DISTRIBUTIONS OF THE EXTREME EIGENVALUES OF BETA–JACOBI RANDOM MATRICES*

IOANA DUMITRIU† AND PLAMEN KOEV‡

Abstract. We present explicit formulas for the distributions of the extreme eigenvalues of the β–Jacobi random matrix ensemble in terms of the hypergeometric function of a matrix argument. For $\beta = 1, 2, 4$, these formulas specialize to the well-known real, complex, and quaternion Jacobi ensembles, respectively.

Key words. random matrix, Jacobi distribution, MANOVA, multivariate beta, hypergeometric function of a matrix argument, eigenvalue

1. Introduction.

Various multivariate statistical techniques such as canonical correlation analysis, multivariate analysis of variance, etc., are based on the distributions of the extreme eigenvalues of random matrices and, in particular, real and complex Jacobi random matrices [3, 5, 17].

The distribution of the extreme eigenvalues of the real Jacobi random matrices are well known (see section 2.3). The contribution of this paper is to generalize this result by deriving explicit expressions for the extreme eigenvalues of all β–Jacobi matrices in terms of the hypergeometric function of a matrix argument. The real, complex, and quaternion Jacobi random matrices are β–Jacobi distributed for $\beta = 1, 2$, and 4, respectively (see section 2 for the formal definitions of the classical Jacobi and β–Jacobi ensembles).

Other than the classical real case [17], the complex ($\beta = 2$) Jacobi matrices are of interest in wireless communication and signal processing [3, 5]. In general, the β–Jacobi ensembles are prominent in statistical physics in the study of the positions of the particles in a log-Coulomb gas at $2/\beta$ temperature, with Jacobi potentials [9].

The parameter β. Historically, the hypergeometric function of a matrix argument has been defined in terms of a parameter α [2, 10]. Elsewhere in random matrix theory, for example in statistical mechanics, the parameter $\beta = \frac{2}{\alpha}$ is prevalent (and known as the Boltzmann constant). This can sometimes be a source of confusion, thus we emphasize the fact that in this paper we are using the parameter β only.

Organization of the paper. In section 2 we define the Wishart, Jacobi, and β–Jacobi ensembles; we review their matrix models, define the hypergeometric function of a matrix argument, and survey the existing formulas for the distributions of the extreme eigenvalues of the real Jacobi ensemble. We present our main results—

formulas for the distributions of the extreme eigenvalues of the β–Jacobi ensemble—in section 3. We present numerical experiments in section 4.

2. Background. In this section we recall the definitions of the hypergeometric function of a matrix argument; we define the classical Jacobi random matrix ensembles, the β–Jacobi distributions and ensembles, and survey the classical relationships between them.

2.1. Hypergeometric function of a matrix argument. This function (defined below) is a series of Jack functions. The [illegible], $C_\kappa^{(\beta)}(X)$, defined for a partition κ and a symmetric matrix X, is a symmetric, homogeneous polynomial in the eigenvalues $x_1, x_2, \ldots, x_m$ of X. It generalizes the (normalized) Schur function, the zonal polynomial [20, Proposition 1.2], and the quaternion zonal polynomial to which it reduces for $\beta = 1, 2$, and 4, respectively [15].

There are several normalizations of the Jack function; in this paper we use the "C" normalization, i.e., the one for which $\sum_{\kappa \vdash k} C_\kappa^{(\beta)}(X) = (\operatorname{tr} X)^k$. The explicit definition and properties of the Jack function are available from the classical paper by Stanley [20]; we do not need them here.

DEFINITION 2.1 (hypergeometric function of a matrix argument). [illegible] $p \geq 0$ [illegible] $q \geq 0$ [illegible] X [illegible] $m \times m$ [illegible] hypergeometric function of a matrix argument X [illegible] $\beta > 0$ [illegible]

$$ {}_pF_q^{(\beta)}(a_1, \ldots, a_p; b_1, \ldots, b_q; X) \equiv \sum_{k=0}^{\infty} \sum_{\kappa \vdash k} \frac{(a_1)_\kappa^{(\beta)} \cdots (a_p)_\kappa^{(\beta)}}{k!(b_1)_\kappa^{(\beta)} \cdots (b_q)_\kappa^{(\beta)}} \cdot C_\kappa^{(\beta)}(X), $$

[illegible] $\kappa \vdash k$, [illegible] $\kappa = (\kappa_1, \kappa_2, \ldots, \kappa_m)$, $\kappa_1 \geq \kappa_2 \geq \cdots \geq \kappa_m \geq 0$, [illegible] k [illegible]

$$ (a)_\kappa^{(\beta)} \equiv \prod_{i=1}^{m} \prod_{j=1}^{\kappa_i} \left(a - \frac{\beta}{2}(i-1) + j - 1 \right) $$

[illegible] generalized Pochhammer symbol

2.2. The classical Jacobi ensembles and the β–Jacobi ensemble. The classical real, complex, and quaternion Jacobi ensembles are defined as "ratios" of real, complex, and quaternion Wishart matrices, respectively. The β–Jacobi ensembles generalize the eigenvalue distributions of the classical Jacobi ensembles, and are defined for any $\beta > 0$.

DEFINITION 2.2 (real, complex, and quaternion Wishart ensembles). [illegible] Z [illegible] $m \times n$ [illegible] $N(0, I_n \otimes \Sigma)$, $\mathcal{C}N(0, I_n \otimes \Sigma)$, $\mathcal{H}N(0, I_n \otimes \Sigma)$ [illegible] [1] [illegible] $A = Z^D Z$ [illegible] $m \times m$ [illegible] n [illegible] Σ [2] [illegible] $W_m^{(\beta)}(n, \Sigma)$, $\beta = 1, 2, 4$ [illegible]

DEFINITION 2.3 (real, complex, and quaternion Jacobi ensembles). [illegible] $A \sim W_m^{(\beta)}(n_1, \Sigma)$ [illegible] $B \sim W_m^{(\beta)}(n_2, \Sigma)$ [illegible] ($\beta = 1, 2, 4$ [illegible]) [illegible] $C = A(A+B)^{-1}$ [illegible] Jacobi [illegible]

[1] The notation $\mathcal{H}$ stands for William Hamilton, who introduced the quaternions in the 1850s.

[2] The notation Z^D stands for the quaternion conjugate transpose of the matrix Z and reduces to the Hermitian transpose Z^H when Z is complex and the transpose Z^T when Z is real.

The real Jacobi distribution is sometimes called "multivariate Beta distribution" [4, 17] and is closely related to the "MANOVA" (Multivariate ANalysis Of VAriance) distribution [17], which, rather than consider the matrix $A(A+B)^{-1}$, examines the matrix AB^{-1}.

REMARK 2.4.

PROPOSITION 2.5. λ C $\lambda \in [0,1]$ If λ is an eigenvalue of C, then there exists an eigenvalue $\tilde{\lambda}$ of AB^{-1} such that $\lambda = \tilde{\lambda}/(1+\tilde{\lambda})$. Since A and B are positive semidefinite, $\tilde{\lambda}$ is positive as a generalized eigenvalue of the matrix pair (A, B), and the desired conclusion follows. □

The following definition is central to this paper.

DEFINITION 2.6 (β–Jacobi ensembles). $\beta > 0$ $a_1, a_2 > \frac{\beta}{2}(m-1)$ β

$$\frac{1}{\mathcal{I}(m,\beta,a_1,a_2)} \prod_{i=1}^{m} \lambda_i^{a_1 - \frac{\beta}{2}(m-1)-1} (1-\lambda_i)^{a_2 - \frac{\beta}{2}(m-1)-1} \prod_{i<j} |\lambda_i - \lambda_j|^{\beta}, \tag{2.1}$$

$$\mathcal{I}(m,\beta,a_1,a_2) = \frac{\Gamma_m^{(\beta)}\big(1+\frac{\beta}{2}m\big)}{\pi^{\frac{m(m-1)\beta}{2}} \Big(\Gamma\big(1+\frac{\beta}{2}\big)\Big)^m} \cdot \frac{\Gamma_m^{(\beta)}(a_1)\,\Gamma_m^{(\beta)}(a_2)}{\Gamma_m^{(\beta)}(a_1+a_2)}$$

[19]

$$\Gamma_m^{(\beta)}(c) \equiv \pi^{\frac{m(m-1)\beta}{4}} \prod_{i=1}^{m} \Gamma\left(c - \frac{\beta}{2}(i-1)\right) \qquad \Re(c) > \frac{\beta}{2}(m-1)$$

multivariate gamma function $\beta > 0$

From Theorem 3.3.4 in Muirhead [17], the real Jacobi matrices are β–Jacobi distributed for $\beta = 1$. By repeating the same argument for $\beta = 2$ and 4 we obtain the following theorem.

THEOREM 2.7. 2.3 C β $a_1 = \frac{\beta}{2}n_1$ $a_2 = \frac{\beta}{2}n_2$ $\beta = 1, 2$ 4

Following the methods of Dumitriu and Edelman [7], several matrix models were proposed that have β–Jacobi distributions [11, 14, 21]; here we present the one from Sutton [21].

THEOREM 2.8. $J \equiv Z^T Z$ β

$$Z \equiv \begin{bmatrix} c_m & -s_m c'_{m-1} & & \\ & c_{m-1} s'_{m-1} & & \\ & & & -s_2 c'_1 \\ & & & c_1 s'_1 \end{bmatrix},$$

$$c_k \sim \sqrt{\mathrm{Beta}\big(a_1 - \tfrac{\beta}{2}(m-k), a_2 - \tfrac{\beta}{2}(m-k)\big)}, \quad s_k = \sqrt{1-c_k^2},$$
$$c'_k \sim \sqrt{\mathrm{Beta}\big(\tfrac{\beta}{2}k, a_1 + a_2 - \tfrac{\beta}{2}(2m-k-1)\big)}, \quad s'_k = \sqrt{1-c_k'^2},$$

Beta

2.3. Survey of the real case ($\beta = 1$). We now survey the well-known distribution of the largest eigenvalue of the real Jacobi matrix (which is β–Jacobi distributed for $\beta = 1$). We generalize this result to any β in section 3.

Let $A \sim W_m^{(1)}(n_1, \Sigma)$, $B \sim W_m^{(1)}(n_2, \Sigma)$, where $n_1 \geq m$ and $n_2 \geq m$, be independent real Wishart matrices. For the distribution of the largest eigenvalue $\lambda_{\max}$ of the real Jacobi matrix $A(A+B)^{-1}$ we have [4, equation (61)]:

$$P(\lambda_{\max} < x) = \frac{\Gamma_m^{(1)}(\frac{n_1+n_2}{2})\Gamma_m^{(1)}(\frac{m+1}{2})}{\Gamma_m^{(1)}(\frac{n_1+m+1}{2})\Gamma_m^{(1)}(\frac{n_2}{2})} \cdot x^{\frac{mn_1}{2}} \cdot {}_2F_1^{(1)}(\tfrac{n_1}{2}, \tfrac{-n_2+m+1}{2}; \tfrac{n_1+m+1}{2}; xI).$$

Using [1, equation (9)] we obtain an explicit expression for the of $\lambda_{\max}$:

$$\begin{aligned}\operatorname{dens}(\lambda_{\max}) = \frac{mn_1}{2} \cdot \frac{\Gamma_m^{(1)}(\frac{n_1+n_2}{2})\Gamma_m^{(1)}(\frac{m+1}{2})}{\Gamma_m^{(1)}(\frac{n_1+m+1}{2})\Gamma_m^{(1)}(\frac{n_2}{2})} \cdot (1-x)^{\frac{n_2-m-1}{2}} x^{\frac{mn_1}{2}-1} \\ \times {}_2F_1^{(1)}\big(\tfrac{n_1-1}{2}, \tfrac{m-n_2+1}{2}; \tfrac{n_1+m+1}{2}; xI_{m-1}\big).\end{aligned}$$

3. The extreme eigenvalues of the β–Jacobi ensembles. We obtain our main result in this paper by integrating the joint eigenvalue density of a β–Jacobi matrix and expressing the resulting integral in terms of the hypergeometric function of a matrix argument.

The connection with ${}_2F_1^{(\beta)}$ comes from Kaneko [10, Theorem 5]:

$$\begin{aligned}(3.1)\quad & {}_2F_1^{(\beta)}(r, a, a+b, tI_m) \\ & = \frac{1}{\mathcal{I}(m, \beta, a, b)} \int_{[0,1]^m} \prod_{i=1}^m x_i^{\lambda_1}(1-x_i)^{\lambda_2}(1-tx_i)^{-r} \prod_{i<j} |x_j - x_i|^\beta dx_1 \cdots dx_m,\end{aligned}$$

where $a = \lambda_1 + \frac{\beta}{2}(m-1) + 1$ and $b = \lambda_2 + \frac{\beta}{2}(m-1) + 1$.

Now let the $m \times m$ matrix J_β be β–Jacobi distributed with parameters a_1, a_2, and let $\lambda_{\max}$ and $\lambda_{\min}$ be its largest and smallest eigenvalues, respectively.

THEOREM 3.1. $\lambda_{\max}$ $\lambda_{\min}$

$$\begin{aligned}P(\lambda_{\max} < x) &= \frac{\Gamma_m^{(\beta)}(a_1+a_2) \cdot \Gamma_m^{(\beta)}\big(\frac{\beta}{2}(m-1)+1\big)}{\Gamma_m^{(\beta)}\big(a_1 + \frac{\beta}{2}(m-1)+1\big) \cdot \Gamma_m^{(\beta)}(a_2)} \cdot x^{ma_1} \\ &\quad \times {}_2F_1^{(\beta)}\left(a_1, \frac{\beta}{2}(m-1)+1-a_2; a_1 + \frac{\beta}{2}(m-1)+1; xI_m\right), \qquad (3.2) \\ P(\lambda_{\min} < x) &= 1 - \frac{\Gamma_m^{(\beta)}(a_1+a_2) \cdot \Gamma_m^{(\beta)}\big(\frac{\beta}{2}(m-1)+1\big)}{\Gamma_m^{(\beta)}\big(a_2 + \frac{\beta}{2}(m-1)+1\big) \cdot \Gamma_m^{(\beta)}(a_1)} \cdot (1-x)^{ma_2} \\ &\quad \times {}_2F_1^{(\beta)}\left(a_2, \frac{\beta}{2}(m-1)+1-a_1; a_2 + \frac{\beta}{2}(m-1)+1; (1-x)I_m\right).\end{aligned}$$

. We start with the joint eigenvalue density of J_β, (2.1), and note that to compute the distribution of the largest eigenvalue of J_β we need to integrate this density from 0 to xI_m. For $b_i \equiv a_i - \frac{\beta}{2}(m-1) - 1$, $i = 1, 2$, we have

$$P(J_\beta < xI_m) = \frac{1}{\mathcal{I}(m, \beta, a_1, a_2)} \int_{[0,x]^m} \prod_{i=1}^m \lambda_i^{b_1}(1-\lambda_i)^{b_2} \prod_{i<j} |\lambda_i - \lambda_j|^\beta d\lambda_1 \cdots d\lambda_m.$$

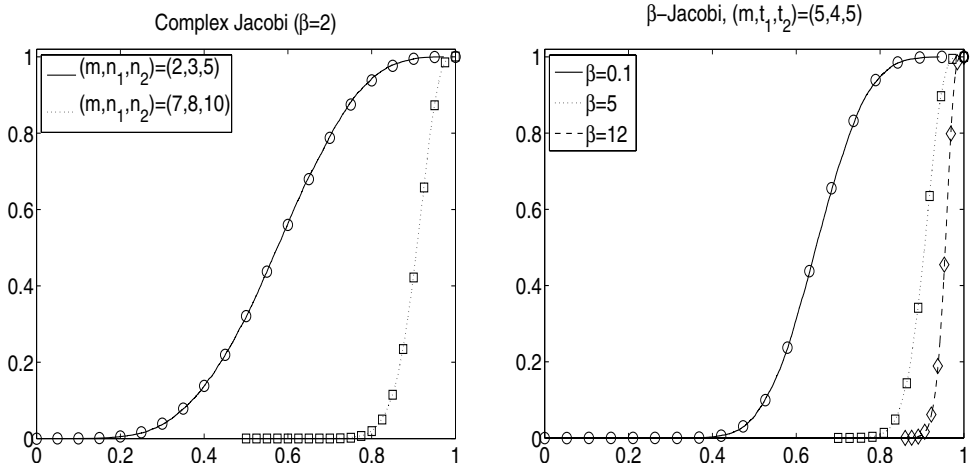

FIG. 1. *Left: Distributions of* $\lambda_{\max}$ *of a complex Jacobi matrix for two sets of parameters* (m, n_1, n_2). *The solid and dotted lines are the empirical distributions with* 10,000 *replications; "*$\circ$*" and "*$\square$*" are the corresponding analytical predictions* (3.2). *Right: Distributions of* $\lambda_{\max}$ *of a* 5×5 β*–Jacobi matrix with* $a_i = t_i + \frac{\beta}{2}(m-1) + 1, i = 1, 2$ *for different values of* β. *The solid, dotted, and dashed lines are the empirical distributions with* 10,000 *replications; "*$\circ$*," "*$\square$*," and "*$\diamond$*" are the corresponding analytical predictions* (3.3).

We make an m-dimensional change of variables $x\tilde{\lambda}_i = \lambda_i$ to obtain

$$P(J_\beta < xI_m) = \frac{x^{ma_1}}{\mathcal{I}(m, \beta, a_1, a_2)} \int_{[0,1]^m} \prod_{i=1}^{m} \tilde{\lambda}_i^{b_1} (1 - x\tilde{\lambda}_i)^{b_2} \prod_{i<j} |\tilde{\lambda}_i - \tilde{\lambda}_j|^\beta d\tilde{\lambda}_1 \cdots d\tilde{\lambda}_m.$$

We evaluate the last integral using (3.1) and get (3.2).

The result for $\lambda_{\min}$ follows immediately by observing that $1 - \lambda_{\min}$ is the largest eigenvalue of $I - J_\beta$, which is β–Jacobi distributed with parameters a_2 and a_1. ∎

When $t \equiv a_2 - \frac{\beta}{2}(m-1) - 1$ is a nonnegative integer, the hypergeometric series in (3.2) terminates and becomes a polynomial of degree mt. Then we can use Proposition 11.47 in Forrester [9] to obtain the expression

$$P(\lambda_{\max} < x) = x^{ma_1} \sum_{k=0}^{mt} \sum_{\kappa \vdash k,\, \kappa_1 \le t} \frac{1}{k!} (a_1)_\kappa^{(\beta)} C_\kappa^{(\beta)}((1-x)I), \tag{3.3}$$

which numerically is often much more feasible than (3.2).

Analogous results extending the well-known distributions of the extreme eigenvalues of real random matrices [4, 17] were obtained for β–Laguerre ensembles in [6, section 10.2] and complex Wishart ensembles in [18].

4. Numerical experiments. We performed extensive numerical tests against Monte-Carlo experiments to confirm the correctness of Theorem 3.2. We report the results of two tests whose results were typical.

In our first experiment we tested formula (3.2) against the empirical distribution of the largest eigenvalue of a complex Jacobi matrix. The more samples we used for the empirical distribution, the better approximation it was to the analytical prediction, with 10,000 samples sufficing for a perfect visual match. We generated our sample matrices in MATLAB [16] as C=A/(A+B), where A and B were complex

Wishart matrices generated as A=Z'*Z/2, where Z=randn(n_1, m)+i*randn(n_1, m), with B generated analogously. We evaluated the analytical formula (3.2), also in MATLAB, using the algorithms for computing ${}_pF_q^{(\beta)}$ from [12, 13]. We plot the results in Figure 1, left.

In our second experiment we demonstrate the β dependence of the largest eigenvalue of a 5×5 β–Jacobi matrix with parameters $a_i = t_i + \frac{\beta}{2}(m-1)+1, i = 1, 2$, where we fixed $t_1 = 4$ and $t_2 = 5$. In Figure 1, right, we plotted the empirical distribution from 10,000 replications which, again, matched the theoretical prediction (3.3) (which we could use since $a_2 - \frac{\beta}{2}(m-1) - 1 = t_2 = 5$ was a nonnegative integer).

In line with the results of [8], this experiment supports a conjecture that as β increases (and so do a_1 and a_2), the largest eigenvalue of the β–Jacobi ensemble approaches $1 = \lim_{a,b \to -1} \lambda^{a,b}$, where $\lambda^{a,b}$ is the largest root of the mth orthogonal Jacobi polynomial $J_m^{a,b}(x)$.

Acknowledgments. We thank Alan Edelman and Iain Johnstone for many illuminating discussions during the preparation of this paper.

RIGIDITY IN FINITE-ELEMENT MATRICES: SUFFICIENT CONDITIONS FOR THE RIGIDITY OF STRUCTURES AND SUBSTRUCTURES*

GIL SHKLARSKI† AND SIVAN TOLEDO†

Abstract. We present an algebraic theory of rigidity for finite-element matrices. The theory provides a formal algebraic definition of finite-element matrices; notions of rigidity of finite-element matrices and of mutual rigidity between two such matrices; and sufficient conditions for rigidity and mutual rigidity. We also present a novel sparsification technique, called *fretsaw extension*, for finite-element matrices. We show that this sparsification technique generates matrices that are mutually rigid with the original matrix. We also show that one particular construction algorithm for fretsaw extensions generates matrices that can be factored with essentially no fill. This algorithm can be used to construct preconditioners for finite-element matrices. Both our theory and our algorithms are applicable to a wide range of finite-element matrices, including matrices arising from finite-element discretizations of both scalar and vector partial differential equations (e.g., electrostatics and linear elasticity). Both the theory and the algorithms are purely algebraic-combinatorial. They manipulate only the element matrices and are oblivious to the geometry, the material properties, and the discretization details of the underlying continuous problem.

Key words. rigidity, finite elements, element matrices, null spaces, combinatorial preconditioners, support preconditioners

1. Introduction.

This paper presents an algebraic-combinatorial theory of rigidity for finite-element matrices and applies this theory to two important problems: determining whether a finite-element matrix represents a rigid structure, and determining whether a matrix representing a structure and a matrix representing a substructure have the same range and null space. The paper addresses these problems by providing simple sufficient conditions for rigidity and null-space equality, and by providing linear-time algorithms (assuming bounded element degrees) to test these conditions.

Our results employ three new technical tools—one combinatorial and two algebraic. One algebraic tool is a purely algebraic definition of the rigidity relationships between two rank-deficient matrices.[1] The other algebraic tool is a definition of a finite-element matrix A as a sum of symmetric semidefinite matrices $\{A_e\}_{e=1}^{k}$ that all satisfy a certain condition. The combinatorial tool is a graph, called the [illegible], that represents the rigidity relationships between the terms A_e of a finite-element matrix $A = \sum_e A_e$. These tools may be applicable to the solution of other problems involving finite-element matrices.

[1]The literature contains another definition of matrix rigidity, originally defined by Valiant [20]. Our definition is completely different and unrelated.

The concept of rigidity is usually associated with elastic structures and with finite-element models of such structures. An elastic structure is rigid if any deformation of it that is not a translation and/or rotation requires energy. A coin is rigid; a door hinge is not. Our theory of rigidity is consistent with the traditional concept of rigidity, but it is purely algebraic and more general. By purely algebraic, we mean that our theory uses only the element matrices A_e and a basis for the rigid body motions (e.g., translations and rotations) of the structure. Our theory and algorithms do not depend on the geometry of the structure or on the details of the finite-element discretization. Our theory generalizes the concept of rigidity in a natural way from finite-element models of elastic structures to models of other physical systems, such as electrostatics.

On the other hand, our theory provides only sufficient conditions for rigidity. Characterizing rigidity exactly is difficult, even if we limit our attention to specific families of elastic structures. Consider, for example, a structure consisting of struts (elastic bars) connected at their endpoints by pin joints. The struts can only elongate or compress, and the struts connected to a pin are free to rotate around the pin. The rigidity of such structures in two dimensions has been extensively studied and is now well understood. However, the conditions that characterize the rigidity of a two-dimensional structure are expensive to check [14], and they do not generalize easily to three-dimensional trusses and to other structures. Our theory of rigidity avoids these difficulties by focusing on characterizations that are simple and general but only sufficient. In fact, structures consisting of struts always fail our sufficient conditions.

Our new theory is essentially an algebraic-combinatorial characterization of finite-element models of structures that are, informally speaking, "evidently rigid." Models of structures that are rigid due to complex nonlocal interactions between parts of the structure will usually fail our conditions. The main contributions of this paper are formal and easily computed characterizations of "evidently rigid" structures. We, therefore, call structures that pass our test [illegible]. We apply these characterizations to the construction of algorithms that find certain minimally rigid substructures of a rigid structure.

The results in this paper are a step toward the generalization of results in spectral graph theory from Laplacians to finite-element matrices. We are particularly interested in an area of spectral graph theory called [illegible] or [illegible]. This area is mostly concerned with constructing an approximation B to a matrix A in three steps: (1) building a graph G_A that represents A, (2) approximating G_A by a simpler graph G_B, and (3) building the matrix B that corresponds to G_B. The graph G_B should be simpler in some way than G_A (e.g., smaller balanced vertex separators), and the generalized eigenvalues λ of $Ax = \lambda Bx$ should not be very large or very small. Much progress has been made in this area, but only when A is a Laplacian [2, 11, 18, 19, 5], is a diagonally dominant symmetric matrix (i.e., G_A is a signed graph) [4, 11], or can be well approximated by a Laplacian [6].

This paper makes three contributions to support preconditioning of finite-element matrices. First, the paper provides a reasonable definition of what a finite-element matrix is: a sum of element matrices whose null spaces are derived from a single global null space. Second, the paper provides a graph model of finite-element matrices and proposes graph algorithms for sparsifying the coefficient matrix A. Third, the paper provides simple combinatorial conditions that allow us to show that the range and null space of the sparsified matrix (the preconditioner) B are the same as those of A. The qualitative range and null-space equalities are weaker statements than quan-

titative bounds on the generalized eigenvalues, but they are a step toward eigenvalue bounds. A weighted rigidity graph may allow us to bound eigenvalues and generalized eigenvalues. The same technical tools may also be applicable to the generalization of other results in spectral graph theory, such as Cheeger-type bounds [7, 9, 1].

We use these three contributions to define algebraic methods to sparsify finite-elements matrices. One method drops elements from the structure. The other method, called fretsaw preconditioning, cuts some of the connections between elements. The fretsaw preconditioning algorithm that we present in the paper constructs, using an almost linear amount of work, a preconditioner that can be applied in linear time in every iteration and which has the same null space as the original matrix (the linear cost is with respect to the number of unknowns assuming a fixed element degree). The construction is purely algebraic—the same algorithm, data structure, and code work on elasticity and electrostatics in two and three dimensions.

The paper is quite technical and fairly complex. It may seem strange that all of this complexity is needed to prove results that are physically intuitive. If a structure is evidently rigid, why is all the algebraic and notational complexity needed? The answer appears to be that the complexity is a result of our insistence on a purely algebraic and combinatorial analysis. We do not rely directly on any physical or continuous properties of the structures that we analyze. Our analysis reaches physically intuitive conclusions, but the algebraic path toward these conclusions is complex. We believe that the generality and software-engineering advantages of a purely algebraic approach are worth the complexity of the paper. Furthermore, the analysis is complex, but the algorithms that we propose are both general and simple.

The paper is organized as follows. Finite-element matrices are sums of very sparse terms called element matrices. Most of the rows and columns in each element matrix contain only zeros. Such matrices have a trivial null space that the zero columns generate and sometimes another null subspace that is more interesting. Our study of rigidity is essentially a study of these nontrivial subspaces. Section 2 defines these subspaces and analyzes their properties. The combinatorial structure that we use, the rigidity graph, is defined by rigidity relationships between pairs of element matrices. These relationships are defined and explored in sections 3 and 4. One of our ultimate goals in this paper is to show that a connected rigidity graph implies that the underlying structure is rigid. Unfortunately, this is not true for collections of arbitrary element matrices; they must have something in common for their rigidity graph to be useful. This common property is called null-space compatibility. Its definition and significance are explained in section 5. The rigidity graph itself is defined in section 6, along with a proof that a connected rigidity graph implies the rigidity of the structure. Section 7 studies three families of finite-element matrices and their rigidity graphs to further illustrate the concepts presented earlier. In section 8 we present two methods for sparsifying a finite-element matrix while preserving its null space. The more sophisticated method, called spanning-tree fretsaw extension, always leads to simplified finite-element matrices that can be factored with essentially no fill. We present four numerical examples of the use of spanning-tree fretsaw extension as preconditioners in section 9. We conclude the paper with a few open problems in section 10.

2. The essential null space of a matrix. Rigidity is closely related to relationships between null spaces. We therefore start our analysis with definitions and lemmas concerning the null space of matrices with zero columns.

DEFINITION 2.1. *Let A be an $m \times n$ matrix, and let $\mathcal{Z}_A \subseteq \{1,\ldots,n\}$ be the largest set of column indices such that there exists a vector x with the following properties. The set $\mathcal{N}_A = \{1,\ldots,n\} \setminus \mathcal{Z}_A$ is called the essential null space of A, and x is called a*

- $Ax = 0$,
- $x_i = 0$, $i \in \mathcal{Z}_A$.

The trivial null space of A is the set $\mathcal{Z}_A$, and a vector x that satisfies $x_i = 0$, $i \in \mathcal{N}_A$ is called an essential null vector, or enull(A), and a trivial null vector, or tnull(A).

Clearly, the essential and trivial null spaces of a matrix are orthogonal, and their span (union) is simply the null space of the matrix.

DEFINITION 2.2. *The restriction of a vector y to the set $\mathcal{N}_A$ is the vector*

$$x_i = \begin{cases} y_i, & i \in \mathcal{N}_A, \\ 0 & \text{otherwise.} \end{cases}$$

(the vector has the same dimension as y) is called the extension with respect to $\mathcal{N}_A$ of x if $x_i = 0$, $i \in \mathcal{Z}_A$, and y is the extension of $y_i = x_i$, $i \in \mathcal{N}_A$.

LEMMA 2.3. *Let y be the extension with respect to $\mathcal{N}_A$ of $x \in \text{enull}(A)$. Then $y \in \text{null}(A)$.*

Proof. Let $z = y - x$, so $y = x + z$. Since $y_i = x_i$ for $i \in \mathcal{N}_e$, we have $z_i = 0$ for $i \in \mathcal{N}_A$. Therefore, $Az = 0$, so $Ay = Ax + Az = 0 + 0 = 0$. ∎

LEMMA 2.4. *Let $y \in \text{null}(A)$. Then $\mathcal{N}_A$ is the union of the supports of two vectors in enull(A).*

Proof. Let $y = y_N + y_Z$ be a splitting of y into a vector y_N with nonzeros only in $\mathcal{N}_A$ and y_Z with nonzeros only in $\mathcal{Z}_A$. Clearly, $Ay_N = Ay_Z = 0$. The result follows from the fact that y_N is the restriction of y to $\mathcal{N}_A$. ∎

LEMMA 2.5. *Let A and B be $n \times n$ matrices such that A is SPSD and $A + B$ is SPSD. Then $\text{null}(A + B) = \text{null}(A) \cap \text{null}(B)$.*

Proof. Let $x \in \text{null}(A + B)$ and suppose for contradiction that $Ax \neq 0$. A has a decomposition $A = LL^T$. Since $Ax \neq 0$, we also have $L^T x \neq 0$, so $x^T LL^T x = x^T Ax > 0$. Therefore, $x^T Bx = x^T (A + B)x - x^T Ax = 0 - x^T Ax < 0$, which is a contradiction. Therefore, $x \in \text{null}(A)$ and, similarly, $x \in \text{null}(B)$. This shows that $\text{null}(A + B) \subseteq \text{null}(A) \cap \text{null}(B)$. The other direction is trivial. ∎

A column that is nonzero in both A and B can be a zero in $A + B$ due to cancellation. The next lemma shows that this cannot happen when the terms are SPSD matrices.

LEMMA 2.6. *Let A and B be $n \times n$ SPSD matrices. Then $\mathcal{N}_{A+B} = \mathcal{N}_A \cup \mathcal{N}_B$.*

Proof. Clearly $\mathcal{N}_{A+B} \subseteq \mathcal{N}_A \cup \mathcal{N}_B$. Suppose for contradiction that the lemma does not hold. Then there is a column index j in $\mathcal{N}_A$ or in $\mathcal{N}_B$ that is not in $\mathcal{N}_{A+B}$. Without loss of generality assume that $j \in \mathcal{N}_A$. Let x be the jth unit vector. Since $j \in \mathcal{N}_A$, Ax, which is simply the jth column of A, is nonzero. But since $j \notin \mathcal{N}_{A+B}$, we also have $(A + B)x = 0$, which is a contradiction to Lemma 2.5. ∎

The last lemma in this section shows the relationship between null-space containment and the sets $\mathcal{N}$ and $\mathcal{Z}$.

LEMMA 2.7. *Let A be an $m \times n$ matrix, and let B be an $l \times n$ matrix. If $\text{null}(B) \subseteq \text{null}(A)$ then $\mathcal{Z}_B \subseteq \mathcal{Z}_A$ and $\mathcal{N}_A \subseteq \mathcal{N}_B$.*

Proof. Let $j \in \mathcal{Z}_B$ and let e_j be the jth unit vector. By definition, $Be_j = 0$. By the assumption on the null spaces, $Ae_j = 0$. This implies that $j \in \mathcal{Z}_A$. Therefore, $\mathcal{Z}_B \subseteq \mathcal{Z}_A$, so the complements of these sets satisfy $\mathcal{N}_A \subseteq \mathcal{N}_B$. ∎

3. Rigidity relationships. This section introduces the main notion of this paper: rigidity relationships.

DEFINITION 3.1. [illegible] A [illegible] m [illegible] n [illegible] A [illegible] B [illegible] ℓ [illegible] n [illegible] $y \in \text{enull}(B)$ [illegible] mapping [illegible] $x \in \text{enull}(A)$ [illegible] $y_i = x_i$ [illegible] $i \in \mathcal{N}_A \cap \mathcal{N}_B$ [illegible] rigid [illegible] x [illegible] A [illegible] rigid with respect to [illegible] B [illegible] $x \in \text{enull}(A)$ [illegible] $y \in \text{enull}(B)$ [illegible] mutually rigid [illegible]

3.2. Mutual rigidity does not follow automatically from one-sided rigidity. Consider, for example,

$$A = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 1 & -1 & 0 \\ 0 & -1 & 1 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}, \quad B = \begin{bmatrix} 1 & -1 & 0 & 0 \\ -1 & 1 & 0 & 0 \\ 0 & 0 & 1 & -1 \\ 0 & 0 & -1 & 1 \end{bmatrix}.$$

A is rigid with respect to B, because vectors in $\text{enull}(A)$ have the form $\begin{bmatrix} 0 & \alpha & \alpha & 0 \end{bmatrix}^T$, and they have a unique extension to vectors in $\text{enull}(B)$, namely, $\begin{bmatrix} \alpha & \alpha & \alpha & \alpha \end{bmatrix}^T$. But vectors in $\text{enull}(B)$, which have the form $\begin{bmatrix} \alpha & \alpha & \beta & \beta \end{bmatrix}^T$, are not in $\text{null}(A)$ unless $\alpha = \beta$.

3.3. Let $A_1 = \begin{bmatrix} 1 & -1 & 0 & 0 \end{bmatrix}$ and $A_2 = \begin{bmatrix} 0 & 1 & -1 & 0 \end{bmatrix}$. The two matrices are mutually rigid. We have

$$\text{enull}\,(A_1) = \text{span}\begin{bmatrix} 1 & 1 & 0 & 0 \end{bmatrix}^T,$$

$$\text{enull}\,(A_2) = \text{span}\begin{bmatrix} 0 & 1 & 1 & 0 \end{bmatrix}^T.$$

Therefore, for every $x = \begin{bmatrix} \alpha & \alpha & 0 & 0 \end{bmatrix}^T \in \text{enull}(A_1)$, there is a unique $y = \begin{bmatrix} 0 & \alpha & \alpha & 0 \end{bmatrix}^T \in \text{enull}(A_1)$, and symmetrically for A_2.

Now let $A_3 = \begin{bmatrix} 0 & 1 & 0 & 0 \end{bmatrix}$ and $A_4 = \begin{bmatrix} 0 & 0 & -1 & 1 \end{bmatrix}$. A_1 is not rigid with respect to either of these two. It is not rigid with respect to A_3 because $\text{enull}(A_3) = \{0\}$, so for an $x \in \text{enull}(A_1)$ there is no rigid y in $\text{enull}(A_3)$. A_1 is not rigid with respect to A_4 because for $x = \begin{bmatrix} \alpha & \alpha & 0 & 0 \end{bmatrix}^T \in \text{enull}(A_1)$, any $y = \begin{bmatrix} 0 & 0 & \beta & \beta \end{bmatrix}^T$ is in $\text{enull}(A_4)$, so the mapping is not unique.

We now show how to test whether a matrix A is rigid with respect to another matrix B. For an m-by-n matrix A, we define Ψ_A and $\Psi_{\bar{A}}$ to be the n-by-n diagonal matrices

$$\left[\Psi_A\right]_{jj} = \begin{cases} 1, & j \in \mathcal{N}_A, \\ 0, & j \in \mathcal{Z}_A, \end{cases} \quad \text{and} \quad \left[\Psi_{\bar{A}}\right]_{jj} = \begin{cases} 0, & j \in \mathcal{N}_A, \\ 1, & j \in \mathcal{Z}_A\,. \end{cases}$$

For two matrices A and B with n columns each, we define $\Psi_{A,B}$ to be the n-by-n diagonal matrix

$$\left[\Psi_{A,B}\right]_{jj} = \begin{cases} 1, & j \in \mathcal{N}_A \cap \mathcal{N}_B, \\ 0 & \text{otherwise.} \end{cases}$$

Let x be a vector in $\text{enull}(A)$. If x has a mapping to $y \in \text{enull}(B)$, then y must

satisfy the equations

$$\Psi_{\bar{B}} y = 0,$$

$$By = 0,$$

$$\Psi_{A,B} y = \Psi_{A,B} x.$$

The first two conditions constrain y to be in enull(B) and the third condition constrains y to be a mapping of x. If this linear system is inconsistent, then x has no rigid mapping to $y \in$ enull(B), so A is not rigid with respect to B. Even if the system is consistent for all $x \in$ enull(A), A is not necessarily rigid with respect to B. If the coefficient matrix $R_{A,B} = \begin{bmatrix} \Psi_{\bar{B}}^T & B^T & \Psi_{A,B}^T \end{bmatrix}^T$ is rank deficient, the mappings are not unique.

Therefore, to test rigidity we must check that for all $x \in$ enull(A), the vector $\begin{bmatrix} 0 & 0 & x^T \Psi_{A,B}^T \end{bmatrix}^T$ is spanned by the columns of $R_{A,B}$ and that the columns of $R_{A,B}$ are linearly independent. We now derive equivalent conditions, but on a much smaller system. First, we drop rows and columns $\mathcal{Z}_B$ from the coefficient matrix and rows $\mathcal{Z}_B$ from y. These rows correspond to equations that constrain $y_i = 0$ for $i \in \mathcal{Z}_B$. Since these elements of y are not used in any of the other equations, we can drop them without making an inconsistent system into a consistent one. Also, these columns are linearly independent, and all the other columns are independent of them. Therefore, dropping these $|\mathcal{Z}_B|$ rows and columns reduces the rank of $R_{A,B}$ by exactly $|\mathcal{Z}_B|$; therefore, $R_{A,B}$ is full rank if and only if the remaining rows and columns form a full-rank matrix. Now we drop all the zero rows from the system—rows $\mathcal{N}_B$ in the $\Psi_{\bar{B}}$ block of $R_{A,B}$, the zero rows from the B block, and the zero rows from the $\Psi_{A,B}$ block. These rows correspond to equations that are consistent for any x and any y; being zero, they do not affect the rank of $R_{A,B}$.

We assume without loss of generality that columns $\mathcal{N}_A \cap \mathcal{N}_B$ are the last among the nonzero columns of B. We denote by $\breve{B}$ the matrix formed by dropping all the zero rows and columns of B and by $y_{\mathcal{N}_B}$ the vector formed by dropping elements $\mathcal{Z}_B$ from y. (For any n-vector v and a set $S \subseteq \{1, \ldots, n\}$, the notation v_S means the $|S|$-vector formed by dropping the elements of v whose indices are not in S, and similarly for matrices.) Our reduced system is

$$\breve{R}_{A,B} y_{\mathcal{N}_B} = \left[\begin{array}{ccc} & \breve{B} & \\ 0 & | & I \end{array}\right] y_{\mathcal{N}_B} = \begin{bmatrix} 0 \\ x_{\mathcal{N}_A \cap \mathcal{N}_B} \end{bmatrix},$$

where the order of the identity matrix is $|\mathcal{N}_A \cap \mathcal{N}_B|$. To test whether A is rigid with respect to B, we construct a matrix N_A whose columns span enull(A) and check

1. whether $\breve{R}_{A,B}$ has full rank, and
2. whether, for every column x in N_A,

$$\breve{R}_{A,B} \breve{R}_{A,B}^{+} \begin{bmatrix} 0 \\ x_{\mathcal{N}_A \cap \mathcal{N}_B} \end{bmatrix} = \begin{bmatrix} 0 \\ x_{\mathcal{N}_A \cap \mathcal{N}_B} \end{bmatrix},$$

where $\breve{R}_{A,B}^{+}$ denotes the Moore–Penrose pseudoinverse of $\breve{R}_{A,B}$.

If B has only a few nonzero rows and columns and if the number of columns in N_A is small, then this is an inexpensive computation. The construction is illustrated in Figure 3.1.

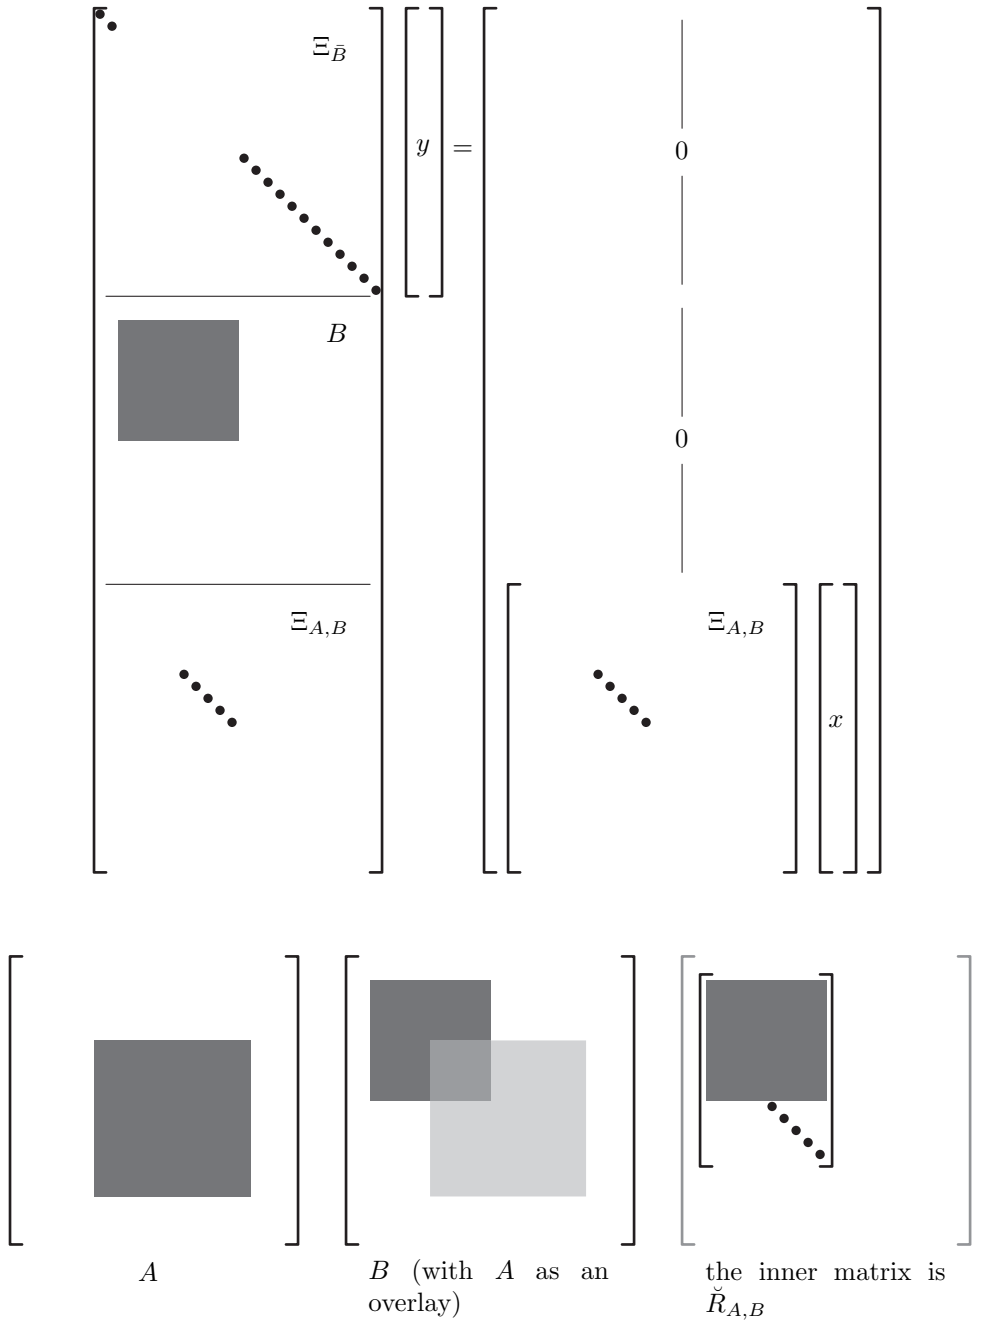

FIG. 3.1. *Testing rigidity. The top part of the figure shows the entire linear system, and the bottom part shows the construction of* $\check{R}_{A,B}$.

The next three lemmas show the relationship between null-space containment and rigidity.

LEMMA 3.4. *Let* A *be* $m \times n$ *and* B *be* $l \times n$. *Then* $\mathrm{null}(A) \subseteq \mathrm{null}(B)$ *if* A *is rigid for* B.

Proof. Let $x \in \text{enull}(A)$. Therefore, $x \in \text{null}(A)$ and $x \in \text{null}(B)$. Define $y = \Psi_B x$. We have that $x_i = y_i$ for all $i \in \mathcal{N}_A \cap \mathcal{N}_B$. By Lemma 2.4, $y \in \text{enull}(B)$. Therefore, y is a mapping of x in $\text{enull}(B)$.

We now show that y is the unique mapping of x. Let $\hat{y}$ be a mapping of x in $\text{enull}(B)$. By Lemma 2.7, $\mathcal{N}_B \subseteq \mathcal{N}_A$. The equalities $y_i = x_i = \hat{y}_i$ hold for every $i \in \mathcal{N}_A \cap \mathcal{N}_B = \mathcal{N}_B$. Therefore, $y = \hat{y}$, so y is the unique mapping of x in $\text{enull}(B)$. This implies that A is rigid with respect to B. □

LEMMA 3.5. *Let A be an $m \times n$ matrix and let B be an $l \times n$ matrix such that $\mathcal{N}_B \subseteq \mathcal{N}_A$. Then $\text{null}(A) \subseteq \text{null}(B)$*

Proof. Let $x \in \text{null}(A)$. We can write x as $y + z$, where $y \in \text{enull}(A)$ and $z \in \text{tnull}(A)$. We have that $z \in \text{tnull}(B)$, since $\mathcal{N}_B \subseteq \mathcal{N}_A$. Therefore, $z \in \text{null}(B)$.

We now show that y is also in $\text{null}(B)$. Let u be y's rigid mapping to $\text{enull}(B)$. We have that $u_i = y_i$ for every $i \in \mathcal{N}_A \cap \mathcal{N}_B = \mathcal{N}_B$. Therefore, we can write y as $y = u + u'$, where $u'_i \neq 0$ only for $i \in \mathcal{N}_A \backslash \mathcal{N}_B$. It is clear that $u' \in \text{tnull}(B) \subseteq \text{null}(B)$. Therefore, $y = u + u' \in \text{null}(B)$ and $x = y + z \in \text{null}(B)$, which is what we need to prove the lemma. □

COROLLARY 3.6. *Let A be an $m \times n$ matrix and let B be an $l \times n$ matrix such that $\mathcal{N}_A = \mathcal{N}_B$ and A and B are mutually rigid. Then $\text{null}(A) = \text{null}(B)$*

Proof. The proof directly follows from Lemmas 3.4 and 3.5. □

The last lemma in this section shows that rigidity relationships are maintained in certain Schur complements.

LEMMA 3.7. *Let A and B be $n \times n$ matrices of the form*

$$A = \begin{bmatrix} A_{11} & 0 \\ 0 & 0 \end{bmatrix}, \; B = \begin{bmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{bmatrix},$$

where A_{11} and B_{11} are $k \times k$ matrices, $0 < k < n$, and A and B are mutually rigid. Then $\mathcal{N}_A = \{1, \ldots, k\}$ and $\mathcal{N}_B = \{1, \ldots, n\}$, and B_{22} is nonsingular. Moreover, $\text{null}(A_{11}) \subseteq \text{null}(B_{11} - B_{12}B_{22}^{-1}B_{21})$ and A_{11} is rigid with respect to $B_{11} - B_{12}B_{22}^{-1}B_{21}$

If, in addition, A and B are mutually rigid, then $\text{null}(A_{11}) = \text{null}(B_{11} - B_{12}B_{22}^{-1}B_{21})$

Proof. Let $x \in \text{null}(A_{11})$. Let $\hat{x}$ be the vector of size n that equals x in its first k coordinates and that contains zeros in its last $(n-k)$ coordinates. Clearly, $\hat{x} \in \text{null}(A)$. Since there are no zero columns in A_{11} we also have that $\hat{x} \in \text{enull}(A)$. Let $\hat{y}$ be the rigid mapping of $\hat{x}$ in $\text{enull}(B)$. The equalities $\hat{y}_i = \hat{x}_i = x_i$ hold for all $i \in \{1, \ldots, k\}$. Let y be a vector of size $(n-k)$ consisting of the last $(n-k)$ elements of $\hat{y}$. Writing the equation $B\hat{y} = 0$ in terms of x and y, we obtain

$$\begin{bmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} B_{11}x + B_{12}y \\ B_{21}x + B_{22}y \end{bmatrix} = 0.$$

Multiplying the second block row by B_{22}^{-1} gives $y = -B_{22}^{-1}B_{21}x$. Substituting y with $-B_{22}^{-1}B_{21}x$ in the first block row, we get $B_{11}x - B_{12}B_{22}^{-1}B_{21}x = 0$. Therefore, $x \in \text{null}(B_{11} - B_{12}B_{22}^{-1}B_{21})$, so $\text{null}(A_{11}) \subseteq \text{null}(B_{11} - B_{12}B_{22}^{-1}B_{21})$. The containment of the null spaces, along with Lemma 3.4, shows that A_{11} is rigid with respect to $B_{11} - B_{12}B_{22}^{-1}B_{21}$.

Now assume A and B are mutually rigid (we add the assumption that B is rigid with respect to A). Let $x \in \text{null}(B_{11} - B_{12}B_{22}^{-1}B_{21})$. Let $\hat{x}$ be the vector of size n that equals x in its first k coordinates and equals $-B_{22}^{-1}B_{21}x$ in its last $(n-k)$ coordinates.

The vector $\hat{x}$ is in enull(B), since

$$B\hat{x} = \begin{bmatrix} B_{11}x + B_{12}(-B_{22}^{-1}B_{21}x) \\ B_{21}x + B_{22}(-B_{22}^{-1}B_{21}x) \end{bmatrix} = 0.$$

Because B is rigid with respect to A, the vector $\hat{x}$ has a unique mapping to enull(A). Since $\mathcal{N}_A \subseteq \mathcal{N}_B$, this mapping is $\Psi_A\hat{x}$. Therefore, $A\Psi_A\hat{x} = 0$, so $x \in$ null(A_{11}). This implies that null($B_{11} - B_{12}B_{22}^{-1}B_{21}$) $\subseteq$ null(A_{11}). Therefore, null($B_{11} - B_{12}$ $B_{22}^{-1}B_{21}$) = null(A_{11}). This concludes the proof of the lemma. ∎

4. Rigidity of sums. Finite-element matrices are sums of mostly zero matrices. This section extends our study of rigidity to sums of matrices.

LEMMA 4.1. [illegible] A [illegible] B [illegible] SPSD n [illegible] n, [illegible] $(A+B)$ [illegible] A [illegible] B

[illegible]. By Lemma 2.5, null($A + B$) $\subseteq$ null(A). Therefore, from Lemma 3.4, $(A + B)$ is rigid with respect to A. By symmetry, $(A + B)$ is rigid with respect to B, too. ∎

The previous lemma showed that a sum of SPSD matrices is rigid with respect to the terms of the sum, but the terms are not always rigid with respect to the sum, even when the terms are SPSD. For example, $A = \left[\begin{smallmatrix} 1 & -1 \\ -1 & 1 \end{smallmatrix}\right]$ is not rigid with respect to $A + \left[\begin{smallmatrix} 0 & 0 \\ 0 & 1 \end{smallmatrix}\right]$, because A is rank deficient but the sum is not. Hence, vectors in enull(A) have no mapping at all to the essential null space of the sum.

Also, the lemma holds for SPSD matrices but not for general matrices. Let $A = \left[\begin{smallmatrix} 1 & 0 \\ 0 & 1 \end{smallmatrix}\right]$ and let $B = \left[\begin{smallmatrix} 0 & -1 \\ 0 & -1 \end{smallmatrix}\right]$. Their sum is $A + B = \left[\begin{smallmatrix} 1 & -1 \\ 0 & 0 \end{smallmatrix}\right]$. The vector $\begin{bmatrix} 1 & 1 \end{bmatrix}^T \in$ enull($A + B$), but this vector has no mapping into enull(A) = $\{0\}$.

The next lemma strengthens both the hypothesis and the consequence of Lemma 4.1. It shows that if the terms are mutually rigid, then rigidity between the terms and the sum is mutual.

LEMMA 4.2. [illegible] A [illegible] B [illegible] SPSD n [illegible] n, [illegible] A [illegible] $A + B$ [illegible] B [illegible] $A + B$ [illegible]

[illegible]. By Lemma 4.1, the sum is rigid with respect to the terms. So all we need to prove is the opposite direction.

Let $x \neq 0$ be a vector in enull(A). Let y be the rigid mapping of x into enull(B). We now show that x has a mapping into enull($A + B$); we shall show the uniqueness of the mapping later. We define

$$w_i = \begin{cases} x_i, & i \in \mathcal{N}_A, \\ x_i = y_i, & i \in \mathcal{N}_A \cap \mathcal{N}_B, \\ y_i, & i \in \mathcal{N}_B, \\ 0 & \text{otherwise.} \end{cases}$$

Because $\mathcal{N}_{A+B} \subseteq \mathcal{N}_A \cup \mathcal{N}_B$, we have $w_i = 0$ for $i \in \mathcal{Z}_{A+B}$. Therefore, to show that $w \in$ enull($A + B$), we need only to show that $(A + B)w = 0$. This is indeed the case because w is an extension of both x and y, so $Aw = Bw = 0$.

We now show that w is the unique mapping of x into enull($A + B$). Suppose that there is another mapping $w' \neq w$. Under this supposition, there must be $w'_i \neq w_i$ for some $i \in \mathcal{N}_B \setminus \mathcal{N}_A$, so the restriction y' of w' to $\mathcal{N}_B$ must be different from y. By Lemmas 2.5 and 2.4, $y' \in$ enull(B). The vectors y and y' are both in enull(B)

and both coincide with x on $\mathcal{N}_A \cap \mathcal{N}_B$, so they are two different mappings of x, contradicting the hypothesis that A and B are mutually rigid. □

LEMMA 4.3. *Let A and B be SPSD $n \times n$ matrices, let C be an $m \times n$ matrix, let $A + B$ be a rigid sum with respect to C, and let $A + \alpha B$ be a rigid sum with respect to C, for some $\alpha > 0$.*

Proof. Let $\alpha > 0$. We first show that $\text{enull}(A + \alpha B) = \text{enull}(A + B)$. It is clear that $\mathcal{N}_{\alpha B} = \mathcal{N}_B$ and that αB is SPSD. From Lemma 2.6 we have $\mathcal{N}_{A+\alpha B} = \mathcal{N}_A \cup \mathcal{N}_{\alpha B} = \mathcal{N}_A \cup \mathcal{N}_B = \mathcal{N}_{A+B}$. By Lemma 2.5,

$$\text{null}(A + \alpha B) = \text{null}(A) \cap \text{null}(\alpha B) = \text{null}(A) \cap \text{null}(B) = \text{null}(A + B).$$

Therefore, $\text{enull}(A + \alpha B) = \text{enull}(A + B)$. The lemma follows directly from the definition of mutual rigidity and the fact that $\text{enull}(A + \alpha B) = \text{enull}(A + B)$. □

In some special cases, mutual rigidity between sums allows us to infer that the terms of the sums are mutually rigid and vice versa.

LEMMA 4.4. *Let A, B, and C be $n \times n$ SPSD matrices such that $\mathcal{N}_C \cap \mathcal{N}_A = \mathcal{N}_C \cap \mathcal{N}_B = \emptyset$. Let A and B be mutually rigid sums with respect to $A + C$ and $B + C$.*

Proof. Assume that A and B are mutually rigid. We show that $A + C$ is rigid with respect to $B + C$. By symmetry, $B + C$ is rigid with respect to $A + C$, so the two sums are mutually rigid.

Let $x \in \text{enull}(A + C)$. By Lemma 2.5, $x \in \text{null}(A)$ and $x \in \text{null}(C)$. Let $\hat{x}$ be x's restriction to $\mathcal{N}_A$, and let $\bar{x}$ be its restriction to $\mathcal{N}_C$. By Lemma 2.4, $\hat{x} \in \text{enull}(A)$ and $\bar{x} \in \text{enull}(C)$. Let $\hat{y}$ be $\hat{x}$'s rigid (unique) mapping to $\text{enull}(B)$. We define the vector

$$y_i = \begin{cases} \hat{y}_i, & i \in \mathcal{N}_B, \\ \bar{x}_i, & i \in \mathcal{N}_C, \\ 0 & \text{otherwise.} \end{cases}$$

The definition is valid because $\mathcal{N}_C \cap \mathcal{N}_B = \emptyset$. We show that y is the rigid mapping of x in $\text{enull}(B+C)$. Multiplying $B+C$ by y we obtain $(B+C)y = By+Cy = B\hat{y}+C\bar{x} = 0+0 = 0$. Since $y_i = 0$ for all $i \notin \mathcal{N}_B \cup \mathcal{N}_C = \mathcal{N}_{B+C}$, $y \in \text{enull}(B+C)$. By definition, $y_i = x_i$ for all $i \in (\mathcal{N}_A \cap \mathcal{N}_B) \cup \mathcal{N}_C = (\mathcal{N}_A \cup \mathcal{N}_C) \cap (\mathcal{N}_B \cup \mathcal{N}_C) = \mathcal{N}_{A+C} \cap \mathcal{N}_{B+C}$. Therefore, y is a mapping of x in $\text{enull}(B + C)$.

We now show that this mapping is indeed unique. Assume that there exists $u \in \text{enull}(B + C)$ that satisfies $u_i = x_i$ for all $i \in \mathcal{N}_{A+C} \cap \mathcal{N}_{B+C}$. We have that $u_i = x_i = y_i$ for all $i \in \mathcal{N}_C \subseteq \mathcal{N}_{A+C} \cap \mathcal{N}_{B+C}$. Let $\hat{u}$ be u's restriction to $\mathcal{N}_B$. We have $\hat{u} \in \text{enull}(B)$ and $\hat{u}_i = x_i = \hat{x}_i$ for all $i \in \mathcal{N}_A \cap \mathcal{N}_B$. Therefore, $\hat{u}$ is a mapping of $\hat{x}$ in $\text{enull}(B)$. Since A and B are mutually rigid, $\hat{u}$ must equal $\hat{y}$. Therefore, $u = y$, and y is the rigid mapping of x in $\text{enull}(B + C)$. This shows that $A + C$ is rigid with respect to $B + C$. Figure 4.1 (a) presents this notation graphically.

We now show the other direction. Assume $A + C$ and $B + C$ are mutually rigid. We show that A is rigid with respect to B; mutual rigidity follows by symmetry. The notation for this part of the proof is presented graphically in part (b) of Figure 4.1. Let $\hat{x} \in \text{enull}(A)$. Since $\mathcal{N}_C \cap \mathcal{N}_\mathcal{A} = \emptyset$, $\hat{x} \in \text{tnull}(C)$. We also have $\hat{x}_i = 0$ for all $i \notin \mathcal{N}_A \cup \mathcal{N}_C = \mathcal{N}_{A+C}$, so $\hat{x} \in \text{enull}(A+C)$. Let $\hat{y}$ be $\hat{x}$'s rigid mapping to $\text{enull}(B+C)$. We show that $\hat{y}$ is $\hat{x}$'s rigid mapping to $\text{enull}(B)$. By Lemma 2.5, $\hat{y} \in \text{null}(B)$. Also, $\hat{y}_i = \hat{x}_i = 0$ for all i in $i \in \mathcal{N}_C \subseteq \mathcal{N}_{B+C}$. Therefore, $\hat{y}_i = 0$ for all $i \notin \mathcal{N}_B$, so $\hat{y} \in \text{enull}(B)$. By definition, $\hat{x}_i = \hat{y}_i$ for all $(\mathcal{N}_A \cap \mathcal{N}_B) \subseteq \mathcal{N}_{A+C} \cap \mathcal{N}_{B+C}$. This implies that $\hat{y}$ is a mapping of $\hat{x}$ in $\text{enull}(B)$.

Finally, we claim that $\hat{y}$ is the unique mapping of $\hat{x}$. Assume that there exists $\hat{u}$ in enull(B) that satisfies $\hat{x}_i = \hat{u}_i$ for all $i \in \mathcal{N}_A \cap \mathcal{N}_B$. We have that $\hat{x}_i = \hat{u}_i = 0$ for all $i \in \mathcal{N}_C$. Since $\hat{u}$ is also in enull($B+C$), it is the rigid mapping of $\hat{x} \in$ enull($A+C$) in enull($B+C$). Because $A+B$ is rigid with respect to $A+C$, we have that $\hat{u} = \hat{y}$. Therefore, $\hat{y}$ is indeed unique. This implies that A is rigid with respect to B, which concludes the proof of the lemma. ∎

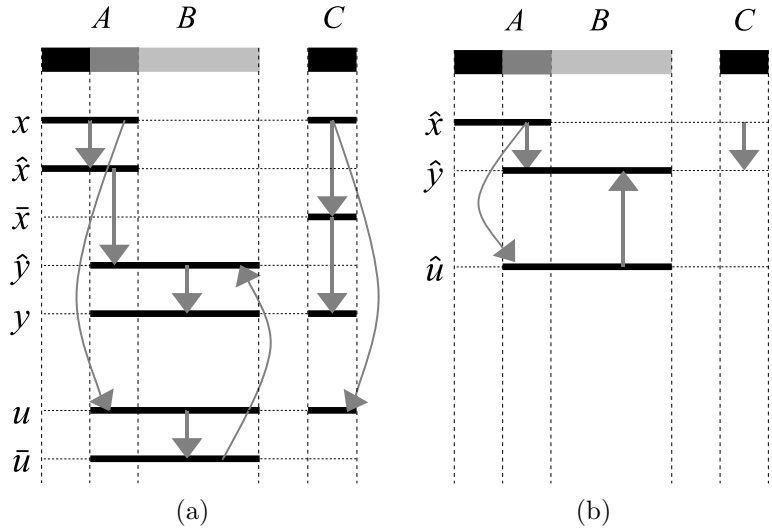

FIG. 4.1. *An illustration of the notation of Lemma* 4.4: (a) *The vectors defined in the proof of the mutual rigidity of* $A+B$ *and* $A+C$. (b) *The vectors defined in the proof of the mutual rigidity of* A *and* B.

We would like to build larger assemblies of mutually rigid matrices from chains of mutual rigidity, but this is not always possible, as the next example shows.

4.5. Let

$$A = \begin{bmatrix} 1 & -1 & 0 \\ -1 & 1 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad B = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 1 & -1 \\ 0 & -1 & 1 \end{bmatrix}, \quad C = \begin{bmatrix} 1 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 1 \end{bmatrix}.$$

These matrices are all SPSD, and their essential null spaces are spanned by $\begin{bmatrix} 1 & 1 & 0 \end{bmatrix}^T$, $\begin{bmatrix} 0 & 1 & 1 \end{bmatrix}^T$, and $\begin{bmatrix} 1 & 0 & -1 \end{bmatrix}^T$, respectively. The matrices A and B are mutually rigid, and so are B and C. The essential null space of $A+B$ is spanned by $\begin{bmatrix} 1 & 1 & 1 \end{bmatrix}^T$, and the essential null space of $B+C$ is spanned by $\begin{bmatrix} 1 & -1 & -1 \end{bmatrix}^T$. Therefore, C is not mutually rigid with $A+B$ and A is not mutually rigid with $B+C$. Moreover, none of A, B, C, $A+B$, or $B+C$ is mutually rigid with $A+B+C$, because $A+B+C$ has full rank. This example is inspired by the analysis of signed graphs in [4], which shows that $A+B+C$ has full rank.

To build larger assemblies of mutually rigid matrices, we need another tool.

5. Null-space compatibility. This section defines and explores a concept that we call null-space compatibility, which is the tool that allows us to build large assemblies of mutually rigid matrices.

DEFINITION 5.1. [illegible] $\mathbb{S} \subseteq \mathbb{R}^n$ [illegible] A [illegible] $\mathbb{S}$-compatible ([illegible] $\mathbb{S}$) [illegible] enull(A) [illegible] $\mathbb{S}$ [illegible] $\mathbb{S}$ [illegible] $\mathcal{N}_A$ [illegible] enull(A)

DEFINITION 5.2. [illegible] A [illegible] n [illegible] A $\mathbb{S}$ [illegible] $\mathcal{N}_A = \{1, \ldots, n\}$ [illegible] A $\mathbb{S}$ rigid [illegible] null$(A) = \mathbb{S}$ [illegible] $\mathcal{N}_A = \{1, \ldots, n\}$ $\mathbb{S}$ [illegible] A [illegible]

Given a basis for $\mathbb{S}$, we can easily check the compatibility of a matrix A. Let the columns of N be a basis for $\mathbb{S}$, and let N_A be a basis for enull(A). A is compatible with $\mathbb{S}$ if and only if $N_A = \Psi_A N_A$ and $\Psi_A N$ have the same range. This can be checked numerically using the singular value decompositions of the two matrices, for example.

[illegible] 5.3. Let $\mathbb{S} = \text{span}\begin{bmatrix}1 & 1 & 1\end{bmatrix}^T$. The matrices A and B from Example 4.5 are compatible with $\mathbb{S}$, but C is not. Note that the mutual rigidity of A and C together with the $\mathbb{S}$-compatibility of A do not imply $\mathbb{S}$-compatibility for C. The matrix $A + B$ from the same example is also compatible with $\mathbb{S}$, and since $\mathcal{N}_{A+B} = \{1, 2, 3\}$, $A + B$ is rigid.

LEMMA 5.4. [illegible] A [illegible] $\mathbb{S}$ [illegible] N [illegible] $\mathbb{S}$ [illegible] enull$(A) = \text{span}(\Psi_A N)$

[illegible]. We first show that enull$(A) \subseteq \text{span}(\Psi_A N)$. Let $x \in \text{enull}(A)$. Since A is $\mathbb{S}$-compatible, x has a unique extension w in $\mathbb{S}$. By definition, there exists a vector y such that $w = Ny$. Substituting w in the equation $x = \Psi_A w$, we get $x = \Psi_A N y$. Therefore, $x \in \text{span}(\Psi_A N)$, so enull$(A) \subseteq \text{span}(\Psi_A N)$.

We now show that $\text{span}(\Psi_A N) \subseteq \text{enull}(A)$. Let $x = \Psi_A N y \in \text{span}(\Psi_A N)$. Define $w = Ny \in \mathbb{S}$. Since A is $\mathbb{S}$-compatible, $x = \Psi_A w \in \text{enull}(A)$. This shows that $\text{span}(\Psi_A N) \subseteq \text{enull}(A)$. ∎

The definition of null-space compatibility is related to the definition of mutual rigidity, but it defines compatibility with respect to a space, not with respect to a particular matrix having that space as a null space. Here is the relationship of $\mathbb{S}$-compatibility with mutual rigidity.

LEMMA 5.5. [illegible] $\mathbb{S} \subseteq \mathbb{R}^m$ [illegible] B [illegible] $\mathbb{S}$ [illegible] A $\mathbb{S}$ [illegible] A [illegible] B [illegible]

[illegible]. The equivalence follows from the fact that enull$(B) = \text{null}(B) = \mathbb{S}$ (because $\mathcal{Z}_B = \emptyset$) and from the fact that $\mathcal{N}_A \cap \mathcal{N}_B = \mathcal{N}_A$. ∎

If the dimension of $\mathbb{S}$ is small, the $\mathbb{S}$-compatibility test given after Definition 5.2 can be much more efficient than the test for mutual rigidity given earlier.

[illegible] 5.6. Two matrices that are both compatible with some null space $\mathbb{S}$ are not necessarily mutually rigid. For example,

$$A = \begin{bmatrix} 1 & -1 & 0 & 0 \\ -1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & -1 \\ 0 & 0 & -1 & 1 \end{bmatrix}$$

are both compatible with $\mathbb{S} = \text{span}\begin{bmatrix}1 & 1 & 1 & 1\end{bmatrix}^T$, but they are not mutually rigid. Also, their sum is not $\mathbb{S}$-compatible. Since $\mathcal{N}_{A+B} = \{1, 2, 3, 4\}$, enull$(A + B) =$

$\text{null}(A+B)$, and so $A+B$ is $\mathbb{S}$-compatible if and only if $\text{null}(A+B) = \mathbb{S}$. However,

$$\text{enull}(A+B) = \text{enull}\begin{bmatrix} 1 & -1 & 0 & 0 \\ -1 & 1 & 0 & 0 \\ 0 & 0 & 1 & -1 \\ 0 & 0 & -1 & 1 \end{bmatrix} = \text{span}\begin{bmatrix} 1 & 0 \\ 1 & 0 \\ 0 & 1 \\ 0 & 1 \end{bmatrix} \neq \mathbb{S} = \text{span}\begin{bmatrix} 1 \\ 1 \\ 1 \\ 1 \end{bmatrix}.$$

The next two lemmas are key results that will allow us to build large assemblies of mutually rigid matrices.

LEMMA 5.7. *A and B are mutually rigid with respect to $\mathbb{S}$ if and only if $\mathbb{S}$ is the only subspace of $\text{enull}(A+B)$ that is also in $\mathbb{S}$.*

Proof. Let u be a vector in $\text{enull}(A+B)$, let x be the restriction of u to $\mathcal{N}_A$, and let y be the restriction to $\mathcal{N}_B$. Clearly, y is the rigid mapping of x in $\text{enull}(B)$. Let w be the extension of x to a vector in $\mathbb{S}$. We claim that w is a unique extension of u to $\mathbb{S}$. If w is not an extension of u, then they must differ on an index in $\mathcal{N}_B \setminus \mathcal{N}_A$, so the restriction of w to $\mathcal{N}_B$ is some $y' \neq y$. The vector y' is also a mapping of x in $\text{enull}(B)$. But both y and $y' \neq y$ are mappings of x in $\text{enull}(B)$, in contradiction to the mutual rigidity of A and B.

We now show that w is the unique extension of u to $\mathbb{S}$. If there is another extension, its restriction to $\mathcal{N}_A$ must differ from x, so it cannot be an extension of u.

We now show that the restriction u of a vector $w \in \mathbb{S}$ is in $\text{enull}(A+B)$. The restriction x of u to $\mathcal{N}_A$ is also the restriction of w to $\mathcal{N}_A$, so $Ax = Au = Aw = 0$. The same is true for the restrictions to $\mathcal{N}_B$. Therefore, $(A+B)u = 0$, so $u \in \text{enull}(A+B)$. ∎

We now introduce a technical lemma that shows how to transform a null-space extension of a vector into the rigid mapping of the same vector.

LEMMA 5.8. *A and B are mutually rigid with respect to $\mathbb{S}$. $x \in \text{enull}(A)$, $w \in \mathbb{S}$, and $\Psi_B w$ is the extension of $x \in \text{enull}(B)$ to u. $x \in \text{enull}(B)$ and $u \in \mathbb{S}$, w is unique.*

Proof. Let $y = \Psi_B w$. We first show that y is the rigid mapping of x to $\text{enull}(B)$. The vector y is in $\text{enull}(B)$, since B is $\mathbb{S}$-compatible and $w \in \mathbb{S}$. From the definition of w and y we have that $x_i = w_i = y_i$ for all $i \in \mathcal{N}_A \cap \mathcal{N}_B$. Therefore, y is a mapping of x in $\text{enull}(B)$, and it is unique because A and B are mutually rigid.

Let u be the rigid mapping of x to $\text{enull}(B)$. Since this mapping is unique, $u = y = \Psi_B w$. The vector w is an extension of u to $\mathbb{S}$. The matrix B is $\mathbb{S}$-compatible, so this extension is unique. ∎

The following lemma is the main result of this section. Compare this lemma to Example 4.5: in the example, the three matrices were not all compatible with some null space $\mathbb{S}$; the conclusion of this lemma does not hold in that example.

LEMMA 5.9. *A, B, C SPSD $n \times n$. $\mathbb{S}$ is a subspace of $\mathbb{R}^n$. A and B are mutually rigid with respect to $\mathbb{S}$, and B and C are mutually rigid with respect to $\mathbb{S}$. $A+B$ and C are mutually rigid with respect to ($B+C$ and A).*

Proof. We first show that $A+B$ is rigid with respect to C. Let u be in $\text{enull}(A+B)$. By Lemma 5.7, the matrix $A+B$ is $\mathbb{S}$-compatible. Let w be u's extension to $\mathbb{S}$. Define $x = \Psi_A^T w$, $y = \Psi_B^T w$, and $z = \Psi_C^T w$. By definition, $u = \Psi_{A+B}^T w$ and therefore $z_i = u_i$ for all $i \in \mathcal{N}_{A+B} \cap \mathcal{N}_C$. Since C is $\mathbb{S}$ compatible, $z \in \text{enull}(C)$. Therefore, z is a mapping of u in $\text{enull}(C)$.

We show that z is unique. The matrices $A+B$ and A are mutually rigid according to Lemma 4.2. According to Lemma 5.8, x is the unique mapping of u in $\text{enull}(A)$, y

is the unique mapping of x in enull(B), and z is the unique mapping of y in enull(C). Therefore, z is the unique mapping of u in enull(C) and $A + B$ is rigid with respect to C.

We show now that C is rigid with respect to $A + B$. Let z be in enull(C). The matrix C is $\mathbb{S}$-compatible. Let w be z's extension to $\mathbb{S}$. Define $x = \Psi_A^T w$, $y = \Psi_B^T w$, and $u = \Psi_{A+B}^T w$. By definition, $z = \Psi_C^T w$ and therefore $z_i = u_i$ for all $i \in \mathcal{N}_{A+B} \cap \mathcal{N}_C$. Therefore, u is a mapping of z in enull($A + B$).

We show that u is unique. According to Lemma 5.8, y is the unique mapping of z in enull(B), x is the unique mapping of y in enull(A), and u is the unique mapping of x in enull($A + B$). Therefore, u is the unique mapping of z in enull($A + B$). This implies that C is rigid with respect to $A + B$ and concludes the proof of the lemma. □

5.10. This example shows that A and C are not necessarily mutually rigid, even if A and B are mutually rigid, B and C are mutually rigid, and all three are $\mathbb{S}$-compatible. Instead of constructing the matrices here, we refer the reader to the construction of section 7.3, where we construct matrices that model elastic triangles. Suppose that the three matrices are 10-by-10, that A corresponds to a triangle (p_1, p_2, p_3) (p_i is a point in the plane; all the points are different), B to $(p_2, , p_3, p_4)$, and C to (p_3, p_4, p_5). We assume that the three triangles are disjoint except for shared edges. The analysis of section 7.3 shows that A and B are mutually rigid and B and C are mutually rigid but A and C are not.

The next lemma characterizes the rigidity and $\mathbb{S}$-compatibility of certain larger sums.

LEMMA 5.11. [illegible] A [illegible] $B_1, B_2, \ldots, B_k$ [illegible] SPSD [illegible] $\mathbb{S}$ [illegible] A [illegible] B_i [illegible] $i = 1, \ldots, k$ [illegible] A [illegible] $A + \sum_{i=1}^{k} B_i$ [illegible] $A + \sum_{i=1}^{k} B_i$ [illegible] $\mathbb{S}$ [illegible].

[illegible]. We prove the lemma by induction on k. The case $k = 1$ is trivial by Lemmas 4.2 and 5.7. We assume that the claim is correct for k smaller than n and show that it is correct for $k = n$. By the inductive assumption, A and $A + \sum_{i=1}^{n-1} B_i$ are mutually rigid and $A + \sum_{i=1}^{n-1} B_i$ is $\mathbb{S}$-compatible. A and B_n are mutually rigid. Therefore, by Lemma 5.9 we have that B_n and $A + A + \sum_{i=1}^{n-1} B_i = 2A + \sum_{i=1}^{n-1} B_i$ are mutually rigid. By Lemma 4.3, B_n and $A + \sum_{i=1}^{n-1} B_i$ are mutually rigid. Therefore, by Lemma 5.9, we have that A and $B_n + A + \sum_{i=1}^{n-1} B_i = A + \sum_{i=1}^{n} B_i$ are mutually rigid. By Lemma 5.7, we also have that $B_n + A + \sum_{i=1}^{n-1} B_i = A + \sum_{i=1}^{n} B_i$ is $\mathbb{S}$-compatible. This concludes the proof of the lemma. □

The following lemma shows that the property of null-space compatiblity simplifies considerably the mutual rigidity test.

LEMMA 5.12. [illegible] A [illegible] B [illegible] $\mathbb{S}$ [illegible] SPSD n [illegible] n [illegible] N [illegible] n [illegible] ℓ [illegible] ℓ [illegible] $\mathbb{S}$ [illegible] A [illegible] B [illegible] $\Psi_{A,B} N$ [illegible] ℓ

[illegible]. We first assume that $\Psi_{A,B} N$ has rank ℓ and show that A is rigid with respect to B. Mutual rigidity follows by symmetry. Let $x \in$ enull(A). We can write $x = \Psi_A N y_A$, where y_A is some length-ℓ vector. Define $u = \Psi_B N y_A$. By definition, $u \in$ enull(B) and since

$$\Psi_{A,B} u = \Psi_{A,B} \Psi_B N y_A = \Psi_{A,B} N y_A = \Psi_{A,B} \Psi_A N y_A = \Psi_{A,B} x,$$

u is a mapping of x.

We now show it is unique. Let $\hat{u} \in$ enull(B), such that $\Psi_{A,B} \hat{u} = \Psi_{A,B} x$. By

definition, $\hat{u} = \Psi_B N y_B$ for some y_B. Clearly,

$$\Psi_{A,B}\hat{u} = \Psi_{A,B}\Psi_B N y_B = \Psi_{A,B} N y_B.$$

Therefore,

$$\Psi_{A,B} N y_A = \Psi_{A,B} x = \Psi_{A,B}\hat{u} = \Psi_{A,B} N y_B,$$

and

$$\Psi_{A,B} N (y_A - y_B) = 0.$$

Since $\Psi_{A,B}N$ has full rank ℓ, $y_A = y_B$, so $u = \hat{u}$. This implies that A is rigid with respect to B.

We show now the other direction. Assume A and B are mutually rigid. We note that for every $0 \neq n \in \mathbb{S}$, $\Psi_A n \neq 0$. Otherwise, both n and 0 are extensions of $0 \in \text{enull}(A)$, which is impossible since A is $\mathbb{S}$-compatible.

Suppose for contradiction that $\Psi_{A,B}N$ is rank deficient. Therefore, there exists an ℓ-vector $y \neq 0$ such that $\Psi_{A,B} N y = 0$. Since N has full rank, $Ny \neq 0$. By the previous paragraph, $\Psi_A N y \neq 0$. Note that the mapping of $\Psi_A N y$ to $\text{enull}(B)$ is $\Psi_B \Psi_A N y = \Psi_{A,B} N y = 0$. Therefore, the mapping of both the zero vector and of $\Psi_A N y$ to $\text{enull}(B)$ is the zero vector. This contradicts the assumption that A and B are mutually rigid. ∎

6. The rigidity graph. Mutual rigidity relationships in a collection of $\mathbb{S}$-compatible SPSD matrices define a graph structure that we can use to demonstrate the rigidity of finite-element matrices.

DEFINITION 6.1. [illegible] $A_1, A_2, \ldots, A_k$ [illegible] $\mathbb{S}$ [illegible] SPSD $n \times n$ [illegible] $\mathbb{S}$ [illegible] rigidity graph $G = (V, E)$ [illegible] $\{A_1, \ldots, A_k\}$ [illegible] $V = \{A_1, \ldots, A_k\}$ [illegible]

$$E = \{(A_e, A_f) : A_e \text{ [illegible] } A_f \text{ [illegible]}\}.$$

We could also define the rigidity graph of a collection of matrices that are not necessarily $\mathbb{S}$-compatible, but Example 4.5 suggests that such a definition might not have interesting applications. On the other hand, the $\mathbb{S}$-compatibility requirement in the definition enables an important result, which we state and prove next.

LEMMA 6.2. [illegible] G [illegible] $A_1, A_2, \ldots, A_k$ [illegible] $\mathbb{S}$ [illegible] SPSD $n \times n$ [illegible] H [illegible] G [illegible] $V(H)$ [illegible] H [illegible] A_e [illegible] H [illegible] A_e [illegible] $\sum_{A_f \in V(H)} A_f$ [illegible] $\sum_{A_f \in V(H)} A_f$ [illegible] $\mathbb{S}$ [illegible]

[illegible]. Let T be a depth-first-search tree of H whose root is A_e. Denote by $\{T_1, T_2, \ldots, T_c\}$ the trees in the forest formed from T by removing A_e. We show by induction on the height h of T that the following claims holds: A_e and $A_e + \sum_{i=1}^{c} \sum_{A_f \in T_i} A_f$ are mutually rigid, and $A_e + \sum_{i=1}^{c} \sum_{A_f \in T_i} A_f$ is $\mathbb{S}$-compatible.

The claim holds trivially for $k = 1$ (a single-vertex tree), because A_e is $\mathbb{S}$-compatible and is mutually rigid with itself.

Now, we assume that the inductive claim is correct for trees with height h or less and we show it is correct for trees with height $h+1$. Let T be a tree of height $h+1$ whose root vertex is A_e, and let $T_1, T_2, \ldots, T_c$ be the subtrees defined above. The height of every T_i is h or less. Let A_i be the root vertex of T_i, and let F_i be the forest of A_i's descendants. By definition, A_e and A_i are mutually rigid. By the inductive claim on

T_i, we have that $A_i + \sum_{A_f \in F_i} A_f$ is $\mathbb{S}$-compatible and mutually rigid with A_i. We note that all the sums of the form $\sum A_f$ are symmetric and positive semidefinite. Therefore, by Lemma 5.9 A_e and $A_i + (A_i + \sum_{A_f \in F_i} A_f) = 2A_i + \sum_{A_f \in F_i} A_f$ are mutually rigid. By Lemma 4.3, we have that A_e and $A_i + \sum_{A_f \in F_i} A_f = \sum_{A_f \in T_i} A_f$ are mutually rigid for every i. By Lemma 5.11, we have that A_e and $A_e + \sum_{i=1}^{c} \sum_{A_f \in T_i} A_f$ are mutually rigid and $A_e + \sum_{i=1}^{c} \sum_{A_f \in T_i} A_f$ is $\mathbb{S}$-compatible. This concludes the proof of the lemma. ∎

The next result generalizes the previous lemma.

THEOREM 6.3. [illegible] G [illegible] $A_1, A_2, \ldots, A_k$ [illegible] $\mathbb{S}$ [illegible] SPSD n [illegible] n [illegible] H_1 [illegible] H_2 [illegible] G [illegible] A_e [illegible] $B = \sum_{A_f \in V(H_1)} A_f$ [illegible] $C = \sum_{A_f \in V(H_2)} A_f$ [illegible]

[illegible]. According to Lemma 6.2, B and A_e are mutually rigid, and so are C and A_e. By Lemma 5.9, we have that B and $A_e + C$ are mutually rigid. The sum $A_e + C$ equals $\sum_{A_f \in V(H_2) \setminus A_e} A_f + 2A_e$. By Lemma 4.3, we have that B and $\sum_{A_f \in V(H_2)} A_f = C$ are mutually rigid. ∎

The next theorem shows that the rigidity graph can sometimes tell us that a finite-element matrix is rigid in the sense that its null space is exactly $\mathbb{S}$. This is only a sufficient condition; it is not necessary.

THEOREM 6.4. [illegible] G [illegible] $A_1, A_2, \ldots, A_k$ [illegible] $\mathbb{S}$ [illegible] n [illegible] n [illegible] $A = \sum_{e=1}^{k} A_e$ [illegible] N [illegible] $\mathbb{S}$ [illegible] G [illegible] $\mathrm{enull}(A) = \mathrm{span}(\Psi_A N)$ [illegible] $\bigcup_{e=1}^{k} \mathcal{N}_{A_e} = \{1, \ldots, n\}$ [illegible] $\mathrm{null}(A) = \mathbb{S}$ [illegible] A [illegible]

[illegible]. According to Lemma 6.2, A is $\mathbb{S}$-compatible. Therefore, by Lemma 5.4, $\mathrm{enull}(A) = \mathrm{span}(\Psi_A N)$.

If $\bigcup_{e=1}^{k} \mathcal{N}_{A_e} = \{1, \ldots, n\}$, then $\Psi_A N = N$ and $\mathrm{enull}(A) = \mathrm{null}(A)$. Therefore, $\mathrm{null}(A) = \mathrm{enull}(A) = \mathrm{span}(\Psi_A N) = \mathrm{span}(N) = \mathbb{S}$. By definition, A is rigid. ∎

When the rigidity graph is not connected, the null space may or may not be $\mathbb{S}$. To show that a disconnected rigidity graph sometimes corresponds to a null space larger than $\mathbb{S}$, consider

$$A_1 = \begin{bmatrix} 1 & -1 & 0 & 0 \\ -1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \quad \text{and} \quad A_2 = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & -1 \\ 0 & 0 & -1 & 1 \end{bmatrix}.$$

Both are compatible with $\mathbb{S} = \mathrm{span}\begin{bmatrix} 1 & 1 & 1 & 1 \end{bmatrix}^T$, but they are not mutually rigid. Therefore, their rigidity graph consists of two disconnected vertices. The null space of $A_1 + A_2$ is spanned by both $\begin{bmatrix} 1 & 1 & 1 & 1 \end{bmatrix}^T$ and $\begin{bmatrix} 1 & 1 & -1 & -1 \end{bmatrix}^T$, so it is indeed larger than $\mathbb{S}$, even though $\mathcal{N}_{A_1} \cup \mathcal{N}_{A_2} = \{1, 2, 3, 4\}$. Examples in which the rigidity graph is not connected but the null space of the sum is $\mathbb{S}$ are more complex; we show an example in section 7.3.

7. Three case studies. This section presents three families of $\mathbb{S}$-compatible SPSD matrices for two different $\mathbb{S}$s. One is well known and we present it without proofs. The second and third are more complex and we present them in full.

7.1. Laplacians. The first family of matrices that we present consists of Laplacians, matrices that are often used in spectral graph theory and in other areas. The results in this section are all adaptations of known results, so we omit the proofs. All the matrices and vectors are of order n.

DEFINITION 7.1. [illegible] (k,j) [illegible] $1 \le k < j \le n$ [illegible] $u^{(k,j)}$

$$u_i^{(k,j)} = \begin{cases} +1, & i = k, \\ -1, & i = j, \\ 0 & \text{[illegible]} \end{cases}$$

[illegible] (k,j) edge matrix [illegible] $A^{(k,j)} = u^{(k,j)}\, u^{(k,j)\,T}$

LEMMA 7.2. [illegible] $1 \le k < j \le n$ [illegible] $A^{(k,j)}$ [illegible]

1. $A^{(k,j)}$ [illegible] SPSD
2. $\mathcal{N}_{A^{(k,j)}} = \{k, j\}$
3. $A^{(k,j)}$ [illegible] $\mathbb{S}_1 = \operatorname{span}\begin{bmatrix}1 & 1 & \cdots & 1\end{bmatrix}^T$

The next lemma gives a sufficient and necessary condition for two edge matrices to be mutually rigid.

LEMMA 7.3. [illegible] $A^{(i,j)}$ [illegible] $A^{(k,\ell)}$ [illegible] $|\{i,j\} \cap \{k,\ell\}| \ge 1$

Laplacians are sums of edge matrices (sometimes of positively scaled edge matrices). They are often defined using an undirected graph $G = (\{1, 2, \ldots, n\}, E)$,

$$A^{(G)} = \sum_{(i,j)\in E} A^{(i,j)}.$$

Each edge matrix $A^{(i,j)}$ is then associated with an edge $(i,j) \in E$ in the graph G. Lemma 7.3 states that two edge matrices are mutually rigid if and only if the corresponding edges are incident on a common vertex.

The rigidity graph of $\{A^{(i,j)} | (i,j) \in E\}$ is a dual of G:

$$G_{\text{dual}} = \left(E, \{(e,f) : e \text{ and } f \text{ share a vertex in } G\}\right).$$

The rigidity graph of Laplacians is special in that its connectivity is not only a sufficient condition for the rigidity of the Laplacian, as shown in Theorem 6.4, but also a necessary condition.

LEMMA 7.4. [illegible] $G = (\{1, 2, \ldots, n\}, E)$ [illegible] $A^{(G)} = \sum_E A^{(i,j)}$ [illegible] G_{dual} [illegible] $\{A^{(i,j)} | (i,j) \in E\}$ [illegible]

[illegible]. We first show that if $A^{(G)}$ is rigid, then G is a connected graph. Assume for contradiction that G is not connected. Therefore, there are two nonempty sets of vertices S and $\bar{S} = \{1, \ldots, n\} \backslash S$ that are disconnected. Define the vector x:

$$x_i = \begin{cases} +1, & i \in S, \\ -1, & i \in \bar{S}. \end{cases}$$

By definition, $A^{(i,j)}x = 0$ for every $(i,j) \in E$. Therefore, $A^{(G)}x = \sum_{(i,j)\in E} A^{(i,j)}x = 0$. The vector x is in enull$(A^{(G)})$ and has no extension to $\mathbb{S}_1$. This contradicts the

assumption that $A^{(G)}$ is rigid, since this assumption implies that it is $\mathbb{S}_1$-compatible. Therefore, G is a connected graph.

It is clear that if G is connected, then G_{dual} is connected. This concludes the proof of the lemma. □

All the results on the rigidity of Laplacians hold for weighted Laplacians, which are sums of positively scaled edge matrices.

7.2. Elastic struts in two dimensions. The second family of matrices model a collection of pin-jointed struts. Such a collection may form a rigid structure called a truss (e.g., a triangle in two dimensions) or a nonrigid structure called a mechanism (e.g., two struts connected by a pin). The rigidity graph of such a structure, however, is never connected: it has no edges at all. Therefore, the rigidity graph can never show that the underlying structure is rigid. This shows that our analysis indeed only provides sufficient, but not necessary, conditions. We carry out the analysis nonetheless to give another example of how to derive mutual rigidity conditions.

We note that there is a combinatorial technique that can determine whether such a structure is rigid, under a technical assumption on the geometrical location of the pins. The structure is modeled by a graph in which vertices correspond to pins (assuming there is a pin at the end of each strut) and in which edges correspond to struts. If the pins are in an appropriately defined general position, then several equivalent conditions on the graph characterize exactly the rigidity of the structure [13, 15, 17, 21, 14]. These conditions can be tested in $O(n^2)$ operations [12].

Our technique is more general but less precise than these techniques. It applies to any finite-element matrix, but it provides only sufficient conditions for rigidity. In the cases of two-dimensional struts, our sufficient conditions are never satisfied. We show later in this section that our technique does work for other families of elastic structures.

DEFINITION 7.5. [illegible] $P = \{p_l\}_{l=1}^{n}$ [illegible] $p_l = (x_l, y_l)$ [illegible] $p_i \neq p_j$ [illegible] $v^{(i,j)}$ [illegible] $2P$ [illegible]

$$v_i^{(k,j)} = \begin{cases} (x_k - x_j)/r_{k,j}, & i = 2k-1, \\ (y_k - y_j)/r_{k,j}, & i = 2k, \\ -(x_k - x_j)/r_{k,j}, & i = 2j-1, \\ -(y_k - y_j)/r_{k,j}, & i = 2j, \\ 0 & \text{[illegible]}, \end{cases}$$

[illegible] $r_{k,j} = \sqrt{(x_k - x_j)^2 + (y_k - y_j)^2}$ [illegible] (i,j) strut matrix [illegible] $A^{(i,j)} = v^{(i,j)}\, v^{(i,j)\,T}$

DEFINITION 7.6. [illegible] $P = \{p_l\}_{l=1}^{n}$ [illegible]

$$N_P^{(x)} = \begin{bmatrix} 1 \\ 0 \\ 1 \\ 0 \\ \\ \\ 1 \\ 0 \end{bmatrix}, \quad N_P^{(y)} = \begin{bmatrix} 0 \\ 1 \\ 0 \\ 1 \\ \\ \\ 0 \\ 1 \end{bmatrix}, \quad \text{[illegible]} \quad N_P^{(r)} = \begin{bmatrix} -y_1 \\ x_1 \\ -y_2 \\ x_2 \\ \\ \\ -y_n \\ x_n \end{bmatrix}.$$

planar null space $\mathbb{S}_P = \operatorname{span} N_P$ $N_P = [N_P^{(x)}\ N_P^{(y)}\ N_P^{(r)}]$

The next lemma shows that the strut matrices are $\mathbb{S}_P$ compatible.

LEMMA 7.7. $P = \{p_l\}_{l=1}^n$

x y

1. $A^{(i,j)}$
2. $\mathcal{N}_{A^{(i,j)}} = \{2i-1, 2i, 2j-1, 2j\}$
3. $A^{(i,j)}$ $\mathbb{S}_P$

The first two claims in the lemma follow directly from the definition of $A^{(i,j)}$. We show that $A^{(i,j)}$ is $\mathbb{S}_P$-compatible by showing that the columns of $\Psi_{A^{(i,j)}} N_P$ form a basis for enull$(A^{(i,j)})$.

A direct calculation, which we omit, shows that $A\Psi_{A^{(i,j)}} N_P = 0$. The points p_i and p_j are different, so the rank of $\Psi_{A^{(i,j)}} N_P$ is 3. The rank of $A^{(i,j)}$ is 1, so its essential null space has dimension 3. Therefore, $\Psi_{A^{(i,j)}} N_P$ spans enull$(A^{(i,j)})$, so $A^{(i,j)}$ is $\mathbb{S}_P$ compatible. ∎

The following lemma indicates that the rigidity graph of a collection of strut matrices contains only trivial edges (self loops, which are always present).

LEMMA 7.8. $P = \{p_l\}_{l=1}^n$

x y $A^{(i,j)}$ $A^{(k,\ell)}$

$A^{(i,j)}$ $A^{(k,\ell)}$ $\{i,j\} = \{k,\ell\}$

Assume $A^{(i,j)}$ and $A^{(k,\ell)}$ are mutually rigid. By Lemma 5.12, rank $(\Psi_{A^{(i,j)},A^{(k,\ell)}} N_P) = 3$. Therefore, using Lemma 7.7, $|\{2i-1, 2i, 2j-1, 2j\} \cap \{2k-1, 2k, 2\ell-1, 2\ell\}| \geq 3$. This implies that $\{i,j\} = \{k,\ell\}$. The other direction is immediate; a matrix is always mutually rigid with itself. ∎

7.3. Elastic triangles in two dimensions. We now study another family of matrices that also arises in two-dimensional linear elasticity—matrices that model triangular elements. The rigidity graph of such a collection can be connected, so the rigidity graph can sometimes tell us that the structure is rigid. There are also cases in which the structure is rigid but its rigidity graph is not connected.

DEFINITION 7.9. $P = \{p_l\}_{l=1}^n$ $p_l = (x_l, y_l)$ $v^{(i,j)}$ $A^{(i,j)}$ 7.5

p_i p_j p_k (i,j,k) element matrix

$$A^{(i,j,k)} = A^{(i,j)} + A^{(i,k)} + A^{(j,k)} = v^{(i,j)}\, v^{(i,j)\,T} + v^{(j,k)}\, v^{(j,k)\,T} + v^{(k,i)}\, v^{(k,i)\,T}.$$

$A^{(i,j,k)}$

)

The next lemma is the equivalent of Lemma 7.7. We omit the proof, which is similar to the proof of Lemma 7.7.

LEMMA 7.10. $P = \{p_l\}_{l=1}^n$

A (i,j,k)

1. A
2. $\mathcal{N}_A = \{2i-1, 2i, 2j-1, 2j, 2k-1, 2k\}$
3. A $\mathbb{S}_P$ $\mathbb{S}_P$ 7.6.

The following lemma characterizes mutual rigidity between $\mathbb{S}_P$-compatible matrices.

LEMMA 7.11. $P = \{p_l\}_{l=1}^n$ A

B $\mathbb{S}_P$ i $j \neq i$

$\{2i-1, 2i, 2j-1, 2j\} \subseteq \mathcal{N}_A \cap \mathcal{N}_B$ A B

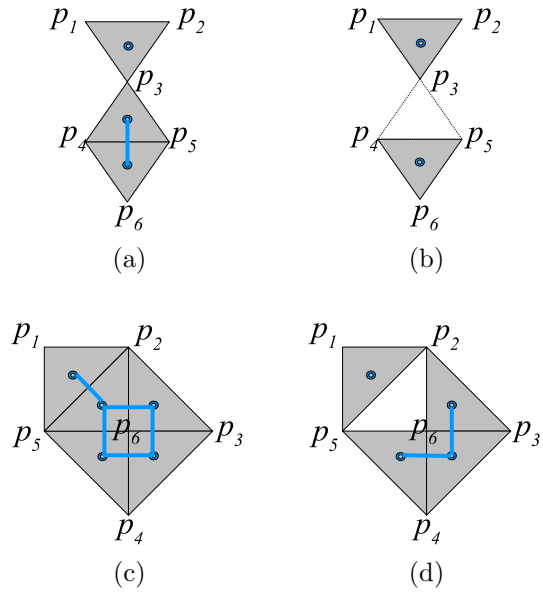

FIG. 7.1. *Triangular plane elements and their rigidity graphs (in blue).*

. By Lemma 5.12, it is sufficient to show that $\Psi_{A,B}N_P$ is rank-3. Indeed, it is easy to validate that since the points are different, $\text{rank}(\Psi_{A,B}N_P) > 3$. ∎

The last lemma of this section shows how to construct the rigidity graph for this family of matrices.

LEMMA 7.12. . $P = \{p_l\}_{l=1}^n$ $A = A^{(i,j,k)}$ $B = A^{(p,q,r)}$ A B $|\{i,j,k\} \cap \{p,q,r\}| \geq 2$

. If $|\{i,j,k\} \cap \{p,q,r\}| \geq 2$, there exist $m \neq l$ such that $\{2m-1, 2m, 2l-1, 2l\} \subseteq \mathcal{N}_A \cap \mathcal{N}_B$. Then, by Lemma 7.11, A and B are mutually rigid.

If A and B are mutually rigid, by Lemma 5.12, $\Psi_{A,B}N_P$ is rank-3. Therefore, $|\mathcal{N}_A \cap \mathcal{N}_B| \geq 3$. By Lemma 7.11, $|\{2i-1, 2i, 2j-1, 2j, 2k-1, 2k\} \cap \{2p-1, 2p, 2q-1, 2q, 2r-1, 2r\}| \geq 3$. Therefore, $|\{i,j,k\} \cap \{p,q,r\}| \geq 2$. ∎

Informally speaking, Lemma 7.12 shows that edges in the rigidity graph correspond to pairs of triangles whose mutual rigidity is evident: they share a side. The lemma can be generalized to higher dimensions: elastic elements are mutually rigid if and only if they share a face. For elasticity, this may be a trivial statement, but it shows that our definition of mutual rigidity indeed captures the domain-specific notion of rigidity.

Figure 7.1 shows a few examples of triangular plane elements and their rigidity graphs. The structures in cases (a) and (b) are not rigid, and the rigidity graph is not connected. Case (c) is rigid, and the rigidity graph is connected. Case (d) is rigid, but the rigidity graph does not show it; the graph is not connected. This shows, again, that connectivity of the rigidity graph is not a necessary condition for rigidity.

8. Rigid sparsifications. Our next goal is to sparsify a matrix A defined as a sum of $\mathbb{S}$-compatible SPSD n-by-n matrices, but without changing $\text{null}(A)$. By sparsify we mean that linear systems of the form $Bz = r$, where B is the sparsification of A, should be easier to solve than linear systems of the form $Ax = b$. In this sense, B is sparser than A if it has a subset of the nonzeros of A, or if the pattern graph of B

has smaller balanced vertex separators than the pattern graph of A [10, 16]. There may be other meanings.

8.1. Dropping vertices from the rigidity graph. Perhaps the most obvious way to sparsify $A = \sum_e A_e$ is to drop some of the element matrices from the assembly. This section gives a condition that guarantees that the subset-sum has the same range and null space as A. The analysis is inductive: it analyzes the effect of dropping one element at a time.

LEMMA 8.1. [illegible] G [illegible] $A_1, A_2, \ldots, A_k$ [illegible] $\mathbb{S}$ [illegible] SPSD n [illegible] n [illegible] $\{H_1, H_2, \ldots, H_\ell\}$ [illegible] G [illegible] $\mathcal{N}_{H_i} \cap \mathcal{N}_{H_j} = \phi$ [illegible] $i \neq j$ [illegible] $A = \sum_{f=1}^{k} A_f$ [illegible]

$$B = \sum_{\substack{f=1 \\ f \neq e}}^{k} A_f = A - A_e$$

[illegible] A_e

1. G [illegible] B [illegible]
2. $\mathcal{N}_A = \mathcal{N}_B$

[illegible] A [illegible] B [illegible]

. By Corollary 3.6 and by the condition $\mathcal{N}_A = \mathcal{N}_B$, it is sufficient to show that A and B are mutually rigid. By Lemma 4.1, $A = B + A_e$ is rigid with respect to B. All that is left to show is that B is rigid with respect to A.

Assume without loss of generality that A_e is in H_1. Let

$$C = \sum_{\substack{A_f \in H_1 \\ f \neq e}} A_f.$$

The first condition of the lemma implies that $H_1 \backslash \{A_e\}$ is a nonempty connected subgraph of G. Therefore, there exists a vertex A_c in $H_1 \backslash \{A_e\}$ such that A_e and A_c are mutually rigid. Applying Theorem 6.3 to $\{A_e, A_c\}$ and to $H_1 \backslash \{A_e\}$ shows that $A_e + A_c$ and C are mutually rigid. Therefore, by Lemma 4.2, C and $C + A_e + A_c$ are mutually rigid. Finally, by Lemma 4.3, C and $C + A_e$ are mutually rigid.

Let $D = \sum_{i=2}^{\ell} \sum_{A_f \in H_i} A_f$. We have that $\mathcal{N}_D \cap \mathcal{N}_C = \phi$ and $\mathcal{N}_D \cap \mathcal{N}_{C+A_e} = \phi$, since $\mathcal{N}_{H_i}$ are pairwise disjoint. By Lemma 4.4, we have that $C + D$ and $C + A_e + D$ are mutually rigid. Therefore, $A = C + A_e + D$ and $B = C + D$ are mutually rigid, so $\text{null}(A) = \text{null}(B)$. □

In particular, if G is connected, then the lemma allows us to drop element matrices only as long as the rigidity graph of the remaining elements remains connected. Clearly, there are cases where we can drop an element matrix that would disconnect the rigidity graph without changing the null space of the sum. In this case dropping the element violates the sufficient condition stated in Lemma 8.1, but without actually changing the null space. For example, dropping $A^{(2,5,6)}$ from the structure shown in Figure 7.1.(c) leads to the structure shown in Figure 7.1.(d), which is also rigid but has a disconnected rigidity graph.

The examples shown in Figure 7.1 (a) and (b) show that the lemma does not hold if the $\mathcal{N}_{H_i}$ are not mutually disjoint. Dropping $A^{(3,4,5)}$ from the structure shown in part (a) of the figure gives the structure shown in (b). The rigidity graphs of both

structures have the same number of connected components, 2, and $\mathcal{N}_A = \mathcal{N}_{A-A^{(3,4,5)}}$. But the null space of the structure in (a) has dimension 4 (rigid body motions and a rotation around p_3), whereas the null space of the structure in (b) has dimension 6 (separate rigid body motions for the two elements).

If we use Lemma 8.1 to construct a preconditioner B by repeatedly dropping element matrices from the sum $A = \sum_i A_i$, the generalized eigenvalues of (B, A) are clearly bounded from above by 1, since for any λ that satisfies $Bx = \lambda Ax$ for an $x \notin \text{null}(A)$ we have

$$\begin{aligned}\lambda &\leq \max_{\substack{x \\ Ax \neq 0}} \frac{x^T B x}{x^T A x} \\ &= \max_{\substack{x \\ Ax \neq 0}} \frac{x^T \left(\sum_{i \in S \subset \{1,\ldots,k\}} A_i \right) x}{x^T \left(\sum_{i=1}^{k} A_i \right) x} \\ &\leq 1.\end{aligned}$$

8.2. Dropping edges from the rigidity graph by fretsaw extensions. We now show and analyze a more sophisticated sparsification technique that drops edges from the rigidity graph. This technique allows us to algebraically express the physical action of cutting slits in a structure without changing its qualitative behavior (its null modes) and its material properties. The technique drops edges from the rigidity graph of a given structure and then modifies the indices of nonzero rows and columns in element matrices to simulate the action of cutting slits along element boundaries where edges have been dropped. Figure 8.1 illustrates the cutting idea and its connection to dropped edges in the rigidity graph. The technique is quite complex to define and analyze.

DEFINITION 8.2. [illegible] extension mapping [illegible] n [illegible] ℓ [illegible] $s = \begin{bmatrix} s_1 & s_2 & \cdots & s_\ell \end{bmatrix}$ [illegible] $1, n$ [illegible] master extension matrix P [illegible] s [illegible] $(n+\ell) \times n$ [illegible] 1 [illegible]

$$P_{ij}^{(s)} = \begin{cases} 1, & i \leq n \text{ and } j = i, \\ 1, & i > n \text{ and } j = s_{i-n}, \\ 0 & \text{otherwise.} \end{cases}$$

[illegible] extension matrix $Q^{(s)}$ [illegible] s [illegible] $(n+\ell) \times n$ [illegible] 1 [illegible] 1 [illegible] $P_{ij}^{(s)} = 0$ [illegible] $Q_{ij}^{(s)} = 0$ [illegible]

In the product $Q^{(s)}A$ of an extension matrix $Q^{(s)}$ and an arbitrary matrix A, each row of the product is either all zeros or a copy of some row of A, and each row of A is mapped to a row of the product. In particular, row i of A is mapped either to row i of the product or to row $n + j$, where $s_j = i$.

The following lemma states some properties of extension matrices and their relation to the projection matrices Ψ_A. We omit its proof.

LEMMA 8.3. [illegible] $P = P^{(s)}$ [illegible] $Q = Q^{(s)}$ [illegible] [illegible] s [illegible] ℓ [illegible] A [illegible] $n \times n$

I_n n n $Q^TQ = P^TQ = Q^TP = I_n$ $\Psi_{QAQ^T} = Q\Psi_A Q^T$

DEFINITION 8.4. $\mathbb{S} \subseteq \mathbb{R}^n$ s $\operatorname{span}\left(P^{(s)}N\right)$ N $\mathbb{S}$ $P^{(s)}\mathbb{S}$

LEMMA 8.5. $P^{(s)}\mathbb{S}$ $P^{(s)}$ $\mathbb{S}$ N N_1 N_2 $\mathbb{S}$ $\operatorname{span}\left(P^{(s)}N_1\right) = \operatorname{span}\left(P^{(s)}N_2\right)$

Proof. Let $x \in \operatorname{span}\left(P^{(s)}N_1\right)$. There exists a vector y such that $x = P^{(s)}N_1 y$. Since $N_1 y \in \mathbb{S}$, there exists a vector z such that $N_1 y = N_2 z$. Therefore, $x = P^{(s)}N_1 y = P^{(s)}N_2 z \in \operatorname{span}(P^{(s)}N_2)$. This implies that $\operatorname{span}\left(P^{(s)}N_1\right) \subseteq \operatorname{span}(P^{(s)}N_2)$. Equality follows by symmetry. ∎

Note that $\operatorname{span}\left(P^{(s)}N\right)$ is essentially the same space as N, but with some coordinates replicated. This observation serves as an intuition for the proofs of the following two lemmas.

The following lemma shows that the extension of an $\mathbb{S}$-compatible SPSD matrix retains its essential properties.

LEMMA 8.6. A $\mathbb{S}$ SPSD $Q = Q^{(s)}$ s QAQ^T SPSD $P^{(s)}\mathbb{S}$

Proof. The matrix QAQ^T is symmetric since A is symmetric. For an arbitrary vector x, let $y = Q^Tx$. We have that $x^TQAQ^Tx = y^TAy \geq 0$, since A is positive semidefinite. This implies that QAQ^T is positive semidefinite.

We now show that QAQ^T is compatible with $P^{(s)}\mathbb{S}$. Let N be a matrix whose columns form a basis for $\mathbb{S}$. It is sufficient to show that $\operatorname{span}(\Psi_{QAQ^T}P^{(s)}N) = \operatorname{enull}(QAQ^T)$.

By Lemma 8.3,

$$\Psi_{QAQ^T}P^{(s)}N = Q\Psi_A Q^T P^{(s)}N = Q\Psi_A N.$$

Therefore, $\operatorname{span}(\Psi_{QAQ^T}P^{(s)}N) = \operatorname{span}(Q\Psi_A N)$. Let E be a matrix whose columns form a basis for $\operatorname{enull}(A)$. Since A is $\mathbb{S}$-compatible, $\operatorname{span}(\Psi_A N) = \operatorname{span}(E)$. Moreover, since Q has full rank, $\operatorname{span}(Q\Psi_A N) = \operatorname{span}(QE)$. Therefore, $\operatorname{span}(\Psi_{QAQ^T}P^{(s)}N) = \operatorname{span}(QE)$.

Now, it is sufficient to show that $\operatorname{span}(QE) = \operatorname{enull}(QAQ^T)$ in order to prove the lemma. In the special case where Q is an $(n+\ell)$-by-n identity matrix, this equality directly follows the fact that $\operatorname{span}(E) = \operatorname{enull}(A)$. In the general case, Q is a row permutation of the $(n+\ell)$-by-n identity matrix, and the equlity holds since renaming the variables does not change anything. ∎

Similarly extended matrices maintain their rigidity relationship.

LEMMA 8.7. $\{A_i\}_{i=1}^k$ $\mathbb{S}$ SPSD $Q_e = Q_e^{(s)}$ $Q_f = Q_f^{(s)}$ s $[Q_e]_{:,j} = [Q_f]_{:,j}$ $j \in \mathcal{N}_{A_e} \cap \mathcal{N}_{A_f}$ $Q_e A_e Q_e^T$ $Q_f A_f Q_f^T$ A_e A_f Q $(n+\ell)$ n $(n+\ell)$ s) (A_e, A_f) $\{A_i\}_{i=1}^k$ (QA_eQ^T, QA_fQ^T) $\{QA_iQ^T\}_{i=1}^k$

. We start by some immediate definitions and observations. Let N be an n-by-ℓ matrix whose columns form a basis for $\mathbb{S}$. Let $P^{(s)}$ be the corresponding master extension matrix. By Lemma 8.6, the matrix $P^{(s)}$ is a basis for $P^{(s)}\mathbb{S}$, and $Q_e A_e Q_e^T$ and $Q_f A_f Q_f^T$ are $P^{(s)}\mathbb{S}$-compatible.

By Lemma 5.12, the matrices A_e and A_f are mutually rigid if and only if $\Psi_{A_e,A_f}N$ is rank-ℓ. The matrix $\Psi_{Q_e A_e Q_e^T, Q_f A_f Q_f^T}P^{(s)}N$ equals the matrix $\Psi_{A_e,A_f}N$. Therefore, $\Psi_{A_e,A_f}N$ is rank-ℓ if and only if $\Psi_{Q_e A_e Q_e^T, Q_f A_f Q_f^T}P^{(s)}N$ is rank-ℓ. Applying Lemma 5.12 again, we get that $\Psi_{Q_e A_e Q_e^T, Q_f A_f Q_f^T}P^{(s)}N$ is rank-ℓ if and only if $Q_e A_e Q_e^T$ and $Q_f A_f Q_f^T$ are mutually rigid. This concludes the proof of the lemma. □

We are particularly interested in certain extensions, described by the following definition.

DEFINITION 8.8. . $\{A_i\}_{i=1}^k$ $\mathbb{S}$ s $\{Q_i\}_{i=1}$ s G $\{A_i\}_{i=1}$ $\hat{G}$ $\{Q_i A_i Q_i^T\}_{i=1}$

- $j \in \mathcal{N}_A$ i $j \in \mathcal{N}_{A_i}$ $[Q_i]_{j,j} = 1$
- $A_{i_1}, \ldots, A_{i_m}$ G $Q_{i_1} A_{i_1} Q_{i_2}^T, \ldots, Q_{i_m} A_{i_m} Q_{i_m}^T$ $\hat{G}$
- $A_{i_1}, \ldots, A_{i_m}$ G $j \in \{i_1, \ldots, i_m\}$ Q_j $(n+\ell)$

$\{Q_i A_i Q_i^T\}_{i=1}^k$ fretsaw extension $\{A_i\}_{i=1}^k$ ( ) Q_i $\mathcal{F}(A)$ $\sum_{i=1}^k Q_i A_i Q_i^T$ fretsaw extension of $A = \sum_{i=1}^k A_i$.

We note that the first fretsaw condition ensures that $\mathcal{N}_A \subseteq \mathcal{N}_{\mathcal{F}(A)}$.

Transforming an extended matrix $B = \sum Q_i^{(s)} A_i \, {Q_i^{(s)}}^T$ back to $A = \sum A_i$ is simple, as shown in the next lemma.

LEMMA 8.9. . $A_1, A_2, \ldots, A_k$ n n P s $\{Q_i\}_{i=1}^k$ s $A = \sum_{i=1}^k A_i$ $B = \sum_{i=1}^k Q_i A_i Q_i^T$ $A = P^T B P$

. By Lemma 8.3, $P^T Q_i = I$, so

$$P^T B P = \sum_{i=1}^k P^T Q_i A_i Q_i^T P = \sum_{i=1}^k A_i = A. \qquad \square$$

DEFINITION 8.10. . B $(n+\ell)$ $(n+\ell)$

$$B = \begin{bmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{bmatrix}$$

B_{11} n n B_{22} ℓ ℓ B_{22} $\mathrm{schur}_\ell(B) = B_{11} - B_{12}B_{22}^{-1}B_{21}$ ℓ $\mathrm{schur}(B)$

The following theorem is the main structural result of this section. The theorem characterizes the relationship of the null spaces of a matrix and its fretsaw extension. In particular, it lists conditions that guarantee the preservation of the null space under a fretsaw extension.

Algorithm 1. Pseudocode for the construction of fretsaw spanning-tree extensions.

THEOREM 8.11. [illegible] $A = \sum_{i=1}^{k} A_i$ [illegible] $A_1, A_2, \ldots, A_k$ [illegible] $\mathbb{S}$ [illegible] n [illegible] n [illegible] Q [illegible] $(n+\ell)$ [illegible] n [illegible] $\mathcal{F}(A)$ [illegible] A [illegible] $\mathcal{N}_A = \{1, \ldots, n\}$ [illegible] $A_1, A_2, \ldots, A_k$ [illegible]:

1. QAQ^T [illegible] $\mathcal{F}(A)$ [illegible]
2. [illegible] $x \in \mathrm{enull}(QAQ^T)$ [illegible] $y \in \mathrm{enull}(\mathcal{F}(A))$ [illegible] $\Psi_{QAQ^T} y = x$
3. $\mathrm{null}(\mathcal{F}(A)) \subseteq \mathrm{null}(QAQ^T)$
4. [illegible] $\mathrm{schur}(\mathcal{F}(A))$ [illegible] $\mathrm{null}(A) = \mathrm{null}(\mathrm{schur}(\mathcal{F}(A)))$

[illegible]. Let $\{Q_i\}_{i=1}^k$ be the collection of the extension matrices used in $\mathcal{F}(A)$. By Lemma 8.6, the matrices in collections $\{Q_i A_i Q_i^T\}_{i=1}^k$ and $\{QA_iQ^T\}_{i=1}^k$ are compatible with $P^{(s)}\mathbb{S}$. By definition, the rigidity graph of $\{Q_iA_iQ_i^T\}_{i=1}^k$ is connected. By Lemma 8.7 and the assumption that the rigidity graph of $\{A_i\}_{i=1}^k$ is connected, the rigidity graph of $\{QA_iQ^T\}_{i=1}^k$ is also connected. By definition, the rigidity graph of $\{QA_iQ^T\}_{i=1}^k$ shares at least one vertex with the rigidity graph of $\{Q_iA_iQ_i^T\}_{i=1}^k$. Therefore, by Lemma 6.3, QAQ^T and $\mathcal{F}(A)$ are mutually rigid.

The second part of the lemma follows the fact that QAQ^T is rigid with respect to $\mathcal{F}(A)$ and that $\mathcal{N}_{QAQ^T} = \mathcal{N}_A \subseteq \mathcal{N}_{\mathcal{F}(A)}$.

The matrix $\mathcal{F}(A)$ is rigid with respect to QAQ^T. We also have that $\mathcal{N}_{QAQ^T} = \mathcal{N}_A \subseteq \mathcal{N}_{\mathcal{F}(A)}$. Therefore, by Lemma 3.5, $\mathrm{null}(\mathcal{F}(A)) \subseteq \mathrm{null}(QAQ^T)$. This proves the third part of the lemma.

The fourth part of the lemma follows from Lemma 3.7 and the fact that QAQ^T and $\mathcal{F}(A)$ are mutually rigid. ∎

8.3. Constructing a fretsaw extension from a spanning tree. We now show a practical way to construct nontrivial fretsaw extensions. The extensions that we build here are essentially as sparse as possible: we can factor $\mathcal{F}(A)$ with no fill. Our simple spanning-tree extensions may not be effective preconditioners (the generalized eigenvalues may be large), but the construction shows that there are efficient algorithms for constructing nontrivial fretsaw extensions.

Let $\mathcal{A} = \{A_1, A_2, \ldots, A_k\}$ be a collection of $\mathbb{S}$-compatible symmetric positive semidefinite n-by-n matrices. Let $G = (\mathcal{A}, E)$ be the rigidity graph of $\mathcal{A}$. Without loss of generality, we assume that G is connected (otherwise we repeat the construction for each connected component of G). The construction builds the Q_is by columns. This introduces a slight notational difficulty, since we do not know the number of rows in the Q_is until the construction ends. We use the convention that the columns are tall enough (nk is tall enough) and then chop the Q_is to remove the rows that are zero in all of them. We denote by e_r the rth (long enough) unit vector.

We use a spanning tree T of G to define an extension $\mathcal{F}(A)$. We initialize a variable r to n. This variable stores the index of the last nonzero row in the Q_is. We also initialize the extension mapping $s = \langle\rangle$. The algorithm iterates over the column indices $j \in \{1, \ldots, n\}$ (in any order). In iteration j, we construct column j of $Q_1, \ldots, Q_k$.

We begin iteration j by setting the jth column of Q_1 to e_j. This ensures that Q_1 is an identity matrix, so the third fretsaw condition is automatically satisfied.

We now construct the set $V^{(j)} = \{A_i \in \mathcal{A} | j \in \mathcal{N}_{A_i}\}$ of elements that are incident on the index j. We also construct the subgraph $G^{(j)} = (V^{(j)}, E^{(j)})$ of T that is induced by $V^{(j)}$. We partition $G^{(j)}$ into its connected components and process each component separately. The ordering of the components is arbitrary, except that if $A_1 \in V^{(j)}$, then we process the component containing A_1 first. Let $\{A_{i_1}, A_{i_2}, \ldots, A_{i_m}\} \subseteq V^{(j)}$ be the vertices of the next component to be processed. If this component is the first component of $G^{(j)}$, then we set the jth columns of $Q_{i_1}, \ldots, Q_{i_m}$ to e_j. Otherwise, we increment r, set the jth columns of $Q_{i_1}, \ldots, Q_{i_m}$ to e_r, and concatenate the current index j to the end of s.

This process specifies the jth column of every Q_i such that $j \in \mathcal{N}_{A_i}$. We complete the construction of the Q_is by setting the jth column of every Q_i such that $j \notin \mathcal{N}_{A_i}$ to e_j.

Sometimes the row/column indices of $A = \sum A_i$ have a natural grouping. For example, in problems arising in two-dimensional linear elasticity, each point in the geometry of the discrete structure is associated with two indices, an x-direction index, say, j_1, and a y-direction index, say, j_2. This usually implies that $G^{(j_1)}$ and $G^{(j_2)}$ are identical graphs. In such cases, it may be wise to [illegible] A [illegible]: we order the connected components of $G^{(j_1)}$ and $G^{(j_2)}$ consistently, which means that $[Q_i]_{:,j_1} = e_{j_1}$ if and only if $[Q_i]_{:,j_2} = e_{j_2}$. A consistent extension has a physical interpretation in terms of slits in the material, whereas an inconsistent extension may have no straightforward physical meaning.

Figure 8.1 illustrates the construction of a spanning-tree fretsaw-extended matrix for a structure consisting of linear elastic elements in two dimensions. The figure explains the rationale behind the term fretsaw. A fretsaw is a fine-toothed saw held under tension, designed for cutting thin slits in flat materials, such as sheets of plywood. When applied to two-dimensional elastic structures, like the one shown in Figure 8.1, the spanning-tree fretsaw construction appears to cut the original structure like a fretsaw.

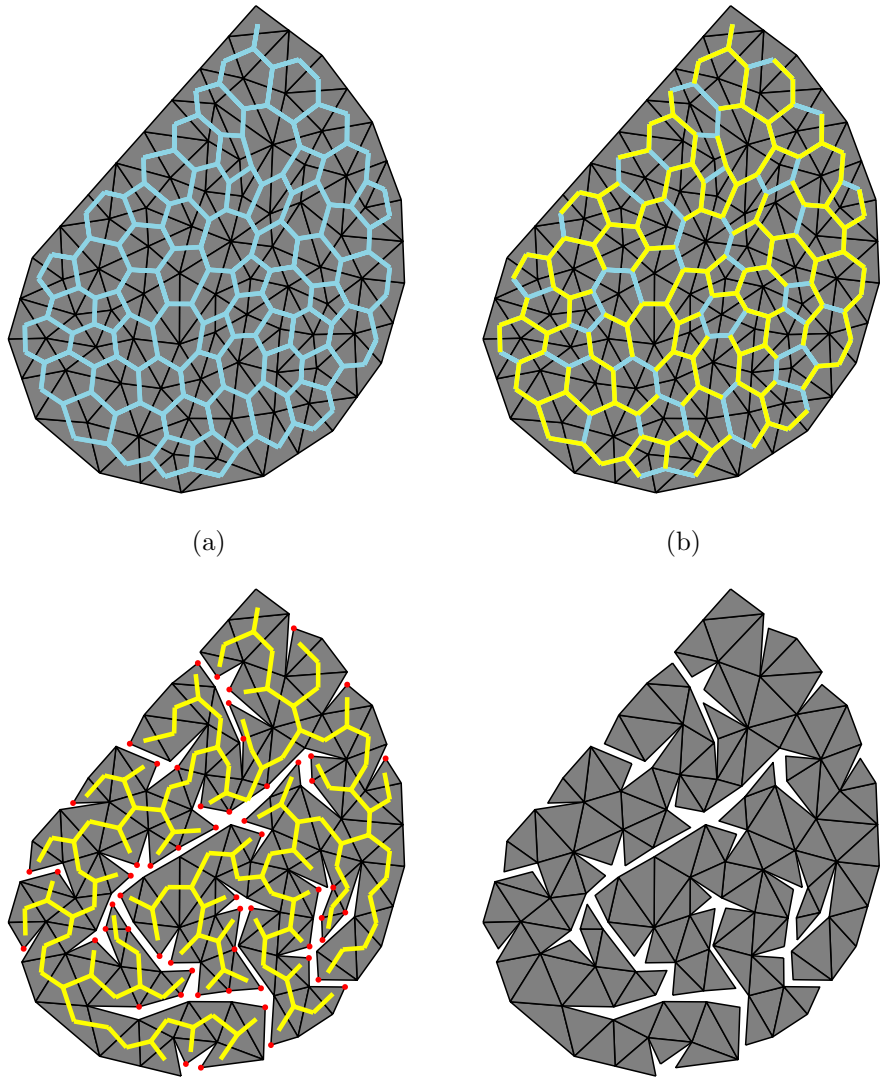

FIG. 8.1. *The construction of a spanning-tree fretsaw-extended matrix.* (a) *The elements of the original structure and its rigidity graph in blue; elements are mutually rigid if and only if they share a side.* (b) *A spanning tree T (yellow) of the rigidity graph.* (c) *The structure induced by the spanning tree; duplicated nodes are marked by red circles. In the illustration, the triangles have been slightly shrunk to show how rigidity relationships have been severed, but the element matrices are only permuted, so they still model the original triangles.* (d) *The fretsaw-extended structure.*

Once the Q_i's are constructed, we form $\mathcal{F}(A) = \sum_{i=1}^{k} Q_i A_i Q_i^T$. The next theorem shows that the Q_i's are extension matrices for some s and that $\mathcal{F}(A)$ is a fretsaw extension of A.

THEOREM 8.12. $\{A_i\}_{i=1}^{k}$ $\mathbb{S}$ SPSD n n s $\{Q_i\}_{i=1}^{k}$ $\mathcal{F}(A) = \sum_{i=1}^{k} Q_i A_i Q_i^T$ A

. We first show that the Q_i's are indeed valid extension matrices for a single s. We construct s step-by-step simultaneously with the construction of the Q_i's. We initialize $s = \langle\rangle$. When we increment the value r, we concatenate the current index j to the end of s. By definition, Q_i contains a nonzero in (r, j) if and only if s contains the value j in its $(r-n)$th position. Therefore, the Q_i's are consistent with $P^{(s)}$. Moreover, by definition, every column j of a matrix Q_i is either e_j or e_r, where $r > n$ and r is unique among the columns of Q_i. Therefore, the Q_i's are valid extension matrices.

Let G be the rigidity graph of $\{A_i\}_{i=1}^k$, and let $\hat{G}$ be the rigidity graph of $\{Q_i A_i Q_i^T\}_{i=1}^k$. We show now that for every connected component $A_{i_1}, A_{i_2}, \ldots, A_{i_m}$ in G, the matrices $Q_{i_1}A_{i_1}Q_{i_1}^T, Q_{i_2}A_{i_2}Q_{i_2}^T, \ldots, Q_{i_m}A_{i_m}Q_{i_m}^T$ form a connected component in $\hat{G}$ and vice versa. Let $A_{i_1}, A_{i_2}, \ldots, A_{i_m}$ be a connected component of G. Let T be the spanning tree used to create $Q_{i_1}, Q_{i_2}, \ldots, Q_{i_m}$. Let A_p and A_q be two matrices adjacent in T. For every index $j \in \mathcal{N}_{A_p} \cap \mathcal{N}_{A_q}$, A_p and A_q belong to the same connected component of $G^{(j)}$. Therefore, Q_p and Q_j coincide on their jth column. Therefore, by Lemma 8.7, $Q_p A_p Q_p^T$ and $Q_q A_q Q_q^T$ are mutually rigid. Therefore, $Q_{i_1}A_{i_1}Q_{i_1}^T, Q_{i_2}A_{i_2}Q_{i_2}^T, \ldots, Q_{i_m}A_{i_m}Q_{i_m}^T$ is a connected component in $\hat{G}$. In a similar manner, if $Q_{i_1}A_{i_1}Q_{i_1}^T, Q_{i_2}A_{i_2}Q_{i_2}^T, \ldots, Q_{i_m}A_{i_m}Q_{i_m}^T$ form a connected component in $\hat{G}$, by Lemma 8.7, $A_{i_1}, A_{i_2}, \ldots, A_{i_m}$ is a connected component in G.

There are two additional properties that need to be verified in order to show that $\mathcal{F}(A)$ is a fretsaw extension. By definition, the construction ensures that there is at least one Q_{i_1} for every connected component which is an $(n+l)$-by-n identity matrix. The second property that we need to show is that $\mathcal{N}_A \subseteq \mathcal{N}_{\mathcal{F}(A)}$. Let $j \in \mathcal{N}_A$. Let A_p be a matrix in the connected component of $G^{(j)}$ that was processed first. By definition, column j of Q_p contains e_j. Therefore, $j \in \mathcal{N}_{Q_p A_p Q_p^T}$. Lemma 2.6 ensures that $j \in \mathcal{N}_{\mathcal{F}(A)}$. □

8.4. Perfect elimination orderings for spanning-tree fretsaw extensions. The spanning-tree fretsaw construction is motivated by an elimination ordering that guarantees that all the fill occurs within the nonzero structure of the element matrices. If $[A_e]_{i,j} \neq 0$ for all $i, j \in \mathcal{N}_A$, this ordering is a no-fill ordering of $\mathcal{F}(A)$.

The analysis in the proof is closely related to the analysis of clique trees. The spanning-tree fretsaw is a tree of cliques that satisfies the clique-intersection property defined by Blair and Peyton [3]. If the elements were guaranteed to be , cliques, then Theorem 3.2 of [3] would guarantee a no-fill elimination ordering. But we are not certain whether element matrices are always maximal cliques in the graph of the assembled matrix, so [3, Theorem 3.2] is not directly applicable.

LEMMA 8.13. . $\mathcal{A} = \{A_1, A_2, \ldots, A_k\}$ $\mathbb{S}$ SPSD n n $\mathcal{F}(A)$ $A = \sum_{i=1}^k A_i$. Γ $L_{i,j}$ L $\Gamma\mathcal{F}(A)\Gamma^T$ $i, j \in \mathcal{N}_{\Gamma Q_e A_e Q_e^T \Gamma^T}$ e (e i j)

. We root the spanning tree T of the rigidity graph at A_1 and take ϕ to be a postorder of this rooted tree. That is, ϕ is an ordering of the element matrices in which the leaves of the rooted tree appear first, followed by parents of leaves, etc. We construct an elimination ordering γ incrementally. Initially, $\gamma = \langle\rangle$ is an empty ordering. Let A_e be the next unprocessed element matrix in ϕ, and let A_f be the parent of A_e in the rooted tree (if it has a parent). Let $\{i_1, \ldots, i_m\}$ be the indices in

$$\mathcal{N}_{Q_e A_e Q_e^T} \setminus \left(\mathcal{N}_{Q_f A_f Q_f^T} \bigcup \gamma\right)$$

(with γ taken to be a set of already ordered indices). We concatenate $\langle i_1, \ldots, i_m \rangle$ to γ in an arbitrary order. The permutation matrix Γ is the matrix that corresponds to γ. That is, $\Gamma_{i,\gamma_i} = 1$.

Now that we have specified Γ, we show that it limits fill as claimed.

A. Let $i \in \{1, \ldots, n, n+1, \ldots, n+\ell\}$. Let j be the column in $P^{(s)}$ such that $P^{(s)}_{i,j} \neq 0$ (recall that every row in $P^{(s)}$ contains exactly one nonzero). We denote by $G^{(j)}_i$ the connected component of $G^{(j)}$ in which j is mapped to i. The graph $G^{(j)}_i$ is a connected subgraph of $G^{(j)}$ which is an induced subgraph of a rooted tree. Therefore, $G^{(j)}_i$ is itself a rooted tree. We claim that i is added to γ during the processing of the root A_h of $G^{(j)}_i$.

A. We first show that if i is added to γ, then it is added during the processing of the root of $G^{(j)}_i$. Let A_e be the element during the processing of which we add i to γ. We first show that $A_e \in G^{(j)}_i$. Clearly, $i \in \mathcal{N}_{Q_e A_e Q_e^T}$. Therefore, $j \in \mathcal{N}_{A_e}$. By the definition of $G^{(j)}$, $A_e \in G^{(j)}$, and by the definition of $G^{(j)}_i$, $A_e \in G^{(j)}_i$. Now suppose for contradiction that A_e is not the root of $G^{(j)}_i$. Then A_e has a parent A_f in $G^{(j)}_i$. Because A_f is in $G^{(j)}_i$, $i \in \mathcal{N}_{Q_f A_f Q_f^T}$, so the algorithm would not have added i to γ during the processing of A_e. Therefore, A_e the root of $G^{(j)}_i$.

To complete the proof of Claim A, we show that i is added to γ. Suppose for contradiction that it is not. When we process the root A_h of $G^{(j)}_i$, $i \notin \gamma$. But i cannot be in $\mathcal{N}_{Q_f A_f Q_f^T}$, where A_f is the parent of A_h in the global rooted tree. If it was, then $j \in \mathcal{N}_{A_f}$, so A_f would be in $G^{(j)}$, and because it is connected to A_h, it must also be in $G^{(j)}_i$. But A_h is the root of $G^{(j)}_i$, so $i \notin \mathcal{N}_{Q_f A_f Q_f^T}$. Therefore, i is added to γ. This concludes the proof of Claim A.

B. Just before A_f is processed, γ is exactly the set

$$\gamma = \left\{ i : i \in \mathcal{N}_{Q_e A_e Q_e^T} \text{ for some } A_e \text{ that appears before } A_f \text{ in } \phi \right\}$$
$$\setminus \left(\mathcal{N}_{Q_f A_f Q_f^T} \cup \left\{ i : i \in \mathcal{N}_{Q_g A_g Q_g^T} \text{ for some } A_g \text{ that appears after } A_f \text{ in } \phi \right\} \right).$$

B. The claim follows by induction from the process of constructing γ and from the fact that ϕ is a postorder of the rooted tree.

C. If $L_{\hat r,\hat c} \neq 0$ then $\hat r, \hat c \in \mathcal{N}_{\Gamma Q_e A_e Q_e^T \Gamma^T}$ for some e.

C. If $L_{\hat r,\hat c} \neq 0$, then either $\left[\Gamma \mathcal{F}(A) \Gamma^T\right]_{\hat r,\hat c} \neq 0$ or there is some $\hat\imath < \hat r, \hat c$ such that $L_{\hat r,\hat\imath} \neq 0$ and $L_{\hat c,\hat\imath} \neq 0$. The first condition cannot violate Claim B, because if $\left[\Gamma \mathcal{F}(A) \Gamma^T\right]_{\hat r,\hat c} \neq 0$ then there is some e such that $\left[\Gamma Q_e A_e Q_e^T \Gamma^T\right]_{\hat r,\hat c} \neq 0$, so $\hat r, \hat c \in \mathcal{N}_{\Gamma Q_e A_e Q_e^T \Gamma^T}$.

If for some $\hat r$ and $\hat c$ we have $L_{\hat r,\hat c} \neq 0$ because of the second condition, then let $\hat\imath$ be the minimal index such that $L_{\hat r,\hat\imath} \neq 0$ and $L_{\hat r,\hat\imath} \neq 0$ $(\hat r, \hat c)$. This definition of $\hat\imath$ guarantees that $\left[\Gamma \mathcal{F}(A) \Gamma^T\right]_{\hat r,\hat\imath} \neq 0$ and $\left[\Gamma \mathcal{F}(A) \Gamma^T\right]_{\hat c,\hat\imath} \neq 0$. Define $i = \gamma_{\hat\imath}$, $r = \gamma_{\hat r}$, and $c = \gamma_{\hat c}$.

Let A_f be the element during the processing of which i was added to γ. Because $\hat\imath < \hat r, \hat c$, when i is added to γ, r and c are not yet in γ. We claim that r and c are in $\mathcal{N}_{Q_f A_f Q_f^T}$; if this is true, Claim C holds. Suppose for contradiction that $r \notin \mathcal{N}_{Q_f A_f Q_f^T}$. By Claim B, $r \in \mathcal{N}_{A_g}$ for some A_g that appears after A_f in ϕ. Because $\left[\Gamma \mathcal{F}(A) \Gamma^T\right]_{\hat r,\hat\imath} \neq 0$ and because A_g is symmetric, we must also have $i \in \mathcal{N}_{A_g}$.

But this implies that i cannot be added to γ when A_f is processed (by Claim B). This concludes the proof of Claim C and the entire proof. ∎

8.5. Quantitative analysis. Lemma 8.11 showed that if the rigidity graph of a finite-element matrix $A = \sum A_e$ is connected and if $\mathrm{schur}(\mathcal{F}(A))$ exists for a fretsaw extension $\mathcal{F}(A)$, then A and $\mathrm{schur}(\mathcal{F}(A))$ have the same range and null space. We now strengthen this result and show that the generalized eigenvalues of $(\mathrm{schur}(\mathcal{F}(A)), A)$ are bounded from above by 1. We note that $\mathrm{schur}(\mathcal{F}(A))$ can be implicitly used as a preconditioner; in the preconditioning step of an iterative linear solver, we can solve a linear system whose coefficient matrix is $\mathcal{F}(A)$—not $\mathrm{schur}(\mathcal{F}(A))$ [11, section 3.3]. In particular, the previous section showed that we can factor a spanning-tree fretsaw extension $\mathcal{F}(A)$ with essentially no fill.

LEMMA 8.14. Let $A_1, A_2, \ldots, A_k$ be matrices in $\mathbb{S}^+$, each SPSD n-by-n, and let $A = \sum_{i=1}^{k} A_i$. Let $\mathcal{F}(A)$ be a fretsaw extension of A such that $\mathrm{schur}(\mathcal{F}(A))$ exists. Let λ be a finite generalized eigenvalue of $(\mathrm{schur}(\mathcal{F}(A)), A)$. Then $\lambda \leq 1$.

Proof. We partition $\mathcal{F}(A)$ into

$$\mathcal{F}(A) = \begin{bmatrix} B_{11} & B_{12} \\ B_{12}^T & B_{22} \end{bmatrix},$$

where B_{11} is n-by-n and B_{22} is ℓ-by-ℓ. By the assumption that $\mathrm{schur}(\mathcal{F}(A))$ exists, B_{22} is symmetric positive definite. In this notation, $\mathrm{schur}(\mathcal{F}(A)) = B_{11} - B_{12}B_{22}^{-1}B_{12}^T$. Let P be the $(n+\ell)$-by-n master extension matrix corresponding to the fretsaw extension $\mathcal{F}(A)$ and let Q be the $(n+\ell)$-by-n identity matrix.

Let $\lambda_{\max}$ be the maximal finite generalized eigenvalue of the pencil $(\mathrm{schur}(\mathcal{F}(A)), A)$ and let x be the corresponding eigenvector. We let

$$\hat{x} = \begin{bmatrix} x \\ -B_{22}^{-1}B_{21}x \end{bmatrix}$$

and multiply it by $\mathcal{F}(A)$:

$$\begin{aligned} \mathcal{F}(A)\hat{x} &= \begin{bmatrix} B_{11}x + B_{12}(-B_{22}^{-1}B_{21}x) \\ B_{21}x + B_{22}(-B_{22}^{-1}B_{21}x) \end{bmatrix} \\ &= \begin{bmatrix} \mathrm{schur}(\mathcal{F}(A))x \\ 0 \end{bmatrix} \\ &= \begin{bmatrix} \lambda_{\max}Ax \\ 0 \end{bmatrix} \\ &= \lambda_{\max}QAQ^T\hat{x}\,. \end{aligned}$$

Multiplying both sides by $\hat{x}^T$, we obtain $\hat{x}^T\mathcal{F}(A)\hat{x} = \lambda_{\max}\hat{x}^TQAQ^T\hat{x}$.

We now show that $\hat{x}^T\mathcal{F}(A)\hat{x} \leq \hat{x}^TQAQ^T\hat{x}$. For a length-$\ell$ vector y, define the function

$$f(y) = \begin{bmatrix} x^T & y^T \end{bmatrix} \mathcal{F}(A) \begin{bmatrix} x \\ y \end{bmatrix}.$$

We note that $f(-B_{22}^{-1}B_{21}x) = \hat{x}^T\mathcal{F}(A)\hat{x}$. For an arbitrary y,

$$\begin{aligned}
\begin{bmatrix} x^T & y^T \end{bmatrix} \mathcal{F}(A) \begin{bmatrix} x \\ y \end{bmatrix} &= \begin{bmatrix} x^T & y^T \end{bmatrix} \begin{bmatrix} B_{11} & B_{12} \\ B_{12}^T & B_{22} \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} \\
&= x^T B_{11} x + y^T B_{12}^T x + x^T B_{12} y + y^T B_{22} y \\
&= x^T \left(B_{11} - B_{12} B_{22}^{-1} B_{12}^T \right) x + x^T B_{12} B_{22}^{-1} B_{12}^T x \\
&\quad + y^T B_{12}^T x + x^T B_{12} y + y^T B_{22} y \\
&= x^T \left(B_{11} - B_{12} B_{22}^{-1} B_{12}^T \right) x \\
&\quad + \left(y + B_{22}^{-1} B_{12}^T x \right)^T B_{22} \left(y + B_{22}^{-1} B_{12}^T x \right).
\end{aligned}$$

Because B_{22} is positive definite, $f(y)$ is minimized at $y = -B_{22}^{-1}B_{12}^T x$.

By Lemma 8.9, $\hat{x}^T Q A Q^T \hat{x} = \hat{x}^T Q (P^T \mathcal{F}(A) P) Q^T \hat{x} = x^T P^T \mathcal{F}(A) P x$. By the definition of a master extension matrix, the vector Px contains the vector x in its first n coordinates, so $Px = \begin{bmatrix} x^T & z^T \end{bmatrix}$ for some z and $x^T P^T \mathcal{F}(A) P x = f(z)$. Since $-B_{22}^{-1}B_{12}^T x$ minimizes f,

$$\hat{x}^T Q A Q^T \hat{x} = x^T P^T \mathcal{F}(A) P x = f(z) \geq f(-B_{22}^{-1} B_{12}^T x) = \hat{x}^T \mathcal{F}(A) \hat{x}.$$

This implies that $\lambda_{\max} \leq 1$ and concludes the proof of the lemma. □

9. Numerical examples. In this section we present experimental results that indicate that fretsaw-tree sparsifications can be used as preconditioners. We do not claim that they are particularly effective. Our only goal in this section is to demonstrate that fretsaw-tree sparsifications can be used computationally as preconditioners. The results presented in this section also suggest that the qualitative convergence behavior of fretsaw-extension preconditioners is similar to that of Vaidya's preconditioners when applied to weighted Laplacians [8].

Figure 9.1 shows convergence results for an iterative solver (preconditioned conjugate gradients) with a fretsaw-tree preconditioner. The figure shows results for two different physical two-dimensional problems that we discretized on the same triangulated mesh. One problem was a Poisson problem and the other a linear elasticity problem, both with constant coefficients and with Neumann (natural) boundary conditions. In each case, we constrained one or three unknowns belonging to a single triangle to transform the coefficient matrix into a nonsingular one.

Each graph shows convergence results for three conjugate-gradient solvers: with no preconditioning, with no-fill incomplete Cholesky preconditioning (denoted [illegible] (0) in the graphs), and with fretsaw-tree preconditioning. The fretsaw trees for the two problems are different, of course, because the rigidity graphs are different. We chose to compare the fretsaw-tree preconditioner with a no-fill incomplete Cholesky preconditioner because both are equally sparse.

Figure 9.2 shows similar plots for two three-dimensional problems defined on a cylinder, a Poisson problem, and a linear elastic problem. The material is isotropic, but the coefficients are variable; the material constant is $1 + 10x + 1000y + 1000z$, where $x \in [0, 35]$ and $y, z \in [0, 0.2]$. The tree that we constructed was a maximum spanning tree, where the weights were chosen heuristically to reflect the norm and condition of element matrices.

The results show that fretsaw trees can be used as preconditioners. The experiments are too limited to fully judge them, but the experiments do indicate that they are not worse than another no-fill preconditioner. Two other observations on the graphs are (1) the fretsaw is better than incomplete Cholesky on the two-dimensional Poisson problem, but the two preconditioners are comparable on the other problems, and (2) the steady linear convergence behavior of the fretsaw trees is similar to the convergence behavior of Vaidya's preconditioners on weighted Laplacians [8].

10. Concluding remarks. To keep the paper readable and of reasonable length, we have omitted from it several topics, which we plan to cover in other papers.

- Element matrices that represent boundary conditions. In much of this paper, we have assumed that all the element matrices are compatible with $\mathbb{S}$. This means, in particular, that the element matrix is singular. In many practical computations, boundary conditions are added to remove the singularity. We kept the discussion focused on singular matrices to reduce clutter. We plan to explore the handling of boundary conditions in a future paper.
- Fretsaw constructions other than spanning-tree fretsaw extensions. Previous work on combinatorial preconditioners indicates, both theoretically and experimentally, that tree and tree-like preconditioners are not effective; aug-

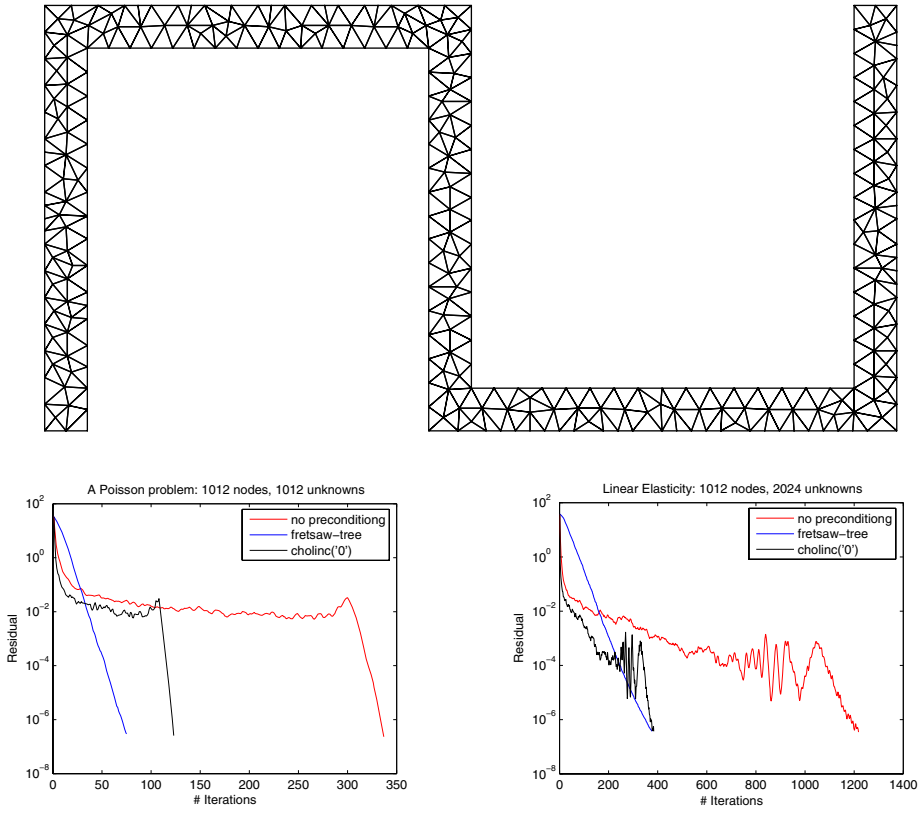

FIG. 9.1. *A triangularization of a two-dimensional domain (top) and convergence plots for two problems discretized on this domain. The triangularization used in the plots is finer than the one shown in the top part of the figure. The graph on the left shows the convergence of iterative solvers on a discretization of a Poisson problem, and the graph on the right shows convergence on a linear elasticity problem, both with constant coefficients.*

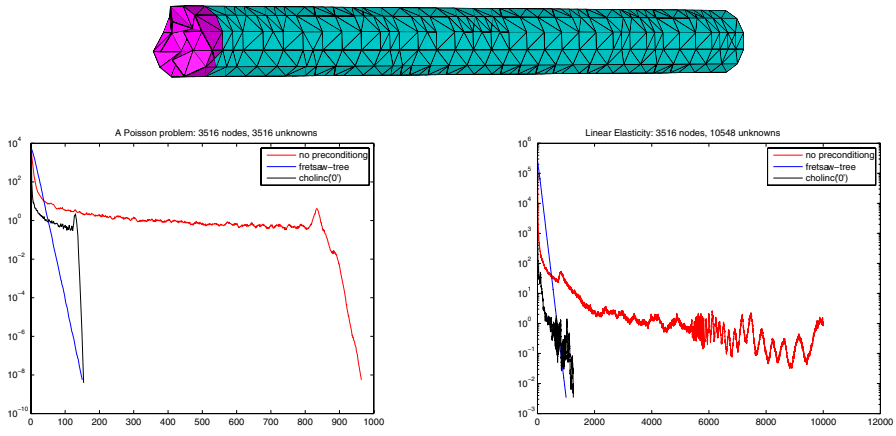

FIG. 9.2. *A tetrahedral meshing of a three-dimensional cylinder (top) and convergence plots for two problems discretized on a similar but longer cylinder (bottom). The leftmost part of the cylinder was removed to reveal the irregular meshing inside.*

mented trees and other constructions usually work better. We have developed augmented spanning-tree fretsaw extension algorithms for Laplacians, but this construction is beyond the scope of this paper.

In addition, there are several interesting problems that we have not yet solved. The most interesting one is proving lower bounds on the generalized eigenvalues of $(\text{schur}(\mathcal{F}(A)), A)$ and finding fretsaw constructions that ensure that this bound is not too small. A particularly interesting question is whether this can be done by assigning weights to the edges of the rigidity graph.

Another question is what other results from spectral graph theory can be generalized to finite-element matrices as defined in this paper, and whether the rigidity graph, perhaps weighted, would be useful in such generalizations.

Acknowledgments. Thanks to the two anonymous referees for numerous comments and suggestions.

GENERALIZED EIGENVALUES OF NONSQUARE PENCILS WITH STRUCTURE*

PABLO LECUMBERRI†, MARISOL GÓMEZ†, AND ALFONSO CARLOSENA‡

Abstract. This work deals with the generalized eigenvalue problem for nonsquare matrix pencils $\mathbf{A} - \lambda\mathbf{B}$ such that matrices $\mathbf{A}, \mathbf{B} \in \mathcal{M}_{\mathbb{C}}(m \times n)$ show a given structure. More precisely, we assume they result from removing the first row of some matrix $\mathbf{G} \in \mathcal{M}_{\mathbb{C}}((m+1), n)$ in the case of $\mathbf{A}$, and its last row in the case of $\mathbf{B}$. This structured generalized eigenvalue problem can be found in signal processing methods and in the numerical computation of the greatest common divisor (GCD) of polynomials. Traditional methods for solving the problem $(\mathbf{A} - \lambda\mathbf{B})\,\mathbf{v} = \mathbf{0}$ do not yield valid solutions when the data are not exact, as is often the case in real applications. In this work we adopt a minimal perturbation approach. Taking into account the structure of the matrices involved, we develop a simple algorithm for the computation of the generalized eigenvalues.

1. Introduction.

1.1. Nonsquare matrix pencils with structure. Given two matrices $\mathbf{A}$, $\mathbf{B}$ of the same dimensions, the set $\{\mathbf{A} - \lambda\mathbf{B};\ \lambda \in \mathbb{C}\}$ constitutes a pencil. The generalized eigenvalues of the matrix pencil are those values of λ for which there exist vectors $\mathbf{v}$ different from zero, called generalized eigenvectors, such that the pair $(\lambda, \mathbf{v})$ satisfies

$$(\mathbf{A} - \lambda\mathbf{B}) \cdot \mathbf{v} = \mathbf{0}.$$

The computation of the generalized eigenvalues has been regarded as a tool of great importance in engineering problems for decades. See [6] for applications in linear systems theory.

Matrices $\mathbf{A}$ and $\mathbf{B}$ form a regular matrix pencil $(\mathbf{A} - \lambda\mathbf{B})$ if they are square and the characteristic polynomial $p(\lambda) = \det(\mathbf{A} - \lambda\mathbf{B})$ is only zero for a finite number of values of λ. The generalized eigenvalue problem for this case has been extensively studied. In [12] there can be found some methods to solve it. The problem is more difficult when the matrices are rectangular or $(\mathbf{A} - \lambda\mathbf{B})$ is square and singular for all values of λ. A matrix pencil built with this kind of matrices is known as a singular matrix pencil and its set of eigenvalues can be finite, empty, or infinite.

It is common to find applications, especially in the field of signal processing, that involve rectangular matrices $\mathbf{A}, \mathbf{B} \in \mathcal{M}_{\mathbb{C}}(m, n)$, $m > n$. Additional measurements, which should allow more accurate estimations, add more rows to matrices $\mathbf{A}$ and $\mathbf{B}$. Besides, matrices $\mathbf{A}$ and $\mathbf{B}$ often show some structure that must be taken into account for a correct treatment of the problem, or that may ease the complexity of

the computation of the generalized eigenvalues. In this work we consider the following structure: We assume that matrix $\mathbf{A}$ is the result of removing the first row of some matrix $\mathbf{G} \in \mathcal{M}_{\mathbb{C}}(m+1, n)$, while matrix $\mathbf{B}$ results from removing the last row of $\mathbf{G}$. These structured nonsquare matrix pencils appear, for example, in some important signal processing applications [13, 9, 17] (in some of these examples, matrices $\mathbf{A}$, $\mathbf{B}$ also show some other structure, namely the Hankel structure of matrix $\mathbf{G}$; this is not considered in this paper), and in the computation of the greatest common divisor of polynomials [14, 15], which in turn has application in diverse fields, such as network theory, automatic control, and computer-aided geometric design.

1.2. The use of the Kronecker canonical form (KCF). The Jordan canonical form of a square matrix, which describes its eigenvalues and invariant subspaces, can be extended to matrix pencils. A pencil $(\mathbf{A} - \lambda\mathbf{B})$ is similar to its KCF [11], which is a pseudodiagonal matrix whose diagonal building blocks are Jordan blocks, with finite and infinite eigenvalues, and, in the case of singular pencils, singular blocks. The development of algorithms for the computation of the KCF has been a matter of research for decades. Nowadays, numerically stable routines are available (see [1] and the references therein). However, the computation of the KCF is an ill-posed problem, in the sense that small perturbations to the pencil may yield a different KCF, probably a generic one, which only contains singular blocks. This feature hampers the application of the KCF to singular pencils derived from imperfectly known data, which is common in fields such as signal processing.

Previous study of perturbations in singular matrix pencils has been carried out under the light of the KCF. Stewart [19] bounds the perturbation on generalized eigenvalues and eigenvectors implicitly assuming that the perturbation on the pencil does not change the structure of the KCF. A similar assumption is used in [5] to bound the change in deflating subspaces of perturbed singular matrix pencils. In that paper, Demmel and Kågström also consider the regular case. Boley in [2] gives bounds for the perturbation that must be applied to $\mathbf{A}$ for the pencil $(\mathbf{A} - \lambda\mathbf{B})$ to have a regular part in its KCF. Edelman, Elmroth, and Kågström in [8] give bounds on the perturbation that makes a pencil less generic. These works give bounds to perturbations, which may be regarded as important information for some linear systems applications, but do not address the computation of the eigenvalues of the perturbed pencils, which in turn would be useful for many other real-world applications.

1.3. Contribution and structure of the paper. The goal of this paper is to propose a numerical method for finding generalized eigenvalues of nonsquare, and thus singular, matrix pencils. Aiming at its application to problems with real data, the method must be robust with respect to perturbations on the matrices of the pencil. This requirement leads us to discard matrix decompositions or transformations that reveal the structure of the pencil. We adopt the minimal perturbation approach (MPA) for the development of the numerical method. This paper can be seen as a follow-up to [3] and [4] which considers a particular structure for the matrix pencil. In those papers, the MPA for the eigenproblem of singular matrix pencils is presented. Roughly speaking, it consists of minimizing the norm of the perturbation that must be applied to a pencil so that it has a fixed number of generalized eigenvalues. The main contribution of this paper, apart from adapting the results in [4] to the considered structure, is the transformation of the constrained optimization problem of the MPA into an unconstrained one with a low-dimensional parameter vector when only one eigenvalue is assumed to exist. Well-known optimization techniques [16] can be applied to solve it, outperforming the numerical algorithm proposed in [3] in terms of

convergence rate and speed.

The paper is organized as follows: Section 2 reviews the MPA presented in [3] and [4] and its relation to pseudospectra. In section 3 the structure considered in this paper for the matrices that form the matrix pencil is introduced and incorporated to the constrained optimization problem that lies at the heart of the MPA. Then, it is shown to be equivalent to a simpler optimization problem and, in the case of seeking a single eigenvalue, it is further transformed into an unconstrained optimization problem that allows the use of simple numerical algorithms. Section 4 includes an example to show the differences between considering the structure of the matrix pencil and not doing so. Finally, we conclude the paper highlighting the main contribution and future research lines.

1.4. Notation. Matrices are denoted by boldface upper-case letters, such as $\mathbf{A}$, whereas boldface lower-case letters, such as $\mathbf{v}$, stand for column vectors. Scalars and polynomials are in roman typography, as λ and $p(x)$, respectively. $\mathbf{A}^{\mathrm{T}}$ stands for the transpose of matrix $\mathbf{A}$, $\mathbf{A}^{\mathrm{H}}$ stands for the conjugate transpose, and λ^* denotes the complex conjugate of scalar λ. The 2-norm and the Frobenius norm of matrices and vectors are denoted by $\|\cdot\|_2$ and $\|\cdot\|_F$, respectively.

The inner product $\langle \mathbf{u}, \mathbf{v} \rangle$ is defined as $\langle \mathbf{u}, \mathbf{v} \rangle = \mathbf{u}^{\mathrm{H}} \cdot \mathbf{v}$. Either notation will be used throughout the text. The projection of vector $\mathbf{u}$ onto the range of $\mathbf{A}$ is denoted by $P_{\mathbf{A}}(\mathbf{u}) = \mathbf{P}_{\mathbf{A}} \cdot \mathbf{u}$, where $\mathbf{P}_{\mathbf{A}}$ is the corresponding matrix projection operator. Matrix $\mathbf{P}_{\mathbf{A}}^{\perp}$ is the projection operator over the complement subspace of the range of $\mathbf{A}$. $\mathbf{0}$ stands for a row or column vector whose elements are all equal to zero. Its actual dimensions will become clear from the context.

The ith singular value of a matrix $\mathbf{M} \in \mathcal{M}_{\mathbb{C}}(m,n)$ is denoted by $\sigma_i(\mathbf{M})$, with $1 \leq i \leq \min(m.n)$. The singular values are assumed to be in decreasing order, i.e., $\sigma_1(\mathbf{A}) \leq \sigma_2(\mathbf{A}) \leq \cdots \leq \sigma_{\min(m,n)}(\mathbf{A})$.

2. Pseudospectra and the minimal perturbation approach. In some problems, particularly in singular matrix pencils, the eigenvalues do not change continuously with perturbations of the matrices involved. In these situations, the pseudospectra has proved to be a more useful tool to gain the insight usually provided by eigenvalues.

The spectra of a square matrix $\mathbf{A} \in \mathcal{M}_{\mathbb{C}}(m,m)$ is defined as its set of eigenvalues:

$$\Lambda(\mathbf{A}) = \{ z \in \mathbb{C} : \exists \mathbf{u} \neq \mathbf{0}, \mathbf{A} \cdot \mathbf{u} = z \cdot \mathbf{u} \}.$$

The ϵ-pseudospectra of $\mathbf{A}$, $\Lambda_\epsilon(\mathbf{A})$, includes those elements of $\mathbb{C}$ that are eigenvalues of a matrix obtained from $\mathbf{A}$ by a perturbation of Frobenius norm at most ϵ [20]:

$$\Lambda_\epsilon(\mathbf{A}) = \{ z \in \mathbb{C} : z \in \Lambda(\mathbf{A}+\mathbf{E}), \|\mathbf{E}\|_F \leq \epsilon \}.$$

The spectra of $\mathbf{A}$ is obtained as the ϵ-pseudospectra when $\epsilon = 0$.

The extension to regular matrix pencils is treated in several papers; [7, 10] are some of them. Given two matrices $\mathbf{A}, \mathbf{B} \in \mathcal{M}_{\mathbb{C}}(m,m)$, the pseudospectra of the pair (allowing perturbation on both matrices) is defined as

$$\Lambda_\epsilon(\mathbf{A}, \mathbf{B}) = \left\{ z \in \mathbb{C} : \exists \mathbf{u} \neq \mathbf{0}, (\mathbf{A}+\mathbf{E}) \cdot \mathbf{u} = z \cdot (\mathbf{B}+\mathbf{F}) \cdot \mathbf{u}, \|E\|_F^2 + \|F\|_F^2 \leq \epsilon^2 \right\}. \tag{2.1}$$

As in the case of a square matrix, when we are dealing with regular matrix pencils, there exists a nonempty spectra $\Lambda(\mathbf{A}, \mathbf{B})$ and any connected region of the pseudospectra has elements of $\Lambda(\mathbf{A}, \mathbf{B})$ inside it [10]. This does not happen with

singular matrix pencils. The definition of pseudospectra is generalized for rectangular matrices and general matrix pencils in [21], considering matrices in $\mathcal{M}_{\mathbb{C}}(m,n)$ in (2.1).

The spectra of a singular matrix pencil may be empty, as well as its pseudospectra for values of ϵ small enough. As the value of ϵ is increased, the pseudospectra will eventually become nonempty. The MPA for the generalized eigenvalue problem for nonsquare matrix pencils [3] aims to find the smallest ϵ that allows a number of eigenvalues to be included in the pseudospectra of the pair $(\mathbf{A},\mathbf{B})$. It yields not only the eigenvalues, but also the exact perturbation matrices. The formulation of the MPA, also referred to as inverse pseudospectra analysis of the pencil, is as follows:

Given $\mathbf{A},\mathbf{B}\in\mathcal{M}_{\mathbb{C}}(m,n)$, find:

$$
\begin{aligned}
&\min_{\left\{\mathbf{A_0},\mathbf{B_0},\{\lambda_k,\mathbf{v}_k\}_{k=1}^{p}\right\}} \|\mathbf{A_0}-\mathbf{A}\|_F^2+\|\mathbf{B_0}-\mathbf{B}\|_F^2\\
&\text{subject to:}\\
&\qquad\left\{\begin{array}{l}(\mathbf{A_0}-\lambda_k\mathbf{B_0})\,\mathbf{v}_k=\mathbf{0}\\ \|\mathbf{v}_k\|_2=1\end{array}\right\},\ k=1,\ldots,p\\
&\qquad\{\mathbf{v}_1,\ldots,\mathbf{v}_p\}\ \text{is an independent set.}
\end{aligned}
\tag{2.2}
$$

This difficult optimization problem is shown in [4] to be equivalent to an optimization over the compact set of $p\times p$ unitary matrices. The result in [4] provides a feasible way to compute the least-squares (LS) estimation (or maximum likelihood estimation provided the errors in the elements of the matrices are independent and follow a Gaussian distribution) of the p finite eigenvalues of a perturbed rectangular pencil. From a practical point of view, the number p of finite eigenvalues (number of finite elementary divisors in the KCF) of the pair $(\mathbf{A_0},\mathbf{B_0})$ must be known beforehand and the optimization process can be complicated due to the large number of parameters.

Two particular cases that allow for a simpler formulation of the optimization problem are studied in [3]. The eigenproblem for matrices $\mathbf{A},\mathbf{B}\in\mathcal{M}_{\mathbb{C}}(m,1)$ is studied in the first place, showing that it is equivalent to a total least squares problem. Then, the problem for matrices in $\mathcal{M}_{\mathbb{C}}(m,n)$, with $n>1$, is considered, assuming that a single finite eigenvalue is known to exist ($p=1$). The simplified formulation of the minimal perturbation approach for this particular case is as follows:

Given $\mathbf{A},\mathbf{B}\in\mathcal{M}_{\mathbb{C}}(m,n)$, find:

$$
\begin{aligned}
&\min_{\{\mathbf{A_0},\mathbf{B_0},\lambda,\mathbf{v}\}} \|\mathbf{A_0}-\mathbf{A}\|_F^2+\|\mathbf{B_0}-\mathbf{B}\|_F^2\\
&\text{subject to:}\\
&\qquad(\mathbf{A_0}-\lambda\mathbf{B_0})\,\mathbf{v}=\mathbf{0},\\
&\qquad\|\mathbf{v}\|_2=1.
\end{aligned}
\tag{2.3}
$$

A method for solving (2.3) is proposed. The optimization problem

$$
\begin{aligned}
&\min_{\{\lambda,\mathbf{v}\}} \frac{\|(\mathbf{A}-\lambda\mathbf{B})\,\mathbf{v}\|_2^2}{1+|\lambda|^2}\\
&\text{subject to:}\\
&\qquad\|\mathbf{v}\|_2^2=1
\end{aligned}
\tag{2.4}
$$

is shown to be equivalent to (2.3) (both objective functions attain their conditioned minimum values at the same points), and a numerical algorithm guaranteed to converge to the local minima of $f(\lambda, \mathbf{v}) = \frac{\|(\mathbf{A}-\lambda\mathbf{B})\mathbf{v}\|_2^2}{1+|\lambda|^2}$ is given. It is also noted that if several eigenvalues exist, $f(\lambda, \mathbf{v})$ has minima at values of λ next to the eigenvalues. Different initial values may result in the optimization process converging at different local minima, and therefore, estimations of different eigenvalues. Note that, simple as this approach may be, the estimation of p finite eigenvalues ($p > 1$) with this method is based on heuristics, unlike the LS estimation presented in [4].

When analyzing pseudospectra, we study a function that gives the norm of the smallest perturbation that must be applied to in order to make λ an eigenvalue. The pseudospectra of a square matrix $\mathbf{A}$ is studied in [20] and the proposed function is the smallest singular value of $(\mathbf{A}-\lambda\mathbf{I})$, $\sigma_{\min}(\mathbf{A}-\lambda\mathbf{I})$, as only perturbations on $\mathbf{A}$ are allowed. In [10], the pseudospectra of regular matrix pencils is studied and another function is considered, as perturbation may occur on both matrices $\mathbf{A}$ and $\mathbf{B}$. In fact, the function that appears in [10] is equivalent to $f(\lambda, \mathbf{v})$, which provides a measurement of the magnitude of the perturbation that must be applied to the pair $(\mathbf{A}, \mathbf{B})$ for λ to be its finite eigenvalue.

The position of the global minimum of $f(\lambda, \mathbf{v})$ yields a LS estimation of the eigenvalue (provided the assumptions $n > 1, p = 1$ are valid and matrices $\mathbf{A}, \mathbf{B}$ are unstructured). However, when using the proposed method for finding several eigenvalues, the minimization of $f(\lambda, \mathbf{v})$ is performed for each eigenvalue on its own, without considering how the perturbation that would make a value of λ an eigenvalue would affect the other eigenvalues in the set. It is not a LS estimation of the set of eigenvalues, but nevertheless it may be accurate enough for many applications.

3. Minimal perturbation approach for structured nonsquare matrix pencils.

3.1. Introduction. We adopt the MPA for nonsquare matrix pencils $(\mathbf{A} - \lambda\mathbf{B})$ with a particular structure, namely matrix $\mathbf{A} \in \mathcal{M}_{\mathbb{C}}(m, n)$ is the bottom $m \times n$ submatrix of some matrix $\mathbf{G} \in \mathcal{M}_{\mathbb{C}}(m+1, n)$, while $\mathbf{B} \in \mathcal{M}_{\mathbb{C}}(m, n)$ is the top $m \times n$ submatrix of $\mathbf{G}$. This structure may be written in a compact way as follows:

$$\begin{aligned} \mathbf{A} &= \begin{bmatrix} \mathbf{0} & \mathbf{I_m} \end{bmatrix} \cdot \mathbf{G}, \\ \mathbf{B} &= \begin{bmatrix} \mathbf{I_m} & \mathbf{0} \end{bmatrix} \cdot \mathbf{G}, \end{aligned} \tag{3.1}$$

where $\mathbf{I_m}$ is an $m \times m$ identity matrix.

Structure (3.1) usually stems from the special characteristics of a particular problem or application, and matrix $\mathbf{G}$ comprises the data that is subject to perturbations. In this framework, as errors appear in the elements of $\mathbf{G}$, it is more natural to take the objective function of the MPA as the norm of the perturbation applied to matrix $\mathbf{G}$, $\|\mathbf{G_o} - \mathbf{G}\|_F^2$, instead of the sum of the norms of the perturbation suffered by matrices $\mathbf{A}$ and $\mathbf{B}$, $\|\mathbf{A_o} - \mathbf{A}\|_F^2 + \|\mathbf{B_o} - \mathbf{B}\|_F^2$. These functions are slightly different, as it can be seen from (3.1) that the elements of the first and last row of the perturbation matrix $\mathbf{G_o} - \mathbf{G}$ contribute once to the latter objective function, whereas the rest of the elements contribute twice. Taking this observation into account, the MPA for a nonsquare matrix pencil that shows structure (3.1) adopts the following conditioned

optimization formulation:

$$
\begin{aligned}
&\min_{\left\{\mathbf{G_o},\{\lambda_k,\mathbf{v}_k\}_{k=1}^{p}\right\}} \|\mathbf{G_o}-\mathbf{G}\|_F^2 \\
&\text{subject to:} \\
&\left\{ \begin{array}{l} \left(\begin{bmatrix}\mathbf{0} & \mathbf{I_m}\end{bmatrix} - \lambda_k \begin{bmatrix}\mathbf{I_m} & \mathbf{0}\end{bmatrix}\right)\mathbf{G_o}\mathbf{v}_k = \mathbf{0} \\ \|\mathbf{v}_k\|_2 = 1 \end{array} \right\},\ k=1,\ldots,p \\
&\{\mathbf{v}_1,\ldots,\mathbf{v}_p\} \text{ independent set.}
\end{aligned} \tag{3.2}
$$

As it is pointed out in [3] and section 2, an easy-to-solve optimization formulation may be obtained if the scope of the problem is limited to simple cases. We assume that matrices $(\mathbf{A},\mathbf{B})$ are such that there exists one single finite eigenvalue. As has been stated previously, if the matrix pencil comes from the perturbation of another pencil with several finite eigenvalues, these will appear as local minima of the MPA function. Problem (3.2) is simplified to

$$
\begin{aligned}
&\min_{\{\mathbf{G_o},\lambda,\mathbf{v}\}} \|\mathbf{G_o}-\mathbf{G}\|_F^2 && \text{(3.3a)} \\
&\text{subject to:} \\
&\left(\begin{bmatrix}\mathbf{0} & \mathbf{I_m}\end{bmatrix} - \lambda \begin{bmatrix}\mathbf{I_m} & \mathbf{0}\end{bmatrix}\right)\mathbf{G_o}\mathbf{v} = \mathbf{0} && \text{(3.3b)} \\
&\|\mathbf{v}\|_2 = 1. && \text{(3.3c)}
\end{aligned}
$$

In this section we give a solution for problem (3.2) as a minimization over the set $\{\{\lambda_k\}_{k=1}^{p}\}$. This solution is then particularized to the case $p=1$ (only a single eigenvalue is assumed to exist) and it is shown that the corresponding constrained optimization problem (3.3) can be transformed into an unconstrained minimization of a function of λ. The objective function of this unconstrained optimization problem can be seen as a scalar function of $\mathbb{R}^2$. Nonlinear optimization algorithms like gradient-descent, conjugate-gradient or Gauss–Newton method can be used to find a local minimum, with the advantage that the reduced number of parameters lowers the complexity of the function and the number of local minima. This procedure is simpler and faster than the iterative algorithm proposed in [3], or the minimization of $f(\lambda,\mathbf{v})$ through standard optimization algorithms.

3.2. Definition of vectors and matrices. Before performing the simplification of the optimization problem, we introduce some preliminary results that will be used. Given a set of complex numbers $\{\{\lambda_k\in\mathbb{C}\}_{k=1}^{p}\}$, matrix $\mathbf{W}_{(\lambda_1,\lambda_2,\ldots,\lambda_p)}\in\mathcal{M}_{\mathbb{C}}(m+1,p)$ is defined as the Vandermonde matrix:

$$
\mathbf{W}_{(\lambda_1,\lambda_2,\ldots,\lambda_p)} = \begin{bmatrix} 1 & 1 & \cdots & 1 \\ \lambda_1 & \lambda_2 & \cdots & \lambda_p \\ \lambda_1^2 & \lambda_2^2 & \cdots & \lambda_p^2 \\ \vdots & \vdots & & \vdots \\ \lambda_1^m & \lambda_2^m & \cdots & \lambda_p^m \end{bmatrix}. \tag{3.4}
$$

In the following, when the list of arguments is clear from the context, it will be omitted for the sake of clarity. A well-known property of Vandermonde matrices is that they have full column rank as long as $\lambda_i\neq\lambda_j$, $1\leq i\neq j\leq p$, and $(m+1)\geq p$.

We also define matrix $\mathbf{D}_{(\lambda)} \in \mathcal{M}_{\mathbb{C}}(m+1, m)$ as

$$\mathbf{D}_{(\lambda)} = \begin{bmatrix} \mathbf{0} \\ \mathbf{I_m} \end{bmatrix} - \lambda^* \begin{bmatrix} \mathbf{I_m} \\ \mathbf{0} \end{bmatrix}. \tag{3.5}$$

Matrix $\mathbf{D}_{(\lambda)}$ has some relevant properties that are easy to prove:

- $\mathbf{D}_{(\lambda)}$ has full column rank m.
- Range$\{\mathbf{D}_{(\lambda)}\}$ is an m-dimensional subspace in $\mathbb{C}^{(m+1)}$.
- The left null space of $\mathbf{D}_{(\lambda)}$ is a subspace of dimension 1 spanned by the Vandermonde vector $\mathbf{W}_{(\lambda)}$. The corresponding unit-norm vector is denoted by $\mathbf{d}_\perp \in \mathbb{C}^{(m+1)}$:

$$\mathbf{d}_\perp = \frac{1}{\sqrt{\sum_{k=0}^{m} |\lambda|^{2k}}} \cdot \begin{bmatrix} 1 \\ \lambda \\ \vdots \\ \lambda^m \end{bmatrix}. \tag{3.6}$$

As $\mathbf{D}_{(\lambda)}$ has full column rank, the hermitian matrix $\mathbf{D}_{(\lambda)}^{\mathrm{H}} \cdot \mathbf{D}_{(\lambda)}$ is regular and the projection operator $\mathbf{P_D} \in \mathcal{M}_{\mathbb{C}}(m, m)$ over Range$\{\mathbf{D}_{(\lambda)}\}$ can be computed as

$$\mathbf{P_D} = \mathbf{D}_{(\lambda)} \cdot \left(\mathbf{D}_{(\lambda)}^{\mathrm{H}} \cdot \mathbf{D}_{(\lambda)}\right)^{-1} \cdot \mathbf{D}_{(\lambda)}^{\mathrm{H}} = \left(\mathbf{I} - \mathbf{d}_\perp \cdot \mathbf{d}_\perp^{\mathrm{H}}\right). \tag{3.7}$$

3.3. Equivalent optimization problems. The following lines give a solution for problem (3.2) as a minimization over the set $\{\{\lambda_k\}_{k=1}^{p}\}$, and then the constrained optimization problem (3.3) is transformed into an unconstrained minimization of a function that only depends on λ. These transformations are made in three steps that we present as theorems.

THEOREM 1. [illegible] (3.2) [illegible]

$$\min_{\{\{\lambda_k\}_{k=1}^{p}\}} \sum_{i=1}^{p} \sigma_{(n-p+i)}\left(\mathbf{P}_{\mathbf{W}}^{\perp} \cdot \mathbf{G}\right), \tag{3.8}$$

[illegible] $\mathbf{P}_{\mathbf{W}}^{\perp}$ [illegible] $\mathbf{W}$ [illegible] (3.4) [illegible] $\mathbf{G_o}$ [illegible] p [illegible] $\mathbf{G}$

$$\mathbf{G_o} = \mathbf{G} - \mathbf{P}_{\mathbf{W}}^{\perp} \cdot \mathbf{G} \cdot \mathbf{Q} \cdot \mathbf{Q}^{\mathrm{H}}, \tag{3.9}$$

[illegible] $\mathbf{Q} \in \mathcal{M}_{\mathbb{C}}(n, p)$ [illegible] $\mathbf{P}_{\mathbf{W}}^{\perp} \cdot \mathbf{G}$ [illegible]

We will begin the transformation of the optimization problem (3.2) by noting that conditions

$$\begin{bmatrix} \mathbf{0} & \mathbf{I_m} \end{bmatrix} \cdot \mathbf{G_o} \cdot \mathbf{v}_k = \lambda_k \cdot \begin{bmatrix} \mathbf{I_m} & \mathbf{0} \end{bmatrix} \cdot \mathbf{G_o} \mathbf{v}_k, \qquad k = 1, \ldots, p \tag{3.10}$$

are equivalent to

$$\begin{cases} [\mathbf{G_o} \cdot \mathbf{v}_k]_1 = h_k, \\ [\mathbf{G_o} \cdot \mathbf{v}_k]_i = \lambda_k \cdot [\mathbf{G_o} \cdot \mathbf{v}_k]_{(i-1)} \quad i = 2, \ldots, m+1, \end{cases} \qquad k = 1, \ldots, p$$

where $[\mathbf{x}]_i$ denotes the ith element of vector $\mathbf{x}$, and $h_k \in \mathbb{C}$, $k = 1, \ldots, p$. Therefore, (3.10) will hold if and only if

$$\mathbf{G_o} \cdot \mathbf{V} = \mathbf{W} \cdot \mathbf{H} \tag{3.11}$$

for some diagonal matrix $\mathbf{H} \in \mathcal{M}_{\mathbb{C}}(p,p)$ built with $h_1, h_2, \ldots, h_p$ as its diagonal elements. Since the Vandermonde matrix $\mathbf{W} \in \mathcal{M}_{\mathbb{C}}(m+1,p)$ has full column rank (3.4), so does $\mathbf{V}$, which amounts to the set $\{\{\mathbf{v}_k\}_{k=1}^{p}\}$ being independent, as required by the last condition of (3.2).

Let $\mathbf{T} \in \mathcal{M}_{\mathbb{C}}(p,p)$ be an invertible matrix such that $\mathbf{V} \cdot \mathbf{T} = \mathbf{Q}$, with $\mathbf{Q} \in \mathcal{M}_{\mathbb{C}}(n,p)$ a matrix with orthonormal columns. Then, multiplying (3.11) by $\mathbf{T}$ we get

$$\mathbf{G_o} \cdot \mathbf{V} \cdot \mathbf{T} = \mathbf{W} \cdot \mathbf{H} \cdot \mathbf{T},$$

or, equivalently,

$$\mathbf{G_o} \cdot \mathbf{Q} = \mathbf{W} \cdot \mathbf{R}. \tag{3.12}$$

Equation (3.12) is equivalent to equation (3.10) and $\mathbf{R} \in \mathcal{M}_{\mathbb{C}}(p,p)$ is a regular matrix.

Let $\mathbf{U} \in \mathcal{M}_{\mathbb{C}}(n, n-p)$ denote a matrix with orthonormal columns such that $\mathbf{S} = \begin{bmatrix} \mathbf{Q} & \mathbf{U} \end{bmatrix}$ is a $n \times n$ unitary matrix. Taking $\mathbf{\Delta} = \mathbf{G_o} - \mathbf{G}$, the objective function of the optimization problem can be written as follows:

$$\begin{aligned} \|\mathbf{G} - \mathbf{G_o}\|_F = \|\mathbf{\Delta}\|_F = \|\mathbf{\Delta} \cdot \mathbf{S}\|_F = \left\| \begin{bmatrix} \mathbf{\Delta} \cdot \mathbf{Q} & \mathbf{\Delta} \cdot \mathbf{U} \end{bmatrix} \right\|_F \\ = \left\| \begin{bmatrix} \mathbf{\Delta}^{(\mathbf{Q})} \cdot \mathbf{Q} & \mathbf{\Delta}^{(\mathbf{U})} \cdot \mathbf{U} \end{bmatrix} \right\|_F . \end{aligned} \tag{3.13}$$

In the last equality, the decomposition of the perturbation matrix $\mathbf{\Delta} = \mathbf{\Delta}^{(\mathbf{Q})} + \mathbf{\Delta}^{(\mathbf{U})}$ has been used:

$$\mathbf{\Delta} = \mathbf{\Delta} \cdot \mathbf{S} \cdot \mathbf{S}^{\mathrm{H}} = \mathbf{\Delta} \cdot \left(\mathbf{Q} \cdot \mathbf{Q}^{\mathrm{H}} + \mathbf{U} \cdot \mathbf{U}^{\mathrm{H}} \right) = \mathbf{\Delta} \cdot \mathbf{Q} \cdot \mathbf{Q}^{\mathrm{H}} + \mathbf{\Delta} \cdot \mathbf{U} \cdot \mathbf{U}^{\mathrm{H}} = \mathbf{\Delta}^{(\mathbf{Q})} + \mathbf{\Delta}^{(\mathbf{U})}.$$

The rows of $\mathbf{\Delta}^{(\mathbf{Q})}$ and $\mathbf{\Delta}^{(\mathbf{U})}$ are the projections of the rows of $\mathbf{\Delta}$ onto the range of $\mathbf{Q}$ and $\mathbf{U}$, respectively, so $\mathbf{\Delta}^{(\mathbf{Q})} \cdot \mathbf{U} = \mathbf{0}$ and $\mathbf{\Delta}^{(\mathbf{U})} \cdot \mathbf{Q} = \mathbf{0}$.

Then, condition (3.12) can be written in terms of the perturbation matrix as

$$\left(\mathbf{G} + \mathbf{\Delta}^{(\mathbf{Q})} \right) \cdot \mathbf{Q} = \mathbf{W} \cdot \mathbf{R}. \tag{3.14}$$

It is clear that the minimum of the objective function (3.13) subject to condition (3.14) will be attained for a perturbation matrix such that $\mathbf{\Delta}^{(\mathbf{U})} = \mathbf{0}$. The objective function can be replaced by $\left\| \mathbf{\Delta}^{(\mathbf{Q})} \cdot \mathbf{Q} \right\|_F$ and, consequently, problem (3.3) is equivalent to

$$\min_{\left\{ \mathbf{G_o}, \{\lambda\}_{k=1}^{p}, \mathbf{Q} \right\}} \|\mathbf{G} \cdot \mathbf{Q} - \mathbf{G_o} \cdot \mathbf{Q}\|_F \tag{3.15a}$$

subject to:

$$\mathbf{G_o} \cdot \mathbf{Q} = \mathbf{W} \cdot \mathbf{R} \tag{3.15b}$$

for some invertible matrix $\mathbf{R} \in \mathcal{M}_{\mathbb{C}}(p,p)$ and with $\mathbf{Q} \in \mathcal{M}_{\mathbb{C}}(n,p)$ a matrix with orthonormal columns. The matrix $\mathbf{G_o}$ that solves the constrained optimization problem satisfies

$$\mathbf{G_o} = \mathbf{G} + \mathbf{\Delta} = \mathbf{G} + \mathbf{\Delta}^{(\mathbf{Q})} = \mathbf{G} + \mathbf{\Delta}^{(\mathbf{Q})} \cdot \mathbf{Q} \cdot \mathbf{Q}^{\mathrm{H}}.$$

From condition (3.14), we have

$$\mathbf{G_o} = \mathbf{G} + \mathbf{W}\cdot\mathbf{R}\cdot\mathbf{Q}^{\mathrm{H}} - \mathbf{G}\cdot\mathbf{Q}\cdot\mathbf{Q}^{\mathrm{H}}. \tag{3.16}$$

Condition (3.15b) can be incorporated to the objective function (3.15a), yielding the following optimization problem:

$$\min_{\left\{\mathbf{R},\{\lambda_k\}_{k=1}^{p},\mathbf{Q}\right\}} \left\|\mathbf{G}\cdot\mathbf{Q} - \mathbf{W}\cdot\mathbf{R}\right\|_F. \tag{3.17}$$

Given matrix $\mathbf{Q}$ and a set $\{\lambda_k\}_{k=1}^{p}$, the value of $\mathbf{R}$ that minimizes the objective function (3.17) is the one that makes the columns of $\mathbf{W}\cdot\mathbf{R}$ equal to the projection of the corresponding columns of $\mathbf{G}\cdot\mathbf{Q}$ over the range of $\mathbf{W}$:

$$\mathbf{W}\cdot\mathbf{R} = \mathbf{P_W}\cdot\mathbf{G}\cdot\mathbf{Q}. \tag{3.18}$$

Hence, the objective function can be written as:

$$\left\|\mathbf{G}\cdot\mathbf{Q} - \mathbf{P_W}\cdot\mathbf{G}\cdot\mathbf{Q}\right\|_F = \left\|(\mathbf{I}-\mathbf{P_W})\cdot\mathbf{G}\cdot\mathbf{Q}\right\|_F = \left\|\mathbf{P}_{\mathbf{W}}^{\perp}\cdot\mathbf{G}\cdot\mathbf{Q}\right\|_F.$$

The minimum of the objective function will be attained for a matrix $\mathbf{Q}$ such that its columns are the singular vectors of $\mathbf{P}_{\mathbf{W}}^{\perp}\cdot\mathbf{G}$ corresponding to its smallest singular values:

$$\min_{\left\{\{\lambda_k\}_{k=1}^{p},\mathbf{Q}\right\}} \left\|\mathbf{P}_{\mathbf{W}}^{\perp}\cdot\mathbf{G}\cdot\mathbf{Q}\right\|_F = \min_{\left\{\{\lambda_k\}_{k=1}^{p}\right\}} \sum_{i=1}^{p} \sigma_{(n-p+i)}\left(\mathbf{P}_{\mathbf{W}}^{\perp}\cdot\mathbf{G}\right).$$

Finally, an expression for the optimal solution $\mathbf{G_o}$ in terms of matrix $\mathbf{G}$ and a perturbation will be given. From (3.16) and (3.18), we have

$$\begin{aligned}\mathbf{G_o} &= \mathbf{G} + \mathbf{P_W}\cdot\mathbf{G}\cdot\mathbf{Q}\cdot\mathbf{Q}^{\mathrm{H}} - \mathbf{G}\cdot\mathbf{Q}\cdot\mathbf{Q}^{\mathrm{H}} \\ &= \mathbf{G} - (\mathbf{I}-\mathbf{P_W})\cdot\mathbf{G}\cdot\mathbf{Q}\cdot\mathbf{Q}^{\mathrm{H}} = \mathbf{G} - \mathbf{P}_{\mathbf{W}}^{\perp}\cdot\mathbf{G}\cdot\mathbf{Q}\cdot\mathbf{Q}^{\mathrm{H}}. \qquad \square\end{aligned}$$

COROLLARY 1. [illegible] (3.3) [illegible]

$$\min_{\{\lambda,\mathbf{v}\}} \mathbf{v}^{\mathrm{H}}\cdot\mathbf{G}^{\mathrm{H}}\cdot\mathbf{P_D}\cdot\mathbf{G}\cdot\mathbf{v} \tag{3.19a}$$

[illegible]

$$\|\mathbf{v}\|_2 = 1 \tag{3.19b}$$

[illegible] $\mathbf{P_D}$ [illegible] (3.7) [illegible] $\mathbf{G_o}$ [illegible] $\mathbf{G}$

$$\mathbf{G_o} = \mathbf{G} - \mathbf{P_D}\cdot\mathbf{G}\cdot\mathbf{v}\cdot\mathbf{v}^{\mathrm{H}}.$$

[illegible]. This corollary follows directly from Theorem 1, taking $p = 1$, and the definitions in section 3.2. Note that in this case $\mathbf{W} = h_1\cdot\mathbf{d}_{\perp}$, for some $h_1 \in \mathbb{C}$, and $\mathbf{Q} = \mathbf{v}$. $\square$

Corollary 1 provides a simple formulation for the MPA when only one eigenvalue is assumed to exist. Still, the minimization problem it poses is complicated due to the number of parameters involved, which discourages the use of standard optimization techniques. The following theorems show that if matrix $\mathbf{G}$ has orthonormal columns,

then problem (3.8) is equivalent to the unconstrained minimization of a function of λ.

The assumption of $\mathbf{G}$ having orthonormal columns is valid in many practical applications. For example, in the case of the greatest common divisor (GCD) computation, the columns of matrix $\mathbf{G}$ span the null-space of a matrix $\mathbf{P}$ defined in terms of the coefficients of the polynomials [14], so $\mathbf{G}$ can be computed with orthonormal columns from the singular value decomposition of $\mathbf{P}$.

On the other hand, the generalized eigenvalues of a matrix pencil that shows structure (3.1) are the roots of the Vandermonde vectors $\begin{bmatrix}1 & \lambda^* & \dots & (\lambda^*)^m\end{bmatrix}^{\mathrm{H}}$ that are included in Range($\mathbf{G}$) [18]. Therefore, a matrix $\widehat{\mathbf{G}}$ with orthonormal columns that has the same range as $\mathbf{G}$ gives rise to a matrix pencil $(\widehat{\mathbf{A}}-\lambda\cdot\widehat{\mathbf{B}})$, with $\widehat{\mathbf{A}}=\begin{bmatrix}\mathbf{0} & \mathbf{I_m}\end{bmatrix}\cdot\widehat{\mathbf{G}}$ and $\widehat{\mathbf{B}}=\begin{bmatrix}\mathbf{I_m} & \mathbf{0}\end{bmatrix}\cdot\widehat{\mathbf{G}}$, that has the same eigenvalues.

Although the MPA yields different results for $\mathbf{G}$ and $\widehat{\mathbf{G}}$, the position of the minima of the objective function when $\widehat{\mathbf{G}}$ is considered may still be a good estimate for the approximate eigenvalues of $(\mathbf{A}-\lambda\mathbf{B})$.

THEOREM 2. [illegible] (3.19) [illegible]

(3.20a) $$\max_{\{\lambda,\mathbf{v}\}} \left|\mathbf{d}_\perp^{\mathrm{H}}\cdot\mathbf{G}\cdot\mathbf{v}\right|^2$$

[illegible]

(3.20b) $$\mathbf{e}_\perp^{\mathrm{H}}\cdot\mathbf{G}\cdot\mathbf{v}=0.$$

(3.20c) $$\|\mathbf{v}\|_2=1.$$

[illegible] We will make use of the inner-product and projection function notation for transforming the objective function (3.19a):

$$\begin{aligned}\mathbf{v}^{\mathrm{H}}\cdot\mathbf{G}^{\mathrm{H}}\cdot\mathbf{P}_{\mathbf{D}}\cdot\mathbf{G}\cdot\mathbf{v} &= \left\langle \mathbf{G}\cdot\mathbf{v}, P_{\mathbf{D}_{(\lambda)}}(\mathbf{G}\cdot\mathbf{v})\right\rangle \\ &= \left\langle P_{\mathbf{D}_{(\lambda)}}(\mathbf{G}\cdot\mathbf{v})+P_{\mathbf{d}_\perp}(\mathbf{G}\cdot\mathbf{v}), P_{\mathbf{D}_{(\lambda)}}(\mathbf{G}\cdot\mathbf{v})\right\rangle \\ &= \left\langle P_{\mathbf{D}_{(\lambda)}}(\mathbf{G}\cdot\mathbf{v}), P_{\mathbf{D}_{(\lambda)}}(\mathbf{G}\cdot\mathbf{v})\right\rangle, \end{aligned} \tag{3.21}$$

where the orthogonality of projections onto the range of $\mathbf{D}_{(\lambda)}$ and $\mathbf{d}_\perp$ has been taken into account.

Under the assumption that the columns of $\mathbf{G}$ are orthonormal, the norm of $\mathbf{G}\cdot\mathbf{v}$ will be the same as the norm of $\mathbf{v}$, which must be equal to 1 (3.19b). This property fixes a relationship between the inner-products of the projections of $\mathbf{G}\cdot\mathbf{v}$:

$$\begin{aligned}\|\mathbf{G}\cdot\mathbf{v}\|_2^2 &= \langle \mathbf{G}\cdot\mathbf{v}, \mathbf{G}\cdot\mathbf{v}\rangle \\ &= \left\langle P_{\mathbf{D}_{(\lambda)}}(\mathbf{G}\cdot\mathbf{v})+P_{\mathbf{d}_\perp}(\mathbf{G}\cdot\mathbf{v}), P_{\mathbf{D}_{(\lambda)}}(\mathbf{G}\cdot\mathbf{v})+P_{\mathbf{d}_\perp}(\mathbf{G}\cdot\mathbf{v})\right\rangle \\ &= \left\langle P_{\mathbf{D}_{(\lambda)}}(\mathbf{G}\cdot\mathbf{v}), P_{\mathbf{D}_{(\lambda)}}(\mathbf{G}\cdot\mathbf{v})\right\rangle + \langle P_{\mathbf{d}_\perp}(\mathbf{G}\cdot\mathbf{v}), P_{\mathbf{d}_\perp}(\mathbf{G}\cdot\mathbf{v})\rangle = 1. \end{aligned} \tag{3.22}$$

From (3.21) and (3.22) it is clear that our objective function is

$$\|\mathbf{G}-\mathbf{G_o}\|_F^2 = \|\mathbf{G}\cdot\mathbf{v}\|_2^2 - \|P_{\mathbf{d}_\perp}(\mathbf{G}\cdot\mathbf{v})\|_2^2 = 1-\|P_{\mathbf{d}_\perp}(\mathbf{G}\cdot\mathbf{v})\|_2^2.$$

Its minimization is equivalent to the maximization of $\|P_{\mathbf{d}_\perp}(\mathbf{G}\cdot\mathbf{v})\|_2^2$.

Consequently, the objective of our optimization problem is the maximization of

$$\|P_{\mathbf{d}_\perp}(\mathbf{G}\cdot\mathbf{v})\|_2^2 = \left\|\mathbf{d}_\perp\cdot\mathbf{d}_\perp^{\mathrm{H}}\cdot\mathbf{G}\cdot\mathbf{v}\right\|_2^2 = \|\mathbf{d}_\perp\|_2^2\cdot\left|\mathbf{d}_\perp^{\mathrm{H}}\cdot\mathbf{G}\cdot\mathbf{v}\right|^2 = \left|\mathbf{d}_\perp^{\mathrm{H}}\cdot\mathbf{G}\cdot\mathbf{v}\right|^2. \qquad \square$$

THEOREM 3. [illegible] (3.20) [illegible]

$$\min_{\lambda} \frac{1}{f(\lambda)} \tag{3.23}$$

[illegible]

$$f(\lambda) = \mathbf{d}_{\perp}^{\mathrm{H}} \cdot \mathbf{G} \cdot \mathbf{G}^{\mathrm{H}} \cdot \mathbf{d}_{\perp}.$$

[illegible] We define vector $\mathbf{x}$ as the vector in the direction of $\mathbf{v}$ that makes $\mathbf{d}_{\perp}^{\mathrm{H}} \cdot \mathbf{G} \cdot \mathbf{x} = 1$. Since $\mathbf{v}$ is a unit-norm vector (3.20c), $\mathbf{v} = \frac{\mathbf{x}}{\|x\|_2}$, and the objective function (3.20a) can be written in terms of $\mathbf{x}$ as

$$\left|\mathbf{d}_{\perp}^{\mathrm{H}} \cdot \mathbf{G} \cdot \mathbf{v}\right|^2 = \frac{\left|\mathbf{d}_{\perp}^{\mathrm{H}} \cdot \mathbf{G} \cdot \mathbf{x}\right|^2}{\|\mathbf{x}\|_2^2} = \frac{1}{\|\mathbf{x}\|_2^2}.$$

Thus, the optimization problem (3.20) is equivalent to

$$\min_{\{\lambda, \mathbf{x}\}} \|\mathbf{x}\|_2^2 \tag{3.24a}$$

subject to:

$$\mathbf{d}_{\perp}^{\mathrm{H}} \cdot \mathbf{G} \cdot \mathbf{x} = 1. \tag{3.24b}$$

Condition (3.24b) poses an undetermined linear system. The minimum norm solution for $\mathbf{x}$ will minimize function (3.24a). For every λ, the minimum norm solution of the respective undetermined linear system can be computed as the product of the Moore–Penrose pseudoinverse of the coefficients matrix and the independent term. The pseudoinverse of $\mathbf{d}_{\perp}^{\mathrm{H}} \cdot \mathbf{G}$ can be constructed from its singular value decomposition [12], $\mathbf{d}_{\perp}^{\mathrm{H}} \cdot \mathbf{G} = u \cdot \sigma \cdot \mathbf{v}^{\mathrm{H}}$, with

$$u = 1 \qquad \sigma = \left\|\mathbf{G}^{\mathrm{H}} \cdot \mathbf{d}_{\perp}\right\|_2 \qquad \mathbf{v} = \frac{\mathbf{G}^{\mathrm{H}} \cdot \mathbf{d}_{\perp}}{\left\|\mathbf{G}^{\mathrm{H}} \cdot \mathbf{d}_{\perp}\right\|_2}.$$

Then, the pseudoinverse of $\mathbf{d}_{\perp}^{\mathrm{H}} \cdot \mathbf{G}$ is defined as

$$\left(\mathbf{d}_{\perp}^{\mathrm{H}} \cdot \mathbf{G}\right)^{+} = \mathbf{v} \cdot \frac{1}{\sigma} \cdot u^{\mathrm{H}} = \frac{\mathbf{G}^{\mathrm{H}} \cdot \mathbf{d}_{\perp}}{\left\|\mathbf{G}^{\mathrm{H}} \cdot \mathbf{d}_{\perp}\right\|_2^2}.$$

And the minimum norm solution of the undetermined linear system is

$$\mathbf{x} = \left(\mathbf{d}_{\perp}^{\mathrm{H}} \cdot \mathbf{G}\right)^{+} \cdot 1 = \left(\mathbf{d}_{\perp}^{\mathrm{H}} \cdot \mathbf{G}\right)^{+}.$$

With this result, the objective function we are trying to minimize is equivalent to

$$\begin{aligned} \|\mathbf{x}\|_2^2 = \mathbf{x}^{\mathrm{H}} \cdot \mathbf{x} &= \frac{\mathbf{d}_{\perp}^{\mathrm{H}} \cdot \mathbf{G} \cdot \mathbf{G}^{\mathrm{H}} \cdot \mathbf{d}_{\perp}}{\left\|\mathbf{G}^{\mathrm{H}} \cdot \mathbf{d}_{\perp}\right\|_2^4} = \frac{\mathbf{d}_{\perp}^{\mathrm{H}} \cdot \mathbf{G} \cdot \mathbf{G}^{\mathrm{H}} \cdot \mathbf{d}_{\perp}}{\left\|\mathbf{G}^{\mathrm{H}} \cdot \mathbf{d}_{\perp}\right\|_2^4} \\ &= \frac{\left\|\mathbf{G}^{\mathrm{H}} \cdot \mathbf{d}_{\perp}\right\|_2^2}{\left\|\mathbf{G}^{\mathrm{H}} \cdot \mathbf{d}_{\perp}\right\|_2^4} = \frac{1}{\left\|\mathbf{G}^{\mathrm{H}} \cdot \mathbf{d}_{\perp}\right\|_2^2} \\ &= \frac{1}{\mathbf{d}_{\perp}^{\mathrm{H}} \cdot \mathbf{G} \cdot \mathbf{G}^{\mathrm{H}} \cdot \mathbf{d}_{\perp}}. \qquad \square \end{aligned} \tag{3.25}$$

4. Example. In order to obtain a matrix pencil with the structure considered in this paper, we pose a numerical GCD computation problem. First, we take a polynomial $p(x)$ with roots -0.5, -1.25, $0.2 \pm 1.4i$ and 0.625:

$$p(x) = (x + 0.5)\cdot(x + 1.25)\cdot\left(x^2 - 0.4x + 2\right)\cdot(x - 0.625)\,.$$

Then we randomly generate 20 polynomials of degree 44 with their coefficients following a normal distribution with zero mean and variance equal to one. After multiplying these polynomials with $p(x)$, we have 20 polynomials whose GCD is $p(x)$. Matrix $\mathbf{X} \in \mathcal{M}_{\mathbb{R}}(50, 20)$ is built with the coefficients of these 20 polynomials as columns. In [14, 17] it is proved that the only generalized eigenvalues of the matrix pencil $\mathbf{A} - \lambda\mathbf{B}$ with $\mathbf{A} = \begin{bmatrix}\mathbf{0} & \mathbf{I}\end{bmatrix}\cdot\mathbf{G}$, $\mathbf{B} = \begin{bmatrix}\mathbf{I} & \mathbf{0}\end{bmatrix}\cdot\mathbf{G}$, and $\mathbf{G} \in \mathcal{M}_{\mathbb{R}}(50, 30)$ the orthogonal complement of $\mathbf{X}$, are the roots of the GCD, $p(x)$. Figure 4.1(a) shows a plot of $\epsilon(\lambda) = \log(1 - f(\lambda))$. This function has been chosen so that its minima can be clearly spotted in Figure 4.1. Five minima, located at values of λ equal to the roots of $p(x)$, can be seen.

The MPA is an alternative to traditional methods (computation of the KCF or other structure-revealing forms) when the available data are contaminated by noise and the latter yield no valid results. Figures 4.1(b) and 4.1(c) show plots of function $e(\lambda)$ for matrix $\mathbf{X}$ perturbed with matrices whose elements are taken from zero-mean normal distributions of variance $\sigma = 0.5$ and $\sigma = 1$, respectively. It can be observed that the minima are not as deep as in the noiseless case (Figure 4.1(a)) and that they are slightly deviated from their correct position. Some minima may vanish for strong perturbations, and therefore, in these situations, the MPA may fail to provide an estimation of the generalized eigenvalues.

Having established the suitability of the MPA for low and moderate noise levels in our example, we proceed to compare the optimization method proposed in [3] and the minimization of function $e(\lambda)$ (3.23). To this end, we must choose a method for the unconstrained minimization of $e(\lambda)$. Due to its simplicity, we make use of the steepest descent method, although more sophisticated strategies, such as trust region methods, show better convergence properties [16].

Figure 4.1(d) shows a plot of $e(\lambda)$ for a perturbation of level $\sigma = 0.5$ with the points reached at every iteration for both minimization methods, starting from a hand-picked initial point. The steepest descent method over $e(\lambda)$ (triangles) converges to the minimum faster than the optimization algorithm proposed in [3] (circles). This can also be seen in Figure 4.2. It shows the values of $e(\lambda)$ at every iteration for two different hand-picked initial points for both optimization methods. Lines of the same style (solid or dashed) denote the same initialization, whereas triangles correspond to points found with the steepest descent method and circles correspond to the method proposed in [3]. Note that this hand-picked starting points are considerably further away from the location of the minima than the initial values of λ obtained by the squaring method of initialization [3].

Apart from the rate of convergence, another issue that should be taken into account is the numerical complexity of each iteration. The method of minimization for unstructured matrix pencils requires the computation of the singular vector related to the smallest singular value of $(\mathbf{A} - \lambda\mathbf{B})$ at every iteration. The SVD for a $m \times n$ matrix is an operation of complexity $O\left(mn^2\right)$ (this value can be lowered by suitable factorization or partial decomposition [12]). On the other hand, the gradient and Hessian of $f(\lambda)$ can be computed with a complexity of $O(m)$.

5. Conclusions and future work. This work has addressed the MPA for nonsquare matrix pencils $(\mathbf{A} - \lambda\mathbf{B})$. We have considered the following structure for matrices $\mathbf{A}, \mathbf{B} \in \mathcal{M}_{\mathbb{C}}(m, n)$:

$$\mathbf{A} = \begin{bmatrix}\mathbf{0} & \mathbf{I}\end{bmatrix}\cdot\mathbf{G}, \qquad \mathbf{B} = \begin{bmatrix}\mathbf{I} & \mathbf{0}\end{bmatrix}\cdot\mathbf{G},$$

with $\mathbf{G} \in \mathcal{M}_{\mathbb{C}}(m+1, n)$. The matrices of the pencil are derived from matrix $\mathbf{G}$. This observation leads to a slightly different MPA formulation, as the norm of the perturbation in $\mathbf{G}$ is considered, instead of the norm of the perturbations in $\mathbf{A}$ and $\mathbf{B}$. The MPA can be formulated as a minimization over the set $\{\{\lambda_k\}_{k=1}^{p}\}$. Besides, when $p = 1$, this structure allows the transformation of the constrained optimization problem that must be solved to compute the solution of the MPA into an unconstrained one. Then, well-known methods for unconstrained minimization can be used, improving the rate of convergence and simplicity of previous algorithm for the computation of the solution.

The structure considered in this paper appears in some signal processing methods and, more notably, in the numerical computation of the GCD of polynomials. However, once the GCD computation problem is formulated as an eigenvalue problem for a rectangular matrix pencil, previous proposed solutions consist in matrix transformations that reveal the generalized eigenvalues. This way of proceeding is not suitable for perturbed data, due to the ill-posedness of the transformations, while the MPA may still yield valid results in this situation. Our work in the future will focus in this application, comparing this method to other numerical GCD computation methods.

Acknowledgments. The authors would like to thank professor I. Lizasoáin for her very helpful comments and suggestions while this article was being written. The authors would also like to thank the referees for their valuable comments and suggestion greatly improving this paper.

FIRST-ORDER METHODS FOR SPARSE COVARIANCE SELECTION*

ALEXANDRE D'ASPREMONT†, ONUREENA BANERJEE‡, AND LAURENT EL GHAOUI‡

Abstract. Given a sample covariance matrix, we solve a maximum likelihood problem penalized by the number of nonzero coefficients in the inverse covariance matrix. Our objective is to find a sparse representation of the sample data and to highlight conditional independence relationships between the sample variables. We first formulate a convex relaxation of this combinatorial problem, we then detail two efficient first-order algorithms with low memory requirements to solve large-scale, dense problem instances.

Key words. covariance selection, semidefinite programming, coordinate descent

1. Introduction.

We discuss a problem of model selection.[1] Given n variables drawn from a Gaussian distribution $\mathcal{N}(0, C)$, where the true covariance matrix C is unknown, we estimate C from a sample covariance matrix Σ by maximizing its log-likelihood. Following [7], setting a certain number of coefficients in the inverse covariance matrix Σ^{-1} to zero, a procedure known as [illegible], improves the stability of this estimation procedure by reducing the number of parameters to estimate and highlight structure in the underlying model.

Here, we focus on the problem of [illegible] this pattern of zeroes in the inverse covariance matrix. We seek to trade-off the log-likelihood of the solution with the number of zeroes in its inverse, and solve the following estimation problem:

$$\begin{array}{ll} \text{maximize} & \log\det X - \langle \Sigma, X\rangle - \rho\,\mathbf{Card}(X) \\ \text{subject to} & \alpha\mathbf{I}_n \preceq X \preceq \beta\mathbf{I}_n \end{array} \tag{1.1}$$

in the variable $X \in \mathbf{S}_n$, where $\Sigma \in \mathbf{S}_n^+$ is the sample covariance matrix, $\mathbf{Card}(X)$ is the cardinality of X, i.e., the number of nonzero components in X, $\rho > 0$ is a parameter controlling the trade-off between log-likelihood and cardinality, and finally, $\alpha,\ \beta > 0$ fix bounds on the eigenvalues of the solution.

Zeroes in the inverse covariance matrix correspond to conditionally independent variables in the model and this approach can be used to simultaneously determine a robust estimate of the covariance matrix and, perhaps more importantly, discover [illegible] in the underlying graphical model. In particular, we can view (1.1) as a model selection problem using Akaike (AIC, see [1]) or Bayes (BIC, see [5]) information criterions. Both these problems can be written as in (1.1) with $\rho = 2/N$ for the AIC problem and $\rho = 2\log(N/2)/N$ for the BIC problem, where N is the sample size.

[1]A subset of the results discussed here appeared in the Proceedings of the International Conference on Machine Learning, Pittsburgh, PA, 2006.

This has applications in speech recognition (see [2, 3]) or gene networks analysis (see [9, 8], for example).

The **Card**(X) penalty term makes the estimation problem (1.1) combinatorial (NP-hard in fact), and our first objective here is to derive a convex relaxation to this problem which can be solved efficiently. We then derive two first-order algorithms geared towards memory efficiency and large-scale, [illegible] problem instances.

In [3], Bilmes proposed a method for covariance selection based on choosing statistical dependencies according to conditional mutual information computed using training data. Other recent work involves identifying those Gaussian graphical models that are best supported by the data and any available prior information on the covariance matrix. This approach is used by [13, 9] on gene expression data. Recently, [6, 12] also considered penalized maximum likelihood estimation for covariance selection. In contrast to our results here, [12] works on the Cholesky decomposition of X using an iterative (heuristic) algorithm to minimize a nonconvex penalized likelihood problem, while [6] proposes a set of large scale interior point algorithms to solve sparse problems, i.e., problems for which the conditional independence structure is already known.

The paper is organized as follows, in section 2, we detail our convex relaxation of problem (1.1) and study the dual. In section 3, we derive two efficient algorithms to solve it. Finally, in section 4 we describe some numerical results.

2. Problem setup.

2.1. Convex relaxation. Given a sample covariance matrix $\Sigma \in \mathbf{S}_n^+$, we can write the following convex relaxation to the estimation problem (1.1):

$$\begin{array}{ll} \text{maximize} & \log\det X - \langle \Sigma, X\rangle - \rho \mathbf{1}^T|X|\mathbf{1} \\ \text{subject to} & \alpha \mathbf{I}_n \preceq X \preceq \beta \mathbf{I}_n, \end{array} \tag{2.1}$$

with variable $X \in \mathbf{S}^n$, where $\mathbf{1}$ is the n-vector of ones, so that $\mathbf{1}^T|X|\mathbf{1} = \sum_{i,j=1}^n |X_{ij}|$. The penalty term involving the sum of absolute values of the entries of X is a proxy for the number of its nonzero elements: the function $\mathbf{1}^T|X|\mathbf{1}$ can be seen as the largest convex lower bound on **Card**(X) on the hypercube, an argument used by [11] for rank minimization. It is also often used in regression techniques, such as the LASSO studied in [19], when sparsity of the solution is a concern. This relaxation is provably tight in certain cases (see [10]). In our model, the bounds (α, β) on the eigenvalues of X are fixed and user-chosen. Although we allow $\alpha = 0$ and $\beta = +\infty$, such bounds are useful in practice to control the condition number of the solution.

When $\alpha = 0$ and $\beta = +\infty$, for $\rho = 0$, provided $\Sigma \succ 0$, problems (1.1) and (2.1) have a unique solution $X^\star = \Sigma^{-1}$, and the corresponding maximum-likelihood estimate is Σ. Due to noise in the data, in practice, the sample estimate Σ may not have a sparse inverse, even if the underlying graphical model exhibits conditional independence properties. By striking a trade-off between the maximality of the likelihood and the number of nonzero elements in the inverse covariance matrix, our approach is potentially useful at [illegible], precisely conditional independence properties in the data. This means that we have to focus on the case where the matrix X is [illegible]. At the same time, it serves as a regularization technique: when Σ is rank-deficient, there is no well-defined maximum-likelihood estimate, whereas the solution to problem (2.1) is always unique and well defined for $\rho > 0$, as seen later.

2.2. Dual problem, robustness. We can rewrite the relaxation (2.1) as the following min-max problem:

$$\max_{\{X:\ \alpha\mathbf{I}_n \preceq X \preceq \beta\mathbf{I}_n\}} \min_{\{U:\ |U_{ij}|\leq\rho\}} \log\det X - \langle \Sigma + U, X\rangle, \tag{2.2}$$

which gives a natural interpretation of problem (2.1) as a worst-case [illegible] problem with componentwise bounded, additive noise on the sample covariance matrix Σ. The corresponding Lagrangian is given by

$$L(X,U,P,Q) = \log\det X - \mathbf{Tr}((\Sigma + U + Q - P)X) - \alpha\,\mathbf{Tr}\,P + \beta\,\mathbf{Tr}\,Q,$$

and we get the following dual to (2.1):

$$\begin{array}{ll} \text{minimize} & -\log\det(\Sigma + U + Q - P) - n + \alpha\,\mathbf{Tr}\,P - \beta\,\mathbf{Tr}\,Q \\ \text{subject to} & P, Q \succeq 0,\ |U_{ij}| \leq \rho, \quad i,j = 1,\ldots,n, \end{array} \tag{2.3}$$

in the variables $U, P, Q \in \mathbf{S}_n$. In what follows, we denote by $\|X\|_2$ the largest singular value of the matrix X and by $\|X\|_F$ its Frobenius norm. When $\alpha = 0$ and $\beta = +\infty$, the first-order optimality conditions impose $X(\Sigma + U) = \mathbf{I}_n$, hence we always have

$$X \succeq \alpha(n)\mathbf{I}_n \quad \text{with} \quad \alpha(n) := \frac{1}{\|\Sigma\|_2 + n\rho};$$

zero duality gap also means $\mathbf{Tr}(\Sigma X) = n - \rho\mathbf{1}^T|X|\mathbf{1}$. Because X and Σ are both positive semidefinite, we get

$$\|X\|_2 \leq \|X\|_F \leq \mathbf{1}^T|X|\mathbf{1} \leq n/\rho,$$

which, together with $\mathbf{Tr}(\Sigma X) \geq \lambda_{\min}(\Sigma)\|X\|_2$, means $\|X\|_2 \leq n/\lambda_{\min}(\Sigma)$. Finally then, we must always have

$$X \preceq \beta(n)\mathbf{I}_n \quad \text{with} \quad \beta(n) := n\min\left(\frac{1}{\rho}, \|\Sigma^{-1}\|_2\right)$$

and $0 < \alpha(n) \leq \lambda(X) \leq \beta(n) < +\infty$ at the optimum. Setting $\alpha = 0$ and $\beta = +\infty$ in problem (2.1) is then equivalent to setting $\alpha = \alpha(n)$ and $\beta = \beta(n)$. Since the objective function of problem (2.1) is strictly convex when $0 < \alpha(n) \leq \lambda(X) \leq \beta(n) < +\infty$, this shows that (2.1) always has a unique solution.

3. Algorithms. In this section, we present two algorithms for solving problem (2.1), one based on an optimal first-order method developed in [18], the other based on a block-coordinate gradient method. Of course, problem (2.1) is convex and can readily be solved using interior point methods (see [4], for example). However, such second-order methods become quickly impractical for solving (1.1), since the corresponding complexity to compute an ϵ-suboptimal solution is $O(n^6\log(1/\epsilon))$. Note, however, that we cannot expect to do better than $O(n^3)$, which is the cost of solving the nonpenalized problem for dense covariance matrices Σ.

3.1. Smooth optimization. The recently-developed first-order algorithms due to [18] trade-off a better dependence on problem size against a worst dependence on accuracy, usually $1/\epsilon$ instead of its logarithm and the method we describe next has a complexity of $O(n^{4.5}/\epsilon)$. In addition, the memory requirement of these first-order methods is much lower than that of interior-point methods, which involve forming a dense Hessian, and hence, become quickly prohibitive with a problem having $O(n^2)$ variables.

Nesterov's method. The algorithm in [18] supposes that the function to minimize conforms to a certain representation. This is the case for our problem here, so we first write (2.2) in the saddle-function format described in [18]:

$$\min_{X\in\mathcal{Q}_1} \; -\log\det X + \langle \Sigma, X\rangle + \rho \mathbf{1}^T|X|\mathbf{1} \equiv \min_{X\in\mathcal{Q}_1}\max_{U\in\mathcal{Q}_2} \; \hat{f}(X) + \langle A(X), U\rangle,$$

where we define $\hat{f}(X) = -\log\det X + \langle \Sigma, X\rangle$, $A = \rho I_{n^2}$, and

$$\mathcal{Q}_1 := \{X \in \mathcal{S}^n \;:\; \alpha \mathbf{I}_n \preceq X \preceq \beta \mathbf{I}_n\}, \quad \mathcal{Q}_2 := \{U \in \mathcal{S}^n \;:\; \|U\|_\infty \leq 1\}.$$

The adjoint of this problem, corresponding to the dual problem (2.3), is then written:

$$\max_{U\in\mathcal{Q}_2} \phi(U) \quad \text{where} \quad \phi(U) := \min_{X\in\mathcal{Q}_1} -\log\det X + \langle \Sigma + U, X\rangle. \tag{3.1}$$

When a function can be represented in this saddle function format, the method described in [18] combines two steps.

Smoothing step. By adding a strongly convex penalty to the saddle function representation of f, the algorithm first computes a smooth ϵ-approximation of f with Lipschitz continuous gradient. This can be seen as a generalized Moreau–Yosida regularization step (see [14], for example).

Optimal first-order scheme. The algorithm then applies the optimal first-order scheme for functions with Lipschitz continuous gradients detailed in [16] to the regularized function. Each iteration requires efficiently computing the regularized function value and its gradient. In all the semidefinite programming applications detailed here, this can be done extremely efficiently, with a complexity of $O(n^3)$ and memory requirements in $O(n^2)$. The method is only efficient if all these steps can be performed explicitly or at least very efficiently. As we will see below, this is the case here.

Prox-functions and strong convexity. To $\mathcal{Q}_1$ and $\mathcal{Q}_2$ we now associate norms and so-called prox-functions. For $\mathcal{Q}_1$, we use the Frobenius norm and a prox-function:

$$d_1(X) = -\log\det X + n\log\beta.$$

The function d_1 is strongly convex on $\mathcal{Q}_1$, with a convexity parameter of $\sigma_1 = 1/\beta^2$, in the sense that $\nabla^2 d_1(X)[H,H] = \mathbf{Tr}(X^{-1}HX^{-1}H) \geq \beta^{-2}\|H\|_F^2$ for every H. Furthermore, the center of the set, $X_0 := \arg\min_{X\in\mathcal{Q}_1} d_1(X)$ is $X_0 = \beta\mathbf{I}_n$ and satisfies $d_1(X_0) = 0$. With our choice, we have $D_1 := \max_{X\in\mathcal{Q}_1} d_1(X) = n\log(\beta/\alpha)$.

To $\mathcal{Q}_2$, we also associate the Frobenius norm and the prox-function $d_2(U) = \|U\|_F^2/2$. With this choice, the center U_0 of $\mathcal{Q}_2$ is $U_0 = 0$. Furthermore, the function d_2 is strongly convex on its domain with a convexity parameter with respect to the 2-norm $\sigma_2 = 1$, and we have $D_2 := \max_{U\in\mathcal{Q}_2} d_2(U) = n^2/2$.

The function $\hat{f}$ has a gradient that is Lipschitz-continuous with respect to the Frobenius norm on the set $\mathcal{Q}_1$ with Lipschitz constant $M = 1/\alpha^2$. Finally, the norm (induced by the Frobenius norm) of the operator $A = \rho I_{n^2}$ is ρ.

Smoothing. The method is based on replacing the objective of the original problem, $f(X)$, with $f_\epsilon(X)$, where $\epsilon > 0$ is the desired accuracy, and f_ϵ is a penalized function involving the prox-function d_2, defined as

$$f_\epsilon(X) := \hat{f}(X) + \max_{U\in\mathcal{Q}_2}\{\langle X, U\rangle - (\epsilon/2D_2)d_2(U)\}. \tag{3.2}$$

The above function turns out to be a smooth uniform approximation to f everywhere, with maximal error $\epsilon/2$. Furthermore, the function f_ϵ has a Lipschitz-continuous gradient with Lipschitz constant given by $L(\epsilon) := M + D_2\|A\|^2/(2\sigma_2\epsilon)$. A specific first-order algorithm detailed in [16] for smooth, constrained convex minimization is then applied to the function f_ϵ to get a convergence rate in $O(1/\epsilon)$.

Choose $\epsilon > 0$ and set $X_0 = \beta\mathbf{I}_n$, the algorithm then updates primal and dual iterates Y_k and $\hat{U}_k$ using the following steps:

1. Compute $\nabla f_\epsilon(X_k) = -X^{-1} + \Sigma + U^*(X_k)$, where $U^*(X)$ solves (3.2).
2. Find $Y_k = \mathrm{argmin}_{Y\in\mathcal{Q}_1}\{\langle\nabla f_\epsilon(X_k), Y - X_k\rangle + \frac{1}{2}L(\epsilon)\|Y - X_k\|_F^2\}$.
3. Find $Z_k = \mathrm{argmin}_{Z\in\mathcal{Q}_1}\left\{\frac{L(\epsilon)d_1(Z)}{\sigma_1} + \sum_{i=0}^k \frac{i+1}{2}(f_\epsilon(X_i) + \langle\nabla f_\epsilon(X_i), Z - X_i\rangle)\right\}$.
4. Update $X_k = \frac{2}{k+3}Z_k + \frac{k+1}{k+3}Y_k$ and $\hat{U}_k = \frac{k\hat{U}_{k-1}+2U^*(X_k)}{(k+2)}$.
5. Repeat until the duality gap is less than the target precision:

$$-\log\det Y_k + \langle\Sigma, Y_k\rangle + \rho\mathbf{1}^T|Y_k|\mathbf{1} - \phi(\hat{U}_k) \leq \epsilon.$$

The key to the method's success is that steps 1–3 and 5 can be performed explicitly and only involve an eigenvalue decomposition. Step one above computes the (smooth) function value and gradient. The second step computes the , which matches the gradient step for unconstrained problems (see [17, p. 86]). Steps three and four update an [17, p. 72] of f_μ whose minimum can be computed explicitly and gives an increasingly tight upper bound on the minimum of f_μ. We now present these steps in detail for our problem.

1 The first step requires computing the gradient of the function

$$f_\epsilon(X) = \hat{f}(X) + \max_{u\in\mathcal{Q}_2}\langle X, U\rangle - (\epsilon/2D_2)d_2(U).$$

This function can be expressed in closed form as $f_\epsilon(X) = \hat{f}(X) + \sum_{i,j}\psi_\mu(X_{ij})$, where

$$\psi_\epsilon(x) := \begin{cases} |x| - (\epsilon/4D_2) & \text{if } |x| \geq (\epsilon/2\rho D_2), \\ D_2x^2/\epsilon & \text{otherwise,} \end{cases}$$

which is simply the Moreau–Yosida regularization of the absolute value and the gradient of the function at X is

$$\nabla f_\mu(X) = -X^{-1} + \Sigma + U^*(X),$$

with

$$U^*(X) := \max(\min(X/\mu, \rho), -\rho),$$

with min. and max. understood componentwise. The cost of this step is dominated by that of computing the inverse of X, which is $O(n^3)$.

2 This step involves a problem of the form

$$T_{\mathcal{Q}_1}(X) = \arg\min_{Y\in\mathcal{Q}_1}\langle\nabla f_\epsilon(X), Y - X\rangle + \frac{1}{2}L\|Y - X\|_F^2,$$

where $X \in \mathcal{Q}_1$ is given. This problem can be reduced to one of projection on $\mathcal{Q}_1$, namely

$$\min_{Y\in\mathcal{Q}_1}\|Y - G\|_F^2,$$

where $G := X - L^{-1}\nabla f_\epsilon(X)$. Using the rotational invariance of this problem, we reduce it to a vector problem:

$$\min_\lambda \ \textstyle\sum_i (\lambda_i - \gamma_i)^2 \ : \ \alpha \leq \lambda_i \leq \beta, \quad i = 1, \ldots, n,$$

where γ is the vector of eigenvalues of G. This problem admits a simple explicit solution:

$$\lambda_i = \min(\max(\gamma_i, \alpha), \beta), \quad i = 1, \ldots, n.$$

The corresponding solution is then $Y = V^T \mathbf{diag}(\lambda) V$, where $G = V^T \mathbf{diag}(\gamma) V$ is the eigenvalue decomposition of G. The cost of this step is dominated by the cost of forming the eigenvalue decomposition of G, which is $O(n^3)$.

Step 3 The third step involves solving a problem of the form

$$Z := \arg\max_{X \in \mathcal{Q}_1} \ d_1(X) + \langle S, X \rangle, \tag{3.3}$$

where S is given. Again, due to the rotational invariance of the objective and feasible set, we can reduce the problem to a one-dimensional problem:

$$\min_\lambda \ \textstyle\sum_i \sigma_i \lambda_i - \log \lambda_i \ : \ \alpha \leq \lambda_i \leq \beta,$$

where σ contains the eigenvalues of S. This problem has a simple, explicit solution:

$$\lambda_i = \min(\max(1/\sigma_i, \alpha), \beta), \quad i = 1, \ldots, n.$$

The corresponding solution is then $Y = V^T \mathbf{diag}(\lambda) V$, where $S = V^T \mathbf{diag}(\sigma) V$ is the eigenvalue decomposition of S. Again, the cost of this step is dominated by the cost of forming the eigenvalue decomposition of S, which is $O(n^3)$.

Computing $\phi(\hat{U}_k)$ For a given matrix $\hat{U}_k$ the function ϕ in (3.1) is computed as

$$\phi(\hat{U}_k) = \min_{X \in \mathcal{Q}_1} - \log\det X + \langle \Sigma + \hat{U}_k, X \rangle.$$

This means projecting $(\Sigma + \hat{U}_k)^{-1}$ on $\mathcal{Q}_1$ only involves an eigenvalue decomposition.

Complexity estimate To summarize, for step 1, the gradient of f_ϵ is readily computed in closed form, via the computation of the inverse of X. Step 2 essentially amounts to projecting on $\mathcal{Q}_1$ and requires an eigenvalue problem to be solved; likewise for step 3. In fact, each iteration costs $O(n^3)$. The number of iterations necessary to achieve an objective with absolute accuracy less than ϵ is then given by

$$N(\epsilon) := 4\|A\| \frac{1}{\epsilon} \sqrt{\frac{D_1 D_2}{\sigma_1 \sigma_2}} + \sqrt{\frac{M D_1}{\sigma_1 \epsilon}} = \frac{\kappa \sqrt{n(\log \kappa)}}{\epsilon} (4n\alpha\rho + \sqrt{\epsilon}), \tag{3.4}$$

where $\kappa = \beta/\alpha$ bounds the solution's condition number. Thus, the overall complexity when $\rho > 0$ is in $O(n^{4.5}/\epsilon)$, as claimed.

3.2. Block-coordinate gradient methods. In this section, we focus on the particular case where $\alpha = 0$ and $\beta = +\infty$ (hence, implicitly $\alpha = \alpha(n)$ and $\beta = \beta(n)$) and derive gradient minimization algorithms that take advantage of the problem structure. We consider the following problem:

$$\max_X \ \log\det X - \langle \Sigma, X \rangle - \rho \mathbf{1}^T |X| \mathbf{1} \tag{3.5}$$

in the variable $X \in \mathbf{S}_n$, where $\rho > 0$ again controls the trade-off between log-likelihood and sparsity of the inverse covariance matrix. Its dual is given by

$$\begin{array}{ll} \text{minimize} & -\log\det(\Sigma + U) - n \\ \text{subject to} & |U_{ij}| \leq \rho, \quad i,j = 1,\ldots,n, \end{array} \tag{3.6}$$

in the variable $U \in \mathbf{S}_n$. We partition the matrices X and U in block format:

$$X = \begin{pmatrix} Z & x \\ x^T & y \end{pmatrix} \quad \text{and} \quad U = \begin{pmatrix} V & u \\ u^T & w \end{pmatrix},$$

where $Z \succ 0$ and U are fixed and $x,\ u \in \mathbf{R}^{(n-1)},\ y,\ w \in \mathbf{R}$ are the variables (row and column) we are updating. We also partition the sample matrix according to the same block structure:

$$\Sigma = \begin{pmatrix} A & b \\ b^T & c \end{pmatrix},$$

where $A \in \mathbf{S}_{(n-1)},\ b \in \mathbf{R}^{(n-1)},\ c \in \mathbf{R}$. In the methods that follow, we will update only one column (and corresponding row) at a time and without loss of generality we can always assume that we are updating the last one.

The dual problem (3.6):

$$\begin{array}{ll} \text{minimize} & -\log\det(\Sigma + U) - n \\ \text{subject to} & |U_{ij}| \leq \rho, \quad i,j = 1,\ldots,n, \end{array}$$

in the variable $U \in \mathbf{S}_n$, can be written in block format as

$$\begin{array}{ll} \text{minimize} & -\log\det(A+V) - \log\big((w+c) - (b+u)^T(A+V)^{-1}(b+u)\big) - n \\ \text{subject to} & |w| \leq \rho,\ |u_i| \leq \rho, \quad i = 1,\ldots,n, \end{array}$$

in the variables $u \in \mathbf{R}^{(n-1)}$ and $w \in \mathbf{R}$ (V is fixed at each iteration). We directly get $w = \rho$ so the diagonal of the optimal solution must be $\rho\mathbf{1}$. The main step at each iteration is then a box constrained quadratic program (QP):

$$\begin{array}{ll} \text{minimize} & (b+u)^T(A+V)^{-1}(b+u) \\ \text{subject to} & |u_i| \leq \rho, \quad i = 1,\ldots,n, \end{array} \tag{3.7}$$

in the variable $u \in \mathbf{R}^{(n-1)}$. To summarize, the block coordinate descent algorithm proceeds as follows:

1. Pick the row and column to update.
2. Compute $(A+V)^{-1}$.
3. Solve the box constrained QP in (3.7).
4. Repeat until duality gap is less than precision: $\langle \Sigma, X\rangle - n + \rho\mathbf{1}^T|X|\mathbf{1} \leq \epsilon$.

At each iteration, we need to compute the inverse of the submatrix $(A+V) \in \mathbf{S}_{(n-1)}$, but we can update this inverse using the Sherman–Woodbury–Morrison formula on two rank-two updates; hence, it is only necessary to compute a full inverse at the first iteration.

Primal block coordinate descent. For a fixed Z, problem (3.5) is equivalent to

$$\begin{array}{ll} \text{maximize} & \log\left(y - x^T Z^{-1} x\right) - 2b^T x - y(c+\rho) - 2\rho\|x\|_1 \\ \text{subject to} & y - x^T Z^{-1} x > 0,\ y > 0, \end{array}$$

in the variables $x \in \mathbf{R}^{(n-1)}$, $y \in \mathbf{R}$, where $Z \succ 0$ (given) and the Schur complement constraints imply $X \succ 0$. We can solve for the optimal y explicitly and the problem in x becomes

$$\max_x -x^T Q x - 2b^T x - 2\rho\|x\|_1,$$

where $Q := (c+\rho)Z^{-1}$. Its dual is also box-constrained QP:

$$\begin{array}{ll} \text{minimize} & (b+u)^T Z (b+u) \\ \text{subject to} & \|u\|_\infty \leq \rho, \end{array}$$

in the variable $u \in \mathbf{R}^{(n-1)}$. At the optimum for this QP, we must have

$$x = -\frac{1}{(c+\rho)} Z(b+u), \quad \text{and} \quad y = \frac{1}{(c+\rho)} + \frac{1}{(c+\rho)^2}(b+u)^T Z (b+u),$$

and we iterate as above.

Dual block coordinate descent. The two block-coordinate methods detailed in this section both amount to solving a sequence of box-constrained quadratic program of the form

$$\begin{array}{ll} \text{minimize} & x^T A x + b^T x \\ \text{subject to} & \|x\|_\infty \leq \rho, \end{array} \tag{3.8}$$

in the variable $x \in \mathbf{R}^n$. The objective function has a Lipschitz continuous gradient with constant $L = 2\lambda^{\max}(A)$ on the box $\mathcal{B} = \{x \in \mathbf{R}^n : \|x\|_\infty \leq \rho\}$, where we can define a prox function $(1/2)\|x\|^2$ which is strongly convex with constant one and bounded above by $(1/2)n\rho^2$ on $\mathcal{B}$. From [16] or [18], we know that solving (3.8) up to a precision ϵ will require at most $2\rho\sqrt{n\lambda^{\max}(A)/\epsilon}$ iterations of the first-order method detailed in [16], with each iteration equivalent to a matrix-vector product and a projection on the box $\mathcal{B}$. This means that the total complexity of solving (3.8) is given by

$$O\left(\rho n^{2.5}\sqrt{\frac{\lambda^{\max}(A)}{\epsilon}}\right).$$

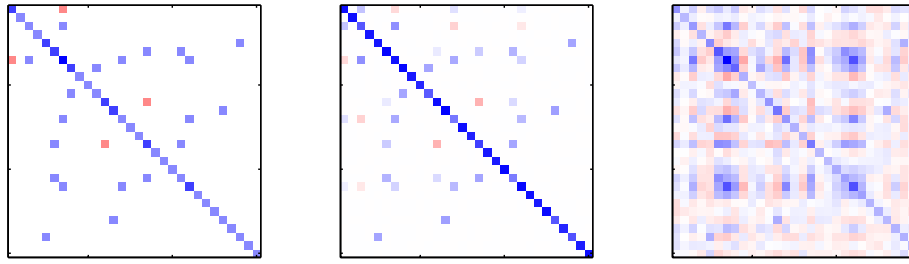
Block coordinate descent. Following [15], with block coordinate descent corresponding to coordinate descent with the almost cyclic rule (defined in [15], it simply means here that we go through each index at least once per outer iteration) and using the fact that $\log\det(X)$ satisfies the strict concavity assumptions in [15, assumption A2], we can show that the convergence rate of the block coordinate descent method is at least linear. Each iteration requires solving a box-constrained QP and takes $O(n^3 log(1/\epsilon))$ operations using an interior point solver or $O(n^{2.5}/\sqrt{\epsilon})$ using the optimal first-order scheme in [16]. We cannot use the same argument to show convergence of block coordinate ascent but empirical performance is comparable. In practice we have found that a small number of sweeps through all columns, independent of problem size n, is sufficient for convergence.

The block coordinate descent methods implemented here correspond to coordinate descent using the almost cyclic rule, alternative row/column selection rules could improve the convergence speed. Also, each iteration of the block coordinate descent method corresponds to two rank-two updates of the inverse matrix; hence, the cost of maintaining the inverse submatrix using the Sherman–Woodbury–Morrison formula is only $O(n^2)$.

4. Numerical results. In this section we test the performance of the methods detailed above on some randomly generated examples. We first form a sparse matrix A with a diagonal equal to one and a few randomly chosen, nonzero off-diagonal terms equal to $+1$ or -1. We then form the matrix

$$B = A^{-1} + \sigma V$$

where $V \in \mathbf{S}_n$ is a symmetric, i.i.d. uniform random matrix. Finally, we make B positive definite by shifting its eigenvalues, and use this noisy, random matrix to test our covariance selection methods.



Original inverse A | Solution for $\rho = 0.5$ | Noisy inverse B^{-1}

FIG. 4.1. *Recovering the sparsity pattern. We plot the original inverse covariance matrix A, the solution to problem* (2.1)*, and the noisy inverse B^{-1}.*

In Figure 4.1, we plot the sparsity patterns of the original inverse covariance matrix A, the solution to problem (2.1), and the noisy inverse B^{-1} in a randomly generated example with $n = 30$, $\sigma = 0.15$, and $\rho = 0.5$. In Figure 4.2 we represent the dependence structure of interest rates (sampled over a year) inferred from the inverse covariance matrix. Each node represents a particular interest rate maturity and the nodes are linked if the corresponding coefficient in the inverse covariance matrix is nonzero (i.e., they are conditionally dependent). We compare the solution to problem (2.1) on this matrix for $\rho = 0$ and $\rho = 0.1$ and notice that in the sparse solution the rates appear clearly clustered by maturity.

In Figure 4.3, we study computing times for various choices of algorithms and problem sizes. On the , , we plot CPU time to reduce the duality gap by a factor 10^{-2} versus problem size n, on randomly generated problems, using the coordinate descent code and the optimal first-order for solving box QPs. On the , , , , we plot duality gap versus CPU time for both smooth minimization and block-coordinate algorithms for a randomly generated problem of size $n = 250$. For the smooth minimization code, we set $\alpha = 1/\lambda^{\max}(B)$ and we plot computing time for both $\beta = 1/(2\lambda^{\min}(B))$ (smooth. opt. 1/2) and $\beta = 2/\lambda^{\min}(B)$ (smooth. opt. 2). In the examples of Figure 4.3, we notice that the numerical cost of our methods grows experimentally as $O(n^3)$.

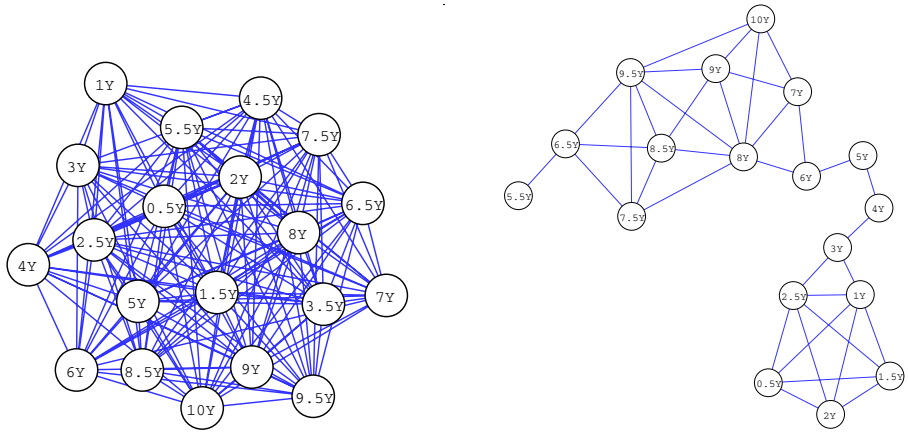


FIG. 4.2. *We plot the network formed using the solution to problem* (2.1) *on an interest rate covariance matrix for* $\rho = 0$ (left) *and* $\rho = 0.1$ (right). *In the sparse solution the rates appear clearly clustered by maturity.*

WAVEFRONT RECONSTRUCTION METHODS FOR ADAPTIVE OPTICS SYSTEMS ON GROUND-BASED TELESCOPES*

JOHNATHAN M. BARDSLEY†

Abstract. The earth's atmosphere is not a perfect media through which to view objects in outer-space; turbulence in the atmospheric temperature distribution results in refractive index variations that interfere with the propagation of light. As a result, wavefronts are nonplanar when they reach the ground. The deviation from planarity of a wavefront is known as phase error, and it is phase error that causes the refractive blurring of images. Adaptive optics systems seek to remove phase error from incoming wavefronts. In ground-based astronomy, an estimate of the phase error in a wavefront is typically obtained from wavefront gradient measurements collected by a Shack–Hartmann sensor. The estimate is then used to create a counter wavefront, e.g., using a deformable mirror that (approximately) removes the phase error from the incoming wavefronts. The problem of reconstructing the phase error from Shack–Hartmann gradient measurements requires the solution of a large linear system whose form is defined by the configuration of the sensor. We derive this system and present both the regular least squares and minimum variance approaches to its solution. The most effective existing approaches are then presented alongside new computational methods, and comparisons are made.

1. Introduction.

The standard mathematical model for image formation in ground-based astronomy is

$$d(x,y) = \int_{\mathbb{R}^2} k(x,y;\xi,\eta) f(\xi,\eta)\, d\xi d\eta. \tag{1.1}$$

Here f is the object being viewed; d is the image of f seen by the telescope; and k is the [illegible] (PSF), which characterizes the blurring effects of the imaging system. In traditional approaches, the PSF characterizes the diffractive blur of the telescope as well as the refractive blur of the atmosphere. Adaptive optics systems, however, seek to remove the refractive effects of the atmosphere prior to image formation. If this is done exactly, so-called [illegible] is obtained, which maximizes angular resolution and sensitivity.

The idea behind adaptive optics can be illustrated using the spatially invariant PSF model

$$k[\phi](x,y) = \left| \mathcal{F}^{-1} \left\{ P(x,y) e^{i\phi(x,y)} \right\} \right|^2, \tag{1.2}$$

which is obtained using techniques from Fourier optics [5]. Here $P(x,y)$ is the telescope's pupil function, and $\phi(x,y)$ denotes the phase error, or simply the phase, and

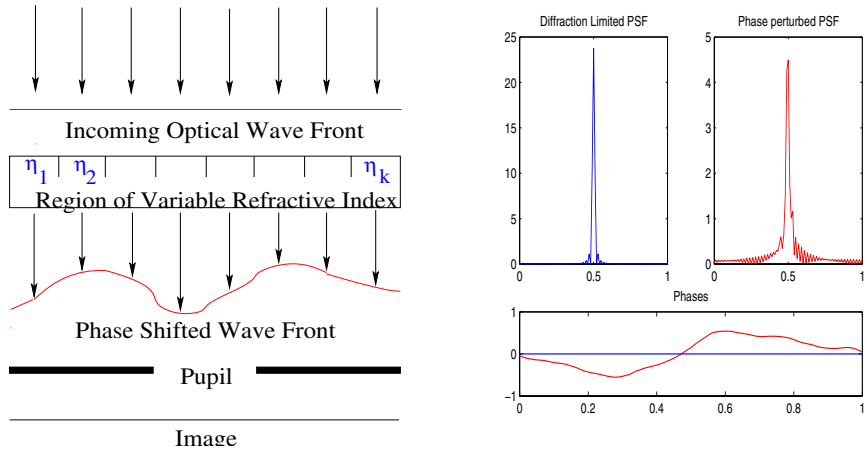

FIG. 1.1. *One-dimensional phase error schematic. On the left, the effects of refractive index variations in the earth's atmosphere are illustrated. On the right, where both diffraction limited and phase perturbed PSFs are plotted, the effects of phase errors on the corresponding PSFs are demonstrated.*

is defined to be the deviation from planarity of the wavefront at the point (x, y). For simulation and analysis, we will assume that $P(x, y)$ is 1 inside the pupil and 0 otherwise, though in practice this will not always be the case as a telescope's mirror can get dirty.

Adaptive optics systems seek to remove the phase error ϕ from the incoming wavefronts. If done exactly, the resulting PSF then has the form

$$k[0](x, y) = \left|\mathcal{F}^{-1}\left\{P(x, y)\right\}\right|^2, \tag{1.3}$$

in which case the [illegible]

$$d_{\mathrm{DL}}(x, y) \stackrel{\mathrm{def}}{=} \int_{\mathbb{R}^2} k[0](x - \xi, y - \eta) f(\xi, \eta)\, d\xi d\eta \tag{1.4}$$

is what is seen by the telescope.

Phase errors arise due to index of refraction variations in the atmosphere. A one-dimensional schematic of this process is given on the left in Figure 1.1. Since the refractive index—denoted by η_i in the schematic—determines the speed of propagation of the wavefront, variations in the refractive index result in wavefront perturbations or phase errors. To see the effects of phase errors on the PSF, on the right-hand side in Figure 1.1 we plot two PSFs—one when phase errors characteristic of atmospheric turbulence are present, and one when the phase error is zero.

The phase can be estimated in a number of ways [2]. The most common approach in ground-based astronomy is to use the Shack–Hartmann sensor, which collects measurements of the gradient of the incoming wavefronts and then seeks to reconstruct the phase from those measurements. The phase estimate is then used to create a counter wavefront distortion ϕ_{DM} via the deformation of an optical component known as a deformable mirror (DM). If the PSF has the form (1.2), then the phase corrected PSF will have the form

$$k[\phi + \phi_{\mathrm{DM}}](x, y) = \left|\mathcal{F}^{-1}\left\{P(x, y) e^{i(\phi + \phi_{\mathrm{DM}})(x, y)}\right\}\right|^2. \tag{1.5}$$

Ideally, the DM created counter wavefront satisfies $\phi_{\mathrm{DM}} = -\phi$ so that the resulting PSF has diffraction limited form (1.3). In practice, however, an accurate approximation of ϕ suffices.

In this paper, our focus is on the problem of estimating the phase from measurements of the wavefront gradient. We assume that the gradient data $\mathbf{g}$ is collected by a Shack–Hartmann sensor. The corresponding discrete phase $\boldsymbol{\phi}$ will then satisfy the stochastic linear equation

$$\mathbf{g} = \boldsymbol{\Gamma}\boldsymbol{\phi} + \mathbf{n}, \tag{1.6}$$

where $\boldsymbol{\Gamma}$ is a discrete gradient matrix, whose form is determined by the configuration of the Shack–Hartmann sensor, and $\mathbf{n}$ is the noise vector. Early and existing approaches to solving this problem involve minimizing the least squares function $||\boldsymbol{\Gamma}\boldsymbol{\phi} - \mathbf{g}||^2$. However, for large-scale adaptive optics systems, least squares solutions can yield unsatisfactory results, and the minimum variance estimator is preferred [6]. Minimum variance estimation is a Bayesian statistical approach in which a prior probability density is assumed on the phase. In our case, it can be accurately assumed that $\boldsymbol{\phi}$ is a realization of a Gaussian random vector with mean $\mathbf{0}$ and known covariance matrix $\boldsymbol{C_\phi}$. This, together with (1.6) and the assumption that the noise vector $\mathbf{n}$ is Gaussian with mean $\mathbf{0}$ and covariance matrix $\sigma^2\mathbf{I}$, yields a linear system of the form

$$(\boldsymbol{\Gamma}^T\boldsymbol{\Gamma} + \sigma^2 \boldsymbol{C_\phi}^{-1})\boldsymbol{\phi} = \boldsymbol{\Gamma}^T\mathbf{g}. \tag{1.7}$$

The problem of efficiently solving (1.7), or, equivalently, of minimizing the penalized least squares function $||\boldsymbol{\Gamma}\boldsymbol{\phi}-\mathbf{g}||^2+\sigma^2\boldsymbol{\phi}^T\boldsymbol{C_\phi}^{-1}\boldsymbol{\phi}$, has seen much recent attention. An efficient direct method for the solution of (1.7) using sparse matrix techniques is explored in [6]. However, the most computationally efficient approaches have involved the use of multigrid to precondition conjugate gradient iterations [9, 10]. In this paper, we introduce two new approaches for approximately solving (1.7). The first involves the use of a symmetric positive definite approximation of $\boldsymbol{\Gamma}^T\boldsymbol{\Gamma}$ as a preconditioner for conjugate gradient iterations. The second approach is completely different and involves first computing the least squares solution of minimum norm $\boldsymbol{\phi}_{\mathrm{MNLS}} = \boldsymbol{\Gamma}^\dagger\mathbf{g}$, where "†" denotes pseudoinverse. The minimum norm solution is then denoised and stabilized via the solution of a linear system motivated by (1.7).

The paper is organized as follows. In section 2, we present the linear system that arises from the use of the Shack–Hartmann sensor; we derive the minimum variance linear system (1.7); and we discuss approximations of the covariance matrix $\boldsymbol{C_\phi}$. Computational methods are presented in section 3 and tested in section 4. We end with conclusions in section 5.

2. Wavefront reconstruction from discrete gradient measurements. In this section, we present the wavefront reconstruction problem that arises when the Shack–Hartmann wavefront sensor is used. The Shack–Hartmann sensor collects measurements of the gradient of incoming wavefronts of light emitted by the object being viewed by the telescope. It consists of an array of lenslets, each of which focuses the light within its aperture, and, typically, a charge coupled device (CCD) camera that records the position of the focal point of the light within each lenslet. A measurement of the average gradient of the wavefront over the lenslet aperture is then given by the position of the focal point. A schematic of the Shack–Hartmann sensor in one dimension is given in Figure 2.1. A more detailed description with further references can be found in [2].

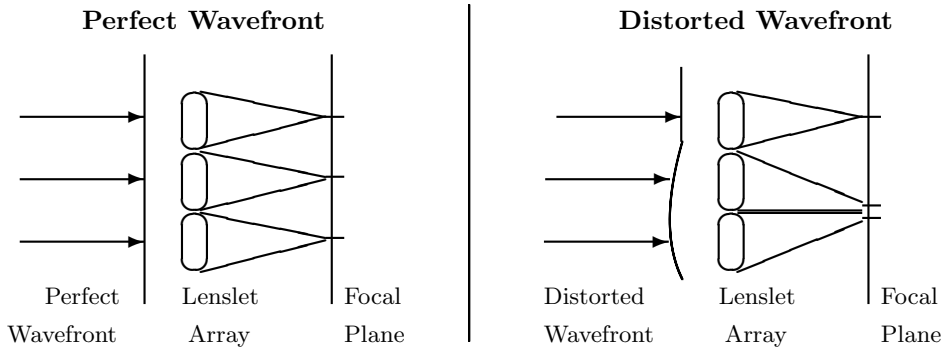

FIG. 2.1. *One-dimensional Shack–Hartman wavefront sensor schematic. The position of the focal points determines the average derivative of the wavefront, and hence of the phase, over each lenslet aperture.*

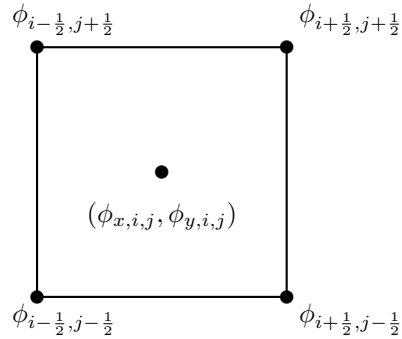

FIG. 2.2. *Fried geometry for the (i,j)th lenslet. The wavefront sensor yields a measurement of the gradient of the phase at (x_i, y_j). The values of the phase at the half grid points, i.e., at the corners of the apertures, are then sought.*

The standard computational methodology for reconstructing the phase from Shack–Hartmann gradient data was introduced by Fried in [4], where, from the gradient measurements, which are assumed to be centered within each lenslet array, the value of the phase at the corners is computed. This is the so-called Fried geometry and is illustrated in Figure 2.2. Assuming a square geometry and uniform computational grid with grid points $\{(x_i, y_j)\}_{i,j=1}^n$, and denoting $\nabla\phi(x_i, y_j) = (\phi_{x,i,j}, \phi_{y,i,j})$, we can approximate ϕ at the half grid points via the following two formulas:

$$\phi_{x,i,j} \approx \frac{1}{2}\left[(\phi_{i+\frac{1}{2},j-\frac{1}{2}} - \phi_{i-\frac{1}{2},j-\frac{1}{2}}) + (\phi_{i+\frac{1}{2},j+\frac{1}{2}} - \phi_{i-\frac{1}{2},j+\frac{1}{2}})\right], \tag{2.1}$$

$$\phi_{y,i,j} \approx \frac{1}{2}\left[(\phi_{i-\frac{1}{2},j+\frac{1}{2}} - \phi_{i-\frac{1}{2},j-\frac{1}{2}}) + (\phi_{i+\frac{1}{2},j+\frac{1}{2}} - \phi_{i+\frac{1}{2},j-\frac{1}{2}})\right]. \tag{2.2}$$

Here we have assumed a grid spacing $\Delta x = \Delta y = 1$. We note that in practice, the corners of the lenslet aperture frequently correspond to the points on the deformable mirror of the adaptive optics system where the deformations are actuated.

By column stacking the $n \times n$ array of the values of ϕ at the half grid points, one obtains an $n^2 \times 1$ vector $\boldsymbol{\phi}$. The equations on the right-hand side of (2.1) and (2.2) can then be written in matrix-vector forms $\boldsymbol{\Gamma}_x\boldsymbol{\phi}$ and $\boldsymbol{\Gamma}_y\boldsymbol{\phi}$, respectively. If the $n \times n \times 2$ array of gradient measurements is also column stacked, an $n^2 \times 2$ array

$$\begin{bmatrix} -1 & 0 & -1 \\ 0 & 4 & 0 \\ -1 & 0 & -1 \end{bmatrix} \qquad \begin{bmatrix} 0 & -1 & 0 \\ -1 & 4 & -1 \\ 0 & -1 & 0 \end{bmatrix}$$

FIG. 2.3. *Grid representations of the Fried Laplacian (on the left) and the Hudgin Laplacian (on the right).*

$\mathbf{g}$ results. The unknown phase can then be reconstructed by solving the stochastic linear system

$$\mathbf{g} = \mathbf{\Gamma}\boldsymbol{\phi} + \mathbf{n}, \tag{2.3}$$

where $\mathbf{\Gamma} = [\mathbf{\Gamma}_x, \mathbf{\Gamma}_y]^T$ and $\mathbf{n} \sim N(\mathbf{0}, \sigma^2\mathbf{I})$. Throughout the paper, the notation $\mathbf{y} \sim N(\boldsymbol{\mu}, \mathbf{C})$ will mean that $\mathbf{y}$ is a random draw from a Gaussian random vector with mean $\boldsymbol{\mu} \in \mathbb{R}^{n^2}$ and covariance matrix $\mathbf{C} \in \mathbb{R}^{n^2 \times n^2}$.

2.1. Least squares wavefront reconstruction. For small-scale wavefront reconstruction problems, the least squares solution of (2.3), given by minimizing

$$\min_{\phi} \|\mathbf{\Gamma}\boldsymbol{\phi} - \mathbf{g}\|_2^2,$$

is known to provide excellent results [6]. One can equivalently solve the normal equations

$$\mathbf{\Gamma}^T\mathbf{\Gamma}\boldsymbol{\phi} = \mathbf{\Gamma}^T\mathbf{g}. \tag{2.4}$$

The matrix $\mathbf{\Gamma}^T\mathbf{\Gamma}$ corresponds to a nonstandard discretization of the Laplacian operator Δ, with the grid representation given on the left in Figure 2.3 and homogeneous Neumann boundary conditions. We will call this the Fried discrete Laplacian. The standard discretization of the Laplacian has the grid representation given on the right in Figure 2.3. We note that this is the discrete Laplacian that results from what is known in the adaptive optics community as Hudgin geometry [13] and is therefore referred to as the Hudgin discrete Laplacian [19]. We will use this terminology in what follows.

Fried geometry yields more robust phase estimates than does Hudgin geometry [20]. However, the null-space of the Fried Laplacian is larger than that of the Hudgin Laplacian. In particular, it contains what is known as the waffle mode, which is the $n \times n$ array with entries

$$[\boldsymbol{\phi}_{\mathrm{WM}}]_{ij} = (-1)^{i+j}. \tag{2.5}$$

In what follows, we will also use $\boldsymbol{\phi}_{\mathrm{WM}}$ to denote the corresponding $n^2 \times 1$ column stacked vector. We say that a vector ϕ contains waffle mode if

$$\boldsymbol{\phi}^T\boldsymbol{\phi}_{\mathrm{WM}} \neq 0.$$

Waffle mode has been observed in operational adaptive optics systems [14], and hence, its presence in the null-space of the Fried Laplacian is not of only academic interest.

Before continuing, we prove an interesting relationship between $\boldsymbol{\phi}_{\mathrm{WM}}$ and the Hudgin discrete Laplacian with homogeneous Dirichlet, homogeneous Neumann, and periodic boundary conditions.

THEOREM 2.1. $n^2 \times n^2$ $\mathbf{L}$, $\boldsymbol{\phi}_{\rm WM}$

$$\max_{\boldsymbol{\phi}} \frac{\boldsymbol{\phi}^T \mathbf{L} \boldsymbol{\phi}}{\|\boldsymbol{\phi}\|^2}. \tag{2.6}$$

$\boldsymbol{\phi}_{\rm WM}$ (2.6) $n \to \infty$

. First, by Gerschgorin's circle theorem, the eigenvalues of $\mathbf{L}$ satisfy $0 \leq \lambda \leq 8$ for each of the three types of boundary conditions. Thus $0 \leq \boldsymbol{\phi}^T \mathbf{L} \boldsymbol{\phi} / \|\boldsymbol{\phi}\|^2 \leq 8$.

In the case of both periodic and homogeneous Neumann boundary conditions, $\boldsymbol{\phi}_{\rm WM}^T \mathbf{L} \boldsymbol{\phi}_{\rm WM} / \|\boldsymbol{\phi}_{\rm WM}\|^2 = 8$, and hence $\boldsymbol{\phi}_{\rm WM}$ solves (2.6).

In the case of homogeneous Dirichlet boundary conditions, we note that $\mathbf{L}$ differs from the discrete Laplacian with periodic boundary conditions in that it has 0 in place of -1 in $4n$ locations. A straightforward calculation together with the fact that $\|\boldsymbol{\phi}_{\rm WM}\|^2 = n^2$ then yields $\boldsymbol{\phi}_{\rm WM}^T \mathbf{L} \boldsymbol{\phi}_{\rm WM} / \|\boldsymbol{\phi}_{\rm WM}\|^2 = 8 - 4/n \to 8$, and hence $\boldsymbol{\phi}_{\rm WM}$ converges to the solution of (2.6) as $n \to \infty$. □

We note that for large-scale problems $8 - 4/n \approx 8$, and hence, $\boldsymbol{\phi}_{\rm WM}$ maximizes, or nearly maximizes, (2.6) in all three cases. This suggests the use of regularization by the Laplacian to remove waffle mode and other high frequency errors in the phase estimates. As we will see in the next section, such an approach can be motivated statistically when the minimum variance approach is taken.

2.2. Minimum variance wavefront reconstruction. The preferred approach for stabilizing least squares phase estimation is to compute a minimum variance estimate for $\boldsymbol{\phi}$ (c.f. [18]). Minimum variance estimation can be viewed as the analogue of least squares estimation in the Bayesian setting. As we will see, the resulting equations are similar. In the minimum variance framework, we assume that the phase satisfies

$$\boldsymbol{\phi} \sim N(\mathbf{0}, \boldsymbol{C}_{\boldsymbol{\phi}}), \tag{2.7}$$

where the covariance $\boldsymbol{C}_{\boldsymbol{\phi}}$ is specified a priori. The minimum variance estimator can then be defined as follows.

DEFINITION 2.2. $\boldsymbol{\phi}$ $\mathbf{g}$

$$\boldsymbol{\phi}_{\rm MV} = \hat{\mathbf{B}} \mathbf{g},$$

$$\hat{\mathbf{B}} = \arg \min_{\mathbf{B} \in \mathbb{R}^{n \times m}} E(\|\mathbf{B}\mathbf{g} - \boldsymbol{\phi}\|^2).$$

E

In our case, the minimum variance estimator has an elegant closed form, which we state in the next theorem. Standard proofs of this theorem use notation from probability theory. Here we present a proof, outlined in [18], from a matrix analysis viewpoint.

THEOREM 2.3. $\mathbf{g}$ (2.3) $\mathbf{n} \sim N(\mathbf{0}, \sigma^2 \mathbf{I})$ $\boldsymbol{\phi} \sim N(\mathbf{0}, \boldsymbol{C}_{\boldsymbol{\phi}})$ $\boldsymbol{C}_{\boldsymbol{\phi}}$ $\mathbf{n}$ $\boldsymbol{\phi}$ $\boldsymbol{\phi}$ $\mathbf{g}$

$$\boldsymbol{\phi}_{\rm MV}^{\sigma} = \left(\boldsymbol{\Gamma}^T \boldsymbol{\Gamma} + \sigma^2 \boldsymbol{C}_{\boldsymbol{\phi}}^{-1} \right)^{-1} \boldsymbol{\Gamma}^T \mathbf{g}. \tag{2.8}$$

. First, we note that

$$\begin{aligned} E(\|\mathbf{Bg}-\boldsymbol{\phi}\|^2) &= \text{trace}\left(E[(\mathbf{Bg}-\boldsymbol{\phi})(\mathbf{Bg}-\boldsymbol{\phi})^T]\right) \\ &= \text{trace}\left(\mathbf{B}E[\mathbf{gg}^T]\mathbf{B}^T - \mathbf{B}E[\mathbf{g}\boldsymbol{\phi}^T] - E[\boldsymbol{\phi}\mathbf{g}^T]\mathbf{B}^T + E[\boldsymbol{\phi}\boldsymbol{\phi}^T]\right). \end{aligned}$$

Then, using the distributive property of the trace function and the identity

$$\frac{d}{d\mathbf{B}}\text{trace}(\mathbf{B}^T\mathbf{C}) = \left(\frac{d}{d\mathbf{B}}\text{trace}(\mathbf{BC})\right)^T = \mathbf{C},$$

we see that $dE(\|\mathbf{Bg}-\boldsymbol{\phi}\|^2)/d\mathbf{B} = \mathbf{0}$ when

$$\hat{\mathbf{B}} = E[\boldsymbol{\phi}\mathbf{g}^T]E[\mathbf{gg}^T]^{-1}.$$

Now, since $\boldsymbol{\phi}$ and $\mathbf{n}$ are independent, $E[\boldsymbol{\phi}\mathbf{n}^T] = E[\mathbf{n}\boldsymbol{\phi}^T] = \mathbf{0}$. Hence, using (2.3), we obtain

$$\begin{aligned} E[\boldsymbol{\phi}\mathbf{g}^T] &= E[\boldsymbol{\phi}(\boldsymbol{\Gamma}\boldsymbol{\phi}+\mathbf{n})^T] \\ &= E[\boldsymbol{\phi}\boldsymbol{\phi}^T]\boldsymbol{\Gamma}^T. \end{aligned}$$

Similarly,

$$\begin{aligned} E[\mathbf{gg}^T] &= E[(\boldsymbol{\Gamma}\boldsymbol{\phi}+\mathbf{n})(\boldsymbol{\Gamma}\boldsymbol{\phi}+\mathbf{n})^T] \\ &= \boldsymbol{\Gamma}E[\boldsymbol{\phi}\boldsymbol{\phi}^T]\boldsymbol{\Gamma}^T + E[\mathbf{nn}^T]. \end{aligned}$$

Thus, since $E[\boldsymbol{\phi}\boldsymbol{\phi}^T] = \boldsymbol{C}_{\boldsymbol{\phi}}$ and $E[\mathbf{nn}^T] = \sigma^2\mathbf{I}$, we have

$$\begin{aligned} \hat{\mathbf{B}}\mathbf{g} &= \boldsymbol{C}_{\boldsymbol{\phi}}\boldsymbol{\Gamma}^T\left(\boldsymbol{\Gamma}^T\boldsymbol{C}_{\boldsymbol{\phi}}\boldsymbol{\Gamma}+\sigma^2\mathbf{I}\right)^{-1}\mathbf{g} \\ &= \left(\boldsymbol{\Gamma}^T\boldsymbol{\Gamma}+\sigma^2{\boldsymbol{C}_{\boldsymbol{\phi}}}^{-1}\right)^{-1}\boldsymbol{\Gamma}^T\mathbf{g}. \end{aligned}$$

The last equality follows from straightforward algebraic manipulation. □

Thus the minimum variance wavefront estimate can be obtained by solving the linear system

$$\left(\boldsymbol{\Gamma}^T\boldsymbol{\Gamma}+\sigma^2{\boldsymbol{C}_{\boldsymbol{\phi}}}^{-1}\right)\boldsymbol{\phi} = \boldsymbol{\Gamma}^T\mathbf{g} \tag{2.9}$$

or, equivalently, by minimizing the penalized least squares function

$$\|\boldsymbol{\Gamma}\boldsymbol{\phi}-\mathbf{g}\|_2^2 + \sigma^2\boldsymbol{\phi}^T{\boldsymbol{C}_{\boldsymbol{\phi}}}^{-1}\boldsymbol{\phi}. \tag{2.10}$$

Note, then, that the minimum variance estimator can be viewed as a Tikhonov estimator, with quadratic regularization term $\sigma^2\boldsymbol{\phi}^T{\boldsymbol{C}_{\boldsymbol{\phi}}}^{-1}\boldsymbol{\phi}$.

2.3. Incorporating the telescope's pupil. For simplicity of implementation, computations are typically done on a square computational grid, even though the telescope pupil geometry is usually either circular or annular. This information is incorporated into the problem formulation using the pupil mask matrix $\mathbf{M}$ defined by

$$[\mathbf{M}]_{ii} = \begin{cases} 1, & i \text{ inside the pupil,} \\ 0 & \text{otherwise.} \end{cases}$$

We then modify the linear stochastic model (2.3) as follows:

$$\mathbf{Mg} = \mathbf{M\Gamma}\boldsymbol{\phi} + \mathbf{n}, \tag{2.11}$$

where $\mathbf{M\Gamma} \stackrel{\text{def}}{=} [\mathbf{M\Gamma}_x, \mathbf{M\Gamma}_y]^T$. Following the minimum variance approach outlined above, the penalized least squares function (2.10) takes the form

$$\|\mathbf{M}(\mathbf{\Gamma}\boldsymbol{\phi} - \mathbf{g})\|_2^2 + \sigma^2 \boldsymbol{\phi}^T {\boldsymbol{C}_{\boldsymbol{\phi}}}^{-1} \boldsymbol{\phi}, \tag{2.12}$$

and the linear system (2.9) is re-expressed as

$$\left(\mathbf{\Gamma}^T \mathbf{M\Gamma} + \sigma^2 {\boldsymbol{C}_{\boldsymbol{\phi}}}^{-1}\right) \boldsymbol{\phi} = \mathbf{\Gamma}^T \mathbf{Mg}. \tag{2.13}$$

The corresponding regular least squares normal equations are given by

$$\mathbf{\Gamma}^T \mathbf{M\Gamma}\boldsymbol{\phi} = \mathbf{\Gamma}^T \mathbf{Mg}. \tag{2.14}$$

2.4. Approximating the phase covariance. The phase covariance $\boldsymbol{C}_{\boldsymbol{\phi}}$ must be chosen so that it is both physically realistic and amenable to fast computational methods. We call attention to the fact that for an actual adaptive optics system, algorithms for solving (2.9) must do so in real time.

Perhaps the most standard approximation for $\boldsymbol{C}_{\boldsymbol{\phi}}$ is to assume that it has the form

$$\boldsymbol{C}_{\boldsymbol{\phi}}^{\mathbf{VK}} = \mathbf{F}^* \mathbf{\Lambda} \mathbf{F}, \tag{2.15}$$

where $\mathbf{F}$ is the two-dimensional discrete Fourier transform matrix, "$*$" denotes conjugate transpose, and the matrix $\mathbf{\Lambda}$ is diagonal with entries coming from the von Karman spatial power spectral density of the atmospheric refractive index fluctuations, with universal $-11/3$ inverse power law:

$$[\mathbf{\Lambda}]_{k,k} = \frac{c^2}{[|k|^2 + 1/L_0^2]^{11/6}}. \tag{2.16}$$

Here k denotes spatial frequency, L_0 is the turbulence outer-scale, which prevents an unphysically infinite amount of energy at the origin, and c is the phase screen strength (c.f. [16]).

However, given the desire for real time computations for large-scale lenslet arrays on very high-order adaptive optics systems, a sparse covariance approximation is desirable. Such an approximation was introduced in [6]. It exploits the fact that

$$|k|^{-11/3} \approx |k|^{-4}.$$

In particular, using the fact that the biharmonic, or squared Laplacian, operator "Δ^2" has spectrum $|k|^4$, the following discrete approximation of the covariance can be used:

$$\boldsymbol{C}_{\boldsymbol{\phi}}^{\mathbf{BH}} = c_0 \, \mathbf{L}^{-2}, \tag{2.17}$$

where $\mathbf{L}$ is a discrete Laplacian matrix. The constant c_0 in (2.17) can be physically interpreted as the strength of the turbulence and is chosen in our simulations so that

$$E[\boldsymbol{\phi}^T (\boldsymbol{C}_{\boldsymbol{\phi}}^{\mathbf{VK}})^{-1} \boldsymbol{\phi}] = E[\boldsymbol{\phi}^T (\boldsymbol{C}_{\boldsymbol{\phi}}^{\mathbf{BH}})^{-1} \boldsymbol{\phi}] \tag{2.18}$$

holds.

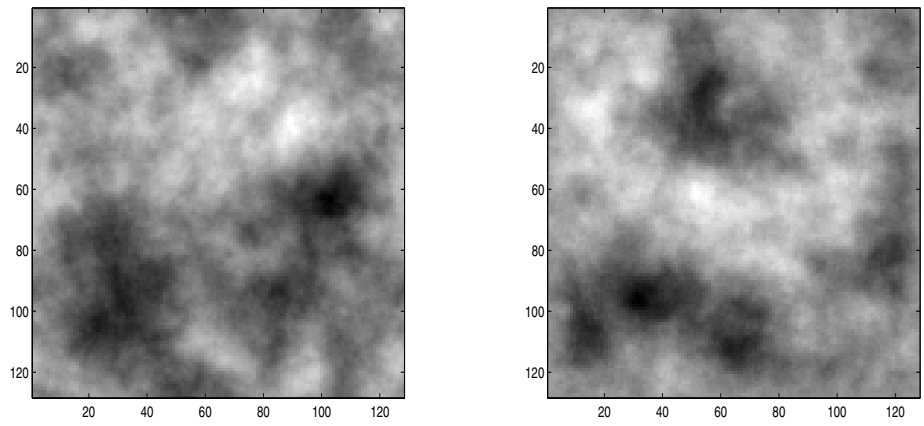

FIG. 2.4. *Random draws from zero mean Gaussian random vectors with (on the left) von Karman covariance defined by* (2.15) *and (on the right) inverse of squared-Laplacian covariance defined in* (2.17).

In order to visually compare the two covariance approximations (2.15) and (2.17), we plot random draws from the zero mean Gaussian random vectors with these as the covariance matrices in Figure 2.4. They clearly exhibit similar characteristics.

REMARK 1. (2.17) (2.12)

3. Numerical methods. In the early papers of Fried [4] and Hudgin [13], the Gauss–Seidel iteration was used for numerically solving the normal equations (2.14). In [17], symmetric Gauss–Seidel is implemented. However, it is well known that iterative methods such these converge slowly in practice. Such methods are effective, however, if used within a multigrid framework or as preconditioners (given that they are symmetric) for conjugate gradient iterations. The use of multigrid for solving (2.14) is explored in [1, 15].

Direct methods for (2.14) are made feasible by the fact that $\boldsymbol{\Gamma}^T\mathbf{M}\boldsymbol{\Gamma}$ is very sparse and is fixed for a specific telescope. In [12], the least squares solution of minimum norm is computed via the pseudoinverse of $\mathbf{M}\boldsymbol{\Gamma}$, which we denote $(\mathbf{M}\boldsymbol{\Gamma})^\dagger$. The pseudoinverse can be efficiently approximated using the Cholesky factorization. In particular, noting that

$$(\mathbf{M}\boldsymbol{\Gamma})^\dagger = \lim_{\epsilon\to 0^+} (\boldsymbol{\Gamma}^T\mathbf{M}\boldsymbol{\Gamma} + \epsilon\,\mathbf{I})^{-1}\boldsymbol{\Gamma}^T\mathbf{M},$$

one can compute a Cholesky factorization of $\boldsymbol{\Gamma}^T\mathbf{M}\boldsymbol{\Gamma} + \epsilon\,\mathbf{I}$ for ϵ small, e.g., the square root of machine epsilon ($\approx 10^{-8}$). Because it will be useful to us later, we give a detailed description of this approach now. After performing a reordering of indices using MATLAB's `symamd` function, $\boldsymbol{\Gamma}^T\mathbf{M}\boldsymbol{\Gamma} + \epsilon\,\mathbf{I}$ has the form

$$\tilde{\mathbf{A}} \stackrel{\text{def}}{=} \begin{bmatrix} \mathbf{A} + \epsilon\,\mathbf{I} & \mathbf{0} \\ \mathbf{0} & \epsilon\,\mathbf{I} \end{bmatrix}, \tag{3.1}$$

where $\mathbf{A}$ is sparse and symmetric positive semidefinite. We can then compute the Cholesky factorization $\tilde{\mathbf{A}} = \mathbf{C}^T\mathbf{C}$. Assuming, without loss of generality, that $\tilde{\mathbf{A}} = \mathbf{\Gamma}^T\mathbf{M}\mathbf{\Gamma}+\epsilon\mathbf{I}$, the minimum norm least squares solution can be efficiently and accurately approximated via

$$\boldsymbol{\phi}_{\text{MNLS}} = (\mathbf{M}\mathbf{\Gamma})^{\dagger}\mathbf{M}\mathbf{g} \approx \mathbf{C}^{-1}\mathbf{C}^{-T}\mathbf{\Gamma}^T\mathbf{M}\mathbf{g}. \tag{3.2}$$

Finally, since $\mathbf{\Gamma}^T\mathbf{M}\mathbf{\Gamma}$ depends only on the inherent structure of the telescope, the above Cholesky factorization can be computed offline, and hence, the cost of computing minimum norm least squares solutions using this approach is restricted to the computation of $\mathbf{\Gamma}^T\mathbf{M}\mathbf{g}$ and to the applications of $\mathbf{C}^{-1}$ and $\mathbf{C}^{-T}$. Also, due to the presence of the pupil mask matrix $\mathbf{M}$ and the use of a sparse reordering of indices, the Cholesky factorization is very sparse, resulting in very efficient computations of $\boldsymbol{\phi}_{\text{MNLS}}$.

In [6], it is shown that for an $N \times N$ Hudgin Laplacian, the scaling law for the number of floating point operations (flops) needed for its Cholesky factorization (after sparse reordering) is $N^{3/2}$. For the Fried Laplacian, the number of flops needed for its Cholesky factorization (again after sparse reordering) should be very nearly the same. Furthermore, the presence of the pupil will further reduce computational requirements. We emphasize again that this Cholesky factorization need only be computed once.

For adaptive optics systems with extremely large lenslet arrays, the minimum variance estimate $\boldsymbol{\phi}^{\sigma}_{\text{MV}}$ obtained by solving (2.13) is preferable to $\boldsymbol{\phi}_{\text{MNLS}}$. An added difficulty arises, however, due to the presence of $\boldsymbol{C}_{\boldsymbol{\phi}}$. Until recently, the von Karman covariance approximation (2.15), (2.16) was standard. The fact that this is a full matrix made direct solutions of (2.13) infeasible. However, the sparse biharmonic approximation (2.17) presented in [6] allowed for a direct approach using a Cholesky factorization of

$$\mathbf{\Gamma}^T\mathbf{M}\mathbf{\Gamma} + (\sigma^2/c_0)\mathbf{L}^2, \tag{3.3}$$

where $\mathbf{L}$ is a discretized Laplacian matrix. However, the Cholesky factorization must be recomputed as σ^2/c_0 changes, which makes the direct approach less desirable for minimum variance estimation.

3.1. Preconditioned conjugate gradient methods. The preconditioned conjugate gradient method (PCG) is an iterative method for minimizing quadratic functions with symmetric positive semidefinite Hessian matrices [18], such as is the case for (2.12). The implementation of PCG requires the solution of a linear system of the form

$$\mathbf{P}\mathbf{z} = \mathbf{v} \tag{3.4}$$

at each iteration, where $\mathbf{P}$ is the symmetric positive definite preconditioning matrix or, simply, the preconditioner. For the resulting implementation of PCG to be efficient, solutions of (3.4) must be efficiently computable.

Thus far, the most computationally efficient approach for minimizing (2.12) is to let $\mathbf{z}$ in (3.4) be what results following the application of one multigrid v-cycle [3] applied to the linear system

$$\left(\mathbf{\Gamma}^T\mathbf{M}\mathbf{\Gamma} + \sigma^2{\boldsymbol{C}_{\boldsymbol{\phi}}}^{-1}\right)\mathbf{z} = \mathbf{v}.$$

The corresponding preconditioning matrix $\mathbf{P}$ is made symmetric either by using a symmetric smoother such as Jacobi or symmetric Gauss–Seidel or by using Gauss–Seidel with forward substitution for the presmoothing iterations and an equal number of Gauss–Seidel iterations with backward substitution for the postsmoothing step. The resulting algorithm, which we denote MGPCG (multigrid PCG), was applied for the von Karman covariance approximation (2.15), (2.16) in [10] and for the biharmonic covariance approximation (2.17) in [9], with further analysis in [19]. The sparsity of the discrete biharmonic makes the latter implementation the more efficient of the two. The effectiveness of multigrid in this setting is not surprising when one considers that $\mathbf{\Gamma}^T\mathbf{M}\mathbf{\Gamma}$ is a discrete Laplacian matrix and that $\boldsymbol{C_\phi}^{-1}$ either is or is well-approximated by a discrete biharmonic matrix. Multigrid is known to be very effective for solving linear systems involving both the discrete Laplacian and the discrete biharmonic matrices.

