We shall refer to this approximation as the "standard Lanczos" method. For $k \ll n$, the procedure projects the matrix problem onto the much smaller subspace $K_k(A, v)$, so that $\exp(H_k)$ can be cheaply evaluated with techniques such as scaling and squaring Padé [22]. The quality of the approximation strongly depends on the spectral properties of A and on the ability of $K_k(A, v)$ to capture them. Typically, convergence starts taking place after a number of iterations at least as large as $\|A\|^{1/2}$ [24]. A first characterization of the approximation was given by Saad in [34, Theorem 3.3], where it is shown that $V_k \exp(H_k)e_1$ represents a polynomial approximation $p(A)v$ to $\exp(A)v$, in which the polynomial p of degree $k-1$ interpolates the exponential in the Hermite sense on the set of eigenvalues of H_k. Other polynomial approximations have been explored; see, e.g., [13], [33].

It is important to realize that the partial fraction expansion and the Krylov subspace approximation may be related in a natural way whenever the exponential is replaced by a rational function. In such a situation, the two approaches may coincide

if, for instance, a Galerkin method is used to obtain the approximate solutions $x_k^{(j)}$. More generally, using (2.5) we can write

$$(2.6)\quad \left|\, \|\exp(A)v - x_k\| - \|\exp(A)v - V_k\mathcal{R}_\nu(H_k)e_1\|\,\right| \le \|\left(\exp(H_k) - \mathcal{R}_\nu(H_k)\right)e_1\|\,.$$

If $\mathcal{R}_\nu$ accurately approximates the exponential, then the two approaches that employ x_k and $V_k\mathcal{R}_\nu(H_k)e_1$ evolve similarly as the Krylov subspace dimension increases; see, e.g., the discussion in [19]. The behavior just described could justify the use of the partial fraction expansion in place of the standard method, especially if acceleration procedures can be determined to efficiently approximate each system solution. In fact, this is the unifying argument of the results in this paper.

3. The shift-invert Lanczos method. In [32] and independently in [41], the authors have proposed a technique for accelerating the standard Lanczos approximation to functions such as the exponential. The method is closely related to the shift-invert technique for eigenvalue problems and consists of first applying the Lanczos recurrence to the matrix $(I - \sigma A)^{-1}$, for some $\sigma \in \mathbb{R}$, $\sigma > 0$, and starting vector $v_1 = v$, $\|v\|$ is the 2-norm of v. giving

$$(3.1)\qquad (I - \sigma A)^{-1}V_m = V_m T_m + \beta_m v_{m+1} e_m^T.$$

An approximation to $y = \exp(A)v$ is then obtained as

$$(3.2)\qquad y_{SI} := V_m \exp((I - T_m^{-1})/\sigma)e_1.$$

The procedure in [32], [41] was tailored to general analytic functions f, and thus is perfectly applicable to the case of rational functions. For $f = \mathcal{R}_\nu$, in the next proposition we describe the shift-invert algorithmic procedure by means of a partial fraction expansion of $\mathcal{R}_\nu$. This allows us to analyze the selection of the shift parameter in [32], [41] for $f = \mathcal{R}_\nu$, that is, in terms of rational functions.

PROPOSITION 3.1. [illegible] $\mathcal{R}_\nu$ [illegible] $\mathcal{R}_\nu(z) = \omega_0 + \sum_{j=1}^{\nu} \omega_j/(z - \xi_j)$ [illegible] $\sigma > 0$ [illegible] y_{SI} [illegible] $y = \mathcal{R}_\nu(A)v$ [illegible] (3.2) [illegible] $\mathcal{R}_\nu$ [illegible] $y_{prec} = \omega_0 v + \sum_{j=1}^{\nu} \omega_j x_m^{(j)}$ [illegible] j $x_m^{(j)}$ [illegible] $x^{(j)} = (A - \xi_j I)^{-1}v$ [illegible] $K_m((A - \frac{1}{\sigma}I)^{-1}(A - \xi_j I), v)$ [illegible] $y_{SI} = y_{prec}$ [illegible]. When the exponential is replaced by $\mathcal{R}_\nu$ in (3.2), y_{SI} can be written as

$$(3.3)\qquad y_{SI} = V_m \left(\omega_0 e_1 + \sum_{j=1}^{\nu} \omega_j \left(-\frac{1}{\sigma} T_m^{-1} + \left(\frac{1}{\sigma} - \xi_j \right) I \right)^{-1} e_1 \right).$$

On the other hand, y_{prec} is obtained as $y_{prec} = \omega_0 v + \sum_{j=1}^{\nu} \omega_j x_m^{(j)}$, where each $x_m^{(j)}$ approximates $x^{(j)} = (A - \xi_j I)^{-1}v$. For $j = 1, \ldots, \nu$, we multiply by $(A - \frac{1}{\sigma}I)^{-1}$ the system $(A - \xi_j I)x^{(j)} = v$ from the left, that is

$$(3.4)\qquad \left(A - \frac{1}{\sigma} I \right)^{-1} (A - \xi_j I) x^{(j)} = \left(A - \frac{1}{\sigma} I \right)^{-1} v,$$

so that $(I + (\frac{1}{\sigma} - \xi_j)(A - \frac{1}{\sigma}I)^{-1})x^{(j)} = (A - \frac{1}{\sigma}I)^{-1}v$. We then determine $x_m^{(j)}$ by using a Galerkin procedure in $K_m((A - \frac{1}{\sigma}I)^{-1}(A - \xi_j I), v)$. Note that this space would not be the "natural" space for a standard Galerkin procedure, which would instead use

$K_m((A-\frac{1}{\sigma}I)^{-1}(A-\xi_j I),(A-\frac{1}{\sigma}I)^{-1}v)$, for left preconditioning. Due to the shift invariance of Krylov subspaces, it holds that

$$K_m\left(\left(A-\frac{1}{\sigma}I\right)^{-1}(A-\xi_j I),v\right)=K_m\left(\left(A-\frac{1}{\sigma}I\right)^{-1},v\right).$$

Moreover, relation (3.1) can be scaled as

$$\left(A-\frac{1}{\sigma}I\right)^{-1}V_m=-V_m\sigma T_m-\sigma\beta_m v_{m+1}e_m^T. \tag{3.5}$$

Therefore, let $x^{(j)}\approx x_m^{(j)}\in K_m((A-\frac{1}{\sigma}I)^{-1},v)$ with $x_m^{(j)}=V_m z_m^{(j)}$. Imposing the Galerkin condition on the residual vector yields

$$V_m^T\left(I+\left(\frac{1}{\sigma}-\xi_j\right)\left(A-\frac{1}{\sigma}I\right)^{-1}\right)V_m z_m^{(j)}=V_m^T\left(A-\frac{1}{\sigma}I\right)^{-1}V_m e_1.$$

Taking into account (3.5), we obtain

$$\left(I-\left(\frac{1}{\sigma}-\xi_j\right)\sigma T_m\right)z_m^{(j)}=-\sigma T_m e_1,$$

or, equivalently, $(-\frac{1}{\sigma}T_m^{-1}+(\frac{1}{\sigma}-\xi_j)I)z_m^{(j)}=e_1$. We have thus shown that

$$y_{prec}=V_m\left(\omega_0 e_1+\sum_{j=1}^{\nu}\omega_j\left(-\frac{1}{\sigma}T_m^{-1}+\left(\frac{1}{\sigma}-\xi_j\right)I\right)^{-1}e_1\right),$$

which is the same as (3.3). ∎

The previous proposition shows that when applied to a rational function, the shift-invert procedure is mathematically equivalent to a Galerkin procedure for the shifted systems involving the poles, appropriately preconditioned with the same matrix $(A-\frac{1}{\sigma}I)$. We will use this insightful relation to derive an automatic selection of the acceleration parameter σ.

3.1. Selecting the acceleration parameter. The effectiveness of the described scheme strongly depends on the choice of the acceleration parameter. In [41], an analysis is performed to select an optimal parameter at each iteration m, and the actual values are tabulated (cf. Table 3.1) by [illegible] evaluating the quantity

$$E_{m-1}^{m-1}(\sigma):=\inf_{r\in\Pi_{m-1}^{m-1}}\sup_{t\geq 0}|r(t)-\exp(-t)|,$$

where $\Pi_i^j=\{p(t)(1+\sigma t)^{-i}\,|\,p\in\Pi_j\}$ and Π_j is the space of polynomials of degree j or less. We stress that the inf-sup problem above depends on m, the iteration index. Our fully algebraic analysis aims to overcome this difficulty by resorting to rational functions in place of exp. Practical guidelines on how to use the tabulated values without varying the parameter at each iteration are also given in [41]. In [30], the author essentially conforms to this strategy. In both cases the employed arguments are tied to the theoretical analysis performed in [36].

TABLE 3.1
Some of the tabulated values in [41] *of the shift-invert parameter. m is the number of SI iterations.*

m	$E_m^m(\sigma_{opt})$	σ_{opt}	m	$E_m^m(\sigma_{opt})$	σ_{opt}
2	$2.0 \cdot 10^{-2}$	$4.93 \cdot 10^{-1}$	12	$1.6 \cdot 10^{-6}$	$1.19 \cdot 10^{-1}$
4	$3.1 \cdot 10^{-3}$	$1.75 \cdot 10^{-1}$	14	$2.5 \cdot 10^{-7}$	$8.64 \cdot 10^{-2}$
6	$4.0 \cdot 10^{-4}$	$1.91 \cdot 10^{-1}$	16	$4.0 \cdot 10^{-8}$	$8.67 \cdot 10^{-2}$
8	$6.5 \cdot 10^{-5}$	$1.90 \cdot 10^{-1}$	18	$6.6 \cdot 10^{-9}$	$6.78 \cdot 10^{-2}$
10	$9.7 \cdot 10^{-6}$	$1.19 \cdot 10^{-1}$	20	$1.1 \cdot 10^{-9}$	$6.82 \cdot 10^{-2}$

The result of Proposition 3.1 leads us to analyze the influence of the parameter σ with a completely different strategy, namely by studying its role in the preconditioned system (2.3), that is,

$$\left(I + \left(\frac{1}{\sigma} - \xi_j\right)\left(A - \frac{1}{\sigma}I\right)^{-1}\right) x^{(j)} = \left(A - \frac{1}{\sigma}I\right)^{-1} v. \tag{3.6}$$

In the rest of this section we omit the dependence of ξ_j and $x^{(j)}$ on j. Moreover, without loss of generality (cf. (2.1)), we consider only the complex poles with positive imaginary part.

We start by observing that the eigenvalues of the coefficient matrix are given by $\hat{\lambda} = 1 + (\frac{1}{\sigma} - \xi)/(\lambda - \frac{1}{\sigma})$, where λ is an eigenvalue of A; this means that the $\hat{\lambda}$'s lie on a line of the complex plane. Assuming that $\frac{1}{\sigma} - \xi \neq 0$ and dividing by $(\frac{1}{\sigma} - \xi)$, we obtain

$$\left(\left(A - \frac{1}{\sigma}I\right)^{-1} - \chi I\right) x = \tilde{v}, \quad \text{with} \quad \chi = \frac{1}{\xi - \frac{1}{\sigma}}, \tag{3.7}$$

and $\tilde{v}$ defined accordingly. The eigenvalues of the coefficient matrix lie on the horizontal line $(\hat{x}, y_0)$ with

$$y_0 := \frac{\Im(\xi)}{|\frac{1}{\sigma} - \xi|^2}, \quad \text{and} \quad \hat{x} \in \left[-\frac{1}{\frac{1}{\sigma}} + \frac{\frac{1}{\sigma} - \Re(\xi)}{|\frac{1}{\sigma} - \xi|^2}, \frac{1}{\alpha - \frac{1}{\sigma}} + \frac{\frac{1}{\sigma} - \Re(\xi)}{|\frac{1}{\sigma} - \xi|^2}\right].$$

The assumption $\frac{1}{\sigma} - \xi \neq 0$ is not restrictive: If $\frac{1}{\sigma} = \xi$ for some (real) ξ, then from (3.6) it follows that the system solution associated with that pole is readily obtained, and the analysis need not be performed.

The coefficient matrix in (3.7) is given by a real negative definite symmetric matrix shifted by a complex multiple of the identity. It was shown in [17], [27] that in this case the performance of Krylov subspace methods may be fully characterized by using spectral information of the coefficient matrix. Therefore, estimates for the optimal parameter σ may be obtained by analyzing the spectrum of $((A - \frac{1}{\sigma}I)^{-1} - \chi I)$ as σ changes. To this end, we recall here the following bound for the linear system error in our notation.

PROPOSITION 3.2 (see [27, Lemma 5.2]). [illegible] $(\widetilde{A} - \chi I)x = \tilde{v}$ [illegible] $\widetilde{A}$ [illegible] $\chi \in \mathbb{C}$, [illegible] x_m [illegible] $K_m(\widetilde{A}, \tilde{v})$ [illegible] $\lambda_{\max}, \lambda_{\min}$ [illegible] $\widetilde{A} - \Re(\chi)I$ [illegible]

$$||x - x_m|| < g(\lambda_{\min}, \lambda_{\max}, \tilde{v}, \chi)\ \frac{1}{\rho^m + 1/\rho^m},$$

... g ... $\widetilde{A}, \tilde{v}$ ... χ ... $\rho = \gamma + \sqrt{\gamma^2 - 1}$ ...

$$\gamma = \frac{|\lambda_{\min} - i\Im(\chi)| + |\lambda_{\max} - i\Im(\chi)|}{|\lambda_{\min} - \lambda_{\max}|}.$$

The proposition above shows that the larger γ, the faster the convergence in terms of the subspace dimension m. We recall that $\mathrm{spec}(A) \subset [\alpha, 0]$ with $\alpha < 0$. In our context, we can apply the result above both to the original partial fraction expansion approximation, as well as to the preconditioned system (3.6). In the former case, setting $\widetilde{A} = A$ and $\chi = \xi$, we obtain

$$\gamma(\xi) = \frac{|\alpha - \xi| + |\xi|}{-\alpha}. \tag{3.8}$$

In the preconditioned case, setting $\widetilde{A} = (A - \frac{1}{\sigma} I)^{-1}$ and $\chi = 1/(\xi - \frac{1}{\sigma})$, after simple algebraic manipulations, we get

$$\gamma^{prec}(\xi, \sigma) = \frac{(\frac{1}{\sigma} - \alpha)|\xi| + \frac{1}{\sigma}|\alpha - \xi|}{-\alpha|\frac{1}{\sigma} - \xi|}. \tag{3.9}$$

The expression in (3.8) shows that for $|\alpha| \gg |\xi|$, the error bound predicts very slow convergence of the linear system, as in this case $\gamma \approx 1$. It is desirable that a well-chosen σ make $\gamma^{prec}(\xi, \sigma)$ much larger than $\gamma(\xi)$, so as to significantly improve the convergence rate. An ideal value of σ would satisfy something like

$$\min_{\xi} \gamma^{prec}(\xi, \sigma) \geq \max_{\xi} \gamma(\xi),$$

to ensure faster convergence for all poles. However, this inequality turned out to be hard to analyze. Nonetheless, it is possible to relate the two convergence coefficients. To simplify the notation, in the rest of this section we use

$$\tau := \frac{1}{\sigma},$$

and, with some abuse of notation, we use $\gamma^{prec}(\xi, \tau)$. We have

$$\gamma^{prec}(\xi, \tau) = F(\alpha, \xi, \tau)\gamma(\xi), \tag{3.10}$$

where

$$F(\alpha, \xi, \tau) = \frac{\tau}{|\tau - \xi|} - \frac{\alpha|\xi|}{(|\alpha - \xi| + |\xi|)|\tau - \xi|} = \frac{\tau - c}{|\tau - \xi|}, \tag{3.11}$$

with $c = \alpha|\xi|/(|\alpha - \xi| + |\xi|)$.

The following proposition shows that, for each pole, it is possible to determine the least value of the parameter that improves convergence, and also the one that maximizes the ratio between the two convergence rates. Unfortunately, the resulting parameter depends on the given pole, and thus it may not be optimal for other poles.

PROPOSITION 3.3. ... α ... ξ ... $F(\tau) = F(\alpha, \xi, \tau)$ ... (3.11) ... ... $\Re(\xi) > \alpha/2$ ... $\Im(\xi) \neq 0$ ...

(i) $F(\tau) \geq 1$ ... $\tau \geq \tau_0$ ... $\tau_0 = \frac{1}{2} \frac{|\xi|^2 - c^2}{\Re(\xi) - c}$ ... $\Re(\xi) > c$

(ii) $F(\tau_{\max}) \geq F(\tau)$ [illegible] τ [illegible]

$$\tau_{\max} = \tau_{\max}(\xi) = \frac{\Re(\xi)c - |\xi|^2}{c - \Re(\xi)} \qquad F(\tau_{\max}) = \frac{|c-\xi|}{|\Im(\xi)|} \geq 1; \tag{3.12}$$

(iii) $\gamma^{prec}(\xi, \tau_0) = \gamma(\xi)$ [illegible] $\lim_{\tau\to\infty} \gamma^{prec}(\xi, \tau) = \gamma(\xi)$

[illegible]. Let $\xi = \xi_R + \imath\xi_I$. We first show that $\xi_R > c$. Since $c < 0$, then clearly $\xi_R > c$ when $\xi_R \geq 0$. For $\xi_R < 0$, using $\alpha < 2\xi_R$ we obtain $\alpha|\xi| < 2\xi_R|\xi| \leq \xi_R|\xi| \leq \xi_R(|\xi| + |\alpha - \xi|)$, from which

$$\xi_R > \frac{\alpha|\xi|}{|\xi| + |\alpha - \xi|} = c.$$

To prove (i), we observe that

$$F(\tau) \geq 1 \qquad \Leftrightarrow \qquad 2(\xi_R - c)\tau \geq |\xi|^2 - c^2. \tag{3.13}$$

Using $\xi_R > c$, the previous requirement corresponds to imposing $\tau \geq \tau_0$.

To prove (ii) we explicitly write

$$F'(\tau) = -\frac{(\tau - \xi_R)}{|\tau - \xi|^3}(\tau - c) + \frac{1}{|\tau - \xi|} = 0 \quad \Leftrightarrow \quad -(\tau - \xi_R)(\tau - c) + |\tau - \xi|^2 = 0,$$

from which the expression for $\tau_{\max}$ follows. Moreover, F is an increasing function for $\tau \leq \tau_{\max}$ and a decreasing one otherwise, so that $F(\tau_{\max})$ is a maximum.

To prove that $F(\tau_{\max}) \geq 1$ we notice that $F(\tau_{\max})^2 = 1 + (c - \xi_R)^2/\xi_I^2$, from which we obtain that $(F(\tau_{\max}) - 1)(F(\tau_{\max}) + 1) = \frac{(c-\xi_R)^2}{\xi_I^2}$. The result follows by taking into account that

$$F(\tau_{\max}) + 1 = \frac{|\xi_I| + |c - \xi|}{|\xi_I|}.$$

Finally, the first equality in (iii) follows from $F(\tau_0) = 1$ in (3.13), while it can be readily verified that $\lim_{\tau\to\infty} F(\tau) = 1$. ∎

In light of Proposition 3.3(i), one could restrict the choice of the parameter τ to the interval $[\tau_0, \infty[$. However, (iii) indicates that values of the parameter that are too close to the extremes of this interval do not accelerate convergence; see similar conclusions in [30]. The hypothesis that $\Re(\xi) > \alpha/2$ is crucial; otherwise $F(\tau) \geq 1$ only for $\tau < 0$. The only (unlikely) exception is $\xi = \alpha/2 \in \mathbb{R}$, in which case $F(\tau) \geq 1$ for any nonnegative τ. On the other hand, for the values of α of interest, $|\alpha| \gg |\xi|$, and thus the hypothesis $\Re(\xi) > \alpha/2$ is clearly verified. It is also important to notice that for $|\alpha| \gg |\xi|$ it follows that $\tau_{\max} \approx |\xi|$, indicating the obvious fact that, for each pole ξ, the best real parameter is related to the pole itself.

Although quite sharp, the results above still depend on the spectrum of A through α and do not provide a simple way to select a good single parameter for all poles. To complete our understanding, we thus look for a quantity that well represents the behavior of γ^{prec}, especially for large $|\alpha|$. To this end, we observe that $-c \leq |\xi|$, so that $F(\xi, \tau) \leq \frac{\tau+|\xi|}{|\tau-\xi|}$. The bound is sharp for $|\alpha| \gg |\xi|$, that is, $\gamma(\xi) \approx 1$, in which case $c \approx -|\xi|$. The quantity $\mathcal{H}(\tau, \xi) := \frac{\tau+|\xi|}{|\tau-\xi|} \geq 1$ also appears explicitly in the following lower bound for γ^{prec}:

$$\gamma^{prec}(\tau, \xi) = \frac{\tau}{|\tau - \xi|}\gamma(\xi) + \frac{|\xi|}{|\tau - \xi|} \geq \frac{\tau}{|\tau - \xi|} + \frac{|\xi|}{|\tau - \xi|} = \mathcal{H}(\tau, \xi), \tag{3.14}$$

TABLE 3.2
Values of $\mathcal{H}(\tau_i, \xi_j)$, $i, j = 1, \ldots, \nu$, for Chebyshev with $\nu = 14$ (complex conjugates are not shown).

$\tau_i = \lvert\xi_i\rvert$	ξ_1	ξ_3	ξ_5	ξ_7	ξ_9	ξ_{11}	ξ_{13}
18.8616	1.1657	1.2516	1.3564	1.4831	1.6260	1.7628	1.8515
14.1496	1.1615	1.2590	1.3905	1.5708	1.8105	2.0910	2.3111
10.9932	1.1515	1.2533	1.4010	1.6254	1.9739	2.4925	3.0433
8.7609	1.1387	1.2391	1.3924	1.6430	2.0832	2.9193	4.3218
7.2115	1.1261	1.2219	1.3727	1.6300	2.1170	3.2233	6.5221
6.2274	1.1160	1.2068	1.3520	1.6045	2.0975	3.3081	8.9488
5.7485	1.1105	1.1981	1.3391	1.5859	2.0716	3.2821	9.5758

and this estimate is again sharp when $\gamma(\xi) \approx 1$. We next analyze the behavior of $\mathcal{H}$, which does not depend on the spectrum of A, but only on the poles and on the parameter. We have

$$\mathcal{H}(\tau, \xi)^2 = 1 + 2(|\xi| + \Re(\xi))\frac{\tau}{|\tau - \xi|^2}.$$

Note that $|\xi| + \Re(\xi) \geq 0$ for any ξ, and for a given nonreal pole ξ it holds that $\frac{\tau}{|\tau-\xi|^2} \leq \frac{|\xi|}{||\xi|-\xi|^2}$, where the right-hand side is attained for $\tau = |\xi|$. Therefore, for each pole ξ_i,

$$\mathcal{H}(|\xi_i|, \xi_i) = \max_{\tau > 0} \mathcal{H}(\tau, \xi_i).$$

To take τ_i as a priori parameter for all systems, we need to make sure that this value of τ is also effective for a different pole ξ_j. Let the poles be sorted with decreasing (positive) imaginary parts. Setting $\tau_i = |\xi_i|$, we state the following discrete problem:[2]

$$\max_{\tau_1, \ldots, \tau_\nu} \min_{\xi_1, \ldots, \xi_\nu} \mathcal{H}(\tau_i, \xi_j), \tag{3.15}$$

which can be solved, once and for all, for a given class of rational functions and for each selected degree. As an example, Table 3.2 reports the values of $\mathcal{H}(\tau_i, \xi_j)$ as τ_i and ξ_j vary, for Chebyshev rational functions and $\nu = 14$ (poles are computed from the coefficients as listed in [9]). In the table, the optimal value of τ for problem (3.15) with $\nu = 14$ is given by $\tau_1 = 18.8616$, ensuring that $\gamma^{prec}(\xi, \tau) \geq \mathcal{H}(\tau_1, \xi_1) = 1.1657$. Note that, for all degrees, the best value of τ turns out to always be associated with ξ_1. Therefore, we propose to use the parameter

$$\tau_{\text{opt}} := |\xi_1| \quad \Leftrightarrow \quad \sigma_{\text{opt}} = \frac{1}{|\xi_1|}. \tag{3.16}$$

The corresponding values associated with Chebyshev rational poles are listed in Table 3.3 for $\nu \leq 20$. The entries in the table can be used as follows: If a final tolerance *tol* on the approximation of $\exp(A)v$ is requested, then the shift-invert approach may be used with a shift value corresponding to $\nu \geq -\log_{10}(tol)$ (e.g., $tol = 10^{-8}$ yields $\nu \geq 8$ so that $\sigma = 0.1062$ or a smaller value in the table may be used).

Our derivation suggests a parameter selection somehow similar to that given in [41] (cf. Table 3.1), although our justification is completely different, and it does not depend on m. This similarity may be viewed as an additional motivation for the reliability of the approach.

[2] A continuous problem in τ and ξ could also be formulated, but the unnecessary added difficulty is beyond the scope of this analysis.

TABLE 3.3
Optimal values of the parameter (cf. (3.16)*) for various rational function degrees.*

3.2. Asymptotic behavior. Our parameter selection is based on asymptotic arguments, that is, on information of the matrix spectral interval and not on the actual eigenvalue distribution. In particular, we recall that the convergence of (symmetric) linear systems often exhibits superlinear behavior, in the sense that the rate of convergence may increase as convergence takes place; see, e.g., the discussion in [39]. Such important characterization is not captured by an asymptotic analysis. Therefore, in some cases other values of the parameter may lead to better convergence than that obtained with our analytically selected choice. As an example, we consider the matrix $\widetilde{A}$ of size $n = 3375$ of Example 5.1 in section 5, whose extreme eigenvalues are $\lambda_{\min} \approx -2329.4$ and $\lambda_{\max} \approx -22.597$, and we define the singular matrix $A = \widetilde{A} - \lambda_{\max} I$. We study the performance of the accelerated process with the optimal parameter $\sigma_{\rm opt} = 0.053$ and with another possible candidate, $\sigma_{\min} = 1/\max_j |\Re(\xi_j)| = 0.1124$, taken for $\nu = 14$ poles. The vector v is taken as a normalized vector of all ones. Figure 3.1 shows the convergence curves of the SI procedure with A and the two parameters (lower solid and dashed curves), showing a slightly better performance of $\sigma_{\min}$ over $\sigma_{\rm opt}$; this is not predicted by our theory. However, our arguments better describe the behavior of the $n \times n$ diagonal matrix D (middle solid and dashed curves), whose nonzero entries are [illegible] values in the same spectral interval as A. The vector v is unchanged. In this case, the convergence slope is steeper when using $\sigma_{\rm opt}$ than with $\sigma_{\min}$. The upper curves show the convergence rate predicted by the asymptotic quantity $\mathcal{H}(1/\sigma, \xi_1)^j$, $j = 1, \ldots, m$, for $\sigma = \sigma_{\rm opt}$ (filled squares) and $\sigma = \sigma_{\min}$ (circles). Note that both curves well represent the initial convergence phase of the shift-invert

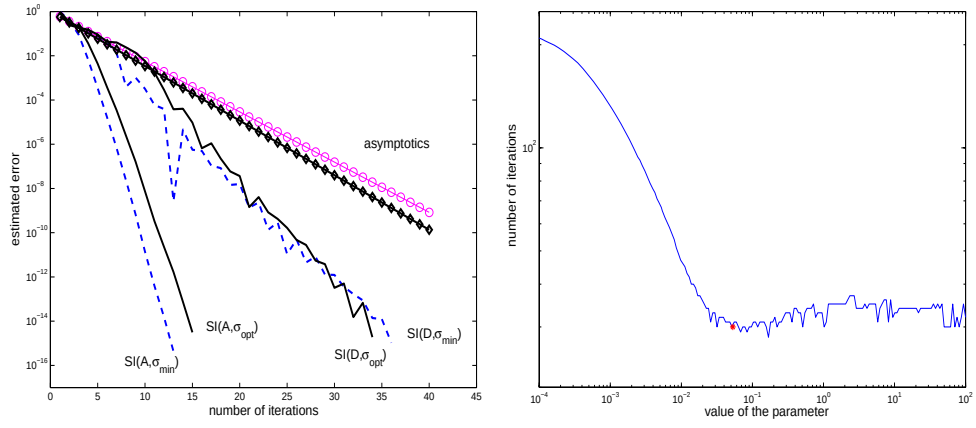

FIG. 3.1. *Left: Convergence history of SI for a matrix stemming from a shifted Laplace operator and for a diagonal matrix D with uniformly distributed eigenvalues in* $\mathrm{spec}(A)$. *Here* $\sigma_{\rm opt} = 0.053$ *and* $\sigma_{\min} = 0.1124$. *Also reported are the asymptotic values* $\mathcal{H}(1/\sigma, \xi_1)^j$, $j = 1, \ldots, m$, *for* $\sigma_{\min}$ *(circles) and* $\sigma_{\rm opt}$ *(filled squares). Right: Number of iterations of SI applied to the diagonal matrix D versus value of the shift σ; the symbol "*" refers to the choice* $\sigma = \sigma_{\rm opt}$.

procedure with D, with a slightly better performance for $\mathcal{H}(1/\sigma_{\text{opt}}, \xi_1)$. To fully appreciate the performance of the choice $\sigma = \sigma_{\text{opt}}$ with the matrix D, in the right plot of Figure 3.1 we display the number of iterations of SI to achieve the required stopping threshold, as the value of the parameter varies in $[10^{-4}, 10^2]$; the symbol "*" refers to the choice $\sigma = \sigma_{\text{opt}}$. Note that the performance of the method is not overly sensitive to overshooting values of σ (and this conforms to the tabulated values in Table 3.1), but it may considerably degrade if σ is chosen too small. In particular, the plot shows that a typical practical value suggested in [41, section 6], namely $\sigma = 0.01$, would force the method to perform more iterations on this matrix.

3.3. Implementation details. The algorithmic aspects of the shift-invert procedure were described in [41]. A possible implementation generates the matrix V_m one vector at a time by means of the Lanczos algorithm (see, e.g., [21]) and the corresponding elements of the tridiagonal matrix T_m in (3.1). It is important to observe that convergence at high accuracy is often obtained for a small approximation space, so that little memory is required to store V_m. The difficulties associated with the approximate solutions with $I - \tau A$ are also treated in [41].

A crucial part in the overall procedure is how to monitor convergence, since the error norm is not available. Although the analysis of stopping criteria is beyond the scope of this paper, we need to face this problem to avoid premature termination; we refer to [19] for a recent analysis and an accurate estimation of the error norm for the approximation of various rational matrix operators. With the notation of (3.5), a classical stopping criterion is given by the quantity

$$t_{m+1,m} |e_m^T \exp((I - T_m^{-1})/\sigma) e_1|, \tag{3.17}$$

which is cheaply available during the computation; in the case of standard Lanczos, using (2.5) the criterion above reduces to $h_{k+1,k} |e_k^T \exp(H_k) e_1|$. It is known that for m very small, this quantity may highly underestimate the true error; cf. the (red) dash-dotted curve of Figure 3.2. In our experiments of sections 5 and 6, for the first few iterations we replace the absolute estimate of the error with a relative quantity, until this falls below a safeguard parameter set to 10^{-2}. In the case of (3.17), this

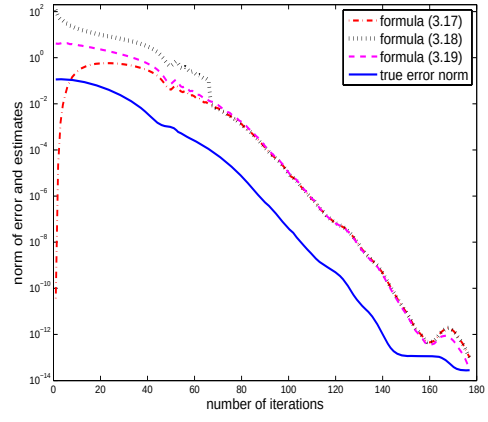

FIG. 3.2. *Convergence history of standard Lanczos and different error estimates. The safeguard parameter for* (3.18) *is equal to* 0.1 *(see text).*

quantity reads as

$$t_{m+1,m}|e_m^T \exp((I - T_m^{-1})/\sigma)e_1|/|e_1^T \exp((I - T_m^{-1})/\sigma)e_1|. \tag{3.18}$$

In practice, this somewhat conservative safeguard procedure is maintained until the components of the approximation vector $\exp((I - T_m^{-1})/\sigma)e_1$ take the expected exponential pattern; see [26]. The reported values in the figure refer to the approximation of $\exp(0.1A)v$, where A is the 4900×4900 matrix stemming from the two-dimensional (2D) Laplace operator with Dirichlet homogeneous boundary conditions, v is the normalized vector of all ones, and the safeguard parameter is equal to 0.1. In Figure 3.2 we also report the behavior of the higher-order estimate (for standard Lanczos)

$$t_{k+1,k}|e_k^T \varphi_1(H_k)e_1|, \quad \varphi_1(z) = \frac{\exp(z) - 1}{z}, \tag{3.19}$$

which was also proposed in [34]. We observe that this estimate seems to cure the problem given by the lower-order estimate in (3.17). In practice, whenever $e_k^T \exp(H_k)e_1$ is too small, so that (3.17) is unreliable, it holds that $|e_k^T \varphi_1(H_k)e_1| \approx |e_k^T H_k^{-1} e_1|$. From Figure 3.2 it is clear that both the safeguard strategy and the higher-order criterion allow one to safely continue the iteration until true convergence takes place. In our experiments we used (3.18) because it is in general cheaper to compute than (3.19). We refer to [12], [19], [27], [34] for further considerations and for higher-order stopping criteria.

4. Application of a real-valued method for solving linear systems. In this section we increase our understanding of a method recently proposed by Axelsson and Kucherov in [1], for solving complex symmetric systems by means of a formulation that only uses real arithmetic computation. The method can be used in our context when a partial fraction expansion of a rational function approximation is employed, as described in section 2. We show that the method can be derived using our preconditioning framework. Moreover, we propose a variant that makes the overall procedure significantly more efficient.

We first briefly recall the main steps of the approach. Given the complex system

$$(R + \imath S)u = b, \tag{4.1}$$

with $u = u_R + \imath\, u_I$ and $b = b_R + \imath\, b_I$, the proposed procedure uses the real form

$$\begin{pmatrix} R - \eta S & \sqrt{1+\eta^2}S \\ \sqrt{1+\eta^2}S & -R - \eta S \end{pmatrix} \begin{pmatrix} u_R \\ z \end{pmatrix} = \begin{pmatrix} b_R \\ (b_I - \eta b_R)/(\sqrt{1+\eta^2}) \end{pmatrix},$$

where $\eta > 0$ is a real parameter and $z = (\eta u_R - u_I)/\sqrt{1+\eta^2}$. The Schur complement reduction provides the following linear system for u_R

$$Cu_R = w \tag{4.2}$$

with $C = R - \eta S + (1+\eta^2)S(R + \eta S)^{-1}S$ and $w = b_R + S(R + \eta S)^{-1}(b_I - \eta b_R)$. The imaginary part, u_I, may be computed by using the relation $R\, u_R - S\, u_I = b_R$. It is shown in [1] that under certain hypotheses on S and R, it is possible to derive an optimal choice of η so that the matrix $B = R + \eta S$ is an effective preconditioner for the system (4.2).

In our context, the complex symmetric system to be solved is $(A-\xi I)u = v$ for a fixed pole $\xi = \xi_R + \imath\xi_I$. Therefore, we have $R = A - \xi_R I$ and $S = -\xi_I I$. Substituting in the coefficient matrix of the system (4.2) we obtain

$$C = -B + 2\eta\,\xi_I\, I - (1+\eta^2)\xi_I^2 B^{-1},$$

where the preconditioner becomes $B = -(R+\eta S) = (\xi_R + \eta\,\xi_I)I - A$, and the preconditioned system reads

$$Mu_R = B^{-1}w, \quad \text{with} \quad \begin{aligned} M &= B^{-1}C = -I + 2\eta\xi_I B^{-1} - \xi_I^2(1+\eta^2)B^{-2}, \\ w &= v - \eta\,\xi_I B^{-1} v. \end{aligned} \tag{4.3}$$

Moreover, $u_I = \frac{1}{\xi_I}(-A+\xi_R I)u_R + \frac{1}{\xi_I}v$. Therefore, for each pole ξ, the original complex symmetric system is transformed into the real (preconditioned) system (4.3), which needs to be solved by an iterative method. We next show in Proposition 4.1 that the matrix $-M$ is symmetric positive definite for any choice of $\eta > 0$ and for all poles, and thus the conjugate gradient method can be used. Moreover, we show that the system (4.3) resulting from the procedure outlined above is nothing but the real part of the normal equation of (2.3) for a special choice of the acceleration parameter.

PROPOSITION 4.1. [illegible] u_R [illegible] $Mu_R = B^{-1}w$ (4.3) [illegible] $\tau = \xi_R + \eta\,\xi_I$, $\eta > 0$, [illegible] the real part of the normal equation

$$(\tau I - A)^{-1}(A - \xi I)u = (\tau I - A)^{-1}v,$$

[illegible] $K = (\tau I - A)^{-1}(A - \xi I)$ [illegible] $M = -K^*K \in \mathbb{R}^{n\times n}$ [illegible] u_R [illegible] $K^*Ku = K^*(\tau I - A)^{-1}v$ [illegible]. Let $R = A - \xi_R I$ and $S = -\xi_I I$, and note that R and S commute so that

$$\begin{aligned} K^*K &= (R+\eta S)^{-2}(R - iS)(R + iS) = (R+\eta S)^{-2}(R^2 + S^2) \\ &= I + 2\eta\xi_I(R+\eta S)^{-1} + \xi_I^2(1+\eta^2)(R+\eta S)^{-2} = -M. \end{aligned}$$

Therefore, K^*K is real symmetric and M is negative definite. Analogously, we can write $K^*(\tau I - A)^{-1}v = (R+\eta S)^{-2}(R - iS)v$ whose real part is given by $\Re(K^*(\tau I - A)^{-1}v) = (R+\eta S)^{-2}Rv = (R+\eta S)^{-1}w$. Therefore, the real part of the equation $K^*Ku = K^*(\tau I - A)^{-1}v$ is given by $-M\Re(u) = -B^{-1}w$, from which it follows that $u_R = \Re(u)$. ∎

The original implementation in [1] provided an optimal parameter τ for each shifted system to be solved, yielding a different acceleration matrix $(\tau I - A)^{-1}$ for each pole. The authors suggested using $\tau = \tau(\xi_j) = |\xi_j|$, for $A - \xi_j I$ having definite symmetric real part. This condition is not satisfied in our case, since $\Re(\xi_j)$ may be either positive or negative. In the next section we show how to select a single τ for all systems, so as to lower the computational costs.

A completely different preconditioning strategy could also be adopted. The use of an optimal preconditioner $(\tau I - A)$ with $\tau = \tau(\xi)$ would be feasible if it were possible to update the factorization for different shifts without recomputing the factors from scratch; see the results in [6] in this direction for linear system preconditioning.

4.1. Selecting the acceleration parameter. In this section we derive a single quasi-optimal positive parameter τ, from which, according to the relation $\tau = \xi_R + \eta\xi_I$, a different η follows for each system in (4.3). Therefore, while M differs for each shifted system, the matrix $B = \tau I - A$ is the same for all shifts.

Proposition 4.1 shows that M is symmetric and negative definite for any $\eta > 0$. Similar conclusions were derived in [1, Remark 1]. The next proposition provides sharp bounds for the condition number of M with no further hypotheses on $A - \xi I$.

PROPOSITION 4.2. [illegible] 4.1 [illegible] $\tau > \max\{0, \Re(\xi)\}$ [illegible]

$$\text{cond}(M) \le \max\left\{\frac{|\xi|^2}{\tau^2}, \frac{|\alpha-\xi|^2}{(\alpha-\tau)^2}\right\}\frac{|\tau-\xi|^2}{\xi_I^2}. \tag{4.4}$$

[illegible] $\tau \le |\xi|$ [illegible] $\frac{|\alpha-\xi|^2}{(\alpha-\tau)^2} \le \frac{|\xi|^2}{\tau^2}$ [illegible]

$$\text{cond}(M) \le \frac{|\xi|^2}{\xi_I^2}\frac{|\tau-\xi|^2}{\tau^2}. \tag{4.5}$$

[illegible]. Writing $-M = (R+\eta S)^{-2}(R^2+S^2) = (R-\eta\xi_I I)^{-2}(R^2+\xi_I^2 I)$, we get

$$\text{spec}(-M) = \left\{\frac{(\lambda-\xi_R)^2+\xi_I^2}{(\lambda-\tau)^2}\middle|\lambda \in \text{spec}(A)\right\}.$$

For $\lambda \in [\alpha, 0]$, let $\mu \in \text{spec}(-M)$, $\mu = g(\lambda) = \frac{\lambda^2-2\lambda\xi_R+|\xi|^2}{(\lambda-\tau)^2}$. We have

$$g'(\lambda) = 2\frac{\lambda(\xi_R-\tau)+\tau\xi_R-|\xi|^2}{(\lambda-\tau)^3} = 0 \quad \Leftrightarrow \quad \hat{\lambda} := \frac{\tau\xi_R-|\xi|^2}{\tau-\xi_R}.$$

Since $\tau > \xi_R$, it holds that $g'(\lambda) > 0$ only for $\lambda > \hat{\lambda}$; hence

$$g(\hat{\lambda}) = \frac{\xi_I^2}{|\tau-\xi|^2} \le \mu \quad \forall \mu \in \text{spec}(-M). \tag{4.6}$$

To derive an upper bound, we notice that, since $\hat{\lambda}$ is the only critical point and it is associated with a minimum, the maximum of g in $[\alpha, 0]$ is given by $\max\{g(\alpha), g(0)\}$. Collecting this bound and (4.6), the bound (4.4) for $\text{cond}(M)$ follows.

We next assume that $\tau \le |\xi|$ holds for all poles ξ. We write

$$g(\alpha) - g(0) = \frac{\alpha^2(\tau^2-|\xi|^2) - 2\alpha\tau(\xi_R\tau-|\xi|^2)}{\tau^2(\tau-\alpha)^2}.$$

For $\tau \le |\xi|$ the first addend in the numerator of the last expression is negative. For the second addend, we separately treat the cases of positive and negative pole's real part. If $\xi_R < 0$, then the second addend gives $-2\alpha\tau(\xi_R\tau - |\xi|^2) \le 0$. If $\xi_R > 0$, then we can get $-2\alpha\tau(\xi_R\tau-|\xi|^2) \le -2\alpha\tau(\tau^2-|\xi|^2) \le 0$. We have thus shown that $g(\alpha) - g(0) \le 0$, which completes the proof. ∎

The bound in (4.4) may be rather sharp. Its sharpness depends on whether the extremes of the function g defined in the proof are attained. Table 4.1 reports the bound in (4.4) for the 125×125 matrix obtained by the discretization of the three-dimensional (3D) Laplacian with homogeneous boundary conditions, shifted so as to have zero largest eigenvalue. The poles correspond to the Chebyshev rational approximation of degree $\nu = 14$. We used $\tau_{\text{opt}} = \min_{j=1,\ldots,\nu}|\xi_j| = 5.7485$; see below for an explanation of this choice.

TABLE 4.1
Condition number of $M = M(\xi_j)$ and its upper bound in (4.4), as the poles vary.

ξ_j ($\nu = 14$)	cond(M)	Estim.	ξ_j ($\nu = 14$)	cond(M)	Estim.

To derive a single parameter τ for all poles ξ, we study the bound in (4.5), which does not depend on the spectrum of A. We will see that for the Chebyshev approximation it is possible to derive a single parameter that satisfies $\tau \leq |\xi|$.

Let $W_\xi(\tau) = \frac{|\tau-\xi|^2}{\tau^2}$ be the part of the upper bound in (4.5) that depends on τ. It can be verified that $W_\xi(\tau)' = -\frac{2}{\tau^3}(-\tau\Re(\xi) + |\xi|^2)$, so that

$$W_\xi(\tau)' = 0 \quad \Leftrightarrow \quad \tau_*(\xi) = \Re(\xi) + \frac{\Im(\xi)^2}{\Re(\xi)} = \frac{|\xi|^2}{\Re(\xi)}.$$

If $\Re(\xi) < 0$, then $W_\xi(\tau_*)$ is a maximum and $\tau_*(\xi)$ is negative. We thus restrict our attention to the poles with positive real parts.[3] Moreover, we observe that, for $\tau > \tau_*$ and $\Re(\xi) < 0$, the function W_ξ is decreasing, so that the larger τ, the smaller the bound for $\Re(\xi) < 0$. We then recall that for (4.5) to hold, the selected parameter τ must satisfy

$$\Re(\xi) \leq \tau \leq |\xi| \quad \forall \xi.$$

Let the poles be sorted as $\Re(\xi_1) \leq \cdots \leq \Re(\xi_\nu)$. Then $\tau_*(\xi_\nu) \geq \Re(\xi_j)$ for $j \leq \nu$, and we define

$$\tau_{\text{opt}} := \min\left\{ \min_{j=1,\ldots,\nu} |\xi_j|, \tau_*(\xi_\nu) \right\}. \tag{4.7}$$

For the Chebyshev poles it holds that $\min_{j=1,\ldots,\nu} |\xi_j| = |\xi_\nu|$ so that

$$\tau_{\text{opt}} = |\xi_\nu|.$$

In Figure 4.1 we report the total number of conjugate gradient iterations required by the method to solve all systems $Mu_R = \hat{w}$ (see Algorithm AK), for different values of the parameter $\tau \in [0, 7]$. The data are as in Example 5.1 and $\nu = 8$. The symbol "*" indicates the number of iterations for the choice $\tau = \tau_{\text{opt}}$, showing the high quality of the a priori selected parameter.

The analysis above conforms with the multiple choice in [1], although in our case extremely fast convergence cannot be achieved for ,, shifted systems. It is also interesting that, as opposed to the shift-invert procedure, the pole with the , ,, , modulo is selected as the optimal parameter.

4.2. Implementation details. The real-valued method for approximating $y = \exp(A)v$ can be summarized as follows. For simplicity and without loss of generality, we take here a rational function of even degree. For odd degree rational approximation, the real shifted system corresponding to the real pole can be solved explicitly without resorting to the method discussed previously.

[3] We recall that in the case of Chebyshev approximation, poles are used with the opposite sign.

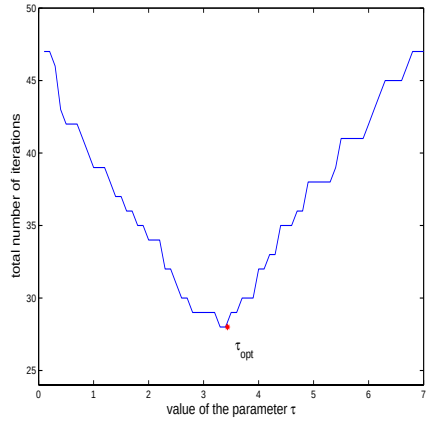

FIG. 4.1. *Total number of iterations for the variant of the Axelsson–Kucherov method, as a function of the parameter τ. The symbol "*" refers to the number of iterations for $\tau = \tau_{\text{opt}}$.*

ALGORITHM AK.

Given A, v, $\xi_1, \ldots, \xi_\nu$, $\omega_1, \ldots, \omega_\nu$

(i) Choose a parameter $\tau > 0$.

(ii) Set $B = \tau I - A$; $w_1 = B^{-1}v$; $w_2 = B^{-1}w_1$.

(iii) For each pole $\xi_j = \xi_R + \imath\xi_I$, $j = 1, 3, 5, \ldots, \nu - 1$:

- Solve $Mu_R = \widehat{w}$ with $M = -I + 2(\tau - \xi_R)B^{-1} - |\tau - \xi|^2 B^{-2}$ and $\widehat{w} = +w_1 - (\tau - \xi_R)w_2$.
- Compute $u_I = \frac{1}{\xi_I}(-Au_R + \xi_R u_R + v)$.
- Set $x_j = u_R + \imath u_I$.

(iv) Compute $y_{AK} = \omega_0 v + 2 \sum_{\substack{j=1 \\ j \text{ odd}}}^{\nu-1} \Re(\omega_j x_j)$.

As already mentioned, the solution of $Mu_R = \widehat{w}$ is performed iteratively, as M should not be explicitly computed but only applied in products such as $y = Mx$, as is the case in conjugate gradient methods. Each matrix-vector multiplication with M requires solving two systems with $B = \tau I - A$, and this is related to the fact that M is the coefficient matrix of the normal equation.

The final attainable accuracy of the overall computation depends primarily on the rational function used, but also on the accuracy with which the linear systems of step (iii) are solved. This requires the stopping tolerance to be smaller than the accuracy requested; in our experiments we noticed that $tol = 10^{-\nu-2}$ delivered a sufficiently accurate final solution to the exponential. No further study was attempted to refine this value.

We consider solving systems with B with both a direct and an iterative method. In the former case, the cost of factorizing the single matrix B is performed once for all systems. This provides significant computational savings over the original method in [1], a sample of which is reported in Table 4.2. In the table we compare the original method, where an optimal $B = B(\tau)$ is determined and factorized for each pole, with Algorithm AK, where a single suboptimal B is computed and factorized at step (ii) of the algorithm. The numbers show that the new strategy improves performance,

especially on large problems, while the total number of iterations does not significantly grow, compared to the optimal shift selection in [1]. The results in the table were obtained by using a direct method for solving the involved inner linear systems. Additional numerical experiments, not reported here, with iterative solves confirmed the superiority of our new approach even in this inner-outer setting.

In the case an iterative solver is used, one is faced with the problem of efficiently solving two systems with B at each iteration of the solver with M. By exploiting the positive definiteness of B, we consider the following alternatives: (a) two calls to the conjugate gradients in sequence; (b) two calls to preconditioned CGs in sequence; (c) one call to a variant of the CG method proposed by van der Vorst in [43] to

simultaneously solve for B and B^2 with a single recurrence. The CPU times obtained for the problems of Examples 5.1 and 5.2 are reported in Table 4.3.

The numbers show that the variant that simultaneously approximates the systems with B and B^2 is faster than both the standard CG method and its preconditioned version. It is important to notice that in the approach proposed in [43] preconditioning is not applicable; nonetheless, its performance is superior to that of standard preconditioned CG applied twice. We should mention that when using the approach in [43], one could employ a different (optimal) B for each shifted system at no additional cost. We decided to maintain Algorithm AK for consistency with the case of the direct solves.

