from $c_{n+1}$ to $w$.

Finally, define $\mathcal{C}_{n+2},\ldots,\mathcal{C}_m$ to be $m$ by 1 column sign patterns, each having no zeros, at least one $+$, and at least one $-$ entry. Then it is easily verified that $D([\mathcal{S} \mid \mathcal{C}_{n+1} \mid \ldots \mid \mathcal{C}_m])$ is strongly connected. Since $\mathcal{S}$ is strong Hall and $[\mathcal{C}_{n+1} \mid \ldots \mid \mathcal{C}_m]$ has no zeros, it is clear that $[\mathcal{S} \mid \mathcal{C}_{n+1} \mid \ldots \mid \mathcal{C}_m]$ is strong Hall, completing the proof. $\square$

Example 2.8. Consider the 6 by 4 sign pattern

$$\mathcal{S} = \begin{bmatrix} + & - & 0 & 0 \\ - & + & 0 & 0 \\ + & - & 0 & 0 \\ 0 & 0 & + & - \\ 0 & 0 & - & + \\ 0 & 0 & 0 & - \end{bmatrix}$$

with



Each column of $\mathcal{S}$ has a $+$ and a $-$ entry, and $\mathcal{S}$ is strong Hall. Thus, by Theorem 2.7, $\mathcal{S}$ allows a PLI. However, $D(\mathcal{S})$ is not strongly connected, illustrating a distinction between the nonsquare and square cases (see Theorem 2.4). In fact, $D(\mathcal{S})$ has one sink strong component $\alpha_1$ that consists of vertex $u_6$, one source strong component $\alpha_2$ with vertices $u_4, u_5, v_3, v_4$, and one isolated strong component $\alpha_3$ with vertices $u_1, u_2, u_3, v_1, v_2$. Taking $r_1 = u_6$, $r_2 = u_5$, $r_3^+ = u_1$, and $r_3^- = u_2$ in the proof of Theorem 2.7, it follows that

$$\mathcal{C}_5 = \begin{bmatrix} - \\ + \\ + \\ + \\ - \\ + \end{bmatrix}.$$

The last column $\mathcal{C}_6$ can be taken to be any 6 by 1 column having a $+$ and a $-$ entry, and no zeros. Let $\mathcal{C} = [\mathcal{C}_5 \mid \mathcal{C}_6]$. In order to determine a matrix $[A \mid C] \in Q([\mathcal{S} \mid \mathcal{C}])$ with a positive (left) inverse $\left[\begin{smallmatrix} B_1 \\ B_2 \end{smallmatrix}\right]$, the algorithm described in the proof of [2, Theorem 9.2.1] can be used. Then $B_1$ is a PLI of $A$, and the rows of $B_2$ are positive left nullvectors of $A$.

The next lemma is used to prove Theorem 2.10, in which square and nonsquare cases are combined.

Lemma 2.9. [illegible] $\mathcal{S}$ [illegible] $m$ [illegible] $n$ [illegible] $n \geq 2$ [illegible] $\mathcal{T}$ [illegible] $\mathcal{S}$ [illegible] $\mathcal{S}$ [illegible]

(i) $\mathcal{S}$ [illegible] $\mathcal{T}$ [illegible]

(ii) $\mathcal{S}$ [illegible] $\mathcal{T}$ [illegible]

[illegible]. Without loss of generality, assume that $\mathcal{S} = \left[\begin{smallmatrix}\mathcal{T}\\ O\end{smallmatrix}\right]$. The proof of (i) follows immediately from the definition of strong Hall.

To prove (ii), suppose first that $\mathcal{S}$ allows a PLI. Let $A_1 \in Q(\mathcal{T})$ and $A = \left[\begin{smallmatrix}A_1\\ O\end{smallmatrix}\right] \in Q(\mathcal{S})$ have $B = [B_1\ B_2]$ as a PLI. Then $B_1 A_1 = I_n$ and hence $\mathcal{T}$ allows a PLI. Next, suppose that $\mathcal{T}$ allows a PLI. Let $A_1 \in Q(\mathcal{T})$ have $B_1$ as a PLI. With $J$ denoting the all 1's matrix, it is easily verified that $B = [B_1\ J]$ is a PLI for $A = \left[\begin{smallmatrix}A_1\\ O\end{smallmatrix}\right] \in Q(\mathcal{S})$. Hence, $\mathcal{S}$ allows a PLI. The nonnegative case can be shown by a similar argument to that above. ☐

Theorem 2.10. [illegible] $m \geq n \geq 2$ [illegible] $m$ [illegible] $n$ [illegible] $\mathcal{S}$ [illegible]

(i) [illegible] $\mathcal{S}$ [illegible] $+$ [illegible] $-$ [illegible]

(ii) $\mathcal{S}$ [illegible]

(iii) [illegible] $D(\mathcal{S}_1)$ [illegible] $\mathcal{S}_1$ [illegible] $\mathcal{S}$ [illegible] $\left[\begin{smallmatrix}\mathcal{S}_1\\ O\end{smallmatrix}\right]$ [illegible] $\mathcal{S}_1$ [illegible] $n$ [illegible] $n$ [illegible]

[illegible]. For the necessity, suppose that $\mathcal{S}$ allows a PLI. Then (i) and (ii) follow from Lemmas 2.2 and 2.3, and (iii) follows from Theorem 2.4 and Lemma 2.9 (ii).

For the sufficiency, first assume $m = n$. Then $\mathcal{S}$ is permutationally equivalent to $\mathcal{S}_1$, and by Theorem 2.4 the result follows from (ii) and (iii). Next, suppose that $m > n$. If $\mathcal{S}$ has no rows of zeros, then, by Theorem 2.7, the result follows from (i) and (ii). Otherwise, without loss of generality, assume that $\mathcal{S} = \left[\begin{smallmatrix}\mathcal{T}\\ O\end{smallmatrix}\right]$, where $\mathcal{T}$ has no rows of zeros. By Lemma 2.9 (i), it follows from (ii) that $\mathcal{T}$ is strong Hall. Thus, if $\mathcal{T}$ is an $n$ by $n$ sign pattern, then (iii) and Theorem 2.4 imply that $\mathcal{T}$ allows a PLI. By Lemma 2.9 (ii), this implies that $\mathcal{S}$ allows a PLI. Otherwise, since it follows from (i) that each column of $\mathcal{T}$ has a $+$ and a $-$ entry, Theorem 2.7 implies that $\mathcal{T}$ allows a PLI. Therefore, by Lemma 2.9 (ii), $\mathcal{S}$ allows a PLI. ☐

[illegible] 2.11. For $m \geq n \geq 2$, let $\mathcal{S}$ be an $m$ by $n$ sign pattern. Then the following hold:

(i) If $\mathcal{S}$ satisfies (i), (ii), and (iii) in Theorem 2.10, then so does every superpattern of $\mathcal{S}$. Hence, if $\mathcal{S}$ allows a PLI, then every superpattern of $\mathcal{S}$ allows a PLI.

(ii) Suppose that $\mathcal{S} = \left[\begin{smallmatrix}\mathcal{S}_1\\ O\end{smallmatrix}\right]$, where $\mathcal{S}_1$ is a square sign pattern, satisfies (iii) in Theorem 2.10. Then, in contrast with Theorem 2.7 (i), there is no matrix $A = \left[\begin{smallmatrix}A_1\\ O\end{smallmatrix}\right] \in Q(\mathcal{S})$ with a PLI that also has a positive left nullvector, since the equation $[y^T\ z^T]\left[\begin{smallmatrix}A_1\\ O\end{smallmatrix}\right] = 0$ and the fact that $A_1$ is nonsingular together imply that $y = 0$.

The following theorem gives sufficient conditions for an $m$ by $n$ sign pattern with $m > n \geq 1$ to have a realization with a PLI and a positive left nullvector.

Theorem 2.12. [illegible] $\mathcal{S}$ [illegible] $m$ [illegible] $n$ [illegible] $m > n$ [illegible] $\mathcal{T}$ [illegible] $t$ [illegible] $n$ [illegible] $\mathcal{S}$ [illegible] $\mathcal{S}$

(i) [illegible] $n = 1$ [illegible] $\mathcal{T}$ [illegible] $+$ [illegible] $-$ [illegible] $Q(\mathcal{S})$ [illegible]

(ii) [illegible] $t > n \geq 2$ [illegible] $\mathcal{T}$ [illegible] $Q(\mathcal{S})$ [illegible]

[illegible]. (i) By Proposition 2.1, a $+$ entry implies the existence of $A \in Q(\mathcal{S})$ with a

PLI. Since $A$ has a positive and a negative entry, it can be easily verified that $A$ has a positive left nullvector.

(ii) When $m = t$, the result follows by Theorem 2.7. If $m > t > n$, then Theorem 2.7 implies that there exists a matrix $A \in Q(\mathcal{T})$ with a PLI $B$ and a positive left nullvector $y^T$. Note that the positive matrix $[B \mid J]$ is a PLI and the vector $[y^T \; 1 \cdots 1]$ is a positive left nullvector of the matrix $\left[\begin{smallmatrix} A \\ O \end{smallmatrix}\right] \in Q(\mathcal{S})$. Hence, the result follows. □

**3. Nonnegative left inverses.** In this section we determine structures of nonsquare sign patterns that allow an NLI, as well as structures of NLIs.

For $m \geq n$, let $\mathcal{S}$ be an $m$ by $n$ sign pattern with a realization of rank $n$. Then, by induction, it can be shown that $\mathcal{S}$ is permutationally equivalent to

$$\begin{bmatrix} \mathcal{S}_{11} & \mathcal{S}_{12} & \cdots & \mathcal{S}_{1k} \\ O & \mathcal{S}_{22} & \cdots & \mathcal{S}_{2k} \\ \vdots & & \ddots & \vdots \\ O & \cdots & O & \mathcal{S}_{kk} \end{bmatrix}, \tag{3.1}$$

where $k \geq 1$, $\mathcal{S}_{ii}$ is a square fully indecomposable sign pattern for each $i \in \{1, \ldots, k-1\}$, and $\mathcal{S}_{kk}$ is strong Hall. Note that $\mathcal{S}$ is strong Hall if and only if $k = 1$. If $\mathcal{S}$ is an $n$ by $n$ fully indecomposable sign pattern, then $\mathcal{S}$ allows a nonnegative (left) inverse if and only if $\mathcal{S}$ allows a positive (left) inverse; see [2, Theorems 9.2.1 and 9.2.3]. In addition, [2, Theorem 9.2.6] provides a complete characterization of $n$ by $n$ partly decomposable sign patterns that allow a nonnegative (left) inverse.

[illegible] 3.1. Suppose $m > n$. Let $\mathcal{S}'$ be the square submatrix of $\mathcal{S}$ obtained by deleting the columns and rows associated with $\mathcal{S}_{kk}$. Suppose that $\mathcal{S}$ allows an NLI. Then the square sign pattern $\mathcal{S}'$ also allows an NLI. Hence, for $k = 2$, $\mathcal{S}'$ is fully indecomposable and must satisfy one of the equivalent conditions in [2, Theorem 9.2.1] (see also Theorem 2.4), and for $k \geq 3$, $\mathcal{S}'$ is partly decomposable and must satisfy the conditions in [2, Theorem 9.2.6]. Furthermore, by an argument similar to that in the proof of Lemma 2.3, it is easily verified that an NLI $B$ of a matrix in $Q(\mathcal{S})$ has the block form $B = [B_{ij}]$ with $1 \leq i, j \leq k$ and the $(i, j)$-block $B_{ij} = O$ whenever $i > j$. Thus, it follows that the strong Hall sign pattern $\mathcal{S}_{kk}$ also allows an NLI.

We now investigate various necessary and/or sufficient conditions for a strong Hall nonsquare sign pattern to allow an NLI. We first consider strong Hall sign patterns with a + and a − entry in each column.

PROPOSITION 3.2. [illegible] $m > n \geq 2$ [illegible] $\mathcal{S}$ [illegible] $m$ [illegible] $n$ [illegible] $+$ [illegible] $-$ [illegible] $\mathcal{T}$ [illegible] $t$ [illegible] $n$ [illegible] $\mathcal{S}$ [illegible] $\mathcal{S}$ [illegible] $t > n$ [illegible] $\mathcal{S}$ [illegible] $t = n$ [illegible] $\mathcal{S}$ [illegible] $D(\mathcal{T})$ [illegible]

[illegible]. The result follows directly from Theorem 2.10 and the fact that if $\mathcal{S}$ allows a PLI, then $\mathcal{S}$ allows an NLI. □

Let $\mathcal{I}_n$ denote the $n$ by $n$ sign pattern with $I_n$ as a realization, i.e., $I_n \in Q(\mathcal{I}_n)$. Clearly, $\mathcal{I}_n$ allows an NLI. Thus, in order to allow an NLI, an $m$ by $n$ sign pattern with $m \geq n$ need not have a − entry in each column as is required to allow a PLI (see Lemma 2.2), but clearly must have a + entry in each column. We first consider the case that $\mathcal{S}$ has a nonnegative column having only + or 0 entries. For ease of notation, we sometimes use $(M)_{ij}$ to denote the $(i, j)$-entry of a matrix $M$.

PROPOSITION 3.3. [illegible] $m \geq n \geq 2$ [illegible] $\mathcal{S}$ [illegible] $m$ [illegible] $n$ [illegible] $\mathcal{S}$ [illegible] $m - n + 1$ [illegible]

[illegible] Let $B$ be an NLI of $A \in Q(\mathcal{S})$, and let $t$ be the number of positive entries in any nonnegative column of $A$. Without loss of generality, assume that the first column of $A$ is a nonnegative column with its first $t$ entries positive. Since $(BA)_{h1} = 0$ for each $h \in \{2, \ldots, n\}$, it follows that $B$ has the block form $B = [B_{ij}]$ with $1 \leq i, j \leq 2$, where the $(2,1)$-block $B_{21}$ is the $(n-1)$ by $t$ zero matrix. Hence, the equality $\operatorname{rank} B = n$ implies that the rank of the $(n-1)$ by $(m-t)$ matrix $B_{22}$ is $n-1$. Thus, $n-1 \leq m-t$ and the result follows. ☐

If all columns are nonnegative, then the following result gives a necessary and sufficient condition for such a sign pattern to allow an NLI.

THEOREM 3.4. [illegible] $m \geq n \geq 1$ [illegible] $\mathcal{S}$ [illegible] $m$ [illegible] $n$ [illegible] $\mathcal{S}$ [illegible] $\mathcal{S}$ [illegible]

$$\begin{bmatrix} \mathcal{I}_n \\ \mathcal{T} \end{bmatrix},$$

[illegible] $\mathcal{T}$ [illegible] $(m-n)$ [illegible] $n$ [illegible]

[illegible] The case $n = 1$ follows directly from Proposition 2.1. Suppose that $n \geq 2$. For the sufficiency, assume without loss of generality that

$$\mathcal{S} = \begin{bmatrix} \mathcal{I}_n \\ \mathcal{T} \end{bmatrix}.$$

Let $T \in Q(\mathcal{T})$ and $A = \left[\begin{smallmatrix} I_n \\ T \end{smallmatrix}\right] \in Q(\mathcal{S})$. Since $[I_n \mid O]\, A = I_n$, it follows that $\mathcal{S}$ allows an NLI.

For the necessity, suppose that $\mathcal{S} = [s_{ij}]$ allows an NLI; i.e., there exist $A = [a_{ij}] \in Q(\mathcal{S})$ and an $n$ by $m$ nonnegative matrix $B = [b_{ij}]$ such that $BA = I_n$. Let $i \in \{1, \ldots, n\}$. Since $(BA)_{ii} = 1$, there exists $j_i \in \{1, \ldots, m\}$ such that $b_{ij_i} a_{j_i i} > 0$. This implies that $s_{j_i i} = +$. Also, for each $k \in \{1, \ldots, n\} \setminus \{i\}$, $(BA)_{ik} = 0$ implies that $b_{ij_i} a_{j_i k} = 0$. Thus, row $j_i$ of $\mathcal{S}$ is equal to row $i$ of $\mathcal{I}_n$. As this holds for each $i \in \{1, \ldots, n\}$, the result follows. ☐

[illegible] 3.5. Let $\mathcal{S} = \left[\begin{smallmatrix} \mathcal{I}_n \\ \mathcal{J} \end{smallmatrix}\right]$ be the $m$ by $n$ nonnegative sign pattern with $m \geq n \geq 2$, where $\mathcal{J}$ is the sign pattern with all entries positive. Then, by Theorem 3.4, $\mathcal{S}$ allows an NLI. However, in contrast with Remark 2.11 (i), Theorem 3.4 implies that no nonnegative superpattern of $\mathcal{S}$ (except $\mathcal{S}$ itself) allows an NLI.

Next, we consider sign patterns that have at least one nonnegative column and at least one column with a $+$ and a $-$ entry. We use $e_i$ to denote the $i$th column vector of an identity matrix.

THEOREM 3.6. [illegible] $m \geq n \geq 2$ [illegible] $\mathcal{S}$ [illegible] $m$ [illegible] $n$ [illegible] $p \geq 1$ [illegible] $n-p \geq 1$ [illegible] $+$ [illegible] $-$ [illegible] $\mathcal{S}$ [illegible] $\mathcal{S}$ [illegible]

$$\begin{bmatrix} \mathcal{I}_p & \mathcal{S}_{12} \\ \mathcal{S}_{21} & \mathcal{S}_{22} \\ O & \mathcal{S}_{32} \end{bmatrix}, \tag{3.2}$$

[illegible] $\mathcal{S}_{21}$ [illegible] $r$ [illegible] $p$ [illegible] $O$ [illegible] $s$ [illegible] $p$ [illegible] $s \geq 1$ [illegible] $n-p$ [illegible] $\mathcal{S}$ [illegible] $+$ [illegible] $-$ [illegible] $\mathcal{S}$ [illegible] $\mathcal{S}_{21}$ [illegible]

[illegible] Without loss of generality, we may assume that the first $p$ columns of $\mathcal{S}$ are nonnegative, and that each of the last $n-p$ columns of $\mathcal{S}$ has a $+$ and a $-$ entry.

Since $\mathcal{S}$ allows an NLI, so does the $m$ by $p$ nonnegative sign pattern consisting of the first $p$ columns of $S$. Therefore, by Theorem 3.4, we may permute the rows of $\mathcal{S}$ to obtain a matrix of the form (3.2), where $S_{21}$ is a nonnegative matrix with no row of zeros, $O$ is an $s$ by $p$ zero matrix with $s \geq 0$, and each of the last $n - p$ columns has a + and a − entry.

Let $A$ be a matrix in $Q(\mathcal{S})$ that has an NLI, say $B$. Since $BA = I_n$, each of the vectors $e_1^T, \dots, e_n^T$ is a nontrivial, nonnegative linear combination of the rows of $A$. Since the first $p$ columns of $A$ are nonnegative and $n > p$, this requires that $s \geq 1$, and we conclude that $\mathcal{S}$ has the desired form.

If $\mathcal{S}_{21}$ is vacuous or has a column of zeros, then $\mathcal{S}$ has an $(m-1)$ by 1 zero submatrix. Hence $\mathcal{S}$ is not strong Hall, and the result follows by taking the contrapositive. ☐

PROPOSITION 3.7. $m \geq n \geq 2$ $\mathcal{S}$ $m$ $n$ $p \geq 1$ $n - p \geq 1$ + − $\mathcal{S}$ (3.2)

$$A = \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \\ O & A_{32} \end{bmatrix} \in Q(\mathcal{S})$$

$B = \left[\begin{smallmatrix} B_{11} & B_{12} & B_{13} \\ B_{21} & B_{22} & B_{23} \end{smallmatrix}\right]$ $A_{21}, A_{22}, B_{12}$ $B_{22}$ $\mathcal{S}$

(i) $B_{11}$ $B_{21}$ $B_{22}$

(ii) $\mathcal{S}_{32}$

(iii) $q$ $\mathcal{S}_{21}$ $q$ $B_{12}$

(iv) $B_{12}$ $B_{12}$ $\mathcal{S}_{21}^T$

Assume that $\mathcal{S}_{21}$ is not vacuous.

Since $BA = I_n$, it follows that $B_{21}A_{11} + B_{22}A_{21} = O$. Moreover, since $B_{21}$, $B_{22}$, $A_{11}$, and $A_{21}$ are nonnegative, and no row of $A_{11}$ or $A_{21}$ is all zeros, $B_{21} = O$ and $B_{22} = O$. Also, $BA = I_n$ implies that $B_{11}A_{11} + B_{12}A_{21} = I_p$. Since $B_{11}$, $B_{12}$, $A_{11}$, and $A_{21}$ are nonnegative, both $B_{11}A_{11}$ and $B_{12}A_{21}$ are diagonal matrices. Since $A_{11} \in Q(\mathcal{I}_p)$, $A_{11}$ is an invertible diagonal matrix, and hence $B_{11}$ is a diagonal matrix. Thus, (i) is proven.

Since $B_{21}$ and $B_{22}$ are zero matrices, and $BA = I_n$, $B_{23}$ is an NLI of $A_{32}$, and (ii) is proven.

Since $B_{12}A_{21}$ is a diagonal matrix and $B_{12}$ is nonnegative, the $i$th row of $B_{12}A_{21}$ is a nonnegative linear combination of the rows of $A_{21}$ (weighted by the entries of the $i$th row of $B_{12}$). As the $i$th row of $B_{12}A_{21}$ is a nonnegative multiple of $e_i^T$, and $A_{21}$ is a nonnegative matrix with no row of zeros, it follows that if the $(i, j)$-entry of $B_{12}$ is nonzero, then the $j$th row of $A_{21}$ is a multiple of $e_i^T$. In particular, this implies that each column of $B_{12}$ has at most one nonzero entry. If the $j$th row of $A_{21}$ has at least two positive entries, then column $j$ of $B_{12}$ is a column of zeros, proving (iii). If the $(i, j)$-entry of $B_{12}$ is nonzero, then the $(j, i)$-entry of $A_{21}$ is nonzero, completing the proof of (iv).

If $\mathcal{S}_{21}$ is vacuous, then $A_{21}, A_{22}, B_{12}$, and $B_{22}$ are vacuous, in which case the proofs of (i) for $B_{11}, B_{21}$ and (ii) are similar, but statements (i) for $B_{22}$, (iii), and (iv) are vacuous. ☐

For $m \geq 2$, Proposition 3.2, Theorem 3.4, and the following theorem completely characterize the $m$ by 2 sign patterns that allow an NLI.

THEOREM 3.8. [illegible] $m \geq 2$ [illegible] $\mathcal{S}$ [illegible] $m$ [illegible] 2 [illegible] $+$ [illegible] $-$ [illegible] $\mathcal{S}$ [illegible] $\mathcal{S}$ [illegible] $+$ [illegible] $[0\ +]$ [illegible] $\mathcal{S}$

[illegible]. Suppose that $\mathcal{S}$ allows an NLI. Then the first column of $\mathcal{S}$ also allows an NLI. Hence, Theorem 3.4 implies that the first column of $\mathcal{S}$ has a + entry. By Theorem 3.6, we may assume without loss of generality that $\mathcal{S}$ is of the form (3.2). Since $\mathcal{S}_{32}$ is a column sign pattern, Propositions 3.7 (ii) and 2.1 imply that $\mathcal{S}_{32}$ has a + entry. Hence, $[0\ +]$ is a row of $\mathcal{S}$.

For the converse, suppose that the first column of $\mathcal{S}$ has a + entry and $[0\ +]$ is a row of $\mathcal{S}$. Suppose that $[+\ -]$ is also a row of $\mathcal{S}$. Then without loss of generality, $A \in \mathcal{S}$ has the form

$$\begin{bmatrix} a & -b \\ u & v \\ 0 & c \end{bmatrix},$$

where $a, b, c > 0$, and $u$ and $v$ are $(m-2)$ by 1 vectors. It is easy to verify that

$$\begin{bmatrix} 1/a & O & b/ac \\ 0 & O & 1/c \end{bmatrix}$$

is an NLI of $A$.

Next suppose that $[+\ -]$ is not a row of $\mathcal{S}$. Then without loss of generality, $A \in \mathcal{S}$ has the form

$$\begin{bmatrix} a & b \\ u & v \\ 0 & -c \\ 0 & d \end{bmatrix},$$

where $a, c, d > 0$, $b \geq 0$, and $u$ and $v$ are $(m-3)$ by 1 vectors. It is easy to verify that

$$\begin{bmatrix} 1/a & O & b/ac & 0 \\ 0 & O & 1/c & 2/d \end{bmatrix}$$

is an NLI of $A$.

Hence, $\mathcal{S}$ allows an NLI. □

Note that the proof of Theorem 3.8 actually shows that if $\mathcal{S}$ is an $m$ by 2 matrix whose first column is nonnegative, second column has a + and a − entry, and $[0\ +]$ is one of its rows, then [illegible] matrix with sign pattern $\mathcal{S}$ has an NLI.

[illegible] 3.9. The strong Hall sign pattern

$$\mathcal{S} = \begin{bmatrix} + & - \\ + & - \\ 0 & + \end{bmatrix}$$

does not allow a PLI (by Lemma 2.2), but does allow an NLI (by Theorem 3.8) since

$$\begin{bmatrix} 1 & 0 & 1/2 \\ 0 & 0 & 1/2 \end{bmatrix} \begin{bmatrix} 1 & -1 \\ 1 & -1 \\ 0 & 2 \end{bmatrix} = I_2.$$

In general (as noted in the introduction) an NLI is not unique. For instance,

$$\begin{bmatrix} 1/2 & 1/2 & 1/2 \\ 0 & 0 & 1/2 \end{bmatrix}$$

is another NLI of the above matrix.

In the next theorem, it is shown that if a sign pattern $\mathcal{S}$ of the form (3.2) has a $(3,2)$-block $\mathcal{S}_{32}$ that allows an NLI or PLI, then some conditions on the negative entries in $\mathcal{S}_{12}$ insure that $\mathcal{S}$ allows an NLI.

THEOREM 3.10. [illegible] $m \geq n \geq 2$ [illegible] $\mathcal{S}$ [illegible] $m$ [illegible] $n$ [illegible] (3.2) [illegible] $p \geq 1$ $n-p \geq 1$ [illegible] $\mathcal{S}_{21}$ $\mathcal{S}_{22}$ [illegible]

(i) [illegible] $\mathcal{S}_{32}$ [illegible] $\mathcal{S}_{12}$ [illegible] 0 [illegible] $-$ [illegible] $\mathcal{S}$ [illegible]

(ii) [illegible] $\mathcal{S}_{32}$ [illegible] $\mathcal{S}_{12}$ [illegible] $-$ [illegible] $\mathcal{S}$ [illegible]

[illegible]. (i) Let

$$A = \begin{bmatrix} I_p & A_{12} \\ A_{21} & A_{22} \\ O & A_{32} \end{bmatrix} \in Q(\mathcal{S}), \tag{3.3}$$

where $-A_{12} \geq 0$ and $A_{32}$ has $B_{23}$ as an NLI. Let

$$B = \begin{bmatrix} I_p & O & B_{13} \\ O & O & B_{23} \end{bmatrix} \tag{3.4}$$

with $B_{13} = -A_{12}B_{23}$, which is a nonnegative matrix. Then $B \geq 0$, $BA = I_n$, and hence the result follows.

(ii) Let $A \in Q(\mathcal{S})$ be of the form (3.3) and let $B$ be of the form (3.4). If $B_{23}$ is a PLI of $A_{32}$ and $B_{13} = -A_{12}B_{23}$, then $B_{13} > 0$, provided that the negative entries of $A_{12}$ are sufficiently large in magnitude, and $BA = I_n$ as required. ☐

## 4. Concluding remarks.

In section 3, we have characterized nonnegative sign patterns, strong Hall sign patterns with each column having a $+$ and a $-$ entry, and $m$ by 2 sign patterns that allow an NLI. For other cases, we have given some necessary or sufficient conditions for $\mathcal{S}$ to allow an NLI. A characterization for the blocks of the last column of a sign pattern $\mathcal{S}$ of the form (3.1) with $k \geq 2$ that allows an NLI remains open. We conclude by showing (in Theorem 4.2) that some conditions on the submatrix $\mathcal{S}_{kk}$ of a sign pattern $\mathcal{S}$ of the form (3.1) with $k \geq 2$ insure that $\mathcal{S}$ allows an NLI for arbitrary $\mathcal{S}_{1k}, \ldots, \mathcal{S}_{k-1,k}$.

Let $\mathcal{S}$ allow a PLI and $A \in Q(\mathcal{S})$. The following proposition, which is used to prove Theorem 4.2, describes a relation between a PLI of $A$ and the qualitative behavior of solutions of $x^TA = b^T$. The latter equation is given in the introduction as motivation for studying PLIs and NLIs.

PROPOSITION 4.1. [illegible] $m \geq n$ [illegible] $A$ [illegible] $m$ [illegible] $n$ [illegible] $A$ [illegible] $n$ [illegible] 1 [illegible] $b \geq 0$ [illegible] $m$ [illegible] 1 [illegible] $x > 0$ [illegible] $x^TA = b^T$

[illegible]. Suppose that an $n$ by $m$ matrix $B > 0$ is a PLI of $A$. For an $n$ by 1 nonzero vector $b \geq 0$, it is clear that $(b^TB)A = b^T$ and $b^TB > 0$. Hence, the result follows.

Next, suppose that for each $n$ by 1 nonzero vector $b \geq 0$ there exists an $m$ by 1 vector $x > 0$ satisfying $x^TA = b^T$. Take $b$ to be the $i$th column $e_i$ of $I_n$ and let $x_i > 0$

be a solution of $x^T A = e_i^T$. Then the matrix

$$B = \begin{bmatrix} x_1^T \\ \vdots \\ x_n^T \end{bmatrix}$$

is a PLI of $A$. □

THEOREM 4.2. [illegible] $m > s \geq 1$ [illegible] $n > t \geq 1$ [illegible] $m > n$ [illegible] $\mathcal{S}_{11}$ [illegible] $s$ [illegible] $t$ [illegible] $\mathcal{S}_{22}$ [illegible] $(m-s)$ [illegible] $(n-t)$ [illegible] $n-t=1$ [illegible] $\mathcal{S}_{22}$ [illegible] $-$ [illegible] $n-t \geq 2$ [illegible] $\mathcal{S}_{22}$ [illegible] $\left[\begin{smallmatrix}\mathcal{T}\\ O\end{smallmatrix}\right]$ [illegible] $\mathcal{T}$ [illegible] $s$ [illegible] $(n-t)$ [illegible] $\mathcal{S}_{12}$ [illegible] $\mathcal{S} = \left[\begin{smallmatrix}\mathcal{S}_{11} & \mathcal{S}_{12}\\ O & \mathcal{S}_{22}\end{smallmatrix}\right]$ [illegible]

[illegible] Let $A_{11}$ be a matrix in $Q(\mathcal{S}_{11})$ with $B_{11}$ as an NLI. By Theorem 2.12, there exists $A_{22} \in Q(\mathcal{S}_{22})$ that has a PLI $B_{22}$ and a positive left nullvector $y^T$. Let $A_{12} \in Q(\mathcal{S}_{12})$. Then $A_{12}$ can be written as $A_{12} = V_1 - V_2$, where $V_1, V_2 \geq 0$ and the entrywise (Hadamard) product $V_1 \circ V_2 = O$. Let $v_i^T \geq 0$ for $1 \leq i \leq s$ denote row $i$ of $V_1$. If $v_i \neq 0$, then by Proposition 4.1 there exists an $(m-s)$ by 1 vector $x_i > 0$ such that $x_i^T A_{22} = v_i^T$. If $v_i = 0$, then $x_i^T A_{22} = v_i^T = 0$ when $x_i^T = y^T$. Thus, $K_1 = [x_1, \ldots, x_s]^T > 0$ and $K_1 A_{22} = V_1$. Similarly, there exists $K_2 > 0$ such that $K_2 A_{22} = V_2$.

Let $A_{12}(\epsilon) = \epsilon V_1 - V_2 = (\epsilon K_1 - K_2) A_{22}$ for a sufficiently small $\epsilon > 0$ such that $K_2 - \epsilon K_1 > 0$. Note that $V_1 \circ V_2 = O$ implies that $A_{12}(\epsilon) \in Q(\mathcal{S}_{12})$. Let $B_{12} = B_{11}(K_2 - \epsilon K_1)$. Since $K_2 - \epsilon K_1 > 0$ and $B_{11} \geq 0$ with no rows of zeros, it follows that $B_{12} > 0$. It can be easily verified that $\left[\begin{smallmatrix} B_{11} & B_{12} \\ O & B_{22}\end{smallmatrix}\right]\left[\begin{smallmatrix} A_{11} & A_{12}(\epsilon) \\ O & A_{22}\end{smallmatrix}\right] = I_n$. Hence, the result follows. □

[illegible] 4.3. Take $\mathcal{S}_{11}$ and $\mathcal{S}_{22}$ in Theorem 4.2 to be $\mathcal{S}'$ in Remark 3.1 and $\mathcal{S}_{kk}$ in the form (3.1) with $k \geq 2$, respectively. Then the conditions on $\mathcal{S}_{kk}$ in Theorem 4.2 insure that the sign pattern $\mathcal{S}$ of the form (3.1) with $k \geq 2$ allows an NLI for arbitrary $\mathcal{S}_{1k}, \ldots, \mathcal{S}_{k-1,k}$.

# FAST QR EIGENVALUE ALGORITHMS FOR HESSENBERG MATRICES WHICH ARE RANK-ONE PERTURBATIONS OF UNITARY MATRICES*

D. A. BINI[†], Y. EIDELMAN[‡], L. GEMIGNANI[†], AND I. GOHBERG[‡]

**Abstract.** Let $\mathcal{H}_n \subset \mathbb{C}^{n\times n}$ be the class of $n \times n$ Hessenberg matrices $A$ which are rank-one modifications of a unitary matrix, that is, $A = H + \boldsymbol{u}\boldsymbol{w}^H$, where $H$ is unitary and $\mathbf{u}, \mathbf{w} \in \mathbb{C}^n$. The class $\mathcal{H}_n$ includes three well-known subclasses: unitary Hessenberg matrices, companion (Frobenius) matrices, and fellow matrices. The paper presents some novel fast adaptations of the shifted QR algorithm for computing the eigenvalues of a matrix $A \in \mathcal{H}_n$ where each step can be performed with $O(n)$ flops and $O(n)$ memory space. Numerical experiments confirm the effectiveness and the robustness of these methods.