A preconditioner that has not been used for PCG applied to the problem of minimizing (2.12) is

$$\mathbf{P} \stackrel{\text{def}}{=} \begin{bmatrix} \mathbf{A} + \epsilon\mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{I} \end{bmatrix}, \tag{3.5}$$

where $\mathbf{A}$ is as defined in (3.1). As in that case, we compute a Cholesky factorization $\mathbf{C}^T\mathbf{C}$ of $\mathbf{P}$. Since $\mathbf{P}$ is noise independent, this can be done off-line. Thus the application of $\mathbf{P}^{-1}$ requires only one forward and one backward substitution. We will call $\mathbf{P}$ in (3.5) the least squares preconditioner, since in this case $\mathbf{P}$ is the coefficient matrix for the regular least squares normal equations, and the resulting method the least squares PCG (LSPCG).

3.2. The denoised least squares method. In this subsection, we introduce a new approach for obtaining approximate solutions of (2.13). First, we denote the Hudgin discrete Laplacian with periodic boundary conditions by $\mathbf{L}$. Then, we have

$$\mathbf{L} = \mathbf{F}^*\text{diag}(\lambda_1, \ldots, \lambda_{n^2})\mathbf{F}, \tag{3.6}$$

where $\lambda_1 \leq \lambda_2 \leq \cdots \leq \lambda_{n^2}$ are the eigenvalues of $\mathbf{L}$, and $\mathbf{F}$ denotes the discrete Fourier transform matrix with $\mathbf{F}^*$ its conjugate transpose. We note that then $\lambda_1 = 0$ corresponds to the constant eigenvector of $\mathbf{L}$, and $\lambda_{n^2} = 8$ corresponds to the waffle mode eigenvector $\boldsymbol{\phi}_{\text{WM}}$ (recall Theorem 2.1).

Multiplying both sides of (2.13) by the pseudoinverse of $\mathbf{\Gamma}^T\mathbf{M}\mathbf{\Gamma}$, we obtain

$$((\mathbf{\Gamma}^T\mathbf{M}\mathbf{\Gamma})^\dagger\mathbf{\Gamma}^T\mathbf{M}\mathbf{\Gamma} + (\sigma^2/c_0)(\mathbf{\Gamma}^T\mathbf{M}\mathbf{\Gamma})^\dagger\mathbf{L}^2)\boldsymbol{\phi} = \boldsymbol{\phi}_{\text{MNLS}}, \tag{3.7}$$

which can in turn be solved to obtain a smoothed, or denoised, approximation of $\boldsymbol{\phi}_{\text{MNLS}}$.

We ignore for the moment the pupil mask matrix $\mathbf{M}$ and consider the matrix product $(\mathbf{\Gamma}^T\mathbf{\Gamma})^\dagger\mathbf{L}$. Recall that the Fried discrete Laplacian $\mathbf{\Gamma}^T\mathbf{\Gamma}$ has the grid representation given in Figure 2.2. Note that after a rotation of the computational grid by $\pi/4$ radians, the grid representation of $\mathbf{\Gamma}^T\mathbf{\Gamma}$ will match that of a Hudgin discrete Laplacian, but with a grid spacing that is larger by a factor of $\sqrt{2}$. Taking this into account, we approximate the Fried discrete Laplacian as follows:

$$\mathbf{\Gamma}^T\mathbf{\Gamma} \approx \mathbf{F}^*\text{diag}(\lambda_1, \ldots, \lambda_r, 0, \ldots, 0)\mathbf{F}, \tag{3.8}$$

where the λ_i's are as in (3.6), and r chosen so that

$$\lambda_r < 8 - \frac{1}{4\sqrt{2}} \leq \lambda_{r+1}. \tag{3.9}$$

Note that $\boldsymbol{\phi}_{\mathrm{WM}}$ has a period of 4 on the computational grid and of $4\sqrt{2}$ on the rotated grid—hence our choice of truncation rule. Furthermore, our own computational experiments indicate that (3.9) is optimal in the sense that it minimizes the error in the phase reconstructions that result when the method we now present is used.

From (3.8), we know that within the telescope's pupil,

$$\boldsymbol{\Gamma}^T\mathbf{M}\boldsymbol{\Gamma} \approx \mathbf{F}^*\mathrm{diag}(\lambda_1,\ldots,\lambda_r,0,\ldots,0)\mathbf{F}. \tag{3.10}$$

Hence,

$$(\boldsymbol{\Gamma}^T\mathbf{M}\boldsymbol{\Gamma})^\dagger\boldsymbol{\Gamma}^T\mathbf{M}\boldsymbol{\Gamma} \approx \mathbf{F}^*\,\mathrm{diag}(1_1,\ldots,1_r,0,\ldots,0)\mathbf{F}, \tag{3.11}$$

$$(\boldsymbol{\Gamma}^T\mathbf{M}\boldsymbol{\Gamma})^\dagger\mathbf{L}^2 \approx \mathbf{F}^*\mathrm{diag}(\lambda_1,\ldots,\lambda_r,0,\ldots,0)\mathbf{F}. \tag{3.12}$$

This leads to the following approximation of (3.7):

$$\mathbf{F}^*\mathbf{D}\mathbf{F}\boldsymbol{\phi} = \boldsymbol{\phi}_{\mathrm{MNLS}}, \tag{3.13}$$

where $\mathbf{D}$ is diagonal with elements

$$[\mathbf{D}]_{ii} = \begin{cases} 1+(\sigma^2/c_0)\lambda_i, & \lambda_i < r, \\ 0, & \lambda_i \geq r. \end{cases} \tag{3.14}$$

Note that (3.13), (3.14) bears some resemblance to a filtered SVD approximation [18, 11] of (3.7).

The denoised minimum norm least squares solution can then be efficiently computed via

$$\boldsymbol{\phi}_{\mathrm{DMNLS}} = \mathbf{F}^*\mathbf{D}^\dagger\mathbf{F}\boldsymbol{\phi}_{\mathrm{MNLS}}, \tag{3.15}$$

where $\mathbf{D}^\dagger$ is the pseudoinverse of $\mathbf{D}$.

As we will see, this approach is effective in practice. However, it also has the benefit of being simple to implement and very computationally efficient. Furthermore, it can be easily incorporated into adaptive optics systems that compute regular least squares solutions other than $\boldsymbol{\phi}_{\mathrm{MNLS}}$. In particular, a general least squares solution $\boldsymbol{\phi}_{\mathrm{LS}}$ can be denoised via

$$\boldsymbol{\phi}_{\mathrm{GDLS}} = \mathbf{F}^*\mathbf{D}^\dagger\mathbf{F}\boldsymbol{\phi}_{\mathrm{LS}}, \tag{3.16}$$

where "GDLS" stands for "gradient denoised least squares." In the next theorem, we show that $\boldsymbol{\phi}_{\mathrm{GDLS}}$ will not contain waffle mode even if $\boldsymbol{\phi}_{\mathrm{LS}}$ does. This suggests that (3.16) should be considered as a method for removing waffle mode from least squares solutions in operational adaptive optics systems [14].

We end the section with a proof that the least squares solution of minimum norm, the minimum variance solution, and the denoised least squares solution do not contain waffle mode.

THEOREM 3.1. [illegible] $\phi_{\mathrm{MNLS}} = (\mathbf{M}\boldsymbol{\Gamma})^\dagger\mathbf{M}\mathbf{g}$, [illegible] $\boldsymbol{\phi}^{\sigma}_{\mathrm{MV}}$ [illegible] (2.8), [illegible] [illegible] (3.16) [illegible] $\boldsymbol{\phi}_{\mathrm{LS}}$ [illegible]. The null-space of $\mathbf{M}\boldsymbol{\Gamma}$ contains $\boldsymbol{\phi}_{\mathrm{WM}}$. The result for $\boldsymbol{\phi}_{\mathrm{MNLS}}$ then follows from the fact that the range of $(\mathbf{M}\boldsymbol{\Gamma})^\dagger$ and the null-space $\mathbf{M}\boldsymbol{\Gamma}$ only trivially intersect.

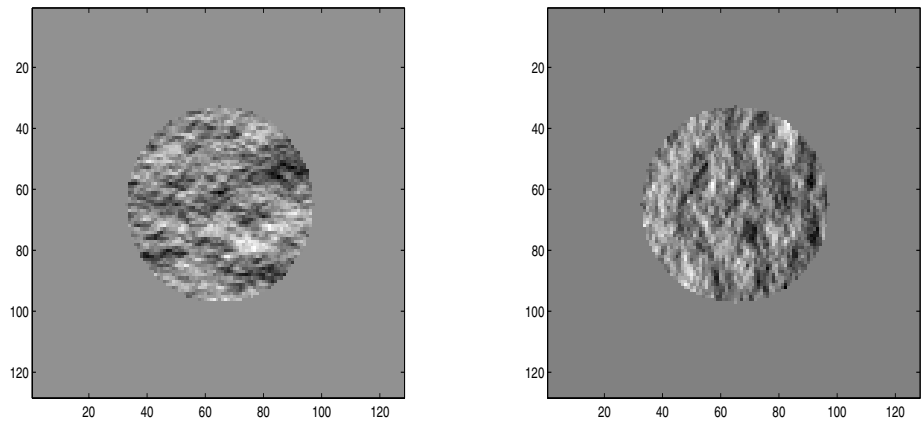

FIG. 4.1. *Noisy gradient data. The x and y components of the gradient data computed via* (2.3) *are seen on the left and right, respectively.*

For the minimum variance solution, we note that $\boldsymbol{\phi}_{\mathrm{WM}}^T \boldsymbol{C}_{\boldsymbol{\phi}}{}^{-1} \boldsymbol{\phi}_{\mathrm{WM}} > 0$ for either choice of $\boldsymbol{C}_{\boldsymbol{\phi}}$. Noting that $\mathbf{M\Gamma}\boldsymbol{\phi}_{\mathrm{WM}} = \mathbf{0}$, it follows immediately that the minimizer of (2.12) does not contain waffle mode.

From (3.16), (3.14), (3.9), and the fact that $\boldsymbol{\phi}_{\mathrm{WM}}$ is an eigenvector of $\mathbf{L}$ with eigenvalue 8, it follows that $\mathbf{F}^*\mathbf{D}^\dagger\mathbf{F}\boldsymbol{\phi}_{\mathrm{WM}} = \mathbf{0}$. Thus $\boldsymbol{\phi}_{\mathrm{DLS}}$ will not contain waffle mode. □

4. Numerical experiments. We now test the effectiveness of the above approaches on simulated Shack–Hartman sensor data. We simulate a phase profile by taking a random draw from the Gaussian random vector $N(\mathbf{0}, \boldsymbol{C}_{\boldsymbol{\phi}}^{\mathbf{KV}})$ with physically realistic values for the parameters in (2.16). The phase screen used in our first experiment is the 128×128 array plotted on the left in Figure 2.4. The noisy gradient data shown in Figure 4.1 was obtained using (2.11) with $\mathbf{n}$ an i.i.d. Gaussian random vector with variance chosen so that the signal-to-noise ratio (SNR) is 20, which is what was used in [19]. Note that

$$\mathrm{SNR} := \frac{\|\mathbf{g}\|^2}{E(\|\mathbf{n}\|^2)} = \frac{\|\mathbf{g}\|^2}{\mathrm{trace}(E[\mathbf{n}\mathbf{n}^T])} = \frac{\|\mathbf{g}\|^2}{2\,N_{\mathrm{pupil}}\,\sigma^2},$$

where N_{pupil} is the number of pixels within the telescope's pupil. For a comprehensive comparison, we also generate noisy gradient data at SNRs of 50, 10, and 5.

In our comparisons, we apply LSPCG and MGPCG to problem (2.12) with covariance (2.17). Our implementation of MGPCG used two iterations of Gauss–Seidel with forward substitution for the presmoothing iterations and two iterations of Gauss–Seidel with backward substitution for the postsmoothing iterations. The grid transfer operator used full-weighting with homogeneous Dirichlet boundary conditions for the restriction and a constant times its transpose for interpolation. See [3] for details on this implementation. We also apply the GDLS method. In all cases, c_0 was computed using (2.18).

Reconstructions at SNR = 20 are given in Figure 4.2, and convergence results are plotted in Figure 4.3. We note that more than two iterations of MGPCG and more

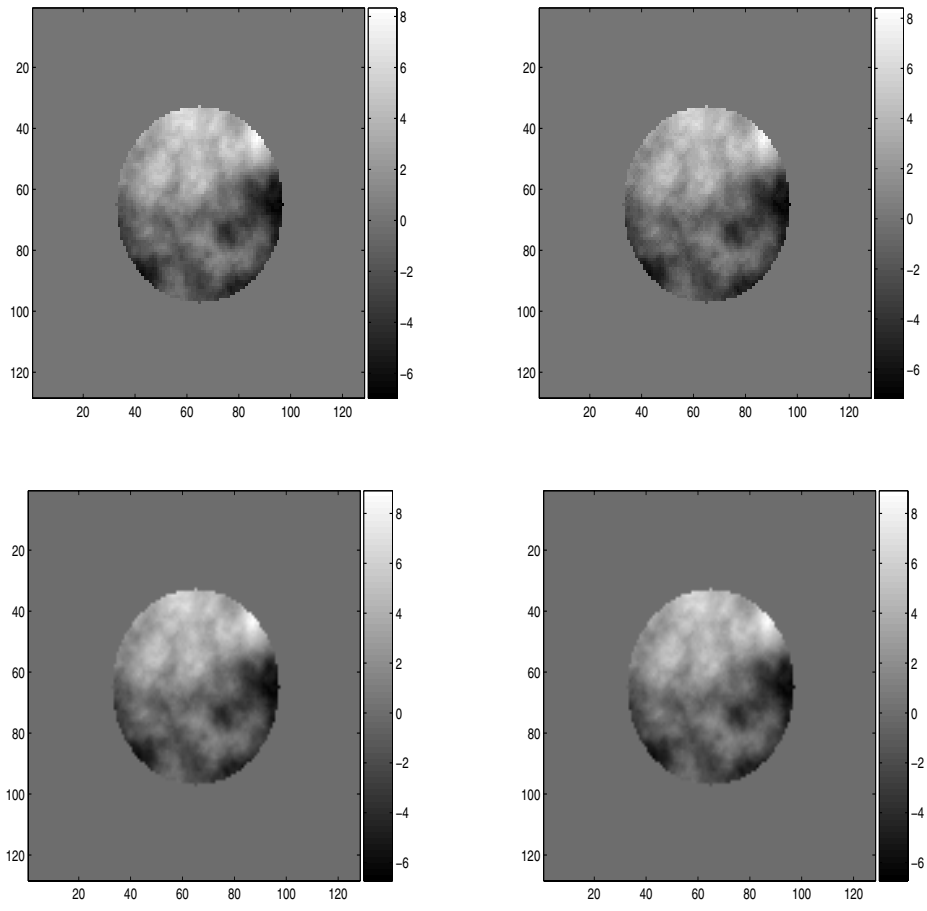

FIG. 4.2. *True phase on top*; *reconstruction obtained with one iteration of LSPCG on the upper right*; *reconstruction obtained with three iterations of MGPCG iterations on the lower left*; *and reconstruction obtained using GDLS on the lower right.*

than one iteration of LSPCG result in, effectively, no additional reduction in relative error. In each plot, we denote the GDLS curve as constant due to the fact that it yields a single estimate. Since it is accuracy in the approximation of the true phase $\boldsymbol{\phi}_{\text{true}}$ that we are concerned with, we plot the relative error

$$\frac{||\boldsymbol{\phi}_* - \boldsymbol{\phi}_{\text{true}}||}{||\boldsymbol{\phi}_{\text{true}}||},$$

where $\boldsymbol{\phi}_*$ is the phase estimate. For the PCG methods, $\boldsymbol{\phi}_* = \boldsymbol{\phi}_k$, where k is the PCG iteration index, whereas for GDLS, $\boldsymbol{\phi}_* = \boldsymbol{\phi}_{\text{DMNLS}}$.

The results in Figure 4.3 indicate that while two iterations of MGPCG yields the smallest relative error in every case, both LSPCG and GDLS are competitive. Furthermore, the reconstructions obtained by GDLS and by one iteration of LSPCG are very similar to those obtained by MGPCG. This can be seen, for SNR = 20, in Figure 4.2, where the true phase and the reconstructions obtained using a single

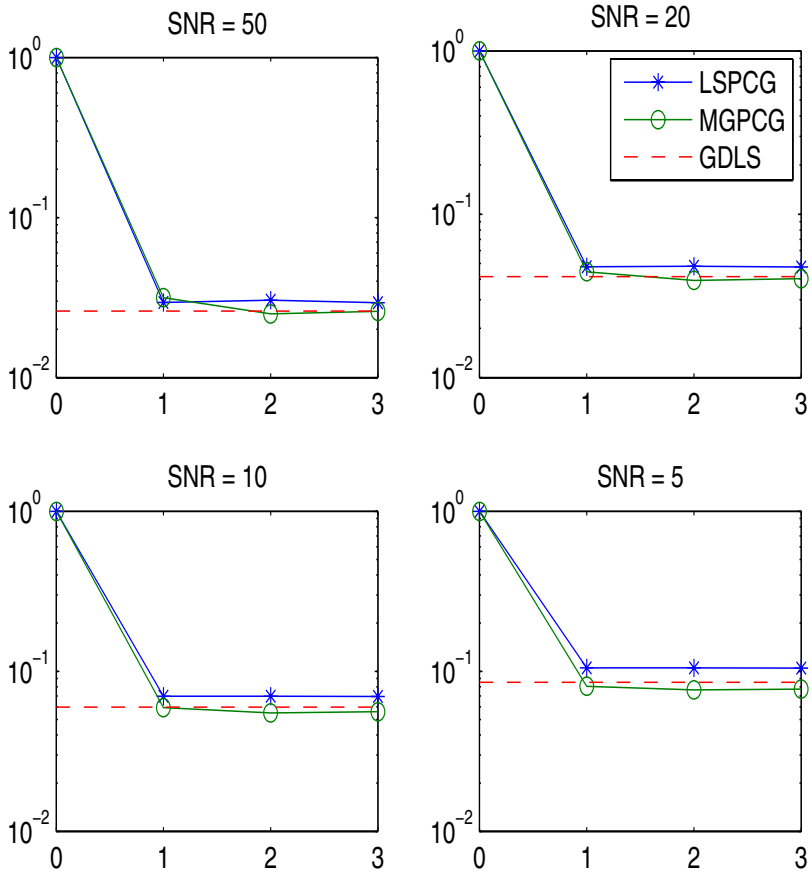

FIG. 4.3. *Relative error plots for LSPCG, MGPCG, and GDLS at SNRs of* 50, 20, 10, *and* 5.

iteration of LSPCG and three iterations of MGPCG are given.

In Table 4.1 we give the average CPU time for each method over three consecutive runs on $n \times n$ grids with $n = 32, 64, 128, 256$, and 512. In each case the SNR was taken to be 20. This table shows that both the LSPCG and GDLS solutions can be obtained much more efficiently than the MGPCG solutions—at least using our implementations of these methods—and that the computation of $\boldsymbol{\phi}_{\text{DMNLS}}$ is the most efficient. In fact, the values in the table indicate that the GDLS estimates are obtained 50–100 times more efficiently than those obtained using two iterations of MGPCG. This together with the facts that GDLS produces reconstructions with low relative error (see Figure 4.3) and that GDLS and MGPCG reconstructions are very similar (see Figure 4.2) suggest that GDLS is an approach that deserves attention.

We note that the choice of the discrete Fourier transform in the decomposition (3.10) will yield ringing artifacts at the boundaries in the phase reconstructions. We do not see this in the reconstructions presented here because there is sufficient distance between the pupil boundary and the boundary of the computational domain (see

TABLE 4.1
CPU times in seconds for various methods on an $n \times n$ computational grid.

n	MGPCG 1	MGPCG 2	LSPCG	GDLS
32	0.16	0.20	0.023	0.0020
64	0.27	0.38	0.032	0.0073
128	0.76	1.15	0.11	0.014
256	3.22	5.05	0.32	0.078
512	15.82	23.85	0.78	0.45

Figure 4.2); however, ringing may present a problem in practice. One way to overcome this would be to instead use a discrete cosine, or sine, transform decomposition, which enforces continuity, or differentiability, respectively, at the boundary. However, we do not pursue this here.

Finally, we acknowledge that the comparisons presented here are not completely comprehensive. Tests on a wider range of data, including wavefront data generated with more accurate turbulence models, e.g., the full Navier–Stokes equations, and real Shack–Hartmann sensor data, should also be done. However, we do not pursue such a study here, as our intention is only a proof of concept. For this, we have used a testing methodology that is standard in the adaptive optics community [6, 9, 10, 19] and hence feel justified in concluding that our methods are worthy of further consideration.

5. Conclusions. We have presented a detailed discussion of the problem of wavefront, or phase, reconstruction from Shack–Hartmann wavefront gradient data. This included a derivation of a discrete, stochastic linear system relating the gradient measurements to the underlying discrete phase $\boldsymbol{\phi}$; a derivation of the minimum variance estimator for $\boldsymbol{\phi}$ given the prior probability density $\boldsymbol{\phi} \sim N(\mathbf{0}, \boldsymbol{C}_{\boldsymbol{\phi}})$; and a discussion of estimates for the covariance $\boldsymbol{C}_{\boldsymbol{\phi}}$.

Computational methods for the phase reconstruction problem were then presented. First, an efficient method for computing an accurate approximation of the minimum norm least squares solution was given; it used a Cholesky factorization with sparse reordering. Then the current gold standard for accuracy and efficiency, the multigrid preconditioned conjugate gradient method (MGPCG), was compared with two new approaches presented in this paper—the so-called least squares preconditioned conjugate gradient method (LSPCG) and the gradient denoised least squares method (GDLS). The results indicate that though MGPCG yields lower values for the relative error, the methods introduced here, and, in particular, GDLS, are more efficient and yield comparable results. The implementation of GDLS used in our comparisons utilized the efficient method for computing the minimum norm least squares solution $\boldsymbol{\phi}_{\text{MNLS}}$ mentioned above, at a cost of two sparse linear system backsolves. The denoised phase estimate $\boldsymbol{\phi}_{\text{DMNLS}}$ was then computed at a computational cost of only two discrete Fourier transforms, making GDLS a very efficient approach.

We also presented results relating what is known in the adaptive optics community as waffle mode to standard discretizations of the Laplacian operator and showed that the minimum norm least squares solution, the minimum variance solution, and the denoised least squares solutions do not contain waffle mode.

Acknowledgments. First, the referees deserve thanks for their careful reading of the paper and for their constructive commentary. The paper is much better because of their efforts. The author would also like to acknowledge the help that he received from Curt Vogel in the form of discussion and for the MATLAB code that was used for data

generation in our experiments. Also, this work would not have been possible without the support of the University of Montana through its International Faculty Exchange Program and the University of Helsinki, the host university for the exchange.

FUNCTIONS PRESERVING NONNEGATIVITY OF MATRICES*

GAUTAM BHARALI† AND OLGA HOLTZ‡

Abstract. The main goal of this work is to determine which entire functions preserve nonnegativity of matrices of a fixed order n—i.e., to characterize entire functions f with the property that $f(A)$ is entrywise nonnegative for every entrywise nonnegative matrix A of size $n \times n$. Toward this goal, we present a complete characterization of functions preserving nonnegativity of (block) upper-triangular matrices and those preserving nonnegativity of circulant matrices. We also derive necessary conditions and sufficient conditions for entire functions that preserve nonnegativity of symmetric matrices. We also show that some of these latter conditions characterize the even or odd functions that preserve nonnegativity of symmetric matrices.

Key words. nonnegative inverse eigenvalue problem, circulant matrices, (block) upper-triangular matrices, symmetric matrices, positive definite matrices, entire functions, divided differences

1. Motivation.

The purpose of this paper is to investigate which entire functions preserve nonnegativity of matrices of a fixed order. More specifically, we consider several classes of structured matrices whose structure is preserved by entire functions and characterize those entire functions f with the property that $f(A)$ is entrywise nonnegative for each entrywise nonnegative matrix A of size $n \times n$. The characterizations that we obtain might be of independent interest in matrix theory and other areas of mathematics. One of our own motivations behind our investigation is its relevance to the inverse eigenvalue problem for nonnegative matrices.

The long-standing inverse eigenvalue problem for nonnegative matrices is the problem of determining, given an n-tuple (multiset) Λ of complex numbers, whether there exists an entrywise nonnegative matrix A whose spectrum $\sigma(A)$ is Λ. The literature on the subject is vast, and we make no attempt to review it. The interested reader is referred to books [25] and [1], expository papers [3], [9], [18], [19], and references therein, as well as to some recent papers [23], [4], [21], [30], [31], [32], [20], [26].

The necessary conditions for a given n-tuple to be realizable as the spectrum of a nonnegative matrix known so far for arbitrary values of n can be divided into three groups: conditions for nonnegativity of moments, Johnson–Loewy–London inequalities, and Newton's inequalities.

Given an n-tuple Λ, its [illegible] are defined as follows:

$$s_m(\Lambda) := \sum_{\lambda \in \Lambda} \lambda^m, \qquad m \in \mathbb{N}.$$

If $\Lambda = \sigma(A)$ for some nonnegative matrix A, then $s_m(\Lambda)$ is nothing but the trace $\operatorname{tr}(A^m)$ and therefore must be nonnegative. Another basic condition follows from the

Perron–Frobenius theory [27], [11]: the largest absolute value $\max_{\lambda\in\Lambda}|\lambda|$ must be the Perron eigenvalue of a realizing matrix A and therefore must itself be in Λ. Finally, the multiset Λ must be closed under complex conjugation, being the spectrum of a real matrix A. Interestingly, the last two conditions are in fact not independent conditions but follow from the nonnegativity of moments, as was shown by Friedland in [10]. Thus, there turns out to be just one set of basic conditions:

$$s_m(\Lambda) \geq 0 \qquad \text{for } m \in \mathbb{N}.$$

The next set of necessary conditions was discovered independently by Loewy and London in [22] and by Johnson in [17]. These conditions relate moments among themselves as follows:

$$s_k^m(\Lambda) \leq n^{m-1} s_{km}(\Lambda), \quad k, m \in \mathbb{N}.$$

Newton's inequalities were conjectured in [14] and proved for M-matrices in [13]. An M-matrix is a matrix of the form $rI - A$, where A is a nonnegative matrix, $r \geq \varrho(A)$, and $\varrho(A)$ is the spectral radius of A:

$$\varrho(A) := \max_{\lambda\in\sigma(A)} |\lambda|.$$

If M is an M-matrix of order n, then the normalized coefficients $c_j(M)$ of its characteristic polynomial defined by

$$\det(\lambda I - M) =: \sum_{j=0}^{n} (-1)^j \binom{n}{j} c_j(M) \lambda^{n-j}$$

must satisfy Newton's inequalities

$$c_j^2(M) \geq c_{j-1}(M) c_{j+1}(M), \quad j = 1, \ldots, n-1.$$

Since the coefficients $c_j(M)$ are determined entirely by the spectrum of M, and the latter is obtained from the spectrum of a nonnegative matrix A by an appropriate shift, Newton's inequalities form yet another set of conditions necessary for an n-tuple to be realizable as the spectrum of a nonnegative matrix. The above three sets of conditions, i.e., nonnegativity of moments, Johnson–Loewy–London inequalities, and Newton's inequalities, are all independent of each other but are not sufficient for realizability of a given n-tuple (see [13]).

Quite a few sufficient conditions are also known (see, e.g., [37], [19], [10], [3]) as well as certain techniques for perturbing or combining realizable n-tuples into new realizable n- or m-tuples (where $m \geq n$) (see, e.g., [34], [33], [31]). Also, necessary and sufficient conditions on an n-tuple to serve as the nonzero part of the spectrum of some nonnegative matrix are due to Boyle and Handelman [2].

Finally, it follows from the Tarski–Seidenberg theorem [38, 29] that all realizable n-tuples form a semialgebraic set (see also [16]); i.e., for any given n, there exist only finitely many polynomial inequalities that are necessary and sufficient for an n-tuple Λ to be realizable as the spectrum of some nonnegative matrix A (this observation was communicated to us by Friedland).

Indeed, each realizable n-tuple $\Lambda = (\lambda_1, \ldots, \lambda_n)$ is characterized by the condition

$$\exists\, A \geq 0 \;:\; \det(\lambda I - A) = \prod_{j=1}^{n} (\lambda - \lambda_j).$$

The last condition is equivalent to each elementary symmetric function $\sigma_j(\Lambda)$ being equal to the jth coefficient of the characteristic polynomial of A multiplied by $(-1)^j$, i.e., to the sum of all principal minors of A of order j, for $j = 1, \ldots, n$. Since the set of all nonnegative matrices is a semialgebraic set in n^2 entries of the matrix and since each sum of all principal minors of A of order j is a polynomial in the entries of A, the lists of coefficients of characteristic polynomials of nonnegative matrices form a semialgebraic set, and hence the n-tuples whose elementary symmetric functions match one of those lists also form a semialgebraic set by the Tarski–Seidenberg theorem.

However, despite so many insights into the subject, and despite the results obtained so far, the nonnegative inverse eigenvalue problem remains open. In fact, the problem remains open when specialized to several important classes of structured matrices—for instance, the class of entrywise nonnegative symmetric matrices.

Note that the three sets of conditions on an n-tuple Λ that we discussed above, i.e., nonnegativity of moments, the Johnson–Loewy–London inequalities, and the Newton inequalities, are necessary conditions for the realizability of Λ as the spectrum of a $n \times n$ matrix with nonnegative entries (provided, of course, that all the entries of Λ are now real). A significant fraction of this paper will be devoted to an idea that has relevance to the inverse eigenvalue problem for nonnegative symmetric matrices. It is an idea that was first expressed by Loewy and London in [22]. When adapted to symmetric matrices, it may be stated as follows: Suppose a primary matrix function f is known to map nonnegative symmetric matrices of some fixed order n into themselves. Thus $f(A)$ is nonnegative whenever A is. Since $f(\sigma(A)) = \sigma(f(A))$, both the spectrum $\sigma(A)$ and its image under the map f must then satisfy the aforementioned conditions for realizability. This enlarges the class of necessary conditions for the symmetric nonnegative inverse eigenvalue problem. Describing this larger class would require knowing exactly what functions f preserve nonnegativity of such matrices (of a fixed order). Toward this end, we provide a characterization of all the and entire functions that preserve entrywise nonnegativity of nonnegative symmetric matrices.

Along the way, we also obtain complete characterizations of all entire functions that preserve nonnegativity of the following classes of structured matrices:

- triangular and block-triangular matrices and
- circulant matrices.

We ought to add here that, for the above classes of structured matrices, our results do not have a bearing on the nonnegative inverse eigenvalue problems associated to them. In fact, the solutions of the latter problems are quite straightforward. To be precise, an n-tuple Λ is the spectrum of an $n \times n$ triangular matrix if and only if all the entries of Λ are nonnegative. As for circulants, the eigenvalues of a circulant matrix A are determined by its first row $\mathbf{a} := [a_0\ a_1 \ldots a_{n-1}]$ (see [7]), and, in fact, there is a constant matrix W (i.e., independent of $\mathbf{a}$ and A) such that $\sigma(A) = \mathbf{a}\mathsf{W}$. Thus the realizable n-tuples in this case are of the form $\mathbf{a}\mathsf{W}$, $\mathbf{a} \in \mathbb{R}^n_+$. Nevertheless, we feel that the problem of characterizing the functions that preserve nonnegativity of the above classes of matrices can be of interest, independently of the nonnegative inverse eigenvalue problem.

2. Outline. This paper is organized as follows. We make several preliminary observations in section 4. Before focusing our attention on aspects of the symmetric nonnegative inverse eigenvalue problem, we study the structured matrices just discussed. In section 5, we characterize the class of functions preserving nonnegativity of triangular and block triangular matrices. It turns out that these are characterized

by nonnegativity conditions on their divided differences over the nonnegative reals. Next, in section 6, we obtain a characterization of functions preserving nonnegativity of circulant matrices. This characterization is quite different from that in section 5; it involves linear combinations of function values taken at certain nonreal points of $\mathbb{C}$. In section 7, we obtain a complete characterization of the class $\mathcal{F}_n$ for small values of n.

The remainder of the paper is essentially devoted to functions that preserve nonnegativity of symmetric matrices. In section 8.1, we review existing results in that direction. In particular, we discuss the restriction of [24, Corollary 3.1] to entire functions, which claims to provide a characterization of entire functions that preserve entrywise nonnegativity of symmetric matrices of a fixed order. We point out that, while this result is true when restricted to nonnegative symmetric matrices, the condition occurring in that result is for an entire function to preserve nonnegativity of all symmetric matrices. The leading to [24, Corollary 3.1], however, turn out to be very useful. We use these techniques, along with some new ideas, to obtain necessary conditions and sufficient conditions and characterizations of the and entire functions that preserve nonnegativity of symmetric matrices of a fixed order. This is the content of sections 8.2 and 8.3. Because of a gap between the necessary and the sufficient conditions, which we also point out in section 8.2, the results of that section do not provide a characterization of functions preserving nonnegativity of symmetric matrices. We end the paper with a list of several open problems in section 9 and suggest various approaches to their solution that we have not explored in this paper.

3. Notation. We use standard notation $\mathbb{R}^{m\times n}$ for real matrices of size $m\times n$, $\mathbb{R}_+$ for nonnegative reals, $\mathbb{Z}_+$ for nonnegative integers, $A \geq 0$ ($A > 0$) to denote that a matrix A is entrywise nonnegative (positive), and $\sigma(A)$ to denote the spectrum of A. For $x \in \mathbb{R}$, we use $\lfloor x \rfloor$ to denote the greatest integer that is less than or equal to x.

4. Preliminaries. The main goal of the paper is to characterize functions f such that the matrix $f(A)$ is (entrywise) nonnegative for any nonnegative matrix A of order n. Since the primary matrix function $f(A)$ is defined in accordance with values of f and its derivatives on the spectrum of A (see, e.g., [15, sections 6.1, 6.2]), we want to avoid functions that are not differentiable at some points in $\mathbb{C}$. Therefore, we restrict ourselves to functions that are analytic everywhere in $\mathbb{C}$, i.e., to entire functions. Thus we consider the class

$$\mathcal{F}_n := \{f \text{ entire} : A \in \mathbb{R}^{n\times n},\ A \geq 0 \implies f(A) \geq 0\}.$$

Note right away that the classes $\mathcal{F}_n$ are ordered by inclusion.

LEMMA 1. $n \in \mathbb{N}$, $\mathcal{F}_n \supseteq \mathcal{F}_{n+1}$

. Let A be a nonnegative matrix of order n, and let $f \in \mathcal{F}_{n+1}$. Consider the block diagonal matrix $B := \operatorname{diag}(A, 0)$ obtained by adding an extra zero row and column to A. Since $f(B) = \operatorname{diag}(f(A), 0)$, the matrix $f(A)$ must be nonnegative. Thus $f \in \mathcal{F}_n$. □

Recall that any entire function can be expanded into its Taylor series around any point in $\mathbb{C}$ and that the resulting series converges everywhere (see, e.g., [5]). We will mostly focus on Taylor series of functions in $\mathcal{F}_n$ centered at the origin. We start with some simple observations regarding a few initial Taylor coefficients of such a function.

PROPOSITION 2. $f(z) = \sum_{j=0}^{\infty} a_j z^j$ $\mathcal{F}_n$, $a_j \geq 0$ $j = 0, \ldots, n-1$

. For $n = 1$, the statement follows from evaluating f at 0. If $n > 1$ and $f \in \mathcal{F}_n$, then evaluate the function f at the matrix

$$A := \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 & 0 \\ 0 & 0 & 1 & \cdots & 0 & 0 \\ 0 & 0 & 0 & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & 0 & 1 \\ 0 & 0 & 0 & \cdots & 0 & 0 \end{bmatrix}.$$

Since

$$f(A) = \begin{bmatrix} a_0 & a_1 & a_2 & \cdots & a_{n-2} & a_{n-1} \\ 0 & a_0 & a_1 & \cdots & a_{n-3} & a_{n-2} \\ 0 & 0 & a_0 & \cdots & a_{n-4} & a_{n-3} \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & a_0 & a_1 \\ 0 & 0 & 0 & \cdots & 0 & a_0 \end{bmatrix},$$

the entries $a_0, \ldots, a_{n-1}$ of $f(A)$ must be nonnegative. This finishes the proof. □

COROLLARY 3. f $\mathcal{F}_n$ $n \in \mathbb{N}$ $f(z) = \sum_{j=0}^{\infty} a_j z^j$ $a_j \geq 0$ $j \in \mathbb{Z}_+$

. One direction follows from Proposition 2. The other direction is trivial: if all terms in the Taylor expansion of f around the origin are nonnegative, then $f(A)$ combines powers of a nonnegative matrix A using nonnegative coefficients, so the resulting matrix is nonnegative. Here we make use of the standard fact [15, Theorem 6.2.8] that the matrix power series $\sum_{j=0}^{\infty} a_j A^j$ converges to $f(A)$. □

. It must be noted that Proposition 2 be a necessary condition for an entire function to belong to $\mathcal{F}_n$. This is easy to see; fix an $n \in \mathbb{N}$ and set

$$F(x) = -x^n + \sum_{j=0}^{n-1} a_j x^j,$$

where we choose $a_j \geq 0$, $j = 0, \ldots, n-1$. Then, there exists an $x_0 > 0$ such that $F(x) < 0$ for all $x \in (x_0, \infty)$. If we set $A = rI$ for some $r \in (x_0, \infty)$, then A is entrywise nonnegative, while the diagonal entries of $F(A)$ are negative. Hence, although $a_j \geq 0$ for $j = 0, \ldots, n-1$, F does not preserve nonnegativity.

To conclude this section, we make two more general observations.

LEMMA 4. f $\mathcal{F}_n$ n

. This is simply due to the continuity of f, since the set of strictly positive matrices is dense in the set of all nonnegative matrices of order n. □

LEMMA 5. f, P, D , $f(A)$ $f($ $)^{-1})$

. Note that $($ $)f(A)($ $)^{-1} = f($ $($ $)^{-1})$ and that both matrices PD and $($ $)^{-1}$ are nonnegative. So, $f(A)$ is nonnegative if and only if the matrix $f($ $($ $)^{-1})$ is nonnegative. □

We now analyze three superclasses of our class $\mathcal{F}_n$:

- entire functions preserving nonnegativity of upper-triangular matrices,
- entire functions preserving nonnegativity of circulant matrices, and
- entire functions preserving nonnegativity of symmetric matrices.

5. Preserving nonnegativity of (block) triangular matrices. We first discuss functions preserving nonnegativity of upper- (or lower-)triangular matrices. The characterization that we obtain makes use of the notion of divided differences. The [illegible] (see, e.g., [8]) of a smooth function f at points $x_1, \dots, x_k$ (which can be thought of as an ordered sequence $x_1 \le \cdots \le x_k$) is usually defined via the recurrence relation

$$f[x_1, \dots, x_k] := \begin{cases} \frac{f[x_2,\dots,x_k]-f[x_1,\dots,x_{k-1}]}{x_k-x_1}, & x_1 \neq x_k, \\ f^{(k-1)}(x_1)/(k-1)!, & x_1 = x_k, \end{cases}$$

and where $f[x] := f(x)$. Divided differences play a large part in this paper. We shall, however, make no attempt to review the results on divided differences that we shall draw upon, especially since they are quite readily accessible. The interested reader is referred to [8].

THEOREM 6. [illegible] f [illegible] n [illegible] n [illegible] $\mathbb{R}_+$ [illegible],

$$f[x_1, \dots, x_k] \ge 0 \quad \text{for } x_1, \dots, x_k \ge 0, \quad k = 1, \dots, n, \tag{1}$$

[illegible] f [illegible] $n-1$ [illegible] $\mathbb{R}_+$ [illegible] Let $A =: (a_{ij})$ be a nonnegative upper-triangular matrix. Suppose a function f satisfies (1). By [28], [35] (see also [36]), the elements of the matrix $f(A)$ can be written explicitly as

$$f(A)_{ij} = \begin{cases} f(a_{ii}), & i = j, \\ \sum_{i<i_1<\cdots<i_k<j} a_{ii_1} \cdots a_{i_kj} f[a_{ii}, a_{i_1i_1}, \dots, a_{i_ki_k}, a_{jj}], & i < j, \\ 0, & i > j. \end{cases} \tag{2}$$

The divided differences appearing in the sum on the right-hand side are of order not exceeding n; hence all the summands, and therefore the sums, are nonnegative.

[illegible] We proceed by induction on n. If f preserves nonnegativity of upper-triangular matrices of order n, it does so also for matrices of order $n-1$. Thus, by our inductive hypothesis, (1) holds up to order $n-1$. To see that all divided differences of order n are also nonnegative over nonnegative reals, consider the matrix A whose first upper diagonal consists of ones, whose main diagonal consists of n arbitrary nonnegative numbers $x_1, \dots, x_n$, and whose other entries are zero. Then, (2) shows that $f(A)_{1n} = f[x_1, \dots, x_n]$ and must be nonnegative.

Finally, since all divided differences of a fixed order k at points in a domain D are nonnegative if and only if $f^{(k-1)}(x)$ is nonnegative for every point $x \in D$ [8], we see that condition (1) is equivalent to all derivatives of f of order up to $n-1$ being nonnegative on $\mathbb{R}_+$. This finishes the proof. □

The proofs of (2) in [35] and [28] are based on the following observation.

RESULT 7 (see [35], [28]). [illegible]

$$M = \begin{bmatrix} A & B \\ 0 & a \end{bmatrix}, \qquad a \in \mathbb{C} \setminus \sigma(A),$$

$$f(M) = \begin{bmatrix} f(A) & (A-aI)^{-1}(f(A)-f(a)I)B \\ 0 & f(a) \end{bmatrix}$$

f

One can prove an analogous statement in the block triangular case.

PROPOSITION 8. f

$$M = \begin{bmatrix} A & B \\ 0 & C \end{bmatrix}, \qquad \sigma(A) \cap \sigma(C) = \emptyset.$$

$$f(M) = \begin{bmatrix} f(A) & f(A)X - Xf(C) \\ 0 & f(C) \end{bmatrix},$$

X $(\quad)$

$$AX - XC = B.$$

. Let X be a solution of the Sylvester equation $AX - XC = B$. Since the spectra of A and C are disjoint, this solution is unique [15, section 4.4]. Then, $M = T^{-1}\operatorname{diag}(A, C)T$, where

$$T = \begin{bmatrix} I & X \\ 0 & I \end{bmatrix}.$$

Hence $f(M) = T^{-1}\operatorname{diag}(f(A), f(C))T$, which proves the proposition. □

As an immediate corollary, we obtain an indirect characterization of functions preserving nonnegativity of block triangular matrices with two diagonal blocks.

COROLLARY 9. f

$$\begin{bmatrix} A & B \\ 0 & C \end{bmatrix}, \qquad A \in \mathbb{R}^{n_1 \times n_1},\ C \in \mathbb{R}^{n_2 \times n_2},$$

(a) $f \in \mathcal{F}_N$, $N := \max\{n_1, n_2\}$;

(b) $f(A)X - Xf(C) \geq 0$ $A \in \mathbb{R}^{n_1 \times n_1}$, $B \in \mathbb{R}^{n_1 \times n_2}$, $C \in \mathbb{R}^{n_2 \times n_2}$ $A, B, C \geq 0$, $\sigma(A) \cap \sigma(C) = \emptyset$ $(\quad)$ X $AX - XC = B$

. For f to preserve nonnegativity of blocks A and C, it has to belong to $\mathcal{F}_N$ (keeping in mind Lemma 1). The remainder of our assertion follows from Proposition 8 and the fact that the matrices with nonnegative blocks A, B, C, such that the spectra of A and C are disjoint, are dense in the set of all block upper-triangular matrices. □

The above proposition, however, does not allow for an explicit formula of the type (1) as in Theorem 6.

. Note that the results of this section characterize functions preserving nonnegativity of the (block) lower-triangular matrices as well.

6. Preserving nonnegativity of circulant matrices. A [illegible] (see, e.g., [7]) A is determined by its first row $(a_0, \dots, a_{n-1})$ as follows:

$$\begin{bmatrix} a_0 & a_1 & a_2 & \cdots & a_{n-1} \\ a_{n-1} & a_0 & a_1 & \cdots & a_{n-2} \\ a_{n-2} & a_{n-1} & a_0 & \cdots & a_{n-3} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ a_1 & a_2 & a_3 & \cdots & a_0 \end{bmatrix}.$$

All circulant matrices of size n are polynomials in the basic circulant matrix

$$\begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ 0 & 0 & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & 0 & 0 & \cdots & 0 \end{bmatrix},$$

which implies in particular that any function $f(A)$ of a circulant matrix is a circulant matrix as well. Moreover, the eigenvalues of a circulant matrix are determined by its first row (see [7]) by the formula

$$\left\{ \sum_{j=0}^{n-1} \omega^{kj} a_j \ : \ k = 0, \dots, n-1 \right\}, \quad \text{where } \omega := e^{2\pi \mathrm{i}/n}.$$

Hence the eigenvalues of $f(A)$ are

$$\left\{ f\left(\sum_{j=0}^{n-1} \omega^{kj} a_j \right) \ : \ k = 0, \dots, n-1 \right\}.$$

Thus, the elements $(f_0, \dots, f_{n-1})$ of the first row of $f(A)$ can be read off from its spectrum:

$$f_l = \frac{1}{n} \sum_{k=0}^{n-1} \omega^{-lk} f\left(\sum_{j=0}^{n-1} \omega^{jk} a_j \right), \quad l = 0, \dots, n-1.$$

This argument proves the following theorem.

THEOREM 10. [illegible] f [illegible] n, [illegible] $l = 0, \dots, n-1$,

$$\sum_{k=0}^{n-1} \omega^{-lk} f\left(\sum_{j=0}^{n-1} \omega^{jk} a_j \right) \geq 0 \quad \textit{whenever } a_j \geq 0, \ j = 0, \dots, n-1, \tag{3}$$

$$\textit{where } \omega = e^{2\pi \mathrm{i}/n}.$$

7. Characterization of $\mathcal{F}_n$ for small values of n. We now focus on the function classes $\mathcal{F}_n$ for small values of n. Recall the inclusion $\mathcal{F}_{n+1} \subseteq \mathcal{F}_n$ from Lemma 1, which means that all conditions satisfied by the functions from $\mathcal{F}_n$ get inherited by the functions from $\mathcal{F}_{n+1}$. Thus we need to find out precisely how to strengthen the conditions that determine $\mathcal{F}_n$ to get to the next class $\mathcal{F}_{n+1}$.

7.1. The case $n = 1$. A function f is in $\mathcal{F}_1$ if and only if f maps nonnegative reals into themselves. While this statement is in a way a characterization in itself, if f is an entire function with , we can give a description of the form that f takes. For such f, the proposition below serves as an alternative characterization.

PROPOSITION 11. [illegible] f [illegible] $\mathcal{F}_1$ [illegible]

$$f(z) = g(z) \prod_{\alpha,\beta} ((z+\alpha)^2 + \beta^2) \prod_{\gamma} (z+\gamma), \tag{4}$$

[illegible] α, [illegible] β, [illegible], [illegible] γ, [illegible], [illegible] g [illegible] $\mathbb{C}$ [illegible] $\mathbb{R}_+$ [illegible].

PROOF. First note that since f takes real values over the nonnegative reals, all its zeros occur in conjugate pairs. Moreover, while the multiplicity of the real negative zeros is not restricted in any way, the nonnegative zeros must occur with even multiplicities. This produces exactly the factors recorded in (4), with nonnegative zeros corresponding to $\beta = 0$. After factoring out all the linear factors, we are left with an entire function—which we call $g(z)$—that has no zeros and takes only positive values on $\mathbb{R}_+$. This gives us the expression (4). □

REMARK. Incidentally, all polynomials f that take only positive values on $\mathbb{R}_+$ are characterized by a theorem due to Poincaré and Pólya (see, e.g., [6, p. 175]): there exists a number $N \in \mathbb{Z}_+$ such that the polynomial $(1+z)^N f(z)$ must have positive coefficients. Since we include nonpolynomial functions in our class $\mathcal{F}_1$, and since we allow functions to have zeros in $\mathbb{R}_+$, the Poincaré–Pólya characterization is not directly relevant to our setup.

7.2. The case $n = 2$. We just saw that functions in $\mathcal{F}_1$ are characterized by one inequality, viz.

$$f(x) \geq 0 \quad \forall\, x \geq 0. \tag{5}$$

In this subsection we will see that functions in $\mathcal{F}_2$ are characterized by two inequalities, one involving a divided difference. We recall two preliminary observations, Lemmas 4 and 5 that were proved in section 4. Their specialization to the case $n = 2$ gives the following corollary.

COROLLARY 12. [illegible] f [illegible] $\mathcal{F}_2$ [illegible] 2 [illegible]

PROOF. A strictly positive 2×2 matrix A can be symmetrized by using the transformation DAD^{-1}, where D is a diagonal matrix with positive diagonal elements. Thus, Lemmas 4 and 5 imply that $f(A)$ is nonnegative for all strictly positive, and hence for all nonnegative, matrices A of order 2 if and only if $f(A)$ is nonnegative for all symmetric matrices. □

Now we are in a position to prove a characterization theorem for the class $\mathcal{F}_2$.

THEOREM 13. [illegible] f [illegible] $\mathcal{F}_2$ [illegible]

$$f(x+y) - f(x-y) \geq 0 \quad \forall\, x, y \geq 0, \tag{6}$$

$$(7) \qquad (x+y-z)f(x-y)+(z-x+y)f(x+y)\geq 0 \quad \forall\, x\geq z\geq 0,\ y\geq x-z,$$

[illegible] f [illegible] (6) [illegible]

$$(8) \qquad (x+y)f(x-y)+(y-x)f(x+y)\geq 0 \quad \forall\, y\geq x\geq 0.$$

[illegible]. If $f\in\mathcal{F}_2$, then, in particular, f preserves nonnegativity of nonnegative circulant matrices. Thus, the conditions (3) are necessary for f to belong to $\mathcal{F}_2$. Observe that the condition (6) is one of the two necessary conditions (3) in case $n=2$ (taking $a_0=x$ and $a_1=y$). Therefore, we need to check that the condition (7) is also necessary and that both together are sufficient. Then we also need to check that conditions (6) and (7) are equivalent to conditions (6) and (8).

By Corollary 12, we can restrict ourselves to the case when A is a positive symmetric matrix, i.e., when

$$A=\begin{bmatrix} a_{11} & b \\ b & a_{22}\end{bmatrix}, \quad a_{11},b,a_{22}>0.$$

Since the value of f at A coincides with the value of its interpolating polynomial of degree 1 with nodes of interpolation chosen at the eigenvalues of A [15, sections 6.1, 6.2], we get

$$f(A)=f[r_1]I+f[r_1,r_2](A-r_1I),$$

where

$$r_j:=\frac{a_{11}+a_{22}}{2}+(-1)^j\frac{\sqrt{(a_{11}-a_{22})^2+4b^2}}{2}, \quad j=1,2.$$

So, the off-diagonal entries of $f(A)$ are equal to

$$f[r_1,r_2]b,$$

while the diagonal entries are

$$f[r_1,r_2](a_{jj}-r_1)+f(r_1), \quad j=1,2.$$

Writing

$$x:=\frac{a_{11}+a_{22}}{2},$$

$$y:=\frac{\sqrt{(a_{11}-a_{22})^2+4b^2}}{2},$$

$$z:=\min(a_{11},a_{22}),$$

we see that the characterization for $\mathcal{F}_2$ consists precisely of conditions (6) and (7).

It remains to prove that (6) and (7) are equivalent to (6) and (8). By simply taking $z=0$ in (7), we see that (7) implies (8). So let us now assume (6) and (8). We begin by stating a simple auxiliary fact. Taking $x=0$ and $y>0$ in (6) and (8), we get $f(y)\pm f(-y)\geq 0$ for all $y>0$. We conclude from this that $f(y)\geq 0$ whenever $y\geq 0$, i.e., that f satisfies (5).

First consider y lying in the range $x - z \leq y \leq x$. In this case, we get

$$(x+y-z)f(x-y) + (z-x+y)f(x+y)$$
$$= (y-(x-z))(f(x+y) - f(x-y)) + 2yf(x-y) \geq 0 \qquad \text{for } \ x \geq z \geq 0.$$

The nonnegativity of the second term above is a consequence of (5), since $x - y$ is nonnegative in this case. Now if $y \geq x$, then (6) and (8) simply imply that

$$(x+y-z)f(x-y) + (z-x+y)f(x+y)$$
$$= ((x+y)f(x-y) + (y-x)f(x+y)) + z(f(x+y) - f(x-y)) \geq 0$$
$$\text{for } \ y \geq x \geq z \geq 0.$$

The last two inequalities show that (6) and (8) imply (6) and (7). This finishes the proof. □

8. Preserving nonnegative symmetric matrices. We now focus on the characterization problem for the class of entire functions which preserve nonnegativity of symmetric matrices. We begin by recalling known facts about functions which preserve nonnegative symmetric matrices that are in addition nonnegative definite, i.e., have only nonnegative eigenvalues.

8.1. Preserving nonnegative definite nonnegative symmetric matrices. Interestingly, the condition necessary and sufficient for preserving nonnegative symmetric matrices that are nonnegative definite turns out to be exactly the same as the condition for preserving upper- (or lower-)triangular nonnegative matrices.

The characterization of functions which preserve the class of [illegible], entrywise nonnegative symmetric matrices is due to Micchelli and Willoughby [24]. We next state a version of their result that is useful for our purposes.

RESULT 14 (version of [24, Corollary 3.1]). [illegible] f [illegible] f [illegible] n [illegible] $\mathbb{R}_+$, [illegible] f [illegible] (1) [illegible] $f^{(j)}$ [illegible] f [illegible] $n-1$ [illegible] $\mathbb{R}_+$

The proof of Result 14 in [24] relies on two facts. The first is that $f(A)$ coincides with the interpolating polynomial of f, with nodes at the eigenvalues of A, evaluated at A, i.e., that

$$f(A) = f[r_1]I + f[r_1, r_2](A - r_1 I) + \cdots + f[r_1, \ldots, r_n](A - r_1 I)\cdots(A - r_{n-1}A). \tag{9}$$

The second fact is the entrywise nonnegativity of all matrix products

$$(A - r_1 I)\cdots(A - r_j I), \qquad j = 1, \ldots, n-1,$$

which holds under the assumption that the eigenvalues $r_1, \ldots r_n$ of A are ordered

$$r_1 \leq r_2 \leq \cdots \leq r_n.$$

Observe, however, that condition (1) is not sufficient for a function to preserve nonnegativity of [illegible] nonnegative symmetric matrices. Indeed, let $n = 2$, and let

$$f(x) = 1 + x + \frac{1}{2}x^2 - \frac{2}{3}x^3 + \frac{1}{4}x^4.$$

This function satisfies the condition (1) with $n = 2$, but it maps the matrix

$$\begin{bmatrix} 0 & M \\ M & 0 \end{bmatrix},$$

which is [illegible], to a matrix with negative off-diagonal entries when $M > 0$ is chosen to be sufficiently large. In fact, any $M > \sqrt{3/2}$ will produce a matrix with negative entries.

Motivated by Result 14, we would therefore like to find out what conditions are necessary and sufficient for a function to preserve nonnegativity of nonnegative symmetric matrices. We begin, in the next subsection, by analyzing even and odd functions.

8.2. Even and odd functions preserving nonnegativity of symmetric matrices. Using the Micchelli–Willoughby result, i.e., Result 14 from the previous section, and an auxiliary result from [12], we shall obtain a characterization of even and odd functions which preserve nonnegativity of symmetric matrices. Our proof below will require the notion of a Jacobi matrix and that of a symmetric antibidiagonal matrix. A [illegible] is a real, nonnegative definite, tridiagonal symmetric matrix having positive subdiagonal entries. A matrix A is called a [illegible] if it has the form

$$A = \begin{bmatrix} 0 & 0 & \cdots & 0 & a_n \\ 0 & 0 & \cdots & a_{n-2} & a_{n-1} \\ \vdots & \vdots & . & \vdots & \vdots \\ 0 & a_{n-2} & \cdots & 0 & 0 \\ a_n & a_{n-1} & \cdots & 0 & 0 \end{bmatrix}, \quad a_1, \ldots, a_n \in \mathbb{R}. \tag{10}$$

We make use of the next two results from [24] and from [12].

RESULT 15 (see [24]). [illegible] f, [illegible] n, [illegible] n, [illegible] f, [illegible] n, (1) [illegible] n, $x_1 \le x_2 \le \cdots \le x_n$ [illegible].

The above result is not stated in precisely these words in [24], but it is easily inferred—it lies at the heart of the proof of [24, Theorem 2.2]. In addition, we shall also need the following result.

RESULT 16 (Corollary 3 in [12]). [illegible] $\mathcal{M}$ [illegible] n, [illegible] $\mathcal{M}$, (10) [illegible] a_j [illegible].

We are now in a position obtain a characterization of even and odd matrix functions that are of interest to us.

THEOREM 17. [illegible] $f(z) =: g(z^2)$, [illegible] n, [illegible] g, [illegible] n $\mathbb{R}_+$, [illegible] g [illegible] (1). [illegible] $f(z) =: zh(z^2)$, [illegible] n, [illegible] h [illegible] (1).

[illegible]. Let f be even. Then, $f(z) = g(z^2)$ for some entire function g. If a matrix A is entrywise nonnegative symmetric, then A^2 is entrywise nonnegative, symmetric, and nonnegative definite. By Result 14, if g satisfies (1), then $g(A^2)$ is nonnegative.

To prove the converse, consider an arbitrary n-tuple $\mathcal{M}$ of positive numbers. We can think of $\mathcal{M}$ as being ordered

$$\mathcal{M} = (x_1, \dots, x_n), \qquad x_1 \le \cdots \le x_n. \tag{11}$$

By Result 16, there exists a nonnegative symmetric antibidiagonal matrix A such that A^2 is a Jacobi matrix with spectrum $\mathcal{M}$. Then, by Result 15, the divided differences of g must be nonnegative when evaluated at the first k points of $\mathcal{M}$ for each $k = 1, \dots, n$. This implies, by the standard density reasoning, that all divided differences of g must be nonnegative over $\mathbb{R}_+$.

Now let f be odd. Then, $f(z) = zh(z^2)$ for some entire function h. If all the divided differences of h up to order n are nonnegative, then by the same argument as above, $h(A^2)$ is nonnegative for each symmetric nonnegative matrix A, and multiplication of $h(A^2)$ by a nonnegative matrix A produces a nonnegative matrix again. To prove the converse, we use induction and a technique from [24]. Since f has to preserve nonnegativity of symmetric matrices of order $n-1$ as well, we can assume the nonnegativity of the divided differences of orders $k = 1, \dots, n-1$. To prove that the nth divided difference is nonnegative, let $\mathcal{M}$ be an arbitrary positive n-tuple (11). As above, by Result 16, there exists a symmetric antibidiagonal matrix A such that A^2 is a Jacobi matrix with spectrum $\mathcal{M}$. By [24], formula (9) shows that the $(1, n)$ entry of the function $h(A^2)$ is a positive multiple of $f[x_1, \dots, x_n]$, and hence the $(1, 1)$ entry of the product $h(A^2)A$ is again a positive multiple of $f[x_1, \dots, x_n]$. Thus the nth divided difference has to be nonnegative as well, which finishes the proof. □

This theorem provides a rather natural characterization of even and odd functions that preserve nonnegativity of symmetric matrices in terms of their divided differences. However, the "natural" idea, that the even and odd parts of any entire function that preserves nonnegativity of symmetric functions must be also nonnegativity-preserving, turns out to be wrong. Here is an example that illustrates why that may not be the case.

18. Let

$$f(z) := \alpha + \beta z - z^3 + z^5 + \gamma z^6,$$

where $\beta > 1/4$ and $\alpha, \gamma > 0$ are chosen to be so large that $f(x) \ge 0$ for all $x \in \mathbb{R}$ and $f'(x) \ge 0$ for all $x \in \mathbb{R}_+$. Then, f preserves nonnegativity of symmetric matrices of order 2, but its odd part f_{odd} does not.

. The function f satisfies conditions (6) and (8). Indeed, since $f \ge 0$ on $\mathbb{R}$, we have

$$(t+s)f(-t) + tf(t+s) \ge 0 \qquad \forall\, s, t \ge 0,$$

which is equivalent to condition (8). Now, the odd part of f is given by

$$f_{odd}(z) = \beta z - z^3 + z^5 =: zh(z^2).$$

Since $\beta > 1/4$, $h(x) > 0$ for all $x \in \mathbb{R}$. Since f is monotone increasing on $\mathbb{R}_+$, we have

$$f(s+t) - f(-s) \ge f(s) - f(-s) = 2f_{odd}(s) \ge 0 \qquad \forall\, s, t \ge 0,$$

which yields condition (6). Thus, by Theorem 13, f preserves nonnegativity of symmetric matrices of order 2. However,

$$h'(x) = 2x - 1 < 0 \qquad \text{for } x < 1/2.$$

Therefore, by Theorem 17, f_{odd} does not preserve nonnegativity of symmetric functions of order 2. □

We conclude this section with a simple observation about even and odd parts of a nonnegativity-preserving function.

PROPOSITION 19. [illegible] f [illegible] n, [illegible] f_{odd} - f_{even} [illegible] $\lfloor n/2 \rfloor$

[illegible]. For n even, consider matrices of the form

$$A = \begin{bmatrix} 0 & B \\ B & 0 \end{bmatrix},$$

and for n odd, matrices of the form

$$A = \operatorname{diag}\left(\begin{bmatrix} 0 & B \\ B & 0 \end{bmatrix}, 0 \right),$$

where B is an $\lfloor n/2 \rfloor \times \lfloor n/2 \rfloor$ symmetric nonnegative matrix. Since

$$f(A) = \begin{bmatrix} f_{even}(B) & f_{odd}(B) \\ f_{odd}(B) & f_{even}(B) \end{bmatrix} \qquad \text{for } n \text{ even},$$

$$f(A) = \operatorname{diag}\left(\begin{bmatrix} f_{even}(B) & f_{odd}(B) \\ f_{odd}(B) & f_{even}(B) \end{bmatrix}, 0 \right) \qquad \text{for } n \text{ odd},$$

we see that f_{even} and f_{odd} must preserve nonnegativity of symmetric functions of order $\lfloor n/2 \rfloor$. □

8.3. Other necessary conditions. Results from [12] allow us to derive an additional set of necessary conditions. The motivation behind these conditions is as follows. We believe that the power of Results 15 and 16—or rather, [illegible] behind those results—have not been exhausted by Theorem 17. Our next theorem is presented as an illustration of this viewpoint. On comparison with Theorem 13, we find that the conditions derived in our next theorem constitute a complete characterization for the functions of interest in the $n = 2$ case. To derive these new necessary conditions, we will need the following two results.

RESULT 20 (Theorem 1 in [12]). [illegible] Λ [illegible] (10) [illegible] a_j [illegible] $\Lambda = (\lambda_1, \ldots, \lambda_n)$ [illegible]

$$\lambda_1 > -\lambda_2 > \lambda_3 > \cdots > (-1)^{n-1}\lambda_n > 0.$$

LEMMA 21. [illegible] A [illegible] n, [illegible] A^p_{ij} [illegible] (i,j) [illegible] A^p [illegible]:

(a) [illegible] (i,j) [illegible] A^{2q-1} [illegible] $2 \le i + j \le (n - q + 1)$, $q \ge 1$

(b) [illegible] (i,j) [illegible] A^{2q} [illegible] $1 + q \le j - i \le n - 1$, $q \ge 1$

(c) [illegible] (10) [illegible] A,

$$A^{2q-1}_{1,n-q+1} = a_n a_{n-1} \ldots a_{n-2q+2}, \qquad 1 \le q \le \lfloor (n+1)/2 \rfloor, \tag{12}$$

$$A^{2q}_{1,1+q} = a_n a_{n-1} \ldots a_{n-2q+1}, \qquad 1 \le q \le \lfloor n/2 \rfloor. \tag{13}$$

. We proceed by induction on q. Note that (a), (b), and (c) are obvious when $q = 1$. Let us now assume that (a) and (b) are true for some $q < n - 3$. Note that since A is antibidiagonal,

$$A_{ij}^{2q+1} = A_{i,n-j+1}^{2q} A_{n-j+1,j} + A_{i,n-j+2}^{2q} A_{n-j+2,j}. \tag{14}$$

However, if $i + j \leq (n - (q + 1) + 1)$, then

$$(n - j + 2) - i \geq (n - j + 1) - i \geq q + 1.$$

Applying our inductive hypothesis on (b), we conclude from the above inequalities that the right-hand side of (14) reduces to zero when $i + j \leq (n - (q + 1) + 1)$. Thus, (a) is established for $q + 1$.

We establish (b) for $q + 1$ in a similar fashion. We note that

$$A_{ij}^{2q+2} = A_{i,n-j+1}^{2q+1} A_{n-j+1,j} + A_{i,n-j+2}^{2q+1} A_{n-j+2,j}. \tag{15}$$

When $j - i \geq 1 + (q + 1)$, then

$$i + (n - j + 1) \leq i + (n - j + 2) \leq n - (q + 1) + 1.$$

Since we just established (a) for $q+1$, the above inequalities tell us that the right-hand side of (15) reduces to zero when $j - i \geq 1 + (q + 1)$. Thus, (b) too is established for $q + 1$. By induction, (a) and (b) are true for all relevant q.

Part (c) now follows easily by substituting $i = 1$ and $j = n - q$ into (14) to carry out the inductive step for (12), and by substituting $i = 1$ and $j = q + 2$ into (15) to carry out the inductive step for (13). □

We can now present the aforementioned necessary conditions.

THEOREM 22. , n, $n \geq 2$, , $(x_1, \ldots, x_n)$,

$$x_1 > -x_2 > x_3 > \cdots > (-1)^{n-1} x_n > 0, \tag{16}$$

$$f[x_1, \ldots, x_n] \geq 0, \tag{17}$$

$k = 1, \ldots, n$,

$$f[x_1, \ldots, x_{k-1}, x_{k+1}, \ldots, x_n] - \left(\sum_{j \neq k} x_j \right) f[x_1, \ldots, x_n] \geq 0. \tag{18}$$

. We choose an n-tuple $(x_1, \ldots, x_n)$ that satisfies (16). By Result 20, there is a symmetric antibidiagonal matrix of the form (10), with all a_j's positive, whose spectrum is $(x_1, \ldots, x_n)$. Let us express $f(A)$ using the formula (9), with the substitutions $r_j = x_j$, $j = 1, \ldots, n$. Then, in view of Lemma 21, the $(1, \lfloor n/2 \rfloor + 1)$ entry of $f(A)$ is $a_n a_{n-1} \ldots a_2 f[x_1, \ldots, x_n]$. Since f preserves nonnegativity, and all the a_j's are positive, $f[x_1, \ldots, x_n]$ has to be nonnegative. This establishes (17).

To demonstrate (18), we look at the entries of $f(A)$ that are to the $(1, \lfloor n/2 \rfloor + 1)$ entry that was considered above. Let us fix a $k = 1, \ldots, n$. This time, however, in using formula (9) to express $f(A)$, we make the following substitutions:

$$r_j = \begin{cases} x_j & \text{if } j < k, \\ x_{j+1} & \text{if } k \leq j < n, \\ x_k & \text{if } j = n. \end{cases}$$

Our analysis splits into two cases.

Case 1. n odd. In this case, let us look at the $(1, \lfloor n/2 \rfloor + 2)$ entry of $f(A)$. By Lemma 21, and the fact that n is odd, the only power of A that contributes to this entry is A^{n-2}. Consequently

$$f(A)_{1,\lfloor n/2 \rfloor+2} = \{f[x_1, \ldots, x_{k-1}, x_{k+1}, \ldots, x_n] - \left(\sum_{j \neq k} x_j\right) f[x_1, \ldots, x_n]\} A^{n-2}_{1,\lfloor n/2 \rfloor+2}$$

$$= a_n a_{n-1} \ldots a_3 \{f[x_1, \ldots, x_{k-1}, x_{k+1} \ldots, x_n] - \left(\sum_{j \neq k} x_j\right) f[x_1, \ldots, x_n]\}.$$

Since f preserves nonnegativity, (18) follows from the above equalities.

Case 2. n even. In this case, we focus on the $(1, \lfloor n/2 \rfloor)$ entry of $f(A)$. We recover (18) by arguing exactly as above.

In either case, (18) is established, which concludes our proof. □

We conclude this section by showing that a subset of the necessary conditions derived above are in fact sufficient to characterize those entire functions that preserve nonnegativity of 2×2 symmetric matrices. Specifically, we show that

$$f[x_1, x_2] \geq 0 \quad \text{and}$$

$$f(x_2) - x_2 f[x_1, x_2] \geq 0 \quad \forall x_1 > -x_2 > 0$$

imply the conditions (6) and (8). This is achieved simply by taking some $y > x > 0$, making the substitutions $x_1 = y + x$ and $x_2 = x - y$, and then invoking continuity to obtain (6) and (8) for all $y \geq x \geq 0$.

9. Open problems and further ideas. We conclude this paper by listing some ideas that we did not pursue but that may lead to further progress.

One can consider matrices that preserve nonnegativity of other classes of structured matrices, such as Toeplitz or Hankel. However, since these classes are not invariant under the action of an arbitrary matrix function, their matrix functions can be quite difficult to analyze. Also, the eigenstructure of some structured matrices is rather involved, which could be an additional obstacle.

Theorem 1.3 of [35] gives an interesting formula for $f(A)$ when f is a polynomial, which therefore must also be true for entire functions. Precisely, if A is a matrix with minimal polynomial p_0 and C is the companion matrix of p_0, then

$$f(A) = \sum_{j=1}^{n} f(C)_{j1} A^{j-1}.$$

In particular, $f(A)$ is nonnegative whenever the first column of $f(C)$ is nonnegative. It would be worthwhile to find out what functions have this property.

Note that the set $\mathcal{F}_n$ contains positive constants and is closed under addition, multiplication, and composition. We are not aware of any work on systems of entire functions (or even polynomials) that satisfy this property. Perhaps one could describe a minimal set of generators (with respect to these three operations) that generate such a system.

For example, in the case $n = 1$, the generators are positive constants, the function $p_1(x) = x$, plus all quadrics of the form $(x - a)^2$, $a > 0$. Incidentally, the set

of polynomials with nonnegative coefficients is generated by positive constants and $p_1(x) = x$. We do not have a characterization of generators for $n \geq 2$.

In particular, $\mathcal{F}_n$ is a semigroup with respect to any of these operations, so some general results on semigroups may prove to be useful in our setting. Also note that the set of nonnegative matrices of order n, on which $\mathcal{F}_n$ acts, is also a semigroup (closed under addition and multiplication), which could also be of potential use.

Finally, both $\mathcal{F}_n$ and the set of nonnegative matrices of order n are also cones, so the problem might also have a cone theoretic form. If we consider polynomials instead of entire functions, we can further restrict ourselves to polynomials of degree bounded by a fixed positive integer. Then, we will obtain a proper cone, whose extreme directions may be of interest. The general problem then can also be looked upon in an appropriate similar setting.

Acknowledgments. We are grateful to Raphael Loewy, Michael Neumann, and Shmuel Friedland for helpful discussions and to anonymous referees for useful suggestions.

THE ARNOLDI PROCESS AND GMRES FOR NEARLY SYMMETRIC MATRICES*

BERNHARD BECKERMANN† AND LOTHAR REICHEL‡

Abstract. Matrices with a skew-symmetric part of low rank arise in many applications, including path following methods and integral equations. This paper explores the properties of the Arnoldi process when applied to such a matrix. We show that an orthogonal Krylov subspace basis can be generated with short recursion formulas and that the Hessenberg matrix generated by the Arnoldi process has a structure, which makes it possible to derive a progressive GMRES method. Eigenvalue computation is also considered.

Key words. low-rank perturbation, iterative method, solution of linear system, eigenvalue computation

DOI. 10.1137/060668274

1. Introduction.

This paper discusses the Arnoldi process applied to a large matrix $A \in \mathbb{R}^{n\times n}$ with a skew-symmetric part

$$A - A^* = \sum_{k=1}^{s} f_k g_k^*, \qquad f_k, g_k \in \mathbb{R}^n, \tag{1.1}$$

of low rank s. In particular, we assume that $s \ll n$. The superscript $*$ denotes transposition and, when applicable, complex conjugation. We present our results for matrices A and vectors f_k and g_k with real entries; however, our algorithms also can be applied to matrices and vectors with complex entries.

Linear systems of equations

$$Ax = b \tag{1.2}$$

with large matrices of this kind arise in path following methods, from integral equations as well as from certain boundary value problems for partial differential equations.

The generalized minimal residual (GMRES) method is one of the most popular iterative methods for the solution of large linear systems of equations with a nonsymmetric matrix. The standard implementation of GMRES is based on the Arnoldi process; see, e.g., Saad [15, section 6.5]. Application of j steps of the Arnoldi process to the matrix A with initial vector $r_0 \neq 0$ yields the decomposition

$$AV_j = V_j H_j + h_j e_j^*, \tag{1.3}$$

where $V_j = [v_1, v_2, \ldots, v_j] \in \mathbb{R}^{n\times j}$ and $h_j \in \mathbb{R}^n$ satisfy $V_j^* V_j = I_j$, $V_j^* h_j = 0$, and $v_1 = r_0/\|r_0\|$. Moreover, $H_j \in \mathbb{R}^{j\times j}$ is an upper Hessenberg matrix. Throughout

this paper I_j denotes the identity matrix of order j, e_k denotes the kth column of an identity matrix of appropriate order, and $\|\cdot\|$ denotes the Euclidean vector norm. For ease of discussion, we will assume that j is small enough so that the decomposition (1.3) with the stated properties exists.

When $h_j \neq 0$, we can express (1.3) in the form

$$AV_j = V_{j+1}\bar{H}_j, \tag{1.4}$$

where $v_{j+1} = h_j/\|h_j\|$ and

$$V_{j+1} = [V_j, v_{j+1}] \in \mathbb{R}^{n\times(j+1)}, \qquad \bar{H}_j = \begin{bmatrix} H_j \\ \|h_j\|e_j^* \end{bmatrix} \in \mathbb{R}^{(j+1)\times j}.$$

The computation of the Arnoldi decompositions (1.3) or (1.4) of a general $n \times n$ matrix A requires the evaluation of j matrix-vector products with A and of about $j^2/2$ inner products with n-vectors. The latter demands $\mathcal{O}(nj^2)$ arithmetic floating point operations (flops) and may dominate the computational work. The Arnoldi process determines the columns of V_j in order and requires access to all the previously generated columns to compute the next one; in particular, all the columns of V_j have to be stored; see, e.g., Saad [15, section 6.3] for a thorough treatment of the Arnoldi process. Computation of the jth iterate by GMRES also requires the whole matrix V_j to be available. To limit the demand of computer memory, GMRES is often restarted periodically, say, every m steps. This restarted GMRES method is denoted by GMRES(m). Restarting may reduce the rate of convergence of GMRES significantly.

In section 2, we show that the property (1.1) of A makes it possible to determine the columns v_k of V_j with a short recursion formula, the number of terms of which depends on s in (1.1) but can be bounded independently of k. The recursion formula allows the computation of all the columns of V_j in only $\mathcal{O}(nj)$ flops. Moreover, the computation of v_k for large k does not require access to all the previously computed columns of V_j. Section 3 discusses the structure of the Hessenberg matrix H_j in (1.3) when A satisfies (1.1) and presents a fast algorithm for determining the Arnoldi decomposition (1.4).

The short recursion formula for the columns of V_j and the structure of H_j make it possible to derive a progressive GMRES method for the solution of linear systems (1.2) with a matrix that satisfies (1.1). Such a method is described in section 4. The storage requirement of the method, as well as the computational effort per iteration, are bounded independently of the number of iterations j. This makes it possible to apply the method without periodic restarts. Computed examples are presented in section 5 and concluding remarks can be found in section 6.

Recently, Barth and Manteuffel [4] presented iterative methods of conjugate gradient type for linear systems of equations of the kind considered in the present paper. Specifically, they considered linear systems of equations with a generalized B-normal(ℓ, m) matrix. This type of matrix is characterized by the existence of polynomials p_ℓ and q_m of degrees ℓ and m, respectively, such that the matrix

$$A^\dagger q_m(A) - p_\ell(A)$$

is of low rank, where $A^\dagger = B^{-1}A^*B$ and B is a Hermitian positive definite matrix. The matrix $A^\dagger$ is the adjoint of A with respect to the B-inner product

$$\langle u, v\rangle_B = u^*Bv.$$

In the terminology of Barth and Manteuffel [4] matrices A that satisfy (1.1) are generalized I-normal$(1,0)$ matrices.

Barth and Manteuffel [4] derived their methods by generalizing the recurrence relations for orthogonal polynomials on the unit circle. The latter type of recurrence relations had previously been applied to iterative methods in [11, 12]; see also Arnold et al. [2] for a recent application to QCD computations. The derivation of our iterative methods for (1.2) differs from the derivation by Barth and Manteuffel [4] of their schemes in that we do not apply properties of orthogonal polynomials on the unit circle. Iterative methods for linear systems of equations with a matrix, whose symmetric part is positive definite and easily invertible, are described by Concus and Golub [7] and Widlund [18].

2. Generation of an orthogonal Krylov subspace basis. Introduce the Krylov subspace

$$\mathcal{K}_j(A,b) = \text{span}\{b, Ab, A^2b, \ldots, A^{j-1}b\}, \tag{2.1}$$

which we assume to be of dimension j. The columns of the matrix V_j in (1.3) form an orthonormal basis of $\mathcal{K}_j(A,b)$.

Let f_k and g_k be the vectors in (1.1) and define the matrices

$$F = [f_1, f_2, \ldots, f_s], \qquad G = [g_1, g_2, \ldots, g_s], \tag{2.2}$$

which we may assume to be of full rank; otherwise we can reduce s. We express (1.1) as

$$A - A^* = FG^* \tag{2.3}$$

and note that

$$FG^* = -GF^*. \tag{2.4}$$

It follows from (2.4) and the fact that F and G are of full rank that s is even and that there is a unique matrix $C \in \mathbb{R}^{s\times s}$, such that

$$G = FC. \tag{2.5}$$

The fact that s is even can be seen by substituting (2.5) into (2.4). This yields $C^* = -C$. Therefore, when s is odd, C is singular and G is not of full rank. Use of the representation (2.5) of G reduces the computational work in the algorithms presented in sections 3 and 4.

2.1. In many applications that involve a matrix A with a skew-symmetric part of low rank, the matrix is given in the form

$$A = M + \sum_{k=1}^{s/2} f_k g_k^*$$

with $M \in \mathbb{R}^{n\times n}$ symmetric. Then (1.1) can be expressed as

$$A - A^* = \sum_{k=1}^{s/2} f_k g_k^* - \sum_{k=1}^{s/2} g_k f_k^*$$

and we may choose

$$F = [f_1, f_2, \ldots, f_{s/2}, g_1, g_2, \ldots, g_{s/2}], \qquad C = \begin{bmatrix} 0 & -I_{s/2} \\ I_{s/2} & 0 \end{bmatrix}.$$

Introduce the vectors

$$f_{\ell,k} = V_k V_k^* f_\ell, \qquad 1 \le \ell \le s, \qquad 1 \le k \le j. \tag{2.6}$$

Then

$$f_{\ell,k} \in \mathcal{K}_k(A, r_0), \qquad f_{\ell,k} - f_\ell \perp \mathcal{K}_k(A, r_0). \tag{2.7}$$

Moreover, for each ℓ, the $f_{\ell,k}$ satisfy the recursion

$$\begin{cases} f_{\ell,k} = f_{\ell,k-1} + v_k v_k^* f_\ell, & k = 2, 3, \ldots, j, \\ f_{\ell,1} = v_1 v_1^* f_\ell. \end{cases} \tag{2.8}$$

Let

$$v_k' = A^* v_k + \sum_{\ell=1}^{s} g_\ell^* v_k (f_\ell - f_{\ell,k}). \tag{2.9}$$

Then (1.1) gives

$$v_k' - A v_k = \sum_{\ell=1}^{s} g_\ell^* v_k (f_\ell - f_{\ell,k}) - (A - A^*) v_k = -\sum_{\ell=1}^{s} g_\ell^* v_k f_{\ell,k}. \tag{2.10}$$

We may assume that $Av_k \notin \mathcal{K}_k(A, r_0)$, because otherwise range(V_k) is an invariant subspace of A, which contains the solution of the linear system (1.2); see, e.g., Saad [15, section 6.5.4] for details. The following properties of v_k' are a consequence of the above discussion.

PROPOSITION 2.2. [illegible] v_k' [illegible] (2.9) [illegible] [illegible] $\dim \mathcal{K}_{k+1}(A, r_0) = k + 1$ [illegible]

$$v_k' \in \mathcal{K}_{k+1}(A, r_0) \setminus \mathcal{K}_k(A, r_0), \qquad v_k' \perp \mathcal{K}_{k-2}(A, r_0). \tag{2.11}$$

[illegible]. The requirement that $\mathcal{K}_{k+1}(A, r_0)$ be of dimension $k + 1$ secures that $Av_k \notin \mathcal{K}_k(A, r_0)$. Equation (2.7) yields that $v_k' - Av_k \in \mathcal{K}_k(A, r_0)$, and this establishes the left-hand side of (2.11).

It follows from the Arnoldi decomposition (1.3) that $v_k \perp Av_\ell$ for $1 \le \ell \le k-2$, or, equivalently, that $A^* v_k \perp v_\ell$ for $1 \le \ell \le k-2$. The latter property, in combination with (2.7) and (2.9), shows the orthogonality relation (2.11). □

Equation (2.10) yields the expression

$$v_k' = A v_k - \sum_{\ell=1}^{s} g_\ell^* v_k f_{\ell,k}, \tag{2.12}$$

which we use to evaluate v_k'. Orthogonalization against the vectors v_{k-1} and v_k, and normalization of the resulting vector, gives the Arnoldi vector v_{k+1}. In what follows we will write this operation more explicitly as

$$v_k' = t_{k+1,k} v_{k+1} + t_{k,k} v_k + t_{k-1,k} v_{k-1}, \qquad k \ge 1, \tag{2.13}$$

where

$$t_{k-1,k} = v_{k-1}^* v_k', \quad t_{k,k} = v_k^* v_k', \quad t_{k+1,k} = v_{k+1}^* v_k', \tag{2.14}$$

with $v_0 = 0$ and $t_{k+1,k} = \|v_k' - t_{k,k} v_k - t_{k,k-1} v_{k-1}\| > 0$. The computations for generating the orthogonal Krylov subspace basis, and for determining the matrix $\bar{H}_j$ in (1.4), are summarized in Algorithm 3.2 of the following section.

3. Structure of the Hessenberg matrices. This section discusses the structure of the matrices $H_j = [h_{k,\ell}]$ and $\bar{H}_j = [h_{k,\ell}]$ in the Arnoldi decompositions (1.3) and (1.4), respectively. It is convenient to introduce the following terminology. For an integer m, the m-diagonal of a matrix $B = [b_{k,\ell}]$ consists of all entries of the form $b_{k,k+m}$. The m-upper (m-lower) triangular part of B is the submatrix comprising all entries on and above (below) the m-diagonal. For instance, the upper Hessenberg matrices H_j and $\bar{H}_j$ have vanishing (-2)-lower triangular parts. Note that the (-2)-upper triangular part is not triangular.

PROPOSITION 3.1. [illegible] $\hat{F}_j = V_j^* F$ [illegible] $\hat{G}_j = V_j^* G$ [illegible] F [illegible] G [illegible] (2.3) [illegible] $j \geq s$ [illegible] H_j [illegible] (1.3) [illegible]

$$H_j - H_j^* = \hat{F}_j \hat{G}_j^*, \qquad \hat{G}_j \hat{F}_j^* = -\hat{F}_j \hat{G}_j^*, \tag{3.1}$$

[illegible] H_j [illegible] s [illegible] H_j [illegible] $\hat{F}_j \hat{G}_j^*$ [illegible] 2 [illegible]. It follows from (1.3) and (2.3) that

$$H_j = V_j^* A V_j = V_j^*(A^* + FG^*)V_j = H_j^* + \hat{F}_j \hat{G}_j^*,$$

which shows (3.1). Since the (-2)-lower triangular part of H_j vanishes, (3.1) yields the 2-upper triangular part of H_j. □

The proposition shows that H_j is an order-$(1, s+1)$ quasi-separable matrix; see, e.g., Eidelman, Gohberg, and Olshevsky [9] for a recent discussion on this kind of matrix.

We turn to the entries in the tridiagonal part of $\bar{H}_j$. In accordance with (2.14), we define the matrix $\bar{T}_j = [t_{m,k}] \in \mathbb{R}^{(j+1)\times j}$ with entries $t_{m,k} = v_m^* v_k'$. Notice that $\bar{T}_j$ is tridiagonal by Proposition 2.2. Substitution of (2.6) into (2.12) gives

$$v_k' = Av_k - \sum_{\ell=1}^{s} (g_\ell^* v_k) V_k V_k^* f_\ell = Av_k - V_k V_k^* F G^* v_k = Av_k - V_k \hat{F}_k \hat{G}_k^* e_k,$$

and, taking into account that $e_m^* \hat{F}_k \hat{G}_k^* e_k = e_m^* \hat{F}_j \hat{G}_j^* e_k$ for $m \leq k \leq j$, we get for the entries $h_{m,k} = v_m^* A v_k$ of $\bar{H}_j$ the formula

$$h_{m,k} = \begin{cases} t_{k+1,k}, & m = k+1, \\ t_{m,k} + e_m^* \hat{F}_j \hat{G}_j^* e_k, & k-1 \leq m \leq k, \\ e_m^* \hat{F}_j \hat{G}_j^* e_k, & 1 \leq m < k-1. \end{cases} \tag{3.2}$$

Thus, the matrix $\hat{F}_j \hat{G}_j^*$ contributes to the upper triangular part of $\bar{H}_j$, and the matrix $\bar{T}_j$, which expresses the orthogonalization of the vectors v_k', contributes to the tridiagonal part; in MATLAB notation, we have

$$\bar{H}_j = \bar{T}_j + \mathsf{triu}(\hat{F}_j \hat{G}_j^*, 0).$$

Combining (2.9) with (2.7) yields

$$v_m^* v_k' = v_m^* A^* v_k = (v_k^* A v_m)^*, \qquad 1 \leq m \leq k,$$

and comparison with (2.14) gives

$$t_{k-1,k} = t_{k,k-1} > 0, \qquad t_{k,k} = h_{k,k}^*. \tag{3.3}$$

We describe an algorithm for the computation of the matrices $\bar{H}_j$ and V_{j+1} in the decomposition (1.4), assuming that the decomposition exists. The matrix $\bar{H}_j$ is represented in decomposed form (3.2) by the matrices $\hat{F}_j$, $\hat{G}_j$, and $\bar{T}_j$, which in the algorithm are represented without subscript j. The subscripts used in the algorithm denote row and column indices. Thus, $\hat{F}_{k,:}$ denotes the kth row of the matrix $\hat{F}_j$. At iteration k, we let $\tilde{F} = [f_{1,k}, f_{2,k}, \ldots, f_{s,k}]$.

ALGORITHM 3.2. [illegible] $\bar{H}_j$ [illegible] V_{j+1}

[illegible] $A \in \mathbb{R}^{n\times n}$, $F = [f_1, f_2, \ldots, f_s], G = [g_1, g_2, \ldots, g_s] \in \mathbb{R}^{n\times s}$, $r_0 \in \mathbb{R}^n$, j

[illegible] $\bar{T} = [t_{\ell,k}] \in \mathbb{R}^{(j+1)\times j}$, $\hat{F}, \hat{G} \in \mathbb{R}^{(j+1)\times s}$, $V_{j+1} = [v_1, v_2, \ldots, v_{j+1}] \in \mathbb{R}^{n\times(j+1)}$

1. $\tilde{F} := 0$
2. $v_1 := r_0/\|r_0\|$
3. [illegible] $k = 1 : j$
   4. $\hat{F}_{k,:} := v_k^* F$, $\hat{G}_{k,:} := v_k^* G$
   5. $\tilde{F} := \tilde{F} + v_k \hat{F}_{k,:}$
   6. $v' := Av_k - \tilde{F}\hat{G}_{k,:}^*$
   7. [illegible] $k > 1$ [illegible]
      8. $t_{k-1,k} := v_{k-1}^* v'$, $v' := v' - t_{k-1,k} v_{k-1}$
   9. [illegible]
   10. $t_{k,k} := v_k^* v'$, $v' := v' - t_{k,k} v_k$, $t_{k+1,k} := \|v'\|$, $v_{k+1} := v'/t_{k+1,k}$
11. [illegible]

We note that the computational effort of line 4 of the algorithm can be essentially halved by using the representation (2.5) of G.

Algorithm 3.2 can be applied to compute approximations of a few extreme eigenvalues and associated eigenvectors of A similarly to the standard implementation of the Arnoldi process. Certain eigenvalues of H_j are used to approximate selected eigenvalues of A. The structure of H_j therefore is of interest.

[illegible] 3.3. Given a unitary matrix $Q \in \mathbb{C}^{j\times j}$, it follows from Proposition 3.1 that for the matrix

$$S = Q^* H_j Q,$$

we have $\Sigma := S - S^* = Q^* \hat{F}_j \hat{G}_j^* Q$, i.e., S has a skew-symmetric part of rank s. If S has an additional sparsity structure, then we may derive results similarly to Proposition 3.1. For instance, the matrix S in the Schur normal form of H_j is upper triangular, and thus S may be written as a diagonal matrix plus the 1-upper triangular part of the matrix Σ. Similarly, the matrix S obtained after one step of the QR-algorithm is upper Hessenberg and therefore may be written as a tridiagonal matrix plus the 2-upper triangular part of the matrix Σ.

We recall that in the QR-algorithm for eigenvalue computations the unitary factor Q is chosen such that $R = Q^* H_j$ is upper triangular.

[illegible] 3.4. Consider the QR-decomposition $H_j = QR$ with orthogonal Q and upper triangular R. Here also the matrix R has a structure: since Q^* is known to be of lower Hessenberg form (see, e.g., the considerations of the next section), we see from Proposition 3.1 that the 3-upper triangular part of $Q^*(H_j - \hat{F}_j \hat{G}_j)$ contains only zeros, or, in other words, the 3-upper triangular parts of R_j and of the matrix $Q^* \hat{F}_j \hat{G}_j$ of rank s coincide.

The structure makes it possible to compute the matrix R in $\mathcal{O}(j)$ flops, by representing H_j in terms of the tridiagonal part of H_j and the matrices $\hat{F}_j$ and $\hat{G}_j$, and by representing R in terms of its 0-, 1-, and 2-diagonals and the matrices $Q^* \hat{F}_j$ and $\hat{G}_j$.

Since the computation of R does not play a role in subsequent considerations, we omit the details.

4. A progressive GMRES algorithm. Let $x_0 \in \mathbb{R}^n$ be an approximate solution of (1.2). GMRES determines a new approximate solution x_j of (1.2), such that

$$\|Ax_j - b\| = \min_{x \in x_0 + \mathcal{K}_j(A,r_0)} \|Ax - b\|, \qquad x_j \in x_0 + \mathcal{K}_j(A, r_0). \tag{4.1}$$

The standard implementation of GMRES determines a correction of x_0, i.e., $x_j = x_0 + V_j x_j$, by substituting the decomposition (1.4) with $r_0 = b - Ax_0$ into (4.1); see, e.g., Saad [15, section 6.5] for details. This gives the equivalent minimization problem

$$\min_{y \in \mathbb{R}^j} \|\bar{H}_j y - e_1 \|r_0\| \|, \tag{4.2}$$

with solution $y_j \in \mathbb{R}^j$.

We solve the least-squares problem (4.2) by using the QR-factorization $\bar{H}_j = Q_{j+1}\bar{R}_j$, where $Q_{j+1} \in \mathbb{R}^{(j+1)\times(j+1)}$ is orthogonal (or unitary in the case of complex A, b) and

$$\bar{R}_j = \begin{bmatrix} R_j \\ 0 \end{bmatrix} \in \mathbb{R}^{(j+1)\times j}, \tag{4.3}$$

with $R_j \in \mathbb{R}^{j\times j}$ upper triangular. Let us first recall in the following paragraph and Proposition 4.1 the well-known construction of a QR-decomposition of the upper Hessenberg matrix $\bar{H}_j$ for a general matrix A. Subsequently, we explain in Proposition 4.2 how the structure of the matrix A helps us to derive a progressive form of GMRES.

Following Saad [15, Chapter 6.5.3], we determine the matrix Q_{j+1} by applying a product of Givens rotations to $\bar{H}_j$. Let $Q_1 = [1]$ and define, for $k = 1, 2, \ldots, j$,

$$Q_{k+1}^* = \Omega_{k+1} \begin{bmatrix} Q_k^* & 0 \\ 0 & 1 \end{bmatrix}, \qquad \Omega_{k+1} = \begin{bmatrix} I_{k-1} & 0 & 0 \\ 0 & c_k^* & s_k \\ 0 & -s_k & c_k \end{bmatrix}, \tag{4.4}$$

with $s_k \geq 0$ and $s_k^2 + |c_k|^2 = 1$ such that Ω_{k+1} is unitary (and reduces to a classical Givens rotation in the case of real data). Using the nested structure of $\bar{H}_j = [h_{k,\ell}]$, i.e., the fact that $\bar{H}_{j-1}$ is the leading $j \times (j-1)$ principal submatrix of $\bar{H}_j$, yields

$$Q_{j+1}^* \bar{H}_j = \Omega_{j+1} \begin{bmatrix} Q_j^* \bar{H}_{j-1} & Q_j^* H_j e_j \\ 0 & h_{j+1,j} \end{bmatrix} = \Omega_{j+1} \begin{bmatrix} R_{j-1} & * \\ 0 & \tau_j \\ 0 & h_{j+1,j} \end{bmatrix},$$

with

$$\tau_j = e_j^* Q_j^* H_j e_j. \tag{4.5}$$

Since multiplication by Ω_{j+1} affects only the last two rows, the matrices R_j and $\bar{R}_j$ also have a nested substructure:

$$\bar{R}_j = \begin{bmatrix} \bar{R}_{j-1} & * \\ 0 & 0 \end{bmatrix}, \qquad R_j = \begin{bmatrix} R_{j-1} & * \\ 0 & * \end{bmatrix}.$$

We have the following formulas for the coefficients c_j, s_j of Ω_{j+1} and for the entries of Q^*_{j+1}.

PROPOSITION 4.1.

$$s_j = \frac{t_{j+1,j}}{\sqrt{t_{j+1,j}^2 + |\tau_j|^2}} \geq 0, \qquad c_j = \frac{\tau_j}{\sqrt{t_{j+1,j}^2 + |\tau_j|^2}}, \tag{4.6}$$

$t_{j+1,j} = h_{j+1,j}$ $\bar{H}_j$ τ_j (4.5). j Q^*_{j+1} Q^*_j Q^*_{j+1} $j \geq 3$

$$e^*_{j+1} Q^*_{j+1} = [\, -s_j e^*_j Q^*_j,\ c_j \,] = [\, *\,,\ s_j s_{j-1} c_{j-2}\,,\ -s_j c_{j-1}\,,\ c_j \,]. \tag{4.7}$$

The proof is obtained by direct calculations. □

We are in a position to describe a progressive recurrence relation for the GMRES residual r_j, a simplified recurrence for its norm, as well as a simplified expression for the quantity τ_j defined by (4.5). In particular, the progressive GMRES algorithm does not require the entries of the matrices R_j, $\bar{H}_j$, and Q_{j+1}. Only the c_k, s_k of the Givens rotations (4.4) and the quantities occurring in the recurrence relation for the Arnoldi vectors v_k are needed.

PROPOSITION 4.2. r_j x_j

$$r_j = b - Ax_j, \tag{4.8}$$

$$\gamma_j = -s_j \gamma_{j-1}, \qquad j \geq 1, \tag{4.9}$$

$\gamma_0 = \|r_0\|$ $\gamma_j = (-1)^j \|r_j\|$

$$r_j = s_j^2 r_{j-1} + \gamma_j c_j^* v_{j+1}, \qquad j \geq 1. \tag{4.10}$$

$p_j \in \mathbb{R}^s$

$$p_j^* = -s_{j-1} p_{j-1}^* + c_{j-1} e_j^* \hat{F}_j, \qquad j \geq 2, \tag{4.11}$$

$p_1^* = \hat{F}_1$ τ_j (4.5)

$$\tau_j = c_{j-1} t_{j,j} - s_{j-1} c_{j-2} t_{j-1,j} + p_j^* \hat{G}_j^* e_j, \qquad j \geq 2, \tag{4.12}$$

$c_0 = 1$ $\tau_1 = t^*_{1,1}$

We start by establishing the formula

$$r_j = \gamma_j V_{j+1} Q_{j+1} e_{j+1}. \tag{4.13}$$

A different proof is presented by Saad [15, Proposition 6.9]. From the definition of GMRES, we have that $r_j = P^{\perp}_{A\mathcal{K}_j(A,r_0)} r_0$, where $P_{A\mathcal{K}_j(A,r_0)}$ denotes the orthogonal projector onto $A\mathcal{K}_j(A, r_0)$ and $P^{\perp}_{A\mathcal{K}_j(A,r_0)} = I - P_{A\mathcal{K}_j(A,r_0)}$ denotes the orthogonal projector onto the complement. Denote by $\bar{Q}_j \in \mathbb{R}^{(j+1)\times j}$ the matrix made up of the first j columns of Q_{j+1}. From (1.4) and (4.3), we obtain that

$AV_j = V_{j+1}Q_{j+1}\bar{R}_j = V_{j+1}\bar{Q}_j R_j$. Since R_j is invertible, we see that an orthonormal basis of $A\mathcal{K}_j(A, r_0)$ is given by the columns of $V_{j+1}\bar{Q}_j$, implying that

$$\begin{aligned} r_j &= r_0 - P_{A\mathcal{K}_j(A,r_0)}r_0 = V_{j+1}Q_{j+1}Q_{j+1}^*V_{j+1}^*r_0 - V_{j+1}\bar{Q}_j\bar{Q}_j^*V_{j+1}^*r_0 \\ &= V_{j+1}(Q_{j+1}Q_{j+1}^* - \bar{Q}_j\bar{Q}_j^*)e_1\|r_0\| = V_{j+1}Q_{j+1}e_{j+1}e_{j+1}^*Q_{j+1}^*e_1\|r_0\|. \end{aligned}$$

It follows from (4.7) and (4.9) that

$$\gamma_0\, e_{j+1}^*Q_{j+1}^*e_1 = \gamma_0(-s_j)\, e_j^*Q_j^*e_1 = \cdots = \gamma_0(-s_j)(-s_{j-1})\ldots(-s_1) = \gamma_j.$$

This establishes (4.13). Since $V_{j+1}Q_{j+1}$ has orthonormal columns and $s_k \geq 0$ by Proposition 4.1, we may conclude by taking norms in (4.13) that $|\gamma_j| = \|r_j\| = (-1)^j\gamma_j$.

The updating formula (4.10) is now an immediate consequence of (4.13): by (4.7),

$$r_j = \gamma_j V_{j+1}[-s_j e_j^*Q_j^*, c_j]^* = -s_j\frac{\gamma_j}{\gamma_{j-1}}r_{j-1} + \gamma_j c_j^* v_{j+1}.$$

It remains to show (4.12). From (4.7) and (4.11) we conclude by recurrence on j that

$$p_j^* = e_j^*Q_j^*\hat{F}_j, \qquad j \geq 1.$$

The structure of H_j, together with (4.7) and (4.13), yields for $j \geq 2$ that

$$\begin{aligned} \tau_j &= e_j^*Q_j^*H_je_j \\ &= e_j^*Q_j^*\left(\begin{bmatrix} 0 \\ \vdots \\ 0 \\ t_{j-1,j} \\ t_{j,j} \end{bmatrix} + \hat{F}_j\hat{G}_j^*e_j\right) = [-s_{j-1}c_{j-2}, c_{j-1}]\begin{bmatrix} t_{j-1,j} \\ t_{j,j} \end{bmatrix} + p_j^*\hat{G}_j^*e_j. \end{aligned}$$

When $j = 1$, we get by using $Q_1 = [1]$ and (3.3) that $\tau_1 = h_{1,1} = t_{1,1}^*$. ∎

By applying a suitable linear operator L, such that $Lr_k = x_k$ for $0 \leq k \leq j+1$, to the recurrence relation (4.10) of the residuals, we obtain an updating formula for the GMRES iterates in terms of the auxiliary vectors $z_k = Lv_k$ and $w_{\ell,k} = Lf_{\ell,k}$, which together with the recursive computation of these new vectors is described in the following proposition.

PROPOSITION 4.3. [illegible] $\dim\mathcal{K}_{j+1}(A, r_0) = j+1$ [illegible]

$$w_{\ell,k} = w_{\ell,k-1} + v_k^*f_\ell z_k, \quad 0 < k \leq j, \tag{4.14}$$

$$z_{k+1} = -\frac{1}{t_{k+1,k}}\left(v_k + t_{k,k}z_k + t_{k-1,k}z_{k-1} + \sum_{\ell=1}^{s} g_\ell^*v_k w_{\ell,k}\right), \quad 1 < k \leq j, \tag{4.15}$$

[illegible]

$$w_{\ell,0} = 0, \qquad z_1 = \frac{x_0}{\gamma_0}, \qquad z_2 = -\frac{1}{t_{2,1}}(v_1 + t_{1,1}^*z_1). \tag{4.16}$$

[illegible] $0 < k \leq j$ [illegible]

$$x_k = s_k^2x_{k-1} + \gamma_k c_k^*z_{k+1}. \tag{4.17}$$

. Consider the QR-factorization

$$[r_0, Ar_0, \ldots, A^j r_0] = V_{j+1} S_{j+1},$$

i.e., $S_{j+1} \in \mathbb{R}^{(j+1)\times(j+1)}$ is upper triangular and invertible by assumption on j. The projector

$$P = V_{j+1} S_{j+1} (I_{j+1} - e_1 e_1^*) S_{j+1}^{-1} V_{j+1}^*$$

satisfies

$$P\left(\sum_{k=0}^{j} \alpha_k A^k r_0\right) = \sum_{k=1}^{j} \alpha_k A^k r_0, \qquad (I-P)\left(\sum_{k=0}^{j} \alpha_k A^k r_0\right) = \alpha_0 r_0.$$

As a consequence, defining the linear operator L by

$$Lv = \frac{r_0^*(I-P)v}{r_0^* r_0} x_0 - A^{-1} P v,$$

we get for any $u \in \mathcal{K}_j(A, r_0)$ that

$$L(b - A(x_0 + u)) = x_0 + u.$$

In particular, we obtain $Lr_k = x_k$ for $0 \le k \le j$, as claimed above. In order to see that the vectors z_{k+1} and $w_{\ell,k}$ defined by

$$z_{k+1} = Lv_{k+1}, \qquad w_{\ell,k} = Lf_{\ell,k}, \qquad 0 \le k \le j,$$

can be computed via the relations (4.14)–(4.16), we argue by recurrence on k: applying L to the relations $f_{\ell,0} = 0$, $v_1 = r_0/\gamma_0 = (b - Ax_0)/\gamma_0$, and $Av_1 = h_{2,1}v_2 + h_{1,1}v_1 = t_{2,1}v_2 + t_{1,1}^* v_1$, respectively, leads to the initializations (4.16). Similarly, for (4.14) we apply L to (2.8), and (4.15) is obtained by applying L both to (2.12) and (2.13), where we notice that $L(Av_k) = -v_k$. Finally, the recurrence relation (4.17) for the GMRES iterates follows by applying L to (4.10). ∎

Let $W_j = [w_{1,j}, w_{2,j}, \ldots, w_{s,j}] \in \mathbb{R}^{n\times s}$. Then (4.14) can be written as

$$W_j = W_{j-1} + z_j e_j^* \hat{F}_j, \qquad W_1 = \frac{x_0}{\gamma_0}\hat{F}_1,$$

and

$$\sum_{\ell=1}^{s} g_\ell^* v_j \, w_{\ell,j} = W_j \hat{G}_j^* e_j.$$

Algorithm 4.4 below works with the matrices W_j rather than with their columns individually. The notation of Algorithm 4.4 follows that of Algorithm 3.2. In particular, the matrices W_j are stored in W.

ALGORITHM 4.4.

$A \in \mathbb{R}^{n\times n}$, $F = [f_1, f_2, \ldots, f_s], G = [g_1, g_2, \ldots, g_s] \in \mathbb{R}^{n\times s}$, $b, x_0 \in \mathbb{R}^n$

$x_j \in \mathbb{R}^n$

%

1. $r_0 := b - Ax_0$ $\gamma_0 := \|r_0\|$
2. $v_1 := r_0/\gamma_0$ $z_1 := x_0/\gamma_0$

% $j = 1$
3. $\hat{F}_{1,:} := v_1^* F$, $\hat{G}_{1,:} := v_1^* G$
4. $p_1^* := \hat{F}_{1,:}$, $\tilde{F} := v_1 \hat{F}_{1,:}$, $W := x_0 \hat{F}_1 / \gamma_0$
5. $v' := Av_1 - \tilde{F}\hat{G}_{1,:}^*$
6. $t_{1,1} := v_1^* v'$, $v' := v' - t_{1,1} v_1$
7. $t_{2,1} := \|v'\|$, $v_2 := v'/t_{2,1}$
8. $\tau_1 := t_{1,1}^*$
9. $c_1 := \tau_1/(|\tau_1|^2 + t_{2,1}^2)^{1/2}$, $s_1 := t_{2,1}/(|\tau_1|^2 + t_{2,1}^2)^{1/2}$, $\gamma_1 := -s_1 \gamma_0$
10. $z_2 := -(v_1 + t_{1,1}^* z_1)/t_{2,1}$, $x_1 := s_1^2 x_0 + \gamma_1 c_1^* z_2$
% $j > 1$
11. for $j = 2, 3, \ldots$ [illegible]
12. $\hat{F}_{j,:} := v_j^* F$, $\hat{G}_{j,:} := v_j^* G$
13. $p_j^* := -s_{j-1} p_{j-1}^* + c_{j-1} \hat{F}_{j,:}$, $\tilde{F} := \tilde{F} + v_j \hat{F}_{j,:}$, $W := W + z_j \hat{F}_{j,:}$
14. $v' := Av_j - \tilde{F}\hat{G}_{j,:}^*$
15. $t_{j-1,j} := v_{j-1}^* v'$, $v' := v' - t_{j-1,j} v_{j-1}$
16. $t_{j,j} := v_j^* v'$, $v' := v' - t_{j,j} v_j$, $t_{j+1,j} := \|v'\|$, $v_{j+1} := v'/t_{j+1,j}$
17. $\tau_j := c_{j-1} t_{j,j} - s_{j-1} c_{j-2} t_{j-1,j} + p_j^* \hat{G}_{j,:}^*$
18. $c_j := \tau_j/(|\tau_j|^2 + t_{j+1,j}^2)^{1/2}$, $s_j := t_{j+1,j}/(|\tau_j|^2 + t_{j+1,j}^2)^{1/2}$, $\gamma_j := -s_j \gamma_{j-1}$
19. $z_{j+1} := -(v_j + t_{j,j} z_j + t_{j-1,j} z_{j-1} + W\hat{G}_{j,:}^*)/t_{j+1,j}$
20. $x_j := s_j^2 x_{j-1} + \gamma_j c_j^* z_{j+1}$
21. [illegible]

Iterations with GMRES are typically terminated when the residual vector (4.8) is sufficiently small, e.g., when

$$\|r_j\|/\|r_0\| \leq \varepsilon \tag{4.18}$$

for a user-specified value of ε. This stopping criterion can be easily evaluated, since Algorithm 4.4 computes γ_j, with $|\gamma_j| = \|r_j\|$, in each iteration. If the residual vectors are desired in each iteration, then one can add the relation (4.10) on line 10 (for $j = 1$) and on line 20 of the algorithm. Stopping criteria of the type (4.18) have recently been discussed by Paige et al. [13, 14]. In particular, the initial vector x_0 should be chosen so that $\|r_0\| \leq \|b\|$ and preferably as the zero-vector.

In order to make the connection between Algorithm 4.4 and the preceding discussion clearer, vectors are equipped with subscripts in the algorithm. However, only the most recently generated vectors p_j^* and x_j have to be stored simultaneously, and only the two most recently generated vectors v_j, v_{j-1} and z_j, z_{j-1} have to be stored at any given time. Only the jth rows of the matrices $\hat{F}$ and $\hat{G}$ have to be stored simultaneously. The matrices $\tilde{F}$ and W have to be stored and require $n \times s$ storage locations each. Moreover, representations of the matrices A, F, and G have to be stored. Ignoring the storage for the latter, the storage requirement for Algorithm 4.4 is bounded by $(2s+6)n + \mathcal{O}(sj)$ storage locations. The computational work per iteration is bounded independent of j; it is $\mathcal{O}(n)$ flops in addition to the arithmetic work required for the evaluation of Av_j. In the special case when $s = 0$, Algorithm 4.4 simplifies to a minimal residual method for the solution of linear systems of equations with a symmetric, possibly indefinite, matrix.

We conclude this section with a comment on FOM, an iterative method that is closely related to GMRES; see Saad [15, section 6.4]. The jth iterate determined by

FOM, $x_j^{\mathrm{FOM}} \in x_0 + \mathcal{K}_j(A, r_0)$, satisfies

$$b - A\, x_j^{\mathrm{FOM}} \perp \mathcal{K}_j(A, r_0).$$

From, e.g., [15, section 6.5.5] we know that the iterate x_j^{FOM} exists if and only if $|s_j| = \|r_{j-1}\|/\|r_j\| < 1$, which is equivalent to $c_j \neq 0$, where s_j and c_j are entries of the Givens rotation Ω_{j+1}; see (4.4). In this case, the relation between x_j^{FOM} and the GMRES iterate x_j is given by

$$x_j = s_j^2\, x_{j-1} + (1 - s_j^2)\, x_j^{\mathrm{FOM}};$$

see Saad [15, section 6.5.5] for details. A comparison with (4.10) shows that

$$x_j^{\mathrm{FOM}} = \frac{\gamma_j}{c_j} z_{j+1},$$

i.e., the vectors z_{j+1} are FOM iterates up to normalization.

5. Computed examples. Linear systems of equations (1.2) with matrices of the form

$$A = \begin{bmatrix} A_{1,1} & A_{1,2} \\ A_{2,1} & A_{2,2} \end{bmatrix} \in \mathbb{R}^{n\times n},$$

with a symmetric leading principal submatrix $A_{1,1} \in \mathbb{R}^{(n-\ell)\times(n-\ell)}$ and $A_{1,2}, A_{2,1}^* \in \mathbb{R}^{(n-\ell)\times\ell}$, $A_{2,2} \in \mathbb{R}^{\ell\times\ell}$, arise in many applications. Example 5.1 outlines a path following method that gives rise to matrices of this kind, and Examples 5.2–5.4 discuss the solution of integral equations. All computations were carried out in MATLAB with machine epsilon about $2 \cdot 10^{-16}$.

5.1. We are interested in computing the solution u of the nonlinear boundary value problem

$$-\Delta u - \lambda \exp(u) = 0 \quad \text{in} \quad S, \tag{5.1}$$

$$u = 0 \quad \text{on} \quad \partial S \tag{5.2}$$

as a function of the parameter λ, where Δ denotes the Laplacian, S the unit square, and ∂S its boundary. This problem is known as the Bratu problem and is a common test problem for path following methods. We discretize S by a uniform grid with $(\ell-1)^2$ interior grid points (s_k, t_k), where $t_k = s_k = k/\ell$, $1 \leq k < \ell$, and approximate the Laplacian by the standard five-point stencil. This yields a system of $(\ell-1)^2$ nonlinear equations

$$G(w, \lambda) = 0, \tag{5.3}$$

where the entries of the vector $w \in \mathbb{R}^{(\ell-1)^2}$ are approximations of the function u at the grid points. Numerous techniques for computing $w(\lambda)$ as λ is increased from, say, λ_0 to λ_1 are available; see, e.g., [1, 5, 6] and the references therein.

The matrix $\partial G/\partial w$ is singular at turning points (w, λ) of the path $\lambda \to (w(\lambda), \lambda)$, and one often introduces an auxiliary parameter η in order to be able to traverse these points. Thus, let $\lambda = \lambda(\eta)$ and assume that $w(\lambda(\hat{\eta}))$ is available, where

$\lambda_0 \leq \lambda(\hat{\eta}) \leq \lambda_1$. We would like to determine $\lambda(\hat{\eta} + \delta\eta)$ and $w(\lambda(\hat{\eta} + \delta\eta))$. Introduce the function

$$L(w, \lambda, \delta\eta) = d^*(w - w(\lambda(\hat{\eta}))) + c(\lambda - \lambda(\hat{\eta})) - \delta\eta \tag{5.4}$$

for some $d \in \mathbb{R}^{(\ell-1)^2}$ and $c \in \mathbb{R}$. The choice of d and c will be commented on below. Let $(w^{(j)}, \lambda^{(j)})$ be an available approximation of the solution of

$$\begin{aligned} G(w, \lambda) &= 0, \\ L(w, \lambda, \delta\eta) &= 0. \end{aligned} \tag{5.5}$$

Newton's method can be used to determine an improved approximation

$$(w^{(j+1)}, \lambda^{(j+1)}) = (w^{(j)} + \delta w, \lambda^{(j)} + \delta\lambda)$$

of the solution $(w(\lambda(\hat{\eta} + \delta\eta)), \lambda(\hat{\eta} + \delta\eta))$ of (5.5), where δw and $\delta\lambda$ satisfy

$$\begin{bmatrix} G_w^{(j)} & G_\lambda^{(j)} \\ d^* & c \end{bmatrix} \begin{bmatrix} \delta w \\ \delta\lambda \end{bmatrix} = \begin{bmatrix} -G^{(j)} \\ -L^{(j)} \end{bmatrix}, \tag{5.6}$$

with

$$\begin{aligned} G^{(j)} &= G(w^{(j)}, \lambda^{(j)}), & L^{(j)} &= L(w^{(j)}, \lambda^{(j)}, \delta\eta), \\ G_w^{(j)} &= \tfrac{\partial}{\partial w} G(w^{(j)}, \lambda^{(j)}), & G_\lambda^{(j)} &= \tfrac{\partial}{\partial \lambda} G(w^{(j)}, \lambda^{(j)}). \end{aligned}$$

The vector d should be chosen to make the matrix in (5.6) nonsingular even when G_w is singular. This allows simple turning points to be traversed. The parameter η is sometimes chosen to be arc length or pseudo–arc length of the curve $\lambda \to (w(\lambda), \lambda)$. The quantities d, c in (5.4) then may be defined by, e.g., $d = dw(\lambda(\hat{\eta}))/d\eta$, $c = d\lambda(\hat{\eta})/d\eta$.

To illustrate the performance of Algorithm 4.4, we discretize (5.1) on a uniform grid with $\ell = 26$. The matrix in (5.6) then is of size 626×626. We choose $\lambda = \exp(\eta) - 1$ and seek to determine the solution of (5.5) with $\delta\eta = 10$, starting with $w^{(0)} = 0$ and $\lambda^{(0)} = 0$, i.e., $x_0 = 0$ in Algorithm 4.4. Then $G_w^{(0)}$ is the negative discrete Laplacian, $G_\lambda^{(0)} = -[1, 1, \ldots, 1]^*$, $G^{(0)} = 0$, and $L^{(0)} = -\delta\eta$. We let $c = 1$ and, since $\partial w/\partial\eta$ is the largest at the center of the unit square, we choose $d = e_{(\ell-1)^2/2}$. This defines the matrix in (5.6), which we will refer to as A. It has skew-symmetric part of rank $s = 2$; cf. (1.1). We choose

$$f_1 = [1, 1, \ldots, 1, 0]^* - e_{(\ell-1)^2/2}, \quad f_2 = e_{(\ell-1)^2+1}, \quad g_1 = f_2, \quad g_2 = -f_1$$

in the computations.

Algorithm 4.4 reduces the residual error from 10 ($= |\delta\eta|$) to $1.84 \cdot 10^{-7}$ in 50 iterations. In the present example, the numerical values of $\|b - Ax_{50}\|$, $\|r_{50}\|$ as computed by (4.10), and $|\gamma_{50}|$ agree to at least five significant digits. Solution of (5.6) by a direct method gave x_{direct} with $\|x_{\text{direct}} - x_{50}\| = 1.42 \cdot 10^{-10}$. Let x'_{50} denote the approximate solution determined by standard GMRES,[1] and let $r'_{50} = b - Ax'_{50}$. Then $\|r'_{50}\| = 1.84 \cdot 10^{-7}$, $\|x_{\text{direct}} - x'_{50}\| = 1.42 \cdot 10^{-10}$, and $\|x'_{50} - x_{50}\| = 4.90 \cdot 10^{-12}$.

[1]Standard GMRES refers to the commonly used GMRES implementation based on the Arnoldi process with orthogonalization of the Arnoldi vectors by the modified Gram–Schmidt method.

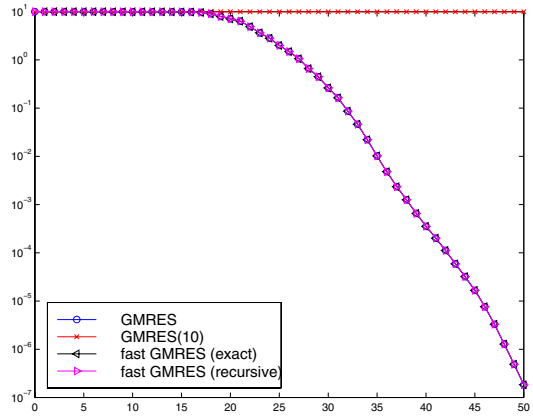

FIG. 5.1. *Residual norms for Algorithm* 4.4 *applied to the data of Example* 5.1. *For comparison, we show both the norm of the exact residuals* $\|b - Ax_k\|$ *(symbol* $\triangleleft$*) and the recursively computed residual norms* $|\gamma_k|$ *(symbol* $\triangleright$*), as well as the norm of the residuals* r'_k *(symbol* $\circ$*) obtained by standard GMRES, which are all of the same size. In contrast, restarted GMRES*(10) *(symbol* $\times$*) fails to converge.*

Figure 5.1 shows the residual errors for standard GMRES and Algorithm 4.4. Let x_k denote the iterates computed by Algorithm 4.4 and let γ_k be the recursively evaluated quantities in the algorithm, such that (in exact arithmetic) $|\gamma_k| = \|b - Ax_k\|$. Figure 5.1 displays $|\gamma_k|$, referred to as [illegible], as well as the evaluated norms $\|b - Ax_k\|$, referred to as [illegible], for $0 \le k \le 50$. The $|\gamma_k|$ are seen to be accurate approximations of $\|b - Ax_k\|$. Moreover, the latter quantities are of the same size as the residual norms produced by standard GMRES.

Convergence is slow during the first 15 iterations and can be sped up by the use of a preconditioner. Note that a symmetric positive definite preconditioner would not change the rank of the skew-symmetric part.

Algorithm 4.4 requires about the same computer storage as GMRES restarted every $2s+6$ iterations. The latter method is referred to as restarted GMRES$(2s+6)$. We also compare Algorithm 4.4 to restarted GMRES$(2s+6)$. For the present example restarted GMRES$(2s+6)$ with $s = 2$ fails to converge; see Figure 5.1.

Both standard and restarted GMRES are implemented using modified Gram–Schmidt orthogonalization of the Arnoldi vectors. Algorithm 4.4 explicitly orthogonalizes each new Arnoldi vector v_{k+1} only against the two most recently generated vectors, v_k and v_{k-1}. Therefore, the orthogonality properties of the matrices $V_k = [v_1, v_2, \ldots, v_k]$ determined by standard GMRES and Algorithm 4.4 in finite precision arithmetic may differ. Figure 5.2 displays the quantities $\|I_k - V_k^* V_k\|^2$, for $1 \le k \le 50$, for matrices V_k determined by standard GMRES and Algorithm 4.4. In this example, the columns of the matrices V_k determined by Algorithm 4.4 are closer to orthonormal than those determined by standard GMRES.

[illegible] 5.2. The integral equation

$$\gamma\, u(\alpha) + \frac{1}{\pi} \int_{-1}^{1} \frac{d}{d^2 + (\alpha - \beta)^2} u(\beta) d\beta = f(\alpha), \qquad -1 \le \alpha \le 1, \tag{5.7}$$

with $\gamma = 1$ and d a positive constant, is known as Love's integral equation. It arises in electrostatics; see, e.g., Baker [3, p. 258]. Let $f(\alpha) = (1 + \alpha)^{1/2}$, let $d = 1/10$, and discretize (5.7) by a Nyström method based on the composite trapezoidal rule with

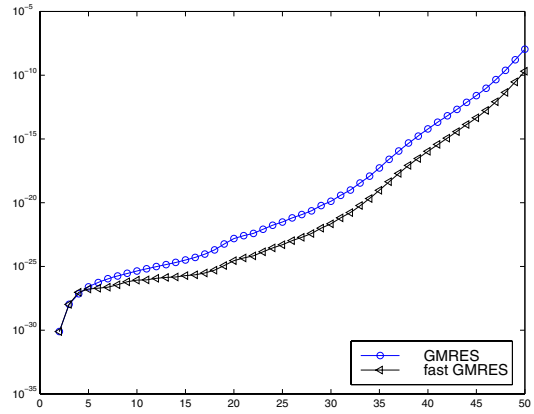

FIG. 5.2. *Orthonormality of the Arnoldi vectors for Example* 5.1: $\|I_k - V_k^* V_k\|^2$ *as a function of* k *for Algorithm* 4.4 *(symbol* $\triangleleft$*) and standard GMRES (symbol* $\circ$*).*

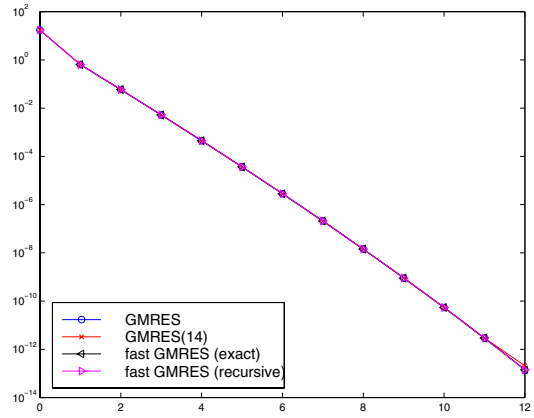

FIG. 5.3. *Residual norms for Algorithm* 4.4 *applied to the data of Example* 5.2. *For comparison, we show both the norm of the exact residuals* $\|b - Ax_k\|$ *(symbol* $\triangleleft$*) and the recursive residual norms* $|\gamma_k|$ *(symbol* $\triangleright$*), which are of the same size. The norm of the residuals* r'_k *obtained by standard GMRES (symbol* $\circ$*) and by restarted GMRES*(14) *(symbol* $\times$*) are also displayed.*

equidistant nodes $\alpha_k = \beta_k = (k-1)/(n-1)$, $1 \le k \le n$, $n = 300$. This gives a linear system of equations with a matrix of the form

$$A = \gamma I + KD, \tag{5.8}$$

where K is a symmetric Toeplitz matrix and $D = \mathrm{diag}[1/2, 1, 1, \ldots, 1, 1/2]$. The skew-symmetric part of A therefore is of rank $s = 4$. The memory requirement of Algorithm 4.4 is about the same as for restarted GMRES(14).

Figure 5.3 shows the residual errors for Algorithm 4.4 as given by $|\gamma_k|$ and $\|b - Ax_k\|$ for $0 \le k \le 12$, as well as the corresponding residual errors for standard GMRES. The initial approximate solution is $x_0 = 0$. The iterations are terminated as soon as the residual error for standard GMRES is of norm smaller than $1 \cdot 10^{-12}$. Convergence is rapid both for Algorithm 4.4 and standard GMRES, and the methods produce iterates with residual errors of nearly the same size.

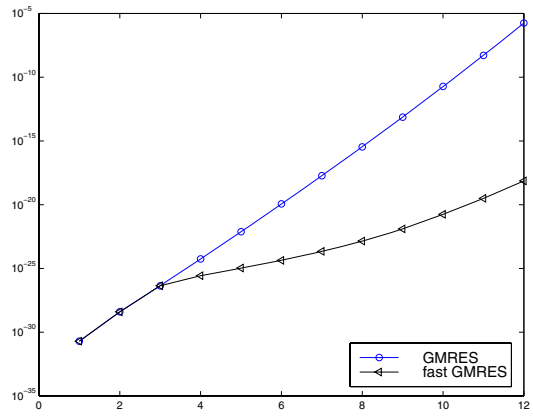

FIG. 5.4. *Orthonormality of the Arnoldi vectors for Example* 5.2: $\|I_k - V_k^* V_k\|^2$ *as a function of* k *for Algorithm* 4.4 *(symbol* $\triangleleft$*) and standard GMRES (symbol* $\circ$*).*

Figure 5.4 is analogous to Figure 5.2 and shows that the Arnoldi vectors generated by Algorithm 4.4 are slightly closer to being orthonormal than the Arnoldi vectors determined by standard GMRES.

The nonsymmetric matrix KD in (5.8) is the discretization of a compact integral operator. It has many eigenvalues close to the origin. Therefore the matrix (5.8) has many eigenvalues close to γ, which has the value one in Example 5.2. In the following examples, we will reduce γ. This reduces the rate of convergence and illustrates that, differently from Examples 5.1 and 5.2, the Arnoldi vectors determined by Algorithm 4.4 may be less close to orthonormal than the Arnoldi vectors determined by the Arnoldi process in the standard GMRES implementation.

EXAMPLE 5.3. We modify the integral equation (5.7) of Example 5.2 by setting $\gamma = 0.1$. This change of γ reduces the rate of convergence. Discretization is carried out in the same manner as in Example 5.2. We use the same initial approximate solution and stopping criterion as in Example 5.2.

Figure 5.5 displays the norm of the residual errors for Algorithm 4.4, standard GMRES, and restarted GMRES(14) and is analogous to Figure 5.3. Figure 5.5 shows the residual errors r_{21} and r_{22} determined by Algorithm 4.4 to be of slightly larger norm than the corresponding residual errors determined by standard GMRES. The cause for this can be found in Figure 5.6(a), which shows the quantities $\|I_k - V_k^* V_k\|^2$ for $1 \leq k \leq 22$. The figure shows the Arnoldi vectors computed by Algorithm 4.4 to be slightly less close to orthonormal than are the Arnoldi vectors determined by standard GMRES.

Figure 5.6(b) displays $\|I_{m+1} - V_{m-k:k}^* V_{m-k:k}\|^2$ as a function of k for $m = 1, 2, \ldots, 5$, thus measuring the orthonormality between the last $m+1$ Arnoldi vectors computed by Algorithm 4.4. Orthonormality is lost fairly rapidly for $m \geq 3$.

EXAMPLE 5.4. We modify the integral equation (5.7) of Examples 5.2 and 5.3 by setting $\gamma = 0.01$. This change of γ reduces the rate of convergence compared with Example 5.3. Discretization is carried out in the same manner as in Examples 5.2 and 5.3, and we use the same initial approximate solution and stopping criterion as in those examples.

Figure 5.7 displays the norm of the residual errors for Algorithm 4.4, standard GMRES, and restarted GMRES(14) and is analogous to Figure 5.5. Figure 5.7 shows

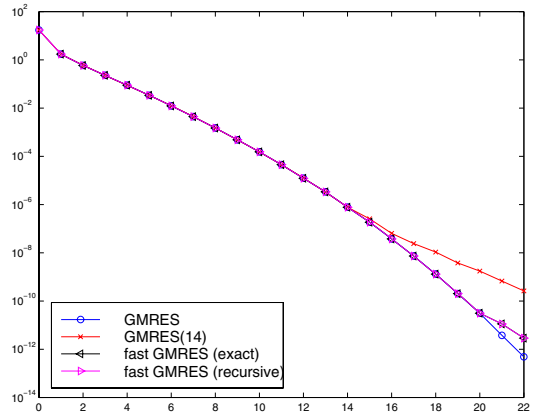

FIG. 5.5. *Residual norms for Algorithm* 4.4 *applied to the data of Example* 5.3. *For comparison, we display both the norm of the exact residuals* $\|b - Ax_k\|$ *(symbol* $\triangleleft$*) and the recursive residual norms* $|\gamma_k|$ *(symbol* $\triangleright$*), which are of the same size, and slightly smaller than those obtained for restarted GMRES*(14) *(symbol* $\times$*). The norms of the residuals* r'_k *determined by standard GMRES (symbol* $\circ$*) are somewhat smaller for* $k \geq 21$.

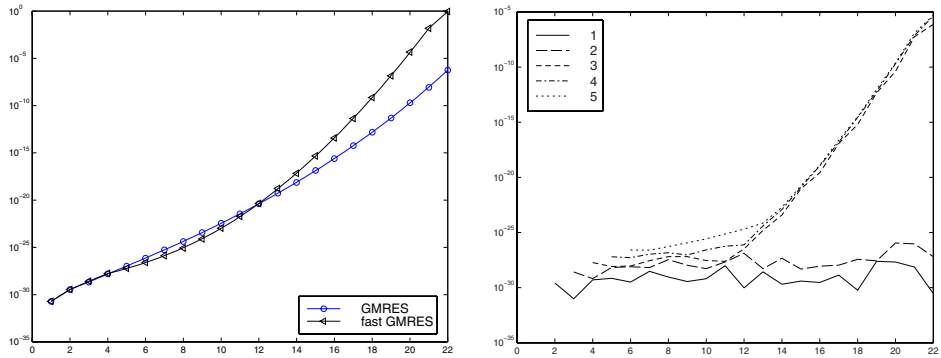

FIG. 5.6. *Orthonormality of the Arnoldi vectors for Example* 5.3: (a) $\|I_k - V_k^* V_k\|^2$ *as a function of* k *for Algorithm* 4.4 *(symbol* $\triangleleft$*) and standard GMRES (symbol* $\circ$*).* (b) *From bottom to top,* $\|I_{m+1} - V_{m-k:k}^* V_{m-k:k}\|^2$ *as a function of* k *for* $m = 1, 2, \ldots, 5$ *for Algorithm* 4.4.

Algorithm 4.4 to reduce the norm of the residual error slower than standard GMRES, but faster than restarted GMRES(14).

The reason for the slower convergence of Algorithm 4.4 is the loss of orthonormality of the Arnoldi vectors generated by the algorithm. The latter is illustrated by Figures 5.8.

Examples 5.3 and 5.4 illustrate that the iterates determined by Algorithm 4.4 may converge slower to the solution than the iterates determined by standard GMRES. A reason for this appears to be that the Arnoldi vectors generated by Algorithm 4.4 may be far from orthonormal; see Example 5.4. The loss of orthogonality and its effect on the convergence of GMRES has received considerable attention in the literature; see, e.g., [8, 10, 13, 14, 16, 17]. For instance, Simoncini and Szyld [16] recently pointed out that loss of orthogonality does not prevent a near-optimal rate of convergence,

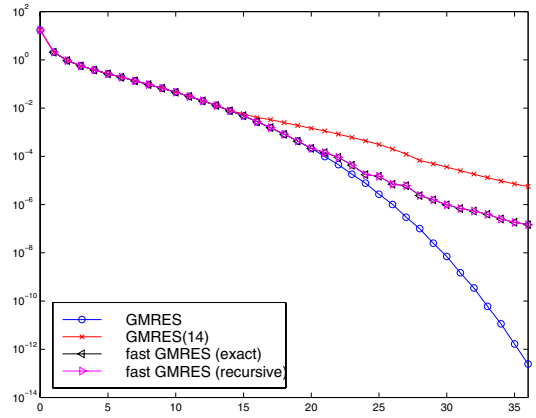

FIG. 5.7. *Residual norms for Algorithm* 4.4 *applied to the data of Example* 5.3. *For comparison, we show both the norm of the exact residuals* $\|b - Ax_k\|$ *(symbol* $\triangleleft$*) and the recursive residual norms* $|\gamma_k|$ *(symbol* $\triangleright$*), which are of the same size, and smaller than those obtained by restarted GMRES*(14) *(symbol* $\times$*). The norms of the residuals* r'_k *obtained by the standard GMRES (symbol* $\circ$*) are much smaller for* $k \geq 30$.

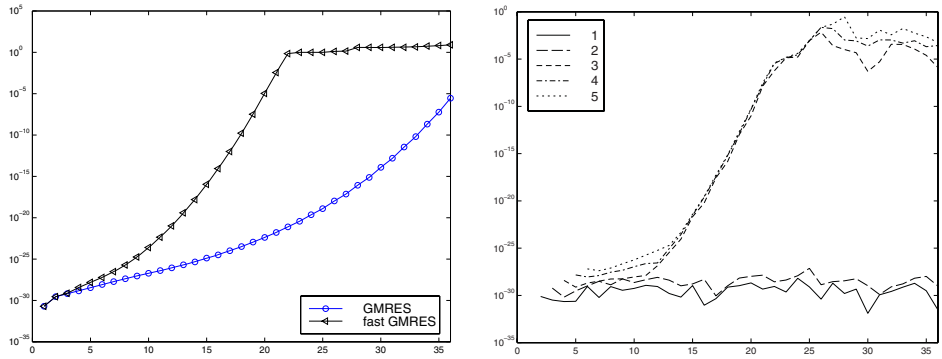

FIG. 5.8. *Orthonormality of the Arnoldi vectors for Example* 5.3: (a) $\|I_k - V_k^* V_k\|^2$ *as a function of* k *for Algorithm* 4.4 *(symbol* $\triangleleft$*) and standard GMRES (symbol* $\circ$*).* (b) *From bottom to top,* $\|I_{m+1} - V_{m-k:k}^* V_{m-k:k}\|^2$ *as a function of* k *for* $m = 1, 2, \ldots, 5$ *for Algorithm* 4.4.

provided that each new Arnoldi vector generated has a sufficiently large angle with the space spanned by the already available Arnoldi vectors. Example 5.4 suggests that the loss of orthogonality also may reduce this angle.

6. Conclusion. Linear systems of equations with a matrix that satisfies (1.1) with a small value of s arise in a variety of applications. For many, but not all, linear systems of equations of this kind, Algorithm 4.4 converges like standard GMRES, but requires less computer storage and arithmetic work. In all our experiments, Algorithm 4.4 converges faster than restarted GMRES($2s+6$), which demands roughly the same amount of computer storage as Algorithm 4.4.

Acknowledgment. We would like to thank a referee for comments.

GRAPH CLUSTERING VIA A DISCRETE UNCOUPLING PROCESS*

STIJN VAN DONGEN†

Abstract. A discrete uncoupling process for finite spaces is introduced, called the *Markov Cluster Process* or the *MCL process*. The process is the engine for the graph clustering algorithm called the *MCL algorithm*. The *MCL process* takes a stochastic matrix as input, and then alternates expansion and inflation, each step defining a stochastic matrix in terms of the previous one. Expansion corresponds with taking the kth power of a stochastic matrix, where $k \in \mathbb{N}$. Inflation corresponds with a parametrized operator Γ_r, $r \geq 0$, that maps the set of (column) stochastic matrices onto itself. The image $\Gamma_r M$ is obtained by raising each entry in M to the rth power and rescaling each column to have sum 1 again. In practice the process converges very fast towards a limit that is invariant under both matrix multiplication and inflation, with quadratic convergence around the limit points. The heuristic behind the process is its expected behavior for (Markov) graphs possessing cluster structure. The process is typically applied to the matrix of random walks on a given graph G, and the connected components of (the graph associated with) the process limit generically allow a clustering interpretation of G. The limit is in general extremely sparse and iterands are sparse in a weighted sense, implying that the *MCL algorithm* is very fast and highly scalable. Several mathematical properties of the *MCL process* are established. Most notably, the process (and algorithm) iterands posses structural properties generalizing the mapping from process limits onto clusterings. The inflation operator Γ_r maps the class of matrices that are diagonally similar to a symmetric matrix onto itself. The phrase *diagonally positive semi-definite* (*dpsd*) is used for matrices that are diagonally similar to a positive semi-definite matrix. For $r \in \mathbb{N}$ and for M a stochastic *dpsd* matrix, the image $\Gamma_r M$ is again *dpsd*. Determinantal inequalities satisfied by a *dpsd* matrix M imply a natural ordering among the diagonal elements of M, generalizing the mapping of process limits onto clusterings. The spectrum of $\Gamma_\infty M$ is of the form $\{0^{n-k}, 1^k\}$, where k is the number of endclasses of the ordering associated with M, and n is the dimension of M. This attests to the uncoupling effect of the inflation operator.

Key words. stochastic uncoupling, graph clustering, Markov graph, Markov matrix, diagonal similarity, positive semi-definite matrices, circulant matrices

1. Introduction.

The subject of study is a parametrized algebraic process called the Markov Cluster Process (, process), which is the engine of a cluster algorithm for graphs, accordingly named the , algorithm. The algorithm is nothing more than a shell in which parameters are set, the , process is computed, and the result is interpreted. The process itself is defined on the space of stochastic matrices. Given a graph G, the algorithm employs the process by applying it to the matrix of random walks on G.

The , algorithm [11, 12] was first applied in the field of protein family detection [18]. In this setting, proteins are nodes in a graph where the edge weights are derived from BLAST (Basic Local Alignment Search Tool) scores between protein amino-acid sequences. Following [18], the algorithm has been widely applied in bioinformatics, in a diversity of settings and applications.

A number of publications have used , for large scale single species or cross-species protein and gene family analysis, e.g., [15, 16, 28, 38, 52, 60]. Other protein-related , applications in bioinformatics are large scale sequence space analysis [19, 37], hybrid , /single-link clustering [29], orthologous groups [41], kinase proteins [24], secreted proteins [7], eye proteins [39], mobile genetic elements [40], protein interaction networks [5, 54], and protein function determination [61]. Additionally, , has been applied in corpus linguistics [13, 14, 25], content-based image retrieval [32], peer-to-peer network analysis [57], and social network analysis [46].

Factors aiding the adoption of the , algorithm include (a) It generates well-balanced flat (nonhierarchic) clusterings. (b) It is intrinsically a bootstrapping method. Seeding information cannot and need not be supplied, especially not the number of clusters. (c) It has a natural parameter (,) affecting cluster granularity. (d) It is amenable to sparse graph/matrix implementation techniques, implying good scalability. (e) Mathematical results tie , process iterands, the cluster interpretation, inflation, and the number of clusters together.

The focus of the present work is largely on (e), the mathematical results describing in a qualitative manner how the , process exposes cluster structure in graphs. Issues of scaling and implementation are discussed, and in two examples the , process and its clustering characteristics are visualized. Relationships with other mathematical frameworks are established, and several conjectures are made. Comparison with other clustering approaches fall outside the scope of this exposition. The field of bioinformatics is very active in this respect, and the reader is referred to the references given above.

The , process is simple to compute and lends itself to drastic scaling by a regime of pruning, as the limits are in general extremely sparse and the iterands sparse in a weighted sense. It is convenient to distinguish between the process and the algorithm, in order to separate mathematical issues from such issues as implementation and scaling (i.e., computing an approximated process in order to gain speed). Section 6 contains a succinct discussion of how an , implementation can efficiently compute a slightly perturbed , process.

The structure of the article is as follows. The clustering heuristic is briefly introduced in the next section. The , process is fully described and the interpretation of a process limit as a clustering of the input graph is given. This is sufficient to define the , algorithm. A summary is given of some issues concerning convergence and the interpretation of limits as clusterings. Several matrix excerpts from one particular process are shown in section 3, including its limit. In section 4 various lemmas and theorems concerning , iterands are given. The process consists of alternation of two operators, expansion, and inflation. Both operators preserve the class of stochastic matrices that are diagonally similar to a symmetric matrix. These matrices are called . Several of their properties are listed. If a matrix is diagonally similar to a positive semi-definite matrix, then it is called a , abbreviated . Under certain weak conditions many iterands are guaranteed to be . Section 5 introduces structure theory for matrices. Such a matrix possesses structural properties inducing a canonical mapping from the matrix onto a directed acyclic graph, generalizing the mapping from , limits onto overlapping clusterings. The structure theory also yields a qualitative statement on the working of the inflation operator in terms of the matrix spectrum. Implementation is discussed in section 6, and conclusions, further research, and related research make up the last section.

2. Preliminaries. The process consists of alternation of matrix expansion and matrix inflation, where expansion means taking the power of a matrix using the usual matrix product, and inflation (denoted Γ_r) means taking the Hadamard power with coefficient r of a stochastic matrix and subsequently scaling its columns to have sum 1 again. The clustering heuristic associated with the process is that a dense region in a graph corresponds with a node set S for which pairs of elements in S have the property that there are relatively many higher length paths completely contained in S itself. By matrix expansion the higher step transition probabilities are obtained; by matrix inflation large probabilities are promoted, and small probabilities are demoted. It is to be expected that probabilities that correspond with edges connecting different dense regions will suffer the most from the process of alternating expansion and inflation. Indeed, iteration of the two operators leads to a limit that is meaningful considering the original heuristic.

The inflation operator Γ_r is defined for arbitrary nonnegative matrices, in a columnwise manner. This implies that column stochastic matrices will be used rather than row stochastic matrices, which is merely a matter of preference and convention. There are no restrictions on the matrix dimensions to fit a square matrix, because this allows Γ_r to act on both matrices and vectors. There is no restriction that the input matrices be stochastic, since it is not strictly necessary, and the extended applicability is sometimes useful. Following the terminology used in [8] and [27], a nonnegative matrix is called if all its columns have at least one nonzero entry. The next definition prepares for the definition of the process.

DEFINITION 2.1. tth Exp_t $\mathrm{Exp}_t A = A^t$

This definition is put in such general terms because the class of dpsd matrices (to be introduced later) allows the introduction of fractional matrix powers in a well-defined way.

DEFINITION 2.2. r $M \in \mathbb{R}_{\geq 0}{}^{m \times n}$ M Γ_r

$$(\Gamma_r M)_{pq} \;=\; (M_{pq})^r \,/\, \sum_{i=1}^{m} (M_{iq})^r.$$

In the setting of the process, positive values r have a sensible interpretation attached to them. Values of r between 0 and 1 increase the homogeneity of the argument probability vector (matrix), whereas values of r between 1 and ∞ increase the inhomogeneity. In both cases, the ordering of the probabilities is not disturbed. Negative values of r invert the ordering, which is not of apparent use. With $\otimes$ denoting the Kronecker product, the identities $\mathrm{Exp}_r(A \otimes B) = \mathrm{Exp}_r(A) \otimes \mathrm{Exp}_r(B)$ and $\mathrm{Exp}_r(\mathrm{Exp}_s(A)) = \mathrm{Exp}_{rs}(A)$ hold. Similarly, $\Gamma_r(A \otimes B) = \Gamma_r(A) \otimes \Gamma_r(B)$ and $\Gamma_r(\Gamma_s(A)) = \Gamma_{rs}(A)$ are true.

DEFINITION 2.3. Γ_∞ $\Gamma_\infty M = \lim_{r \to \infty} \Gamma_r M$

This definition is meaningful, and it is easy to derive the structure of $\Gamma_\infty M$. Each column q of $\Gamma_\infty M$ has k nonzero entries equal to $1/k$, (k depending on q), where k is the number of elements that equal $\max_p M_{pq}$, and the positions of the nonzero entries in $\Gamma_\infty M[1, \ldots, n|q]$ correspond with the positions of the maximal entries in $M[1, \ldots, n|q]$. Following [44], if x denotes a real vector of length n, then $x_{[1]} \geq x_{[2]} \geq \cdots \geq x_{[n]}$ denote the entries of x in decreasing order.

DEFINITION 2.4. [illegible] x, y [illegible] n [illegible] y [illegible] x [illegible] $x \prec y$,

$$\sum_{i=1}^{k} y_{[i]} \geq \sum_{i=1}^{k} x_{[i]} \quad k = 1, \ldots, n, \tag{2.1}$$

$$\sum_{i=1}^{n} y_{[i]} = \sum_{i=1}^{n} x_{[i]}. \tag{2.2}$$

LEMMA 2.5. [illegible] x [illegible] $r, s \in \mathbb{R}_{>0}$, $r < s$ [illegible] $\Gamma_r(x) \prec \Gamma_s(x)$

The proof of this lemma is straightforward [11].

DEFINITION 2.6. [illegible] process [illegible] M [illegible] M [illegible] M [illegible] $e_{(i)}$, $r_{(i)}$ [illegible] $e_i \in \mathbb{N}, e_i > 1$ [illegible] $r_i \in \mathbb{R}, r_i \geq 0$ [illegible]

$$(M, e_{(i)}, r_{(i)}). \tag{2.3}$$

[illegible] $(M, e_{(i)}, r_{(i)})$ [illegible] $M_{(i)}$ [illegible] $M_1 = M$, $M_{2i} = \mathrm{Exp}_{e_i}(M_{2i-1})$ [illegible] $M_{2i+1} = \Gamma_{r_i}(M_{2i})$, $i = 1, \ldots, \infty$

It must be stressed that the [illegible] process has no stochastic interpretation. The heuristic on which it is grounded uses stochastic terminology, but each [illegible] process $(M, e_{(i)}, r_{(i)})$ is (for varying M) really a rather complex dynamical system based on the alternation of two operators, expansion and inflation. The fact that expansion and inflation distribute over the Kronecker yields the following lemma.

LEMMA 2.7. [illegible]

Note. In practice, clustering with the [illegible] algorithm is best done with all expansion values e_i set to two. The reasoning behind this is pragmatic, as inflation can be used to control the mixing properties of the process, whereas expansion is computationally costly. Applying (columnwise) pruning in order to scale the process renders prolonged expansion virtually useless. Nevertheless it seems best to formulate the [illegible] process in the general terms of Definition 2.6, as this supplies a natural framework for questions and conjectures (section 7). The canonical mapping between graphs with nonnegative weights and nonnegative matrices is given below. In order to work with column stochastic matrices, an arbitrary choice is made to identify matrix columns with lists of neighbors.

DEFINITION 2.8. [illegible] associated graph [illegible] A [illegible] n [illegible] n [illegible] $\{1, \ldots, n\}$ [illegible] q, p [illegible] A_{pq}. $A_{pq} > 0$

The following theorem is preparatory to the mapping from nonnegative idempotent matrices to overlapping clusterings in Definition 2.11. Its proof is given in [11] and can also be derived from the decomposition of nonnegative idempotent matrices given in [2, p. 65]. It represents a very basic result on the structural properties of nonnegative idempotent matrices. Theorem 5.4 will show a more general structure to be present in [illegible] iterands, so that in the setting of the [illegible] process Theorem 2.9 becomes a limiting case of Theorem 5.4. It will be shown that for M stochastic [illegible] a finite power of the matrix $\Gamma_\infty(M)$ is idempotent (section 5).

THEOREM 2.9 (see Theorem 1 in [11, p. 18]). [illegible] M [illegible] n [illegible] G [illegible] s, t [illegible] G [illegible] $s \to t$ [illegible] G [illegible] s, t [illegible]

$s \to t \iff M_{ts} \neq 0$ [illegible] α, β, γ [illegible] G [illegible]

$$(\alpha \to \beta) \wedge (\beta \to \gamma) \implies \alpha \to \gamma, \tag{2.4}$$

$$(\alpha \to \alpha) \wedge (\alpha \to \beta) \implies \beta \to \alpha, \tag{2.5}$$

$$\alpha \to \beta \implies \beta \to \beta. \tag{2.6}$$

The theorem basically states that the graph associated with the matrix consists for one part of subgraphs that are complete, with all nodes having loops as well. The other part consists of nodes without loops that, given a complete subgraph, are connected either to all or to none of the nodes in that subgraph. It is convenient to introduce the notions of [illegible] and [illegible]. The second is a (maximal) complete subgraph, and the first is a node in such a subgraph.

Definition 2.10. [illegible] G [illegible] M [illegible] n [illegible] $1, \ldots, n$ [illegible] α [illegible] attractor [illegible] $M_{\alpha\alpha} \neq 0$ [illegible] α [illegible] α [illegible] attractor system

By Theorem 2.9, each attractor system in G induces a weighted subgraph in G that is complete. These subgraphs form the cores of the clustering associated with a (nonnegative idempotent) matrix M as stated below. An attractor system is simply extended with all the nodes that reach it.

Definition 2.11. [illegible] M [illegible] n [illegible] G [illegible] $V = \{1, \ldots, n\}$ [illegible] $E_i, i = 1, \ldots, k$ [illegible] G [illegible] $v \in V$ [illegible] $v \to E_i$ [illegible] $e \in E_i$ [illegible] $v \to e$ [illegible] $\mathcal{C} = \{C_1, \ldots, C_k\}$ [illegible] M [illegible]

$$C_i = E_i \cup \{v \in V \mid v \to E_i\}. \tag{2.7}$$

Theorem 2.9 implies that $v \to f$ for all $f \in E_i$.

The simplest example of a limit matrix inducing overlap is the matrix below, giving rise to the clustering $\{1, 3\}, \{2, 3\}$:

$$\begin{pmatrix} 1 & 0 & 1/2 \\ 0 & 1 & 1/2 \\ 0 & 0 & 0 \end{pmatrix}.$$

Combining the previous simple results, it is possible to rewrite each nonnegative column allowable idempotent matrix M as a form $P^T AP$, where P is a permutation matrix, and

$$A = \begin{pmatrix} B_1 & & & f_{11} & f_{12} & \ldots & f_{1l} \\ & \ddots & & \vdots & \vdots & \vdots & \vdots \\ & & B_k & f_{k1} & f_{k2} & \ldots & f_{kl} \\ 0 & \ldots & 0 & 0 & 0 & \ldots & 0 \end{pmatrix}.$$

Each matrix B_i is square, has rank one with all columns identical, contains only positive entries, and there are no other nonzero entries in the corresponding columns of A. Each matrix B_i corresponds with an attractor system, and k is the number of resulting clusters. Each f_{ij} is a column vector with the same number of (row) entries as B_i. Either all entries in f_{ij} are zero or they are all nonzero, and for each j at least one f_{ij} is nonzero. If the vector f_{ij} is nonzero, then it corresponds with a node

(identified by j) that is in the cluster defined by the attractor system corresponding with B_i. If f_{ij} is nonzero for more than one i, then those i determine clusters that overlap in the node identified by j.

In practice, cluster overlap is very rare. The phenomenon is inherently unstable, in the sense that applying the process to a perturbation of a limit matrix that induces overlap leads the process to converge to a limit no longer inducing overlap. A node previously in overlap will then be associated with just one of the multiple clusters it was associated with before [12]. All current evidence suggests that cluster overlap implies the existence of a graph automorphism of the graph associated with the input matrix, leaving the overlapping part invariant and mapping the overlapping clusters onto each other. In the simple example above, the automorphism would send $(1, 2, 3)$ to $(2, 1, 3)$.

The phenomenon of attractor systems of cardinality greater than one is also unstable in nature, but a small perturbation of a matrix limit having such a system will not change the associated clustering (assuming that the parameter r of Γ_r is bounded). The main reason for this is that if J is a stochastic matrix of rank one and E is a perturbation matrix (with zero column sums) of sufficiently small norm, then (restricting attention to a special case) $\mathrm{Exp}_2(\Gamma_2(J + E))$ is of the form $J' + E'$, with J' stochastic of rank one and the norm of E' being of order square the norm of E. Current evidence also suggests that attractor systems of cardinality greater than one imply the existence of a set of automorphisms by which each of the attractors (of one system) can be mapped to any of the other. An example is shown in Figure 3.2 for the graph in Figure 3.1. In this case, the automorphism would leave all nodes in place except for interchanging 9 and 11.

Assuming that e_i equals two and r_i is bounded eventually, it is true that the process converges quadratically in the neighborhood of matrices that (i) are , that is, invariant both under expansion (multiplication) and inflation, and (ii) have in each column one entry equal to 1 and all other entries equal to 0. This is straightforward (though tedious) to verify—proofs are given in [11]. The issue is somewhat clouded by the fact that the process may also converge towards a limit matrix that does not satisfy condition (ii). A small perturbation of such a matrix is amplified by the inflation operator so that the sequence of iterands departs from it.

The algorithm consists of three steps. First, given an arbitrary input graph G, loops are added resulting in a graph informally denoted as $G + \Delta$. Some remarks on the necessity of this step are made in the next section. How weights are chosen for the loops to be added is the responsibility of the algorithm. Subsequently, an process is applied to the matrix of random walks associated with $G + \Delta$. Third, the limit thus computed is interpreted as a clustering according to Definition 2.11. One can obtain a fast, robust, and well-scaling implementation of the algorithm at http://micans.org/mcl/, which allows a simple type of parametrization: The expansion values e_i are all set to 2 and the inflation values r_i can assume two values, changing once from the first to the second value.

In general the limit of an process is extremely sparse, as the inflation operator is a force driving towards sparse columns. iterands tend to be sparse in a weighted sense, and this supplies the means to scale the algorithm drastically by incorporating a regime of pruning into the process (cf. section 6).

The natural way to use the process for the purpose of clustering a graph is

by applying it to the matrix which represents the standard concept of a random walk on the graph, where loops have been added to the graph. This matrix is obtained as the incidence matrix multiplied by the diagonal matrix of inverse column (row) sums, so that the product is column (row) stochastic. If the graph is undirected, then the resulting stochastic matrix is diagonally similar to a symmetric matrix.

3. Examples.

Example I. In Figure 3.2, four excerpts are given of an , process. These are the input matrix M, the iterand $M_3 = \Gamma_2 M^2$, the iterand $M_5 = \Gamma_2(\Gamma_2 M^2 \cdot \Gamma_2 M^2)$, and the stable limit denoted L_M. The process consists entirely of alternation of Exp_2 and Γ_2. The graph H associated with M is depicted in Figure 3.1. Every node in H has a loop; these are all left out in the figure. Weights are omitted as well. Note that there exists a diagonal matrix d such that Md is symmetric. This implies that $d^{-1/2}Md^{1/2}$ is symmetric and thus the spectrum of M is real. Interpreting L_M according to Definition 2.11 yields the clustering $\{\{1,6,7,10\},\{2,3,5\},\{4,8,9,11,12\}\}$. It is necessary to add loops to the nodes before applying , in order to prevent a result reflecting the bipartite characteristics of H. Without adding loops, the resulting , process limit yields the clustering $\{\{1,5,10\},\{2,6,7\},\{3,4,8,9,11,12\}\}$. This is in line with the heuristic underlying the process: The probabilities that are initially boosted correspond with 2-step paths in H.

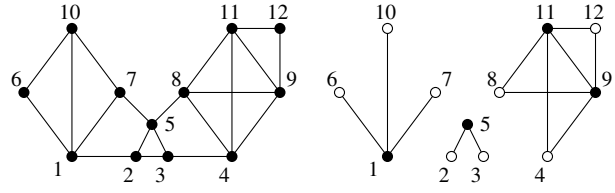

FIG. 3.1. *On the left a graph H, on the right the graph associated with the limit of an MCL process applied to H, loops added to H. Dark circles signify attractors; nodes* 9 *and* 11 *form an attractor system (refer to section* 5*). Compare with the matrix iterands and limit matrix in Figure* 3.2 *and with Figure* 3.3*, and see the discussion in Example* I.

Example II. Figure 3.3 depicts different iterands of an , process triggered by a geometric graph. This graph was first used in [21] as a test case for graph partitioning. It is shown in the upper left of the figure. Two nodes are connected if their distance is at most $\sqrt{8}$ Euclidean units. The edge weights were taken inversely proportional to the Manhattan distance, and loops were added to each node with a weight equal to the largest weight found in the edges in which it participates. The matrix of random walks on this graph was input to an , process in which the sequence $e_{(i)}$ assumed the constant 2 everywhere, and the sequence $r_{(i)}$ assumed the constant 1.3 everywhere.

The other graphs in Figure 3.3 represent a pictorial representation of four , iterands (stochastic matrices) and the limit in the lower right. The degree of shading of a bond between two nodes indicates the maximum value of the corresponding transition probabilities taken over the two directions. The darker the bond, the larger the maximum. The degree of shading of a node indicates the total sum of incoming transition probabilities. Thus, a dark bond between a white node and a black node indicates that the maximum transition probability is found in the direction of the black node, and that the probability attached to the reverse arc is negligible. The limit graph, depicted in the lower right, contains all necessary information needed for

Limit L_M resulting from iterating $(\Gamma_2 \circ \mathrm{Exp}_2)$ with initial matrix M, which is the matrix of random walks associated with the graph in Figure 3.1.

Entries marked "−−" are either zero because that is the exact value they assume (this is true for the first two matrices) or because the computed value fell below the machine precision.

FIG. 3.2. *Iteration of* $(\Gamma_2 \circ \mathrm{Exp}_2)$.

constructing the , -invariant limit matrix. Dark nodes in this graph are attractors.

The examples in Figures 3.3 and 3.2 indicate that the , process has remarkable convergence properties, regarding the structural properties of its iterands. Considering this evidence, to some extent an analogy is suggested with the normal Markov process.

Assuming that the associated graph of the input matrix M is strongly connected and contains at least one loop, it follows by Perron–Frobenius theory that 1 is the only eigenvalue of M of modulus 1 and that it is simple.

By considering the spectrum of the powers M^k it follows that the normal Markov process converges towards a rank-one idempotent matrix, having spectrum $\{0^{n-1}, 1\}$. In the example shown in Figure 3.2 the process also converges towards an idempotent limit. The multiplicity of its eigenvalue 1 is 3, however, equaling (of course) the number of strongly connected components in the associated graph of the limit. Section 4 will give some insight into the spectral phenomena that play a role in the , process by focusing attention onto two classes of stochastic matrices.

4. Properties of the inflation operator and stochastic *dpsd* matrices. At first sight the inflation operator seems hard to get a grasp on mathematically, though its behavior for vectors is well understood. Lemma 2.5 states that for a stochastic vector x and parameters $r, s \in \mathbb{R}_{>0}$, $r < s$, one has that $\Gamma_r(x) \prec \Gamma_s(x)$, where $\prec$ denotes the majorization relationship. This implies that the orbit $\Gamma_r x$, $(r > 0)$ is fairly well understood, since the limiting cases $\Gamma_r x$, $r \to \infty$ and $\Gamma_r x$, $r \downarrow 0$ are also easily derived. However, majorization results for vectors do not carry over to matrices in such a way that statements can be made about algebraic properties of two matrices subject to a columnwise majorization relationship. In [44] this issue is discussed at length.

To some extent it is possible to give a qualitative account of the behavior of the inflation operator, using structural properties of the matrices in a particular class preserved by inflation. Several preparatory results are derived in the current section. In the following section simple structure theory is developed, explaining the uncoupling effect of the inflation operator in qualitative terms.

In general $\Gamma_r M$ can be described in terms of a Hadamard matrix power that is postmultiplied with a diagonal matrix. For a restricted class of matrices there is an even stronger connection with the Hadamard product. These are the class of stochastic diagonally symmetric matrices and a subclass of the latter, the class of stochastic diagonally positive semi-definite matrices.

The Hadamard (entrywise) product of two matrices A and B that have the same dimensions is written $A \circ B$ and satisfies $[A \circ B]_{pq} = A_{pq} B_{pq}$. The entrywise Hadamard power with exponent r of a matrix A is written $A^{\circ r}$ and satisfies $[A^{\circ r}]_{pq} = {A_{pq}}^r$.

The concept of diagonal symmetrizability can easily be transferred to complex matrices, and most of the results in this paper can be derived in that more general setting. This is not needed in the , setting and hence the definitions and results here are simply stated for real matrices.

DEFINITION 4.1. A diagonally symmetric x Diag$(x)^{-1} A$ Diag(x)

The following useful identity is easy to verify.

LEMMA 4.2. A 4.1 Diag$(x)^{-1} A$ Diag(x) $= [A \circ A^T]^{\circ 1/2}$

DEFINITION 4.3. [illegible] diagonally positive semi-definite [illegible] diagonally positive definite [illegible] dpsd [illegible] dpd [illegible] If M is diagonally symmetric stochastic, and y is such that $M\,\mathrm{Diag}(y)$ is symmetric, then $My = y$; thus y represents the equilibrium distribution of M. In the theory of Markov chains, a stochastic diagonally symmetric matrix is called [illegible] or said to satisfy the [illegible] condition (see, e.g., [43] and [59]). A slightly more general definition and different terminology was chosen here. The main reason is that the term "time reversible" is coupled tightly with the idea of studying a stochastic chain via (powers of) its associated stochastic matrix, and is also used for continuous-time Markov chains. The [illegible] process studied in this article does not have a straightforward stochastic interpretation, and the relationship between an input matrix and the subsequent iterands is much more complex. Moreover, it is natural to introduce the concepts of a matrix being diagonally similar to a positive (semi-) definite matrix; clinging to "time reversible" in this abstract setting would be both contrived and unhelpful. The proposed phrases seem appropriate, since several properties of symmetric and [illegible] matrices remain valid in the more general setting of diagonally symmetric and [illegible] matrices. Lemma 4.4 lists the most important ones, which are easy to verify. Probably all of these results are known.

In the following, submatrices of a matrix A are written $A[u|v]$, where u denotes a list of row indices, and v denotes a list of column indices.

LEMMA 4.4. [illegible] A [illegible] n [illegible] α [illegible] $1,\dots,n$ [illegible] k [illegible] l [illegible] $1,\dots,n$ [illegible] x [illegible] $S = \mathrm{Diag}(x)^{-1} A\,\mathrm{Diag}(x)$ [illegible] $A = \mathrm{Diag}(x) S\,\mathrm{Diag}(x)^{-1}$ [illegible] λ_i [illegible] A ([illegible] S) [illegible] a_i [illegible] A

(a) $A[\alpha|\alpha] = \mathrm{Diag}(x)[\alpha|\alpha]\ \ S[\alpha|\alpha]\ \ \mathrm{Diag}(x)[\alpha|\alpha]^{-1}$ [illegible] A [illegible] S [illegible] A [illegible] A

$$\sum_{i=1}^{k} \lambda_{[i]} \ \geq\ \sum_{i=1}^{k} a_{[i]} \quad k = 1,\dots,n.$$

(b) [illegible] A [illegible] dpsd [illegible] $A_{kk} = 0$ [illegible] k [illegible] k [illegible] A [illegible] A [illegible] dpsd [illegible] $\det A[kl|kl] = 0$ [illegible] k [illegible] l [illegible] k [illegible] l

(c) [illegible] A [illegible] dpsd [illegible] $k \in \mathbb{N}$ [illegible] dpsd [illegible] B [illegible] $B^k = A$ [illegible] $B = \mathrm{Diag}(x) Q \Lambda^{1/k} Q^H \mathrm{Diag}(x)^{-1}$ [illegible] $Q\Lambda Q^H$ [illegible] S [illegible] Λ [illegible] S [illegible] $\Lambda^{1/k}$ [illegible] Λ [illegible] k [illegible] dpsd A [illegible] A^t $t \in \mathbb{R}_{\geq 0}$ [illegible]

(d) A, B n dpsd dpd $A \circ B$ dpsd dpd

. Most statements are easy to verify. For extensive discussion of the majorization relationship between diagonal entries and eigenvalues of symmetric (or hermitian) matrices, as well as results on interlacing inequalities, see [3, 34, 35]. The first statement in (b) follows from the fact that principal minors (of dimension 2) are nonnegative. The second statement can easily be proven by first considering the case where A is symmetric. The determinant $\det A[klm|klm]$ of an extended submatrix equals zero and rewriting the constituent terms yields proportionality as stated in (b). The result for matrices follows trivially. For (c) it is sufficient to use the fact that $Q\Lambda^{1/k}Q^H$ is the unique positive semi-definite kth root of S [34, p. 405]. Statement (d) follows from the identity $(\mathrm{Diag}(x)^{-1}A\ \mathrm{Diag}(x)) \circ (\mathrm{Diag}(y)^{-1}B\ \mathrm{Diag}(y)) = \mathrm{Diag}(x \circ y)^{-1}(A \circ B)\mathrm{Diag}(x \circ y)$ and the fact that the analogous statements for symmetric matrices are true—known under the denomination of [34, p. 458].

. The two most notable properties that do not generalize from symmetric matrices to diagonally symmetric matrices are the absence of an orthogonal basis of eigenvectors for the latter, and the fact that the sum of two diagonally symmetric matrices is in general not diagonally symmetric as well.

Statements (a) and (b) in Lemma 4.4 are used in associating a directed acyclic graph with each matrix in Theorem 5.4. First, the behavior of the inflation operator on diagonally symmetric and matrices is described.

THEOREM 4.5. M n, $\mathrm{Diag}(x)$ $S = \mathrm{Diag}(x)^{-1}M\ \mathrm{Diag}(x)$ r z, $z_k = x_k{}^r(\sum_i M_{ik}{}^r)^{1/2}$ T, $T_{kl} = 1/(\sum_i M_{ik}{}^r)^{1/2}(\sum_i M_{il}{}^r)^{1/2}$

$$\mathrm{Diag}(z)^{-1}\ (\ \Gamma_r M)\ \ \mathrm{Diag}(z) \ \ = \ \ S^{\circ r} \circ T.$$

$\Gamma_r M$

. Define the vector t by $t_k = \sum_i M_{ik}{}^r$. Then

$$\begin{aligned}
\Gamma_r M &= M^{\circ r}\ \mathrm{Diag}(t)^{-1} \\
&= (\mathrm{Diag}(x)\ S\ \mathrm{Diag}(x)^{-1})^{\circ r}\ \mathrm{Diag}(t)^{-1} \\
&= \mathrm{Diag}(x)^{\circ r}\ \ S^{\circ r}\ \ (\mathrm{Diag}(x)^{\circ r})^{-1}\ \mathrm{Diag}(t)^{-1} \\
&= \mathrm{Diag}(t)^{1/2}\mathrm{Diag}(t)^{-1/2}\ \mathrm{Diag}(x)^{\circ r}\ \ S^{\circ r}\ (\mathrm{Diag}(x)^{\circ r})^{-1}\mathrm{Diag}(t)^{-1/2}\mathrm{Diag}(t)^{-1/2} \\
&= (\mathrm{Diag}(t)^{1/2}\mathrm{Diag}(x)^{\circ r})\ (\mathrm{Diag}(t)^{-1/2}S^{\circ r}\mathrm{Diag}(t)^{-1/2})\ (\mathrm{Diag}(t)^{1/2}\mathrm{Diag}(x)^{\circ r})^{-1}.
\end{aligned}$$

Since the matrix $\mathrm{Diag}(t)^{-1/2}S^{\circ r}\mathrm{Diag}(t)^{-1/2}$ equals $S^{\circ r} \circ T$, the lemma holds. □

COROLLARY 4.6. M z, S T 4.5

(i) $\Gamma_r M$ $r \in \mathbb{R}$

(ii) M dpsd $\Gamma_r M$ dpsd $r \in \mathbb{N}$ M dpd $\Gamma_r M$ dpd $r \in \mathbb{N}$

. Statement (i) follows immediately from Theorem 4.5. Statement (ii) follows from the fact that a Hadamard product of matrices is positive (semi-) definite if

each of the factors is positive (semi-) definite. Moreover, if at least one of the factors is positive definite, and none of the other factors has a zero diagonal entry, then the product is positive definite (see, e.g., [35, p. 309], or [23]). These are basic results in the theory of Hadamard products, an area now covered by a vast body of literature. Standard references in this area are [3, 35]. It should be noted that $r \in \mathbb{N}$ is in general a necessary condition [35, p. 453]. □

THEOREM 4.7. *M*
$(M, e_{(i)}, r_{(i)})$
(i)
(ii) $r_i = 2$ $e_i = 2$
$(M, e_{(i)}, r_{(i)})$ dpsd

These statements[1] follow from the fact that Exp_2 maps diagonally symmetric matrices onto matrices and from Corollary 4.6. □

Theorem 4.7 represents a qualitative result on the process. Under fairly basic assumptions the spectra of the iterands are real and nonnegative. In [11] it was furthermore proven that the process converges quadratically in the neighborhood of nonnegative -invariant matrices. These combined facts indicate that the process has a sound mathematical foundation. Still, much less can be said about the connection between successive iterands than in the case of the discrete Markov process.

The question now rises whether the process can be further studied aiming at quantitative results. It was seen that $\Gamma_r M$, $r \in \mathbb{N}$ can be described in terms of a Hadamard product of positive semi-definite matrices relating the symmetric matrices associated with M and $\Gamma_r M$ (in Theorem 4.5). There are many results on the spectra of such products. The results are generically in terms of a majorization relationship such as

$$\sum_{i=1}^{k} \sigma_i(A \circ B) \;\leq\; \sum_{i=1}^{k} f_i(A)\sigma_i(B), \quad k = 1, \ldots, n.$$

Here $\sigma_i()$ denotes the i-largest singular value, and $f_i(A)$ may stand (among others) for the i-largest singular value of A, the i-largest diagonal entry of A, the i-largest Euclidean column length, or the i-largest Euclidean row length. Well-known references in this field are [3, 35]. Unfortunately such inequalities go the wrong way in a sense. Since the inflation operator has apparently the ability to press several large eigenvalues towards 1, what is needed are inequalities of the type

$$\sum_{i=1}^{k} \sigma_i(A \circ B) \;\geq\; \text{(something nice here)}.$$

However, the number of eigenvalues pressed towards 1 by Γ_r can be any number including zero (noting that one eigenvalue 1 is always present). Moreover, Γ_r also has the ability to press small eigenvalues towards zero. Clearly, one cannot expect to find inequalities of the "$\geq$" type without assuming additional characteristics of M. It is shown in the next section that the classic majorization relation formulated in

[1] Clearly the condition under (ii) can be weakened; it is only necessary that e_i is at least one time even for an index $i = k$ such that $r_i \in \mathbb{N}$ for $i \geq k$. However, the assumptions under (ii) can be viewed as a standard way of enforcing convergence in a setting genuinely differing from the discrete Markov process.

Lemma 4.4 (a) between the eigenvalues and diagonal entries of a $\cdot,\cdot$ matrix, plus a classification of the diagonal entries of a $\cdot,\cdot$ matrix, gives useful information on the relationship between eigenvalues of a stochastic $\cdot,\cdot$ matrix and its image under Γ_r.

5. Structure in *dpsd* matrices. The main objective for the remainder of this paper is to establish structure theory for the class of $\cdot,\cdot$ matrices and study the behavior of Γ_∞ using these results. It will be shown that for stochastic $\cdot,\cdot$ M the spectrum of the matrix Γ_∞ is of the form $\{0^{n-k}, 1^k\}$, where k is related to a structural property of M. Throughout this section two symbols are used that are associated with a $\cdot,\cdot$ matrix A, namely the symbol $\looparrowright$ which denotes an arc relation defined on the indices of A, and the symbol $\sim$ which denotes an equivalence relation on the indices of A. It should be clear from the context which matrix they refer to. All results in this section are stated in terms of columns; the analogous statements in terms of rows hold as well.

DEFINITION 5.1. $\cdot$ A $\cdot$ dpsd $\cdot,\cdot$ $\cdot$ n $\cdot,\cdot$ $\cdot$ k $\cdot$ l $\cdot$ $\cdot,\cdot$ $\cdot,\cdot$ $1,\ldots,n$

(i) $\cdot,\cdot$ $\cdot,\cdot$ $\sim$ $\cdot,\cdot$ $\cdot,\cdot$ $\{1,\ldots,n\}$ $\cdot$ $k \sim l \equiv$ columns k and l of A are scalar multiples of each other via scalars on the complex unit circle

(ii) $\cdot,\cdot$ $\cdot,\cdot$ $\looparrowright$ $\cdot,\cdot$ $\cdot,\cdot$ $\{1,\ldots,n\}$ $\cdot,\cdot$ $p \neq q$ $\cdot$ $q \looparrowright p \equiv |A_{pq}| \geq |A_{qq}|$

(iii) $\cdot$ E $\cdot$ F $\cdot,\cdot$ $\cdot,\cdot$ $\cdot,\cdot$ $\cdot,\cdot$ $\{1,\ldots,n\}/\sim$ $\cdot,\cdot$ $\cdot,\cdot$ $\looparrowright$ $\cdot,\cdot$ $F \looparrowright E \equiv \exists e \in E, \exists f \in F[f \looparrowright e]$ $\cdot,\cdot$ $\looparrowright$ $\cdot,\cdot$ $\sim$ $\cdot,\cdot$ $\cdot,\cdot$ $\cdot,\cdot$ $\forall e' \in E, \forall f' \in F[f' \looparrowright e']$

LEMMA 5.2. $\cdot$ A $\cdot$ dpsd $\cdot,\cdot$ $\cdot$ n $\cdot,\cdot$ $\cdot$ k $\cdot$ l $\cdot,\cdot$ $\cdot,\cdot$ $1,\ldots,n$ $\cdot,\cdot$

$$l \looparrowright k \wedge k \looparrowright l \cdot,\cdot \cdot,\cdot k \sim l$$

This follows from Lemma 4.4 (b) and the fact that the assumption implies $\det A[kl|kl] = 0$. The following lemma prepares for a mapping of $\cdot,\cdot$ matrices onto directed acyclic graphs.

LEMMA 5.3. $\cdot$ A $\cdot$ dpsd $\cdot,\cdot$ $\cdot$ n $\cdot,\cdot$ $\cdot,\cdot$ $\cdot$ k $\cdot,\cdot$ $\cdot,\cdot$ $p_i, i = 1,\ldots,k, k > 1$ $\cdot,\cdot$ $\cdot,\cdot$ $p_1 \looparrowright p_2 \looparrowright \ldots \looparrowright p_k \looparrowright p_1$ $\cdot,\cdot$ $p_1 \sim p_2 \sim \ldots \sim p_k$ $\cdot,\cdot$ $\cdot,\cdot$ $p_i, i = 1,\ldots,k$ $\cdot,\cdot$ $\cdot,\cdot$ $\cdot,\cdot$ $\cdot,\cdot$ $\cdot,\cdot$ $\{1,\ldots,n\}/\sim$ $\cdot,\cdot$ $\cdot,\cdot$ $\cdot,\cdot$ A $\cdot,\cdot$ $\cdot,\cdot$ $\cdot,\cdot$ $\cdot,\cdot$ $\cdot,\cdot$ $A[p_1 \ldots p_k|p_i]$ $\cdot,\cdot$ $\cdot,\cdot$ $\cdot,\cdot$ $\cdot,\cdot$ $\cdot,\cdot$ $\cdot,\cdot$ k

$\cdot,\cdot$. Without loss of generality, assume $1 \looparrowright 2 \looparrowright \ldots \looparrowright k \looparrowright 1$. The following inequalities hold, where the left-hand side inequalities follow from the inequalities implied by $\det A[i\,i{+}1] \geq 0$ and $i \looparrowright i+1$,

$$\begin{array}{ccccc} |A_{i\,i+1}| & \leq & |A_{i+1\,i+1}| & \leq & |A_{i+2\,i+1}| \\ |A_{k-1\,k}| & \leq & |A_{kk}| & \leq & |A_{1k}| \\ |A_{k1}| & \leq & |A_{11}| & \leq & |A_{21}|. \end{array}$$

Now let x be positive such that $x_q A_{pq} = x_p A_{qp}$. On the one hand, $|A_{kk}| \leq |A_{1k}|$. On

the other hand,

$$\begin{aligned} |A_{kk}| &\geq |A_{k-1\,k}| \\ &= \tfrac{x_{k-1}}{x_k}|A_{k\,k-1}| \\ &\geq \tfrac{x_{k-1}}{x_k}|A_{k-2\,k-1}| \\ &= \tfrac{x_{k-1}}{x_k}\tfrac{x_{k-2}}{x_{k-1}}|A_{k-1\,k-2}| \\ &\cdots \\ &\geq \tfrac{x_{k-1}}{x_k}\tfrac{x_{k-2}}{x_{k-1}}\cdots\tfrac{x_1}{x_2}|A_{k1}| \\ &= \tfrac{x_1}{x_k}|A_{k1}| \\ &= |A_{1k}|. \end{aligned}$$

This implies that $|A_{k-1\,k}| = |A_{kk}| = |A_{1k}|$ and the identities $|A_{i-1\,i}| = |A_{ii}| = |A_{i+1\,i}|$ are established by abstracting from the index k. From this it follows that $\det A[i, i+1|i, i+1] = 0$, and consequently $i \sim i+1$ for $i = 1, \ldots, k-1$ by Lemma 5.2. The identities $|A_{i-1\,i}| = |A_{ii}| = |A_{i+1\,i}|$ also imply the last statement of the lemma. □

Lemma 5.2 can now be generalized towards Theorem 5.4.

THEOREM 5.4. [illegible] A [illegible] dpsd [illegible] n

[illegible] $\mapsto$ [illegible] [illegible] $(\ldots)$ [illegible] $\{1, \ldots, n\}/\sim$

Note that the theorem is stated in a columnwise manner. The analogous statement for rows is of course also true. The proof of this theorem follows from Lemma 5.3.

THEOREM 5.5. [illegible] M [illegible] dpsd [illegible] n [illegible] D [illegible] [illegible] $\Gamma_\infty M$ [illegible] $\{1, \ldots, n\}/\sim$ [illegible] 5.1 [illegible] 5.4 [illegible] d [illegible] D [illegible] D [illegible] k [illegible] $\{1, \ldots, n\}/\sim$ [illegible] D [illegible] $(\ldots)$ [illegible] p [illegible] M_{pp} [illegible] p

[illegible] $\Gamma_\infty M$ [illegible] $\{0^{n-k}, 1^k\}$ [illegible] $(\Gamma_\infty M)^d$ [illegible]

[illegible]. For the duration of this proof, write S_A for the symmetric matrix to which a diagonally symmetric matrix A is similar. For the first statement, consider the identity

$$S_{(\Gamma_r M)} = \left[\Gamma_r M \circ (\Gamma_r M)^T\right]^{\circ 1/2}$$

given in Lemma 4.2. The matrices $\Gamma_r M$ and $S_{\Gamma_r M}$ have the same spectrum. Now, let r approach infinity. The identity is in the limit not meaningful, since $\Gamma_\infty M$ is not necessarily diagonalizable, and thus the left-hand side may not exist in the sense that there is no symmetric matrix to which $\Gamma_\infty M$ is similar. However, the identity [spectrum of $\Gamma_\infty M$ = spectrum of $\left[\Gamma_\infty M \circ (\Gamma_\infty M)^T\right]^{\circ 1/2}$] [illegible] remain true, since the spectrum depends continuously on matrix entries [34, p. 540], and both limits exist. Thus, it is sufficient to compute the spectrum of S_∞, which is defined as

$$S_\infty = \left[\Gamma_\infty M \circ (\Gamma_\infty M)^T\right]^{\circ 1/2}.$$

Note that the nonzero entries of $\Gamma_\infty M$ correspond with the entries of M which are maximal in their column. Whenever $[\Gamma_\infty M]_{kl} \neq 0$ [illegible] $[\Gamma_\infty M]_{lk} \neq 0$, it is true that $k \looparrowright l$ and $l \looparrowright k$. Now consider a column q in S_∞, and assume that all nonzero entries in column q of S_∞ are enumerated $S_{\infty p_i q} \neq 0$, for $i = 1, \ldots, t$. It follows that $q \looparrowright p_i \wedge p_i \looparrowright q$ for all i, thus $q \sim p_i$ for all i, and $S_\infty[p_1 \ldots p_t | p_1 \ldots p_t]$ is a positive submatrix equal to $t^{-1}J_t$, where J_t denotes the all-one matrix of dimension t. This implies that S_∞ is block diagonal (after permutation), with each block corresponding with an equivalence class in $\{1, \ldots, n\}/\sim$ which has no outgoing arc in the $\looparrowright$ arc relation. Each block contributes an eigenvalue 1 to the spectrum of S_∞. Since the spectrum of S_∞ equals the spectrum of $\Gamma_\infty M$, and there are assumed to be k equivalence classes with the stated properties, this proves the first statement.

A second approach proves both the first and the second statement. Consider $\Gamma_\infty M$ and the DAG D associated with it. Each index i for which $[\Gamma_\infty M]_{ii} \neq 0$ must be in an endclass of D because Γ_∞ annihilates all but the maximal elements in each column. Moreover, the nonzero diagonal block (possibly 1-dimensional) associated with such an index is idempotent. This implies that $\Gamma_\infty M$ can be decomposed into an idempotent part (consisting of the diagonal block) and a nilpotent part (the rest). Some calculations now verify that $(\Gamma_\infty M)^d$ is idempotent, where d is the depth of D. □

Theorems 5.4 and 5.5 shed light on the structure and the spectral properties of the iterands of the [illegible] process. Theorem 5.4 also gives the means to associate an overlapping clustering with each [illegible] iterand of an [illegible] process, simply by defining the endnodes of the associated [illegible] as the unique cores of the clustering, and adding to each set of attractors all nodes that reach it.

Consider a discrete Markov process with [illegible] input matrix M. Then the difference $M^k - M^l$, $k < l$, is again [illegible] (they have the same symmetrizing diagonal matrix, and the spectrum of $M^k - M^l$ is nonnegative). From this it follows that all sequences of diagonal entries $M^{(k)}{}_{ii}$, for fixed diagonal position ii, are nonincreasing. In contrast, given a stochastic [illegible] matrix M, the Γ_r operator, $r > 1$, (in the setting of [illegible] matrices) always increases some diagonal entries (at least one). The sum of the increased diagonal entries, of which there are at least k if k is the number of endnodes of the [illegible] associated with both M and $\Gamma_r M$, is a lower bound for the sum of the k largest eigenvalues of $\Gamma_r M$ (see Lemma 4.4 (a)).

The [illegible] process converges quadratically in the neighborhood of the [illegible]-invariant stable states. Proving (near-) global convergence seems to be a difficult task. I do believe, however, that a strong result will hold, where a provision has to be made for a special class of matrices, here dubbed flip-flop matrices. A flip-flop matrix M satisfies $\Gamma_2 M = M^{1/2}$. There exists a family of positive semi-definite flip-flop matrices of the form $aI_n + (1-a)n^{-1}J_n$, $n \in \mathbb{N}$ [12]. The simplest example is found in the case $n = 3$, where substituting $a = 1/2$ in the form yields a flip-flop matrix. For such a matrix it is relatively easy to prove that a small perturbation lands it on a trajectory away from the flip-flop state (with respect to alternation of Exp_2 and Γ_2) [12]. It can be noted that flip-flop matrices and circulant matrices in general form sets that are invariant under [illegible] iterations.

CONJECTURE 1. [illegible] $(M, e_{(i)}, r_{(i)})$ [illegible] $e_i = 2, r_i = 2$ [illegible] M [illegible] dpsd [illegible]

The requirement of irreducibility is present in order to exclude matrices that are

a direct sum of smaller-dimensional matrices.

6. Implementation and scalability. A mature, implementation of the MCL algorithm is available from http://micans.org/mcl/. This implementation is used in all of the references cited in the introduction. It scales subquadratically given conditions set forth below.

A fast implementation requires that the requirement of exact computation is dropped. For any interesting class of real-life graphs scaling towards tens of thousands of nodes and beyond, exact computation requires $O(N^2)$ memory resources and $O(N^3)$ time steps, where N is the number of nodes in the input graph, reflecting the basic costs of matrix multiplication. Even for sparse graphs, , iterands will fill rapidly as interesting graphs tend to be well-connected and have only few connected components.

The key observation is that in the presence of cluster structure, columns of , iterands generally possess a very skewed (weight) distribution of entries. The majority of the stochastic mass of any column is contained in a minority of the total set of nonzero entries (of that column), as inflation keeps the leveling power of expansion (multiplication) in check. In the , process limits, the matrix columns generally are extremely skewed, with a single nonzero entry per column (equaling one). This implies that , iterands never stray very far from the skewed weight distribution just described, and it suggests a way to compute a perturbed process that is tractable. That is to simply throw away some of the smallest entries, preferably adding to only a small percentage of the column weight, and rescale the remaining entries to have sum one again. This is the setup in the implementation described here.

The implementation uses a standard sparse matrix implementation where only nonzero entries are stored in arrays representing stochastic matrix columns (known as compressed column or column-major storage). During matrix multiplication, each new column is computed separately. First, the new column is computed exactly and nothing is disregarded. Then, the smallest entries are removed in a two-stage process where first entries smaller than a fixed threshold are removed, and then entries are recovered if the threshold turns out to be too severe, or more entries are removed if the threshold turns out to be insufficiently severe. The selection and recovery of entries is efficiently done using max and min heaps. The final assembly of entries is rescaled to have sum one. The implementation tracks how much mass is kept for each column during each iteration, and extensively reports on pruning characteristics.

This procedure has not yet been subjected to numerical analysis. The task appears to be nontrivial if a relationship with the effect on process limits is to be established, due to the general difficulties in analyzing the (nonlinear) , process. However, experiments on smaller graphs (with up to thousands of nodes) that allow exact computation indicate that perturbing the process in this manner has very minor impact on the resulting clusterings. The pruning reports in the setting of protein family analysis indicate rather limited pruning of stochastic mass. Additionally, nodes requiring severe pruning can be pruned in advance from the graph to allow for a more precise computation. In this respect, data preprocessing may aid , the same way it aids approaches to other large scale computational challenges.

Typically for large graphs of several hundreds of thousands of nodes, a maximum K of inbetween $1000-2000$ entries per column is kept. Newly computed columns may contain a number of nonzero entries L amounting to tens of thousands, and selecting the largest K entries from those L using threshold pruning and selection/recovery with min/max heaps has time requirements of order $O(L \log(K))$.

7. Conclusions, further research, and related research. The process presented here appears to be both of practical and mathematical interest. A clear relationship was established between matrices, a (defined on indices column or rowwise) that can be associated with every such matrix (Theorem 5.4), and the effect of the inflation operator on column stochastic matrices (Theorem 5.5). The defined on column indices of matrices generalizes the mapping of nonnegative -invariant matrices onto overlapping clusterings, and allows the association of an overlapping clustering with each matrix. In the process, the inflation step effectively strengthens the associated structure, the expansion step may change it. Many interesting and difficult questions remain. A worthy long standing goal is to prove or disprove Conjecture 1. Two more conjectures are made after the following list of objectives.

(i) For a fixed process $(\cdot, e_{(i)}, r_{(i)})$, what can be said about the basins of attraction of the process. Are they connected?
(ii) What can be said about the union of all basins of attraction for all limits corresponding with the same overlapping clustering (i.e., differing only in the distribution of attractors)?
(iii) Can the set of limits reachable from a fixed nonnegative matrix M for all processes $(M, e_{(i)}, r_{(i)})$ be characterized? Can it be related to a structural property of M?
(iv) Given a node set $I = \{1, \ldots, n\}$ and two directed acyclic graphs D_1 and D_2 defined on I, under what conditions on D_1 and D_2 does there exist a matrix M such that the s associated with M according to Theorem 5.4, via rows and columns, respectively, equals D_1 and D_2? What if M is also required to be column stochastic?
(v) Under what conditions do the clusters in the cluster interpretation of the limit of a convergent process $(M, e_{(i)}, r_{(i)})$ correspond with connected subgraphs in the associated graph of M?
(vi) For M, in which ways can the associated with M^2 be related to the associated with M?
(vii) Is it possible to specify a subclass $\mathcal{S}$ of the stochastic matrices and a subset R' of the reals larger than $\mathbb{N}$, such that $\Gamma_r M$ is in $\mathcal{S}$ if $r \in R'$ and $M \in \mathcal{S}$?

. The following is a relaxation of (iv): Given any DAG D is there a symmetric positive semi-definite matrix S such that D is the DAG associated with S (via either columns or rows)? This is easily answered in the affirmative via a constructive and inductive argument, working backwards from sinks to sources, at each step bordering the previously obtained matrix with zeros and adding a suitably constructed rank-one matrix.

. There is no obvious nontrivial hypothesis regarding item (vi), unless such a hypothesis takes quantitative properties of M into account. This is because the breaking up of strongly connected components that can be witnessed in the process is always reversible—uncoupling can only happen in the limit. With respect to (v), I conjecture the following.

CONJECTURE 2. $\mathcal{C}$ dpsd M M

Next, consider an process $(M, e_{(i)} \stackrel{c}{=} 2, r_{(i)} \stackrel{c}{=} 2)$, with M, that converges towards an -invariant matrix L, and let G be the associated graph

of M. The observations in section 2 suggest the following conjecture. Note that a graph automorphism of G implies the existence of a permutation matrix P such that $M = PMP^T$.

CONJECTURE 3. [illegible] L [illegible] (k,l) [illegible] G [illegible] k [illegible] l [illegible] L [illegible] G [illegible]

There are several lines of research that may inspire answers to the questions posed here. However, for none of them the connection seems so strong that existing theorems can immediately be applied. The main challenge is to further develop the framework in which the interplay of Γ_r and Exp_s can be studied. Hadamard-Schur theory was discussed in section 4. Perron-Frobenius theory, graph partitioning by eigenvectors (e.g., [55] and [56]), and work regarding the second largest eigenvalue of a graph (e.g., [1] and [9]), are a natural source of inspiration, and so is the theory of Perron complementation and stochastic complementation as introduced by Meyer ([47] and [48]). There are also papers that address the topic of the structure of matrices which have the subdominant eigenvalue close to the dominant eigenvalue ([30] and [53]). It should be noted that in the former paper matrices are studied that do not have nonnegative spectrum. In the setting of [illegible] matrices, much stronger results can be expected to hold regarding the relationship between uncoupling measures and spectrum. The literature on the subject of diagonal similarity does not seem to be of immediate further use, as it is often focused on scaling problems (e.g., [17] and [33]). For the study of flip-flop equilibrium states the many results on circulant matrices are likely to be valuable, for example the monograph [10], and the work on group majorization in the setting of circulant matrices in [26]. It may also be fruitful to investigate the relationship with [illegible] and the [illegible] for positive matrices, as studied in [4, 6, 8, 27, 58].

Acknowledgments. The author wishes to thank the anonymous referees for their many detailed and useful comments that have significantly contributed to the exposition of the paper.

A DIVIDE-AND-CONQUER METHOD FOR THE TAKAGI FACTORIZATION*

WEI XU† AND SANZHENG QIAO†

Abstract. This paper presents a divide-and-conquer method for computing the symmetric singular value decomposition, or Takagi factorization, of a complex symmetric and tridiagonal matrix. An analysis of accuracy shows that our method produces accurate Takagi values and orthogonal Takagi vectors. Our preliminary numerical experiments have confirmed our analysis and demonstrated that our divide-and-conquer method is much more efficient than the implicit QR method even for moderately large matrices.

Key words. divide-and-conquer method, symmetric SVD, Takagi factorization

1. Introduction.

The Takagi factorization of a complex symmetric matrix A can be written as [7]

$$A = V\Sigma V^T,$$

where V is a unitary matrix, V^T is the transpose of V, and Σ is a nonnegative diagonal matrix. The columns of V are called the Takagi vectors of A and the diagonal elements of Σ are its Takagi values. Since $V^T = \bar{V}^H$, where $\bar{V}$ denotes the complex conjugate of V, the Takagi factorization is a symmetric form of the singular value decomposition (SVD); but there are differences. A pair of left-right singular vectors are unique up to a complex scaling factor with unit modulus, while the Takagi vectors are unique up to a sign change. Therefore, if $\mathbf{v}_i$ is a Takagi vector, then $(\mathbf{v}_i,\ \bar{\mathbf{v}}_i)$ is a pair of left-right singular vectors, but a left singular vector is not necessarily a Takagi vector; see an example below.

Similar to the computation of the SVD, a standard algorithm for computing the Takagi factorization consists of two stages. The first stage reduces a complex symmetric matrix A of order n to a complex symmetric tridiagonal matrix:

$$A = PTP^T \equiv P \begin{bmatrix} a_1 & b_1 & & 0 \\ b_1 & \ddots & \ddots & \\ & \ddots & \ddots & b_{n-1} \\ 0 & & b_{n-1} & a_n \end{bmatrix} P^T, \tag{1}$$

where P is a unitary matrix of order n and T is tridiagonal. For example, the Lanczos tridiagonalization method with partial orthogonalization [9, 12] can be used. The second stage computes the Takagi factorization $T = Q\Sigma Q^T$ of the complex symmetric tridiagonal T. Combining the two stages, we have

$$A = P(Q\Sigma Q^T)P^T = V\Sigma V^T,$$

where $V = PQ$.

In this paper, we focus on the computation of the Takagi factorization of the complex symmetric tridiagonal T using the divide-and-conquer method based on rank-one tearing of TT^H. It is known that the divide-and-conquer method is one of the most efficient methods for computing the eigenvalues and eigenvectors of a large, normally of order larger than dozens, Hermitian tridiagonal matrix [3]. Apparently, the Takagi vectors of T—that is, the columns of Q—are the eigenvectors of the positive semidefinite Hermitian matrix TT^H, since $TT^H = Q\Sigma Q^T \bar{Q}\Sigma Q^H = Q\Sigma^2 Q^H$. However, an eigenvector of TT^H may not be a Takagi vector of T. For example, let

$$T = \begin{bmatrix} 1 & i \\ i & -1 \end{bmatrix}, \quad \text{where} \quad i = \sqrt{-1};$$

then

$$TT^H = \begin{bmatrix} \frac{\sqrt{2}}{4} + \frac{\sqrt{6}}{4}i & -\frac{\sqrt{2}}{2} \\ -\frac{\sqrt{6}}{4} + \frac{\sqrt{2}}{4}i & \frac{\sqrt{2}}{2}i \end{bmatrix} \begin{bmatrix} 4 & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} \frac{\sqrt{2}}{4} - \frac{\sqrt{6}}{4}i & -\frac{\sqrt{6}}{4} - \frac{\sqrt{2}}{4}i \\ -\frac{\sqrt{2}}{2} & -\frac{\sqrt{2}}{2}i \end{bmatrix}$$

is an eigenvalue decomposition of TT^H. Using the algorithm in [10], we can obtain the Takagi factorization

$$T = Q\Sigma Q^T = \begin{bmatrix} -\frac{\sqrt{2}}{2} & \frac{1}{2} + \frac{1}{2}i \\ -\frac{\sqrt{2}}{2}i & \frac{1}{2} - \frac{1}{2}i \end{bmatrix} \begin{bmatrix} 2 & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} -\frac{\sqrt{2}}{2} & -\frac{\sqrt{2}}{2}i \\ \frac{1}{2} + \frac{1}{2}i & \frac{1}{2} - \frac{1}{2}i \end{bmatrix}.$$

In fact, it is shown in [7, Corollary 4.4.5] that if A is complex symmetric and the eigenvalues of AA^H are distinct, and if $AA^H = U\Sigma^2 U^H$, then there exists a diagonal matrix $D = \mathrm{diag}(e^{i\theta_1}, \ldots, e^{i\theta_n})$ with real θ_i such that $A = V\Sigma V^T$ with $V = UD$. The diagonal entries of D are determined by the relation $A\bar{U} = U\Sigma D^2$. In the above example, $e^{i\theta_1} = -1/2 + \sqrt{3}\,i/2$ and $e^{i\theta_2} = -\sqrt{2}/2 - \sqrt{2}\,i/2$. However, if σ_i^2 is a multiple eigenvalue of AA^H, then, following the proof of Theorem 4.4.3 in [7], we can construct the Takagi vector $\mathbf{v}_i$ corresponding to the singular value σ_i of A from the eigenvector $\mathbf{u}_i$ corresponding to σ_i^2 using

$$\mathbf{v}_i = \alpha_i(A\bar{\mathbf{u}}_i + \sigma_i \mathbf{u}_i),$$

where $\alpha_i = 1/\|A\bar{\mathbf{u}}_i + \sigma_i \mathbf{u}_i\|_2$ is the normalization factor. The details of the transformation will be described in section 3.

The basic idea behind our method is to apply the divide-and-conquer method to TT^H to compute its eigenvectors and eigenvalues. The square roots of the eigenvalues of TT^H are the Takagi values of T. Since an eigenvector of TT^H may not be a Takagi vector of T, we then transform the eigenvectors of TT^H into the Takagi vectors of T. However, explicitly computing TT^H is too expensive and also destroys the tridiagonal structure of T. We will introduce an implicit method for computing the eigenvalue decomposition of TT^H.

The rest of this paper is organized as follows. Section 2 describes a divide-and-conquer method for computing the eigenvalue decomposition of TT^H without explicitly forming TT^H. In section 3, we propose a method for transforming the eigenvectors of TT^H into the Takagi vectors of T. We analyze the sensitivity of the Takagi vectors of T in section 4. Finally, our preliminary numerical experiments are demonstrated in section 5 to show the stability, accuracy, and efficiency of our algorithm.

2. Divide-and-conquer scheme. Let the Takagi factorization of the complex symmetric tridiagonal matrix T in (1) be

$$Q^H T \bar{Q} \;=\; \Sigma \;=\; \mathrm{diag}(\sigma_1, \ldots, \sigma_n) \quad \text{or} \quad T = Q \Sigma Q^T.$$

In the first step, we tear the tridiagonal matrix T into two tridiagonal submatrices of half size. For simplicity, we assume that n is a power of 2 and $m = n/2$; then

$$T = \begin{bmatrix} T_1 & b_m \mathbf{e}_m \mathbf{e}_1^T \\ b_m \mathbf{e}_1 \mathbf{e}_m^T & T_2 \end{bmatrix}, \tag{2}$$

where

$$T_1 = \begin{bmatrix} a_1 & b_1 & & 0 \\ b_1 & \ddots & \ddots & \\ & \ddots & \ddots & b_{m-1} \\ 0 & & b_{m-1} & a_m \end{bmatrix}, \quad T_2 = \begin{bmatrix} a_{m+1} & b_{m+1} & & 0 \\ b_{m+1} & \ddots & \ddots & \\ & \ddots & \ddots & b_{n-1} \\ 0 & & b_{n-1} & a_n \end{bmatrix},$$

and $\mathbf{e}_1$ and $\mathbf{e}_m$ are unit vectors, $[1, 0, \ldots, 0]^T$ and $[0, \ldots, 0, 1]^T$, respectively. In this section, we present a divide-and-conquer method for computing the eigenvalue decomposition of TT^H given the eigenvalue decompositions of $T_1 T_1^H$ and $T_2 T_2^H$. Our method is based on the rank-one modification of symmetric eigenvalue decomposition.

2.1. Dividing the matrix. We first establish the relations between the eigenvalues and eigenvectors of $T_i T_i^H$, $i = 1, 2$, and those of TT^H as follows. From (2), we get

$$\begin{aligned}
TT^H &= \begin{bmatrix} T_1 & b_m \mathbf{e}_m \mathbf{e}_1^T \\ b_m \mathbf{e}_1 \mathbf{e}_m^T & T_2 \end{bmatrix} \begin{bmatrix} T_1^H & \bar{b}_m \mathbf{e}_m \mathbf{e}_1^T \\ \bar{b}_m \mathbf{e}_1 \mathbf{e}_m^T & T_2^H \end{bmatrix} \\
&= \begin{bmatrix} T_1 T_1^H + |b_m|^2 \mathbf{e}_m \mathbf{e}_m^T & b_m \mathbf{e}_m \mathbf{e}_1^T T_2^H + \bar{b}_m T_1 \mathbf{e}_m \mathbf{e}_1^T \\ \bar{b}_m T_2 \mathbf{e}_1 \mathbf{e}_m^T + b_m \mathbf{e}_1 \mathbf{e}_m^T T_1^H & T_2 T_2^H + |b_m|^2 \mathbf{e}_1 \mathbf{e}_1^T \end{bmatrix} \\
&= \begin{bmatrix} T_1 T_1^H & 0 \\ 0 & T_2 T_2^H \end{bmatrix} + \begin{bmatrix} |b_m|^2 \mathbf{e}_m \mathbf{e}_m^T & b_m \mathbf{e}_m \mathbf{e}_1^T T_2^H \\ \bar{b}_m T_2 \mathbf{e}_1 \mathbf{e}_m^T & 0 \end{bmatrix} \\
&\quad + \begin{bmatrix} 0 & \bar{b}_m T_1 \mathbf{e}_m \mathbf{e}_1^T \\ b_m \mathbf{e}_1 \mathbf{e}_m^T T_1^H & |b_m|^2 \mathbf{e}_1 \mathbf{e}_1^T \end{bmatrix} \\
&= \begin{bmatrix} T_1 T_1^H & 0 \\ 0 & T_2 (I_m - \mathbf{e}_1 \mathbf{e}_1^T) T_2^H \end{bmatrix} + \begin{bmatrix} b_m \mathbf{e}_m \\ T_2 \mathbf{e}_1 \end{bmatrix} \begin{bmatrix} \bar{b}_m \mathbf{e}_m^T & \mathbf{e}_1^T T_2^H \end{bmatrix} \\
&\quad + \begin{bmatrix} 0 & \bar{b}_m T_1 \mathbf{e}_m \mathbf{e}_1^T \\ b_m \mathbf{e}_1 \mathbf{e}_m^T T_1^H & |b_m|^2 \mathbf{e}_1 \mathbf{e}_1^T \end{bmatrix} \\
&= \begin{bmatrix} T_1 (I_m - \mathbf{e}_m \mathbf{e}_m^T) T_1^H & 0 \\ 0 & T_2 (I_m - \mathbf{e}_1 \mathbf{e}_1^T) T_2^H \end{bmatrix} + \begin{bmatrix} b_m \mathbf{e}_m \\ T_2 \mathbf{e}_1 \end{bmatrix} \begin{bmatrix} \bar{b}_m \mathbf{e}_m^T & \mathbf{e}_1^T T_2^H \end{bmatrix} \\
&\quad + \begin{bmatrix} T_1 \mathbf{e}_m \\ b_m \mathbf{e}_1 \end{bmatrix} \begin{bmatrix} \mathbf{e}_m^T T_1^H & \bar{b}_m \mathbf{e}_1^T \end{bmatrix} \\
&= \begin{bmatrix} T_1 (I_m - \mathbf{e}_m \mathbf{e}_m^T) T_1^H & 0 \\ 0 & T_2 (I_m - \mathbf{e}_1 \mathbf{e}_1^T) T_2^H \end{bmatrix} + \mathbf{z}_1 \mathbf{z}_1^H + \mathbf{z}_2 \mathbf{z}_2^H,
\end{aligned} \tag{3}$$

where

$$\mathbf{z}_1 = \begin{bmatrix} b_m \mathbf{e}_m \\ T_2 \mathbf{e}_1 \end{bmatrix} \quad \text{and} \quad \mathbf{z}_2 = \begin{bmatrix} T_1 \mathbf{e}_m \\ b_m \mathbf{e}_1 \end{bmatrix}.$$

From (3), if the eigenvalue decompositions

$$T_1 T_1^H = U_1 \Sigma_1^2 U_1^H \quad \text{and} \quad T_2 T_2^H = U_2 \Sigma_2^2 U_2^H \tag{4}$$

of the positive semidefinite Hermitian matrices $T_1 T_1^H$ and $T_2 T_2^H$ are available, then we can find the eigenvalue decomposition of TT^H by four rank-one modifications. Thus, if the Takagi factorizations of T_1 and T_2 are available, then we can compute the Takagi values of T and the eigenvectors of TT^H by four rank-one modifications. Later in section 3, we will show how to transform the eigenvectors into the Takagi vectors.

Now, we discuss the rank-one modification. Cuppen [2, Theorem 2.1] characterizes the eigenvalues and eigenvectors of the real symmetric rank-one modification. We generalize it to the complex case. The proof is analogous to the one in [2], so it is omitted.

THEOREM 2.1. [illegible] D^2 [illegible] $\operatorname{diag}(d_1^2, \ldots, d_n^2)$ [illegible] $d_1^2 > d_2^2 > \cdots > d_n^2$, $\mathbf{z} \in C^n$ [illegible] $\rho > 0$ [illegible] $D^2 + \rho \mathbf{z}\mathbf{z}^H$ [illegible] n [illegible] $\delta_1^2 > \delta_2^2 > \cdots > \delta_n^2$ [illegible]

$$w(\delta^2) = 1 + \rho \mathbf{z}^H (D^2 - \delta^2 I)^{-1} \mathbf{z} = 1 + \rho \sum_{j=1}^{n} \frac{|z_j|^2}{d_j^2 - \delta^2}. \tag{5}$$

[illegible] $\mathbf{g}_1, \mathbf{g}_2, \ldots, \mathbf{g}_n$ [illegible] $D^2 + \rho \mathbf{z}\mathbf{z}^H$ [illegible]

$$\mathbf{g}_j = (D^2 - \delta_j^2 I)^{-1} \mathbf{z} / \|(D^2 - \delta_j^2 I)^{-1} \mathbf{z}\|_2, \tag{6}$$

[illegible] d_j^2 [illegible] δ_j^2

$$d_n^2 < \delta_n^2 < d_{n-1}^2 < \delta_{n-1}^2 < \cdots < d_1^2 < \delta_1^2 < d_1^2 + \rho \mathbf{z}^H \mathbf{z}.$$

Applying the above theorem, we can compute the eigenvalue decomposition of TT^H from those in (4) via four rank-one modifications. Specifically, suppose that the eigenvalue decomposition $T_1 T_1^H = U_1 \Sigma_1^2 U_1^H$ in (4) is available; then

$$\begin{aligned} &T_1 (I_m - \mathbf{e}_m \mathbf{e}_m^T) T_1^H = T_1 T_1^H - T_1 \mathbf{e}_m \mathbf{e}_m^T T_1^H \\ &= U_1 (\Sigma_1^2 - (U_1^H T_1 \mathbf{e}_m)(U_1^H T_1 \mathbf{e}_m)^H) U_1^H. \end{aligned}$$

Applying Theorem 2.1 to $-\Sigma_1^2 + (U_1^H T_1 \mathbf{e}_m)(U_1^H T_1 \mathbf{e}_m)^H$, we obtain the eigenvalue decomposition of $T_1 T_1^H - T_1 \mathbf{e}_m \mathbf{e}_m^T T_1^H$. Similarly, the eigenvalue decomposition of $T_2 T_2^H - T_2 \mathbf{e}_1 \mathbf{e}_1^T T_2^H$ can be obtained from $T_2 T_2^H = U_2 \Sigma_2^2 U_2^H$ by applying Theorem 2.1. Thus, we suppose

$$T_1 T_1^H - T_1 \mathbf{e}_m \mathbf{e}_m^T T_1^H = \hat{U}_1 \hat{\Sigma}_1^2 \hat{U}_1^H \quad \text{and} \quad T_2 T_2^H - T_2 \mathbf{e}_1 \mathbf{e}_1^T T_2^H = \hat{U}_2 \hat{\Sigma}_2^2 \hat{U}_2^H. \tag{7}$$

Applying the above decompositions to (3), we have

$$TT^H = \begin{bmatrix} \hat{U}_1 & \\ & \hat{U}_2 \end{bmatrix} \left(\begin{bmatrix} \hat{\Sigma}_1^2 & \\ & \hat{\Sigma}_2^2 \end{bmatrix} + \begin{bmatrix} \hat{\mathbf{u}}_1 \\ \hat{\mathbf{u}}_2 \end{bmatrix} \begin{bmatrix} \hat{\mathbf{u}}_1 \\ \hat{\mathbf{u}}_2 \end{bmatrix}^H + \begin{bmatrix} \hat{\mathbf{v}}_1 \\ \hat{\mathbf{v}}_2 \end{bmatrix} \begin{bmatrix} \hat{\mathbf{v}}_1 \\ \hat{\mathbf{v}}_2 \end{bmatrix}^H \right) \begin{bmatrix} \hat{U}_1 & \\ & \hat{U}_2 \end{bmatrix}^H, \tag{8}$$

where $\hat{\mathbf{u}}_1 = b_m \hat{U}_1^H \mathbf{e}_m$, $\hat{\mathbf{u}}_2 = \hat{U}_2^H T_2 \mathbf{e}_1$, $\hat{\mathbf{v}}_1 = \hat{U_1}^H T_1 \mathbf{e}_m$, and $\hat{\mathbf{v}}_2 = b_m \hat{U}_2^H \mathbf{e}_1$. This shows that the eigenvalue decomposition of TT^H can be obtained by two more rank-one modifications.

The numerical computation of the rank-one modification, i.e., the roots of the rational function (5) and the eigenvectors (6) will be treated in section 4.

2.2. Deflation. In this subsection, we remove the assumptions of distinctiveness of the diagonal entries d_i and no zero entries in the modification vector $\mathbf{z}$ by applying the deflation technique given in [14]. We first consider the case when $\mathbf{z}$ has zero entries. It can be easily verified that $(d_i^2, \mathbf{e}_i)$ is an eigenpair of $D^2 + \rho \mathbf{z}\mathbf{z}^H$ if $z_i = 0$. In this case, the problem can be deflated by one for each zero entry in $\mathbf{z}$. Next, we consider the case when there are two equal diagonal elements in D^2, say $d_i^2 = d_j^2$. Let P be a Givens rotation such that

$$P \begin{bmatrix} z_i \\ z_j \end{bmatrix} = \begin{bmatrix} * \\ 0 \end{bmatrix};$$

then

$$P \left(\begin{bmatrix} d_i^2 & 0 \\ 0 & d_j^2 \end{bmatrix} + \begin{bmatrix} z_i \\ z_j \end{bmatrix} \begin{bmatrix} z_i \\ z_j \end{bmatrix}^H \right) P^H = \begin{bmatrix} d_i^2 & 0 \\ 0 & d_j^2 \end{bmatrix} + \begin{bmatrix} * \\ 0 \end{bmatrix} \begin{bmatrix} * \\ 0 \end{bmatrix}^H.$$

Thus, when $d_i^2 = d_j^2$ for some $i \neq j$, we can assume $z_i = 0$ or $z_j = 0$. So, the case of equal diagonal elements in D is changed to the case of zero entries in $\mathbf{z}$.

Due to the rounding errors, we regard two elements d_i^2 and d_j^2 equal if the difference between them is less than a predetermined tolerance *tol*. How do we determine the tolerance? In our deflation procedure, when d_i^2 and d_j^2 are numerically equal, we find a Givens rotation to transform $[z_i, z_j]^T$ into $[*, 0]^T$. Let $c = \bar{z}_i / \sqrt{|z_i|^2 + |z_j|^2}$ and $s = -\bar{z}_j / \sqrt{|z_i|^2 + |z_j|^2}$; then

$$\begin{bmatrix} c & -s \\ \bar{s} & \bar{c} \end{bmatrix} \begin{bmatrix} d_i^2 & \\ & d_j^2 \end{bmatrix} \begin{bmatrix} \bar{c} & s \\ -\bar{s} & c \end{bmatrix} = \begin{bmatrix} d_i^2 & \\ & d_j^2 \end{bmatrix} + E,$$

where

$$E = (d_i^2 - d_j^2) \begin{bmatrix} -|s|^2 & cs \\ \bar{c}\bar{s} & |s|^2 \end{bmatrix}.$$

We set the tolerance *tol* so that $\|E\|_F \leq \epsilon \, \|\mathrm{diag}(d_i^2, d_j^2)\|_F$ when $|d_i^2 - d_j^2| \leq tol$, where ϵ is the machine precision. Taking the Frobenius norm on E and $\mathrm{diag}(d_i^2, d_j^2)$, we get

$$\|E\|_F = \sqrt{2}\,|s|\,|d_i^2 - d_j^2| \quad \text{and} \quad \|\mathrm{diag}(d_i^2, d_j^2)\|_F \leq \sqrt{2}\, d_{\max}^2,$$

where $d_{\max} = \max(d_i, d_j)$. Thus, we set the tolerance

$$tol = \frac{d_{\max}^2}{|s|} \epsilon.$$

3. Takagi factorization. As described in the previous section, given the Takagi factorizations of T_1 and T_2 in (2), we can compute the eigenvalue decomposition $TT^H = U \Sigma^2 U^H$ through four rank-one modifications. Let $T = Q \Sigma Q^T$ be the Takagi factorization of T. It is obvious that the Takagi values of T are the square roots of

the eigenvalues of TT^H. It then remains to convert the eigenvectors of TT^H into the Takagi vectors of T. Specifically, given an eigenvector $\mathbf{u}_i$ of TT^H, we want to convert it into a vector $\mathbf{q}_i$ satisfying $T\bar{\mathbf{q}}_i = \sigma_i \mathbf{q}_i$. First, in the case when the eigenvalues are distinct, the eigenvectors of TT^H are uniquely defined up to a scaling factor with unit modulus, which implies that the Takagi vector $\mathbf{q}_i$ is a scalar multiple of the corresponding eigenvector $\mathbf{u}_i$. Let $T\bar{\mathbf{u}}_i = \xi\sigma_i\mathbf{u}_i$ for some scalar ξ such that $|\xi| = 1$, denote $\xi = e^{2i\phi}$ and define

$$\mathbf{q}_i \equiv e^{i\phi}\mathbf{u}_i. \tag{9}$$

Then

$$T\bar{\mathbf{q}}_i = e^{-i\phi}T\bar{\mathbf{u}}_i = e^{-i\phi}e^{2i\phi}\sigma_i\mathbf{u}_i = e^{i\phi}\sigma_i e^{-i\phi}\mathbf{q}_i = \sigma_i\mathbf{q}_i$$

as desired. Specifically, ξ can be obtained by $\xi = (\mathbf{u}_i^H T\bar{\mathbf{u}}_i)/\sigma_i$ if $\sigma_i \neq 0$; otherwise $\xi = 1$.

Next, in the case of multiple eigenvalues, $T\bar{\mathbf{u}}_i$ may not equal $\xi\sigma_i\mathbf{u}_i$. We construct

$$\mathbf{q}_i = \alpha_i(T\bar{\mathbf{u}}_i + \sigma_i\mathbf{u}_i), \tag{10}$$

where $\alpha_i = 1/\|T\bar{\mathbf{u}}_i + \sigma_i\mathbf{u}_i\|_2$ is the normalization factor. Then

$$T\bar{\mathbf{q}}_i = \alpha_i T(\overline{T\bar{\mathbf{u}}_i + \sigma_i\mathbf{u}_i}) = \alpha_i(T\bar{T}\mathbf{u}_i + \sigma_i T\bar{\mathbf{u}}_i) = \alpha_i(\sigma_i^2\mathbf{u}_i + \sigma_i T\bar{\mathbf{u}}_i) = \sigma_i\mathbf{q}_i.$$

Finally, we check the orthogonality of the Takagi vectors of T converted from the eigenvectors of TT^H. It is obvious that the orthogonality is maintained among the Takagi vectors corresponding to distinct Takagi values because of the orthogonality of the eigenvectors corresponding to distinct eigenvalues. Now, assume that $\mathbf{q}_i, \ldots, \mathbf{q}_{i+k-1}$ are the Takagi vectors corresponding to a multiple Takagi value σ_i of multiplicity $k > 1$. The construction of $\mathbf{q}_i$ shows that the subspace spanned by $\mathbf{q}_i, \ldots, \mathbf{q}_{i+k-1}$ is the same as the one spanned by $\mathbf{u}_i, \ldots, \mathbf{u}_{i+k-1}$, since $\mathbf{q}_i, \ldots, \mathbf{q}_{i+k-1}$ are the eigenvectors associated with σ_i^2. Thus, $\mathbf{q}_{i+t}$ $(t = 0, \ldots, k-1)$ are orthogonal to $\mathbf{q}_j$, the Takagi vector corresponding to σ_j, if $\sigma_j \neq \sigma_i$. However, the Takagi vectors corresponding to the equal Takagi values may lose their orthogonality. So, the modified Gram–Schmidt orthogonalization is applied to these vectors to restore the orthogonality. Suppose that $\mathbf{q}_{i+t}$ is one of the Takagi vectors corresponding to σ_i computed from (10), then we orthogonalize it against the previous t vectors $\mathbf{q}_i, \ldots, \mathbf{q}_{i+t-1}$ using the modified Gram–Schmidt method.

Now, we give the divide-and-conquer algorithm for computing the Takagi factorization of a complex symmetric tridiagonal matrix.

ALGORITHM 3.1. [illegible] T [illegible] $T = Q\Sigma Q^T$ [illegible] $TT^H = U\Sigma^2 U^H$ [illegible] $\mathbf{q}_i$ [illegible] T [illegible] $\mathbf{u}_i$ [illegible] TT^H

1. Partition T as (2). If T_1 and T_2 are small enough, then directly compute the eigenvalue decompositions

$$T_1T_1^H = U_1\Sigma_1U_1^H \quad \text{and} \quad T_2T_2^H = U_2\Sigma_2U_2^H.$$

   If T_1 and T_2 are large, apply this algorithm to T_1 and T_2.
2. Apply the deflation and the rank-one modification Theorem 2.1 to $T_1T_1^H - T_1\mathbf{e}_m\mathbf{e}_m^TT_1^H$ and $T_2T_2^H - T_2\mathbf{e}_1\mathbf{e}_1^TT_2^H$ to obtain their eigenvalue decompositions (7). Thus, TT^H has the form (8).

3. Compute the eigenvalue decomposition of TT^H via two rank-one modifications using the deflation and Theorem 2.1.
4. The Takagi values of T are the square roots of the eigenvalues of TT^H.
5. For a single Takagi value, its corresponding Takagi vector $\mathbf{q}_i$ is computed using (9); for a multiple Takagi value, its Takagi vector $\mathbf{q}_i$ is computed using (10) and then orthogonalized against the previously computed Takagi vectors corresponding to the same Takagi value by the modified Gram–Schmidt orthogonalization.

Finally, we present a complexity comparison between the divide-and-conquer method and the implicit QR method. Let $t(n)$ be the number of flops required by the divide-and-conquer method, then

$$\begin{aligned} t(n) &= 2t(n/2) && \text{for the two small submatrices } T_1 \text{ and } T_2 \\ &\quad + O(n^2) && \text{find the eignevalues and eigenvectors of } D+\rho\mathbf{z}\mathbf{z}^H \\ &\quad + 2.25cn^3 && \text{update } U. \end{aligned}$$

Thus, updating U is the major cost in our divide-and-conquer method. Ignoring the $O(n^2)$ terms, we get $t(n) \approx 3cn^3$. The constant c represents the deflation and is much smaller than one in practice [3]. In comparison, the implicit QR method in [10] requires about $6n^3$ flops. Hence, our divide-and-conquer method is more efficient than the implicit QR method.

4. Orthogonality of Takagi vectors. In the previous section, we presented a divide-and-conquer algorithm for computing the Takagi factorization of T. It is based on the rank-one update of the symmetric eigenvalue decomposition. Due to the rounding errors, the orthogonality of the eigenvectors computed by Theorem 2.1 may be lost. In this section, we present an analysis of the orthogonality of the computed eigenvectors and propose techniques for assuring good orthogonality. For simplicity, we assume that the given matrix in the rank-one modification is already deflated.

First, we derive a formula for the eigenvectors $\mathbf{g}_j$ in Theorem 2.1. Differentiating both sides of the function $w(t)$ in (5) with respect to t, we get

$$\|(D^2-\delta^2 I)^{-1}\mathbf{z}\|_2^2 = \sum_{j=1}^{n} \frac{|z_j|^2}{(d_j^2-\delta^2)^2} = \rho^{-1}|w'(\delta^2)|.$$

Then (6) can be rewritten as

$$\mathbf{g}_j = \left[\frac{z_1}{d_1^2-\delta_j^2}, \frac{z_2}{d_2^2-\delta_j^2}, \ldots, \frac{z_n}{d_n^2-\delta_j^2}\right] \frac{\sqrt{\rho}}{\sqrt{w'(\delta_j^2)}}. \tag{11}$$

Let $\hat{\delta}_i^2$ be a computed root of w in (5). In the following, by extending the results in [8], we show that if the relative error in $d_j^2-\hat{\delta}_i^2$ is small for all i and j, then the computed eigenvectors $\mathbf{g}_i$ have good orthogonality.

THEOREM 4.1. [illegible] $\hat{\delta}_i^2$ [illegible] $\hat{\delta}_k^2$ [illegible] w [illegible] (5) [illegible] $d_j^2-\hat{\delta}_i^2$ [illegible] $d_j^2-\hat{\delta}_k^2$ [illegible] θ_i [illegible] θ_k [illegible]

$$d_j^2-\hat{\delta}_i^2 = (d_j^2-\delta_i^2)(1+\theta_i) \quad \text{and} \quad d_j^2-\hat{\delta}_k^2 = (d_j^2-\delta_k^2)(1+\theta_k),$$

[illegible] $|\theta_i|,\ |\theta_k| \le \tau \ll 1$ [illegible] j [illegible]

$$|\hat{\mathbf{g}}_i^H \hat{\mathbf{g}}_k| = |\mathbf{g}_i^H E \mathbf{g}_k| \le \tau(2+\tau)\left(\frac{1+\tau}{1-\tau}\right)^2,$$

$\hat{\mathbf{g}}_i$ $\hat{\mathbf{g}}_k$ (11) E

(12)
$$E_{ii} = \frac{\theta_i + \theta_k + \theta_i\theta_k}{(1+\theta_i)(1+\theta_k)} \left(\frac{w'(\delta_i^2)w'(\delta_k^2)}{w'(\hat{\delta}_i^2)w'(\hat{\delta}_k^2)} \right)^{1/2}.$$

. From (11), we have

$$\begin{aligned}
&-\hat{\mathbf{g}}_i^H \hat{\mathbf{g}}_k \\
&= -\left(\sum_{j=1}^{n} \frac{|z_j|^2}{(d_j^2 - \delta_k^2)(d_j^2 - \delta_i^2)(1+\theta_i)(1+\theta_k)} \right) \frac{\rho}{(w'(\hat{\delta}_i^2)w'(\hat{\delta}_k^2))^{1/2}} \\
&= \left(\sum_{j=1}^{n} \frac{|z_j|^2}{(d_j^2 - \delta_k^2)(d_j^2 - \delta_i^2)} - \sum_{j=1}^{n} \frac{|z_j|^2}{(d_j^2 - \delta_k^2)(d_j^2 - \delta_i^2)(1+\theta_i)(1+\theta_k)} \right) \\
&\quad \frac{\rho}{(w'(\hat{\delta}_i^2)w'(\hat{\delta}_k^2))^{1/2}}
\end{aligned}$$

since $\mathbf{g}_i^H \mathbf{g}_k = 0$. Thus, we have

$$\begin{aligned}
&|\hat{\mathbf{g}}_i^H \hat{\mathbf{g}}_k| \\
&= \left| \sum_{j=1}^{n} \left(\frac{|z_j|^2}{(d_j^2 - \delta_k^2)(d_j^2 - \delta_i^2)} \right) \left(1 - \frac{1}{(1+\theta_i)(1+\theta_k)} \right) \frac{\rho}{(w'(\hat{\delta}_i^2)w'(\hat{\delta}_k^2))^{1/2}} \right| \\
&= \left| \sum_{j=1}^{n} \left(\frac{|z_j|^2}{(d_j^2 - \delta_k^2)(d_j^2 - \delta_i^2)} \right) \left(\frac{\theta_i + \theta_k + \theta_i\theta_k}{(1+\theta_i)(1+\theta_k)} \right) \left(\frac{w'(\delta_i^2)w'(\delta_k^2)}{w'(\hat{\delta}_i^2)w'(\hat{\delta}_k^2)} \right)^{1/2} \right. \\
&\quad \left. \frac{\rho}{(w'(\delta_i^2)w'(\delta_k^2))^{1/2}} \right| \\
&= |\mathbf{g}_i^H E \mathbf{g}_k| \le \|E\|_2,
\end{aligned}$$

where E is a diagonal matrix, whose diagonal elements are given by (12).

On the other hand, it is easy to show that

(13)
$$\frac{w'(\delta_i^2)}{w'(\hat{\delta}_i^2)} = \frac{\sum_{j=1}^{n} \frac{|z_j|^2}{(d_j^2 - \delta_i^2)^2}}{\sum_{j=1}^{n} \frac{|z_j|^2}{(d_j^2 - \delta_i^2)^2(1+\theta_i)^2}} \le (1+\tau)^2.$$

Substituting $w'(\delta_i^2)/w'(\hat{\delta}_i^2)$ in (12) with (13), we have

$$\max(|E_{ii}|) \le \frac{\tau + \tau + \tau^2}{(1-\tau)^2}(1+\tau)^2 = \tau(2+\tau)\left(\frac{1+\tau}{1-\tau} \right)^2.$$

This completes the proof. □

Apparently, if the roots δ_i^2 of w are computed in high accuracy, then the relative errors in $d_j^2 - \hat{\delta}_i^2$ are small, provided that the eigenvalues δ_i^2 are not clustered. Consequently, from the above theorem, the computed eigenvectors $\hat{\mathbf{g}}_i$ have good orthogonality.

We adopt the stable method in [5] for computing the roots δ_i of $w(\delta^2)$ in (5). It is well known that if two quantities x and y are close, then in finite-precision arithmetic it is more accurate to compute $x^2 - y^2$ via the formula $(x+y)(x-y)$ [6]. To avoid explicitly calculating the differences between squared quantities, we reformulate $w(\delta^2)$ in (5) as

$$w(\delta^2) = 1 + \psi_i(\mu) + \varphi_i(\mu) \equiv f_i(\mu),$$

where

$$\psi_1(\mu) = 0, \quad \varphi_1(\mu) = \sum_{j=1}^{n} \frac{|z_j|^2}{(\zeta_j - \mu)(d_j + d_i + \rho\mu)},$$

and

$$\psi_i(\mu) = \sum_{j=1}^{i-1} \frac{|z_j|^2}{(\zeta_j - \mu)(d_j + d_{i-1} + \rho\mu)}, \quad \varphi_i(\mu) = \sum_{j=i}^{n} \frac{|z_j|^2}{(\zeta_j - \mu)(d_j + d_{i-1} + \rho\mu)},$$

for $i > 1$, and

$$\zeta_j = (d_j - d_i)/\rho, \qquad \mu = (\delta - d_i)/\rho, \qquad \text{when } \delta^2 \in (d_i^2,\ (d_{i-1}^2 + d_i^2)/2),$$
$$\zeta_j = (d_j - d_{i-1})/\rho, \quad \mu = (\delta - d_{i-1})/\rho, \quad \text{when } \delta^2 \in [(d_{i-1}^2 + d_i^2)/2,\ d_{i-1}^2).$$

In the above formulation, an important property of $f_i(\mu)$ is that it can be evaluated accurately. Moreover, we have formulated the functions $\psi_i(\mu)$ and $\varphi_i(\mu)$ so that explicit calculation of the differences of squares such as $d_j^2 - d_i^2$ and $\delta^2 - d_i^2$ are avoided. There are many zero finding methods, for example, the rational interpolation [1] and bisection and its variations [11, 13]. Following [5], our algorithm for finding the zeros of $f_i(\mu)$ is based on the rational interpolation strategy [1] and its LAPACK implementation `slasd4`. Thus, from [5], the computed eigenvalues have high relative accuracy. The eigenvectors are computed from the computed eigenvalues following the method for computing the eigenvectors in [5], which guarantees numerical orthogonality. Thus, the computed Takagi vectors are numerically orthogonal since they are obtained by converting the eigenvectors.

Finding a root of $f_i(\mu)$ is an iterative process. The stopping criterion plays an important role in the accuracy of the computed roots. Similar to [4], we propose the stopping criterion:

$$|f_i(\mu)| \le \epsilon n(|\psi_i(\mu)| + |\varphi_i(\mu)| + 1). \tag{14}$$

In the following, we show that by using this criterion, the computed roots $\hat{\delta}_i^2$ of $w(\delta^2)$ are accurate.

Since $w(\delta_i^2) = 0$, we have

$$\begin{aligned} w(\hat{\delta}_i^2) &= w(\hat{\delta}_i^2) - w(\delta_i^2) = \rho \sum_{j=1}^{n} \frac{|z_j|^2}{d_j^2 - \hat{\delta}_i^2} - \rho \sum_{j=1}^{n} \frac{|z_j|^2}{d_j^2 - \delta_i^2} \\ &= \rho(\hat{\delta}_i^2 - \delta_i^2) \sum_{j=1}^{n} \frac{|z_j|^2}{(d_j^2 - \hat{\delta}_i^2)(d_j^2 - \delta_i^2)}. \end{aligned}$$

According to the stopping criterion (14), since $f_i(\mu)$ can be evaluated accurately, we have

$$|w(\hat{\delta}_i^2)| \le \epsilon n \left(1 + \rho \sum_{j=1}^{n} \frac{|z_j|^2}{|d_j^2 - \hat{\delta}_i^2|}\right) \le \rho\epsilon n \left(\sum_{j=1}^{n} \frac{|z_j|^2}{|d_j^2 - \hat{\delta}_i^2|} + \sum_{j=1}^{n} \frac{|z_j|^2}{|d_j^2 - \delta_i^2|}\right)$$

since $1 = -\rho \sum_{j=1}^{n} \frac{|z_j|^2}{d_j^2 - \delta_i^2}$. Without loss of generality, we assume δ_i^2 and $\hat{\delta}_i^2$ are in the same interval, say $(d_i^2,\ d_{i-1}^2)$. It follows that $(d_j^2 - \delta_i^2)(d_j^2 - \hat{\delta}_i^2) > 0$. So,

$$\begin{aligned} |w(\hat{\delta}_i^2)| = \rho|\hat{\delta}_i^2 - \delta_i^2| \sum_{j=1}^{n} \frac{|z_j|^2}{|(d_j^2 - \hat{\delta}_i^2)(d_j^2 - \delta_i^2)|} &\le \rho\epsilon n \left(\sum_{j=1}^{n} \frac{|z_j|^2}{|d_j^2 - \hat{\delta}_i^2|} + \sum_{j=1}^{n} \frac{|z_j|^2}{|d_j^2 - \delta_i^2|}\right) \\ &\le \rho\epsilon n(4\|D^2 + \rho\mathbf{z}\mathbf{z}^H\|_2 + |\hat{\delta}_i^2 - \delta_i^2|) \sum_{j=1}^{n} \frac{|z_j|^2}{|(d_j^2 - \hat{\delta}_i^2)(d_j^2 - \delta_i^2)|}, \end{aligned}$$

since $|d_j^2 - \hat{\delta}_i^2| + |d_j^2 - \delta_i^2| \le 2|d_j^2 - \delta_i^2| + |\hat{\delta}_i^2 - \delta_i^2| \le 4\|D^2 + \rho\mathbf{z}\mathbf{z}^H\|_2 + |\hat{\delta}_i^2 - \delta_i^2|$. From the above equation, we can get the upper bound for $|\hat{\delta}_i^2 - \delta_i^2|$:

$$|\hat{\delta}_i^2 - \delta_i^2| \le \frac{4\epsilon n\|D^2 + \rho\mathbf{z}\mathbf{z}^H\|_2}{1 - \epsilon n}.$$

In conclusion, we apply the rational interpolation zero finding method to $f_i(\mu)$ using the stopping criterion (14). We can then obtain accurate eigenvalues δ_i^2. Provided that the eigenvalues are not clustered, it results in the high relative accuracy of the difference $d_i^2 - \hat{\delta}_i^2$, which implies good orthogonality of the computed eigenvectors of TT^H.

5. Numerical examples. We programmed our divide-and-conquer Algorithm 3.1 in MATLAB and tested it on three types of complex symmetric and tridiagonal matrices. Our experiments were carried out on a server with two 2.4 GHz Xeon CPUs, 1GB RAM, and 80GB disk. The complex symmetric and tridiagonal matrices with predetermined Takagi values were generated as follows. First, a random vector uniformly distributed on $(0, 1]$ was generated and sorted in descending order as a Takagi value vector d. Then, a random unitary matrix was generated as a Takagi vector matrix V. The product $A = V\Sigma V^T$, where $\Sigma = \mathrm{diag}(d)$, was computed as a complex symmetric matrix. Finally, a complex symmetric and tridiagonal T was obtained by applying the Householder transformations to both sides of A. Denoting $\hat{Q}$ and $\hat{d}$ as the computed Takagi vector matrix and Takagi value vector, respectively, the error in the computed Takagi factorization was measured by

$$\gamma_t = \|\hat{Q}\hat{\Sigma}\hat{Q}^T - T\|_2, \quad \text{where} \quad \hat{\Sigma} = \mathrm{diag}(\hat{d}).$$

The error in the computed Takagi values was measured by

$$\gamma_v = \|d - \hat{d}\|_2,$$

and the orthogonality of the computed Takagi vector matrix $\hat{Q}$ was measured by

$$\gamma_o = \|\hat{Q}\hat{Q}^H - I\|_2.$$

TABLE 1
The Takagi factorization of five 256×256 *testing matrices with distinct Takagi values.*

Example	γ_o	γ_v	γ_t
1	1.3558E−14	3.1347E−14	4.1149E−12
2	2.1679E−14	1.0854E−14	4.3920E−12
3	9.7087E−14	8.4093E−15	1.1309E−12
4	1.1040E−14	1.2622E−14	5.5019E−12
5	3.0840E−14	1.1658E−14	1.1243E−12

1. Five random complex symmetric and tridiagonal matrices of order 256 were generated as described above. In this example, the Takagi values of each matrix were distinct. Table 1 shows that the computed Takagi values and Takagi vectors are accurate.

2. Five random complex symmetric and tridiagonal matrices of order 256 were generated. In this example, we set the five largest Takagi values equal and the four smallest Takagi values equally. Table 2 shows the results.

TABLE 2
The Takagi factorization of five 256×256 *testing matrices with multiple Takagi values of small multiplicity.*

Example	γ_o	γ_v	γ_t
1	7.5222E−12	1.1331E−14	1.0564E−12
2	2.5397E−12	1.9208E−14	2.6242E−12
3	2.4214E−12	6.0150E−14	6.1179E−12
4	1.9582E−12	4.8421E−14	3.2142E−12
5	6.3841E−12	1.0580E−14	2.4453E−12

TABLE 3
The Takagi factorization of five 256×256 *testing matrices with multiple Takagi values of large multiplicity.*

Example	γ_o	γ_v	γ_t
1	7.8816E−13	8.8186E−14	4.0040E−12
2	3.7709E−12	2.4154E−14	8.4231E−12
3	4.3532E−13	1.3427E−14	3.4808E−12
4	6.2713E−12	7.4803E−14	1.7887E−12
5	4.5237E−12	5.1166E−14	6.4702E−12

3. Five random T of order 256 were generated. In this example, however, we set the 31 largest Takagi values equal. Table 3 shows that the computed results are accurate.

For performance, we tested our algorithm on random complex symmetric and tridiagonal matrices of five different sizes. For each size, we generated five matrices and ran our divide-and-conquer (DAC) method and the implicit QR (IQR) method [10]. In our divide-and-conquer method, when the size of the submatrices T_i, for $i = 1, 2$, in (2) is less than or equal to 10, its Takagi factorization is computed directly by the implicit QR method. Table 4 shows the average running time and the average factorization error γ_t of the five matrices of same size. The results in Table 4 demonstrate that our method is significantly more efficient than the implicit QR method even for matrices of moderately large size.

TABLE 4
The performance and accuracy comparison of the divide-and-conquer (DAC) method and the implicit QR (IQR) method.

	Running time (sec)		γ_t	
matrix size	DAC method	IQR method	DAC method	IQR method
100	1.14	1.16	1.3352E−14	2.4668E−14
200	3.01	5.47	2.0272E−12	2.9772E−14
400	9.51	26.05	1.7014E−12	6.4860E−14
800	46.88	187.05	1.1338E−11	9.0250E−14
1600	286.14	2091.12	4.2198E−11	2.1552E−13

6. Conclusion. We have proposed a divide-and-conquer method for computing the Takagi factorization of a complex symmetric and tridiagonal matrix and presented an analysis, which shows that our method computes accurate Takagi values and vectors provided that the Takagi values are not clustered. Our preliminary experiments have demonstrated that our method produces accurate results even for matrices with multiple Takagi values and is much more efficient than the implicit QR method [10].

ON THE ESTIMATION OF THE DISTANCE TO UNCONTROLLABILITY FOR HIGHER ORDER SYSTEMS*

EMRE MENGI†

Abstract. A higher order dynamical system of order k is called controllable if the trajectory of the system as well as its first $k-1$ derivatives can be adjusted to pass through any given point at a finite time by choosing the input appropriately. The distance to uncontrollability is the norm of the smallest perturbation yielding an uncontrollable system. We derive a singular value minimization characterization for the distance to uncontrollability and present a trisection algorithm exploiting the singular value characterization. The algorithm is devised for low accuracy and depends on the extraction of the imaginary eigenvalues of even-odd matrix polynomials of degree $2k$ and size $2n$ with n denoting the size of the system. The well-studied first order distance to uncontrollability can be recovered as a special case.

1. Introduction.

A fundamental question concerning the kth order continuous time-invariant dynamical system

$$K_k x^{(k)}(t) + \cdots + K_1 x'(t) + K_0 x(t) = Bu(t), \quad x(0) = x'(0) = \cdots = x^{(k-1)} = 0 \tag{1.1}$$

is the dimension of the subspace of reachable configurations at a given time t' where $B \in \mathbb{C}^{n\times m}$, $K_0, K_1, \ldots K_k \in \mathbb{C}^{n\times n}$, $x(t) \in \mathbb{C}^n$, and $u(t) \in \mathbb{C}^m$. Here $x(t)$ denotes the state vector, $u(t)$ denotes the control input, and $c_0, c_1, \ldots, c_{k-1} \in \mathbb{C}^n$ are given initial conditions. By a configuration at time t' we mean the vector consisting of $x(t')$ as well as its first $k-1$ time derivatives at time t'. We define the space of reachable configurations at time t' as

$$\mathcal{R}_{t'} = \{[\varepsilon_0, \varepsilon_1, \ldots, \varepsilon_{k-1}] \ : \quad \exists u(t) \text{ such that (1.1) satisfies } \varepsilon_0 = x(t'),\ \varepsilon_1 = x'(t'), \ldots,\ \varepsilon_{k-1} = x^{(k-1)}(t')\}.$$

We have full control over the system (1.1) if all of the configurations can be attained by choosing $u(t)$ appropriately, that is

$$\dim(\mathcal{R}_{t'}) = nk. \tag{1.2}$$

In this case the system (1.1) is called controllable. Otherwise, the system is called uncontrollable. For convenience we will frequently refer to the tuple of matrices $(K_k, \ldots, K_1, K_0, B)$ as controllable whenever the system (1.1) is controllable.

Controllability of a first order system, specifically with $k = 1$, $K_1 = I$ (the identity matrix) and $K_0 = -A$ (an arbitrary matrix), is well known [9] to be equivalent to

either of the conditions

$$\operatorname{rank}([B \;\; AB \;\; A^2B \;\; \cdots \;\; A^{n-1}B]) = n$$

or

$$\operatorname{rank}([A - \lambda I \;\; B]) = n \text{ for all } \lambda \in \mathbb{C}. \tag{1.3}$$

A similar characterization for the controllability of a descriptor system with $k = 1$, $K_1 = E$, and $K_0 = -A$ exists [7, 8]. In particular when E is nonsingular the controllability reduces to the condition

$$\operatorname{rank}([A - \lambda E \;\; B]) = n \text{ for all } \lambda \in \mathbb{C}. \tag{1.4}$$

When E is singular, the above condition needs to be accompanied by an additional rank condition that involves the null space of E. Throughout this paper we will assume that the leading coefficient is nonsingular and additionally, when perturbations to the leading coefficient are allowed, the leading coefficient remains nonsingular under all perturbations under consideration. (This condition is stated formally in Lemma 2.2.) Under this nonsingularity assumption, the rank characterizations (1.3) and (1.4) can be generalized to the higher order system and the nearby systems as follows. First observe that (1.1) can be embedded into the first order system

$$\tilde{x}'(t) = \mathcal{A}\tilde{x}(t) + \mathcal{B}u(t), \qquad \tilde{x}(0) = \begin{bmatrix} c_{k-1} \\ c_{k-2} \\ \vdots \\ c_0 \end{bmatrix}, \tag{1.5}$$

where

$$\tilde{x}(t) = \begin{bmatrix} x^{(k-1)}(t) \\ x^{(k-2)}(t) \\ x^{(k-3)}(t) \\ \vdots \\ x(t) \end{bmatrix}, \quad \mathcal{B} = \begin{bmatrix} K_k^{-1}B \\ 0 \\ 0 \\ \vdots \\ 0 \end{bmatrix}, \qquad \text{and}$$

$$\mathcal{A} = \begin{bmatrix} -K_k^{-1}K_{k-1} & -K_k^{-1}K_{k-2} & \dots & -K_k^{-1}K_1 & -K_k^{-1}K_0 \\ I & 0 & & 0 & 0 \\ 0 & I & & 0 & 0 \\ \vdots & & \ddots & & \vdots \\ 0 & 0 & & I & 0 \end{bmatrix}.$$

Now the higher order system is controllable if and only if the matrix $[\mathcal{A} - \lambda I \;\; \mathcal{B}]$ has full rank for all λ. Furthermore, for a given λ suppose

$$[\mathcal{A} - \lambda I \;\; \mathcal{B}] \begin{bmatrix} x_{k-1} \\ \vdots \\ x_0 \\ y_0 \end{bmatrix} = 0.$$

Using the definitions of $\mathcal{A}$ and $\mathcal{B}$, it is straightforward to deduce that $x_j = \lambda^j x_0$ and

$$[P(\lambda) \;\; B] \begin{bmatrix} x_0 \\ y_0 \end{bmatrix} = 0,$$

where

$$P(\lambda) = \sum_{j=0}^{k} \lambda^j K_j. \tag{1.6}$$

Therefore the null spaces of $[\mathcal{A} - \lambda I \;\; \mathcal{B}]$ and $[P(\lambda) \;\; B]$ have the same dimension, say $l \geq m$, which means $\text{rank}([\mathcal{A} - \lambda I \;\; \mathcal{B}]) = nk + m - l$ and $\text{rank}([P(\lambda) \;\; B]) = n + m - l$. We conclude that the controllability of the higher order system is equivalent to

$$\text{rank}([P(\lambda) \;\; B]) = n \text{ for all } \lambda \in \mathbb{C} \tag{1.7}$$

which was already mentioned in [18] without derivation.

Controllability is thus a rank determination problem, which cannot be performed reliably in the presence of rounding errors. A controllable system may still have nearby uncontrollable systems which potentially is an indicator of a problem with the model. Therefore in [22] for the first order system the distance to uncontrollability was defined as

$$\tau(A, B) = \inf\{\|[\Delta A \;\; \Delta B]\| : \text{the pair } (A + \Delta A, B + \Delta B) \text{ is uncontrollable}\} \tag{1.8}$$

with $\|\cdot\|$ denoting either the spectral norm or the Frobenius norm. Later Eising [10] proved that, in both cases, the distance to uncontrollability is equivalent to a minimization problem involving complex vectors of size n

$$\tau(A, B) = \inf_{q \in \mathbb{C}^n, \|q\| = 1} \sqrt{q^* B B^* q + q^* A (I - qq^*) A^* q} \tag{1.9}$$

and a singular value minimization problem, i.e.,

$$\tau(A, B) = \inf_{\lambda \in \mathbb{C}} \sigma_{\min}([A - \lambda I \;\; B]), \tag{1.10}$$

where $\sigma_{\min}$ denotes the smallest singular value. The most efficient computational techniques for the distance to uncontrollability exploit the definition (1.10), though there are hybrid-algorithms [24] developed following Eising's characterizations that make use of both (1.9) and (1.10). Boley observed the connection between the sensitivity of the Kronecker structure of a matrix pencil and distance to uncontrollability and based on (1.10) suggested a practical but an imprecise way to approximate the distance by solving a standard eigenvalue problem [1]. Byers introduced classes of algorithms working on one dimensional or two dimensional grids [5] to minimize $\sigma_{\min}([A - \lambda I \;\; B])$. Later Gao and Neumann [11] and He [16] modified Byers' idea for more efficient computation. Byers' grid-based algorithms and its successors are well-suited for the computation of the distance to uncontrollability with a few digits of precision but are too costly for high accuracy. Gu's bisection algorithm [14] is the first technique that retrieves the global minimum for the problem (1.10) within a factor of two without depending on a grid. Gu's algorithm later was improved by Burke, Lewis, and Overton [3] who suggested a trisection algorithm that computes $\tau(A, B)$ to arbitrary precision. With $O(n^6)$ complexity[1] these algorithms are applicable only to small systems. In [15], it is described how we can benefit from inverse iteration and shift-and-invert preconditioned Arnoldi to reduce the average running time to $O(n^4)$

[1] When we refer to operation counts, we assume eigenvalue computations are atomic operations with cubic complexity.

making the computation of the distance to uncontrollability for medium size systems feasible. For descriptor systems the distance to uncontrollability is discussed and a generalization of the characterization (1.10) is provided in [6].

In this work we extend the definition (1.8) for the first order system to the higher order system (1.1) as

(1.11)
$$\begin{aligned}\tau(P,B,\alpha) = \inf\{\|[\Delta K_k \ \cdots \ \Delta K_1 \ \Delta K_0 \ \Delta B]\| : \text{ the tuple} \\ (K_k+\alpha_k\Delta K_k,\ldots,K_0+\alpha_0\Delta K_0, B+\Delta B) \text{ is uncontrollable}\},\end{aligned}$$

where the vector $\alpha = [\alpha_k \ \cdots \ \alpha_1 \ \alpha_0]$ consists of nonnegative real numbers. Notice that with $k = 1$, $K_1 = I$, $K_0 = -A$, and $\alpha = [0\ 1]$ we recover the definition (1.8) for the first order system. Our motivation in introducing the scaling α is mainly to restrict the perturbations to some of the coefficient matrices, by choosing the scaling corresponding to other coefficients to be zero. It also serves the purpose of weighting the perturbations to the coefficients. For instance one may be interested in perturbations in a relative sense with respect to the norm of the coefficients in which case it is desirable to set $\alpha = [\|K_k\| \ \cdots \ \|K_1\| \ \|K_0\|]$.

The distance to uncontrollability of the higher order system defined by (1.11) and the embedded system (1.5) are related yet different quantities. The closest uncontrollable descriptor system to the embedded system would usually be obtained by perturbing the block rows of $\mathcal{A}$ other than the first one, so the resulting uncontrollable system does not correspond to an embedding of a higher order system. For instance if one of the coefficient matrices, say K_j, is considerably larger than the other coefficients as well as B in norm and $K_k^{-1}K_j$ is close to a multiple of the identity matrix, then small perturbations to the $(j+1)$th block row of $[\mathcal{A} \ \mathcal{B}]$ makes it rank deficient and the embedding uncontrollable. Typically we expect that $\tau(\mathcal{A},\mathcal{B}) < \tau(P,B,\alpha)$, since in the definition of $\tau(\mathcal{A},\mathcal{B})$ we have more degrees of freedom when choosing perturbations. Such an example where these two distances differ significantly is given in section 4.2. It is not clear how the existing algorithms to compute $\tau(\mathcal{A},\mathcal{B})$ can be modified to impose the constraints on perturbations to $\mathcal{A}$ and $\mathcal{B}$ so that perturbed systems correspond to the embeddings of higher order systems.

In the next section we provide a singular value minimization characterization for the definition (1.11). We will see that the definition (1.11) in the spectral norm and the Frobenius norm are equivalent just as in the first order case and the characterization we derive reduces to (1.10) for the first order system. The derivation of the singular value characterization uses the rank definition of the controllability (1.7) for the higher order system and all nearby systems which holds only if the leading coefficient is nonsingular and sufficiently away from the closest singular matrix. The equivalent singular value characterization is typically nonconvex. A standard optimization technique such as BFGS will converge only to a local minimum. Applying BFGS repeatedly with various starting points might occasionally fail to return a global minimum. Therefore in section 3 we describe a trisection algorithm locating the global minimum of the equivalent optimization problem. This algorithm is not a generalization of the algorithm of [3], because such an approach is too expensive. The first few steps of the new algorithm are comparatively cheap, but as we require more accuracy the algorithm becomes computationally intensive. With a complexity of $O\left(\frac{1}{\arccos(1-(\frac{tol}{k})^2)}n^3k^4\right)$ with tol denoting the accuracy required, it is devised for a few digits of precision. Section 4 is devoted to numerical examples illustrating the efficiency of the algorithm.

2. Properties of the higher order distance to uncontrollability and a singular value characterization. The set of controllable tuples is clearly a dense subset of the whole space of matrix tuples. But this does not mean that the uncontrollable tuples are isolated points. On the contrary there are uncontrollable subspaces. For instance the system (1.1) with $K_0 = 0$ and $\text{rank}(B) < n$ is uncontrollable for all $K_k, \ldots, K_1$. Therefore we shall first see that $\tau(P, B, \alpha)$ is indeed attained at some $(\Delta K_k, \ldots, \Delta K_0, \Delta B)$. Note that throughout this work we usually use $\|\cdot\|$ for either the spectral or the Frobenius norm interchangeably when the results hold for both of the norms or when the type of the norm is clear from the context. At other times we clarify the choice of norm using the notation $\|\cdot\|_2, \|\cdot\|_F$ for the spectral and the Frobenius norm, respectively.

LEMMA 2.1. [illegible] $(K_k+\alpha_k\Delta K_k, \ldots, K_0+\alpha_0\Delta K_0, B+\Delta B)$ [illegible] $\tau(P, B, \alpha) = \|[\Delta K_k \ \cdots \ \Delta K_0 \ \ \Delta B]\|$ [illegible] $\|\Delta K_j\| \leq \|B\|$ [illegible] j $\|\Delta B\| \leq \|B\|$

[illegible]. The matrix $[P(\lambda) \ \ 0]$ is rank deficient at the eigenvalues of P. Therefore $\tau(P, B, \alpha) \leq \|B\|$ meaning we can restrict the perturbations to the ones satisfying $\|\Delta K_j\| \leq \|B\|$ and $\|\Delta B\| \leq \|B\|$.

Furthermore the set of uncontrollable tuples is closed. To see this, consider any sequence $\{(K_k', \ldots, K_0', B')\}$ of uncontrollable tuples. Now for any tuple in the sequence define the associated polynomial as $P'(\lambda) = \sum_{j=0}^{k} \lambda^j K_j'$. The matrix $[P'(\lambda) \ \ B']$ is rank deficient for some λ, so all combinations of n columns of this matrix are linearly dependent. Let us denote the $l = \binom{m+n}{n}$ polynomials associated with the determinants of the combinations of n columns by $p_1(\lambda), p_2(\lambda), \ldots, p_l(\lambda)$ in any order. These polynomials must share a common root; otherwise $[P'(\lambda) \ \ B']$ would not be rank deficient for some λ. The common roots $r_1, r_2, \ldots, r_l$ are continuous functions of the tuple $\{(K_k', \ldots, K_0', B')\}$ which means at any cluster point of the sequence $r_1 = r_2 = r_3 = \cdots = r_l$. This shows that the set is closed.

Since we are minimizing the spectral or the Frobenius norm over a compact set, $\tau(P, B, \alpha)$ must be attained at some $\|[\Delta K_k \ \cdots \ \Delta K_0 \ \ \Delta B]\|$. □

The main result of this section establishes the equivalence of $\tau(P, B, \alpha)$ to the solution of the singular value minimization problem

$$\xi(P, B, \alpha) = \inf_{\lambda \in \mathbb{C}} \sigma_{\min} \left(\begin{bmatrix} P(\lambda) \\ \hline \sqrt{s_\alpha(|\lambda|)} \end{bmatrix} \ \ B \right) \tag{2.1}$$

when $\alpha_0 \neq 0$, where

$$s_\alpha(|\lambda|) = \sum_{j=0}^{k} \alpha_j^2 |\lambda|^{2j}.$$

When establishing this equivalence, we seek the perturbations ΔP and ΔB yielding a matrix function $[(P + \Delta P)(\lambda) \ B + \Delta B]$ that is rank deficient at some λ. A relevant problem is the distance to instability of a matrix polynomial which can be posed as

$$\beta(P, \alpha)$$
$$= \inf \left\{ \|[\Delta K_k \ \Delta K_{k-1} \ldots \Delta K_0]\| : (P + \Delta P)(\lambda) = 0, \ \exists \lambda \in \mathbb{C}_b, \ \Delta P = \sum_{j=0}^{k} \alpha_j \lambda^j \Delta K_j \right\}$$

where $\mathbb{C}_b$ is a closed subset of the complex plane corresponding to the unstable region and $\|\cdot\|$ is the spectral norm. A simplified version of this problem with α equal to

the vector of ones was studied in [13]. Let $\partial\mathbb{C}_b$ denote the boundary of the unstable region. It is straightforward to modify Lemma 8 in [13] to deduce the equivalence of $\beta(P,\alpha)$ with the minimization problem

$$\inf_{\lambda\in\partial\mathbb{C}_b} \sigma_{\min}\left(\left[\frac{P(\lambda)}{\sqrt{s_\alpha(|\lambda|)}}\right]\right).$$

Another similar problem is the pseudospectrum of a matrix polynomial which consists of the set of eigenvalues of nearby matrix polynomials. Let us formally define the ϵ-pseudospectrum as

$$\Lambda_\epsilon(P,\alpha) = \left\{\lambda\in\mathbb{C} : (P+\Delta P)(\lambda)=0,\ \Delta P=\sum_{j=0}^{k}\alpha_j\lambda^j\Delta K_j,\ \|[\Delta K_k\ \Delta K_{k-1}\ \cdots\ \Delta K_0]\|\le\epsilon\right\}$$

where $\|\cdot\|$ denotes the spectral norm. Here we slightly depart from the original definition suggested by Tisseur and Higham in [23] in the way the nearness to a matrix polynomial is measured. (In [23] the norm of each of the perturbations ΔK_j is constrained to be less than ϵ.) The technique in [23] leads us to the singular value characterization

$$\Lambda_\epsilon(P,\alpha) = \left\{\lambda\in\mathbb{C} : \sigma_{\min}\left(\left[\frac{P(\lambda)}{\sqrt{s_\alpha(|\lambda|)}}\right]\right)\le\epsilon\right\}.$$

The condition $\alpha_0\neq 0$, that is assumed throughout the derivations below, means that the perturbations to K_0 cannot be blocked and avoids the indeterminate case, when $s_\alpha(|\lambda|)=0$. At the end of this section we will present a more general equivalence result that holds no matter what value is assigned to α as long as all of its components are nonnegative. With this restriction on α_0, $\xi(P,B,\alpha)$ must be attained either at a finite λ or at ∞. The latter case is eliminated by the next lemma.

LEMMA 2.2. [illegible] (1.1) [illegible] $\alpha_k\xi(P,B,\alpha)$ [illegible] $\alpha_0\neq 0$ [illegible]

$$\xi(P,B,\alpha) < \lim_{\lambda\to\infty}\sigma_{\min}\left(\left[\frac{P(\lambda)}{\sqrt{s_\alpha(|\lambda|)}}\quad B\right]\right)$$

[illegible]. When $\alpha_k=0$, the result immediately follows. When $\alpha_k>0$, we have

$$\sigma_{\min}\left(\left[\frac{K_k}{\alpha_k}\quad B\right]\right) = \lim_{\lambda\to\infty}\sigma_{\min}\left(\left[\frac{P(\lambda)}{\sqrt{s_\alpha(|\lambda|)}}\quad B\right]\right).$$

Suppose $\xi(P,B,\alpha)$ is attained at ∞ and therefore there exist $u_1, v\in\mathbb{C}^n$ and $u_2\in\mathbb{C}^m$ such that

$$\begin{bmatrix}\left(\frac{K_k}{\alpha_k}\right)^*\\ B^*\end{bmatrix} v = \xi(P,B,\alpha)\begin{bmatrix}u_1\\ u_2\end{bmatrix},$$

where $[u_1^T \ u_2^T]^T$ and v have unit length. Multiplying the upper blocks by α_k, the right-hand side by v^*v and collecting all terms on the left yields

$$\begin{bmatrix} K_k^* - \alpha_k \xi(P,B,\alpha) u_1 v^* \\ B^* - \xi(P,B,\alpha) u_2 v^* \end{bmatrix} v = 0.$$

Consequently a perturbation to the leading coefficient with norm at most $\alpha_k \xi(P,B,\alpha)$ yields the singular matrix $K_k - \alpha_k \xi(P,B,\alpha) v u_1^*$, which contradicts the nonsingularity assumption. □

THEOREM 2.3. [illegible] 2.2 [illegible] (1.1) [illegible] $\tau(P,B,\alpha) = \xi(P,B,\alpha)$ [illegible] τ [illegible] (1.11) [illegible]

[illegible]. First we assume that $\tau(P,B,\alpha)$ in (1.11) is defined in the spectral norm and show that $\xi(P,B,\alpha) \leq \tau(P,B,\alpha)$. From Lemma 2.1, there exists $\Delta P(\lambda) = \sum_{j=0}^{k} \alpha_j \lambda^j \Delta K_j$ such that

$$\tau(P,B,\alpha) = \|[\Delta K_k \ \cdots \ \Delta K_0 \ \ \Delta B]\|$$

and for some $\tilde{\lambda}$ the matrix $[(P+\Delta P)(\tilde{\lambda}) \ \ B + \Delta B]$ is rank deficient, that is

$$\begin{bmatrix} ((P+\Delta P)(\tilde{\lambda}))^* \\ B^* + \Delta B^* \end{bmatrix} v = 0$$

for some unit $v \in \mathbb{C}^n$. We collect the perturbations on the right and divide the upper blocks by $\sqrt{s_\alpha(|\tilde{\lambda}|)}$ to obtain

$$\begin{bmatrix} \left(\frac{P(\tilde{\lambda})}{\sqrt{s_\alpha(|\tilde{\lambda}|)}}\right)^* \\ B^* \end{bmatrix} v = \begin{bmatrix} \left(-\frac{\Delta P(\tilde{\lambda})}{\sqrt{s_\alpha(|\tilde{\lambda}|)}}\right)^* \\ -\Delta B^* \end{bmatrix} v.$$

Therefore

$$\begin{aligned} \xi(P,B,\alpha) &\leq \sigma_{\min}\left(\begin{bmatrix} \frac{P(\tilde{\lambda})}{\sqrt{s_\alpha(|\tilde{\lambda}|)}} & B \end{bmatrix}\right) \\ &= \sigma_{\min}\left(\begin{bmatrix} \left(\frac{P(\tilde{\lambda})}{\sqrt{s_\alpha(|\tilde{\lambda}|)}}\right)^* \\ B^* \end{bmatrix}\right) \leq \left\| \begin{bmatrix} \left(\frac{P(\tilde{\lambda})}{\sqrt{s_\alpha(|\tilde{\lambda}|)}}\right)^* \\ B^* \end{bmatrix} v \right\| \\ &= \left\| \begin{bmatrix} \left(\frac{\Delta P(\tilde{\lambda})}{\sqrt{s_\alpha(|\tilde{\lambda}|)}}\right)^* \\ \Delta B^* \end{bmatrix} v \right\| \leq \left\| \begin{bmatrix} \left(\frac{\Delta P(\tilde{\lambda})}{\sqrt{s_\alpha(|\tilde{\lambda}|)}}\right)^* \\ \Delta B^* \end{bmatrix} \right\| = \left\| \begin{bmatrix} \frac{\Delta P(\tilde{\lambda})}{\sqrt{s_\alpha(|\tilde{\lambda}|)}} & \Delta B \end{bmatrix} \right\|. \end{aligned}$$

Moreover,

$$\begin{bmatrix} \frac{\Delta P(\tilde{\lambda})}{\sqrt{s_\alpha(|\tilde{\lambda}|)}} & \Delta B \end{bmatrix} = [\Delta K_k \ \cdots \ \Delta K_0 \ \ \Delta B] \begin{bmatrix} \frac{\alpha_k \tilde{\lambda}^k I}{\sqrt{s_\alpha(|\tilde{\lambda}|)}} & 0 \\ \vdots & \vdots \\ \frac{\alpha_1 \tilde{\lambda} I}{\sqrt{s_\alpha(|\tilde{\lambda}|)}} & 0 \\ \frac{\alpha_0 I}{\sqrt{s_\alpha(|\tilde{\lambda}|)}} & 0 \\ 0 & I \end{bmatrix},$$

where the spectral norm of the rightmost matrix is one. It follows from the Cauchy–Schwarz inequality that

$$\xi(P,B,\alpha) \le \left\| \begin{bmatrix} \dfrac{\Delta P(\tilde{\lambda})}{\sqrt{s_\alpha(|\tilde{\lambda}|)}} & \Delta B \end{bmatrix} \right\| \le \|[\Delta K_k \ \cdots \ \Delta K_0 \ \ \Delta B]\| = \tau(P,B,\alpha).$$

For the reverse inequality, still using the spectral norm, we have from Lemma 2.2 that for some φ,

$$\xi(P,B,\alpha) = \sigma_{\min}\left(\begin{bmatrix} \dfrac{P(\varphi)}{\sqrt{s_\alpha(|\varphi|)}} & B \end{bmatrix} \right) = \sigma_{\min}\left(\begin{bmatrix} \left(\dfrac{P(\varphi)}{\sqrt{s_\alpha(|\varphi|)}}\right)^* \\ B^* \end{bmatrix} \right)$$

or equivalently

$$\begin{bmatrix} \frac{(P(\varphi))^*}{\sqrt{s_\alpha(|\varphi|)}} \\ B^* \end{bmatrix} v = \xi(P,B,\alpha) \begin{bmatrix} u_1 \\ u_2 \end{bmatrix},$$

where $v, u_1 \in \mathbb{C}^n$, $u_2 \in \mathbb{C}^m$, and the vectors v and $[u_1^T \ u_2^T]^T$ have unit length. We multiply the right-hand side by v^*v, the upper blocks by $\sqrt{s_\alpha(|\varphi|)}$ and collect all terms on the left to obtain

$$\begin{bmatrix} (P(\varphi))^* - \sqrt{s_\alpha(|\varphi|)}\xi(P,B,\alpha)u_1v^* \\ B^* - \xi(P,B,\alpha)u_2v^* \end{bmatrix} v = 0.$$

In other words, the matrix

$$\begin{bmatrix} P(\varphi) - \sqrt{s_\alpha(|\varphi|)}\xi(P,B,\alpha)vu_1^* & B - \xi(P,B,\alpha)vu_2^* \end{bmatrix}$$

is rank deficient. If we set $\Delta K_j = \frac{-\alpha_j \bar{\varphi}^j \xi(P,B,\alpha)vu_1^*}{\sqrt{s_\alpha(|\varphi|)}}$ and $\Delta B = -\xi(P,B,\alpha)vu_2^*$ and define $\Delta P(\lambda) = \sum_{j=0}^m \alpha_j \lambda^j \Delta K_j$, then by noting

$$\Delta P(\varphi) = \sum_{j=0}^m \alpha_j \varphi^j \Delta K_j = -\sqrt{s_\alpha(|\varphi|)}\xi(P,B,\alpha)vu_1^*$$

we see that

$$[(P+\Delta P)(\lambda) \ \ B + \Delta B]$$

is rank deficient at $\lambda = \varphi$. The norm of the perturbations satisfies

$$\begin{aligned} &\|[\Delta K_k \ \cdots \ \Delta K_0 \ \ \Delta B]\| \\ &= \xi(P,B,\alpha) \left\| \begin{bmatrix} \alpha_k \bar{\varphi}^k \dfrac{vu_1^*}{\sqrt{s_\alpha(|\varphi|)}} & \dots & \alpha_0 \dfrac{vu_1^*}{\sqrt{s_\alpha(|\varphi|)}} & vu_2^* \end{bmatrix} \right\| \le \xi(P,B,\alpha). \end{aligned}$$

Therefore $\tau(P,B,\alpha) \le \|[\Delta K_k \ \cdots \ \Delta K_0 \ \ \Delta B]\| \le \xi(P,B,\alpha)$ as desired.

For the claim about the equality when $\tau(P,B,\alpha)$ is defined in the Frobenius norm, to show $\xi(P,B,\alpha) \le \tau(P,B,\alpha)$ the proof in the first part applies noting that

$$\xi(P,B,\alpha) \le \|[\Delta K_k \ \cdots \ \Delta K_0 \ \ \Delta B]\|_2 \le \|[\Delta K_k \ \cdots \ \Delta K_0 \ \ \Delta B]\|_F = \tau(P,B,\alpha).$$

The second part to show $\tau(P,B,\alpha) \leq \xi(P,B,\alpha)$ applies without modification. ∎

The second part of Theorem 2.3 explicitly constructed the closest uncontrollable system which we state in the next corollary.

COROLLARY 2.4. [illegible] 2.2 [illegible] $\xi(P,B,\alpha)$ [illegible] λ_* [illegible] $[u_1^T\ u_2^T]^T$ [illegible] v [illegible]

$$\sigma_{\min}\left(\begin{bmatrix} \dfrac{P(\lambda_*)}{s_\alpha(|\lambda_*|)} & B \end{bmatrix}\right),$$

[illegible] $u_1, v \in \mathbb{C}^n$ [illegible] $u_2 \in \mathbb{C}^m$ [illegible] $(K_k + \alpha_k\Delta K_k, \ldots, K_0 + \alpha_0\Delta K_0, B + \Delta B)$ [illegible]

$$\Delta K_j = \frac{-\alpha_j \bar{\lambda}_*^j \xi(P,B,\alpha) v u_1^*}{\sqrt{s_\alpha(|\lambda_*|)}}, \quad j = 0, \ldots, k$$

[illegible]

$$\Delta B = -\xi(P,B,\alpha) v u_2^*.$$

Finally to remove the condition that $\alpha_0 \neq 0$, clearly $\tau(P,B,\alpha)$ depends on α_0 continuously when $\alpha_0 > 0$ and is continuous from the right when $\alpha_0 = 0$. (Consider the distance of $(K_k, K_{k-1}, \ldots, B)$ to any fixed uncontrollable tuple as a function of α_0 with all other α_j fixed. If such a distance function is bounded around a given α_0, then it is continuous from the right and the minimum of these continuous distance functions is $\tau(P,B,\alpha)$ as a function of α_0.) Therefore if $\alpha_0 = 0$, which is particularly the case when $s_\alpha(|\lambda|) = 0$, then the limiting value of $\xi(P,B,\alpha)$ from the right must approach $\tau(P,B,\alpha)$.

THEOREM 2.5. [illegible] 2.2 [illegible] α_0-[illegible] [illegible] [illegible]

$$\tau(P,B,[\alpha_k,\alpha_{k-1},\ldots,\alpha_0]) = \lim_{\alpha_0' \to \alpha_0^+} \xi(P,B,[\alpha_k,\alpha_{k-1},\ldots,\alpha_0'])$$

[illegible] τ [illegible]

Specifically when $\tau(P,B,\alpha) = \|[0\ 0 \cdots \Delta B]\| = \|\Delta B\|$, that is a closest uncontrollable system can be obtained just by perturbing B (this has to be the case when $\alpha = 0$), the result above amounts to a minimization problem over the vectors that are constrained to lie in the left eigenspace of P, $\mathcal{S}_P$, which we can see as follows. If we restrict the perturbations only to B and without loss of generality assume $\alpha = 0$, then the definition of the higher order distance to uncontrollability simplifies as

$$\begin{aligned}\tau(P,B) &= \inf\{\|\Delta B\| : v^*[P(\lambda)\ \ B + \Delta B] = 0,\ \exists v \in \mathbb{C}^n,\ \lambda \in \mathbb{C}\} \\ &= \inf\{\|\Delta B\| : v^* B = -v^* \Delta B,\ v \in \mathcal{S}_P\}.\end{aligned}$$

The last minimization problem must be attained at a ΔB such that $\|\Delta B\| = \|v^*\Delta B\|$, where $v \in \mathcal{S}_P$, because otherwise we can obtain a matrix ΔB smaller in norm by replacing all of the singular values larger than $\|v^*\Delta B\|$ with 0 that still satisfies the constraint $v^*B = -v^*\Delta B$. Therefore the last minimization problem is equivalent to

$$\tau(P,B) = \inf\{\|v^*\Delta B\| : v \in \mathcal{S}_p, v^*B = -v^*\Delta B\} = \inf_{v \in \mathcal{S}_p} \|v^*B\|.$$

Now we can verify Theorem 2.5 for this special case, as indeed

$$\lim_{\alpha_0\to 0^+} \xi(P,B,[0\ 0\ \cdots\ \alpha_0]) = \lim_{\alpha_0\to 0^+} \inf_{\lambda\in\mathbb{C}} \sigma_{\min}\left(\begin{bmatrix} P(\lambda) \\ \alpha_0 \end{bmatrix} B\right)$$
$$= \lim_{\alpha_0\to 0^+} \inf_{\lambda\in\mathbb{C}, v\in\mathbb{C}^n} \left\| v^* \begin{bmatrix} P(\lambda) \\ \alpha_0 \end{bmatrix} B \right\|.$$

Furthermore as $\alpha_0 \to 0^+$, any solution pair λ, v of the minimization problem must correspond to an eigenvalue of P and the associated left eigenvector, respectively. Therefore the minimization problem reduces to

$$\lim_{\alpha_0\to 0^+} \xi(P,B,[0\ 0\ \cdots\ \alpha_0]) = \inf_{v\in\mathcal{S}_P} \|v^*B\| = \tau(P,B).$$

3. A practical algorithm exploiting the singular value characterization. In Theorem 2.3 we established the equality

$$\tau(P,B,\alpha) = \xi(P,B,\alpha) = \inf_{r\geq 0,\theta\in[0,2\pi)} f(r,\theta)$$

when $\alpha_0 \neq 0$, where

$$f(r,\theta) = \sigma_{\min}\left(\begin{bmatrix} \dfrac{P(re^{i\theta})}{\sqrt{s_\alpha(r)}} & B \end{bmatrix}\right).$$

When $\alpha_0 = 0$, the limit of $\xi(P,B,\alpha)$ as $\alpha_0 \to 0^+$ approaches the distance to uncontrollability. Therefore, in essence the computation of the distance to uncontrollability can be achieved by minimizing $f(r,\theta)$. In this section we present a trisection algorithm to minimize the function $f(r,\theta)$ in polar coordinates. Let δ_1 and δ_2 trisect the interval $[L,U]$ containing the distance to uncontrollability (see Figure 3.1). At each iteration the algorithm updates either the upper bound to δ_1 or the lower bound to δ_2 depending on whether the δ-level set of $f(r,\theta)$

$$\{re^{i\theta} : f(r,\theta) = \delta\}$$

is intersected by any line in the set of lines passing through the origin with slopes multiples of η, where δ and η are determined by δ_1 and δ_2 as

$$\delta = \delta_1, \quad \eta = \frac{2}{k}\arccos\left(1 - \frac{1}{2}\left(\frac{\delta_1-\delta_2}{ckK_{\max}}\right)^2\right).$$

Above c is a positive real constant depending on the modulus of a point in the complex plane where $\xi(P,B,\alpha)$ is attained and $K_{\max}$ is a positive real constant depending on the norms of the coefficient matrices. (The constants c and $K_{\max}$ are defined precisely in the paragraph preceding Theorem 3.2.) We say the angle η subtends all of the components of the δ-level set of f, when no component has a pair of points whose angles differ by more than η. At each iteration we verify only one of the following (even though both of them may sometimes be true);

FIG. 3.1. *The trisection algorithm keeps track of an interval* $[L,U]$ *containing* $\xi(P,B,\alpha)$. *At each iteration either* L *is updated to* δ_2 *or* U *is updated to* δ_1.

- the δ-level set of f is not empty,
- the angle η subtends all of the components of the δ-level set of f.

By the definition of $\xi(P, B, \alpha)$ when the δ-level set is not empty

$$\delta = \delta_1 \geq \xi(P, B, \alpha) \tag{3.1}$$

and when η subtends all of the components of the δ-level set we will see below that

$$\xi(P, B, \alpha) > \delta_2 \tag{3.2}$$

because of the choice of η and δ. The algorithm we present is inspired by the trisection algorithm of [3] for the first order distance to uncontrollability. However, the technique we use to verify which one of (3.1) and (3.2) holds is new and has no similarity with the verification technique used in [3] to trisect an interval known to contain the first order distance to uncontrollability. A straightforward modification of the technique for the first order distance to uncontrollability would require the solution of polynomial eigenvalue problems quadratic in size and double in degree as compared to the original polynomial eigenvalue problem, which is too expensive even for systems of small size.

The trisection algorithm starts with the trivial upper bound $U = \sigma_{\min}([K_k/\alpha_k \;\; B])$ (or when $\alpha_k = 0$, $U = \sigma_{\min}(B)$) and the lower bound $L = 0$. At each iteration we either update the upper bound to δ_1 if the inequality (3.1) is verified or the lower bound to δ_2 if the inequality (3.2) is verified. First we need to be equipped with a technique that checks for a given δ and θ whether there exists an r satisfying

$$f(r, \theta) = \delta, \tag{3.3}$$

that is whether the line with slope θ passing through the origin, say $\mathcal{L}(\theta)$, intersects the δ-level set of f. Our first result in this section shows how this can be achieved by solving a polynomial eigenvalue problem of double size and of double degree. Similar results relating the δ-level set of $g(x, y) = \sigma_{\min}(A - (x + yi)I)$, where $A \in \mathbb{C}^{n\times n}$, $x, y \in \mathbb{R}$ and the imaginary eigenvalues of a matrix $G(x, \delta)$ of double size can be found in [4] and [2]. More precisely these results suggest how to find the intersection points of the δ-level set of $g(x, y)$ and a vertical line; that is the results deduce that if $\delta = g(x, y)$, then yi is an eigenvalue of $G(x, \delta)$.

THEOREM 3.1. [illegible] $\theta \in [0, 2\pi)$ [illegible] δ [illegible] $[\frac{P(re^{i\theta})}{\sqrt{s_\alpha(r)}} \;\; B]$ [illegible] δ [illegible] $Q(\lambda, \theta, \delta) = \sum_{j=0}^{2k} \lambda^j Q_j(\theta, \delta)$ [illegible] ri

$$Q_0(\theta, \delta) = \begin{bmatrix} -\delta\alpha_0^2 I & K_0^* \\ K_0 & BB^*/\delta - \delta I \end{bmatrix},$$

[illegible] l-[illegible]

$$Q_l(\theta, \delta) = \begin{bmatrix} 0 & (-1)^{(l+1)/2} i K_l^* e^{-il\theta} \\ (-1)^{(l+1)/2} i K_l e^{il\theta} & 0 \end{bmatrix} \quad 1 \leq l \leq k,$$

$$Q_l(\theta, \delta) = 0 \quad k+1 \leq l < 2k,$$

[illegible] l-[illegible]

$$Q_l(\theta, \delta) = \begin{bmatrix} (-1)^{l/2+1}\delta\alpha_{l/2}^2 I & (-1)^{l/2} K_l^* e^{-il\theta} \\ (-1)^{l/2} K_l e^{il\theta} & 0 \end{bmatrix} \quad 1 \leq l \leq k,$$

$$Q_l(\theta, \delta) = \begin{bmatrix} (-1)^{l/2+1}\delta\alpha_{l/2}^2 I & 0 \\ 0 & 0 \end{bmatrix} \quad k+1 \leq l \leq 2k.$$

. The matrix $[\frac{P(re^{i\theta})}{\sqrt{s_\alpha(r)}} \;\; B]$ has δ as a singular value if and only if both of the equations

$$\begin{bmatrix} \frac{P(re^{i\theta})}{\sqrt{s_\alpha(r)}} & B \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \end{bmatrix} = \delta u,$$
$$\begin{bmatrix} \left(\frac{P(re^{i\theta})}{\sqrt{s_\alpha(r)}}\right)^* \\ B^* \end{bmatrix} u = \delta \begin{bmatrix} v_1 \\ v_2 \end{bmatrix}$$

are satisfied. From the bottom block of the second equation we have $v_2 = B^*u/\delta$. By eliminating v_2 from the other equation, we obtain

$$\begin{aligned} &\begin{bmatrix} -\delta I & \left(\frac{P(re^{i\theta})}{\sqrt{s_\alpha(r)}}\right)^* \\ \frac{P(re^{i\theta})}{\sqrt{s_\alpha(r)}} & BB^*/\delta - \delta I \end{bmatrix} \begin{bmatrix} v_1 \\ u \end{bmatrix} \\ &= \begin{bmatrix} -\delta s_\alpha(r) I & \left(P(re^{i\theta})\right)^* \\ P(re^{i\theta}) & BB^*/\delta - \delta I \end{bmatrix} \begin{bmatrix} v_1/\sqrt{s_\alpha(r)} \\ u \end{bmatrix} \\ &= \sum_{j=0}^{2k} (ri)^j Q_j(\theta, \delta) \begin{bmatrix} v_1/\sqrt{s_\alpha(r)} \\ u \end{bmatrix} = 0. \end{aligned}$$

Therefore ri is an eigenvalue of $Q(\lambda, \theta, \delta)$. □

Suppose $\delta \le \lim_{\lambda\to\infty} \sigma_{\min}([\frac{P(\lambda)}{\sqrt{s_\alpha(|\lambda|)}} \;\; B])$. To establish the existence of an r satisfying (3.3), it is sufficient that the polynomial $Q(\lambda, \theta, \delta)$ has an imaginary eigenvalue. When $Q(\lambda, \theta, \delta)$ has an imaginary eigenvalue $r'i$, $f(r', \theta) \le \delta$. Since $\delta \le f(r, \theta)$ in the limit as $r \to \infty$, by the continuity of f with respect to r we deduce $f(\hat{r}, \theta) = \delta$ for some $\hat{r} \ge r'$.