5. Numerical experiments. In this section we report on our numerical experience with the discussed methods, which we summarize as follows:

- (PFE). Computation of (2.1) by explicitly solving each complex symmetric system. Systems corresponding to conjugate pairs are coupled.
- . Classical Lanczos approach described in section 2; see, e.g., [34].
- (AK). Variant of method by Axelsson and Kucherov described in section 4.
- (SI). Acceleration procedure described in section 3 [41].

When using methods that explicitly rely on the partial fraction expansion, namely PFE and AK, the final accuracy influences the number of terms in the expansion, and thus the number of shifted systems to be solved. In our implementation of the shift-invert procedure, the parameter selection is also guided by the required accuracy; cf. Table 3.3. In general, this is not strictly necessary, and one could choose σ as the optimal parameter associated with an approximation of large degree, say $\nu = 14$.

Since the error norm cannot be explicitly monitored, stopping criteria were introduced as discussed in previous sections. In the small examples, however, we computed the actual error and verified that a satisfactory tolerance was reached, achieving the required order of magnitude for the absolute error norm. It should be mentioned that the solution norm influences the stopping criterion. Indeed, depending on the spectrum of A, the vector $\exp(A)v$ may have a very small norm, which makes a loose stopping tolerance completely useless, yielding an approximate solution with no digit accuracy. In all problems considered, the vector $\exp(tA)v$ with $t = 0.1$ had a norm not smaller than 10^{-4}.

All methods except the standard Lanczos procedure require solving real or complex shifted systems. In all of these cases, such a step employs over 95% of the total computational efforts, so that it is really the only bottleneck of these methods. In the next two subsections we report results when solving these systems by either a direct or an iterative method, yielding in this latter case an inner-outer procedure.

All numerical experiments of this section were performed in MATLAB [28], version 7.0.1 (R14-SP1), and CPU timings were obtained with the function `cputime`. We like to mention that different CPU time performance was observed when using different MATLAB versions or releases, which in some cases significantly affected the comparison among the methods.

5.1. Using direct methods. In this section, we report our experiments when a direct method is used to solve with $(A-\xi_j I)$ or $(\tau I - A)$. When dealing with the symmetric and positive definite matrix $(\tau I - A)$, the Cholesky factorization is performed, after a reordering of the matrix entries (MATLAB function `symamd`). Permutation sig-

nificantly improves the overall cost of solving with the shifted matrix (both the factorization and the solution phases). In the following, the matrix is always reordered, and the reported timings include the factorization cost. The LU decomposition without pivoting the complex symmetric matrix $(A - \xi_j I)$ yields a (symmetric) LDL^T factorization. After reordering, the number of (now complex) nonzero entries is the same as for the real factor. We emphasize, however, that in the case of the PFE, the complex system solutions were carried out by means of the MATLAB backslash operation "\", which is significantly faster than the two-step procedure of first factorizing the matrix and then solving with the factors.

In all tables, the number of iterations for standard Lanczos and for SI coincides with the dimension of the generated Krylov subspace. For AK, the number in parentheses is the global number of iterations performed to solve all shifted systems with $M = M(\xi_j)$. The stopping tolerance $tol = 10^{-\nu}$ is fixed for all codes. Methods employing the rational function approximation thus use the corresponding function degree ν.

5.1. We consider the $n \times n$ matrix stemming from the finite difference discretization of the 3D Laplace operator on the unit cube and Dirichlet homogeneous boundary conditions, with eigenvalues in $[-179.14, -12.862]$ for $n = 125$. Different discretization refinements are considered. These data represent a typical benchmark for the approximate evaluation of the matrix exponential in PDE contexts. We approximate the vector $\exp(tA)v$, with $t = 0.1$ and v a normalized normally distributed random vector. The elapsed time and the number of iterations (in parentheses) for various problem dimensions and final tolerances are reported in Table 5.1.

TABLE 5.1

Example 5.1. *CPU time (and number of iterations in parentheses when appropriate) for all methods when systems with shifted matrices are solved with a direct method. Different dimension problems and various stopping tolerances are reported.*

	10^{-11}	4.76 (113)	69.03	54.68 (51)	14.22 (17)
	10^{-14}	7.25 (130)	90.20	77.31 (84)	16.96 (24)

Several comments are in order. First, we observe that explicitly dealing with the PFE by means of direct solvers becomes significantly more expensive, especially for the large size matrix. Moreover, all methods behave quite consistently as the problem dimension increases, and the performance ranking is already clear for $n = 3375$.

Second, on this problem, standard Lanczos is the most efficient approach, as far as CPU time is concerned; the shift-invert procedure shows the second best performance. Memory requirements for standard Lanczos, however, become increasingly high as the number of iterations increases, since the whole basis needs to be stored. This problem may be overcome by resorting to a two-pass strategy. In the first pass, the Lanczos

basis is not stored, but only the projected solution is; in the second pass, the Lanczos basis vectors are recomputed one at a time to form the final solution; see [19] for more details. This approach drastically reduces memory needs, but requires almost twice the time to complete the computation, making the performance of the method more comparable to that of SI. For the latter method, we observe that the number of iterations does not grow (in fact, it decreases) as the problem dimension increases for the same required tolerance; see, e.g., [30], [41] for a discussion.

Third, the AK approach does not perform satisfactorily, as compared to the Lanczos methods, although its memory requirements are roughly limited to the Cholesky factor and to a few CG vectors. The number of iterations does not grow significantly as the problem dimension increases for a fixed final tolerance. We should mention that AK improves the performance of the original PFE method on the large matrix. This seems to indicate that AK may be advantageous for approximating the action of other matrix rational functions for which the standard Lanczos procedure does not show superlinear convergence. Moreover, the method's limitations are less apparent when a loose final accuracy is required, which is precisely the context suggested in the original paper [1].

In summary, this example shows that for moderately large spectra, the standard Lanczos approach is still competitive, and the analyzed acceleration procedures do not seem to significantly improve its performance. The next example faces a more extreme case for which using an acceleration procedure is mandatory.

EXAMPLE 5.2. In this example we approximate $\exp(tA)v$, $t = 0.1$, where the $n \times n$ matrix A stems from the finite difference discretization of the 2D operator

$$\mathcal{L}(u) = (a(x,y)u_x)_x + (b(x,y)u_y)_y, \qquad a(x,y) = 1 + y - x, \quad b(x,y) = 1 + x + x^2$$

on the unit square, with Dirichlet homogeneous boundary conditions [41]. Two grid refinements have been considered. The spectrum is contained in the interval $[-35424, -25.256]$ for the smaller problem. The vector v is taken as in the previous example. The CPU time and number of iterations, when appropriate, are reported in Table 5.2. This example has special features that make it very different compared to the previous one. In particular, $\|A\|$ and the spectral range are significantly large, penalizing the standard Lanczos method. Moreover, the finite difference discretization of the 2D operator generates a sparser matrix than in Example 5.1, allowing cheaper system solves. We can thus predict especially good performance of all acceleration techniques, including PFE, compared to standard Lanczos. The results in Table 5.2 fully confirm these considerations.

5.2. Using iterative methods. The use of iterative methods for solving the large linear systems provides a significantly different picture from what is shown in the previous section. In the case of AK and SI, the resulting algorithm is an inner-outer procedure. We next compare the standard Lanczos method with the following iterative procedures:

- PFE+QMR. Partial fraction expansion where each complex shifted system is solved by a preconditioned simplified QMR method [18]. The preconditioner is a complex symmetric LDL^T incomplete factorization of the shifted matrix, obtained by a simple modification of the factors computed with the MATLAB `luinc` factorization with dropping tolerance equal to 10^{-2}. The system stopping threshold is $10^{-\nu}$.
- SI+PCG. Shift-invert Lanczos where systems with $I - \sigma A$ are solved with preconditioned conjugate gradients. The MATLAB `cholinc` function with

TABLE 5.2

n	*tol*	Standard Lanczos	PFE	AK	SI
2500	10^{-5}	16 (194)	0.22	0.29 (11)	0.12 (10)
	10^{-8}	18 (200)	0.33	0.50 (27)	0.13 (11)
	10^{-11}	53 (242)	0.44	0.92 (51)	0.20 (19)
	10^{-14}	111 (280)	0.53	1.39 (84)	0.24 (24)
10000	10^{-5}	615 (406)	1.24	1.39 (9)	0.67 (11)
	10^{-8}	610 (406)	1.87	2.53 (25)	0.66 (11)
	10^{-11}	1221 (484)	2.55	4.71 (47)	0.94 (17)
	10^{-14}	- (> 500)	3.20	7.49 (82)	1.24 (23)

dropping tolerance 10^{-2} is used to generate the preconditioner. The inner system stopping threshold is $10^{-\nu}$.

- AK+Variant. We report the results of Table 4.3 of the variant of the Axelsson–Kucherov method, which solves systems with $B = \tau I - A$ and B^2 with a single iterative method. If occurring, the system with the real pole is solved with preconditioned conjugate gradients as in SI+PCG. The inner system stopping threshold is $10^{-\nu-3}$.

In SI+PCG and AK+Variant, the shifted matrix was reordered with a Cuthill–McKee permutation (MATLAB function `symrcm`) before building the preconditioner, whereas minimum degree reordering was used for PFE+QMR; see [5] for a comprehensive discussion of various permutations related to preconditioning. We should mention that, in SI, it is not necessary to solve the inner system at high accuracy but that, on the contrary, the accuracy can be relaxed as convergence takes place [41], [38]. We postpone the exploration of this alternative to the next section, where enhancement strategies for the PFE+QMR algorithm are also devised.

The CPU times for the two test problems are reported in Table 5.3 (the results for $n = 125$ are omitted). For SI+PCG and AK+Variant, the total number of outer iterations and the average number of inner iterations are shown. For PFE+QMR, the average number of iterations is also shown in parentheses. For ease of comparison, we also reproduce the CPU time of standard Lanczos from Tables 5.1–5.2.

Compared to the previous results that used a direct solver for the shifted systems, we can see that the overall costs have significantly decreased for all methods except SI. In the case of the 3D Laplace operator (Example 5.1), the standard Lanczos method remains the method of choice even after a two-step procedure, although the differences are far less prominent. For the 2D operator the solution of the shifted systems in (1.1) with an appropriately preconditioned iterative solver yields the most competitive approach, even for the small size problem. It appears that, for these examples, the two preconditioners $(A - \tau I)$, corresponding to SI and the incomplete LDL^T factorization for PFE, show comparable performance in approximating the PFE, in spite of stemming from rather different approximation strategies.

6. Further tests. In this section we explore performance enhancements for the two methods SI+PCG and PFE+QMR. All experiments in this section were carried out on one processor of a Sun Fire V40z with 2390.895 MHz and 16 GB RAM, running MATLAB 7.4. We first discuss some natural implementation improvements for both algorithms and then analyze their performance on a time-stepping problem, so as to

	10^{-14}	-	11.74 (51)	15.4 (13/37)	29.5 (95/13)

provide a more realistic framework.

As already mentioned, the inner-outer version of SI may be implemented so as to relax the accuracy with which the inner system is solved at each Lanczos iteration. Given a fixed tolerance $\epsilon > 0$, in [41, (5.4)] the following stopping tolerance η_j for the inner system was proposed:

$$\eta_j = \frac{\epsilon}{\|e_{j-1}\| + \epsilon},$$

where e_{j-1} is the error in the approximation of the exponential operator at the previous iteration, $j-1$. In practice, $\|e_{j-1}\|$ is replaced by an estimate; in our implementation we used the estimate associated with (4.9) in [41], and we fixed ϵ to be equal to the initial inner tolerance. Clearly, η_j increases towards one as $\|e_{j-1}\| \to 0$, so that the inner solver may be stopped earlier as the outer iteration converges, thus hopefully decreasing the overall computational costs. We refer to [38], [42] for a general discussion on relaxation strategies.

A straightforward enhancement for the partial fraction evaluation (hereafter PFE+QMR+mono) is to compute a single preconditioner, and then to apply it to all systems. This strategy makes the SI+PCG and the PFE+QMR methods even closer to each other, since we have shown that SI+PCG may be viewed as a special way of preconditioning the PFE systems with a single, parameter dependent matrix. Here, we take as a single preconditioner of PFE+QMR+mono the factor of the incomplete Cholesky factorization (MATLAB 7.4 function `cholinc`) with dropping tolerance 10^{-2} of the shifted complex symmetric matrix $A - \xi_1 I$, where ξ_1 is the pole with the largest imaginary part, which provided the best performance. Reordering with `symamd` of the matrix A (and of I) was performed before calling `cholinc`. The results obtained for the problem of Example 5.2 are reported in Table 6.1. The original methods PFE+QMR and SI+PCG, together with their enhanced versions, PFE+QMR+mono and SI+PCG+relax, are displayed. For SI+PCG+relax, the initial inner tolerance was

equal to the outer tolerance. The improvement over the corresponding original method is significant, reaching almost 50% for SI+PCG+relax in some instances. Note that, on this problem, the single preconditioned PFE+QMR+mono is very effective for all systems, allowing for the same average number of iterations as of the original method. In bold are the best timings, which show that the two different enhanced preconditioned techniques, PFE+QMR+mono and SI+PCG+relax, behave quite similarly. In general, timings are so close, the difference being within the MATLAB timings fluctuation that it is difficult to depict a clear winner.

We next consider the discretization of the following parabolic equation in two spatial dimensions [41]:

$$\frac{\partial}{\partial t}u = \mathcal{L}(u), \quad (x,y) \in (0,1)^2, \quad 0 \le t \le \mathbf{T}, \tag{6.1}$$

where the solution $u = u(t,x,y)$ is subject to the initial condition $u(0,x,y) = u_0(x,y)$ and to mixed boundary conditions (b.c.): homogeneous Dirichlet b.c. on the western and eastern boundaries, and homogeneous Neumann b.c. on the northern and southern boundaries of the domain. The operator $\mathcal{L}$ is as in Example 5.2. After standard centered finite difference space discretization, the solution at $t = \mathbf{T}$ is approximated by a sequence of $\mathbf{T}/\delta t$ applications of $\exp(\delta t A)$ as $\exp(\delta t A) \cdots \exp(\delta t A) u_0$, where δt is the time step length and u_0 is the initial vector. We considered different possible space and time discretizations so as to approximate the exact solution at $\mathbf{T} = 0.1$. The results of our experiments for $\delta t = 0.005, 0.01, 0.05, 0.1$ are reported in Table 6.2; u_0 is the normalized vector of all ones. The standard Lanczos and the enhanced versions of the SI and PFE methods are considered. Different final accuracies were also used, which are of interest in the context of evolution problems. All inner and outer stopping thresholds were tuned so as to reach the requested final accuracy.

The acceleration procedures allow the discretization process to take much larger time steps than with standard Lanczos, to the point that in all examples a single time step ($\delta t = 0.1$) is faster than the best Lanczos timing. This is clearly a welcome event and is one of the main reasons for using acceleration procedures in the context of parabolic equations. In addition, we explicitly observe that as the number of time steps decreases, so does the cost of the acceleration procedures, whereas that of standard Lanczos becomes unacceptably high due to the increasing value of $\|\delta t A\|$.

In PFE, the common preconditioner is computed once and for all, whereas each shifted system is solved separately. This is the major remaining drawback of the enhanced PFE+QMR method when a few time steps are performed, since many systems need to be solved. On the other hand, SI precisely avoids this step, since it constructs a single preconditioner that, in the case of a rational function, still allows one to keep the shifted form of the systems, so that all systems can be solved simultaneously with a single SI iteration as in (3.6); see also [19]. Albeit limited, our numerical experiments confirm that the relaxed SI method is able to efficiently solve the parabolic system when few time steps are taken, compared to standard Lanczos. As already noticed in the previous example, a single time step makes the generic enhanced PFE procedure more competitive. Due to these favorable results of the PFE+QMR method, it would be interesting to further explore enhancement techniques for this approach, such as those in [7].

7. Conclusions. In this paper we have presented a common framework for some recently developed acceleration techniques for approximating the action of the matrix exponential to a vector. This framework is based on the rational function approximation to the exponential, which allows one to transform the approximation problem into that of solving several algebraic linear systems. It is thus natural to compare the performance of the acceleration techniques with that of methods such as PFE that explicitly solve these systems. We can summarize our theoretical and experimental findings as follows:

(i) Whenever the exponential is replaced by its rational function approximation, we have shown that the analyzed methods SI and AK are simply different ways of preconditioning the given linear systems.

(ii) Our framework allowed us to derive an a priori fully algebraic and iteration-free selection of the involved single parameter in both methods.

(iii) We have performed a numerical comparison among various acceleration methods, including their enhanced versions, thus filling a gap in the current literature. In our opinion, these experiments provide a new perspective and new insights on when and which acceleration procedures should be preferred. The experiment on a parabolic 2D problem shows the effectiveness of the enhanced SI and PFE+QMR processes, allowing the time discretization for truly large iteration steps.

Our findings are in fact quite general. It would be interesting to see whether similar conclusions can be generalized to other functions for which a rational function approximation is available; see, e.g., [19]. The case of nonsymmetric A is also very challenging, since the rational Chebyshev approximation is not optimal in this case.

Acknowledgments. The authors would like to thank Marlis Hochbruck and Igor Moret for insightful conversations, and the two anonymous referees for their constructive criticism, which led to the addition of section 6. Finally, we are grateful to Andreas Frommer for his handling of the manuscript.

DEFLATION AND BALANCING PRECONDITIONERS FOR KRYLOV SUBSPACE METHODS APPLIED TO NONSYMMETRIC MATRICES*

YOGI A. ERLANGGA† AND REINHARD NABBEN†

Abstract. For quite some time, the deflation preconditioner has been proposed and used to accelerate the convergence of Krylov subspace methods. For symmetric positive definite linear systems, the convergence of conjugate gradient methods combined with deflation has been analyzed and compared with other preconditioners, e.g., with the abstract balancing preconditioner [R. Nabben and C. Vuik, *SIAM J. Sci. Comput.*, 27 (2006), pp. 1742–1759]. In this paper, we extend the convergence analysis to nonsymmetric linear systems in the context of GMRES iteration and compare it with the abstract nonsymmetric balancing preconditioner. We are able to show that many results for symmetric positive definite matrices carry over to arbitrary nonsymmetric matrices. First we establish that the spectra of the preconditioned systems are similar. Moreover, we show that under certain conditions, the 2-norm of residuals produced by GMRES combined with deflation is never larger than the 2-norm of residuals produced by GMRES combined with the abstract balancing preconditioner. Numerical experiments are done to nonsymmetric linear systems arising from a finite volume discretization of the convection-diffusion equation, and the numerical results confirm our theoretical results.

Key words. deflation, balancing preconditioner, nonsymmetric matrix, GMRES, convection-diffusion

1. Introduction.

For a linear system

$$Au = b, \qquad A \in \mathbb{R}^{n\times n}, \tag{1.1}$$

where A is a large but sparse nonsymmetric, nonsingular matrix, GMRES [23], among others, is a popular method to iteratively solve it. Such a system is encountered, for example, when a discretization is applied to the steady convection-diffusion equation. For starting vector u_0, GMRES constructs a sequence of vectors (called Arnoldi vectors) using Arnoldi orthogonalization [2], which forms the basis for the Krylov subspace, i.e., the subspace

$$\mathcal{K}^k(A, r_0) = \text{span}\{r_0, Ar_0, A^2r_0, \ldots, A^{k-1}r_0\}, \quad r_0 = b - Au_0. \tag{1.2}$$

The approximate solution at the kth iteration, denoted by u_k, is then contained in the affine subspace $u_0 + \mathcal{K}^k(A, r_0)$, i.e.,

$$u_k \in u_0 + \mathcal{K}^k(A, r_0). \tag{1.3}$$

In case of GMRES, u_k minimizes the 2-norm of the residual over the subspace.

In many applications, however, GMRES exhibits slow convergence. Since all Arnoldi vectors are needed during orthogonalization, slow convergence increases the

†Institut für Mathematik, TU Berlin, MA 3-3, Strasse des 17. Juni 136, D-10623 Berlin, Germany (erlangga@math.tu-berlin.de, nabben@math.tu-berlin.de).

number of Arnoldi vectors being used and stored in the computer memory. This makes GMRES often impractical. A simple remedy to the memory requirement is by restarting GMRES after j iterations, as already suggested in [23], denoted by GMRES(j) throughout. The suitable value of j, the restarting parameter, is generally not known, and an inappropriate value of j may lead GMRES to stagnation.

Morgan [15] proposed a remedy in the context of GMRES(j) by reusing information already obtained during the first j iterations. Vectors related to the converged eigenvectors available during the first j GMRES iterations are added to the subspace before restarting; thus, the subspace is [illegible]. Adding these vectors removes (or [illegible]) the corresponding (small) eigenvalues from the spectrum. Related work can also be found in [11, 9, 4]. See also [8] for a unified overview on this class of methods. Recently, these deflation techniques have been successfully used in the numerical solution of several practical problems; see, e.g., [6, 1, 5, 20, 12].

A similar idea has also been used in the context of preconditioned conjugate gradient (CG) methods for symmetric positive definite (spd) systems; see, e.g., [18, 10]. As the convergence of CG is related to the condition number of the spd linear system to solve, deflation is used to improve the condition number by shifting some of the smallest eigenvalues to zero. Since the corresponding eigenvectors no longer have components during the iterations [18], CG will converge faster. Here, we can speak of the [illegible] condition number after deflation, which is never larger than the [illegible] condition number. In [16, 17], the deflation-based preconditioner is analyzed and compared with the [illegible] form of the coarse-grid correction preconditioner [19] and the [illegible] form of the balancing preconditioner [13]. In theory, the deflation vectors are not necessarily invariant vectors and, more generally, can also be related to the prolongation matrix in the multigrid language.

It is somewhat worthwhile to extend the analysis to nonsymmetric systems. This is the aim of this paper. In addition, we compare deflation with the abstract balancing preconditioner as well. For this purpose, we define the abstract deflation preconditioners as

$$P_D = I - AZE^{-1}Y^T, \quad Q_D = I - ZE^{-1}Y^TA, \quad E = Y^TAZ, \tag{1.4}$$

where P_D and Q_D are related to the left and right preconditioners, respectively. One can easily show that P_D and Q_D are projectors, i.e., $P_D^2 = P_D$ and $Q_D^2 = Q_D$. Here, Z and Y are suitable deflation subspaces of dimension $n \times r$, where $r \ll n$, and hence E is presumably easy to compute and invert. Note that Z and Y are arbitrary matrices. We do not assume that their columns are eigenvectors or approximations of eigenvectors.

In deflation, the solution of (1.1) is computed as follows. We decompose the solution u into

$$u = (I - Q_D)u + Q_Du = ZE^{-1}Y^Tb + Q_Du. \tag{1.5}$$

As the first term on the right-hand side is easily computed, the factor Q_Du is then obtained by computing $\widetilde{u}$ from

$$P_DA\widetilde{u} = P_Db \tag{1.6}$$

and then premultiplying it by Q_D. To solve (1.6) we apply a Krylov subspace method for nonsymmetric systems, e.g., GMRES or Bi-CGSTAB [25]. In case of (1.6), however, the system is singular. A singular system can still, however, be solved as long as it is consistent (i.e., $b \in \mathcal{R}(A)$). This is actually the case for (1.6) because the

same projection is applied to both sides. Furthermore, Brown and Walker [3] noted that the least-squares problems in GMRES will give a solution without breakdown if $\mathcal{N}(A) = \mathcal{N}(A^T)$ or if $\mathcal{N}(A) \cap \mathcal{R}(A) = \{0\}$, even though $\mathcal{N}(A) \neq \mathcal{N}(A^T)$.

For symmetric systems the balancing preconditioner was proposed by Mandel [13]. It is used in domain decomposition methods and has been analyzed by several other authors in [14, 7, 22, 21, 24]. For nonsymmetric systems we consider the [illegible] balancing preconditioner of the form

$$P_B = Q_D M^{-1} P_D + Z E^{-1} Y^T, \tag{1.7}$$

with M a nonsingular and possibly nonsymmetric preconditioning matrix. For spd cases (Q_D is replaced by P_D^T in (1.7)), this preconditioner has already been compared with deflation in [17]. With respect to preconditioning with M, the deflated preconditioning system can be written as

$$M^{-1} P_D A u = M^{-1} P_D b. \tag{1.8}$$

As mentioned above, in general some assumptions have to be satisfied to guarantee that GMRES will converge for nonsingular systems. However, we will prove that GMRES applied to (1.6) and (1.8) will converge without any further assumption.

We first compare spectral properties of deflation and the balancing preconditioner. We prove that $P_B A$ and $M^{-1} P_D A$ have the same spectra except for the first r eigenvalues. With this information, bounds of GMRES convergence can be derived. These are presented in section 2. In section 3, GMRES residuals for $M^{-1} P_D A$ and $P_B A$ are compared. With a special starting vector, a relation between residuals of GMRES combined with deflation and the abstract balancing preconditioner can be established for arbitrary full ranked Z and Y. We prove that the preconditioned residual obtained by using the deflation method is less than or equal to the preconditioned residual obtained by using the abstract balancing method. Numerical examples are shown in section 4 for the convection-diffusion equation. Finally, conclusions are drawn in section 5.

2. Spectral properties and GMRES convergence bounds. In this section we evaluate spectral properties of $P_D A$ and their connections with convergence bound of GMRES, and then compare them with $P_B A$. Before doing so, we recall in the following lemma some properties related to P_D and Q_D, whose proofs are easily shown by direct computation.

LEMMA 2.1. [illegible] P_D [illegible] Q_D [illegible] (1.4) [illegible] $Z, Y \in \mathbb{R}^{n \times r}$ [illegible] r [illegible]

(i) $P_D A Z = 0$, $Y^T A Q_D = 0$
(ii) $Q_D Z = 0$, $Y^T P_D = 0$
(iii) $P_D A = A Q_D$

Next we present the convergence bound of GMRES for the unpreconditioned system $Au = b$ due to Saad and Schultz [23], along with its proof.

[illegible] 2.2. $A \in \mathbb{R}^{n \times n}$ is nonsymmetric and diagonalizable, with spectral decomposition $A = X \Lambda X^{-1}$. Here, $X = [x_1 \dots x_n]$ are right eigenvectors of A and $\Lambda = \mathrm{diag}(\lambda_1, \dots, \lambda_n)$, satisfying $A x_i = \lambda_i x_i$, $i = 1, \dots, n$. The eigenvalues λ_i are assumed to be real and nondefective, and $0 < \lambda_i < \lambda_j$ for $i < j$.

THEOREM 2.3. [illegible] A [illegible] 2.2 [illegible] k [illegible] $Au = b$ [illegible] u_0 [illegible]

$$\|r_k\|_2 \leq \kappa_2(X) \epsilon^k \|r_0\|_2, \tag{2.1}$$

... $\kappa_2(X) = \|X\|_2\|X^{-1}\|_2$ ... X, $r_0 = b - Au_0$ ...

$$\epsilon^k = \min_{p\in\mathbb{P}^k, p(0)=1} \max_{i=1,\dots,n} |p(\lambda_i)|, \tag{2.2}$$

... p ... $k-1$ ... $p(0) = 1$ ...

... Let p be a polynomial of degree no larger than $k-1$ with constraint $p(0) = 1$, and let u be a vector in $\mathcal{K}^k$ associated with the residual $b - Au = p(A)r_0$. Then, for $A = X\Lambda X^{-1}$,

$$\|b - Au\|_2 = \|p(A)r_0\|_2 = \|Xp(\Lambda)X^{-1}r_0\|_2 \le \|X\|_2\|X^{-1}\|_2\|\|p(\Lambda)\|_2\|r_0\|_2.$$

Since Λ is a diagonal matrix, $\|p(\Lambda)\|_2 = \max_{i=1,\dots,n} |p(\lambda_i)|$. Consider now u_k, extracted from $\mathcal{K}^k$ but now related to GMRES approximation. Since u_k minimizes the 2-norm of the residual over $u_0 + \mathcal{K}^k$, then for any polynomial p

$$\|b - Au_k\|_2 \le \|b - Au\|_2 \le \|X\|_2\|X^{-1}\|_2\|\|r_0\|_2 \max_{i=1,\dots,n} |p(\lambda_i)|. \tag{2.3}$$

Choosing a polynomial which minimizes the right-hand side, one has

$$\|b - Au_k\|_2 \le \|X\|_2\|X^{-1}\|_2\|\|r_0\|_2 \min_{p\in\mathbb{P}^k, p(0)=1} \max_{i=1,\dots,n} |p(\lambda_i)|,$$

leading to the theorem, with $\|X\|_2\|X^{-1}\|_2 =: \kappa_2(X)$. ∎

A further result is obtained by considering the min-max problem above as the shifted and scaled Chebyshev polynomial in the interval $[\lambda_1, \lambda_n]$,

$$\hat{C}_k(t) = \frac{C_k\left(1 + 2\frac{\lambda_1 - t}{\lambda_n - \lambda_1}\right)}{C_k\left(1 + 2\frac{\lambda_1 - \gamma}{\lambda_n - \lambda_1}\right)}, \tag{2.4}$$

with $\gamma < \lambda_1$. In this case, setting $\gamma = 0$, the constraint results in

$$\min_{p\in\mathbb{P}^k, p(0)=1} \max_{i=1,\dots,n} |p(\lambda_i)| = \min_{p\in\mathbb{P}^k, p(0)=1} \max_{\lambda\in[\lambda_1,\lambda_n]} |p(\lambda_i)| = \frac{1}{C_k\left(2\frac{\mu}{\lambda_n - \lambda_1}\right)}, \tag{2.5}$$

where $\mu = (\lambda_1 + \lambda_n)/2$. As $C_k(t)$ can alternatively be written as

$$C_k(t) = \frac{1}{2}\left[\left(t + \sqrt{t^2-1}\right)^k + \left(t + \sqrt{t^2-1}\right)^{-k}\right] \ge \frac{1}{2}\left(t + \sqrt{t^2-1}\right)^k, \tag{2.6}$$

we see, after some manipulations, that $C_k(2\mu/(\lambda_n - \lambda_1)) \ge 1 - 1/(\sqrt{\kappa} + 1)$, where $\kappa = \lambda_n/\lambda_1$. We then have the following corollary.

COROLLARY 2.4. ... A ... 2.2 ... $\kappa := \lambda_n/\lambda_1$ ... k ...

$$\|r_k\|_2 \le 2\kappa_2(X)\left(1 - \frac{2}{\sqrt{\kappa} + 1}\right)^k \|r_0\|_2. \tag{2.7}$$

This convergence bound is similar to the convergence bound of CG, except that the bound is now represented by the 2-norm of residuals. If A is spd, then $\kappa_2(X) = 1$. For more general cases, $\kappa_2(X)$ is not known and is too expensive to compute. Furthermore, $\kappa = \lambda_n/\lambda_1$ is not the condition number as usually referred to in case of spd systems. Under Assumption 2.2 we may still, however, associate κ in (2.7) with the quality of eigenvalues clustering. The smaller the value is, the more clustered the eigenvalues are.

2.1. Spectrum of deflation and balancing preconditioners. In this section we compare spectral properties of $P_D A$ and $P_B A$. For generality, we consider the deflated linear system (1.8), with M any nonsingular and possibly nonsymmetric matrix. The eigenvalues of A and $M^{-1}A$ are in general not known.

LEMMA 2.5. [illegible] A [illegible] M [illegible] Z [illegible] Y, $M^{-1}P_D A$ [illegible] $P_B A$ [illegible] r [illegible] 0 [illegible] 1 [illegible].

[illegible]. For deflation, for any $Z \in \mathbb{R}^{n\times r}$, $M^{-1}P_D AZ = 0$ because $P_D AZ = 0$. Thus, r eigenvalues are equal to 0. By using the definition of P_B, we have $P_B AZ = Q_D M^{-1}P_D AZ + ZE^{-1}Y^T AZ = Z$, because $Y^T AZ = E$. In this case, r eigenvalues are equal to 1.

In both cases, $Z = [z_1, \ldots, z_r]$ are the eigenvectors of $M^{-1}P_D A$ and $P_B A$ associated with eigenvalues equal to 0 and 1, respectively. ∎

In Krylov subspace methods, a preconditioner is chosen such that the preconditioned linear system is better conditioned than the original system. With an effective preconditioner M, we usually have $\sigma(M^{-1}A) \neq \sigma(A)$, but $\kappa(M^{-1}A) \leq \kappa(A)$. An explicit relation between $\sigma(M^{-1}A)$ and $\sigma(A)$ is generally not known and is often difficult to determine. This is also the case with $M^{-1}P_D A$. This explicit relation is, however, not necessary in this paper as our purpose is mainly to compare deflation and the abstract balancing preconditioner. To result in such a comparison, we need some intermediate results.

By using Lemma 2.5, we denote the spectrum of $M^{-1}P_D A$ by $\sigma(M^{-1}P_D A) = \{0, \ldots, 0, \mu_{r+1}, \ldots, \mu_n\}$, where in general $\mu_i \neq \lambda_i$, $\lambda_i \in \sigma(A)$, $r+1 \leq i \leq n$. Regarding $M^{-1}P_D A$, we have the following spectral equivalence.

LEMMA 2.6. [illegible] A, M [illegible] $Y^T AZ$ [illegible]

$$\sigma(Q_D M^{-1}P_D A) = \sigma(M^{-1}P_D A) = \sigma(Q_D M^{-1}A). \tag{2.8}$$

[illegible]. We have

$$\sigma(Q_D M^{-1}P_D A) = \sigma(M^{-1}P_D AQ_D) = \sigma(M^{-1}P_D^2 A) = \sigma(M^{-1}P_D A),$$

which proves the first equality. The second equality is proved in a similar way. ∎

LEMMA 2.7. [illegible] A, M [illegible] $Y^T AZ$ [illegible]

$$\sigma((Q_D M^{-1}P_D + ZE^{-1}Y^T)A) = \sigma((M^{-1}P_D + ZE^{-1}Y^T)A). \tag{2.9}$$

[illegible]. We note that

$$\begin{aligned}(M^{-1}P_D + ZE^{-1}Y^T)A &= M^{-1}P_D^2 A + ZE^{-1}Y^T A \\ &= M^{-1}P_D AQ_D + ZE^{-1}Y^T A \\ &= (M^{-1}P_D A - I)Q_D + I. \end{aligned} \tag{2.10}$$

Hence

$$\lambda \in \sigma((M^{-1}P_D + ZE^{-1}Y^T)A) \Leftrightarrow \lambda = \mu + 1 \quad \text{for } \mu \in \sigma((M^{-1}P_D A - I)Q_D).$$

However,

$$\sigma((M^{-1}P_D A - I)Q_D) = \sigma(Q_D(M^{-1}P_D A - I)) = \sigma(Q_D M^{-1}P_D A - Q_D).$$

Thus

$$\begin{aligned}\sigma((M^{-1}P_D + ZE^{-1}Y^T)A) &= \sigma(Q_D M^{-1}P_D A - Q_D + I)\\ &= \sigma(Q_D M^{-1}P_D A + ZE^{-1}Y^T A)\\ &= \sigma((Q_D M^{-1}P_D + ZE^{-1}Y^T)A),\end{aligned} \tag{2.11}$$

which proves the lemma. ∎

We then have the following spectral relation between $M^{-1}P_D A$ and $P_B A$.

THEOREM 2.8. [illegible] $M^{-1}P_D A$ [illegible]

$$\sigma(M^{-1}P_D A) = \{0, \ldots, 0, \mu_{r+1}, \ldots, \mu_n\}.$$

[illegible]

$$\sigma(P_B A) = \{1, \ldots, 1, \mu_{r+1}, \ldots, \mu_n\}.$$

[illegible] $P_B A$ [illegible]

$$\sigma(P_B A) = \{1, \ldots, 1, \mu_{r+1}, \ldots, \mu_n\},$$

[illegible]

$$\sigma(M^{-1}P_D A) = \{0, \ldots, 0, \mu_{r+1}, \ldots, \mu_n\}.$$

[illegible]. For $i = 1, \ldots, r$, $P_B AZ = Q_D M^{-1}P_D AZ + ZE^{-1}Y^T AZ = Z$, because $P_D AZ = 0$. Hence, the eigenvectors of $P_B AZ$ which correspond to eigenvalues equal to 1 are the same as those corresponding to eigenvalues equal to 0 of $M^{-1}P_D A$, i.e., $Z = [z_1 \ldots z_r]$.

For $r + 1 \le i \le n$, suppose that $\widetilde{v}_i$ satisfies $M^{-1}P_D A\widetilde{v}_i = \mu_i \widetilde{v}_i$, where μ_i is the corresponding eigenvalue. In this case, we have that $M^{-1}P_D A\widetilde{v}_i = M^{-1}P_D^2 A\widetilde{v}_i = M^{-1}P_D AQ_D\widetilde{v}_i = \mu_i\widetilde{v}_i \neq 0$, implying that $Q_D\widetilde{v}_i \neq 0$ for $\mu_i \neq 0$. Thus,

$$\begin{aligned}P_B AQ_D\widetilde{v}_i &= Q_D M^{-1}P_D AQ_D\widetilde{v}_i + ZE^{-1}Y^T AQ_D\widetilde{v}_i = Q_D M^{-1}P_D^2 A\widetilde{v}_i\\ &= Q_D M^{-1}P_D A\widetilde{v}_i = \mu_i Q_D\widetilde{v}_i.\end{aligned}$$

Hence, for $i = r + 1, \ldots, n$, the eigenvalues of $P_B A$ are the same as the eigenvalues of $M^{-1}P_D A$, with eigenvectors $Q_D\widetilde{v}_i$.

To prove the second statement, we know that for $i = 1, \ldots, r$, $P_B AZ = Z$, which gives, by expanding P_B, $Q_D M^{-1}P_D AZ = 0$. Hence, $0 \in \sigma(Q_D M^{-1}P_D A)$, implying $0 \in \sigma(M^{-1}P_D A)$ due to Lemma 2.6.

For $i = r + 1, \ldots, n$, notice that

$$P_B A\widetilde{v}_i = Q_D M^{-1}P_D A\widetilde{v}_i + ZE^{-1}Y^T A\widetilde{v}_i = \mu_i\widetilde{v}_i$$

implies

$$Q_D P_B A\widetilde{v}_i = Q_D M^{-1}P_D A\widetilde{v}_i = Q_D M^{-1}P_D AQ_D\widetilde{v}_i = \mu_i Q_D\widetilde{v}_i,$$

because $Q_D Z = 0$. Thus, μ_i is an eigenvalue of $Q_D M^{-1}P_D A$. However, due to Lemma 2.6, it is also an eigenvalue of $M^{-1}P_D A$. This completes the proof. ∎

Thus, for any full ranked Z and Y and any nonsingular matrix M, deflation and the balancing preconditioner have similar spectra. Furthermore, $P_B A$ has eigenvectors $Q_D\widetilde{v}_i$, with $\widetilde{v}_i$ the eigenvectors of $M^{-1}P_D A$.

THEOREM 2.9. [illegible] Z [illegible] Y [illegible] M [illegible] P_BA [illegible] $M^{-1}P_DA$ [illegible] P_BA [illegible]. Assume that P_BA is singular. Then there is a vector $x_i \neq 0$ such that $P_BAx_i = \mu_i \cdot x_i = 0$. So, $\mu_i = 0$. From the proof of Theorem 2.8, we know that $x_i = Q_D\widetilde{v}_i$, where $\widetilde{v}_i$ is the eigenvector of $M^{-1}P_DA$ associated with $\mu_i = 0$. Therefore, $M^{-1}P_DA\widetilde{v}_i = 0 \cdot \widetilde{v}_i = 0$. Since M is nonsingular, $P_DA\widetilde{v}_i = 0$, which immediately implies $A\widetilde{v}_i = AZE^{-1}Y^TA\widetilde{v}_i$ or $\widetilde{v}_i = ZE^{-1}Y^TA\widetilde{v}_i$, due to the definition of P_D. In this case, $x_i = Q_D\widetilde{v}_i = Q_DZE^{-1}Y^TA\widetilde{v}_i = 0$, because $Q_DZ = 0$, which does not satisfy the assumption. Hence, $\mu_i = 0$ is not an eigenvalue of P_BA, and henceforth P_BA is nonsingular.

Now suppose that $M^{-1}P_DA\widetilde{v}_i = 0$. Thus, we have

$$P_BA\widetilde{v}_i = Q_DM^{-1}P_DA\widetilde{v}_i + ZE^{-1}Y^TA\widetilde{v}_i = ZE^{-1}Y^TA\widetilde{v}_i. \tag{2.12}$$

This means that $P_BA\widetilde{v}_i = \widetilde{v}_i$ because $\widetilde{v}_i = ZE^{-1}Y^TA\widetilde{v}_i$ as above. Hence, any zero eigenvalues in case of deflation are shifted to one by the balancing preconditioner. ∎

For completeness, we consider a special case where $M = I$, and Z and Y satisfy the following assumption.

[illegible] 2.10. We set $Z = [v_1 \dots v_r]$, where $Av_i = \lambda_iv_i$, $i = 1, \dots, r$. Also, we set $Y = [w_1 \dots w_r]$ the left eigenvector matrix of A, determined from $w_i^TA = \lambda_iw_i^T$ and chosen such that $Y^TZ = I_r$, where I_r is the identity matrix of dimension r. For the left eigenvectors, $W = [w_1 \dots w_n]$.

THEOREM 2.11. [illegible] Z [illegible] Y [illegible] 2.10 [illegible] $M = I$ [illegible] P_B [illegible]

$$\sigma(P_DA) = \{0, \dots, 0, \lambda_{r+1}, \dots, \lambda_n\},$$
$$\sigma(P_BA) = \{1, \dots, 1, \lambda_{r+1}, \dots, \lambda_n\}.$$

[illegible]. Under Assumption 2.10, obviously $E = Y^TAZ = \mathrm{diag}(\lambda_1, \dots, \lambda_r) =: \Lambda_r$. For deflation, we see that for $i = 1, \dots, r$

$$P_DAv_i = \left(I - AZ\Lambda_r^{-1}Y^T\right)Av_i = \lambda_iv_i - Z\Lambda_rY^Tv_i = 0,$$

because $Y^TZ = I$. Similarly, for $i = r+1, \dots, n$, $P_DAv_i = \lambda_iv_i - Z\Lambda_rY^Tv_i = \lambda_iv_i$, because $Y^Tv_i = 0$. This leads to the first result.

For the balancing preconditioner, one can also proceed with the same procedure as above. In this case

$$P_BAv_i = (I - ZE^{-1}Y^TA)(I - AZE^{-1}Y^T)Av_i + ZE^{-1}Y^TAv_i. \tag{2.13}$$

By expanding (2.13) and making use of orthogonality of eigenvectors, we have

$$P_BAv_i = v_i, \quad i = 1, \dots, r. \tag{2.14}$$

Again, due to orthogonality we also have $P_BAv_i = \lambda_iv_i$ for $i = r+1, \dots, n$. ∎

So, in this very particular case P_DA and P_BA have similar spectra with A, but with r eigenvalues shifted to 0 and 1, respectively. The rest of the spectrum of A is untouched. Furthermore, P_DA and P_BA share the same eigenvectors, which are equal to the eigenvectors of A.

2.2. GMRES convergence bounds. Next we provide a GMRES convergence bound for $M^{-1}P_DA$ and P_BA. Here we restrict our discussion to the case satisfying Assumptions 2.2 and 2.10, and $M = I$. We note that, because of Assumptions 2.2 and 2.10,

(i) $X = [Z\, X_{n-r}]$, $X_{n-r} = [x_{r+1} \ \dots \ x_n]$, $W = [Y\, W_{n-r}]$, $W_{n-r} = [w_{r+1} \ \dots \ w_n]$, and

(ii) $E = Y^TAZ = Y^TZ\Lambda_r = \Lambda_r$, where $\Lambda_r = \mathrm{diag}(\lambda_1, \dots, \lambda_r)$.

For deflation we have the following lemma.

LEMMA 2.12. [illegible] $\Lambda_D = \mathrm{diag}\,(0, \dots, 0, \lambda_{r+1}, \dots, \lambda_n)$ [illegible] $\widetilde{r}_{0,D} = P_D(b - A\widetilde{u}_0)$ [illegible] 2.2 [illegible] 2.10 [illegible] k [illegible] $P_DA\widetilde{u} = P_Db$.

$$\mathcal{K}^k(P_DA, \widetilde{r}_{0,D}) = \{\widetilde{r}_{0,D}, X\Lambda_DX^{-1}\widetilde{r}_{0,D}, \dots, X\Lambda_D^{k-1}X^{-1}\widetilde{r}_{0,D}\}. \tag{2.15}$$

[illegible]. For $k = 1$, $\widetilde{r}_0 = P_D(b - A\widetilde{u}_{0,D})$. For $k = 2$,

$$P_DA = (I - AZE^{-1}Y^T)A = A - AZE^{-1}Y^TA = X(I - \Lambda X^{-1}ZE^{-1}Y^TX)\Lambda X^{-1}.$$

Note that, because $W^TX = I$, where $A^TW = W\Lambda$,

$$\begin{aligned} X^{-1}ZE^{-1}Y^TX = W^TZE^{-1}Y^TX &= \begin{bmatrix} Y^T \\ W_{n-r}^T \end{bmatrix} Z\Lambda^{-1}Y^T \begin{bmatrix} Z & X_{n-r} \end{bmatrix}, \\ &= \begin{bmatrix} Y^TZ\Lambda^{-1} \\ W_{n-r}^TZ\Lambda^{-1} \end{bmatrix} \begin{bmatrix} Y^TZ & Y^TX_{n-r} \end{bmatrix} = \begin{bmatrix} \Lambda^{-1} \\ 0 \end{bmatrix} \begin{bmatrix} I_r & 0 \end{bmatrix}, \\ &= \begin{bmatrix} \Lambda_r^{-1} & 0 \\ 0 & 0 \end{bmatrix}. \end{aligned} \tag{2.16}$$

Thus,

$$\begin{aligned} P_DA &= X\left(I - \Lambda\begin{bmatrix} \Lambda_r^{-1} & 0 \\ 0 & 0 \end{bmatrix}\right)\Lambda X^{-1} = X\left(I - \begin{bmatrix} I_r & 0 \\ 0 & 0 \end{bmatrix}\right)\begin{bmatrix} \Lambda_r & 0 \\ 0 & \Lambda_{n-r} \end{bmatrix}X^{-1}, \\ &= X\Lambda_DX^{-1}. \end{aligned}$$

For $k = 3$, $(P_DA)^2 = P_DAP_DA = X\Lambda_DX^{-1}X\Lambda_DX^{-1} = X\Lambda_D^2X^{-1}$. By repeating the computation for $l = 4, \dots, k-1$ the desired result is obtained. ∎

THEOREM 2.13. [illegible] Z [illegible] Y [illegible] 2.2 [illegible] 2.10 [illegible] $M = I$ [illegible] $\kappa_D = \lambda_n/\lambda_{r+1}$ [illegible] $\widetilde{u}_0$ [illegible] $P_DA\widetilde{u} = P_Db$ [illegible] 2 [illegible]

$$\|\widetilde{r}_{k,D}\|_2 \le 2\kappa_2(X)\left(1 - \frac{2}{\sqrt{\kappa_D} + 1}\right)^k \|\widetilde{r}_{0,D}\|_2, \tag{2.17}$$

[illegible] $\widetilde{r}_{k,D} = P_D(b - Au_k)$ [illegible]. Here, we have $\widetilde{r} = p(P_DA)\widetilde{r}_{0,D} = Xp(\Lambda_D)X^{-1}\widetilde{r}_{0,D}$, due to Lemma 2.12, where p is a polynomial of degree no larger than $k-1$, with $p(0) = 1$. Hence,

$$\|\widetilde{r}\|_2 \le \|X\|_2\|X^{-1}\|_2\|p(\Lambda_D)\|_2\|\widetilde{r}_{0,D}\|_2.$$

Noting that $\widetilde{u}_k$ minimizes the 2-norm of residual over $\widetilde{u}_0 + \mathcal{K}^k(P_DA, \widetilde{r}_{0,D})$ and $\|p(\Lambda_D)\|_2 = \max_{i=r+1,\dots,n}|p(\lambda_i)|$, choosing a polynomial which minimizes the right-hand side leads to

$$\|\widetilde{r}_{k,D}\|_2 := \|P_D(b - A\widetilde{u}_{k,D})\|_2 \le \|X\|_2\|X^{-1}\|_2\|\widetilde{r}_0\|_2 \min_{p\in\mathbb{P}^k, p(0)=1} \max_{i=r+1,\dots,n} |p(\lambda_i)|.$$

Taking the shifted and scaled Chebyshev polynomial as the trial polynomial with $\lambda \in [\lambda_{r+1}, \lambda_n]$ and repeating the same procedure as in the previous section one arrives at the desired inequality, with $\kappa_D = \lambda_n/\lambda_{r+1}$. ∎

We see that A and $P_D A$ share the same eigenvectors. Since $\lambda_{r+1} \geq \lambda_1$, $\kappa_D \leq \kappa$, GMRES with deflation preconditioner will asymptotically converge faster than without deflation preconditioner.

2.14. Note that this comparison is not fair because $\widetilde{r}$ is the residual of the preconditioned system, and not of the original system. In practice one usually is more interested in the residual of the original system, which is not the by-product of the left preconditioning GMRES. A more detailed residual analysis in section 3 reveals, however, that in the way the solution is computed, GMRES combined with deflation produces actual residuals which are the same as the preconditioned residuals; see Theorem 3.1.

For the balancing preconditioner, the Krylov subspace associated with it is written as

$$\begin{aligned} &\mathcal{K}^k(P_B A, P_B(b - Au_0)) \\ &= \operatorname{span}\{P_B(b - Au_0), P_B A P_B(b - Au_0), \ldots, (P_B A)^{k-1} P_B(b - Au_0)\}. \end{aligned} \tag{2.18}$$

For cases under Assumptions 2.2 and 2.10 we have the following lemma.