## 1. Introduction.

The subject of this paper is the efficient computation of the eigenvalues of certain upper Hessenberg matrices $A \in \mathbb{C}^{n\times n}$ of the form

$$A = H + \boldsymbol{u}\boldsymbol{w}^H, \tag{1.1}$$

where $H \in \mathbb{C}^{n\times n}$ is unitary and $\boldsymbol{u}, \boldsymbol{w} \in \mathbb{C}^n$. Let $\mathcal{H}_n$ denote this class of matrices. If $A \in \mathcal{H}_n$ is invertible, then from the Sherman–Morrison formula one has

$$A^{-1} = H^H - \sigma H^H \boldsymbol{u}\boldsymbol{w}^H H^H, \quad \sigma = (1 + \boldsymbol{w}^H H^H \boldsymbol{u})^{-1} \in \mathbb{C},$$

which can be combined with (1.1) to give

$$A - A^{-H} = \boldsymbol{u}\boldsymbol{w}^H + \bar{\sigma} H \boldsymbol{w}\boldsymbol{u}^H H. \tag{1.2}$$

The shifted QR algorithm with shifts $\alpha_k \in \mathbb{C}$, $k = 0, 1, \dots,$

$$\begin{aligned} A_0 &= A, \\ A_k - \alpha_k I_n &= Q_k R_k, \\ A_{k+1} &:= R_k Q_k + \alpha_k I_n, \end{aligned} \tag{1.3}$$

is a well-known standard method for computing the eigenvalues of a dense matrix $A$ [13, 17, 25]. For simplicity, we refer to (1.3) as the QR iteration. A careful exploitation of (1.2) says that each matrix $A_k$, $k = 0, 1, \dots,$ generated by the QR iteration (1.3) applied to $A_0 = A \in \mathcal{H}_n$ can be represented by $O(n)$ parameters. Therefore, our main goal is to find fast and numerically robust adaptations of the customary QR iteration (1.3) for an input matrix $A_0 \in \mathcal{H}_n$ which require $O(n)$ floating point operations (flops) per iteration and $O(n)$ memory space.

**1.1. The class $\mathcal{H}_n$.** The class $\mathcal{H}_n$ includes three well-known subclasses: unitary Hessenberg matrices, companion (Frobenius) matrices, and *fellow* matrices.

The interest on eigenvalues computation for unitary Hessenberg matrices is motivated by several applications such as signal processing [16] and least squares approximation by trigonometric polynomials [3, 18]. A fast QR iteration for unitary Hessenberg matrices was first presented in [14]. The algorithm relies upon the Schur representation of a unitary Hessenberg matrix as product of (modified) Givens rotations [12]. Suitable variants of the algorithm of [14] are developed in [15, 24, 23], while the potential stability problems encountered by these algorithms are analyzed in [19].

The companion (Frobenius) matrix associated with the $n$-degree polynomial $f(z) = \sum_{i=0}^{n} f_i z^i$, $f_n \neq 0$, is defined by $F = C + \boldsymbol{f}\boldsymbol{e}_n^T$, where $C = (c_{i,j})$ is the generator of the *circulant* matrix algebra such that $c_{i,j} = 1$ for $i - j = 1 \mod n$, $c_{i,j} = 0$, otherwise $\boldsymbol{e}_n$ stands for the $n$th column of the $n \times n$ identity matrix $I_n$ and $\boldsymbol{f}^T = [-f_0/f_n - 1, -f_1/f_n, \ldots, -f_{n-1}/f_n]$. Matrix methods based on the QR iteration applied to a companion matrix are customary for polynomial root-finding: in fact, the MATLAB[1] command `roots` relies on this approach.

Matrices of the more general form $F = H + \boldsymbol{u}\boldsymbol{e}_n^T$, where $H$ is unitary Hessenberg, are referred to as fellow matrices in [6]. The root-finding problem for a polynomial expressed as a linear combination of Szegö polynomials is reduced to the solution of an eigenvalue problem for a fellow matrix (see [1] and also [2]).

From the Schur parameterization it immediately follows that any unitary Hessenberg matrix $H$ has low rank submatrices in its off-diagonal blocks. The property extends to companion and fellow matrices and is a manifestation of their *quasiseparable* structure, i.e., of the fact that all the submatrices of $H$ which do not contain the diagonal have small rank. The class of (block) quasiseparable matrices was introduced and studied in the papers [8, 9, 10, 11], in the monograph [7], and in [21]. We refer the reader to section 2 for a formal definition of quasiseparable matrices.

By using (1.2), it is also found that the quasiseparable structure of an invertible matrix $A \in \mathcal{H}_n$ is inherited by each matrix $A_k$ generated by the QR iteration (1.3) applied to $A_0 = A$. A fast QR iteration for nonsingular companion matrices based on the formula (1.2) has been recently designed in [5]. The algorithm is computationally appealing but numerically unstable due to the appearance of the inverse matrix in the formula (1.2).

**1.2. Summary of the results.** In this paper we present a unified approach to the computation of eigenvalues of unitary Hessenberg, companion, and fellow matrices by using fast, stable adaptations of the structured QR iteration. The new algorithms do not suffer the instabilities and/or the computational problems of previous works on fast QR algorithms for fellow matrices [6] and companion matrices [5]; for unitary Hessenberg matrices the new algorithms do not have shift restrictions as for previous methods [15, 24, 23].

The key idea of our approach is to find a compact representation of the matrices $A_k$, $k = 0, 1, \ldots$, generated by the QR iteration (1.3) which does not involve quantities expressed in terms of the entries of $A_k^{-1}$. To do this we elaborate on the relation (1.1). By using $A_{k+1} = Q_k^H A_k Q_k$, one obtains that

$$A_{k+1} = H_{k+1} + \boldsymbol{u}_{k+1}\boldsymbol{w}_{k+1}^H, \quad k \geq 0, \tag{1.4}$$

---

[1] MATLAB is a registered trademark of The Mathworks, Inc.

where $H_{k+1}$ is unitary and, moreover, $H_{k+1} = Q_k^H H_k Q_k$, $\boldsymbol{u}_{k+1} = Q_k^H \boldsymbol{u}_k$, and $\boldsymbol{w}_{k+1} = Q_k^H \boldsymbol{w}_k$ subjected to the initializations $H_0 = H$, $\boldsymbol{u}_0 = \boldsymbol{u}$, and $\boldsymbol{w}_0 = \boldsymbol{w}$. Since $A_{k+1}$ is Hessenberg, from (1.4) we deduce that $H_{k+1}$ has a quasiseparable structure in its strictly lower triangular part. By exploiting this property, we derive a quasiseparable representation for the whole matrix $H_{k+1}$. Combining this representation with the formula (1.4) yields the desired compact description of the matrix $A_{k+1}$ in terms of number of parameters which is linear in $n$.

The computation of the quasiseparable representation of the matrix $H_{k+1}$ in floating point arithmetic leads to some additional difficulties and sometimes in numerical tests performed with very large matrices ($n \geq 1000$) it turned out to be prone to numerical instabilities. In particular, if $fl(H_{k+1}) = \tilde{H}_{k+1} + \tilde{\Delta}_{k+1}$, where $\tilde{H}_{k+1}$ is numerically unitary, then the computation can amplify the previously accumulated error $\tilde{\Delta}_{k+1}$. A renormalization technique is used in our algorithm to overcome this drawback. The new iterate at step $k+1$ is defined as a small perturbation of $A_{k+1}$ which is both upper Hessenberg and a rank-one perturbation of a numerically unitary matrix $U_{k+1}$. In this way, the quasiseparable structure of $U_{k+1}$ and, a fortiori of the new iterate, can be computed without any amplification of previously accumulated errors. The overall computational cost of the resulting algorithm is $O(n)$ flops per iteration and $O(n)$ storage locations. Numerical experiments show that the algorithm is stable.

**1.3. Paper organization.** The paper is organized as follows. In section 2 we recall some basic properties and algorithms for quasiseparable matrices. In section 3 we first characterize the structure of a unitary matrix $H$ such that $H + \boldsymbol{u}\boldsymbol{w}^H \in \mathcal{H}_n$ for vectors $\boldsymbol{u}$ and $\boldsymbol{w}$, then we apply this result to determine a numerically suited quasiseparable representation for the matrices $A_k$ generated by the QR iteration (1.3) applied to an input matrix $A = A_0 \in \mathcal{H}_n$. In section 4, we develop fast algorithms to carry out one QR iteration in a fast and robust way using linear time and linear memory space. In section 5 we discuss practical implementations of our QR iteration algorithm and present the results of numerical experiments. Finally, the conclusion and a discussion are the subjects of section 6.

## 2. Quasiseparable structures: Definitions and fast algorithms.

For any $n \times n$ matrix $B = (b_{i,j}) \in \mathbb{C}^{n\times n}$ we adopt the MATLAB notation $\mathrm{triu}(B,p) = (t_{i,j})$ to denote the upper triangular portion of $B$ such that $t_{i,j} = b_{i,j}$ for $j - i \geq p$, and $t_{i,j} = 0$ elsewhere. Analogously, the $n \times n$ matrix $T = \mathrm{tril}(B,p)$ is formed by the lower triangular portion of $B$ such that $t_{i,j} = b_{i,j}$ for $j - i \leq p$, and $t_{i,j} = 0$ elsewhere.

A matrix $A \in \mathbb{C}^{n\times n}$ is called order $(n_L, n_U)$-[illegible] [8] if

$$n_L = \max_{1\leq k\leq n-1} \operatorname{rank} A[k+1\colon n, 1\colon k], \quad n_U = \max_{1\leq k\leq n-1} \operatorname{rank} A[1\colon k, k+1\colon n],$$

where $B[i\colon j, k\colon l]$ is the submatrix of $B$ with entries having row and column indices in the ranges $i$ through $j$ and $k$ through $l$, respectively. In the case $n_U = n_L = r$ one refers to $A$ as an order-$r$-quasiseparable matrix. A computationally important property of $n \times n$ quasiseparable matrices is that they can be represented by only $O((n_L + n_U)n)$ parameters via [illegible]. Given the set of $m \times m$ matrices $\{B_j\}_{j=2}^{n-1}$ and two positive integers $i, j$ such that $1 < i + 1 \leq j \leq n$, we define the matrix $B_{i,j}^{\times}$ as follows: $B_{i,j}^{\times} = B_{i+1} \cdots B_{j-1}$ for $n \geq j > i+1$ and $B_{j,j+1}^{\times} = I_m$ for $1 \leq j \leq n-1$. Analogously, if $j + 1 \leq i \leq n$, then ${}^{\times}B_{i,j} = B_{i-1} \cdots B_{j+1}$ for $n \geq i > j+1$ and ${}^{\times}B_{i,i-1} = I_m$ for $2 \leq i \leq n$. Then an order $(n_L, n_U)$-[illegible] matrix $A =$

$(a_{i,j}) \in \mathbb{C}^{n\times n}$ can be represented as follows (see [7] and [8]):

$$a_{i,j} = \begin{cases} \boldsymbol{p}_i^T {}^{\times}B_{i,j}\boldsymbol{q}_j, & 1 \le j < i \le n, \\ \boldsymbol{g}_i^T C^{\times}_{i,j}\boldsymbol{h}_j, & 1 \le i < j \le n. \end{cases} \tag{2.1}$$

The diagonal entries $a_{i,i}$, $1 \le i \le n$ are arbitrary and do not satisfy any structural constraint. Here $\boldsymbol{p}_i \in \mathbb{C}^{n_L}$, $2 \le i \le n$, $\boldsymbol{q}_i \in \mathbb{C}^{n_L}$, $1 \le i \le n-1$, and $B_i \in \mathbb{C}^{n_L\times n_L}$, $2 \le i \le n-1$; these elements are said to be [illegible] of the matrix $A$. Similarly, the elements $\boldsymbol{g}_i \in \mathbb{C}^{n_U}$, $1 \le i \le n-1$, $\boldsymbol{h}_i \in \mathbb{C}^{n_U}$, $2 \le i \le n$, and $C_i \in \mathbb{C}^{n_U\times n_U}$, $2 \le i \le n-1$ are said to be [illegible] of the matrix $A$.

The quasiseparable structure provides a generalization of the [illegible] structure. If $C_i = C$, $B_i = B$, and $B^{n_L} = 0$, $C^{n_U} = 0$, then the matrix $A$ defined by (2.1) is a band matrix with upper and lower bandwidth $n_U$ and $n_L$, respectively. In particular, if $n_L = 1$ and $B_i = 0$, then ${}^{\times}B_{i,j} = \delta_{i-1,j}$ is the Kronecker delta and $A$ reduces to an upper Hessenberg matrix. Roughly speaking, the quasiseparable structure is maintained under arithmetic operations, inversion, and LU and QR factorization. More precisely, the matrices generated by these operations are still quasiseparable with generally a different order of quasiseparability. Fast $O(n)$ algorithms for performing these operations, based upon generator manipulations, have already been devised in [8, 11, 10].

For our purposes a special mention is due to the algorithm for computing a QR factorization of a (block) quasiseparable matrix $A = QR$ presented in [11] (derived there via applying the more general Dewilde-van der Veen method [7] to finite quasiseparable matrices). The algorithm first reduces the matrix $A$ into block upper Hessenberg form $S = V^HA$ and then transforms $S$ into a triangular matrix $R = U^HS$ where $U$ and $V$ are unitary. It is worth observing that in certain cases where $A$ has a very special quasiseparable structure in its lower triangular part, the triangularization process above can be modified in such a way that $Q = VU$ can be constructed in the usual manner as a product of Givens rotations. This latter representation of $Q$ is equivalent to the representation via generators obtained by multiplying the quasiseparable matrices $U$ and $V$ using the multiplication algorithm in [8]. Nevertheless, the approach based on Givens rotations is much more familiar in the numerical analysis community and will be pursued in this paper whenever possible.

## 3. The quasiseparable structure of QR iterates.

In this section we show the quasiseparable structure of the matrices $A_k$, $k = 0, 1, \ldots$, generated by the QR iteration (1.3) applied to the input Hessenberg matrix $A = A_0 \in \mathcal{H}_n$, $A = H + \boldsymbol{u}\boldsymbol{w}^H$, where $H \in \mathbb{C}^{n\times n}$ is unitary and $\boldsymbol{u}, \boldsymbol{w} \in \mathbb{C}^n$. The main result follows from a basic property of the matrix $H$ which is both unitary and a rank-one perturbation of a Hessenberg matrix. More precisely, in the next subsection we prove that any matrix $B \in \mathbb{C}^{n\times n}$ which satisfies these two properties must be an order-2-quasiseparable matrix.

### 3.1. The quasiseparable structure of certain unitary matrices.

Let $P \in \mathbb{C}^{n\times n}$ be a unitary matrix such that the matrix $B = P - \boldsymbol{v}\boldsymbol{z}^H$ is a Hessenberg matrix for two suitable vectors $\boldsymbol{v}, \boldsymbol{z} \in \mathbb{C}^n$. Under these assumptions we establish a condensed quasiseparable representation for the matrix $P$.

At first we consider in detail the case already studied in the literature of a unitary Hessenberg matrix. A unitary upper Hessenberg matrix $P$ with real nonnegative subdiagonal entries can be represented as a product of (modified) Givens rotations

[14], i.e.,

$$P = G_1(a_1)G_2(a_2)\cdots G_n(a_n),$$

$$G_j(a_j) = I_{j-1} \oplus \mathcal{G}(a_j) \oplus I_{n-j-1},\ \mathcal{G}(a_j) = \begin{bmatrix} -a_j & b_j \\ b_j & \bar{a}_j \end{bmatrix}, \quad 1 \le j \le n-1, \tag{3.1}$$

$$G_n(a_n) = I_{n-1} \oplus (-a_n), \quad b_j \ge 0, |a_j|^2 + b_j^2 = 1, |a_n| = 1.$$

The decomposition is usually referred to as the [illegible] of $P$. The $a_j$'s are the [illegible] of $P$ and the $b_j$'s are the [illegible]. From (3.1) we obtain the representation of $P = (p_{i,j})$ via generators [12]

$$p_{i,j} = \begin{cases} b_{i-1}\delta_{i-1,j}1, & 1 \le j < i \le n, \\ -\bar{a}_{i-1}b^{\times}_{i-1,j}a_j, & 1 \le i \le j \le n, \end{cases}$$

where $\delta_{i,j}$ denotes the Kronecker delta. It is worth noting that, different from the representation (2.1), here the quasiseparable structure includes also the diagonal entries. Given a unitary upper Hessenberg matrix $U \in \mathbb{C}^{n\times n}$ we can always determine a unitary diagonal matrix $D = \mathrm{diag}[\mathrm{e}^{\mathrm{i}\theta_1}, \ldots, \mathrm{e}^{\mathrm{i}\theta_n}]$ such that $P = D^H U D$ has nonnegative subdiagonal entries. In this way it is found that $U = (u_{i,j})$ admits the representation

$$u_{i,j} = \begin{cases} \bar{\psi}_{i-1}\delta_{i-1,j}1, & 1 \le j < i \le n, \\ -\bar{\phi}_{i-1}\psi^{\times}_{i-1,j}\phi_j, & 1 \le i \le j \le n, \end{cases} \tag{3.2}$$

for complex numbers $\phi_j$ and $\psi_j$ such that $|\phi_j|^2 + |\psi_j|^2 = 1$.

[illegible] 3.1. The computation of a Schur-like parameterization of a unitary Hessenberg matrix $U$ can be accomplished in a robust way by factoring $U$ in the QR form. If $U = QR$, where $Q$ is unitary and $R$ is upper triangular with nonnegative diagonal entries, then necessarily one has $R = I_n$ and $Q = U$. Moreover, we can transform $U$ to upper triangular form by using $n-1$ (modified) Givens rotations to annihilate the $n-1$ subdiagonal entries.

Relation (3.2) says that any unitary Hessenberg matrix is $(1,1)$ quasiseparable. The following results generalize this property to the case where the unitary matrix has a more general (quasiseparable) structure in its lower triangular part.

THEOREM 3.2. [illegible] $P = (p_{i,j}) \in \mathbb{C}^{n\times n}$ [illegible] $\mathrm{tril}(P,-2) = \mathrm{tril}(\boldsymbol{v}\boldsymbol{z}^H,-2)$ [illegible] $n$ [illegible] $\boldsymbol{v} = [v_1,\ldots,v_n]^T$ [illegible] $\boldsymbol{z} = [z_1,\ldots,z_n]^T$ [illegible] $P$ [illegible] $P = VSU$ [illegible] $V$ [illegible] $S$ [illegible] $U$ [illegible] $V$ [illegible] $S$ [illegible] $V^H = G_3(\tilde{a}_3)\cdots G_{n-1}(\tilde{a}_{n-1})$ [illegible] $S^H = G_{n-1}(\hat{a}_{n-1})\cdots G_2(\hat{a}_2)$ [illegible]

[illegible]. The reduction of the matrix $P$ into an upper Hessenberg form can be split in two stages. In the first stage the matrix $P$ is transformed into a matrix $\tilde{P}$ of lower bandwidth 2, i.e., $\tilde{p}_{i,j} = 0$ whenever $i > j+2$. The task is accomplished as follows. Choose the first rotation $G_{n-1}(\tilde{a}_{n-1}) = I_{n-2} \oplus \mathcal{G}(\tilde{a}_{n-1})$ to yield

$$\mathcal{G}(\tilde{a}_{n-1}) \begin{bmatrix} v_{n-1} \\ v_n \end{bmatrix} = \begin{bmatrix} \hat{v}_{n-1} \\ 0 \end{bmatrix}.$$

Similarly, choose the successive rotations $G_j(\tilde{a}_j) = I_{j-1} \oplus \mathcal{G}(\tilde{a}_j) \oplus I_{n-j+1}$, $3 \le j \le n-2$ to yield

$$\mathcal{G}(\tilde{a}_j) \begin{bmatrix} v_j \\ \hat{v}_{j+1} \end{bmatrix} = \begin{bmatrix} \hat{v}_j \\ 0 \end{bmatrix}, \quad j = n-2, \ldots, 3.$$

In the second stage the matrix $\tilde{P} = G_3(\tilde{a}_3) \cdots G_{n-1}(\tilde{a}_{n-1})P = V^H P$ is reduced to an upper Hessenberg form by premultiplication by the matrices $G_2(\hat{a}_2), \ldots, G_{n-1}(\hat{a}_{n-1})$ suitably chosen to annihilate the entries along the second subdiagonal. At the end of the process we find that the matrix $U = G_{n-1}(\hat{a}_{n-1}) \cdots G_2(\hat{a}_2)\tilde{P} = S^H \tilde{P}$ is unitary Hessenberg. □

3.3. The reduction process described in the proof can easily be completed to produce a QR factorization of the quasiseparable matrix $P$. Indeed, the unitary lower Hessenberg matrix $V$ in the previous theorem is similar to the matrix $V$ determined at the first stage of the algorithm in [11] applied for computing a QR factorization of the quasiseparable matrix $P$. At the second stage the cited algorithm reduces $\tilde{P}$ into a triangular form by annihilating its subdiagonal entries column-by-column. Differently, in the scheme above the annihilation of the subdiagonal entries of $\tilde{P}$ is performed one subdiagonal at the time.

The factorization $P = VSU$ stated in the previous theorem leads to a characterization of the entries in the strictly upper triangular part of the matrix $P$. More specifically, let $U = U^{(0)}$, $P = P^{(0)}$, and recall that $U$ can be represented in the form (3.2) for suitable elements $\phi_j$ and $\psi_j$ of modulus less than or equal to 1. The reduction process described in the proof of Theorem 3.2 proceeds as follows:

$$\begin{aligned} P = P^{(0)} &\xrightarrow{\mathcal{G}(\tilde{a}_{n-1})} P^{(1)} \xrightarrow{\mathcal{G}(\tilde{a}_{n-2})} \cdots \xrightarrow{\mathcal{G}(\tilde{a}_3)} P^{(n-3)}, \\ P^{(n-3)} = \tilde{P} &\xrightarrow{\mathcal{G}(\hat{a}_2)} \cdots \xrightarrow{\mathcal{G}(\hat{a}_{n-1})} P^{(2n-5)} = U^{(0)}, \end{aligned} \tag{3.3}$$

where at the $j$th step $P^{(j-1)}$ is premultiplied by the corresponding Givens rotation to obtain $P^{(j)}$. Let us define $U^{(s)} = P^{(2n-5-s)} = (u_{i,j}^{(s)})$ for $0 \leq s \leq 2n-5$. The desired characterization of the entries of $P$ is thus found by carrying out the scheme (3.3) in the reverse order, i.e.,

$$\begin{aligned} U = U^{(0)} &\xrightarrow{\mathcal{G}(\hat{a}_{n-1})^H} U^{(1)} \xrightarrow{\mathcal{G}(\hat{a}_{n-2})^H} \cdots \xrightarrow{\mathcal{G}(\hat{a}_2)^H} U^{(n-2)}, \\ U^{(n-2)} = \tilde{P} &\xrightarrow{\mathcal{G}(\tilde{a}_3)^H} \cdots \xrightarrow{\mathcal{G}(\tilde{a}_{n-1})^H} U^{(2n-5)} = P, \end{aligned} \tag{3.4}$$

where at the $j$th step $U^{(j-1)}$ is premultiplied by the corresponding Givens rotation to obtain $U^{(j)}$. Based on the scheme (3.4), we determine the structure of the matrix $\tilde{P} = SU$ and then the structure of the matrix $P = V\tilde{U}$.

The next result shows that the upper triangular part of the matrix $\tilde{P} = SU$ obtained in the middle of the process (3.4) is order-2-quasiseparable. Note that here the structure includes the diagonal entries. A simple proof of the rank property is based on the following argument. For any fixed integer $k$, $1 \leq k \leq n-1$, we easily find that

$$U^{(j)}[1:k, k:n] = U[1:k, k:n], \quad 0 \leq j \leq n-1-k,$$

and, hence, $\operatorname{rank}(U^{(j)}[1:k, k:n]) = 1$. At the $(n-k)$th step of (3.4) the matrix $U^{(n-k)}$ is determined as $U^{(n-k)} = G(\hat{a}_k)^H U^{(n-k-1)}$. This produces a modification in the last row of $U^{(n-k)}[1:k, k:n]$ so that $\operatorname{rank}(U^{(n-k)}[1:k, k:n]) \leq 2$. The successive transformations only perform linear combinations among the rows of the considered submatrix and, therefore, do not modify this value of the rank. By using appropriate parameterizations for the matrices involved, the proof can be turned into an algorithm to compute recursively the generators of the quasiseparable structure of $\tilde{P}$.

LEMMA 3.4. [illegible] 3.2 [illegible] $S$ [illegible]

$$S^H = G_{n-1}(\hat{a}_{n-1}) \cdots G_2(\hat{a}_2),$$

[illegible] $U$ [illegible] (3.2) [illegible] $\boldsymbol{q}_j \in \mathbb{C}^2$ $\boldsymbol{t}_j \in \mathbb{C}^2$ $1 \leq j \leq n$ [illegible] $B_j \in \mathbb{C}^{2\times 2}$ $1 \leq j \leq n-1$ [illegible]

$$(\tilde{P})_{i,j} = \boldsymbol{q}_i^T B^{\times}_{i-1,j} \boldsymbol{t}_j, \quad 1 \leq i \leq j \leq n. \tag{3.5}$$

[illegible] $B_j$ [illegible] $\boldsymbol{q}_j$ [illegible] $\boldsymbol{t}_j$ [illegible]

$$B_1 = I_2, \quad B_j = \begin{bmatrix} \psi_{j-1} & 0 \\ \bar{\hat{a}}_j \bar{\phi}_{j-1} & \hat{b}_j \end{bmatrix}, \; 2 \leq j \leq n-1; \tag{3.6}$$

$$\boldsymbol{q}_1^T = [-1, 0], \; \boldsymbol{q}_2^T = [0, 1], \quad \boldsymbol{q}_j^T = \left[-\hat{b}_{j-1}\bar{\phi}_{j-2}, \hat{a}_{j-1}\right], \quad 3 \leq j \leq n; \tag{3.7}$$

$$\boldsymbol{t}_1 = \begin{bmatrix} \phi_1 \\ 0 \end{bmatrix}, \quad \boldsymbol{t}_j = \begin{bmatrix} \psi_{j-1}\phi_j \\ u^{(n-j)}_{j,j} \end{bmatrix}, \quad 2 \leq j \leq n; \tag{3.8}$$

[illegible]

$$u^{(n-j)}_{j,j} = -\bar{\hat{a}}_j u^{(0)}_{j,j} - \hat{b}_j \bar{\hat{a}}_{j+1} \bar{\psi}_j, \quad 2 \leq j \leq n-1.$$

[illegible] The proof is by induction. The premultiplication of $U^{(n-k-1)}$ by $G(\hat{a}_k)^H$ only changes the rows $k$ and $k+1$ of $U^{(n-k-1)}$. Observe that

$$U^{(n-k-1)}[k+2:n, 1:n] = \tilde{P}[k+2:n, 1:n], \quad U^{(n-k-1)}[1:k, 1:n] = U[1:k, 1:n].$$

Let us suppose that

$$u^{(n-k-1)}_{k+1,k} = -\bar{\hat{a}}_{k+1}\bar{\psi}_k, \; u^{(n-k-1)}_{k+1,j} = [0, 1]\, B^{\times}_{k,j} \boldsymbol{t}_j, \quad k+1 \leq j \leq n,$$

where $B_j$ and $\boldsymbol{t}_j$, $k+1 \leq j \leq n$ are defined as in (3.6) and (3.8). Since the matrices $B_j$ are lower triangular, it is easily verified that the entries located on the $k$th row in the strictly upper triangular part of $U$ can be specified by

$$u^{(n-k-1)}_{k,j} = \left[-\bar{\phi}_{k-1}, 0\right] B^{\times}_{k,j} \boldsymbol{t}_j, \quad k+1 \leq j \leq n.$$

The thesis follows by observing that

$$\mathcal{G}(\hat{a}_k)^H \begin{bmatrix} -\bar{\phi}_{k-1} & 0 \\ 0 & 1 \end{bmatrix} = \begin{bmatrix} [0, 1]\, B_k \\ \boldsymbol{q}^T_{k+1} \end{bmatrix}. \qquad \square$$

The description of the upper triangular part of $\tilde{P} = U^{(n-2)}$ via generators yields a quasiseparable representation of the upper triangular part of $P = U^{(2n-5)}$ generated at the end of the process (3.4). In fact, each of the remaining steps $U^{(j)} \to U^{(j+1)}$ in (3.4), $n-2 \leq j \leq 2n-6$ amounts to performing a linear combination between two consecutive rows of $U^{(j)}$ starting from the third row without modifying the general rank structure of the matrix. Taking a look at the Givens transformations performed, we arrive at the following theorem.

THEOREM 3.5. [illegible] 3.2 [illegible] $V$ [illegible] $S$ [illegible]

$$V^H = G_3(\tilde{a}_3)\cdots G_{n-1}(\tilde{a}_{n-1}), \quad S^H = G_{n-1}(\hat{a}_{n-1})\cdots G_2(\hat{a}_2),$$

[illegible] $U$ [illegible] (3.2) [illegible] $\tilde{\boldsymbol{q}}_j \in \mathbb{C}^2$ $1 \le j \le n-1$ [illegible] $\boldsymbol{t}_j \in \mathbb{C}^2$ $2 \le j \le n$ [illegible] $B_j \in \mathbb{C}^{2\times 2}$ $2 \le j \le n-1$ [illegible]

$$(P)_{i,j} = \tilde{\boldsymbol{q}}_i^T B_{i,j}^{\times} \boldsymbol{t}_j, \quad 1 \le i < j \le n. \tag{3.9}$$

[illegible] $B_j$ [illegible] $\boldsymbol{t}_j$ [illegible] (3.6) [illegible] (3.8) [illegible] $\tilde{\boldsymbol{q}}_j$ [illegible]

$$\begin{aligned} \tilde{\boldsymbol{q}}_j^T &= -\bar{\tilde{a}}_j \hat{\boldsymbol{q}}_j^T B_j + \tilde{b}_j \boldsymbol{q}_{j+1}^T, \\ \hat{\boldsymbol{q}}_{j+1}^T &= \tilde{b}_j \hat{\boldsymbol{q}}_j^T B_j + \tilde{a}_j \boldsymbol{q}_{j+1}^T, \quad j = 3 \ldots n-1, \end{aligned}$$

[illegible] $\boldsymbol{q}_j$ [illegible] (3.7) $\tilde{\boldsymbol{q}}_1^T = \boldsymbol{q}_1^T B_1$ $\tilde{\boldsymbol{q}}_2^T = \boldsymbol{q}_2^T B_2$ [illegible] $\hat{\boldsymbol{q}}_3^T = \boldsymbol{q}_3^T$

[illegible] The proof is by induction. The matrices $U^{(j+n-5)}$ and $U^{(j+n-4)} = G(\tilde{a}_j)U^{(j+n-5)}$, $3 \le j \le n-1$ only differ in the rows $j$ and $j+1$. Let us assume that

$$u_{j,k}^{(j+n-5)} = \hat{\boldsymbol{q}}_j^T B_{j-1,k}^{\times} \boldsymbol{t}_k, \quad j \le k \le n,$$

where $B_k$ and $\boldsymbol{t}_k$, $j \le k \le n$ are defined as in Lemma 3.4 and $\hat{\boldsymbol{q}}_j^T$ is generated after $j-3$ iterations of the two-step procedure above. Since we have

$$u_{j+1,k}^{(j+n-5)} = \boldsymbol{q}_{j+1}^T B_{j,k}^{\times} \boldsymbol{t}_k, \quad j+1 \le k \le n,$$

we find

$$\mathcal{G}(\tilde{a}_j)^H \begin{bmatrix} \hat{\boldsymbol{q}}_j^T B_j \\ \boldsymbol{q}_{j+1}^T \end{bmatrix} = \begin{bmatrix} \tilde{\boldsymbol{q}}_j^T \\ \hat{\boldsymbol{q}}_{j+1}^T \end{bmatrix},$$

and, therefore,

$$u_{j,k}^{(j+n-4)} = \tilde{\boldsymbol{q}}_j^T B_{j,k}^{\times} \boldsymbol{t}_k, \quad j < k \le n,$$

and

$$u_{j+1,k}^{(j+n-4)} = \hat{\boldsymbol{q}}_{j+1}^T B_{j,k}^{\times} \boldsymbol{t}_k, \quad j+1 \le k \le n. \qquad \square$$

### 3.2. The main result.

We are now ready to prove the main result of this section concerning the quasiseparable structure of the matrices $A_k = (a_{i,j}^{(k)})$, $k = 0, 1, \ldots$, generated by the QR iteration (1.3) applied to the input Hessenberg matrix $A = A_0 \in \mathcal{H}_n$, $A = H + \boldsymbol{u}\boldsymbol{w}^H$, where $H \in \mathbb{C}^{n\times n}$ is unitary and $\boldsymbol{u}, \boldsymbol{w} \in \mathbb{C}^n$. Since $A = A_0$ is upper Hessenberg each iterate $A_k$ has the same Hessenberg shape as $A_0$. For notational convenience we also denote $\beta_j^{(k)} = a_{j+1,j}^{(k)}$, $1 \le j \le n-1$, the subdiagonal entries of $A_k$. Since $A_{k+1} = Q_k^H A_k Q_k$ for any $k \ge 0$, from (1.1) we obtain

$$\begin{aligned} A_{k+1} &= H_{k+1} + \boldsymbol{u}_{k+1}\boldsymbol{w}_{k+1}^H, \\ H_{k+1} &= Q_k^H H_k Q_k, \\ \boldsymbol{u}_{k+1} &= Q_k^H \boldsymbol{u}_k, \ \boldsymbol{w}_{k+1} = Q_k^H \boldsymbol{w}_k, \end{aligned} \tag{3.10}$$

subjected to the initializations $H = H_0 \in \mathbb{C}^{n\times n}$, $\boldsymbol{u}_0 = \boldsymbol{u} = \left[u_1^{(0)}, \ldots, u_n^{(0)}\right]^T$, and $\boldsymbol{w}_0 = \boldsymbol{w} = \left[w_1^{(0)}, \ldots, w_n^{(0)}\right]^T$.

Based on the relations (3.10), we derive a quasiseparable representation for the matrices $A_k$, $k \geq 0$. Because of the Hessenberg form of $A_k$ from (3.10), we obtain that each matrix $H_k$ meets the assumption of Theorem 3.2. Therefore, by substituting the representation provided by Theorem 3.5 into the equations (3.10) we obtain the following theorem.