For our trisection algorithm it suffices to check whether any of the lines $\mathcal{L}(0), \mathcal{L}(\eta), \mathcal{L}(2\eta), \ldots, \mathcal{L}(\lfloor \frac{\pi}{\eta} \rfloor \eta)$ intersect the δ-level set of f as illustrated in Figure 3.2. When there is an intersection point the δ-level set is not empty; otherwise the angle η subtends all of the components. The only part of the algorithm that is not clarified so far is how we conclude a lower bound on $\xi(P, B, \alpha)$ when η subtends all of the components, in particular the relation between δ_2 in (3.2) and the pair δ and η. For the next theorem addressing these issues let (r_*, θ_*) be a point where $\xi(P, B, \alpha)$ is attained. We assume the existence of a constant c known , , satisfying

$$c \ge \max_{0\le j\le k} \frac{r_*^j}{\sqrt{s_\alpha(r_*)}} = \max\left(\frac{1}{\sqrt{s_\alpha(r_*)}}, \frac{r_*^k}{\sqrt{s_\alpha(r_*)}}\right). \tag{3.4}$$

Finding a constant c may be tedious in some special cases. However, when both α_k and α_0 are nonzero we can set $c = \frac{1}{\min(\alpha_0, \alpha_k)}$. We furthermore use the notation $K_{\max} = \max_{1\le j\le k} \|K_j\|$. The algorithms in [14, 15, 3] for the first order distance to uncontrollability benefit from an analogous result in [14] which can be stated as, given a $\delta \ge \tau(A, B)$ for all $\eta \in [0, 2(\delta - \tau(A, B))]$ there exists a pair of real numbers x, y satisfying $\sigma_{\min}([A - (x + yi)I \;\; B]) = \sigma_{\min}([A - (x + \eta + yi)I \;\; B]) = \delta$. Throughout the rest of this section we omit the parameters of $\xi(P, B, \alpha)$ assuming P, B, and α are fixed.

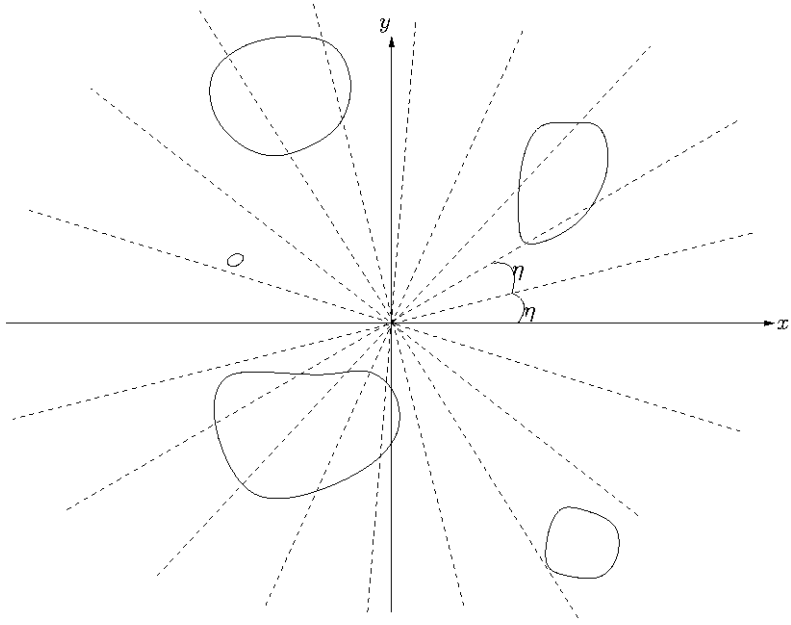

FIG. 3.2. *To verify which one of* (3.1) *and* (3.2) *hold we check the intersection points of the* δ*-level set of* f *and the set of lines with slopes multiples of* η *ranging from 0 to* π*. The closed curves are the* δ*-level sets.*

THEOREM 3.2.

$$\lim_{\lambda\to\infty} \sigma_{\min}\left(\left[\frac{P(\lambda)}{\sqrt{s_\alpha(|\lambda|)}} \;\; B\right]\right) \geq \delta > \xi.$$

$\eta \in [0, \frac{1}{k}\arccos(1-\frac{1}{2}(\frac{\delta-\xi}{ckK_{\max}})^2)]$ r_1 r_2 (η)

$$\sigma_{\min}\left(\left[\frac{P(r_1 e^{i(\theta_*+\eta)})}{\sqrt{s_\alpha(r_1)}} \;\; B\right]\right) = \delta \quad \text{and} \quad \sigma_{\min}\left(\left[\frac{P(r_2 e^{i(\theta_*-\eta)})}{\sqrt{s_\alpha(r_2)}} \;\; B\right]\right) = \delta.$$

. We prove the first equality. The proof of the second equality is similar. Assume

$$\sigma_{\min}\left(\left[\frac{P(re^{i(\theta_*+\eta)})}{\sqrt{s_\alpha(r)}} \;\; B\right]\right) > \delta \tag{3.5}$$

holds for all r for an η in the interval specified. Since the singular values of a matrix X are the eigenvalues of the symmetric matrix

$$\begin{bmatrix} 0 & X \\ X^* & 0 \end{bmatrix},$$

they are globally Lipschitz with constant 1 (see Weyl's Theorem [19, Theorem (4.3.1)]) meaning

$$\delta - \xi < \sigma_{\min}\left(\begin{bmatrix} \frac{P(r_* e^{i(\theta_*+\eta)})}{\sqrt{s_\alpha(r_*)}} & B \end{bmatrix}\right) - \sigma_{\min}\left(\begin{bmatrix} \frac{P(r_* e^{i\theta_*})}{\sqrt{s_\alpha(r_*)}} & B \end{bmatrix}\right)$$
$$\leq \left\| \begin{bmatrix} \frac{P(r_* e^{i(\theta_*+\eta)})}{\sqrt{s_\alpha(r_*)}} & B \end{bmatrix} - \begin{bmatrix} \frac{P(r_* e^{i\theta_*})}{\sqrt{s_\alpha(r_*)}} & B \end{bmatrix} \right\| = \left\| \frac{\sum_{j=1}^{k} r_*^j e^{ij\theta_*} K_j (e^{ij\eta} - 1)}{\sqrt{s_\alpha(r_*)}} \right\|.$$

Notice that $\eta \leq \pi/k$ implying $\cos k\eta \leq \cos j\eta$ for $j = 0, \ldots, k$. Therefore

$$kcK_{\max}\sqrt{2 - 2\cos k\eta} \geq \sum_{j=1}^{k} c\|K_j\sqrt{2 - 2\cos j\eta}\| \geq \left\| \frac{\sum_{j=1}^{k} r_*^j e^{ij\theta_*} K_j (e^{ij\eta} - 1)}{\sqrt{s_\alpha(r_*)}} \right\| > \delta - \xi$$

or

$$1 - \frac{1}{2}\left(\frac{\delta - \xi}{kcK_{\max}}\right)^2 > \cos k\eta.$$

Since the $\cos$ function is strictly decreasing in the interval $[0, \pi]$, we obtain the contradiction that

$$\eta > \frac{1}{k}\arccos\left(1 - \frac{1}{2}\left(\frac{\delta - \xi}{kcK_{\max}}\right)^2\right).$$

Thus, (3.5) cannot hold, so there exists r_1' satisfying

$$\sigma_{\min}\left(\begin{bmatrix} \frac{P(r_1' e^{i(\theta_*+\eta)})}{\sqrt{s_\alpha(r_1')}} & B \end{bmatrix}\right) \leq \delta.$$

The first equality must therefore hold for some $r_1 \geq r_1'$ because of the continuity of $f(r, \theta_* + \eta)$ with respect to r and the fact that $\lim_{r\to\infty} f(r, \theta_* + \eta) \geq \delta$. □

As we have already indicated in (3.1), we first set $\delta = \delta_1$. The assignment

$$\eta = \frac{2}{k}\arccos\left(1 - \frac{1}{2}\left(\frac{\delta_1 - \delta_2}{ckK_{\max}}\right)^2\right) \tag{3.6}$$

leads us to the lower bound (3.2) in the case that none of the lines $\mathcal{L}(0), \mathcal{L}(\eta), \mathcal{L}(2\eta), \ldots, \mathcal{L}(\lfloor \frac{\pi}{\eta} \rfloor \eta)$ intersect the δ-level set of f, which we can see as follows. According to Theorem 3.2 for all θ in the interval

$$\left[\theta_* - \frac{1}{k}\arccos\left(1 - \frac{1}{2}\left(\frac{\delta - \xi}{ckK_{\max}}\right)^2\right), \theta_* + \frac{1}{k}\arccos\left(1 - \frac{1}{2}\left(\frac{\delta - \xi}{ckK_{\max}}\right)^2\right)\right], \tag{3.7}$$

the line $\mathcal{L}(\theta)$ intersects the δ-level set of f. When none of the lines $\mathcal{L}(0), \mathcal{L}(\eta), \mathcal{L}(2\eta), \ldots, \mathcal{L}(\lfloor \frac{\pi}{\eta} \rfloor \eta)$ intersects the δ-level set of f, it follows that η must be greater than the length of the interval in (3.7), that is

$$\eta = \frac{2}{k}\arccos\left(1 - \frac{1}{2}\left(\frac{\delta_1 - \delta_2}{ckK_{\max}}\right)^2\right) > \frac{2}{k}\arccos\left(1 - \frac{1}{2}\left(\frac{\delta - \xi}{ckK_{\max}}\right)^2\right).$$

From this inequality it is straightforward to deduce the lower bound (3.2). Algorithm 1 summarizes the approach described.

As the accuracy and efficiency of the algorithm depend on the extraction of the imaginary eigenvalues of the matrix polynomial $Q(\lambda, \theta, \delta)$, it is worth pointing out how these eigenvalues can be computed numerically in a reliable fashion. The matrix polynomial $Q(\lambda, \theta, \delta)$ has a special structure; its even coefficients are Hermitian, while its odd coefficients are skew-Hermitian. The eigenvalues of polynomials with this structure are either imaginary or in pairs $(\lambda, -\bar{\lambda})$ [20]. The standard way to solve a polynomial eigenvalue problem of size $2n$ and degree $2k$ is to reduce it to an equivalent generalized eigenvalue problem $\mathcal{H} - \lambda\mathcal{N}$ of size $4nk$ by a transformation called linearization. The most widely used linearization is the companion form [21]. In [21] vector spaces of linearizations that are generalizations of the companion form are introduced. There are two issues one needs to consider when selecting a linearization. First the structure must be preserved, that is the matrices $\mathcal{H}, \mathcal{N}$ in the transformation above must be Hermitian and skew-Hermitian, respectively. Sec-

Algorithm 1 Trisection algorithm for the higher order distance to uncontrollability

Call:	$[L, U] \leftarrow$ `HODU`(P,B,α,tol,c).
Input:	$P \in \mathbb{C}^{k\times n\times n}$ (the matrix polynomial), $B \in \mathbb{C}^{n\times m}$, $\alpha \in \mathbb{R}^k$ (nonnegative scaling factors, not all zero), tol (desired tolerance), c (a positive real number satisfying (3.4)).
Output:	L, U with $L < U$, $U - L \leq tol$. The interval $[L, U]$ contains the higher order distance to uncontrollability.

Initially set

$$U \leftarrow \sigma_{\min}\left(\begin{bmatrix} \frac{K_k}{\alpha_k} & B \end{bmatrix}\right) \quad \text{if } \alpha_k > 0,$$
$$U \leftarrow \sigma_{\min}(B) \quad \text{if } \alpha_k = 0,$$

and $L \leftarrow 0$.
while $U - L > tol$ **do**
  % Trisection step
  Set $\delta_1 \leftarrow L + 2(U - L)/3$ and $\delta_2 \leftarrow L + (U - L)/3$.
  Set $\delta \leftarrow \delta_1$ and η as defined in (3.6)
  Set $Intersection \leftarrow FALSE$.
  for $\theta = 0$ to π in increments of η **do**
    Compute the eigenvalues of $Q(\lambda, \theta, \delta)$.
    if $Q(\lambda, \theta, \delta)$ has an imaginary eigenvalue **then**
      % An intersection point is detected
      Update the upper bound, $U \leftarrow \delta_1$.
      $Intersection \leftarrow TRUE$.
      Break. (Leave the for loop.)
    end if
  end for
  if $\neg Intersection$ **then**
    % No intersection point is detected
    Update the lower bound, $L \leftarrow \delta_2$.
  end if
end while
Return $[L, U]$.

ond the eigenvalues of the pencil $\mathcal{H} - \lambda\mathcal{N}$ have different condition numbers than the eigenvalues of the matrix polynomial $Q(\lambda, \theta, \delta)$. Ideally we must use a linearization preserving the structure that does not degrade the conditioning of the eigenvalues of the original problem. The linearizations in the vector spaces specified in [21] that preserve the even-odd structure of $Q(\lambda, \theta, \delta)$ are identified in [20]. Furthermore in [17] it was shown that in these vector spaces there are linearizations preserving the conditioning of the eigenvalues of $Q(\lambda, \theta, \delta)$. How best to find such a linearization preserving the structure and the conditioning combined with an even-odd generalized eigenvalue solver is still under investigation. When such an implementation is used, simple imaginary eigenvalues remain on the imaginary axis even in the presence of rounding errors. Therefore tolerances are not needed.

At each iteration the algorithm requires the solution of the eigenvalue problems $Q(\lambda, 0, \delta), Q(\lambda, \eta, \delta), \ldots, Q(\lambda, \lfloor \frac{\pi}{\eta} \rfloor \eta, \delta)$, each typically at a cost of $O(n^3k^3)$. The overall complexity of an iteration is

$$O\left(\frac{n^3k^4}{\arccos\left(1 - \frac{1}{2}\left(\frac{\delta_1 - \delta_2}{ckK_{\max}}\right)^2\right)}\right). \tag{3.8}$$

It is apparent that the initial iterations for which $\delta_1 - \delta_2$ is relatively large are cheaper, while the last iteration for which $\delta_1 - \delta_2 \approx tol/2$ is the most expensive.

4. Numerical results. All of the numerical experiments in this section are performed with MATLAB 6.5 running on a PC with 1000 MHz Intel processor and 256MB RAM.

4.1. Computing the distance to uncontrollability for first order systems. Even though it is much slower than the methods in [14, 3, 15], the trisection algorithm suggested can be applied to estimate the first order distance to uncontrollability with $k = 1$, $K_1 = I$, and $\alpha = [0\ 1]$ so that perturbations to $K_1 = I$ are not allowed. It is well known that in this case the distance to uncontrollability is attained at a point λ_* with $|\lambda_*| = c \le 2(\|K_0\| + \|B\|)$. We choose K_0 as the Toeplitz matrix

$$\begin{bmatrix} 1 & 3 & 0 & 0 \\ -2 & 1 & 3 & 0 \\ 0 & -2 & 1 & 3 \\ 0 & 0 & -2 & 1 \end{bmatrix}$$

and $B = [2\ 2\ 2\ 2]^T$. When we require an interval of length 10^{-2} or less, Algorithm 1 returns $[0.473, 0.481]$ in 12 iterations which contains the distance to uncontrollability 0.477. Table 4.1 lists the cumulative running time after each iteration in seconds. Overall we observe that reaching one digit accuracy is considerably cheaper than two digit accuracy. When we allow the perturbations to the leading coefficient by setting $\alpha = [1\ 1]$, there is a closer uncontrollable system at a distance of $\tau(P, B, \alpha) \le 0.145$ which is the upper bound returned by Algorithm 1.

4.2. A quadratic brake model. In [12] the vibrations of a drum brake system are modeled by the quadratic equation

$$Mx^{(2)}(t) + K(\mu)x(t) = f(t) \tag{4.1}$$

TABLE 4.1

with the mass and stiffness matrices

$$M = \begin{bmatrix} m & 0 \\ 0 & m \end{bmatrix}, \quad K(\mu) = g \begin{bmatrix} (\sin\gamma + \mu\cos\gamma)\sin\gamma & -\mu - (\sin\gamma + \mu\cos\gamma)\cos\gamma \\ (\mu\sin\gamma - \cos\gamma)\sin\gamma & 1 + (-\mu\sin\gamma + \cos\gamma)\cos\gamma \end{bmatrix}.$$

Suppose the force on the brake system has just the vertical component determined by the input

$$f(t) = \begin{bmatrix} f_x(t) \\ f_y(t) \end{bmatrix} = \begin{bmatrix} 0 \\ 1 \end{bmatrix} u(t).$$

For the parameters $m = 5$, $g = 1$ and $\gamma = \frac{\pi}{100}$, we consider two cases. First by setting $\alpha = [1\ 0\ 1]$, we impose equal importance on the perturbations to the mass and stiffness matrices. Notice that for small μ and γ, the system is close to being uncontrollable. In the second column in Table 4.2 the intervals of length 10^{-2} or less containing the distance to uncontrollability returned by Algorithm 1 are provided for various values of μ. The algorithm iterates 16 times to reach two digit accuracy. Second we assign scaling to the perturbations proportional to the norms of the mass and stiffness matrices, that is $\alpha = [\|M\|\ 0\ \|K\|]$. The intervals returned by Algorithm 1 for this second case are given in the rightmost column in Table 4.2. As expected the distance to uncontrollability again increases with respect to μ. The system (4.1) is closer to being uncontrollable in a relative sense than in an absolute sense.

If we allow perturbations to all coefficients with equal scaling (e.g., $\alpha = [1\ 1\ 1]$), then usually the first order distance uncontrollability of the embedded system (1.5) is

TABLE 4.3
Running time of the trisection algorithm in seconds with respect to the size and order of the systems with normally distributed coefficient matrices.

Size / order	First order	Quadratic	Cubic
5	10 (10)	192 (12)	1237 (13)
10	83 (12)	1392 (11)	12485 (12)
15	271 (13)	6390 (14)	37324 (12)

considerably smaller than the actual value $\tau(P, B, \alpha)$, since the perturbations are not constrained so that the structure of the embedding can be preserved. For instance, for the drum brake system with $\alpha = [1\ 1\ 1]$ and $\mu = 0.1$, $\tau(P, B, \alpha) \in [0.097, 0.105]$ (up to two digit accuracy it does not make any difference whether we allow perturbations to the zero coefficient K_1 or not) whereas the standard unstructured distance to uncontrollability of the embedding lies in the interval $[0.012, 0.020]$.

4.3. Running time with respect to the size and order of the system. We run the trisection algorithm on systems with random coefficients of various size and order. To be precise the entries of all of the coefficient matrices are chosen from a normal distribution with zero mean and variance one independently. Table 4.3 illustrates how the running time in seconds varies with respect to the size and order of the system. In all of the examples intervals of length at most 10^{-2} containing the absolute distance to uncontrollability (α is the vector of ones) are returned. The numbers in parentheses correspond to the number of trisection iterations needed. The variation in the running time with respect to the size and order is consistent with the complexity suggested by (3.8).

Acknowledgments. A MATLAB implemention of the trisection algorithm is available on the author's web page.[2] Most of this work was completed during the author's Ph.D. study at New York University and some part was completed during the author's visit to the numerical analysis and modeling group at the Technical University of Berlin. The author is grateful to Michael Overton and Daniel Kressner for reading a preliminary version of this paper, Volker Mehrmann for pointing out the importance of the even-odd matrix polynomials and insightful discussions regarding preserving the even-odd structure, and two anonymous referees.

AN EQUILIBRIUM PROBLEM FOR THE LIMITING EIGENVALUE DISTRIBUTION OF BANDED TOEPLITZ MATRICES*

MAURICE DUITS† AND ARNO B. J. KUIJLAARS‡

Abstract. We study the limiting eigenvalue distribution of $n \times n$ banded Toeplitz matrices as $n \to \infty$. From classical results of Schmidt, Spitzer, and Hirschman it is known that the eigenvalues accumulate on a special curve in the complex plane and the normalized eigenvalue counting measure converges weakly to a measure on this curve as $n \to \infty$. In this paper, we characterize the limiting measure in terms of an equilibrium problem. The limiting measure is one component of the unique vector of measures that minimizes an energy functional defined on admissible vectors of measures. In addition, we show that each of the other components is the limiting measure of the normalized counting measure on certain generalized eigenvalues.

Key words. banded Toeplitz matrix, equilibrium problem, potential theory, limiting eigenvalue distribution, generalized eigenvalues

1. Introduction.

For an integrable function $a : \{z \in \mathbb{C} \mid |z| = 1\} \to \mathbb{C}$ defined on the unit circle in the complex plane, the $n \times n$ Toeplitz matrix $T_n(a)$ with symbol a is defined by

$$\big(T_n(a)\big)_{jk} = a_{j-k}, \qquad j,k = 1,\dots,n, \tag{1.1}$$

where a_k is the kth Fourier coefficient of a,

$$a_k = \frac{1}{2\pi}\int_0^{2\pi} a(\mathrm{e}^{\mathrm{i}\theta})\mathrm{e}^{-\mathrm{i}k\theta}\,\mathrm{d}\theta. \tag{1.2}$$

In this paper we study banded Toeplitz matrices for which the symbol has only a finite number of nonzero Fourier coefficients. We assume that there exist $p, q \geq 1$ such that

$$a(z) = \sum_{k=-q}^{p} a_k z^k, \qquad a_p \neq 0, \quad a_{-q} \neq 0. \tag{1.3}$$

Thus $T_n(a)$ has at most $p + q + 1$ nonzero diagonals. As in [1, page 263], we also assume, without loss of generality, that

$$\gcd\{k \in \mathbb{Z} \mid a_k \neq 0\} = 1. \tag{1.4}$$

We are interested in the limiting behavior of the spectrum of $T_n(a)$ as $n \to \infty$. We use $\operatorname{sp} T_n(a)$ to denote the spectrum of $T_n(a)$:

$$\operatorname{sp} T_n(a) = \{\lambda \in \mathbb{C} \mid \det(T_n(a) - \lambda I) = 0\}.$$

Spectral properties of banded Toeplitz matrices are the topic of the recent book [1] by Böttcher and Grudsky. We will refer the reader to this book frequently, in particular to Chapter 11 where the limiting behavior of the spectrum is discussed.

The limiting behavior of $\operatorname{sp} T_n(a)$ was characterized by Schmidt and Spitzer [10]. They considered the set

$$\liminf_{n\to\infty} \operatorname{sp} T_n(a) \tag{1.5}$$

consisting of all $\lambda \in \mathbb{C}$ such that there exists a sequence $\{\lambda_n\}_{n\in\mathbb{N}}$, with $\lambda_n \in \operatorname{sp} T_n(a)$, converging to λ, and the set

$$\limsup_{n\to\infty} \operatorname{sp} T_n(a) \tag{1.6}$$

consisting of all λ such that there exists a sequence $\{\lambda_n\}_{n\in\mathbb{N}}$, with $\lambda_n \in \operatorname{sp} T_n(a)$, that has a subsequence converging to λ. Schmidt and Spitzer showed that these two sets are equal and can be characterized in terms of the algebraic equation

$$a(z) - \lambda = \sum_{k=-q}^{p} a_k z^k - \lambda = 0. \tag{1.7}$$

For every $\lambda \in \mathbb{C}$ there are $p + q$ solutions for (1.7), which we denote by $z_j(\lambda)$ for $j = 1, \ldots, p + q$. We order these solutions by absolute value, so that

$$0 < |z_1(\lambda)| \le |z_2(\lambda)| \le \cdots \le |z_{p+q}(\lambda)|. \tag{1.8}$$

When all inequalities in (1.8) are strict then the values $z_k(\lambda)$ are unambiguously defined. If equalities occur, then we choose an arbitrary numbering so that (1.8) holds. The result by Schmidt and Spitzer [10], [1, Theorem 11.17] is that

$$\liminf_{n\to\infty} \operatorname{sp} T_n(a) = \limsup_{n\to\infty} \operatorname{sp} T_n(a) = \Gamma_0, \tag{1.9}$$

where

$$\Gamma_0 := \{\lambda \in \mathbb{C} \mid |z_q(\lambda)| = |z_{q+1}(\lambda)|\}. \tag{1.10}$$

This result gives a description of the asymptotic location of the eigenvalues. The eigenvalues accumulate on the set Γ_0, which is known to be a disjoint union of a finite number of (open) analytic arcs and a finite number of exceptional points [1, Theorem 11.9]. It is also known that Γ_0 is connected (see [13], [1, Theorem 11.19]) and that $\mathbb{C} \setminus \Gamma_0$ need not be connected (see [1, Theorem 11.20], [2, Proposition 5.2]). See [1] for many beautiful illustrations of eigenvalues of banded Toeplitz matrices.

The limiting eigenvalue distribution was determined by Hirschman [5], [1, Theorem 11.16]. He showed that there exists a Borel probability measure μ_0 on Γ_0 such that the normalized eigenvalue counting measure of $T_n(a)$ converges weakly to μ_0 as $n \to \infty$. That is,

$$\frac{1}{n} \sum_{\lambda \in \operatorname{sp} T_n(a)} \delta_\lambda \to \mu_0, \tag{1.11}$$

where in the sum each eigenvalue is counted according to its multiplicity. The measure μ_0 is absolutely continuous with respect to the arclength measure on Γ_0 and has an analytic density on each open analytic arc in Γ_0, which can be explicitly represented in terms of the solutions of the algebraic equation (1.7) as follows. Equip every open analytic arc in Γ_0 with an orientation. The orientation induces $\pm$ sides on each arc, where the $+$ side is on the left when traversing the arc according to its orientation, and the $-$ side is on the right. The limiting measure μ_0 is then given by

$$\mathrm{d}\mu_0(\lambda) = \frac{1}{2\pi \mathrm{i}} \sum_{j=1}^{q} \left(\frac{z'_{j+}(\lambda)}{z_{j+}(\lambda)} - \frac{z'_{j-}(\lambda)}{z_{j-}(\lambda)} \right) \mathrm{d}\lambda, \tag{1.12}$$

where $\mathrm{d}\lambda$ is the complex line element on Γ_0 (taken according to the orientation), and where $z_{j\pm}(\lambda)$, $\lambda \in \Gamma_0$, is the limiting value of $z_j(\lambda')$ as $\lambda' \to \lambda$ from the $\pm$ side of the arc. These limiting values exist for every $\lambda \in \Gamma_0$, with the possible exception of the finite number of exceptional points.

Note that the right-hand side of (1.12) is a priori a complex measure, and it is not immediately clear that it is in fact a probability measure. In the original paper [5] and in the book [1, Theorem 11.16], the authors give a different expression for the limiting density, from which it is clear that the measure is nonnegative. We prefer to work with the complex expression (1.12), since it allows for a direct generalization which we will need in this paper.

Note also that if we reverse the orientation on an arc in Γ_0, then the $\pm$ sides are reversed. Since the complex line element $\mathrm{d}\lambda$ changes sign as well, the expression (1.12) does not depend on the choice of orientation.

The following is a very simple example, which, however, serves as a motivation for the results in the paper.

EXAMPLE 1.1. Consider the symbol $a(z) = z + 1/z$. In this case we find that $\Gamma_0 = [-2, 2]$ and μ_0 is absolutely continuous with respect to the Lebesgue measure and has density

$$\frac{\mathrm{d}\mu_0(\lambda)}{\mathrm{d}\lambda} = \frac{1}{\pi\sqrt{4-\lambda^2}}, \qquad \lambda \in (-2, 2). \tag{1.13}$$

This measure is well known in potential theory and is called the arcsine measure or the equilibrium measure of Γ_0; see, e.g., [9]. It has the property that it minimizes the energy functional I, defined by

$$I(\mu) = \iint \log \frac{1}{|x-y|} \, \mathrm{d}\mu(x) \, \mathrm{d}\mu(y), \tag{1.14}$$

among all Borel probability measures μ on $[-2, 2]$. The measure μ_0 is also characterized by the equilibrium condition

$$\int \log|x-\lambda| \, \mathrm{d}\mu_0(\lambda) = 0, \qquad x \in [-2, 2], \tag{1.15}$$

which is the Euler–Lagrange variational condition for the minimization problem.

The fact that μ_0 is the equilibrium measure of Γ_0 is special for symbols a with $p = q = 1$. In that case one may think of the eigenvalues of $T_n(a)$ as charged particles on Γ_0, each eigenvalue having a total charge $1/n$, that repel each other with logarithmic interaction. The particles seek to minimize the energy functional (1.14).

As $n \to \infty$, they distribute themselves according to μ_0, and μ_0 is the minimizer of (1.14) among all probability measures supported on Γ_0.

The aim of this paper is to characterize μ_0 for general symbols a of the form (1.3) also in terms of an equilibrium problem from potential theory. The corresponding equilibrium problem is more complicated since it involves not only the measure μ_0, but a sequence of $p+q-1$ measures

$$\mu_{-q+1}, \mu_{-q+2}, \ldots, \mu_{-1}, \mu_0, \mu_1, \ldots, \mu_{p-2}, \mu_{p-1}$$

that jointly minimize an energy functional.

2. Statement of results.

2.1. The energy functional. To state our results we need to introduce some notions from potential theory. Main references for potential theory in the complex plane are [8] and [9].

We will mainly work with finite positive measures on $\mathbb{C}$, but we will also use $\nu_1 - \nu_2$, where ν_1 and ν_2 are positive measures. The measures need not have bounded support. If ν has unbounded support, then we assume that

$$\int \log(1+|x|)\, \mathrm{d}\nu(x) < \infty. \tag{2.1}$$

In that case the logarithmic energy of ν is defined as

$$I(\nu) = \int \log \frac{1}{|x-y|}\, \mathrm{d}\nu(x)\mathrm{d}\nu(y) \tag{2.2}$$

and $I(\nu) \in (-\infty, +\infty]$.

DEFINITION 2.1. [illegible] $\mathcal{M}_e$ [illegible] ν [illegible] $\mathbb{C}$ [illegible] (2.1) [illegible] $I(\nu) < +\infty$ [illegible] $c > 0$ [illegible]

$$\mathcal{M}_e(c) = \{\nu \in \mathcal{M}_e \mid \nu(\mathbb{C}) = c\}. \tag{2.3}$$

The mutual energy $I(\nu_1, \nu_2)$ of two measures ν_1 and ν_2 is

$$I(\nu_1, \nu_2) = \int \log \frac{1}{|x-y|}\, \mathrm{d}\nu_1(x)\mathrm{d}\nu_2(y). \tag{2.4}$$

It is well defined and finite if $\nu_1, \nu_2 \in \mathcal{M}_e$, and in that case we have

$$I(\nu_1 - \nu_2) = I(\nu_1) + I(\nu_2) - 2I(\nu_1, \nu_2). \tag{2.5}$$

If $\nu_1, \nu_2 \in \mathcal{M}_e(c)$ for some $c > 0$, then

$$I(\nu_1 - \nu_2) \geq 0 \tag{2.6}$$

with equality if and only if $\nu_1 = \nu_2$. This is a well-known result if ν_1 and ν_2 have compact support [9]. For measures in $\mathcal{M}_e(c)$ with unbounded support, this is a recent result of Simeonov [11], who obtained this from a very elegant integral representation for $I(\nu_1 - \nu_2)$. It is a consequence of (2.6) that I is strictly convex on $\mathcal{M}_e(c)$, since

$$\begin{aligned} I\left(\frac{\nu_1+\nu_2}{2}\right) &= \frac{1}{2}\left(I(\nu_1) + I(\nu_2)\right) - I\left(\frac{\nu_1-\nu_2}{2}\right) \\ &\leq \frac{1}{2}\left(I(\nu_1) + I(\nu_2)\right) \qquad \text{for } \nu_1, \nu_2 \in \mathcal{M}_e(c) \end{aligned}$$

with equality if and only if $\nu_1 = \nu_2$.

Before we can state the equilibrium problem we also need to introduce the sets

$$\Gamma_k := \{\lambda \in \mathbb{C} \mid |z_{q+k}(\lambda)| = |z_{q+k+1}(\lambda)|\}, \qquad k = -q+1, \dots, p-1, \tag{2.7}$$

which for $k = 0$ reduce to the definition (1.10) of Γ_0. We will show that each Γ_k is the disjoint union of a finite number of open analytic arcs and a finite number of exceptional points. All Γ_k are unbounded, except for Γ_0 which is compact.

The equilibrium problem will be defined for a vector of measures denoted by $\vec{\nu} = (\nu_{-q+1}, \dots, \nu_{p-1})$. The component ν_k is a measure on Γ_k satisfying some additional properties that are given in the following definition.

DEFINITION 2.2. [illegible] $\vec{\nu} = (\nu_{-q+1}, \dots, \nu_{p-1})$ [illegible] $\nu_k \in \mathcal{M}_e$, ν_k [illegible] Γ_k [illegible]

$$\nu_k(\Gamma_k) = \begin{cases} \frac{q+k}{q} & \text{if } k \le 0, \\ \frac{p-k}{p} & \text{if } k \ge 0 \end{cases} \tag{2.8}$$

[illegible] $k = -q+1, \dots, p-1$

Now we are ready to state our first result. The proof is given in section 4.

THEOREM 2.3. [illegible] a [illegible] (1.3) [illegible] (1.4) [illegible] Γ_k [illegible] (2.7) [illegible] $k \in \{-q+1, \dots, p-1\}$ [illegible] μ_k [illegible] Γ_k [illegible]

$$\mathrm{d}\mu_k(\lambda) = \frac{1}{2\pi \mathrm{i}} \sum_{j=1}^{q+k} \left(\frac{z'_{j+}(\lambda)}{z_{j+}(\lambda)} - \frac{z'_{j-}(\lambda)}{z_{j-}(\lambda)} \right) \mathrm{d}\lambda, \tag{2.9}$$

[illegible] $\mathrm{d}\lambda$ [illegible] Γ_k [illegible] Γ_k [illegible] (1.12)) [illegible]

(a) $\vec{\mu} = (\mu_{-q+1}, \dots, \mu_{p-1})$ [illegible]

(b) [illegible] l_k [illegible]

$$\begin{aligned} 2 \int \log|\lambda - x| \, \mathrm{d}\mu_k(x) &= \int \log|\lambda - x| \, \mathrm{d}\mu_{k+1}(x) \\ &\quad + \int \log|\lambda - x| \, \mathrm{d}\mu_{k-1}(x) + l_k \end{aligned} \tag{2.10}$$

[illegible] $k = -q+1, \dots, p-1$ [illegible] $\lambda \in \Gamma_k$ [illegible] μ_{-q} [illegible] μ_p [illegible]

(c) $\vec{\mu} = (\mu_{-q+1}, \dots, \mu_{p-1})$ [illegible] J [illegible]

$$J(\vec{\nu}) = \sum_{k=-q+1}^{p-1} I(\nu_k) - \sum_{k=-q+1}^{p-2} I(\nu_k, \nu_{k+1}) \tag{2.11}$$

[illegible] $\vec{\nu} = (\nu_{-q+1}, \dots, \nu_{p-1})$

The relations (2.10) are the Euler–Lagrange variational conditions for the minimization problem for J among admissible vectors of measures.

It may not be obvious that the energy functional (2.11) is bounded from below. This can be seen from the alternative representation

$$\begin{aligned} J(\vec{\nu}) = &\left(\frac{1}{q} + \frac{1}{p} \right) I(\nu_0) + \sum_{k=1}^{q-1} k(k+1) \, I\left(\frac{\nu_{-q+k}}{k} - \frac{\nu_{-q+k+1}}{k+1} \right) \\ &+ \sum_{k=1}^{p-1} k(k+1) \, I\left(\frac{\nu_{p-k}}{k} - \frac{\nu_{p-k-1}}{k+1} \right). \end{aligned} \tag{2.12}$$

We leave the calculation leading to this identity to the reader. Under the normalizations (2.8) it follows by (2.6) that each term in the two finite sums on the right-hand side of (2.12) is nonnegative, so that

$$J(\vec{\nu}) \geq \left(\frac{1}{q} + \frac{1}{p}\right) I(\nu_0).$$

Since ν_0 is a Borel probability measure on Γ_0 and Γ_0 is compact, we indeed have that the energy functional is bounded from below on admissible vectors of measures $\vec{\nu}$.

The alternative representation (2.12) will play a role in the proof of Theorem 2.3.

Yet another representation for J is

$$J(\vec{\nu}) = \sum_{j,k=-q+1}^{p-1} A_{jk}\, I(\nu_j, \nu_k), \tag{2.13}$$

where the interaction matrix A has entries

$$A_{jk} = \begin{cases} 1 & \text{if } j = k, \\ -\frac{1}{2} & \text{if } |j-k| = 1, \\ 0 & \text{if } |j-k| \geq 2. \end{cases} \tag{2.14}$$

The energy functional in the form (2.13) and (2.14) also appears in the theory of simultaneous rational approximation, where it is the interaction matrix for a Nikishin system [7, Chapter 5].

It allows for the following physical interpretation: on each of the curves Γ_k one puts charged particles with total charge $(q+k)/q$ or $(p-k)/p$, depending on whether $k \leq 0$ or $k \geq 0$. Particles that lie on the same curve repel each other. The particles on two consecutive curves interact in the sense that they attract each other but in a way that is half as strong as the repulsion on a single curve. Particles on different curves that are not consecutive do not interact with each other in a direct way.

2.2. The measures μ_k as limiting measures of generalized eigenvalues. By (1.12) and Theorem 2.3 we know that the measure μ_0 that appears in the minimizer of the energy functional J is the limiting measure for the eigenvalues of $T_n(a)$. It is natural to ask about the other measures μ_k that appear in the minimizer. In our second result we show that the measures μ_k can be obtained as limiting counting measures for certain generalized eigenvalues.

Let $k \in \{-q+1, \ldots, p-1\}$. We use $T_n(z^{-k}(a-\lambda))$ to denote the Toeplitz matrix with the symbol $z \mapsto z^{-k}(a(z)-\lambda)$. For example, for $k=1$, $q=1$, and $p=2$, we have

$$T_n(z^{-k}(a-\lambda)) = \begin{pmatrix} a_1 & a_0-\lambda & a_{-1} & & & & \\ a_2 & a_1 & a_0-\lambda & a_{-1} & & & \\ & a_2 & a_1 & a_0-\lambda & a_{-1} & & \\ & & \ddots & \ddots & \ddots & \ddots & \\ & & & a_2 & a_1 & a_0-\lambda & a_{-1} \\ & & & & a_2 & a_1 & a_0-\lambda \\ & & & & & a_2 & a_1 \end{pmatrix}_{n\times n}.$$

Definition 2.4. [illegible] $k \in \{-q+1, \ldots, p-1\}$ [illegible] $n \geq 1$ [illegible] $P_{k,n}$ [illegible]

$$P_{k,n}(\lambda) = \det T_n(z^{-k}(a-\lambda)) \tag{2.15}$$

... k ... $T_n(a)$ ...

$$\operatorname{sp}_k T_n(a) = \{\lambda \in \mathbb{C} \mid P_{k,n}(\lambda) = 0\}. \tag{2.16}$$

... $\mu_{k,n}$ ... $\operatorname{sp}_k T_n(a)$

$$\mu_{k,n} = \frac{1}{n} \sum_{\lambda \in \operatorname{sp}_k T_n(a)} \delta_\lambda, \tag{2.17}$$

... λ ... $P_{k,n}$

Note that $\lambda \in \operatorname{sp}_k T_n(a)$ is a generalized eigenvalue (in the usual sense) for the matrix pencil $(T_n(z^{-k}a), T_n(z^{-k}))$, that is, $\det(A - \lambda B) = 0$ with $A = T_n(z^{-k}a)$ and $B = T_n(z^{-k})$. If $k = 0$, then $B = I$ and $\operatorname{sp}_0 T_n(a) = \operatorname{sp} T_n(a)$. If $k \neq 0$, then B is not invertible and the generalized eigenvalue problem is singular, causing there to be fewer than n generalized eigenvalues. In fact, since $T_n(z^{-k}(a-\lambda))$ has exactly $n - |k|$ entries $a_0 - \lambda$, we easily get that the degree of $P_{k,n}$ is at most $n - |k|$ and so there are at most $n - |k|$ generalized eigenvalues. Due to the band structure of $T_n(z^{-k}(a-\lambda))$, the actual number of generalized eigenvalues is substantially smaller.

PROPOSITION 2.5. ... $k \in \{-q+1, \dots, p-1\}$ ... $P_{k,n}(\lambda) = \gamma_{k,n}\lambda^{d_{k,n}} + \cdots$ ... $d_{k,n}$ ... $\gamma_{k,n} \neq 0$ ...

$$d_{k,n} \leq \begin{cases} \frac{q+k}{q} n & \text{... } k < 0, \\ \frac{p-k}{p} n & \text{... } k > 0. \end{cases} \tag{2.18}$$

... (2.18) ... $k > 0$ ... n ... p ... $k < 0$ ... n ... q ...

$$\gamma_{k,n} = \begin{cases} (-1)^{(k+1)n} a_{-q}^{|k|n/q} & \text{... } k < 0 \text{ ... } n \equiv 0 \bmod q, \\ (-1)^{(k+1)n} a_p^{kn/p} & \text{... } k > 0 \text{ ... } n \equiv 0 \bmod p. \end{cases} \tag{2.19}$$

We now come to our second main result. It is the analogue of the results of Schmidt, Spitzer, and Hirschman for the generalized eigenvalues.

THEOREM 2.6. ... $k \in \{-q+1, \dots, p-1\}$ ...

$$\liminf_{n\to\infty} \operatorname{sp}_k T_n(a) = \limsup_{n\to\infty} \operatorname{sp}_k T_n(a) = \Gamma_k, \tag{2.20}$$

...

$$\lim_{n\to\infty} \int_{\mathbb{C}} \phi(z)\, \mathrm{d}\mu_{k,n}(z) = \int_{\mathbb{C}} \phi(z)\, \mathrm{d}\mu_k(z) \tag{2.21}$$

... ϕ ... $\mathbb{C}$

The key element in the proof of Theorem 2.6 is a beautiful formula of Widom [14] (see [1, Theorem 2.8]) for the determinant of a banded Toeplitz matrix. In the present situation Widom's formula yields the following. Let $\lambda \in \mathbb{C}$ be such that the solutions $z_j(\lambda)$ of the algebraic equation (1.7) are mutually distinct. Then

$$P_{k,n}(\lambda) = \det T_n(z^{-k}(a-\lambda)) = \sum_M C_M(\lambda)\, (w_M(\lambda))^n, \tag{2.22}$$

where the sum is over all subsets $M \subset \{1, 2, \ldots, p+q\}$ of cardinality $|M| = p-k$ and for each such M we have

$$w_M(\lambda) := (-1)^{p-k} a_p \prod_{j \in M} z_j(\lambda) \tag{2.23}$$

and (with $\overline{M} := \{1, 2, \ldots, p+q\} \setminus M$)

$$C_M(\lambda) := \prod_{j \in M} z_j(\lambda)^{q+k} \prod_{\substack{j \in M \\ l \in \overline{M}}} (z_j(\lambda) - z_l(\lambda))^{-1}. \tag{2.24}$$

The formula (2.22) shows that for large n the main contribution comes from those M for which $|w_M(\lambda)|$ is the largest possible. For $\lambda \in \mathbb{C} \setminus \Gamma_k$ there is a unique such M, namely

$$M = M_k := \{q+k+1, q+k+2, \ldots, p+q\}, \tag{2.25}$$

because of the ordering (1.8).

2.3. Overview of the rest of the paper. In section 3 we will state some preliminary results about analyticity properties of the solutions z_j of the algebraic equation (1.7). These results will be needed in the proof of Theorem 2.3 which is given in section 4. In section 5 we will prove Proposition 2.5 and Theorem 2.6. Finally, we conclude the paper by giving some examples in section 6.

3. Preliminaries. In this section we collect a number of properties of the curves Γ_k and the solutions $z_1(\lambda), \ldots, z_{p+q}(\lambda)$ of the algebraic equation (1.7). For convenience we define throughout the rest of the paper

$$\Gamma_{-q} = \Gamma_p = \emptyset \qquad \text{and} \qquad \mu_{-q} = \mu_p = 0 \qquad \text{(the zero measure)}.$$

Occasionally, we also use

$$z_0(\lambda) = 0, \qquad z_{p+q+1}(\lambda) = +\infty.$$

3.1. The structure of the curves Γ_k. We start with a definition; cf. [1, section 11.2].

DEFINITION 3.1. [illegible] $\lambda_0 \in \mathbb{C}$ [illegible] $a(z) - \lambda_0 = 0$ [illegible] $\lambda_0 \in \Gamma_k$ [illegible] Γ_k [illegible] λ_0 [illegible] U [illegible] λ [illegible] $\Gamma_k \cap U$ [illegible] ∂U

If λ_0 is a branch point, then there is a z_0 such that $a(z_0) = \lambda_0$ and $a'(z_0) = 0$. Then we may assume that $z_0 = z_{q+k}(\lambda_0) = z_{q+k+1}(\lambda_0)$ for some k and $\lambda_0 \in \Gamma_k$. For a symbol a of the form (1.3), the derivative a' has exactly $p+q$ zeros (counted with multiplicity), so that there are exactly $p+q$ branch points counted with multiplicity.

The solutions $z_k(\lambda)$ also have branching at infinity (unless $p = 1$ or $q = 1$). There are p solutions of (1.7) that tend to infinity as $\lambda \to \infty$ and q solutions that tend to 0. Indeed, we have

$$z_k(\lambda) = \begin{cases} c_k \lambda^{-1/q}(1 + \mathcal{O}(\lambda^{-1/q})) & \text{for } k = 1, \ldots, q, \\ c_k \lambda^{1/p}(1 + \mathcal{O}(\lambda^{-1/p})) & \text{for } k = q+1, \ldots, p+q \end{cases} \tag{3.1}$$

as $\lambda \to \infty$. Here $c_1, \dots, c_q$ are the q distinct solutions of $c^q = a_{-q}$ (taken in some order depending on λ), and $c_{q+1}, \dots, c_{p+q}$ are the p distinct solutions of $c^p = a_p^{-1}$ (again taken in some order depending on λ).

The following proposition gives the structure of Γ_k at infinity.

PROPOSITION 3.2. [illegible] $k \in \{-q+1, \dots, p-1\} \setminus \{0\}$ [illegible] $R > 0$ [illegible] $\Gamma_k \cap \{\lambda \in \mathbb{C} \mid |\lambda| > R\}$ [illegible] $|\lambda| = R$ [illegible].

[illegible]. The proof is similar to the proof of [1, Proposition 11.8] where a similar structure theorem was proved for finite branch points. We omit the details. □

It follows from Proposition 3.2 that the exceptional points for Γ_k are in a bounded set. Since the set of exceptional points is discrete we conclude that there are only finitely many exceptional points. Then we have the following result about the structure of Γ_k.

PROPOSITION 3.3. [illegible] $k \in \{-q+1, \dots, p-1\}$ [illegible] Γ_k [illegible] Γ_k [illegible].

[illegible]. This was proved for $k = 0$ in [10] and [1, Theorem 11.9]. For general k, there are only finitely many exceptional points, and the proof follows in a similar way. □

3.2. The Riemann surface. From Proposition 3.3 it follows that the curves Γ_k can be taken as cuts for the $p+q$-sheeted Riemann surface of the algebraic equation (1.7). We number the sheets from 1 to $p+q$, where the kth sheet of the Riemann surface is

$$\mathcal{R}_k = \{\lambda \in \mathbb{C} \mid |z_{k-1}(\lambda)| < |z_k(\lambda)| < |z_{k+1}(\lambda)|\} = \mathbb{C} \setminus (\Gamma_{-q+k-1} \cup \Gamma_{-q+k}). \tag{3.2}$$

Thus z_k is well defined and analytic on $\mathcal{R}_k$.

The easiest case to visualize is the case where consecutive cuts are disjoint, that is, $\Gamma_{-q+k-1} \cap \Gamma_{-q+k} = \emptyset$ for every $k = 2, \dots, p+q-2$. In that case we have that $\mathcal{R}_k$ is connected to $\mathcal{R}_{k+1}$ via Γ_{-q+k} in the usual crosswise manner, and z_{k+1} is the analytic continuation of z_k across Γ_{-q+k}.

The general case is described in the following proposition.

PROPOSITION 3.4. [illegible] A [illegible] $A \subset \Gamma_{-q+k}$ [illegible] $k = k_1, \dots, k_2$ [illegible] $A \cap (\Gamma_{-q+k_1-1} \cup \Gamma_{-q+k_2+1}) = \emptyset$ [illegible] $k = k_1, \dots, k_2+1$ [illegible] z_k [illegible] A [illegible] $z_{k_1+k_2-k+1}$ [illegible] A [illegible] $\mathcal{R}_k$ [illegible] $\mathcal{R}_{k_1+k_2-k+1}$ [illegible].

[illegible]. We have that

$$|z_{k_1}(\lambda)| = |z_{k_1+1}(\lambda)| = \cdots = |z_{k_2}(\lambda)| = |z_{k_2+1}(\lambda)|$$

for $\lambda \in A$, with strict inequalities ($<$) for λ on either side of A. Choose an orientation for A. Then there is a permutation π of $\{k_1, \dots, k_2+1\}$ such that $z_{\pi(k)}$ is the analytic continuation of z_k from the $+$ side of A to the $-$ side of A.

Assume that there are $k, k' \in \{k_1, \dots, k_2+1\}$ such that $k < k'$ and $\pi(k) < \pi(k')$. Take a regular $\lambda_0 \in A$ and a small neighborhood U of λ_0 such that $A \cap U = \Gamma_{-q+k} \cap U = \Gamma_{-q+k'} \cap U$ and $A \cap U$ is an analytic arc starting and terminating on ∂U. Then we have a disjoint union $U = U_+ \cup U_- \cup (A \cap U)$, where U_+ (U_-) is the part of U on the $+$ side ($-$ side) of A. The function ϕ defined by

$$\phi(\lambda) = \begin{cases} \frac{z_k(\lambda)}{z_{k'}(\lambda)} & \text{for } \lambda \in U_+, \\ \frac{z_{\pi(k)}(\lambda)}{z_{\pi(k')}(\lambda)} & \text{for } \lambda \in U_- \end{cases}$$

has an analytic continuation to U and satisfies $|\phi(\lambda)| < 1$ for $\lambda \in U_+ \cup U_-$ and $|\phi(\lambda)| = 1$ for $\lambda \in A \cap U$. This contradicts the maximum principle for analytic functions. Therefore $\pi(k) > \pi(k')$ for every $k, k' \in \{k_1, \ldots, k_2 + 1\}$ with $k < k'$, and this implies that $\pi(k) = k_1 + k_2 - k + 1$ for every $k = k_1, \ldots, k_2 + 1$, and the proposition follows. □

3.3. The functions $w_k(\lambda)$. A major role is played by the functions w_k which, for $k \in \{-q+1, \ldots, p-1\}$, are defined by

$$w_k(\lambda) = \prod_{j=1}^{q+k} z_j(\lambda) \qquad \text{for } \lambda \in \mathbb{C} \setminus \Gamma_k. \tag{3.3}$$

Note that $w_k = (-1)^{p-k} a_p^{-1} w_{\{1,\ldots,k\}}$ in the notation of (2.23).

PROPOSITION 3.5. [illegible] w_k [illegible] $\mathbb{C} \setminus \Gamma_k$ [illegible]. Since z_j is analytic on $\mathcal{R}_j = \mathbb{C} \setminus (\Gamma_{-q+j-1} \cup \Gamma_{-q+j})$ (see (3.2)), we obtain from its definition that w_k is analytic in $\mathbb{C} \setminus \bigcup_{j=1}^{k+q} \Gamma_{-q+j}$. Let A be an analytic arc in $\Gamma_{-q+j} \setminus \Gamma_k$ for some $j < k + q$. Choose an orientation on A. Since the arc is disjoint from Γ_k, we have that $z_{j+}(\lambda) = z_{\pi(j)-}(\lambda)$, for $\lambda \in A$ and $j = 1, \ldots, q + k$, where π is a permutation of $\{1, \ldots, q+k\}$. Since w_k is symmetric in the z_j's for $j = 1, \ldots, q+k$, it then follows that

$$w_{k+}(\lambda) = w_{k-}(\lambda) \qquad \text{for } \lambda \in A,$$

which shows the analyticity in $\mathbb{C} \setminus \Gamma_k$ with the possible exception of isolated singularities at the exceptional points of Γ_{-q+1}, Γ_{-q+2}, …, Γ_{k-1}. However, each z_j, and therefore also w_k, is bounded near such an exceptional point, so that any isolated singularity is removable. □

In the rest of the paper we make frequent use of the logarithmic derivative w_k'/w_k of w_k. By the fact that w_k does not vanish on $\mathbb{C} \setminus \Gamma_k$ and by Proposition 3.5, it follows that w_k'/w_k is analytic in $\mathbb{C} \setminus \Gamma_k$. By Proposition 3.4 it, moreover, has an analytic continuation across every open analytic arc $A \subset \Gamma_k$. Near the exceptional points that are not branch points w_k'/w_k remains bounded. At the branch points it can, however, have singularities of a certain order.

PROPOSITION 3.6. [illegible] $\lambda_0 \in \Gamma_k$ [illegible] Γ_k [illegible] $m \in \mathbb{N}$ [illegible]

$$\frac{w_k'(\lambda)}{w_k(\lambda)} = \mathcal{O}\left((\lambda - \lambda_0)^{-m/(m+1)}\right) \tag{3.4}$$

[illegible] $\lambda \to \lambda_0$ [illegible] $\lambda \in \mathbb{C} \setminus \Gamma_k$ [illegible]. Let $1 \le j \le q + k$. We investigate the behavior of $z_j(\lambda)$ when $\lambda \to \lambda_0$ such that λ remains in a connected component of $\mathbb{C} \setminus (\Gamma_{j-1} \cup \Gamma_j)$. Then $z_j(\lambda) \to z_0$ for some $z_0 \in \mathbb{C}$ with $a(z_0) = \lambda_0$. Let $m_0 + 1$ be the multiplicity of z_0 as a solution of $a(z) = \lambda_0$. Then

$$a(z) = \lambda_0 + c_0(z - z_0)^{m_0+1}(1 + \mathcal{O}(z - z_0)), \qquad z \to z_0, \tag{3.5}$$

for some nonzero constant c_0. Therefore,

$$z_j(\lambda) = z_0 + \mathcal{O}((\lambda - \lambda_0)^{1/(m_0+1)}) \tag{3.6}$$

and

$$z_j'(\lambda) = \mathcal{O}((\lambda - \lambda_0)^{-m_0/(m_0+1)}) \tag{3.7}$$

for $\lambda \to \lambda_0$ such that λ remains in the same connected component of $\mathbb{C} \setminus (\Gamma_{j-1} \cup \Gamma_j)$. Let m be the maximum of all the multiplicities of the roots of $a(z) = \lambda_0$. Then it follows from (3.6) and (3.7) that

$$\frac{z_j'(\lambda)}{z_j(\lambda)} = \mathcal{O}((\lambda - \lambda_0)^{-m/(m+1)})$$

as $\lambda \to \lambda_0$ with $\lambda \in \mathbb{C} \setminus \Gamma_k$. Then we obtain (3.4) in view of (3.3). □

We end this section by giving the asymptotics of w_k'/w_k for $\lambda \to \infty$.

PROPOSITION 3.7. [illegible] $\lambda \to \infty$ [illegible] $\lambda \in \mathbb{C} \setminus \Gamma_k$ [illegible]

$$\frac{w_k'(\lambda)}{w_k(\lambda)} = \begin{cases} -\frac{q+k}{q}\lambda^{-1} + \mathcal{O}\left(\lambda^{-1-1/q}\right) & \text{[illegible]} \quad k = -q+1, \dots, -1, \\ -\lambda^{-1} + \mathcal{O}(\lambda^{-2}) & \text{[illegible]} \quad k = 0, \\ -\frac{p-k}{p}\lambda^{-1} + \mathcal{O}\left(\lambda^{-1-1/p}\right) & \text{[illegible]} \quad k = 1, \dots, p-1. \end{cases} \tag{3.8}$$

[illegible]. This follows directly from (3.1) and (3.3). □

4. Proof of Theorem 2.3. We use the function w_k introduced in (3.3). We define μ_k by the formula (2.9) and we note that

$$\mathrm{d}\mu_k(\lambda) = \frac{1}{2\pi \mathrm{i}} \left(\frac{w_{k+}'(\lambda)}{w_{k+}(\lambda)} - \frac{w_{k-}'(\lambda)}{w_{k-}(\lambda)} \right) \mathrm{d}\lambda. \tag{4.1}$$

PROPOSITION 4.1. [illegible] $k = -q+1, \dots, p-1$ [illegible] μ_k [illegible] Γ_k [illegible] $\mu_k(\Gamma_k) = (q+k)/q$, $k \geq 0$ [illegible] $\mu_k(\Gamma_k) = (p-k)/p$, $k \geq 0$ [illegible]. We first show that μ_k is a measure, i.e., that it is nonnegative on each analytic arc of Γ_k. Let A be an analytic arc in Γ_k consisting only of regular points. Let $t \mapsto \lambda(t)$ be a parametrization of A in the direction of the orientation of Γ_k. Then

$$\begin{aligned} \mathrm{d}\mu_k(\lambda) &= \frac{1}{2\pi \mathrm{i}} \left(\frac{w_{k+}'(\lambda(t))}{w_{k+}(\lambda(t))} - \frac{w_{k-}'(\lambda(t))}{w_{k-}(\lambda(t))} \right) \lambda'(t) \mathrm{d}t \\ &= \frac{1}{2\pi \mathrm{i}} \left(\frac{\mathrm{d}}{\mathrm{d}t} \log \frac{w_{k+}(\lambda(t))}{w_{k-}(\lambda(t))} \right) \mathrm{d}t. \end{aligned}$$

To conclude that μ_k is nonnegative on A, it is thus enough to show that

$$\operatorname{Re} \log \frac{w_{k+}(\lambda)}{w_{k-}(\lambda)} = 0 \qquad \text{for } \lambda \in A \tag{4.2}$$

and

$$\operatorname{Im} \log \frac{w_{k+}(\lambda)}{w_{k-}(\lambda)} \quad \text{increases along } A. \tag{4.3}$$

Since $|w_{k+}(\lambda)| = |w_{k-}(\lambda)|$ for $\lambda \in A$, we have (4.2) so that it only remains to prove (4.3).

There is a neighborhood U of A such that $U \setminus \Gamma_k$ has two components, denoted U_+ and U_-, where U_+ is on the $+$ side of Γ_k and U_- on the $-$ side. It follows from Proposition 3.4 that w_k has an analytic continuation from U_- to U, which we denote by $\hat{w}_k$, and that $|w_k(\lambda)| < |\hat{w}_k(\lambda)|$ for $\lambda \in U_+$, and equality $|w_{k+}(\lambda)| = |\hat{w}_k(\lambda)|$ holds for $\lambda \in A$. Thus it follows that

$$\frac{\partial}{\partial n} \operatorname{Re} \log \left(\frac{w_k(\lambda)}{\hat{w}_k(\lambda)} \right) \leq 0 \qquad \text{for } \lambda \in A,$$

where $\frac{\partial}{\partial n}$ denotes the normal derivative to A in the direction of U_+. Then by the Cauchy–Riemann equations we have that $\operatorname{Im}\log(\frac{w_{k+}(\lambda)}{\hat{w}_{k+}(\lambda)})$ is increasing along A. Since $\hat{w}_{k+}(\lambda) = w_{k-}(\lambda)$ for $\lambda \in A$, we obtain (4.3). Thus μ_k is a measure.

Next we show that μ_k is a finite measure, which means that we have to show that

$$\frac{w'_{k+}(\lambda)}{w_{k+}(\lambda)} - \frac{w'_{k-}(\lambda)}{w_{k-}(\lambda)} \tag{4.4}$$

is integrable near infinity on Γ_k and near every branch point on Γ_k. This follows from Propositions 3.7 and 3.6. Indeed, from Proposition 3.7 it follows that

$$\frac{w'_{k+}(\lambda)}{w_{k+}(\lambda)} - \frac{w'_{k-}(\lambda)}{w_{k-}(\lambda)} = \mathcal{O}\left(\lambda^{-1-\delta}\right) \qquad \text{as } \lambda \to \infty,\ \lambda \in \Gamma_k, \tag{4.5}$$

where $\delta = 1/q$ if $k < 0$ and $\delta = 1/p$ if $k > 0$. Since $\delta > 0$ we see that (4.4) is integrable near infinity. For a branch point λ_0 of Γ_k, we have from Proposition 3.6 that there exists an $m \geq 1$ such that

$$\frac{w'_{k+}(\lambda)}{w_{k+}(\lambda)} - \frac{w'_{k-}(\lambda)}{w_{k-}(\lambda)} = \mathcal{O}\left((\lambda-\lambda_0)^{-m/(m+1)}\right) \qquad \text{as } \lambda \to \lambda_0,\ \lambda \in \Gamma_k. \tag{4.6}$$

This shows that (4.4) is integrable near every branch point. Thus μ_k is a finite measure.

Finally we compute the total mass of μ_k. Let $D(0,R) = \{z \in \mathbb{C} \mid |z| < R\}$. Then for R large enough, so that $D(0,R)$ contains all exceptional points of Γ_k and all connected components of $\mathbb{C} \setminus \Gamma_k$ (if any),

$$\mu_k(\Gamma_k \cap D(0,R)) = \frac{1}{2\pi \mathrm{i}} \left(\int_{\Gamma_k \cap D(0,R)} \frac{w'_{k+}(\lambda)}{w_{k+}(\lambda)} \mathrm{d}\lambda - \int_{\Gamma_k \cap D(0,R)} \frac{w'_{k-}(\lambda)}{w_{k-}(\lambda)} \mathrm{d}\lambda \right), \tag{4.7}$$

where we have used the behavior (4.6) near the branch points in order to be able to split the integrals. Again using (4.6) we can then turn the two integrals into a contour integral over a contour $\tilde{\Gamma}_{k,R}$ as in Figure 4.1. The contour $\tilde{\Gamma}_{k,R}$ passes along the $\pm$ sides of $\Gamma_k \cap D(0,R)$, and if we choose the orientation that is also shown in Figure 4.1 (and which is independent of the choice of orientation for Γ_k), then

$$\mu_k(\Gamma_k \cap D(0,R)) = \frac{1}{2\pi \mathrm{i}} \int_{\tilde{\Gamma}_{k,R}} \frac{w'_k(\lambda)}{w_k(\lambda)} \mathrm{d}\lambda. \tag{4.8}$$

The parts of $\tilde{\Gamma}_{k,R}$ that belong to bounded components of $\mathbb{C} \setminus \Gamma_k$ form closed contours along the boundary of each bounded component. By Cauchy's theorem their contribution to the integral (4.8) vanishes. The parts of $\tilde{\Gamma}_{k,R}$ that belong to the unbounded components of $\mathbb{C} \setminus \Gamma_k$ can be deformed to the circle $\partial D(0,R)$ with the clockwise orientation. Thus if we use the positive orientation on $\partial D(0,R)$ as in Figure 4.1, then we obtain from (4.8)

$$\mu_k(\Gamma_k \cap D(0,R)) = -\frac{1}{2\pi \mathrm{i}} \oint_{\partial D(0,R)} \frac{w'_k(\lambda)}{w_k(\lambda)} \mathrm{d}\lambda.$$

Letting $R \to \infty$ and using Proposition 3.7, we then find that μ_k is a measure on Γ_k with total mass $\mu_k(\Gamma_k) = (q+k)/q$ if $k \leq 0$ and $\mu_k(\Gamma_k) = (p-k)/p$ if $k \geq 0$. □

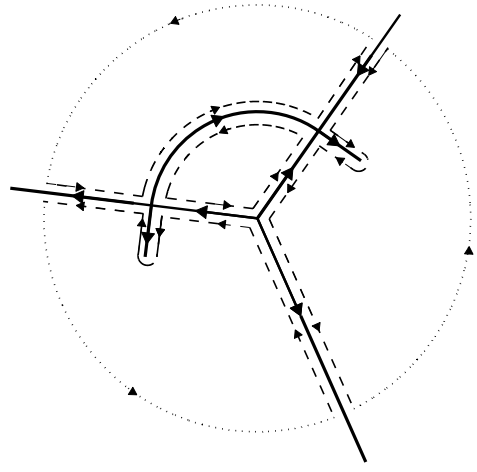

FIG. 4.1. *Illustration for the proofs of Propositions* 4.1 *and* 4.2. *The solid line is a sketch of a possible contour* Γ_k. *The dashed line is the contour* $\tilde{\Gamma}_{k,R}$, *and the dotted line is the boundary of a disk of radius* R *around* 0.

The following proposition is the next step in showing that the measures μ_k from (2.9) satisfy (2.10).

PROPOSITION 4.2. $k = -q+1, \ldots, p-1$

$$\int \frac{\mathrm{d}\mu_k(x)}{x-\lambda} = \frac{w_k'(\lambda)}{w_k(\lambda)} \qquad \lambda \in \mathbb{C} \setminus \Gamma_k \tag{4.9}$$

$$\int \log|\lambda - x| \, \mathrm{d}\mu_k(x) = -\log|w_k(\lambda)| + \alpha_k \qquad \lambda \in \mathbb{C}, \tag{4.10}$$

α_k

$$\alpha_k = \begin{cases} \log|a_{-q}| + \frac{k}{q}\log|a_{-q}| & k \le 0, \\ \log|a_{-q}| - \frac{k}{p}\log|a_p| & k \ge 0. \end{cases} \tag{4.11}$$

. To prove (4.9), we follow the same arguments as in the calculation of $\mu_k(\Gamma_k)$ in the end of the proof of Proposition 4.1. Let $\lambda \in \mathbb{C} \setminus \Gamma_k$, and choose $R > 0$ as in the proof of Proposition 4.1. We may assume $R > |\lambda|$. Then similar to (4.7) and (4.8) we can write

$$\int_{\Gamma_k \cap D(0,R)} \frac{\mathrm{d}\mu_k(x)}{x-\lambda} = \frac{1}{2\pi \mathrm{i}} \int_{\tilde{\Gamma}_{k,R}} \frac{w_k'(x)}{w_k(x)(x-\lambda)} \mathrm{d}x,$$

where $\tilde{\Gamma}_{k,R}$ has the same meaning as in the proof of Proposition 4.1; see also Figure 4.1. As in the proof of Proposition 4.1 we deform to an integral over $\partial D(0,R)$, but now we have to take into account that the integrand has a pole at $x = \lambda$ with residue $w_k'(\lambda)/w_k(\lambda)$. Therefore, by Cauchy's theorem

$$\int_{\Gamma_k \cap D(0,R)} \frac{\mathrm{d}\mu_k(x)}{x-\lambda} = \frac{w_k'(\lambda)}{w_k(\lambda)} - \frac{1}{2\pi \mathrm{i}} \int_{\partial D(0,R)} \frac{w_k'(x)}{w_k(x)(x-\lambda)} \mathrm{d}x. \tag{4.12}$$

Letting $R \to \infty$ and using Proposition 3.7 gives (4.9).

Next we integrate (4.9) over a Jordan curve J in $\mathbb{C} \setminus \Gamma_k$ from λ_1 to λ_2,

$$\begin{aligned}\int_{\lambda_1}^{\lambda_2} \int_{\Gamma_k} \frac{1}{x-\lambda}\, \mathrm{d}\mu_k(x)\, \mathrm{d}\lambda &= -\int \int_{\lambda_1}^{\lambda_2} \frac{1}{x-\lambda}\, \mathrm{d}\lambda\, \mathrm{d}\mu_k(x) \\ &= \int \left(\log|\lambda_1 - x| - \log|\lambda_2 - x| + \mathrm{i}\Delta_J[\arg(\lambda - x)]\right) \mathrm{d}\mu_k(x), \end{aligned} \tag{4.13}$$

where $\Delta_J[\arg(\lambda - x)]$ denotes the change in argument of $\lambda - x$ as when λ varies over J from λ_1 to λ_2. By (4.9) the integral (4.13) is equal to

$$\int_{\lambda_1}^{\lambda_2} \frac{w_k'(\lambda)}{w_k(\lambda)} \mathrm{d}\lambda = \log|w_k(\lambda_2)| - \log|w_k(\lambda_1)| + \mathrm{i}\Delta_J[\arg w_k(\lambda)]. \tag{4.14}$$

Equating the real parts of (4.13) and (4.14), we get

$$\int \left(\log|\lambda_1 - x| - \log|\lambda_2 - x|\right) \mathrm{d}\mu_k(x) = -\log|w_k(\lambda_1)| + \log|w_k(\lambda_2)|. \tag{4.15}$$

Since λ_1 and λ_2 can be taken arbitrarily in a connected component of $\mathbb{C} \setminus \Gamma_k$, we find that there exists a constant $\alpha_k \in \mathbb{R}$ (which a priori could depend on the connected component) such that

$$\int \log|\lambda - x|\, \mathrm{d}\mu_k(x) = -\log|w_k(\lambda)| + \alpha_k \tag{4.16}$$

for all λ in a connected component of $\mathbb{C} \setminus \Gamma_k$. By continuity, (4.16) extends to the closure of the connected component, which shows that the same constant α_k is valid for all connected components. Thus (4.16) holds for all $\lambda \in \mathbb{C}$.

The exact value of α_k can then be determined by expanding (4.16) for large λ. Suppose, for example, that $k < 0$. Then by (3.1) and (3.3)

$$|w_k(\lambda)| = \prod_{j=1}^{q+k} |z_j(\lambda)| = |a_{-q}|^{(q+k)/q} |\lambda|^{-(q+k)/q} \left(1 + \mathcal{O}(\lambda^{-1/q})\right)$$

as $\lambda \to \infty$. Thus

$$-\log|w_k(\lambda)| = \frac{q+k}{q} \log|\lambda| - \frac{q+k}{q} \log|a_{-q}| + \mathcal{O}(\lambda^{-1/q}). \tag{4.17}$$

Since

$$\int \log|\lambda - x|\, \mathrm{d}\mu_k(x) = \log|\lambda| \mu_k(\Gamma_k) + o(1) = \frac{q+k}{q} \log|\lambda| + o(1) \qquad \text{as } \lambda \to \infty, \tag{4.18}$$

the value (4.11) for α_k follows from (4.16), (4.17), and (4.18). The argument for $k > 0$ is similar. This completes the proof of the proposition. □

To prove part (c) of Theorem 2.3 we also need the following lemma.

LEMMA 4.3. [illegible] $\vec{\nu}_1 = (\nu_{1,-q+1} \ldots, \nu_{1,p-1})$ [illegible] $\vec{\nu}_2 = (\nu_{2,-q+1} \ldots, \nu_{2,p-1})$ [illegible] $J(\vec{\nu}_1 - \vec{\nu}_2)$ [illegible]

$$J(\vec{\nu}_1 - \vec{\nu}_2) \geq 0 \tag{4.19}$$

[illegible] $\vec{\nu}_1 = \vec{\nu}_2$

. Since both $\vec{\nu}_1$ and $\vec{\nu}_2$ have finite energy, we find that $J(\vec{\nu}_1 - \vec{\nu}_2)$ is well defined. According to the alternative representation (2.12), we have

$$\begin{aligned} J(\vec{\nu}_1 - \vec{\nu}_2) = &\left(\frac{1}{q} + \frac{1}{p}\right) I(\nu_{1,0} - \nu_{2,0}) \\ &+ \sum_{k=1}^{q-1} k(k+1) I\left(\frac{\nu_{1,-q+k}}{k} - \frac{\nu_{2,-q+k}}{k} - \frac{\nu_{1,-q+k+1}}{k+1} + \frac{\nu_{2,-q+k+1}}{k+1}\right) \\ &+ \sum_{k=1}^{p-1} k(k+1) I\left(\frac{\nu_{1,p-k}}{k} - \frac{\nu_{2,p-k}}{k} - \frac{\nu_{1,p-k-1}}{k+1} + \frac{\nu_{2,p-k-1}}{k+1}\right). \end{aligned} \tag{4.20}$$

Using (2.6) and (2.8), we see that all terms in (4.20) are nonnegative and therefore (4.19) holds.

Suppose now that $J(\vec{\nu}_1 - \vec{\nu}_2) = 0$. Then all terms in the right-hand side of (4.20) are zero, so that

$$\nu_{1,0} = \nu_{2,0}, \tag{4.21}$$

$$\frac{\nu_{1,-q+k}}{k} + \frac{\nu_{2,-q+k+1}}{k+1} = \frac{\nu_{1,-q+k+1}}{k+1} + \frac{\nu_{2,-q+k}}{k} \qquad \text{for } k = 1, \dots, q-1, \tag{4.22}$$

$$\frac{\nu_{1,p-k}}{k} + \frac{\nu_{2,p-k-1}}{k+1} = \frac{\nu_{1,p-k-1}}{k+1} + \frac{\nu_{2,p-k}}{k} \qquad \text{for } k = 1, \dots, p-1. \tag{4.23}$$

Using (4.21) in (4.22) with $k = q-1$, we find $\nu_{1,-1} = \nu_{2,-1}$. Proceeding inductively we then obtain from (4.22) that $\nu_{1,k} = \nu_{2,k}$ for all $k = -q+1, \dots, 0$. Similarly, from (4.21) and (4.23) it follows that $\nu_{1,k} = \nu_{2,k}$ for $k = 0, \dots, p-1$, so that $\vec{\nu}_1 = \vec{\nu}_2$ as claimed. □

Now we are ready for the proof of Theorem 2.3.

2.3 (a) In view of Proposition 4.1 it remains to show only that $\mu_k \in \mathcal{M}_e$ for every $k = -q+1, \dots, p-1$. The decay estimate (4.5) implies that

$$\int \log(1 + |\lambda|)\, \mathrm{d}\mu_k(\lambda) < \infty.$$

The fact that $I(\mu_k) < +\infty$ follows from (4.10). Indeed,

$$I(\mu_k) = -\iint \log|\lambda - x| \mathrm{d}\mu_k(x) \mathrm{d}\mu_k(\lambda) = \int (\log|w_k(\lambda)| - \alpha_k) \mathrm{d}\mu_k(\lambda),$$

and this is finite since μ_k is a finite measure on Γ_k with a density that decays as in (4.5) and $\log|w_k(\lambda)|$ is continuous on Γ_k and grows only as a constant times $\log|\lambda|$ as $\lambda \to \infty$. Thus $\vec{\mu}$ is admissible, and part (a) is proved.

(b) According to (4.10) we have

$$\begin{aligned} &2\int \log|\lambda - x|\ \mathrm{d}\mu_k(x) - \int \log|\lambda - x|\ \mathrm{d}\mu_{k+1}(\lambda) - \int \log|\lambda - x|\ \mathrm{d}\mu_{k-1}(\lambda) \\ &\quad = -2\log|w_k(\lambda)| + 2\alpha_k + \log|w_{k+1}(\lambda)| - \alpha_{k+1} + \log|w_{k-1}(\lambda)| - \alpha_{k-1} \\ &\quad = \log\left|\frac{w_{k+1}(\lambda) w_{k-1}(\lambda)}{w_k(\lambda)^2}\right| + 2\alpha_k - \alpha_{k+1} - \alpha_{k-1} \\ &\quad = \log\left|\frac{z_{q+k+1}(\lambda)}{z_{q+k}(\lambda)}\right| + 2\alpha_k - \alpha_{k+1} - \alpha_{k-1}. \end{aligned} \tag{4.24}$$

Since $|z_{q+k}(\lambda)| = |z_{q+k+1}(\lambda)|$ for $\lambda \in \Gamma_k$, we see from (4.24) that (2.10) holds with constant

$$l_k = 2\alpha_k - \alpha_{k-1} + \alpha_{k+1}. \tag{4.25}$$

Note that for $k = -q+1$ and $k = p-1$ we are using the convention that $\mu_{-q} = \mu_p = 0$, and we also have put $\alpha_{-q} = \alpha_p = 0$. This proves part (b).

(c) Let $\vec{\nu} = (\nu_{-q+1}, \ldots, \nu_{p-1})$ be any admissible vector of measures. From the representation (2.13) we get

$$\begin{aligned} J(\vec{\nu}) &= J(\vec{\mu} + \vec{\nu} - \vec{\mu}) \\ &= J(\vec{\mu}) + J(\vec{\nu} - \vec{\mu}) + 2 \sum_{j,k=-q+1}^{p-1} A_{jk} I(\mu_j, \nu_k - \mu_k). \end{aligned} \tag{4.26}$$

Using (2.14), we find from (4.26) that

$$J(\vec{\nu}) = J(\vec{\mu}) + J(\vec{\nu} - \vec{\mu}) + \sum_{k=-q+1}^{p-1} I(2\mu_k - \mu_{k-1} - \mu_{k+1}, \nu_k - \mu_k). \tag{4.27}$$

For each $k = -q+1, \ldots, p-1$, we have

$$\begin{aligned} &I(2\mu_k - \mu_{k-1} - \mu_{k+1}, \nu_k - \mu_k) \\ &\quad = \int \left(\int \log|\lambda - x| \, \mathrm{d}(2\mu_k - \mu_{k-1} - \mu_{k+1})(x) \right) d(\nu_k - \mu_k)(\lambda). \end{aligned} \tag{4.28}$$

By (2.10) the inner integral in the right-hand side of (4.28) is constant for $\lambda \in \Gamma_k$. Since ν_k and μ_k are finite measures on Γ_k with $\nu_k(\Gamma_k) = \mu_k(\Gamma_k)$, we find from (4.28) that

$$I(2\mu_k - \mu_{k-1} - \mu_{k+1}, \nu_k - \mu_k) = 0 \qquad \text{for } k = -q+1, \ldots, p-1.$$

Then (4.27) shows that $J(\vec{\nu}) = J(\vec{\mu}) + J(\vec{\nu} - \vec{\mu})$, which by Lemma 4.3 implies that $J(\vec{\nu}) \geq J(\vec{\mu})$ and equality holds if and only if $\vec{\nu} = \vec{\mu}$. This completes the proof of Theorem 2.3. □

5. Proofs of Proposition 2.5 and Theorem 2.6.

5.1. Proof of Proposition 2.5. We will now prove Proposition 2.5, which follows by a combinatorial argument.

[illegible] 2.5 We prove (2.18) and (2.19) for $k > 0$. The case $k < 0$ is similar. Let us first expand the determinant in the definition of $P_{k,n}$,

$$P_{k,n}(\lambda) = \det T_n(z^{-k}(a - \lambda)) = \sum_{\pi \in S_n} \prod_{j=1}^{n} (a - \lambda)_{j - \pi(j) + k}. \tag{5.1}$$

Here S_n denotes the set of all permutation on $\{1, \ldots, n\}$. By the band structure of $T_n(z^{-k}(a - \lambda))$ it follows that we have only nonzero contributions from permutations π that satisfy

$$k - p \leq \pi(j) - j \leq q + k \qquad \text{for all } j = 1, \ldots, n. \tag{5.2}$$

Define, for $\pi \in S_n$,

$$N_\pi = \{j \mid \pi(j) = j + k\} \tag{5.3}$$

and denote the number of elements of N_π by $|N_\pi|$. For each $\pi \in S_n$ we have that $\prod_{j=1}^n (a-\lambda)_{j-\pi(j)+k}$ is a polynomial in λ of degree at most $|N_\pi|$. So by (5.1)

$$d_{k,n} = \deg P_{k,n} \le \max_\pi |N_\pi|, \tag{5.4}$$

where we maximize over permutations $\pi \in S_n$ satisfying (5.2).

Let $\pi \in S_n$ satisfy (5.2). We prove (2.18) by giving an upper bound for $|N_\pi|$. Since $\sum_{j=1}^n (\pi(j) - j) = 0$ we obtain

$$\sum_{j=1}^n (\pi(j) - j)_+ = \sum_{j=1}^n (j - \pi(j))_+, \tag{5.5}$$

where $(\cdot)_+$ is defined as $(a)_+ = \max(0, a)$ for $a \in \mathbb{R}$. Each $j \in N_\pi$ gives a contribution k to the left-hand side of (5.5). Therefore the left-hand side is at least $k|N_\pi|$. By (5.2) we have that each term in the right-hand side is at most $p - k$. Moreover, there are at most $n - |N_\pi|$ nonzero terms in this sum. Combining this with (5.5) leads to

$$k|N_\pi| \le \sum_{j=1}^n (\pi(j) - j)_+ = \sum_{j=1}^n (j - \pi(j))_+ \le (n - |N_\pi|)(p - k). \tag{5.6}$$

Hence, if π is a permutation satisfying (5.2), then

$$|N_\pi| \le \frac{n(p-k)}{p}. \tag{5.7}$$

Now (2.18) follows by combining (5.7) and (5.4).

To prove (2.19) we assume that $n \equiv 0 \bmod p$. We claim that there exists a unique π such that equality holds in (5.7). Then equality holds in both inequalities of (5.6), and the above arguments show that this can happen only if

$$\pi(j) = j + k \qquad \text{or} \qquad \pi(j) = j - p + k \tag{5.8}$$

for every $j = 1, \ldots, n$. We claim that there exists a unique such permutation, namely

$$\pi(j) = \begin{cases} j + k & \text{if } j \equiv 1, \ldots, (p-k) \bmod p, \\ j - p + k & \text{if } j \equiv (p-k+1), \ldots, p \bmod p. \end{cases} \tag{5.9}$$

To see this let π be a permutation satisfying (5.8). The numbers $1, \ldots, p-k$ cannot satisfy $\pi(j) = j - p + k$ and thus satisfy $\pi(j) = j + k$. On the other hand, the numbers $1, \ldots, k$ cannot be the image of numbers j satisfying $\pi(j) = j + k$, and thus $\pi(j) = j - p + k$ for $j = p - k + 1, \ldots, p$. So (5.9) holds for $j = 1, \ldots, p$. This means in particular that the restriction of π to $\{p+1, \ldots, n\}$ is again a permutation, but now on $\{p+1, \ldots, n\}$. By the same arguments we then find that (5.9) holds for $j = p+1, \ldots, 2p$, and so on. The result is that (5.9) is indeed the only permutation that satisfies (5.8).

Finally, a straightforward calculation shows that the coefficient of $\lambda^{(p-k)n/p}$ in $\prod_{j=1}^n (a-\lambda)_{j-\pi(j)+k}$ with π as in (5.9) is nonzero and given by (2.19). This proves the proposition. □

5.2. Proof of Theorem 2.6. Before we start with the proof of Theorem 2.6 we first prove the following proposition concerning the asymptotics for $P_{k,n}$ for $n \to \infty$.

Proposition 5.1. [illegible] $M_k = \{q+k+1, \dots, p+q\}$ [illegible]

$$P_{k,n}(\lambda) = (w_{M_k}(\lambda))^n C_{M_k}(\lambda)\left(1 + \mathcal{O}(\exp(-c_K n))\right), \qquad n \to \infty, \tag{5.10}$$

[illegible] K [illegible] $\mathbb{C} \setminus \Gamma_k$ [illegible] c_K [illegible] K

[illegible] First rewrite (2.22) as

$$P_{k,n}(\lambda) = (w_{M_k}(\lambda))^n C_{M_k}(\lambda)\left(1 + R_{k,n}(\lambda)\right) \tag{5.11}$$

with $R_{k,n}$ defined by

$$R_{k,n}(\lambda) = \sum_{M \neq M_k} \frac{(w_M(\lambda))^n C_M(\lambda)}{(w_{M_k}(\lambda))^n C_{M_k}(\lambda)}. \tag{5.12}$$

Let K be a compact subset of $\mathbb{C} \setminus \Gamma_k$. If K does not contain branch points, then there exist $A, B > 0$ such that

$$A < |C_M(\lambda)| < B \tag{5.13}$$

for all $\lambda \in K$ and M. Moreover, we have

$$\left|\frac{w_M(\lambda)}{w_{M_k}(\lambda)}\right| \leq \left|\frac{z_{q+k}(\lambda)}{z_{q+k+1}(\lambda)}\right| \leq \sup_{\lambda \in K}\left|\frac{z_{q+k}(\lambda)}{z_{q+k+1}(\lambda)}\right| < 1 \tag{5.14}$$

for all $\lambda \in K$ and $M \neq M_k$. Therefore one readily verifies from (5.11) that there exist c_K such that $|R_{k,n}(\lambda)| \leq \exp(-c_K n)$ for all $\lambda \in K$ and n large enough. This proves the statement in case K does not contain branch points.

Suppose that K does contain branch points. Without loss of generality, we can assume that all branch points lie in the interior of K (otherwise we replace K by a bigger compact set). The boundary ∂K of K is a compact set with no branch points, and therefore (5.10) holds for ∂K by the above arguments. Since w_{M_k} and C_{M_k} are analytic in K, we find by (5.11) that $R_{k,n}$ is analytic in K. The maximum modulus principle for analytic functions states that $\sup_{z \in K} |R_{k,n}(z)| = \sup_{z \in \partial K} |R_{k,n}(z)|$, and thereby we obtain that (5.10) also holds for K with the same constant $c_K = c_{\partial K}$. □

We now state two particular consequences of (5.10).

Corollary 5.2. [illegible] $k \in \{-q+1, \dots, p-1\}$ [illegible] $K \subset \mathbb{C} \setminus \Gamma_k$ [illegible] $\mu_{k,n}(K) = 0$ [illegible] n [illegible]

[illegible] Let K be a compact subset of $\mathbb{C} \setminus \Gamma_k$. By (5.10) it follows that $P_{k,n}$ has no zeros in K for large n. Since $n\mu_{k,n}(K)$ equals the number of zeros of $P_{k,n}$ in K the corollary follows. □

Corollary 5.3. [illegible] $k \in \{-q+1, \dots, p-1\}$ [illegible]

$$\lim_{n \to \infty} \int_{\mathbb{C}} \frac{\mathrm{d}\mu_{k,n}(x)}{x - \lambda} = \int_{\Gamma_k} \frac{\mathrm{d}\mu_k(x)}{x - \lambda} \tag{5.15}$$

[illegible] $\mathbb{C} \setminus \Gamma_k$

[illegible] Let K be a compact subset of $\mathbb{C} \setminus \Gamma_k$. Note that

$$\int \frac{\mathrm{d}\mu_{k,n}(x)}{x - \lambda} = \frac{1}{n} \sum_{\lambda_i \in \mathrm{sp}_k T_n(a)} \frac{1}{\lambda_i - \lambda} = -\frac{P_{k,n}'(\lambda)}{nP_{k,n}(\lambda)} \tag{5.16}$$

for all $\lambda \in K$. With M_k and c_K as in Proposition 5.1 we obtain from (5.10) that

$$\frac{P'_{k,n}(\lambda)}{nP_{k,n}(\lambda)} = \frac{w'_{M_k}(\lambda)}{w_{M_k}(\lambda)} + \mathcal{O}(1/n), \qquad n \to \infty, \tag{5.17}$$

uniformly on K. Let us rewrite the right-hand side of (5.17). By expanding both sides of $z^q(a(z) - \lambda) = a_p \prod_{j=1}^{p+q}(z - z_j(\lambda))$ and collecting the constant terms we obtain

$$\prod_{j=1}^{p+q}(-z_j(\lambda)) = \frac{a_{-q}}{a_p}. \tag{5.18}$$

Since $\lambda \notin \Gamma_k$, we can split this product into two parts, take the logarithmic derivative, and use (3.3) and (2.23) to obtain

$$0 = \sum_{j=1}^{q+k} \frac{z'_j(\lambda)}{z_j(\lambda)} + \sum_{j=q+k+1}^{p+q} \frac{z'_j(\lambda)}{z_j(\lambda)} = \frac{w'_k(\lambda)}{w_k(\lambda)} + \frac{w'_{M_k}(\lambda)}{w_{M_k}(\lambda)}. \tag{5.19}$$

Combining (5.16), (5.17), and (5.19), we obtain

$$\lim_{n\to\infty} \int \frac{\mathrm{d}\mu_{k,n}(x)}{x - \lambda} = \frac{w'_k(\lambda)}{w_k(\lambda)} \tag{5.20}$$

uniformly on K. Then (5.15) follows from (5.20) and (4.9). □

Now we are ready for the proof of Theorem 2.6.

Proof of Theorem 2.6 First we prove (2.21). By Proposition 2.5 and the fact that $\vec{\mu}$ is admissible, we get (see (2.8))

$$\mu_{k,n}(\mathbb{C}) = \frac{1}{n} \deg P_{k,n} \le \mu_k(\mathbb{C}) \tag{5.21}$$

for every $n \in \mathbb{N}$.

Let $C_0(\mathbb{C})$ be the Banach space of continuous functions on $\mathbb{C}$ that vanish at infinity. The dual space $C_0(\mathbb{C})^*$ of $C_0(\mathbb{C})$ is the space of regular complex Borel measures on $\mathbb{C}$. By (5.21) the sequence $(\mu_{k,n})_{n\in\mathbb{N}}$ belongs to the ball in $C_0(\mathbb{C})^*$ centered at the origin with radius $\mu_k(\mathbb{C})$, which is weak* compact by the Banach–Alaoglu theorem. Let $\mu_{k,\infty}$ be the limit of a weak* convergent subsequence of $(\mu_{k,n})_{n\in\mathbb{N}}$.

By weak* convergence and Corollary 5.2 we obtain that $\mu_{k,\infty}$ is supported on Γ_k. Combining this with (5.15) and the weak* convergence leads to

$$\frac{1}{2\pi\mathrm{i}} \int_{\Gamma_k} \frac{\mathrm{d}\mu_k(x)}{x - \lambda} = \frac{1}{2\pi\mathrm{i}} \int_{\Gamma_k} \frac{\mathrm{d}\mu_{k,\infty}(x)}{x - \lambda} \tag{5.22}$$

for every $\lambda \in \mathbb{C} \setminus \Gamma_k$. The integrals in (5.22) are known in the literature as the Cauchy transforms of the measures μ_k and $\mu_{k,\infty}$. The Cauchy transform on Γ_k is an injective map that maps measures on Γ_k to functions that are analytic in $\mathbb{C} \setminus \Gamma_k$ (one can find explicit inversion formulae; see, for example, the arguments in [9, Theorem II.1.4] or the Stieltjes–Perron inversion formula in the special case $\Gamma_k \subset \mathbb{R}$). Thus it follows from (5.22) that $\mu_{k,\infty} = \mu_k$. Therefore

$$\lim_{n\to\infty} \mu_{k,n} = \mu_k \tag{5.23}$$

in the sense of weak* convergence in $C_0(\mathbb{C})^*$. Thus (2.21) holds if ϕ is a continuous function that vanishes at infinity.

From (5.21) and (5.23) it also follows that

$$\lim_{n\to\infty} \mu_{k,n}(\mathbb{C}) = \mu_k(\mathbb{C}). \tag{5.24}$$

Then the sequence $(\mu_{k,n})_{n\in\mathbb{N}}$ is tight. That is, for every $\varepsilon > 0$ there exists a compact K such that $\mu_{k,n}(\mathbb{C}\setminus K) < \varepsilon$ for every $n \in \mathbb{N}$. By a standard approximation argument one can now show that (2.21) holds for every bounded continuous function ϕ on $\mathbb{C}$.

Having (2.21) and Proposition 5.1, we can prove (2.20) as in [1, Theorem 11.17]. Indeed, the sets $\liminf_{n\to\infty} \operatorname{sp}_k T_n(a)$ and $\limsup_{n\to\infty} \operatorname{sp}_k T_n(a)$ equal the support of μ_k, which is Γ_k. □

6. Examples.

6.1. Example 1. As a first example, consider the symbol a defined by

$$a(z) = \frac{4(z+1)^3}{27z}. \tag{6.1}$$

In this case we have $p = 2$ and $q = 1$. So we obtain two contours Γ_0 and Γ_1 with two associated measures μ_0 and μ_1. This example appeared in [3], in which the authors gave explicit expressions for Γ_0 and μ_0. The following proposition also contains expressions for Γ_1 and μ_1. In what follows we take the principal branches for all fractional powers.

PROPOSITION 6.1. [illegible] a [illegible] (6.1) [illegible] $\Gamma_0 = [0,1]$ [illegible]

$$\mathrm{d}\mu_0(\lambda) = \frac{\sqrt{3}}{4\pi} \frac{\left(1+\sqrt{1-\lambda}\right)^{1/3} + \left(1-\sqrt{1-\lambda}\right)^{1/3}}{\lambda^{2/3}\sqrt{1-\lambda}}\, \mathrm{d}\lambda. \tag{6.2}$$

[illegible] $\Gamma_1 = (-\infty, 0]$ [illegible]

$$\mathrm{d}\mu_1(\lambda) = \frac{\sqrt{3}}{4\pi} \frac{\left(1+\sqrt{1-\lambda}\right)^{1/3} - \left(\sqrt{1-\lambda}-1\right)^{1/3}}{(-\lambda)^{2/3}\sqrt{1-\lambda}}\, \mathrm{d}\lambda. \tag{6.3}$$

[illegible]. A straightforward calculation shows that $\lambda = 0$ and $\lambda = 1$ are the branch points.

Let $\lambda \in \Gamma_0 \cup \Gamma_1$ and assume that λ is not a branch point. There exist $y_1, y_2 \in \mathbb{C}$ such that $y_1 \neq y_2$, $|y_1| = |y_2|$, and $a(y_1) = a(y_2) = \lambda$. Then it follows from (6.1) that $|y_1 + 1| = |y_2 + 1|$. Therefore y_1 and y_2 are intersection points of a circle centered at -1 and a circle centered at the origin. Since $y_1 \neq y_2$, this means that $y_1 = \overline{y_2}$ and therefore $\lambda = a(y_1) = a(\overline{y_2}) = \overline{a(y_1)} = \overline{\lambda}$, so that $\lambda \in \mathbb{R}$. A further investigation shows that $a(z) - \lambda$ has three different real zeros if $\lambda > 1$. If $\lambda < 1$ and $\lambda \neq 0$, then $a(z) - \lambda$ has precisely one real zero and two conjugate complex zeros. Therefore, $\Gamma_0 \cup \Gamma_1 = (-\infty, 1]$.

Now we will show that $\Gamma_0 = [0,1]$ and $\Gamma_1 = (-\infty, 0]$. By Cardano's formula the solutions of the algebraic equation $a(z) = \lambda$ are given by

$$z_j(\lambda) = -1 - \frac{3\lambda^{1/3}}{2}\left(\omega^j\left(1+(1-\lambda)^{1/2}\right)^{1/3} + \omega^{-j}\left(1-(1-\lambda)^{1/2}\right)^{1/3}\right) \tag{6.4}$$

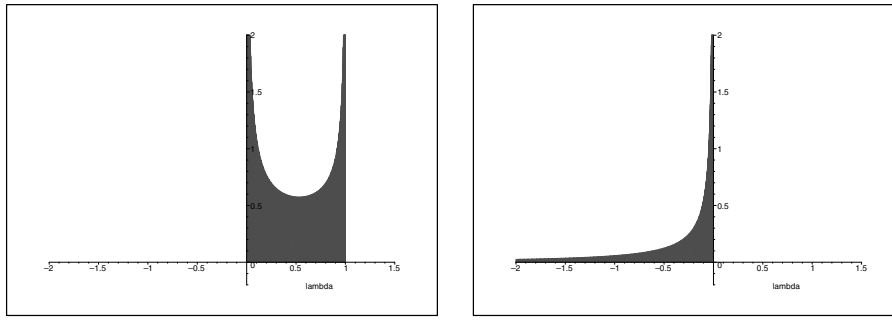

FIG. 6.1. *Illustration for Example* 1: *The densities of the measures* μ_0 *(left) and* μ_1 *(right) for* $a = \frac{4(z+1)^3}{27z}$.

for $\lambda \in [0, 1]$ and

(6.5)
$$z_j(\lambda) = -1 + \frac{3(-\lambda)^{1/3}}{2}\left(\omega^{j+2}\left(1 + (1-\lambda)^{1/2}\right)^{1/3} - \omega^{-j-2}\left((1-\lambda)^{1/2} - 1\right)^{1/3}\right)$$

for $\lambda \in (-\infty, 0]$. Here $\omega = \mathrm{e}^{2\pi \mathrm{i}/3}$. One can check that $|z_1(\lambda)| = |z_2(\lambda)| < |z_3(\lambda)|$ for $\lambda \in (0, 1]$ and $|z_1(\lambda)| < |z_2(\lambda)| = |z_3(\lambda)|$ for $\lambda \in (-\infty, 0)$. Moreover, for $\lambda = 0$ we have $z_1(0) = z_2(0) = z_3(0) = -1$. Therefore $\Gamma_0 = [0, 1]$ and $\Gamma_1 = (-\infty, 0]$.

The density (6.2) was already given in [3], and (6.3) follows in a similar way. ∎

In Figure 6.1 we plot the densities of μ_0 and μ_1. Note that, due to the interaction between μ_0 and μ_1 in the energy functional, there is more mass of μ_0 near 0 than near 1. We also see that the singularities of the densities for μ_0 and μ_1 are of order $\mathcal{O}(|\lambda|^{-2/3})$ for $\lambda \to 0$, whereas the typical nature of a singularity in each of the measures is a square root singularity. The stronger singularity is due to the fact that $a(z) - \lambda$ has a triple root for $\lambda = 0$.

In Figure 6.2 we plot the eigenvalues and generalized eigenvalues for $n = 50$. It is known that the eigenvalues are simple and positive [3, section 2.3], which we also see in Figure 6.2.

6.2. Example 2. For the symbol a defined by

(6.6)
$$a(z) = z^2 + z + z^{-1} + z^{-2},$$

we have $p = q = 2$. From the symmetry $a(1/z) = a(z)$ it follows that $\Gamma_{-1} = \Gamma_1$ and $\mu_{-1} = \mu_1$.

The interesting feature of this example is that the contours Γ_0 and $\Gamma_{\pm 1}$ overlap. To be precise, the interval $(-9/4, 0)$ is contained in all three contours Γ_{-1}, Γ_0, and Γ_1. This can be most easily seen by investigating the image of the unit circle under a. Consider

(6.7)
$$a(\mathrm{e}^{\mathrm{i}t}) = 2\cos 2t + 2\cos t \qquad \text{for } t \in [0, 2\pi).$$

A straightforward analysis shows that for every $\lambda \in (-9/4, 0)$ the equation $a(\mathrm{e}^{\mathrm{i}t}) = \lambda$ has four different solutions for t in $[0, 2\pi)$. This means that the four solutions of the equation $a(z) = \lambda$ are on the unit circle, and so in particular have the same absolute value.

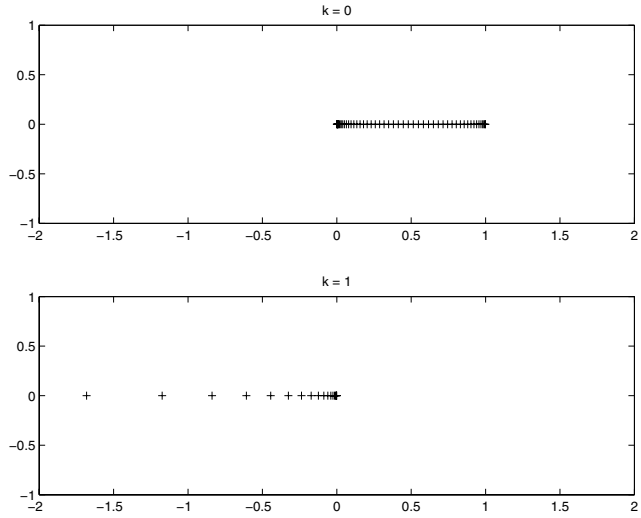

FIG. 6.2. *Illustration for Example* 1: *The spectrum* $\operatorname{sp} T_{50}(a)$ *(top) and the generalized spectrum* $\operatorname{sp}_1 T_{50}(a)$ *(bottom) for the symbol* $a = \frac{4(z+1)^3}{27z}$.

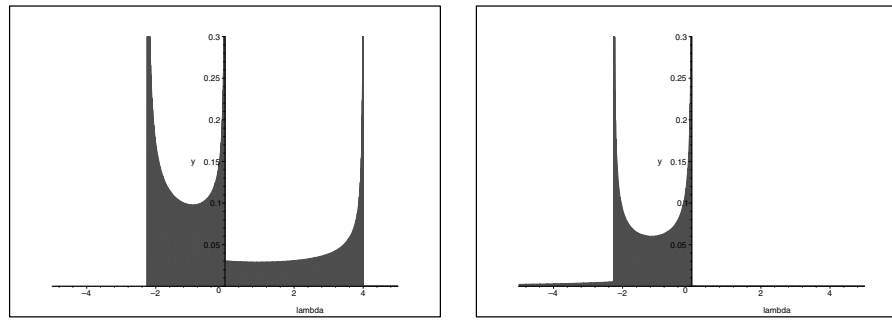

FIG. 6.3. *Illustration for Example* 2: *The densities of the measures* μ_0 *(left) and* $\mu_1 = \mu_{-1}$ *(right) for* $a(z) = z^2 + z + z^{-1} + z^{-2}$.

The equation $a(z) - \lambda = 0$ can be explicitly solved by introducing the variable $y = z + 1/z$. In exactly the same way as in the previous example one can obtain the limiting measures. We will not give the explicit formulae, but only plot the densities in Figure 6.3. The branch points are $\lambda = -9/4$, $\lambda = 0$, and $\lambda = 4$. The contours are given by

$$\Gamma_0 = [-9/4, 4], \qquad \Gamma_{-1} = \Gamma_1 = (-\infty, 0]. \tag{6.8}$$

The densities have singularities at the branch points in the interior of their supports. The singularities are felt only at one side of the branch points. Consider first μ_0, whose density has a singularity at 0. However, the limiting value when 0 is approached from the positive real axis is finite. The change in behavior of μ_0 has to do with the fact that z_1 is analytic on $(0, 4)$ but not on $(-9/4, 0)$. Therefore we find by (1.12) that

$$\mathrm{d}\mu_0(\lambda) = \frac{1}{2\pi \mathrm{i}} \left(\frac{z_{1+}'(\lambda)}{z_{1+}(\lambda)} + \frac{z_{2+}'(\lambda)}{z_{2+}(\lambda)} - \frac{z_{1-}'(\lambda)}{z_{1-}(\lambda)} - \frac{z_{2-}'(\lambda)}{z_{2-}(\lambda)} \right) \mathrm{d}\lambda \tag{6.9}$$

on $(-9/4, 0)$ and

$$\mathrm{d}\mu_0(\lambda) = \frac{1}{2\pi \mathrm{i}} \left(\frac{z_{2+}'(\lambda)}{z_{2+}(\lambda)} - \frac{z_{2-}'(\lambda)}{z_{2-}(\lambda)} \right) \mathrm{d}\lambda \tag{6.10}$$

on $(0, 4)$.

For $\mu_{-1} = \mu_1$ a similar phenomenon happens at $\lambda = -9/4$. This is a consequence of the fact that z_1 has an analytic continuation into z_2 when we cross $(-\infty, -9/4)$, but it has an analytic continuation into z_4 when we cross $(-9/4, 0)$.

6.3. Example 3. As a final example, consider the symbol

$$a(z) = z^p + z^{-q} \tag{6.11}$$

with $p, q \geq 1$ and $\gcd(p, q) = 1$. This example appeared in [10], where the authors mentioned that Γ_0 is given by the star

$$\Gamma_0 = \{ r\omega^j \mid j = 1, \ldots, p+q,\ 0 \leq r \leq R \} \tag{6.12}$$

with $\omega = \mathrm{e}^{2\pi \mathrm{i}/(p+q)}$ and $R = (p+q)p^{-p/(p+q)}q^{-q/(p+q)}$. The other contours also have a star shape, namely

$$\Gamma_k = \{ (-1)^k r\omega^j \mid j = 1, \ldots, p+q,\ 0 \leq r < \infty \} \tag{6.13}$$

for $k \neq 0$. Note that the star Γ_k for $k \neq 0$ is unbounded.

In Figure 6.4 we plot the eigenvalues and the generalized eigenvalues for $p = 2$, $q = 3$, and $n = 50$. All the (generalized) eigenvalues appear to lie exactly on the

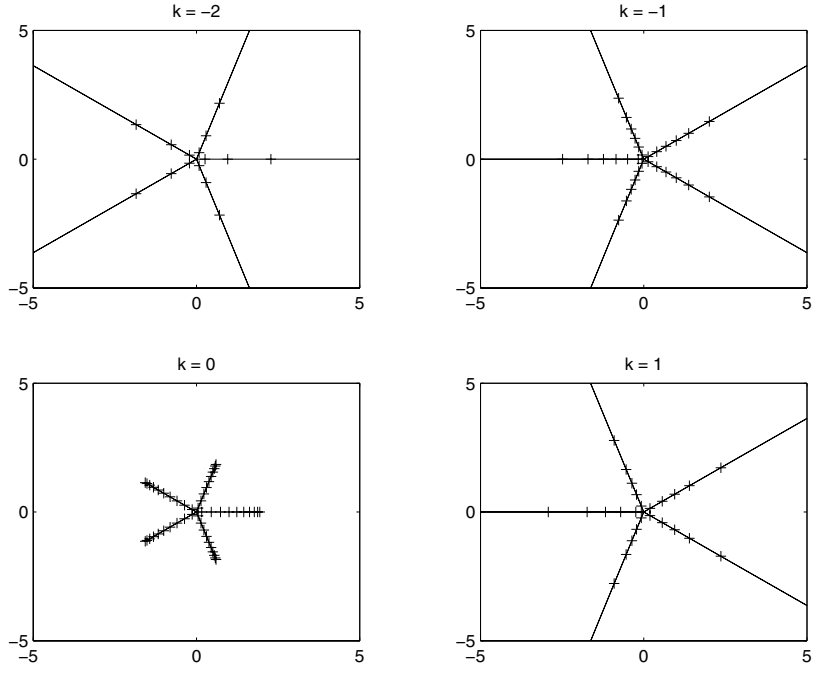

FIG. 6.4. *Illustration for Example* 3: *The contours* Γ_k *and the eigenvalues and generalized eigenvalues for* $T_{50}(a)$ *for the symbol* $a = z^2 + z^{-3}$.

contours. In the special case $p = 1$ it is known that the eigenvalues of $T_n(a)$ lie indeed precisely on the star (6.12) and are all simple (possibly except for 0) [4, Theorem 3.2]; see also [6] for a connection to Chebyshev-type quadrature.

6.4. Numerical stability. In Figures 6.2 and 6.4 the eigenvalues and the generalized eigenvalues of $T_{50}(a)$ were computed numerically. To control the stability of the numerical computation of the eigenvalues one needs to analyze the pseudospectrum. For banded Toeplitz matrices the pseudospectrum is well understood [12, Theorem 7.2]. To this date, a similar analysis of the pseudospectrum for the matrix pencil $(T_n(z^{-k}a), T_n(z^{-k}))$ has not been carried out. See [12, section X.45] for some remarks on the pseudospectrum for the generalized eigenvalue problem.

ALGEBRAIC CHARACTERIZATIONS FOR POSITIVE REALNESS OF DESCRIPTOR SYSTEMS*

DELIN CHU† AND ROGER C. E. TAN†

Abstract. In this paper, algebraic characterizations for the positive realness of descriptor systems are studied. It is shown that the positive realness of descriptor systems can be determined by solving a linear matrix inequality, and hence the celebrated positive real lemma for standard state space systems is extended to descriptor systems. In addition, the lossless positive realness of both standard state space systems and descriptor systems is characterized explicitly based on the controllable staircase forms of standard state space systems and the generalized controllable staircase forms of descriptor systems, respectively.

Key words. positive realness, descriptor systems, linear matrix inequality

DOI. 10.1137/060669061

1. Introduction.

In this paper we study the algebraic characterizations for the positive realness of descriptor systems in circuit and control theory. Throughout this paper, the following notation will be used:

- $M > 0$ (≥ 0) means that M is symmetric and positive definite (positive semidefinite);
- $M < 0$ (≤ 0) means $-M > 0$ (≥ 0);
- $j := \sqrt{-1}$, $\mathbf{C}_0 := \{s \mid s \in \mathbf{C},\ \mathrm{Re}(s) = 0\}$, $\mathbf{C}_+ := \{s \mid s \in \mathbf{C},\ \mathrm{Re}(s) > 0\}$.

Consider a system of the form

$$\begin{cases} E\dot{x}(t) = Ax(t) + Bu(t), \\ \quad y(t) = Cx(t) + Du(t), \end{cases} \tag{1}$$

where $E, A \in \mathbf{R}^{n\times n}$, $B \in \mathbf{R}^{n\times m}$, $C \in \mathbf{R}^{m\times n}$, and $D \in \mathbf{R}^{m\times m}$. System (1) is called a standard state space system if $E = I$. It is called a descriptor system (or a generalized state space system, or a singular system) if E is singular and the pencil (E, A) is regular (i.e., $\det(sE - A) \neq 0$ for some $s \in \mathbf{C}$).

DEFINITION 1. (i) [illegible] (1) [illegible] (E, A) [illegible]

$$\deg(sE - A) = \mathrm{rank}(E).$$

(ii) [illegible] (1) [illegible] (E, A) [illegible] ($\mathbf{C}_0 \cup \mathbf{C}_+$)

[illegible] 1. Let the pencil (E, A) be regular. There exist nonsingular matrices Q and P such that

$$QAP = \begin{bmatrix} A_{11} & 0 \\ 0 & I \end{bmatrix} \begin{matrix} \}n_1 \\ \}n_2 \end{matrix}, \quad QEP = \begin{bmatrix} I & 0 \\ 0 & \mathcal{N} \end{bmatrix} \begin{matrix} \}n_1 \\ \}n_2 \end{matrix}, \tag{2}$$

where $\mathcal{N}$ is nilpotent. Then system (1) is impulse-free if and only if $\mathcal{N} = 0$.

DEFINITION 2. [illegible] $E, A \in \mathbf{R}^{n\times n}$ [illegible] $B \in \mathbf{R}^{n\times m}$

(i) [illegible] $(E; A, B)$ [illegible]

$$\operatorname{rank}\begin{bmatrix} \alpha E - \beta A & B \end{bmatrix} = n \quad \forall (\alpha, \beta) \in \mathbf{C}^2 \backslash \{0, 0\}.$$

(ii) [illegible] $(E; A, B)$ [illegible]

$$\operatorname{rank}\begin{bmatrix} \alpha E - A & B \end{bmatrix} = n \quad \forall \alpha \in \mathbf{C}.$$

(iii) [illegible] (A, B) [illegible]

$$\operatorname{rank}\begin{bmatrix} \alpha I - A & B \end{bmatrix} = n \quad \forall \alpha \in \mathbf{C}.$$

Let

$$G(s) = D + C(sE - A)^{-1}B. \tag{3}$$

$G(s)$ is the transfer function of system (1). The positive realness of system (1) can be defined as follows.

DEFINITION 3 (see [3]).

(i) [illegible] (1) [illegible] $G(s)$ [illegible] $\mathbf{C}_+$ [illegible]

$$G(s) + (G(s))^H \geq 0 \quad \forall s \in \mathbf{C}_+.$$

(ii) [illegible] (1) [illegible]

$$G(j\omega) + (G(j\omega))^H = 0$$

[illegible] $\omega \in \mathbf{R}$ [illegible] $j\omega$ [illegible] $G(s)$

(iii) [illegible] (1) [illegible] $G(s)$ [illegible] $\mathbf{C}_0 \cup \mathbf{C}_+$ [illegible]

$$G(j\omega) + (G(j\omega))^H > 0 \quad \forall \omega \in \mathbf{R}.$$

(iv) [illegible] (1) [illegible] $G(s)$ [illegible]

$$G(j\infty) + (G(j\infty))^H > 0.$$

The concept of positive realness is motivated by network theory [7]. That is, a positive real rational function can be realized as the driving point impedance of a passive network, and, conversely, a passive network has a driving point impedance that is rational and positive real. As addressed in [5], reduced-order modeling techniques based on Krylov subspace iterations have become popular tools to tackle the large-scale dynamic systems that arise in the simulation of VLSI circuits [15]. These techniques are mostly applied to very large passive networks, and then it is important to check whether the reduced-order model preserves the passivity of the original network. Hence, the positive realness plays a major role in circuit theory.

The positive realness is also an important concept in control theory. It has many applications in model reference adaptive control, absolute stability of perturbed systems, robust control, inverse problem of optimal control, and flexible space structure; see [25, 35, 26, 27, 1, 36, 14, 28, 4, 6]. The list here is far from complete.

The positive realness of standard state space systems has been studied extensively; see [1, 3, 23, 38, 42, 2, 41]. Over the last three decades, several approaches for testing

the positive realness of a standard state space system have been developed. Among them, one powerful approach is to employ the celebrated positive real lemma, which characterizes the positive realness of a standard state space system by means of a linear matrix inequality (LMI).

The well-known positive real lemma can be stated as follows.

LEMMA 4 (positive real lemma [3]). [illegible] (1) [illegible] $E = I$ [illegible] (A, B) [illegible] (A^T, C^T) [illegible]

(i) [illegible] (1) [illegible] $X \in \mathbf{R}^{n\times n}$ [illegible]

$$\begin{bmatrix} A^TX + XA & XB - C^T \\ B^TX - C & -D - D^T \end{bmatrix} \le 0,\ X \ge 0. \tag{4}$$

(ii) [illegible] (1) [illegible] $X \in \mathbf{R}^{n\times n}$ [illegible]

$$\begin{bmatrix} A^TX + XA & XB - C^T \\ B^TX - C & -D - D^T \end{bmatrix} = 0,\ X \ge 0. \tag{5}$$

Lemma 4 was developed in the 1960s [25, 26, 27, 1, 36] and now is also known as the Kalman–Yakubovich lemma or the Yakubovich–Kalman–Popov–Anderson lemma. For a detailed analysis of the implication of Lemma 4, we refer the reader to [3, 36]. In addition, the analogy of Lemma 4 for system (1) with E nonsingular can be found in [18, 40].

The strict positive realness of standard state space systems is characterized algebraically in the following result, which is a generalization of Lemma 4(i).

LEMMA 5 (see [29, 34]). [illegible] (1) [illegible] $E = I$ [illegible] (A, B) [illegible] (A^T, C^T) [illegible] (1) [illegible] $X, L \in \mathbf{R}^{n\times n}$ [illegible] $W \in \mathbf{R}^{n\times m}$ [illegible]

$$\begin{bmatrix} A^TX + XA & XB - C^T \\ B^TX - C & -D - D^T \end{bmatrix} = -\begin{bmatrix} L^T \\ W^T \end{bmatrix}\begin{bmatrix} L & W \end{bmatrix},\ X \ge 0,$$

[illegible] (A^T, L^T) [illegible]

$$\operatorname{rank}\begin{bmatrix} A - j\omega I & B \\ L & W \end{bmatrix} = n + m \quad \forall \omega \in \mathbf{R}.$$

It is now well known that the descriptor systems have many important applications, for example, in circuit simulation, economic systems, network analysis, and biological systems. In fact, many systems in practical applications are singular in nature. The positive realness of descriptor systems has been considered recently under various assumptions. The following interesting results have been presented in [16, 32, 31, 45], respectively.

THEOREM 6 (see [16]). (a) [illegible] (1) [illegible] (E, A) [illegible] $\mathbf{C}_+$ [illegible]

$$\begin{bmatrix} A^TX + X^TA & X^TB - C^T \\ B^TX - C & -D - D^T \end{bmatrix} \le 0, \quad E^TX = X^TE \ge 0, \tag{6}$$

[illegible] X

(b) [illegible] (1) [illegible] (6) [illegible]

(i) [illegible] $(E;A,B)$ [illegible] $(E^T;A^T,C^T)$ [illegible]
(ii) [illegible] (1) [illegible]

$$A\ker(E) \subseteq \mathrm{Im}(E);$$

(iii) [illegible] $G(s)=\sum_{i=-\infty}^{p} s^i M_i$, [illegible] $G(s)$ [illegible] $s=\infty$ [illegible]

$$D + D^T \geq M_0 + M_0^T. \tag{7}$$

THEOREM 7 (see [32, 31]). [illegible] (1) [illegible] $X \in \mathbf{R}^{n\times n}$ [illegible] $Y \in \mathbf{R}^{n\times m}$ [illegible]

$$\begin{bmatrix} A^TX + X^TA & A^TY + X^TB - C^T \\ Y^TA + B^TX - C & Y^TB + B^TY - D - D^T \end{bmatrix} < 0,\ E^TX = X^TE \geq 0,\ E^TY = 0. \tag{8}$$

THEOREM 8 (see [45]). [illegible] (1) [illegible] $D + D^T > 0$ [illegible] $X \in \mathbf{R}^{n\times n}$ [illegible]

$$\begin{bmatrix} A^TX + X^TA & (C - B^TX)^T \\ C - B^TX & -(D + D^T) \end{bmatrix} < 0, \quad E^TX = X^TE \geq 0. \tag{9}$$

THEOREM 9 (see [45]). [illegible] (1) [illegible] $D + D^T > 0$ [illegible] $X \in \mathbf{R}^{n\times n}$ [illegible]

$$A^TX + X^TA + (C - B^TX)^T(D + D^T)^{-1}(C - B^TX) = 0, \quad E^TX = X^TE \geq 0. \tag{10}$$

The following statements are clear:

- Theorem 6 indicates that the solvability of the linear matrix inequality (6) is sufficient and, under the additional assumption (7), also necessary for the positive realness of descriptor system (1). However, in general, the assumption (7) may not be satisfied.
- Theorems 7–9 rely on the assumption that system (1) is impulse-free, which is strong. In fact, if system (1) is impulse-free, then there exist nonsingular matrices $P \in \mathbf{R}^{n\times n}$ and $Q \in \mathbf{R}^{n\times n}$ such that (2) holds with $\mathcal{N} = 0$. Consequently,

$$G(s) = (D - \mathcal{CB}) + C_1(sI - A_{11})^{-1}B_1, \tag{11}$$

where

$$QB = \begin{bmatrix} B_1 \\ \mathcal{B} \end{bmatrix} \begin{matrix} \}n_1 \\ \}n_2 \end{matrix}, \quad CP = \begin{matrix} n_1 & n_2 \\ \end{matrix} \begin{bmatrix} C_1 & \mathcal{C} \end{bmatrix}. \tag{12}$$

As a result, the impulse-free system (1) is extended strictly positive real if and only if the standard state space system

$$\begin{cases} \dot{x}(t) = A_{11}x(t) + B_1u(t), \\ y(t) = C_1x(t) + (D - \mathcal{CB})u(t) \end{cases}$$

is strictly positive real and $(D-\mathcal{CB}) + (D-\mathcal{CB})^T > 0$. Thus, existing results on the strictly positive realness of standard state space systems are applicable to the extended strictly positive realness of descriptor systems.

- If system (1) is minimal but not impulse-free, then, with the notation in (2) and (12), we have

$$G(s) = (D - \mathcal{C}\mathcal{B}) + C_1(sI - A_{11})^{-1}B_1 - \sum_{i=1}^{n_2-1} s^i \mathcal{C}\mathcal{N}^i\mathcal{B}$$
$$\neq (D - \mathcal{C}\mathcal{B}) + C_1(sI - A_{11})^{-1}B_1.$$

  Hence, the approaches used in [32, 31, 45] cannot be used to characterize all forms of the positive realness of system (1).

Based on the observations above, we conclude that in Theorems 6–9 there is obviously a gap between the sufficient condition and the necessary condition for the positive realness of descriptor systems (1). To the best of our knowledge, we are not aware of any conditions which are similar to (4) and are both necessary and sufficient for the positive realness of descriptor systems. In this sense, Lemma 4, which is the positive real lemma for standard state space systems, has not been extended to descriptor systems in the existing literature. In this paper we further develop the work in [16] and establish the positive real lemma for descriptor systems. It is surprising that our matrix inequality (14) in Theorem 13 of the next section is very close to the matrix inequality (8) in Theorem 7. However, these two inequalities play different roles in the sense that inequality (8) can only characterize the extended strictly positive realness of system (1) under the condition that system (1) is admissible, but cannot characterize the positive realness of system (1) in the general setting, while inequality (14) in the next section is not only necessary but also sufficient for the positive realness of system (1) in the general setting. In addition, the explicit algebraic characterizations for the lossless positive realness of both standard state space systems and descriptor systems will also be derived in this paper based on the controllable staircase forms of standard state space systems and the generalized controllable staircase forms of descriptor systems, respectively.

2. Main results. We derive the algebraic characterizations for the positive realness of descriptor systems in this section. For this purpose, we need some preliminary lemmas.

LEMMA 10 (see [3]). [illegible] $G(s)$ [illegible]

$$G(s) = G_1(s) + sM_1 + \sum_{i=2}^{p} s^i M_i, \quad G_1(\infty) < \infty.$$

[illegible] $G(s)$ [illegible] $G_1(s)$ [illegible] $M_1 \geq 0$ [illegible] $M_i = 0$, $i = 2, \ldots, p$

LEMMA 11. [illegible]

(13)
$$\mathcal{N} = \begin{array}{c} \\ \tau_1 \\ \tau_3 \\ \tau_2 \end{array} \begin{array}{c} \begin{array}{ccc} \tau_1 & \tau_2 & \tau_3 \end{array} \\ \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & I \\ 0 & 0 & 0 \end{bmatrix} \end{array}, \quad \mathcal{B} = \begin{array}{c} \\ \tau_1 \\ \tau_3 \\ \tau_2 \end{array} \begin{bmatrix} \mathcal{B}_{12} \\ \mathcal{B}_{22} \\ \mathcal{B}_{32} \end{bmatrix}, \quad \mathcal{C} = \begin{array}{c} \begin{array}{ccc} \tau_1 & \tau_2 & \tau_3 \end{array} \\ \begin{bmatrix} \mathcal{C}_{21} & \mathcal{C}_{22} & \mathcal{C}_{23} \end{bmatrix} \end{array}, \ \tau_2 \leq \tau_3.$$

[illegible]

$$\operatorname{rank} \begin{bmatrix} \alpha\mathcal{N} - \beta I & \mathcal{B} \end{bmatrix} = \operatorname{rank} \begin{bmatrix} \alpha\mathcal{N} - \beta I \\ \mathcal{C} \end{bmatrix} = \sum_{i=1}^{3} \tau_i \quad \forall \{\alpha, \beta\} \in \mathbf{C}^2 \backslash \{0, 0\}.$$

$$\mathcal{C}\mathcal{N}^i\mathcal{B} = 0, \quad i = 2, \ldots, \sum_{i=1}^{3} \tau_i - 1,$$

$\tau_2 = \tau_3$. Let $\tau = \sum_{i=1}^{3} \tau_i$. Note that the property

$$\operatorname{rank} \begin{bmatrix} \alpha\mathcal{N} - \beta I & \mathcal{B} \end{bmatrix} = \tau \quad \forall \{\alpha, \beta\} \in \mathbf{C}^2 \backslash \{0, 0\}$$

implies the controllability of $(\mathcal{N}, \mathcal{B})$. Consequently, we have from [43] that

$$\operatorname{rank} \begin{bmatrix} \mathcal{B} & \mathcal{N}\mathcal{B} & \cdots & \mathcal{N}^{\tau-1}\mathcal{B} \end{bmatrix} = \tau.$$

Because $\mathcal{N}$ is nilpotent and $\mathcal{N}^j = 0$ for all integer $j \geq \tau$, then

$$\begin{aligned}
&\mathcal{C}\mathcal{N}^i\mathcal{B} = 0, \quad i = 2, \ldots, \tau - 1 \\
\Longleftrightarrow\ &(\mathcal{C}\mathcal{N}^2)\mathcal{N}^i\mathcal{B} = 0, \quad i = 0, 1, \ldots, \tau - 1 \\
\Longleftrightarrow\ &\mathcal{C}\mathcal{N}^2 \begin{bmatrix} \mathcal{B} & \mathcal{N}\mathcal{B} & \cdots & \mathcal{N}^{\tau-1}\mathcal{B} \end{bmatrix} = 0 \\
\Longleftrightarrow\ &\mathcal{C}\mathcal{N}^2 = 0 \\
\Longleftrightarrow\ &\begin{bmatrix} \mathcal{C}_{22} & \mathcal{C}_{23} \end{bmatrix} \begin{bmatrix} I_{\tau_3 - \tau_2} \\ 0 \end{bmatrix} = 0 \quad (\text{since } \tau_2 \leq \tau_3).
\end{aligned}$$

However, it is given that $\operatorname{rank} \begin{bmatrix} \alpha\mathcal{N} - \beta I \\ \mathcal{C} \end{bmatrix} = \tau$ for all $\{\alpha, \beta\} \in \mathbf{C}^2 \backslash \{0, 0\}$; hence, $\mathcal{C}_{22}$ is of full column rank. Therefore, we obtain that $\mathcal{C}\mathcal{N}^i\mathcal{B} = 0$ $(i = 2, \ldots, \tau - 1)$ if and only if $\tau_2 = \tau_3$. □

LEMMA 12 (see [11, 10, 9]). $\mathcal{A} \in \mathbf{R}^{n \times n}$, $\mathcal{B} \in \mathbf{R}^{n \times m}$ $\mathcal{C} \in \mathbf{R}^{p \times n}$

(i)

$$\max_{s \in \mathbf{C}} \operatorname{rank} \begin{bmatrix} \mathcal{A} - sI & \mathcal{B} \\ \mathcal{C} & 0 \end{bmatrix} = n$$

$$\mathcal{C}\mathcal{A}^i\mathcal{B} = 0, \quad i = 0, 1, 2, \ldots.$$

(ii) $(\mathcal{A}, \mathcal{B})$

$$\max_{s \in \mathbf{C}} \operatorname{rank} \begin{bmatrix} \mathcal{A} - sI & \mathcal{B} \\ \mathcal{C} & 0 \end{bmatrix} = n$$

$$\mathcal{C} = 0.$$

We are now ready to characterize the positive realness of descriptor systems.

THEOREM 13. (1) $(E; A, B)$ $(E^T; A^T, C^T)$

(i) [illegible] (1) [illegible] $X \in \mathbf{R}^{n\times n}$ [illegible] $Y \in \mathbf{R}^{n\times m}$ [illegible]

$$\begin{cases} \begin{bmatrix} A^TX + X^TA & A^TY + X^TB - C^T \\ Y^TA + B^TX - C & B^TY + Y^TB - D - D^T \end{bmatrix} \le 0, \\ E^TX = X^TE \ge 0, \quad E^TY = 0. \end{cases} \tag{14}$$

(ii) [illegible] (1) [illegible] $X \in \mathbf{R}^{n\times n}$ [illegible] $Y \in \mathbf{R}^{n\times m}$ [illegible]

$$\begin{cases} \begin{bmatrix} A^TX + X^TA & A^TY + X^TB - C^T \\ Y^TA + B^TX - C & B^TY + Y^TB - D - D^T \end{bmatrix} = 0, \\ E^TX = X^TE \ge 0, \quad E^TY = 0. \end{cases} \tag{15}$$

(iii) [illegible] (1) [illegible] $X, L \in \mathbf{R}^{n\times n}$, $Y \in \mathbf{R}^{n\times m}$ [illegible] $W \in \mathbf{R}^{n\times m}$ [illegible]

$$\begin{cases} \begin{bmatrix} A^TX + X^TA & A^TY + X^TB - C^T \\ Y^TA + B^TX - C & B^TY + Y^TB - D - D^T \end{bmatrix} = -\begin{bmatrix} L^T \\ W^T \end{bmatrix} \begin{bmatrix} L & W \end{bmatrix}, \\ E^TX = X^TE \ge 0, \quad E^TY = 0. \end{cases} \tag{16}$$

$(E^T; A^T, L^T)$ [illegible]

$$\operatorname{rank} \begin{bmatrix} A - j\omega E & B \\ L & W \end{bmatrix} = n + m \quad \forall \omega \in \mathbf{R}. \tag{17}$$

[illegible]. We prove the necessity first and then the sufficiency.

By matrix pencil theory [17], there exist nonsingular matrices $P, Q \in \mathbf{R}^{n\times n}$ such that (2), (12), and (13) hold. Consequently,

$$\begin{aligned} G(s) &= D + C_1(sI - A_{11})^{-1}B_1 + \mathcal{C}(s\mathcal{N} - I)^{-1}\mathcal{B} \\ &= D - \mathcal{C}\mathcal{B} + C_1(sI - A_{11})^{-1}B_1 - \sum_{i=1}^{n_2-1} s^i \mathcal{C}\mathcal{N}^i\mathcal{B}. \end{aligned}$$

[illegible] (i). Let $G(s)$ be positive real. By Lemma 10, $D - \mathcal{C}\mathcal{B} + C_1(sI - A_{11})^{-1}B_1$ is positive real, and

$$\mathcal{C}\mathcal{N}\mathcal{B} \le 0, \quad \mathcal{C}\mathcal{N}^i\mathcal{B} = 0, \ i = 2, \ldots, n_2 - 1.$$

Since $(E; A, B)$ and $(E^T; A^T, C^T)$ are controllable, it is easy to verify that (A_{11}, B_1) and (A_{11}^T, C_1^T) are controllable, and

$$\operatorname{rank} \begin{bmatrix} \alpha\mathcal{N} - \beta I & \mathcal{B} \end{bmatrix} = \operatorname{rank} \begin{bmatrix} \alpha\mathcal{N} - \beta I \\ \mathcal{C} \end{bmatrix} = n_2 = \sum_{i=1}^{3} \tau_i \quad \forall \{\alpha, \beta\} \in \mathbf{C}^2 \backslash \{0, 0\}. \tag{18}$$

Then by Lemmas 4(i) and 11, there exist $X_{11}, L_1 \in \mathbf{R}^{n_1\times n_1}$ and $W_1 \in \mathbf{R}^{n_1\times m}$ such that

$$\begin{cases} A_{11}^T X_{11} + X_{11}^T A_{11} = -L_1^T L_1, \\ X_{11}^T B_1 - C_1^T = -L_1^T W_1, \\ -(D - \mathcal{CB}) - (D - \mathcal{CB})^T = -W_1^T W_1, \\ X_{11} \geq 0, \end{cases} \tag{19}$$

and $\tau_2 = \tau_3$.

Because (18) means $\operatorname{rank}(\mathcal{C}_{22}) = \operatorname{rank}(\mathcal{B}_{32}) = \tau_2$, and the property $\tau_2 = \tau_3$ implies that $\mathcal{CNB} \leq 0$ is equivalent to

$$\mathcal{C}_{22}\mathcal{B}_{32} = \mathcal{B}_{32}^T\mathcal{C}_{22}^T \leq 0,$$

thus

$$\mathcal{Z}_{23} := -\mathcal{C}_{22}^T\mathcal{B}_{32}^T(\mathcal{B}_{32}\mathcal{B}_{32}^T)^{-1}, \quad \mathcal{X} := \begin{matrix} \\ \\ \\ \end{matrix} \begin{matrix} \tau_1 & \tau_2 & \tau_2 \\ \end{matrix} \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & \mathcal{Z}_{23} \\ 0 & -\mathcal{Z}_{23}^T & 0 \end{bmatrix} \begin{matrix} \}\tau_1 \\ \}\tau_2 \\ \}\tau_3 \end{matrix}$$

satisfy

$$\mathcal{Z}_{23} = \mathcal{Z}_{23}^T \geq 0$$

and

$$\begin{cases} \mathcal{N}^T\mathcal{X} = \mathcal{X}^T\mathcal{N} \geq 0, \\ \mathcal{X} + \mathcal{X}^T = 0, \\ \mathcal{N}^T(\mathcal{C}^T - \mathcal{X}^T\mathcal{B}) = 0. \end{cases} \tag{20}$$

Moreover, we have

(21)

$$\begin{cases} \begin{bmatrix} A_{11} & 0 \\ 0 & I \end{bmatrix}^T \begin{bmatrix} X_{11} & 0 \\ 0 & \mathcal{X} \end{bmatrix} + \begin{bmatrix} X_{11} & 0 \\ 0 & \mathcal{X} \end{bmatrix}^T \begin{bmatrix} A_{11} & 0 \\ 0 & I \end{bmatrix} = -\begin{bmatrix} L_1^T \\ 0 \end{bmatrix} \begin{bmatrix} L_1 & 0 \end{bmatrix}, \\ \begin{bmatrix} A_{11} & 0 \\ 0 & I \end{bmatrix}^T \begin{bmatrix} 0 \\ \mathcal{C}^T - \mathcal{X}^T\mathcal{B} \end{bmatrix} + \begin{bmatrix} X_{11} & 0 \\ 0 & \mathcal{X} \end{bmatrix}^T \begin{bmatrix} B_1 \\ \mathcal{B} \end{bmatrix} - \begin{bmatrix} C_1 & \mathcal{C} \end{bmatrix}^T \\ \qquad = -\begin{bmatrix} L_1^T \\ 0 \end{bmatrix} W_1, \\ \begin{bmatrix} B_1 \\ \mathcal{B} \end{bmatrix}^T \begin{bmatrix} 0 \\ \mathcal{C}^T - \mathcal{X}^T\mathcal{B} \end{bmatrix} + \begin{bmatrix} 0 \\ \mathcal{C}^T - \mathcal{X}^T\mathcal{B} \end{bmatrix}^T \begin{bmatrix} B_1 \\ \mathcal{B} \end{bmatrix} - D - D^T = -W_1^T W_1, \\ \begin{bmatrix} I & 0 \\ 0 & \mathcal{N} \end{bmatrix}^T \begin{bmatrix} X_{11} & 0 \\ 0 & \mathcal{X} \end{bmatrix} = \begin{bmatrix} X_{11} & 0 \\ 0 & \mathcal{X} \end{bmatrix}^T \begin{bmatrix} I & 0 \\ 0 & \mathcal{N} \end{bmatrix} \geq 0, \\ \begin{bmatrix} I & 0 \\ 0 & \mathcal{N} \end{bmatrix}^T \begin{bmatrix} 0 \\ \mathcal{C}^T - \mathcal{X}^T\mathcal{B} \end{bmatrix} = 0. \end{cases}$$

Define

$$X = Q^T \begin{bmatrix} X_{11} & 0 \\ 0 & \mathcal{X} \end{bmatrix} P^{-1}, \quad Y = Q^T \begin{bmatrix} 0 \\ \mathcal{C}^T - \mathcal{X}^T\mathcal{B} \end{bmatrix} \tag{22}$$

and

$$L = \begin{bmatrix} L_1 & 0 \\ 0 & 0 \end{bmatrix} P^{-1} \in \mathbf{R}^{n\times n}, \quad W = \begin{bmatrix} W_1 \\ 0 \end{bmatrix} \in \mathbf{R}^{n\times m}. \tag{23}$$

Then we have by using (2), (12), (13), and (21) that

$$\begin{cases} A^TX + X^TA = -L^TL, \\ A^TY + X^TB - C^T = -L^TW, \\ B^TY + Y^TB - D - D^T = -W^TW, \\ E^TX = X^TE \geq 0, \\ E^TY = 0, \end{cases}$$

i.e., (14) holds.

(ii). We have from the necessity proof of part (i) that

$$G(s) = D - \mathcal{CB} + C_1(sI - A_{11})^{-1}B_1 - s\mathcal{CNB}, \quad \tau_2 = \tau_3, \quad \mathcal{CNB} \leq 0,$$

and $D - \mathcal{CB} + C_1(sI - A_{11})^{-1}B_1$ is positive real. Note that

$$D-\mathcal{CB}+C_1(j\omega I-A_{11})^{-1}B_1+(D-\mathcal{CB}+C_1(j\omega I-A_{11})^{-1}B_1)^H = G(j\omega)+(G(j\omega))^H$$

for all $\omega \in \mathbf{R}$ with $j\omega$ not a pole of $G(s)$, and $D - \mathcal{CB} + C_1(sI - A_{11})^{-1}B_1$ and $G(s)$ have the same poles; we get that $D - \mathcal{CB} + C_1(sI - A_{11})^{-1}B_1$ is lossless positive real. Thus, by Lemma 4(ii), there exists $X_{11} \in \mathbf{R}^{n_1\times n_1}$ such that

$$\begin{cases} A_{11}^TX_{11} + X_{11}^TA_{11} = 0, \\ X_{11}^TB_1 - C_1^T = 0, \\ -(D - \mathcal{CB}) - (D - \mathcal{CB})^T = 0, \\ X_{11} \geq 0. \end{cases}$$

Let X and Y be defined by (22). Then it is easy to verify that

$$\begin{cases} A^TX + X^TA = 0, \\ A^TY + X^TB - C^T = 0, \\ B^TY + Y^TB - D - D^T = 0, \\ E^TX = X^TE \geq 0, \\ E^TY = 0, \end{cases}$$

i.e., (15) holds.

(iii). We know from the necessity proof of part (i) that $\tau_2 = \tau_3$, $\mathcal{CNB} \leq 0$, and $D-\mathcal{CB}+C_1(sI-A_{11})^{-1}B_1$ is positive real. Moreover, $D-\mathcal{CB}+C_1(sI-A_{11})^{-1}B_1$ is strictly positive real. So, according to Lemma 5, there exist $X_{11}, L_1 \in \mathbf{R}^{n_1\times n_1}$ and $W_1 \in \mathbf{R}^{n_1\times m}$ such that (19) is satisfied, (A_{11}^T, L_1^T) is controllable, and

$$\operatorname{rank}\begin{bmatrix} A_{11} - j\omega I & B_1 \\ L_1 & W_1 \end{bmatrix} = n_1 + m \quad \forall \omega \in \mathbf{R}.$$

Let X, Y, L, and W be defined by (22) and (23); we have that (16) holds,

$$\begin{aligned}\operatorname{rank}\begin{bmatrix} \alpha E^T - A^T & L^T \end{bmatrix} &= \operatorname{rank}\begin{bmatrix} \alpha I - A_{11}^T & 0 & L_1^T \\ 0 & \alpha\mathcal{N}^T - I & 0 \end{bmatrix} \\ &= \operatorname{rank}\begin{bmatrix} \alpha I - A_{11}^T & L_1^T \end{bmatrix} + \operatorname{rank}(\alpha\mathcal{N}^T - I) \\ &= n_1 + n_2 = n \quad \forall \alpha \in \mathbf{C},\end{aligned}$$

equivalently, $(E^T; A^T, L^T)$ is R-controllable, and moreover

$$\begin{aligned}\operatorname{rank}\begin{bmatrix} A - j\omega E & B \\ L & W \end{bmatrix} &= \operatorname{rank}\begin{bmatrix} A_{11} - j\omega I & 0 & B_1 \\ 0 & I - j\omega\mathcal{N} & \mathcal{B} \\ L_1 & 0 & W_1 \end{bmatrix} \\ &= \operatorname{rank}\begin{bmatrix} A_{11} - j\omega I & B_1 \\ L_1 & W_1 \end{bmatrix} + n_2 \\ &= (n_1 + m) + n_2 = n + m \quad \forall \omega \in \mathbf{R}.\end{aligned}$$

[illegible] (i). In this case, (14) implies that

$$\begin{bmatrix} A^TX + X^TA & A^TY + X^TB - C^T \\ Y^TA + B^TX - C & B^TY + Y^TB - D - D^T \end{bmatrix} = -\begin{bmatrix} L^T \\ W^T \end{bmatrix}\begin{bmatrix} L & W \end{bmatrix} \tag{24}$$

for some $L \in \mathbf{R}^{n\times n}$ and $W \in \mathbf{R}^{n\times m}$.

Let us first show that $G(s)$ is analytic in $\mathbf{C}_+$. For this purpose, we show that the pencil (E, A) has no finite generalized eigenvalues in $\mathbf{C}_+$.

By contradiction, assume that $\lambda \in \mathbf{C}_+$ is a finite generalized eigenvalue of the pencil (E, A) and $y \in \mathbf{C}^n$ is a corresponding eigenvector. Then

$$Ay = \lambda Ey, \quad y \neq 0. \tag{25}$$

So, (24) and $E^TX = X^TE \geq 0$ yield that

$$\begin{aligned}0 &\geq -y^HL^TLy \\ &= y^H(A^TX + X^TA)y \\ &= \bar{\lambda}y^HE^TXy + \lambda y^HX^TEy \\ &= 2\mathrm{Re}(\lambda)y^HE^TXy \\ &\geq 0, \qquad (26)\end{aligned}$$

which together with $\lambda \in \mathbf{C}_+$ gives that

$$X^TEy = E^TXy = 0. \tag{27}$$

In return, we get by using (25), (26), and (27) that

$$X^TAy = 0, \quad Ly = 0 \tag{28}$$

and

$$A^T Xy = (A^T X + X^T A)y - X^T Ay = -L^T Ly - X^T Ay = 0. \tag{29}$$

Note that the pencil (E, A) is regular; thus $\operatorname{rank}\left[\begin{smallmatrix} E^T \\ A^T \end{smallmatrix}\right] = n$. In addition, we have shown that $\left[\begin{smallmatrix} E^T \\ A^T \end{smallmatrix}\right] Xy = 0$. Hence, we get $Xy = 0$. Consequently,

$$Cy = (Y^T A + B^T X + W^T L)y = Y^T Ay = \lambda Y^T Ey = \lambda (E^T Y)^T y = 0.$$

This and (25) give

$$\begin{bmatrix} A - \lambda E \\ C \end{bmatrix} y = 0.$$

Because the controllability of $(E^T; A^T, C^T)$ implies $\operatorname{rank}\left[\begin{smallmatrix} A - \lambda E \\ C \end{smallmatrix}\right] = n$, we obtain

$$y = 0,$$

which contradicts the fact $y \neq 0$. Therefore, the pencil (E, A) has no finite generalized eigenvalues in $\mathbf{C}_+$ and thus $G(s)$ is analytic in $\mathbf{C}_+$.

Next, we have using $E^T X = X^T E$ that

$$(sE - A)^H X + X^T (sE - A) = L^T L + 2\mathrm{Re}(s) E^T X$$

and

$$\begin{aligned} G(s) &= D + C(sE - A)^{-1} B = D + (Y^T A + B^T X + W^T L)(sE - A)^{-1} B \\ &= D + Y^T A(sE - A)^{-1} B + W^T L(sE - A)^{-1} B \\ &\quad + ((sE - A)^{-1} B)^H (sE - A)^H X (sE - A)^{-1} B \quad \forall s \in \mathbf{C}_+, \end{aligned}$$

which together with $E^T X = X^T E$ and $E^T Y = 0$ yield that

$$\begin{aligned} G(s) + (G(s))^H &= B^T Y + Y^T B + Y^T A(sE - A)^{-1} B + ((sE - A)^{-1} B)^H A^T Y \\ &\quad + [W + L(sE - A)^{-1} B]^H [W + L(sE - A)^{-1} B] \\ &\quad + 2\mathrm{Re}(s)((sE - A)^{-1} B)^H E^T X (sE - A)^{-1} B \\ &= sY^T E(sE - A)^{-1} B + (sY^T E(sE - A)^{-1} B)^H \\ &\quad + [W + L(sE - A)^{-1} B]^H [W + L(sE - A)^{-1} B] \\ &\quad + 2\mathrm{Re}(s)((sE - A)^{-1} B)^H E^T X (sE - A)^{-1} B \\ &= [W + L(sE - A)^{-1} B]^H [W + L(sE - A)^{-1} B] \\ &\quad + 2\mathrm{Re}(s)((sE - A)^{-1} B)^H E^T X (sE - A)^{-1} B \end{aligned} \tag{30}$$

for any $s \in \mathbf{C}_+$. Hence, $G(s) + (G(s))^H \geq 0$ because $E^T X = X^T E \geq 0$. Therefore, $G(s)$ is positive real.

(ii). By part (i) we know that $G(s)$ is positive real. Moreover, same as the derivation of (30), we have

$$G(j\omega) + (G(j\omega))^H = 2\mathrm{Re}(j\omega)((j\omega E - A)^{-1}B)^H E^T X (j\omega E - A)^{-1}B = 0$$

for all $\omega \in \mathbf{R}$ with $j\omega$ not a pole of $G(s)$. So, $G(s)$ is lossless positive real.

(iii). By part (i), $G(s)$ is positive real. Let $\lambda \in \mathbf{C}_0$ be a finite generalized eigenvalue of the pencil (E, A) and let $y \in \mathbf{C}^n$ be a corresponding eigenvector. Then (26) holds and thus $Ly = 0$. So, we obtain

$$\begin{bmatrix} \lambda E - A \\ L \end{bmatrix} y = 0,$$

which together with the R-controllability of $(E^T; A^T, L^T)$ yields that

$$y = 0.$$

This contradicts the fact $y \neq 0$. Therefore, the pencil (E, A) has no finite generalized eigenvalues in $\mathbf{C}_0$. Hence, $G(s)$ is analytic in $\mathbf{C}_+ \cup \mathbf{C}_0$ because $G(s)$ is positive real.

Next, we also have by using (17) and (30)

$$\begin{aligned} G(j\omega) + (G(j\omega))^H &= [W + L(j\omega E - A)^{-1}B]^H [W + L(j\omega E - A)^{-1}B] \\ &> 0 \quad \forall \omega \in \mathbf{R}. \end{aligned}$$

Hence, $G(s)$ is strictly positive real. □

If $E = I$, then Theorem 13(i) and (ii) reduce to Lemma 4(i) and (ii), respectively. Hence, Theorem 13(i) and (ii) can be regarded as the positive real lemma for descriptor systems. Therefore, we have extended the well-known positive real lemma from standard state space systems to descriptor systems and show that the positive realness of descriptor systems can be tested by solving a linear matrix inequality of the form (14).

The following two corollaries are trivial consequences of the sufficiency proofs in Theorem 13.

COROLLARY 14. (1) (E, A)

(i) $X \in \mathbf{R}^{n\times n}$ $Y \in \mathbf{R}^{n\times m}$ (14) (1)

(ii) $X \in \mathbf{R}^{n\times n}$ $Y \in \mathbf{R}^{n\times m}$ (15) (1)

(iii) $X, L \in \mathbf{R}^{n\times n}$ $Y \in \mathbf{R}^{n\times m}$ $W \in \mathbf{R}^{m\times n}$ (16) (17) $(E^T; A^T, L)$ (1)

COROLLARY 15. (1) $(E^T; A^T, C^T)$

$$\mathrm{rank}\begin{bmatrix} \alpha E - A \\ C \end{bmatrix} = n \quad \forall \alpha \in \mathbf{C}_0 \cup \mathbf{C}_+,$$

$$\mathrm{rank}\begin{bmatrix} \alpha E - A \\ C \end{bmatrix} = n$$

$\alpha \in \mathbf{C}$ (E, A)

(i) $X \in \mathbf{R}^{n\times n}$ $Y \in \mathbf{R}^{n\times m}$ (14) (1).

(ii) $X \in \mathbf{R}^{n\times n}$ $Y \in \mathbf{R}^{n\times m}$ (15) (1).

(iii) $X, L \in \mathbf{R}^{n\times n}$, $Y \in \mathbf{R}^{n\times m}$, $W \in \mathbf{R}^{m\times n}$ (16) (17) $(E^T; A^T, L)$ (1).

In the following we derive explicit algebraic characterizations for the lossless positive realness of both standard state space systems and descriptor systems based on the controllable staircase form theory.

THEOREM 16. (1) $E = I$ (A, B) (A^T, C^T) $P \in \mathbf{R}^{2n\times 2n}$ $(P^T\left[\begin{smallmatrix} A & 0 \\ 0 & -A^T \end{smallmatrix}\right]P, P^T\left[\begin{smallmatrix} B \\ C^T \end{smallmatrix}\right])$ [39]:

$$P^T \begin{bmatrix} A & 0 \\ 0 & -A^T \end{bmatrix} P = \begin{matrix} \\ \mu_1 \\ \mu_2 \end{matrix} \begin{matrix} \begin{matrix} \mu_1 & \mu_2 \end{matrix} \\ \begin{bmatrix} \Phi_{11} & \Phi_{12} \\ 0 & \Phi_{22} \end{bmatrix} \end{matrix}, \quad P^T \begin{bmatrix} B \\ C^T \end{bmatrix} = \begin{matrix} \\ \mu_1 \\ \mu_2 \end{matrix} \begin{matrix} \\ \begin{bmatrix} \Psi_1 \\ 0 \end{bmatrix} \end{matrix}, \tag{31}$$

(Φ_{11}, Ψ_1)

$$\begin{bmatrix} C & -B^T \end{bmatrix} P = \begin{matrix} \begin{matrix} \mu_1 & \mu_2 \end{matrix} \\ \begin{bmatrix} \mathcal{K}_1 & \mathcal{K}_2 \end{bmatrix} \end{matrix}, \quad P = \begin{matrix} \begin{matrix} \mu_1 & \mu_2 \end{matrix} \\ \begin{bmatrix} P_{11} & P_{12} \\ P_{21} & P_{22} \end{bmatrix} \end{matrix} \begin{matrix} \\ \}n \\ \}n \end{matrix}. \tag{32}$$

(1)

$$D + D^T = 0, \quad \mathcal{K}_1 = 0, \quad P_{11}^T P_{21} \geq 0. \tag{33}$$

$\mu_1 = \mu_2 = n$, P_{11} X (5)

$$X = P_{21} P_{11}^{-1}. \tag{34}$$

. We prove the necessity first and then the sufficiency.

. Since system (1) is lossless positive real, by Lemma 4(ii),

$$D + D^T = 0,$$

and there exists a matrix $X \in \mathbf{R}^{n\times n}$ such that

$$A^T X + XA = 0, \quad C = B^T X, \quad X \geq 0.$$

Consequently, we obtain

$$CA^i B = B^T (-A^T)^i C^T, \quad i = 0, 1, 2, \ldots,$$

i.e.,

$$\begin{bmatrix} C & -B^T \end{bmatrix} \begin{bmatrix} A & 0 \\ 0 & -A^T \end{bmatrix}^i \begin{bmatrix} B \\ C^T \end{bmatrix} = 0, \quad i = 0, 1, 2, \ldots.$$

So, we have using Lemma 12(i) that

$$\max_{s\in\mathbf{C}} \operatorname{rank} \begin{bmatrix} sI-A & 0 & B \\ 0 & sI+A^T & C^T \\ C & -B^T & 0 \end{bmatrix} = 2n,$$

which is equivalent to

$$\mu_1+\mu_2 = 2n = \max_{s\in\mathbf{C}} \operatorname{rank} \begin{bmatrix} sI-\Phi_{11} & -\Phi_{12} & \Psi_1 \\ 0 & sI-\Phi_{22} & 0 \\ \mathcal{K}_1 & \mathcal{K}_2 & 0 \end{bmatrix}$$

$$= \mu_2 + \max_{s\in\mathbf{C}} \operatorname{rank} \begin{bmatrix} sI-\Phi_{11} & \Psi_1 \\ \mathcal{K}_1 & 0 \end{bmatrix},$$

i.e.,

$$\max_{s\in\mathbf{C}} \operatorname{rank} \begin{bmatrix} sI-\Phi_{11} & \Psi_1 \\ \mathcal{K}_1 & 0 \end{bmatrix} = \mu_1.$$

Note that (Φ_{11}, Ψ_1) is controllable, and thus Lemma 12(ii) gives

$$\mathcal{K}_1 = 0.$$

In addition,

$$\max_{s\in\mathbf{C}} \operatorname{rank} \begin{bmatrix} sI-A & 0 & B \\ 0 & sI+A^T & C^T \\ X^T & -I & 0 \end{bmatrix}$$

$$= \max_{s\in\mathbf{C}} \operatorname{rank} \begin{bmatrix} sI-A & 0 & B \\ -X^T(sI-A)+(sI+A^T)X^T & sI+A^T & C^T-X^TB \\ 0 & -I & 0 \end{bmatrix}$$

$$= \max_{s\in\mathbf{C}} \operatorname{rank} \begin{bmatrix} sI-A & 0 & B \\ 0 & sI+A^T & 0 \\ 0 & -I & 0 \end{bmatrix} = 2n,$$

which gives that

$$\mu_1+\mu_2 = 2n = \max_{s\in\mathbf{C}} \operatorname{rank} \begin{bmatrix} sI-\Phi_{11} & -\Phi_{12} & \Psi_1 \\ 0 & sI-\Phi_{22} & 0 \\ X^TP_{11}-P_{21} & X^TP_{12}-P_{22} & 0 \end{bmatrix}$$

$$= \mu_2 + \max_{s\in\mathbf{C}} \operatorname{rank} \begin{bmatrix} sI-\Phi_{11} & \Psi_1 \\ X^TP_{11}-P_{21} & 0 \end{bmatrix},$$

i.e.,

$$\max_{s\in\mathbf{C}} \operatorname{rank} \begin{bmatrix} sI-\Phi_{11} & \Psi_1 \\ X^TP_{11}-P_{21} & 0 \end{bmatrix} = \mu_1,$$

which together with the controllability of (Φ_{11}, Ψ_1) yields that

$$X^T P_{11} - P_{21} = 0.$$

Therefore, the property $X^T = X \geq 0$ leads to

$$P_{11}^T P_{21} = P_{11}^T X^T P_{11} \geq 0.$$

. We have using the property $\mathcal{K}_1 = 0$ that

$$\max_{s \in \mathbf{C}} \operatorname{rank} \begin{bmatrix} sI - A & 0 & B \\ 0 & sI + A^T & C^T \\ C & -B^T & 0 \end{bmatrix}$$

$$= \max_{s \in \mathbf{C}} \operatorname{rank} \begin{bmatrix} sI - \Phi_{11} & -\Phi_{12} & \Psi_1 \\ 0 & sI - \Phi_{22} & 0 \\ 0 & \mathcal{K}_2 & 0 \end{bmatrix} = \mu_1 + \mu_2 = 2n.$$

So, it follows from Lemma 12(i) that

$$\begin{bmatrix} C & -B^T \end{bmatrix} \begin{bmatrix} A & 0 \\ 0 & -A^T \end{bmatrix}^i \begin{bmatrix} B \\ C^T \end{bmatrix} = 0, \quad i = 0, 1, 2, \ldots.$$

Thus,

$$CA^i \begin{bmatrix} B & AB & \cdots & A^{n-1}B \end{bmatrix}$$

$$= B^T(-A^T)^i \begin{bmatrix} C^T & (-A^T)C^T & \cdots & (-A^T)^{n-1}C^T \end{bmatrix}, \quad i = 0, 1, 2, \ldots,$$

which yields that for $i = 0, 1, 2, \ldots,$

$$CA^i \begin{bmatrix} B & AB & \cdots & A^{n-1}B \end{bmatrix} \begin{bmatrix} B^T \\ B^T A^T \\ \vdots \\ B^T (A^T)^{n-1} \end{bmatrix}$$

$$= B^T(-A^T)^i \begin{bmatrix} C^T & (-A^T)C^T & \cdots & (-A^T)^{n-1}C^T \end{bmatrix} \begin{bmatrix} B^T \\ B^T A^T \\ \vdots \\ B^T (A^T)^{n-1} \end{bmatrix}.$$

Since (A, B) is controllable, it is well known [43] that

$$\operatorname{rank} \begin{bmatrix} B & AB & \cdots & A^{n-1}B \end{bmatrix} = n,$$

so,

$$\begin{bmatrix} B & AB & \cdots & A^{n-1}B \end{bmatrix} \begin{bmatrix} B^T \\ B^T A^T \\ \vdots \\ B^T (A^T)^{n-1} \end{bmatrix}$$

is nonsingular and, further,

(35)
$$CA^i = B^T(-A^T)^i X,$$
$$\text{i.e., } \begin{bmatrix} X^T & -I \end{bmatrix} \begin{bmatrix} A & 0 \\ 0 & -A^T \end{bmatrix}^i \begin{bmatrix} B \\ C^T \end{bmatrix} = X^T A^i B - (-A^T)^i C^T = 0, \quad i = 0, 1, 2, \ldots,$$

in particular,

$$C = B^T X, \tag{36}$$

where

$$X = \begin{bmatrix} C^T & (-A^T)C^T & \cdots & (-A^T)^{n-1}C^T \end{bmatrix} \begin{bmatrix} B^T \\ B^T A^T \\ \vdots \\ B^T (A^T)^{n-1} \end{bmatrix} \left(\begin{bmatrix} B & AB & \cdots & A^{n-1}B \end{bmatrix} \begin{bmatrix} B^T \\ B^T A^T \\ \vdots \\ B^T (A^T)^{n-1} \end{bmatrix} \right)^{-1}.$$

Hence, Lemma 12(i) implies that

$$\max_{s \in \mathbf{C}} \operatorname{rank} \begin{bmatrix} sI - A & 0 & B \\ 0 & sI + A^T & C^T \\ X^T & -I & 0 \end{bmatrix} = 2n. \tag{37}$$

In return, we obtain that

$$\begin{aligned} &\max_{s \in \mathbf{C}} \operatorname{rank} \begin{bmatrix} sI - \Phi_{11} & \Psi_1 \\ X^T P_{11} - P_{21} & 0 \end{bmatrix} \\ &= \max_{s \in \mathbf{C}} \operatorname{rank} \begin{bmatrix} sI - \Phi_{11} & -\Phi_{12} & \Psi_1 \\ 0 & sI - \Phi_{22} & 0 \\ X^T P_{11} - P_{21} & X^T P_{12} - P_{22} & 0 \end{bmatrix} - \mu_2 \\ &= \max_{s \in \mathbf{C}} \operatorname{rank} \begin{bmatrix} sI - A & 0 & B \\ 0 & sI + A^T & C^T \\ X^T & -I & 0 \end{bmatrix} - \mu_2 \\ &= 2n - \mu_2 = (\mu_1 + \mu_2) - \mu_2 \\ &= \mu_1, \end{aligned}$$

which together with Lemma 12(ii) and the controllability of (Φ_{11}, Ψ_1) implies that

$$X^T P_{11} - P_{21} = 0 \tag{38}$$

and

$$\begin{aligned}
\left[\begin{array}{cc} X^T & -I \end{array}\right] P &= \left[\begin{array}{cc} 0 & X^T P_{12} - P_{22} \end{array}\right], \\
\left[\begin{array}{cc} X^T & -I \end{array}\right] &= \left[\begin{array}{cc} 0 & X^T P_{12} - P_{22} \end{array}\right] P^T \\
&= \left[\begin{array}{cc} (X^T P_{12} - P_{22}) P_{12}^T & (X^T P_{12} - P_{22}) P_{22}^T \end{array}\right].
\end{aligned}$$

So, we have by taking $P_{22} \in \mathbf{R}^{n \times \mu_2}$ into account that

$$\begin{aligned}
n &= (\operatorname{rank} \left[\begin{array}{cc} X^T & -I \end{array}\right] P) = \operatorname{rank}(X^T P_{12} - P_{22}) \leq \mu_2 = 2n - \mu_1, \\
-I &= (X^T P_{12} - P_{22}) P_{22}^T, \\
n &= \operatorname{rank}(-I) = \operatorname{rank}((X^T P_{12} - P_{22}) P_{22}^T) \leq \operatorname{rank}(P_{22}^T) \leq n,
\end{aligned}$$

i.e.,

$$n \leq \mu_2 = 2n - \mu_1, \quad n = \operatorname{rank}(P_{22}). \tag{39}$$

Because (A, B) is controllable, μ_1 in the controllable staircase form (31) must satisfy

$$n \leq \mu_1, \tag{40}$$

and we get using (39) and (40) that

$$n = \mu_1 = \mu_2, \quad \operatorname{rank}(P_{22}) = n = \mu_2.$$

This means that P_{22} is nonsingular and so P_{11} is also nonsingular as P is orthogonal. As a result, (38) and $P_{11}^T P_{21} \geq 0$ lead to

$$X^T = P_{21} P_{11}^{-1} = P_{11}^{-T} (P_{11}^T P_{21}) P_{11}^{-1} \geq 0, \text{ i.e., } X = P_{21} P_{11}^{-1} \geq 0. \tag{41}$$

Furthermore, we also have using $C^T = X^T B = XB$ that

$$\begin{aligned}
2n &= \max_{s \in \mathbf{C}} \operatorname{rank} \begin{bmatrix} sI - A & 0 & B \\ 0 & sI + A^T & C^T \\ X^T & -I & 0 \end{bmatrix} = \max_{s \in \mathbf{C}} \operatorname{rank} \begin{bmatrix} sI - A & 0 & B \\ 0 & sI + A^T & C^T \\ X & -I & 0 \end{bmatrix} \\
&= \max_{s \in \mathbf{C}} \operatorname{rank} \begin{bmatrix} sI - A & 0 & B \\ (sI + A^T)X - X(sI - A) & sI + A^T & 0 \\ 0 & -I & 0 \end{bmatrix} \\
&= n + \max_{s \in \mathbf{C}} \operatorname{rank} \begin{bmatrix} sI - A & B \\ A^T X + XA & 0 \end{bmatrix},
\end{aligned}$$

i.e.,

$$n = \max_{s \in \mathbf{C}} \operatorname{rank} \begin{bmatrix} sI - A & B \\ A^T X + XA & 0 \end{bmatrix}.$$

However, (A, B) is controllable, so we must have by Lemma 12(ii) that

$$A^T X + XA = 0. \tag{42}$$

Therefore, the lossless positive realness of system (1) follows directly from the property $D + D^T = 0$, equalities (36), (41), and (42), and Lemma 4(ii). □

We turn to consider the explicit verification of the lossless positive realness of descriptor systems.

THEOREM 17. [illegible] (1) [illegible] $(E; A, B)$ [illegible] $(E^T; A^T, C^T)$ [illegible]

$$

(i) $\mathcal{U}_{11}$ $\mathcal{V}_{22}$ $\zeta_2 \le \zeta_1$

(ii) (1)

$$
(49)\qquad \mathcal{K}_1 = 0, \quad P_{11}^T(\mathcal{U}_{11}E_{11})^T P_{21} \ge 0,
$$

$$
(50)\qquad \operatorname{rank}\begin{bmatrix} A_{22}\mathcal{V}_{22} & 0 & B_2 \\ 0 & (A_{22}\mathcal{V}_{22})^T & C_2^T \\ C_2 & B_2^T & D+D^T \end{bmatrix} = 2n_2,
$$

$$
(51)\qquad \operatorname{rank}\begin{bmatrix} A_{22} & 0 & 0 & 0 & B_2 \\ -E_{22} & A_{22}\mathcal{V}_{22} & 0 & 0 & 0 \\ 0 & 0 & A_{22}^T & -E_{22}^T & 0 \\ 0 & 0 & 0 & (A_{22}\mathcal{V}_{22})^T & C_2^T \\ 0 & C_2 & -B_2^T & 0 & 0 \end{bmatrix} = 4n_2,
$$

$$
(52)\qquad \operatorname{rank}\begin{bmatrix} A_{22} & 0 & B_2 \\ -E_{22} & A_{22}\mathcal{V}_{22} & 0 \\ 0 & C_2 & sI \end{bmatrix} = 2n_2+m \quad \forall s \in \mathbf{C}_+,
$$

$$
(53)\qquad \zeta_1 = \zeta_2.
$$

(i) First, a simple calculation yields that

$$
EV\begin{bmatrix} \mathcal{V}_{12} \\ \mathcal{V}_{22} \end{bmatrix} = AV\begin{bmatrix} \mathcal{V}_{12} \\ \mathcal{V}_{22} \end{bmatrix} \mathcal{A}_{22}^{-T}\mathcal{E}_{22}^T,
$$

which with the nonsingularity of $\mathcal{E}_{11}$ and the property (44) implies that the columns of $V\left[\begin{smallmatrix}\mathcal{V}_{12}\\ \mathcal{V}_{22}\end{smallmatrix}\right]$ form a basis of the eigenspace of the pencil $sE-A$ corresponding to all its infinite generalized eigenvalues [19]. Next, since all generalized eigenvalues of

$sE_{11}-A_{11}$ are finite and all generalized eigenvalues of $sE_{22}-A_{22}$ are infinite, therefore there exist unique $X \in \mathbf{R}^{n_1\times n_2}$ and $Y \in \mathbf{R}^{n_2\times n_1}$ such that

$$\begin{bmatrix} I & X \\ 0 & I \end{bmatrix} U(sE-A)V \begin{bmatrix} I & Y \\ 0 & I \end{bmatrix} = \begin{bmatrix} sE_{11}-A_{11} & 0 \\ 0 & sE_{22}-A_{22} \end{bmatrix}.$$

This means that the columns of $V\left[\begin{smallmatrix} Y \\ I \end{smallmatrix}\right]$ also form a basis of the eigenspace of the pencil $sE-A$ corresponding to all its infinite generalized eigenvalues. Thus,

$$\begin{bmatrix} Y \\ I \end{bmatrix} = \begin{bmatrix} \mathcal{V}_{12} \\ \mathcal{V}_{22} \end{bmatrix} \mathcal{Z}$$

for some nonsingular $\mathcal{Z} \in \mathbf{R}^{n_2\times n_2}$, and so $\mathcal{V}_{22}$ is nonsingular. Similarly, we can show that $\mathcal{U}_{11}$ is also nonsingular.

Note that $sE_{22}-A_{22}$ is nonsingular for all $s \in \mathbf{C}$, and therefore ζ_1 and ζ_2 in (46) must satisfy

$$\zeta_2 \le \zeta_1.$$

(ii) Since

$$\begin{aligned} &\begin{bmatrix} \mathcal{U}_{11} & \mathcal{U}_{12} \\ 0 & I \end{bmatrix} U(sE-A)V \begin{bmatrix} I & \mathcal{V}_{12} \\ 0 & \mathcal{V}_{22} \end{bmatrix} \\ &\qquad = \begin{bmatrix} s\mathcal{U}_{11}E_{11}-\mathcal{U}_{11}A_{11} & 0 \\ 0 & sE_{22}\mathcal{V}_{22}-A_{22}\mathcal{V}_{22} \end{bmatrix}, \end{aligned} \tag{54}$$

we have

$$\begin{aligned} G(s) &= D + C(sE-A)^{-1}B \\ &= D + C_1(s\mathcal{U}_{11}E_{11}-\mathcal{U}_{11}A_{11})^{-1}B_1 + C_2(sE_{22}\mathcal{V}_{22}-A_{22}\mathcal{V}_{22})^{-1}B_2 \\ &= D + C_1(sI-(\mathcal{U}_{11}E_{11})^{-1}\mathcal{U}_{11}A_{11})^{-1}(\mathcal{U}_{11}E_{11})^{-1}B_1 \\ &\quad - C_2(I-s(A_{22}\mathcal{V}_{22})^{-1}E_{22}\mathcal{V}_{22})^{-1}(A_{22}\mathcal{V}_{22})^{-1}B_2 \\ &= G_1(s) - sC_2\mathcal{V}_{22}^{-1}A_{22}^{-1}E_{22}A_{22}^{-1}B_2 \\ &\quad - \sum_{k=2}^{n_2-1} s^k C_2((A_{22}\mathcal{V}_{22})^{-1}E_{22}\mathcal{V}_{22})^k(A_{22}\mathcal{V}_{22})^{-1}B_2, \end{aligned}$$

where

$$G_1(s) = D - C_2(A_{22}\mathcal{V}_{22})^{-1}B_2 + C_1(sI-(E_{11})^{-1}A_{11})^{-1}(\mathcal{U}_{11}E_{11})^{-1}B_1.$$

Consequently, we obtain using Lemma 10 that $G(s)$ is lossless positive real if and only if the following conditions hold:

(a) $G_1(s)$ is lossless positive real;

(b) $C_2\mathcal{V}_{22}^{-1}A_{22}^{-1}E_{22}A_{22}^{-1}B_2 \le 0$, i.e.,

$$\begin{cases} C_2\mathcal{V}_{22}^{-1}A_{22}^{-1}E_{22}A_{22}^{-1}B_2 = (C_2\mathcal{V}_{22}^{-1}A_{22}^{-1}E_{22}A_{22}^{-1}B_2)^T, \\ \operatorname{rank}(sI - C_2\mathcal{V}_{22}^{-1}A_{22}^{-1}E_{22}A_{22}^{-1}B_2) = m \quad \forall s \in \mathbf{C}_+; \end{cases}$$

(c) $C_2((A_{22}\mathcal{V}_{22})^{-1}E_{22}\mathcal{V}_{22})^k(A_{22}\mathcal{V}_{22})^{-1}B_2 = 0,\ i = 2, \ldots, n_2 - 1.$

Regarding (a), (b), and (c) above, we observe the following:

(1) Equations (47) and (48) can be rewritten as

$$\begin{cases} \left(\begin{bmatrix} \Theta_{11} & \Theta_{12} \\ 0 & \Theta_{22} \end{bmatrix}^{-1} \mathcal{P} \begin{bmatrix} \mathcal{U}_{11}E_{11} & 0 \\ 0 & I \end{bmatrix} \right)^{-1} = \begin{bmatrix} I & 0 \\ 0 & (\mathcal{U}_{11}E_{11})^T \end{bmatrix} P \\ \qquad = \begin{bmatrix} P_{11} & P_{12} \\ (\mathcal{U}_{11}E_{11})^T P_{21} & (\mathcal{U}_{11}E_{11})^T P_{22} \end{bmatrix}, \\ \left(\begin{bmatrix} I & 0 \\ 0 & (\mathcal{U}_{11}E_{11})^T \end{bmatrix} P \right)^{-1} \begin{bmatrix} E_{11}^{-1}A_{11} & 0 \\ 0 & -A_{11}^T(E_{11})^{-T} \end{bmatrix} \begin{bmatrix} I & 0 \\ 0 & (\mathcal{U}_{11}E_{11})^T \end{bmatrix} P \\ \qquad = \begin{bmatrix} \Theta_{11}^{-1}\Phi_{11} & \Theta_{11}^{-1}\Phi_{12} - \Theta_{11}^{-1}\Theta_{12}\Theta_{22}^{-1}\Phi_{22} \\ 0 & \Theta_{22}^{-1}\Phi_{22} \end{bmatrix}, \\ \left(\begin{bmatrix} I & 0 \\ 0 & (\mathcal{U}_{11}E_{11})^T \end{bmatrix} P \right)^{-1} \begin{bmatrix} (\mathcal{U}_{11}E_{11})^{-1}B_1 \\ C_1^T \end{bmatrix} = \begin{bmatrix} \Theta_{11}^{-1}\Psi_1 \\ 0 \end{bmatrix} \end{cases}$$

and

$$\begin{bmatrix} C_1 & -B_1^T(\mathcal{U}_{11}E_{11})^{-T} \end{bmatrix} \begin{bmatrix} I & 0 \\ 0 & (\mathcal{U}_{11}E_{11})^T \end{bmatrix} P = \begin{bmatrix} C_1 & -B_1^T \end{bmatrix} P = \begin{bmatrix} \mathcal{K}_1 & \mathcal{K}_2 \end{bmatrix},$$

respectively. By (45) and (54), the controllability of $(E; A, B)$ and $(E^T; A^T, C^T)$ implies the controllability of $(E_{11}^{-1}A_{11}, (\mathcal{U}_{11}E_{11})^{-1}B_1)$ and $((E_{11}^{-1}A_{11})^T, C_1^T)$. According to Theorem 16, $G_1(s)$ is lossless positive real if and only if

$$\mathcal{K}_1 = 0, \quad P_{11}^T(\mathcal{U}_{11}E_{11})^T P_{21} \ge 0,$$

and

$$(D - C_2(A_{22}\mathcal{V}_{22})^{-1}B_2) + (D - C_2(A_{22}\mathcal{V}_{22})^{-1}B_2)^T = 0,$$

$$\text{i.e., } \operatorname{rank} \begin{bmatrix} A_{22}\mathcal{V}_{22} & 0 & B_2 \\ 0 & (A_{22}\mathcal{V}_{22})^T & C_2^T \\ C_2 & B_2^T & D + D^T \end{bmatrix} = 2n_2,$$

equivalently, if and only if the conditions (49) and (50) hold.

(2) It is also easy to see that

$$C_2\mathcal{V}_{22}^{-1}A_{22}^{-1}E_{22}A_{22}^{-1}B_2 \le 0$$

if and only if the conditions (51) and (52) hold.

(3) Since $sE_{22}-A_{22}$ is nonsingular for all $s \in \mathbf{C}$, there exists a nonsingular matrix Z [17] such that

$$Z^{-1}(\mathcal{V}_{22}^{-1}A_{22}^{-1}E_{22}\mathcal{V}_{22})Z = \begin{array}{c} \begin{matrix} \tau_1 & \tau_2 & \tau_3 \end{matrix} \\ \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & I \\ 0 & 0 & 0 \end{bmatrix} \end{array} \begin{matrix} \}\tau_1 \\ \}\tau_3 \\ \}\tau_2 \end{matrix}, \quad \tau_2 \le \tau_3. \tag{55}$$

By (45) and (54) again, the controllability of $(E; A, B)$ and $(E^T; A^T, C^T)$ implies

$$\operatorname{rank}\begin{bmatrix} \alpha(A_{22}\mathcal{V}_{22})^{-1}E_{22}\mathcal{V}_{22} - \beta I & (A_{22}\mathcal{V}_{22})^{-1}B_2 \end{bmatrix}$$

$$= \begin{bmatrix} \alpha(A_{22}\mathcal{V}_{22})^{-1}E_{22}\mathcal{V}_{22} - \beta I \\ C_2 \end{bmatrix} = n_2$$

for all $(\alpha, \beta) \in \mathbf{C}^2\backslash\{0,0\}$. Hence, we have using Lemma 11 that $C_2((A_{22}\mathcal{V}_{22})^{-1}E_{22}\mathcal{V}_{22})^k(A_{22}\mathcal{V}_{22})^{-1}B_2 = 0$ $(k = 2, \ldots, n_2 - 1)$ if and only if

$$\tau_2 = \tau_3. \tag{56}$$

To find the relation between the conditions (53) and (56), let us refine the factorization (46). Since A_{22} is nonsingular, therefore Γ_{12} and Γ_{21} in (46) are of full column rank and full row rank, respectively, and

$$\zeta_2 \le \zeta_1. \tag{57}$$

Note that A_{22}, Γ_{33}, and Λ_{11} are nonsingular, Γ_{12} is of full column rank, and Γ_{21} is of full row rank. It is easy to see that there exist nonsingular matrices $\mathcal{Y}_1$ and $\mathcal{Y}_2$ such that

$$\mathcal{Y}_1\mathcal{Q}^T A_{22}Q\mathcal{Y}_2 = \begin{array}{c} \begin{matrix} \zeta_2 & \zeta_1-\zeta_2 & \zeta_2 & \zeta_3 \end{matrix} \\ \begin{bmatrix} 0 & 0 & I & 0 \\ 0 & I & 0 & 0 \\ I & 0 & 0 & 0 \\ 0 & 0 & 0 & I \end{bmatrix} \end{array} \begin{matrix} \}\zeta_2 \\ \}\zeta_1-\zeta_2 \\ \}\zeta_2 \\ \}\zeta_3 \end{matrix},$$

$$\mathcal{Y}_1\mathcal{Q}^T E_{22}Q\mathcal{Y}_2 = \begin{array}{c} \begin{matrix} \zeta_2 & \zeta_1-\zeta_2 & \zeta_2 & \zeta_3 \end{matrix} \\ \begin{bmatrix} \Lambda_{11}^{(1,1)} & \Lambda_{11}^{(1,2)} & 0 & 0 \\ \Lambda_{11}^{(2,1)} & \Lambda_{11}^{(2,2)} & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \end{array} \begin{matrix} \}\zeta_2 \\ \}\zeta_1-\zeta_2 \\ \}\zeta_2 \\ \}\zeta_3 \end{matrix},$$

where

$$\operatorname{rank}\begin{bmatrix} \Lambda_{11}^{(1,1)} & \Lambda_{11}^{(1,2)} \\ \Lambda_{11}^{(2,1)} & \Lambda_{11}^{(2,2)} \end{bmatrix} = \operatorname{rank}(\Lambda_{11}) = \zeta_1 = \zeta_2 + (\zeta_1 - \zeta_2). \tag{58}$$

Consequently, there exist permutation matrices $\mathcal{Y}_3$ and $\mathcal{Y}_4$ such that

$$\mathcal{Y}_3\mathcal{Y}_1\mathcal{Q}^T A_{22}Q\mathcal{Y}_2\mathcal{Y}_4 = \begin{array}{c} \begin{matrix} \zeta_3 & \zeta_2 & \zeta_1-\zeta_2 & \zeta_2 \end{matrix} \\ \left[\begin{array}{cccc} I & 0 & 0 & 0 \\ 0 & I & 0 & 0 \\ 0 & 0 & I & 0 \\ 0 & 0 & 0 & I \end{array}\right] \end{array} \begin{matrix} \}\zeta_3 \\ \}\zeta_2 \\ \}\zeta_1-\zeta_2 \\ \}\zeta_2 \end{matrix}$$

and

$$\mathcal{Y}_3\mathcal{Y}_1\mathcal{Q}^T E_{22}Q\mathcal{Y}_2\mathcal{Y}_4 = \begin{array}{c} \begin{matrix} \zeta_3 & \zeta_2 & \zeta_1-\zeta_2 & \zeta_2 \end{matrix} \\ \left[\begin{array}{cccc} 0 & 0 & 0 & 0 \\ 0 & 0 & \Lambda_{11}^{(1,2)} & \Lambda_{11}^{(1,1)} \\ 0 & 0 & \Lambda_{11}^{(2,2)} & \Lambda_{11}^{(2,1)} \\ 0 & 0 & 0 & 0 \end{array}\right] \end{array} \begin{matrix} \}\zeta_3 \\ \}\zeta_2 \\ \}\zeta_1-\zeta_2 \\ \}\zeta_2 \end{matrix},$$

which gives

(59)

$$(\mathcal{Y}_2\mathcal{Y}_4)^{-1}(Q^{-1}A_{22}^{-1}E_{22}Q)(\mathcal{Y}_2\mathcal{Y}_4) = \begin{array}{c} \begin{matrix} \zeta_3 & \zeta_2 & \zeta_1-\zeta_2 & \zeta_2 \end{matrix} \\ \left[\begin{array}{cccc} 0 & 0 & 0 & 0 \\ 0 & 0 & \Lambda_{11}^{(1,2)} & \Lambda_{11}^{(1,1)} \\ 0 & 0 & \Lambda_{11}^{(2,2)} & \Lambda_{11}^{(2,1)} \\ 0 & 0 & 0 & 0 \end{array}\right] \end{array} \begin{matrix} \}\zeta_3 \\ \}\zeta_2 \\ \}\zeta_1-\zeta_2 \\ \}\zeta_2 \end{matrix}.$$

By a simple comparison between (59) and (55), we know by taking (57) and (58) into account that

$$\zeta_3 = \tau_1, \quad \zeta_2 = \tau_2, \quad \zeta_1 = \tau_3.$$

Thus, (56) holds if and only if (53) holds.

Therefore, Theorem 17 follows. □

2. The condition (52) is equivalent to stating that the pencil

$$\left(\begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & I \end{bmatrix}, \begin{bmatrix} -A_{22} & 0 & -B_2 \\ E_{22} & -A_{22}\mathcal{V}_{22} & 0 \\ 0 & -C_2 & 0 \end{bmatrix}\right)$$

has no finite generalized eigenvalues on $\mathbf{C}_+$. Hence, it can be verified easily, as follows:

- Compute the finite generalized eigenvalues of the pencil

$$\left(\begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & I \end{bmatrix}, \begin{bmatrix} -A_{22} & 0 & -B_2 \\ E_{22} & -A_{22}\mathcal{V}_{22} & 0 \\ 0 & -C_2 & 0 \end{bmatrix}\right).$$

  If such finite generalized eigenvalues are all on $\mathbf{C}\backslash\mathbf{C}^+$, then the condition (52) holds; otherwise, it does not hold.

3. The form (46) can be computed easily, as follows:

- Compute the SVD of E_{22} [19] to get orthogonal matrices Q_1 and $\mathcal{Q}_1$ such that

$$\mathcal{Q}_1^T E_{22} Q_1 = \begin{array}{c} \begin{matrix} \zeta_1 & n_2 - \zeta_1 \end{matrix} \\ \begin{bmatrix} \Lambda_{11} & 0 \\ 0 & 0 \end{bmatrix} \end{array} \begin{matrix} \}\zeta_1 \\ \}n_2 - \zeta_1 \end{matrix},$$

where Λ_{11} is nonsingular. Set

$$\mathcal{Q}_1^T A_{22} Q_1 = \begin{array}{c} \begin{matrix} \zeta_1 & n_2 - \zeta_1 \end{matrix} \\ \begin{bmatrix} \Gamma_{11} & \Gamma_{12}^{(1)} \\ \Gamma_{21}^{(1)} & \Gamma_{22}^{(1)} \end{bmatrix} \end{array} \begin{matrix} \}\zeta_1 \\ \}n_2 - \zeta_1 \end{matrix}.$$

- Compute the SVD of $\Gamma_{22}^{(1)}$ to get orthogonal matrices Q_2 and $\mathcal{Q}_2$ such that

$$\mathcal{Q}_2^T \Gamma_{22}^{(1)} Q_2 = \begin{array}{c} \begin{matrix} \zeta_2 & \zeta_3 \end{matrix} \\ \begin{bmatrix} 0 & 0 \\ 0 & \Gamma_{33} \end{bmatrix} \end{array} \begin{matrix} \}\zeta_2 \\ \}\zeta_3 \end{matrix},$$

where Γ_{33} is nonsingular. Set

$$\Gamma_{12}^{(1)} Q_2 = \begin{array}{c} \begin{matrix} \zeta_2 & \zeta_3 \end{matrix} \\ \begin{bmatrix} \Gamma_{12} & \Gamma_{13} \end{bmatrix} \end{array}, \quad \mathcal{Q}_2^T \Gamma_{21}^{(1)} = \begin{array}{c} \\ \begin{bmatrix} \Gamma_{21} \\ \Gamma_{31} \end{bmatrix} \end{array} \begin{matrix} \\ \}\zeta_2 \\ \}\zeta_3 \end{matrix}$$

and

$$Q = Q_1 \begin{bmatrix} I & 0 \\ 0 & Q_2 \end{bmatrix}, \quad \mathcal{Q} = \mathcal{Q}_1 \begin{bmatrix} I & 0 \\ 0 & \mathcal{Q}_2 \end{bmatrix}.$$

Then $\mathcal{Q}^T(sE_{22} - A_{22})Q$ is in the form (46).

3. Conclusions. We have studied the algebraic characterizations for the positive realness of descriptor systems in this paper. The main contributions of the present work are as follows:

- In Theorem 13 we have algebraically characterized the positive realness of descriptor systems by using a linear matrix inequality of the form (14) and thus extended the well-known positive real lemma for standard state space systems to descriptor systems.
- We have also shown in Theorems 16 and 17 that the lossless positive realness of standard state space systems and descriptor systems can be tested easily using the controllable staircase forms of the standard state space systems and the generalized controllable staircase forms of descriptor systems, respectively.

Acknowledgments. We are grateful to the anonymous referees and the associate editor Professor Peter Benner for their valuable comments and suggestions.

ON NUMERICAL ISSUES OF INTERIOR POINT METHODS*

CSABA MÉSZÁROS†

Abstract. This paper concerns some numerical stability issues of factorizations in interior point methods. In our investigation we focus on regularization techniques for the augmented system. We derive the fundamental property of regularization and necessary conditions for the convergence of iterative refinement. A relaxation technique is described that improves on convergence properties. We introduce a practical, adaptive technique to determine the required amount of regularization in numerically difficult situations. Numerical experiments on large-scale, numerically difficult linear programming problems are presented.

Key words. regularization, indefinite Cholesky factorization, interior point methods

DOI. 10.1137/050633354

1. Introduction. During the past 15 years, interior point methods (IPMs) proved to be efficient in practice and numerically robust for solving large-scale optimization problems [7, 1]. The important practical issue, the stability of the computations in IPMs, deserved special attention in the literature [6, 24, 27, 26]. For most interior point algorithms, the major computational task is to solve symmetric systems of linear equations, which is usually done by factorization in practice. One of the most important difficulties for IPMs is the ill-conditioning of these linear systems when the method approaches the optimal solution of the optimization problem. It has been shown that, in general, degeneracy in the optimization problem causes ill-conditioning, but in such a case the possible numerical errors appear to be in a subspace [17]. This situation can be handled well with a modified factorization scheme by skipping columns corresponding to small pivots during numerical computations [27, 17]. In [17] it was pointed out that ill-conditioning may also appear when the optimal solution of the problem is scaled badly, i.e., if the values of the strictly positive components in the optimal solution vector are of different orders of magnitude. A situation like this may easily occur in real-life optimization problems, resulting in a breakdown of the modified factorization scheme, as demonstrated in [17]. In such a case, a regularization technique can help to avoid numerical problems. In the present paper regularization means that prior to the symmetric factorizations, some "small" diagonal matrix values are replaced by "reasonably large" ones. Naturally, regularization is very sensitive to the manner of how the "small" values are identified and of how the "reasonably large" values are set.

In this paper we investigate regularization techniques. We introduce the practical linear algebra operations of IPMs in section 2. In section 3 we introduce a regularization scheme for the diagonal scaling matrix of IPMs and derive necessary and sufficient conditions for the convergence of iterative refinement on the regularized system. In section 4 we discuss special cases and describe a relaxation technique to improve the

convergence of iterative refinement. In section 5 an adaptive scheme for the use of regularization is described. Section 6 presents numerical results.

2. Interior point methods and symmetric factorizations. We consider the linear programming problem and a primal-dual log barrier interior point method for further investigations. It is to be noted that the underlying linear algebra of other interior point approaches is fairly similar.

Let us consider the linear programming problem

$$\begin{array}{rcl} \min\ c^T x, & & \\ Ax & = & b, \\ x & \geq & 0, \end{array} \tag{2.1}$$

where $x, c \in \mathcal{R}^n$, $A \in \mathcal{R}^{m \times n}$ is of full row rank, and $b \in \mathcal{R}^m$. The associated dual problem is

$$\begin{aligned} \max \quad & b^T y, \\ & A^T y + z = c, \\ & z \geq 0, \end{aligned}$$

where $y \in R^m$ and $z \in R^n$. The logarithmic barrier problem corresponding to (2.1) is

$$\begin{aligned} \min\ & c^T x - \mu \sum_{i=1}^{n} \ln\, x_i, \\ & Ax = b, \quad x > 0, \end{aligned} \tag{2.2}$$

where μ is a positive scalar barrier parameter. A log barrier IPM approaches the optimal solution on the central path (x^*, y^*, z^*) by a sequence of barrier problems (2.2), while the barrier parameter is decreased toward zero. Following the classical introduction of the primal-dual log barrier method [12, 8, 25], the algorithm can be derived by applying Newton's method to solve the Karush–Kuhn–Tucker system of (2.2). Present efficient implementations employ the predictor-corrector and higher-order correction techniques [13, 1].

The computational task in each iteration of the resulting methods is the solution of systems of linear equations

$$\begin{bmatrix} D & A^T \\ A & 0 \end{bmatrix} \begin{bmatrix} \Delta x \\ \Delta y \end{bmatrix} = \begin{bmatrix} \alpha \\ \beta \end{bmatrix}, \tag{2.3}$$

where

$$D = \operatorname{diag}\left(x_i^{-1} z_i\right).$$

Later, the matrix of (2.3) is referred to as the augmented system. For the predictor-corrector primal-dual method, two systems should be solved with the same matrix and different right-hand sides, while higher-order methods require more solutions of systems like the above.

In practice, a Cholesky-like decomposition of the permuted matrix is computed as

$$L \Lambda L^T = P \begin{bmatrix} D & A^T \\ A & 0 \end{bmatrix} P^T, \tag{2.4}$$

where L is lower triangular, Λ is diagonal with both positive and negative values, and P is a permutation. Implementations either use the normal equations, for which

$$L = \begin{bmatrix} D^{\frac{1}{2}} & \\ AD^{-\frac{1}{2}} & \hat{L} \end{bmatrix}, \quad \Lambda = \begin{bmatrix} I & \\ & -I \end{bmatrix}, \quad P = \begin{bmatrix} I & \\ & \hat{P} \end{bmatrix},$$

where $\hat{L}\hat{L}^T$ is the Cholesky decomposition of $AD^{-1}A^T$ [20, 1], or alter the matrix to be quasi-definite, so it can be factorized with any P by indefinite Cholesky factorization [23, 22]. Our implementation uses a heuristic to select one of these two approaches. The indefinite Cholesky factorization is used only if a reduction in the fill-in seems possible [10]. From now on we will omit the permutation P, as it has no influence on the algebraic properties.

During interior point iterations the diagonal values of D converge to zero or to infinity, depending on the analytic center x^* of the optimal face of problem (2.1):

$$D_{ii} \to \begin{cases} 0 & \text{if } x_i^* > 0, \\ \infty & \text{if } x_i^* = 0, \end{cases}$$

resulting in increasing ill-conditioning of the augmented system. Supposing that the original constraint matrix A is well-conditioned, in most cases ill-conditioning like this presents no numerical difficulties, except if the solution x^* is scaled badly; i.e., its positive components have a significantly different order of magnitude [17]. We investigate this situation where the usual factorization approaches may break down.

In interior point implementations, iterative refinement is a standard technique for improving numerical accuracy. The classical normal equations approach, where (2.3) is reduced to

$$-AD^{-1}A^T\Delta y = \beta - D^{-1}A^T\alpha \tag{2.5}$$

and (2.5) is solved for Δy, is very attractive because the positive definiteness of the matrix $AD^{-1}A^T$ allows powerful iterative techniques, such as the preconditioned conjugate gradient method. But we have observed that iterative methods for (2.5) often fail in interior point implementations in numerically difficult cases. The reason is that the matrix $AD^{-1}A^T$ often cannot be formed accurately, so that Δy will be inaccurate, and then Δx will be inaccurately obtained from $D\Delta x = \alpha - A^T\Delta y$. Therefore, we apply iterative refinement on the augmented system, which feeds back corrections corresponding to the residuals in the spaces of both Δx and Δy. Regarding the pure least squares problem, this approach was justified as well by theory [3, 2].

The steps of a refinement scheme like this can be written as

$$\begin{aligned} &\text{solve} \quad \bar{M}\begin{bmatrix} \Delta x \\ \Delta y \end{bmatrix}^0 = \begin{bmatrix} \alpha \\ \beta \end{bmatrix}, \\ &\text{solve} \quad \bar{M}\begin{bmatrix} \Delta x \\ \Delta y \end{bmatrix} = \begin{bmatrix} \alpha \\ \beta \end{bmatrix} - M\begin{bmatrix} \Delta x \\ \Delta y \end{bmatrix}^k, \\ &\text{form} \quad \begin{bmatrix} \Delta x \\ \Delta y \end{bmatrix}^{k+1} = \begin{bmatrix} \Delta x \\ \Delta y \end{bmatrix}^k + \begin{bmatrix} \Delta x \\ \Delta y \end{bmatrix}, \end{aligned} \tag{2.6}$$

where

$$M = \begin{bmatrix} D & A^T \\ A & 0 \end{bmatrix}$$

and $\bar{M}$ is an approximation of M suitable for the solve operation. Later, we will consider iterative refinement in the following standard form:

$$\begin{bmatrix} \Delta x \\ \Delta y \end{bmatrix}^{k+1} = \left(I - \bar{M}^{-1}M\right) \begin{bmatrix} \Delta x \\ \Delta y \end{bmatrix}^{k} + \begin{bmatrix} \Delta x \\ \Delta y \end{bmatrix}^{0}. \tag{2.7}$$

In the implementation we use the IEEE standard double precision arithmetic for all computation steps. Note that "iterative refinement" normally requires additional precision in computing the right-hand side of (6), but here we are solving systems involving a modified $\bar{M}$ instead of the required M. This is similar to using inaccurate factors from an unstable factorization of M. In such contexts, a few steps of "refinement" can be helpful even without extra precision.

3. Regularization. In choosing $\bar{M}$, our approach is to modify the diagonals of M. In this way we regularize D, the so-called diagonal scaling matrix of interior methods. Let us suppose that scaling factors different from D are used. Let $\bar{D}$ be a diagonal positive definite $n \times n$ matrix and consider the regularized augmented matrix

$$\bar{M} = \begin{bmatrix} \bar{D} & A^T \\ A & 0 \end{bmatrix}.$$

In our approach we factorize $\bar{M}$ and apply iterative refinement to achieve the solution of (2.3). In exact arithmetic, the iterative process converges if the eigenvalues λ of the refinement operator satisfy $\left|\lambda\left(I - \bar{M}^{-1}M\right)\right| < 1$ [4]. Thus we investigate the eigenvalues by examining the solutions of the equation

$$\det\left(I - \bar{M}^{-1}M - \lambda I\right) = 0. \tag{3.1}$$

Since $\bar{M}$ is nonsingular, (3.1) is equivalent to

$$\det\left(\bar{M}^{-1}\right) \det\left(M - (1-\lambda)\bar{M}\right) = 0.$$

The block matrix $M - (1-\lambda)\bar{M}$ can be simplified as

$$M - (1-\lambda)\bar{M} = \begin{bmatrix} D - (1-\lambda)\bar{D} & A^T - (1-\lambda)A^T \\ A - (1-\lambda)A & 0 \end{bmatrix} = \begin{bmatrix} D - (1-\lambda)\bar{D} & \lambda A^T \\ \lambda A & 0 \end{bmatrix}.$$

This shows that 0 is an eigenvalue with multiplicity of at least $2m$, since

$$\det\left(M - (1-\lambda)\bar{M}\right) = \lambda^{2m} \det \begin{bmatrix} D - (1-\lambda)\bar{D} & A^T \\ A & 0 \end{bmatrix}.$$

Thus, we can reduce (3.1) to

$$\det \begin{bmatrix} D - (1-\lambda)\bar{D} & A^T \\ A & 0 \end{bmatrix} = 0.$$

Now we state the main lemma.

LEMMA 3.1. [illegible] $\left(I - \bar{M}^{-1}M\right)$ [illegible]

[illegible] Let us suppose that there exists a complex eigenvalue: $\exists \lambda \in \mathcal{C} \setminus \mathcal{R}$. Since $\bar{D}_{ii} > 0$, the inverse of the diagonal complex matrix $(D - (1-\lambda)\bar{D})$ exists because its imaginary part is of full rank:

$$\exists \left(D - (1-\lambda)\bar{D}\right)^{-1} \in \mathcal{C}^{n \times n}.$$

We show that $A\left(D-(1-\lambda)\bar{D}\right)^{-1}A^T$ is of full rank, which contradicts the assumption. Since both λ and its complex conjugate $\bar{\lambda}$ are eigenvalues, we can assume that λ is of the form of $\lambda=\lambda_1-i\lambda_2$, where $\lambda_2>0$. Since for any $a,b\in\mathcal{R}$,

$$(a-ib)^{-1}=\frac{a+ib}{a^2+b^2},$$

the matrix $\left(D-(1-\lambda)\bar{D}\right)^{-1}$ can be written as

$$\left(D-(1-\lambda)\bar{D}\right)^{-1}=F+iG,$$

where F is diagonal and G is diagonal positive definite. Therefore,

$$A\left(D-(1-\lambda)\bar{D}\right)^{-1}A^T=AFA^T+iAGA^T,$$

and, furthermore,

$$\operatorname{rank}\left(AFA^T+iAGA^T\right)=\operatorname{rank}\left(\left(AGA^T\right)^{-1}AFA^T+iI\right).$$

The eigenvalues of $\left(AGA^T\right)^{-1}AFA^T$ are all real numbers because it is similar to a symmetric real matrix:

$$\left(AGA^T\right)^{-1}AFA^T\sim\left(AGA^T\right)^{-1/2}AFA^T\left(AGA^T\right)^{-1/2}.$$

This means that the eigenvalues of the matrix $\left(AGA^T\right)^{-1}AFA^T+iI$ have the form

$$\lambda\left(\left(AGA^T\right)^{-1}AFA^T+iI\right)=r+i,$$

where $r\in\mathcal{R}$. Therefore, no eigenvalue can be 0, because of the nonzero imaginary part. This shows that $A\left(D-(1-\lambda)\bar{D}\right)^{-1}A^T$ is of full rank for any $\lambda\in\mathcal{C}\setminus\mathcal{R}$. Thus, all eigenvalues of $\left(I-\bar{M}^{-1}M\right)$ should be in $\mathcal{R}$.

THEOREM 3.2. [illegible] $\left(I-\bar{M}^{-1}M\right)$ [illegible] 1 [illegible] For $\lambda\geq 1$, the matrix $D-(1-\lambda)\bar{D}$ is positive definite and

$$\begin{bmatrix} D-(1-\lambda)\bar{D} & A^T \\ A & 0 \end{bmatrix}$$

is of full rank. Therefore, for $\lambda\geq 1$ (3.1) cannot be satisfied.

THEOREM 3.3. [illegible] $\left(I-\bar{M}^{-1}M\right)$ [illegible] $\min_i\left(1-D_{ii}/\bar{D}_{ii}\right)$.

[illegible] For $\lambda<\min_i\left(1-D_{ii}/\bar{D}_{ii}\right)$ the matrix $D-(1-\lambda)\bar{D}$ is negative definite and

$$\begin{bmatrix} D-(1-\lambda)\bar{D} & A^T \\ A & 0 \end{bmatrix}$$

is of full rank.

COROLLARY 3.4. [illegible] $\left(I-\bar{M}^{-1}M\right)$ [illegible] -1.

$$\max\frac{D_{ii}}{\bar{D}_{ii}}<2. \tag{3.2}$$

We can now derive sufficient conditions for the convergence of iterative refine-

ment:

- the diagonals of D are increased arbitrarily, or
- the diagonals of D are decreased by less than 50%.

Note that the last condition is sharp, which can be demonstrated by the following example:

$$A = [1, 1], \quad D = \begin{bmatrix} 2 & \\ & 2 \end{bmatrix}, \quad \bar{D} = \begin{bmatrix} 1 & \\ & 1 \end{bmatrix}.$$

Iterative refinement does not converge because

$$\lambda\left(\begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} - \begin{bmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \\ 1 & 1 & 0 \end{bmatrix}^{-1} \begin{bmatrix} 2 & 0 & 1 \\ 0 & 2 & 1 \\ 1 & 1 & 0 \end{bmatrix}\right) = \{0,\ 0,\ -1\}.$$

4. Speeding up convergence. Let $R = I - \bar{M}^{-1}M$ denote the matrix of the iterative refinement (2.7). Observe that the following upper bound can be easily derived regarding the absolute value of the eigenvalues of R:

$$\max |\lambda(R)| \leq \max_i \left|1 - \frac{D_{ii}}{\bar{D}_{ii}}\right|. \tag{4.1}$$

This upper bound helps to improve the convergence rate of iterative refinement. Our idea is to use a relaxation technique and consider the matrix

$$\bar{M}_\gamma = \begin{bmatrix} \gamma\bar{D} & A^T \\ A & 0 \end{bmatrix}$$

and choose $\gamma > 0$ such that

$$\max_i \left|1 - \frac{D_{ii}}{\gamma\bar{D}_{ii}}\right|$$

is minimized. Then, $\bar{M}_\gamma$ is factored and used in the iterative refinement process (2.7).

The case $\gamma > 1$ is called overrelaxation and $\gamma < 1$ is underrelaxation. Since in our situation, usually $\bar{D}_{ii} \geq D_{ii}$, we may use underrelaxations only with $\gamma \leq 1$. In practice, we have $\bar{D}_{ii} = D_{ii}$ for several indices i, which requires that $\gamma > \frac{1}{2}$.

A relaxation technique like this can relax condition (3.2) since, for any $\bar{M}$, it is possible to find a large enough γ such that

$$\max \left|\lambda\left(I - \bar{M}_\gamma^{-1}M\right)\right| < 1.$$

This means that for any positive definite diagonal $\bar{D}$, we can determine a relaxation parameter γ such that iterative refinement will converge to the solution of (2.3).

In practice we determine γ by solving

$$\min_\gamma \sum_{i=1}^{n} \left(D_{ii} - \gamma\bar{D}_{ii}\right)^2. \tag{4.2}$$

In this way we reduce the Frobenius distance between the original and regularized scaling matrices.

4.1. Further properties of the regularization. Observe that if $m = n$, then R is nilpotent, i.e., $\exists k \leq m + n$ positive integer so that $R^k = 0$. Therefore, in exact arithmetic, iterative refinement converges in a finite number of steps. The same is true if the "regularized" columns of A are linearly independent of the other columns, i.e., if

$$D_{ii} \neq \bar{D}_{ii} \Longrightarrow a_i \notin \mathrm{Span}(a_1, \ldots, a_{i-1}, a_{i+1}, \ldots, a_n).$$

Then, the matrix R is nilpotent, which again implies a finite number of steps for iterative refinement in exact arithmetic.

Next, we consider a regularization scheme similar to the Tyhonov–Levenberg regularization for LSQR [19], as used in [22]. We set

$$\bar{M} = \begin{bmatrix} \bar{D} & A^T \\ A & -D^+ \end{bmatrix}, \tag{4.3}$$

where $\bar{D}$ and D^+ are positive definite diagonal. The regularization D^+ corresponds to a regularization of the free variables in the dual problem [15]. We apply regularization like this to alter $\bar{M}$ to be quasi-definite for the indefinite Cholesky factorization in case the matrix of normal equations has significant fill [16]. For the behavior of regularizations of this type, we investigate the eigenvalues again by examining the solutions of

$$\det \begin{bmatrix} D - (1-\lambda)\bar{D} & \lambda A^T \\ \lambda A & (1-\lambda)D^+ \end{bmatrix} = 0. \tag{4.4}$$

Since $D^+_{ii} > 0$, no eigenvalue is 0 in this case. But it is easy to see that, similar to the previous case, all solutions of (4.4) are real numbers and the same conditions for iterative refinement are valid. In particular, all eigenvalues of R are less than 1, since for $\lambda \geq 1$ the matrix $D - (1-\lambda)\bar{D}$ is positive definite and $(1-\lambda)D^+$ is negative definite. Thus, $(1-\lambda)D^+ - \lambda^2 A \left(D - (1-\lambda)\bar{D}\right)^{-1} A^T$ is negative definite and (4.4) cannot hold for $\lambda \geq 1$.

Furthermore, if $\bar{D}$ is chosen such that

$$\max \frac{D_{ii}}{\bar{D}_{ii}} < 2,$$

then all eigenvalues will be greater than -1, since for $\lambda \leq -1$, the matrix $D - (1-\lambda)\bar{D}$ is negative definite, $(1-\lambda)D^+$ is positive definite, and $(1-\lambda)D^+ - \lambda^2 A \left(D - (1-\lambda)\bar{D}\right)^{-1} A^T$ is positive definite. This shows that dual regularization does not affect the convergence conditions.

In [22] Saunders perturbed the diagonal of M by a small multiples of I in order to permit the use of existing sparse Cholesky factorization software and ensure sufficient stability. The key feature of our approach is that it is more adaptive: the diagonal values of $\bar{D}$ and D^+ can all be modified by a different amount, bounded in order to ensure convergence of the refinement process.

Finally, let us note that a special case of regularization was discussed in [15] for handling free variables in interior point methods. In this case zero diagonal elements in D were replaced by positive ones. Note that condition (3.2) in this case holds for any $\bar{D}_{ii} > 0$ value.

5. Regularization in practice. In our implementation we intend to achieve 10^{-8} relative error in the Euclidean norm when solving system (2.3):

$$\left\| \begin{bmatrix} D & A^T \\ A & 0 \end{bmatrix} \begin{bmatrix} \Delta x \\ \Delta y \end{bmatrix} - \begin{bmatrix} \alpha \\ \beta \end{bmatrix} \right\| \leq 10^{-8} \max\left(1, \left\| \begin{bmatrix} \alpha \\ \beta \end{bmatrix} \right\|\right).$$

We use a direct factorization approach with iterative refinement, which is stopped if the desired accuracy is achieved or if the Euclidean norm of the residual increases. The strategy for choosing $\bar{D}$ plays an important role in our approach, because it balances stability and efficiency. Increasing the diagonals in $\bar{D}$ may result in more stable factorizations, but may make the iterative refinement process longer. Here we describe an adaptive procedure to determine $\bar{D}$ at each iteration.

Our practical assumption is that improving the condition of $\bar{D}$ reduces the ill-conditioning of $A\bar{D}^{-1}A^T$ and $\bar{M}$. Our approach sets $\bar{D}$ such that its condition number is kept below an adaptively determined threshold with small modification of D. In the case of the factorization of the normal equations system, modification like this reduces the quantity $\text{cond}(A)^2\text{cond}(\bar{D})$, which is an upper bound for the condition number of $A\bar{D}^{-1}A^T$, while for the indefinite Cholesky factorization of (4.3) it reduces the upper bound [22] on the effective condition of $\bar{M}$ [21].

At iteration k, we define the tentative partition P^k of the primal variables that are positive at the optimum, as

$$P^k = \left\{ j \in \{1, \ldots, n\} : \frac{|\Delta x_j^a|}{x_j} \leq \frac{|\Delta z_j^a|}{z_j} \right\}, \tag{5.1}$$

where $(\Delta x^a, \Delta z^a)$ is the primal-dual affine scaling direction at the previous iteration [14]. Furthermore, let $N^k = \{1, \ldots, n\} \setminus P^k$. We chose this indicator because it is independent of problem scaling and has been justified by both theory and practice [1]. Since $A_{N^k} D_{N^k}^{-1} A_{N^k}^T$ vanishes as the IPM approaches the optimal solution, we assume that variables defined by N^k play a less important role, and we concentrate on the behavior of the variables defined by P^k. Thus, we consider the "important" part of the augmented system

$$\begin{pmatrix} D_{P^k} & A_{P^k}^T \\ A_{P^k} & 0 \end{pmatrix},$$

and monitor the quantity $\text{cond}(D_{P^k})$. In our regularization scheme we set $\bar{D}_{N^k} = D_{N^k}$ and regularize D_{P^k} if necessary. We divide the interior point iteration process into two parts. In the first part we monitor the stability during the iterations and determine the largest value for $\text{cond}(D_{P^k})$, referred to as ω, that still results in numerically "safe" computations. There is no regularization applied in this phase. The second phase is called the "regularization phase" and it is activated if system (2.3) cannot be solved to a numerically sufficient accuracy by iterative refinement. In this phase we derive $\bar{D}$ from D and ω and may modify ω if necessary. Our process can be described as follows:

1. Monitoring phase.
   - Set $\omega = 1$ and $k = 0$.
   - At iteration k computes the affine scaling direction (2.3) [13].
     - If iterative refinement converges rapidly, consider the system as numerically "safe" and set $\omega = \max(\omega, \text{cond}(D_{P^k}))$. Continue with the IPM iterations, set $k \longleftarrow k + 1$.

- If iterative refinement converges, but the convergence is rather slow, leave ω unchanged. Continue with the IPM iterations, set $k \longleftarrow k+1$.
- If iterative refinement does not converge, switch to the "regularization phase."

2. Regularization phase.
   - Define $\bar{D}_{N^k} = D_{N^k}$.
   - Set $\delta = \max_{i \in P^k} (D_{ii})$.
   - For all $i \in P^k$ set $\bar{D}_{ii} = \max(D_{ii},\ \delta/\omega)$.
   - Determine γ from (4.2).
   - Compute the factorization of $\bar{M}_\gamma$ and compute the affine scaling direction (2.3).
     - If iterative refinement converges, leave ω unchanged and continue with the IPM iterations, set $k \longleftarrow k+1$.
     - If iterative refinement does not converge, increase ω and restart the computation of iteration k.

It can be observed that δ becomes large during the iterations. Note that increasing ω in the regularization phase may be necessary to compensate for the increase of $cond(A_{P^k})$, relative to $cond(A_{P^{k-1}})$. In our implementation we multiply ω by 10 in a case like this. Also note that the regularization phase may be skipped if sufficient numerical accuracy is achieved for (2.3) during all interior point iterations. This is the case on all NETLIB [5] and QPLIB [11] problems with our solver, for example.

6. Numerical results. We demonstrate the usability of our regularization scheme by solving numerically difficult problems. Let us note that the present NETLIB and QPLIB problem sets do not contain any problems with numerical challenges for modern interior point solvers, and all of these problems are easily solvable without the regularization techniques. We assembled a set of challenging problems from academic and industrial applications. Those available for the public can be accessed from http://www.sztaki.hu/~meszaros/public_ftp/lptestset/. Table 6.1 gives the characteristics of the problems before and after our presolve procedure. During presolve the problem data was scaled by rows and columns as described in [18]. Note that none of these problems was solvable by our implementation BPMPD [16] without the described regularization scheme.

The problem statistics show that numerical difficulties are not related to the problem size, as our test set contains small problems with a few hundred variables, as well as large ones with up to 2 million variables.

Table 6.2 summarizes the numerical properties of the test problems. We denote the partition (5.1) of the optimal solution by P^* and use notation $X = \mathrm{diag}(x_1, \ldots, x_n)$. Thus, the second column of Table 6.2 presents the ratio of the largest and smallest primal values among the primal variables that are positive in the optimal solution. The third column presents the condition number of the scaling matrix D_{P^*} at the last iterate of the interior point method. The fourth column presents the value of ω used for the last iteration. Finally, the iteration numbers of the monitoring and regularization phases are given.

The results indicate that most of the problems are very badly scaled for interior point methods, resulting in badly conditioned scaling matrices D. The results also explain why refinement methods for the normal equation system do not work in these cases: during the computation of $A_{P^*} D_{P^*}^{-1} A_{P^*}^T$ a significant amount of information is lost because of the bad conditioning of D_{P^*}. For some problems, the Cholesky

factorization is sufficiently accurate up to the last few iterations, such as on problems ,. .96 4, 4, and . On several problems, however, the Cholesky factorization broke down at an early stage of the iteration process, leaving significant work for the regularization phase. Problems like this include 11 ,. 3 5 75 ,. .96 1, and ,. .96 2.

Interior point algorithms terminate when the first-order optimality conditions are satisfied with some predetermined tolerance. This is translated to the following conditions imposed on the relative primal and dual feasibility and the relative duality

gap:

$$\frac{||Ax-b||}{1+||b||} \le \epsilon, \quad \frac{||A^T y - c||}{1+||c||} \le \epsilon, \quad \frac{\left|c^T x - b^T y\right|}{1+|b^T y|} \le \epsilon,$$

where ϵ is a positive tolerance. We stopped our IPM implementation if ϵ of order 10^{-8} was achieved, or if the accuracy of the solution was not decreased by at least one order of magnitude during the last 10 iterations. Table 6.3 displays the relative primal and dual infeasibility and the relative duality gap at the termination. Furthermore, the last column of Table 6.3 shows the average number of iterative refinement steps in the regularization phase for computing the "composite" infeasible predictor-corrector direction [9]. The results show that the desired accuracy was achieved on the majority of the problems, while the number of necessary iterative refinement steps was kept moderate. The numerically most ill-conditioned problem appeared to be , but taking into account the condition number of D_{P^*} observed on this problem, the achieved accuracy can be considered to be adequate.

Note that the iterative refinement converged in some cases very rapidly. Interestingly, on problem , no refinement steps were necessary during the regularization phase. Most of the refinement steps were necessary on problems and 4, but these problems required only few iterations in the computationally more expensive regularization phase. The rest of the problems required a moderate number of refinements.

7. Summary. In [17] it was pointed out for interior point methods that if the values of the strictly positive components in the primal optimal solution vector are of different orders of magnitude, then it presents numerically challenging cases for current implementation technology, based on the modified Cholesky decomposition. Here we described a regularization scheme for handling this situation and for solving numerically challenging linear programming problems. We proved that, with some conditions for the regularization, one can compute search directions using a factorization of the regularized system and iterative refinement. A relaxation technique was

described whose application can relax the derived condition and may increase the rate of convergence of the iterative refinement. We discussed several special aspects and properties of the regularization scheme and showed that in some cases the convergence of the iterative refinement can be guaranteed in a finite number of steps because of the nilpotent property of the underlying transformation matrix. Based on an upper bound on the effective condition number of the augmented system $\overline{M}$ (12), we provided an adaptive control mechanism for the regularization. Our scheme classifies the ill-conditioned part of $\overline{M}$ in a scaling-independent way and adaptively determines the necessary amount of regularization.

Our numerical experiments confirmed that the regularization scheme improves the numerical stability and makes interior point implementations more robust.

Acknowledgments. We would like to thank the anonymous referees for their careful reading and valuable advice.

ORTHOGONALIZATION VIA DEFLATION: A MINIMUM NORM APPROACH FOR LOW-RANK APPROXIMATIONS OF A MATRIX*

ACHIYA DAX†

Abstract. In this paper we introduce a new orthogonalization method. Given a real $m \times n$ matrix A, the new method constructs an SVD-type decomposition of the form $A = \hat{U}\hat{\Sigma}\hat{V}^T$. The columns of $\hat{U}$ and $\hat{V}$ are orthonormal, or nearly orthonormal, while $\hat{\Sigma}$ is a diagonal matrix whose diagonal entries approximate the singular values of A. The method has three versions: a "left-side" orthogonalization scheme in which the columns of $\hat{U}$ constitute an orthonormal basis of Range(A), a "right-side" orthogonalization scheme in which the columns of $\hat{V}$ constitute an orthonormal basis of Range(A^T), and a third version in which both $\hat{U}$ and $\hat{V}$ have orthonormal columns, but the decomposition is not exact. The new decompositions may substitute the SVD in many applications.

Key words. orthogonalization via deflation, low-rank approximations, rectangular iterations, missing data estimation

1. Introduction.

In this paper we introduce a new orthogonalization method. Let A be a real $m \times n$ matrix. The new method constructs an SVD-type decomposition of the form

$$A = \hat{U}\hat{\Sigma}\hat{V}^T,$$

where the columns of $\hat{U}$ and $\hat{V}$ are orthonormal (or nearly orthonormal) and $\hat{\Sigma}$ is a diagonal matrix whose diagonal entries approximate the singular values of A. The name of the method, "orthogotheonalization via deflation," comes from the similarity to Hotelling's deflation by subtraction method. Given a symmetric positive semidefinite matrix S, the last method computes the eigenpairs of S, one after another in decreasing order, using the power method to compute dominant eigenpairs of the deflated matrices, e.g., [16], [17], [26], [32]. It is well known, however, that the convergence of the power method can be very slow. This raises the question of whether there are better ways to compute a dominant eigenpair. In the general case we need an effective method for calculating a dominant pair of singular vectors.

Let $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_n \geq 0$ denote the eigenvalues of S. Then a dominant eigenvector of S satisfies $S\mathbf{q} = \lambda_1\mathbf{q}$ and $\mathbf{q} \neq \mathbf{0}$. The minimum norm approach proposed in this paper computes $\mathbf{q}$ by solving the minimum norm problem

$$\text{minimize } E(\mathbf{q}) = \|S - \mathbf{q}\mathbf{q}^T\|_F^2, \tag{1.1}$$

where $\|\cdot\|_F$ denotes the Frobenius matrix norm and $\mathbf{q} = (q_1, q_2, \ldots, q_n)^T$ denotes the vector of unknowns. An equivalent way to write (1.1) is

$$\text{minimize } E(q_1, \ldots, q_n) = \sum_{i=1}^{n} \sum_{j=1}^{n} (s_{ij} - q_i q_j)^2, \tag{1.2}$$

where s_{ij} denotes the (i,j) entry of S. If $\mathbf{q}_1$ is a dominant eigenvector of S, then the vector $\mathbf{q}^* = (\lambda_1)^{1/2}\mathbf{q}_1/\|\mathbf{q}_1\|_2$ solves (1.1). The converse is also true: Let $\mathbf{q}^*$ solve (1.1), and then $\mathbf{q}^*$ is a dominant eigenvector of S. These observations are easily derived from the symmetric quotients equality that we establish in section 4. Here and henceforth

$$\|\mathbf{q}\|_2 = (\mathbf{q}^T\mathbf{q})^{1/2} = \left(\sum_{j=1}^{n} q_j^2\right)^{1/2}$$

denotes the Euclidean vector norm. Casting the problem of calculating a dominant eigenpair as a minimum norm problem opens the door for effective minimization techniques. For example, minimizing $E(q_1,\ldots,q_n)$ by changing one variable at a time results in a "point relaxation" algorithm that requires about the same computational effort per iteration as the power method but enjoys a faster rate of convergence. See [8] for computational details and numerical experiments.

A similar approach is proposed for calculating a dominant pair of singular vectors of a real $m \times n$ matrix A. In this case we consider the minimum norm problem

$$\text{minimize } F(\mathbf{u},\mathbf{v}) = \|A - \mathbf{u}\mathbf{v}^T\|_F^2, \tag{1.3}$$

where $\mathbf{u} = (u_1, u_2, \ldots, u_m)^T \in \mathbb{R}^m$ and $\mathbf{v} = (v_1, v_2, \ldots, v_n)^T \in \mathbb{R}^n$ denote the vectors of unknowns. An alternative way to write (1.3) is

$$\text{minimize } F(u_1,\ldots,u_m,v_1,\ldots,v_n) = \sum_{i=1}^{m}\sum_{j=1}^{n}(a_{ij} - u_i v_j)^2, \tag{1.4}$$

where a_{ij} denotes the (i,j) entry of A. To simplify our notations we make the assumption that $m \geq n$. In this case A has an SVD of the form

$$A = U\Sigma V^T, \tag{1.5}$$

where $U = [\mathbf{u}_1,\ldots,\mathbf{u}_m]$ is an $m \times m$ orthogonal matrix, $V = [\mathbf{v}_1,\ldots,\mathbf{v}_n]$ is an $n \times n$ orthogonal matrix, and $\Sigma = \text{diag}\{\sigma_1,\ldots,\sigma_n\}$ is an $m \times n$ diagonal matrix. There is no loss of generality in assuming that the singular values are nonnegative and sorted to satisfy

$$\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_n \geq 0.$$

The columns of U are called left singular vectors, while the columns of V are called right singular vectors. A pair of nonzero vectors that satisfy

$$\|\hat{\mathbf{u}}\|_2 = 1, \quad \|\hat{\mathbf{v}}\|_2 = 1, \quad A\hat{\mathbf{v}} = \sigma_1\hat{\mathbf{u}}, \quad \text{and} \quad A^T\hat{\mathbf{u}} = \sigma_1\hat{\mathbf{v}}$$

is called a dominant singular pair. In this case the vectors $\mathbf{u}^* = (\sigma_1)^{1/2}\hat{\mathbf{u}}$ and $\mathbf{v}^* = (\sigma_1)^{1/2}\hat{\mathbf{v}}$ solve (1.3). The converse claim is also true: If the vectors $\mathbf{u}^*$ and $\mathbf{v}^*$ solve (1.3), then $\hat{\mathbf{u}} = \mathbf{u}^*/\|\mathbf{u}^*\|_2$ and $\hat{\mathbf{v}} = \mathbf{v}^*/\|\mathbf{v}^*\|_2$ form a dominant singular pair with $\sigma_1 = \hat{\mathbf{u}}^T A\hat{\mathbf{v}}$. These observations are a corollary of the well-known Eckart–Young theorem, e.g., [3] or [11]. (The last theorem is also called the Schmidt–Mirsky theorem, e.g., [28].) The rectangular quotient equality that we establish in section 5 provides an alternative way to conclude these observations.

Recall that (1.5) implies the equality

$$A = \sum_{j=1}^{n} \sigma_j \mathbf{u}_j \mathbf{v}_j^T, \tag{1.6}$$

while a partial sum of the form

$$B_\ell = \sum_{j=1}^{\ell} \sigma_j \mathbf{u}_j \mathbf{v}_j^T \tag{1.7}$$

is called a low-rank approximation of order ℓ (also called truncated SVD). The orthogonal decomposition proposed in this paper has similar structure and may replace the SVD in many applications. It is especially attractive in cases when standard SVD algorithms are not applicable.

The paper is divided into two parts. The first one concentrates on symmetric positive semidefinite matrices. The second part extends the results to general $m \times n$ matrices. This helps to see the motivation behind the proposed methods and the close links between the two cases. The plan of the paper is as follows. It starts with a brief overview of the power method and its basic features. By using deflation by subtraction the power method is harnessed to yield a complete eigensystem of S. The modified deflation scheme proposed in section 3 is essentially an orthogonalization process that has important advantages over the classical deflation by subtraction process.

The second part of the paper starts by extending the Rayleigh quotient to real $m \times n$ matrices. Given two vectors $\mathbf{u} \in \mathbb{R}^m$ and $\mathbf{v} \in \mathbb{R}^n$, the [illegible]

$$\rho(\mathbf{u}, \mathbf{v}) = \mathbf{u}^T A \mathbf{v} / (\|\mathbf{u}\|_2 \|\mathbf{v}\|_2) \tag{1.8}$$

estimates the corresponding singular value of A. The [illegible], which is proved in section 5, connects the minimum norm problem (1.3) with $\rho(\mathbf{u}, \mathbf{v})$, showing that minimizing $\|A - \mathbf{u}\mathbf{v}^T\|_F$ is equivalent to maximizing $\rho(\mathbf{u}, \mathbf{v})$. The [illegible] that we propose solve this problem in an effective way. The new orthogonalization process is introduced in section 8. An advantage of the proposed approach is its ability to handle problems in which some entries of A are missing. This issue is briefly discussed in section 9.

2. The power method and deflation by subtraction. As before, S denotes a symmetric positive semidefinite matrix of order n with eigenvalues

$$\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_n \geq 0.$$

Let $\mathbf{q}_1, \mathbf{q}_2, \ldots \mathbf{q}_n$ denote the corresponding system of orthonormal eigenvectors. That is, $\|\mathbf{q}_j\|_2 = 1$ and $S\mathbf{q}_j = \lambda_j \mathbf{q}_j$ for $j = 1, \ldots, n$, and $\mathbf{q}_i^T \mathbf{q}_j = 0$ when $i \neq j$. The power method is an iterative algorithm for computing a dominant eigenpair of S. The deflation by subtraction process enables us to harness the power method for calculating the other eigenpairs of S. In this section we briefly overview the basic features of these methods.

2.1. The power method. Starting with some initial unit vector $\mathbf{p}_0$, the kth iteration $k = 1, 2, \ldots$ is composed of the following three steps:

1. Compute $\mathbf{w}_k = S\mathbf{p}_{k-1}$.
2. Compute $\rho_k = \mathbf{p}_{k-1}^T \mathbf{w}_k$.
3. Compute $\mathbf{p}_k = \mathbf{w}_k / \|\mathbf{w}_k\|_2$.

The definition of $\mathbf{p}_k$ implies the equality

$$\mathbf{p}_k = S^k\mathbf{p}_0/\|S^k\mathbf{p}_0\|_2,$$

while the starting vector has a unique presentation in the form

$$\mathbf{p}_0 = \alpha_1\mathbf{q}_1 + \alpha_2\mathbf{q}_2 + \cdots + \alpha_n\mathbf{q}_n,$$

where $\alpha_1, \ldots, \alpha_n$ are real numbers. So

$$S^k\mathbf{p}_0 = \alpha_1\lambda_1^k\mathbf{q}_1 + \alpha_2\lambda_2^k\mathbf{q}_2 + \cdots + \alpha_n\lambda_n^k\mathbf{q}_n.$$

Thus, when $\alpha_1 \neq 0$ and $\lambda_1 > \lambda_2$, the sequence $\{\mathbf{p}_k\}$ converges toward $\mathbf{q}_1$ at a linear rate proportional to the ratio λ_2/λ_1. The definition of ρ_k implies the relations

$$\begin{aligned}\rho_{k+1} &= \mathbf{p}_k^T S\mathbf{p}_k = (S^k\mathbf{p}_0)^T S(S^k\mathbf{p}_0)/(S^k\mathbf{p}_0)^T S^k\mathbf{p}_0 \\ &= \left(\sum_{j=1}^n \alpha_j^2\lambda_j^{2k+1}\right)\Bigg/\left(\sum_{j=1}^n \alpha_j^2\lambda_j^{2k}\right) \\ &= \lambda_1\left(\sum_{j=1}^n \alpha_j^2\beta_j^{2k+1}\right)\Bigg/\left(\sum_{j=1}^n \alpha_j^2\beta_j^{2k}\right),\end{aligned}$$

where $\beta_j = \lambda_j/\lambda_1$, $j = 1, \ldots, n$. The last equality shows that

$$0 \leq \rho_k \leq \lambda_1 \quad \text{for } k = 1, 2, \ldots .$$

It is also easy to verify that

$$\lambda_1 - \rho_{k+1} \leq (\lambda_2/\lambda_1)^2(\lambda_1 - \rho_k) \tag{2.1}$$

and

$$0 \leq \rho_1 \leq \rho_2 \leq \cdots \leq \rho_k \leq \rho_{k+1} \leq \cdots \leq \lambda_1. \tag{2.2}$$

So the sequence $\{\rho_k\}$ converges monotonously toward λ_1 at a linear rate proportional to $(\lambda_2/\lambda_1)^2$.

Of course, if λ_j is considerably smaller than λ_2, then the jth component of $\mathbf{p}_k$ vanishes at a much faster rate. Therefore, when a large portion of $\mathbf{p}_0$ is related to "small" eigenvalues, the initial rate of convergence is much faster than the asymptotic rate, which depends on the ratio λ_2/λ_1. More precisely, assume for a moment that α_1 is not too small and that λ_j is a small eigenvalue that satisfies $\lambda_j/\lambda_1 \leq 1/2$. In this case the size of the product $\mathbf{q}_j^T\mathbf{p}_k$ is, at least, halved every iteration. Thus, unless $|\mathbf{q}_j^T\mathbf{p}_0|$ is much larger than $|\mathbf{q}_1^T\mathbf{p}_0|$, the product $\mathbf{q}_j^T\mathbf{p}_k$ actually vanishes after a small number of iterations. In other words, unless $\mathbf{p}_0$ is nearly perpendicular to $\mathbf{q}_1$, a few power iterations are likely to wipe out components of small eigenvectors, turning $\mathbf{p}_k$ into a linear combination of "large" eigenvectors. Consequently ρ_k provides a good estimate of λ_1 within a small number of iterations. This feature is illustrated in Table 2.1 for various distributions of eigenvalues. The test problems are defined with $\lambda_1 = 1$ and $\alpha_j = 1/\sqrt{n}$, $j = 1, \ldots, n$. The figures in Table 2.1 give the values of $\rho_5, \rho_{10}, \rho_{20}$, and ρ_{40}, rounded to four decimals. Thus, for example, the second row of Table 2.1 considers the case when $n = 200$ and $\lambda_j = (201 - j)/200$, $j = 1, \ldots, 200$. In this

TABLE 2.1
Initial rates of convergence of the power method.

Matrix $\lambda_1 = 1$, $\lambda_j,\ j = 2, \ldots, n$	n	Values of ρ_k $k = 5$	$k = 10$	$k = 20$	$k = 40$
$\lambda_j = (n+1-j)/n$	20	0.9375	0.9744	0.9929	0.9922
$\lambda_j = (n+1-j)/n$	200	0.9189	0.9569	0.9786	0.9901
$\lambda_j = (1/2)^{j-1}$	20	0.9995	>0.9999	>0.9999	>0.9999
$\lambda_j = (1/2)^{j-1}$	200	0.9995	>0.9999	>0.9999	>0.9999
$\lambda_j = (1/\sqrt{2})^{j-1}$	20	0.9906	0.9997	>0.9999	>0.9999
$\lambda_j = (1/\sqrt{2})^{j-1}$	200	0.9906	0.9997	>0.9999	>0.9999
$\lambda_j = (0.9)^{j-1}$	20	0.9492	0.9863	0.9985	>0.9999
$\lambda_j = (0.9)^{j-1}$	200	0.9492	0.9863	0.9985	>0.9999
$\lambda_j = (0.99)^{j-1}$	20	0.9393	0.9602	0.9802	0.9920
$\lambda_j = (0.99)^{j-1}$	200	0.9136	0.9570	0.9802	0.9920
$\lambda_j = (0.999)^{j-1}$	20	0.9909	0.9912	0.9919	0.9931
$\lambda_j = (0.999)^{j-1}$	200	0.9353	0.9561	0.9762	0.9881
Random λ_j	20	0.9528	0.9722	0.9829	0.9934
Random λ_j	200	0.9256	0.9630	0.9814	0.9903

case the ratio $\lambda_2/\lambda_1 = 0.995$ dictates a slow asymptotic rate of convergence. Yet the resulting values of ρ_k are $\rho_5 = 0.9189,\ \rho_{10} = 0.9569,\ \rho_{20} = 0.9786$, and $\rho_{40} = 0.9901$. That is, ρ_k provides a fair estimate of $\lambda_1 = 1$ after a small number of iterations, in spite of slow asymptotic convergence. For a detailed discussion of this feature see [21].

Although the power method is well known, the question of how to choose the starting point $\mathbf{p}_0$ has no definite answer, especially when no approximation to $\mathbf{q}_1$ is available. In such a case taking $\mathbf{p}_0$ to be a random vector is a reasonable option, e.g., [10], [27], or [29]. The stopping condition can be based on the error bound (4.7).

2.2. Deflating by subtraction. This method is based on the following idea. Consider the spectral decomposition

$$S = \sum_{j=1}^{n} \lambda_j \mathbf{q}_j \mathbf{q}_j^T, \tag{2.3}$$

and let the matrices $S_1, S_2, \ldots, S_n$, be defined by the rule: $S_1 = S$ and

$$S_{\ell+1} = S_\ell - \lambda_\ell \mathbf{q}_\ell \mathbf{q}_\ell^T, \qquad \ell = 1, \ldots, n-1.$$

Then $S_\ell,\ \ell = 1, \ldots, n$, is a symmetric positive semidefinite matrix whose largest eigenvalue is λ_ℓ. The power method enables us to compute a dominant eigenpair of S_ℓ and to construct $S_{\ell+1}$. This way the eigenpairs of S are computed one after another in decreasing order. The practical implementation of this idea is carried out as follows. The deflation process is composed of (at most) n stages. The ℓth stage, $\ell = 1, \ldots, n$, starts with a matrix $\tilde{S}_\ell$ and ends with $\tilde{S}_{\ell+1}$. (The matrix $\tilde{S}_\ell$ denotes a computed estimate of S_ℓ.) At the ℓth deflation stage the power method is applied to the matrix $\tilde{S}_\ell$ to provide an estimated dominant eigenpair of $\tilde{S}_\ell$. (The starting point and the number of iterations can be arbitrary.) Let $\tilde{\lambda}_\ell$ and $\tilde{\mathbf{q}}_\ell,\ \|\tilde{\mathbf{q}}_\ell\|_2 = 1$, denote the computed eigenpair. Then $\tilde{S}_{\ell+1}$ is constructed by the rule

$$\tilde{S}_{\ell+1} = \tilde{S}_\ell - \tilde{\lambda}_\ell \tilde{\mathbf{q}}_\ell \tilde{\mathbf{q}}_\ell^T. \tag{2.4}$$

The idea of deflation by subtraction is often attributed to Hotelling [16], [17]. For further discussions of this method see [26] and [32]. Parlett [26, p. 82] gives a detailed error analysis that quantifies the change in distant eigenvalues caused by the error in the computed dominant eigenpair.

3. Orthogonalization via deflation: The symmetric case. By starting with $\hat{S}_1 = S$, the new deflation by subtraction process constructs a sequence of symmetric matrices, $\hat{S}_1, \hat{S}_2, \ldots, \hat{S}_\ell, \hat{S}_{\ell+1} \ldots$, where $\hat{S}_{\ell+1}$ is obtained from $\hat{S}_\ell$ in the following way. If $\hat{S}_\ell = 0$, the algorithm terminates. Otherwise, we choose a unit vector $\hat{\mathbf{q}}_\ell$ such that

$$\|\hat{\mathbf{q}}_\ell\|_2 = 1 \qquad \text{and} \qquad \hat{\mathbf{q}}_\ell \in \text{Range}(\hat{S}_\ell) \tag{3.1}$$

and define

$$\hat{S}_{\ell+1} = \hat{S}_\ell - (\hat{S}_\ell \hat{\mathbf{q}}_\ell)(\hat{S}_\ell \hat{\mathbf{q}}_\ell)^T / \hat{\mathbf{q}}_\ell^T \hat{S}_\ell \hat{\mathbf{q}}_\ell. \tag{3.2}$$

An alternative way to write (3.2) is

$$\hat{S}_{\ell+1} = \hat{S}_\ell - \mu_\ell \mathbf{u}_\ell \mathbf{u}_\ell^T, \tag{3.3}$$

where

$$\mathbf{u}_\ell = \hat{S}_\ell \hat{\mathbf{q}}_\ell / \|\hat{S}_\ell \hat{\mathbf{q}}_\ell\|_2 \quad \text{and} \quad \mu_\ell = \hat{\mathbf{q}}_\ell^T \hat{S}_\ell^2 \hat{\mathbf{q}}_\ell / \hat{\mathbf{q}}_\ell^T \hat{S}_\ell \hat{\mathbf{q}}_\ell. \tag{3.4}$$

THEOREM 1. [illegible] $\hat{Q}_\ell = [\hat{\mathbf{q}}_1, \ldots, \hat{\mathbf{q}}_\ell]$ [illegible] $n \times \ell$ [illegible] $\hat{\mathbf{q}}_1, \ldots, \hat{\mathbf{q}}_\ell$ [illegible] r [illegible] S [illegible] $\ell = 1, 2, \ldots, r$

$$\hat{Q}_\ell^T \hat{Q}_\ell = I, \quad \hat{S}_{\ell+1} \hat{Q}_\ell = 0, \quad \text{and} \quad \text{Range}(\hat{Q}_\ell) \subseteq \text{Range}(S). \tag{3.5}$$

[illegible] $\ell = r$ [illegible] $\hat{Q}_r$ [illegible] Range(S),

$$\hat{S}_{r+1} = 0 \tag{3.6}$$

[illegible]

$$S = \sum_{\ell=1}^{r} \mu_\ell \mathbf{u}_\ell \mathbf{u}_\ell^T = U_r D_r U_r^T, \tag{3.7}$$

[illegible]

$$U_r = [\mathbf{u}_1, \ldots, \mathbf{u}_r] \quad \text{and} \quad D_r = \text{diag}\{\mu_1, \ldots, \mu_r\}.$$

[illegible]. The proof of (3.5) is by induction on ℓ. For $\ell = 1$ the relations in (3.5) follow from the definitions of $\hat{\mathbf{q}}_1$ and $\hat{S}_2$. Assume now that (3.5) holds for $\ell - 1$. That is, $\hat{Q}_{\ell-1}^T \hat{Q}_{\ell-1} = I$, $\hat{S}_\ell \hat{Q}_{\ell-1} = 0$, and Range$(\hat{Q}_{\ell-1}) \subseteq$ Range(S). Assume further that $\hat{\mathbf{q}}_\ell$ and $\hat{S}_{\ell+1}$ satisfy (3.1) and (3.2). Then, clearly, $\hat{S}_{\ell+1} \hat{\mathbf{q}}_\ell = \mathbf{0}$ and $\hat{Q}_\ell^T S_{\ell+1} = 0$. Similarly, from $\hat{Q}_{\ell-1} \hat{S}_\ell = 0$ and (3.1) we conclude that $\hat{Q}_\ell^T \hat{Q}_\ell = I$. Finally, since $\hat{\mathbf{q}}_\ell \in$ Range(S) and Range$(\hat{Q}_{\ell-1}) \subseteq$ Range(S), it follows that Range$(\hat{Q}_\ell) \subseteq$ Range(S). □

At the end of the ℓth deflation step we are able to construct two low-rank approximations of S:

$$B_\ell = U_\ell D_\ell U_\ell^T = \sum_{j=1}^{\ell} \mu_j \mathbf{u}_j \mathbf{u}_j^T \tag{3.8}$$

and

$$\hat{B}_\ell = \hat{Q}_\ell \hat{D}_\ell \hat{Q}_\ell^T = \sum_{j=1}^{\ell} \hat{\rho}_j \hat{\mathbf{q}}_j \hat{\mathbf{q}}_j^T, \tag{3.9}$$

where

$$\hat{D}_\ell = \mathrm{diag}\{\hat{\rho}_1, \ldots, \hat{\rho}_\ell\}$$

and $\hat{\rho}_j$ denotes the Rayleigh quotient corresponding to $\hat{\mathbf{q}}_j$. That is,

$$\hat{\rho}_j = \hat{\mathbf{q}}_j S \hat{\mathbf{q}}_j.$$

It is interesting to compare these approximations and the corresponding Hotelling low-rank approximation

$$\tilde{B}_\ell = \tilde{Q}_\ell \tilde{D}_\ell \tilde{Q}_\ell^T = \sum_{j=1}^{\ell} \tilde{\lambda}_j \, \tilde{\mathbf{q}}_j \, \tilde{\mathbf{q}}_j^T. \tag{3.10}$$

Our experience shows that, if both schemes use the same number of power iterations at each deflation step, the differences between $\|S - \tilde{B}_\ell\|_F$, $\|S - B_\ell\|_F$, and $\|S - \hat{B}_\ell\|_F$ remain negligible until $\ell = r$. Yet the new deflation process enjoys important advantages. First, the "finite termination" property (3.6) and the "exactness" property (3.7) provide an effective "rank-revealing" decomposition. Second, the orthogonality of $\hat{Q}_\ell$ and the resulting orthogonal decomposition (3.9) are useful in many applications. Perhaps the more striking feature of the new deflation process is that these properties hold regardless of the quality of $\hat{\mathbf{q}}_\ell$ as a substitute for a dominant eigenvector of $\hat{S}_\ell$. Thus, for example, when $\hat{\mathbf{q}}_\ell$ is computed by applying the power method to $\hat{S}_\ell$, the number of iterations does not effect these properties. Moreover, as we have seen, a few power iterations per eigenpair are sufficient to produce a meaningful estimate of the spectral decomposition. Indeed, preliminary experiments that we have done support this view; see [8].

Let us turn now to see how rounding errors affect the new deflation process. Assume for simplicity that $\mathbf{u}_\ell$ and μ_ℓ provide a fair estimate of a dominant eigenpair of $\hat{S}_\ell$, $\ell = 1, \ldots, r$. Then, on one hand, the size of $\|\hat{S}_{\ell+1}\|_F$ is expected to be about $\lambda_{\ell+1} + \cdots + \lambda_n$. On the other hand, in floating point arithmetic the ℓth deflation step (3.3) adds rounding errors into the entries of $\hat{S}_{\ell+1}$. The size of the resulting error matrix is about the size of the matrix $\varepsilon \mu_\ell \mathbf{u}_\ell \mathbf{u}_\ell^T$, where ε denotes the machine precision (or unit roundoff) in our computations. Hence the overall rounding errors in the entries of $\hat{S}_{\ell+1}$ constitute an error matrix $E_{\ell+1}$, whose Frobenius norm is about $\varepsilon(\lambda_1 + \cdots + \lambda_\ell)$. That is,

$$\|E_{\ell+1}\|_F / \|\hat{S}_{\ell+1}\|_F \approx \varepsilon(\lambda_1 + \cdots + \lambda_\ell)/(\lambda_{\ell+1} + \cdots + \lambda_n). \tag{3.11}$$

This exposes a certain deficiency of the deflation by subtraction approach. If S is an ill-conditioned matrix, then small eigenvalues are computed with a large relative error. The smaller the ratio $\lambda_{\ell+1}/(\lambda_1 + \cdots + \lambda_\ell)$, the larger the relative error in the computed

value of $\lambda_{\ell+1}$. A similar remark applies to the relative error in a computed dominant eigenvector of $\hat{S}_{\ell+1}$.

Another feature that characterizes ill-conditioned matrices is the gradual loss of orthogonality in the columns of $\hat{Q}_\ell$. Observe that every column of the rounding errors matrix $E_{\ell+1}$ is expected to have a component in Range($\hat{Q}_\ell$) whose size is not much smaller than the column's size. Thus, as the ratio (3.11) becomes meaningful, the columns of $\hat{S}_{\ell+1}$ lose their orthogonality against the columns of $\hat{Q}_\ell$. Hence the fact that $\hat{\mathbf{q}}_{\ell+1}$ belongs to Range($\hat{S}_{\ell+1}$) is not sufficient to ensure its orthogonality against the columns of $\hat{Q}_\ell$.

This loss of orthogonality is easily recovered by replacing (3.1) with the following modification. Let $\mathbf{z}_1$ be a unit vector that belongs to Range($\hat{S}_\ell$). (Here $\mathbf{z}_1$ denotes our estimate to a dominant eigenvector of $\hat{S}_\ell$.) Then $\mathbf{z}_1$ is orthogonalized against $\hat{\mathbf{q}}_1, \ldots, \hat{\mathbf{q}}_{\ell-1}$, by using Gram–Schmidt orthogonalization. This way, one generates a sequence of ℓ vectors, $\mathbf{z}_1, \ldots, \mathbf{z}_\ell$, where $\mathbf{z}_{i+1}$ is obtained from $\mathbf{z}_i$ by the rule

$$\mathbf{z}_{i+1} = \mathbf{z}_i - (\mathbf{z}_i^T \hat{\mathbf{q}}_i)\hat{\mathbf{q}}_i, \quad i = 1, \ldots, \ell - 1. \tag{3.12}$$

In practice $\mathbf{z}_{i+1}$ is overwritten on $\mathbf{z}_i$, so only one vector storage is needed for this process. Once the orthogonalization process is finished, the vector $\hat{\mathbf{q}}_\ell$ which is used in (3.1) is redefined as

$$\hat{\mathbf{q}}_\ell = \mathbf{z}_\ell / \|\mathbf{z}_\ell\|_2. \tag{3.13}$$

(If $\|\mathbf{z}_\ell\|_2$ is smaller than $\|\mathbf{z}_1\|_2/2$, say, then $\mathbf{z}_\ell$ is reorthogonalized against the columns of $\hat{Q}_{\ell-1}$. However, as we have seen, a small number of power iterations is likely to provide a fair estimate of a dominant vector of $\hat{S}_\ell$. In this case $\|\mathbf{z}_\ell\|_2$ is not expected to be much smaller than $\|\mathbf{z}_1\|_2$, so reorthogonalization is seldom needed.)

Summarizing the above discussion we stress that rounding errors cause only tiny perturbations to the eigenvalues of $\hat{S}_{\ell+1}$, as every eigenvalue of $\hat{S}_{\ell+1}$ lies in at least one of the circular discs

$$\{\lambda \,|\, |\hat{\lambda}_i - \lambda| \le \|E_{\ell+1}\|_2\}, \qquad i = 1, \ldots, n, \tag{3.14}$$

where $\hat{\lambda}_1, \ldots, \hat{\lambda}_n$ denote the eigenvalues of $\hat{S}_{\ell+1} - E_{\ell+1}$ and

$$\|E_{\ell+1}\|_2 \le \|E_{\ell+1}\|_F \approx \varepsilon(\lambda_1 + \cdots + \lambda_\ell).$$

Note also that $\|S - U_r D_r U_r^T\|_F$ is not expected to be much larger than $\varepsilon(\lambda_1 + \cdots + \lambda_r)$. Hence the resulting decompositions (3.8) and (3.9) provide valuable information on S, unless one is interested in tiny eigenvalues and their eigenvectors.

4. Symmetric quotients. In this section we introduce a new quantity (the symmetric quotient) and derive its basic features. Let $\mathbf{u} \neq \mathbf{0}$ be a given vector in $\mathbb{R}^n$, and consider the one-parameter function

$$f(\theta) = \|S - \theta \mathbf{u}\mathbf{u}^T\|_F^2. \tag{4.1}$$

Then the [illegible]

$$\gamma = \gamma(\mathbf{u}) = \mathbf{u}^T S \mathbf{u} / (\mathbf{u}^T \mathbf{u})^2 \tag{4.2}$$

provides the value of θ which minimizes $f(\theta)$. That is,

$$\gamma = \arg\min f(\theta). \tag{4.3}$$

The validity of (4.3) is easily verified by rewriting $f(\theta)$ in the form

$$f(\theta) = \|\theta\mathbf{y} - \mathbf{z}\|_2^2,$$

where $\mathbf{y}$ and $\mathbf{z}$ are n^2 vectors. This presentation implies that

$$\arg\min f(\theta) = \mathbf{y}^T\mathbf{z}/\mathbf{y}^T\mathbf{y}.$$

Hence the equalities

$$\mathbf{y}^T\mathbf{z} = \sum_{i=1}^{n}\sum_{j=1}^{n} u_i u_j s_{ij} = \mathbf{u}^T S\mathbf{u}$$

and

$$\mathbf{y}^T\mathbf{y} = \sum_{i=1}^{n}\sum_{j=1}^{n}(u_i u_j)^2 = \|\mathbf{u}\mathbf{u}^T\|_F^2 = (\mathbf{u}^T\mathbf{u})^2$$

prove (4.3).

At this point it is instructive to compare the symmetric quotient with the corresponding [illegible]

$$\rho = \rho(\mathbf{u}) = \mathbf{u}^T S\mathbf{u}/\mathbf{u}^T\mathbf{u}. \tag{4.4}$$

Recall that

$$\rho = \arg\min g(\theta), \tag{4.5}$$

where

$$g(\theta) = \|S\mathbf{u} - \theta\mathbf{u}\|_2^2. \tag{4.6}$$

Another useful feature of $\rho(\mathbf{u})$ is the existence of an eigenvalue λ of S that satisfies the bound

$$|\lambda - \rho(\mathbf{u})| \le \|S\mathbf{u} - \rho(\mathbf{u})\mathbf{u}\|_2/\|\mathbf{u}\|_2; \tag{4.7}$$

see [26, p. 69]. Thus, roughly speaking, $\rho(\mathbf{u})$ approximates the eigenvalue corresponding to $\mathbf{u}$. For a detailed discussion of the Rayleigh quotient and its properties, see [10], [25], [26], [29], [32].

Scaling of $\mathbf{u}$ affects $\rho(\mathbf{u})$ and $\gamma(\mathbf{u})$ in different ways. Let $\alpha \neq 0$ be a given scalar. Then

$$\rho(\alpha\mathbf{u}) = \rho(\mathbf{u}),$$

but

$$\gamma(\alpha\mathbf{u}) = \gamma(\mathbf{u})/\alpha^2.$$

Moreover, define $\mathbf{v} = \alpha\mathbf{u}$, and then

$$\|S - \gamma(\mathbf{v})\mathbf{v}\mathbf{v}^T\|_F^2 = \|S - \gamma(\mathbf{u})\mathbf{u}\mathbf{u}^T\|_F^2.$$

The basic relation that connects $\gamma(\mathbf{u})$ and $\rho(\mathbf{u})$ is the [illegible]

$$\|S - \gamma(\mathbf{u})\mathbf{u}\mathbf{u}^T\|_F^2 = \|S\|_F^2 - (\rho(\mathbf{u}))^2. \tag{4.8}$$

As we have seen, scaling of $\mathbf{u}$ does not affect this equality. Hence, when proving (4.8) there is no loss of generality in assuming that $\|\mathbf{u}\|_2 = 1$. In this case $\gamma = \rho = \mathbf{u}^T S\mathbf{u}$, $\|\mathbf{u}\mathbf{u}^T\|_F = 1$, and

$$\begin{aligned}
\|S - \gamma\mathbf{u}\mathbf{u}^T\|_F^2 &= \|S - \rho\mathbf{u}\mathbf{u}^T\|_F^2 = \sum_{i=1}^{n}\sum_{j=1}^{n}(s_{ij} - \rho u_i u_j)^2 \\
&= \sum_{i=1}^{n}\sum_{j=1}^{n}\left[s_{ij}^2 - 2\rho s_{ij}u_i u_j + \rho^2(u_i u_j)^2\right] \\
&= \|S\|_F^2 - 2\rho\mathbf{u}^T S\mathbf{u} + \rho^2\|\mathbf{u}\mathbf{u}^T\|_F^2 \\
&= \|S\|_F^2 - 2\rho^2 + \rho^2 = \|S\|_F^2 - \rho^2.
\end{aligned}$$

The meaning of the symmetric quotient equality (4.8) is that solving the minimum norm problem (1.1) is equivalent to solving the problem

$$\text{maximize } \rho(\mathbf{u}) = \mathbf{u}^T S\mathbf{u}/\mathbf{u}^T\mathbf{u}. \tag{4.9}$$

By using the spectral decomposition (2.3) one can show that a point $\mathbf{u}^* \in \mathbb{R}^n$ solves (4.9) if and only if $\mathbf{u}^*$ is a dominant eigenvector of S, so the optimal value of $\rho(\mathbf{u})$ is $\rho(\mathbf{u}^*) = \lambda_1$. The proof of this claim is outlined at the end of the next section, in which we establish similar results for rectangular matrices. Further extensions of the symmetric quotients equality are derived in [9].

5. Rectangular quotients. In this section we consider the rectangular minimum norm problem (1.3), by using the notations of section 1. We shall start by introducing a new useful quantity, the [illegible]. Given two nonzero vectors $\mathbf{u} = (u_1, \ldots, u_m)^T \in \mathbb{R}^m$ and $\mathbf{v} = (v_1, \ldots, v_n)^T \in \mathbb{R}^n$, the rectangular quotient

$$\eta = \eta(\mathbf{u}, \mathbf{v}) = \mathbf{u}^T A\mathbf{v}/(\|\mathbf{u}\|_2^2\ \|\mathbf{v}\|_2^2) \tag{5.1}$$

solves the one-parameter minimization problem

$$\text{minimize } f(\theta) = \|A - \theta\mathbf{u}\mathbf{v}^T\|_F^2. \tag{5.2}$$

That is,

$$\eta = \arg\min f(\theta). \tag{5.3}$$

To prove the last statement we rewrite (5.2) in the form

$$\text{minimize } f(\theta) = \|\mathbf{a} - \theta\mathbf{w}\|_2^2, \tag{5.4}$$

where here $\mathbf{a}$ and $\mathbf{w}$ are mn-vectors. The last problem has a unique solution at the point

$$\theta^* = \mathbf{w}^T\mathbf{a}/\mathbf{w}^T\mathbf{w}.$$

Hence the equalities

$$\mathbf{w}^T\mathbf{a} = \sum_{i=1}^{m}\sum_{j=1}^{n} u_i v_j a_{ij} = \mathbf{u}^T A\mathbf{v}$$

and

$$\mathbf{w}^T\mathbf{w} = \sum_{i=1}^{m}\sum_{j=1}^{n}(u_i v_j)^2 = \|\mathbf{u}\mathbf{v}^T\|_F^2 = \|\mathbf{u}\|_2^2\,\|\mathbf{v}\|_2^2$$

prove (5.3).

Observe that the rectangular quotient $\eta(\mathbf{u},\mathbf{v})$ does not necessarily provide an estimate of the singular value that "corresponds" to $\mathbf{u}$ and $\mathbf{v}$. For that purpose we introduce another quantity, the [illegible]. Let the unit vectors $\hat{\mathbf{u}} = \mathbf{u}/\|\mathbf{u}\|_2$ and $\hat{\mathbf{v}} = \mathbf{v}/\|\mathbf{v}\|_2$ be obtained from $\mathbf{u}$ and $\mathbf{v}$, respectively. Then the following three problems:

$$\text{minimize} \quad f_1(\theta) = \|A - \theta\hat{\mathbf{u}}\hat{\mathbf{v}}^T\|_F^2, \tag{5.5}$$

$$\text{minimize} \quad f_2(\theta) = \|A\hat{\mathbf{v}} - \theta\hat{\mathbf{u}}\|_2^2, \tag{5.6}$$

$$\text{minimize} \quad f_3(\theta) = \|A^T\hat{\mathbf{u}} - \theta\hat{\mathbf{v}}\|_2^2, \tag{5.7}$$

share the same solution

$$\hat{\theta} = \hat{\mathbf{u}}^T A\hat{\mathbf{v}} = \mathbf{u}^T A\mathbf{v}/(\|\mathbf{u}\|_2\,\|\mathbf{v}\|_2). \tag{5.8}$$

This observation suggests that the [illegible]

$$\rho = \rho(\mathbf{u},\mathbf{v}) = \mathbf{u}^T A\mathbf{v}/(\|\mathbf{u}\|_2\,\|\mathbf{v}\|_2) \tag{5.9}$$

approximates the singular value of A that corresponds to $\mathbf{u}$ and $\mathbf{v}$.

Let us turn now to see how scaling affects rectangular quotients. Let $\alpha > 0$ and $\beta > 0$ be two positive real numbers. Then

$$\begin{aligned}\rho(\alpha\mathbf{u},\beta\mathbf{v}) &= \rho(\mathbf{u},\mathbf{v}),\\ \eta(\alpha\mathbf{u},\beta\mathbf{v}) &= \eta(\mathbf{u},\mathbf{v})/(\alpha\beta),\end{aligned}$$

and

$$\|A - \eta(\alpha\mathbf{u},\beta\mathbf{v})(\alpha\mathbf{u})(\beta\mathbf{v}^T)\|_F^2 = \|A - \eta(\mathbf{u},\mathbf{v})\mathbf{u}\mathbf{v}^T\|_F^2.$$

The basic feature that connects between $\eta(\mathbf{u},\mathbf{v})$ and $\rho(\mathbf{u},\mathbf{v})$ is the [illegible]

$$\|A - \eta(\mathbf{u},\mathbf{v})\mathbf{u}\mathbf{v}^T\|_F^2 = \|A\|_F^2 - \Big(\rho(\mathbf{u},\mathbf{v})\Big)^2. \tag{5.10}$$

Since scaling of $\mathbf{u}$ and $\mathbf{v}$ does not affect this equality, there is no loss of generality in assuming that $\|\mathbf{u}\|_2 = 1$ and $\|\mathbf{v}\|_2 = 1$. In this case

$$\begin{aligned}\eta = \rho &= \mathbf{u}^T A\mathbf{v},\\ \|\mathbf{u}\mathbf{v}^T\|_F &= 1,\end{aligned}$$

and

$$\begin{aligned}\|A - \eta\mathbf{u}\mathbf{v}^T\|_F^2 &= \|A - \rho\mathbf{u}\mathbf{v}^T\|_F^2 = \sum_{i=1}^{m}\sum_{j=1}^{n}(a_{ij} - \rho u_i v_j)^2\\ &= \sum_{i=1}^{m}\sum_{j=1}^{n}\Big[a_{ij}^2 - 2\rho a_{ij}u_i v_j + \rho^2(u_i v_j)^2\Big]\\ &= \|A\|_F^2 - 2\rho\mathbf{u}^T A\mathbf{v} + \rho^2\|\mathbf{u}\mathbf{v}^T\|_F^2\\ &= \|A\|_F^2 - 2\rho^2 + \rho^2 = \|A\|_F^2 - \rho^2,\end{aligned}$$

which proves (5.10). The meaning of the rectangular quotient equality is that solving the minimum norm problem (1.3) is equivalent to solving the problem

$$\text{maximize} \quad \rho(\mathbf{u},\mathbf{v}) = \mathbf{u}^T A\mathbf{v}/(\|\mathbf{u}\|_2\,\|\mathbf{v}\|_2). \tag{5.11}$$

An equivalent way to write the last problem is

$$\begin{aligned} &\text{maximize} \quad \sigma(\mathbf{u},\mathbf{v}) = \mathbf{u}^T A\mathbf{v} \\ &\text{subject to} \quad \|\mathbf{u}\|_2 = 1 \quad \text{and} \quad \|\mathbf{v}\|_2 = 1. \end{aligned} \tag{5.12}$$

By using the SVD of A (see (1.5)–(1.6)) the unit vectors in problem (5.12) can be expressed as

$$\mathbf{u} = \tilde{U}\tilde{\mathbf{u}}, \quad \|\tilde{\mathbf{u}}\|_2 \le 1, \quad \mathbf{v} = V\tilde{\mathbf{v}}, \quad \|\tilde{\mathbf{v}}\|_2 = 1, \tag{5.13}$$

where $\tilde{\mathbf{u}} = (\tilde{u}_1,\ldots,\tilde{u}_n)^T$, $\tilde{\mathbf{v}} = (\tilde{v}_1,\ldots,\tilde{v}_n)^T$, and $\tilde{U}$ is composed of the first n columns of U. This way, (5.12) is reduced to the problem

$$\begin{aligned} &\text{maximize} \quad \tilde{\sigma}(\tilde{\mathbf{u}},\tilde{\mathbf{v}}) = \sum_{i=1}^{n} \sigma_i \tilde{u}_i \tilde{v}_i \\ &\text{subject to} \quad \sum_{i=1}^{n} \tilde{u}_i^2 \le 1 \quad \text{and} \quad \sum_{i=1}^{n} \tilde{v}_i^2 = 1, \end{aligned} \tag{5.14}$$

whose solution is obtained at the points $\tilde{\mathbf{u}} = \tilde{\mathbf{v}} = \pm\mathbf{e}_1$. This shows that a pair of unit vectors, say, $\mathbf{u}^*$ and $\mathbf{v}^*$, solves (5.12) if and only if $\mathbf{u}^*$ and $\mathbf{v}^*$ constitute a dominant singular pair, and the corresponding optimal value is

$$\sigma(\mathbf{u}^*,\mathbf{v}^*) = \rho(\mathbf{u}^*,\mathbf{v}^*) = \sigma_1.$$

6. Retrieval of singular vectors. The question discussed in this section is how to retrieve a left singular vector from a right one, and vice versa. The aim of this note is to point out that the ultimate retrieval rule is both a minimization process and an orthogonalization process. This observation motivates the schemes proposed in the next sections. Further benefits of the retrieval rules are the error bounds derived at the end of this section.

Assume for a moment that $\mathbf{v}$ is a right singular vector of A that satisfies $A\mathbf{v} \neq \mathbf{0}$ and $\|\mathbf{v}\|_2 = 1$. Then the corresponding left singular vector $\mathbf{u}$ satisfies $A\mathbf{v} = \sigma\mathbf{u}$ and $\|\mathbf{u}\|_2 = 1$, where $\sigma > 0$ denotes the corresponding singular value of A. That is,

$$\mathbf{u} = A\mathbf{v}/\|A\mathbf{v}\|_2 \tag{6.1}$$

and

$$\sigma = \|A\mathbf{v}\|_2 = \mathbf{u}^T A\mathbf{v}. \tag{6.2}$$

In the general case $\mathbf{v}$ is just a given estimate for a right singular vector of A that satisfies $A\mathbf{v} \neq \mathbf{0}$. Nevertheless, as we are about to show, the above formulas remain useful for estimating the corresponding left singular vector and the corresponding singular value.

For this purpose we consider the problem

$$\text{minimize}\, F_\ell(\mathbf{u}) = \|A - \mathbf{u}\mathbf{v}^T\|_F^2, \tag{6.3}$$

where $\mathbf{u} = (u_1, \ldots, u_m)^T \in \mathbb{R}^m$ denotes the vector of unknowns. This problem is essentially a linear least squares problem whose solution is obtained by considering one unknown (one row) at a time. Let $\hat{\mathbf{u}} = (\hat{u}_1, \ldots, \hat{u}_m)^T \in \mathbb{R}^m$ denote the unique solution of this problem. Then, clearly,

$$\hat{u}_i = \mathbf{r}_i^T \mathbf{v} / \mathbf{v}^T \mathbf{v} \quad \text{for} \quad i = 1, \ldots, m, \tag{6.4}$$

where $\mathbf{r}_i^T$ denote the ith row of A. In other words,

$$\hat{\mathbf{u}} = A\mathbf{v} / \mathbf{v}^T \mathbf{v}. \tag{6.5}$$

Let $\hat{\mathbf{r}}_i^T$ denote the ith row of the matrix $\hat{A} = A - \hat{\mathbf{u}}\mathbf{v}^T$. Then $\hat{\mathbf{r}}_i^T = \mathbf{r}_i^T - \hat{u}_i \mathbf{v}^T$ is obtained by orthogonalizing $\mathbf{r}_i$ against $\mathbf{v}$. Consequently $\hat{\mathbf{r}}_i^T \mathbf{v} = 0$ and $\hat{A}\mathbf{v} = \mathbf{0}$. Of course, if $\mathbf{v}$ and $\hat{\mathbf{u}}$ are normalized to be unit vectors, then (6.5) coincides with (6.1).

A similar approach enables us to derive a right singular vector from a left one. Assume first that $\mathbf{u}$ is a left singular vector of A that satisfies $A^T\mathbf{u} \neq \mathbf{0}$ and $\|\mathbf{u}\|_2 = 1$. Then the corresponding right singular vector $\mathbf{v}$ and the corresponding singular value σ must satisfy

$$\mathbf{v} = A^T \mathbf{u} / \|A^T \mathbf{u}\|_2 \tag{6.6}$$

and

$$\sigma = \|A^T \mathbf{u}\|_2 = \mathbf{u}^T A \mathbf{v}. \tag{6.7}$$

In the general case, when $\mathbf{u}$ is just an estimate for a left singular vector, the last equalities provide estimates of the corresponding right singular vector $\mathbf{v}$ and the corresponding singular value. To see this point we consider the minimum norm problem

$$\text{minimize} \quad F_r(\mathbf{v}) = \|A - \mathbf{u}\mathbf{v}^T\|_F^2, \tag{6.8}$$

where here $\mathbf{v} = (v_1, \ldots, v_n)^T \in \mathbb{R}^n$ denotes the vector of unknowns. In this case the solution vector

$$\hat{\mathbf{v}} = A^T \mathbf{u} / \mathbf{u}^T \mathbf{u} \tag{6.9}$$

is obtained by orthogonalizing the columns of A against $\mathbf{u}$.

The retrieval formulas enable us to derive simple error bounds that resemble (4.7). Let $\hat{\mathbf{v}} \in \mathbb{R}^n$ be a given unit vector that satisfies $A\hat{\mathbf{v}} \neq \mathbf{0}$, and let

$$\hat{\mathbf{u}} = A\hat{\mathbf{v}} / \|A\hat{\mathbf{v}}\|_2$$

and

$$\hat{\sigma} = \|A\hat{\mathbf{v}}\|_2 = \hat{\mathbf{u}}^T A \hat{\mathbf{v}}$$

provide the corresponding estimates of a left singular vector and a singular value, respectively. Below we derive a bound on the distance between $\hat{\sigma}$ and a singular value of A. Recall that the squares of the singular values of A are the eigenvalues of $A^T A$. Note also that $\hat{\sigma}^2 = \hat{\mathbf{v}}^T A^T A \hat{\mathbf{v}}$ is the symmetric Rayleigh quotient of $A^T A$ related to $\hat{\mathbf{v}}$. Thus by using (4.7) with $S = A^T A$ we conclude the existence of a singular value of A, $\sigma \geq 0$, such that

$$|\sigma^2 - \hat{\sigma}^2| \leq \|A^T A \hat{\mathbf{v}} - \hat{\sigma}^2 \mathbf{v}\|_2.$$

The last inequality can be rewritten as

$$|\sigma - \hat{\sigma}| \cdot |\sigma + \hat{\sigma}| \leq \hat{\sigma}\|A^T\hat{\mathbf{u}} - \hat{\sigma}\hat{\mathbf{v}}\|_2,$$

which leads to

$$|\sigma - \hat{\sigma}| \leq |\hat{\sigma}/(\sigma + \hat{\sigma})| \cdot \|A^T\hat{\mathbf{u}} - \hat{\sigma}\hat{\mathbf{v}}\|_2 \leq \|A^T\hat{\mathbf{u}} - \hat{\sigma}\hat{\mathbf{v}}\|_2.$$

That is,

$$|\sigma - \hat{\sigma}| \leq \|A^T\hat{\mathbf{u}} - \hat{\sigma}\hat{\mathbf{v}}\|_2. \tag{6.10}$$

The treatment of a left singular vector is done in a similar way. Let $\tilde{\mathbf{u}} \in \mathbb{R}^m$ be a given unit vector that satisfies $A^T\tilde{\mathbf{u}} \neq \mathbf{0}$, and let

$$\tilde{\mathbf{v}} = A^T\tilde{\mathbf{u}}/\|A^T\tilde{\mathbf{u}}\|_2$$

and

$$\tilde{\sigma} = \|A^T\tilde{\mathbf{u}}\|_2 = \tilde{\mathbf{u}}^T A\tilde{\mathbf{v}}$$

denote the corresponding estimates of a right singular vector and a singular value, respectively. Then similar arguments prove the existence of a singular value of A, $\sigma \geq 0$, such that

$$|\sigma - \tilde{\sigma}| \leq \|A\tilde{\mathbf{v}} - \tilde{\sigma}\tilde{\mathbf{u}}\|_2. \tag{6.11}$$

7. Rectangular iterations. In this section we present a simple iterative algorithm for solving the minimum norm problem

$$\text{minimize } F(\mathbf{u}, \mathbf{v}) = \|A - \mathbf{u}\mathbf{v}^T\|_F^2. \tag{7.1}$$

The kth iteration, $k = 1, 2, 3, \ldots$, starts with $\mathbf{u}_{k-1}$ and $\mathbf{v}_{k-1}$ and ends with $\mathbf{u}_k$ and $\mathbf{v}_k$. Given $\mathbf{v}_{k-1}$, the vector $\mathbf{u}_k$ is obtained by solving the problem

$$\text{minimize } \varphi(\mathbf{u}) = \|A - \mathbf{u}\mathbf{v}_{k-1}^T\|_F^2.$$

That is,

$$\mathbf{u}_k = A\mathbf{v}_{k-1}/\mathbf{v}_{k-1}^T\mathbf{v}_{k-1}. \tag{7.2}$$

Then $\mathbf{v}_k$ is obtained by solving the problem

$$\text{minimize } \Psi(\mathbf{v}) = \|A - \mathbf{u}_k\mathbf{v}^T\|_F^2,$$

which gives

$$\mathbf{v}_k = A^T\mathbf{u}_k/\mathbf{u}_k^T\mathbf{u}_k. \tag{7.3}$$

Observe that the iteration (7.2)–(7.3) is essentially the retrieval rules (6.5) and (6.9). Note also that minimizing $F(\mathbf{u}, \mathbf{v})$ by changing one variable at a time (in the order $u_1, \ldots, u_m, v_1, \ldots, v_n$) results in the same basic iteration. Furthermore, let

$$\hat{\mathbf{v}}_k = \mathbf{v}_k/\|\mathbf{v}_k\|_2, \quad k = 0, 1, 2, \ldots,$$

denote the corresponding sequence of unit vectors. Let the sequence $\tilde{\mathbf{v}}_k, k = 0, 1, 2, \ldots,$ be generated by applying the power method to A^TA, with $\tilde{\mathbf{v}}_0 = \hat{\mathbf{v}}_0$ as the starting point. Then, in exact arithmetic,

$$\tilde{\mathbf{v}}_k = \hat{\mathbf{v}}_k \quad \text{for} \quad k = 1, 2, \ldots .$$

Similarly, the sequence

$$\hat{\mathbf{u}}_k = \mathbf{u}_k / \|\mathbf{u}_k\|_2, \quad k = 1, 2, \ldots,$$

is obtained by applying the power method to AA^T, with $\hat{\mathbf{u}}_1$ as the starting point.

Replacing the order of $\mathbf{u}$ and $\mathbf{v}$ results in the iteration

$$\mathbf{v}_k = A^T\mathbf{u}_{k-1} / \mathbf{u}_{k-1}^T\mathbf{u}_{k-1} \tag{7.4}$$

and

$$\mathbf{u}_k = A\mathbf{v}_k / \mathbf{v}_k^T\mathbf{v}_k, \tag{7.5}$$

which satisfies similar relations with the power method applied to AA^T. In order to distinguish between the two schemes we introduce the following terminology. The scheme (7.2)–(7.3) is called the "[illegible]," while (7.4)–(7.5) is called the "[illegible]." The reason for these names and the difference between the two schemes are explained in the next section. Both iterations satisfy the equality

$$(\mathbf{u}_k^T\mathbf{u}_k)(\mathbf{v}_k^T\mathbf{v}_k) = \mathbf{u}_k^TA\mathbf{v}_k, \tag{7.6}$$

so the corresponding rectangular quotients satisfy

$$\eta_k \equiv \eta(\mathbf{u}_k, \mathbf{v}_k) = 1 \tag{7.7}$$

and

$$\rho_k \equiv \rho(\mathbf{u}_k, \mathbf{v}_k) = \|\mathbf{u}_k\|_2 \, \|\mathbf{v}_k\|_2. \tag{7.8}$$

Combining these relations with the rectangular quotient equality shows that

$$\|A - \mathbf{u}_k\mathbf{v}_k^T\|_F^2 = \|A\|_F^2 - (\mathbf{u}_k^T\mathbf{u}_k)(\mathbf{v}_k^T\mathbf{v}_k). \tag{7.9}$$

Therefore, since the sequence $\{\|A - \mathbf{u}_k\mathbf{v}_k^T\|_F^2\}$ decreases monotonously, the sequences $\{(\mathbf{u}_k^T\mathbf{u}_k)(\mathbf{v}_k^T\mathbf{v}_k)\}$ and $\{\rho_k\}$ increase monotonously. Moreover, assume for simplicity that $\sigma_1 > \sigma_2$, and let $\mathbf{u}^*$ and $\mathbf{v}^*$ denote the corresponding left and right dominant singular vectors, where $\|\mathbf{u}^*\|_2 = 1$ and $\|\mathbf{v}^*\|_2 = 1$. Then the close links with the power method imply that

$$\lim_{k\to\infty} \hat{\mathbf{u}}_k = \mathbf{u}^* \tag{7.10}$$

and

$$\lim_{k\to\infty} \hat{\mathbf{v}}_k = \mathbf{v}^* \tag{7.11}$$

and that these sequences converge at a linear rate, proportional to σ_2^2/σ_1^2. A further use of (7.6) shows that in left iterations

$$(\mathbf{u}_k^T\mathbf{u}_k)(\mathbf{v}_k^T\mathbf{v}_k) = \hat{\mathbf{u}}_k^TAA^T\hat{\mathbf{u}}_k,$$

while in right iterations

$$(\mathbf{u}_k^T\mathbf{u}_k)(\mathbf{v}_k^T\mathbf{v}_k) = \hat{\mathbf{v}}_k^TA^TA\hat{\mathbf{v}}_k.$$

Thus in both cases

$$\lim_{k\to\infty} \rho_k^2 = \lim_{k\to\infty} (\mathbf{u}_k^T \mathbf{u}_k)(\mathbf{v}_k^T \mathbf{v}_k) = \sigma_1^2$$

and

$$\lim_{k\to\infty} \rho_k = \sigma_1, \tag{7.12}$$

where the sequence $\{\rho_k\}$ converges at a linear rate, proportional to σ_2^2/σ_1^2.

Recall, however, that the initial rate of convergence is expected to be faster than the asymptotic rate: If the starting point $\mathbf{u}_0$ (or $\mathbf{v}_0$) is not nearly perpendicular to $\mathbf{u}^*$ (or $\mathbf{v}^*$), then a few rectangular iterations are likely to provide a fair estimate of a dominant singular triplet. If no preliminary information is available, then taking $\mathbf{u}_0$ (or $\mathbf{v}_0$) to be the column (or row) of A that has the largest Euclidean norm is a reasonable choice (see the next section). Note also that the error bounds (6.10) and (6.11) provide useful stopping conditions.

8. Orthogonalization via deflation. In this section we present a new orthogonalization method that is called orthogonalization via deflation. By starting from $A_1 = A$ the new method generates a sequence of matrices $A_1, A_2, A_3, \ldots$, where $A_{\ell+1}$ is obtained from A_ℓ by the rule

$$A_{\ell+1} = A_\ell - \tilde{\sigma}_\ell \tilde{\mathbf{u}}_\ell \tilde{\mathbf{v}}_\ell^T, \quad \ell = 1, 2, \ldots, \tag{8.1}$$

where $\tilde{\mathbf{u}}_\ell \in \mathbb{R}^m$ and $\tilde{\mathbf{v}}_\ell \in \mathbb{R}^n$ are unit vectors and $\tilde{\sigma}_\ell > 0$ is a positive number that estimates the corresponding singular value. Below, we describe three basic versions of the method, which differ in the definition of the rank-one matrix $\tilde{\sigma}_\ell \tilde{\mathbf{u}}_\ell \tilde{\mathbf{v}}_\ell^T$.

. Here $\tilde{\mathbf{u}}_\ell$ is an arbitrary unit vector from Range(A_ℓ),

$$\tilde{\mathbf{v}}_\ell = A_\ell^T \tilde{\mathbf{u}}_\ell / \|A_\ell^T \tilde{\mathbf{u}}_\ell\|_2, \quad \text{and} \quad \tilde{\sigma}_\ell = (\tilde{\mathbf{u}}_\ell)^T A_\ell \tilde{\mathbf{v}}_\ell. \tag{8.2}$$

. Here $\tilde{\mathbf{v}}_\ell$ is an arbitrary unit vector from Range(A_ℓ^T),

$$\tilde{\mathbf{u}}_\ell = A_\ell \tilde{\mathbf{v}}_\ell / \|A_\ell \tilde{\mathbf{v}}_\ell\|_2, \quad \text{and} \quad \tilde{\sigma}_\ell = (\tilde{\mathbf{u}}_\ell)^T A_\ell \tilde{\mathbf{v}}_\ell. \tag{8.3}$$

. Let $\hat{\mathbf{u}}_\ell$ and $\hat{\mathbf{v}}_\ell$ be an arbitrary pair of unit vectors that satisfy

$$\hat{\mathbf{u}}_\ell \in \text{Range}(A_\ell), \quad \hat{\mathbf{v}}_\ell \in \text{Range}(A_\ell^T), \qquad \text{and} \quad \hat{\mathbf{u}}_\ell^T A_\ell \hat{\mathbf{v}}_\ell > 0. \tag{8.4}$$

Then here

$$A_{\ell+1} = A_\ell - (A_\ell \hat{\mathbf{v}}_\ell)(A_\ell^T \hat{\mathbf{u}}_\ell)^T / (\hat{\mathbf{u}}_\ell^T A_\ell \hat{\mathbf{v}}_\ell). \tag{8.5}$$

That is, here (8.1) is carried out with

$$\tilde{\mathbf{u}}_\ell = A_\ell \hat{\mathbf{v}}_\ell / \|A_\ell \hat{\mathbf{v}}_\ell\|_2,$$

$$\tilde{\mathbf{v}}_\ell = A_\ell^T \hat{\mathbf{u}}_\ell / \|A_\ell^T \hat{\mathbf{u}}_\ell\|_2,$$

and

$$\tilde{\sigma}_\ell = (\|A_\ell \hat{\mathbf{v}}_\ell\|_2 \|A_\ell^T \hat{\mathbf{u}}_\ell\|_2) / (\hat{\mathbf{u}}_\ell^T A_\ell \hat{\mathbf{v}}_\ell).$$

To analyze the proposed methods we introduce the following notations. Let $\tilde{U}_\ell$ denote the $m \times \ell$ matrix whose columns are $\tilde{\mathbf{u}}_1, \ldots, \tilde{\mathbf{u}}_\ell$. Let $\tilde{V}_\ell$ denote the $n \times \ell$ matrix whose columns are $\tilde{\mathbf{v}}_1, \ldots, \tilde{\mathbf{v}}_\ell$. Let $\tilde{D}_\ell$ denote a diagonal $\ell \times \ell$ matrix whose diagonal entries are $\tilde{\sigma}_1, \ldots, \tilde{\sigma}_\ell$. That is,

$$\tilde{U}_\ell = [\tilde{\mathbf{u}}_1, \ldots, \tilde{\mathbf{u}}_\ell], \quad \tilde{V}_\ell = [\tilde{\mathbf{v}}_1, \ldots, \tilde{\mathbf{v}}_\ell], \quad \text{and} \quad \tilde{D}_\ell = \operatorname{diag}\{\tilde{\sigma}_1, \ldots, \tilde{\sigma}_\ell\}. \tag{8.6}$$

Then, at the end of the ℓth deflation stage,

$$A_{\ell+1} = A - \sum_{j=1}^{\ell} \tilde{\sigma}_j \tilde{\mathbf{u}}_j (\tilde{\mathbf{v}}_j)^T = A - \tilde{U}_\ell \tilde{D}_\ell \tilde{V}_\ell^T = A - \tilde{B}_\ell, \tag{8.7}$$

where

$$\tilde{B}_\ell = \sum_{j=1}^{\ell} \tilde{\sigma}_j \tilde{\mathbf{u}}_j (\tilde{\mathbf{v}}_j)^T = \tilde{U}_\ell \tilde{D}_\ell \tilde{V}_\ell^T \tag{8.8}$$

may serve as a low-rank approximation of A. The differences between the three schemes are explained below. Yet, as we shall see, the three schemes share the "exactness property"

$$A = \tilde{U}_r \tilde{D}_r \tilde{V}_r^T, \tag{8.9}$$

where $r = \operatorname{rank}(A)$. The titles of the theorems refer to the rule which defines the triplet $\{\tilde{\sigma}_\ell, \tilde{\mathbf{u}}_\ell, \tilde{\mathbf{v}}_\ell\}$.