LEMMA 2.15. $\Lambda_B = \operatorname{diag}(1, \ldots, 1, \lambda_{r+1}, \ldots, \lambda_n)$ $\widetilde{r}_{0,B} = P_B(b - Au_0)$ 2.2 2.10 $M = I$

$$\mathcal{K}^k(P_B A, \widetilde{r}_{0,B}) = \{\widetilde{r}_{0,B}, X\Lambda_B X^{-1}\widetilde{r}_{0,B}, \ldots, X(\Lambda_B)^{k-1}X^{-1}\widetilde{r}_{0,N}\}.$$

. For $k = 1$, $\widetilde{r}_{0,B} := P_B(b - Au_0) = P_B r_0$. For $k = 2$,

$$\begin{aligned} P_B A &= (Q_D P_D + ZE^{-1}Y^T)A = (I - ZE^{-1}Y^T A)(I - AZE^{-1}Y^T)A + ZE^{-1}Y^T A \\ &= A - ZE^{-1}Y^T AA - AZE^{-1}Y^T A + ZE^{-1}Y^T AAZE^{-1}Y^T A + ZE^{-1}Y^T A \\ &= X(I - X^{-1}ZE^{-1}Y^T AX - \Lambda X^{-1}ZE^{-1}Y^T X \\ &\quad + X^{-1}ZE^{-1}Y^T AAZE^{-1}Y^T X + X^{-1}ZE^{-1}Y^T X)\Lambda X^{-1}. \end{aligned}$$

From the proof of Theorem 2.12, we then have that

$$\begin{aligned} P_B A &= X\left(I - \begin{bmatrix} \Lambda_r^{-1} & 0 \\ 0 & 0 \end{bmatrix}\Lambda - \Lambda\begin{bmatrix} \Lambda_r^{-1} & 0 \\ 0 & 0 \end{bmatrix} + X^{-1}ZY^T X + \begin{bmatrix} \Lambda_r^{-1} & 0 \\ 0 & 0 \end{bmatrix}\right)\Lambda X^{-1} \\ &= X\begin{bmatrix} \Lambda_r^{-1} & 0 \\ 0 & I_{n-r} \end{bmatrix}\Lambda X^{-1} = X\begin{bmatrix} I_r & 0 \\ 0 & \Lambda_{n-r} \end{bmatrix}X^{-1} =: X\Lambda_B X^{-1}, \end{aligned}$$

because

$$X^{-1}ZY^T X = W^T ZY^T X = \begin{bmatrix} I_r & 0 \\ 0 & 0 \end{bmatrix}.$$

We can also compute $(P_B A)^k$ for $k > 2$. This leads to the above lemma. ∎

Making use of Lemma 2.15, we have the GMRES convergence bound for the balancing preconditioner.

THEOREM 2.16. . Z Y P_B 2.2 2.10 $M = I$ $\kappa_B = \max\{1, \lambda_n\}/\min\{1, \lambda_{r+1}\}$ u_0 2 $P_B A u = P_B b$

$$\|\widetilde{r}_{k,B}\|_2 \leq 2\kappa_2(X)\left(1 - \frac{2}{\sqrt{\kappa_B} + 1}\right)^k \|\widetilde{r}_{0,B}\|_2. \tag{2.19}$$

. Note that $\|\widetilde{r}_B\| = Xp(\Lambda_B)X^{-1}\widetilde{r}_{0,B}$. The proof then follows along the same lines as in Theorem 2.13. □

Comparing Theorems 2.13 and 2.16, it is clear that GMRES combined with deflation has a convergence bound which is lower than or equal to GMRES combined with the balancing preconditioner. Therefore, we may expect that GMRES applied to a deflation-preconditioned linear system will converge faster than GMRES with the balancing preconditioner.

3. Comparison of GMRES residuals. To have a more detailed comparison between P_DA and P_BA, in this section we evaluate the approximate solutions built by GMRES and the related residuals. We first recall that when applied to (1.1), a Krylov subspace method generates an approximation solution in the Krylov subspace $\mathcal{K}^k(A, r_0)$, defined in (1.2). In case of left preconditioning, the subspace is now spanned by vectors related to the preconditioned system. For

$$BAu = Bb, \tag{3.1}$$

with B any preconditioner, the Krylov subspace related to the initial residual $\widetilde{r}_0 = B(b - Au_0)$, where u_0 is the starting vector, is given by

$$\mathcal{K}^k(BA, \widetilde{r}_0) = \text{span}\{\widetilde{r}_0, BA\widetilde{r}_0, \ldots, (BA)^{k-1}\widetilde{r}_0\}. \tag{3.2}$$

GMRES then minimizes the residual norm

$$\|B(b - A\eta)\|_2, \tag{3.3}$$

where $\eta \in u_0 + \mathcal{K}^k(BA, \widetilde{r}_0)$. The approximate solution is determined by

$$u_k = u_0 + p_{k-1}(BA)\widetilde{r}_0, \tag{3.4}$$

where p_{k-1} is the polynomial of degree $k-1$, which minimizes the residual norm (3.3) among all other polynomials of degree $\leq k-1$.

In deflation, we know that the approximate solution at the kth iteration is obtained from the relation

$$u_{k,D} = (I - Q_D)u + Q_D\widetilde{u}_{k,D} = ZE^{-1}Y^Tb + Q_D\widetilde{u}_{k,D}, \tag{3.5}$$

where $\widetilde{u}_{k,D}$ is computed iteratively from

$$M^{-1}P_DA\widetilde{u} = M^{-1}P_Db, \tag{3.6}$$

with M an appropriate nonsingular and possibly nonsymmetric preconditioning matrix. If GMRES is used in (3.6), the approximate solution extracted from the affine subspace

$$\widetilde{u}_{0,D} + \mathcal{K}^k(M^{-1}P_DA, \widetilde{r}_{0,D}) \tag{3.7}$$

minimizes the 2-norm of the residual $\widetilde{r}_{k,D} = M^{-1}P_D(b - A\eta)$, where $\eta \in \widetilde{u}_{0,D} + \mathcal{K}^k(M^{-1}P_D, \widetilde{r}_{0,D})$. This approximate solution does not, however, minimize the 2-norm of the actual residual $r := b - Au_{k,D}$. A similar situation is also encountered in the case of the abstract balancing preconditioner.

For deflation, however, the following residual relation holds.

THEOREM 3.1. [illegible] Z, Y [illegible] M [illegible] $\widetilde{u}_{0,D} = 0$ [illegible]

$$\begin{aligned} \|M^{-1}r_{k,D}\|_2 &= \|M^{-1}P_D(b - A\widetilde{u}_{k,D})\|_2 \\ &= \min_{\eta \in \mathcal{K}^k(M^{-1}P_DA, M^{-1}P_Db)} \|M^{-1}P_D(b - A\eta)\|_2. \end{aligned} \tag{3.8}$$

[illegible]. By construction, with $\widetilde{u}_{0,D} = 0$,

$$r_{k,D} =: b - Au_{k,D} = b - A(ZE^{-1}Y^Tb + Q_D\widetilde{u}_{k,D}) = P_D(b - A\widetilde{u}_{k,D}),$$

where $\widetilde{u}_{k,D} \in \mathcal{K}^k(M^{-1}P_DA, M^{-1}P_Db)$. Premultiplying the above equality by M^{-1}, we have

$$\|M^{-1}r_{k,D}\|_2 = \|M^{-1}P_D(b - A\widetilde{u}_{k,D})\|_2 = \min_{\eta \in \mathcal{K}^k(M^{-1}P_DA, M^{-1}P_Db)} \|M^{-1}P_D(b - A\eta)\|_2.$$

Clearly, the optimality property holds only for the preconditioned residuals. ∎

By Theorem 3.1, we immediately see that in the case $M = I$, $\|r_{k,D}\|_2 = \|P_D(b - A\widetilde{u}_{k,D})\|_2$; i.e., the actual residual is equal to the deflated residual.

Next we compare the GMRES residuals for deflation and the abstract balancing preconditioner. For nonsymmetric cases with arbitrary starting vector u_0 such a comparison is, however, difficult. Nevertheless, it is still practically useful to make a comparison for specially chosen starting vectors.

We consider $u_{0,B} = ZE^{-1}Y^Tb$ and $\widetilde{u}_{0,D} = 0$. Such a choice of $u_{0,B}$ has particular reasons in terms of implementation. As one notices from the definition of P_B, with a naive implementation, the balancing preconditioner requires two more matrix-vector multiplications than deflation. If A is symmetric positive definite, this choice of $u_{0,B}$ greatly simplifies the CG algorithm and reduces the amount of work of the balancing preconditioner to only one matrix-vector multiplication, which is the same as deflation; see [13, 24]. As shown in [17], for spd systems, such starting vectors lead to exactly the same A-norm of errors of the CG iterant.

First, we define the Krylov subspace corresponding to P_BA and starting vector $u_{0,B} = ZE^{-1}Y^Tb$.

LEMMA 3.2. [illegible] $u_{0,B} = ZE^{-1}Y^Tb$ [illegible] M [illegible] k [illegible] $ZE^{-1}Y^Tb + \mathcal{K}^k(P_BA, \widetilde{r}_{0,B})$ [illegible]

$$\begin{aligned} &\mathcal{K}^k(P_BA, \widetilde{r}_{0,B}) \\ &= Q_D[illegible]\{M^{-1}P_Db, M^{-1}P_DAM^{-1}P_Db, \ldots, (M^{-1}P_DA)^{k-1}M^{-1}P_Db\}, \end{aligned} \tag{3.9}$$

[illegible] $\widetilde{r}_{0,B} = Q_DM^{-1}P_Db$

[illegible]. For $k = 1$, $\widetilde{r}_{0,B} = P_B(b - Au_{0,B}) = Q_DM^{-1}P_Db$. The proof is done by recursive computations for $(P_BA)^l\widetilde{r}_{0,B}$, $l = 2, \ldots, k$. ∎

THEOREM 3.3. [illegible] Z [illegible] Y [illegible] M [illegible] $u_{0,B} = ZE^{-1}Y^Tb$ [illegible] $\widetilde{u}_{0,D} = 0$ [illegible]

$$\|M^{-1}(b - Au_{k,D})\|_2 \leq \|M^{-1}(b - Au_{k,B})\|_2. \tag{3.10}$$

[illegible]. For the abstract balancing preconditioner, the solution of GMRES at the kth iteration is

$$u_{k,B} \in ZE^{-1}Y^Tb + \mathcal{K}^k(P_BA, \widetilde{r}_{0,B}), \quad \widetilde{r}_{0,B} = P_B(b - Au_{0,B}), \tag{3.11}$$

or, by Lemma 3.2,

$$u_{k,B} = ZE^{-1}Y^T b + Q_D\eta, \qquad \eta \in \mathcal{K}^k(M^{-1}P_DA, M^{-1}P_Db), \tag{3.12}$$

whose residual is $r_{k,B} = b - Au_{k,B} = P_D(b - A\eta)$. Thus, $M^{-1}r_{k,B} = M^{-1}P_D(b - A\eta)$, implying $\|M^{-1}r_{k,B}\|_2 = \|M^{-1}P_D(b - A\eta)\|_2$. If ζ minimizes $\|M^{-1}P_D(b - A\zeta)\|_2$ over the subspace $\mathcal{K}^k(M^{-1}P_DA, M^{-1}P_Db)$, then

$$\|M^{-1}P_D(b - A\eta)\|_2 \geq \min_{\zeta \in \mathcal{K}^k(M^{-1}P_DA, M^{-1}P_Db)} \|M^{-1}P_D(b - A\zeta)\|_2. \tag{3.13}$$

In this case, ζ can be obtained by GMRES applied to $M^{-1}P_DA\widetilde{u} = M^{-1}P_Db$ with zero initial guess. Thus, $\zeta = \widetilde{u}_{k,D}$. By using Theorem 3.1, we finally get

$$\|M^{-1}r_{k,B}\|_2 := \|M^{-1}P_D(b - A\eta)\|_2 \geq \|M^{-1}P_D(b - A\widetilde{u}_{k,D})\|_2 =: \|M^{-1}r_{k,D}\|_2,$$

where $r_{k,D} = b - Au_{k,D}$ and $r_{k,B} = b - Au_{k,B}$. ∎

In Theorem 3.3 we proved that the preconditioned residual obtained by using the deflation method is less than or equal to the preconditioned residual obtained by using the abstract balancing method.

Moreover, Theorem 3.3 guarantees that GMRES preconditioned by the singular deflation preconditioner will also converge without any further assumption.

COROLLARY 3.4. [illegible] Z [illegible] Y [illegible] M [illegible] $\widetilde{u}_{0,D} = 0$ [illegible]

$$M^{-1}P_DA\widetilde{u} = M^{-1}P_Db$$

[illegible]. Since the abstract balancing preconditioner is nonsingular (cf. Theorem 2.9), GMRES applied to

$$P_BAu = P_Bb$$

will converge. By Theorem 3.3 the statement then follows immediately. ∎

4. Numerical examples. In this section we perform numerical experiments to confirm our theoretical results. We base our numerical experiments on the linear systems arising from a finite volume discretization of the steady-state convection-diffusion equation

$$\frac{\partial u}{\partial x} + \frac{\partial u}{\partial y} - \nabla \cdot \left(\frac{1}{Pe}\nabla u\right) = f \qquad \text{in } \Omega = (0,1)^2, \tag{4.1}$$

with $Pe > 0$ the Péclet number, and f the forcing term. We first consider the one-dimensional (1D) version of (4.1), in which eigenvalues and eigenvectors of the corresponding linear system can be computed cheaply. Later in this section, a two-dimensional (2D) convection-diffusion problem is also discussed.

4.1. Description of the test problem. For our 1D convection-diffusion problem, we consider an artificial 1D problem with jumps in Pe. Problems with jumps in Pe lead to linear systems with very large difference between the largest and the smallest eigenvalues (in magnitude). In our case, we set

$$Pe(x) = \begin{cases} 1, & 0 \leq x < 0.8, \\ 200, & 0.8 \leq x \leq 1. \end{cases} \tag{4.2}$$

The boundary conditions are $u(0) = 0$ and $u(1) = 1$, which resemble extremely thin boundary layer flows near $x = 1$ and $f = 0$. The 1D convection-diffusion equation is discretized by using the cell-centered finite volume discretization. The convective flux term is approximated by the central discretization. In order to avoid wiggly numerical solutions, the grid is refined at the vicinity of $x = 1$, keeping the mesh Péclet number less than 2 for numerical stability reason. (At this moment we are, however, not concerned with the accuracy of the approximate solutions, and are more interested in the validity of the theoretical results for a specific problem.) In the subdomain where $Pe = 1$, 40 cells are used. In total 200 cells are used. The resultant linear system has real and simple eigenvalues, with 18 of them having value less than 1. The largest eigenvalue is ~ 399.9, while the smallest one is ~ 0.12, giving a ratio of an order of 10^3. The eigenvalues and the associated eigenvectors are computed by the MATLAB routine `eig`.

For the 2D case, we consider the convection-diffusion problem with Dirichlet boundary conditions at $x = 1$ and $y = 0$, and homogeneous Neumann boundary conditions at $x = 0$ and $y = 1$ (see [26]). The equation is discretized by using a finite volume discretization. The convection flux term is approximated by an upwind scheme. The Péclet number is 200. The grid is refined in the y-direction in the vicinity of $y = 0$, while in the x-direction the grid size is kept constant. In this case the eigenvalues of the resultant discretization matrix are easily computed.

4.2. Results. We first consider numerical tests from the 1D convection-diffusion equation. Here, we choose Z based on the subdomain structuring proposed in [18] and used in [10]. Suppose that the domain Ω with index set $\mathcal{I} = \{i | u_i \in \Omega\}$ is partitioned into m nonoverlapping subdomains Ω_j, $j = 1, \ldots, m$, with respective index $\mathcal{I}_j = \{i \in \mathcal{I} | u_i \in \Omega_j\}$. Then Z is defined by

$$z_{ij} = \begin{cases} 1, & i \in \mathcal{I}_j, \\ 0, & i \notin \mathcal{I}_j, \end{cases} \tag{4.3}$$

and $Y = Z$. Particularly in this example we first partition Ω into two subdomains of the same Péclet number. Based on this partition, partitioning is done further until the number of deflation vectors needed is reached.

Figure 4.1 shows the GMRES convergence history with deflation and the abstract balancing preconditioner, and $M = I$. In case of the abstract balancing preconditioner, $u_{0,B} = ZE^{-1}Y^T b$. For deflation, zero initial guess is used. Even though both preconditioners result in almost identical convergence, clearly deflation still produces smaller 2-norms of residuals compared to the abstract balancing preconditioner.

Similar results are obtained for $M \neq I$; see Figure 4.2. In this case, we choose $M = \text{diag}(A)$. GMRES combined with deflation produces a preconditioned residual (i.e., $M^{-1}r_k$) whose 2-norm is smaller than with the abstract balancing preconditioner. For the actual residual, this conclusion does not necessarily hold (see right figure). In the right figure, we observe at some steps that the abstract balancing preconditioner produces a smaller 2-norm of the actual residuals than deflation.

Next we consider the 2D model problem. The domain is partitioned into 10×10 subdomains. Deflation vectors are constructed based on (4.3). We choose $M = \text{diag}(A)$. Figure 4.3 shows convergence results for starting vector $\widetilde{u}_{0,D} = 0$ and $u_{0,B} = ZE^{-1}Y^T b$. In this case, residuals related to deflation and the abstract balancing preconditioners are very similar. Figure 4.4 (left) shows that the preconditioned residual (based on M) of the balancing preconditioner is never smaller than that of

deflation. This is, however, not always the case for the actual residual (Figure 4.4 (right)).

5. Conclusion. In this paper a comparison between deflation and the abstract balancing preconditioner for nonsymmetric linear systems has been given, within the context of GMRES. We were able to show that many results for symmetric positive definite matrices carry over to some classes of nonsymmetric matrices. We first established that the spectra of the preconditioned systems are similar. Moreover, our analysis shows that with special starting vectors, for nonsingular, nonsymmetric matrix A deflation generates approximate solutions whose related residuals (with respect to M) are never larger than the balancing preconditioner. If the deflation vectors are chosen to be the eigenvectors, the 2-norm of the actual residuals of deflation is always never larger than the balancing preconditioner. For general deflation vectors we proved that the 2-norm of preconditioned residual of GMRES combined with deflation is smaller than that of GMRES combined with the balancing preconditioner. Numerical experiments confirmed the theoretical results and showed that the methods behave similarly.

REACHABILITY AND HOLDABILITY OF NONNEGATIVE STATES*

DIMITRIOS NOUTSOS† AND MICHAEL J. TSATSOMEROS‡

Abstract. Linear differential systems $\dot{x}(t) = Ax(t)$ ($A \in \mathbb{R}^{n\times n}$, $x_0 = x(0) \in \mathbb{R}^n$, $t \geq 0$) whose solutions become and remain nonnegative are studied. It is shown that the eigenvalue of A furthest to the right must be real and must possess nonnegative right and left eigenvectors. Moreover, for some $a \geq 0$, $A + aI$ must be eventually nonnegative, that is, its powers must become and remain entrywise nonnegative. Initial conditions x_0 that result in nonnegative states $x(t)$ in finite time are shown to form a convex cone that is related to the matrix exponential e^{tA} and its eventual nonnegativity.

Key words. eventually nonnegative matrix, exponentially nonnegative matrix, point of nonnegative potential, Perron–Frobenius, Metzler matrix, convex cone

1. Introduction.

In dynamical systems theory, one is frequently interested in qualitative information regarding state evolution. In particular, due to physical and modeling constraints arising in engineering, biological, medical, behavioral, and economic applications, it is commonly of interest to impose or consider conditions for nonnegativity of the states; see, e.g., [2, 6]. Such applications typically draw on the theory, or directly take the form, of a linear differential system,

$$\dot{x}(t) = Ax(t), \quad A \in \mathbb{R}^{n\times n}, \quad x(0) = x_0 \in \mathbb{R}^n, \quad t \geq 0, \tag{1.1}$$

whose solution is given by $x(t) = e^{tA}x_0$. We shall refer here to the set

$$\{x(t) = e^{tA}x_0 \mid t \in [0,\infty)\}$$

as the [illegible] x_0 and say that x_0 gives rise to this trajectory. In this paper we will consider conditions for the entrywise nonnegativity of the trajectories associated with (1.1). Our main concern is the following "hit and hold" problem:

[illegible] x_0 [illegible]

More specifically, we will seek characterizations of system parameters that lead to a trajectory becoming nonnegative at a finite time ([illegible] $\mathbb{R}^n_+$) and remaining nonnegative for all time thereafter ([illegible] $\mathbb{R}^n_+$). This endeavor will comprise two related efforts:

(1) Study matrices $A \in \mathbb{R}^{n\times n}$ for which there exists $t_0 \in [0,\infty)$ such that $e^{tA} \geq 0$ for all $t \geq t_0$. We shall term such matrices [illegible].

(2) Given an eventually exponentially nonnegative matrix A, study initial points $x_0 \in \mathbb{R}^n$ for which there exists $\hat{t} \in [0,\infty)$ such that $e^{tA}x_0 \geq 0$ for all $t \geq \hat{t}$. We shall refer to such initial points as [illegible].

Some comments regarding these two goals and the structure of this paper are in order.

First, matrices all of whose off-diagonal entries are nonnegative (known as essentially nonnegative or Metzler matrices) are eventually exponentially nonnegative (with $t_0 = 0$). However, as we shall see in section 3, the eventually exponentially nonnegative matrices form a larger matrix class. They are closely related to the eventually nonnegative matrices, namely, matrices whose powers become and remain nonnegative. It is this latter fact that provides further motivation for our study, as eventually nonnegative matrices arise in the theory of positive control systems; see e.g., [16].

Second, it is clear that $\mathbb{R}^n_+$ (the nonnegative orthant) comprises points of nonnegative potential but as we shall see, in the general case, the totality of such points forms a convex cone that strictly contains $\mathbb{R}^n_+$. Our relevant analysis is in section 4, where points of nonnegative potential and the asymptotic behavior of solutions are connected to the matrix exponential e^{tA} and its eventual nonnegativity. We note that even in applications where initial points and states are de facto nonnegative, points of nonnegative potential outside $\mathbb{R}^n_+$ can be of practical interest. For example, suppose that for some $x_0 \in \mathbb{R}^n$, $\hat{x}_0 = Ax_0$ is a point of nonnegative potential. Then there exists $\hat{t} \geq 0$ such that for all $t \geq \hat{t}$,

$$\dot{x}(t) \;=\; \frac{d}{dt}(e^{tA}x_0) \;=\; Ae^{tA}x_0 \;=\; e^{tA}Ax_0 \;=\; e^{tA}\hat{x}_0 \geq 0;$$

that is, the trajectory emanating from x_0 becomes (at $t = \hat{t}$) and remains entrywise nondecreasing. This situation occurs, e.g., when (1.1) models species that reach a symbiotic state after which none of the populations decreases; see [9].

2. Notation, definitions, and preliminaries. Given an $n \times n$ matrix A, the spectrum of A is denoted by $\sigma(A)$ and its spectral radius by $\rho(A) = \max\{|\lambda| \mid \lambda \in \sigma(A)\}$. An eigenvalue λ of A is said to be [illegible] if $|\lambda| = \rho(A)$. The [illegible] of A is defined and denoted by $\lambda(A) := \max\{\mathrm{Re}\,\lambda \mid \lambda \in \sigma(A)\}$. By $\mathrm{index}_0(A)$ we denote the degree of 0 as a root of the minimal polynomial of A. Consequently, when we say $\mathrm{index}_0(A) \leq 1$, we mean that either A is invertible or that the size of the largest nilpotent Jordan block in the Jordan canonical form of A is 1×1.

The [illegible] in $\mathbb{R}^n$, that is, the set of all nonnegative vectors in $\mathbb{R}^n$, is denoted by $\mathbb{R}^n_+$. For $x \in \mathbb{R}^n$, we use the notation $x \geq 0$ interchangeably with $x \in \mathbb{R}^n_+$.

An $n \times n$ matrix A is called [illegible] if there exists a permutation matrix P such that

$$PAP^T \;=\; \begin{bmatrix} A_{11} & A_{12} \\ 0 & A_{22} \end{bmatrix},$$

where A_{11} and A_{22} are square, nonvacuous matrices. Otherwise, A is called [illegible]. Recall that irreducibility of A is equivalent to the directed graph of A, $G(A)$, being strongly connected, namely, the existence of a path of edges leading from any vertex i to any other vertex j. For details and further terminology regarding directed graphs, see [1].

Every reducible matrix A can be symmetrically permuted to its [illegible]; namely, for every reducible matrix $A \in \mathbb{R}^{n\times n}$, there exists a permutation matrix P such that

$$PAP^T \;=\; \begin{bmatrix} A_{11} & A_{12} & \cdots & A_{1p} \\ 0 & A_{22} & \cdots & A_{2p} \\ \vdots & & \ddots & \vdots \\ 0 & \cdots & 0 & A_{pp} \end{bmatrix},$$

where each diagonal block A_{jj} $(j = 1, 2, \ldots, p)$ is square and either irreducible or the 1×1 zero matrix. Note that the diagonal blocks in the Frobenius normal form correspond to a partition of the vertices of $G(A)$ into classes of strongly connected vertex subsets (a singleton is considered strongly connected).

To the Frobenius normal form of A above we associate the [illegible] $R(A)$ of A defined as follows: $R(A)$ has p vertices, each one of them corresponding to a strongly connected set of vertices in the directed graph of A. $R(A)$ has a directed edge from i to j if and only if $A_{ij} \neq 0$. In section 3 we will consider the [illegible] of $R(A)$, $\overline{R(A)}$, which is the directed graph obtained from $R(A)$ having an edge from i to j if and only if there is a path from i to j in $R(A)$.

DEFINITION 2.1. [illegible] $n \times n$ [illegible] $A = [a_{ij}]$ [illegible]

- nonnegative (positive) [illegible] $A \geq 0$ $(A > 0)$, $a_{ij} \geq 0$ (> 0) [illegible] i [illegible] j
- essentially nonnegative (positive) [illegible] $A \overset{\text{s}}{\geq} 0$ $(A \overset{\text{s}}{>} 0)$, $a_{ij} \geq 0$ $(a_{ij} > 0)$ [illegible] $i \neq j$
- eventually nonnegative (positive) [illegible] $A \overset{\text{v}}{\geq} 0$ $(A \overset{\text{v}}{>} 0)$, [illegible] [illegible] k_0 [illegible] $A^k \geq 0$ $(A^k > 0)$ [illegible] $k \geq k_0$ [illegible] [illegible] $k_0 = k_0(A)$ [illegible] power index [illegible] A
- exponentially nonnegative (positive) [illegible] $t \geq 0$, $e^{tA} = \sum_{k=0}^{\infty} \frac{t^k A^k}{k!} \geq 0$ $(e^{tA} > 0)$
- eventually exponentially nonnegative (positive) [illegible] $t_0 \in [0, \infty)$ [illegible] [illegible] $t \geq t_0$, $e^{tA} \geq 0$ $(e^{tA} > 0)$ [illegible] [illegible] $t_0 = t_0(A)$ [illegible] exponential index [illegible] A

LEMMA 2.2. [illegible] $A \in \mathbb{R}^{n \times n}$ [illegible]

(i) A [illegible]

(ii) [illegible] $a \in \mathbb{R}$ [illegible] $A + aI$ [illegible]

(iii) [illegible] $a \in \mathbb{R}$, $A + aI$ [illegible]

[illegible] The equivalences follow readily from the fact that as aI and A commute,

$$e^{t(A+aI)} = e^{atI} e^{tA} = e^{at} e^{tA}. \qquad \square$$

We conclude this section with some notions crucial to the analysis in section 3.

DEFINITION 2.3. [illegible] $A \in \mathbb{R}^{n \times n}$ [illegible]

- [illegible] Perron–Frobenius property [illegible] $\rho(A) > 0$, $\rho(A) \in \sigma(A)$ [illegible] [illegible] $\rho(A)$
- [illegible] strong Perron–Frobenius property [illegible] [illegible] [illegible] $\rho(A)$ [illegible]

$$\rho(A) > |\lambda| \quad \text{for all} \quad \lambda \in \sigma(A), \ \lambda \neq \rho(A),$$

[illegible] $\rho(A)$

By the Perron–Frobenius theorem, every nonnilpotent $A \geq 0$ has the Perron–Frobenius property and every primitive $A \geq 0$ has the strong Perron–Frobenius property; see [1].

3. Eventually exponentially nonnegative matrices. There is a well-known equivalence between the notions of exponential nonnegativity and essential nonnegativity; see [1, Chapter 6, Theorem (3.12)]. We include a proof of this result next for completeness.

LEMMA 3.1. $A \in \mathbb{R}^{n\times n}$ [illegible] $A \overset{s}{\geq} 0$ [illegible]. If $A \overset{s}{\geq} 0$, then there exists large enough $\alpha \geq 0$ such that $A + \alpha I \geq 0$. Hence, as A and αI commute, we have that for all $t \geq 0$,

$$e^{tA} = e^{-t\alpha I} e^{t(A+\alpha I)} = e^{-t\alpha} e^{t(A+\alpha I)} \geq 0.$$

Conversely, let $e^{tA} \geq 0$ for all $t \geq 0$ and by way of contradiction suppose that $a_{ij} < 0$ for some $i \neq j$. Then, denoting the entries of A^k by $a_{ij}^{(k)}$, we have

$$(e^{tA})_{ij} = ta_{ij} + \frac{t^2}{2!}a_{ij}^{(2)} + \frac{t^3}{3!}a_{ij}^{(3)} + \cdots.$$

Thus, letting $t \to 0^+$ we have that for some $t > 0$, $(e^{tA})_{ij} < 0$, a contradiction. ∎

As a consequence of the above lemma, every essentially nonnegative matrix A is eventually exponentially nonnegative with exponential index $t_0 = 0$. We proceed with a characterization of eventually exponentially positive matrices based on some recent results proven in [11].

THEOREM 3.2 (see [11, Theorem 2.2]). [illegible] $A \in \mathbb{R}^{n\times n}$ [illegible]

(i) [illegible] A [illegible] A^T [illegible]

(ii) A [illegible]

(iii) A^T [illegible]

Our main result thus far is the following extension of Theorem 3.2.

THEOREM 3.3. [illegible] $A \in \mathbb{R}^{n\times n}$ [illegible]

(i) [illegible] $a \geq 0$ [illegible] $A+aI$ [illegible] A^T+aI [illegible]

(ii) $A + aI$ [illegible] $a \geq 0$

(iii) $A^T + aI$ [illegible] $a \geq 0$

(iv) A [illegible]

(v) A^T [illegible]

. The equivalence of (i)–(iii) is the content of Theorem 3.2 applied to $A+aI$. We will argue the equivalence of (ii) and (iv), with the equivalence of (iii) and (v) being analogous:

Let $A + aI$ be eventually positive and let k_0 be a positive integer such that $(A + aI)^k > 0$ for all $k \geq k_0$. Then there exists large enough $t_0 > 0$ so that the first $k_0 - 1$ terms of the series

$$e^{t(A+aI)} = \sum_{m=0}^{\infty} \frac{t^m (A + aI)^m}{m!}$$

are dominated by the remaining terms, rendering every entry of $e^{t(A+aI)}$ positive for all $t \geq t_0$. It follows that $e^{tA} = e^{-ta}e^{t(A+aI)}$ is positive for all $t \geq t_0$. That is, A is eventually exponentially positive. Conversely, suppose A is eventually exponentially positive. As $(e^A)^k = e^{kA}$, it follows that e^A is eventually positive. Thus, by Theorem 3.2, e^A has the strong Perron–Frobenius property. Recall that $\sigma(e^A) = \{e^\lambda : \lambda \in \sigma(A)\}$ and so $\rho(e^A) = e^\lambda$ for some $\lambda \in \sigma(A)$. Then for each $\mu \in \sigma(A)$ with $\mu \neq \lambda$ we have

$$e^\lambda > |e^\mu| = |e^{\operatorname{Re}\mu + i\operatorname{Im}\mu}| = e^{\operatorname{Re}\mu}.$$

Hence λ is the spectral abscissa of A, namely, $\lambda > \operatorname{Re}\mu$ for all $\mu \in \sigma(A)$ with $\mu \neq \lambda$. In turn, this means that there exists large enough $a > 0$ such that

$$\lambda + a > |\mu + a| \quad \text{for all } \mu \in \sigma(A), \ \ \mu \neq \lambda.$$

As $A + aI$ shares its eigenspaces with e^A, it follows that $A + aI$ has the strong Perron–Frobenius property. Invoking Theorem 3.2 once more, we have that $A + aI$ is eventually positive. □

3.4. Note that the equivalence of (ii) and (iv) in Theorem 3.3 represents a generalization of the fact that $A \overset{s}{>} 0$ is equivalent to A being exponentially positive.

3.5. Consider the matrix

$$A = \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 \\ -1 & 1 & 1 & 1 \\ 1 & 0 & 1 & 1 \end{bmatrix}$$

and observe that

$$A^2 = \begin{bmatrix} 2 & 3 & 4 & 4 \\ 2 & 3 & 4 & 4 \\ 0 & 1 & 2 & 2 \\ 1 & 2 & 3 & 3 \end{bmatrix}, \quad A^3 = \begin{bmatrix} 5 & 9 & 13 & 13 \\ 5 & 9 & 13 & 13 \\ 1 & 3 & 5 & 5 \\ 3 & 6 & 9 & 9 \end{bmatrix}.$$

It is easily checked that A is an eventually positive matrix with power index $k_0 = 3$, so by Theorem 3.3, A is an eventually exponentially positive matrix. Computing e^{tA} for $t = 1, 2$ we obtain, respectively,

$$\begin{bmatrix} 5.0401 & 6.3618 & 8.6836 & 8.6836 \\ 4.0401 & 7.3618 & 8.6836 & 8.6836 \\ -0.4655 & 2.7873 & 5.0401 & 4.0401 \\ 2.7873 & 3.5746 & 6.3618 & 7.3618 \end{bmatrix}, \begin{bmatrix} 71.2660 & 134.1429 & 198.0199 & 198.0199 \\ 70.2660 & 135.1429 & 198.0199 & 198.0199 \\ 18.4960 & 45.3810 & 71.2660 & 70.2660 \\ 45.3810 & 88.7620 & 134.1429 & 135.1429 \end{bmatrix}.$$

Taking into consideration the location of the nonpositive entries of A and A^2, we infer that the exponential index of A is $t_0 \in (1, 2)$.

Next we focus on eventually exponentially [illegible] matrices and connect them to eventually [illegible] matrices. In what follows we state and prove conditions that are sufficient for eventual exponential nonnegativity and investigate necessary conditions. To do so, we first need to discuss the relationship among the Frobenius normal forms of the powers of an eventually nonnegative matrix. This topic and its relation to the spectrum are studied extensively in [3, 4]. Below we summarize and paraphrase some of these results.

THEOREM 3.6 (see [3, Theorems 3.4 and 3.5]). [illegible] $A \in \mathbb{R}^{n\times n}$ [illegible] $\operatorname{index}_0(A) \leq 1$ [illegible] q [illegible] P [illegible]

(i) $A^k \geq 0$ [illegible] $k \geq q$

(ii) PAP^T [illegible] PA^qP^T [illegible]

(iii) $\overline{R(A)} = \overline{R(A^q)}$

THEOREM 3.7. [illegible] $A \in \mathbb{R}^{n\times n}$ [illegible] $\operatorname{index}_0(A) \leq 1$ [illegible] A [illegible]

[illegible]. To avoid trivialities, suppose $n \geq 2$ and recall Theorem 3.6(ii). Without loss of generality, assume $P = I$; otherwise our considerations apply to a permutational similarity of A. Thus A and A^q are assumed to be in Frobenius normal form

as follows:

$$(3.1)\quad A = \begin{bmatrix} A_{11} & \cdots & \cdots & A_{1p} \\ 0 & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \vdots \\ 0 & \cdots & 0 & A_{pp} \end{bmatrix} \quad \text{and} \quad A^q = \begin{bmatrix} A_{11}^{(q)} & \cdots & \cdots & A_{1p}^{(q)} \\ 0 & \ddots & \ddots & A_{2k}^{(q)} \\ \vdots & \ddots & \ddots & \vdots \\ 0 & \cdots & \cdots & A_{pp}^{(q)} \end{bmatrix}.$$

Consider the power series $e^{tA} = \sum_{k=0}^{\infty} \frac{t^m A^k}{k!}$ partitioned in blocks conformably to the matrices in (3.1) and let $c_{ij}(t)$ be the (i,j)th entry of e^{tA}. Abusing slightly the notation, let $\{1, 2, \ldots, p\}$ denote the p strongly connected classes in $G(A)$ implied by (3.1). Let i belong to class u and j to class v, where $u, v \in \{1, 2, \ldots, p\}$. The following cases ensue:

Suppose that $p = 1$. As $n \geq 2$, A is irreducible. Thus for all powers $k \geq q$, the (i,j)th entry of A^k is nonnegative and is indeed positive for at least some powers $\geq q$. As a consequence, as $t \geq 0$ increases, $c_{ij}(t)$ is dominated in the power series by positive terms. That is, $c_{ij}(t)$ becomes and remains positive for all large enough $t \geq 0$.

Suppose next that $p > 1$. The blocks in the lower triangular part of the block partition of each A^k implied by (3.1) must be zero; namely, if $u > v$, then $c_{ij}(t) = 0$ for all $t \geq 0$.

If $u = v$, that is, if i, j belong to the same equivalence class, then either A_{uu} and $A_{uu}^{(q)}$ are both equal to the 1×1 zero matrix or they are both irreducible. In the former case, $c_{ij}(t) = 0$ for all $t \geq 0$, and in the latter case, $c_{ij}(t)$ becomes and remains positive for all large enough $t \geq 0$ analogously to the $p = 1$ case above.

Finally, let us consider the sign of $c_{ij}(t)$ when $u < v$. Let $a_{ij}^{(k)}$ denote the (i,j)th entry of A^k. If $a_{ij}^{(k)} = 0$ for all $k < q$, then by Theorem 3.6(i) we have that $c_{ij}(t) \geq 0$ for all $t \geq 0$. If $a_{ij}^{(k)} \neq 0$ for some $k < q$, then there must be a path form i to j in $G(A)$. Thus there is a path from u to v in $R(A)$. By Theorem 3.6(iii), $\overline{R(A)} = \overline{R(A^q)}$ and so there must be a path from u to v in $R(A^q)$. It follows that there is a path from i to j in $G(A^q)$. In turn, this implies that there is a power $m \geq q$ such that $a_{ij}^{(m)} > 0$. As $a_{ij}^{(k)} \geq 0$ for all $k \geq q$, we have once again that $c_{ij}(t)$ is dominated in the power series by positive terms and so it becomes and remains positive for all large enough $t \geq 0$.

To conclude, we have shown that each entry $c_{ij}(t)$ of e^{tA} becomes and remains nonnegative for all large enough $t \geq 0$, namely, that A is eventually exponentially positive. □

COROLLARY 3.8. [illegible] $A \in \mathbb{R}^{n \times n}$ [illegible] $A + aI$ [illegible] $a \in [a_1, a_2]$ $(a_1 < a_2)$ [illegible] A [illegible].

[illegible]. Since $\sigma(A)$ is a finite set, there exists $a \in [a_1, a_2]$ such that $A + aI$ is invertible. Hence $\text{index}_0(A + aI) = 0$ and so by Theorem 3.7, $A + aI$ is eventually exponentially nonnegative. By Lemma 2.2, it follows that A is eventually exponentially nonnegative. □

We illustrate the above results on eventual nonnegativity with the following examples.

EXAMPLE 3.9. Consider

$$A = \begin{bmatrix} 0 & 1 & 1 & -1 \\ 1 & 0 & 1 & 1 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 1 \end{bmatrix}$$

for which

$$A^2 = \begin{bmatrix} 1 & 0 & 1 & 1 \\ 0 & 1 & 3 & 1 \\ 0 & 0 & 2 & 2 \\ 0 & 0 & 2 & 2 \end{bmatrix}, \quad A^3 = \begin{bmatrix} 0 & 1 & 3 & 1 \\ 1 & 0 & 5 & 5 \\ 0 & 0 & 4 & 4 \\ 0 & 0 & 4 & 4 \end{bmatrix},$$

$$A^4 = \begin{bmatrix} 1 & 0 & 5 & 5 \\ 0 & 1 & 11 & 9 \\ 0 & 0 & 8 & 8 \\ 0 & 0 & 8 & 8 \end{bmatrix}, \quad A^5 = \begin{bmatrix} 0 & 1 & 11 & 9 \\ 1 & 0 & 21 & 21 \\ 0 & 0 & 16 & 16 \\ 0 & 0 & 16 & 16 \end{bmatrix}.$$

Notice that A is reducible, eventually nonnegative, and, referring to Theorem 3.6, $q = k_0 = 2$. Since $\text{index}_0(A) = 1$, Theorem 3.7 implies that A is an eventually exponentially nonnegative matrix. For illustration, we compute e^{tA} for $t = 1, 2$ to be, respectively,

$$\begin{bmatrix} 1.5431 & 1.1752 & 2.3404 & -0.0100 \\ 1.1752 & 1.5431 & 4.0487 & 2.9625 \\ 0 & 0 & 4.1945 & 3.1945 \\ 0 & 0 & 3.1945 & 4.1945 \end{bmatrix}, \begin{bmatrix} 3.7622 & 3.6269 & 18.1543 & 10.9006 \\ 3.6269 & 3.7622 & 35.4439 & 29.9195 \\ 0 & 0 & 27.7991 & 26.7991 \\ 0 & 0 & 26.7991 & 27.7991 \end{bmatrix}.$$

This confirms A is an eventually exponentially nonnegative matrix with $1 < t_0 < 2$.

EXAMPLE 3.10. Consider the matrix

$$A = \begin{bmatrix} 1 & 1 & -1 & 1 \\ 1 & 1 & 1 & -1 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 1 \end{bmatrix}$$

and its sequence of powers

$$A^k = \begin{bmatrix} 2^{k-1} & 2^{k-1} & 0 & 0 \\ 2^{k-1} & 2^{k-1} & 0 & 0 \\ 0 & 0 & 2^{k-1} & 2^{k-1} \\ 0 & 0 & 2^{k-1} & 2^{k-1} \end{bmatrix} \quad (k = 2, 3, \ldots).$$

The matrix A is eventually nonnegative with $k_0 = 2$. As the $(1, 2)$ block of A^k is 0 for all $k \geq 2$, while the one of A is not and contains negative entries, A is not eventually exponentially nonnegative. In agreement, the assumptions of Theorem 3.7 do not hold since $\text{index}_0(A) = 2$.

The failure of eventual nonnegativity to force eventual exponential nonnegativity observed in the above example can occur even if A is irreducible, as the following example shows.

3.11. Consider the matrix

$$A = \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 \\ -1 & 1 & 1 & 1 \\ 1 & -1 & 1 & 1 \end{bmatrix}$$

and its sequence of powers

$$A^k = \begin{bmatrix} 2^{k-1} & 2^{k-1} & k2^{k-1} & k2^{k-1} \\ 2^{k-1} & 2^{k-1} & k2^{k-1} & k2^{k-1} \\ 0 & 0 & 2^{k-1} & 2^{k-1} \\ 0 & 0 & 2^{k-1} & 2^{k-1} \end{bmatrix} \quad (k = 2, 3, \ldots).$$

The matrix A is an eventually nonnegative matrix with $k_0 = 2$ and $\text{index}_0(A) = 2$. As the assumptions of Theorem 3.7 do not hold, we may not conclude that A is eventually exponentially nonnegative. The $(2,1)$ block of A^k is 0 for all $k \geq 2$, while the one of A is not and contains negative entries. Thus A is not eventually exponentially nonnegative. Indeed,

$$e^A = \begin{bmatrix} 4.1945 & 3.1945 & 7.3891 & 7.3891 \\ 3.1945 & 4.1945 & 7.3891 & 7.3891 \\ -1 & 1 & 4.1945 & 3.1945 \\ 1 & -1 & 3.1945 & 4.1945 \end{bmatrix}, \quad e^{3A} = \begin{bmatrix} 202.2 & 201.2 & 1210.3 & 1210.3 \\ 201.2 & 202.2 & 1210.3 & 1210.3 \\ -3 & 3 & 202.2 & 201.2 \\ 3 & -3 & 201.2 & 202.2 \end{bmatrix}.$$

We now turn our attention to necessary conditions for eventual exponential nonnegativity for which we need to quote some results from [11]. Note that in the first theorem below from [11], we have added the assumption that A is not nilpotent; the need for this assumption is observed in [5].

THEOREM 3.12 (see [11, Theorem 2.3]). $A \in \mathbb{R}^{n\times n}$ A A^T

THEOREM 3.13 (see [11, Theorem 2.4]). $A \in \mathbb{R}^{n\times n}$ A^T $\rho(A)$ A

$$\lim_{k\to\infty} \left(\frac{A}{\rho(A)}\right)^k = xy^T,$$

x y A $\rho(A)$ $x^T y = 1$

THEOREM 3.14. $A \in \mathbb{R}^{n\times n}$

(i) e^A e^{A^T}

(ii) $\rho(e^A)$ e^A $\rho(e^A) = e^{\rho(A)}$ $a_0 \geq 0$ $\lim_{k\to\infty}((A + aI)/(\rho(A + aI))^k = xy^T$ $a > a_0$ x y A $\rho(A)$ $x^T y = 1$

(i) Let A be eventually exponentially nonnegative. As $(e^A)^k = e^{kA}$, it follows that e^A is eventually nonnegative. Thus, by Theorem 3.12 and since e^A and e^{A^T} are not nilpotent, they have the Perron–Frobenius property.

(ii) From (i) we specifically have that $\rho(e^A) \in \sigma(e^A)$. Let x, y be right and left nonnegative eigenvectors, respectively, corresponding to $\rho(e^A)$ and normalized so that $x^T y = 1$. As in the proof of Theorem 3.3, $\rho(e^A) = e^\lambda$ for some $\lambda \in \sigma(A)$ with $\lambda > \operatorname{Re}\mu$ for all $\mu \in \sigma(A) \setminus \{\lambda\}$. This means that there exists large enough $a_0 > 0$, such that for all $a \geq a_0$,

$$\rho(A + aI) = \lambda + a > |\mu + a| \quad \text{for all } \mu \in \sigma(A), \ \ \mu \neq \lambda.$$

As $A + aI$ and e^A share eigenvectors, we obtain that for all $a > a_0$, $A + aI$ and $A^T + aI$ both have the Perron–Frobenius property, with $\lambda + a$ being simple and their only dominant eigenvalue. Applying Theorem 3.13 to $A + aI$, we thus obtain

$$\lim_{k\to\infty} \frac{1}{\rho(A+aI)^k}(A + aI)^k = xy^T \geq 0. \qquad \square \tag{3.2}$$

. 3.15. Referring to the proof of Theorem 3.14, by (3.2) we have that if $(xy^T)_{ij} > 0$, then $\left((A + aI)^k\right)_{ij} > 0$ for all k sufficiently large. In particular, if $xy^T > 0$, then $A + aI$ is eventually nonnegative for all $a > a_0$. If, however, xy^T is nonnegative but not strictly positive, $A + aI$ can fail to be eventually nonnegative for all $a \in \mathbb{R}$. This situation is illustrated by the matrix A in Example 3.11.

4. Points of nonnegative potential. In this section $A \in \mathbb{R}^{n\times n}$ denotes an eventually exponentially nonnegative matrix with exponential index $t_0 = t_0(A) \geq 0$. We will study points of nonnegative potential, that is, the set

$$X_A(\mathbb{R}^n_+) \ = \ \{x_0 \in \mathbb{R}^n \mid (\exists \hat{t} = \hat{t}(x_0) \geq 0)\,(\forall t \geq \hat{t})\,[e^{tA}x_0 \geq 0]\}. \tag{4.1}$$

$X_A(\mathbb{R}^n_+)$ comprises all initial points giving rise to trajectories of (1.1) that reach $\mathbb{R}^n_+$ at some finite time and stay in $\mathbb{R}^n_+$ for all time thereafter.

First, let us recall some basic facts and terminology on convex cones in $\mathbb{R}^n$. Our references are [1, Chapter 1] and [12]. A convex set $K \subseteq \mathbb{R}^n$ is called a , if $aK \subseteq K$ for all $a \geq 0$. A convex cone is called , if it consists of all finite nonnegative linear combinations of the elements of a finite set. A convex cone K is , if $K \cap (-K) = \{0\}$ and , if its topological interior is nonempty. A pointed, solid convex cone is called a , . The nonnegative orthant $\mathbb{R}^n_+$ is indeed a proper cone; it is also a polyhedral cone, comprising all finite nonnegative combinations of the standard basis vectors. Any subset of $\mathbb{R}^n$ of the form $K = S\mathbb{R}^n_+$, where S is an invertible matrix, is a proper polyhedral cone and referred to as a .

Given an eventually exponentially nonnegative matrix $A \in \mathbb{R}^{n\times n}$ with exponential index $t_0 = t_0(A) \geq 0$, define the simplicial cone

$$K = e^{t_0 A}\mathbb{R}^n_+ = \{x_0 \in \mathbb{R}^n \mid (\exists y \geq 0)\,[x_0 = e^{t_0 A}y]\}$$

and consider the sets

$$Y_A(K) \ = \ \{x_0 \in \mathbb{R}^n \mid (\exists \hat{t} = \hat{t}(x_0) \geq 0)\,[e^{\hat{t}A}x_0 \in K]\} \tag{4.2}$$

and

$$X_A(K) \ = \ \{x_0 \in \mathbb{R}^n \mid (\exists \hat{t} = \hat{t}(x_0) \geq 0)\,(\forall t \geq \hat{t})\,[e^{tA}x_0 \in K]\}. \tag{4.3}$$

LEMMA 4.1. . K, $Y_A(K)$ $K \subseteq \mathbb{R}^n_+ \subseteq Y_A(K)$

. We have that $K \subseteq \mathbb{R}^n_+$ since $e^{t_0 A} \geq 0$. If $x_0 \in \mathbb{R}^n_+$, then for $\hat{t} = 2t_0$, $e^{\hat{t}A}x_0 = e^{t_0 A}\,(e^{t_0 A}x_0) \in K$. Hence, $\mathbb{R}^n_+ \subseteq Y_A(K)$. □

Note that the sets $Y_A(K)$, $X_A(K)$, and $X_A(\mathbb{R}^n_+)$ are convex cones. They are not necessarily closed sets, however. For example, when

$$A = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix},$$

it can be shown that $X_A(\mathbb{R}^2_+)$ consists of the whole upper plane excluding the negative x-axis.

The set $Y_A(K)$ comprises initial points for which the trajectories enter K at some time. The set $X_A(K)$ comprises initial points for which the trajectories enter K at some time and remain in K for all time thereafter. The set of points of nonnegative potential, $X_A(\mathbb{R}^n_+)$, comprises initial points for which the trajectories at some time become nonnegative and remain nonnegative for all time thereafter. Next we shall argue that $Y_A(K)$, $X_A(K)$, and $X_A(\mathbb{R}^n_+)$ coincide and interpret this result subsequently.