THEOREM 3.6. [illegible] $A_k = (a_{i,j}^{(k)})$ [illegible] (1.3) [illegible] $A_0 = H_0 + \boldsymbol{u}_0\boldsymbol{w}_0^H \in \mathcal{H}_n$ [illegible] $\boldsymbol{q}_j^{(k)} \in \mathbb{C}^2$ $1 \leq j \leq n-1$ [illegible] $\boldsymbol{t}_j^{(k)} \in \mathbb{C}^2$ $2 \leq j \leq n$ [illegible] $B_j^{(k)} \in \mathbb{C}^{2\times 2}$ $2 \leq j \leq n-1$ [illegible]

$$a_{i,j}^{(k)} = \boldsymbol{q}_i^{(k)^T} B_{i,j}^{(k)^\times} \boldsymbol{t}_j^{(k)} + u_i^{(k)} \bar{w}_j^{(k)}, \qquad 1 \leq i < j \leq n. \tag{3.11}$$

[illegible] 3.7. Quasiseparable representations where the parameters are allowed to vary greatly in magnitude can be prone to numerical instabilities [22]. This raises the important question of finding a well-conditioned parameterization among all the possible sets of generators of a given quasiseparable matrix. It is instructive to discuss the robustness of (3.9)–(3.11) compared with a different parameterization for the matrix $A_k$ used in [5] and derived from (1.2). It is immediately found that $\| \boldsymbol{t}_j \|_2 \leq \sqrt{2}$, $\| B_j \|_F \leq \sqrt{2}$ and $\| B_{i,j}^\times \|_F = O(\sqrt{j-i})$. Moreover, for the vectors $\boldsymbol{q}_j$ defined in (3.7) we have $\| \boldsymbol{q}_j \|_2 \leq 1$ and $\| \left[ B_{0,j}^{\times^T} \boldsymbol{q}_1, \ldots, B_{j-1,j}^{\times^T} \boldsymbol{q}_j \right]^T \|_F = O(j)$. Since the Frobenius norm is invariant under multiplication by a unitary matrix, it follows that the vectors $\tilde{\boldsymbol{q}}_j$ and $\hat{\boldsymbol{q}}_j$ generated by the coupled recurrences in Theorem 3.5 are such that $\| \tilde{\boldsymbol{q}}_j \|_2 = O(j)$ and $\| \hat{\boldsymbol{q}}_j \|_2 = O(j)$. Therefore we may conclude that the parameters used in the representation (3.9) of the strictly upper triangular part of $P$ can be bounded from above in magnitude by $O(n)$ and, hence, the parameterization (3.11) is numerically robust. In contrast to this there are cases where the formula (1.2) would generate large cancellation errors and would not be robust. To see this, let us suppose that $A = A_0$ is ill conditioned; more precisely, assume that $A$ has a fixed norm but $A^{-1}$ has an arbitrarily large norm. Since $A_k$ is unitarily similar to $A$, we have $\| A_k \|_2 = \| A \|_2$. The algorithm in [5] employs the formula (1.2) to obtain a representation of the strictly upper triangular part of $A_k$ as the sum of the strictly upper triangular parts of three rank-one matrices. The first matrix is $\boldsymbol{u}_k\boldsymbol{w}_k^H$ which is uniformly bounded. The other two rank-one matrices can have entries with arbitrarily large moduli which must combine together so that the cumulative contribution has bounded norm.

## 4. The structured QR iteration.

In this section we describe a fast adaptation of the QR iteration (1.3) for an input matrix $A = A_0 \in \mathcal{H}_n$. By exploiting the quasiseparable structure (3.11) of each iterate $A_k$, we obtain linear time and linear memory space per iteration. Given a condensed representation of the form (3.11) for the matrix $A_k$ our algorithm computes a similar representation for the matrix $A_{k+1}$ defined as in (1.3). The resulting process is referred to as the [illegible]. The computation proceeds as follows:

1. Compute $Q_k$ and $R_k$ such that $A_k - \alpha_k I_n = Q_k R_k$ provides a QR factorization of the left-hand side matrix.
2. Determine the vectors $\boldsymbol{u}_{k+1} := Q_k^H \boldsymbol{u}_k$, $\boldsymbol{w}_{k+1} := Q_k^H \boldsymbol{w}_k$ and the unitary matrix $H_{k+1} := Q_k^H H_k Q_k = R_k Q_k + \alpha_k I_n - \boldsymbol{u}_{k+1}\boldsymbol{w}_{k+1}^H$.
3. Set $A_{k+1} := H_{k+1} + \boldsymbol{u}_{k+1}\boldsymbol{w}_{k+1}^H$.

In view of (3.10), we see that the computed matrix $A_{k+1}$ coincides with the one obtained after having performed one step of the shifted QR process (1.3) starting from

$A_k$. From Theorem 3.6 it follows that both $A_k$ and $A_{k+1}$ can be represented in the condensed form (3.11) by means of $O(n)$ parameters. In what follows, we will show that the same holds for all the data structures involved in the computational process above. In this way matrix operations can be reduced to manipulating $O(n)$ rather than $O(n^2)$ elements with a dramatic reduction of the operation count.

Let us first specify the parameterization used for the matrices $A_k$ and $H_k$. According to the notations introduced in the previous section, the input data at iteration $k+1$ are given by: the vector $\boldsymbol{\beta}^{(k)} = \left[\beta_1^{(k)}, \dots, \beta_{n-1}^{(k)}\right]^T \in \mathbb{C}^{n-1}$ of the subdiagonal entries of $A_k$; the vector $\boldsymbol{a}^{(k)} = \left[a_{1,1}^{(k)}, \dots, a_{n,n}^{(k)}\right]^T \in \mathbb{C}^n$ of the diagonal entries of $A_k$; the vector $\boldsymbol{h}^{(k)} = \left[h_{1,1}^{(k)}, \dots, h_{n,n}^{(k)}\right]^T \in \mathbb{C}^n$ of the diagonal entries of $H_k$; the vectors $\boldsymbol{q}_j^{(k)} \in \mathbb{C}^2$, $1 \le j \le n-1$; the vectors $\boldsymbol{t}_j^{(k)} \in \mathbb{C}^2$, $2 \le j \le n$; the lower triangular matrices $B_j^{(k)} = \begin{bmatrix} \hat{\psi}_j^{(k)} & 0 \\ \hat{\phi}_j^{(k)} & \hat{\rho}_j^{(k)} \end{bmatrix} \in \mathbb{C}^{2\times 2}$, $2 \le j \le n-1$; the vector $\boldsymbol{u}_k = \left[u_1^{(k)}, \dots, u_n^{(k)}\right]^T \in \mathbb{C}^n$; the vector $\boldsymbol{w}_k = \left[w_1^{(k)}, \dots, w_n^{(k)}\right]^T \in \mathbb{C}^n$, and the shift $\alpha_k$. The entries of the unitary matrix $H_k = (h_{i,j}^{(k)})$ are expressed in terms of these parameters as

$$
\begin{aligned}
h_{i,j}^{(k)} &= -u_i^{(k)} \bar{w}_j^{(k)} \text{ for } i-j \ge 2, \\
h_{j+1,j}^{(k)} &= \beta_j^{(k)} - u_{j+1}^{(k)} \bar{w}_j^{(k)}, \\
h_{j,j}^{(k)} &= (\boldsymbol{h}^{(k)})_j, \\
h_{i,j}^{(k)} &= \boldsymbol{q}_i^{(k)T} B_{i,j}^{(k)\times} \boldsymbol{t}_j^{(k)} \text{ for } j-i \ge 1.
\end{aligned}
\tag{4.1}
$$

Analogously, the nonzero entries of the upper Hessenberg matrix $A_k$ are defined by

$$
\begin{aligned}
a_{j+1,j}^{(k)} &= \beta_j^{(k)}, \\
a_{j,j}^{(k)} &= (\boldsymbol{a}^{(k)})_j, \\
a_{i,j}^{(k)} &= \boldsymbol{q}_i^{(k)T} B_{i,j}^{(k)\times} \boldsymbol{t}_j^{(k)} + u_i^{(k)} \bar{w}_j^{(k)} \text{ for } j-i \ge 1.
\end{aligned}
\tag{4.2}
$$

If $H_0$ is unitary Hessenberg, then at the very beginning for $k=0$ we may set $\boldsymbol{q}_j^{(0)} = \left[-\bar{\phi}_{j-1}^{(0)} \psi_j^{(0)}, 0\right]$, $\boldsymbol{t}_j^{(0)} = \left[\phi_j^{(0)}, 0\right]^T$, and $B_j^{(0)} = \begin{bmatrix} \psi_j^{(0)} & 0 \\ 0 & 0 \end{bmatrix}$, where the $\phi_j^{(0)}$'s and the $\psi_j^{(0)}$'s define the (modified) Schur parameterization for $H_0$. Otherwise, if $H_0$ is not in Hessenberg form, the entries of $\boldsymbol{q}_j^{(0)}$, $\boldsymbol{t}_j^{(0)}$, and $B_j^{(0)}$ are to be determined according to Theorem 3.5 and Remark 3.1 by performing a preliminary QR factorization of $H_0$.

In the next subsection the structure of the matrix $A_k$ is used in order to prove that the unitary factor $Q_k$ and the upper triangular factor $R_k$ can be determined in linear time. The design of an efficient method for computing the parameterization of $H_{k+1}$ given a structural representation for $A_k$, $Q_k$, and $R_k$ is the subject in subsections 4.2 and 4.3. Finally, in subsection 4.4 we give the details about the deflation strategy.

**4.1. The QR step.** In this section we describe the QR step applied to $A_k$ and obtain the structure of $R_k$ and $Q_k$. For the sake of notational simplicity we omit the superscript $(k)$ for the matrix and the vector entries and denote by $\alpha$ the shift parameter $\alpha_k$. Since $A_k - \alpha I_n$ is upper Hessenberg, the reduction to upper triangular form can be achieved by means of a sequence of Givens rotations $G_1(\hat{a}_1), \dots, G_{n-1}(\hat{a}_{n-1})$ suitably chosen to annihilate the subdiagonal entries. The triangularization process proceeds as follows:

$$A - \alpha I_n = A^{(0)} \overset{\mathcal{G}(\hat{a}_1)}{\rightarrow} A^{(1)} \overset{\mathcal{G}(\hat{a}_2)}{\rightarrow} \dots \overset{\mathcal{G}(\hat{a}_{n-1})}{\rightarrow} A^{(n-1)} = R,$$

where at the $j$th step $A^{(j-1)}$ is premultiplied by the corresponding Givens rotation $G_j(\hat{a}_j)$ to obtain $A^{(j)}$. The vectors $\boldsymbol{q}_i$ and the scalars $u_i$ are modified twice according to the scheme $\boldsymbol{q}_i \rightarrow \hat{\boldsymbol{q}}_{\boldsymbol{i}} \rightarrow \tilde{\boldsymbol{q}}_{\boldsymbol{i}}$, $u_i \rightarrow \hat{\boldsymbol{u}}_{\boldsymbol{i}} \rightarrow \tilde{\boldsymbol{u}}_{\boldsymbol{i}}$, where $\boldsymbol{q}_i$, $u_i$ are used to represent the initial matrix $A$ in (4.2), $\hat{\boldsymbol{q}}_{\boldsymbol{i}}$, $\hat{\boldsymbol{u}}_{\boldsymbol{i}}$ are intermediate quantities and $\tilde{\boldsymbol{q}}_{\boldsymbol{i}}$, $\tilde{\boldsymbol{u}}_{\boldsymbol{i}}$ are the parameters of the quasiseparable representation of the final matrix $R$.

At the first step $G_1(\hat{a}_1)$ is chosen so that the entry in position $(2,1)$ of $G_1(\hat{a}_1)A^{(0)} = A^{(1)} = (a_{i,j}^{(1)})$ is made zero. Observe that only the entries in the first two rows of $A^{(1)}$ differ from the entries of $A^{(0)}$. These entries satisfy

$$a_{1,j}^{(1)} = \tilde{\boldsymbol{q}}_{\boldsymbol{1}}{}^T B_{2,j}^{\times} \boldsymbol{t}_j + \tilde{u}_1 \bar{w}_j, \quad a_{2,j}^{(1)} = \hat{\boldsymbol{q}}_{\boldsymbol{2}}{}^T B_{2,j}^{\times} \boldsymbol{t}_j + \hat{u}_2 \bar{w}_j, \quad j > 2,$$

where

$$\mathcal{G}(\hat{a}_1) \begin{bmatrix} \boldsymbol{q_1}^T B_2 \\ \boldsymbol{q_2}^T \end{bmatrix} = \begin{bmatrix} \tilde{\boldsymbol{q}}_{\boldsymbol{1}}{}^T \\ \hat{\boldsymbol{q}}_{\boldsymbol{2}}{}^T \end{bmatrix}, \quad \mathcal{G}(\hat{a}_1) \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} = \begin{bmatrix} \tilde{u}_1 \\ \hat{u}_2 \end{bmatrix}. \tag{4.3}$$

The remaining entries in the $2 \times 2$ leading principal submatrix of $A^{(1)}$ are given by

$$\begin{bmatrix} d_1 & g_1 \\ 0 & d_2 \end{bmatrix} = \mathcal{G}(\hat{a}_1) A^{(0)}[1:2, 1:2].$$

The values of $\tilde{\boldsymbol{q}}_{\boldsymbol{1}}{}^T$, $\tilde{u}_1$, $d_1$, and $g_1$ are not modified by the subsequent Givens rotations, while the values of $\hat{\boldsymbol{q}}_{\boldsymbol{2}}{}^T$, $\hat{u}_2$, and $d_2$ only change at the second step where the matrix $A^{(1)}$ is premultiplied by $G_2(\hat{a}_2)$. At the $j$th step, $G_j(\hat{a}_j)$ is chosen so that the entry in position $(j+1, j)$ of $A^{(j)} = G_j(\hat{a}_j)A^{(j-1)}$ is made zero. Let $A^{(j-1)}[j : j+1, j : n]$ be given by

$$\begin{bmatrix} d_j & \hat{\boldsymbol{q}}_{\boldsymbol{j}}{}^T \boldsymbol{t}_{j+1} & \hat{\boldsymbol{q}}_{\boldsymbol{j}}{}^T B_{j+1} \boldsymbol{t}_{j+2} & \cdots & \hat{\boldsymbol{q}}_{\boldsymbol{j}}{}^T B_{j,n}^{\times} \boldsymbol{t}_n \\ \beta_j & d_{j+1} & \boldsymbol{q}_{\boldsymbol{j+1}}{}^T \boldsymbol{t}_{j+1} & \cdots & \boldsymbol{q}_{\boldsymbol{j+1}}{}^T B_{j+1,n}^{\times} \boldsymbol{t}_n \end{bmatrix} + \begin{bmatrix} \hat{u}_j \\ u_{j+1} \end{bmatrix} \boldsymbol{w}^H[j:n].$$

We set

$$\mathcal{G}(\hat{a}_j) \begin{bmatrix} d_j \\ \beta_j \end{bmatrix} = \begin{bmatrix} \vartheta \\ 0 \end{bmatrix}, \quad d_j \leftarrow \vartheta,$$

$$\mathcal{G}(\hat{a}_j) \begin{bmatrix} \hat{q}_j^T \boldsymbol{t}_{j+1} \\ d_{j+1} \end{bmatrix} = \begin{bmatrix} g_j \\ \gamma \end{bmatrix}, \quad d_{j+1} \leftarrow \gamma,$$

and

$$\mathcal{G}(\hat{a}_j) \begin{bmatrix} \hat{\boldsymbol{q}}_{\boldsymbol{j}}{}^T B_{j+1} \\ \boldsymbol{q}_{\boldsymbol{j+1}}{}^T \end{bmatrix} = \begin{bmatrix} \tilde{\boldsymbol{q}}_{\boldsymbol{j}}{}^T \\ \hat{\boldsymbol{q}}_{\boldsymbol{j+1}}{}^T \end{bmatrix}, \quad \mathcal{G}(\hat{a}_j) \begin{bmatrix} \hat{u}_j \\ u_{j+1} \end{bmatrix} = \begin{bmatrix} \tilde{u}_j \\ \hat{u}_{j+1} \end{bmatrix}.$$

Hence, after $j$ steps the matrix $A^{(j)}[j : j+1, j : n] = \mathcal{G}(\hat{a}_j)A^{(j-1)}[j : j+1, j : n]$ is given by

$$\begin{bmatrix} d_j & g_1 & \tilde{\boldsymbol{q}}_{\boldsymbol{j}}{}^T \boldsymbol{t}_{j+2} & \cdots & \tilde{\boldsymbol{q}}_{\boldsymbol{j}}{}^T B_{j+1,n}^{\times} \boldsymbol{t}_n \\ 0 & d_{j+1} & \hat{\boldsymbol{q}}_{\boldsymbol{j+1}}{}^T \boldsymbol{t}_{j+1} & \cdots & \hat{\boldsymbol{q}}_{\boldsymbol{j+1}}{}^T B_{j+1,n}^{\times} \boldsymbol{t}_n \end{bmatrix} + \begin{bmatrix} \tilde{u}_j \\ \hat{u}_{j+1} \end{bmatrix} \boldsymbol{w}^H[j:n].$$

At the end of the entire process the upper triangular matrix $R = R_k = (r_{i,j})$ turns out to be represented as follows:

$$\begin{aligned} r_{i,i} &= d_i, \\ r_{i,i+1} &= g_i, \\ r_{i,j} &= \tilde{\boldsymbol{q}}_i^T B^{\times}_{i+1,j} \boldsymbol{t}_j + \tilde{u}_i \bar{w}_j \text{ for } j - i \geq 2. \end{aligned} \tag{4.4}$$

The parameterization involves approximately $9n$ parameters and it is computed at the cost of about $40n$ flops. From (3.1) it follows that the unitary matrix $Q = Q_k = (G_{n-1}(\hat{a}_{n-1}) \cdots G_1(\hat{a}_1))^H$ is upper Hessenberg with Schur parameters $\{\bar{\hat{a}}_j\}$, $\hat{a}_n = -1$, and complementary parameters $\{\bar{\hat{b}}_j\}$. The computation of the new iterate $A_{k+1}$ essentially reduces to evaluating the entries of the product $S = RQ$. Since both factors are quasiseparable matrices, it is found that $S$ inherits the quasiseparable structure. In principle, the generators of $S$ and, a fortiori of $A_{k+1} = S + \alpha I_n$, can be computed by means of the multiplication algorithm of [8] or by the simpler method presented in the next subsection which makes direct use of the Schur parameterization of $Q$. However, such an approach has the following noticeable drawback: We know that the strictly upper triangular part of $A_{k+1}$ admits a quasiseparable representation of order 3 but the parameterization computed by multiplying the structures of $R$ and $Q$ has order 4. To circumvent this difficulty, we devise a compression strategy based on the computation of an additional QR factorization of the unitary matrix $H = H_{k+1}$. From the order-4 representation of $A_{k+1}$ we obtain a parameterization of order $(2, 3)$ for the entries of $H$. Then we show that the computation of a QR factorization of $H$ generates a new parameterization of this matrix of order $(2, 2)$. This finally leads to the desired parameterization of minimal length for $A_{k+1}$.

**4.2. Computing nonminimal quasiseparable representations of $\boldsymbol{A_{k+1}}$ and $\boldsymbol{H_{k+1}}$.** Nonminimal quasiseparable representations for the entries of $A_{k+1}$ and $H_{k+1}$ are easily obtained from the generators of the quasiseparable matrix $S = RQ$. By using the Schur parameterization of $Q = (G_{n-1}(\hat{a}_{n-1}) \cdots G_1(\hat{a}_1))^H$ we can split the computation of the matrix product into $n - 1$ simpler steps:

$$R = R^{(0)} \overset{\mathcal{G}(\hat{a}_1)^H}{\rightarrow} R^{(1)} \overset{\mathcal{G}(\hat{a}_2)^H}{\rightarrow} \cdots \overset{\mathcal{G}(\hat{a}_{n-1})^H}{\rightarrow} R^{(n-1)} = S,$$

where at the $j$th step $R^{(j-1)}$ is postmultiplied by $G_j(\hat{a}_j)^H$ to obtain $R^{(j)}$. The scalars $\bar{w}_j$ used to represent the matrix $R$ in (4.4) are changed twice according to the scheme $\bar{w}_j \to \hat{w}_j \to \tilde{w}_j$, where $\tilde{w}_j$ are elements of the quasiseparable structure of the final matrix $S$. The superdiagonal entries $g_i$ are modified in a similar way, $g_i \to \hat{g}_i \to \tilde{g}_i$, and, then, incorporated in the quasiseparable structure of $S$ by setting

$$\tilde{g}_i = \hat{\boldsymbol{q}}_{\boldsymbol{i}}^T \begin{bmatrix} \boldsymbol{0} \\ 1 \end{bmatrix} = \begin{bmatrix} \tilde{\boldsymbol{q}}_i^T, \tilde{g}_i \end{bmatrix} \begin{bmatrix} \boldsymbol{0} \\ 1 \end{bmatrix}.$$

At the first step we have

$$\begin{bmatrix} \tilde{d}_1 & \hat{g}_1 \\ \beta_1 & \tilde{d}_2 \end{bmatrix} = \begin{bmatrix} d_1 & g_1 \\ 0 & d_2 \end{bmatrix} \mathcal{G}(\hat{a}_1)^H, \; d_1 \leftarrow \tilde{d}_1, d_2 \leftarrow \tilde{d}_2, \; [\tilde{w}_1, \hat{w}_2] = [\bar{w}_1, \bar{w}_2]\, \mathcal{G}(\hat{a}_1)^H.$$

At the successive step $\mathcal{G}(\hat{a}_2)^H$ acts on the second and third rows of $R^{(1)}$. We can rewrite

$$R^{(1)}[1:2, 2:3] = \begin{bmatrix} \tilde{g}_1 + \tilde{u}_1 \tilde{w}_2 & \tilde{\boldsymbol{q}}_1^T \boldsymbol{t}_3 + \tilde{u}_i \bar{w}_3 \\ d_2 & g_2 \end{bmatrix}$$

as

$$R^{(1)}[1:2,2:3] = \left[\begin{array}{cc} \hat{\boldsymbol{q}}_1^T \begin{bmatrix}\mathbf{0}\\ 1\end{bmatrix} + \tilde{u}_1\tilde{w}_2 & \hat{\boldsymbol{q}}_1^T \begin{bmatrix}\boldsymbol{t}_3\\ 0\end{bmatrix} + \tilde{u}_i\bar{w}_3 \\ d_2 & g_2 \end{array}\right], \quad \hat{\boldsymbol{q}}_1^T = \left[\tilde{\boldsymbol{q}}_1^T, \tilde{g}_1\right].$$

Hence, we obtain

$$R^{(1)}[1:3,2:3]\mathcal{G}(\hat{a}_2)^H = \left[\begin{array}{cc} \hat{\boldsymbol{q}}_1^T\tilde{\boldsymbol{z}}_2 + \tilde{u}_1\tilde{w}_2 & \hat{\boldsymbol{q}}_1^T\hat{\boldsymbol{z}}_2 + \tilde{u}_i\hat{w}_3 \\ \tilde{d}_2 & \hat{g}_2 \\ \beta_2 & \tilde{d}_3 \end{array}\right],$$

where

$$[\tilde{\boldsymbol{z}}_2, \hat{\boldsymbol{z}}_{\boldsymbol{2}}] = \begin{bmatrix}\mathbf{0} & \boldsymbol{t}_3\\ 1 & 0\end{bmatrix}\mathcal{G}(\hat{a}_2)^H,\ d_2 \leftarrow \tilde{d}_2,\ d_3 \leftarrow \tilde{d}_3,,\ [\tilde{w}_2, \hat{w}_3] = [\hat{w}_2, \bar{w}_3]\,\mathcal{G}(\hat{a}_2)^H.$$

Since

$$\hat{\boldsymbol{q}}_1^T\hat{\boldsymbol{z}}_2 = \hat{\boldsymbol{q}}_1^T\left[\begin{array}{c|c} \dfrac{B_3}{\mathbf{0}^T} & \hat{\boldsymbol{z}}_2 \end{array}\right]\begin{bmatrix}\mathbf{0}\\ 1\end{bmatrix} = \hat{\boldsymbol{q}}_1^T F_2\begin{bmatrix}\mathbf{0}\\ 1\end{bmatrix}, \quad F_2 \in \mathbb{C}^{3\times 3},$$

and $\tilde{\boldsymbol{q}}_1^T B_3\boldsymbol{t}_4 = \hat{\boldsymbol{q}}_1^T F_2\left[\begin{smallmatrix}\boldsymbol{t}_4\\ 0\end{smallmatrix}\right]$, then the process can be continued. At the $j$th step we find

$$R^{(j-1)}[1:j+1,j:j+1] = \left[\begin{array}{cc} \hat{\boldsymbol{q}}_1^T F_{1,j}^{\times}\begin{bmatrix}\mathbf{0}\\ 1\end{bmatrix} + \tilde{u}_1\hat{w}_j & \hat{\boldsymbol{q}}_1^T F_{1,j}^{\times}\begin{bmatrix}\boldsymbol{t}_{j+1}\\ 0\end{bmatrix} + \tilde{u}_1 w_{j+1} \\ \vdots & \vdots \\ \hat{\boldsymbol{q}}_{j-1}^T\begin{bmatrix}\mathbf{0}\\ 1\end{bmatrix} + \tilde{u}_1\hat{w}_j & \hat{\boldsymbol{q}}_{j-1}^T\begin{bmatrix}\boldsymbol{t}_{j+1}\\ 0\end{bmatrix} + \tilde{u}_1 w_{j+1} \\ d_j & g_j \\ 0 & d_{j+1} \end{array}\right],$$

which gives the following representation of $R^{(j)}[1:j+1,j:j+1] = R^{(j-1)}[1:j+1,j:j+1]\mathcal{G}(\hat{a}_j)^H$

$$R^{(j)}[1:j+1,j:j+1] = \left[\begin{array}{cc} \hat{\boldsymbol{q}}_1^T F_{1,j}^{\times}\tilde{\boldsymbol{z}}_j + \tilde{u}_1\tilde{w}_j & \hat{\boldsymbol{q}}_1^T F_{1,j}^{\times}\hat{\boldsymbol{z}}_j + \tilde{u}_1\hat{w}_{j+1} \\ \vdots & \vdots \\ \hat{\boldsymbol{q}}_{j-1}^T\tilde{\boldsymbol{z}}_j + \tilde{u}_1\tilde{w}_j & \hat{\boldsymbol{q}}_{j-1}^T\hat{\boldsymbol{z}}_j + \tilde{u}_1\hat{w}_{j+1} \\ \tilde{d}_j & \hat{g}_j \\ \beta_j & \tilde{d}_{j+1} \end{array}\right],$$

where $d_j \leftarrow \tilde{d}_j,\ d_{j+1} \leftarrow \tilde{d}_{j+1}$, and

$$[\tilde{\boldsymbol{z}}_j, \hat{\boldsymbol{z}}_{\boldsymbol{j}}] = \begin{bmatrix}\mathbf{0} & \boldsymbol{t}_{j+1}\\ 1 & 0\end{bmatrix}\mathcal{G}(\hat{a}_j)^H, \quad [\tilde{w}_j, \hat{w}_{j+1}] = [\hat{w}_j, \bar{w}_{j+1}]\,\mathcal{G}(\hat{a}_j)^H.$$

After $n-1$ steps the matrix $S = R^{(n-1)} = (s_{i,j})$ is given by

$$\begin{aligned} &s_{i,j} = \hat{\boldsymbol{q}}_{\boldsymbol{i}}{}^T F_{i,j}^{\times}\tilde{\boldsymbol{z}}_j + \tilde{u}_i\tilde{w}_j \text{ for } j-i \geq 1,\\ &s_{i,i} = d_i,\\ &s_{i+1,i} = \beta_i,\\ &s_{i,j} = 0 \text{ for } i-j \geq 2. \end{aligned}$$

The generators of this representation are computed at the cost of $20n$ flops. The quasiseparable representation of $S = RQ$ provides a parameterization of $H = (h_{i,j}) = S + \alpha I_n - \tilde{\boldsymbol{u}}\tilde{\boldsymbol{w}}^H$ of order $(2,3)$. On the other hand, $H$ satisfies the hypotheses of Theorem 3.2, that is, $H = H_{k+1}$ is unitary and $h_{i,j} = -\tilde{u}_i\tilde{w}_j$ for $i \geq j+2$; therefore, its strictly upper triangular part must be 2-quasiseparable. In the next subsection we describe a method to compress the given parameterization of $H$ which relies upon the properties of the QR factorization of the matrix.

**4.3. Compressing the quasiseparable representation of $\boldsymbol{H_{k+1}}$.** According to Theorem 3.2 the quasiseparable structure of $H = H_{k+1}$ can be recovered from the coefficients of the Givens rotation matrices employed in the process of computing a QR factorization of the matrix. More specifically, $H$ can be first reduced to upper Hessenberg form by applying a sequence of $2n-5$ Givens rotations suitably chosen to annihilate the entries in the left-bottom corner. The transformed matrix is still unitary and, therefore, its $QR$ factorization gives the Schur and complementary parameters of its structured representation (3.2) (compare with Remark 3.1). The parameters can finally be combined with the coefficients of the previously determined Givens rotations to define the structure of the upper triangular part of $H$.

At first the matrix $H = P^{(0)}$ is transformed into a matrix $\tilde{P}$ of lower bandwidth 2 by applying a sequence of Givens rotations $G_{n-1}(\tilde{a}_{n-1}), \dots, G_3(\tilde{a}_3)$ according to the scheme given by the first relation in (3.3). The matrix $\mathcal{G}(\tilde{a}_j)$ is determined to satisfy

$$\mathcal{G}(\tilde{a}_j)\begin{bmatrix} \tilde{u}_j \\ \hat{u}_{j+1} \end{bmatrix} = \begin{bmatrix} \hat{u}_j \\ 0 \end{bmatrix}, \quad (\hat{u}_n = \tilde{u}_n).$$

The transformation $P^{(j-1)} \to P^{(j)} = G_{n-j}(\tilde{a}_{n-j})P^{(j-1)}$ only modifies the entries in the rows $n-j$ and $n-j+1$. The updating of the quasiseparable structure in the strictly upper triangular part of $P^{(j-1)}$ is performed by means of the same techniques used in the previous subsection for the matrix $R^{(j-1)}$. At the end of the process the entries in the upper triangular part of $\tilde{P} = (\tilde{p}_{i,j})$ satisfy

$$\tilde{p}_{i,j} = \tilde{\boldsymbol{p}}_{\boldsymbol{i}}^T E^{\times}_{i-1,j}\widehat{\boldsymbol{z}}_j \text{ for } j-i \geq 0,$$

for suitable vectors $\tilde{\boldsymbol{p}}_{\boldsymbol{i}}, \widehat{\boldsymbol{z}}_i \in \mathbb{C}^4$, $1 \leq i \leq n$, and matrices $E_i \in \mathbb{C}^{4\times 4}$, $1 \leq i \leq n-1$. The computation of these generators requires approximately $20n$ flops.

At the second stage the matrix $\tilde{P}$ is reduced to a Hessenberg form $\widehat{P}$ by means of a sequence of $n-2$ Givens rotations $G_2(\hat{a}_2), \dots, G_{n-1}(\hat{a}_{n-1})$ suitably chosen to annihilate the second lower subdiagonal. The reduction is carried out according to scheme provided by the second relation in (3.3) at the overall cost of about $35n$ flops. The modifications of the quasiseparable structure in the strictly upper triangular part of $\tilde{P}$ are described in the proof of Theorem 3.5. At the end of the process the entries in the strictly upper triangular part of the unitary Hessenberg matrix $\widehat{P} = (\widehat{p}_{i,j}) = G_{n-1}(\hat{a}_{n-1})\cdots G_2(\hat{a}_2)\tilde{P}$ can be represented as follows:

$$\widehat{p}_{i,j} = \widehat{\boldsymbol{p}}_{\boldsymbol{i}}^T E^{\times}_{i,j}\widehat{\boldsymbol{z}}_j \text{ for } j-i \geq 1.$$

Finally, the matrix $\widehat{P}$ can be converted into the identity matrix of order $n$ by applying $n$ modified rotations of the form

$$G_j(a'_j) = I_{j-1} \oplus \begin{bmatrix} -a'_j & b'_j \\ \bar{b}'_j & \bar{a}'_j \end{bmatrix} \oplus I_{n-j-1}, \quad 1 \leq j \leq n-1, \quad |a'_j|^2 + |b'_j|^2 = 1,$$
$$G_n(a'_n) = I_{n-1} \oplus (-a'_n), \quad |a'_n| = 1,$$

chosen in such a way that $G_n(a'_n)G_{n-1}(a'_{n-1})\cdots G_1(a'_1)\widehat{P}$ is an upper triangular matrix with nonnegative diagonal entries. The coefficients $a'_j$ and $b'_j$, $1 \le j \le n$ are computed at the cost of $20n$ flops and define the parameters $\phi_j = \overline{a'_j}$ and $\psi_j = b'_j$ used in Theorem 3.5 to describe the structure in the strictly upper triangular part of the matrix $P$. Here we have

$$P^H = H^H = G_{n-1}(a'_{n-1})\cdots G_1(a'_1)G_{n-1}(\hat{a}_{n-1})\cdots G_2(\hat{a}_2)G_3(\tilde{a}_1)\cdots G_{n-1}(\tilde{a}_{n-1}).$$

The matrix $H = H_{k+1}$ can thus be reconstructed in the desired form using the procedure given in Theorem 3.5 at the cost of approximately $20n$ flops.

**4.4. Deflation in the QR algorithm.** When an eigenvalue has been approximated by the QR iteration with sufficiently high precision, a deflation technique is generally employed before proceeding with the computation of the remaining eigenvalues. Sometimes it also happens during the computation that one of the subdiagonal entries other than the bottom one becomes practically zero so that the eigenvalue problem can be broken into two smaller subproblems. For the sake of clarity, suppose that after $k$ iterations of the QR algorithm the matrix $A_k$ has the form

$$A_k = \begin{bmatrix} A_k^{(1)} & \star \\ \bigcirc & A_k^{(2)} \end{bmatrix},$$

where $A_k^{(1)} \in \mathbb{C}^{(n-s)\times(n-s)}$ and $A_k^{(2)} \in \mathbb{C}^{s\times s}$. Now $A_k^{(1)}$ and $A_k^{(2)}$ can be reduced into upper triangular form separately. The process is called [illegible] and continuing in this fashion, by operating on smaller and smaller matrices, we may approximate all the eigenvalues of $A$.