THEOREM 2 (left-side orthogonalization). [illegible] $\ell = 1, \ldots, r$

$$\operatorname{Range}(A_{\ell+1}) \subseteq \operatorname{Range}(A_\ell), \tag{8.10}$$

$$\operatorname{Range}(\tilde{U}_\ell) \subseteq \operatorname{Range}(A), \tag{8.11}$$

$$\tilde{U}_\ell^T A_{\ell+1} = 0, \tag{8.12}$$

[illegible]

$$\tilde{U}_\ell^T \tilde{U}_\ell = I. \tag{8.13}$$

[illegible] $\ell = r$ [illegible] $\tilde{U}_r$ [illegible] Range(A),

$$A_{r+1} = 0, \tag{8.14}$$

[illegible]

$$A = \tilde{U}_r \tilde{D}_r \tilde{V}_r^T. \tag{8.15}$$

[illegible]. The proof is by induction on ℓ. For $\ell = 1$ the relations (8.10)–(8.13) are direct consequences of the definition of $\{\tilde{\sigma}_1, \tilde{\mathbf{u}}_1, \tilde{\mathbf{v}}_1\}$. Assume now that (8.10)–(8.13) hold for $\ell - 1$. That is,

$$\operatorname{Range}(A_\ell) \subseteq \operatorname{Range}(A),$$
$$\operatorname{Range}(\tilde{U}_{\ell-1}) \subseteq \operatorname{Range}(A),$$
$$\tilde{U}_{\ell-1}^T A_\ell = 0,$$

and

$$U_{\ell-1}^T \tilde{U}_{\ell-1} = I.$$

On the other hand, the definition of the triplet $\{\tilde{\sigma}_\ell, \tilde{\mathbf{u}}_\ell, \tilde{\mathbf{v}}_\ell\}$ implies the relations

$$\tilde{\mathbf{u}}_\ell \in \mathrm{Range}(A_\ell) \subseteq \mathrm{Range}(A), \quad \tilde{\mathbf{u}}_\ell^T \tilde{\mathbb{U}}_{\ell-1} = \mathbf{0}, \quad \text{and} \quad \tilde{\mathbf{u}}_\ell^T A_{\ell+1} = \mathbf{0}.$$

So combining these relations with the induction assumptions yields (8.10)–(8.13). □

Recall that Gram–Schmidt orthogonalization has three basic versions: classical Gram–Schmidt, a column-oriented version of modified Gram–Schmidt (MGS), and a row-oriented version of MGS. The last version is the only one that is able to incorporate column pivoting. Yet, in exact arithmetic and without column pivoting, all of these versions produce the same QR factorization of A, which is closely related to Householder QR factorization of the $(m+n)\times n$ matrix $\binom{0}{A}$. For a detailed discussion of these methods see [3], [6], [7], [14], [20], [28].

COROLLARY 3 (relation to Gram–Schmidt orthogonalization). [illegible] $\tilde{\mathbf{u}}_\ell$ [illegible] A_ℓ [illegible] $\mathbf{c}_j$, $j = 1, \ldots, n$, [illegible] j [illegible] A_ℓ [illegible] j^* [illegible]

$$\|\mathbf{c}_{j^*}\|_2 = \max\{\|\mathbf{c}_1\|_2, \ldots, \|\mathbf{c}_n\|_2\}.$$

[illegible]

$$\tilde{\mathbf{u}}_\ell = \mathbf{c}_{j^*} / \|\mathbf{c}_{j^*}\|_2. \tag{8.16}$$

[illegible] A_ℓ [illegible] $\mathbf{c}_\ell = \mathbf{c}_{j^*}$ [illegible] (8.1)–(8.2) [illegible] A [illegible]. By using induction on ℓ it is easy to verify that the first ℓ columns of $A_{\ell+1}$ are null vectors, while the other columns of $A_{\ell+1}$ are obtained by orthogonalizing the columns of A_ℓ against the ℓth column of A_ℓ. Consequently the first $\ell-1$ entries of $\tilde{\mathbf{v}}_\ell$ are zeros, while the other entries are defined by the corresponding orthogonalization factors. □

THEOREM 4 (right-side orthogonalization). [illegible] $\ell = 1, \ldots, r$

$$\mathrm{Range}(A_{\ell+1}^T) \subseteq \mathrm{Range}(A_\ell^T), \tag{8.17}$$

$$\mathrm{Range}(\tilde{V}_\ell) \subseteq \mathrm{Range}(A^T), \tag{8.18}$$

$$A_{\ell+1}\tilde{V}_\ell = 0, \tag{8.19}$$

[illegible]

$$\tilde{V}_\ell^T \tilde{V}_\ell = I. \tag{8.20}$$

[illegible] $\ell = r$ [illegible] $\tilde{V}_r$ [illegible] $\mathrm{Range}(A^T)$,

$$A_{r+1} = 0, \tag{8.21}$$

[illegible]

$$A = \tilde{U}_r \tilde{D}_r \tilde{V}_r^T. \tag{8.22}$$

[illegible]. The proof is achieved by using induction on ℓ, as in Theorem 2. □

COROLLARY 5 (relation to Gram–Schmidt orthogonalization). $\tilde{\mathbf{v}}_\ell$ A_ℓ A^T

THEOREM 6 (two-sides orthogonalization). $\hat{U}_\ell \in \mathbb{R}^{m\times\ell}$, $\hat{V}_\ell \in \mathbb{R}^{n\times\ell}$, $\hat{D}_\ell \in \mathbb{R}^{\ell\times\ell}$

$$\hat{U}_\ell = [\hat{\mathbf{u}}_1, \ldots, \hat{\mathbf{u}}_\ell], \quad \hat{V}_\ell = [\hat{\mathbf{v}}_1, \ldots, \hat{\mathbf{v}}_\ell], \quad \text{and} \quad \hat{D}_\ell = \operatorname{diag}\{\hat{\sigma}_1, \ldots, \hat{\sigma}_\ell\}, \tag{8.23}$$

$$\hat{\sigma}_j = \hat{\mathbf{u}}_j^T A \hat{\mathbf{v}}_j \quad \text{for} \quad j = 1, \ldots, r. \tag{8.24}$$

$\ell = 1, \ldots, r$

$$\operatorname{Range}(A_{\ell+1}) \subseteq \operatorname{Range}(A_\ell), \quad \operatorname{Range}(A_{\ell+1}^T) \subseteq \operatorname{Range}(A_\ell^T), \tag{8.25}$$

$$\operatorname{Range}(\hat{U}_\ell) \subseteq \operatorname{Range}(A), \quad \operatorname{Range}(\hat{V}_\ell) \subseteq \operatorname{Range}(A^T), \tag{8.26}$$

$$\hat{U}_\ell^T A_{\ell+1} = 0, \qquad A_{\ell+1}\hat{V}_\ell = 0, \tag{8.27}$$

$$\hat{U}_\ell^T \hat{U}_\ell = I, \quad \text{and} \quad \hat{V}_\ell^T \hat{V}_\ell = I. \tag{8.28}$$

$\ell = r$ $\hat{U}_r$ $\hat{V}_r$ $\operatorname{Range}(A)$ $\operatorname{Range}(A^T)$

$$A_{r+1} = 0 \tag{8.29}$$

$$A = \tilde{U}_r \tilde{D}_r \tilde{V}_r. \tag{8.30}$$

. The proof is by induction on ℓ. The key observation is that here the deflation step (8.5) implies that

$$A_{\ell+1}^T \hat{\mathbf{u}}_\ell = \mathbf{0} \quad \text{and} \quad A_{\ell+1}\hat{\mathbf{v}}_\ell = \mathbf{0}. \tag{8.31}$$

From this point, continue as in the proof of Theorem 2. ∎

The quality of the resulting factorizations, as substitutes for the SVD, depends on the quality of the deflating triplets $\{\tilde{\sigma}_\ell, \tilde{\mathbf{u}}_\ell, \tilde{\mathbf{v}}_\ell\}$, as substitutes for a dominant triplet of A_ℓ. As we have seen, a small number of rectangular iterations is likely to provide a fair estimate of a dominant triplet of A_ℓ. Furthermore, the relation to pivoted MGS suggests a natural starting point for the rectangular iterations: Take a column (or row) of A_ℓ that has the largest Euclidean norm. Note also that the error bounds (6.10) and (6.11) provide useful stopping conditions for the rectangular iterations.

The two-sides orthogonalization process (8.4)–(8.5) constructs two low-rank approximations of A:

$$\tilde{B}_\ell = \tilde{U}_\ell \tilde{D}_\ell \tilde{V}_\ell^T = \sum_{j=1}^{\ell} \tilde{\sigma}_j \tilde{\mathbf{u}}_j \tilde{\mathbf{v}}_j^T \tag{8.32}$$

and

$$\hat{B}_\ell = \hat{U}_\ell \hat{D}_\ell \hat{V}_\ell^T = \sum_{j=1}^{\ell} \hat{\sigma}_j \hat{\mathbf{u}}_j \hat{\mathbf{v}}_j^T. \tag{8.33}$$

The second decomposition has the advantage that both $\hat{U}_\ell$ and $\hat{V}_\ell$ have orthonormal columns, which makes it a valuable substitute for the SVD's low-rank approximation. The definition (8.24) of the diagonal matrix $\hat{D}_\ell$ is motivated by the observation that the diagonal entries of this matrix solve the minimum norm problem

$$\text{minimize} \quad F(\sigma_1, \ldots, \sigma_\ell) = \left\| A - \sum_{j=1}^{\ell} \sigma_j \hat{\mathbf{u}}_j \hat{\mathbf{v}}_j^T \right\|_F^2 . \tag{8.34}$$

Of course, if one is interested only in (8.33), then there is no need to store the matrices $\tilde{U}_\ell$ and $\tilde{V}_\ell$.

As noted by one referee, the two-sides orthogonalization process (8.4)–(8.5) is a special case of a more general method, the Wedderburn–Egervary rank-reducing (WERR) process, e.g., [4], [12], [31]. By using our notations the ℓth step of a WERR process has the form

$$A_{\ell+1} = A_\ell - (A_\ell \hat{\mathbf{v}}_\ell)(A_\ell^T \hat{\mathbf{u}}_\ell)^T / (\hat{\mathbf{u}}_\ell^T A_\ell \hat{\mathbf{v}}_\ell), \quad \ell = 1, 2, \ldots, \tag{8.35}$$

where the vectors $\hat{\mathbf{u}}_\ell \in \mathbb{R}^m$ and $\hat{\mathbf{v}}_\ell \in \mathbb{R}^n$ need to satisfy

$$\hat{\mathbf{u}}_\ell^T A_\ell \hat{\mathbf{v}}_\ell \neq 0. \tag{8.36}$$

The name "rank-reducing process" comes from the observation that

$$\operatorname{rank}(A_{\ell+1}) = \operatorname{rank}(A_\ell) - 1, \tag{8.37}$$

which implies the "finite termination" property $A_{r+1} = 0$. It is illustrated in [4] that several important matrix factorizations belong to this class of methods. However, to the best of our knowledge, the two-sides orthogonalization process (8.4)–(8.5) is a new method, distinguished by the orthogonality of the matrices $\hat{U}_\ell$ and $\hat{V}_\ell$, which is gained by replacing (8.36) with (8.4). That is, orthogonality is gained by choosing the vectors $\hat{\mathbf{u}}_\ell$ and $\hat{\mathbf{v}}_\ell$ from $\operatorname{Range}(A_\ell)$ and $\operatorname{Range}(A_\ell^T)$, respectively. Another feature that characterizes our approach is the use of rectangular iterations to estimate a dominant pair of singular vectors and to use the computed vectors in (8.35). It is the incorporation of these two properties that makes the resulting decomposition a valuable substitute for the SVD. Similar remarks apply to left-side and right-side orthogonalizations, although the relation of these methods to the WERR process (8.35) is somewhat less obvious.

The treatment of rounding errors is done as in the symmetric case, by using singular values instead of eigenvalues. To simplify the coming discussion we concentrate on the left-side process (8.2), assuming that each triplet $\{\rho_\ell, \mathbf{u}_\ell, \mathbf{v}_\ell\}$ provides a fair estimate of a dominant triplet of A_ℓ. The last assumption means that the size of $\|A_\ell\|_F$ is about $\sigma_\ell + \cdots + \sigma_n$. On the other hand, in floating point arithmetic the computed matrix A_ℓ contains an error matrix E_ℓ whose Frobenius norm is about $\varepsilon(\sigma_1 + \cdots + \sigma_{\ell-1})$, where ε denotes the machine precision in our computations. That is,

$$\|E_{\ell+1}\|_F / \|A_{\ell+1}\|_F \approx \varepsilon(\sigma_1 + \cdots + \sigma_\ell) / (\sigma_{\ell+1} + \cdots + \sigma_n). \tag{8.38}$$

Thus, when A is an ill-conditioned matrix, small singular values are computed with a large relative error. Nevertheless, the overall perturbation of the singular values is small: Let $\tilde{\sigma}_1, \ldots, \tilde{\sigma}_n$ denote the singular values of A_ℓ, and let $\hat{\sigma}_1, \ldots, \hat{\sigma}_n$ denote those of $A_\ell - E_\ell$. Then from Weyl's theorem [28, p. 69] one obtains

$$|\hat{\sigma}_i - \tilde{\sigma}_i| \leq \|E_\ell\|_2 \leq \|E_\ell\|_F \approx \varepsilon(\sigma_1 + \cdots + \sigma_{\ell-1}), \quad i = 1, \ldots, n. \tag{8.39}$$

A further difficulty that arises as the ratio (8.38) grows is the gradual loss of orthogonality. Yet, as in the symmetric case, this difficulty is easily resolved by applying reorthogonalization. For example, in the ℓth step of a left-orthogonalization process, $\mathbf{u}_\ell$ is orthogonalized against $\mathbf{u}_1, \ldots, \mathbf{u}_{\ell-1}$. Similarly, in the ℓth step of a right-orthogonalization process, $\mathbf{v}_\ell$ is orthogonalized against $\mathbf{v}_1, \ldots, \mathbf{v}_{\ell-1}$, and so forth.

9. Missing data estimation. In this section we discuss the case when some entries of the data matrix A are unknown. In such a situation it is often desired to construct a low-rank estimate of A in spite of the missing data, e.g., [1], [2], [13], [15], [30]. The minimum norm approach is easily adapted to handle this difficulty. Consider, for example, the rectangular minimum norm problem (7.1) when some entries of A are missing. In this case the problem to be solved is redefined as

$$\text{minimize} \quad F(\mathbf{u}, \mathbf{v}) = \sum_{(i,j)\in\mathbb{K}} (a_{ij} - u_i v_j)^2, \tag{9.1}$$

where

$$\mathbb{K} = \{(i,j) \,|\, a_{ij} \text{ is known}\}.$$

That is, the sum in (9.1) is restricted to known entries of A. Let the set

$$\mathbb{C}_j = \{i \,|\, a_{ij} \text{ is known}\}$$

contain the row indices of known entries in the jth column of A, $j = 1, \ldots, n$. Then a second way to write (9.1) is

$$\text{minimize} \quad F(\mathbf{u}, \mathbf{v}) = \sum_{j=1}^{n} \sum_{i\in\mathbb{C}_j} (a_{ij} - u_i v_j)^2. \tag{9.2}$$

Similarly, let

$$\mathbb{R}_i = \{j \,|\, a_{ij} \text{ is known}\}$$

contain the column indices of known entries in the ith row of A, $i = 1, \ldots, m$. Then a third way to write (9.1) is

$$\text{minimize} \quad F(\mathbf{u}, \mathbf{v}) = \sum_{i=1}^{m} \sum_{j\in\mathbb{R}_j} (a_{ij} - u_i v_j)^2. \tag{9.3}$$

The adaptation of the "left iteration" (7.2)–(7.3) to solve (9.1) is done in the following way. As before, the kth iteration, $k = 1, 2, 3, \ldots$, starts with $\mathbf{u}_{k-1}$ and $\mathbf{v}_{k-1}$ and ends with $\mathbf{u}_k$ and $\mathbf{v}_k$. Given $\mathbf{v}_{k-1} = (\tilde{v}_1, \tilde{v}_2, \ldots, \tilde{v}_n)^T$, the vector $\mathbf{u}_k = (\hat{u}_1, \hat{u}_2, \ldots, \hat{u}_m)^T$ is obtained by solving the problem

$$\text{minimize} \quad \varphi(\mathbf{u}) = \sum_{i=1}^{m} \sum_{j\in\mathbb{R}_i} (a_{ij} - u_i \tilde{v}_j)^2.$$

That is,

$$\hat{u}_i = \left(\sum_{j\in\mathbb{R}_i} a_{ij}\tilde{v}_j \right) \Big/ \left(\sum_{j\in\mathbb{R}_i} \tilde{v}_j^2 \right) \quad \text{for} \quad i = 1, \ldots, m. \tag{9.4}$$

Then $\mathbf{v}_k = (\hat{v}_1, \hat{v}_2, \ldots, \hat{v}_n)^T$ is obtained by solving the problem

$$\text{minimize} \quad \Psi(\mathbf{v}) = \sum_{j=1}^{n} \sum_{i \in \mathbb{C}_j} (a_{ij} - \hat{u}_i v_j)^2.$$

That is,

$$\hat{v}_j = \left(\sum_{i \in \mathbb{C}_j} a_{ij} \hat{u}_i \right) \Big/ \left(\sum_{i \in \mathbb{C}_j} \hat{u}_i^2 \right) \quad \text{for} \quad j = 1, \ldots, n. \tag{9.5}$$

The "right iteration" (7.4)–(7.5) is adapted in a similar way.

The ability to solve (9.1) enables us to apply the deflation by subtraction process when some entries of A are unknown. The ℓth stage of this process, $\ell = 1, 2, \ldots$, needs only minor changes. Let $a_{ij}^{(\ell)}$ denote the (i, j) component of A_ℓ. Then the problem

$$\text{minimize} \quad F_\ell(\mathbf{u}, \mathbf{v}) = \sum_{(i,j) \in \mathbb{K}} (a_{ij}^{(\ell)} - u_i v_j)^2 \tag{9.6}$$

is solved by the modified iterations described above. Let $\mathbf{u}^*$ and $\mathbf{v}^*$ denote the computed solution of (9.6). Then $A_{\ell+1}$ is obtained from A_ℓ by the rule

$$A_{\ell+1} = A_\ell - \mathbf{u}^*(\mathbf{v}^*)^T = A_\ell - \rho_\ell^* \mathbf{u}_\ell^* (\mathbf{v}_\ell^*)^T, \tag{9.7}$$

where

$$\mathbf{u}_\ell^* = \mathbf{u}^* / \|\mathbf{u}^*\|_2, \quad \mathbf{v}_\ell^* = \mathbf{v}^* / \|\mathbf{v}^*\|_2, \quad \text{and} \quad \rho_\ell^* = \|\mathbf{u}^*\|_2 \, \|\mathbf{v}^*\|_2.$$

Note that the entries of $A_{\ell+1}$ which correspond to unknown entries of A are still considered as unknown. Note also that the sequence

$$\xi_\ell = \sum_{(i,j) \in \mathbb{K}} (a_{ij}^{(\ell)})^2, \qquad \ell = 1, 2, \ldots, \tag{9.8}$$

decreases monotonously. Thus, once we reach an iteration index ℓ^* for which ξ_{ℓ^*} is considerably smaller than ξ_1, the sum

$$B_{\ell^*} = \sum_{\ell=1}^{\ell^*} \rho_\ell^* \mathbf{u}_\ell^* (\mathbf{v}_\ell^*)^T \tag{9.9}$$

may serve as a low-rank approximation of A.

10. Concluding remarks. The power method, the deflation by subtraction process, and the Rayleigh quotient are among the early tools for solving symmetric eigenvalue problems. It is interesting, however, to ask whether these methods and concepts can be extended for calculating the SVD of rectangular matrices. The minimum norm approach that we introduce gives a definite answer to this question. At the same time it reveals new features of these tools and paves the way for modified schemes.

The new deflation by subtraction process for symmetric matrices has clear advantages over the classical method of Hotelling [16], [17], namely, the "finite termination" property, the "exactness" property, the "orthogonality" property, and the fact that

these features hold regardless the quality of the computed eigenpairs. One aim of the paper is to point out that a small number of power iterations per eigenpair are sufficient to provide a meaningful characterization of the eigensystem.

The symmetric quotient equality (4.8) is a new useful relation that directly connects the minimum norm problem (1.1) and the Rayleigh quotient, showing that minimizing (1.1) is equivalent to maximizing the Rayleigh quotient. An extended version of this equality sheds new light on Key Fan's maximum principle; see [9]. The ability to find a dominant eigenpair by solving (1.1) opens the door for effective minimization techniques. The simple relaxation method proposed in [8] illustrates this point.

When moving to rectangular matrices, singular values take the role of eigenvalues, while the rectangular Rayleigh quotient (5.9) replaces the Rayleigh quotient (4.4). The minimum norm approach enables us to see the similarity between the two cases. The rectangular quotient equality (5.10) directly connects the minimum norm problem (1.3) and the rectangular Rayleigh quotient (5.9), showing that minimizing (1.3) is equivalent to maximizing the rectangular Rayleigh quotient. In [9] we establish an extended version of this equality, which adds new insight into the Eckart–Young theorem.

At this point it is instructive to see the difference between the rectangular Rayleigh quotient (5.9) and the generalized Rayleigh quotient proposed by Ostrowsky [23]. Let A be a general (nonnormal) real square matrix of order n, and let $\mathbf{u}$ and $\mathbf{v}$ be two n-vectors that satisfy $\mathbf{u}^*\mathbf{v} \neq 0$, where $\mathbf{u}^*$ denotes the conjugate transpose of $\mathbf{u}$. Then the "generalized Rayleigh quotient"

$$\rho(\mathbf{u}, \mathbf{v}) = \mathbf{u}^* A\mathbf{v} / (\mathbf{u}^*\mathbf{v}) \tag{10.1}$$

is aimed to approximate an eigenvalue of A that is "common" to $\mathbf{u}$ and $\mathbf{v}$. One justification for this definition lies in the following observation: Let $\mathbf{u}_0$ and $\mathbf{v}_0$ be left and right eigenvectors of A corresponding to the same eigenvalue λ_0 and satisfy $\mathbf{u}_0^*\mathbf{v}_0 \neq 0$. Then $\lambda_0 = \rho(\mathbf{u}_0, \mathbf{v}_0)$. A second justification comes from the "stationary property" of $\rho(\mathbf{u}, \mathbf{v})$ at the point $(\mathbf{u}_0, \mathbf{v}_0)$, e.g., [23], [25]. These features motivate the "generalized Rayleigh quotient iteration" proposed by Ostrowsky [23], [24]. On the other hand, unlike the other quotients, it is difficult to associate (10.1) with a certain optimization problem. For further discussions of the generalized Rayleigh quotient and related topics, see [22], [23], [24], [25], [32].

The "rectangular iterations" that we propose are closely related to the power method applied to the matrices A^TA and AA^T. A similar power method iteration is used in the HITS algorithm for information retrieval, e.g., [18], [19]. However, the use of rectangular iterations has further interpretations: On one hand, it can be viewed as iterative retrieval of singular vectors, which is carried out by successive orthogonalizations. On the other hand, it is a minimization method ("point relaxation") that is aimed at solving the minimum norm problem (7.1). These observations add new insight into the power method and expose new useful results. A further merit of the minimum norm approach is that it opens the door for more sophisticated minimization techniques. The modified scheme for missing data illustrates this point. Another fruitful idea is the use of a line search acceleration; see [5], [8].

The task of computing an orthonormal basis for Range(A) is called "the orthonormal basis problem," e.g., [14]. This problem is often solved by applying Householder orthogonalization, or Gram–Schmidt orthogonalization, to produce a QR factorization of A. In practice both methods are carried out with some "column pivoting" policy, and the basis is completely determined by this policy. See, for example, [3],

[6], [7], [14], [28]. The "orthogonalization via deflation" method has larger freedom in the choice of the basis: Consider, for example, the left-side orthogonalization process. Then at the ℓth deflation stage, $\ell = 1, 2, \ldots$, the new vector that enters the basis can be any unit vector from Range(A_ℓ). The Gram–Schmidt orthogonalization process uses the ℓth column of A_ℓ, while pivoted Gram–Schmidt chooses a column of A_ℓ that has the largest Euclidean norm. The ultimate choice is $\mathbf{u}_\ell$, a left dominant singular vector of A_ℓ. However, accurate computation of this vector can be "too expensive." The theme of the paper is to point out that a few rectangular iterations with A_ℓ are likely to produce a fair estimate of $\mathbf{u}_\ell$. This way, the resulting orthogonal decomposition provides a meaningful substitute for the SVD of A. Preliminary experiments that we have done support this view; see [8].

The practical value of our approach lies in problems where standard SVD algorithms are not applicable, as in problems with missing data. Another favorable situation arises when the rank of the approximation ℓ is much smaller than $\min\{m, n\}$. In this case the algorithm performs only ℓ deflation stages, which reduces the computational cost. The last situation is likely to occur when A is a large sparse matrix. In this case $A_{\ell+1}$ is kept in the form

$$A_{\ell+1} = A - \sum_{j=1}^{\ell} \tilde{\sigma}_j \tilde{\mathbf{u}}_j \tilde{\mathbf{v}}_j^T,$$

so the matrix-vector products are able to take advantage of the sparsity pattern in A.

THE SINKHORN–KNOPP ALGORITHM: CONVERGENCE AND APPLICATIONS*

PHILIP A. KNIGHT†

Abstract. As long as a square nonnegative matrix A contains sufficient nonzero elements, then the Sinkhorn–Knopp algorithm can be used to balance the matrix, that is, to find a diagonal scaling of A that is doubly stochastic. It is known that the convergence is linear, and an upper bound has been given for the rate of convergence for positive matrices. In this paper we give an explicit expression for the rate of convergence for fully indecomposable matrices. We describe how balancing algorithms can be used to give a measure of web page significance. We compare the measure with some well known alternatives, including PageRank. We show that, with an appropriate modification, the Sinkhorn–Knopp algorithm is a natural candidate for computing the measure on enormous data sets.

DOI. 10.1137/060659624

1. Introduction. If a graph has the appropriate structure, we can generate a random walk on it by taking its connectivity matrix and applying a suitable scaling to transform it into a stochastic matrix. This simple idea has a wide range of applications. In particular, we can rank pages on the Internet by generating the appropriate connectivity matrix G and applying a scaling induced by a diagonal matrix D of column sums so that $P_c = GD^{-1}$ is column stochastic.[1] Ordering pages according to the size of the components in the stationary distribution of P_c gives us a ranking. Roughly speaking, this is how Google's PageRank is derived.

An alternative method of generating a random walk on G is to apply a diagonal scaling to both sides of G to form a doubly stochastic matrix $P = DGE$. Of course, if we use this approach, then the stationary distribution is absolutely useless for ranking purposes. However, in section 5 we argue that the entries of D and E can be used as alternative measures. We will also see that, if we apply the Sinkhorn–Knopp (SK) algorithm on an appropriate matrix to find D and E, we can compute our new ranking with a cost comparable to that of finding the PageRank. In order to justify this conclusion, we need to establish the rate of convergence of the SK algorithm, which we do in section 4. Before that, in section 2 we review pertinent details about the SK algorithm, and in section 3 we look at the symmetric case. Our numerical results are collected in section 6.

2. The Sinkhorn–Knopp algorithm. The SK algorithm is perhaps the simplest method for finding a doubly stochastic scaling of a nonnegative matrix A. It does this by generating a sequence of matrices whose rows and columns are normalized alternately. The algorithm can be thought of in terms of matrices

$$A_0 = A,\ A_1,\ A_2, \ldots,$$

[1]If any of the columns are empty, we first modify G by, for example, adding a column of ones.

whose limit is the doubly stochastic matrix we are after, or in terms of pairs of diagonal matrices

$$(D_0, E_0),\ (D_1, E_1),\ (D_2, E_2), \ldots,$$

whose limit gives the desired scaling of A. We will predominantly use the second interpretation in this paper.

To describe the algorithm more formally, we introduce the operator $\mathcal{D} : \mathbb{R}^n \to \mathbb{R}^{n\times n}$, where $\mathcal{D}(x) = \mathrm{diag}(x)$. Starting with $D_0 = E_0 = I$, we let

$$r_k = D_{k-1} A E_{k-1} e, \tag{2.1}$$

where e is a vector of ones, and $D_k = \mathcal{D}(r_k)^{-1}$. Now let

$$c_k^T = e^T D_k A E_{k-1}, \tag{2.2}$$

and $E_k = \mathcal{D}(c_k)^{-1}$.

Not surprisingly, the simplicity of the method has led to its repeated discovery. It is claimed to have first been used in the 1930s for calculating traffic flow [5] and appeared in 1937 as a method for predicting telephone traffic distribution [15].[2] In the numerical analysis community it is most usually named after Sinkhorn and Knopp, who proved convergence results for the method in the 1960s [22], but it is also known by many other names, such as the RAS method [1] and Bregman's balancing method [16]. The letters R, A, and S represent symbolically the matrices used in decomposing the original matrix into doubly stochastic form. Many matrix decompositions are expressed in this way (e.g., CS and QT decompositions).

Perhaps the simplest representation of the method is given in [13]. Suppose that $P = \mathcal{D}(r) A \mathcal{D}(c)$ is doubly stochastic. Manipulation of the identities $Pe = e$ and $P^T e = e$ gives

$$c = \mathcal{D}(A^T r)^{-1} e, \quad r = \mathcal{D}(Ac)^{-1} e, \tag{2.3}$$

which suggests the fixed point iteration

$$c_{k+1} = \mathcal{D}(A^T r_k)^{-1} e, \quad r_{k+1} = \mathcal{D}(A c_{k+1})^{-1} e. \tag{2.4}$$

It is straightforward to show that this iteration is precisely the SK algorithm when $r_0 = e$. Note that this can be achieved by repeatedly issuing the commands

$$\mathtt{c = 1./(A' * r)}, \quad \mathtt{r = 1./(A * c)}$$

in MATLAB.

Convergence of the SK algorithm depends on the nonzero structure of A. Recall that a nonnegative matrix A has total support if $A \neq 0$ and all its nonzero elements lie on a positive diagonal. This rather terse definition is standard in the literature [19, 22] but can be usefully interpreted in terms of graphs. If a graph has an adjacency matrix with the same nonzero pattern as a matrix with total support, then every edge in the graph is part of a circuit. A matrix is fully indecomposable if it is impossible to find permutation matrices P and Q such that

$$PAQ = \begin{bmatrix} A_1 & 0 \\ A_2 & A_3 \end{bmatrix},$$

[2] A more detailed history of the method can be found in [7].

with A_1 square. This property is also known as the strong Hall property. Sinkhorn and Knopp proved the following result [22].

THEOREM 2.1 (Sinkhorn–Knopp). [illegible]

Note that we are not claiming that D and E are unique but rather that if $D_1AE_1 = D_2AE_2 = P$, then there exists $\alpha > 0$ such that $D_1 = \alpha D_2$ and $E_2 = \alpha E_1$.

By thinking of the iteration in terms of the approximate doubly stochastic matrices

$$A_0,\ A_1,\ A_2, \ldots,$$

Sinkhorn and Knopp also showed that the algorithm converges whenever A has at least one positive diagonal. For example, if we were to scale the matrix

$$\begin{bmatrix} a & b \\ 0 & c \end{bmatrix}$$

repeatedly, we would converge to the identity matrix; however, the diagonal matrices in the identity $A_k = D_kAE_k$ would diverge.

The rate of convergence of the SK algorithm has also been studied by a number of authors. Soules [23] has shown that the algorithm is linearly convergent whenever the original matrix has total support. However, he gives no explicit value for the rate of convergence. Soules establishes his result by treating the algorithm as a fixed point iteration on matrices and looking at the Jacobian matrix. Our interpretation of the method as an iteration on vectors enables us to improve this result.

Franklin and Lorenz [11] give a bound on the rate of convergence when $A > 0$. They use Hilbert's projective metric for vectors $x, y \in \mathbb{R}^n_+$, namely,

$$d(x, y) = \log \max_{i,j} \frac{x_i y_j}{x_j y_i}.$$

For $A \in \mathbb{R}^{m\times n}_+$, we can define

$$\theta(A) = \sup\{d(Ax, Ay) | x, y \in \mathbb{R}^n_+\} = \max_{i,j,k,l} \frac{a_{ik}a_{jl}}{a_{jk}a_{il}}. \tag{2.5}$$

Franklin and Lorenz show that $\theta(A) = \theta(A_m)$ is constant for the sequence of matrices $\{A_m\}$ generated by the SK algorithm with initial matrix A. They are also able to show that the rate of convergence of the method is bounded above by

$$C = \left(\frac{\sqrt{\theta(A)} - 1}{\sqrt{\theta(A)} + 1} \right)^2. \tag{2.6}$$

This is an a priori bound on the rate of convergence, but it can be very weak in practice. Furthermore, the result holds only for positive matrices. As the smallest element of A approaches zero, it can be seen that C approaches 1. The result we establish in section 4 is sharp and applies whenever A is fully indecomposable.

It is worth noting that we can generate a stopping criterion for the SK algorithm that can be computed very efficiently. We want to stop when $\mathcal{D}(r_k)Ac_k$ and $\mathcal{D}(c_k)A^T r_k$ are both close to e. After each SK step, the first of these criteria is satisfied (up to round-off error) as we will have just balanced the rows of A. To get an estimate of the error in the column sums, we note that $A^T r_k = \mathcal{D}(c_{k+1})^{-1}e$, so in the middle of the step we can estimate our error by computing

$$err_k = \|c_k \circ d_{k+1} - e\|_1, \tag{2.7}$$

where $d_{k+1} = \mathcal{D}(c_{k+1})^{-1}e$ and $\circ$ represents the Hadamard product.

Matrix balancing can be used as a simple technique for preconditioning a matrix. Given a fully indecomposable matrix $A \in \mathbb{R}^{n\times n}$ we can find two $n \times n$ diagonal matrices D and E such that the p-norms of the rows and columns of DAE are all equal. This idea was explored in [2, 10] as a method for finding a diagonal scaling such that $\kappa(DAE) \ll \kappa(A)$. By applying the SK algorithm to the matrix whose (i, j)th element is $|a_{ij}^p|$, it is easily seen that the problem is essentially identical for $1 < p < \infty$. The case $p = \infty$ is studied in [8, 20].

3. Balancing symmetric matrices. If A is symmetric, then it is natural to look for a diagonal matrix D such that DAD is doubly stochastic. We can do this by using the SK algorithm: If $\mathcal{D}(r)A\mathcal{D}(c)$ is doubly stochastic, then so is its transpose $\mathcal{D}(c)A\mathcal{D}(r)$, and since, up to a scalar factor, the balancing is unique (by Theorem 2.1), $r = \alpha c$. If $\alpha \neq 1$, we can scale our limiting vectors to regain symmetry.

During the iteration, though, symmetry is lost, and an alternative approach is to generate a sequence of symmetric iterates. The symmetric analogues of (2.3) and (2.4) are

$$x = \mathcal{D}(Ax)^{-1}e \tag{3.1}$$

and

$$x_k = \mathcal{D}(Ax_{k-1})^{-1}e \tag{3.2}$$

respectively. We note that this iteration can be coded in MATLAB by repeated application of the single instruction `x = 1./(A*x)`, which must make it one of the most compact algorithms in numerical analysis!

While the iteration superficially retains symmetry, it is in fact no different from the SK algorithm. By comparing (3.2) with (2.4) we see that, for $k \geq 0$, $x_{2k} = r_k$ and $x_{2k+1} = c_{k+1}$.

Conversely, we can use the iteration given by (3.2) on nonsymmetric matrices: Simply apply it to

$$S = \begin{bmatrix} 0 & A \\ A^T & 0 \end{bmatrix}. \tag{3.3}$$

This is more than an academic exercise. To establish the rate of convergence of the SK algorithm we first find the convergence rate of (3.2). This will be sufficient, as in exact arithmetic the iterates coincide.

To see this, let

$$x_k = \begin{bmatrix} y_k \\ z_k \end{bmatrix},$$

and (3.2) becomes

$$y_{k+1} = \mathcal{D}(Az_k)^{-1}e, \tag{3.4}$$

$$z_{k+1} = \mathcal{D}(A^T y_k)^{-1}e. \tag{3.5}$$

Hence

$$y_{k+1} = \mathcal{D}(A\mathcal{D}(A^T y_{k-1})^{-1}e)^{-1}e,$$
$$z_{k+1} = \mathcal{D}(A^T\mathcal{D}(Az_{k-1})^{-1}e)^{-1}e.$$

However, from (2.4), we have

$$c_k = \mathcal{D}(A\mathcal{D}(A^T c_{k-1})^{-1}e)^{-1}e,$$
$$r_k = \mathcal{D}(A^T\mathcal{D}(Ar_{k-1})^{-1}e)^{-1}e,$$

and we conclude that one step of the SK algorithm is equivalent to two steps of (3.2) applied to S.

Symmetric balancing is also considered in [18], where the equation $\mathcal{D}(Ax)x = e$ is solved by using a Gauss–Seidel–Newton method.

4. The rate of convergence of the Sinkhorn–Knopp algorithm. We now consider the convergence of the symmetric SK algorithm in (3.2) by adapting as necessary the standard tools for analysis of a fixed point iteration. At this stage, we restrict ourselves to fully indecomposable matrices as in this case (3.2) has a unique positive fixed point, but we will comment on the more general case (matrices with total support) at the end of the section.

There are two complications we have to consider when trying to establish convergence. The first is that, in general, the iteration does not converge as when the SK algorithm is used on a symmetric matrix the sequences $\{r_k\}$ and $\{c_k\}$ will almost surely converge to different limits. Eventually we oscillate between a pair of vectors that are scalar multiples of the fixed point. However, our ultimate goal is to establish a sharp convergence result for the general SK algorithm, and it will suffice to consider the alternating subsequences.

The second complication is that, around the fixed point, the Jacobian matrix has spectral radius one, and so we cannot make direct use of the contraction mapping theorem. However, the nature of the subspace associated with the principal eigenvector means that this, too, can be dealt with. Soules makes similar observations regarding the SK algorithm in [23] and proves linear convergence. As we are trying to put a number to this rate, we cannot use Soules's result. Instead, by using our compact representation of the iteration, we present a simple analysis that leads to an explicit value for the rate of convergence.

We first prove a couple of lemmas to confirm some of the statements made in the preceding discussion.

LEMMA 4.1. [illegible] A [illegible] x_* [illegible] $\mathcal{D}(x_*)A\mathcal{D}(x_*) = P$ [illegible] P [illegible].

. This is a trivial consequence of Theorem 2.1. For existence, suppose that $\mathcal{D}(r)A\mathcal{D}(c) = P$, and let $x_* = \sqrt{\mathcal{D}(r)\mathcal{D}(c)}e$ (by symmetry r and c are collinear). If $\mathcal{D}(x)A\mathcal{D}(x) = \mathcal{D}(y)A\mathcal{D}(y)$, then, for some $\alpha > 0$, $x = \alpha y$ and $y = \alpha x$. Hence $x = y$. □

LEMMA 4.2. [illegible] A [illegible] x_* [illegible] $\mathcal{D}(x_*)A\mathcal{D}(x_*) = P$ [illegible].

P [illegible] $f(x) = \mathcal{D}(Ax)^{-1}e$ [illegible] $f(x)$ [illegible]

1. [illegible] $x \in \mathbb{R}^n_+$, $J(x) = -\mathcal{D}(Ax)^{-2}A$
2. [illegible] $\alpha \in \mathbb{R}_+$,

$$J(\alpha x_*) = -\frac{1}{\alpha^2}\mathcal{D}(x_*)P\mathcal{D}(x_*)^{-1}.$$

[illegible]

1. This can be confirmed by a straightforward componentwise calculation or by tensor calculus. We restrict ourselves to positive vectors to ensure that $Ax > 0$ and hence that $\mathcal{D}(Ax)$ is invertible.

2. At the fixed point, $\mathcal{D}(Ax_*) = \mathcal{D}(x_*)^{-1}$; hence $\mathcal{D}(A(\alpha x_*)) = \alpha\mathcal{D}(x_*)^{-1}$ and

$$J(\alpha x_*) = -\frac{1}{\alpha}^2\mathcal{D}(x_*)^2A = \mathcal{D}(x_*)(\mathcal{D}(x_*)A\mathcal{D}(x_*))\mathcal{D}(x)^{-1} = -\frac{1}{\alpha}^2\mathcal{D}(x_*)P\mathcal{D}(x_*)^{-1}. \quad \square$$

We now consider the behavior of $f(x)$ when x is in the neighborhood of αx_*. Because of the alternating behavior, we consider the effects of two iterations at a time.

LEMMA 4.3. [illegible] A [illegible] $\mathcal{D}(x_*)A\mathcal{D}(x_*) = P$ [illegible] x_* [illegible] P [illegible] $f(x) = \mathcal{D}(Ax)^{-1}e$ [illegible] $\alpha > 0$ [illegible] $\widehat{x}$ [illegible] ϵ [illegible] αx_* [illegible]

$$\min_{v\in\mathcal{V}} \|f^2(\widehat{x}) - v\| \le |\lambda_2|^2\epsilon + o(\epsilon), \tag{4.1}$$

[illegible] $\mathcal{V}$ [illegible] x_* [illegible]. Suppose that, for some $\epsilon > 0$, $\widehat{x} = \alpha x_* + d$, with $\|d\| < \epsilon$. Let $D = \mathcal{D}(x_*)$, and note that $f(\alpha x_*) = x_*/\alpha$ and $f^2(\alpha x_*) = \alpha x_*$. We can write

$$\begin{aligned} f^2(\widehat{x}) &= f(f(\alpha x_*) + J(\alpha x_*)d + o(\epsilon)) \\ &= f^2(\alpha x_*) + J(x_*/\alpha)J(\alpha x_*)d + o(\epsilon) \\ &= \alpha x_* + (-\alpha^2 DPD^{-1})(-\alpha^{-2}DPD^{-1})d + o(\epsilon) \\ &= \alpha x_* + DP^2D^{-1}d + o(\epsilon) = \alpha x_* + J^2d + o(\epsilon), \end{aligned}$$

where $J = DPD^{-1}$. As $\rho(P) = 1$, we cannot use the contraction mapping theorem to show that $\|f^2(\widehat{x}) - \alpha x_*\| < \|\widehat{x} - \alpha x_*\|$. However, observe that A is fully indecomposable; hence P is, too, and since doubly stochastic matrices with this property are primitive [3], P has a single simple eigenvalue of modulus one. The corresponding eigenvector of J is x_*. By using Wielandt deflation [26], we can write

$$J = -(x_*y^T + J_0),$$

where

$$\sigma(J_0) = \sigma(P) - \{1\} \cup \{0\} = \{\lambda_2, \ldots, \lambda_n, 0\}$$

by choosing, for example, $y = x_*/{x_*}^T x_*$. Since $J_0x_* = 0$,

$$\begin{aligned} f^2(\widehat{x}) &= \alpha x_* + (x_*y^T + J_0)^2 d + o(\epsilon) \\ &= J_0^2 d + (1 + y^T(J_0 + I)d)x_* + o(\epsilon). \end{aligned}$$

Choosing our norm so that $\|J_0\| \leq |\lambda_2| + \epsilon$ and letting $v = (1 + y^T(J_0 + I)d)x_*$ establishes (4.1). □

We can conclude that, as our iterates approach the subspace spanned by x_*, the contribution to our iterates from other directions diminishes linearly at a rate governed by the second eigenvalue of P. The fact that we are heading for a fixed line rather than a fixed point is sufficient for us to find the scaling we crave. Since we already know that the SK algorithm converges, we can be sure that we eventually lie in a neighborhood that satisfies the conditions of Lemma 4.3.

THEOREM 4.4. [illegible] A [illegible] $\mathcal{D}(x_*)A\mathcal{D}(x_*) = P$ [illegible] P [illegible] $\{x_k\}$ [illegible] (3.2) [illegible] $x_0 = e$ [illegible] $\epsilon > 0$ [illegible] $K_1 \in \mathbb{Z}$ [illegible] $k \geq K_1$, $x_k = \alpha_k x_* + d_k$ [illegible] $\|d_k\| < \epsilon$ [illegible] α_k [illegible] $K_2 \in \mathbb{Z}$ [illegible] $k \geq K_2$,

$$\|d_{k+2}\| \leq |\lambda_2|^2 \|d_k\|,$$

[illegible] λ_2 [illegible] P [illegible]. The existence of K_1 is guaranteed by Theorem 2.1 and our observation on the equivalence of the SK algorithm and (3.2). The existence of K_2 follows from Lemma 4.3. □

The result does not immediately extend to the nonsymmetric case as when we form S by using (3.3) we lose indecomposability. This isn't a problem though.

THEOREM 4.5. [illegible] A [illegible] r_* [illegible] c_* [illegible] $\mathcal{D}(r_*)A\mathcal{D}(c_*) = P$ [illegible] P [illegible] $K \in \mathbb{Z}$ [illegible] $k \geq K$,

$$\left\| \begin{bmatrix} r_{k+1} \\ c_{k+1} \end{bmatrix} - \begin{bmatrix} r_* \\ c_* \end{bmatrix} \right\| \leq \sigma_2^2 \left\| \begin{bmatrix} r_k \\ c_k \end{bmatrix} - \begin{bmatrix} r_* \\ c_* \end{bmatrix} \right\|,$$

[illegible] σ_2 [illegible] P [illegible]. The convergence of the algorithm is guaranteed by Theorem 2.1. To determine the rate of convergence we need to adapt Lemma 4.3. Consider the spectrum of $J(x_*)$ when we form the matrix S by using (3.3). This will be the same as the spectrum of

$$Q = \begin{bmatrix} 0 & P \\ P^T & 0 \end{bmatrix}.$$

The conditions imposed on A ensure that P is primitive, and hence so is P^TP. Since the spectrum of Q is the set of positive and negative square roots of the eigenvalues[3] of P^TP, we have an additional eigenvalue of modulus one. We need to consider how the iteration behaves in the neighborhood of the associated subspace $\mathcal{V}$.

The two eigenvectors of $J(x_*)$ corresponding to the maximal eigenvalues take the form

$$v_1 = \begin{bmatrix} r_* \\ c_* \end{bmatrix} \quad \text{and} \quad v_2 = \begin{bmatrix} r_* \\ -c_* \end{bmatrix}.$$

By assuming $\widehat{x}$ is in an ϵ-neighborhood of $\mathcal{V}$, we can again show that

$$\min_{v \in \mathcal{V}} \|f^2(\widehat{x}) - v\| \leq |\lambda_2(Q)|^2 \epsilon + o(\epsilon),$$

and $|\lambda_2(Q)| = \sigma_2(P)$.

[3] Or singular values of P.

We have essentially proved the theorem; we just have to identify the iterates from the symmetric algorithm that appear as iterates in the SK algorithm. By following the discussion at the end of section 3 we can identify r_k as the top half of x_{2k} and c_k as the bottom half of x_{2k-1}. This explains why the rate of convergence of the SK algorithm is σ_2^2. SK algorithm avoids the oscillations in the symmetric algorithm as r_k and c_k are formed from convergent subsequences of $\{x_k\}$. □

Theorem 2.1 states that the SK algorithm is convergent if A has total support, while Theorem 4.5 applies only if A is fully indecomposable. This gap is easily reconciled: If A has total support but is not fully indecomposable, then it must be a direct sum of fully indecomposable matrices. Such a matrix can be permuted into block diagonal form

$$\begin{bmatrix} A_1 & & & \\ & A_2 & & \\ & & \ddots & \\ & & & A_k \end{bmatrix},$$

where each diagonal block is fully indecomposable. The behavior of the SK algorithm is unaffected by permutations (unlike the symmetric variant). If we apply the SK algorithm to the block diagonal form, then clearly the convergence in each block will be independent of all others, and the doubly stochastic matrix we converge towards can be written

$$\begin{bmatrix} P_1 & & & \\ & P_2 & & \\ & & \ddots & \\ & & & P_k \end{bmatrix},$$

where each P_i is itself doubly stochastic and fully indecomposable. The asymptotic rate of convergence to P_i is $\sigma_2^2(P_i)$. If we want to talk about an overall asymptotic convergence, then it will be bounded above by

$$\max_{1 \le i \le k} \sigma_2^2(P_i).$$

However, we may not see this upper bound reached, for example, in the case that some of the A_i are already doubly stochastic.

5. Ranking web pages. The PageRank algorithm, introduced by Brin et al. [6], has proved to be an incredibly successful technique for ordering large sets of connected data. In essence, the method takes a matrix G representing the connectivity of a network and scales the columns so that the matrix is column stochastic.[4] The stationary distribution of this scaled matrix is then calculated, typically by using the power method, and the size of the probabilities is used to order the nodes in the network. A thorough description of the method and associated theory can be found in [17]. We note that the column scaling is trivial to achieve (requiring half a step of the SK algorithm) and the main work is in computing the stationary distribution. In this section we use the SK algorithm to compute an alternative method for ordering data which has a similar cost to PageRank but which has two principal advantages. First,

[4] In our connectivity matrix the (i, j)th entry is one if there is a link from the jth node to the ith node.

for each node in our network we get two measures rather than one which we claim are analogous to the authorities and hubs of Kleinberg's Hypertext Induced Topic Selection (HITS) algorithm [14]. Second, there is no need to treat dangling nodes differently to any other, whereas in the PageRank algorithm it is necessary to preprocess the connectivity matrix in some way, because otherwise the column scaling fails [21].

The guiding heuristic behind the PageRank model is simple to state, namely, that the random walk will visit significant web pages more frequently than insignificant ones, and the success of this graph interpretation in mimicking the subjective property of significance is one of the main reasons behind its current ubiquity.

We offer a simple heuristic to justify our application of the SK algorithm to the problem. Clearly the probabilities in the associated distribution tell us nothing as the distribution is uniform.[5] If we think in terms of the traffic flowing around the network represented by G, then our aim is to balance the flow through each node. That is, we want to scale G so that its stationary distribution is uniform or, equivalently, so that it is doubly stochastic. Suppose then that $\mathcal{D}(r)G\mathcal{D}(c)$ is doubly stochastic. If node i in the unweighted graph draws traffic in disproportionately, then this will have to be compensated for by r_i being relatively small. Similarly, if a node has a tendency to emit traffic, then c_i will need to be relatively small. We associate the tendency of a node to emit traffic with it being a hub, a node which points to several sources of information on a topic. The tendency to draw in traffic is associated with authoritativeness, a node that contains definitive information on a particular topic. We can order the nodes with respect to each of these properties by reversing the order of the entries of r and c. This heuristic is very similar to that behind the ordinary gravity model in transport planning [1, 16], where the SK algorithm has been successfully employed.

While we believe the use of the SK algorithm in web applications is new, it is related to a technique proposed by Tomlin in [24]. Here one looks to find a vector d such that similarity transformation induced by $\mathcal{D}(d)$ on the connectivity matrix $P = D^{-1}GD$ fixes the sum of the entries of P and, for $1 \le i \le n$,

$$\sum_{j=1}^{n}(p_{ij} - p_{ji}) = 0. \tag{5.1}$$

Tomlin argues that the authoritativeness of the jth node is proportional to the size of d_j, while the jth row/column sum can be used as a hub measure. Tomlin suggests an iterative algorithm for computing d, the iterative step for which can be written in MATLAB as

$$\texttt{d} = \texttt{sqrt}((\texttt{G} * \texttt{d})./(\texttt{G}' * (1./\texttt{d}))),$$

but no conditions for convergence are given although it is claimed to work in practice. A criticism of Tomlin's technique is that, if G is symmetric, (5.1) is satisfied with $D = I$, and the method fails to identify authorities. While G will not be symmetric in web applications, there seems to be no justification for this phenomenon.

5.1. Practicalities. On any large set of web data it is unreasonable to expect the nodes to form a single strongly connected component, and our matrix is highly unlikely to be fully indecomposable. Hence it is necessary to make a perturbation to G for the SK algorithm to converge. In PageRank a damping factor is used: If P

[5] We can claim categorically that this is the worst possible method for ranking web pages!

```
function [c, r] = sk(G, tol, g)
[n, n] = size(G);
r = ones(n,1); c = r;
d = G'*r + g*sum(r);
while norm(c.*d - 1,1) > tol
    c = 1./d;
    r = 1./(G*c+ g*sum(c));
    d = G'*r + g*sum(r);
end
```

FIG. 5.1. *A balancing algorithm for web ranking.*

is the column stochastic scaling of the web graph, then we compute the stationary distribution of

$$P_\alpha = \alpha P + (1-\alpha)ee^T/n. \tag{5.2}$$

Inspired by this idea, we simply make a rank one perturbation to G by adding a constant γ to each element. Our justification for doing this is similar to that in PageRank: If we wish to model a random crawl on the web, we have to allow a mechanism for moving between any pair of nodes. Clearly we do not want to make the perturbation explicitly as we want to take advantage of the sparsity in G, and indeed it is easily avoided. By using (2.4), and the fact that all of the iterates are positive, we can write

$$c_{k+1} = \mathcal{D}((G+\gamma ee^T)^T r_k)^{-1} e = \mathcal{D}(G^T r_k + \gamma \|r_k\|_1 e)^{-1} e$$

and similarly

$$r_{k+1} = \mathcal{D}(G^T c_{k+1} + \gamma \|c_{k+1}\|_1 e)^{-1} e.$$

A MATLAB program for carrying out balancing of $G + \alpha ee^T$ by using the stopping criterion for the SK algorithm (2.7) is given in Figure 5.1. All the user needs to supply is the connectivity graph and a choice of tolerance and the parameter γ. The cost of the algorithm is dominated by the two matrix-vector multiplies at each step. For very large values of n, the cost of the transpose is likely to be significant, and the algorithm should be adapted to work with G and G^T efficiently.

The damping factor in PageRank controls the rate of convergence of the power method by fixing the size of the second eigenvalue of P_α. This is a consequence of the following theorem, due to Brauer [4], a simple proof of which can be found in [9].

THEOREM 5.1. [illegible]

$$1, \lambda_2, \ldots, \lambda_n.$$

[illegible] $0 \le \alpha \le 1$ [illegible] P_α [illegible] (5.2) [illegible] $\{1, \alpha\lambda_2, \ldots, \alpha\lambda_n\}$

The result is also true for a more general set of rank one perturbations, but if we restrict ourselves to this particular one, we can extend the result to determine the singular values in the doubly stochastic case.

COROLLARY 5.2. [illegible]

$$1, \sigma_2, \ldots, \sigma_n.$$

[illegible] $0 \le \alpha \le 1$ [illegible] P_α [illegible] $\{1, \alpha\sigma_2, \ldots, \alpha\sigma_n\}$

. Since

$$\begin{aligned} P_\alpha^T P_\alpha &= \alpha^2 P^T P + \frac{\alpha(1-\alpha)}{n}(ee^T P + Pee^T) + \frac{(1-\alpha)^2}{n^2} ee^T ee^T \\ &= \alpha^2 P^T P + \frac{2\alpha(1-\alpha)}{n} ee^T + \frac{(1-\alpha)^2}{n} ee^T \\ &= \alpha^2 P^T P + \frac{1-\alpha^2}{n} ee^T, \end{aligned}$$

the result follows by applying Theorem 5.1 to $P^T P$. □

In many applications, α is given the value 0.85, but care must be taken to ensure that P_α sufficiently resembles P [12]. For the balancing algorithm we are unable to prove a result as strong as Theorem 5.1. However, by using our convergence result for the SK algorithm, we argue that the criteria for making a good choice for the parameter γ are similar to those used in PageRank.

We can apply the Franklin–Lorenz bound (2.6) in the perturbed case to get an idea of the effect of varying γ. Since G contains only zeros and ones we have, from (2.5),

$$\theta(G + \gamma ee^T) = \max_{i,j,k,l} \frac{(g_{ik}+\gamma)(g_{jl}+\gamma)}{(g_{jk}+\gamma)(g_{il}+\gamma)} \leq \frac{(1+\gamma)^2}{\gamma^2},$$

and hence the rate of convergence can be bounded above by $1/(1+2g)$. While this shows that we can expect the convergence of the algorithm to improve by increasing γ, experimental evidence shows that this severely underestimates the effect of the parameter, and a more realistic upper bound would be of the form $1/p(n,\gamma)$ for some low degree polynomial in n and γ. Such a bound is simple to prove in certain important special cases.

For example, suppose that P is doubly stochastic, and we use the SK algorithm on $P' = P + \gamma ee^T$. Then $\mathcal{D}(r_k)P'\mathcal{D}(c_k)$ converges to $Q = (1+n\gamma)^{-1}P'$, since this is clearly a doubly stochastic diagonal scaling of P', and, by Theorem 2.1, such a scaling is unique. Notice that $Q = P_\alpha$, where $\alpha = (1+n\gamma)^{-1}$, and so, by Corollary 5.2 and Theorem 4.5, the SK algorithm will converge asymptotically with rate $(1+n\gamma)^{-2}$. For example, choosing $\gamma = 0.1/n$ gives a convergence rate of around 0.83.

6. Results. In section 4 we showed that if the SK algorithm is used on a fully indecomposable nonnegative matrix and it converges to the doubly stochastic matrix P, then the rate of convergence is asymptotically equal to the square of the second singular value of P. Generally, we have found that this asymptotic convergence rate is approached fairly quickly. This is illustrated in Figure 6.1 for three matrices. A is the 10×10 upper Hessenberg matrix whose nonzero entries are all 1; B and C are random 50×50 matrices whose nonzero entries are uniformly distributed in $[0,1]$. They are generated so that approximately 30 percent of B's elements and 15 percent of C's elements are nonzero. The solid lines show the error as the iteration progresses using (2.7); the dashed lines represent the asymptotic rates predicted by Theorem 4.5.

In section 5.1 we claimed that the rate of convergence of the SK algorithm was significantly faster when we made a uniform rank one perturbation to the original graph. In Figures 6.2 and 6.3 we provide evidence for our claim that the rate of convergence of the SK algorithm on the $n \times n$ matrix $A + \gamma ee^T$ can be bounded by $1/p(n,\gamma)$ for some low degree polynomial in n and γ.

In Figure 6.2 we show the results of varying γ on a sparse random symmetric 1000×1000 matrix with a positive diagonal (which ensures that the matrix is fully indecomposable).

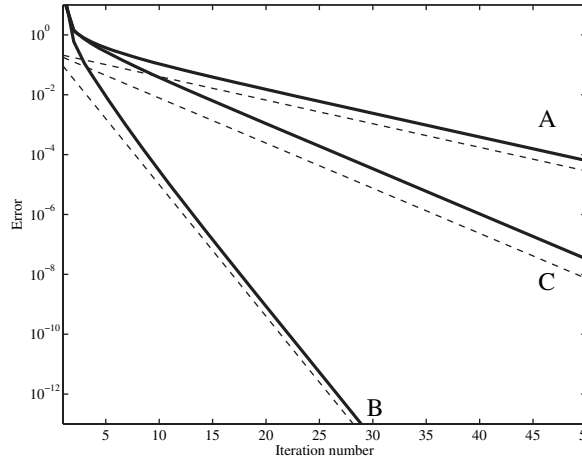

FIG. 6.1. *Rate of convergence of the Sinkhorn–Knopp algorithm.*

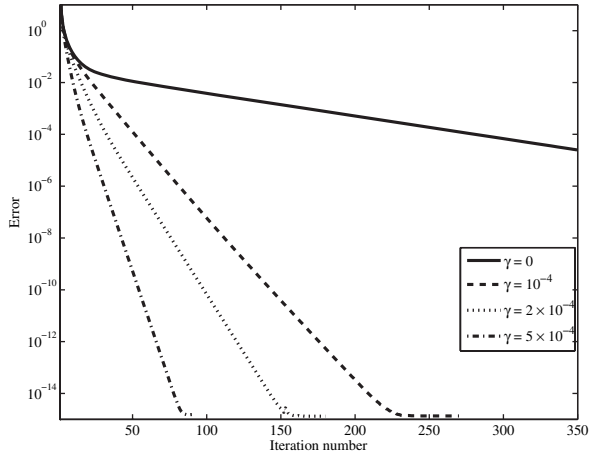

FIG. 6.2. *Varying γ for a random sparse matrix.*

In Figure 6.3 we show the results of varying γ on the connectivity graph for a 2002 web crawl of Stanford University websites [27]. There are 281093 nodes, and the matrix has roughly 2 million nonzero entries. While this particular matrix has been criticized [25] for not having a representative web structure, it usefully illustrates the effects of varying γ. In this case, if $\gamma = 0$, the matrix is not fully indecomposable. The lines show how convergence speeds up as we vary γ through the values $0.01/n$, $0.1/n$, $0.5/n$, $1/n$, $2/n$, and $4/n$.

We now investigate how our new measure compares with PageRank. In our first example, we look at the toy example of a graph of six web pages used in [17], whose connectivity is illustrated in Figure 6.4.

By using PageRank with $\alpha = .9$, the nodes are ordered (from most significant to least) 4, 6, 5, 2, 3, 1. By using the HITS algorithm, the order of authoritativeness is 5, 2, 6, 1, 4, 3, while the hub ordering is 3, 4, 1, 5, 6, 2. By using the algorithm in Figure 5.1 (and with $\gamma = 1/60$) we find that our ordering of authoritativeness matches PageRank exactly. Our ordering of the hubs differs from HITS only in that nodes

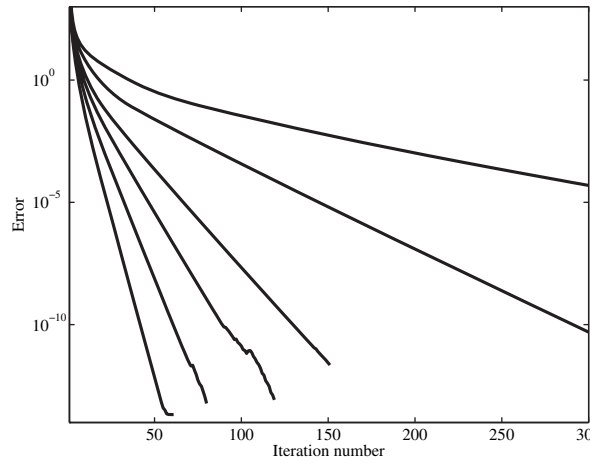

FIG. 6.3. *Varying γ for the Stanford matrix.*

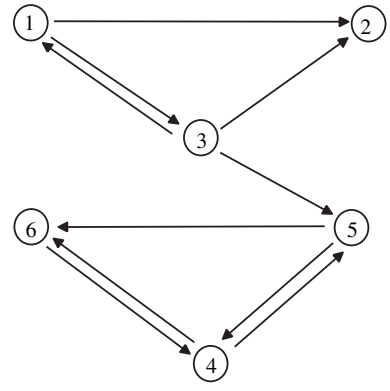

FIG. 6.4. *A miniature web graph.*

1 and 4 are transposed. We should not expect the exact correspondence between PageRank and our new measure to extend to larger systems as we are trying to measure something different.

We have carried out a number of experiments on the graph of all of the links between articles in the Wikipedia online database, collated in 2005. The resulting graph has just over 1.1 million nodes, and there are roughly 18.3 million nonzeros in the connectivity matrix. Figure 6.5 shows a comparison of PageRank ($\alpha = .85$) against the authorities computed by the SK algorithm ($\gamma = .1/n$). The graph shows the proportion of nodes that are among the top N authorities and are in the top N for high PageRank for $1 \leq N \leq 1000$. We note the strong correlation between the two.

Finally, we investigate how well the SK algorithm allows us to distinguish between hubs and authorities. Table 6.1 shows the top 10 or so nodes[6] in the Wikipedia dataset according to a variety of measures. The first column is ordered according to PageRank ($\alpha = .85$) and the second according to the authorities as measured with the SK algorithm. In the third column we have filtered out authorities whose hub rating

[6]We have grouped certain linked terms that appeared consecutively.

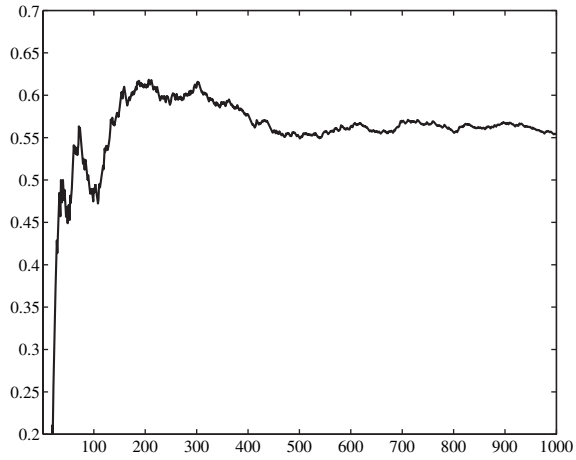

FIG. 6.5. *Comparison of web measures on Wikipedia data.*

TABLE 6.1
Highest ranked subjects in Wikipedia.

PageRank	Authorities	Filtered auth.	Filtered hubs
United States	2000	2000	Political parties
Race (U.S. Census)	Pop. density	Marriage	Environment topics
United Kingdom	km^2	U.S.	State leaders
France	Census	2003,2004,2005	Airlines
2005,2004,2000	Square mile	UK/England	2 letter combinations
Canada	Marriage	Canada	Masts
England	Per capita income	Japan	Mathematicians
Cat. by country	U.S. Census	Australia	Peerage of the UK
2003	Poverty line	2001, 2002	Record labels
Cat.:Culture	Race (U.S. Census)	Germany	Biblical names

is particularly low. Our rationale for doing this is that if an authoritative page has a high hub rating it will be linked to many other subjects and is therefore likely to be of more general interest. This is precisely what we see here, where we have listed only authorities that are also in the top 2% of hubs. The fourth column lists the top hubs, this time filtered to include only those among the top 25% of authorities. We note that all of the top hubs are either tables or lists.

7. Concluding remarks. The SK algorithm can be viewed (for symmetric matrices) as a power method like technique for solving the matrix problem $Ax = 1/x$. This connection can be seen in the similar convergence properties and costs of the two algorithms. The results of our experiments back our claim that the SK algorithm can be used to distinguish between hubs and authorities in web-type graphs at a cost similar to that of PageRank. The notion of quality of an ordering is fairly subjective, but we feel that the results in Table 6.1 demonstrate that we can obtain useful information with this approach.

In order to balance speed and quality in ordering web data with the algorithm given in Figure 5.1, we suggest choosing the parameter γ to lie in the range $.01 \leq \gamma n \leq 1$. Evidence that a choice in this range can be used to compute a measure in a comparable time to PageRank is supplied by our experiments and the partial results in section 5.1.

Acknowledgment. We thank David Gleich at Stanford University for providing the data from Wikipedia.

A FAST NEWTON'S METHOD FOR A NONSYMMETRIC ALGEBRAIC RICCATI EQUATION*

DARIO A. BINI†, BRUNO IANNAZZO‡, AND FEDERICO POLONI§

Abstract. A special instance of the algebraic Riccati equation $XCX - XE - AX + B = 0$ where the $n \times n$ matrix coefficients A, B, C, E are rank structured matrices is considered. Relying on the structural properties of Cauchy-like matrices, an algorithm is designed for performing the customary Newton iteration in $O(n^2)$ arithmetic operations (ops). The same technique is used to reduce the cost of the algorithm proposed by L.-Z. Lu in [*Numer. Linear Algebra Appl.*, 12 (2005), pp. 191–200] from $O(n^3)$ to $O(n^2)$ ops while still preserving quadratic convergence in the generic case. As a byproduct we show that the latter algorithm is closely related to the customary Newton method by simple formal relations. In critical cases where the Jacobian at the required solution is singular and quadratic convergence turns to linear, we provide an adaptation of the shift technique in order to get rid of the singularity. The original equation is transformed into an equivalent Riccati equation where the singularity is removed while the matrix coefficients maintain the same structure as in the original equation. This leads to a quadratically convergent algorithm with complexity $O(n^2)$ which provides approximations with full precision. Numerical experiments and comparisons which confirm the effectiveness of the new approach are reported.

1. Introduction.

Consider the following nonsymmetric algebraic Riccati equation (NARE) arising in transport theory:

$$XCX - XE - AX + B = 0, \tag{1.1}$$

where $A, B, C, E \in \mathbb{R}^{n\times n}$ are given by

$$A = \Delta - eq^T, \quad B = ee^T, \quad C = qq^T, \quad E = D - qe^T, \tag{1.2}$$

and

$$\begin{array}{lll} e = (1, 1, \ldots, 1)^T, & & \\ q = (q_1, q_2, \ldots, q_n)^T & \text{with} & q_i = \frac{w_i}{2t_i}, \\ \Delta = \operatorname{diag}(\delta_1, \delta_2, \ldots, \delta_n) & \text{with} & \delta_i = \frac{1}{ct_i(1+\alpha)}, \\ D = \operatorname{diag}(d_1, d_2, \ldots, d_n) & \text{with} & d_i = \frac{1}{ct_i(1-\alpha)}. \end{array} \tag{1.3}$$

The matrices and vectors above depend on the parameters $0 < c \leqslant 1$, $0 \leqslant \alpha < 1$ and on the sequences $0 < t_n < \cdots < t_2 < t_1 < 1$ and $w_i > 0$, $i = 1, 2, \ldots, n$, such

that $\sum_i w_i = 1$. For more details and for the physical meaning of these parameters, we refer the reader to [13] and to the references therein. The solution of interest is the minimal positive one, which exists as proved by Juang and Lin in [13].

It was shown by Guo [6] that this equation falls in the class of NAREs associated with a nonsingular M-matrix or a singular irreducible M-matrix; in fact, arranging the coefficients as

$$M = \begin{bmatrix} E & -C \\ -B & A \end{bmatrix} \tag{1.4}$$

yields an M-matrix.

For this class of AREs, several suitable algorithms exist for computing the minimal positive solution: the Newton method [10], the logarithmic and cyclic reduction [2, 7], and the structure-preserving doubling algorithm [9, 11]. All these algorithms share the same order of complexity, that is, $O(n^3)$ arithmetic ops per step, and provide quadratic convergence in the generic case.

Observing that (1.1) is defined by a linear number of parameters, it is quite natural to aim to design algorithms which exploit the structure of the matrices and thus have a cost of order lower than $O(n^3)$ ops.

A step in this direction has been done by Lu [15] who has designed a vector iteration whose limit allows one to easily recover the solution. The iteration has a computational cost of $O(n^2)$ ops per step and converges linearly for $\alpha \neq 0$ or $c \neq 1$. The linear convergence is a drawback since the algorithm in many cases needs a large number of iterations to [illegible] and it is outperformed by algorithms with quadratic convergence and $O(n^3)$ ops. In fact, the same author in [14] proposes a mixed algorithm to speed up the computation. The algorithm starts with the linear iteration of complexity $O(n^2)$ and switches to a quadratically convergent one, of complexity $O(n^3)$, when some conditions are satisfied.

In this paper we consider the customary Newton method applied to (1.1). By exploiting the rank structure of the matrix coefficients, we design an algorithm for performing the Newton step in $O(n^2)$ ops. The new approach relies on a suitable modification of the fast LU factorization algorithm for Cauchy-like matrices proposed by Gohberg, Kailath, and Olshevsky in [4].

The same idea is applied to implement the quadratically convergent iteration of Lu [14] by an algorithm with cost $O(n^2)$ ops. We also provide formal relations between the sequences generated by Lu's and Newton's iterations which enable one to deduce the convergence of Lu's algorithm directly from the well-known properties of Newton's method.

In the critical but still important case where the Jacobian at the solution is singular, the convergence of Newton's (and therefore Lu's) iteration turns to linear; also the mixed iteration proposed in [14] loses its quadratic convergence while the iteration of [15] converges sublinearly.

In this case, which is encountered when $\alpha = 0$, $c = 1$, we can get rid of the singularity of the Jacobian and consequently all the above-mentioned drawbacks. The idea is to apply the shift technique originally introduced by He, Meini, and Rhee [12] and used in the framework of Riccati equations by Guo, Iannazzo, and Meini in [9] and by Guo [7]. With this technique, we replace the original Riccati equation with a new one having the same minimal solution as the original equation (1.1) but where the singularity of the Jacobian is removed. We prove that the matrix coefficients of the new equation share the same rank structure properties of the coefficients of (1.1). This enables us to design a fast Newton iteration which preserves the quadratic

convergence and keeps the same $O(n^2)$ complexity even in the critical case.

As a byproduct of this analysis, we find that the approximation to the minimal solution of (1.1) that we compute from the "shifted" equation is much more accurate than the one obtained by applying the algorithm to the original equation. More precisely, it has been shown by Guo and Higham [8] that in order to achieve high accuracy it is necessary to use the singularity of M in the design of algorithms; otherwise, we can expect only to achieve an accuracy of $O(\sqrt{\varepsilon})$, where ε is the machine precision. With the use of the shift technique [9], the information on the singularity of M is plugged into the algorithm, and we may achieve full accuracy in the approximation as confirmed by the numerical experiments.

The paper is organized as follows. After some preliminaries presented in section 2, we show in section 3 how to reduce one step of Newton's iteration for (1.1) to the solution of a linear system with a structured matrix, and in section 4 we deal with the problem of solving such a system in $O(n^2)$ ops. In section 5 we show that the iteration proposed by Lu [14] shares the same displacement structure and thus its complexity can be reduced to $O(n^2)$ as well, and we exploit the connection between it and the Newton iteration. In section 6 we deal with the critical case where the Jacobian is singular, by using the shift technique. In section 7 we address the main numerical stability issues, and in section 8 we present some numerical examples. From the experiments performed so far, our method turns out to be much faster and accurate than the existing methods. Finally, in section 9, we discuss some possible generalizations of this algorithm together with some research lines.

2. Preliminaries. A basic tool which we use is the concept of a Cauchy-like matrix [4]. A matrix $C = (c_{ij})_{i,j=1,\dots,n}$ is called [illegible] if its elements are of the form $c_{ij} = \frac{u_i v_j}{r_i - s_j}$ for some constants u_i, v_i, r_i, s_i, $i = 1, \dots, n$, such that $r_i \neq s_j$ for each i, j. If we define $R = \operatorname{diag}(r_1, r_2, \dots, r_n)$ and $S = \operatorname{diag}(s_1, s_2, \dots, s_n)$, we have $RC - CS = uv^T$, where $u = [u_1, u_2, \dots, u_n]^T$ and $v = [v_1, v_2, \dots, v_n]^T$. The operator $C \mapsto RC - CS$ is called the [illegible], and u, v^T are called the [illegible] of C. Generalizing, if there exist two diagonal matrices R, S such that $RC - CS$ has rank r, we say that C has [illegible] r. When r is small with respect to the size of C, C is called a [illegible] with respect to the pair (R, S).

Note that, using (1.2), equation (1.1) can be rewritten as

$$XD + \Delta X = (Xq + e)(e^T + q^T X);$$

therefore any solution X is Cauchy-like with respect to $(\Delta, -D)$ and its generators are $u = Xq + e$ and $v^T = e^T + q^T X$.

We will also need some basic facts on M-matrices. A matrix $A = (a_{i,j}) \in \mathbb{R}^{n \times n}$ is called a Z [illegible] if $a_{ij} \leqslant 0$ for all $i \neq j$. A Z-matrix A is called an M [illegible] if there exists a nonnegative matrix B with spectral radius $\rho(B) = r$ such that $A = cI_n - B$ and $r \leqslant c$, where I_n is the identity matrix of order n.

The following results are well known and can be found in [1].

LEMMA 2.1. [illegible] Z [illegible] A [illegible]

1. A [illegible] M [illegible] $v > 0$ [illegible] $Av \geqslant 0$ [illegible] $w > 0$ [illegible] $w^T A \geqslant 0$
2. [illegible] A [illegible] A [illegible] M [illegible] $A^{-1} \geqslant 0$

LEMMA 2.2. [illegible] A [illegible] M [illegible] A [illegible] M [illegible]

Here and hereafter, inequalities on matrices and vectors are used in the componentwise sense.

Another useful tool is the Sherman–Morrison–Woodbury (SMW) matrix identity [5, p. 50].

LEMMA 2.3 (SMW formula). Let $D \in \mathbb{R}^{n\times n}$, $C \in \mathbb{R}^{k\times k}$, $U \in \mathbb{R}^{n\times k}$, $V \in \mathbb{R}^{k\times n}$. Then $D-UCV$ is nonsingular if and only if $C^{-1}-VD^{-1}U$ is nonsingular, and

$$(D - UCV)^{-1} = D^{-1} + D^{-1}U(C^{-1} - VD^{-1}U)^{-1}VD^{-1}.$$

The following lemma relates the SMW formula and M-matrices.

LEMMA 2.4. Let D, C, U, V satisfy the hypotheses of Lemma 2.3. Then D is a nonsingular M-matrix and C is a nonsingular M-matrix with $D, C, U, V \geqslant 0$ if and only if $D-UCV$ is (a nonsingular) M-matrix and $C^{-1} - VD^{-1}U$ is (a nonsingular) M-matrix.

Proof. Letting $C^{-1} - VD^{-1}U$ be a nonsingular M-matrix, the SMW formula yields

$$(D - UCV)^{-1} = D^{-1} + D^{-1}U(C^{-1} - VD^{-1}U)^{-1}VD^{-1},$$

and since all terms on the right-hand side are nonnegative, one has $(D - UCV)^{-1} > 0$, so $D-UCV$ is a nonsingular M-matrix by Lemma 2.1; the converse is analogous. By a continuity argument, the result can be extended to singular M-matrices. ∎

3. Newton's method. Newton's iteration applied to (1.1), for a suitable initial value $X^{(0)}$, generates the matrix sequence $\{X^{(k)}\}$ defined by the solution of the Sylvester equation [10]

$$(X^{(k+1)} - X^{(k)})(E - CX^{(k)}) + (A - X^{(k)}C)(X^{(k+1)} - X^{(k)}) = \mathcal{R}(X^{(k)}), \tag{3.1}$$

where $\mathcal{R}(X) = XCX - XE - AX + B$ is the Riccati operator. Using the Kronecker product notation, this can be written as

$$\operatorname{vec} X^{(k+1)} - \operatorname{vec} X^{(k)} = \left((E - CX^{(k)})^T \otimes I_n + I_n \otimes (A - X^{(k)}C)\right)^{-1} \operatorname{vec} \mathcal{R}(X^{(k)}), \tag{3.2}$$

where the vec operator stacks the columns of a matrix one above the other to form a single vector. Thus Newton's iteration is well defined when the matrix $M_{X^{(k)}} = (E - CX^{(k)})^T \otimes I_n + I_n \otimes (A - X^{(k)}C)$ is nonsingular for each k. With abuse of notation, we call the matrix M_X the Jacobian at X; in fact, it is the Jacobian matrix of the vector function $-\operatorname{vec} \circ R \circ \operatorname{vec}^{-1}$ at $\operatorname{vec}(X)$.

The following result, proved in [8] by Guo and Higham, provides sufficient conditions for the convergence of the Newton method.

THEOREM 3.1. Let

$$M = \begin{bmatrix} E & -C \\ -B & A \end{bmatrix}$$

be a nonsingular M-matrix and M be a singular irreducible M-matrix. Then $X^{(0)} = 0$ is such that (3.1) is a well-defined sequence $\{X^{(k)}\}$ converging to the minimal nonnegative solution of (1.1). Moreover, $M_{X^{(k)}} = (E - CX^{(k)})^T \otimes I + I \otimes (A - X^{(k)}C) \in \mathbb{R}^{n^2\times n^2}$ is a nonsingular M-matrix for $k \geqslant 0$.

Note that the problem stated in (1.2) satisfies the hypotheses of the previous theorem: in fact, we have

$$M = \begin{bmatrix} D & 0 \\ 0 & \Delta \end{bmatrix} - \begin{bmatrix} q \\ e \end{bmatrix} \begin{bmatrix} e^T & q^T \end{bmatrix},$$

and by Lemma 2.4 M is an M-matrix if and only if

$$0 \leqslant 1 - \begin{bmatrix} e^T & q^T \end{bmatrix} \begin{bmatrix} D^{-1} & 0 \\ 0 & \Delta^{-1} \end{bmatrix} \begin{bmatrix} q \\ e \end{bmatrix},$$

which reduces to

$$1 \geqslant e^T D^{-1} q + q^T \Delta^{-1} e = \sum_{i=1}^{n} \frac{c(1-\alpha)}{2} w_i + \sum_{i=1}^{n} \frac{c(1+\alpha)}{2} w_i = c, \tag{3.3}$$

in view of (1.3). This fact was also observed in [6].

In the following, we will consider a slightly more general case, i.e., when the matrix M is a generic diagonal plus rank-one matrix. Hence, (1.2) becomes

$$A = \Delta - \widetilde{e} q^T, \quad B = \widetilde{e} e^T, \quad C = \widetilde{q} q^T, \quad E = D - \widetilde{q} e^T, \tag{3.4}$$

where e, q, $\widetilde{e}$, $\widetilde{q}$ are any nonnegative vectors such that M, as defined in Theorem 3.1, is a nonsingular M-matrix or a singular irreducible M-matrix. Such generalization will prove useful when dealing with the critical case.

Observe that Newton's iteration for the coefficients of (1.1) defined in (3.4) can be rewritten as

$$\begin{aligned} X^{(k+1)} D + \Delta X^{(k+1)} = &-(X^{(k)} \widetilde{q} - X^{(k+1)} \widetilde{q})(q^T X^{(k)} - q^T X^{(k+1)}) \\ &+ (X^{(k+1)} \widetilde{q} + \widetilde{e})(e^T + q^T X^{(k+1)}); \end{aligned} \tag{3.5}$$

i.e., $X^{(k+1)}$ is a generalized Cauchy-like matrix with displacement rank 2. This property holds for all the iterates $X^{(k)}$, $k \geqslant 1$, of Newton's method obtained with any starting matrix $X^{(0)}$.

The Jacobian at $X^{(k)}$, in Kronecker product notation, takes the form

$$M_{X^{(k)}} = D^T \otimes I_n + I_n \otimes \Delta - (e + X^{(k)T} q) \widetilde{q}^T \otimes I_n - I_n \otimes (\widetilde{e} + X^{(k)} \widetilde{q}) q^T.$$

By setting $\mathcal{D} = D^T \otimes I_n + I_n \otimes \Delta$, $u^{(k)} = \widetilde{e} + X^{(k)} \widetilde{q}$, $v^{(k)} = e + X^{(k)T} q$, and

$$U^{(k)} = \begin{bmatrix} v^{(k)} \otimes I_n & I_n \otimes u^{(k)} \end{bmatrix}, \quad V = \begin{bmatrix} \widetilde{q}^T \otimes I_n \\ I_n \otimes q^T \end{bmatrix}, \tag{3.6}$$

we can rewrite $M_{X^{(k)}}$ as

$$M_{X^{(k)}} = \mathcal{D} - U^{(k)} V. \tag{3.7}$$

Since $U^{(k)} \in \mathbb{R}^{n^2 \times 2n}$ and $V \in \mathbb{R}^{2n \times n^2}$, the inversion of $M_{X^{(k)}}$ can be reduced to the inversion of a $2n \times 2n$ matrix using the SMW formula:

$$M_{X^{(k)}}^{-1} = \mathcal{D}^{-1} + \mathcal{D}^{-1} U^{(k)} (I_{2n} - V \mathcal{D}^{-1} U^{(k)})^{-1} V \mathcal{D}^{-1}. \tag{3.8}$$

This provides a new algorithm for implementing the Newton step, denoted by Algorithm 1, which relies on the function `fast_solve` for the fast solution of the system

$$\begin{aligned} &R^{(k)} x = b, \\ &R^{(k)} = I_{2n} - V \mathcal{D}^{-1} U^{(k)} \end{aligned} \tag{3.9}$$

function $X^{(k+1)}$=NewtonStep$(X^{(k)})$
$u^{(k)} = \widetilde{e} + X^{(k)} * \widetilde{q}$;
$v^{(k)} = e + X^{(k)T} * q$;
$\mathcal{R}(X^{(k)}) = u^{(k)} * v^{(k)T} - X^{(k)}D - \Delta X^{(k)}$;
$R_1 = [\widetilde{q}^T \otimes I_n\,; I_n \otimes q^T] * (\mathcal{D}^{-1} * \mathrm{vec}(\mathcal{R}(X^{(k)})))$;
$R_2 = \mathtt{fast\_solve}((I_{2n} - V\mathcal{D}^{-1}U^{(k)})R_2 = R_1)$;
$X^{(k+1)} = \mathcal{D}^{-1}(\mathrm{vec}(\mathcal{R}(X^{(k)})) + [v^{(k)} \otimes I_n \;\; I_n \otimes u^{(k)}] * R_2)$;
return $X^{(k+1)}$
end function

Algorithm 1: Fast Newton's step.

in $O(n^2)$ ops. The function `fast_solve` is described in the next section.

Note that since $\mathcal{D}$ is a diagonal matrix of size $n^2 \times n^2$, the matrix-vector product with matrix $\mathcal{D}^{-1}$ costs $O(n^2)$ ops, and the identities

$$(v^T \otimes I_n)\,\mathrm{vec}(W) = Wv,$$
$$(I_n \otimes v^T)\,\mathrm{vec}(W) = W^T v$$

allow one to compute the remaining products in $O(n^2)$ as well. Therefore the overall cost of Algorithm 1 is $O(n^2)$.

4. Fast Gaussian elimination for Cauchy-like matrices. We now address the problem of solving the linear system (3.9) given the vector b and the vectors $q, u^{(k)}, v^{(k)}$ such that

$$R^{(k)} = I_{2n} - \begin{bmatrix} \widetilde{q}^T \otimes I_n \\ I_n \otimes q^T \end{bmatrix} \mathcal{D}^{-1} \begin{bmatrix} v^{(k)} \otimes I_n & I_n \otimes u^{(k)} \end{bmatrix}. \tag{4.1}$$

First note that under the hypotheses of Theorem 3.1, $R^{(k)}$ is a nonsingular M-matrix by Lemma 2.4 applied to the nonsingular M-matrix $M_{X^{(k)}}$ of (3.7). Carrying out the products in (4.1) yields

$$R^{(k)} = I_{2n} - \begin{bmatrix} G^{(k)} & H^{(k)} \\ K^{(k)} & L^{(k)} \end{bmatrix} \tag{4.2}$$

with

$$\begin{aligned} G^{(k)} &= \mathrm{diag}(g_i^{(k)}), \quad & g_i^{(k)} &= \sum_{l=1}^{n} \frac{v_l^{(k)} \widetilde{q}_l}{d_l + \delta_i}, \\ H^{(k)} &= (h_{ij}^{(k)}), & h_{ij}^{(k)} &= \frac{u_i^{(k)} \widetilde{q}_j}{d_j + \delta_i}, \\ K^{(k)} &= (\kappa_{ij}^{(k)}), & \kappa_{ij}^{(k)} &= \frac{v_i^{(k)} q_j}{d_i + \delta_j}, \\ L^{(k)} &= \mathrm{diag}(l_i^{(k)}), \quad & l_i^{(k)} &= \sum_{l=1}^{n} \frac{u_l^{(k)} q_l}{d_i + \delta_l}. \end{aligned} \tag{4.3}$$

Thus $G^{(k)}$ and $L^{(k)}$ are diagonal, and $H^{(k)}$ and $K^{(k)}$ are Cauchy-like. Their displacement equations are

$$\Delta H^{(k)} + H^{(k)} D = u^{(k)} \widetilde{q}^T, \quad DK^{(k)} + K^{(k)} \Delta = v^{(k)} q^T.$$

Partition x and b according to the block structure of $R^{(k)}$ as $x = [x_1^T, x_2^T]^T$, $b = [b_1^T, b_2^T]^T$. Performing the block LU factorization of $R^{(k)}$ enables one to rewrite the system $R^{(k)} x = b$ as

$$\begin{bmatrix} I - G^{(k)} & -H^{(k)} \\ 0 & S^{(k)} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \begin{bmatrix} b_1 \\ \widehat{b}_2 \end{bmatrix}, \tag{4.4}$$

where $S^{(k)} = I - L^{(k)} - K^{(k)}(I - G^{(k)})^{-1} H^{(k)}$ and $\widehat{b}_2 = b_2 - K^{(k)}(I - G^{(k)})^{-1} b_1$. The matrices $I - G^{(k)}$ and $S^{(k)}$ are nonsingular as they are a principal submatrix and the Schur complement of a nonsingular M-matrix, respectively. Moreover, $S^{(k)}$ enjoys the following displacement structure:

$$DS^{(k)} - S^{(k)} D = K^{(k)}(I - G^{(k)})^{-1} u^{(k)} \widetilde{q}^T - v^{(k)} q^T (I - G^{(k)})^{-1} H^{(k)}.$$

This can be easily proved since D, Δ, $I - G^{(k)}$, $I - L^{(k)}$ all commute because they are diagonal; in fact,

$$\begin{aligned} DS^{(k)} &= D(I - L^{(k)}) - DK^{(k)}(I - G^{(k)})^{-1} H^{(k)} \\ &= (I - L^{(k)})D + (K^{(k)}\Delta - v^{(k)} q^T)(I - G^{(k)})^{-1} H^{(k)} \\ &= (I - L^{(k)})D + K^{(k)}(I - G^{(k)})^{-1} \Delta H^{(k)} - v^{(k)} q^T (I - G^{(k)})^{-1} H^{(k)} \\ &= (I - L^{(k)})D - K^{(k)}(I - G^{(k)})^{-1}(H^{(k)} D - u^{(k)} \widetilde{q}^T) - v^{(k)} q^T (I - G^{(k)})^{-1} H^{(k)} \\ &= S^{(k)} D + K^{(k)}(I - G^{(k)})^{-1} u^{(k)} \widetilde{q}^T - v^{(k)} q^T (I - G^{(k)})^{-1} H^{(k)}. \end{aligned}$$

Thus $S^{(k)}$ is a generalized Cauchy-like matrix with displacement rank 2 with respect to the singular operator $DS^{(k)} - S^{(k)} D$. We can use this property to develop an ad hoc variation of the Gohberg–Kailath–Olshevsky (GKO) algorithm for the fast LU factorization of matrices with displacement structure [4]. The GKO algorithm, for a generalized Cauchy-like matrix S with generators M_1 and N_1, essentially goes on as follows (ignoring pivoting for the sake of simplicity):

1. From the generators M_1, N_1 of

   $$S = \begin{bmatrix} d_1 & u_1 \\ l_1 & S_2 \end{bmatrix},$$

   such that $DS - SD = M_1 N_1$, recover the first row and the first column of S and store them as the first column of L,

   $$\begin{bmatrix} 1 \\ \frac{l_1}{d_1} \end{bmatrix},$$

   and the first row of U,

   $$\begin{bmatrix} d_1 & u_1 \end{bmatrix},$$

   in the LU factorization of S.

2. Compute the generators M_2, N_2 of the Schur complement $S_2 - \frac{l_1 u_1}{d_1}$ as

$$M_2 = M_{12} - \frac{l_1}{d_1} m_{11}, \quad N_2 = N_{12} - n_{11} \frac{u_1}{d_1},$$

where

$$M_1 = \begin{bmatrix} m_{11} \\ M_{12} \end{bmatrix}, \quad N_1 = \begin{bmatrix} n_{11} & N_{12} \end{bmatrix}.$$

3. Apply the algorithm recursively to compute the LU factorization $L_2 U_2$ of the Schur complement $S_2 - \frac{l_1 u_1}{d_1}$; then reconstruct the factors

$$L = \begin{bmatrix} 1 & \frac{l_1}{d_1} \\ 0 & L_2 \end{bmatrix}, \quad U = \begin{bmatrix} d_1 & u_1 \\ 0 & U_2 \end{bmatrix}.$$

The problem in our context is that d_1 cannot be retrieved from the generators, due to the singularity of the operator $S \mapsto DS - SD$. In fact, it is easy to see that the null space of $DS - SD$ is the set of all diagonal matrices. Thus, we need a different method to compute and update the diagonal elements of S through the LU factorization. Our approach consists in storing the main diagonal of S in a vector s and updating it at each step of the Gaussian elimination as if we were performing a customary (nonstructured) Gaussian elimination. This can be achieved at the general step k by using the relation $S_{ii} \leftarrow S_{ii} - L_{ik} U_{ki}$. Since we have to update only n elements at each step, the overhead of updating the diagonal is $O(n^2)$, and thus the complete algorithm requires $O(n^2)$ ops. A simple implementation, which includes partial pivoting, is given in Algorithm 2 and requires $10n^2$ ops.

```
function [PL,U]=fastPLU(d,s,M,N)
u=[1,1,...,1]'; L=U=zeros(n,n);
for k=1:n
 L_ik=(∑_j M_ij N_jk)/(d_i−d_k) for all i≠k such that u_i=1;
 L_kk=s_k if u_i=1;
 choose p such that |L_pk|=max_i |L_ik|;
 u_p=0;
 U_kk=L_pk;
 L_ik=L_ik/U_kk for all i such that u_i=1
 U_kj=(∑_i M_pi N_ij)/(d_p−d_j) for all j=k+1,...,n, j≠p;
 U_kp=s_p;
 M_ij=M_ij − L_ik M_pj for all j, i such that u_i=1;
 N_ij=N_ij − N_ik U_kj/U_kk for all i=1,...,n, j=k+1,...,n;
 s_i=s_i − L_ik U_ki for all i such that u_i=1;
 return L,U;
end function
```

Algorithm 2: Fast LU factorization.

Using this algorithm, complemented with back-substitution, provides an implementation of the function `fast_solve`$(R^{(k)}x = b)$ of complexity $O(n^2)$ that was used in Algorithm 1.

5. Lu's iteration. Lu [14] proposed a different approach for solving the Riccati equation (1.1) when the coefficients are in the form (3.4). The idea is applying Newton's iteration to an equation involving the displacement generators $u = X\widetilde{q} + \widetilde{e}$ and $v = X^T q + e$ of the solution X. His algorithm can be expressed as the following iteration for the sequences $\{\widehat{u}^{(k)}\}$, $\{\widehat{v}^{(k)}\}$, $k \geqslant -1$:

$$\begin{bmatrix} \widehat{u}^{(k+1)} \\ \widehat{v}^{(k+1)} \end{bmatrix} = (\widehat{R}^{(k)})^{-1} \begin{bmatrix} \widetilde{e} - \widehat{H}^{(k)}\widehat{v}^{(k)} \\ e - \widehat{K}^{(k)}\widehat{u}^{(k)} \end{bmatrix}, \tag{5.1}$$

starting from $\widehat{u}^{(-1)} = \widehat{v}^{(-1)} = 0$ (as we will see later on, indexing from $k = -1$ will simplify the subsequent analysis). Here $\widehat{R}^{(k)}$, $\widehat{H}^{(k)}$, and $\widehat{K}^{(k)}$ are defined as

$$\widehat{R}^{(k)} = I_{2n} - \begin{bmatrix} \widehat{G}^{(k)} & \widehat{H}^{(k)} \\ \widehat{K}^{(k)} & \widehat{L}^{(k)} \end{bmatrix}, \tag{5.2}$$

$$\begin{aligned} \widehat{G}^{(k)} &= \operatorname{diag}(\widehat{g}_i^{(k)}), & \widehat{g}_i^{(k)} &= \sum_{l=1}^{n} \frac{\widehat{v}_l^{(k)}\widetilde{q}_l}{d_l + \delta_i}, \\ \widehat{H}^{(k)} &= (\widehat{h}_{ij}^{(k)}), & \widehat{h}_{ij}^{(k)} &= \frac{\widehat{u}_i^{(k)}\widetilde{q}_j}{d_j + \delta_i}, \\ \widehat{K}^{(k)} &= (\widehat{\kappa}_{ij}^{(k)}), & \widehat{\kappa}_{ij}^{(k)} &= \frac{\widehat{v}_i^{(k)} q_j}{d_i + \delta_j}, \\ \widehat{L}^{(k)} &= \operatorname{diag}(\widehat{l}_i^{(k)}), & \widehat{l}_i^{(k)} &= \sum_{l=1}^{n} \frac{\widehat{u}_l^{(k)} q_l}{d_i + \delta_l}, \end{aligned} \tag{5.3}$$

which are, formally, the same relations as in (4.2) and (4.3).

As a first result, since both algorithms are based on the solution of a system with the same structure, we obtain that Algorithm 2 can also be used in the implementation of Lu's iteration to reduce its computational cost to $O(n^2)$. But there is a deeper connection between the two algorithms.

THEOREM 5.1. [illegible] $\{\widehat{u}^{(k)}\}$ $\{\widehat{v}^{(k)}\}$ $k \geqslant -1$ [illegible] (1.1) [illegible] (3.4) [illegible] $\{X^{(k)}\}$ $k \geqslant 0$ [illegible] $X^{(0)} = 0$ [illegible] $k \geqslant 0$ [illegible]

$$\widehat{u}^{(k)} = X^{(k)}\widetilde{q} + \widetilde{e}, \quad \widehat{v}^{(k)} = X^{(k)T} q + e.$$

[illegible]. We will prove the result by induction over k. It is easy to check from the definitions that $\widehat{R}^{(-1)} = I_{2n}$, and thus $\widehat{u}^{(0)} = \widetilde{e}$, $\widehat{v}^{(0)} = e$; therefore the base step $k = 0$ holds. As a side note, this means that we can save an iteration by starting the computation from $u^{(0)} = \widetilde{e}$, $v^{(0)} = e$.

Assuming by induction that $\widehat{u}^{(k)} = X^{(k)}\widetilde{q} + \widetilde{e} = u^{(k)}$, $\widehat{v}^{(k)} = X^{(k)T} q + e = v^{(k)}$, we find that (4.3) and (5.2) define the same matrices; therefore, from now on, we will drop the superscript (k) and the hat symbol to ease the notation.

We have

$$V\mathcal{D}^{-1} \operatorname{vec}\mathcal{R}(X) = V\mathcal{D}^{-1} \operatorname{vec}(uv^T) - V \operatorname{vec} X = \begin{bmatrix} \widetilde{e} - (I - G)u \\ e - (I - L)v \end{bmatrix},$$

in view of the relations

$$\mathcal{D}^{-1}\operatorname{vec}(XD+\Delta X)=\operatorname{vec}X,$$
$$V\mathcal{D}^{-1}\operatorname{vec}(uv^T)=\begin{bmatrix} Gu \\ Lv \end{bmatrix},$$

which can be easily verified from the definitions of $\mathcal{D}$, G, and L, where V is the matrix defined in (3.6).

Applying the operator V to both sides of (3.2) yields

(5.4)
$$\begin{aligned} V\operatorname{vec}(X^{(k+1)}-X) &= V\mathcal{D}^{-1}\operatorname{vec}\mathcal{R}(X)+V\mathcal{D}^{-1}U(I_{2n}-V\mathcal{D}^{-1}U)^{-1}V\mathcal{D}^{-1}\operatorname{vec}\mathcal{R}(X)\\ &= (I_{2n}+V\mathcal{D}^{-1}U(I_{2n}-V\mathcal{D}^{-1}U)^{-1})V\mathcal{D}^{-1}\operatorname{vec}\mathcal{R}(X)\\ &= (I_{2n}-V\mathcal{D}^{-1}U)^{-1}V\mathcal{D}^{-1}\operatorname{vec}\mathcal{R}(X), \end{aligned}$$

where the last equation holds since $I+M(I-M)^{-1}=(I-M)^{-1}$.

We recall that $R=(I_{2n}-V\mathcal{D}^{-1}U)$ and

$$\begin{bmatrix} \widehat{u}^{(k+1)} \\ \widehat{v}^{(k+1)} \end{bmatrix} = R^{-1}\begin{bmatrix} \widetilde{e}-Hu \\ e-Kv \end{bmatrix}$$

(the latter being Lu's iteration). Now we can explicitly compute

$$\begin{aligned} R\begin{bmatrix} \widehat{u}^{k+1}-u \\ \widehat{v}^{k+1}-v \end{bmatrix} &= \begin{bmatrix} \widetilde{e}-Hu \\ e-Kv \end{bmatrix}-\left(I_{2n}-\begin{bmatrix} G & H \\ K & L \end{bmatrix}\right)\begin{bmatrix} u \\ v \end{bmatrix}\\ &= \begin{bmatrix} \widetilde{e}-Hv \\ e-Ku \end{bmatrix}-\begin{bmatrix} u \\ v \end{bmatrix}+\begin{bmatrix} Gu+Hv \\ Ku+Lv \end{bmatrix}=\begin{bmatrix} \widetilde{e}-(I-G)u \\ e-(I-L)v \end{bmatrix}=V\mathcal{D}^{-1}\operatorname{vec}\mathcal{R}(X), \end{aligned}$$

and substitute it into (5.4) to get

$$V\operatorname{vec}(X^{(k+1)}-X)=\begin{bmatrix} \widehat{u}^{k+1}-u \\ \widehat{v}^{k+1}-v \end{bmatrix}.$$

Finally, using the definition of V in (3.6), we find that

$$\begin{bmatrix} \widehat{u}^{k+1}-u \\ \widehat{v}^{k+1}-v \end{bmatrix}=V\operatorname{vec}(X^{(k+1)}-X)=\begin{bmatrix} X^{(k+1)}\widetilde{q}-X\widetilde{q} \\ X^{(k+1)T}q-X^Tq \end{bmatrix}=\begin{bmatrix} X^{(k+1)}\widetilde{q}+\widetilde{e}-u \\ X^{(k+1)T}q+e-v \end{bmatrix}$$

and thus $\widehat{u}^{k+1}=X^{(k+1)}\widetilde{q}+\widetilde{e}$, $\widehat{v}^{k+1}=X^{(k+1)T}q+e$. □

The theorem brings deeper insight into Newton's and Lu's iterations. For example, Theorem 6 of [14], which states that Lu's iteration is well defined and converges monotonically to the minimal solution of the NARE, can now be seen as a special case of Theorem 3.1. Moreover, Lu's iteration can be viewed as a structured Newton's iteration exploiting the displacement structure found in (3.5). Therefore, the two algorithms take the same number of iterations to converge, as the computation they perform is the same. Observe also that Lu's version of this algorithm is slightly faster, since it updates only the $2n$ entries of the generators of the matrix $\{X^{(k)}\}$ instead of all the n^2 entries. For this reason, we will present only numerical results regarding Lu's iteration.

6. Shift technique. In the case where $(c, \alpha) = (1, 0)$, the Jacobian M_X appearing in the Newton iteration is singular when X is the solution of the NARE. We refer to this as the [illegible]. Several drawbacks are encountered in the critical case; see the analysis of Guo and Higham in [8] for more details. The singularity of the Jacobian does not guarantee the quadratic convergence of Newton's iteration; in fact, Newton's and therefore Lu's method converge linearly. Moreover, a perturbation $O(\varepsilon)$ in the coefficients of the equation leads to an $O(\sqrt{\varepsilon})$ variation in the solution.

These drawbacks can be easily removed by means of the shift technique originally introduced by He, Meini, and Rhee in [12] and applied to Riccati equations in [9] and [2].

A characterization of the critical case can be given in terms of the eigenvalues of the matrix

$$H = \begin{bmatrix} E & -C \\ B & -A \end{bmatrix}, \tag{6.1}$$

obtained by premultiplying the M-matrix M defined in (1.4) by the matrix $J = \operatorname{diag}(I_n, -I_n)$. In fact, the matrix H has a double zero eigenvalue corresponding to a 2×2 Jordan block (see [9] and the references therein).

The shift technique, as described in [9], consists in a rank-one correction to the matrix H of (6.1) which gives $\widetilde{H} = H + \eta v p^T$, where $\eta > 0$, v is a right eigenvector of H corresponding to the zero eigenvalue, and p is an arbitrary vector such that $p^T v = 1$.

The nice feature of this transformation is that the Riccati equation associated with the matrix $\widetilde{H}$ has the same minimal solution as the original one, although the new Jacobian matrix at the solution is not singular. This removes the above-mentioned drawbacks. Now the point is to show that it is still possible to provide a fast implementation of Newton's iteration for the new equation obtained by means of the shift technique. This is the goal of this section.

Under the assumptions (1.2), (1.3) a right eigenvector of H corresponding to zero is $v = \begin{bmatrix} v_1^T & v_2^T \end{bmatrix}^T$, where $v_1 = D^{-1}q$, $v_2 = \Delta^{-1}e$. This can be seen by direct inspection using the fact that $e^T D^{-1} q + q^T \Delta^{-1} e = c = 1$ (see (3.3)).

The rank-one correction we construct is

$$\widetilde{H} = H + \eta \begin{bmatrix} v_1 \\ v_2 \end{bmatrix} p^T,$$

where $0 < \eta \leqslant d_1$ and $p^T = \begin{bmatrix} e^T & q^T \end{bmatrix}$. It holds that $p^T v = 1$; in fact, $p^T v = e^T D^{-1} q + q^T \Delta^{-1} e = 1$. It is proved in [9] that $\widetilde{H}$ has a simple zero eigenvalue.

The matrix $\widetilde{H}$ defines the new Riccati equation

$$X\widetilde{C}X - X\widetilde{E} - \widetilde{A}X + \widetilde{B} = 0, \tag{6.2}$$

with

$$\widetilde{A} = A - \eta v_2 q^T, \quad \widetilde{B} = B + \eta v_2 e^T, \quad \widetilde{C} = C - \eta v_1 q^T, \quad \widetilde{E} = E + \eta v_1 e^T. \tag{6.3}$$

It is proved in [9] that the minimal nonnegative solution of (1.1) is the minimal nonnegative solution of (6.2).

With the choice of $p^T = [e^T \; q^T]$, $\widetilde{H}$ remains a diagonal plus rank-one matrix as well as $\widetilde{M} = J\widetilde{H}$; hence, we need only prove that $\widetilde{M}$ is an M-matrix to ensure that

the algorithms proposed in sections 3 and 5 can be applied to (6.2). In fact, we have

$$\widetilde{M} = \begin{bmatrix} D & 0 \\ 0 & \Delta \end{bmatrix} - \begin{bmatrix} q - \eta v_1 \\ e + \eta v_2 \end{bmatrix} \begin{bmatrix} e^T & q^T \end{bmatrix},$$

and since we chose $0 < \eta \leqslant d_1 < d_2 < \cdots < d_n$, and $q \geqslant 0$, it holds that $q - \eta v_1 = (I_n - \eta D^{-1})q \geqslant 0$; thus $\widetilde{M}$ is a Z-matrix. By the Perron–Frobenius theorem applied to $\rho I - M$, there exists a vector $u > 0$ such that $u^T M = 0$, and in the critical case we have $u^T J v = 0$ (observe that $u^T J$ is a left eigenvector of $H = JM$ corresponding to the zero eigenvalue and recall that right and left eigenvectors corresponding to the same eigenvalue in a Jordan block of dimension $n \geqslant 2$ are orthogonal); therefore,

$$u^T \widetilde{M} = u^T M + \eta u^T J v p^T = 0,$$

and thus by part 1 of Lemma 2.1 $\widetilde{M}$ is an M-matrix.

In this way, Newton's iteration applied to (6.2) provides a quadratically convergent algorithm of complexity $O(n^2)$ for solving the Riccati equation (1.1) in the critical case. Moreover, since the singularity has been removed, it is expected that X, as minimal solution of (6.2), is better conditioned with respect to the coefficients of (1.1), and that a higher precision can be reached in the computed solution. This fact is confirmed by the numerical experiments as shown in section 8.

7. Numerical stability. Our first concern about numerical stability is proving that the matrix $R^{(k)} = I_{2n} - V\mathcal{D}^{-1}U^{(k)}$ resulting after the application of the SMW formula to the Jacobian $\mathcal{D} - U^{(k)}V$ is well-conditioned whenever the Jacobian is. In the following analysis, we will assume that the norm $\left\|(\mathcal{D} - U^{(k)}V)^{-1}\right\|_1$ is bounded, and we will drop the superscripts (k) to simplify the notation.

Observe that $0 \leqslant \mathcal{D}^{-1} \leqslant (\mathcal{D} - UV)^{-1}$; therefore $\mathcal{D}$ is well-conditioned. Moreover, one has

$$\mathcal{B}^{-1} = \begin{bmatrix} (\mathcal{D} - UV)^{-1} & 0 \\ V(\mathcal{D} - UV)^{-1} & I \end{bmatrix} \begin{bmatrix} I & U \\ 0 & I \end{bmatrix}, \quad \text{with} \quad \mathcal{B} = \begin{bmatrix} \mathcal{D} & -U \\ -V & I \end{bmatrix};$$

therefore $\mathcal{B}$ is an M-matrix and is well-conditioned. Now, $R = I - V\mathcal{D}^{-1}U$ is the Schur complement of $\mathcal{D}$ in $\mathcal{B}$, and thus R^{-1} is a submatrix of $\mathcal{B}^{-1}$ [5]. This implies $\left\|R^{-1}\right\|_1 \leqslant \left\|\mathcal{B}^{-1}\right\|_1$; hence R is well-conditioned, too.

Another stability problem could arise from the generators' growth during the fast Gaussian elimination step. Generator growth has been reported in some cases with the GKO algorithm [17], especially when the starting generators are ill-conditioned. This is not our case, since the starting generators are bounded, and no significant generator growth has been observed during our experiments.

8. Numerical experiments. We consider the numerical examples suggested in [10] and used also in [14]. The sequences t_i and w_i, which appear in the discretization as the nodes and weights of a Gaussian quadrature method, are obtained by dividing the interval $[0, 1]$ into $n/4$ subintervals of equal length and by applying to each one the 4-node Gauss–Legendre quadrature.

The computation has been performed with three different choices of the parameters (c, α), namely, $(0.5, 0.5)$, $(1 - 10^{-6}, 10^{-8})$, and $(1, 0)$. The latter is the critical case, and thus the quadratic convergence of Newton's method is not guaranteed. In this case, the algorithms are more prone to numerical problems, since the matrices to be inverted are near-to-singular.

The algorithms have been implemented in Fortran 90, and the tests have been carried out using the Lahey Fortran compiler on a Xeon biprocessor with 2.8 GHz. We have compared Lu's algorithm presented in [14] with its fast version based on Algorithm 2. In the critical case, we have also made a comparison with the shifted algorithm of section 6. To compute the step (5.1) of Lu's algorithm we have solved a linear system using the LAPACK `la_gesv` function.

TABLE 8.1

Comparison of CPU time in seconds of Lu's algorithm (Lu), its fast version presented here (LuF), and the shifted algorithm in the critical case (LuFS).

	$\alpha = 0.5$, $c = 0.5$		$\alpha = 10^{-8}$, $c = 1 - 10^{-6}$		$\alpha = 0$, $c = 1$		
n	Lu	LuF	Lu	LuF	Lu	LuF	LuFS
32	0.002	0.001	0.005	0.002	0.007	0.004	0.001
64	0.009	0.002	0.028	0.009	0.040	0.015	0.005
128	0.050	0.010	0.175	0.034	0.290	0.054	0.015
256	0.401	0.053	1.369	0.167	2.253	0.278	0.074

1024	40.5	1.456	141.3	4.959	212.6	7.957	2.251
2048	327	5.785	1146	19.914	1850	32.478	9.061
4096	2775	28.503	9669	89.78	15974	147.3	40.917

TABLE 8.2

Comparison of the relative error (and in parentheses the number of steps) of Lu's algorithm (Lu), its fast version presented here (LuF), and the shifted algorithm in the critical case (LuFS).

	$\alpha = 0.5$, $c = 0.5$	
n	Lu	LuF
32	$4.8 \cdot 10^{-16}$ (4)	$2.3 \cdot 10^{-16}$ (5)
256	$1.6 \cdot 10^{-15}$ (4)	$4.0 \cdot 10^{-16}$ (5)

	$\alpha = 0$, $c = 1$		
n	Lu	LuF	LuFS
32	$5.2 \cdot 10^{-8}$ (25)	$4.2 \cdot 10^{-8}$ (26)	$4.4 \cdot 10^{-16}$ (6)
256	$4.6 \cdot 10^{-8}$ (25)	$8.0 \cdot 10^{-8}$ (25)	$1.2 \cdot 10^{-15}$ (6)

In Table 8.1 we compare the timing of Lu's algorithm, which has a computational cost of $O(n^3)$ ops, with that of its fast version, which costs $O(n^2)$. The numerical results highlight the different order of complexity. Observe that in the critical case the shift technique reduces the timings even further.

In Table 8.2 we compare the relative error of the two methods and the number of steps required. Here the error is computed as $\|\widetilde{X} - X\|_1 / \|X\|_1$, where $\widetilde{X}$ and X are the solution computed in double and in quadruple precision, respectively.

The stopping criterion is based on the computation of

$$\mathrm{Res} = \frac{\|u_k - u_{k-1}\|_1 + \|v_k - v_{k-1}\|_1}{2}.$$

Observe that the cost of computing Res is negligible.

As one can see, in the critical case the accuracy of the solution obtained with the nonshifted algorithms is of the order of $O(\sqrt{\varepsilon})$, where ε is the machine precision, in strict accordance with [8]. The speedup obtained is greater than 2 even for small values of n. In the critical case with size $n = 4096$ our algorithm is about 390 times faster than Lu's original algorithm. The problems deriving from the large number of steps and the poor accuracy are completely removed by the shift technique.

9. Generalizations and future work. Our algorithm can be easily extended to the case where M is diagonal plus rank k.

A challenging issue is to prove that Lu's iteration for this problem can be effectively computed with less than $O(n^2)$ ops. Actually, the literature provides algorithms for computing the Cauchy matrix-vector product [3] and for approximating the inverse of a Cauchy matrix [16] with $O(n \log^2 n)$ ops (, , ,).

However, the bottleneck for this improvement is computing the product of $\mathcal{D}^{-1}$ by the vector $v = \mathrm{vec}(\mathcal{R}(X^{(k)}))$, which apparently requires n^2 multiplications. In fact, the size of $\mathcal{D}$ is n^2. Observe that this problem concerns only the algorithm presented in section 3. In fact, Lu's version of Newton's iteration shown in section 5 is expressed through matrix-vector products and solutions of linear systems where the involved matrices are Cauchy-like.

If the superfast algorithms can be adapted to deal with singular displacement operators and if the approximation and the numerical errors introduced do not destroy the quadratic convergence of Newton's method, then the computational cost of Lu's iteration could be reduced further.

Another interesting issue is the acceleration of existing algorithms like the (shifted) structure-preserving doubling algorithm [9, 11] or the (shifted) logarithmic and cyclic reduction [2, 7], relying once again on the specific structure of the problem.

Acknowledgments. The authors are indebted to Luca Gemignani and Beatrice Meini for the many stimulating discussions which helped to improve the presentation of the paper. The authors wish to thank the anonymous referees for their useful comments and remarks.

ON ASYMPTOTIC CONVERGENCE OF NONSYMMETRIC JACOBI ALGORITHMS*

CHRISTIAN MEHL†

Abstract. The asymptotic convergence behavior of cyclic versions of the nonsymmetric Jacobi algorithm for the computation of the Schur form of a general complex matrix is investigated. Similar to the symmetric case, the nonsymmetric Jacobi algorithm proceeds by applying a sequence of rotations that annihilate a pivot element in the strict lower triangular part of the matrix until convergence to the Schur form of the matrix is achieved. In this paper, it is shown that the cyclic nonsymmetric Jacobi method converges locally and asymptotically quadratically under mild hypotheses if special ordering schemes are chosen, namely, ordering schemes that lead to so-called northeast directed sweeps. The theory is illustrated by the help of numerical experiments. In particular, it is shown that there are ordering schemes that lead to asymptotic quadratic convergence for the cyclic symmetric Jacobi method, but only to asymptotic linear convergence for the cyclic nonsymmetric Jacobi method. Finally, a generalization of the nonsymmetric Jacobi method to the computation of the Hamiltonian Schur form for Hamiltonian matrices is introduced and investigated.

1. Introduction.

Jacobi's method [21] for the diagonalization of a symmetric matrix $A = (a_{ij}) \in \mathbb{R}^{n\times n}$ is a famous, successful, and easy-to-implement algorithm for the computation of eigenvalues of symmetric matrices. No wonder that this algorithm has been generalized or adapted to many other classes of matrices; see, among other references, [1, 3, 5, 9, 11, 12, 13, 15, 16, 29, 34]. In this paper, we will focus on a particular cyclic Jacobi-like algorithm for the computation of the Schur form of a complex matrix. The basic idea of the algorithm is a direct adaption of Jacobi's method to the nonsymmetric case that was proposed in 1955 by Greenstadt [13] and later was taken up and modified by various authors [4, 10, 14, 19, 24, 32]. Given a matrix $M = (m_{ij}) \in \mathbb{C}^{n\times n}$, the algorithm selects in each step a pivot element m_{kl}, $k < l$ in the strict lower triangular part. Then a similarity transformation with a rotation $U = (u_{ij}) \in \mathbb{C}^{n\times n}$ is applied to M that annihilates the entry m_{kl} of M:

$$\begin{bmatrix} 1 & & & & & \\ & \overline{u}_{kk} & & \overline{u}_{lk} & & \\ & & 1 & & & \\ & & & 1 & & \\ & \overline{u}_{kl} & & \overline{u}_{ll} & & \\ & & & & & 1 \end{bmatrix} \begin{bmatrix} * & * & * & * & * & * \\ \cdot & * & * & * & * & * \\ \cdot & \cdot & * & * & * & * \\ \cdot & \cdot & \cdot & * & * & * \\ \cdot & m_{kl} & \cdot & \cdot & * & * \\ \cdot & \cdot & \cdot & \cdot & \cdot & * \end{bmatrix} \begin{bmatrix} 1 & & & & & \\ & u_{kk} & & u_{kl} & & \\ & & 1 & & & \\ & & & 1 & & \\ & u_{lk} & & u_{ll} & & \\ & & & & & 1 \end{bmatrix} = \begin{bmatrix} * & * & * & * & * & * \\ \cdot & * & * & * & * & * \\ \cdot & \cdot & * & * & * & * \\ \cdot & \cdot & \cdot & * & * & * \\ \cdot & 0 & \cdot & \cdot & * & * \\ \cdot & \cdot & \cdot & \cdot & \cdot & * \end{bmatrix}$$

Here, U coincides with the identity except for the elements $u_{kk} = u_{ll} = \cos x$, and $u_{kl} = -e^{-i\alpha} \sin x$, $u_{lk} = e^{i\alpha} \sin x$ for some $x, \alpha \in \mathbb{R}$.

Generically, there are two choices for the transformation matrix U, and throughout this paper, we will always choose the transformation matrix that is closest to the identity. This corresponds to choosing always the rotation matrix with the smaller rotation angle, a fact that is crucial for the proof of asymptotic quadratic convergence of Jacobi's algorithm for symmetric matrices. Concerning global convergence, this strategy need not be the best. Actually, convergence can be accelerated by sorting the diagonal entries of the occurring 2×2 submatrices, a technique that sometimes requires the application of the rotation corresponding to the larger angle. In this paper, however, we focus on the asymptotic convergence behavior and, therefore, we restrict ourselves to the use of rotations corresponding to the smaller angle.

Cyclic version of Jacobi's algorithm use a fixed sequence of pivot elements to be annihilated in that order. If every element in the strict lower triangular part is annihilated at least once; then the sequence of corresponding Jacobi steps on the matrix is called a [illegible], and it is repeated until convergence has been achieved.

In contrast to Jacobi's original algorithm, its generalization to general complex matrices has not yet become a well-known and widely used algorithm, probably mainly for two reasons. First, neither global nor local convergence proofs of the method could be given so far, although convergence has been observed in numerical experiments. (In [19], Huang proved convergence of the method for the case $n = 3$, but the case $n > 3$ remains an open problem.) Second, the algorithm converges slowly and is expensive. A flop count reveals that three sweeps of the cyclic nonsymmetric Jacobi method are approximately as expensive as a full run of the QR algorithm as implemented in Matlab. Moreover, the average number of sweeps needed for convergence for a 70×70 matrix is already as high as 30, making the method 10 times more expensive then the QR algorithm in that case. Since the average number of sweeps needed for convergence even increases with increasing dimension of the matrix, the algorithm seemed to be out of competition.

However, in recent years there has been renewed interest in nonsymmetric Jacobi methods, because they can easily be adapted to the solution of structured eigenvalue problems, e.g., of Hamiltonian eigenvalue problems [1], for generalized Hermitian eigenvalue problems [27], for palindromic eigenvalue problems [18, 25], and for doubly structured eigenvalue problems [11]. For those eigenvalue problems, a satisfactory generalization of the QR algorithm is not available due to the lack of a corresponding reduction to a structured version of the Hessenberg form in finitely many steps. (This phenomenon is known as "Van Loan's curse" [6].) Thus, the competition for other algorithms is open again. In fact, a variant of the nonsymmetric Jacobi method designed for the solution of the generalized palindromic eigenvalue problem (i.e., the eigenvalue problem $\lambda Ax = A^T x$) has been successfully used in [25] as an ingredient for a structure-preserving eigensolver, where it was applied to the solution of small (i.e., of size $\mathcal{O}(10)$) eigenvalue problems with eigenvalues close to the unit circle.

On the other hand, the nonsymmetric Jacobi method converges fast for matrices that are already close to triangular form, and thus it has the potential to become a useful tool for the solution of parameter-depending eigenvalue problems. Indeed, assume that $A(\omega)$ is a matrix-valued function that depends continuously on the parameter ω. Once the eigenvalue problem has solved for a specific value of ω, say, ω_0, then the transformation that reduces $A(\omega_0)$ to Schur form will transform matrices $A(\omega)$ to a form that is close to being triangular whenever ω is sufficiently close to ω_0. It may then be useful to apply a nonsymmetric Jacobi method to $A(\omega)$ to obtain the Schur form within one or two sweeps. Finally, it was shown in [7] that Jacobi's algorithm for symmetric matrices is more accurate than the QR algorithm if the right

stopping criterion is used. Extending this theory to nonsymmetric Jacobi methods may produce a highly accurate algorithm. In this paper, however, we restrict ourselves to the investigation of the asymptotic convergence behavior of the method.

The remainder of the paper is organized as follows. In the following section, we explain why the convergence theory for nonsymmetric Jacobi algorithms is challenging and different from the theory for the symmetric case. In section 3, we prove asymptotic quadratic convergence of the cyclic nonsymmetric Jacobi algorithm if so-called northeast directed sweeps are used. In section 4, we investigate generalizations of the algorithm to the solution of the Hamiltonian eigenvalue problem. In particular, we explain why the Jacobi-like algorithm proposed in [1] does not show asymptotic quadratic convergence and we show how convergence can be accelerated. Finally, we illustrate the theoretical results by the results of numerical experiments in section 5.

2. Why convergence of nonsymmetric Jacobi algorithms is not obvious. It is well known that Jacobi's classical algorithm as well as many cyclic versions are asymptotically quadratically convergent; see, e.g., [16, 17, 31, 35]. The same is also known for several generalizations; see [20] for a general proof of local quadratic convergence of Jacobi-type methods. However, these results are usually based on the minimization of a particular smooth function in each Jacobi step. For the standard eigenvalue problem with a Hermitian matrix $M = (m_{ij}) \in \mathbb{C}^{n\times n}$ this smooth function is the quantity

$$\operatorname{off}(M) := \sqrt{\sum_{i>j} |m_{ij}|^2} \tag{2.1}$$

that is sometimes called . In contrast to the Hermitian case, the quantity $\operatorname{off}(M)$ need not decrease in a single step of the nonsymmetric Jacobi algorithm. This effect can be explained heuristically with the help of the following sketch:

$$\begin{bmatrix} * & * & * & * & * & * \\ \cdot & \circ & * & * & \circ & * \\ \cdot & \diamond & * & * & \bullet & * \\ \cdot & \cdot & \cdot & * & * & * \\ \cdot & \circ & \cdot & \cdot & \circ & * \\ \cdot & \cdot & \cdot & \cdot & \cdot & * \end{bmatrix}$$

If the pivot element is chosen such that, currently, the 2×2 subproblem indicated by $\circ$ is under investigation, then a very large entry in, e.g., the position marked with $\bullet$ may lead to a temporary increase in $\operatorname{off}(M)$, because the element in the $\diamond$-position will be linearly combined with the element in the $\bullet$-position. It is this effect which makes the convergence analysis of nonsymmetric Jacobi methods so delicate. Indeed, the general results of [20] cannot be applied here, because $\operatorname{off}(M)$ is not minimized in each step.

At this stage, the reader might stop and ask whether it would not be advisable to modify the algorithm in such a way that $\operatorname{off}(M)$ decreases monotonically. Indeed, such generalizations have already been considered. For example, Stewart [32] proposed to use pivot elements only from the first subdiagonal. Indeed, this avoids the effect explained in the previous paragraph and it was shown that $\operatorname{off}(M)$ then decreases monotonically. But unfortunately, it turned out that the Jacobi algorithm obtained in this way is characterized by extreme slow convergence: it appears to be almost stagnant. On the other hand, one may also consider variants of nonsymmetric Jacobi algorithm that again allow pivot elements from the whole strict lower triangular part

of the matrix but that minimize $\mathrm{off}(M)$ in each step rather than annihilate the pivot element. This, however, would require the solution of a minimization problem in each step and one would have to take into account "global information," i.e., the knowledge of all elements in the strict lower triangular part of the matrix would be necessary. In contrast, the transformation annihilating the pivot element can be easily computed from considering the corresponding 2×2 problem only, thus only taking into account "local information." Consequently, a single Jacobi step of the modified method would be much more expensive than a single Jacobi step of a cyclic nonsymmetric Jacobi method. Thus, although $\mathrm{off}(M)$ does not decrease monotonically in each step, cyclic methods seem to be the cheapest and most reliable variants of nonsymmetric Jacobi algorithms for the general complex eigenvalue problem.

But the nonmonotone behavior of the quantity $\mathrm{off}(M)$ is not the only point in which the general case differs from the symmetric case. The asymptotic convergence behavior of a cyclic Jacobi method may be completely different for symmetric matrices on the one hand and general complex matrices on the other hand. As an example let us consider the cyclic Jacobi method using [illegible] given by the sequence of indices

$$\big((2,1),(3,1),\dots,(n,1),(3,2),\dots,(n,2),\dots,(n,n-1)\big) \tag{2.2}$$

versus the the one using [illegible] given by

$$\big((n,1),(n-1,1),\dots,(2,1),(n,2),\dots,(3,2),\dots,(n,n-1)\big). \tag{2.3}$$

Both methods appear to be asymptotically quadratically convergent in the symmetric case, while the nonsymmetric case shows quadratic convergence for the "bottom-to-top" variant but linear convergence for the "top-to-bottom" variant. (See section 5 for numerical experiments on this topic.) Again this effect can be explained heuristically with the help of a sketch:

$$\Downarrow \text{ top to bottom} \qquad \begin{bmatrix} \circ & * & * & \circ & * & * \\ \diamond & * & * & \bullet & * & * \\ \diamond & \cdot & * & \bullet & * & * \\ \circ & \cdot & \cdot & \circ & * & * \\ \cdot & \cdot & \cdot & \cdot & * & * \\ \cdot & \cdot & \cdot & \cdot & \cdot & * \end{bmatrix} \qquad \Uparrow \text{ bottom to top} \qquad \begin{bmatrix} \circ & * & * & \circ & * & * \\ \cdot & * & * & * & * & * \\ \cdot & \cdot & * & * & * & * \\ \circ & \cdot & \cdot & \circ & * & * \\ \diamond & \cdot & \cdot & \triangle & * & * \\ \diamond & \cdot & \cdot & \triangle & \cdot & * \end{bmatrix}$$

Assume that the matrix under consideration is already close to triangular form so that the algorithm may have reached the expected phase of quadratic convergence. If the pivot element is chosen in such a way that the corresponding 2×2 subproblem under consideration is the one displayed by the symbol $\circ$, then the elements marked by $\diamond$ are the ones that have already been annihilated once in the current sweep. If the top-to-bottom column-by-column sweep is used, then the current Jacobi step linearly combines those elements with possibly large elements from the strict upper triangular part from the matrix marked with the symbol $\bullet$. On the other hand, if the bottom-to-top column-by-column sweep is used, then the current Jacobi step linearly combines the $\diamond$-elements with elements from the strict lower triangular part, marked by the symbol $\triangle$, that are expected to be sufficiently small. Thus, the increase of modulus of elements that have already been annihilated once may be much higher when top-to-bottom column-by-column are used and that is exactly what can be observed in practice. In the symmetric case, however, this observation does not apply, because in this case also the elements in the strict upper triangular part are expected to be sufficiently small.

3. A proof of asymptotic quadratic convergence. Wilkinson's proof [35] of asymptotic quadratic convergence of the classical symmetric Jacobi method makes extensive use of the fact that the offnorm $\mathrm{off}(M)$ decreases monotonically over the steps of the algorithm. As pointed out in section 2, this is no longer true for the nonsymmetric Jacobi method. Thus, we will have to investigate in detail the possible changes in the moduli of the entries in the strict lower triangular part of the matrix in a single Jacobi step. Let us introduce the following notation. Starting with the matrix $M \in \mathbb{C}^{n\times n}$, let us denote by $M_\nu = (m_{ij}^{(\nu)})$ the matrix that we have obtained after performing ν Jacobi steps. (In particular, we have $M_0 = M$.) Moreover, we denote

$$\varrho_\nu := \min_{i\neq j} \left| m_{i,i}^{(\nu)} - m_{j,j}^{(\nu)} \right|, \tag{3.1}$$

$$\eta_\nu := \max\left\{ |m_{ij}^{(\nu)}| \;\middle|\; i,j = 1,\dots,n \right\}, \tag{3.2}$$

$$\varepsilon_\nu := \max\left\{ |m_{ij}^{(\nu)}| \;\middle|\; i > j \right\}, \tag{3.3}$$

i.e., ϱ_ν is the smallest distance between two diagonal elements of the matrix M_ν, η_ν is the modulus of the largest element in modulus of M_ν, and ε_ν is the modulus of the largest element in modulus of the strict lower triangular part of M_ν. In the following, let ν be fixed and assume we have

$$\varrho_\nu > 0 \quad \text{and} \quad 4\frac{\varepsilon_\nu \eta_\nu}{\varrho_\nu^2} < 1. \tag{3.4}$$

Suppose that the (k,l)-element of M_ν is the pivot element of the current $((\nu+1)\text{st})$ step of the algorithm. We then compute the unitary matrix

$$Q = \begin{bmatrix} \cos x & -e^{-i\alpha}\sin x \\ e^{i\alpha}\sin x & \cos x \end{bmatrix}, \quad x, \alpha \in \mathbb{R},$$

that satisfies

$$Q^* \begin{bmatrix} m_{ll}^{(\nu)} & m_{lk}^{(\nu)} \\ m_{kl}^{(\nu)} & m_{kk}^{(\nu)} \end{bmatrix} Q = \begin{bmatrix} m_{ll}^{(\nu+1)} & m_{lk}^{(\nu+1)} \\ 0 & m_{kk}^{(\nu+1)} \end{bmatrix} \tag{3.5}$$

and that is closest to the identity matrix among all matrices satisfying (3.5). To obtain an estimate for the modulus of $\sin x$, we will use the following lemma, which is a special case of Theorem V.2.1 in [33].

LEMMA 3.1. [illegible] $A \in \mathbb{C}^{2\times 2}$ [illegible]

$$A = \begin{bmatrix} a & \eta \\ \varepsilon & b \end{bmatrix}, \text{ [illegible]} \quad 4\frac{|\varepsilon|\cdot|\eta|}{|a-b|^2} < 1.$$

[illegible] v [illegible] A [illegible]

$$v = \begin{bmatrix} 1 \\ p \end{bmatrix} \text{ [illegible]} \quad |p| < 2\frac{\varepsilon}{|a-b|}.$$

Using this lemma and taking into account (3.4), it is clear that the parameter x in Q satisfies $|\sin x| < 2\varepsilon_\nu/\varrho_\nu$. If the transformation induced by Q is applied to M_ν,

then it acts only on elements in the kth and lth rows and columns of M_ν. For the elements that have been altered in $M_{\nu+1}$, we obtain that

$$\begin{aligned} m_{lj}^{(\nu+1)} &= m_{lj}^{(\nu)} \cos x + m_{kj}^{(\nu)} e^{-i\alpha} \sin x, \\ m_{kj}^{(\nu+1)} &= m_{kj}^{(\nu)} \cos x - m_{lj}^{(\nu)} e^{i\alpha} \sin x, \\ m_{il}^{(\nu+1)} &= m_{il}^{(\nu)} \cos x + m_{ik}^{(\nu)} e^{i\alpha} \sin x, \\ m_{ik}^{(\nu+1)} &= m_{ik}^{(\nu)} \cos x - m_{il}^{(\nu)} e^{-i\alpha} \sin x \end{aligned}$$

for $i, j = 1, \dots, n$. Using these identities and using $|\cos x| \leq 1$ and $|\sin x| < 2\varepsilon_\nu/\varrho_\nu$, we obtain that $|m_{ij}^{(\nu+1)}| \leq w_{ij}$, where w_{ij} is given in the following table:

(3.6)

w_{ij}	$j < l$	$j = l$	$l < j < k$	$j = k$	$k < j$
$i < l$	$\lvert m_{ij}^{(\nu)}\rvert$	$\eta_{\nu+1}$	$\lvert m_{ij}^{(\nu)}\rvert$	$\eta_{\nu+1}$	$\lvert m_{ij}^{(\nu)}\rvert$
$i = l$	$\lvert m_{ij}^{(\nu)}\rvert + 2\frac{\varepsilon_\nu^2}{\varrho_\nu}$	$\eta_{\nu+1}$	$\eta_{\nu+1}$	$\eta_{\nu+1}$	$\eta_{\nu+1}$
$l < i < k$	$\lvert m_{ij}^{(\nu)}\rvert$	$\lvert m_{ij}^{(\nu)}\rvert + 2\frac{\varepsilon_\nu \eta_\nu}{\varrho_\nu}$	$\lvert m_{ij}^{(\nu)}\rvert$	$\eta_{\nu+1}$	$\lvert m_{ij}^{(\nu)}\rvert$
$i = k$	$\lvert m_{ij}^{(\nu)}\rvert + 2\frac{\varepsilon_\nu^2}{\varrho_\nu}$	0	$\lvert m_{ij}^{(\nu)}\rvert + 2\frac{\varepsilon_\nu \eta_\nu}{\varrho_\nu}$	$\eta_{\nu+1}$	$\eta_{\nu+1}$
$k < i$	$\lvert m_{ij}^{(\nu)}\rvert$	$\lvert m_{ij}^{(\nu)}\rvert + 2\frac{\varepsilon_\nu^2}{\varrho_\nu}$	$\lvert m_{ij}^{(\nu)}\rvert$	$\lvert m_{ij}^{(\nu)}\rvert + 2\frac{\varepsilon_\nu^2}{\varrho_\nu}$	$\lvert m_{ij}^{(\nu)}\rvert$

In this table, we can see the effect that has been heuristically explained in section 2. If we are in the stage that $\varepsilon_\nu \ll \eta_\nu$, i.e., our matrix under consideration is already close to triangular form, then the modulus of entries in the strict lower triangular part in positions (i, j) with $j < l$ or $k < i$ may have increased by $2\varepsilon_\nu^2/\varrho_\nu$ only, while the modulus of entries in positions (i, j) with $l \leq j$ and $i \leq k$ may have increased by $2\eta_\nu\varepsilon_\nu/\varrho_\nu \gg 2\varepsilon_\nu^2/\varrho_\nu$. Thus, the sweep should start from the lower left corner of the lower triangular part and then proceed to the northeast in order to guarantee that entries that have been eliminated once are increased by at most $2\varepsilon_\nu^2/\varrho_\nu$. This motivates the following definition.

DEFINITION 3.2. [illegible] $n \in \mathbb{N}$, $N = \frac{n(n-1)}{2}$ [illegible] $S = \big((i_1, j_1), (i_2, j_2) \dots, (i_N, j_N)\big)$ [illegible] N [illegible] $(i_\nu, j_\nu) \in \{1, 2, \dots, n\} \times \{1, 2, \dots, n\}$, [illegible] $i_\nu > j_\nu$, $\nu = 1, \dots, N$ [illegible] S [illegible] northeast directed sweep sequence

$$\nu < \mu \quad \Rightarrow \quad (i_\nu > i_\mu, \quad j_\nu < j_\mu)$$

[illegible] $\nu, \mu \in \{1, \dots, N\}$ [illegible] northeast directed sweep

Particular example of northeast directed sweep sequences are given by the sequence (2.3) that induces a bottom-to-top column-by-column sweep or by the sequence

$$\big((n, 1), (n-1, 1), (n, 2), (n-2, 1), (n-1, 2), (n, 3), \dots, (2, 1), (3, 2), \dots, (n, n-1)\big).$$

We continue by analyzing how the values of ε_ν, η_ν, and ϱ_ν have changed after one Jacobi step (regardless what kind of sweep is used). Since $\varepsilon_\nu \leq \eta_\nu$, we obtain from the discussion above that

$$\varepsilon_{\nu+1} \leq \varepsilon_\nu \left(1 + 2\frac{\eta_\nu}{\varrho_\nu}\right). \tag{3.7}$$

We could also produce a bound for $\eta_{\nu+1}$, but for our purpose it is sufficient to note that η_μ is bounded by $\|M\|_F$ for any $\mu \in \mathbb{N} \cup \{0\}$. It remains to investigate how ϱ_ν has changed. Therefore, we have to investigate in particular the changes on the diagonal of M_ν. Clearly, we have

$$\begin{aligned} m_{ll}^{(\nu+1)} &= m_{ll}^{(\nu)}(1-\sin^2 x) + m_{kl}^{(\nu)} e^{-ia}\sin x\cos x + m_{lk}^{(\nu)} e^{ia}\sin x\cos x + m_{kk}^{(\nu)}\sin^2 x, \\ m_{kk}^{(\nu+1)} &= m_{ll}^{(\nu)}\sin^2 x - m_{kl}^{(\nu)} e^{-ia}\sin x\cos x - m_{lk}^{(\nu)} e^{ia}\sin x\cos x + m_{kk}^{(\nu)}(1-\sin^2)x. \end{aligned}$$

Thus, we obtain $m_{ll}^{(\nu+1)} = m_{ll}^{(\nu)} + \Delta_l$, $m_{kk}^{(\nu+1)} = m_{kk}^{(\nu)} + \Delta_k$, where

$$\begin{aligned} &|\Delta_l| = |\Delta_k| \\ &\le \left|m_{ll}^{(\nu)}\sin^2 x\right| + \left|m_{kl}^{(\nu)} e^{-ia}\sin x\cos x\right| + \left|m_{lk}^{(\nu)} e^{ia}\sin x\cos x\right| + \left|m_{kk}^{(\nu)}\sin^2 x\right| \\ &\le \eta_\nu \cdot 4\frac{\varepsilon_\nu^2}{\varrho_\nu^2} + \varepsilon_\nu \cdot 2\frac{\varepsilon_\nu}{\varrho_\nu} + \eta_\nu \cdot 2\frac{\varepsilon_\nu}{\varrho_\nu} + \eta_\nu \cdot 4\frac{\varepsilon_\nu^2}{\varrho_\nu^2} \\ &\le 2\left(\frac{\varepsilon_\nu^2}{\varrho_\nu} + 4\eta_\nu\frac{\varepsilon_\nu^2}{\varrho_\nu^2} + \eta_\nu\frac{\varepsilon_\nu}{\varrho_\nu}\right). \end{aligned}$$

It follows that $|m_{ii}^{(\nu+1)} - m_{jj}^{(\nu+1)}| \ge |m_{ii}^{(\nu)} - m_{jj}^{(\nu)}| - |\Delta_l| - |\Delta_k|$ for all $i, j = 1, \dots, n$, and thus

$$\varrho_{\nu+1} \ge \varrho_\nu - 4\left(\frac{\varepsilon_\nu^2}{\varrho_\nu} + 4\eta_\nu\frac{\varepsilon_\nu^2}{\varrho_\nu^2} + \eta_\nu\frac{\varepsilon_\nu}{\varrho_\nu}\right). \tag{3.8}$$

Using the above, we will now show that the cyclic nonsymmetric Jacobi method using northeast directed sweeps is quadratically convergent if the matrix under consideration is sufficiently close to triangular form.

THEOREM 3.3. [illegible] $M = (m_{ij}) \in \mathbb{C}^{n\times n}$ [illegible] $M_\nu = (m_{ij}^{(\nu)})$ [illegible] M [illegible] ν [illegible] δ_0 [illegible] δ_μ [illegible] $M = M_0$ [illegible] M [illegible] μ [illegible]

$$\delta_\mu := \max\left\{|m_{ij}^{(\mu N)}| \;\middle|\; i > j\right\}, \quad \mu \in \mathbb{N} \cup \{0\}. \tag{3.9}$$

[illegible] $N := n(n-1)/2$ [illegible]

$$\eta := \|M\|_F, \quad \varrho := \frac{1}{2}\min_{i\ne j}|m_{ii} - m_{jj}|, \quad \delta := 2\delta_0\left(1 + 2\frac{\eta}{\varrho}\right)^N. \tag{3.10}$$

[illegible] $\varrho > 0$ [illegible] δ_0 [illegible]

$$\frac{\delta\eta}{\varrho^2} < \frac{1}{4}, \qquad \frac{\delta^2}{\varrho} + 4\eta\frac{\delta^2}{\varrho^2} + \eta\frac{\delta}{\varrho} \le \frac{\varrho_0}{4N}, \qquad 2\frac{N\delta^2}{\varrho} \le \delta_0, \tag{3.11}$$

[illegible] $\mu \in \mathbb{N} \cup \{0\}$ [illegible]

$$\delta_{(\mu+1)N} \le \left(1 + 2\frac{\eta}{\varrho}\right)^{2N}\frac{2N}{\varrho}\delta_{\mu N}^2,$$

[illegible]

. Let η_ν, ε_ν, and ϱ_ν be defined as in (3.1)–(3.3). Then we have

$$\delta_\mu = \varepsilon_{\mu N} \quad \text{and} \quad \varrho = \frac{\varrho_0}{2}.$$

From (3.7) and (3.8) we obtain that ε_ν (and ϱ_ν, respectively) may increase (or decrease, respectively) in each Jacobi step. We first show by induction that this increase (decrease, respectively) remains under control, i.e., that for $\mu \in \mathbb{N} \cup \{0\}$ and $p = 0, \dots, N$, we have that

$$\varepsilon_{\mu N} \le \frac{\delta_0}{2^\mu}, \qquad \varrho_{\mu N} \ge \varrho_0 - \sum_{j=1}^{\mu} \frac{\varrho_0}{2^{j+1}} > \varrho, \quad \text{and} \tag{3.12}$$

$$\varepsilon_{\mu N+p} \le \varepsilon_{\mu N} \left(1 + 2\frac{\eta}{\varrho}\right)^p, \qquad \varrho_{\mu N+p} \ge \varrho_{\mu N} - p\frac{\varrho_0}{2^{\mu+1}N}. \tag{3.13}$$

$(\mu, p) = (0, 0)$: There is nothing to prove.

$(\mu, p) \Rightarrow (\mu, p+1)$: Let $p \le N$. By the induction hypothesis for (μ, p) and $(\mu, 0)$, we have that

$$\varepsilon_{\mu N+p} \le \varepsilon_{\mu N} \left(1 + 2\frac{\eta}{\varrho}\right)^p \le \frac{\delta_0}{2^\mu} \left(1 + 2\frac{\eta}{\varrho}\right)^p \le \frac{\delta}{2^{\mu+1}} \tag{3.14}$$

using (3.10) and

$$\varrho_{\mu N+p} \ge \varrho_{\mu N} - p\frac{\varrho_0}{2^{\mu+1}N} \ge \varrho_0 - \sum_{j=1}^{\mu} \frac{\varrho_0}{2^{j+1}} - N\frac{\varrho_0}{2^{\mu+1}N} = \varrho_0 - \sum_{j=1}^{\mu+1} \frac{\varrho_0}{2^{j+1}} > \varrho. \tag{3.15}$$

Now assume $p < N$. Then we obtain using (3.7), (3.8), (3.14), and (3.15) and the induction hypothesis that

$$\begin{aligned}
\varepsilon_{\mu N+p+1} &\le \varepsilon_{\mu N+p} \left(1 + 2\frac{\eta_{\mu N+p}}{\varrho_{\mu N+p}}\right) \le \varepsilon_{\mu N+p} \left(1 + 2\frac{\eta}{\varrho}\right) \le \varepsilon_{\mu N} \left(1 + 2\frac{\eta}{\varrho}\right)^{p+1}; \\
\varrho_{\mu N+p+1} &\ge \varrho_{\mu N+p} - 4\left(\frac{\varepsilon_{\mu N+p}^2}{\varrho_{\mu N+p}} + 4\eta_{\mu N+p}\frac{\varepsilon_{\mu N+p}^2}{\varrho_{\mu N+p}^2} + \eta_{\mu N+p}\frac{\varepsilon_{\mu N+p}}{\varrho_{\mu N+p}}\right) \\
&\ge \varrho_{\mu N} - p\frac{\varrho_0}{2^{\mu+1}N} - 4\left(\frac{\delta^2}{(2^{\mu+1})^2\varrho} + 4\eta\frac{\delta^2}{(2^{\mu+1})^2\varrho^2} + \eta\frac{\delta}{2^{\mu+1}\varrho}\right) \\
&\ge \varrho_{\mu N} - p\frac{\varrho_0}{2^{\mu+1}N} - \frac{4}{2^{\mu+1}}\left(\frac{\delta^2}{\varrho} + 4\eta\frac{\delta^2}{\varrho^2} + \eta\frac{\delta}{\varrho}\right) \\
&\ge \varrho_{\mu N} - (p+1)\frac{\varrho_0}{2^{\mu+1}N}. \qquad \Big(\text{by (3.11)}\Big).
\end{aligned}$$

$(\mu, p) \Rightarrow (\mu+1, 0)$: For obtaining a bound for $\varepsilon_{(\mu+1)N}$, let us note that during the $(\mu+1)$st sweep each entry (i, j) in the strict lower triangular part of the current pencil is set to zero at one step. Afterward, during the remainder of the sweep, it is affected $k < N$ times in the steps, say, $\mu N + \ell_1, \dots, \mu N + \ell_k$, where k and $\ell_1, \dots, \ell_k$ depend on i, j. Since a northeast directed sweep is used, we obtain from table (3.6) that the modulus of the (i, j)-element of the matrix $M_{((\mu+1)N)}$ obtained after completing the

$(\mu+1)$st sweep is bounded by

$$|m_{ij}^{((\mu+1)N)}| \le 2\frac{\varepsilon_{\mu N+\ell_1}^2}{\varrho_{\mu N+\ell_1}} + \cdots + 2\frac{\varepsilon_{\mu N+\ell_k}^2}{\varrho_{\mu N+\ell_k}} \le \sum_{p=1}^{N} 2\frac{\varepsilon_{\mu N+p}^2}{\varrho_{\mu N+p}} \le N\left(\frac{\delta}{2^{\mu+1}}\right)^2 \frac{2}{\varrho}, \tag{3.16}$$

because $k \le N$ and $\varepsilon_{\mu N+p} \le \delta/2^{\mu+1}$ and $\varrho_{\mu N+p} \ge \varrho$ for $p = 0, \ldots, N$. Since the right-hand side of (3.16) is independent of the indices i and j, we then obtain

$$\varepsilon_{(\mu+1)N} \le N\left(\frac{\delta}{2^{\mu+1}}\right)^2 \frac{2}{\varrho} \le \frac{\delta_0}{(2^{\mu+1})^2} \le \frac{\delta_0}{2^{\mu+2}}. \tag{3.17}$$

This concludes the proof of (3.12) and (3.13). Now observe that (3.13) implies that

$$\varepsilon_{\mu N+p} \le \varepsilon_{\mu N}\left(1+2\frac{\eta}{\varrho}\right)^N = \delta_\mu\left(1+2\frac{\eta}{\varrho}\right)^N$$

for $p = 0, \ldots, N$. Using this inequality instead of (3.14), we obtain analogously to (3.17) that

$$\delta_{\mu+1} = \varepsilon_{(\mu+1)N} \le \sum_{p=1}^{N} 2\frac{\varepsilon_{\mu N+p}^2}{\varrho_{\mu N+p}} \le N\delta_\mu^2\left(1+2\frac{\eta}{\varrho}\right)^{2N}\frac{2}{\varrho},$$

which concludes the proof. □

Theorem 3.3 guarantees asymptotic quadratic convergence in terms of the largest modulus ε_ν of subdiagonal entries. Since the so-called offnorm

$$\operatorname{off}(M_\nu) := \sqrt{\sum_{i>j} |m_{ij}^{(\nu)}|^2}$$

is bounded by $\varepsilon_\nu \le \operatorname{off}(M_\nu) \le \sqrt{N}\varepsilon_\nu$, we also obtain asymptotic quadratic convergence in terms of the offnorm.

3.4. Note that in general the assumption $\varrho > 0$ in Theorem 3.3 cannot be weakened in order to guarantee convergence. Consider, for example, the matrix

$$M = \begin{bmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ \varepsilon & 0 & 1 \end{bmatrix},$$

where $\varepsilon > 0$ is arbitrarily small. Then the sequence of matrices generated by the nonsymmetric Jacobi method becomes periodic as long as exact arithmetic is performed:

$$\begin{bmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ \varepsilon & 0 & 1 \end{bmatrix} \rightsquigarrow \begin{bmatrix} 1 & 0 & \varepsilon \\ 1 & 1 & 0 \\ 0 & 1 & 1 \end{bmatrix} \rightsquigarrow \begin{bmatrix} 1 & 1 & 0 \\ 0 & 1 & \varepsilon \\ 1 & 0 & 1 \end{bmatrix} \rightsquigarrow \begin{bmatrix} 1 & 0 & 1 \\ \varepsilon & 1 & 0 \\ 0 & 1 & 1 \end{bmatrix}$$
$$\rightsquigarrow \begin{bmatrix} 1 & \varepsilon & 0 \\ 0 & 1 & 1 \\ 1 & 0 & 1 \end{bmatrix} \rightsquigarrow \begin{bmatrix} 1 & 0 & 1 \\ 1 & 1 & 0 \\ 0 & \varepsilon & 1 \end{bmatrix} \rightsquigarrow \begin{bmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ \varepsilon & 0 & 1 \end{bmatrix}.$$

However, if finite precision arithmetic is used, then roundoff errors break the periodicity and the algorithm starts to converge. For example, with $\varepsilon = 1/100$ our Matlab implementation of the algorithm needed eight sweeps for convergence.

4. Hamiltonian Jacobi methods. As pointed out in the introduction, the nonsymmetric Jacobi method may not be competitive in comparison to the highly efficient QR algorithm. However, this changes if one is interested in structure-preserving algorithms for the solution of structured eigenvalue problems. As an example, we consider the [illegible]. A matrix $H \in \mathbb{C}^{2n\times 2n}$ is called [illegible] if

$$H^T J + JH = 0, \quad \text{where } J = J_{2n} = \begin{bmatrix} 0 & I_n \\ -I_n & 0 \end{bmatrix},$$

or, equivalently, if

$$H = (h_{ij}) = \begin{bmatrix} A & C \\ D & -A^T \end{bmatrix}, \quad \text{where } A, C, D \in \mathbb{C}^{n\times n},\ C = C^T,\ D = D^T. \tag{4.1}$$

In some sources, matrices $H \in \mathbb{C}^{2n\times 2n}$ satisfying $H^*J + JH = 0$ are called Hamiltonian. For the sake of clear distinction, we refer to such matrices as [illegible], while we call matrices satisfying (4.1) [illegible]. The real and complex conjugate Hamiltonian eigenvalue problems have been extensively studied in the literature; see, e.g., [22, 28] and the references therein. Also, the complex transpose Hamiltonian eigenvalue problem has attracted some attention in recent years due to its relation to the so-called palindromic eigenvalue problem that arises in an application in the vibration analysis of rail tracks; see [18, 26, 25].

The solution of the Hamiltonian eigenvalue problem is in general tackled by computing condensed forms under unitary symplectic similarity transformations, i.e., transformations of the form $H \mapsto U^{-1}HU$, where $U \in \mathbb{F}^{2n\times 2n}$ is unitary and [illegible], i.e., it satisfies $U^\star JU = J$, where $\star = T$ in the real Hamiltonian and complex transpose Hamiltonian case and $\star = *$ in the complex conjugate Hamiltonian case. It is easy to check that unitary symplectic similarity transformations preserve the Hamiltonian structure, i.e., if H is Hamiltonian, then so is $U^{-1}HU$. The condensed form one is aiming at is the [illegible]. A Hamiltonian matrix H is said to be in Hamiltonian Schur form if

$$H = \begin{bmatrix} R & B \\ 0 & -R^\star \end{bmatrix}, \tag{4.2}$$

where $\star = T$ or $\star = *$, respectively. This form can always be achieved for complex transpose Hamiltonian matrices. For complex conjugate Hamiltonian matrices, it can be achieved if there are no eigenvalues on the imaginary axis [23].

What makes the Hamiltonian eigenvalue problem challenging is the fact that although a Hamiltonian QR algorithm, i.e., a structure-preserving version of the QR algorithm, has been developed [2], a preliminary structure-preserving reduction to a Hessenberg-like form is missing—a phenomenon that is known in the literature as Van Loan's curse [6, 30]. Thus, the Hamiltonian QR algorithm is in general not efficient, because it is of complexity $\mathcal{O}(n^4)$, and so, the competition is open for other kinds of structure-preserving algorithms.

In [3] and [1] Jacobi-like algorithms for Hamiltonian matrices have been proposed. Both algorithms are based on the solution of 4×4 subproblems in each Jacobi step. Byers [3] follows the idea of Stewart [32] of using only a selected set of pivot elements which results in an extreme slow convergence behavior. Therefore, we omit a detailed discussion of the first algorithm and focus on the algorithm proposed in [1] as well

as on a direct generalization of the nonsymmetric Jacobi method to Hamiltonian matrices which results in a Hamiltonian Jacobi method that is based on the solution of 2×2 subproblems in each step.

We restrict our attention to complex transpose Hamiltonian matrices. (A generalization of the discussion to the case of complex conjugate Hamiltonian matrices is possible, but more involved, because one has to take into account the fact that some of the subproblems may not be solvable. This is because reduction to Hamiltonian Schur form is not always possible in the complex conjugate Hamiltonian case if there are eigenvalues on the imaginary axis.) Our transformation matrices are supposed to be unitary and symplectic, so they must have the form

$$U = \begin{bmatrix} U_1 & -\overline{U}_2 \\ U_2 & \overline{U}_1 \end{bmatrix}, \quad U_1, U_2 \in \mathbb{C}^{n \times n},$$

where $U_1^* U_1 + U_2^* U_2 = I_n$ and $U_2^T U_1 - U_1^T U_2 = 0$.

The reason 4×4 subproblems instead of 2×2 problems are considered in the algorithm proposed in [1] becomes obvious from the following sketch:

$$\left[\begin{array}{cccc|cccc} * & * & * & * & * & * & * & * \\ \cdot & \bullet & \bullet & * & * & \bullet & \bullet & * \\ \cdot & \diamond & \bullet & * & * & \bullet & \bullet & * \\ \cdot & \cdot & \cdot & * & * & * & * & * \\ \hline \cdot & \cdot & \cdot & \cdot & * & \cdot & \cdot & \cdot \\ \cdot & \circ & \circ & \cdot & * & \bullet & \circ & \cdot \\ \cdot & \circ & \circ & \cdot & * & \bullet & \bullet & \cdot \\ \cdot & \cdot & \cdot & \cdot & * & * & * & * \end{array}\right]$$

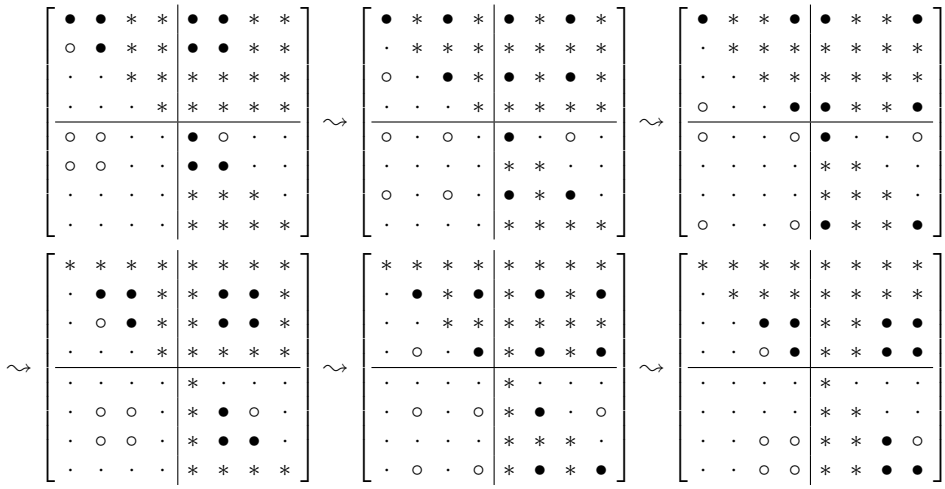
If the element displayed by $\diamond$ has been chosen as pivot element, then the 4×4 submatrix displayed by the symbols $\circ$ and $\bullet$ is the smallest Hamiltonian submatrix that contains the pivot element. (Here, $\circ$ refers to elements in the subproblem that are annihilated, while $\bullet$ stands for entries that may remain large in norm.) For details concerning the solution of the 4×4 subproblem, see [1]. (The discussion in [1] involves complex conjugate Hamiltonian matrices only, but the generalization to the complex transpose Hamiltonian case is straightforward.) Among all possible transformation matrices, we once again choose the one that is closest to the identity in order to enable asymptotic quadratic convergence.

A sweep of the Hamiltonian Jacobi algorithm as proposed in [1] is then given by the following sequence of indices, where the quadrupel of indices (i, j, k, l) refers to the 4×4 subproblem consisting of the rows and columns i, j, k, l:

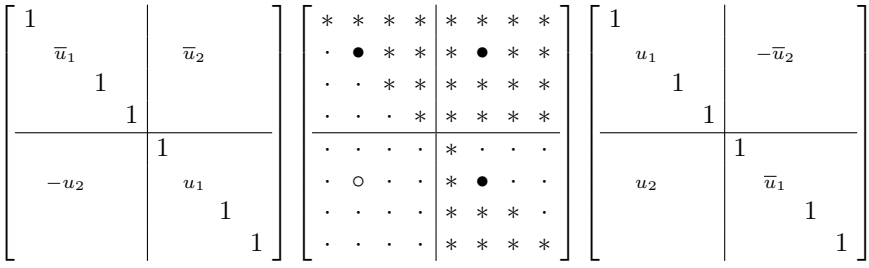
$$\begin{aligned} &(1, 2, n+1, n+2), (1, 3, n+1, n+3), \ldots, (1, n, n+1, 2n), \\ &(2, 3, n+2, n+3), (2, 4, n+2, n+4), \ldots, (n-1, n, 2n-1, 2n). \end{aligned} \tag{4.3}$$

Indeed, one easily checks that each pivot element is eliminated at least once during the sweep. On the other hand, the elements in the $(j, n+j)$ positions are annihilated $n-1$ times in each sweep, a fact that cannot be avoided when Hamiltonian 4×4 subproblems are considered. In the following, we will refer to the cyclic Hamiltonian Jacobi algorithm as proposed in [1] as [illegible] when sweeps based on the sequence of indices (4.3) are used. As an example, we display such a sweep for an

8×8 Hamiltonian matrix in the sketch below:



Next we consider a Jacobi-like algorithm for Hamiltonian matrices that is based on the solution of 2×2 subproblems. (This algorithm is related to the algorithm JIGH2 in [27] that was designed for the solution of the generalized Hermitian eigenvalue problem.) In this algorithm, we have to distinguish between pivot elements that are on the diagonal of C in (4.1) and those that are not. Indeed, if we select a pivot element $h_{n+k,k}$ from the diagonal of C, then there is a corresponding Hamiltonian 2×2 subproblem that contains this element, as indicated in the following sketch:



This 2×2 subproblem can be solved as in the nonsymmetric Jacobi method for general complex matrices by choosing $x, \alpha \in \mathbb{R}$ such that

$$Q = \begin{bmatrix} u_1 & -\overline{u}_2 \\ u_2 & \overline{u}_1 \end{bmatrix} = \begin{bmatrix} \cos x & -e^{-i\alpha} \sin x \\ e^{i\alpha} \sin x & \cos x \end{bmatrix}$$

annihilates the pivot element $h_{n+k,k}$ and is the matrix that is closest to the identity among all matrices that do so. If the matrix U is then obtained from the $2n \times 2n$ identity matrix by substituting $u_{kk} = u_{n+k,n+k} = u_1$, and $u_{k,n+k} = -\overline{u}_2$, $u_{n+k,k} = u_2$, we find that U is not only unitary, but also symplectic and thus the transformation with U will preserve the Hamiltonian structure of H.

The situation is different when the pivot element is not on the diagonal of C as then there is no Hamiltonian 2×2 subproblem that contains the given pivot element. To be specific, let $h_{k\ell}$ be a pivot element satisfying $\ell < k \leq n$ or $n + \ell < k \leq 2n$, i.e., the pivot element is in the strict lower triangular part of either the block A or the

block C in (4.1). As in the previous we then compute the matrix

$$Q = \begin{bmatrix} u_1 & -\overline{u}_2 \\ u_2 & \overline{u}_1 \end{bmatrix} = \begin{bmatrix} \cos x & -e^{-i\alpha}\sin x \\ e^{i\alpha}\sin x & \cos x \end{bmatrix} \tag{4.4}$$

that triangularizes the 2×2 submatrix $\hat{H}$ consisting of the elements $h_{\ell\ell}$, $h_{\ell k}$, $h_{k\ell}$, and h_{kk} and that is closest to the identity among all matrices of the form (4.4) that do so. Note that Q is not only unitary but also symplectic. However, when embedding Q into an $2n\times 2n$ matrix U by setting U to be the identity matrix except for the elements $u_{\ell\ell} = u_1$, $u_{\ell k} = -\overline{u}_2$, $u_{k\ell} = u_2$, $u_{kk} = \overline{u}_1$, then the resulting matrix U is unitary, but not symplectic, so we have to set $u_{n+\ell,n+\ell} = \overline{u}_1$, $u_{n+\ell,p} = -u_2$, $u_{p,n+\ell} = \overline{u}_2$, and $u_{p,p} = u_1$, where $p = n+k$ if $k \le n$ and $p = k-n$ if $n+\ell < k \le 2n$ to make it unitary and symplectic. Let us investigate this in detail. Denote $A = (a_{ij})$, $C = (c_{ij})$, $D = (d_{ij})$, where the submatrices A, C, D are given as in (4.1), and consider first the case $k \le n$, i.e., we have

$$\hat{H} = \begin{bmatrix} a_{\ell\ell} & a_{\ell k} \\ a_{k\ell} & a_{kk} \end{bmatrix},$$

and thus the pivot element is from the strict lower triangular part of A. The situation is depicted in the following sketch, where the pivot element is displayed with the symbol $\circ$ and the subproblem $\hat{H}$ is marked with the symbols $\circ$ and $\bullet$:

$$\left[\begin{array}{cccc|cccc} 1 & & & & & & & \\ & \overline{u}_1 & \overline{u}_2 & & & & & \\ & -u_2 & u_1 & & & & & \\ & & & 1 & & & & \\ \hline & & & & 1 & & & \\ & & & & & u_1 & u_2 & \\ & & & & & -\overline{u}_2 & \overline{u}_1 & \\ & & & & & & & 1 \end{array}\right] \left[\begin{array}{cccc|cccc} * & * & * & * & * & * & * & * \\ \cdot & \bullet & \bullet & * & * & * & * & * \\ \cdot & \circ & \bullet & * & * & * & * & * \\ \cdot & \cdot & \cdot & * & * & * & * & * \\ \hline \cdot & \cdot & \cdot & \cdot & * & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & * & + & \diamond & \cdot \\ \cdot & \cdot & \cdot & \cdot & * & + & + & \cdot \\ \cdot & \cdot & \cdot & \cdot & * & * & * & * \end{array}\right] \left[\begin{array}{cccc|cccc} 1 & & & & & & & \\ & u_1 & -\overline{u}_2 & & & & & \\ & u_2 & \overline{u}_1 & & & & & \\ & & & 1 & & & & \\ \hline & & & & 1 & & & \\ & & & & & \overline{u}_1 & -u_2 & \\ & & & & & \overline{u}_2 & u_1 & \\ & & & & & & & 1 \end{array}\right]$$

Due to the special structure of U, we find that a second 2×2 subproblem given by

$$\widetilde{H} = \begin{bmatrix} h_{n+\ell,n+\ell} & h_{n+\ell,n+k} \\ h_{n+k,n+\ell} & h_{n+k,n+k} \end{bmatrix} = \begin{bmatrix} -a_{\ell\ell} & -a_{k\ell} \\ -a_{\ell k} & -a_{kk} \end{bmatrix} = -\hat{H}^T$$

is solved as well. This subproblem is depicted in the sketch above by the symbols $+$ and $\diamond$, where the symbol $\diamond$ display the element that will be annihilated by the transformation with U. Indeed, $\widetilde{H}$ will be transformed as

$$\begin{bmatrix} u_1 & u_2 \\ -\overline{u}_2 & \overline{u}_1 \end{bmatrix} \widetilde{H} \begin{bmatrix} \overline{u}_1 & -u_2 \\ \overline{u}_2 & u_1 \end{bmatrix} = -Q^T \hat{H}^T \overline{Q} = -(Q^* \hat{H} Q)^T = \begin{bmatrix} * & 0 \\ * & * \end{bmatrix}.$$

We have a similar situation for the case $n+\ell < k \le 2n$, i.e., when the pivot element is from the strict lower triangular part of C. Again, besides

$$\hat{H} = \begin{bmatrix} a_{\ell\ell} & c_{\ell k} \\ d_{k\ell} & -a_{kk} \end{bmatrix},$$

a second subproblem $\widetilde{H}$ is solved when the transformation with U is applied. Here, we have

$$\widetilde{H} = \begin{bmatrix} h_{k-n,k-n} & h_{k-n,n+\ell} \\ h_{n+\ell,k-n} & h_{n+\ell,n+\ell} \end{bmatrix} = \begin{bmatrix} a_{kk} & c_{\ell k} \\ d_{k\ell} & -a_{\ell\ell} \end{bmatrix} = -J_2^T \hat{H}^T J_2, \quad J_2 = \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix},$$

since $c_{k\ell} = c_{\ell k}$ and $d_{k\ell} = d_{\ell k}$. Then, $\widetilde{H}$ will be transformed as

$$Q^*\widetilde{H}Q = (J_2^T Q^T J_2)(-J_2^T \hat{H}^T J_2)(J_2^T \overline{Q} J_2) = -J_2^T (Q^* \hat{H} Q)^T J_2 = \begin{bmatrix} * & * \\ 0 & * \end{bmatrix},$$

where we used that Q is both unitary and symplectic, i.e., $Q = J_2^T Q^{-T} J_2 = J_2^T \overline{Q} J_2$. The situation is depicted in the sketch below, where $\hat{H}$ is displayed by the symbols $\circ$ and $\bullet$ and $\widetilde{H}$ is displayed by the symbols $\diamond$ and $+$:

$$\left[\begin{array}{ccc|ccc}
1 & & & & & \\
 & \overline{u}_1 & & & \overline{u}_2 & \\
 & & \overline{u}_1 & & \overline{u}_2 & \\
 & & & 1 & & \\
\hline
 & & & 1 & & \\
 & & -u_2 & & u_1 & \\
 & -u_2 & & & & u_1 \\
 & & & & & 1
\end{array}\right]
\left[\begin{array}{cccc|cccc}
* & * & * & * & * & * & * & * \\
\cdot & \bullet & * & * & * & * & \bullet & * \\
\cdot & \cdot & + & * & * & + & * & * \\
\cdot & \cdot & \cdot & * & * & * & * & * \\
\hline
\cdot & \cdot & \cdot & \cdot & * & \cdot & \cdot & \cdot \\
\cdot & \cdot & \diamond & \cdot & * & + & \cdot & \cdot \\
\cdot & \circ & \cdot & \cdot & * & * & \bullet & \cdot \\
\cdot & \cdot & \cdot & \cdot & * & * & * & *
\end{array}\right]
\left[\begin{array}{ccc|ccc}
1 & & & & & \\
 & u_1 & & & -\overline{u}_2 & \\
 & & u_1 & & -\overline{u}_2 & \\
 & & & 1 & & \\
\hline
 & & & 1 & & \\
 & & u_2 & & \overline{u}_1 & \\
 & u_2 & & & & \overline{u}_1 \\
 & & & & & 1
\end{array}\right]$$

(Again, $\circ$ and $\diamond$ stand for the elements that are annihilated by the transformation with U.)

It becomes clear from this discussion that it is sufficient to annihilate all elements in the strict lower triangular parts of A and C during one sweep. But how should a sweep be organized? The answer follows by noting that the Hamiltonian matrix H as in (4.2) is in Hamiltonian Schur form if and only if the matrix

$$\mathcal{F}H\mathcal{F} = \begin{bmatrix} R & BF_n \\ 0 & -F_n R^T F_n \end{bmatrix}, \quad \mathcal{F} = \begin{bmatrix} I_n & 0 \\ 0 & F_n \end{bmatrix}, \quad F_n = \begin{bmatrix} 0 & & 1 \\ & \iddots & \\ 1 & & 0 \end{bmatrix} \tag{4.5}$$

is in Schur form. Here, F_n denotes the [illegible], i.e., the matrix with ones on the southeast northwest diagonal and zeros elsewhere. (It is straightforward to check that a matrix L is lower triangular if and only if $F_n L F_n$ is upper triangular.) If we then carry out a [illegible] given by the sequence of indices

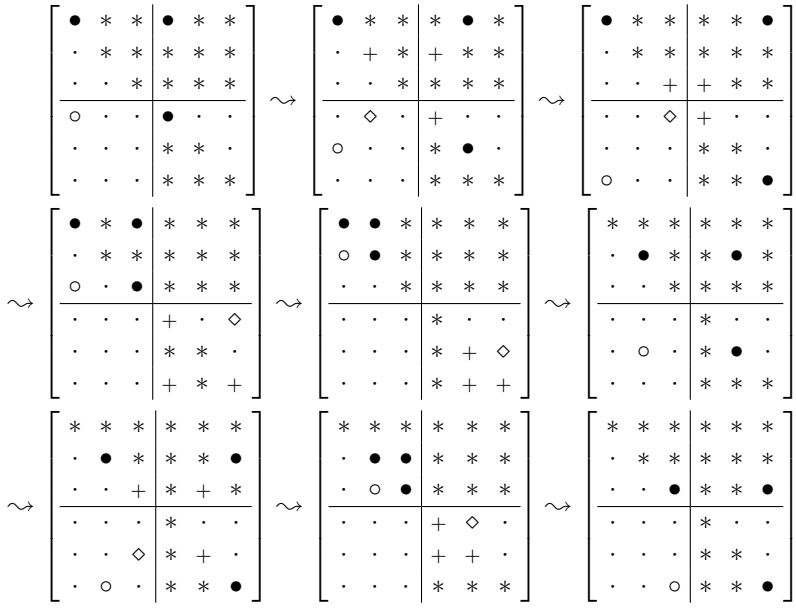
$$((n{+}1,1),(n{+}2,1),\ldots,(2n,1),(n,1),(n{-}1,1),\ldots,(2,1),(n{+}2,2),(n{+}3,2),\ldots,(2n,n)),$$

then given the fact that most of the time two elements are annihilated during a single Jacobi step, we find that the elements are annihilated in the order

$$\begin{aligned}
&((n{+}1,1),(n{+}2,1),(n{+}1,2),(n{+}3,1),(n{+}1,3),\ldots,(2n,1),(n{+}1,n),\\
&(n,1),(n{+}1,2n),(n{-}1,1),(n{+}1,2n{-}1),\ldots,(2,1),(n{+}1,n{+}2),\\
&(n{+}2,2),(n{+}3,2),(n{+}2,3),\ldots,(2n,n)).
\end{aligned}$$

It is then straightforward to check that this corresponds to a northeast directed sweep on the matrix $\mathcal{F}H\mathcal{F}$, and thus the Hamiltonian Jacobi algorithm for H using a Hamiltonian sweep corresponds to the nonsymmetric Jacobi algorithm for $\mathcal{F}H\mathcal{F}$ using a special northeast directed sweep. Therefore, by Theorem 3.3 we expect asymptotic quadratic convergence for the Hamiltonian Jacobi algorithm when Hamiltonian sweeps are used, and this is exactly what can be observed in numerical experiments. We de-

pict one Hamiltonian sweep for the case $n = 3$:



The Hamiltonian Jacobi algorithm based on the solution of 2×2 subproblems will be referred to as [illegible] 2 [illegible] if Hamiltonian sweeps are used.

Let us return to the Hamiltonian 4-Jacobi. Surprisingly, only linear asymptotic convergence of the method can be observed, as we will see in section 5. This behavior can be explained by looking at the order in which the pivot elements are annihilated. One easily finds that, for example, the pivot element in the $(2,1)$-position is annihilated in the step preceding the annihilation of the element in the $(3,1)$-position. Thus, the sweep given by the sequence of indices (4.3) [illegible] on the matrix $\mathcal{F}H\mathcal{F}$. In order to ensure this, we have to modify the sequence of indices as

$$\begin{aligned}
&(1,2,n{+}1,n{+}2),(1,3,n{+}1,n{+}3),\dots,(1,n{-}1,n{+}1,2n{-}1),(1,n,n{+}1,2n),\\
&(1,n{-}1,n{+}1,2n{-}1),\dots,(1,3,n{+}1,n{+}3),(1,2,n{+}1,n{+}2),\\
&(2,3,n{+}2,n{+}3),\dots,(2,n,n{+}2,2n),\dots,(2,3,n{+}2,n{+}3),\dots,(n{-}1,n,2n{-}1,2n).
\end{aligned} \tag{4.6}$$

Here, the majority of pivot elements is annihilated at least twice during a sweep, but the order in which the pivot elements are annihilated the last time during a sweep is now

$$((n{+}1,1),(n{+}2,1),\dots,(2n,1),(n,1),(n{-}1,1),\dots,(2,1),(n{+}2,2),(n{+}3,2),\dots,(2n,n)),$$

which corresponds to a northeast directed sweep on the matrix $\mathcal{F}H\mathcal{F}$. We refer to the Hamiltonian Jacobi method based on the solution of 4×4 subproblems using sweeps given by the sequence of indices (4.6) as [illegible] 4 [illegible]. By the discussion above, we now expect asymptotic quadratic convergence of the method, and this is what can be observed in experiments; see section 5.

Concerning the computational effort, one can roughly say that one sweep of the improved Hamiltonian 4-Jacobi is approximately twice as expensive as the Hamiltonian 4-Jacobi. On the other hand, one sweep of the Hamiltonian 2-Jacobi needs approximately 80% of the number of flops (floating point operations) of one sweep of the Hamiltonian 4-Jacobi (and thus about 40% of the number of flops of one sweep of the improved Hamiltonian 4-Jacobi).

5. Numerical experiments. We implemented the cyclic nonsymmetric Jacobi algorithm in Matlab Version 7 and ran it on a PC with a Pentium III processor (800 MHz). As a stopping criterion we used $\text{maxoff}(A) := \max_{i>j} |a_{ij}| < 10\texttt{eps}\,\|A\|_2$.

First, the nonsymmetric Jacobi method was run for 100 random complex matrices (generated with the Matlab command `randn`) of size $n \times n$, where $n = 10, 20, \ldots, 150$, after normalization to spectral norm equal to one; see Figure 5.1.

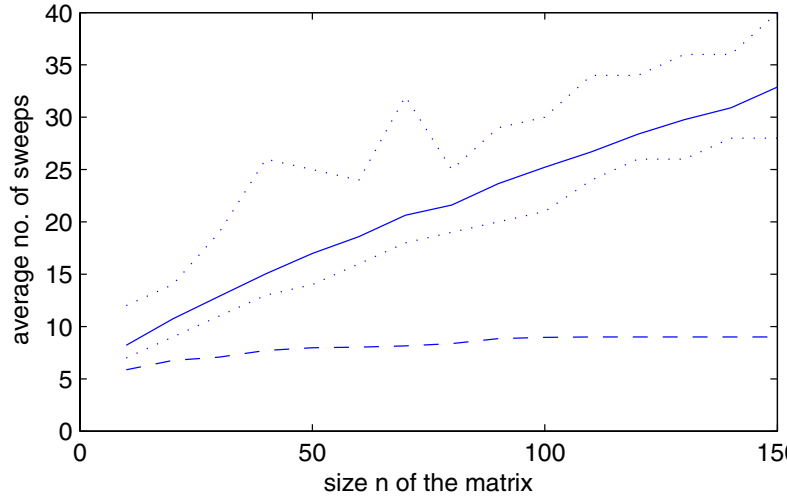


FIG. 5.1. *Test for* 100 *random matrices of different sizes.*

The solid line in Figure 5.1 displays the average number of sweeps needed for convergence for random complex matrices while the dashed line displays the corresponding number for Hermitian matrices. Thus, the method runs much faster for Hermitian matrices than for general complex matrices, an effect that had already been observed by Eberlein [10]. The dotted lines display the maximal and minimal number of sweeps that were needed for convergence for random complex matrices; e.g., for $n = 100$ the algorithm needed between 21 and 30 sweeps. The distribution of the number of sweeps for the tests on 100×100 matrices is shown in Figure 5.2.

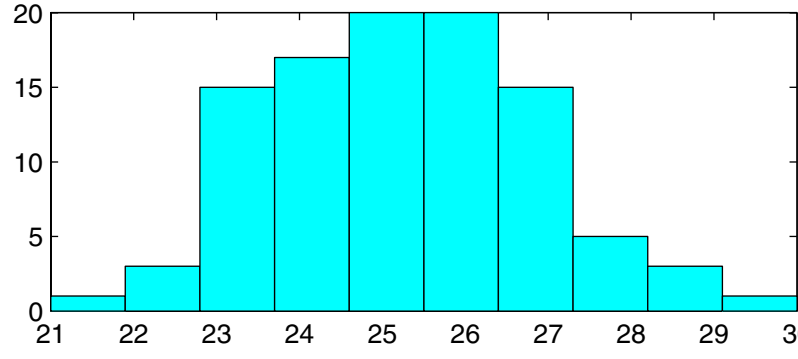

FIG. 5.2. *Distribution of number of sweeps needed for convergence.*

Figure 5.3 displays the typical convergence behavior of the nonsymmetric Jacobi algorithm for a random complex matrix of size 50×50 using top-to-bottom sweeps versus using bottom-to-top sweeps.

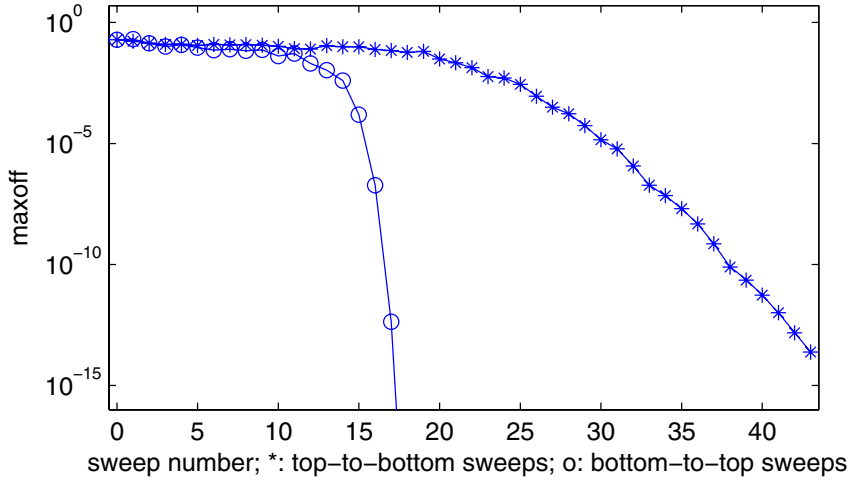

FIG. 5.3. *Typical convergence behavior for general matrices.*

In both cases, the algorithm starts with a phase of "sorting elements" that is characterized by almost stagnation. As expected, it can be observed that maxoff(A) does not decrease monotonically over the number of sweeps. The phase of almost stagnation is followed by the phase of convergence. As predicted by the theory, the convergence rate becomes asymptotically quadratic in the case of bottom-to-top sweeps. However, the convergence rate appears to be only linear in the case of top-to-bottom sweeps.

The situation is completely different when the algorithm is applied to a Hermitian matrix. Figure 5.4 shows the typical convergence behavior of the nonsymmetric Jacobi algorithm for a 50×50 Hermitian matrix. There is hardly any difference in the convergence behavior of the algorithm when using bottom-to-top sweeps compared to using top-to-bottom sweeps and both methods show asymptotic quadratic convergence.

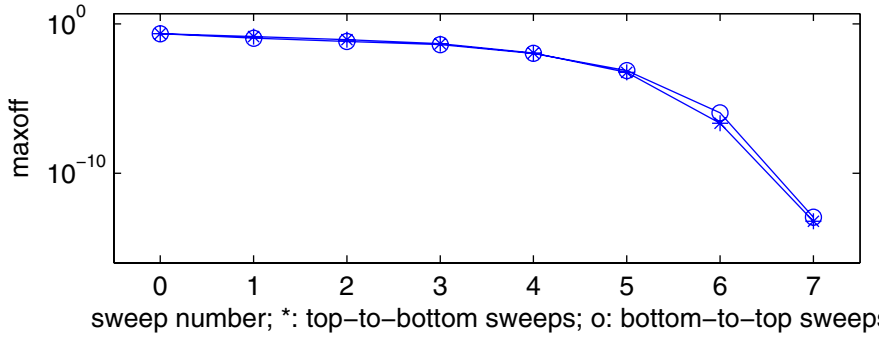

FIG. 5.4. *Typical convergence behavior for Hermitian matrices.*

A second test has been run for 100 matrices close to Schur form. For this, 100 random complex $n \times n$ matrices have been generated and normalized to norm one. Then, the Schur form has been computed by using the Matlab function `schur`, and a random perturbation of norm $1/100$ has been added. Then the nonsymmetric Jacobi algorithm has been run on the perturbed Schur form. The results are displayed in Figure 5.5.

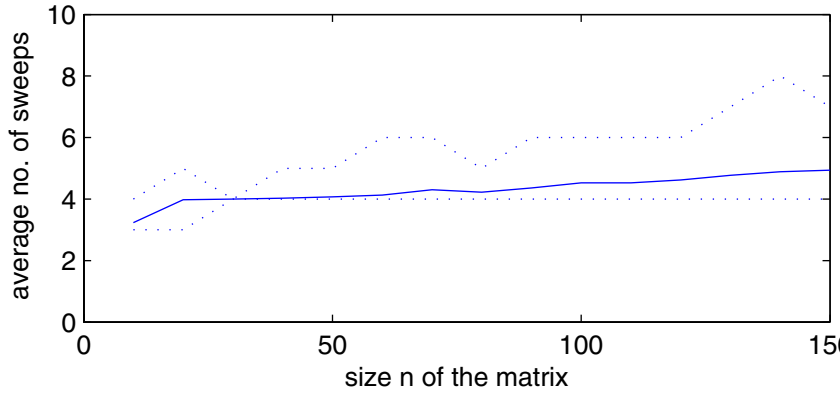

FIG. 5.5. *Test for* 100 *matrices close to Schur form.*

Once again, the solid line displays the average number of sweeps that were needed for convergence, while the dotted lines display the maximal and minimal number of needed sweeps. Even for matrices of size 150×150, the algorithm needs only about five sweeps for convergence, because the entries in the strict lower triangular part of the matrices are of magnitude of order $1/100$ compared to the entries in the upper triangular part, and thus the hypothesis of Theorem 3.3 is very likely to be satisfied so that we may have a quadratic rate of convergence right from the beginning.

Figure 5.6 displays the typical convergence behavior of the nonsymmetric Jacobi algorithm for a matrix of size 50×50 that is close to Schur form. While the algorithm

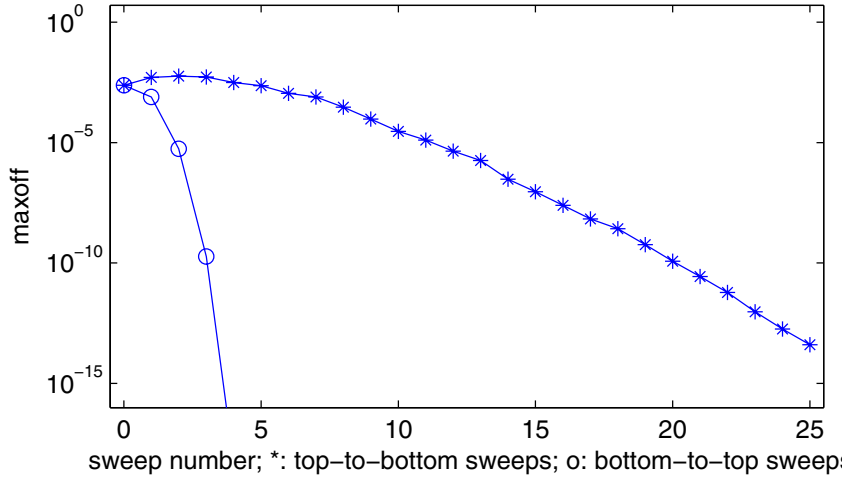

FIG. 5.6. *Typical convergence behavior for matrices close to Schur form.*

almost immediately enters the phase of quadratic convergence when using bottom-to-top sweeps, the convergence rate appears once again to be only linear when using top-to-bottom sweeps. Next, we tested the performance of the Hamiltonian Jacobi algorithms described in section 4 for 100 random Hamiltonian matrices normalized to spectral norm equal to one for the sizes $2n = 10, 20, \ldots, 100$.

Figure 5.7 displays the average number of sweeps that was needed for convergence. The Hamiltonian 2-Jacobi performs similarly to the nonsymmetric Jacobi algorithm for general complex matrices as expected. On the other hand, the Hamiltonian 4-Jacobi needs a much larger number of sweeps. This changes drastically when passing to the improved Hamiltonian 4-Jacobi.

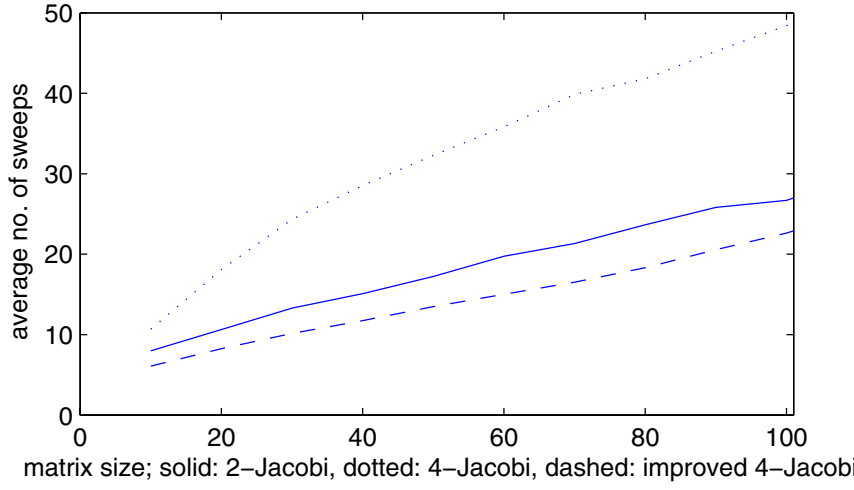

FIG. 5.7. *Test for* 100 *random Hamiltonian matrices of different sizes.*

Figure 5.8 displays the typical convergence behavior of the Hamiltonian Jacobi methods. As expected, the Hamiltonian 2-Jacobi and the improved Hamiltonian 4-

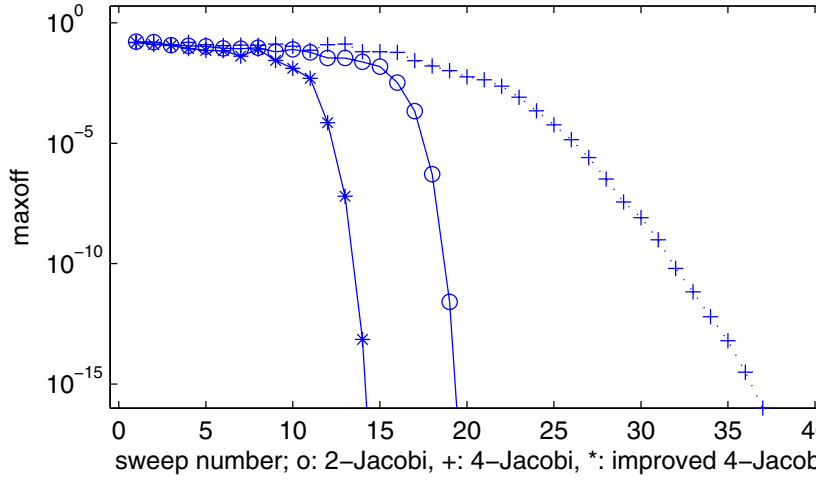

FIG. 5.8. *Typical convergence behavior for Hamiltonian matrices.*

Jacobi show asymptotic quadratic convergence. On the other hand, the asymptotic convergence rate of the Hamiltonian 4-Jacobi appears to be only linear, which explains the large average number of sweeps that is needed for convergence. Although the improved Hamiltonian 4-Jacobi method needs the least number of sweeps for convergence in general, the Hamiltonian 2-Jacobi turns out to be the most efficient version of the Hamiltonian Jacobi methods because the cost of one sweep of the Hamiltonian 2-Jacobi is only about 40% of the cost of one sweep of the improved Hamiltonian 4-Jacobi.

6. Conclusions. We have revisited the nonsymmetric Jacobi algorithm for the computation of the Schur form of a general complex matrix. In particular, asymptotic quadratic convergence of the cyclic version of the method can be proved if northeast directed sweeps are used. Other sweeps, in turn, seem to lead to a linear convergence rate only. Based on this convergence theory, we were able to explain why the convergence behavior of the Hamiltonian Jacobi algorithm proposed in [1] is less satisfactory than expected and what can be done to overcome this inconvenience.

Still, there are many aspects that have not yet been investigated. First, a proof of global convergence is still missing. Then, the convergence behavior of the algorithm is not yet optimal, because the initial phase of almost stagnation is very long and the phase of quadratic convergence is entered rather late. Therefore, preconditioning methods should be introduced and investigated in order to improve the convergence, like it has been done for example, for a Jacobi algorithm for computing the singular value decomposition; see [8]. Another important issue is parallelization. Since the solution of 2×2 subproblems requires only local information, it is possible to implement parallel version of Jacobi-like algorithms, as already considered in [10]. However, the discussion in section 2 shows that further investigation is necessary as a naive parallel implementation of the algorithm may lead to a loss of the property of asymptotic quadratic convergence.

Acknowledgment. I would like to thank Heike Fassbender for valuable discussions and for giving helpful comments on an earlier draft of the paper.

A CLASS OF SPARSE UNIMODULAR MATRICES GENERATING MULTIRESOLUTION AND SAMPLING ANALYSIS FOR DATA OF ANY LENGTH*

N. D. ATREAS†, C. KARANIKAS†, AND P. POLYCHRONIDOU†

Abstract. We introduce a class of sparse unimodular matrices U^m of order $m \times m$, $m = 2, 3, \ldots$. Each matrix U^m has all entries 0 except for a small number of entries 1. The construction of U^m is achieved by iteration, determined by the prime factorization of a positive integer m and by new dilation operators and block matrix operators. The iteration above gives rise to a multiresolution analysis of the space V_m of all m-periodic complex-valued sequences, suitable to reveal information at different scales and providing sampling formulas on the multiresolution subspaces of V_m. We prove that the matrices U^m are invertible, and we present a recursion equation to compute the inverse matrices. Finally, we connect the transform induced by the matrix U^m with the underlying natural tree structure and random walks on trees.

Key words. sparse matrices, multiresolution analysis, sampling theory, tree structures

1. Introduction.

The evolution of large digital libraries has dramatically transformed the processing, storage, and retrieval of information (see [2]). In order to handle a large amount of information, we need fast computations and storage saving, and the role of sparse matrices to both aforementioned requirements becomes very important. Since sparse matrices have a "small" number of nonzero elements, a variety of techniques have been developed for storing and processing them efficiently (see [4], [8]). Sparse matrices are used mainly in combinatorics and in application areas such as graph theory, for describing a low density of significant data or connections, and for numerical solution of linear partial differential equations, where the partial differentiable operators are approximated by finite difference operators, giving rise to a system of equations which involves a sparse coefficient matrix. It is natural to wonder whether we can build sparse matrices for extracting local information.

One of the widely used tools for extracting local information is multiresolution analysis (MRA). A multiresolution analysis of a Hilbert space V is a nested sequence of closed, shift invariant subspaces $\{V_i \subset V_{i+1} : i = 0, 1, 2 \ldots\}$ of V whose union is dense in V such that the subspaces V_i are scaled versions of each other under the action of a dilation operator $D : V_i \to V_{i+1}$. As a consequence, each subspace V_i reveals information at different scales/resolutions, and the resolution of the subspace V_{i+1} is higher than the resolution of the subspace V_i (see [5] for an overview of MRAs on various spaces). We notice here that most MRAs provide sampling formulas associated to the subspaces V_i (see [9], [10]). In [1], we presented the sampling formula associated to the subspaces V_i of a MRA of the space of p^M-periodic sequences. Recall that an M-dimensional subspace W of a space V of sequences of length N has a [illegible] $\{s_0, \ldots, s_{M-1}\}$, if there exist M positive integers $0 \le n_1 < \cdots < n_M < N$ such

†Department of Informatics, Aristotle University of Thessaloniki, 54-124, Thessaloniki, Greece (natreas@csd.auth.gr, karanika@csd.auth.gr, ppolychr@csd.auth.gr).

that for any sequence $\mathbf{t} = \{t_1, \ldots, t_N\} \in W$ we have

$$t(n) = \sum_{j=0}^{M-1} t(n_j) s_j(n),\ 0 \le n \le N-1.$$

In particular, we say that W has a s, if there exist M positive integers $0 \le n_1 < \cdots < n_M < N$ such that for any sequence $\mathbf{t} \in W$ we have

$$t(n) = \sum_{j=0}^{M-1} t(n_j) s(n - n_j),\ 0 \le n \le N-1.$$

In both cases, we say that W is a of V.

Another tool used for extracting local information is a tree transform. Local information in a tree is stored in , starting with a root node and ending with terminal nodes called . For example, a binary tree transform associated to data $T = \{t_1, \ldots, t_{2^N}\}$ is a collection of numbers:

$$\boldsymbol{\alpha} = \{\alpha_{n,k}(T),\ k = 1, \ldots, 2^n,\ n = 0, \ldots, N\}.$$

The collection $\boldsymbol{\alpha}$ has a binary tree structure with $N+1$ resolution levels. Each resolution level cuts T into 2^n equal pieces. If we denote

$$T(n,k) = \{t_s,\ s = (k-1)2^{N-n} + 1, \ldots, k2^{N-n}\},$$

then the number $a_{0,1}(T)$ corresponds to the initial node of the tree; the number $a_{n,k}(T)$ corresponds to the k-node of the nth generation and encodes the information associated to the subset $T(n,k)$. In [7], one of the authors has developed a discrete tree transform (DTT), which has been used for a pattern recognition process (see [3]).

In order to build our sparse matrices U^m of order $m \times m$, we exploit the basic properties of a MRA construction on matrices.

In section 2, a construction is presented for U^m in different scales by an iteration process, determined by the prime factorization of a positive integer m : $m = p_1 p_2 \ldots p_N$ $(p1 \ge p2 \ldots \ge p_N)$ and by repetitive dilation and block-matrix operations (see Definitions 1–6). Our construction starts with the matrix $U^m(0) = \{1\}$. $U^m(n+1)$ is a block matrix obtained from joining two matrices: a matrix derived by a dilation process on $U^m(n)$ and a properly selected permutation matrix. In the Nth scale the resulting matrix $U^m(N) = U^m$ is a $(0,1)$-matrix admitting the following properties:

- It is a unimodular matrix (see Proposition 1);
- the inverse matrix $(U^m)^{-1}$ is also a sparse matrix with entries $1, 0, -1$ constructed by a recursion equation on matrices, which can be easily implemented via an algorithm (see Theorem 1).

In section 3, we see that the matrices U^m encode local information. In fact:

- in Definition 7 we see that the matrix U^m gives rise to a multiresolution analysis $\{W_0 \subset \ldots \subset W_N = V_m\}$ of the space V_m of all m-periodic complex-valued sequences. The subspaces W_i are spanned by properly selected row vectors of U_m and display information at different resolution levels. In addition, in Theorem 2 we prove that the resolution subspaces W_i are sampling subspaces, and we present the sampling formula for W_i.

- The transform $L_m : V_m \to V_m,\ L_m(\mathbf{t}) = U^m\mathbf{t}$ has tree structure. In fact, in (8) we established its connection with the discrete tree transform given in [7].

2. Construction and properties of U^m. (see also [6]): Let $\mathsf{M}_{n,m}$ be the set of all $n \times m$ matrices over the field of complex numbers. If $n = m$, then $\mathsf{M}_{n,m}$ is abbreviated to M_n. We shall use the symbolism $A = [A_{ij}]$ to denote a matrix A with elements A_{ij}. The notation

$$A_i = \{A_{ij} : j = 1, \dots, m\}$$

shall be used to denote the i-row of a matrix $A \in \mathsf{M}_{n,m}$, and often it will be referred to as the ith of the matrix A. We use the notation A^T to denote the transpose of a matrix A. A square matrix $A \in \mathsf{M}_n$ is invertible, if there is a unique square matrix $A^{-1} \in \mathsf{M}_n$ called the inverse matrix of A such that $AA^{-1} = \mathbf{I}_n$, where $\mathbf{I}_n$ is the identity matrix. A matrix having a small number of nonzero elements is called $P \in \mathsf{M}_n$ is a matrix, if it is formed from the identity matrix $\mathbf{I}_n$ by reordering its columns (or rows). The determinant of a permutation matrix P is given by:

$$\mathrm{Det}(P) = \mathrm{sgn}\,\sigma,$$

where $\sigma = \{\sigma(i) : i = 1, \dots, n\}$ is the permutation of its columns and the signature $\mathrm{sgn}\,\sigma$ equals $(-1)^r$, where r is the number of transpositions of pairs of columns that must be composed to build up the permutation. In practice, in order to estimate r we compute the number of elements $\sigma(i) : \sigma(1) > \sigma(i), i = 2, \dots, n$, then we compute the number of elements $\sigma(i) : \sigma(2) > \sigma(i),\ i = 3, \dots, n$, etc., and finally we sum all previously computed numbers. A square matrix with determinant ± 1 is called

The of a real number x shall be denoted by $\lceil x \rceil = \inf\{n \in \mathbf{Z} : x \le n\}$ ($\mathbf{Z}$ is the set of integers). If p, q are natural numbers, we denote by $\mathrm{Mod}(p, q)$ the remainder on division of p by q, and we shall use the symbolism $[q]_p = \{q + tp : t \in \mathbf{Z}\}$ to denote the residue class of **q modulo p**.

We consider the unique (up to a rearrangement of factors) prime factorization of a positive integer m:

$$m = p_1 p_2 \dots p_N, \tag{1}$$

where $p_1 \ge p_2 \ge \dots \ge p_N$, and we denote:

$$J(0) = 1,\ \ J(n) = \prod_{i=1}^{n} p_i,\ \ n = 1, \dots, N, \tag{1a}$$

$$A(i) = \prod_{r=i}^{N} p_r,\ \ i = 1, \dots, N,\ \ A(N+1) = 1. \tag{1b}$$

We define the following dilation operators D_p and H_p on the set $\mathsf{M}_{n,m}$, where $p = 2, 3, \dots$.

Definition 1. $D_p : \mathsf{M}_{n,m} \to \mathsf{M}_{n,pm}$

$$D_p(M) = \left\{ M_{i,\lceil \frac{j}{p} \rceil},\ \ i = 1, \dots, n,\ \ j = 1, \dots, pm \right\}.$$

Notice that D_p can be written as a block matrix:

$$D_p(M) = \begin{pmatrix} D_p(M_{11}) & \dots & D_p(M_{1m}) \\ \vdots & \ddots & \vdots \\ D_p(M_{n1}) & \dots & D_p(M_{nm}) \end{pmatrix}, \tag{2}$$

where $D_p(M_{ij}) \in \mathsf{M}_{1,p}$: $D_p(M_{ij}) = \{M_{ij}, M_{ij}, \dots, M_{ij}\}$.

$$D_2\left(\begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix}\right) = \begin{pmatrix} a_{11} & a_{11} & a_{12} & a_{12} \\ a_{21} & a_{21} & a_{22} & a_{22} \end{pmatrix},$$

$$D_3\left(\begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix}\right) = \begin{pmatrix} a_{11} & a_{11} & a_{11} & a_{12} & a_{12} & a_{12} \\ a_{21} & a_{21} & a_{21} & a_{22} & a_{22} & a_{22} \end{pmatrix}.$$

Definition 2. $H_p : \mathsf{M}_{n,m} \to \mathsf{M}_{pn,m}$

$$H_p(M) = \left\{ \begin{array}{ll} M_{\lceil \frac{i}{p} \rceil, j}, & \text{whenever } i \in [0]_p, \\ 0, & \text{whenever } i \notin [0]_p, \end{array} \quad i = 1, \dots, pn, j = 1, \dots, m \right\}.$$

$$H_2\left(\begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix}\right) = \begin{pmatrix} 0 & 0 \\ a_{11} & a_{12} \\ 0 & 0 \\ a_{21} & a_{22} \end{pmatrix}, \quad H_3\left(\begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix}\right) = \begin{pmatrix} 0 & 0 \\ 0 & 0 \\ a_{11} & a_{12} \\ 0 & 0 \\ 0 & 0 \\ a_{21} & a_{22} \end{pmatrix}.$$

Definition 3. $S(.,\dots,.) : \mathsf{M}_{n_1,m} \times \cdots \times \mathsf{M}_{n_k,m} \to \mathsf{M}_{n_1+\cdots+n_k,m}$

$$S(M_1, \dots, M_k) = \begin{pmatrix} M_1 \\ \\ M_k \end{pmatrix}.$$

Definition 4. $Q_p : \mathsf{M}_{n,m} \to \mathsf{M}_{pn,pm}$ $(p \geq 1)$

$$Q_p(M) = \underbrace{M \oplus \cdots \oplus M}_{p\text{-times}} = \begin{pmatrix} M & \boldsymbol{O} \\ \\ \boldsymbol{O} & M \end{pmatrix}, \tag{3}$$

$\oplus$ direct sum $\boldsymbol{O}$ $n \times m$

Definition 5. p_1, p_2 $p_2 > 1$ $R(p_1, p_2) \in \mathsf{M}_{p_1(p_2-1),p_1p_2}$

$$R(p_1, p_2) = S\left(Q_1\left(\mathbf{e}_1^{p_2}\right), \dots, Q_{p_1}\left(\mathbf{e}_{p_2-1}^{p_2}\right)\right),$$

$\boldsymbol{e}_i^{p_2}$ i $\boldsymbol{I}_{p_2}$

Let $p_1 = 2$, $p_2 = 2$; then $\mathbf{e}_1^2 = \{1, 0\}$, $\mathbf{O} = \{0, 0\}$ and

$$R(2,2) = Q_2\left(\mathbf{e}_1^2\right) = \begin{pmatrix} \mathbf{e}_1^2 & \mathbf{O} \\ \mathbf{O} & \mathbf{e}_1^2 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix}.$$

Let $p_1 = 2$, $p_2 = 3$; then $\mathbf{e}_1^3 = \{1, 0, 0\}$, $\mathbf{e}_2^3 = \{0, 1, 0\}$, $\mathbf{O} = \{0, 0, 0\}$, and

$$R(2,3) = S\left(Q_2\left(\mathbf{e}_1^3\right), Q_2\left(\mathbf{e}_2^3\right)\right) = \begin{pmatrix} \mathbf{e}_1^3 & \mathbf{O} \\ \mathbf{O} & \mathbf{e}_1^3 \\ \mathbf{e}_2^3 & \mathbf{O} \\ \mathbf{O} & \mathbf{e}_2^3 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \end{pmatrix}.$$

Remark 1. (i) Let r, s be positive integers. It is easy to see that $D_r D_s(M) = D_{rs}(M)$. The same is also true for the operators H_p and Q_p.

(ii) Since the matrix $Q_{p_1}\left(\mathbf{e}_{p_2}^{p_2}\right)$ has not been used for the construction of the matrix $R(p_1, p_2)$, we have $(R(p_1, p_2))_{\cdot, lp_2} = 0$, for any $l = 1, \ldots, p_1$.

Definition 6. [illegible] (1) [illegible] m, [illegible] $U^m(n) \in M_{J(n)}$ ($J(n)$ [illegible] (1a)), [illegible] $n = 0, \ldots, N$, [illegible]

$$U^m(n) = \begin{cases} \{1\}, & n = 0, \\ S\left(D_{p_1}\left(U^m(0)\right), R(1, p_1)\right), & n = 1, \\ S\left(D_{p_n}\left(U^m(n-1)\right), R\left(J(n-1), p_n\right)\right), & n = 2, \ldots, N. \end{cases}$$

[illegible] $n = N$, [illegible] $U^m(N) = U^m$ [illegible]

$$U^p(1) = \begin{pmatrix} D_p(\{1\}) \\ R(1,p) \end{pmatrix} = \begin{pmatrix} 1 & 1 & \ldots & 1 & 1 \\ 1 & 0 & \ldots & 0 & 0 \\ 0 & 1 & \ldots & 0 & 0 \\ \ldots & \ldots & \ldots & \ldots & \ldots \\ 0 & 0 & \ldots & 1 & 0 \end{pmatrix}. \tag{4}$$

Let $m = 12 = p_1 p_2 p_3$, where $p_1 = 3$, $p_2 = 2$, $p_3 = 2$; then $N = 3$, and we have

$$U^{12}(1) = \begin{pmatrix} 1&1&1 \\ 1&0&0 \\ 0&1&0 \end{pmatrix}, \quad U^{12}(2) = \begin{pmatrix} 1&1&1&1&1&1 \\ 1&1&0&0&0&0 \\ 0&0&1&1&0&0 \\ 1&0&0&0&0&0 \\ 0&0&1&0&0&0 \\ 0&0&0&0&1&0 \end{pmatrix}, \quad U^{12}(3) = \begin{pmatrix} 1&1&1&1&1&1&1&1&1&1&1&1 \\ 1&1&1&1&0&0&0&0&0&0&0&0 \\ 0&0&0&0&1&1&1&1&0&0&0&0 \\ 1&1&0&0&0&0&0&0&0&0&0&0 \\ 0&0&0&0&1&1&0&0&0&0&0&0 \\ 0&0&0&0&0&0&0&0&1&1&0&0 \\ 1&0&0&0&0&0&0&0&0&0&0&0 \\ 0&0&1&0&0&0&0&0&0&0&0&0 \\ 0&0&0&0&1&0&0&0&0&0&0&0 \\ 0&0&0&0&0&0&1&0&0&0&0&0 \\ 0&0&0&0&0&0&0&0&1&0&0&0 \\ 0&0&0&0&0&0&0&0&0&0&1&0 \end{pmatrix}.$$

Now let $j = 1, \ldots, p_n - 1$, and we define the following column matrices $V_j^{p_n} = \{v_{kj}^{p_n} : k = 1, \ldots, p_n\}$:

$$v_{kj}^{p_n} = \begin{cases} 1 & \text{whenever } k = j, \\ -1 & \text{whenever } k = p_n, \\ 0 & \text{elsewhere.} \end{cases} \tag{5}$$

PROPOSITION 1. [illegible] $\{p_n : n = 1, \dots, N\}$ [illegible] m [illegible] (1) [illegible] $J(n)$ [illegible] (1a) [illegible]

$$\operatorname{Det}\left(U^m(n)\right) = \begin{cases} (-1)^{p_1+1}, & n = 1, \\ (-1)^{q_n} \operatorname{Det}(U^m(n-1)), & n = 2, \dots, N, \end{cases}$$

[illegible] $q_n = \frac{p_n - 1}{4} J(n-1)\left(J(n) - p_n + 4\right)$ [illegible] $U^m(n)$ unimodular [illegible]. For $n = 1$, we use (4) to get $\operatorname{Det}(U^m(1)) = (-1)^{1+p_1} \operatorname{Det}(M^{1,p_1})$, where M^{1,p_1} is a minor of the matrix $U^m(1)$. Since $M^{1,p_1} = \mathbf{I}_{p_1-1}$, we get $\operatorname{Det}(U^m(1)) = (-1)^{1+p_1}$.

Let $n > 1$, and let $\mathbf{e}_i^{p_n}$ be the ith row vector of the identity matrix $\mathbf{I}_{p_n}$; we consider the following block matrix $C(n) \in \mathsf{M}_{J(n)}$:

$$C(n) = \begin{pmatrix} Q_{J(n-1)}\left(\left(\mathbf{e}_{p_n}^{p_n}\right)^T\right) & Q_{J(n-1)}\left(V_1^{p_n}\right) & \dots & Q_{J(n-1)}\left(V_{p_n-1}^{p_n}\right) \end{pmatrix},$$

where the block submatrices $Q_{J(n-1)}((\mathbf{e}_{p_n}^{p_n})^T)$ and $Q_{J(n-1)}\left(V_j^{p_n}\right)$, $j = 1, \dots, p_n - 1$, are in $\mathsf{M}_{J(n),J(n-1)}$ (the column matrices $V_j^{p_n}$ are given in (5)). The block-matrix multiplication $U^m(n)C(n)$ derives the following block diagonal matrix (for a proof of (6), see Appendix A):

$$\begin{aligned} U^m(n)C(n) &= \begin{pmatrix} D_{p_n}\left(U^m(n-1)\right) \\ Q_{J(n-1)}\left(\mathbf{e}_1^{p_n}\right) \\ \vdots \\ Q_{J(n-1)}\left(\mathbf{e}_{p_n-1}^{p_n}\right) \end{pmatrix} \\ &\qquad \begin{pmatrix} Q_{J(n-1)}\left(\left(\mathbf{e}_{p_n}^{p_n}\right)^T\right) & Q_{J(n-1)}\left(V_1^{p_n}\right) & \dots & Q_{J(n-1)}\left(V_{p_n-1}^{p_n}\right) \end{pmatrix} \\ &= \begin{pmatrix} U^m(n-1) & & & \mathbf{O} \\ & \mathbf{I}_{J(n-1)} & & \\ & & \ddots & \\ \mathbf{O} & & & \mathbf{I}_{J(n-1)} \end{pmatrix}, \end{aligned} \tag{6}$$

where the zero matrix $\mathbf{O}$ in the right-hand side of (6) belongs in $\mathsf{M}_{J(n-1)}$. As a result we get

$$\operatorname{Det}(U^m(n)) \operatorname{Det}(C(n)) = \operatorname{Det}(U^m(n-1)).$$

The computation of $\operatorname{Det}(C(n))$ is equivalent to computing $\operatorname{Det}(K(n))$, where

$$K(n) = \begin{pmatrix} Q_{J(n-1)}\left(\left(\mathbf{e}_{p_n}^{p_n}\right)^T\right) & Q_{J(n-1)}\left(\left(\mathbf{e}_1^{p_n}\right)^T\right) & \dots & Q_{J(n-1)}\left(\left(\mathbf{e}_{p_n-1}^{p_n}\right)^T\right) \end{pmatrix}$$

is a block matrix in $\mathsf{M}_{J(n)}$ resulting from $C(n)$ by replacing each block submatrix

$Q_{J(n-1)}\left(V_j^{p_n}\right)$ with the linear combination:

$$Q_{J(n-1)}\left(V_j^{p_n}\right) + Q_{J(n-1)}\left(\left(\mathbf{e}_{p_n}^{p_n}\right)^T\right) = Q_{J(n-1)}\left(\left(\mathbf{e}_j^{p_n}\right)^T\right), \quad j = 1, \ldots, p_n - 1.$$

$K(n)$ is a permutation matrix, so $\mathrm{Det}(K(n)) = \mathrm{sgn}\ \sigma_n$, where σ_n is the permutation of its columns, and thus

$$\mathrm{Det}(U^m(n)) = \mathrm{sgn}\ \sigma_n\ \mathrm{Det}(U^m(n-1)).$$

The permutation $\sigma_n = \{\sigma_n(1), \ldots, \sigma_n(J(n))\}$ of the columns of the matrix $K(n)$ can be written as:

$$\sigma_n = \Upsilon_{0,n} \bigcup_{i=1}^{p_n - 1} \Upsilon_{i,n},$$

where $\Upsilon_{0,n} = \{tp_n : 1 \le t \le J(n-1)\}$ and $\Upsilon_{i,n} = \{i + tp_n : 0 \le t \le J(n-1) - 1\}$, $i \ge 1$. In Appendix B we prove that $\mathrm{sgn}\ \sigma_n = (-1)^{q_n}$, where $q_n = \frac{p_n - 1}{4} J(n-1)\,(J(n) - p_n + 4)$, and we complete the proof. □

THEOREM 1. [illegible] $U^m(n)$ [illegible]

$$(U^m(n))^{-1} = \begin{cases} \{1\}, & n = 0, \\ \left(H_{p_n}\left((U^m(n-1))^{-1}\right) \quad Q_{J(n-1)}(V_1^{p_n}) \quad \ldots \quad Q_{J(n-1)}(V_{p_n-1}^{p_n})\right), & n = 1, \ldots, N \end{cases}$$

[illegible] We multiply both sides of (6) with the block diagonal matrix

$$\begin{pmatrix} (U^m(n-1))^{-1} & & & \mathbf{O} \\ & \mathbf{I}_{J(n-1)} & & \\ & & \ddots & \\ \mathbf{O} & & & \mathbf{I}_{J(n-1)} \end{pmatrix},$$

whose block submatrices are in $\mathsf{M}_{J(n-1)}$, and we deduce that the inverse matrix $(U^m(n))^{-1}$ results from the following block-matrix multiplication:

$$\begin{aligned} (U^m(n))^{-1} &= \left(Q_{J(n-1)}\left(\left(\mathbf{e}_{p_n}^{p_n}\right)^T\right) \quad Q_{J(n-1)}\left(V_1^{p_n}\right) \quad \ldots \quad Q_{J(n-1)}\left(V_{p_n-1}^{p_n}\right)\right) \\ &\quad \cdot \begin{pmatrix} (U^m(n-1))^{-1} & & & \mathbf{O} \\ & \mathbf{I}_{J(n-1)} & & \\ & & \ddots & \\ \mathbf{O} & & & \mathbf{I}_{J(n-1)} \end{pmatrix} \\ &= \left(Q_{J(n-1)}\left(\left(\mathbf{e}_{p_n}^{p_n}\right)^T\right) \cdot (U^m(n-1))^{-1} \quad Q_{J(n-1)}\left(V_1^{p_n}\right) \quad \ldots \quad Q_{J(n-1)}\left(V_{p_n-1}^{p_n}\right)\right) \\ &= \left(H_{p_n}\left(\mathbf{I}_{J(n-1)}\right) \cdot (U^m(n-1))^{-1} \quad Q_{J(n-1)}\left(V_1^{p_n}\right) \quad \ldots \quad Q_{J(n-1)}\left(V_{p_n-1}^{p_n}\right)\right) \\ &= \left(H_{p_n}\left((U^m(n-1))^{-1}\right) \quad Q_{J(n-1)}\left(V_1^{p_n}\right) \quad \ldots \quad Q_{J(n-1)}\left(V_{p_n-1}^{p_n}\right)\right). \quad \square \end{aligned}$$

$$\left(U^{12}(2)\right)^{-1} = \begin{pmatrix} 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 1 & -1 & -1 & 0 & 0 & -1 \end{pmatrix},$$

$$\left(U^{12}(3)\right)^{-1} = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & -1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & -1 & 0 & 0 & 0 & -1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & -1 & 0 & 0 & 0 & 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 1 & -1 & -1 & 0 & 0 & -1 & 0 & 0 & 0 & 0 & 0 & -1 \end{pmatrix}.$$

3. The matrices U^m and multiresolution-type sampling spaces. Let V_m be the space consisting of all m-periodic complex-valued sequences, where m satisfies the prime factorization (1), i.e., $m = p_1 p_2 \dots p_N$, where $p_1 \geq p_2 \geq \cdots \geq p_N$, and then there exists a unique sequence of scalars $\boldsymbol{\alpha} = \{\alpha_n : n = 1, \dots, m\}$ such that any element $\mathbf{t} = \{t(n) : n = 1, \dots, m\} \in V_m$ can be written as:

$$\mathbf{t} = \sum_{i=1}^{m} \alpha_i U_i^m,$$

where U_i^m is the ith row vector of the matrix U^m. In addition, there holds $\alpha_i = \langle t(.), ((U^m)^{-1})_{.,i} \rangle$, where $\langle ., . \rangle$ is the usual inner product of V_m.

DEFINITION 7. $\{J(n) : n = 1, \dots, N\}$ (1a) $\{W_0 \subset \cdots \subset W_N = V_m\}$ V_m $\{U_r^m : r = 1, \dots, J(i)\}$ W_i multiresolution analysis V_m

Let

$$B(i) = \begin{pmatrix} U_1^m \\ \vdots \\ U_{J(i)}^m \end{pmatrix}, \; i = 0, \dots, N, \tag{7}$$

then $B(i) \in \mathsf{M}_{J(i),m}$, and the following applies.

LEMMA 1. $B(i) = S\left(D_m(\{1\}), \left\{D_{A(k+2)}(R(J(k), p_{k+1})), k = 0, \dots, i-1\right\}\right)$, $i \geq 1$ $\{A(i) : i = 1, \dots, N\}$ (1b)

. From the recursion equation of Definition 6, we have

$$\text{for } n = 1: \;\; U^m(1) = S\left(D_{p_1}(\{1\}), R(1, p_1)\right),$$

$$\text{for } n = 2: \;\; U^m(2) = S\left(D_{p_1 p_2}(\{1\}), D_{p_2}(R(1, p_1)), R(J(1), p_2)\right), \dots,$$

$$\text{for } n = N: \;\; U^m = S\left(D_m(\{1\}), D_{p_2 \dots p_N}(R(1, p_1)), D_{p_3 \dots p_N}(R(J(1), p_2)), \; \dots,\right.$$

$$\left. D_{p_N}(R(J(N-2), p_{N-1})), R(J(N-1), p_N)\right)$$

$$= S\left(D_m(\{1\}), D_{A(2)}(R(J(0), p_1)), \dots, D_{A(N+1)}(R(J(N-1), p_N))\right).$$

We observe that $D_m(\{1\}) \in \mathsf{M}_{1,m}$, $D_{A(2)}(R(J(0),p_1)) \in \mathsf{M}_{p_1-1,m}, \ldots, D_{A(i+1)}(R(J(i-1),p_i)) \in \mathsf{M}_{J(i)-J(i-1),m}$, and we have the result. □

THEOREM 2. [illegible] W_i $(i = 0, \ldots, N)$ [illegible] 7 [illegible] $\boldsymbol{t} = \{t(n) : n = 1, \ldots, m\} \in W_i$ [illegible]

$$t(n) = \sum_{k=1}^{J(i)} t(kA(i+1))\, c(n-(k-1)A(i+1)),$$

[illegible] $c(n) = \begin{cases} 1, & n = 1, \ldots, A(i+1) \\ 0, & \text{elsewhere} \end{cases}$ [illegible] $\{A(k) : k = 1, \ldots, N+1\}$ [illegible] (1b)

[illegible]. Since the space W_i is the span of the first $J(i)$ rows of the matrix U^m, there exists a sequence of scalars $\mathbf{d} = \{d_1, \ldots, d_{J(i)}\}$:

$$\mathbf{t} = \sum_{k=1}^{J(i)} d_k U_k^m = \mathbf{d}B(i),$$

where the matrix $B(i)$ is defined in (7). From Lemma 1 and (2) we deduce that

$$B(i) = D_{A(i+1)}(M_i),$$

where

$$M_i = S\left(D_{J(i)}(\{1\}), \left\{D_{p_{k+2}\ldots p_i}(R(J(k),p_{k+1})), k = 0, \ldots, i-2\right\}, R(J(i-1),p_i)\right),\ i \geq 1,$$

$M_i \in \mathsf{M}_{J(i)}$, and we use Definition 1 to get

$$\mathbf{t} = \mathbf{d}B(i) = \mathbf{d}D_{A(i+1)}(M_i) = \left\{\mathbf{d}(M_i)_{\cdot,\left\lceil \frac{n}{A(i+1)} \right\rceil} : n = 1, \ldots, m\right\}.$$

We define $\alpha_j = \mathbf{d}(M_i)_{\cdot,j}$ $(j = 1, \ldots, J(i))$, so we have

$$t(n) = \left\{a_{\left\lceil \frac{n}{A(i+1)} \right\rceil} :\ n = 1, \ldots, m\right\}.$$

Let $c(n) = \begin{cases} 1, & n = 1, \ldots, A(i+1) \\ 0, & \text{elsewhere} \end{cases}$ be an m-periodic sequence; then we can write:

$$t(n) = \sum_{k=1}^{J(i)} \alpha_k c(n-(k-1)A(i+1)),$$

and we observe that whenever $n = sA(i+1),\ s = 1, \ldots, J(i)$, then

$$t(sA(i+1)) = \sum_{k=1}^{J(i)} \alpha_k c((s-(k-1))A(i+1)) = \sum_{k=1}^{J(i)} \alpha_k \delta_{s-(k-1),1} = \alpha_s,$$

so the theorem is proved. □

[illegible] Let $\mathbf{t} = \{t_1, \ldots, t_{12}\}$. Since $12 = 3\ 2\ 2$, we have $p_1 = 3$, $p_2 = 2$, and $p_3 = 2$, and the matrix U^{12} is presented above. Obviously, $A(1) = 12$, $A(2) = 4$,

$A(3) = 2$, so if $Pi(\mathbf{t})$ is the orthogonal projection of $\mathbf{t}$ into the subspaces $W_i,\ i = 0, 1, 2$, then by Theorem 2 we have

$$P_0(\mathbf{t}) = \{t_{12}, t_{12} \ldots, t_{12}\},$$

$$P_1(\mathbf{t}) = \{t_4, t_4, t_4, t_4, t_8, t_8, t_8, t_8, t_{12}, t_{12}, t_{12}, t_{12}\},$$

$$P_2(\mathbf{t}) = \{t_2, t_2, t_4, t_4, t_6, t_6, t_8, t_8, t_{10}, t_{10}, t_{12}, t_{12}\}.$$

. . 2. By working as in Lemma 1 we can see that:

$$(U^m)^{-1} = \left(\begin{array}{cc} H_m(\{1\}) & \left\{ H_{A(i+2)}\left(Q_{J(i)}(V_k^{p_{i+1}})\right), k = 1, \ldots, p_{i+1} - 1,\ i = 0, \ldots, N-1 \right\} \end{array} \right),$$

so the first column of $(U^m)^{-1}$ has only one nonzero entry $((U^m)^{-1})_{m,1} = 1$. All other columns result from dilation and translation of the column vector defined in (5); thus all columns of $(U^m)^{-1}$ have always two nonzero entries 1 and -1.

Finally, we establish a connection of the linear invertible transform: $T^m : \mathbf{C^m} \to \mathbf{C^m}$, $T^m(\mathbf{x}) = U^m\mathbf{x}$, with the DTT, which is a standard way in computer science and elsewhere for organizing information (see [7]). Recall that for any nonnegative collection of data $\mathbf{x} = \{x_r :\ r = 1, \ldots, m\}$, where m satisfies (1), the structure of DTT consists of N generations, with $J(n)$-branches in each generation, which we call walks:

$$a_{n,k} = \begin{cases} 0 & \text{if } R\left(n-1, \left\lceil \frac{k}{p_n} \right\rceil\right) = 0, \\ \frac{R(n,k)}{R\left(n-1, \left\lceil \frac{k}{p_n} \right\rceil\right)} & \text{if } R\left(n-1, \left\lceil \frac{k}{p_n} \right\rceil\right) \neq 0, \end{cases} \quad n = 1, \ldots N, k = 1, \ldots, J(n),$$

where $R(n,k)(\mathbf{x}) = \sum_{r=(k-1)A(n+1)+1}^{kA(n+1)} x_r$ and $J(n)$ and $A(n)$ are as in (1a) and (1b), respectively. The connection of the linear transform T^m with the DTT is obtained throughout the following estimation:

$$R(n,k) = \begin{cases} \left(T^m(\mathbf{x})\right)(1) & \text{if } n = 0, \\ \left(T^m(\mathbf{x})\right)\left(k - \lceil \frac{k}{p_n} \rceil + 2\right) & \text{if } k \notin [0]_{p_n} \text{ and } n = 1, \\ \left(T^m(\mathbf{x})\right)\left(J(n-1) + \lceil \frac{k}{p_n} \rceil + J(n-1)\mathrm{Mod}(k-1, p_n)\right) & \text{if } k \notin [0]_{p_n} \text{ and } n > 1, \\ R\left(n-1, \lceil \frac{k}{p_n} \rceil\right) - \sum_{i=k-p_n+1}^{k-1} R(n,i), & \text{if } k \in [0]_{p_n} \end{cases}$$

(8)

for $k = 1, \ldots, J(n)$.

Appendix A. Let $\mathbf{e}_i^{p_n}$ be row vectors of the identity matrix $\mathbf{I}_{p_n}$, and $V_j^{p_n}$, $j = 1, \ldots, p_n - 1$, are column matrices defined in (5); then

$$\begin{pmatrix} D_{p_n}(U^m(n-1)) \\ Q_{J(n-1)}\left(\mathbf{e}_1^{p_n}\right) \\ \vdots \\ Q_{J(n-1)}\left(\mathbf{e}_{p_n-1}^{p_n}\right) \end{pmatrix} \begin{pmatrix} Q_{J(n-1)}\left(\left(\mathbf{e}_{p_n}^{p_n}\right)^T\right) & Q_{J(n-1)}\left(V_1^{p_n}\right) & \ldots & Q_{J(n-1)}\left(V_{p_n-1}^{p_n}\right) \end{pmatrix}$$

$$= \begin{pmatrix} U^m(n-1) & & & \mathbf{O} \\ & \mathbf{I}_{J(n-1)} & & \\ & & \ddots & \\ \mathbf{O} & & & \mathbf{I}_{J(n-1)} \end{pmatrix}.$$

It suffices to prove that

(i) $D_{p_n}(U^m(n-1))Q_{J(n-1)}((\mathbf{e}_{p_n}^{p_n})^T) = U^m(n-1)$;

(ii) $D_{p_n}(U^m(n-1))Q_{J(n-1)}(V_j^{p_n}) = \mathbf{O},\ k = 1,\dots,p_n-1$, where $\mathbf{O}$ is the zero matrix in $\mathsf{M}_{J(n-1)}$;

(iii) $Q_{J(n-1)}(\mathbf{e}_k^{p_n})Q_{J(n-1)}((\mathbf{e}_{p_n}^{p_n})^T) = \mathbf{O},\ k = 1,\dots,p_n-1$, where $\mathbf{O}$ is the zero matrix in $\mathsf{M}_{J(n-1)}$;

(iv) $Q_{J(n-1)}(\mathbf{e}_j^{p_n})Q_{J(n-1)}(V_l^{p_n}) = \delta_{j,l}\mathbf{I}_{J(n-1)},\ j,l = 1,\dots,p_n-1$, and $\delta_{j,l}$ is Kronecker's delta.

Indeed we have the following:

(i) We use (2) and (3) to perform the following block-matrix multiplication:

$$D_{p_n}\left(U^m(n-1)\right)Q_{J(n-1)}\left(\left(\mathbf{e}_{p_n}^{p_n}\right)^T\right) = \left[D_{p_n}\left(\left(U^m(n-1)\right)_{i,j}\right)\left(\mathbf{e}_{p_n}^{p_n}\right)^T\right]_{i,j=1}^{J(n-1)} = U^m(n-1).$$

(ii) We observe that all column matrices $V_j^{p_n}$ have zero mean, so the block-matrix multiplication leads to:

$$D_{p_n}\left(U^m(n-1)\right)Q_{J(n-1)}\left(V_j^{p_n}\right) = \left[D_{p_n}\left(\left(U^m(n-1)\right)_{k,l}\right)V_j^{p_n}\right]_{k,l=1}^{J(n-1)}.$$

Since $D_{p_n}((U^m(n-1))_{k,l})V_j^{p_n} = (U^m(n-1))_{k,l}\sum_{r=1}^{p_n} v_{rj}^{p_n} = 0$, we have the result.

(iii) The obvious consequence of the fact that $\mathbf{e}_k^{p_n}\left(\mathbf{e}_{p_n}^{p_n}\right)^T = 0,\ k = 1,\dots,p_n-1$.

(iv) $Q_{J(n-1)}\left(\mathbf{e}_j^{p_n}\right)Q_{J(n-1)}\left(V_l^{p_n}\right) = \begin{pmatrix} \mathbf{e}_j^{p_n}V_l^{p_n} & & \mathbf{O} \\ & \ddots & \\ \mathbf{O} & & \mathbf{e}_j^{p_n}V_l^{p_n} \end{pmatrix}$,

$j,l = 1,\dots,p_n-1$. Since $\mathbf{e}_j^{p_n}V_l^{p_n} = \sum_{k=1}^{p_n}\delta_{k,j}v_{k,l}^{p_n} = \delta_{j,l}$, we get the result. □

Appendix B. Let σ_n be the permutation defined in Proposition 1, then $\operatorname{sgn}\sigma_n = (-1)^{q_n}$, where q_n is the number of all inversions in the permutation σ_n and q_n equals to

$$q_n = \frac{p_n-1}{2}J(n-1)\left(1 + J(n-1) + \frac{p_n-2}{2}(J(n-1)-1)\right).$$

A pair of elements $(\sigma_n(i),\sigma_n(j))$ is called an inversion, if $i<j$ and $\sigma_n(i) > \sigma_n(j)$. The number of elements less than i to the right of i in σ_n gives the ith element of the inversion vector IV_{σ_n} corresponding to σ_n, and q_n equals the sum of all inversion vector elements.

The last column of the following matrix gives the elements of the inversion vector:

i	$\boldsymbol{\sigma_n}$(i)	**Inversion vector elements** $IV_{\sigma_n}(i)$
$1,\dots,J(n-1)$	ip_n	$i(p_n-1)$
$J(n-1)+1,\dots,2J(n-1)$	$1+\mathrm{Mod}(i-1,J(n-1))p_n$	$\mathrm{Mod}(i-1,J(n-1))(p_n-2)$
...	...	...
$(p_n-2)J(n-1)+1,\dots,(p_n-1)J(n-1)$	$p_n-2+\mathrm{Mod}(i-1,J(n-1))p_n$	$\mathrm{Mod}(i-1,J(n-1))$
$(p_n-1)J(n-1)+1,\dots,J(n)$	$p_n-1+\mathrm{Mod}(i-1,J(n-1))p_n$	0 for all i's

Now we have $\operatorname{sgn}\sigma_n = (-1)^{q_n}$, where

$$q_n = \sum_{i=1}^{J(n)} IV_{\sigma_n}(i) = \sum_{i=1}^{J(n-1)} i(p_n-1) + \sum_{i=J(n-1)+1}^{2J(n-1)} \operatorname{Mod}(i-1, J(n-1))(p_n-2) + \cdots$$

$$= (p_n-1)\sum_{i=1}^{J(n-1)} i + (p_n-2)\sum_{i=1}^{J(n-1)-1} i + \cdots + \sum_{i=1}^{J(n-1)-1} i$$

$$= (p_n-1)\frac{J(n-1)\,(1+J(n-1))}{2} + \frac{J(n-1)\,(J(n-1)-1)}{2}\,\frac{(p_n-2)(p_n-1)}{2},$$

and elementary calculations yield the result. □

OPTIMIZING THE COUPLING BETWEEN TWO ISOMETRIC PROJECTIONS OF MATRICES*

CATHERINE FRAIKIN†, YURII NESTEROV‡, AND PAUL VAN DOOREN†

Abstract. In this paper, we analyze the coupling between the isometric projections of two square matrices. These two matrices of dimensions $m \times m$ and $n \times n$ are restricted to a lower k-dimensional subspace under isometry constraints. We maximize the coupling between these isometric projections expressed as the trace of the product of the projected matrices. First we connect this problem to notions such as the generalized numerical range, the field of values, and the similarity matrix. We show that these concepts are particular cases of our problem for special choices of m, n, and k. The formulation used here applies to both real and complex matrices. We characterize the objective function, its critical points, and its optimal value for Hermitian and normal matrices, and, finally, give upper and lower bounds for the general case. An iterative algorithm based on the singular value decomposition is proposed to solve the optimization problem.

Key words. trace maximization, generalized numerical range, isometry, singular value decompostion

1. Introduction.

The problem of projection of matrices in lower-dimensional subspaces is of great interest for a large field of applications. The projection of matrices provides an easier visualization and comprehension of the initial problem and is often used to reduce the complexity of some computational problems. Moreover the coupling between these projections can reveal some particularities inherent to the data which can be analyzed and interpreted.

We consider the coupling or similarity between two "projected" matrices A and B, respectively, of dimensions $m \times m$ and $n \times n$, expressed as the real part of the trace of the product of the isometric projections U^*AU and V^*BV:

$$\Re \operatorname{tr}(U^*AUV^*B^*V) \tag{1.1}$$

under the constraint that $U^*U = V^*V = I_k$, where I_k denotes the identity matrix of dimension k, with $k \leq \min(m, n)$. In this paper, we will consider both real and complex matrices. The notation will be different for the real and complex cases, i.e., ^{T} and *, respectively for the transpose and complex conjugate transpose, the real inner product and real-valued inner product, respectively, for the real and complex case (see the notations in section 2.1). In particular, for real matrices, the coupling we consider is the following:

$$\operatorname{tr}(U^TAUV^TB^TV). \tag{1.2}$$

Most results are developed for the complex case. When results are different for the real and complex problems, we explicitly mention this; otherwise, we consider only the complex problem.

This is a generic problem which can be linked to various applications treated in the literature and which has been studied extensively in a variety of contexts for particular dimensions of the projection and of the matrices. A first field of application for real matrices lies in the analysis of graphs. The notion of the graph similarity matrix, which is a matrix that expresses how similar the nodes of two graphs are, has recently been introduced in [2]. For undirected graphs, the similarity matrix is the product of the isometries U and V^T maximizing (1.2) where A and B are real symmetric adjacency matrices and which is obtained with k equal to one. The graph similarity matrix is, e.g., useful for the development of efficient search engines or the automatic extraction of synonyms in a dictionary. Another important task in graph analysis is that of graph matching, which is a fundamental problem in pattern recognition and in shape and image analysis (see, e.g., [6] for an overview of graph matching techniques). A common class of methods in graph matching is the spectral methods in which spectral properties of characteristic matrices are used to compare the graphs. The spectral method developed in [4] combines a projection technique and a clustering algorithm to match the graphs in a lower-dimensional subspace. It can be shown that the step of projection used by the authors is equivalent to maximizing (1.2) for symmetric matrices A and B. A second field of application where relevant matrices are complex concerns experiments in quantum mechanics and in particular the task of maximizing the signal intensity in coherent ensemble spectroscopy (see, e.g., [7], [9], [16]). Indeed, the spectroscopic experiments require optimal unitary transformations of a given initial operator onto a target operator maximizing the overlap between these two operators. From a mathematical point of view, maximizing this overlap is equivalent to maximizing an expression similar to (1.1) where all of the matrices are square. The optimal value constitutes a transfer bound called the generalized numerical radius of A.

In the linear algebra literature, problem (1.1) has also been studied for particular cases and dimensions, and it hence constitutes an extension of a variety of known problems. For the case where all of the matrices are square, this problem corresponds to the generalized numerical range. See, e.g., [13] or [14] for a survey on the properties of the generalized numerical range. For the scalar case, which corresponds to a one-dimensional projection, the expression (1.1) is equivalent to the product of the field of values of two matrices (see, e.g., [12]). In this paper we consider matrices A and B of different dimensions and an arbitrary dimension k. We treat also the complex and real cases.

There exist many numerical algorithms to maximize (1.1) for particular dimensions of the matrices (e.g., [1], [3], [7], [9]). We develop here a simple recursive algorithm valid for the general case, i.e., for complex or real problems and for all dimensions of the matrices. Characterizations of the fixed points of the algorithm are presented.

The paper is organized as follows. In section 2, we introduce some notations. In section 3, we define the problem considered in the paper which consists of maximizing an expression similar to (1.1). We recall some important results from the literature that we can link to our problem. The first one concerns square matrices and appears in the field of the generalized numerical range and in the context of semidefinite programming relaxations. The second case is about one-dimensional projections and is linked to the field of values of matrices. We extend also some of these results. The

main new results are in section 4, where we characterize the critical points of the problem. Then we focus on the case of Hermitian and normal matrices, and we give lower and upper bounds for the optimal value. In section 5, we propose a simple algorithm to solve the optimization problem. Some numerical experiments are also presented. The last section 6 summarizes the results and describes some directions for future research.

2. Notations. In this section, we introduce some notations used in the paper. The first part treats the complex and real-valued inner product of matrices. The second part summarizes some definitions and results about gradients of functions with matrix arguments. Finally, the definitions of an isometry and of an isometric projection are given.

2.1. Inner product. Let $\mathbb{R}^{m\times n}$ and $\mathbb{C}^{m\times n}$ denote the set of all $m \times n$ real and complex matrices, respectively, and let X^T, $\bar{X}$, and X^* represent, respectively, the transpose, the complex conjugate, and the complex conjugate transpose of X. The inner product between matrices is defined as follows. For X, $Y \in \mathbb{R}^{m\times n}$, the [illegible] is denoted by

$$\langle X, Y\rangle = \sum_{i=1}^{m}\sum_{j=1}^{n} X_{ij}Y_{ij} \tag{2.1}$$

and can be linked to the trace function of a matrix:

$$\langle X, Y\rangle = \operatorname{tr}(XY^T) = \operatorname{tr}(X^TY).$$

For complex matrices X, $Y \in \mathbb{C}^{m\times n}$, another inner product often useful in optimization is the [illegible] defined by:

$$\langle X, Y\rangle_H = \langle \Re(X), \Re(Y)\rangle + \langle \Im(X), \Im(Y)\rangle, \tag{2.2}$$

where $\Re(X)$ and $\Im(X)$ represent the real and the imaginary part of X, respectively. This inner product can be linked again to the trace

$$\langle X, Y\rangle_H = \Re \operatorname{tr}(X^*Y)$$

and satisfies the following properties:

$$\langle X, Y\rangle_H = \langle Y^*, X^*\rangle_H = \overline{\langle X^*, Y^*\rangle_H}. \tag{2.3}$$

For complex vectors x, $y \in \mathbb{C}^n$, the real-valued inner product is defined similarly by:

$$\langle x, y\rangle_H = \sum_{i=1}^{n} \Re(\bar{x}_i y_i) = \langle \Re(x), \Re(y)\rangle + \langle \Im(x), \Im(y)\rangle. \tag{2.4}$$

2.2. Gradients. Let $f : \mathbb{C}^{m\times n} \to \mathbb{R}$ be a differentiable real-valued function with matrix argument X. Then the first-order approximation of f at a point X can be expressed as

$$f(X + \Delta) = f(X) + \langle \nabla f(X), \Delta\rangle_H + o(\|\Delta\|), \tag{2.5}$$

where the gradient $\nabla f(X)$ is the $m\times n$ matrix whose (i, j) entry is $\frac{\partial f(X)}{\partial X_{i,j}}$. As particular examples, we provide some gradients of inner-product functions with respect to a matrix X:

$$\nabla\langle A, X^*X\rangle_H = X(A + A^*), \tag{2.6}$$

$$\nabla\langle X^*AX, B\rangle_H = AXB^* + A^*XB. \tag{2.7}$$

2.3. Isometry and isometric projection. Let $A \in \mathbb{C}^{m\times m}$ and $U \in \mathbb{C}^{m\times k}$, $k \leq m$, be given. If $U^*U = I_k$, with I_k the identity matrix of dimension k, then U is called an [illegible] and U^*AU is called an [illegible] of A.

3. Main known results and some extensions of these results. For $A \in \mathbb{C}^{m\times m}$ and $B \in \mathbb{C}^{n\times n}$, we consider the following problem:

$$\max_{\substack{U^*U=I_k\\ V^*V=I_k}} \langle U^*AU, V^*BV\rangle_H, \tag{3.1}$$

where $U \in \mathbb{C}^{m\times k}$ and $V \in \mathbb{C}^{n\times k}$, with $k \leq \min(m,n)$. If the matrices A and B are real, one could restrict U and V to be real also which is then a different problem expressed by:

$$\max_{\substack{U^TU=I_k\\ V^TV=I_k}} \langle U^TAU, V^TBV\rangle. \tag{3.2}$$

It will be clear, depending on the context, which case we consider. Since the algebraic structure of the constraints and the objective function is the same, most results for both problems will be essentially the same. Let us remark that, for $k = \min(m,n)$, (3.1) is equivalent to

$$\max_{Q^*Q=I_n} \langle Q^*AQ, B\rangle_H, \tag{3.3}$$

where $Q = UV^*$ is an isometry of dimension $m \times n$. The general problem is then reduced to an optimization problem over only one variable Q.

This problem has largely been studied for particular dimensions of m, n, and k. Section 3.1 contains results for $k = m = n$, while section 3.2 summarizes some properties for $k = 1$.

3.1. Square matrices U and V. In the case where m, n, and k are equal, U and V are square matrices, and the problem is reduced to (3.3). This problem has been studied in a variety of contexts. In the rest of the section, we summarize some important results for the generalized numerical range (or C-numerical range) and for semidefinite programming relaxations providing bounds on the problem. To link the notations used in the literature for this problem with (3.3), we point out that

$$\langle Q^*AQ, B\rangle_H = \Re\left(\operatorname{tr}(AQB^*Q^*)\right) = \Re\left(\operatorname{tr}(B^*Q^*AQ)\right).$$

3.1.1. C-numerical range. The problem (3.3) is equivalent to maximizing the real part of the C-numerical range of A (or generalized numerical range) introduced by [8] and defined by

$$W_C(A) := \{\operatorname{tr}(C^*Q^*AQ) : Q \text{ is unitary}\}. \tag{3.4}$$

See, e.g., [13] for a survey on the properties of the C-numerical range. In the literature it is pointed out that the C-numerical range and in particular its geometry can be quite complicated. For all $A \in \mathbb{C}^{n\times n}$, $W_C(A)$ is convex if C is Hermitian or if C is normal with its eigenvalues colinear in the complex plane. Moreover, for general A and C, $W_C(A)$ is always star-shaped with respect to the star-center $(\operatorname{tr} A)(\operatorname{tr} C)/n$ [5] but not necessarily convex. For example, [19] gave an example in which C is normal but not Hermitian and where $W_C(A)$ is not convex. Upper bounds on the size of

$W_C(A)$ are given in [9]. In the general case there is no closed formula for computing the C-numerical range. One can only come up with an approximation. For example, [9] provides a gradient flow leading to a numerical algorithm to approach the set of critical points of $\Re(\mathrm{tr}(C^*Q^*AQ))$. See also [3] and [7].

The C-numerical range has been studied by many authors in the past few decades and has many domains of applications, e.g., in quantum dynamics for the study of the efficiency of polarization or coherence transfer between quantized states under unitary transformations. This application is equivalent to computing the C-numerical radius of A for certain sparse nilpotent matrices C and A (e.g., [7], [9], [16]). Some authors have also used the numerical range to study problems on norms of operators (see, e.g., [15]).

3.1.2. Semidefinite programming relaxations.

In the case of real and symmetric matrices A and B, the problem (3.3) is reduced to a classical problem called the quadratically constrained quadratic program defined over orthogonal matrices:

$$\mu_P = \max_{Q^TQ=I} \mathrm{tr}(AQBQ^T). \tag{3.5}$$

This problem can be solved exactly, and the optimal value is obtained by performing spectral decompositions of A and B (see, e.g., [1] or [18]). Let us suppose that the orthogonal diagonalizations of A, B are $A = UD_AU^T$ and $B = VD_BV^T$, respectively, where the eigenvalues in D_A and in D_B are ordered in a nondecreasing fashion. Then the optimal value of (3.5) is $\mathrm{tr}\, D_AD_B$, and the optimal solution is obtained by using the orthogonal matrices that yield the diagonalizations, i.e., $Q_{opt} = UV^T$.

For real matrices and by a reasoning similar to the one developed in [20], we construct the following primal problem ν_P and its semidefinite programming relaxation ν_D:

$$\begin{aligned}
&\nu_P = \max_{\substack{Q^TQ=I\\ QQ^T=I}} \mathrm{tr}(AQB^TQ^T),\\
&\nu_D = \min\ \mathrm{tr}\, S + \mathrm{tr}\, T \qquad (3.6)\\
&\quad \text{such that (s.t.)} \quad \frac{B\otimes A}{2} + \frac{B^T\otimes A^T}{2} - S\otimes I - I\otimes T \preceq 0,\\
&\qquad\qquad\qquad\quad S = S^T,\\
&\qquad\qquad\qquad\quad T = T^T,
\end{aligned}$$

where S and T are the symmetric matrices of Lagrange multipliers used to relax the constraints $Q^TQ = I$ and $QQ^T = I$ and $\otimes$ denotes the Kronecker product. The redundant constraint $QQ^T = I$ is added in order to close the duality gap for symmetric matrices A and B. Indeed, for symmetric A and B, it is proved that strong duality holds; $\nu_P = \nu_D$ [1]. A few examples show that there can be a nonzero duality gap in the case of arbitrary matrices which are not symmetric. Strong duality does not hold in this case, but this semidefinite relaxation provides an upper bound ν_D for the problem we consider $\nu_P \leq \nu_D$. See section 5.3.2 for an example where a duality gap occurs.

A complex matrix $A = A_R + jA_I$, with $j = \sqrt{-1}$, of dimension $n \times n$ can be represented by a real matrix $\tilde{A}$ of dimension $2n \times 2n$ of the form:

$$\tilde{A} = \begin{pmatrix} A_R & A_I \\ -A_I & A_R \end{pmatrix}. \tag{3.7}$$

For a Hermitian matrix A, $\tilde{A}$ is symmetric, while, for a unitary matrix Q, $\tilde{Q}$ is orthogonal. If the matrices A, B, and $Q \in \mathbb{C}^{n\times n}$ are represented by the matrices $\tilde{A}$, $\tilde{B}$, and $\tilde{Q} \in \mathbb{C}^{2n\times 2n}$, respectively, we obtain the following link between the two trace functions:

$$2\Re \operatorname{tr}(AQB^*Q^*) = \operatorname{tr}(\tilde{A}\tilde{Q}\tilde{B}^T\tilde{Q}^T). \tag{3.8}$$

One can easily prove this relation by developing the two terms of the equality. The problem (3.5) in terms of complex matrices is thus equivalent to maximizing

$$\max_{\tilde{Q}^T\tilde{Q}=I} \frac{1}{2} \operatorname{tr}(\tilde{A}\tilde{Q}\tilde{B}^T\tilde{Q}^T) \tag{3.9}$$

expressed in terms of real matrices. The dual method developed previously for real matrices can then be applied in the same way and provides an upper bound for the problem.

For Hermitian matrices A and B, strong duality holds because the representations $\tilde{A}$ and $\tilde{B}$ are symmetric, and then the gap between the primal and dual problems is zero. In this case, we know that the solution is simply the trace of the product of the diagonal matrices of the eigenvalues of $\tilde{A}$ and $\tilde{B}$ ordered in an adequate way $\operatorname{tr} D_{\tilde{A}} D_{\tilde{B}}$. By developing the expressions one can easily see that $\operatorname{tr} D_{\tilde{A}} D_{\tilde{B}} = 2 \operatorname{tr} D_A D_B$. The optimal value obtained for Hermitian matrices is then the product of the eigenvalues of the matrices. For general complex matrices A and B, the dual problem provides only an upper bound for the initial problem.

3.2. The one-dimensional case. When k equals one, the matrices U and V are reduced to vectors u and v, respectively, and the problem (3.1) becomes

$$\max_{\substack{u^*u=1\\ v^*v=1}} \langle u^*Au, v^*Bv\rangle_H. \tag{3.10}$$

This problem is related to the notion of the field of values. The field of values of a matrix A (also known as the numerical range) is defined by [12]

$$F(A) := \{x^*Ax : x \in \mathbb{C}^n,\, x^*x = 1\}.$$

The problem is then reduced to obtaining the maximum of the products of the elements from the fields of values of A and of B.

The field of values is known to be a convex subset of the complex plane, while the product of two fields of values $F(A)F(B)$ is generally not a convex set. We provide a simple counterexample.

1. Let

$$A = \begin{pmatrix} 1 & 0 \\ 0 & j \end{pmatrix}, \quad B = \begin{pmatrix} -1 & 0 \\ 0 & -j \end{pmatrix}.$$

Then $F(A)$ is the line segment joining 1 and j, and $F(B)$ is the line segment joining -1 and $-j$. Thus $F(A)F(B)$ is not a convex set since $1, -1 \in F(A)F(B)$ and $0 \notin F(A)F(B)$.

In the real and Hermitian cases, we obtain the exact optimal value of the function.

3.2.1. Hermitian case. For a Hermitian matrix A, the field of values is the interval

$$[\lambda_{min}(A), \lambda_{max}(A)],$$

with $\lambda_{min}(A)$ and $\lambda_{max}(A)$ the smallest and largest eigenvalues of A, respectively. The solution of (3.10) is then the product of the adequate extremal (smallest and largest) eigenvalues of the Hermitian matrices A and B depending on their signs. The solutions u and v providing the optimum are the eigenvectors of A and B corresponding to the eigenvalues providing the solution, respectively.

3.2.2. Real case. For a real matrix A, the field of values could be complex in general. The , field of values associated with a real square matrix A is defined by [12]

$$F_R(A) := \{x^T A x : x \in \mathbb{R}^n, x^T x = 1\}.$$

If we notice that $F_R(A) = F_R(A_H)$, with $A_H = \frac{A+A^T}{2}$ the symmetric part of A, then it is sufficient to consider only the symmetric part of the matrix in order to study the real field of values. $F_R(A)$ is the real interval joining the smallest and the largest eigenvalues of A_H and is thus always convex. The solution of (3.10), for A, B, u, and v real, is then the product of the adequate extremal eigenvalues of A_H and B_H depending on their signs.

In the particular case of real symmetric matrices, this scalar case can be linked to the concept of the similarity matrix S introduced in [2]. This matrix expresses how similar vertices of two graphs are and is defined as a particular fixed point of the iteration

$$S_{k+1} = \frac{AS_kB^T + A^TS_kB}{\|AS_kB^T + A^TS_kB\|_F}, \tag{3.11}$$

with the Frobenius norm $\|.\|_F = \sqrt{\langle .,. \rangle}$ and where A and B, representing the adjacency matrices of the graphs, have nonnegative elements. In the case where the adjacency matrix of one graph is normal, the similarity matrix has rank one and can then be decomposed into the product of two vectors u and v, $S = uv^T$, and it satisfies the equation $\rho S = ASB^T + A^TSB$ [2]. In the case of undirected graphs which are characterized by symmetric adjacency matrices, u and v are the Perron vectors of A and B. The solutions u and v of (3.10) are then those giving the similarity matrix S. In general S is not of rank one, but we will see in section 5.1 an algorithm to solve the corresponding optimization problem. The similarity matrix can be linked to our problem and is obtained as the limit of the normalized iterates $Au_iv_i^TB^T + A^Tu_iv_i^TB$.

4. The general case. In this section we provide some results obtained for the general problem

$$\max_{\substack{U^*U=I_k \\ V^*V=I_k}} \langle U^*AU, V^*BV \rangle_H, \tag{4.1}$$

where $A \in \mathbb{C}^{m\times m}$, $B \in \mathbb{C}^{n\times n}$, $U \in \mathbb{C}^{m\times k}$, and $V \in \mathbb{C}^{n\times k}$, with $k \leq \min(m,n)$.

We derive first the expressions for the critical points of the optimization problem. Then we consider some particular cases, i.e., when one matrix is Hermitian and when the two matrices are normal. An upper and a lower bound to the general problem are also obtained by decomposing the problem into the sum of two Hermitian problems. Let us mention that the techniques used in the rest of the section are quite similar to the ones used in [9].

4.1. Critical points. We consider the following problem:

$$\max_{\substack{U^*U=I_k \\ V^*V=I_k}} F(U,V), \tag{4.2}$$

where the objective function

$$F(U,V) = \langle U^*AU, V^*BV\rangle_H = \frac{1}{2}\left[\langle U^*AU, V^*BV\rangle_H + \langle U^*A^*U, V^*B^*V\rangle_H\right] \tag{4.3}$$

according to the trace properties (2.3). The problem is equivalent to maximizing the coupling between two constrained matrices A and B. This is an optimization problem of a continuous function $F(U,V)$ on a compact domain. In particular, the constraint set constitutes a smooth manifold as a product of two compact Stiefel manifolds (see, e.g., [10]). There always exists a solution U and V optimizing the function such that the first-order conditions are satisfied.

The first-order optimality conditions for (4.2) can be derived from the Lagrangian $L(U,V,X,Y)$

$$\begin{aligned} L(U,V,X,Y) = \frac{1}{2}[&\langle U^*AU, V^*BV\rangle_H + \langle U^*A^*U, V^*B^*V\rangle_H \\ &+ \langle X, I - U^*U\rangle_H + \langle Y, I - V^*V\rangle_H], \end{aligned} \tag{4.4}$$

where X and Y are Hermitian matrices of Lagrange multipliers for the isometry constraints. Partial gradients of L with respect to (U,V) according to (2.6) and (2.7) lead to the following first-order optimality conditions:

$$\begin{aligned} \nabla_U L &= AU\,(V^*B^*V) + A^*U\,(V^*BV) - UX = 0, \\ \nabla_V L &= BV\,(U^*A^*U) + B^*V\,(U^*AU) - VY = 0 \end{aligned}$$

or, equivalently,

$$\begin{aligned} UX &= AU(V^*B^*V) + A^*U(V^*BV), \\ VY &= BV(U^*A^*U) + B^*V(U^*AU), \end{aligned}$$

and of course the constraints $U^*U = V^*V = I$. It easily follows from this that $X = Y$. If we decompose $X = Y$ by an eigendecomposition $\hat{U}\Lambda\hat{U}^*$, where $\hat{U} \in \mathbb{C}^{k\times k}$ is an unitary matrix, then we can replace U by $U\hat{U}$ and V by $V\hat{U}$ which amounts to changing the bases in which we describe the spaces $Im(U)$ and $Im(V)$, the images of U and V. In this particular coordinate system the above first-order conditions would have a real diagonal matrix Λ with ordered diagonal elements $\lambda_i \geq \lambda_{i+1}$, $i = 1,\ldots,k-1$:

$$\begin{aligned} U\Lambda &= AU(V^*B^*V) + A^*U(V^*BV), \\ V\Lambda &= BV(U^*A^*U) + B^*V(U^*AU). \end{aligned} \tag{4.5}$$

4.2. Case where one matrix is Hermitian. If A is Hermitian or $A = A^*$, the maximum of (4.1) is achieved for matrices U and V corresponding, respectively, to the dominant eigenvectors of A and $(B + B^*)$. Moreover $U\Lambda V^*$ is exactly of rank k. In other words, in this case the problem is decoupled regarding the matrices A and B, and the solutions U and V satisfy

$$\begin{aligned} AU &= UA_{sub}, \\ (B + B^*)V &= VB_{sub}, \end{aligned} \tag{4.6}$$

where A_{sub} and B_{sub} are diagonal matrices of dimension k whose elements are the dominant eigenvalues of A and $(B+B^*)$, respectively. The following theorem provides a characterization of the maximum of (4.1).

THEOREM 4.1. , $A = A^*$,

$$\max_{\substack{U^*U=I_k \\ V^*V=I_k}} \langle U^*AU, V^*BV\rangle_H = \frac{1}{2}\max_{\pi_1,\pi_2}\left(\sum_{i=1}^{k}\alpha_{\pi_1(i)}\beta_{\pi_2(i)}\right), \tag{4.7}$$

, $\alpha_1,\ldots,\alpha_m$, $\beta_1,\ldots,\beta_n$, , , , , A , $(B+B^*)$, $\pi_1(.)$, $\pi_2(.)$, , , , , $1,\ldots,m$, $1,\ldots n$, , , , . The solution (U,V) satisfies the equations for the critical points

$$\begin{aligned} \Lambda &= U^*AUV^*(B+B^*)V, \\ \Lambda &= V^*(B+B^*)VU^*AU, \end{aligned} \tag{4.8}$$

which point out that the two matrices U^*AU and $V^*(B+B^*)V$ commute and are thus simultaneously diagonalizable under the same unitary transformation W such that

$$\begin{aligned} W^*U^*AUW &= D_A, \\ W^*V^*(B+B^*)VW &= D_B. \end{aligned} \tag{4.9}$$

The expressions in (4.8) become

$$\begin{aligned} W^*\Lambda W = \hat{\Lambda} &= D_AD_B, \\ W^*\Lambda W = \hat{\Lambda} &= D_BD_A, \end{aligned} \tag{4.10}$$

where $\hat{\Lambda}$ is diagonal as a product of two diagonal matrices D_A and D_B. In this coordinate system, the critical point condition (4.5) can be expressed as

$$\begin{aligned} u_i\lambda_i &= Au_i\beta_i, \\ v_i\lambda_i &= (B+B^*)v_i\alpha_i, \end{aligned}$$

where α_i and β_i are the eigenvalues of A and $(B+B^*)$, respectively. If $\lambda_i \neq 0$, it is obvious that u_i and v_i are eigenvectors of A and $(B+B^*)$, respectively. The matrices U and V providing the optimum are thus composed of the dominant eigenvectors. If $\lambda_i = 0$, the above formulas do not imply that both u_i and v_i are eigenvectors, since only one of α_i and β_i needs to be zero, but it easy to see that one can choose both u_i and v_i to be eigenvectors without altering the objective function.

It follows from (4.8) and (4.10) that the value of F for a critical point is equal to the trace of

$$\frac{1}{2}W^*U^*AUV^*(B+B^*)VW. \tag{4.11}$$

The maximal value for all of the critical points is therefore obtained by

$$\frac{1}{2}\max_{\pi_1,\pi_2}\left(\sum_{i=1}^{k}\alpha_{\pi_1(i)}\beta_{\pi_2(i)}\right), \tag{4.12}$$

where $\alpha_1,\ldots,\alpha_m$ and $\beta_1,\ldots,\beta_n$ are the real eigenvalues of A and $(B+B^*)$ and $\pi_1(.)$ and $\pi_2(.)$ permutations of $1,\ldots,m$ and $1,\ldots n$, respectively. □

Let us remark that, in the square case ($k = m = n$), Theorem 4.1 is a well-known fact (see, e.g., [1]). In practice, problem (4.12) can be solved by the following theorem (see Figure 4.1 for the notations).

LEMMA 4.2. [illegible] $\{\alpha_i, i = 1, \dots, m\}$ [illegible] $\{\beta_i, i = 1, \dots, n\}$ [illegible] A [illegible] $(B + B^*)$ [illegible] m_+ [illegible] m_- [illegible] ([illegible]) [illegible] A [illegible] n_+ [illegible] n_- [illegible] $(B + B^*)$ [illegible] $k_+ = \min(m_+, n_+)$, $k_- = \min(m_-, n_-)$ [illegible] $l = k - (k_+ + k_-)$

[illegible] $k \le k_+ + k_-$ [illegible] (4.12) [illegible] k_+ [illegible] $\{(\alpha_i, \beta_i), i = 1, \dots, k_+\}$ [illegible] k_- [illegible] $\{(\alpha_{m-i+1}, \beta_{n-i+1}), i = 1, \dots, k_-\}$ [illegible] k [illegible]

[illegible] $k > k_+ + k_-$ [illegible] $k_+ + k_-$ [illegible] l [illegible]

$$\begin{cases} (\alpha_{m_+-i+1}, \beta_{n_++l-i+1}), i = 1, \dots, l & \text{if } k_- = m_-, \\ (\alpha_{m_++l-i+1}, \beta_{n_+-i+1}), i = 1, \dots, l & \text{if } k_- = n_-. \end{cases} \tag{4.13}$$

[illegible]. Let us put the points $\{\alpha_i, i = 1, \dots, m\}$ and $\{\beta_i, i = 1, \dots, n\}$ on two parallel axes and connect the elements of the selected couples by a line (see Figure 4.1). The optimal couples satisfy two properties.

1. The elements have to be coupled such that no crossing between the pairs appears. In other words, only parallel couplings are allowed. Indeed, if we consider the couples (α_p, β_q) and (α_r, β_s), with $p > r$, $q > s$, i.e., $\alpha_p \le \alpha_r$ and $\beta_q \le \beta_s$, we have

$$\alpha_p\beta_q + \alpha_r\beta_s - \alpha_p\beta_s - \alpha_r\beta_q = (\alpha_p - \alpha_r)(\beta_q - \beta_s) \ge 0.$$

The combination of the two couples (α_p, β_q) and (α_r, β_s) produces therefore a larger value than the value obtained for (α_p, β_s) and (α_r, β_q).

2. The pairs formed by elements of the same sign have to be chosen first, since their product is nonnegative and therefore larger than a product of two elements of different sign.

Following these two properties, one can easily see that, for $k \le k_+ + k_-$, the couples of eigenvalues producing (4.12) are the couples formed by the extremal eigenvalues of A and $(B + B^*)$. Indeed these products are all nonnegative and maximize the function.

For $k > k_+ + k_-$, we take into account as well negative products that have to be as small as possible in absolute value for all of the combinations of eigenvalues. Two cases may occur: $k_- = m_-$ or $k_- = n_-$. We consider $k_- = m_-$ (see Figure 4.1), and the reasoning for $k_- = n_-$ is similar. In this case, the first $k_+ + k_-$ pairs are the pairs formed by elements of the same sign according to the second property. The l remaining couples are formed as expressed by (4.13), which takes into account the first property of no crossing between the elements. This expression also takes into account that only the elements closest to zero are kept. Indeed, permuting any element from this set with an element farther from zero will give a product, of negative value, greater in absolute value. For example, if we take α_{m_+-3} instead of α_{m_+-2} in Figure 4.1, we obtain the couple $\alpha_{m_+-3}\beta_{n_++1}$, which is smaller than $\alpha_{m_+-2}\beta_{n_++1}$. By reasoning similarly for all of the elements, one proves that only the elements closest to zero yield (4.12). □

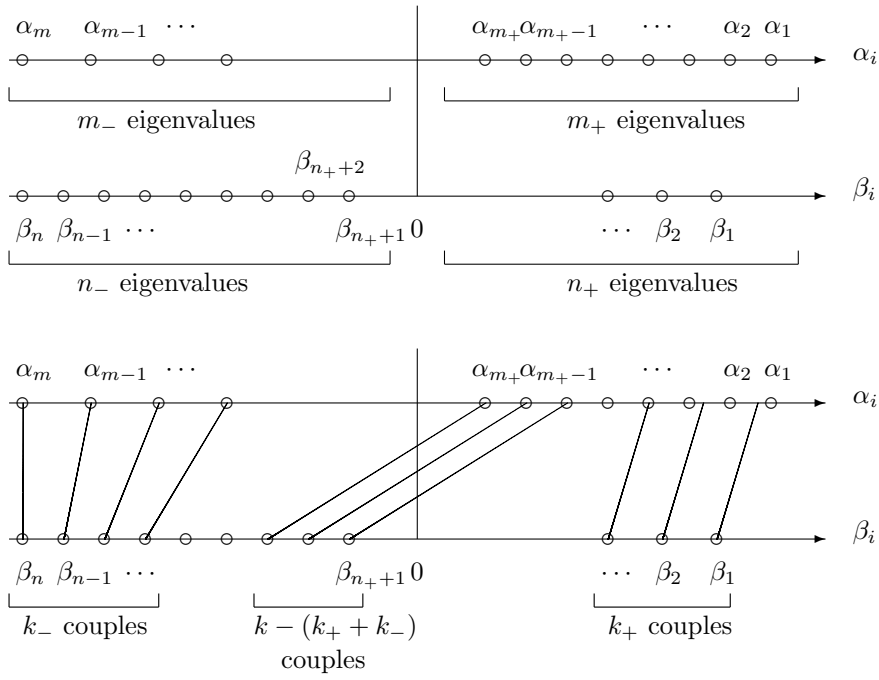

FIG. 4.1. *Representation of the eigenvalues α_i of A and β_i of B with their numbering (on the top) and of the k adequate couples for finding the maximal combination* (4.12) *(on the bottom).*

4.3. Sum of two Hermitian problems. The square matrices A and B can always be decomposed into

$$A = A_H + jA_S, \quad B = B_H + jB_S,$$

where the matrices $A_H = \frac{A+A^*}{2}$ and $A_S = \frac{A-A^*}{2j}$ are Hermitian matrices. The objective function can also then be decomposed into a sum of two Hermitian problems

$$\frac{1}{2}\langle U^*A_HU, V^*B_HV\rangle_H + \frac{1}{2}\langle U^*A_SU, V^*B_SV\rangle_H. \tag{4.14}$$

This expression of the objective function provides an upper bound for the optimal value. This bound is expressed in the following corollary.

COROLLARY 4.3. [illegible] 4.1 [illegible] (4.2) [illegible] $F(U,V)$ [illegible] (4.14)[illegible]

$$\frac{1}{2}\max_{\pi_1,\pi_2}\left(\sum_{i=1}^{k}\alpha^H_{\pi_1(i)}\beta^H_{\pi_2(i)}\right) + \frac{1}{2}\max_{\pi_1,\pi_2}\left(\sum_{i=1}^{k}\alpha^S_{\pi_1(i)}\beta^S_{\pi_2(i)}\right), \tag{4.15}$$

[illegible] α^H_i [illegible] β^H_i [illegible] A_H [illegible] B_H [illegible] α^S_j [illegible] β^S_j [illegible] A_S [illegible] B_S [illegible] $\pi_1(.)$ [illegible] $\pi_2(.)$ [illegible] $1,\ldots,m$ [illegible] $1,\ldots n$ [illegible]

Let us point out that the permutations π_1 and π_2 in these two terms at the respective maxima can be different. A lower bound can also be found by choosing the matrices U and V optimizing one of the two Hermitian problems and by calculating the value of (4.14) for this pair of matrices (U,V). For example, if we take U_1, V_1 optimum

for $\frac{1}{2}\langle U^*A_HU, V^*B_HV\rangle_H$, the optimal solution is lower and upper bounded by

$$\begin{aligned}
&\frac{1}{2}\max_{\pi_1,\pi_2}\left(\sum_{i=1}^{k}\alpha^H_{\pi_1(i)}\beta^H_{\pi_2(i)}\right)+\frac{1}{2}\langle U_1^*A_SU_1, V_1^*B_SV_1\rangle_H \\
&\le \max_{\substack{U^*U=I_k\\ V^*V=I_k}} \frac{1}{2}\langle U^*A_HU, V^*B_HV\rangle_H+\frac{1}{2}\langle U^*A_SU, V^*B_SV\rangle_H \qquad (4.16)\\
&\le \frac{1}{2}\max_{\pi_1,\pi_2}\left(\sum_{i=1}^{k}\alpha^H_{\pi_1(i)}\beta^H_{\pi_2(i)}\right)+\frac{1}{2}\max_{\pi_1,\pi_2}\left(\sum_{i=1}^{k}\alpha^S_{\pi_1(i)}\beta^S_{\pi_2(i)}\right).
\end{aligned}$$

4.4. Case of two normal matrices. In the case of normal matrices A and B (i.e., $AA^* = A^*A$ and $BB^* = B^*B$), the optimal value for the objective function can be found for $k = 1$ and $k = m = n$. For general $k \le \min(m, n)$, only an upper bound for the optimal value of the problem can be obtained. The following developments are based on the fact that all normal matrices are diagonalizable under unitary transformation. We can thus make the matrices A and B diagonal matrices D_A and D_B by unitary transformations, with $D_A = D_{A_R} + jD_{A_I}$ and $D_B = D_{B_R} + jD_{B_I}$, where the subscripts $_R$ and $_I$ denote, respectively, the real and imaginary parts of the matrices. In the rest of the section, α_i, $i = 1, \ldots, m$, and β_i, $i = 1 \ldots, n$, are the eigenvalues of A and B, respectively.

4.4.1. One-dimensional case.

THEOREM 4.4. [illegible] $k = 1$ [illegible] A [illegible] B [illegible]

$$\max_{\substack{u^*u=1\\ v^*v=1}} \langle u^*D_Au, v^*D_Bv\rangle_H = \max_{i,j} \Re(\alpha_i\beta_j). \qquad (4.17)$$

[illegible]. For $k = 1$, and by using the diagonalization of the normal matrices A and B, the maximization (4.1) can be expressed as follows:

$$\max_{\substack{u^*u=1\\ v^*v=1}} \langle u^*D_Au, v^*D_Bv\rangle_H. \qquad (4.18)$$

This problem is equivalent to

$$\begin{aligned}
&\max \Re\left(\sum_{i=1}^{n}\mu_i\alpha_i\right)\left(\sum_{i=1}^{m}\nu_i\beta_i\right)\\
&\text{s.t.}\quad \sum_i \mu_i = 1,\\
&\qquad \sum_i \nu_i = 1,\\
&\qquad \mu_i^i \ge 0,\ \nu_i \ge 0,
\end{aligned} \qquad (4.19)$$

where $\mu_i = |u_i|^2$ and $\nu_i = |v_i|^2$ are nonnegative real numbers. This amounts to optimizing the real part of the products of convex combinations of the eigenvalues of A and B. This problem is a bilinear form with respect to μ_i and ν_i. If we fix μ_i, the problem is linear in ν_i and amounts to a linear programming problem. The feasible set forms a polyhedron, and the optimal solution is situated on a vertex of this polyhedron (or on a face of the polyhedron). We then apply the same reasoning for μ_i to obtain the optimal solution. The problem is then equivalent to finding the indices i and j maximizing

$$\max_{i,j} \Re(\alpha_i\beta_j) = \max_{i,j} (\alpha_{i_R}\beta_{j_R} + \alpha_{i_I}\beta_{j_I}), \qquad (4.20)$$

where the subscripts $_R$ and $_I$ denote, respectively, the real and imaginary parts. ∎

This problem can be solved in $O(mn)$ operations by merely trying out all products.

4.4.2. Square matrices.

THEOREM 4.5. [illegible] $k = m = n$ [illegible] A [illegible] B [illegible]

$$\max_{Q^*Q=I} \langle Q^*AQ, B\rangle_H = \max_{\pi_2} \sum_{i=1}^{n} (\alpha_{i_R}\beta_{\pi_2(i)_R} + \alpha_{i_I}\beta_{\pi_2(i)_I}), \tag{4.21}$$

[illegible] $\pi_2(.)$ [illegible] $1, 2, \ldots, n$ [illegible]. By using again the diagonalization of the matrices, the maximization can be expressed as follows:

$$\max_{Q^*Q=I} \left(\langle Q^*D_{A_R}Q, D_{B_R}\rangle_H + \langle Q^*D_{A_I}Q, D_{B_I}\rangle_H\right). \tag{4.22}$$

If we develop the first term in the function and we define $d_{A_R} = \mathrm{diag}(D_{A_R})$, $d_{B_R} = \mathrm{diag}(D_{B_R})$, α_{i_R} and β_{i_R} the elements i of d_{A_R} and d_{B_R}, and q_i the row i of Q, we obtain

$$\langle Q^*D_{A_R}Q, D_{B_R}\rangle_H = \sum_{i=1}^{n} \langle |q_i|^2, d_{A_R}\rangle \beta_{i_R}.$$

The last expression is equivalent to

$$\langle \hat{Q} d_{A_R}, d_{B_R}\rangle_H,$$

where $\hat{Q}_{ij} = |Q_{ij}|^2$. $\hat{Q}$ is an orthostochastic[1] matrix and hence a type of doubly stochastic matrix, i.e., $\hat{Q}_{ij} \geq 0$ for all i, j and $\hat{Q}e = \hat{Q}^T e = e$, with e the vector whose entries are all equal to 1. The fact that the row and column sums are all $+1$ follows from the fact that the rows and columns of Q are all Euclidean unit vectors. From Birkhoff's theorem (see [11]), $\hat{Q}$ is a convex combination of permutation matrices, i.e., $\hat{Q} = \sum_{i=1}^{n!} c_i P_i$, with $\sum_{i=1}^{n!} c_i = 1$ and $c_i > 0$. The above quantity $\langle \hat{Q} d_{A_R}, d_{B_R}\rangle$ is real, and then the problem (4.22) is bounded by the maximum of

$$\langle \hat{Q} d_{A_R}, d_{B_R}\rangle + \langle \hat{Q} d_{A_I}, d_{B_I}\rangle \tag{4.23}$$

for all $\hat{Q}$ doubly stochastic matrices. We are optimizing over the set of doubly stochastic matrices, but the solution is a permutation matrix and hence corresponds to a permutation matrix Q as well. The maximal value of (4.23) is the solution of a corresponding linear programming problem. This value is simply

$$\max_{\pi_2} \sum_{i=1}^{n} (\alpha_{i_R}\beta_{\pi_2(i)_R} + \alpha_{i_I}\beta_{\pi_2(i)_I}), \tag{4.24}$$

where $\pi_2(.)$ is a permutation of $1, 2, \ldots, n$. □

In the case of Hermitian matrix A or B, the problem simplifies further and is equivalent to optimizing

$$\langle \hat{Q} d_{A_R}, d_{B_R}\rangle$$

because the eigenvalues of a Hermitian matrix are real. We retrieve then the original problem developed in section 4.2.

[1] A square matrix X of the form $X = U \circ \bar{U}$ (i.e., X is the Hadamard product of U with itself, $X_{ij} = U_{ij}^2$) for some unitary U is said to be orthostochastic.

TABLE 4.1
Summary of the results and bounds obtained for particular matrices and dimensions.