PROPOSITION 4.2. . $A \in \mathbb{R}^{n\times n}$. $t_0 = t_0(A) \geq 0$. $K = e^{t_0 A}\mathbb{R}^n_+$

$$Y_A(K) \;=\; X_A(\mathbb{R}^n_+) \;=\; X_A(K).$$

. We begin by proving the first equality. If $x_0 \in Y_A(K)$, then there exists $\hat{t} \geq 0$ and $y \geq 0$ such that $e^{\hat{t}A}x_0 = e^{t_0 A}y$. Thus, $x_0 = e^{(t_0-\hat{t})A}y$ and so $e^{tA}x_0 = e^{(t+t_0-\hat{t})A}y \geq 0$ if $t + t_0 - \hat{t} \geq t_0$, i.e., for all $t \geq \hat{t}$. It follows that $x_0 \in X_A(\mathbb{R}^n_+)$, i.e., $Y_A(K) \subseteq X_A(\mathbb{R}^n_+)$. For the opposite containment, let $x_0 \in X_A(\mathbb{R}^n_+)$; that is, there exists $\hat{t} \geq 0$ such that $e^{tA}x_0 \geq 0$ for all $t \geq \hat{t}$. Let $\tilde{t} = \hat{t} + t_0$. Then $e^{\tilde{t}A}x_0 = e^{t_0 A}(e^{\hat{t}Ax_0}) \in K$, proving that $X_A(\mathbb{R}^n_+) \subseteq Y_A(K)$ and thus equality holds.

For the second equality, clearly $X_A(K) \subseteq X_A(\mathbb{R}^n_+)$ since $K \subseteq \mathbb{R}^n_+$. To show the opposite containment, let $x_0 \in X_A(\mathbb{R}^n_+)$. Then there exists $\hat{t} \geq 0$ such that $e^{t_0 A}e^{sA}x_0 \in K$ for all $s \geq \hat{t}$. That is, $e^{tA}x_0 \in K$ for all $t \geq t_0 + \hat{t}$ and thus $x_0 \in X_A(K)$. □

. 4.3. Referring to Proposition 4.2, we must make the following observations:

(i) If $t_0 = 0$ (i.e., if $A \overset{\mathrm{s}}{\geq} 0$, or equivalently if $e^{tA} \geq 0$ for all $t \geq 0$), then $K = \mathbb{R}^n_+$. In this case, $X_A(\mathbb{R}^n_+)$ coincides with the . of the nonnegative orthant for an essentially nonnegative matrix, which is studied in detail in [10, 9].

(ii) The equality $X_A(\mathbb{R}^n_+) = X_A(K)$, in conjunction with Lemma 4.1, can be interpreted as saying that the simplicial cone $K = e^{t_0 A}\mathbb{R}^n_+$ serves as an attractor set for trajectories emanating at points of nonnegative potential; in other words, trajectories emanating in $X_A(\mathbb{R}^n_+)$ always reach and remain in $K \subseteq \mathbb{R}^n_+$ after a finite time.

(iii) Our observations so far imply that the trajectory emanating from a point of nonnegative potential will enter cone K; however, it may subsequently exit K while it remains nonnegative, and it will eventually re-enter K and remain in K for all finite time thereafter. This situation is illustrated by the following example.

. 4.4. Consider the matrix

$$A = \begin{bmatrix} 0.3929 & -0.8393 & 1.1071 & 1.3393 \\ 1.0357 & 0.6964 & -0.5357 & 0.8036 \\ 1.0357 & -0.3036 & 0.4643 & 0.8036 \\ 1.4643 & 1.0536 & -0.9643 & 0.4464 \end{bmatrix}.$$

It can be checked that A and A^T have the strong Perron–Frobenius property and so, by Theorems 3.2 and 3.3, A is an eventually exponentially positive matrix. Using MATLAB and a bisection method, we estimated (within five decimals) the exponential index to be $t_0 = t_0(A) = 2.64378$. The matrices e^A and $e^{t_0 A}$ are

$$e^A = \begin{bmatrix} 3.6277 & -0.7991 & 1.4260 & 3.1345 \\ 3.0341 & 2.2579 & -0.6987 & 2.7958 \\ 3.0341 & -0.4604 & 2.0196 & 2.7958 \\ 3.3050 & 1.4836 & -0.9696 & 3.5701 \end{bmatrix}$$

and

$$e^{t_0 A} = \begin{bmatrix} 91.902 & 3.5982 & 14.0615 & 88.299 \\ 91.499 & 18.162 & 0.3981 & 87.801 \\ 91.499 & 4.0959 & 14.4643 & 87.801 \\ 91.897 & 17.494 & 0 & 88.469 \end{bmatrix}.$$

Hence the cone $K = e^{t_0 A}\mathbb{R}^n_+$ is the cone generated by the columns of the matrix $e^{t_0 A}$ above. Consider now the following trajectory points $x(t) = e^{tA}x(0)$:

$$x_0 = x(0) = \begin{bmatrix} -1.1617 \\ 0.6014 \\ 0.9693 \\ 1.0887 \end{bmatrix}, \quad x(1) = e^A x_0 = \begin{bmatrix} 0.1 \\ 0.2 \\ 1.2 \\ 0 \end{bmatrix}, \quad x(2) = e^{2A}x_0 = \begin{bmatrix} 1.9141 \\ -0.0834 \\ 2.6348 \\ -0.5363 \end{bmatrix},$$

$$e^{(t_0+1)A}x_0 = \begin{bmatrix} 26.7836 \\ 13.2600 \\ 27.3263 \\ 12.6884 \end{bmatrix}, \quad e^{(t_0+2)A}x_0 = \begin{bmatrix} 165.3049 \\ 127.5845 \\ 165.8206 \\ 126.9949 \end{bmatrix}, \quad e^{(2t_0+1)A}x_0 = \begin{bmatrix} 4013.8 \\ 3816.4 \\ 4014.3 \\ 3815.8 \end{bmatrix}.$$

Observe the following: $e^{(t_0+1)A}x_0 \in K$ since $e^A x_0 \in \mathbb{R}^n_+$; $e^{(t_0+2)A}x_0 \notin K$ since $e^{2A}x_0 \notin \mathbb{R}^n_+$; $e^{(2t_0+1)A}x_0 \in K$ since $e^{(t_0+1)A}x_0 \in \mathbb{R}^n_+$; finally, trajectory points $x(t)$ are in K for all $t \geq 2t_0 + 1$. In other words, the trajectory emanating at x_0 enters K, exits K, and eventually re-enters and remains in K for all time thereafter.

In view of the above example, a natural question arises: When is it possible that all trajectories emanating in $X_A(\mathbb{R}^n_+)$ reach and never exit K? This is equivalent to asking whether or not $e^{tA}K \subseteq K$ for all $t \geq 0$. To resolve this question, we will invoke the following extension of Lemma 3.1 from $\mathbb{R}^n_+$ to simplicial cones, which can be found in [13, 14].

LEMMA 4.5. [illegible] $A \in \mathbb{R}^{n\times n}$ [illegible] $K = S\mathbb{R}^n_+$ [illegible] $S \in \mathbb{R}^{n\times n}$ [illegible] $a \geq 0$ [illegible] $(A + aI)K \subseteq K$ [illegible] $e^{tA}K \subseteq K$ [illegible] $t \geq 0$

[illegible]. Consider the similarity transformation $A \to B = S^{-1}AS$. We claim that there exists $a \geq 0$ such that $(A + aI)K \subseteq K$ if and only if $B \overset{\text{s}}{\geq} 0$. Indeed, if $(A + aI)K \subseteq K$, then

$$(B + aI)\mathbb{R}^n_+ = S^{-1}(A + aI)S\mathbb{R}^n_+ = S^{-1}(A + aI)K \subseteq S^{-1}K = \mathbb{R}^n_+.$$

Conversely, if $B \overset{\text{s}}{\geq} 0$, then there exists $a \geq 0$ such $B + aI = S^{-1}(A + aI)S \geq 0$. Hence for each $x \in K$, there exists $y \geq 0$ such that

$$S^{-1}(A + aI)x = S^{-1}(A + aI)Sy = z \geq 0.$$

That is, $(A + aI)Sy = Sz \in K$. Similarly, one can show that $e^{tA}K \subseteq K$ for all $t \geq 0$ if and only if $e^{tB} \geq 0$ for all $t \geq 0$. □

We note in passing that Lemma 4.5 holds more generally for every polyhedral cone K; see [13, 14].

COROLLARY 4.6. [illegible] $A \in \mathbb{R}^{n\times n}$ [illegible] $t_0 = t_0(A) \geq 0$ [illegible] $K = e^{t_0 A}\mathbb{R}^n_+$ [illegible] $e^{tA}K \subseteq K$ [illegible] $t \geq 0$ [illegible] $t_0 = 0$ ([illegible] $A \overset{s}{\geq} 0$)

[illegible]. If $t_0 = 0$, then $K = \mathbb{R}^n_+$ and $e^{tA} \geq 0$ for all $t \geq 0$. For the converse, suppose $e^{tA}K \subseteq K$ for all $t \geq 0$. We must show that $t_0 = 0$. Let $y \geq 0$ and consider $x_0 = e^{t_0 A}y \in K$. As $e^{tA}x_0 \in K$ for all $t \geq 0$, there must exist $z \geq 0$ such that

$$e^{(t+t_0)A}\, y \;=\; e^{t_0 A}\, z \quad \text{for all } t \geq 0.$$

But this means $e^{tA}y = z \geq 0$ for all $t \geq 0$. Since y was taken arbitrary in $\mathbb{R}^n_+$, we have $e^{tA}\mathbb{R}^n_+ \subseteq \mathbb{R}^n_+$ for all $t \geq 0$; that is, $t_0 = 0$. □

We conclude this section with a discussion on a possible numerical test for points of nonnegative potential. When $A = [a_{ij}] \overset{s}{\geq} 0$, $X_A(\mathbb{R}^n_+)$ admits a numerical characterization reported in [10] and briefly described in the following. Consider the sequence $\{x_k\}$ generated from x_0 by the Cauchy–Euler finite differences scheme

$$x_k = (I + hA)^k x_0, \quad k = 0, 1, \ldots,$$

which we refer to as [illegible] ([illegible] h) [illegible] x_0. Define the quantity

$$h(A) = \sup\left\{ h \mid \min_{1\leq i\leq n} (1 + ha_{ii}) > 0 \right\}$$

and notice that $h(A) = \sup\{h \mid (I + hA) \geq 0\} > 0$, as well as that $h(A) = \infty$ when $A \geq 0$.

For any $h \in (0, h(A))$, denote by $X_{A,h}(\mathbb{R}^n_+)$ the set of all initial states $x_0 \in \mathbb{R}^n$ that give rise to discrete trajectories $\{x_k\}$ which become and remain (due to nonnegativity of $I + hA$) nonnegative; that is,

$$X_{A,h}(\mathbb{R}^n_+) = \{x_0 \in \mathbb{R}^n \mid (\exists k_0 = k_0(x_0) \geq 0)\,(\forall k \geq k_0)\,[(I + hA)^k x_0 \in \mathbb{R}^n_+]\}.$$

We refer to $X_{A,h}(\mathbb{R}^n)$ as the [illegible] ([illegible] $\mathbb{R}^n_+$ [illegible] A [illegible] h). The geometric and algebraic properties of the discrete reachability cone are studied extensively in [8, 10].

THEOREM 4.7 (see [10]). [illegible] $A \in \mathbb{R}^{n\times n}$ [illegible] $h \in (0, h(A))$ [illegible] $(I + hA)$ [illegible] $X_A(\mathbb{R}^n_+) = X_{A,h}(\mathbb{R}^n_+)$

When $A \overset{s}{\geq} 0$, Theorem 4.7 suggests a simple test to find out whether or not a given initial point x_0 belongs to $X_A(\mathbb{R}^n_+)$: 1. Choose a positive $h < h(A)$ such that the iteration matrix $I + hA$ is invertible. 2. Check whether for some nonnegative integer k, $x_k = (I + hA)^k x_0$ is nonnegative (in which case $x_0 \in X_A(\mathbb{R}^n_+)$) or decide that x_k will never be nonnegative (in which case $x_0 \notin X_A(\mathbb{R}^n_+)$).

As noted in [15], Theorem 4.7 can be generalized from $\mathbb{R}^n_+$ to any simplicial cone K such that $e^{tA}K \subseteq K$ for all $t \geq 0$. Thus, in view of Proposition 4.2, the question arising is whether the above test can be extended to $X_A(\mathbb{R}^n_+) = X_A(K)$, when A is eventually exponentially nonnegative with exponential index $t_0 \geq 0$ and $K = e^{t_0 A}\mathbb{R}^n_+$. By Corollary 4.6, however, it follows that the answer is in the negative when

$t_0 > 0$. The development of a characterization of points of nonnegative potential in terms of discrete trajectories will likely require a close examination of the generalized eigenspaces of A as in the proof of Theorem 4.7. We plan to undertake this task in future work, as well as perform a numerical analysis of the associated test.

5. Conclusions. We considered the problem of when a trajectory $x(t) = e^{tA}x_0$ $(t \geq 0)$ becomes and remains nonnegative. Naturally, we needed to study (1) matrices A for which e^{tA} becomes and remains nonnegative and (2) initial points x_0 giving rise to nonnegative trajectories, which we called points of nonnegative potential. The combination of such matrices and initial points results in trajectories that reach and stay in the nonnegative orthant. We discovered that eventual nonnegativity of the exponential matrix is intimately related to eventual nonnegativity of the powers of A (section 3). We also found that the collection of points of nonnegative potential coincides with the collection of initial points that reach and stay in a certain simplicial cone K associated with e^{tA}. Interestingly, trajectories emanating at points of nonnegative potential may enter and subsequently exit this cone K; however, K eventually attracts such trajectories permanently (section 4). Our results generalize and parallel well-known facts in nonnegative systems theory and are illustrated with several examples.

Acknowledgment. The authors would like to sincerely thank the anonymous referees and the editor, Daniel Szyld, for several comments that helped us correct and improve the original manuscript.

NONNEGATIVE MATRIX FACTORIZATION BASED ON ALTERNATING NONNEGATIVITY CONSTRAINED LEAST SQUARES AND ACTIVE SET METHOD*

HYUNSOO KIM† AND HAESUN PARK†

Abstract. Nonnegative matrix factorization (NMF) determines a lower rank approximation of a matrix $A \in \mathbb{R}^{m\times n} \approx WH$ where an integer $k \ll \min(m,n)$ is given and nonnegativity is imposed on all components of the factors $W \in \mathbb{R}^{m\times k}$ and $H \in \mathbb{R}^{k\times n}$. NMF has attracted much attention for over a decade and has been successfully applied to numerous data analysis problems. In applications where the components of the data are necessarily nonnegative, such as chemical concentrations in experimental results or pixels in digital images, NMF provides a more relevant interpretation of the results since it gives nonsubtractive combinations of nonnegative basis vectors. In this paper, we introduce an algorithm for NMF based on alternating nonnegativity constrained least squares (NMF/ANLS) and the active set–based fast algorithm for nonnegativity constrained least squares with multiple right-hand side vectors, and we discuss its convergence properties and a rigorous convergence criterion based on the Karush–Kuhn–Tucker (KKT) conditions. In addition, we also describe algorithms for sparse NMFs and regularized NMF. We show how we impose a sparsity constraint on one of the factors by L_1-norm minimization and discuss its convergence properties. Our algorithms are compared to other commonly used NMF algorithms in the literature on several test data sets in terms of their convergence behavior.

1. Introduction.

Given a nonnegative matrix $A \in \mathbb{R}^{m\times n}$ and a desired rank $k \ll \min(m,n)$, nonnegative matrix factorization (NMF) searches for nonnegative factors W and H that give a lower rank approximation of A as

$$A \approx WH \quad \text{s.t.} \quad W, H \geq 0, \tag{1.1}$$

where $W, H \geq 0$ means that all elements of W and H are nonnegative. The problem in (1.1) is commonly reformulated as the following optimization problem:

$$\min_{W,H} f(W,H) \equiv \frac{1}{2}\|A - WH\|_F^2 \quad \text{s.t.} \quad W, H \geq 0, \tag{1.2}$$

where $W \in \mathbb{R}^{m\times k}$ is a basis matrix and $H \in \mathbb{R}^{k\times n}$ is a coefficient matrix. In many data analysis problems, typically each column of A corresponds to a data point in the m-dimensional space.

NMF may give a simple interpretation due to nonsubtractive combinations of nonnegative basis vectors and has recently received much attention. Applications of

NMF are numerous, including image processing [21], text data mining [31], subsystem identification [19], and cancer class discovery [4, 8, 18]. It has been over a decade since NMF was first proposed by Paatero and Tapper [27] (in fact, as positive matrix factorization) in 1994. Various types of NMF techniques have been proposed in the literature [5, 13, 25, 32, 34], which include Lee and Seung's popular iterative multiplicative update algorithms [21, 22], gradient descent methods [24], and alternating least squares [1]. Paatero and Tapper [27] originally proposed an algorithm for NMF using a constrained alternating least squares algorithm to solve (1.2). Unfortunately, this approach has not obtained wide attention especially after Lee and Seung's multiplicative update algorithm was proposed [1, 24]. The main difficulty was extremely slow speed caused by a vast amount of hidden redundant computation related to satisfying the nonnegativity constraints exactly. One may try to deal with the nonnegativity constraints in an approximate sense for faster algorithm. However, we will show that it is important to satisfy the constraints exactly for the overall convergence of the algorithm and that this property provides very practical and faster algorithm as well. In addition, faster algorithms that exactly satisfy the nonnegativity constraints in the least squares with multiple right-hand sides already exist [27, 36], which we will discuss and utilize in our proposed NMF algorithms.

In this paper, we provide a framework of the two-block coordinate descent method for NMF. This framework provides a convenient way to explain and compare most of the existing commonly used NMF algorithms and to discuss their convergence properties. We then introduce an NMF algorithm which is based on alternating nonnegativity constrained least squares (NMF/ANLS) and the active set method. Although many existing NMF algorithms produce the factors which are often sparse, the formulation of the NMF shown in (1.2) does not guarantee the sparsity in the factors. We introduce an NMF formulation and algorithm that imposes sparsity constraint on one of the factors by L_1-norm minimization and discuss its convergence properties. The L_1-norm minimization term is formulated in such a way that the proposed sparse NMF algorithm also fits into the framework of the two-block coordinate descent method and accordingly its convergence properties become easy to understand.

The rest of this paper is organized as follows. We present the framework of the two-block coordinate descent method and provide a brief overview of various existing NMF algorithms in section 2. In section 3, we introduce our NMF/ANLS algorithm and discuss its convergence properties. In section 4, we describe some variations of the NMF/ANLS algorithm, which include the method designed to impose sparsity on one of the factors through the addition of an L_1-norm minimization term in the problem formulation. Our algorithms are compared to other commonly used NMF algorithms in the literature on several test data sets in section 6. Finally, summary and discussion are given in section 7.

2. A two-block coordinate descent framework for NMF algorithms and convergence properties. In most of the currently existing algorithms for NMF, the basic framework is to reformulate the nonconvex minimization problem shown in (1.2) as a two-block coordinate descent problem [2]. Given a nonnegative matrix $A \in \mathbb{R}^{m \times n}$ and an integer $k < \min(m, n)$, one of the factors, say $H \in \mathbb{R}^{k \times n}$, is initialized with nonnegative values. Then one may iterate the following alternating nonnegativity constrained least squares (ANLS) until a convergence criterion is satisfied:

$$\min_{W \geq 0} \|H^T W^T - A^T\|_F^2, \tag{2.1}$$

where H is fixed, and

$$\min_{H \geq 0} \|WH - A\|_F^2, \tag{2.2}$$

where W is fixed. Alternatively, after initializing W, one may iterate (2.2) and then (2.1) until a convergence criterion is satisfied. Each subproblem shown in (2.1)–(2.2) can be solved by projected quasi-Newton optimization [37, 15], projected gradient descent optimization [24], or nonnegativity constrained least squares [27, 16, 28].

Note that the original NMF problem of (1.2) is nonconvex, and most nonconvex optimization algorithms guarantee only the stationarity of limit points. Since the problem formulation is symmetric with respect to initialization of the factors H or W, for simplicity of discussion, we will assume that the iteration is performed with the initialization of the factor H. Then the above iteration can be expressed as follows:

- Initialize H with a nonnegative matrix $H^{(0)}$; $t \leftarrow 0$.
- Repeat until a stopping criterion is satisfied:
  - $W^{(t+1)} = \arg\min_W f(W, H^{(t)})$ s.t. $W \geq 0$.
  - $H^{(t+1)} = \arg\min_H f(W^{(t+1)}, H)$ s.t. $H \geq 0$.
  - $t \leftarrow t + 1$.

According to the Karush–Kuhn–Tucker (KKT) optimality conditions, (W, H) is a stationary point of (1.2) if and only if

$$\begin{aligned} &W \geq 0, && H \geq 0, \\ &\nabla_W f(W,H) = WHH^T - AH^T \geq 0, && \nabla_H f(W,H) = W^TWH - W^TA \geq 0, \\ &W. * \nabla_W f(W,H) = 0, && H. * \nabla_H f(W,H) = 0, \end{aligned} \tag{2.3}$$

where $.*$ denotes componentwise multiplication [11].

For (1.2), when the block coordinate descent algorithm is applied, then no matter how many subblocks into which the problem is partitioned, if the subproblems have unique solutions, then the limit point of the sequence is a stationary point [2]. For two-block problems, Grippo and Siandrone [12] presented a stronger result. The result does not require uniqueness of the solution in each subproblem, which is that any limit point of the sequence generated based on the optimal solutions of each of the two subblocks is a stationary point. Since the subproblems (2.1) and (2.2) are convex but not strongly convex, they do not necessarily have unique solutions. However, according to the two-block result, it is still the case that any limit point will be a stationary point. We emphasize that for convergence to a stationary point, it is important to find an optimal solution for each subproblem.

In one of the most commonly utilized NMF algorithms due to Lee and Seung [21, 22], NMF is computed using the following norm-based multiplicative update rules (NMF/NUR) of W and H, which is a variation of the gradient descent method:

$$W_{iq} \leftarrow W_{iq} \frac{(AH^T)_{iq}}{(W(HH^T))_{iq}} \tag{2.4}$$

for $1 \leq i \leq m$ and $1 \leq q \leq k$,

$$H_{qj} \leftarrow H_{qj} \frac{(W^TA)_{qj}}{((W^TW)H)_{qj}} \tag{2.5}$$

for $1 \leq q \leq k$ and $1 \leq j \leq n$. Each iteration may in fact break down since the denominators in both (2.4) and (2.5) can be zeros. Accordingly, in practical algorithms, a small positive number is added to each denominator to prevent division by zero. There are several variations of NMF/NUR [8, 30, 6].

Lee and Seung also designed an NMF algorithm using the divergence-based multiplicative update rules (NMF/DUR) [22] to minimize the divergence:

$$D(A||WH) = \sum_{i=1}^{m}\sum_{j=1}^{n}\left(A_{ij}\ln\frac{A_{ij}}{(WH)_{ij}} - A_{ij} + (WH)_{ij}\right) \quad \text{s.t.} \quad W, H \geq 0. \tag{2.6}$$

Strictly speaking, this formulation is not a bound constrained problem, which requires the objective function to be well-defined at any point of the bounded region, since the log function is not well-defined if $A_{ij} = 0$ or $(WH)_{ij} = 0$ [24]. The divergence is also nonincreasing during iterations. Gonzales and Zhang [11] claimed that these nonincreasing properties of multiplicative update rules may not imply the convergence to a stationary point within a realistic amount of run time for problems of meaningful sizes. Lin [24] devised an NMF algorithm based on projected gradient methods. However, it is known that gradient descent methods may suffer from slow convergence due to a possible zigzag phenomenon.

Berry et al. [1] proposed an NMF algorithm based on alternating least squares (NMF/ALS). This algorithm computes the solutions to the subproblems (2.1) and (2.2) as an unconstrained least squares problems with multiple right-hand sides and sets negative values in the solutions W and H to zero during iterations to enforce nonnegativity. Although this may give a faster algorithm for approximating each subproblem, the convergence of the overall algorithm is difficult to analyze since the subproblems are formulated as constrained least squares problems but the solutions are not those of the constrained least squares.

Zdunek and Cichocki [37] developed a quasi-Newton optimization approach with projection. In this algorithm, the negative values of W and H are replaced with a very small positive value. Again, setting negative values to zero or small positive values for imposing nonnegativity makes theoretical analysis of the convergence of the algorithm difficult [3]. The projection step can increase the objective function value and may lead to nonmonotonic changes in the objective function value resulting in inaccurate approximations.

A more detailed review of NMF algorithms can be found in [1].

3. NMF based on alternating nonnegativity constrained least squares and the active set method. In this section, we describe our NMF algorithm based on alternating nonnegativity constrained least squares (NMF/ANLS) that satisfies the nonnegativity constraints in each of the subproblems in (2.1) and (2.2) exactly and therefore has the convergence property that every limit point is a stationary point.

The structures of the two nonnegativity constrained least squares (NLS) problems with multiple right-hand sides shown in (2.1) and (2.2) are essentially the same, and therefore we will concentrate on a general form of the NLS with multiple right-hand sides

$$\min_{G \geq 0} \|BG - Y\|_F^2, \tag{3.1}$$

where $B \in \mathbb{R}^{p \times q}$ and $Y \in \mathbb{R}^{p \times l}$ are given, which can be decoupled into l independent

NLS problems each with single right-hand side as

$$\min_{G\geq 0}\|BG-Y\|_F^2 \rightarrow \min_{\mathbf{g}_1\geq 0}\|B\mathbf{g}_1-\mathbf{y}_1\|_2^2, \quad \ldots \quad ,\min_{\mathbf{g}_l\geq 0}\|B\mathbf{g}_l-\mathbf{y}_l\|_2^2, \tag{3.2}$$

where $G=[\mathbf{g}_1,\ldots,\mathbf{g}_l]\in\mathbb{R}^{q\times l}$ and $Y=[\mathbf{y}_1,\ldots,\mathbf{y}_l]\in\mathbb{R}^{p\times l}$. This objective function is not strictly convex so that it does not ensure a unique solution unless B is full column rank. In the context of the NMF computation, we implicitly assume that the fixed matrices H^T and W involved in (2.1) and (2.2) are of full column rank since they are interpreted as basis matrices for A^T and A, respectively. Each of the NLS problems with single right-hand side vector

$$\min_{\mathbf{g}_j\geq 0}\|B\mathbf{g}_j-\mathbf{y}_j\|_2 \tag{3.3}$$

for $1\leq j\leq l$ can be solved by using the active set method of Lawson and Hanson [20], which is implemented in MATLAB [26] as the function [illegible]. The algorithm is summarized in Algorithm 1.

The following theorem states the necessary and sufficient conditions for a vector g to be a solution for the problem NLS.

THEOREM 1 (Kuhn–Tucker conditions for problem NLS). [illegible] $g\in\mathbb{R}^{n\times 1}$ [illegible]

$$\min\|Bg-b\| \quad s.t. \quad g\geq 0 \tag{3.4}$$

[illegible] $r\in\mathbb{R}^{m\times 1}$ [illegible] 1 [illegible] m [illegible] $\mathcal{E}$ [illegible] $\mathcal{S}$ [illegible] $r=B^T(Bg-y)$

$$g_i=0 \quad i\in\mathcal{E}, \qquad g_i>0 \quad i\in\mathcal{S}, \tag{3.5}$$

$$r_i\geq 0 \quad i\in\mathcal{E}, \qquad r_i=0 \quad i\in\mathcal{S}. \tag{3.6}$$

On termination of Algorithm NLS, the solution vector g satisfies

$$g_i>0, \quad i\in\mathcal{S} \quad \text{and} \quad g_i=0, \quad i\in\mathcal{E} \tag{3.7}$$

and is a solution vector for the [illegible] least squares problem

$$\min_x\|B_{\mathcal{S}}g-y\|_2. \tag{3.8}$$

The dual vector $w=-r=B^T(y-Bg)$ satisfies

$$w_i=0 \quad i\in\mathcal{S} \quad \text{and} \quad w_i\leq 0 \quad j\in\mathcal{E}. \tag{3.9}$$

To enhance the computational speed in solving (3.1) based on Algorithm NLS, we utilize the fast algorithms by Bro and de Jong [3] and van Benthem and Keenan [36]. Bro and de Jong [3] made a substantial speed improvement for solving (3.1) which has multiple right-hand side vectors over a naive application of Algorithm NLS, which is for a single right-hand side problem, by precomputing cross-product terms that appear in the normal equations of the unconstrained least squares problems. Van Benthem and Keenan [36] devised an algorithm that further improves the performance of NLS for multivariate data by initializing the active set $\mathcal{E}$ based on the result from the unconstrained least squares solution and reorganizing the calculations to take advantage of the combinatorial nature of the active set–based solution methods for the NLS with [illegible] right-hand sides.

Algorithm 1 NLS: This algorithm computes the solution for the problem $\min_{g \geq 0} \|Bg - y\|_2$ by the active set method, where $B \in \mathbf{R}^{m \times n}$ and $y \in \mathbf{R}^{m \times 1}$ are given.

Initialization:
$g := 0$
$\mathcal{E} := \{1, 2, \ldots, n\}$ % Initially all indices belong to Active set since $g := 0$
$\mathcal{S} := \phi$ % Initially Passive set is empty
$w := B^T(b - Bg)$.

Do While ($\mathcal{E} \neq \phi$ and $\exists\ j \in \mathcal{E}$ such that $w_j > 0$)

1. Find an index $t \in \mathcal{E}$ such that $w_t = \max\{w_j : j \in \mathcal{E}\}$ % t is the column index of B that can potentially reduce the objective function value by maximum when brought into the Passive set.
2. Move the index t from set $\mathcal{E}$ to set $\mathcal{S}$.
3. Let $B_{\mathcal{S}}$ denote the $m \times n$ matrix defined by
   Column j of $B_{\mathcal{S}} := \begin{cases} \text{column } j \text{ of } B & \text{if } j \in \mathcal{S}, \\ 0 & \text{if } j \in \mathcal{E}. \end{cases}$
   Solve $\min_z \|B_{\mathcal{S}} z - b\|_2$. (% Only the components z_j, $j \in \mathcal{S}$, are determined by this problem.)
   $z_j := 0$ for $j \in \mathcal{E}$.
4. **Do While** ($z_j \leq 0$ for any $j \in \mathcal{S}$)
   (a) Find an index $q \in \mathcal{S}$ such that $g_q/(g_q - z_q) = \min\{g_j/(g_j - z_j) :\ z_j \leq 0, j \in \mathcal{S}\}$.
   (b) $\alpha := g_q/(g_q - z_q)$.
   (c) $g := g + \alpha(z - g)$.
   (d) Move from set $\mathcal{S}$ to set $\mathcal{E}$ all indices $j \in \mathcal{S}$ for which $g_j = 0$.
   (e) Define $B_{\mathcal{S}}$ as in step 3 and
   Solve $\min_z \|B_{\mathcal{S}} z - b\|_2$.
5. **End While** (% $z_j > 0$ for all $j \in \mathcal{S}$)
6. $g := z$.
7. $w := B^T(b - Bg)$.

End While (% $\mathcal{E}$ is empty (all indices are passive) or $w_j \leq 0$ for all $j \in \mathcal{E}$ (objective function value cannot be reduced anymore))

To illustrate the situation in a simpler context, let us for now assume that there is no nonnegativity constraints in the least squares problems shown in (3.2) and (3.3). Then, since an optimal solution $\mathbf{g}_j^*$ for $\min_{\mathbf{g}_j} \|B\mathbf{g}_j - \mathbf{y}_j\|_2$ is $B^\dagger \mathbf{y}_j$ for $j = 1, \ldots, l$, the pseudoinverse $B^\dagger$ of B [9] needs to be computed [illegible] (in fact, we do not recommend forming the pseudoinverse explicitly and it is used here only for explanation). Clearly, it would be extremely inefficient if we treat each subproblem independently and process the matrix B each time. In the case of NLS with multiple right-hand side vectors, the scenario is not this simple since the active set $\mathcal{E}$ may differ in each iteration and for each right-hand side vector, and a solution is obtained based on a subset of columns of the matrix B that corresponds to the passive set in each iteration, as shown in step 3 of Algorithm NLS. However, much of the computation which is potentially redundant in each iteration can be identified and precomputed only once. For example, if the matrix B has full column rank, then by precomputing B^TB and B^TY only once and extracting the necessary components from these for

each passive set, one can obtain the solution efficiently by extracting the normal equations for each passive set avoiding redundant computations [3]. In addition, for the multiple right-hand side case, the computations can be rearranged to be column parallel; i.e., the passive set columns in each step of the active set iteration for all right-hand side vectors are identified collectively at once. Thus, larger sets of common passive sets can be found and more redundant computations can be avoided. More detailed explanations of this algorithm can be found in [36].

As we stated earlier, with the above-mentioned solution method NMF/ANLS, which satisfies the nonnegativity constraint exactly, any limit point will be a stationary point [2, 12]. Lin [24] also discussed the convergence properties of alternating nonnegativity constrained least squares and showed that any limit point of the sequence (W, H) generated by alternating nonnegativity constrained least squares is a stationary point of (1.2) when the objective function is convex, and not necessarily strictly convex. The NMF is clearly not unique since there exist nonsingular matrices $X \in \mathbb{R}^{k\times k}$ including scaling and permutation matrices satisfying $WX \geq 0$ and $X^{-1}H \geq 0$, and these factors give $\|A - WH\|_F = \|A - WXX^{-1}H\|_F$. To provide a fair comparison among the computed factors based on various algorithms in the presence of this nonuniqueness, after convergence, the columns of the basis matrix W are often normalized to unit L_2-norm and the rows of H are adjusted so that the objective function value is not changed. However, we would like to note that normalizing the computed factors after each iteration makes the convergence results of the two-block coordinate descent method not applicable since the normalization alters the objective function of the subproblems expressed in (2.1) and (2.2).

4. Algorithms for sparse NMF based on alternating nonnegativity constrained least squares. One of the interesting properties of NMF is that it often generates sparse factors that allow us to discover parts-based basis vectors. Although the results presented in [21] show that the computed NMF generated parts-based basis vectors, the generation of a parts-based basis by NMF depends on the data and the algorithm [14, 23]. Several approaches [7, 14, 29, 30] have been proposed to explicitly control the degree of sparseness in the factors of NMF. In this section, we propose algorithms for the sparse NMF that follows the framework of the two-block coordinate descent methods and therefore guarantees that every limit point is a stationary point. In particular, we propose an L_1-norm–based constrained NMF formulation to control the sparsity of one of the factors.

4.1. Constrained NMF based on alternating nonnegativity constrained least squares. Pauca, Piper, and Plemmons [30] proposed the following constrained NMF (CNMF) formulation for the purpose of obtaining a sparse NMF:

$$\min_{W,H} \frac{1}{2}\{\|A - WH\|_F^2 + \alpha\|W\|_F^2 + \beta\|H\|_F^2\} \quad \text{s.t.} \quad W, H \geq 0, \tag{4.1}$$

where $\alpha \geq 0$ and $\beta \geq 0$ are the parameters to be chosen and are supposed to control the sparsity of W and H, respectively. An algorithm was developed based on multiplicative update rules for the CNMF formulation.

We now show how the formulation in (4.1) can be recast into the ANLS framework and developed into an algorithm CNMF/ANLS for which every limit point is a stationary point. The algorithm CNMF/ANLS begins with the initialization of H

with nonnegative values. Then the following ANLS can be iterated:

$$\min_{W\geq 0} \left\| \begin{pmatrix} H^T \\ \sqrt{\alpha} I_k \end{pmatrix} W^T - \begin{pmatrix} A^T \\ 0_{k\times m} \end{pmatrix} \right\|_F^2, \tag{4.2}$$

where I_k is a $k \times k$ identity matrix and $0_{k\times m}$ is a zero matrix of size $k \times m$, and

$$\min_{H\geq 0} \left\| \begin{pmatrix} W \\ \sqrt{\beta} I_k \end{pmatrix} H - \begin{pmatrix} A \\ 0_{k\times n} \end{pmatrix} \right\|_F^2, \tag{4.3}$$

where $0_{k\times n}$ is a zero matrix of size $k \times n$. Similarly, one may initialize $W \in \mathbb{R}^{m\times k}$ and alternate the above in the order of solving (4.3) and (4.2). Equation (4.1) is differentiable in the feasible region and (4.2)–(4.3) are strictly convex. Then again according to convergence analysis for block coordinate descent methods [2], any limit point of our CNMF/ANLS algorithm will be a stationary point.

4.2. Sparse NMF with L_1-norm constraint. The idea of imposing L_1-norm–based constraints for the purpose of achieving sparsity in the solution has been successfully utilized in a variety of problems [35]. For NMF, we propose the following formulation of NMF that imposes sparsity on the right-side factor H (SNMF/R) [16, 18],

$$\min_{W,H} \frac{1}{2} \left\{ \|A - WH\|_F^2 + \eta \|W\|_F^2 + \beta \sum_{j=1}^{n} \|\mathbf{h}_j\|_1^2 \right\} \quad \text{s.t.} \quad W, H \geq 0, \tag{4.4}$$

where $\mathbf{h}_j$ is the jth column vector of H, the parameter $\eta \geq 0$ suppresses the growth of W, and the parameter $\beta \geq 0$ balances the trade-off between the accuracy of the approximation and the sparseness of H. Note that due to the nonnegativity constraint on H, the last term in (4.4) becomes equivalent to $\beta \sum_{j=1}^{n} (\sum_{i=1}^{k} h_{ij})^2$ and accordingly (4.4) is differentiable in the feasible domain. The SNMF/R algorithm begins with the initialization of W with nonnegative values. Then it iterates the following ANLS until a convergence criterion is satisfied:

$$\min_{H\geq 0} \left\| \begin{pmatrix} W \\ \sqrt{\beta} \mathbf{e}_{1\times k} \end{pmatrix} H - \begin{pmatrix} A \\ \mathbf{0}_{1\times n} \end{pmatrix} \right\|_F^2, \tag{4.5}$$

where $\mathbf{e}_{1\times k} \in \mathbb{R}^{1\times k}$ is a row vector with all components equal to one and $\mathbf{0}_{1\times n} \in \mathbb{R}^{1\times n}$ is a zero vector, and

$$\min_{W\geq 0} \left\| \begin{pmatrix} H^T \\ \sqrt{\eta} I_k \end{pmatrix} W^T - \begin{pmatrix} A^T \\ 0_{k\times m} \end{pmatrix} \right\|_F^2, \tag{4.6}$$

where $0_{k\times m}$ is a zero matrix of size $k \times m$. Equation (4.5) minimizes the L_1-norm of each column of $H \in \mathbb{R}^{k\times n}$.

Similarly, sparsity in the NMF can be imposed on the left-side factor W (SNMF/L) through the following formulation:

$$\min_{W,H} \frac{1}{2} \left\{ \|A - WH\|_F^2 + \zeta \|H\|_F^2 + \alpha \sum_{i=1}^{m} \|\mathbf{w}_i\|_1^2 \right\} \quad \text{s.t.} \quad W, H \geq 0, \tag{4.7}$$

where $\mathbf{w}_i^T$ is the ith row vector of W, $\zeta \geq 0$ is a parameter to suppress $\|H\|_F^2$, and $\alpha \geq 0$ is a parameter to balance the trade-off between accuracy of approximation and

sparseness of W. The corresponding algorithm SNMF/L begins with an initialization of the nonnegative matrix H. Then it iterates the following ANLS until a convergence criterion is satisfied:

$$\min_{W} \left\| \begin{pmatrix} H^T \\ \sqrt{\alpha}\mathbf{e}_{1\times k} \end{pmatrix} W^T - \begin{pmatrix} A^T \\ \mathbf{0}_{1\times m} \end{pmatrix} \right\|_F^2 \quad \text{s.t.} \quad W \geq 0, \tag{4.8}$$

where $\mathbf{e}_{1\times k} \in \mathbb{R}^{1\times k}$ is a row vector whose elements are all one and $\mathbf{0}_{1\times m} \in \mathbb{R}^{1\times m}$ is a zero vector, and

$$\min_{H} \left\| \begin{pmatrix} W \\ \sqrt{\zeta} I_k \end{pmatrix} H - \begin{pmatrix} A \\ 0_{k\times n} \end{pmatrix} \right\|_F^2 \quad \text{s.t.} \quad H \geq 0, \tag{4.9}$$

where I_k is a $k \times k$ identity matrix and $0_{k\times n}$ is a zero matrix of size $k \times n$. Note that (4.8) can be rewritten as

$$\min_{W} \|H^T W^T - A^T\|_2^2 + \alpha \sum_{i=1}^{m} \left(\sum_{q=1}^{k} W^T(q,i) \right)^2 \quad \text{s.t.} \quad W \geq 0, \tag{4.10}$$

and since all elements in W are nonnegative, (4.10) in turn becomes the following by the definition of the L_1-norm of a vector:

$$\min_{W\geq 0} \left\{ \|H^T W^T - A^T\|_2^2 + \alpha \sum_{i=1}^{m} \|\mathbf{w}_i\|_1^2 \right\}, \tag{4.11}$$

which involves the L_1-norm minimization of each row of W.

An advantage of the above formulation and algorithms is that they follow the framework of the two-block coordinate descent method and therefore guarantee convergence of limit points to a stationary point. Imposing additional sparsity constraints on W or H may provide sparser factors and a simpler interpretation. However, imposing sparsity in the factors does not necessarily improve the solution or interpretation. Indeed, as the sparse constraints become stronger, the magnitude of perturbations to the basic NMF solution may become larger and the degree of simplification becomes higher.

5. Regularized NMF based on alternating nonnegativity constrained least squares. As shown in section 2, in the algorithm NMF/ANLS, one of the factors W and H is initialized and the iterations are repeated fixing one of the factors. Let us assume that H is initialized. In NMF, the columns of the computed factor W are interpreted as basis vectors, therefore, implicitly assumed to be of full rank and, in fact, many of the NMF algorithms are designed assuming that the fixed matrices H^T and W involved in the subproblems are of full rank. We propose the following regularized version of the NMF/ANLS, which we call RNMF/ANLS, where the terms $\sqrt{\alpha}I$ and $\sqrt{\beta}I$ with very small parameters $\alpha > 0$ and $\beta > 0$ are attached to the fixed matrices for the purpose of numerical stability. In RNMF/ANLS, after the matrix H is initialized the following steps are iterated: solve

$$\min_{W\geq 0} \left\| \begin{pmatrix} H^T \\ \sqrt{\alpha} I_k \end{pmatrix} W^T - \begin{pmatrix} A^T \\ 0_{k\times m} \end{pmatrix} \right\|_F^2, \tag{5.1}$$

where I_k is a $k \times k$ identity matrix and $0_{k \times m}$ is a zero matrix of size $k \times m$, and solve

$$\min_{H \geq 0} \left\| \begin{pmatrix} W \\ \sqrt{\beta} I_k \end{pmatrix} H - \begin{pmatrix} A \\ 0_{k \times n} \end{pmatrix} \right\|_F^2, \tag{5.2}$$

where $0_{k \times n}$ is a zero matrix of size $k \times n$. Similarly, one may initialize $W \in \mathbb{R}^{m \times k}$ and alternate the above in the order to solve (5.2) and then (5.1).

The above RNMF/ANLS is one way to formulate a two-block coordinate descent method for the objective function

$$\min_{W,H} \frac{1}{2} \{ \|A - WH\|_F^2 + \alpha \|W\|_F^2 + \beta \|H\|_F^2 \} \quad \text{s.t.} \quad W, H \geq 0, \tag{5.3}$$

where $\alpha \geq$ and $\beta \geq$ are very small regularization parameters. Note that the objective function (5.3) and ANLS iterations (5.1) and (5.2) are identical to the CNMF formulation and our proposed CNMF/ANLS algorithm presented in section 4.1. However, the purpose of the CNMF [30] was to obtain a sparser NMF and the role of the parameters α and β was supposed to control the sparsity of W and H. On the other hand, the purpose of the RNMF/ANLS is to impose strong convexity on the subproblems of NMF/ANLS. The role of the parameters α and β with very small values is to impose full rank on the matrices on the left side of solution matrices in the NLS subproblems. Consequently, we can guarantee that the symmetric square matrix appearing in the normal equations for solving least squares subproblems in the fast NLS algorithm [36] is symmetric positive definite with any passive set of columns, so that the solution can be computed via the Cholesky factorization.

6. Numerical experiments and discussion. In this section, we present several numerical experimental results to illustrate the behavior of our proposed algorithms and compare them to two of the most commonly used algorithms in the literature, NMF/NUR [21, 22] and NMF/ALS [1]. We implemented all algorithms in MATLAB 6.5 [26] on a P3 600MHz machine with 512MB memory.

6.1. Data sets in experiments. We have used four data sets for our empirical tests, of which two are from microarray analysis and are presented in [8, 16, 18] and the others are artificially generated. All data sets contain only nonnegative entries.

I. Data set ALLAML. The leukemia gene expression data set ALLAML [10] contains acute lymphoblastic leukemia (ALL) that has B and T cell subtypes, and acute myelogenous leukemia (AML) that occurs more commonly in adults than in children. This gene expression data set consists of 38 bone marrow samples (19 ALL-B, 8 ALL-T, and 11 AML) with 5,000 genes forming a data matrix $A \in \mathbb{R}^{5,000 \times 38}$. The gene expression values were in the range between 20 and 61,225, where a lower cutoff threshold value of 20 was used to eliminate noisy fluctuations.

II. Data set CNS. The central nervous system tumors data set CNS [33] is composed of four categories of CNS tumors with 5,597 genes. It consists of 34 samples representing four distinct morphologies: 10 classic medulloblastomas, 10 malignant gliomas, 10 rhabdoids, and 4 normals, forming a data matrix $A \in \mathbb{R}^{5,597 \times 34}$. In addition to a lower cutoff threshold value of 20, an upper cutoff threshold value of 16,000 was used to eliminate expression values that are too high and may undesirably dominate the objective function value in (1.2).

III. Artificial data sets with zero residual. We generated the first artificial data matrix A_a of size 200×50 by $A_a = W_a H_a$, where $W_a \in \mathbb{R}^{200\times 6}$ and $H_a \in \mathbb{R}^{6\times 50}$ are artificial positive matrices. The rank of A_a is 6 and a zero residual solution for the NMF with $k = 6$ exists. Accordingly, the NMF algorithms are expected to produce the solutions W and H, which give very small relative residual $\|A_a - WH\|_F/\|A_a\|_F$ with $k = 6$. We generated another artificial data matrix A_s of size $2{,}500 \times 28$ by $A_s = W_s H_s$, where $W_s \in \mathbb{R}^{2{,}500\times 3}$ and $H_s \in \mathbb{R}^{3\times 28}$ are artificial nonnegative matrices. The basis matrix W_s has columns of unit L_2-norm. The maximal value in H_s is 10^5. The rank of A_s is 3 and a zero residual solution for the NMF with $k = 3$ exists.

6.2. Convergence criteria. Reaching a smaller approximation error $\|A - W_* H_*\|_F$, where W_* and H_* are the solution matrices obtained from an algorithm for the NMF formulation in (1.2), indicates the superiority of an algorithm in terms of approximation capability. Accordingly, the convergence of the proposed algorithms may be tested by checking the decrease in the residual of the objective function $f(W, H)$. We may also test the convergence to a stationary point by checking the KKT optimality conditions. The KKT conditions shown in (2.3) can be rewritten as

$$\begin{aligned} &\min(W, \partial f(W,H)/\partial W) = 0, \\ &\min(H, \partial f(W,H)/\partial H) = 0, \end{aligned} \tag{6.1}$$

where the minimum is taken componentwise [11]. The normalized KKT residual Δ is then defined as $\Delta = \frac{\Delta_o}{\delta_W + \delta_H}$, which reflects the average of convergence errors for elements in W and H that did not converge, where

$$\begin{aligned} \Delta_o = &\sum_{i=1}^{m}\sum_{q=1}^{k} |\min(W_{iq}, (\partial f(W,H)/\partial W)_{iq})| \\ &+ \sum_{q=1}^{k}\sum_{j=1}^{n} |\min(H_{qj}, (\partial f(W,H)/\partial H)_{qj})|, \end{aligned} \tag{6.2}$$

$\delta_W = \#(\min(W, \partial f(W,H) \ / \ \partial W) \neq 0)$, and $\delta_H = \#(\min(H, \partial f(W,H) \ / \ \partial H) \neq 0)$. Then the convergence criterion is defined as

$$\Delta \leq \epsilon \Delta_1, \tag{6.3}$$

where Δ_1 is the value of Δ after one iteration and ϵ is an assigned tolerance.

6.3. Performance comparisons. In this subsection, we present performance results based on the three data sets described earlier. In the tests, we used the KKT convergence criterion shown in (6.3) with $\epsilon = 10^{-9}$.

I. Test results on the ALLAML data set. Table 6.1 shows the performance comparison among NMF/NUR, NMF/ALS, and NMF/ANLS on the ALLAML leukemia data matrix with $k = 3$. There are three clusters in this data set.[1] We report the percentage of zero elements in the computed factors W and H, relative approximation error (i.e., $\|A - WH\|_F/\|A\|_F$), the number of iterations, and computing time. The results show that to reach the same convergence criterion, NMF/NUR and NMF/ALS took much longer than NMF/ANLS, and the NMF/ALS generated the solutions with the largest relative approximation error among them. We believe

[1] The results of NMF algorithms with $k = 4$ and $k = 5$ can be found in our paper [17].

TABLE 6.1

*Performance comparison among NMF/NUR [22], NMF/ALS [1], and NMF/ANLS on the leukemia ALLAML data set with $k = 3$. We present the percentages of zero elements in W and H, relative approximation error, the number of iterations, and computing time. *For NMF/NUR, the computed W and H factors were not sparse, so the percentages of the number of nonnegative elements that are smaller than 10^{-8} in W and H are shown instead.*

Algorithms	NMF/NUR	NMF/ALS	NMF/ANLS
$\#(W = 0)$ (%)	2.71%*	2.83%	2.71%
$\#(H = 0)$ (%)	18.42%*	16.67%	18.42%
$\|A - WH\|_F / \|A\|_F$	0.5027	0.5032	0.5027
No. of iterations	5385	3670	90
Computing time	284.0 sec.	192.8 sec.	8.3 sec.