Let us suppose that at the subsequent iterations $j \ge k$ the QR algorithm only operates on the submatrix $A_j^{(1)}$. The matrix $H_k$ can be partitioned accordingly with $A_k$ as follows:

$$H_k = \begin{bmatrix} H_k^{(1)} & \star \\ -\boldsymbol{u}_k^{(2)}\boldsymbol{w}_k^{(1)^H} & H_k^{(2)} \end{bmatrix},$$

where $\boldsymbol{u}_k^{(2)}$ is formed from the last $s$ components of the vector $\boldsymbol{u}_k$ and $\boldsymbol{w}_k^{(1)}$ is defined by the first $n-s$ elements of $\boldsymbol{w}_k$. A unitary upper Hessenberg matrix $U_s \in \mathbb{C}^{s\times s}$ such that $U_s\boldsymbol{u}_k^{(2)} = \left[\tilde{u}_{n-s+1}, \boldsymbol{0}^T\right]^T$ can be determined at the cost of $O(n)$ flops. Then we have

$$(I_{n-s} \oplus U_s)H_k(I_{n-s} \oplus U_s)^H = \begin{bmatrix} H_k^{(1)} & \star \\ -u_{n-s+1}\boldsymbol{e}_1\boldsymbol{w}_k^{(1)^H} & \star \end{bmatrix},$$

where $\boldsymbol{e}_1$ is the first column of $I_s$. In this way the computation of the quasiseparable structure in the strictly upper triangular part of $A_j^{(1)}$, $j \ge k$, can be reduced to finding a QR factorization of the $(n-s+1)\times(n-s)$ matrix

$$\left[\begin{array}{c} H_j^{(1)} \\ \hline -u_{n-s+1}\boldsymbol{w}_j^{(1)^H} \end{array}\right]$$

instead of the whole matrix $H_j$.

**5. Experimental issues.** In this section we first discuss the behavior of the [illegible] when performed in finite precision arithmetic. Then we design a practical implementation of the algorithm and present the results of extensive numerical experiments.

**5.1. The practical algorithm.** The proposed fast variant of the QR algorithm for input matrices $A \in \mathcal{H}_n$ relies upon two basic properties: $A$ is upper Hessenberg and, moreover, $A$ is a rank-one modification of a unitary matrix. Theoretically each matrix $A_k$ generated by the QR iteration applied to $A = A_0$ inherits these two properties. In practice, due to roundoff errors, the matrix $H_k = A_k - \boldsymbol{u}_k \boldsymbol{w}_k^H$ may deviate from orthogonality. This phenomenon is also observed in the customary shifted QR iteration. The error analysis in [20] says that the upper Hessenberg matrix $fl(A_k)$ generated after $k$ iterations of the classical method satisfies $fl(A_k) = \tilde{Q}^H(H_0 + \boldsymbol{u}_0\boldsymbol{w}_0^H + \epsilon\Delta_k)\tilde{Q}$, where $\epsilon$ is the machine precision, $\tilde{Q}$ and $H_0$ are unitary, and $\| \Delta_k \|_2 = O(kn\sqrt{n} \| A_0 \|_2)$. This means that $fl(A_k) = \tilde{H}_k + \tilde{\Delta}_k + \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{w}}_k^H$, where $\tilde{H}_k$ is unitary. In the structured QR iteration an important source of error amplification is the computation of the quasiseparable structure in the strictly upper triangular part of $fl(\tilde{H}_k + \tilde{\Delta}_k) = fl(fl(A_k) - \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{w}}_k^H)$ by means of the algorithm outlined in Theorem 3.5. In light of Remark 3.7, by performing a forward error analysis of the coupled recurrences for the vectors $\tilde{\boldsymbol{q}}_j$ it is found that the norm of the absolute perturbation $\tilde{\Delta}_k$ in the input data can be amplified in the output by a factor $n^2$. The combined effect of these two mechanisms, i.e., the departure from orthogonality of $fl(H_k)$ and the amplification of its absolute perturbation in the process of reconstructing the quasiseparable structure of the upper triangular part, can produce a possible deterioration in the accuracy of the computed eigenvalues. Extensive numerical tests with large random matrices ($n \geq 1000$) confirmed this claim. Sometimes the very last computed eigenvalues were significantly less accurate than the corresponding approximations returned by the customary QR iteration.

To avoid the possible amplification of errors in the computation of the structural representation of $H_k$ we proceed as follows. Assume that $H_k$ is a small perturbation of a unitary matrix. Its QR factorization is $H_k = U_k S_k$, where $U_k$ is unitary and $S_k = I_n + \Delta$ is upper triangular. Hence, from $A_k = H_k + \boldsymbol{u}_k \boldsymbol{w}_k^H$ we obtain $A_k S_k^{-1} = U_k + \boldsymbol{u}_k \boldsymbol{w}_k^H S_k^{-1}$. The matrix $A_k S_k^{-1}$ is a small perturbation of $A_k$ which is both upper Hessenberg and a rank-one modification of the numerically unitary matrix $U_k$. Thus we replace the matrix $A_k$ by the matrix $A_k S_k^{-1}$. The latter belongs to the class $\mathcal{H}_n$ and is a correction of the matrix $A_k$.

Moreover, the quasiseparable structure of $U_k$ and, a fortiori of $A_k$, can be computed as described in Theorem 3.5 without any amplification of previously accumulated errors. Therefore, in our implementation we compute the new iterate $A_k$ as $A_k := U_k + \boldsymbol{u}_k \tilde{\boldsymbol{w}}_k^H$, where $\tilde{\boldsymbol{w}}_k^H$ is formed by the first $n-2$ elements of the corrected vector $\boldsymbol{w}_k^H S_k^{-1}$ and the last 2 elements of $\boldsymbol{w}_k^H$. Since $\boldsymbol{u}_k$ and $\boldsymbol{w}_k$ are already known, we may determine the quantities $\tilde{w}_i^{(k)}$, $1 \leq i \leq n-2$, by a direct inspection of the entries $\gamma_i^{(k)}$, $1 \leq i \leq n-2$, in the second subdiagonal of $U_k$ without explicitly computing the matrix $S_k$. We set $\tilde{w}_i^{(k)} = w_i^{(k)}(1 + \delta_i^{(k)})$ and then find $(1 + \delta_i^{(k)}) = -\gamma_i^{(k)}/(u_{i+2}^{(k)} w_i^{(k)})$. Specific rules can also be defined in the case where some coefficient is zero. The resulting process is summarized below.

1. Compute $Q_k$ and $R_k$ such that $A_k - \alpha_k I_n = Q_k R_k$ provides a QR factorization of the left-hand side matrix.
2. Determine the matrix $A_{k+1} := R_k Q_k + \alpha_k I_n$ and the vectors $\boldsymbol{u}_{k+1} := Q_k^H \boldsymbol{u}_k$, $\boldsymbol{w}_{k+1} := Q_k^H \boldsymbol{w}_k$.

3. Compute $H_{k+1} = A_{k+1} - \boldsymbol{u}_{k+1}\boldsymbol{w}_{k+1}^H$.
4. Find the unitary matrix $U_{k+1}$ such that $H_{k+1} = U_{k+1}S_{k+1}$ is a QR factorization of $H_{k+1}$ and $S_{k+1}$ is upper triangular with real positive diagonal entries.
5. Compute the vector $\tilde{\boldsymbol{w}}_{k+1}$ and set $A_{k+1} := U_{k+1} + \boldsymbol{u}_{k+1}\tilde{\boldsymbol{w}}_{k+1}^H$.

This algorithm has been implemented in MATLAB and then applied to the computation of the eigenvalues of companion matrices of both small and large size. The program is available as a MATLAB function at www.dm.unipi.it/~gemignan/ric.html/compqr.m. The results of extensive numerical experiments confirm the robustness and efficiency of the proposed approach.

Our implementation requires 180 $n + O(1)$ flops per iteration. The main program incorporates the following shifting strategy suggested in [25, p. 549]. At the beginning the shift parameter $\sigma$ is equal to zero. If $A_s = (a_{i,j}^{(s)}) \in \mathbb{C}^{n\times n}$ satisfies $|a_{n,n}^{(s-1)} - a_{n,n}^{(s)}| \leq 0.3|a_{n,n}^{(s-1)}|$, then we apply nonzero shifts by setting $\sigma_k = a_{n,n}^{(k)}$, $k = s, s+1, \ldots$. We say that $a_{n,n}^{(k)}$ provides a numerical approximation of an eigenvalue $\lambda$ of $A_0$ whenever $|\beta_n^{(k)}| \leq \mathit{eps}\ (|a_{n,n}^{(k)}| + |a_{n-1,n-1}^{(k)}|)$, where *eps* is the machine precision, i.e., $\mathit{eps} \simeq 2.2 \cdot 10^{-16}$. If this condition is fulfilled, then we set $\lambda = a_{n,n}^{(k)}$ and deflate the matrix. After nonzero shifting has begun, we check for the convergence of the last diagonal entries of the currently computed iterate $A_k$. If convergence fails to occur after 15 iterations, then at the 16th iteration we set $\sigma_k = 1.5\ (|a_{n,n}^{(k)}| + |\beta_n^{(k)}|)$ and continue with nonzero shifting. If $a_{n,n}^{(k)}$ does not converge in the next 15 iterations, then the program reports failure. In our experiments such failure has never been encountered.

**5.2. Numerical experiments.** We tested companion matrices $C$ associated with the following polynomials:

1. the scaled "Wilkinson polynomial": $p(z) = \prod_{k=1}^{n}(z - k/n)$;
2. the polynomial $p(z) = z^n - 1$ with zeros equispaced on the unit circle;
3. the monic polynomial with zeros equally spaced on the curve $z = x + \mathtt{i}\sin(\pi x)$, $-1 \leq x \leq 1$, namely $p(z) = \prod_{k=-n/2}^{n/2-1}(z - \frac{2(k+0.5)}{n-1} - \mathtt{i}\sin(\frac{2(k+0.5)}{n-1}))$;
4. the polynomial $p(z) = \sum_{j=0}^{n-1} a_j z^j + z^n$ with $a_j = \text{rand} + \mathtt{i}\ \text{rand}$, $j = 0, \ldots, n-1$, where rand is a pseudorandom number uniformly distributed in $[0, 1]$;
5. the polynomial $p(z) = \sum_{j=0}^{n-1} a_j z^j + z^n$, where $a_j = a_{1,j} \times 10^{e_{1,j}} + \mathtt{i}\ a_{2,j} \times 10^{e_{2,j}}$, $a_{i,j} = \text{rand} + \mathtt{i}\ \text{rand}$, $e_{i,j} = 10 \times (\text{rand} - 0.5) + \mathtt{i}\ 10 \times (\text{rand} - 0.5)$, $i = 1, 2$, $j = 0, \ldots, n-1$.

An estimate of the maximum error expected in the computation of the eigenvalues of $C$ by using the QR iteration without balancing is $K \cdot \mathit{eps} \cdot \max(\mathtt{condeig}(C)) \cdot \parallel C \parallel$, where $K$ actually depends on the size of $C$ and on the number of QR steps. Our test program returns the value $\mathit{est\_err} = \mathit{eps} \cdot \max(\mathtt{condeig}(C)) \cdot \parallel C \parallel_2$, where the MATLAB function `condeig` is used to approximate the eigenvalue condition numbers.

Tables 5.1, 5.2, and 5.3 show the results of our numerical experiments for the above polynomials from 1. to 3. by reporting the degree $n$, the value of *est_err* and the maximum absolute error of the computed roots. Table 5.3 also reports the average number *it* of QR iterations per eigenvalue. The total number of iterations performed to compute all the eigenvalues is less than $6n$. Our implementation is not optimized for time efficiency. However, for the sake of illustration we have compared the running times of our program to a customary implementation of the standard QR eigenvalue algorithm for Hessenberg matrices written in MATLAB. The timings for the tests of Table 5.3 are reported in Figure 5.1. These results say that our implementation is

faster than the standard method for $n$ between 300 and 400 and becomes definitely faster for larger $n$.

Figures 5.2 and 5.3 cover our tests with random polynomials of the form 4.–5. of high degree. Each figure shows the *error* and the value of *est_err* for polynomials of

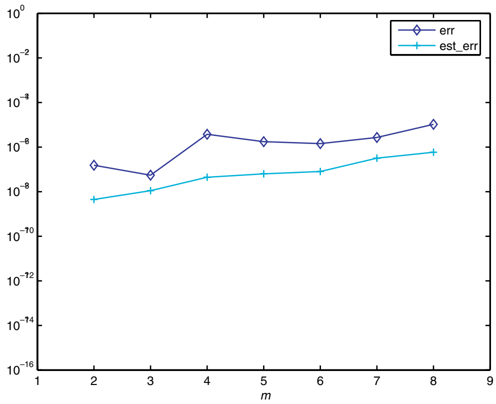

FIG. 5.3. *Random polynomials of form* 5. *of degree* $n(m) = 2^{2+m}$.

degree $n(m) = 2^{2+m}$ for $m = 1, 2, \ldots$. For each size we carried out 100 numerical experiments and reported the average values of *error* and *est_err*. The *error* measures the distance between the set of the computed eigenvalues and the set of eigenvalues returned by the function `eig` with the same input data. Let $\lambda(A)$ denote the set of eigenvalues computed by the MATLAB function `eig`. Let $\tilde{\lambda}(A)$ denote the set of eigenvalues computed by our algorithm, and define the distance between the sets $\lambda(A)$ and $\tilde{\lambda}(A)$ by $\mathrm{dist}(\lambda(A), \tilde{\lambda}(A)) = \max\{\max_{\tilde{\lambda}\in\tilde{\lambda}(A)} \parallel \tilde{\lambda} - \lambda(A) \parallel, \max_{\lambda\in\lambda(A)} \parallel \lambda - \tilde{\lambda}(A) \parallel\}$, where $\parallel \lambda - \tilde{\lambda}(A) \parallel = \min_{\tilde{\lambda}\in\tilde{\lambda}(A)} |\lambda - \tilde{\lambda}|$. We refer to this distance as the error in the eigenvalues computed by our algorithm. Therefore, we tacitly assume that the MATLAB function `eig` computes the eigenvalues exactly.

## 6. Conclusion.

In this paper we have presented a novel QR eigenvalue algorithm for a class of Hessenberg matrices which are rank-one perturbations of unitary matrices. The method is appealing because of its low memory requirements and low computational cost. In fact, the exploitation of the quasiseparable structure of the associated eigenvalue problems leads to a $O(n^2)$ complexity algorithm requiring only $O(n)$ memory space. The results of extensive numerical experiments confirm the robustness and effectiveness of the proposed approach. The accuracy of computed results is generally in accordance with the estimates on the conditioning of the input matrix.

# CONVEXITY AND LIPSCHITZ BEHAVIOR OF SMALL PSEUDOSPECTRA*

J. V. BURKE†, A. S. LEWIS‡, AND M. L. OVERTON§

**Abstract.** The $\epsilon$-pseudospectrum of a matrix $A$ is the subset of the complex plane consisting of all eigenvalues of complex matrices within a distance $\epsilon$ of $A$, measured by the operator 2-norm. Given a nonderogatory matrix $A_0$, for small $\epsilon > 0$, we show that the $\epsilon$-pseudospectrum of any matrix $A$ near $A_0$ consists of compact convex neighborhoods of the eigenvalues of $A_0$. Furthermore, the dependence of each of these neighborhoods on $A$ is Lipschitz.

**Key words.** pseudospectrum, eigenvalue optimization, nonsmooth analysis, Lipschitz multifunction, robust optimization

**AMS subject classifications.** Primary, 15A18, 65K05; Secondary, 90C30, 93D09

**DOI.** 10.1137/050645841

## 1. Introduction.

Given a matrix $A$ in the space of $n \times n$ complex matrices $\mathbf{M}^n$, the spectrum $\Lambda(A)$ is an informative analytic tool, but must be interpreted with care. In particular, when $A$ has a multiple eigenvalue, small perturbations cause the spectrum to behave in a non-Lipschitz fashion.

Pseudospectra are robust analogs of the spectrum, enjoying many useful modelling properties. A comprehensive reference is [9]. We denote the operator 2-norm on $\mathbf{M}^n$ by $\|\cdot\|$. For real $\epsilon > 0$, the $\epsilon$ [illegible] of $A$ is the subset of the complex plane consisting of all eigenvalues of all complex matrices within a distance $\epsilon$ of $A$, measured by the operator 2-norm:

$$\Lambda_\epsilon(A) = \bigcup_{\|X-A\|\le\epsilon} \Lambda(X). \tag{1.1}$$

This subset of the complex plane $\mathbf{C}$ is semialgebraic (meaning that it can be described as a finite union of sets each defined via finitely many polynomial inequalities [2]) and consists of at most $n$ connected components; each component is compact and contains an eigenvalue of $A$. Visual plots of pseudospectra are richly informative and are conveniently computable via the EigTool package [5]. Note that, by contrast to our definition, [9] defines pseudospectra via the [illegible] inequality $\|X - A\| < \epsilon$.

Our aim in this work is to show how shifting attention from the spectrum to pseudospectra has a regularizing effect on variational behavior. Specifically, for matrices $A$ that are in a certain sense typical, even in the presence of multiple eigenvalues, if

the parameter $\epsilon$ is small, the $\epsilon$-pseudospectrum consists of compact convex neighborhoods of the eigenvalues and varies in a Lipschitz fashion with respect to the Hausdorff distance.

## 2. Examples.

We begin with two examples to illustrate the potential difficulties. We first observe how the pseudospectrum can vary in a non-Lipschitz fashion even around a two-by-two matrix with simple eigenvalues. Second, we note that the component of the $\epsilon$-pseudospectrum containing a derogatory eigenvalue may fail to be convex, no matter how small the parameter $\epsilon > 0$.

To help our calculations, we use a well-known description of the pseudospectrum, more convenient than the definition (1.1). Denoting the smallest singular value by $\sigma_{\min} : \mathbf{M}^n \to \mathbf{R}$, the pseudospectrum is related to the reciprocal of the norm of the resolvent,

$$\sigma_{\min}(A - zI) = \|(A - zI)^{-1}\|^{-1},$$

via the useful characterization

$$\Lambda_\epsilon(A) = \{z \in \mathbf{C} : \sigma_{\min}(A - zI) \le \epsilon\}.$$

For our first example, we consider the behavior of the pseudospectrum $\Lambda_{\phi-1}(\cdot)$, where $\phi$ is the golden ratio $(1 + \sqrt{5})/2$, for matrices close to

$$\widehat{A} = \begin{bmatrix} 1 & 1 \\ 0 & -1 \end{bmatrix}.$$

An elementary calculation shows, for real $r$ and $\theta$, the formula

$$2\sigma_{\min}^2(\widehat{A} - re^{i\theta}I) \;=\; 3 + 2r^2 - \sqrt{5 + 4r^2(3 + 2\cos 2\theta)}. \tag{2.1}$$

This leads to a description of the pseudospectrum of $\widehat{A}$:

$$\Lambda_{\phi-1}(\widehat{A}) \;=\; \{re^{i\theta} : r^2 \le 2(2 - \phi + \cos 2\theta)\}.$$

The boundary of this set is a lemniscate centered at zero (see Figure 2.1); its interior consists of two disjoint open sets, each containing one of the eigenvalues $\pm 1$. In particular, notice that the pseudospectrum is contained in its tangent cone at zero:

$$\Lambda_{\phi-1}(\widehat{A}) \;\subset\; \{re^{i\theta} : \cos 2\theta \ge \phi - 2\}. \tag{2.2}$$

Now consider the point $ri$ on the imaginary axis as $r \downarrow 0$. The inclusion (2.2) implies a lower bound on the distance from this point to the pseudospectrum $\Lambda_{\phi-1}(\widehat{A})$ of the form

$$d(ri, \Lambda_{\phi-1}(\widehat{A})) \ge \alpha r, \tag{2.3}$$

for some constant $\alpha > 0$. On the other hand, formula (2.1) implies

$$\sigma_{\min}(\widehat{A} - re^{i\theta}I) = \phi - 1 + O(r^2), \tag{2.4}$$

so for some constant $\beta > 0$ we know that

$$ri \in \Lambda_{\phi-1+\beta r^2}(\widehat{A}).$$

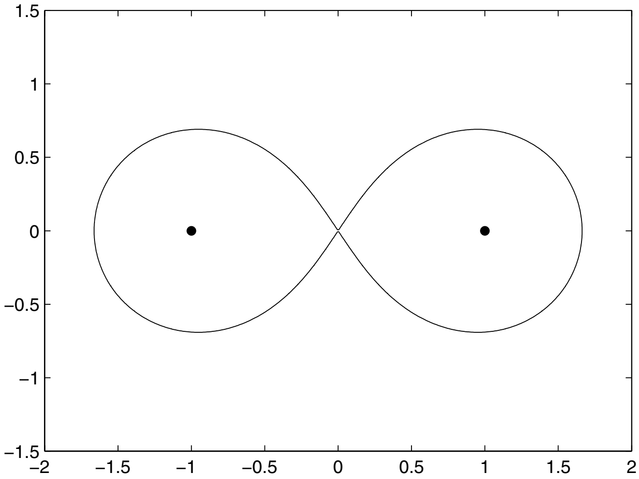

FIG. 2.1. *Pseudospectrum of $\hat{A}$.*

Using the definition of the pseudospectrum (1.1), we can rewrite the right-hand side as

$$\bigcup_{\|A-\widehat{A}\|\leq\beta r^2} \Lambda_{\phi-1}(A),$$

so there exists a matrix $A_r$ satisfying

$$\|A_r - \widehat{A}\| \leq \beta r^2 \quad \text{and} \quad ri \in \Lambda_{\phi-1}(A_r). \tag{2.5}$$

The [illegible] between two nonempty sets $K, L \subset \mathbf{C}$ is the quantity

$$H(K,L) = \max\left\{\sup_{z\in K} d(z,L), \sup_{z\in L} d(z,K)\right\},$$

where $d(z,L)$ is the distance from $z$ to $L$. Now, in conjunction with inequality (2.3), the relationships (2.5) imply that the Hausdorff distance between the pseudospectra $\Lambda_{\phi-1}(\widehat{A})$ and $\Lambda_{\phi-1}(A_r)$ is at least $\alpha r$, and yet the distance between the matrices $\widehat{A}$ and $A_r$ is at most $\beta r^2$. Thus the variation of the mapping $\Lambda_{\phi-1}$ around $\widehat{A}$ is not Lipschitz.

The pathology in this example is caused by the existence of a critical point of the function $z \mapsto \sigma_{\min}(\widehat{A} - zI)$ at a point on the boundary of the pseudospectrum (in this case $z = 0$): this can be seen directly from formula (2.4), or by observing that the left and right singular vectors of the matrix $\widehat{A}$ corresponding to the smallest singular value $\phi - 1$ are orthogonal (see [3, Cor. 7.2]). A direct calculation is also illuminating. Since $\sigma_{\min}(\widehat{A}) = \phi - 1$, replacing by zero the diagonal entry $\phi - 1$ in the singular value decomposition of $\widehat{A}$ makes a perturbation of size $\phi - 1$ and results in a singular matrix. But a straightforward calculation shows that this singular matrix is similar to a two-by-two Jordan block, so further perturbations of size $\delta$ result in the zero eigenvalue splitting into two distinct eigenvalues of size proportional to $\sqrt{\delta}$. It is this splitting that causes the pseudospectrum to behave in a non-Lipschitz fashion. In the development that follows, we avoid this possibility by focusing on the case of small $\epsilon$.

We discuss various aspects of the growth of pseudospectra as the parameter $\epsilon$ grows in a forthcoming work [4]. In particular, we can quantitatively estimate the component of the pseudospectrum $\Lambda_\epsilon(A)$ containing the eigenvalue $\lambda$: classical eigenvalue perturbation theory shows that the component approximates a disk of radius $(\alpha\epsilon)^{1/m}$ as $\epsilon \downarrow 0$, where $m$ is the multiplicity of $\lambda$ as a root of the minimal polynomial for $A$, and $\alpha$ is its associated condition number [4].

Despite approximating disks, small pseudospectral components may be nonconvex in general, as shown by our second example, suggested by [8]. Consider the matrix

$$\tilde{A} = \begin{bmatrix} 0 & 1 \\ 0 & 1 \end{bmatrix}.$$

An easy calculation shows

$$\begin{aligned} f(r,\theta) &= \sigma^2_{\min}(\tilde{A} - re^{i\theta}I) = 1 - r\cos\theta + r^2 - \sqrt{(1 - r\cos\theta)^2 + r^2} \\ &\qquad\qquad\qquad\qquad = \frac{r^2}{2}(1 - r\cos\theta) + O(r^4) \ \text{ as } r \downarrow 0. \end{aligned}$$

Hence the component of the pseudospectrum $\Lambda_\epsilon(\tilde{A})$ containing zero, which we denote $\Lambda^0_\epsilon(\tilde{A})$, is a slightly distorted disk centered at zero and with radius approximately $\sqrt{2}\epsilon$, for small $\epsilon > 0$.

When $\theta = \pi/2$, another calculation shows

$$\frac{\partial f}{\partial r} = 2r\Big(1 - \frac{1}{\sqrt{1 + r^2}}\Big) > 0 \ \text{ for all } r > 0.$$

Hence for $\theta$ near $\pi/2$, the equation $f(r,\theta) = \epsilon^2$ implicitly defines $r$ as a smooth function $g(\theta)$, and for $r$ near $g(\pi/2) = \sqrt{2}\epsilon + O(\epsilon^2)$, the pseudospectrum is

$$\{re^{i\theta} : r \le g(\theta)\}.$$

One more calculation shows

$$g'(\pi/2) \ = \ \frac{\sqrt{1 + g^2(\pi/2)} - 1}{2\sqrt{1 + g^2(\pi/2)} - 1} \ = \ \epsilon^2 + O(\epsilon^3).$$

To summarize, the pseudospectral boundary for the matrix $\tilde{A}$ crosses the positive imaginary axis at a unique point $z_\epsilon = (\sqrt{2}\epsilon + O(\epsilon^2))i$. The boundary nearby is a smooth curve crossing the imaginary axis nonorthogonally and bounding the pseudospectral component below it. Clearly, exactly the same properties hold for the matrix $-\tilde{A}$, and the two boundaries are mirror images in the imaginary axis. Finally, consider the matrix

$$A = \begin{bmatrix} \tilde{A} & 0 \\ 0 & -\tilde{A} \end{bmatrix}.$$

Since the singular values of block-diagonal matrices are just the singular values of the blocks, we have $\Lambda_\epsilon(A) = \Lambda_\epsilon(\tilde{A}) \cup \Lambda_\epsilon(-\tilde{A})$, so we know $\Lambda^0_\epsilon(A) = \Lambda^0_\epsilon(\tilde{A}) \cup \Lambda^0_\epsilon(-\tilde{A})$. By considering a neighborhood of the point $z_\epsilon$, this latter set cannot be convex.

In this example the difficulty is caused by the fact that the zero eigenvalue is derogatory. In what follows, we show good behavior of pseudospectra around nonderogatory eigenvalues, providing the parameter $\epsilon$ is sufficiently small.

**3. Background results.** We recall some results from [3]. A real-valued function on a real vector space is [illegible] at zero if in some neighborhood of zero it can be written as the sum of an absolutely convergent power series in the coordinates relative to some basis, and we make an analogous definition at other points. In particular, such functions are $C^\infty$ near the point in question.

The smallest singular value of the matrix $Z$ is [illegible] when the smallest eigenvalue of the Hermitian matrix $Z^*Z$ is simple. Since the eigenvalues of matrices depend continuously on the matrix, the set of matrices $Z$ with simple smallest singular values is open.

We consider the function $h : \mathbf{M}^n \times \mathbf{C} \to \mathbf{R}$ defined by

$$h(A, z) = (\sigma_{\min}(A - zI))^2.$$

For any $A \in \mathbf{M}^n$, we also define a function $h_A : \mathbf{C} \to \mathbf{R}$ by $h_A(z) = h(A, z)$. Treating $\mathbf{C}$ as a Euclidean space with inner product $\langle w, z\rangle = \operatorname{Re}(w^*z)$, we can interpret gradients $\nabla h_A(z)$ as elements of $\mathbf{C}$.

Theorem 3.1 (analytic singular value). [illegible] $Z$ [illegible] $\sigma^2_{\min}$ [illegible] $Z$

An eigenvalue of $A$ is [illegible] if it has geometric multiplicity one. Among multiple eigenvalues, the nonderogatory ones are the most typical (from the perspective of the dimensions of the corresponding manifolds in $\mathbf{M}^n$ [1]). The matrix $A$ is [illegible] if all its eigenvalues are nonderogatory.

The following result is very well known.

Proposition 3.2 (nonderogatory eigenvalues). [illegible] $A$ [illegible] $\lambda$ [illegible] $A - \lambda I$

The next result, an immediate consequence of [3, Thm. 7.4 and Cor. 7.8], shows that the resolvent norm is well-behaved near any nonderogatory eigenvalue of $A$. For a symmetric matrix $X$, we write $X \succ 0$ to mean $X$ is positive-definite.

Theorem 3.3 (growth near an eigenvalue). [illegible] $\lambda$ [illegible] $A$ [illegible] $z \neq \lambda$ [illegible] $\lambda$ [illegible] $h_A$ [illegible] $\nabla h_A(z) \neq 0$ [illegible] $\nabla^2 h_A(z) \succ 0$

Related results appear in [6].

**4. Convexity.** In [3] we observe, as a consequence of Theorem 3.3 (growth near an eigenvalue), that if $\lambda$ is a nonderogatory eigenvalue of a matrix $A$, then for small $\epsilon > 0$ the part of the pseudospectrum $\Lambda_\epsilon(A)$ near $\lambda$ is strictly convex. (We call a closed set $S \subset \mathbf{C}$ [illegible] if the open line segment $(u, v)$ lies in $\operatorname{int} S$ for any distinct points $u, v \in S$.) The first step in our development is to generalize this result to allow the matrix $A$ to vary. We denote the closed unit disk in $\mathbf{C}$ by $D$ and the closed unit ball in $\mathbf{M}^n$ by $B$.

We begin with a rather technical statement of our basic tool.

Theorem 4.1 (small pseudospectra). [illegible] $\lambda$ [illegible] $A_0 \in \mathbf{M}^n$ [illegible] $\mu > 0$ [illegible] $\bar\epsilon \in (0, \mu)$ [illegible] $\mu$ [illegible] $\epsilon \in (0, \bar\epsilon)$ [illegible]

1. [illegible] $A \in \mathbf{M}^n$ [illegible] $A_0$ [illegible] $\mu$ [illegible] $\epsilon$ [illegible]

$$\hat\Lambda_\epsilon(A) = \Big\{ z \in \Lambda_\epsilon(A) : |z - \lambda| < \mu \Big\} \tag{4.1}$$

[illegible] $\Lambda_\epsilon(A)$ [illegible] $\lambda$ [illegible] $A_0$ [illegible] $\lambda$

2. [illegible] $\bar{\eta} \in (0, \mu)$ [illegible] $\mu$ [illegible] $\epsilon$ [illegible] $\eta \in (0, \bar{\eta})$ [illegible] $A$ [illegible] $A_0$ [illegible] $\mu$ $\epsilon$ [illegible] $\eta$ [illegible]

(i) $\hat{\Lambda}_\epsilon(A)$ [illegible] $\lambda + \eta D$ [illegible] $z \in \lambda + \mu D$

(ii) [illegible] $A - zI$ [illegible]

(iii) [illegible] $|z - \lambda| \geq \eta$ [illegible] $\nabla h_A(z) \neq 0$ [illegible] $\nabla^2 h_A(z) \succ 0$

[illegible] Without loss of generality, $\lambda = 0$. By Theorem 3.3 (growth near an eigenvalue), there exists a number $\mu > 0$ such that

$$0 < |z| \leq \mu \;\; \Rightarrow \;\; \nabla h_{A_0}(z) \neq 0 \text{ and } \nabla^2 h_{A_0}(z) \succ 0. \tag{4.2}$$

Hence the function $h_{A_0}$ is strictly convex on the disk $\mu D$, with a strict local minimum value of zero at zero. In particular, we deduce

$$\Lambda(A_0) \cap \mu D = \{0\}. \tag{4.3}$$

Consider the open set

$$\Omega \;=\; \Big\{(A, z) \in \mathbf{M}^n \times \mathbf{C} : \text{the smallest singular value of } A - zI \text{ is simple}\Big\}.$$

Theorem 3.1 (analytic singular value) implies that the function $h$ is real-analytic throughout $\Omega$, so the function $(A, z) \mapsto \nabla^2 h_A(z)$ is continuous on $\Omega$. Clearly $(A_0, 0) \in \Omega$. Hence, by reducing $\mu$ if necessary, we can suppose there exists a number $\delta_1 > 0$ such that

$$\Big\{(A, z) \in \mathbf{M}^n \times \mu D : \|A - A_0\| < \delta_1\Big\} \;\subset\; \Omega.$$

Choose any number $\mu_1 \in (0, \mu)$. Then we claim

$$\Lambda_\epsilon(A_0) \subset \mu_1 D \cup \mu D^c \tag{4.4}$$

for all small $\epsilon > 0$ (where $D^c$ denotes the complement of $D$). If this were not the case, there would exist sequences of parameters $\epsilon_r \downarrow 0$ and points $z_r \in \Lambda_{\epsilon_r}(A_0)$ satisfying $\mu_1 < |z_r| \leq \mu$. By compactness, we can suppose $z_r$ approaches a nonzero point $z \in \mu D$. However, since $\sigma_{\min}(A_0 - z_r I) \leq \epsilon_r$ for all $r$, we then deduce $\sigma_{\min}(A_0 - zI) \leq 0$, so $z \in \Lambda(A_0)$, contradicting (4.3).

Fix any $\epsilon > 0$ small enough to ensure inclusion (4.4), and choose any number $\mu_2 \in (\mu_1, \mu)$. We claim there exists a number $\delta_2 \in (0, \delta_1)$ such that

$$\|A - A_0\| < \delta_2 \;\Rightarrow\; \hat{\Lambda}_\epsilon(A) \subset \mu_2 D. \tag{4.5}$$

Indeed, if this fails, there are sequences of matrices $A_r \to A_0$ and points $z_r \in \hat{\Lambda}_\epsilon(A_r)$ satisfying $\mu_2 < |z_r| < \mu$. By compactness, we can suppose $z_r$ approaches a point $z \in \mu D$ satisfying $|z| \geq \mu_2 > \mu_1$. However, since $\sigma_{\min}(A_r - z_r I) \leq \epsilon$ for all $r$, we deduce $\sigma_{\min}(A_0 - zI) \leq \epsilon$, and hence $z \in \Lambda_\epsilon(A_0)$. But this contradicts inclusion (4.4).

The inclusion $\hat{\Lambda}_\epsilon(A) \subset \mu_2 D$ implies that the set $\hat{\Lambda}_\epsilon(A)$ is compact, being the intersection of the two compact sets $\Lambda_\epsilon(A)$ and $\mu_2 D$.