Dimensions	Matrices	Optimum/Upper bound
$k = m = n$	A Hermitian, B arbitrary	Optimum: maximal combination of the eigenvalues of A and $(B + B^*)$ (4.7): $\frac{1}{2}\max_{\pi_1,\pi_2}(\sum_{i=1}^{k}\alpha_{\pi_1(i)}\beta_{\pi_2(i)})$
	A, B normal	Optimum: maximal combination of the eigenvalues of A and B (4.24): $\max_{\pi_2}\sum_{i=1}^{n}(\alpha_{i_R}\beta_{\pi_2(i)_R} + \alpha_{i_I}\beta_{\pi_2(i)_I})$
	A, B arbitrary	Bound: solution of the semidefinite programming relaxation ν_D (3.6) or (4.15).
$k = 1$	A, B real	Optimum: product of the adequate extremal eigenvalues of the symmetric parts of A and B (section 3.2.2)
	A, B Hermitian	Optimum: product of the adequate eigenvalues of A and B (section 3.2.1)
	A, B normal	Optimum: maximal combination of the real and imaginary parts of an eigenvalue of A and an eigenvalue of B (4.20): $\max_{i,j}(\alpha_{R_i}\beta_{R_j} + \alpha_{I_i}\beta_{I_j})$
	A, B arbitrary	Bound: maximal sum of the products of the adequate extremal eigenvalues of the Hermitian and skew-Hermitian parts of A and B (4.15)
$k \leq \min(m, n)$	A Hermitian, B arbitrary	Optimum: maximal sum of the products of k eigenvalues of A and $(B + B^*)$ (4.7): $\frac{1}{2}\max_{\pi_1,\pi_2}(\sum_{i=1}^{k}\alpha_{\pi_1(i)}\beta_{\pi_2(i)})$
	A, B normal	Bound: maximal sum of the combinations of the real and imaginary parts of k eigenvalues of A and B (4.25): $\max_{\pi_1,\pi_2}\sum_{i=1}^{k}(\alpha_{\pi_1(i)_R}\beta_{\pi_2(i)_R}) +$ $\max_{\pi_1,\pi_2}\sum_{i=1}^{k}(\alpha_{\pi_1(i)_I}\beta_{\pi_2(i)_I})$
	A, B arbitrary	Bound: maximal sum of the combinations of the eigenvalues of k Hermitian and skew-Hermitian parts of A and B (4.15): $\frac{1}{2}\max_{\pi_1,\pi_2}(\sum_{i=1}^{k}\alpha^H_{\pi_1(i)}\beta^H_{\pi_2(i)}) +$ $\frac{1}{2}\max_{\pi_1,\pi_2}(\sum_{i=1}^{k}\alpha^S_{\pi_1(i)}\beta^S_{\pi_2(i)})$

4.4.3. General case. In the general case of normal matrices $A \in \mathbb{C}^{m\times m}$ and $B \in \mathbb{C}^{n\times n}$, for $1 \leq k \leq \min(m, n)$ an upper bound for the general problem (4.1) can be found. We optimize the function

$$\max_{\substack{U^*U=I_k \\ V^*V=I_k}} \left(\langle U^*D_{A_R}U, V^*D_{B_R}V\rangle_H + \langle U^*D_{A_I}U, V^*D_{B_I}V\rangle_H\right).$$

An upper bound to this problem is then

$$\max_{\pi_1,\pi_2}\sum_{i=1}^{k}(\alpha_{\pi_1(i)_R}\beta_{\pi_2(i)_R}) + \max_{\pi_1,\pi_2}\sum_{i=1}^{k}(\alpha_{\pi_1(i)_I}\beta_{\pi_2(i)_I}), \tag{4.25}$$

where α_{i_R} and β_{i_R} are the elements of $\mathrm{diag}(D_{A_R})$ and $\mathrm{diag}(D_{B_R})$, respectively, and α_{i_I} and β_{i_I} the elements of $\mathrm{diag}(D_{A_I})$ and $\mathrm{diag}(D_{B_I})$, respectively. This problem is combinatorial and differs from (4.24).

4.5. Summary of optimal values and bounds. Table 4.1 summarizes the results and the bounds for the problem (4.1) developed in the previous sections. These results and bounds depend on the kind of matrices and their sizes.

5. Numerical computation. In this section we present first an iterative algorithm to find a critical point of (4.1). We then show the equivalence between the fixed

points of the iteration and the critical points of (4.1). At the end of the section, we present some numerical experiments of the algorithm applied to nilpotent matrices.

5.1. Algorithm. The proposed algorithm to solve (4.1) is based on the following relations:

$$\begin{aligned} F(U,V) &= \langle U^*AU, V^*BV\rangle_H \\ &= \frac{1}{2}\langle UV^*, AUV^*B^* + A^*UV^*B\rangle_H \\ &= \frac{1}{2}\left(\langle UV^*, AUV^*B^* + A^*UV^*B + sUV^*\rangle_H - sk\right) \end{aligned}$$

resulting from the properties (2.3) and where s is a constant scalar. Let us now define the linear map $M_s(X) = AXB^* + A^*XB + sX$, and then the problem of maximizing $F(U,V)$ is equivalent to the following constrained maximization problem:

$$\max_X G(X) = \langle X, M_s(X)\rangle_H \qquad \text{s.t.} \qquad X = UV^*,\ U^*U = V^*V = I_k. \tag{5.1}$$

An algorithm for this problem is given in this section, but it relies on a few intermediate results. In order to show the uniqueness of the iterates of our algorithm, we will need the following two lemmas.

LEMMA 5.1. [illegible] $M \in \mathbb{C}^{m\times n}$ [illegible]

$$M = \left[\begin{array}{c|c} P_1 & P_2 \end{array}\right] \left[\begin{array}{c|c} \Sigma_1 & 0 \\ \hline 0 & \Sigma_2 \end{array}\right] \left[\begin{array}{c|c} Q_1 & Q_2 \end{array}\right]^*,$$

[illegible] $P_1 \in \mathbb{C}^{m\times k}$, $P_2 \in \mathbb{C}^{m\times(m-k)}$, $Q_1 \in \mathbb{C}^{n\times k}$, $Q_2 \in \mathbb{C}^{n\times(n-k)}$, $\Sigma_1 \in \mathbb{R}^{k\times k}$, $\Sigma_2 \in \mathbb{R}^{(m-k)\times(n-k)}$ [illegible] $k \le \min(m,n)$ [illegible] $P_1Q_1^*$ [illegible] $\sigma_{min}(\Sigma_1) > \sigma_{max}(\Sigma_2)$, $k < \min(m,n)$ [illegible] $\sigma_{min}(\Sigma_1) > 0$, $k = \min(m,n)$ [illegible]. This is a well-known result, discussed, e.g., in [12, Theorems 3.1.1 and 3.1.1']. □

Notice that the pairs of matrices (P_1, Q_1) are not unique but are all given by (P_1R, Q_1R), where R is a unitary matrix commuting with Σ_1. But the degree of freedom R disappears in the product $P_1Q_1^*$.

LEMMA 5.2. [illegible] $a_i, b_i \in \mathbb{R}$, $i = 1,\dots,m$, [illegible] $b_1 \ge b_2 \ge \cdots \ge b_m \ge 0$ [illegible] $\sum_{i=1}^m a_i \le k$, $k \le m$, [illegible] $0 \le a_i \le 1$, $i = 1,\dots,m$, [illegible]

$$\sum_{i=1}^m a_ib_i \le \sum_{i=1}^k b_i.$$

[illegible] $a_i = 1$, $i \le k$, [illegible] $a_i = 0$, $i > k$ [illegible] [illegible] $b_k > b_{k+1}$ $(k < m)$, $b_k > 0$ $(k = m)$ [illegible]. The inequality results from Proposition B.7 for majorized sequences in [17] by remarking that $\sum_{i=1}^m a_ib_i = b^Ta$ and $\sum_{i=1}^k b_i = b^Tv$, with

$$v = (\underbrace{1,\dots,1}_{k},\underbrace{0,\dots,0}_{m-k}).$$

The upper bound is achieved if $\sum_{i=1}^k (1-a_i)b_i = \sum_{i=k+1}^m a_ib_i$. The terms are all nonnegative because $b_i \ge 0$ and $0 \le a_i \le 1$ for $i = 1,\dots,m$. The condition $\sum_{i=1}^m a_i \le k$ implies that

$$\sum_{i=1}^k a_i \le k - \epsilon, \qquad \sum_{i=k+1}^m a_i \le \epsilon,$$

with $0 \leq \epsilon$. Therefore

$$\sum_{i=1}^{k}(1-a_i)b_i \geq b_k \sum_{i=1}^{k}(1-a_i) \geq b_k\epsilon$$

and

$$\sum_{i=k+1}^{m} a_i b_i \leq b_{k+1}\epsilon.$$

If $b_k > b_{k+1}$ (or $b_k > 0$ if $k = m$), the equality $\sum_{i=1}^{k}(1-a_i)b_i = \sum_{i=k+1}^{m} a_i b_i$ is thus achieved if and only if $\epsilon = 0$, i.e., all of the terms equal 0. This happens if $a = v$, which is the unique solution. □

We now propose an algorithm to solve (5.1) by using an iteration

$$X_{i+1} = \arg\max_{X} \langle X, M_s(X_i)\rangle_H$$

which is analyzed in the following theorem.

THEOREM 5.3. [illegible] $M_s(X_i) \in \mathbb{C}^{m\times n}$ [illegible]

$$M_s(X_i) = AX_iB^* + A^*X_iB + sX_i, \qquad X_i = U_iV_i^*,\ U_i^*U_i = I_k = V_i^*V_i,$$

[illegible] $A \in \mathbb{C}^{m\times m}$, $B \in \mathbb{C}^{n\times n}$, $U_i \in \mathbb{C}^{m\times k}$, [illegible] $V_i \in \mathbb{C}^{n\times k}$, [illegible] $k \leq \min(m,n)$, [illegible] s [illegible] $s_{min} := 4\|A\|_2\|B\|_2$ [illegible] $M_s(X_i)$ [illegible]

$$M_s(X_i) = \begin{bmatrix} P_1 \mid P_2 \end{bmatrix} \left[\begin{array}{c|c} \Sigma_1 & 0 \\ \hline 0 & \Sigma_2 \end{array}\right] \begin{bmatrix} Q_1 \mid Q_2 \end{bmatrix}^* = P\Sigma Q^*, \tag{5.2}$$

[illegible] $P_1 \in \mathbb{C}^{m\times k}$, $P_2 \in \mathbb{C}^{m\times(m-k)}$, $Q_1 \in \mathbb{C}^{n\times k}$, $Q_2 \in \mathbb{C}^{n\times(n-k)}$, $\Sigma_1 \in \mathbb{R}^{k\times k}$, $\Sigma_2 \in \mathbb{R}^{(m-k)\times(n-k)}$ [illegible] $U \in \mathbb{C}^{m\times k}$, $V \in \mathbb{C}^{n\times k}$ [illegible]

$$\max_{\substack{X=UV^* \\ U^*U=I_k=V^*V}} \langle X, M_s(X_i)\rangle_H = \sum_{i=1}^{k}\sigma_i(M_s) \tag{5.3}$$

[illegible] $\{\sigma_i(M_s)\}$ [illegible] $M_s(X_i)$ [illegible] X [illegible] $P_1Q_1^*$ [illegible]. We first show that $\sigma_k(M_s) > s_{min}/2$ and $\sigma_{k+1}(M_s) \leq s_{min}/2$ and hence that there is a gap between $\sigma_k(M_s)$ and $\sigma_{k+1}(M_s)$. This is proved as follows. The k leading singular values of sX_i are given by s and the others by 0, and the largest singular value $\sigma_1(M_0)$ of $M_0(X_i) = AX_iB^* + A^*X_iB$ is upper bounded by $s_{min}/2$ because

$$\begin{aligned}\sigma_1(M_0) &= \|AX_iB^* + A^*X_iB\|_2 \\ &\leq \|AX_iB^*\|_2 + \|A^*X_iB\|_2 \\ &\leq \|A\|_2\|B\|_2 + \|A\|_2\|B\|_2 = 2\|A\|_2\|B\|_2 = s_{min}/2.\end{aligned}$$

We now apply the perturbation result (Theorem 3.3.16 in [12]) to $M_S(X_i) = M_0(X_i) + sX_i$ and obtain

$$\sigma_{k+1}(M_s) \leq \sigma_{k+1}(sX_i) + \sigma_1(M_0) \leq s_{min}/2$$

and

$$\sigma_k(M_s) \geq \sigma_k(sX_i) - \sigma_1(M_0) > s_{min}/2.$$

We have

$$\langle X, M_s(X_i)\rangle_H = \langle X, P\Sigma Q^*\rangle_H = \langle P^*XQ, \Sigma\rangle_H,$$

and the following two problems are equivalent:

$$\max_{\substack{X=UV^* \\ U^*U=I_k=V^*V}} \langle X, M_s(X_i)\rangle_H = \max_{\substack{\tilde{X}=\tilde{U}\tilde{V}^* \\ \tilde{U}^*\tilde{U}=I_k=\tilde{V}^*\tilde{V}}} \langle \tilde{X}, \Sigma\rangle_H,$$

where $\tilde{U} = P^*U$ and $\tilde{V} = Q^*V$. Without loss of generality, we assume that $n \leq m$ (otherwise the proof is very similar). Then

$$\langle \tilde{X}, \Sigma\rangle_H = \sum_{i=1}^{n} \Re(\tilde{X}_{ii})\sigma_i(M_s) \leq \sum_{i=1}^{n} |\tilde{X}_{ii}\sigma_i(M_s)| \leq \sum_{i=1}^{n} \sigma_i(\tilde{X}^*\Sigma) \leq \sum_{i=1}^{k} \sigma_i(M_s) \tag{5.4}$$

according to Formula 3.3.10b and Lemma 3.3.1 in [12]. Moreover, since $\tilde{U}$ and $\tilde{V}$ are isometries, we have

$$0 \leq |\tilde{X}_{ii}| \leq 1, \qquad i = 1, \ldots, n,$$

and, by a reasoning similar to (5.4) with a matrix $M_s(X_i)$ for which $\sigma_i(M_s) = 1$, $i = 1, \ldots, n$,

$$\sum_{i=1}^{n} |\tilde{X}_{ii}| \leq k.$$

According to Lemma 5.2, $\sum_{i=1}^{n} |\tilde{X}_{ii}|\sigma_i(M_s) = \sum_{i=1}^{k} \sigma_i(M_s)$ in (5.4) when $|\tilde{X}_{ii}| = 1$ for $i = 1, \ldots, k$ and $|\tilde{X}_{ii}| = 0$ for $i > k$. The upper bound in (5.4) is achieved if all inequalities are equalities. This implies that $\Re(\tilde{X}_{ii}) = |\tilde{X}_{ii}| = 1$, $i = 1, \ldots, k$, and $\Re(\tilde{X}_{ii}) = |\tilde{X}_{ii}| = 0$, $i > k$, i.e., if and only if $\tilde{X}_{ii} = 1$, $i = 1, \ldots, k$, and $\tilde{X}_{ii} = 0$, $i > k$. Since $\tilde{X} = \tilde{U}\tilde{V}^*$ and $\tilde{U}$ and $\tilde{V}$ are isometries, it happens only when $\tilde{X} = \tilde{U}\tilde{V}^* = P^*UV^*Q = \left(\begin{smallmatrix} I_k & 0 \\ 0 & 0 \end{smallmatrix}\right)$, i.e., when $X = UV^* = P_1Q_1^*$. The conditions of Lemma 5.1 are satisfied, and the solution X is therefore unique. ∎

The proposed iterative algorithm to solve (4.1) is then the following one. Choose initial isometries U_0, V_0, and, for $i \geq 0$ until convergence, compute

$$X_{i+1} = f_s(X_i) = \arg \max_{\substack{X=UV^* \\ U^*U=I_k=V^*V}} \langle X, M_s(X_i)\rangle_H, \tag{5.5}$$

where we assume that $\sigma_k(M_s) > \sigma_{k+1}(M_s)$, which is always satisfied by choosing adequately s. Theorem 5.3 gives the maximizing solution and shows that it is unique. In practice, we apply the following procedure in which we switch again to the formulation in terms of U and V: Choose initial isometries U_0 and V_0 and a value for s, and, for $i = 0, 1, \ldots$ until convergence, compute the SVD:

$$\left[\begin{array}{c|c} U_{i+1} & U_\perp \end{array}\right] \left[\begin{array}{c|c} \Sigma_1 & 0 \\ \hline 0 & \Sigma_2 \end{array}\right] \left[\begin{array}{c|c} V_{i+1} & V_\perp \end{array}\right]^* = AU_iV_i^*B^* + A^*U_iV_i^*B + sU_iV_i^*.$$

When the product $U_iV_i^*$ converges (i.e., when $\|U_iV_i^* - U_{i+1}V_{i+1}^*\| \to 0$), there exists a diagonal matrix $\Lambda = \Sigma_1 - sI_k$ such that

$$U\Lambda V^* = AUV^*B^* + A^*UV^*B - U_\perp \Sigma_2 V_\perp^*, \tag{5.6}$$

where $U_\perp$ and $V_\perp$ are matrices such that every column of $U_\perp$ (resp., $V_\perp$) is orthogonal to every column of U (resp., V). Σ_2 is a diagonal matrix with elements which are all smaller than the elements of Σ_1. The scalar s must be larger than $s_{min} = 4\|A\|_2\|B\|_2$. The convergence is not proved, but in all experiments the process always converged linearly to a solution.

[illegible] 1. An indication that the method has typically linear convergence can be seen from the case $k = 1$ and one of the matrices Hermitian (say, $A = A^*$) (with $|\alpha_1| \geq |\alpha_i|, i = 1, \ldots, m$, $|\beta_1| \geq |\beta_i|, i = 1, \ldots, n$, and $\alpha_1\beta_1 > 0$ to simplify the reasoning; indeed the parameter s could then be zero). In this particular case, the iteration becomes

$$u_{i+1}\sigma_{i+1}v_{i+1}^* = Au_iv_i^*(B + B^*) \tag{5.7}$$

because the right-hand side is exactly of rank one. This algorithm corresponds to the combination of two power methods for A and $B + B^*$. Linear convergence is thus guaranteed. The reasoning could be extended for arbitrary $k \leq \min(m, n)$ and for $s = 0$ in the iteration.

5.2. Relation to the optimization problem. In this part we show that solving the iteration (5.5) is equivalent to solving the optimization problem (4.1), whose critical points are expressed by (4.5).

THEOREM 5.4. [illegible] $s \geq s_{min}$, [illegible] $M_s(UV^*)$ [illegible] $f_s(UV^*)$ [illegible] (U, V) [illegible] $F(U, V)$ [illegible] (U, V) [illegible] $F(U, V)$ [illegible] UV^* [illegible] $f_s(UV^*)$

[illegible]. Let UV^* be a fixed point of $f_s(UV^*)$. Then according to Theorem 5.3

$$U\Sigma_1V^* + U_\perp\Sigma_2V_\perp^* = AUV^*B^* + A^*UV^*B + sUV^*.$$

Multiply this matrix by V and its Hermitian conjugate by U to get

$$U(\Sigma_1 - sI_k) = AUV^*B^*V + A^*UV^*BV,$$
$$V(\Sigma_1 - sI_k) = BVU^*A^*U + B^*VU^*AU.$$

This is nothing but the condition for a critical point (U, V) of $F(U, V)$ (see (4.5)).

Conversely, let (U, V) be a critical point of $F(U, V)$, and then

$$U\Lambda = AU(V^*B^*V) + A^*U(V^*BV),$$
$$V\Lambda = BV(U^*A^*U) + B^*V(U^*AU),$$

where we have chosen the diagonal ordered form for Λ (see (4.5)). Then, if we define $\Sigma_1 = \Lambda + sI$, with $s > 4\|A\|_2\|B\|_2$,

$$U\Sigma_1 = M_s(UV^*)V, \qquad \Sigma_1V^* = U^*M_s(UV^*).$$

These equations express that the diagonal elements of Σ_1 are singular values of $M_s(UV^*)$ and that the columns of U and V are corresponding right and left singular vectors. Hence there exists an SVD

$$M_s(UV^*) = \left[\begin{array}{c|c} U & U_\perp \end{array}\right] \left[\begin{array}{c|c} \Sigma_1 & 0 \\ \hline 0 & \Sigma_2 \end{array}\right] \left[\begin{array}{c|c} V & V_\perp \end{array}\right]^*,$$

TABLE 5.1
Conjectured values for (5.10) *given in* [9].

n	1	2	3	4	5	6
f_n^{max}	2	4	$4(1+\sqrt{3})$	$8(1+\sqrt{3})$	$16(1+\sqrt{3})+4\sqrt{5}$	$32(1+\sqrt{3})+8\sqrt{5}$

where $\Sigma_2, U_\perp, V_\perp$ contain the remaining singular values and vectors of $M_s(UV^*)$ (where we can choose to order the diagonal elements of Σ_2 as well). Moreover $\sigma_{min}(\Sigma_1) > 2\|A\|_2\|B\|_2 \geq \sigma_{max}(\Sigma_2)$ (see proof of Theorem 5.3). This is the condition for a fixed point UV^* of $f_s(UV^*)$, according to Theorem 5.3. □

Remark that, for arbitrary matrices A and B, local minima and local maxima can exist, and then the algorithm may not always converge to the global optimum of the function.

5.3. Numerical experiments. As an illustration of the algorithm, we consider the problem of maximizing (4.1) in the case of special nilpotent matrices A_n and B_n. For any $n \in \mathbb{N}$, the nilpotent $(2^{n+1} \times 2^{n+1})$ matrices are recursively defined by

$$A_n = \begin{pmatrix} N_n & 0 \\ 0 & N_n \end{pmatrix}, \qquad B_n = \begin{pmatrix} 0 & 0 \\ I_{2^n} & 0 \end{pmatrix}, \tag{5.8}$$

with I_m the $m \times m$ identity matrix and N_n given inductively by

$$N_n = \begin{pmatrix} N_{n-1} & 0 \\ I_{2^{n-1}} & N_{n-1} \end{pmatrix}, \qquad N_0 = 0. \tag{5.9}$$

The matrices U and V are chosen of the same dimension $2^{n+1} \times 2^{n+1}$. The problem (3.1) is equivalent to maximizing the C-numerical range of A_n

$$\max_{Q^*Q=I} \langle Q^* A_n Q, B_n \rangle_H. \tag{5.10}$$

In [9], the authors provide conjectured maximal values of the function, depending on n. These values are represented in Table 5.1 and have been proved to be correct for $n = 1, 2$.

5.3.1. Numerical values by application of the algorithm. We apply the algorithm given in section 5.1 for nilpotent matrices A_n and B_n defined above (for $n = 1, \ldots, 6$). Initial unitary matrices U_0 and V_0 are randomly generated. The results are presented in Figure 5.1. Each plot combines the trajectories for three different initial values. The function

$$\text{residual} = f_n^{max} - \max_{\substack{U^*U=I \\ V^*V=I}} \langle U^* A_n U, V^* B_n V \rangle_H \tag{5.11}$$

is plotted on a logarithmic scale against the number of iterations. The values of f_n^{max} are taken from the above conjecture. The termination criteria we used for the different plots are represented in Table 5.2. We observe a convergence to a maximum defined by the values of the conjecture given in [9].

5.3.2. Duality gap. In this part we show that a duality gap can occur for the problem (3.6) in the case of nonsymmetric matrices. Consider (3.6) for nilpotent matrices A_3 and B_3. In the assumption that the conjecture in [9] is true, $\nu_P = 4(1+\sqrt{3}) = 10.92$. The value obtained for the dual problem is $\nu_D = 11$. That proves that a nonduality gap can occur, i.e., $\nu_P \leq \nu_D$.

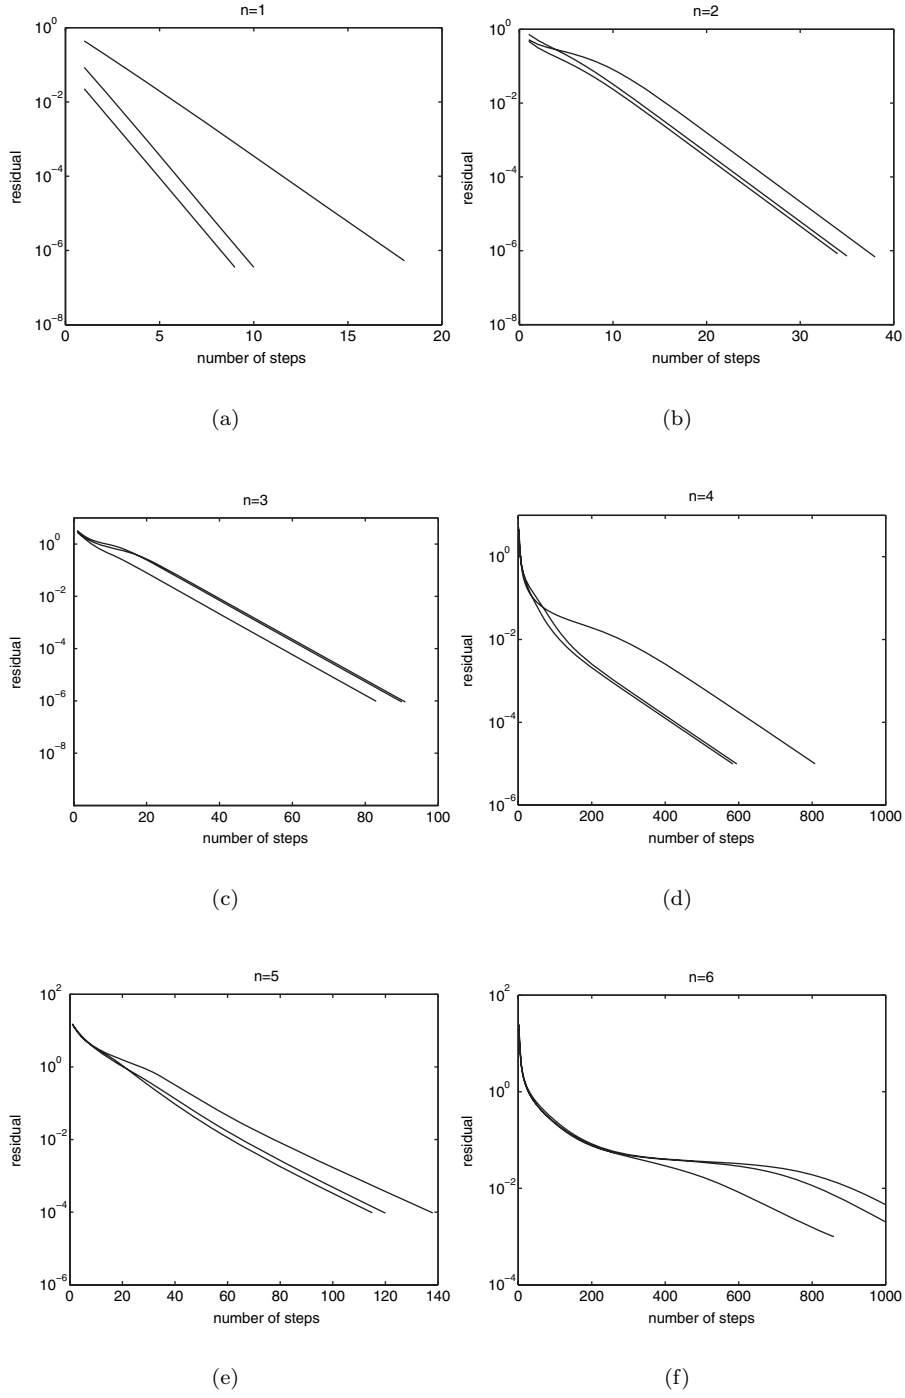

FIG. 5.1. *Minimization of the residual* (5.11) *by application of the SVD algorithm.*

TABLE 5.2
Termination criteria for the plots.

n	Residual	or	Number of steps
1	$< 10^{-6}$		> 1000
2	$< 10^{-6}$		> 1000
3	$< 10^{-6}$		> 1000
4	$< 10^{-5}$		> 1000
5	$< 10^{-4}$		> 1000
6	$< 10^{-3}$		> 1000

6. Conclusion. In this paper, we analyze the coupling between two restricted matrices under isometry constraints. Our problem provides a method to project simultaneously the matrices in a subspace of arbitrary dimension k and can be applied to both real and complex matrices. We indicate that it is an extension of various problems found in the literature. Many applications can arise from this formulation.

We present some mathematical properties of the problem and we characterize the maximal coupling for particular matrices such as Hermitian or normal matrices. In general only an upper bound can be found theoretically.

We develop an iterative algorithm in order to reach the optimum, and we characterize the fixed points. This algorithm is very simple to implement and is based on the singular value decomposition. Because this problem is not convex, the analysis of convergence and stability of the fixed points is difficult to realize.

Investigations of mathematical properties and applications of the similarity between restricted matrices can be pursued in several directions. A deeper analysis of the convergence of the algorithm is worthwhile to consider. We outline in the rest of the section a nonexhaustive list of some possible improvements and future research directions.

The first possible improvement concerns the convergence of the algorithm. Experimentally we observe a linear convergence to the optimum, but this convergence has not yet been proved and remains an important point to develop in the future. Second, because the problem is not convex, the analysis of the stability of the fixed points and the study of their basins of attraction are not easy to obtain. This last point is thus a delicate but interesting task to explore. From a more applied point of view, another topic of interest is to investigate how the mathematical concepts proposed here can be used, possibly in modified form, for applications in various areas. Some research for the use of the algorithm in the graph matching problem has been initiated but still needs further investigation. We can conclude that the problem envisaged in this paper gives rise to the study of interesting mathematical properties but also to various applications in different areas.

Acknowledgment. The authors thank the anonymous referee whose enormous work largely improved this paper.

CONVERGENCE OF THE DOMINANT POLE ALGORITHM AND RAYLEIGH QUOTIENT ITERATION*

JOOST ROMMES† AND GERARD L. G. SLEIJPEN‡

Abstract. The dominant poles of a transfer function are specific eigenvalues of the state space matrix of the corresponding dynamical system. In this paper, two methods for the computation of the dominant poles of a large scale transfer function are studied: two-sided Rayleigh quotient iteration (RQI) and the dominant pole algorithm (DPA). First, a local convergence analysis of DPA will be given, and the local convergence neighborhoods of the dominant poles will be characterized for both methods. Second, theoretical and numerical results will be presented that indicate that for DPA the basins of attraction of the dominant pole are larger than those for two-sided RQI. The price for the better global convergence is only a few additional iterations, due to the asymptotically quadratic rate of convergence of DPA, against the cubic rate of two-sided RQI.

Key words. eigenvalues, eigenvectors, dominant poles, two-sided Rayleigh quotient iteration, dominant pole algorithm, subspace accelerated Newton method, rate of convergence, transfer function, modal model reduction

1. Introduction.

The transfer function of a large scale dynamical system often has only a small number of dominant poles compared to the number of state variables. The computation of the dominant poles that are specific eigenvalues of the system matrix, and the corresponding modes, requires specialized eigenvalue methods. In [15] Newton's method is used to compute a dominant pole of single input single output (SISO) transfer function: the dominant pole algorithm (DPA). In two recent publications this algorithm is improved and extended to a robust and efficient method for the computation of the dominant poles and modes of large scale SISO [23] and MIMO [22] transfer functions.

This paper is concerned with the convergence behavior of DPA. First, DPA will be related to the two-sided or generalized Rayleigh quotient iteration (RQI) [18, 20]. A local convergence analysis will be given, showing the asymptotically quadratic rate of convergence. Furthermore, for systems with a symmetric state-space matrix, a characterization of the local convergence neighborhood of the dominant pole will be presented for both DPA and RQI. The results presented in this paper are sharp (in some sense), in contrast to those found in the literature, for example, by Ostrowski [17, 18] for DPA, and by Beattie and Fox [5] for RQI. Second, theoretical and numerical results indicate that for DPA the basins of attraction of the most dominant poles are larger than for two-sided RQI. In practice, the asymptotically quadratic (DPA) instead of cubic rate (two-sided RQI) of convergence costs about two or three iterations.

The outline of this paper is as follows. Definitions and properties of transfer functions and dominant poles and further motivation are given in section 2. The

dominant pole algorithm (DPA) and its relation to the two-sided Rayleigh quotient iteration (RQI) are discussed in section 3. In section 4 the local convergence of DPA is analyzed. The basins of attraction of DPA and two-sided RQI are studied in section 5. Section 6 concludes the paper.

2. Transfer functions and poles. The motivation for this paper comes from dynamical systems $(A, E, \mathbf{b}, \mathbf{c}, d)$ of the form

$$\left\{ \begin{array}{rcl} E\dot{\mathbf{x}}(t) & = & A\mathbf{x}(t) + \mathbf{b}u(t), \\ y(t) & = & \mathbf{c}^*\mathbf{x}(t) + du(t), \end{array} \right. \tag{2.1}$$

where $A, E \in \mathbb{R}^{n\times n}$, E may be singular but the pencil (A, E) is regular, $\mathbf{b}, \mathbf{c}, \mathbf{x}(t) \in \mathbb{R}^n$, and $u(t), y(t), d \in \mathbb{R}$. The vectors $\mathbf{b}$ and $\mathbf{c}$ are called the input and output vectors, respectively. The transfer function $H : \mathbb{C} \longrightarrow \mathbb{C}$ of (2.1) is defined as

$$H(s) = \mathbf{c}^*(sE - A)^{-1}\mathbf{b} + d. \tag{2.2}$$

The poles of transfer function (2.2) are a subset of the eigenvalues $\lambda_i \in \mathbb{C}$ of the matrix pencil (A, E). An eigentriplet $(\lambda_i, \mathbf{v}_i, \mathbf{w}_i)$ is composed of an eigenvalue λ_i of (A, E) and corresponding right and left eigenvectors $\mathbf{v}_i, \mathbf{w}_i \in \mathbb{C}^n$:

$$\begin{aligned} A\mathbf{v}_i &= \lambda_i E\mathbf{v}_i, \qquad \mathbf{v}_i \neq 0, \\ \mathbf{w}_i^*A &= \lambda_i \mathbf{w}_i^*E, \qquad \mathbf{w}_i \neq 0. \end{aligned}$$

It is well known that left and right eigenvectors corresponding to distinct eigenvalues are E-orthogonal: $\mathbf{w}_i^*E\mathbf{v}_j = 0$ if $\lambda_i \neq \lambda_j$.

If the pencil is nondefective, then the eigentriplets may be selected such that the first $\tilde{n}$ eigenvalues are distinct and finite ($\lambda_i \neq \lambda_j$ if $i \neq j$, $i, j \leq \tilde{n}$):

$$\mathbf{b} = \sum_{i=1}^{\tilde{n}} \beta_i E\mathbf{v}_i + \beta_\infty A\mathbf{v}_\infty, \quad \text{and} \quad \mathbf{c} = \sum_{i=1}^{\tilde{n}} \gamma_i E^*\mathbf{w}_i + \gamma_\infty A^*\mathbf{w}_\infty;$$

i.e., $\mathbf{b}$ and $\mathbf{c}$ determine the eigenvectors to be selected in the eigenspaces $\{\mathbf{v} \mid A\mathbf{v} = \lambda_i E\mathbf{v}\}$ and $\{\mathbf{w} \mid \mathbf{w}^*A = \lambda_i \mathbf{w}^*E\}$, respectively. The vectors $\mathbf{v}_\infty$ and $\mathbf{w}_\infty$ are in the kernel of E and E^*, respectively. They correspond to the eigenvalue at ∞. It is assumed that both $\mathbf{v}_i$ and $\mathbf{w}_i$ are nonzero and at least one of the coefficients β_i or γ_i is nonzero. The right and left eigenvectors $\mathbf{v}_i$ and $\mathbf{w}_i$ with $\mathbf{w}_i^*E\mathbf{v}_i \neq 0$ corresponding to finite eigenvales are assumed to be scaled so that $\mathbf{w}_i^*E\mathbf{v}_i = 1$.

The transfer function $H(s)$ can be expressed as a sum of residues $R_i \in \mathbb{C}$ [14]:

$$H(s) = \sum_{i=1}^{\tilde{n}} \frac{R_i}{s - \lambda_i} + R_\infty + d, \tag{2.3}$$

where the residues R_i are

$$R_i = (\mathbf{c}^*\mathbf{v}_i)(\mathbf{w}_i^*\mathbf{b}),$$

R_∞ (which is often zero) is the constant contribution of the poles at infinity, and $\tilde{n} \leq n$ is the number of finite first order poles (to be assumed to be numbered first). Note that $R_i = 0$ if $\mathbf{w}_i^*E\mathbf{v}_i = 0$.

Although there are different indices of modal dominance [2, 10, 23, 29], the following [11] will be used in this paper.

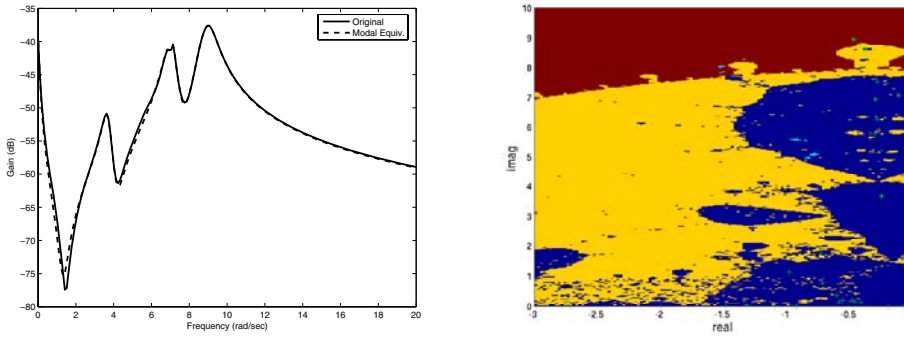

FIG. 2.1. *The left figure shows the Bode plot of the transfer function ($n = 66$ states) of the New England test system* [15]*, together with the Bode plot of the $k = 11$th order modal equivalent, constructed by projecting the system onto the modes of the 6 most dominant poles, which may belong to complex conjugated pairs. The right figure shows part of the complex plane with part of the pole spectrum (dominant poles are marked by asterisks, other poles by plus-signs), together with the initial shifts for which DPA (marked yellow and red grid points) and two-sided RQI (light-blue and red) converge to the most dominant pole $\lambda = -0.467 \pm 8.96i$. Dark blue regions denote convergence to less dominant poles. Real (imaginary) parts of initial shifts are at the horizontal (vertical) axis.*

DEFINITION 2.1. [illegible] λ_i [illegible] $H(s)$ [illegible] $\mathbf{v}_i$ [illegible] $\mathbf{w}_i$ ($\mathbf{w}_i^* E \mathbf{v}_i = 1$) [illegible] $|R_i| > |R_j|$ [illegible] $j \neq i$

An approximation of $H(s)$ that consists of $k < n$ terms with $|R_j|$ above some value determines the effective transfer function behavior [25] and is also known as the transfer function modal equivalent (assuming $R_\infty = 0$):

$$H_k(s) = \sum_{j=1}^{k} \frac{R_j}{s - \lambda_j} + d.$$

More generally, a pole λ_i is called dominant if $|R_i|$ is not very small compared to $|R_j|$ for all $j \neq i$. A dominant pole can be well observable and controllable in the transfer function. Its presence can be observed in the Bode plot corresponding to (2.2) (see Figure 2.1), which is a plot of $|H(i\omega)|$ against $\omega \in \mathbb{R}$: in this example, peaks occur at frequencies ω close to the imaginary parts of the dominant poles of $H(s)$. The height of the peaks, and the controllability/observability of the (dominant) pole that causes the peak, also depends on the size of the real part of that pole (cf. (2.3)). Therefore, in light of model order reduction by modal truncation, Definition 2.1 may not be suitable, and a characterization in terms of $|R_i|/|\mathrm{Re}(\lambda_i)|$ might be more appropriate. The purpose of this paper, however, is to analyze the convergence of the dominant pole algorithm (DPA) [15], described in the following section, and compare it to the convergence of the RQI. For this purpose, Definition 2.1 will do. For an overview of model order reduction techniques, see [3].

The dominant poles are specific (complex) eigenvalues of the pencil (A, E) and usually form a small subset of the spectrum of (A, E). They can be located anywhere in the spectrum; see also Figure 2.1. The two algorithms to compute poles (eigenvalues) that will be discussed in this paper, DPA and two-sided RQI, both start with an initial shift s_0 but behave notably differently: as can be seen in Figure 2.1, DPA converges to the most dominant pole for many more initial shifts than two-sided RQI (marked by yellow and red points, and light-blue and red points, respectively;

red denotes convergence for both DPA and two-sided RQI, while dark-blue denotes convergence to less dominant poles). In section 5 more of such figures will be presented and for all figures the following holds: the larger the yellow areas (compared to light-blue areas), the better the performance of DPA over two-sided RQI. The typical behavior of DPA will be discussed in more detail in sections 4 and 5.

In both DPA and two-sided RQI, the [illegible] plays a central role. This quotient is defined as follows (cf. [18, 20]).

DEFINITION 2.2. [illegible] $\rho(\mathbf{x},\mathbf{y})$ [illegible] $\rho(\mathbf{x},\mathbf{y}) \equiv \rho(\mathbf{x},\mathbf{y},A,E) \equiv \mathbf{y}^*A\mathbf{x}/\mathbf{y}^*E\mathbf{x}$, [illegible] $\mathbf{y}^*E\mathbf{x} \neq 0$

Note that $\mathbf{y}^*E\mathbf{x}$ can be zero even if E is nonsingular.

Since the dominance of a pole is independent of d (where d is as in (2.3)), without loss of generality $d = 0$ in the following.

3. The dominant pole algorithm (DPA). The poles of transfer function (2.2) are the $\lambda \in \mathbb{C}$ for which $\lim_{s\to\lambda} |H(s)| = \infty$. Consider now the function $G : \mathbb{C} \longrightarrow \mathbb{C}$:

$$G(s) = \frac{1}{H(s)}.$$

For a pole λ of $H(s)$, $\lim_{s\to\lambda} G(s) = 0$. In other words, the poles are the roots of $G(s)$, and a good candidate to find these roots is Newton's method. This idea is the basis of DPA [15] (and can be generalized to MIMO systems as well; see [16, 22]).

The derivative of $G(s)$ with respect to s is given by

$$G'(s) = -\frac{H'(s)}{H^2(s)}. \tag{3.1}$$

The derivative of $H(s)$ with respect to s is

$$H'(s) = -\mathbf{c}^*(sE - A)^{-1}E(sE - A)^{-1}\mathbf{b}. \tag{3.2}$$

Equations (3.1) and (3.2) lead to the following Newton scheme:

$$\begin{aligned} s_{k+1} &= s_k - \frac{G(s_k)}{G'(s_k)} \\ &= s_k + \frac{1}{H(s_k)}\frac{H^2(s_k)}{H'(s_k)} \\ &= s_k - \frac{\mathbf{c}^*(s_kE - A)^{-1}\mathbf{b}}{\mathbf{c}^*(s_kE - A)^{-1}E(s_kE - A)^{-1}\mathbf{b}}. \end{aligned} \tag{3.3}$$

The formula (3.3) was originally derived in [6, 7]. Using $\mathbf{x}_k = (s_kE - A)^{-1}\mathbf{b}$ and $\mathbf{y}_k = (s_kE - A)^{-*}\mathbf{c}$, the Newton update (3.3) can also be written as the generalized two-sided Rayleigh quotient $\rho(\mathbf{x}_k, \mathbf{y}_k)$, provided $\mathbf{y}_k^*E\mathbf{x}_k \neq 0$:

$$\begin{aligned} s_{k+1} &= s_k - \frac{\mathbf{c}^*(s_kE - A)^{-1}\mathbf{b}}{\mathbf{c}^*(s_kE - A)^{-1}E(s_kE - A)^{-1}\mathbf{b}} \\ &= \frac{\mathbf{c}^*(s_kE - A)^{-1}A(s_kE - A)^{-1}\mathbf{b}}{\mathbf{c}^*(s_kE - A)^{-1}E(s_kE - A)^{-1}\mathbf{b}} \\ &= \frac{\mathbf{y}_k^*A\mathbf{x}_k}{\mathbf{y}_k^*E\mathbf{x}_k}. \end{aligned}$$

Algorithm 1. The dominant pole algorithm (DPA).

INPUT: System $(A, E, \mathbf{b}, \mathbf{c})$, initial pole estimate s_0, tolerance $\epsilon \ll 1$
OUTPUT: Dominant pole λ and corresponding right and left eigenvectors $\mathbf{v}$ and $\mathbf{w}$

1. Set $k = 0$
2. **while** not converged
3. Solve $\mathbf{x}_k \in \mathbb{C}^n$ from $(s_k E - A)\mathbf{x}_k = \mathbf{b}$
4. Solve $\mathbf{y}_k \in \mathbb{C}^n$ from $(s_k E - A)^* \mathbf{y}_k = \mathbf{c}$
5. Compute the new pole estimate

$$s_{k+1} = s_k - \frac{\mathbf{c}^* \mathbf{x}_k}{\mathbf{y}_k^* E \mathbf{x}_k} = \frac{\mathbf{y}_k^* A \mathbf{x}_k}{\mathbf{y}_k^* E \mathbf{x}_k}$$

6. The pole $\lambda = s_{k+1}$ with $\mathbf{v} = \mathbf{x}_k$ and $\mathbf{w} = \mathbf{y}_k$ has converged if

$$\|A\mathbf{x}_k - s_{k+1} E \mathbf{x}_k\|_2 < \epsilon$$

7. Set $k = k + 1$
8. **end while**

An implementation of this Newton scheme is represented in Algorithm 1. It is also known as the dominant pole algorithm [15].

The two linear systems that need to be solved in steps 3 and 4 of Algorithm 1 can be efficiently solved using one LU-factorization $LU = s_k E - A$, by noting that $U^* L^* = (s_k E - A)^*$. In this paper it will be assumed that an exact LU-factorization is available, although this may not always be the case for real-life examples, depending on the size and condition of the system. If an exact LU-factorization is not available, one has to use inexact Newton schemes, such as inexact RQI and Jacobi–Davidson style methods [24, 13, 26], a topic that is described in [21].

With $\mathbf{r}_k \equiv A\mathbf{x}_k - s_{k+1} E \mathbf{x}_k$ and $\Delta A \equiv \frac{1}{\mathbf{y}_k^* E \mathbf{x}_k} \mathbf{r}_k \mathbf{y}_k^* E$, $(s_{k+1}, \mathbf{x}_k)$ is an exact (right) eigenpair of the pencil $(A - \Delta A, E)$, showing that the so-called [illegible] can be bounded by $\|\Delta A\|_2 \leq \frac{1}{|\mathbf{y}_k^* E \mathbf{x}_k|} \|\mathbf{r}_k\|_2 \, \|E^* \mathbf{y}_k\|_2$. This expression can be used to adopt the stopping criterions in Algorithm 1 (step 6) and Algorithm 2 (step 7) to accommodate for a backward error less than $\epsilon \|A\|_2$. Symmetric versions, treating $\mathbf{x}_k$ and $\mathbf{y}_k$ equally, are possible; other, more convenient, norms such as $\|\cdot\|_\infty$ can be selected, and perturbations on E can be allowed as well. For a thorough discussion, see [9] and [12].

3.1. DPA and two-sided Rayleigh quotient iteration (RQI). In Algorithm 2, the two-sided RQI [18, 20] is shown. The only difference with DPA is that the right-hand sides in steps 3 and 4 of Algorithm 1 are kept fixed, while the right-hand sides in steps 4 and 5 of Algorithm 2 are updated at every iteration.

While the use of the fixed right-hand sides drops the asymptotic convergence rate from cubic to quadratic, it is exactly this use of fixed right-hand sides that causes the typical better convergence to dominant poles, as will be shown later. In that light the quadratic instead of cubic local convergence, that in practice makes only a small difference in the number of iterations, is even more acceptable. Moreover, based on criteria in [5, 27] for switching from inverse iteration to RQI, one could define similar criteria to switch from DPA to two-sided RQI in the final phase of the process, to save some iterations. However, such techniques are not considered in this paper, since the primary goal is to study the convergence behavior.

Algorithm 2. Two-sided Rayleigh quotient iteration (RQI)

INPUT: System $(A, E, \mathbf{b}, \mathbf{c})$, initial pole estimate s_0, tolerance $\epsilon \ll 1$
OUTPUT: Pole λ and corresponding right and left eigenvectors $\mathbf{v}$ and $\mathbf{w}$

1. $\mathbf{x}_0 = (s_0E - A)^{-1}\mathbf{b}$, $\mathbf{y}_0 = (s_0E - A)^{-*}\mathbf{c}$, and $s_1 = \rho(\mathbf{x}_0, \mathbf{y}_0)$
2. Set $k = 1$
3. **while** not converged
4. Solve $\mathbf{x}_k \in \mathbb{C}^n$ from $(s_kE - A)\mathbf{x}_k = E\mathbf{x}_{k-1}/\|\mathbf{x}_{k-1}\|_2$
5. Solve $\mathbf{y}_k \in \mathbb{C}^n$ from $(s_kE - A)^*\mathbf{y}_k = E^*\mathbf{y}_{k-1}/\|\mathbf{y}_{k-1}\|_2$
6. Compute the new pole estimate

$$s_{k+1} = \rho(\mathbf{x}_k, \mathbf{y}_k) = \frac{\mathbf{y}_k^* A \mathbf{x}_k}{\mathbf{y}_k^* E \mathbf{x}_k}$$

7. The pole $\lambda = s_{k+1}$ has converged if

$$\|A\mathbf{x}_k - s_{k+1}E\mathbf{x}_k\|_2 < \epsilon$$

8. Set $k = k + 1$
9. **end while**

4. Local convergence analysis. The generalized two-sided Rayleigh quotient (Definition 2.2) has some well-known basic properties (see [18, 20]):

- Homogeneity: $\rho(\alpha\mathbf{x}, \beta\mathbf{y}, \gamma A, \delta E) = (\gamma/\delta)\rho(\mathbf{x}, \mathbf{y}, A, E)$ for $\alpha, \beta, \gamma, \delta \neq 0$.
- Translation invariance: $\rho(\mathbf{x}, \mathbf{y}, A - \alpha E, E) = \rho(\mathbf{x}, \mathbf{y}, A, E) - \alpha$.
- Stationarity (all directional derivatives are zero): $\rho = \rho(\mathbf{x}, \mathbf{y}, A, E)$ is stationary if and only if $\mathbf{x}$ and $\mathbf{y}$ are right and left eigenvectors of (A, E), respectively, with eigenvalue ρ and $\mathbf{y}^*E\mathbf{x} \neq 0$.

4.1. Asymptotically quadratic rate of convergence. In [20, p. 689] it is proved that the asymptotic convergence rate of two-sided RQI is cubic for nondefective matrices. Along the same lines it can be shown that the asymptotic convergence rate of DPA is quadratic. For the eigenvalue, this also follows from the fact that DPA is an exact Newton method, but for the corresponding left and right eigenvectors the following lemma is needed, which gives a useful expression for $(\rho_{k+1} - \lambda)$ (using $s_{k+1} \equiv \rho_k \equiv \rho(\mathbf{x}_k, \mathbf{y}_k, A, E)$ from now on).

LEMMA 4.1. $\mathbf{v}$ $\mathbf{w}$ (A, E) λ $(A - \lambda E)\mathbf{v} = 0$ $\mathbf{w}^*(A - \lambda E) = 0$ $\mathbf{w}^*E\mathbf{v} = 1$ $\mathbf{w}^*\mathbf{b} \neq 0$ $\mathbf{c}^*\mathbf{x} \neq 0$ ρ_k (A, E) $\tau_k, \omega_k \in \mathbb{C}$ $\mathbf{x}_k$ $\mathbf{y}_k$

$$(\rho_kE - A)\mathbf{x}_k = \tau_k\mathbf{b} \qquad (\rho_kE - A)^*\mathbf{y}_k = \omega_k\mathbf{c} \tag{4.1}$$

$$\mathbf{x}_k = \mathbf{v} + \mathbf{d}_k \qquad \mathbf{y}_k = \mathbf{w} + \mathbf{e}_k, \tag{4.2}$$

$\mathbf{w}^*E\mathbf{d}_k = \mathbf{e}_k^*E\mathbf{v} = 0$ $\mathbf{u} \equiv (I - E\mathbf{v}\mathbf{w}^*)\frac{\mathbf{b}}{\mathbf{w}^*\mathbf{b}}$ $\mathbf{z} \equiv (I - E^*\mathbf{w}\mathbf{v}^*)\frac{\mathbf{c}}{\mathbf{v}^*\mathbf{c}}$

$$\mathbf{u} = (\rho_k - \lambda)^{-1}(\rho_kE - A)\mathbf{d}_k \perp \mathbf{w} \qquad \mathbf{z} = (\rho_k - \lambda)^{-*}(\rho_kE - A)^*\mathbf{e}_k \perp \mathbf{v},$$

[illegible] $\rho_{k+1} = \mathbf{y}_k^* A\mathbf{x}_k/(\mathbf{y}_k^* E\mathbf{x}_k)$ [illegible]

$$\rho_{k+1} - \lambda = (\rho_k - \lambda)\mu_k, \quad \text{[illegible]} \quad \mu_k = \frac{\mathbf{e}_k^* E\mathbf{d}_k - \mathbf{e}_k^*\mathbf{u}}{1 + \mathbf{e}_k^* E\mathbf{d}_k}. \tag{4.3}$$

[illegible] $\mathbf{u}$ [illegible] $\mathbf{z}$ [illegible]. Substitution of (4.2) into (4.1) and multiplication from the left by $\mathbf{w}^*$ and $\mathbf{v}^*$, respectively, give

$$\tau_k = \frac{\rho_k - \lambda}{\mathbf{w}^*\mathbf{b}} \quad \text{and} \quad \omega_k = \frac{(\rho_k - \lambda)^*}{\mathbf{v}^*\mathbf{c}}.$$

It follows that

$$(\rho_k E - A)\mathbf{d}_k = (\rho_k - \lambda)(I - E\mathbf{v}\mathbf{w}^*)\frac{\mathbf{b}}{\mathbf{w}^*\mathbf{b}} \equiv (\rho_k - \lambda)\mathbf{u} \perp \mathbf{w}$$

and

$$(\rho_k E - A)^*\mathbf{e}_k = (\rho_k - \lambda)^*(I - E^*\mathbf{w}\mathbf{v}^*)\frac{\mathbf{c}}{\mathbf{v}^*\mathbf{c}} \equiv (\rho_k - \lambda)^*\mathbf{z} \perp \mathbf{v},$$

where $\mathbf{u}$ and $\mathbf{z}$ are independent of the iteration. With $\rho_{k+1} = \mathbf{y}_k^* A\mathbf{x}_k/(\mathbf{y}_k^* E\mathbf{x}_k)$, it follows that

$$\rho_{k+1} - \lambda = \frac{\mathbf{y}_k^*(A - \lambda E)\mathbf{x}_k}{\mathbf{y}_k^* E\mathbf{x}_k} = \frac{\mathbf{e}_k^*(A - \lambda E)\mathbf{d}_k}{1 + \mathbf{e}_k^* E\mathbf{d}_k}.$$

Note that $\mathbf{e}_k^*(A-\lambda E)\mathbf{d}_k = \mathbf{e}_k^*(A-\rho_k E)\mathbf{d}_k + (\rho_k - \lambda)\mathbf{e}_k^* E\mathbf{d}_k = (\rho_k - \lambda)(\mathbf{e}_k^* E\mathbf{d}_k - \mathbf{e}_k^*\mathbf{u})$, which shows (4.3). □

This lemma will be used in the proof of the following theorem, which shows the asymptotically quadratic rate of convergence of DPA, and expression (4.3) in particular will be used to derive the local convergence neighborhoods of DPA and RQI in section 4.2.

THEOREM 4.2. [illegible] $\mathbf{v}$ [illegible] $\mathbf{w}$ [illegible] (A, E) [illegible] λ [illegible] $(A-\lambda E)\mathbf{v} = 0$ [illegible] $\mathbf{w}^*(A-\lambda E) = 0$ [illegible] $\mathbf{w}^* E\mathbf{v} = 1$ [illegible] $\lim_{k\to\infty} \mathbf{x}_k = \mathbf{v}$ [illegible] $\lim_{k\to\infty} \mathbf{y}_k = \mathbf{w}$ [illegible] $s_{k+1} = \rho_k = \rho(\mathbf{x}_k, \mathbf{y}_k)$ [illegible] λ [illegible]

[illegible]. The proof is an adaptation of the proofs in [20, p. 689] and [13, p. 150]. The main difference here is that for DPA the right-hand sides of the linear systems are kept fixed during the iterations. Let the iterates $\mathbf{x}_k$ and $\mathbf{y}_k$ (see Lemma 4.1) be of the form

$$\mathbf{x}_k = \mathbf{v} + \mathbf{d}_k \quad \text{and} \quad \mathbf{y}_k = \mathbf{w} + \mathbf{e}_k,$$

where $\mathbf{w}^* E\mathbf{d}_k = \mathbf{e}_k^* E\mathbf{v} = 0$ and $\mathbf{w}^* E\mathbf{v} = 1$. Put $\mathbf{d}_k = (\rho_k - \lambda)\tilde{\mathbf{d}}_k$ with $(\rho_k E - A)\tilde{\mathbf{d}}_k = \mathbf{u}$, and $\mathbf{e}_k = (\rho_k - \lambda)^*\tilde{\mathbf{e}}_k$ with $(\rho_k E - A)^*\tilde{\mathbf{e}}_k = \mathbf{z}$. Let $\mathcal{V}$ and $\mathcal{W}$ be the associated right and left eigenspaces for λ. Then there are two orthogonal decompositions of $\mathbb{C}^n$:

$$\mathbb{C}^n = \mathcal{V} \oplus (E^*\mathcal{W})^\perp = (E\mathcal{V})^\perp \oplus \mathcal{W},$$

and it can be shown that for all $z \in \mathbb{C}$, one has $(zE - A) : (E^*\mathcal{W})^\perp \longrightarrow \mathcal{W}^\perp$ and $(zE - A)^* : (E\mathcal{V})^\perp \longrightarrow \mathcal{V}^\perp$. Since these mappings are onto for all z sufficiently close to λ, there is a neighborhood $\mathcal{N}$ of λ and a constant $m > 0$ such that

$$\|(zE - A)\mathbf{s}\| \geq m\|\mathbf{s}\| \quad \text{and} \quad \|(zE - A)^*\mathbf{t}\| \geq m\|\mathbf{t}\|$$

for all $z \in \mathcal{N}$, $\mathbf{s} \in (E^*\mathcal{W})^\perp$, and $\mathbf{t} \in (E\mathcal{V})^\perp$. It follows that if $\rho_k \to \lambda$, then for sufficiently large k

$$\|\mathbf{d}_k\| \le \frac{|\rho_k - \lambda|}{m}\|\mathbf{u}\|, \tag{4.4}$$

and similarly

$$\|\mathbf{e}_k\| \le \frac{|\rho_k - \lambda|}{m}\|\mathbf{z}\|, \tag{4.5}$$

and $\mathbf{d}_k$ and $\mathbf{e}_k$, and $\tilde{\mathbf{d}}_k$ and $\tilde{\mathbf{e}}_k$, are bounded. Hence, $\mathbf{x}_k \to \mathbf{v}$ and $\mathbf{y}_k \to \mathbf{w}$ if $\rho_k \to \lambda$. The converse follows from the continuity of the Rayleigh quotient if and only if $\mathbf{x}_k \to \mathbf{v}$ and $\mathbf{y}_k \to \mathbf{w}$.

To prove the asymptotically quadratic rate of convergence, first note that

$$\rho_{k+1} - \lambda = \rho(\mathbf{x}_k, \mathbf{y}_k) = (\rho_k - \lambda)^2 \frac{\tilde{\mathbf{e}}_k^*(A - \lambda E)\tilde{\mathbf{d}}_k}{1 + (\rho_k - \lambda)^2 \tilde{\mathbf{e}}_k^* E \tilde{\mathbf{d}}_k},$$

and hence

$$|\rho_{k+1} - \lambda| = (\rho_k - \lambda)^2 |\tilde{\mathbf{e}}_k^*(A - \lambda E)\tilde{\mathbf{d}}_k| + O((\rho_k - \lambda)^4), \tag{4.6}$$

which proves that ρ_k converges quadratically toward λ.

The boundedness of $\tilde{\mathbf{d}}_k$ and $\tilde{\mathbf{e}}_k$ implies that, for ρ_k sufficiently close to λ,

$$|\rho_k - \lambda|^2 |\tilde{\mathbf{e}}_k^* E \mathbf{d}_k| \le \frac{1}{2}.$$

This leads to an estimate of $|\rho_{k+1} - \lambda|$ by $2|\rho_k - \lambda|^2 |\tilde{\mathbf{e}}_k^*(A - \lambda E)\tilde{\mathbf{d}}_k| = |\mathbf{e}_k^*(A - \lambda E)\mathbf{d}_k|$. A combination with (4.4) leads to

$$\begin{aligned} \|\mathbf{v} - \mathbf{x}_{k+1}\| &= \|\mathbf{d}_{k+1}\| \\ &\le \frac{\|A - \lambda E\|\ \|\mathbf{u}\|}{2m}\|\mathbf{v} - \mathbf{x}_k\|\|\mathbf{w} - \mathbf{y}_k\| \end{aligned}$$

for k sufficiently large, and similarly, a combination with (4.5) leads to

$$\begin{aligned} \|\mathbf{w} - \mathbf{y}_{k+1}\| &= \|\mathbf{e}_{k+1}\| \\ &\le \frac{\|A - \lambda E\|\ \|\mathbf{z}\|}{2m}\|\mathbf{v} - \mathbf{x}_k\|\|\mathbf{w} - \mathbf{y}_k\|, \end{aligned}$$

which proves the asymptotically quadratic convergence. □

4.2. Convergence neighborhood. In this section it will be assumed that A is a symmetric matrix and that $E = I$. In [17] Ostrowski characterizes the convergence neighborhood of the iteration

$$(A - \rho_k I)\mathbf{x}_k = \tau_k \mathbf{b}, \quad k = 0, 1, \ldots, \tag{4.7}$$

for symmetric matrices A, where ρ_0 is arbitrary, $\rho_{k+1} = \rho(\mathbf{x}_k, A) \equiv \rho(\mathbf{x}_k, \mathbf{x}_k, A, E)$ $(k > 0)$, and τ_k is a scalar so that $\|\mathbf{x}_k\|_2 = 1$. It can be seen that DPA for symmetric matrices (with $E = I$, $\mathbf{b} = \mathbf{c}$),

$$(\rho_k I - A)\mathbf{x}_k = \tau_k \mathbf{b}, \quad k = 0, 1, \ldots, \tag{4.8}$$

is similar, and hence Ostrowski's approach can be used to characterize the local convergence neighborhood of DPA for symmetric matrices A with $\mathbf{c} = \mathbf{b} = (b_1, \ldots, b_n)^T$. In fact, a larger convergence neighborhood of DPA will be derived here. This result gives insight into the typical convergence behavior of DPA.

Since the two-sided Rayleigh quotient and (4.7), (4.8) are invariant under unitary similarity transforms, without loss of generality A will be a diagonal matrix $\mathrm{diag}(\lambda_1, \ldots, \lambda_n)$ with $\lambda_1 < \cdots < \lambda_n$. Note that $R_j = \|\mathbf{b}\|_2 \cos^2 \angle(\mathbf{v}_j, \mathbf{b})$ and that λ_J with $J = \mathrm{argmax}_j(\cos(\angle(\mathbf{v}_j, \mathbf{b})))$ is the dominant pole. The main results of this paper, sharp bounds for the convergence neighborhoods of DPA and RQI, respectively, are stated in Theorems 4.3 and 4.4, respectively. The proofs are given in section 4.2.1.

THEOREM 4.3. [illegible] $(\lambda, \mathbf{v})$ [illegible] A [illegible] A [illegible] $\mathbf{b}$ [illegible] ρ_0 [illegible] $\mathbf{x}_k$ [illegible] τ_k [illegible]

$$\|\mathbf{x}_k\| = 1, \quad (\rho_k I - A)\mathbf{x}_k = \tau_k \mathbf{b} \quad \text{[illegible]} \quad \rho_{k+1} \equiv \mathbf{x}_k^* A \mathbf{x}_k \quad (k \geq 0),$$

[illegible] $\gamma = \min_{\lambda_i \neq \lambda} |\lambda_i - \lambda|$ [illegible] $\alpha_k \equiv \frac{|\rho_k - \lambda|}{\gamma}$ [illegible] $\tilde{\alpha}_k \equiv \frac{\alpha_k}{1-\alpha_k}$ [illegible]

$$\alpha_0 < \alpha_{dpa} \equiv \frac{1}{1+\zeta^2} \quad \text{[illegible]} \quad \zeta \equiv \tan \angle(\mathbf{v}, \mathbf{b}), \tag{4.9}$$

[illegible] $\rho_k \to \lambda$ $(k \to \infty)$ [illegible] $k \geq 0$ [illegible]

$$\tilde{\alpha}_{k+1}\zeta^2 \leq \left(\tilde{\alpha}_k \zeta^2\right)^2 < 1.$$

With $c \equiv \cos \angle(\mathbf{v}, \mathbf{b})$ one has $c^2 = \frac{1}{1+\zeta^2}$, and hence condition (4.9) is equivalent to $\frac{|\rho_0 - \lambda|}{\gamma c^2} < 1$. In the setting of this paper, Ostrowski's convergence condition [17, equation (19), p. 235] is given by

$$\frac{|\rho_0 - \lambda|}{\gamma c^2} \leq \frac{1}{2} \min\left(\frac{1}{2(1-c^2)}, \frac{1}{c^2}\right).$$

Because $\frac{1}{2}\min(\frac{1}{2(1-c^2)}, \frac{1}{c^2}) \leq \frac{3}{4} < 1$, it is clear that the convergence neighborhood $\{\rho_0 \mid \text{condition (4.9) holds}\}$ that follows from Theorem 4.3 is larger than that from Ostrowski's condition.

In [17, p. 239], the convergence neighborhood of standard RQI,

$$(A - \rho_k I)\mathbf{x}_k = \tau_k \mathbf{x}_{k-1}, \quad k = 0, 1, \ldots, \tag{4.10}$$

where $\mathbf{x}_{-1}$ arbitrary, $\rho_{k+1} = \rho(\mathbf{x}_k, A)$ $(k > 0)$, and τ_k is a scalar so that $\|\mathbf{x}_k\|_2 = 1$, is derived. Here a sharper bound is derived.

THEOREM 4.4. [illegible] $(\lambda, \mathbf{v})$ [illegible] A [illegible] A [illegible] $\mathbf{b}$ [illegible] ρ_0 [illegible] $\mathbf{x}_{-1} = \mathbf{b}$ [illegible] $\mathbf{x}_k$ [illegible] τ_k [illegible]

$$\|\mathbf{x}_k\| = 1, \quad (\rho_k I - A)\mathbf{x}_k = \tau_k \mathbf{x}_{k-1} \quad \text{[illegible]} \quad \rho_{k+1} \equiv \mathbf{x}_k^* A \mathbf{x}_k \quad (k \geq 0),$$

[illegible] $\gamma = \min_{\lambda_i \neq \lambda} |\lambda_i - \lambda|$ [illegible] $\alpha_k \equiv \frac{|\rho_k - \lambda|}{\gamma}$, $\tilde{\alpha}_k \equiv \frac{\alpha_k}{1-\alpha_k}$, [illegible] $\zeta_{k+1} \equiv \tan \angle(\mathbf{v}, \mathbf{x}_k)$ [illegible]

$$\alpha_0 < \alpha_{rqi} \equiv \frac{1}{1+\zeta} \quad \zeta \equiv \zeta_0 \equiv \tan\angle(\mathbf{v}, \mathbf{b}), \tag{4.11}$$

$\zeta_1 < 1$, $|\rho_1 - \lambda| < \frac{1}{2}\gamma$, $\rho_k \to \lambda$ $(k \to \infty)$, $k \geq 0$,

$$\tilde{\alpha}_{k+1} \leq (\tilde{\alpha}_k \zeta_k)^2, \quad \zeta_{k+1} \leq \tilde{\alpha}_k \zeta_k, \quad \tilde{\alpha}_{k+1}\zeta_{k+1} \leq (\tilde{\alpha}_k \zeta_k)^3 \leq 1.$$

Note that the last inequality in the theorem also shows the cubic rate of convergence of RQI.

In [5, Thm. 1] it is shown that, with $\gamma_b = \beta - \alpha$ a known gap in the spectrum of A (for instance, $\gamma = \min_{\lambda_i \neq \lambda} |\lambda - \lambda_i|$), if $\rho_1 < (\alpha+\beta)/2$ $\|\mathbf{r}_1\| = \|A\mathbf{x}_0 - \rho_1 \mathbf{x}_0\| \leq \gamma_b$, then $\rho_k < (\alpha+\beta)/2$ for $k \geq 1$, and similarly for the case $\rho_1 > (\alpha+\beta)/2$. The first condition of this theorem implies that $|\rho_1 - \lambda| < \gamma/2$, while $\|\mathbf{r}_1\| \leq \gamma$ is possible only if $\angle(\mathbf{v}, \mathbf{x}_0) < 45°$. In other words, $\zeta < 1$ and $|\rho_1 - \lambda|/\gamma < 1/2 < 1/(1+\zeta)$. As can be learned from the proof of Theorem 4.4 in section 4.2.1, this is the situation after one iteration step. Theorem 4.4 seems to allow a weaker start. To see this, consider the two-dimensional example $A = \mathrm{diag}(-1, 1)$. With $\rho_0 = 0.01$, $\mathbf{x}_{-1} = \mathbf{b} = [\sqrt{2}/2, \sqrt{2}/2]$, and $\mathbf{x}_0 = (A - \rho_0 I)^{-1}\mathbf{x}_{-1}$, it follows that $|\lambda - \rho_0| < 1$ and condition (4.11) is satisfied, while $\|\mathbf{r}_1\| = \|A\mathbf{x}_0 - \rho_1\mathbf{x}_0\| \approx 1.03 > 1$. Hence, the result in Theorem 4.4 is sharper.

The results of Theorems 4.3 and 4.4 are sharp in the following sense.

THEOREM 4.5. 4.3 4.4 $\mathbf{b}$ ρ_0 λ λ_{i_0} ρ_k 4.3 (4.4) λ $|\rho_0 - \lambda| < \alpha_{dpa}$ $(< \alpha_{rqi}$) i_0 $\gamma = |\lambda_{i_0} - \lambda|$

Let $\mathbf{b} = c\mathbf{v} + c_j \mathbf{v}_{i_0}$. For ease of notation, write $(\lambda_1, \mathbf{v}_1) = (\lambda, \mathbf{v})$ and $(\lambda_2, \mathbf{v}_2) = (\lambda_{i_0}, \mathbf{v}_{i_0})$.

With $\alpha_0^i \equiv |\rho_0 - \lambda_i|/\gamma$ and $\zeta_0^{(i)} \equiv \tan\angle(\mathbf{v}_i, \mathbf{b})$ $(i = 1, 2)$, one has that $\alpha_0^{(2)} = 1 - \alpha_0^{(1)}$ and $\zeta_0^{(1)} = 1/\zeta_0^{(2)}$. Therefore, if $\alpha_0^{(1)} > \gamma/(1 + (\zeta_0^{(1)})^p)$, then $\alpha_0^{(2)} < \gamma/(1 + (\zeta_0^{(2)})^p)$ $(p = 1, 2)$, and Theorem 4.3 (take $p = 2$) and Theorem 4.4 (take $p = 1$) guarantee convergence toward λ_2.

If $\alpha_0^{(1)} = \gamma/(1 + (\zeta_0^{(1)})^p)$, then $\alpha_0^{(2)} = \gamma/(1 + (\zeta_0^{(2)})^p)$, and, as can be seen in the proof of the corresponding theorem, the contraction statement in the theorem holds for both $\lambda = \lambda_1$ and $\lambda = \lambda_2$. This implies stagnation of the sequence of $|\rho_k - \lambda|$. ∎

Note that it is actually proved that Theorem 4.5 is correct for any nontrivial $\mathbf{b}$ in the two-dimensional subspace spanned by $\mathbf{v}$ and $\mathbf{v}_j$ with j such that $\gamma = |\lambda_j - \lambda|$.

In Figure 4.1, α_{dpa} and α_{rqi} (see equations (4.9) and (4.11), respectively) are plotted for c_j^2, where $c_j = \cos\angle(\mathbf{v}, \mathbf{b})$. As c_j^2 increases, i.e., as mode j becomes more dominant, both local convergence neighborhoods increase and $\alpha \to 1$, while the bound for the DPA neighborhood is larger for $c_j^2 > 1/2$, or $\angle(\mathbf{v}, \mathbf{b}) < 45°$.

The price one has to pay for the cubic convergence is the smaller local convergence neighborhood of the dominant pole, as it becomes more dominant, for RQI. While DPA emphasizes the dominant mode at every iteration by keeping the right-hand side fixed, RQI takes advantage of this only in the first iteration, and for initial shifts too far from the dominant pole, the dominant mode may be damped out from the iterates $\mathbf{x}_k$. In that sense, RQI is closer to the inverse power method or inverse iteration, which converges to the eigenvalue closest to the shift, while DPA takes advantage of the information in the right-hand side $\mathbf{b}$.

Because the results are in fact lower bounds for the local convergence neighborhood, theoretically speaking, no conclusions can be drawn about the global basins of attraction. But the results strengthen the intuition that for DPA the basin of attraction of the dominant pole is larger than that for RQI.

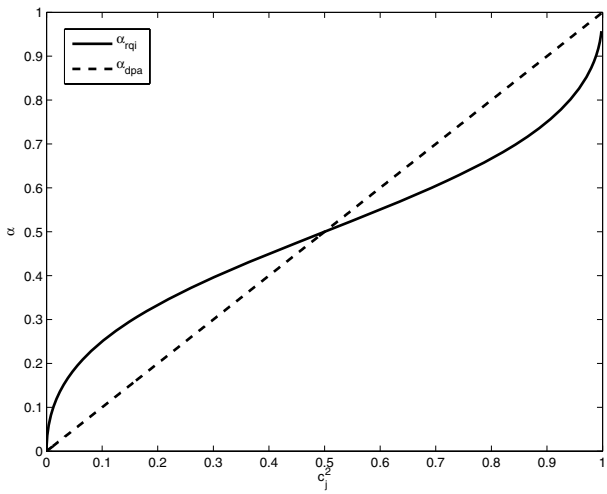

FIG. 4.1. *Bounds of the local convergence neighborhood for DPA (dashed) and best-case RQI (solid). If, with* $\gamma = \min_{i \neq j} |\lambda_i - \lambda_j|$, *one has* $|\lambda_j - \rho_\ell| \leq \alpha\gamma$ *for some* ℓ, *then the sequence of* ρ_k *converges to* λ_j. *Here,* $\alpha = \alpha_{dpa}$ *or* $\alpha = \alpha_{rqi}$. *Along the horizontal axis* c_j^2 *is varied between* 0 *(***b** *is orthogonal to* $\mathbf{v}_j$*) and* 1 *(***b** *is a multiple of* $\mathbf{v}_j$*):* $c_j \equiv \cos\angle(\mathbf{v}_j, \mathbf{b})$.

4.2.1. Proofs of Theorems 4.3 and 4.4. The following two lemmas provide expressions and bounds that are needed for the proofs of Theorems 4.3 and 4.4.

LEMMA 4.6. [illegible] $\mathbf{v}$ [illegible] $A = A^T$ [illegible] λ [illegible] $\|\mathbf{v}\| = 1$, [illegible] $\tau_k \in \mathbb{R}$ [illegible] $\mathbf{x}_k$ [illegible]

$$(\rho_k I - A)\mathbf{x}_k = \tau_k \mathbf{b}$$

[illegible]

$$\mathbf{x}_k = \mathbf{v} + \mathbf{d}_k, \tag{4.12}$$

[illegible] $\mathbf{v}^*\mathbf{d}_k = 0$ [illegible] $\mathbf{z} = (\rho_k - \lambda)^{-1}(\rho_k I - A)\mathbf{d}_k$ [illegible] $\rho_{k+1} = \mathbf{x}_k^* A\mathbf{x}_k / (\mathbf{x}_k^*\mathbf{x}_k)$ [illegible]

$$\rho_{k+1} - \lambda = (\rho_k - \lambda)\mu_k,$$

[illegible]

$$\mu_k = \frac{\mathbf{d}_k^*\mathbf{d}_k - \mathbf{d}_k^*\mathbf{z}}{1 + \mathbf{d}_k^*\mathbf{d}_k}. \tag{4.13}$$

[illegible]. The result follows from Lemma 4.1, by noting that $A = A^T$ and $E = I$. □

LEMMA 4.7. [illegible] 4.6 [illegible] $\gamma = \min_{\lambda_i \neq \lambda} |\lambda_i - \lambda|$, $c = \cos\angle(\mathbf{v}, \mathbf{b})$, $\zeta = \|\mathbf{z}\|$, $\alpha_k = \frac{|\rho_k - \lambda|}{\gamma}$ [illegible] $\tilde{\alpha}_k = \alpha_k/(1 - \alpha_k)$ [illegible] [illegible]

$$\alpha_k < 1 \quad \Rightarrow \quad \|\mathbf{d}_k\| \leq \tilde{\alpha}_k \zeta, \tag{4.14}$$

$\alpha_k \le c = 1/\sqrt{1+\zeta^2}$

$$\alpha_k < 1 \quad \Rightarrow \quad \tilde{\alpha}_{k+1} \equiv \frac{\alpha_{k+1}}{1-\alpha_{k+1}} \le (\tilde{\alpha}_k \zeta)^2. \tag{4.15}$$

Put $\zeta_k = \|\mathbf{d}_k\|$. Then by (4.13)

$$|\mu_k| \le \phi(\zeta_k), \text{ where } \phi(\tau) \equiv \frac{\zeta\tau + \tau^2}{1+\tau^2} \quad (\tau \in \mathbb{R}).$$

The function ϕ is increasing on $[0, \tau_{\max}]$, where $\tau_{\max} = (1+\sqrt{1+\zeta^2})/\zeta$, or, using $c \equiv \cos\angle(\mathbf{v}, \mathbf{b}) = 1/\sqrt{1+\zeta^2}$, $\tau_{\max} = \sqrt{(1+c)/(1-c)}$, and $0 \le \phi \le \frac{1+c}{2c}$ on $(0, \infty)$.

Since $\|(A-\rho_k)^{-1}|_{\mathbf{v}^\perp}\| \le |1/(\gamma - |\lambda - \rho_k|)|$, it follows that

$$\zeta_k \equiv \|\mathbf{d}_k\| \le |\rho_k - \lambda| \|(A-\rho_k)^{-1}|_{\mathbf{v}^\perp}\| \|\mathbf{z}\| \le \frac{|\rho_k - \lambda|}{|\gamma - |\rho_k - \lambda||} = \frac{\alpha_k}{1-\alpha_k}\zeta,$$

which proves (4.14). The statement that if $\alpha_k \le c = 1/\sqrt{1+\zeta^2}$, then $\zeta_k \le \tilde{\alpha}_k\zeta \le \tau_{\max}$ and

$$|\mu_k| \le \phi(\zeta_k) \le \phi(\tilde{\alpha}_k\zeta) \le \frac{\tilde{\alpha}_k + \tilde{\alpha}_k^2}{1+\tilde{\alpha}_k^2\zeta^2}\zeta^2 = \frac{\alpha_k\zeta^2}{(1-\alpha_k)^2 + \alpha_k^2\zeta^2} \tag{4.16}$$

now follows from the observation that $\alpha_k\zeta/(1-\alpha_k) \le \tau_{\max}$ if and only if $\alpha_k \le 1/\sqrt{1+\zeta^2} = c$. Furthermore, if $\alpha_k \le c = 1/\sqrt{1+\zeta^2}$, then

$$|\mu_k| \le 1 \quad \text{if} \quad \tilde{\alpha}_k\zeta^2 \le 1 \quad \left(\Leftrightarrow \quad \alpha_k \le \frac{1}{1+\zeta^2} = c^2\right). \tag{4.17}$$

This follows readily from $\phi(\tilde{\alpha}_k\zeta) \le 1$, statement (4.14), and the definition $\tilde{\alpha}_k = \alpha_k/(1-\alpha_k)$.

Finally, statement (4.15) follows from the fact that (4.16) and (4.15) imply $\alpha_{k+1} \le (\tilde{\alpha}_k\zeta)^2/(1+(\tilde{\alpha}_k\zeta)^2)$. □

Note that it is essential that the function ϕ is increasing, since this allows us to use upper bound (4.14) to also handle the denominator in (4.13), leading to (4.16).

In the two-dimensional case, the estimate in (4.16) is sharp (equality), since both $\mathbf{z}$ and $\mathbf{d}_k$ are in the same direction (orthogonal to $\mathbf{v}$). Furthermore, in (4.17), $|\mu| \le 1$ if and only if $\tilde{\alpha}_k\zeta^2 \le 1$.

4.3. Note that $\zeta \equiv \zeta_0$ is the same in all iterations, and recall that $\alpha_k \equiv |\rho_k - \lambda|/\gamma$. Since $c^2 = 1/(1+\zeta^2)$, condition (4.9) implies $\alpha_0(1+\zeta^2) < 1$, and by induction and (4.15) of Lemma 4.7, it follows that

$$\tilde{\alpha}_{k+1}\zeta^2 \le (\tilde{\alpha}_k\zeta^2)^2 \quad \text{if} \quad \tilde{\alpha}_0\zeta^2 \le 1 \qquad (k \ge 0), \tag{4.18}$$

which implies convergence if $\tilde{\alpha}_0\zeta_0^2 < 1$. □

4.4. Note that $\zeta_{k+1} = \tan\angle(\mathbf{v}, \mathbf{x}_k)$ changes every iteration, and recall that $\alpha_k \equiv |\rho_k - \lambda|/\gamma$ and $\tilde{\alpha}_k = \alpha_k/(1-\alpha_k)$. Condition (4.11) implies $\alpha_0 < 1/(1+\zeta)$ or, equivalently, $\tilde{\alpha}_0\zeta_0 < 1$. By (4.15) it follows that $\zeta_1 < 1$ and $\alpha_1 < 1/2$, or, equivalently, $|\rho_1 - \lambda| < \gamma/2$, as announced in the discussion following Theorem 4.4. Since $\tilde{\alpha}_k\zeta_k < 1$ implies that $\alpha_k < 1/\sqrt{1+\zeta_k^2}$, results (4.14) and (4.15) of Lemma 4.7 can be applied to obtain

$$\tilde{\alpha}_{k+1} \le (\tilde{\alpha}_k\zeta_k)^2 \quad \text{and} \quad \tilde{\alpha}_{k+1}\zeta_{k+1} \le (\tilde{\alpha}_k\zeta_k)^3$$

if $\tilde{\alpha}_k\zeta_k < 1$. Here it is used that (4.14) reads in this context as $\zeta_{k+1} \le \tilde{\alpha}_k\zeta_k$. Since $\tilde{\alpha}_0\zeta_0 < 1$, an induction argument shows the cubic rate of convergence. □

4.3. General systems. Theorems 4.3 and 4.4 can readily be generalized for normal matrices, but it is difficult to obtain such bounds for general matrices without making specific assumptions. To see this, note that it is difficult to give sharp bounds for (4.3) in Lemma 4.1. However, the following theorem states that DPA is invariant under certain transformations and helps in getting more insight into DPA for general, nondefective systems $(A, E, \mathbf{b}, \mathbf{c})$.

THEOREM 4.8. [illegible] (A, E) [illegible] $X, Y \in \mathbb{C}^{n\times n}$ [illegible] $(A, E, \mathbf{b}, \mathbf{c}, s_0)$ [illegible] $(\mathbf{x}_k, \mathbf{y}_k, s_{k+1})$ [illegible] $(Y^*AX, Y^*EX, Y^*\mathbf{b}, X^*\mathbf{c}, s_0)$ [illegible] $(X^{-1}\mathbf{x}_k, Y^{-1}\mathbf{y}_k, s_{k+1})$ [illegible]. If $\mathbf{x} = \mathbf{x}_k$ is the solution of

$$(sE - A)\mathbf{x} = \mathbf{b},$$

then $\tilde{\mathbf{x}} = \tilde{\mathbf{x}}_k = X^{-1}\mathbf{x}$ is the solution of

$$(sY^*EX - Y^*AX)\tilde{\mathbf{x}} = Y^*\mathbf{b},$$

and vice versa. Similar relations hold for $\mathbf{y} = \mathbf{y}_k$ and $\tilde{\mathbf{y}} = \tilde{\mathbf{y}}_k = Y^{-1}\mathbf{y}$. Noting that

$$s_{k+1} = \frac{\tilde{\mathbf{y}}^*Y^*AX\tilde{\mathbf{x}}}{\tilde{\mathbf{y}}^*Y^*EX\tilde{\mathbf{x}}} = \frac{\mathbf{y}^*A\mathbf{x}}{\mathbf{y}^*E\mathbf{x}} = s_{k+1}$$

completes the proof. □

Let W and V have as their columns the left and right eigenvectors of (A, E), respectively, i.e., $AV = EV\Lambda$ and $W^*A = \Lambda W^*E$, with $\Lambda = \mathrm{diag}(\lambda_1, \ldots, \lambda_n)$. Furthermore, let W and V be scaled so that $W^*EV = \Delta$, where Δ is a diagonal matrix with $\delta_{ii} = 1$ for finite λ_i and $\delta_{ii} = 0$ for $|\lambda_i| = \infty$. According to Theorem 4.8, DPA$(A, E, \mathbf{b}, \mathbf{c})$ and DPA$(\Lambda, \Delta, W^*\mathbf{b}, V^*\mathbf{c})$ produce the same pole estimates s_k. In $\tilde{\mathbf{b}} = W^*\mathbf{b}$ and $\tilde{\mathbf{c}} = V^*\mathbf{c}$, the new right-hand sides, one recognizes the contributions to the residues $R_i = \tilde{\mathbf{c}}_i\tilde{\mathbf{b}}_i = (\mathbf{c}^*\mathbf{v}_i)(\mathbf{w}_i^*\mathbf{b})$. The more dominant pole λ_i is, the larger the corresponding coefficients $\tilde{\mathbf{b}}_i$ and $\tilde{\mathbf{c}}_i$ are, and, since (Λ, Δ) is a diagonal pencil, the larger the chance that DPA converges to the unit vectors $\tilde{\mathbf{v}} = \mathbf{e}_i$ and $\tilde{\mathbf{w}} = \mathbf{e}_i$, which correspond to the right and left eigenvectors $\mathbf{v}_i = V\mathbf{e}_i$ and $\mathbf{w}_i = W\mathbf{e}_i$, respectively.

As observed earlier, DPA emphasizes the dominant mode every iteration by keeping the right-hand sides fixed and thereby can be expected to enlarge the convergence neighborhood also for general systems, compared to two-sided RQI. In practice, the quadratic instead of cubic rate of local convergence costs at most 2 or 3 iterations. Numerical experiments confirm that the basins of attraction of the dominant eigenvalues are larger for DPA, as will be discussed in the following section.

5. Basins of attraction and typical convergence behavior. It is not straightforward to characterize the global convergence of DPA, not even for symmetric matrices (see [17, pp. 236–237]). Basins of attraction of RQI in the three-dimensional case are studied in [1, 4, 19], while in [5, 27] local convergence neighborhoods are described. Because the DPA residuals $\mathbf{r}_k = (A - \rho_k I)\mathbf{b}$ are not monotonically decreasing (in contrast to the inverse iteration residuals $\mathbf{r}_k = (A - \sigma I)\mathbf{x}_k$ and the RQI residuals $\mathbf{r}_k = (A - \rho_k I)\mathbf{x}_k$; see [5, 19, 20]), it is not likely that similar results can be obtained for DPA. Numerical experiments, however, may help us to get an idea of the typical convergence behavior of DPA and may show why DPA is to be preferred over two-sided RQI for the computation of dominant poles.

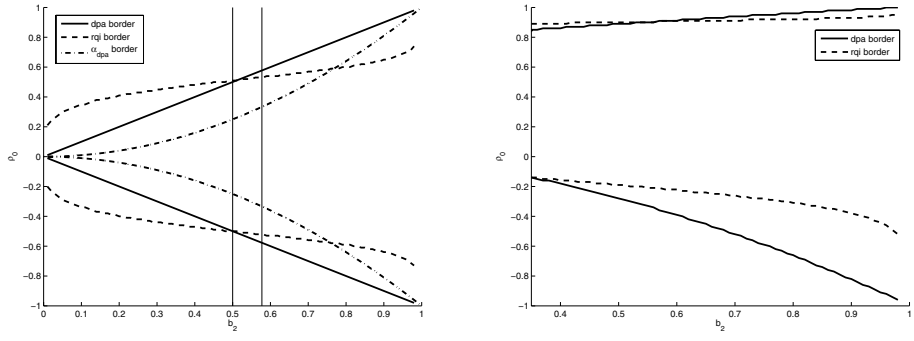

FIG. 5.1. *Convergence regions for DPA (solid borders) and RQI (dashed), and the theoretical DPA border (dash-dot; see Theorem 4.3) for the matrix* $A = diag(-1, s, 1)$ *for* $s = 0$ *(left) and* $s = 0.8$. *The regions of convergence to* $\lambda_2 = s$ *for DPA and RQI, respectively, are enclosed between the lower and upper borders of DPA and RQI, respectively. The regions of convergence to* $\lambda_1 = -1$ *(*$\lambda_3 = 1$*) are below (above) the lower (upper) border.*

An unanswered question is how to choose the initial shift of DPA. An obvious choice is the two-sided Rayleigh quotient $s_0 = (\mathbf{c}^* A\mathbf{b})/(\mathbf{c}^* E\mathbf{b})$. This choice will work in the symmetric case $A = A^*, E = I, \mathbf{c} = \mathbf{b}$. In the general nonsymmetric case this choice will not always be possible: the vectors $\mathbf{b}$ and $\mathbf{c}$ are often very sparse (only $O(1)$ nonzero entries), and, moreover, it may happen that $\mathbf{c}^* E\mathbf{b} = 0$. In that case the initial shift should be based on heuristics. For two-sided RQI, an obvious choice is to take as the initial vectors $\mathbf{x}_0 = \mathbf{b}$ and $\mathbf{y}_0 = \mathbf{c}$, but similarly, if $\mathbf{y}_0^* E\mathbf{x}_0 = 0$, this fails. Therefore, in the following experiments an initial shift s_0 will be chosen and the (normalized) initial vectors for two-sided RQI are $\mathbf{x}_0 = (A - s_0 E)^{-1}\mathbf{b}$ and $\mathbf{y}_0 = (A - s_0 E)^{-1}\mathbf{c}$; see Algorithm 2.

All experiments were executed in MATLAB 7 [28]. The criterion for convergence was $\|A\mathbf{x}_k - s_{k+1} E\mathbf{x}_k\|_2 < 10^{-8}$.

5.1. Three-dimensional symmetric matrices. Because RQI and DPA are shift and scaling invariant, the region of all 3×3 symmetric matrices can be parametrized by $A = \mathrm{diag}(-1, s, 1)$, with $0 \le s < 1$ due to symmetry (see [19]). In order to compute the regions of convergence of RQI and DPA (as defined in (4.7), (4.8)), the algorithms are applied to A for initial shifts in the range $(-1, 1)\backslash\{s\}$, with $\mathbf{c} = \mathbf{b} = (b_1, b_2, b_3)^T$, where $0 < b_2 \le 1$ and $b_1 = b_3 = \sqrt{(1 - b_2^2)/2}$. In Figure 5.1 the results are shown for $s = 0$ and $s = 0.8$. The intersections $\rho = \rho_{\lambda_1}$ and $\rho = \rho_{\lambda_3}$ at $b_2 = b$ with the borders define the convergence regions: for $-1 \le \rho_0 < \rho_{\lambda_1}$ there is convergence to $\lambda_1 = -1$, for $\rho_{\lambda_1} \le \rho_0 < \rho_{\lambda_3}$ there is convergence to $\lambda_2 = s$, while for $\rho_{\lambda_3} \le \rho_0 \le 1$ there is convergence to $\lambda_3 = 1$.

For the case $s = 0$ it can be observed that (see vertical lines) for $0 \le b_2 \lesssim 0.5$, the convergence region to the dominant extremal eigenvalues is larger for DPA. For $0.5 \lesssim b_2 \le 1/\sqrt{3} \approx 0.577$, the point at which λ_2 becomes dominant, the convergence region of RQI is larger. However, for $b_2 \gtrsim 0.5$, the convergence region of λ_2 is clearly larger for DPA. Note also that the theoretical (lower bound $\alpha_{dpa}\gamma$ of the) local convergence neighborhood for DPA (Theorem 4.3) is even larger than the practical convergence neighborhood of two-sided RQI for $b_2 \gtrsim 0.8$.

A similar observation can be made for the case $s = 0.8$. There, due to the decentralized location of λ_2, the figure is not symmetric and the region of convergence

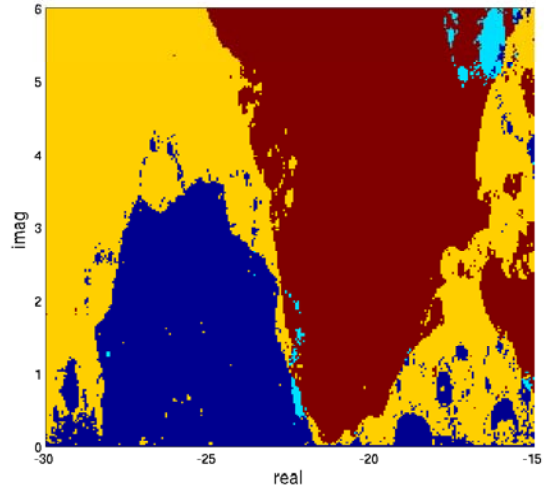

FIG. 5.2. *Convergence regions for DPA and two-sided RQI for the example of section* 5.2. *The center of the domain is the pole* $\lambda \approx -20.5 \pm 1.1i$, *with residue norm* $|R| \approx 6.2 \cdot 10^{-3}$. *Yellow and red points (light-blue and red points) mark initial shifts for which convergence to the target takes place for DPA (two-sided RQI); dark-blue points denote convergence to less dominant poles. Real (imaginary) parts of initial shifts are at the horizontal (vertical) axis. Horizontal and vertical strides are* 15/250 *and* 6/250, *respectively.*

of λ_2 is clearly larger for DPA. For $0 \leq b_2 \lesssim 0.35$, DPA and RQI appear to be very sensitive to the initial shift. While the convergence region for λ_1 was similar to the case $s = 0$, convergence for $-0.1 \lesssim \rho_0 \lesssim 0.8$ was irregular in the sense that for initial shifts in this interval both λ_2 and λ_3 could be computed; hence the regions are shown only for $b_2 \gtrsim 0.35$. Because the theoretical lower bounds are much smaller, since $d = \min_{i \neq j} |\lambda_i - \lambda_j| = 0.2$, and make the figure less clear, they are not shown (the theoretical DPA border still crosses the practical two-sided RQI border around $b_2 \approx 0.9$).

It is almost generic that, apart from a small interval of values of b_2, the area of convergence of the dominant eigenvalue is larger for DPA than for RQI. The following example discusses a large scale general system.

5.2. A large scale example. This example is a test model of the Brazilian Interconnect Power System (BIPS) [23, 22]. The sparse matrices A and E are of dimension $n = 13,251$ and E is singular. The input and output vectors $\mathbf{b}$ and $\mathbf{c}$ have only one nonzero entry, and, furthermore, $\mathbf{c}^T E \mathbf{b} = 0$; the choice $\mathbf{x}_0 = \mathbf{b}$ and $\mathbf{y}_0 = \mathbf{c}$ is not practical; see the beginning of this section. The pencil (A, E) is nonnormal and the most dominant poles appear in complex conjugated pairs. It is not feasible to determine the convergence regions for the entire complex plane, but the convergence behavior in the neighborhood of a dominant pole can be studied by comparing the found poles for a number of initial shifts in the neighborhood of the pole, for both DPA and two-sided RQI (Algorithms 1 and 2). The result is shown in Figure 5.2.

Initial shifts for which DPA and two-sided RQI converge to the target (the most dominant pole $\lambda \approx -20.5 \pm 1.1i$) or its complex conjugate are marked by yellow and red points, and light-blue and red points, respectively. Red grid points denote convergence to the most dominant pole for both DPA and two-sided RQI. Dark-blue grid points denote convergence to a less dominant pole.

In Figure 5.2 the target is the most dominant pole of the system. It can be clearly observed that for DPA the number of initial shifts that converge to the dominant pole (yellow and red points) is larger than for two-sided RQI (light-blue and red points). The basin of attraction of the dominant pole is larger for DPA: except for regions in the neighborhood of other relatively dominant poles (see, for instance, the poles in the interval $(-28, -24)$ on the real axis), there is convergence to the most dominant pole. For DPA typically the size of the basin of attraction increases with the relative dominance of the pole, while for two-sided RQI the effect is less strong; cf. Theorem 4.3, Theorem 4.4, and the discussion in section 4.2. The figure is symmetric with respect to the real axis: if for initial shift s_0, DPA (two-sided RQI) produces the sequence $(\mathbf{x}_k, \mathbf{y}_k, s_{k+1})$ converging to $(\mathbf{v}, \mathbf{w}, \lambda)$, then for $\bar{s}_0$ it produces the sequence $(\bar{\mathbf{x}}_k, \bar{\mathbf{y}}_k, \bar{s}_{k+1})$ converging to $(\bar{\mathbf{v}}, \bar{\mathbf{w}}, \bar{\lambda})$.

It can be seen that for many initial shifts (yellow points) DPA converges to the most dominant pole, but two-sided RQI does not. On the other hand, for a very small number of initial shifts (light-blue points), two-sided RQI converges to the most dominant pole while DPA does not. This is a counterexample for the obvious thought that if two-sided RQI converges to the dominant pole, then DPA also converges to it.

The average number of iterations needed by DPA to converge to the most dominant pole was 7.2, while two-sided RQI needed an average number of 6.0 iterations. The average numbers over the cases where both DPA and two-sided RQI converged to the most dominant pole were 6.1 and 5.9 iterations, respectively.

Similar behavior is observed for other systems and transfer functions. Although the theoretical and experimental results do not provide hard evidence in the sense that they prove that the basin of attraction of the dominant pole is larger for DPA than for two-sided RQI, they at least indicate an advantage of DPA over two-sided RQI.

5.3. PEEC example. The PEEC system [8] is a well-known benchmark system for model order reduction applications. One of the difficulties with this system of order $n = 480$ is that it has many equally dominant poles that lie close to each other in a relatively small part, $[-1, 0] \times [-10i, 10i]$, of the complex plane. This explains why in Figure 5.3 for only a relatively small part of the plane there is convergence (marked by yellow and red, and light-blue and red, for DPA and two-sided RQI, respectively) to the most dominant pole $\lambda \approx -0.14 \pm 5.4i$.

Although the difference is less pronounced than in the previous examples, DPA still converges to the most dominant pole in more cases than two-sided RQI, and the average residue norm of the found poles was also larger: $R_{avg}^{dpa} \approx 5.2 \cdot 10^{-3}$ versus $R_{avg}^{rqi} \approx 4.5 \cdot 10^{-3}$. Again a remarkable observation is that even for some initial shifts very close to another pole, DPA converges to the most dominant pole, while two-sided RQI converges to the nearest pole; e.g., for initial shift $s_0 = 5i$ DPA converges to the most dominant pole $\lambda \approx -0.143 + 5.38i$ with $|R| \approx 7.56 \cdot 10^{-3}$, while two-sided RQI converges to the less dominant pole $\lambda \approx -6.3 \cdot 10^{-3} + 4.99i$ with $|R| \approx 3.90 \cdot 10^{-5}$.

The average number of iterations needed by DPA to converge to the most dominant pole was 9.8, while two-sided RQI needed an average number of 7.9 iterations. The average numbers over the cases where both DPA and two-sided RQI converged to the most dominant pole were 9.4 and 7.7 iterations, respectively.

Another nice observation is the appearance of fractal boundaries, typical for Newton processes.

6. Conclusions. The theoretical and numerical results confirm the intuition, and justify the conclusion, that the dominant pole algorithm (DPA) has better global

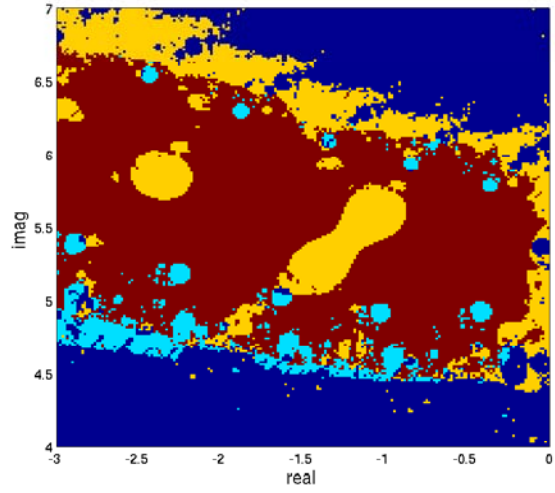

FIG. 5.3. *Convergence regions for DPA and two-sided RQI. The target is the dominant pole* $\lambda \approx -0.14 \pm 5.4i$*, with residue norm* $|R| \approx 7.6 \cdot 10^{-3}$*. Yellow and red points (light-blue and red points) mark initial shifts for which convergence to the target takes place for DPA (two-sided RQI); dark-blue points denote convergence to less dominant poles. Real (imaginary) parts of initial shifts are at the horizontal (vertical) axis. Horizontal and vertical strides are both* 3/200.

convergence than two-sided Rayleigh quotient iteration (RQI) to the dominant poles of a large scale dynamical system. The derived local convergence neighborhoods of dominant poles are larger for DPA, as the poles become more dominant, and numerical experiments indicate that the local basins of attraction of the dominant poles are larger for DPA than for two-sided RQI.

Both DPA and two-sided RQI need to solve two linear systems at every iteration. The difference between DPA and two-sided RQI is that DPA keeps the right-hand sides fixed to the input and output vectors of the system, while two-sided RQI updates the right-hand sides at every iteration. The more dominant a pole is, the bigger the difference in convergence behavior between DPA and two-sided RQI. The other way around, for considerably less dominant poles, the basins of attraction are much smaller for DPA than for two-sided RQI. This could be observed in cases where the initial shift was very close to a less dominant pole and DPA converged to a more dominant pole, while two-sided RQI converged to the nearest, less dominant pole.

The fact that DPA has an asymptotically quadratic rate of convergence, against a cubic rate for two-sided RQI, is of minor importance, since this has only a very local effect and hence leads to a small difference in the number of iterations (typically a difference of 1 or 2 iterations).

Acknowledgments. We are grateful to Nelson Martins for fruitful discussions about DPA [15] and its follow-ups SADPA [23] and SAMDP [22]. He also provided us with the New England and BIPS test systems. We thank Henk van der Vorst for useful comments on earlier versions of this paper and for suggestions that helped us to improve the presentation of the paper. Finally, we are much indebted to the anonymous referees, whose detailed comments and suggestions led to improved readability and presentation of the paper.

COMMENTS ON "JORDAN CANONICAL FORM OF THE GOOGLE MATRIX"*

GANG WU† AND YIMIN WEI‡

Abstract. The Google matrix is a Web hyperlink matrix which is given by $P(\alpha) = \alpha P + (1-\alpha)E$, where P is a row stochastic matrix, E is a row stochastic rank-one matrix, and $0 < \alpha < 1$. In this paper we explore the analytic expression of the Jordan canonical form and point out that a theorem due to Serra-Capizzano (cf. Theorem 2.3 in [*SIAM J. Matrix Anal. Appl.*, 27 (2005), pp. 305–312]) can be used for estimating the condition number of the PageRank vector as a function of α now viewed in the complex field. Furthermore, we give insight into a more efficient scaling matrix in order to minimize the condition number.

Key words. PageRank, Google matrix, Jordan canonical form, condition number

DOI. 10.1137/070682204

1. Preliminaries.

An important problem in Web searches is determining the importance of each page. The major ingredient in determining the order to display Web pages is PageRank [4]. The PageRank vector is the stationary distribution of the Google matrix, a stochastic and irreducible matrix whose dimension can reach 10^9 [1, 7, 11].

Analysis of the PageRank formula provides an interesting topic for the PageRank problem [6, 8, 9, 10]. Recently, Horn and Serra-Capizzano [6] and Serra-Capizzano [8, 9] determined the analytic expression of the Jordan canonical form of the Google matrix. Theorem 2.3 in [8] (see also Theorem 8.2 in [9]) is quoted as follows, which depicts the eigenvalues and invariant subspace of the Google matrix.

THEOREM 1. P n $\alpha \in (0,1)$ $E = ev^H$ n e v n $v_i \geq 0$ $||v||_1 = 1$ $P(\alpha) = \alpha P + (1-\alpha)E$ $P = XJ(1)X^{-1}$ $X = [e, x_2, \ldots, x_n]$, $Y = (X^{-1})^H = [y_1, y_2, \ldots, y_n]$,

$$J(\alpha) = \begin{bmatrix} 1 & & & & \\ & \alpha\lambda_2 & \alpha \cdot * & & \\ & & & & \\ & & & \alpha\lambda_{n-1} & \alpha \cdot * \\ & & & & \alpha\lambda_n \end{bmatrix},$$

(1) $$J(\alpha) = D^{-1} \begin{bmatrix} 1 & & & & \\ & \alpha\lambda_2 & * & & \\ & & \ddots & & \\ & & & \alpha\lambda_{n-1} & * \\ & & & & \alpha\lambda_n \end{bmatrix} D, \ D = \mathrm{diag}(1, \alpha, \ldots, \alpha^{n-1}),$$

(2) $$P(\alpha) = ZJ(\alpha)Z^{-1}, \quad Z = XR^{-1},$$

$$R = I + e_1 w^H, \quad w^H = (0, w_2, \ldots, w_n),$$

$$w_2 = (1-\alpha)v^H x_2/(1-\alpha\lambda_2),$$

$$w_j = \Big[(1-\alpha)v^H x_j + [J(\alpha)]_{j-1,j} w_{j-1}\Big]/(1-\alpha\lambda_j), \qquad j = 3, 4, \ldots, n.$$

We mention that in the original paper by Serra-Capizzano, there is a typo since D and D^{-1} are exchanged in (1). The following corollary due to Serra-Capizzano [8, Corollary 2.4] gives an analytic expression of the PageRank vector.

COROLLARY 2. $[y^J(\alpha)]^H$

(3) $$[y^J(\alpha)]^H = y_1^H + \sum_{j=2}^{n} w_j y_j^H.$$

As was pointed out in [8], a strong challenge posed by formula (3) is the possibility of using vector extrapolation for obtaining the expression of $[y^J(1)]^H$. The idea of the extrapolation procedure is to start from values of $[y^J(\alpha)]^H$ for some different values of α (possibly far from 1), then to compute the unknowns appearing in (3), and finally to compute $[y^J(1)]^H$. This subject is under investigation in [2, 3].

2. On the condition number of the PageRank vector. Recall from (1) and (2) that the PageRank vector $[y^J(\alpha)]^H$ is the first row of the matrix $DZ^{-1} = DRX^{-1}$, that is, $[y^J(\alpha)]^H = e_1^H(DRX^{-1})$. If we denote $W = XR^{-1}D^{-1}$, then formula (3) can be rewritten as

(4) $$[y^J(\alpha)]^H \cdot W = e_1^H.$$

It is well known that the sensitivity of the linear system (4) is closely related to the condition number $\kappa(W)$ of W [5], where

$$\begin{aligned} \kappa(W) &= ||W||\ ||W^{-1}|| \\ &= ||XR^{-1}D^{-1}||\ ||DRX^{-1}|| \\ &\le \kappa(X) \cdot \kappa(DR). \end{aligned}$$

Therefore, W will be ill-conditioned, provided either X or DR is ill-conditioned. We have the following theorem on the conditioning of DR with respect to ∞-norm.

THEOREM 3. [illegible] $D = \mathrm{diag}(1, \alpha, \ldots, \alpha^{n-1})$ [illegible] $0 < \alpha < 1$, [illegible]

$$\kappa_\infty(DR) = \max\Big\{\Big(1 + \sum_{j=2}^{n} |w_j|\Big)\Big(1 + \sum_{j=2}^{n} \frac{|w_j|}{\alpha^{j-1}}\Big),\ \frac{1}{\alpha^{n-1}}\Big(1 + \sum_{j=2}^{n} |w_j|\Big)\Big\}, \tag{5}$$

[illegible]

$$|w_2| = \frac{(1-\alpha)|v^H x_2|}{|1-\alpha\lambda_2|},$$

[illegible]

$$\begin{aligned} |w_j| \le{}& \alpha^{j-2} \cdot \frac{(1-\alpha)|v^H x_2|}{|(1-\alpha\lambda_2)\cdots(1-\alpha\lambda_j)|} + \alpha^{j-3} \cdot \frac{(1-\alpha)|v^H x_3|}{|(1-\alpha\lambda_3)\cdots(1-\alpha\lambda_j)|} \\ &+ \cdots + \frac{(1-\alpha)|v^H x_j|}{|1-\alpha\lambda_j|}, \quad j = 3, 4, \ldots, n. \end{aligned}$$

[illegible] P [illegible]

$$\kappa_\infty(DR) \ge \Big(1 + \sum_{j=2}^{n} \frac{(1-\alpha)|v^H x_j|}{|1-\alpha\lambda_j|}\Big)\ \Big(1 + \sum_{j=2}^{n} \frac{(1-\alpha)\cdot|v^H x_j|}{\alpha^{j-1}\cdot|1-\alpha\lambda_j|}\Big). \tag{6}$$

[illegible]. Since

$$R = \begin{bmatrix} 1 & w_2 & \cdots & w_n \\ & 1 & & \\ & & \ddots & \\ & & & 1 \end{bmatrix},$$

it is easy to verify that

$$R^{-1} = \begin{bmatrix} 1 & -w_2 & \cdots & -w_n \\ & 1 & & \\ & & \ddots & \\ & & & 1 \end{bmatrix}, \qquad DR = \begin{bmatrix} 1 & w_2 & w_3 & \cdots & w_n \\ & \alpha & & & \\ & & \alpha^2 & & \\ & & & \ddots & \\ & & & & \alpha^{n-1} \end{bmatrix},$$

and

$$R^{-1}D^{-1} = \begin{bmatrix} 1 & -w_2/\alpha & -w_3/\alpha^2 & \cdots & -w_n/\alpha^{n-1} \\ & 1/\alpha & & & \\ & & 1/\alpha^2 & & \\ & & & \ddots & \\ & & & & 1/\alpha^{n-1} \end{bmatrix}.$$

Therefore,

$$||DR||_\infty = 1 + \sum_{j=2}^{n} |w_j|, \quad ||R^{-1}D^{-1}||_\infty = \max\Big\{1 + \sum_{j=2}^{n} \frac{|w_j|}{\alpha^{j-1}},\ \frac{1}{\alpha^{n-1}}\Big\},$$

and

$$\begin{aligned}\kappa_\infty(DR) &= ||DR||_\infty ||R^{-1}D^{-1}||_\infty \\ &= \max\Big\{\Big(1+\sum_{j=2}^{n}|w_j|\Big)\Big(1+\sum_{j=2}^{n}\frac{|w_j|}{\alpha^{j-1}}\Big),\ \ \frac{1}{\alpha^{n-1}}\Big(1+\sum_{j=2}^{n}|w_j|\Big)\Big\}.\end{aligned}$$

Recall from Theorem 1 that

$$w_2 = \frac{(1-\alpha)v^H x_2}{1-\alpha\lambda_2}, \qquad w_3 = \frac{(1-\alpha)v^H x_3 + (\alpha\cdot *)w_2}{1-\alpha\lambda_3},$$

where $*$ stands for either 0 or 1. Notice that

$$\begin{aligned}|w_3| &\le \frac{(1-\alpha)|v^H x_3| + \alpha\cdot|w_2|}{|1-\alpha\lambda_3|} \\ &= \alpha\cdot\frac{(1-\alpha)|v^H x_2|}{|(1-\alpha\lambda_2)(1-\alpha\lambda_3)|} + (1-\alpha)\cdot\frac{|v^H x_3|}{|1-\alpha\lambda_3|}.\end{aligned}$$

Inductively, suppose that

$$\begin{aligned}|w_{j-1}| \le \alpha^{j-3}\cdot\frac{(1-\alpha)|v^H x_2|}{|(1-\alpha\lambda_2)\cdots(1-\alpha\lambda_{j-1})|} &+ \alpha^{j-4}\cdot\frac{(1-\alpha)|v^H x_3|}{|(1-\alpha\lambda_3)\cdots(1-\alpha\lambda_{j-1})|} \\ &+\cdots+\frac{(1-\alpha)|v^H x_{j-1}|}{|1-\alpha\lambda_{j-1}|}.\end{aligned}$$

From Theorem 1, we obtain

$$w_j = \big[(1-\alpha)v^H x_j + (\alpha\cdot *)w_{j-1}\big]/(1-\alpha\lambda_j),$$

so

$$\begin{aligned}|w_j| &\le \frac{(1-\alpha)|v^H x_j| + \alpha\cdot|w_{j-1}|}{|1-\alpha\lambda_j|} \\ &\le \alpha^{j-2}\cdot\frac{(1-\alpha)|v^H x_2|}{|(1-\alpha\lambda_2)\cdots(1-\alpha\lambda_j)|} + \alpha^{j-3}\cdot\frac{(1-\alpha)|v^H x_3|}{|(1-\alpha\lambda_3)\cdots(1-\alpha\lambda_j)|} \\ &\quad +\cdots+\alpha\frac{(1-\alpha)|v^H x_{j-1}|}{|(1-\alpha\lambda_{j-1})(1-\alpha\lambda_j)|} + \frac{(1-\alpha)|v^H x_j|}{|1-\alpha\lambda_j|}, \qquad j=3,4,\ldots,n.\end{aligned}$$

Specifically, when P is diagonalizable, it follows from (5) that

$$\kappa_\infty(DR) \ge \Big(1+\sum_{j=2}^{n}|w_j|\Big)\Big(1+\sum_{j=2}^{n}\frac{|w_j|}{\alpha^{j-1}}\Big), \tag{7}$$

and recall from Theorem 2.1 in [8] that

$$|w_j| = \frac{(1-\alpha)|v^H x_j|}{|1-\alpha\lambda_j|}, \qquad j=2,3,\ldots,n, \tag{8}$$

and (6) is obtained from combining (7) and (8). □

Theorem 3 indicates that DR may be ill-conditioned as the number n in (5) and (6) is often very huge, being the total number of Web pages (in millions or billions).

Consequently, W can be ill-conditioned in practice. Actually, one is not recommended to use (3) directly. One reason is that the dimension n is huge, and the expression in (3) is simplified by replacing n with a much smaller value m [3]. Theorem 3 gives another reason: as we have just observed, W may be [illegible] even if X is [illegible] and α is far from 1, which implies that a small change in W can give a dramatic change in the PageRank vector.

However, we would like to point out that the results presented in Theorem 3 are not so strong. In Theorem 1, the matrix D is chosen as $\mathrm{diag}(1, \alpha, \ldots, \alpha^{n-1})$. In fact, the scaling matrix is not unique. For instance, if we choose $\hat{D} = \mathrm{diag}(1, \alpha^{1-n}, \ldots, \alpha^{-1})$, then $DJ(\alpha)D^{-1} = \hat{D}J(\alpha)\hat{D}^{-1}$. So it is interesting to take into account the more efficient scaling matrix D (which is not unique at all) in order to decrease the estimate of the condition number discussed in Theorem 3.

3. How to use clever choices of the scaling matrix. The conditioning for nonnegative α less than one is known to be bounded by $2/(1-\alpha)$ [7]. Therefore the interest of this paper is for α outside the unit cycle (i.e., $\alpha \in \mathcal{C}$ and $|\alpha| > 1$ [6, 9]), and to find interesting results one should use [illegible] of the scaling matrix D that minimizes the condition number. That is, we consider how to define a new matrix $\tilde{D}$ such that

$$\kappa_\infty(\tilde{D}R) = \min_{\substack{D \text{ is diagonal} \\ \text{and nonsingular}}} \kappa_\infty(DR), \tag{9}$$

with the constraint that

$$DJ(\alpha)D^{-1} = \tilde{D}J(\alpha)\tilde{D}^{-1} = \hat{J}, \tag{10}$$

where $\hat{J}$ is the Jordan canonical form of $P(\alpha)$.

However, determining an optimal matrix of minimal conditioning is a very complicated task, and the result is problem dependent. In this paper we give insight into three special cases, and the results extend easily to cover the general case, at the cost of much heavier notation. We assume from now on that $\alpha \in \mathcal{C},\ |\alpha| > 1$, and $1 - \alpha\lambda_j \neq 0$ $(j = 2, 3, \ldots, n)$ so that w_j can be well defined; see Theorem 1. Furthermore, we emphasize that all the analysis given below also applies to the case when $\alpha \in \mathcal{C},\ |\alpha| < 1$.

Let $1, \lambda_2, \ldots, \lambda_n$ be the eigenvalues of P. Then we have from Theorem 1 that the eigenvalues of $P(\alpha)$ are $1, \alpha\lambda_2, \ldots, \alpha\lambda_n$. Suppose that $|\lambda_2| = |\lambda_3| = \cdots = |\lambda_p| = 1$, and $|\lambda_j| < 1,\ j \geq p+1$. It follows from Theorem 8.2 (ii) of [6] (see also Theorem 7.2 (ii) of [9]) that $\alpha\lambda_2, \alpha\lambda_3, \ldots, \alpha\lambda_p$ are (semi)simple eigenvalues of $P(\alpha)$, thus the Jordan canonical form of $P(\alpha)$ takes the form

$$\hat{J} = [1] \oplus [\alpha\lambda_2] \oplus \cdots \oplus [\alpha\lambda_p] \oplus J_{n_1}(\alpha\nu_1) \oplus \cdots \oplus J_{n_k}(\alpha\nu_k) \tag{11}$$

and

$$J(\alpha) = [1] \oplus [\alpha\lambda_2] \oplus \cdots \oplus [\alpha\lambda_p] \oplus \alpha J_{n_1}(\nu_1) \oplus \cdots \oplus \alpha J_{n_k}(\nu_k), \tag{12}$$

where

$$J_{n_i}(\nu_i) = \begin{bmatrix} \nu_i & * & & \\ & \ddots & \ddots & \\ & & \nu_i & * \\ & & & \nu_i \end{bmatrix} \in \mathcal{C}^{n_i \times n_i}, \qquad i = 1, 2, \ldots, k,$$

and $\{\nu_1, \nu_2, \ldots, \nu_k\} \subset \{\lambda_2, \lambda_3, \ldots, \lambda_n\}$.

1. $J_{n_i}(\alpha\nu_i) = \mathrm{diag}(\alpha\nu_i, \ldots, \alpha\nu_i)$, $i = 1, 2, \ldots, k$.

In this case, $P(\alpha)$ is diagonalizable, and for any nonsingular diagonal matrix D there holds $J(\alpha) = D^{-1}\hat{J}D$. We have the following theorem.

THEOREM 4. $P(\alpha)$

$$\tilde{D} = \mathrm{diag}\Big(1,\ 1 + \sum_{j=2}^{n} |w_j|, \ldots, 1 + \sum_{j=2}^{n} |w_j|\Big), \tag{13}$$

$$\kappa_\infty(\tilde{D}R) = 1 + 2\sum_{j=2}^{n} |w_j|. \tag{14}$$

. Without loss of generality, let $D = \mathrm{diag}(1, d_2, \ldots, d_n)$ with $d_j \neq 0$, $j = 2, 3, \ldots, n$. So we have

$$DR = \begin{bmatrix} 1 & w_2 & \cdots & w_n \\ & d_2 & & \\ & & \ddots & \\ & & & d_n \end{bmatrix},$$

and

$$||DR||_\infty = \max\Big\{1 + \sum_{j=2}^{n} |w_j|,\ \max_{2\le j\le n} |d_j|\Big\}.$$

On the other hand,

$$R^{-1}D^{-1} = \begin{bmatrix} 1 & -w_2/d_2 & \cdots & -w_n/d_n \\ & 1/d_2 & & \\ & & \ddots & \\ & & & 1/d_n \end{bmatrix}$$

and

$$||R^{-1}D^{-1}||_\infty = \max\Big\{1 + \sum_{j=2}^{n} |w_j/d_j|,\ \frac{1}{\min_{2\le j\le n} |d_j|}\Big\}.$$

(a) If $\max_{2\le j\le n} |d_j| \le 1 + \sum_{j=2}^{n} |w_j|$, then

$$\kappa_\infty(DR) = \max\left\{\Big(1 + \sum_{j=2}^{n} |w_j|\Big)\Big(1 + \sum_{j=2}^{n} |w_j/d_j|\Big),\ \frac{1 + \sum_{j=2}^{n} |w_j|}{\min_{2\le j\le n} |d_j|}\right\}. \tag{15}$$

So as to minimize the condition number, we have to pick $\min_{2\le j\le n} |d_j|$ as large as possible. As a result, $\min_{2\le j\le n} |d_j| = \max_{2\le j\le n} |d_j| = 1 + \sum_{j=2}^{n} |w_j|$ is a reasonable choice.

(b) If $\max_{2\le j\le n} |d_j| \ge 1 + \sum_{j=2}^{n} |w_j|$, then

$$\kappa_\infty(DR) = \max\left\{\max_{2\le j\le n} |d_j|\Big(1 + \sum_{j=2}^{n} |w_j/d_j|\Big),\ \frac{\max_{2\le j\le n} |d_j|}{\min_{2\le j\le n} |d_j|}\right\}. \tag{16}$$

So as to minimize the condition number, we have to set $\max_{2\le j\le n}|d_j|$ and $\frac{\max_{2\le j\le n}|d_j|}{\min_{2\le j\le n}|d_j|}$ as small as possible. As a result, $\min_{2\le j\le n}|d_j| = \max_{2\le j\le n}|d_j| = 1+\sum_{j=2}^{n}|w_j|$ is a reasonable choice, and (14) is a direct conclusion from (15) or (16). □

2.

$$J_{n_i}(\alpha\nu_i) = \begin{bmatrix} \alpha\nu_i & 1 & & \\ & \ddots & \ddots & \\ & & \alpha\nu_i & 1 \\ & & & \alpha\nu_i \end{bmatrix} \in \mathcal{C}^{n_i\times n_i}, \qquad i = 1,2,\ldots,k.$$

In this case, all the eigenvalues $\alpha\nu_i$ $(i = 1,2,\ldots,k)$ of $P(\alpha)$ are defective, where $\{\nu_1,\nu_2,\ldots,\nu_k\} \subset \{\lambda_{p+1},\lambda_{p+2},\ldots,\lambda_n\}$, and

$$J(\alpha) = \operatorname{diag}(1,\alpha\lambda_2,\ldots,\alpha\lambda_p) \oplus \begin{bmatrix} \alpha\lambda_{p+1} & \alpha & & \\ & \ddots & \ddots & \\ & & \alpha\lambda_{n-1} & \alpha \\ & & & \alpha\lambda_n \end{bmatrix}$$

and

$$\hat{J} = \operatorname{diag}(1,\alpha\lambda_2,\ldots,\alpha\lambda_p) \oplus \begin{bmatrix} \alpha\lambda_{p+1} & 1 & & \\ & \ddots & \ddots & \\ & & \alpha\lambda_{n-1} & 1 \\ & & & \alpha\lambda_n \end{bmatrix}.$$

We consider the scaling matrix of the form $D = \operatorname{diag}(1,\ldots,1,\delta_{p+1},\ldots,\delta_n) \in \mathcal{C}^{n\times n}$. The following lemma gives a necessary and sufficient condition for the matrix D satisfying $J(\alpha) = D^{-1}\hat{J}D$.

LEMMA 5. $D = \operatorname{diag}(1,\ldots,1,\delta_{p+1},\ldots,\delta_n) \in \mathcal{C}^{n\times n}$

$$J(\alpha) = D^{-1}\hat{J}D \Longleftrightarrow \delta_j = \alpha\delta_{j-1}, \qquad j = p+2,p+3,\ldots,n. \tag{17}$$

. Note that $J(\alpha) = D^{-1}\hat{J}D \Longleftrightarrow DJ(\alpha) = \hat{J}D$. On the one hand,

$$D\cdot J(\alpha) = \operatorname{diag}(1,\alpha\lambda_2,\ldots,\alpha\lambda_p) \oplus \begin{bmatrix} \alpha\delta_{p+1}\lambda_{p+1} & \alpha\delta_{p+1} & & \\ & \ddots & \ddots & \\ & & \alpha\delta_{n-1}\lambda_{n-1} & \alpha\delta_{n-1} \\ & & & \alpha\delta_n\lambda_n \end{bmatrix}.$$

On the other hand,

$$\hat{J}\cdot D = \operatorname{diag}(1,\alpha\lambda_2,\ldots,\alpha\lambda_p) \oplus \begin{bmatrix} \alpha\delta_{p+1}\lambda_{p+1} & \delta_{p+2} & & \\ & \ddots & \ddots & \\ & & \alpha\delta_{n-1}\lambda_{n-1} & \delta_n \\ & & & \alpha\delta_n\lambda_n \end{bmatrix},$$

and (17) is obtained trivially by comparing the superdiagonal of the two matrices. □

Therefore, it follows from Lemma 5 that D takes the form

$$D = \mathrm{diag}(1, \ldots, 1, \delta_{p+1}, \alpha\delta_{p+1}, \ldots, \alpha^{n-p-1}\delta_{p+1}), \quad \delta_{p+1} \neq 0, \tag{18}$$

and the problem of defining the optimal matrix $\tilde{D}$ resorts to determining an appropriate value δ_{p+1}.

THEOREM 6. [illegible] (18). [illegible] $\alpha \in \mathcal{C}$, $|\alpha| > 1$, [illegible] $\eta = (1 + \sum_{j=2}^{n} |w_j|)/|\alpha|^{n-p-1}$ [illegible] 2 [illegible]"

[illegible]

$$\tilde{D} = \mathrm{diag}(1, \ldots, 1, \eta, \alpha\eta, \ldots, \alpha^{n-p-1}\eta), \tag{19}$$

[illegible]"

$$\kappa_\infty(\tilde{D}R) = \max\left\{\Big(1 + \sum_{j=2}^{n} |w_j|\Big)\Big(1 + \sum_{j=2}^{p} |w_j|\Big) + \sum_{j=p+1}^{n} |w_j\alpha^{n-j}|, |\alpha|^{n-p-1}\right\}. \tag{20}$$

[illegible]. For any nonsingular matrix $D = \mathrm{diag}(1, \ldots, 1, \ \delta_{p+1}, \ \alpha\delta_{p+1}, \ldots, \alpha^{n-p-1}\delta_{p+1})$, we have

$$DR = \begin{bmatrix} 1 & \cdots & w_p & w_{p+1} & \cdots & w_n \\ & \ddots & & & & \\ & & 1 & & & \\ & & & \delta_{p+1} & & \\ & & & & \ddots & \\ & & & & & \alpha^{n-p-1}\delta_{p+1} \end{bmatrix},$$

which implies

$$||DR||_\infty = \max\left\{1 + \sum_{j=2}^{n} |w_j|, \ |\alpha^{n-p-1}\delta_{p+1}|\right\},$$

since $|\alpha| > 1$. On the other hand,

$$R^{-1}D^{-1} = \begin{bmatrix} 1 & -w_2 & \cdots & -w_p & -w_{p+1}/\delta_{p+1} & \cdots & -w_n/(\alpha^{n-p-1}\delta_{p+1}) \\ & 1 & & & & & \\ & & \ddots & & & & \\ & & & 1 & & & \\ & & & & 1/\delta_{p+1} & & \\ & & & & & \ddots & \\ & & & & & & 1/(\alpha^{n-p-1}\delta_{p+1}) \end{bmatrix}$$

and

$$||R^{-1}D^{-1}||_\infty = \max\left\{1 + \sum_{j=2}^{p} |w_j| + \sum_{j=p+1}^{n} \Big|\frac{w_j}{\alpha^{j-p-1}\delta_{p+1}}\Big|, \ \frac{1}{|\delta_{p+1}|}\right\}.$$

(a) If $|\delta_{p+1}| \leq (1 + \sum_{j=2}^{n} |w_j|)/|\alpha|^{n-p-1}$, then

$$\kappa_\infty(DR) = \max\left\{\Big(1 + \sum_{j=2}^{n} |w_j|\Big)\Big[1 + \sum_{j=2}^{p} |w_j| + \frac{1}{|\delta_{p+1}|}\sum_{j=p+1}^{n} \Big|\frac{w_j}{\alpha^{j-p-1}}\Big|\Big], \right.$$
$$\left. \Big(1 + \sum_{j=2}^{n} |w_j|\Big)\frac{1}{|\delta_{p+1}|}\right\}. \tag{21}$$

In order to minimize the condition number, we have to choose $|\delta_{p+1}|$ as large as possible. Since $|\delta_{p+1}| \le (1+\sum_{j=2}^{n}|w_j|)/|\alpha|^{n-p-1}$, we can choose $|\delta_{p+1}| = (1+\sum_{j=2}^{n}|w_j|)/|\alpha|^{n-p-1} \equiv \eta$.

(b) If $|\delta_{p+1}| \ge (1+\sum_{j=2}^{n}|w_j|)/|\alpha|^{n-p-1}$, then

(22)
$$\kappa_\infty(DR) = \max\left\{|\alpha|^{n-p-1}|\delta_{p+1}|\Big(1+\sum_{j=2}^{p}|w_j|\Big)+\sum_{j=p+1}^{n}|w_j\alpha^{n-j}|,\quad |\alpha|^{n-p-1}\right\}.$$

In order to minimize the condition number, it is desirable to choose $|\delta_{p+1}|$ as small as possible. Since $|\delta_{p+1}| \ge (1+\sum_{j=2}^{n}|w_j|)/|\alpha|^{n-p-1}$, we can choose $|\delta_{p+1}| = (1+\sum_{j=2}^{n}|w_j|)/|\alpha|^{n-p-1} = \eta$. It is easy to see that (20) is a direct result of choosing $|\delta_{p+1}| = (1+\sum_{j=2}^{n}|w_j|)/|\alpha|^{n-p-1}$ in (21) or (22). □

3.

$$J_{n_i}(\alpha\nu_i) = \begin{bmatrix} \alpha\nu_i & 0 & & & \\ & \alpha\nu_i & 1 & & \\ & & \ddots & \ddots & \\ & & & \alpha\nu_i & 1 \\ & & & & \alpha\nu_i \end{bmatrix} \in \mathcal{C}^{n_i\times n_i}, \qquad i = 1,2,\ldots,k.$$

Let $D = \operatorname{diag}(I_p, D_1, \ldots, D_k)$, where I_p is the $p\times p$ identity matrix and

$$D_i = \operatorname{diag}(d_{i_1}, d_{i_2}, \ldots, d_{i_{n_i}}) \in \mathcal{C}^{n_i\times n_i}, \qquad i = 1,2,\ldots,k,$$

are nonsingular matrices. Similar to the proof in Case 2, we have

$$D\cdot J(\alpha) = \hat{J}\cdot D \Leftrightarrow D_i\cdot \alpha J_{n_i}(\nu_i) = J_{n_i}(\alpha\nu_i)\cdot D_i \Leftrightarrow d_{i_3} = \alpha d_{i_2}, \ldots, d_{i_{n_i}} = \alpha d_{i_{n_i-1}},$$
$$i = 1,2,\ldots,k,$$

so D takes the form

(23) $$D = I_p \oplus \operatorname{diag}(1, d_{1_2}, \ldots, \alpha^{n_1-2}d_{1_{n_1}}) \oplus \cdots \oplus \operatorname{diag}(1, d_{k_2}, \ldots, \alpha^{n_k-2}d_{k_{n_k}}).$$

For simplicity, we consider D_i of the form $D_i = \operatorname{diag}(1, \delta, \alpha\delta, \ldots, \alpha^{n_i-2}\delta)$, $i = 1,2,\ldots,k$. Consequently,

(24) $$D = I_p \oplus \operatorname{diag}(1,\delta,\ldots,\alpha^{n_1-2}\delta) \oplus \cdots \oplus \operatorname{diag}(1,\delta,\ldots,\alpha^{n_k-2}\delta), \quad \delta \ne 0.$$

Partition the first row of R^{-1} conformably with D

$$[1, -w_2, \ldots, -w_n] = \big[U_p, V_1, \ldots, V_k\big],$$

where $U_p = [1, -w_2, \ldots, -w_p]$, $V_i \equiv [\tilde{w}_{i_1}, \ldots, \tilde{w}_{i_{n_i}}] \in \mathcal{C}^{n_i}$, and $\{\tilde{w}_{i_{n_1}}, \ldots, \tilde{w}_{i_{n_i}}\} \subset \{-w_{p+1}, \ldots, -w_n\}$, $i = 1,2,\ldots,k$. We have the following theorem.

THEOREM 7. [illegible] (24) [illegible] $\alpha \in \mathcal{C}$, $|\alpha| > 1$, [illegible] $n_q = \max_{1\le i\le k}\{n_i\}$ [illegible] $\mu = (1+\sum_{j=2}^{n}|w_j|)/|\alpha|^{n_q-2}$ [illegible] 3 [illegible]

(25) $$\tilde{D} = I_p \oplus \operatorname{diag}(1,\mu,\alpha\mu,\ldots,\alpha^{n_1-2}\mu) \oplus \cdots \oplus \operatorname{diag}(1,\mu,\alpha\mu,\ldots,\alpha^{n_k-2}\mu),$$

(26)

$$\kappa_\infty(\tilde{D}R) = \max\left\{\left(1+\sum_{j=2}^{n}|w_j|\right)\left(1+\sum_{j=2}^{p}|w_j|+\sum_{i=1}^{k}|\tilde{w}_{i_1}|\right)+|\alpha|^{n_q-2}\Delta,\quad |\alpha|^{n_q-2}\right\},$$

$\Delta = \sum_{i=1}^{k}\left(|\tilde{w}_{i_2}|+|\tilde{w}_{i_3}|/|\alpha|+\cdots+|\tilde{w}_{i_{n_i}}|/|\alpha|^{n_i-2}\right)$

. For any matrix D that takes the form (24), we have

$$DR = \begin{bmatrix} 1 & w_2 & \cdots & w_p & \cdots & \cdots & w_n \\ & 1 & & & & & \\ & & \ddots & & & & \\ & & & 1 & & & \\ & & & & D_1 & & \\ & & & & & \ddots & \\ & & & & & & D_k \end{bmatrix}$$

and

$$||DR||_\infty = \max\left\{1+\sum_{i=2}^{n}|w_i|,\ \ |\alpha|^{n_q-2}|\delta|\right\},$$

where $n_q = \max_{1\le i\le k}\{n_i\}$. It is easy to verify that

$$R^{-1}D^{-1} = \begin{bmatrix} 1 & -w_2 & \cdots & -w_p & V_1D_1^{-1} & \cdots & V_kD_k^{-1} \\ & 1 & & & & & \\ & & \ddots & & & & \\ & & & 1 & & & \\ & & & & D_1^{-1} & & \\ & & & & & \ddots & \\ & & & & & & D_k^{-1} \end{bmatrix},$$

so we get

$$||R^{-1}D^{-1}||_\infty = \max\left\{||U_p||_1+\sum_{i=1}^{k}||V_iD_i^{-1}||_1,\ \frac{1}{|\delta|}\right\}.$$

Note that

$$V_iD_i^{-1} = \left[\tilde{w}_{i_1}, \tilde{w}_{i_2}/\delta, \ldots, \tilde{w}_{i_{n_i}}/(\alpha^{n_i-2}\delta)\right]$$

and

$$||V_iD_i^{-1}||_1 = |\tilde{w}_{i_1}|+\frac{1}{|\delta|}\left(|\tilde{w}_{i_2}|+|\tilde{w}_{i_3}|/|\alpha|+\cdots+|\tilde{w}_{i_{n_i}}|/|\alpha|^{n_i-2}\right),\qquad i=1,2,\ldots,k.$$

Therefore,

$$\sum_{i=1}^{k}||V_iD_i^{-1}||_1 = \sum_{i=1}^{k}|\tilde{w}_{i_1}|+\frac{1}{|\delta|}\sum_{i=1}^{k}\left(|\tilde{w}_{i_2}|+|\tilde{w}_{i_3}|/|\alpha|+\cdots+|\tilde{w}_{i_{n_i}}|/|\alpha|^{n_i-2}\right).$$

(a) If $|\delta| \le (1+\sum_{j=2}^{n}|w_j|)/|\alpha|^{n_q-2}$, then

$$\kappa_\infty(DR) = \Big(1+\sum_{j=2}^{n}|w_j|\Big)\max\Big\{||U_p||_1+\sum_{i=1}^{k}||V_iD_i^{-1}||_1,\ \frac{1}{|\delta|}\Big\}. \tag{27}$$

In order to minimize the condition number, we have to choose $|\delta|$ as large as possible. Since $|\delta| \le (1+\sum_{j=2}^{n}|w_j|)/|\alpha|^{n_q-2}$, we can choose $|\delta| = (1+\sum_{j=2}^{n}|w_j|)/|\alpha|^{n_q-2} \equiv \mu$.

(b) If $|\delta| \ge (1+\sum_{j=2}^{n}|w_j|)/|\alpha|^{n_q-2}$, then

$$\kappa_\infty(DR) = \max\Big\{|\alpha^{n_q-2}\delta|\Big(||U_p||_1+\sum_{i=1}^{k}||V_iD_i^{-1}||_1\Big),\ |\alpha|^{n_q-2}\Big\}. \tag{28}$$

In order to minimize the condition number, it is desirable to choose $|\delta|$ as small as possible. Since $|\delta| \ge (1+\sum_{j=2}^{n}|w_j|)/|\alpha|^{n_q-2}$, we can choose $|\delta| = (1+\sum_{j=2}^{n}|w_j|)/|\alpha|^{n_q-2} = \mu$, and (26) is a direct conclusion from (27) or (28). □

In [9], Serra-Capizzano proposed that the "optimal" diagonal matrix of minimal conditioning can be chosen as

$$\breve{D} = I_p \oplus \mathrm{diag}(1,\alpha,\dots,\alpha^{n_1-1}) \oplus \cdots \oplus \mathrm{diag}(1,\alpha,\dots,\alpha^{n_k-1}),$$

which is obviously different from ours since the diagonal elements of the two matrices are different; see (25). Moreover, it seems that our choice is more general.

Acknowledgments. The authors would like to express their sincere thanks to Prof. R. Horn and Prof. S. Serra-Capizzano for their preprints [6, 9] and for many stimulating discussions, and to Prof. D. O'Leary for her insightful suggestions on the previous version of the manuscript.

THE METRIC NEARNESS PROBLEM*

JUSTIN BRICKELL†, INDERJIT S. DHILLON†, SUVRIT SRA†, AND JOEL A. TROPP‡

Abstract. Metric nearness refers to the problem of optimally restoring metric properties to distance measurements that happen to be nonmetric due to measurement errors or otherwise. Metric data can be important in various settings, for example, in clustering, classification, metric-based indexing, query processing, and graph theoretic approximation algorithms. This paper formulates and solves the *metric nearness problem*: Given a set of pairwise dissimilarities, find a "nearest" set of distances that satisfy the properties of a metric—principally the triangle inequality. For solving this problem, the paper develops efficient *triangle fixing* algorithms that are based on an iterative projection method. An intriguing aspect of the metric nearness problem is that a special case turns out to be equivalent to the all pairs shortest paths problem. The paper exploits this equivalence and develops a new algorithm for the latter problem using a primal-dual method. Applications to graph clustering are provided as an illustration. We include experiments that demonstrate the computational superiority of triangle fixing over general purpose convex programming software. Finally, we conclude by suggesting various useful extensions and generalizations to metric nearness.

Key words. matrix nearness problems, metric, distance matrix, metric nearness, all pairs shortest paths, triangle inequality

1. Introduction.

Most applications make some assumptions about the properties that the input data should satisfy. Due to measurement errors, noise, or an inability to gather data completely, an application may receive data that does not conform to its requirements. For example, imagine taking measurements as a part of some experiment. The theory suggests that the quantities measured should represent distance values amongst points in a discrete metric space. However, measurements being what they are, one ends up with a set of numbers that do not represent actual distance values, primarily because they fail to satisfy the triangle inequality. It might be beneficial to somehow optimally massage the measurements to obtain a set of "nearest" distance values that obey the properties of a metric.

It could also happen that experimental expenses and difficulties prevent one from making all the measurements. Before this incomplete set of measurements can be used in an application it might need to be tweaked, preferably minimally. As before, obtaining a "nearest" set of distance values (measurements) seems to be desirable.

Both scenarios above lead to the [illegible] : Given a set of input distances, find a "nearest" set of output distances that satisfy the properties of a metric. The notion of nearness is quantified by the function that measures distortion between the input and output distances.

Matrix nearness problems [10] offer a natural framework for pursuing the above-mentioned ideas. If there are n points, we may collect the measurements into an

$n \times n$ symmetric matrix whose (j, k) entry represents the distance between points j and k. Then we seek to approximate this matrix by another (say $\boldsymbol{M}$) whose entries satisfy the triangle inequalities. That is, $m_{ij} \leq m_{ik} + m_{kj}$ for every triple (i, k, j). Any such matrix will represent the distances among n points in some metric space. We calculate approximation error with a distortion measure that depends on how the corrected matrix should relate to the input matrix. For example, one might prefer to change a few entries significantly or to change all the entries a little. This paper considers metric nearness problems that use vector norms for characterizing distortion.

There is no analytic solution to the metric nearness problem. Fortunately this problem lends itself to a convex formulation, whereby developing algorithms for solving it becomes much easier. However, despite the natural convexity of the formulations, the large number of triangle inequality constraints can make traditional approaches or general purpose convex programming software much too slow. This paper provides solutions to the metric nearness problem that exploit its inherent structure for efficiency gains.

The remainder of this paper is structured as follows. Section 1.1 highlights the principal contributions of this paper. Section 2 develops a convex formulation of the metric nearness problem. Following that, section 3 provides efficient triangle fixing algorithms for solving the metric nearness problems described in section 2. An interesting connection of metric nearness with the all pairs shortest paths (APSP) problem is studied in section 4. This connection leads to a curious new primal-dual algorithm for APSP (Algorithm 4.1).

Applications of metric nearness to clustering are discussed in section 5. Experiments highlighting running time studies and comparisons against the CPLEX software are given in section 6.1, whereas experiments illustrating the behavior of the primal-dual metric nearness algorithm are the subject of section 6.2.

Section 7.1 discusses some variations to the metric nearness problem that may also be studied. Section 7.2 describes possible future work and extensions to this paper, while two open problems are mentioned in section 7.3. Finally, section 7.4 summarizes related work and concludes this paper.

1.1. Contributions of this paper. In preliminary work [7], the authors presented the basic ideas about convex formulations of metric nearness and [illegible] algorithms. However, many of the details necessary for understanding and actually implementing the triangle fixing algorithms were missing. This paper fills that gap by presenting a detailed derivation for ℓ_1 (consequently ℓ_∞) and ℓ_2 norm–based metric nearness problems. Pseudocode for both the ℓ_1 and ℓ_2 problems is given along with the derivations.

When one allows only decreasing changes to the input, then metric nearness becomes equivalent to the APSP problem [22]. This paper studies this decrease-only version of metric nearness, and consequently obtains a new primal-dual algorithm for solving the APSP problem. This algorithm possesses some interesting characteristics related to its convergence behavior that are discussed in this paper.

The paper discusses applications to the Max-Cut problem. We also developed efficient C++ code for metric nearness that outperforms CPLEX by factors of up to 30, and it may be requested from the authors.

2. Problem formulation. We begin our formulation with a few basic definitions. We define a [illegible] to be a symmetric, nonnegative matrix with a zero diagonal. Such matrices are used to represent pairwise proximity data between objects of a certain type. A [illegible] is defined to be a dissimilarity matrix

whose entries satisfy the triangle inequalities. Specifically, $\boldsymbol{M}$ is a distance matrix if

$$m_{ij} \geq 0, \qquad m_{ii} = 0, \quad m_{ij} = m_{ji},$$

and

$$m_{ij} \leq m_{ik} + m_{kj} \quad \text{for distinct triples } (i, k, j).$$

We remark that symmetry, while part of the definition of a metric, is not crucial to our algorithms; asymmetry can be handled at the expense of doubling the running time and storage.

The distance matrices studied in this paper are assumed to arise from measuring interpoint distances between n points in a pseudometric space (i.e., two distinct points can lie at zero distance from each other). Consequently, distance matrices contain $N = \binom{n}{2}$ parameters, and we denote the set of all $n \times n$ distance matrices by $\mathscr{M}_N$. We observe that the set $\mathscr{M}_N$ is a closed, convex polyhedral cone.

Assume that the input is a dissimilarity matrix $\boldsymbol{D}$. Metric nearness seeks a distance matrix $\boldsymbol{M}$ that is closest to $\boldsymbol{D}$, with respect to some measure of "closeness." Formally, we seek a matrix $\boldsymbol{M}$ so that

$$\boldsymbol{M} \in \operatorname*{argmin}_{\boldsymbol{X} \in \mathscr{M}_N} \|\boldsymbol{X} - \boldsymbol{D}\|, \tag{2.1}$$

where $\|\cdot\|$ is a norm. Though it is possible to use any norm in the metric nearness problem (2.1), we restrict our attention to the ℓ_p norms, wherein we treat the strict upper triangular part of our matrices as vectors.

THEOREM 2.1 (attainment of minimum). [illegible] $f(\boldsymbol{X}) = \|\boldsymbol{X} - \boldsymbol{D}\|$ [illegible] $\mathscr{M}_N$ [illegible]

[illegible]. The latter claim follows immediately from the convexity of f. It remains to show that $f(\boldsymbol{X})$ always attains its minimum on the cone $\mathscr{M}_N$. For convenience, we pass to the function $g(\boldsymbol{Y}) = \|\boldsymbol{Y}\|$. Notice that if g attains a minimum on $\mathscr{M}_N - \boldsymbol{D}$, then $f(\boldsymbol{X})$ attains a minimum on $\mathscr{M}_N$. The function g is a closed convex function, and it is homogeneous of degree one, so we can compute its recession function as

$$(g0^+)(\boldsymbol{Y}) = \lim_{h \to 0} (g(h\,\boldsymbol{Y}) - g(\boldsymbol{0}))/h = \lim_{h \to 0} g(h\,\boldsymbol{Y})/h = g(\boldsymbol{Y}).$$

But g is nonnegative, so its only directions of recession are directions in which it is constant. Since $\mathscr{M}_N - \boldsymbol{D}$ is a closed, [illegible] cone, we may apply [23, Theorem 27.3] to conclude that g attains a minimum on this cone, whereby f attains its minimum on $\mathscr{M}_N$. □

2.1. Metric nearness for the ℓ_2 norm. We start with a formulation for the vector ℓ_2 norm–based metric nearness problem. Given the input dissimilarity matrix $\boldsymbol{D} = [d_{ij}]$ (where $d_{ij} = d_{ji}$), we wish to obtain a distance matrix $\boldsymbol{X}$ that minimizes the squared error

$$\frac{1}{2} \sum_{i<j} (x_{ij} - d_{ij})^2.$$

Note that the sum above ranges over $i < j$, since the involved matrices are symmetric and have a zero diagonal.

Let T_n be the set of $3\binom{n}{3}$ triples, each of which corresponds to a triangle inequality that the entries of an $n \times n$ distance matrix must satisfy. Formally,

$$T_n = \{(i,j,k),(j,k,i),(k,i,j) : 1 \le i < k < j \le n\}, \tag{2.2}$$

where the triple (i,k,j) corresponds to the triangle inequality

$$x_{ij} \le x_{ik} + x_{kj}.$$

With the introduction of an auxiliary matrix $\boldsymbol{E} = \boldsymbol{X} - \boldsymbol{D}$ that represents the changes to the original dissimilarities, the ℓ_2 metric nearness problem can be rewritten as the following quadratic program:

$$\underset{e_{ij}}{\text{minimize}} \ \frac{1}{2}\sum_{i<j} e_{ij}^2 \tag{2.3}$$

$$\text{subject to} \ \ e_{ij} - e_{ik} - e_{kj} \le d_{ik} + d_{kj} - d_{ij} = v_{ikj} \quad \text{for all } (i,k,j) \in T_n. \tag{2.4}$$

The triangle inequality constraints are encoded by (2.4). Since the ℓ_2 norm is strictly convex, the solution to (2.3) is unique. The variable v_{ikj} quantifies the violation in the (i,k,j) triangle inequality. Note that nonnegativity of x_{ij} need not be enforced explicitly as it is implied by the triangle inequalities.

2.2. Metric nearness for the ℓ_1 and ℓ_∞ norms. When measuring approximation error using the ℓ_1 norm, we wish to minimize

$$\sum_{i<j} |e_{ij}|, \tag{2.5}$$

where $e_{ij} = x_{ij} - d_{ij}$ as in the previous section. However, to write the problem as a linear program, we need to introduce additional variables $f_{ij} = |e_{ij}|$. The resulting problem is the following linear program:

$$\underset{e_{ij}, f_{ij}}{\text{minimize}} \ \ \sum_{i<j} \big(1 \cdot f_{ij} + 0 \cdot e_{ij}\big) \tag{2.6}$$

$$\begin{aligned} \text{subject to} \quad & e_{ij} - e_{ik} - e_{kj} \le v_{ikj} && \text{for all } (i,k,j) \in T_n, \\ & -e_{ij} - f_{ij} \le 0, && 1 \le i < j \le n, \\ & e_{ij} - f_{ij} \le 0, && 1 \le i < j \le n. \end{aligned} \tag{2.7}$$

The fact that $f_{ij} = |e_{ij}|$ is accomplished by the last two sets of inequalities in (2.7).

Similarly, for the ℓ_∞ nearness problem, we introduce a variable $\zeta = \max_{ij} |e_{ij}|$ that represents the vector ℓ_∞ norm of $\boldsymbol{E}$. The ℓ_∞ nearness problem becomes

$$\underset{e_{ij}, \zeta}{\text{minimize}} \ \ \zeta + \sum_{i<j} 0 \cdot e_{ij} \tag{2.8}$$

$$\begin{aligned} \text{subject to} \quad & e_{ij} - e_{ik} - e_{kj} \le v_{ikj} && \text{for all } (i,k,j) \in T_n, \\ & -e_{ij} - \zeta \le 0, && 1 \le i < j \le n, \\ & e_{ij} - \zeta \le 0, && 1 \le i < j \le n. \end{aligned} \tag{2.9}$$

The last two sets of inequalities in (2.9) express the fact $|e_{ij}| \le \zeta$ for all i and j.

2.3. Metric nearness for ℓ_p norms. Metric nearness may be easily formulated for ℓ_p norms, where $1 < p < \infty$. The problem is the following convex program:

$$\begin{aligned} &\underset{e_{ij}}{\text{minimize}} \quad \frac{1}{p}\sum_{i<j} |e_{ij}|^p \\ &\text{subject to} \quad e_{ij} - e_{ik} - e_{kj} \le v_{ikj} \quad \text{for all } (i,k,j) \in T_n. \end{aligned}$$

Since the ℓ_p norms are strictly convex for $1 < p < \infty$, the associated metric nearness problems have unique solutions. There is a basic intuition for choosing p when solving the nearness problems. The ℓ_1 norm error is computed as the absolute sum of changes to the input matrix, while ℓ_∞ reflects only the maximum absolute change. The other ℓ_p norms interpolate between these two extremes. Thus, a small value of p typically results in a solution that prefers a few large changes to the original data, while a large p typically results in a solution with many small changes. In practice, however, the ℓ_1, ℓ_2, and ℓ_∞ problems are computationally easier to solve than those using arbitrary ℓ_p norms. Thus, we focus primarily on these three problems.

3. Triangle fixing algorithms. The previous section formulated the metric nearness problem as a quadratic program for the ℓ_2 norm, as a linear program for ℓ_1 and ℓ_∞ norms, and as a convex program for ℓ_p norms. Using off-the-shelf software for these formulations might appear to be an attractive way to solve the corresponding problems. However, it turns out that the computational time and storage requirements of such an approach can be prohibitive. An efficient algorithm must exploit the inherent structure offered by the triangle inequalities. In this section, we develop [illegible], which take advantage of this structure to efficiently solve the problem for ℓ_p norms. These algorithms iterate through the triangle inequalities, optimally enforcing any inequality that is not satisfied. While enforcing the triangle inequalities, one needs to introduce appropriate correction terms to guide the iterative algorithm to the globally optimal solution. The details are provided below.

3.1. Triangle fixing for ℓ_2 metric nearness. Our approach for solving (2.3) is iterative, and is based on the technique described in [2]. Collecting all the e_{ij} values into vector $\boldsymbol{e}$ and the violation amounts v_{ijk} into $\boldsymbol{v}$, problem (2.3) may be rewritten as

$$\begin{aligned} &\min_{\boldsymbol{e}} \quad \frac{1}{2}\boldsymbol{e}^T\boldsymbol{e} \\ &\text{subject to} \quad \boldsymbol{A}\boldsymbol{e} \le \boldsymbol{v}, \end{aligned} \tag{3.1}$$

where matrix $\boldsymbol{A}$ encodes the triangle inequalities (2.4), whereby each row of $\boldsymbol{A}$ has one $+1$ entry and two -1 entries.

The Lagrangian of (3.1) is

$$L(\boldsymbol{e}, \boldsymbol{z}) = \frac{1}{2}\boldsymbol{e}^T\boldsymbol{e} + \langle \boldsymbol{z}, \boldsymbol{A}\boldsymbol{e} - \boldsymbol{v}\rangle,$$

where $\boldsymbol{z}$ is the dual vector. A necessary condition for optimality of (3.1) is

$$\frac{\partial L}{\partial \boldsymbol{e}} = 0 \quad \Longrightarrow \quad \boldsymbol{e} = -\boldsymbol{A}^T\boldsymbol{z}, \quad \boldsymbol{z} \ge \boldsymbol{0}. \tag{3.2}$$

Using (3.2) we see that the dual problem corresponding to (3.1) is

$$\max_{\boldsymbol{z}\ge\boldsymbol{0}} \quad g(\boldsymbol{z}) = -\frac{1}{2}\boldsymbol{z}^T\boldsymbol{A}\boldsymbol{A}^T\boldsymbol{z} - \boldsymbol{z}^T\boldsymbol{v}. \tag{3.3}$$

Algorithm 3.1. Metric nearness for ℓ_2 norm.

METRIC_NEARNESS_L2($\boldsymbol{D}$, κ)
Input: Dissimilarity matrix $\boldsymbol{D}$, tolerance κ
Output: $\boldsymbol{M} = \operatorname{argmin}_{\mathrm{X} \in \mathscr{M}_N} \|\boldsymbol{X} - \boldsymbol{D}\|_2$.
{Initialize the primal and the dual variables}
$e_{ij} \leftarrow 0$ for $1 \le i < j \le n$
$(z_{ijk}, z_{jki}, z_{kij}) \leftarrow 0$ for $1 \le i < k < j \le n$
$\delta \leftarrow 1 + \kappa$
while $(\delta > \kappa)$ {convergence test}
  foreach triangle inequality (i, k, j)
    $v \leftarrow d_{ik} + d_{kj} - d_{ij}$ {Compute violation}
    $\theta^* \leftarrow \frac{1}{3}(e_{ij} - e_{ik} - e_{kj} - v)$ $(\star)$
    $\theta \leftarrow \max\{\theta^*, -z_{ikj}\}$ {Stay within half-space of constraint}
    $e_{ij} \leftarrow e_{ij} - \theta$, $e_{ik} \leftarrow e_{ik} + \theta$, $e_{kj} \leftarrow e_{kj} + \theta$ $(\star\star)$
    $z_{ikj} \leftarrow z_{ikj} + \theta$ {Update dual variable}
  end *foreach*
  $\delta \leftarrow$ sum of changes in the e_{ij} values
end *while*
return $\boldsymbol{M} = \boldsymbol{D} + \boldsymbol{E}$

We solve (3.1) iteratively, wherein we initialize both $\boldsymbol{e}$ and $\boldsymbol{z}$ to zero as this choice satisfies (3.2). At each subsequent iteration we update the dual vector $\boldsymbol{z}$ one coordinate at a time, thereby resulting in a [illegible] procedure, while maintaining (3.2). Assume that the dual variable corresponding to inequality (i, k, j) is updated, i.e., $z'_{ikj} = z_{ikj} + \theta$. Then the corresponding update to the primal is obtained via (3.2), i.e., $\boldsymbol{e}' = \boldsymbol{e} - \theta \boldsymbol{a}_{ikj}$ (using the fact that $\boldsymbol{e}' = -\boldsymbol{A}^T \boldsymbol{z}'$), where $\boldsymbol{a}_{ikj}$ is the column vector containing the entries of the (i, j, k) [illegible] of $\boldsymbol{A}$. Recall that $\boldsymbol{a}_{ikj}$ has only three nonzero entries corresponding to the edges (i, j), (i, k), and (k, j). Thus, the update to $\boldsymbol{e}$ amounts to "fixing" (enforcing) one triangle inequality at a time, hence the name of our procedure. The parameter θ is computed by solving

$$\begin{aligned} \max_{\theta} \quad & g(\boldsymbol{z} + \theta \mathbf{1}_{ikj}) \\ \text{subject to} \quad & z_{ikj} + \theta \ge 0, \end{aligned} \tag{3.4}$$

where $\mathbf{1}_{ikj}$ indicates the standard basis vector that is zero in all positions except the ikj entry, which equals unity. Using (3.2) and (3.3), we may rewrite (3.4) as

$$\begin{aligned} \max_{\theta} \quad & g(\boldsymbol{z}) - \frac{1}{2}\|\boldsymbol{a}_{ikj}\|^2 \theta^2 + (\boldsymbol{a}_{ikj}^T \boldsymbol{e} - v_{ikj})\theta \\ \text{subject to} \quad & \theta \ge -z_{ikj}. \end{aligned} \tag{3.5}$$

Consider optimizing (3.5) in an unconstrained manner. It is easily seen that

$$\theta^* = \frac{1}{\|\boldsymbol{a}_{ikj}\|^2}(\boldsymbol{a}_{ikj}^T \boldsymbol{e} - v_{ikj}) = \frac{1}{3}(\boldsymbol{a}_{ikj}^T \boldsymbol{e} - v_{ikj}) \tag{3.6}$$

is the maximum. If $\theta^* \ge -z_{ikj}$, we are done; otherwise the maximum of (3.5) will be achieved at $\theta = -z_{ikj}$. Thus, we obtain $\theta = \max\{\theta^*, -z_{ikj}\}$ as the answer to (3.5). Algorithm 3.1 puts together all these ideas to give the complete iterative triangle fixing procedure.

The procedure derived above ensures that at each iteration $g(\boldsymbol{z}') \geq g(\boldsymbol{z})$, i.e., it is a [illegible] procedure. Following [2], it can be shown that in the limit, the $\boldsymbol{A}\boldsymbol{e} \leq \boldsymbol{v}$ constraints are satisfied. Since (3.2) is also maintained at each step, the KKT conditions, which are necessary and sufficient for this problem, are satisfied in the limit. Thus, the triangle fixing procedure converges to the optimal solution of (3.1). In fact, Algorithm 3.1 is an efficient version of Bregman's method for minimizing a convex function subject to linear inequality constraints [2]. Our algorithm exploits the structure of the problem to obtain its efficiency.

3.2. Triangle fixing for ℓ_1 and ℓ_∞. Triangle fixing is somewhat less direct for the ℓ_1 and ℓ_∞ problems. The reason these norms pose an additional challenge is because they are not strictly convex; the convergence of the basic triangle fixing procedure depends on the strict convexity of the norm used. We illustrate only the ℓ_1 case; the development for ℓ_∞ takes the same course.

With the introduction of vector and matrix notation, the ℓ_1 matrix nearness problem may be rewritten as

$$\begin{aligned} &\min_{\boldsymbol{e},\boldsymbol{f}} \ \mathbf{0}^T\boldsymbol{e} + \mathbf{1}^T\boldsymbol{f} \\ &\text{subject to } \ \boldsymbol{A}\boldsymbol{e} \leq \boldsymbol{v}, \quad -\boldsymbol{e} - \boldsymbol{f} \leq \mathbf{0}, \quad \boldsymbol{e} - \boldsymbol{f} \leq \mathbf{0}. \end{aligned} \tag{3.7}$$

The auxiliary variable $\boldsymbol{f}$ is interpreted as the elementwise absolute value of $\boldsymbol{e}$. The violations to the triangle inequalities are again given by the vector $\boldsymbol{v}$.

To solve the linear program (3.7) without sacrificing the advantages of triangle fixing we replace it with an equivalent quadratic program. This replacement hinges upon a connection between linear and quadratic programs that may be motivated by the observation

$$\operatorname{argmin}_{\boldsymbol{g}} \|\boldsymbol{g} + \epsilon^{-1}\boldsymbol{c}\|^2 = \operatorname{argmin}_{\boldsymbol{g}} \ (\boldsymbol{g}^T\boldsymbol{g} + 2\epsilon^{-1}\boldsymbol{g}^T\boldsymbol{c} + \epsilon^{-2}\boldsymbol{c}^T\boldsymbol{c}) \approx \operatorname{argmin}_{\boldsymbol{g}} \ \boldsymbol{g}^T\boldsymbol{c}$$

if ϵ is chosen to be sufficiently small (so that the $2\epsilon^{-1}\boldsymbol{g}^T\boldsymbol{c}$ term dominates the objective function). The following theorem, which follows from a result of [17, Theorem 2.1-a-i], makes the above connection concrete.

THEOREM 3.1 (ℓ_1 metric nearness). [illegible] $\boldsymbol{g} = [\boldsymbol{e}; \boldsymbol{f}]$ [illegible] $\boldsymbol{c} = [\mathbf{0}; \mathbf{1}]$ [illegible] (3.7) [illegible] $\epsilon_0 > 0$ [illegible] $\epsilon \leq \epsilon_0$.

$$\operatorname*{argmin}_{\boldsymbol{g} \in G} \ \|\boldsymbol{g} + \epsilon^{-1}\boldsymbol{c}\|_2 = \operatorname*{argmin}_{\boldsymbol{g} \in G^\star} \ \|\boldsymbol{g}\|_2, \tag{3.8}$$

[illegible] G [illegible] (3.7) [illegible] $G^\star$ [illegible] (3.7) [illegible] (3.8).

From (3.7) one can see that the triangle inequality constraints involve only $\boldsymbol{e}$ and not $\boldsymbol{f}$. This circumstance permits us to use triangle fixing once again. As before, we go through the constraints one by one. The first $3\binom{n}{3}$ constraints are triangle constraints and are handled by triangle fixing. The remaining $2\binom{n}{2}$ absolute value constraints are very simple and thus are enforced easily.

For the ℓ_2 case, the dual variables (corresponding to each constraint) were represented by the vector $\boldsymbol{z}$. For (3.8), we let the dual variables be $[\boldsymbol{z};\ \boldsymbol{\lambda};\ \boldsymbol{\mu}]$; vector $\boldsymbol{z}$ corresponds to the triangle inequalities, while vectors $\boldsymbol{\lambda}$ and $\boldsymbol{\mu}$ correspond to $-\boldsymbol{e} - \boldsymbol{f} \leq \mathbf{0}$ and $\boldsymbol{e} - \boldsymbol{f} \leq \mathbf{0}$, respectively. Together, nonnegative values of $\boldsymbol{z}$, $\boldsymbol{\lambda}$, and $\boldsymbol{\mu}$ correspond to the feasible set G alluded to by Theorem 3.1.

Algorithm 3.2. Metric nearness for ℓ_1 norm.

METRIC_NEARNESS_L1($\boldsymbol{D}$, ϵ, κ)
Input: Dissimilarity matrix $\boldsymbol{D}$; tolerance κ; ℓ_1 parameter ϵ
Output: $\boldsymbol{M} \in \{\text{argmin}_{\mathrm{X} \in \mathscr{M}_N} \ \|\boldsymbol{X} - \boldsymbol{D}\|_1\}$
{Initialize primal and dual variables}
$e_{ij} \leftarrow 0$; $f_{ij} = -\epsilon^{-1}$ for $1 \le i < j \le n$ {Primal variables}
$(z_{ijk}, z_{jki}, z_{kij}) \leftarrow 0$ for $1 \le i < k < j \le n$ {Dual variables – triangles}
$\lambda_{ij} \leftarrow \pi_{ij} \leftarrow 0$ for $1 \le i < j \le n$ {Dual variables – Other}
$\delta \leftarrow 1 + \kappa$
while $(\delta > \kappa)$ {convergence test}
  Do triangle fixing on the e_{ij} as in Algorithm 3.1
  {Enforce $-\boldsymbol{e} - \boldsymbol{f} \le \boldsymbol{0}$ and $\boldsymbol{e} - \boldsymbol{f} \le \boldsymbol{0}$ as follows}
  $\boldsymbol{\mu} \leftarrow \frac{1}{2}(\boldsymbol{e} + \boldsymbol{f})$ {Projection parameters}
  $\boldsymbol{\theta} \leftarrow \min\{\boldsymbol{\mu}, \boldsymbol{\lambda}\}$ {Update amount}
  $\boldsymbol{\lambda} \leftarrow \boldsymbol{\lambda} - \boldsymbol{\theta}$ {Update dual vector corr. to $-\boldsymbol{e} - \boldsymbol{f} \le \boldsymbol{0}$}
  $\boldsymbol{e} \leftarrow \boldsymbol{e} - \boldsymbol{\theta}$; $\boldsymbol{f} \leftarrow \boldsymbol{f} - \boldsymbol{\theta}$ {Update primal variables}
  $\boldsymbol{\nu} \leftarrow \frac{1}{2}(\boldsymbol{f} - \boldsymbol{e})$
  $\boldsymbol{\theta} \leftarrow \min\{\boldsymbol{\nu}, \boldsymbol{\pi}\}$ {Update amount}
  $\boldsymbol{\pi} \leftarrow \boldsymbol{\pi} - \boldsymbol{\theta}$ {Update dual vector corr. to $\boldsymbol{e} - \boldsymbol{f} \le \boldsymbol{0}$}
  $\boldsymbol{e} \leftarrow \boldsymbol{e} + \boldsymbol{\theta}$; $\boldsymbol{f} \leftarrow \boldsymbol{f} - \boldsymbol{\theta}$ {Update primal variables}
  {Update convergence test parameter}
  $\delta \leftarrow$ sum of absolute changes in e_{ij}.
end.

Our augmented triangle fixing procedure is as follows. First we initialize $\boldsymbol{e}$, $\boldsymbol{f}$, $\boldsymbol{z}$, $\boldsymbol{\lambda}$, and $\boldsymbol{\mu}$ so that the first order optimality conditions derived from (3.8) are initially true. Thereafter, we enforce constraints one by one to ensure that the dual functional corresponding to (3.8) is increasing and that first order optimality conditions are maintained. Written out as Algorithm 3.2, this procedure becomes an efficient adaptation of Bregman's method, thereby, after a sufficient number of iterations, converging to the globally optimal solution.

Algorithm 3.2 depends on the parameter ϵ that governs convergence to the true optimal solution. It is an open problem to obtain an ϵ that guarantees convergence. However, upon experimentation with random dissimilarity matrices we found that setting $\epsilon^{-1} \approx \max_{ij} d_{ij}$ worked well, i.e., led to convergence, for Algorithm 3.2. Furthermore, from Theorem 3.1 we know that there exists a range within which ϵ can lie, and in practice running Algorithm 3.2 a small number (2–3) of times (with early stopping to save time) helps to determine a suitable value for ϵ for an arbitrary input matrix.

3.3. Triangle fixing for other ℓ_p norms. We can go a step further and extend triangle fixing to solve the metric nearness problem for all ℓ_p $(1 < p < \infty)$ norms. The problem may be compactly stated as

$$\min_{\boldsymbol{e}} \ \frac{1}{p} \|\boldsymbol{e}\|_p^p \qquad \text{subject to} \qquad \boldsymbol{A}\boldsymbol{e} \le \boldsymbol{v}. \tag{3.9}$$

Recall that for ℓ_2 metric nearness, at each iterative step we obtained $\boldsymbol{e}'$ from $\boldsymbol{e}$ by solving (3.2) after updating the dual variables $\boldsymbol{z}$ in a single coordinate. This update to $\boldsymbol{e}$ may be viewed as the result of an orthogonal projection of $\boldsymbol{e}$ onto the hyperplane defined by $\langle \boldsymbol{a}_{ikj}, \boldsymbol{e}' \rangle = v_{ikj}$ (ignoring inequalities for the moment). For the ℓ_p norm problem, we must instead perform a generalized projection, called a

, which involves solving the problem

$$\min_{\boldsymbol{e}'} \ \varphi(\boldsymbol{e}') - \varphi(\boldsymbol{e}) - \langle \nabla\varphi(\boldsymbol{e}), \boldsymbol{e}' - \boldsymbol{e}\rangle \quad \text{such that } \langle \boldsymbol{a}_{ikj}, \boldsymbol{e}'\rangle = \boldsymbol{v}_{ikj}, \tag{3.10}$$

where $\varphi(\boldsymbol{x}) = \frac{1}{p}\|\boldsymbol{x}\|_p^p$. We use $(\nabla\varphi(\boldsymbol{x}))_i = \operatorname{sgn}(x_i)\,|x_i|^{p-1}$ to determine the projection (3.10) by solving

$$\nabla\varphi(\boldsymbol{e}') = \nabla\varphi(\boldsymbol{e}) + \mu\boldsymbol{a}_{ikj} \qquad \text{so that} \qquad \langle \boldsymbol{a}_{ikj}, \boldsymbol{e}'\rangle = v_{ikj}. \tag{3.11}$$

Since $\boldsymbol{a}_{ikj}$ has only three nonzero entries, once again $\boldsymbol{e}$ needs to be updated in only three components. Therefore, in Algorithm 3.1 we may replace $(\star)$ by an appropriate numerical computation of the parameter μ, and replace $(\star\star)$ by the computation of the new value of $\boldsymbol{e}$ as resulting from (3.11). As before, each iteration maintains the necessary condition $\partial L(\boldsymbol{e}, \boldsymbol{z})/\partial \boldsymbol{e} = 0$ while correcting the dual vector $\boldsymbol{z}$, and the overall algorithm converges to the optimum of (3.9).

4. Metric nearness and APSP. The APSP problem [3] is an important and well-studied problem in graph theory that still continues to interest researchers. For a given weighted graph G, APSP computes an associated matrix of distances M whose entry m_{ij} gives the weight of a shortest path between vertices i and j. Optionally, shortest paths between all pairs of vertices corresponding to these distances are also obtained.

On the surface, APSP appears to have no connection with the metric nearness problem. However, it turns out that APSP can be viewed as a special case of metric nearness. We develop this connection below. Note that in the previous sections we considered only symmetric matrices. However, in this section we consider asymmetric distance matrices, which are more natural for the APSP problem, as they correspond to directed graphs.

4.1. The relation of metric nearness to APSP. Let the input be a weighted complete directed graph. We represent this graph by the (nonsymmetric) matrix $\boldsymbol{D}$, where d_{ij} denotes the edge weight of edge (i, j). On $\boldsymbol{D}$ we perform a restricted version of metric nearness that permits only decreasing changes to the d_{ij} values. Curiously this decrease-only version of metric nearness is equivalent to APSP.

LEMMA 4.1 (decrease-only metric nearness is APSP). . $\boldsymbol{M}^A \in \mathscr{M}_N$ .. . $\boldsymbol{D}$. $\boldsymbol{M}^A$ . . . . . ". . . . . $\boldsymbol{M} \in \mathscr{M}_N$ .. . . . . $\boldsymbol{D}$ . . . . $\boldsymbol{M}^A$ . . . . $\boldsymbol{M} \in \mathscr{M}_N$ .. $\boldsymbol{M} \le \boldsymbol{D}$ .. . $\boldsymbol{M} \le \boldsymbol{M}^A$

A proof of this lemma may be found in Appendix A.1. This connection between APSP and decrease-only metric nearness (DOMN) suggests that the latter may be solved by using any off-the-shelf algorithm for APSP. More interestingly, one can turn the problem around and obtain a new method to solve APSP by solving the DOMN problem. In this section, we present a new algorithm for APSP based on solving a linear programming formulation of DOMN.

APSP for dense graphs is commonly performed using the Floyd–Warshall algorithm, which has a complexity of $\Theta(n^3)$. Unlike the Floyd–Warshall algorithm, which proceeds by fixing the triangles of the graph in a predetermined order, our DOMN algorithm fixes triangles in a data-dependent order. Empirically, our algorithm converges more quickly to the solution than the Floyd–Warshall algorithm does, despite having the same asymptotic worst-case behavior.

4.2. The linear programming formulation of DOMN and its dual. Lemma 4.1 suggests that APSP solves the DOMN problem regardless of the norm used to measure the error. We, however, focus on the ℓ_1 norm problem along with its linear programming formulation. The linear program is interesting both because it is a novel formulation for solving APSP and because its dual allows us to construct shortest paths, if desired. We apply the primal-dual technique for solving the resulting linear programs and obtain a new APSP algorithm as a consequence.

4.2.1. Formulation. Let $\boldsymbol{X}$ represent a decrease-only distance matrix corresponding to the input matrix $\boldsymbol{D}$. Then the entries of $\boldsymbol{X}$ must satisfy,

$$x_{ij} \leq d_{ij} \quad \text{for all } (i,j), \tag{4.1}$$

$$x_{ij} \leq x_{ik} + x_{kj} \quad \text{for all } (i,k,j). \tag{4.2}$$

Finding the matrix with the least ℓ_1 perturbation requires solving the problem

$$\underset{x_{ij}}{\text{minimize}} \quad \sum_{ij}(d_{ij} - x_{ij}) \quad \text{subject to (4.1) and (4.2).}$$

Note that we are dealing directly with the values x_{ij} rather than the error values $e_{ij} = d_{ij} - x_{ij}$, as we did in sections 2.1 and 2.2. Since the d_{ij} are fixed we may replace this minimization by the equivalent problem

$$\begin{aligned} &\underset{x_{ij}}{\text{maximize}} \ \sum_{ij} x_{ij} \\ &\text{subject to} \quad x_{ij} \leq d_{ij} \text{ for all } (i,j), \\ &\qquad\qquad x_{ij} - x_{ik} - x_{kj} \leq 0 \quad \text{for all } (i,k,j). \end{aligned} \tag{4.3}$$

The dual problem corresponding to (4.3) is

$$\begin{aligned} &\underset{\pi_{ij}}{\text{minimize}} \ \sum_{ij} \pi_{ij} d_{ij} \\ &\text{subject to } \pi_{ij} + \sum_{k \neq i,j} (\gamma_{ikj} - \gamma_{ijk} - \gamma_{kij}) = 1 \ \text{ for all } (i,j), \\ &\qquad\qquad \pi_{ij} \geq 0 \ \text{ for all } (i,j), \\ &\qquad\qquad \gamma_{ikj} \geq 0 \ \text{ for all } (i,k,j), \end{aligned} \tag{4.4}$$

where the dual variables π_{ij} and γ_{ikj} correspond to the decrease-only constraints (4.1) and the triangle inequality constraints (4.2), respectively.

It is illustrative to cast the linear program (4.4) as a network flow problem, in which we must satisfy a demand for a single unit of flow between every pair of vertices i and j. We can accomplish this by either sending the flow [illegible] via the edge (i,j) (which corresponds to setting $\pi_{ij} = 1$) or [illegible] the edge (i,j) and routing through some other vertex k (which corresponds to setting $\gamma_{ikj} = 1$); in the latter case, we increase the demand for flow between (i,k) and (k,j) by 1.

We note that while there is a unique optimal solution to the linear program (4.3), the linear program (4.4) has several optimal solutions, some of which involve nonintegral assignments to the γ_{ikj} variables. This nonuniqueness is not unexpected, because while there is only one value that the shortest distance between two nodes in M can attain, there can be several shortest paths that achieve this distance value (paths which may contain many intermediate nodes, each of which allows a γ_{ikj} variable to assume a positive assignment).

4.3. A primal-dual algorithm for DOMN/APSP. We apply the primal-dual method [19, 16] to solve the linear programs for DOMN, and thereby obtain a new algorithm for APSP. Most treatments of the primal-dual method have a minimization of the primal problem and a maximization of the dual problem. Thus we will call (4.3) the dual problem, and (4.4) the primal problem. The primal-dual method begins with a feasible solution to the dual that is improved at each step by optimizing an [illegible] problem. In our case, we find it easier to optimize the associated restricted dual, whereby our method proceeds as follows:

1. Begin with a feasible solution to the dual problem. One such feasible solution is to set each x_{ij} to the smallest d_{ij} value.
2. Find the set P consisting of those constraints that do not have any additional slack. The decrease-only constraint $x_{ij} \leq d_{ij}$ (corresponding to dual variable π_{ij}) will be in P iff $x_{ij} = d_{ij}$, and the triangle constraint $x_{ij} - x_{ik} - x_{kj} \leq 0$ (corresponding to dual variable γ_{ikj}) will be in P iff $x_{ij} = x_{ik} + x_{kj}$.
3. Find a solution to the associated restricted dual

$$\begin{aligned} &\text{maximize} && \sum_{ij} u_{ij} \\ &\text{subject to} && u_{ij} \leq 0 && \text{if } \pi_{ij} \in P, \\ & && u_{ij} - u_{ik} - u_{kj} \leq 0 && \text{if } \gamma_{ikj} \in P, \\ & && u_{ij} \leq 1 && \text{for all } (i,j). \end{aligned} \tag{4.5}$$

   The solution u_{ij} to the associated restricted dual identifies which variables can be increased while maintaining dual feasibility.
4. If $u_{ij} = 0$, then the current value of x_{ij} is the optimal dual variable assignment. Otherwise, improve the x_{ij} assignment by adding ϵu_{ij} to x_{ij}, where ϵ is as large as possible while still maintaining dual feasibility. Return to step 2 with the new x_{ij} assignment.

By characterizing the solution of the associated restricted dual and the calculation of ϵ for the DOMN problem, we can give an efficient primal-dual algorithm. Observe that the solution to the associated restricted dual is that $u_{ij} = 1$ if the edge (i,j) is [illegible], and 0 otherwise. Computing ϵ is equivalent to determining which of the increasable edges has the least capacity for increase. Rather than use linear programming to determine the increasable edge set and computing ϵ explicitly, we can track upper bounds u_{ij} in addition to the lower bounds tracked by the x_{ij} variables. These upper bounds start as the d_{ij} values, but are reduced as edges become triangle constrained. Then the increasable set is simply the set of edges for which $x_{ij} < u_{ij}$, and ϵ is the difference between the lower bound of edges in the increasable set and the largest upper bound. Algorithm 4.1 implements these optimizations. I, the set of increasable edges, is the complement of P.

4.4. Priority queue DOMN algorithm. Algorithm 4.1 requires $O(n^4)$ time, but we can do better by noticing that the only time the lower bounds are used is to check the condition $u_e = l_e$. For edges (i,j) not in I, we have $u_{ij} = l_{ij}$, whereas all edges (i,j) in I have l_{ij} equal to the smallest upper bound. Therefore, we can replace I with a priority queue ordered by upper bound, and we do not need to keep track of lower bounds at all (even though the original dual variable values x_{ij} were lower bounds). Algorithm 4.2 implements these changes and requires only $O(n^3)$ time when implemented using a Fibonacci heap. Like the Floyd–Warshall algorithm, Algorithm 4.2 considers all edges in some order, and then fixes all triangles involving that edge. However, the Floyd–Warshall algorithm uses a fixed data-independent

Algorithm 4.1. DOMN: simple $O(n^4)$ implementation.

```
DOMN_ALG1(D)
Input: Dissimilarity matrix D
Output: M = APSP(D).
{Initialization}
u_ij ← d_ij for all i, j                          {Initial upper bounds}
x_ij ← min_{e'∈E} u_e'                            {Initial lower bounds}
I ← E                                             {Initial set of increasable edges}
while (I ≠ ∅)
    foreach (i, j) ∈ I with u_ij = x_ij
        I ← I − {(i, j)}                          {(i, j) is no longer increasable}
        foreach k ≠ i, j
            u_ik = min(u_ik, u_ij + u_jk)         {Update upper bounds}
        end foreach
    end foreach
    foreach (i, j) ∈ I
        x_ij ← min_{e'∈I} u_e'                    {Update lower bounds}
    end foreach
end while
return M where m_ij = x_ij
```

Algorithm 4.2. DOMN: improved $O(n^3)$ implementation.

```
DOMN_ALG2(D)
Input: Dissimilarity matrix D
Output: M = APSP(D).
{Initialization}
u_ij ← d_ij  for all i, j                         {Initial upper bounds}
Q.ENQUEUE((i, j), u_ij)  for all (i, j)           {Put all edges in priority-queue}
while (Q ≠ ∅)
    (i, j) ← Q.FIRST()                            {Remove edge with lowest upper bound}
    foreach k ≠ i, j
        u_ik = min(u_ik, u_ij + u_jk)             {Update upper bounds}
        Q.UPDATEPRIORITY((i, k), u_ik)            {Reorder priority queue}
    end foreach
end while
return M where m_ij = u_ij
```

order, whereas our algorithm uses a data-dependent order. As a result, our algorithm converges to the APSP/DOMN solution more rapidly, even though it still requires $O(n^3)$ time to complete.

5. An application to clustering. The metric nearness problem can be used to develop efficient algorithms for clustering that provide guarantees on the quality of the output in comparison with the optimal clustering. The MAX-CUT problem offers an especially attractive example. A cut of a graph is a partition of the vertices into two disjoint sets, and the value of a cut is the total weight of all edges that cross the partition. MAX-CUT simply asks for the cut of a graph with maximum value. If the size of each edge weight is proportional to the dissimilarity between the two vertices, solving MAX-CUT can be interpreted as finding the best clustering of the vertices into two sets.

For a general set of weights, MAX-CUT is hard enough [20] that the solution cannot be well approximated in polynomial time (unless $\mathsf{P} = \mathsf{NP}$) [1]. On the other hand, for weights that do satisfy the triangle inequality, de la Vega and Kenyon have exhibited a randomized algorithm that can approximate the solution arbitrarily well in polynomial time [5]. That is, for a given $\varepsilon > 0$, their method can (with high probability) compute in polynomial time a cut whose value is no smaller than $(1 - \varepsilon)$ times the value of the optimal cut. Of course, the time complexity grows quickly as ε shrinks.

Metric nearness plays an important role here. First, we approximate the original graph by a metric graph. Then we use the fast algorithm to produce a nearly optimal cut of the metric graph. The same cut of the original graph also has a nearly optimal value, which can be bounded in terms of the approximation error from the metric nearness problem.

THEOREM 5.1. *Let $\boldsymbol{D}$ be a dissimilarity matrix, and let $\boldsymbol{M}$ be a metric matrix. Suppose that $\mathcal{S}$ is a cut of $\boldsymbol{M}$ with value $(1-\varepsilon)\operatorname{maxcut}(\boldsymbol{M})$. Then*

$$\operatorname{cut}_{\mathcal{S}}(\boldsymbol{D}) \geq (1-\varepsilon)\operatorname{maxcut}(\boldsymbol{D}) - \left(1 - \frac{\varepsilon}{2}\right) \|\boldsymbol{M} - \boldsymbol{D}\|_1 \tag{5.1}$$

$$\operatorname{cut}_{\mathcal{S}}(\boldsymbol{D}) \geq \frac{1-\varepsilon}{\|\boldsymbol{M}/\boldsymbol{D}\|_\infty \, \|\boldsymbol{D}/\boldsymbol{M}\|_\infty} \operatorname{maxcut}(\boldsymbol{D}), \tag{5.2}$$

where $\|\cdot\|_\infty$ is the ℓ_∞ operator norm. In particular, $m_{jk} = d_{jk} = 0$ whenever (j,k) is a cut edge.

To find the optimal $\boldsymbol{M}$ for bound (5.1), we simply solve the ℓ_1 metric nearness problem. The optimal $\boldsymbol{M}$ for (5.2) cannot be obtained without solving a nonconvex optimization problem.

Proof. For a set of vertices $\mathcal{S}$, the value of the corresponding cut is computed by the linear function

$$\operatorname{cut}_{\mathcal{S}}(\boldsymbol{D}) = \sum_{j \in \mathcal{S}} \sum_{k \notin \mathcal{S}} d_{jk}.$$

The maximum cut just optimizes this functional over all subsets $\mathcal{S}$ of the vertex set $\{1, 2, \ldots, n\}$:

$$\operatorname{maxcut}(\boldsymbol{D}) = \max_{\mathcal{S}} \sum_{j \in \mathcal{S}} \sum_{k \notin \mathcal{S}} d_{jk}.$$

Obviously, $\operatorname{cut}_{\mathcal{S}}(\boldsymbol{D}) \leq \operatorname{maxcut}(\boldsymbol{D})$. It can be shown that $\operatorname{maxcut}(|\cdot|)$ is a matrix norm. In particular, it satisfies the triangle inequality for norms. It is also clear that

$$\operatorname{maxcut}(|\boldsymbol{T}|) \leq \frac{1}{2} \sum_{j \neq k} |t_{jk}| = \frac{1}{2} \|\boldsymbol{T}\|_1$$

for any symmetric matrix $\boldsymbol{T}$ with a zero diagonal.

Let us begin with bound (5.1). Suppose that $\mathcal{S}$ is a $(1-\varepsilon)$-optimal cut of $\boldsymbol{M}$.

Then

$$\begin{aligned}
\operatorname{cut}_{\mathcal{S}}(\boldsymbol{D}) &= \operatorname{cut}_{\mathcal{S}}(\boldsymbol{M}) + \operatorname{cut}_{\mathcal{S}}(\boldsymbol{D}-\boldsymbol{M}) \\
&\geq (1-\varepsilon)\ \operatorname{maxcut}(\boldsymbol{M}) - \operatorname{cut}_{\mathcal{S}}(|\boldsymbol{D}-\boldsymbol{M}|) \\
&\geq (1-\varepsilon)\ \operatorname{maxcut}(\boldsymbol{D}+(\boldsymbol{M}-\boldsymbol{D})) - \frac{1}{2}\,\|\boldsymbol{D}-\boldsymbol{M}\|_1 \\
&\geq (1-\varepsilon)\,(\operatorname{maxcut}(\boldsymbol{D}) - \operatorname{maxcut}(|\boldsymbol{M}-\boldsymbol{D}|)) - \frac{1}{2}\,\|\boldsymbol{M}-\boldsymbol{D}\|_1 \\
&\geq (1-\varepsilon)\ \operatorname{maxcut}(\boldsymbol{D}) - (1-\varepsilon/2)\,\|\boldsymbol{M}-\boldsymbol{D}\|_1.
\end{aligned}$$

The proof for the bound (5.2) follows a similar outline. First, we implicitly define a relative error matrix $\boldsymbol{E}$ with the relation $\boldsymbol{M} = \boldsymbol{D} \odot \boldsymbol{E}$. We assume that $m_{jk} = 0$ iff $d_{jk} = 0$ to ensure that $\boldsymbol{E}$ can be defined. If not, the resulting error bound would be trivial anyway. Let $r = \min\{e_{jk} : d_{jk} \neq 0\}$ and $R = \max\{e_{jk} : d_{jk} \neq 0\}$. For any zero entry of $\boldsymbol{D}$, take the corresponding entry of $\boldsymbol{E}$ in the range $[r, R]$. In what follows, we use "/" for elementwise division.

Next, observe that

$$\begin{aligned}
\operatorname{cut}_{\mathcal{S}}(\boldsymbol{M}) = \operatorname{cut}_{\mathcal{S}}(\boldsymbol{D} \odot \boldsymbol{E}) &= \sum_{j\in\mathcal{S}} \sum_{k\notin\mathcal{S}} d_{jk}\, e_{jk} \\
&\leq \max_{j\neq k} e_{jk} \sum_{j\in\mathcal{S}} \sum_{k\notin\mathcal{S}} d_{jk} \\
&\leq \|\boldsymbol{E}\|_\infty\ \operatorname{cut}_{\mathcal{S}}(\boldsymbol{D}).
\end{aligned}$$

Similarly,

$$\operatorname{maxcut}(\boldsymbol{D}) = \operatorname{maxcut}(\boldsymbol{M}/\boldsymbol{E}) \leq \|\mathbf{1}/\boldsymbol{E}\|_\infty\ \operatorname{maxcut}(\boldsymbol{M}).$$

Then we compute

$$\begin{aligned}
\operatorname{cut}_{\mathcal{S}}(\boldsymbol{D}) &\geq \frac{\operatorname{cut}_{\mathcal{S}}(\boldsymbol{M})}{\|\boldsymbol{E}\|_\infty} \\
&\geq \frac{1-\varepsilon}{\|\boldsymbol{E}\|_\infty}\ \operatorname{maxcut}(\boldsymbol{M}) \\
&\geq \frac{1-\varepsilon}{\|\boldsymbol{E}\|_\infty\,\|\mathbf{1}/\boldsymbol{E}\|_\infty}\ \operatorname{maxcut}(\boldsymbol{D}).
\end{aligned}$$

This technique can be extended to other types of problems that are computationally easier for metric graphs [12]. Mettu and Plaxton have also considered fast algorithms for clustering "nearly metric" data, but their approach relies instead on weak versions of the triangle inequality [18]. Fast approximation algorithms for various other metric problems such as k-median, MAX-TSP, etc., are discussed in [13]; our method allows extending these approximation algorithms to nonmetric data.

6. Experiments. We implemented metric nearness in C++ wherein we coded Algorithms 3.1 and 3.2. In this section we describe some experiments based on our implementation. All experiments were carried out in double precision on a P4/2.5GHz processor machine with 2GB RAM, running Linux.

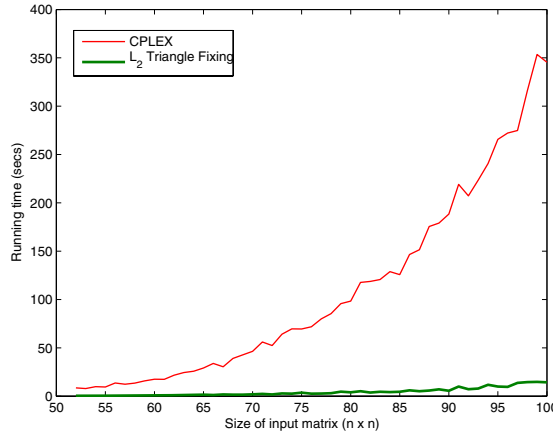

FIG. 6.1. *Running time comparison between CPLEX and the ℓ_2 triangle fixing algorithm.*

6.1. Running time. In this section we show some running time comparisons between CPLEX—a state-of-the-art linear and quadratic optimization software—and our implementations of triangle fixing. Our results clearly indicate the superiority of triangle fixing over CPLEX. For these experiments, we used random dissimilarity matrices of dimensions up to 100×100. The final values of the objective function achieved by CPLEX and our implementation agreed to five significant digits.

Figure 6.1 compares CPLEX quadratic programming to our implementation of ℓ_2 triangle fixing (see Algorithm 3.1). From the figure one can see that the triangle fixing procedure is up to 30 times faster than CPLEX's fastest method for solving the metric nearness quadratic program. Our experiments suggest that the ℓ_2 triangle fixing procedure scales as $O(n^3)$.

For ℓ_1 metric nearness, we compared CPLEX's fastest algorithm for metric nearness (determined by running all six choices available and selecting the fastest timing), and our implementation of the augmented triangle fixing procedure for solving the ℓ_1 metric nearness problem. Our implementation runs up to 15 times faster than CPLEX, as indicated by Figure 6.2. As suggested previously, we used $\epsilon = \max_{ij} d_{ij}$ for our experiments.

6.2. Decrease only metric nearness/APSP experiments. Although the Floyd–Warshall algorithm and the primal-dual algorithm, Algorithm 4.2, both have an asymptotic runtime of $O(n^3)$, the latter converges more quickly to the answer for certain classes of problems. Floyd–Warshall chooses an order of triangles to correct without any guidance, whereas the primal-dual algorithm prefers to correct triangles that include shorter edges. We can certainly imagine a problem instance where the violating triangles have longer edges, and in this case the preference for shorter edges does not help.

For randomly generated test cases, however, our primal-dual algorithm does converge more quickly than Floyd–Warshall. To illustrate this observation, we generated random matrices of dimension 200×200 that had a zero diagonal and entries between 0.1 and 10. We then determined the correct answer before running both algorithms, halting the computation at each iteration to determine the distance between the current distance matrix and the final metric. Distance was computed as the l_1 vector

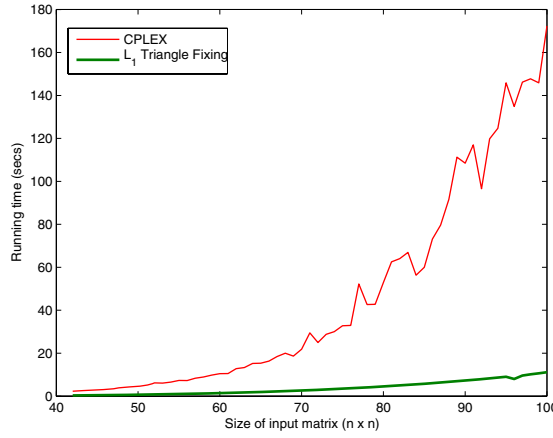

FIG. 6.2. *Running time comparison between CPLEX and augmented triangle fixing (ℓ_1).*

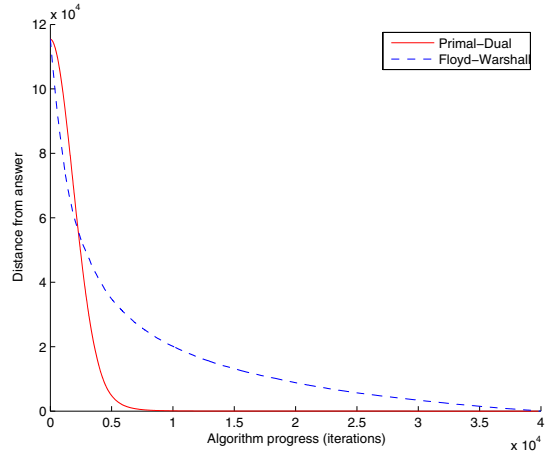

FIG. 6.3. *Convergence comparison of Floyd–Warshall and the primal-dual algorithm*

distance. Figure 6.3 gives these results, which clearly show the primal-dual algorithm converging faster than Floyd–Warshall.

To determine the approximate time to convergence as a function of n, we generated $n \times n$ matrices for values of n from 25 to 225. Figure 6.4 plots the number of iterations required to converge for both Floyd–Warshall and the primal dual algorithm. The exponents in the big-O notation runtimes were approximated by fitting the curve to the best $a \cdot n^b$ approximation. While Floyd–Warshall takes the entire $O(n^3)$ time to converge, the primal-dual algorithm converges in about $O(n^{2.8})$ time. Even more striking is Figure 6.5, which plots the number of iterations the algorithms required to converge (where nearly converging means being within $0.5 * n$ of the metric solution). Here Floyd–Warshall still required $O(n^3)$ time, but the primal-dual algorithm needed only about $O(n^{2.5})$ time.

Unfortunately, we cannot yet take advantage of this rapid convergence to improve

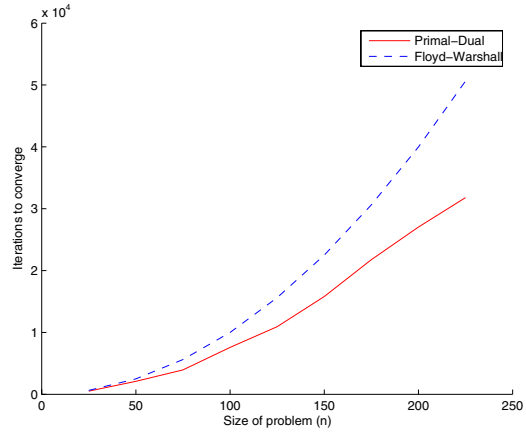

FIG. 6.4. *Iterations to converge for Floyd–Warshall and the primal-dual algorithm. Each iteration represents $O(n)$ computations.*

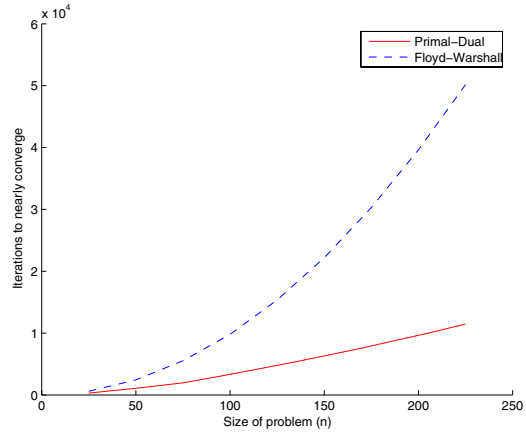

FIG. 6.5. *Iterations to nearly converge for Floyd–Warshall and the primal-dual algorithm. Each iteration represents $O(n)$ computations.*

the runtime of the APSP primal-dual algorithms. Ideally, we could terminate the algorithm when we had modified enough edges to cause the graph to be a metric. After the graph is a metric, there are no triangles in violation, so the additional steps of the algorithm do not modify the graph in any way. However, we are unaware of any computationally efficient way to solve the problem of [illegible]. That is, given a graph, return "true" if the graph is a metric, and "false" otherwise. One way to solve this is to run APSP on the graph, and then check to see if any edges were shortened. This observation yields an upper bound of $O(APSP)$ on the metricity problem. It follows that we cannot terminate the APSP primal-dual algorithms early, even if they have converged to the correct result, because testing for the termination condition has the same complexity as the problem itself.

7. Discussion. Metric nearness is a rich problem. In this paper we formally introduced the problem and derived iterative algorithms for solving it for the vector

ℓ_p norms. A special case of metric nearness was shown to be equivalent to the all pairs shortest paths problem, which led to a new algorithm for APSP. We studied applications of metric nearness to MAX-CUT clustering. Experimental results illustrate the computational advantages of triangle fixing over generic optimization methods.

7.1. Variations. One may derive numerous variations of the metric nearness problem. The simplest of these involve the modification of the triangle inequality constraints in some interesting manners. These variations are all easily solved using our framework. Examples follow.

1. In section 4 we discussed metric nearness with the restriction that permitted only decreasing changes to the entries of the input dissimilarity matrix. Similarly, one may also look at the problem where only increasing changes are permitted. Geometric or graph theoretic interpretations of this problem remain to be considered.
2. When performing metric nearness on nonsymmetric input graphs, one can choose either not to impose symmetry (as we did in the decrease-only section) or to impose symmetry. The latter case introduces additional constraints, but can be solved in our framework with only slight modifications.
3. Some applications may desire $\cdot$ or order constraints to be enforced. That is, if the input satisfies $d_{ij} < d_{pq}$, then we also require $m_{ij} < m_{pq}$. Such a requirement can be useful in scenarios where the relative ordering of the dissimilarity values has a significance for the underlying application.
4. Box constraints, i.e., constraints of type $l_{ij} \leq m_{ij} \leq u_{ij}$. Such constraints can be useful when a true metric, as opposed to a pseudometric, is desired (achieved by setting $l_{ij} > 0$). Upper bounds on the distance values may be utilized to prevent certain undesirable solutions.
5. Enforcement of λ-triangle inequalities that take the form $\lambda_{ij} m_{ij} \leq \lambda_{ik} m_{ik} + \lambda_{kj} m_{kj}$. Since the structure of the inequalities remains unaltered, this problem can also be solved by triangle fixing.

Other variations involve generalization of the basic problem. The most important of such generalizations is one that introduces a weighting scheme to the problem. Here we propose to obtain a distance matrix $\boldsymbol{M}$ such that

$$\boldsymbol{M} \in \operatorname*{argmin}_{\boldsymbol{X} \in \mathscr{M}_N} \|\boldsymbol{W} \odot (\boldsymbol{X} - \boldsymbol{D})\|,$$

where $\|\cdot\|$ is a norm, $\odot$ denotes the elementwise matrix product, and $\boldsymbol{W}$ is a weighting matrix (a symmetric nonnegative matrix). The weight matrix reflects our confidence in the entries of $\boldsymbol{D}$. When each d_{ij} represents a measurement with variance σ_{ij}^2, we might set $w_{ij} = 1/\sigma_{ij}^2$. If an entry of $\boldsymbol{D}$ is missing, one can set the corresponding weight to zero (however, the resulting problem loses strict convexity, whereby one should set this weight to a small value instead of zero).

7.2. Future work. Metric nearness is a relatively new problem. Many aspects could form a basis for future work and further consideration. The most immediate concerns that interest us are as follows:

1. Extensions to triangle fixing; for example, one may speed up the procedure by fixing all the independent triangle inequalities in parallel. One could also attempt to fix a few dependent triangle inequalities at the same time, and such an approach will result in a dual block coordinate ascent scheme [27].
2. Studying the convergence of the triangle fixing algorithms at least for the ℓ_2 case. If possible, it would be interesting to furnish a proof of convergence for

our algorithms that is independent of the convergence of the more general Bregman's method.

3. Exploring applications of metric nearness, e.g., applications to constrained clustering or various other applications that make use of proximity data and would profit from having metric data.

7.3. Open problems. Two interesting open problems spring out of metric nearness. First is the metricity problem that seeks to verify if the input dissimilarity matrix is actually a distance matrix. Some related work that probabilistically tests metric properties of an input dissimilarity matrix can be found in [21]. Whether the metric verification problem has the same complexity as the metric nearness problem remains to be ascertained. Second is the search for faster algorithms for the general metric nearness problem. Along with faster algorithms, the possibility of guaranteed polynomial-time (noniterative procedures) algorithms still remains.

7.4. Related work. Metric nearness is a relatively new problem that was introduced by the authors, where preliminary work includes [6, 7].

The most relevant research appears in recent papers of Roth et al. [24, 25]. They observe that machine learning applications often require metric data, and they propose a technique for converting general dissimilarity data into metric data. Their method, constant-shift embedding, increases all the dissimilarities by an equal amount to produce a set of Euclidean distances (i.e., a set of numbers that can be realized as the pairwise distances among an ensemble of points in a Euclidean space). The size of the translation depends on the data, so the relative and absolute changes to the dissimilarity values can be large. Our approach is completely different. We seek a consistent set of distances that [illegible] from the original measurements. In our approach, the resulting set of distances can arise from an arbitrary metric space; we do not restrict our attention to obtaining Euclidean distances. In consequence, we expect metric nearness to provide superior denoising. Moreover, our techniques can also learn distances that are missing entirely.

The technique of shifting the spectrum leads to an omission of the information carried by the negative eigenvalues of the input matrix. Laub and Müller [15] explore how the negative part of the spectrum could code for relevant features of the underlying data. Their method once again is based around computing an embedding, which is different from metric nearness, since the latter aims to only obtain a metric and constructs no embedding.

There is at least one other method for inferring a metric that proposes a technique for learning a Mahalanobis distance for data in $\mathbb{R}^s$ [28], that is, a metric $\text{dist}(\boldsymbol{x}, \boldsymbol{y}) = \sqrt{(\boldsymbol{x}-\boldsymbol{y})^T \boldsymbol{G}(\boldsymbol{x}-\boldsymbol{y})}$, where $\boldsymbol{G}$ is an $s \times s$ positive semidefinite matrix. The user specifies that various pairs of points are similar or dissimilar. Then the matrix $\boldsymbol{G}$ is computed by minimizing the total [illegible] distances between similar points while forcing the total distances between dissimilar points to exceed one. The article provides explicit algorithms for the cases where $\boldsymbol{G}$ is diagonal and where $\boldsymbol{G}$ is an arbitrary positive semidefinite matrix. In comparison, the metric nearness problem is not restricted to Mahalanobis distances; it can learn a general discrete metric. It also allows us to use specific distance measurements and to indicate our confidence in those measurements (by means of a weight matrix), rather than forcing a binary choice of "similar" or "dissimilar."

The metric nearness problem may appear similar to metric multidimensional scaling [14], but we emphasize that the two problems are [illegible]. The latter problem endeavors to find an ensemble of points in a [illegible] metric space—usually a Eu-

clidean space—such that the distances between these points are close to the set of input distances. In contrast, metric nearness does not seek an embedding—it does not impose any hypotheses on the underlying space other than requiring it to be a metric space. For more details on Euclidean distance matrices, see [9, 10, 26].

Related to metrics are ultrametrics; a distance matrix $\boldsymbol{M}$ is said to be an ultrametric if $m_{ij} \leq \max\{m_{ik}, m_{kj}\}$ for every distinct triple of indices (i, k, j). It is known that finding the nearest (in ℓ_1 and ℓ_2 norms) ultrametric to a given input matrix is NP-complete [4]. However, the ℓ_∞-nearest ultrametric can be computed in $O(n^2)$ time [8]. Hubert, Arabie, and Meulman [11] consider the problem of representing a dissimilarity matrix by a sum of matrices having a particular form, including a form that restricts the matrices to being ultrametrics.

Appendix. More on metric nearness. This appendix includes additional informative material pertinent to metric nearness.

A.1. Metric nearness and APSP. Lemma A.1 formalizes the equivalence between a "decrease-only" version of metric nearness and APSP. This equivalence was originally suggested by [22].

LEMMA A.1 (decrease only metric nearness is APSP). . $\boldsymbol{M}^A \in \mathscr{M}_N$ . .
. $\boldsymbol{D}$ . . $\boldsymbol{M}^A$ . . . . . ."
. . . . . $\boldsymbol{M} \in \mathscr{M}_N$. $\boldsymbol{M} \leq \boldsymbol{D}$ . . $\boldsymbol{M} \leq \boldsymbol{M}^A$
. . . We prove the last statement of the lemma, noting that it immediately implies the rest.

Assume the edge weights m_{ij}^A of $\boldsymbol{M}^A$ are sorted in increasing order, and that the least-weighted edge for which $\boldsymbol{M}$ exceeds $\boldsymbol{M}^A$ is m_{ij}, i.e., $m_{ij} > m_{ij}^A$. Since $\boldsymbol{M}^A$ is an APSP solution for $\boldsymbol{D}$, each edge weight m_{ij}^A either equals d_{ij} or is the sum of weights of edges involved in a shortest path of length less than d_{ij}, as shown in Figure A.1.

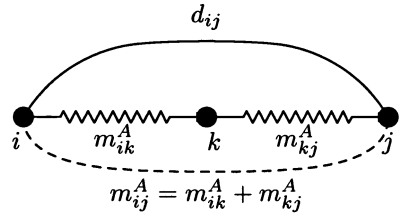

FIG. A.1. *Shortest path between i and j via k.*

In the figure, k is some intermediate vertex on a shortest path from i to j. The zig-zag lines denote paths from $i \to k$ and $k \to j$. Since $\boldsymbol{M}$ is a metric solution, $m_{ij} \leq m_{ik} + m_{kj}$. Now $m_{ik}^A \leq m_{ij}^A$ and $m_{kj}^A \leq m_{ij}^A$, since $m_{ij}^A = m_{ik}^A + m_{kj}^A$. By our assumption $m_{ij} > m_{ij}^A$ is the first place where a component of $\boldsymbol{M}$ exceeds a component of $\boldsymbol{M}^A$ (taken in sorted order), hence $m_{ik} \leq m_{ik}^A$ and $m_{kj} \leq m_{kj}^A$, which in turn implies that $m_{ij} \leq m_{ij}^A$. We have arrived at a contradiction to our initial assumption, which completes the proof of our claim. □

A.1.1. Equivalence of APSP to DOMN. Lemma A.1 shows that the optimal assignment of the x_{ij} variables in linear program (4.3) is the same as the . . . given by the APSP solution. In this section, we will investigate an equivalence between the optimal assignment of the π_{ij} and γ_{ikj} variables in linear program (4.4) and the . . . given by the APSP solution.

Given an APSP solution, we construct an optimal solution to the DOMN problem (4.3) using the following procedure:

- If the edge (i, j) is used by n shortest paths, then set $\pi_{ij} = n$.
- If the edge (i, j) is used by n shortest paths en route to node k, then set $\gamma_{ijk} = n$.

Clearly the nonnegativity constraints $\pi_{ij} \geq 0$ and $\gamma_{ikj} \geq 0$ are satisfied. We must show that the constraint

$$\pi_{ij} + \sum_{k \neq i,j} (\gamma_{ikj} - \gamma_{ijk} - \gamma_{kij}) = 1$$

is satisfied for all edges (i, j).

For vertex pairs i and j in which the shortest path from i to j is the edge (i, j), this assignment will be consistent with the constraint because all shortest paths involving the edge (i, j) fall into one of three categories: the path from i to j, paths to j that end with the edge (i, j), and paths to another vertex k that pass through the edge (i, j). The latter two categories contribute both a $+1$ and a -1 to the constraint, while the first category contributes a $+1$, resulting in a net sum of 1.

For vertex pairs i and j in which the shortest path from i to j begins with the edge (i, k), this assignment is also consistent with the constraint. There are two types of shortest paths ending at node j and using edge (i, k): the path that starts at i, and paths that start at a node l and pass through (i, k) before finishing at j. The latter type of path contributes both a $+1$ and a -1 to the constraint, while the first type contributes a $+1$ for a total of 1.

Under the proposed variable assignment procedure, the objective function for (4.4) is the sum of all path distances. Because the paths were taken from an APSP solution, this objective is minimized.

Given a optimal solution to (4.4), we construct an APSP solution using the following procedure:

- If π_{ij} is positive, then the edge (i, j) is a shortest path from i to j.
- If γ_{ikj} is positive, then there is a shortest path from i to j that passes through k; we may recursively find the shortest paths from i to k and from k to j.

COMPUTATION OF LARGE INVARIANT SUBSPACES USING POLYNOMIAL FILTERED LANCZOS ITERATIONS WITH APPLICATIONS IN DENSITY FUNCTIONAL THEORY*

C. BEKAS†, E. KOKIOPOULOU‡, AND YOUSEF SAAD§

Abstract. The most expensive part of all electronic structure calculations based on density functional theory lies in the computation of an invariant subspace associated with some of the smallest eigenvalues of a discretized Hamiltonian operator. The dimension of this subspace typically depends on the total number of valence electrons in the system, and can easily reach hundreds or even thousands when large systems with many atoms are considered. At the same time, the discretization of Hamiltonians associated with large systems yields very large matrices, whether with planewave or real-space discretizations. The combination of these two factors results in one of the most significant bottlenecks in computational materials science. In this paper we show how to efficiently compute a large invariant subspace associated with the smallest eigenvalues of a symmetric/Hermitian matrix using polynomially filtered Lanczos iterations. The proposed method does not try to extract individual eigenvalues and eigenvectors. Instead, it constructs an orthogonal basis of the invariant subspace by combining two main ingredients. The first is a filtering technique to dampen the undesirable contribution of the largest eigenvalues at each matrix-vector product in the Lanczos algorithm. This technique employs a well-selected low pass filter polynomial, obtained via a conjugate residual-type algorithm in polynomial space. The second ingredient is the Lanczos algorithm with partial reorthogonalization. Experiments are reported to illustrate the efficiency of the proposed scheme compared to state-of-the-art implicitly restarted techniques.

1. Introduction and preliminaries.

Ab initio electronic structure calculations, in the framework of density functional theory (DFT) [8, 11], have proven remarkably accurate in providing a wealth of information concerning several important physical properties of complex materials. However, DFT calculations are extremely demanding and have stretched our computational capabilities to their very limits. Therefore, advances in better simulation techniques and algorithms receive much attention in this very active field of research.

The core problem in DFT calculations is the solution of the time-independent Schrödinger equation

$$\mathcal{A}_\varrho \Psi_\varrho = E\Psi_\varrho, \tag{1}$$

where ϱ is the charge density of the electrons distribution, $\mathcal{A}_\varrho$ is the Hamiltonian operator, Ψ_ϱ are the wavefunctions, and E is the energy of the system. Observe that this is a nonlinear eigenvalue problem, since the Hamiltonian and the wavefunctions depend upon each other through the charge density ϱ. Recent decades have seen many methods that attempt to efficiently solve (1). All of them utilize some sort of iteration which aims to improve some initially selected wavefunctions so that at the end of the iteration the approximate energy E is as small as possible, or in other words the solution of (1) is self-consistent.

The charge density $\varrho(r)$ at a point r in space is calculated from the eigenfunctions Ψ_i of the Hamiltonian $\mathcal{A}$ via the formula

$$\varrho(r) = \sum_{i=1}^{n_o} |\Psi_i(r)|^2, \tag{2}$$

where the summation is taken over all occupied states (valence electrons) n_o of the system under study. This is a crucial calculation in DFT since the potential V of the Hamiltonian $\mathcal{A} = \nabla^2 + V$ depends on the charge density ϱ, which in turn depends on the eigenvectors Ψ_i of $\mathcal{A}$ (see (2)), and, as a result, an iterative loop is required to achieve self-consistence. Computing the charge density $\varrho(r)$ via (2) requires eigenvectors, though it is more accurate to say that what is needed is an orthogonal basis of the invariant subspace associated with the n_o algebraically smallest eigenvalues of the Hamiltonian. This is because $\varrho(r)$ is invariant under orthogonal transformations of the basis of eigenfunctions $\{\Psi_i\}$. If the symmetric matrix A is the discretization of the Hamiltonian $\mathcal{A}$ and the vectors ψ_i are the corresponding discretizations of the eigenfunctions $\Psi_i(r)$ with respect to r, then the charge densities are the diagonal entries of the "functional density matrix"

$$P = Q_{n_o} Q_{n_o}^\top \quad \text{with} \quad Q_{n_o} = [\psi_1, \ldots, \psi_{n_o}]. \tag{3}$$

Specifically, the charge density at the jth point r_j is the jth diagonal entry of P. In fact, any orthogonal basis $\mathcal{Q}$ which spans the same subspace as the eigenvectors ψ_i, $i = 1, \ldots, n_o$, can be used. This observation has led to improved schemes which do not focus on extracting individual eigenvectors. For example, [1] showed that the semiorthogonal basis computed by the Lanczos algorithm with partial reorthogonalization can be used in order to extract accurate approximations to the charge density. This scheme results in substantial savings relative to schemes which rely on the full reorthogonalization of the Lanczos vectors and the accurate calculations of the eigenvectors. When using standard diagonalization software, much attention is paid to obtaining accurate eigenvectors, at a cost that is often quite high. If one focuses on invariant subspaces, all that is needed is that a good basis of the subspace be computed, but this basis does not need to be a basis of accurate eigenvectors. For example, a set of m vectors which are linearly independent and which are known to have no components in the undesired eigenvectors will constitute such a basis, and an orthonormal basis can be obtained from it if we want to compute the charge density ϱ. Approximate eigenvectors can be extracted from this basis (by a Rayleigh–Ritz projection process) but this is not necessary. Shifting the focus from individual eigenvectors to bases of invariant subspaces can reduce the cost considerably.

In simple terms, the problem considered in this paper can be stated as follows. Given a real symmetric (or complex Hermitian) matrix $A \in \mathbb{R}^{n \times n}$ with eigenvalues $\lambda_1 \leq \lambda_2 \leq \cdots \leq \lambda_n$, compute the invariant subspace $\mathcal{S}_{n_o}$ associated with the

eigenvalues which do not exceed a certain limit γ. In electronic structures, γ is the Fermi energy level and the interval $[a, \gamma]$ contains the (algebraically) smallest occupied eigenstates $\lambda_1, \ldots, \lambda_{n_o}$. We assume that we are given an interval $[\alpha, \beta]$ which (tightly) contains the spectrum of A. The nature of the algorithms used in this paper also requires that $\alpha \geq 0$. If this is not satisfied, we shift matrix A by a scalar σ so that $A + \sigma I$ does not have any negative eigenvalues. Methods for computing an interval $[\alpha, \beta]$ when this is not readily available are discussed in section 3.1.

When the number of desired eigenvalues is rather small, say on the order of a few dozen, the problem can be addressed by a number of successful algorithms. Among these is an extensively used general purpose method based on implicitly restarted Lanczos iterations [33], and implemented in the software package `ARPACK` [16]. However, the problem becomes much harder in the case when we seek to compute the invariant subspace associated with a large number of eigenvalues that reach deep into the interior of the spectrum of the matrix at hand. Indeed, in electronic structure calculations, the dimension of the corresponding invariant subspace is equal to the number of occupied states n_o, which typically depends upon the number of free electrons of the system under study. Current state-of-the-art calculations may involve hundreds or even thousands of states. In addition, the dimension n of the Hamiltonian A also depends on the number of atoms and the topology of the system and is typically on the order of a few hundred thousand to several million.

The method proposed in this paper exploits two distinct and complementary tools to address the problem stated above. The first is a filtering technique which is used to dampen the undesirable contribution of the largest eigenvalues at each matrix-vector product in the Lanczos algorithm. This technique employs a well-selected low pass filter polynomial, obtained via a conjugate residual- (CR-)type algorithm in polynomial space. The second ingredient is the Lanczos algorithm with partial reorthogonalization. The main rationale for this approach is that filtering will help reduce the size of the Krylov subspace required for convergence, and this will result in substantial savings both in memory and in computational costs.

Earlier papers presented these two tools in the literature. For example, the filter polynomial used here is borrowed from [28], and earlier variants were used in [12] and [6]. The use of the partial reorthogonalization Lanczos (PR-Lanczos) was suggested in [1]. However, one of the difficulties with the method in [1] is that very large bases are often required. Thus, the goal of the present paper is to show how to effectively combine these two distinct and powerful tools, namely, polynomial filtering on the one hand and PR-Lanczos on the other, to solve the difficult problem of extracting large invariant subspaces. The motivation for using polynomial filtering in various applications, including computing large invariant subspaces, was also discussed in [28].

1.1. Previous work. An alternative viewpoint which appears in existing DFT codes is to replace diagonalization by "direct minimization," which in effect amounts to computing the subspace of minimum trace, i.e., an orthogonal basis $Q = [q_1, \ldots, q_{n_0}]$ such that $\mathrm{tr}(Q^T A Q)$ is minimum. In fact, many publications of the mid 1990s focused on avoiding orthogonality, which turned out to be hard to achieve. A method that was explicitly based on "trace-minimization" was proposed by Sameh and Wisniewski [30] as far back as 1982. Many methods used in planewave codes are variants of the same theme and are similar to subspace iteration and trace-min iteration. They begin with a certain subspace of size n_o (or close) and then improve each vector individually while the others are fixed. Clearly, when iterating on the ith vector, orthogonality

must be enforced against the first $i-1$ vectors. While this does not refer directly to eigenvectors, the algorithm implicitly computes these eigenvectors individually.

Other codes offered an alternative to this type of scheme in the form of the block-Davidson algorithm. When planewave bases are used, it is easy to precondition the eigenvalue problem for a number of reasons [25]. For example, preconditioners for eigenvalue problems in which planewaves are used can be easily extracted from matrices which use lower-dimensional representations of the Hamiltonian, i.e., Hamiltonians obtained from using fewer planewaves and extended to higher dimensions in some simple way. The lower-dimensional Hamiltonians have good representatives of the desired eigenvectors of the higher-dimensional ones, and this class of preconditioners can be quite effective in this context. In real-space methods, the situation is quite different. In this case, we found that preconditioning the eigenvalue problem is much harder [29]. Generally the gains with the standard preconditioners that were attempted were small, and these are outweighed by the additional cost of applying the preconditioner and by the loss of the 3-term recurrence of the Lanczos procedure. Specifically, one can potentially use the Lanczos procedure with an inexpensive form of reorthogonalization, but this is no longer possible with the Davidson approach, which requires a full orthogonalization at each step. In [1] we explored this approach. The Lanczos algorithm was adapted in a number of ways, the most important of which was to replace the reorthogonalization step by a partial reorthogonalization scheme [15, 24, 31, 32].

The use of matrix polynomials and filtering has been used in other ways, and the idea has played a prominent role in linear scaling and related methods; see, for example, [9, 10, 17, 21, 22]. In some cases, these methods will consist of computing the entire density matrix (3) [21] or a small part of it as an approximation [10].

1.2. The Lanczos procedure. The Lanczos algorithm [14] (see also [3, 4, 7, 24, 26]) builds a sequence of vectors $q_1, q_2, \ldots, q_m$ which form an orthonormal basis $Q_m \in \mathbb{R}^{n\times m}$ of the Krylov subspace

$$\mathcal{K}_m(A, q_1) = \mathtt{span}\{q_1, Aq_1, A^2q_1, \ldots, A^{m-1}q_1\}, \tag{4}$$

where q_1 is an arbitrary (typically random) initial vector with $\|q_1\| = 1$. As is well known, this sequence of vectors satisfies the 3-term recurrence

$$\beta_{i+1}q_{i+1} = Aq_i - \alpha_i q_i - \beta_i q_{i-1}. \tag{5}$$

Note that each step of the Lanczos algorithm requires the matrix A only in the form of matrix-vector products, which can be quite appealing in some situations, such as when A is available in stencil form.

If $Q_m = [q_1, \ldots, q_m]$ and if T_m denotes the symmetric tridiagonal matrix

$$T_m = \begin{bmatrix} \alpha_1 & \beta_2 & & & \\ \beta_2 & \alpha_2 & \beta_2 & & \\ & \ddots & \ddots & \ddots & \\ & & \beta_{m-1} & \alpha_{m-1} & \beta_m \\ & & & \beta_m & \alpha_m \end{bmatrix}, \tag{6}$$

where the scalars α_i, β_i are computed by the Lanczos algorithm, then it can be verified that $AQ_m = Q_mT_m + \beta_{m+1}q_{m+1}e_m^\top$, where e_m is the mth column of the canonical basis and q_{m+1} is the last vector computed by the Lanczos algorithm.

The eigenvalues of matrix A are approximated by those of matrix T_m. The Lanczos algorithm quickly yields good approximations to extremal eigenvalues of A. In contrast, convergence is typically much slower for the interior of the spectrum [24].

2. Computing large eigenspaces with the Lanczos procedure. In the situation when large eigenspaces are to be computed by the Lanczos algorithm, the number m of Lanczos steps required for all the desired eigenvectors to converge can be quite large. Therefore, if the algorithm is to be applied without any form of restarting or preconditioning, then we will have to deal with two related demands: (1) the need to apply some form of reorthogonalization to the Lanczos vectors [1, 15, 24, 31, 32], and (2) the need to store the Lanczos basis Q_m because it is needed by the reorthogonalization steps. The first constraint increases computational cost, and some care must be exercised for the reorthogonalization process not to become too expensive. The second raises the issue of memory costs. Storing the Lanczos basis Q_m will require a large memory size, and may even force one to resort to secondary storage.

Note that reorthogonalization will ultimately require all basis vectors to be fetched from main memory and that the cost of orthogonalizing the vector q_k against all previous ones will incur a cost of $O(kn)$, which yields a quadratic total cost of $O(m^2n)$ when summed over m steps. This cost will eventually overwhelm any other computation done, and it is the main reason why so many attempts have been made in the past to avoid or reduce the orthogonalization penalty in electronic structures codes; see, e.g., [5, 13, 18, 19, 36].

Note also that there is an additional severe penalty due to memory traffic as the size of the system increases, because modern processors work at a much faster rate than memory subsystems. It was argued in [1] that memory requirements do not necessarily pose a significant problem for the matrix sizes encountered and the machines typically in use for large calculations. For example, storing 2000 vectors of length 1 million requires "only" 16 GB of memory, which is certainly within reach of most high-performance computers.[1] However, for larger calculations this will be an enormous burden and out-of-core algorithms would be needed.

2.1. Use of partial reorthogonalization. A remarkable property of the Lanczos algorithm is that, in theory (exact arithmetic), it computes a basis of the Krylov subspace, which is , . This is done with a simple 3-term recurrence. However, in practice, i.e., in the presence of finite precision arithmetic (e.g., double precision floating point arithmetic), the basis vectors quickly start to lose orthogonality. The onset of loss of orthogonality is sudden and takes place as soon as one or more eigenvectors start converging, as was discovered in the seminal work of Paige [23]. As soon as this happens, the orthogonality is completely lost very rapidly, indicating an unstable underlying computation. As an illustration, consider the Hamiltonian ($n = 17077$) corresponding to $\mathtt{Si}_{10}\mathtt{H}_{16}$, which was obtained by the real-space code PARSEC.[2] We test the orthogonality of the bases Q_i, $i = 1, \ldots, m$, with $m = 200$ by computing the norm $\|Q_i^\top Q_i - I_i\|_2$, where I_i is the identity matrix of size i. The left plot in Figure 1 illustrates the rapid deterioration of orthogonality among basis vectors.

A number of existing reorthogonalization schemes are often employed to remedy the problem. The simplest of these consists of a full reorthogonalization approach,

[1] In modern high-performance computers this will typically be available in a single node.
[2] http://www.ices.utexas.edu/parsec/index.html

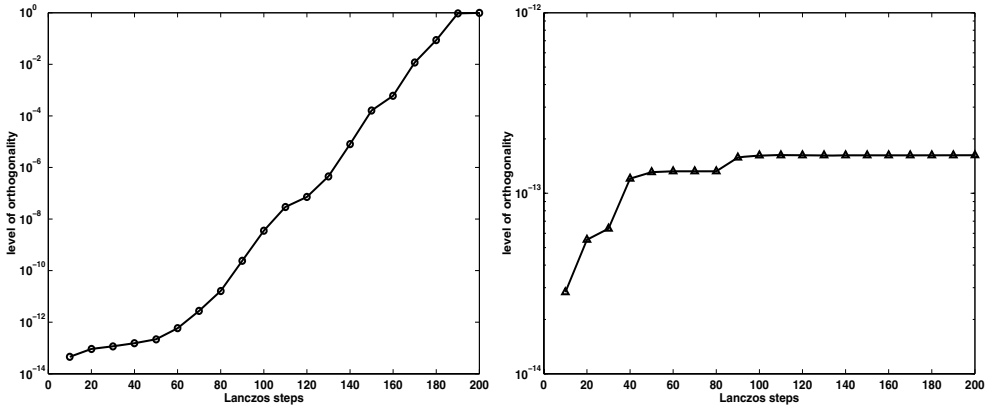

FIG. 1. *Levels of orthogonality of the Lanczos basis for the Hamiltonian ($n = 17077$) corresponding to* $Si_{10}H_{16}$. *Left: Lanczos without reorthogonalization. Right: Lanczos with partial reorthogonalization. The number of reorthogonalizations was* 34 *with an additional* 3400 *inner vector products.*

whereby the orthogonality of the basis vector q_i is enforced against all previous vectors at each step i. This means that the vector q_i, which in theory is already orthogonal against $q_1, \ldots, q_{i-1}$, is orthogonalized (a second time) against these vectors. In principle, we no longer have a 3-term recurrence, but this is not an issue as the corrections are small and usually ignored (see, however, Stewart [34]). However, full reorthogonalization can be a costly procedure.

An alternative is [illegible], which attempts to reorthogonalize only when it is deemed necessary. The goal is not so much to guarantee that the vectors are exactly orthogonal as to ensure that they are at least nearly orthogonal. Typically, the loss of orthogonality is allowed to grow to roughly the square root of the machine precision before a reorthogonalization is performed. A result by Simon [31] ensures that we can get fully accurate approximations to the Ritz values (eigenvalues of the tridiagonal matrix T_m) in spite of a reduced level of orthogonality among the Lanczos basis vectors. Furthermore, a key to the successful utilization of this result is the existence of clever recurrences which allow us to estimate the level of orthogonality among the basis vectors [15, 32]. It must be stressed that the cost of updating the recurrence is very modest. Let $\omega_{i,j} = q_i^\top q_j$ denote the "loss of orthogonality" between any basis vectors q_i and q_j. Then the following is the so-called ω-recurrence [32]:

$$\beta_i \omega_{i+1,j} = (\alpha_j - \alpha_i)\omega_{i,j} + \beta_{j-1}\omega_{i,j-1} - \beta_{i-1}\omega_{i-1,j}, \tag{7}$$

where the scalars α_i and β_i, $i = 1, \ldots,$ are identical to the ones computed by the Lanczos algorithm.

Thus, we can cheaply and efficiently probe the level of orthogonality of the current vector (say q_i) and determine whether a reorthogonalization step against previous basis vectors is required. The right plot in Figure 1 illustrates the corresponding level of orthogonality when partial reorthogonalization is applied. Only 34 reorthogonalization steps were required, compared with the 200 that would have been required if full reorthogonalization was employed.

It was shown in [1] that partially reorthogonalized Lanczos combined with techniques that avoid explicit computation of eigenvectors can lead to significant savings

in computing charge densities for electronic structure calculations. Partial reorthogonalization will play a key role in the algorithm to be described in the next section.

2.2. Polynomial acceleration and restarting techniques. The above discussion strongly suggests that it is critical to use a Lanczos basis that is as small as possible. In order to achieve this, we can apply the Lanczos process not to the original matrix A but rather on a matrix $p(A)$, where $p(t)$ is a polynomial of small degree, designed to be close to zero for large eigenvalues and close to one for the eigenvalues of interest. Of course, polynomial acceleration in Krylov techniques is not a new idea (see, for example, [26] and the references therein). Typically, the goal is to restart the Lanczos procedure after a fixed number of iterations with a starting vector from which unwanted eigendirections have been filtered out. In this paper we follow a different approach. We do not employ any restarts, but rather filter each matrix-vector product in the Lanczos process using a small number of CR-type iterations with the matrix A. As can be expected, the proposed scheme will require a much smaller number of basis vectors than without filtering. However, each matrix-vector product is now more costly. Experiments will show that the trade-off is in favor of filtering.

Observe that in exact arithmetic, if the starting vector q_1 is orthogonal to an eigenvector ψ_j, then the Krylov subspace $\mathcal{K}_m$ will never have any components in ψ_j, regardless of the number of steps m. Restarting techniques utilize this property to speed up the computation of the desired invariant subspace. The goal is to progressively construct a starting vector $q_1^{(k)}$, which at each restart k will have larger components in desired eigendirections, and smaller ones in undesired eigendirections. In contrast to the standard Lanczos procedure, the dimension of the Krylov subspace is not allowed to grow indefinitely. When a maximum number of iterations $M_{\max}$ is reached, a new starting vector $q_1^{(k+1)}$ is selected and the process is restarted; see [26, 33] for details.

Whether explicit or implicit, restarting can be designed to filter out eigendirections corresponding to eigenvalues $\lambda_j > \lambda_{n_o}$. The goal is to accelerate convergence towards the algebraically smallest eigenvalues. However, round-off will cause eigendirections in the largest eigenvalues to quickly reappear. This is illustrated in Figure 2. The matrix that is tested corresponds to a second order finite difference approximation of the two-dimensional Laplace differential operator. The starting vector is the sum

$$q_1 = \sum_{k=1}^{n_o} \psi_i$$

of the eigenvectors corresponding to the smallest $n_o = 200$ eigenvalues of the matrix. The left plot of Figure 2 illustrates that at the first step of the Lanczos procedure, the vector q_1 is orthogonal (up to machine precision) to the unwanted eigenvectors. However, it takes only $m = 13$ steps of Lanczos for the coefficients in the largest eigenvectors to start dominating the last basis vector q_m.

What happened can be easily explained. Let ϵ denote the machine precision and assume that $\langle q_1, \psi_i \rangle = \epsilon$ for a given eigenvector ψ_i with $i > n_o$. Recall that the Lanczos vector q_{m+1} is of the form $q_{m+1} = z_m(A)q_1$, where z_m is a polynomial of degree m, called the $(m+1)$st Lanczos polynomial. The sequence of polynomials z_k, $k = 1, \ldots, m$, is orthogonal with respect to a certain discrete inner product. Since the initial vector has very small components in the eigenvectors associated with eigenvalues $\lambda_i > \lambda_{n_o}$, it is to be expected that the Lanczos polynomial z_m is such

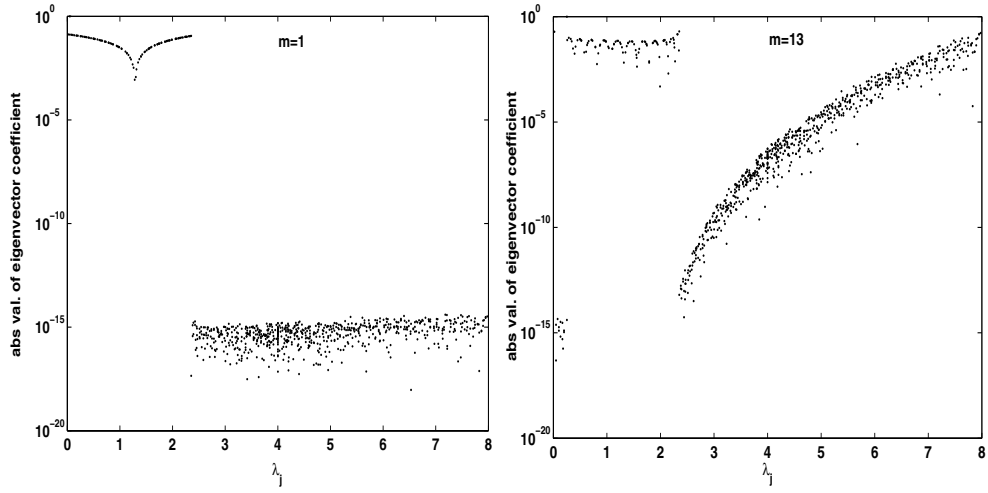

FIG. 2. *Coefficients of the last basis vector q_m of the Lanczos procedure (no partial reorthogonalization was required) for the discretization of the Laplacian, when the starting vector does not have any components in undesired eigenvectors. Left: one step. Right: $m = 13$ steps.*

that $z_m(\lambda_i) \gg 1$ for $i > n_o$. Therefore, we will have

$$\begin{aligned} \langle q_{m+1}, \psi_i \rangle &= \langle z_m(A) q_1, \psi_i \rangle \\ &= \langle q_1, z_m(A) \psi_i \rangle \\ &= z_m(\lambda_i) \langle q_1, \psi_i \rangle \\ &= z_m(\lambda_i) \epsilon. \end{aligned} \tag{8}$$

As a result, the small component ϵ will be amplified by the factor $z_m(\lambda_i)$, which is likely to be very large.

The situation can be remedied by replacing A by an operator of the form $B = p(A)$, where $p(\lambda_i)$ is small. If B is used in the Lanczos algorithm, then note that every time we multiply q by B, a component in the direction ψ_i that is small (relative to the others) will remain small.

Before we state the result in detail, we must recall that in inexact arithmetic, the Lanczos relation (5) is replaced by a relation of the form

$$A q_i = \beta_{i+1} q_{i+1} + \alpha_i q_i + \beta_i q_{i-1} - z_i, \tag{9}$$

where z_i is an error vector which, in general, remains small.

LEMMA 2.1. $\lambda > \lambda_{n_o}$ ψ $\delta \equiv p(\lambda)$ $\{q_i\}$ (9) $\epsilon_i^{\psi} = \langle \psi, z_i \rangle$ $\sigma_i = \langle q_i, \psi \rangle$

$$\beta_{i+1}\sigma_{i+1} + (\alpha_i - \delta)\sigma_i + \beta_i \sigma_{i-1} = \epsilon_i^{\psi} \tag{10}$$

$\beta_{m+1} e_1^\top (T_m - \delta I)^{-1} e_m \neq 0$ σ_{m+1} q_{m+1} ψ

$$\sigma_{m+1} = \frac{\varepsilon_m^\top (T_m - \delta I)^{-1} e_1 - \sigma_1}{\beta_{m+1} e_m^\top (T_m - \delta I)^{-1} e_1}, \tag{11}$$

[illegible] $\varepsilon_m = [\epsilon_1^\psi, \epsilon_2^\psi, \ldots, \epsilon_m^\psi]^\top$ [illegible] T_m [illegible] (6)
[illegible]. Let $B \equiv p(A)$. We begin with the relation

$$Bq_i = \beta_{i+1} q_{i+1} + \alpha_i q_i + \beta_i q_{i-1} - z_i.$$

Taking the inner product with ψ yields

$$\langle Bq_i, \psi \rangle = \beta_{i+1} \langle q_{i+1}, \psi \rangle + \alpha_i \langle q_i, \psi \rangle + \beta_i \langle q_{i-1}, \psi \rangle - \epsilon_i^\psi.$$

Since $B\psi = \delta\psi$, this readily yields the expression (10).

Define the vector $s_m = [\sigma_1, \sigma_2, \ldots, \sigma_m]^\top$. We can rewrite the relations (10) for $i = 1, \ldots, m$ in matrix form as

$$(T_m - \delta I) s_m = \varepsilon_m - \beta_{m+1} \sigma_{m+1} e_m,$$

which yields the relation $s_m = (T_m - \delta I)^{-1} \varepsilon_m - \beta_{m+1} \sigma_{m+1} (T_m - \delta I)^{-1} e_m$. Now, we add the condition that σ_1 is known:

$$\sigma_1 = e_1^\top s_m = e_1^\top (T_m - \delta I)^{-1} \varepsilon_m - \beta_{m+1} \sigma_{m+1} e_1^\top (T_m - \delta I)^{-1} e_m,$$

from which we obtain the desired expression (11). □

The main point of the above lemma is that it explicitly provides the amplification factor for the coefficient in the direction ψ in terms of computed quantities. This factor is the denominator of the expression (11). Note that in exact arithmetic, the vector ε_m is zero and the initial error of σ_1 in the direction of ψ is divided by the factor $\beta_{m+1} e_1^\top (T_m - \delta I)^{-1} e_m$. We can obtain a slightly simpler expression by "folding" the term σ_1 into the vector ε_m. This is helpful if σ_1 is of the same order as the ϵ_i^ψ's as it simplifies the expression. Set

$$\hat{\varepsilon}_m = \varepsilon_m - \sigma_1 (T_m - \delta I) e_1.$$

Note that only ϵ_1^ψ and ϵ_2^ψ are modified into $\hat{\epsilon}_1^\psi = \epsilon_1^\psi - (\alpha_1 - \delta)\sigma_1$ and $\hat{\epsilon}_2^\psi = \epsilon_2^\psi - \beta_2 \sigma_1$, while the other terms remain unchanged, i.e., $\hat{\epsilon}_i^\psi = \epsilon_i^\psi$ for $i > 2$. Then (11) becomes

$$\sigma_{m+1} = \frac{\hat{\varepsilon}_m^\top (T_m - \delta I)^{-1} e_1}{\beta_{m+1} e_m^\top (T_m - \delta I)^{-1} e_1}. \tag{12}$$

Let us consider the unfavorable scenario first. When $B \equiv A$ then T_m is simply the tridiagonal matrix obtained from the Lanczos algorithm and δ is an eigenvalue of A. Assume that $\lambda = \lambda_n$, the largest (unwanted) eigenvalue. Even if q_1 has very small components in the direction of λ, convergence will eventually take place (see (8)), and T_m will tend to have an eigenvalue close to λ, so $(T_m - \delta I)^{-1} e_1 \equiv y_m$ is close to an eigenvector of T_m associated with its largest eigenvalue. As is well known, the last components of (converged) eigenvectors of T_m will tend to be much smaller than the first ones. Therefore, if $\hat{\varepsilon}_m$ is a small random vector, then σ_m will become larger and larger because the numerator will converge to a certain quantity while the denominator will converge to zero.

The use of a proper inner polynomial $p(t)$ prevents this from happening early by [illegible]. In this situation δ is an eigenvalue of B among many others that are clustered around zero, so convergence is considerably slower towards the corresponding eigenvector. By the time convergence takes place, the desirable subspace will have already been computed.

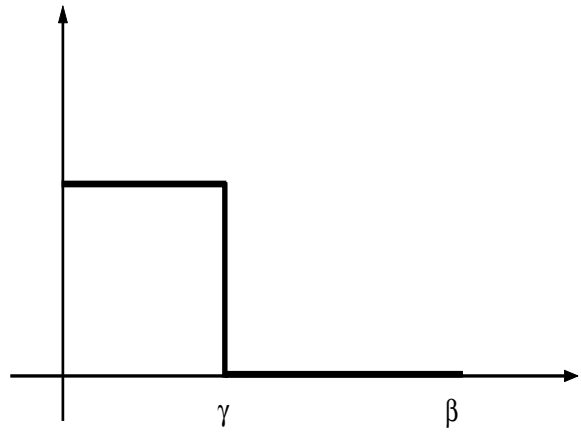

FIG. 3. *The Heaviside function for the interval* $[\gamma, \beta]$.

3. The filtered Lanczos procedure. Partial reorthogonalization can significantly extend the applicability of Lanczos in electronic structure calculations (see [1]), but there are computational issues related to the use of very long Lanczos bases when a large invariant subspace is sought. These issues can be addressed by employing polynomial filtering in the Lanczos procedure.

In exact arithmetic, the ideal solution to this problem is to use an initial vector which is filtered so that it has no eigencomponents associated with λ_i, $i > n_o$. However, we saw earlier that in the course of the Lanczos procedure, components along the largest eigenvectors will quickly return. We discussed the reasons for this behavior and suggested a simple remedy which consists of replacing the matrix-vector product Aq_i in the usual Lanczos algorithm by $p(A)q_i$, where $p(t)$ is a low-degree polynomial filter that approximates the Heaviside function (see Figure 3). The interval $[\gamma, \beta]$ contains all the unwanted (largest) eigenvalues, which are approximately mapped by $p(t)$ to zero.

All that is required to implement the proposed filtered Lanczos scheme is to substitute the matrix-vector product Aq_i with a function $\mathcal{P}(A, q_i, d)$ which evaluates the product of the matrix polynomial $p(A)$ with the vector q_i. Let d be the degree of the polynomial $p(t)$. Then the cost per step of the filtered Lanczos procedure, compared with the plain Lanczos procedure, is d additional matrix-vector products.

Observe that the filtered Lanczos process constructs an approximate invariant subspace for the matrix $p(A)$ which is also an invariant subspace for A itself. However, while the restriction of $p(A)$ on the orthogonal Lanczos basis Q_m is a tridiagonal matrix, i.e., $Q_m^\top p(A) Q_m = T_m$ is tridiagonal, this is no longer true for A, i.e.,

$$Q_m^\top A Q_m = \tilde{T}_m, \tag{13}$$

where $\tilde{T}_m$ is in general dense. The eigenvalues of A are approximated by those of $\tilde{T}_m$, while the eigenvalues of T_m approximate those of $p(A)$. However, A and $p(A)$ have the same eigenvectors. Thus, if we consider the matrix of normalized eigenvectors Y of T_m and $\tilde{Y}$ of $\tilde{T}_m$, respectively, then approximations to the eigenvectors of A are given either by the columns of the matrices $Q_m Y$ or $Q_m \tilde{Y}$. Furthermore, approximations to the eigenvalues of A are available from the eigenvalues of $\hat{T}_m = Y^\top Q_m^\top A Q_m Y$.

Similarly to the Lanczos procedure, the basis vectors q_i in the filtered Lanczos

procedure are also expected to rapidly lose orthogonality. Thus, the partial reorthogonalization techniques of section 2.1 will prove to be particularly useful in the practical deployment of the method.

The larger the degree of the polynomial $p(t)$, the closer it can be made to the Heaviside function. On the other hand, using a larger degree d will induce a higher computational cost. It is important to note that in practice we do not seek to approximate the Heaviside function everywhere on its domain of definition. We would like the polynomial $p(t)$ to take small values on the region of the unwanted eigenvalues. Section 4 discusses a CR-type iteration that achieves this goal. In order to describe the filtered Lanczos iteration, it suffices for the time being to consider the application of the filtering polynomial as a "black box" function $\mathcal{P}(A, q_i, d)$.

3.1. The algorithm. In order to compute a basis for an invariant subspace $\mathcal{S}_{n_o}$ for the n_o algebraically smallest eigenvalues of matrix A, we assume that we are given an interval $(\gamma, \beta]$, which contains all the unwanted eigenvalues $\lambda_j > \lambda_{n_o}$. Assuming that the matrix A does not have any negative eigenvalues, it suffices to consider only the left endpoint γ of the interval. In electronic structure calculations, the problem is often a variation of this one, in that we wish to compute an invariant subspace associated with the n_o smallest eigenvalues. However, there is an outer loop, and previous information can be used to obtain a good interval on which to restrict the search. There are also instances where the number of eigenvalues n_o is unknown, but rather we are given an upper bound γ for the eigenvalues that need to be considered.

Starting vector. It is important that the starting vector q_1 be free of components in the undesired eigenvectors. To this end we apply a high-degree polynomial filter p_h on a random vector $\tilde{q}$, such that $q_1 = p_h(A)\tilde{q}$. The degree of this first polynomial can be quite high (say $d_h = 200$ or so) to get a good elimination of the undesired components. A systematic way to stop this initial iteration is to monitor the norm of the residual of the CR iteration, which indicates how well the sequence of the orthogonal CR polynomials approximate the base filter function. Once this norm, which is cheap to compute (see section 4.1), falls below a user-specified tolerance, the iteration is stopped. This in turn will guarantee that unwanted large eigendirections have been adequately dampened.

Bounding intervals. If we are not given an interval $[\alpha, \beta]$ that tightly contains the eigenvalues, then we employ a number of unrestarted Lanczos iterations in order to obtain approximations for the bounds α and β. In practice, the number of these iterations is kept low. Let r_1 and r_n be the residual vectors for the approximate extremal eigenvalues $\tilde{\lambda}_1$ and $\tilde{\lambda}_n$ of matrix A obtained from a few Lanczos steps. Then we use the practical bounds $\tilde{\alpha} = \tilde{\lambda}_1 - \|r_1\|$ and $\tilde{\beta} = \tilde{\lambda}_n + \|r_n\|$. If $\tilde{\alpha}$ is negative, then we shift the Hamiltonian so as to make all its eigenvalues positive. The "interval of wanted eigenvalues" is user-defined. Standard "self-consistent field" iterations in electronic structure methods are inherently nonlinear iterations and as such information from previous iterations can be exploited to obtain a good estimate for the wanted interval. At the beginning of the self-consistent field loop, there are adequate initializations based on superposition of atomic wavefunctions that can be exploited. The "unwanted" interval is readily defined from the above.

Inner polynomial transformation. The main Lanczos iteration will be performed with a filter polynomial of A, i.e., the Lanczos algorithm is run with $B = p(A)$. The degree d of p is much smaller than that of p_h, in order to reduce the overall cost. Typically $d \equiv 8$.

Convergence criterion. Equally important in limiting the computational cost is the convergence test. Let $(\tilde{\lambda}_i, \tilde{x}_i)$ be an approximate eigenpair, where $x_i = Q_m y_i$ and $(\tilde{\lambda}_i, y_i)$ is an eigenpair of the dense matrix $\tilde{T}_m$ (13). Then it is natural to monitor the norm of the residual $r_i = A\tilde{x}_i - \tilde{\lambda}_i\tilde{x}_i$. It is well known (see, e.g., [24]) that

$$\|r_i\| = \|A\tilde{x}_i - \tilde{\lambda}_i\tilde{x}_i\| = |\beta_{m+1}|\,|y_i^m|,$$

where y_i^m is the last element of the eigenvector y_i. In order to reduce the computational cost as well as the memory load, we opt to avoid calculating the eigenvectors y_i at every step. Thus, we choose to monitor, during the iteration, the sum of the eigenvalues $\tilde{\lambda}_i$ of matrix $\tilde{T}_k$, which correspond to those eigenvalues of A that are smaller than the upper bound γ, $s_k = \sum_{\tilde{\lambda}_i<\gamma} \tilde{\lambda}_i$. Only when the change in the sum s_k, in comparison to s_{k-1}, is less than a user-defined tolerance do we calculate the eigenvectors y_i and thus check convergence by means of the residual norms $\|r_i\|$. If all residual norms are adequately small, then we stop the iteration. Otherwise, we continue the iteration and repeat the process. Further savings are achieved by not performing the convergence test for s_k at every Lanczos step, but only infrequently, for example, at fixed intervals.

Computation of the projection matrix $\tilde{T}_m$. Observe that

$$\tilde{T}_i = Q_{i+1}^\top A\, Q_{i+1} = [Q_i \quad q_{i+1}]^\top A[Q_i \quad q_{i+1}] = \begin{bmatrix} Q_i^\top AQ_i & Q_i^\top Aq_{i+1} \\ q_{i+1}^\top AQ_i & q_{i+1}^\top Aq_{i+1} \end{bmatrix}. \tag{14}$$

Thus, matrix $\tilde{T}_m$ can be computed incrementally during the course of the algorithm. Obviously, if $\tilde{T}_m$ is updated at every step i, then no additional memory is required. However, a more efficient `BLAS 3` implementation is possible if we postpone the update of $\tilde{T}_m$ and rather perform it at fixed intervals (which can be made to coincide with the intervals at which convergence is checked). This will come at the expense of a few additional vectors in memory. In particular, we will have to store the vectors Aq_{i+1} for a number of consecutive steps.

Figure 4 shows a high-level algorithmic description of the filtered Lanczos iteration.

4. Polynomial filters. This section focuses on the problem of defining and applying the polynomial filter. Details on the algorithms described here can be found in [28]. We begin with a brief summary of filtering techniques when solving linear systems of equation by "regularization" [20]. In regularized solution methods, one seeks to find an approximate solution to the linear system $Ax = b$ by inverting A only in the space associated with the largest eigenvalues, leaving the other part untouched. As was explained in [28], computing a filtered solution amounts to computing a vector $s(A)b$ whose residual vector $p(A)b = b - As(A)b$ is a certain filter polynomial, typically one that is computed to be close to 1 for small eigenvalues and close to 0 for larger eigenvalues. In other words, it would resemble the desired filter polynomial, such as the one shown on the right of Figure 7.

The approximate solutions produced by Krylov subspace methods for solving a linear system $Ax = b$ are of the form $s_j(A)r_0$, where s_j is a polynomial of degree $\leq j$. The corresponding residual vector is $p_{j+1}(\lambda) = 1 - \lambda s_j(\lambda)$. This polynomial is of degree $j + 1$ and has value 1 at $\lambda = 0$. In standard (unfiltered) methods one attempts to make the polynomial $\lambda s_j(\lambda)$ close to the function 1 on the (discrete) set of eigenvalues. Chebyshev methods attempt to make the polynomial $\lambda s(\lambda)$ close to the function 1,

FIG. 4. *The filtered Lanczos algorithm. The inner product for vectors is denoted by* $\langle ., . \rangle$.

uniformly, on the (continuous) set $[\alpha, \beta]$ containing the spectrum (with $0 < \alpha < \beta$). A number of other methods have been developed which attempt to make the polynomial $\lambda s(\lambda)$ close to the function 1, in some least-squares sense, on the interval $[\alpha, \beta]$.

In the standard CR algorithm (see, e.g., [27]), the solution polynomial s_j minimizes the norm $\|(I - As(A))r_0\|_2$, which is nothing but a discrete least-squares norm when expressed in the eigenbasis of A:

$$\|(I - As(A))r_0\|_2 = \left[\sum_1^N (1 - \lambda_i s(\lambda_i))^2\right]^{1/2} \equiv \|1 - \lambda s(\lambda)\|_D.$$

It is possible to write a CR-like algorithm which minimizes $\|1 - \lambda s(\lambda)\|_g$ for any least-squares norm associated with a (proper) inner product of polynomials

$$\langle p, q \rangle_g.$$

The related generic CR algorithm is given in Figure 5.

It can be easily shown that the residual polynomial p_j generated by this algorithm minimizes $\|p(\lambda)\|_g$ among all polynomials of the form $p(\lambda) = 1 - \lambda s(\lambda)$, where s is any polynomial of degree $\leq j - 1$. In other words, p_j minimizes $\|p(\lambda)\|_g$ among all

FIG. 5. *Generic CR algorithm.*

polynomials p of degree $\leq j$, such that $p(0) = 1$. In addition, the polynomials $\lambda\pi_j$ are orthogonal to each other.

In order to add filtering to the above algorithm, note that filtering amounts to minimizing some norm of $\phi(\lambda) - \lambda s(\lambda)$, where ϕ is the given filter function. One must remember that $\phi(A)v$ is not necessarily easy to evaluate for a given vector v. In particular, $\phi(A)r_0$ may not be available.

The relation between regularized filtered iterations and polynomial iterations, such as the one we are seeking for the eigenvalue problem, may not be immediately clear. Observe that the residual polynomial $p_m(t)$ can be used as a filter polynomial for a given iteration. For example, the residual polynomial shown on the right of Figure 7, which is of the form $p(\lambda) = 1 - \lambda s(\lambda)$, can be used for computing all eigenvalues in the interval $[0, 1.7]$. The dual filter $1 - p(\lambda)$ has small values in $[0, 1.7]$ and can be used to compute the invariant subspace associated with the eigenvalues in the interval $[2.3, 8]$, though this may possibly require a large subspace. Notice that one of the main difficulties with this class of techniques is precisely the issue of the dimension of the subspace, as there is no inexpensive way of knowing in advance how many eigenvalues there are in a given interval.

4.1. Corrected CR algorithm. The standard way of computing the best polynomial is to generate an orthogonal sequence of polynomials and expand the least-squares solution in it. This approach was taken in [6] and more recently in [12].

The formulation of the solution given next is based on the following observation. The polynomials associated with the residual vectors of the (standard) CR algorithm are such that $\{\lambda\pi_j\}$ is an orthogonal sequence of polynomials, and so it can be used as an intermediate sequence in which to express the solution. We can generate the residual polynomial which will help obtain the p_i's: [illegible], i.e., the same r vectors as those of the generic CR algorithm (see Figure 5). It is interesting to note that with this sequence of residual vectors, which will be denoted by $\tilde{r}_j$, it is easy to generate the directions p_i [illegible] for both algorithms. The idea becomes straightforward: obtain the auxiliary residual polynomials $\tilde{p}_j$ that are those associated with the [illegible] CR algorithm and exploit them to obtain the π_i's in the same way as in the CR algorithm. The polynomials $\lambda\pi_j$ are orthogonal and therefore the expression of the desired approximation is the same. The algorithm is described in Figure 6, where now $\tilde{p}_j$ is the polynomial associated with the auxiliary sequence $\tilde{r}_j$.

FILTERED CONJUGATE RESIDUAL POLYNOMIALS ALGORITHM.

1.	Compute $\tilde{r}_0 := b - Ax_0$, $p_0 := \tilde{r}_0$	$\pi_0 = \tilde{p}_0 = 1$
2.		Compute $\lambda\pi_0$
3.	**for** $j = 0, 1, \ldots,$ until convergence:	
4.	$\tilde{\alpha}_j := \langle \tilde{p}_j, \lambda\tilde{p}_j \rangle_w / \langle \lambda\pi_j, \lambda\pi_j \rangle_w$	
5.	$\alpha_j := \langle \phi, \lambda\pi_j \rangle_w / \langle \lambda\pi_j, \lambda\pi_j \rangle_w$	
6.	$x_{j+1} := x_j + \alpha_j p_j$	
7.	$\tilde{r}_{j+1} := \tilde{r}_j - \tilde{\alpha}_j A p_j$	$\tilde{p}_{j+1} = \tilde{p}_j - \tilde{\alpha}_j \lambda\pi_j$
8.	$\beta_j := \langle \tilde{p}_{j+1}, \lambda\tilde{p}_{j+1} \rangle_w / \langle \tilde{p}_j, \lambda\tilde{p}_j \rangle_w$	
9.	$p_{j+1} := r_{j+1} + \beta_j p_j$	$\pi_{j+1} := \tilde{p}_{j+1} + \beta_j \pi_j$
10.		Compute $\lambda\pi_{j+1}$
11.	**end**	

FIG. 6. *The filtered CR polynomials algorithm.*

The only difference with a generic CR-type algorithm (see, e.g., Figure 5) is that the updates to x_{j+1} use different coefficients α_j from the updates to the vectors $\tilde{r}_{j+1}$. Observe that the residual vectors $\tilde{r}_j$ obtained by the algorithm are just auxiliary vectors that do not correspond to the actual residuals $r_j = b - Ax_j$. Needless to say, these actual residuals, the r_j's, can also be generated after line 5 (or 6) from $r_{j+1} = r_j - \alpha_j A p_j$. Depending on the application, it may or may not be necessary to include these computations.

The solution vector x_{j+1} computed at the jth step of the corrected CR algorithm is of the form $x_{j+1} = x_0 + s_j(A)r_0$, where s_j is the jth degree polynomial:

$$s_j(\lambda) = \alpha_0\pi_0(\lambda) + \cdots + \alpha_j\pi_j(\lambda). \tag{15}$$

The polynomials π_j and the auxiliary polynomials $\tilde{p}_{j+1}(\lambda)$ satisfy the orthogonality relations,

$$\langle \lambda\pi_j(\lambda), \lambda\pi_i(\lambda) \rangle_w = \langle \lambda\tilde{p}_j(\lambda), \tilde{p}_i(\lambda) \rangle_w = 0 \quad \text{for} \quad i \neq j. \tag{16}$$

In addition, the filtered residual polynomial $\phi - \lambda s_j(\lambda)$ minimizes $\|\phi - \lambda s(\lambda)\|_w$ among all polynomials s of degree $\leq j - 1$.

It is worth mentioning that there is an alternative formula for α_j, which is

$$\alpha_j = \tilde{\alpha}_j - \frac{\langle 1 - \phi, \lambda\pi_j \rangle}{\langle \lambda\pi_j, \lambda\pi_j \rangle}, \tag{17}$$

whose merit, relative to the expression used in line 4 of the algorithm, is that it clearly establishes the new algorithm as a corrected version of the generic CR algorithm of Figure 5. In the special situation when $\phi \equiv 1$, $\alpha_i = \tilde{\alpha}_i$, and the two algorithms coincide as expected.

4.2. The base filter function. The solutions computed by the algorithms just seen consist of generating polynomial approximations to a certain base filter function ϕ. It is generally not a good idea to use ϕ as the step function because this function is discontinuous and approximations to it by high-degree polynomials will exhibit very wide oscillations near the discontinuities. It is preferable to take as a "base" filter, i.e., the filter which is ultimately approximated by polynomials, a smooth function such as the one illustrated in Figure 7.

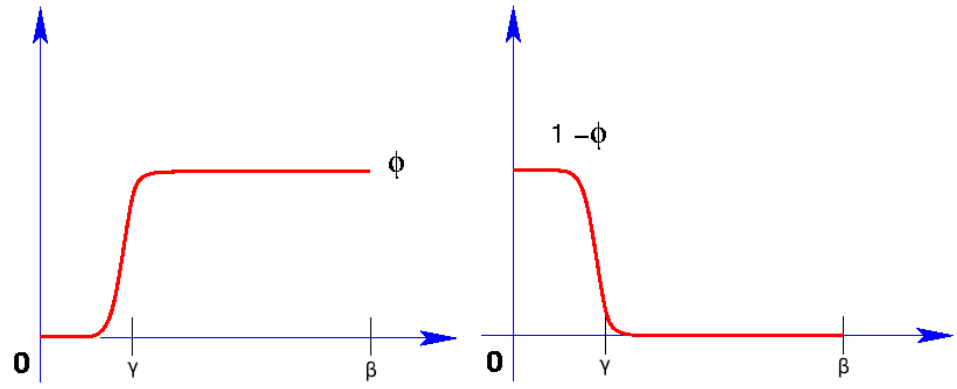

FIG. 7. *A typical filter function ϕ and its dual filter $1-\phi$.*

The filter function in Figure 7 can be a piecewise polynomial consisting of two pieces: A function which increases from 0 to 1 when λ increases smoothly from 0 to γ, and the constant function unity in the interval $[\gamma, \beta]$. Alternatively, the function can begin with the value 0 in the interval $[0, \gamma_1]$, then increase smoothly from 0 to 1 in a second interval $[\gamma_1, \gamma_2]$, and finally take the value 1 in $[\gamma_2, \beta]$. This second part of the function (the first part for the first scenario) bridges the values 1 and 1 by a smooth function and was termed a "bridge function" in [6].

A systematic way of generating base filter functions is to use bridge functions obtained from Hermite interpolation. The bridge function is an interpolating polynomial (in the Hermite sense) depending on two integer parameters m_0, m_1 and denoted by $\Theta_{[m_0,m_1]}$ which satisfies the following conditions:

$$
\begin{aligned}
&\Theta_{[m_0,m_1]}(0) = 0; \quad \Theta'_{[m_0,m_1]}(0) = \cdots = \quad \Theta^{(m_0)}_{[m_0,m_1]}(0) = 0, \\
&\Theta_{[m_0,m_1]}(\gamma) = 1; \quad \Theta'_{[m_0,m_1]}(\gamma) = \cdots = \quad \Theta^{(m_1)}_{[m_0,m_1]}(\gamma) = 0.
\end{aligned} \tag{18}
$$

Thus, $\Theta_{[m_0,m_1]}$ has degree m_0+m_1+1 and m_0, m_1 define the degree of smoothness at the points 0 and α, respectively. The ratio $\frac{m_1}{m_0}$ determines the localization of the inflection point. Making the polynomial increase rapidly from 0 to 1 in a small interval can be achieved by taking high-degree polynomials, but this has the effect of slowing down convergence toward the desired filter, as it causes undesired oscillations. Two examples are shown in Figures 8 and 9.

Once the base filter is selected, the filtered CR algorithm can be executed. It remains, however, to define the inner products. Details on the weight functions and the actual techniques for computing inner products of polynomials can be found in [28]. We only mention that it is possible to avoid numerical integration by defining the inner products by using classical weights (e.g., Chebyshev) in each subinterval of the whole interval where the base filter is defined. Since the base filter is a standard polynomial in each of these subintervals, inner products in these intervals can be evaluated without numerical integration. This, in effect, is equivalent to using Gaussian quadrature in each of these subintervals.

The support of the bridge function, an interval in which the base function drops from 1 to 0, can be determined by the interval of wanted eigenvalues and the largest eigenvalue of the matrix. We already discussed how to get the required bounds for the largest and smallest eigenvalues of A from a few steps of the Lanczos algorithm.

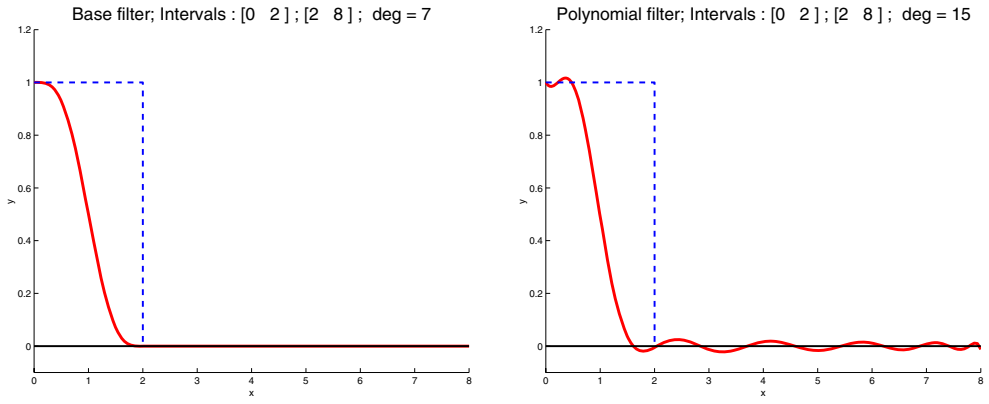

FIG. 8. *The base filter* $\Theta_{[4,4]}$ *in* $[0,2]$ *and one in* $[2,8]$ *(left) and its polynomial approximation of degree* 15 *(right).*

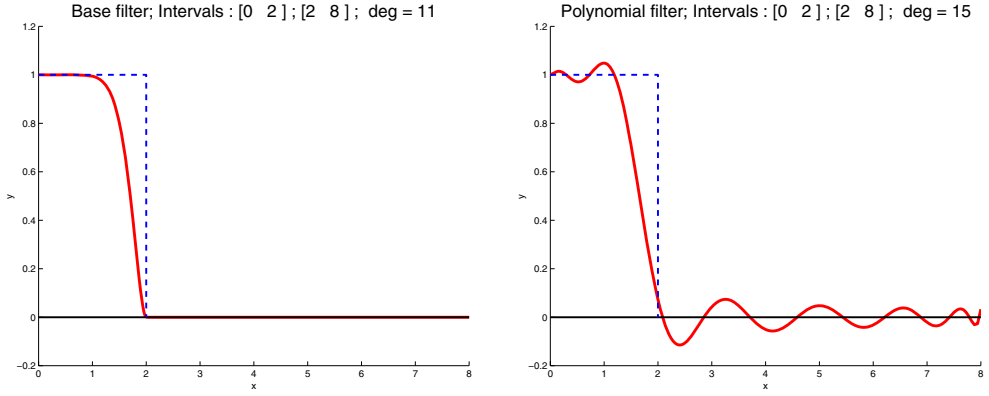

FIG. 9. *The base filter* $\Theta_{[10,2]}$ *in* $[0,2]$ *and one in* $[2,8]$ *(left) and its polynomial approximation of degree* 15 *(right).*

The bridge interval should be large enough so as to include all the eigenvalues of the wanted set, but not so large as to contain too many unwanted eigenvalues. In practice, augmenting the interval of wanted eigenvalues slightly only minimally hampers performance but helps improve the robustness of the procedure.

There are a number of parameters which can be exploited to yield a desired filter polynomial. In addition to the degrees of the polynomials m_0, m_1, one can also define the weight functions differently. For example, more or less emphasis can be placed in each subinterval. Our experience shows that using an equal weighting scheme for each subinterval is a very reasonable choice for most applications, including electronic structure calculations.

5. Numerical experiments. This section reports on a few numerical experiments with matrices taken from electronic structure calculations and from the Harwell–Boeing collection. Two other good reference points for a useful comparison would be the partially reorthogonalized Lanczos (which was used in [1]) and the implicitly restarted Lanczos iteration as it is implemented in the popular package `ARPACK` [16, 33]. We compare these two algorithms with the filtered Lanczos (`F. Lanczos`) algorithm with partial reorthogonalization.

All the experiments which follow were performed on an SGI Origin 2000 system using a single R12000 processor at 300 MHz clock. The filtered Lanczos code is available from the authors upon request. `F. Lanczos` is implemented purely in C while `ARPACK` is implemented in Fortran 77. The Lanczos algorithm with partial reorthogonalization is based in the Fortran 77 code `PLANSO` [35]. The convergence tolerance was set to 10^{-10} for all methods. Notice that although in electronic structure calculations the convergence tolerance is typically taken 2–3 orders of magnitude larger, `F. Lanczos` (similar to `ARPACK` and Lanczos) can be used for other applications as well (this is why we include the test matrix from the Harwell–Boeing collection). In order to conduct a rather strict test we have chosen the above convergence tolerance. For `ARPACK` the maximum dimension of the Lanczos basis was always set equal to twice the number of requested eigenvalues. Thus, the number of implicit QR steps in `ARPACK` was equal to the number of the wanted eigenvalues. We point out that these settings are typically used in `ARPACK`.

For `F. Lanczos` the number of filtered Lanczos iterations for the initial vector was set to 200, while the degree of the inner CR polynomial was 8. In the latest (stabilized) version of the code we use 2 intervals for the base function: one for the wanted and another for the unwanted ones. The degrees m_1, m_2 for the smooth base function are set to $m_1 = 5$ and $m_2 = 15$. The number of Lanczos iterations for the determination of the bounding interval $[\alpha, \beta]$ for the spectrum was determined by a convergence tolerance of 10^{-6}. The above settings were the same for all test cases.

For partial reorthogonalization we used the default parameters defined in the `PLANSO` code. It is worth mentioning that the maximum loss of orthogonality allowed was set to the square root of the machine precision.

In implicitly restarted techniques, such as those implemented in `ARPACK`, a basis of length equal to the number of required eigenvalues is updated at each restart. Thus, such methods are not designed to compute all eigenvalues in a given interval. This, of course, is in contrast to the filtered Lanczos iteration, as well as to the unrestarted Lanczos algorithm. In order to facilitate a performance comparison we have used the following setting: for each test matrix, we are interested in a given number of its algebraically smallest eigenvalues. We compute these using `ARPACK`. Then we use the filtered Lanczos iteration and the unrestarted Lanczos iteration with partial reorthogonalization to compute all eigenvalues that are smaller than or equal to the largest of the requested eigenvalues computed by `ARPACK`. Of course, this comparison is not carried out on completely equal terms. However, our goal is to demonstrate that a strategy of exchanging memory accesses with additional matrix-vector products can significantly lower the overall computational cost. This was previously shown in [1], however, at the important expense of additional memory, relative to implicitly restarted techniques. The experiments that follow clearly show that the filtered Lanczos iteration can achieve both goals: it can operate on limited memory while significantly reducing the overall computational cost.

Test matrices. We have used four matrices from electronic structure calculations for the tests. These are Hamiltonians obtained from a real-space code [2]. In addition, we have also used a test matrix, namely, the `Andrews` matrix, from the University of Florida sparse matrix collection,[3] so as to give an example of applicability of our method in other applications as well. Table 1 provides the characteristics of the test matrices. For the Hamiltonians the number of the requested eigenvalues

[3] http://www.cise.ufl.edu/research/sparse/

TABLE 1
Characteristics of test matrices: nnz is the total number of nonzeros, so the last column shows the average number of nonzeros per row.

Matrix	Size n	nnz	nnz/n
$\mathtt{Si_{10}H_{16}}$	17077	875923	51.3
$\mathtt{Ge_{99}H_{100}}$	94341	6332795	67.2
$\mathtt{Ge_{87}H_{76}}$	94341	5963003	63.2
$\mathtt{Si_{34}H_{36}}$	97569	5156379	52.8
`Andrews`	60000	760154	12.7

generally correspond to physical properties of the corresponding molecular system. For example, $\mathtt{Si_{10}H_{16}}$ has 28 occupied states, while $\mathtt{Si_{34}H_{36}}$ has 86, $\mathtt{Ge_{87}H_{76}}$ has 212, and $\mathtt{Ge_{99}H_{100}}$ has 248. In order to test the scalability of the methods under study, we requested additional eigenvalues as well. For the matrix `Andrews` we arbitrarily requested 100–400 eigenvalues. We point out that all statistics for the `F. Lanczos` algorithm include an initial call to the unrestarted Lanczos algorithm, with partial reorthogonalization, in order to approximate (upper and lower) bounds for the extremal eigenvalues. Observe that our choice of matrices spans different degrees of sparsity in order to demonstrate the effect of the latter on the overall cost, since the `F. Lanczos` algorithm makes heavy use of matrix-vector products.

Discussion. The experimental results clearly illustrate that the `F. Lanczos` algorithm achieves significant improvements over the other two competing methods. The performance improvement becomes more evident as the number of requested eigenvalues increases.

All of our test matrices are sparse. However, the degree of sparsity (as measured by the average number of nonzeros per row, shown in the last column of Table 1) differs significantly between the "denser" $\mathtt{Ge_{99}H_{100}}$ Hamiltonian and the "sparser" `Andrews` matrix. A careful look in the results illustrated in Table 2 clearly suggests that the improvements in run-times of the `F. Lanczos` algorithm over `ARPACK` is more pronounced for the sparser test matrices. Thus, although the number of matrix-vector products in `F. Lanczos` increases relative to `ARPACK`, a significant gain results from avoiding the updating of a large number of eigenvectors, which standard methods do at every step.

The use of partial reorthogonalization is indeed beneficial in both `F. Lanczos` and Partial Lanczos. However, the main advantage of `F. Lanczos` is the reduction of traffic in memory. For example, let us look at the case of $\mathtt{Si_{34}H_{36}}$ and $n_o = 200$ (last row of subtable, Table 2). Observe that `F. Lanczos` uses 640 basis vectors, while Partial Lanczos has to move 3580 basis vectors from memory. For `ARPACK` we have 30 restarts, and at each restart the algorithm will "touch" 400 vectors (twice the number of sought eigenvalues); thus we have a total of at least 12000 basis vectors moving between memory and CPU (including other costs such as full reorthogonalization).

In electronic structure calculations the required accuracy is close to $0.5 \cdot 10^{-6}$, which is larger than the semiorthogonality level of 10^{-8} that is ensured by partial reorthogonalization. However, in applications that have stricter accuracy requirements, semiorthogonality of basis vectors may not be adequate. If this is the case, then we can use full reorthogonalization in `F. Lanczos`. Of course, we can expect the benefits over `ARPACK` to reduce somewhat; however, the major improvement which results from the small basis of `F. Lanczos` and its unrestarted nature, and thus its much lesser use of memory, is still there. On the other hand, using a large convergence tolerance could prove tricky in `ARPACK` as this code relies on deflation techniques in order to improve

TABLE 2

Summary of experimental results for all 5 *test matrices.* MV *denotes the total number of matrix-vector products, which for the Lanczos algorithm with partial reorthogonalization is also the dimension of the Lanczos basis used. For the* F. Lanczos *algorithm, the numbers in parentheses in the* MV *column denote the dimension of the Lanczos basis.* RTH *denotes the number of reorthogonalization steps.* RES *is the number of restarts for* ARPACK. MEM *denotes the required memory in Mbytes and* t *is the total time in secs. Finally, n_o is the number of requested eigenvalues.*

convergence. Thus, poorly converged (large) eigenvectors will reenter in the iteration, slowing convergence towards small eigenvalues.

In comparison with the unrestarted partially reorthogonalized Lanczos procedure, observe that the filtered Lanczos method always requires far less memory. In fact, the amount of additional memory in comparison to ARPACK is quite modest. Typically, the new method will require a Lanczos basis with length close to three times the number of computed eigenvalues. We also observe that for rather dense matrices and small number of eigenvalues (i.e., $Si_{34}H_{36}$ and $Si_{10}H_{16}$) the unrestarted Lanczos method with partial reorthogonalization is the fastest of the three methods. However, when a large invariant subspace is sought, then the unrestarted Lanczos method will tend to require a long basis, ultimately causing even infrequent reorthogonalizations and a significant increase in memory traffic, and to dramatically prolong the run-times.

6. Conclusions. This paper presented a filtered Lanczos iteration for computing large invariant subspaces associated with the algebraically smallest eigenvalues of very large and sparse matrices. In contrast to restarted techniques (e.g., ARPACK),

which repeatedly update a fixed number of basis vectors, filtered Lanczos is allowed to augment the search subspace until all eigenvalues smaller than a predetermined upper bound have converged. The loss of orthogonality of the Lanczos basis vectors is treated by a partial reorthogonalization scheme [31]. One technique which filtered Lanczos and explicit/implicit restarted Krylov subspace algorithms have in common is the use of filtering polynomials, designed to dampen eigencomponents along "unwanted" parts of the spectrum. However, while restarted techniques apply these polynomials periodically (i.e., at each restart), the filtered Lanczos procedure applies a fixed, precomputed, low-degree polynomial of A to the working Lanczos vector, which amounts to a polynomial preconditioning technique applied to A. We showed that if the unwanted eigendirections are thoroughly filtered from the starting vector of the Lanczos algorithm, then the application of the aforementioned small-degree polynomial successfully prevents the unwanted directions from reappearing into the iteration, thus expediting convergence towards the desired invariant subspace. Earlier work (see, e.g., [28]) showed how one can design a CR-type iteration that efficiently applies a low pass filter in order to solve regularized linear systems. The low-degree polynomial which is involved in this procedure is used in the filtered Lanczos algorithm.

Experimental evidence clearly shows that the new method achieves significant performance improvements over the most sophisticated restarted technique (i.e., `ARPACK`), while at the same time incurring very modest additional memory requirements. These gains in efficiency are obtained by essentially trading the repeated and costly updates of the working eigenbasis, which is inherit in restarted techniques, for additional matrix-vector products. Thus, the method will work quite well whenever matrix-vector products are not expensive.

Acknowledgments. This work would not have been possible without the availability of excellent source codes for diagonalization. Specifically, our experiments made use of the `PLANSO` code developed by Wu and Simon [35] and the `ARPACK` code of Lehoucq, Sorensen, and Yang [16]. The first author would like to thank A. Stathopoulos, R. Lehoucq, and C. Yang for useful discussions concerning implicitly restarted methods.

A FAST METHOD FOR FINDING THE GLOBAL SOLUTION OF THE REGULARIZED STRUCTURED TOTAL LEAST SQUARES PROBLEM FOR IMAGE DEBLURRING*

AMIR BECK†, AHARON BEN-TAL‡, AND CHRISTIAN KANZOW§

Abstract. Given a linear system $\mathbf{Ax} \approx \mathbf{b}$ over the real or complex field, where both $\mathbf{A}$ and $\mathbf{b}$ are subject to noise, the total least squares (TLS) problem seeks to find a correction matrix and a correction right-hand side vector of minimal norm which makes the linear system feasible. To avoid ill posedness, a regularization term is added to the objective function; this leads to the so-called regularized TLS problem. A further complication arises when the matrix $\mathbf{A}$ and correspondingly the correction matrix must have a specific structure. This is modeled by the regularized structured TLS (RSTLS) problem. In general this problem is nonconvex and hence difficult to solve. However, the RSTLS problem arising from image deblurring applications under reflexive or periodic boundary conditions possesses a special structure where all relevant matrices are simultaneously diagonalizable (SD). In this paper we introduce an algorithm for finding the *global* optimum of the RSTLS problem with this SD structure. The devised method is based on decomposing the problem into single variable problems and then transforming them into one-dimensional unimodal real-valued minimization problems which can be solved globally. Based on the uniqueness and attainment properties of the RSTLS solution we show that a constrained version of the problem possesses a strong duality result and can thus be solved via a sequence of RSTLS problems.