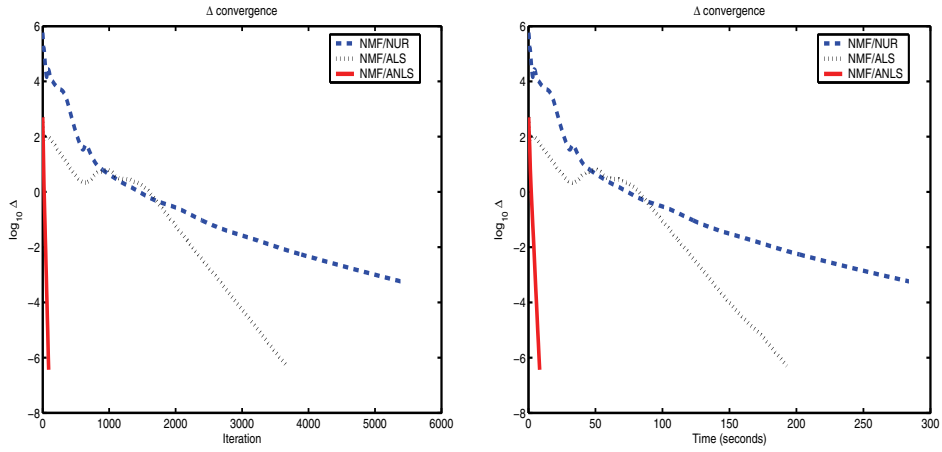

FIG. 6.1. *The values of Δ vs. the number of iterations for NMF/ANLS, NMF/NUR [22], and NMF/ALS [1] on the leukemia ALLAML data set with $k = 3$. We used the KKT convergence criterion with $\epsilon = 10^{-9}$.*

that the overall faster performance of the NMF/ANLS is a result of its convergence properties. In the factors W and H, the NMF/NUR produced very small nonnegative elements ($< 10^{-8}$) in W and H, which are not necessarily zeros, while NMF/ANLS generated the exact zero elements. This is an interesting property of the NMF algorithms and illustrates that the NMF/ANLS does better at generating sparser factors, which can be helpful in reducing computing complexity and storage requirement for handling sparse data sets.

Figure 6.1 further illustrates the convergence behavior of NMF/ANLS, NMF/NUR, and NMF/ALS on the ALLAML data set with $k = 3$. As for NMF/ALS, we solved each least squares subproblem by normal equations and set the negative values to zeros. All three algorithms began with the same random initial matrix of H_o. An additional random initial matrix of W_o was needed for NMF/NUR. The NMF/ALS generated the smallest Δ_1 (Δ value after the first iteration), whereas NMF/NUR produced the largest Δ_1. While NMF/NUR converged after more than 5,000 iterations from relatively large Δ_1, the final Δ value is still larger than those of other algorithms. We observed that the NMF/ALS algorithm required more running time than NMF/ANLS even though its subproblem (unconstrained least squares problem)

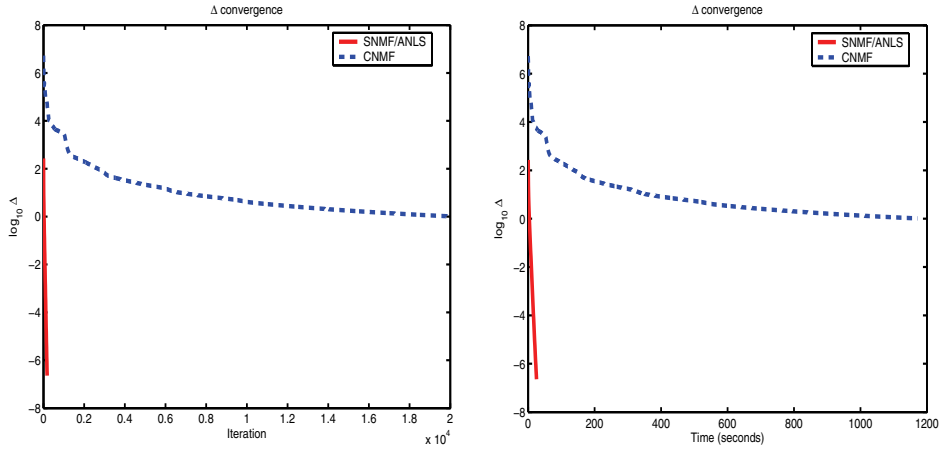

FIG. 6.2. *The values of* Δ *vs. the number of iterations for SNMF/R* [18] *with* $\beta = 0.01$ *and CNMF based on multiplicative update rules* [30] *with* $\alpha = 0$ *and* $\beta = 0.01$ *on the leukemia ALLAML data set with* $k = 3$. *We used the KKT convergence criterion with* $\epsilon = 10^{-9}$.

requires less floating point operations. This slower computational time can be ascribed to the lack of convergence property of the NMF/ALS algorithm. In this test, NMF/ANLS outperformed the others in terms of convergence speed.

Figure 6.2 illustrates the converge behavior of SNMF/R with $\beta = 0.01$ and CNMF with $\alpha = 0$ and $\beta = 0.01$ on the ALLAML data set with $k = 3$. We used the KKT convergence criterion corresponding to each of the objective functions for SNMF/R and CNMF. The η parameter in SNMF/R was set to the square of the maximal value in the ALLAML data matrix. As for CNMF, we used the CNMF algorithm based on multiplicative update rules [30] without column normalization of W in each iteration. Two algorithms began with a random initial matrix W_o that has columns of unit L_2-norm. A random initial matrix of H_o was used only in CNMF. SNMF/R generated much smaller Δ than CNMF within a short time. The percentages of zero elements in W and H obtained from SNMF/R were 2.17% and 30.70%. On the other hand, the percentages of elements in the range of $[0, 10^{-8})$ in W and H obtained from CNMF were 2.71% and 18.42% and only a small number of elements in W were exactly zeros. It illustrates that the SNMF/R is more effective in producing a sparser H.

II. Test results on the CNS tumors data set. Table 6.2 shows the performance comparison on the CNS tumors data set with various k values where NMF/ANLS was a few orders of magnitude faster than NMF/NUR. NMF/NUR did not satisfy the KKT convergence criterion within 20,000 iterations. The relative approximation errors of NMF/NUR at the last iteration were still slightly larger than those of NMF/ANLS after less than 200 iterations.

The sparsity obtained from NMF/NUR or NMF/ANLS is a general result due to nonnegativity constraints. Even when the original data set has no zero element, the factors W and H may have zero components. In case of NMF/ANLS, this becomes clear when we note that at the core of NMF/ANLS is the active set–based iterations, and in each iteration the solution components that correspond to the active set index are set to be zeros.

TABLE 6.2

*Performance comparison between NMF/NUR [22] and NMF/ANLS on the CNS tumors data set. We report the percentages of zero elements in W and H, relative approximation error, the number of iterations, and computing time (in seconds). *For NMF/NUR, the computed W and H factors were not sparse, so the percentages of the number of nonnegative elements that are smaller than 10^{-8} in W and H are shown instead.*

Algorithm	NMF/NUR		
Reduced rank k	3	4	5
$\#(\lvert W_{ij}\rvert < 10^{-8})$ (%)	8.70%*	9.05%*	12.32%*

$\lVert A - WH\rVert_F / \lVert A\rVert_F$	0.40246175028	0.37312046948	0.35409574992
No. of iterations	150	130	130
Computing time	14.8 sec.	16.6 sec.	20.4 sec.

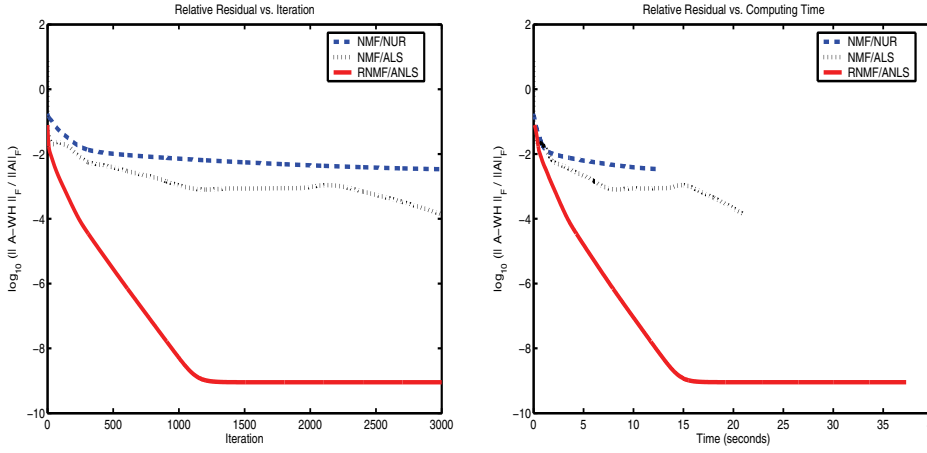

FIG. 6.3. *The relative residuals vs. the number of iterations for RNMF/ANLS with $\alpha = \beta = 10^{-8}$, NMF/NUR [22], and NMF/ALS [1] with $k = 6$ for 3,000 iterations on the first artificial data matrix $A_a = W_a H_a$ of size 200×50, where $W_a \in \mathbb{R}^{200\times 6}$ and $H_a \in \mathbb{R}^{6\times 50}$ are artificial positive matrices, and $\mathrm{rank}(A_a) = 6$.*

III. Test results on the zero residual artificial data sets. Figure 6.3 shows the performance of the three NMF algorithms, RNMF/ANLS, NMF/NUR, and NMF/ALS, on the first artificial data matrix $A_a = W_a H_a$ of size 200×50 where $W_a \in \mathbb{R}^{200\times 6}$ and $H_a \in \mathbb{R}^{6\times 50}$ are artificial positive matrices. The relative residuals versus iteration or computing time are shown. We used $\alpha = \beta = 10^{-8}$ for the RNMF/ANLS and implemented NMF/ALS with pseudoinverse. We note that NMF/ALS sometimes generated ill-conditioned W and H when negative values are set to zeros, which may happen even when we solve the least squares problem by a

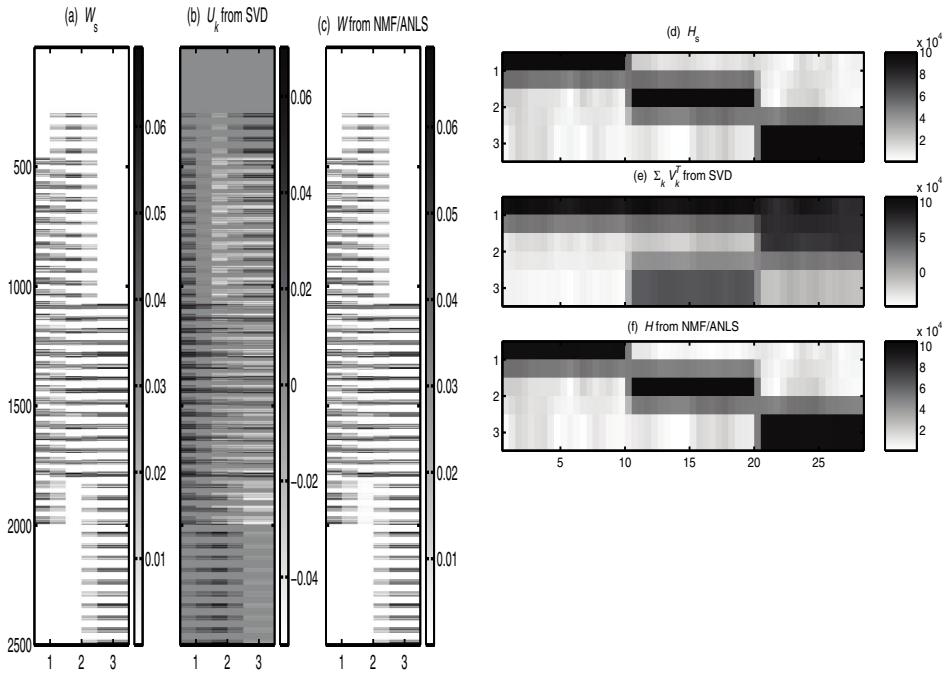

FIG. 6.4. *The factors obtained from the truncated SVD* [9] *($A_s \approx U_k \Sigma_k V_k^T$) and NMF/ANLS ($A_s \approx WH$ s.t. $W, H \geq 0$) with $k = 3$ on the second artificial data matrix $A_s = W_s H_s$ of size* $2{,}500 \times 28$*, where $W_s \in \mathbb{R}^{2,500 \times 3}$ and $H_s \in \mathbb{R}^{3 \times 28}$ are artificial nonnegative matrices, and* $\mathrm{rank}(A_s) = 3$. *The gray scale indicates the values of the elements in the matrix.*

stable algorithm. In the worst case, the entire row or column in the matrices W or H may become zero. The RNMF/ANLS rapidly converged, while NMF/NUR did not converge to near zero residual within 3,000 iterations. The relative residual in the middle of iterative optimization of NMF/ALS sometimes increased.

Figure 6.4 shows the comparison between the truncated SVD [9] and NMF/ANLS on the second artificial data matrix $A_s = W_s H_s$ of size $2{,}500 \times 28$, where $W_s \in \mathbb{R}^{2,500 \times 3}$ and $H_s \in \mathbb{R}^{3 \times 28}$ are artificial nonnegative matrices. We presented U_k and $\Sigma_k V_k^T$ obtained from the truncated SVD ($A_s \approx U_k \Sigma_k V_k^T$) with $k = 3$. We also illustrated W and H obtained from NMF/ANLS ($A_s \approx WH$ s.t. $W, H \geq 0$) with $k = 3$. Although the approximation error of NMF/ANLS was larger than that of the truncated SVD, it surprisingly recovered W_s and H_s factors much better. Our NMF algorithm can be utilized for blind source separation when basis vectors are nonnegative and observations are nonsubtractive combinations of basis vectors.

6.4. Summary of experimental results. In our tests, the convergence of NMF/NUR was slower and, due to this, the algorithm was often prematurely terminated before it reached a convergence criterion, whether it was based on the relative residual or the KKT residual. The NMF/ALS does not provide a solution in a least squares sense for each nonnegativity constrained subproblem although the problem is formulated as a least squares problem. Therefore, its convergence is difficult to analyze and exhibits nonmonotonic changes in the objective function value throughout the iterations. On the other hand, NMF/ANLS generated solutions with satisfactory accuracy within a reasonable time.

An algorithm for nonnegativity constrained least squares is an essential component of NMF/ANLS. There are several ways to solve the NLS problem with multiple right-hand sides and we chose van Benthem and Keenan's NLS algorithm [36]. This algorithm is based on the active set method that is guaranteed to terminate in [illegible] of matrix computations. Some other implementations of NLS are based on traditional gradient descent or quasi-Newton optimization methods. They are iterative methods that require explicit convergence check parameters. Their speed and accuracy depend on their convergence check parameters.

7. Summary and discussion. We have introduced the NMF algorithms based on alternating nonnegativity constrained least squares, for which every limit point is a stationary point. The core of our algorithm is the nonnegativity constrained least squares algorithm for multiple right-hand sides based on the active set method, which terminates in [illegible]. We applied the well-known convergence theory for block coordinate descent methods in bound constrained optimization and built a rigorous convergence criterion based on the KKT conditions.

We have established a framework of NMF/ANLS which is theoretically sound and practically efficient. This framework was utilized to design formulations and algorithms for sparse NMFs and regularized NMF. Some theoretical characteristics of our proposed algorithms explain their superior behavior shown in the test results. The NMF algorithms based on gradient descent method exhibit slow convergence. Thus, it is possible, though undesirable, to use premature solutions for data analysis owing to termination before convergence, which may sometimes lead to unreliable conclusions. The [illegible] NMF/ALS algorithm [1] sets the negative components in the unconstrained least squares solution to zero. Although the inexact method may solve the subproblems faster, its convergence behavior is problematic. On the other hand, our algorithm satisfies the nonnegativity constraints exactly in each subproblem and shows faster overall convergence. The converged solutions obtained from our algorithms make it possible to reach more physically reliable conclusions in many applications of NMF. The NMF/ANLS can be applied to a wide variety of practical problems in the fields of text data mining, image analysis, bioinformatics, computational biology, and so forth, especially when preserving nonnegativity is beneficial to meaningful interpretation.

Acknowledgment. We would like to thank Prof. Chih-Jen Lin and Prof. Luigi Grippo for discussions on the convergence properties.

ON THE MINIMUM RANK AMONG POSITIVE SEMIDEFINITE MATRICES WITH A GIVEN GRAPH*

MATTHEW BOOTH†, PHILIP HACKNEY‡, BENJAMIN HARRIS§, CHARLES R. JOHNSON¶, MARGARET LAY‖, LON H. MITCHELL#, SIVARAM K. NARAYAN††, AMANDA PASCOE‡‡, KELLY STEINMETZ§§, BRIAN D. SUTTON¶¶, AND WENDY WANG‖‖

Abstract. Let $\mathcal{P}(G)$ be the set of all positive semidefinite matrices whose graph is G, and $\mathrm{msr}(G)$ be the minimum rank of all matrices in $\mathcal{P}(G)$. Upper and lower bounds for $\mathrm{msr}(G)$ are given and used to determine $\mathrm{msr}(G)$ for some well-known graphs, including chordal graphs, and for all simple graphs on less than seven vertices.

Key words. rank, positive semidefinite, graph of a matrix

1. Introduction. If A is an n-by-n Hermitian matrix, then its graph $G(A)$ is the undirected, simple graph on vertices $\{1, 2, \ldots, n\}$, which has an edge between vertices i and j if and only if the i, j entry of A is nonzero and $i \neq j$. The graph is independent of the real diagonal entries of A. The set of all Hermitian matrices that share a common graph G is denoted $\mathcal{H}(G)$: $\mathcal{H}(G) = \{ A \mid A = A^*, G(A) = G \}$. If G is a simple connected graph, then matrices in $\mathcal{H}(G)$ may be viewed as the discrete version of the continuous Schrödinger operators with magnetic fields [3].

The possible multiplicities of the eigenvalues among matrices in $\mathcal{H}(G)$ have been of much recent interest [6, 7, 9, 10, 11, 13]. It is known, for example, that if G is a tree, then the smallest eigenvalue of any matrix in $\mathcal{H}(G)$ has multiplicity one [10, Corollary

3.9]. This implies that any Hermitian positive semidefinite (psd) matrix whose graph is a tree has rank at least $n-1$. The Laplacian matrix of a tree on n vertices is a psd matrix with rank equal to $n-1$ [14]. A converse to this statement, that, for any nontree the minimum rank of a psd matrix is less than $n-1$, was proved independently (Lemma 5, [8] and Theorem 4.1, [17]). This raises the following interesting question, given a graph G, what is the minimum rank among psd matrices in $\mathcal{H}(G)$?

Let $\mathcal{P}(G)$ denote the psd matrices in $\mathcal{H}(G)$. Define the [illegible] G, $\operatorname{msr}(G)$, as $\min\{\operatorname{rank} A : A \in \mathcal{P}(G)\}$. We present here some results about $\operatorname{msr}(G)$, which give $\operatorname{msr}(G)$ for every chordal graph and for most graphs on fewer than seven vertices. The few exceptions can be handled by separate arguments. It is equally interesting to find the minimum psd rank over the symmetric real matrices instead of Hermitian matrices. It is not known if these two problems are different, though there can be differences in some related problems [12].

If G is not connected, it is clear that $\operatorname{msr}(G)$ is the sum of the minimum semidefinite ranks of each of G's connected components, so that we may (and do) confine our attention to connected graphs. Note that, if G is a connected graph with two or more vertices, the diagonal entries of $A \in \mathcal{P}(G)$ are positive.

2. Lower bounds using induced subgraphs. We will obtain several lower bounds using induced subgraphs. An [illegible] H of a graph G is obtained by deleting all vertices except for the vertices in a subset S. Since a principal submatrix of a psd matrix is psd [5, p. 397], and the rank of a submatrix can never be greater than that of the matrix, we have the following.

LEMMA 2.1. [illegible] $\operatorname{msr}(H) \leq \operatorname{msr}(G)$

Equality can occur in the inequality of Lemma 2.1 in important ways; of course, strict inequality is common. One case of equality is that in which the induced subgraph is the result of the deletion of a duplicate vertex from G. For a vertex w, let $n(w)$ denote the set of all vertices adjacent to w. The [illegible] of w is $n(w) \cup \{w\}$. A vertex u is a [illegible] of a vertex v of G if u and v are adjacent, and their closed neighborhoods are the same. We denote the induced subgraph of G resulting from the deletion of a vertex u by $G - u$. We then have the following.

PROPOSITION 2.2. [illegible] $\operatorname{msr}(G-u) = \operatorname{msr}(G)$

[illegible]. From Lemma 2.1, $\operatorname{msr}(G-u) \leq \operatorname{msr}(G)$. Let $A' \in \mathcal{P}(G-u)$ be a psd matrix such that $\operatorname{rank} A' = \operatorname{msr}(G-u)$. By permuting the rows and columns of A' let the first row and column of A' correspond to the vertex v. If $A' = B^*B$, then consider $A = \begin{bmatrix} B^* \\ e_1^{\mathrm{T}} B^* \end{bmatrix} \begin{bmatrix} B & Be_1 \end{bmatrix}$ where $e_1^{\mathrm{T}} = (1, 0, \ldots, 0)$. Then $\operatorname{rank} A = \operatorname{rank} A'$ and $A \in \mathcal{P}(G)$. Thus $\operatorname{msr}(G) \leq \operatorname{msr}(G-u)$. □

From a sequential deletion of duplicate vertices and application of Proposition 2.2 we get the following.

COROLLARY 2.3. [illegible] $\operatorname{msr}(H) = \operatorname{msr}(G)$

[illegible] 2.4. As an easy consequence of Corollary 2.3, we obtain that, for $n \geq 2$, $\operatorname{msr}(K_n) = 1$ where K_n denotes the complete graph on n vertices. Note that Proposition 2.2 is incorrect if applied to two [illegible] vertices with the same neighbors. To see this, let G be K_4 minus an edge. Deletion of a degree 3 vertex gives $\operatorname{msr}(G) = 2$ using Proposition 2.2, but deletion of a degree 2 vertex results in K_3 whose msr equals one.

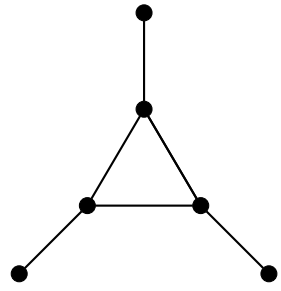

FIG. 2.1. $\mathrm{fm}(G) = 4$.

Another important application of Lemma 2.1 is that in which H is an induced tree on the maximum possible number of vertices as we know the msr for any tree. For a graph G, we consider its "tree size," denoted $\mathrm{ts}(G)$, which is the number of vertices in a maximum induced tree [4]. As already noted, when T is a tree, $\mathrm{msr}(T)$ is one less than the number of vertices of T. This fact, combined with Lemma 2.1, immediately gives the following.

LEMMA 2.5. [illegible] $\mathrm{msr}(G) \geq \mathrm{ts}(G) - 1$

As mentioned in the introduction, equality in Lemma 2.5 occurs whenever G is a tree. It also occurs for any nontree G on n vertices for which $\mathrm{ts}(G) = n - 1$; in this case $\mathrm{msr}(G) \geq n - 2$ by Lemma 2.5, and $\mathrm{msr}(G) \leq n - 2$ because G is not a tree. Thus $\mathrm{msr}(G) = n - 2$. For example, if G is a cycle on n vertices, the tree size is $n - 1$ (because deletion of any one vertex leaves a path on $n - 1$ vertices). Therefore, the msr of a cycle on n vertices is $n - 2$ (cf. [17, Theorem 4.3]).

For an induced forest of G with components $T_1, T_2, \ldots, T_k$, count $\mathrm{ts}(T_1) + \mathrm{ts}(T_2) + \cdots + \mathrm{ts}(T_k) -$ (the number of components that are not isolated vertices). Among all the induced forests of G maximize this count and call this result $\mathrm{fm}(G)$, the "forest measure" of G. Any isolated vertices occurring in an induced subgraph of a connected graph G contribute 1, rather than 0, to $\mathrm{msr}(G)$, as an irreducible psd matrix has positive diagonal entries. We then have the following.

PROPOSITION 2.6. [illegible] $\mathrm{msr}(G) \geq \mathrm{fm}(G) \geq \mathrm{ts}(G) - 1$

Figure 2.1 illustrates that strict inequality is possible in the second inequality of Proposition 2.6, as $\mathrm{fm}(G) = 4$ by deleting any single interior vertex.

One special case of an induced forest is an induced set of isolated vertices. The maximum cardinality of such a set is the [illegible] $i(G)$, the greatest number of vertices among which there are no edges. Clearly $\mathrm{fm}(G) \geq i(G)$, so that we have the following.

COROLLARY 2.7. [illegible] G, $\mathrm{msr}(G) \geq i(G)$

Suppose G is a connected graph with vertex set $V = \{v_1, v_2, \ldots, v_n\}$. We call a set of vectors $\overrightarrow{V} = \{\overrightarrow{v_1}, \overrightarrow{v_2}, \ldots, \overrightarrow{v_n}\}$ in $\mathbb{C}^m$ a [illegible] (or [illegible]) of G if

$$\begin{bmatrix} \overrightarrow{v_1} \\ \overrightarrow{v_2} \\ \vdots \\ \overrightarrow{v_n} \end{bmatrix} \begin{bmatrix} \overrightarrow{v_1} \\ \overrightarrow{v_2} \\ \vdots \\ \overrightarrow{v_n} \end{bmatrix}^* = A \in \mathcal{P}(G).$$

In other words, we associate a vector $\overrightarrow{v_i} \in \mathbb{C}^m$ to each vertex $v_i \in V(G)$ such that, for $i \neq j$, $\langle \overrightarrow{v_i}, \overrightarrow{v_j} \rangle \neq 0$ if v_i and v_j are adjacent in G, and $\langle \overrightarrow{v_i}, \overrightarrow{v_j} \rangle = 0$ if v_i and v_j

are not adjacent. Since every psd matrix $A \in \mathcal{P}(G)$ can be written as $A = B^*B$ for some matrix B, we can always find a vector representation of $G(A)$ that produces A. Also, the rank of the matrix and the dimension of the span of the vectors in the vector representation (which we call the [illegible] of the vector representation) are always the same [5, p. 408].

We end this section by giving a sufficient condition on G so that $\operatorname{msr}(G) = \operatorname{ts}(G) - 1$. To prove the result we need the following lemma.

LEMMA 2.8. [illegible] $X_1, \ldots, X_m$, $X_i \subseteq \mathbb{C}^n$, $1 \le i \le m$, [illegible] $G_1, \ldots, G_m$ [illegible] G [illegible]

- [illegible] v, w [illegible] G [illegible] i [illegible] v [illegible] w [illegible] G_i [illegible]
- [illegible] v, w [illegible] G [illegible] $\overrightarrow{x_v}$ [illegible] v, [illegible] X_i [illegible] $\overrightarrow{x_w}$ [illegible] w, [illegible] X_j, $\langle \overrightarrow{x_v}, \overrightarrow{x_w} \rangle = 0$

[illegible] X [illegible] G [illegible]

$$\operatorname{rank} X \le \operatorname{rank}\left(\bigcup_{1 \le i \le m} \operatorname{span} X_i \right) \le \sum_{1 \le i \le m} \operatorname{rank} X_i.$$

[illegible]. We prove the statement for the case of two vector representations as the result can be easily generalized. Let $X_1 = \{\overrightarrow{x_i}\}$ and $X_2 = \{\overrightarrow{w_i}\}$ be vector representations of subgraphs G_1 and G_2 of a graph G. Extend X_1 and X_2 to represent all of the vertices of G by adding copies of the zero vector if need be. We claim there exists $c \in \mathbb{R}$ such that $\{\overrightarrow{x_i} + c\overrightarrow{w_i}\}$ is a vector representation of G.

If $(v_i, v_j) \notin E$, then $\langle \overrightarrow{x_i}, \overrightarrow{x_j} \rangle = \langle \overrightarrow{w_i}, \overrightarrow{w_j} \rangle = \langle \overrightarrow{x_i}, \overrightarrow{w_j} \rangle = \langle \overrightarrow{w_i}, \overrightarrow{x_j} \rangle = 0$. This implies that $\langle \overrightarrow{x_i} + c\overrightarrow{w_i}, \overrightarrow{x_j} + c\overrightarrow{w_j} \rangle = 0$ for any $c \in \mathbb{C}$. If v_i and v_j are adjacent, then $\{\langle \overrightarrow{x_i} + c\overrightarrow{w_i}, \overrightarrow{x_j} + c\overrightarrow{w_j} \rangle\}$ is a set of quadratics in c having finitely many roots. Thus we may choose $c \in \mathbb{R}$ so that $\{\overrightarrow{x_i} + c\overrightarrow{w_i}\}$ is a vector representation of G. □

Suppose T is a maximum induced tree. If w is a vertex not belonging to T, denote by $\mathcal{E}(w)$ the edge set of all paths in T between every pair of the vertices of T that are adjacent to w.

THEOREM 2.9. [illegible] G, $\operatorname{msr}(G) = \operatorname{ts}(G) - 1$ [illegible] ⊛ [illegible]

⊛ [illegible] T [illegible] u [illegible] w [illegible] T, $\mathcal{E}(u) \cap \mathcal{E}(w) \neq \varnothing$ [illegible] u [illegible] w [illegible] G

[illegible]. If G is a tree, we have already seen that $\operatorname{msr}(G) = \operatorname{ts}(G) - 1$. If G is not a tree, we will cover G with subgraphs that have vector representations satisfying the conditions of Lemma 2.8. If ⊛ holds for a maximum induced tree T of G, then every vertex w not on T must be adjacent to some vertex on T. Moreover, by the definition of T, w is adjacent to at least two vertices of T. Assign an orthonormal set of vectors $\{\overrightarrow{x_e}\}$ of dimension $(\operatorname{ts}(G) - 1)$ to the edges of T, one vector per edge. If $v \in V(T)$, assign the vector $\overrightarrow{v} = \sum_e \overrightarrow{x_e}$ to v, where the summation is over all edges incident to v. This gives a vector representation $\overrightarrow{T}$ of T.

For any path $p = (e_1, e_2, \ldots, e_m)$ in T, let

$$\overrightarrow{p} = \sum_{j=1}^{m} (-1)^j \overrightarrow{x_{e_j}}.$$

Given a vertex w not on T and an adjacent vertex v_1 on T, w must have another neighbor v_2 on T. If p is a path between v_1 and v_2 in T, letting $\overrightarrow{p}$ represent w and $\overrightarrow{T}$ represent T yields a vector representation of a subgraph of G containing the edge between w and v_1.

Given two vertices w_1 and w_2 not on T that are adjacent, by $\circledast$ there exist intersecting paths p_1 and p_2 in T so that the end vertices of p_i are neighbors of w_i, $i = 1, 2$. Letting $\overrightarrow{p_i}$ represent w_i for $i = 1, 2$ and $\overrightarrow{T}$ represent T yields a representation of a subgraph of G containing the edge connecting w_1 and w_2.

By construction, these representations cover all the edges of G and are contained in $\operatorname{span}\{\overrightarrow{x_e}\colon e \text{ an edge of } T\}$. We now show that these representations satisfy the conditions of Lemma 2.8. If v and w are adjacent in G, we have explicitly constructed above a representation of a subgraph of G in which v and w are adjacent.

If v and w are not adjacent, there are three cases to consider. First, if v and w are both vertices in T, then in any two representations, v and w are represented by the corresponding vectors in $\overrightarrow{T}$, which are orthogonal. For other cases, first notice that, if a vertex w is not on T, then w is represented by $\overrightarrow{p}$ derived from a path p. If v is a vertex on T not adjacent to w, then v cannot be an endpoint of p. Thus the vector representing v in $\overrightarrow{T}$ is orthogonal to $\overrightarrow{p}$. Suppose v and w are both not on T and are not adjacent in G. The vectors $\overrightarrow{q}$ and $\overrightarrow{p}$ representing v and w, respectively, are derived from paths q and p, respectively. By $\circledast$ the paths p and q have no edges in common and thus $\overrightarrow{p}$ and $\overrightarrow{q}$ must be orthogonal. Applying Lemma 2.8 we get $\operatorname{msr}(G) \leq \operatorname{ts}(G) - 1$. □

3. Chordal graphs. The sum of two psd matrices is psd, and the rank of a sum is never more than the sum of the ranks [5, p. 13]. If we cover all of the edges of a graph G with (not necessarily induced) subgraphs of known msr, this can lead to useful upper bounds for $\operatorname{msr}(G)$. First, suppose that G is labeled and that $G_1, \ldots, G_k$ are (labeled) subgraphs of G, that is, each $G_i, i = 1, \ldots, k$ is the result of deleting some edges and/or vertices from G. We say that $G_1, \ldots, G_k$ [illegible] G if each vertex of G is a vertex of at least one G_i, and for every pair of adjacent vertices v, w of G, v and w are adjacent in at least one G_i. The cover $C_1, \ldots, C_k$ of G is called a [illegible] of G if each of $C_1, \ldots, C_k$ is a clique of G. The [illegible] $\operatorname{cc}(G)$ (see [15]) of G is the minimum value of k for which there is a clique cover $C_1, \ldots, C_k$ of G.

PROPOSITION 3.1. [illegible] G, $\operatorname{msr}(G) \leq \operatorname{cc}(G)$ [illegible]. The proof follows from Lemma 2.8 and Remark 2.4. □

Since the clique cover number of a cycle on $n \geq 4$ vertices is n but its msr is $n-2$, strict inequality is possible in Proposition 3.1.

Given a vector representation $\overrightarrow{V}$ of G, with $\overrightarrow{v}$ representing vertex v, replace each vector $\overrightarrow{w} \in \overrightarrow{V}$ with the orthogonal projection

$$\overrightarrow{w} - \frac{\langle \overrightarrow{v}, \overrightarrow{w} \rangle}{\langle \overrightarrow{v}, \overrightarrow{v} \rangle} \overrightarrow{v}$$

to yield a set of vectors denoted $\overrightarrow{V} \ominus \overrightarrow{v}$. It is easily verified that $\operatorname{rank}(\overrightarrow{V})$ is one more than $\operatorname{rank}(\overrightarrow{V} \ominus \overrightarrow{v})$.

Consider the graph corresponding to $\overrightarrow{V} \ominus \overrightarrow{v}$. It is obtained from the original graph G, first by removing the vertex v and then modifying the graph in the following manner: For $u, w \in n(v)$, if (u, w) is not an edge of G, then (u, w) is an edge of the modified graph and if (u, w) is an edge of G, then (u, w) may or may not be an edge

of the modified graph. Notice in the latter case that the "may or may not" depends on the choice of vector representation $\overrightarrow{V}$. In what follows, we consider graphs which have multiple edges. This allows us to define below a graph $G \ominus v$, which better captures the relationship between $\overrightarrow{V} \ominus \overrightarrow{v}$ and the "orthogonal removal of vertex v."

Following van der Holst [17], let G be an undirected graph with no loops but possibly multiple edges, with vertex set $V = \{1, 2, \ldots, n\}$. Let $\mathcal{H}_G$ be the set of all n-by-n Hermitian matrices $A = [a_{ij}]$ such that

- $a_{ij} \neq 0$ if i and j are connected by exactly one edge;
- $a_{ij} = 0$ if i and j are not adjacent, and $i \neq j$.

Notice that we make no restriction on a_{ij} if i and j are connected by more than one edge. Now, $\overrightarrow{V} = \{\overrightarrow{v_1}, \ldots, \overrightarrow{v_n}\}$ in $\mathbb{C}^m$ is a [illegible] of a graph G with multiple edges when $\langle \overrightarrow{v_i}, \overrightarrow{v_j} \rangle \neq 0$ if i and j are connected by a single edge and $\langle \overrightarrow{v_i}, \overrightarrow{v_j} \rangle = 0$ if i and j are not adjacent.

Let G be a graph (with multiple edges). The graph $G \ominus v$, called the [illegible] v [illegible] G, is obtained as follows: In the induced subgraph $G - v$ of G, between any $u, w \in n(v)$ add $e - 1$ edges, where e is the sum of the number of edges between u and v and the number of edges between w and v.

[illegible] 3.2. If $\overrightarrow{V}$ is a vector representation of a graph G, then $\overrightarrow{V} \ominus \overrightarrow{v}$ is a vector representation of $G \ominus v$. As mentioned earlier, this process results in a representation that has rank one less than rank $\overrightarrow{V}$. Unfortunately, $\operatorname{msr}(G) - \operatorname{msr}(G \ominus v)$ may be arbitrarily large as demonstrated by the complete bipartite graph $K_{2,n}$: For $n \geq 3$, by Corollary 2.7, $\operatorname{msr}(K_{2,n}) \geq n$, but the orthogonal removal of a vertex from the smaller independent set yields the complete graph on $n+1$ vertices, K_{n+1}, and $\operatorname{msr}(K_{n+1}) = 1$ by Remark 2.4.

We say that subgraphs $G_1, \ldots, G_m$ [illegible] a graph G with multiple edges if each vertex of G is a vertex of at least one G_i and, for every pair of vertices v and w of G joined by [illegible] one edge, there exists an i such that v and w are joined by [illegible] one edge in G_i. We now restate Lemma 2.8 for graphs with multiple edges.

LEMMA 3.3. [illegible] $X_1, \ldots, X_m$ $X_i \subseteq \mathbb{C}^n$ [illegible] $1 \leq i \leq m$ [illegible] $G_1, \ldots, G_m$ [illegible] G [illegible]

- $G_1, \ldots, G_m$ [illegible] G
- [illegible] v, w [illegible] G, [illegible] $\overrightarrow{x_v}$ [illegible] v [illegible] X_i [illegible] $\overrightarrow{x_w}$ [illegible] w [illegible] X_j $\langle \overrightarrow{x_v}, \overrightarrow{x_w} \rangle = 0$ [illegible] X [illegible] G [illegible]

$$\operatorname{rank} X \leq \operatorname{rank}\left(\bigcup_{1 \leq i \leq m} \operatorname{span} X_i\right) \leq \sum_{1 \leq i \leq m} \operatorname{rank} X_i.$$

Recall that a vertex v such that $n(v)$ induces a complete graph is said to be [illegible]

LEMMA 3.4. [illegible] v [illegible] G [illegible] $\operatorname{msr}(G) = \operatorname{msr}(G \ominus v) + 1$

[illegible]. From Remark 3.2, we have that $\operatorname{msr}(G) \geq \operatorname{msr}(G \ominus v) + 1$. From Remark 2.4, we may find a vector representation of rank one of the subgraph of G induced by v and its neighbors. Choosing this representation to be orthogonal to a representation of $G \ominus v$, we may apply Lemma 3.3 to see that $\operatorname{msr}(G) \leq \operatorname{msr}(G \ominus v) + 1$. ∎

The following corollary simplifies finding the minimum rank of graphs with vertices, which are simply vertices of degree 1. This corollary is also found in [17, Lemma 3.6] with a different proof.

COROLLARY 3.5. $\operatorname{msr}(G) = \operatorname{msr}(G - v) + 1$

A graph is said to be if it has no induced cycles C_n with $n \geq 4$. It is known that every nonempty chordal graph has at least one simplicial vertex [2, p. 175]. A clique cover of a graph G with multiple edges is a collection of cliques of G that cover every edge between the vertices of G. As before, the clique cover number of G $\operatorname{cc}(G)$ is the minimum number of cliques in a clique cover of G. We are now able to show that, for chordal graphs, the msr is the clique cover number.

THEOREM 3.6. $\operatorname{msr}(G) = \operatorname{cc}(G)$

. Induct on the number of vertices of G. We start the induction with an edge. For graphs with three or more vertices, identify a simplical vertex v of G. If, in addition, v is a duplicate vertex, then $\operatorname{cc}(G - v) = \operatorname{cc}(G)$ and $\operatorname{msr}(G - v) = \operatorname{msr}(G)$. If v is not a duplicate vertex and not connected to any other vertex by exactly one edge, then $\operatorname{cc}(G - v) = \operatorname{cc}(G)$ and $\operatorname{msr}(G - v) = \operatorname{msr}(G)$.

Finally, if v is not a duplicate vertex and is connected to at least one other vertex by exactly one edge, we observe that $\operatorname{cc}(G \ominus v) = \operatorname{cc}(G) - 1$. To see this, when v is simplicial, there are multiple edges between each pair of vertices in $n(v)$ in $G \ominus v$. Thus remove exactly one clique from a minimum clique cover of G to obtain a clique cover of $G \ominus v$. Now using Lemma 3.4 we get $\operatorname{msr}(G) = \operatorname{cc}(G)$. □

4. Minimum psd rank for graphs on less than seven vertices. For all the graphs G with $|V(G)| \leq 6$, with a few exceptions listed below, we can determine $\operatorname{msr}(G)$ using results discussed in this paper. A catalog of these graphs can be found in [16]. Table 4.1 lists the minimum psd ranks of 142 graphs on 2 or more vertices but less than seven vertices using the numbering found in [16].

We now detail how to use the results of this paper to find the msr of the graphs listed in Table 4.1. The graphs G174, G175, G198, and G204 are the exceptional cases which cannot be handled by the results presented above. We provide alternate methods for these graphs.

The complete graphs G3, G7, G18, G52, and G208 have msr equal to 1 by Remark 2.4. As mentioned in the introduction, the msr of a tree is one less than the number of vertices. This gives the msr for the trees G3, G6, G13, G14, G29–31, G77–81, and G83.

Among the nontree, noncomplete graphs, the following 64 graphs are chordal: G15, G17, G34–36, G40–42, G45–47, G49, G51, G92–95, G97, G100, G102, G111–

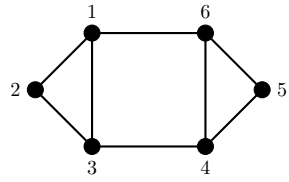

FIG. 4.2. *G*152.

115, G117, G119, G120, G123, G130, G133–139, G142, G144, G150, G156, G157, G160–165, G167, G177–181, G183, G191–193, G195, G200–G202, G205, and G207. Theorem 3.6 gives that the msr of a chordal graph is its clique cover number. For example, we have cc(G163) = msr(G163) = 3 (Figure 4.1).

There are 20 nonchordal graphs whose msr is 4. All but graph G152 (Figure 4.2) satisfy $\mathrm{ts}(G) = 5$. The discussion following Lemma 2.5 shows that, for these graphs, $\mathrm{msr}(G) = 4$. For G152, if we orthogonally remove simplicial vertices 2 and 5 and apply Lemma 3.4, we observe that msr(G152) = 4. In addition, G152 is not chordal, but $\mathrm{msr}(G) = \mathrm{cc}(G) = 4$, indicating that the converse to Theorem 3.6 is false.

Among the 32 nonchordal graphs whose msr is 3, G37, G38, G43, and G44 have $\mathrm{ts}(G) = 4$, hence they have $\mathrm{msr}(G) = 3$. The msr of G140, G141, G143, G158, and G159 is 3 by Corollary 3.5. A duplicate vertex is removed in G126, G153, G168, G169, G170, G172, G185, and G189, and the resulting graph on 5 vertices has msr equal to 3. The graphs G151, G154, G166, G171, G173, G182, G184, G186–G188, G196, and G197 satisfy the sufficient condition of Theorem 2.9. The exceptional cases are G174, G175, and G198. These three graphs could be handled using a construction as shown below or by applying Theorem 3.1 and Proposition 3.2 of [17] along with Lemma 2.5.

A maximum induced tree of G198 (Figure 4.3) is induced by $\{v_1, v_2, v_3, v_4\}$. Using the Laplacian matrix of this tree in the top left 4-by-4 block, we construct rows 5 and 6 to represent the graph G198,

$$\begin{bmatrix} 1 & -1 & 0 & 0 & -1 & 1 \\ -1 & 2 & -1 & 0 & 1 & -1 \\ 0 & -1 & 2 & -1 & 1 & 1 \\ 0 & 0 & -1 & 1 & -1 & -1 \\ -1 & 1 & 1 & -1 & 2 & 0 \\ 1 & -1 & 1 & -1 & 0 & 2 \end{bmatrix}.$$

The graph G198, with this rank 3 psd matrix, is an example which shows that the $\circledast$ condition of Theorem 2.9 is not necessary.

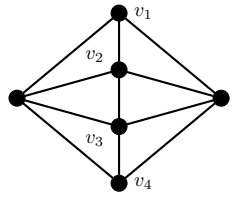

FIG. 4.3. $G198$.

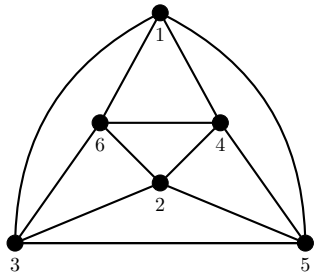

FIG. 4.4. $G204$.

Among the 9 nonchordal graphs whose msr is 2, G16 is a cycle on 4 vertices, while G50 and G203 satisfy the sufficient condition of Theorem 2.9. Removing one duplicate vertex from G48 and G206, and removing two duplicate vertices from G190, G194 and G199 reduce the graph to a known case. The one exceptional case is G204 (see Figure 4.4).

Suppose $\overrightarrow{e_1} = \left[\begin{smallmatrix}1\\0\end{smallmatrix}\right]$ and $\overrightarrow{e_2} = \left[\begin{smallmatrix}0\\1\end{smallmatrix}\right]$. Then we can write a vector representation for G204 as follows: $\overrightarrow{v_1} = \overrightarrow{e_1}$, $\overrightarrow{v_2} = \overrightarrow{e_2}$, $\overrightarrow{v_3} = 2\overrightarrow{e_1} + \overrightarrow{e_2}$, $\overrightarrow{v_4} = \overrightarrow{e_1} - 2\overrightarrow{e_2}$, $\overrightarrow{v_5} = \overrightarrow{e_1} + \overrightarrow{e_2}$, and $\overrightarrow{v_6} = \overrightarrow{e_1} - \overrightarrow{e_2}$. Thus msr(G204) = 2. Alternatively, we may use [1, Theorem 15].

Acknowledgments. The authors thank one of the referees for suggesting a shorter approach to the proof of Theorem 3.6. B. Harris, M. Lay, S. Narayan, A. Pascoe, K. Steinmetz, and W. Wang participated in an NSF–REU program at Central Michigan University during the summers of 2003 and 2004. M. Booth, C. Johnson, and B. Sutton participated in an NSF–REU program at the College of William and Mary in 2003.

MATRIX VALUED ORTHOGONAL POLYNOMIALS ARISING FROM GROUP REPRESENTATION THEORY AND A FAMILY OF QUASI-BIRTH-AND-DEATH PROCESSES*

F. ALBERTO GRÜNBAUM† AND MANUEL D. DE LA IGLESIA‡

Abstract. We consider a family of matrix valued orthogonal polynomials obtained by Pacharoni and Tirao in connection with spherical functions for the pair $(\mathrm{SU}(N+1), \mathrm{U}(N))$; see [I. Pacharoni and J. A. Tirao, *Constr. Approx.*, 25 (2007), pp. 177–192]. After an appropriate conjugation, we obtain a new family of matrix valued orthogonal polynomials where the corresponding block Jacobi matrix is stochastic and has special probabilistic properties. This gives a highly nontrivial example of a nonhomogeneous quasi-birth-and-death process for which we can explicitly compute its "n-step transition probability matrix" and its invariant distribution. The richness of the mathematical structures involved here allows us to give these explicit results for a several parameter family of quasi-birth-and-death processes with an arbitrary (finite) number of phases. Some of these results are plotted to show the effect that choices of the parameter values have on the invariant distribution.

Key words. matrix valued orthogonal polynomials, Markov chains, block tridiagonal transition matrix, quasi-birth-and-death processes

AMS subject classifications. 60J10, 42C05

1. Purpose and contents of the paper. The aim of this paper is to tie together two subjects that have received quite a bit of attention recently. We will not give a detailed explanation of either one of them, since this would require too much space and it has been done properly in the literature already. Besides, since these two subjects require rather different backgrounds, an ab-initio exposition would be a formidable task. To compensate for this we give a brief historical view of how these topics developed and then combine them at the appropriate point. The contents of this paper can be divided into three parts.

A first part gives a brief account of the subjects that are going to play a role in this paper. The introduction contains some historical developments tying the moment problem with spectral theory and a quick look at birth-and-death processes, including the appearance of the appropriate orthogonal polynomials. Section 3 reviews very briefly Kreĭn's theory of matrix valued orthogonal polynomials and discusses the first example relevant to our considerations. Section 4 gives a minimal description of the class of Markov chains known as quasi-birth-and-death processes and talks about the very natural connection between this and the previous section.

The second part introduces the family of examples arising from group representation theory that we are going to use in this paper. Section 5 gives a guide to the literature on matrix valued spherical functions aimed at showing how the examples discussed in section 6 arose. Section 6 gives the bare-bones details of the extensive

work carried out in [30] in the case of the complex projective space. Section 7 shows how to conjugate the weight matrix from [30] to obtain a family of matrix valued orthogonal polynomials with extra probabilistic properties.

The third part concentrates on the probabilistic aspects of our family of examples. Section 8 deals with a number of issues of probabilistic nature and displays the network associated with our examples. In particular we find explicit expressions for the invariant distribution. Section 9 gives graphical displays of some results obtained from the exact formulas in the previous sections. The goal here is to show that by varying the parameters afforded by the group theoretical situation one can obtain quite a range of different probabilistic behaviors. Finally, section 10 gives a summary of the results of the paper and the challenges that lie ahead.

2. Introduction. The classical Hausdorff moment problem, that of determining a measure $d\psi(x)$ in the interval $[-1, 1]$ from its moments

$$\sigma_n = \int_{-1}^{1} x^n d\psi(x),$$

originated in very concrete problems at the end of the 19th century and was discussed by people such as Chebyshev, Markov, and Stieltjes. In the hands of Weyl and a few others, this showed the far reaching power of the modern theory of functional analysis in the early part of the 20th century. The main ingredient here is to connect this problem with the spectral theory of a second order difference operator (built from the moments σ_n) acting on functions defined on the nonnegative integers. The moments in question determine (up to scalars) a family of polynomials $\{Q_n(x)\}_{n\geq 0}$, and these polynomials are the eigenfunctions of the second order difference operator alluded to above. In the appropriate Hilbert space this operator is symmetric, and the problem of finding $d\psi(x)$ is the problem of finding self-adjoint extensions of this symmetric operator. Under certain conditions there is a unique such extension and thus a unique solution to the moment problem we started from, but at any rate any extension gives a measure $d\psi(x)$ that makes the polynomials orthogonal with respect to each other.