For our next step, observe that, by continuity, we know there exists a number $\eta \in (0, \mu)$ such that $\sigma_{\min}(A_0 - zI) < \epsilon$ for all points $z \in \eta D$. We now claim there exists a number $\delta_3 \in (0, \delta_2)$ such that

$$\|A - A_0\| < \delta_3 \;\Rightarrow\; \eta D \subset \operatorname{int} \hat{\Lambda}_\epsilon(A). \tag{4.6}$$

Suppose this property fails, so there are sequences of matrices $A_r \to A_0$ and points $z_r \in \eta D$ satisfying $z_r \notin \operatorname{int} \hat{\Lambda}_\epsilon(A_r)$, and hence $\sigma_{\min}(A_r - z_r I) \geq \epsilon$. By compactness, we can suppose $z_r$ approaches a point $z \in \eta D$, giving the contradiction $\sigma_{\min}(A_0 - zI) \geq \epsilon$.

We next claim there exists a number $\delta \in (0, \delta_3)$ such that, whenever $\|A - A_0\| \leq \delta$ and $\eta \leq |z| \leq \mu$, we have

$$\nabla h_A(z) \neq 0 \quad \text{and} \quad \nabla^2 h_A(z) \succ 0. \tag{4.7}$$

If this fails, there are sequences of matrices $A_r \to A_0$ and points $z_r$ satisfying $\eta \leq |z_r| \leq \mu$ and

$$\min \Big\{ |\nabla h_{A_r}(z_r)|, \lambda_{\min}(\nabla^2 h_{A_r}(z_r)) \Big\} \leq 0$$

for all $r$. By compactness, we can suppose $z_r$ approaches a point $\hat{z}$ satisfying $\eta \leq |\hat{z}| \leq \mu$. By the continuity with respect to $(A, z) \in \Omega$ of the functions $\nabla h_A(z)$ and $\nabla^2 h_A(z)$, we deduce

$$\min \Big\{ |\nabla h_{A_0}(\hat{z})|, \lambda_{\min}(\nabla^2 h_{A_0}(\hat{z})) \Big\} \leq 0,$$

contradicting statement (4.2).

We next prove that the set $\hat{\Lambda}_\epsilon(A)$ is strictly convex. To this end, consider any matrix $A$ satisfying $\|A - A_0\| < \delta$ and any two distinct points $u, v \in \hat{\Lambda}_\epsilon(A)$. We want to show the open line segment $(u, v)$ lies in $\operatorname{int} \hat{\Lambda}_\epsilon(A)$. By property (4.6), we know that

$$\eta D \subset \operatorname{int} \hat{\Lambda}_\epsilon(A). \tag{4.8}$$

We consider various cases.

(i) $|u|, |v| \leq \eta$. The result then follows by inclusion (4.8).

(ii) $(u, v) \cap \eta D = \emptyset$. In this case, we know $h_A(u) \leq \epsilon^2$ and $h_A(v) \leq \epsilon^2$, and the function $h_A$ is strictly convex on the line segment $[u, v]$, by property (4.7), so the result follows.

(iii) $|u| \leq \eta$ and $|v| > \eta$. Then consider the unique number $\gamma \in [0, 1]$ such that the point $w = \gamma u + (1 - \gamma)v$ satisfies $|w| = \eta$. Then $[u, w] \subset \operatorname{int} \hat{\Lambda}_\epsilon(A)$ by inclusion (4.8), while $(w, v) \subset \operatorname{int} \hat{\Lambda}_\epsilon(A)$ by case (ii).

(iv) $|u| > \eta$ and $|v| \leq \eta$. By swapping $u$ and $v$, we obtain case (iii).

(v) $|u|, |v| > \eta$ and $(u, v) \cap \eta D \neq \emptyset$. Consider the two (possibly equal) solutions $\gamma_1 \geq \gamma_2$ in $[0, 1]$ to the quadratic equation $|\gamma u + (1 - \gamma)v|^2 = \eta^2$. For each $j = 1, 2$, set $w_j = \gamma_j u + (1 - \gamma_j)v$. Then $[w_1, w_2] \subset \operatorname{int} \hat{\Lambda}_\epsilon(A)$ by inclusion (4.8), while both intervals $(u, w_1)$ and $(w_2, v)$ lie in $\operatorname{int} \hat{\Lambda}_\epsilon(A)$ by case (ii).

This completes the proof of strict convexity.

To see that the set $\hat{\Lambda}_\epsilon(A)$ must be the component of the pseudospectrum $\Lambda_\epsilon(A)$ containing $\lambda$, note that the function $A \mapsto \sigma_{\min}(A - \lambda I)$ is continuous on $\mathbf{M}^n$, and $\sigma_{\min}(A_0 - \lambda I) = 0$, so $\lambda \in \hat{\Lambda}_\epsilon(A)$ for all $A$ near $A_0$. Since the $\hat{\Lambda}_\epsilon(A)$ is a connected subset of $\Lambda_\epsilon(A)$, being convex, the result follows. $\square$

COROLLARY 4.2 (strict convexity). [illegible] $\lambda$ [illegible] $A_0 \in \mathbf{M}^n$ [illegible] $\epsilon > 0$ [illegible] $\Lambda_\epsilon(A)$ [illegible] $\lambda$ [illegible] $A$ [illegible] $A_0$

**5. Sensitivity.** We are now ready to study the dependence of a fixed component of the pseudospectrum $\Lambda_\epsilon(A)$ on the matrix $A$.

LEMMA 5.1 (gradient continuity). [illegible] 4.1 [illegible] $w$ [illegible] $\alpha_w : \mathbf{M}^n \to \mathbf{R}$ [illegible]

$$\alpha_w(A) = \sup\{\mathrm{Re}\,(w^* z) : z \in \hat{\Lambda}_\epsilon(A)\}. \tag{5.1}$$

[illegible] $(A, w) \mapsto \alpha_w(A)$ [illegible] $C^\infty$ [illegible]

$$\Big\{(A, w) \in \mathbf{M}^n \times \mathbf{C} : \|A - A_0\| \le \delta,\ w \ne 0\Big\}.$$

[illegible]. The supremum (5.1) is attained at a unique point $z(A, w) \in \hat{\Lambda}_\epsilon(A)$, since the set $\hat{\Lambda}_\epsilon(A)$ is compact and strictly convex. We can also write the supremum as a smooth optimization problem,

$$\alpha_w(A) = \sup\Big\{\mathrm{Re}\,(w^* z) : h_A(z) \le \epsilon^2,\ |z - \lambda| < \mu\Big\}.$$

By continuity, the optimal solution $z(A, w)$ must satisfy $h_A(z(A, w)) = \epsilon^2$. The function $h_A$ is real-analytic (so, in particular, $C^\infty$), and satisfies the condition

$$\nabla h_A(z(A, w)) \ne 0 \ \text{ and } \ \nabla^2 h_A(z(A, w)) \succ 0. \tag{5.2}$$

We now apply a standard sensitivity argument to show that the dependence of the optimal solution $z(A, w)$ on the parameters $(A, w)$ is also $C^\infty$. We argue as follows. Since $\nabla h_A(z(A, w)) \ne 0$, there exists a Lagrange multiplier $\gamma(A, w) \in \mathbf{R}$ corresponding to the optimal solution. Thus $z = z(A, w)$ and $\gamma = \gamma(A, w)$ solve the system

$$\begin{aligned} w + \gamma \nabla h_A(z) &= 0, \\ h_A(z) &= \epsilon^2. \end{aligned}$$

But it is easy to check that condition (5.2) implies that the Jacobian for the left-hand side is surjective at $(z(A, w), \gamma(A, w))$. Hence the implicit function theorem implies that the mapping $(A, w) \mapsto z(A, w)$ is $C^\infty$. The result follows. ◻

We can now prove our main result.

THEOREM 5.2 (component Lipschitz behavior). [illegible] $\lambda$ [illegible] $A_0 \in \mathbf{M}^n$ [illegible] $\mu > 0$ [illegible] $\bar{\epsilon} \in (0, \mu)$ [illegible] $\mu$ [illegible] $\epsilon \in (0, \bar{\epsilon})$ [illegible] $A \in \mathbf{M}^n$ [illegible] $A_0$ [illegible] $\mu$ [illegible] $\epsilon$ [illegible]

$$\hat{\Lambda}_\epsilon(A) \ = \ \Big\{z \in \Lambda_\epsilon(A) : |z - \lambda| < \mu\Big\}$$

[illegible]

(i) $\hat{\Lambda}_\epsilon(A)$ [illegible] $\Lambda_\epsilon(A)$ [illegible] $\lambda$

(ii) $\hat{\Lambda}_\epsilon(A)$ [illegible] $A_0$ [illegible] $\lambda$

(iii) $\hat{\Lambda}_\epsilon(A)$ [illegible]

(iv) [illegible] $\hat{\Lambda}_\epsilon$ [illegible] $A_0$ [illegible]

[illegible]. We apply Theorem 4.1 (small pseudospectra) and Corollary 4.2 (strict convexity). Using Lemma 5.1 (gradient continuity), we can define a number

$$L = \max\Big\{\|\nabla\alpha_w(A)\| : A \in \Gamma,\ |w| = 1\Big\},$$

where the set $\Gamma$ is the neighborhood of the matrix $A_0$ referred to in Theorem 4.1. Consider any two matrices $A_1, A_2 \in \Gamma$. According to [7, Lemma 2], the Hausdorff distance between the sets $\hat{\Lambda}_\epsilon(A_1)$ and $\hat{\Lambda}_\epsilon(A_2)$ is given by

$$\max_{|w|=1} \Big|\alpha_w(A_1) - \alpha_w(A_2)\Big|,$$

and, by the definition of $L$, this quantity cannot exceed $L\|A_1 - A_2\|$. ◻

In particular, we obtain the following variational property of the entire pseudopectrum.

COROLLARY 5.3 (pseudospectral Lipschitz behavior). [illegible] $A_0 \in \mathbf{M}^n$ [illegible] $\epsilon > 0$ [illegible] $\Lambda_\epsilon(A)$ [illegible] $A \in \mathbf{M}^n$ [illegible] $A_0$ [illegible]

[illegible]. Denote the distinct eigenvalues of $A_0$ by $\lambda_1, \lambda_2, \ldots, \lambda_m$, and denote the separation of the eigenvalues by $\nu = \min_{j\neq k} |\lambda_j - \lambda_k|$. Now apply the preceding result successively at each eigenvalue $\lambda_j$ to obtain a number $\mu < \nu/3$ such that any small $\epsilon > 0$ has the following property: for all matrices $A$ near $A_0$ and each index $j = 1, 2, \ldots, m$, the component of the pseudospectrum $\Lambda_\epsilon(A)$ containing $\lambda_j$ is

$$\Lambda_\epsilon^j(A) = \{z \in \Lambda_\epsilon(A) : |z - \lambda_j| < \mu\},$$

and the set-valued mapping $\Lambda_\epsilon^j$ is Lipschitz around $A_0$.

Now consider any matrices $A_1, A_2 \in \mathbf{M}^n$ near $A_0$. For any fixed index $j$, we have

$$z \in \Lambda_\epsilon^j(A_1) \quad \Rightarrow \quad d(z, \Lambda_\epsilon(A_2)) = d(z, \Lambda_\epsilon^j(A_2)). \tag{5.3}$$

To see this, notice that $d(z, \Lambda_\epsilon^j(A_2)) < \mu$ because $\lambda_j \in \Lambda_\epsilon^j(A_2)$. On the other hand, for indices $k \neq j$, we know

$$|z - \lambda_j| < \mu, \quad |\lambda_j - \lambda_k| > 3\mu, \quad \Lambda_\epsilon^k(A_2) \subset \lambda_k + \mu D,$$

so $d(z, \Lambda_\epsilon^k(A_2)) > \mu$. Since

$$d(z, \Lambda_\epsilon(A_2)) = \min_k d(z, \Lambda_\epsilon^k(A_2)),$$

our claim (5.3) now follows.

As a consequence of the implication (5.3), we obtain

$$\sup_{z\in\Lambda_\epsilon(A_1)} d(z, \Lambda_\epsilon(A_2)) = \max_j \sup_{z\in\Lambda_\epsilon^j(A_1)} d(z, \Lambda_\epsilon(A_2)) = \max_j \sup_{z\in\Lambda_\epsilon^j(A_1)} d(z, \Lambda_\epsilon^j(A_2)),$$

and similarly,

$$\sup_{z\in\Lambda_\epsilon(A_2)} d(z, \Lambda_\epsilon(A_1)) = \max_k \sup_{z\in\Lambda_\epsilon^k(A_2)} d(z, \Lambda_\epsilon^k(A_1)).$$

Hence the Hausdorff distance between the pseudospectra $\Lambda_\epsilon(A_1)$ and $\Lambda_\epsilon(A_2)$ is given by

$$\begin{aligned} H\Big(\Lambda_\epsilon(A_1), \Lambda_\epsilon(A_2)\Big) &= \max\Big\{ \sup_{z\in\Lambda_\epsilon(A_1)} d(z, \Lambda_\epsilon(A_2)), \sup_{z\in\Lambda_\epsilon(A_2)} d(z, \Lambda_\epsilon(A_1))\Big\} \\ &= \max\Big\{ \max_j \sup_{z\in\Lambda_\epsilon^j(A_1)} d(z, \Lambda_\epsilon^j(A_2)), \max_k \sup_{z\in\Lambda_\epsilon^k(A_2)} d(z, \Lambda_\epsilon^k(A_1))\Big\} \\ &= \max_r \ \max\Big\{ \sup_{z\in\Lambda_\epsilon^r(A_1)} d(z, \Lambda_\epsilon^r(A_2)), \sup_{z\in\Lambda_\epsilon^r(A_2)} d(z, \Lambda_\epsilon^r(A_1))\Big\} \\ &= \max_r H\Big(\Lambda_\epsilon^r(A_1), \Lambda_\epsilon^r(A_2)\Big). \end{aligned}$$

The result now follows. □

# OPTIMAL EMBEDDINGS AND EIGENVALUES IN SUPPORT THEORY*

ERIK G. BOMAN[†], STEPHEN GUATTERY[‡], AND BRUCE HENDRICKSON[†]

**Abstract.** Support theory is a methodology for bounding eigenvalues and generalized eigenvalues of matrices and matrix pencils; such bounds have been stated both in algebraic terms and in combinatorial terms based on embeddings of the underlying graphs of the matrices. In this paper, we present a theorem that demonstrates the connection between these various bounding techniques and also suggest a possible approach to generating approximate inverses for preconditioning. The theorem shows, given matrices $A = UD_AU^*$ and $B = VD_BV^*$ (where $D_A$ and $D_B$ are invertible Hermitian matrices, and $U$ and $V$ are not necessarily square), that it is possible to define a matrix $W$ such that $W^*D_B^{-1}WD_A$ has the same nonzero eigenvalues counting multiplicity as $B^+A$. In the special case that $U$ is the orthogonal projector onto the range space of $B$ and $D_A = I$ (and hence that $A = UU^* = U^2 = U$), then $W^*D_B^{-1}W = B^+$. This suggests that finding an approximation to $W$ might lead to an approximate inverse that can be used in preconditioning. We also describe how this theorem generalizes the idea of graph embeddings in an algebraic sense.

## 1. Introduction.

Support theory is a methodology for bounding eigenvalues and generalized eigenvalues (and more generally support numbers) of matrices and matrix pencils; it has applications such as the analysis of the performance of interative solvers for symmetric positive definite systems. Support theory bounds have been stated both in algebraic terms and in terms of combinatorial techniques based on the underlying graphs of the matrices involved. In this paper, we present a theorem that demonstrates the connection between these various bounding techniques and also suggest a possible approach to generating approximate inverses for preconditioning.

Given a preconditioned system $B^{-1}A$, support theory is concerned with generating bounds on $\lambda_{\max}(B^{-1}A)$ and $\lambda_{\max}(A^{-1}B)$, which are used to bound the condition number of the system. More generally, if $A$ and $B$ are singular, bounds are generated on the support numbers $\sigma(A, B)$ and $\sigma(B, A)$. Bounds are generated in terms of factorizations $A = UU^T$ and $B = VV^T$ of the matrices where $U$ and $V$ are not restricted to be square. Given the factorizations, a matrix $W$ is constructed subject to the condition $U = VW$. This is the key formulation of support theory [3].

We present a theorem that shows, given matrices $A = UD_AU^*$ and $B = VD_BV^*$ (where $D_A$ and $D_B$ are invertible Hermitian matrices and the columns of $U$ are in the range of $B$), that there exists a matrix $W_{opt}$ such that $W_{opt}^*D_B^{-1}W_{opt}D_A$ has the same nonzero eigenvalues counting multiplicity as $B^+A$. This result was previously

unknown even in the special case where $D_A = D_B = I$. In the special case that $U$ is the orthogonal projector of the range space of $B$ and $D_A = I$ (and hence that $A = UU^* = U^2 = U$), then $W_{opt}^* D_B^{-1} W_{opt} = B^+$, where $B^+$ is the pseudoinverse of $B$. This suggests that finding an approximation to $W_{opt}$ might lead to an approximate inverse that can be used in preconditioning.

We describe how this theorem generalizes the idea of embedding in an algebraic sense and show how it can be used to generalize and simplify the proofs of previous results. In particular, this allows the ideas to be applied to a broader range of matrices. We also place the theorem in the context of two branches of support theory research that focus on matrix eigenvalue bounds and matrix pencil bounds, respectively.

The paper starts with a section on notation (section 2) and some background on the development of some basic ideas in support theory (section 3). The main theorem is presented in section 4, along with a version applicable to non-Hermitian matrices. We use this proof to give a new and more general proof of a result by Boman and Hendrickson [3]. In section 6 we give new and more general proofs of results by Guattery [6] linking a generalized notion of embedding with the pseudoinverses of Hermitian matrices. The results in this paper subsume the results in that technical report. Finally, in section 7 we discuss the implications of this work for preconditioning, particularly in terms of approximate inverses.

## 2. Notation.

We use capital letters to represent matrices. Individual matrix entries are denoted by the corresponding lower case letter with subscripts showing the row and column of the entry, e.g., $a_{ij}$ is the entry of $A$ in row $i$ and column $j$. $I$ represents an identity matrix. When it is useful to indicate the size of an identity matrix, a single subscript indicates the number of rows and columns: $I_k$ is the $k \times k$ identity matrix. A matrix of all zeros is denoted by 0.

For a matrix $A$ with real entries, $|A|$ denotes the matrix whose entries are the absolute values of the corresponding entries of $A$: the entry in row $i$ and column $j$ of $|A|$ is $|a_{ij}|$.

The notations $A^T$ represents the transpose of $A$; $A^*$ represents $A$'s conjugate transpose; and $A^+$ represents the pseudoinverse of $A$ (i.e., the Moore–Penrose generalized inverse of $A$).

We denote the range space of the columns of a matrix $A$ by $R(A)$. The orthogonal projector onto a vector space $\mathcal{S}$ is denoted as $P_{\mathcal{S}}$. Thus $P_{R(A)}$ is the orthogonal projector onto the range space of the columns of $A$.

Vectors are denoted by lower case letters with an arrow above, e.g., $\vec{v}$. A column vector of all zeros is denoted as $\vec{0}$; if a specific size is specified, it is given as a subscript: $\vec{0}_k$ is a vector of $k$ 0's.

## 3. Background.

A key application of support theory is the analysis of preconditioned symmetric and Hermitian systems. When solving linear systems $Ax = b$ using an iterative method, it is frequently useful to have a good preconditioner to accelerate convergence. This has often involved constructing a preconditioner $B \approx A$. In this sense, $B$ is a good preconditioner if both (i) the eigenvalues of $B^{-1}A$ are clustered around one, and (ii) the matrix $B$ is easy to solve for (invert). (Note that if $A$ is singular, one may wish to let $B$ be singular with the same null space. In this case, $B^+A$ is the preconditioned matrix of interest.)

For Hermitian positive definite systems, the eigenvalues are real and positive, and a lower bound on the rate of convergence is the spectral condition number, $\kappa(C) = \lambda_{\max}(C)/\lambda_{\min}(C)$. In our case, either $C = B^{-1}A$ or $C = B^{-1/2}AB^{-1/2}$ (where $B^{-1/2}$ is Hermitian), and the condition number can be expressed using support numbers.

The [illegible] for a matrix pencil $(A, B)$, where $A$ and $B$ are Hermitian, is defined as

$$\sigma(A, B) = \min \{ t \in \mathbb{R} \,|\, x^*(\tau B - A)x \geq 0 \text{ for all } x \in \mathbb{C}^n \text{ and for all } \tau \geq t \} .$$

It has been shown that when $B$ is symmetric positive definite, $\sigma(A, B) = \lambda_{\max}(A, B)$, the largest generalized eigenvalue [3]. Furthermore,

$$\kappa(B^{-1/2}AB^{-1/2}) = \sigma(A, B)\sigma(B, A).$$

Support numbers exist even when $A$ or $B$ is singular, but may not be finite. Support theory is useful for analyzing preconditioners because support numbers give bounds on the spectral condition number. See [3] for further information on support theory.

For symmetric positive semidefinite systems, bounds on support numbers are generated in terms of factorizations $A = UU^T$ and $B = VV^T$ of the matrices. Based on the factorizations, a matrix $W$ is constructed subject to the condition $U = VW$. This key algebraic formulation of support theory is due to Boman and Hendrickson [3] and is at the heart of the symmetric product support theorem.

THEOREM 3.1 (see Theorem 4.5 from [3]). [illegible] $U \in \mathbb{R}^{n \times k}$ [illegible] $V \in \mathbb{R}^{n \times p}$ [illegible]

$$\sigma(UU^T, VV^T) = \min_W \|W\|_2^2 \quad \textit{subject to}\, VW = U.$$

It is further noted in [3] that for $\hat{W} = V^+U$, $\sigma(UU^T, VV^T) = \|\hat{W}\|_2^2$.

Boman and Hendrickson also proved the following theorem.

THEOREM 3.2 (see Theorem 4.7 from [3]). [illegible] $U \in \mathbb{R}^{n \times k}$ [illegible] $V \in \mathbb{R}^{n \times p}$ [illegible] $D \in \mathbb{R}^{k \times k}$ [illegible] $W$ [illegible] $VW = U$

$$\sigma(UDU^T, VV^T) \leq \lambda_{\max}(WDW^T) \leq \lambda_{\max}(D)\|W\|_2^2.$$

The use of the term [illegible] in this paper is intended to suggest the relationship to the use of combinatorial embeddings in early work in the area, which typically involved Laplacian (and related) matrices. Laplacians have a well-known graphical interpretation in which a Laplacian $L$ can be factored into $L = UU^T$, where $U$ is a [illegible]. In such a matrix, each row represents a vertex of the underlying graph of the Laplacian. Each column represents an edge and has one $+1$ and one $-1$ in the rows corresponding to the endpoints of the edge. Note that this (arbitrarily) directs the edges, though this direction is lost in the product that forms the Laplacian. (Entries can be scaled appropriately for weighted graphs.)

Graph embedding techniques were used to analyze the quality of support graph preconditioners, which were formulated in terms of the combinatorial structure of the Laplacian matrices. Examples include Vaidya's preconditioners based on spanning trees [13] (see [2] for a more readily available description of Vaidya's preconditioner) and Gremban and Miller's support tree preconditioners [5]. Bounds on the condition number of a preconditioned system were calculated in terms of properties of the embeddings of the underlying graphs of the preconditioner into the Laplacian and vice versa.

The embeddings used in this analysis were typically path embeddings, in which each edge in $U$ (e.g., the vertex-edge incidence matrix of the original Laplacian) was represented as a directed path constructed from the edges in $V$ (e.g., the vertex-edge incidence matrix of the preconditioner). While these embeddings were not typically expressed in matrix form, it is easy to construct the matrix $W$ corresponding to the embedding: Each path in the embedding shows up as a column in $W$. The rows in $W$ correspond to the edges in $V$; if an edge in $V$ is in the path, a $+1$ or $-1$ occurs in that row of $W$, depending on whether the direction of the edge in $V$ is in the same or opposite direction of the path, respectively. (Again, entries in $W$ can be scaled to deal with weighted graphs.) In this representation, $U = VW$ expresses the mapping defined by the embedding.

Properties of the paths were used to compute bounds. This was typically done in combinatorial rather than algebraic terms. One method, suggested in Vaidya's work (see the section, "An Analogy with Resistive Networks," on p. 6 of [13]) and developed by Gremban and Miller (see the discussion starting with the last two paragraphs on p. 65 and continuing to the start of section 4.5 on the next page of [5]), involved summing the congestions (defined for each edge in the graph embedded into the number of paths in the embedding incident to that edge) along each path. The maximum sum taken over all paths provided an upper bound on $\lambda_{\max}(B^{-1}A)$.

This method was also applied in a line of research that considered bounding the smallest nontrivial eigenvalue of a Laplacian or related matrix (the earliest work in this direction was aimed at bounding the second largest eigenvalues of time-reversible Markov chains in order to bound the mixing time for random walks [10, 12]). This typically involved embedding the complete graph into a Laplacian or a generalization of the Laplacian that allowed weighted edges. Later work involved a further generalization that included Dirichlet boundary conditions (these conditions resulted in entries on the diagonal that exceeded the sum of the weights of the incident edges). For such matrices, a star was embedded instead of a clique.

Analysis using path congestions and related techniques initially did not express the embedding in matrix form. However, some work along these lines developed an algebraic representation of embeddings. Kahale [11] looked at computing lower bounds on the smallest nontrivial eigenvalue of a Laplacian using a method that assigned a length to each path, then looked for the edge that had the greatest sum of the lengths of the incident paths. He computed embedding properties in terms of $|W|$, the absolute value of the matrix $W$ representing the embedding, and expressed the best bound that could be computed for any embedding in terms of $\lambda_{\max}(|W|^T|W|)$. Guattery, Leighton, and Miller [7] formulated the path resistance method, an extension of the sum-of-congestions method applied to lower bounds of smallest nontrivial Laplacian eigenvalues. They showed that, given an embedding $W$, the best possible bound computed using the path resistance method was the same as the best possible bound computed using Kahale's edge-length method and that the value $\lambda_{\max}(|W||W|^T) = \lambda_{\max}(|W|^T|W|)$ was a term in the expression for this best bound.

Guattery and Miller [8] made the observation that including directions in embeddings typically improved the best possible lower bounds on smallest nontrivial eigenvalues of generalized Laplacians that could be derived from the embeddings. Guattery and Miller allowed multiple paths in embedding each edge and they also kept the signs corresponding to direction in the embedding matrix $W$, which corresponds to working with $W$ rather than $|W|$. At this point the notion of embedding has been generalized to the point that any matrix $W$ such that $U = VW$ can be viewed as a [illegible] of $U$ into $V$, where $U$ and $V$ are vertex-edge incidence matrices. Guattery and Miller also proved that there existed a particular embedding $W_{cf}$ (referred to as the [illegible] such that the smallest nontrivial eigenvalue could be computed exactly in terms of $\lambda_{\max}(W_{cf}W_{cf}^T)$ for that embedding. They also showed that $W_{cf}$ was a factor of the inverse for this embedding applied to the case of a generalized Laplacian with a Dirichlet boundary condition.

Guattery [6] extended these ideas to all Hermitian matrices. In particular, he considered what he called the [illegible] $W_{cf}$ of the orthogonal projector onto the range of the columns of $B = VDV^*$ (where $D$ is a diagonal matrix with nonzeros on the diagonal) into $V$. He showed that the pseudoinverse of $B$ could be expressed as $W_{cf}D^{-1}W_{cf}^*$. The formulation is still in terms of a slightly generalized vertex-edge incidence matrix although, as shown in section 6, the ideas can be generalized to any factorization $VDV^*$.

The results in this paper tie together ideas from the algebraic and combinatorial (path embedding) views of support theory, and express them in a common notation.

**4. The main theorem.** Consider the matrix pencil $(A, B)$, where $A$ and $B$ are $n \times n$ complex, Hermitian matrices. Assume that there exist matrices $U$ and $V$ such that $A = UD_AU^*$ and $B = VD_BV^*$, where $U$ is $n \times m$, $V$ is $n \times k$, and $D_B$ and $D_A$ are invertible Hermitian matrices with dimensions $k \times k$ and $m \times m$, respectively. The main theorem can be stated as follows.

THEOREM 4.1 (main theorem). [illegible] $(A, B)$ [illegible] $U$ [illegible] $B$ [illegible] $W_{opt}$ [illegible] $VW_{opt} = U$ [illegible] $W_{opt}^* D_B^{-1} W_{opt} D_A$ [illegible] $B^+A$ [illegible]

Before proving the main theorem, it is helpful to lay out some supporting lemmas. Define the $(n + k) \times (n + k)$ block matrix $M$ as follows:

$$M = \begin{bmatrix} D_B^{-1} & V^* \\ V & 0 \end{bmatrix}. \tag{4.1}$$

The proof of the main theorem is based on solutions to the following block system:

$$\begin{bmatrix} D_B^{-1} & V^* \\ V & 0 \end{bmatrix} \begin{bmatrix} W_{opt} \\ Z \end{bmatrix} = \begin{bmatrix} 0 \\ U \end{bmatrix}. \tag{4.2}$$

The $k \times m$ matrix $W_{opt}$ is of particular interest. The following lemma gives necessary and sufficient conditions for the existence of a solution, and hence immediately implies the existence of $W_{opt}$:

LEMMA 4.2. [illegible] if and only if [illegible] $U$ [illegible] $B$

[illegible]. We can apply Gaussian elimination to $M$ as follows:

$$\begin{bmatrix} I & 0 \\ -VD_B & I \end{bmatrix} \begin{bmatrix} D_B^{-1} & V^* \\ V & 0 \end{bmatrix} \begin{bmatrix} W_{opt} \\ Z \end{bmatrix} = \begin{bmatrix} I & 0 \\ -VD_B & I \end{bmatrix} \begin{bmatrix} 0 \\ U \end{bmatrix}$$

to get the following reduced system:

$$\begin{bmatrix} D_B^{-1} & V^* \\ 0 & -B \end{bmatrix} \begin{bmatrix} W_{opt} \\ Z \end{bmatrix} = \begin{bmatrix} 0 \\ U \end{bmatrix}. \tag{4.3}$$

Proving the result for the reduced matrix is sufficient because it has the same solutions as the original system.

Assuming that a solution to the reduced system exists, there must be a $Z$ such that $-BZ = U$. That is, a solution exists only if the columns of $U$ are in the range of $B$.

Assuming that the columns of $U$ are in the range of $B$, then a $Z$ that satisfies $-BZ = U$ exists. For the block system to have a solution, we must also have a solution to the equation $D_B^{-1}W_{opt} + V^*Z = 0$. The solution exists if there is a $W_{opt}$ such that $W_{opt} = -D_B V^* Z$. Since the matrices $D_B$, $V^*$ and $Z$ exist by assumption, a solution does exist and the lemma holds. ☐

It is possible that there is more than one solution. In some arguments below we require a solution that is orthogonal to the null space of $M$; where this is the case, it is noted explicitly.

Theorem 1.3.20 from [9] is useful in our arguments. We restate (in slightly revised form) the pertinent result below.

THEOREM 4.3. [illegible] $Y$ [illegible] $r \times s$ [illegible] $Z$ [illegible] $s \times r$ [illegible] $r \leq s$ [illegible] $ZY$ [illegible] $YZ$ [illegible] $s - r$ [illegible] $0$

We can now prove the main theorem.

[illegible] Given the factorizations assumed in the theorem statement, we can construct the block system in (4.2). As in Lemma 4.2, we can apply Gaussian elimination to get the reduced system from (4.3). Assume that the columns of $U$ are in the range of $B$. By Lemma 4.2, a solution to the reduced system exists. That immediately yields the equation

$$-BZ = U.$$

Multiplying through on both sides by $-B^+$ gives

$$P_{R(B^+)}Z = -B^+U.$$

It is a fact that $P_{R(B^+)} = P_{R(B^*)}$ (see p. 10 of [4]). Thus we can rewrite the equation as follows:

$$P_{R(B^*)}Z = -B^+U. \tag{4.4}$$

The assumption that the columns of $U$ are in the range of $B$ also implies that $U = P_{R(B)}U$. Taking the conjugate transpose gives $U^* = U^*P_{R(B)}^* = U^*P_{R(B)}$, the last equality following because orthogonal projectors are Hermitian by definition. Because $B$ is Hermitian, $P_{R(B)} = P_{R(B^*)}$. Thus we have the following equation:

$$U^* = U^*P_{R(B^*)}. \tag{4.5}$$

From the original block system we have that

$$D_B^{-1}W_{opt} = -V^*Z \tag{4.6}$$

and also that, after taking the conjugate transpose,

$$W_{opt}^*V^* = U^*. \tag{4.7}$$

Applying (4.6), (4.7), (4.5), and (4.4) in turn, we have

$$\begin{aligned} W_{opt}^*D_B^{-1}W_{opt}D_A &= -W_{opt}^*V^*ZD_A \\ &= -U^*ZD_A \\ &= -U^*P_{R(B^*)}ZD_A \\ &= U^*B^+UD_A. \end{aligned} \tag{4.8}$$

We can apply Theorem 4.3 to show that each nonzero eigenvalue of $U^*B^+UD_A$ is an eigenvalue of $B^+A$ and vice-versa.

If $m > n$, we apply Theorem 4.3 to $B^+A = B^+UD_AU^*$. Noting that $B^+UD_A$ is $n \times m$ and $U^*$ is $m \times n$, we immediately have that $B^+A$ has the same nonzero eigenvalues (counting multiplicity) as $U^*B^+UD_A$, plus $m - n$ additional zero eigenvalues.

If $m \leq n$, we apply Theorem 4.3 to $U^*B^+UD_A$. We immediately have that $B^+UD_AU^* = B^+A$ has the same nonzero eigenvalues as $U^*B^+UD_A$ (counting multiplicity), plus $n - m$ additional zero eigenvalues if $n$ is strictly greater than $m$.

This completes the proof. ☐

As a consequence of Theorem 4.1, we have the additional result.

THEOREM 4.4. [illegible] $U \in \mathbb{R}^{n\times k}$ [illegible] $V \in \mathbb{R}^{n\times p}$ [illegible] $W$ [illegible] $VW = U$ [illegible] $W^TW$ [illegible] $(VV^T)^+UU^T$

[illegible] The result follows immediately from Theorem 4.1, with $D_B = I$ and $D_A = I$. ☐

Note that in this case, $D_B = I$ in the system from (4.2), so in the solution orthogonal to the null space of $M$ from (4.1), $W$ is the solution to the equation $VW = U$ with the minimum two-norm. This is consistent with Theorem 3.1 (see Theorem 4.5 from [3]).