Key words. structured total least squares, nonconvex optimization, image deblurring, unimodal functions, simultaneously diagonalizable matrices

AMS subject classifications. 90C26, 15A29

DOI. 10.1137/070709013

1. Introduction.

Given a linear system $\mathbf{Ax} \approx \mathbf{b}$ over the real or complex field, where both the matrix $\mathbf{A}$ and the right-hand side vector $\mathbf{b}$ are subjected to noise, the total least squares (TLS) problem seeks to minimize the sum of squared norms of the perturbations to both the model matrix and vector $\|\mathbf{E}\|^2 + \|\mathbf{w}\|^2$ subject to the condition that the perturbed system holds: $(\mathbf{A} + \mathbf{E})\mathbf{x} = \mathbf{b} + \mathbf{w}$. Although this problem is nonconvex, it can be solved efficiently and globally by using a spectral decomposition of the augmented matrix $(\mathbf{A}, \mathbf{b})$; see [14, 20].

In many applications, the matrix $\mathbf{A}$ has a specific linear structure, e.g., Toeplitz or Hankel, which imposes a requirement on the perturbation matrix $\mathbf{E}$ to possess a corresponding special structure. The TLS solution does not take into account this requirement, and consequently the structured TLS (STLS)[1] attracted intensive research; see, e.g., [1, 29, 34, 28, 25, 22]. The formulation of the STLS problem is

§Institute of Mathematics, University of Würzburg, Am Hubland, 97074 Würzburg, Germany (kanzow@mathematik.uni-wuerzburg.de).

[1]In some papers the STLS problem is also called *constrained total least squares*.

$$\text{(STLS):}\quad \begin{array}{ll} \min\limits_{\mathbf{E},\mathbf{x},\mathbf{w}} & \|\mathbf{E}\|^2 + \|\mathbf{w}\|^2 \\ \text{s.t.} & (\mathbf{A}+\mathbf{E})\mathbf{x} = \mathbf{b}+\mathbf{w}, \\ & \mathbf{E} \in \mathcal{L}, \end{array}$$

where $\mathcal{L}$ is a linear subspace. We remark that there are several generalizations of the above STLS formulation that are able to deal with multiple right-hand sides (that is, $\mathbf{b}$ and $\mathbf{x}$ are matrices) [23], structure of the right-hand side noise vector $\mathbf{w}$ [23], and other norms such as l_1, l_∞ [34], and weighted l_2 norms [24].

The STLS problem is a nonconvex problem, and thus finding its global solution is in general a difficult task. There are only a few exceptions to this state of affairs. For block circulant structures with unstructured blocks the corresponding STLS problem can be solved by decomposing the problem into several smaller TLS problems using the discrete Fourier transform [6]. Another tractable case arises when some of the columns of $\mathbf{A}$ are error-free while the others are subjected to noise. This problem is called the [illegible] problem or [illegible] problem, and its solution can be obtained by computing a QR factorization of $\mathbf{A}$ and then solving a TLS problem of reduced dimension [19]. A more general problem is the [illegible] problem introduced in [21]. There it is assumed that $(\mathbf{E}, \mathbf{w}) = \mathbf{D}_1 \tilde{\mathbf{E}} \mathbf{C}_1$, where $\mathbf{D}_1$ and $\mathbf{C}_1$ are known matrices and $\widetilde{\mathbf{E}}$ is unknown. As was shown in [21], by choosing the matrices $\mathbf{D}_1$ and $\mathbf{C}_1$ appropriately, the restricted TLS problem contains as special cases any weighted least squares (LS), generalized LS, TLS, and generalized TLS problems. The restricted TLS problem can be solved by using the restricted singular value decomposition [37].

In this paper we consider yet another tractable class of STLS problems in which the global solution can efficiently be found. We deal with structures in which all of the matrices in $\mathcal{L}$ are square and can be diagonalized by a certain fixed orthogonal (or unitary in the complex case) matrix. These structures are called [illegible] (SD) structures. The motivation for considering such structures stems from image deblurring problems with spatially invariant point spread functions (PSF). For two-dimensional image deblurring problems it is well known that the matrix describing the blur operator can be diagonalized by a two-dimensional discrete Fourier transform matrix when [illegible] are assumed. For [illegible] with symmetric PSF the corresponding matrix can be diagonalized by a two-dimensional discrete cosine transform matrix. Similar structures can be found in one-dimensional deconvolution problems. Section 2 contains a brief review of these structures.

A characteristic feature of image deblurring problems is that the matrix $\mathbf{A}$ is ill-conditioned, and as a result the STLS solution usually has a huge norm and as such is meaningless. Regularization is required in order to stabilize the solution. For the unstructured TLS problem several regularization methods are well known. Among them are truncation methods [11, 17] and Tikhonov regularization [13, 7], in which a quadratic penalty is added to the objective function or a quadratic constraint bounding the size of the solution norm is added to the problem [36, 33, 13, 8, 5].

For the STLS problem, Tikhonov regularization seems to be the most popular method. The resulting problem is called the regularized STLS problem (RSTLS) and is given by

$$\text{(RSTLS):}\quad \begin{array}{ll} \min\limits_{\mathbf{E},\mathbf{x},\mathbf{w}} & \|\mathbf{E}\|^2 + \|\mathbf{w}\|^2 + \rho\|\mathbf{L}\mathbf{x}\|^2 \\ \text{s.t.} & (\mathbf{A}+\mathbf{E})\mathbf{x} = \mathbf{b}+\mathbf{w}, \\ & \mathbf{E} \in \mathcal{L}. \end{array}$$

Common choices for $\mathbf{L}$ are the identity or a matrix approximating the first or second order derivative operator [16, 13, 18].

The RSTLS problem for structures arising in image deblurring was studied in several works. In [27] periodic boundary conditions are considered. By using the discrete Fourier transform the problem is decomposed into many complex-valued single-variable problems. The complex univariate problems are solved as two-variable nonconvex problems over the real domain by using the Davidon–Fletcher–Powell optimization algorithm.

In [31] an iterative algorithm of quasi-Newton form is applied for the RSTLS problem for reflexive boundary conditions that exploits the diagonalization properties of the associated matrices. The work [32] extends the structured total least norm algorithm [34] to include regularization, and image deblurring examples are discussed. This approach was also advocated in [12] for image deblurring problems with separable PSFs and in [26] for problems with zero boundary conditions.

In all of the above-mentioned works the optimization problems that need to be solved are nonconvex, and consequently the devised algorithms are not guaranteed to converge to a global optimum but rather to a stationary point. The main contribution of the present paper is the introduction of a method capable of obtaining the [illegible] of the RSTLS problem for SD structures.

The paper is organized as follows. In section 2 we present a precise problem formulation followed by a brief review of the essential ingredients from image deblurring. The decomposition of the RSTLS problem into single-variable real- or complex-valued problems is discussed in section 3. These univariate problems are not necessarily unimodal, but we show in section 4 that they can be transformed into single-variable real-valued unimodal problems. Attainment and uniqueness conditions are also obtained. In section 5 we concentrate on circulant structures and show that, when the data are real-valued, there exists at least one real-valued optimal solution (although the corresponding single-variable problems are complex-valued). In section 6 we tackle the constrained version of the RSTLS problem, called CSTLS, and show that, based on the derived uniqueness properties and on a strong duality result, the constrained problem can be solved by a sequence of RSTLS problems. The paper ends in section 7 with detailed descriptions of the numerical algorithms and a demonstration of our method as applied to an image deblurring problem. A MATLAB implementation and documentation of the RSTLS and CSTLS methods for image deblurring problems with either periodic or reflexive boundary conditions can be found in [38].

1.1. Notation. A vector or matrix is called real-valued (complex-valued) if all of its entries are real (complex). For a complex scalar a, the complex conjugate is denoted by $\bar{a}$. Given a matrix $\mathbf{A}$ (a vector $\mathbf{v}$), the complex conjugate is denoted by $\mathbf{A}^*$ ($\mathbf{v}^*$). For a real-valued matrix $\mathbf{Q}$, the complex conjugate $\mathbf{Q}^*$ translates to the usual transpose $\mathbf{Q}^T$, and unitarity translates to orthogonality: $\mathbf{Q}^T\mathbf{Q} = \mathbf{I}$. The root of -1 is denoted by $\mathbf{i} = \sqrt{-1}$. For a given vector $\mathbf{v}$, $\|\mathbf{v}\|$ denotes the Euclidean norm of $\mathbf{v}$, and, for a matrix $\mathbf{A}$, $\|\mathbf{A}\|$ denotes the Frobenius norm of the matrix. The Kronecker product of two matrices $\mathbf{A}$ and $\mathbf{B}$ is denoted by $\mathbf{A} \otimes \mathbf{B}$.

2. RSTLS for simultaneously diagonalizable structures.

2.1. Problem formulation. The RSTLS problem can be written as follows:

$$\text{(RSTLS):} \quad \begin{array}{ll} \min & \|\mathbf{E}\|^2 + \|\mathbf{w}\|^2 + \rho\|\mathbf{L}\mathbf{x}\|^2 \\ \text{s.t.} & (\mathbf{A}+\mathbf{E})\mathbf{x} = \mathbf{b} + \mathbf{w}, \\ & \mathbf{E} \in \mathcal{L}, \\ & \mathbf{x} \in \mathbb{F}^n, \mathbf{w} \in \mathbb{F}^m, \end{array} \tag{2.1}$$

where $\mathbf{A} \in \mathbb{F}^{m\times n}$ and $\mathbf{b} \in \mathbb{F}^m$, with $\mathbb{F}$ being either the real or the complex number field ($\mathbb{R}$ or $\mathbb{C}$, respectively). The parameter ρ is a positive real number, and the set $\mathcal{L}$ is a linear subspace of the set of all $m \times n$ matrices $\mathbb{F}^{m\times n}$. As was discussed in the introduction, this formulation was considered in several papers; see, e.g., [27, 31, 32, 12, 26].

In this paper we consider the case in which $m = n$ and $\mathcal{L}$ is a linear subspace of the set of all $n \times n$ matrices diagonalizable by a given unitary matrix. That is, $\mathcal{L} = \mathcal{L}_{\mathbf{Q}}$, where

$$\mathcal{L}_{\mathbf{Q}} = \{\mathbf{Q}^* \mathrm{diag}(\boldsymbol{\lambda})\mathbf{Q} : \boldsymbol{\lambda} \in \mathbb{F}^n\}, \tag{2.2}$$

with $\mathbf{Q}$ being a given unitary matrix (i.e., $\mathbf{Q}^*\mathbf{Q} = \mathbf{I}$). Such a structure is called a SD structure, with unitary transform. In our derivations we also assume that $\mathbf{A}, \mathbf{L} \in \mathcal{L}_{\mathbf{Q}}$. This particular structure is also discussed in, e.g., [27, 31].

In section 3 we will show that, as opposed to most structures, the RSTLS problem with an SD structure can be solved globally and efficiently. Before doing so, we will describe some image deblurring examples in which SD structures appear.

2.2. SD structures associated with image deblurring. We will now present four classes of SD structures that arise naturally in image deblurring problems. In addition to two-dimensional images, we will also consider one-dimensional signals and refer to them as "one-dimensional images." Before examining the four classes, we briefly review some essential facts and notation from image processing.

Many image deblurring problems can be modeled as $\mathbf{g} = \mathbf{Sf}$, where $\mathbf{g} \in \mathbb{R}^n$ is the blurred image and $\mathbf{f} \in \mathbb{R}^n$ is the unknown true image, whose size is assumed to be the same as the one of $\mathbf{g}$. The matrix $\mathbf{S}$ describes the blur operator. In the case of spatially invariant blurs, $\mathbf{Sf}$ is usually a convolution of a corresponding PSF and the true image $\mathbf{f}$.

The structure of the matrix $\mathbf{S}$ depends on the choice of boundary conditions, that is, the underlying assumptions on the image outside the field of view. Three very popular boundary conditions are (i) [illegible], in which all pixels outside the borders are assumed to be zero, (ii) [illegible], in which it is assumed that the image repeats itself in all directions, (iii) [illegible], in which it is assumed that the scene outside of the boundaries is an image mirror of the image boundaries.

Let us illustrate the three types of boundary conditions. First, in the one-dimensional case consider the image

$$\begin{pmatrix} 1 \\ 2 \\ 3 \end{pmatrix},$$

and then for zero, periodic, and reflexive boundary conditions the larger image looks like

$$\left(\begin{array}{c} 0 \\ 0 \\ 0 \\ \hline 1 \\ 2 \\ 3 \\ \hline 0 \\ 0 \\ 0 \end{array}\right), \qquad \left(\begin{array}{c} 1 \\ 2 \\ 3 \\ \hline 1 \\ 2 \\ 3 \\ \hline 1 \\ 2 \\ 3 \end{array}\right), \qquad \left(\begin{array}{c} 3 \\ 2 \\ 1 \\ \hline 1 \\ 2 \\ 3 \\ \hline 3 \\ 2 \\ 1 \end{array}\right),$$

respectively. In the two-dimensional case if we consider the image

$$\begin{pmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \\ 7 & 8 & 9 \end{pmatrix},$$

then for zero, periodic, and reflexive boundary conditions the larger image looks like

$$\left(\begin{array}{ccc|ccc|ccc} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ \hline 0 & 0 & 0 & 1 & 2 & 3 & 0 & 0 & 0 \\ 0 & 0 & 0 & 4 & 5 & 6 & 0 & 0 & 0 \\ 0 & 0 & 0 & 7 & 8 & 9 & 0 & 0 & 0 \\ \hline 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{array}\right), \quad \left(\begin{array}{ccc|ccc|ccc} 1 & 2 & 3 & 1 & 2 & 3 & 1 & 2 & 3 \\ 4 & 5 & 6 & 4 & 5 & 6 & 4 & 5 & 6 \\ 7 & 8 & 9 & 7 & 8 & 9 & 7 & 8 & 9 \\ \hline 1 & 2 & 3 & 1 & 2 & 3 & 1 & 2 & 3 \\ 4 & 5 & 6 & 4 & 5 & 6 & 4 & 5 & 6 \\ 7 & 8 & 9 & 7 & 8 & 9 & 7 & 8 & 9 \\ \hline 1 & 2 & 3 & 1 & 2 & 3 & 1 & 2 & 3 \\ 4 & 5 & 6 & 4 & 5 & 6 & 4 & 5 & 6 \\ 7 & 8 & 9 & 7 & 8 & 9 & 7 & 8 & 9 \end{array}\right),$$

$$\left(\begin{array}{ccc|ccc|ccc} 9 & 8 & 7 & 7 & 8 & 9 & 9 & 8 & 7 \\ 6 & 5 & 4 & 4 & 5 & 6 & 6 & 5 & 4 \\ 3 & 2 & 1 & 1 & 2 & 3 & 3 & 2 & 1 \\ \hline 3 & 2 & 1 & 1 & 2 & 3 & 3 & 2 & 1 \\ 6 & 5 & 4 & 4 & 5 & 6 & 6 & 5 & 4 \\ 9 & 8 & 7 & 7 & 8 & 9 & 9 & 8 & 7 \\ \hline 9 & 8 & 7 & 7 & 8 & 9 & 9 & 8 & 7 \\ 6 & 5 & 4 & 4 & 5 & 6 & 6 & 5 & 4 \\ 3 & 2 & 1 & 1 & 2 & 3 & 3 & 2 & 1 \end{array}\right),$$

respectively. The structure of the matrix $\mathbf{S}$ depends on the underlying boundary conditions. Here we consider spatially invariant blurs which, as was already mentioned, imply that the blur is a convolution of given a PSF with the true (larger) image. For one-dimensional problems the PSF is just a vector $\mathbf{p} \in \mathbb{R}^d$ with an associated center $c \in \{1, 2, \ldots, d\}$. The convolution operation is then:

$$g_i = \sum_{j=1}^{d} p_j f_{i+c-j}, \quad i = 1, \ldots, n,$$

where $\mathbf{f} \in \mathbb{R}^d$ is the true image. Notice that the above formula uses values of $\mathbf{f}$ beyond the boundaries (indices smaller than 1 and larger than n), but these values are determined by the boundary conditions. For example, consider a one-dimensional image of length three: $\mathbf{f} = (f_1, f_2, f_3)^T$, and let the PSF array be $\mathbf{p} = (p_1, p_2, p_3)^T$ with $c = 2$. Then the blurred image $\mathbf{g}$ depends on the true image $\mathbf{f}$ via the relation $\mathbf{g} = \mathbf{S}\mathbf{f}$, where

$$\mathbf{S} = \begin{pmatrix} p_2 & p_1 & 0 \\ p_3 & p_2 & p_1 \\ 0 & p_3 & p_2 \end{pmatrix}, \begin{pmatrix} p_2 & p_1 & p_3 \\ p_3 & p_2 & p_1 \\ p_1 & p_3 & p_2 \end{pmatrix}, \begin{pmatrix} p_2 + p_3 & p_1 & 0 \\ p_3 & p_2 & p_1 \\ 0 & p_3 & p_2 + p_1 \end{pmatrix}$$

for zero, periodic, and reflexive boundary conditions, respectively. Note that the above three matrices have different structures (Toeplitz, circulant, and Toeplitz-plus-

Hankel). We now discuss four SD structures arising from one- and two-dimensional problems with either periodic or reflexive boundary conditions:[2]

1. [illegible] [10]. For one-dimensional images with periodic boundary conditions, the structure of the model matrix is circulant, i.e., has the form

$$\mathbf{S} = \begin{pmatrix} s_1 & s_2 & \cdots & s_n \\ s_n & s_1 & \cdots & s_{n-1} \\ \vdots & \vdots & & \vdots \\ s_2 & s_3 & \cdots & s_1 \end{pmatrix}.$$

All $n \times n$ circulant matrices are diagonalizable by the unitary discrete Fourier transform (DFT) matrix $\mathbf{F}_n$ given by

$$\mathbf{F}_n = \left(\frac{1}{\sqrt{n}} \omega^{(j-1)(k-1)} \right)_{j,k=1}^{n},$$

where $\omega = e^{\frac{2\pi \mathbf{i}}{n}}$. Multiplications of the DFT matrix $\mathbf{F}_n$ with vectors, as well as eigenvalue computation of circulant matrices, can be done very efficiently by using the fast Fourier transform (FFT) with a complexity of $O(n \log n)$.

2. [illegible] [2]. For two-dimensional images of size $m \times n$ with periodic boundary conditions, the model matrix has a block circulant matrix with circulant blocks (BCCB) structure:

$$\mathbf{S} = \begin{pmatrix} \mathbf{C}_1 & \mathbf{C}_2 & \dots & \mathbf{C}_n \\ \mathbf{C}_n & \mathbf{C}_1 & \dots & \mathbf{C}_{n-1} \\ \vdots & \vdots & & \vdots \\ \mathbf{C}_2 & \mathbf{C}_3 & \dots & \mathbf{C}_1 \end{pmatrix},$$

where $\mathbf{C}_1, \dots, \mathbf{C}_n$ are $m \times m$ circulant matrices. All BCCB matrices of the above size are diagonalizable by the unitary two-dimensional DFT matrix $\mathbf{F}_n \otimes \mathbf{F}_m$. As in the circulant case, computations with BCCB matrices can be performed by using the FFT.

3. [illegible] [30]. For one-dimensional images with reflexive boundary conditions and symmetric PSF, the matrix $\mathbf{S}$ has a Toeplitz-plus-Hankel structure of the form [30]

$$T(\mathbf{s}) + H(\mathbf{s}),$$

where, for a given vector $\mathbf{s} = (s_1, \dots, s_n)^T \in \mathbb{R}^n$, $T(\mathbf{s})$ is the symmetric Toeplitz matrix whose first column is $\mathbf{s}$ and $H(\mathbf{s})$ is the Hankel matrix whose first and last columns are $(s_1, s_2, \dots, s_n, 0)^T$ and $(0, s_n, \dots, s_2, s_1)^T$, respectively. All Toeplitz-plus-Hankel matrices of the above form are diagonalizable by the orthogonal discrete cosine transform (DCT) matrix $\mathbf{C}_n$ given by

$$\mathbf{C}_n = \left(\sqrt{(2 - \delta_{k1})/n} \cos \frac{\pi(2j-1)(k-1)}{2n} \right)_{j,k=1}^{n},$$

where, for two indices i and j, δ_{ij} denotes the Kronecker sign. Multiplications of the DCT matrix $\mathbf{C}_n$ with vectors, as well as eigenvalue computation

[2] We do not consider in this paper the zero boundary condition as it does not lead to an SD structure.

of circulant matrices, can be done very efficiently by using the fast cosine transform (FCT) with a complexity of $O(n \log n)$.

4. BTTB+BTHB+BHTB+BHHB [15, 30]. For two-dimensional images of size $m \times n$ with reflexive boundary conditions and a symmetric PSF, the matrix $\mathbf{S}$ is a sum of a BTTB (block Toeplitz with Toeplitz blocks), BTHB (block Toeplitz with Hankel blocks), BHTB (block Hankel with Toeplitz blocks), and BHHB (block Hankel with Hankel blocks) matrices. All matrices of this form are diagonalizable by the orthogonal two-dimensional DCT matrix $\mathbf{C}_n \otimes \mathbf{C}_m$. We note that the symmetry condition does occur in practice, for example, the Gaussian model for atmospheric turbulence blur, out-of-focus blurs, and certain classes of Moffat blurs [15].

We have thus described four SD structures arising from one- and two-dimensional deblurring problems. The first two classes correspond to $\mathbb{F} = \mathbb{C}$ (since the DFT matrix is complex-valued), and the last two classes correspond to $\mathbb{F} = \mathbb{R}$. Coming back to the RSTLS problem, we note that it is very natural to assume that the boundary conditions also apply to the regularization operator, and we can thus assume that $\mathbf{L} \in \mathcal{L}_{\mathbf{Q}}$.

3. Decomposition of the RSTLS problem for SD structures. We begin by showing that the RSTLS problem (2.1) with an SD structure can be decomposed into n one-dimensional minimization problems.

THEOREM 3.1. (2.1) $m = n$ $\mathcal{L} = \mathcal{L}_{\mathbf{Q}}$ (2.2) $\mathbf{Q} \in \mathbb{F}^{n \times n}$ $\mathbf{A}, \mathbf{L} \in \mathcal{L}_{\mathbf{Q}}$ $\boldsymbol{\alpha}, \mathbf{l}$ $\mathbf{A}$ $\mathbf{L}$

$$\mathbf{QAQ}^* = \operatorname{diag}(\boldsymbol{\alpha}), \quad \mathbf{QLQ}^* = \operatorname{diag}(\mathbf{l}). \tag{3.1}$$

$\mathbf{x} = \mathbf{Q}^*\hat{\mathbf{x}}$ $i = 1, \ldots, n$ $\hat{\mathbf{x}}$ $\hat{x}_i$

$$\min_{\hat{x}_i} \left\{ \frac{|\alpha_i \hat{x}_i - \hat{b}_i|^2}{1 + |\hat{x}_i|^2} + \rho |l_i|^2 |\hat{x}_i|^2 \right\}, \tag{3.2}$$

$\hat{\mathbf{b}} = \mathbf{Qb}$ $\mathbf{E}$

$$\mathbf{E} = \mathbf{Q}^* \operatorname{diag}(\mathbf{r}) \mathbf{Q}, \tag{3.3}$$

$$r_i = -\frac{\overline{\hat{x}_i}(\alpha_i \hat{x}_i - \hat{b}_i)}{1 + |\hat{x}_i|^2}. \tag{3.4}$$

. By using the relation $\mathbf{w} = (\mathbf{A} + \mathbf{E})\mathbf{x} - \mathbf{b}$, we can rewrite (2.1) as the following problem in the variables $\mathbf{E}$ and $\mathbf{x}$:

$$\min_{\mathbf{E},\mathbf{x}} \{ \|\mathbf{E}\|^2 + \|(\mathbf{A} + \mathbf{E})\mathbf{x} - \mathbf{b}\|^2 + \rho \|\mathbf{Lx}\|^2 : \mathbf{E} \in \mathcal{L}_{\mathbf{Q}}, \mathbf{x} \in \mathbb{F}^n \},$$

which, by the unitarity property of $\mathbf{Q}$, is the same as

$$\min_{\mathbf{E},\mathbf{x}} \{ \|\mathbf{QEQ}^*\|^2 + \|\mathbf{Q}(\mathbf{A} + \mathbf{E})\mathbf{Q}^*\mathbf{Qx} - \mathbf{Qb}\|^2 + \rho \|\mathbf{QLQ}^*\mathbf{Qx}\|^2 : \mathbf{E} \in \mathcal{L}_{\mathbf{Q}}, \mathbf{x} \in \mathbb{F}^n \}. \tag{3.5}$$

Since $\mathbf{E} \in \mathcal{L}_{\mathbf{Q}}$, we can make the change of variables $\mathbf{QEQ}^* = \mathrm{diag}(\mathbf{r})$, where $\mathbf{r} \in \mathbb{F}^n$ is an unknown variables vector. By combining this with (3.1) we conclude that (3.5) can be reformulated as

$$\min_{\mathbf{r},\hat{\mathbf{x}}} \{\|\mathrm{diag}(\mathbf{r})\|^2 + \|\mathrm{diag}(\boldsymbol{\alpha} + \mathbf{r})\hat{\mathbf{x}} - \hat{\mathbf{b}}\|^2 + \rho\|\mathrm{diag}(\mathbf{l})\hat{\mathbf{x}}\|^2 : \mathbf{r}, \hat{\mathbf{x}} \in \mathbb{F}^n\},$$

where $\hat{\mathbf{x}} = \mathbf{Q}\mathbf{x}$, and more explicitly as

$$\min_{\mathbf{r},\hat{\mathbf{x}}} \left\{ \sum_{i=1}^{n} (|r_i|^2 + |(\alpha_i + r_i)\hat{x}_i - \hat{b}_i|^2 + \rho|l_i|^2|\hat{x}_i|^2) : \mathbf{r}, \hat{\mathbf{x}} \in \mathbb{F}^n \right\}.$$

The above optimization problem is separable with respect to the pairs of variables

$$(r_1, \hat{x}_1), (r_2, \hat{x}_2), \ldots, (r_n, \hat{x}_n),$$

implying that, for every i, the optimal $(r_i, \hat{x}_i)$ is the solution to the two-dimensional problem

$$\min_{r_i,\hat{x}_i} \left\{ |r_i|^2 + |(\alpha_i + r_i)\hat{x}_i - \hat{b}_i|^2 + \rho|l_i|^2|\hat{x}_i|^2 : r_i, \hat{x}_i \in \mathbb{F} \right\}. \tag{3.6}$$

Next, we fix $\hat{x}_i$ and minimize with respect to r_i. The result is

$$r_i = -\frac{\overline{\hat{x}_i}(\alpha_i\hat{x}_i - \hat{b}_i)}{1 + |\hat{x}_i|^2}.$$

By substituting the above expression back into the objective function of (3.6) with some simple algebraic manipulations, we arrive at the following equivalent problem in the single variable $\hat{x}_i$:

$$\min_{\hat{x}_i} \left\{ \frac{|\alpha_i\hat{x}_i - \hat{b}_i|^2}{1 + |\hat{x}_i|^2} + \rho|l_i|^2|\hat{x}_i|^2 \right\},$$

establishing the result. □

4. Solution and analysis of the RSTLS problem for SD structures. In this section we study the one-dimensional (1D) problems (3.2) arising in the decomposition of the RSTLS problem. We show in section 4.1 that, although these problems are not unimodal,[3] they can be transformed into (strictly) unimodal problems and consequently solved efficiently and globally. This is especially crucial in image deblurring applications in which there are hundreds of thousands or even millions of 1D problems to be solved. Based on the uniqueness and attainment properties of the 1D problems, corresponding conditions for the RSTLS problem are established in section 4.2.

4.1. Solution of the single-variable problem. Our goal in this section is to analyze the one-dimensional problem (3.2) and to devise an efficient solution method for solving it. Consider the problem

$$\min_{x\in\mathbb{F}} \left\{ f(x) = \frac{|ax - b|^2}{1 + |x|^2} + |c|^2|x|^2 \right\}, \tag{4.1}$$

[3] A function $f : I \to \mathbb{R}$, $I \subseteq \mathbb{R}$ being a closed interval, is (strictly) unimodal if it has a unique local minimizer on I and is (strictly) decreasing from the left boundary of the interval to this unique minimum and (strictly) increasing from the minimum to the right boundary of the interval.

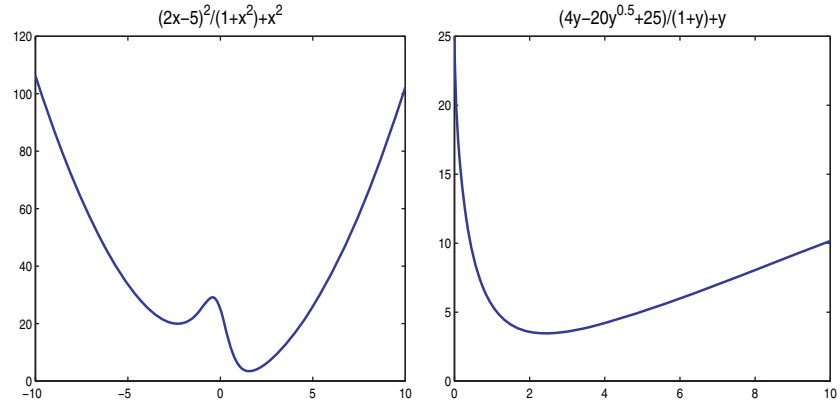

FIG. 1. *The objective function of problems* (4.5) *(left) and* (4.6) *(right).*

where $a, b, c \in \mathbb{F}$. If $c \neq 0$, then the objective function is coercive, and consequently its minimum is attained. The objective function of (4.1) is not unimodal (cf. Figure 1) and thus finding its global minimum efficiently is in principle a hard task. We will show in the next result that it can be solved via the minimization problem

$$\min_{y \geq 0} \left\{ g(y) \equiv \frac{|a|^2 y - 2|ab|\sqrt{y} + |b|^2}{1+y} + |c|^2 y \right\} \tag{4.2}$$

in the real nonnegative variable y. Before stating the result we briefly recall that for a real number $x \in \mathbb{R}$ the sign function is defined by

$$\operatorname{sgn}(x) \equiv \begin{cases} 1 & x > 0, \\ 0 & x = 0, \\ -1 & x < 0, \end{cases}$$

and for a complex number $z \in \mathbb{C}$ the sign function is given by

$$\operatorname{sgn}(z) \equiv \begin{cases} \frac{z}{|z|} & z \neq 0, \\ 0 & z = 0. \end{cases}$$

LEMMA 4.1 (equivalence of problems (4.1) and (4.2)). [illegible] (4.1) [illegible] $a, b, c \in \mathbb{F}$ [illegible]

(i) [illegible] $ab \neq 0$ [illegible] $\tilde{y}$ [illegible] (4.2) [illegible] $\tilde{x} =$ [illegible] $(\bar{a}b)\sqrt{\tilde{y}}$ [illegible] (4.1)

(ii) [illegible] $ab = 0$ [illegible] $\tilde{y}$ [illegible] (4.2) [illegible] $\tilde{x} = z\sqrt{\tilde{y}}$ [illegible] (4.1) [illegible] $z \in \mathbb{F}$ [illegible] $|z| = 1$ [illegible]. Let $\tilde{x}$ be an optimal solution of (4.1). Then by the optimality of $\tilde{x}$ we have

$$f(\tilde{x}) \leq f(z\tilde{x}) \text{ for every } z \in \mathbb{F} \text{ satisfying } |z| = 1,$$

which is the same as

$$\frac{|a\tilde{x} - b|^2}{1 + |\tilde{x}|^2} + |c|^2 |\tilde{x}|^2 \leq \frac{|a(z\tilde{x}) - b|^2}{1 + |z\tilde{x}|^2} + |c|^2 |z\tilde{x}|^2.$$

The latter inequality reduces to

$$\Re((1 - z)a\bar{b}\tilde{x}) \geq 0. \tag{4.3}$$

We will now show that $a\bar{b}\tilde{x}$ is a nonnegative real number. This is obviously true if $\tilde{x} = 0$. Otherwise, we split the analysis into two cases:

I. If $ab \neq 0$, then substituting

$$z = \frac{\overline{a\bar{b}\tilde{x}}}{|a\bar{b}\tilde{x}|}$$

into (4.3) yields

$$\Re(a\bar{b}\tilde{x}) \geq |a\bar{b}\tilde{x}|,$$

implying that $a\bar{b}\tilde{x}$ is a nonnegative real number and, in particular, that $\operatorname{sgn}(\tilde{x}) = \operatorname{sgn}(\bar{a}b)$.

II. If $ab = 0$, the function f satisfies $f(zx) = f(x)$ for every $x, z \in \mathbb{F}$ such that $|z| = 1$ and thus $z\tilde{x}$ is also an optimal solution for every z satisfying $|z| = 1$.

A conclusion from the above two cases is that if the minimum of (4.1) is attained at a nonzero solution, then there must be at least one optimal solution $\tilde{x}$ for which $\operatorname{sgn}(\tilde{x}) = \operatorname{sgn}(\bar{a}b)$; consequently, we can make the change of variables $x = \operatorname{sgn}(\bar{a}b)\sqrt{y}$ which transforms problem (4.1) into (4.2). □

4.1. Consider problem (4.1) with $\mathbb{F} = \mathbb{C}$ but with real data, i.e., $a, b, c \in \mathbb{R}$. Then a direct consequence of Lemma 4.1 is that if the optimal set of (4.1) is nonempty, then there must exist at least one real-valued optimal solution.

The following simple lemma establishes some key properties of problem (4.2). In particular, it is shown that problem (4.2) is strictly unimodal (in all interesting cases) and thus can be solved efficiently. This is in fact the main motivation for transforming problem (4.1) into (4.2).

LEMMA 4.2 (properties of problem (4.2)). (4.2) $a, b, c \in \mathbb{F}$

(i) $g(y)$ (4.2) [4] $[0, \infty)$

(ii) $c \neq 0$ $\tilde{y}$ (4.2) $\tilde{y} \leq \frac{|b|^2}{|c|^2}$

(iii) (4.2) $(a, c) \neq (0, 0)$

(iv) $(a, c) \neq (0, 0)$ $g(y)$ (4.2) $[0, \infty)$

(i) We need to show that the level set $\{y : g(y) \leq \alpha\}$ is convex. Indeed,

$$\{y \geq 0 : g(y) \leq \alpha\} = \{y \geq 0 : (|a|^2 + |c|^2 - \alpha)y - 2|ab|\sqrt{y} + |c|^2 y^2 + |b|^2 - \alpha \leq 0\}.$$

The latter is the zero level set of a convex function and hence convex.

(ii) Note that for $y \geq 0$

$$g(y) = \frac{(|a|\sqrt{y} - |b|)^2}{1 + y} + |c|^2 y \geq |c|^2 y.$$

Therefore, for $y > \frac{|b|^2}{|c|^2}$ we have

$$g(y) \geq |c|^2 y > |b|^2 = g(0),$$

showing that there are no optimal solutions for (4.2) larger than $\frac{|b|^2}{|c|^2}$.

[4] A function $f : I \to \mathbb{R}$ ($I \subseteq \mathbb{R}$ being an interval) is quasi-convex if all of its level sets $\{x \in I : f(x) \leq \alpha\}$ are convex.

(iii) First consider the case $(a, c) = (0, 0)$. Then $g(y) = |b|^2/(1 + y)$. Hence it follows either that g does not attain a minimum (if $b \neq 0$) or that the minimum (namely, all $y \geq 0$) is nonunique (if $b = 0$). Now consider the case $(a, c) \neq (0, 0)$. We split the analysis into two subcases.

I. If $c \neq 0$, then $\lim_{y\to\infty} g(y) = \infty$, implying the attainment of the minimum. To show the uniqueness of the minimum in this case, assume in contradiction that the optimal solution of (4.2) is not unique. Then since the optimal set is convex (by quasi convexity) we conclude that the optimal set is an interval $I \subseteq [0, \infty)$ with a nonempty interior. Denote the optimal value by f^*. Then

$$g(y) = f^* \text{ for every } y \in I,$$

which can be explicitly written as

$$(|a|^2 + |c|^2 - f^*)y - 2|ab|\sqrt{y} + |c|^2y^2 + |b|^2 - f^* = 0 \text{ for every } y \in I.$$

By making the change of variables $z = \sqrt{y}$, we obtain

$$(|a|^2 + |c|^2 - f^*)z^2 - 2|ab|z + |c|^2z^4 + |b|^2 - f^* = 0 \text{ for every } z \in J, \tag{4.4}$$

where $J = \{z : z^2 \in I\}$ is an interval with a nonempty interior. However, (4.4) is impossible since an univariate quartic equation has at most four roots and thus cannot have an infinite number of roots.

II. Suppose that $c = 0$. Then $a \neq 0$, and it is easy to see that g attains a unique minimum at $|b|^2/|a|^2$.

(iv) Since $(a, c) \neq (0, 0)$, we know from part (iii) that g attains a unique global minimum on the interval $[0, \infty)$. Hence it remains to show that it is strictly decreasing from the origin to this minimum and strictly increasing when we go from this minimum to plus infinity. Suppose that this is not true. Then the function g must have a stationary point in $(0, \infty)$ which is different from the unique minimum. However, we will show that, for any $y > 0$ such that $g'(y) = 0$, we automatically have $g''(y) > 0$; hence this stationary point y is at least a local minimum and, therefore, must be equal to the unique minimum of g on the interval $[0, \infty)$. Elementary differentiation gives

$$g'(y) = \frac{(|a|\sqrt{y} - |b|)(|a|\frac{1}{\sqrt{y}} + |b|)}{(1 + y)^2} + |c|^2.$$

Now let $\tilde{y} > 0$ be such that $g'(\tilde{y}) = 0$. Then

$$\begin{aligned} g''(\tilde{y}) &= -\frac{2}{(1+\tilde{y})^3}(|a|\sqrt{\tilde{y}} - |b|)\left(|a|\frac{1}{\sqrt{\tilde{y}}} + |b|\right) + \frac{|a||b|}{2(1+\tilde{y})^2\sqrt{\tilde{y}}}\left(1 + \frac{1}{\tilde{y}}\right) \\ &\overset{g'(\tilde{y})=0}{=} \frac{2|c|^2}{1+\tilde{y}} + \frac{|a||b|}{2(1+\tilde{y})^2\sqrt{\tilde{y}}}\left(1 + \frac{1}{\tilde{y}}\right) > 0, \end{aligned}$$

where the positivity of the last expression comes from the fact that $(a, c) \neq (0, 0)$; hence this last expression can be equal to zero only if both $c = 0$ and $b = 0$, but then, by taking into account that $\tilde{y}$ is also a stationary point, we would obtain $a = 0$ as well, in contrast to $(a, c) \neq (0, 0)$. ∎

The most important property of the function g is its strict unimodality (as stated in Lemma 4.2 (iv)). The strict unimodality property implies that there are no nonglobal local minima and thus enables us to invoke efficient one-dimensional solvers for

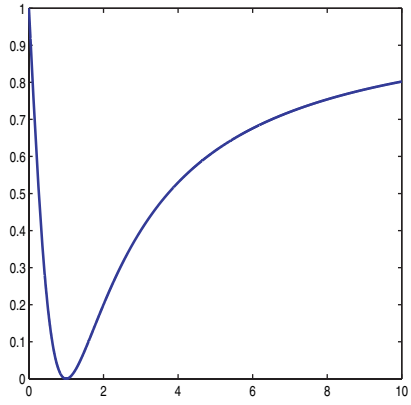

FIG. 2. *The function* $\frac{(\sqrt{y}-1)^2}{1+y}$ *from Remark* 4.2.

(strictly) unimodal functions that are guaranteed to converge to the global minimum. The following example illustrates this property.

1. Consider problem (4.1) with $\mathbb{F} = \mathbb{R}$, $a = 2, b = 5$, and $c = 1$. In this case, problems (4.1) and (4.2) are given by

$$\min_x \left\{ \frac{(2x-5)^2}{1+x^2} + x^2 \right\} \tag{4.5}$$

and

$$\min_{y \geq 0} \left\{ \frac{4y - 20\sqrt{y} + 25}{1+y} + y \right\}, \tag{4.6}$$

respectively. The plots of the two functions are given in Figure 1.

Clearly, the objective function in (4.5) is not unimodal and indeed possesses a nonglobal local minimizer. The global solution of (4.5) is $\tilde{x} = 1.5606$ (given in four-digit accuracy). The objective function in (4.6) is, as guaranteed by Lemma 4.1, an unimodal function. The global minimum is $\tilde{y} = 2.4354$, and the relation $\tilde{x} = \sqrt{\tilde{y}}$ holds.

4.2. A natural question here is whether g is even more than quasi-convex, namely, convex. The answer to this question is negative. For example, for $a = b = 1$ and $c = 0$, the function g is clearly nonconvex as can be seen from Figure 2. Note, however, that this figure also illustrates the quasi convexity of g.

Combining Lemmas 4.1 and 4.2, we are now able to state the basic properties of problem (4.1).

LEMMA 4.3 (uniqueness for problem (4.1)).
(4.1).
(i) $a \neq 0$
(ii) $a = 0, c \neq 0$ $|b| \leq |c|$

. We will split the analysis into four cases:

I. $a \neq 0$ and $b \neq 0$. By Lemma 4.2(iii), since $a \neq 0$, the optimal solution of (4.2) is uniquely attained. Moreover, since $ab \neq 0$, then by Lemma 4.1, there is a one-to-one correspondence between optimal solutions of (4.1) and (4.2) (via the relation $\tilde{x} = \operatorname{sgn}(\bar{a}b)\sqrt{\bar{y}}$), implying the uniqueness and attainment of the optimal solution of (4.1).

II. $a \neq 0$ and $b = 0$. The objective function of (4.2) in this case is strictly increasing, implying that the unique optimal solution of (4.2) is $\tilde{y} = 0$ and hence that the unique optimal solution of (4.1) is $\tilde{x} = 0$.

III. $a = 0$ and $b \neq 0$. By Lemma 4.2(iii), to guarantee the uniqueness and attainment of the optimal solution of (4.2) we must further assume that $c \neq 0$. The solution of (4.1) is unique if and only if the optimal solution $\tilde{y}$ of (4.2) is zero (otherwise, $z\sqrt{\tilde{y}}$ will be an optimal solution of (4.1) for every z satisfying $|z| = 1$). By the unimodality of g, the optimal solution is 0 if and only if $g'(0) \geq 0$, which is equivalent to $|b| \leq |c|$.

IV. $a = 0$ and $b = 0$. Again, as in the previous case, we further assume that $c \neq 0$. Here it is evident that the unique optimal solution is $\tilde{x} = 0$.

By combining the four cases we obtain the result. ∎

4.2. Uniqueness and attainment of the RSTLS solution. The result in section 4.1 collectively can be summed up in the following result.

THEOREM 4.1. [illegible] (2.1) [illegible] $m = n$ [illegible] $\mathcal{L} = \mathcal{L}_{\mathbf{Q}}$ ([illegible] (2.2)) [illegible] $\mathbf{Q} \in \mathbb{F}^{n\times n}$ [illegible] $\hat{\mathbf{b}} = \mathbf{Q}^*\mathbf{b}$ [illegible] $\mathbf{A}, \mathbf{L} \in \mathcal{L}_{\mathbf{Q}}$ [illegible] $\boldsymbol{\alpha}, \mathbf{l}$ [illegible] $\mathbf{A}$ [illegible] $\mathbf{L}$ [illegible]

$$\mathbf{Q}^*\mathbf{A}\mathbf{Q} = \operatorname{diag}(\boldsymbol{\alpha}), \quad \mathbf{Q}^*\mathbf{L}\mathbf{Q} = \operatorname{diag}(\mathbf{l}). \tag{4.7}$$

[illegible] $i = 1, \ldots, n$ [illegible]

(i) $\alpha_i \neq 0$

(ii) $\alpha_i = 0, l_i \neq 0$ [illegible] $|\hat{b}_i| \leq \sqrt{\rho}|l_i|$

[illegible]. Note that the optimal $\mathbf{E}$ is uniquely defined via the optimal $\mathbf{x}$ by (3.3) and (3.4). Therefore, the uniqueness and/or attainment properties of the optimal solution of (2.1) amount to uniqueness and/or attainment of the single-variable problems (3.2), which combined with Lemma 4.3 establishes the result. ∎

Theorem 4.1 provides conditions for the optimal solution of the RSTLS problem to be uniquely attained. Based on this, we can derive a simpler condition:

$$\operatorname{Null}(\mathbf{A}) \cap \operatorname{Null}(\mathbf{L}) = \{\mathbf{0}\}, \tag{4.8}$$

which is sufficient for attainment of the optimal solution and necessary for the unique attainment of the optimal solution, as shown in the following theorem.

THEOREM 4.2. [illegible] 4.1 [illegible]

(i) [illegible] (2.1) [illegible] (4.8) [illegible]

(ii) [illegible] (4.8) [illegible] (2.1) [illegible]

(iii) [illegible] $\mathbf{A}$ [illegible] (2.1) [illegible]

[illegible]. (i) Note that by Theorem 4.1 a necessary condition for the optimal solution of (2.1) to be uniquely attained is that $|\alpha_i|^2 + |l_i|^2 \neq 0$ for every i, that is, α_i and l_i are not both zero for any given i. The eigenvalues of the matrix $\mathbf{A}^*\mathbf{A} + \mathbf{L}^*\mathbf{L}$ are exactly $|\alpha_i|^2 + |l_i|^2$, implying that $\mathbf{A}^*\mathbf{A} + \mathbf{L}^*\mathbf{L}$ is nonsingular; therefore,

$$\operatorname{Null}(\mathbf{A}) \cap \operatorname{Null}(\mathbf{L}) = \operatorname{Null}(\mathbf{A}^*\mathbf{A} + \mathbf{L}^*\mathbf{L}) = \{\mathbf{0}\}.$$

(ii) Assume that condition (4.8) holds. By Theorem 3.1, it is enough to show that for every $i = 1, \ldots, n$ the one-dimensional problem (3.2) has at least one optimal solution. Now by Lemma 4.1 it is sufficient to establish the attainment of the solution

of

$$\min_{y\geq 0}\left\{\frac{|\alpha_i|^2 y - 2|\alpha_i\hat{b}_i|\sqrt{y}+|\hat{b}_i|^2}{1+y}+\rho|l_i|^2 y\right\} \tag{4.9}$$

for every $i=1,\dots,n$, where $\alpha_i,\hat{b}_i$, and l_i are defined in the premise of Theorem 3.1. By Lemma 4.2(iii), this is guaranteed if $(\alpha_i,l_i)\neq(0,0)$ for every i, which, as shown in the proof of (i), is equivalent to condition (4.8).

(iii) It follows from the nonsingularity of $\mathbf{A}$ that all of its eigenvalues are nonzero, which, by Theorem 4.1, implies that the solution of (2.1) is uniquely attained. □

The following example shows by suitable counterexamples that the assumptions used in Theorem 4.2 are sufficient, but not necessary, for the corresponding statements to be true.

2. (i) Consider problem (2.1) with $n=m=1, A=(0), L=(1), b=(2), \rho=1$, and $\mathbb{F}=\mathbb{R}$. Then condition (4.8) holds, but problem (2.1) has the two solutions $(E,x)=(1,1)$ and $(E,x)=(-1,-1)$. This shows that the unique attainment of a solution of problem (2.1) is sufficient for condition (4.8) to hold but not necessary.

(ii) Consider problem (2.1) with $n=m=1, A=(0), L=(0), b=(0), \rho=1$, and $\mathbb{F}=\mathbb{R}$. Then every vector (E,x), with $E=0$ and $x\in\mathbb{R}$ arbitrary, is a solution of problem (2.1), although condition (4.8) does not hold. Hence this condition is sufficient for problem (2.1) to have a nonempty solution set but not necessary.

It is interesting to compare the above conditions to the corresponding attainment/uniqueness conditions for the regularized least squares problem:

$$\text{(RLS):}\quad \min \|\mathbf{Ax}-\mathbf{b}\|^2+\rho\|\mathbf{Lx}\|^2.$$

The optimal solution of (RLS), as opposed to the solution of the RSTLS problem, is always attained; it is unique if and only if condition (4.8) holds. This is in contrast to the RSTLS problem where condition (4.8) is only a necessary condition for unique attainment of the solution.

5. The RSTLS problem with circulant structure. The RSTLS problem (2.1) with $\mathcal{L}=\mathcal{L}_{\mathbf{F}_n}$ ($\mathbf{F}_n$ being the $n\times n$ DFT matrix) corresponds to problems with circulant-structured matrices. Here the underlying number field is $\mathbb{F}=\mathbb{C}$ since the matrix $\mathbf{F}_n$ is complex-valued. However, in many applications the data $\mathbf{A},\mathbf{b}$, and $\mathbf{L}$ are real-valued. The main result in this section is that if the optimal set of the RSTLS problem is nonempty, then there exists at least one real-valued optimal solution. Therefore, there is no drawback in analyzing the RSTLS problem over the complex field even when the data are real-valued.

THEOREM 5.1. [illegible] $\mathbb{F}=\mathbb{C}, \mathcal{L}=\mathcal{L}_{\mathbf{F}_n}$ [illegible] $\mathbf{F}_n$ [illegible] $n\times n$ [illegible] $\mathbf{A}$, $\mathbf{b}$ [illegible] $\mathbf{L}$ [illegible] $\mathbf{A}\in\mathbb{R}^{n\times n}, \mathbf{b}\in\mathbb{R}^n$, [illegible] $\mathbf{L}\in\mathbb{R}^{n\times n}$ [illegible] (RSTLS) [illegible]. We will require the following notation:

$$\mathcal{A}=\{\mathbf{z}\in\mathbb{C}^n : z_1\in\mathbb{R}, z_{j+1}=\overline{z_{n+1-j}} \text{ for every } j=1,\dots,n-1\}.$$

To simplify the notation we omit the subscript in the $n\times n$ DFT matrix and denote it by $\mathbf{F}$ rather than by $\mathbf{F}_n$. The proof is based on the following three claims:

(i) Let $\mathbf{w}=\mathbf{Fv}$ for some $\mathbf{v}\in\mathbb{R}^n$. Then $\mathbf{w}\in\mathcal{A}$.

(ii) Let $\boldsymbol{\alpha}$ be the vector of eigenvalues of a real-valued circulant matrix $\mathbf{A}$. Then $\boldsymbol{\alpha} \in \mathcal{A}$.

(iii) Let $\mathbf{z} \in \mathcal{A}$. Then $\mathbf{F}^*\mathbf{z} \in \mathbb{R}^n$.

Proof. (i). First,

$$w_1 = (\mathbf{F}\mathbf{v})_1 = \frac{1}{\sqrt{n}} \sum_{i=1}^{n} v_i,$$

proving that $w_1 \in \mathbb{R}$. Next, for every $j = 1, \ldots, n-1$ we have

$$w_{j+1} = (\mathbf{F}\mathbf{v})_{j+1} = \sum_{i=1}^{n} F_{j+1,i} v_i = \frac{1}{\sqrt{n}} \sum_{i=1}^{n} \omega^{j(i-1)} v_i. \tag{5.1}$$

On the other hand,

$$\begin{aligned} \overline{w_{n+1-j}} = \overline{(\mathbf{F}\mathbf{v})_{n+1-j}} &= \sum_{i=1}^{n} \overline{F_{n+1-j,i}} v_i = \frac{1}{\sqrt{n}} \sum_{i=1}^{n} \overline{\omega^{(n-j)(i-1)}} v_i \\ &= \frac{1}{\sqrt{n}} \sum_{i=1}^{n} \omega^{j(i-1)} v_i \overset{(5.1)}{=} w_{j+1}. \end{aligned}$$

Proof. (ii). Let $(s_1, s_2, \ldots, s_n)$ be the first row of $\mathbf{A}$. The jth eigenvalue of the circulant matrix $\mathbf{A}$ is given by $\alpha_j = \sum_{i=1}^{n} \omega^{(i-1)(j-1)} s_i$. Then

$$\alpha_1 = \sum_{i=1}^{n} s_i \in \mathbb{R}$$

and

$$\overline{\alpha_{n+1-j}} = \overline{\sum_{i=1}^{n} \omega^{(i-1)(n-j)} s_i} = \sum_{i=1}^{n} \omega^{(i-1)j} s_i = \alpha_{j+1}$$

for every $j = 1, \ldots, n-1$. Thus, $\boldsymbol{\alpha} \in \mathcal{A}$.

Proof. (iii). For every $i = 1, 2, \ldots, n$:

$$\begin{aligned} \sqrt{n}(\mathbf{F}^*\mathbf{w})_i &= \sqrt{n} \sum_{j=1}^{n} \overline{F_{j,i}} w_j = \sum_{j=1}^{n} \omega^{-(i-1)(j-1)} w_j \\ &\overset{\mathbf{w} \in \mathcal{A}}{=} w_1 + \sum_{j=2}^{n} \omega^{-(i-1)(j-1)} \overline{w_{n+2-j}} = w_1 + \sum_{j=2}^{n} \omega^{(i-1)(n+1-j)} \overline{w_{n+2-j}} \\ &\overset{k \leftarrow n+2-j}{=} w_1 + \sum_{k=2}^{n} \omega^{(i-1)(k-1)} \overline{w_k} = \sqrt{n} \sum_{k=1}^{n} F_{k,i} \overline{w_k} \\ &= \overline{\sqrt{n} \sum_{k=1}^{n} \overline{F_{k,i}} w_k} = \sqrt{n}\, \overline{(\mathbf{F}^*\mathbf{w})_i}. \end{aligned}$$

By Theorem 3.1, an optimal solution of the RSTLS problem is given by $\mathbf{x} = \mathbf{F}^*\hat{\mathbf{x}}$, where $\hat{x}_i$, the ith component of $\hat{\mathbf{x}}$, is an optimal solution of (3.2). Recall that $\hat{\mathbf{b}} = \mathbf{F}\mathbf{b}$ for real-valued $\mathbf{b}$ and that $\boldsymbol{\alpha}$ and $\mathbf{l}$ are the eigenvalues vectors of the real-valued circulant matrices $\mathbf{A}$ and $\mathbf{L}$, respectively. Therefore, by properties (i) and (ii), $\hat{\mathbf{b}}, \boldsymbol{\alpha}, \mathbf{l} \in$

$\mathcal{A}$. Hence, $\hat{x}_1$ is the solution of (3.2) with $i = 1$ and with real data, which by Remark 4.1 implies that $\hat{x}_1$ is real. Moreover, for every $j = 1, \ldots, n-1$, $\hat{x}_j$ and $\hat{x}_{n+1-j}$ are the optimal solutions of

$$\min_{\hat{x}_{j+1}} \left\{ \frac{|\alpha_{j+1}\hat{x}_{j+1} - \hat{b}_{j+1}|^2}{1 + |\hat{x}_{j+1}|^2} + \rho |l_j|^2 |\hat{x}_j|^2 \right\},$$

$$\min_{\hat{x}_{n+1-j}} \left\{ \frac{|\alpha_{j+1}\overline{\hat{x}_{n+1-j}} - \hat{b}_{j+1}|^2}{1 + |\overline{\hat{x}_{n+1-j}}|^2} + \rho |l_{j+1}|^2 |\overline{\hat{x}_{n+1-j}}|^2 \right\},$$

respectively. Therefore, we can always choose the optimal solutions of these problems to satisfy $\hat{x}_{n+1-j} = \overline{\hat{x}_{j+1}}$. Thus, for the mentioned choice $\hat{\mathbf{x}} \in \mathcal{A}$ and by property (iii) this proves that $\mathbf{x} = \mathbf{F}^* \hat{\mathbf{x}}$ is real-valued. □

5.1. It can be shown by using the same methodology employed in the proof of Theorem 5.1 that there always exists a real-valued solution for the RSTLS problem with $\mathbf{Q} = \mathbf{F}_n \otimes \mathbf{F}_m$ (BCCB structure) whenever $\mathbf{A}, \mathbf{L}$, and $\mathbf{b}$ are real-valued.

The following two examples demonstrate the validity of Theorem 5.1.

3. Let $\mathbf{Q} = \mathbf{F}_3$ (3×3 circulant matrices) and

$$\mathbf{A} = \begin{pmatrix} 1 & 2 & 3 \\ 3 & 1 & 2 \\ 2 & 3 & 1 \end{pmatrix}, \qquad \mathbf{b} = \begin{pmatrix} 4 \\ 5 \\ 6 \end{pmatrix}, \qquad \mathbf{L} = \begin{pmatrix} 1 & -1 & 0 \\ 0 & 1 & -1 \\ -1 & 0 & 1 \end{pmatrix}, \qquad \rho = 1.$$

Then

$$\boldsymbol{\alpha} = \operatorname{diag}(\mathbf{F}_3 \mathbf{A} \mathbf{F}_3^*) = \begin{pmatrix} 6 \\ -1.5 - 0.866025\mathbf{i} \\ -1.5 + 0.866025\mathbf{i} \end{pmatrix},$$

$$\hat{\mathbf{b}} = \mathbf{F}_3 \mathbf{b} = \begin{pmatrix} 8.660254 \\ -0.866025 + 0.5\mathbf{i} \\ -0.866025 - 0.5\mathbf{i} \end{pmatrix}, \qquad \mathbf{l} = \begin{pmatrix} 0 \\ 1.5 - 0.866025\mathbf{i} \\ 1.5 + 0.866025\mathbf{i} \end{pmatrix}.$$

The vector $\hat{\mathbf{x}}$ consisting of the optimal solutions the three arising optimization problems is

$$\hat{\mathbf{x}} = \begin{pmatrix} 1.443375 \\ 0.143941 - 0.249314\mathbf{i} \\ 0.143941 + 0.249314\mathbf{i} \end{pmatrix},$$

and the optimal solution

$$\mathbf{x} = \mathbf{F}_3^* \hat{\mathbf{x}} = \begin{pmatrix} 0.999543 \\ 0.999543 \\ 0.500913 \end{pmatrix}$$

is indeed real.

4. Consider the RSTLS problem with $\mathbf{Q} = \mathbf{F}_3$ (3×3 circulant matrices) and

$$\mathbf{A} = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix}, \qquad \mathbf{b} = \begin{pmatrix} 2 \\ 4 \\ 6 \end{pmatrix}, \qquad \mathbf{L} = \begin{pmatrix} 1 & -1 & 0 \\ 0 & 1 & -1 \\ -1 & 0 & 1 \end{pmatrix}, \qquad \rho = 1.$$

Then

$$\boldsymbol{\alpha} = \operatorname{diag}(\mathbf{F}_3\mathbf{A}\mathbf{F}_3^*) = \begin{pmatrix} 3 \\ 0 \\ 0 \end{pmatrix}, \qquad \hat{\mathbf{b}} = \mathbf{F}_3\mathbf{b} = \begin{pmatrix} 6.928203 \\ -1.732050 + \mathbf{i} \\ -1.732050 - \mathbf{i} \end{pmatrix}.$$

In this example the optimal solutions of the arising one-dimensional problems are not unique, and they consist of the collection of vectors $\hat{\mathbf{x}}$ of the form:

$$\hat{\mathbf{x}} = \begin{pmatrix} 2.309401 \\ 0.393319z_1 \\ 0.393319z_2 \end{pmatrix},$$

where z_1 and z_2 are complex numbers satisfying $|z_1| = |z_2| = 1$. Correspondingly, the set of optimal solutions of (RSTLS) consists of all vectors $\mathbf{F}_3^*\hat{\mathbf{x}}$, where $\hat{\mathbf{x}}$ is of the above form and is thus equal to

$$\{(a + z_1 b + z_2 c, a + b z_1 \bar{\omega} + c z_2 \omega, a + b z_1 \omega + c z_2 \bar{\omega})^T : |z_1| = |z_2| = 1\},$$

where $a = 2.309401, b = 0.393319$, and $\omega = e^{\frac{2\pi\mathbf{i}}{3}}$. The above set certainly contains complex-valued optimal solutions, but, if we choose $z_1 = \bar{z}_2$, we obtain a subset of real-valued optimal solutions:

$$\left\{ \frac{1}{\sqrt{3}}(a + 2\cos(\theta)c, a + 2\cos(\theta + 2\pi/3)c, a + 2\cos(\theta - 2\pi/3)b)^T : 0 \le \theta \le 2\pi \right\}.$$

6. Solution of the CSTLS problem with SD structure. When the regularization is made by adding a constraint rather than by penalization, the problem becomes

$$\text{(CSTLS):} \quad \begin{array}{ll} \min\limits_{\mathbf{E},\mathbf{x}} & \|\mathbf{E}\|^2 + \|(\mathbf{A} + \mathbf{E})\mathbf{x} - \mathbf{b}\|^2 \\ \text{s.t.} & \|\mathbf{L}\mathbf{x}\|^2 \le \alpha, \\ & \mathbf{E} \in \mathcal{L}_{\mathbf{Q}}, \\ & \mathbf{x} \in \mathbb{F}^n, \end{array} \tag{6.1}$$

where $\alpha > 0$. We will show that the CSTLS problem can be solved by a sequence of RSTLS problems using a dual approach. We assume throughout this section that $\mathbf{A}$ is nonsingular. This assumption prevails in many image deblurring problems, although the matrix is often extremely ill conditioned.

The Lagrangian dual problem of (6.1) is given by

$$\max_{\lambda \ge 0} q(\lambda), \tag{6.2}$$

where

$$q(\lambda) = \begin{array}{ll} \min\limits_{\mathbf{E},\mathbf{x}} & \|\mathbf{E}\|^2 + \|(\mathbf{A} + \mathbf{E})\mathbf{x} - \mathbf{b}\|^2 + \lambda(\|\mathbf{L}\mathbf{x}\|^2 - \alpha) \\ \text{s.t.} & \mathbf{E} \in \mathcal{L}_{\mathbf{Q}}, \mathbf{x} \in \mathbb{F}^n. \end{array} \tag{6.3}$$

Therefore, evaluating a value of the dual objective function amounts to solving a single RSTLS problem which can be solved efficiently as shown in the previous sections. Since $\mathbf{A}$ is nonsingular, then by Theorem 4.2 (iii), the optimal solution of (6.3) is uniquely attained for all $\lambda \ge 0$, and we denote it by $(\mathbf{x}_\lambda, \mathbf{E}_\lambda)$. The function q has

several important properties which are summarized in Lemma 6.1 below. The differentiability property of q (part (ii) of Lemma 6.1), relies on the uniqueness property and on the following well known result [9, Proposition 6.1.1].

THEOREM 6.1. [illegible] f [illegible] g [illegible] X [illegible]

$$h(\lambda) \equiv \min_{\mathbf{x}\in X} \{f(\mathbf{x}) + \lambda g(\mathbf{x})\}, \quad \lambda \in [\lambda_1, \lambda_2],$$

[illegible] $\mathbf{x}_\lambda$ [illegible] $\lambda \in [\lambda_1, \lambda_2]$ [illegible] $\mathbf{x}_\lambda$ [illegible] h [illegible] $\lambda \in (\lambda_1, \lambda_2)$ [illegible] $h'(\lambda) = g(\mathbf{x}_\lambda)$

In our case the compactness assumption is not satisfied; however, this difficulty can be avoided. We will use the following notation:

$$\begin{aligned} s(\mathbf{x}, \mathbf{E}) &= \|\mathbf{E}\|^2 + \|(\mathbf{A} + \mathbf{E})\mathbf{x} - \mathbf{b}\|^2, \\ t(\mathbf{x}, \mathbf{E}) &= \|\mathbf{L}\mathbf{x}\|^2 - \alpha, \\ Y &= \{(\mathbf{x}, \mathbf{E}) : \mathbf{x} \in \mathbb{F}^n, \mathbf{E} \in \mathcal{L}_{\mathbf{Q}}\}. \end{aligned}$$

Then, in this notation, the CSTLS problem can be written as

$$\min_{\mathbf{x},\mathbf{E}} \{s(\mathbf{x}, \mathbf{E}) : t(\mathbf{x}, \mathbf{E}) \le 0, (\mathbf{x}, \mathbf{E}) \in Y\}. \tag{6.4}$$

LEMMA 6.1. [illegible] q [illegible] (6.3) [illegible]

(i) q [illegible] $[0, \infty)$

(ii) $q(\lambda)$ [illegible] $\lambda > 0$ [illegible] $q'(\lambda) = \|\mathbf{L}\mathbf{x}_\lambda\|^2 - \alpha$

(iii) $\lim_{\lambda\to\infty} q(\lambda) = -\infty$

[illegible] (i) $q(\lambda)$ is the pointwise minimum of functions which are linear in λ and hence concave.

(ii) Let $\tilde{\lambda} > 0$, and let $\lambda_2 > \lambda_1 > 0$ be two positive numbers for which $\tilde{\lambda} \in (\lambda_1, \lambda_2)$. The dual objective can be written as

$$q(\lambda) = \min\{s(\mathbf{x}, \mathbf{E}) + \lambda t(\mathbf{x}, \mathbf{E}) : (\mathbf{x}, \mathbf{E}) \in Y\}. \tag{6.5}$$

From the nonsingularity of $\mathbf{A}$ and Theorem 4.2(iii) it follows that there exists a unique minimizer to the above problem which we denote by $(\mathbf{x}_\lambda, \mathbf{E}_\lambda)$. By Theorem 3.1 it follows that $\mathbf{x}_\lambda = \mathbf{Q}^*\mathbf{y}^\lambda$, where the ith component of $\mathbf{y}^\lambda$, y_i^λ, is the solution to

$$\min_{y_i} \left\{ \frac{|\alpha_i y_i - \hat{b}_i|^2}{1 + |y_i|^2} + \rho\lambda |l_i|^2 |y_i|^2 \right\}.$$

If $l_i = 0$, then $y_i^\lambda = \frac{\hat{b}_i}{\alpha_i}$ ($\alpha_i \neq 0$ for every i as an eigenvalue of a nonsingular matrix). Otherwise,

$$\rho\lambda |l_i|^2 |y_i^\lambda|^2 \le \frac{|\alpha_i y_i^\lambda - \hat{b}_i|^2}{1 + |y_i^\lambda|^2} + \rho\lambda |l_i|^2 |y_i^\lambda|^2 \le \frac{|\alpha_i 0 - \hat{b}_i|^2}{1 + 0^2} + \rho\lambda |l_i|^2 0^2 = |\hat{b}_i|^2,$$

so that $|y_i^\lambda|^2 \le \frac{|\hat{b}_i|^2}{\rho\lambda |l_i|^2}$. Consequently, for every $\lambda \in [\lambda_1, \lambda_2]$,

$$|y_i^\lambda|^2 \le \begin{cases} \left|\frac{\hat{b}_i}{\alpha_i}\right|^2 & l_i = 0, \\ \frac{|\hat{b}_i|^2}{\rho\lambda_1 |l_i|^2} & l_i \neq 0. \end{cases}$$

Hence, $\mathbf{y}^\lambda$ is bounded for every $\lambda \in [\lambda_1, \lambda_2]$ showing that $\mathbf{x}_\lambda = \mathbf{Q}^*\mathbf{y}^\lambda$ is also bounded over $[\lambda_1, \lambda_2]$; that is, there exists $\beta > 0$ for which $\|\mathbf{x}_\lambda\| \le \beta, \lambda \in [\lambda_1, \lambda_2]$. Moreover, by the relation between the optimal $\mathbf{E}$ and the optimal $\mathbf{x}$ given by (3.3) and (3.4), it follows that $\mathbf{E}_\lambda$ is also bounded over $[\lambda_1, \lambda_2]$; namely, there exists $\gamma > 0$ for which $\|\mathbf{E}_\lambda\| \le \gamma$. The dual objective function can thus be written as

$$q(\lambda) = \min\{s(\mathbf{x}, \mathbf{E}) + \lambda t(\mathbf{x}, \mathbf{E}) : (\mathbf{x}, \mathbf{E}) \in \tilde{Y}\},$$

where

$$\tilde{Y} = \{(\mathbf{x}, \mathbf{E}) : \mathbf{x} \in \mathbb{F}^n, \mathbf{E} \in \mathcal{L}_\mathbf{Q}, \|\mathbf{x}\| \le \beta, \|\mathbf{E}\| \le \gamma\}$$

is a compact set. Therefore, by Theorem 6.1, q is differentiable over (λ_1, λ_2) and in particular at $\tilde{\lambda}$ and $q'(\tilde{\lambda}) = t(\mathbf{x}_{\tilde{\lambda}}, \mathbf{E}_{\tilde{\lambda}}) = \|\mathbf{L}\mathbf{x}_{\tilde{\lambda}}\|^2 - \alpha$.

(iii) Since $\mathbf{E} = \mathbf{0}, \mathbf{x} = \mathbf{0}$ is feasible for (6.3), we obtain

$$q(\lambda) \le \|\mathbf{b}\|^2 - \lambda\alpha,$$

establishing that $q(\lambda) \to -\infty$ as $\lambda \to \infty$. □

We will now show that, despite the nonconvexity of the CSTLS problem, strong duality holds.

THEOREM 6.2 (strong duality for CSTLS). [illegible] $\lambda^* > 0$ [illegible] (6.2) [illegible] $q(\lambda^*)$ [illegible] (6.1) [illegible] $(\mathbf{x}_{\lambda^*}, \mathbf{E}_{\lambda^*})$ [illegible] (6.1) [illegible]. Since $\lambda^* > 0$ is the optimal solution of (6.2) and q is differentiable by Lemma 4.2(ii), we have $\|\mathbf{L}\mathbf{x}_{\lambda^*}\|^2 - \alpha = q'(\lambda^*) = 0$. Therefore, $\mathbf{x}_{\lambda^*}$ is a feasible solution of the primal problem (6.1), and

$$q(\lambda^*) = s(\mathbf{x}_{\lambda^*}, \mathbf{E}_{\lambda^*}) + \lambda^*(\|\mathbf{L}\mathbf{x}_{\lambda^*}\|^2 - \alpha) = s(\mathbf{x}_{\lambda^*}, \mathbf{E}_{\lambda^*}),$$

which, from basic duality theory, implies that λ^* and $(\mathbf{x}_{\lambda^*}, \mathbf{E}_{\lambda^*})$ are the dual and primal optimal solutions, respectively. □

The optimal λ^* is a root of the nondecreasing function $q'(\lambda)$ and can thus be found via a simple bisection procedure.

7. Implementation and a numerical example.

7.1. Implementation. The core of the numerical method for solving the RSTLS problem is the solution of n single-variable problems of the form (4.1). Since the number of these 1D problems might be huge (for example, for a two-dimensional 1024×1024 image, there are more than one million problems), it is imperative to find the [illegible] solution of each of them. The method will produce an erroneous solution even if one of the 1D problems is not solved correctly.

From numerical considerations the algorithm is split into two phases. In the first phase, we find the optimal solution of (4.2) up to a moderate tolerance ε (in our experiments $\varepsilon = 10^{-4}$). That is, the output of the first phase is an interval $[\ell, u]$, with $u - \ell < \varepsilon$, in which the optimal solution of (4.2) is guaranteed to reside. The goal of the first phase is to find a "small enough" interval in which the global solution is guaranteed to reside. Since in the course of the change of variables $x = \operatorname{sgn}(\bar{a}b)\sqrt{y}$ the accuracy of the solution might be reduced from ε to $\sqrt{\varepsilon}$, a second phase is invoked in which we seek the global minimizer x^* of the problem

$$\min_x \left\{ \frac{|a|^2x^2 - 2|ab|x + |b|^2}{1 + x^2} + |c|^2x^2 \right\} \tag{7.1}$$

in the interval $[\sqrt{\ell}, \sqrt{u}]$ up to a tolerance ε^2. The interval $[\sqrt{\ell}, \sqrt{u}]$ is small enough so that for all practical purposes the function in (7.1) is unimodal over $[\sqrt{\ell}, \sqrt{u}]$ and the global optimal solution given by $\text{sign}(\bar{a}b)x^*$ is obtained. A detailed description of the algorithm follows.

ALGORITHM SOLVE1D(a, b, c).

input	$a, b, c \in \mathbb{C}$
output	x - an optimal solution of (4.1).
comments	1. It is assumed that a and c are not both zero.
	2. The functions f_1 and f_2 called in the solver are given by
	$f_1(x; a, b, c) = \frac{(\lvert a\rvert\sqrt{x}-\lvert b\rvert)^2}{1+x} + \lvert c\rvert^2 x,$
	$f_2(x; a, b, c) = \frac{(\lvert a\rvert x-\lvert b\rvert)^2}{1+x^2} + \lvert c\rvert^2 x^2.$

If c is equal to zero up to some tolerance, then the output of the algorithm is b/a; otherwise, the upper bound is chosen.

if $c < 10^{-8}$
  $x = \frac{b}{a}$
  stop
else
  $u = \left|\frac{b}{c}\right|^2$
end if
$\ell = 0$
$s = \text{sgn}\,(\bar{a}b)$
Phase I. Activating an unimodal solver on the function f_1
while $(u - \ell) > \varepsilon$
  $x^- = \frac{2}{3}\ell + \frac{1}{3}u$
  $x^+ = \frac{1}{3}\ell + \frac{2}{3}u$
  $f^+ = f_1(x^+; a, b, c)$
  $f^- = f_1(x^-; a, b, c)$
  if $f^- \le f^+$
    $u = x^+$
  else
    $\ell = x^-$
  end if
end while
Updating the lower and upper bounds.
$\ell = \sqrt{\ell}$
$u = \sqrt{u}$
Phase II. Activating an unimodal solver on the function f_2.
while $(u - \ell) > \varepsilon^2$
  $x^- = \frac{2}{3}\ell + \frac{1}{3}u$
  $x^+ = \frac{1}{3}\ell + \frac{2}{3}u$
  $f^+ = f_2(x^+; a, b, c)$
  $f^- = f_2(x^-; a, b, c)$
  if $f^- \le f^+$
    $u = x^+$
  else
    $\ell = x^-$
  end if

end while
$x = s\frac{x^+ + x^-}{2}$
stop

We note that in the MATLAB implementation the minimization of the n 1D problems is done simultaneously using MATLAB's vector operations. For the exact implementation please see the (small) RSTLS MATLAB package available at [38]. Given the 1D solver, the solution of the RSTLS problem (2.1) is obtained via the following procedure.

ALGORITHM RSTLS $(\mathbf{Q}, \mathbf{A}, \mathbf{L}, \rho)$.

input	$\mathbf{Q} \in \mathbb{F}^{n\times n}$ - a unitary matrix.
	$\mathbf{A}, \mathbf{L} \in \mathcal{L}_{\mathbf{Q}}, \mathbf{b} \in \mathbb{F}^n$.
	$\rho \in \mathbb{R}_{++}$.
output	The $\mathbf{x}$-part of the optimal solution of (2.1).

Step 1. $\hat{\mathbf{b}} = \mathbf{Q}\mathbf{b}$.
Step 2. Compute the eigenvalues vectors $\boldsymbol{\alpha}, \mathbf{l}$ of $\mathbf{A}$ and $\mathbf{L}$ defined by the relations (3.1).
Step 3. For each $i = 1, \ldots, n$ call algorithm SOLVE1D with input $\alpha_i, \hat{b}_i, c_i$ and obtain an output $\hat{x}_i$.
Step 4. $\mathbf{x} = \mathbf{Q}^*\hat{\mathbf{x}}$, where $\hat{\mathbf{x}} = (\hat{x}_i)_{i=1}^n$.

Based on the RSTLS algorithm, the constrained version, problem (CSTLS), is solved via a simple bisection algorithm applied to $q'(\lambda)$, where q is the dual function defined by (6.3). The bisection is over the logarithm of base 10 of the dual variable λ.

ALGORITHM CSTLS$(\mathbf{Q}, \mathbf{A}, \mathbf{L}, \alpha)$.

input	$\mathbf{Q} \in \mathbb{F}^{n\times n}$ - a unitary matrix.
	$\mathbf{A}, \mathbf{L} \in \mathcal{L}_{\mathbf{Q}}, \mathbf{b} \in \mathbb{F}^n$.
	$\alpha \in \mathbb{R}_{++}$.
output	The $\mathbf{x}$-part of the optimal solution of (6.1).

Step 1. $u = 2, \ell = -4$.
Step 2. **while** $(u - \ell) > 0.1$
$h = \frac{u+\ell}{2}$
call Algorithm RSTLS with input $\mathbf{Q}, \mathbf{A}, \mathbf{L}, 10^h$ and obtain an output $\tilde{\mathbf{x}}$
if $\|\mathbf{L}\tilde{\mathbf{x}}\|^2 < \alpha$
$u = h$
else
$\ell = h$
end if
end while
Step 3. $\mathbf{x} = \tilde{\mathbf{x}}$.

Note that the RSTLS and CSTLS algorithms use matrix-vector multiplications with the matrices $\mathbf{Q}$ and $\mathbf{Q}^*$ and require the computation of the eigenvalues of the matrices $\mathbf{A}$ and $\mathbf{L}$. When $\mathcal{L}_{\mathbf{Q}}$ is one of the four SD structures described in section 2.2 in the context of image deblurring, these operations can be efficiently performed by utilizing fast transforms: one- or two-dimensional FFT for periodic boundary conditions and one- or two-dimensional FCT for reflexive boundary conditions.

7.2. A numerical example. To demonstrate our approach we consider an image deblurring example. We start with the 512×512 Lena gray image (top left image of Figure 3) scaled so that all of the pixels are in the interval $[0, 1]$ and blur it with a Gaussian PSF of dimension 9×9 with standard deviation 6 implemented in the command psfGauss([9,9],6) from [15]; the values in the PSF range between 0.0095 and 0.0148. We assume that the blurring is not exactly known and that the observed PSF is a Gaussian PSF of dimension 9×9 with standard deviation 8. We then cut the margins by 20 rows and columns resulting in 492×492 and add a Gaussian white noise with standard deviation 10^{-3} (top right image of Figure 3). By assuming reflexive boundary conditions, the poor naive solution construction (i.e., $\mathbf{A}^{-1}\mathbf{b}$) is given in the left middle image of Figure 3. This poor quality of the naive solution is not surprising since the problem is extremely ill conditioned. In our experiments, the regularization matrix $\mathbf{L}$ represents a discretization of a differential operator corresponding to the PSF

$$\begin{pmatrix} -1 & -1 & -1 \\ -1 & 8 & -1 \\ -1 & -1 & -1 \end{pmatrix}.$$

The constrained least squares solution, that is, the solution of the problem

$$\min\{\|\mathbf{A}\mathbf{x} - \mathbf{b}\|^2 : \|\mathbf{L}\mathbf{x}\|^2 \leq \alpha\},$$

is presented in the right middle image. The CSTLS reconstructions under periodic and reflexive boundary conditions are the left and right bottom images, respectively. The parameter α is chosen as $1.2\|\mathbf{L}\mathbf{x}_{\text{true}}\|^2$. Clearly, the best reconstruction is provided by the CSTLS algorithm with reflexive boundary conditions. The artifacts in the CSTLS reconstruction with periodic boundary conditions are much more prominent. The relative error of the CSTLS reconstruction with reflexive boundary conditions, $\frac{\|\mathbf{x}_{\text{true}} - \mathbf{x}_{\text{CSTLS-R}}\|}{\|\mathbf{x}_{\text{true}}\|}$, is 0.0961, while for periodic boundary conditions the relative error is 0.1393. The constrained least squares solution gave the worst relative error: 0.15.

8. Conclusion and discussion. In this paper we have shown that the RSTLS problem for structures involving matrices which are simultaneously diagonalizable by a given unitary matrix can be efficiently and globally solved (as opposed to general structures). These SD structures appear in image deblurring problems with either reflexive or periodic boundary conditions. The solution method consists of first decomposing the problem into several real or complex one-dimensional problems which are not necessarily unimodal. In the described image deblurring examples, the decomposition is performed by using the FFT or the FCT. The one-dimensional problems are then globally solved by invoking an unimodal solver on a transformation of the problems. Numerical results demonstrate the effectiveness of the proposed approach.

Another type of boundary conditions are antireflective boundary conditions introduced in [35].[5] As stated in [35], antireflective boundary conditions further reduce the boundary artifacts. The reason is that zero Dirichlet and periodic boundary conditions introduce an artificial discontinuity at the border of the field of view; reflexive boundary conditions impose that the reflected image is globally continuous but introduce an artificial discontinuity of the first derivative, while antireflective boundary conditions using a central symmetry are able to maintain C^1 continuity in the case of signals and C^0 with normal derivative continuity for images.

[5] We thank an anonymous reviewer for referring us to the literature on this type of boundary conditions.

FIG. 3. *Deblurring of Lena.*

In analogy with the reflexive boundary conditions, matrix-vector operations, solution of linear systems, and eigenvalue computations in the antireflective setting can be done in $O(n \log n)$ real operations [4] (using the fast sine transform). It is also known

that for these types of boundary conditions and with symmetric PSFs the set of all possible matrices is simultaneously diagonalizable [3]. However, the diagonalizing matrix is not unitary. The unitary property is essential to the analysis introduced in the current paper. Specifically, the decomposition of the RSTLS problem described in Theorem 3.1 will not be valid if the diagonalization is via a nonunitary matrix. Therefore, it does not seem possible to analyze the RSTLS problem with antireflective boundary conditions within the setting of the paper. It is an open question whether it is possible to exploit the special properties of antireflective boundary conditions in order to construct an efficient method for solving the corresponding RSTLS problem.

Acknowledgment. We thank two anonymous referees for their helpful comments and suggestions which helped to improve the presentation of the paper.

ON THE COMPUTATION OF NULL SPACES OF SPARSE RECTANGULAR MATRICES*

CRAIG GOTSMAN† AND SIVAN TOLEDO‡

Abstract. Computing the null space of a sparse matrix is an important part of some computations, such as embeddings and parametrization of meshes. We propose an efficient and reliable method to compute an orthonormal basis of the null space of a sparse square or rectangular matrix (usually with more rows than columns). The main computational component in our method is a sparse LU factorization with partial pivoting of the input matrix; this factorization is significantly cheaper than the QR factorization used in previous methods. The paper analyzes important theoretical aspects of the new method and demonstrates experimentally that it is efficient and reliable.

Key words. null space, inverse iteration, rectangular matrices, LU factorization, sparse matrices polynomial

1. Introduction.

We propose a new method for computing an orthonormal basis for the null space of a rectangular m-by-n matrix A with $m \geq n$. The main computational component of the new method is a conventional LU factorization with partial pivoting of A. For many classes of sparse matrices, an appropriate preordering of the columns leads to sparse factors, usually significantly sparser than the QR factors and than the factors of any rank-revealing factorization [24, 26]. There are several recent high-quality sparse LU codes that can perform partial pivoting [2, 18, 19, 20, 31, 32]. Experts on sparse-matrix factorizations, including experts on sparse QR, believe that sparse LU factorizations with partial pivoting are intrinsically cheaper than sparse QR.[1] This belief is driven both by theoretical results and by computational experience. The theoretical results show that the nonzero pattern of the R factor in the QR factorization of a square matrix with no zeros on the diagonal contains the nonzero pattern of the L and U factors in the LU factorization with partial pivoting, so the L and U factors are at most as dense as R [23]. Therefore, the new method is particularly suitable for large sparse matrices with a small-dimensional null space. (Because we compute an orthonormal basis, in the computation of a high-dimensional null space, the cost of orthogonalizing the null vectors dominates.)

We also revisit a somewhat more expensive method, which is based on a QR factorization. This method is not new, but is not widely known either. Because of this, and because it can be used to compute not only the null space, but also additional singular triplets corresponding to small singular values, we mention it here briefly too.

[1]Private discussions with John Gilbert, Pontus Matstoms, and Esmond Ng in April and June 2005.

There are several applications to the computation of the null space and, more generally, to the computation of singular vectors or singular subspaces associated with small singular values. The first application that we describe involves computation with matrices derived from graphs. We start with a discussion of the square and symmetric case, and then describe extensions of these applications to rectangular matrices.

The spectrum of matrices related to the adjacency matrix of a graph is extremely interesting. Typically the lowest eigenvalues and eigenvectors are the most useful, as they characterize various properties of the graph. The most famous example is the second smallest eigenvalue of the graph Laplacian, which characterizes how strongly it is connected, hence its mixing rate [13]. The smallest eigenvalue is zero, corresponding to a fixed-valued eigenvector. The eigenvector corresponding to the second eigenvector (the so-called Fiedler vector) is also useful for ordering the vertices of the graph (using the components of this vector) for embedding [33] and partitioning [1] purposes. In general, the d eigenvectors corresponding to the d smallest nonzero eigenvalues may be used to form partitions and embed in $\mathbb{R}^d$. Singular vectors associated with the smallest singular values also play an important role in techniques for embedding graphs in $\mathbb{R}^d$. For example, the null space of the so-called Colin de Verdière matrices [16, 29, 37] are used in convex embeddings of closed manifold genus-0 graphs in $\mathbb{R}^d$, and the null space of stress matrices [17] is used in unique (up to rigid transformations) embeddings of a graph with given edge lengths. When the graphs arise from a three-dimensional (3D) mesh structure, as frequently happens in computer graphics applications, or from a k-nearest-neighbor graph, as in feature-learning applications, the graphs tend to be very sparse, and the sparsity should be exploited in the computation of the small singular subspace.

Another area where the null space of rectangular matrices arises is the parameterization of manifold 3D meshes of genus $g > 0$ [28, 30, 44]. In this application, a graph is considered a discrete version of a vector field on a surface, and a discrete version of the one-form is defined for it. Of particular interest are the so-called harmonic one-forms, which satisfy certain balance conditions. The search for harmonic one-forms on a given mesh graph results in the formulation of a set of linear equations for unknowns corresponding to the edges of a graph. Some of the equations are derived for the edges incident on vertices, and some are derived from the edges bounding faces. The size of the matrix is N-by-E, where E is the number of edges in the graph, and N is typically close to E, but is also influenced by the genus. These matrices are sparse and rectangular, and the nullity (the dimension of the nullspace) is typically $2g$.

Approximate null vectors are also used in at least two areas of numerical linear algebra. One area is condition-number estimation. The spectral condition number of a matrix A is the ratio of its extreme singular values $\sigma_{\max}/\sigma_{\min}$. Estimating the largest singular value is relatively easy; the hard part is estimating $\sigma_{\min}$. This is done almost invariably by trying to find a vector v with a unit norm such that $\|Av\|$ is small. When A is nearly singular, this problem is roughly equivalent to finding an approximate null vector. Note that in condition-number estimation, the estimate can be accurate enough even when v is not a good approximation of the singular vector associated with the smallest singular value. Therefore, the methods for finding such a v are not very similar to the methods that we describe here; condition-number estimators usually favor speed over accuracy; many of them are reliable in practice but may fail on some matrices. For further details, see [34, Chapter 15] and the references therein.

Approximate null vectors are also used in algorithms that compute rank-revealing factorizations and algorithms that solve rank-deficient least-squares problems without

a rank-revealing factorization [11, 12, 21, 39]. Here, too, a relatively inaccurate approximate null vector is good enough. On the other hand, some of the rank-revealing factorizations require approximate null vector of a sequence of nested upper-triangular matrices (the incrementally constructed factor of A). There are specialized incremental condition-number estimators for these applications [8, 9]; our approach is not efficient enough for such applications.

We focus on the $m \geq n$ matrices because the problems of computing a basis for the null space when $m > n$ and when $m < n$ are fundamentally different. When $m < n$ the nullity is at least $n-m$. When n is much larger than m, the nullity is high, and the space and time costs of computing an orthogonal basis for the null space are dominated by the usually dense basis vectors and by the cost of orthogonalizing them. Thus, when $m < n$ the standard approach is to compute a sparse but not necessarily orthogonal basis. This topic has been researched extensively and is outside the scope of this paper [7, 14, 15, 25]. When $m \geq n$ or when m is only slightly larger than n the nullity can be small and the orthogonal-basis algorithms that we discuss are appropriate.

The rest of the paper is organized as follows. The next section introduces inverse iteration. Section 3 introduces symmetric inverse iterations for nonnormal and for rectangular matrices, and in particular symmetric R iteration. Section 4 presents our main contribution, an LU-based symmetric inverse iteration. Section 5 describes the results of numerical experiments, and section 6 compares our work to previously published work. Section 7 presents some conclusions and open questions.

2. Inverse iteration. Given a square matrix A, inverse iteration repeatedly solves the equation $Ax^{(t)} = x^{(t-1)}/\|x^{(t-1)}\|$ for $x^{(t)}$. The starting vector $x^{(0)}$ can be random, although there are alternatives that often work a little better. When A is symmetric, the iteration converges to an eigenvector associated with the smallest eigenvalue of A (in absolute value). If the equation is solved using a backward stable factorization, such as QR or LU with partial pivoting, the iteration converges even if A is singular. In fact, if A is singular, then the iteration converges very quickly, in most cases in one or two iterations.

If the nullity of A is larger than one, we can start with an n-by-k matrix $Y^{(0)}$, and in each iteration we solve $AY^{(t)} = X^{(t-1)}$ for $Y^{(t)}$ and then orthonormalize the columns of $Y^{(t)}$ to produce $X^{(t)}$. If k is at least as large as the dimension of null(A), then the first $n-\text{rank}(A)$ columns of $X^{(t)}$ converge to an orthonormal basis of null(A). This technique is essentially the inverse version of simultaneous iteration or subspace iteration. The same idea applies to all the inverse iterations that we describe in the rest of the paper.

When A is square but not normal, the method often works, but it may also fail [35]. When A is not even square, standard inverse iteration does not apply at all.

One issue that is outside the scope of this paper, but should be mentioned, is overflows in inverse iteration. Suppose that we apply inverse iteration using a QR factorization, such that the exact R factor of A is

$$R = \begin{bmatrix} 0 & 1 & & & \\ & 0 & \ddots & & \\ & & \ddots & 1 & \\ & & & 0 & 1 \\ & & & & 0 \end{bmatrix},$$

and that due to rounding errors the computed factor is

$$\tilde{R} = \begin{bmatrix} \epsilon & 1 & & & \\ & \epsilon & \ddots & & \\ & & \ddots & 1 & \\ & & & \epsilon & 1 \\ & & & & \epsilon \end{bmatrix}.$$

Consider solving $Rx = \vec{1}$ (the right-hand side is the vector of all ones). As ϵ shrinks, the solution converges to $[\epsilon^{-n}\ \epsilon^{-(n-1)}\ \cdots\ \epsilon^{-1}]^T$. If there are no overflows, this is a good approximation of the exact null vector $[1\ 0\ \cdots\ 0]^T$, as expected. But obviously ϵ^{-n} is extremely likely to overflow. There are techniques to mitigate this danger [35], but they are difficult to apply in the case of subspace iteration. We shall see examples of this behavior in the numerical results below.

3. Symmetric iterations and symmetric inverse *R* iteration. When A is not normal or not even square, a variant of inverse iteration can still be applied reliably. This variant is not new, but not widely appreciated either. We call this variant [illegible] inverse iteration.

Symmetric power iteration repeatedly applies A^*A to a starting vector, and symmetric inverse iteration repeatedly solves equations of the form $A^*Ax^{(t)} = x^{(t-1)}/\|x^{(t-1)}\|$ for $x^{(t)}$. The Gram matrix A^*A is symmetric (Hermitian in the complex case), so inverse iteration works on it reliably. Symmetric iterations, both power and inverse, work without ever computing A^*A. The eigenvalues of A^*A are the squares of the singular values of A, so small singular values become a lot smaller: singular values near or below $\|A\|\sqrt{\epsilon_{\text{machine}}}$ become eigenvalues near or below $\|A\|\epsilon_{\text{machine}}$. If we compute A^*A explicitly, rounding errors usually make these small but nonzero singular values indistinguishable from the zero singular values of A, and inverse iteration will always produce linear combinations of the corresponding singular vectors. In other words, inverse iteration on an explicit A^*A may be unstable and may produce vectors that are far from null vectors of A.

But iterating on A^*A implicitly does not suffer from this instability. If A is square, we solve $A^*Ax^{(t)} = x^{(t-1)}/\|x^{(t-1)}\|$ by factoring A using any backward-stable factorization, say LU with partial pivoting, and solving

$$\begin{aligned} A^*w &= x^{(t-1)}/\|x^{(t-1)}\|, \\ Ax^{(t)} &= w\ . \end{aligned}$$

As far as we can tell, this idea is due to Stewart [42].

When A is not even square, we can still solve $A^*Ax^{(t)} = x^{(t-1)}/\|x^{(t-1)}\|$ if we compute the reduced QR factorization of A. In this factorization, Q is m-by-n (like A) with orthonormal columns, and R is n-by-n and upper triangular. Here, too, we need a backward-stable, but not rank-revealing, factorization. (So when A is sparse, we can use an arbitrary row and column preorderings to minimize fill and work.) Since $A = QR$, we have $A^*A = R^*Q^*QR = R^*R$. To solve $A^*Ax^{(t)} = R^*Rx^{(t)} = x^{(t-1)}/\|x^{(t-1)}\|$, we perform two triangular solves,

$$\begin{aligned} R^*w &= x^{(t-1)}/\|x^{(t-1)}\|, \\ Rx^{(t)} &= w\ . \end{aligned}$$

Björck [10, p. 109] credits Chan [12] with this technique, although Chan's paper is not explicit about how to carry out the inverse iteration. We refer to this technique as [illegible] R [illegible]. The simultaneous/subspace version of this technique can be used to compute multiple singular vectors associated with the smallest singular values of A.

Both the implicit normalization idea and the use of the R factor are not new, but neither are they widely appreciated. Virtually all the research on inverse iteration, surveyed by Ipsen [35], ignores normalization and focuses instead on less reliable and more complex methods to enhance inverse iteration for the nonnormal case. In that literature, there is essentially no discussion of rectangular matrices. So although normalization and the use of the R factor are mentioned in the literature, they are not widely known. For example, LAPACK [3] uses unsymmetric inverse iteration to compute eigenvalues of tridiagonal matrices [35].

4. *LU*-based symmetric inverse iterations. This section presents the main contribution of the paper, symmetric inverse iterations with the triangular factors computed by LU with partial pivoting. The algorithms start with a factorization

$$PA = LU = \begin{bmatrix} L_1 \\ L_2 \end{bmatrix} U , \tag{1}$$

where P is an m-by-m permutation matrix, L is an m-by-n upper trapezoidal matrix, and U is an n-by-n upper triangular matrix. Thanks to partial pivoting, L has 1's on the diagonal and the magnitude of all of its elements is bounded by 1. We partition L into pivot and nonpivot rows: L_1 is the square n-by-n triangular part of L, containing the pivot rows, and L_2 is the subdiagonal block containing the remaining $m-n$ rows.

In exact arithmetic, A, U, and L_1U all have exactly the same null space. Therefore, we can try to compute the null space of A by performing symmetric inverse iteration on U or on L_1U, both of which are square. The matrix U is upper triangular, and once we compute the factorization (1), we have a triangular factorization of L_1U. This allows us to perform symmetric inverse iteration with either L_1U or with U without any additional preprocessing. The following trivial lemma proves that A, U, and L_1U all have the same null space. Once we prove it, we analyze the effect of rounding errors on this process.

LEMMA 4.1. [illegible]

$$PA = LU = \begin{bmatrix} L_1 \\ L_2 \end{bmatrix} U$$

[illegible] LU [illegible] A [illegible] L_1 [illegible] $\operatorname{null}(A) = \operatorname{null}(L_1U) = \operatorname{null}(U)$

[illegible]. The row permutation P is irrelevant for null vectors, so without loss of generality we assume that $P = I$. Because L_1 is nonsingular, $\operatorname{null}(L_1U) = \operatorname{null}(U)$. Therefore, all we need to show is that $\operatorname{null}(A) = \operatorname{null}(L_1U)$. If $Ux = 0$, then we also have $L_2Ux = 0$, so $Ax = LUx = 0$. This shows that $\operatorname{null}(A) \subseteq \operatorname{null}(U) = \operatorname{null}(L_1U)$. On the other hand, if $Ax = LUx = 0$, then in particular $L_1Ux = 0$. This shows that $\operatorname{null}(A) \supseteq \operatorname{null}(L_1U) = \operatorname{null}(U)$, which concludes the proof. ∎

We now analyze the relationships between the approximate null spaces of A, U, and L_1U, still without taking into account rounding errors in the factorization of A. The relationships that we describe now motivate the structure and the numerics of our algorithm. The next theorem shows that

- all the small singular values of U correspond to small singular values of A (but A may have more small singular values than U);
- moreover, approximate null vectors of U are also approximate null vectors of A;
- all the small singular values of A correspond to small singular values of L_1U;
- approximate null vectors of A are approximate null vectors of L_1U.

THEOREM 4.2.

$$PA = LU = \begin{bmatrix} L_1 \\ L_2 \end{bmatrix} U$$

LU A L 1’ 1 x

$$\frac{3}{\sqrt{4^n + 6n - 1}}\sigma_k(U) \le \sigma_k(A) \le \sqrt{mn}\sigma_k(U), \tag{2}$$

$$\frac{3}{\sqrt{4^n + 6n - 1}}\|Ux\|_2 \le \|Ax\|_2 \le \sqrt{mn}\|Ux\|_2, \tag{3}$$

$$\sigma_k(L_1U) \le \sigma_k(A) \le \sqrt{1 + (m-n)n\frac{4^n + 6n - 1}{9}}\sigma_k(L_1U), \tag{4}$$

$$\|L_1Ux\|_2 \le \|Ax\|_2 \le \sqrt{1 + (m-n)n\frac{4^n + 6n - 1}{9}}\|L_1Ux\|_2. \tag{5}$$

(2) (3), $\sigma_k(U)$ $\sigma_k(A)$ $\sigma_k(U)$ m A U (2) (3) $\sigma_k(A)$ $2^n/3$ smaller $\sigma_k(U)$ A U U (4) (5) L_1U A A L_1U (4) (5) . We again assume without loss of generality that $P = I$.

The singular-value inequalities use the following singular-value bounds [6, Propositions 9.6.1 and 9.6.4], which hold for any $A = XY$ where X is m-by-ℓ and Y is ℓ-by-n:

$$\sigma_k(X)\sigma_\ell(Y) \le \sigma_k(A) \le \sigma_k(X)\sigma_{\max}(Y)\,. \tag{6}$$

We apply these bounds to two factorizations of A. When applied to $A^* = U^*L^*$, the inequalities gives

$$\sigma_k(U)\sigma_n(L) \le \sigma_k(A) \le \sigma_k(U)\sigma_{\max}(L)\,. \tag{7}$$

We also apply the bounds (6) to the conjugation of the factorization $A = M\,(L_1U)$, where

$$M = \begin{bmatrix} I \\ L_2L_1^{-1} \end{bmatrix}\,.$$

On $A^* = (L_1 U)^* M^*$, the singular-value bounds give

$$\sigma_k(L_1 U)\sigma_n(M) \le \sigma_k(A) \le \sigma_k(L_1 U)\sigma_{\max}(M) \; . \tag{8}$$

We now bound the smallest and largest singular values of L and M. Because the magnitude of all the elements of L are all bounded by 1, we have

$$\|L\|_2 \le \|L\|_F = \sqrt{\sum_{i,j} L_{i,j}^2} \le \sqrt{mn} \; .$$

The smallest singular value of L is bounded by that of L_1:

$$\begin{aligned}
\sigma_n(L) &= \min_{\|x\|_2=1} \|Lx\|_2 \\
&= \min_{\|x\|_2=1} \sqrt{\|L_1 x\|_2^2 + \|L_2 x\|_2^2} \\
&\ge \min_{\|x\|_2=1} \sqrt{\|L_1 x\|_2^2} \\
&= \sigma_n(L_1) \; .
\end{aligned}$$

Barlow and Zha [5, Lemmas 2.1 and 2.2] showed that

$$\sigma_n(L_1) \ge \left(\frac{4^n + 6n - 1}{9} \right)^{-1/2} \; ,$$

and this also bounds $\sigma_n(L)$. Combining these bounds with (7), we get

$$\sqrt{\frac{9}{4^n + 6n - 1}} \sigma_k(U) \le \sigma_k(A) \le \sqrt{mn}\sigma_k(U) \; .$$

We relate the singular values of A to those of $L_1^{-1} L_2$. The smallest singular value of M is at least 1, since

$$\begin{aligned}
\sigma_n(M) &= \min_{\|x\|_2=1} \|Mx\|_2 \\
&= \min_{\|x\|_2=1} \sqrt{\|Ix\|_2^2 + \|L_2 L_1^{-1} x\|_2^2} \\
&= \min_{\|x\|_2=1} \sqrt{1 + \|L_2 L_1^{-1} x\|_2^2} \\
&\ge 1 \; .
\end{aligned}$$

The largest singular value of M is bounded by

$$\begin{aligned}
\sigma_{\max}(M) = \|M\|_2 &= \max_{\|x\|_2=1} \sqrt{1 + \|L_2 L_1^{-1} x\|_2^2} \\
&\le \sqrt{1 + \|L_2 L_1^{-1}\|_2^2} \\
&\le \sqrt{1 + \|L_2\|_2^2 \|L_1^{-1}\|_2^2} \\
&\le \sqrt{1 + \|L_2\|_F^2 \sigma_n(L_1)^{-2}} \\
&\le \sqrt{1 + (m-n)n \frac{4^n + 6n - 1}{9}} \; .
\end{aligned}$$

Substituting the bounds on the singular values of M in (8), we get

$$\sigma_k(L_1U) \le \sigma_k(A) \le \sqrt{1 + (m-n)n\frac{4^n + 6n - 1}{9}}\sigma_k(L_1U) \ .$$

The bounds on approximate null vectors in the statement of the theorem are now easy to derive. One side follows from $\|Ax\|_2 \le \|L\|_2\|Ux\|_2$ (and similarly for $A = ML_1U$). The other side follows from

$$\sigma_n(L) = \min_y \frac{\|Ly\|_2}{\|y\|_2} \ ,$$

which imply that for $y = Ux$ we have $\sigma_n(L) \le \|Ly\|_2/\|y\|_2$, so $\sigma_n(L)\|Ux\|_2 \le \|Ly\|_2 = \|LUx\|_2 = \|Ax\|_2$. □

Rounding errors in the factorization do not loosen these bounds in a significant way, as long as the factorization is backward stable.

LEMMA 4.3. [illegible]

$$A + E = PLU = P\begin{bmatrix} L_1 \\ L_2 \end{bmatrix} U$$

[illegible] LU [illegible] m [illegible] n [illegible] A [illegible]

$$\|E\|_F \le \epsilon$$

[illegible] ϵ [illegible]

$$\begin{aligned} \sigma_k(A) &\le \sqrt{mn}\sigma_k(U) + \epsilon, \\ \|Ax\|_2 &\le \sqrt{mn}\|Ux\|_2 + \epsilon\|x\|_2, \\ \sigma_k(L_1U) &\le \sigma_k(A) + \epsilon, \\ \|L_1Ux\|_2 &\le \|Ax\|_2 + \epsilon\|x\|_2 \ . \end{aligned}$$

[illegible]. We again assume without loss of generality that $P = I$.

The standard perturbation theory for singular values ensures that [27, Theorem 8.6.4]

$$\sum_{k=1}^{n} (\sigma_k(A+E) - \sigma_k(A))^2 \le \|E\|_F^2 \ .$$

Therefore, $\sigma_k(A+E) - \sigma_k(A) \le \epsilon$, so using (2) we obtain

$$\sigma_k(A) \le \sigma_k(A+E) + \epsilon \le \sqrt{mn}\sigma_k(U) + \epsilon \ .$$

As for the approximate null vectors, we have

$$\begin{aligned} \|Ax\|_2 &= \|LUx - Ex\|_2 \\ &\le \|LUx\|_2 + \|Ex\|_2 \\ &\le \sqrt{mn}\|Ux\|_2 + \|E\|_2\|x\|_2 \\ &\le \sqrt{mn}\|Ux\|_2 + \|E\|_F\|x\|_2 \\ &\le \sqrt{mn}\|Ux\|_2 + \epsilon\|x\|_2 \ . \end{aligned}$$

Clearly, for this bound we could have used a bound on the 2-norm of E.

The proofs for the bounds on L_1U are similar. □

These results suggest the following algorithm.

1. Compute an LU factorization with partial pivoting $PA = LU = \left[\begin{smallmatrix} L_1 \\ L_2 \end{smallmatrix}\right] U$.
2. Perform subspace symmetric inverse iteration with U to find k approximate null vectors of U and to estimate the value of $\sigma_{k+1}(U)$. By Lemma 4.3, the approximate null vectors are also approximate null vectors of A, but there may be more.
3. Estimate $\sigma_n(L_1)$ using symmetric inverse iteration with L_1. If $\sigma_n(L_1)\sigma_{k+1}(U)$ is large, then

$$\sigma_{k+1}(A) \geq \sigma_n(L)\sigma_{k+1}(U) \geq \sigma_n(L_1)\sigma_{k+1}(U)$$

   is also large, so there is no need to search for additional approximate null vectors of A. If $\sigma_n(L_1)$ is too small, go to step 5; otherwise, continue.
4. L_1 is not ill conditioned: the vectors that we computed in step 2 should be a basis for the null space of A. Report the numerical rank of A and the basis for the null space, and return.
5. L_1 is ill conditioned enough to allow for approximate null vectors for A that are not approximate null vectors of U. Run subspace symmetric inverse iteration on $L'U$ to find a basis for its approximate null space.
6. If the iteration in step 5 produced approximate null vectors of $L'U$, then by Lemma 4.3 their number is an upper bound on the numerical rank deficiency of A (this number is possibly larger than the number of vectors found in step 2).
7. Determine which of the vectors produced in step 5 is also an approximate null vector of A and linearly independent of the vectors produced in step 2. Return these vectors, along with the vectors produced in step 2. Also report the upper bound computed in step 6.

The lower trapezoidal factor L that LU with partial pivoting produces is usually well conditioned, so we expect that the algorithm will usually perform steps 1–4 and stop there. If the algorithm does continue to steps 5–7, then the approximate null vectors that it returns may or may not constitute a basis for the null space of A. More specifically, if their number is smaller than the upper bound on the nullity, the vectors may span only a proper subspace of $\text{null}(A)$, or they constitute a basis but the upper bound is loose.

The details of steps 3 and 5 are as follows. Since step 3 is more complex (it needs to find an approximation to a nonzero singular value, in addition to finding a basis for the approximate null space), we explain how it works. We use a simple version of subspace iteration (see [43] for details) in which we orthogonalize the basis in every iteration. We do not use Schur–Raleigh–Ritz refinement or deflation. We apply the iteration implicitly to $U^{-1}U^{-*}$. To ensure that U has an inverse, we replace zero diagonal entries by the value $\epsilon_{\text{machine}}\|U\|_1$. This amounts to a small perturbation that does not change the null space of U in a significant way. Since we are looking for approximate null vectors, we perform very few iterations within each subspace iteration, usually 3. We perform this iteration repeatedly, each time with twice as many basis vectors, starting from two. We stop this repeated doubling when not all the vectors returned by the iteration are approximate null vectors of U. When this happens, we use the Raleigh quotient of the first nonnull vector that is returned as an approximation to $\sigma_{k+1}(U)$. Other symmetric/Hermitian subspace eigensolvers can also be used as the inner iteration of these steps.

5. Numerical experiments. In this section we provide a few illustrative examples to demonstrate the behavior of the LU- and QR-based algorithms, including pathological behaviors.

We carried out the experiments using MATLAB version 7.0 on a 3 GHz Pentium 4 computer with 1 GB of main memory running Linux. The LU factorization was performed using the function call `[L,U,P,Q]=lu(A,1.0)`, which calls UMFPACK version 4.3 (`P` and `Q` are row and column permutations). This syntax enforces partial pivoting and allows the sparse factorization code to reorder rows and columns for sparsity (under the partial pivoting constraint). We also ran a symmetric inverse R iteration, to compare the runtimes. We computed the R factor using the function call `R=qr(A(:,colamd(A)),0)`, which avoids the expensive computation of an explicit Q. The reordering of the columns tends to reduce fill and work, and is generally similar to the column ordering that UMFPACK uses.

The codes implement the algorithms from sections 3 and 4. They apply the iterations first to 1 vector, then 2, then 4, and so on, until the dimension of the computed null space stops growing. The codes always run 3 iterations of the appropriate strategy, starting from a matrix consisting of uniformly distributed random numbers between 0 and 1.[2]

5.1. Accuracy. We created random matrices with singular values $1, \ldots, 1, \sigma_2, 0$ for $\sigma_2 = 10^{-16}, 10^{-15}, \ldots, 10^{0}$. The matrices are all 200-by-100, and they were computed by generating random orthonormal singular vectors and multiplying the singular vectors and singular values appropriately. We generated 100 random matrices for each σ_2. For each matrix, we used our algorithm to compute its null vector. We also used MATLAB's singular value decomposition (`svd`) on both A and $A^T A$. On all of these matrices, our algorithm computed the null space of A by iterating on U; L was never ill conditioned. The results of the experiment, shown in Figure 1, show that our algorithm is less accurate than a full SVD computation, but not significantly so. In particular, the results show that the qualitative behavior of our algorithm is similar to that of a full SVD: the accuracy degrades smoothly as σ_2 approaches $\epsilon_{\text{machine}}\|A\|$.

We also ran experiments on matrices whose U factors have tiny diagonal values near the upper left corner. We did this by generating two independent columns, then a column that depends on the first two, and then another column that almost depends on the first two, but not exactly. We then completed the matrices with 96 additional linearly independent columns. This yielded matrices with norm around 1, one zero singular value, and one singular value near 10^{-8}. On the diagonal of U we have U_{33} close to $\epsilon_{\text{machine}}$ and U_{44} is small. We have also conducted experiments in which the dependent and almost-dependent columns were columns 4 and 3, to swap the small and numerically zero elements on the diagonal of U. The accuracy in these experiments was similar to the accuracy achieved in the previous experiments. From this experiment it appears that the position of small elements on the diagonal of U does not have a significant influence on the accuracy of the algorithm.

5.2. Large matrices. We conduced experiments on a few large sparse matrices from Davis's sparse matrix collection.[3] More precisely, we took matrices from this collection and modified them slightly to make them rectangular and singular. This experiment serves three purposes. First, it shows that the algorithm runs reasonably quickly even on large matrices. Second, it shows that our LU-based algorithm is

[2]The main code, `nulls.m`, is publicly available at http://www.tau.ac.il/~stoledo/research.html.
[3]http://www.cise.ufl.edu/research/sparse/matrices/.

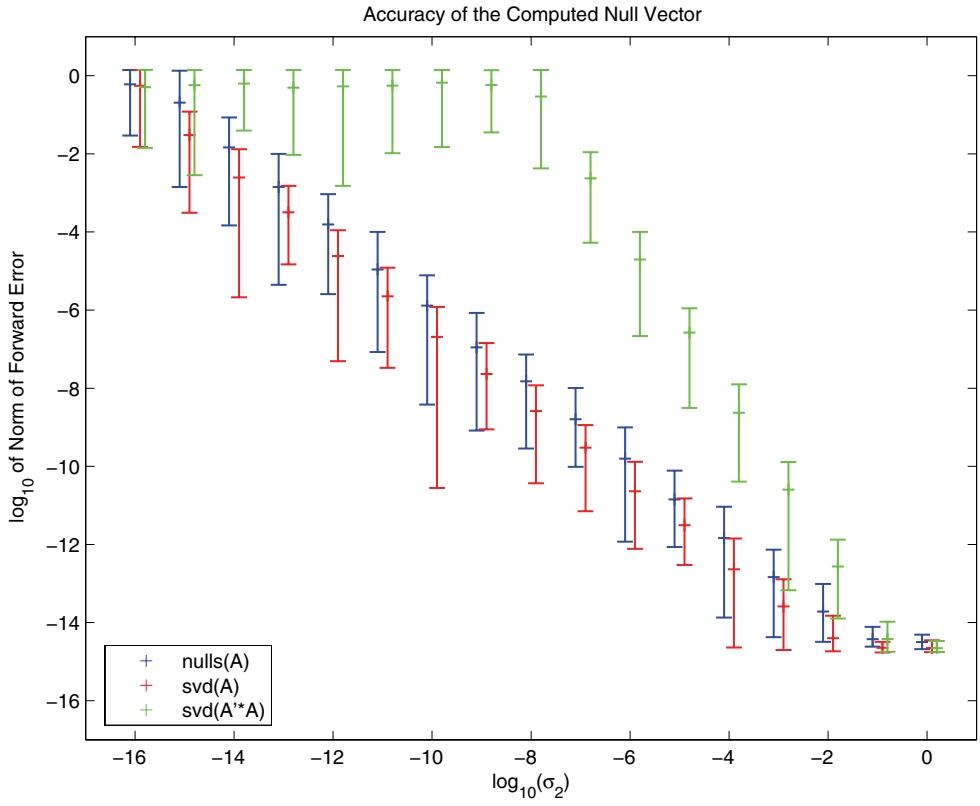

FIG. 1. *The results of the accuracy experiments. The bars show the range of accuracies for each* σ_2 *in* 100 *experiments; the mark along each range is the mean log accuracy. For each value of* σ_2*, the graph shows the accuracy of our algorithm (denoted* `nulls`*), of MATLAB's SVD implementation, and of the SVD applied to* A^TA*. The three bars for each* σ_2 *are slightly offset so that they don't overlap, but they all represent experiments with exactly the same* σ_2*.*

much faster than symmetric inverse R iteration. Third, it shows that the algorithm can fail; the failures are not specific to the LU-based algorithm but to inverse iteration in general. We believe that the failures are mostly due to scaling and overflow problems, similar to the ones discussed in section 2. In principle, these problems can be addressed by exploiting the capabilities of floating-point hardware better, but we have not implemented such measures.

We constructed the matrices as follows. All the matrices were initially square. From each matrix we dropped the first and last rows, and then duplicated rows 11 to 20 at the bottom of the matrix. This created $(n+8)$-by-n rectangular matrices with rank at most $n-2$.

The results of the experiments are summarized in Tables 1 and 2. Table 1 lists the matrices and the dimensions of the computed null spaces. Since the matrices were constructed to have null spaces of dimension at least 2, any dimension less than 2 indicates failure. Dimensions larger than 2 reflect matrices that were originally singular. One group of matrices, MULT_DCOP, caused difficulties to the LU-based algorithm, resulting in two failures. One of the failures led to overflows, but the other was silent. (The QR factorization of these matrices ran out of memory.) Two of these matrices, MULT_DCOP_02 and 03, have highly skewed row scaling, which may

TABLE 1

Our test matrices and the sizes of the computed null spaces. The columns denoted d display the dimensions of the computed null spaces, and the $\overset{NaN}{\infty}$ columns show whether any overflows or NaN's were detected during the iterations. contribute to the difficulty: the ratio between the extreme ∞-norms of rows is 10^{12} for MULT_DCOP_03, and even larger for 02. Another matrix, SHYY41, which was originally singular, caused similar difficulties for the QR-based algorithm. This shows that this class of numerical difficulties is not associated with our new LU-based algorithm, but with inverse iteration in general.

Table 2 shows the performance of the two algorithms. On all the matrices, the LU-based algorithms ran in less than 30 seconds. On several large matrices it ran in less than 10 seconds. We argue that these are acceptable running times. The table also shows that in all the experiments, the QR-based algorithm was slower, in most cases substantially slower. This is probably due both to the fact that MATLAB 7 uses a state-of-the-art sparse LU factorization but a much older sparse QR, and to the intrinsic differences in the costs of sparse LU and QR factorizations. A comparison of the fill in the LU factors and the fill in the QR factor shows that the R factor is denser, but not significantly more than L and U combined.

5.3. Extreme examples. We now describe matrices that cause extreme behaviors in inverse-iteration algorithms. Experiments with these matrices constitute a partial coverage test of our implementation, because they exercise parts of the code that are rarely reached on real-world matrices.

We start with a particularly pathological matrix, suggested to us as an example by G. W. Stewart. This matrix has the form

$$A_S = \begin{bmatrix} 1 & & & & & \\ -1 & 1 & & & & \\ \vdots & & \ddots & & & \\ -1 & & & 1 & & \\ -1 & -1 & \cdots & -1 & 1 & \\ 0.5 & 0.5 & 0.5 & 0.5 & 0.5 \end{bmatrix}.$$

The matrix A_s is $(n+1)$-by-n, has 1's on the diagonal, -1 below the diagonal in rows 1 through n, and 0.5 in all the entries in row $n+1$. The LU factorization with partial pivoting of A_S is $A_S = A_S I$, because A_S is already lower trapezoidal and its subdiagonal entries are bounded by 1 in absolute value. This matrix is well conditioned, so symmetric inverse iterations should not find any approximate null vectors. Indeed, if we perform symmetric inverse iteration with the upper triangular factor, we find no approximate null vectors. However, L_1, consisting of the first n rows of A_S, is very ill conditioned, since $L_1(1\ 2\ 4\ \ldots\ 2^n)^T = (1\ 1\ 1\ \ldots\ 1)^T$. This implies that the condition number of L' is exponential in n. When we run symmetric inverse iteration on either L_1 or L_1U, we find an approximation of the small singular vector of L_1. In this particular case, the large condition number of L_1 will cause our algorithm to iterate on $L_1 I$. This will return a single candidate vector and an upper bound of 1 on the rank deficiency. In this particular case, since the upper bound is 1, there is only one candidate vector x that is easy to rule out by observing that $\|A_S x\|$ is large. But this example shows that the exponential bound shown in Lemma 4.3 can be attained, and it shows that L_1 can be ill conditioned. The exponential bound implies that the dimension of the null space computed by iterating on L_1U is only an upper bound, and the ill conditioning of L_1 shows that the dimension of the null space computed by iterating on U is only a lower bound. Put together, this means that the method may fail to reliably estimate the rank deficiency (but it will report this failure explicitly, because it will detect the ill conditioning of L_1).

We also ran the algorithms on a block matrix of the form

$$\begin{bmatrix} A_S & 0 \\ 0 & A_R \end{bmatrix},$$

where A_S is the matrix describe above, and A_R is a random matrix with given singular values: all 1's except for four, which are three 0's and one 10^{-8}. On this matrix the QR-based algorithm correctly computes the rank deficiency, 3, and null space correctly, which is essentially the null space of A_R. The LU-based algorithm performs all the steps in the algorithm (that is, it does not stop at step 4 because it correctly detects that L' is ill conditioned). It finds three null vectors using inverse iteration on U, but since L_1U has four approximate null vectors, the algorithm returns the three null vectors but reports that the rank deficiency might be 4. In this particular case it is possible to determine the null space correctly, of course, but the example shows that the algorithm may need to resort to reporting a too-lax upper bound on the deficiency.

The next example shows that normalization may be necessary. The class of square matrices

$$A_I = \begin{bmatrix} 1 & \eta & & \\ & 1 & \ddots & \\ & & \ddots & \eta \\ & & & 1 \end{bmatrix},$$

where $\eta > 1$ is a parameter, was used by Ipsen [35] to show that without normalization, inverse iteration may fail. Their inverses are

$$A_I^{-1} = \begin{bmatrix} 1 & \eta & \eta^2 & \cdots & \eta^{n-1} \\ & \ddots & \ddots & \ddots & \vdots \\ & & \ddots & \ddots & \eta^2 \\ & & & \ddots & \eta \\ & & & & 1 \end{bmatrix}.$$

The norm of the matrices is $O(1+\eta)$ but the norm of the inverses is $O(1+\eta^{n-1})$. Therefore, the matrices are highly ill conditioned, so inverse iteration methods should find a vector x such that $A_I x$ has a small norm. However, without normalization, inverse iteration fails. With normalization, inverse iteration works. (Since A_I is upper triangular, iterating with A_I or with its R factor or with its U factor are exactly equivalent methods.)

5.4. Embeddings graphs on surfaces. We have also performed experiments on the following class of matrices. We describe the application where they arise, but we do not provide detailed results, since we detected no surprising or interesting behaviors on these matrices.

An instance of a nonnormal matrix whose null space is of interest is derived from a graph $G = (V, E, F)$ which has been embedded on a closed manifold surface of genus $g > 0$ in $\mathbb{R}^3$ (e.g., a torus). The graph G has $|V|$ vertices, $|E|$ edges, and $|F|$ faces. A value x_h may be attached to each half-edge h of G, such that $x_h = -x_{t(h)}$, where $t(h)$ is the (opposite) twin half-edge of h. Given an orientation for each edge, the vector x of the values corresponding to the half-edges in this orientation is known as a [illegible], or just one-form for short, of G [30]. A [illegible] one-form is one which satisfies some balance conditions, derived from each vertex and face of G. For a set of symmetric weights $w_h = w_{t(h)}$, each vertex v induces the [illegible] linear equation on x,

$$\sum_{h \in \delta v} w_h x_h = 0 ,$$

where δv is the set of half-edges emanating from v. Each face f induces the closedness linear equation,

$$\sum_{e \in \partial f} x_h = 0 ,$$

where ∂f is the set of half-edges bounding f.

In total, there are $|V| + |F|$ equations in $|E|$ unknowns, whose rank turns out to be $|V| + |F| - 2$. The Euler–Poincaré formula for manifold graphs asserts that $|V| + |F| - |E| = 2 - 2g$, so this rank is $|E| - 2g$. Thus, solving for a basis for the subspace of harmonic one-forms involves computation of the $2g$-dimensional nullspace of a nonnormal matrix of size $|E| + 2 - 2g$ by $|E|$.

By integrating harmonic one-forms, it is possible to parameterize manifold mesh data very efficiently. This has many applications in computer graphics and geometry processing [28, 30, 44].

6. Related work. Unsymmetric inverse iteration for square matrices is a well-researched area. The method was invented by Wielandt in 1944 and was studied by Wilkinson, who published his findings in several papers and books over a period of almost 30 years. For a comprehensive survey of these results, along with many newer results, see Ipsen's survey [35].

Symmetric inverse iteration for square matrices seems to have been first proposed by Stewart [42]. Symmetric inverse R iteration is due to Chan [12] (see also [10, p. 109]).

Symmetric inverse iteration with U or with L_1U is, to the best of our knowledge, new. It is remotely related to an idea by Saunders [40] to use U to precondition an iterative least-squares solver. There are additional least-squares preconditioners that are based on an LU factorization, but they all use the L'' block as well, so they are not really related to our proposed method (see [10, section 7.5.3] and the references cited there). Our algorithm is also related to the Peters–Wilkinson family of methods for solving least-squares problems using an LU factorization [38], in that both rely on the fact that L is usually well conditioned.

For square matrices, Schwetlick and Schnabel [41] proposed a bordering iteration as an alternative to inverse iteration. The advantage of their method is that the linear systems that their method solves in each iteration is nonsingular, so they can potentially be solved by an iterative linear solver, such as GMRES. However, the method is limited to square matrices that are numerically rank deficient by only one.

Friedman [22] proposed an algorithm to compute the null space of a symmetric positive definite matrix by shifting it so that the 0 eigenvalue, if there is one, is shifted to become the largest in magnitude, and then to apply power iteration. The motivation for the algorithm is related to the application that motivated our research, the application that we mentioned in section 5.4. Friedman's algorithm works as follows (we explain how to use it to compute the null space of A^*A). First, the algorithm uses power iteration on A^*A to compute an estimate $\tilde{\lambda}$ to the largest eigenvalue λ_n of A^*A. The estimate can be fairly inaccurate, but it should satisfy

$$\frac{2}{3}\lambda_n \le \tilde{\lambda} \le 2\lambda_n$$

with high probability. Now the algorithm performs power iteration on $B = \tilde{\lambda}I - A^*A$. The eigenvalues μ_i of B are $\mu_i = \tilde{\lambda} - \lambda_i$, where λ_i are the eigenvalues of A^*A. In particular, the zero eigenvalue of A^*A, if there is one, is shifted to $\tilde{\lambda}$, along with the invariant subspace. All the other μ_i's are smaller in magnitude than $\tilde{\lambda}$, by at least $\min(1/3, \lambda_{k+1})$, where λ_{k+1} is the smallest nonzero eigenvalue of A^*A. Therefore, power iteration on B converges to a null vector of A. The trouble with this approach is that the convergence is very slow if λ_{k+1} is small. This power iteration converges

linearly with a convergence rate that is proportional to

$$\frac{\lambda_n(A^*A) - \lambda_{k+1}(A^*A)}{\lambda_n(A^*A)} = 1 - \frac{\sigma_{k+1}^2(A)}{\sigma_n^2(A)}.$$

Convergence will be slow if $\sigma_{k+1}(A)$ is smaller than $\sigma_n(A)$, even if it is not dramatically smaller. The method does not converge at all to a null vector in floating point if $\sigma_{k+1}(A)/\sigma_n(A) \leq \sqrt{\epsilon_{\text{machine}}}$. The slow convergence or no convergence implies that the algorithm should probably be used only if (1) the only allowed use of A is multiplication by A and its conjugate, and (2) if it is known a priori that $\sigma_{k+1}(A)/\sigma_n(A)$ is relatively large, if at all.

The standard way to compute a basis for the null space of a rectangular matrix is using a rank-revealing factorization, such as a rank-revealing LU or QR factorization. For dense matrices, sophisticated rank-revealing factorizations are only slightly more expensive than backward-stable but non-rank-revealing ones. However, for sparse matrices, such factorizations can be significantly more expensive to compute than LU with partial pivoting or QR, because rank-revealing factorizations require column pivoting. In sparse QR and LU with partial pivoting, the column ordering is chosen so as to minimize fill and computation, so pivoting to reveal the rank typically leads to more fill and more work. Furthermore, sparse rank-revealing factorizations have not been implemented much, and those that have are not widely available. (The state of the art in this area is an algorithm by Pierce and Lewis [39], but the code is not publicly available; an earlier method proposed by Foster [21] uses similar techniques to detect dependent columns and to retriangularize R; see also [4].) In contrast, several recent and high-quality sparse LU with partial pivoting codes, which lie at the heart of our method, are publicly available [2, 18, 19, 20, 31, 32]. Some of these can exploit parallel computers and/or clusters. Even general-purpose interactive numerical engines, such as MATLAB, now contain excellent sparse LU codes (MATLAB 7 uses UMFPACK 4.3 [18]).

One method that might seem relevant but is not is inverse iteration on an augmented matrix

$$H = \begin{bmatrix} 0 & A^* \\ A & 0 \end{bmatrix}.$$

The augmented matrix is symmetric (Hermitian), and its eigenvalues are the singular values of A with both signs and additional $m - n$ zero eigenvalues. The eigenvectors of H associated with nonzero eigenvalues are concatenations of left and right singular vectors of A. The difficulty is that the dimension of null(H) is larger by $m - n$ than the dimension of null(A). There is no straightforward way to compute a basis from null(A) from a basis for null(H). Also, if m is significantly larger than n, then H has a high-dimensional null space that is expensive to compute. This method is appropriate for computing bases for singular subspaces of A associated with a singular value $\sigma \gg 0$, by inverse iteration on $H - \sigma I$ (for σ close to zero, the null space of H causes inaccuracies in the computed singular vectors). MATLAB, for example, uses the augmentation idea in its sparse SVD routine `svds` (which fails when applied to the computation of the null space).

Finally, we mention that our ideas also apply to iterative Arnoldi/Lanczos-type algorithms. When these algorithms are used to find the smallest eigenpairs, they usually iterate on a representation of the inverse. This is the case, for example, in ARPACK [36], an Arnoldi-based package (ARPACK is the code that MATLAB's `eigs`

calls). Therefore, as in other forms of inverse iteration, the cost of these algorithms is likely to be dominated by the cost of factoring A. MATLAB's `eigs`, for example, calls exactly the same sparse LU factorization routine that our code calls. Also, if the inversion scheme is unsymmetric, these methods can suffer from the same problems that simple inverse iteration suffers from. This implies that applying Lanczos to the implicitly symmetric inverse is likely to be more reliable than applying Arnoldi to an unsymmetric inverse (this is possible when the application can use singular triplets rather than eigenpairs, which is the case when computing the null space).

We summarize the discussion of Arnoldi/Lanczos algorithms as follows. First, when applied to an unsymmetric inverse, they can be unreliable. We recommend that a symmetric inverse be used when using these algorithms to compute the null space. Second, our analysis in section 4 is also applicable when the null spaces of U, L', and possibly L_1U are computed using a symmetric Lanczos procedure rather than simultaneous inverse iteration.

7. Conclusions. We have shown how to utilize an LU factorization with partial pivoting of a nonnormal and possibly rectangular matrix to compute its null space. The algorithm is usually reliable and accurate. Furthermore, if the case of failure is ill conditioning in L_1, then it reports that it failed (rather than fail silently) and provides a reliable upper bound on the nullity, possibly along with a basis for a subspace of the null space.

Our new algorithm can also fail due to overflows or scaling problems, but this is a property of inverse iterations in general, not of this particular variant. These problems can be addressed by exploiting the capabilities of floating-point hardware, but our implementation does not take these measures. This makes the algorithm somewhat less reliable than rank-revealing factorizations, but it is also much cheaper.

Because our algorithm uses an LU factorization, it can be easily applied to large sparse matrices, using one of several available factorization codes. Relying on an LU rather than a QR factorization reduces the total cost, especially in the sparse case, where a QR factorization can be substantially more expensive to compute.

Our method can use a Lanczos iteration, rather than simple inverse iteration (to compute the null spaces of U, L_1, and possibly L_1U). The issue that our algorithm addresses is not the iteration itself, but the representation of the inverse, and the representations that we proposed are also applicable to Lanczos iterations.

Acknowledgments. Thanks to the two anonymous referees for constructive suggestions that helped improve the paper considerably. In particular, one of the referees suggested the elegant analysis given in Theorem 4.2. Our original analysis was done in a mixture of norms rather than just in the 2-norm, and was not as illuminating. The same referee also suggested using an estimate for $\sigma_{k+1}(U)$ in order to assess the degree of ill conditioning in L_1 that should cause the algorithm to iterate on L_1U. Our original criterion was not conservative enough when $\sigma_{k+1}(U)$ is small. Thanks to Pete Stewart and to Chen Greif for extensive comments on early drafts of this paper.

A QR-BASED SOLVER FOR RANK STRUCTURED MATRICES*

STEVEN DELVAUX† AND MARC VAN BAREL†

Abstract. In this paper we show how to compute the QR-factorization of a rank structured matrix in an efficient way by means of the Givens-weight representation. We also show how the QR-factorization can be used as a preprocessing step for the solution of linear systems. Provided the representation is chosen in an appropriate manner, the complexity of the QR-factorization is $O((ar^2+brs+cs^2)n)$ operations, where n is the matrix size, r is some measure for the average rank of the rank structure, s is some measure for the bandwidth of the unstructured matrix part around the main diagonal, and $a, b, c \in \mathbb{R}$ are certain weighting parameters. The complexity of the solution of the linear system with given QR-factorization is then only $O((dr+es)n)$ operations for suitable $d, e \in \mathbb{R}$. The performance of this scheme will be demonstrated by some numerical experiments.

Key words. rank structured matrix, Givens-weight representation, QR-factorization, structure inheritance, linear system solution

1. Introduction.

In this paper we describe how for a rank structured matrix with available Givens-weight representation, one can efficiently compute its QR-factorization and subsequently use this factorization for the solution of linear systems.

A matrix will be called [illegible] if the ranks of certain submatrices starting from its bottom left corner, as well as the ranks of certain submatrices starting from its top right corner, are small compared to the matrix size.

Although one can devise several ways to obtain a compact representation for a rank structured matrix, there seem to be two classes of representations frequently used in the literature, which we call *uv* [illegible] and [illegible], following the terminology of [3]. Let us give a brief survey.

The class of *uv*-representations was historically the first; see, e.g., [10]. We mention that this type of representation is possible only under certain conditions.

A different and more flexible class of block quasi-separable representations was introduced in the book of Dewilde and van der Veen [6]. Many algorithms for these representations have since been developed in the literature. After their initial appearance in [6], they were then used by Eidelman and Gohberg, who also introduced the name (block) "quasi-separable representation"; see, e.g., [8]. More recently, these

matrices appeared under the name of "sequentially semiseparable representations" in the work of Chandrasekaran et al.; see, e.g., [2].

In the paper [3], we introduced yet another type of representation for rank structured matrices, which we called the . This representation is a generalization of the so-called Givens-vector representation introduced in [12]. We showed that our representation is theoretically equivalent with the block quasi-separable representations in or described in the book [6]. Nevertheless, we note that we are not aware of any systematic treatment of the use of the latter representations in the literature. We also showed how the unitary-weight representation could be further fine-tuned to what we called the .

In the present paper, we consider the problem of solving linear systems with rank structured coefficient matrix. Many methods for doing this have already been described in the literature. At the risk of making a too crude distinction, these methods can be divided in at least three categories.

A first type of solvers is based on the Sherman–Morrison formula and its generalizations; see, e.g., [7, section 7] and [9, section 4] for the case of uv-representable matrices with low rank blocks lying just below the main diagonal.

A second type of solvers is based on LU-factorizations and Gaussian operations without pivoting, a fact which is often revealed by the condition that the matrix must be strongly nonsingular. See, e.g., [7, section 5] for the case of block quasi-separable matrices with low rank blocks lying just below the main diagonal, and see [9, section 5] for an algorithm in the uv-representable case.

Finally, a third type of solver is based on QR- or URV-factorizations. Such algorithms can be devised in a stable way and are therefore numerically superior to the other classes of solvers. The first algorithm of this kind was the URV-decomposition solver for block quasi-separable matrices, reported in a more general operator-theoretical context in the book [6, Chapter 7]. More efficient versions of this algorithm for the case of finite matrices were then obtained in [8] using the QR-decomposition (see also [11]), and more recently in [2] using a URV-decomposition in the case where the low rank blocks are situated just below the main diagonal. The latter algorithm is a generalization of earlier work on uv-representations originating from [1].

In the present paper, we follow the solution strategy of [8] by developing a linear system solver that is based on a preliminary QR-factorization. The algorithm will be expressed in terms of the Givens-weight representation. The computation of the QR-factorization will require about $O((ar^2 + brs + cs^2)n)$ operations, where n is the matrix size, r is some measure for the average rank of the rank structure, s is some measure for the bandwidth of the unstructured matrix part around the main diagonal, and $a, b, c \in \mathbb{R}$ are certain weighting parameters. This QR-factorization can then be used for the efficient solution of a linear system, the latter requiring only $O((dr+es)n)$ operations for suitable $d, e \in \mathbb{R}$.

The algorithm in this paper will be able to capture rank structure, irrespective of the position of the low rank blocks with respect to (w.r.t.) each other and to the main diagonal. The only restriction is that the low rank blocks in the block lower triangular part may not overlap with those in the block upper triangular part.

The remainder of this paper is organized as follows. In section 2 we recall the basic ideas of the Givens-weight representation from [3]. Section 3 considers the QR-factorization of a rank structured matrix. This section contains both a theoretical part concerning structure inheritance by the Q- and R-factors of the QR-factorization, as well as a practical part concerning the algorithmic exploitation of these inheritance

results. Section 4 deals with the linear system solver. Finally, section 5 reports on the results of some numerical experiments.

2. Givens-weight representation. In this section we review the basic ideas of the Givens-weight representation from [3].

First we define the class of rank structured matrices.

DEFINITION 1 (see, e.g., [5]). $\mathcal{R}$ $\mathbb{C}^{m\times n}$ $\mathcal{R} = \{\mathcal{B}_k\}_k$ $\mathcal{B}_k$ 3.

$$\mathcal{B}_k = (i_k, j_k, r_k),$$

i_k j_k r_k $A \in \mathbb{C}^{m\times n}$ $\mathcal{R}$ k

$$\text{Rank } A(i_k : m, 1 : j_k) \leq r_k.$$

$A(i_k : m, 1 : j_k)$ A $i_k, \ldots, m$ $1, \ldots, j_k$

The above definition uses the word to distinguish from the more general rank structures which were handled in [5]. Since these more general structures do not occur in the present paper, we will simplify notation by just dropping the word everywhere from the notation.

Note that by definition all structure blocks can be identified as contiguous blocks situated in the bottom left corner of the matrix. A pictorial illustration of a pure rank structure with two structure blocks is shown in Figure 2.1.

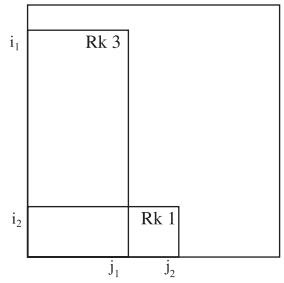

FIG. 2.1. *Example of a rank structure with two structure blocks $\mathcal{B}_1$ and $\mathcal{B}_2$. The notation "*Rk r_k*" denotes that the structure block is of rank at most r_k, $k = 1, 2$.*

In practice, it often happens that also the block triangular part is rank structured, i.e., that also the matrix A^T satisfies rank structure in the sense of Definition 1. By abuse of notation, we will indiscriminately use the term also in this case.

We will assume in what follows that we are working with a rank structure $\mathcal{R}$ for which there are no structure blocks that are "contained" in each other, i.e., for which the structure blocks $\mathcal{B}_k$ can be ordered such that both their row and column indices i_k and j_k increase in a strictly monotonic way. (Actually, these nested structure blocks are not completely useless, in the sense that they lead to an additional sparsity pattern in the Givens-weight representation, but we will not be concerned about this here.)

Now we will try to indicate the underlying ideas of the unitary-weight representation, following [3]. To this end we will take the structure in Figure 2.2 as a didactical

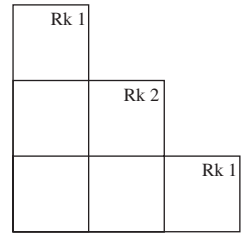

FIG. 2.2. *Example of a rank structure with three structure blocks, $\mathcal{B}_1, \mathcal{B}_2$, and $\mathcal{B}_3$. We will use this example to explain the mechanism of the unitary-weight and Givens-weight representations during the following paragraphs. From now on the surrounding matrix box, as in Figure* 2.1*, will not be shown anymore.*

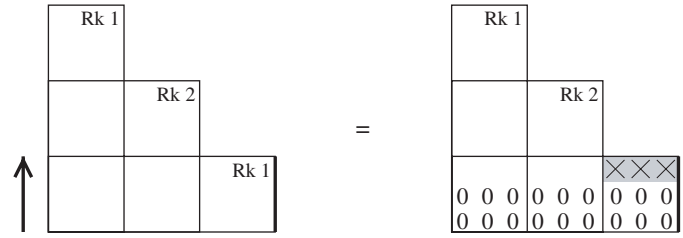

FIG. 2.3. *We apply a unitary transformation to transform the bottom two rows of the structure into zeros. This transformation acts only on the columns on the left of the vertical line, which is indicated in boldface in the left part of the figure; this line borders the* action radius *of the unitary transformation. Having performed this unitary transformation, the elements indicated on a gray background in the right part of the figure are stored; they are called* weights.

example. First, it may be noted that this figure does not show the surrounding matrix box anymore: This reflects the fact that only the area spanned by the structure blocks will be relevant for the representation, and that the "outside world" will be inaccessible.

In what follows, we will often work with [illegible]. These are defined as unitary matrices having a block diagonal form $U = I_a \oplus Q \oplus I_b$, where I_a, I_b denote identity matrices of suitable sizes a, b. When such a unitary operation U acts on the rows of a given matrix, we will represent it in a pictorial way by a vertical line segment, placed on the position of the rows on which it acts. (Sometimes we will actually denote it as a vertical [illegible], instead of a line segment, as an auxiliary means for visualizing the algorithm flow; see further.)

The unitary-weight representation is obtained by reducing the structure blocks into blocks of zeros by the use of unitary row transformations. First we apply an (elementary) unitary transformation to transform the bottom Rk 1 block into a block of zeros, with one row less; see Figure 2.3.

Note that this unitary transformation acts only on the columns on the left of the vertical line, which is indicated in boldface in the figure. We say that this line borders the [illegible] of the unitary transformation. Thus the action radius of the current unitary transformation is equal to 9.

Having applied this operation, note that in columns 7, 8, and 9 we have already reached the "top" of the structure. Therefore, this is now the right moment to consider the top elements of these columns, and to store them. These elements will be called [illegible], and they are visualized on a gray background in the right part of Figure 2.3.

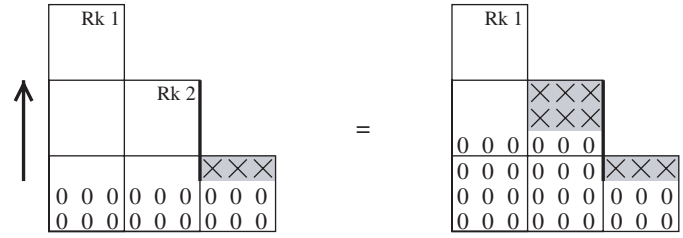

FIG. 2.4. *We apply the next unitary transformation, and store the new block of weights.*

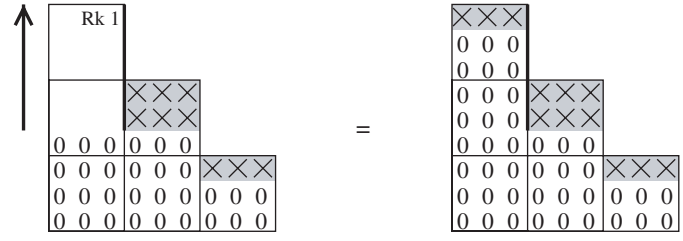

FIG. 2.5. *We apply the final unitary transformation, and store the new block of weights.*

From now on we consider columns 7, 8, and 9 as finished, and we restrict our perspective to the previous columns. We can then apply a unitary transformation to transform the middle Rk 2 block into a block of zeros, with two rows less; see Figure 2.4.

Note that again this unitary operation acts only on the columns on the left of the vertical line indicated in boldface in the figure. Thus the action radius of the current unitary transformation is equal to 6.

Having applied this operation, note that also in columns 4, 5, and 6 we have reached the top of the structure. Therefore, this is now the right moment to consider the top elements of these columns, and to store them. This yields us a second block of weights, which is again visualized on a gray background in Figure 2.4.

From now on we drop columns 4, 5, and 6 from our perspective. We can then apply a unitary transformation to transform the top Rk 1 block into a block of zeros, with one row less; see Figure 2.5. We conclude by storing the final block of weights.

The weights can now be collected into a single matrix, which we call the [illegible]. Together with the computed unitary transformations, this matrix yields us the complete [illegible] of the given matrix; see Figure 2.6.

Of course, to be a useful representation, the unitary-weight representation should allow the possibility of restoring the original matrix from which we started. This can be done by reversing the above steps. This reversal process is called [illegible] the unitary-weight representation and is described in [3].

Now we can come to the general definition of unitary-weight representations.

DEFINITION 2 (index sets). [illegible] $\mathcal{R} = \{\mathcal{B}_k\}_{k=1}^{K}$ [illegible] $i_1 < \cdots < i_K$ [illegible] $j_1 < \cdots < j_K$ [illegible] $I_k = \{i_k, \ldots, i_{k+1} - 1\}$, $I_{k,\text{top}} = \{i_k, \ldots, i_k + r_k - 1\}$, $J_k = \{j_{k-1}+1, \ldots, j_k\}$, $k = 1, \ldots, K$ [illegible] $i_{K+1} := N + 1$ [illegible] $j_0 := 0$ [illegible] $r_{K+1} := 0$

DEFINITION 3 (unitary-weight representation). [illegible] $A \in \mathbb{C}^{m \times n}$ [illegible] $\mathcal{R} = \{\mathcal{B}_k\}_{k=1}^{K}$ [illegible]

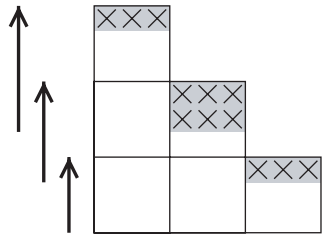

FIG. 2.6. *Schematic picture of the unitary-weight representation for the rank structure in Figure* 2.2.

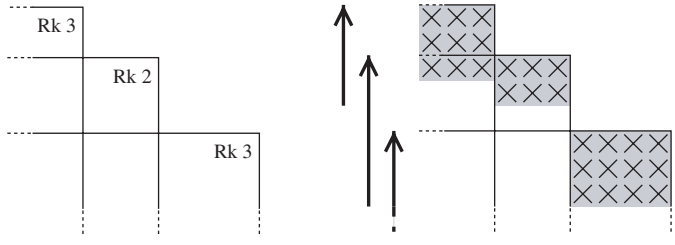

(a) (b)

FIG. 2.7. *For the rank structure in the left picture, the right figure shows a schematic picture of the unitary-weight representation.*

$i_1 < \cdots < i_K$ $j_1 < \cdots < j_K$ unitary-weight representation A $\mathcal{R}$ $(\{U_k\}_{k=1}^K, W)$. U_k $I_k \cup I_{k+1,\text{top}}$ $\bigcup_{l=1}^k J_l$ $I_{k,\text{top}}$ U_k $k = K, K-1, \ldots, 1$ $W \in \mathbb{C}^{m \times n}$ weight matrix $I_{k,\text{top}}$ J_k U_k 2.7

We can now specify from unitary-weight to Givens-weight representations. In what follows, we will use the term to denote an elementary unitary operation which differs from the identity matrix only in two subsequent rows and columns i and $i+1$. This transformation will sometimes be denoted as $G_{i,i+1}$, and the index i will be called the of the Givens transformation. Similarly to our notation for elementary unitary operations, we will graphically denote the Givens transformation $G_{i,i+1}$ by means of a vertical line segment, with the height at which this line segment is standing in the figure determined by the row index i (see further).

Rather than individual Givens transformations, it will be useful to work with : these are defined as products of the form $G_{i+k,i+k+1} \ldots G_{i,i+1}$ for some $k \geq 0$. Graphically, this can be considered as a collection of Givens transformations where each Givens transformation is situated precisely one position below the previous one; see Figure 2.8.

The number of Givens transformations of which a Givens arrow consists will be called the of the Givens arrow. Moreover, we define the and the of the Givens arrow to be, respectively, the largest and the smallest row index of the Givens transformations of which the Givens arrow consists. These notions have an obvious graphical interpretation.

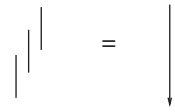

FIG. 2.8. *A Givens arrow $G_{i+2,i+3}G_{i+1,i+2}G_{i,i+1}$ consisting of* 3 *Givens transformations. Concerning this figure, we remind the reader that we consider each Givens transformation as "acting" on the rows of an (invisible) matrix standing on the right of it, and hence that the Givens transformations in the figure should be evaluated from right to left, hereby explaining the downward direction of the Givens arrow.*

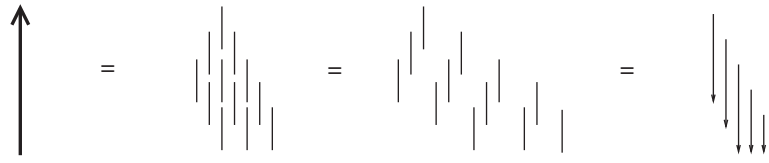

FIG. 2.9. *Suppose that the current structure block is* Rk 3*, and that the corresponding unitary transformation U_k spans over* 6 *rows. Then we assume for this unitary transformation a decomposition into a product of Givens arrows of width at most* 3.

DEFINITION 4 (Givens-weight representation [3]). $A \in \mathbb{C}^{m\times n}$ $\mathcal{R} = \{\mathcal{B}_k\}$ $i_1 < \cdots < i_K$ $j_1 < \cdots < j_K$ Givens-weight representation A $\mathcal{R}$ U_k

- r_k
- U_k

2.9

Let us comment on Figure 2.9. The left part of the figure denotes a unitary component U_k of the Givens-weight representation. The middle and rightmost part of the figure show then the required decomposition of this unitary component U_k into a product of Givens transformations. In particular, the equivalence between the two rightmost pictures in Figure 2.9 follows by repeatedly inserting Figure 2.8. On the other hand, the equivalence between the two pictures in Figure 2.9 is purely aesthetic: These are two different ways for visualizing the same product of Givens transformations.

We should still explain why the assumption is made that each Givens arrow in the decomposition of U_k has width at most r_k. To this end, recall that the unitary transformation U_k serves to create zeros in a certain $\mathrm{Rk}(r_k)$ submatrix, except for its top r_k rows. This effect can always be realized by a succession of Givens arrows as prescribed; see [3, section 3] for more details.

Note that by decomposing each unitary transformation U_k as specified in Definition 4, we formally obtain a decomposition into a product of Givens transformations, in the sense that the beginning and ending Givens transformations of two subsequent unitary transformations U_k may overlap. In relation to this, it was shown in [3] that one can always find a representation for the rank structured part containing only $O(rn)$ parameters, where n is the matrix size and r is some measure

for the average rank of the rank structure, and this applies to [illegible] distribution of structure blocks. However, since the description of the algorithms in this paper will remain exactly the same for all these cases, we will restrict ourselves to a full Givens distribution as in Figure 2.9, for reasons of clarity. (The more efficient Givens-weight representations in [3] follow then as a special case by taking some of these Givens transformations equal to the identity matrix.)

Finally, we note that the above results for obtaining a Givens-weight representation can be trivially extended to obtain a Givens-weight representation for the structured [illegible] triangular part of the matrix A. To this end, it suffices to apply the above results with A replaced by A^T. In this way, one will obtain a representation based on unitary [illegible] operations, rather than unitary row operations.

Suppose then that we have Givens-weight representations for the structured lower and upper triangular parts of the matrix A, respectively. We can then "glue" the weight matrices of these two representations together. This glued matrix will again be called the [illegible] W. An example is shown in Figure 3.6; note that the structured lower and upper triangular part are represented here by means of a row-based and a column-based Givens-weight representation, respectively. Note also that this figure shows a few real-size elements around the main diagonal, corresponding to the unstructured matrix part. These elements are distinguished from the actual weights by putting them on a white instead of a gray background in Figure 3.6.

3. QR-factorization. In this section we describe an algorithm that performs the QR-factorization of a rank structured matrix, assuming that there is available a Givens-weight representation for this matrix. The output of the algorithm consists of the Q- and R-factors of the QR-factorization, where the Q-factor is decomposed as a product of elementary unitary transformations, and where the R-factor has the form of a Givens-weight representation.

Before describing the algorithm, we will start with some theory concerning the structure which we may hope to exploit.

3.1. Some theory. In this subsection we recall and provide some theoretical results concerning the structure inheritance by the Q- and R-factors of a QR-factorization $A = QR$, where A is assumed to be a rank structured matrix.

The inheritance of structure by the Q-factor in terms of Givens transformations was handled in [4] (see also [6, 8] for related results). We considered there the matrix[1] Q^H as a product of Givens transformations "acting" on the matrix A, hereby transforming it into an upper triangular matrix $R = Q^H A$. This process proceeds in two phases.

For the first phase, we recall from section 2 that for a rank structured matrix A, a sequence of elementary unitary operations can be applied to transform the given Rk r_k structure blocks of A into blocks of zeros, except for their top r_k rows. This process proceeds from the bottom to the top of the matrix. We will call this the [illegible]

For the second phase, we note that the resulting matrix A at the end of the preparative phase will be almost zero in its lower triangular part, except for a few nonzero elements around the main diagonal. These remaining nonzero elements can then be annihilated by a sequence of upward-pointing Givens sequences, proceeding from the top to the bottom of the matrix. We will call this the [illegible]

[1] Throughout this paper, we use the notation Q^H to denote the Hermitian transpose of Q, i.e., the complex conjugate transpose.

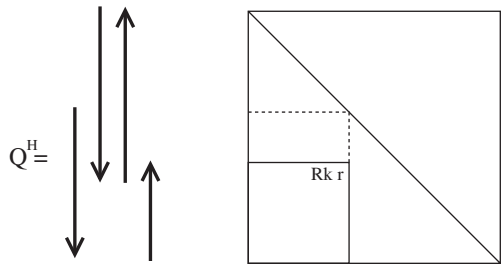

FIG. 3.1. *For the structure block $\mathcal{B}$ shown on the right, the left picture shows the corresponding sparsity pattern of the matrix Q^H w.r.t. this structure block, transforming it into an upper triangular matrix $Q^H A = R$. The picture shows a decomposition into preparative (upward) and residual (downward) unitary transformations.*

We note that the preparative and residual phase correspond to the so-called [illegible] and [illegible] in [8], respectively.

We now want to investigate the inheritance of structure by the upper triangular matrix $R = Q^H A$ obtained at the end of the residual phase. It turns out that we have to exclude some pathological cases.

DEFINITION 5 (structure implying rank deficiency). [illegible] $\mathcal{B} = (i, j, r)$ [illegible] $n_{\mathcal{B}} = \max\{0, j - i + 1\}$ [illegible] $\mathcal{B}$ [illegible] imply rank deficiency [illegible] $n_{\mathcal{B}} > r$ [illegible] $\mathcal{R} = \{\mathcal{B}_k\}_k$ [illegible]

It can be shown that a structure block implying rank deficiency is equivalent with the structure block [illegible], causing a linear dependency between the columns of the underlying matrix. In particular, in the case of square matrices the definition reduces to that of [illegible] as defined in [4]; but we will use Definition 5 for any values of m and n.

In what follows, we will assume that the structure does not imply rank deficiency. This is not really a restriction, since for a structure block implying rank deficiency, one can just remove a few rows or columns from the structure block until it does not imply rank deficiency anymore.

DEFINITION 6 (sparsity pattern). [illegible] $A \in \mathbb{C}^{m \times n}$ [illegible] $\mathcal{B} = (i, j, r)$ [illegible] $A = QR$ [illegible] sparsity pattern induced by the structure block $\mathcal{B}$. Q^H [illegible] $Q^H = Q_3^H Q_2^H Q_1^H$ [illegible]

- Q_1^H [illegible] $i, \ldots, m$ ([illegible] $\mathcal{B}$ [illegible] r [illegible])
- Q_2^H [illegible] $1, \ldots, i + r - 1$ ([illegible] $\mathcal{B}$)
- Q_3^H [illegible] $j + 1, \ldots, m$ ([illegible] $\mathcal{B}$)

[illegible] 3.1

Note that the above definition makes sense since if A fulfills a structure block $\mathcal{B}$, then A admits a QR-factorization satisfying the sparsity pattern induced by $\mathcal{B}$.

We should stress that the above definition was formulated from the point of view of a [illegible] structure block. In practical situations, there will probably be more than one structure block, causing each of the unitary components Q_i^H, $i = 1, 2, 3$, to have an additional decomposition into a sparse product of elementary unitary transformations. To stress this point, we indicated in Figure 3.1 the relation with the

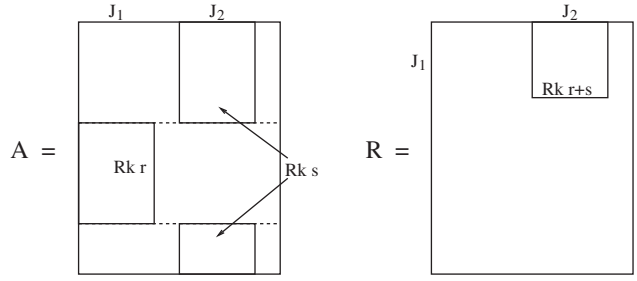

FIG. 3.2. *The figure shows the inheritance of structure by the R-factor for a general example. We note that the index sets I_1 and I_2 must be complementary to each other.*

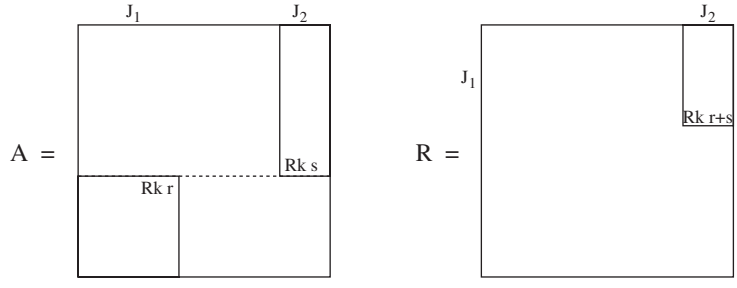

FIG. 3.3. *The figure shows the practical form in which we will exploit the inheritance of structure by the R-factor of Figure* 3.2. *In particular, it is assumed in this figure and in what follows that the index set J_2 takes the form $\{j_2, \ldots, n\}$ for certain j_2, since this is the practical form in which the inheritance result will be exploited.*

preparative and residual unitary transformations, corresponding to the upward- and downward-pointing arrows, respectively.

Since Definition 6 was formulated from the point of view of a [illegible] structure block, it does not reflect the complete sparsity pattern of the preparative and residual unitary operations. Nevertheless, it will be sufficiently strong for establishing the following result, which is a generalization of earlier results in the literature for some very special types of rank structures [8, 11].

THEOREM 7 (inheritance of structure by the R-factor). [illegible] $A \in \mathbb{C}^{m \times n}$ [illegible] $A(I_1, J_1) = \mathrm{Rk}\ r$ [illegible] $A(I_2, J_2) = \mathrm{Rk}\ s$ [illegible]

- I_1 [illegible] I_2 [illegible] $\{1, 2, \ldots, m\}$
- $J_1 = \{1, 2, \ldots, j_1\}$ [illegible] j_1
- J_2 [illegible]

[illegible] $A = QR$ [illegible] $R(J_1, J_2) = \mathrm{Rk}(r+s)$ ([illegible] 3.2) [illegible] A [illegible]

A [illegible] P [illegible] I_1 [illegible] I_2 [illegible] $\{1, 2, \ldots, i\}$ [illegible] $\{i+1, i+2, \ldots, m\}$ [illegible] i [illegible] 3.3 [illegible] $\mathrm{Rk}\ r$ [illegible] $\mathcal{B}$ [illegible] $PA = PQR$ [illegible] $\mathcal{B}$ [illegible]

. First consider the case where A is nonsingular. First, we claim that the Q-factor must "inherit" each of the Rk r low rank blocks situated entirely at the left border of A. Indeed, this is evident by using the equation $Q = AR^{-1}$, where the matrix R^{-1} takes linear combinations of the columns of A, hereby only involving "previous" columns, and hence not destroying such low rank blocks (see also [5]). This establishes the inheritance of structure by the Q-factor, i.e., $Q(I_1, J_1) = \text{Rk } r$. It follows that

$$\begin{aligned} R(J_1, J_2) &= Q^H(J_1, \{1, \ldots, m\})A(\{1, \ldots, m\}, J_2) \\ &= Q^H(J_1, I_1)A(I_1, J_2) + Q^H(J_1, I_2)A(I_2, J_2) \\ &= \text{Rk } r + \text{Rk } s \\ &= \text{Rk}(r + s), \end{aligned}$$

where the first transition follows from the QR-equation $R = Q^H A$, where the second transition follows from our assumption that I_1 and I_2 form a partition of $\{1, \ldots, m\}$, and where the third transition uses the fact that $Q(I_1, J_1) = \text{Rk } r$ and $A(I_2, J_2) = \text{Rk } s$.

Let us now consider the case where A is a general rectangular matrix. From our assumption that Q^H satisfies the sparsity pattern induced by the Rk r structure block, it can be shown that the equation $Q(I_1, J_1) = \text{Rk } r$ remains valid in this case (see also [4]), and hence one could use exactly the same proof as above. Alternatively, one could proceed by a direct argument; see Figure 3.4. □

One may ask where in Figure 3.4 the condition is used that the rank structure does not imply rank deficiency. This is done in Figure 3.4(b), where this condition guarantees that the created block of zeros is situated entirely in the strictly lower triangular part of the matrix. If this were not the case, then the index set indicated on the extreme left of Figure 3.4(c) would be a subset $\tilde{J}_1 \subset J_1$, so that Figure 3.4(d) would only lead to the weaker conclusion $R(\tilde{J}_1, J_2) = \text{Rk}(r + s)$.

For the remainder of this section, we turn to the practical exploitation of the above rank inheritance results for the Q- and R-factors of the QR-factorization.

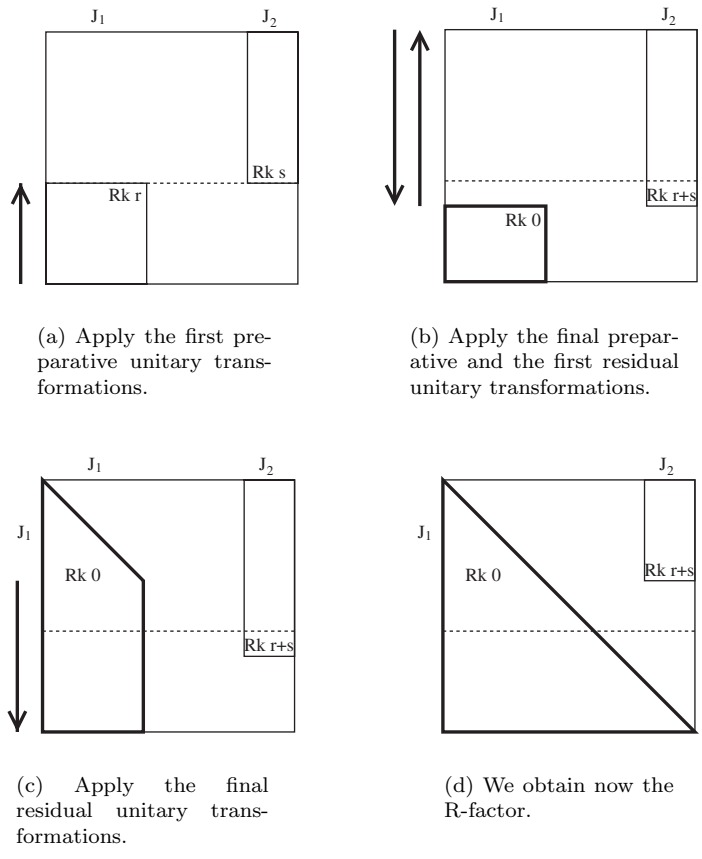
3.2. Algorithm for the preparative phase. In the next two subsections, we will work under the condition that A is a rank structured matrix for which a Givens-weight representation is available. More precisely, it will be assumed that the structured lower triangular part of A is represented by a -based Givens-weight representation, while the structured upper triangular part is represented by a - based Givens-weight representation; cf. section 2. Moreover, the structure blocks of the block lower triangular part are not allowed to intersect those of the block upper triangular part.

Given these input conditions, we will first describe an algorithm for the first phase of the QR-factorization, the so-called . We will illustrate the algorithm for a general type of rank structure, a slice of which is shown in Figure 3.5.

The corresponding Givens-weight representation is then shown in Figure 3.6.

Note that the subsequent unitary operations U_k, $k = K, \ldots, 1$, which will serve to compress the structure blocks in the lower triangular part are already in the Givens-weight representation, precisely by the concept of Givens-weight representation. Therefore, the algorithm will suffice with these operations from the representation, in a sense to be explained further.

During the algorithm, we are faced with the following problem: The Givens-weight representation is by definition an representation, based on a QR-factorization, where the weights were stored each time just at the moment when they would go beyond the top border of the structure (section 2). The problem is now that we want



(a) Apply the first preparative unitary transformations.

(b) Apply the final preparative and the first residual unitary transformations.

(c) Apply the final residual unitary transformations.

(d) We obtain now the R-factor.

FIG. 3.4. *The figure shows the inheritance of structure by the R-factor of Figure* 3.3 *using a direct argument in terms of the sparsity pattern of the matrix* Q^H.

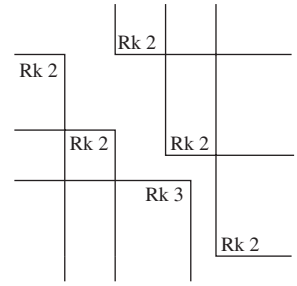


FIG. 3.5. *Starting rank structure.*

to apply the unitary transformations U_k, $k = K, \ldots, 1$, to the [illegible] matrix, hereby also updating the representation in the upper triangular part.

To update the structure in the upper triangular part of the matrix, the algorithm makes use of the general techniques for updating the Givens-weight representation under the influence of elementary unitary transformations described in [3] in the form of what we called there a [illegible]. The process is shown in Figure 3.7.

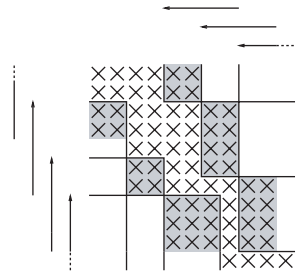

FIG. 3.6. *Starting Givens-weight representation for the rank structure in Figure* 3.5. *For clarity of the figure, the Givens transformations are shown grouped together as unitary operations.*

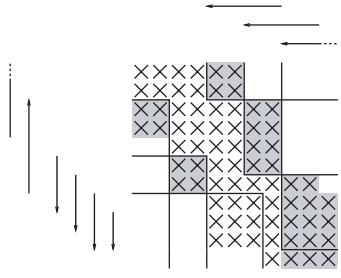
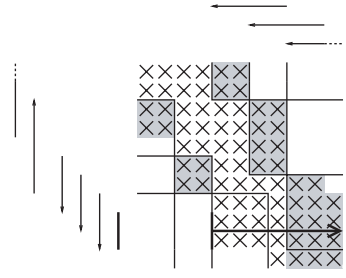
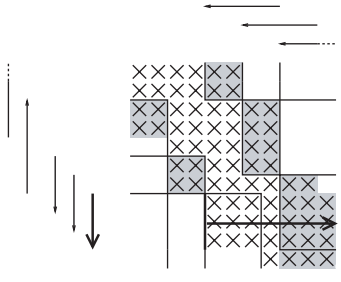


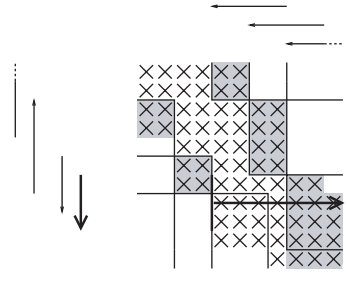
(a) Givens-weight representation after having reduced the Rk 3 block into a block of zeros, except for its top 3 rows.



(b) Apply the next Givens arrow. We apply it only to columns $5, 6, \ldots,$ since the result in columns $1, \ldots, 4$ is already available.



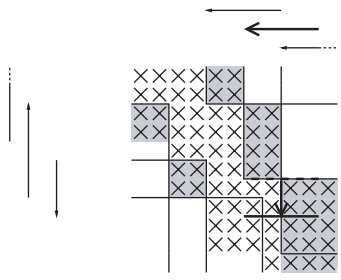
(c) Apply the second Givens arrow.



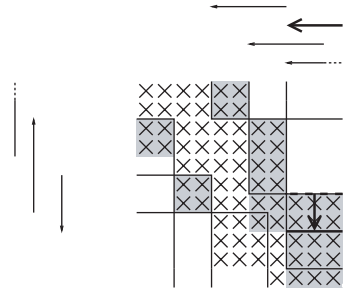
(d) Apply the third Givens arrow.

FIG. 3.7. *Preparative phase* (a)–(d).

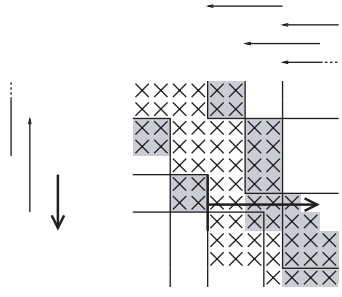
Let us comment on this figure. Figure 3.7(a) shows the starting Givens-weight representation. We assume here that the bottommost structure block $\mathcal{B}_{k+1}$ (say) has already been transformed into its zeroed form. This has resulted in the fact that the corresponding unitary compression operation U_{k+1}, corresponding to the thin upward pointing arrow acting on rows $8, 9, 10, 11$ in Figure 3.6, has already been peeled off, i.e., it has disappeared from the representation. Correspondingly, the weight block in rows $8, 9, 10$ and columns $5, 6, 7$ of the weight matrix in Figure 3.7(a) has turned from gray into white. The bottom right elements in Figure 3.7(a) are assumed to be disturbances coming from previous operations.



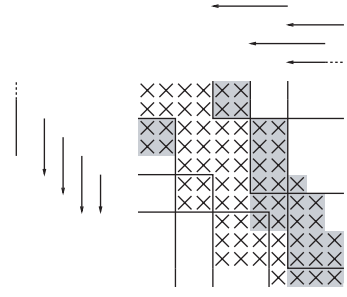
(e) Enlarge the action radius of the indicated unitary component $V_{l,1}$ from 6 to 8.



(f) Apply a unitary operation $V_{l,2}$ to bring the weights as much as possible to the left, and update $V_{l,1} := V_{l,1}V_{l,2}$.



(g) Apply the fourth Givens arrow.



(h) The current Rk 2 structure block has now been completely reduced into a block of zeros, except for its top 2 rows. In the figure, the next unitary operation is already shown as a decomposition of Givens arrows.

FIG. 3.7. *Preparative phase* (e)–(h).

We are then at the point of applying the next unitary compression operation U_k. Figure 3.7(a) shows this unitary operation U_k in the form of an explicit decomposition as a product of four downward-pointing Givens arrows.

Figures 3.7(b), 3.7(c), and 3.7(d) show the application of the Givens transformations belonging to the first three Givens arrows of the unitary compression operation U_k. Since part of their application is already available, by the concept of Givens-weight representation, these Givens arrows should be applied only to the columns lying strictly on the right of their current action radius, in this case columns $5, 6, \ldots$. These columns are indicated by the range of the bold horizontal arrow in Figures 3.7(b), 3.7(c), and 3.7(d).

In these figures, we used the following graphical code. The "active" Givens arrow which is currently being applied to the rows or columns of the matrix is always shown in boldface. This may be both a Givens arrow belonging already to the Givens-weight

representation (as in the present case) or a new Givens arrow or unitary operation coming from outside (see further). On the other hand, Givens arrows or unitary operations belonging to the Givens-weight representation, but which are not active in the current step of the algorithm, are always represented by [illegible] arrows.

For example, the operation in Figure 3.7(b) can be expressed in MATLAB notation as

$$W([9:10],[5:11]) := GW([9:10],[5:11]),$$

where G denotes the applied Givens arrow (consisting in this case only of a single Givens transformation), and where W denotes the weight matrix of the Givens-weight representation. Similar expressions hold for the operations in Figures 3.7(c) and 3.7(d).

We should still explain why it is valid to apply the row operations directly to the weights of the upper triangular representation, as in columns $9, 10, 11$ of Figures 3.7(b), 3.7(c), and 3.7(d). To this end, we recall that the weights contain a kind of compressed information about the matrix, and that in order to obtain these elements in full form, the weights should first be spread out by the unitary column operations of the Givens-weight representation of the upper triangular part. But clearly, by the associativity of matrix multiplication, it does not matter whether we first spread out the weights by the use of these [illegible] operations, or instead first apply the disturbing [illegible] operations. This shows that, indeed, it is correct to apply the row operations directly to the weights.

We are now at the point of applying also the fourth Givens arrow of U_k to the rows. But the application of this fourth Givens arrow would lead to a mix of real-size elements and weights in the submatrix $W([6:8],[7:8])$, which is definitely not correct.

The solution to this problem consists in "enlarging" the column representation. This means that we bring the two rows lying just below the new structure block $\mathcal{B}_l$, whose bottom leftmost element has coordinates $(6,7)$ in Figure 3.7(d), "into" the column representation. Practically, this is achieved by [illegible] of the corresponding unitary column operation of the Givens-weight representation of the upper triangular part (let us call this operation $V_{l,1}$); i.e., we should apply $V_{l,1}$ to all rows between its present and its new action radius, in the present case rows 7, 8. See Figure 3.7(e).

The operation in Figure 3.7(e) can be expressed in MATLAB notation as

$$W([7:8],[7:10]) := W([7:8],[7:10])V_{l,1}.$$

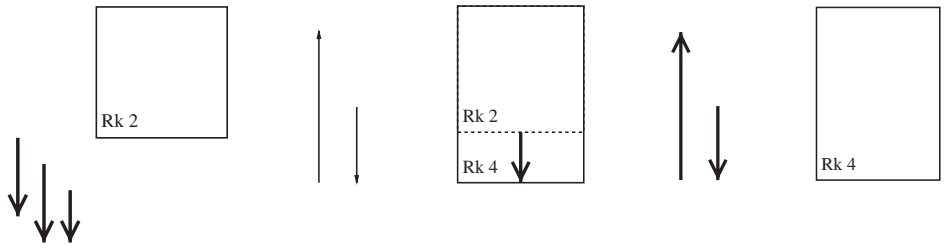
Having enlarged the action radius of $V_{l,1}$, it is now safe to apply the fourth Givens arrow of U_k to the rows. Before doing this, however, we note that applying all these row operations would ultimately lead to a complete fill-in in the upper triangular part of the weight matrix. Since we want to minimize this fill-in as far as possible, we first apply an auxiliary unitary compression transformation $V_{l,2}$ to the columns, in order to bring the newly introduced weights as far as possible to the left. See Figure 3.7(f).

The operation in Figure 3.7(f) can be expressed in MATLAB notation as

$$W([7:8],[9:11]) := W([7:8],[9:11])V_{l,2},$$

where $V_{l,2}$ is chosen such that $W([7:8],[9:11])V_{l,2}$ takes a lower triangular form.

Note that this auxiliary operation $V_{l,2}$ is really new in the sense that it was not present yet in the original Givens-weight representation. Moreover, we apply it only



(a) Apply the first Givens arrows. This corresponds to Figures 3.7(b), 3.7(c), and 3.7(d).

(b) Add two new rows to the structure block. This corresponds to Figure 3.7(e).

(c) Apply the next Givens arrow and unitary operation. This corresponds to Figure 3.7(g).

FIG. 3.8. *Mechanism underlying the structure block movement in the preparative phase.*

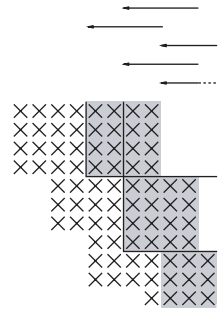


FIG. 3.9. *Givens-weight representation after the complete preparative phase.*

to the upper triangular rank structured part of the matrix, in the present case rows 7, 8. This means that $V_{l,2}$ is an "internal" operation, which should be concatenated to the Givens-weight representation of the upper triangular part; i.e., we should update the unitary component as $V_l := V_{l,1}V_{l,2}$.

Having done all these preparations, we can finally apply the fourth Givens arrow of U_k to the rows; see Figure 3.7(g). We have then completely finished the Givens arrows belonging to the current unitary transformation U_k. Note that the corresponding weight block, lying on the intersection of rows 6, 7 and columns 3, 4 of Figure 3.7(h), has turned from gray into white: This indicates the fact that these elements no longer contain any "encoded" information, but that they contain precisely the real-size elements standing there at this particular moment of the algorithm. The reason underlying this is nothing but the concept of Givens-weight representation.

At this moment, we are at the point of embarking the Givens arrows belonging to the next unitary operation U_{k-1}. Because the situation in Figure 3.7(h) is similar to the one we started from in Figure 3.7(b), this process is not shown.

Figure 3.8 summarizes the explained mechanism of the preparative phase in terms of the structure blocks in the structured upper triangular part. Note that we use here the same graphical code as in the previous figures; i.e., in each step, only the boldfaced vertical line segments are actually applied to the rows of the matrix.

Figure 3.9 shows the final situation for the example in Figure 3.7 at the end of the complete preparative phase. Note that the column representation has "grown," corresponding to the fact that the ranks in the upper triangular part have increased, which is consistent with Figure 3.8.

It can also be seen from this figure that the representation for the block lower triangular part has completely been peeled off, i.e., it has [illegible]. This underlies the fact that the structure blocks in the block lower triangular part have been transformed into their zeroed form.

In order to make the matrix completely upper triangular, we should then still remove a few subdiagonals. The process of doing this will be the subject of the next subsection.

3.3. Algorithm for the residual phase. In this subsection, we show that by using the Givens-weight representation, the second phase of the QR-factorization can also be performed in an efficient way, the so-called [illegible].

We will explain the algorithm for the Givens-weight representation shown in Figure 3.9.

The application of the residual phase makes use of the general techniques for updating the Givens-weight representation under the influence of Givens transformations described in [3] in the form of what we called there a [illegible]. This process is shown in Figure 3.10.

Let us comment on Figure 3.10. The basic flow of the algorithm is determined by applying a sequence of upward-pointing Givens arrows making the subsequent columns k upper triangular, $k = 1, \ldots, n-1$.

Figure 3.10(a) shows the application of the Givens arrow $G_{1,2}G_{2,3}G_{3,4}$ making the first column upper triangular.

The action of Figure 3.10(a) can be expressed in MATLAB notation as

$$W([1:4],[1:8]) = G_{1,2}G_{2,3}G_{3,4}W([1:4],[1:8]),$$

where the Givens transformations $G_{i,i+1}$, $i = 3, 2, 1$, are chosen such that the column vector $G_{1,2}G_{2,3}G_{3,4}W([1:4],1)$ is brought in upper triangular form.

Figure 3.10(b) shows the application of the Givens arrow making the second column upper triangular.

We would then like to apply the Givens arrow making the third column upper triangular. But we should be careful that there is no mixture of real-size elements and weights in the weight matrix during this process. Therefore, before making the third column upper triangular, we first have to [illegible]; i.e., we first have to regress the action radius of the unitary component $V_l = V_{l,1}V_{l,2}$ highlighted in Figure 3.10(c). We regress here from row 4 down to row 2, since we are intending to apply in the next step an operation acting on rows $3, \ldots, 7$.

The action of Figure 3.10(c) can be expressed in MATLAB notation as

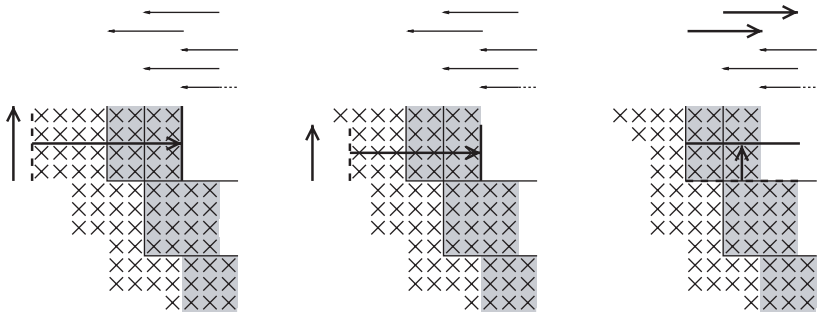
$$W([3:4],[5:8]) = W([3:4],[5:8])V_l^H.$$

Having done this regression operation, the next two columns are made upper triangular in Figures 3.10(d) and 3.10(e).

At this moment, we are at the point of embarking the following columns and making them upper triangular. Because this problem is similar to the one from which we started in Figure 3.10(a), this process is not shown.

Figure 3.11 summarizes the explained mechanism of the residual phase in terms of the structure blocks in the upper triangular part.

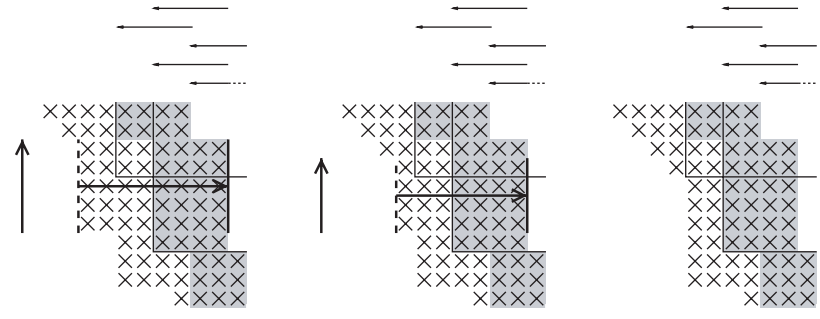
Figure 3.12 shows the final situation at the end of the complete residual phase. Note that the column representation has "lost" some terrain in the sense that it has regressed to the direction of the top right corner of the matrix. This is consistent



(a) Bring the first column in upper triangular form.

(b) Bring the second column in upper triangular form.

(c) Regress the action radius of the indicated unitary operation $V_l = V_{l,1}V_{l,2}$ from row 4 to row 2.



(d) Bring the third column in upper triangular form.

(e) Bring the fourth column in upper triangular form.

(f) The first four columns are now upper triangular.

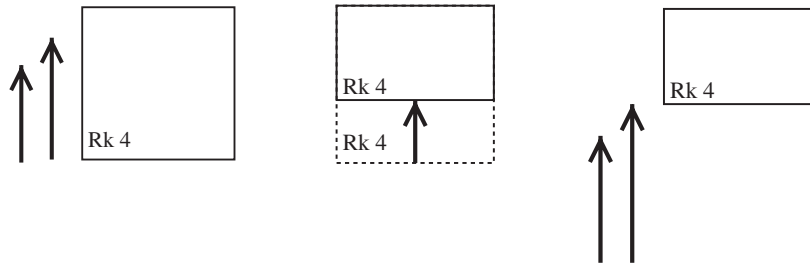
FIG. 3.10. *Residual phase.*

with the mechanism illustrated in Figure 3.11. On the other hand, note that the unitary transformations involved in the Givens-weight representation for the block upper triangular part have remained exactly the same. This underlies the fact that the ranks and the induced column dependencies have been left unchanged under the regression process.

For a global overview, the reader could also have a second look at the original algorithm flow which was sketched in Figure 3.4.

Let us note that the above procedure for the residual phase guarantees that the structure blocks of R are all lying in the strictly upper triangular part of this matrix. In a certain sense, this may seem to conflict with Figure 3.3, which predicts that in certain cases, the structure blocks of R could reach beyond the main diagonal. In fact, the above algorithm will have performed an implicit [illegible] of structure in this case. But this did not occur for the example which we have chosen.

Summarizing, by the algorithm of the current section, we have obtained a QR-factorization $A = QR$, where the Q-factor is decomposed as a product of Givens transformations, and where the R-factor is represented by a column-based Givens-



(a) Make the first columns upper triangular. This corresponds to Figures 3.10(a) and 3.10(b).

(b) Remove two rows from the structure block. This corresponds to Figure 3.10(c).

(c) Make the next columns upper triangular. This corresponds to Figures 3.10(d) and 3.10(e).

FIG. 3.11. *Mechanism underlying the structure block movement in the residual phase.*

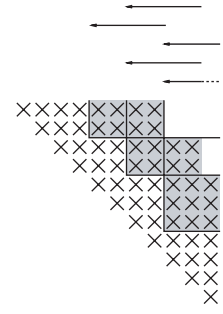


FIG. 3.12. *Givens-weight representation after the complete residual phase. The reader should check that the underlying structure blocks correspond with the predictions in Theorem* 7.

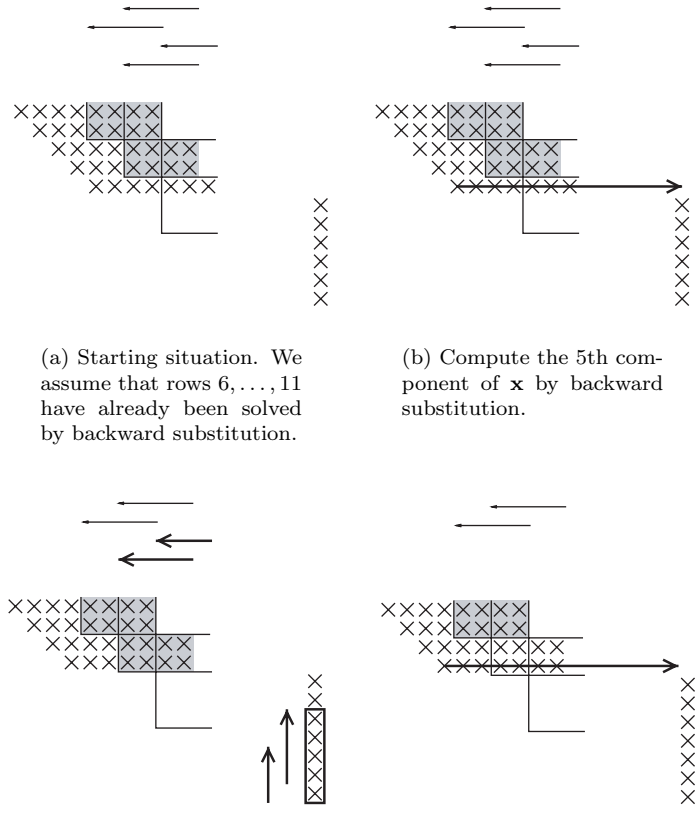
weight representation. In the next section, we will show how this QR-factorization can be used for the solution of a linear system.

. . . 8 (algorithm complexity). For the types of rank structures occurring in practice, the complexity of the preparative and residual phase can be estimated as follows. Assume that the starting Givens-weight representation was efficient in the sense that it consists of a number of $O(rn)$ Givens transformations, where n is the matrix size and r is some measure for the average rank of the rank structure. Denote with s some measure for the bandwidth of the unstructured matrix part around the main diagonal. Then in both the preparative and residual phase, we apply a number of $O(rn) + O(sn)$ Givens transformations to the rows of the matrix A. Moreover, each of these Givens transformations acts on a number of approximately $O(r) + O(s)$ elements of the weight matrix. It follows that the global algorithm complexity for the QR-factorization equals $O((ar^2 + brs + cs^2)n)$ operations, where $a, b, c \in \mathbb{R}$ are certain weighting parameters.

4. Solution of a linear system. In this section we shall use the QR-factorization to solve a linear system $A\mathbf{x} = \mathbf{b}$. We do this by rewriting the linear system in the form

$$R\mathbf{x} = Q^H\mathbf{b} =: \tilde{\mathbf{b}}, \tag{4.1}$$

which can then be solved by backward substitution; see Figure 4.1.



(a) Starting situation. We assume that rows $6, \ldots, 11$ have already been solved by backward substitution.

(b) Compute the 5th component of $\mathbf{x}$ by backward substitution.

(c) Apply available unitary operations V_l to compress the matrix R. (No actual operations have to be performed.) Multiply (a working copy of) the vector $\mathbf{x}$ with the inverse operations.

(d) We can now go on to compute the 4th component of $\mathbf{x}$ by backward substitution.

FIG. 4.1. *Direct solution of a linear system.*

Let us comment on this figure. The basic flow of the algorithm is determined by solving the subsequent rows of the linear system (4.1) by backward substitution, hereby obtaining the subsequent components of the indeterminate vector $\mathbf{x}$.

Figure 4.1(a) shows the starting situation. We assume here that rows $11, \ldots, 6$ of the linear system (4.1) have already been solved by backward substitution, thereby obtaining the corresponding components $x_{11}, \ldots, x_6$ of the vector $\mathbf{x}$. In the right part of the figure, we use a column of vertical crosses to denote these already computed components of $\mathbf{x}$. Note also that the elements in rows $11, \ldots, 6$ of the weight matrix have been dropped from the figure. We do this as an intuitive means of indicating that these elements will no longer be needed during the rest of the algorithm.

We can now solve the 5th row of the linear system (4.1), hereby obtaining the component x_5. This is indicated pictorially in Figure 4.1(b). Note that the arrow

in this figure serves as an intuitive means to denote that the 5th component of $\mathbf{x}$ is computed from the information in the elements in the 5th row of the weight matrix, hereby explaining the rightward direction of this arrow.

Using MATLAB notation, the action in Figure 4.1(b) can be expressed as

$$\mathbf{x}(5) := \frac{1}{W(5,5)}(\tilde{\mathbf{b}}(5) - W(5,[6:11])\mathbf{x}([6:11])).$$

Having performed the action in Figure 4.1(b), the elements in the 5th row of the weight matrix will no longer be needed, and so we can drop them from the figure. We would then like to compute the next component x_4. But then we are going to enter a new structure block $\mathcal{B}_l$ in the upper triangular part of the weight matrix. Since we would like to have the coefficient matrix of our linear system as sparse as possible, this is now a good moment to multiply the upper triangular matrix R by means of the available unitary column operation $V_l = V_{l,1}V_{l,2}$ associated to this structure block $\mathcal{B}_l$, hereby compressing the structure of this matrix. Although this compression may sound rather expensive, from the computational point of view, nothing has to be done since the effect of this unitary operation V_l is already [illegible] by the concept of the Givens-weight representation. (In principle, we should still apply V_l to the rows below its current action radius, in the present case to the elements in rows $5, 6, \ldots$. But this is not necessary since the elements in rows $5, 6, \ldots$ have no function anymore during the rest of the algorithm.)

In other words, the compression operation of the matrix R shown in the left part of Figure 4.1(c) serves only for understanding the algorithm, but does not require any actual operation.

We have now modified the linear system (4.1) as

$$R\mathbf{x} = (RV_l)(V_l^{-1}\mathbf{x}) = \tilde{\mathbf{b}}.$$

Thus the indeterminate vector $\mathbf{x}$ should be multiplied with the inverse of the unitary operation V_l. (Of course, in order not to overwrite the already computed values of $\mathbf{x}$, one should use a working copy $\tilde{\mathbf{x}}$ of the vector $\mathbf{x}$ on which to perform these operations!) The latter operations are indicated by the fat vertical arrows shown in the right part of Figure 4.1(c).

Using MATLAB notation, the action in Figure 4.1(c) can be expressed as

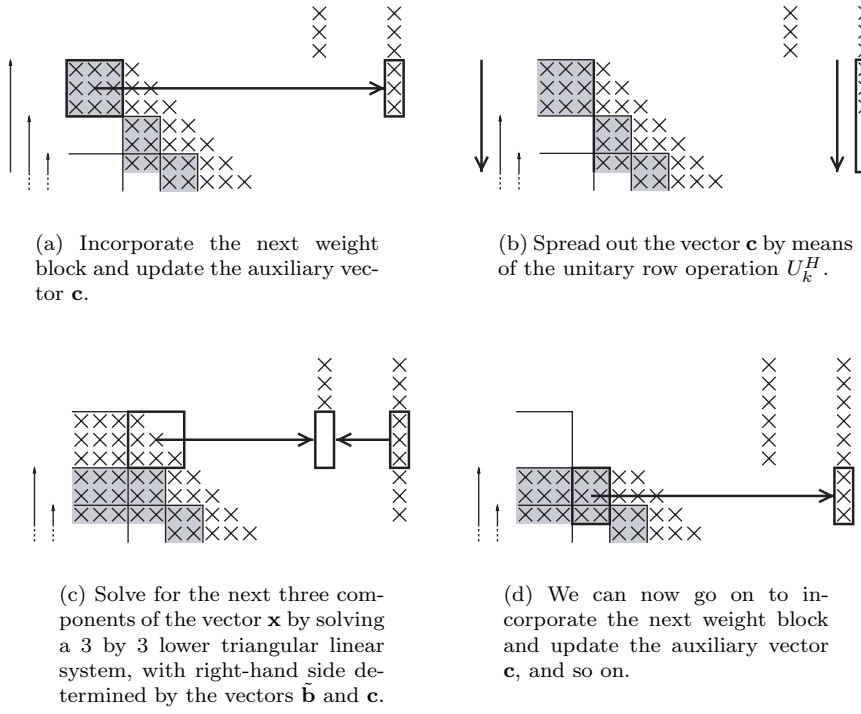
$$\mathbf{x}([7:11]) = V_l^H \mathbf{x}([7:11]),$$

where, as we already remarked, the already computed components of $\mathbf{x}$ should first be stored in a safe place to avoid losing them.

We can then go on to compute the next two components x_4, x_3 of the indeterminate vector by backward substitution. Since the situation in Figure 4.1(d) is similar to the one in Figure 4.1(b), these operations are not shown.

At the end of this process we will have obtained the full indeterminate vector $\mathbf{x}$, hereby solving the linear system.

For completeness of this paper, let us now describe a similar solution algorithm in cases where the R-factor is described by a [illegible] representation. Actually, we prefer to explain the algorithm in terms of a [illegible] matrix L (which is an equivalent problem since we could rewrite $R\mathbf{x} = \tilde{\mathbf{b}}$ as $LJ\mathbf{x} = J\tilde{\mathbf{b}}$, where $L := JRJ$, and with J the antidiagonal matrix; the row-based Givens-weight representation for R transforms in this way into a row-based Givens-weight representation for the matrix L).



(a) Incorporate the next weight block and update the auxiliary vector **c**.

(b) Spread out the vector **c** by means of the unitary row operation U_k^H.

(c) Solve for the next three components of the vector **x** by solving a 3 by 3 lower triangular linear system, with right-hand side determined by the vectors $\tilde{\mathbf{b}}$ and **c**.

(d) We can now go on to incorporate the next weight block and update the auxiliary vector **c**, and so on.

FIG. 4.2. *Direct solution of a linear system in the case of a row-based Givens-weight representation.*

Thus we will solve a linear system of the form

$$L\mathbf{x} = \tilde{\mathbf{b}}. \tag{4.2}$$

This will be achieved by computing the subsequent components $x_1, x_2, \ldots$ of **x** by forward substitution. The algorithm is explained in Figure 4.2.

Let us comment on this figure. Figure 4.2(a) shows the starting situation, where it is assumed that the first three components, x_1, x_2, x_3, have already been computed by forward substitution. These components are depicted by the vertical sequence consisting of three crosses in the top right part of the figure. The elements in the first three rows of the weight matrix will no longer be needed during the rest of the algorithm, and therefore they have been dropped from the figure.

Note that the top right part of Figure 4.2(a) shows also a second vector **c**, of which already six components have been computed. This will be an auxiliary vector. It contains the matrix-vector product of the already computed components of **x** with the structured lower triangular matrix part of the lower triangular matrix L.

Figure 4.2(a) shows how to update this auxiliary vector **c** by incorporating the indicated weight block of the weight matrix and multiplying it with the first three components of **x**. This contribution is then added to the vector **c**.

In MATLAB notation, the operation in Figure 4.2(a) corresponds to updating

$$\mathbf{c}([4:6]) = \mathbf{c}([4:6]) + W([4:6],[1:3])\mathbf{x}([1:3]).$$

The left part of Figure 4.2(b) shows how we spread out the weight matrix by means of the next unitary component U_k^H in order to obtain the real-size form of

the elements in rows $4, 5, 6$ of the lower triangular matrix L. These spreading-out operations serve only as an aid for understanding the algorithm, but they are not actually computed. What we do perform is spreading out the vector $\mathbf{c}$ by means of this same operation U_k^H, as illustrated in the right part of Figure 4.2(b).

In MATLAB notation, the operation in Figure 4.2(b) corresponds to updating

$$\mathbf{c}([4:9]) = U_k^H \mathbf{c}([4:9]).$$

Having performed this spreading-out operation, the elements in rows $4, 5, 6$ of the weight matrix in Figure 4.2(c) now contain the corresponding real-size elements of the lower triangular matrix L. Therefore, these rows can now be used to solve for the components x_4, x_5, x_6 of the indeterminate vector. The coefficient matrix of this linear system is given by the lower triangular 3 by 3 matrix surrounded by the thick black box in Figure 4.2(c). The right-hand side of the linear system is determined by the actual right-hand side vector $\tilde{\mathbf{b}}$, from which is subtracted the contribution of the matrix-vector product of the already computed components of $\mathbf{x}$ with the structured lower triangular matrix part, which is contained in the vector $\mathbf{c}$.

In MATLAB notation, the operation in Figure 4.2(c) corresponds to setting

$$\mathbf{x}([4:6]) = W([4:6],[4:6])^{-1}(\tilde{\mathbf{b}}([4:6]) - \mathbf{c}([4:6])).$$

Having computed the components x_4, x_5, x_6, the elements in rows $4, 5, 6$ of the weight matrix can now be dropped from the next figures, starting with Figure 4.2(d). We can then move on to the next weight block, which is shown boxed in Figure 4.2(d), and use it to update the vector $\mathbf{c}$:

$$\mathbf{c}([7:9]) = \mathbf{c}([7:9]) + W([7:9],[4:5])\mathbf{x}([4:5]).$$

The next operations are not shown.

We note that the flow of this row-based algorithm is very similar to that for block quasi-separable matrices, first reported in [8]. On the other hand, the column-based algorithm described earlier in this section does not seem to have such an interpretation.

. . . 9 (overdetermined systems). In this and the previous section, we implicitly assumed that the coefficient matrix A, and hence the R-factor of its QR-factorization, were , matrices. But this condition is irrelevant: Also in the case of a (full-rank) overdetermined linear system with $A \in \mathbb{C}^{m \times n}$ and $m \geq n$, one can compute the QR-factorization and the corresponding least-squares solution to a linear system in exactly the same way as before.

. . . 10 (algorithm complexity). Note that in the above algorithms for the solution of a linear system, each parameter of the Givens-weight representation is used , during the algorithm, each time counting for $O(1)$ floating point operations. Thus if the starting Givens-weight representation was efficient, it follows that the global algorithm complexity for the solution of the linear system equals $O((dr + es)n)$ operations for suitable $d, e \in \mathbb{R}$. Compare with Remark 8.

5. Numerical experiments. To check the accuracy and the numerical stability of the algorithms in computing the QR-factorization and solving the corresponding linear system based on this factorization, we have performed several numerical experiments. The algorithms were implemented in MATLAB. The experiments were executed on an Intel PC running MATLAB Version 7.0.1.24704 (R14) under Linux having 1 GByte of memory and an Intel Pentium 4 processor running at 3.2 GHz. The software of these numerical experiments can be requested from the authors.

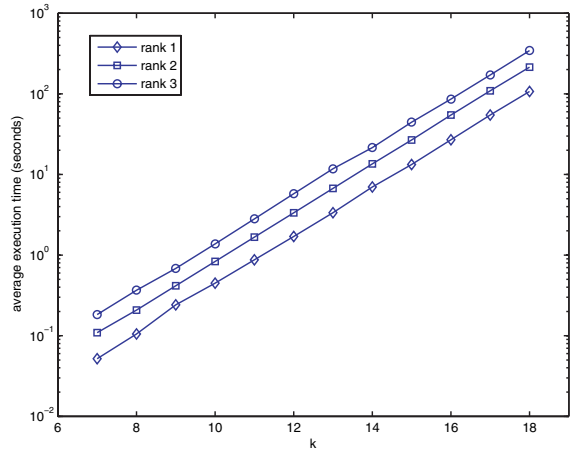


FIG. 5.1. *Average execution time for* 5 *random samples of size* $n = 2^k$ *and rank* $r = 1, 2, 3$.

Experiment 1. We constructed nonsymmetric rank structured matrices of sizes n by n, with $n = 2^k$ for $k = 7, \ldots, 18$. The structure blocks were situated just below the main diagonal, following immediately one after the other, and all having the same rank index r. Formally, this means that $\mathcal{B}_k : (i_k, j_k, r_k) = (k+1, k, r)$, $k = 1, \ldots, n-1$. The upper triangular part was rank structured in the same way as the lower triangular part; in particular, the bandwidth of the rank unstructured matrix part s was equal to one. To guarantee working with a Givens-weight representation consisting of only $O(rn)$ parameters, we made use of the canonical Givens-weight representation "of type 1" described in [3].

For each matrix size n, the rank indices $r = 1, 2, 3$ were taken. For each of these sizes n and each of these rank indices r, 5 samples were considered. The right-hand side $\mathbf{b} \in \mathbb{C}^n$ of each linear system $A\mathbf{x} = \mathbf{b}$ was generated with entries uniformly random distributed between 0 and 1.

Figure 5.1 shows for each size $n = 2^k$ and each rank index r the execution time $T_{k,r}$ averaged over the 5 samples of computing the QR-factorization and solving the corresponding linear system.

To check that the computational complexity is linear in the size n of the matrix, Figure 5.2 shows the fraction $T_{k+1,r}/T_{k,r}$ averaged over the 5 samples and over the ranks $r = 1, 2, 3$.

Figure 5.3 gives the average percentage of the total execution time spent to solve the linear system. It is seen from this figure that this takes only about 15% of the total execution time. In other words, once the QR-factorization has been computed as described in section 3, the subsequent solution of the linear system as described in section 4 is a relatively cheap process. This distinction becomes even more pronounced in case of higher ranks, since the QR-factorization has complexity $O(r^2 n)$, whereas the actual solver has complexity only $O(rn)$ (cf. Remark 10).

To check the accuracy of the algorithm, we considered matrices having singular values equidistant between 10^{-1} and 1; i.e., the condition number of each of the 5 samples is equal to 10. In the same way we took for each size n and each rank r 5 samples having condition number 10^{10}. To measure the accuracy, we computed the relative residual norm

$$\frac{\|A\mathbf{x} - \mathbf{b}\|}{\|A\|\|\mathbf{x}\| + \|\mathbf{b}\|}. \tag{5.1}$$

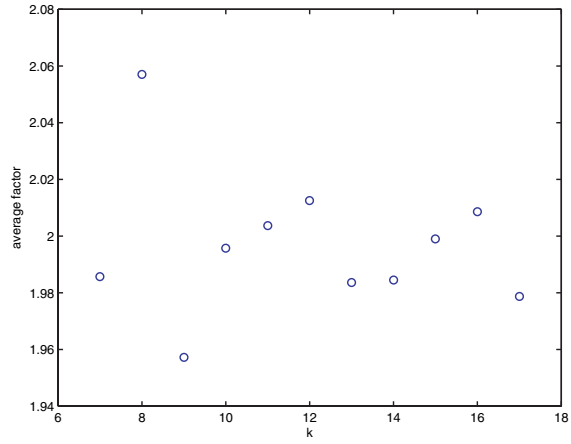

FIG. 5.2. *Fraction $T_{k+1,r}/T_{k,r}$ averaged over 5 random samples and over ranks $r = 1, 2, 3$ in function of size $n = 2^k$.*

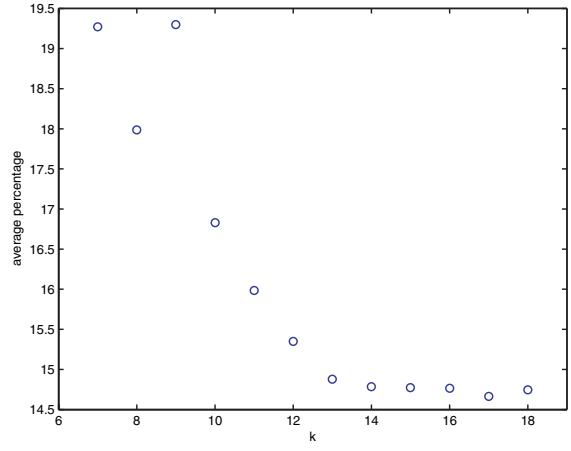

FIG. 5.3. *Percentage of total computing time spent to solve the linear system averaged over 5 random samples and over ranks $r = 1, 2, 3$ in function of size $n = 2^k$.*

(We evaluated the numerator in an efficient way by means of the algorithm for matrix-vector multiplication with a Givens-weight representation described in [3].) Figure 5.4 shows the relative residual norm averaged over the 5 samples and the ranks $r = 1, 2, 3$ for each of the condition numbers and each of the sizes.

From this figure, one can note the odd fact that the algorithm appears to be more stable for ill-conditioned than for well-conditioned linear systems. This is probably an artifact of the measure of stability that we used: It can be imagined that for ill-conditioned matrices with geometrically distributed singular values, the bound (5.1) is too pessimistic, in the sense that the denominator could grow faster than the numerator.

Finally, let us give some more details on the construction of the above test matrices. Starting from a diagonal matrix containing the desired singular values, we applied to rows and columns a "disturbing" sequence of Givens arrows of width r. This resulted in a nonsymmetric matrix having the required rank structure in both

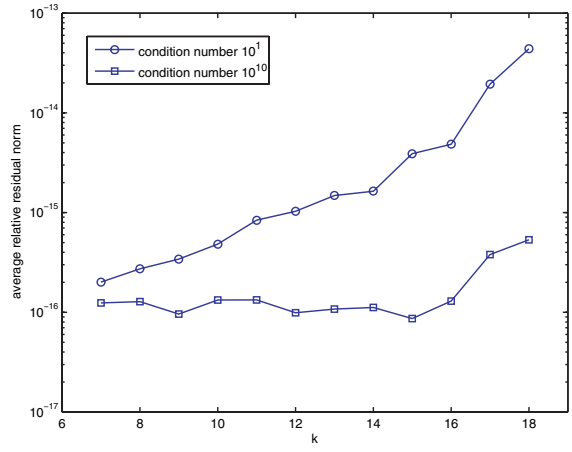

FIG. 5.4. *Relative residual norm averaged over* 5 *random samples and over ranks* $r = 1, 2, 3$ *in function of size* $n = 2^k$ *and condition number* 10^1 *and* 10^{10}.

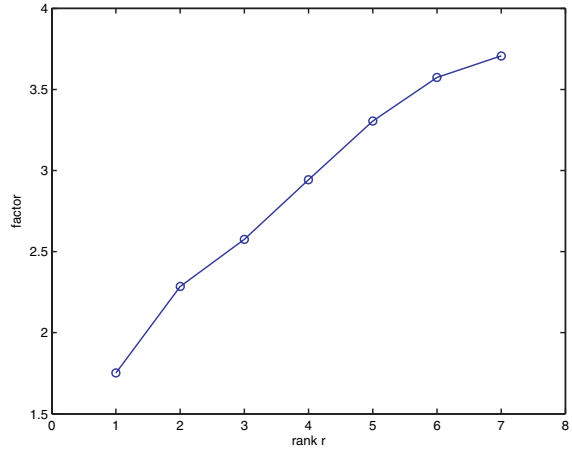

FIG. 5.5. *Fraction* T_{2r}/T_r *in function of the rank index* $r = 2^l$ *with* $l = 1, 2, \ldots, 7$.

lower and upper triangular parts.

Since it can be argued that the above construction yields rather "special" rank structured matrices, we next applied a "randomization" procedure. We did this by applying Givens transformations to rows and columns in such a way that both the lower and the upper rank structures of the matrix were preserved. Let us point out that this randomization procedure took about 95% of our total execution time. A detailed description of this perturbation method will not be given here. Moreover, we note that the results are quite the same with and without this perturbation approach.

Experiment 2. To check the computational complexity as a function of the rank index r, we considered the execution time T_r for matrices of fixed size $n = 2^{10} = 1024$ and varying rank index $r = 2^l$ with $l = 1, 2, \ldots, 8$. The actual construction of the test matrices was performed in exactly the same way as before. Figure 5.5 gives the fraction T_{2r}/T_r for subsequent ranks. Note that the fraction tends to approximate 4 for large rank indices r but is much smaller for small values of r. This value of 4

agrees with the fact that the starting Givens-weight representation consists of $O(rn)$ parameters, in which case the updating processes in section 3 both have an $O(r^2n)$ complexity (cf. Remark 8).

Finally, let us mention that the methods of this paper have been tested for other, more irregular examples of rank structures as well. The results are similar to those above.

6. Conclusion. In this paper we described an algorithm for performing the QR-factorization of a rank structured matrix using the Givens-weight representation. We showed how this QR-factorization could be used as a first step for solving linear systems. We described the underlying propagation of rank structure during the algorithm. The numerical performance of the algorithm was demonstrated by means of some numerical experiments.

A NOTE ON GENERIC KRONECKER ORBITS OF MATRIX PENCILS WITH FIXED RANK*

FERNANDO DE TERÁN† AND FROILÁN M. DOPICO†

Abstract. The set of $m \times n$ complex matrix pencils with rank (normal rank) at most r defines a subset of pencils in a complex $2mn$ dimensional space. For $r = 1, \ldots, \min\{m, n\} - 1$, we show that this subset is a closed set, which is the union of $r+1$ irreducible components. Each of these irreducible components is the closure of a certain orbit of strictly equivalent pencils with rank r. The Kronecker canonical forms of these orbits are explicitly described, and their dimensions are counted. These are the Kronecker canonical forms of generic pencils of rank at most r. If $m \neq n$, then each irreducible component has a codimension distinct from the others, and the least of these codimensions is the codimension of the set of matrix pencils with rank at most r. This is $(n-r)(2m-r)$ if $m \geq n$ and $(m-r)(2n-r)$ otherwise.

Key words. Kronecker canonical form, matrix pencils, orbits, closures, irreducible components

DOI. 10.1137/060662538

1. Introduction.

The Kronecker canonical form (KCF) [6, Chapter XII] of matrix pencils may reflect important physical properties of the systems modelled by pencils, such as controllability [4, 10]. Very significant advances in the development of algorithms to compute the KCF have been seen in recent years (see [5] and the references therein). Despite this fact, computing the KCF of matrix pencils is an expensive and delicate task. Therefore, theoretical results that describe generic KCFs of some subsets of matrix pencils, i.e., the KCFs of almost all pencils in the subset, are interesting from an applied point of view.

The [illegible] of full rank $m \times n$ complex matrix pencils $A - \lambda B$ with $m \neq n$ was explicitly described in [3, Corollary 7.1] (see also [5, section 3.3]). For $n \times n$ singular matrix pencils, there are n possible generic KCFs, each of them corresponding to an orbit of strictly equivalent matrix pencils of codimension $n+1$. These Kronecker structures were explicitly described in [11, Theorem 1] (see also [3, Corollary 7.2] and [5, section 3.3]). In rigorous mathematical terms, one can say, in the language of algebraic geometry [11], that the set of $n \times n$ singular matrix pencils has exactly n irreducible components of codimension $n+1$, or, in the language introduced in [5], that the set of $n \times n$ singular matrix pencils is the union of the closures of n maximal orbits of strictly equivalent matrix pencils. Another relevant result in this context is that the set of $m \times n$ matrices with rank at most r is a manifold in $\mathbb{C}^{mn}$ of codimension $(m-r)(n-r)$ [3, Lemma 3.3]. However, as far as we know, no similar results exist for pencils with rank at most r. To develop these kinds of results is the purpose of this paper.

We prove that there are exactly $r+1$ generic KCFs for $m \times n$ pencils with rank r. More precisely, for $r = 1, \ldots, \min\{m,n\} - 1$, we show that the set of matrix pencils with rank [illegible] r is the union of the closures of the orbits corresponding to these KCFs, and that these closures are maximal in the sense that they are not contained in the closure of any other orbit of pencils with rank at most r. In addition, the dimensions of these orbits are counted and their KCFs explicitly described. The generic KCFs of the pencils with rank r have no regular part, as it happens for the generic KCFs of full rank $m \times n$ pencils and of $n \times n$ singular pencils [3, Corollaries 7.1 and 7.2], and they have both right and left singular blocks. Each of the generic KCFs with rank r depends on the sum of the right minimal indices [6], which may take values $0, 1, \ldots, r$, or, equivalently, on the sum of the left minimal indices. It is important to note that the orbits corresponding to these $r+1$ generic KCFs have different dimensions in the case $m \neq n$. To prove these results, we use techniques introduced in [3, 5] (see also [1]). Finally, we present an additional result on the irreducibility of the closures of the orbits of the generic KCFs in the Zariski topology [11, section 1]. Our results include, as a particular case, the KCFs of generic $n \times n$ singular matrix pencils.

The [illegible] of the pencil $A - \lambda B$ is defined in [6, Chapter VI] as the order of its largest minor that is not equal to the zero polynomial in λ. This is also frequently called [illegible] [1, 5]. We will use the more classical name [illegible] throughout this note, because this concept corresponds to the usual rank of matrices if we consider a matrix pencil as a matrix with elements in the field of rational functions in λ.

The fact that the KCFs of generic pencils with rank r depend not only on the rank, but also on the sum of the right (or, equivalently, left) minimal indices is related to a recent result presented in [2]. In [2], the generic change of the KCF of a pencil under low rank perturbations is studied, and it is proved that this change depends on the rank of the perturbation, and also on the sum of its left and right minimal indices.

A different kind of generic singular matrix pencils is considered in [8]. The definition of [illegible] in [8, p. 250] can be useful to study the KCF of very sparse pencils, but it is different from the one that we use in this work. As explained above, our definition of generic KCFs means that the union of the closures of the corresponding orbits is the whole set of pencils with rank at most r, and that these orbits are maximal. This is also the concept used in [5, 11]. This implies, for instance, that most pencils with rank r and generic KCF have all of the entries different from zero.[1] However, in the sense of [8], generic $m \times n$ pencils with rank r do not have all of their entries different from zero [8, Lemma 3.1]; therefore, they are not generic in our sense. We have already remarked that we will describe explicitly the generic KCFs of pencils with rank r; see Theorem 3.2. This cannot be done for the generic pencils with rank r in the sense of [8], where only the sums of the minimal indices of the KCF can be implicitly determined [8, Theorems 7.2 and 7.3].

This paper is organized as follows: In section 2 some background is introduced. The main results—Theorems 3.2, 3.3, and 3.5—are presented in section 3.

2. Previous results. In this section we briefly summarize the results needed in this note. Simultaneously, the basic notation is introduced.

[1] Note that the set of pencils with rank at most r and all of the entries different from zero is open and dense in the set of pencils with rank at most r. To see this in $r = 1$, note that every pencil with rank at most one can be written as $p(\lambda)q(\lambda)^T$, where $p(\lambda)$ and $q(\lambda)$ are polynomial vectors, one of them of degree 0 and the other one of degree at most 1. Most pencils of this type have all of the entries different from zero.

2.1. Orbits and the Kronecker canonical form. We will use the same notation as in [5]. The orbit $\mathcal{O}(\mathcal{M})$ of an $m \times n$ matrix pencil $\mathcal{M}(\lambda) = A - \lambda B$ is the set of matrix pencils strictly equivalent to $\mathcal{M}(\lambda)$:

$$\mathcal{O}(\mathcal{M}) = \{P\mathcal{M}(\lambda)Q : \ P \in \mathbb{C}^{m\times m}, Q \in \mathbb{C}^{n\times n} \ , \ P, Q \text{ nonsingular}\}.$$

These orbits are manifolds in the vector space $\mathbb{C}^{2mn}$, and we will refer to the dimension of $\mathcal{O}(\mathcal{M})$ as the codimension in this space. We will denote by $\overline{\mathcal{O}}(\mathcal{M})$ the closure of this orbit.

The most significant element of the orbit $\mathcal{O}(\mathcal{M})$ is the Kronecker canonical form (KCF) (e.g., see [6]) of $\mathcal{M}(\lambda)$. The KCF is the direct sum of the right singular, left singular, and regular structures, consisting of L_k blocks of dimension $k \times (k+1)$ for the right singular structure and L_k^T blocks for the left singular structure. The regular structure consists of Jordan blocks $J_k(\mu)$ corresponding to eigenvalue μ, and N_k corresponding to the infinite eigenvalue. The KCF of $\mathcal{M}(\lambda)$ determines uniquely the orbit $\mathcal{O}(\mathcal{M})$, and, in particular, it fully determines the codimension of $\mathcal{O}(\mathcal{M})$ [3, Theorem 2.2].

2.2. Inclusion relationships between orbit closures. The relation $\geq$ in the set of sequences of nonnegative integers specifies that $(a_1, a_2, \ldots) \geq (b_1, b_2, \ldots)$ if $a_1 + \cdots + a_i \geq b_1 + \cdots + b_i$ for $i = 1, 2, \ldots$. We say that $(a_1, a_2, \ldots) > (b_1, b_2, \ldots)$ if $(a_1, a_2, \ldots) \geq (b_1, b_2, \ldots)$ and $(a_1, a_2, \ldots) \neq (b_1, b_2, \ldots)$ [5, section 2.1].

For every matrix pencil $\mathcal{M}(\lambda)$ with rank r, we consider the following three sequences defined in [5]:

$$\mathcal{R}(\mathcal{M}) + r = (r_0 + r, r_1 + r, r_2 + r, \ldots);$$

where r_i is the number of right singular blocks L_j in the KCF of $\mathcal{M}(\lambda)$ with $j \geq i$;

$$\mathcal{L}(\mathcal{M}) + r = (l_0 + r, l_1 + r, l_2 + r, \ldots),$$

where l_i is the number of left singular blocks L_j^T in the KCF of $\mathcal{M}(\lambda)$ with $j \geq i$; and, for every $\mu \in \mathbb{C} \cup \{\infty\}$,

$$\mathcal{J}_\mu(\mathcal{M}) + p = (w_1(\mu) + p, w_2(\mu) + p, \ldots),$$

where $w_i(\mu)$ is the number of Jordan blocks associated with the eigenvalue μ of dimension greater than or equal to i in the regular structure of the KCF of $\mathcal{M}(\lambda)$, and p is the number of right singular blocks in the KCF of $\mathcal{M}(\lambda)$. These sequences allow us to obtain inclusion relationships between the closures of the orbits of two different matrix pencils. This is presented in Theorem 2.1 below, obtained in [9], and later reformulated in [1] and [5]. We state the theorem as it appears in [5].

THEOREM 2.1 (see [5, Theorem 3.1]). Let $\mathcal{M}_1, \mathcal{M}_2$ be $m \times n$ matrix pencils with $p(\mathcal{M}_1)$ and $p(\mathcal{M}_2)$ the number of right singular blocks in their KCF's. Then $\overline{\mathcal{O}}(\mathcal{M}_1) \supseteq \overline{\mathcal{O}}(\mathcal{M}_2)$ if and only if

(i) $\mathcal{R}(\mathcal{M}_1) + \operatorname{rank}(\mathcal{M}_1) \geq \mathcal{R}(\mathcal{M}_2) + \operatorname{rank}(\mathcal{M}_2)$,
(ii) $\mathcal{L}(\mathcal{M}_1) + \operatorname{rank}(\mathcal{M}_1) \geq \mathcal{L}(\mathcal{M}_2) + \operatorname{rank}(\mathcal{M}_2)$,
(iii) $\mathcal{J}_\mu(\mathcal{M}_1) + p(\mathcal{M}_1) \leq \mathcal{J}_\mu(\mathcal{M}_2) + p(\mathcal{M}_2)$

for all $\mu \in \mathbb{C} \cup \{\infty\}$.

3. The set of singular pencils of rank at most r. If we restrict ourselves to the set of $m \times n$ matrix pencils with fixed rank equal to r, then the conditions in Theorem 2.1 simplify significantly. In this case, $\overline{\mathcal{O}}(\mathcal{M}_1) \supseteq \overline{\mathcal{O}}(\mathcal{M}_2)$ if and only if

the following conditions hold: (i) $\mathcal{R}(\mathcal{M}_1) \geq \mathcal{R}(\mathcal{M}_2)$, (ii) $\mathcal{L}(\mathcal{M}_1) \geq \mathcal{L}(\mathcal{M}_2)$, and (iii) $\mathcal{J}_\mu(\mathcal{M}_1) \leq \mathcal{J}_\mu(\mathcal{M}_2)$ for all $\mu \in \mathbb{C} \cup \{\infty\}$ (because $p(\mathcal{M}) = n - \operatorname{rank}(\mathcal{M})$).

We will make use of the following result whose proof is immediate.

LEMMA 3.1. [illegible] $\mathcal{T} = \operatorname{diag}(\mathcal{G}, \mathcal{H})$ [illegible] $\mathcal{G} \in \overline{\mathcal{O}}(\mathcal{M}_1)$ [illegible] $\mathcal{H} \in \overline{\mathcal{O}}(\mathcal{M}_2)$ [illegible] $\mathcal{M}_1$ [illegible] $\mathcal{M}_2$ [illegible] $\overline{\mathcal{O}}(\mathcal{T}) \subseteq \overline{\mathcal{O}}(\operatorname{diag}(\mathcal{M}_1, \mathcal{M}_2))$

Our main result characterizes the set of singular pencils with rank at most r through a set of maximal orbits of pencils with rank exactly r.

THEOREM 3.2. [illegible] r [illegible] $1 \leq r \leq \min\{m,n\}-1$ [illegible] $m \times n$ [illegible] r [illegible] $r+1$ [illegible]

$$\mathcal{K}_a(\lambda) = \operatorname{diag}(\underbrace{L_{\alpha+1}, \ldots, L_{\alpha+1}}_{s}, \underbrace{L_\alpha, \ldots, L_\alpha}_{n-r-s}, \underbrace{L_{\beta+1}^T, \ldots, L_{\beta+1}^T}_{t}, \underbrace{L_\beta^T, \ldots, L_\beta^T}_{m-r-t}) \tag{1}$$

[illegible] $a = 0, 1, \ldots, r$ [illegible] $\alpha = \lfloor a/(n-r) \rfloor$, $s = a \bmod (n-r)$, $\beta = \lfloor (r-a)/(m-r) \rfloor$ [illegible] $t = (r-a) \bmod (m-r)$ [illegible]

(i) [illegible] $m \times n$ [illegible] $\mathcal{M}(\lambda)$ [illegible] r [illegible] a [illegible] $\overline{\mathcal{O}}(\mathcal{K}_a) \supseteq \overline{\mathcal{O}}(\mathcal{M})$

(ii) $\overline{\mathcal{O}}(\mathcal{K}_a) \not\supseteq \overline{\mathcal{O}}(\mathcal{K}_{a'})$ [illegible] $a \neq a'$

(iii) [illegible] $m \times n$ [illegible] r [illegible] $\bigcup_{0 \leq a \leq r} \overline{\mathcal{O}}(\mathcal{K}_a)$

[illegible]. For each $a = 0, 1, \ldots, r$, let $\mathcal{D}_a$ be the set of block-diagonal matrix pencils in the form $\operatorname{diag}(\mathcal{G}, \mathcal{H})$, where $\mathcal{G}$ and $\mathcal{H}$ are, respectively, $a \times (a+n-r)$ and $(m-a) \times (r-a)$ matrix pencils. The generic KCFs of $\mathcal{G}$ and $\mathcal{H}$ are, respectively, $\operatorname{diag}(L_{\alpha+1}, \overset{s)}{\ldots}, L_{\alpha+1}, L_\alpha, \overset{n-r-s)}{\ldots}, L_\alpha)$ and $\operatorname{diag}(L_{\beta+1}^T, \overset{t)}{\ldots}, L_{\beta+1}^T, L_\beta^T, \overset{m-r-t)}{\ldots}, L_\beta^T)$ (where $\overset{k)}{\ldots}$ means that there is a series of exactly k equal terms), with α, β, s, and t as in the statement (see [3, Corollary 7.1]). Now, to prove the first part of the theorem, it remains to show only that any matrix pencil of rank at most r is strictly equivalent to a block-diagonal pencil in $\mathcal{D}_a$, for some $a = 0, 1, \ldots, r$, and apply Lemma 3.1.

Let $\mathcal{M}(\lambda)$ be a matrix pencil with rank $r' \leq r$ and KCF given by

$$\mathcal{K}_{\mathcal{M}}(\lambda) = \operatorname{diag}(L_{\alpha_1}, \ldots, L_{\alpha_{n-r'}}, L_{\beta_1}^T, \ldots, L_{\beta_{m-r'}}^T, J),$$

where J is the regular structure of the KCF. Then, since $r' \leq r$, we can consider

$$\mathcal{G} = \operatorname{diag}(L_{\alpha_1}, \ldots, L_{\alpha_{n-r}})$$

and $\mathcal{H}$ being the block-diagonal matrix pencil containing the remaining blocks in $\mathcal{K}_{\mathcal{M}}(\lambda)$. Notice that $\mathcal{G}$ is of size $a \times (a+n-r)$, with $a = \alpha_1 + \cdots + \alpha_{n-r}$. Then $\mathcal{M}(\lambda)$ is equivalent to $\operatorname{diag}(\mathcal{G}, \mathcal{H})$, and this last matrix pencil is in the class $\mathcal{D}_a$.

Now, we show that $\overline{\mathcal{O}}(\mathcal{K}_a) \not\supseteq \overline{\mathcal{O}}(\mathcal{K}_{a'})$ whenever $a \neq a'$. For this, it suffices to check that for distinct $a, a' \in \{0, 1, \ldots, r\}$ the simplified versions of the three conditions (i), (ii), and (iii) in Theorem 2.1 do not hold simultaneously. This fact is immediate, because $a > a'$ implies (with the same notation as in the statement)

$$\alpha > \alpha' \quad \text{or} \quad \alpha = \alpha' \text{ and } s > s',$$

which implies $\mathcal{R}(\mathcal{K}_a) > \mathcal{R}(\mathcal{K}_{a'})$, and also

$$\beta < \beta' \quad \text{or} \quad \beta = \beta' \text{ and } t < t',$$

which implies $\mathcal{L}(\mathcal{K}_a) < \mathcal{L}(\mathcal{K}_{a'})$.

Finally, notice that the third item in Theorem 3.2 is a direct consequence of the first item, $\operatorname{rank}(\mathcal{K}_a(\lambda)) = r$ for all a, and the fact that the set of pencils of rank at most r is closed. □

Theorem 3.2 is, in essence, a consequence of Corollary 7.1 in [3], though we have stated it using the concepts and terminology from [5]. Notice also that although the rank of the KCFs in (1) is exactly r, the closures of their orbits include the set of all pencils with rank smaller than or equal to r.

Next, we pay attention to the codimension of the orbits $\mathcal{O}(\mathcal{K}_a)$ of the generic KCFs of pencils with rank at most r. We will see that these codimensions are distinct if $m \neq n$. In this case, the codimension (dimension) of the set of matrix pencils with rank at most r is defined, according to [11], as the least (largest) of the codimensions (dimensions) of $\mathcal{O}(\mathcal{K}_a)$, for $a = 0, 1, \ldots, r$.

THEOREM 3.3. [illegible] r [illegible] $1 \leq r \leq \min\{m, n\} - 1$ [illegible] $\mathcal{K}_a(\lambda)$ [illegible] $a = 0, 1, \ldots, r$ [illegible] $r + 1$ [illegible] (1) [illegible]

1. [illegible] $\mathcal{O}(\mathcal{K}_a)$ [illegible] $(n - r)(2m - r) + a(m - n)$.
2. [illegible] $m \times n$ [illegible] r [illegible]
   (i) $(n - r)(2m - r)$ [illegible] $m \geq n$ [illegible]
   (ii) $(m - r)(2n - r)$ [illegible] $m \leq n$

[illegible]. The first item is a direct consequence of [3, Theorem 2.2]. The second item follows from computing $\min_a\{(n - r)(2m - r) + a(m - n)\}$. □

3.1. Irreducibility in Zariski topology. All of the topological ideas used so far refer to the usual topology in $\mathbb{C}^{2mn}$. The Zariski topology was used by Waterhouse to prove that the set of $n \times n$ singular matrix pencils with entries in an arbitrary infinite field has exactly n irreducible components, each of codimension $n + 1$ [11, Theorem 1]. In this subsection, we will prove that the closures $\overline{\mathcal{O}}(\mathcal{K}_a(\lambda))$ of the orbits of the KCFs appearing in (1) are irreducible in the Zariski topology. A clear and concise summary of Zariski topology appears in the introduction of [11]. Here we recall only the following ideas: (i) a subset of $\mathbb{C}^q$ is closed in the Zariski topology if it is the set of common zeros of some polynomials, (ii) Zariski-closed sets are closed in the usual sense but the opposite is not true, (iii) a subset of $\mathbb{C}^q$ is irreducible if it is not the union of two relatively closed proper subsets in the Zariski topology, and (iv) every Zariski-closed set is the finite union of maximal irreducible subsets called its irreducible components.

An important result in this context is that the closures of an orbit of strictly equivalent pencils are the same in both the Zariski and the usual topology of $\mathbb{C}^{2mn}$ [7]. Therefore, there is no ambiguity in using the symbol $\overline{\mathcal{O}}(\mathcal{K}_a)$ in this subsection because it refers to exactly the same set as in the rest of this paper. The main result in this section states that orbits of pencils are irreducible.

LEMMA 3.4. [illegible] $\overline{\mathcal{O}}(\mathcal{M})$ [illegible] $\mathcal{O}(\mathcal{M})$ [illegible] $m \times n$ [illegible] $\mathcal{M}(\lambda)$ [illegible]

[illegible]. Let us identify the set of matrix pencils of size $m \times n$ with $\mathbb{C}^{2mn}$, where the pencil $\mathcal{M}(\lambda) = A - \lambda B$ is identified with the pair (A, B). Let U be the set of pairs (P, Q) with $P \in \mathbb{C}^{m \times m}$ and $Q \in \mathbb{C}^{n \times n}$ nonsingular. This is a dense open set of $\mathbb{C}^{m^2+n^2}$ (that is, $\overline{U} = \mathbb{C}^{m^2+n^2}$). Given a matrix pencil (A, B), we can consider

the continuous (polynomial) mapping $\varphi_{\mathcal{M}}$ from $\mathbb{C}^{m^2+n^2}$ to $\mathbb{C}^{2mn}$ defined by sending (P,Q) to (PAQ, PBQ). We have $\mathcal{O}(\mathcal{M}) = \varphi_{\mathcal{M}}(U)$. By [11, section 1] we know that $\overline{\varphi_{\mathcal{M}}(\mathbb{C}^{m^2+n^2})}$ is an irreducible set. On the other hand, for every continuous mapping φ, we have $\varphi(\overline{W}) \subset \overline{\varphi(W)}$, where W is an arbitrary set, and this implies $\overline{\varphi(\overline{W})} = \overline{\varphi(W)}$. In the present case, we have

$$\overline{\varphi_{\mathcal{M}}(U)} = \overline{\varphi_{\mathcal{M}}(\mathbb{C}^{m^2+n^2})},$$

and this equals $\overline{\mathcal{O}}(\mathcal{M})$, which concludes the proof. □

With this lemma, Theorem 3.2 can be complemented as follows.

THEOREM 3.5. [illegible] $1 \leq r \leq \min\{m,n\} - 1$, [illegible] $\mathcal{K}_a(\lambda)$, [illegible] $a = 0, 1, \ldots, r$, [illegible] $r+1$ [illegible] (1) [illegible] $m \times n$ [illegible] r [illegible] $r+1$. [illegible] $\overline{\mathcal{O}}(\mathcal{K}_a)$, $a = 0, 1, \ldots, r$

This theorem includes [11, Theorem 1], mentioned at the beginning of this section, as a particular case.

Acknowledgments. The authors thank two anonymous referees for suggesting the use of block-diagonal pencils to prove Theorem 3.2. This idea has enhanced the presentation very much. The authors also thank the editor, Prof. Bo Kågström, for pointing out reference [8].

ON INVERSES OF TRIDIAGONAL MATRICES ARISING FROM MARKOV CHAIN-RANDOM WALK I*

MOHAMED A. EL-SHEHAWEY†

Abstract. Explicit expressions for the entries of the inverse of a general diagonal matrix are derived via the decomposition approach. In particular, three-term recurrence relations with variable coefficients are given, and with their solutions closed form expressions for each entry of the fundamental matrix of a Markov chain-random walk (MC-RW) model are established. We also obtain explicit formulas for the absorption probabilities and the mean time to absorption as well as the mean number of steps before absorption of the MC-RW model in the presence of two semiabsorbing boundaries.

Key words. tridiagonal matrix, three-term recurrence relations, Markov chain-random walk, semiabsorbing barriers, time to absorption

1. Introduction. There is an intimate relationship between Markov chain-random walk (MC-RW), tridiagonal matrices, and three-term recurrence relations. The latter two are known to be powerful tools for counting walks with various specifications, are frequently used to describe the motion of a particle in a one-dimensional chain. Tridiagonal matrices appear frequently in various branches of mathematics, modern physics, and engineering. Therefore this class of matrices is studied extensively and a great deal of theory is known about their inverses. For historical remarks and physical motivations, cf. [21, 20, 29, 6, 19, 25, 10, 1, 15]. Three-term recurrence relations lie at the heart of continued fractions, orthogonal polynomials, and birth-death processes, cf. [7, 4, 30, 16, 17, 18, 3, 2]. The MC-RW is a venerable model, finding its applications in many areas including biology, chemistry, and physics, but it is also a useful tool in randomized algorithms in computer science. Despite its long history, novel aspects continue to surface. For comprehensive treatments of MC-RW and its applications, cf. [5, 11, 28, 13, 25, 8, 12, 23, 9]. The MC-RW is a stochastic process $X = \{X_k : k \geq 0\}$ characterized by the transition matrix, $P = (p_{ij})_{ij}$, given via the entries of the three vectors $q = (q_0, q_1, \ldots, q_n)$, $r = (r_0, r_1, \ldots, r_n)$, $p = (p_0, p_1, \ldots, p_n)$ as $P = P(q, r, p)$ with

$$P = \begin{pmatrix} r_0 & p_0 & 0 & & \cdots & 0 \\ q_1 & r_1 & p_1 & 0 & & \vdots \\ 0 & q_2 & r_2 & p_2 & \ddots & \\ & 0 & \ddots & \ddots & \ddots & 0 \\ \vdots & & \ddots & q_{n-1} & r_{n-1} & p_{n-1} \\ 0 & \cdots & & 0 & q_n & r_n \end{pmatrix}. \tag{1.1}$$

Here, $p_{ij} = \Pr(X_{k+1} = j \mid X_k = i)$ is the one-step transition probability. The definition of an MC-RW implies that $r_j + p_j + q_j = 1$ and $r_j,\ p_j,\ \ q_j \geq 0$. The boundary probabilities p_0, r_0, r_n, and q_n reflect boundary conditions of the model under investigation. We allow $q_0 = 1 - p_0 - r_0 \geq 0$, $p_n = 1 - q_n - r_n \geq 0$. If $q_0 = 0$ and $p_n = 0$, then the matrix P is stochastic and the MC-RW is said to have reflecting barriers at 0 and n. If $q_0 > 0$ (or $p_n > 0$), then the MC-RW has an (ignored) absorbing state at -1 (or at $n+1$), which can be reaching through state 0 (or n) only. In many stochastic models, in particular Markov chains in discrete or continuous time and Markov renewal processes, a Markov chain arises either directly or indirectly through some form of embedding. The analysis of many problems of interest associated with these models, e.g., the moments of first passage time distributions and the moments of occupation time random variables, often concerns the inverse of the matrix $I - P$. In the present paper we wish to obtain closed form expressions for each entry of the fundamental matrix of the MC-RW model which are not readily available in the literature on either matrix theory or probability theory. This leads to explicit expressions for the aforementioned problems. Many interesting particular cases can be derived from this study through an appropriate choice of the boundary probabilities p_0, q_n, r_0, and r_n. We shall restrict our attention to MC-RW in the presence of two semiabsorbing boundaries, $p_0 = \rho$, $q_n = \omega$, and $r_0 = r_n = 0$. Physically, this corresponds to the situation where upon reaching the barrier 0 (or n) the particle is either lost from the system with probability $1 - \rho$ (or $1 - \omega$) or turned back to the system with probability ρ (or ω) and reduces to the classical problem of random walk. This leads to a list of particular cases: (i) MC-RW in the presence of two symmetric semiabsorbing barriers at 0 and n, for $\rho = \omega$, $0 < \rho < 1$, and $0 < \omega < 1$. (ii) MC-RW in the presence of two asymmetric partially reflecting barriers at 0 and n, for $\rho \neq \omega$, $0 < \rho < 1$ and $0 < \omega < 1$. (iii) MC-RW in the presence of two perfectly absorbing barriers at 0 and n, for $\rho = \omega = 0$. (iv) MC-RW in the presence of two perfectly reflecting barriers at 0 and n, for $\rho = \omega = 1$. (v) MC-RW in the presence of two different barriers, one of which at 0 (or at n) is perfectly absorbing and the other at n (or at 0) is semireflecting, for $\rho = 0$, $0 < \omega < 1$ (or $0 < \rho < 1$, $\omega = 0$), respectively. (vi) MC-RW in the presence of two different barriers, one of which at 0 (or at n) is perfectly absorbing and the other at n (or at 0) is perfectly reflecting, for $\rho = 0, \omega = 1$ (or $\rho = 1, \omega = 0$), respectively. (vii) MC-RW having a single (partially or perfectly) absorbing barrier at the origin, by taking the limit when $n \to \infty$.

A computational approach to finding the inverse of the general tridiagonal matrix P in (1.1) is given in a recent paper by Mallik [19]. To do this he imposed the restrictive conditions $p_0, p_1, \ldots, p_{n-1} \neq 0$ and $q_1, q_2, \ldots, q_n \neq 0$. In section 2 of the present paper, the elements of the inverse of the tridiagonal matrix P in (1.1), without imposing any restrictive conditions, via the Cholesky decompositional approach, are expressed in terms of the determinants of tridiagonal submatrices of P in (1.1). These determinants are solutions of a linear second-order difference equation with variable coefficients. In section 3, difference equations with variable coefficients are resolved explicitly. With these simple solutions, new results are obtained in sections 4 and 5; explicit expressions for the elements of the fundamental matrix of the model under investigation, with some interesting particular cases, are presented in section 4. In section 5, the results are applied to the MC-RW problem, in the presence of two semiabsorbing boundaries.

2. Inverse of the tridiagonal matrix P. Consider a general $(n+1)\times(n+1)$ tridiagonal matrix P of the form (1.1). For suitable (unique) diagonal matrices

$$D_1 = \mathrm{diag}(\alpha_0, \alpha_1, \ldots, \alpha_n),\ D_2 = \mathrm{diag}(\gamma_0, \gamma_1, \ldots, \gamma_n), \tag{2.1}$$

the matrix P can be decomposed into the following two factorizations:

$$P = U_1 D_1^{-1} L_1 \text{ and } P = L_2 D_2^{-1} U_2, \tag{2.2}$$

where

$$\begin{array}{l} U_1 = P\,(0, \alpha, p)\,, L_1 = P\,(q, \alpha, 0)\,, \\ U_2 = P\,(q, \gamma, 0)\,, L_2 = P\,(0, \gamma, p)\,, \end{array} \tag{2.3}$$

and D_k^{-1} is the inverse of D_k, $k = 1, 2$. Equating the entries on either side of (2.2), respectively, gives

$$\alpha_i = \begin{cases} r_i - \frac{p_i\, q_{i+1}}{\alpha_{i+1}} & \text{for } i = 0, 1, \ldots, n-1, \\ r_n & \text{for } i = n, \end{cases} \tag{2.4}$$

$$\gamma_i = \begin{cases} r_0 & \text{for } i = 0, \\ r_i - \frac{p_{i-1}\, q_i}{\gamma_{i-1}} & \text{for } i = 1, 2, \ldots, n. \end{cases} \tag{2.5}$$

The elements of the inverse P^{-1}can be computed according to the following theorem (cf. [2, 6, 14, 19, 29]). We use the convention that empty products and terms that have indices greater than n must be taken equal to 1.

THEOREM 2.1. [illegible] P [illegible] (1.1) [illegible] $Q = P^{-1} = (q_{ij})_{i,j}$ [illegible]

$$q_{ij} = \begin{cases} (-1)^{j-i} \left(\prod_{k=i}^{j-1} p_k \right) \frac{\alpha_{j+1}\alpha_{j+2}\cdots\alpha_n}{\gamma_i\gamma_{i+1}\cdots\gamma_n} & \text{[illegible]} \quad i \le j, \\ (-1)^{i-j} \left(\prod_{k=j+1}^{i} q_k \right) \left[\frac{\alpha_{i+1}\alpha_{i+2}\cdots\alpha_n}{\gamma_j\gamma_{j+1}\cdots\gamma_n} \right] & \text{[illegible]} \quad i \ge j. \end{cases} \tag{2.6}$$

[illegible] (2.5) [illegible] (2.4) [illegible]

$$\gamma_i = \frac{\Delta_i}{\Delta_{i-1}} \text{ [illegible]} \quad i = 1, 2, \ldots, n \qquad \text{[illegible]} \quad \Delta_{-1} = 1, \Delta_0 = r_0,$$

$$\alpha_i = \frac{\nabla_i}{\nabla_{i+1}} \text{ [illegible]} \quad i = 0, 1, 2, \ldots, n-1 \quad \text{[illegible]} \quad \nabla_{n+1} = 1, \nabla_n = r_n,$$

[illegible]

$$\Delta_i = r_i\Delta_{i-1} - p_{i-1}q_i\Delta_{i-2} \text{ [illegible]} \quad i = 1, 2, \cdots, n \tag{2.7}$$

[illegible] $\Delta_{-1} = 1$ [illegible] $\Delta_0 = r_0$ [illegible]

$$\nabla_i = r_i\nabla_{i+1} - p_iq_{i+1}\nabla_{i+2} \text{ [illegible]} \quad i = 0, 1, 2, \cdots, n-1 \tag{2.8}$$

[illegible] $\nabla_{n+1} = 1$ [illegible] $\nabla_n = r_n$

Rewriting formula (2.6), in terms of Δ_i and ∇_i, we get the following theorem.

THEOREM 2.2. [illegible] P [illegible] (1.1) [illegible] $Q = P^{-1} = (q_{ij})_{i,j}$ [illegible]

$$q_{ij} = \frac{1}{\Delta_n} \begin{cases} (-1)^{j-i} \left(\prod_{k=i}^{j-1} p_k \right) \Delta_{i-1} \nabla_{j+1} & \text{[illegible]} \quad i \le j, \\ (-1)^{i-j} \left(\prod_{k=j+1}^{i} q_k \right) \Delta_{j-1} \nabla_{i+1} & \text{[illegible]} \quad i \ge j, \end{cases} \tag{2.9}$$

[illegible] Δ_i [illegible] ∇_i [illegible] (2.7) [illegible] (2.8) [illegible]
[illegible] Δ_i [illegible] ∇_i [illegible]

$$\Delta_i = \det P\left((q_0, \dots, q_i), (r_0, \dots, r_i), (p_0, \dots, p_i)\right),$$
$$\nabla_i = \det P\left((q_i, \dots, q_n), (r_i, \dots, r_n), (p_i, \dots, p_n)\right).$$

[illegible] (2.7) [illegible] (2.8) [illegible]

$$\begin{aligned} \det P &= \alpha_0 \alpha_1 \cdots \alpha_{n-1} \alpha_n = \nabla_0 \\ &= \gamma_0 \gamma_1 \cdots \gamma_{n-1} \gamma_n = \Delta_n, \end{aligned}$$

[illegible] P [illegible] (2.7) [illegible] (2.8)

3. Solution of three-term recurrence relations. Difference equations with variable coefficients have been studied in many papers (cf. [2, 3, 16, 17, 18, 19, 24, 30]). In [16, 17, 18, 19], Mallik introduced the definition of a set $S_q(l+1, m)$ as follows: Let $\mathbb{N}$ denote the set of natural numbers. For $q, L, U \in \mathbb{N}$, $S_q(L, U)$ is the set of all q-tuples with elements from $\{L, L+1, \dots, U\}$ arranged in ascending order so that no consecutive elements are present. Mallik then proved the following result (cf. formulas (18) and (63a)–(63b) in [19].

PROPOSITION 3.1. [illegible]

$$E_m(l) = -\frac{r_m}{p_m} E_{m-1}(l) - \frac{q_{m-1}}{p_m} E_{m-2}(l), \quad 1 \le m \le n, 1 \le l \le m \tag{3.1}$$

[illegible]

$$E_m(l) := \begin{cases} \dfrac{(-1)^{m-l+1}}{\prod_{j=l}^{m} p_j} \left(\prod_{j=l}^{m} r_j + \sum_{q=1}^{\lfloor \frac{m-l+1}{2} \rfloor} \sum_{(k_1, \dots, k_q) \in S_q(l+1, m)} \sigma_{l,m}(k_1, \dots, k_q) \right) \\ \qquad \text{[illegible]} \quad l = 1, \dots, m-1; m = 2, \dots, n, \\ -\frac{r_m}{p_m} \quad \text{[illegible]} \quad l = m; \ m = 1, \dots, n, \\ 1 \quad \text{[illegible]} \quad l = m+1; \ m = 0, \dots, n, \\ 0 \quad \text{[illegible]} \end{cases} \tag{3.2}$$

[illegible]

$$E_{-1}(1) = 0, \quad E_m(m+1) = 1 \text{ [illegible]} \quad 0 \le m \le n, \ E_m(m) = -\frac{r_m}{p_m} \text{ [illegible]} \quad 1 \le m \le n,$$

$$\sigma_{l,m}(k_1,\dots,k_q) := (-1)^q \left(\prod_{j=l}^{m} r_j\right) \prod_{i=1}^{q} \frac{p_{k_i-1}q_{k_i-1}}{r_{k_i-1}r_{k_i}}$$

$E_m(l)$ (3.2)

LEMMA 3.1. (2.7) (2.8)

$$\Delta_i = r_0 \prod_{j=1}^{i} \gamma_j \quad \nabla_i = r_n \prod_{j=i}^{n-1} \alpha_j, \tag{3.3}$$

γ_j α_j (2.5) (2.4) . The proof is easily obtained. □

With the assumptions that $r_m + p_m + q_m = 1$, $r_0 + p_0 \geq 0$, and $r_n + q_n \geq 0$, we obtain the following corollary.

COROLLARY 3.1.

$$\begin{cases} Y_m = (1-r_m)Y_{m-1} - p_{m-1}q_m Y_{m-2}, & m \geq 1, \\ Y_0 = 1 - r_0 \quad Y_{-1} = 1, \end{cases} \tag{3.4}$$

$$\begin{cases} Y_m = (1-r_m)Y_{m+1} - p_m q_{m+1} Y_{m+2}, & m < n, \\ Y_n = 1 - r_n \quad Y_{n+1} = 1, \end{cases} \tag{3.5}$$

$$Y_m = (1-r_0-p_0)\sum_{u=0}^{m}\left(\prod_{j=1}^{m-u} q_j\right)\left(\prod_{j=m-u+1}^{m} p_j\right) + \left(\prod_{j=0}^{m} p_j\right), \quad m \geq 1, \tag{3.6}$$

$$Y_m = (1-r_n-q_n)\sum_{u=0}^{n-m}\left(\prod_{j=m}^{m+u-1} q_j\right)\left(\prod_{j=m+u}^{n-1} p_j\right) + \left(\prod_{j=m}^{n} q_j\right), \quad m < n \tag{3.7}$$

COROLLARY 3.2.

$$\begin{cases} Y_m = (1-r_m)Y_{m-1} - p_{m-1}q_m Y_{m-2}, & m \geq 2, \\ Y_1 = 1 - r_1 \quad Y_0 = 1, \end{cases} \tag{3.8}$$

$$\begin{cases} Y_m = (1-r_m)Y_{m+1} - p_m q_{m+1} Y_{m+2}, & m < n-1, \\ Y_{n-1} = 1 - r_{n-1} \quad Y_n = 1, \end{cases} \tag{3.9}$$

$$Y_m = \sum_{u=0}^{m}\left(\prod_{j=1}^{m-u} q_j\right)\left(\prod_{j=m-u+1}^{m} p_j\right), \quad m \geq 1, \tag{3.10}$$

$$Y_m = \sum_{u=0}^{n-m}\left(\prod_{j=m}^{m+u-1} q_j\right)\left(\prod_{j=m+u}^{n-1} p_j\right), \quad m < n \tag{3.11}$$

COROLLARY 3.3. $r + p + q = 1$

$$\begin{cases} Y_m = (1-r)Y_{m-1} - pqY_{m-2}, & m = 2,3,\dots,n-1, \\ Y_1 = 1 - r - \rho q \quad Y_0 = 1, \end{cases} \tag{3.12}$$

$$\begin{cases} Y_m = (1-r)Y_{m+1} - pqY_{m+2}, & m = n-2, n-1, \dots, 2, 1, \\ Y_{n-1} = 1 - r - p\omega \quad Y_n = 1, \end{cases} \tag{3.13}$$

$$Y_m = \frac{1}{p-q}\left[\left(1-\frac{q\rho}{p}\right)p^{m+1} - (1-\rho)q^{m+1}\right], \tag{3.14}$$

$$Y_{n-m} = \frac{1}{p-q}\left[(1-\omega)p^{m+1} - \left(1-\frac{p\omega}{q}\right)q^{m+1}\right]. \tag{3.15}$$

4. Closed form expressions for the fundamental matrix. Consider a finite-state MC-RW whose states are numbered so that $T = \{0, 1, \ldots, n\}$ denotes the set of transient states. Note that since P, as in (1.1), specifies only the transition probabilities from transient-to-transient states, some of its row sums are less than 1. Let $N_{ij}(n)$ be the number of visits to state j by time n given that $X_0 = i$; then $\{N_{ij}(n), n \geq 1\}$ is a delayed renewal process. A renewal occurs whenever the chain enters state j. For transient states i and j, let $\mathbf{m}_{ij} = E[N_{ij}(\infty)]$ be the expected total number of time periods spent in state j, starting in i; then

$$\mathbf{m}_{ij} = \delta(i,j) + \sum_{k=0}^{n} p_{ik}\mathbf{m}_{kj},$$

where $\delta(i,j)$ is the Kronecker delta. This equality holds from the fact that $\mathbf{m}_{ij} = 0$ when k is a recurrent state.

Let $M = (\mathbf{m}_{ij})_{i,j}$; then

$$M = (I-P)^{-1}.$$

Therefore, the (i,j)th element of the fundamental matrix M, $\mathbf{m}_{ij}$ is the mean number of visits to transient state j from state i before the chain enters any absorbing state. For $i \in T, j \in T$ the probability of ever visiting state j, starting in state i, is given by

$$f_{ij} = \frac{\mathbf{m}_{ij}}{\mathbf{m}_{jj}}.$$

The next theorem is immediate from Theorem 2.1 and Corollary 3.1.

THEOREM 4.1. $M = (\mathbf{m}_{ij})_{i,j}$ $\mathbf{m}_{ij}$ $i,j = 0,1,2,\ldots,n$, $0 \leq r_0, r_n < 1$, $0 \leq r_0 + p_0 \leq 1$, $0 \leq r_n + q_n \leq 1$,

$$\mathbf{m}_{ij} = \frac{1}{\Delta_n}\begin{cases} \Delta_1 & i = j = 0, \\ p_0\Delta_2 & i = 0, j = 1, \\ \left(\prod_{k=i}^{j-1} p_k\right)\Delta_{i-1}\nabla_{j+1} & 1 \leq i \leq j \leq n-1, \\ \left(\prod_{k=j+1}^{i} q_k\right)\Delta_{j-1}\nabla_{i+1} & 1 \leq j < i \leq n-1, \\ q_n\nabla_{n-2} & i = n, j = n-1, \\ \nabla_{n-1} & i = j = n, \end{cases} \tag{4.1}$$

$$\nabla_j = (1-r_n-q_n)\sum_{u=0}^{n-j}\left(\prod_{k=j}^{j+u-1} q_k\right)\left(\prod_{k=j+u}^{n-1} p_k\right) + \left(\prod_{k=j}^{n} q_k\right), \tag{4.2}$$

$$\Delta_i = (1-r_0-p_0)\sum_{u=0}^{i}\left(\prod_{k=1}^{i-u} q_k\right)\left(\prod_{k=i-u+1}^{i} p_k\right) + \left(\prod_{k=0}^{i} p_k\right), \tag{4.3}$$

$$\Delta_n = \nabla_0 = (1 - r_0 - p_0)\left(\prod_{k=1}^{n} q_k\right) + (1 - r_n - q_n)\left(\prod_{k=0}^{n-1} p_k\right)$$
$$+(1 - r_0 - p_0)(1 - r_n - q_n)\sum_{u=0}^{n-1}\left(\prod_{k=1}^{n-u-1} q_k\right)\left(\prod_{k=n-u}^{n-1} p_k\right) \tag{4.4}$$

$$P_0 = P\left((q_1, \ldots, q_n), (r_1, \ldots, r_n), (p_1, \ldots, p_n)\right),$$
$$P_n = P\left((q_0, \ldots, q_{n-1}), (r_0, \ldots, r_{n-1}), (p_0, \ldots, p_{n-1})\right), \text{and}$$
$$P_{0,n} = P\left((q_1, \ldots, q_{n-1}), (r_1, \ldots, r_{n-1}), (p_1, \ldots, p_{n-1})\right)$$

2.2 3.1–3.3 $M_0 = (I - P_0)^{-1}$, $M_n = (I - P_n)^{-1}$ $M_{0,n} = (I - P_{0,n})^{-1}$.

COROLLARY 4.1. $M_0 = (m_{ij})_{i,j}$

$$m_{ij} = \frac{1}{\Delta_n}\begin{cases} \left(\prod_{k=i}^{j-1} p_k\right)\Delta_{i-1}\nabla_{j+1} & 1 \le i \le j \le n-1, \\ \left(\prod_{k=j+1}^{i} q_k\right)\Delta_{j-1}\nabla_{i+1} & 1 \le j < i \le n-1, \\ q_n\nabla_{n-2} & i = n, j = n-1, \\ \nabla_{n-1} & i = j = n, \end{cases} \tag{4.5}$$

$$\nabla_j = (1 - r_n - q_n)\sum_{u=0}^{n-j}\left(\prod_{k=j}^{j+u-1} q_k\right)\left(\prod_{k=j+u}^{n-1} p_k\right) + \left(\prod_{k=j}^{n} q_k\right) \tag{4.6}$$

$$\Delta_i = \sum_{u=0}^{i}\left(\prod_{k=1}^{i-u} q_k\right)\left(\prod_{k=i-u+1}^{i} p_k\right) \tag{4.7}$$

$$\Delta_n = \left(\prod_{k=1}^{n} q_k\right) + (1 - r_n - q_n)\sum_{u=0}^{n-1}\left(\prod_{k=1}^{n-u-1} q_k\right)\left(\prod_{k=n-u}^{n-1} p_k\right) \tag{4.8}$$

COROLLARY 4.2. $M_n = (m_{ij})_{i,j}$

$$m_{ij} = \frac{1}{\Delta_n}\begin{cases} \Delta_1 & i = j = 0, \\ p_0\Delta_2 & i = 0, j = 1, \\ \left(\prod_{k=i}^{j-1} p_k\right)\Delta_{i-1}\nabla_{j+1} & 1 \le i \le j \le n-1, \\ \left(\prod_{k=j+1}^{i} q_k\right)\Delta_{j-1}\nabla_{i+1} & 1 \le j < i \le n-1, \end{cases} \tag{4.9}$$

$$\nabla_j = \sum_{u=0}^{n-j}\left(\prod_{k=j}^{j+u-1} q_k\right)\left(\prod_{k=j+u}^{n-1} p_k\right) \tag{4.10}$$

$$\Delta_i = (1 - r_0 - p_0)\sum_{u=0}^{i}\left(\prod_{k=1}^{i-u} q_k\right)\left(\prod_{k=i-u+1}^{i} p_k\right) + \left(\prod_{k=0}^{i} p_k\right) \tag{4.11}$$

$$\Delta_n = \left(\prod_{k=0}^{n-1} p_k\right) + (1 - r_0 - p_0) \sum_{u=0}^{n-1} \left(\prod_{k=1}^{n-u-1} q_k\right) \left(\prod_{k=n-u}^{n-1} p_k\right) \tag{4.12}$$

COROLLARY 4.3. $M_{0,n} = (m_{ij})_{i,j}$

$$m_{ij} = \frac{1}{\Delta_n} \begin{cases} \left(\prod_{k=i}^{j-1} p_k\right) \Delta_{i-1} \nabla_{j+1} & 1 \le i \le j \le n-1, \\ \left(\prod_{k=j+1}^{i} q_k\right) \Delta_{j-1} \nabla_{i+1} & 1 \le j < i \le n-1, \end{cases} \tag{4.13}$$

$$\nabla_j = \sum_{u=0}^{n-j} \left(\prod_{k=j}^{j+u-1} q_k\right) \left(\prod_{k=j+u}^{n-1} p_k\right), \tag{4.14}$$

$$\Delta_i = \sum_{u=0}^{i} \left(\prod_{k=1}^{i-u} q_k\right) \left(\prod_{k=i-u+1}^{i} p_k\right), \tag{4.15}$$

$$\Delta_n = \sum_{u=0}^{n-1} \left(\prod_{k=1}^{n-u-1} q_k\right) \left(\prod_{k=n-u}^{n-1} p_k\right) \tag{4.16}$$

(4.13), (4.16) [27] $q_i = \beta$, $p_i = \alpha, i = 1, 2, \ldots, n-1$ 4.1 $M_1 = (I - P)^{-1}$.

COROLLARY 4.4. $M_1 = (h_{ij})_{i,j}$

$$h_{ij} = \frac{1}{\Sigma} \begin{cases} (1 - r_0) a_n - \beta p_0 a_{n-1} & i = j = 0, \\ p_0 \left[(1 - r_0) a_{n-1} - \beta p_0 a_{n-2}\right] & i = 0, j = 1, \\ \alpha^{j-i} \left[(1 - r_0) a_i - \beta p_0 a_{i-1}\right] \left[(1 - r_n) a_{n-j} - \alpha q_n a_{n-j-1}\right] & 1 \le i \le j, \\ \beta^{i-j} \left[(1 - r_0) a_j - \beta p_0 a_{j-1}\right] \left[(1 - r_n) a_{n-i} - \alpha q_n a_{n-i-1}\right] & j \le i \le n-1, \\ q_n \left[(1 - r_n) a_{n-1} - \alpha q_n a_{n-2}\right] & i = n, j = n-1, \\ (1 - r_n) a_n - \alpha q_n a_{n-1} & i = j = n, \end{cases} \tag{4.17}$$

$$\begin{aligned} \Sigma = {} & (1 - r_0)(1 - r_n) a_n + \alpha\beta p_0 q_n a_{n-2} \\ & - \left[(1 - r_0)\alpha q_n + (1 - r_n)\beta p_0\right] a_{n-1}, \end{aligned} \tag{4.18}$$

$$a_i = \begin{cases} \frac{\alpha^i - \beta^i}{\alpha - \beta} & \alpha \ne \beta, \\ i\alpha^{i-1} & \alpha = \beta. \end{cases}$$

5. MC-RW in the presence of two semiabsorbing boundaries. In this section, we derive the absorption probabilities of an asymmetric one-dimensional random walk on the integers $\{0, 1, \ldots, n\}$ from the mean of the occupation totals in the presence of partially absorbing barriers at 0 and n. When the particle hits the barrier 0 (or n) it is either annihilated with probability $1 - \rho$ (or $1 - \omega$) or reflected back to the system with probability ρ (or ω), $0 \le \rho, \omega \le 1$. Physically, this corresponds to the situation when, reaching the barrier 0 (or n), the particle is either lost from the system with probability $1 - \rho$ (or $1 - \omega$) or tuned back to the system with probability ρ (or ω) and reduces to the classical problem of random walk. Assume that

X_k, $k = 1, 2, \ldots, n-1$ denotes a random variable associated with the kth step of the particle such that $X_k = 0$ if it stays put and is equal to 1 or -1 if it moves one unit to the right or to the left with respective probabilities γ, α and β; $\beta + \gamma + \alpha = 1$. Thus the present problem may be governed by the one-step transition probability matrix $P = P\left((1-\rho, \beta, \ldots, \beta, \omega), (0, \gamma, \ldots, \gamma, 0), (\rho, \alpha, \ldots, \alpha, 1-\omega)\right)$. Explicit expressions are investigated for the mean h_{ij} of the occupation totals, from which the absorption probabilities are determined as well as the mean time to absorption and the mean number of steps taken before absorption. Many interesting particular cases can be derived from the results through an appropriate choice of the reflection probabilities ρ and ω; see the introduction. After some simplifications, Corollary 4.3 gives

$$h_{0j} = \frac{1}{(1-\frac{\rho\beta}{\alpha})\Sigma} \begin{cases} \left(\frac{\alpha}{\beta}\right)^n - \frac{\beta-\omega\alpha}{\beta(1-\omega)} & \text{for } j = 0; \alpha \neq \beta, \\ \frac{\rho}{\alpha}\left[\left(\frac{\alpha}{\beta}\right)^{n-j} - \frac{\beta-\omega\alpha}{\beta(1-\omega)}\right]\left(\frac{\alpha}{\beta}\right)^j & \text{for } j = 1, 2, \ldots, n; \alpha \neq \beta, \end{cases}$$

$$= \frac{1}{(1-\rho)\Sigma_0} \begin{cases} n + \frac{\omega}{1-\omega} & \text{for } j = 0; \alpha = \beta, \\ \frac{\rho}{\alpha}\left[(n-j) + \frac{\omega}{1-\omega}\right] & \text{for } j = 1, 2, \ldots, n; \alpha = \beta, \end{cases} \tag{5.1}$$

$$h_{ij} = \frac{1}{(\alpha-\beta)\Sigma} \begin{cases} \left(\left(\frac{\alpha}{\beta}\right)^j - \frac{\alpha(1-\rho)}{\alpha-\beta\rho}\right)\left(\left(\frac{\alpha}{\beta}\right)^{n-i} - \frac{\beta-\omega\alpha}{\beta(1-\omega)}\right) & \\ \qquad \text{for } j \leq i; \alpha \neq \beta, & \\ \left(\left(\frac{\alpha}{\beta}\right)^i - \frac{\alpha(1-\rho)}{\alpha-\beta\rho}\right)\left(\left(\frac{\alpha}{\beta}\right)^{n-i} - \frac{\beta-\omega\alpha}{\beta(1-\omega)}\left(\frac{\alpha}{\beta}\right)^{j-i}\right) & \\ \qquad \text{for } j \geq i; \alpha \neq \beta & \end{cases}$$

$$= \frac{1}{\beta\Sigma_0} \begin{cases} \left(j + \frac{\rho}{1-\rho}\right)\left((n-i) + \frac{\omega}{1-\omega}\right) & \text{for } j \leq i; \alpha = \beta, \\ \left(i + \frac{\rho}{1-\rho}\right)\left((n-j) + \frac{\omega}{1-\omega}\right) & \text{for } j \geq i; \alpha = \beta, \end{cases} \tag{5.2}$$

$$h_{nj} = \frac{1}{(1-\omega)\Sigma} \begin{cases} \frac{\omega}{\beta}\left(\left(\frac{\alpha}{\beta}\right)^j - \frac{\alpha(1-\rho)}{\alpha-\beta\rho}\right) & \text{for } j = 0, 1, 2, \ldots, n-1; \alpha \neq \beta, \\ \left(\frac{\alpha}{\beta}\right)^n - \frac{\alpha(1-\rho)}{\alpha-\beta\rho} & \text{for } j = n; \alpha \neq \beta, \end{cases}$$

$$= \frac{1}{(1-\omega)\Sigma_0} \begin{cases} \frac{\omega}{\beta}\left(j + \frac{\rho}{1-\rho}\right) & \text{for } j = 0, 1, 2, \ldots, n-1; \alpha = \beta, \\ n + \frac{\rho}{1-\rho} & \text{for } j = n; \alpha = \beta, \end{cases} \tag{5.3}$$

where

$$\Sigma = \left(\frac{\alpha}{\beta}\right)^n - \frac{\alpha(1-\rho)(\beta-\alpha\omega)}{\beta(\alpha-\rho\beta)(1-\omega)}, \; \Sigma_0 = n + \frac{\rho}{1-\rho} + \frac{\omega}{1-\omega}. \tag{5.4}$$

Formulae (5.1)–(5.4) agree with the well-known result for MC-RW between two perfectly absorbing barriers, $\rho = \omega = 0$ (cf. [13, p. 100] in the case $\gamma = 0$).

Let $q(0 \mid i)$ and $q(n \mid i)$ denote the absorption probabilities at the boundary states 0 and n, respectively, given that i was the initial state. Therefore

$$q(0 \mid 0) = (1-\rho) \begin{cases} 1 + \frac{\rho\alpha}{(\alpha-\beta\rho)\Sigma}\left(\left(\frac{\alpha}{\beta}\right)^{n-1} - \frac{\beta-\alpha\omega}{\beta(1-\omega)}\right) & \text{for } \alpha \neq \beta, \\ 1 + \frac{\rho}{(1-\rho)\Sigma_0}\left(n - \frac{1-2\omega}{1-\omega}\right) & \text{for } \alpha = \beta, \end{cases} \tag{5.5}$$

$$(5.6)\quad q(n \mid n) = (1-\omega)\begin{cases} 1 + \frac{\omega\alpha}{\beta(1-\omega)\Sigma}\left(\left(\frac{\alpha}{\beta}\right)^{n-1} - \frac{\alpha(1-\rho)}{\alpha-\rho\beta}\right) & \text{for } \alpha \neq \beta, \\ 1 + \frac{\omega}{(1-\omega)\Sigma_0}\left(n - \frac{1-2\rho}{1-\rho}\right) & \text{for } \alpha = \beta, \end{cases}$$

$$(5.7)\quad q(0 \mid i) = \frac{1}{\Sigma_0}\left(n - i + \frac{\omega}{1-\omega}\right) \qquad \text{for } i = 1, 2, \ldots, n; \alpha = \beta,$$

$$(5.8)\quad q(n \mid i) = \frac{1}{\Sigma_0}\left(i + \frac{\rho}{1-\rho}\right) \qquad \text{for } i = 0, 1, \ldots, n-1; \alpha = \beta,$$

where Σ, and Σ_0 are given in (5.4). Obviously

$$q(0 \mid i) + q(n \mid i) = 1 \qquad \text{for } i = 1, 2, \ldots, n-1,$$
$$q(0 \mid 0) = \rho q(n \mid 1) \text{ and } \quad q(0 \mid n) = \omega q(0 \mid n-1).$$

We see that with the appropriate change of notation, (5.6)–(5.7) agree with the results of [26] in the special case $\rho = \omega$, $\gamma = 0$, and $i = 1, 2, \ldots, n-1$ (cf. [11, pp. 344–349], [13, p. 108] for $i = 1, 2, \ldots, n$, $\rho = \omega = \gamma = 0$, and [9]).

Let t_i be the mean time to absorption, given the starting state i, $i = 0, 1, 2, \ldots, n$. Obviously, the ith component of Me, e being the column vector of length $n+1$ with all entries equal to 1, is the mean time to absorption given by

$$t_0 = \frac{\alpha}{(\alpha-\rho\beta)\Sigma}\begin{Bmatrix} \left[1 + \frac{\rho}{\alpha}\left[n - \frac{\alpha}{\alpha-\beta}\left(\frac{\beta-\omega\alpha}{\beta(1-\omega)}\right)\right]\right]\left(\frac{\alpha}{\beta}\right)^n \\ -\frac{\beta-\omega\alpha}{\beta(1-\omega)}\left(1 - \frac{\rho}{\alpha-\beta}\right) \end{Bmatrix} \qquad \text{for } \alpha \neq \beta,$$

$$(5.9)\qquad = \frac{1}{(1-\rho)\Sigma_0}\left\{\left[1 + \frac{\rho}{2\alpha}\left[n - 1 + \frac{2\omega}{1-\omega}\right]\right]n + \frac{\omega}{1-\omega}\right\} \qquad \text{for } \alpha = \beta,$$

$$t_i = \frac{1}{\alpha-\beta}\begin{Bmatrix} \frac{1}{\Sigma}\left(\frac{\alpha}{\beta}\right)^{n-i}\left[n + \frac{\beta\rho}{\alpha(1-\rho)} + \frac{\omega\alpha}{\beta(1-\omega)}\right] \\ \left[\left(\frac{\alpha}{\beta}\right)^i - \frac{1-\rho}{1-\rho/\delta}\right] - i - \frac{\rho\beta}{\alpha(1-\rho)} \end{Bmatrix} \qquad \text{for } \alpha \neq \beta,$$

$$(5.10)\quad = \frac{1}{2\beta}\left\{\frac{1}{\Sigma_0}\begin{Bmatrix} \left[n\left(i + \frac{\rho}{1-\rho}\right) + \frac{\rho}{1-\rho}\right] \\ \left(n + \frac{2\omega}{1-\omega}\right) + i\left(\frac{\omega}{1-\omega} - \frac{\rho}{1-\rho}\right) \end{Bmatrix} - i^2\right\} \qquad \text{for } \alpha = \beta,$$

for $i = 1, 2, \ldots, n-1$, and

$$t_n = \frac{1}{(1-\omega)\Sigma}\begin{Bmatrix} \left(1 + \frac{\omega}{\alpha-\beta}\right)\left(\frac{\alpha}{\beta}\right)^n - \frac{\alpha(1-\rho)}{\alpha-\beta\rho} \\ \left(\frac{\omega}{\beta}n + 1\right) - \frac{\omega}{\alpha-\beta} \end{Bmatrix} \qquad \text{for } \alpha \neq \beta,$$

$$(5.11)\quad = \frac{1}{(1-\omega)\Sigma_0}\left\{\left[1 + \frac{\omega}{2\beta}\left[n - 1 + \frac{2\rho}{1-\rho}\right]\right]n + \frac{\rho}{1-\rho}\right\} \qquad \text{for } \alpha = \beta,$$

where Σ and Σ_0 are given in (5.4).

We see that the expressions (5.9)–(5.11) with the appropriate change of notation agree with the well-known results for a random walk between two perfectly absorbing barriers, $\rho = \omega = 0$, in the case $\gamma = 0$ (cf. [11, p. 348], [13, p. 108], [26], and [9]).

6. Conclusions. In the present paper a detailed connection between tridiagonal matrices, three-term recurrence relations, and the Markov chain random walk model is given. Closed form expressions for the entries of the inverse of the tridiagonal matrix $P = P(q, r, p)$ with $q = (q_0, q_1, \ldots, q_n)$, $r = (r_0, r_1, \ldots, r_n)$, and $p = (p_0, p_1, \ldots, p_n)$, via the Cholesky decompositional approach, in terms of the determinants of tridiagonal submatrices of P, are introduced. These determinants are solutions of a linear second-order homogeneous difference equation with variable coefficients. The presented results provide a simple and convenient approach to finding explicit expressions for the fundamental matrix of the model under investigation, with some interesting particular cases**.** In particular, the results are applied to MC-RW problems, in the presence of two semiabsorbing boundaries at 0 and n. Very simple expressions for the entries of the fundamental matrix are also given. This allows us to obtain general expressions for the mean of the occupation total explicitly in terms of the reflection probabilities ρ, ω and the basic transition probabilities $p_{ij}, i, j = 0, 1, \ldots, n$. These expressions generalize the results of [13, p. 100] to the case ρ, ω and γ nonzero. Exact analytical expressions for the absorption probabilities at the boundaries are also obtained. These expressions generalize the results of [9] to the case γ nonzero and the results of [26] to the case $\rho \neq \omega, \gamma \neq 0$ and $i = 0, 1, \ldots, n$.

Appendix. Proof of Corollary 3.1. Equation (3.4) can be reduced from second order to first order:

$$Y_m = p_m Y_{m-1} + (1 - r_0 - p_0) \prod_{j=1}^{m} q_j, m \geq 1. \tag{A.1}$$

One may obtain the solution of the associated homogeneous equation of (A.1) by a simple iteration:

$$Y_m = (1 - r_0) \prod_{j=1}^{m} p_j. \tag{A.2}$$

The unique solution of the nonhomogeneous equation (A.1) may be found by dividing both the left- and right-hand sides of (A.1) by $\prod_{j=1}^{m} p_j$, which can be written as

$$\Delta Y_m \left(\prod_{j=1}^{m} p_j \right)^{-1} = (1 - r_0 - p_0) \prod_{j=1}^{m+1} \frac{q_j}{p_j},$$

where Δ is the first difference operator. Therefore, a particular solution of (A.1) is

$$Y_m \left(\prod_{j=1}^{m} p_j \right)^{-1} = \Delta^{-1} \left((1 - r_0 - p_0) \prod_{j=1}^{m+1} \frac{q_j}{p_j} \right),$$

which can be expressed as

$$Y_m = (1 - r_0 - p_0) \prod_{j=1}^{m} p_j \sum_{u=1}^{m} \prod_{j=1}^{u} \frac{q_j}{p_j}. \tag{A.3}$$

From (A.2) and (A.3), the general solution of (A.1) is given as (3.6). Formula (3.7) can be proven in a completely analogous manner.

Acknowledgment. I am grateful to a referee for his valuable comments and helpful remarks which helped to improve the final version of this paper.

DESCRIPTION OF SYMMETRIC AND SKEW–SYMMETRIC SOLUTION SET*

MILAN HLADÍK†

Abstract. We consider a linear system $Ax = b$, where A is varying inside a given interval matrix $\mathbf{A}$, and b is varying inside a given interval vector $\mathbf{b}$. The solution set of such a system is described by the well-known Oettli–Prager Theorem. But if we are restricted only on symmetric/skew–symmetric matrices $A \in \mathbf{A}$, the problem is much more complicated. So far, the symmetric/skew–symmetric solution set description could be obtained only by a lengthy Fourier–Motzkin elimination applied on each orthant. We present an explicit necessary and sufficient characterization of the symmetric and skew–symmetric solution set by means of nonlinear inequalities. The number of the inequalities is, however, still exponential w.r.t. the problem dimension.

Key words. linear interval systems, solution set, interval matrix, symmetric matrix

NOTATION

$\mathbb{IR}^{m\times n}$	the set of all m-by-n interval matrices
$\mathbb{IR}^n$	the set of all n-dimensional interval vectors
$\square S$	interval hull of a set $S \subset \mathbb{R}^n$, i.e., the smallest box $[a_1, b_1] \times \cdots \times [a_n, b_n]$ that contains all the elements of S
$\prec_{\text{lex}}$	strict lexicographic ordering of vectors, i.e., $u \prec_{\text{lex}} v$ if for some k we have $u_i = v_i$, $i < k$, and $u_k < v_k$
$\preceq_{\text{lex}}$	lexicographic ordering of vectors, i.e., $u \preceq_{\text{lex}} v$ if $u \prec_{\text{lex}} v$ or $u = v$
$\lvert v\rvert$	absolute value of a vector v, i.e., the vector with components $\lvert v\rvert_i = \lvert v_i\rvert$
$A_{i,\bullet}$	the ith row of a matrix A
e_k	the kth basis vector (with convenient dimension), i.e., the kth column of the identity matrix
r^+	positive part of a real number r, i.e., $r^+ = \max(0, r)$

1. Introduction.

Real-life problems are often subject to uncertainties in data measurements. Such uncertainties can be dealt with by methods of interval analysis [1] instead of exact values we compute with compact real intervals. An interval matrix is defined as

$$\boldsymbol{A} = [\underline{A}, \overline{A}] = \{A \in \mathbb{R}^{m\times n} \mid \underline{A} \le A \le \overline{A}\},$$

where $\underline{A} \le \overline{A}$ are fixed matrices (n-dimensional interval vectors can be regarded as interval matrices n-by-1). By

$$A^c \equiv \frac{1}{2}(\underline{A} + \overline{A}), \quad A^\Delta \equiv \frac{1}{2}(\overline{A} - \underline{A})$$

we denote the midpoint and radius of $\boldsymbol{A}$, respectively.

Let us consider a system of linear interval equations

$$\boldsymbol{A}x = \boldsymbol{b}.$$

The solution set

$$\Sigma \equiv \{x \in \mathbb{R}^n \mid Ax = b,\ A \in \boldsymbol{A},\ b \in \boldsymbol{b}\}$$

is described by the well-known Oettli–Prager condition [11]

$$x \in \Sigma \quad \Leftrightarrow \quad A^{\Delta}|x| + b^{\Delta} \geq |A^c x - b^c|.$$

In interval analysis, we usually suppose, that values vary in given intervals independently. But in some applications, dependencies can occur (cf. [5], [9]). Especially, we focus on some types of the matrix A. The symmetric solution set is defined as

$$\Sigma_{sym} \equiv \{x \in \mathbb{R}^n \mid Ax = b,\ A = A^T,\ A \in \boldsymbol{A},\ b \in \boldsymbol{b}\},$$

and the skew–symmetric solution set as

$$\Sigma_{skew} \equiv \{x \in \mathbb{R}^n \mid Ax = b,\ A = -A^T,\ A \in \boldsymbol{A},\ b \in \boldsymbol{b}\}.$$

These sets have been exhaustively studied in recent years (see [2], [3], [4], [5], [6], and [7]). Applications involve Markov chains [8] and truss mechanics [10], for instance. Descriptions of Σ_{sym} and Σ_{skew} can be obtained by a Fourier–Motzkin elimination applied on each of 2^n orthants. Contrary to Σ, the symmetric solution set Σ_{sym} is not polyhedral, its shape is described by quadrics (see [3], [4], [5], and [6]), and it is not convex in general, even if intersected with an orthant.

The paper is organized as follows. In section 2 we derive a solution set characterization for a system of linear interval equations, where specific dependences occur. As consequences, we obtain a description of the symmetric solution set Σ_{sym} (section 3), and a description of the skew–symmetric solution set Σ_{skew} (section 4). The basic properties of Σ_{sym}, which were mentioned above, simply follow from the proposed Theorem 3.1 in section 3 (illustrated by Figures 3.1 and 3.2).

2. Linear interval equations with particular dependences. This section provides a characterization of the linear interval system equipped with a certain dependency (Theorem 2.2); the matrix A occurs twice in the system—in (2.3) and transposed in (2.4). We will see later in sections 3 and 4 that the description of the symmetric/skew–symmetric solution set is a simple consequence of Theorem 2.2. Another reason for dealing with such a dependency is that similar relations (occurrence of a matrix and its transposition in a system) can appear in some applications, e.g., optimality conditions in linear programming.

First we state an auxiliary result.