To get closer to our subject we need a few more ingredients. One of them is given in the rest of this section, and the other two in sections 3 and 4.

The presence of a second order difference operator acting on the space of functions defined on the nonnegative integers, i.e., a semi-infinite tridiagonal matrix, makes it natural to think of a very special kind of Markov chain on the space of nonnegative integers. These are the so-called birth-and-death processes where at each discrete unit of time a transition is allowed from state i to state j with probability P_{ij} and we put $P_{ij} = 0$ if $|i - j| > 1$. The one-step transition probability matrix is given by

$$P = \begin{pmatrix} r_0 & p_0 & & & \\ q_1 & r_1 & p_1 & & \\ & q_2 & r_2 & p_2 & \\ & & \ddots & \ddots & \ddots \end{pmatrix}. \tag{2.1}$$

We will assume that $p_j > 0$, $q_{j+1} > 0$, and $r_j \geq 0$ for $j \geq 0$. We also assume $p_j + r_j + q_j = 1$ for $j \geq 1$ and by putting $p_0 + r_0 \leq 1$ we allow for the state $j = 0$ to be an absorbing state (with probability $1 - p_0 - r_0$). Some of these conditions can be relaxed.

The problem here is to obtain an expression for the so-called "n-step transition probability matrix," giving the probability of going between any two states in n steps. By making use of the ideas mentioned above, i.e., by bringing in an appropriate Hilbert space and applying then the spectral theorem, Karlin and McGregor [20] obtained a neat representation formula for the quantity of interest, as recalled below.

If one introduces the polynomials $\{Q_n(x)\}_{n\geq 0}$ by the conditions $Q_{-1}(x) = 0$, $Q_0(x) = 1$ and by using the notation

$$\phi = \begin{pmatrix} Q_0(x) \\ Q_1(x) \\ \vdots \end{pmatrix},$$

one insists on the recursion relation

$$P\phi = x\phi,$$

it is possible to prove the existence of a unique measure $d\psi(x)$ supported in $[-1, 1]$ such that

$$\int_{-1}^{1} Q_i(x)Q_j(x)d\psi(x) \Big/ \int_{-1}^{1} Q_j(x)^2 d\psi(x) = \delta_{ij}$$

and one gets the Karlin–McGregor representation formula

$$P_{ij}^n = \int_{-1}^{1} x^n Q_i(x)Q_j(x)d\psi(x) \Big/ \int_{-1}^{1} Q_j(x)^2 d\psi(x). \tag{2.2}$$

If time is taken to be continuous, as it is done in other papers by Karlin and McGregor, then this formula and the matrix P suffer only cosmetic changes.

It is interesting to notice that this seminal paper of Karlin and McGregor refers both to the standard text on the moment problem at the time [33], as well as to the fact that Feller and McKean had already recognized the relevance of the Hilbert space setup in the study of diffusion processes; see [7, 26]. One can mention other papers, such as [8, 17, 19, 25], where similar ideas were at play.

The last section of [20] deals with the case of a finite state space and the case when the nonnegative integers are replaced by the set of all integers. Since one is using a very powerful tool such as the spectral theorem it is clear that an adaptation of the ideas from birth-and-death processes will work here too. In the case of the integers, one is dealing with a state space with two singular points (one at each end of the line), and in this case Weyl and others had already found the correct tool: one replaces the spectral measure $d\psi(x)$ by a 2×2 nonnegative matrix. The paper of Karlin and McGregor concludes with the explicit computation of this matrix in the case of the doubly infinite random walk. The general formula is given in expression (12) of [20] for the case of discrete time and also in (6.8) of [18] for continuous time.

The representation formula given above is of intrinsic interest: the computation of the left-hand side of (2.2) for fixed i, j and arbitrary values of n involves all of the entries of (2.1). However, if $d\psi(x)$ is known, then the right-hand side of (2.2) gives a way of computing this quantity using only a fixed number of entries of (2.1).

The applicability of (2.2) depends to a large extent on our ability to obtain useful expressions for the orthogonal polynomials and the orthogonality measure associated

with P. If one looks around in the literature one discovers that the number of cases where this is possible is rather small.

We close this section by showing how one can compute in the case of a stochastic matrix P its invariant (stationary) distribution, i.e., the (unique up to scalars) row vector

$$\boldsymbol{\pi} = (\pi_0, \pi_1, \pi_2, \dots)$$

such that

$$\boldsymbol{\pi} P = \boldsymbol{\pi}.$$

Recall that a matrix P with nonnegative entries is called stochastic if the sum of the elements in any row equals unity.

We first obtain, using $r_0 + p_0 = 1$, that $\pi_1 = \pi_0 p_0/q_1$. Then one proves by induction that for $i \geq 1$ we have

$$\pi_i = \pi_0(p_0 p_1 \dots p_{i-1})/(q_1 q_2 \dots q_i).$$

This has the consequence that

$$\pi_{i+1}/\pi_i = p_i/q_{i+1}.$$

Now for $i \geq 0$ we have

$$xQ_i(x) = p_i Q_{i+1}(x) + r_i Q_i(x) + q_i Q_{i-1}(x)$$

with $q_0 = 0$. Integrating this after multiplication by Q_{i+1} or Q_{i-1} gives

$$\int_{-1}^{1} xQ_i(x)Q_{i+1}(x)d\psi(x) = p_i \int_{-1}^{1} Q_{i+1}^2(x)d\psi(x) = q_{i+1} \int_{-1}^{1} Q_i^2(x)d\psi(x).$$

Combining these two results we get that the ratio of the two integrals above is given by the common value

$$q_{i+1}/p_i = \pi_i/\pi_{i+1}.$$

The moral of this is that the solution to $\boldsymbol{\pi} P = \boldsymbol{\pi}$ can be computed (up to a common multiplicative scalar) either from the matrix P itself or from the knowledge of the integrals

$$\int_{-1}^{1} Q_i^2(x)d\psi(x).$$

In particular if we have an homogeneous birth-and-death process where $p_i = p$ and $q_i = q$ independently of the value of i, then we have that the components of $\boldsymbol{\pi}$ are given by $\pi_i = \pi_0(p/q)^i$, $i \geq 0$.

3. Matrix valued orthogonal polynomials. We need two more characters to be able to start our tale. The first one is the theory of matrix valued orthogonal polynomials, whose bare-bones development is given in two papers by Kreĭn [21, 22]. There is no written account of the motivation that led Kreĭn to this theory, but one can easily see the connection with the spectral theory of difference operators on the integers. This is very nicely discussed in the book by Berezans'kiĭ [2]. In fact the study

of the classical second order difference operator on the integers is done in detail in [2] and may constitute the first example of the theory of Kreĭn, where the polynomials and their orthogonality weight matrix $W(x)$ are both explicitly given. This is, of course, a special case of the matrix that appears in the last section of [20] for general values of p and q $(p+q=1)$.

We give now a brief account of Kreĭn's theory.

Given a positive definite matrix valued measurable weight function $W = W(x)$ with finite moments we can consider the skew symmetric bilinear form defined for any pair of matrix valued polynomial functions $P(x)$ and $Q(x)$ by the numerical matrix

$$(P,Q) = (P,Q)_W = \int_{\mathbb{R}} P(x)W(x)Q^*(x)dx,$$

where $Q^*(x)$ denotes the conjugate transpose of $Q(x)$. We define the matrix valued norm of P by

$$\|P\|^2 = (P,P)_W. \tag{3.1}$$

One can also deal with a more general weight matrix $W(x)$; see [4].

This leads, using the Gram–Schmidt process, to the existence of a sequence of matrix valued orthogonal polynomials with nonsingular leading coefficients. Given an orthogonal sequence $\{Q_n(x)\}_{n\geq 0}$ one gets a three term recursion relation

$$xQ_n(x) = A_nQ_{n+1}(x) + B_nQ_n(x) + C_nQ_{n-1}(x), \tag{3.2}$$

where A_n is nonsingular. We will denote by $\mathcal{L}$ the corresponding [illegible], defined by the following block tridiagonal semi-infinite matrix:

$$\mathcal{L} = \begin{pmatrix} B_0 & A_0 & & & \\ C_1 & B_1 & A_1 & & \\ & C_2 & B_2 & A_2 & \\ & & \ddots & \ddots & \ddots \end{pmatrix}.$$

Using the notation

$$\Phi = \begin{pmatrix} Q_0(x) \\ Q_1(x) \\ \vdots \end{pmatrix}$$

the relation (3.2) becomes

$$\mathcal{L}\Phi = x\Phi. \tag{3.3}$$

We will reserve the symbol P for the case where $\mathcal{L}$ becomes a one-step transition probability matrix, thought of as a scalar matrix. The corresponding Markov chain (to appear in section 4) will have a state space that is more complicated than the set $\{0,1,2,\dots\}$ corresponding to a birth-and-death process featured in section 2.

In the scalar case, concrete examples of orthogonal polynomials, including explicit formulas for them as well as their orthogonality measure preceded the development of any general theory. Prominent examples are the Hermite, Laguerre, and Jacobi

polynomials. These examples arose from concrete problems in the eighteenth and nineteenth centuries and played a fundamental role, in the hands of Schrödinger, in the development of quantum mechanics around 1925.

The situation in the matrix valued case is entirely different: the general theory just described above came first. Until a few years ago, it may be that the only nontrivial example was the one included in Berezans'kiĭ's book [2], alluded to above and recalled below for the benefit of the reader.

Consider the block tridiagonal matrix

$$\mathcal{L} = \begin{pmatrix} B_0 & I & & & \\ C_1 & B_1 & I & & \\ & C_2 & B_2 & I & \\ & & \ddots & \ddots & \ddots \end{pmatrix}$$

with 2×2 blocks given as follows:

$$B_0 = \frac{1}{2}\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad B_n = 0 \quad \text{if } n \geq 1,$$

$$C_n = \frac{1}{4} I \quad \text{if } n \geq 1,$$

where I stands for the identity matrix. In this case one can compute explicitly the matrix valued polynomials $\{Q_n(x)\}_{n\geq 0}$ given by

$$xQ_n(x) = Q_{n+1}(x) + B_n Q_n(x) + C_n Q_{n-1}(x), \quad Q_{-1}(x) = 0, \quad Q_0(x) = I.$$

One gets

$$Q_n(x) = \frac{1}{2^n}\begin{pmatrix} U_n(x) & -U_{n-1}(x) \\ -U_{n-1}(x) & U_n(x) \end{pmatrix},$$

where $U_n(x)$ are the Chebyshev polynomials of the second kind.

The orthogonality measure is read off from the identity

$$\frac{4^i}{\pi}\int_{-1}^{1} Q_i(x) \frac{1}{\sqrt{1-x^2}} \begin{pmatrix} 1 & x \\ x & 1 \end{pmatrix} Q_j^*(x)dx = \delta_{ij} I.$$

Proceeding as in [3, 10, 20] one obtains a Karlin–McGregor representation. We get, for $n = 0, 1, 2, \ldots,$

$$\mathcal{L}_{ij}^n = \frac{4^i}{\pi}\int_{-1}^{1} x^n Q_i(x) \frac{1}{\sqrt{1-x^2}} \begin{pmatrix} 1 & x \\ x & 1 \end{pmatrix} Q_j^*(x)dx,$$

where $\mathcal{L}_{ij}^n$ stands for the (i, j) block of the matrix $\mathcal{L}^n$. As is usual for birth-and-death processes, the indices i, j run from 0 on.

In this way, as noticed in [10], one can compute the entries of the powers $\mathcal{L}^n$ with

$\mathcal{L}$ thought of as a pentadiagonal scalar matrix, namely

$$\mathcal{L} = \begin{pmatrix} 0 & \frac{1}{2} & 1 & 0 & & \\ \frac{1}{2} & 0 & 0 & 1 & 0 & \\ \frac{1}{4} & 0 & 0 & 0 & 1 & \ddots \\ & \frac{1}{4} & 0 & 0 & 0 & \ddots \\ & & \ddots & \ddots & \ddots & \ddots \end{pmatrix}.$$

$\mathcal{L}$ is not a stochastic matrix since its rows do not add up to unity. Nevertheless, defining Δ to be the 2×2 block diagonal matrix with $\Delta_{ii} = 2^i I$ for every block, we get from (3.3) that $\Delta\mathcal{L}\Delta^{-1}\Delta\Phi = x\Delta\Phi$ and thus if $P = \Delta\mathcal{L}\Delta^{-1}$ and $\widetilde{\Phi} = \Delta\Phi$, we have $P\widetilde{\Phi} = x\widetilde{\Phi}$. The scalar version of P is now the stochastic matrix

$$P = \begin{pmatrix} 0 & \frac{1}{2} & \frac{1}{2} & 0 & & \\ \frac{1}{2} & 0 & 0 & \frac{1}{2} & 0 & \\ \frac{1}{2} & 0 & 0 & 0 & \frac{1}{2} & \ddots \\ & \frac{1}{2} & 0 & 0 & 0 & \ddots \\ & & \ddots & \ddots & \ddots & \ddots \end{pmatrix}.$$

Observe that the norm of $\widetilde{Q}_n$, defined in (3.1), satisfies $\|\widetilde{Q}_n\|^2 = \pi$. This is nothing but the example considered at the end of [20] in the special case of $p = q = 1/2$.

In the last few years a number of new families of matrix valued orthogonal polynomials have been computed explicitly along with their orthogonality measure. Typically they are joint eigenfunctions of some fixed differential operator with matrix coefficients. This search was initiated in [5], but nontrivial examples were not discovered until [6] and [13, 16]. The family of examples we will consider later is related to one of these examples and is obtained by modifying the situation discussed in [30].

4. Quasi-birth-and-death processes. Now we come to the last character of our story. For our purposes, we consider a two dimensional Markov chain with discrete time. The state space consists of the pair of integers (i, j), $i \in \{0, 1, 2, \dots\}$, $j \in \{1, \dots, d\}$. The first component is usually called the level and the second one the phase. The one-step transition probability matrix, which we will denote (as before) by P has a block tridiagonal structure (see (4.2)). This indicates that in one unit of time a transition can change the phase without changing the level, or can change the level (and possibly the phase) to either of the adjacent levels. The probability of going in one step from state (i, j) to state (i', j') is given by the (j, j') element of the block $P_{i,i'}$. Clearly in the case when the number of phases d is one we are back to the case of an ordinary birth-and-death process. In general, these processes are known as (discrete time) quasi-birth-and-death processes.

For a much more detailed presentation of this field, as well as its connections with queueing problems in network theory as well as the general field of communication systems, the reader should consult [24, 27] and some of the references in [3].

Once one has the notions introduced in the previous sections it is very natural to connect them and to analyze these interesting Markov chains in terms of the

corresponding spectral properties of the resulting family of matrix valued orthogonal polynomials. As pointed out before one can see the seed for this in the work of Kreĭn, as well as in the original paper [20].

We have identified two references where the corresponding Karlin–McGregor representation formula has been explicitly given, but there may be others since this is such a natural extension of the scalar theory; see [3] and [10]. In the case of quasi-birth-and-death processes one replaces (2.2) by

$$P_{ij}^n = \left(\int x^n Q_i(x) W(x) Q_j^*(x) dx \right) \left(\int Q_j(x) W(x) Q_j^*(x) dx \right)^{-1}. \tag{4.1}$$

A different but related path to this circle of ideas in connection with network models can be seen in [1].

In [3] one finds some interesting examples where this representation formula is computed explicitly, including a new derivation of the result dealing with the case of random walk on the integers. In [10] one finds an example, taken from [9], where the observation is made that one has a stochastic matrix. The family of examples to be considered in the following sections is an extension of this example.

Given the block transition probability matrix P, the problem of computing an invariant distribution row vector, i.e., a vector with nonnegative entries π_j^i,

$$\boldsymbol{\pi} = (\boldsymbol{\pi}^0; \boldsymbol{\pi}^1; \dots) \equiv (\pi_1^0, \pi_2^0, \dots, \pi_d^0; \pi_1^1, \pi_2^1, \dots, \pi_d^1; \dots)$$

such that

$$\boldsymbol{\pi} P = \boldsymbol{\pi}$$

leads to a complicated system of equations.

If

$$P = \begin{pmatrix} B_0 & A_0 & & & \\ C_1 & B_1 & A_1 & & \\ & C_2 & B_2 & A_2 & \\ & & \ddots & \ddots & \ddots \end{pmatrix}, \tag{4.2}$$

we have

$$\boldsymbol{\pi}^0 B_0 + \boldsymbol{\pi}^1 C_1 = \boldsymbol{\pi}^0$$

and then, for $n \geq 1$,

$$\boldsymbol{\pi}^{n-1} A_{n-1} + \boldsymbol{\pi}^n B_n + \boldsymbol{\pi}^{n+1} C_{n+1} = \boldsymbol{\pi}^n.$$

This gives, as is easy to check, the rather unpleasant expressions

$$\boldsymbol{\pi}^1 = \boldsymbol{\pi}^0 (I - B_0) C_1^{-1},$$

$$\boldsymbol{\pi}^2 = \boldsymbol{\pi}^0 [(I - B_0) C_1^{-1} (I - B_1) - A_0] C_2^{-1},$$

$$\boldsymbol{\pi}^3 = \boldsymbol{\pi}^0 [(I - B_0) C_1^{-1} (I - B_1) C_2^{-1} (I - B_2) - A_0 C_2^{-1} (I - B_2) - (I - B_0) C_1^{-1} A_1] C_3^{-1}.$$

These formulas require that the matrices C_n be invertible. Under these conditions, one can derive nicer looking expressions for the invariant distribution (see [23]). There are

many issues here that we leave untouched in this analysis. For instance, the possibility of choosing $\boldsymbol{\pi}^0$ with nonnegative entries so that all the subsequent $\boldsymbol{\pi}^n$ will have this property requires extra conditions.

The general theory of quasi-birth-and-death processes is not restricted to the case when the matrices A_n, B_n, and C_n are all square matrices of the same size and A_n and C_n are nonsingular. It remains an interesting challenge to find a mathematical setup that can accommodate such a situation.

Now that we have seen how to extend the Karlin–McGregor representation formula to the block tridiagonal case it is important to get examples where the polynomials and the orthogonality matrix can be explicitly written down. This is the purpose of the next three sections.

5. Matrix valued spherical functions and matrix valued orthogonal polynomials. The theory of matrix valued spherical functions, initially discussed in [34], is one of the routes leading to explicit families of matrix valued orthogonal polynomials and their orthogonality measure. The first family of examples appeared in [13, 16] in connection with $G = \mathrm{SU}(3)$. The size of the matrices here is already arbitrary, and the orthogonality matrix has a scalar factor of the form $x^\alpha(1-x)$. The extension to the case where this scalar factor can be taken to be $x^\alpha(1-x)^\beta$ for arbitrary $\alpha, \beta > -1$ was undertaken in [9] in the 2×2 case without any reference to group representation theory. Further examples of this kind are given in [14]. The role of group representation theory in getting away from the 2×2 case can be seen in [15]. Finally, [30] displays for the case of $G = \mathrm{SU}(N+1)$ families of orthogonal polynomials depending on three parameters, α, β, and k. In the special case of $k = \frac{\beta+1}{2}$, one recovers the results of [9].

These orthogonal polynomials are given by properly "packaged and conjugated" sets of matrix valued spherical functions. These spherical functions correspond to irreducible representations of $\mathrm{U}(N)$ and therefore are parameterized by partitions

$$\mu = (m_1, m_2, \ldots, m_N) \in \mathbb{Z}^N \quad \text{such that} \quad m_1 \geq m_2 \geq \cdots \geq m_N.$$

In this paper, following [30], we use only "one step" representations given by a partition

$$\mu = (\underbrace{m+\ell, \ldots, m+\ell}_{k}, \underbrace{m, \ldots, m}_{N-k}), \quad 1 \leq k \leq N-1.$$

In terms of the parameters α and β, one has $\alpha = m$ and $\beta = N-1$. The remaining free parameter ℓ will determine the size of the corresponding matrix valued orthogonal polynomials and is independent of N. In the next section it will be related to the parameter d appearing in [3].

The examples that have been worked out so far indicate that the matrix valued orthogonal polynomials that result from matrix valued spherical functions lead to a block tridiagonal matrix that can be made into a stochastic one. This will be seen, for our family of examples, in section 8.

Although it is possible to obtain examples of stochastic matrices arising in a different fashion, see, for instance [2], we are not aware of any other general scheme that would produce these desirable kinds of matrices in a systematic fashion.

6. A family of examples arising from the complex projective space. In what follows we shall use E_{ij} to denote the matrix with entry (i,j), which is equal to 1 and 0 elsewhere, where the indices i, j run from 0 on.

Let $d \in \{1, 2, 3, \dots\}$, $\alpha, \beta > -1$ and $0 < k < \beta + 1$. From [30] we have that the differential operator

$$D = x(1-x)\frac{d^2}{dx^2} + (C - xU)\frac{d}{dx} + V,$$

with matrix coefficients given by

$$C = \sum_{i=0}^{d-1}(\alpha + d - i)E_{ii} - \sum_{i=0}^{d-2}(i+1)E_{i+1,i}, \quad U = \sum_{i=0}^{d-1}(\alpha + \beta + d + i + 1)E_{ii},$$

$$V = -\sum_{i=0}^{d-1} i(\alpha + \beta - k + i + 1)E_{ii} + \sum_{i=0}^{d-2}(d - i - 1)(\beta - k + i + 1)E_{i,i+1},$$

admits as eigenfunctions (the conjugates of) a family of orthogonal polynomials with respect to the $d \times d$ weight function

$$W(x) = x^{\alpha}(1-x)^{\beta}Z(x), \quad x \in [0, 1],$$

where

$$Z(x) = \sum_{i,j=0}^{d-1}\left(\sum_{r=0}^{d-1}\binom{r}{i}\binom{r}{j}\binom{d+k-r-2}{d-r-1}\binom{\beta-k+r}{r}(1-x)^{i+j}x^{d-r-1}\right)E_{ij}.$$

Initially the value of k is an integer, but (with the appropriate notation) this can be taken to be any value in the range indicated above. Likewise, in the group theoretical setup of [30] one first takes α and β to be integers but then observes that this holds for α and β as above.

In the language of [14], $\{W, D\}$ is a [illegible].

In [28] one finds an explicit expression for a family of eigenfunctions of D in terms of the matrix valued hypergeometric function ${}_2F_1$ introduced in [35].

In principle it is possible to obtain the coefficients for the three term recursion relation satisfied by any family of orthogonal polynomials whose existence is proved in [30]. We have not done this, but instead, since our goal is to obtain a family of matrix valued orthogonal polynomials $\{Q_n(x)\}_{n\geq 0}$ with specific probabilistic properties, we modify appropriately the classical pair in [30]. This is the goal of the next section.

[illegible] Notice that the notation in [13, 14, 15, 16, 30] and the one in [3] (which we follow here) are related by $d = \ell + 1$.

7. The new equivalent classical pair. Let us consider the following nonsingular upper triangular matrix:

$$T = \sum_{i\leq j}(-1)^i \frac{(-j)_i}{(1-d)_i}\frac{(\alpha + \beta - k + j + 1)_i}{(\beta - k + 1)_i}E_{ij},$$

where $(a)_n$ will denote the Pochhammer symbol defined by $(a)_n = a(a+1)\cdots(a+n-1)$ for $n > 0$, $(a)_0 = 1$. The purpose of choosing T as above will be made clear below.

Let us consider the new classical pair $\{\widetilde{W}, \widetilde{D}\}$, where

$$\widetilde{W} = T^* W T$$

and

$$\widetilde{D} = T^{-1}DT = x(1-x)\frac{d^2}{dx^2} + (\widetilde{C} - x\widetilde{U})\frac{d}{dx} + \widetilde{V},$$

where

$$\begin{aligned}
\widetilde{C} = &\sum_{i=0}^{d-1}\left(\alpha + d - i + \frac{i(d-i)(\beta-k+i)}{\alpha+\beta-k+2i} - \frac{(i+1)(d-i-1)(\beta-k+i+1)}{\alpha+\beta-k+2i+2}\right)E_{ii} \\
&+ \sum_{i=0}^{d-2}\left(1 + i + \frac{(i+1)(d-i-2)(\beta-k+i+2)}{\alpha+\beta-k+2i+3}\right. \\
&\qquad\left. - \frac{(i+1)(d-i-1)(\beta-k+i+1)}{\alpha+\beta-k+2i+2}\right)E_{i,i+1} \\
&+ \sum_{i=0}^{d-2}\left(\frac{(i+1)(d-i-1)(\beta-k+i+1)}{\alpha+\beta-k+2i+2} - \frac{i(d-i-1)(\beta-k+i+1)}{\alpha+\beta-k+2i+1}\right)E_{i+1,i},
\end{aligned}$$

$$\widetilde{U} = \sum_{i=0}^{d-1}(\alpha+\beta+d+i+1)E_{ii} + \sum_{i<j}\left((-1)^{j-i}(i+1)_{j-i}\frac{\alpha+\beta-k+2i+1}{(\alpha+\beta-k+i+1)_{j-i}}\right)E_{ij},$$

$$\widetilde{V} = -\sum_{i=0}^{d-1} i(\alpha+\beta-k+i+1)E_{ii}.$$

The pair $\{\widetilde{W}, \widetilde{D}\}$ is equivalent to $\{W, D\}$ according to the definitions in [14]. Note that T is chosen so that $\widetilde{V}$ turns out to be diagonal.

We now produce a particular family of polynomials $\{Q_n(x)\}_{n\geq 0}$ satisfying $Q_0(x) = I$ and $\widetilde{D}Q_n^*(x) = Q_n^*(x)\Lambda_n$ with

$$\Lambda_n = -\sum_{i=0}^{d-1}(n^2 + (\alpha+\beta+d+i)n + i(\alpha+\beta-k+i+1))E_{ii}.$$

If we put $Q_n(x) = \sum_{j=0}^{n} A_j^n x^j$, we see that the leading coefficient A_n^n can be conveniently chosen to be the lower triangular matrix

$$\begin{aligned}
&\sum_{i\leq j}(-1)^{i+j}\binom{j}{i}(\alpha+\beta-k+2i+1) \\
&\times \frac{(n)_{j-i}(k+n)_{d-j-1}(\alpha+\beta-k+n+j+1)_i(\alpha+\beta+n+d+j)_n}{(k)_{d-j-1}(\beta+d)_n(\alpha+\beta-k+i+1)_{j+1}}E_{ji},
\end{aligned}$$

and that this determines A_j^n for $j = n-1, n-2, \ldots, 0$. This is very similar to the analysis in section 3.1 of [11], where the final result is equations (3)–(5), expressing these polynomials in terms of the matrix valued hypergeometric function ${}_2F_1$ of Tirao; see [35]. As mentioned in the last section, such an expression in terms of ${}_2F_1$ is obtained in [28] for a family of polynomials that are related to $\{Q_n(x)\}_{n\geq 0}$ in the form $Q_n(x) = A_n^n T^*(\widetilde{A}_n^n)^{-1}P_n(x)(T^*)^{-1}$, where $P_n(x) = \widetilde{A}_n^n x^n + \cdots$. These $\{P_n(x)\}_{n\geq 0}$ do

not satisfy the same recursion relation as ours. This choice of A_n^n above is motivated by the remarkable fact that then our $\{Q_n(x)\}_{n\geq 0}$ satisfy

$$Q_n(1)\mathbf{e}_d^* = \mathbf{e}_d^*, \tag{7.1}$$

where $\mathbf{e}_d$ is the d-dimensional row vector with all entries equal to 1. In other words, the sum of the elements in each row of $Q_n(1)$ gives the value 1.

Below, we give the explicit expression for the stochastic block tridiagonal matrix going with the sequence $\{Q_n(x)\}_{n\geq 0}$.

THEOREM 7.1. [illegible]

$$xQ_n(x) = A_nQ_{n+1}(x) + B_nQ_n(x) + C_nQ_{n-1}(x), \quad n \geq 0, \tag{7.2}$$

[illegible] $Q_{-1}(x) = 0$ [illegible] $Q_0(x) = I$ [illegible] $n \geq 0$, A_n [illegible]

$$A_n = \sum_{i=0}^{d-1} \frac{(k+n)(\beta+n+d)(\alpha+\beta+n+d+i)(\alpha+\beta-k+n+i+1)}{(k+n+d-i-1)(\alpha+\beta-k+n+2i+1)(\alpha+\beta+2n+d+i)_2} E_{ii}$$

$$+ \sum_{i=0}^{d-2} \frac{(i+1)(k+n)(k+d-i-2)(\beta+n+d)}{(\alpha+\beta+2n+d+i+1)(\alpha+\beta-k+n+2i+3)(k+n+d-i-2)_2} E_{i+1,i},$$

[illegible] $n \geq 1$, C_n [illegible]

$$C_n = \sum_{i=0}^{d-1} \frac{n(\alpha+n+i)(k+n+d-1)(\alpha+\beta-k+n+d+i)}{(k+n+d-i-1)(\alpha+\beta-k+n+2i+1)(\alpha+\beta+2n+d+i-1)_2} E_{ii}$$

$$+ \sum_{i=0}^{d-2} \frac{n(d-i-1)(k+n+d-1)(\beta-k+i+1)}{(\alpha+\beta+2n+d+i)(\alpha+\beta-k+n+2i+1)(k+n+d-i-2)_2} E_{i,i+1},$$

$n \geq 0$, B_n [illegible]

$$B_n = \sum_{i=0}^{d-1} \Bigg(1 + \frac{n(k+n-1)(k+n+d-1)(\beta+n+d-1)}{(\alpha+\beta+2n+d+i-1)(k+n+d-i-2)_2}$$

$$- \frac{(n+1)(k+n)(k+n+d)(\beta+n+d)}{(\alpha+\beta+2n+d+i+1)(k+n+d-i-1)_2}$$

$$+ \frac{i(d-i)(k+d-i-1)(\beta-k+i)}{(\alpha+\beta-k+n+2i)(k+n+d-i-1)_2}$$

$$- \frac{(i+1)(d-i-1)(k+d-i-2)(\beta-k+i+1)}{(\alpha+\beta-k+n+2i+2)(k+n+d-i-2)_2} \Bigg) E_{ii}$$

$$+ \sum_{i=0}^{d-2} \frac{(d-i-1)(\beta-k+i+1)(\alpha+\beta-k+n+i+1)(\alpha+\beta+n+d+i)}{(k+n+d-i-1)(\alpha+\beta+2n+d+i)(\alpha+\beta-k+n+2i+1)_2} E_{i,i+1}$$

$$+ \sum_{i=0}^{d-2} \frac{(i+1)(\alpha+n+i+1)(k+d-i-2)(\alpha+\beta-k+n+d+i+1)}{(k+n+d-i-2)(\alpha+\beta+2n+d+i+1)(\alpha+\beta-k+n+2i+2)_2} E_{i+1,i}.$$

[illegible]. The tools required to prove these formulas are implicitly included in [12] and [29] for the special case of $\beta = k = 1$. The detailed proof of these results can be obtained following the program described above. □

The advantage of dealing with this equivalent classical pair $\{\widetilde{W}, \widetilde{D}\}$, normalized as above, shows up, for instance, in the fact that we have a stochastic matrix. The entries of A_n, B_n, and C_n are nonnegative, and by applying both sides of the identity (7.2) to the vector $\mathbf{e}_d^*$, setting $x = 1$, and using (7.1) we obtain that the sum of the entries in each row of our block tridiagonal matrix equals one.

In [31] one finds a nice and different proof for the fact that our Jacobi matrix is stochastic in the special case of $\beta = k = 1$.

There are further advantages in dealing with the pair $\{\widetilde{W}, \widetilde{D}\}$: an expression for the norms of the family $\{Q_n(x)\}_{n\geq 0}$ with respect to the matrix measure $\widetilde{W}$, defined in (3.1), is given by the diagonal matrix

(7.3)

$$\|Q_n\|^2_{\widetilde{W}} = (Q_n, Q_n)_{\widetilde{W}} = \sum_{i=0}^{d-1} (-1)^i \frac{\Gamma(n+1)\Gamma(\beta+d)\Gamma(\alpha+n+i+1)(1-k-d-n)_i}{\binom{d-1}{i}\Gamma(d)\Gamma(\alpha+\beta+d+i+2n+1)}$$

$$\times \frac{(k+d-i-1)_n(\alpha+\beta+d+i+n)_n(\alpha+\beta-k+i+n+1)_d}{(\alpha+\beta-k+2i+n+1)(k)_n(\beta-k+1)_i(\beta+d)_n} E_{ii},$$

where Γ is the standard Gamma function. We point out that these matrix valued norms are given in our case by diagonal matrices, a fact that will play an important role later on.

For the benefit of the reader we include here the expression for all the quantities above in the case $d = 1$. The weight $\widetilde{W}$ and differential operator $\widetilde{D}$ are given by

$$\widetilde{W}(x) = x^\alpha (1-x)^\beta, \quad \widetilde{D} = x(1-x)\frac{d^2}{dx^2} + (\alpha + 1 + x(\alpha+\beta+2))\frac{d}{dx}.$$

Hence, we have that the coefficients of the three term recursion relation and the norms of the orthogonal polynomials are given by

$$A_n = \frac{(n+\beta+1)(n+\alpha+\beta+1)}{(2n+\alpha+\beta+1)(2n+\alpha+\beta+2)}, \quad n \geq 0,$$

$$B_n = 1 + \frac{n(n+\beta)}{2n+\alpha+\beta} - \frac{(n+1)(n+\beta+1)}{2n+\alpha+\beta+2}, \quad n \geq 0,$$

$$C_n = \frac{n(n+\alpha)}{(2n+\alpha+\beta)(2n+\alpha+\beta+1)}, \quad n \geq 1,$$

$$\|Q_n\|^2_{\widetilde{W}} = \frac{\Gamma(n+1)\Gamma(n+\alpha+1)\Gamma(\beta+1)^2}{\Gamma(n+\beta+1)\Gamma(n+\alpha+\beta+1)(2n+\alpha+\beta+1)}, \quad n \geq 0.$$

The polynomials $\{Q_n(x)\}_{n\geq 0}$ are exactly the Jacobi polynomials in the interval $[0,1]$, normalized to satisfy $Q_n(1) = 1$.

The case $d = 2$, for the special case of $k = \frac{\beta+1}{2}$, can be found in [9].

8. Probabilistic aspects of our family of examples. The corresponding Jacobi matrix

$$P = \mathcal{L} = \begin{pmatrix} B_0 & A_0 & & & \\ C_1 & B_1 & A_1 & & \\ & C_2 & B_2 & A_2 & \\ & & \ddots & \ddots & \ddots \end{pmatrix} \tag{8.1}$$

made up from the coefficients introduced in Theorem 7.1 is stochastic; that is, $P\mathbf{e} = \mathbf{e}$, where $\mathbf{e}$ denotes the semi-infinite column vector with all entries equal to 1. Therefore, it gives a block tridiagonal transition probability matrix depending on three parameters, α, β, and k.

The Markov process that results from P is [illegible] and [illegible]. Indeed, one can see that for any pair of states (i,j), (i',j'), every entry in the (i,i')-block of P^n is positive if n is large enough.

THEOREM 8.1. [illegible] P [illegible] $-1 < \beta \leq 0$ [illegible] $\beta > 0$ [illegible].

. One can use directly the Karlin–McGregor representation formula (4.1) to obtain Corollary 4.1 of [3]. The process turns out to be recurrent if and only if

$$e_j^T \left(\int_0^1 \frac{\widetilde{W}(x)}{1-x} S_0^{-1} dx \right) e_j = \infty \tag{8.2}$$

for some $j \in \{1, \ldots, d\}$, where $e_j^T = (0, \ldots, 0, 1, 0, \ldots, 0)$ denotes the jth unit vector and $S_0 = \int_0^1 \widetilde{W}(x)dx = \|Q_0\|^2_{\widetilde{W}}$ is the first moment. Otherwise, the process is transient. The explicit expression of the weight matrix in our case is $\widetilde{W}(x) = x^\alpha (1-x)^\beta \widetilde{Z}(x)$, where $\widetilde{Z}(x)$ is a matrix polynomial and a detailed look shows that

$$\widetilde{Z}(1) = \frac{(\beta+1)_{d-1}}{(d-1)!} \sum_{i,j=0}^{d-1} E_{ij}.$$

Hence, condition (8.2) holds if and only if $-1 < \beta \leq 0$.

Corollary 4.2 of [3] gives a necessary and sufficient condition for a process to be positive recurrent. This happens exactly when one of the entries of the measure $\widetilde{W}$ has a jump at the point 1. But this is not true in our case given the form of $\widetilde{W}$ indicated above. So our process is never positive recurrent. This means that for $-1 < \beta \leq 0$ the process is null recurrent. □

All the considerations above result from explicit expressions for $\widetilde{W}(x)$ and the entries of P.

Now we come to a very delicate issue: the explicit computation of an invariant distribution. As noticed in (7.3), our matrix valued orthogonal polynomials $\{Q_n(x)\}_{n\geq 0}$ have the remarkable property that their norms are diagonal matrices. This provides us, for each n, with d scalars which could be used (inspired by the case of birth-and-death processes) as a way of getting an invariant row vector

$$\boldsymbol{\pi} = (\boldsymbol{\pi}^0; \boldsymbol{\pi}^1; \dots)$$

with the property that

$$\boldsymbol{\pi} P = \boldsymbol{\pi}.$$

Thus, we find the remarkable fact that the components of $\boldsymbol{\pi}$ can be computed by the recipe

$$\boldsymbol{\pi}^n = \mathbf{e}_d(\|Q_n\|^2_{\widetilde{W}})^{-1}, \quad n \geq 0,$$

where $\mathbf{e}_d$ is the d-dimensional row vector with all entries equal to 1. The fact that the process is never positive recurrent implies that there exists no invariant distribution such that $\boldsymbol{\pi}\mathbf{e} < \infty$.

The unicity of the invariant distribution $\boldsymbol{\pi}$ holds as a consequence of the extended Perron–Frobenius theorem for countable nonnegative matrices (see [32, Theorem 5.4]), when the process is recurrent, i.e., $-1 < \beta \leq 0$. However, we have extensive numerical evidence that this is true for all values of $\beta > -1$.

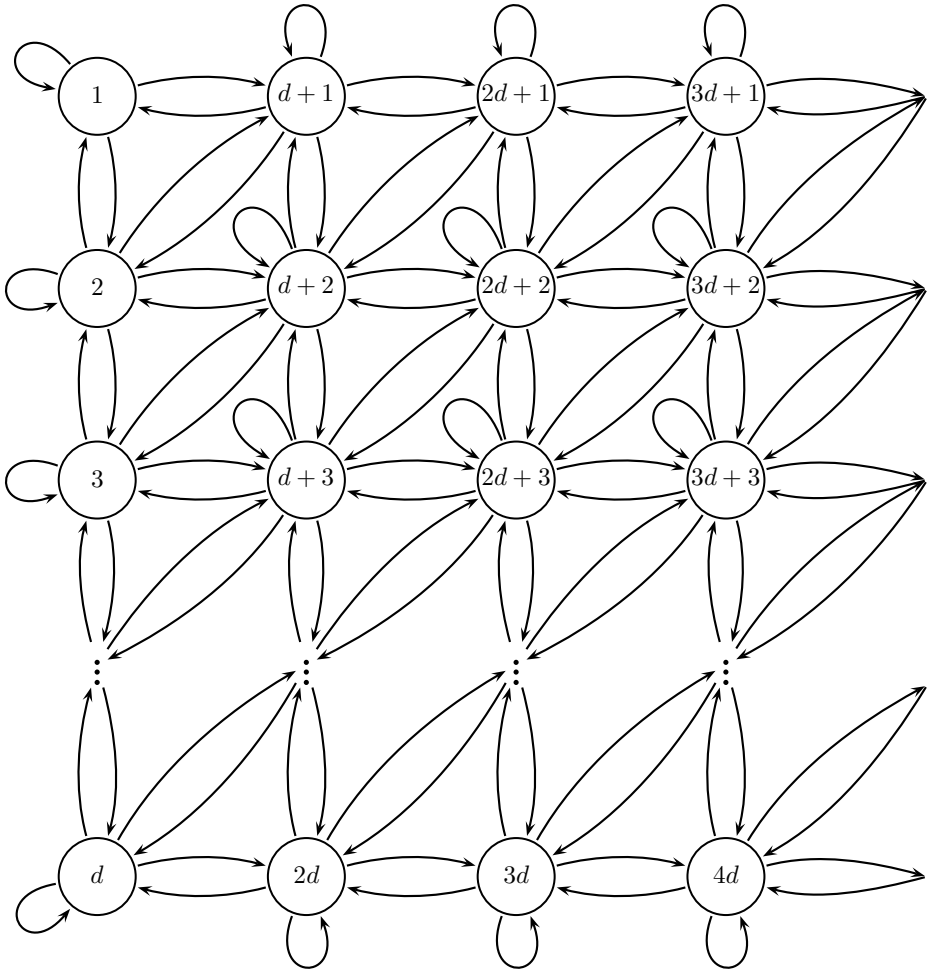
The case of random walk on the integers with general values of p and q ($p+q=1$) treated in [20] gives (for $p \neq q$) an example of a transient process where the invariant distribution is not unique. As mentioned above, it appears that even for values of β when our process is transient we still have a unique invariant distribution which can be computed explicitly in terms of the norms of our orthogonal polynomials.

To conclude this section we exhibit the network associated with our family of examples. The states of our network are labeled (as in any two dimensional situation) by two indices $i = 0, 1, 2, \dots$ and $j = 1, 2, \dots, d$. However, to write down a one-step transition probability matrix, one needs to agree on some linear order for the states. We use the convenient ordering

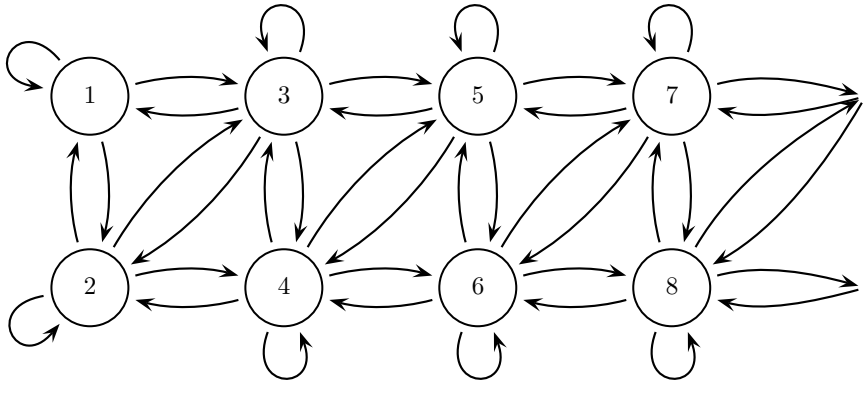
$$(0,1), (0,2), \dots, (0,d), (1,1), (1,2), \dots, (1,d), (2,1), (2,2), \dots, (2,d), \dots$$

so that, for instance, the label 3 in the following graph refers to $(0,3)$, while the label $d+2$ refers to $(1,2)$, etc. This choice of lexicographic order in one of the components and then in the other is an unpleasant feature that cannot be avoided completely.

The state space and the corresponding one-step transitions appear as follows:



9. The shape of the invariant distribution. In this section we will study in more detail the behavior of the invariant distribution when the number of phases d is equal to two, a luxury we can afford since we have an analytic expression. In this case, the associated network takes the form



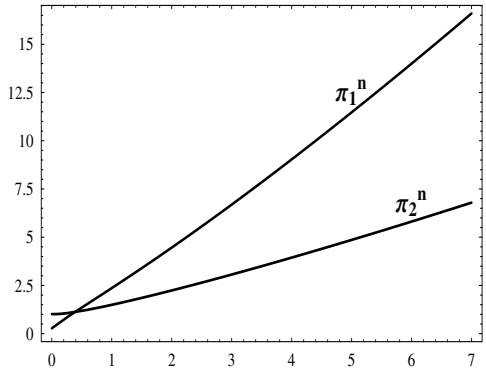


FIG. 9.1. $\alpha = -0.9, \beta = 0.1, k = 0.8$.

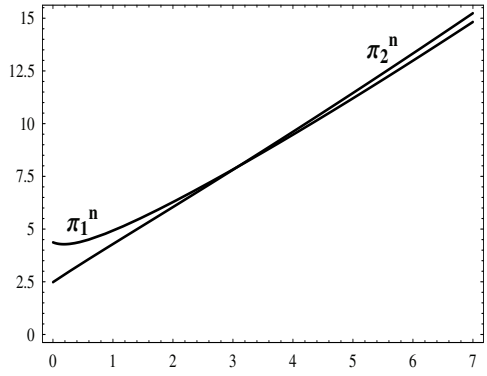

FIG. 9.2. $\alpha = 2.5, \beta = 0.1, k = 0.55$.

The invariant distribution $\boldsymbol{\pi}$ such that $\boldsymbol{\pi} P = \boldsymbol{\pi}$ is given by

$$\boldsymbol{\pi} = (\boldsymbol{\pi}^0; \boldsymbol{\pi}^1; \dots),$$

where $\boldsymbol{\pi}^n, n \geq 0$, is the 2-dimensional vector given by

$$\boldsymbol{\pi}^n = \frac{\Gamma(n+\alpha+\beta+2)\Gamma(n+\beta+2)}{\Gamma(n+\alpha+1)\Gamma(n+1)\Gamma(\beta+2)^2(n+\alpha+\beta-k+2)} \left(\frac{k(2n+\alpha+\beta+2)}{n+k} , \frac{(\beta-k+1)(2n+\alpha+\beta+3)(n+\alpha+\beta+2)}{(n+\alpha+1)(n+k+1)} \right).$$

From this explicit expression we can easily obtain several quantities. Data of special interest may be the initial value and the asymptotic behavior. The initial value is given by

$$\boldsymbol{\pi}^0 = \frac{\Gamma(\alpha+\beta+3)}{\Gamma(\alpha+1)\Gamma(\beta+2)(\alpha+\beta-k+2)} \left(1 , \frac{(\beta-k+1)(\alpha+\beta+3)}{(\alpha+1)(k+1)} \right).$$

The asymptotic behavior follows using asymptotic formulas for the Gamma function such as $\frac{\Gamma(z+\alpha)}{\Gamma(z)} \approx z^\alpha$ as $|z| \to \infty$. Hence, we have

$$\lim_{n\to\infty} \boldsymbol{\pi}^n = \begin{cases} (\infty, \infty) & \text{if} \quad \beta > -\frac{1}{2}, \\ \frac{4}{\pi}(2k, 1-2k) & \text{if} \quad \beta = -\frac{1}{2}, \\ (0,0) & \text{if} \quad -1 < \beta < -\frac{1}{2}. \end{cases}$$

In what follows we shall include plots of the two components $\boldsymbol{\pi}_1^n$ and $\boldsymbol{\pi}_2^n$, as functions of n, in a few representative cases. The general shape of both curves can change depending on the values of the parameters α, β, and k. A look at the role of the parameter β gives rise to four regions, namely $-1 < \beta < -1/2$, $\beta = -1/2$, $-1/2 < \beta < 0$, and $\beta \geq 0$. The parameter α only has influence on cosmetic changes like curvature and initial values depending on $-1 < \alpha < 0$ or $\alpha \geq 0$, while k affects the shape of the plots when its value is the middle point $\frac{\beta+1}{2}$ of its possible range and the situation in the rest of values is quite symmetric.

Figures 9.1 and 9.2 show the most interesting situations when $\beta > 0$.

Figures 9.3 and 9.4 show how the situation can change for small perturbations around $\beta = -1/2$. In Figure 9.3 both curves have a logarithmic growth and the second component has a minimum, while in Figure 9.4 both curves tend to 0.

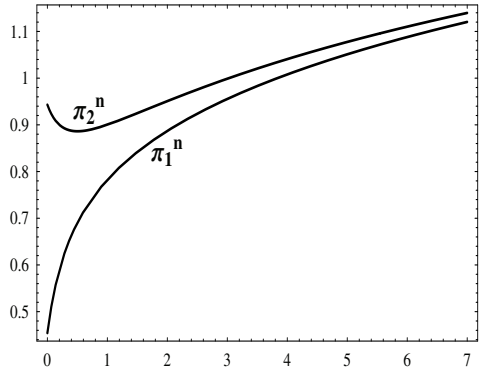

FIG. 9.3. $\alpha = -0.8, \beta = -0.4, k = 0.3$.

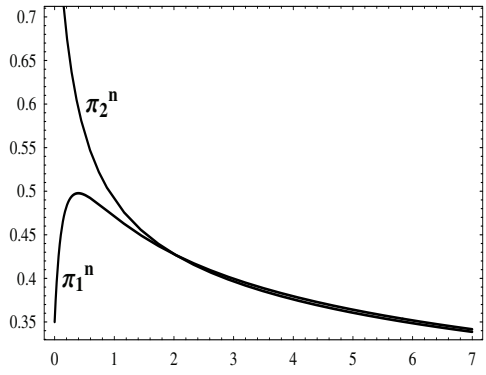

FIG. 9.4. $\alpha = -0.9, \beta = -0.6, k = 0.2$.

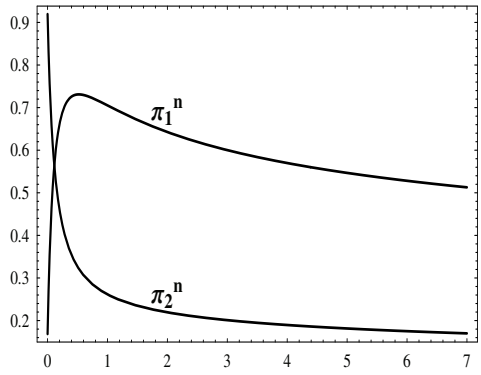

FIG. 9.5. $\alpha = -0.98, \beta = -0.6, k = 0.3$.

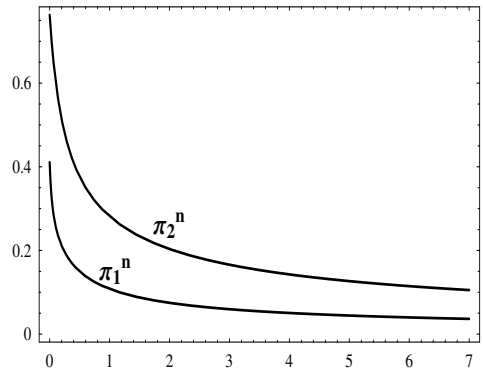

FIG. 9.6. $\alpha = -0.9, \beta = -0.8, k = 0.05$.