## 5. The non-Hermitian case.

A related theorem can be proved for invertible, complex non-Hermitian matrices of the form $A = EF^*$, where $A$ is $n \times n$, and $E$ and $F$ are $n \times m$, with $m \geq n$. Consider the following two block systems: one for $A$:

$$\begin{bmatrix} I_m & F^* \\ E & 0 \end{bmatrix} \begin{bmatrix} W \\ Z \end{bmatrix} = \begin{bmatrix} 0 \\ I_n \end{bmatrix}, \tag{5.1}$$

and one for $A^* = FE^*$:

$$\begin{bmatrix} I_m & E^* \\ F & 0 \end{bmatrix} \begin{bmatrix} X \\ Y \end{bmatrix} = \begin{bmatrix} 0 \\ I_n \end{bmatrix}. \tag{5.2}$$

With respect to these systems and the assumption that $A$ is invertible, we have the following theorem.

THEOREM 5.1. $X^*W = A^{-1}$

[illegible] The system in (5.1) yields the equations

$$W = -F^*Z$$

and

$$EW = I_n, \tag{5.3}$$

which, when combined, yield the equation

$$-EF^*Z = I_n,$$

which implies that

$$-Z = A^{-1}.$$

Likewise the system in (5.2) yields the equations

$$X = -E^*Y, \tag{5.4}$$

$$FX = I_n,$$

$$-FE^*Y = I_n,$$

and

$$-Y = (A^*)^{-1}. \tag{5.5}$$

Hence

$$\begin{aligned} X^*W &= -Y^*EW && \text{(by (5.4))} \\ &= -Y^* && \text{(by (5.3))} \\ &= A^{-1} && \text{(by (5.5))}. \quad \square \end{aligned}$$

**6. Generalized embeddings and pseudoinverses.** The main theorem can also be applied to producing pseudoinverses. Guattery, in a technical report [6], showed that by applying a generalized version of embedding to the orthogonal projector onto the range space of any symmetric matrix, it is possible to generate factors of that matrix's pseudoinverse. He also showed how to extend this result to all Hermitian matrices by splitting them into a real and an imaginary part and working with a system twice as big. Theorem 4.1 allows us to prove the results from this technical report in a simpler way. The new proof covers the Hermitian case directly.

Let $B$ be a Hermitian matrix, with $B = VDV^*$, $D$ Hermitian, and invertible. Let $\begin{bmatrix} W \\ Z \end{bmatrix}$ be the solution to the system

$$\begin{bmatrix} D^{-1} & V^* \\ V & 0 \end{bmatrix} \begin{bmatrix} W \\ Z \end{bmatrix} = \begin{bmatrix} 0 \\ P_{R(B)} \end{bmatrix}, \tag{6.1}$$

where $P_{R(B)}$ is the orthogonal projector onto the range space of $B$. The matrix $W$ here corresponds to what Guattery termed a [illegible].

The following two theorems are direct consequences of Theorem 4.1 and its proof.

THEOREM 6.1. $W^*D^{-1}W = B^+$

[illegible]. Viewing the system above in terms of the system in Theorem 4.1, we can make the substitutions $U = P_{R(B)}$, $D_B = D$, and $D_A = I_n$. Substituting these values in (4.8) from the proof of Theorem 4.1 gives

$$W^*D^{-1}W = P^*_{R(B)}B^+P_{R(B)}.$$

Note that $P_{R(B^+)} = P_{R(B^*)}$ (see [4]). Recall that $P_{R(B)} = P_{R(B^*)}$ since $B$ is Hermitian and that $P^*_{R(B)} = P_{R(B)}$ because orthogonal projectors are Hermitian by definition. These equations also imply that $P_{R(B^+)} = P_{R(B)}$. Hence we have the following:

$$P^*_{R(B)}B^+P_{R(B)} = P_{R(B^+)}B^+P_{R(B)} = B^+P_{R(B)} = B^+.$$

The last equality follows from the fact that $B^+$ is Hermitian, so $R(B^+)$ is a reducing subspace. Proposition 0.2.3 from [4] thus gives us that

$$P_{R(B^+)}B^+ = B^+P_{R(B^+)} = B^+.$$

Since $P_{R(B^+)} = P_{R(B)}$ (as noted above), this proves the theorem. $\square$

In the proof above, note that the factor embedded, $P_{R(B)}$, is also equal to the symmetric product of the factor and its conjugate transpose. This is done to ensure $W$ has the proper dimensions to serve as a factor of the pseudoinverse.

One possibility hidden in the argument is that the rank of $B$ may be less than the rank of $V$. In such cases the matrix $D$ projects part of the range of $V^*$ into the null space of $V$. When this does not happen, however, we can prove an interesting property. Let matrices $V$, $D$, and $B$ be defined as for Theorem 6.1. Let $\left[\begin{smallmatrix} W \\ Z \end{smallmatrix}\right]$ be a solution to (6.1) that is orthogonal to the null space of the block matrix. We have the following theorem.

THEOREM 6.2. rank(B) = rank(V) $-Z = B^{+}$

. Assume that the order of $D$ is $k$ and that $V$ is an $n \times k$ matrix. We can apply Gaussian elimination to the system in (6.1) as follows:

$$\begin{bmatrix} I & 0 \\ -VD & I \end{bmatrix} \begin{bmatrix} D^{-1} & V^{*} \\ V & 0 \end{bmatrix} \begin{bmatrix} W \\ Z \end{bmatrix} = \begin{bmatrix} I & 0 \\ -VD & I \end{bmatrix} \begin{bmatrix} 0 \\ P_{R(B)} \end{bmatrix}$$

to get the following block upper triangular system:

$$\begin{bmatrix} D^{-1} & V^{*} \\ 0 & -B \end{bmatrix} \begin{bmatrix} W \\ Z \end{bmatrix} = \begin{bmatrix} 0 \\ P_{R(B)} \end{bmatrix},$$

The rank of the block matrix (referred to as $M$ below) is greater than or equal to the sum of the ranks of $B$ and $D^{-1}$ (see, e.g., [9]). Since $D^{-1}$ has full rank, this also implies that the dimension of the null space of $M$ is less than or equal to the size of the null space of $B$.

Note that we have $-BZ = P_{R(B)}$.

If $B$ is nonsingular, then the result follows immediately: $P_{R(B)} = I$ and $-BZ = I$. By the uniqueness of the inverse, $Z = -B^{-1}$.

If $B$ has less than full rank, multiplying through on both sides by $B^{+}$ gives the equation

$$-P_{R(B)}Z = B^{+}P_{R(B)} = B^{+},$$

where the last equality follows by the argument given in Theorem 6.1. The theorem therefore holds if the columns of $Z$ are in the range of $B$.

Since $B = VDV^{*}$, the null space of $V^{*}$ is contained in the null space of $B$. The condition in the theorem statement that the ranks of $B$ and $V$ are the same thus implies that the null spaces of $B$ and $V^{*}$ are the same.

We can construct a basis for the null space of the block matrix $M$ as follows: Assume the size of the null space of $B$ is $j \geq 1$. Construct an orthogonal basis for the null space of $B$ consisting of vectors $\vec{v_1} \cdots \vec{v_j}$. Consider the $j$ vectors of the form $\vec{w_i} = \left[\begin{smallmatrix} \vec{0}_k \\ \vec{v_i} \end{smallmatrix}\right]$, where $\vec{0}_k$ is the column vector consisting of $k$ zeros. These vectors are clearly orthogonal. Because $B$ and $V^{*}$ have the same null spaces, each such vector is in the null space of $M$. And because (as noted above) the size of the null space of $M$ is less than or equal to size of the null space of $B$, the $\vec{w_i}$'s span the null space of $M$, and hence form a basis for it.

By assumption, the solution $\left[\begin{smallmatrix} W \\ Z \end{smallmatrix}\right]$ is orthogonal to the null space of $M$. By the structure of the vectors in the null space of $M$, this means that $Z$ is orthogonal to the null space of $B$. Hence $Z$ is in the range of $B$, and the theorem holds. ☐

**7. Approximate inverse preconditioning.** In preconditioning linear systems $Ax = b$, one often constructs a preconditioner $B \approx A$. In the iterative method, one has to solve for (invert) $B$. An alternative is to algebraically construct a matrix $M$ such that $MA \approx I$. Since $M$ approximates the inverse of $A$, one only needs to multiply by $M$ in the iterative method, which has certain advantages (e.g., in parallel computing).

Many strategies have been proposed for constructing approximate inverses; see, e.g., [1]. One practical condition is that $M$ must be sparse. Some try to minimize $\|MA - I\|$ (with certain sparsity constraints) directly, while others construct $M$ as the product of two triangular factors.

An interesting open question is whether our Theorem 6.1 can be used as a starting point for constructing approximate inverses. This theorem provides a novel factorization for the inverse of a symmetric matrix. Are there cases in which we could compute an inexpensive approximation $\tilde{W}$ to $W$? Then $\tilde{W}^* D^{-1} \tilde{W}$ would be an approximation to the inverse.

The key issues to be settled are whether there exist classes of matrices for which a good, sparse approximation to $W$ exists. Additionally, there is the question of which factorization of $A$ (if any) can be used to find good approximate factors, and how the approximation is constructed based on such a factorization.

It is also interesting to consider a similar strategy applied to nonsymmetric matrices using Theorem 5.1. Can good approximations to the factors $X$ and $W$ of our nonsymmetric matrix be generated by approximately solving (5.1) or (5.2)?

We remark that approximate inverses of this type are in factored form but the factors may be rectangular (nonsquare), which would make such an approach distinctively different from existing factored approximate inverses.

# REGULARIZATION IN REGRESSION WITH BOUNDED NOISE: A CHEBYSHEV CENTER APPROACH*

AMIR BECK[†] AND YONINA C. ELDAR[‡]

**Abstract.** We consider the problem of estimating a vector $\mathbf{z}$ in the regression model $\mathbf{b} = \mathbf{A}\mathbf{z}+\mathbf{w}$, where $\mathbf{w}$ is an unknown but bounded noise. As in many regularization schemes, we assume that an upper bound on the norm of $\mathbf{z}$ is available. To estimate $\mathbf{z}$ we propose a relaxation of the Chebyshev center, which is the vector that minimizes the worst-case estimation error over all feasible vectors $\mathbf{z}$. Relying on recent results regarding strong duality of nonconvex quadratic optimization problems with two quadratic constraints, we prove that in the *complex domain* our approach leads to the exact Chebyshev center. In the real domain, this strategy results in a "pretty good" approximation of the true Chebyshev center. As we show, our estimate can be viewed as a Tikhonov regularization with a special choice of parameter that can be found efficiently by solving a convex optimization problem with two variables or a semidefinite program with three variables, regardless of the problem size. When the norm constraint on $\mathbf{z}$ is a Euclidean one, the problem reduces to a single-variable convex minimization problem. We then demonstrate via numerical examples that our estimator can outperform other conventional methods, such as least-squares and regularized least-squares, with respect to the estimation error. Finally, we extend our methodology to other feasible parameter sets, showing that the total least-squares (TLS) and regularized TLS can be obtained as special cases of our general approach.

**Key words.** Chebyshev center, nonconvex quadratic optimization, strong duality, bounded error estimation

## 1. Introduction.

Many problems in data fitting and estimation give rise to a system of linear equations $\mathbf{A}\mathbf{z} \approx \mathbf{b}$ where the right-hand side $\mathbf{b}$ is contaminated by noise. More specifically, we consider the linear model

$$\mathbf{b} = \mathbf{A}\mathbf{z} + \mathbf{w}, \tag{1}$$

where $\mathbf{A} \in \mathbb{F}^{m\times n}$ is the model matrix, $\mathbf{b} \in \mathbb{F}^m$ is the observation vector, $\mathbf{w} \in \mathbb{F}^m$ is the unknown noise (or "error"), and $\mathbf{z} \in \mathbb{F}^n$ is the unknown parameter vector. Here $\mathbb{F}$ denotes either the real number field $\mathbb{R}$ or the complex number field $\mathbb{C}$. Given the observation $\mathbf{b}$, we seek an estimator $\hat{\mathbf{z}}$ of $\mathbf{z}$ that is close in some sense to $\mathbf{z}$. This estimation problem arises in a large variety of areas in science and engineering, e.g., communication, economics, signal processing, seismology, and control.

The celebrated least-squares (LS) approach [5, 18] to estimating $\mathbf{z}$ in the model (1) is to seek the vector $\hat{\mathbf{z}}_{\mathrm{LS}}$ that minimizes the norm of the data error $\|\mathbf{A}\hat{\mathbf{z}} - \mathbf{b}\|^2$, where $\|\mathbf{v}\|$ stands for the Euclidean norm of the vector $\mathbf{v}$. When $\mathbf{A}$ has full column rank, $\hat{\mathbf{z}}_{\mathrm{LS}}$ is given by

$$\hat{\mathbf{z}}_{\mathrm{LS}} = (\mathbf{A}^*\mathbf{A})^{-1}\mathbf{A}^*\mathbf{b}. \tag{2}$$

In practical situations the matrix $\mathbf{A}$ is often ill-conditioned—for example, when the system is obtained via discretization of ill-posed problems such as integral equations of the first kind (see, e.g., [16] and references therein). In these cases the LS solution might give poor results with respect to the estimation error. A well-established approach for stabilizing the LS estimate is to incorporate prior information on the true parameter vector $\mathbf{z}$ into the optimization problem (2) by adding a quadratic constraint:

$$\hat{\mathbf{z}}_{\mathrm{RLS}} \in \operatorname*{argmin}_{\mathbf{z}\in\mathbb{F}^n}\{\|\mathbf{A}\mathbf{z}-\mathbf{b}\|^2 : \|\mathbf{L}\mathbf{z}\|^2 \leq \eta\}. \tag{3}$$

The matrix $\mathbf{L}$ is often chosen as the identity, or as a discrete approximation of some derivative operator (see [5, 16]). The resulting estimator is referred to as the [illegible] LS (RLS) estimator [5]. It is well known that $\hat{\mathbf{z}}_{\mathrm{RLS}}$ is either equal to the LS solution when $\|\mathbf{L}\mathbf{z}_{\mathrm{LS}}\|^2 \leq \eta$ or given by $\hat{\mathbf{z}}_{\mathrm{RLS}} = \mathbf{z}_\lambda$, where $\mathbf{z}_\lambda$ satisfies the generalized normal equations [5]

$$(\mathbf{A}^*\mathbf{A} + \lambda\mathbf{L}^*\mathbf{L})\mathbf{z}_\lambda = \mathbf{A}^*\mathbf{b}. \tag{4}$$

The parameter $\lambda$ is determined by the secular equation $\|\mathbf{L}\mathbf{z}_\lambda\|^2 = \eta$. Therefore, the RLS solution is a [illegible] estimator [28] with a choice of regularization parameter $\lambda$ that takes into account the norm constraint $\|\mathbf{L}\mathbf{z}\|^2 \leq \eta$.

It is important to note that both the LS and the RLS strategies are based on minimizing the data error. However, in an estimation context, typically we would like to minimize the squared [illegible] $\|\hat{\mathbf{z}} - \mathbf{z}\|^2$. When the noise $\mathbf{w}$ in (1) is assumed to be random with zero mean and known covariance matrix, the squared estimation error will also be a random variable. Using the known statistics of $\mathbf{w}$, the average squared estimation error, referred to as the mean-squared error (MSE), can be computed. Several different strategies based on the MSE have been recently proposed [25, 9, 8, 2, 7]. These methods consider [illegible] estimates of $\mathbf{z}$ and assume knowledge of the statistics of $\mathbf{w}$.

**1.1. Bounded error estimation.** In some scenarios, the distribution of the noise might not be known exactly (or at all). There are also cases where the noise is not inherently random (for example, in problems resulting from quantizing a continuous-time signal). This leads to the [illegible] approach which deals with unknown but bounded noise (see, e.g., [19] and the survey papers [21, 24]). In this paper we adopt the bounded error methodology and assume that the noise is norm-bounded $\|\mathbf{w}\|^2 \leq \rho$. As in the RLS strategy, in order to obtain a stable solution, we further restrict $\mathbf{z}$ to have weighted bounded norm.

The first stage in the deterministic bounded error approach is to construct all admissible solutions to the linear system (1); for this reason this approach is also referred to as [illegible] [21]. In our setting, the feasible parameter set (FPS) is given by the intersection of two ellipsoids[1]:

$$\mathrm{FPS} = \{\mathbf{z} \in \mathbb{F}^n : \|\mathbf{L}\mathbf{z}\|^2 \leq \eta, \|\mathbf{A}\mathbf{z}-\mathbf{b}\|^2 \leq \rho\}. \tag{5}$$

The second step is to choose a central representative of the FPS. A popular choice is the Chebyshev center [29], which is defined as the solution $\hat{\mathbf{z}}$ to the following min-max problem:

$$\min_{\hat{\mathbf{z}}\in\mathbb{F}^n} \max_{\mathbf{z}\in\mathrm{FPS}} \|\mathbf{z} - \hat{\mathbf{z}}\|^2. \tag{6}$$

---

[1] Note that here the norm bound $\|\mathbf{w}\|^2 \leq \rho$ translates to $\|\mathbf{A}\mathbf{z}-\mathbf{b}\|^2 \leq \rho$.

Geometrically, the Chebyshev center is the center of the minimum radius ball enclosing the FPS; the optimal value of (6) is the squared radius of the minimal ball enclosing the set. This is illustrated in Figure 1 with the filled area being the intersection of two ellipsoids. The dotted circle is the minimum inscribing circle of the intersection of the ellipsoids.

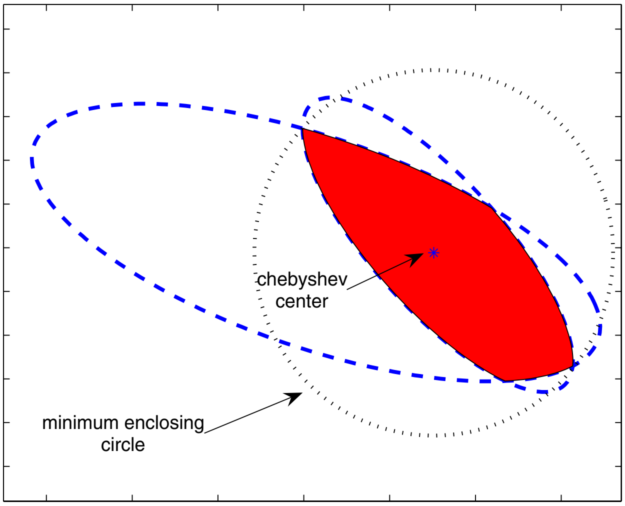

FIG. 1. *The Chebyshev center of the intersection of two ellipsoids.*

The Chebyshev center of the FPS gives the best worst-case estimation error over the set. Thus, it is aimed at optimizing an objective that depends on the estimation error rather than the data error. In section 5 we demonstrate by simulations that an estimator based on the Chebyshev center typically performs worse than the LS and RLS approaches with respect to the data error; however, it appears to perform [illegible] better in terms of the estimation error even when only loose bounds on the norm of the noise ($\rho$) are known. Thus, this approach can improve the estimation error without requiring much more knowledge than the RLS strategy.

Finding a Chebyshev center of a convex set is, in general, a hard problem. Two exceptions are the case where the set is polyhedral and the enclosing ball is the $l_\infty$ ball [20], and the case when the set is finite (see, e.g., [30] and references therein).

The Chebyshev center problem (6) we tackle in this paper is seemingly hard. To better understand the intrinsic difficulty of this min-max problem, note that the inner maximization problem is a [illegible] quadratic optimization problem. However, relying on some recent strong duality results derived in the context of quadratic optimization [1], we will show that despite the nonconvexity of the problem, it can be solved efficiently when $\mathbb{F} = \mathbb{C}$. The same approach can be used when $\mathbb{F} = \mathbb{R}$ to develop an approximation of the Chebyshev center. Simulation results show that this approximation is pretty good in the sense that it yields favorable estimation performance.

**1.2. Paper layout and main results.** A review of the relevant optimization concepts and the strong duality results of [1] is given in section 2. These results are then used in section 3 to reduce the problem of finding the Chebyshev center of the intersection of two level sets of quadratic functions[2] with $\mathbb{F} = \mathbb{C}$ to a convex optimization problem in only two variables. This problem can also be recast as a semidefinite program (SDP) involving linear matrix inequality (LMI) constraints, with three variables.

In section 4 we present the relaxed Chebyshev center (RCC) estimator, which is exactly the Chebyshev center of the FPS in the case $\mathbb{F} = \mathbb{C}$ under strict feasibility constraints. We show that the RCC, like the RLS solution, is a Tikhonov estimator. However, in the RCC approach, as opposed to the RLS method, the regularization parameter is chosen to account for [illegible] constraints defining the FPS. Furthermore, it is designed to minimize an estimation error rather than a data error. We also show that when considering the FPS with a Euclidean norm constraint on $\mathbf{z}$ (i.e., $\mathbf{L} = \mathbf{I}$), the problem reduces to a convex optimization problem with a single variable.

Section 5 presents numerical examples demonstrating the effectiveness of the RCC strategy. We also compare two methods for evaluating the RCC estimator: an implementation of the ellipsoid method [3] (described in full detail in Appendix A) and a standard interior point method applied to the resulting SDP. We show both theoretically and numerically that in our problem the ellipsoid method is more efficient.

Finally, in section 6, we extend our approach to several related problems, and show that the total LS (TLS) [13, 17] and regularized TLS (RTLS) estimators [12] can be viewed as special cases of our general methodology.

**1.3. Notation.** Throughout the paper, the following notation is used: vectors are denoted by boldface lowercase letters, e.g., $\mathbf{y}$, and matrices by boldface uppercase letters, e.g., $\mathbf{A}$. The $i$th component of a vector $\mathbf{y}$ is written as $y_i$, and $\hat{(\cdot)}$ is an estimated vector. The identity matrix is denoted by $\mathbf{I}$. The real and imaginary parts of scalars, vectors, or matrices are written as $\Re(\cdot)$ and $\Im(\cdot)$. For a matrix $\mathbf{A}$, $\mathbf{A}^*, \mathbf{A}^T, \mathbf{A}^\dagger$, and $\mathcal{R}(\mathbf{A})$ are the Hermitian conjugate, transpose, Moore-Penrose generalized inverse [14], and image space. For a square symmetric matrix, $\lambda_{\min}(\mathbf{A})$ is the minimum eigenvalue of $\mathbf{A}$. Given two matrices $\mathbf{A}$ and $\mathbf{B}$, $\mathbf{A} \succ \mathbf{B}$ ($\mathbf{A} \succeq \mathbf{B}$) means that $\mathbf{A} - \mathbf{B}$ is positive definite (semidefinite). The value of the optimal objective function of an optimization problem

$$(P): \min / \max\{f(\mathbf{x}) : \mathbf{x} \in C\}$$

is denoted by $\mathrm{val}(P)$. For simplicity, instead of inf/sup we use min/max; however this does not mean that we assume that the optimum is attained and/or finite.

## 2. Quadratically constrained quadratic programs: A review.

Our goal is to find the Chebyshev center of the FPS (5). The difficulty is that the inner maximization in (6)

$$\max_{\mathbf{z} \in \mathrm{FPS}} \|\mathbf{z} - \hat{\mathbf{z}}\|^2$$

is not convex. In this section, we summarize prior results concerning the minimization of a general quadratic form subject to quadratic constraints. We will then show, in sections 3 and 4, how these results can be applied in order to solve (6).

---

[2] This is a more general form than a set that is an intersection of two ellipsoids.

Consider the general form quadratically constrained quadratic problem

$$(\mathrm{QP}_m) \quad \min_{\mathbf{z}\in\mathbb{F}^n}\{f_0(\mathbf{z}) : f_i(\mathbf{z}) \le 0, i = 1,\dots,m\},$$

where $m$ denotes the number of constraints, and

$$f_i(\mathbf{z}) = \mathbf{z}^*\mathbf{A}_i\mathbf{z} + 2\Re(\mathbf{b}_i^*\mathbf{z}) + c_i$$

with $\mathbf{A}_i = \mathbf{A}_i^* \in \mathbb{F}^{n\times n}, \mathbf{b}_i \in \mathbb{F}^n$, and $c_i \in \mathbb{R}$ for $i = 0,\dots,m$. Note that in the case $\mathbb{F} = \mathbb{R}$, the quadratic functions $f_i(\mathbf{z})$ can be written as $\mathbf{z}^T\mathbf{A}_i\mathbf{z} + 2\mathbf{b}_i^T\mathbf{z} + c_i$.

The problem $(\mathrm{QP}_m)$ is in general not convex since $\mathbf{A}_i$ are not necessarily positive semidefinite. The Lagrangian dual of $(\mathrm{QP}_m)$ is the maximization problem [4, 26]

$$\max_{\boldsymbol{\alpha}}\{q(\boldsymbol{\alpha}) : \boldsymbol{\alpha} \ge 0\}, \tag{7}$$

where $q(\boldsymbol{\alpha})$ is the dual objective function defined by

$$q(\boldsymbol{\alpha}) = \min_{\mathbf{z}\in\mathbb{F}^n}\left\{f_0(\mathbf{z}) + \sum_{i=1}^m \alpha_i f_i(\mathbf{z})\right\}.$$

The function $q(\boldsymbol{\alpha})$ can also be written in the form

$$q(\boldsymbol{\alpha}) = \max_{\lambda}\left\{\lambda : f_0(\mathbf{z}) + \sum_{i=1}^m \alpha_i f_i(\mathbf{z}) \ge \lambda \text{ for every } \mathbf{z} \in \mathbb{F}^n\right\}. \tag{8}$$

To obtain a more convenient representation of $q(\boldsymbol{\alpha})$ we exploit the following well-known lemma.

LEMMA 2.1 (see [3, p. 163]). [illegible] $g : \mathbb{F}^n \to \mathbb{R}$ [illegible] $g(\mathbf{z}) = \mathbf{z}^*\mathbf{A}\mathbf{z} + 2\Re(\mathbf{b}^*\mathbf{z}) + c$ [illegible] $\mathbf{A} = \mathbf{A}^* \in \mathbb{F}^{n\times n}, \mathbf{b} \in \mathbb{F}^n$ [illegible] $c \in \mathbb{R}$ [illegible]

(i) $g(\mathbf{z}) \ge 0$ [illegible] $\mathbf{z} \in \mathbb{F}^n$

(ii) $\begin{pmatrix} \mathbf{A} & \mathbf{b} \\ \mathbf{b}^* & c \end{pmatrix} \succeq \mathbf{0}$

Applying Lemma 2.1 to (8), we can represent $q(\boldsymbol{\alpha})$ as

$$q(\boldsymbol{\alpha}) = \max_{\lambda}\left\{\lambda : \begin{pmatrix} \mathbf{A}_0 & \mathbf{b}_0 \\ \mathbf{b}_0^* & c_0 - \lambda \end{pmatrix} + \sum_{i=1}^m \alpha_i \begin{pmatrix} \mathbf{A}_i & \mathbf{b}_i \\ \mathbf{b}_i^* & c_i \end{pmatrix} \succeq \mathbf{0}\right\}.$$

The dual problem (7) then becomes

$$(\mathrm{D}_m) \quad \max_{\alpha_i\ge 0,\lambda}\left\{\lambda : \begin{pmatrix} \mathbf{A}_0 & \mathbf{b}_0 \\ \mathbf{b}_0^* & c_0 - \lambda \end{pmatrix} + \sum_{i=1}^m \alpha_i \begin{pmatrix} \mathbf{A}_i & \mathbf{b}_i \\ \mathbf{b}_i^* & c_i \end{pmatrix} \succeq \mathbf{0}\right\}.$$

Note that $(\mathrm{D}_m)$, also called Shor's relaxation, is an SDP [3], i.e., a problem involving the minimization of a linear function subject to LMIs.

The [illegible] [4] states that one always has $\mathrm{val}(\mathrm{D}_m) \le \mathrm{val}(\mathrm{QP}_m)$. A fundamental question is whether or not there is [illegible], i.e., is $\mathrm{val}(\mathrm{QP}_m) = \mathrm{val}(\mathrm{D}_m)$? When all the functions $f_i, i = 0,\dots,m$, are convex and strict feasibility holds, the answer is affirmative (this follows from the well-known strong duality theorem for convex programming [26]). However, if even one of the functions is not convex, then strong duality can be violated. Two exceptions are (i) the case of a single quadratic constraint ($m = 1$) (see, e.g., [10, 22]) and (ii) the case of two quadratic constraints ($m = 2$) in which the underlying number field is complex (strong duality is guaranteed when $\mathbb{F} = \mathbb{R}$). The latter result was recently derived in [1] and is recalled in Theorem 2.1.

Theorem 2.1 (see [1]). $\mathbb{F} = \mathbb{C}$ $(QP_2)$ i.e., $\tilde{\mathbf{z}} \in \mathbb{F}^n$ $f_1(\tilde{\mathbf{z}}) < 0, f_2(\tilde{\mathbf{z}}) < 0$

$$\exists \gamma_1 \geq 0, \gamma_2 \geq 0 : \gamma_1 \mathbf{A}_1 + \gamma_2 \mathbf{A}_2 \succ \mathbf{0}. \tag{9}$$

2 2 $(\ \ 2) = (\ \ 2)$

## 3. The two-quadratic Chebyshev center.

We now apply the results of the previous section to the problem of finding the Chebyshev center of the intersection of two level sets of quadratic functions. Specifically, we show that if the underlying number field is complex ($\mathbb{F} = \mathbb{C}$), then the Chebyshev center can be found by solving a convex optimization problem with two variables, or an SDP with three variables, thus rendering the problem tractable. In the case $\mathbb{F} = \mathbb{R}$ the proposed methodology results in an approximation of the exact Chebyshev center.

Consider the set $\Omega$ given as the intersection of level sets of two quadratic functions:

$$\Omega = \{\mathbf{z} \in \mathbb{F}^n : f_i(\mathbf{z}) \leq 0, i = 1, 2\}, \tag{10}$$

where $f_i(\mathbf{z}) = \mathbf{z}^* \mathbf{A}_i \mathbf{z} + 2\Re(\mathbf{b}_i^* \mathbf{z}) + c_i$ with $\mathbf{A}_i = \mathbf{A}_i^* \in \mathbb{F}^{n \times n}, \mathbf{b}_i \in \mathbb{F}^n$, and $c_i \in \mathbb{R}$ for $i = 1, 2$. We assume that condition (9) holds true. This is the case, for example, when at least one of the functions is strictly convex, which is equivalent to saying that the corresponding level set is a nondegenerate ellipsoid.

The Chebyshev center of $\Omega$ is the vector $\hat{\mathbf{z}} \in \mathbb{F}^n$ which is the solution to

$$\min_{\hat{\mathbf{z}} \in \mathbb{F}^n} \max_{\mathbf{z} \in \Omega} \|\mathbf{z} - \hat{\mathbf{z}}\|^2. \tag{11}$$

Theorem 3.1 below shows that finding the Chebyshev center of $\Omega$ can be recast as a convex optimization problem with only two variables. In order to prove the theorem, we will require the following lemma on Schur complements of singular matrices.

Lemma 3.1 (see [6, Appendix A.5]).

$$\mathbf{X} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{B}^* & \mathbf{C} \end{pmatrix},$$

$\mathbf{A} = \mathbf{A}^* \in \mathbb{F}^{k \times k}, \mathbf{B} \in \mathbb{F}^{k \times p}$ $\mathbf{C} = \mathbf{C}^* \in \mathbb{F}^{p \times p}$ $\mathbf{X} \succeq \mathbf{0}$

$$\mathbf{A} \succeq \mathbf{0}, \quad \mathbf{C} - \mathbf{B}^* \mathbf{A}^\dagger \mathbf{B} \succeq \mathbf{0}, \quad (\mathbf{I} - \mathbf{A}\mathbf{A}^\dagger)\mathbf{B} = \mathbf{0}.$$

3.1. Note that the condition $(\mathbf{I} - \mathbf{A}\mathbf{A}^\dagger)\mathbf{B} = \mathbf{0}$ is equivalent to saying that $\mathbf{A}\mathbf{Y} = \mathbf{B}$ for some $\mathbf{Y} \in \mathbb{F}^{p \times k}$.