LEMMA 2.1. [illegible] $a^1, b^1, d^1 \in \mathbb{R}^m$, $a^2, b^2, d^2 \in \mathbb{R}^n$, [illegible] $C \in \mathbb{R}^{m \times n}$ [illegible]

$$f(u,v) \equiv (a^1)^T u + (b^1)^T |u| + (a^2)^T v + (b^2)^T |v| + \sum_{i=1}^{m} \sum_{j=1}^{n} c_{ij} |d_j^2 u_i + d_i^1 v_j| \tag{2.1}$$

[illegible] $u \in \mathbb{R}^m$ [illegible] $v \in \mathbb{R}^n$ [illegible] u, v [illegible]

(i) $u_i \in \{0, d_i^1\}\ \forall\ i = 1, \ldots, m$, [illegible] $v_j \in \{0, -d_j^2\}\ \forall\ j = 1, \ldots, n$
(ii) $u_i \in \{0, -d_i^1\}\ \forall\ i = 1, \ldots, m$, [illegible] $v_j \in \{0, d_j^2\}\ \forall\ j = 1, \ldots, n$
(iii) $(u^T, v^T)^T = \pm e_k$ [illegible] $k \in \{1, \ldots, m+n\}$

. One implication is obvious: If $f(u,v)$ is nonnegative for all $u \in \mathbb{R}^m$ and $v \in \mathbb{R}^n$, then it is nonnegative in particular points.

The converse will be proven by induction w.r.t. the dimension $m+n$.

If $m+n=1$, then without loss of generality (w.l.o.g.) assume $m=1$, $n=0$. The function $f(u)=a^1u+b^1|u|$ is nonnegative for all real u iff it is nonnegative for $u=\pm 1$, which is managed by the third condition of Lemma 2.1.

The induction step will be proven by contradiction. Let us assume that $f(u,v)<0$ for some vectors u,v.

(a) Suppose there are some vectors u,v such that $f(u,v)<0$ and $u_i=0$ for some index i. Delete the ith component in u and denote the resulting vector by $\tilde{u}$. Replace b^2 by $\tilde{b}^2$, where $\tilde{b}^2_j = b^2_j + c_{ij}|d^1_i|$, $j=1,\dots,n$, and apply the induction hypothesis to $\tilde{u},v$. Hence $f(\tilde{u}',v')\geq 0$ for some vectors $\tilde{u}'\in\mathbb{R}^{m-1}$ and $v'\in\mathbb{R}^n$ satisfying one of the conditions (i)–(iii). Canonical embedding of $\tilde{u}'$ to the space $\mathbb{R}^m$ yields the pair of vectors $u'\in\mathbb{R}^m$ and $v'\in\mathbb{R}^n$ such that $f(u',v')\geq 0$, and one of the conditions (i)–(iii) is true. Thus, a contradiction.

(b) Suppose there are some vectors u,v such that $f(u,v)<0$ and $v_j=0$ for some index j. Here the assertion follows analogously to case (a).

(c) Assume—as the remaining case—that no component of u,v is zero for all vectors u,v with $f(u,v)<0$.

First we show that $d^1_i\neq 0$ for every $i=1,\dots,m$, and $d^2_j\neq 0$ for every $j=1,\dots,n$. If w.l.o.g. $d^1_i=0$ for some i, then we have

$$f(u,v)=f(u_1,\dots,u_{i-1},0,u_{i+1},\dots,u_m,v)+f(0,\dots,0,u_i,0,\dots,0,0)<0.$$

That is, one of the two summands is negative, which contradicts our assumption.

Now, choose vectors $\tilde{u},\tilde{v}$ with $f(\tilde{u},\tilde{v})<0$ such that the number of absolute values in (2.1) that are zero is maximal. Define the graph $G=(V,E)$, where the vertex set V consist of $\tilde{u}_i$, $i=1,\dots,m$, and $\tilde{v}_j$, $j=1,\dots,n$. The edge set E contains such pairs $\{\tilde{u}_i,\tilde{v}_j\}$ for which $d^2_j\tilde{u}_i + d^1_i\tilde{v}_j = 0$. We distinguish three cases and show that each of them contradicts some assumption.

1. The graph G is connected. Choose $(\tilde{u}_{i^*},\tilde{v}_{j^*})\in E$ and define $z^*\equiv -\frac{\tilde{v}_{j^*}}{d^2_{j^*}}\neq 0$. Then $\tilde{u}_{i^*}=d^1_{i^*}z^*$, and $\tilde{v}_{j^*}=-d^2_{j^*}z^*$. Due to the connectivity of G, we can extend this property by induction to all i,j: If $(\tilde{u}_i,\tilde{v}_j)\in E$ and $\tilde{u}_i=d^1_iz^*$, then $\tilde{v}_j=-d^2_jz^*$. If $(\tilde{u}_i,\tilde{v}_j)\in E$ and $\tilde{v}_j=-d^2_jz^*$, then $\tilde{u}_i=d^1_iz^*$. Hence

$$\tilde{u}_i = d^1_iz^* \ \ \forall\ i=1,\dots,m, \quad \tilde{v}_j=-d^2_jz^*\ \forall\ j=1,\dots,n. \tag{2.2}$$

Define $u'\equiv\frac{1}{|z^*|}\tilde{u}$, $v'\equiv\frac{1}{|z^*|}\tilde{v}$. Vectors u',v' satisfy the first or the second condition of Lemma 2.1 (depending on the sign of z^*), but $f(u',v')=\frac{1}{|z^*|}f(u,v)<0$. Thus, a contradiction.

2. The graph G is not connected and $E\neq\emptyset$. We will construct vectors u',v' with $f(u',v')<0$ and at least one component of u' or v' to be zero, which contradicts the assumption of case (c).

Take a connected component $G'=(V',E')$ of G such that $E'\neq\emptyset$. Then the property (2.2) holds when restricted on G':

$$\tilde{u}_i = d^1_iz^* \ \ \forall\ i:\tilde{u}_i\in V', \quad \tilde{v}_j=-d^2_jz^*\ \ \forall\ j:\tilde{v}_j\in V'.$$

Consider the function $g(z) \equiv f(u(z), v(z))$ as a function of variable z, where

$$u_i(z) = \begin{cases} d_i^1 z & \tilde{u}_i \in V', \\ \tilde{u}_i & \text{otherwise}, \end{cases} \qquad v_j(z) = \begin{cases} -d_j^2 z & \tilde{v}_j \in V', \\ \tilde{v}_j & \text{otherwise}. \end{cases}$$

Then $g(z)$ is a piecewise linear function (broken line) on $\mathbb{R}$. Moreover, it is linear on a neighborhood $N(z^*)$ of z^*, that is, $g(z) = pz + q$, $z \in N(z^*)$ for some $p, q \in \mathbb{R}$. W.l.o.g. assume that $z^* > 0$ and consider two possibilities.

Let $g(z)$ be nondecreasing on $N(z^*)$. In this case $g(z)$ is nondecreasing on the interval $[0, z^*]$, since otherwise there is a break point in $(0, z^*)$ contradicting our assumption on the maximal number of zero absolute values. From $g(0) \le g(z^*) = f(\tilde{u}, \tilde{v}) < 0$ we get $g(0) = f(u(0), v(0)) < 0$ with $u(0)_i = 0$ for all indices i such that $\tilde{u}_i \in V'$ (at least one exists due to $E' \neq \emptyset$). This contradicts the assumption of case (c).

Let $g(z)$ be decreasing on $N(z^*)$. Then $g(z)$ is decreasing on $[z^*, \infty)$ (otherwise we are in contradiction with our assumption on the maximal number of zero absolute values). Moreover, for sufficiently large z we have $f(u', v') < 0$, where

$$u_i' = \begin{cases} d_i^1 z & \tilde{u}_i \in V', \\ 0 & \text{otherwise}, \end{cases} \qquad v_j' = \begin{cases} -d_j^2 z & \tilde{v}_j \in V', \\ 0 & \text{otherwise}. \end{cases}$$

As $V' \subsetneqq V$, the vectors u', v' contradict the assumption of case (c).

3. The graph G is not connected and $E = \emptyset$. Define the function $g(z) \equiv f(\tilde{u}_1 z, \tilde{u}_2, \dots, \tilde{u}_m, \tilde{v}_1, \dots, \tilde{v}_n)$. This function is linear on a neighborhood $N(z^*)$ of $z^* \equiv 1$.

If $g(z)$ is nondecreasing on $N(z^*)$, then it is nondecreasing on $[0, z^*]$ (otherwise we are in contradiction with our assumption on the maximal number of zero absolute values). From $g(0) \le g(z^*) = f(\tilde{u}, \tilde{v}) < 0$ we get $g(0) = f(0, \tilde{u}_2, \dots, \tilde{u}_m, \tilde{v}_1, \dots, \tilde{v}_n) < 0$. This contradicts the assumption of case (c).

If $g(z)$ is decreasing on $N(z^*)$, then it is decreasing on $[z^*, \infty)$ (otherwise we are in contradiction with our assumption on the maximal number of zero absolute values). Moreover, for sufficiently large z we have $f(\tilde{u}_1 z, 0, \dots, 0, 0, \dots, 0) < 0$. This also contradicts the assumption of case (c). □

THEOREM 2.2. [illegible] $\boldsymbol{A} \in \mathbb{IR}^{n \times n}$, $\boldsymbol{b} \in \mathbb{IR}^n$, [illegible] $\boldsymbol{d} \in \mathbb{IR}^n$ [illegible] $x, y \in \mathbb{R}^n$ [illegible]

$$Ax = b, \tag{2.3}$$

$$A^T y = d \tag{2.4}$$

[illegible] $A \in \boldsymbol{A}$, $b \in \boldsymbol{b}$, [illegible] $d \in \boldsymbol{d}$. [illegible]

$$A^\Delta |x| + b^\Delta \ge |r^1|, \tag{2.5}$$

$$A^\Delta |y| + d^\Delta \ge |r^2|, \tag{2.6}$$

$$\sum_{i,j=1}^n a_{ij}^\Delta |y_i x_j (p_i - q_j)| + \sum_{i=1}^n (b_i^\Delta |y_i p_i| + d_i^\Delta |x_i q_i|) \ge \left| \sum_{i=1}^n (r_i^1 y_i p_i - r_i^2 x_i q_i) \right| \tag{2.7}$$

$\forall\, p, q \in \{0,1\}^n$, [illegible] $r^1 \equiv -A^c x + b^c$, $r^2 \equiv -(A^c)^T y + d^c$

. Let $x, y \in \mathbb{R}^n$. Then x, y satisfy (2.3)–(2.4) iff for a certain $\alpha \in [-1,1]^{n\times n}$ the following relations hold:

$$A^c_{i,\bullet}x + \sum_{k=1}^{n} \alpha_{ik} a^\Delta_{ik} x_k \in [b^c_i - b^\Delta_i, b^c_i + b^\Delta_i] \ \forall\ i = 1,\dots,n,$$
$$\left(A^c_{\bullet,j}\right)^T y + \sum_{k=1}^{n} \alpha_{kj} a^\Delta_{kj} y_k \in [d^c_j - d^\Delta_j, d^c_j + d^\Delta_j] \ \forall\ j = 1,\dots,n.$$

Equivalently, iff the following linear programming problem

$$\max \sum_{i,j=1}^{n} 0 \cdot \alpha_{ij}$$

subject to

$$-\sum_{k=1}^{n} \alpha_{ik} a^\Delta_{ik} x_k \le -r^1_i + b^\Delta_i \ \forall\ i = 1,\dots,n,$$
$$\sum_{k=1}^{n} \alpha_{ik} a^\Delta_{ik} x_k \le r^1_i + b^\Delta_i \ \forall\ i = 1,\dots,n,$$
$$-\sum_{k=1}^{n} \alpha_{kj} a^\Delta_{kj} y_k \le -r^2_j + d^\Delta_j \ \forall\ j = 1,\dots,n,$$
$$\sum_{k=1}^{n} \alpha_{kj} a^\Delta_{kj} y_k \le r^2_j + d^\Delta_j \ \forall\ j = 1,\dots,n,$$
$$\alpha_{ij} \le 1 \ \forall\ i,j = 1,\dots,n,$$
$$-\alpha_{ij} \le 1 \ \forall\ i,j = 1,\dots,n$$

has an optimal solution.

Recall duality in linear programming [12], [13]. The linear programs

$$\max \tilde{b}^T \tilde{y} \ \text{ subject to } \ \tilde{A}^T \tilde{y} \le \tilde{c}$$

and

$$\min \tilde{c}^T \tilde{x} \ \text{ subject to } \ \tilde{A}\tilde{x} = \tilde{b}, \tilde{x} \ge 0$$

are dual to each other. Moreover, their optimal values are equal as long as at least one of the problems is feasible (i.e., the constraints are satisfiable).

Thus our linear programming problem has an optimal solution iff the dual problem

$$\min \ \Big\{(-r^1 + b^\Delta)^T w^1 + (r^1 + b^\Delta)^T w^2 + (-r^2 + d^\Delta)^T w^3 + \ (r^2 + d^\Delta)^T w^4 + \sum_{i,j=1}^{n} (w^5_{ij} + w^6_{ij})\Big\}$$

subject to

$$-a^\Delta_{ij} x_j w^1_i + a^\Delta_{ij} x_j w^2_i - a^\Delta_{ij} y_i w^3_j + a^\Delta_{ij} y_i w^4_j + w^5_{ij} - w^6_{ij} = 0 \ \forall\ i,j = 1,\dots,n,$$
$$w^1, w^2, w^3, w^4, w^5, w^6 \ge 0$$

has an optimal solution. The dual problem is feasible as its constraints are fulfilled when all the variables are equal to zero, for instance. After substitution $u \equiv w^2 - w^1$,

$v \equiv w^4 - w^3$ we can rewrite this problem:

$$\min\ (r^1 + b^\Delta)^T u + 2(b^\Delta)^T w^1 + (r^2 + d^\Delta)^T v + 2(d^\Delta)^T w^3 + \sum_{i,j=1}^{n} (w^5_{ij} + w^6_{ij})$$

subject to

$$\begin{aligned} a^\Delta_{ij} x_j u_i + a^\Delta_{ij} y_i v_j + w^5_{ij} - w^6_{ij} = 0 \ \forall\ i,j = 1,\dots,n,\\ w^1 \geq -u,\\ w^3 \geq -v,\\ w^1, w^3, w^5, w^6 \geq 0. \end{aligned}$$

For w^1, w^3, w^5, and w^6 some necessary optimality conditions can be given.

For each i,j at least one of w^5_{ij},w^6_{ij} is zero (otherwise subtract from them a sufficiently small $\varepsilon > 0$ and obtain a better solution). If $w^5_{ij} = 0$, then $w^6_{ij} = a^\Delta_{ij} x_j u_i + a^\Delta_{ij} y_i v_j \geq 0$, and hence $w^5_{ij} + w^6_{ij} = |a^\Delta_{ij} x_j u_i + a^\Delta_{ij} y_i v_j|$. Similarly, if $w^6_{ij} = 0$, then $w^5_{ij} = -(a^\Delta_{ij} x_j u_i + a^\Delta_{ij} y_i v_j) \geq 0$, and hence $w^5_{ij} + w^6_{ij} = |a^\Delta_{ij} x_j u_i + a^\Delta_{ij} y_i v_j|$. Therefore

$$w^5_{ij} + w^6_{ij} = |a^\Delta_{ij} x_j u_i + a^\Delta_{ij} y_i v_j|$$

holds in any case.

Next, the only constraints involving the variable w^1_i, $i \in \{1,\dots,n\}$ are $w^1_i \geq -u_i$ and $w^1_i \geq 0$. Since the objective function coefficient by w^1_i is nonnegative, the optimal w^1_i should be as small as possible. That is, $w^1_i = \max(-u_i, 0) = (-u_i)^+$. Hence we have $w^1 = (-u)^+$, and the equation $w^3 = (-v)^+$ follows analogously.

Using these necessary optimality conditions, the optimization problem can be reformulated as an unconstrained optimization problem:

$$\begin{aligned} \min_{u,v\in\mathbb{R}^n}\ \Big\{ &(r^1 + b^\Delta)^T u + 2(b^\Delta)^T (-u)^+ + (r^2 + d^\Delta)^T v \\ &+ 2(d^\Delta)^T (-v)^+ + \sum_{i,j=1}^{n} a^\Delta_{ij} |x_j u_i + y_i v_j| \Big\}. \end{aligned}$$

The positive part of a real number p is equal to $p^+ = \frac{1}{2}(p + |p|)$, and the problem comes in the form

$$\min_{u,v\in\mathbb{R}^n}\ (r^1)^T u + (b^\Delta)^T |u| + (r^2)^T v + (d^\Delta)^T |v| + \sum_{i,j=1}^{n} |a^\Delta_{ij} x_j u_i + a^\Delta_{ij} y_i v_j|.$$

As a^Δ_{ij} is nonnegative (because it is the radius of an interval), the objective function can be written

$$f(u,v) \equiv (r^1)^T u + (b^\Delta)^T |u| + (r^2)^T v + (d^\Delta)^T |v| + \sum_{i,j=1}^{n} a^\Delta_{ij} |x_j u_i + y_i v_j|. \tag{2.8}$$

Note that, it is positive homogeneous, that is,

$$f(\lambda u, \lambda v) = \lambda f(u,v) \ \forall\ \lambda \geq 0.$$

If $f(\tilde{u}, \tilde{v}) < 0$ for some vectors $\tilde{u}, \tilde{v} \in \mathbb{R}^n$, then $f(\lambda\tilde{u}, \lambda\tilde{v})$ tends to $-\infty$ for $\lambda \to \infty$, and the problem does not attain an optimum. On the other hand, if $f(u,v) \geq 0$ for

all $u, v \in \mathbb{R}^n$, then the optimal solution is $u = v = 0$. Thus the optimization problem has an optimal solution iff the objective function is nonnegative for all $u, v \in \mathbb{R}^n$.

We now use Lemma 2.1 with $a^1 \equiv r^1$, $a^2 \equiv r^2$, $b^1 \equiv b^\Delta$, $b^2 \equiv d^\Delta$, $C \equiv A^\Delta$, $d^1 \equiv y$, $d^2 \equiv x$, and $m = n$. It follows that it is sufficient to test nonnegativity of $f(u, v)$ for three cases:

1. $u_i \in \{0, y_i\}\ \forall\ i = 1, \dots, n$, and $v_j \in \{0, -x_j\}\ \forall\ j = 1, \dots, n$;
2. $u_i \in \{0, -y_i\}\ \forall\ i = 1, \dots, n$, and $v_j \in \{0, x_j\}\ \forall\ j = 1, \dots, n$;
3. $(u^T, v^T)^T = \pm e_k$ for some $k \in \{1, \dots, 2n\}$.

The first and second cases yield

$$\pm \sum_{i=1}^{n} r_i^1 y_i p_i + \sum_{i=1}^{n} b_i^\Delta |y_i p_i| \mp \sum_{i=1}^{n} r_i^2 x_i q_i + \sum_{i=1}^{n} d_i^\Delta |x_i q_i| + \sum_{i,j=1}^{n} a_{ij}^\Delta |y_i x_j (p_i - q_j)| \geq 0$$

or

$$\sum_{i,j=1}^{n} a_{ij}^\Delta |y_i x_j (p_i - q_j)| + \sum_{i=1}^{n} (b_i^\Delta |y_i p_i| + d_i^\Delta |x_i q_i|) \geq \left| \sum_{i=1}^{n} (r_i^1 y_i p_i - r_i^2 x_i q_i) \right|,$$

where $p, q \in \{0, 1\}^n$. In the third case when $u = \pm e_k$ and $v = 0$, we get

$$\pm r_k^1 + b_k^\Delta + \sum_{j=1}^{n} a_{kj}^\Delta |x_j| \geq 0,$$

which is the kth Oettli–Prager inequality in (2.5). Likewise $u = 0$, $v = \pm e_k$ yields the kth Oettli–Prager inequality in (2.6). □

3. Symmetric solution set. In this section, we suppose w.l.o.g. that $\boldsymbol{A} = \boldsymbol{A}^T$, i.e., matrices A^c, A^Δ are symmetric. Otherwise we restrict our considerations on the interval matrix $(\boldsymbol{a}_{ij} \cap \boldsymbol{a}_{ji})_{i,j=1}^n$.

Theorem 3.1, which is a simple corollary of Theorem 2.2, enables us to obtain an explicit description of the symmetric solution set Σ_{sym}. Nevertheless, the number of inequalities in the description is still exponential. Therefore when checking $x \in \Sigma_{sym}$ for only one vector x, it is better from the theoretical viewpoint to use the linear programming problem (from the proof of Theorem 2.2), which is polynomially solvable [13]. The question whether Σ_{sym} can be described by a polynomial number of inequalities is still open.

THEOREM 3.1. [illegible] $r \equiv -A^c x + b^c$ [illegible] Σ_{sym} [illegible]

[illegible]

$$A^\Delta |x| + b^\Delta \geq |r|, \tag{3.1}$$

$$\sum_{i,j=1}^{n} a_{ij}^\Delta |x_i x_j (p_i - q_j)| + \sum_{i=1}^{n} b_i^\Delta |x_i (p_i + q_i)| \geq \left| \sum_{i=1}^{n} r_i x_i (p_i - q_i) \right| \tag{3.2}$$

[illegible] $p, q \in \{0, 1\}^n \setminus \{0, 1\}$ [illegible]

$$p \prec_{\text{lex}} q \quad (p = 1 - q \vee \exists\ i : p_i = q_i = 0). \tag{3.3}$$

[illegible]. For every $A \in \boldsymbol{A}$, the matrix $\frac{1}{2}(A + A^T) \in \boldsymbol{A}$ is symmetric, and for every $b^1, b^2 \in \boldsymbol{b}$ we have $\frac{1}{2}(b^1 + b^2) \in \boldsymbol{b}$. Thus, Σ_{sym} can be equivalently described as the set of all $x \in \mathbb{R}^n$ satisfying

$$Ax = b^1, \tag{3.4}$$

$$A^T x = b^2 \tag{3.5}$$

for some $A \in \boldsymbol{A}$, $b^1, b^2 \in \boldsymbol{b}$. Put $y \equiv x$, $\boldsymbol{d} \equiv \boldsymbol{b}$ and apply Theorem 2.2 on system (3.4)–(3.5). We obtain that Σ_{sym} is described by (3.1)–(3.2) for all $p, q \in \{0,1\}^n$. To reduce the number of inequalities in (3.2), it is sufficient due to symmetry to consider only vectors $p, q \in \{0,1\}^n$ for which $p \preceq_{\text{lex}} q$. Obviously, the case $p = q$ is also redundant.

The inequality (3.2) corresponding to $p = 0$ and any $q \in \{0,1\}^n$ can be omitted for the following reason. Multiplying the Oettli–Prager system (3.1) by the vector $(|x_1 q_1|, \dots, |x_n q_n|)$ we obtain

$$\sum_{i,j=1}^{n} a_{ij}^{\Delta} |x_i x_j q_i| + \sum_{i=1}^{n} b_i^{\Delta} |x_i q_i| \geq \sum_{i=1}^{n} |r_i x_i q_i| \geq \left| \sum_{i=1}^{n} r_i x_i q_i \right|.$$

Due to the symmetry of A^{Δ} the first sum is equal to $\sum_{i,j=1}^{n} a_{ij}^{\Delta} |x_i x_j q_j|$, and hence the inequality

$$\sum_{i,j=1}^{n} a_{ij}^{\Delta} |x_i x_j q_j| + \sum_{i=1}^{n} b_i^{\Delta} |x_i q_i| \geq \left| \sum_{i=1}^{n} r_i x_i q_i \right|$$

is a consequence of the Oettli–Prager system.

The inequality (3.2) corresponding to any $p \in \{0,1\}^n$ and $q = 1$ is redundant as it is a consequence of the inequality (3.2) with $p' \equiv 1 - p$, $q' \equiv 0$ (which is redundant for the same reason as before); the right-hand sides of the inequalities are the same, and the left-hand side of the former inequality includes all of the left-hand side terms of the latter inequality and possibly some more positive terms.

Finally, we prove redundancy for all inequalities (3.2) with $p, q \in \{0,1\}^n \setminus \{0,1\}$, $p \prec_{\text{lex}} q$, and

$$p \neq 1 - q \text{ and } \forall\, i : (p_i = 1 \vee q_i = 1). \tag{3.6}$$

Clearly, (3.6) is equivalent to

$$\forall\, i : (p_i = 1 \vee q_i = 1) \text{ and } \exists\, i : p_i = q_i = 1. \tag{3.7}$$

Such an inequality is a consequence of the inequality (3.2) with $p' \equiv 1 - q$, $q' \equiv 1 - p$. The vectors p', q' satisfy the condition (3.3). □

We compute the number of inequalities for system (3.2).

PROPOSITION 3.2. [illegible] (3.2) [illegible] $\frac{1}{2}(4^n - 3^n - 2 \cdot 2^n + 3)$ [illegible]

[illegible] There are $(2^n - 2)^2$ pairs of vectors p, q satisfying $p, q \in \{0,1\}^n \setminus \{0,1\}$. Since for each pair p, q just one of the conditions $p \prec_{\text{lex}} q$, $p = q$, or $q \prec_{\text{lex}} p$ is true, the number of the vectors p, q satisfying $p, q \in \{0,1\}^n \setminus \{0,1\}$, $p \prec_{\text{lex}} q$, is equal to $\frac{1}{2}\big((2^n - 2)^2 - (2^n - 2)\big) = \frac{1}{2}(2^n - 2)(2^n - 3)$.

Now we focus on condition (3.7) which determines the "bad" cases. For every p, q define

$$I_{p,q} \equiv \{i = 1, \dots, n \mid p_i = q_i = 1\},\ J_{p,q} \equiv \{i = 1, \dots, n \mid p_i + q_i = 1\}.$$

Vectors $p, q \in \{0,1\}^n$ satisfy (3.7) iff $|I_{p,q}| \geq 1$ and $|I_{p,q}| + |J_{p,q}| = n$. The value $\binom{n}{k} 2^{n-k}$ identifies the number of $p, q \in \{0,1\}^n$ for which $|I_{p,q}| = k$ and $|J_{p,q}| = n - k$. Summing up for all $k = 1, \dots, n$ and using binomial expansion of $(1+2)^n$ we obtain the number of pairs $p, q \in \{0,1\}^n$ with property (3.7) is equal to

$$\binom{n}{1} 2^{n-1} + \binom{n}{2} 2^{n-2} + \cdots + \binom{n}{n} 2^0 = 3^n - 2^n.$$

From this amount we have to exclude the cases when $p = 1$ or $q = 1$:

$$3^n - 2^n - 2 \cdot (2^n - 1) + 1.$$

Exactly half of them satisfy $p \prec_{\text{lex}} q$. Eventually, we obtain the number in question:

$$\frac{1}{2}(2^n - 2)(2^n - 3) - \frac{1}{2}\big(3^n - 2^n - 2 \cdot (2^n - 1) + 1\big) = \frac{1}{2}(4^n - 3^n - 2 \cdot 2^n + 3). \qquad \square$$

The number of inequalities in (3.2) is exponential, but not as tremendous as by using Fourier–Motzkin elimination (no better upper bound is known than the double exponential one). Moreover, system (3.2) is characterized explicitly and is much more easy to handle.

Concretely, for $n = 2$ we have only one additional inequality (in comparison to two inequalities obtained by Fourier–Motzkin elimination [4]), for $n = 3$ this number rises up to 12 (cf. [3], [4], [6]; Fourier–Motzkin elimination leads to 44 inequalities).

3.3. For the two-dimensional case, the symmetric solution set is described by the system consisting of the Oettli–Prager inequalities (3.1)

$$a_{11}^{\Delta}|x_1| + a_{12}^{\Delta}|x_2| + b_1^{\Delta} \geq |-a_{11}^{c}x_1 - a_{12}^{c}x_2 + b_1^{c}|$$
$$a_{21}^{\Delta}|x_1| + a_{22}^{\Delta}|x_2| + b_2^{\Delta} \geq |-a_{21}^{c}x_1 - a_{22}^{c}x_2 + b_2^{c}|$$

supplemented by only one inequality (3.2)

$$a_{11}^{\Delta}x_1^2 + a_{22}^{\Delta}x_2^2 + b_1^{\Delta}|x_1| + b_2^{\Delta}|x_2| \geq |\,-a_{11}^{c}x_1^2 + a_{22}^{c}x_2^2 + b_1^{c}x_1 - b_2^{c}x_2|.$$

In the list below we mention some particular examples. Figures 3.1 and 3.2 illustrate a solution set (light gray color) and a symmetric solution set (gray color):

1. (Figure 3.1) $\boldsymbol{A} = \left(\begin{smallmatrix}[1,2] & [0,a]\\ [0,a] & -1\end{smallmatrix}\right)$, $\boldsymbol{b} = \left(\begin{smallmatrix}2\\2\end{smallmatrix}\right)$; here the interval hull $\square\Sigma$ can be arbitrarily larger than $\square\Sigma_{sym}$, depending on the real parameter $a > 0$.
2. (Figure 3.2) $\boldsymbol{A} = \left(\begin{smallmatrix}-1 & [-5,5]\\ [-5,5] & 1\end{smallmatrix}\right)$, $\boldsymbol{b} = \left(\begin{smallmatrix}1\\ [1,3]\end{smallmatrix}\right)$; here Σ is unbounded, but Σ_{sym} is bounded.

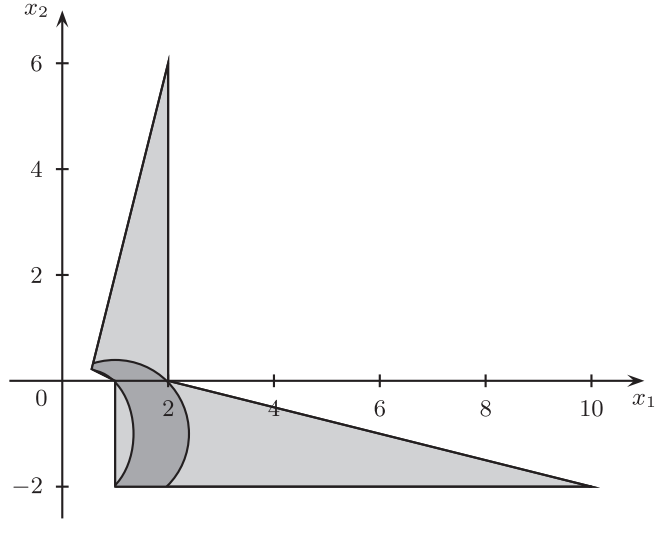

FIG. 3.1. *Solution set arbitrarily larger than symmetric solution set, $a = 4$.*

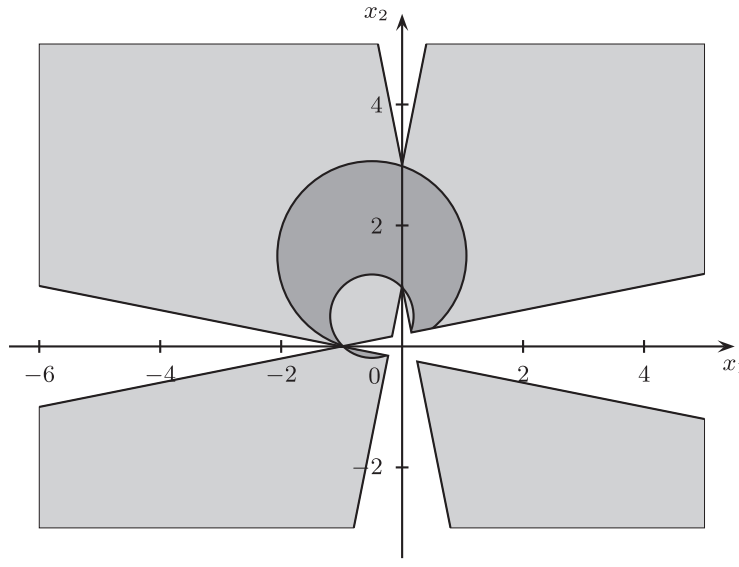

FIG. 3.2. *Unbounded solution set and bounded symmetric solution set.*

3. For $\boldsymbol{A} = \left(\begin{smallmatrix} [0,1] & [1,2] \\ [1,2] & [-1,0] \end{smallmatrix}\right)$, $\boldsymbol{b} = \left(\begin{smallmatrix} [-1,1] \\ [-1,1] \end{smallmatrix}\right)$ we have $\Sigma = \Sigma_{sym}$ and both are bounded.
4. For $\boldsymbol{A} = \left(\begin{smallmatrix} [-1,1] & [0,2] \\ [0,2] & [-1,1] \end{smallmatrix}\right)$, $\boldsymbol{b} = \left(\begin{smallmatrix} [0,1] \\ [0,1] \end{smallmatrix}\right)$ we have $\Sigma = \Sigma_{sym}$ and both are unbounded.

4. Skew–symmetric solution set. In this section, let us suppose w.l.o.g. that $\boldsymbol{A} = -\boldsymbol{A}^T$ and the diagonal of $\boldsymbol{A}$ is zero. Therefore A^c is skew–symmetric and A^Δ is a symmetric matrix. The description of the skew–symmetric solution set Σ_{skew} is a consequence of Theorem 2.2.

PROPOSITION 4.1. [illegible] $r \equiv -A^c x + b^c$ [illegible] Σ_{skew} [illegible]

$$A^\Delta |x| + b^\Delta \geq |r|, \tag{4.1}$$

$$\sum_{i,j=1}^{n} a_{ij}^\Delta |x_i x_j (p_i - q_j)| + \sum_{i=1}^{n} b_i^\Delta |x_i (p_i + q_i)| \geq \left| \sum_{i=1}^{n} r_i x_i (p_i + q_i) \right|$$

$$\forall\, p, q \in \{0,1\}^n \setminus \{0\},\ p \preceq_{\text{lex}} q. \tag{4.2}$$

[illegible]. For all $A \in \boldsymbol{A}$ and $b^1, b^2 \in \boldsymbol{b}$ we have that $\frac{1}{2}(A - A^T) \in \boldsymbol{A}$ is a skew–symmetric matrix and $\frac{1}{2}(b^1 + b^2) \in \boldsymbol{b}$. Thus, Σ_{skew} can be equivalently described as the set of all $x \in \mathbb{R}^n$ satisfying

$$Ax = b^1, \tag{4.3}$$

$$A^T(-x) = b^2 \tag{4.4}$$

for some $A \in \boldsymbol{A}$, $b^1, b^2 \in \boldsymbol{b}$. Put $y \equiv -x$, $\boldsymbol{d} \equiv \boldsymbol{b}$. Then

$$r^1 = -A^c x + b^c = -(-A^c)(-x) + b^c = -(A^c)^T y + d^c = r^2 \equiv r.$$

Apply Theorem 2.2 on system (4.3)–(4.4). We obtain that Σ_{skew} is described by (4.1)–(4.2). To reduce the number of inequalities in (4.2), it is sufficient due to symmetry to consider only vectors $p, q \in \{0,1\}^n \setminus \{0\}$ for which $p \preceq_{\text{lex}} q$. □

The number of inequalities in (4.2) is $2^{n-1}(2^n - 1)$ and can be furthermore decreased to the number $2^n - n - 1$; see Theorem 4.2 where we claim that it is sufficient to consider only such inequalities for which $p = q$, the others being redundant.

THEOREM 4.2. [illegible] $r \equiv -A^c x + b^c$ [illegible] Σ_{skew} [illegible]

$$A^{\Delta}|x| + b^{\Delta} \geq |r|, \tag{4.5}$$

$$\sum_{i<j} a_{ij}^{\Delta}|x_i x_j (p_i - p_j)| + \sum_{i=1}^{n} b_i^{\Delta}|x_i p_i| \geq \left|\sum_{i=1}^{n} r_i x_i p_i\right| \quad \forall\, p \in \{0,1\}^n \setminus \{0\},\ p \neq e_k. \tag{4.6}$$

[illegible]. For given vectors $p, q \in \{0,1\}^n$ denote the inequality (4.2) corresponding to p, q by $Ineq(p,q)$. Let p, q be fixed, and define vectors $s, t \in \{0,1\}^n$ componentwise by

$$s_i = \begin{cases} 1 & p_i = q_i = 1, \\ 0 & \text{otherwise}, \end{cases} \qquad t_i = \begin{cases} 1 & (p_i = 1) \vee (q_i = 1), \\ 0 & \text{otherwise}. \end{cases}$$

We prove that $Ineq(p,q)$ is a consequence of the inequality

$$\frac{1}{2}\big(Ineq(s,s) + Ineq(t,t)\big) \tag{4.7}$$

and hence can be omitted.

The right-hand side of the inequality $Ineq(p,q)$ is $|\sum_{p_i=1} r_i x_i + \sum_{q_i=1} r_i x_i| = |\sum_{s_i=1} r_i x_i + \sum_{t_i=1} r_i x_i|$, which is not greater than $|\sum_{s_i=1} r_i x_i| + |\sum_{t_i=1} r_i x_i|$, the right-hand side of (4.7). The second sum in $Ineq(p,q)$ is equal to $\sum_{p_i=1} b_i^{\Delta}|x_i| + \sum_{q_i=1} b_i^{\Delta}|x_i|$, which is equal to $\sum_{s_i=1} b_i^{\Delta}|x_i| + \sum_{t_i=1} b_i^{\Delta}|x_i|$, the second sum in (4.7). To prove the similar relations for the corresponding first sums let us note that diagonal terms (i.e., when $i = j$) in $Ineq(p,q)$ are nonnegative, while diagonal terms are zero in (4.7). We gather the remaining terms into symmetric pairs and show that for each $i < j$ one has

$$\begin{aligned} a_{ij}^{\Delta}|x_i x_j (p_i - q_j)| + a_{ij}^{\Delta}|x_j x_i (p_j - q_i)| &\geq \frac{1}{2}\Big(a_{ij}^{\Delta}|x_i x_j (s_i - s_j)| + a_{ij}^{\Delta}|x_i x_j (t_i - t_j)|\Big) \\ &\quad + \frac{1}{2}\Big(a_{ij}^{\Delta}|x_j x_i (s_j - s_i)| + a_{ij}^{\Delta}|x_j x_i (t_j - t_i)|\Big) \\ &= a_{ij}^{\Delta}|x_i x_j (s_i - s_j)| + a_{ij}^{\Delta}|x_i x_j (t_i - t_j)|. \end{aligned}$$

In fact, we prove a stronger inequality

$$|p_i - q_j| + |p_j - q_i| \geq |s_i - s_j| + |t_i - t_j|.$$

This can be shown simply by the enumeration of all possible values of p_i, p_j, q_i, and q_j, which is done in the following:

p_i	p_j	q_i	q_j	$\lvert p_i - q_j\rvert + \lvert p_j - q_i\rvert$	s_i	s_j	t_i	t_j	$\lvert s_i - s_j\rvert + \lvert t_i - t_j\rvert$
0	0	0	0	0	0	0	0	0	0
1	0	0	0	1	0	0	1	0	1
0	1	0	0	1	0	0	0	1	1
1	1	0	0	2	0	0	1	1	0
0	0	1	0	1	0	0	1	0	1
1	0	1	0	2	1	0	1	0	2
0	1	1	0	0	0	0	1	1	0
1	1	1	0	1	1	0	1	1	1
0	0	0	1	1	0	0	0	1	1
1	0	0	1	0	0	0	1	1	0
0	1	0	1	2	0	1	0	1	2
1	1	0	1	1	0	1	1	1	1
0	0	1	1	2	0	0	1	1	0
1	0	1	1	1	1	0	1	1	1
0	1	1	1	1	0	1	1	1	1
1	1	1	1	0	1	1	1	1	0

Now we have that the right-hand side of $Ineq(p,q)$ is less or equal to the right-hand side of (4.7), and the left-hand side of $Ineq(p,q)$ is greater or equal to the left-hand side of (4.7). Therefore, $Ineq(p,q)$ is redundant, and (4.2) can be replaced by the system

$$\sum_{i<j} a_{ij}^{\Delta}|x_i x_j(p_i - p_j)| + \sum_{i=1}^{n} b_i^{\Delta}|x_i p_i| \geq \left|\sum_{i=1}^{n} r_i x_i p_i\right| \quad \forall\, p \in \{0,1\}^n \setminus \{0\}. \tag{4.8}$$

The last reduction follows from the fact that for each unit vector $p \equiv e_k$ the corresponding inequality in (4.8) represents an $|x_k|$-multiple of the kth Oettli–Prager inequality (4.5). □

The resulting number of inequalities in the description is again exponential. But in comparison with the upper bound $8\left(\frac{3}{2}\right)^{2^{\kappa+1}}$, $\kappa = \frac{1}{2}n(n+1)$, for the final number of inequalities obtained by Fourier–Motzkin elimination (see [4]), the improvement is significant. For $n = 2$, system (4.6) comprises one inequality, and for $n = 3$ we get four inequalities. In these cases, Fourier–Motzkin elimination yields two and eight inequalities, respectively.

Example 4.3. For $n = 2$, system (4.6) is composed of only one inequality

$$b_1^{\Delta}|x_1| + b_2^{\Delta}|x_2| \geq |b_1^c x_1 + b_2^c x_2|.$$

In this two-dimensional case the set Σ_{skew} represents a polyhedral set, which is convex in each orthant (cf. [4]). The following are some particular examples:

1. For $\boldsymbol{A} = \begin{pmatrix} 0 & [1,2] \\ [-2,-1] & 0 \end{pmatrix}$, $\boldsymbol{b} = \begin{pmatrix} [0,2] \\ [-2,2] \end{pmatrix}$ we have $\Sigma = \Sigma_{skew}$ and both are bounded.
2. For $\boldsymbol{A} = \begin{pmatrix} 0 & [-1,1] \\ [-1,1] & 0 \end{pmatrix}$, $\boldsymbol{b} = \begin{pmatrix} [0,2] \\ [-2,2] \end{pmatrix}$ we have $\Sigma = \Sigma_{skew}$ and both are unbounded.

ON CONVERGENCE OF THE DQDS ALGORITHM FOR SINGULAR VALUE COMPUTATION*

KENSUKE AISHIMA†, TAKAYASU MATSUO†, KAZUO MUROTA†, AND MASAAKI SUGIHARA†

Abstract. We prove global convergence, in exact arithmetic, for the differential quotient difference algorithm that is currently implemented in LAPACK for the computation of the singular values of a bidiagonal matrix. Our results cover any shift strategy that preserves positivity. We also show that the asymptotic rate for the Johnson shift is 3/2.

Key words. singular value, bidiagonal matrix, dqds algorithm, Johnson bound

1. Introduction. Every $n \times m$ real matrix A with $\mathrm{rank}(A) = r$ can be decomposed into

$$A = U\Sigma V^{\mathrm{T}}$$

with suitable orthogonal matrices $U \in \mathbf{R}^{n\times n}$ and $V \in \mathbf{R}^{m\times m}$, where

$$\Sigma = \begin{pmatrix} D & O_{r,m-r} \\ O_{n-r,r} & O_{n-r,m-r} \end{pmatrix}, \qquad D = \mathrm{diag}(\sigma_1, \ldots, \sigma_r),$$

and $\sigma_1 \geq \cdots \geq \sigma_r > 0$. The notation $O_{k,l}$ means a $k \times l$ zero matrix. The nonzero diagonal elements $\sigma_1, \ldots, \sigma_r$ are the nonzero singular values of A, which play important roles in application areas. Accordingly, numerical methods for computing singular values are of great importance in practice.

The singular values of A are equal to the square roots of the eigenvalues of $A^{\mathrm{T}}A$ and hence an iterative computation is inevitable for singular values. Usually, the given matrix A is first transformed to a bidiagonal matrix to reduce the overall computational cost. In the case of $n \geq m$, for example, the matrix A can be transformed, with appropriate orthogonal matrices $\tilde{U} \in \mathbf{R}^{n\times n}$ and $\tilde{V} \in \mathbf{R}^{m\times m}$, as

$$\tilde{U}^{\mathrm{T}} A \tilde{V} = \begin{pmatrix} B \\ O_{n-m,m} \end{pmatrix},$$

where $B \in \mathbf{R}^{m\times m}$ is an upper bidiagonal matrix. The singular values of B coincide with those of A.

Most of the current methods for computing singular values of bidiagonal matrices are based on the QR algorithm [3]. Demmel and Kahan's improvement [2] upon the

QR algorithm, awarded the second SIAM prize in numerical linear algebra, is available as DBDSQR in LAPACK [1, 10]. The so-called differential quotient difference algorithm with shifts (dqds) was introduced by Fernando and Parlett in 1994 in [7]. The dqds algorithm has received majority support due to its accuracy, speed, and numerical stability, and is implemented as DLASQ in LAPACK. The dqds is integrated into multiple relatively robust representations (MR^3) algorithm [4, 5, 6]. The dqds algorithm that is implemented in subroutine DLASQ, and is much faster than the QR based DBDSQR, has an unusually complicated shift strategy. This strategy evolved in order to achieve efficiency both in the average case and in the worst case.

Although [7] describes various shift strategies it does not recommend any particular one, and that aspect is taken up in [13]. Consequently, [7] makes no mention of global convergence and might leave the impression that this property is in doubt. As we explain later, in this section, that fear is not warranted but the arguments are indirect and not readily accessible.

Our objective in this paper is to provide an elegant proof of global convergence of dqds in the context of exact arithmetic. The way we accomplish this task, without getting lost in the details of the strategy, is by first establishing global convergence for a sequence of nonnegative shifts that keeps the matrix entries positive (Theorem 4.1). Our analysis also enables us to give convergence rates for all of the matrix entries in terms of the accumulated shifts (Theorem 4.2). These are linear, as expected, for all of the entries except perhaps for the last row. When the accumulated shift converges to the smallest singular value squared, these last entries converge superlinearly. Furthermore we show that, if the shift is determined by the Johnson bound [9], then the asymptotic rate of convergence is 1.5 (Theorem 5.6).

Finally, we explain the present status of the convergence proof in some detail, primarily for the experts. In exact arithmetics, the dqds algorithm is equivalent to the Cholesky LR method with shifts for the eigenvalue computation of tridiagonal matrices. A convergence theorem for the latter is given by Rutishauser [15, Satz 2]. It should be noted, however, that the theorem involves a technical assumption that the case of "disorder of latent roots" is excluded. This means that the theorem applies in the (generic) case where the Cholesky LR method without shifts does not result in "disorder of latent roots." It is important to recognize that the theorem of Rutishauser [15], as it stands, is a generic convergence theorem which does not claim convergence in the exceptional case of "disorder of latent roots." In fact, this point is fully recognized by Rutishauser [14, 16] with a concrete example:

$$A = \begin{pmatrix} 5 & 4 & 1 & 1 \\ 4 & 5 & 1 & 1 \\ 1 & 1 & 4 & 2 \\ 1 & 1 & 2 & 4 \end{pmatrix}.$$

This matrix has eigenvalues 10, 5, 2, and 1, whereas the Cholesky LR method (without shifts) for this matrix converges to $\mathrm{diag}(10, 1, 5, 2)$. This example demonstrates that "disorder of latent roots" does occur, and, accordingly, Rutishauser's convergence theorem is indeed a generic convergence theorem.

For tridiagonal symmetric matrices, on the other hand, it is known in the literature (e.g., [7]) that the Cholesky LR method without shifts converges to a diagonal matrix with well-ordered diagonal elements. By combining this with Rutishauser's theorem mentioned above we can see that the Cholesky LR method with shifts is guaranteed to converge for tridiagonal symmetric matrices. This implies, in turn, that

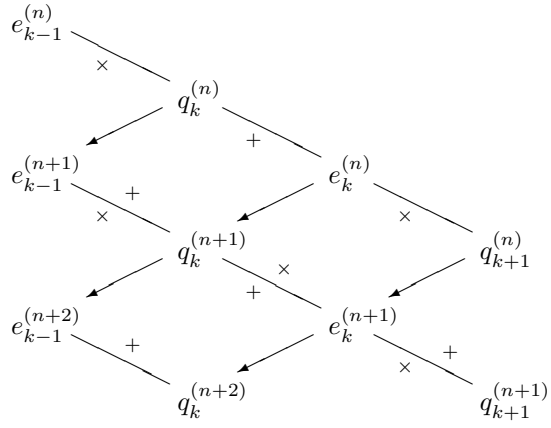

FIG. 1. *The rhombus rules.*

the dqds method is guaranteed to converge. Thus, a convergence proof of the dqds method for bidiagonal matrices can be obtained from a combination of known facts. Compared with this proof, our proof is simple, direct, and self-contained. Moreover, our proof is flexible enough to be modified to establish theorems about convergence rates, such as Theorem 5.6 for the Johnson shift.

2. Notation. Assume that the given real matrix A has already been transformed to a bidiagonal matrix

$$B = \begin{pmatrix} b_1 & b_2 & & \\ & b_3 & \ddots & \\ & & \ddots & b_{2m-2} \\ & & & b_{2m-1} \end{pmatrix}. \tag{2.1}$$

Following [7], we assume that the matrix is normalized to satisfy the following assumption.

Assumption (A). The bidiagonal elements of B are positive, i.e., $b_k > 0$ for $k = 1, 2, \ldots, 2m-1$.This assumption guarantees (see [12]) that the singular values of B are all distinct: $\sigma_1 > \cdots > \sigma_m > 0$.

In our problem setting we have assumed real matrices, whereas the singular value decomposition is also defined for complex matrices. Our restriction to real matrices is justified by the fact that any complex matrix can be transformed to a real bidiagonal matrix by, say, (complex) Householder transformations, while keeping its singular values [7].

3. The dqds algorithm. In this section, the dqds and related algorithms are summarized. Before describing the dqds algorithm, we review the pqds algorithm, which is mathematically equivalent to the dqds and serves as the main target in the subsequent theoretical analysis. The pqds algorithm is the pqd algorithm where shifts are incorporated to accelerate the convergence [8, 11, 16]. The pqd algorithm consists of the so-called [illegible] (Figure 1).

The pqds algorithm, in computer program form, is shown in Algorithm 3.1. The outermost loop is terminated when some suitable convergence criterion, say $|e_{m-1}^{(n)}| \leq \epsilon$

Algorithm 3.1 The pqds algorithm.

Initialization: $q_k^{(0)} = (b_{2k-1})^2$ $(k = 1, 2, \ldots, m)$; $e_k^{(0)} = (b_{2k})^2$ $(k = 1, 2, \ldots, m-1)$
1: **for** $n := 0, 1, \ldots$ **do**
2: choose shift $s^{(n)} (\geq 0)$
3: $e_0^{(n+1)} := 0$
4: **for** $k := 1, \ldots, m-1$ **do**
5: $q_k^{(n+1)} := q_k^{(n)} - e_{k-1}^{(n+1)} + e_k^{(n)} - s^{(n)}$
6: $e_k^{(n+1)} := e_k^{(n)} q_{k+1}^{(n)} / q_k^{(n+1)}$
7: **end for**
8: $q_m^{(n+1)} := q_m^{(n)} - e_{m-1}^{(n+1)} - s^{(n)}$
9: **end for**

for some prescribed constant $\epsilon > 0$, is satisfied. At the termination we have

$$\sigma_m{}^2 \approx q_m^{(n)} + \sum_{l=0}^{n-1} s^{(l)}, \tag{3.1}$$

and hence σ_m can be approximated by $\sqrt{q_m^{(n)} + \sum_{l=0}^{n-1} s^{(l)}}$. Then by the deflation process the problem is shrunk to an $(m-1)\times(m-1)$ problem, and the same procedure is repeated until $\sigma_{m-1}, \ldots, \sigma_1$ are obtained in turn.

It is convenient to introduce additional subdiagonal elements:

$$e_0^{(n)} = 0, \quad e_m^{(n)} = 0 \quad (n = 0, 1, \ldots) \tag{3.2}$$

to simplify the expression of the algorithm. Put

$$B^{(n)} = \begin{pmatrix} b_1^{(n)} & b_2^{(n)} & & \\ & b_3^{(n)} & \ddots & \\ & & \ddots & b_{2m-2}^{(n)} \\ & & & b_{2m-1}^{(n)} \end{pmatrix}, \tag{3.3}$$

$b_k^{(0)} = b_k$ $(k = 1, 2, \ldots, 2m-1)$, and

$$q_k^{(n)} = (b_{2k-1}^{(n)})^2 \quad (k = 1, 2, \ldots, m;\ n = 0, 1, \ldots), \tag{3.4}$$

$$e_k^{(n)} = (b_{2k}^{(n)})^2 \quad (k = 1, 2, \ldots, m-1;\ n = 0, 1, \ldots). \tag{3.5}$$

Then Algorithm 3.1 can be rewritten in terms of the Cholesky decomposition (with shifts):

$$(B^{(n+1)})^{\mathrm{T}} B^{(n+1)} = B^{(n)} (B^{(n)})^{\mathrm{T}} - s^{(n)} I, \tag{3.6}$$

where $B^{(0)} = B$. It follows that

$$(B^{(n)})^{\mathrm{T}} B^{(n)} = W^{(n)} \left((B^{(0)})^{\mathrm{T}} B^{(0)} - \sum_{l=0}^{n-1} s^{(l)} I \right) (W^{(n)})^{-1}, \tag{3.7}$$

where $W^{(n)} = (B^{(n-1)} \cdots B^{(0)})^{-\mathrm{T}}$ is a nonsingular matrix (see Lemma 3.1). Therefore the eigenvalues of $(B^{(n)})^{\mathrm{T}} B^{(n)}$ are the same as those of $(B^{(0)})^{\mathrm{T}} B^{(0)} - \sum_{l=0}^{n-1} s^{(l)} I$. In

actual computation it is often observed that $B^{(n)}$ converges to a diagonal matrix as $n \to \infty$, and then, by (3.7), the singular values of B can be obtained from the diagonal elements of $B^{(n)}$ for sufficiently large n. We give a theoretical proof for the global convergence in the next section.

The following lemma states that, if $s^{(n)} < (\sigma_{\min}^{(n)})^2$ in each iteration n, where $\sigma_{\min}^{(n)}$ is the smallest singular value of $B^{(n)}$, then the variables in the pqds algorithm are always positive so that the algorithm does not break down.

LEMMA 3.1 (positivity of the variables in the pqds algorithm). [illegible] B [illegible] (A) [illegible] $s^{(n)} < (\sigma_{\min}^{(n)})^2$ $(n = 0, 1, 2, \ldots)$ [illegible] $(B^{(n)})^{\mathrm{T}} B^{(n)}$ [illegible] $q_k^{(n)} > 0$ $(k = 1, \ldots, m)$ [illegible] $e_k^{(n)} > 0$ $(k = 1, \ldots, m-1)$ [illegible] $n = 0, 1, 2, \ldots$

[illegible]. We prove by induction. Under Assumption (A), we have $q_k^{(0)} > 0$, $e_k^{(0)} > 0$, and that $(B^{(0)})^{\mathrm{T}} B^{(0)}$ is positive definite. Suppose that $(B^{(n)})^{\mathrm{T}} B^{(n)}$ is positive definite and $q_k^{(n)} > 0$, $e_k^{(n)} > 0$. By (3.6), if $s^{(n)} < (\sigma_{\min}^{(n)})^2$, then $(B^{(n+1)})^{\mathrm{T}} B^{(n+1)}$ is positive definite because $B^{(n)}(B^{(n)})^{\mathrm{T}} - s^{(n)} I$ is positive definite. Therefore all of the diagonal elements of B are nonzero ($b_{2k-1}^{(n+1)} \neq 0$), and hence $q_k^{(n+1)} > 0$ because of (3.4). By line 6 of Algorithm 3.1, we have $e_k^{(n+1)} > 0$. □

The dqds algorithm is obtained from the pqds algorithm by introducing the auxiliary quantities $d_k^{(n+1)}$ defined as follows [7]:

$$d_1^{(n+1)} = q_1^{(n)} - s^{(n)}; \quad d_k^{(n+1)} = q_k^{(n)} - e_{k-1}^{(n+1)} - s^{(n)} \quad (k = 2, \ldots, m). \tag{3.8}$$

The resulting algorithm is presented as Algorithm 3.2. Generally, the dqds algorithm is more accurate than the pqds algorithm. Since the variables of the dqds algorithm are positive (see Lemma 3.2) and no subtractions are used in the algorithm except for computing the shifts, the numerical instability due to a loss of significant digits is less likely to happen in the dqds algorithm.

Algorithm 3.2 The dqds algorithm.

Initialization: $q_k^{(0)} = (b_{2k-1})^2$ $(k = 1, 2, \ldots, m)$; $e_k^{(0)} = (b_{2k})^2$ $(k = 1, 2, \ldots, m-1)$

1: **for** $n := 0, 1, \ldots$ **do**
2: choose shift $s^{(n)} (\geq 0)$
3: $d_1^{(n+1)} := q_1^{(n)} - s^{(n)}$
4: **for** $k := 1, \ldots, m-1$ **do**
5: $q_k^{(n+1)} := d_k^{(n+1)} + e_k^{(n)}$
6: $e_k^{(n+1)} := e_k^{(n)} q_{k+1}^{(n)} / q_k^{(n+1)}$
7: $d_{k+1}^{(n+1)} := d_k^{(n+1)} q_{k+1}^{(n)} / q_k^{(n+1)} - s^{(n)}$
8: **end for**
9: $q_m^{(n+1)} := d_m^{(n+1)}$
10: **end for**

LEMMA 3.2 (positivity of the variables in the dqds algorithm). [illegible] B [illegible] (A) [illegible] $s^{(n)} < (\sigma_{\min}^{(n)})^2$ $(n = 0, 1, 2, \ldots)$ [illegible] $(B^{(n)})^{\mathrm{T}} B^{(n)}$ [illegible] $q_k^{(n)} > 0$ $(k = 1, \ldots, m)$, $e_k^{(n)} > 0$ $(k = 1, \ldots, m-1)$ [illegible] $d_k^{(n)} > 0$ $(k = 1, \ldots, m)$ [illegible] $n = 0, 1, 2, \ldots$

[illegible]. By Lemma 3.1, we have $e_k^{(n)} > 0$ and $q_k^{(n)} > 0$. The inequality $d_k^{(n)} > 0$ is proved by contradiction as follows. If we had $d_k^{(n)} \leq 0$ for some k, then we would

have $d_{k+1}^{(n)} \leq 0$ by line 7 of Algorithm 3.2, and then $q_m^{(n)} = d_m^{(n)} \leq 0$. This contradicts $q_m^{(n)} > 0$. □

4. Convergence of the dqds. In this section,we prove that, for any matrix B that satisfies Assumption (A), the variables $q_k^{(n)}$ and $e_k^{(n)}$ in the dqds algorithm converge as far as the shift is chosen such that $0 \leq s^{(n)} < (\sigma_{\min}^{(n)})^2$, where $\sigma_{\min}^{(n)}$ is the smallest singular value of $B^{(n)}$.

The next theorem establishes the convergence of the dqds. Moreover, the theorem states that the variables $q_k^{(n)}$ converge to the square of the singular values minus the sum of the shifts, and that they are placed in the descending order.

THEOREM 4.1 (convergence of the dqds algorithm). [illegible] B [illegible] (A) [illegible] $0 \leq s^{(n)} < (\sigma_{\min}^{(n)})^2$ [illegible]

$$\sum_{n=0}^{\infty} s^{(n)} \leq {\sigma_m}^2. \tag{4.1}$$

[illegible]

$$\lim_{n\to\infty} e_k^{(n)} = 0 \quad (k = 1, 2, \ldots, m-1), \tag{4.2}$$

$$\lim_{n\to\infty} q_k^{(n)} = {\sigma_k}^2 - \sum_{n=0}^{\infty} s^{(n)} \quad (k = 1, 2, \ldots, m). \tag{4.3}$$

[illegible]

$$\lim_{n\to\infty} (B^{(n)})^{\mathrm{T}} B^{(n)} = \operatorname{diag}\left({\sigma_1}^2 - \sum_{n=0}^{\infty} s^{(n)}, \ldots, {\sigma_m}^2 - \sum_{n=0}^{\infty} s^{(n)} \right).$$

[illegible]. On the basis of the equivalence between the dqds algorithm and the pqds algorithm, we show the convergence of the pqds to prove this theorem.

By the assumption and Lemma 3.1, $(B^{(n)})^{\mathrm{T}} B^{(n)}$ is a positive-definite symmetric matrix. It then follows from (3.7) that

$$\sum_{n=0}^{N} s^{(n)} < {\sigma_m}^2 \tag{4.4}$$

holds for any $N \geq 1$. In the limit of $N \to \infty$, we obtain (4.1).

Next, we prove $\lim_{n\to\infty} e_k^{(n)} = 0$. By Lemma 3.1, we have $e_k^{(n)} > 0$. Therefore it is sufficient to prove $\sum_{n=0}^{\infty} e_k^{(n)} < +\infty$. Adding both sides of line 5 of Algorithm 3.1 for over n with k fixed, we obtain

$$q_k^{(n+1)} = q_k^{(0)} + \sum_{l=0}^{n} e_k^{(l)} - \sum_{l=0}^{n} e_{k-1}^{(l+1)} - \sum_{l=0}^{n} s^{(l)} \quad (k = 1, 2, \ldots, m). \tag{4.5}$$

Since $q_k^{(n+1)} > 0$ by Lemma 3.1, it follows that

$$\sum_{l=0}^{n} e_{k-1}^{(l+1)} < q_k^{(0)} + \sum_{l=0}^{n} e_k^{(l)} - \sum_{l=0}^{n} s^{(l)} \leq q_k^{(0)} + \sum_{l=0}^{n} e_k^{(l)} \quad (k = 1, 2, \ldots, m). \tag{4.6}$$

Setting $k = m$ in (4.6), we obtain $\sum_{l=0}^{\infty} e_{m-1}^{(l+1)} \leq q_m^{(0)}$, with the aid of (3.2). Similarly, setting $k = m-1,\ m-2, \ldots,\ 2$ in (4.6), we obtain

$$\sum_{l=0}^{\infty} e_k^{(l+1)} \leq \sum_{j=k+1}^{m} q_j^{(0)} < +\infty \qquad (k = m-1, m-2, \ldots, 1),$$

which completes the proof for $e_k^{(n)}$.

Next, we prove (4.3). By (4.5) with $n \to \infty$, we see

$$\lim_{n\to\infty} q_k^{(n)} = q_k^{(0)} + \lim_{n\to\infty} \sum_{l=0}^{n} e_k^{(l)} - \lim_{n\to\infty} \sum_{l=0}^{n} e_{k-1}^{(l+1)} - \lim_{n\to\infty} \sum_{l=0}^{n} s^{(l)}. \tag{4.7}$$

Since the right-hand side of (4.7) converges, $q_k^{(\infty)} = \lim_{n\to\infty} q_k^{(n)}$ exists. Because $\lim_{n\to\infty} e_k^{(n)} = 0$, (3.7) reads

$$\begin{aligned} &\lim_{n\to\infty} W^{(n)} \left((B^{(0)})^{\mathrm{T}} B^{(0)} - \sum_{l=0}^{n-1} s^{(l)} I \right) (W^{(n)})^{-1} \\ &= \lim_{n\to\infty} (B^{(n)})^{\mathrm{T}} B^{(n)} = \mathrm{diag}(q_1^{(\infty)}, \ldots, q_m^{(\infty)}), \end{aligned}$$

which shows the convergence of the form

$$q_k^{(\infty)} = {\sigma_{p(k)}}^2 - \sum_{l=0}^{\infty} s^{(l)} \qquad (k = 1, \ldots, m),$$

where $p(k)$ denotes a permutation of indices k $(k = 1, \ldots, m)$. It remains to show that $q_k^{(\infty)}$ are in the descending order. From line 6 of Algorithm 3.1, we have

$$e_k^{(n)} = e_k^{(0)} \prod_{l=0}^{n-1} \frac{q_{k+1}^{(l)}}{q_k^{(l+1)}} \quad (k = 1, \ldots, m-1).$$

Because all of the singular values are distinct, $\sigma_1 > \cdots > \sigma_m$, by the assumption, the limits $q_1^{(\infty)}, \ldots, q_m^{(\infty)}$ are also distinct. Since $\lim_{n\to\infty} e_k^{(n)} = 0$, we have

$$q_k^{(\infty)} > q_{k+1}^{(\infty)} \quad (k = 1, 2, \ldots, m-1).$$

This completes the proof of Theorem 4.1. □

The next theorem states the asymptotic rate of convergence of the dqds algorithm. Let us define

$$\rho_k = \frac{{\sigma_{k+1}}^2 - \sum_{n=0}^{\infty} s^{(n)}}{{\sigma_k}^2 - \sum_{n=0}^{\infty} s^{(n)}} \qquad (k = 1, \ldots, m-1), \tag{4.8}$$

$$r_k^{(n)} = \left(q_k^{(n)} + \sum_{l=0}^{n-1} s^{(l)} \right) - {\sigma_k}^2 \qquad (k = 1, \ldots, m). \tag{4.9}$$

In view of (3.1), $r_k^{(n)}$ is the error in the approximated eigenvalue of $B^{\mathrm{T}}B$. Note that $0 < \rho_k < 1$ $(k = 1, \ldots, m-2)$, and $0 < \rho_{m-1} < 1$ if ${\sigma_m}^2 - \sum_{n=0}^{\infty} s^{(n)} > 0$ and $\rho_{m-1} = 0$ if ${\sigma_m}^2 - \sum_{n=0}^{\infty} s^{(n)} = 0$.

THEOREM 4.2 (rate of convergence of the dqds algorithm). [illegible] 4.1 [illegible]

$$\lim_{n\to\infty} \frac{e_k^{(n+1)}}{e_k^{(n)}} = \rho_k \qquad (k = 1, \ldots, m-1), \tag{4.10}$$

$$\lim_{n\to\infty} \frac{r_1^{(n+1)}}{r_1^{(n)}} = \rho_1, \tag{4.11}$$

$$\lim_{n\to\infty} \frac{r_m^{(n+1)}}{r_m^{(n)}} = \rho_{m-1}. \tag{4.12}$$

[illegible] $\rho_{k-1} \neq \rho_k$ $(k = 2, \ldots, m-1)$ [illegible]

$$\lim_{n\to\infty} \frac{r_k^{(n+1)}}{r_k^{(n)}} = \max\{\rho_{k-1}, \rho_k\} \qquad (k = 2, \ldots, m-1). \tag{4.13}$$

[illegible] $e_k^{(n)}$ $(k = 1, \ldots, m-2)$ [illegible] $r_k^{(n)}$ $(k = 1, \ldots, m-1)$ [illegible] $n \to \infty$ [illegible] $e_{m-1}^{(n)}$ [illegible] $r_m^{(n)}$ [illegible] $\rho_{m-1} > 0$, [illegible] $\sigma_m^2 - \sum_{n=0}^{\infty} s^{(n)} > 0$, [illegible] $\rho_{m-1} = 0$, [illegible] $\sigma_m^2 - \sum_{n=0}^{\infty} s^{(n)} = 0$ [illegible]. From line 6 of Algorithm 3.1, we have

$$\frac{e_k^{(n+1)}}{e_k^{(n)}} = \frac{q_{k+1}^{(n)}}{q_k^{(n+1)}} \quad (k = 1, \ldots, m-1).$$

Then (4.10) is obvious from (4.3) and (4.8).

In order to prove the rest of the theorem, we first express $r_k^{(n)}$ in terms of $e_k^{(n)}$ whose asymptotic behavior is now known. From (4.5), we have

$$q_k^{(n)} + \sum_{l=0}^{n-1} s^{(l)} = q_k^{(0)} + \sum_{l=0}^{n-1} e_k^{(l)} - \sum_{l=0}^{n-1} e_{k-1}^{(l+1)}. \tag{4.14}$$

From (4.3) and (4.7), we also have

$$\sigma_k{}^2 = q_k^{(\infty)} + \sum_{l=0}^{\infty} s^{(l)} = q_k^{(0)} + \sum_{l=0}^{\infty} e_k^{(l)} - \sum_{l=0}^{\infty} e_{k-1}^{(l+1)}. \tag{4.15}$$

Subtracting (4.15) from (4.14), we obtain

$$r_k^{(n)} = \left(q_k^{(n)} + \sum_{l=0}^{n-1} s^{(l)} \right) - \sigma_k{}^2 = \sum_{l=n}^{\infty} e_{k-1}^{(l+1)} - \sum_{l=n}^{\infty} e_k^{(l)} \quad (k = 1, \ldots, m). \tag{4.16}$$

Thus, our task is now to evaluate

$$\frac{r_k^{(n+1)}}{r_k^{(n)}} = \frac{\sum_{l=n+1}^{\infty} e_{k-1}^{(l+1)} - \sum_{l=n+1}^{\infty} e_k^{(l)}}{\sum_{l=n}^{\infty} e_{k-1}^{(l+1)} - \sum_{l=n}^{\infty} e_k^{(l)}} \tag{4.17}$$

for $k = 1, \dots, m$ in the limit of $n \to \infty$. When $k = 1$, $e_0^{(l)}$ vanishes due to (3.2), and thus

$$\lim_{n\to\infty} \frac{r_1^{(n+1)}}{r_1^{(n)}} = \lim_{n\to\infty} \left(\frac{e_1^{(n)}}{\sum_{l=n}^{\infty} e_1^{(l)}} \cdot \frac{\sum_{l=n+1}^{\infty} e_1^{(l)}}{e_1^{(n+1)}} \cdot \frac{e_1^{(n+1)}}{e_1^{(n)}} \right) = \rho_1, \tag{4.18}$$

which is the claim (4.10). In the calculation above, we used the identity

$$\lim_{n\to\infty} \frac{\sum_{l=n}^{\infty} e_k^{(l)}}{e_k^{(n)}} = \sum_{l=0}^{\infty} \lim_{n\to\infty} \left(\frac{e_k^{(n+l)}}{e_k^{(n)}} \right) = \sum_{l=0}^{\infty} (\rho_k)^l = \frac{1}{1-\rho_k} \quad (k = 1, \dots, m-1), \tag{4.19}$$

which is obtained from (4.10). The claim (4.12) can be proved in a similar manner.

In the cases where $k = 2, \dots, m-1$, the assumption $\rho_{k-1} \neq \rho_k$ $(k = 2, \dots, m-1)$ is required. First, let us fix some k and consider the case $\rho_{k-1} > \rho_k$. In this case, an identity

$$\lim_{n\to\infty} \frac{e_k^{(n)}}{e_{k-1}^{(n)}} = 0 \tag{4.20}$$

holds, because

$$\lim_{n\to\infty} \left\{ \left(\frac{e_k^{(n+1)}}{e_{k-1}^{(n+1)}} \right) \cdot \left(\frac{e_k^{(n)}}{e_{k-1}^{(n)}} \right)^{-1} \right\} = \lim_{n\to\infty} \left\{ \left(\frac{e_k^{(n+1)}}{e_k^{(n)}} \right) \cdot \left(\frac{e_{k-1}^{(n)}}{e_{k-1}^{(n+1)}} \right) \right\} = \frac{\rho_k}{\rho_{k-1}} < 1.$$

Therefore, from (4.19) and (4.20) we obtain

$$\lim_{n\to\infty} \frac{\sum_{l=n}^{\infty} e_k^{(l)}}{e_{k-1}^{(n)}} = \lim_{n\to\infty} \left(\frac{e_k^{(n)}}{e_{k-1}^{(n)}} \cdot \frac{\sum_{l=n}^{\infty} e_k^{(l)}}{e_k^{(n)}} \right) = 0, \tag{4.21}$$

which then yields

$$\begin{aligned} \lim_{n\to\infty} \frac{\sum_{l=n+1}^{\infty} e_{k-1}^{(l+1)} - \sum_{l=n+1}^{\infty} e_k^{(l)}}{e_{k-1}^{(n+1)}} &= \lim_{n\to\infty} \left(\frac{\sum_{l=n+1}^{\infty} e_{k-1}^{(l)}}{e_{k-1}^{(n+1)}} - 1 - \frac{\sum_{l=n+1}^{\infty} e_k^{(l)}}{e_{k-1}^{(n+1)}} \right) \\ &= \frac{1}{1-\rho_{k-1}} - 1 \\ &= \frac{\rho_{k-1}}{1-\rho_{k-1}} \end{aligned}$$

with (4.19). Finally, we obtain

$$\begin{aligned} \lim_{n\to\infty} \frac{r_k^{(n+1)}}{r_k^{(n)}} &= \lim_{n\to\infty} \frac{\sum_{l=n+1}^{\infty} e_{k-1}^{(l+1)} - \sum_{l=n+1}^{\infty} e_k^{(l)}}{\sum_{l=n}^{\infty} e_{k-1}^{(l+1)} - \sum_{l=n}^{\infty} e_k^{(l)}} \\ &= \lim_{n\to\infty} \left\{ \frac{(\sum_{l=n+1}^{\infty} e_{k-1}^{(l+1)} - \sum_{l=n+1}^{\infty} e_k^{(l)})/e_{k-1}^{(n+1)}}{(\sum_{l=n}^{\infty} e_{k-1}^{(l+1)} - \sum_{l=n}^{\infty} e_k^{(l)})/e_{k-1}^{(n)}} \cdot \frac{e_{k-1}^{(n+1)}}{e_{k-1}^{(n)}} \right\} \\ &= \rho_{k-1}. \end{aligned} \tag{4.22}$$

When $\rho_{k-1} < \rho_k$, a similar argument leads us to the same conclusion with ρ_{k-1} replaced by ρ_k. This completes the proof. □

. . . . 1. When $\rho_{k-1} = \rho_k$, considering the ratio (4.17) does not make sense, since the numerator and the denominator can oscillate around zero. Instead, we can show a weaker claim as follows. From (4.16) we have

$$r_k^{(n)} = \frac{\sum_{l=n+1}^{\infty} e_{k-1}^{(l)}}{e_{k-1}^{(n+1)}} \cdot e_{k-1}^{(n+1)} - \frac{\sum_{l=n}^{\infty} e_k^{(l)}}{e_k^{(n)}} \cdot e_k^{(n)}.$$

Moreover, from (4.10) we see, for any small $\epsilon > 0$,

$$|e_{k-1}^{(n)}| \le O((\rho_{k-1} + \epsilon)^n), \quad |e_k^{(n)}| \le O((\rho_k + \epsilon)^n).$$

Thus, in case of $\rho_{k-1} = \rho_k$, we obtain

$$|r_k^{(n)}| \le O((\rho_k + \epsilon)^n) \qquad (k = 2, \ldots, m-1)$$

from (4.19). That is, the convergence is at least linear and can be even better occasionally.

5. Convergence rate of the dqds with the Johnson bound. In this section, we prove that the asymptotic rate of convergence of the dqds algorithm is 1.5 if the shift is determined by the Johnson bound [9]. In the proofs we will work with the pqds in place of the dqds, as we did in the previous section.

Though the Johnson bound is valid for a general matrix, we present here its version for a bidiagonal matrix B.

LEMMA 5.1 (Johnson bound [9]). . . . . B . . . . . (2.1) . . .

$$\lambda = \min_{k=1,\ldots,m} \left\{ |\, b_{2k-1} \,| - \frac{|\, b_{2k-2} \,| + |\, b_{2k} \,|}{2} \right\},$$

. . $b_0 = b_{2m} = 0$ . . . . . σ_m . . . . . B . . . $\sigma_m \ge \lambda$ . . . . . $(b_2, b_4, \ldots, b_{2m-2})$ . . . . . $\sigma_m > \lambda$

With reference to (3.3), (3.4), and (3.5), we define the shift by the Johnson bound as follows:

$$\lambda^{(n)} = \min_{k=1,\ldots,m} \left\{ \sqrt{q_k^{(n)}} - \frac{1}{2} \left(\sqrt{e_{k-1}^{(n)}} + \sqrt{e_k^{(n)}} \right) \right\}, \tag{5.1}$$

$$s^{(n)} = \left(\max\{\lambda^{(n)},\ 0\} \right)^2. \tag{5.2}$$

This choice of the shift guarantees the condition $0 \le s^{(n)} < (\sigma_{\min}^{(n)})^2$ in each iteration n, and hence the dqds is convergent by Theorem 4.1. The precise rate of convergence can be revealed through a scrutiny of the shift.

The next lemma shows that the Johnson bound $\lambda^{(n)}$ is determined solely by $q_m^{(n)}$ and $e_{m-1}^{(n)}$ when n is large enough. As a corollary of this fact we see that $q_m^{(n)}$ approaches zero.

LEMMA 5.2. . . . . (A) . . . . . (5.2) . . . . . n . . . . .

$$\lambda^{(n)} = \sqrt{q_m^{(n)}} - \frac{1}{2}\sqrt{e_{m-1}^{(n)}}. \tag{5.3}$$

(5.1) $k = m$. Let $k < m$, and consider the identity

$$\left[\sqrt{q_k^{(n)}} - \frac{1}{2}\left(\sqrt{e_{k-1}^{(n)}} + \sqrt{e_k^{(n)}}\right)\right] - \left[\sqrt{q_m^{(n)}} - \frac{1}{2}\left(\sqrt{e_{m-1}^{(n)}} + \sqrt{e_m^{(n)}}\right)\right]$$
$$= \left(\sqrt{q_k^{(n)}} - \sqrt{q_m^{(n)}}\right) - \frac{1}{2}\left(\sqrt{e_{k-1}^{(n)}} + \sqrt{e_k^{(n)}} - \sqrt{e_{m-1}^{(n)}} - \sqrt{e_m^{(n)}}\right).$$

From Theorem 4.1, the first term on the right-hand side remains positive:

$$\lim_{n\to\infty}\left(\sqrt{q_k^{(n)}} - \sqrt{q_m^{(n)}}\right) = \sqrt{{\sigma_k}^2 - \sum_{n=0}^{\infty} s^{(n)}} - \sqrt{{\sigma_m}^2 - \sum_{n=0}^{\infty} s^{(n)}} > 0,$$

while the second term vanishes since $\lim_{n\to\infty} e_k^{(n)} = 0$ for each k. Thus the minimum on the right-hand side of (5.1) is attained at $k = m$. □

LEMMA 5.3. 5.2

$$\sum_{n=0}^{\infty} s^{(n)} = {\sigma_m}^2, \tag{5.4}$$

$$\lim_{n\to\infty} q_k^{(n)} = {\sigma_k}^2 - {\sigma_m}^2 \quad (k = 1, \ldots, m-1); \quad \lim_{n\to\infty} q_m^{(n)} = 0. \tag{5.5}$$

. By (5.3) and (4.2), $\lim_{n\to\infty} \lambda^{(n)} = \lim_{n\to\infty} \sqrt{q_m^{(n)}} \geq 0$, and hence

$$\lim_{n\to\infty} s^{(n)} = \lim_{n\to\infty} (\max\{\lambda^{(n)}, 0\})^2 = \lim_{n\to\infty} q_m^{(n)}.$$

Since $\lim_{n\to\infty} s^{(n)} = 0$ by (4.1), we have $\lim_{n\to\infty} q_m^{(n)} = 0$. This, together with (4.3), proves (5.4) and (5.5). □

The next lemma shows $\lambda^{(n)} > 0$ for all sufficiently large n.

LEMMA 5.4 (positivity of the Johnson bound in the dqds). 5.2 N $\lambda^{(n)} > 0$ $n > N$

. The proof consists of showing two facts: (i) For every integer N', there exists $n > N'$ such that $\lambda^{(n)} > 0$; (ii) There exists an integer N'' such that, for all $n > N''$, $\lambda^{(n)} > 0$ implies $\lambda^{(n+1)} > 0$.

(i) The proof is done by contradiction. Suppose that there exists some N' such that $\lambda^{(n)} \leq 0$ for every $n > N'$. Then $s^{(n)} = 0$ (for all $n > N'$), and by (4.3) and (4.4) in Theorem 4.1, we have

$$\lim_{n\to\infty} q_m^{(n)} = {\sigma_m}^2 - \sum_{n=0}^{\infty} s^{(n)} = {\sigma_m}^2 - \sum_{n=0}^{N'} s^{(n)} > 0,$$

which contradicts Lemma 5.3.

(ii) Assume $\lambda^{(n)} > 0$ for some large n such that (5.3) holds. In this case, $s^{(n)} =$

$(\lambda^{(n)})^2$ and

$$
\begin{aligned}
q_m^{(n+1)} &= q_m^{(n)} - e_{m-1}^{(n+1)} - s^{(n)} \\
&= \sqrt{e_{m-1}^{(n)} q_m^{(n)}} - e_{m-1}^{(n+1)} - \frac{1}{4} e_{m-1}^{(n)} \\
&> \frac{1}{2} \sqrt{e_{m-1}^{(n)} q_m^{(n)}} - e_{m-1}^{(n+1)} \\
&= \sqrt{e_{m-1}^{(n+1)}} \left(\frac{1}{2} \sqrt{q_{m-1}^{(n+1)}} - \sqrt{e_{m-1}^{(n+1)}} \right),
\end{aligned} \tag{5.6}
$$

where line 5 of Algorithm 3.1 is used in the first equality, (5.3) in the second equality, the assumption $\lambda^{(n)} > 0$ $\left(\text{i.e.,} \sqrt{q_m^{(n)}} > \frac{1}{2}\sqrt{e_{m-1}^{(n)}}\right)$ in the inequality, and line 6 of Algorithm 3.1 in the last equality. From (5.6) it follows that

$$
\sqrt{q_{m-1}^{(n+1)}} > \frac{5}{2} \sqrt{e_{m-1}^{(n+1)}} \implies q_m^{(n+1)} > \frac{1}{4} e_{m-1}^{(n+1)} \iff \lambda^{(n+1)} > 0.
$$

Since $\lim_{n\to\infty} q_{m-1}^{(n+1)} > 0$ and $\lim_{n\to\infty} e_{m-1}^{(n+1)} = 0$, there exists an integer N'' such that the first inequality holds for all $n > N''$. □

Using Lemmas 5.2 and 5.4, we see that for sufficiently large n the shift is given as follows.

LEMMA 5.5 (shift in the dqds). [illegible] 5.2 [illegible]

$$
s^{(n)} = (\lambda^{(n)})^2 = q_m^{(n)} - \sqrt{e_{m-1}^{(n)} q_m^{(n)}} + \frac{1}{4} e_{m-1}^{(n)} \; > 0 \tag{5.7}
$$

[illegible] n

We are now in position to prove that the rate of convergence of the dqds is 1.5. The next theorem refers only to the lower right two elements of $B^{(n)}$, and the error in the approximation of the smallest eigenvalue of $B^{\mathrm{T}}B$. This is sufficient from the practical point of view since whenever the lower right elements converge to zero, the deflation is applied to reduce the matrix size.

THEOREM 5.6 (rate of convergence of the dqds). [illegible] B [illegible] (A) [illegible]

$$
\lim_{n\to\infty} \frac{e_{m-1}^{(n+1)}}{(e_{m-1}^{(n)})^{3/2}} = \frac{1}{\sqrt{{\sigma_{m-1}}^2 - {\sigma_m}^2}}, \tag{5.8}
$$

$$
\lim_{n\to\infty} \frac{q_m^{(n+1)}}{(q_m^{(n)})^{3/2}} = \frac{1}{\sqrt{{\sigma_{m-1}}^2 - {\sigma_m}^2}}, \tag{5.9}
$$

$$
\lim_{n\to\infty} \frac{r_m^{(n+1)}}{(r_m^{(n)})^{3/2}} = \frac{1}{\sqrt{{\sigma_{m-1}}^2 - {\sigma_m}^2}}. \tag{5.10}
$$

[illegible] 1.5 [illegible] (3.3) [illegible] $B^{(n)}$ [illegible] $b_{2m-2}^{(n)}$ [illegible] $b_{2m-1}^{(n)}$ [illegible] 0 [illegible] 1.5 [illegible]

[illegible] $B^{\mathrm{T}}B$ [illegible] 0 [illegible]

$$\lim_{n\to\infty} \frac{\sqrt{e_{m-1}^{(n)}}}{q_m^{(n)}} = \frac{1}{\sqrt{{\sigma_{m-1}}^2 - {\sigma_m}^2}}, \tag{5.11}$$

$$\lim_{n\to\infty} \frac{r_m^{(n)}}{e_{m-1}^{(n)}} = 0. \tag{5.12}$$

[illegible] First, we compute the rate of convergence of $e_{m-1}^{(n)}$. By Lemma 5.5 the shift is determined by (5.7) for sufficiently large n, and we have

$$q_m^{(n+1)} = \sqrt{e_{m-1}^{(n)} q_m^{(n)}} - e_{m-1}^{(n+1)} - \frac{1}{4} e_{m-1}^{(n)} \tag{5.13}$$

from the second equality in (5.6). We also have

$$q_m^{(n+1)} = q_{m-1}^{(n+2)} e_{m-1}^{(n+2)} / e_{m-1}^{(n+1)}, \qquad q_m^{(n)} = q_{m-1}^{(n+1)} e_{m-1}^{(n+1)} / e_{m-1}^{(n)}, \tag{5.14}$$

from the 6th line of Algorithm 3.1. Thus we have

$$\begin{aligned} \frac{e_{m-1}^{(n+2)}}{(e_{m-1}^{(n+1)})^{3/2}} &= \frac{q_m^{(n+1)}}{q_{m-1}^{(n+2)}} \cdot \sqrt{\frac{q_{m-1}^{(n+1)}}{e_{m-1}^{(n)} q_m^{(n)}}} \\ &= \frac{\sqrt{q_{m-1}^{(n+1)}}}{q_{m-1}^{(n+2)}} \left(1 - \frac{e_{m-1}^{(n+1)}}{\sqrt{e_{m-1}^{(n)} q_m^{(n)}}} - \frac{e_{m-1}^{(n)}}{4\sqrt{e_{m-1}^{(n)} q_m^{(n)}}} \right) \\ &= \frac{\sqrt{q_{m-1}^{(n+1)}}}{q_{m-1}^{(n+2)}} \left(1 - \frac{\sqrt{e_{m-1}^{(n+1)}}}{\sqrt{q_{m-1}^{(n+1)}}} - \frac{1}{4\sqrt{q_{m-1}^{(n+1)}}} \cdot \frac{e_{m-1}^{(n)}}{\sqrt{e_{m-1}^{(n+1)}}} \right). \end{aligned} \tag{5.15}$$

The first equality is from (5.14), the second one is from (5.13), and the last one is from the second equation of (5.14). In the rest of this paragraph, we prove that the value in the parentheses on the right-hand side of (5.15) converges to 1. First, note that $\lim_{n\to\infty} q_{m-1}^{(n+1)} > 0$ by (5.5). By (4.2), $\lim_{n\to\infty} e_{m-1}^{(n+1)} = 0$, and hence the second term in the parentheses converges to 0. As for the third term, we see

$$e_{m-1}^{(n+1)} = \frac{e_{m-1}^{(n)}}{q_{m-1}^{(n+1)}} \cdot q_m^{(n)} \geq \frac{\sqrt{q_{m-1}^{(n)}} - 2\sqrt{e_{m-1}^{(n)}}}{2q_{m-1}^{(n+1)}} \left(e_{m-1}^{(n)} \right)^{3/2}$$

from (5.14) and (5.6) (with $n+1$ replaced by n). Thus, from (4.2) and (5.5) we see that

$$\lim_{n\to\infty} \frac{e_{m-1}^{(n)}}{\sqrt{e_{m-1}^{(n+1)}}} \leq \lim_{n\to\infty} \left(\frac{\sqrt{q_{m-1}^{(n)}} - 2\sqrt{e_{m-1}^{(n)}}}{2q_{m-1}^{(n+1)}} \right)^{-1/2} \left(e_{m-1}^{(n)} \right)^{1/4} = 0,$$

and hence the value in the parentheses on the right-hand side of (5.15) converges to 1. By using this, together with (5.5), we obtain the claim (5.8):

$$\lim_{n\to\infty} \frac{e_{m-1}^{(n+1)}}{(e_{m-1}^{(n)})^{3/2}} = \lim_{n\to\infty} \frac{\sqrt{q_{m-1}^{(n+1)}}}{q_{m-1}^{(n+2)}} = \frac{1}{\sqrt{{\sigma_{m-1}}^2 - {\sigma_m}^2}}. \tag{5.16}$$

Next, by the second equation in (5.14), and by (5.5) and (5.16), we obtain the claim (5.11):

$$\lim_{n\to\infty} \frac{q_m^{(n)}}{\sqrt{e_{m-1}^{(n)}}} = \lim_{n\to\infty} q_{m-1}^{(n+1)} \frac{e_{m-1}^{(n+1)}}{(e_{m-1}^{(n)})^{3/2}} = \sqrt{{\sigma_{m-1}}^2 - {\sigma_m}^2},$$

which then immediately yields the claim (5.9):

$$\begin{aligned}\lim_{n\to\infty} \frac{q_m^{(n+1)}}{(q_m^{(n)})^{3/2}} &= \lim_{n\to\infty} \frac{q_m^{(n+1)}}{\sqrt{e_{m-1}^{(n+1)}}} \left(\frac{q_m^{(n)}}{\sqrt{e_{m-1}^{(n)}}}\right)^{-3/2} \left(\frac{e_{m-1}^{(n+1)}}{(e_{m-1}^{(n)})^{3/2}}\right)^{1/2} \\ &= ({\sigma_{m-1}}^2 - {\sigma_m}^2)^{1/2-3/4-1/4} \\ &= ({\sigma_{m-1}}^2 - {\sigma_m}^2)^{-1/2}.\end{aligned}$$

Finally, we prove the claims concerning $r_m^{(n)}$. By (3.2), (4.16), and (4.19), we see

$$\lim_{n\to\infty} \frac{r_m^{(n)}}{e_{m-1}^{(n+1)}} = \lim_{n\to\infty} \frac{\sum_{l=n}^{\infty} e_{m-1}^{(l+1)}}{e_{m-1}^{(n+1)}} = \frac{1}{1-\rho_{m-1}} = 1, \tag{5.17}$$

where in the last equality we used the fact that $\rho_{m-1} = 0$, which follows from (4.8) and (5.4). Then, by (4.10) we immediately obtain the claim (5.12):

$$\lim_{n\to\infty} \frac{r_m^{(n)}}{e_{m-1}^{(n)}} = \lim_{n\to\infty} \left(\frac{e_{m-1}^{(n+1)}}{e_{m-1}^{(n)}} \cdot \frac{r_m^{(n)}}{e_{m-1}^{(n+1)}}\right) = \rho_{m-1} = 0.$$

The claim (5.10) also follows from (5.17) as

$$\lim_{n\to\infty} \frac{r_m^{(n+1)}}{(r_m^{(n)})^{3/2}} = \lim_{n\to\infty} \frac{e_{m-1}^{(n+2)}}{(e_{m-1}^{(n+1)})^{3/2}} = \frac{1}{\sqrt{{\sigma_{m-1}}^2 - {\sigma_m}^2}}. \qquad \square$$

6. A numerical experiment. In this section, a simple numerical experiment is presented to illustrate the theory. We consider an $m \times m$ symmetric tridiagonal matrix

$$T = \begin{pmatrix} a & b & & 0 \\ b & a & \ddots & \\ & \ddots & \ddots & b \\ 0 & & b & a \end{pmatrix}, \tag{6.1}$$

the eigenvalues of which are

$$a + 2b\cos\left(\frac{\pi k}{m+1}\right) \quad (k = 1, \ldots, m).$$

The parameters are taken as $m = 10$, $a = 1.0$, and $b = 0.2$, which makes T positive definite. The dqds algorithm is applied to the bidiagonal matrix B obtained from the Cholesky decomposition of T.

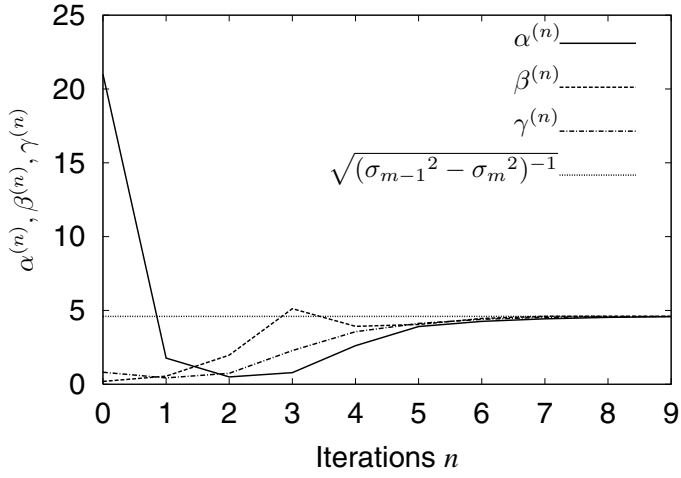

FIG. 2. *Convergence of* $\alpha^{(n)}$, $\beta^{(n)}$, *and* $\gamma^{(n)}$.

TABLE 1
Critical index k^* *for the Johnson bound* (5.1) *in the dqds algorithm.*

n	0	1	2	3	4	5	6	7	8	9
k^*	9	9	10	10	10	10	10	10	10	10

In view of Theorem 5.6, we define

$$\alpha^{(n)} = \frac{e_{m-1}^{(n+1)}}{(e_{m-1}^{(n)})^{3/2}}, \qquad \beta^{(n)} = \frac{q_m^{(n+1)}}{(q_m^{(n)})^{3/2}}, \qquad \gamma^{(n)} = \frac{r_m^{(n+1)}}{(r_m^{(n)})^{3/2}},$$

which should converge to the constant $1/\sqrt{({\sigma_{m-1}}^2 - {\sigma_m}^2)}$ according to the theory. The result is shown in Figure 2. The solid line (——) shows $\alpha^{(n)}$, the dashed line (- - - -) shows $\beta^{(n)}$, and the dashed-dotted line (- · - · -) shows $\gamma^{(n)}$. The dotted line (· · · · · ·) shows $1/\sqrt{({\sigma_{m-1}}^2 - {\sigma_m}^2)} = 4.60$ in this problem setting. The solid line, the dashed line, and the dashed-dotted line approach the dotted line in Figure 2.

In Figure 3, $e_{m-1}^{(n)}$, $q_m^{(n)}$, and $r_m^{(n)}$ are plotted in the single logarithmic graph. The solid line shows $e_{m-1}^{(n)}$, the dashed line shows $q_m^{(n)}$, and the dashed-dotted line shows $r_m^{(n)}$. The variables $e_{m-1}^{(n)}$, $q_m^{(n)}$, and $r_m^{(n)}$ converge to zero. By Figures 2 and 3 we can say that the rate of convergence is 1.5. Table 1 presents the index $k = k^*$, which attains the minimum on the right-hand side of (5.1). If $\lambda^{(n)} < 0$, then k^* is defined to be 0. The result shows that $k^* = m$ for $n \geq 2$, which is consistent with Lemma 5.5.

Acknowledgments. The authors are thankful to Yusaku Yamamoto for a number of helpful comments, and also to the anonymous referees for their constructive suggestions which improved this presentation.

LOW RANK PERTURBATION OF WEIERSTRASS STRUCTURE*

FERNANDO DE TERÁN†, FROILÁN M. DOPICO†, AND JULIO MORO†

Abstract. Let $A_0 + \lambda A_1$ be a regular matrix pencil, and let λ_0 be one of its finite eigenvalues having g elementary Jordan blocks in the Weierstrass canonical form. We show that for most matrices B_0 and B_1 with $\operatorname{rank}(B_0+\lambda_0 B_1) < g$ there are $g-\operatorname{rank}(B_0+\lambda_0 B_1)$ Jordan blocks corresponding to the eigenvalue λ_0 in the Weierstrass form of the perturbed pencil $A_0+B_0+\lambda(A_1+B_1)$. If $\operatorname{rank}(B_0+\lambda_0 B_1)+\operatorname{rank}(B_1)$ does not exceed the number of λ_0-Jordan blocks in $A_0+\lambda A_1$ of dimension greater than one, then the λ_0-Jordan blocks of the perturbed pencil are the $g-\operatorname{rank}(B_0+\lambda_0 B_1)-\operatorname{rank}(B_1)$ smallest λ_0-Jordan blocks of $A_0+\lambda A_1$, together with $\operatorname{rank}(B_1)$ blocks of dimension one. Otherwise, all $g-\operatorname{rank}(B_0+\lambda_0 B_1)$ λ_0-Jordan blocks of the perturbed pencil are of dimension one. This happens for any pair of matrices B_0 and B_1 except those in a proper algebraic submanifold in the set of matrix pairs. If $A_0 + \lambda A_1$ has an infinite eigenvalue, then the corresponding result follows from considering the zero eigenvalue of the dual pencils $A_1 + \lambda A_0$ and $A_1 + B_1 + \lambda(A_0 + B_0)$.

1. Introduction.

The change of the Jordan structure of a matrix A under perturbations B of low rank has been recently studied by several authors [5, 7, 8, 9, 10]. It is known that if λ_0 is one of the eigenvalues of A having g elementary Jordan blocks in the Jordan canonical form of A, then [illegible] B satisfying $\operatorname{rank}(B) < g$, the Jordan blocks of $A + B$ with eigenvalue λ_0 are just the $g - \operatorname{rank}(B)$ smallest Jordan blocks of A with eigenvalue λ_0. As far as we know, this generic behavior was first proved in [5] and again in [7] and [8, 9, 10]. The proof in [7] uses only elementary linear algebra results, and allows us to explicitly characterize the set of perturbation matrices B for which this generic behavior does not happen. This is done through a scalar determinantal equation involving B and some of the λ_0-eigenvectors of A. Thus, this behavior can be properly termed as [illegible], since it happens for any perturbation matrix B except those belonging to a proper algebraic submanifold in the set of $n \times n$ matrices of given rank. It is interesting to note that the result in [5] remains valid for infinite dimensional compact linear operators in Banach spaces.

The purpose of this paper is to study which is the generic change of the Weierstrass canonical form [4] of a regular $n \times n$ pencil of matrices $A_0 + \lambda A_1$ under a low rank perturbation $B_0 + \lambda B_1$. We will see that this change is rather different from the change described above for matrices. The regular matrix pencil $A_0+\lambda A_1$ may have an [illegible] eigenvalue, whose Jordan blocks in the Weiertrass canonical form are precisely the Jordan blocks associated with the [illegible] eigenvalue in the Weierstrass form of the [illegible] pencil $A_1 + \lambda A_0$. Therefore, we may focus on finite eigenvalues of $A_0 + \lambda A_1$. The perturbation results for the infinite eigenvalue follow from results for the zero eigenvalue of the dual pencil.

Let λ_0 be a finite eigenvalue with geometric multiplicity g of the regular $n \times n$ matrix pencil $A_0 + \lambda A_1$. Recall that a pencil is regular if the polynomial $\det(A_0 + \lambda A_1)$ in λ is not identically zero, and that the geometric multiplicity of λ_0 is $g = \dim \ker(A_0 + \lambda_0 A_1)$, where ker denotes the null space. The elementary inequalities $\operatorname{rank}(C + D) \leq \operatorname{rank}(C) + \operatorname{rank}(D)$ and $\operatorname{rank}(C) \leq \operatorname{rank}(C + D) + \operatorname{rank}(D)$, valid for any pair of matrices C and D, lead to

$$\operatorname{rank}(A_0 + \lambda_0 A_1 + B_0 + \lambda_0 B_1) \leq \operatorname{rank}(A_0 + \lambda_0 A_1) + \operatorname{rank}(B_0 + \lambda_0 B_1),$$
$$\operatorname{rank}(A_0 + \lambda_0 A_1) \leq \operatorname{rank}(A_0 + \lambda_0 A_1 + B_0 + \lambda_0 B_1) + \operatorname{rank}(B_0 + \lambda_0 B_1).$$

Combining both inequalities, one gets

$$g - \operatorname{rank}(B_0 + \lambda_0 B_1) \leq \dim \ker(A_0 + \lambda_0 A_1 + B_0 + \lambda_0 B_1) \leq g + \operatorname{rank}(B_0 + \lambda_0 B_1). \tag{1.1}$$

Therefore, whenever

$$\operatorname{rank}(B_0 + \lambda_0 B_1) < g, \tag{1.2}$$

the eigenvalue λ_0 of $A_0 + \lambda A_1$ stays as an eigenvalue of the perturbed pencil

$$A_0 + B_0 + \lambda(A_1 + B_1). \tag{1.3}$$

As a consequence, by "low" rank perturbation we will mean in what follows that B_0 and B_1 satisfy (1.2), a condition which depends on the particular eigenvalue λ_0 we are considering. It is well known that for a regular pencil $L_0 + \lambda L_1$ the number of Jordan blocks associated with λ_0 in its Weierstrass canonical form is equal to $\dim \ker(L_0 + \lambda_0 L_1)$. Therefore, assuming that (1.3) is still regular, (1.1) implies that the perturbation $B_0 + \lambda B_1$ can destroy at most $\operatorname{rank}(B_0 + \lambda_0 B_1)$ Jordan blocks of $A_0 + \lambda A_1$, and can create at most $\operatorname{rank}(B_0 + \lambda_0 B_1)$ new Jordan blocks associated with the finite eigenvalue λ_0 of $A_0 + \lambda A_1$. This allows many different choices for the number and dimensions of the Jordan blocks appearing in the Weierstrass form of $A_0 + B_0 + \lambda(A_1 + B_1)$. The goal of this work is to find out which is the generic behavior in this respect.[1]

The result we present depends on two quantities [illegible] λ_0, namely

$$\rho_0 = \operatorname{rank}(B_0 + \lambda_0 B_1) \quad \text{and} \quad \rho_1 = \operatorname{rank}(B_1).$$

Assuming that condition (1.2) holds, we will prove that [illegible] B_0, B_1 there are precisely $g - \rho_0$ Jordan blocks associated with λ_0 in the Weierstrass canonical form of the perturbed pencil (1.3). Moreover, if we denote by d_0 the number of Jordan blocks in $A_0 + \lambda A_1$ with eigenvalue λ_0 of dimension greater than one, we will prove that whenever $\rho_0 + \rho_1 \leq d_0$, the largest ρ_0 Jordan blocks of $A_0 + \lambda A_1$ associated with λ_0 disappear, and the second-largest ρ_1 blocks of λ_0 turn into 1×1 blocks, while the rest of the Jordan blocks of λ_0 in $A_0 + \lambda A_1$ remain as Jordan blocks in the perturbed pencil (1.3). If $\rho_0 + \rho_1 > d_0$, then there will be only 1×1 blocks corresponding to λ_0 in the Weierstrass form of (1.3). This generic behavior coincides with the one previously described for low rank perturbations of the Jordan canonical form of matrices in the case $B_1 = 0$, while it is rather different when $B_1 \neq 0$. [illegible]

[1] The assumption that $A_0 + B_0 + \lambda(A_1 + B_1)$ is a regular pencil holds except for very particular choices of B_0 and B_1.

Inequality (1.1) makes clear that $B_0 + \lambda_0 B_1$ is bound to play a relevant role in the perturbation of the Weierstrass structure, since it determines the geometric multiplicity of λ_0 in (1.3). To understand why B_1 plays a separate role on its own, recall that a Jordan chain of $A_0 + \lambda A_1$ of length s associated with λ_0 satisfies the equations $(A_0 + \lambda_0 A_1)v_1 = 0$ and $(A_0 + \lambda_0 A_1)v_k = A_1 v_{k-1}$ for $2 \leq k \leq s$. Therefore, it is expected that perturbing A_1 affects to the length of the Jordan chains. In plain words, the generic behavior described above corresponds to a cooperation between $B_0 + \lambda_0 B_1$ and B_1 to destroy some of the blocks, and to decrease the dimension of as many of the largest Jordan blocks as possible, while still fulfilling the constraint (1.1) on the geometric multiplicity.

The results obtained in the present paper, as those in [7], are valid for perturbations of [illegible] satisfying the low rank condition (1.2), i.e., they are not first-order perturbation results. Notice also that we are not paying attention to the perturbation of the eigenvalues corresponding to the destroyed Jordan blocks. First order perturbation results for this problem are enumerated in [6] for general matrix polynomials, and, more recently, in [2]. In [13] first order multiparametric perturbations have been considered for multiple semisimple eigenvalues. Several perturbation bounds, valid for perturbations of finite size, appear in [11], but they do not apply to multiple defective eigenvalues, except in the case of some Gerschgorin-like inclusion regions.

Now, we summarize the [illegible] of a regular pencil [4], and introduce some notation to be used throughout the paper. For any regular $n \times n$ complex matrix pencil $A_0 + \lambda A_1$ having λ_0 as one of its eigenvalues, there exist nonsingular $n \times n$ matrices P and Q, independent of λ, such that

$$Q(A_0 + \lambda A_1)P = \operatorname{diag}(J_{n_1}(-\lambda_0), \ldots, J_{n_g}(-\lambda_0), \widetilde{J}, I_\infty) + \lambda \operatorname{diag}(I_1, I_2, N), \tag{1.4}$$

where $\operatorname{diag}(C, E)$ denotes a block diagonal matrix with square diagonal blocks C and E; $J_{n_i}(-\lambda_0)$ stands for a Jordan block of dimension n_i with $-\lambda_0$ on the main diagonal; $\widetilde{J}$ is a matrix in Jordan canonical form corresponding to the other finite eigenvalues of the pencil; and N is a matrix in Jordan canonical form whose eigenvalues are all equal to zero. N contains the spectral structure of the infinite eigenvalue of the pencil. Finally, I_1, I_2 and I_∞ are identity matrices of matching dimensions to those of $\operatorname{diag}(J_{n_1}(-\lambda_0), \ldots, J_{n_g}(-\lambda_0))$, $\widetilde{J}$ and N, respectively. The right-hand side of (1.4) is the Weierstrass canonical form of the pencil $A_0 + \lambda A_1$, and it is unique up to permutation of the diagonal Jordan blocks. The Weierstrass canonical form displays all of the spectral information of the regular pencil $A_0 + \lambda A_1$. From (1.4), one can easily see that the [illegible] of λ_0 is g and its [illegible] is

$$a_{A_0+\lambda A_1}(\lambda_0) = n_1 + \cdots + n_g. \tag{1.5}$$

Without loss of generality, we assume the dimensions n_i to be ordered decreasingly, i.e.,

$$n_1 \geq n_2 \geq \cdots \geq n_g. \tag{1.6}$$

The paper is organized as follows: Section 2 contains one of the main results (Theorem 2.2) concerning the change of the Weierstrass structure. It gives a lower bound on the algebraic multiplicity associated with each eigenvalue in the perturbed pencil, and suggests that the generic behavior for the Jordan blocks of the perturbed pencil is the one happening when this lower bound is attained. In section 3, we prove that this behavior is indeed generic by showing that it holds for all perturbations except those in a proper algebraic submanifold in the set of matrix pencils. Finally, Theorem 3.3 summarizes the results obtained throughout this paper.

2. Lower bounds on the algebraic multiplicities and the dimensions of Jordan blocks in the perturbed pencil. Throughout this section we follow a notation consistent with (1.5), and denote by

$$a_{R(\lambda)}(\lambda_0) \tag{2.1}$$

the algebraic multiplicity of the eigenvalue λ_0 in the regular matrix pencil $R(\lambda)$. Our aim is to determine the generic Weierstrass structure of λ_0 in a perturbed matrix pencil $A_0 + B_0 + \lambda(A_1 + B_1)$, starting from the structure of this eigenvalue in the unperturbed pencil $A_0 + \lambda A_1$. For this, we need to know $a_{A_0+B_0+\lambda(A_1+B_1)}(\lambda_0)$, as well as how this algebraic multiplicity is distributed among the Jordan blocks of λ_0. At least two approaches are possible to solve this problem. First, one can start with Jordan chains of $A_0 + \lambda A_1$ associated with λ_0, and then explicitly build new Jordan chains for λ_0 in $A_0 + B_0 + \lambda(A_1 + B_1)$, exhausting the algebraic multiplicity $a_{A_0+B_0+\lambda(A_1+B_1)}(\lambda_0)$. This approach was used in [7, 8, 9] for the standard eigenvalue problem $A - \lambda I$. It has the advantage of providing the new Jordan chains, and the drawback of being rather intricate in the case of pencils. In this paper we use a simpler approach: First, we determine lower bounds on the number and the dimensions of the Jordan blocks associated with λ_0 in the perturbed pencil. This method, based on a result by Thompson [12], involves the use of the invariant factors of the pencils. Then, we prove that the generic behavior corresponds to the case when these lower bounds are attained.

We begin by recalling that the rank of an arbitrary matrix pencil, regular or singular, $T(\lambda) = T_0 + \lambda T_1$ is r if all of the minors of $T(\lambda)$ of dimension greater than r are identically equal to zero, but $T(\lambda)$ has minors of dimension r which are polynomials in λ not identically equal to zero. As a consequence, the rank of a regular $n \times n$ matrix pencil is equal to n.

The next auxiliary lemma is a consequence of [12, Theorem 1]. It establishes lower bounds on the number and dimensions of the Jordan blocks in the Weierstrass form of a regular matrix pencil $(R+T)(\lambda)$, where $R(\lambda)$ is a regular matrix pencil and $T(\lambda)$ is any pencil of rank r.

LEMMA 2.1. $R(\lambda) = R_0 + \lambda R_1$ $T(\lambda) = T_0 + \lambda T_1$ r λ_0 $R(\lambda)$ g $d_1 \geq \cdots \geq d_g$ $R(\lambda)$ $(R + T)(\lambda)$ $r \leq g$ $(R+T)(\lambda)$ $g - r$ λ_0 $\beta_{r+1} \geq \cdots \geq \beta_g$ $\beta_i \geq d_i$ $r + 1 \leq i \leq g$

. First, let us assume that the rank of $T(\lambda)$ is exactly r. We begin by proving that any pencil $T(\lambda)$ of rank r is the sum of r singular pencils of rank 1. This can be seen by using the Kronecker canonical form of singular pencils [4, Chapter XII]. Let $K_0 + \lambda K_1$ be the Kronecker canonical form of $T(\lambda) = T_0 + \lambda T_1$, and write $K_0 + \lambda K_1$ as the sum of the following matrices:

1. For any singular block L_k of dimension $k \times (k + 1)$ appearing in $K_0 + \lambda K_1$ [4, p. 39], we have that $L_k = L_k^{(1)} + \cdots + L_k^{(k)}$, where the jth row of $L_k^{(j)}$ is equal to the jth row of L_k, and the rest of the rows of $L_k^{(j)}$ are zero. Therefore L_k is the sum of k singular pencils with rank 1.

2. An analogous expression holds for any singular block L_p^T of dimension $(p + 1) \times p$ appearing in $K_0 + \lambda K_1$.

3. Finally, for the $m \times m$ regular part $F(\lambda) = F_0 + \lambda F_1$ of $K_0 + \lambda K_1$, we have again that $F(\lambda) = F^{(1)} + \cdots + F^{(m)}$, where $F^{(j)}$ has the jth row equal to the jth row of $F(\lambda)$ and the rest of the rows of $F^{(j)}$ are zero. Therefore $F(\lambda)$ is the sum of m singular pencils with rank 1.

The pencil $K_0 + \lambda K_1$ can be expressed as the sum of r singular pencils of rank 1 just by combining the previous expansions of its singular blocks and of its regular part. The same holds for $T(\lambda)$ because it is strictly equivalent to $K_0 + \lambda K_1$. Let this decomposition be

$$T(\lambda) = T_1(\lambda) + \cdots + T_r(\lambda),$$

where $\operatorname{rank} T_i(\lambda) = 1$ for $1 \leq i \leq r$.

For any $n \times n$ regular pencil $P(\lambda) = P_0 + \lambda P_1$, we denote by

$$h_n(P)|h_{n-1}(P)|\cdots|h_1(P)$$

its invariant polynomials [3, Chapter VI], also called invariant factors. As usual, $h_n(P)|h_{n-1}(P)$ means that $h_n(P)$ divides $h_{n-1}(P)$. Notice also that $h_1(P) \neq 0$ because the pencil is regular.

Let

$$(\lambda - \lambda_0)^{d_g}|(\lambda - \lambda_0)^{d_{g-1}}|\cdots|(\lambda - \lambda_0)^{d_1}$$

be the elementary divisors [3, Chapter VI] of $R(\lambda)$ associated with λ_0. Each elementary divisor $(\lambda - \lambda_0)^{d_i}$ corresponds to a Jordan block of λ_0 of dimension d_i in the Weierstrass form of $R(\lambda)$. It is well known that

$$\begin{array}{c} (\lambda - \lambda_0)^{d_1}|h_1(R) \\ (\lambda - \lambda_0)^{d_2}|h_2(R) \\ \vdots \quad \vdots \quad \vdots \\ (\lambda - \lambda_0)^{d_g}|h_g(R). \end{array}$$

Now, consider the sequence of pencils $R(\lambda), R(\lambda)+T_1(\lambda), R(\lambda)+T_1(\lambda)+T_2(\lambda), \ldots, R(\lambda) + T(\lambda)$, and note that each of them is a rank 1 perturbation of the preceding one. Applying [12, Theorem 1][2] to this sequence leads to

$$\begin{array}{l} (\lambda - \lambda_0)^{d_{r+1}}|h_{r+1}(R)|h_r(R+T_1)|\ldots|h_1(R+T), \\ (\lambda - \lambda_0)^{d_{r+2}}|h_{r+2}(R)|h_{r+1}(R+T_1)|\ldots|h_2(R+T), \\ \qquad\qquad \vdots \qquad\qquad \vdots \qquad\qquad \vdots \quad \vdots \\ (\lambda - \lambda_0)^{d_g}|h_g(R)|h_{g-1}(R+T_1)|\ldots|h_{g-r}(R+T), \end{array}$$

where $h_1(R+T) \neq 0$ because the pencil $(R+T)(\lambda)$ is regular. These divisibility chains mean that the pencil $(R+T)(\lambda)$ has $g-r$ elementary divisors associated with λ_0:

$$(\lambda - \lambda_0)^{\beta_g}|(\lambda - \lambda_0)^{\beta_{g-1}}|\cdots|(\lambda - \lambda_0)^{\beta_{r+1}},$$

[2]Theorem 1 in [12] states that if $P(\lambda)$ and $Q(\lambda)$ are $n \times n$ matrix polynomials with invariant polynomials $h_n(P)|h_{n-1}(P)|\cdots|h_1(P)$ and $h_n(Q)|h_{n-1}(Q)|\cdots|h_1(Q)$, respectively, and if the rank of $P(\lambda) - Q(\lambda)$ is equal to one, then $h_n(P)|h_{n-1}(Q)|h_{n-2}(P)|h_{n-3}(Q)|\cdots$ and $h_n(Q)|h_{n-1}(P)|h_{n-2}(Q)|h_{n-3}(P)|\cdots$.

with $d_i \leq \beta_i$ for $r+1 \leq i \leq g$. Each of these elementary divisors corresponds to a $\beta_i \times \beta_i$ Jordan block associated with λ_0 in the Weierstrass form of $(R+T)(\lambda)$.

If the rank of $T(\lambda)$ is $r_1 < r$, then the result we have just proved can be applied to show that the Weierstrass form of $(R+T)(\lambda)$ has at least $g - r_1 > g - r$ Jordan blocks associated with λ_0 of dimensions $\beta_i \geq d_i$, $i = r_1 + 1, \ldots, g$, and the result follows. □

The previous lemma allows us to obtain the main result in the first part of the present paper.

THEOREM 2.2. [illegible] λ_0 [illegible] $A_0 + \lambda A_1$ [illegible] $n_1 \geq \cdots \geq n_g$ [illegible] λ_0 [illegible] $B_0 + \lambda B_1$ [illegible] $A_0 + B_0 + \lambda(A_1 + B_1)$ [illegible] $g \geq \operatorname{rank}(B_0 + \lambda_0 B_1)$ [illegible] $\rho = \operatorname{rank}(B_0 + \lambda_0 B_1) + \operatorname{rank} B_1$ [illegible] $n_m = 1$ [illegible] $m = g+1, \ldots, \rho$ [illegible] λ_0 [illegible]

$$a_{A_0+B_0+\lambda(A_1+B_1)}(\lambda_0) \geq a_{A_0+\lambda A_1}(\lambda_0) + \operatorname{rank} B_1 - n_1 - \cdots - n_\rho, \tag{2.2}$$

[illegible] (2.1) [illegible] λ_0 [illegible] $A_0 + B_0 + \lambda(A_1 + B_1)$ [illegible] ρ [illegible] $n_1, \ldots, n_g, \underbrace{1, \ldots, 1}_{\operatorname{rank} B_1}$ [illegible]. Notice that

$$\operatorname{rank}(B_0 + \lambda B_1) = \operatorname{rank}(B_0 + \lambda_0 B_1 + (\lambda - \lambda_0) B_1) \leq \operatorname{rank}(B_0 + \lambda_0 B_1) + \operatorname{rank}(B_1) = \rho.$$

So, in the case $\rho < g$, Lemma 2.1 guarantees the existence of $g - \rho$ Jordan blocks associated with λ_0 of dimensions $\beta_{\rho+1} \geq n_{\rho+1}, \ldots, \beta_g \geq n_g$ in the Weierstrass canonical form of the perturbed pencil $A_0 + B_0 + \lambda(A_1 + B_1)$. Moreover, the left side in the inequality (1.1) implies that there are at least $\rho_1 = \operatorname{rank} B_1$ additional Jordan blocks of sizes $\alpha_1 \geq 1, \ldots, \alpha_{\rho_1} \geq 1$ associated with λ_0. Thus,

$$a_{A_0+B_0+\lambda(A_1+B_1)})(\lambda_0) \geq \beta_{\rho+1} + \cdots + \beta_g + \alpha_1 + \cdots + \alpha_{\rho_1} \geq n_{\rho+1} + \cdots + n_g + \rho_1.$$

Obviously, this inequality is equivalent to (2.2). If $g \leq \rho$, then inequality (2.2) becomes

$$a_{A_0+B_0+\lambda(A_1+B_1)}(\lambda_0) \geq g - \operatorname{rank}(B_0 + \lambda_0 B_1).$$

This fact is trivial because of inequality (1.1) and the evident spectral inequality

$$a_{A_0+B_0+\lambda(A_1+B_1)}(\lambda_0) \geq \dim \ker (A_0 + \lambda_0 A_1 + B_0 + \lambda_0 B_1).$$

Finally, notice that the previous inequalities become equalities if and only if the number and dimensions of the Jordan blocks associated with λ_0 in the Weierstrass form of $A_0 + B_0 + \lambda(A_1 + B_1)$ are those appearing in the statement of Theorem 2.2. □

[illegible] 1. Notice that the unnatural definition $n_m = 1$ for $m = g+1, \ldots, \rho$ allows us to express inequality (2.2) in a unified way for both cases $\rho < g$ and $\rho \geq g$. The reader is invited to check that the number and dimensions of the Jordan blocks of the perturbed pencil associated with λ_0 in the case of equality in (2.2) are

precisely those appearing in the generic behavior described in the abstract and the introduction.

Theorem 2.2 gives us all the sizes of the Jordan blocks associated with λ_0 in the perturbed pencil $A_0+B_0+\lambda(A_1+B_1)$ when the inequality in (2.2) is an equality. As we will see in the following section, this is the case for most perturbations $B_0+\lambda B_1$.

3. The generic behavior. The quantity

$$\widetilde{a} = a_{A_0+\lambda A_1}(\lambda_0) + \text{rank } B_1 - n_1 - \cdots - n_\rho$$

in (2.2), where $\rho = \text{rank}\,(B_0+\lambda_0 B_1) + \text{rank } B_1$ as in the statement of Theorem 2.2, is a lower bound on the algebraic multiplicity of λ_0 as an eigenvalue of the perturbed pencil $A_0+B_0+\lambda(A_1+B_1)$. This means that for each perturbation $B_0+\lambda B_1$ of $A_0+\lambda A_1$ such that $g \geq \text{rank}(B_0+\lambda_0 B_1)$,

$$\det\,(A_0+B_0+\lambda(A_1+B_1)) = (\lambda-\lambda_0)^{\widetilde{a}} q(\lambda-\lambda_0) \tag{3.1}$$

for some polynomial $q(\lambda-\lambda_0)$. Therefore, if the perturbed pencil is regular the algebraic multiplicity of λ_0 in the perturbed pencil is exactly $\widetilde{a}$ if and only if the coefficient $q(0)$ of $(\lambda-\lambda_0)^{\widetilde{a}}$ in (3.1) is not equal to zero. Clearly, once A_0 and A_1 are fixed, this coefficient is a multivariate polynomial in the entries of B_0 and B_1. Therefore, if this coefficient is not identically zero for all B_0 and B_1 such that $\text{rank}(B_0+\lambda_0 B_1) = \rho_0 \leq g$ and $\text{rank}(B_1) = \rho_1$, for fixed integers ρ_0 and ρ_1, the equation $q(0)=0$ defines an algebraic submanifold in the set of pairs (B_0, B_1) with $\text{rank}(B_0+\lambda_0 B_1) = \rho_0 \leq g$ and $\text{rank}(B_1) = \rho_1$ that characterizes the set of perturbation pencils for which the generic behavior described in the introduction does not happen. The only goal of this section is to show that this algebraic submanifold is proper or, in other words, that the coefficient $q(0)$ is not zero for all perturbations $B_0+\lambda B_1$ such that $\text{rank}(B_0+\lambda_0 B_1) = \rho_0 \leq g$ and $\text{rank}(B_1) = \rho_1$. This is done in Lemma 3.2. This will allow us to say that the change in the dimensions of the Jordan blocks described in Theorem 2.2, when the equality in (2.2) holds, is [illegible]. The reader is referred to [1] for a detailed description of the algebraic submanifold $q(0)=0$ in terms of a determinantal equation involving the entries of B_0 and B_1.

The simple Lemma 3.1 studies some specific perturbations of the blocks appearing in the Weierstrass canonical form (1.4). It will be used in the proof of Lemma 3.2.

LEMMA 3.1. [illegible] $J_k(\alpha)$ [illegible] $k\times k$ [illegible] α [illegible] $E_k(\beta)$ [illegible] $k\times k$ [illegible] β [illegible] $(k,1)$ [illegible] $D_k(\lambda) = (\lambda-\lambda_0)\,\text{diag}(s_1,\ldots,s_k)$ [illegible] $s_i = 0$ [illegible] 1 [illegible] i [illegible] $D_k(\lambda)$ [illegible]

1. λ_0 [illegible] $\lambda I + J_k(-\lambda_0) + E_k(\lambda-\lambda_0) + D_k(\lambda)$ [illegible] 1
2. λ_0 [illegible] $\lambda I + J_k(-\lambda_0) + E_k(1) + D_k(\lambda)$
3. λ_0 [illegible] $\lambda I + J_k(-\lambda_1) + D_k(\lambda)$ [illegible] $\lambda_1 \neq \lambda_0$
4. λ_0 [illegible] $\lambda J_k(0) + I + D_k(\lambda)$

[illegible] Check that

1.

$$\begin{aligned}&\det(\lambda I + J_k(-\lambda_0) + E_k(\lambda-\lambda_0) + D_k(\lambda))\\ &\qquad = (\lambda-\lambda_0)\left[(\lambda-\lambda_0)^{k-1}\left(\prod_{i=1}^{k}(1+s_i)\right) + (-1)^{k+1}\right],\end{aligned}$$

2.

$$\det(\lambda I + J_k(-\lambda_0) + E_k(1) + D_k(\lambda)) = (\lambda - \lambda_0)^k \left(\prod_{i=1}^{k} (1 + s_i) \right) + (-1)^{k+1},$$

3.

$$\det(\lambda I + J_k(-\lambda_1) + D_k(\lambda)) = \prod_{i=1}^{k} \left[(\lambda - \lambda_1) + s_i(\lambda - \lambda_0) \right],$$

4.

$$\det(\lambda J_k(0) + I + D_k(\lambda)) = \prod_{i=1}^{k} \left[1 + s_i(\lambda - \lambda_0) \right]. \qquad \square$$

LEMMA 3.2. [illegible] λ_0 [illegible] $n \times n$ [illegible] $A_0 + \lambda A_1$ [illegible] $n_1 \geq \cdots \geq n_g$ [illegible] λ_0 [illegible] ρ_0 [illegible] ρ_1 [illegible] $\rho_0 \leq g$ [illegible] $\rho_1 \leq n$ [illegible] $B_0 + \lambda B_1$ [illegible]

$$\rho_0 = \operatorname{rank}(B_0 + \lambda_0 B_1), \qquad \rho_1 = \operatorname{rank}(B_1),$$

[illegible] λ_0 [illegible] $A_0 + B_0 + \lambda(A_1 + B_1)$ [illegible] $a_{A_0+\lambda A_1}(\lambda_0) + \rho_1 - n_1 - \cdots - n_\rho$ [illegible] $\rho := \rho_0 + \rho_1$ [illegible] $n_m = 1$ [illegible] $m = g + 1, \ldots, \rho$

[illegible] It suffices to prove the result when $A_0 + \lambda A_1$ is in Weierstrass canonical form because, otherwise, we can consider the strict equivalence (1.4), apply the result to the matrix pencil in Weierstrass canonical form in the right-hand side (with $B_0 + \lambda B_1$ as the perturbation pencil), and take $Q^{-1}(B_0 + \lambda B_1)P^{-1}$.

So, assume that $A_0 + \lambda A_1$ is in Weierstrass canonical form given by the right-hand side of (1.4). We consider separately the following two cases.

(i) Case $\rho < g$. Define the matrices

$$B_0 = \operatorname{diag}(E_{n_1}(1), \ldots, E_{n_{\rho_0}}(1), E_{n_{\rho_0+1}}(-\lambda_0), \ldots, E_{n_{\rho_0+\rho_1}}(-\lambda_0), 0, \ldots, 0)$$

and

$$B_1 = \operatorname{diag}(\overbrace{0, \ldots, 0}^{\rho_0 \ blocks}, E_{n_{\rho_0+1}}(1), \ldots, E_{n_{\rho_0+\rho_1}}(1), 0, \ldots, 0),$$

where zeros denote matrices, and the partition in diagonal blocks is conformal to the one of the Weierstrass form (1.4). It can be checked that the pencil $B_0 + \lambda B_1$ verifies the conditions mentioned in the statement, by using the first two items in Lemma 3.1 with $D_k(\lambda) = 0$.

(ii) Case $\rho \geq g$. Now, we define

$$\widehat{B}_0 = \operatorname{diag}(E_{n_1}(1), \ldots, E_{n_{\rho_0}}(1), E_{n_{\rho_0+1}}(-\lambda_0), \ldots, E_g(-\lambda_0), 0, \ldots, 0)$$

and

$$\widehat{B}_1 = \operatorname{diag}(\overbrace{0, \ldots, 0}^{\rho_0 \ blocks}, E_{n_{\rho_0+1}}(1), \ldots, E_{n_g}(1), 0, \ldots, 0),$$

where the partition is again conformal to the one in the Weierstrass canonical form (1.4). Notice that $\operatorname{rank}(\widehat{B}_1) = g - \rho_0 \leq \rho_1$, and that by appropriate choices of $\{s_1, \ldots, s_n\}$, $s_i = 0$ or 1 for all i, $\operatorname{rank}(\widehat{B}_1 + \operatorname{diag}(s_1, \ldots, s_n))$ may take any value between $g - \rho_0$ and n. Let $\{\tilde{s}_1, \ldots, \tilde{s}_n\}$ be such that $\operatorname{rank}(\widehat{B}_1 + \operatorname{diag}(\tilde{s}_1, \ldots, \tilde{s}_n)) = \rho_1$, and define the pencil $D(\lambda) = D_0 + \lambda D_1 = (\lambda - \lambda_0)\operatorname{diag}(\tilde{s}_1, \ldots, \tilde{s}_n)$. Then the pencil $B_0 + \lambda B_1 \equiv \widehat{B}_0 + \lambda \widehat{B}_1 + D(\lambda)$ verifies the conditions mentioned in the statement, because $\operatorname{rank}(B_1) = \rho_1$,

$$\operatorname{rank}(B_0 + \lambda_0 B_1) = \operatorname{rank}(\widehat{B}_0 + \lambda_0 \widehat{B}_1) = \rho_0,$$

and Lemma 3.1 implies that the algebraic multiplicity of λ_0 in $A_0 + B_0 + \lambda(A_1 + B_1)$ is $g - \rho_0$, which is exactly $a_{A_0+\lambda A_1}(\lambda_0) + \rho_1 - n_1 - \cdots - n_\rho$. ∎

Theorem 2.2 and Lemma 3.2 allow us to give a complete answer to the problem originally posed in the introduction: Given a regular pencil $A_0 + \lambda A_1$ with eigenvalue λ_0, perturbed by a pencil $B_0 + \lambda B_1$, determine the generic Weierstrass structure associated with λ_0 as an eigenvalue of the perturbed pencil (1.3) when the low rank condition (1.2) holds for the perturbation. Notice that if $B_0 + \lambda B_1$ is in the set consisting of perturbation pencils for which $q(0) \neq 0$ (with $q(\lambda)$ as in (3.1)), then the perturbed pencil $A_0 + B_0 + \lambda(A_1 + B_1)$ is regular. With this observation in mind we can state the main theorem of this paper in the following way.

THEOREM 3.3. [illegible] λ_0 [illegible] $n \times n$ [illegible] $A_0 + \lambda A_1$ [illegible] (1.4) [illegible] g [illegible] λ_0 [illegible] $A_0 + \lambda A_1$ [illegible] $B_0 + \lambda B_1$ [illegible] $n \times n$ [illegible]

$$\rho_0 := \operatorname{rank}(B_0 + \lambda_0 B_1), \qquad \rho_1 := \operatorname{rank}(B_1), \qquad \rho := \rho_0 + \rho_1.$$

[illegible] $\rho_0 < g$ [illegible] λ_0 [illegible]

$$A_0 + B_0 + \lambda(A_1 + B_1), \tag{3.2}$$

[illegible] $A_0 + B_0 + \lambda(A_1 + B_1)$ [illegible] λ_0 [illegible] $A_0 + B_0 + \lambda(A_1 + B_1)$ [illegible] ρ [illegible] $n_1, \ldots, n_g, \underbrace{1, \ldots, 1}_{\rho_1}$

[illegible] 2. 1. An analogous result holds for the infinite eigenvalue of $A_0 + \lambda A_1$, by applying the previous theorem to the zero eigenvalue of the dual pencils $A_1 + \lambda A_0$ and $A_1 + B_1 + \lambda(A_0 + B_0)$.

2. Theorem 3.3 describes in a concise way the generic behavior presented in the introduction of this paper.

Acknowledgments. The third author thanks Prof. Sergey Savchenko for bringing to his attention Theorem 1 in [12] and the reference [5]. The authors are also indebted to an anonymous referee for valuable comments which very much improved the original manuscript.

BOUNDS ON CHANGES IN RITZ VALUES FOR A PERTURBED INVARIANT SUBSPACE OF A HERMITIAN MATRIX*

M. E. ARGENTATI†, A. V. KNYAZEV†, C. C. PAIGE‡, AND I. PANAYOTOV§

Abstract. The Rayleigh–Ritz method is widely used for eigenvalue approximation. Given a matrix X with columns that form an orthonormal basis for a subspace $\mathcal{X}$, and a Hermitian matrix A, the eigenvalues of $X^H AX$ are called Ritz values of A with respect to $\mathcal{X}$. If the subspace $\mathcal{X}$ is A-invariant, then the Ritz values are some of the eigenvalues of A. If the A-invariant subspace $\mathcal{X}$ is perturbed to give rise to another subspace $\mathcal{Y}$, then the vector of absolute values of changes in Ritz values of A represents the absolute eigenvalue approximation error using $\mathcal{Y}$. We bound the error in terms of principal angles between $\mathcal{X}$ and $\mathcal{Y}$. We capitalize on ideas from a recent paper [*SIAM J. Matrix Anal. Appl.*, 29 (2006), pp. 15–32] by Knyazev and Argentati, where the vector of absolute values of differences between Ritz values for subspaces $\mathcal{X}$ and $\mathcal{Y}$ was weakly (sub)majorized by a constant times the sine of the vector of principal angles between $\mathcal{X}$ and $\mathcal{Y}$, the constant being the spread of the spectrum of A. In that result no assumption was made on either subspace being A-invariant. It was conjectured there that if one of the trial subspaces is A-invariant, then an analogous weak majorization bound should be much stronger as it should involve only terms of the order of sine squared. Here we confirm this conjecture. Specifically we prove that the absolute eigenvalue error is weakly majorized by a constant times the sine squared of the vector of principal angles between the subspaces $\mathcal{X}$ and $\mathcal{Y}$, where the constant is proportional to the spread of the spectrum of A. For many practical cases we show that the proportionality factor is simply one and that this bound is sharp. For the general case we can prove the result only with a slightly larger constant, which we believe is artificial.

1. Introduction.

Eigenvalue problems appear in many applications. For example, eigenvalues represent the frequencies of vibration in mechanical vibrations, while the energy levels of a system are the eigenvalues of the Hamiltonian in quantum mechanics. Eigenvalue problems are used today in these and many other applications, including spectral data clustering and internet search engines.

Eigenvalues cannot be computed exactly except in some trivial cases, so numerical approximation is required. Eigenvalue a posteriori and a priori error bounds describe the eigenvalue approximation quality, and this is a classical and important topic in matrix analysis. A posteriori bounds are based on information readily computable, e.g., the eigenvector residuals, and are necessary, e.g., for adaptive numerical methods for eigenvalue approximation. A priori bounds are given in terms of theoretical properties and can be very useful in assessing the relative performance of algorithms.

The widely used Rayleigh–Ritz method is well known for its ability to generate high quality approximations to eigenvalues of Hermitian matrices. It is the basis for many numerical procedures for computing eigenvalues, such as finite element methods and the Lanczos eigenproblem iteration. Eigenvalue error bounds for the Rayleigh–Ritz method are important, since they provide estimates and predictions of the quality of eigenvalue approximations and can be used, e.g., to predict the number of iterations needed in the Lanczos method for computing some eigenvalues to within a given accuracy. There is a vast literature on Rayleigh–Ritz eigenvalue methods and error bounds; see, e.g., [16, Chapter 4], [19, Chapters 10–13], and [20, Chapters 3–5].

We contribute to this traditional area of research with a new twist—using weak majorization. Majorization is a classical technique that can be used to formulate and prove a great variety of inequalities in a concise and elegant way. It is widely used in matrix analysis, e.g., to bound perturbations of eigenvalues via Lidskii's beautiful theorem [17]. In the context of Rayleigh–Ritz eigenvalue error bounds, weak majorization was introduced in the celebrated work of Davis and Kahan [3] to bound eigenvalue errors a posteriori. In the present paper we propose and prove what appear to be the first theorems based on weak majorization for a priori Rayleigh–Ritz eigenvalue error bounds. Our results provide a theoretical foundation that can be applied in a number of situations, e.g., for finite element methods [4] and for block Lanczos iterations such as in [5]; see [14].

We use several well known majorization results found, e.g., in [1, 7, 18]. We give references throughout the paper for the concepts we introduce. For a more thorough background and reference list, see [13].

The rest of the paper is organized as follows. Section 2 contains all necessary definitions and basic facts on majorization that we need for our eigenvalue and singular value bounds. Section 3 is the main part of the paper, where we motivate and formulate our conjectures and theorems. Section 4 has all of our proofs. In section 5 we show that our main results are sharp; we also discuss our proofs and the possibility that our bound for the most general case might be slightly improved.

2. Definitions and prerequisites. We introduce the definitions and tools we need, together with some mild motivation. We do not provide proofs for the results in this section—instead we refer the reader to some of the relevant literature.

2.1. Notation. For a real vector $x = [x_1, \ldots, x_n]^T$, we use $x^\downarrow \equiv [x_1^\downarrow, \ldots, x_n^\downarrow]^T$ to denote x with its elements rearranged in descending order, while $x^\uparrow \equiv [x_1^\uparrow, \ldots, x_n^\uparrow]^T$ denotes x with its elements rearranged in ascending order. We use $|x|$ to denote the vector x with the absolute value of its components. We use the $\leq$ symbol to compare real vectors componentwise. For real vectors x and y the expression $x \prec y$ means that x is majorized by y, while $x \prec_w y$ means that x is weakly (sub)majorized by y; see section 2.2.

We consider the Euclidean space $\mathbb{C}^n$ of column vectors equipped with the standard scalar product $x^H y$ and the norm $\|x\| = \sqrt{x^H x}$. We use the same notation $\|A\|$ for the induced matrix norm of a complex matrix $A \in \mathbb{C}^{n\times n}$. $\mathcal{X} = \mathcal{R}(X) \subset \mathbb{C}^n$ means the subspace $\mathcal{X}$ is equal to the range of the matrix X with n rows. The unit matrix is I, and the zero matrix (not necessarily square) is 0, while $e = [1, \ldots, 1]^T$. We use $\mathcal{H}(n)$ to denote the set of $n \times n$ Hermitian matrices and $\mathcal{U}(n)$ to denote the set of $n \times n$ unitary matrices in the set $\mathbb{C}^{n\times n}$ of all $n \times n$ complex matrices.

We write $\lambda(A) = \lambda^\downarrow(A)$ for the vector of eigenvalues of $A \in \mathcal{H}(n)$ arranged in descending order, and we write $s(B) = s^\downarrow(B)$ for the vector of singular values of B

arranged in descending order. Individual eigenvalues and singular values are denoted by $\lambda_i(A)$ and $s_i(B)$, respectively, so, e.g., $\mathrm{spr}(A) = \lambda_1(A) - \lambda_n(A)$ and $s_1(B) = \|B\|$.

Let subspaces $\mathcal{X}$ and $\mathcal{Y} \subseteq \mathbb{C}^n$ have the same dimension, with orthonormal bases given by the columns of the matrices X and Y, respectively. We denote the vector of principal angles between $\mathcal{X}$ and $\mathcal{Y}$ arranged in descending order by $\theta(\mathcal{X}, \mathcal{Y}) = \theta^{\downarrow}(\mathcal{X}, \mathcal{Y})$ and define it by using $\cos\theta(\mathcal{X}, \mathcal{Y}) = s^{\uparrow}(X^H Y)$, e.g., [2], [6, section 12.4.3].

2.2. Majorization and weak majorization. We now briefly define the concepts of majorization and weak majorization which are comparison relations between two real vectors. For detailed information we refer the reader to [1, 7, 18].

We say that $x \in \mathbb{R}^n$ is weakly (sub)majorized by $y \in \mathbb{R}^n$, written $x \prec_w y$, if

$$\sum_{i=1}^{k} x_i^{\downarrow} \le \sum_{i=1}^{k} y_i^{\downarrow}, \qquad 1 \le k \le n, \tag{2.1}$$

while x is (strongly) majorized by y, written $x \prec y$, if (2.1) holds together with

$$\sum_{i=1}^{n} x_i = \sum_{i=1}^{n} y_i. \tag{2.2}$$

Our final results in the paper are weak majorization bounds of the form $x \prec_w y$, with $x \ge 0$. On the one hand, we can see from (2.1) that $x \le y \Rightarrow x \prec_w y$; i.e., the inequality implies weak majorization. In our case the advantage of using weak majorization is that the inequality $x \le y$ (the values of x and y become apparent later) is simply wrong, while the weak majorization bound $x \prec_w y$ does hold. On the other hand, a weak majorization bound $x \prec_w y$ implies that $\max(x) \le \max(y)$. So if the bound $\max(x) \le \max(y)$ is already known, but it is also known that $x \le y$ does not hold, it makes sense to conjecture and to try to prove $x \prec_w y$.

Strong "$\prec$" and weak "$\prec_w$" majorization relations share only some properties with the usual inequality $\le$ relation, so one should deal with them carefully. For example, $\prec$ and $\prec_w$ are reflexive and transitive, but $x \prec y$ and $y \prec x$ do not imply that $x = y$; e.g., [1, Remark II.1.2]. Similarly $x \prec y$ does not imply the intuitive $x + z \prec y + z$, as is seen in the example $x = (0, 0, 0)$, $y = (2, -1, -1)$, $z = (-2, 0, 0)$. So we must be particularly careful of the ordering when we [illegible] results. Thus it can be seen from (2.1) and (2.2) that $x + u \prec x^{\downarrow} + u^{\downarrow}$, e.g., [1, Corollary II.4.3], and

$$\{x \prec_w y\} \,\&\, \{u \prec_w v\} \,\&\, \cdots \;\Rightarrow\; x+u+\cdots \prec x^{\downarrow}+u^{\downarrow}+\cdots \prec_w y^{\downarrow}+v^{\downarrow}+\cdots, \tag{2.3}$$

where this also holds with $\prec_w$ replaced by $\prec$.

Some of the other basic majorization and related results we use are fairly obvious:

$$A \in \mathcal{H}(n) \Rightarrow |\lambda(\pm A)|^{\downarrow} = s(A); \tag{2.4}$$

$$|x \pm y| \prec_w |x|^{\downarrow} + |y|^{\downarrow}, \quad \text{since from (2.3)} \quad |x \pm y| \le |x| + |y| \prec |x|^{\downarrow} + |y|^{\downarrow}; \tag{2.5}$$

$$x \prec y \Rightarrow |x| \prec_w |y|; \quad \text{see, e.g., [1, Example II.3.5].} \tag{2.6}$$

Arithmetic operations, e.g., the sum and the product, on vectors used in majorization are performed componentwise. In the subsequent Theorems 2.3 and 2.4 for rectangular matrices we may need to operate with nonnegative vectors of different lengths. A standard agreement in this case is to add zeros at the end of the shorter vector to match the sizes needed for componentwise arithmetic operations and comparisons. We also use this agreement in later proofs.

Many inequality relations between eigenvalues and singular values are succinctly expressed as majorization or weak majorization relations; a beautiful example is the following.

THEOREM 2.1 (Lidskii [17]; see also, e.g., [1, p. 69]). *For $A, B \in \mathcal{H}(n)$ [illegible] A, B, $A - B$ [illegible] $\lambda(A) - \lambda(B) \prec \lambda(A - B)$*

Recall here that $\lambda(A) - \lambda(B) = \lambda^{\downarrow}(A) - \lambda^{\downarrow}(B)$. Note that the equivalent of (2.2) holds here by using $\operatorname{trace}(A) = \sum_i \lambda_i(A)$. We will use the following corollary.

COROLLARY 2.2 (e.g., [18, Chapter 9, G.1.d], [7, Corollary 3.4.3]). *For $A, B \in \mathbb{C}^{n\times n}$ [illegible] $s(A \pm B) \prec_w s(A) + s(B)$*

This corollary also follows from a weaker statement than Lidskii's theorem, e.g., [1, Exercises II.1.14 and II.1.15].

By using (2.3) we can see that Corollary 2.2 extends to the case of three or more matrices, because all vectors $s(A), s(B), \ldots$ are nonincreasing.

We also use results for the singular values of a product of matrices.

THEOREM 2.3 (e.g., [7, Theorem 3.3.14]). *$s(AB) \prec_w s(A)s(B)$ [illegible] A [illegible] B [illegible] AB*

THEOREM 2.4 (e.g., [7, Theorem 3.3.16], [1, Problem III.6.2]). *$s(AB) \le \|A\| s(B)$ [illegible] $s(AB) \le \|B\| s(A)$ [illegible] A [illegible] B [illegible] AB*

3. Motivation and main results. The Rayleigh–Ritz method for approximating eigenvalues of a Hermitian matrix A finds the eigenvalues of $X^H AX$, where the columns of the matrix X form an orthonormal basis for a subspace $\mathcal{X}$. Here $\mathcal{X}$ is called a trial subspace. The eigenvalues of $X^H AX$ do not depend on the particular choice of basis and are called Ritz values of A with respect to $\mathcal{X}$. If $\mathcal{X}$ is one-dimensional and spanned by the unit vector x, there is only one Ritz value—namely, the Rayleigh quotient $x^H Ax$.

When the trial subspace $\mathcal{X}$ is perturbed to become the subspace $\mathcal{Y}$, it is useful to know how the Ritz values of A vary. For one-dimensional $\mathcal{X}$ and $\mathcal{Y}$, spanned by unit vectors x and y, respectively, the following result appears in, e.g., [12, Theorem 1]:

$$|x^H Ax - y^H Ay| \le \operatorname{spr}(A) \sin\theta(x, y). \tag{3.1}$$

Here and below, $\theta(x, y)$ is the acute angle between the two unit vectors x and y defined by $\theta(x, y) = \arccos|x^H y| \in [0, \pi/2]$.

It is well known that every eigenvector is a stationary point of the Rayleigh quotient (considered as a function of a vector)—i.e., in the vicinity of an eigenvector, the Rayleigh quotient changes very slowly. The classic result that motivates this paper is the following: The Rayleigh quotient approximates an eigenvalue of a Hermitian matrix with accuracy proportional to the [illegible] of the eigenvector approximation error. The following simple bound, e.g., [12, Theorem 4], demonstrates this:

$$|x^H Ax - y^H Ay| \le \operatorname{spr}(A) \sin^2\theta(x, y), \tag{3.2}$$

where we assume that one of the unit vectors x or y is an eigenvector of A. To give a thorough background to our results, we rederive this important basic bound. Let $Ax = x\lambda$, and then $x^H Ax = \lambda$ so $|x^H Ax - y^H Ay| = |y^H (A - \lambda I)y|$. We now plug in the orthogonal decomposition $y = u + v$, where $u \in \operatorname{span}\{x\}$ and $v \in (\operatorname{span}\{x\})^{\perp}$. Thus $(A - \lambda I)u = 0$ and $\|v\| = \sin\theta(x, y)$, which results in $|y^H (A - \lambda I)y| = |v^H (A - \lambda I)v| \le \|A - \lambda I\| \|v\|^2 = \|A - \lambda I\| \sin^2\theta(x, y)$. But $\|A - \lambda I\| \le \operatorname{spr}(A)$, giving (3.2).

Let us now discuss some generalizations of (3.1) and (3.2) for subspaces $\mathcal{X}$ and $\mathcal{Y}$ of dimensions higher than one, with $\dim\mathcal{X} = \dim\mathcal{Y}$. Let X and Y be two matrices

whose columns form orthonormal bases for $\mathcal{X}$ and $\mathcal{Y}$, respectively, and suppose that the Ritz values of A with respect to $\mathcal{X}$ and $\mathcal{Y}$ are arranged in descending (more precisely "nonincreasing") order. To generalize (3.1) and (3.2) we replace the usual notion of angles between vectors by a more general one of principal angles between subspaces and replace the inequality symbol by the weak (sub)majorization symbol $\prec_w$.

Let $\lambda(A)$ denote the vector of descending eigenvalues $\lambda_i(A)$ of a Hermitian matrix A, $s(B)$ the vector of descending singular values of a matrix B, and $\theta(\mathcal{X}, \mathcal{Y})$ the vector of descending principal angles $\theta_i(\mathcal{X}, \mathcal{Y})$ between the subspaces $\mathcal{X}$ and $\mathcal{Y}$, defined such that the vectors $\cos\theta(\mathcal{X}, \mathcal{Y})$ and $s(X^H Y)$ are the same, except for the reversed order; see, e.g., [2], [6, section 12.4.3]. A recent paper [13] generalizes (3.1) to:

$$|\lambda(X^H AX) - \lambda(Y^H AY)| \prec_w \operatorname{spr}(A) \sin\theta(\mathcal{X}, \mathcal{Y}). \tag{3.3}$$

The weak majorization bound (3.3) implies, e.g., a bound for its largest term:

$$\max_i |\lambda_i(X^H AX) - \lambda_i(Y^H AY)| \leq \operatorname{spr}(A) \operatorname{gap}(\mathcal{X}, \mathcal{Y}), \tag{3.4}$$

where $\operatorname{gap}(\mathcal{X}, \mathcal{Y}) = \max_i\{\sin\theta_i(\mathcal{X}, \mathcal{Y})\}$ in this case, e.g., [11, 13].

Both bounds (3.3) and (3.4) generalize (3.1) to multidimensional subspaces, but no assumption of A-invariance is made in either case. What is the bound that generalizes (3.2), assuming that one of the subspaces $\mathcal{X}$ or $\mathcal{Y}$ is A-invariant? A natural conjecture, made in [13], is that such a bound could be obtained in terms of $\sin^2\theta(\mathcal{X}, \mathcal{Y})$. No majorization result of this kind is known, but simpler results—for the largest error only—are available; e.g., the following important bound is proved in [9] and reproduced in [4, Theorem 2, p. 477] and [15, Theorem 2.4], with a different proof suggested in [8, Theorem 2.2.3, p. 56]; for an English translation of the latter, see [10, Theorem 2.3, p. 383]. We present here a slightly modified formulation to make it consistent with (3.4): If $\mathcal{X}$ or $\mathcal{Y}$ is A-invariant and corresponds to a contiguous set of the extreme, i.e., largest or smallest, eigenvalues of A, then

$$\max_i |\lambda_i(X^H AX) - \lambda_i(Y^H AY)| \leq \operatorname{spr}(A) \operatorname{gap}^2(\mathcal{X}, \mathcal{Y}). \tag{3.5}$$

Bound (3.5) generalizes (3.2) but does not take advantage of majorization. By comparing (3.3) and (3.4) with (3.1), and (3.5) with (3.2), we make an educated guess for the general case where the invariant subspace is not necessarily associated with a contiguous set of extreme eigenvalues:

CONJECTURE 3.1. [illegible] $\mathcal{X}$ [illegible] $\mathcal{Y}$ [illegible] X [illegible] Y [illegible] A [illegible] $\mathcal{X}$ [illegible] $\mathcal{Y}$ [illegible] A [illegible]

$$|\lambda(X^H AX) - \lambda(Y^H AY)| \prec_w \operatorname{spr}(A) \sin^2\theta(\mathcal{X}, \mathcal{Y}). \tag{3.6}$$

We emphasize that the bound (3.6) involves the sine [illegible], and, since convergence analyses are of particular interest for small angles, this is a great improvement over (3.3). This is just as we would hope, since one of the subspaces is A-invariant in (3.6). The exact A-invariance assumption is equivalent to the subspace being spanned by some exact eigenvectors of A, and Conjecture 3.1 is an a priori Rayleigh–Ritz eigenvalue error bound which can be used to examine how the subspaces $\mathcal{Y}$ of an iterative eigenproblem algorithm approach an ideal A-invariant subspace $\mathcal{X}$. As we mentioned in the introduction, eigenvalue error bounds are important in many applications. We

refer the reader to the follow-up paper [14], where we extend some results of this paper to Hilbert spaces and discuss in detail applications to finite element methods and subspace iterations.

The implications of the weak majorization inequality (3.6) in Conjecture 3.1 may not be obvious to every reader. The weak majorization bound (3.6) directly implies that

$$\sum_{i=1}^{j} |\lambda_i(X^H AX) - \lambda_i(Y^H AY)|^{\downarrow} \le \mathrm{spr}(A) \sum_{i=1}^{j} \sin^2(\theta_i(\mathcal{X},\mathcal{Y}))^{\downarrow}, \quad j = 1,\dots,k;$$

see (2.1), where $k = \dim \mathcal{X} = \dim \mathcal{Y}$. For example, for $j = k$ we obtain

$$\sum_{i=1}^{k} |\lambda_i(X^H AX) - \lambda_i(Y^H AY)| \le \mathrm{spr}(A) \sum_{i=1}^{k} \sin^2(\theta_i(\mathcal{X},\mathcal{Y})),$$

and for $j = 1$ we get (3.5). Moreover, for real vectors x and y the weak majorization $x \prec_w y$ is equivalent to the inequality $\sum_{i=1}^{n} \phi(x_i) \le \sum_{i=1}^{n} \phi(y_i)$ holding for any continuous nondecreasing convex real-valued function ϕ; see, e.g., [18, Statement 4.B.2]. If, for example, we take $\phi(t) = t^p$, with $p \ge 1$, the bound (3.6) also implies that

$$\left(\sum_{i=1}^{k} |\lambda_i(X^H AX) - \lambda_i(Y^H AY)|^p \right)^{\frac{1}{p}} \le \mathrm{spr}(A) \left(\sum_{i=1}^{k} \sin^{2p}(\theta_i(\mathcal{X},\mathcal{Y})) \right)^{\frac{1}{p}}.$$

We have not proven that Conjecture 3.1 holds in [illegible] circumstances, and indeed it might not (but we suspect that it does). But we have proven that it [illegible] holds if we multiply the bound by 1.5. In section 4 we also show that Conjecture 3.1 does hold in some very useful circumstances:

THEOREM 3.1. [illegible] (3.6) [illegible] 3.1 [illegible] 3.1 [illegible]

(a) [illegible] A [illegible] $\mathcal{X}$ $\mathcal{Y}$ [illegible] A

(b) [illegible] A [illegible] A [illegible] $\mathcal{X}$ $\mathcal{Y}$ [illegible] A [illegible] $[\lambda_1(A)+\lambda_n(A)]/2$ [illegible] A [illegible]

This does not cover all known cases where (3.6) holds, but it does cover many practical cases. For example, in approximating the eigenvalues of a Hermitian matrix, perhaps by using Lanczos' eigenvalue algorithm, e.g., [6, section 9], we are often interested in just one end of the spectrum. In section 4 we also show that a weaker result [illegible] holds.

THEOREM 3.2. [illegible] 3.1 [illegible]

$$|\lambda(X^H AX) - \lambda(Y^H AY)| \prec_w \mathrm{spr}(A) \left[e - \cos\theta(\mathcal{X},\mathcal{Y}) + \frac{1}{2}\sin^2\theta(\mathcal{X},\mathcal{Y}) \right]. \tag{3.7}$$

Here and below, we use "e" to indicate a vector of ones. Note that the individual elements for both vectors $e - \cos\theta(\mathcal{X},\mathcal{Y})$ and $\sin^2\theta(\mathcal{X},\mathcal{Y})$ are decreasing, since both functions $1 - \cos\theta$ and $\sin^2\theta$ are monotonically increasing within $[0, \pi/2]$, and the vector $\theta(\mathcal{X},\mathcal{Y})$ is chosen to be decreasing. We now deduce two simple corollaries of

Theorem 3.2. By using elementary trigonometry, for $\theta \in [0, \pi/2]$:

$$\begin{aligned} 2 - 2\cos\theta &= 2 - 2\cos\theta - (1-\cos\theta)^2 + (1-\cos\theta)^2 \\ &= \sin^2\theta + (1-\cos\theta)^2 = \sin^2\theta + \sin^4\theta/(1+\cos\theta)^2 \\ &\leq \sin^2\theta + \sin^4\theta. \end{aligned}$$

We first conclude that bound (3.7) is slightly worse than bound (3.6) from Conjecture 3.1; and second, we immediately obtain from (3.7) the following.

COROLLARY 3.3. [illegible] 3.1 [illegible]

$$|\lambda(X^H AX) - \lambda(Y^H AY)| \prec_w \operatorname{spr}(A)\left[\sin^2\theta(\mathcal{X},\mathcal{Y}) + \frac{1}{2}\sin^4\theta(\mathcal{X},\mathcal{Y})\right] \tag{3.8}$$

$$\leq \frac{3}{2}\operatorname{spr}(A)\sin^2\theta(\mathcal{X},\mathcal{Y}). \tag{3.9}$$

By extending the above trigonometric relation we see that

$$2 - 2\cos\theta = \sin^2\theta\left(1 + \frac{\sin^2\theta}{(1+\cos\theta)^2}\right) = \frac{2\sin^2\theta}{1+\cos\theta} = \frac{\sin^2\theta}{\cos^2(\theta/2)} \leq \tan^2\theta$$

for $\theta \in [0, \pi/2]$; and with $\sin^2\theta \leq \tan^2\theta$, bound (3.7) implies another corollary.

COROLLARY 3.4. [illegible] 3.1 [illegible]

$$|\lambda(X^H AX) - \lambda(Y^H AY)| \prec_w \operatorname{spr}(A)\tan^2\theta(\mathcal{X},\mathcal{Y}). \tag{3.10}$$

We give an example in section 5 demonstrating that the conjectured bound (3.6) cannot be any tighter. Our numerical tests suggest that Conjecture 3.1 holds, i.e., that bound (3.7) can probably be improved to (3.6). However, we show in section 5 that already the first step in our proof of Theorem 3.2 does not allow us to prove the better bound (3.6), so a completely different approach is apparently needed to support Conjecture 3.1 in all cases—see section 5 for more thoughts on this.

Conjecture 3.1 turns out to be easy to formulate but hard to prove in its generality. We believe that the present publication, which proves Conjecture 3.1 in several practically interesting particular cases and provides slightly weaker bounds (3.7)–(3.10) for the general case, is important since it serves as a theoretical foundation for our future work on applications, e.g., [14]. It is also novel—we know of no other case where majorization is used for a priori Rayleigh–Ritz error bounds. The only somewhat related result known to us is the pioneering work of [3], where majorization is applied to bound eigenvalue errors a posteriori.

4. Proofs. We have all of the tools needed to prove our main results of Theorems 3.1 and 3.2. At first, both proofs develop along the same lines; later they split.

By the assumptions in the theorems, $\mathcal{X}$ and $\mathcal{Y}$ are two subspaces of $\mathbb{C}^n$ of the same dimension k and are the column ranges of matrices X and Y with orthonormal columns that are arbitrary up to unitary transformations of their columns. By using the singular value decomposition we choose such a pair of matrices X and Y with orthonormal columns so that $C \equiv X^H Y$ is real, square, and diagonal, with the diagonal entries in increasing order. Thus by the definition of angles between subspaces,

$$C = \operatorname{diag}\left(s^{\uparrow}(X^H Y)\right) = \operatorname{diag}\left(\cos\theta(\mathcal{X},\mathcal{Y})\right). \tag{4.1}$$

We arbitrarily complete X and Y to unitary matrices $[X, X_\perp]$ and $[Y, Y_\perp] \in \mathcal{U}(n)$, respectively, and consider the 2×2 partition of their unitary product $[X, X_\perp]^H [Y, Y_\perp]$.

By construction of X and Y, its $k \times k$ upper left block is C. We denote its $(n-k) \times k$ lower left block by $S \equiv (X_\perp)^H Y$. Since $[X, X_\perp]^H [Y, Y_\perp]$ is unitary, the entries C and S of its first block column satisfy $C^2 + S^H S = I$. So $\lambda(S^H S) = \lambda(I - C^2) = e - \cos^2\theta(\mathcal{X}, \mathcal{Y}) = \sin^2\theta(\mathcal{X}, \mathcal{Y})$, where e is the vector of ones, and so the vectors of singular values $s(C)$ and $s(S)$ are closely connected, and we derive from this that

$$\sin\theta(\mathcal{X}, \mathcal{Y}) = [s(S), 0, \ldots, 0], \tag{4.2}$$

where $\max\{2k-n, 0\}$ zeros are added on the right-hand side to match the number k of angles in the vector $\theta(\mathcal{X}, \mathcal{Y})$ with the number $\min\{k, n-k\}$ of singular values in the vector $s(S)$.

Both theorems assume that either $\mathcal{X}$ or $\mathcal{Y}$ is A-invariant, so without loss of generality let $\mathcal{X}$ be A-invariant. Then since $[X, X_\perp]$ is unitary:

$$[X, X_\perp]^H A\, [X, X_\perp] = \operatorname{diag}(A_{11}, A_{22}) \text{ and } A = [X, X_\perp] \operatorname{diag}(A_{11}, A_{22}) [X, X_\perp]^H.$$

Here $X^H A X = A_{11} \in \mathcal{H}(k)$ and $(X_\perp)^H A X_\perp = A_{22} \in \mathcal{H}(n-k)$. We can now use $Y^H [X, X_\perp] = [C^H, S^H] = [C, S^H]$ to show that

$$Y^H A Y = Y^H \left([X, X_\perp] \operatorname{diag}(A_{11}, A_{22}) [X, X_\perp]^H \right) Y = C A_{11} C + S^H A_{22} S. \tag{4.3}$$

The expression we want to bound in Theorems 3.1 and 3.2 now takes the form

$$\begin{aligned} \lambda(X^H A X) - \lambda(Y^H A Y) &= \lambda(A_{11}) - \lambda(C A_{11} C + S^H A_{22} S) \\ &= \lambda(A_{11}) - \lambda(C A_{11} C) + \lambda(C A_{11} C) - \lambda(C A_{11} C + S^H A_{22} S) \\ &\prec [\lambda(A_{11}) - \lambda(C A_{11} C)]^{\downarrow} + \lambda(-S^H A_{22} S), \end{aligned} \tag{4.4}$$

where the last line used Lidskii's Theorem 2.1 with (2.3). See the discussion following (5.1) for more about this choice. Next (2.4), Theorems 2.3 and 2.4, and (4.2) give

$$\left| \lambda(-S^H A_{22} S) \right|^{\downarrow} = s(S^H A_{22} S) \prec_w \|A_{22}\| \sin^2\theta(\mathcal{X}, \mathcal{Y}). \tag{4.5}$$

At this point, the proofs split. Each proof will use a different majorization of $\lambda(A_{11}) - \lambda(C A_{11} C)$ in (4.4), but both will use (4.5). We first establish Theorem 3.1. Neither (3.6) nor (3.7) is altered by replacing A by $\pm A + \alpha I$, where α is an arbitrary real constant, and so we can make the new A_{11} nonnegative definite in each of the parts (a) and (b) of Theorem 3.1 by choosing the appropriate sign and the shift α.

[illegible] 3.1. The starting point of the proof is (4.4), but now we assume that A_{11} is nonnegative definite and so has a nonnegative definite square root $\sqrt{A_{11}}$. We deal with $\lambda(A_{11}) - \lambda(C A_{11} C)$ first. For arbitrary square matrices F and G, we have $\lambda(FG) = \lambda(GF)$. By taking $F = C\sqrt{A_{11}}$ and $G = \sqrt{A_{11}} C$, we get $\lambda(C A_{11} C) = \lambda(\sqrt{A_{11}} C^2 \sqrt{A_{11}})$. By using this and Lidskii's Theorem 2.1, we see that

$$\begin{aligned} \lambda(A_{11}) - \lambda(C A_{11} C) &= \lambda(A_{11}) - \lambda\left(\sqrt{A_{11}} C^2 \sqrt{A_{11}} \right) \\ &\prec \lambda\left(\sqrt{A_{11}} \sqrt{A_{11}} - \sqrt{A_{11}} C^2 \sqrt{A_{11}} \right) \\ &= \lambda\left(\sqrt{A_{11}} \left(I - C^2\right) \sqrt{A_{11}} \right) = \lambda\left(\sqrt{A_{11}} S^H S \sqrt{A_{11}} \right), \end{aligned}$$

since $C^2 + S^H S = I$. Then by using (2.6) with Theorem 2.4 (twice) and (4.2), we obtain

$$|\lambda(A_{11}) - \lambda(C A_{11} C)| \prec_w s\left(\sqrt{A_{11}} S^H S \sqrt{A_{11}} \right) \le \|A_{11}\| \sin^2\theta(\mathcal{X}, \mathcal{Y}).$$

Apply (2.6) to (4.4); then (2.5), (2.3), and (4.5) with the above bound give

$$\begin{aligned}\left|\lambda(X^HAX) - \lambda(Y^HAY)\right| &\prec_w \left|[\lambda(A_{11}) - \lambda(CA_{11}C)]^{\downarrow} + \lambda(-S^HA_{22}S)\right| \\ &\prec_w |\lambda(A_{11}) - \lambda(CA_{11}C)|^{\downarrow} + \left|\lambda(-S^HA_{22}S)\right|^{\downarrow} \\ &\prec_w (\|A_{11}\| + \|A_{22}\|)\sin^2\theta(\mathcal{X},\mathcal{Y}). \qquad (4.6)\end{aligned}$$

Here this proof splits, and we first prove part (a) of Theorem 3.1. By assumption the invariant subspace $\mathcal{X}$ corresponds to a contiguous set of the largest (or smallest) eigenvalues of A. Here we present the proof for the case of the largest eigenvalues. The case of the smallest eigenvalues follows immediately by substituting $-A$ for A. We replace A with $A + \alpha I$, where α is chosen as the constant real shift that makes the new A_{11} positive semidefinite (nonnegative definite and singular), so that $\sqrt{A_{11}}$ exists. Since $\dim \mathcal{X} = k$, and the invariant subspace $\mathcal{X}$ corresponds to a contiguous set of the largest eigenvalues of A, $\alpha = -\lambda_k(A)$. After the shift $\lambda_k(A)$ becomes zero, the eigenvalues of the block A_{11} become nonnegative, with $\lambda_1(A)$ being the largest in absolute value, and the eigenvalues of the block A_{22} become nonpositive, with $\|A_{22}\| = -\lambda_n(A)$. Thus $\|A_{11}\| + \|A_{22}\| = \lambda_1(A) - \lambda_n(A) = \mathrm{spr}(A)$. Using this together with (4.6) gives (3.6), completing the proof of part (a).

For part (b) of Theorem 3.1 we prove the case where the eigenvalues of A_{11} lie in the top half of the spectrum of A; the remaining case is proven by substituting $-A$ for A. Choose the shift so that, for the new A, $\lambda_1(A) = -\lambda_n(A)$, ensuring with the assumptions that A_{11} is nonnegative definite and that $\|A_{11}\| \le \mathrm{spr}(A)/2$ and $\|A_{22}\| \le \mathrm{spr}(A)/2$, so that (4.6) again leads to (3.6). ∎

In fact whenever we can choose the sign and shift in $\pm A + \alpha I$ so that this new A has A_{11} nonnegative definite with $\|A_{11}\| + \|A_{22}\| \le \mathrm{spr}(A)$, then (3.6) will be satisfied.

We return again to (4.4) and (4.5) to establish Theorem 3.2.

Proof of Theorem 3.2. Applying Lidskii's Theorem 2.1 with (2.3) to (4.4) gives

$$\begin{aligned}\lambda(X^HAX) - \lambda(Y^HAY) &\prec [\lambda(A_{11}) - \lambda(CA_{11}C)]^{\downarrow} + \lambda(-S^HA_{22}S) \\ &\prec \lambda(A_{11} - CA_{11}C) + \lambda(-S^HA_{22}S). \qquad (4.7)\end{aligned}$$

In order to bound this we will use the identity

$$A_{11} - CA_{11}C = (I-C)A_{11} + CA_{11}(I-C), \qquad (4.8)$$

together with the following results obtained by using (4.1) with Theorems 2.4 and 2.3:

$$s((I-C)A_{11}) \le \|A_{11}\|s(I-C) = \|A_{11}\|(e - \cos\theta(\mathcal{X},\mathcal{Y})), \qquad (4.9)$$

$$\begin{aligned}s(CA_{11}(I-C)) &\prec_w s(C)s(A_{11}(I-C)) \le s(A_{11}(I-C)) \\ &\le \|A_{11}\|s(I-C) = \|A_{11}\|(e - \cos\theta(\mathcal{X},\mathcal{Y})). \qquad (4.10)\end{aligned}$$

Discarding the first C in $s(CA_{11}(I-C))$ is no real loss; see section 5. Using (4.8) and applying (2.4), Corollary 2.2, and (2.3) with (4.9) and (4.10) gives

$$\begin{aligned}|\lambda(A_{11} - CA_{11}C)|^{\downarrow} &= s((I-C)A_{11} + CA_{11}(I-C)) \\ &\prec_w s((I-C)A_{11}) + s(CA_{11}(I-C)) \\ &\prec_w 2\|A_{11}\|(e - \cos\theta(\mathcal{X},\mathcal{Y})). \qquad (4.11)\end{aligned}$$

Now apply (2.6) to (4.7), followed by (2.5), and use (4.11) and (4.5) with (2.3), together with $\|A_{11}\|, \|A_{22}\| \le \|A\|$, to obtain:

$$\begin{aligned} \left|\lambda(X^HAX) - \lambda(Y^HAY)\right| &\prec_w \left|\lambda(A_{11} - CA_{11}C) + \lambda(-S^HA_{22}S)\right| \\ &\prec_w \left|\lambda(A_{11} - CA_{11}C)\right|^{\downarrow} + \left|\lambda(-S^HA_{22}S)\right|^{\downarrow} \\ &\prec_w \|A\| \left[2(e - \cos\theta(\mathcal{X},\mathcal{Y})) + \sin^2\theta(\mathcal{X},\mathcal{Y})\right]. \end{aligned} \tag{4.12}$$

Our final step is to replace $\|A\|$ by an expression involving $\mathrm{spr}(A)$. Observe here that the difference between Ritz values is invariant under shift $\alpha \in \mathbb{R}$. So we shift A in a way to minimize $\|A\|$. This situation occurs when 0 is exactly in the middle of the spectrum, in which case $\|A\| = \mathrm{spr}(A)/2$. Combining this observation with (4.12) completes the proof of (3.7). ∎

5. Discussion. The following example shows that the conjectured bound (3.6) cannot be improved as a general result. Let $n = 2m$, and let an arbitrary set of m angles θ_i be given, where $\pi/2 \ge \theta_1 \ge \cdots \ge \theta_m \ge 0$. Let $C = \mathrm{diag}(\cos(\theta_1), \ldots, \cos(\theta_m))$, $X = [I, 0]^H$, $Y = \left[C, \sqrt{I - C^2}\right]^H$, and $A = \begin{bmatrix} I & 0 \\ 0 & -I \end{bmatrix}$, where all unit matrices I are of size m, so that X and Y are $n \times m$ and A is $n \times n$. Then the θ_i become the principal angles between the pair of $k = m$ dimensional subspaces $\mathcal{X} \equiv \mathcal{R}(X)$ and $\mathcal{Y} \equiv \mathcal{R}(Y)$. Moreover the Ritz values are the eigenvalues of $X^HAX = I$ and $Y^HAY = 2C^2 - I$, and so $\left|\lambda(X^HAX) - \lambda(Y^HAY)\right|^{\downarrow} = 2\sin^2\theta(\mathcal{X},\mathcal{Y})$. In this example $\mathrm{spr}(A) = 1 - (-1) = 2$, so (3.6) turns into an equality.

Asymptotically where all of the angles are small, bounds (3.6), (3.7), (3.8), and (3.10) are all equivalent. Moreover our numerical tests support Conjecture 3.1 in all cases. Perhaps in practical terms, from the point of view of a numerical analyst, we are done. However, it would be pleasing to know whether Conjecture 3.1 holds theoretically in its generality, since bound (3.6) looks more aesthetic and cannot be improved as a general result.

One important thing we know is that our approach of starting with Theorem 2.1 to deduce (4.4) (used in the proof of (3.7)) cannot reduce bound (3.7) to bound (3.6) in general, no matter how we modify the rest of the proof. This can be seen from the following example in $\mathbb{C}^4$. Let $A = \mathrm{diag}(A_{11}, A_{22})$ and $C = X^HY$, $S = X_\perp^HY$ be as in

$$A = \left[\begin{array}{cc|cc} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ \hline 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{array}\right], \quad [X, X_\perp] = I_4, \quad [Y, Y_\perp] = \left[\begin{array}{cc|cc} 0 & 0 & -1 & 0 \\ 0 & 1 & 0 & 0 \\ \hline 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{array}\right], \tag{5.1}$$

where I_4 is the 4×4 unit matrix, so that $X, X_\perp, Y, Y_\perp$ all have two columns. Then $[X, X_\perp]^H[Y, Y_\perp] = [Y, Y_\perp]$ are chosen as in our proofs, and we see that $\theta(\mathcal{X},\mathcal{Y}) = [\pi/2, 0]^T$, $CA_{11}C = 0$, $S^HA_{22}S = \mathrm{diag}(1, 0)$. Here the largest and smallest eigenvalues of A are ± 1, so $\mathrm{spr}(A) = 2$. Hence by direct calculation

$$X^HAX = A_{11} = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad Y^HAY = CA_{11}C + S^HA_{22}S = S^HA_{22}S = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix},$$

$$\left|\lambda(X^HAX) - \lambda(Y^HAY)\right| = \left|\begin{bmatrix} 1 \\ -1 \end{bmatrix} - \begin{bmatrix} 1 \\ 0 \end{bmatrix}\right| = \begin{bmatrix} 0 \\ 1 \end{bmatrix} \prec_w \begin{bmatrix} 2 \\ 0 \end{bmatrix} = \mathrm{spr}(A)\sin^2\theta(\mathcal{X},\mathcal{Y}),$$

so example (5.1) satisfy (3.6).

Let us now attempt to use (4.4) for (5.1). The right-hand side of (4.4) is

$$a \equiv [\lambda(A_{11}) - \lambda(CA_{11}C)]^{\downarrow} + \lambda(-S^H A_{22} S) = \begin{bmatrix} 1 \\ -1 \end{bmatrix} - \begin{bmatrix} 0 \\ 0 \end{bmatrix} + \begin{bmatrix} 0 \\ -1 \end{bmatrix} = \begin{bmatrix} 1 \\ -2 \end{bmatrix},$$

where it is true that $|a| \prec_w \operatorname{spr}(A) \sin^2 \theta(\mathcal{X}, \mathcal{Y})$. That is, the absolute value of the right-hand side of (4.4) is not always weakly majorized by $\operatorname{spr}(A) \sin^2 \theta(\mathcal{X}, \mathcal{Y})$, so we cannot obtain a general proof of (3.6) by starting from the majorization in (4.4).

Example (5.1) can tell us even more. For matrix $M = M^H$ we have the following generalization of (4.7) ($M = CA_{11}C$ in (4.4) and (4.7)):

$$\begin{aligned} \lambda(X^H AX) - \lambda(Y^H AY) &= \lambda(X^H AX) - \lambda(M) + \lambda(M) - \lambda(Y^H AY) \\ &\prec \lambda(X^H AX - M) + \lambda(M - Y^H AY) \equiv \tilde{a}. \end{aligned}$$

It might be thought that if, e.g., $X^H AX$ is indefinite, some such M could be chosen to minimize $\tilde{a}$ and to prove (3.6). But in example (5.1) it can be shown that there is real symmetric M giving $\tilde{a}$ satisfying the desired bound $|\tilde{a}| \prec_w \operatorname{spr}(A) \sin^2 \theta(\mathcal{X}, \mathcal{Y})$. In particular $M = Y^H AY$ will not give this bound, as the reader can check via (5.1). That is, using $\lambda(X^H AX) - \lambda(Y^H AY) \prec \lambda(A_{11} - CA_{11}C - S^H A_{22} S)$ in place of (4.4) will still not give (3.6) via our approach.

So, on the one hand, we cannot improve bound (3.7) to give (3.6) except possibly by considering a different approach to our present way of using Lidskii's Theorem 2.1 or equivalent in the first step; see (4.4) and (4.7). On the other hand, our numerical tests suggest that the tighter bound (3.6) holds. Thus if we are to prove (3.6) for widely spread interior eigenvalues, we appear to need an approach more sophisticated than our particular application of Lidskii's theorem in the first step.

An essentially equivalent first step was used in [12, Theorem 10] in an earlier attempt to prove (3.3), where it led to an artificial multiplier $\sqrt{2}$ in the right-hand side of (3.3). The subsequent paper [13] used an unusual technique to extend an arbitrary Hermitian operator to an orthogonal projector in a higher-dimensional space, preserving its Ritz values, to prove (3.3) as it is stated, without the multiplier $\sqrt{2}$. Perhaps the same technique might shed light here and help us to establish Conjecture 3.1, but this currently remains an open question.

6. Conclusions. We clarify a conjecture of Knyazev and Argentati [13] on a bound for the absolute difference between Ritz values of a Hermitian matrix A for two trial subspaces, one of which is A-invariant. We prove the conjecture for the cases where (a) the A-invariant subspace corresponds to a contiguous set of the largest (or smallest) eigenvalues of A and (b) the eigenvalues of A corresponding to the A-invariant subspace all lie in the top (or the bottom) half of the spectrum of A. We prove a slightly weaker bound for general invariant subspaces. We believe that the conjecture holds, i.e., that this weaker bound can be improved, and this is supported by our numerical tests, but the proof of the conjecture in its generality (if it is true) may require an unorthodox approach, perhaps one such as that used in [13]. These results are useful in practice and, for example, are applicable to the analysis of routines which use the Rayleigh–Ritz method, such as some Krylov subspace methods. We refer the reader to the subsequent paper [14], where we extend some results of this paper to Hilbert spaces and discuss in detail their application to finite element methods and subspace iterations.

EIGENVALUES OF THE SUM OF MATRICES FROM UNITARY SIMILARITY ORBITS*

CHI-KWONG LI†, YIU-TUNG POON‡, AND NUNG-SING SZE§

Abstract. Let A and B be $n \times n$ complex matrices. Characterization is given for the set $\mathcal{E}(A, B)$ of eigenvalues of matrices of the form $U^*AU + V^*BV$ for some unitary matrices U and V. Consequences of the results are discussed and computer algorithms and programs are designed to generate the set $\mathcal{E}(A, B)$. The results refine those of Wielandt on normal matrices. Extensions of the results to the sum of matrices from three or more unitary similarity orbits are also considered.

Key words. eigenvalues, sum of matrices, unitary similarity orbits, Davis–Wielandt shell

1. Introduction. Denote by M_n the set of $n \times n$ complex matrices. Let $A, B \in M_n$. There has been a great deal of interest in studying the eigenvalues of matrices of the form $U^*AU + V^*BV$ for some unitary matrices $U, V \in M_n$ because of motivations from theory as well as applications; see [1, 2, 4, 7, 11, 18, 19]. The study has been very successful for Hermitian matrices. Klyachko [12] (see also [9, 11, 13], etc.) gave necessary and sufficient conditions for the real numbers $c_1, \ldots, c_n$ to be the eigenvalues of the sum of two Hermitian matrices in M_n with eigenvalues $a_1, \ldots, a_n$ and $b_1, \ldots, b_n$.

The problem for non-Hermitian matrices is more challenging. For two given matrices $A, B \in M_n$, let $\mathcal{E}(A, B)$ be the set of eigenvalues of matrices of the form $U^*AU + V^*BV$ for some unitary matrices U and V. Wielandt [20] (see also [3] and [16]) determined the set $\mathcal{E}(A, B)$ for two normal matrices $A, B \in M_n$. There is not much information about the set $\mathcal{E}(A, B)$ for general matrices $A, B \in M_n$. The purpose of this paper is to address this problem.

In section 2, we characterize $\mathcal{E}(A, B)$ for two given matrices $A, B \in M_n$. Additional results concerning normal matrices and essentially Hermitian matrices (normal matrices with collinear eigenvalues) are presented in sections 3 and 4. In section 5, we consider an extension of our results to the sum of three of more matrices and mention some related problems. In section 6, we describe how to use our results to design computer algorithms and programs to generate the set $\mathcal{E}(A, B)$.

2. Main results. First, we characterize the matrix pair $(A, B) \in M_n \times M_n$ such that $0 \notin \mathcal{E}(A, B)$. We need the concept of Davis–Wielandt shell [5, 6] of $A \in M_n$ defined by

$$DW(A) = \{(x^*Ax, x^*A^*Ax) : x \in \mathbb{C}^n, x^*x = 1\} \subseteq \mathbb{C} \times \mathbb{R} \sim \mathbb{R}^3.$$

THEOREM 2.1. [illegible] $A, B \in M_n$ [illegible]
(a) $\det(U^*AU + V^*BV) \neq 0$ [illegible] $U, V \in M_n$
(b) $DW(A) \cap DW(-B) = \emptyset$
(c) [illegible] $\xi \in \mathbb{C}$ [illegible] $A+\xi I_n$ [illegible] $B-\xi I_n$ [illegible] $[0, \infty)$

[illegible]. If (c) holds, then $\|(A+\xi I_n)u\| > \|(B-\xi I_n)v\|$ for all unit vectors $u,\ v \in \mathbb{C}^n$, or $\|(A+\xi I_n)u\| < \|(B-\xi I_n)v\|$ for all unit vectors $u,\ v \in \mathbb{C}^n$. Thus, $(U^*AU + V^*BV)x \neq 0$ for all unitary matrices $U,\ V$ and unit vector $x \in \mathbb{C}^n$. Hence, condition (a) holds.

Suppose (a) holds. Assume that $DW(A) \cap DW(-B)$ is nonempty. Then there are orthonormal pairs (u_1, u_2) and (v_1, v_2) such that

$$Au_1 = \mu u_1 + \nu u_2 \quad \text{and} \quad -Bv_1 = \mu v_1 + \nu v_2$$

with $(\mu, \mu^2+\nu^2) \in DW(A) \cap DW(-B)$. Suppose U is unitary with u_1, u_2 as its first two columns, and V is unitary with v_1, v_2 as its first two columns. Then $U^*AU + V^*BV$ has zero first column, and hence has zero determinant, which is a contradiction. So, (b) holds.

Suppose (b) holds. Assume $n \geq 3$. Since $DW(A)$ and $DW(-B)$ are compact convex sets, by the separation theorem, there is a linear functional f such that $f(\alpha) > f(\beta)$ for all $(\alpha, \beta) \in DW(A) \times DW(-B)$. So, there is $\nu \in \mathbb{R}$ and $\mu \in \mathbb{C}$ such that

$$x^*(\nu A^*A + \mu A + \overline{\mu} A^*)x > y^*(\nu B^*B - \mu B - \overline{\mu} B^*)y$$

for any unit vectors $x, y \in \mathbb{C}^n$. We may perturb ν and assume that $\nu \neq 0$. Furthermore, we assume that $\nu > 0$; otherwise, multiply -1 to the inequality. Then for $\xi = \bar{\mu}/\sqrt{\nu}$, we see that

$$x^*(A + \xi I_n)^*(A + \xi I_n)x > y^*(B - \xi I_n)^*(B - \xi I_n)y$$

for all unit vectors $x, y \in \mathbb{C}^n$. So, condition (c) holds. □

Assume n = 2. Let $S = \{(\mu, r) \in \mathbb{R} \times \mathbb{C},\ |\mu|^2 \leq r\}$ and ∂S denote the boundary of S. By Theorem 2.1(b) and Theorem 2.2 in [15], $DW(A)$ is an ellipsoid in S and $(\mu, |\mu|^2) \in DW(A) \cap \partial S$ for every eigenvalue μ of A. Similarly, $DW(-B)$ is an ellipsoid in S and $(\tilde{\mu}, |\tilde{\mu}|^2) \in DW(-B) \cap \partial S$ for every eigenvalue $\tilde{\mu}$ of $-B$. Since $DW(A) \cap DW(-B) = \emptyset$, we see that $DW(-B)$ cannot lie in the interior of conv $DW(A)$, the convex hull of $DW(A)$. Otherwise, $DW(-B) \cap \mathcal{S} = \emptyset$. Similarly, $DW(A)$ cannot lie in the interior of conv $DW(-B)$. So, conv $DW(A) \cap$ conv $DW(-B) = \emptyset$. We can apply the argument for the cases when $n \geq 3$ to show that condition (c) holds.

Note that $\mu \in \mathcal{E}(A, B)$ if and only if there exist unitary matrices $U, V \in M_n$ such that $\det(UAU^* + VBV^* - \mu I_n) = 0$. Using Theorem 2.1, we have the following.

THEOREM 2.2. [illegible] $A, B \in M_n$ [illegible] $\mu \in \mathbb{C}$ [illegible]
(a) $\mu \notin \mathcal{E}(A, B)$
(b) $DW(A) \cap DW(\mu I_n - B) = \emptyset$
(c) [illegible] $\xi \in \mathbb{C}$ [illegible] $A+\xi I_n$ [illegible] $B-\mu I_n-\xi I_n$ [illegible] $[0, \infty)$

3. Normal matrices. If $A, B \in M_n$ are normal, then $DW(A)$ and $DW(\mu I_n - B)$ are polytopes with at most n vertices in $\mathbb{C} \times \mathbb{R} \sim \mathbb{R}^3$. We have the following.

THEOREM 3.1. [illegible] $A, B \in M_n$ [illegible] (a)–(c) [illegible] 2.2 [illegible]

(d) [illegible] A, $\mu I_n - B$ [illegible].

Proof. Suppose A and B are normal. Then the singular values of A and $\mu I_n - B$ are the absolute values of the eigenvalues of the two matrices. One readily sees that Theorem 2.2(c) is equivalent to condition (d). □

Theorem 3.1 has been proven by Wielandt [20, Theorem 1], where both lines and circles are used for the separation. As pointed out in [20], $\mathcal{E}(A, B)$ depends only on the spectra $\sigma(A)$, $\sigma(B)$ of A and B. Hence, for any nonempty finite subsets S, T of $\mathbb{C}$, we can define $\mathcal{E}(S, T) = \mathcal{E}(A, B)$, where A and B are any normal matrices of the same size such that $\sigma(A) = S$ and $\sigma(B) = T$.

If each of A and B has at most two distinct eigenvalues, then $\mathcal{E}(A, B)$ can be easily determined by Theorem 4.6 in section 4. For other cases, we have the following theorem, which is useful in constructing the set $\mathcal{E}(A, B)$ analytically or using computer programs; see section 6.

THEOREM 3.2. [illegible] $A, B \in M_n$ [illegible] 3 [illegible] 2 [illegible] (a)–(c) [illegible] 2.2 [illegible]

(e) [illegible] $(p, q) \in \{(2, 3), (3, 2)\}$ [illegible] p [illegible] A [illegible] q [illegible] B [illegible]

[illegible]

$$\mathcal{E}(A, B) = \bigcup \{\mathcal{E}(S, T) : S \subseteq \sigma(A), T \subseteq \sigma(B) \text{ [illegible] } (|S|, |T|) \in \{(2, 3), (3, 2)\}\},$$

[illegible] $|S|$ [illegible] $|T|$ [illegible] S [illegible] T [illegible].

Proof. Suppose A or B has at least 3 distinct eigenvalues and the other has at least 2 distinct eigenvalues. Then condition (d) fails to hold if and only if there are p distinct eigenvalues of A and q distinct eigenvalues of B with $(p, q) \in \{(3, 2), (2, 3)\}$ constituting an obstacle for the existence of the circle [14, Theorem 8.2]. Thus, Theorem 3.1(d) is equivalent to (e). □

To construct $\mathcal{E}(A, B)$, one can further reduce the collection of subsets in the above theorem. To this end, we need the following lemma showing that there is a one-one correspondence between the triangles on the boundary faces of the convex set $DW(B)$ and those on the boundary faces of $DW(\mu I - B)$ with $\mu = s + it$.

LEMMA 3.3. [illegible] $s, t, a_j, b_j \in \mathbb{R}$, $1 \le j \le 5$ [illegible]

$$P_j = \left(a_j, b_j, a_j^2 + b_j^2\right) \text{ [illegible] } Q_j = \left(s - a_j, t - b_j, (s - a_j)^2 + (t - b_j)^2\right).$$

[illegible] P_1, P_2, P_3 [illegible] P_4 [illegible] P_5 [illegible] ([illegible]) [illegible] P_1, P_2, P_3 [illegible] Q_4 [illegible] Q_5 [illegible] ([illegible]) [illegible] Q_1, Q_2, Q_3 [illegible].

Proof. Suppose P_1, P_2, P_3 are not collinear. Then Q_1, Q_2, Q_3 are not collinear. Let Π_1 and Π_2 be the planes determined by P_1, P_2, P_3 and Q_1, Q_2, Q_3, respectively.

For $(a_{pq}) \in M_3$, denote by $\det((a_{pq})) = |a_{pq}|$. For $j = 4, 5$, we have

$$((P_2-P_1)\times(P_3-P_1))\cdot(P_j-P_1)=\begin{vmatrix} a_2-a_1 & b_2-b_1 & a_2^2+b_2^2-a_1^2-b_1^2 \\ a_3-a_1 & b_3-b_1 & a_3^2+b_3^2-a_1^2-b_1^2 \\ a_j-a_1 & b_j-b_1 & a_j^2+b_j^2-a_1^2-b_1^2 \end{vmatrix}$$

and

$$\begin{aligned} & ((Q_2-Q_1)\times(Q_3-Q_1))\cdot(Q_j-Q_1) \\ = & \begin{vmatrix} a_1-a_2 & b_1-b_2 & a_2^2+b_2^2-a_1^2-b_1^2+2s(a_1-a_2)+2t(b_1-b_2) \\ a_1-a_3 & b_1-b_3 & a_3^2+b_3^2-a_1^2-b_1^2+2s(a_1-a_3)+2t(b_1-b_3) \\ a_1-a_j & b_1-b_j & a_j^2+b_j^2-a_1^2-b_1^2+2s(a_1-a_j)+2t(b_1-b_j) \end{vmatrix} \\ = & \begin{vmatrix} a_1-a_2 & b_1-b_2 & a_2^2+b_2^2-a_1^2-b_1^2 \\ a_1-a_3 & b_1-b_3 & a_3^2+b_3^2-a_1^2-b_1^2 \\ a_1-a_j & b_1-b_j & a_j^2+b_j^2-a_1^2-b_1^2 \end{vmatrix} \\ = & ((P_2-P_1)\times(P_3-P_1))\cdot(P_j-P_1). \end{aligned}$$

The result follows from the fact that P_4 and P_5 lie in the same open half space determined by Π_1 if and only if the triple products

$$((P_2-P_1)\times(P_3-P_1))\cdot(P_4-P_1) \quad \text{and} \quad ((P_2-P_1)\times(P_3-P_1))\cdot(P_5-P_1)$$

have the same sign and similar assertion for Q_j and Π_2. □

THEOREM 3.4. [illegible] $A, B \in M_n$ [illegible] $a_1, \ldots, a_n$ [illegible] $b_1, \ldots, b_n$ [illegible] $\mu \in \mathcal{E}(A,B)$ [illegible] $X = \operatorname{diag}(w_1, w_2, w_3)$ [illegible] $Y = \operatorname{diag}(z_1, z_2)$ [illegible] $DW(X) \cap DW(\mu I_2 - Y) \neq \emptyset$ [illegible]

(a) $w_1, w_2, w_3 \in \sigma(A)$ [illegible] $z_1, z_2 \in \sigma(B)$ [illegible] $DW(\operatorname{diag}(w_1, w_2, w_3))$ [illegible] $DW(A)$ [illegible] $DW(\operatorname{diag}(z_1, z_2))$ [illegible] $DW(B)$.

(b) $w_1, w_2, w_3 \in \sigma(B)$ [illegible] $z_1, z_2 \in \sigma(A)$ [illegible] $DW(\operatorname{diag}(w_1, w_2, w_3))$ [illegible] $DW(B)$ [illegible] $DW(\operatorname{diag}(z_1, z_2))$ [illegible] $DW(A)$.

[illegible]. Note that for any $z_1, z_2, z_3 \in \sigma(B)$, $DW(\operatorname{diag}(\mu - z_1, \mu - z_2, \mu - z_3))$ lies on the boundary of $DW(\mu I_n - B)$ if and only if $DW(\operatorname{diag}(z_1, z_2, z_3))$ lies on the boundary of $DW(B)$. Now, $DW(A)$ and $DW(\mu I_n - B)$ are two convex polytopes in $\mathbb{C} \times \mathbb{R}$ with vertices in $\mathbf{P} = \{(z, |z|^2) : z \in \mathbb{C}\}$. So, $DW(A) \cap DW(\mu I_n - B) \neq \emptyset$ if and only if one of the polytopes intersects a boundary face of the other polytopes. Suppose $DW(\mu I_n - B)$ intersects a boundary face of $DW(A)$. Then there are three vertices, say $(w_j, |w_j|^2)$ with $w_j \in \sigma(A)$ for $j = 1, 2, 3$, of the boundary face of $DW(A)$ intersecting $DW(\mu I_n - B)$. Note that the vertices of $DW(\mu I_n - B)$ belong to $\mathbf{P}$. So, $DW(\operatorname{diag}(w_1, w_2, w_2))$ must intersect with some boundary face of $DW(\mu I_n - B)$. Consequently, there are three vertices on the boundary face of $DW(\mu I_n - B)$ whose convex hull intersects with $DW(\operatorname{diag}(w_1, w_2, w_3))$. Now, for two triangular laminas each having vertices in $\mathbf{P}$ to have a nonempty intersection, there must be a nonempty intersection of a triangular lamina with an edge of another triangular lamina. By Lemma 3.3, there is a one-one correspondence between the triangles on the boundary faces of $DW(\mu I_n - B)$ and those on the boundary faces of $DW(B)$. Thus, condition (a) or (b) holds. □

One can also consider the boundary $\partial\mathcal{E}(A,B)$ of $\mathcal{E}(A,B)$. By Theorem 4.6 in section 4, if $A, B \in M_n$ are normal and each has at most two distinct eigenvalues,

then $\mathcal{E}(A,B)$ has an empty interior, i.e., $\partial\mathcal{E}(A,B) = \mathcal{E}(A,B)$. We will exclude these special cases. The following lemma is needed for further discussion.

LEMMA 3.5. [illegible] $S = \{w_1, w_2, w_3\}$ [illegible] $T = \{z_1, z_2\}$ [illegible] $\mathbb{C}$ [illegible]

$$\partial\mathcal{E}(S,T) = \mathcal{E}(\{w_1,w_2\},T) \cup \mathcal{E}(\{w_1,w_3\},T) \cup \mathcal{E}(\{w_2,w_3\},T).$$

[illegible]. Clearly, the result holds if S or T is a singleton. In the following, we may assume that $z_1 \neq z_2$. If $w_j = w_k$ for some $1 \leq j < k \leq 3$, then $\mathcal{E}(S,T) = \mathcal{E}(\{w_i, w_l\},T)$, where $l \notin \{j,k\}$, which has no interior point.

Suppose $w_1, w_2, w_3 \in \mathbb{C}$ are distinct. Let $X = \operatorname{diag}(w_1,w_2,w_3)$, $Y = \operatorname{diag}(z_1,z_2)$, and $X_{jk} = \operatorname{diag}(w_j, w_k)$ for $1 \leq j < k \leq 3$. By Theorem 2.2, $\mu \in \mathcal{E}(S,T)$ if and only if $DW(X) \cap DW(\mu I_2 - Y) \neq \emptyset$. Note that $DW(\mu I_2 - Y)$ is a line segment with vertices in $\mathbf{P}$ while $DW(X)$ is a triangular lamina with three edges, $DW(X_{12})$, $DW(X_{23})$, and $DW(X_{13})$. Thus, μ is a boundary point of $\mathcal{E}(S,T)$ if and only if the line segment $DW(\mu I_2 - Y)$ intersects the triangular lamina $DW(X)$ at its boundary, which is the union of line segments $DW(X_{12})$, $DW(X_{23})$, and $DW(X_{13})$. The result follows. □

By Lemma 3.5 and Theorem 3.2, we have the following theorem.

THEOREM 3.6. [illegible] $A, B \in M_n$ [illegible] 2 [illegible]

$$\partial\mathcal{E}(A,B) \subseteq \bigcup \{\mathcal{E}(S,T) : S \subseteq \sigma(A), T \subseteq \sigma(B) \text{ [illegible] } |S| = |T| = 2\}.$$

4. Essentially Hermitian matrices. Recall that a normal matrix is essentially Hermitian if all of its eigenvalues lie on a straight line. Let us warm up our discussion with the following results and examples on Hermitian matrices.

THEOREM 4.1. [illegible] $A, B \in M_n$ [illegible] $a_1 \geq a_2 \geq \cdots \geq a_n$ [illegible] $b_1 \geq b_2 \geq \cdots \geq b_n$ [illegible]

$$\mathcal{E}(A,B) = [a_n + b_n,\ a_1 + b_1] \setminus \bigcup_{j=1}^{n-1} (a_{j+1} + b_1,\ a_j + b_n) \cup (b_{j+1} + a_1,\ b_j + a_n),$$

[illegible] $(c,d) = \emptyset$, $c \geq d$

[illegible]. By Theorem 3.1(d), $\mu \notin \mathcal{E}(A,B)$ if and only if $\{a_1, a_2, \ldots, a_n\}$ can be separated from $\{\mu - b_1, \mu - b_2, \ldots, \mu - b_n\}$ by a circle. For $\mu \in \mathbb{R}$, this happens if and only if one of the following conditions is satisfied:

1. $\mu - b_1 > a_1 \Leftrightarrow \mu > a_1 + b_1$.
2. $\mu - b_n < a_n \Leftrightarrow \mu < a_n + b_n$.
3. For some $1 \leq j \leq n-1$, $a_{j+1} < \mu - b_1 \leq \mu - b_n < a_j \Leftrightarrow a_{j+1} + b_1 < \mu < a_j + b_n$.
4. For some $1 \leq j \leq n-1$, $\mu - b_j < a_n \leq a_1 < \mu - b_{j+1} \Leftrightarrow b_{j+1} + a_1 < \mu < b_j + a_n$.

Hence, the result follows. □

We have the following corollary.

COROLLARY 4.2. [illegible] $A, B \in M_n$ [illegible] 4.1 [illegible]

$$b_1 - b_n \geq \max_{1 \leq j \leq n-1} (a_j - a_{j+1}) \quad \text{[illegible]} \quad a_1 - a_n \geq \max_{1 \leq j \leq n-1} (b_j - b_{j+1}),$$

[illegible] $\mathcal{E}(A,B) = [a_n + b_n,\ a_1 + b_1]$

EXAMPLE 4.3. Suppose $n \geq 2$, $A, B \in M_n$ are Hermitian with eigenvalues $a_1 = 5$, $a_n = 2$, $b_1 = 4$, and $b_n = 1$. Then $\mathcal{E}(A, B) = [3, 9]$ is independent of the choices of a_i and b_j for $2 \leq i,\ j \leq n-1$.

EXAMPLE 4.4. Suppose $A, B \in M_3$ are Hermitian with eigenvalues $a_1 = 5$, $a_3 = 1$, $b_1 = 4$, and $b_3 = 2$. If $a_2 = 3$, then $\mathcal{E}(A, B) = [3, 9]$; if $a_2 \neq 3$, then $\mathcal{E}(A, B) \subsetneq [3, 9]$.

It is interesting to note that sometimes the set $\mathcal{E}(A, B)$ depends only on the extreme eigenvalues of A and B as shown in Example 4.3, but this is not always the case, as shown in Example 4.4.

In perturbation theory, if $A, B \in M_n$ are Hermitian such that $\|B\|$ is larger than the smallest singular value of A, then it may happen that $A + B$ is singular. However, if we know more about the eigenvalues of A and B, one can get a better perturbation bound.

EXAMPLE 4.5. Suppose $A, B \in M_n$ are Hermitian such that $\sigma(A) \subseteq \mathbb{R} \setminus (-r, s)$ for some $r, s \in (0, \infty)$ and $\sigma(B) \subseteq [-u, v]$ for some $u, v \in [0, \infty)$ such that $-r + v < 0$ and $-u + s > 0$. Then $A + B$ is invertible.

In [20, Theorem 2], Wielandt described a procedure to construct $\mathcal{E}(A, B)$ for a Hermitian matrix A and a skew-Hermitian matrix B with eigenvalues $a_1, \ldots, a_n$ and $b_1, \ldots, b_n$. In particular, it was shown that the set $\mathcal{E}(A, B)$ is the intersection of all hyperbolic regions containing the set $\{a_j + b_k : 1 \leq j, k \leq n\}$. However, details of the proof were not given. In the following, we extend the result of Wielandt to any pair of essentially Hermitian matrices A and B. A detailed proof is given for the result.

To present the result and proof, we need some basic facts in the coordinate geometry of $\mathbb{R}^2$ (identified with $\mathbb{C}$). Suppose $w_1, w_2, z_1, z_2 \in \mathbb{C}$ such that $P = \operatorname{conv}\{w_r + z_s : r, s \in \{1, 2\}\}$ is a nondegenerate parallelogram. Then there is a unique rectangular hyperbola passing through the vertices of P. The hyperbola degenerates to a pair of perpendicular lines if and only if the four sides of P have equal length. Otherwise, each branch of the hyperbola will pass through a pair of vertices of P corresponding to a side of P with shorter length, i.e., the two sides of P of longer lengths lie in the closed region lying between the two branches of the hyperbola. For a nondegenerate rectangular hyperbola, the connected closed region with the hyperbola as boundary is the [illegible], and the two disconnected closed regions with the hyperbola as boundary form the [illegible]. Of course, the complement of a closed hyperbolic region is an open hyperbolic region, and vice versa. In case the hyperbola degenerates to a pair of perpendicular lines, the inner (and outer) hyperbolic region becomes the union of two unbounded triangular regions connected at their vertices.

Suppose A and B are two essentially Hermitian matrices. If the line through $\sigma(A)$ and the line through $\sigma(B)$ are parallel, then there are $\alpha, \beta \in \mathbb{C}$ and $\phi \in \mathbb{R}$ such that $H = e^{-i\phi}(A - \alpha I)$ and $K = e^{-i\phi}(B - \beta I)$ are Hermitian. Then

$$\mathcal{E}(A, B) = e^{i\phi}\mathcal{E}(H, K) + (\alpha + \beta)$$

and the result follows from Theorem 4.1. For the other cases, we have the following result.

THEOREM 4.6. [illegible] $A, B \in M_n$ [illegible] $\alpha, \beta \in \mathbb{C}$, $r_1 \geq r_2 \geq \cdots \geq r_n$, $s_1 \geq s_2 \geq \cdots \geq s_n$, $\phi, \theta \in \mathbb{R}$, [illegible] A, B [illegible] $a_j = \alpha + r_j e^{i\phi}$, $1 \leq j \leq n$, [illegible] $b_j = \beta + s_j e^{i\theta}$, $1 \leq j \leq n$, [illegible] $\Gamma = [r_n, r_1] \times [s_n, s_1]$ [illegible] $e^{i(\phi-\theta)} \notin \{1, -1\}$, [illegible]

(i) Let $S(a,b) = \{a_u + b_v : 1 \le u, v \le n\}$. For $1 \le j < n$, if $a_j \ne a_{j+1}$, then $S(a,b)$

$$H(a,j) = \{e^{i\phi}x + e^{i\theta}y + \alpha + \beta : (x,y) \in \mathbb{R}^2, (y-s_1)(y-s_n) \le (x-r_j)(x-r_{j+1})\};$$

If $b_j \ne b_{j+1}$, then $S(a,b)$

$$H(b,j) = \{e^{i\phi}x + e^{i\theta}y + \alpha + \beta : (x,y) \in \mathbb{R}^2, (y-s_j)(y-s_{j+1}) \ge (x-r_1)(x-r_n)\}.$$

(ii) If $\mathcal{E}(A,B)$ is nonempty, then $P = \operatorname{conv}\{a_r + b_s : r, s \in \{1,n\}\}$ by (i).

(iii) If $\mathcal{E}(A,B)$ is nonempty, then by (i) A and B are unitarily similar to $a_1 I_k \oplus A_1$ and $b_1 I_\ell \oplus B_1$, where $a_1 = \cdots = a_k \ne a_{k+1} = \cdots = a_n$ and $b_1 = \cdots = b_\ell \ne b_{\ell+1} = \cdots = b_n$. Then $\mathcal{E}(A,B)$

$$\begin{aligned}\mathcal{E}(A,B) &= P \cap H(a,k) \cap H(b,\ell)\\ &= \{e^{i\phi}x + e^{i\theta}y + \alpha + \beta : (x,y) \in \Gamma, (y-s_1)(y-s_n) = (x-r_1)(x-r_n)\}.\end{aligned}$$

Our proof depends on the following lemma.

LEMMA 4.7. Let $A, B \in M_n$ be as in Theorem 4.6 and $\mu \notin \mathcal{E}(A,B)$.

(a) $\mu - b_1, \mu - b_n$ lie on the same open side of the line through a_1, a_n.

(b) There exist $t_1, t_2 \in [0,1]$ and $j \in \{1, \ldots, n-1\}$ such that

$$\mu - (t_1 b_1 + (1-t_1)b_n) = t_2 a_j + (1-t_2)a_{j+1} \text{ and}$$

$$t_1|\mu - b_1|^2 + (1-t_1)|\mu - b_n|^2 < t_2|a_j|^2 + (1-t_2)|a_{j+1}|^2.$$

(c) There exist $t_1, t_2 \in [0,1]$ and $j \in \{1, \ldots, n-1\}$ such that

$$\mu - (t_1 b_j + (1-t_1)b_{j+1}) = t_2 a_1 + (1-t_2)a_n \text{ and}$$

$$t_1|\mu - b_j|^2 + (1-t_1)|\mu - b_{j+1}|^2 > t_2|a_1|^2 + (1-t_2)|a_n|^2.$$

Proof. Under the given assumption, $DW(A)$ and $DW(\mu I_n - B)$ will be vertical polygonal disks in $\mathbb{C} \times \mathbb{R}$ with vertices in $\{(z, |z|^2) : z \in \mathbb{C}\}$. The two disks have no intersection if and only if

(1) the projections of the two disks on $\mathbb{C}$ do not intersect, or

(2) the projections on $\mathbb{C}$ intersect, but one disk is above the other.

Case (1) is equivalent to (a), and (2) is equivalent to (b) or (c). □

Proof of Theorem 4.6. Suppose $\mu \notin \mathcal{E}(A,B)$. Consider the three cases in Lemma 4.7:

(a) The line segment joining a_1, a_n and the line segment joining $\mu - b_1, \mu - b_n$ have no intersection if and only if for all $0 \le t_1,\ t_2 \le 1$,

$$\begin{aligned} t_2a_1 + (1-t_2)a_n &\neq t_1(\mu - b_1) + (1-t_1)(\mu - b_n), \\ \Leftrightarrow \qquad \mu &\neq t_1b_1 + (1-t_1)b_n + t_2a_1 + (1-t_2)a_n, \\ \Leftrightarrow \qquad \mu &\notin P = \operatorname{conv}\{a_r + b_s : r, s \in \{1, n\}\}, \\ \Leftrightarrow \qquad \mu &\notin \{e^{i\phi}x + e^{i\theta}y + \alpha + \beta : (x, y) \in \Gamma\}. \end{aligned}$$

(b) Suppose for some $t_1, t_2 \in [0, 1]$ and $j \in \{1, \dots, n-1\}$ that

$$\mu - (t_1b_1 + (1-t_1)b_n) = t_2a_j + (1-t_2)a_{j+1} \tag{4.1}$$

and

$$t_1|\mu - b_1|^2 + (1-t_1)|\mu - b_n|^2 < t_2|a_j|^2 + (1-t_2)|a_{j+1}|^2. \tag{4.2}$$

Let $\mu - \alpha - \beta = e^{i\phi}u + e^{i\theta}v$ with $u, v \in \mathbb{R}$. From (4.1), $a_j = \alpha + e^{i\phi}r_j$, and $b_j = \beta + e^{i\theta}s_j$ for $1 \le j \le n$ with $e^{i(\phi-\theta)} \notin \{1, -1\}$, we have

$$u = t_2r_j + (1-t_2)r_{j+1} \quad \text{and} \quad v = t_1s_1 + (1-t_1)s_n$$

or, equivalently,

$$t_1 = \frac{s_n - v}{s_n - s_1} \quad \text{and} \quad t_2 = \frac{r_{j+1} - u}{r_{j+1} - r_j}.$$

We have

$$\begin{aligned} & t_2|a_j|^2 + (1-t_2)|a_{j+1}|^2 \\ &= t_2|\alpha + e^{i\phi}r_j|^2 + (1-t_2)|\alpha + e^{i\phi}r_{j+1}|^2 \\ &= t_2(|\alpha|^2 + (\overline{\alpha}e^{i\phi} + \alpha e^{-i\phi})r_j + r_j^2) + (1-t_2)(|\alpha|^2 + (\overline{\alpha}e^{i\phi} + \alpha e^{-i\phi})r_{j+1} + r_{j+1}^2) \\ &= |\alpha|^2 + (\overline{\alpha}e^{i\phi} + \alpha e^{-i\phi})u + (r_j + r_{j+1})u - r_jr_{j+1} \end{aligned}$$

as $t_2r_j + (1-t_2)r_{j+1} = u$ and $t_2r_j^2 + (1-t_2)r_{j+1}^2 = (r_j + r_{j+1})u - r_jr_{j+1}$. Then

$$\begin{aligned} & t_1|\mu - b_1|^2 + (1-t_1)|\mu - b_n|^2 \\ &= t_1|\alpha + e^{i\phi}u + e^{i\theta}(v - s_1)|^2 + (1-t_1)|\alpha + e^{i\phi}u + e^{i\theta}(v - s_n)|^2 \\ &= t_1\big[|\alpha|^2 + (\overline{\alpha}e^{i\phi} + \alpha e^{-i\phi})u + (\overline{\alpha}e^{i\theta} + \alpha e^{-i\theta})(v - s_1) \\ &\quad + (e^{i(\theta-\phi)} + e^{-i(\theta-\phi)})u(v - s_1) + u^2 + (v - s_1)^2\big] \\ &\quad + (1-t_1)\big[|\alpha|^2 + (\overline{\alpha}e^{i\phi} + \alpha e^{-i\phi})u + (\overline{\alpha}e^{i\theta} + \alpha e^{-i\theta})(v - s_n) \end{aligned}$$

$$+(e^{i(\theta-\phi)}+e^{-i(\theta-\phi)})u(v-s_n)+u^2+(v-s_n)^2\big]$$

$$=|\alpha|^2+(\overline{\alpha}e^{i\phi}+\alpha e^{-i\phi})u+u^2-(v-s_1)(v-s_n)$$

as $t_1(v-s_1)+(1-t_1)(v-s_n)=0$ and $t_1(v-s_1)^2+(1-t_1)(v-s_n)^2=-(v-s_1)(v-s_n)$.

Putting these values into (4.2), we have

$$0<t_2|a_j|^2+(1-t_2)|a_{j+1}|^2-t_1|\mu-b_1|^2-(1-t_1)|\mu-b_n|^2$$

$$=(v-s_1)(v-s_n)-(u-r_j)(u-r_{j+1}).$$

For any $z=e^{i\phi}x+e^{i\theta}y+\alpha+\beta$ with $x,y\in\mathbb{R}$, define

$$f(z)=(y-s_1)(y-s_n)-(x-r_j)(x-r_{j+1}).$$

With $a_k+b_m=e^{i\phi}r_k+e^{i\theta}s_m+\alpha+\beta$, we have

$$f(a_k+b_m)=(s_m-s_1)(s_m-s_n)-(r_k-r_j)(r_k-r_{j+1})\le 0.$$

Thus, $H(a,j)=\{z:f(z)\le 0\}$ is a closed hyperbolic region satisfying (i).

Similarly, if condition (c) in Lemma 4.7 is satisfied, then we have a closed hyperbolic region $H(b,j)$ satisfying (i).

By Lemma 4.7 and (i), we see that $\mathcal{E}(A,B)$ is a subset of the intersection of P and the hyperbolic regions described in (i), and no points in the complement of the intersection belong to $\mathcal{E}(A,B)$. Thus, assertion (ii) of the theorem follows.

From the above discussion, we can see that the complement of $\mathcal{E}(A,B)$ is a union of open hyperbolic regions. So, if $z\in\mathbb{C}\setminus\mathcal{E}(A,B)$, then there exists a half line L containing z with $L\cap\mathcal{E}(A,B)=\emptyset$. Hence, every connected component of $\mathcal{E}(A,B)$ is simply connected.

Suppose the boundary of the parallelogram $P=\operatorname{conv}\{a_u+b_v:u,v\in\{1,n\}\}$ is graduated by the points a_r+b_j and a_j+b_r with $r\in\{1,n\}$ and $j\in\{1,\dots,n\}$. Then the intersection of the hyperbolas $H(a,j)$ (respectively, $H(b,j)$) with P will have endpoints a_r+b_s with $r\in\{j,j+1\}$ and $s\in\{1,n\}$ (respectively, $r\in\{1,n\}$ and $s\in\{j,j+1\}$).

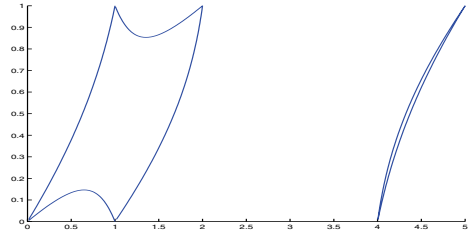
Combining the arguments in the last two paragraphs, we get condition (iii). □

4.8. The above result gives a simple procedure to determine the region $\mathcal{E}(A,B)$ for A and B satisfying the conditions in Theorem 4.6.

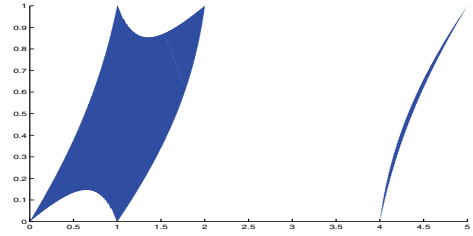
Sketch the hyperbolas corresponding to the intersection of P and the closed hyperbolic regions $H(a,j)$ and $H(b,j)$ for $1\le j<n$ (see section 6.2). Then $\mathcal{E}(A,B)$ consists of the simply connected regions in P determined by these curves.

4.9. Notice that all 2×2 normal matrices are essentially Hermitian. Then for any 2×2 nonscalar normal matrices A and B, $\mathcal{E}(A,B)$ is either a union of line segments or a pair of hyperbola by Theorems 4.1 and 4.6. In both cases, $\mathcal{E}(A,B)$ has an empty interior.

4.10. Consider $A=\operatorname{diag}(0,1,4)$ and $B=\operatorname{diag}(0,1+i)$. The following pictures depict the segments of hyperbolas corresponding to $H(a,1)$, $H(a,2)$, $H(b,1)$, and the set $\mathcal{E}(A,B)$.



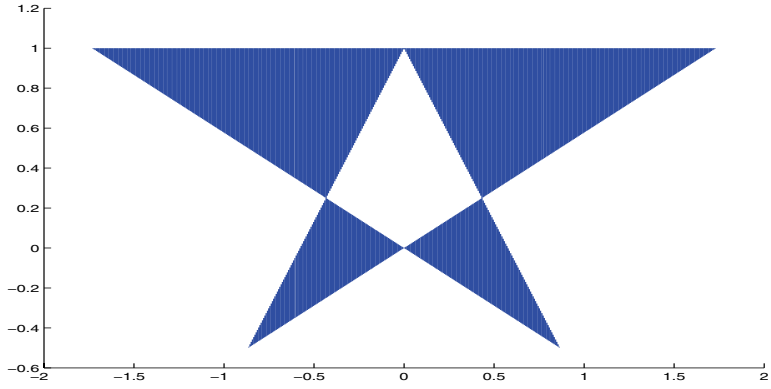
Example 4.10: $H(a,1),\cup H(a,2),\cup H(b,1)$



Example 4.10: $\mathcal{E}(A,B)$

Suppose $A, B \in M_n$ are normal matrices. The connected components of $\mathcal{E}(A,B)$ may not be simply connected in general as shown in the following example.

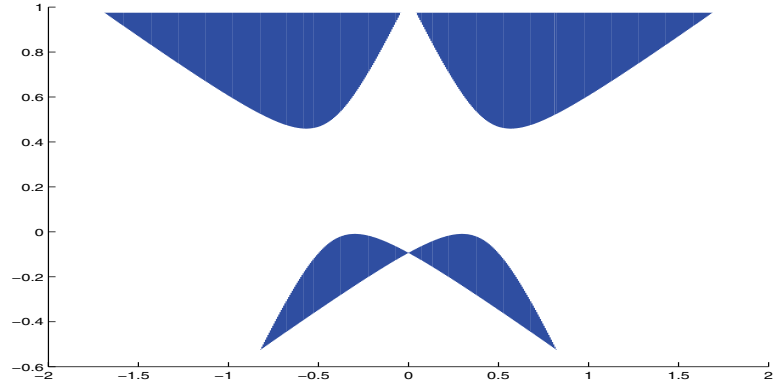
4.11. Let $\omega = e^{i2\pi/3}$. Using the method described in section 6, we can show that for $A = \operatorname{diag}(-i, -i\omega, -i\omega^2)$ and $B = \operatorname{diag}(-i\omega, -i\omega, -i\omega^2)$, $\mathcal{E}(A,B)$ is not simply connected.



Example 4.11: $\mathcal{E}(A,B)$

Although the conclusion of Theorem 4.6 does not hold for arbitrary normal matrices $A, B \in M_n$, one can see form Theorem 3.6 that the boundary of $\mathcal{E}(A,B)$ is a subset of the union of hyperbolas determined by eigenvalue pairs of A and eigenvalue pairs of B. We have the following example.

4.12. Here we let $\omega = e^{i2\pi/3}$, $A = \operatorname{diag}(-i, -i\omega, -i\omega^2)$, and $B = 0.95\operatorname{diag}(-i\omega, -i\omega, -i\omega^2)$. Then the boundary of $\mathcal{E}(A,B)$ are subsets of the union of hyperbolas.



Example 4.12: $\mathcal{E}(A,B)$

It is interesting to note that the matrices in Example 4.12 are obtained from those in Example 4.11 by shrinking B by a factor of 0.95, and hence the two pictures of $\mathcal{E}(A,B)$ have some resemblance even though part of the boundary changes from straight-line segments to curve segments. In general, it is not hard to show that $(A,B) \mapsto \mathcal{E}(A,B)$ is a continuous function, say, by using the usual topology on $M_n \times M_n$ and the Hausdorff metric for compact sets in $\mathbb{C}$.

5. Extensions and open problems. One may ask whether the results can be extended to the sum of k matrices from k different unitary similarity orbits for $k > 2$. For Hermitian matrices $A_1, \ldots, A_k$, there is a complete description of the eigenvalues of the matrices in $\mathcal{U}(A_1)+\cdots+\mathcal{U}(A_k)$; see [8]. For non-Hermitian matrices $A_1, \ldots, A_k \in M_n$, we can extend the idea in section 2 to determine the set of complex numbers μ, which is the eigenvalue of a matrix in $\mathcal{U}(A_1) + \cdots + \mathcal{U}(A_k)$. To this end, we need the concept of the modified Davis–Wielandt shell of $A \in M_n$ defined by

$$MDW(A) = \left\{ \left(x^*Ax, \sqrt{\|Ax\|^2 - |x^*Ax|^2} e^{it} \right) : x \in \mathbb{C}^n,\ x^*x = 1,\ t \in \mathbb{R} \right\} \subseteq \mathbb{C} \times \mathbb{C}.$$

Note that $(\mu_1, \mu_2) \in MDW(A)$ if and only if there is a unitary matrix U such that the first column of U^*AU equals $[\mu_1, \mu_2, 0, \ldots, 0]^t$.

THEOREM 5.1. [illegible] $A_1, \ldots, A_k \in M_n$ [illegible] $\mu \in \mathbb{C}$ [illegible]

(a) [illegible] $U_1, \ldots, U_k \in M_n$ [illegible] $\det(\sum_{j=1}^k U_j A_j U_j^* - \mu I_n) = 0$

(b) $(\mu, 0) \in MDW(A_1) + \cdots + MDW(A_k)$

(c) $[MDW(A_1) + \cdots + MDW(A_{k-1})] \cap MDW(\mu I_n - A_k) \neq \emptyset$

[illegible]. We may assume that $k \geq 3$. The implications $(c) \iff (b) \Rightarrow (a)$ are clear. Suppose (a) holds. Then there are unitary matrices $U_1, \ldots, U_k$ such that the first column of $\sum_{j=1}^k U_j^* A_j U_j$ equals $[\mu, 0, \ldots, 0]^t$. Let v_j be obtained from the first column of $U_j^* A_j U_j$ by removing its first entry μ_j. Then $\sum_{j=1}^k v_j = 0$. Relabel A_j so that $\|v_1\| \geq \cdots \geq \|v_k\|$. Then $\|v_1\| \leq \|v_2\| + \cdots + \|v_k\|$. Thus, there exist $t_1, \ldots, t_k \in \mathbb{R}$ such that $\sum_{j=1}^k \|v_j\| e^{it_j} = 0$. It follows that $(\mu_j, \|v_j\| e^{it_j}) \in MDW(A_j)$ for $j = 1, \ldots, k$ such that $(\mu, 0) = \sum_{j=1}^k (\mu_j, \|v_j\| e^{it_j})$. Thus, condition (b) holds. ∎

Besides the unitary similarity orbits, one may consider orbits of matrices under other group actions and consider the eigenvalues of the sum of matrices from different orbits.

For example, we can consider the usual similarity orbit of $A \in M_n$,

$$\mathcal{S}(A) = \{SAS^{-1} : S \in M_n \text{ is invertible}\};$$

the unitary equivalence orbit of $A \in M_n$,

$$\mathcal{V}(A) = \{UAV : U, V \in M_n \text{ are unitary}\};$$

and the unitary congruence orbit of $A \in M_n$,

$$\mathcal{U}^t(A) = \{UAU^t : U \in M_n \text{ is unitary}\}.$$

For example, if $A, B \in M_n$ are not scalar, then any $\mu \in \mathbb{C}$ can be an eigenvalue of $SAS^{-1} + B$. Can we prove this for complex orthogonal similarity?

One may also consider the eigenvalues of usual product, Lie product, and Jordan product of matrices from different orbits; e.g., see [10, 17]. Of course, one may address similar problems for matrices over reals or arbitrary fields or rings.

For example, our results in section 2 hold for real eigenvalues for real matrices $UAU^t + VBV^t$, where U, V are real orthogonal matrices.

6. Computer algorithms and programs. Using the result in section 2, we can use any positive semidefinite programming package to test whether $\mu \in \mathcal{E}(A, B)$ as follows. For every $(\xi, |\xi|^2) \in DW(\mu I - B)$, we check whether $(\xi, |\xi|^2) \in DW(A)$; equivalently, we check whether a real linear combination of the three Hermitian matrices

$$\mathrm{Re}(A - \xi I), \quad \mathrm{Im}(A - \xi I), \quad A^*A - |\xi|^2 I$$

is positive definite. (This can be done by any positive semidefinite programming package.) If there is no such combination, then $(\xi, |\xi|^2) \in DW(A)$.

Of course, the above test is inefficient and hard to implement. The situation will improve significantly for normal matrices. One can use any standard linear programming package to check whether the two convex polytopes $DW(A)$ and $DW(\mu I - B)$ have nonempty intersection.

The situation further improves if we use Theorem 3.4 and focus on $DW(X) \cap DW(\mu I_2 - Y)$ for normal matrices $X \in M_3$ and $Y \in M_2$. For convenience, we use $\mathcal{E}(X, Y)$ to denote the set of $\mu \in \mathbb{C}$ such that $DW(X) \cap DW(\mu I_2 - Y) \neq \emptyset$; even X and Y may not have the same size. Then the set $\mathcal{E}(A, B)$ is the union of $\mathcal{E}(X, Y)$, where $X = \mathrm{diag}\,(w_1, w_2, w_3) \in M_3$ and $Y = \mathrm{diag}\,(z_1, z_2) \in M_2$ as described in Theorem 3.4. Furthermore, if both A and B have only two distinct eigenvalues, respectively, say w_1, w_2 and z_1, z_2, then $\mathcal{E}(A, B) = \mathcal{E}(X, Y)$ with $X = \mathrm{diag}\,(w_1, w_2)$ and $Y = \mathrm{diag}\,(z_1, z_2)$.

In the following, we will focus on $\mathcal{E}(X, Y)$ so that either $(X, Y) \in M_2 \times M_2$ or $(X, Y) \in M_3 \times M_2$ with distinct eigenvalues. Also as $\mathcal{E}(X, Y)$ depends only on the eigenvalues of X and Y, we may assume that X and Y are diagonal in our discussion.

We describe an easy pointwise test for $x + iy \in \mathcal{E}(X, Y)$ in the following.

6.1. A pointwise test. The (2, 2) case. We begin with the simple case when $X = \mathrm{diag}\,(w_1, w_2), Y = \mathrm{diag}\,(z_1, z_2) \in M_2$, and determine whether a given point $x + iy \in \mathcal{E}(X, Y)$, for four given complex numbers $w_1 = a_1 + ib_1$, $w_2 = a_2 + ib_2$, $z_1 = c_1 + id_1$, and $z_2 = c_2 + id_2$ so that w_1, w_2 are distinct and z_1, z_2 are distinct.

Let $P_j = \left(a_j, b_j, a_j^2 + b_j^2\right)$ and $Q_j = \left(x - c_j, y - d_j, (x - c_j)^2 + (y - d_j)^2\right)$ for $j = 1, 2$. Then $x + iy \in \mathcal{E}$ if and only if

$$\overline{P_1P_2} \cap \overline{Q_1Q_2} \neq \emptyset. \tag{6.1}$$

Since all four points P_1, P_2, Q_1, Q_2 lie on the boundary of the convex set $\{(x, y, z) : x^2 + y^2 \leq z\} \subseteq \mathbb{R}^3$, (6.1) holds if and only if the four points lie on the same plane and P_1 and P_2 lie on the opposite closed half plane determined by the line through Q_1 and Q_2.

Let $\mathbf{u} = \overrightarrow{Q_1Q_2}$, $\mathbf{v} = \overrightarrow{Q_1P_2}$, and $\mathbf{r} = \mathbf{u} \times \mathbf{v} = (r_1, r_2, r_3)$. Define

$$\Delta_0 = \begin{vmatrix} c_1 - c_2 & a_1 + c_1 - x & a_2 - a_1 \\ d_1 - d_2 & b_1 + d_1 - y & b_2 - b_1 \\ (x-c_2)^2 + (y-d_2)^2 & a_1^2 + b_1^2 - (x-c_1)^2 - (y-d_1)^2 & a_2^2 + b_2^2 - a_1^2 - b_1^2 \\ -(x-c_1)^2 - (y-d_1)^2 & & \end{vmatrix},$$

$$\Delta_1 = \begin{vmatrix} c_1 - c_2 & a_1 + c_1 - x & r_1 \\ d_1 - d_2 & b_1 + d_1 - y & r_2 \\ (x-c_2)^2 + (y-d_2)^2 & a_1^2 + b_1^2 - (x-c_1)^2 - (y-d_1)^2 & r_3 \\ -(x-c_1)^2 - (y-d_1)^2 & & \end{vmatrix}.$$

Then P_1, P_2, Q_1, Q_2 all lie on the same plane if and only if $\Delta_0 = 0$. Suppose $\Delta_0 = 0$. Then P_1 and P_2 lie on the opposite closed half plane determined by the line through Q_1 and Q_2 if and only if $\Delta_1 \le 0$.

ASSERTION 6.1. [illegible] $X, Y \in M_2$ [illegible] $x + iy \in \mathcal{E}(X,Y)$ [illegible] $\Delta_0 = 0$ [illegible] $\Delta_1 \le 0$

The (3, 2) case. Next, we describe the test to determine whether a given point

$$x + iy \in \mathcal{E}\left(\operatorname{diag}(w_1, w_2, w_3), \operatorname{diag}(z_1, z_2)\right)$$

for any given complex numbers w_1, w_2, w_3, z_1, z_2 so that w_1, w_2, w_3 are distinct and z_1, z_2 are distinct. Let $w_j = a_j + ib_j$ for $j = 1, 2, 3$, and $z_k = c_k + id_k$ for $k = 1, 2$. Then $x + iy \in \mathcal{E}(X, Y)$ if and only if there exist $0 \le t_1 \le 1$, $0 \le t_2,\ t_3$ and $t_2 + t_3 \le 1$ such that

$$(1-t_1)\begin{pmatrix} x - c_1 \\ y - d_1 \\ (x-c_1)^2 + (y-d_1)^2 \end{pmatrix} + t_1 \begin{pmatrix} x - c_2 \\ y - d_2 \\ (x-c_2)^2 + (y-d_2)^2 \end{pmatrix}$$

$$= (1 - t_2 - t_3)\begin{pmatrix} a_1 \\ b_1 \\ a_1^2 + b_1^2 \end{pmatrix} + t_2 \begin{pmatrix} a_2 \\ b_2 \\ a_2^2 + b_2^2 \end{pmatrix} + t_3 \begin{pmatrix} a_3 \\ b_3 \\ a_3^2 + b_3^2 \end{pmatrix},$$

or, equivalently,

$$\begin{pmatrix} c_2 - c_1 & a_2 - a_1 & a_3 - a_1 \\ d_2 - d_1 & b_2 - b_1 & b_3 - b_1 \\ (x-c_1)^2 + (y-d_1)^2 & a_2^2 + b_2^2 - a_1^2 - b_1^2 & a_3^2 + b_3^2 - a_1^2 - b_1^2 \\ -(x-c_2)^2 - (y-d_2)^2 & & \end{pmatrix} \begin{pmatrix} t_1 \\ t_2 \\ t_3 \end{pmatrix}$$

$$= \begin{pmatrix} x - c_1 - a_1 \\ y - d_1 - b_1 \\ (x-c_1)^2 + (y-d_1)^2 \\ -\left(a_1^2 + b_1^2\right) \end{pmatrix}.$$

Let

$$\Delta_0 = \begin{vmatrix} c_2-c_1 & a_2-a_1 & a_3-a_1 \\ d_2-d_1 & b_2-b_1 & b_3-b_1 \\ (x-c_1)^2+(y-d_1)^2 & a_2^2+b_2^2-a_1^2-b_1^2 & a_3^2+b_3^2-a_1^2-b_1^2 \\ -(x-c_2)^2-(y-d_2)^2 & & \end{vmatrix},$$

$$\Delta_1 = \begin{vmatrix} x-c_1-a_1 & a_2-a_1 & a_3-a_1 \\ y-d_1-b_1 & b_2-b_1 & b_3-b_1 \\ (x-c_1)^2+(y-d_1)^2 & a_2^2+b_2^2-a_1^2-b_1^2 & a_3^2+b_3^2-a_1^2-b_1^2 \\ -\left(a_1^2+b_1^2\right) & & \end{vmatrix},$$

$$\Delta_2 = \begin{vmatrix} c_2-c_1 & x-c_1-a_1 & a_3-a_1 \\ d_2-d_1 & y-d_1-b_1 & b_3-b_1 \\ (x-c_1)^2+(y-d_1)^2 & (x-c_1)^2+(y-d_1)^2 & a_3^2+b_3^2-a_1^2-b_1^2 \\ -(x-c_2)^2-(y-d_2)^2 & -\left(a_1^2+b_1^2\right) & \end{vmatrix},$$

$$\Delta_3 = \begin{vmatrix} c_2-c_1 & a_2-a_1 & x-c_1-a_1 \\ d_2-d_1 & b_2-b_1 & y-d_1-b_1 \\ (x-c_1)^2+(y-d_1)^2 & a_2^2+b_2^2-a_1^2-b_1^2 & (x-c_1)^2+(y-d_1)^2 \\ -(x-c_2)^2-(y-d_2)^2 & & -\left(a_1^2+b_1^2\right) \end{vmatrix}.$$

By the above discussion, we have the following.

ASSERTION 6.2. [illegible] $X \in M_3$ [illegible] $Y \in M_2$ [illegible] $\Delta_0 \neq 0$ [illegible] $x+iy \in \mathcal{E}(A,B)$ [illegible]

$$(\Delta_1, \Delta_2, \Delta_3, \Delta_0-\Delta_1, \Delta_0-\Delta_2-\Delta_3)/\Delta_0$$

[illegible]

Suppose $\Delta_0 = 0$. Let

$$P_j = \left(a_j, b_j, a_j^2+b_j^2\right) \text{ for } j = 1,2,3, \quad \text{and}$$

$$Q_k = \left(x-c_k, y-d_k, (x-c_k)^2+(y-d_k)^2\right) \text{ for } k = 1,2.$$

Then the line L through Q_1 and Q_2 is parallel to the plane Π determined by P_1, P_2, and P_3. Since all five points P_1, P_2, P_3, Q_1, Q_2 lie on the boundary of the convex set $\{(x,y,z) : x^2+y^2 \leq z\} \subseteq \mathbb{R}^3$, $x+iy \in \mathcal{E}(X,Y)$ if and only if L lies on Π and divides Π into two closed half planes with L as the common boundary such that each of these two closed half planes contains some P_i. Hence, L lies on Π if and only if $\Delta_0 = \Delta_1 = 0$. In such a case, let

$$\mathbf{u} = \overrightarrow{Q_1Q_2} = \left(c_1-c_2, d_1-d_2, (x-c_2)^2-(x-c_1)^2+(y-d_2)^2-(y-d_1)^2\right).$$

For $1 \leq j \leq 3$, let

$$\mathbf{v_j} = \overrightarrow{Q_1P_j} = \left(a_j-x+c_1, b_j-y+d_1, a_j^2+b_j^2-(x-c_1)^2-(y-d_1)^2\right).$$

If P_j and P_k lie on different half planes determined by L, then the cross products $\mathbf{u} \times \mathbf{v_j}$ and $\mathbf{u} \times \mathbf{v_k}$ are normals to Π, pointing in opposite directions. For $1 \leq j \leq 3$,

let $\mathbf{r_j} = \mathbf{u} \times \mathbf{v_j} = (r_{1j}, r_{2j}, r_{3j})$ and

$$\Delta'_j = \begin{vmatrix} a_2 - a_1 & a_3 - a_1 & r_{1j} \\ b_2 - b_1 & b_3 - b_1 & r_{2j} \\ a_2^2 + b_2^2 - a_1^2 - b_1^2 & a_3^2 + b_3^2 - a_1^2 - b_1^2 & r_{3j} \end{vmatrix}.$$

We can now describe the remaining case in the following.

ASSERTION 6.3. [illegible] $X \in M_3$ [illegible] $Y \in M_2$ [illegible] $\Delta_0 = 0$ [illegible] $x + iy \in \mathcal{E}(X, Y)$ [illegible] $\Delta_1 = 0$ [illegible] $\Delta'_j \le 0 \le \Delta'_k$ [illegible] $1 \le j, k \le 3$

Based on Assertions 6.1–6.3 with Theorem 3.4, we have written the MATLAB program PT.m (see http://www.math.wm.edu/~ckli/program/PT.m) to test whether a point $x + iy$ lies in $\mathcal{E}(A, B)$.

Also, if $A, B \in M_n$ are normal matrices, then $\mathcal{E}(A, B)$ is a subset of the set

$$\operatorname{conv}(\sigma(A) + \sigma(B)) = \operatorname{conv}\{a + b : a \in \sigma(A), b \in \sigma(B)\}.$$

One can then consider a grid in $\operatorname{conv}(\sigma(A)+\sigma(B))$ and apply the pointwise test to the grid points to plot $\mathcal{E}(A, B)$. The MATLAB program PPT.m (see http://www.math.wm.edu/~ckli/program/PPT.m) is written based on this idea. An example of $\mathcal{E}(A, B)$ generated by the program will be given in section 6.4.

6.2. Parametrization of $\mathcal{E}(A, B)$ for normal matrices. In this subsection, we give a parametrization of $\mathcal{E}(A, B)$. We start with the $(3, 2)$ case.

The (3, 2) case. Consider the case when $X = \operatorname{diag}(w_1, w_2, w_3) \in M_3$ and $Y = \operatorname{diag}(z_1, z_2) \in M_2$. Write $w_j = a_j + ib_j$ for $j = 1, 2, 3$ and $z_k = c_k + id_k$ for $k = 1, 2$. Let $P_j = \left(a_j, b_j, a_j^2 + b_j^2\right)$ for $j = 1, 2, 3$ and $Q_k = (x - c_k, y - d_k, (x - c_k)^2 + (y - d_k)^2)$ for $k = 1, 2$. As $\mu \in \mathcal{E}(X, Y)$ if and only if $\mu - w_1 - z_1 \in \mathcal{E}(X - w_1 I_3, Y - z_1 I_2)$, we may assume that $w_1 = z_1 = 0$, i.e., $a_1 = b_1 = c_1 = d_1 = 0$.

Notice that $\mathcal{E}(X, Y)$ is the set of $x + iy \in \mathbb{C}$ such that $\Delta(P_1P_2P_3) \cap \overline{Q_1Q_2} \neq \emptyset$. This holds if and only if there exists $0 \le t \le 1$ such that $\overline{P_1P_4} \cap \overline{Q_1Q_2} \neq \emptyset$, where

(6.2)
$$P_4 = (a_4, b_4, r_4) = \left(ta_2 + (1-t)a_3,\ tb_2 + (1-t)b_3,\ t(a_2^2 + b_2^2) + (1-t)(a_3^2 + b_3^2)\right).$$

By the convexity of the function $(x, y) \mapsto x^2 + y^2$, we have $r_4 \ge a_4^2 + b_4^2$. Thus, there are $0 \le t_1, t_2 \le 1$ such that

$$(1 - t_1)\begin{pmatrix} x \\ y \\ x^2 + y^2 \end{pmatrix} + t_1 \begin{pmatrix} x - c_2 \\ y - d_2 \\ (x - c_2)^2 + (y - d_2)^2 \end{pmatrix} = (1 - t_2)\begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix} + t_2 \begin{pmatrix} a_4 \\ b_4 \\ r_4 \end{pmatrix},$$

or, equivalently,

$$x = c_2 t_1 + a_4 t_2, \qquad y = d_2 t_1 + b_4 t_2, \tag{6.3}$$

and

$$t_1(x^2 + y^2 - (x - c_2)^2 - (y - d_2)^2) + r_4 t_2 = x^2 + y^2. \tag{6.4}$$

Substituting (6.3) into (6.4) we get

$$(c_2^2+d_2^2)t_1(t_1-1)-(a_4^2+b_4^2)t_2^2+r_4t_2=0$$

which is a hyperbolic equation of t_1 and t_2 on $[0,1]$. Then

$$t_1=\frac{1}{2}\pm\sqrt{\frac{1}{4}+\left(\frac{a_4^2+b_4^2}{c_2^2+d_2^2}\right)t_2^2-\left(\frac{r_4}{c_2^2+d_2^2}\right)t_2}, \tag{6.5}$$

As $r_4\geq a_4^2+b_4^2$, it is easy to check that t_1 is well defined and $0\leq t_1\leq 1$ whenever $t_2\in[0,1]$ if $r_4^2\leq(a_4^2+b_4^2)(c_2^2+d_2^2)$, and

$$t_2\in\left[0,\frac{r_4-\sqrt{r_4^2-(a_4^2+b_4^2)(c_2^2+d_2^2)}}{2(a_4^2+b_4^2)}\right]\cup\left[\frac{r_4+\sqrt{r_4^2-(a_4^2+b_4^2)(c_2^2+d_2^2)}}{2(a_4^2+b_4^2)},1\right]$$

if $r_4^2>(a_4^2+b_4^2)(c_2^2+d_2^2)$.

ASSERTION 6.4. [illegible] $X\in M_3$ [illegible] $Y\in M_2$ [illegible] $t\in[0,1]$ [illegible] t_1 [illegible] t_2 [illegible] (6.2) [illegible] (6.5) [illegible] $x+iy\in\mathcal{E}(X,Y)$ [illegible] (6.3) [illegible] t_1 [illegible] t_2

The (2, 2) case. Next, we consider the $(2,2)$ case. By an argument similar to the $(3,2)$ case with $(a_4,b_4,r_4)=(a_2,b_2,a_2^2+b_2^2)$, we have

$$x=c_2t_1+a_2t_2,\qquad y=d_2t_1+b_2t_2, \tag{6.6}$$

and

$$(c_2^2+d_2^2)t_1(t_1-1)-(a_2^2+b_2^2)t_2(t_2-1)=0,$$

which is a hyperbolic equation of t_1 and t_2 on $[0,1]$. Then

$$t_1=\frac{1}{2}\pm\sqrt{\frac{1}{4}+\left(\frac{a_2^2+b_2^2}{c_2^2+d_2^2}\right)t_2(t_2-1)} \tag{6.7}$$

lies in $[0,1]$ whenever $t_2\in[0,1]$ if $c_2^2+d_2^2\geq a_2^2+b_2^2$, or

$$t_2=\frac{1}{2}\pm\sqrt{\frac{1}{4}+\left(\frac{c_2^2+d_2^2}{a_2^2+b_2^2}\right)t_1(t_1-1)} \tag{6.8}$$

lies in $[0,1]$ whenever $t_1\in[0,1]$ if $c_2^2+d_2^2<a_2^2+b_2^2$.

ASSERTION 6.5. [illegible] $X=\operatorname{diag}(0,w_2)\in M_2$ [illegible] $Y=\operatorname{diag}(0,z_2)\in M_2$ [illegible] $x+iy\in\mathcal{E}(X,Y)$ [illegible] (6.6) [illegible] t_1 [illegible] t_2 [illegible] (6.7) [illegible] (6.8)

Based on Assertions 6.4 and 6.5 and Theorem 3.4, we have written the MATLAB program HPT.m (see http://www.math.wm.edu/~ckli/program/HPT.m) to generate $\mathcal{E}(X,Y)$. An example of $\mathcal{E}(A,B)$ generated by the program will be given in section 6.4.

Using Theorem 3.6 and Assertion 6.5, we have written the MATLAB program BD32.m (see http://www.math.wm.edu/~ckli/program/BD32.m) to generate $\partial\mathcal{E}(X,Y)$, the boundary of $\mathcal{E}(X,Y)$ for normal $X\in M_3$ and $Y\in M_2$.

6.3. A different algorithm. To use the parametric approach in the previous subsection, one has to determine t_1 and t_2 in $[0,1]$, and draw two curves in terms of t_1 and t_2. Here, we introduce a different algorithm to generate $\mathcal{E} = \mathcal{E}(X,Y)$ with $X = \operatorname{diag}(w_1, w_2, w_3)$ and $Y = \operatorname{diag}(z_1, z_2)$. To generate the points $x+iy \in \mathcal{E}(X,Y)$, we first determine the range for x. Then for each x in the range, we determine the range of y. Here we consider the $(3,2)$ case only.

Let $w_j = a_j + ib_j$ and $z_k = c_k + id_k$ for $j = 1,2,3$ and $k = 1,2$. Since $\mathcal{E}(\mu X, \mu Y) = \mu\mathcal{E}(X,Y)$ and $\mathcal{E}(X+\nu I, Y-\nu I) = \mathcal{E}(X,Y)$, we may assume that $d_1 = d_2$. Also by a suitable relabeling, we can always assume $c_1 < c_2$ and $b_1 \le b_2 \le b_3$. Evidently, if $x+iy \in \mathcal{E}(X,Y)$, then

$$\min\{a_1,a_2,a_3\} + c_1 \le x \le \max\{a_1,a_2,a_3\} + c_2.$$

Now we choose an x satisfying the above inequalities and determine y so that $x+iy$ lies in $\mathcal{E}(X,Y)$.

In fact, except for the case when $b_1 = b_2 = b_3$, we may further assume that $b_1 < b_2 \le b_3$. In the exceptional case, $X - ib_1 I_3$ and $Y - id_1 I_2$ are Hermitian matrices. Then the result follows from Theorem 4.1. In detail, we have the following.

ASSERTION 6.6. [illegible] $a_1 < a_2 < a_3$, $b_1 = b_2 = b_3$, $c_1 < c_2$, [illegible] $d_1 = d_2$ [illegible] $x+iy \in \mathcal{E}(X,Y)$ [illegible] $y = b_1 + d_1$ [illegible]

$$x \in [a_1+c_1, a_3+c_2] \backslash (a_1+c_2, a_2+c_1) \cup (a_2+c_2, a_3+c_1) \cup (a_3+c_1, a_1+c_2).$$

From now on, we suppose that $b_1 < b_2 \le b_3$. As $\mathcal{E}(X - \mu I_3, Y + \mu I_2) = \mathcal{E}(X,Y)$, we can also assume that $|w_1| = |w_2| \ne |w_3|$ if w_1, w_2, w_3 are collinear and $|w_1| = |w_2| = |w_3|$, otherwise.

Note that as $d_1 = d_2$ and $|w_1| = |w_2|$, the determinants Δ_i defined in section 6.1 become

$$\Delta_0 = \begin{vmatrix} c_2 - c_1 & a_2 - a_1 & a_3 - a_1 \\ 0 & b_2 - b_1 & b_3 - b_1 \\ (x-c_1)^2 - (x-c_2)^2 & 0 & a_3^2 + b_3^2 - a_1^2 - b_1^2 \end{vmatrix},$$

$$\Delta_1 = \begin{vmatrix} x - c_1 - a_1 & a_2 - a_1 & a_3 - a_1 \\ y - d_1 - b_1 & b_2 - b_1 & b_3 - b_1 \\ (x-c_1)^2 + (y-d_1)^2 - (a_1^2 + b_1^2) & 0 & a_3^2 + b_3^2 - a_1^2 - b_1^2 \end{vmatrix},$$

$$\Delta_2 = \begin{vmatrix} c_2 - c_1 & x - c_1 - a_1 & a_3 - a_1 \\ 0 & y - d_1 - b_1 & b_3 - b_1 \\ (x-c_1)^2 - (x-c_2)^2 & (x-c_1)^2 + (y-d_1)^2 - (a_1^2 + b_1^2) & a_3^2 + b_3^2 - a_1^2 - b_1^2 \end{vmatrix},$$

$$\Delta_3 = \begin{vmatrix} c_2 - c_1 & a_2 - a_1 & x - c_1 - a_1 \\ 0 & b_2 - b_1 & y - d_1 - b_1 \\ (x-c_1)^2 - (x-c_2)^2 & 0 & (x-c_1)^2 + (y-d_1)^2 - (a_1^2 + b_1^2) \end{vmatrix},$$

where the last three determinants can been expressed in the form

$$\Delta_i = \Delta_{i2}(y-d_1)^2 + \Delta_{i1}(y-d_1) + \Delta_{i0} \quad i = 1,2,3,$$

with

$$\Delta_{12} = \begin{vmatrix} a_2 - a_1 & a_3 - a_1 \\ b_2 - b_1 & b_3 - b_1 \end{vmatrix},$$

$$\Delta_{11} = -\begin{vmatrix} a_2 - a_1 & a_3 - a_1 \\ 0 & a_3^2 + b_3^2 - a_1^2 - b_1^2 \end{vmatrix},$$

$$\Delta_{10} = \begin{vmatrix} x - c_1 - a_1 & a_2 - a_1 & a_3 - a_1 \\ -b_1 & b_2 - b_1 & b_3 - b_1 \\ (x-c_1)^2 - (a_1^2 + b_1^2) & 0 & a_3^2 + b_3^2 - a_1^2 - b_1^2 \end{vmatrix},$$

$$\Delta_{22} = -\begin{vmatrix} c_2 - c_1 & a_3 - a_1 \\ 0 & b_3 - b_1 \end{vmatrix},$$

$$\Delta_{21} = \begin{vmatrix} c_2 - c_1 & a_3 - a_1 \\ (x-c_1)^2 - (x-c_2)^2 & a_3^2 + b_3^2 - a_1^2 - b_1^2 \end{vmatrix},$$

$$\Delta_{20} = \begin{vmatrix} c_2 - c_1 & x - c_1 - a_1 & a_3 - a_1 \\ 0 & -b_1 & b_3 - b_1 \\ (x-c_1)^2 - (x-c_2)^2 & (x-c_1)^2 - (a_1^2 + b_1^2) & a_3^2 + b_3^2 - a_1^2 - b_1^2 \end{vmatrix},$$

$$\Delta_{32} = \begin{vmatrix} c_2 - c_1 & a_2 - a_1 \\ 0 & b_2 - b_1 \end{vmatrix},$$

$$\Delta_{31} = -\begin{vmatrix} c_2 - c_1 & a_2 - a_1 \\ (x-c_1)^2 - (x-c_2)^2 & 0 \end{vmatrix},$$

$$\Delta_{30} = \begin{vmatrix} c_2 - c_1 & a_2 - a_1 & x - c_1 - a_1 \\ 0 & b_2 - b_1 & -b_1 \\ (x-c_1)^2 - (x-c_2)^2 & 0 & (x-c_1)^2 - (a_1^2 + b_1^2) \end{vmatrix}.$$

Note that

$$\Delta_0 = (c_2 - c_1)\begin{vmatrix} b_2 - b_1 & b_3 - b_1 \\ 0 & a_3^2 + b_3^2 - a_1^2 - b_1^2 \end{vmatrix} + ((x-c_1)^2 - (x-c_2)^2)\begin{vmatrix} a_2 - a_1 & a_3 - a_1 \\ b_2 - b_1 & b_3 - b_1 \end{vmatrix}.$$

Therefore, $\Delta_0 = 0$ if and only if

$$w_1, w_2, w_3 \text{ are not collinear and } x = (c_1 + c_2)/2. \tag{6.9}$$

Suppose (6.9) holds. Then $\Delta_0 = 0$ and by Assertion 6.3, $x + iy \in \mathcal{E}(X, Y)$ only if $\Delta_1 = 0$, in which the equality holds when

$$y = d_1 \pm \sqrt{(x - c_1)^2 - (a_1^2 + b_1^2)}.$$

Now we can check whether the point $x + iy$ in $\mathcal{E}(X, Y)$ holds by considering the values of Δ_i' defined in Assertion 6.3.

Exclude the above case. Then $\Delta_0 \neq 0$. By Assertion 6.2, $x + iy \in \mathcal{E}(X, Y)$ if and only if

$$\Delta_1/\Delta_0 \geq 0, \quad \Delta_2/\Delta_0 \geq 0, \quad \Delta_3/\Delta_0 \geq 0,$$
$$(\Delta_0 - \Delta_1)/\Delta_0 \geq 0, \quad \text{and} \quad (\Delta_0 - \Delta_2 - \Delta_3)/\Delta_0 \geq 0.$$

In the following, we determine the possible range of y that satisfies the above inequalities.

Suppose $\alpha_1 \leq \beta_1, \ldots, \alpha_5 \leq \beta_5$ are the real solutions, if they exist, of the following quadratic equations:

$$\Delta_1 = \Delta_{12}(y - d_1)^2 + \Delta_{11}(y - d_1) + \Delta_{10} = 0, \tag{6.10}$$

TABLE 1

(6.11)	(6.12)	$\Delta_0 > 0$	$\Delta_0 < 0$
Y	Y	$[\alpha_2, \beta_2] \backslash (\alpha_3, \beta_3)$	$[\alpha_3, \beta_3] \backslash (\alpha_2, \beta_2)$
Y	N	$[\alpha_2, \beta_2]$	no solution
N	Y	no solution	$[\alpha_3, \beta_3]$
N	N	no solution	no solution

TABLE 2

	$b_2 \neq b_3 \quad (\Delta_{22} + \Delta_{32} \neq 0)$		$b_2 = b_3 \quad (\Delta_{22} + \Delta_{32} = 0)$	
(6.14)	$\Delta_0 > 0$	$\Delta_0 < 0$	$(\Delta_{21} + \Delta_{31})/\Delta_0 > 0$	$(\Delta_{21} + \Delta_{31})/\Delta_0 < 0$
Y	$(-\infty, \alpha_5] \cup [\beta_5, \infty)$	$[\alpha_5, \beta_5]$	$(-\infty, \alpha_5]$	$[\alpha_5, \infty)$
N	$(-\infty, \infty)$	no solution	/	/

$$\Delta_2 = \Delta_{22}(y - d_1)^2 + \Delta_{21}(y - d_1) + \Delta_{20} = 0, \tag{6.11}$$

$$\Delta_3 = \Delta_{32}(y - d_1)^2 + \Delta_{31}(y - d_1) + \Delta_{30} = 0, \tag{6.12}$$

$$\Delta_0 - \Delta_1 = -\Delta_{12}(y - d_1)^2 - \Delta_{11}(y - d_1) - \Delta_{10} + \Delta_0 = 0, \tag{6.13}$$

$$\begin{aligned}\Delta_0 - \Delta_2 - \Delta_3 = -(\Delta_{22} + \Delta_{32})(y - d_1)^2 - (\Delta_{21} + \Delta_{31})(y - d_1) \\ -(\Delta_{20} + \Delta_{30}) + \Delta_0 = 0.\end{aligned} \tag{6.14}$$

Also, we continue to use α_i to denote the corresponding real solution if the quadratic equation is linear.

As $b_1 < b_2 \leq b_3$,

$$\Delta_{22} = -(c_2 - c_1)(b_3 - b_1) < 0 \quad \text{and} \quad \Delta_{32} = (c_2 - c_1)(b_2 - b_1) > 0.$$

Thus, the inequalities $\Delta_2/\Delta_0 \geq 0$ and $\Delta_3/\Delta_0 \geq 0$ are satisfied if and only if y lies in the interval specified in Table 1 where "Y" denotes the corresponding equation having real solution(s) and "N" otherwise.

Now we turn to (6.14). Note that

$$\Delta_{22} + \Delta_{32} = \begin{vmatrix} c_2 - c_1 & a_2 - a_3 \\ 0 & b_2 - b_3 \end{vmatrix} \leq 0.$$

Therefore the equation is linear, equivalently $\Delta_{22} + \Delta_{32} = 0$, if and only if $b_2 = b_3$, which can hold only if w_1, w_2, w_3 are not collinear. In this case, $a_3^2 + b_3^2 - a_1^2 - b_1^2 = |w_3|^2 - |w_1|^2 = 0$ and so

$$\Delta_{21} + \Delta_{31} = \begin{vmatrix} c_2 - c_1 & a_3 - a_2 \\ (x - c_1)^2 - (x - c_2)^2 & a_3^2 + b_3^2 - a_1^2 - b_1^2 \end{vmatrix} \neq 0.$$

Therefore the inequality $(\Delta_0 - \Delta_2 - \Delta_3)/\Delta_0 \geq 0$ is satisfied if and only if y lies in the intervals specified in Table 2.

TABLE 3

		Noncollinear ($\Delta_{12} \neq 0$)		Collinear ($\Delta_{12} = 0$)		
(6.10)	(6.13)	$\Delta_{12}/\Delta_0 > 0$	$\Delta_{12}/\Delta_0 < 0$	$\Delta_{11}/\Delta_0 > 0$	$\Delta_{11}/\Delta_0 = 0$	$\Delta_{11}/\Delta_0 < 0$
Y	Y	$[\alpha_4, \beta_4] \backslash (\alpha_1, \beta_1)$	$[\alpha_1, \beta_1] \backslash (\alpha_4, \beta_4)$	$[\alpha_1, \alpha_4]$	$(-\infty, \infty)$	$[\alpha_4, \alpha_1]$
Y	N	no solution	$[\alpha_1, \beta_1]$	/	/	/
N	Y	$[\alpha_4, \beta_4]$	no solution	/	/	/
N	N	no solution	no solution	/	/	/

Finally, we consider (6.10) and (6.13). Clearly, the equations are linear, i.e., $\Delta_{12} = 0$, if and only if w_1, w_2, w_3 are collinear. In addition, the equations are constant functions, i.e., $\Delta_{12} = 0$ and $\Delta_{11} = 0$, if and only if $a_1 = a_2 = a_3$. In the case of being a constant function,

$$\Delta_0 = (c_2 - c_1)(b_2 - b_1)(a_3^2 + b_3^2 - a_1^2 - b_1^2) \quad \text{and} \quad \Delta_1 = (x - c_1 - a_1)(b_2 - b_1)(a_3^2 + b_3^2 - a_1^2 - b_1^2).$$

Thus, the inequalities $\Delta_1/\Delta_0 \geq 0$ and $(\Delta_0 - \Delta_1)/\Delta_0 \geq 0$ are satisfied if and only if $c_1 \leq x - a_1 \leq c_2$, which always holds by our assumption on x.

Combining with the quadratic and linear cases, the inequalities $\Delta_1/\Delta_0 \geq 0$ and $(\Delta_0 - \Delta_1)/\Delta_0 \geq 0$ are satisfied if and only if y lies in the intervals specified in Table 3.

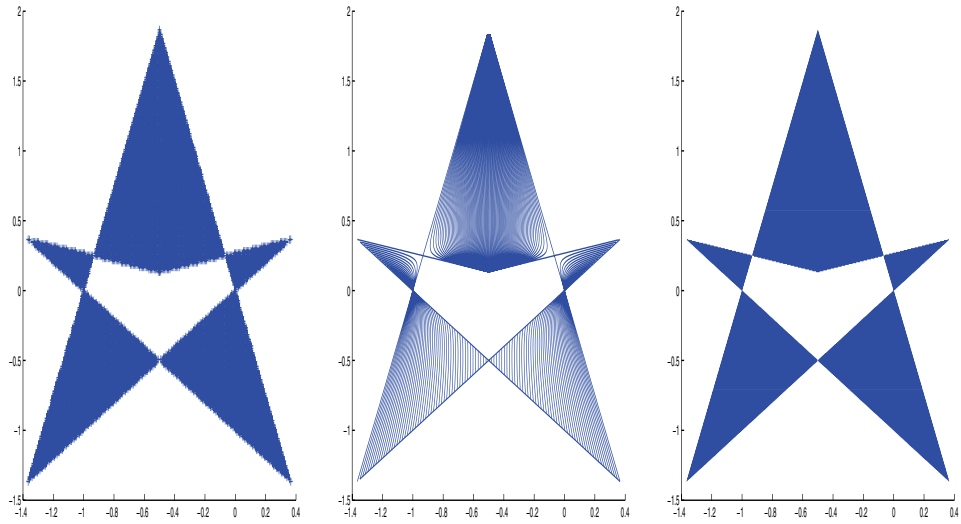
ASSERTION 6.7. [illegible] $b_1 < b_2 \leq b_3$, $c_1 < c_2$, $d_1 = d_2$ [illegible] (i) $|w_1| = |w_2| \neq |w_3|$, w_1, w_2, w_3 [illegible] (ii) $|w_1| = |w_2| = |w_3|$ [illegible] (6.9) [illegible] $x \in [a_{\min} + c_1, a_{\max} + c_2]$ [illegible] $a_{\min} = \min\{a_1, a_2, a_3\}$ [illegible] $a_{\max} = \max\{a_1, a_2, a_3\}$, $x + iy \in \mathcal{E}(X, Y)$ [illegible] y [illegible] 1, 2 [illegible] 3

Based on Assertions 6.6–6.7, we have written another MATLAB program IPT.m (see http://www.math.wm.edu/~ckli/program/IPT.m) to generate $\mathcal{E}(A, B)$ for normal matrices A and B. An example of $\mathcal{E}(A, B)$ generated by the program will be given in section 6.4.

6.4. An example of $\mathcal{E}(A, B)$ generated by the three approaches.

[illegible] 6.8. Let $A = \text{diag}\,(i, i\omega, i\omega^2)$ and $B = \text{diag}\,(\omega, \omega^2)$ with $\omega = e^{i2\pi/3}$. The region of $\mathcal{E}(A, B)$ is plotted using MATLAB programs based on the three different algorithms in sections 6.1–6.3.

In the above example, we see that the first program took the longest computer time and a lot of memory to determine and store $\mathcal{E}(A, B)$. The second program took less computer time and less memory, but it is not effective in approximating the straight line boundary of $\mathcal{E}(A, B)$ (using hyperbolas). Finally, the third program used the least amount of computer time and memory to produce and store $\mathcal{E}(A, B)$.



$\mathcal{E}(A,B)$ plotted by PPT.m $\mathcal{E}(A,B)$ plotted by HPT.m $\mathcal{E}(A,B)$ plotted by IPT.m

COMBINATION PRECONDITIONING AND THE BRAMBLE–PASCIAK$^+$ PRECONDITIONER*

MARTIN STOLL† AND ANDY WATHEN†

Abstract. It is widely appreciated that the iterative solution of linear systems of equations with large sparse matrices is much easier when the matrix is symmetric. It is equally advantageous to employ symmetric iterative methods when a nonsymmetric matrix is self-adjoint in a nonstandard inner product. Here, general conditions for such self-adjointness are considered. A number of known examples for saddle point systems are surveyed and combined to make new combination preconditioners which are self-adjoint in different inner products. In particular, a new method related to the Bramble–Pasciak CG method is introduced and it is shown that a combination of the two outperforms the widely used classical method on a number of examples. Furthermore, we combine Bramble and Pasciak's method with a recently introduced method by Schöberl and Zulehner. The result gives a new preconditioner and inner product that can outperform the original methods of Bramble–Pasciak and Schöberl–Zulehner.

Key words. linear systems, Krylov subspaces, nonstandard inner products

DOI. 10.1137/070688961

1. Introduction.

In 1988, Bramble and Pasciak [6] introduced a block triangular preconditioner for the discrete Stokes problem (matrix) which had the almost magical effect of turning the original indefinite symmetric matrix problem into a nonsymmetric matrix which is both self-adjoint and, in certain practical circumstances, positive definite in a nonstandard inner product; thus the conjugate gradient method could be used in the nonstandard inner product.

Precisely, the symmetric saddle point problem

$$\underbrace{\begin{bmatrix} A & B^T \\ B & -C \end{bmatrix}}_{\mathcal{A}} x = b \tag{1.1}$$

with symmetric positive definite $A \in \mathbb{R}^{n\times n}$, symmetric positive semidefinite $C \in \mathbb{R}^{m\times m}$, $m < n$, and $B \in \mathbb{R}^{m\times n}$ of row full rank m, if preconditioned on the left by

$$\mathcal{P} = \begin{bmatrix} A_0 & 0 \\ B & -I \end{bmatrix} \text{ with } \mathcal{P}^{-1} = \begin{bmatrix} A_0^{-1} & 0 \\ BA_0^{-1} & -I \end{bmatrix}, \tag{1.2}$$

results in the nonsymmetric matrix

$$\widehat{\mathcal{A}} = \mathcal{P}^{-1}\mathcal{A} = \begin{bmatrix} A_0^{-1}A & A_0^{-1}B^T \\ BA_0^{-1}A - B & BA_0^{-1}B^T + C \end{bmatrix}, \tag{1.3}$$

†Oxford University Computing Laboratory, Wolfson Building, Parks Road, Oxford, OX1 3QD, UK (martin.stoll@comlab.ox.ac.uk, andy.wathen@comlab.ox.ac.uk).

which turns out to be self-adjoint (many would say "symmetric") in the inner product $\langle \cdot, \cdot \rangle_{\mathcal{H}}$ defined by $\langle w, y \rangle_{\mathcal{H}} := w^T \mathcal{H} y$, where

$$\mathcal{H} = \begin{bmatrix} A - A_0 & 0 \\ 0 & I \end{bmatrix}.$$

Moreover, $\langle w, \widehat{\mathcal{A}} w \rangle_{\mathcal{H}} > 0$ for all $w \neq 0$ so that $\widehat{\mathcal{A}}$ is also positive definite. For these results to hold, the matrix block A_0 has to be symmetric and positive definite and must be scaled in order that $A - A_0$ is also positive definite so that $\langle \cdot, \cdot \rangle_{\mathcal{H}}$ not only defines a symmetric bilinear form but also satisfies the positivity requirement $\langle x, x \rangle_{\mathcal{H}} > 0$ for $x \neq 0$ which ensures that it is an inner product.

The outcome is that the conjugate gradient (CG) method [26] based on this inner product can be applied and the system can be solved efficiently; see, for example, Algorithm 2.1 in [11] for the CG method in an arbitrary inner product. This Bramble–Pasciak CG method is a very powerful and widely used tool to solve saddle point systems. Further analysis and applications can be found in [47, 9, 29, 28, 7, 1, 48, 22, 2, 3, 37].

The Bramble–Pasciak CG method is not the only solver of this kind where a matrix is preconditioned and then a nonstandard inner product can be found such that efficient Krylov subspace solvers like CG can be applied. More examples are given in [15, 42, 5, 34, 28, 31, 40, 8] and will be explained and used later in this paper.

We comment that alternative approaches for the Stokes and other saddle point problems use symmetric preconditioners and iterative methods such as MINRES and ITFQMR (see [11, Chapter 6], [4, 17]). We show some comparisons with such methods; see also [9]. We explore some abstract but elementary algebraic structures which enable some broadening of the set of available preconditioners for which saddle point problems may be treated by symmetric iterative methods in nonstandard inner-products. The outcome is some new preconditioning techniques which might be useful in practice. In particular, we derive and test numerically a new method which requires exactly the same work per iteration as the widely used Bramble–Pasciak method but which converges in fewer iterations for several examples we have computed. We furthermore introduce a method that combines the Bramble–Pasciak method and a recently introduced method by Schöberl and Zulehner with promising numerical results. Our algebraic results apply generally but we have not considered anything other than saddle point examples.

2. Background. For linear systems with large dimensions, it is well known that iterative methods are most often the only feasible solution approaches; direct methods for dense and sparse or structured matrices work well provided the bandwidth/skyline is not too large, but if fill-in in the computed triangular factors is too great such methods are usually infeasible beyond a certain dimension. Amongst the available iterative methods, multigrid approaches are extremely attractive for certain classes of problems (see, for example, [11]), and in more generality, Krylov subspace methods can be excellent solvers provided suitably fast convergence can be achieved; preconditioning is almost always required to achieve this.

For symmetric matrix systems, the CG method [26] for positive definite systems and minimum residual (MINRES) or SYMMLQ methods [35] for indefinite systems are based on short term recurrences and are the Krylov subspace methods of choice. The CG method is especially popular because of its efficiency. By contrast, for nonsymmetric matrix systems there is a large number of methods (GMRES, BICGSTAB, QMR; see [39, 45, 19]) and various hybrid methods (GMRESR, BICGSTAB(ℓ); see [46, 44])

reflecting that convergence is not as well understood than in the symmetric case and the best method for any particular problem is usually not clear; see [43] for a good overview and further references. This situation is rather unsatisfactory. Certainly if it were computationally possible to somehow convert a nonsymmetric system to an equivalent one with a symmetric matrix so that CG or MINRES or some other symmetric method could be employed then this could be very attractive. Even in the case of a symmetric and indefinite matrix system, conversion to a symmetric and positive definite matrix system is attractive since it enables use of CG (the above mentioned case of the Bramble–Pasciak method is an example). Use of the normal equations approach—replacing $Ax = b$ with $A^TAx = A^Tb$—is usually not so attractive because for other than a matrix which is very well conditioned this usually leads to much poorer convergence of iterative methods.

One can broaden the possibilities by allowing nonstandard inner-products—the important/desirable matrices are then the matrices which are self-adjoint with respect to such an inner product. The self-adjointness in a nonstandard inner-product enables the use of CG for positive definite systems and MINRES for self-adjoint but indefinite systems in that inner product. A method like the ideal transpose-free quasi minimal residuals (ITFQMR) [17] can be used if a matrix is only self-adjoint in a symmetric bilinear form (cf. section 7.4). For related considerations, in particular in connection with Krylov subspace methods, see [43, section 13].

Here, we use the term symmetric when referring to matrices which are self-adjoint in the usual Euclidean inner product defined by $\langle w, y\rangle := w^Ty = \sum w_iy_i$, i.e., those matrices whose entries satisfy $a_{i,j} = a_{j,i}$. Correspondingly, by $A^T(= B)$ we mean the matrix with entries $b_{i,j} = a_{j,i}$, i.e., the adjoint matrix in the usual Euclidean inner product.

3. Basic properties. First, we review the basic mathematics. We consider here only real Euclidean vector spaces; we see no reason that our theory should not apply in the complex case or indeed for other vector spaces, but we have not done so.

We say that

$$\langle\cdot,\cdot\rangle : \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R} \tag{3.1}$$

is a symmetric bilinear form if

- $\langle w, y\rangle = \langle y, w\rangle$ for all $w, y \in \mathbb{R}^n$
- $\langle \alpha w + y, z\rangle = \alpha\langle w, z\rangle + \langle y, z\rangle$ for all $w, y, z \in \mathbb{R}^n$ and all $\alpha \in \mathbb{R}$.

With the addition of a nondegeneracy condition, Gohberg, Lancaster, and Rodman (cf. [23]) use the term "indefinite inner product"; general properties of such forms can also be found here.

If, additionally, the positivity conditions

$$\langle w, w\rangle > 0 \text{ for } w \neq 0 \quad \text{with} \quad \langle w, w\rangle = 0 \text{ if and only if } w = 0$$

are satisfied, then (3.1) defines an inner product on $\mathbb{R}^n$.

For any real symmetric matrix, $\mathcal{H}$, $\langle\cdot,\cdot\rangle_{\mathcal{H}}$ defined by

$$\langle w, y\rangle_{\mathcal{H}} := w^T\mathcal{H}y \tag{3.2}$$

is easily seen to be a symmetric bilinear form which is an inner product if and only if $\mathcal{H}$ is positive definite.

A matrix $\mathcal{A} \in \mathbb{R}^{n\times n}$ is self-adjoint in $\langle\cdot,\cdot\rangle$ if and only if

$$\langle \mathcal{A}w, y\rangle = \langle w, \mathcal{A}y\rangle \qquad \text{for all } w, y.$$

Self-adjointness of the matrix $\mathcal{A}$ in $\langle\cdot,\cdot\rangle_{\mathcal{H}}$ thus means that

$$w^T\mathcal{A}^T\mathcal{H}y = \langle \mathcal{A}w, y\rangle_{\mathcal{H}} = \langle w, \mathcal{A}y\rangle_{\mathcal{H}} = w^T\mathcal{H}\mathcal{A}y$$

for all w, y so that

$$\mathcal{A}^T\mathcal{H} = \mathcal{H}\mathcal{A} \tag{3.3}$$

is the basic relation for self-adjointness of $\mathcal{A}$ in $\langle\cdot,\cdot\rangle_{\mathcal{H}}$.

Furthermore, we want to describe basic properties of bilinear forms and nonstandard inner products. This can also be viewed in terms of real symmetric matrices since (3.3) states that $\mathcal{A}^T\mathcal{H}$ is a real symmetric matrix. Here, we prefer the language of inner products since we feel it indicates more of the mathematical structure which leads to the development of new methods based on nonstandard inner products.

We emphasize that $\langle\cdot,\cdot\rangle$, $\langle\cdot,\cdot\rangle_{\mathcal{H}}$ must be symmetric bilinear forms here, but we do not require them to be inner products for the theory presented in this section. For practical reasons, we will consider positivity/nonpositivity of symmetric bilinear forms and positive definiteness/indefiniteness of self-adjoint matrices separately from our considerations of symmetry and self-adjointness. Whenever we write $\langle\cdot,\cdot\rangle_{\mathcal{H}}$, $\mathcal{H}$ will be symmetric.

It is easy to verify the following lemmas.

LEMMA 3.1. [illegible] $\mathcal{A}_1$ [illegible] $\mathcal{A}_2$ [illegible] $\langle\cdot,\cdot\rangle_{\mathcal{H}}$ [illegible] $\alpha, \beta \in \mathbb{R}$, $\alpha\mathcal{A}_1 + \beta\mathcal{A}_2$ [illegible] $\langle\cdot,\cdot\rangle_{\mathcal{H}}$

LEMMA 3.2. [illegible] $\mathcal{A}$ [illegible] $\langle\cdot,\cdot\rangle_{\mathcal{H}_1}$ [illegible] $\langle\cdot,\cdot\rangle_{\mathcal{H}_2}$ [illegible] $\mathcal{A}$ [illegible] $\langle\cdot,\cdot\rangle_{\alpha\mathcal{H}_1+\beta\mathcal{H}_2}$ [illegible] $\alpha, \beta \in \mathbb{R}$

Now if $\mathcal{A}$ is preconditioned on the left by $\mathcal{P}$, then from (3.3), $\widehat{\mathcal{A}} = \mathcal{P}^{-1}\mathcal{A}$ is self-adjoint in $\langle\cdot,\cdot\rangle_{\mathcal{H}}$ if and only if

$$(\mathcal{P}^{-1}\mathcal{A})^T\mathcal{H} = \mathcal{H}\mathcal{P}^{-1}\mathcal{A} \tag{3.4}$$

which is

$$\mathcal{A}^T\mathcal{P}^{-T}\mathcal{H} = \mathcal{H}\mathcal{P}^{-1}\mathcal{A}$$

or

$$\mathcal{A}^T(\mathcal{P}^{-T}\mathcal{H}) = (\mathcal{P}^{-T}\mathcal{H})^T\mathcal{A}$$

since $\mathcal{H}$ is symmetric. Thus if $\mathcal{A}$ is also symmetric we get

$$(\mathcal{P}^{-T}\mathcal{H})^T\mathcal{A} = \mathcal{A}(\mathcal{P}^{-T}\mathcal{H}) \tag{3.5}$$

and so we have the following lemma.

LEMMA 3.3. [illegible] $\mathcal{A}$, $\widehat{\mathcal{A}} = \mathcal{P}^{-1}\mathcal{A}$ [illegible] $\langle\cdot,\cdot\rangle_{\mathcal{H}}$ [illegible] $\mathcal{P}^{-T}\mathcal{H}$ [illegible] $\langle\cdot,\cdot\rangle_{\mathcal{A}}$

[illegible]. The proof follows directly from the above lemmas and (3.3). □

[illegible] 3.4. Lemma 3.3 includes the even more simple situations that $\mathcal{P}^{-1}\mathcal{A}$ is self-adjoint in $\langle\cdot,\cdot\rangle_{\mathcal{P}}$ and $\mathcal{A}\mathcal{P}^{-1}$ is self-adjoint in $\langle\cdot,\cdot\rangle_{\mathcal{A}^{-1}}$ when both $\mathcal{A}$ and $\mathcal{P}$ are

symmetric since I is trivially self-adjoint in any symmetric bilinear form. Clearly invertibility of $\mathcal{P}$ and $\mathcal{A}$, respectively, are needed in these two cases.

Now for symmetric $\mathcal{A}$, if $\mathcal{P}_1$ and $\mathcal{P}_2$ are such that $\mathcal{P}_i^{-1}\mathcal{A}$ is self-adjoint in $\langle\cdot,\cdot\rangle_{\mathcal{H}_i}$, $i = 1, 2$, for symmetric matrices $\mathcal{H}_1$, $\mathcal{H}_2$, then

$$(\mathcal{P}_1^{-1}\mathcal{A})^T\mathcal{H}_1 = \mathcal{H}_1(\mathcal{P}_1^{-1}\mathcal{A}) \quad \text{and} \quad (\mathcal{P}_2^{-1}\mathcal{A})^T\mathcal{H}_2 = \mathcal{H}_2(\mathcal{P}_2^{-1}\mathcal{A}). \tag{3.6}$$

Using Lemma 3.3, $\mathcal{P}_i^{-T}\mathcal{H}_i$ is self-adjoint in $\langle\cdot,\cdot\rangle_{\mathcal{A}}$ for $i = 1, 2$, and thus by Lemma 3.1

$$\alpha\mathcal{P}_1^{-T}\mathcal{H}_1 + \beta\mathcal{P}_2^{-T}\mathcal{H}_2$$

is also self-adjoint in $\langle\cdot,\cdot\rangle_{\mathcal{A}}$ for any $\alpha, \beta \in \mathbb{R}$. Now, if for some α, β we are able to decompose the matrix $(\alpha\mathcal{P}_1^{-T}\mathcal{H}_1 + \beta\mathcal{P}_2^{-T}\mathcal{H}_2) = \mathcal{P}_3^{-T}\mathcal{H}_3$ for some symmetric matrix $\mathcal{H}_3$, then $\mathcal{P}_3^{-T}\mathcal{H}_3$ is self-adjoint in $\langle\cdot,\cdot\rangle_{\mathcal{A}}$, and a further application of Lemma 3.3 yields that $\mathcal{P}_3^{-1}\mathcal{A}$ is self-adjoint in $\langle\cdot,\cdot\rangle_{\mathcal{H}_3}$. We have now proved the following lemma.

LEMMA 3.5. $\mathcal{P}_1$ $\mathcal{P}_2$ $\mathcal{A}$ $\mathcal{H}_1$ $\mathcal{H}_2$ $\mathcal{P}_1^{-1}\mathcal{A}$ $\langle\cdot,\cdot\rangle_{\mathcal{H}_1}$ $\mathcal{P}_2^{-1}\mathcal{A}$ $\langle\cdot,\cdot\rangle_{\mathcal{H}_2}$

$$\alpha\mathcal{P}_1^{-T}\mathcal{H}_1 + \beta\mathcal{P}_2^{-T}\mathcal{H}_2 = \mathcal{P}_3^{-T}\mathcal{H}_3$$

$\mathcal{P}_3$ $\mathcal{H}_3$ $\mathcal{P}_3^{-1}\mathcal{A}$ $\langle\cdot,\cdot\rangle_{\mathcal{H}_3}$

Lemma 3.5 shows a possible way to generate new preconditioners for $\mathcal{A}$. In section 6 we show practical examples of its use.

The construction of $\mathcal{P}_3$, $\mathcal{H}_3$ in Lemma 3.5 also allows straightforward inheritance of positive definiteness—for this to be a useful property it is essential that $\langle\cdot,\cdot\rangle_{\mathcal{H}}$ defines an inner product, i.e., that $\mathcal{H}$ is positive definite. It is trivial to construct examples of indefinite diagonal matrices $\mathcal{A}$ and $\mathcal{H}$ for which $\langle\mathcal{A}w, w\rangle_{\mathcal{H}} > 0$ for all nonzero w, but in order to be able to take advantage of positive definiteness, for example, by employing conjugate gradients, it is important that $\langle w, w\rangle_{\mathcal{H}} = w^T\mathcal{H}w > 0$ for all nonzero w.