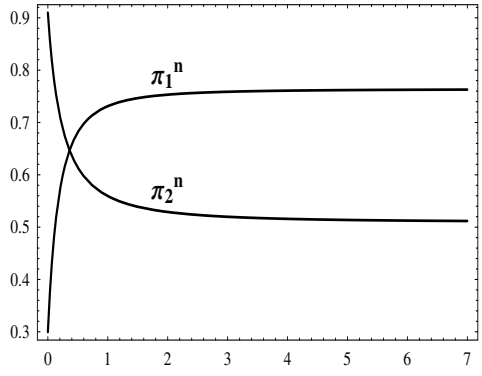

FIG. 9.7. $\alpha = -0.92, \beta = -0.5, k = 0.3$.

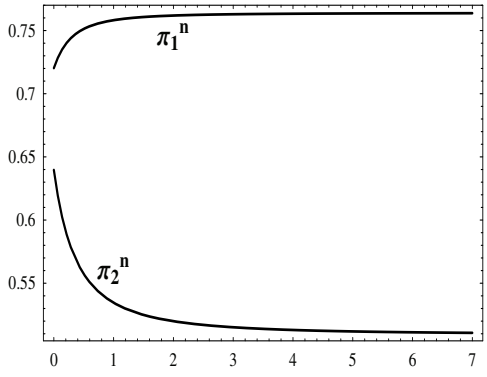

FIG. 9.8. $\alpha = -0.6857, \beta = -0.5, k = 0.3$.

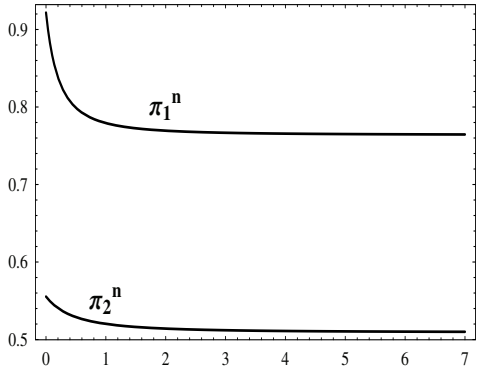

FIG. 9.9. $\alpha = -0.4857, \beta = -0.5, k = 0.3$.

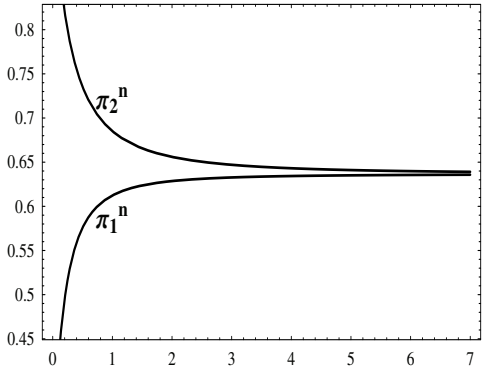

FIG. 9.10. $\alpha = -0.9, \beta = -0.5, k = 0.25$.

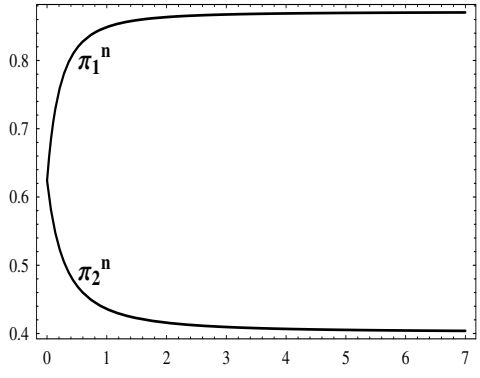

FIG. 9.11. $\alpha = -0.8, \beta = -0.5, k = 0.3421$.

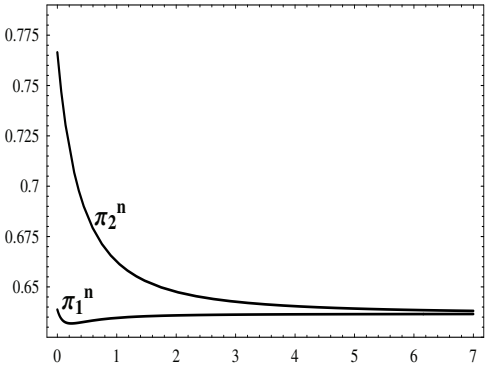

FIG. 9.12. $\alpha = -0.7, \beta = -0.5, k = 0.25$.

We observe that Figure 9.5, with k now approaching $\beta+1$, is similar to Figure 9.4. In Figure 9.6 we observe the consequences of k being very small.

The remaining figures refer to the case $\beta = -1/2$, where both components converge for large n. In Figure 9.7 we observe that the initial value of the first component is always lower than that of the second component and that the initial value of the second component is always greater than that of the first component. A small change of the value of α has the effect that the first component is always greater than the second component, as we can see in Figure 9.8.

Small perturbations on α change the curvatures of the components in Figure 9.9 with respect to Figure 9.8. In Figure 9.10 both components tend to the same value without ever touching, a consequence of choosing $k = \frac{\beta+1}{2}$.

The last two figures show how the situation can change for small perturbations of α and k. In Figure 9.11 both curves start from the same value and then they converge to different limits, while in Figure 9.12 both components converge to the same limit.

10. Concluding remarks. A block tridiagonal matrix $\mathcal{L}$ with nonnegative entries and individual rows that add up to 1 gives rise to a quasi-birth-and-death process. The explicit evaluation of $\mathcal{L}^n$, for arbitrary $n = 1, 2, 3, \ldots$, can be greatly simplified by using ideas that go back to Karlin and McGregor and have been explicitly set forth in [3, 10]. The only major difficulty here is that of computing the weight matrix $W(x)$. In this paper we start from a rich group theoretical situation that yields $W(x)$ as well

as a matrix $\mathcal{L}$ of the type envisaged previously. There are enough free parameters here to give instances of transient as well as recurrent Markov chains. It remains as interesting challenge to find some real life applications to this large collection of examples.

PERTURBATION BOUNDS FOR DETERMINANTS AND CHARACTERISTIC POLYNOMIALS*

ILSE C. F. IPSEN† AND RIZWANA REHMAN†

Abstract. We derive absolute perturbation bounds for the coefficients of the characteristic polynomial of a $n \times n$ complex matrix. The bounds consist of elementary symmetric functions of singular values, and suggest that coefficients of normal matrices are better conditioned with regard to absolute perturbations than those of general matrices. When the matrix is Hermitian positive-definite, the bounds can be expressed in terms of the coefficients themselves. We also improve absolute and relative perturbation bounds for determinants. The basis for all bounds is an expansion of the determinant of a perturbed diagonal matrix.

Key words. elementary symmetric functions, singular values, eigenvalues, condition number, determinant

1. Introduction.

The characteristic polynomial of a $n \times n$ complex matrix A is defined as

$$\det(\lambda I - A) = \lambda^n + c_1\lambda^{n-1} + \cdots + c_{n-1}\lambda + c_n,$$

where in particular $c_n = (-1)^n \det(A)$ and $c_1 = -\operatorname{trace}(A)$.

The coefficients of the characteristic polynomial of a complex matrix are of central importance in a quantum physics application. There they supply information about thermodynamic properties of fermionic systems, which arise, for instance, in the study of structure and evolution of neutron stars. These thermodynamic quantities are calculated from partition functions. It turns out that the partition function Z_k for k noninteracting fermions is given by $Z_k = (-1)^k c_k$, where the matrix A is a function of the particle Hamiltonian operator [9]. Partition functions for systems of interacting fermions require repeated calculation of noninteracting partition functions. The matrices A in these problems have fairly small dimension ($n \leq 1000$) and no discernible structure.

In order to assess the stability of numerical methods for computing the characteristic polynomial, though, we first need to know the conditioning of the c_k and their sensitivity to perturbations in the matrix A. To this end, we derive perturbation bounds for absolute normwise perturbations.

Main results. The main idea behind our perturbation bounds is a determinant expansion of a perturbed diagonal matrix (Theorem 2.3). The expansion can be extended to any square matrix via the SVD (Corollary 2.4). The resulting absolute perturbation bounds contain elementary symmetric functions of singular values. Below we present weaker, first-order versions of these bounds.

Let $\sigma_1 \geq \cdots \geq \sigma_n \geq 0$ be the singular values of A, and let $A + E$ be a $n \times n$ complex matrix with $\|E\|_2 < 1$ and characteristic polynomial $\det(\lambda I - (A + E)) =$

$\lambda^n + \tilde{c}_1\lambda^{n-1} + \cdots + \tilde{c}_{n-1}\lambda + \tilde{c}_n$. The extreme coefficients c_1 and c_n have the simplest bounds. The linearity of the trace implies

$$|\tilde{c}_1 - c_1| = |\operatorname{trace}(A+E) - \operatorname{trace}(A)| = |\operatorname{trace}(E)| \leq n\|E\|_2,$$

so that coefficient c_1 is well conditioned with regard to absolute perturbations if the matrix order n is not too large. The determinant satisfies to first order (Remark 2.9)

$$|\tilde{c}_n - c_n| = |\det(A) - \det(A+E)| \leq s_{n-1}\|E\|_2 + \mathcal{O}(\|E\|_2^2),$$

where s_{n-1} is the $(n-1)$st elementary symmetric function in the singular values and has the upper bound $s_{n-1} \leq n\sigma_1 \ldots \sigma_{n-1}$.

The remaining coefficients c_k satisfy to first order (Remark 3.4)

$$|\tilde{c}_k - c_k| \leq \binom{n}{k} s_{k-1}^{(k)}\|E\|_2 + \mathcal{O}(\|E\|_2^2), \qquad 2 \leq k \leq n,$$

where $s_{k-1}^{(k)}$ is the $(k-1)$st elementary symmetric function in the k largest singular values, and $s_{k-1}^{(k)} \leq k\sigma_1 \ldots \sigma_{k-1}$. However, if the matrix is normal or Hermitian, then the bound improves to (Remark 3.6)

$$|\tilde{c}_k - c_k| \leq (n-k+1)s_{k-1}\|E\|_2 + \mathcal{O}(\|E\|_2^2), \qquad 2 \leq k \leq n,$$

where s_{k-1} is the $(k-1)$st function in all singular values. Also, since A is normal, $\sigma_i = |\lambda_i|$, where λ_i are the eigenvalues. Since the binomial term $\binom{n}{k}$ is reduced to $n-k+1$, the coefficients of a normal matrix are likely to be better conditioned than those of a general matrix.

When the matrix is Hermitian positive-definite, eigenvalues are equal to singular values, and the above bound can be written as (Corollary 3.7)

$$|\tilde{c}_k - c_k| \leq (n-k+1)|c_{k-1}|\|E\|_2 + \mathcal{O}(\|E\|_2^2), \qquad 2 \leq k \leq n.$$

As a result, c_k is well conditioned in the absolute sense if the magnitude of the preceding coefficient $|c_{k-1}|$ is not too large.

Overview. Section 2 deals with determinants. We first derive expansions for determinants (section 2.1), and from them absolute perturbation bounds in terms of elementary symmetric functions of singular values (section 2.2), as well as relative bounds for determinants (section 2.3), and local sensitivity results (section 2.4). Section 3 deals with coefficients c_k of the characteristic polynomial. We derive absolute perturbation bounds for general matrices (section 3.1) and normal matrices (section 3.2), as well as normwise bounds (section 3.3).

Notation. The matrix A is a $n \times n$ complex matrix with singular values $\sigma_1 \geq \cdots \geq \sigma_n \geq 0$, and eigenvalues λ_i, labelled so that $|\lambda_1| \geq \cdots \geq |\lambda_n|$. The two-norm is $\|A\|_2 = \sigma_1$, and A^* is the conjugate transpose of A. The matrix $I = \operatorname{diag}\begin{pmatrix}1 & \ldots & 1\end{pmatrix}$ is the identity matrix, with columns e_i, $i \geq 1$. We denote by A_i the principal submatrix of order $n-1$ that is obtained by removing row and column i of A, and by $A_{i_1 \ldots i_k}$ the principal submatrix of order $n-k$, obtained by removing rows and columns $i_1 \ldots i_k$.

2. Determinants. We derive expansions and perturbation bounds for determinants. We start with expansions for determinants of perturbed matrices (section 2.1), and from them derive absolute perturbation bounds in terms of elementary symmetric functions of singular values (section 2.2), as well as relative bounds for determinants (section 2.3), and local sensitivity results (section 2.4).

2.1. Expansions. We derive expansions for determinants of perturbed matrices in several steps, by considering perturbations that have only a single nonzero diagonal element (Lemma 2.1), perturbations of diagonal matrices (Theorem 2.3), and at last perturbations of general matrices (Corollary 2.4).

LEMMA 2.1. [illegible] A [illegible] $n \times n$ [illegible] α [illegible] A_i [illegible] $n-1$ [illegible] i [illegible] A [illegible] $B = A + \alpha e_i e_i^*$ [illegible] $\det(B) = \det(A) + \alpha \det(A_i)$, $1 \le i \le n$ [illegible]. This follows from a cofactor expansion [8, Theorem 2.3.1] along row i or column i of B. ∎

The above expansion can be used to expand the determinant of a perturbed diagonal matrix. Before deriving this expansion, we motivate its expression on matrices of order 2 and 3.

[illegible] 2.2. If

$$D = \begin{pmatrix} \delta_1 & \\ & \delta_2 \end{pmatrix}, \qquad F = \begin{pmatrix} f_{11} & f_{12} \\ f_{21} & f_{22} \end{pmatrix},$$

then $\det(D+F) = \det(D) + \det(F) + S_1$, where $S_1 \equiv \delta_1 f_{22} + \delta_2 f_{11}$.

If

$$D = \begin{pmatrix} \delta_1 & & \\ & \delta_2 & \\ & & \delta_3 \end{pmatrix}, \qquad F = \begin{pmatrix} f_{11} & f_{12} & f_{13} \\ f_{21} & f_{22} & f_{23} \\ f_{31} & f_{32} & f_{33} \end{pmatrix},$$

then $\det(D+F) = \det(D) + \det(F) + S_1 + S_2$, where

$$S_1 \equiv \delta_1 \det \begin{pmatrix} f_{22} & f_{23} \\ f_{32} & f_{33} \end{pmatrix} + \delta_2 \det \begin{pmatrix} f_{11} & f_{13} \\ f_{31} & f_{33} \end{pmatrix} + \delta_3 \det \begin{pmatrix} f_{11} & f_{12} \\ f_{21} & f_{22} \end{pmatrix},$$

and $S_2 \equiv \delta_1\delta_2 f_{33} + \delta_1\delta_3 f_{22} + \delta_2\delta_3 f_{11}$.

These examples illustrate that the expansion of $\det(D+F)$ can be written as a sum, where each term consists of a product of k diagonal elements of D and the determinant of the "complementary" submatrix of order $n-k$ of F.

To derive expansions for diagonal matrices of any order, we denote by $F_{i_1 \dots i_k}$ the principal submatrix of order $n-k$ obtained by deleting rows and columns $i_1 \dots i_k$ of the $n \times n$ matrix F.

THEOREM 2.3 (expansion for diagonal matrices). [illegible] D [illegible] F [illegible] $n \times n$ [illegible] $D = \operatorname{diag}(\delta_1 \ \dots \ \delta_n)$ [illegible]

$$\det(D+F) = \det(D) + \det(F) + S_1 + \cdots + S_{n-1},$$

[illegible]

$$S_k \equiv \sum_{1 \le i_1 < \cdots < i_k \le n} \delta_{i_1} \cdots \delta_{i_k} \det(F_{i_1 \dots i_k}), \qquad 1 \le k \le n-1.$$

[illegible] $\delta_1 = \cdots = \delta_j = 0$ [illegible] $1 \le j \le n-1$ [illegible]

$$\det(D+F) = \det(F) + S_1 + \cdots + S_{n-j},$$

[illegible]

$$S_k = \sum_{j+1 \le i_1 < \cdots < i_k \le n} \delta_{i_1} \cdots \delta_{i_k} \det(F_{i_1 \dots i_k}), \qquad 1 \le k \le n-j.$$

The proof is by induction over the matrix order n, and Example 2.2 represents the induction basis. Assuming the statement is true for matrices of order $n-1$, we show that it is also true for matrices of order n. Let

$$D^{(j)} \equiv \operatorname{diag}\begin{pmatrix} 0 & \dots & 0 & \delta_{j+1} & \dots & \delta_n \end{pmatrix}$$

be a diagonal matrix of order n with j leading zeros. Applying Lemma 2.1 to $A \equiv D^{(1)} + F$ and $B \equiv A + \delta_1 e_1 e_1^*$ gives

$$\det(D + F) = \delta_1 \det(D_1 + F_1) + \det(D^{(1)} + F).$$

We repeat this process on the second summand $\det(D^{(1)} + F)$ to remove the diagonal elements δ_j one by one; $j \geq 2$. To this end, we apply Lemma 2.1 to $A \equiv D^{(j)} + F$ and $B \equiv A + \delta_j e_j e_j^*$, and denote by $(D^{(j)})_j$ the matrix of order $n-1$ obtained by removing row and column j from $D^{(j)}$. This gives

$$\det(D^{(1)} + F) = \sum_{j=2}^{n-1} \delta_j \det\left((D^{(j)})_j + F_j\right) + \delta_n \det(F_n) + \det(F).$$

Putting the above expression into the expansion for $\det(D + F)$ yields

$$\det(D + F) = \det(F) + \delta_1 \det(D_1 + F_1) + \sum_{j=2}^{n-1} \delta_j \det\left((D^{(j)})_j + F_j\right) + \delta_n \det(F_n).$$

Since $D_1 + F_1$ and $(D^{(j)})_j + F_j$ are matrices of order $n-1$, we can apply the induction hypothesis. To take advantage of the fact that the $j-1$ top diagonal elements of $(D^{(j)})_j$ are zero, we define the following sums for matrices of order $n-1$,

$$S_k^{(j)} \equiv \sum_{j+1 \leq i_1 < \dots < i_k \leq n} \delta_{i_1} \cdots \delta_{i_k} \det(F_{j i_1 \dots i_k}), \qquad 1 \leq j \leq n-1, \quad 1 \leq k \leq n-j,$$

where $F_{j i_1 \dots i_k}$ is the matrix of order $n-k-1$ obtained by removing rows and columns $j, i_1, \dots, i_k$ of F. The induction hypothesis yields

$$\begin{aligned} \det(D_1 + F_1) &= \det(D_1) + \det(F_1) + S_1^{(1)} + \dots + S_{n-2}^{(1)}, \\ \det\left((D^{(j)})_j + F_j\right) &= \det(F_j) + S_1^{(j)} + \dots + S_{n-j}^{(j)}, \qquad 2 \leq j \leq n-2, \\ \det\left((D^{(n-1)})_{n-1} + F_{n-1}\right) &= \det(F_{n-1}) + S_1^{(n-1)}. \end{aligned}$$

Now substitute the above expansions into the expression for $\det(D + F)$ and use the fact that $\delta_1 \det(D_1) = \det(D)$, $\sum_{i=1}^{n} \delta_i \det(F_i) = S_1$, and

$$\sum_{i=1}^{n-j} \delta_i S_j^{(i)} = S_{j+1}, \qquad 1 \leq j \leq n-2. \qquad \square$$

When the leading j diagonal elements of D are zero, then at most $n-j$ of the S_k are nonzero, and within each S_k one needs to account only for the nonzero summands. We now extend Theorem 2.3 to general matrices, by transforming them to diagonal form via the SVD. Let $A = U \Sigma V^*$ be a SVD of A, where $\Sigma = \operatorname{diag}\begin{pmatrix} \sigma_1 & \dots & \sigma_n \end{pmatrix}$ with $\sigma_1 \geq \dots \geq \sigma_n \geq 0$, and U and V are unitary.

COROLLARY 2.4 (expansion for general matrices). Let A and E be $n \times n$ matrices, and let $F \equiv U^*EV$.

$$\det(A+E) = \det(A) + \det(E) + S_1 + \cdots + S_{n-1},$$

where

$$S_k \equiv \det(UV^*) \sum_{1 \le i_1 < \cdots < i_k \le n} \sigma_{i_1} \cdots \sigma_{i_k} \det(F_{i_1 \ldots i_k}), \qquad 1 \le k \le n-1.$$

If $\operatorname{rank}(A) = r$, $1 \le r \le n-1$, then

$$\det(A+E) = \det(E) + S_1 + \cdots + S_r,$$

where

$$S_k = \det(UV^*) \sum_{1 \le i_1 < \cdots < i_k \le r} \sigma_{i_1} \cdots \sigma_{i_k} \det(F_{i_1 \ldots i_k}), \qquad 1 \le k \le r.$$

Proof. The SVD of A implies $A + E = U(\Sigma + F)V^*$, and Theorem 2.3 implies

$$\det(\Sigma + F) = \det(\Sigma) + \det(F) + \hat{S}_1 + \cdots + \hat{S}_{n-1},$$

where

$$\hat{S}_k \equiv \sum_{1 \le i_1 < \cdots < i_k \le n} \sigma_{i_1} \cdots \sigma_{i_k} \det(F_{i_1,\ldots,i_k}), \qquad 1 \le k \le n-1.$$

With $S_k \equiv \det(UV^*)\hat{S}_k$ we obtain $\det(A+E) = \det(A) + \det(E) + S_1 + \cdots + S_{n-1}$.

Now suppose $\operatorname{rank}(A) = r \le n-1$. Then $n-r$ singular values are zero, so that all products of $r+1$ or more singular values are zero. In particular, $\det(A) = 0$. If $\operatorname{rank}(A) = r < n-1$, then $S_{r+1} = \cdots = S_{n-1} = 0$. Moreover, the terms $S_1, \ldots, S_r$ contain only the nonzero singular values $\sigma_1, \ldots, \sigma_r$. ∎

Corollary 2.4 shows that the number of summands in the expansion decreases with the rank of the matrix.

2.2. Absolute perturbation bounds. We derive absolute perturbation bounds for determinants in terms of elementary symmetric functions of singular values. These bounds give rise to absolute first-order condition numbers. We also derive simpler, but weaker normwise bounds.

To bound the perturbations we need the following inequalities.

LEMMA 2.5 (Hadamard's inequality). Let B be $n \times n$, and let $\|Be_i\|_2$ be the 2-norm of column i of B. Then

$$|\det(B)| \le \prod_{i=1}^{n} \|Be_i\|_2 \le \|B\|_2^n.$$

Proof. The first inequality is Hadamard's inequality [6, Corollary 7.8.2]. ∎

The bounds also contain elementary symmetric functions, which are defined as follows [6, Definition 1.2.9].

DEFINITION 2.6 (elementary symmetric functions of singular values). Let A be $n \times n$, and let $\sigma_1 \ge \ldots \ge \sigma_n$ be its singular values. Then

$$s_0 \equiv 1, \qquad s_k \equiv \sum_{1 \le i_1 < \cdots < i_k \le n} \sigma_{i_1} \cdots \sigma_{i_k}, \qquad 1 \le k \le n,$$

are the kth elementary symmetric functions of the singular values of A.

Now we are ready to derive the first perturbation bound for determinants of general matrices.

COROLLARY 2.7 (general matrices). [illegible] A [illegible] E [illegible] $n \times n$ [illegible]

$$|\det(A) - \det(A+E)| \le \sum_{i=1}^{n} s_{n-i}\|E\|_2^i.$$

[illegible] $\operatorname{rank}(A) = r$ [illegible] $1 \le r \le n-1$ [illegible]

$$|\det(A+E)| \le \|E\|_2^{n-r} \sum_{i=0}^{r} s_{r-i}\|E\|_2^i,$$

[illegible] s_j [illegible] r [illegible] A, $1 \le j \le r$

[illegible] $E = \epsilon UV^*$ [illegible] $\epsilon > 0$, [illegible] $A = U\Sigma V^*$ [illegible] A

[illegible]. Corollary 2.4 implies $|\det(A) - \det(A+E)| \le |\det(E)| + |S_1| + \cdots + |S_{n-1}|$. To bound $|S_k|$ use the fact that $|\det(UV^*)| = 1$ and $\sigma_i \ge 0$ to obtain

$$\begin{aligned} |S_k| &\le \max_{1 \le i_1 < \cdots < i_k \le n} |\det(F_{i_1 \ldots i_k})| \sum_{1 \le i_1 < \cdots < i_k \le n} \sigma_{i_1} \cdots \sigma_{i_k} \\ &= \max_{1 \le i_1 < \cdots < i_k \le n} |\det(F_{i_1 \ldots i_k})| s_k. \end{aligned}$$

Lemma 2.5 implies $|\det(E)| \le \|E\|_2^n$, and $|\det(F_{i_1 \ldots i_k})| \le \|F\|_2^{n-k} = \|E\|_2^{n-k}$. Hence $|S_k| \le s_k \|E\|_2^{n-k}$, $1 \le k \le n-1$.

Now suppose $\operatorname{rank}(A) = r$. Then Corollary 2.4 implies

$$|\det(A+E)| \le |\det(E)| + |S_1| + \cdots + |S_r| \le \|E\|_2^{n-r} \sum_{i=0}^{r} s_{r-i}\|E\|_2^i,$$

where the terms s_{r-i} contain only nonzero singular values.

If $E = \epsilon UV^*$, then $F = \epsilon I$ and $\det(F_{i_1 \ldots i_k}) = \epsilon^{n-k} = \|E\|_2^{n-k}$, so that $S_k = |S_k| = \|E\|_2^{n-k} s_k$. □

Corollary 2.7 bounds the absolute error in $\det(A+E)$ by elementary symmetric functions of singular values and powers of $\|E\|_2$. Although the bounds for nonsingular and rank-r matrices look different, because the sums start at different indices, they are consistent. If $\operatorname{rank}(A) \le n-k$ for some $k \ge 1$, then $|\det(A+E)|$ is bounded by a multiple of $\|E\|_2^k$. Hence if $\|E\|_2 < 1$ then determinants of rank-deficient matrices tend to be better conditioned in the absolute sense.

[illegible] 2.8 (Hermitian positive-definite matrices). In the special case when A is Hermitian positive-definite, singular values are equal to eigenvalues, so that we can write the elementary symmetric functions in terms of the eigenvalues $\lambda_1 \ge \cdots \ge \lambda_n \ge 0$. Hence in Corollary 2.7

$$s_k = \sum_{1 \le i_1 < \cdots < i_k \le n} \lambda_{i_1} \cdots \lambda_{i_k}, \qquad 1 \le k \le n-1.$$

Note that $A+E$ does not have to be Hermitian positive-definite, because no restrictions are placed on E.

[illegible] 2.9 (first-order absolute condition numbers). Let A be a $n \times n$ complex matrix with $\operatorname{rank}(A) \ge n-1$ and $\|E\|_2 < 1$. Corollary 2.7 implies the first-order bound

$$|\det(A) - \det(A+E)| \le s_{n-1}\|E\|_2 + \mathcal{O}\left(\|E\|_2^2\right),$$

where $s_{n-1} \leq n\sigma_1 \dots \sigma_{n-1}$. Hence we can view s_{n-1} or $n\sigma_1 \dots \sigma_{n-1}$ as first-order condition numbers for absolute perturbations in A.

2.10. The perturbation of a diagonally scaled Jordan block below illustrates that the first-order bound in Remark 2.9 can hold with equality. Let

$$A = \begin{pmatrix} 0 & \alpha_1 & 0 & \dots & 0 \\ \vdots & 0 & \alpha_2 & \ddots & \vdots \\ \vdots & & \ddots & \ddots & 0 \\ 0 & & & 0 & \alpha_{n-1} \\ 0 & 0 & \dots & \dots & 0 \end{pmatrix}, \qquad E = \epsilon e_n e_1^*,$$

where $|\epsilon| \leq 1$ and $\alpha_i > 0$, $1 \leq i \leq n-1$. Then $|\det(A+E) - \det(A)| = \alpha_1 \dots \alpha_{n-1}\epsilon$. Since the singular values of A are 0 and $\alpha_i > 0$, $1 \leq i \leq n-1$, we obtain $|\det(A+E) - \det(A)| = s_{n-1}\|E\|_2$.

Replacing the singular values in Corollary 2.7 by powers of $\|A\|_2$ gives the simpler, but weaker bounds below.

COROLLARY 2.11 (normwise bounds). [illegible] A [illegible] E [illegible] $n \times n$ [illegible]

$$\begin{aligned} |\det(A+E) - \det(A)| &\leq \sum_{i=1}^{n} \binom{n}{i} \|A\|_2^{n-i} \|E\|_2^i \\ &= (\|A\|_2 + \|E\|_2)^n - \|A\|_2^n. \end{aligned}$$

[illegible] $\operatorname{rank}(A) = r$ [illegible] $1 \leq r \leq n-1$ [illegible]

$$\begin{aligned} |\det(A+E)| &\leq \|E\|_2^{n-r} \sum_{i=0}^{r} \binom{r}{i} \|A\|_2^{r-i} \|E\|_2^i \\ &= \|E\|_2^{n-r} (\|A\|_2 + \|E\|_2)^r. \end{aligned}$$

[illegible]. This follows from Corollary 2.7 and $s_{n-i} \leq \binom{n}{n-i}\|A\|_2^{n-i} = \binom{n}{i}\|A\|_2^{n-i}$, $1 \leq i \leq n-1$. ∎

A bound similar to the one in Corollary 2.11 was already derived in [1, section 20], [2, Problem I.6.11], [3, Theorem 4.7] for any p-norm, by taking Fréchet derivatives of wedge products. Below we give a basic proof from first principles for the two-norm.

THEOREM 2.12 (section 20 in [1], problem I.6.11 in [2], Theorem 4.7 in [3]). [illegible] A [illegible] E [illegible] $n \times n$ [illegible]

$$|\det(A+E) - \det(A)| \leq n\|E\|_2 \max\{\|A\|_2, \|A+E\|_2\}^{n-1}.$$

[illegible]. We first show the statement for a diagonal matrix. That is, if $D = \operatorname{diag}(\delta_1 \ \dots \ \delta_n)$ is diagonal, then

$$\det(D+F) = \det(D) + z, \qquad \text{where} \quad |z| \leq n\|F\|_2 \max\{\|D\|_2, \|D+F\|_2\}^{n-1}.$$

The proof is by induction. For $n = 2$

$$D = \begin{pmatrix} \delta_1 & \\ & \delta_2 \end{pmatrix}, \qquad F = \begin{pmatrix} f_{11} & f_{12} \\ f_{21} & f_{22} \end{pmatrix},$$

and

$$z \equiv \det(D+F) - \det(D) = \delta_1 f_{22} + \det \begin{pmatrix} f_{11} & f_{12} \\ f_{21} & \delta_2 + f_{22} \end{pmatrix}.$$

Lemma 2.5 implies

$$|z| \le \|F\|_2\|D\|_2 + \left\|\begin{pmatrix} f_{11} \\ f_{21}\end{pmatrix}\right\|_2 \left\|\begin{pmatrix} f_{12} \\ \delta_2 + f_{22}\end{pmatrix}\right\|_2 \le \|F\|_2\|D\|_2 + \|F\|_2\|D+F\|_2$$
$$\le 2\|F\|_2 \max\{\|D\|_2, \|D+F\|_2\}.$$

This completes the induction basis. Assuming the statement is true for matrices of order $n-1$, we show that it is also true for matrices of order n. As in the proof of Theorem 2.3, let $D^{(1)} \equiv \operatorname{diag}\begin{pmatrix}0 & \delta_2 & \dots & \delta_n\end{pmatrix}$ be the matrix obtained from D by replacing δ_1 with 0, and apply Lemma 2.1 to conclude

$$\det(D+F) = \delta_1 \det(D_1 + F_1) + \det(D^{(1)} + F).$$

Since $D_1 + F_1$ is a matrix of order $n-1$, the induction hypothesis applies and gives $\det(D_1 + F_1) = \det(D_1) + z_1$, where

$$|z_1| \le (n-1)\|F_1\|_2 \max\{\|D_1\|_2, \|D_1 + F_1\|_2\}^{n-2}$$
$$\le (n-1)\|F\|_2 \max\{\|D\|_2, \|D+F\|_2\}^{n-2}.$$

Substitute the above expression into the expansion for $\det(D+F)$ to obtain

$$z \equiv \det(D+F) - \det(D) = \delta_1 z_1 + \det(D^{(1)} + F),$$

where $|\delta_1 z_1| \le (n-1)\|F\|_2 \max\{\|D\|_2, \|D+F\|_2\}^{n-1}$. Applying Lemma 2.5 to $\det(D^{(1)} + F)$ yields

$$\det(D^{(1)} + F) \le \|Fe_1\|_2 \prod_{i=2}^{n} \|(D+F)e_i\|_2 \le \|F\|_2\|D+F\|_2^{n-1}.$$

Therefore we have proved the theorem for diagonal matrices D.

To prove the theorem for general matrices A, let $A = U\Sigma V^*$ be a SVD of A. Then $\det(A+E) = \det(UV^*)\det(\Sigma + F)$, where $F \equiv U^*EV$. Since Σ is diagonal, $\det(\Sigma + F) = \det(\Sigma) + z$, where

$$|z| \le n\|F\|_2 \max\{\|\Sigma\|_2, \|\Sigma + F\|_2\}^{n-1} = n\|E\|_2 \max\{\|A\|_2, \|A+E\|_2\}^{n-1}.$$

Hence $\det(A+E) - \det(A) = \det(UV^*)z$, and the result follows from $|\det(UV^*)| = 1$. □

2.3. Relative perturbation bounds. We derive expansions for relative perturbations of determinants, as well as relative perturbation bounds that improve existing bounds.

THEOREM 2.13 (expansion). [illegible] A [illegible] E [illegible] $n \times n$ [illegible] A [illegible]

$$\frac{\det(A+E) - \det(A)}{\det(A)} = \det(A^{-1}E) + S_1 + \cdots + S_{n-1},$$

[illegible]

$$S_k \equiv \sum_{1 \le i_1 < \cdots < i_k \le n} \det((A^{-1}E)_{i_1 \dots i_k}), \qquad 1 \le k \le n-1.$$

. Write $\det(A+E) = \det(A)\det(I + A^{-1}E)$ and apply Theorem 2.3 to $\det(I + A^{-1}E)$. □

COROLLARY 2.14 (relative perturbation bound). . A . E $n \times n$ . . . A.

$$\frac{|\det(A+E) - \det(A)|}{|\det(A)|} \leq \left(\kappa \frac{\|E\|_2}{\|A\|_2} + 1\right)^n - 1,$$

. $\kappa \equiv \|A\|_2 \|A^{-1}\|_2$

. Apply Corollary 2.7 to

$$\frac{|\det(A+E) - \det(A)|}{|\det(A)|} = |\det(I + A^{-1}E) - \det(I)|,$$

and bound $\|A^{-1}E\|_2 \leq \kappa \|E\|_2 / \|A\|_2$. □

. 2.15. Corollary 2.14 is more general and tighter than the following bound from [4, (1.6)], [5, Problem 14.15]:

$$\frac{|\det(A+E) - \det(A)|}{|\det(A)|} \leq \frac{n\kappa \|E\|_2/\|A\|_2}{1 - n\kappa \|E\|_2/\|A\|_2},$$

which holds only for $n\kappa\|E\|_2/\|A\|_2 < 1$. This is true because of the following. With $q \equiv \|A^{-1}\|_2 \|E\|_2 = \kappa \|E\|_2/\|A\|_2$ we can write the first term in the bound of Corollary 2.14 as

$$(q+1)^n = \sum_{i=0}^{n} \binom{n}{i} q^i \leq \sum_{i=0}^{n} n^i q^i \leq \sum_{i=0}^{\infty} (nq)^i.$$

If $nq < 1$, then $\sum_{i=0}^{\infty} (nq)^i = \frac{1}{1-nq}$, so that

$$(q+1)^n - 1 \leq \frac{1}{1-nq} - 1 = \frac{nq}{1-nq}.$$

This implies for the bound in Corollary 2.14

$$\left(\kappa \frac{\|E\|_2}{\|A\|_2} + 1\right)^n - 1 \leq \frac{n\kappa ||E\|_2/\|A\|_2}{1 - n\kappa \|E\|_2/\|A\|_2},$$

where the last expression is the bound in [4, inequality (1.6)], [5, Problem 14.15].

2.4. Local sensitivity. We derive a local condition number for determinants from directional derivatives. The directional derivative for $\det(A)$ in the direction E is $\frac{d^k}{dx^k} \det(A + xE)$.

Although we derive the expressions below from the expansion in Theorem 2.3, we could have also used the expression for derivatives of $A(x)$ in [7, equation (6.5.9)].

THEOREM 2.16. . A . E $n \times n$ . . . $F \equiv U^*EV$. x .

$$\det(A + xE) = \sum_{i=1}^{n} S_{n-i} x^i + \det(A),$$

.

$$S_0 \equiv \det(E), \qquad S_k \equiv \det(UV^*) \sum_{1 \leq i_1 < \cdots < i_k \leq n} \sigma_{i_1} \cdots \sigma_{i_k} \det(F_{i_1 \ldots i_k}), \quad 1 \leq k \leq n-1,$$

$$\frac{d^k}{dx^k}\det(A+xE)|_{x=0} = k!S_{n-k}, \qquad 1 \le k \le n.$$

. If $D = \operatorname{diag}(\delta_1 \ \dots \ \delta_n)$ is a diagonal matrix, then Theorem 2.3 implies $\det(D+xF) = \det(xF)+\tilde{S}_1+\cdots+\tilde{S}_{n-1}+\det(D)$, where $\det(xF) = x^n\det(F) = x^nS_0$ and

$$\tilde{S}_k = \sum_{1\le i_1<\cdots<i_k\le n} \delta_{i_1}\cdots\delta_{i_k}\det(xF_{i_1\dots i_k}) = x^{n-k}S_k.$$

To derive the expansion for a general matrix, use the SVD as in Corollary 2.4. □

The first derivative gives the local condition number of the determinant with regard to small perturbations.

COROLLARY 2.17 (local condition number). . A . E . $n\times n$ . . . x . . . .

$$\left|\frac{d}{dx}\det(A+xE)|_{x=0}\right| \le s_{n-1}\|E\|_2, \qquad \text{where} \quad s_{n-1} \le n\sigma_1\dots\sigma_{n-1}.$$

. Theorem 2.16 implies for the first derivative

$$\frac{d}{dx}\det(A+xE)|_{x=0} = \det(UV^*)\sum_{1\le i_1<\cdots<i_{n-1}\le n}\sigma_{i_1}\cdots\sigma_{i_{n-1}}\det(F_{i_1\dots i_{n-1}}),$$

where $F_{i_1\dots i_{n-1}}$ is a diagonal element of F. Lemma 2.5 implies $|\det(F_{i_1\dots i_{n-1}})| \le \|F\|_2 = \|E\|_2$. □

Corollary 2.17 shows that the sensitivity of $\det(A)$ to small perturbations in any direction E is determined by s_{n-1} or $n\sigma_1\dots\sigma_{n-1}$. A comparison with Remark 2.9 shows that the local condition number for $\det(A)$ is identical to the first-order condition number.

3. Characteristic polynomial. Based on the determinant results in section 2, we derive absolute perturbation bounds for the coefficients of the characteristic polynomial for general matrices (section 3.1) and normal matrices (section 3.2), as well as simpler, but weaker normwise bounds (section 3.3).

Applying Theorem 2.3 to the characteristic polynomial

$$\det(\lambda I - A) = \lambda^n + c_1\lambda^{n-1} + \cdots + c_{n-1}\lambda + c_n$$

of the $n\times n$ matrix A gives the well-known expressions [6, Theorem 1.2.12]

$$c_{n-k} = (-1)^{n-k}\sum_{1\le i_1<\dots<i_k\le n}\det(A_{i_1\dots i_k}), \quad 0 \le k \le n-1,$$

where $A_{i_1\dots i_k}$ is the principal submatrix of order $n-k$ obtained by deleting rows and columns $i_1\dots i_k$ of A. The characteristic polynomial of the perturbed matrix $A+E$ is

$$\det(\lambda I - (A+E)) = \lambda^n + \tilde{c}_1\lambda^{n-1} + \cdots + \tilde{c}_{n-1}\lambda + \tilde{c}_n,$$

where $\tilde{c}_n = (-1)^n\det(A+E)$ and

$$\tilde{c}_{n-k} = (-1)^{n-k}\sum_{1\le i_1<\dots<i_k\le n}\det(A_{i_1\dots i_k}+E_{i_1\dots i_k}), \qquad 1 \le k \le n-1.$$

The following example illustrates that products of singular values play an important role in the conditioning of the coefficients c_k.

EXAMPLE 3.1 (companion matrices). The $n \times n$ matrix

$$A = \begin{pmatrix} \alpha_1 & \alpha_2 & \dots & \dots & \alpha_n \\ \eta & 0 & \dots & \dots & 0 \\ 0 & \eta & \ddots & & \vdots \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & \dots & 0 & \eta & 0 \end{pmatrix}, \qquad \eta > 0,$$

is a multiple of a companion matrix, and let $E = e_1 \begin{pmatrix} \epsilon & \dots & \epsilon \end{pmatrix}$ with $\epsilon > 0$. The respective coefficients of the characteristic polynomials of A and $A+E$ are [5, section 28.6]

$$c_i = \alpha_i \eta^{i-1}, \qquad \tilde{c}_i = (\alpha_i + \epsilon)\eta^{i-1}, \qquad 1 \le i \le n.$$

Then $|\tilde{c}_i - c_i| = \epsilon\eta^{i-1}$, $1 \le i \le n$. The singular values of A are [5, section 28.6]

$$\sigma_1^2 = \frac{1}{2}\left(\alpha + \sqrt{\alpha^2 - 4|\alpha_n|^2}\right), \qquad \sigma_n^2 = \frac{1}{2}\left(\alpha - \sqrt{\alpha^2 - 4|\alpha_n|^2}\right),$$

where $\alpha \equiv 1 + |\alpha_1|^2 + \dots + |\alpha_n|^2$, and $\sigma_i = \eta$, $2 \le i \le n-1$. Therefore the conditioning of the coefficients c_k is determined by products of singular values.

The products of singular values in our perturbation bounds are expressed in terms of elementary symmetric functions of only the largest singular values of A.

DEFINITION 3.2 (elementary symmetric functions in the largest singular values). Let A be $n \times n$, with singular values $\sigma_1 \ge \dots \ge \sigma_n$. Then

$$s_0^{(k)} \equiv 1, \qquad s_j^{(k)} \equiv \sum_{1 \le i_1 < \dots < i_j \le k} \sigma_{i_1} \dots \sigma_{i_j}, \qquad 1 \le j \le k, \quad 1 \le k \le n,$$

are the elementary symmetric functions in the largest k singular values of A. We set $s_j^{(n)} = s_j$, where s_j is the jth elementary symmetric function in all singular values of A.

3.1. General matrices. We use the determinant expansion in Corollary 2.4 to derive perturbation bounds for coefficients c_k of general matrices.

THEOREM 3.3 (general matrices). Let A and E be $n \times n$, with $\|E\|_2 < \sigma_n$. Then

$$|\tilde{c}_k - c_k| \le \binom{n}{k} \sum_{i=1}^{k} s_{k-i}^{(k)} \|E\|_2^i, \qquad 1 \le k \le n.$$

If $\operatorname{rank}(A) = r$, with $1 \le r \le n-1$, then

$$|\tilde{c}_k - c_k| \le \binom{n}{k} \|E\|_2^{k-r} \sum_{i=0}^{r} s_{r-i}^{(k)} \|E\|_2^i, \qquad r+1 \le k \le n.$$

PROOF. In the perturbed coefficient

$$\tilde{c}_{n-k} = (-1)^{n-k} \sum_{1 \le i_1 < \dots < i_k \le n} \det(A_{i_1 \dots i_k} + E_{i_1 \dots i_k}),$$

the matrices $A_{i_1\dots i_k} + E_{i_1\dots i_k}$ are of order $n-k$. Fix the indices $i_1,\dots,i_k$; set $B \equiv A_{i_1\dots i_k}$ and $F \equiv E_{i_1\dots i_k}$; and let $\mu_1 \geq \dots \geq \mu_{n-k}$ be the singular values of B. Corollary 2.4 implies $\det(B+F) = \det(B) + \det(F) + S_1 + \dots + S_{n-k-1}$, where

$$S_j = \sum_{1\leq i_1<\dots<i_j\leq n-k} \mu_{i_1}\dots\mu_{i_j}\det(F_{i_1\dots i_j}), \qquad 1 \leq j \leq n-k-1.$$

Since B is a submatrix of A, the singular values interlace [6, Theorem 7.3.9], so that $\sigma_j \geq \mu_j$, $1 \leq j \leq n-k$. With Lemma 2.5 we obtain $|S_j| \leq s_j^{(n-k)}\|E\|_2^{n-k-j}$. Hence $|S_1| + \dots + |S_{n-k-1}| \leq \sum_{i=1}^{n-k} s_{n-k-i}^{(n-k)}\|E\|_2^i$. Summing up the terms associated with all $\binom{n}{k}$ submatrices $A_{i_1\dots i_k} + E_{i_1\dots i_k}$ gives the desired bound for $|\tilde{c}_{n-k} - c_{n-k}|$.

Now suppose $\operatorname{rank}(A) = r \leq n-1$. Since r singular values are nonzero, the elementary symmetric functions $s_j^{(k)}$ in the k largest singular values remain unchanged for $k \leq r$.

Since $n-r$ singular values are equal to zero, all products of $r+1$ or more singular values are zero. Hence for $k \geq r+1$ we have $s_j^{(k)} = 0$ whenever $j \geq r+1$, so that

$$\sum_{i=1}^{k} s_{k-i}^{(k)}\|E\|_2^i = \|E\|_2^{k-r}\sum_{i=0}^{r} s_{r-i}^{(k)}\|E\|_2^i.$$

Moreover, for $j \leq r$ the $s_j^{(k)}$ are functions of the r largest singular values only, so that $s_j^{(k)} = s_j^{(r)}$. Therefore $\sum_{i=0}^{k} s_{k-i}^{(k)}\|E\|_2^i = \|E\|_2^{k-r}\sum_{i=0}^{r} s_{r-i}^{(r)}\|E\|_2^i$, giving the desired bound for $|\tilde{c}_k - c_k|$ when $k \geq r+1$. □

For the two extreme coefficients, Theorem 3.3 produces the expected bounds: In the case of $c_n = (-1)^n\det(A)$, the bound coincides with the determinant bound in Corollary 2.7, while for $c_1 = -\operatorname{trace}(A)$ we obtain $|\tilde{c}_1 - c_1| \leq n\|E\|_2$. Theorem 3.3 shows that the conditioning of c_k with regard to absolute perturbations is determined by the binomial term $\binom{n}{k}$ and the elementary symmetric functions in the k largest singular values. The binomial coefficient is largest for c_k with $k \approx n/2$, because $\binom{n}{n-k} = \binom{n}{k}$, and $\binom{n}{k}$ is monotonically increasing for $k < n/2$. In particular, if n is even, then for $k = n/2$ we have $k\binom{n}{k} \geq k\left(\frac{n}{k}\right)^k = n2^{n/2-1}$.

If $\operatorname{rank}(A) = r \leq n-2$, then the bounds for the coefficients $c_{r+1},\dots,c_n$ contain higher powers of $\|E\|_2$. Hence if $\|E\|_2 < 1$, then the coefficients $c_{r+1},\dots,c_n$ of rank-deficient matrices tend to be better conditioned in the absolute sense.

3.4 (first-order absolute condition numbers for general matrices). Theorem 3.3 implies for $\|E\|_2 < 1$ the first-order bound

$$|\tilde{c}_k - c_k| \leq \binom{n}{k} s_{k-1}^{(k)}\|E\|_2 + \mathcal{O}(\|E\|_2^2), \qquad 1 \leq k \leq n,$$

where $s_{k-1}^{(k)} \leq k\sigma_1\dots\sigma_{k-1}$. Hence we can view $\binom{n}{k}s_{k-1}^{(k)}$ or $\binom{n}{k}k\sigma_1\dots\sigma_{k-1}$ as first-order condition numbers for absolute perturbations in the coefficient c_k.

3.2. Normal matrices. We show that for normal matrices, the conditioning of the coefficients improves because the binomial term is smaller, and the elementary symmetric functions depend on all singular values, not just the largest ones. Note that all statements for normal matrices apply in particular to Hermitian matrices.

THEOREM 3.5 (normal matrices). Let A be an $n \times n$ normal matrix, and let

$$|\tilde{c}_k - c_k| \leq \sum_{i=1}^{k} \binom{n-k+i}{i} s_{k-i}\|E\|_2^i, \qquad 1 \leq k \leq n.$$

[illegible] $E = \epsilon I$ [illegible] $\epsilon > 0$ [illegible]. Since A is normal, it has an eigenvalue decomposition $A = V\Lambda V^*$, where $\Lambda = \operatorname{diag}(\lambda_1 \quad \cdots \quad \lambda_n)$ is complex diagonal, $|\lambda_1| \geq \ldots \geq |\lambda_n|$, and V is unitary. Set $D \equiv \lambda I - \Lambda$ and $F \equiv -V^*EV$, so that $\det(\lambda I - (A+E)) = \det(D+F)$. Theorem 2.3 implies $\det(D+F) = \det(D) + \det(F) + S_1 + \cdots + S_{n-1}$. Substituting $\det(D) = \lambda^n + \sum_{k=1}^n c_k \lambda^{n-k}$ and $\det(D+F) = \lambda^n + \sum_{k=1}^n \tilde{c}_k \lambda^{n-k}$ in the above expansion gives

$$\sum_{k=1}^{n} (\tilde{c}_k - c_k)\lambda^{n-k} = \det(F) + S_1 + \cdots + S_{n-1}.$$

Thus $\tilde{c}_k - c_k$ is equal to the coefficient of λ^{n-k} on the right-hand side, i.e., in $\det(F) + S_1 + \cdots + S_{n-1}$. Since

$$S_{n-j} \equiv \sum_{1 \leq i_1 < \cdots < i_{n-j} \leq n} (\lambda - \lambda_{i_1}) \cdots (\lambda - \lambda_{i_{n-j}}) \det(F_{i_1 \ldots i_{n-j}}), \qquad 1 \leq j \leq n-1,$$

has as highest power λ^{n-j}, the term λ^{n-k} can occur only in $S_{n-k}, \ldots, S_{n-1}$. This means $\tilde{c}_k - c_k$ is the sum of the coefficients of λ^{n-k} in $S_{n-1}, \ldots, S_{n-k}$. To bound the coefficient of λ^{n-k} in S_{n-j} in particular, we first bound all coefficients in S_{n-j}.