Theorem 3.1. $\Omega$ (10) $\mathbb{F} = \mathbb{C}$ $\tilde{\mathbf{z}} \in \mathbb{F}^n$ $f_1(\tilde{\mathbf{z}}) < 0$ $f_2(\tilde{\mathbf{z}}) < 0$ (9) (11)

$$\hat{\mathbf{z}} = -\left(\alpha_1 \mathbf{A}_1 + \alpha_2 \mathbf{A}_2\right)^{-1} \left(\alpha_1 \mathbf{b}_1 + \alpha_2 \mathbf{b}_2\right), \tag{12}$$

[illegible] $(\alpha_1, \alpha_2)$ [illegible]

$$\text{(13)}\quad \begin{array}{ll} \min_{\alpha_1,\alpha_2} & \left\{-c_1\alpha_1 - c_2\alpha_2 + (\alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2)^*(\alpha_1\mathbf{A}_1 + \alpha_2\mathbf{A}_2)^{-1}(\alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2)\right\} \\ & \alpha_1\mathbf{A}_1 + \alpha_2\mathbf{A}_2 \succeq \mathbf{I}, \alpha_1 \geq 0, \alpha_2 \geq 0. \end{array}$$

[illegible]. Problem (11) can be rewritten as

$$\min_{\hat{\mathbf{z}} \in \mathbb{F}^n} \left\{ \|\hat{\mathbf{z}}\|^2 + \max_{\mathbf{z} \in \Omega} \left\{ \|\mathbf{z}\|^2 - 2\mathbf{z}^*\hat{\mathbf{z}} \right\} \right\}.$$

By using the strong duality result of Theorem 2.1 (note that all the conditions are satisfied), we conclude that the value of the inner maximization

$$\max_{\mathbf{z} \in \Omega} \{\|\mathbf{z}\|^2 - 2\mathbf{z}^*\hat{\mathbf{z}}\}$$

is equal to the value of the dual minimization problem (see section 2):

$$\begin{array}{ll} \min_{\alpha_1,\alpha_2,\lambda} & \lambda \\ \text{s.t.} & \begin{pmatrix} -\mathbf{I} & \hat{\mathbf{z}} \\ \hat{\mathbf{z}}^* & \lambda \end{pmatrix} + \alpha_1 \begin{pmatrix} \mathbf{A}_1 & \mathbf{b}_1 \\ \mathbf{b}_1^* & c_1 \end{pmatrix} + \alpha_2 \begin{pmatrix} \mathbf{A}_2 & \mathbf{b}_2 \\ \mathbf{b}_2^* & c_2 \end{pmatrix} \succeq \mathbf{0}, \\ & \alpha_1 \geq 0, \alpha_2 \geq 0. \end{array}$$

Therefore, we can write (11) as

$$\text{(14)}\quad \begin{array}{ll} \min_{\alpha_1,\alpha_2,\hat{\mathbf{z}},\lambda} & \{\lambda + \|\hat{\mathbf{z}}\|^2\} \\ \text{s.t.} & \begin{pmatrix} -\mathbf{I} + \alpha_1\mathbf{A}_1 + \alpha_2\mathbf{A}_2 & \hat{\mathbf{z}} + \alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2 \\ (\hat{\mathbf{z}} + \alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2)^* & \lambda + \alpha_1 c_1 + \alpha_2 c_2 \end{pmatrix} \succeq \mathbf{0}, \\ & \alpha_1 \geq 0, \alpha_2 \geq 0. \end{array}$$

Using Lemma 3.1 and Remark 3.1, problem (14) is equivalent to

$$\text{(15)}\quad \begin{array}{ll} \min_{\alpha_1,\alpha_2,\hat{\mathbf{z}},\lambda} & \{\lambda + \|\hat{\mathbf{z}}\|^2\} \\ \text{s.t.} & \mathcal{B}_\alpha \succeq \mathbf{0}, \\ & \hat{\mathbf{z}} + \alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2 \in \mathcal{R}(\mathcal{B}_\alpha), \\ & \lambda + \alpha_1 c_1 + \alpha_2 c_2 \geq (\hat{\mathbf{z}} + \alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2)\mathcal{B}_\alpha^\dagger(\hat{\mathbf{z}} + \alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2), \\ & \alpha_1 \geq 0, \alpha_2 \geq 0, \end{array}$$

where we defined

$$\mathcal{B}_\alpha \equiv -\mathbf{I} + \alpha_1\mathbf{A}_1 + \alpha_2\mathbf{A}_2.$$

Noting that at the optimum we will have equality in the third constraint of (15), our problem reduces to

$$\text{(16)}\quad \begin{array}{ll} \min_{\alpha_1,\alpha_2,\hat{\mathbf{z}}} & \left\{-\alpha_1 c_1 - \alpha_2 c_2 + (\hat{\mathbf{z}} + \alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2)\mathcal{B}_\alpha^\dagger(\hat{\mathbf{z}} + \alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2) + \|\hat{\mathbf{z}}\|^2\right\} \\ \text{s.t.} & \mathcal{B}_\alpha \succeq \mathbf{0}, \\ & \hat{\mathbf{z}} + \alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2 \in \mathcal{R}(\mathcal{B}_\alpha), \\ & \alpha_1 \geq 0, \alpha_2 \geq 0. \end{array}$$

The constraint $\hat{\mathbf{z}} + \alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2 \in \mathcal{R}(\mathcal{B}_\alpha)$ is satisfied if and only if there exists $\mathbf{w} \in \mathbb{F}^n$ such that $\hat{\mathbf{z}} + \alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2 = \mathcal{B}_\alpha\mathbf{w}$. Using this observation combined with the identity $\mathcal{B}_\alpha\mathcal{B}_\alpha^\dagger\mathcal{B}_\alpha = \mathcal{B}_\alpha$, (16) becomes

$$\text{(17)}\quad \begin{array}{ll} \min_{\alpha_1,\alpha_2,\mathbf{w}} & \{-\alpha_1 c_1 - \alpha_2 c_2 + \mathbf{w}^*\mathcal{B}_\alpha\mathbf{w} + \| - \alpha_1\mathbf{b}_1 - \alpha_2\mathbf{b}_2 + \mathcal{B}_\alpha\mathbf{w}\|^2\} \\ \text{s.t.} & \mathcal{B}_\alpha \succeq \mathbf{0}, \\ & \alpha_1 \geq 0, \alpha_2 \geq 0. \end{array}$$

Fixing $(\alpha_1, \alpha_2)$ and minimizing with respect to $\mathbf{w}$, we obtain that an optimal $\mathbf{w}$ is any vector satisfying

$$\mathcal{B}_\alpha(\mathbf{I} + \mathcal{B}_\alpha)\mathbf{w} = \mathcal{B}_\alpha(\alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2).$$

Choosing $\mathbf{w} = (\mathbf{I} + \mathcal{B}_\alpha)^{-1}(\alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2)$ together with the identity

$$\mathcal{B}_\alpha(\mathbf{I} + \mathcal{B}_\alpha)^{-1} = \mathbf{I} - (\mathbf{I} + \mathcal{B}_\alpha)^{-1}$$

leads to the following form of (11):

$$\begin{array}{ll} \min_{\alpha_1,\alpha_2} & \{-\alpha_1 c_1 - \alpha_2 c_2 + (\alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2)^*(\alpha_1\mathbf{A}_1 + \alpha_2\mathbf{A}_2)^{-1}(\alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2)\} \\ \text{s.t.} & \alpha_1\mathbf{A}_1 + \alpha_2\mathbf{A}_2 \succeq \mathbf{I}, \\ & \alpha_1 \geq 0, \alpha_2 \geq 0. \end{array} \tag{18}$$

Since the objective in (18) is convex and the constraints are convex conic constraints, the problem (18) is convex. Finally,

$$\begin{aligned} \hat{\mathbf{z}} &= -\alpha_1\mathbf{b}_1 - \alpha_2\mathbf{b}_2 + \mathcal{B}_\alpha\mathbf{w} \\ &= (-\mathbf{I} + \mathcal{B}_\alpha(\mathbf{I} + \mathcal{B}_\alpha)^{-1})(\alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2) \\ &= -(\mathbf{I} + \mathcal{B}_\alpha)^{-1}(\alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2), \end{aligned}$$

completing the proof. ∎

An immediate consequence of Theorem 3.1 is that at the expense of adding an additional variable, we can recast the problem of finding the Chebyshev center of $\Omega$ as an SDP with three variables.

COROLLARY 3.2. [illegible] 3.1 [illegible] (11) [illegible]

$$\hat{\mathbf{z}} = -\left(\alpha_1\mathbf{A}_1 + \alpha_2\mathbf{A}_2\right)^{-1}(\alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2), \tag{19}$$

[illegible] $(\alpha_1, \alpha_2)$ [illegible]

$$\begin{array}{ll} \min_{\alpha_1,\alpha_2,t} & \{-\alpha_1 c_1 - \alpha_2 c_2 + t\} \\ \text{s.t.} & \alpha_1\mathbf{A}_1 + \alpha_2\mathbf{A}_2 \succeq \mathbf{I}, \\ & \begin{pmatrix} \alpha_1\mathbf{A}_1 + \alpha_2\mathbf{A}_2 & \alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2 \\ (\alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2)^* & t \end{pmatrix} \succeq \mathbf{0}, \\ & \alpha_1 \geq 0, \alpha_2 \geq 0. \end{array} \tag{20}$$

[illegible]. The proof follows from rewriting (13) as

$$\begin{array}{ll} \min_{\alpha_1,\alpha_2,t} & \{-\alpha_1 c_1 - \alpha_2 c_2 + t\} \\ \text{s.t.} & \alpha_1\mathbf{A}_1 + \alpha_2\mathbf{A}_2 \succeq \mathbf{I}, \\ & (\alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2)^*(\alpha_1\mathbf{A}_1 + \alpha_2\mathbf{A}_2)^{-1}(\alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2) \leq t, \\ & \alpha_1 \geq 0, \alpha_2 \geq 0, \end{array}$$

and invoking Lemma 3.1. ∎

Since problem (20) is an SDP, it can be solved efficiently via interior point methods [23]. Alternatively, we may solve the convex optimization problem (13) using the ellipsoid method [3], which is attractive given the small number of variables (two). In section 5 we compare these approaches.

The Chebyshev center of $\Omega$ can be calculated using Theorem 3.1 only when $\mathbb{F} = \mathbb{C}$. In the real case ($\mathbb{F} = \mathbb{R}$), strong duality is not guaranteed, and therefore the vector $\hat{\mathbf{z}}$

defined by (12), with $(\alpha_1, \alpha_2)$ being the optimal solution of (13) (or of (20)), is not necessarily the exact Chebyshev center. In fact, the weak duality theorem implies that the resulting ball will enclose the set but will not necessarily be the smallest one possible. In Figure 2, four examples of intersections of ellipsoids in the real domain are given. The vector $\hat{\mathbf{z}}$ was calculated by solving the SDP problem (20) with the software package SeDuMi [27]. The radius of each ball is the square root of the corresponding optimal value of problem (20). In the two upper examples it seems that strong duality holds while in the two lower examples it is evident that the circle defined by Theorem 3.1 (or Corollary 3.2) is not minimal.

An important property of an solution $(\bar{\alpha}_1, \bar{\alpha}_2)$ of problem (13) is that the matrix $\bar{\alpha}_1\mathbf{A}_1 + \bar{\alpha}_2\mathbf{A}_2 - \mathbf{I}$ is positive definite, i.e., the minimum eigenvalue of $\bar{\alpha}_1\mathbf{A}_1 + \bar{\alpha}_2\mathbf{A}_2 - \mathbf{I}$ is zero. This is proved in Theorem 3.3 below. This result is valid both in the complex and real domains. In section 4.2 we use this result in order to further reduce (13) to a convex optimization problem when $\mathbf{L} = \mathbf{I}$.

Theorem 3.3. $\tilde{\mathbf{z}} \in \mathbb{F}^n$ $f_1(\tilde{\mathbf{z}}) < 0$ $f_2(\tilde{\mathbf{z}}) < 0$ (9) $(\bar{\alpha}_1, \bar{\alpha}_2)$ (13) $\lambda_{\min}(\bar{\alpha}_1\mathbf{A}_1 + \bar{\alpha}_2\mathbf{A}_2 - \mathbf{I}) = 0$

Denote the objective function in (13) by

$$h(\boldsymbol{\alpha}) = -c_1\alpha_1 - c_2\alpha_2 + (\alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2)^*(\alpha_1\mathbf{A}_1 + \alpha_2\mathbf{A}_2)^{-1}(\alpha_1\mathbf{b}_1 + \alpha_2\mathbf{b}_2).$$

Then the following hold:

(i) $h(\boldsymbol{\alpha})$ is homogeneous, i.e., $h(\lambda\boldsymbol{\alpha}) = \lambda h(\boldsymbol{\alpha})$ for every $\lambda \neq 0$ and feasible $\boldsymbol{\alpha}$.

(ii) $h(\bar{\boldsymbol{\alpha}}) > 0$.

The first property is obvious by a simple substitution. To prove the second property note that by the weak duality theorem, $h(\bar{\boldsymbol{\alpha}})$ is greater than or equal to the value of the min-max problem (11). Let $\hat{\mathbf{z}}$ be the optimal solution of (11). Then $h(\bar{\boldsymbol{\alpha}}) \geq \max_{\mathbf{z}\in\Omega} \|\mathbf{z} - \hat{\mathbf{z}}\|^2$ and $\max_{\mathbf{z}\in\Omega} \|\mathbf{z} - \hat{\mathbf{z}}\|^2$ must be positive since, by our assumptions, $\Omega$ has a nonempty interior.

Suppose that $\bar{\alpha}_1\mathbf{A}_1 + \bar{\alpha}_2\mathbf{A}_2 \succ \mathbf{I}$. Then there exists $0 < \lambda < 1$ such that $\lambda\bar{\alpha}_1\mathbf{A}_1 + \lambda\bar{\alpha}_2\mathbf{A}_2 \succ \mathbf{I}$ so that $(\lambda\bar{\alpha}_1, \lambda\bar{\alpha}_2)$ is a feasible point of (13). However, from properties (i) and (ii),

$$h(\lambda\bar{\boldsymbol{\alpha}}) = \lambda h(\bar{\boldsymbol{\alpha}}) < h(\bar{\boldsymbol{\alpha}}),$$

contradicting the optimality of $\bar{\boldsymbol{\alpha}}$. □

## 4. The RCC estimator.

### 4.1. The RCC: Definition and form.

We now return to the problem of finding the Chebyshev center of FPS (5), which is the solution of the min-max problem (6). The set FPS can be represented as an intersection of two ellipsoids:

$$\text{FPS} = \{\mathbf{z} \in \mathbb{F}^n : \mathbf{z}^*\mathbf{L}^*\mathbf{L}\mathbf{z} \leq \eta, \quad \mathbf{z}^*\mathbf{A}^*\mathbf{A}\mathbf{z} - 2\Re(\mathbf{b}^*\mathbf{A}\mathbf{z}) + \|\mathbf{b}\|^2 \leq \rho\}.$$

We assume that condition (9) is satisfied, which means that

$$\exists\gamma_1 \geq 0, \gamma_2 \geq 0, \quad \gamma_1\mathbf{L}^*\mathbf{L} + \gamma_2\mathbf{A}^*\mathbf{A} \succ \mathbf{0}. \tag{21}$$

By Theorem 3.1, if $\mathbb{F} = \mathbb{C}$ and there exists $\tilde{\mathbf{z}}$ such that $\|\mathbf{A}\tilde{\mathbf{z}} - \mathbf{b}\|^2 < \rho$, $\|\mathbf{L}\tilde{\mathbf{z}}\|^2 < \eta$, then the Chebyshev center of FPS has the form

$$\hat{\mathbf{z}} = \alpha_2(\alpha_1\mathbf{L}^*\mathbf{L} + \alpha_2\mathbf{A}^*\mathbf{A})^{-1}\mathbf{A}^*\mathbf{b},$$

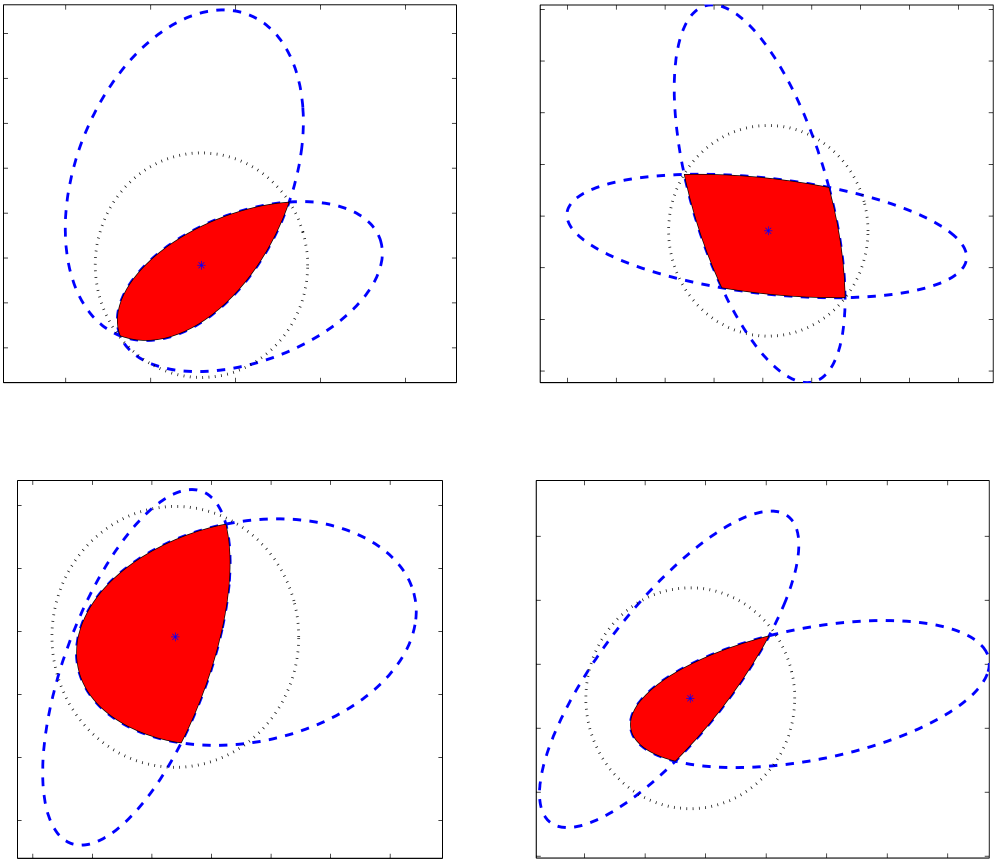

Fig. 2. *Four examples of intersection of ellipsoids (dashed lines). The filled area is the intersection of the ellipsoids. The center of the dotted circle is given by* (12) *with* $(\alpha_1, \alpha_2)$ *being an optimal solution of* (13) *and the radius being the square root of the corresponding optimal value.*

where $(\alpha_1, \alpha_2)$ is an optimal solution of the problem

$$\begin{array}{lll} & \min_{\alpha_1,\alpha_2} & \left\{\alpha_1\eta + \alpha_2(\rho - \|\mathbf{b}\|^2) + \alpha_2^2\mathbf{b}^*\mathbf{A}(\alpha_1\mathbf{L}^*\mathbf{L} + \alpha_2\mathbf{A}^*\mathbf{A})^{-1}\mathbf{A}^*\mathbf{b}\right\} \\ (22) & \text{s.t.} & \alpha_1\mathbf{L}^*\mathbf{L} + \alpha_2\mathbf{A}^*\mathbf{A} \succeq \mathbf{I}, \\ & & \alpha_1, \alpha_2 \geq 0. \end{array}$$

We now define $\hat{\mathbf{z}}$ for both the real and complex domains, and for the case when the conditions stated above are not necessarily satisfied.

Definition 4.1. [illegible]

$$\hat{\mathbf{z}}_{\mathrm{RCC}} = \alpha_2(\alpha_1\mathbf{L}^*\mathbf{L} + \alpha_2\mathbf{A}^*\mathbf{A})^{-1}\mathbf{A}^*\mathbf{b},$$

[illegible] $(\alpha_1, \alpha_2)$ [illegible] (22)

If the optimal $\alpha_2$ is positive, then the RCC estimator can be written as

$$\hat{\mathbf{z}}_{\mathrm{RCC}} = (\mathbf{A}^*\mathbf{A} + (\alpha_1/\alpha_2)\mathbf{L}^*\mathbf{L})^{-1}\mathbf{A}^*\mathbf{b}. \tag{23}$$

Therefore, the RCC estimator is essentially a Tikhonov regularization with a special choice of $\lambda$ that also takes into account the bounded noise constraint. This is in contrast to the choice of the regularization parameter in the RLS estimator that exploits only the norm constraint $\|\mathbf{Lz}\|^2 \leq \eta$.

In section 5 we demonstrate that although the RCC estimator is only an approximation of the Chebyshev center in the real domain, it can still significantly outperform the LS and RLS methods with respect to the estimation error. This is the case even when the bound on the noise is loose; thus, with almost the same information as used by the RLS approach, we can significantly reduce the estimation error by using our proposed strategy. The two key ingredients that lead to the improved performance are treating the estimation error directly and the added constraint on the noise.

**4.2. The case $\mathbf{L} = \mathbf{I}$.** We now show that in the interesting special case $\mathbf{L} = \mathbf{I}$, the task of calculating the RCC estimator reduces to a single-variable convex minimization problem. To this end we rely on Theorem 3.3.

THEOREM 4.1. $\mathbf{L} = \mathbf{I}$ $\delta = \lambda_{\min}(\mathbf{A}^*\mathbf{A})$

$$\hat{\mathbf{z}}_{\mathrm{RCC}} = \begin{cases} (\mathbf{A}^*\mathbf{A} + \lambda\mathbf{I})^{-1}\mathbf{A}^*\mathbf{b}, & 0 \leq \lambda < \infty, \\ \mathbf{0}, & \lambda = \infty, \end{cases}$$

$\lambda$ [3]

(i) $\delta > 0$ $\lambda = 1/\mu - \delta$ $\mu$

$$\min_{0 \leq \mu \leq 1/\delta} \left\{(1-\delta\mu)\eta + \mu(\rho - \|\mathbf{b}\|^2) + \mu^2\mathbf{b}^*\mathbf{A}(\mu(\mathbf{A}^*\mathbf{A} - \delta\mathbf{I}) + \mathbf{I})^{-1}\mathbf{A}^*\mathbf{b}\right\}. \tag{24}$$

(ii) $\delta = 0$ $\lambda = 1/\xi$ $\xi$

$$\min_{\xi \geq 0} \left\{\xi(\rho - \|\mathbf{b}\|^2) + \xi^2\mathbf{b}^*\mathbf{A}(\xi\mathbf{A}^*\mathbf{A} + \mathbf{I})^{-1}\mathbf{A}^*\mathbf{b}\right\}. \tag{25}$$

Substituting $\mathbf{L} = \mathbf{I}$ into (22) we find

$$\begin{array}{ll} \min_{\alpha_1,\alpha_2} & \left\{\alpha_1\eta + \alpha_2(\rho - \|\mathbf{b}\|^2) + \alpha_2^2\mathbf{b}^*\mathbf{A}(\alpha_2\mathbf{A}^*\mathbf{A} + \alpha_1\mathbf{I})^{-1}\mathbf{A}^*\mathbf{b}\right\} \\ \text{s.t.} & \alpha_2\mathbf{A}^*\mathbf{A} + \alpha_1\mathbf{I} \succeq \mathbf{I}, \\ & \alpha_1, \alpha_2 \geq 0. \end{array} \tag{26}$$

The LMI constraint can be written equivalently as

$$\alpha_2\lambda_{\min}(\mathbf{A}^*\mathbf{A}) + \alpha_1 = \alpha_2\delta + \alpha_1 \geq 1. \tag{27}$$

From Theorem 3.3, we conclude that (27) must be satisfied with equality. Therefore,

$$\alpha_1 = 1 - \delta\alpha_2. \tag{28}$$

Substituting (28) into (26) we obtain that in the case $\delta > 0$, (26) becomes

$$\begin{array}{ll} \min_{\alpha_2} & \left\{(1-\delta\alpha_2)\eta + \alpha_2(\rho - \|\mathbf{b}\|^2) + \alpha_2^2\mathbf{b}^*\mathbf{A}(\alpha_2(\mathbf{A}^*\mathbf{A} - \delta\mathbf{I}) + \mathbf{I})^{-1}\mathbf{A}^*\mathbf{b}\right\} \\ \text{s.t.} & 0 \leq \alpha_2 \leq 1/\delta, \end{array}$$

---

[3] We use the standard terminology $\frac{a}{0} = \infty$ whenever $a > 0$.

which is the same as (24) after $\mu$ is replaced by $\alpha_2$. The result for the case $\delta = 0$ is similarly derived. $\square$

To solve the single-variable convex problems (24) and (25), we can use any solver of one-dimensional convex minimization problems—for instance, a simple bisection algorithm on the derivative of the function. Denoting by $q(\mu)$ and $q'(\mu)$ the objective in (24) and its derivative, respectively, we have

$$\begin{aligned} q'(\mu) = {} & -\delta\eta + \rho - \|\mathbf{b}\|^2 + 2\mu\mathbf{b}^*\mathbf{A}(\mu(\mathbf{A}^*\mathbf{A} - \delta\mathbf{I}) + \mathbf{I})^{-1}\mathbf{A}^*\mathbf{b} \\ & -\mu^2\mathbf{b}^*\mathbf{A}(\mu(\mathbf{A}^*\mathbf{A} - \delta\mathbf{I}) + \mathbf{I})^{-1}(\mathbf{A}^*\mathbf{A} - \delta\mathbf{I})(\mu(\mathbf{A}^*\mathbf{A} - \delta\mathbf{I}) + \mathbf{I})^{-1}\mathbf{A}^*\mathbf{b}. \end{aligned}$$

Since $\mu(\mathbf{A}^*\mathbf{A} - \delta\mathbf{I}) + \mathbf{I}$ is a positive definite matrix for every choice of $\mu \geq 0$, we can calculate the derivative using a single Cholesky factorization in the following manner.

[illegible] $q'(\mu)$.

```
1. Calculate a Cholesky factorization $\mathbf{D}^*\mathbf{D} = \mu(\mathbf{A}^*\mathbf{A} - \delta\mathbf{I}) + \mathbf{I}$.
2. Solve the system $\mathbf{D}^*\mathbf{y} = \mathbf{A}^*\mathbf{b}$.
3. Solve the system $\mathbf{D}\mathbf{x} = \mathbf{y}$.
4. The derivative is given by $q'(\mu) = -\delta\eta + \rho - \|\mathbf{b}\|^2 + 2\mu\mathbf{b}^*\mathbf{A}\mathbf{x} - \mu^2\mathbf{x}^*(\mathbf{A}^*\mathbf{A} - \delta\mathbf{I})\mathbf{x}$.
```

Note that the Cholesky factorization is the most expensive component in the calculation of $q'(\mu)$ (the calculation of $\mathbf{A}^*\mathbf{A}$ is done in a preprocess). The other operations—solution of triangular systems and matrix/vector multiplications—are significantly cheaper. An alternative approach for computing the derivative is using the singular value decomposition of $\mathbf{A}$. This approach is viable for small-size problems but is not applicable for medium- and large-scale problems in which the Cholesky or the sparse Cholesky factorization can be employed. The complete description of the algorithm for calculating the RCC estimator when $\mathbf{L} = \mathbf{I}$ and $\delta > 0$ is as follows.

**Algorithm RCC-S.**

**Input:** $\mathbf{A} \in \mathbb{F}^{m\times n}$, the model matrix; $\mathbf{b} \in \mathbb{F}^m$, the (noisy) right-hand side vector; $\eta$, an upper bound on $\|\mathbf{z}\|^2$; and $\rho$, an upper bound on the squared-norm of the noise $\|\mathbf{A}\mathbf{z} - \mathbf{b}\|^2$.

**Output:** The RCC estimator $\hat{\mathbf{z}}_{\mathrm{RCC}}$, which is the solution to problem (22) with $\mathbf{L} = \mathbf{I}$.

```
1. If $q'(0) \geq 0$ then $h = 0$, and go to step 5.
2. If $q'(1/\delta) \leq 0$ then $h = 1/\delta$, and go to step 5.
3. Set $lb = 0, ub = 1/\delta$.
4. Repeat the following steps until $|ub - lb| < \eta$:
    (a) Set $h = \frac{lb+ub}{2}$.
    (b) Calculate $d = q'(h)$.
    (c) If $d \geq 0$ then $ub = h$; else $lb = h$.
5. Set $\hat{\mathbf{z}}_{\mathrm{RCC}} = (\mathbf{A}^*\mathbf{A} + (1 - \delta h)/h\mathbf{I})^{-1}\mathbf{A}^*\mathbf{b}$.
```

A similar algorithm can be defined for the case $\delta = 0$.

**5. Numerical examples.** We now present some examples comparing the RCC estimator with the LS and RLS methods, given by (2) and (3), respectively. The comparison was employed on two sets of problems: randomly chosen problems and the discretized inverse heat equation from "Regularization tools" [15]. All experiments were performed in MATLAB.

We note that in the simulations we assume knowledge of a very loose bound $\rho$ on the noise so that essentially our method exploits almost the same knowledge as the RLS approach.

**5.1. Random test problems.** We chose a problem with dimensions $m = 10, n = 7$. Each component of $\mathbf{A}$ was randomly generated from a uniform distribution (i.e., $\mathbf{A} = \text{rand}(m, n)$). The "true" vector $\mathbf{z}_{\text{T}}$ is the vector of all ones. In the constraints, $\mathbf{L} = \mathbf{I}$ and $\eta = 2\|\mathbf{z}_{\text{T}}\|^2$. The observed vector $\mathbf{b}$ was generated by

$$\mathbf{b} = \mathbf{A}\mathbf{z}_{\text{T}} + \sigma\mathbf{w},$$

where $\sigma$ takes the values $0.01, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1$ and each component of $\mathbf{w}$ was randomly generated from a standard normal distribution. The upper bound on the squared norm of the noise was chosen as $10\|\mathbf{w}\|^2$ (i.e., 10 times the true squared norm).

Table 1 describes the average of the data error $\|\mathbf{A}\hat{\mathbf{z}} - \mathbf{b}\|^2$ (here $\hat{\mathbf{z}}$ is $\hat{\mathbf{z}}_{\text{LS}}, \hat{\mathbf{z}}_{\text{RLS}}$, or $\hat{\mathbf{z}}_{\text{RCC}}$) and the squared error residual $\|\mathbf{z}_{\text{T}} - \hat{\mathbf{z}}\|^2$ over 100 realizations of $\mathbf{w}$. The best results in each half row are marked in boldface. The RLS approach (3) was implemented using the function lsqi from [15] and the RCC estimator was generated by the RCC-S algorithm of section 4.2.

TABLE 1

*Comparison of the LS, RLS, and RCC estimators with respect to estimation error and data error.*

| $\sigma$ | Squared estimation error | | | Squared data error | | |
|---|---|---|---|---|---|---|
| | LS | RLS | RCC | LS | RLS | RCC |
| 0.01 | **1.9e-3** | **1.9e-3** | **1.9e-3** | **3.0e-4** | **3.0e-4** | **3.0e-4** |
| 0.1 | 2.1e-1 | 2.1e-1 | **1.8e-1** | **3.0e-2** | **3.0e-2** | 3.1e-2 |
| 0.2 | 6.6e-1 | 6.6e-1 | **3.6e-1** | **1.2e-1** | **1.2e-1** | 1.5e-1 |
| 0.3 | 1.8e+0 | 1.8e+0 | **2.0e-1** | **2.6e-1** | **2.6e-1** | 1.2e+0 |
| 0.4 | 3.1e+0 | 2.9e+0 | **2.5e-1** | **5.3e-1** | **5.3e-1** | 2.7e+0 |
| 0.5 | 4.3e+0 | 3.9e+0 | **3.3e-1** | **7.2e-1** | 7.3e-1 | 4.8e+0 |
| 0.6 | 6.5e+0 | 5.0e+0 | **4.7e-1** | **1.1e+0** | 1.2e+0 | 7.3e+0 |
| 0.7 | 9.6e+0 | 5.4e+0 | **5.5e-1** | **1.5e+0** | 1.7e+0 | 1.0e+1 |
| 0.8 | 1.4e+1 | 6.6e+0 | **6.8e-1** | **2.1e+0** | 2.4e+0 | 1.4e+1 |
| 0.9 | 1.5e+1 | 6.7e+0 | **9.0e-1** | **2.4e+0** | 2.9e+0 | 1.8e+1 |
| 1.0 | 1.8e+1 | 6.8e+0 | **9.9e-1** | **2.8e+0** | 3.6e+0 | 2.2e+1 |

It is evident that the LS and RLS estimators are significantly and consistently worse than the RCC method with respect to the estimation error. This is despite the fact that the bound on the data error was chosen to be very large—much larger than the true bound. Thus, this approach does not require much prior information. On the other hand, the LS and RLS estimators result in a smaller data error than the RCC approach. This is not surprising since, as was already mentioned, the RCC method is designed to minimize a measure of estimation error while the LS and RLS strategies are aimed at minimizing the data error, which is less relevant in an [illegible] context.

Note that the RCC method was implemented in the case $\mathbb{F} = \mathbb{R}$. Recall that in the real domain the RCC estimator is only an approximation of the Chebyshev center of the FPS. We also implemented a set of random examples over $\mathbb{F} = \mathbb{C}$. The results were essentially the same as those reported in Table 1. Therefore, it seems that at least from an empirical point of view the RCC strategy is a "good enough" approximation of the Chebyshev center.

As we already pointed out, both the RCC and RLS strategies are Tikhonov estimators with different regularization parameters. In all the simulations in this section we observed that the regularization parameter of the RCC method,[4] denoted by $\lambda_{\text{RCC}}$,

---

[4] $\alpha_2$ was always nonzero in our experiments.

is consistently greater than or equal to the parameter $\lambda_{\mathrm{RLS}}$ of the RLS approach. Furthermore, the RCC estimator was always feasible so that $\|\mathbf{L}\hat{\mathbf{z}}_{\mathrm{RCC}}\|^2 \leq \eta$. The latter observation explains why $\lambda_{\mathrm{RCC}} \geq \lambda_{\mathrm{RLS}}$. To see this, we define $\varphi(\lambda) \equiv \|\mathbf{L}\mathbf{z}_\lambda\|^2$, where $\mathbf{z}_\lambda$ is given by (4). It is straightforward to show that the function $\varphi$ is strictly decreasing under our assumption (21). Now, if $\|\mathbf{L}\hat{\mathbf{z}}_{\mathrm{LS}}\|^2 \leq \eta$, then $\lambda_{\mathrm{RLS}} = 0$, which immediately implies $\lambda_{\mathrm{RCC}} \geq \lambda_{\mathrm{RLS}}$. Otherwise, when $\|\mathbf{L}\hat{\mathbf{z}}_{\mathrm{LS}}\|^2 > \eta$, $\lambda_{\mathrm{RLS}}$ satisfies $\varphi(\lambda_{\mathrm{RLS}}) = \eta$. On the other hand, $\varphi(\lambda_{\mathrm{RCC}}) = \|\mathbf{L}\hat{\mathbf{z}}_{\mathrm{RCC}}\|^2 \leq \eta$, and by the fact that $\varphi$ is decreasing, $\lambda_{\mathrm{RCC}} \geq \lambda_{\mathrm{RLS}}$.

**5.2. Inverse heat equation.** We now treat the problem of estimating the function $f(t)$ that solves the heat equation

$$\int_0^1 k(s-t)f(t) = g(s),$$

with $k(t) = \frac{t^{-3/2}}{2\sqrt{\pi}}\exp\left(-\frac{1}{4t}\right)$. By means of a simple collocation and midpoint rule with $n$ points, the problem reduces to an $n \times n$ linear system $\mathbf{A}\mathbf{z}_{\mathrm{T}} = \mathbf{b}_{\mathrm{T}}$. This system and its solution $\mathbf{z}_{\mathrm{T}}$ are implemented in the function heat(n,1) from [15]. We note that this example is ill-conditioned. We compare the RCC estimator to the RLS method (the results for the LS approach are not given because it produces extremely poor results).

The perturbed right-hand side is chosen as

$$\mathbf{b} = \mathbf{b}_{\mathrm{T}} + 10^{-4}\mathbf{w}, \tag{29}$$

where each component of $\mathbf{w}$ is generated from a standard normal distribution. The matrix $\mathbf{L}$ approximates the first-derivative operator implemented in the function get_l(n,1) from [15]. The upper bound $\eta$ was chosen to be $2\|\mathbf{L}\mathbf{z}_{\mathrm{T}}\|^2$. In Figure 3 three possible values of $\rho$ were employed: $\rho = \|\mathbf{w}\|^2$ (exact squared norm), $\rho = 2\|\mathbf{w}\|^2$, and $\rho = 10\|\mathbf{w}\|^2$. The results of the RCC estimator in these three cases are very similar and are much closer to the true vector $\mathbf{z}_{\mathrm{T}}$ than the RLS solution $\hat{\mathbf{z}}_{\mathrm{RLS}}$. Therefore, it seems that at least in this example, the performance of the RCC method is quite robust with respect to the choice of $\rho$. The fourth plot in Figure 3 describes the three vectors $\mathbf{A}\mathbf{z}_{\mathrm{T}}, \mathbf{A}\hat{\mathbf{z}}_{\mathrm{RLS}}$, and $\mathbf{A}\hat{\mathbf{z}}_{\mathrm{RCC}}$ (for $\rho = 10\|\mathbf{w}\|^2$). It can be readily seen that the three vectors are almost identical, implying that the data errors of the RLS and RCC approaches are both negligible.