LEMMA 3.6. 3.5 $\mathcal{P}_i^{-1}\mathcal{A}$ $\langle\cdot,\cdot\rangle_{\mathcal{H}_i}$ $i = 1, 2$ $\mathcal{P}_3^{-1}\mathcal{A}$ $\langle\cdot,\cdot\rangle_{\mathcal{H}_3}$ α β

. Positive definiteness of $\mathcal{P}^{-1}\mathcal{A}$ in $\langle\cdot,\cdot\rangle_{\mathcal{H}}$ means that

$$\langle\mathcal{P}^{-1}\mathcal{A}w, w\rangle_{\mathcal{H}} > 0 \quad \text{for} \quad w \neq 0,$$

i.e., that $w^T\mathcal{A}\mathcal{P}^{-T}\mathcal{H}w > 0$ so that $\mathcal{A}\mathcal{P}^{-T}\mathcal{H}$ is a symmetric matrix with all eigenvalues positive. Thus all of $\mathcal{A}\mathcal{P}_1^{-T}\mathcal{H}_1$ and $\mathcal{A}\mathcal{P}_2^{-T}\mathcal{H}_2$ is symmetric and positive definite, and it follows that

$$\alpha\mathcal{A}\mathcal{P}_1^{-T}\mathcal{H}_1 + \beta\mathcal{A}\mathcal{P}_2^{-T}\mathcal{H}_2 = \mathcal{A}\mathcal{P}_3^{-T}\mathcal{H}_3$$

must also be symmetric and positive definite for at least the positive values of α and β. ∎

We comment that there will, in general, be some negative values of α or β for which $\mathcal{P}_3^{-1}\mathcal{A}$ remains positive definite but at least one of α and β needs to be positive in this case. The precise limits on the values that α and β can take whilst positive definiteness is preserved depend on the extreme eigenvalues of $\mathcal{A}\mathcal{P}_1^{-T}\mathcal{H}_1$ and $\mathcal{A}\mathcal{P}_2^{-T}\mathcal{H}_2$.

Unfortunately, even if $\mathcal{H}_1$ and $\mathcal{H}_2$ are positive definite there is no guarantee that $\mathcal{H}_3$ will be also.

We can also consider right preconditioning: If $\widehat{\mathcal{A}} = \mathcal{A}\mathcal{P}^{-1}$ is self-adjoint in $\langle\cdot,\cdot\rangle_{\mathcal{H}}$, then

$$\mathcal{P}^{-T}\mathcal{A}^T\mathcal{H} = \mathcal{H}\mathcal{A}\mathcal{P}^{-1} \text{ which is } (\mathcal{P}^{-1})^T(\mathcal{A}^T\mathcal{H}) = (\mathcal{A}^T\mathcal{H})^T\mathcal{P}^{-1}. \tag{3.7}$$

Thus, we have the following lemma.

LEMMA 3.7. [illegible] $\mathcal{P}$ [illegible] $\widehat{\mathcal{A}} = \mathcal{A}\mathcal{P}^{-1}$ [illegible] $\langle\cdot,\cdot\rangle_{\mathcal{H}}$ [illegible] $\mathcal{H}$ [illegible] $\mathcal{A}^T\mathcal{H}$ [illegible] $\langle\cdot,\cdot\rangle_{\mathcal{P}^{-1}}$

Lemma 3.7 shows that we could combine problem matrices and symmetric bilinear forms for the same preconditioner. This is obviously more of a theoretical than a practical result compared to obtaining new preconditioners for a given problem as in the case of left preconditioning noted earlier. One of the decompositions as $\mathcal{P}_3^{-T}\mathcal{H}_3$, that we introduce in section 6 will provide not only a symmetric inner product matrix but also a symmetric preconditioner and therefore fulfills the conditions of Lemma 3.7.

We now want to discuss very briefly the eigenvalues of matrices which are self-adjoint according to our definition which allows indefinite symmetric bilinear forms. Assume that $\mathcal{A}^T\mathcal{H} = \mathcal{H}\mathcal{A}$ holds and that (λ, v) is a given eigenpair of $\mathcal{A}$. Thus,

$$\mathcal{A}v = \lambda v, \qquad v \neq 0. \tag{3.8}$$

Multiplying (3.8) from the left by $v^*\mathcal{H}$, where v^* is the conjugate transpose of v, gives

$$v^*\mathcal{H}\mathcal{A}v = \lambda v^*\mathcal{H}v. \tag{3.9}$$

Notice that the left-hand side of (3.9) is real since $\mathcal{H}\mathcal{A}$ is real symmetric. On the right-hand side $v^*\mathcal{H}v$ is also real since $\mathcal{H}$ is real symmetric, therefore the eigenvalue λ must be real. Note that, a matrix $\mathcal{H}$ always exists such that $\mathcal{A}^T\mathcal{H} = \mathcal{H}\mathcal{A}$ since any matrix is similar to its transpose; see, for example, Chapter 3.2 in [27]. In the context of the above theory, the interesting candidates for $\mathcal{H}$ are the real symmetric matrices; a complex symmetric matrix $\mathcal{H}$ always exists such that $\mathcal{A}^T\mathcal{H} = \mathcal{H}\mathcal{A}$ (cf. [27, section 2.3]).

Note that the above arguments establish that there is no symmetric bilinear form in which $\mathcal{A}$ is self-adjoint unless $\mathcal{A}$ has real eigenvalues.

It is also known that for a real diagonalizable matrix $\mathcal{A}$ which has only real eigenvalues there always exist inner products in which $\mathcal{A}$ is self-adjoint.

LEMMA 3.8. [illegible] $\mathcal{A} = R^{-1}\Lambda R$ [illegible] $\mathcal{A}$ [illegible] Λ [illegible] $\mathcal{A}$ [illegible] $\langle\cdot,\cdot\rangle_{R^T\Theta R}$ [illegible] Θ [illegible]. The conditions (3.3) for self-adjointness of $\mathcal{A}$ in $\langle\cdot,\cdot\rangle_{\mathcal{H}}$ are

$$R^T\Lambda R^{-T}\mathcal{H} = \mathcal{H}R^{-1}\Lambda R$$

which are clearly satisfied for $\mathcal{H} = R^T\Theta R$ whenever Θ is diagonal because then Θ and Λ commute. Clearly $\mathcal{H}$ is positive definite whenever the diagonal entries of Θ are positive. □

We remark that this result is not of great use in practice since knowledge of the complete eigensystem of $\mathcal{A}$ is somewhat prohibitive.

4. Saddle point examples. The first example is the classical method by Bramble and Pasciak already mentioned in the introduction. The preconditioner is given by

$$\mathcal{P} = \begin{bmatrix} A_0 & 0 \\ B & -I \end{bmatrix} \quad \text{and} \quad \mathcal{P}^{-1} = \begin{bmatrix} A_0^{-1} & 0 \\ BA_0^{-1} & -I \end{bmatrix} \tag{4.1}$$

and the symmetric bilinear form defined by the matrix

$$\mathcal{H} = \begin{bmatrix} A - A_0 & 0 \\ 0 & I \end{bmatrix}. \tag{4.2}$$

There are also extensions to the classical Bramble–Pasciak case; see [34, 28, 42]. In [34], for example, a Schur complement preconditioner S_0 is introduced into $\mathcal{P}$ giving

$$\mathcal{P} = \begin{bmatrix} A_0 & 0 \\ B & -S_0 \end{bmatrix} \quad \text{and} \quad \mathcal{P}^{-1} = \begin{bmatrix} A_0^{-1} & 0 \\ S_0^{-1}BA_0^{-1} & -S_0^{-1} \end{bmatrix}; \tag{4.3}$$

under certain conditions positive definiteness of the preconditioned saddle point system can still be guaranteed in a nonstandard inner product similar to (4.2), i.e.,

$$\mathcal{H} = \begin{bmatrix} A - A_0 & 0 \\ 0 & S_0 \end{bmatrix}. \tag{4.4}$$

A similar analysis was provided by Zulehner in 2002; see [48]. Zulehner considered a preconditioner of the form (4.3) for an inexact Uzawa method which under certain conditions can admit the usability of a CG acceleration; see [33] for the connection of CG and the inexact Uzawa algorithm as a Richardson iteration method.

In 2006, Benzi and Simoncini gave a further example; see [5], which is an extension of an earlier work by Fischer et al. (cf. [15]). Namely,

$$\mathcal{P} = \mathcal{P}^{-1} = \begin{bmatrix} I & 0 \\ 0 & -I \end{bmatrix} \tag{4.5}$$

and

$$\mathcal{H} = \begin{bmatrix} A - \gamma I & B^T \\ B & \gamma I \end{bmatrix}. \tag{4.6}$$

Recently, Liesen and Parlett made an extension to this result taking a nonzero matrix C in (1.1) into account; see [30, 31]. In the language used here, the preconditioner is again

$$\mathcal{P} = \mathcal{P}^{-1} = \begin{bmatrix} I & 0 \\ 0 & -I \end{bmatrix} \tag{4.7}$$

but the symmetric bilinear form is now defined by

$$\mathcal{H} = \begin{bmatrix} A - \gamma I & B^T \\ B & \gamma I - C \end{bmatrix}. \tag{4.8}$$

There are certain conditions which must be satisfied by the parameter γ in order to guarantee positive definiteness of $\mathcal{H}$ so that CG in the inner product $\langle \cdot, \cdot \rangle_{\mathcal{H}}$ can be reliably employed; see [5, 30, 31].

Liesen and Parlett also showed in [31] that the matrix $\widehat{\mathcal{A}} = \mathcal{P}^{-1}\mathcal{A}$ is self-adjoint in every bilinear form of the type $\mathcal{H}p(\widehat{\mathcal{A}})$, where $\mathcal{H} = \mathcal{P}$ and $p(\widehat{\mathcal{A}})$ is any real polynomial in $\widehat{\mathcal{A}}$. The proof is based on a technique introduced by Freund (cf. [16]), where the matrix $\mathcal{H}$ can be shifted from one side of the polynomial $p(\mathcal{A})$ to the other by successively using $\widehat{\mathcal{A}}^T\mathcal{H} = \mathcal{H}\widehat{\mathcal{A}}$; see also section 7.3 of this paper. Trivially, this observation holds for general $\mathcal{H}$ whenever the condition $\widehat{\mathcal{A}}^T\mathcal{H} = \mathcal{H}\widehat{\mathcal{A}}$ is satisfied for any real symmetric $\mathcal{H}$ and not just for the matrix $\mathcal{H} = \mathcal{P}$. Through the choice of the polynomial p, the approach presented by Liesen and Parlett provides a whole set of interesting bilinear forms that may give useful examples.

Another example was given in Zulehner [48] in the context of inexact Uzawa methods and in [40] by Schöberl and Zulehner where the saddle point problem with $C = 0$ is preconditioned by the constraint preconditioner

$$\mathcal{P} = \begin{bmatrix} A_0 & B^T \\ B & BA_0^{-1}B^T - \hat{S} \end{bmatrix}$$

with A_0 and $\hat{S}$ being symmetric and positive definite. Then the preconditioned matrix is self-adjoint in the inner product defined by

$$\mathcal{H} = \begin{bmatrix} A_0 - A & 0 \\ 0 & BA_0^{-1}B^T - \hat{S} \end{bmatrix}.$$

Another example using a constraint preconditioner was given by Dohrmann and Lehoucq in [8]. They consider the general saddle point problem given in (1.1) with the constraint preconditioner

$$\mathcal{P} = \begin{bmatrix} \hat{S}_A & B^T \\ B & \hat{C} \end{bmatrix},$$

where $\hat{S}_A$ is an approximation to a penalized primal Schur complement $S_A = A + B^T\hat{C}^{-1}B$ and a symmetric and positive definite $\hat{C}$. The inner product in which the preconditioned matrix is self-adjoint is given by

$$\mathcal{H} = \begin{bmatrix} S_A - \hat{S}_A & 0 \\ 0 & \hat{C} - C \end{bmatrix}.$$

5. The modified Bramble–Pasciak preconditioner. The original Bramble–Pasciak CG method requires that the matrix

$$\mathcal{H} = \begin{bmatrix} A - A_0 & 0 \\ 0 & I \end{bmatrix}$$

is positive definite. The obvious drawback of this method is the necessity to scale the matrix A_0 such that $A - A_0$ is positive definite. Usually an eigenvalue problem for $A_0^{-1}A$ or at least an eigenvalue estimation problem has to be solved which can be costly; see [24] for a survey of methods that could be applied.

In contrast, we introduce the preconditioner

$$\mathcal{P}^+ = \begin{bmatrix} A_0 & 0 \\ -B & S_0 \end{bmatrix} \quad \text{and} \quad \left(\mathcal{P}^+\right)^{-1} = \begin{bmatrix} A_0^{-1} & 0 \\ BA_0^{-1} & S_0^{-1} \end{bmatrix} \tag{5.1}$$

and obtain by left preconditioning with $\mathcal{P}^+$

$$\widehat{\mathcal{A}} = \left(\mathcal{P}^+\right)^{-1}\mathcal{A} = \begin{bmatrix} A_0^{-1}A & A_0^{-1}B^T \\ S_0^{-1}BA_0^{-1}A + S_0^{-1}B & S_0^{-1}BA_0^{-1}B^T - S_0^{-1}C \end{bmatrix}. \tag{5.2}$$

Simple algebra shows that $\widehat{\mathcal{A}}$ is self-adjoint in the inner product induced by

$$\mathcal{H}^+ = \begin{bmatrix} A + A_0 & 0 \\ 0 & S_0 \end{bmatrix}, \tag{5.3}$$

where S_0 is a symmetric and positive definite Schur-complement preconditioner. An inner product of similar form to (5.3) was used by Zulehner in [48] in the analysis of inexact Uzawa methods. Note that for a positive definite preconditioner A_0 the matrix $\mathcal{H}^+$ is always positive definite due to the positive definiteness of the matrices A, A_0, and S_0. Thus, we are in this case always with an inner product and not just a symmetric bilinear form—whatever symmetric and positive definite A_0 is chosen—and so the appropriate Krylov subspace method can be used in this inner product. We will discuss the eigenvalue properties of the preconditioned matrix in section 8.

For the classical Bramble–Pasciak method (1.2), (1.3), Klawonn shows in [28] that the matrix

$$\widehat{\mathcal{A}}^T\mathcal{H} = \begin{bmatrix} AA_0^{-1}A - A & AA_0^{-1}B^T - B^T \\ BA_0^{-1}A - B & BA_0^{-1}B^T + C \end{bmatrix} \tag{5.4}$$

can be factorized as

$$\begin{bmatrix} I & 0 \\ BA^{-1} & I \end{bmatrix} \begin{bmatrix} AA_0^{-1}A - A & 0 \\ 0 & BA^{-1}B^T + C \end{bmatrix} \begin{bmatrix} I & A^{-1}B^T \\ 0 & I \end{bmatrix}, \tag{5.5}$$

which is a congruence transformation. Now note that we can rewrite $AA_0^{-1}A - A$ as

$$A(A_0^{-1} - A^{-1})A,$$

which will be positive definite if $A_0^{-1} - A^{-1}$ is positive definite or, equivalently,

$$y^T A_0 y < y^T A y. \tag{5.6}$$

The condition (5.6) is precisely that required for $\mathcal{H}$ to be positive definite in this case. Since $BA^{-1}B^T + C$ is positive definite, Sylvester's law of inertia applied to (5.5) guarantees that $\widehat{\mathcal{A}}^T\mathcal{H}$ is positive definite, i.e., that $\widehat{\mathcal{A}}$ is self-adjoint and positive definite in $\langle\cdot,\cdot\rangle_{\mathcal{H}}$.

The same has to be shown for the new preconditioner $\mathcal{P}^+$. Using Klawonn's approach we get for the matrix

$$\widehat{\mathcal{A}}^T\mathcal{H}^+ = \begin{bmatrix} AA_0^{-1}A + A & AA_0^{-1}B^T + B^T \\ BA_0^{-1}A + B & BA_0^{-1}B^T - C \end{bmatrix} \tag{5.7}$$

the decomposition

$$\begin{bmatrix} I & 0 \\ BA^{-1} & I \end{bmatrix} \begin{bmatrix} AA_0^{-1}A + A & 0 \\ 0 & -BA^{-1}B^T - C \end{bmatrix} \begin{bmatrix} I & A^{-1}B^T \\ 0 & I \end{bmatrix}. \tag{5.8}$$

This shows that $\widehat{\mathcal{A}}^T\mathcal{H}^+$ is indefinite since $-BA^{-1}B^T - C$ is always negative definite and $AA_0^{-1}A + A$ is positive definite. Therefore the reliable applicability of the CG

method cannot be guaranteed. One alternative is to use a special implementation of MINRES which will be introduced in section 7.2.

We want to mention that the Bramble–Pasciak$^+$ preconditioner can also be interpreted as the classical Bramble–Pasciak preconditioner applied to the matrix $\mathcal{J}\mathcal{A}$, where $\mathcal{J} = \mathrm{diag}(I_n, -I_m)$ with I_j the identity of dimension $j = \{m, n\}$.

6. Examples of combination preconditioning.

6.1. Bramble–Pasciak combination preconditioning. Using Lemma 3.5 we want to analyze the possibility of combining the classical Bramble–Pasciak configuration with the Bramble–Pasciak$^+$ preconditioner introduced in the last section. Therefore, we have the preconditioners

$$\mathcal{P}_1 = \begin{bmatrix} A_0 & 0 \\ B & -I \end{bmatrix} \quad \text{and} \quad \mathcal{P}_2 = \begin{bmatrix} A_0 & 0 \\ -B & I \end{bmatrix}$$

and for the inner products

$$\mathcal{H}_1 = \begin{bmatrix} A - A_0 & 0 \\ 0 & I \end{bmatrix} \quad \text{and} \quad \mathcal{H}_2 = \begin{bmatrix} A + A_0 & 0 \\ 0 & I \end{bmatrix}.$$

Instead of $\alpha, \beta \in \mathbb{R}$ we use the combination parameters α and $1 - \alpha$ and get

$$\alpha \mathcal{P}_1^{-T} \mathcal{H}_1 + (1-\alpha)\mathcal{P}_2^{-T} \mathcal{H}_2 = \begin{bmatrix} A_0^{-1}A + (1-2\alpha)I & A_0^{-1}B^T \\ 0 & (1-2\alpha)I \end{bmatrix}.$$

If we find a decomposition as described in Lemma 3.5, then a new preconditioner and bilinear form are given. One factorization possibility would be

$$P_3^{-T} = \begin{bmatrix} A_0^{-1} & A_0^{-1}B^T \\ 0 & (1-2\alpha)I \end{bmatrix} \Longrightarrow P_3 = \begin{bmatrix} A_0 & 0 \\ \frac{1}{(2\alpha-1)}B & \frac{1}{1-2\alpha}I \end{bmatrix}$$

as the new preconditioner, and the bilinear form is then defined by

$$\mathcal{H}_3 = \begin{bmatrix} A + (1-2\alpha)A_0 & 0 \\ 0 & I \end{bmatrix}.$$

Note that, for $\alpha = 1$ we obtain the classical Bramble–Pasciak configuration, and $\alpha = 0$ gives the Bramble–Pasciak$^+$ setup. The obtained preconditioner can also be viewed as a special instance of an inexact Uzawa preconditioner; see [48].

We now have to analyze if positivity in the new bilinear form can be achieved and if the bilinear form is an inner product which can be exploited for short-term recurrence methods. Hence, the matrix

$$\widehat{\mathcal{A}}^T \mathcal{H}_3$$

with $\widehat{\mathcal{A}} = \mathcal{P}_3^{-1}\mathcal{A}$ has to be analyzed. The matrix

$$\widehat{\mathcal{A}}^T \mathcal{H}_3 = \begin{bmatrix} AA_0^{-1}A + (1-2\alpha)A & AA_0^{-1}B^T + (1-2\alpha)B^T \\ BA_0^{-1}A + (1-2\alpha)B & BA_0^{-1}B^T - (1-2\alpha)C \end{bmatrix}$$

can, similarly to the above, be factorized as the congruence transform

$$\widehat{\mathcal{A}}^T \mathcal{H}_3 =$$

$$\begin{bmatrix} I & 0 \\ BA^{-1} & I \end{bmatrix} \begin{bmatrix} AA_0^{-1}A + (1-2\alpha)A & 0 \\ 0 & (2\alpha-1)BA^{-1}B^T - (1-2\alpha)C \end{bmatrix} \begin{bmatrix} I & A^{-1}B^T \\ 0 & I \end{bmatrix}.$$

The Sylvester law of inertia indicates that the number of positive and negative eigenvalues is determined by the eigenvalues of the matrix

$$\begin{bmatrix} AA_0^{-1}A + (1-2\alpha)A & 0 \\ 0 & (2\alpha-1)(BA_0^{-1}B^T + C) \end{bmatrix}$$

which we can analyze in a similar manner to (5.4), (5.5). We first consider the case where $C = 0$, and then it is easy to see that the block $(2\alpha - 1)BA_0^{-1}B^T$ is positive for $\alpha > 1/2$. With this choice for α we have to find conditions such that the block $AA_0^{-1}A + (1-2\alpha)A$ is also positive definite. Similar to the analysis made in section 7.1, we note the equivalence

$$A\left(A_0^{-1} + (1-2\alpha)A^{-1}\right)A,$$

and therefore positivity is given if $y^T A_0 y < (2\alpha - 1)y^T Ay$ which can also be written as

$$A_0 < (2\alpha - 1)A.$$

In addition, we want the matrix $\mathcal{H}_3$ to define an inner product which will be satisfied if the block $A + (1-2\alpha)A_0 > 0$, which is equivalent to

$$\frac{1}{2\alpha - 1}A > A_0.$$

Again, the case $\alpha = 1$ gives the Bramble–Pasciak configuration, and $\alpha = 0$ shows that there is no configuration that makes the Bramble–Pasciak$^+$ setup positive definite and CG reliably applicable. It is still possible to obtain a reliable CG method in the combination preconditioning case, i.e., if

$$A_0 < \min\left\{(2\alpha - 1)A, \frac{1}{2\alpha - 1}A\right\}$$

which is a more general restriction on A_0 than the Bramble–Pasciak case, $\alpha = 1$. The case $C \neq 0$ can be treated similarly since the block $(2\alpha - 1)(BA_0^{-1}B^T + C)$ will be positive for all $\alpha > 1/2$ and the above analysis applies.

6.2. Bramble–Pasciak and Benzi–Simoncini. As another less practical example which nevertheless shows how even very different methods can be combined, we consider $\mathcal{P}_1, \mathcal{H}_1$ defined by the classical Bramble–Pasciak method (4.1), (4.2) and $\mathcal{P}_2, \mathcal{H}_2$ defined by the Benzi–Simoncini approach (4.5), (4.6). From Lemma 3.5 we get

$$(\alpha\mathcal{P}_1^{-T}\mathcal{H}_1 + \beta\mathcal{P}_2^{-T}\mathcal{H}_2) = \begin{bmatrix} (\alpha A_0^{-1} + \beta I)A - (\alpha + \beta\gamma)I & (\alpha A_0^{-1} + \beta I)B^T \\ -\beta B & -(\alpha + \beta\gamma)I \end{bmatrix}, \tag{6.1}$$

which is self-adjoint for all $\alpha, \beta \in \mathbb{R}$ in $\langle\cdot,\cdot\rangle_{\mathcal{A}}$. If we are able to split this into a new preconditioner $\mathcal{P}_3$ and a symmetric matrix $\mathcal{H}_3$, Lemma 3.5 guarantees that $\mathcal{P}_3^{-1}\mathcal{A}$ will be self-adjoint in $\langle\cdot,\cdot\rangle_{\mathcal{H}_3}$.

One possibility is that

$$\mathcal{P}_3^{-T} = \begin{bmatrix} \alpha A_0^{-1} + \beta I & 0 \\ 0 & -\beta I \end{bmatrix} \text{ and } \mathcal{H}_3 = \begin{bmatrix} A - (\alpha + \beta\gamma)(\alpha A_0^{-1} + \beta I)^{-1} & B^T \\ B & \frac{\alpha+\beta\gamma}{\beta}I \end{bmatrix}. \tag{6.2}$$

Numerical results we have computed with this combination were less promising and we have omitted them. The bilinear form $\langle\cdot,\cdot\rangle_{\mathcal{H}_3}$ is not so convenient to work with.

6.3. Bramble–Pasciak and Schöberl–Zulehner. We now combine the Bramble–Pasciak CG and the method proposed by Schöberl and Zulehner in [40]. Therefore, we consider the preconditioners

$$\mathcal{P}_1 = \begin{bmatrix} A_0 & 0 \\ B & -S_0 \end{bmatrix} \quad \text{and} \quad \mathcal{P}_2 = \begin{bmatrix} A_0 & B^T \\ B & BA_0^{-1}B^T - \hat{S} \end{bmatrix}$$

and the inner products

$$\mathcal{H}_1 = \begin{bmatrix} A - A_0 & 0 \\ 0 & S_0 \end{bmatrix} \quad \text{and} \quad \mathcal{H}_2 = \begin{bmatrix} A_0 - A & 0 \\ 0 & BA_0^{-1}B^T - \hat{S} \end{bmatrix}.$$

Again, we are looking for a factorization of $\alpha\mathcal{P}_1^{-T}\mathcal{H}_1 + \beta\mathcal{P}_2^{-T}\mathcal{H}_2$ as $\mathcal{P}_3^{-T}\mathcal{H}_3$. Setting $S_0 = BA_0^{-1}B^T - \hat{S}$ yields

$$\begin{aligned} \alpha\mathcal{P}_1^{-T}\mathcal{H}_1 + \beta\mathcal{P}_2^{-T}\mathcal{H}_2 &= \alpha \begin{bmatrix} A_0^{-1} & A_0^{-1}B^TS_0^{-1} \\ 0 & -S_0^{-1} \end{bmatrix} \begin{bmatrix} A - A_0 & \\ & S_0 \end{bmatrix} \\ &\quad + \beta \begin{bmatrix} I & -A_0^{-1}B^T \\ 0 & I \end{bmatrix} \begin{bmatrix} A_0^{-1} & 0 \\ \hat{S}^{-1}BA_0^{-1} & -\hat{S}^{-1} \end{bmatrix} \begin{bmatrix} A_0 - A & \\ & S_0 \end{bmatrix}, \end{aligned} \tag{6.3}$$

which can be reformulated using

$$\begin{bmatrix} -I & 0 \\ 0 & I \end{bmatrix} \begin{bmatrix} A_0 - A & 0 \\ 0 & S_0 \end{bmatrix} = \begin{bmatrix} A - A_0 & 0 \\ 0 & S_0 \end{bmatrix} \tag{6.4}$$

and

$$\begin{bmatrix} I & -A_0^{-1}B^T \\ 0 & I \end{bmatrix} \begin{bmatrix} -A_0^{-1} & 0 \\ 0 & -S_0^{-1} \end{bmatrix} = \begin{bmatrix} -A_0^{-1} & A_0^{-1}B^TS_0^{-1} \\ 0 & -S_0^{-1} \end{bmatrix}. \tag{6.5}$$

Hence, (6.3) simplifies to

$$\begin{bmatrix} I & -A_0^{-1}B^T \\ 0 & I \end{bmatrix} \left(\alpha \begin{bmatrix} -A_0^{-1} & 0 \\ 0 & -S_0^{-1} \end{bmatrix} + \beta \begin{bmatrix} A_0^{-1} & 0 \\ \hat{S}^{-1}BA_0^{-1} & -\hat{S}^{-1} \end{bmatrix} \right) \begin{bmatrix} A - A_0 & 0 \\ 0 & S_0 \end{bmatrix}$$

with

$$\mathcal{P}_3^{-1} = \begin{bmatrix} (\beta - \alpha)A_0^{-1} & \beta A_0^{-1}B^T\hat{S}^{-1} \\ 0 & -(\alpha S_0^{-1} + \beta\hat{S}^{-1}) \end{bmatrix} \begin{bmatrix} I & 0 \\ -BA_0^{-1} & I \end{bmatrix}$$

as the inverse of the new preconditioner, and as an inner product matrix we get

$$\mathcal{H}_3 = \begin{bmatrix} A - A_0 & 0 \\ 0 & S_0 \end{bmatrix}.$$

The block $-(\alpha S_0^{-1} + \beta\hat{S}^{-1})$ of $\mathcal{P}_3^{-1}$ is not well suited for numerical purposes and we therefore try a different approach combining the Schöberl–Zulehner method with the Bramble–Pasciak CG. Thus, we consider the preconditioners

$$\mathcal{P}_1 = \begin{bmatrix} A_0 & 0 \\ B & -\hat{S} \end{bmatrix} \quad \text{and} \quad \mathcal{P}_2 = \begin{bmatrix} A_0 & B^T \\ B & BA_0^{-1}B^T - \hat{S} \end{bmatrix}$$

and the inner products

$$\mathcal{H}_1 = \begin{bmatrix} A - A_0 & 0 \\ 0 & \hat{S} \end{bmatrix} \quad \text{and} \quad \mathcal{H}_2 = \begin{bmatrix} A_0 - A & 0 \\ 0 & BA_0^{-1}B^T - \hat{S} \end{bmatrix}.$$

Once more, we try to find a decomposition as $\mathcal{P}_3^{-T}\mathcal{H}_3$ of

$$\begin{aligned} \alpha\mathcal{P}_1^{-T}\mathcal{H}_1 + \beta\mathcal{P}_2^{-T}\mathcal{H}_2 &= \alpha \begin{bmatrix} A_0^{-1} & A_0^{-1}B^T\hat{S}^{-1} \\ 0 & -\hat{S}^{-1} \end{bmatrix} \begin{bmatrix} A - A_0 & \\ & \hat{S} \end{bmatrix} \\ &+ \beta \begin{bmatrix} I & -A_0^{-1}B^T \\ 0 & I \end{bmatrix} \begin{bmatrix} A_0^{-1} & 0 \\ \hat{S}^{-1}BA_0^{-1} & -\hat{S}^{-1} \end{bmatrix} \begin{bmatrix} A_0 - A & \\ & BA_0^{-1}B^T - \hat{S} \end{bmatrix}. \end{aligned} \tag{6.6}$$

Using a simple modification of (6.4) then gives for (6.6)

$$\begin{aligned} \Bigg(\alpha \begin{bmatrix} A_0^{-1} & A_0^{-1}B^T\hat{S}^{-1} \\ 0 & -\hat{S}^{-1} \end{bmatrix} + \beta \begin{bmatrix} I & -A_0^{-1}B^T \\ 0 & I \end{bmatrix} \begin{bmatrix} A_0^{-1} & 0 \\ \hat{S}^{-1}BA_0^{-1} & -\hat{S}^{-1} \end{bmatrix} \\ \begin{bmatrix} -I & \\ & (BA_0^{-1}B^T - \hat{S})\hat{S}^{-1} \end{bmatrix}\Bigg) \begin{bmatrix} A - A_0 & 0 \\ 0 & \hat{S} \end{bmatrix}. \end{aligned} \tag{6.7}$$

This can be further simplified using a modification of (6.5) for which the result is

$$\begin{bmatrix} I & -A_0^{-1}B^T \\ 0 & I \end{bmatrix} \begin{bmatrix} (\alpha - \beta)A_0^{-1} & 0 \\ -\beta\hat{S}^{-1}BA_0^{-1} & (\beta - \alpha)\hat{S}^{-1} + \beta\hat{S}^{-1}BA_0^{-1}B^T\hat{S}^{-1} \end{bmatrix} \begin{bmatrix} A - A_0 & 0 \\ 0 & \hat{S} \end{bmatrix}.$$

The preconditioner is then given by

$$\mathcal{P}_3^{-1} = \begin{bmatrix} (\alpha - \beta)A_0^{-1} & -\beta A_0^{-1}B^T\hat{S}^{-1} \\ 0 & (\beta - \alpha)\hat{S}^{-1} - \beta\hat{S}^{-1}BA_0^{-1}B^T\hat{S}^{-1} \end{bmatrix} \begin{bmatrix} I & 0 \\ -BA_0^{-1} & I \end{bmatrix} \tag{6.8}$$

with

$$\mathcal{H}_3 = \begin{bmatrix} A - A_0 & 0 \\ 0 & \hat{S} \end{bmatrix} \tag{6.9}$$

defining the bilinear form. It is also possible to reformulate the preconditioner presented by Schöberl and Zulehner using (6.8), i.e., $\beta = 1$ and $\alpha = 0$.

The method generated by combination preconditioning has a slightly more expensive preconditioner (6.8), i.e., one additional solve with $\hat{S}$ but the inner product matrix (6.9) is less expensive to evaluate because there is no need to solve with A_0. We assume here that $\hat{S}$ and A_0 are explicitly given which might not be the case when working with multigrid preconditioning for example.

7. Methods for solving the $\mathcal{P}^+$-preconditioned system.

7.1. The conjugate gradients method. The Hestenes and Stiefel [26] conjugate gradient method in an inner product $\langle \cdot, \cdot \rangle_{\mathcal{H}}$ is given in Algorithm 1; alternatively, see Chapter 2.1 in [11].

Algorithm 1 computes iterates such that $\|x - x_k\|_{\mathcal{H}\widehat{\mathcal{A}}}$ is minimal; for more details, see also Theorem 2.2 in [11]. It is clear that $\|\cdot\|_{\mathcal{H}\widehat{\mathcal{A}}}$ defines a norm when $\mathcal{H}\widehat{\mathcal{A}}$ is symmetric and positive definite. Algorithm 1 can be reliably applied whenever $\mathcal{H}$ and $\mathcal{H}\widehat{\mathcal{A}}$ are positive definite.

ALGORITHM 1 ALGORITHM FOR CG WITH INNER PRODUCT $\langle \cdot, \cdot \rangle_{\mathcal{H}}$.

Compute $r_0 = b - \widehat{\mathcal{A}} x_0$
Set $p_0 = r_0$
for $k = 1, 2, \ldots,$ **do**
  $\alpha_k = \langle r_k, r_k \rangle_{\mathcal{H}} / \langle \widehat{\mathcal{A}} p_k, p_k \rangle_{\mathcal{H}}$,
  $x_{k+1} = x_k + \alpha_k p_k$,
  $r_{k+1} = r_k - \alpha_k \widehat{\mathcal{A}} p_k$,
  $\beta_k = \langle r_{k+1}, r_{k+1} \rangle_{\mathcal{H}} / \langle r_k, r_k \rangle_{\mathcal{H}}$,
  $p_{k+1} = r_{k+1} + \beta_k p_k$,
end for

7.2. MINRES for the saddle point problem. In section 5 we showed that for positive definite preconditioners A_0 and S_0 the inner product matrix $\mathcal{H}^+$ will always be symmetric positive definite. Therefore, MINRES (minimal redisual method) introduced in 1975 by Paige and Saunders in [35], can be employed. It is typically the method of choice for symmetric indefinite systems. Since the preconditioned matrix $\widehat{\mathcal{A}}$ is symmetric in the inner product induced by $\mathcal{H}^+$, we can use a version of the classical Lanczos method to generate a basis for the Krylov subspace and then minimize the $\mathcal{H}^+$-norm of the residual. The $\mathcal{H}^+$-Lanczos method (cf. Algorithm 2) generates an $\mathcal{H}^+$-orthonormal basis for the Krylov subspace which can be expressed in matrix terms as

$$\widehat{\mathcal{A}} V_k = V_k T_{k,k} + \beta_k v_{k+1} e_k^T \tag{7.1}$$

with

$$T_{k,k} = \begin{bmatrix} \alpha_1 & \beta_1 & & \\ \beta_1 & \ddots & \ddots & \\ & \ddots & \ddots & \beta_{k-1} \\ & & \beta_{k-1} & \alpha_k \end{bmatrix} \text{ and } V_k = [v_1, v_2, \ldots, v_k]$$

as well as $V_k^T \mathcal{H}^+ V_k = I$.

ALGORITHM 2 ALGORITHM FOR $\mathcal{H}^+$-LANCZOS.

Choose start vector $v_1 \mathbb{R}^n$ with $\|v_1\| = 1$.
Set $\beta_0 = 0$
for $k = 1, 2, \ldots,$ **do**
  $\tilde{v}_{k+1} = \widehat{\mathcal{A}} v_k - \beta_{k-1} v_{k-1}$,
  Compute $\alpha_k = \langle \tilde{v}_{k+1}, v_k \rangle_{\mathcal{H}^+}$
  $\tilde{v}_{k+1} = \tilde{v}_{k+1} - \alpha_k v_k$
  Set $\beta_k = \|\tilde{v}_{k+1}\|_{\mathcal{H}^+}$
  Set $v_{k+1} = \tilde{v}_{k+1} / \beta_k$
end for

Using the $\mathcal{H}^+$-Lanczos method it is easy to show that

$$\|r_k\|_{\mathcal{H}^+} = \| \|r_0\| \, e_1 - T_{k+1,k} y_k \|_{\mathcal{H}^+} \tag{7.2}$$

holds. Based on (7.2) we can implement a $\mathcal{H}^+$-MINRES process which minimizes the $\mathcal{H}^+$-norm of the residual (7.2) in complete analogy to the standard MINRES algorithm; details can be found in [35, 14, 25].

Applying the $\mathcal{H}^+$-MINRES method can also be justified by studying the problem in the context of the Faber–Manteuffel theorem. In 1984, Faber and Manteuffel [13] proved that only matrices which are normal(s) in some inner product admit an $(s+2)$-term recurrence method which minimizes some relevant quantity at each iteration step. In the most common case of 3-term recurrence methods such as CG or MINRES the normal(1) condition implies that the eigenvalues of the problem matrix lie on a straight line in the complex plane. A survey paper by Liesen and Strakoš (see [32]) gives a description of the Faber and Manteuffel paper in more accessible linear algebra terms. Recently, a new more elementary proof to the Faber–Manteuffel theorem was proposed in [12]. Essentially, a matrix M admits an $(s+2)$-term recurrence method if the G-adjoint,[1] $M^{\#} = GM^TG^{-1}$, can be expressed as a polynomial of degree s in M, i.e.,

$$M^{\#} = p_s(M).$$

With the choice of $M = \widehat{\mathcal{A}}$ and $G = (\mathcal{H}^+)^{-1}$ we get that for $\mathcal{H}^+$ and $\mathcal{P}^+$ a 3-term recurrence method always exists.

7.3. The simplified Lanczos method. The nonsymmetric Lanczos process (cf. [25, 38, 17, 20, 21]) generates two sequences of vectors v_k and w_k that are orthogonal to each other and are generated by

$$\rho_{k+1}v_{k+1} = \widehat{\mathcal{A}}v_k - \mu_k v_k - \nu_{k-1}v_{k-1} \tag{7.3}$$

for the first sequence and

$$\zeta_{k+1}w_{k+1} = \widehat{\mathcal{A}}^T w_k - \mu_k w_k - \tfrac{\nu_{k-1}\rho_k}{\zeta_k} w_{k-1} \tag{7.4}$$

for the second sequence with $\mu_k = w_k^T\widehat{\mathcal{A}}v_k/w_k^Tv_k$ and $\nu_k = \zeta_k w_k^T v_k/w_{k-1}^T v_{k-1}$. There is more than one way to scale the two vectors in every iteration step. Here, we use $\|v_j\| = 1$ and $\|w_j\| = 1$. The biorthogonality condition between W_k and V_k, i.e., $W_k^TV_k = D_k$, gives

$$D_k = \operatorname{diag}(\delta_1, \delta_2, \ldots, \delta_k), \text{ where } \delta_j = w_j^T v_j. \tag{7.5}$$

Furthermore, we can now write the recursions in terms of matrices and get

$$\widehat{\mathcal{A}}V_k = V_{k+1}T_{k+1,k} \tag{7.6}$$

as well as

$$\widehat{\mathcal{A}}^T W_k = W_{k+1}\Gamma_{k+1}^{-1}T_{k+1,k}\Gamma_{k+1}, \tag{7.7}$$

where the matrix Γ_k is defined as

$$\Gamma_k = \operatorname{diag}(\gamma_1, \gamma_2, \ldots, \gamma_k) \text{ with } \gamma_j = \begin{cases} 1 & \text{if } j = 1, \\ \gamma_{j-1}\rho_j/\zeta_j & \text{if } j > 1. \end{cases} \tag{7.8}$$

[1] G is a symmetric positive definite inner product matrix.

One advantage of the nonsymmetric Lanczos process is that $T_{k+1,k}$ is a tridiagonal matrix with $T_{k,k}$ typically nonsymmetric. There are different cases where the nonsymmetric Lanczos process can break down. The first case, the so-called [illegible], indicates that the solution lies already in the current Krylov space. In the case of $w_j^T v_j = 0$, neither v_{j+1} nor w_{j+1} are zero and the so-called [illegible] occurs. A remedy is to use look-ahead strategies; see [36, 18] for more details. For the so-called [illegible] the look-ahead strategies fail.

The nonsymmetric Lanczos process can now be simplified using the self-adjointness of $\widehat{\mathcal{A}}$ in the $\mathcal{H}^+$-inner product, i.e.,

$$\widehat{\mathcal{A}}^T \mathcal{H}^+ = \mathcal{H}^+ \widehat{\mathcal{A}}.$$

In [20] Freund and Nachtigal observe that for the Lanczos vectors the relations

$$v_j = \phi_j(\widehat{\mathcal{A}}) v_1 \quad \text{and} \quad w_j = \gamma_j \phi_j(\widehat{\mathcal{A}}^T) w_1 \tag{7.9}$$

hold, where ϕ is the so-called [illegible] which is of polynomial degree $j-1$. Using (7.9) and setting $w_1 = \mathcal{H}^+ v_1$, we get

$$w_j = \gamma_j \phi_j(\widehat{\mathcal{A}}^T) w_1 = \gamma_j \phi_j(\widehat{\mathcal{A}}^T) \mathcal{H}^+ v_1 = \gamma_j \mathcal{H}^+ \phi_j(\widehat{\mathcal{A}}) v_1 = \gamma_j \mathcal{H}^+ v_j.$$

Hence, we can compute the vector w_j without multiplying by $\widehat{\mathcal{A}}^T$. Instead,

$$w_{j+1} = \gamma_{j+1} \mathcal{H}^+ v_{j+1} \tag{7.10}$$

can be used. The parameter $\gamma_{j+1} = \gamma_j \rho_{j+1} / \zeta_{j+1}$ involves ζ_{j+1} which cannot be computed at that time. Thus the relation (7.10) has to be reformulated to

$$\tilde{w}_{j+1} = \zeta_{j+1} w_{j+1} = \gamma_j \rho_{j+1} \mathcal{H}^+ v_{j+1} = \gamma_j \mathcal{H}^+ \tilde{v}_{j+1}$$

which gives us now a computable version of the simplified Lanczos method; see Algorithm 3.

ALGORITHM 3 ALGORITHM FOR THE SIMPLIFIED LANCZOS METHOD.

Choose v_1 and compute $w_1 = \mathcal{H}^+ v_1$
Compute $\rho_1 = \|v_1\|$ and $\zeta_1 = \|w_1\|$
Set $\gamma_1 = \frac{\rho_1}{\zeta_1}$
for $k = 1, 2, \ldots,$ **do**
  Compute $\mu_k = (w_k^T \widehat{\mathcal{A}} v_k)/(w_k^T v_K)$
  Set $\nu_k = \zeta_k (w_k^T v_k)/(w_{k-1}^T v_{k-1})$
  $v_{k+1} = A v_k - \mu_k v_k - \nu_k v_{k-1}$
  $w_{k+1} = \gamma_k v_{k+1}$
  Compute $\rho_{k+1} = \|v_{k+1}\|$ and $\zeta_{k+1} = \|w_{k+1}\|$
  Set $\gamma_{k+1} = \gamma_k \rho_{k+1} / \zeta_{k+1}$
end for

7.4. The ideal transpose-free QMR method. In [17] Freund introduced the ideal transpose-free QMR method (ITFQMR) by using the simplification of the Lanczos method. Freund's implementation is based on a QMR-from-BICG procedure and coupled two-term recurrence relations; details can be found in [17, 21]. The method is also sometimes called SQMR or simplified QMR.

Here, we introduce the ITFQMR algorithm based on the simplified Lanczos method. In more detail, we have

$$\widehat{\mathcal{A}}V_k = V_{k+1}T_{k+1,k} \tag{7.11}$$

from the nonsymmetric Lanczos process and as a result get

$$r_k = V_{k+1}(\|r_0\| e_1 - T_{k+1,k}y_k) \tag{7.12}$$

for the residual. The term $(\|r_0\| e_1 - T_{k+1,k}y_k)$ is called the quasi-residual. A method based on minimizing the quasi-residual is QMR which was introduced in [19]. There the least squares problem $(\|r_0\| e_1 - T_{k+1,k}y_k)$ can be solved via an updated QR factorization that only requires one Givens rotation per step, a technique well known from MINRES [35].

The ITFQMR method is based on minimizing the quasi-residual in the same way QMR does but in the underlying nonsymmetric Lanczos process multiplications with the transpose are omitted and replaced by multiplications with the matrix $\mathcal{H}^+$. When using QMR and similar methods, we have to keep in mind that the quantities minimized here, the quasi-residual in the case of ITFQMR, are much less understood as the corresponding quantities used in MINRES and CG. Furthermore, as a method based on the nonsymmetric Lanczos, ITFQMR can break down and look-ahead strategies have to be employed; see [36, 18] for more details. There are also incurable breakdowns but from our experience it is hard to find them in practical applications.

8. Eigenvalue analysis. For a better understanding of the convergence behavior of the presented methods, we analyze the eigenvalues of $(\mathcal{P}^+)^{-1}\mathcal{A}$ by looking at the generalized eigenvalue problem $\mathcal{A}v = \lambda\mathcal{P}^+v$, i.e.,

$$\begin{bmatrix} A & B^T \\ B & -C \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \end{bmatrix} = \lambda \begin{bmatrix} A_0 & 0 \\ -B & S_0 \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \end{bmatrix}. \tag{8.1}$$

From (8.1) we get

$$Av_1 + B^Tv_2 = \lambda A_0 v_1 \tag{8.2}$$

and

$$Bv_1 - C^Tv_2 = -\lambda Bv_1 + \lambda S_0 v_2. \tag{8.3}$$

We first analyze the case where $A_0 = A$ and for $\lambda = 1$ from (8.2) get that $B^Tv_2 = 0$, and therefore $v_2 = 0$ under the condition that $Bv_1 = 0$. Since the kernel of B is $(n-m)$-dimensional we have $\lambda = 1$ with multiplicity $n - m$. For the case $\lambda \neq 1$, (8.2) gives

$$v_1 = \frac{1}{\lambda - 1}A^{-1}B^Tv_2,$$

which we substitute into (8.3) to get

$$BA^{-1}B^Tv_2 = \frac{\lambda(\lambda-1)}{\lambda+1}S_0v_2 + \frac{\lambda-1}{\lambda+1}Cv_2.$$

For $C = 0$ the remaining $2m$ eigenvalues of the preconditioned matrix $\widehat{\mathcal{A}}$ are given by the eigenvalues σ of

$$S_0^{-1}BA^{-1}B^T$$

and the relation

$$\sigma = \frac{\lambda(\lambda - 1)}{\lambda + 1}.$$

Hence, the eigenvalues of $\widehat{\mathcal{A}}$ become

$$\lambda_{1,2} = \frac{1+\sigma}{2} \pm \sqrt{\frac{(1+\sigma)^2}{4} + \sigma}. \tag{8.4}$$

Obviously, $\sigma > 0$, and therefore we have m negative eigenvalues given by (8.4). This shows that there are $2m + 1$ different eigenvalues, and we expect the method to terminate in at most $2m+1$ steps. A similar analysis for the classical Bramble–Pasciak can be found in [42].

In contrast, the eigenvalues of the preconditioned saddle point problem $\mathcal{P}^{-1}\mathcal{A}$ in the case of $\mathcal{P}$ being the block diagonal preconditioner

$$\mathcal{P} = \begin{bmatrix} A_0 & 0 \\ 0 & S_0 \end{bmatrix}$$

with $A_0 = A$ and $C = 0$ are given by $n-m$ unit eigenvalues and again the eigenvalues σ of

$$S_0^{-1} B A^{-1} B^T$$

via the relation

$$\sigma = \lambda(\lambda - 1) \text{ with } \lambda_{1,2} = \frac{1}{2} \pm \sqrt{\frac{1}{4} + \sigma}.$$

Since we expect S_0 to be a good preconditioner for $BA^{-1}B^T$, we expect the eigenvalues to not differ too much from unit eigenvalues which would give a similar convergence for the block-diagonal and the Bramble–Pasciak$^+$ preconditioner. Figure 8.1 illustrates how the eigenvalues of the preconditioned matrix in the case of block-diagonal preconditioning (dashed line), and in the case of Bramble–Pasciak$^+$ preconditioning (solid line) depend on the eigenvalues σ of $BA^{-1}B^T$ in a region around 1.

The indefiniteness of $(\mathcal{P}^+)^{-1}\mathcal{A}$ indicates that methods such as $\mathcal{H}^+$-MINRES or ITFQMR should be used. We will illustrate their convergence behavior in section 9 by applying them to Stokes examples from the IFISS software [10].

Following the analysis presented in [42], we also want to analyze the case $A_0 \neq A$. Therefore, we consider the symmetric and positive-definite block-diagonal preconditioner

$$\mathcal{M} = \begin{bmatrix} A_0 & 0 \\ 0 & S_0 \end{bmatrix}$$

and the generalized eigenvalue problem $\mathcal{A}u = \lambda \mathcal{P}^+ u$. Using $v = \mathcal{M}^{1/2}u$ we get $\mathcal{M}^{-1/2}\mathcal{A}\mathcal{M}^{-1/2}v = \lambda \mathcal{M}^{-1/2}\mathcal{P}^+\mathcal{M}^{-1/2}v$. This gives rise to a new generalized eigenvalue problem $\tilde{\mathcal{A}}v = \lambda \tilde{P} v$ with

$$\tilde{\mathcal{A}} = \begin{bmatrix} A_0^{-1/2} A A_0^{-1/2} & A_0^{-1/2} B^T S_0^{-1/2} \\ S_0^{-1/2} B A_0^{-1/2} & -S_0^{-1/2} C S_0^{-1/2} \end{bmatrix} = \begin{bmatrix} \tilde{A} & \tilde{B}^T \\ \tilde{B} & -\tilde{C} \end{bmatrix}$$

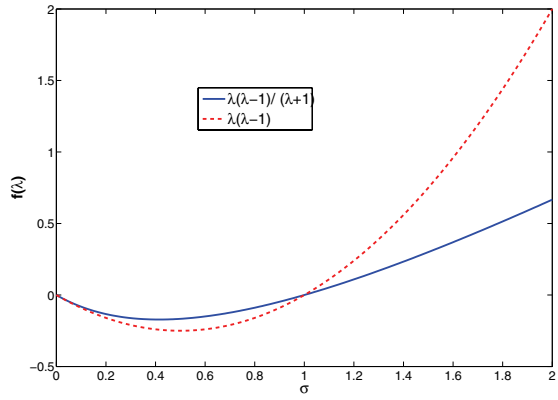

FIG. 8.1. *Dependence of eigenvalues on* σ.

and

$$\tilde{\mathcal{P}} = \begin{bmatrix} I & 0 \\ -S_0^{-1/2} B A_0^{-1/2} & I \end{bmatrix} = \begin{bmatrix} I & 0 \\ -\tilde{B} & I \end{bmatrix}.$$

The eigenvalue problem can hence be reformulated as

$$\tilde{A}v_1 + \tilde{B}^T v_2 = \lambda v_1, \tag{8.5}$$

$$\tilde{B}v_1 - \tilde{C}v_2 = -\lambda \tilde{B}v_1 + \lambda v_2. \tag{8.6}$$

Assume now that $v_2 = 0$ yields $\tilde{A}v_1 = \lambda v_1$ with λ an eigenvalue of the symmetric positive definite matrix $\tilde{A}$ if only $(1+\lambda)\tilde{B}v_1 = 0$. The case $v_1 = 0$ implies that $\tilde{B}^T v_2 = 0$, but since $\tilde{B}^T$ is of full rank $v_2 = 0$. Thus, we assume that $v_1 \neq 0$ and $v_2 \neq 0$. If we multiply (8.5) on the left by the conjugate transpose v_1^*, then we obtain

$$v_1^* \tilde{A} v_1 + v_1^* \tilde{B}^T v_2 = \lambda v_1^* v_1 \Longrightarrow v_1^* \tilde{B}^T v_2 = \lambda v_1^* v_1 - v_1^* \tilde{A} v_1. \tag{8.7}$$

The conjugate transpose of (8.6) multiplied on the right by v_2 gives

$$v_1^* \tilde{B}^T v_2 - v_2^* \tilde{C} v_2 = -\bar{\lambda} v_1^* \tilde{B} v_2 + \bar{\lambda} v_2^* v_2. \tag{8.8}$$

Using (8.7) for (8.8), we obtain

$$(1+\bar{\lambda})(\lambda v_1^* v_1 - v_1^* \tilde{A} v_1) - v_2^* \tilde{C} v_2 = \bar{\lambda} v_2^* v_2,$$

which can be further simplified to

$$(\lambda + |\lambda|^2) \|v_1\|^2 - (1+\bar{\lambda}) v_1^* \tilde{A} v_1 - v_2^* \tilde{C} v_2 - \bar{\lambda} \|v_2\|^2 = 0. \tag{8.9}$$

Assuming that $\lambda = a + ib$, we can analyze the imaginary part of (8.9) and obtain

$$b(\|v_1\|^2 + v_1^* \tilde{A} v_1 + \|v_2\|^2) = 0$$

which states that $b = 0$, and therefore all eigenvalues must be real. This underlines the argument made earlier about the use of short-term recurrence methods such as MINRES since all eigenvalues of the preconditioned matrix are on the real line.

We analyze (8.9) further knowing that λ is real and under the assumption that $\|v\| = 1$ with $\|v_2\|^2 = 1 - \|v_1\|^2$ and obtain

$$(\lambda + |\lambda|^2)\|v_1\|^2 - \lambda v_1^* \tilde{A} v_1 - \lambda + \lambda \|v_1\|^2 - v_1^* \tilde{A} v_1 - v_2^* \tilde{C} v_2 = 0. \tag{8.10}$$

We then get for λ

$$\lambda_\pm = \frac{v_1^* \tilde{A} v_1 + 1 - 2\|v_1\|^2}{2\|v_1\|^2} \pm \sqrt{\frac{(v_1^* \tilde{A} v_1 + 1 - 2\|v_1\|^2)^2}{4\|v_1\|^4} + \frac{v_1^* \tilde{A} v_1 + v_2^* \tilde{C} v_2}{\|v_1\|^2}}. \tag{8.11}$$

Note that, $v_1^* \tilde{A} v_1 + v_2^* \tilde{C} v_2 \geq 0$ for all v_1 and v_2. Since $\tilde{A}$ and $\tilde{C}$ are both symmetric matrices, we have the following bounds:

$$\mu_{min}^{\tilde{C}} \leq v_2^* \tilde{C} v_2 \leq \mu_{max}^{\tilde{C}}$$

and

$$\mu_{min}^{\tilde{A}} \leq v_1^* \tilde{A} v_1 \leq \mu_{max}^{\tilde{A}}$$

with $\mu_{min}^{\tilde{C}}$ and $\mu_{min}^{\tilde{A}}$ the minimal eigenvalue of $\tilde{C}$ and $\tilde{A}$, respectively, and $\mu_{max}^{\tilde{C}}$ and $\mu_{max}^{\tilde{A}}$ the maximal eigenvalue of $\tilde{C}$ and $\tilde{A}$, respectively. We first assume that $v_1^* \tilde{A} v_1 + 1 - 2\|v_1\|^2 \geq 0$ and get

$$\frac{\mu_{min}^{\tilde{A}} + 1 - 2\|v_1\|^2}{2\|v_1\|^2} + \sqrt{\frac{(\mu_{min}^{\tilde{A}} + 1 - 2\|v_1\|^2)^2}{4\|v_1\|^4} + \mu_{min}^{\tilde{A}} + \mu_{min}^{\tilde{C}}} \leq \lambda_+$$

and

$$\lambda_+ \leq \frac{\mu_{max}^{\tilde{A}} + 1 - 2\|v_1\|^2}{2\|v_1\|^2} + \sqrt{\frac{(\mu_{max}^{\tilde{A}} + 1 - 2\|v_1\|^2)^2}{4\|v_1\|^4} + \mu_{max}^{\tilde{A}} + \mu_{max}^{\tilde{C}}}$$

as well as

$$\frac{\mu_{min}^{\tilde{A}} + 1 - 2\|v_1\|^2}{2\|v_1\|^2} - \sqrt{\frac{(\mu_{max}^{\tilde{A}} + 1 - 2\|v_1\|^2)^2}{4\|v_1\|^4} + \mu_{max}^{\tilde{A}} + \mu_{max}^{\tilde{C}}} \leq \lambda_-$$

and

$$\lambda_+ \leq \frac{\mu_{max}^{\tilde{A}} + 1 - 2\|v_1\|^2}{2\|v_1\|^2} - \sqrt{\frac{(\mu_{min}^{\tilde{A}} + 1 - 2\|v_1\|^2)^2}{4\|v_1\|^4} + \mu_{min}^{\tilde{A}} + \mu_{min}^{\tilde{C}}}.$$

A similar analysis can be made for the case $v_1^* \tilde{A} v_1 + 1 - 2\|v_1\|^2 < 0$.

9. Numerical experiments. In this section we show the results of our numerical experiments. The matrices are coming from the Stokes problem and, in particular, were generated using the IFISS[2] package [10]. The Stokes problem is given by

$$\begin{aligned} -\nabla^2 u + \nabla p &= f, \\ \nabla \cdot u &= 0 \end{aligned} \tag{9.1}$$

[2]http://www.maths.manchester.ac.uk/~djs/ifiss/.

with appropriate boundary conditions which can be found in [11]. Namely, we consider the flow over the channel domain (Example 5.1.1 in [11]) and the flow over a backward facing step (Example 5.1.2 in [11]). Equation (9.1) can be transformed using a weak formulation which can then be treated using the finite element method; see [11] for details. The linear system governing the finite element method for the Stokes problem is a saddle point problem

$$\begin{bmatrix} A & B^T \\ B & -C \end{bmatrix},$$

where $C \neq 0$ for stabilized elements. This matrix is symmetric but indefinite and could be treated with MINRES in the first place. But in order to improve the convergence we have to compare our Bramble–Pasciak$^+$ preconditioner to other suitable methods. One candidate would be the block-diagonal preconditioning introduced by Silvester and Wathen in [47, 41]. There a block-diagonal preconditioner

$$\mathcal{P} = \begin{bmatrix} A_0 & 0 \\ 0 & S_0 \end{bmatrix} \tag{9.2}$$

is used in which A_0 is a preconditioner for A and S_0 is a Schur complement preconditioner. We can use MINRES with this type of preconditioner; see [4] for details. In the Bramble–Pasciak$^+$ setup the preconditioned matrix is symmetric in the $\mathcal{H}^+$-inner product. This enables us to use the $\mathcal{H}^+$-MINRES method introduced in section 7.2. We will compare this method to the classical MINRES algorithm for the block-diagonal preconditioner. In the IFISS implementation the preconditioner S_0 is chosen to be the positive-definite pressure mass matrix; see Chapter 6.2 in [11]. The right-hand side for each example is also given by IFISS.

9.1. The first example considered is based on the flow over a backward facing step. The size of the system matrix $\mathcal{A}$ is given by 6659×6659 with $m = 769$ and $n = 5890$. The results shown in Figure 9.1 are obtained by using the $\mathcal{H}^+$-MINRES method and the classical preconditioned MINRES as given in [47, 41] as well as CG for the classical Bramble–Pasciak setup. The preconditioner A_0 is given by the incomplete Cholesky factorization. In particular, we use MATLAB's implementation with no additional fill-in; see [38] for details. S_0 is given by IFISS as the pressure mass matrix. The blue (dashed) curve is showing the results of the preconditioned MINRES with a block-diagonal preconditioner. The corresponding preconditioned residual is given in the 2-norm. The black (dash-dotted) line shows the 2-norm preconditioned residuals computed by the $\mathcal{H}^+$-MINRES algorithm. The red (solid) curve shows the preconditioned residuals for CG with the Bramble–Pasciak setup. As expected from the eigenvalue analysis in section 8, the results for MINRES and $\mathcal{H}^+$-MINRES are very similar and are both outperformed by the Bramble–Pasciak CG except for rather large convergence tolerances.

9.2. This example comes again from IFISS and is representing the flow of a channel domain. The size of the system matrix $\mathcal{A}$ is given by 9539×9539 with $m = 1089$ and $n = 8450$. The results shown in Figure 9.2 are obtained by using the $\mathcal{H}^+$-MINRES method and the classical preconditioned MINRES, as given in [47, 41], as well as ITFQMR for the classical Bramble–Pasciak setup. The preconditioners are chosen such that $A_0 = A$ and S_0 is given by IFISS as the pressure mass matrix. The blue (dashed) curve is showing the results of the preconditioned MINRES with a block-diagonal preconditioner. The corresponding preconditioned residual is given in the 2-norm. The black (dash-dotted) line shows the 2-norm preconditioned residuals

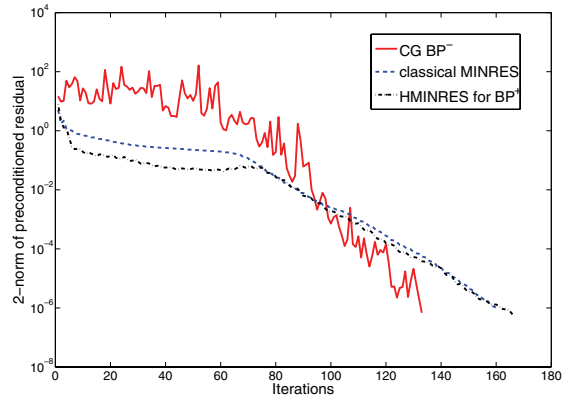

FIG. 9.1. *Results for* $\mathcal{H}^+$-MINRES, *classical preconditioned* MINRES, *and* CG *for classical Bramble–Pasciak.*

computed by the $\mathcal{H}^+$-MINRES algorithm. The red (solid) curve shows the preconditioned residuals for ITFQMR with the Bramble–Pasciak setup. Again, the results for MINRES and $\mathcal{H}^+$-MINRES are very similar.

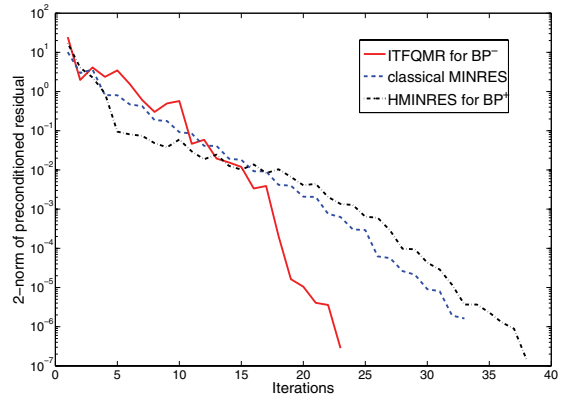

FIG. 9.2. *Results for* $\mathcal{H}^+$-MINRES, *classical preconditioned* MINRES, *and* ITFQMR *for classical Bramble–Pasciak.*

We now show results for the combination preconditioning with the Bramble–Pasciak and the Bramble–Pasciak$^+$ setup.

9.3. In this example the matrix represents the flow over a channel domain and is of size 9539×9539. Our choice for A_0 is again the incomplete Cholesky decomposition with zero fill-in and S_0 the pressure mass matrix. Figure 9.3 shows the results for different values of α. The choice for $\alpha = 2/3$ shown in the black (solid) curve performs better than the original Bramble–Pasciak method reflected by $\alpha = 1$ in the blue (dashed) line. For comparison we also show the results for the preconditioned MINRES in the red (dashed) line. Further values of α are shown.

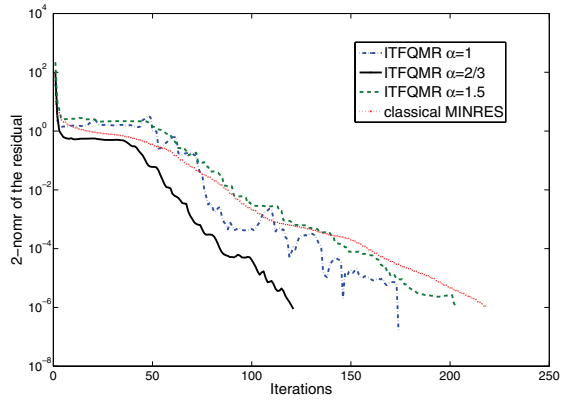

FIG. 9.3. ITFQMR *results for combination preconditioning with different values for* α.

EXAMPLE 9.4. The setup for this example is identical to the one described in Example 9.3, only the underlying matrix now comes from the flow over the backward facing step. The dimension of $\mathcal{A}$ is 6659×6659. Again for $\alpha = 2/3$, the combination preconditioning outperforms ITFQMR with the Bramble–Pasciak setup; see Figure 9.4.

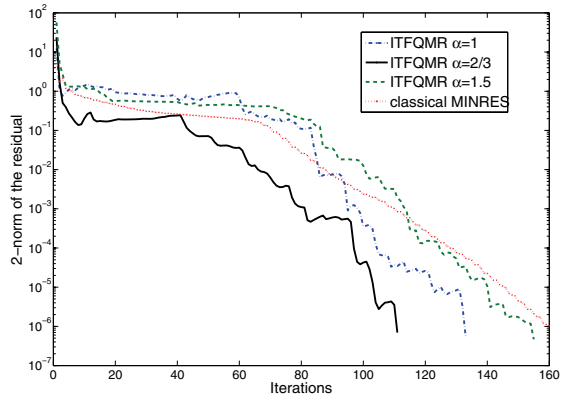

FIG. 9.4. ITFQMR *results for combination preconditioning with different values for* α.

The combination of the Bramble–Pasciak setup and the method of Schöberl and Zulehner as presented in section 6.3 is given by the preconditioner

$$\mathcal{P}_3^{-1} = \begin{bmatrix} (\alpha-\beta)A_0^{-1} & -\beta A_0^{-1}B^T\hat{S}^{-1} \\ 0 & (\beta-\alpha)\hat{S}^{-1} - \beta\hat{S}^{-1}BA_0^{-1}B^T\hat{S}^{-1} \end{bmatrix} \begin{bmatrix} I & 0 \\ -BA_0^{-1} & I \end{bmatrix}$$

and inner product

$$\mathcal{H}_3 = \begin{bmatrix} A - A_0 & 0 \\ 0 & \hat{S} \end{bmatrix}.$$

EXAMPLE 9.5. In this example we apply CG with the combination preconditioning setup for Schöberl–Zulehner and Bramble–Pasciak to a linear system coming from

the flow over a backward facing step of dimension 6659 as shown in Figure 9.5. The preconditioner A_0 is chosen to be the zero fill-in incomplete Cholesky factorization and $\hat{S}$ is the pressure mass matrix given in IFISS. For the parameter choice $\alpha = -.3$ and $\beta = .5$ the combination is able to outperform the method of Schöberl and Zulehner.

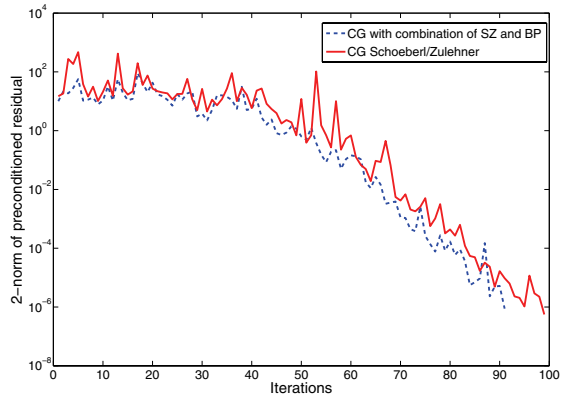

FIG. 9.5. *CG for Schöberl–Zulehner and combination preconditioning for* $\alpha = -.3$ *and* $\beta = .5$.

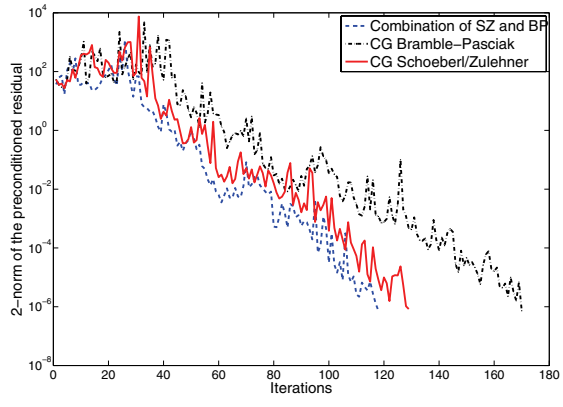

FIG. 9.6. *CG for Schöberl–Zulehner, Bramble–Pasciak, and combination preconditioning for* $\alpha = -.3$ *and* $\beta = .5$.

9.6. In this example we apply CG with the combination preconditioning setup for Schöberl–Zulehner and Bramble–Pasciak to a linear system coming from the flow over the channel domain of dimension 9539. In addition, we also show the results for CG with the Bramble–Pasciak setup; see Figure 9.6. The preconditioner A_0 is chosen to be the zero fill-in incomplete Cholesky factorization and $\hat{S}$ is the pressure mass matrix given in IFISS. For the parameter choice $\alpha = -.3$ and $\beta = .5$ the combination is able to outperform the method of Schöberl and Zulehner.

10. Conclusions. We have explained the general concept of self-adjointness in nonstandard inner products or symmetric bilinear forms and, in the specific case of saddle point problems, have shown how a number of known examples fit into this

paradigm. We have indicated how self-adjointness may be taken advantage of in the choice of the iterative solution method of Krylov subspace type—in general, it is more desirable to be able to work with iterative methods for self-adjoint matrices rather than general nonsymmetric matrices because of the greater efficiency of symmetric iterative methods. The understanding of the convergence of symmetric iterative methods like CG is much more secure and descriptive than for nonsymmetric methods.

The possibility of combination preconditioning by exploiting self-adjointness in different nonstandard inner products or symmetric bilinear forms has been analyzed and examples given of how two methods can be combined to obtain a new preconditioner and a different symmetric bilinear form. The first example combines the new BP^+ method which we have introduced with the classical Bramble–Pasciak method. We demonstrate that a particular combination outperforms the widely used classical method; it requires fewer iterations while the work per iteration is the same. The second example is of more academic than practical value. The third example combines the BP method and a recently introduced method by Schöberl and Zulehner. The combination preconditioning method was able to outperform both the Bramble–Pasciak CG and Schöberl–Zulehner CG method.

Our analysis may provide the basis for the discovery of further useful examples where self-adjointness may hold in nonstandard inner products and also shows how preconditioning can usefully be employed to create rather than destroy symmetry of matrices.

Acknowledgment. The authors would like to thank the two anonymous referees for their careful reading and helpful comments.

$\mathcal{H}_2$ MODEL REDUCTION FOR LARGE-SCALE LINEAR DYNAMICAL SYSTEMS*

S. GUGERCIN†, A. C. ANTOULAS‡, AND C. BEATTIE†

Abstract. The optimal $\mathcal{H}_2$ model reduction problem is of great importance in the area of dynamical systems and simulation. In the literature, two independent frameworks have evolved focusing either on solution of Lyapunov equations on the one hand or interpolation of transfer functions on the other, without any apparent connection between the two approaches. In this paper, we develop a new unifying framework for the optimal $\mathcal{H}_2$ approximation problem using best approximation properties in the underlying Hilbert space. This new framework leads to a new set of local optimality conditions taking the form of a structured orthogonality condition. We show that the existing Lyapunov- and interpolation-based conditions are each equivalent to our conditions and so are equivalent to each other. Also, we provide a new elementary proof of the interpolation-based condition that clarifies the importance of the mirror images of the reduced system poles. Based on the interpolation framework, we describe an iteratively corrected rational Krylov algorithm for $\mathcal{H}_2$ model reduction. The formulation is based on finding a reduced order model that satisfies interpolation-based first-order necessary conditions for $\mathcal{H}_2$ optimality and results in a method that is numerically effective and suited for large-scale problems. We illustrate the performance of the method with a variety of numerical experiments and comparisons with existing methods.

Key words. model reduction, rational Krylov, $\mathcal{H}_2$ approximation

1. Introduction.

Given a dynamical system described by a set of first-order differential equations, the model reduction problem seeks to replace this original set of equations with a (much) smaller set of such equations so that the behavior of both systems is similar in an appropriately defined sense. Such situations arise frequently when physical systems need to be simulated or controlled; the greater the level of detail that is required, the greater the number of resulting equations. In large-scale settings, computations become infeasible due to limitations on computational resources as well as growing inaccuracy due to numerical ill-conditioning. In all these cases the number of equations involved may range from a few hundred to a few million. Examples of large-scale systems abound, ranging from the design of VLSI (very large scale integration) chips to the simulation and control of MEMS (microelectromechanical system) devices. For an overview of model reduction for large-scale dynamical systems we refer to the book [2]. See also [23] for a recent collection of large-scale benchmark problems.

In this paper, we consider single input/single output (SISO) linear dynamical systems represented as

$$G : \begin{cases} \dot{\mathbf{x}}(t) = \mathbf{A}\mathbf{x}(t) + \mathbf{b}\,u(t) \\ y(t) = \mathbf{c}^T\mathbf{x}(t) \end{cases} \qquad \text{or} \qquad G(s) = \mathbf{c}^T(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{b}, \tag{1.1}$$

where $\mathbf{A} \in \mathbb{R}^{n\times n}$, $\mathbf{b}, \mathbf{c} \in \mathbb{R}^n$; we define $\mathbf{x}(t) \in \mathbb{R}^n$, $u(t) \in \mathbb{R}$, $y(t) \in \mathbb{R}$ as the , , , and , respectively, of the system. (We comment on extensions to the multiple input/multiple output (MIMO) case in section 3.2.1, but will confine our analysis and examples to the SISO case.)

$G(s)$ is the transfer function of the system: if $\widehat{u}(s)$ and $\widehat{y}(s)$ denote the Laplace transforms of the input and output $u(t)$ and $y(t)$, respectively, then $\widehat{y}(s) = G(s)\widehat{u}(s)$. With a standard abuse of notation, we will denote both the system and its transfer function by G. The "dimension of G" is taken to be the dimension of the underlying state space, $\dim G = n$ in this case. It will always be assumed that the system, G, is , that is, that the eigenvalues of $\mathbf{A}$ have strictly negative real parts.

The model reduction process will yield another system,

$$G_r : \begin{cases} \dot{\mathbf{x}}_r(t) = \mathbf{A}_r\mathbf{x}_r(t) + \mathbf{b}_r u(t) \\ y_r(t) = \mathbf{c}_r^T\mathbf{x}_r(t) \end{cases} \quad \text{or} \quad G_r(s) = \mathbf{c}_r^T(s\mathbf{I} - \mathbf{A}_r)^{-1}\mathbf{b}_r, \tag{1.2}$$

having (much) smaller dimension $r \ll n$, with $\mathbf{A}_r \in \mathbb{R}^{r\times r}$ and $\mathbf{b}_r$, $\mathbf{c}_r \in \mathbb{R}^r$.

We want $y_r(t) \approx y(t)$ over a large class of inputs $u(t)$. Different measures of approximation and different choices of input classes will lead to different model reduction goals. Suppose one wants to ensure that $\max_{t>0} |y(t) - y_r(t)|$ is small uniformly over all inputs, $u(t)$, having bounded "energy," that is, $\int_0^\infty |u(t)|^2\, dt \le 1$. Observe first that $\widehat{y}(s) - \widehat{y}_r(s) = [G(s) - G_r(s)]\, \widehat{u}(s)$ and then

$$\begin{aligned}
\max_{t>0} |y(t) - y_r(t)| &= \max_{t>0} \left| \frac{1}{2\pi} \int_{-\infty}^{\infty} (\widehat{y}(\imath\omega) - \widehat{y}_r(\imath\omega))\, e^{\imath\omega t}\, d\omega \right| \\
&\le \frac{1}{2\pi} \int_{-\infty}^{\infty} |\widehat{y}(\imath\omega) - \widehat{y}_r(\imath\omega)|\, d\omega = \frac{1}{2\pi} \int_{-\infty}^{\infty} |G(\imath\omega) - G_r(\imath\omega)|\, |\widehat{u}(\imath\omega)|\, d\omega \\
&\le \left(\frac{1}{2\pi} \int_{-\infty}^{\infty} |G(\imath\omega) - G_r(\imath\omega)|^2\, d\omega \right)^{1/2} \left(\frac{1}{2\pi} \int_{-\infty}^{\infty} |\widehat{u}(\imath\omega)|^2\, d\omega \right)^{1/2} \\
&\le \left(\frac{1}{2\pi} \int_{-\infty}^{\infty} |G(\imath\omega) - G_r(\imath\omega)|^2\, d\omega \right)^{1/2} \left(\int_0^{\infty} |u(t)|^2\, dt \right)^{1/2} \\
&\le \left(\frac{1}{2\pi} \int_{-\infty}^{+\infty} |G(\imath\omega) - G_r(\imath\omega)|^2\, d\omega \right)^{1/2} \stackrel{\text{def}}{=} \|G - G_r\|_{\mathcal{H}_2}.
\end{aligned}$$

We seek a reduced order dynamical system, G_r, such that

(i) $\|G - G_r\|_{\mathcal{H}_2}$, the "$\mathcal{H}_2$ error," is as small as possible;
(ii) critical system properties for G (such as stability) exist also in G_r; and
(iii) the computation of G_r (i.e., the computation of $\mathbf{A}_r$, $\mathbf{b}_r$, and $\mathbf{c}_r$) is both efficient and numerically stable.

The problem of finding reduced order models that yield a small $\mathcal{H}_2$ error has been the object of many investigations; see, for instance, [6, 37, 34, 9, 21, 26, 22, 36, 25, 13] and the references therein. Finding a global minimizer of $\|G - G_r\|_{\mathcal{H}_2}$ is a hard task, so the goal in making $\|G - G_r\|_{\mathcal{H}_2}$ "as small as possible" becomes, as for many optimization problems, identification of reduced order models, G_r, that satisfy first-order necessary conditions for local optimality. There is a wide variety of such conditions that may be derived, yet their interconnections are generally unclear. Most methods that can identify reduced order models satisfying such first-order necessary conditions will require dense matrix operations, typically the solution of a sequence of matrix Lyapunov equations, a task which becomes computationally intractable

rapidly as the dimension increases. Such methods are unsuitable even for medium-scale problems. In section 2, we review the moment matching problem for model reduction, its connection with rational Krylov methods (which are very useful for large-scale problems), and basic features of the $\mathcal{H}_2$ norm and inner product.

We offer in section 3 what appears to be a new set of first-order necessary conditions for local optimality of a reduced order model comprising in effect a structured orthogonality condition. We also show its equivalence with two other $\mathcal{H}_2$ optimality conditions that have been previously known (thus showing them all to be equivalent).

An iterative algorithm that is designed to force optimality with respect to a set of conditions that is computationally tractable is described in section 4. The proposed method also forces optimality with respect to the other equivalent conditions as well. It is based on computationally effective use of rational Krylov subspaces and so is suitable for systems whose dimension n is of the order of many thousands of state variables. Numerical examples are presented in section 5.

2. Background.

2.1. Model reduction by moment matching. Given the system (1.1), reduction by [illegible] consists in finding a system (1.2) so that $G_r(s)$ interpolates the values of $G(s)$, and perhaps also derivative values as well, at selected interpolation points (also called [illegible]) σ_k in the complex plane. For our purposes, simple Hermite interpolation suffices, so our problem is to find $\mathbf{A}_r$, $\mathbf{b}_r$, and $\mathbf{c}_r$ so that

$$G_r(\sigma_k) = G(\sigma_k) \quad \text{and} \quad G_r'(\sigma_k) = G'(\sigma_k) \quad \text{for} \quad k = 1, \ldots, r$$

or, equivalently,

$$\mathbf{c}^T(\sigma_k\mathbf{I} - \mathbf{A})^{-1}\mathbf{b} = \mathbf{c}_r^T(\sigma_k\mathbf{I} - \mathbf{A}_r)^{-1}\mathbf{b}_r \quad \text{and} \quad \mathbf{c}^T(\sigma_k\mathbf{I} - \mathbf{A})^{-2}\mathbf{b} = \mathbf{c}_r^T(\sigma_k\mathbf{I} - \mathbf{A}_r)^{-2}\mathbf{b}_r$$

for $k = 1, \ldots, r$. The quantity $\mathbf{c}^T(\sigma_k\mathbf{I} - \mathbf{A})^{-(j+1)}\mathbf{b}$ is called the jth moment of $G(s)$ at σ_k. Moment matching for finite $\sigma \in \mathbb{C}$ becomes [illegible]; see, for example, [3]. Importantly, these problems can be solved in a recursive and numerically effective way by means of [illegible] procedures.

To see this we first consider reduced order models that are constructed by Galerkin approximation: Let $\mathcal{V}_r$ and $\mathcal{W}_r$ be given r-dimensional subspaces of $\mathbb{R}^n$ that are generic in the sense that $\mathcal{V}_r \cap \mathcal{W}_r^\perp = \{0\}$. Then for any input $u(t)$ the reduced order output $y_r(t)$ is defined by

$$\begin{aligned} &\text{Find} \quad \mathbf{v}(t) \in \mathcal{V}_r \quad \text{such that} \quad \dot{\mathbf{v}}(t) - \mathbf{A}\mathbf{v}(t) - \mathbf{b}u(t) \perp \mathcal{W}_r \quad \text{for all } t; \\ &\qquad\qquad \text{then} \quad y_r(t) \stackrel{\text{def}}{=} \mathbf{c}^T\mathbf{v}(t). \end{aligned} \tag{2.1}$$

Denote by $\mathrm{Ran}(\mathbf{M})$ the range of a matrix $\mathbf{M}$. Let $\mathbf{V}_r \in \mathbb{R}^{n\times r}$ and $\mathbf{W}_r \in \mathbb{R}^{n\times r}$ be matrices defined so that $\mathcal{V}_r = \mathrm{Ran}(\mathbf{V}_r)$ and $\mathcal{W}_r = \mathrm{Ran}(\mathbf{W}_r)$. Then the assumption $\mathcal{V}_r \cap \mathcal{W}_r^\perp = \{0\}$ is equivalent to $\mathbf{W}_r^T\mathbf{V}_r$ being nonsingular. The Galerkin approximation (2.1) can be interpreted as $\mathbf{v}(t) = \mathbf{V}_r\mathbf{x}_r(t)$ with $\mathbf{x}_r(t) \in \mathbb{R}^r$ for each t and

$$\mathbf{W}_r^T\left(\mathbf{V}_r\dot{\mathbf{x}}_r(t) - \mathbf{A}\mathbf{V}_r\mathbf{x}_r(t) - \mathbf{b}\,u(t)\right) = 0$$

leading then to the reduced order model (1.2) with

$$\mathbf{A}_r = (\mathbf{W}_r^T\mathbf{V}_r)^{-1}\mathbf{W}_r^T\mathbf{A}\mathbf{V}_r, \quad \mathbf{b}_r = (\mathbf{W}_r^T\mathbf{V}_r)^{-1}\mathbf{W}_r^T\mathbf{b}, \quad \text{and} \quad \mathbf{c}_r^T = \mathbf{c}^T\mathbf{V}_r. \tag{2.2}$$

Evidently the choice of $\mathbf{V}_r$ and $\mathbf{W}_r$ determines the quality of the reduced order model.

Rational interpolation by projection was first proposed by Skelton et al. in [11, 38, 39]. Grimme [17] showed how one can obtain the required projection using the rational Krylov method of Ruhe [33]. Krylov-based methods are able to match moments without ever computing them explicitly. This is important since the computation of moments is in general ill-conditioned. This is a fundamental motivation behind the Krylov-based methods [12].

In Lemma 2.1 and Corollary 2.2 below, we present new short proofs of rational interpolation by Krylov projection that are substantially simpler than those found in the original works [17, 11, 38, 39].

LEMMA 2.1. $\sigma \in \mathbb{C}$ $\mathbf{A}$ $\mathbf{A}_r$

(2.3) $(\sigma\mathbf{I}-\mathbf{A})^{-1}\mathbf{b} \in \mathcal{V}_r$, $G_r(\sigma) = G(\sigma)$.

(2.4) $(\overline{\sigma}\,\mathbf{I}-\mathbf{A}^T)^{-1}\mathbf{c} \in \mathcal{W}_r$, $G_r(\sigma) = G(\sigma)$.

$(\sigma\mathbf{I}-\mathbf{A})^{-1}\mathbf{b} \in \mathcal{V}_r$ $(\overline{\sigma}\,\mathbf{I}-\mathbf{A}^T)^{-1}\mathbf{c} \in \mathcal{W}_r$,

(2.5) $G_r(\sigma) = G(\sigma)$ $G_r'(\sigma) = G'(\sigma)$.

Define $\mathbf{N}_r(z) = \mathbf{V}_r(z\mathbf{I}-\mathbf{A}_r)^{-1}(\mathbf{W}_r^T\mathbf{V}_r)^{-1}\mathbf{W}_r^T(z\mathbf{I}-\mathbf{A})$ and $\widetilde{\mathbf{N}}_r(z) = (z\mathbf{I}-\mathbf{A})\mathbf{N}_r(z)(z\mathbf{I}-\mathbf{A})^{-1}$. Both $\mathbf{N}_r(z)$ and $\widetilde{\mathbf{N}}_r(z)$ are analytic matrix-valued functions in a neighborhood of $z=\sigma$. One may directly verify that $\mathbf{N}_r^2(z) = \mathbf{N}_r(z)$ and $\widetilde{\mathbf{N}}_r^2(z) = \widetilde{\mathbf{N}}_r(z)$ and that $\mathcal{V}_r = \operatorname{Ran}\mathbf{N}_r(z) = \operatorname{Ker}(\mathbf{I}-\mathbf{N}_r(z))$ and $\mathcal{W}_r^{\perp} = \operatorname{Ker}\widetilde{\mathbf{N}}_r(z) = \operatorname{Ran}\big(\mathbf{I}-\widetilde{\mathbf{N}}_r(z)\big)$ for all z in a neighborhood of σ. Then

$$G(z)-G_r(z) = \big[(z\mathbf{I}-\mathbf{A}^T)^{-1}\mathbf{c}\big]^T\Big(\mathbf{I}-\widetilde{\mathbf{N}}_r(z)\Big)(z\mathbf{I}-\mathbf{A})\Big(\mathbf{I}-\mathbf{N}_r(z)\Big)(z\mathbf{I}-\mathbf{A})^{-1}\mathbf{b}.$$

Evaluating at $z=\sigma$ leads to (2.3) and (2.4). Evaluating at $z=\sigma+\varepsilon$ and observing that $(\sigma\mathbf{I}+\varepsilon\mathbf{I}-\mathbf{A})^{-1} = (\sigma\mathbf{I}-\mathbf{A})^{-1} - \varepsilon(\sigma\mathbf{I}-\mathbf{A})^{-2} + \mathcal{O}(\varepsilon^2)$ yields

$$G(\sigma+\varepsilon)-G_r(\sigma+\varepsilon) = \mathcal{O}(\varepsilon^2),$$

which gives (2.5) as a consequence. ∎

COROLLARY 2.2. G $\mathbf{A},\mathbf{b},\mathbf{c}$ $\{\sigma_k\}_{k=1}^r$ $\mathbf{V}_r$ $\mathbf{W}_r$

(2.6) $\operatorname{Ran}(\mathbf{V}_r) = \operatorname{span}\big\{(\sigma_1\mathbf{I}-\mathbf{A})^{-1}\mathbf{b}, \quad \ldots, \quad (\sigma_r\mathbf{I}-\mathbf{A})^{-1}\mathbf{b}\big\}$

(2.7) $\operatorname{Ran}(\mathbf{W}_r) = \operatorname{span}\big\{(\sigma_1\mathbf{I}-\mathbf{A}^T)^{-1}\mathbf{c}, \quad \ldots, \quad (\sigma_r\mathbf{I}-\mathbf{A}^T)^{-1}\mathbf{c}\big\}.$

$\mathbf{V}_r$ $\mathbf{W}_r$ G_r $\mathbf{A}_r = (\mathbf{W}_r^T\mathbf{V}_r)^{-1}\mathbf{W}_r^T\mathbf{A}\mathbf{V}_r$, $\mathbf{b}_r = (\mathbf{W}_r^T\mathbf{V}_r)^{-1}\mathbf{W}_r^T\mathbf{b}$, $\mathbf{c}_r^T = \mathbf{c}^T\mathbf{V}_r$ $G(s)$ σ_k $G(\sigma_k) = G_r(\sigma_k)$ $G'(\sigma_k) = G_r'(\sigma_k)$, $k=1,\ldots,r$

For Krylov-based model reduction, one chooses interpolation points and then constructs $\mathbf{V}_r$ and $\mathbf{W}_r$ satisfying (2.6) and (2.7), respectively. Note that, in a numerical implementation, one does not actually compute $(\sigma_i\mathbf{I}-\mathbf{A})^{-1}$, but instead computes a (potentially sparse) factorization (one for each interpolation point σ_i), uses it to solve a system of equations having $\mathbf{b}$ as a right-hand side, and uses its transpose to solve a system of equations having $\mathbf{c}$ as a right-hand side. The interpolation points are chosen so as to minimize the deviation of G_r from G in a sense that is detailed in the next section. Unlike Gramian-based model reduction methods such as balanced truncation (see section 2.2 below and [2]), Krylov-based model reduction requires only

matrix-vector multiplications and some sparse linear solvers, and can be iteratively implemented; hence it is computationally effective; for details, see also [15, 16].

2.2. Model reduction by balanced truncation. One of the most common model reduction techniques is [illegible] [28, 27]. In this case, the modeling subspaces $\mathbf{V}_r$ and $\mathbf{W}_r$ depend on the solutions to the two Lyapunov equations

$$\mathbf{AP} + \mathbf{PA}^T + \mathbf{bb}^T = \mathbf{0}, \qquad \mathbf{A}^T\mathbf{Q} + \mathbf{QA} + \mathbf{c}^T\mathbf{c} = \mathbf{0}. \tag{2.8}$$

$\mathbf{P}$ and $\mathbf{Q}$ are called the reachability and observability Gramians, respectively. Under the assumption that $\mathbf{A}$ is stable, both $\mathbf{P}$ and $\mathbf{Q}$ are positive semidefinite matrices. Square roots of the eigenvalues of the product $\mathbf{PQ}$ are the singular values of the Hankel operator associated with $G(s)$ and are called the Hankel singular values of $G(s)$, denoted by $\eta_i(G)$.

Let $\mathbf{P} = \mathbf{UU}^T$ and $\mathbf{Q} = \mathbf{LL}^T$. Let $\mathbf{U}^T\mathbf{L} = \mathbf{ZSY}^T$ be the singular value decomposition with $\mathbf{S} = \operatorname{diag}(\eta_1, \eta_2, \ldots, \eta_n)$. Let $\mathbf{S}_r = \operatorname{diag}(\eta_1, \eta_2, \ldots, \eta_r)$, $r < n$. Construct

$$\mathbf{W}_r = \mathbf{LY}_r\mathbf{S}_r^{-1/2} \qquad \text{and} \qquad \mathbf{V}_r = \mathbf{UZ}_r\mathbf{S}_r^{-1/2}, \tag{2.9}$$

where $\mathbf{Z}_r$ and $\mathbf{Y}_r$ denote the leading r columns of left singular vectors, $\mathbf{Z}$, and right singular vectors, $\mathbf{Y}$, respectively. The rth-order reduced order model via [illegible], $G_r(s)$, is obtained by reducing $G(s)$ using $\mathbf{W}_r$ and $\mathbf{V}_r$ from (2.9).

Another important dynamical systems norm (besides the $\mathcal{H}_2$ norm) is the $\mathcal{H}_\infty$ norm defined as $\|G\|_{\mathcal{H}_\infty} := \sup_{\omega\in\mathbb{R}} |G(\imath\omega)|$. The reduced order system $G_r(s)$ obtained by balanced truncation is asymptotically stable and the $\mathcal{H}_\infty$ norm of the error system satisfies $\|G - G_r\|_{\mathcal{H}_\infty} \le 2(\eta_{r+1} + \cdots + \eta_n)$.

The value of having, for reduced order models, guaranteed stability and an explicit error bound is widely recognized, though it is achieved at potentially considerable cost. As described above, balanced truncation requires the solution of two Lyapunov equations of order n, which is a formidable task in large-scale settings. For more details and background on balanced truncation, see section III.7 of [2].

2.3. The $\mathcal{H}_2$ norm. $\mathcal{H}_2$ will denote the set of functions, $g(z)$, that are analytic for z in the open right half plane, $\operatorname{Re}(z) > 0$, and such that for each fixed $\operatorname{Re}(z) = x > 0$, $g(x + \imath y)$ is square integrable as a function of $y \in (-\infty, \infty)$ in such a way that

$$\sup_{x>0} \int_{-\infty}^{\infty} |g(x + \imath y)|^2 \, dy < \infty.$$

$\mathcal{H}_2$ is a Hilbert space and holds our interest because transfer functions associated with stable SISO finite-dimensional dynamical systems are elements of $\mathcal{H}_2$. Indeed, if $G(s)$ and $H(s)$ are transfer functions associated with real stable SISO dynamical systems, then the $\mathcal{H}_2$ inner product can be defined as

$$\langle G,\ H\rangle_{\mathcal{H}_2} \stackrel{\text{def}}{=} \frac{1}{2\pi}\int_{-\infty}^{\infty} \overline{G(\imath\omega)}H(\imath\omega)\, d\omega = \frac{1}{2\pi}\int_{-\infty}^{\infty} G(-\imath\omega)H(\imath\omega)\, d\omega, \tag{2.10}$$

with a norm defined as

$$\|G\|_{\mathcal{H}_2} \stackrel{\text{def}}{=} \left(\frac{1}{2\pi}\int_{-\infty}^{+\infty} |G(\imath\omega)|^2\, d\omega\right)^{1/2}. \tag{2.11}$$

Notice in particular that if $G(s)$ and $H(s)$ represent real dynamical systems, then $\langle G,\ H\rangle_{\mathcal{H}_2} = \langle H,\ G\rangle_{\mathcal{H}_2}$ and $\langle G,\ H\rangle_{\mathcal{H}_2}$ must be real.

There are two alternate characterizations of this inner product that make it far more computationally accessible.

LEMMA 2.3. Let $\mathbf{A} \in \mathbb{R}^{n\times n}$, $\mathbf{B} \in \mathbb{R}^{m\times m}$, $\mathbf{b}, \mathbf{c} \in \mathbb{R}^n$, $\widetilde{\mathbf{b}}, \widetilde{\mathbf{c}} \in \mathbb{R}^m$, be such that

$$G(s) = \mathbf{c}^T (s\mathbf{I} - \mathbf{A})^{-1} \mathbf{b} \quad \text{and} \quad H(s) = \widetilde{\mathbf{c}}^T (s\mathbf{I} - \mathbf{B})^{-1} \widetilde{\mathbf{b}}.$$

Then $\langle G,\ H\rangle_{\mathcal{H}_2}$ can be computed in the following ways:

(2.12) $\mathbf{P}$ satisfies $\mathbf{A}\mathbf{P} + \mathbf{P}\mathbf{B}^T + \mathbf{b}\widetilde{\mathbf{b}}^T = 0$, then $\langle G,\ H\rangle_{\mathcal{H}_2} = \mathbf{c}^T\mathbf{P}\widetilde{\mathbf{c}}$.

(2.13) $\mathbf{Q}$ satisfies $\mathbf{Q}\mathbf{A} + \mathbf{B}^T\mathbf{Q} + \widetilde{\mathbf{c}}\mathbf{c}^T = 0$, then $\langle G,\ H\rangle_{\mathcal{H}_2} = \widetilde{\mathbf{b}}^T\mathbf{Q}\mathbf{b}$.

(2.14) $\mathbf{R}$ satisfies $\mathbf{A}\mathbf{R} + \mathbf{R}\mathbf{B} + \mathbf{b}\widetilde{\mathbf{c}}^T = 0$, then $\langle G,\ H\rangle_{\mathcal{H}_2} = \mathbf{c}^T\mathbf{R}\widetilde{\mathbf{b}}$.

In the case where $\mathbf{A} = \mathbf{B}$, $\mathbf{b} = \widetilde{\mathbf{b}}$, and $\mathbf{c} = \widetilde{\mathbf{c}}$, the matrix $\mathbf{P}$ is the "observability gramian" of $G(s)$, $\mathbf{Q}$ is the "controllability gramian" of $G(s)$, and $\mathbf{R}$ is the "cross gramian" of $G(s)$:

$$\|G\|_{\mathcal{H}_2}^2 = \mathbf{c}^T\mathbf{P}\mathbf{c} = \mathbf{b}^T\mathbf{Q}\mathbf{b} = \mathbf{c}^T\mathbf{R}\mathbf{b}. \tag{2.15}$$

Gramians play a prominent role in the analysis of linear dynamical systems; refer to [2] for more information.

We detail the proof of (2.12); proofs of (2.13) and (2.14) are similar. Since $\mathbf{A}$ and $\mathbf{B}$ are stable, the solution, $\mathbf{P}$, to the Sylvester equation of (2.12) exists and is unique. For any $\omega \in \mathbb{R}$, rearrange this equation to obtain in sequence

$$\begin{aligned}
(-\imath\omega\mathbf{I} - \mathbf{A})\,\mathbf{P} + \mathbf{P}\left(\imath\omega\mathbf{I} - \mathbf{B}^T\right) - \mathbf{b}\widetilde{\mathbf{b}}^T &= 0,\\
(-\imath\omega\mathbf{I} - \mathbf{A})^{-1}\,\mathbf{P} + \mathbf{P}\left(\imath\omega\mathbf{I} - \mathbf{B}^T\right)^{-1} &= (-\imath\omega\mathbf{I} - \mathbf{A})^{-1}\,\mathbf{b}\widetilde{\mathbf{b}}^T\left(\imath\omega\mathbf{I} - \mathbf{B}^T\right)^{-1},\\
\mathbf{c}^T(-\imath\omega\mathbf{I} - \mathbf{A})^{-1}\,\mathbf{P}\widetilde{\mathbf{c}} + \mathbf{c}^T\mathbf{P}\left(\imath\omega\mathbf{I} - \mathbf{B}^T\right)^{-1}\widetilde{\mathbf{c}} &= G(-\imath\omega)H(\imath\omega),
\end{aligned}$$

and finally

$$\begin{aligned}
\mathbf{c}^T\left(\int_{-L}^{L}(-\imath\omega\mathbf{I} - \mathbf{A})^{-1}\,d\omega\right)\mathbf{P}\widetilde{\mathbf{c}} + \mathbf{c}^T\mathbf{P}\left(\int_{-L}^{L}\left(\imath\omega\mathbf{I} - \mathbf{B}^T\right)^{-1}\,d\omega\right)\widetilde{\mathbf{c}}&\\
= \int_{-L}^{L} G(-\imath\omega)H(\imath\omega)\,d\omega.&
\end{aligned}$$

Taking $L \to \infty$ and using Lemma A.1 in the appendix leads to

$$\begin{aligned}
\int_{-\infty}^{\infty} G(-\imath\omega)H(\imath\omega)\,d\omega &= \mathbf{c}^T\left(\text{P.V.}\int_{-\infty}^{\infty}(-\imath\omega\mathbf{I} - \mathbf{A})^{-1}\,d\omega\right)\mathbf{P}\widetilde{\mathbf{c}}\\
&\quad + \mathbf{c}^T\mathbf{P}\left(\text{P.V.}\int_{-\infty}^{\infty}\left(\imath\omega\mathbf{I} - \mathbf{B}^T\right)^{-1}\,d\omega\right)\widetilde{\mathbf{c}}\\
&= 2\pi\ \mathbf{c}^T\mathbf{P}\widetilde{\mathbf{c}}. \qquad \square
\end{aligned}$$

Recently, Antoulas [2] obtained a new expression for $\|G\|_{\mathcal{H}_2}$ based on the poles and residues of the transfer function $G(s)$ that complements the widely known alternative expression (2.15). We provide a compact derivation of this expression and the associated $\mathcal{H}_2$ inner product.

If $f(s)$ is a meromorphic function with a pole at λ, denote the residue of $f(s)$ at λ by $\mathsf{res}[f(s), \lambda]$. Thus, if λ is a simple pole of $f(s)$, then $\mathsf{res}[f(s), \lambda] = \lim_{s\to\lambda}(s-\lambda)f(s)$, and if λ is a double pole of $f(s)$, then $\mathsf{res}[f(s), \lambda] = \lim_{s\to\lambda} \frac{d}{ds}\left[(s-\lambda)^2 f(s)\right]$.

LEMMA 2.4. [illegible] $G(s)$ [illegible] $\lambda_1, \lambda_2, \ldots, \lambda_n$ [illegible] $H(s)$ [illegible] $\mu_1, \mu_2, \ldots, \mu_m$ [illegible]

$$\langle G,\ H\rangle_{\mathcal{H}_2} = \sum_{k=1}^{m} \mathsf{res}[G(-s)H(s), \mu_k] = \sum_{k=1}^{n} \mathsf{res}[H(-s)G(s), \lambda_k]. \tag{2.16}$$

[illegible]

- [illegible] μ_k [illegible] $H(s)$ [illegible]
$$\mathsf{res}[G(-s)H(s), \mu_k] = G(-\mu_k)\mathsf{res}[H(s), \mu_k];$$
- [illegible] μ_k [illegible] $H(s)$ [illegible]
$$\mathsf{res}[G(-s)H(s), \mu_k] = G(-\mu_k)\,\mathsf{res}[H(s), \mu_k] - G'(-\mu_k)\cdot h_0(\mu_k),$$
[illegible] $h_0(\mu_k) = \lim_{s\to\mu_k}\left((s-\mu_k)^2 H(s)\right)$.

[illegible] Notice that the function $G(-s)H(s)$ has singularities at $\mu_1, \mu_2, \ldots, \mu_m$ and $-\lambda_1, -\lambda_2, \ldots, -\lambda_n$. For any $R > 0$, define the semicircular contour in the left half plane:

$$\Gamma_R = \{z\,|z = \imath\omega \text{ with } \omega \in [-R, R]\,\} \cup \left\{ z \,\middle|\, z = R\,e^{\imath\theta} \text{ with } \theta \in \left[\frac{\pi}{2}, \frac{3\pi}{2}\right] \right\}.$$

Γ_R bounds a region that for sufficiently large R contains all the system poles of $H(s)$ and so, by the residue theorem,

$$\begin{aligned}\langle G,\ H\rangle_{\mathcal{H}_2} &= \frac{1}{2\pi}\int_{-\infty}^{+\infty} G(-\imath\omega)H(\imath\omega)\,d\omega \\ &= \lim_{R\to\infty}\frac{1}{2\pi\imath}\int_{\Gamma_R} G(-s)H(s)\ ds = \sum_{k=1}^{m}\mathsf{res}[G(-s)H(s), \mu_k].\end{aligned}$$

Evidently, if μ_k is a simple pole for $H(s)$, it is also a simple pole for $G(-s)H(s)$ and

$$\mathsf{res}[G(-s)H(s),\ \mu_k] = \lim_{s\to\mu_k}(s-\mu_k)G(-s)H(s) = G(-\mu_k)\lim_{s\to\mu_k}(s-\mu_k)H(s).$$

If μ_k is a double pole for $H(s)$, then it is also a double pole for $G(-s)H(s)$ and

$$\begin{aligned}\mathsf{res}[G(-s)H(s),\ \mu_k] &= \lim_{s\to\mu_k}\frac{d}{ds}(s-\mu_k)^2 G(-s)H(s) \\ &= \lim_{s\to\mu_k} G(-s)\frac{d}{ds}(s-\mu_k)^2 H(s) - G'(-s)(s-\mu_k)^2 H(s) \\ &= G(-\mu_k)\lim_{s\to\mu_k}\frac{d}{ds}(s-\mu_k)^2 H(s) - G'(-\mu_k)\lim_{s\to\mu_k}(s-\mu_k)^2 H(s). \qquad \square\end{aligned}$$

Lemma 2.4 immediately yields the expression for $\|G\|_{\mathcal{H}_2}$ given by Antoulas [2, p. 145] based on poles and residues of the transfer function $G(s)$.

COROLLARY 2.5. [illegible] $G(s)$ [illegible] $\lambda_1, \lambda_2, \ldots, \lambda_n$, [illegible]

$$\|G\|_{\mathcal{H}_2} = \left(\sum_{k=1}^{n}\mathsf{res}[G(s), \lambda_k]G(-\lambda_k)\right)^{1/2}.$$

3. Optimal $\mathcal{H}_2$ model reduction. In this section, we investigate three frameworks of necessary conditions for $\mathcal{H}_2$ optimality. The first utilizes the inner product structure $\mathcal{H}_2$ and leads to what could be thought of as a geometric condition for optimality. This appears to be a new characterization of $\mathcal{H}_2$ optimality for reduced order models. The remaining two frameworks, interpolation-based [26] and Lyapunov-based [36, 22], are easily derived from the first framework and in this way can be seen to be equivalent to one another—a fact that is not a priori evident. This equivalence proves that solving the optimal $\mathcal{H}_2$ problem in the Krylov framework is equivalent to solving it in the Lyapunov framework, which leads to the proposed Krylov-based method for $\mathcal{H}_2$ model reduction in section 4.

Given G, a stable SISO finite-dimensional dynamical system as described in (1.1), we seek a stable reduced order system G_r of order r as described in (1.2), which is the best stable rth-order dynamical system approximating G with respect to the $\mathcal{H}_2$ norm:

$$\|G - G_r\|_{\mathcal{H}_2} = \min_{\substack{\dim(\widetilde{G}_r)=r \\ \widetilde{G}_r \text{ : stable}}} \|G - \widetilde{G}_r\|_{\mathcal{H}_2}. \tag{3.1}$$

Many researchers have worked on problem (3.1), the [illegible] $\mathcal{H}_2$ [illegible]. See [37, 34, 9, 21, 26, 22, 36, 25] and the references therein.

3.1. Structured orthogonality optimality conditions. The set of all stable rth-order dynamical systems do not constitute a subspace of $\mathcal{H}_2$, so the best rth-order $\mathcal{H}_2$ approximation is not so easy to characterize, the Hilbert space structure of $\mathcal{H}_2$ notwithstanding. This observation does suggest the following narrower though simpler result.

THEOREM 3.1. [illegible] $\mu_1, \mu_2, \ldots, \mu_r \subset \mathbb{C}$ [illegible] $\mathcal{M}(\boldsymbol{\mu})$ [illegible] $\mu_1, \mu_2, \ldots, \mu_r$ [illegible]

- $H \in \mathcal{M}(\boldsymbol{\mu})$ [illegible] H [illegible] $\dim(H) = r$
- $\mathcal{M}(\boldsymbol{\mu})$ [illegible] $(r-1)$ [illegible] $\mathcal{H}_2$
- $G_r \in \mathcal{M}(\boldsymbol{\mu})$ [illegible]

$$\|G - G_r\|_{\mathcal{H}_2} = \min_{\widetilde{G}_r \in \mathcal{M}(\boldsymbol{\mu})} \|G - \widetilde{G}_r\|_{\mathcal{H}_2} \tag{3.2}$$

[illegible]

$$\langle G - G_r,\, H \rangle_{\mathcal{H}_2} = 0 \qquad \text{[illegible]} \quad H \in \mathcal{M}(\boldsymbol{\mu}). \tag{3.3}$$

[illegible] G_r [illegible] (3.2) [illegible]

[illegible]. The key observation is that $\mathcal{M}(\boldsymbol{\mu})$ is a closed subspace of $\mathcal{H}_2$. Then the equivalence of (3.2) and (3.3) follows from the classic projection theorem in Hilbert space (cf. [32]). □

One consequence of Theorem 3.1 is that if $G_r(s)$ interpolates a real system $G(s)$ at the [illegible] of its own poles (i.e., at the poles of $G_r(s)$ reflected across the imaginary axis), then $G_r(s)$ is guaranteed to be an [illegible] approximation of $G(s)$ relative to the $\mathcal{H}_2$ norm among all reduced order systems having the same reduced system poles $\{\mu_i\}_{i=1}^r$. An analogous result for optimal rational approximants to analytic functions on the unit disk can be found in [14]. The set of stable rth-order dynamical systems is not convex, and so the original problem (3.1) allows for

multiple minimizers. Indeed there may be "local minimizers" that do not solve (3.1). A reduced order system, G_r, is a [illegible] for (3.1) if, for all $\varepsilon > 0$ sufficiently small,

$$\|G - G_r\|_{\mathcal{H}_2} \leq \|G - \widetilde{G}_r^{(\varepsilon)}\|_{\mathcal{H}_2} \tag{3.4}$$

for all stable dynamical systems $\widetilde{G}_r^{(\varepsilon)}$ with $\dim(\widetilde{G}_r^{(\varepsilon)}) = r$ and $\|G_r - \widetilde{G}_r^{(\varepsilon)}\|_{\mathcal{H}_2} \leq C\,\varepsilon$, with C being a constant that may depend on the particular family $\widetilde{G}_r^{(\varepsilon)}$ considered. As a practical matter, the global minimizers that solve (3.1) are difficult to obtain with certainty; current approaches favor seeking reduced order models that satisfy a local (first-order) necessary condition for optimality. Even though such strategies do not guarantee global minimizers, they often produce effective reduced order models nonetheless. In this spirit, we give necessary conditions for optimality for the reduced order system, G_r, that appear as structured orthogonality conditions similar to (3.3).

THEOREM 3.2. [illegible] G_r [illegible] G [illegible] (3.4) [illegible] G_r [illegible]

$$\langle G - G_r,\ G_r \cdot H_1 + H_2 \rangle_{\mathcal{H}_2} = 0 \tag{3.5}$$

[illegible] H_1 [illegible] H_2 [illegible] G_r

($G_r \cdot H_1$ here denotes pointwise multiplication of scalar functions.)

[illegible] Theorem 3.1 implies (3.5) with $H_1 = 0$, so it suffices to show that the hypotheses imply that $\langle G - G_r,\ G_r \cdot H \rangle_{\mathcal{H}_2} = 0$ for all real dynamical systems H having the same poles with the same multiplicities as G_r.

Suppose that $\{\widetilde{G}_r^{(\varepsilon)}\}_{\varepsilon>0}$ is a family of real stable dynamical systems with $\dim(\widetilde{G}_r^{(\varepsilon)}) = r$ and $\|G_r - \widetilde{G}_r^{(\varepsilon)}\|_{\mathcal{H}_2} < C\varepsilon$ for some constant $C > 0$. Then for all $\varepsilon > 0$ sufficiently small,

$$\begin{aligned}
\|G - G_r\|_{\mathcal{H}_2}^2 &\leq \|G - \widetilde{G}_r^{(\varepsilon)}\|_{\mathcal{H}_2}^2 \\
&\leq \|(G - G_r) + (G_r - \widetilde{G}_r^{(\varepsilon)})\|_{\mathcal{H}_2}^2 \\
&\leq \|G - G_r\|_{\mathcal{H}_2}^2 + 2\left\langle G - G_r,\ G_r - \widetilde{G}_r^{(\varepsilon)} \right\rangle_{\mathcal{H}_2} + \|G_r - \widetilde{G}_r^{(\varepsilon)})\|_{\mathcal{H}_2}^2.
\end{aligned}$$

This in turn implies for all $\varepsilon > 0$ sufficiently small that

$$0 \leq 2\left\langle G - G_r,\ G_r - \widetilde{G}_r^{(\varepsilon)} \right\rangle_{\mathcal{H}_2} + \|G_r - \widetilde{G}_r^{(\varepsilon)}\|_{\mathcal{H}_2}^2. \tag{3.6}$$

By considering a few different "directions of approach" of $\widetilde{G}_r^{(\varepsilon)}$ to G_r as $\varepsilon \to 0$, (3.6) will lead to a few different necessary conditions for G_r to be a locally optimal reduced order model. Denote the poles of G_r as $\mu_1, \mu_2, \ldots, \mu_r$ and suppose they are ordered so that the first m_R are real and the next m_C are in the upper half plane. Write $\mu_i = \alpha_i + \imath\beta_i$. Any real rational function having the same poles as $G_r(s)$ can be written as

$$H(s) = \sum_{i=1}^{m_R} \frac{\gamma_i}{s - \mu_i} + \sum_{i=m_R+1}^{m_R+m_C} \frac{\rho_i(s - \alpha_i) + \tau_i}{(s - \alpha_i)^2 + \beta_i^2},$$

with arbitrary real-valued choices for γ_i, ρ_i, and τ_i. Now suppose that μ is a real pole for G_r and that

$$\left\langle G - G_r,\ \frac{G_r(s)}{s - \mu} \right\rangle_{\mathcal{H}_2} \neq 0. \tag{3.7}$$

Write $G_r(s) = \frac{p_{r-1}(s)}{(s-\mu)\,q_{r-1}(s)}$ for real polynomials $p_{r-1},\ q_{r-1} \in \mathcal{P}_{r-1}$ and define

$$\widetilde{G}_r^{(\varepsilon)}(s) = \frac{p_{r-1}(s)}{[s-\mu-(\pm\varepsilon)]\ q_{r-1}(s)},$$

where the sign of $\pm\varepsilon$ is chosen to match that of $\left\langle G - G_r,\ \frac{G_r(s)}{s-\mu}\right\rangle_{\mathcal{H}_2}$. Then we have

$$\widetilde{G}_r^{(\varepsilon)}(s) = G_r(s) \pm \varepsilon \frac{p_{r-1}(s)}{(s-\mu)^2\, q_{r-1}(s)} + \mathcal{O}(\varepsilon^2),$$

which leads to $G_r(s) - \widetilde{G}_r^{(\varepsilon)}(s) = \mp\varepsilon \frac{G_r(s)}{s-\mu} + \mathcal{O}(\varepsilon^2)$ and

$$\left\langle G - G_r,\ G_r - \widetilde{G}_r^{(\varepsilon)}\right\rangle_{\mathcal{H}_2} = -\varepsilon \left| \left\langle G - G_r,\ \frac{G_r(s)}{s-\mu}\right\rangle_{\mathcal{H}_2}\right| + \mathcal{O}(\varepsilon^2). \tag{3.8}$$

Then (3.6) implies that as $\varepsilon \to 0$, $0 < \left|\left\langle G - G_r,\ \frac{G_r(s)}{s-\mu}\right\rangle_{\mathcal{H}_2}\right| \le C\varepsilon$ for some constant C, which then contradicts (3.7).

Now suppose that $\mu = \alpha + \imath\beta$ is a pole for G_r with a nontrivial imaginary part, $\beta \neq 0$, and so is one of a conjugate pair of poles for G_r. Suppose further that

$$\left\langle G - G_r,\ \frac{G_r(s)}{(s-\alpha)^2+\beta^2}\right\rangle_{\mathcal{H}_2} \neq 0 \quad \text{and} \quad \left\langle G - G_r,\ \frac{(s-\alpha)\,G_r(s)}{(s-\alpha)^2+\beta^2}\right\rangle_{\mathcal{H}_2} \neq 0. \tag{3.9}$$

Write $G_r(s) = \frac{p_{r-1}(s)}{[(s-\alpha)^2+\beta^2]\,q_{r-2}(s)}$ for some choice of real polynomials $p_{r-1} \in \mathcal{P}_{r-1}$ and $q_{r-2} \in \mathcal{P}_{r-2}$. Arguments exactly analogous to the previous case lead to the remaining assertions. In particular,

$$\begin{aligned}
\text{to show} \quad & \left\langle G - G_r,\ \frac{G_r(s)}{(s-\alpha)^2+\beta^2}\right\rangle_{\mathcal{H}_2} = 0, \\
& \text{consider} \quad \widetilde{G}_r^{(\varepsilon)}(s) = \frac{p_{r-1}(s)}{[(s-\alpha)^2+\beta^2-(\pm\varepsilon)]\,q_{r-2}(s)}; \\
\text{to show} \quad & \left\langle G - G_r,\ \frac{(s-\alpha)\,G_r(s)}{(s-\alpha)^2+\beta^2}\right\rangle_{\mathcal{H}_2} = 0, \\
& \text{consider} \quad \widetilde{G}_r^{(\varepsilon)}(s) = \frac{p_{r-1}(s)}{[(s-\alpha-(\pm\varepsilon))^2+\beta^2]\,q_{r-2}(s)}.
\end{aligned}$$

The conclusion follows then by observing that if G_r is a locally optimal $\mathcal{H}_2$ reduced order model, then

$$\begin{aligned}
\langle G - G_r,\ G_r \cdot H_1 + H_2\rangle_{\mathcal{H}_2} = & \sum_{i=1}^{m_R} \gamma_i \left\langle G - G_r,\ \frac{G_r(s)}{s-\mu_i}\right\rangle_{\mathcal{H}_2} \\
& + \sum_{i=m_R+1}^{m_R+m_C} \rho_i \left\langle G - G_r,\ \frac{(s-\alpha_i)\,G_r(s)}{(s-\alpha_i)^2+\beta_i^2}\right\rangle_{\mathcal{H}_2} \\
& + \sum_{i=m_R+1}^{m_R+m_C} \tau_i \left\langle G - G_r,\ \frac{G_r(s)}{(s-\alpha_i)^2+\beta_i^2}\right\rangle_{\mathcal{H}_2} \\
& + \langle G - G_r,\ H_2(s)\rangle_{\mathcal{H}_2} = 0.
\end{aligned}$$

Theorem 3.2 describes new necessary conditions for the $\mathcal{H}_2$ approximation problem as structured orthogonality conditions. This new formulation amounts to a unifying framework for the optimal $\mathcal{H}_2$ problem. Indeed, as we show in sections 3.2 and 3.3, two other known optimality frameworks, namely, interpolatory- [26] and Lyapunov-based conditions [36, 22], can be directly obtained from our new conditions by using an appropriate form for the $\mathcal{H}_2$ inner product. The interpolatory framework uses the residue formulation of the $\mathcal{H}_2$ inner product as in (2.16); the Lyapunov framework uses the Sylvester equation formulation of the $\mathcal{H}_2$ norm as in (2.12).

3.2. Interpolation-based optimality conditions. Corollary 2.5 immediately yields an observation regarding the $\mathcal{H}_2$ norm of the error system, which serves as a main motivation for the interpolation framework of the optimal $\mathcal{H}_2$ problem.

PROPOSITION 3.3. [illegible] $G(s)$ [illegible] $G_r(s)$ [illegible] λ_i [illegible] $\widetilde{\lambda}_i$ [illegible] $G(s)$ [illegible] $G_r(s)$ [illegible] $G_r(s)$ [illegible] ϕ_i [illegible] $\widetilde{\phi}_j$ [illegible] $G(s)$ [illegible] $G_r(s)$ [illegible] λ_i [illegible] $\widetilde{\lambda}_i$ [illegible] $\phi_i = \mathsf{res}[G(s), \lambda_i]$, $i = 1, \ldots, n$ [illegible] $\widetilde{\phi}_j = \mathsf{res}[G_r(s), \widetilde{\lambda}_j]$, $j = 1, \ldots, r$. [illegible] $\mathcal{H}_2$ [illegible]

$$\begin{aligned}\|G - G_r\|_{\mathcal{H}_2}^2 &= \sum_{i=1}^{n} \mathsf{res}\left[\left(G(-s) - G_r(-s)\right)\left(G(s) - G_r(s)\right), \lambda_i\right] \\ &\quad + \sum_{j=1}^{r} \mathsf{res}\left[\left(G(-s) - G_r(-s)\right)\left(G(s) - G_r(s)\right), \widetilde{\lambda}_j\right] \\ &= \sum_{i=1}^{n} \phi_i \Big(G(-\lambda_i) - G_r(-\lambda_i)\Big) - \sum_{j=1}^{r} \widetilde{\phi}_j \Big(G(-\widetilde{\lambda}_j) - G_r(-\widetilde{\lambda}_j)\Big). \end{aligned} \tag{3.10}$$

The $\mathcal{H}_2$ error expression (3.10) is valid for any reduced order model regardless of the underlying reduction technique and generalizes a result of [20, 18] to the most general setting.

Proposition 3.3 has the system-theoretic interpretation that the $\mathcal{H}_2$ error is due to mismatch of the transfer functions $G(s)$ and $G_r(s)$ at mirror images of the full-order poles λ_i and reduced order poles $\widetilde{\lambda}_i$. This expression reveals that for good $\mathcal{H}_2$ performance, $G_r(s)$ should approximate $G(s)$ well at $-\lambda_i$ and $-\widetilde{\lambda}_j$. Note that $\widetilde{\lambda}_i$ is not known a priori. Therefore, to minimize the $\mathcal{H}_2$ error, Gugercin and Antoulas [20] proposed choosing $\sigma_i = -\lambda_i(\mathbf{A})$, where $\lambda_i(\mathbf{A})$ are those system poles having big residuals ϕ_i. They have illustrated that this selection of interpolation points works quite well; see [18, 20]. However, as (3.10) illustrates, there is a second part of the $\mathcal{H}_2$ error due to the mismatch at $-\widetilde{\lambda}_j$. Indeed, as we will show below, interpolation at $-\widetilde{\lambda}_i$ is more important for model reduction and is a necessary condition for optimal $\mathcal{H}_2$ model reduction; i.e., $\sigma_i = -\widetilde{\lambda}_i$ is the optimal shift selection.

THEOREM 3.4. [illegible] $G(s) = \mathbf{c}^T(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{b}$, $G_r(s) = \mathbf{c}_r^T(s\mathbf{I} - \mathbf{A}_r)^{-1}\mathbf{b}_r$ [illegible] r, [illegible] $\mathcal{H}_2$ [illegible] (3.1) [illegible] $G_r(s)$ [illegible] $\widetilde{\lambda}_i$, $i = 1, \ldots, r$ [illegible] $G_r(s)$ [illegible] $G(s)$ [illegible] $-\widetilde{\lambda}_i$, $i = 1, \ldots, r$

$$G_r(-\widetilde{\lambda}_i) = G(-\widetilde{\lambda}_i) \quad \text{and} \quad G_r'(-\widetilde{\lambda}_i) = G'(-\widetilde{\lambda}_i) \quad \text{for} \quad i = 1, \ldots, r. \tag{3.11}$$

[illegible] From (3.5), consider first the case $H_1 = 0$ and H_2 is an arbitrary transfer function with simple poles at $\widetilde{\lambda}_i$, $i = 1, \ldots, r$. Denote $\widetilde{\phi}_i = \mathsf{res}[H_2(s), \widetilde{\lambda}_i]$. Then (2.16)

leads to

$$\langle G - G_r,\ H_2\rangle_{\mathcal{H}_2} = \sum_{i=1}^{r} \mathsf{res}[(G(-s) - G_r(-s))\, H_2(s), \widetilde{\lambda}_i] = \sum_{i=1}^{r} \widetilde{\phi}_i \left(G(-\widetilde{\lambda}_i) - G_r(-\widetilde{\lambda}_i)\right) = 0.$$

Since this is true for arbitrary choices of $\widetilde{\phi}_i$, we have $G(-\widetilde{\lambda}_i) = G_r(-\widetilde{\lambda}_i)$. Now consider the case $H_2 = 0$ and H_1 is an arbitrary transfer function with simple poles at $\widetilde{\lambda}_i$, $i = 1, \ldots, r$. Then $G_r(s)H_1(s)$ has double poles at $\widetilde{\lambda}_i$, $i = 1, \ldots, r$, and since $G(-\widetilde{\lambda}_i) = G_r(-\widetilde{\lambda}_i)$ we have

$$\langle G - G_r,\ G_r \cdot H_1\rangle_{\mathcal{H}_2} = \sum_{i=1}^{r} \mathsf{res}[(G(-s) - G_r(-s))\, G_r(s)H_1(s), \widetilde{\lambda}_i] = -\sum_{i=1}^{r} \widetilde{\phi}_i\, \mathsf{res}[G_r, \widetilde{\lambda}_i] \left(G'(-\widetilde{\lambda}_i) - G_r'(-\widetilde{\lambda}_i)\right) = 0,$$

where we have calculated

$$\lim_{s\to\widetilde{\lambda}_i} \left((s - \widetilde{\lambda}_i)^2 G_r(s) \cdot H_1(s)\right) = \mathsf{res}[H_1(s), \widetilde{\lambda}_i] \cdot \mathsf{res}[G_r(s), \widetilde{\lambda}_i] = \widetilde{\phi}_i\, \mathsf{res}[G_r, \widetilde{\lambda}_i]. \qquad \square$$

We refer to the first-order conditions (3.11) as Meier–Luenberger conditions, recognizing the work of [26], although we have here directly obtained them from the newly derived structured orthogonality conditions (3.5).

In Theorem 3.4, we assume that the reduced order poles (eigenvalues of $\mathbf{A}_r$) are simple; analogous results for the case that G_r has a higher order pole are straightforward and correspond to interpolation conditions of higher derivatives at the mirror images of reduced order poles.

3.2.1. Multiple input/multiple output systems. Many of these considerations extend naturally to the multiple input/multiple output (MIMO) setting:

$$\mathbf{G}: \begin{cases} \dot{\mathbf{x}}(t) = \mathbf{A}\mathbf{x}(t) + \mathbf{B}\,\mathbf{u}(t) \\ \mathbf{y}(t) = \mathbf{C}\mathbf{x}(t) \end{cases} \quad \text{or} \quad \mathbf{G}(s) = \mathbf{C}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{B}, \tag{3.12}$$

where the state vector $\mathbf{x}(t) \in \mathbb{R}^n$ as before, but now the system has an input $\mathbf{u}(t) \in \mathbb{R}^m$ and output $\mathbf{y}(t) \in \mathbb{R}^p$, so that $\mathbf{B} \in \mathbb{R}^{n\times m}$ and $\mathbf{C} \in \mathbb{R}^{p\times n}$ for some $m, p \geq 1$. The transfer function, $\mathbf{G}(s)$, in (3.12) becomes matrix valued. A reduced order system analogous to (1.2) is sought with the same number of inputs m and outputs p, but with lower state space dimension $r \ll n$. If $\mathbf{V}_r \in \mathbb{R}^{n\times r}$ and $\mathbf{W}_r \in \mathbb{R}^{n\times r}$ such that $\mathbf{W}_r^T\mathbf{V}_r$ is nonsingular, we can define a (matrix-valued) reduced order transfer function $\mathbf{G}_r(s) = \mathbf{C}_r(s\mathbf{I} - \mathbf{A}_r)^{-1}\mathbf{B}_r$ with

$$\mathbf{A}_r = (\mathbf{W}_r^T\mathbf{V}_r)^{-1}\mathbf{W}_r^T\mathbf{A}\mathbf{V}_r, \quad \mathbf{B}_r = (\mathbf{W}_r^T\mathbf{V}_r)^{-1}\mathbf{W}_r^T\mathbf{B}, \quad \text{and} \quad \mathbf{C}_r = \mathbf{C}\mathbf{V}_r.$$

In order to assess "closeness" of MIMO systems, there is a natural extension of the Hilbert space, $\mathcal{H}_2$, to $p \times m$ matrix-valued functions. In particular, if $\mathbf{G}(s)$ and $\mathbf{H}(s)$ are $p \times m$ matrix-valued transfer functions associated with real stable MIMO dynamical systems, then the associated $\mathcal{H}_2$ inner product is

$$\langle \mathbf{G},\ \mathbf{H}\rangle_{\mathcal{H}_2} \stackrel{\text{def}}{=} \frac{1}{2\pi}\int_{-\infty}^{\infty} \mathsf{tr}\left(\overline{\mathbf{G}(\imath\omega)}\,\mathbf{H}^T(\imath\omega)\right) d\omega = \frac{1}{2\pi}\int_{-\infty}^{\infty} \mathsf{tr}\left(\mathbf{G}(-\imath\omega)\mathbf{H}^T(\imath\omega)\right) d\omega, \tag{3.13}$$

where "$\mathsf{tr}(\mathbf{M})$" denotes the trace of the matrix $\mathbf{M}$. The $\mathcal{H}_2$ norm is then

$$\|\mathbf{G}\|_{\mathcal{H}_2} \stackrel{\text{def}}{=} \left(\frac{1}{2\pi} \int_{-\infty}^{+\infty} \|\mathbf{G}(\imath\omega)\|_F^2 \, d\omega \right)^{1/2}, \tag{3.14}$$

where $\|\mathbf{F}\|_F \stackrel{\text{def}}{=} \left(\sum_{ij} |F_{ij}|^2 \right)^{1/2}$ denotes the usual Frobenius matrix norm. As before, if $\mathbf{G}(s)$ and $\mathbf{H}(s)$ represent real dynamical systems, then $\langle \mathbf{G},\ \mathbf{H} \rangle_{\mathcal{H}_2} = \langle \mathbf{H},\ \mathbf{G} \rangle_{\mathcal{H}_2}$ and $\langle \mathbf{G},\ \mathbf{H} \rangle_{\mathcal{H}_2}$ is real.

Necessary conditions for $\mathcal{H}_2$ optimality built on structured orthogonality paralleling the results of section 3.1 can be derived in this setting as well. In particular, the residue form for the inner product is a straightforward analogue of Lemma 2.4 and leads naturally to interpolation conditions. If $\mathbf{F}(s)$ is a matrix-valued meromorphic function with a pole at λ, then $\mathbf{F}(s)$ has a Laurent expansion (with matrix coefficients), and its residue, $\mathsf{res}[\mathbf{F}(s), \lambda]$, will be the coefficient matrix associated with the expansion term $(s-\lambda)^{-1}$. For example, suppose that $\mathbf{F}(s)$ has the realization $\mathbf{F}(s) = \widetilde{\mathbf{C}}\big(s\mathbf{I} - \widetilde{\mathbf{A}}\big)^{-1}\widetilde{\mathbf{B}}$. If λ is a simple pole of $\mathbf{F}(s)$, then we can assume that λ is a simple eigenvalue of $\widetilde{\mathbf{A}}$ associated with a rank-1 spectral projector $\mathbf{E}_\lambda$ and then $\mathbf{F}(s) = \frac{1}{s-\lambda}\mathbf{E}_\lambda + \mathbf{D}(s)$, where $\mathbf{D}(s)$ is analytic at $s = \lambda$, and $\mathsf{res}[\mathbf{F}(s), \lambda] = \lim_{s\to\lambda}(s-\lambda)\mathbf{F}(s) = \widetilde{\mathbf{C}}\mathbf{E}_\lambda\widetilde{\mathbf{B}}$. If λ is a double pole, then we can assume that λ is a double eigenvalue of $\widetilde{\mathbf{A}}$ associated with a rank-2 spectral projector $\mathbf{E}_\lambda$ and a rank-1 nilpotent matrix $\mathbf{N}_\lambda$ such that $\widetilde{\mathbf{A}}\mathbf{E}_\lambda = \lambda\mathbf{E}_\lambda + \mathbf{N}_\lambda$. Then $\mathbf{F}(s) = \frac{1}{(s-\lambda)^2}\mathbf{N}_\lambda + \frac{1}{(s-\lambda)}\mathbf{E}_\lambda + \mathbf{D}(s)$, where $\mathbf{D}(s)$ is analytic at $s = \lambda$, and so $\mathsf{res}[\mathbf{F}(s), \lambda] = \lim_{s\to\lambda} \frac{d}{ds}\left[(s-\lambda)^2\mathbf{F}(s)\right] = \widetilde{\mathbf{C}}\mathbf{E}_\lambda\widetilde{\mathbf{B}}$.

LEMMA 3.5. [illegible] $\mathbf{G}(s)$ [illegible] $\lambda_1, \lambda_2, \ldots, \lambda_n$ [illegible] $\mathbf{H}(s)$ [illegible] $\widetilde{\lambda}_1, \widetilde{\lambda}_2, \ldots, \widetilde{\lambda}_{\tilde{n}}$ [illegible]

$$\langle \mathbf{G},\ \mathbf{H} \rangle_{\mathcal{H}_2} = \sum_{k=1}^{\tilde{n}} \mathsf{tr}\left(\mathsf{res}[\mathbf{G}(-s)\mathbf{H}^T(s), \widetilde{\lambda}_k] \right). \tag{3.15}$$

[illegible] $\mathbf{H}(s)$ [illegible] $\mathbf{H}(s) = \widetilde{\mathbf{C}}(s\mathbf{I} - \widetilde{\mathbf{A}})^{-1}\widetilde{\mathbf{B}}$

- $\widetilde{\lambda}_k$ [illegible] $\mathbf{H}(s)$ [illegible] $\widetilde{\lambda}_k$ [illegible] $\widetilde{\mathbf{A}}$ $\widetilde{\mathbf{y}}_k$ [illegible] $\widetilde{\mathbf{x}}_k$ [illegible]

$$\widetilde{\mathbf{A}}\widetilde{\mathbf{x}}_k = \widetilde{\lambda}_k\,\widetilde{\mathbf{x}}_k, \qquad \widetilde{\mathbf{y}}_k^*\widetilde{\mathbf{A}} = \widetilde{\lambda}_k\,\widetilde{\mathbf{y}}_k^*, \qquad \text{[illegible]} \qquad \widetilde{\mathbf{y}}_k^*\widetilde{\mathbf{x}}_k = 1,$$

[illegible]

$$\mathsf{tr}\left(\mathsf{res}[\mathbf{G}(-s)\mathbf{H}^T(s), \widetilde{\lambda}_k] \right) = \widetilde{\mathbf{c}}_k^T\mathbf{G}(-\widetilde{\lambda}_k)\widetilde{\mathbf{b}}_k,$$

[illegible] $\widetilde{\mathbf{b}}_k^T = \widetilde{\mathbf{y}}_k^*\widetilde{\mathbf{B}}$ [illegible] $\widetilde{\mathbf{c}}_k = \widetilde{\mathbf{C}}\widetilde{\mathbf{x}}_k$

- $\widetilde{\lambda}_k$ [illegible] $\mathbf{H}(s)$ [illegible] $\widetilde{\lambda}_k$ [illegible] $\widetilde{\mathbf{y}}_k$ [illegible] $\widetilde{\mathbf{x}}_k$, $\widetilde{\mathbf{A}}$ [illegible] $\widetilde{\mathbf{z}}_k$ [illegible] $\widetilde{\mathbf{w}}_k$ [illegible]

$$\widetilde{\mathbf{A}}\widetilde{\mathbf{x}}_k = \widetilde{\lambda}_k\,\widetilde{\mathbf{x}}_k, \quad \widetilde{\mathbf{A}}\widetilde{\mathbf{w}}_k = \widetilde{\lambda}_k\,\widetilde{\mathbf{w}}_k + \widetilde{\mathbf{x}}_k, \quad \widetilde{\mathbf{y}}_k^*\widetilde{\mathbf{A}} = \widetilde{\lambda}_k\,\widetilde{\mathbf{y}}_k^*, \quad \widetilde{\mathbf{z}}_k^*\widetilde{\mathbf{A}} = \widetilde{\lambda}_k\,\widetilde{\mathbf{z}}_k^* + \widetilde{\mathbf{y}}_k^*,$$
$$\text{[illegible]} \quad \widetilde{\mathbf{y}}_k^*\widetilde{\mathbf{x}}_k = 0, \quad \widetilde{\mathbf{z}}_k^*\widetilde{\mathbf{w}}_k = 0, \quad \text{[illegible]} \quad \widetilde{\mathbf{z}}_k^*\widetilde{\mathbf{x}}_k = \widetilde{\mathbf{y}}_k^*\widetilde{\mathbf{w}}_k = 1,$$

[illegible]

$$\mathsf{tr}\left(\mathsf{res}[\mathbf{G}(-s)\mathbf{H}^T(s), \widetilde{\lambda}_k] \right) = \widetilde{\mathbf{d}}_k^T\mathbf{G}(-\widetilde{\lambda}_k)\widetilde{\mathbf{b}}_k + \widetilde{\mathbf{c}}_k^T\mathbf{G}(-\widetilde{\lambda}_k)\widetilde{\mathbf{e}}_k - \widetilde{\mathbf{c}}_k^T\mathbf{G}'(-\widetilde{\lambda}_k)\widetilde{\mathbf{b}}_k,$$

[illegible] $\widetilde{\mathbf{b}}_k$ [illegible] $\widetilde{\mathbf{c}}_k$ [illegible] $\widetilde{\mathbf{e}}_k^T = \widetilde{\mathbf{z}}_k^*\widetilde{\mathbf{B}}$ [illegible] $\widetilde{\mathbf{d}}_k = \widetilde{\mathbf{C}}\widetilde{\mathbf{w}}_k$

Now assume that $\mathbf{G}_r$ is an optimal reduced order model minimizing $\|\mathbf{G}-\mathbf{G}_r\|_{\mathcal{H}_2}$ in the sense described in (3.1) and suppose further that $\mathbf{G}_r$ has simple poles $\widetilde{\lambda}_i$. Take $\mathbf{H}(s)=\mathbf{G}_r$ in (3.5) so that $\mathbf{G}_r(s)=\sum_k \frac{1}{s-\widetilde{\lambda}_k}\widetilde{\mathbf{c}}_k\widetilde{\mathbf{b}}_k^T$ and the residue of $\mathbf{G}_r(s)$ at $\widetilde{\lambda}_k$ is matrix valued and rank one: $\mathsf{res}[\mathbf{G}_r(s),\widetilde{\lambda}_k]=\widetilde{\mathbf{c}}_k\widetilde{\mathbf{b}}_k^T$. An analysis paralleling what we have carried out above yields analogous error expressions (see also [2]) and first-order necessary conditions for the MIMO optimal $\mathcal{H}_2$ reduction problem:

$$\begin{aligned}\mathbf{G}(-\widetilde{\lambda}_k)\widetilde{\mathbf{b}}_k &= \mathbf{G}_r(-\widetilde{\lambda}_k)\widetilde{\mathbf{b}}_k,\\ \widetilde{\mathbf{c}}_k^T\mathbf{G}(-\widetilde{\lambda}_k) &= \widetilde{\mathbf{c}}_k^T\mathbf{G}_r(-\widetilde{\lambda}_k), \quad \text{and}\\ \widetilde{\mathbf{c}}_k^T\mathbf{G}'(-\widetilde{\lambda}_k)\widetilde{\mathbf{b}}_k &= \widetilde{\mathbf{c}}_k^T\mathbf{G}_r'(-\widetilde{\lambda}_k)\widetilde{\mathbf{b}}_k, \quad \text{for } k=1,\ldots,r.\end{aligned} \tag{3.16}$$

The SISO ($m=p=1$) conditions are replaced in the MIMO case by left tangential, right tangential, as well as bi-tangential interpolation conditions. From the discussion of section 2.1, if $\mathrm{Ran}(\mathbf{V}_r)$ contains $(\widetilde{\lambda}_k\mathbf{I}+\mathbf{A})^{-1}\mathbf{B}\widetilde{\mathbf{b}}_k$ and $\mathrm{Ran}(\mathbf{W}_r)$ contains $(\widetilde{\lambda}_k\mathbf{I}+\mathbf{A})^{-T}\mathbf{C}^T\widetilde{\mathbf{c}}_k$ for each $k=1,2,\ldots,r$, then the $\mathcal{H}_2$ optimality conditions given above hold. First-order interpolatory MIMO conditions have been obtained recently in other independent works as well; see [24, 35].

3.2.2. The discrete time case. An nth-order SISO discrete-time dynamical system is defined by a set of difference equations

$$G:\begin{cases}\mathbf{x}(t+1)=\mathbf{A}\mathbf{x}(t)+\mathbf{b}\,u(t)\\ y(t)=\mathbf{c}^T\mathbf{x}(t)\end{cases}\qquad\text{or}\qquad G(z)=\mathbf{c}^T(z\mathbf{I}-\mathbf{A})^{-1}\mathbf{b}, \tag{3.17}$$

where $t\in\mathbb{Z}$ and $\mathbf{A}\in\mathbb{R}^{n\times n}$, $\mathbf{b},\mathbf{c}\in\mathbb{R}^n$. $G(z)$ is the transfer function of the system, so that if $\hat{u}(z)$ and $\hat{y}(z)$ denote the z-transforms of $u(t)$ and $y(t)$, respectively, then $\hat{y}(z)=G(z)\hat{u}(z)$. In this case, stability of G means that $\mid\lambda_i(\mathbf{A})\mid<1$ for $i=1,\ldots,n$. Also, the h_2 norm is defined as $\|G\|_{h_2}^2=\frac{1}{2\pi}\int_0^{2\pi}\mid G(e^{\imath\theta})\mid^2 d\theta$. Model reduction for discrete-time systems is defined similarly. In this setting, interpolatory (necessary) conditions for h_2 optimality of the rth-order reduced model $G_r(z)=\mathbf{c}_r^T(z\mathbf{I}-\mathbf{A}_r)^{-1}\mathbf{b}_r$ become $G\big(1/\widetilde{\lambda}_i\big)=G_r\big(1/\widetilde{\lambda}_i\big)$ and $G'\big(1/\widetilde{\lambda}_i\big)=G_r'\big(1/\widetilde{\lambda}_i\big)$ for $i=1,\ldots,r$, where $\widetilde{\lambda}_i$ denotes the ith eigenvalue of $\mathbf{A}_r$. This is a special case of results for discrete-time MIMO systems formulated previously in [10].

3.3. Lyapunov-based $\mathcal{H}_2$ optimality conditions. In this section we briefly review the Lyapunov framework for the first-order $\mathcal{H}_2$ optimality conditions and present its connection to our structured orthogonality framework.

Given a stable SISO system $G(s)=\mathbf{c}^T(s\mathbf{I}-\mathbf{A})^{-1}\mathbf{b}$, let $G_r(s)=\mathbf{c}_r^T(s\mathbf{I}-\mathbf{A}_r)^{-1}\mathbf{b}_r$ be a local minimizer of dimension r for the optimal $\mathcal{H}_2$ model reduction problem (3.1) and suppose that $G_r(s)$ has simple poles at $\widetilde{\lambda}_i$, $i=1,\ldots,r$.

It is convenient to define the error system

$$G_{err}(s)\stackrel{\text{def}}{=}G(s)-G_r(s)=\mathbf{c}_{err}^T\left(s\mathbf{I}-\mathbf{A}_{err}\right)^{-1}\mathbf{b}_{err} \tag{3.18}$$

$$\text{with}\quad \mathbf{A}_{err}=\begin{bmatrix}\mathbf{A}&0\\0&\mathbf{A}_r\end{bmatrix},\quad \mathbf{b}_{err}=\begin{bmatrix}\mathbf{b}\\\mathbf{b}_r\end{bmatrix},\quad \text{and } \mathbf{c}_{err}^T=[\mathbf{c}^T\ \ -\mathbf{c}_r^T]. \tag{3.19}$$

Let $\mathbf{P}_{err}$ and $\mathbf{Q}_{err}$ be the Gramians for the error system $G_{err}(s)$; i.e., $\mathbf{P}_{err}$ and $\mathbf{Q}_{err}$ solve

$$\mathbf{A}_{err}\mathbf{P}_{err}+\mathbf{P}_{err}\mathbf{A}_{err}^T+\mathbf{b}_{err}\mathbf{b}_{err}^T=0, \tag{3.20}$$

$$\mathbf{Q}_{err}\mathbf{A}_{err}+\mathbf{A}_{err}^T\mathbf{Q}_{err}+\mathbf{c}_{err}\mathbf{c}_{err}^T=0. \tag{3.21}$$

Partition $\mathbf{P}_{err}$ and $\mathbf{Q}_{err}$:

$$\mathbf{P}_{err} = \begin{bmatrix} \mathbf{P}_{11} & \mathbf{P}_{12} \\ \mathbf{P}_{12}^T & \mathbf{P}_{22} \end{bmatrix}, \qquad \mathbf{Q}_{err} = \begin{bmatrix} \mathbf{Q}_{11} & \mathbf{Q}_{12} \\ \mathbf{Q}_{12}^T & \mathbf{Q}_{22} \end{bmatrix}, \tag{3.22}$$

where $\mathbf{P}_{11}, \mathbf{Q}_{11} \in \mathbb{R}^{n\times n}$ and $\mathbf{P}_{22}, \mathbf{Q}_{22} \in \mathbb{R}^{r\times r}$. Wilson [36] showed that the reduced order model $G_r(s) = \mathbf{c}_r^T(s\mathbf{I}-\mathbf{A}_r)^{-1}\mathbf{b}_r$ can be defined in terms of a Galerkin framework as well by taking

$$\mathbf{V}_r = \mathbf{P}_{12}\mathbf{P}_{22}^{-1} \quad \text{and} \quad \mathbf{W}_r = -\mathbf{Q}_{12}\mathbf{Q}_{22}^{-1}, \tag{3.23}$$

and the resulting reduced order model satisfies the first-order conditions of the optimal $\mathcal{H}_2$ problem. It was also shown in [36] that $\mathbf{W}_r^T\mathbf{V}_r = \mathbf{I}$. The next result states the Lyapunov-based Wilson conditions for $\mathcal{H}_2$ optimality and shows their equivalence to our structured orthogonality framework.

THEOREM 3.6. [illegible] $\mathcal{H}_2$ [illegible]

$$\mathbf{P}_{12}^T\mathbf{Q}_{12} + \mathbf{P}_{22}\mathbf{Q}_{22} = 0, \tag{3.24}$$

$$\mathbf{Q}_{12}^T\mathbf{b} + \mathbf{Q}_{22}\mathbf{b}_r = 0, \tag{3.25}$$

$$\mathbf{c}_r^T\mathbf{P}_{22} - \mathbf{c}^T\mathbf{P}_{12} = 0, \tag{3.26}$$

[illegible] 3.2 [illegible]. From (3.5), consider first the case $H_1 = 0$ and H_2 is an arbitrary transfer function with simple poles at $\widetilde{\lambda}_i$, $i = 1, \ldots, r$. Write $H_2(s) = \widetilde{\mathbf{c}}^T(s\mathbf{I} - \mathbf{A}_r)^{-1}\widetilde{\mathbf{b}}$, where $\widetilde{\mathbf{b}}$ and $\widetilde{\mathbf{c}}$ can vary arbitrarily. Then from (2.12), if, for any $\widetilde{\mathbf{b}} \neq 0$, $[\widetilde{\mathbf{P}}_1^T, \widetilde{\mathbf{P}}_2^T]^T$ solves

$$\begin{bmatrix} \mathbf{A} & 0 \\ 0 & \mathbf{A}_r \end{bmatrix} \begin{bmatrix} \widetilde{\mathbf{P}}_1 \\ \widetilde{\mathbf{P}}_2 \end{bmatrix} + \begin{bmatrix} \widetilde{\mathbf{P}}_1 \\ \widetilde{\mathbf{P}}_2 \end{bmatrix} \mathbf{A}_r^T + \begin{bmatrix} \mathbf{b} \\ \mathbf{b}_r \end{bmatrix} \widetilde{\mathbf{b}}^T = 0, \tag{3.27}$$

we have for arbitrary $\widetilde{\mathbf{c}}$

$$\langle G - G_r,\ H_2\rangle_{\mathcal{H}_2} = [\mathbf{c}^T \ \ -\mathbf{c}_r^T] \begin{bmatrix} \widetilde{\mathbf{P}}_1 \\ \widetilde{\mathbf{P}}_2 \end{bmatrix} \widetilde{\mathbf{c}} = 0.$$

Notice that $\widetilde{\mathbf{P}}_1$ and $\widetilde{\mathbf{P}}_2$ are independent of $\widetilde{\mathbf{c}}$, so for each choice of $\widetilde{\mathbf{b}}$ we must have

$$\mathbf{c}^T\widetilde{\mathbf{P}}_1 - \mathbf{c}_r^T\widetilde{\mathbf{P}}_2 = 0.$$

For $\widetilde{\mathbf{b}} = \mathbf{b}_r$, one may check directly that $\widetilde{\mathbf{P}}_1 = \mathbf{P}_{12}$ and $\widetilde{\mathbf{P}}_2 = \mathbf{P}_{22}$ in $\mathbf{P}_{err}$ that solves (3.20) in Wilson's conditions.

Likewise, from (2.13) for each choice of $\widetilde{\mathbf{c}}$, if $[\widetilde{\mathbf{Q}}_1, \widetilde{\mathbf{Q}}_2]$ solves

$$[\widetilde{\mathbf{Q}}_1, \widetilde{\mathbf{Q}}_2] \begin{bmatrix} \mathbf{A} & 0 \\ 0 & \mathbf{A}_r \end{bmatrix} + \mathbf{A}_r^T[\widetilde{\mathbf{Q}}_1, \widetilde{\mathbf{Q}}_2] + \widetilde{\mathbf{c}}[\mathbf{c}^T,\ -\mathbf{c}_r^T] = 0, \tag{3.28}$$

then we have for every $\widetilde{\mathbf{b}}$

$$\langle G - G_r,\ H_2\rangle_{\mathcal{H}_2} = \widetilde{\mathbf{b}}^T[\widetilde{\mathbf{Q}}_1, \widetilde{\mathbf{Q}}_2] \begin{bmatrix} \mathbf{b} \\ \mathbf{b}_r \end{bmatrix} = 0.$$

Similarly to the first case, $[\widetilde{\mathbf{Q}}_1, \widetilde{\mathbf{Q}}_2]$ is independent of $\widetilde{\mathbf{b}}$, so for each choice of $\widetilde{\mathbf{c}}$ we must have

$$\widetilde{\mathbf{Q}}_1\mathbf{b} + \widetilde{\mathbf{Q}}_2\mathbf{b}_r = 0,$$

and for the particular case $\widetilde{\mathbf{c}} = -\mathbf{c}_r$, one may check directly that $\widetilde{\mathbf{Q}}_1 = \mathbf{Q}_{12}^T$ and $\widetilde{\mathbf{Q}}_2 = \mathbf{Q}_{22}$ in $\mathbf{Q}_{err}$ that solves (3.21) in Wilson's conditions. The structured orthogonality condition $\langle G - G_r,\ H\rangle_{\mathcal{H}_2} = 0$ taken over all systems $H(s)$ with the same poles as G_r leads directly to the Wilson conditions (3.25) and (3.26).

The additional orthogonality condition $\langle G - G_r,\ G_r \cdot H\rangle_{\mathcal{H}_2} = 0$ taken over all $H(s)$ with the same poles as G_r will yield the remaining Wilson condition (3.24).

Observe that

$$\begin{aligned} G_r(s)H(s) &= \mathbf{c}_r^T(s\mathbf{I} - \mathbf{A}_r)^{-1}\mathbf{b}_r\,\widetilde{\mathbf{c}}^T(s\mathbf{I} - \mathbf{A}_r)^{-1}\widetilde{\mathbf{b}} \\ &= [\mathbf{c}_r^T, 0]\left(s\mathbf{I}_{2r} - \begin{bmatrix} \mathbf{A}_r & \mathbf{b}_r\widetilde{\mathbf{c}}^T \\ 0 & \mathbf{A}_r \end{bmatrix}\right)^{-1}\begin{bmatrix} 0 \\ \widetilde{\mathbf{b}} \end{bmatrix}. \end{aligned}$$

Referring to (2.12), the condition $\langle G - G_r,\ G_r \cdot H\rangle_{\mathcal{H}_2} = 0$ leads to a Sylvester equation,

$$\begin{bmatrix} \mathbf{A} & 0 \\ 0 & \mathbf{A}_r \end{bmatrix}\begin{bmatrix} \widetilde{\mathbf{W}}_1 & \widetilde{\mathbf{P}}_1 \\ \widetilde{\mathbf{W}}_2 & \widetilde{\mathbf{P}}_2 \end{bmatrix} + \begin{bmatrix} \widetilde{\mathbf{W}}_1 & \widetilde{\mathbf{P}}_1 \\ \widetilde{\mathbf{W}}_2 & \widetilde{\mathbf{P}}_2 \end{bmatrix}\begin{bmatrix} \mathbf{A}_r^T & 0 \\ \widetilde{\mathbf{c}}\mathbf{b}_r^T & \mathbf{A}_r^T \end{bmatrix} + \begin{bmatrix} \mathbf{b} \\ \mathbf{b}_r \end{bmatrix}[0,\ \widetilde{\mathbf{b}}^T] = 0,$$

where the use of $\widetilde{\mathbf{P}}_1$ and $\widetilde{\mathbf{P}}_2$ is intended to indicate that they solve (3.27) as well. Then

$$\langle G - G_r,\ G_r \cdot H_2\rangle_{\mathcal{H}_2} = [\mathbf{c}^T,\ -\mathbf{c}_r^T]\begin{bmatrix} \widetilde{\mathbf{W}}_1 & \widetilde{\mathbf{P}}_1 \\ \widetilde{\mathbf{W}}_2 & \widetilde{\mathbf{P}}_2 \end{bmatrix}\begin{bmatrix} \mathbf{c}_r \\ 0 \end{bmatrix} = 0.$$

Alternatively, from (2.13),

(3.29)
$$\begin{bmatrix} \widetilde{\mathbf{Q}}_1 & \widetilde{\mathbf{Q}}_2 \\ \widetilde{\mathbf{Y}}_1 & \widetilde{\mathbf{Y}}_2 \end{bmatrix}\begin{bmatrix} \mathbf{A} & 0 \\ 0 & \mathbf{A}_r \end{bmatrix} + \begin{bmatrix} \mathbf{A}_r^T & 0 \\ \widetilde{\mathbf{c}}\mathbf{b}_r^T & \mathbf{A}_r^T \end{bmatrix}\begin{bmatrix} \widetilde{\mathbf{Q}}_1 & \widetilde{\mathbf{Q}}_2 \\ \widetilde{\mathbf{Y}}_1 & \widetilde{\mathbf{Y}}_2 \end{bmatrix} + \begin{bmatrix} \mathbf{c}_r \\ 0 \end{bmatrix}[\mathbf{c}^T,\ -\mathbf{c}_r^T] = 0$$

($\widetilde{\mathbf{Q}}_1$ and $\widetilde{\mathbf{Q}}_2$ here also solve (3.28)) and

$$\langle G - G_r,\ G_r \cdot H_2\rangle_{\mathcal{H}_2} = [0,\ \widetilde{\mathbf{b}}^T]\begin{bmatrix} \widetilde{\mathbf{Q}}_1 & \widetilde{\mathbf{Q}}_2 \\ \widetilde{\mathbf{Y}}_1 & \widetilde{\mathbf{Y}}_2 \end{bmatrix}\begin{bmatrix} \mathbf{b} \\ \mathbf{b}_r \end{bmatrix} = 0.$$

Since this last equality is true for all $\widetilde{\mathbf{b}}$, and since $\widetilde{\mathbf{Y}}_1$ and $\widetilde{\mathbf{Y}}_2$ are independent of $\widetilde{\mathbf{b}}$, we see that $\widetilde{\mathbf{Y}}_1\mathbf{b} + \widetilde{\mathbf{Y}}_2\mathbf{b}_r = 0$. We know already that $\widetilde{\mathbf{Q}}_1\mathbf{b} + \widetilde{\mathbf{Q}}_2\mathbf{b}_r = 0$, so

$$\begin{bmatrix} \widetilde{\mathbf{Q}}_1 & \widetilde{\mathbf{Q}}_2 \\ \widetilde{\mathbf{Y}}_1 & \widetilde{\mathbf{Y}}_2 \end{bmatrix}\begin{bmatrix} \mathbf{b} \\ \mathbf{b}_r \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}.$$

Define $\left[\begin{smallmatrix} \tilde{\mathbf{Q}}_1 & \tilde{\mathbf{Q}}_2 \\ \tilde{\mathbf{Y}}_1 & \tilde{\mathbf{Y}}_2 \end{smallmatrix}\right]\left[\begin{smallmatrix} \tilde{\mathbf{P}}_1 \\ \tilde{\mathbf{P}}_2 \end{smallmatrix}\right] = \left[\begin{smallmatrix} \tilde{\mathbf{R}}_1 \\ \tilde{\mathbf{R}}_2 \end{smallmatrix}\right]$. We will show that $\widetilde{\mathbf{R}}_1 = 0$. Premultiply (3.27) by $\left[\begin{smallmatrix} \tilde{\mathbf{Q}}_1 & \tilde{\mathbf{Q}}_2 \\ \tilde{\mathbf{Y}}_1 & \tilde{\mathbf{Y}}_2 \end{smallmatrix}\right]$, postmultiply (3.29) by $\left[\begin{smallmatrix} \tilde{\mathbf{P}}_1 \\ \tilde{\mathbf{P}}_2 \end{smallmatrix}\right]$, and subtract the resulting equations to get

$$\widetilde{\mathbf{R}}_1\mathbf{A}_r^T - \mathbf{A}_r^T\widetilde{\mathbf{R}}_1 = 0 \qquad \text{and} \qquad \widetilde{\mathbf{R}}_2\mathbf{A}_r^T - \mathbf{A}_r^T\widetilde{\mathbf{R}}_2 = \widetilde{\mathbf{c}}\mathbf{b}_r^T\widetilde{\mathbf{R}}_1.$$

The first equation asserts that $\widetilde{\mathbf{R}}_1$ commutes with $\mathbf{A}_r^T$, and since $\mathbf{A}_r^T$ has distinct eigenvalues, $\widetilde{\mathbf{R}}_1$ must have the same eigenvectors as $\mathbf{A}_r^T$. Let $\widetilde{\mathbf{y}}_i$, $\widetilde{\mathbf{x}}_i$ be left and right eigenvectors of $\mathbf{A}_r$ associated with $\widetilde{\lambda}_i$ (respectively, right and left eigenvectors of $\mathbf{A}_r^T$): $\mathbf{A}_r\widetilde{\mathbf{x}}_i = \widetilde{\lambda}_i\widetilde{\mathbf{x}}_i$ and $\widetilde{\mathbf{y}}_i^T\mathbf{A}_r = \widetilde{\lambda}_i\widetilde{\mathbf{y}}_i^T$. Then $\widetilde{\mathbf{R}}_1\widetilde{\mathbf{y}}_i = d_i\widetilde{\mathbf{y}}_i$. Now premultiply the second equation by $\widetilde{\mathbf{x}}_i^T$ and postmultiply by $\widetilde{\mathbf{y}}_i$ to find

$$\begin{aligned}\widetilde{\mathbf{x}}_i^T\left(\widetilde{\mathbf{R}}_2\mathbf{A}_r^T - \mathbf{A}_r^T\widetilde{\mathbf{R}}_2\right)\widetilde{\mathbf{y}}_i &= \widetilde{\mathbf{x}}_i^T\widetilde{\mathbf{c}}\mathbf{b}_r^T\widetilde{\mathbf{R}}_1\widetilde{\mathbf{y}}_i,\\ \widetilde{\mathbf{x}}_i^T\widetilde{\mathbf{R}}_2\widetilde{\mathbf{y}}_i\widetilde{\lambda}_i - \widetilde{\lambda}_i\widetilde{\mathbf{x}}_i^T\widetilde{\mathbf{R}}_2\widetilde{\mathbf{y}}_i &= \widetilde{\mathbf{x}}_i^T\widetilde{\mathbf{c}}\mathbf{b}_r^T\widetilde{\mathbf{R}}_1\widetilde{\mathbf{y}}_i,\\ 0 &= \left(\widetilde{\mathbf{x}}_i^T\widetilde{\mathbf{c}}\right)\left(\mathbf{b}_r^T\widetilde{\mathbf{y}}_i\right)\ d_i.\end{aligned}$$

Either $d_i = 0$ or one of $\widetilde{\mathbf{x}}_i^T\widetilde{\mathbf{c}}$ and $\mathbf{b}_r^T\widetilde{\mathbf{y}}_i$ must vanish, which would then imply that either $\dim H < r$ or $\dim G_r < r$. Thus $d_i = 0$ for all $i = 1, \ldots, r$ and $\widetilde{\mathbf{R}}_1 = 0$, which proves the final Wilson condition (3.24).

The converse is omitted here since it follows in a straightforward way by reversing the preceding arguments. □

Hyland and Bernstein [22] offered conditions that are equivalent to the Wilson conditions. Suppose $G_r(s)$ defined by $\mathbf{A}_r$, $\mathbf{b}_r$, and $\mathbf{c}_r^T$ solves the optimal $\mathcal{H}_2$ problem. Then there exist positive nonnegative matrices $\mathbf{P}, \mathbf{Q} \in \mathbb{R}^{n\times n}$ and two $n \times r$ matrices $\mathbf{F}_r$ and $\mathbf{Y}_r$ such that

$$\mathbf{PQ} = \mathbf{F}_r\mathbf{M}\mathbf{Y}_r^T, \quad \mathbf{Y}_r^T\mathbf{F}_r = \mathbf{I}_r, \tag{3.30}$$

where $\mathbf{M}$ is similar to a positive definite matrix. Then $G_r(s)$ is given by $\mathbf{A}_r$, $\mathbf{b}_r$, and $\mathbf{c}_r^T$ with $\mathbf{A}_r = \mathbf{Y}_r^T\mathbf{A}\mathbf{F}_r$, $\mathbf{b}_r = \mathbf{Y}_r^T\mathbf{b}$, and $\mathbf{c}_r^T = \mathbf{c}^T\mathbf{Y}_r$ such that, with the skew projection $\mathbf{\Pi} = \mathbf{F}_r\mathbf{Y}_r^T$, the following conditions are satisfied:

$$\operatorname{rank}(\mathbf{P}) = \operatorname{rank}(\mathbf{Q}) = \operatorname{rank}(\mathbf{PQ}), \tag{3.31}$$

$$\mathbf{\Pi}\left[\mathbf{AP} + \mathbf{PA}^T + \mathbf{bb}^T\right] = 0, \tag{3.32}$$

$$\left[\mathbf{A}^T\mathbf{Q} + \mathbf{QA} + \mathbf{cc}^T\right]\mathbf{\Pi} = 0. \tag{3.33}$$

Note that in both [36] and [22], the first-order necessary conditions are given in terms of (coupled) Lyapunov equations. Both [36] and [22] proposed iterative algorithms to obtain a reduced order model satisfying these Lyapunov-based first-order conditions. However, the main drawback in each case is that both approaches require solving two large-scale Lyapunov equations at each step of the algorithm. [40] discusses computational issues related to solving associated linearized problems within each step.

Theorems 3.4 and 3.6 show the equivalence between the structured orthogonality conditions and Lyapunov- and interpolation-based conditions for $\mathcal{H}_2$ optimality, respectively. To complete the discussion, we formally state the equivalence between the Lyapunov and interpolation frameworks.

LEMMA 3.7 (equivalence of Lyapunov and interpolation frameworks). [illegible] [22] [illegible] (3.31)–(3.33) [illegible] [36] [illegible] (3.23) [illegible] [26] [illegible] (3.11) [illegible] [36, 22] [illegible] $\mathcal{H}_2$ [illegible]

We note that the connection between the Lyapunov and interpolation frameworks has not been observed in the literature before. This result shows that solving the optimal $\mathcal{H}_2$ problem in the Krylov framework is equivalent to solving it in the Lyapunov framework. This leads to the Krylov-based method proposed in the next section.

4. Iterated interpolation. We propose an effective numerical algorithm that produces a reduced order model $G_r(s)$ satisfying the interpolation-based first-order necessary conditions (3.11). Effectiveness of the proposed algorithm results from the fact that we use rational Krylov steps to construct a $G_r(s)$ that meets the first-order conditions (3.11). No Lyapunov solvers or dense matrix decompositions are needed. Therefore, the method is suited for large-scale systems where $n \gg 1000$.

Several approaches have been proposed in the literature to compute reduced order models that satisfy [illegible] of first-order necessary conditions; see [37, 34, 9, 21, 26, 22, 36, 25]. However, these approaches do not seem to be suitable for large-scale problems. The ones based on Lyapunov-based conditions, e.g., [36, 22, 34, 37], require solving a couple of Lyapunov equations at each step of the iteration. To our knowledge, the only methods that depend on interpolation-based necessary conditions have been proposed in [25] and [26]. The authors work directly with the transfer functions of $G(s)$ and $G_r(s)$; make an iteration on the denominator [25] or poles and residues [26] of $G_r(s)$; and explicitly compute $G(s)$, $G_r(s)$, and their derivatives at certain points in the complex plane. However, working with the transfer function, its values, and its derivative values explicitly is not desirable in large-scale settings. Indeed, one will most likely be given a state space representation of $G(s)$ rather than the transfer function. And trying to compute the coefficients of the transfer function can be highly ill-conditioned. These approaches are similar to [30, 31], where interpolation is done by explicit usage of transfer functions. On the other hand, our approach, which is detailed below, is based on the connection between interpolation and effective rational Krylov iteration, and is therefore numerically effective and stable.

Let $\boldsymbol{\sigma}$ denote the set of interpolation points $\{\sigma_1, \ldots, \sigma_r\}$; use these interpolation points to construct a reduced order model, $G_r(s)$, that interpolates both $G(s)$ and $G'(s)$ at $\{\sigma_1, \ldots, \sigma_r\}$; let $\boldsymbol{\lambda}(\boldsymbol{\sigma}) = \{\widetilde{\lambda}_1, \ldots, \widetilde{\lambda}_r\}$ denote the resulting reduced order poles of $G_r(s)$; hence $\boldsymbol{\lambda}(\boldsymbol{\sigma})$ is a function from $\mathbb{C}^r \mapsto \mathbb{C}^r$. Define the function $\mathbf{g}(\boldsymbol{\sigma}) = \boldsymbol{\lambda}(\boldsymbol{\sigma}) + \boldsymbol{\sigma}$. Note that $\mathbf{g}(\boldsymbol{\sigma}) : \mathbb{C}^r \mapsto \mathbb{C}^r$. Aside from issues related to the ordering of the reduced order poles, $\mathbf{g}(\boldsymbol{\sigma}) = \mathbf{0}$ yields $\boldsymbol{\lambda}(\boldsymbol{\sigma}) = -\boldsymbol{\sigma}$; i.e., the reduced order poles $\boldsymbol{\lambda}(\boldsymbol{\sigma})$ are mirror images of the interpolation points $\boldsymbol{\sigma}$. Hence, $\mathbf{g}(\boldsymbol{\sigma}) = \mathbf{0}$ is equivalent to (3.11) and is a necessary condition for $\mathcal{H}_2$ optimality of the reduced order model, $G_r(s)$. Thus one can formulate a search for optimal $\mathcal{H}_2$ reduced order systems by considering the root-finding problem $\mathbf{g}(\boldsymbol{\sigma}) = \mathbf{0}$. Many plausible approaches to this problem originate with Newton's method, which appears as

$$\boldsymbol{\sigma}^{(k+1)} = \boldsymbol{\sigma}^{(k)} - (\mathbf{I} + \mathbf{J})^{-1} \left(\boldsymbol{\sigma}^{(\mathbf{k})} + \boldsymbol{\lambda} \left(\boldsymbol{\sigma}^{(\mathbf{k})} \right) \right). \tag{4.1}$$

In (4.1), $\mathbf{J}$ is the usual $r \times r$ Jacobian of $\boldsymbol{\lambda}(\boldsymbol{\sigma})$ with respect to $\boldsymbol{\sigma}$: for $\mathbf{J} = [J_{i,j}]$, $J_{i,j} = \frac{\partial \widetilde{\lambda}_i}{\partial \sigma_j}$ for $i, j = 1, \ldots, r$. How to compute $\mathbf{J}$ will be clarified in section 4.3.

4.1. Proposed algorithm. We seek a reduced order transfer function $G_r(s)$ that interpolates $G(s)$ at the mirror images of the poles of $G_r(s)$ by solving the equivalent root-finding problem, say by a variant of (4.1). It is often the case that in the neighborhood of an $\mathcal{H}_2$ optimal shift set, the entries of the Jacobian matrix become small and simply setting $\mathbf{J} = 0$ might serve as a relaxed iteration strategy. This leads to a successive substitution framework: $\sigma_i \leftarrow -\lambda_i(\mathbf{A}_r)$; successive interpolation steps using a rational Krylov method are used so that at the $(i+1)$st step interpolation points are chosen as the mirror images of the Ritz values from the ith step. Despite its simplicity, this appears to be a very effective strategy in many circumstances.

Here is a sketch of the proposed algorithm.

ALGORITHM 4.1. An iterative rational Krylov algorithm (IRKA).

1. [illegible] σ_i, $i = 1, \ldots, r$ [illegible] tol
2. [illegible] $\mathbf{V}_r$ [illegible] $\mathbf{W}_r$ [illegible] $\mathrm{Ran}(\mathbf{V}_r) = \mathrm{span}\left\{(\sigma_1\mathbf{I} - \mathbf{A})^{-1}\mathbf{b}, \ldots, (\sigma_r\mathbf{I} - \mathbf{A})^{-1}\mathbf{b}\right\}$, $\mathrm{Ran}(\mathbf{W}_r) = \mathrm{span}\left\{(\sigma_1\mathbf{I} - \mathbf{A}^T)^{-1}\mathbf{c}, \ldots, (\sigma_r\mathbf{I} - \mathbf{A}^T)^{-1}\mathbf{c}\right\}$ [illegible] $\mathbf{W}_r^T\mathbf{V}_r = \mathbf{I}$
3. [illegible] ($\{\sigma_i\} >$ tol)
   (a) $\mathbf{A_r} = \mathbf{W_r^T A V_r}$
   (b) [illegible] $\sigma_i \longleftarrow -\lambda_i(\mathbf{A_r})$, $i = 1, \ldots, r$
   (c) [illegible] $\mathbf{V}_r$ [illegible] $\mathbf{W}_r$ [illegible] $\mathrm{Ran}(\mathbf{V}_r) = \mathrm{span}\left\{(\sigma_1\mathbf{I} - \mathbf{A})^{-1}\mathbf{b}, \ldots, (\sigma_r\mathbf{I} - \mathbf{A})^{-1}\mathbf{b}\right\}$, $\mathrm{Ran}(\mathbf{W}_r) = \mathrm{span}\left\{(\sigma_1\mathbf{I} - \mathbf{A}^T)^{-1}\mathbf{c}, \ldots, (\sigma_r\mathbf{I} - \mathbf{A}^T)^{-1}\mathbf{c}\right\}$, [illegible] $\mathbf{W}_r^T\mathbf{V}_r = \mathbf{I}$
4. $\mathbf{A_r} = \mathbf{W_r^T A V_r}$, $\mathbf{b}_r = \mathbf{W}_r^T\mathbf{b}$, $\mathbf{c}_r^T = \mathbf{c}^T\mathbf{V}_r$

Upon convergence, the first-order necessary conditions (3.11) for $\mathcal{H}_2$ optimality will be satisfied. Notice that step 3(b) could be replaced with some variant of a Newton step (4.1).

We have implemented the above algorithm and applied it to many different large-scale systems. In each of our numerical examples, the algorithm worked very effectively: It has always converged after a small number of steps and resulted in stable reduced systems. For those standard test problems we tried where a global optimum is known, Algorithm 4.1 converged to this global optimum.

It should be noted that the solution is obtained via Krylov projection methods only and its computation is suitable for large-scale systems. To our knowledge, this is the first numerically effective approach for the optimal $\mathcal{H}_2$ reduction problem.

We know that the reduced model $G_r(s)$ resulting from the above algorithm will satisfy the first-order optimality conditions. Moreover, from Theorem 3.1 this reduced order model is globally optimal in the following sense.

COROLLARY 4.1. [illegible] $G_r(s)$ [illegible] 4.1 [illegible] $G_r(s)$ [illegible] $G(s)$ [illegible] $\mathcal{H}_2$ [illegible] $G_r(s)$

Therefore Algorithm 4.1 generates a reduced model, $G_r(s)$, which is the optimal solution for a restricted $\mathcal{H}_2$ problem.

4.2. Initial shift selection. For the proposed algorithm, the final reduced model can depend on the initial shift selection. Nonetheless for most of the cases, a random initial shift selection resulted in satisfactory reduced models. For small-order benchmark examples taken from [22, 25, 37, 34], the algorithm converged to the global minimizer. For larger problems, the results were as good as those obtained by balanced truncation. Therefore, while staying within a numerically effective Krylov projection framework, we have been able to produce results close to or better than those obtained by balanced truncation (which requires the solution of two large-scale Lyapunov equations).

We outline some initialization strategies that can be expected to improve the results. Recall that at convergence, interpolation points are mirror images of the eigenvalues of $\mathbf{A}_r$. The eigenvalues of $\mathbf{A}_r$ might be expected to approximate the eigenvalues of $\mathbf{A}$. Hence, at convergence, interpolation points will lie in the mirror spectrum of $\mathbf{A}$. Therefore, one could choose initial shifts randomly distributed within a region containing the mirror image of the numerical range of $\mathbf{A}$. The boundary of the numerical range can be estimated by computing the eigenvalues of $\mathbf{A}$ with the smallest and largest real and imaginary parts using numerically effective tools such as the implicitly restarted Arnoldi (IRA) algorithm.

The starting point for another initialization strategy is the $\mathcal{H}_2$ expression presented in Proposition 3.3. Based on this expression, it is appropriate to initiate the proposed algorithm with $\sigma_i = -\lambda_i(\mathbf{A})$, where $\lambda_i(\mathbf{A})$ are the poles with big residues, ϕ_i for $i = 1, \ldots, r$. The main disadvantage of this approach is that it requires a modal state space decomposition for $G(s)$, which will be numerically expensive for large-scale problems. However, there might be some applications where the original state space representation is in the modal form and ϕ_i might be directly read from the entries of the matrices $\mathbf{b}$ and $\mathbf{c}^T$.

Unstable reduced order models are not acceptable candidates for optimal $\mathcal{H}_2$ reduction. Nonetheless stability of a reduced model is not guaranteed a priori and might depend on the initial shift selection. We have observed that if one avoids making extremely unrealistic initial shift selections, stability will be preserved. In our simulations we have never generated an unstable system when the initial shift selection was not drastically different from the mirror spectrum of $\mathbf{A}$, but otherwise random. We were able to produce an unstable reduced order system; however, this occurred for a case where the real parts of the eigenvalues of $\mathbf{A}$ were between -1.5668×10^{-1} and -2.0621×10^{-3}, yet we chose initial shifts bigger than 50. We believe that with a good starting point, stability will not be an issue. These considerations are illustrated for many numerical examples in section 5.

. . . 4.1. Based on the first-order conditions (3.16) discussed in section 3.2.1 for MIMO systems $\mathbf{G}(s) = \mathbf{C}(s\mathbf{I}-\mathbf{A})^{-1}\mathbf{B}$, one can extend IRKA to the MIMO case by replacing $(\sigma_i\mathbf{I}-\mathbf{A})^{-1}\mathbf{b}$ with $(\sigma_i\mathbf{I}-\mathbf{A})^{-1}\mathbf{B}\widetilde{\mathbf{b}}_i$ and $(\sigma_i\mathbf{I}-\mathbf{A}^T)^{-1}\mathbf{c}$ with $(\sigma_i\mathbf{I}-\mathbf{A})^{-1}\mathbf{C}^T\widetilde{\mathbf{c}}_i$ in Algorithm 4.1, where $\widetilde{\mathbf{b}}_i$ and $\widetilde{\mathbf{c}}_i$ are as defined in section 3.2.1.

. . . 4.2. In the discrete-time case described in (3.17) above, the root-finding problem becomes $\mathbf{g}(\boldsymbol{\sigma}) = \boldsymbol{\Sigma}\boldsymbol{\lambda}(\boldsymbol{\sigma}) - \mathbf{e}$, where $\mathbf{e}^T = [1, 1, \ldots, 1]$ and $\boldsymbol{\Sigma} = \mathrm{diag}(\boldsymbol{\sigma})$. Therefore, for discrete-time systems, step 3(b) of Algorithm 4.1 becomes $\sigma_i \leftarrow 1/\lambda_i(\mathbf{A_r})$ for $i = 1, \ldots, r$. Moreover, the associated Newton step is

$$\boldsymbol{\sigma}^{(k+1)} = \boldsymbol{\sigma}^{(k)} - (\mathbf{I} + \boldsymbol{\Lambda}^{-1}\boldsymbol{\Sigma}\mathbf{J})^{-1}\left(\boldsymbol{\sigma}^{(k)} - \boldsymbol{\Lambda}^{-1}\mathbf{e}\right),$$

where $\Lambda = \mathrm{diag}(\boldsymbol{\lambda})$.

4.3. A Newton framework for IRKA. As discussed above, Algorithm 4.1 uses the successive substitution framework by simply setting $\mathbf{J} = \mathbf{0}$ in the Newton step (4.1). The Newton framework for IRKA can be easily obtained by replacing step 3(b) of Algorithm 4.1 with the Newton step (4.1). The only point to clarify for the Newton framework is the computation of the Jacobian, which measures the sensitivity of the reduced system poles with respect to shifts.

Given $\mathbf{A} \in \mathbb{R}^{n\times n}$ and $\mathbf{b}, \mathbf{c} \in \mathbb{R}^n$, suppose that σ_i, $i = 1, \ldots, r$, are r distinct points in $\mathbb{C}$, none of which are eigenvalues of $\mathbf{A}$, and define the complex r-tuple $\boldsymbol{\sigma} = [\sigma_1, \sigma_2, \ldots, \sigma_r]^T \in \mathbb{C}^r$ together with related matrices:

$$\mathbf{V}_r(\boldsymbol{\sigma}) = \begin{bmatrix} (\sigma_1\mathbf{I} - \mathbf{A})^{-1}\mathbf{b} & (\sigma_2\mathbf{I} - \mathbf{A})^{-1}\mathbf{b} & \ldots & (\sigma_r\mathbf{I} - \mathbf{A})^{-1}\mathbf{b} \end{bmatrix} \in \mathbb{C}^{n\times r} \tag{4.2}$$

and

$$\mathbf{W}_r^T(\boldsymbol{\sigma}) = \begin{bmatrix} \mathbf{c}^T(\sigma_1\mathbf{I} - \mathbf{A})^{-1} \\ \mathbf{c}^T(\sigma_2\mathbf{I} - \mathbf{A})^{-1} \\ \vdots \\ \mathbf{c}^T(\sigma_r\mathbf{I} - \mathbf{A})^{-1} \end{bmatrix} \in \mathbb{C}^{r\times n}. \tag{4.3}$$

We normally suppress the dependence on $\boldsymbol{\sigma}$ and write $\mathbf{V}_r(\boldsymbol{\sigma}) = \mathbf{V}_r$ and $\mathbf{W}_r(\boldsymbol{\sigma}) = \mathbf{W}_r$. Hence, the reduced order system matrix $\mathbf{A}_r$ is given by $\mathbf{A}_r = (\mathbf{W}_r^T\mathbf{V}_r)^{-1}\mathbf{W}_r^T\mathbf{A}\mathbf{V}_r$, where $(\mathbf{W}_r^T\mathbf{V}_r)^{-1}\mathbf{W}_r$ plays the role of $\mathbf{W}_r$ in Algorithm 4.1. Let $\widetilde{\lambda}_i$, for $i = 1, \ldots, r$, denote the eigenvalues of $\mathbf{A}_r$. Hence, the Jacobian computation amounts to computing $\mathbf{J}(i,j) = \frac{\partial\widetilde{\lambda}_i}{\partial\sigma_j}$. The following result shows how to compute the Jacobian for the Newton formulation of the IRKA method proposed here.

LEMMA 4.2. [illegible] $\mathbf{A}_r = (\mathbf{W}_r^T\mathbf{V}_r)^{-1}\mathbf{W}_r^T\mathbf{A}\mathbf{V}_r$ [illegible] $\widetilde{\lambda}_i$ [illegible] $|\widetilde{\mathbf{x}}_i^T\mathbf{W}_r^T\mathbf{V}_r\widetilde{\mathbf{x}}_i| = 1$ [illegible] $\mathbf{W}_r^T\mathbf{A}\mathbf{V}_r\widetilde{\mathbf{x}}_i = \widetilde{\lambda}_i\mathbf{W}_r^T\mathbf{V}_r\widetilde{\mathbf{x}}_i$ [illegible]

$$\frac{\partial\widetilde{\lambda}_i}{\partial\sigma_j} = \widetilde{\mathbf{x}}_i^T\partial_j\mathbf{W}_r^T\left(\mathbf{A}\mathbf{V}_r\widetilde{\mathbf{x}}_i - \widetilde{\lambda}_i\mathbf{V}_r\widetilde{\mathbf{x}}_i\right) + \left(\widetilde{\mathbf{x}}_i^T\mathbf{W}_r^T\mathbf{A} - \widetilde{\lambda}_i\widetilde{\mathbf{x}}_i^T\mathbf{W}_r^T\right)\partial_j\mathbf{V}_r\widetilde{\mathbf{x}}_i, \tag{4.4}$$

[illegible] $\partial_j\mathbf{W}_r^T = \frac{\partial}{\partial\sigma_j}\mathbf{W}_r^T = -\mathbf{e}_j\,\mathbf{c}(\sigma_j\mathbf{I}-\mathbf{A})^{-2}$ and $\partial_j\mathbf{V}_r = \frac{\partial}{\partial\sigma_j}\mathbf{V}_r = -(\sigma_j\mathbf{I}-\mathbf{A})^{-2}\mathbf{b}\,\mathbf{e}_j^T$. [illegible]. With $\mathbf{V}_r(\boldsymbol{\sigma}) = \mathbf{V}_r$ and $\mathbf{W}_r(\boldsymbol{\sigma}) = \mathbf{W}_r$ defined as in (4.2) and (4.3), both $\mathbf{W}_r^T\mathbf{A}\mathbf{V}_r$ and $\mathbf{W}_r^T\mathbf{V}_r$ are complex symmetric matrices. Write $\widetilde{\lambda}$ for $\widetilde{\lambda}_i$ and $\widetilde{\mathbf{x}}$ for $\widetilde{\mathbf{x}}_i$, so

$$\text{(a) } \mathbf{W}_r^T\mathbf{A}\mathbf{V}_r\widetilde{\mathbf{x}} = \widetilde{\lambda}\mathbf{W}_r^T\mathbf{V}_r\widetilde{\mathbf{x}} \quad\text{and}\quad \text{(b) } \widetilde{\mathbf{x}}^T\mathbf{W}_r^T\mathbf{A}\mathbf{V}_r = \widetilde{\lambda}\,\widetilde{\mathbf{x}}^T\mathbf{W}_r^T\mathbf{V}_r. \tag{4.5}$$

Equation (4.5b) is obtained by transposition of (4.5a). $\widetilde{\mathbf{x}}^T\mathbf{W}_r^T\mathbf{V}_r$ is a left eigenvector for $\mathbf{A}_r$ associated with $\widetilde{\lambda}_i$. Differentiate (4.5a) with respect to σ_j, premultiply with $\widetilde{\mathbf{x}}^T$, and simplify using (4.5b):

$$\widetilde{\mathbf{x}}^T\partial_j\mathbf{W}_r^T\left(\mathbf{A}\mathbf{V}_r\widetilde{\mathbf{x}} - \widetilde{\lambda}\mathbf{V}_r\widetilde{\mathbf{x}}\right) + \left(\widetilde{\mathbf{x}}^T\mathbf{W}_r^T\mathbf{A} - \widetilde{\lambda}\widetilde{\mathbf{x}}^T\mathbf{W}_r^T\right)\partial_j\mathbf{V}_r\widetilde{\mathbf{x}} = \left(\frac{\partial\widetilde{\lambda}}{\partial\sigma_j}\right)\widetilde{\mathbf{x}}^T\mathbf{W}_r^T\mathbf{V}_r\widetilde{\mathbf{x}},$$

where $\partial_j\mathbf{W}_r^T = \frac{\partial}{\partial\sigma_j}\mathbf{W}_r^T = \mathbf{e}_j\,\mathbf{c}^T(\sigma_j\mathbf{I}-\mathbf{A})^{-2}$ and $\partial_j\mathbf{V}_r = \frac{\partial}{\partial\sigma_j}\mathbf{V} = (\sigma_j\mathbf{I}-\mathbf{A})^{-2}\mathbf{b}\,\mathbf{e}_j^T$. This completes the proof. ∎

5. Numerical examples. We first compare our approach with the earlier approaches [22, 25, 37] on [illegible] benchmark examples presented in those papers. We show that in each case we attain the minimum, the main difference being that we achieve this minimum in a numerically efficient way. For each low-order model, comparisons are made using data taken from the original sources [22, 25, 37]. We then test our method in large-scale settings.

5.1. Low-order models and comparisons. Consider the following 4 models:

- FOM-1: Example 6.1 in [22]. State space representation of FOM-1 is given by

$$\mathbf{A} = \begin{bmatrix} 0 & 0 & 0 & -150 \\ 1 & 0 & 0 & -245 \\ 0 & 1 & 0 & -113 \\ 0 & 0 & 1 & -19 \end{bmatrix}, \quad \mathbf{b} = \begin{bmatrix} 4 \\ 1 \\ 0 \\ 0 \end{bmatrix}, \quad \mathbf{c} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \end{bmatrix}.$$

  We reduce the order to $r = 3, 2, 1$ using the proposed successive rational Krylov algorithm, denoted by IRKA, and compare our results with the gradient flow method of [37], denoted by GFM; the orthogonal projection method of [22], denoted by OPM; and the balanced truncation method, denoted by BTM.

- FOM-2: Example in [25]. Transfer function of FOM-2 is given by

$$G(s) = \frac{2s^6 + 11.5s^5 + 57.75s^4 + 178.625s^3 + 345.5s^2 + 323.625s + 94.5}{s^7 + 10s^6 + 46s^5 + 130s^4 + 239s^3 + 280s^2 + 194s + 60}.$$

We reduce the order to $r = 6, 5, 4, 3$ using IRKA and compare our results with GFM, OPM, BTM, and the method proposed in [25], denoted by LMPV.

- FOM-3: Example 1 in [34]. Transfer function of FOM-3 is given by

$$G(s) = \frac{s^2 + 15s + 50}{s^4 + 5s^3 + 33s^2 + 79s + 50}.$$

We reduce the order to $r = 3, 2, 1$ using IRKA and compare our results with GFM, OPM, BTM, and the method proposed in [34], denoted by SMM.

- FOM-4: Example 2 in [34]. Transfer function of FOM-4 is given by

$$G(s) = \frac{10000s + 5000}{s^2 + 5000s + 25}.$$

We reduce the order to $r = 1$ IRKA and compare our results with GFM, OPM, BTM, and SMM.

For all these cases, the resulting relative $\mathcal{H}_2$ errors $\frac{\|G(s)-G_r(s)\|_{\mathcal{H}_2}}{\|G(s)\|_{\mathcal{H}_2}}$ are tabulated in Table 5.1 below, which clearly illustrates that the proposed method is the only one that attains the minimum in each case. More importantly, the proposed method achieves this value in a numerically efficient way staying in the Krylov projection framework. No Lyapunov solvers or dense matrix decompositions are needed. The

only arithmetic operations involved are LU decompositions and some linear solvers. Moreover, our method does not require starting from an initial balanced realization, as suggested in [37] and [22]. In all these simulations, we have chosen a random initial shift selection, and the algorithm converged in a small number of steps.

To illustrate the evolution of the $\mathcal{H}_2$ error throughout the iteration, consider the model FOM-2 with $r = 3$. The proposed method yields the following third-order optimal reduced model:

$$G_3(s) = \frac{2.155s^2 + 3.343s + 33.8}{s^3 + 7.457s^2 + 10.51s + 17.57}.$$

Poles of $G_3(s)$ are $\widetilde{\lambda}_1 = -6.2217$ and $\widetilde{\lambda}_{2,3} = -6.1774 \times 10^{-1} \pm \imath 1.5628$, and it can be shown that $G_3(s)$ interpolates the first two moments of $G(s)$ at $-\widetilde{\lambda}_i$ for $i = 1, 2, 3$. Hence, the first-order interpolation conditions are satisfied. This also means that if we start Algorithm 4.1 with the mirror images of these Ritz values, the algorithm converges at the first step. However, we will try four random, but , , initial selections. In other words, we start away from the optimal solution. We test the following four selections: $\mathcal{S}_1 = \{-1.01,\ -2.01,\ -30000\}$, $\mathcal{S}_2 = \{0,\ 10,\ 3\}$, $\mathcal{S}_3 = \{1,\ 10,\ 3\}$, and $\mathcal{S}_4 = \{0.01,\ 20,\ 10000\}$. With selection $\mathcal{S}_1$, we have initiated the algorithm with some negative shifts close to system poles, and consequently with a relative $\mathcal{H}_2$ error bigger than 1. However, in all four cases including $\mathcal{S}_1$, the algorithm converged in 5 steps to the same reduced model. The results are depicted in Figure 5.1.

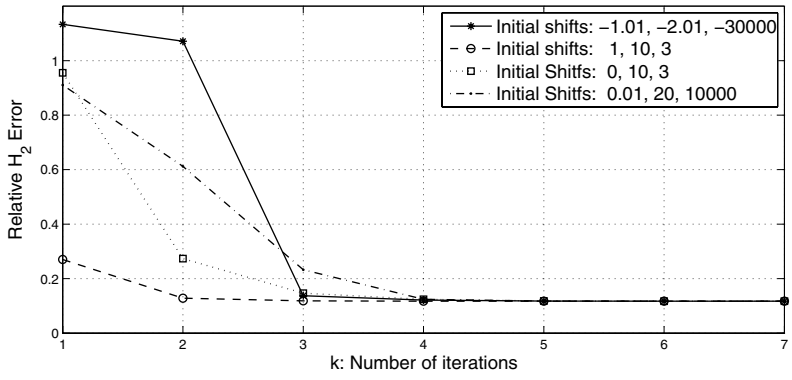

FIG. 5.1. *$\mathcal{H}_2$ norm of the error system vs. the number of iterations.*

Before testing the proposed method in large-scale settings, we investigate FOM-4 further. As pointed out in [34], since $r = 1$, the optimal $\mathcal{H}_2$ problem can be formulated as only a function of the reduced system pole. It was shown in [34] that there are two local minima: (i) one corresponding to a reduced pole at -0.0052 and consequently a reduced order model $G_1^l(s) = \frac{1.0313}{s+0.0052}$ and a relative error of 0.9949, and (ii) one to a reduced pole at -4998 and consequently a reduced model $G_1^g = \frac{9999}{s+4998}$ with a relative error of 0.0985. It follows that the latter, i.e., $G_1^g(s)$, is the global minimum. The first-order balanced truncation for FOM-4 can be easily computed as $G_1^b(s) = \frac{1.0308}{s+0.0052}$. Therefore, it is highly likely that if one starts from a balanced realization, the algorithm would converge to the local minimum $G_1^l(s)$. This was indeed the case as reported in [34]. SMM converged to the local minimum for all starting poles bigger than -0.47. On the other hand, SMM converged to the

global minimum when it was started with an initial pole smaller than -0.47. We have observed exactly the same situation in our simulations. When we start from an initial shift selection smaller than 0.48, IRKA converged to the local minimum. However, when we start with any initial shift bigger than 0.48, the algorithm converged to the global minimum in at most 3 steps. Therefore, for this example we were not able the avoid the local minimum if we started from a [illegible] shift. These observations perfectly agree with the discussion of section 4.2. Note that the transfer function of FOM-4 can be written as

$$G(s) = \frac{10000s + 5000}{s^2 + 5000s + 25} = \frac{0.99}{s + 0.0050} + \frac{9999}{s + 5000}.$$

The pole at -5000 is the one corresponding to the large residue of 9999. Therefore, a good initial shift is 5000. And if we start the proposed algorithm with an initial shift at 5000, or close, the algorithm converges to the global minimum.

5.2. CD player example. The original model describes the dynamics between a lens actuator and the radial arm position in a portable CD player. The model has 120 states, i.e., n = 120, with a single input and a single output. As illustrated in [4], the Hankel singular values of this model do not decay rapidly and hence the model is relatively hard to reduce. Moreover, even though the Krylov-based methods resulted in good local behavior, they are observed to yield large $\mathcal{H}_\infty$ and $\mathcal{H}_2$ error compared to balanced truncation.

We compare the performance of the proposed method, Algorithm 4.1, with that of balanced truncation. Balanced truncation is well known to lead to small $\mathcal{H}_\infty$ and $\mathcal{H}_2$ error norms; see [4, 19]. This is due mainly to global information available through the two system Gramians, the reachability and observability Gramians, which are each solutions of a different Lyapunov equation. We reduce the order to r, with r varying from 2 to 40; and for each r value, we compare the $\mathcal{H}_2$ error norms due to balanced truncation and due to Algorithm 4.1. For the proposed algorithm, two different selections have been tried for the initial shifts. (1) Mirror images of the eigenvalues corresponding to large residuals, and (2) a random selection with real parts in the interval $[10^{-1}, 10^3]$ and the imaginary parts in the interval $[1, 10^5]$. To make this selection, we looked at the poles of $G(s)$ having the maximum/minimum real and imaginary parts. The results showing the relative $\mathcal{H}_2$ error for each r are depicted in Figure 5.2. The figure reveals that both selection strategies work quite well. Indeed, the random initial selection behaves better than the residual-based selection and outperforms balanced truncation for almost all the r values except $r = 2, 24, 36$. However, even for these r values, the resulting $\mathcal{H}_2$ error is not far away from the one due to balanced truncation. For the range $r = [12, 22]$, the random selection clearly outperforms the balanced truncation. We would like to emphasize that these results were obtained by a [illegible] shift selection and staying in the numerically effective Krylov projection framework [illegible] requiring any solutions to large-scale Lyapunov equations. This is the main difference our proposed algorithm has with existing methods and what makes it numerically effective in large-scale settings.

To examine convergence behavior, we reduce the order to $r = 8$ and $r = 10$ using Algorithm 4.1. At each step of the iteration, we compute the $\mathcal{H}_2$ error due to the current estimate and plot this error versus the iteration index. The results are shown in Figure 5.3. The figure illustrates two important properties for both cases $r = 8$ and $r = 10$: (1) At each step of the iteration, the $\mathcal{H}_2$ norm of the error is reduced. (2) The algorithm converges after 3 steps. The resulting reduced models are stable for both cases.

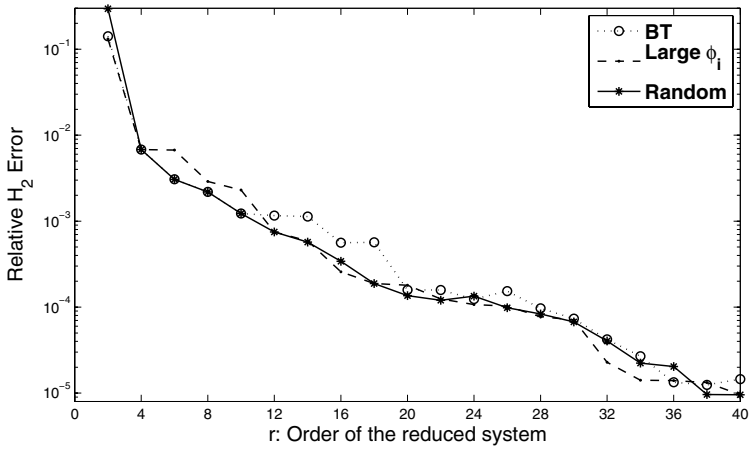

FIG. 5.2. *Relative $\mathcal{H}_2$ norm of the error system vs. r.*

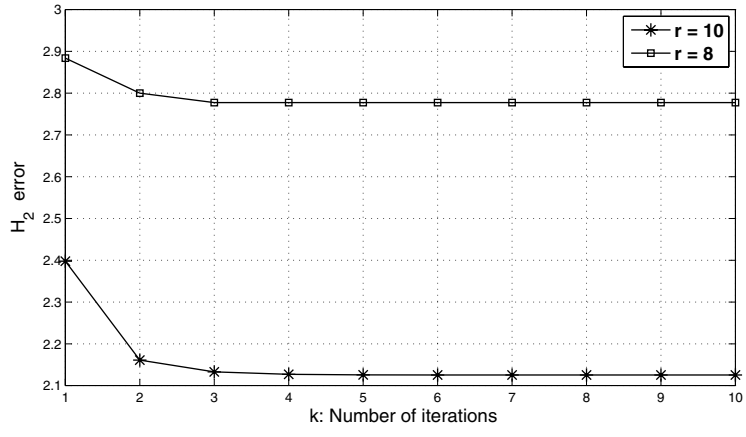

FIG. 5.3. *$\mathcal{H}_2$ norm of the error system vs. the number of iterations.*

5.3. A semidiscretized heat transfer problem for optimal cooling of steel profiles. This problem arises during a cooling process in a rolling mill when different steps in the production process require different temperatures of the raw material. To achieve high throughput, one seeks to reduce the temperature as fast as possible to the required level before entering the next production phase. This is realized by spraying cooling fluids on the surface and must be controlled so that material properties, such as durability or porosity, stay within given quality standards. The problem is modeled as boundary control of a two-dimensional heat equation. A finite element discretization using two steps of mesh refinement with maximum mesh width of 1.382×10^{-2} results in a system of the form

$$\mathbf{E}\dot{\mathbf{x}}(t) = \mathbf{A}\mathbf{x}(t) + \mathbf{b}u(t), \qquad y(t) = \mathbf{c}^T\mathbf{x}(t),$$

with state dimension $n = 20209$, i.e., $\mathbf{A}, \mathbf{E} \in \mathbb{R}^{20209\times 20209}$, $\mathbf{b} \in \mathbb{R}^{20209\times 7}$, $\mathbf{c}^T \in \mathbb{R}^{6\times 20209}$. Note that in this case $\mathbf{E} \neq \mathbf{I}$, but the algorithm works with the obvious

modifications. For details regarding the modeling, discretization, optimal control design, and model reduction for this example, see [29, 7, 8]. We consider the full-order SISO system that associates the sixth input of this system with the second output. We apply our algorithm and reduce the order to $r = 6$. Amplitude Bode plots of $G(s)$ and $G_r(s)$ are shown in Figure 5.4. The output response of $G_r(s)$ is virtually indistinguishable from $G(s)$ in the frequency range considered. IRKA converged in 7 iteration steps in this case, although some interpolation points converged in the first 2–3 steps. The relative $\mathcal{H}_\infty$ error obtained with our sixth order system was 7.85×10^{-3}. Note that in order to apply balanced truncation in this example, one would need to solve [illegible] Lyapunov equations (since $\mathbf{E} \neq \mathbf{I}$) of order 20209. This presents a severe computational challenge, though there have been interesting approaches to addressing it (e.g., [5]).

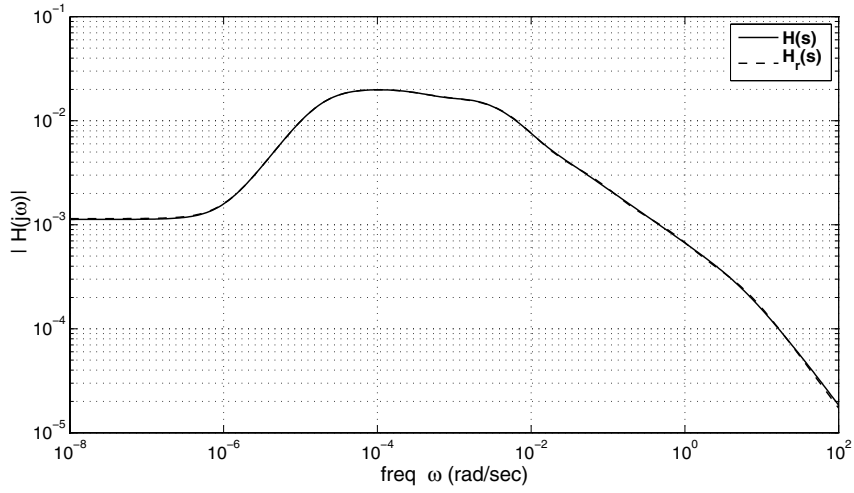

FIG. 5.4. *Amplitude Bode plots of $H(s)$ and $H_r(s)$.*

5.4. Successive substitution vs. Newton framework. In this section, we present two examples to show the effect of the Newton formulation for IRKA on two low-order examples.

The first example is FOM-1 from section 5.1. For this example, for reduction to $r = 1$, the optimal shift is $\sigma = 0.4952$. We initiate both iterations, successive substitution and Newton frameworks, away from this optimal value with an initial selection $\sigma_0 = 10^4$. Figure 5.5 illustrates how each process converges. As the figure shows, even though it takes almost 15 iterations with oscillations for the successive substitution framework to converge, the Newton formulation reaches the optimal shift in 4 steps.

The second example in this section is a third-order model with a transfer function

$$G = \frac{-s^2 + (7/4)s + 5/4}{s^3 + 2s^2 + (17/16)s + 15/32}.$$

One can exactly compute the optimal $\mathcal{H}_2$ reduced model for $r = 1$ as

$$G_r(s) = \frac{0.97197}{s + 0.2727272}$$

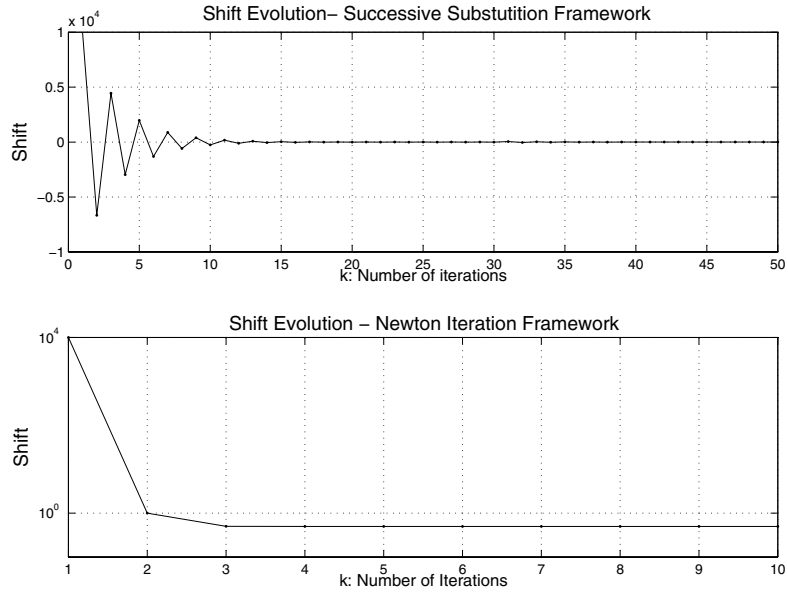

FIG. 5.5. *Comparison for* FOM-1.

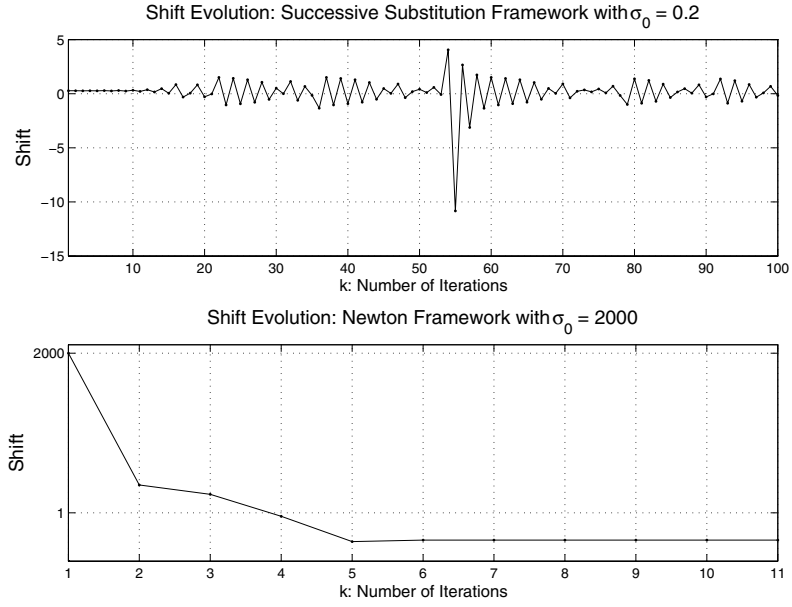

FIG. 5.6. *Comparison for the random third-order model.*

and easily show that this reduced model interpolates $G(s)$ and its derivative at $\sigma = 0.2727272$. We initiate Algorithm 4.1 with $\sigma_0 = 0.27$, very close to the optimal shift. We initiate the Newton framework at $\sigma_0 = 2000$, far away from the optimal solution. Convergence behavior of both models is depicted in Figure 5.6. The figure shows that for this example, the successive substitution framework is divergent and indeed

$\frac{\partial\tilde{\lambda}}{\partial\sigma} \approx 1.3728$. On the other hand, the Newton framework is able to converge to the optimal solution in a small number of steps.

6. Conclusions. We have developed an interpolation-based rational Krylov algorithm that iteratively corrects interpolation locations until first-order $\mathcal{H}_2$ optimality conditions are satisfied. The resulting method proves numerically effective and well suited for large-scale problems. A new derivation of the interpolation-based necessary conditions is presented and shown to be equivalent to two other common frameworks for $\mathcal{H}_2$ optimality.

Appendix.

LEMMA A.1. [illegible] $\mathbf{M}$ [illegible]

$$\int_{-\infty}^{+\infty} (\imath\omega - \mathbf{M})^{-1}\, d\omega \stackrel{def}{=} \lim_{L\to\infty} \int_{-L}^{L} (\imath\omega - \mathbf{M})^{-1}\, d\omega = \pi\mathbf{I}.$$

[illegible] Observe that for any $L > 0$,

$$\int_{-L}^{L} (\imath\omega - \mathbf{M})^{-1}\, d\omega = \int_{-L}^{L} (-\imath\omega - \mathbf{M})(\omega^2 + \mathbf{M}^2)^{-1}\, d\omega = \int_{-L}^{L} (-\mathbf{M})(\omega^2\mathbf{I} + \mathbf{M}^2)^{-1}\, d\omega.$$

Fix a contour Γ contained in the open left half plane so that the interior of Γ contains all eigenvalues of $\mathbf{M}$. Then

$$-\mathbf{M}(\omega^2\mathbf{I} + \mathbf{M}^2)^{-1} = \frac{1}{2\pi\imath} \int_{\Gamma} \frac{-z}{\omega^2 + z^2} (z\mathbf{I} - \mathbf{M})^{-1}\, dz.$$

For any fixed value z in the left half plane,

$$\text{P.V.} \int_{-\infty}^{+\infty} \frac{d\omega}{\imath\omega - z} = \lim_{L\to\infty} \int_{-L}^{L} \frac{-z}{\omega^2 + z^2}\, d\omega = \pi.$$

Thus,

$$\begin{aligned}\lim_{L\to\infty} \int_{-L}^{L} (-\mathbf{M})(\omega^2\mathbf{I} + \mathbf{M}^2)^{-1}\, d\omega &= \frac{1}{2\pi\imath} \int_{\Gamma} \lim_{L\to\infty} \left(\int_{-L}^{L} \frac{-z}{\omega^2 + z^2}\, d\omega \right) (z\mathbf{I} - \mathbf{M})^{-1}\, dz \\ &= \frac{1}{2\pi\imath} \int_{\Gamma} \pi\, (z\mathbf{I} - \mathbf{M})^{-1}\, dz = \pi\mathbf{I}. \qquad \square\end{aligned}$$

ANALYTIC RESULTS FOR THE EIGENVALUES OF CERTAIN TRIDIAGONAL MATRICES*

ALLAN R. WILLMS†

Abstract. The eigenvalue problem for a certain tridiagonal matrix with complex coefficients is considered. The eigenvalues and eigenvectors are shown to be expressible in terms of solutions of a certain scalar trigonometric equation. Explicit solutions of this equation are obtained for several special cases, and further analysis of this equation in several other cases provides information about the distribution of eigenvalues.

Key words. eigenvalues, eigenvectors, tridiagonal matrices, analytic solutions

AMS subject classification. 15A18

DOI. 10.1137/070695411

1. Introduction.

Recently Yueh [9], Kouachi [6], and da Fonseca [4] have studied the eigenvalues of certain tridiagonal matrices, developing a trigonometric equation whose solution yields the eigenvalues. In several special cases this equation has explicit solutions, and exact expressions for the eigenvalues and eigenvectors were obtained. In this paper, we extend their work by more completely describing one further special case where an explicit solution is possible and by analyzing this equation in a number of further cases where information about the distribution of eigenvalues can be obtained.

Consider the tridiagonal matrix

$$A = \begin{bmatrix} -\alpha + b & c_1 & & & \\ a_1 & b & c_2 & & \\ & a_2 & \ddots & \ddots & \\ & & \ddots & b & c_{n-1} \\ & & & a_{n-1} & -\beta + b \end{bmatrix} \tag{1}$$

with the restriction

$$\sqrt{a_i c_i} = d \neq 0, \quad 1 \leq i < n. \tag{2}$$

All variables are, in general, complex. Without loss of generality we may assume that d is the principal square root of $a_i c_i$ so that its argument is in the range $(-\pi/2, \pi/2]$. The matrix A has $n+3$ (complex) degrees of freedom: a_i, $1 \leq i < n$, b, d, α, and β (c_i being determined by a_i and d). However, since the eigenvalues of the matrix $M + bI$ are equal to $\lambda_i + b$, where λ_i are the eigenvalues of the matrix M, it follows that the eigenvalues of A will be of the form $\lambda = b + f(a_i, c_i, \alpha, \beta)$. It is also not difficult to see that the quantities a_i and c_i always occur as a product in the characteristic polynomial for A, so that the eigenvalues are in fact of the form $\lambda = b + f(d, \alpha, \beta)$. Thus the eigenvalues of A have four complex degrees of freedom. Since b simply appears in an

†Department of Mathematics and Statistics, University of Guelph, Guelph, ON N1G 2W1, Canada (AWillms@uoguelph.ca).

additive way, we will concentrate on $\mathbb{C}^3$, the space of parameters (d, α, β). We identify the complex plane with $\mathbb{R}^2$, and thus the matrix parameter space is six-dimensional. Most of the special cases yielding explicit solutions for the eigenvalues of A are two-dimensional manifolds in this space, although one case is four-dimensional. In addition we will obtain information about the distribution of eigenvalues in various other three- and four-dimensional manifolds in this space.

Yueh [9] considered matrices of the form A but with constant subdiagonal and superdiagonal entries, that is, $a_i = a$ and $c_i = c$, $1 \le i < n$. He established that the eigenvalues of the $n \times n$ matrix A are of the form $\lambda = b + 2\sqrt{ac}\cos\theta$, and the eigenvectors can also be given in terms of θ, where θ is a solution of

$$(3)\quad ac\sin\big((n+1)\theta\big) + (\alpha+\beta)\sqrt{ac}\sin(n\theta) + \alpha\beta\sin\big((n-1)\theta\big) = 0, \qquad \theta \ne k\pi,\ k \in \mathbb{Z}.$$

He solved this equation explicitly in several special cases:

1. $\alpha = \beta = 0$. In this case the matrix A is Toeplitz, and the analytic expressions for the eigenvalues and eigenvectors are well known [8, p. 514] to be

$$\lambda_m = b + 2\sqrt{ac}\cos\left(\frac{m\pi}{n+1}\right), \quad v_j^{(m)} = \left(\frac{a}{c}\right)^{j-1}\sin\left(\frac{jm\pi}{n+1}\right), \quad 1 \le m \le n,$$

2. $\alpha = 0$, $\beta = \pm\sqrt{ac}$ (or switch α and β),
3. $\alpha = \beta = \pm\sqrt{ac}$,
4. $\alpha = -\beta = \pm\sqrt{ac}$.

The resulting expressions for the eigenvalues and eigenvectors in the last three cases are similar in flavor to the first case [9]. He did not explicitly solve for the special case $\alpha = -c$, $\beta = -a$. But, by using (3), since $\sin((n+1)\theta)+\sin((n-1)\theta) = 2\sin(n\theta)\cos\theta$, for this case we get

$$\sin(n\theta) = 0, \quad \text{or} \quad 2\sqrt{ac}\cos\theta - (a+c) = 0,$$

which results in eigenvalues

$$\lambda_m = b + 2\sqrt{ac}\cos\left(\frac{m\pi}{n}\right), \quad 1 \le m < n, \quad \text{and} \quad \lambda_n = b + a + c.$$

For $b = -(a+c)$ this result was known at least as far back as 1954 [7, pp. 365–366].

Kouachi [6] used a different method to study eigenvalues and eigenvectors of the matrix A and generalized to the case where the off-diagonal entries satisfy

$$a_i c_i = \begin{cases} d_1^2 & \text{if } i \text{ is odd,} \\ d_2^2 & \text{if } i \text{ is even.} \end{cases}$$

As in Yueh's work, the eigenvalues are given in terms of $\cos\theta$ and a nonlinear equation involving θ is specified. In addition to the special cases considered by Yueh, Kouachi also found explicit expressions for the eigenvalues and eigenvectors in the case $\alpha\beta = d_2^2$, n even. This amounts to a generalization of Ledermann and Reuter's [7] result, although only for even n, and, unfortunately, there are a number of substantial typographical errors in Kouachi's paper particularly in the exposition of this case.

The eigenvalues of certain perturbed tridiagonal k-Toeplitz matrices were recently studied by da Fonseca [4]. In particular, da Fonesca gives a trigonometric relation satisfied by the eigenvalues of a 2-Toeplitz matrix with perturbed entries in the top left and bottom right corners. This result is more general than those of Yueh and

Kouachi, and those presented here, since the matrix A and those studied by Yueh and Kouachi are special types of 2-Toeplitz matrices. However, da Fonseca gives an explicit formula for the eigenvalues in just one special case of the perturbation parameters (α and β) but no others. (Incidentally, there is a typographical error in his paper for this formula also: $b_1^2 + b_2^2$ on page 65 should be $b_1 + b_2$.)

We also note another recent result by da Fonseca [5] which relates the eigenvalues of the matrix

$$C = [\mu \min\{i, j\} - \nu]_{i,j=1,\dots,n}, \qquad \mu > 0, \quad \mu \neq \nu,$$

to those of a matrix of the form A (1) with $a_i = c_i = -1$, $i = 1, \dots, n-1$, $b = 2$, $\alpha = 1 - \mu/(\mu - \nu)$, and $\beta = 1$. However, he obtains explicit results only for a couple of special values for μ and ν, which turn out to be two of the special cases that we consider here.

In this paper we provide a general expression for the eigenvalues and eigenvectors of the matrix A, which generalizes Yueh's result and is contained within Kouachi's and da Fonseca's. We enumerate ,, of the special cases where this general expression yields explicit results for the eigenvalues and eigenvectors; particularly, we describe the case $\alpha\beta = d^2$ fully, extending the work of Yueh and Kouachi. In addition, we provide analysis in several other special cases not considered by any of the above three authors where explicit solutions are not possible but information on the distribution of eigenvalues can be obtained.

2. General results. Similar to Yueh [9], we utilize the methods of symbolic calculus of semi-infinite sequences [3]. The pertinent facts are as follows. The convolution of two sequences $x = \{x_j\}_{j=0}^{\infty}$ and $y = \{y_j\}_{j=0}^{\infty}$ is the sequence $z = \{z_n\}_{n=0}^{\infty}$ whose nth component is

$$z_n = \sum_{j=0}^{n} x_j y_{n-j}.$$

Convolution is a symmetric operation $xy = yx$, distributes over addition $x(y + z) = xy + xz$, and is associative with respect to scalar multiplication $x(cy) = c(xy)$ for any scalar c. We define $I = \{1, 0, \dots\}$ and $S = \{0, 1, 0, \dots\}$. Thus

$$Ix = x \quad \text{and} \quad Sx = \{0, x_0, x_1, \dots\},$$

and, in particular,

$$S\{x_{j+1}\}_{j=0}^{\infty} = \{0, x_1, x_2, \dots\} = x - x_0 I$$

and

$$S^2\{x_{j+2}\}_{j=0}^{\infty} = \{0, 0, x_2, x_3, \dots\} = x - x_0 I - x_1 S.$$

Each sequence x with $x_0 \neq 0$ has a unique inverse y such that $xy = I$, where $y_0 = 1/x_0$ and y_n, $n > 0$, is defined recursively by $y_n = -(\sum_{j=1}^{n} x_j y_{n-j})/x_0$. In particular, the inverse of $(S - \gamma I)$, for scalar γ, is

$$(S - \gamma I)^{-1} = \left\{ \frac{-1}{\gamma^{j+1}} \right\}_{j=0}^{\infty}. \tag{4}$$

Consider now the eigenproblem for the matrix A, $Av = \lambda v$, which can be written as follows:

$$\begin{aligned}(b-\lambda)v_1 + c_1 v_2 &= \alpha v_1,\\ a_1 v_1 + (b-\lambda)v_2 + c_2 v_3 &= 0,\\ &\vdots\\ a_{n-2}v_{n-2} + (b-\lambda)v_{n-1} + c_{n-1}v_n &= 0,\\ a_{n-1}v_{n-1} + (b-\lambda)v_n &= \beta v_n.\end{aligned} \tag{5}$$

Since $d^2 = a_j c_j$, for all $j = 1, \ldots, n-1$, it follows that $d/c_j = a_j/d$. Define $q_1 = 1$ and q_j, $1 < j \le n$, by the recursion

$$q_j = \frac{d}{c_{j-1}} q_{j-1} = \frac{a_{j-1}}{d} q_{j-1}, \qquad 1 < j \le n. \tag{6}$$

Formally, the q_j are given by

$$q_j = \left(\frac{1 a_1 a_2 \cdots a_{j-1}}{1 c_1 c_2 \cdots c_{j-1}} \right)^{1/2}; \tag{7}$$

however, the specific branch of the square root function that needs to be used for each subsequent j is not always the principal branch but rather is determined by the requirement that $q_j = d q_{j-1}/c_{j-1}$. Note that, by (2), a_j and c_j, and hence q_j, are all nonzero so that the vector u given by

$$v_j = q_j u_j, \quad 1 \le j \le n, \tag{8}$$

is well defined. Substitute (8) into system (5), dividing the jth equation by q_j. By using (6) this process yields the system

$$\begin{aligned}(b-\lambda)u_1 + d u_2 &= \alpha u_1,\\ d u_1 + (b-\lambda)u_2 + d u_3 &= 0,\\ &\vdots\\ d u_{n-2} + (b-\lambda)u_{n-1} + d u_n &= 0,\\ d u_{n-1} + (b-\lambda)u_n &= \beta u_n.\end{aligned} \tag{9}$$

We now extend the vector u to a semi-infinite sequence $\{u_j\}_{j=0}^{\infty}$ and impose $u_0 = 0$ and $u_{n+1} = 0$. System (9) can then be written as

$$d\,\{u_{j+2}\}_{j=0}^{\infty} + (b-\lambda)\,\{u_{j+1}\}_{j=0}^{\infty} + d\,\{u_j\}_{j=0}^{\infty} = \{f_{j+1}\}_{j=0}^{\infty}, \tag{10}$$

where f is the sequence defined by

$$f_j = \begin{cases} \alpha u_1 & \text{if } j = 1,\\ \beta u_n & \text{if } j = n,\\ 0 & \text{otherwise.}\end{cases} \tag{11}$$

Taking the convolution of (10) with S^2 gives

$$d\,(u - u_0 I - u_1 S) + (b-\lambda) S\,(u - u_0 I) + d S^2 u = S\,(f - f_0 I),$$

and by using the facts that $u_0 = 0$ and $f_0 = 0$ we have

$$\big(dS^2 + (b-\lambda)S + dI\big)u = (f + du_1 I)\, S. \tag{12}$$

Let

$$\gamma_\pm = \frac{1}{2d}\left[-(b-\lambda) \pm \sqrt{\omega}\right], \tag{13}$$

where $\omega = (b-\lambda)^2 - 4d^2$, be the two roots of $dx^2 + (b-\lambda)x + d = 0$. Note that $\gamma_+\gamma_- = 1$, and thus we may write $\gamma_\pm = e^{\pm i\theta}$, where $\theta \in \mathbb{C}$ by taking $\theta = \arg\gamma_+ - i\ln|\gamma_+|$. Since $-(b-\lambda)/d = \gamma_+ + \gamma_- = e^{i\theta} + e^{-i\theta} = 2\cos\theta$, the eigenvalues are given by

$$\lambda = b + 2d\cos\theta. \tag{14}$$

Further, since $\cos(x+iy) = \cosh(y)\cos(a) - i\sinh(b)\sin(a)$, it follows that the eigenvalue is real either if θ is real or if $\mathrm{Re}(\theta) = k\pi$, $k \in \mathbb{Z}$. With this notation, (12) becomes

$$d(S - \gamma_+ I)(S - \gamma_- I)u = (f + du_1 I)\, S,$$

and from (4) we obtain

$$\begin{aligned}
u &= \left\{\frac{-1}{\gamma_+^{j+1}}\right\}_{j=0}^{\infty} \left\{\frac{-1}{\gamma_-^{j+1}}\right\}_{j=0}^{\infty} \left(\frac{1}{d}f + u_1 I\right) S \\
&= \left\{\sum_{j=0}^{m} \frac{1}{\gamma_+^{j+1}\gamma_-^{m-j+1}}\right\}_{m=0}^{\infty} \left(\frac{1}{d}f + u_1 I\right) S \\
&= \left\{\sum_{j=0}^{m} \gamma_-^{j}\gamma_+^{m-j}\right\}_{m=0}^{\infty} \left(\frac{1}{d}f + u_1 I\right) S \\
&= \begin{cases} \left\{\dfrac{\gamma_+^{m+1} - \gamma_-^{m+1}}{\gamma_+ - \gamma_-}\right\}_{m=0}^{\infty} \left(\dfrac{1}{d}f + u_1 I\right) S & \text{if } \gamma_+ \neq \gamma_-, \\ \left\{(m+1)\gamma_+^m\right\}_{m=0}^{\infty} \left(\dfrac{1}{d}f + u_1 I\right) S & \text{if } \gamma_+ = \gamma_-, \end{cases} \\
&= \begin{cases} \left\{\dfrac{\sin((m+1)\theta)}{\sin\theta}\right\}_{m=0}^{\infty} \left(\dfrac{1}{d}f + u_1 I\right) S & \text{if } \gamma_+ \neq \gamma_-, \\ \left\{(m+1)e^{im\theta}\right\}_{m=0}^{\infty} \left(\dfrac{1}{d}f + u_1 I\right) S & \text{if } \gamma_+ = \gamma_-. \end{cases}
\end{aligned} \tag{15}$$

If we define the function $g : \mathbb{Z} \times \mathbb{C} \to \mathbb{C}$ as

$$g(n,\theta) = \begin{cases} \dfrac{\sin(n\theta)}{\sin\theta} & \text{if } \theta \neq k\pi,\ k \in \mathbb{Z}, \\ n & \text{if } \theta = 2k\pi,\ k \in \mathbb{Z}, \\ (-1)^{n-1}n & \text{if } \theta = (2k+1)\pi,\ k \in \mathbb{Z}, \end{cases} \tag{16}$$

then g is continuous in θ, and, since $\gamma_+ = \gamma_-$ is equivalent to $\theta = k\pi$, $k \in \mathbb{Z}$, both of the cases in (15) collapse to

$$u = \left\{ g(m+1,\theta) \right\}_{m=0}^{\infty} \left(\frac{1}{d} f + u_1 I \right) S. \tag{17}$$

Computing the convolutions in this last expression and noting from (11) that the only nonzero entries of the sequence f are $f_1 = \alpha u_1$ and $f_n = \beta u_n$ yields $u_0 = 0$ and

$$u_j = u_1 \left[g(j,\theta) + \frac{\alpha}{d} g(j-1,\theta) \right] + H(j-n-1) \frac{\beta}{d} u_n g(j-n,\theta), \qquad j \geq 1, \tag{18}$$

where $H(x)$ is the unit step function: $H(x) = 1$ if $x \geq 0$, and $H(x) = 0$ if $x < 0$. By using (18) with $j = n+1$, the condition $u_{n+1} = 0$ becomes

$$\left[g(n+1,\theta) + \frac{\alpha}{d} g(n,\theta) \right] u_1 + \frac{\beta}{d} u_n = 0, \tag{19}$$

where we have used the fact that $g(1,\theta) = 1$. Finally, by using (18) at $j = n$ and noting that u_1 cannot be zero (otherwise, the vector v must be zero) we obtain the necessary and sufficient condition for $\lambda = b + 2d\cos\theta$ to be an eigenvalue of A, namely,

$$g(n+1,\theta) + \frac{\alpha+\beta}{d} g(n,\theta) + \frac{\alpha\beta}{d^2} g(n-1,\theta) = 0. \tag{20}$$

Equations (20) and (14) correspond to those derived by Yueh; however, he multiplied (20) by $d^2 \sin\theta$ to clear the denominator and dealt with the case $\theta = k\pi$ separately.

We now show that there are exactly n solutions (counting multiplicity) of (20) in the region

$$R = \{ \theta = (x+iy) \mid 0 \leq x \leq \pi,\ x, y \in \mathbb{R} \}, \tag{21}$$

where roots on the boundary of R are counted with half weight. The continuous function g is 2π-periodic in θ and is an even function of θ. Consequently once the roots of (20) in R are found, all roots of (20) can be determined. Setting $\xi = e^{i\theta}$ and multiplying (20) by the nonzero quantity $d^2\xi^{n+1}/\xi$ gives

$$\frac{d^2(\xi^{2n+2} - 1) + d(\alpha+\beta)\xi(\xi^{2n} - 1) + \alpha\beta\xi^2(\xi^{2n-2} - 1)}{\xi^2 - 1} = 0. \tag{22}$$

Clearly $\xi = \pm 1$ are roots of the numerator; hence, $\xi^2 - 1$ divides the numerator, and we are left with a $2n$th order polynomial in ξ which necessarily has $2n$ roots, some possibly repeated. Since $e^{i\theta}$ is 2π-periodic, it follows that there are $2n$ roots of (20) in the region $R \cup \hat{R}$, where $\hat{R} = \{\theta \mid -\pi < \mathrm{Re}(\theta) < 0\}$. By the even property of g, every root in $\mathrm{int}(R)$ (the interior of R) has a corresponding root in $\hat{R}$. Since R and $\hat{R}$ are disjoint, it follows that twice the number or roots in $\mathrm{int}(R)$ plus the number of roots on the boundary of R is $2n$. Further, roots on the left boundary of R of the form $\theta = iy$, $y > 0$, have corresponding roots $\theta = -iy$ also on the left boundary, and similarly roots on the right boundary of R of the form $\theta = \pi + iy$, $y > 0$, have corresponding roots $\theta = -\pi - iy + 2\pi = \pi - iy$, also on the right boundary. Since the cosine is also even and 2π-periodic, each of these corresponding pairs of roots of (20) yield identical eigenvalues of A through (14). We may thus focus entirely on finding

roots of (20) in the region R and may also exclude the portions of the boundary of R with $\mathrm{Im}(\theta) < 0$. Each such distinct root θ corresponds to a distinct eigenvalue λ.

From (18) and (8), the components of the eigenvectors are given by

$$v_j = v_1 q_j \left[g(j,\theta) + \frac{\alpha}{d} g(j-1,\theta) \right], \quad 1 < j \le n. \tag{23}$$

But, since $q_1 = 1$, $g(0,\theta) = 0$, and $g(1,\theta) = 1$, we may express the eigenvectors as

$$v_j = \begin{cases} q_j \left[\sin(j\theta) + \frac{\alpha}{d} \sin\big((j-1)\theta\big) \right] & \text{if } \theta \notin \{0,\pi\}, \\ q_j \left[j + \frac{\alpha}{d}(j-1) \right] & \text{if } \theta = 0, \\ q_j (-1)^{j-1} \left[j - \frac{\alpha}{d}(j-1) \right] & \text{if } \theta = \pi, \end{cases} \qquad 1 \le j \le n. \tag{24}$$

3. Special cases. In this section we examine various relationships between the matrix parameters d, α, and β which, when enforced, allow (20) to be solved explicitly or to be simplified to the form $F(\theta) = p(d,\alpha,\beta)$. These simplifications are the result of standard trigonometric identities. We list here several simplifications that we use for our function g:

$$g(j+1,\theta) + g(j-1,\theta) = 2g(j,\theta)\cos\theta, \tag{25}$$

$$g(j+1,\theta) - g(j-1,\theta) = 2\cos(j\theta), \tag{26}$$

$$g(j,\theta) + g(j-1,\theta) = g(2j-1,\theta/2), \tag{27}$$

$$g(j,\theta) - g(j-1,\theta) = \begin{cases} \cos\big((2j-1)\theta/2\big)/\cos(\theta/2) & \text{if } 0 < \theta < \pi, \\ 1 & \text{if } \theta = 0, \\ (-1)^{j-1}(2j-1) & \text{if } \theta = \pi. \end{cases} \tag{28}$$

Note that all of the above are identities for g and are valid for all $\theta \in \mathbb{C}$, including $\theta = k\pi$, $k \in \mathbb{Z}$.

3.1. Explicit solutions.

3.1.1. $\alpha = \beta = 0$. If $\alpha = \beta = 0$, then the matrix A, although not Toeplitz, has the same eigenvalues as the corresponding Toeplitz matrix ($a_i = a$ and $c_i = c$ for all i), since (20) collapses to $g(n+1,\theta) = 0$, whose solutions are $\theta_m = \frac{m\pi}{n+1}$, $1 \le m \le n$, giving eigenvalues

$$\lambda_m = b + 2d\cos\left(\frac{m\pi}{n+1}\right), \qquad 1 \le m \le n, \tag{29}$$

with corresponding eigenvectors

$$v_j^{(m)} = q_j \sin\left(\frac{jm\pi}{n+1}\right), \qquad 1 \le j \le n,\ 1 \le m \le n. \tag{30}$$

3.1.2. $\alpha = 0$, $\beta = d$. If $\alpha = 0$, $\beta = d$, then by using (27), (20) becomes

$$g(2n+1,\theta/2) = 0,$$

whose solutions are $\theta_m = \frac{2m\pi}{2n+1}$, giving eigenvalues

$$\lambda_m = b + 2d\cos\left(\frac{2m\pi}{2n+1}\right), \qquad 1 \le m \le n, \tag{31}$$

and corresponding eigenvectors

$$v_j^{(m)} = q_j \sin\left(\frac{2mj\pi}{2n+1}\right), \qquad 1 \le j \le n,\ 1 \le m \le n. \tag{32}$$

3.1.3. $\alpha = d$, $\beta = 0$. If $\alpha = d$, $\beta = 0$, the eigenvalues are the same as the above case (31), and the eigenvectors are

$$v_j^{(m)} = q_j \cos\left(\frac{(2j-1)2m\pi}{2(2n+1)}\right), \qquad 1 \le j \le n,\ 1 \le m \le n. \tag{33}$$

3.1.4. $\alpha = 0$, $\beta = -d$. If $\alpha = 0$, $\beta = -d$, we may use (28) to reduce (20) to

$$\cos\big((2n+1)\theta/2\big) = 0,$$

whose solutions are $\theta_m = (2m-1)\pi/(2n+1)$, $1 \le m \le n$, giving eigenvalues

$$\lambda_m = b + 2d\cos\left(\frac{(2m-1)\pi}{2n+1}\right), \qquad 1 \le m \le n, \tag{34}$$

and corresponding eigenvectors

$$v_j^{(m)} = q_j \sin\left(\frac{j(2m-1)\pi}{2n+1}\right), \qquad 1 \le j \le n,\ 1 \le m \le n. \tag{35}$$

3.1.5. $\alpha = -d$, $\beta = 0$. If $\alpha = -d$, $\beta = 0$, the eigenvalues are the same as the previous case (34), and the corresponding eigenvectors are

$$v_j^{(m)} = q_j \cos\left(\frac{(2j-1)(2m-1)\pi}{2(2n+1)}\right), \qquad 1 \le j \le n,\ 1 \le m \le n. \tag{36}$$

3.1.6. $\alpha = d$, $\beta = -d$. If $\alpha = -\beta = d$, (20) simplifies by using (26) to become $\cos(n\theta) = 0$. Hence $\theta_m = \frac{(2m-1)\pi}{2n}$, $1 \le m \le n$, and the eigenvalues are

$$\lambda_m = b + 2d\cos\left(\frac{(2m-1)\pi}{2n}\right), \qquad 1 \le m \le n, \tag{37}$$

with corresponding eigenvectors

$$v_j^{(m)} = q_j \sin\left(\frac{(2j-1)(2m-1)\pi}{4n}\right), \qquad 1 \le j \le n,\ 1 \le m \le n. \tag{38}$$

3.1.7. $\alpha = -d$, $\beta = d$. If $\alpha = -\beta = -d$, the eigenvalues are the same as the previous case (37), and the corresponding eigenvectors are

$$v_j^{(m)} = q_j \cos\left(\frac{(2j-1)(2m-1)\pi}{4n}\right), \qquad 1 \le j \le n,\ 1 \le m \le n. \tag{39}$$

3.1.8. $\alpha\beta = d^2$. Now consider the case $\alpha\beta = d^2$. Whereas the previous special cases were two-dimensional real manifolds in (d, α, β)-space, this case is a four-dimensional manifold in $\mathbb{R}^6$. By using (25), (20) becomes

$$g(n,\theta)\left(2\cos\theta + \frac{\alpha+\beta}{d}\right) = 0.$$

From this we immediately obtain

$$\theta_m = \frac{m\pi}{n}, \quad 1 \le m < n, \qquad \text{or} \qquad 2d\cos\theta_n = -(\alpha+\beta),$$

giving eigenvalues

$$\lambda_m = b + 2d\cos\left(\frac{m\pi}{n}\right), \quad 1 \le m < n, \qquad \text{and} \qquad \lambda_n = b - (\alpha + \beta). \tag{40}$$

The more specialized cases with $\alpha = \beta = d$ or $\alpha = \beta = -d$ were the only ones with $\alpha\beta = d^2$ that were considered by Yueh. In the case $\alpha = \beta = d$, by using (24) and (27), the eigenvectors are

$$v_j^{(m)} = q_j \sin\left(\frac{(2j-1)m\pi}{2n}\right), \qquad 1 \le j \le n,\ 1 \le m < n, \tag{41}$$

and, for the nth eigenpair, $\theta_n = \pi$, $\lambda_n = b - 2d$, and

$$v_j^{(n)} = q_j(-1)^{j-1}, \qquad 1 \le j \le n, \tag{42}$$

which we note is the same form as (41) with $m = n$. The case $\alpha = \beta = -d$ gives eigenvectors

$$v_j^{(m)} = q_j \cos\left(\frac{(2j-1)m\pi}{2n}\right), \qquad 1 \le j \le n,\ 1 \le m < n, \tag{43}$$

and $\theta_n = 0$, $\lambda_n = b + 2d$, and, by using (28),

$$v_j^{(n)} = q_j, \qquad 1 \le j \le n. \tag{44}$$

Outside these more specialized cases, it is impossible for θ_n to be zero or π, and so, from (24), we may write the eigenvectors as

$$v_j^{(m)} = q_j \left[\sin\left(\frac{jm\pi}{n}\right) + \frac{\alpha}{d}\sin\left(\frac{(j-1)m\pi}{n}\right)\right], \qquad 1 \le j \le n,\ 1 \le m < n, \tag{45}$$

and

$$v_j^{(n)} = q_j \left[\sin(j\theta_n) + \frac{\alpha}{d}\sin\big((j-1)\theta_n\big)\right], \qquad 1 \le j \le n, \tag{46}$$

where $\theta_n = \arccos(-(\alpha + \beta)/2d)$.

3.2. Eigenvalue distribution results. Here we examine various three- and four-dimensional real manifolds in (d, α, β)-space, where information on the distribution of the eigenvalues can be inferred. For this analysis it is convenient to partition the interval $[0, \pi]$ into subintervals in one of several ways. In the first way, $[0, \pi]$ is partitioned into $n+1$ subintervals, the first and last of which have width $1/(2n)$ while the remaining have width $1/n$:

$$\begin{aligned} I_0 &= \left[0, \frac{\pi}{2n}\right), \\ I_k &= \left[\frac{(2k-1)\pi}{2n}, \frac{(2k+1)\pi}{2n}\right), \qquad 1 \le k < n-1, \\ I_n &= \left[\frac{(2n-1)\pi}{2n}, \pi\right]. \end{aligned} \tag{47}$$

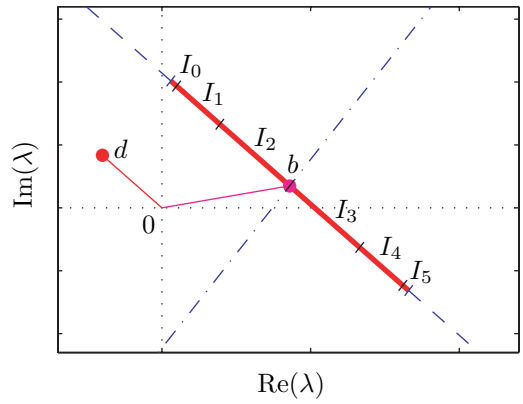

FIG. 1. *The location of eigenvalues $\lambda = b + 2d\cos(\theta)$ in the complex plane for various θ. If $\theta \in [0, \pi]$, then λ lies on the thick solid line segment. For illustration, this segment is divided into the images of the intervals I_k, $0 \le k \le n$, $n = 5$. Other partitionings of $[0, \pi]$ would divide the line segment differently. The dashed line extending beyond this line segment shows the location of λ when $\theta = iy$ or $\theta = \pi + iy$, $y \in \mathbb{R}$. The dotted-dashed line orthogonal to the thick line segment is the image of the line $\theta = \pi/2 \pm iy$, $y \in \mathbb{R}$.*

A second useful partitioning of $[0, \pi]$ is one where the subintervals have width $2/(2n+1)$ except for the first, which has half that width:

$$
\begin{aligned}
J_0 &= \left[0, \frac{\pi}{2n+1}\right), \\
J_k &= \left[\frac{(2k-1)\pi}{2n+1}, \frac{(2k+1)\pi}{2n+1}\right), \qquad 1 \le k < n-1, \\
J_n &= \left[\frac{(2n-1)\pi}{2n+1}, \pi\right].
\end{aligned} \tag{48}
$$

Finally, consider partitioning $[0, \pi]$ into n equal length intervals:

$$
\begin{aligned}
K_k &= \left[\frac{(k-1)\pi}{n}, \frac{k\pi}{n}\right), \qquad 1 \le k < n, \\
K_n &= \left[\frac{(n-1)\pi}{n}, \pi\right].
\end{aligned} \tag{49}
$$

Typically, the following results make statements such as "Under the stated assumptions, there is one real solution of (20) lying in each of the intervals I_0 to I_{n-1}." The eigenvalues of A are given by $\lambda = b + 2d\cos(\theta)$. Real values of θ on the interval $[0, \pi]$ thus correspond to eigenvalues on a line segment of length $4|d|$ parallel to the ray from the origin to d and centered at b, as depicted in Figure 1. The various subintervals defined above correspond to portions of this line segment. Sometimes complex solutions for θ of the form $\theta = iy$, $\theta = \pi + iy$, or $\theta = \pi/2 \pm iy$, $y \in \mathbb{R}$, are also shown to exist. In the first two cases, the corresponding eigenvalues are $\lambda = b \pm 2d\cosh(y)$, respectively, which lie on the same line as the intervals shown in Figure 1 but further away from b. In the case $\theta = \pi/2 \pm iy$, the corresponding eigenvalues are $\lambda = b \pm i2d\sinh(y)$, which lie an equal distance from b on a line through b orthogonal to the ray through d. Of course, if b and d are real, then each of these distinct real solutions for θ and the complex solutions with $\mathrm{Re}(\theta) \in \{0, \pi\}$ yield distinct real eigenvalues for A.

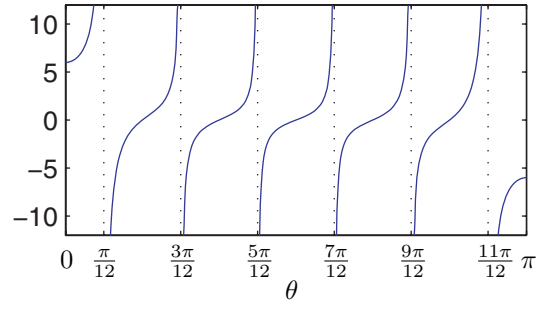

FIG. 2. *The function* $\theta \mapsto \tan(n\theta)/\sin(\theta)$, $\theta \in [0, \pi]$, *for the case* $n = 6$. *The intervals* I_k, $0 \le k \le n$, *are demarcated by the dotted vertical lines.*

For some of this analysis it is convenient to express the necessary and sufficient condition for θ, (20), in an equivalent form. By expanding $\sin((n \pm 1)\theta)$ and simplifying, (20) becomes

$$\frac{\sin(n\theta)}{\sin(\theta)} \left[\left(1 + \frac{\alpha\beta}{d^2} \right) \cos(\theta) + \frac{\alpha + \beta}{d} \right] + \cos(n\theta) \left(1 - \frac{\alpha\beta}{d^2} \right) = 0. \tag{50}$$

3.2.1. $\boldsymbol{\alpha\beta = -d^2}$**.** Consider the four-dimensional manifold $\alpha\beta = -d^2$, but exclude the cases $\alpha = -\beta = \pm d$ as these have already been considered. In this case, (50) simplifies to

$$\frac{\sin(n\theta)}{\sin(\theta)} \left[\frac{\alpha + \beta}{d} \right] + 2\cos(n\theta) = 0. \tag{51}$$

Since we have excluded the possibility that $\alpha + \beta = 0$, for (51) to hold $\cos(n\theta)$ cannot be zero, and hence we may write this equation as

$$\frac{\tan(n\theta)}{\sin(\theta)} = \frac{-2d}{\alpha + \beta}. \tag{52}$$

Let $F(\theta) = \tan(n\theta)/\sin(\theta)$ and $p(d, \alpha, \beta) = -2d/(\alpha + \beta)$, and assume that the value of p is real. (We are now restricted to a three-dimensional manifold.) The function F on $[0, \pi]$ is an odd function with respect to $\pi/2$. It monotonically increases from $-\infty$ to $+\infty$ on each interval I_k, $1 \le k < n$. On the interval I_0 it monotonically increases from n to $+\infty$, and on the interval I_n it monotonically increases from $-\infty$ to $-n$; see Figure 2. Consequently, if $|p| \ge n$, there are exactly n distinct real solutions of (52) for θ in $[0, \pi]$, one in each of the intervals $I_1, \ldots, I_{n-1}$ and the last one in either I_0 (if $p > 0$) or in I_n (if $p < 0$). These n distinct values for θ correspond to n distinct real eigenvalues λ. If $|p| < n$, then there are only $n - 1$ real solutions of (52), one in each of the intervals $I_1, \ldots, I_{n-1}$, corresponding to $n - 1$ real eigenvalues for A. In the event that all variables in A are real, the last eigenvalue must also be real, since they must occur in complex conjugate pairs. (It turns out that, even if just b, d, and p are real, the last eigenvalue is also real.) But for $\theta = x + iy$, $x, y \in \mathbb{R}$,

$$\cos(\theta) = \cos(x + iy) = \cosh(y)\cos(x) - i\sinh(y)\sin(x),$$

thus $\lambda = b + 2d\cos(\theta)$ will be real if b and d are real, and θ is real or $\mathrm{Re}(\theta) = k\pi$. We are thus led to look for the nth solution of (52) on the boundary of R by taking

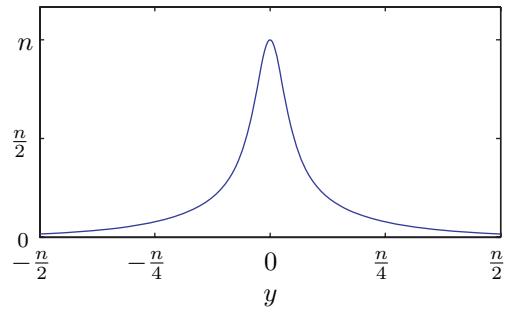

FIG. 3. *The function* $y \mapsto \tanh(ny)/\sinh(y)$.

$\theta = iy$ or $\theta = \pi + iy$, $y > 0$. (Recall that on the boundary of R we need only consider $y \geq 0$.) If $0 < p < n$, substituting $\theta = iy$, $y \in \mathbb{R}$, into (52) gives

$$\frac{\tanh(ny)}{\sinh(y)} = p. \tag{53}$$

A plot of this function is shown in Figure 3. Since it monotonically decreases from n to zero as y increases from zero, there is exactly one solution y^* of (53), with $y^* > 0$. If $-n < p < 0$, substituting $\theta = \pi + iy$, $y \in \mathbb{R}$, into (52) gives

$$\frac{\tanh(ny)}{\sinh(y)} = -p, \tag{54}$$

again yielding exactly one more root y^*, with $y^* > 0$. If $|p|$ is large ($|\alpha + \beta|$ is small), then the solutions for θ asymptotically approach $\theta_m = (2m-1)\pi/(2n)$, $1 \leq m \leq n$, as expected since these are the solutions for $\alpha = -\beta = \pm d$. But in any event the real solutions of (52) are approximately spaced by a distance of π/n as is readily apparent in Figure 2.

3.2.2. $\alpha\beta = 0$. If the product $\alpha\beta$ is zero (but α and β are not both zero and one is not $\pm d$, as these cases have been previously considered), then (20) becomes

$$g(n+1,\theta) + \frac{\alpha+\beta}{d} g(n,\theta) = 0. \tag{55}$$

This can be written as

$$\frac{\sin\big((n+1/2)\theta + \theta/2\big)}{\sin(2\theta/2)} + \left(\frac{\alpha+\beta}{d}\right) \frac{\sin\big((n+1/2)\theta - \theta/2\big)}{\sin(2\theta/2)} = 0,$$

which upon expanding and simplifying yields

$$\left(1 + \frac{\alpha+\beta}{d}\right)\left[\frac{\sin\big((2n+1)\theta/2\big)}{\sin(\theta/2)}\right] + \left(1 - \frac{\alpha+\beta}{d}\right)\left[\frac{\cos\big((2n+1)\theta/2\big)}{\cos(\theta/2)}\right] = 0.$$

Now, since we are assuming that $\alpha + \beta \neq \pm d$, both factors in parentheses in the above expression are nonzero. This means that if one of the factors in square brackets is zero, both must be zero for the equation to hold. However, this is impossible since the first factor in square brackets is $g(2n+1, \theta/2)$, which is zero only when $(2n+1)\theta/2 = k\pi$,

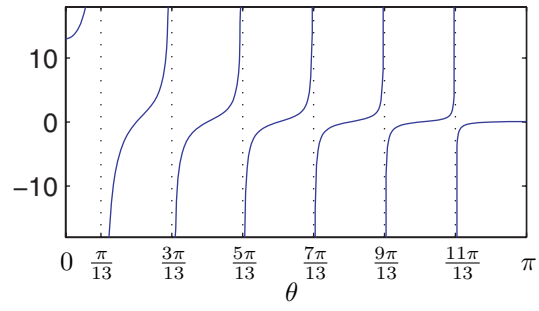

FIG. 4. *The function* $\theta \mapsto \tan((2n+1)\theta/2)/\tan(\theta/2)$, $\theta \in [0,\pi]$, *for the case* $n = 6$. *The intervals* J_k, $0 \le k \le n$, *are demarcated by the dotted vertical lines.*

$1 \le k \le n$, which implies that $\cos((2n+1)\theta/2) = \cos(k\pi) \neq 0$. We may thus validly rearrange the above expression to obtain

$$\frac{\tan\big((2n+1)\theta/2\big)}{\tan(\theta/2)} = \frac{\alpha+\beta-d}{\alpha+\beta+d}. \tag{56}$$

Let $F(\theta)$ and $p(d,\alpha,\beta)$ be the left and right sides of the above equation, respectively, and assume that the value of p is real. (Again, we are now restricted to a three-dimensional manifold.) The function F on $[0,\pi]$ is plotted in Figure 4 for the case $n = 6$. F is monotonically increasing from $-\infty$ to $+\infty$ on the intervals J_k, $1 \le k < n$, monotonically increasing from $2n+1$ to $+\infty$ on J_0, and monotonically increasing from $-\infty$ to $1/(2n+1)$ on J_n. Thus if p is real and at least as big as $2n+1$, there are exactly n real solutions, one in each of the intervals J_k, $0 \le k \le n-1$. If p is real and equal to or smaller than $1/(2n+1)$, there is one real solution in each of the intervals J_k, $1 \le k \le n$. All of these real roots are approximately separated by a distance of $2\pi/(2n+1)$. Substituting $\theta = iy$, $y \in \mathbb{R}$, into (56) gives

$$\frac{\tanh\big((2n+1)y/2\big)}{\tanh(y/2)} = p, \tag{57}$$

while substituting $\theta = \pi + iy$, $y \in \mathbb{R}$, into (56) gives

$$\frac{\coth\big((2n+1)y/2\big)}{\coth(y/2)} = p. \tag{58}$$

The functions on the left sides of the above expressions are shown in Figure 5. The first decreases monotonically from $2n+1$ to 1, while the second increases from $1/(2n+1)$ to 1 as y increases from zero. Thus if $1/(2n+1) < p < 1$, there is one solution of (56) of the form $\theta = \pi + iy^*$, $y^* > 0$, and if $1 < p < (2n+1)$, there is one solution of the form $\theta = iy^*$, $y^* > 0$. (Note that since $d \neq 0$ it is impossible for $p = 1$.)

3.2.3. $\alpha + \beta = 0$. If $\alpha + \beta = 0$, then (50) may be written as

$$\left(1 + \frac{\alpha\beta}{d^2}\right)\left[\frac{\sin(n\theta)\cos(\theta)}{\sin(\theta)}\right] + \left(1 - \frac{\alpha\beta}{d^2}\right)\cos(n\theta) = 0. \tag{59}$$

The cases $\alpha\beta = 0$ and $\alpha\beta = \pm d^2$ have already been considered, so here we may assume that neither factor in parentheses is zero and these two factors are not equal.

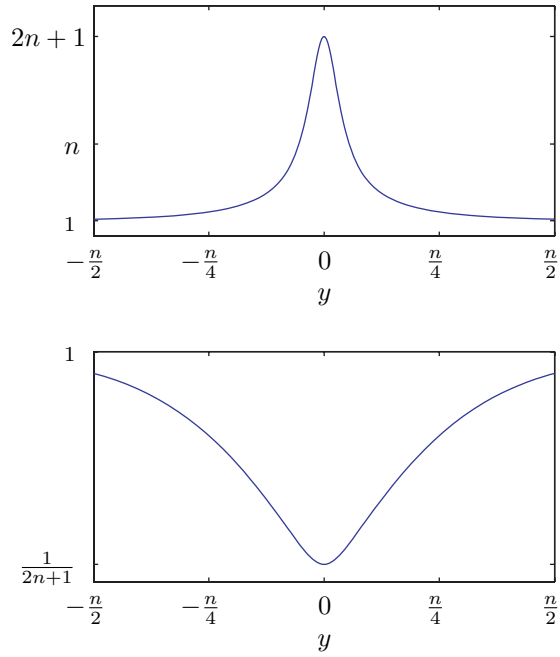

FIG. 5. *Top: The function* $y \mapsto \tanh((2n+1)y/2)/\tanh(y/2)$. *Bottom: The function* $y \mapsto \coth((2n+1)y/2)/\coth(y/2)$.

If $\cos(n\theta) = 0$, then $\theta_m = \frac{(2m-1)\pi}{2n}$, $1 \le m \le n$, are all of the possible values of θ in $[0, \pi]$. The factor $\sin(n\theta)$ clearly cannot be zero for these θ_m; hence, for the equation to hold, $\cos\theta_m$ must be zero, that is, $\theta_m = \pi/2$, which means that n must be odd and $m = (n+1)/2$. Thus the condition on θ may be written

$$\frac{\tan(n\theta)}{\tan(\theta)} = \frac{\alpha\beta - d^2}{\alpha\beta + d^2}, \qquad \theta \neq \pi/2, \tag{60}$$

where $\theta = \pi/2$ is an additional solution in the case n is odd. (Thus one eigenvalue of A is always b when n is odd and $\alpha + \beta = 0$.) Again, let $F(\theta)$ and $p(d, \alpha, \beta)$ be the left and right sides of (60), respectively, and suppose that the value of p is real. Figure 6 displays a graph of F on $[0, \pi]$ for both an even and an odd n case. F is even around $\pi/2$ and is equal to n at both $\theta = 0$ and $\theta = \pi$. The subintervals of interest are the I_k given by (47). On I_0 the function F increases monotonically from n to $+\infty$, and on intervals I_k, $1 \le k \le n/2 - 1$, it increases monotonically from $-\infty$ to $+\infty$. On the center interval(s) ($I_{n/2}$ if n is even, $I_{(n-1)/2} \cup I_{(n+1)/2}$ if n is odd), F increases from $-\infty$ to a maximum value of zero at $\pi/2$ and then decreases back to $-\infty$. The behavior on the other intervals is dictated by the fact that F is even around $\pi/2$. Thus if $p \ge n$, there is one real solution of (60) on each of the intervals I_k, $0 \le k \le n/2 - 1$, and $n/2 + 1 \le k \le n$. If p is smaller than zero, there is one real solution of (60) on each of the intervals I_k, $1 \le k \le n/2 - 1$, and $n/2 + 1 \le k \le n - 1$ and two in the center interval(s) ($I_{n/2}$ if n is even, $I_{(n-1)/2} \cup I_{(n+1)/2}$ if n is odd). This accounts for all n solutions for θ (provided we add in the additional solution $\theta = \pi/2$ if n is odd). As $|p|$ gets large ($\alpha\beta \to -d^2$), these solutions approach $\theta_m = (2m-1)\pi/(2n)$, as expected.

Now suppose that $0 \le p < n$. First, if $1 < p < n$, there is one real solution of (60) on each of the intervals I_k, $1 \le k < n/2 - 1$, and $n/2 + 1 \le k \le n - 1$. By adding in

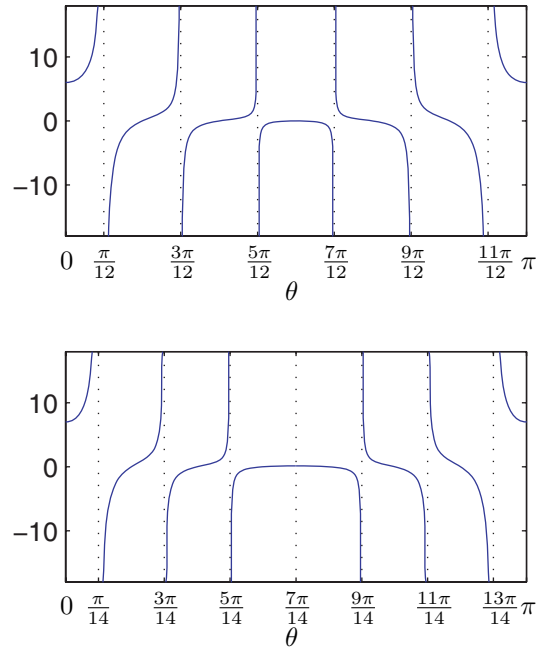

FIG. 6. *The function* $\theta \mapsto \tan(n\theta)/\tan(\theta)$, $\theta \in [0, \pi]$, *for an even case,* $n = 6$ *(top), and an odd case,* $n = 7$ *(bottom). The intervals* I_k, $0 \le k \le n$, *are demarcated by the dotted vertical lines.*

the solution $\theta = \pi/2$ if n is odd, this accounts for $n-2$ real solutions for θ. However, a pair of complex solutions $\theta = iy$ and $\theta = \pi + iy$ exist, since both of these values for θ, when substituted into (60), yield

$$\frac{\tanh(ny)}{\tanh(y)} = p, \tag{61}$$

which has a unique solution y^*, with $y^* > 0$, when $1 < p < n$. (The plot of $\tanh(ny)/\tanh(y)$ is similar to that depicted in the top panel of Figure 5 but with maximum value n rather than $2n+1$.) It is impossible to have $d \neq 0$ and $p = 1$, and, since we have dealt with $\alpha\beta = d^2$ previously, we have assumed that $p \neq 0$; however, we have not yet dealt with the case $0 < p < 1$. As p increases through zero, two real roots annihilate each other at $\pi/2$, and we therefore substitute $\theta = \pi/2 + iy$ into (60) yielding

$$\frac{\tanh(ny)}{\coth(y)} = p. \tag{62}$$

The function on the left side of (62) is plotted in Figure 7, where we note that there are two solutions $\pm y^*$ for each value of $p \in (0, 1)$. These two solutions for y correspond to two distinct values θ in R and a pair of eigenvalues λ given by

$$\lambda = b \pm i2d\sinh(y^*).$$

If b and d are real, these are a complex conjugate pair.

3.2.4. $(\alpha + \beta)/d$ and $\alpha\beta/d^2$ are real. If the matrix parameters d, α, and β are such that the quantities $(\alpha + \beta)/d$ and $\alpha\beta/d^2$ are real, then we can conclude

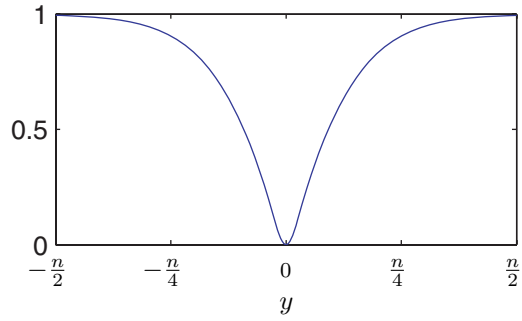

FIG. 7. *The function* $y \mapsto \tanh(ny)/\coth(y)$.

that there are at least $n-2$ real solutions to (20) and provide sufficient conditions under which n real solutions exist. We shall assume that $\alpha\beta \neq d^2$ since that case was previously discussed.

The quantities $(\alpha+\beta)/d$ and $\alpha\beta/d^2$ are both real if and only if either both α/d and β/d are real or they are complex conjugates, which we may express as one of the following two options:

1. $\alpha = sd$, $\beta = td$, $s, t \in \mathbb{R}$,
2. $\alpha = (s+it)d$, $\beta = (s-it)d$, $s, t \in \mathbb{R}$.

Thus the manifold of points that we are considering is four-dimensional. Note that we have not restricted ourselves to the situation where the matrix is real, although that case is included as part of option 1 above.

Denote the left side of (20) (or equivalently the left side of (50)) as $T(\theta)$, so that the necessary and sufficient condition for θ is $T(\theta) = 0$. From (20) and (16) we have

$$\begin{aligned} T(0) &= (n+1) + \frac{\alpha+\beta}{d}n + \frac{\alpha\beta}{d^2}(n-1) \\ &= \left(1 + \frac{\alpha+\beta}{d} + \frac{\alpha\beta}{d^2}\right)n + \left(1 - \frac{\alpha\beta}{d^2}\right) \end{aligned}$$

and

$$\begin{aligned} T(\pi) &= (1-)^n(n+1) + (-1)^{n-1}\frac{\alpha+\beta}{d}n + (-1)^{n-2}\frac{\alpha\beta}{d^2}(n-1) \\ &= (-1)^n\left[\left(1 - \frac{\alpha+\beta}{d} + \frac{\alpha\beta}{d^2}\right)n + \left(1 - \frac{\alpha\beta}{d^2}\right)\right]. \end{aligned}$$

Evaluating T at $\theta = m\pi/n$, $1 \leq m < n$, via (50) immediately gives

$$T\left(\frac{m\pi}{n}\right) = (-1)^m\left(1 - \frac{\alpha\beta}{d^2}\right).$$

Since we are assuming that $\alpha\beta \neq d^2$, the continuous function T alternates sign at the points $m\pi/n$, $1 \leq m < n$. This immediately implies that there are $n-2$ real roots of T, one in each of the intervals $K_2, K_3, \ldots, K_{n-1}$. The interval K_1 will contain an additional root provided $T(0)$ is zero or has opposite sign from $T(\pi/n)$, that is, $T(0)/T(\pi/n) \leq 0$. This can be expressed as

$$\frac{1 + \frac{\alpha+\beta}{d} + \frac{\alpha\beta}{d^2}}{1 - \frac{\alpha\beta}{d^2}} \geq -\frac{1}{n}. \tag{63}$$

Analogously, the interval K_n will contain an additional root provided

$$\frac{1-\frac{\alpha+\beta}{d}+\frac{\alpha\beta}{d^2}}{1-\frac{\alpha\beta}{d^2}} \geq -\frac{1}{n}. \tag{64}$$

The inequalities (63) and (64) are sufficient conditions for a root to exist in K_1 or K_n, respectively. However, it is possible that two roots exist in one of these intervals if both inequalities fail to hold.

Substituting $\theta = iy$ or $\theta = \pi + iy$, $y \in \mathbb{R}$, into (50) yields the equivalent condition

$$\frac{\tanh(ny)}{\sinh(y)}\left[\frac{1+\frac{\alpha\beta}{d^2}}{1-\frac{\alpha\beta}{d^2}}\cosh(y) \pm \frac{\frac{\alpha+\beta}{d}}{1-\frac{\alpha\beta}{d^2}}\right] = -1, \tag{65}$$

where the + sign is for $\theta = iy$ and the − sign for $\theta = \pi + iy$. The function $y \to \tanh(ny)(X\cosh(y)+Z)/\sinh(y)$ has limiting values of $n(X+Z)$ and X as y tends to 0 and ∞, respectively. However, it is not necessarily monotonic on $y > 0$. Nonetheless, since it is continuous, we can conclude the following. If -1 lies between the values

$$n\left(\frac{1+\frac{\alpha+\beta}{d}+\frac{\alpha\beta}{d^2}}{1-\frac{\alpha\beta}{d^2}}\right) \qquad \text{and} \qquad \frac{1+\frac{\alpha\beta}{d^2}}{1-\frac{\alpha\beta}{d^2}},$$

there will be at least one solution of (65) in the form $\theta = iy$, $y \in \mathbb{R}$. If -1 lies between the values

$$n\left(\frac{1-\frac{\alpha+\beta}{d}+\frac{\alpha\beta}{d^2}}{1-\frac{\alpha\beta}{d^2}}\right) \qquad \text{and} \qquad \frac{1+\frac{\alpha\beta}{d^2}}{1-\frac{\alpha\beta}{d^2}},$$

there will be at least one solution of (65) in the form $\theta = \pi + iy$, $y \in \mathbb{R}$. (Note that either of the two values in each of the above pairs may be the smaller one, depending on d, α, and β.)

4. Conclusion. The eigenvalues of the tridiagonal matrix A given by (1) are of the form $\lambda_m = b+2d\cos(\theta_m)$, where θ_m are the solutions to the nonlinear equation (20) in the region R defined by (21). The corresponding eigenvectors are given by (24).

The space of matrix parameters d, α, and β is $\mathbb{C}^3$, which can be identified with $\mathbb{R}^6$. Restriction to a number of two-dimensional manifolds in this space permits explicit solutions of (20), and these cases were itemized. In addition, the four-dimensional manifold of points $\alpha\beta = d^2$ also yields explicit solutions, and these were given. Information about the distribution of eigenvalues was also described for several other three- and four-dimensional manifolds. Many of these were cases where (20) could be separated into the form $F(\theta) = p(d, \alpha, \beta)$, where F is a certain ratio of trigonometric functions of multiples of θ and p is real-valued. In most of these cases, this equation has either n real roots or $n-1$ real roots and one complex root, but the corresponding eigenvalues are all real (assuming that b and d are also real). In one case, $\alpha+\beta = 0$, a single complex conjugate pair of eigenvalues is possible if $0 < (\alpha\beta-d^2)/(\alpha\beta+d^2) < 1$. The four-dimensional manifold of points specified by the requirement that both the quantities $(\alpha+\beta)/d$ and $\alpha\beta/d^2$ be real was shown to yield at least $n-2$ real eigenvalues for A. Sufficient conditions for when the remaining two eigenvalues are also real were provided. This case includes the case where the matrix A is real to begin with.

Efficient numerical algorithms exist, based on the QR factorization, for the computation of the eigenvalues of general tridiagonal matrices [2]. The nonlinear equation (20) we have presented here would generally need to be solved with a root-finding

algorithm to find the θ_m in the region R, which may or may not be as efficient as the QR-based algorithms. However, the various special cases that we have enumerated provide additional information on the distribution of the solutions θ_m, specifying various subintervals of $[0, \pi]$ wherein exactly one solution must lie. Within these subintervals, more refined estimates of the locations of solutions are often easily obtained by plotting the appropriate function F described herein and noting where it crosses the value of p.

Tridiagonal matrices frequently occur in applications where it is desirable to know their eigenvalues. As just one example, consider a simple Markov process with n states arranged in a chain formation where $x_i(t)$ is the probability of being in state i at time t, $i = 1, \ldots, n$. Let a be the rate at which a particle moves to the right (from state i to state $i+1$) and c the rate at which a particle moves to the left through the states:

$$x_1 \underset{c}{\overset{a}{\longleftrightarrow}} x_1 \underset{c}{\overset{a}{\longleftrightarrow}} x_2 \cdots x_{n-1} \underset{c}{\overset{a}{\longleftrightarrow}} x_n. \tag{66}$$

Such systems are commonly employed as models or parts of models for ion channel gating [1]. The governing system is

$$x' = Ax, \tag{67}$$

where A is given by (1) with $b = -a - c$, $d = \sqrt{ac}$, $\alpha = -c$, and $\beta = -a$. From (40) we immediately conclude that the eigenvalues are

$$\lambda_m = -(a + c) + 2\sqrt{ac}\cos\left(\frac{m\pi}{n}\right), \quad 1 \le m < n, \qquad \lambda_n = 0.$$

From (7), (45), and (46), the corresponding eigenvectors are

$$v_j^{(m)} = \left(\frac{a}{c}\right)^{(j-1)/2}\left[\sin\left(\frac{jm\pi}{n}\right) - \sqrt{\frac{c}{a}}\sin\left(\frac{(j-1)m\pi}{n}\right)\right], \quad 1 \le j \le n,\ 1 \le m < n,$$

and

$$v_j^{(n)} = \left(\frac{a}{c}\right)^{(j-1)/2}\left[\sin(j\theta_n) - \sqrt{\frac{c}{a}}\sin\big((j-1)\theta_n\big)\right], \qquad 1 \le j \le n,$$

where $\theta_n = \arccos\left((a + c)/2\sqrt{ac}\right)$.

ACCELERATION TECHNIQUES FOR APPROXIMATING THE MATRIX EXPONENTIAL OPERATOR*

M. POPOLIZIO† AND V. SIMONCINI‡

Abstract. In this paper we investigate some well-established and more recent methods that aim at approximating the vector $\exp(A)v$ when A is a large symmetric negative semidefinite matrix, by efficiently combining subspace projections and spectral transformations. We show that some recently developed acceleration procedures may be restated as preconditioning techniques for the partial fraction expansion form of an approximating rational function. These new results allow us to devise a priori strategies to select the associated acceleration parameters; theoretical and numerical results are shown to justify these choices. Moreover, we provide a performance evaluation among several numerical approaches to approximate the action of the exponential of large matrices. Our numerical experiments provide a new, and in some cases, unexpected picture of the actual behavior of the discussed methods.

1. Introduction.

In this paper we are interested in the numerical approximation of the action of the matrix exponential to a vector, namely

$$y = \exp(A)v,$$

when the real $n \times n$ matrix A is large and symmetric negative semidefinite. In the following we assume that $\|v\| = 1$, where $\|\cdot\|$ denotes the Euclidean norm. We investigate some well-established and more recent methods that aim at approximating the vector y by efficiently combining subspace projections and spectral transformations. We refer the reader to [29] for a more complete recent survey.

Two apparently distinct classes of approaches have been discussed in literature when A is large and sparse. In the first type of strategy, the matrix is projected onto a possibly much smaller space, the exponential is then applied to the reduced matrix, and finally the approximation is projected back to the original large space. If H and e denote the projected and restricted versions of A and v, respectively, then this process can be summarized as follows:

$$y \approx V \exp(H)e,$$

where the columns of V form a basis of the projection space; see, e.g., [14], [15], [16], [23], [31], [32], [33], [34], [41]. In particular, van den Eshof and Hochbruck have recently devised an acceleration method based on a spectral transformation, which appears to significantly reduce the dimension of the approximation space without sacrificing accuracy and efficiency [41].

In the second class of methods, the exponential function is first approximated by an appropriate simpler function, and then the action of this matrix function is evaluated; see, e.g., [4], [8], [10], [27], [29], [31]. To this end, a special role is played by rational function approximation to the exponential; see, e.g., [3], [9], [11], [40]. Let $\mathcal{R}_\nu$ be such a rational function, so that $\mathcal{R}_\nu(A)v \approx \exp(A)v$, and assume that $\mathcal{R}_\nu$ admits the following partial fraction expansion:

$$\exp(A)v \;\approx\; \mathcal{R}_\nu(A)v = \omega_0 v + \sum_{j=1}^{\nu} \omega_j (A - \xi_j I)^{-1} v. \tag{1.1}$$

In this approach, an approximation to y can be obtained by first solving the shifted linear systems appearing in the sum, and then by collecting the sum terms; see, e.g., [4], [20]. The computation of the system solutions can be either carried out by a direct method, or, if memory requirements become unacceptable, by iterative methods such as Krylov subspace solvers [35]. In particular, some of these methods can fully exploit the recent developments in iterative linear system solvers; see, e.g., [39].

In this paper we argue that the distinction between the two aforementioned categories is in fact very vague, and that increased understanding can be gained by exploiting both viewpoints.

The aim of this paper is twofold. On the one hand, we show that the acceleration method by van den Eshof and Hochbruck cited above may be restated as a preconditioning technique of the rational function approximation in (1.1) when the exponential is replaced by an approximating rational function. In addition, we show that another recently proposed method (see [1]) may also be viewed as a preconditioning technique for appropriately solving the shifted systems in (1.1). These new results allow us to devise a priori strategies to select the associated acceleration parameters; our completely algebraic analysis complements proposed selections based in some cases (cf. [41]) on the [illegible] approximation of the solution to analytic problems; numerical results are shown to justify our choices.

Available comparisons of different schemes in the two categories above are very limited; see, e.g., [37]. Our second aim is to provide a performance evaluation among several numerical approaches to approximate the exponential, therefore filling a gap in the recent literature. Our numerical experiments show that the ranking of the methods changes significantly depending on whether linear systems can be solved by a direct method. In particular, our numerical findings highlight the competitiveness of the simple partial fraction expansion form in (1.1) over newly developed acceleration procedures when appropriate iterative methods are used. On the other hand, in the case when direct methods are applicable, ad hoc and acceleration techniques, such as (shift-invert) Lanczos, are superior to the partial fraction expansion method.

This paper is organized as follows. Section 2 reviews the role of rational functions in the matrix exponential context and recalls the notation and basic facts associated with the approximation in the Krylov subspace. Section 3 discusses an acceleration method based on the shift-invert Lanczos (SI), while section 3.1 provides a theoretical justification of the parameter selection in the shift-invert step. Some theoretical and computational guidelines for the method are reported in sections 3.2 and 3.3, respectively. Section 4 discusses a second acceleration method, and a cheaper strategy is proposed to deal with the acceleration matrix. The associated parameter is analyzed in section 4.1, where a theoretical justification for its selection is provided; some implementation improvements are discussed in section 4.2. Section 5 and its subsections report on our numerical experience with all analyzed methods. Finally, section

6 presents further experiments with enhanced implementations of the discussed acceleration procedures, while section 7 summarizes our final conclusions.

Throughout this paper we assume that the spectrum of A, $\mathrm{spec}(A)$, is contained in the interval $[\alpha, 0]$, for some $\alpha < 0$. This is not a restrictive assumption. Indeed, if $\mathrm{spec}(A) \subset [\alpha, \beta]$, with $\beta < 0$, then the spectrum of $A_1 = A - \beta I$ is contained in $[\alpha - \beta, 0]$ and $\exp(A) = \exp(A_1)\exp(\beta)$. Therefore the behavior of $\exp(A)$ can be recovered from that of $\exp(A_1)$. As we shall see, standard procedures are particularly slow for large values of $\|A\| = |\alpha|$, and thus in the context of acceleration procedures, our main interest will be in large $\|A\|$. Throughout our analysis we assume to work in exact arithmetic and we refer to the paper by Druskin, Greenbaum, and Knizhnerman [12] for an analysis of Krylov subspace methods for matrix functions in finite precision arithmetic.

2. Rational function approximation and Krylov subspaces. Let $\mathcal{R}_\nu(z) = \mathcal{N}_\nu(z)/\mathcal{D}_\nu(z)$ be a rational function approximating the exponential function, with $\mathcal{N}_\nu, \mathcal{D}_\nu$ polynomials of degree ν. When $\mathcal{R}_\nu$ is the rational Chebyshev function it holds (see [9] and references therein) that

$$\sup_{\lambda \geq 0} |\exp(-\lambda) - R_\nu(\lambda)| \approx 10^{-\nu},$$

which implies a similar estimate for $\|\exp(A)v - R_\nu(-A)\|$ when A is symmetric and negative semidefinite. Due to this nice approximation property, Chebyshev rational functions are commonly employed to approximate $\exp(A)v$ when A has a wide spectrum.

Let (1.1) be the partial fraction expansion of $\mathcal{R}_\nu$; note that Chebyshev rational functions have distinct poles, so that (1.1) can be correctly employed in this case. Since A is real, the poles in (1.1) come in complex conjugates; therefore we can write[1]

$$\mathcal{R}_\nu(A)v = \omega_0 v + \sum_{\substack{j=1 \\ j \text{ odd}}}^{\nu-1} 2\Re\left(\omega_j (A - \xi_j I)^{-1} v\right) + \omega_\nu (A - \xi_\nu I)^{-1} v, \tag{2.1}$$

where ξ_ν denotes the real pole if ν is odd.

When dealing with large dimension problems, the shifted systems can be solved by means of iterative methods. The simplified quasi-minimal residual (QMR) method [18] can be used to obtain an approximation to $x^{(j)} = (A - \xi_j I)^{-1} v$ separately for each j. The method is an appropriately refined version of the non-Hermitian Lanczos algorithm, which exploits the (shifted) complex symmetric form of the coefficient matrix to devise a single short-term recurrence. Preconditioning can be successfully applied to this variant as long as the preconditioner is also complex symmetric. We refer to this approach as PFE+QMR in our numerical experiments of section 5.2. An alternative choice is to use the single Krylov subspace $K_k(A, v) = \mathrm{span}\{v, Av, \ldots, A^{k-1}v\}$ as the approximation space. Assuming a zero initial solution approximation, for each j the kth iterate $x_k^{(j)}$ belongs to $K_k(A - \xi_j I, v) = K_k(A, v)$, where the last equality

[1] The use of Chebyshev functions implies a change of sign of the coefficient matrix in $\mathcal{R}_\nu(-A)$ and in its partial fraction expansion. If ζ denotes a Chebyshev pole, then the system to be solved is $(-A - \zeta I)x = v$, which is equivalent to $(A - \xi I)x = -v$, with $\xi = -\zeta$. In the following we omit specifying this change, and in practice, it is sufficient to change each pole's sign when Chebyshev approximation is used.

is due to the shift invariance of Krylov subspaces. Then the linear combination

$$x_k = \omega_0 v + \sum_{j=1}^{\nu} \omega_j x_k^{(j)} \in K_k(A, v) \tag{2.2}$$

is an approximation to $\mathcal{R}_\nu(A)v$. To speed up convergence without loosing the shifted form, it is possible to precondition all systems with the same matrix, say $(A - \tau I)^{-1}$ with $\tau > 0$, namely

$$(A - \tau I)^{-1}(A - \xi I)x = (A - \tau I)^{-1}v, \tag{2.3}$$

for an appropriate selection of a single τ for all poles. The matrix $(A-\tau I)^{-1}(A-\xi I)$ is known as a Cayley transformation in the eigenvalue context; see, e.g., [2]. Interestingly enough, this preconditioning approach has not appeared to have been investigated explicitly in this context, possibly because of the requirement to solve systems with the (real) matrix $A-\tau I$. We show in section 3 that this is precisely what the recently proposed method in [33], [41] performs when the exponential is replaced by a rational function. In section 4 we also show that the method in [1] amounts to solving (2.3) by first resorting to the normal equation and then applying a conjugate gradient (CG) method.

A seemingly different approach consists of approximating the operation $\exp(A)v$ by projecting the problem onto a subspace of a possibly much smaller dimension. Krylov subspaces have been extensively explored to this purpose, due to their favorable computational and approximation properties; see, e.g., [14], [15], [16], [20], [24], [25], [43]. Let $V_k = [v_1, \ldots, v_k]$ be an $n \times k$ matrix whose orthonormal columns span $K_k(A, v)$. The vectors v_i, $i = 1, \ldots, k$, can be generated by means of the following Lanczos recurrence:

$$AV_k = V_{k+1}H_{k+1,k} = V_k H_k + h_{k+1,k} v_{k+1} e_k^T, \qquad v = V_k e_1, \tag{2.4}$$

where e_i is the ith column of the identity matrix of a given dimension, e_k^T is the transpose of e_k, and $H_k = V_k^T A V_k$, $H_k = (h_{ij})$ is a symmetric tridiagonal matrix. An approximation to $x = \exp(A)v$ may be obtained as

$$x_k = V_k \exp(H_k) e_1. \tag{2.5}$$