**5.3. Ellipsoid versus interior-point methods.** In the case when $\mathbf{L} \neq \mathbf{I}$ (as in the inverse heat equation problem), we are required to solve the convex optimization problem (22) with two variables, or the SDP

$$\begin{array}{ll} \min_{\alpha_1,\alpha_2,t} & \{\alpha_1\eta + \alpha_2(\rho - \|\mathbf{b}\|^2) + t\} \\ \text{s.t.} & \alpha_1\mathbf{L}^*\mathbf{L} + \alpha_2\mathbf{A}^*\mathbf{A} \succeq \mathbf{I}, \\ & \begin{pmatrix} \alpha_1\mathbf{L}^*\mathbf{L} + \alpha_2\mathbf{A}\mathbf{A} & -\alpha_2\mathbf{A}^*\mathbf{b} \\ -\alpha_2\mathbf{A}\mathbf{b}^* & t \end{pmatrix} \succeq \mathbf{0}, \alpha_1 \geq 0, \alpha_2 \geq 0. \end{array} \tag{30}$$

Now, consider an SDP of the general form

$$\min\left\{\mathbf{c}^T\mathbf{x} : \sum_{i=1}^m x_i\mathbf{B}_i \succeq \mathbf{E}\right\},$$

where $\mathbf{c} \in \mathbb{R}^m$ and $\mathbf{E}, \mathbf{B}_i, i = 1, \ldots, m$, are $n \times n$ Hermitian matrices. In order to solve the general form SDP we can use a primal-dual interior-point method, which

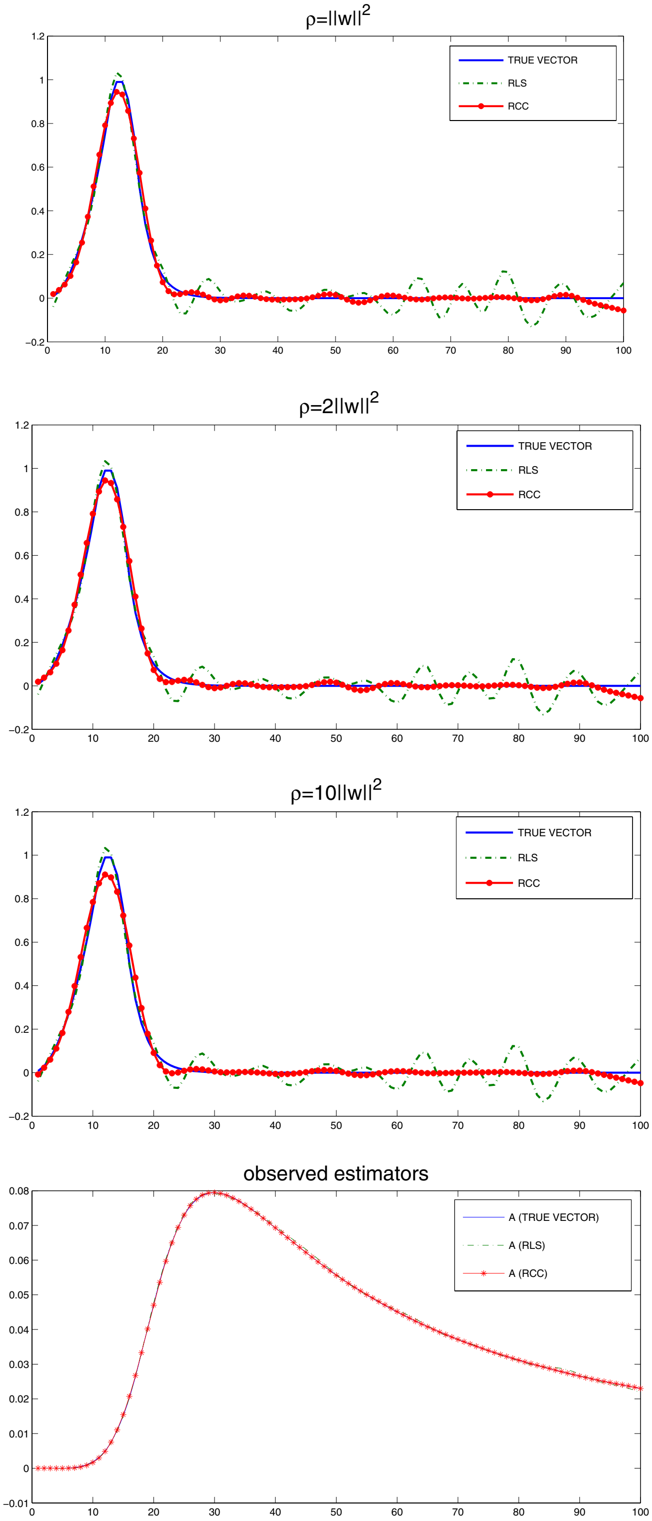

Fig. 3. *Results for the inverse heat problem of the RCC and RLS estimators.*

requires $O(n^{3.5}m^{1.5}+n^{2.5}m^2+n^{0.5}m^{2.5})$ operations per accuracy digit. For the specific problem (30) we have $m=3$, and the amount of operations is therefore $O(n^{3.5})$.

Another alternative is to use the ellipsoid method [3] directly on the problem (22). This algorithm requires $O(n^3)$ operations per accuracy digit since it requires at most two Cholesky factorizations at each iteration. Therefore, it is cheaper than the SDP approach by a factor of order $\sqrt{n}$. To compare the performance of the two algorithms, we implemented the ellipsoid method (see the appendix for full details) and compared it to the interior-point method implemented in SeDuMi [27] on the inverse heat equation problem with various values of $n$. The CPU time in seconds of the ellipsoid and interior-point algorithms averaged over 10 realizations of the noise $\mathbf{w}$ is given in Table 2 below ($\sigma$ was fixed to be 1e-4). For $n=1000$ SeDuMi failed due to memory difficulties. Table 2 demonstrates the efficiency of the ellipsoid method.

TABLE 2

*CPU time in seconds on a Pentium* 4, 1.8*Ghz.*

| $n$ | Ellipsoid | SeDuMi |
|---|---|---|
| 10 | 1.4e-1 | 5.5e-1 |
| 20 | 1.6e-1 | 9.3e-1 |
| 50 | 2.9e-1 | 3.5e+0 |

| 1000 | 2.4e+2 | – |

## 6. Extensions to other estimation problems.

The RCC estimator was constructed to handle the situation in which only the right-hand side of the linear system $\mathbf{Ax}\approx\mathbf{b}$ is contaminated by noise. The same methodology can be applied to deal with other sources of noise. In this section, we briefly outline the resulting estimators in two scenarios: (i) both $\mathbf{A}$ and $\mathbf{b}$ are uncertain, and (ii) $\mathbf{A}$ and $\mathbf{b}$ are uncertain and regularization is required. In the first scenario, the proposed estimator has a similar structure to the well-known TLS method [13, 17], and in the second scenario, the estimator has a form similar to that of the RTLS solution [12]. Thus, these popular methods of handling uncertainties in the basic regression model (1) can be shown to be special cases of our general results.

The derivation of the estimators is very similar to that described in section 3; therefore, we present the main results without proof.

### 6.1. Uncertainty in both A and b.

Suppose that both $\mathbf{A}$ and $\mathbf{b}$ are uncertain and are given by $\mathbf{A}+\boldsymbol{\Delta},\mathbf{b}+\mathbf{w}$ with $\boldsymbol{\Delta},\mathbf{w}$ being unknown but bounded perturbations. This setting is assumed in the robust LS approach [11]. We assume that the bound constraint is given by[5] $\|(\boldsymbol{\Delta},\mathbf{w})\|_{\mathrm{F}}^2\le\rho$. The corresponding FPS is

$$\mathrm{FPS}_1=\{\mathbf{z}\in\mathbb{F}^n:\exists\boldsymbol{\Delta}\in\mathbb{F}^{m\times n},\mathbf{w}\in\mathbb{F}^m:(\mathbf{A}+\boldsymbol{\Delta})\mathbf{z}=\mathbf{b}+\mathbf{w},\|(\boldsymbol{\Delta},\mathbf{w})\|_{\mathrm{F}}^2\le\rho\}.$$

To apply our results, we first note that $\mathrm{FPS}_1$ can be written as the single quadratic constraint

$$\mathrm{FPS}_1=\{\mathbf{z}\in\mathbb{F}^n:\mathbf{z}^*(\mathbf{A}^*\mathbf{A}-\rho\mathbf{I})\mathbf{z}-2\mathbf{z}^*\mathbf{A}^*\mathbf{b}+\|\mathbf{b}\|^2-\rho\le 0\}. \tag{31}$$

This follows from writing $\mathrm{FPS}_1$ as

$$\mathrm{FPS}_1=\{\mathbf{z}\in\mathbb{F}^n:\mathbf{Az}-\mathbf{b}=\mathbf{E}\tilde{\mathbf{z}}\text{ for some }\|\mathbf{E}\|_{\mathrm{F}}^2\le\rho\}$$

---

[5] For a matrix $\mathbf{B}$, $\|\mathbf{B}\|_{\mathrm{F}}$ denotes the Frobenius norm of $\mathbf{B}$.

and applying the following simple lemma.

LEMMA 6.1. [illegible] $\mathbf{x} \in \mathbb{F}^n$ [illegible] $\mathbf{y} \in \mathbb{F}^m$ [illegible] $\eta$ [illegible]

(i) [illegible] $\Delta \in \mathbb{F}^{m \times n}$ [illegible] $\Delta\mathbf{x} = \mathbf{y}$ [illegible] $\|\Delta\|_F \leq \eta$

(ii) [illegible] $\|\mathbf{y}\| \leq \eta\|\mathbf{x}\|$ [illegible]

Under the assumption that $\rho < \lambda_{\min}(\mathbf{A}^*\mathbf{A})$, it can be shown, using the same line of analysis of section 3, that the Chebyshev center of $\text{FPS}_1$ is given by

$$\hat{\mathbf{z}} = (\mathbf{A}^*\mathbf{A} - \rho\mathbf{I})^{-1}\mathbf{A}^*\mathbf{b}, \tag{32}$$

which is a [illegible] of the LS solution. Since $\text{FPS}_1$ consists of a single quadratic constraint, this result is valid both in the real and in the complex domains. We note that when $\rho > \lambda_{\min}(\mathbf{A}^*\mathbf{A})$, $\text{FPS}_1$ is unbounded, and as a result the value of the inner maximization problem in (6) is always $\infty$, which implies that the Chebyshev center in this case is meaningless.

If we choose

$$\rho = \lambda_{\min}\begin{pmatrix} \mathbf{A}^*\mathbf{A} & \mathbf{A}^*\mathbf{b} \\ \mathbf{b}^*\mathbf{A} & \|\mathbf{b}\|^2 \end{pmatrix},$$

then the estimator (32) coincides with the TLS estimator [17, Theorem 2.7].

### 6.2. Uncertainty in both A and b with regularization.

Suppose now we add regularization to the previous scenario; i.e., we consider the feasible set

$$\text{FPS}_2 = \{\mathbf{z} \in \mathbb{F}^n : \|\mathbf{L}\mathbf{z}\|^2 \leq \eta, \exists \mathbf{\Delta} \in \mathbb{F}^{m\times n}, \mathbf{w} \in \mathbb{F}^m : (\mathbf{A}+\mathbf{\Delta})\mathbf{z} = \mathbf{b}+\mathbf{w}, \|(\mathbf{\Delta}, \mathbf{w})\|_{\text{F}}^2 \leq \rho\},$$

which can also be written as

$$\text{FPS}_2 = \{\mathbf{z} \in \mathbb{F}^n : \|\mathbf{L}\mathbf{z}\|^2 \leq \eta, \mathbf{z}^*(\mathbf{A}^*\mathbf{A} - \rho\mathbf{I})\mathbf{z} - 2\mathbf{z}^*\mathbf{A}^*\mathbf{b} + \rho - \|\mathbf{b}\|^2 \leq 0\}.$$

In the case $\mathbb{F} = \mathbb{C}$, the Chebyshev center of $\text{FPS}_2$ is given by

$$\hat{\mathbf{z}} = \alpha_2(\alpha_1\mathbf{L}^*\mathbf{L} + \alpha_2(\mathbf{A}^*\mathbf{A} - \rho\mathbf{I}))^{-1}\mathbf{A}^*\mathbf{b}, \tag{33}$$

where $(\alpha_1, \alpha_2)$ is an optimal solution of the convex optimization problem

$$\begin{array}{ll} \min_{\alpha_1,\alpha_2} & \{\alpha_1\eta + \alpha_2(\rho - \|\mathbf{b}\|^2) + \alpha_2^2\mathbf{b}^*\mathbf{A}(\alpha_1\mathbf{L}^*\mathbf{L} + \alpha_2(\mathbf{A}^*\mathbf{A} - \rho\mathbf{I}))^{-1}\mathbf{A}^*\mathbf{b}\} \\ \text{s.t.} & \alpha_1\mathbf{L}^*\mathbf{L} + \alpha_2\mathbf{A}^*\mathbf{A} \succeq \mathbf{I}, \\ & \alpha_1, \alpha_2 \geq 0. \end{array}$$

If $\alpha_2 \neq 0$ then $\hat{\mathbf{z}}$ of (33) can be written as

$$\hat{\mathbf{z}} = (\mathbf{A}^*\mathbf{A} - \rho\mathbf{I} + \alpha_1/\alpha_2\mathbf{L}^*\mathbf{L})^{-1}\mathbf{A}^*\mathbf{b}.$$

This estimator has the same structure as the RTLS method, which solves the equation

$$(\mathbf{A}^*\mathbf{b} - \lambda\mathbf{I} + \mu\mathbf{L}^*\mathbf{L})\mathbf{x}_{\text{RTLS}} = \mathbf{A}^*\mathbf{b}$$

for some choice of parameters $\lambda, \mu$ [12].

**7. Conclusion.** In this paper we discussed a Chebyshev center regularization method that is based on an estimation error criterion. In contrast to previous regularization strategies that invoke a data error–based criterion, here we focus on the estimation error and try to minimize it in some sense. Since the estimation error depends on the unknown vector, we choose as our estimate the Chebyshev center of an FPS, which consists of a constraint both on the data error and on the weighted norm of the true parameter. Although the resulting problem is nonconvex, by exploiting recent duality results, we show that in the complex domain it can be formulated as a solution to a convex optimization problem in two unknowns, and in the real case the same approach can be used to get a "pretty good" approximation of the true Chebyshev center. From a numerical standpoint, we provide two solution methods and compare their performance. The first is based on an SDP and the second on an ellipsoid algorithm. The latter turns out to be more efficient as the problem size grows. Finally, we show that the popular TLS and RTLS methods can also be formulated within our framework.

## Appendix. The ellipsoid method for problem (13).

In this appendix we describe in detail the ellipsoid method as applied to the convex optimization problem (13).

The two basic ingredients in the ellipsoid method are a separation oracle and a first-order oracle (see, e.g., [3]). The main linear algebra procedure we use in both oracles is the Cholesky factorization. We assume that the input to the Cholesky procedure is a symmetric matrix $\mathbf{B}$, and its output consists of three arguments **flag,** $\mathbf{D}$, and $\mathbf{x}$. If $\mathbf{flag} = \mathbf{1}$ then $\mathbf{B}$ is positive definite, $\mathbf{B} = \mathbf{D}^*\mathbf{D}$ with $\mathbf{D}$ being a lower triangular matrix, and $\mathbf{x}$ is NULL. If $\mathbf{flag} = \mathbf{0}$ then $\mathbf{B}$ is not positive definite, $\mathbf{x}$ is a vector satisfying $\mathbf{x}^*\mathbf{B}\mathbf{x} \leq 0$, and $\mathbf{D}$ is NULL.

The input to the separation oracle is a vector $\boldsymbol{\alpha} \in \mathbb{R}^2$. The output is either a statement that the vector is feasible (up to some tolerance) or a hyperplane separating the vector from the feasible set. $\epsilon$ is a tolerance parameter chosen as $10^{-6}$ in our implementation.

```
Algorithm SEP-ORA.
Input: $\boldsymbol{\alpha} = (\alpha_1, \alpha_2)^T \in \mathbb{R}^2$.
Output: flag equals one if $\boldsymbol{\alpha}$ is feasible (up to some tolerance) and zero otherwise.
$\mathbf{d} \in \mathbb{R}^2$ is a separating hyperplane.
    1. If $\alpha_1 \leq -\epsilon$ then flag=0, $\mathbf{d} = (-1, 0)^T$, STOP.
    2. If $\alpha_2 \leq -\epsilon$ then flag=0, $\mathbf{d} = (0, -1)^T$, STOP.
    3. Set $\mathbf{M} = \alpha_1\mathbf{A}_1 + \alpha_2\mathbf{A}_2 - \mathbf{I} + \epsilon\mathbf{I}$.
    4. Invoke the Cholesky factorization procedure with input $\mathbf{M}$ and obtain an
       output {flag, D, x}.
        (a) If flag = 1 then STOP.
        (b) If flag = 0 then $(d_1, d_2) = (\mathbf{x}^*\mathbf{A}_1\mathbf{x}, \mathbf{x}^*\mathbf{A}_2\mathbf{x})$, STOP.
```

The first-order oracle is invoked in the case when the current vector $\boldsymbol{\alpha} = (\alpha_1, \alpha_2)^T$ is feasible. Its main computational effort is the Cholesky factorization of the matrix $\alpha_1\mathbf{A}_1 + \alpha_2\mathbf{A}_2$, which by feasibility of $\boldsymbol{\alpha}$, must be positive definite.

```
Algorithm FO-ORA.
Input: $\boldsymbol{\alpha} = (\alpha_1, \alpha_2)^T \in \mathbb{R}^2$, an $\eta$-feasible solution of (13).
Output: f, the gradient of the objective function of (13) at $\boldsymbol{\alpha}$.
    1. Set $\mathbf{M} = \alpha_1\mathbf{A}_1 + \alpha_2\mathbf{A}_2$.
    2. Invoke the Cholesky factorization procedure with input $\mathbf{M}$ and obtain an
       output $\{\mathbf{flag}, \mathbf{D}, \mathbf{x}\}$.
```

```
3. Solve the following linear systems in $\mathbf{x}_1, \mathbf{x}_2$: $\mathbf{D}^*\mathbf{x}_1 = \mathbf{b}_1, \mathbf{D}^*\mathbf{x}_2 = \mathbf{b}_2$.
4. Solve the following linear systems in $\mathbf{v}_1, \mathbf{v}_2$: $\mathbf{D}\mathbf{v}_1 = \mathbf{x}_1, \mathbf{D}\mathbf{v}_2 = \mathbf{x}_2$.
5. Set
     $f_1 = -c_1 + 2\alpha_1 \mathbf{b}_1^* \mathbf{v}_1 - \alpha_1^2 \mathbf{v}_1^* \mathbf{A}_1 \mathbf{v}_1 + 2\alpha_2 \mathbf{b}_1^* \mathbf{v}_2 - 2\alpha_1\alpha_2 \mathbf{v}_1^* \mathbf{A}_1 \mathbf{v}_2 - \alpha_2^2 \mathbf{v}_2^* \mathbf{A}_1 \mathbf{v}_2,$
     $f_2 = -c_2 + 2\alpha_2 \mathbf{b}_2^* \mathbf{v}_2 - \alpha_2^2 \mathbf{v}_2^* \mathbf{A}_2 \mathbf{v}_2 + 2\alpha_1 \mathbf{b}_1^* \mathbf{v}_2 - 2\alpha_1\alpha_2 \mathbf{v}_1^* \mathbf{A}_2 \mathbf{v}_2 - \alpha_1^2 \mathbf{v}_1^* \mathbf{A}_2 \mathbf{v}_1.$
```

We are now ready to describe the implementation of the ellipsoid method on the convex optimization problem (13).

**Algorithm Ellipsoid**.

**Input:** The optimization problem (13).

**Output:** $\boldsymbol{\alpha} \in \mathbb{R}^2$, a solution to problem (13) (up to some tolerance).

```
1. Set $R = 10^8, \mathbf{B} = R\mathbf{I}_2, \boldsymbol{\alpha} = (0,0)^T, v = \pi 10^{16}$.
2. Repeat the following steps until $v < \epsilon$.
   (a) Invoke the separation oracle SEP-ORA with input $\boldsymbol{\alpha}$ and obtain an output $\{\mathbf{flag}, \mathbf{d}\}$. If $\mathbf{flag} = \mathbf{0}$ then go to step (c).
   (b) Invoke the first-order oracle FO-ORA with input $\boldsymbol{\alpha}$ and obtain an output $\mathbf{d}$.
   (c) $\mathbf{p} = \frac{\mathbf{B}^T\mathbf{d}}{\sqrt{\mathbf{d}^T\mathbf{B}\mathbf{B}^T\mathbf{d}}}$.
   (d) $\boldsymbol{\alpha} = \boldsymbol{\alpha} - \frac{1}{3}\mathbf{B}\mathbf{p}$.
   (e) $\mathbf{B} = \frac{2}{\sqrt{3}}\mathbf{B} + (\frac{2}{3} - \frac{2}{\sqrt{3}})\mathbf{B}\mathbf{p}\mathbf{p}^T$.
   (f) $v = \pi \det(\mathbf{B})$.

# COVARIANCE MATRICES FOR PARAMETER ESTIMATES OF CONSTRAINED PARAMETER ESTIMATION PROBLEMS*

HANS GEORG BOCK[†], EKATERINA KOSTINA[†], AND OLGA KOSTYUKOVA[‡]

**Abstract.** In this paper we show how, based on the conjugate gradient method, to compute the covariance matrix of parameter estimates and confidence intervals for constrained parameter estimation problems as well as their derivatives.

**Key words.** PDE constrained parameter estimation and optimal experiment design problems, covariance matrix of parameter estimates, iterative linear algebra methods

## 1. Introduction.

Parameter estimation and optimal design of experiments are important steps in establishing models that reproduce a given process quantitatively correctly. The aim of parameter estimation is to reliably identify model parameters from sets of noisy experimental data. The "accuracy" of the parameters, i.e., their statistical distribution depending on data noise, can be estimated up to first order by means of an approximation of a covariance matrix for parameter estimates and corresponding confidence regions. In practical applications, however, one often finds that the experiments performed to obtain the required measurements are expensive, but nevertheless do not guarantee satisfactory parameter accuracy. In order to maximize the accuracy of the parameter estimates, additional experiments can be designed with optimal experimental settings or controls (e.g., initial conditions, measurement devices, sampling times, temperature profiles, feed streams, etc.) subject to constraints. As an objective functional, a suitable function of the covariance matrix (e.g., trace, determinant, maximal eigenvalue, etc.) can be used. The possible constraints in this problem describe costs, feasibility of experiments, domain of models, etc. Using Newton-type methods for solving constrained optimal design problems implies the knowledge of the derivatives of the objective function, which is, let us repeat, a function of the covariance matrix. Hence, methods of computing the covariance matrix and its derivatives are of great importance in parameter estimation and optimal design of experiments.

While a representation of the covariance matrix is well known for unconstrained parameter estimation (see, e.g., [2]) we are interested in the covariance matrix for the [illegible]. And this for a good reason! Since the seventies, general nonlinear parameter estimation problems in dynamic processes described by ordinary or partial differential-algebraic equations (DAEs) have attracted much attention from researchers. Applying the so-called boundary value problem approach [3], [4], also

known nowadays as "all-at-once" methods, to such problems leads to [illegible] nonlinear parameter estimation problems, where the implicit constraint is treated by infeasible point methods. One of the issues of this paper is to formulate a suitable representation of the covariance matrix and confidence regions for constrained parameter estimation. Another question is how to numerically compute the covariance matrix.

So far numerical methods for parameter estimation and optimal design of experiments in dynamic processes have been based on direct linear algebra methods for computing the covariance matrix and its derivatives. The direct methods are variants of Gaussian elimination and involve an explicit matrix factorization for solving linear systems of equations. They were originally developed for systems of nonlinear ODEs or DAEs, where direct linear algebra methods are more effective for forward model problems than iterative methods. The iterative methods work by repeatedly improving an approximate solution until it is accurate enough.

On the other hand, for very large scale constrained systems with sparse matrices of special structure, e.g., originating from discretization of partial differential equations (PDEs), direct linear algebra methods based on Gauss elimination or orthogonal decompositions are not competitive with iterative linear algebra methods (see, e.g., [17]) even for forward models. Hence, in case of parameter estimation in PDE models, generalizations of iterative linear algebra methods to the computation of the covariance matrix and its derivatives are crucial for practical applications, and this defines the aim of this paper. One of the intriguing results of this paper is that by solving nonlinear constrained least squares problems by conjugate gradient methods, we get as a by-product the covariance matrix and confidence intervals as well as their derivatives.

The paper is organized as follows. In the next section we introduce constrained parameter estimation problems and sketch their solution with a generalized Gauss–Newton method. A representation of the covariance matrix and confidence regions for constrained parameter estimation problems is described in section 3. An interpretation of the covariance matrix as a solution of a linear system is given in section 4. Further, it is shown there that the columns of the covariance matrix solve special constrained quadratic problems. Based on this observation, a conjugate gradient method for constrained quadratic problems is outlined in section 5, which serves as a prototype of an iterative solution method. Section 6 describes a numerical procedure to compute the covariance matrix as a by-product of a conjugate gradient method used to solve the linearized PDE constrained parameter estimation problems at the iterations of a generalized Gauss–Newton method.

## 2. Constrained parameter estimation problems.

We consider that the model is described by a model response, a nonlinear function $M(x,t) \in \mathbb{R}$ depending on variables $x$ and time $t$. The vector $x$ includes unknown parameters and the so-called state variables, that is, the variables resulting from discretization of dynamic systems. It is assumed that, at times $t_j$, $j = 1, \ldots, m_1$, measurements $\eta_j$, $j = 1, \ldots, m_1$, are available,

$$\eta_j = M(x^{true}, t_j) + \varepsilon_j,$$

which are subject to measurement errors $\varepsilon_j$. Here $x^{true}$ denotes the "true" values of the parameters and state variables. We assume then the errors are independent and normally distributed with zero mean and variances $\sigma$. Then minimization of the weighted least squares functional

$$||F_1(x)||_2^2 := \sum_j \frac{(\eta_j - M(x,t_j))^2}{\sigma^2} \tag{2.1}$$

is known since Gauss [6] to deliver a maximum likelihood estimate. Frequently, the model is given implicitly; then the variables $x$ satisfy equality constraints

$$F_2(x) = 0.$$

For the case under consideration in this paper, $F_2$ represents a discretized PDE boundary value problem. Summing up, the nonlinear constrained parameter estimation problem can be formulated as

$$\begin{aligned} \min_{x\in\mathbb{R}^n} \ & \frac{1}{2}||F_1(x)||_2^2 \\ \text{s.t.} \ & F_2(x) = 0. \end{aligned} \tag{2.2}$$

For simplicity we assume that the functions $F_i : D \subset R^n \to \mathbb{R}^{m_i}$, $i = 1, 2$, are twice-continuously differentiable. Further we assume that $m_2 < n$ and $m_1 + m_2 \geq n$. Note that the inequality $m_2 \geq n$, together with the condition $\operatorname{rank} \partial F_2(x)/\partial x = n$ $\forall\, x \in \mathcal{X} := \{x \in R^n : \ F_2(x) = 0\}$, implies that the feasible set $\mathcal{X}$ consists of isolated points.

The method of choice for the boundary value problem or all-at-once approach to solve problem (2.2) is a generalized Gauss–Newton method, because it almost shows performance of the second order method requiring only provision of the first order derivatives. According to a generalized Gauss–Newton method, a new iterate is (basically) generated by

$$x^{k+1} = x^k + t^k \Delta x^k, \ \ 0 < t^k \leq 1, \tag{2.3}$$

where the increment $\Delta x^k$ is the solution of the linearized problem at $x = x^k$:

$$\begin{aligned} \min_{\Delta x\in\mathbb{R}^n} \ & \frac{1}{2}||F_1(x) + J_1(x)\Delta x||_2^2 \\ \text{s.t.} \ & F_2(x) + J_2(x)\Delta x = 0, \end{aligned} \tag{2.4}$$

and the stepsize $t_k$ is determined by an appropriate line search. Here $J_i(x)$ denotes a Jacobian $J_i(x) = \frac{\partial F_i(x)}{\partial x}$, $i = 1, 2$.

If the Jacobians $J_1$ and $J_2$ satisfy two regularity assumptions on $D$,

$$\operatorname{rank}\ J_2(x) = m_2, \tag{2.5}$$

$$\operatorname{rank}\ J = n, \ \ J = J(x) = \begin{pmatrix} J_1(x) \\ J_2(x) \end{pmatrix}, \tag{2.6}$$

then the linearized problem (2.4) has a unique solution $\Delta x^k$ and a unique Lagrange vector $\lambda^k$ satisfying the following optimality conditions:

$$\begin{aligned} J_1^T(x)J_1(x)\Delta x^k + J_2^T(x)\lambda^k &= -J_1^T(x)F_1(x), \\ J_2(x)\Delta x^k &= -F_2(x). \end{aligned} \tag{2.7}$$

Using (2.7) one can easily show that $\Delta x^k$ can be formally written, with the help of a solution operator $J^+$, as

$$\Delta x^k = -J^+(x^k)F(x^k),\ F(x) = \begin{pmatrix} F_1(x) \\ F_2(x) \end{pmatrix}.$$

The solution operator $J^+$ is a generalized inverse, that is, it satisfies $J^+JJ^+ = J^+$ and is explicitly given by

$$J^+(x) = \begin{pmatrix} \mathbb{I} & 0 \end{pmatrix} \begin{pmatrix} J_1^T(x)J_1(x) & J_2(x)^T \\ J_2(x) & 0 \end{pmatrix}^{-1} \begin{pmatrix} J_1(x)^T & 0 \\ 0 & \mathbb{I} \end{pmatrix}. \tag{2.8}$$

Here $\mathbb{I}$ denotes an identity matrix. Let us note once again that the conditions (2.5) and (2.6) guarantee that the matrix

$$\begin{pmatrix} J_1^T(x)J_1(x) & J_2(x)^T \\ J_2(x) & 0 \end{pmatrix}$$

is nonsingular. By definition, $J^+$ satisfies $J^+J = \mathbb{I}$, which will be used later.

**3. Approximation of the covariance matrix and computation of confidence regions.** It is important for parameter estimation problems to compute not only parameters but also a statistical assessment of the accuracy of these parameter estimates. This can be done by means of the covariance matrix. A representation of the covariance matrix for unconstrained nonlinear parameter estimation problems is well known; see, e.g., [2]. In the following, this notion is generalized to constrained parameter estimation problems.

Let $J$ be the Jacobian at the solution $x^*$ and $J^+$ be the corresponding generalized inverse computed according to (2.8). Due to the statistical errors of the data as input of the parameter estimation problem, the estimate as the result of the solution procedure is a random variable. Indeed, the parameter estimation problem (2.2) can be rewritten in the form

$$\begin{aligned} &\min_x \ \frac{1}{2}||F_1(x,\varepsilon)||_2^2 \\ &\text{s.t.}\ \ F_2(x) = 0, \end{aligned} \tag{3.1}$$

depending on the measurement errors $\varepsilon = (\varepsilon_j, j = 1, \dots, m_1)$. Here

$$F_{1j}(x,\varepsilon) := \frac{M(x,t_j) - \eta_j}{\sigma} = \frac{M(x,t_j) - (M(x^{true},t_j) + \varepsilon_j)}{\sigma},\ j = 1,\dots,m_1,$$

with the measurement errors $\varepsilon \in \mathcal{N}(0,\sigma^2\mathbb{I})$. Consider now solution $x(\varepsilon)$ of problem (3.1) and suppose that $x(\varepsilon) \to x(0) = x^{true}$ when $\|\varepsilon\| \to 0$. For problem (3.1) the optimality conditions, together with constraints, read

$$\mathcal{F}(x,\lambda,\varepsilon) = 0,\ \mathcal{F}(x,\lambda,\ \varepsilon) := \begin{pmatrix} J_1^T(x,\varepsilon)F_1(x,\varepsilon) + J_2^T(x)\lambda \\ F_2(x) \end{pmatrix}. \tag{3.2}$$

For the error $\varepsilon = 0$ we have $x(0) = x^{true}$, $F_2(x^{true}) = 0$, and $F_1(x^{true},0) = 0$, and hence, by the regularity assumptions it follows from (3.2) that $\lambda(0) = 0$. Further, the Jacobian

$$\left.\frac{\partial \mathcal{F}(x,\lambda,\varepsilon)}{\partial(x,\lambda)}\right|_{\varepsilon=0} = \begin{pmatrix} J_1^T(x(0),0)J_1(x(0),0) & J_2(x(0))^T \\ J_2(x(0)) & 0 \end{pmatrix}$$

is nonsingular, and we may apply the implicit function theorem. According to the theorem, in the neighborhood of $\varepsilon_0 = 0$ there exist unique functions $x(\varepsilon)$, $\lambda(\varepsilon)$ satisfying (3.2) and the initial conditions $x(0) = x^{true}$ and $\lambda(0) = 0$, and the derivatives $\frac{\partial x(0)}{\partial \varepsilon} \in \mathbb{R}^{n \times m_1}$ and $\frac{\partial \lambda(0)}{\partial \varepsilon} \in \mathbb{R}^{m_2 \times m_1}$ satisfy the linear system

$$\begin{pmatrix} J_1^T(x(0),0)J_1(x(0),0) & J_2(x(0))^T \\ J_2(x(0)) & 0 \end{pmatrix} \begin{pmatrix} \frac{\partial x(0)}{\partial \varepsilon} \\ \frac{\partial \lambda(0)}{\partial \varepsilon} \end{pmatrix} = - \begin{pmatrix} J_1^T(x(0),0)(-\frac{1}{\sigma}\mathbb{I}) \\ 0 \end{pmatrix}.$$

By Taylor expansion one obtains

$$x(\varepsilon) = x(0) + \frac{\partial x(0)}{\partial \varepsilon}\varepsilon + O(||\varepsilon||^2) = x^{true} + J^+(x^{true}) \begin{pmatrix} \frac{1}{\sigma}\varepsilon \\ 0 \end{pmatrix} + O(||\varepsilon||^2). \tag{3.3}$$

Consequently, up to the first order $x(\varepsilon)$ is normally distributed with expected value $\mathcal{E}(x(\varepsilon)) = x^{true}$ and variances

$$\mathcal{E}\Big((x(\varepsilon) - x^{true})(x(\varepsilon) - x^{true})^T\Big). \tag{3.4}$$

Thus, due to (3.3), (3.4) we may approximate a variance-covariance matrix by the following matrix which we will later call, for the sake of brevity, [illegible] :