Observe that S_{n-j} is a sum of $\binom{n}{n-j}$ products $(\lambda - \lambda_{i_1}) \cdots (\lambda - \lambda_{i_{n-j}})$. For fixed $i_1, \ldots, i_{n-j}$ we can write the product as

$$(\lambda - \lambda_{i_1}) \cdots (\lambda - \lambda_{i_{n-j}}) = \lambda^{n-j} + \gamma_1 \lambda^{n-j-1} + \cdots + \gamma_{n-j-1}\lambda + \gamma_{n-j}.$$

The coefficient γ_l is a sum of $\binom{n-j}{l}$ products $\lambda_{j_1} \ldots \lambda_{j_l}$. Hence S_{n-j} contains $\binom{n}{n-j}\binom{n-j}{l}$ such products. Therefore we can bound $|S_{n-j}|$ by a sum of $\binom{n}{n-j}\binom{n-j}{l}$ products $|\lambda_{j_1}| \ldots |\lambda_{j_l}|$. Since A is normal $|\lambda_i| = \sigma_i$, so that these products are also summands of the elementary symmetric function s_l. The sum s_l contains $\binom{n}{l}$ such summands. Therefore the number of occurrences of s_l in the bound for $|S_{n-j}|$ is $\binom{n}{n-j}\binom{n-j}{l} / \binom{n}{l} = \binom{n-l}{j}$.

Now we are ready to return to the coefficient of λ^{n-k} in particular; it is γ_{k-j}. Applying the above counting argument with $l = k - j$ shows that the coefficient of λ^{n-k} in S_{n-j} is bounded by $\binom{n-k+j}{j} s_{k-j} |\det(F_{i_1 \ldots i_{n-j}})|$. Lemma 2.5 implies $|\det(F_{i_1 \ldots i_{n-j}})| \leq \|F\|_2^j = \|E\|_2^j$. Summing up the contributions from all S_{n-j}, $1 \leq j \leq k$, gives the desired result.

If $E = \epsilon I$, then $F = \epsilon I$ and $\det(F_{i_1 \ldots i_k}) = \epsilon^{n-k} = \|E\|_2^{n-k}$. ∎

[illegible] 3.6 (first-order absolute condition numbers for normal matrices). If A is normal and $\|E\|_2 < 1$, then Theorem 3.5 implies the first-order bound

$$|\tilde{c}_k - c_k| \leq (n-k+1)s_{k-1}\|E\|_2 + \mathcal{O}(\|E\|_2^2), \qquad 1 \leq k \leq n,$$

where $s_{k-1} \leq k|\lambda_1 \ldots \lambda_{k-1}|$. Hence we can view $(n-k+1)s_{k-1}$ or $(n-k+1)k|\lambda_1 \ldots \lambda_{k-1}|$ as first-order condition numbers for absolute perturbations in the coefficient c_k.

For Hermitian positive-define matrices, the bound in Theorem 3.5 can be expressed in terms of the coefficients c_k.

COROLLARY 3.7 (Hermitian positive-definite matrices). [illegible] $n \times n$ [illegible] A [illegible]

$$|\tilde{c}_k - c_k| \leq \sum_{i=1}^{k} \binom{n-k+i}{i} |c_{k-i}| \|E\|_2^i, \qquad 1 \leq k \leq n.$$

. The coefficients c_k are also elementary symmetric functions in the eigenvalues [6, section 1.2], and the eigenvalue of a Hermitian positive-definite is equal to the singular values. Thus $c_k = (-1)^k s_k$, and the result follows from Theorem 3.5. ∎

To first order, the conditioning of coefficient c_k is determined by the magnitude of the preceding coefficient, $|c_{k-1}|$. As in Corollary 2.8, the matrix $A+E$ in Corollary 3.7 does not have to be Hermitian positive-definite, because E can be arbitrary. Below we illustrate that one cannot use the expression in Corollary 3.7 for indefinite matrices; that is, positive-definiteness of A is crucial for the expression in Corollary 3.7.

3.8. Corollary 3.7 is not valid for indefinite Hermitian matrices and in particular matrices with zero trace.

To see this, let

$$A = \begin{pmatrix} \alpha & \\ & -\alpha \end{pmatrix}, \qquad \tilde{A} = \begin{pmatrix} \alpha - \epsilon & \\ & -\alpha + \epsilon \end{pmatrix},$$

where $\alpha > 0$ and $\epsilon > 0$. The characteristic polynomials are

$$\det(\lambda I - A) = \lambda^2 - \alpha^2, \qquad (\lambda I - (A + E)) = \lambda^2 - (\alpha - \epsilon)^2,$$

so that $\tilde{c}_2 - c_2 = 2\alpha\epsilon - \epsilon^2$. However, $|\tilde{c}_2 - c_2|$ cannot be bounded in terms of c_1, as required by Corollary 3.7, because $c_1 = 0$.

3.3. Normwise bounds. Replacing the singular value products by powers of $\|A\|_2$ gives the following simpler, but weaker bounds.

COROLLARY 3.9 (normwise bounds). . A . E . $n \times n$.

$$\begin{aligned} |\tilde{c}_k - c_k| &\le k\binom{n}{k} \sum_{i=1}^{k} \binom{k}{i} \|A\|_2^{k-i} \|E\|_2^i, \\ &= \binom{n}{k} \left((\|A\|_2 + \|E\|_2)^k - \|A\|^k \right), \qquad 1 \le k \le n. \end{aligned}$$

. $\operatorname{rank}(A) = r$ . . $1 \le r \le n-1$.

$$\begin{aligned} |\tilde{c}_k - c_k| &\le k\binom{n}{k} \|E\|_2^{k-r} \sum_{i=1}^{r} \binom{k}{i} \|A\|_2^{r-i} \|E\|_2^i, \\ &= \binom{n}{k} \|E\|_2^{k-r} \left((\|A\|_2 + \|E\|_2)^r - \|A\|^r \right), \qquad r+1 \le k \le n. \end{aligned}$$

. This follows from Theorem 3.3 and

$$s_{k-i}^{(k)} \le \binom{k}{k-i} \|A\|_2^{k-i} = \binom{k}{i} \|A\|_2^{k-i}, \qquad 1 \le i \le k-1. \quad ∎$$

A similar bound was was already derived in [1, section 20] and [2, Problem I.6.11] for any p-norm, by taking Fréchet derivatives of wedge products. Below we give a basic proof from first principles for the two-norm.

THEOREM 3.10 (section 20 in [1], problem I.6.11 in [2]). . A . E . $n \times n$.

$$|\tilde{c}_k - c_k| \le k\binom{n}{k} \|E\|_2 \max\{\|A\|_2, \|A + E\|_2\}^{k-1}, \qquad 1 \le k \le n.$$

. As in the proof of Theorem 3.3, we use

$$\tilde{c}_{n-k} = (-1)^{n-k} \sum_{1 \le i_1 < \ldots < i_k \le n} \det(A_{i_1 \ldots i_k} + E_{i_1 \ldots i_k}).$$

This gives for the absolute error

$$|\tilde{c}_{n-k} - c_{n-k}| \le \sum_{1 \le i_1 < \ldots < i_k \le n} |\det(A_{i_1 \ldots i_k} + E_{i_1 \ldots i_k}) - \det(A_{i_1 \ldots i_k})|.$$

Theorem 2.12 implies that $|\det(A_{i_1 \ldots i_k} + E_{i_1 \ldots i_k}) - \det(A_{i_1 \ldots i_k})|$ is bounded by

$$(n-k)\|E_{i_1 \ldots i_k}\|_2 \max\{\|A_{i_1 \ldots i_k}\|_2, \|(A+E)_{i_1 \ldots i_k}\|_2\}^{n-k-1}.$$

Bounding the principal submatrices by the norms of the respective matrices and recognizing that the sum contains $\binom{n}{n-k}$ summands yields the desired bound. ∎

Acknowledgment. We thank Dean Lean for many helpful discussions and for bringing this problem to our attention.

LDU FACTORIZATION OF NONSINGULAR TOTALLY NONPOSITIVE MATRICES*

RAFAEL CANTÓ†, PLAMEN KOEV‡, BEATRIZ RICARTE†, AND ANA M. URBANO†

Abstract. An $n \times n$ real matrix A is said to be (totally negative) totally nonpositive if every minor is (negative) nonpositive. In this paper, we study the properties of a totally nonpositive matrix and characterize the case of a nonsingular totally nonpositive matrix A, with $a_{11} < 0$ in terms of its LDU factorization ($L(U)$ is a unit lower- (upper-) triangular matrix, respectively, and D is a diagonal matrix). This characterization allows us to significantly reduce the number of minors to be checked in order to decide the total nonpositivity of a nonsingular matrix with a negative $(1, 1)$ entry.

Key words. nonsingular matrix, totally nonpositive matrix, LDU factorization

DOI. 10.1137/060662897

1. Introduction.

Several types of matrices have an important role in the various branches of mathematics and other sciences. A particular case of these matrices are the totally positive matrices, which have a wide variety of applications in approximation theory, numerical mathematics, statistics, economics, computer aided geometric design, and others fields [6, 12].

We recall that a matrix is called [illegible] if all its minors are nonnegative (positive) and are abbreviated as TP and STP, respectively.

If, instead, all minors of a matrix are nonpositive (negative), the matrix is called [illegible] and are abbreviated as t.n.p. and t.n., respectively.

The TP and STP matrices have been studied by several authors ([1, 2, 3, 4, 5, 6, 7, 8, 11]) who have obtained properties and characterizations in terms of the factorizations obtained by Gaussian or Neville elimination that allow one to significantly reduce the number of minors to be checked in order to decide if a matrix is TP or STP.

For t.n. matrices, a characterization in terms of the parameters obtained from Neville elimination is given in [9]. The spectral properties and [illegible] factorizations are analyzed in [5]. [illegible] factorization ($U(L)$) is a unit upper- (lower-) triangular matrix, respectively, and D is a diagonal matrix).

In this paper we extend the characterization of t.n. matrices given in [5] to nonsingular t.n.p. matrices. In particular, we characterize the t.n.p. matrices in terms of the factors of their [illegible] factorization and provide a criteria to determine if a matrix is t.n.p., which requires that only the sign of minors containing contiguous rows or columns, and include the first row or column, respectively, be checked.

We follow the notation of [1]. Given $k, n \in \mathbb{N}$, $1 \le k \le n$, $\mathcal{Q}_{k,n}$ denotes the set of all increasing sequences of k natural numbers less than or equal to n. If A is an $n \times n$ matrix and $\alpha, \beta \in \mathcal{Q}_{k,n}$, $A[\alpha|\beta]$ denotes the $k \times k$ submatrix of A lying in rows α and columns β. The principal submatrix $A[\alpha|\alpha]$ is abbreviated as $A[\alpha]$.

For a given k, $1 \le k \le n$, a vector $\epsilon = (\epsilon_1, \epsilon_2, \ldots, \epsilon_k)$ is called [illegible] if $|\epsilon_i| = 1$, $i = 1, 2, \ldots, k$. The matrix A is called sign-regular (strictly sign-regular) with signature ϵ if $\epsilon_k \det A[\alpha|\beta] \ge 0$ (> 0), $\alpha, \beta \in \mathcal{Q}_{k,n}$, $k = 1, 2, \ldots, n$ [1]. In particular, if $\epsilon_i = 1$, $i = 1, 2, \ldots, n$, then A is TP and if $\epsilon_i = -1$, $i = 1, 2, \ldots, n$, then A is t.n.p.

Throughout this paper, an [illegible] will mean the corresponding factorization resulting from Gaussian elimination with no pivoting where L and U are unit lower- and upper-triangular matrices, respectively, and D is diagonal.

2. Characterization of nonsingular t.n.p. matrices by triangular *LDU* factorization. In this section we derive a characterization of t.n.p. matrices in terms of their LDU factorizations. We use the fact that if $A = LDU$ is the LDU factorization of a nonsingular TP matrix, then L (U) is a unit lower- (upper-) triangular TP matrix, respectively, and D is a positive diagonal matrix [1, 2].

THEOREM 2.1. [illegible] A [illegible] $n \times n$ [illegible] $a_{11} < 0$ [illegible] $A = LDU$ [illegible] L (U) [illegible] D [illegible] $(1,1)$ [illegible].

Let P be the permutation matrix $[n, n-1, \ldots, 2, 1]$. From Cauchy–Binet, $G = PAP$ is also a nonsingular t.n.p. matrix.[1]

Let $S = \operatorname{diag}(1, -1, 1, \ldots, \pm 1)$. By [5, Theorem 2.4], $B = SG^{-1}S$ is sign-regular with signature $\epsilon = (1, 1, \ldots, 1, -1)$. Since $a_{11} < 0$,

$$\det B[1, 2, \ldots, n-1] = \det(SG^{-1}S)[1, 2, \ldots, n-1] = \frac{\det G[n]}{\det G} = \frac{a_{11}}{\det A} > 0.$$

Thus we can choose an $x > -1/a_{11}$ so that $C = B + xE_{nn}$ is TP where E_{nn} is the $n \times n$ matrix whose only nonzero entry is 1 in position (n, n). Therefore, $C = L'D'U'$ where L' (U') is a unit lower- (upper-) triangular TP matrix, and D' is a positive diagonal matrix. Consider

$$\begin{aligned} B = C - xE_{nn} &= L'D'U' - xE_{nn} \\ &= \begin{bmatrix} L_1 & 0 \\ l_1 & 1 \end{bmatrix} \begin{bmatrix} D_1 & 0 \\ 0 & d_{nn} \end{bmatrix} \begin{bmatrix} U_1 & u_1 \\ 0 & 1 \end{bmatrix} - x \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix} \\ &= \begin{bmatrix} L_1 & 0 \\ l_1 & 1 \end{bmatrix} \begin{bmatrix} D_1 & 0 \\ 0 & d_{nn} - x \end{bmatrix} \begin{bmatrix} U_1 & u_1 \\ 0 & 1 \end{bmatrix} = L'D''U'. \end{aligned}$$

Since D' is a positive diagonal matrix, D_1 is a positive diagonal matrix and since $\det B < 0$, we have $d_{nn} - x < 0$. Now

$$\begin{aligned} A = PGP &= P(SB^{-1}S)P = P(S(L'D''U')^{-1}S)P \\ &= P(S(U')^{-1}(D'')^{-1}(L')^{-1}S)P \\ &= [P(S(U')^{-1}S)P][P(S(D'')^{-1}S)P][P(S(L')^{-1}S)P] \\ &= (PU''P)(PD'''P)(PL''P) = LDU. \end{aligned}$$

By [5, Theorem 2.4], $L = P(S(U')^{-1}S)P$ is a unit lower-triangular TP matrix, $U = P(S(L')^{-1}S)P$ is a unit upper-triangular TP matrix, and $D = P(S(D'')^{-1}S)P$ is diagonal with all diagonal entries positive except for a negative $(1,1)$ entry. ∎

[1] Note that other permutation similarity transformations do not necessarily preserve the t.n.p. structure.

2.2. Consider the *LDU* factorization of a nonsingular t.n.p. matrix A, with $a_{11} < 0$. The entries of the first column (row) of L (U) are positive because if $l_{j1} = 0$ or $u_{1j} = 0$ for some $j \in \{2, 3, \ldots, n\}$, then $a_{jj} > 0$, which is a contradiction. Moreover, since L (U) is a TP matrix, we have $\det L[j, i|1, j] \geq 0$ ($\det U[1, j|j, i] \geq 0$), and thus $l_{ij} > 0$ ($u_{ji} > 0$) for all $i > j$.

Therefore, L (U) is a unit lower- (upper-) triangular TP matrix with positive entries below (above) the diagonal.

The converse of Theorem 2.1 is not true in general, as the next example shows.

2.3. The matrix

$$A = LDU = \begin{bmatrix} 1 & 0 & 0 \\ 2 & 1 & 0 \\ 1 & 2 & 1 \end{bmatrix} \begin{bmatrix} -3 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 5 \end{bmatrix} \begin{bmatrix} 1 & 2 & 4 \\ 0 & 1 & 2 \\ 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} -3 & -6 & -12 \\ -6 & -10 & -20 \\ -3 & -2 & 1 \end{bmatrix}$$

is not t.n.p. despite the fact that L and U are TP matrices, and D has positive diagonal entries except for the negative $(1, 1)$ entry.

The following theorem gives a necessary condition for a product LDU to be a t.n.p. matrix. Recall that an $n \times n$ triangular matrix is said to be a $\triangle$STP matrix if all of its nontrivial minors are positive.

THEOREM 2.4. [illegible] $A = LDU$ [illegible] $n \times n$ [illegible] $a_{nn} \leq 0$, L (U) [illegible] ($\ldots$) [illegible] ($\ldots$) [illegible] $D = \operatorname{diag}(-d_1, d_2, \ldots, d_n)$ [illegible] $d_i > 0$, $i = 1, 2, \ldots, n$ [illegible] A [illegible].

[illegible]. First consider the case $a_{nn} < 0$. Since L is a unit lower-triangular TP matrix, it can be written as a product of bidiagonal lower-triangular matrices [10] in the form:

$$L = (E_n(m_{n1})E_{n-1}(m_{n-1,1}) \cdots E_2(m_{21}))\,(E_n(m_{n2}) \cdots E_3(m_{32})) \cdots E_n(m_{n,n-1}),$$

where m_{ij} are the multipliers of the Neville elimination of L and $E_i(x)$ is a bidiagonal matrix which differs from the identity only in its $(i, i-1)$ entry x.

Since L is TP, we have $m_{ij} \geq 0$. If we replace the zero multipliers m_{ij} in L by $\delta > 0$, then the resulting matrix, $L(\delta)$ is $\triangle$STP [10]. Analogously, from U we obtain a $\triangle$STP matrix $U(\delta)$.

Now consider $A(\delta) = L(\delta)DU(\delta)$. From Cauchy–Binet,

$$A(\delta) = A + \left[\begin{array}{c|ccc} 0 & 0 & \ldots & 0 \\ \hline 0 & & & \\ \vdots & & p_{ij}(\delta) & \\ 0 & & & \end{array}\right],$$

where $p_{ij}(\delta)$ are polynomials in δ with nonnegative coefficients such that

$$\lim_{\delta \to 0} p_{ij}(\delta) = 0.$$

Since $a_{nn} < 0$ and $A(\delta)(n, n) = a_{nn} + p_{nn}(\delta)$, there exists δ_0 such that $A(\delta)(n, n) < 0$ for all $\delta < \delta_0$. By [5, Theorem 4.2], $A(\delta)$ is a t.n. matrix for all $\delta < \delta_0$ and, in particular,

$$\det A(\delta)[\alpha|\beta] < 0 \qquad \forall\ \alpha, \beta \in \mathcal{Q}_{k,n}, \quad k = 1, 2, \ldots, n.$$

In turn

$$\det A[\alpha|\beta] = \lim_{\delta \to 0} \det A(\delta)[\alpha|\beta] \leq 0 \qquad \forall\ \alpha, \beta \in \mathcal{Q}_{k,n}, \quad k = 1, 2, \ldots, n,$$

that is, A is t.n.p.

Now, suppose that $a_{nn} = 0$. Then the (n, n) entry of $B = A - xE_{nn}$ is $-x$. We have

$$B = A - xE_{nn} = LDU - xE_{nn} = L \begin{bmatrix} -d_1 & & & \\ & d_2 & & \\ & & \ddots & \\ & & & d_n - x \end{bmatrix} U.$$

Therefore for $0 < x < d_n$, by applying the previous case, B is a t.n.p. matrix.

By construction,

$$\det A[\alpha|\beta] = \det B[\alpha|\beta] \leq 0 \quad \forall\, \alpha, \beta \in \mathcal{Q}_{k,n}, \quad k = 1, 2, \ldots, n, \quad n \notin \alpha \cap \beta,$$

and consequently

$$\det A[\{\alpha, n\}|\{\beta, n\}] = \det B[\{\alpha, n\}|\{\beta, n\}] + x \det A[\alpha|\beta] \leq 0.$$

Thus, again, A is t.n.p. □

Combining Theorems 2.1 and 2.4 we obtain the following result.

THEOREM 2.5. [illegible] $n \times n$ [illegible] A [illegible] $a_{11} < 0$ [illegible] $a_{nn} \leq 0$, [illegible] $A = LDU$ [illegible] L (U) [illegible] ([illegible]) [illegible] ([illegible]) [illegible] D [illegible] $(1, 1)$ [illegible]

[illegible] 2.6. By [5, Corollary 4.3], an $n \times n$ matrix A with $a_{nn} < 0$ is t.n. if and only if $A = LDU$ where L (U) is a unit lower- (upper-) $\triangle$STP matrix, and D is a diagonal matrix with all diagonal entries positive except for the negative $(1, 1)$ entry.

3. Some properties of nonsingular t.n.p. matrices. In this section we show some properties of nonsingular t.n.p. matrices analogous to those satisfied by nonsingular TP matrices. From Theorem 2.1 we obtain the following result.

PROPOSITION 3.1. [illegible] A [illegible] $n \times n$ [illegible] [illegible] $a_{11} < 0$, [illegible] $\det A[1, \alpha] < 0$ [illegible] $\alpha \subset \{2, 3, \ldots, n\}$

By Proposition 3.1, the leading principal minors of a nonsingular t.n.p. matrix A with $a_{11} < 0$ are less than zero, that is, $\det A[1, 2, \ldots, k] < 0$ for $k = 1, 2, 3, \ldots, n$. It is not difficult, but is tedious, to prove that this fact is also satisfied when $a_{11} = 0$ and $k = 2, 3, \ldots, n$.

When $a_{11} = 0$ but $a_{nn} < 0$, we have that, PAP, where P is the permutation matrix $[n, n-1, \ldots, 2, 1]$, is a nonsingular t.n.p. matrix with a nonzero $(1, 1)$ entry. So, the matrix PAP admits an LDU factorization, and

$$A = PLDUP = (PLP)(PDP)(PUP) = \hat{U}\hat{D}\hat{L}.$$

Consequently, A admits a $\hat{U}\hat{D}\hat{L}$ factorization where $\hat{L}$ $(\hat{U})$ is a unit lower- (upper-) triangular TP matrix and $\hat{D}$ is a diagonal matrix with positive diagonal entries except for a negative (n, n) entry. A triangular factorization of this type has been obtained in [5, Theorem 4.1] for t.n. matrices, with L (U) being a $\triangle$STP matrix.

Now, from Remark 2.2 we prove the following result about the entries of a nonsingular t.n.p. matrix A with $a_{11} < 0$.

PROPOSITION 3.2. [illegible] A [illegible] $n \times n$ [illegible] [illegible] $a_{11} < 0$, [illegible] $a_{ij} < 0$ [illegible] $i, j = 1, 2, \ldots, n$, [illegible] $(i, j) \neq (n, n)$

[illegible]. By Remark 2.2 the entries of the first row and the first column of A are negative.

Now suppose $a_{ij} = 0$ where $(i,j) \neq (n,n)$ and (say) $i \leq j$ (the case $i \geq j$ being analogous). Then $\det A[1,i|j,j+s] \leq 0$ implies $a_{i,j+s} = 0$ for $s = 1,2,\ldots,n-j$. In turn $\det A[i,t|1,j+s] = 0$ implies that $a_{t,j+s} = 0$ for all $t = i+1, i+2, \ldots, n$, $s = 0,1,2,\ldots,n-j$. In particular, $A[n-1,n|n-1,n] = 0$. From the LDU factorization $A = LDU$ we get

$$A[n-1,n|n-1,n] = L[n-1,n|1,2,\ldots,n] \cdot D \cdot U[1,2,\ldots,n|n-1,n] = 0,$$

which is impossible, since $\operatorname{rank}(L[n-1,n|1,2,\ldots,n]) = \operatorname{rank}(U[1,2,\ldots,n|n-1,n]) = 2$ and $\operatorname{rank}(D) = n$. □

We note that this result still holds when A is a nonsingular t.n.p. matrix with $a_{11} = 0$.

Now, by Propositions 3.1 and 3.2, we prove an important property of nonsingular t.n.p. matrices analogous to the one of nonsingular TP matrices [1, Corollary 3.8].

PROPOSITION 3.3. [illegible] A [illegible] $n \times n$ [illegible] $a_{11} < 0$ [illegible] $a_{nn} < 0$ [illegible] $\det A[\alpha] < 0$ [illegible] $\alpha \in \mathcal{Q}_{k,n}$, $k = 1,2,\ldots,n$ [illegible]. We proceed by induction on the cardinality of α. If $|\alpha| = 1$, there is nothing to prove by Proposition 3.2.

Assume that the result holds for $|\alpha| = k-1$, and consider $\alpha = (\alpha_1, \alpha_2, \ldots, \alpha_k)$. By Proposition 3.1, $\det A[1,\alpha] < 0$, and using Sylvester's identity,

$$\det A[1,\alpha] = \frac{\det A[1,\alpha_1,\alpha_2,\ldots,\alpha_{k-1}] \det A[\alpha_1,\alpha_2,\ldots,\alpha_k]}{\det A[\alpha_1,\alpha_2,\ldots,\alpha_{k-1}]} - \frac{\det A[1,\alpha_1,\ldots,\alpha_{k-1}|\alpha_1,\alpha_2,\ldots,\alpha_k] \det A[\alpha_1,\alpha_2,\ldots,\alpha_k|1,\alpha_1,\ldots,\alpha_{k-1}]}{\det A[\alpha_1,\alpha_2,\ldots,\alpha_{k-1}]},$$

we conclude that $\det A[\alpha] < 0$, which concludes the induction. □

4. A simplified characterization of nonsingular t.n.p. matrices by minors. The following result provides a simple characterization of nonsingular t.n.p. matrices in terms of the sign of some of their minors when the $(1,1)$ entry is negative.

THEOREM 4.1. [illegible] A [illegible] $n \times n$ [illegible] (n,n) [illegible] A [illegible] $k = 1,2,\ldots,n$ [illegible]

$$\det A[\alpha|1,2,\ldots,k] \leq 0 \quad \text{[illegible] } \alpha \in \mathcal{Q}_{k,n}, \tag{4.1}$$

$$\det A[1,2,\ldots,k|\beta] \leq 0 \quad \text{[illegible] } \beta \in \mathcal{Q}_{k,n}, \tag{4.2}$$

$$\det A[1,2,\ldots,k] < 0. \tag{4.3}$$

[illegible]. If A is t.n.p., then the inequalities (4.1) and (4.2) follow from the definition of a t.n.p. matrix, and (4.3) is given in Proposition 3.1.

Conversely, from (4.3), let $A = LDU$ be its LDU factorization. Then $D = \operatorname{diag}(-d_1, d_2, \ldots, d_n)$ where $d_i > 0$, $i = 1,2,\ldots,n$. Hence, from Cauchy–Binet and (4.1),

$$\begin{aligned}\det(LD)[\alpha|1,2,\ldots,k] &= \det L[\alpha|1,2,\ldots,k](-d_1)d_2 \cdots d_k \\ &= \det A[\alpha|1,2,\ldots,k] \leq 0 \quad \text{for all } \alpha \in \mathcal{Q}_{k,n},\ k = 1,2,\ldots,n.\end{aligned}$$

Therefore, $\det L[\alpha|1,2,\ldots,k] \geq 0$ and, by [1, Corollary 2.2], L is a TP matrix. Moreover, since the entries of the first column of A are negative, the entries of the first column of L are positive. By Remark 2.2, L is a unit lower-triangular TP matrix with

positive entries below the diagonal. Analogously, U is a unit upper-triangular TP matrix with positive entries above the diagonal. Now, by Theorem 2.4, the nonsingular matrix A is t.n.p. □

4.2. By Remark 2.6 and [1, Corollary 2.6], we obtain the following characterization for t.n. matrices in terms of their minors. An $n \times n$ matrix A is t.n. if and only if for each $k = 1, 2, \ldots, n$, the following inequalities hold:

$$\begin{aligned} &\det A[\alpha|1,2,\ldots,k] < 0 \quad \text{for all } \alpha \in \mathcal{Q}_{k,n} \quad \text{with } \ d(\alpha) = 0, \\ &\det A[1,2,\ldots,k|\beta] < 0 \quad \text{for all } \beta \in \mathcal{Q}_{k,n} \quad \text{with } \ d(\beta) = 0. \end{aligned}$$

The characterizations given in Theorem 4.1 and Remark 4.2 for t.n.p. and t.n. matrices are analogous to the results for nonsingular TP and STP matrices given in [8].

OPTIMIZATION OF GENERALIZED MEAN-SQUARE ERROR IN NOISY LINEAR ESTIMATION*

WILLIAM W. HAGER† AND JIANGTAO LUO†

Abstract. A class of least squares problems that arises in linear Bayesian estimation is analyzed. The data vector $\mathbf{y}$ is given by the model $\mathbf{y} = \mathbf{P}(\mathbf{H}\boldsymbol{\theta} + \boldsymbol{\eta}) + \mathbf{w}$, where $\mathbf{H}$ is a known matrix, while $\boldsymbol{\theta}$, $\boldsymbol{\eta}$, and $\mathbf{w}$ are uncorrelated random vectors. The goal is to obtain the best estimate for $\boldsymbol{\theta}$ from the measured data. Applications of this estimation problem arise in multisensor data fusion problems and in wireless communication. The unknown matrix $\mathbf{P}$ is chosen to minimize the expected mean-squared error $\mathbf{E}(\|\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}\|^2)$ subject to a power constraint "trace $(\mathbf{P}\mathbf{P}^*) \le P$," where $\hat{\boldsymbol{\theta}}$ is the best affine estimate of $\boldsymbol{\theta}$. Earlier work characterized an optimal $\mathbf{P}$ in the case where the noise term $\boldsymbol{\eta}$ vanished, while this paper analyzes the effect of $\boldsymbol{\eta}$, assuming its covariance is a multiple of $\mathbf{I}$. The singular value decomposition of an optimal $\mathbf{P}$ is expressed in the form $\mathbf{V}\boldsymbol{\Sigma}\boldsymbol{\Pi}\mathbf{U}^*$ where $\mathbf{V}$ and $\mathbf{U}$ are unitary matrices related to the covariance of either $\boldsymbol{\theta}$ or $\mathbf{w}$, and singular vectors of $\mathbf{H}$, $\boldsymbol{\Sigma}$ is diagonal, and $\boldsymbol{\Pi}$ is a permutation matrix. The analysis is carried out in two special cases: (i) $\mathbf{H} = \mathbf{I}$ and (ii) covariance of $\boldsymbol{\theta}$ is $\mathbf{I}$. In case (i), $\boldsymbol{\Pi}$ does not depend on the power P. In case (ii), $\boldsymbol{\Pi}$ generally depends on P. The optimal $\boldsymbol{\Pi}$ is determined in the limit as the power tends to zero or infinity; a good approximation to an optimal $\boldsymbol{\Pi}$ is found for general P.

1. Introduction.

Suppose that $\mathbf{y} \in \mathbb{C}^m$ is a random vector that obeys the model

$$\mathbf{y} = \mathbf{P}(\mathbf{H}\boldsymbol{\theta} + \boldsymbol{\eta}) + \mathbf{w}, \tag{1.1}$$

where $\mathbf{H} \in \mathbb{C}^{n\times l}$ is a known matrix, while $\boldsymbol{\theta} \in \mathbb{C}^l$, $\boldsymbol{\eta} \in \mathbb{C}^n$, and $\mathbf{w} \in \mathbb{C}^m$ are uncorrelated random vectors with the property that $\boldsymbol{\eta}$ and $\mathbf{w}$ have zero mean. The matrix $\mathbf{P} \in \mathbb{C}^{m\times n}$ is a "filter" which is applied to the noisy measurement $\mathbf{H}\boldsymbol{\theta} + \boldsymbol{\eta}$, and which is chosen to achieve an optimal estimate of the signal $\boldsymbol{\theta}$. We consider affine estimators of the form

$$\hat{\boldsymbol{\theta}} = \mathbf{A}\mathbf{y} + \mathbf{a},$$

where $\mathbf{A} \in \mathbb{C}^{l\times m}$ is a constant matrix and $\mathbf{a} \in \mathbb{C}^l$ is a constant vector. For any random vector $\mathbf{v}$, let $\mathbf{C}_v$ denote the covariance defined by

$$\mathbf{C}_v = \mathbf{E}\big((\mathbf{v} - \mathbf{E}(\mathbf{v}))(\mathbf{v} - \mathbf{E}(\mathbf{v}))^*\big),$$

where $\mathbf{E}$ is expectation and * is conjugate transpose. According to [4, Thm. 12.1], the affine estimator that minimizes the expected mean-square error $\mathbf{E}(\|\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}\|^2)$ is given by

$$\hat{\boldsymbol{\theta}} = \mathbf{E}(\boldsymbol{\theta}) + (\mathbf{C}_\theta^{-1} + \mathbf{H}^*\mathbf{P}^*\mathbf{C}_{\eta w}^{-1}\mathbf{P}\mathbf{H})^{-1}(\mathbf{P}\mathbf{H})^*\mathbf{C}_{\eta w}^{-1}(\mathbf{y} - \mathbf{P}\mathbf{H}\mathbf{E}(\boldsymbol{\theta})),$$

where $\mathbf{C}_{\eta w} = \mathbf{P}\mathbf{C}_\eta\mathbf{P}^* + \mathbf{C}_w$. Moreover, the error $\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}$ has zero mean and covariance

$$\mathbf{C} = \mathbf{E}\big((\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})^*\big) = \big((\mathbf{P}\mathbf{H})^*(\mathbf{C}_w + \mathbf{P}\mathbf{C}_\eta\mathbf{P}^*)^{-1}\mathbf{P}\mathbf{H} + \mathbf{C}_\theta^{-1}\big)^{-1}. \tag{1.2}$$

Since $\hat{\boldsymbol{\theta}}$ depends on $\mathbf{P}$, the estimation error $\mathbf{E}(\|\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}\|^2)$ depends on $\mathbf{P}$. The filter $\mathbf{P}$ is chosen to minimize the estimation error, subject to the constraint tr $(\mathbf{P}\mathbf{P}^*) \le P$, where P is a positive scalar and "tr" denotes the trace of a matrix. The constraint tr $(\mathbf{P}\mathbf{P}^*) \le P$ represents a bound on the power associated with $\mathbf{P}$.

Multisensor data fusion problems (see [6, 10, 15] and the references therein) fit within the framework of the model (1.1). In these applications, $\boldsymbol{\theta}$ is a random parameter vector that is being measured by a collection of sensors. The sensor measurements correspond to the observation matrix $\mathbf{H}$. The term $\boldsymbol{\eta}$ in the model (1.1) could represent sensor noise. The output of the observer is sent to the "fusion center" which leads to the final output $\mathbf{y}$ in (1.1). If the dimension of the column space of $\mathbf{P}$ is less than the dimension of the row space, then there is a reduction in dimensionality of the data. The term $\mathbf{w}$ might represent either noise or quantization error in the transmission to the fusion center. The constraint tr $(\mathbf{P}\mathbf{P}^*) \le P$ might also be viewed as a constraint on the amplifier gain to prevent the amplified observations from exceeding the dynamic range of the quantizer.

Another application which fits the model (1.1) concerns spreading sequence optimization for code division multiple access (CDMA) communication systems [12, 13]. In CDMA systems, many users simultaneously share a communication channel. In modeling the uplink (communication from the mobile units to the base station), $\mathbf{y}$ is the signal received at the base station, the jth column of $\mathbf{P}$ is the "spreading sequence" assigned to the jth user, and θ_j is the symbol transmitted from the jth user. $\mathbf{H}$ is a diagonal matrix corresponding to channel gains.

The problem of estimating the channel matrix for a multiple input, single output (MISO) system can be expressed in the form (1.1) as observed in [2]. In this context, there are multiple transmit antennas and a single receiver. The jth column of $\mathbf{P}$ is the training signal to transmit from the jth antenna to obtain the best estimate for the communication channel gains; the matrix $\mathbf{H}$ is the square root of the correlation between the transmit antennas. The noise in the channel gains and in the transmitted signal associated with atmospheric conditions is modeled by $\boldsymbol{\eta}$ and $\mathbf{w}$.

The model (1.1) is related to the channel estimation problem for multiple input, multiple output (MIMO) systems [5, 14]. That is, in [5] it is shown that when $\mathbf{H}$ and $\mathbf{C}_w$ have a special Kronecker product form and when $\mathbf{C}_\eta = \mathbf{0}$, then the covariance of the best channel estimate is a multiple of $\mathbf{C}$ in (1.2). The model (1.1) is loosely connected with joint linear transmitter-receiver design in MIMO communication [8, 9]. In MIMO communication, the precoder $\mathbf{P}$ precedes the channel matrix $\mathbf{H}$. Hence, in the special case $\mathbf{H} = \mathbf{I}$, the model (1.1) corresponds to a MIMO communication channel with two noise terms.

Since $\mathbf{E}(\|\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}\|^2)$ is the trace of $\mathbf{C}$, minimizing the trace of the covariance $\mathbf{C}$ is equivalent to minimizing $\mathbf{E}(\|\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}\|^2)$. Hence, the $\mathbf{P}$ that minimizes the expected mean-square error $\mathbf{E}(\|\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}\|^2)$ is a solution of the problem

$$\begin{aligned} &\min_{\mathbf{P}} \ \text{tr}\ \big((\mathbf{P}\mathbf{H})^*(\mathbf{W} + \mathbf{P}\mathbf{N}\mathbf{P}^*)^{-1}\mathbf{P}\mathbf{H} + \mathbf{T}\big)^{-1} \\ &\text{subject to} \ \ \text{tr}\ (\mathbf{P}\mathbf{P}^*) \le P, \quad \mathbf{P} \in \mathbb{C}^{m\times n}, \end{aligned} \tag{1.3}$$

where $\mathbf{W} = \mathbf{C}_w$, $\mathbf{N} = \mathbf{C}_\eta$, and $\mathbf{T} = \mathbf{C}_\theta^{-1}$. Both $\mathbf{C}_w$ and $\mathbf{C}_\theta$ are assumed positive definite. This holds, for example, if the probability density function associated with

$\boldsymbol{\theta}$ and $\mathbf{w}$ is continuous. The wireless communication applications in [2] correspond to $\mathbf{N} = \mathbf{0}$ and $\mathbf{T} = \mathbf{I}$. The application in [5] corresponds to $\mathbf{N} = \mathbf{0}$ and $\mathbf{H} = \mathbf{I}$. In this paper, we again consider the cases (i) $\mathbf{H} = \mathbf{I}$ or (ii) $\mathbf{T} = \mathbf{I}$; however, the noise covariance $\mathbf{N}$ is no longer zero, but a multiple of $\mathbf{I}$. By a rescaling of the variables $\mathbf{P}$, $\mathbf{H}$, and the power P, there is no loss of generality in assuming that $\mathbf{N} = \mathbf{I}$. In the multisensor data fusion problem studied in [6], it is pointed out that when the sensor noise is uncorrelated with the signal $\boldsymbol{\theta}$ and when the sensor noise is spatially uncorrelated with zero mean, then by appropriate pre- and post-whitening if necessary, there is no loss of generality in assuming that $\mathbf{N} = \mathbf{I}$ and $\mathbf{T} = \mathbf{I}$. Hence, we focus on the problem

$$\begin{aligned} &\min_{\mathbf{P}} \ \operatorname{tr}\left((\mathbf{PH})^*(\mathbf{W}+\mathbf{PP}^*)^{-1}\mathbf{PH}+\mathbf{T}\right)^{-1} \\ &\text{subject to } \ \operatorname{tr}(\mathbf{PP}^*) \le P, \quad \mathbf{P} \in \mathbb{C}^{m\times n}. \end{aligned} \tag{1.4}$$

A unified analysis is developed for (1.4) which handles the special cases (i) or (ii) and which exposes the similarities and differences in these two problems. In both cases, the singular value decomposition of an optimal solution is expressed in the form $\mathbf{V\Sigma\Pi U}^*$ where $\mathbf{V}$ and $\mathbf{U}$ are unitary matrices related to eigenvectors of $\mathbf{W}$ or $\mathbf{T}$ or singular vectors of $\mathbf{H}$, with a specific ordering for the columns described below. The matrix $\mathbf{\Sigma}$ is diagonal, and $\mathbf{\Pi}$ is a permutation matrix. A fundamental difference in these problems is that in case (i) ($\mathbf{H} = \mathbf{I}$), the permutation is independent of P, which is the same result obtained in [5] for $\boldsymbol{\eta} = \mathbf{0}$. For case (ii) ($\mathbf{T} = \mathbf{I}$), $\mathbf{\Pi}$ depends on the choice of P and the singular values of $\mathbf{H}$. When the noise term $\boldsymbol{\eta}$ vanishes and P is large, the permutation arranges the singular values of $\mathbf{H}$ in increasing order, as obtained in [2]; when noise $\boldsymbol{\eta}$ with covariance $\mathbf{I}$ is included in the model, the singular values of $\mathbf{H}$ smaller than one are arranged in decreasing order, while the singular values greater than one are arranged in increasing order (see Theorem 5.1). As a result, depending on the size of the power P and the distribution of the singular values of $\mathbf{H}$, the noise term $\boldsymbol{\eta}$ can have a significant effect on the structure of the optimal solution.

The paper is organized as follows: In section 2 we derive the singular value decomposition $\mathbf{V\Sigma\Pi U}^*$ of a solution to (1.4). Section 3 gives the optimal solution, assuming the permutation $\mathbf{\Pi}$ is known. In section 4, we evaluate $\mathbf{\Pi}$ in the special case $\mathbf{H} = \mathbf{I}$. When $\mathbf{H} \neq \mathbf{I}$, $\mathbf{\Pi}$ depends on P. Section 5 evaluates the permutation in the limit as P tends to infinity, while section 6 analyzes the limit as P tends to zero. Finally, section 7 explores the dependence of the permutation on P using randomly generated test problems. For general P, we present a family of permutations which often contains the optimal $\mathbf{\Pi}$.

Throughout the paper, we use the following notation: $\mathbf{U\Lambda V}^*$ is the singular value decomposition of $\mathbf{H}$ (see Figure 1.1) and $\boldsymbol{\lambda}$ is the diagonal of $\mathbf{\Lambda}$. The diagonal of a rectangular matrix $\mathbf{\Lambda}$ are the entries $\mathbf{\Lambda}_{ii}$, $i = 1, 2, \ldots, \min\{m, n\}$. $\mathbf{V}_w\mathbf{\Omega V}_w^*$ and $\mathbf{V}_t\mathbf{\Theta V}_t^*$ are diagonalizations of the Hermitian matrices $\mathbf{W}$ and $\mathbf{T}$, respectively, while $\boldsymbol{\omega}$ and $\boldsymbol{\theta}$ are the diagonals of $\mathbf{\Omega}$ and $\mathbf{\Theta}$. The diagonal elements are ordered as follows:

$$\lambda_i \ge \lambda_{i+1}, \quad \theta_i \le \theta_{i+1}, \quad \text{and} \quad \omega_i \le \omega_{i+1}. \tag{1.5}$$

M denotes the minimum of m and the rank of $\mathbf{H}$. The trace of a matrix is denoted "tr," "*" denotes conjugate transpose, $\mathcal{S}^c$ denotes complement of the set $\mathcal{S}$, and $|\mathcal{S}|$ is the number of elements in $\mathcal{S}$. A diagonal matrix $\mathbf{D}$ is said to be nondegenerate if

Decomposition	Dimension	Description
$\mathbf{H} = \mathbf{U}\mathbf{\Lambda}\mathbf{V}^*$	$n \times l$	Singular value decomposition of observer
$\mathbf{W} = \mathbf{V}_w\mathbf{\Omega}\mathbf{V}_w^*$	$m \times m$	Diagonalization of covariance of $\mathbf{w}$
$\mathbf{T} = \mathbf{V}_t\mathbf{\Theta}\mathbf{V}_t^*$	$l \times l$	Diagonalization of inverse of covariance of $\boldsymbol{\theta}$
$\mathbf{P} = \mathbf{V}_w\mathbf{S}\mathbf{V}_t^*$	$m \times n$	Change of variables when $\mathbf{H} = \mathbf{I}$
$\mathbf{P} = \mathbf{V}_w\mathbf{S}\mathbf{U}^*$	$m \times n$	Change of variables when $\mathbf{\Theta} = \mathbf{I}$

FIG. 1.1. *Summary of decompositions, $l = n$ without loss of generality.*

the following condition is satisfied:

$$d_{ii} \neq d_{jj} > 0 \text{ for all } i \neq j. \tag{1.6}$$

For any matrix $\mathbf{A}$, $\mathrm{Col}_k(\mathbf{A})$ denotes the submatrix formed by the first k columns, while $\mathrm{Prin}_k(\mathbf{A})$ denotes the k by k leading principal submatrix. $\mathcal{P}_m$ is the set of bijections of $\{1, 2, \ldots, m\}$ onto itself (the set of all permutations of the integers between 1 and m).

2. Solution structure. We begin by analyzing the structure of an optimal solution to (1.4). Let us make the following change of variables:

$$\mathbf{P} = \mathbf{V}_w\mathbf{S}\mathbf{U}^* \ \ (\text{if } \mathbf{\Theta} = \mathbf{I}) \quad \text{or} \quad \mathbf{P} = \mathbf{V}_w\mathbf{S}\mathbf{V}_t^* \ \ (\text{if } \mathbf{H} = \mathbf{I}). \tag{2.1}$$

With these substitutions, (1.4) reduces to the following problem in the cases $\mathbf{H} = \mathbf{I}$ or $\mathbf{T} = \mathbf{I}$:

$$\begin{aligned} \min_{\mathbf{S}} \quad & \mathrm{tr}\ ((\mathbf{S}\mathbf{\Lambda})^*(\mathbf{\Omega} + \mathbf{S}\mathbf{S}^*)^{-1}\mathbf{S}\mathbf{\Lambda} + \mathbf{\Theta})^{-1} \\ \text{subject to} \quad & \mathrm{tr}\ (\mathbf{S}\mathbf{S}^*) \leq P, \quad \mathbf{S} \in \mathbb{C}^{m \times n}. \end{aligned} \tag{2.2}$$

If $\mathbf{H} = \mathbf{I}$, then $l = n$. We now show that in general (2.2) can always be transformed to an equivalent problem with $l = n$. Note though that the transformed problem may have zero singular values in $\mathbf{H}$ even when the singular values of the original $\mathbf{H}$ are strictly positive. If $l > n$, then define $\overline{\mathbf{\Lambda}} = \mathrm{Col}_n(\mathbf{\Lambda})$, the submatrix formed by the first n columns of $\mathbf{\Lambda}$, and define

$$\overline{\mathbf{C}} = ((\mathbf{S}\overline{\mathbf{\Lambda}})^*(\mathbf{\Omega} + \mathbf{S}\mathbf{S}^*)^{-1}\mathbf{S}\overline{\mathbf{\Lambda}} + \mathbf{\Theta}_1)^{-1},$$

where $\mathbf{\Theta}_1 = \mathrm{Prin}_n(\mathbf{\Theta})$, the leading n by n principal submatrix of $\mathbf{\Theta}$. Since the last $l - n$ columns of $\mathbf{\Lambda}$ are zero, the covariance matrix

$$\mathbf{C} = ((\mathbf{S}\mathbf{\Lambda})^*(\mathbf{\Omega} + \mathbf{S}\mathbf{S}^*)^{-1}\mathbf{S}\mathbf{\Lambda} + \mathbf{\Theta})^{-1}$$

has the structure

$$\mathbf{C} = \begin{bmatrix} \overline{\mathbf{C}} & \mathbf{0} \\ \mathbf{0} & \mathbf{\Theta}_2 \end{bmatrix},$$

where $\mathbf{\Theta}_2$ is the trailing $l - n$ by $l - n$ submatrix of $\mathbf{\Theta}$. Hence,

$$\mathrm{tr}\ (\mathbf{C}) = \mathrm{tr}\ (\overline{\mathbf{C}}) + \mathrm{tr}\ (\mathbf{\Theta}_2^{-1}),$$

and minimizing the trace of $\mathbf{C}$ is equivalent to minimizing the trace of $\overline{\mathbf{C}}$ (since $\mathbf{\Theta}_2$ does not depend on $\mathbf{S}$).

On the other hand, suppose that $l < n$. Let $\mathbf{\Lambda}_0$ be the matrix obtained by appending $n-l$ columns of zeros to the right side of $\mathbf{\Lambda}$, let $\overline{\mathbf{\Theta}}$ be the matrix obtained by appending $n-l$ trailing ones on the diagonal of $\mathbf{\Theta}$, and define

$$\mathbf{C}_0 = ((\mathbf{S}\mathbf{\Lambda}_0)^*(\mathbf{\Omega} + \mathbf{S}\mathbf{S}^*)^{-1}\mathbf{S}\mathbf{\Lambda}_0 + \overline{\mathbf{\Theta}})^{-1}.$$

The matrix $\mathbf{C}_0$ has the following structure:

$$\mathbf{C}_0 = \begin{bmatrix} \mathbf{C} & \mathbf{0} \\ \mathbf{0} & \mathbf{I} \end{bmatrix}.$$

Hence, tr $(\mathbf{C}_0)$ = tr $(\mathbf{C}) + n - l$, and minimizing the trace of $\mathbf{C}$ is equivalent to minimizing the trace of $\mathbf{C}_0$. In either case $l > n$ or $l < n$, we are able to formulate a problem with the associated $\mathbf{\Lambda}$ square and with the same solution as the original problem. Consequently, it is assumed henceforth that $l = n$. We begin by formulating the first-order optimality conditions for (2.2).

LEMMA 2.1. [illegible] (2.2) [illegible] $\boldsymbol{\lambda} > \mathbf{0}$ [illegible] $\mu > 0$ [illegible]

(2.3) $$(\mathbf{I} - \mathbf{S}^*\mathbf{L}^{-1}\mathbf{S})\mathbf{\Lambda}\mathbf{M}^{-2}\mathbf{\Lambda}\mathbf{S}^*\mathbf{L}^{-1} = \mu\mathbf{S}^*,$$

[illegible]

(2.4) $$\mathbf{L} = \mathbf{\Omega} + \mathbf{S}\mathbf{S}^* \quad \text{and} \quad \mathbf{M} = \mathbf{\Lambda}\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}\mathbf{\Lambda} + \mathbf{\Theta}.$$

[illegible] $\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}$ [illegible] $\mathbf{\Lambda}\mathbf{M}^{-2}\mathbf{\Lambda}$ [illegible]

[illegible]. If $\mathbf{S} = \mathbf{0}$, then the results hold trivially. Suppose that $\mathbf{S} \neq \mathbf{0}$. The first-order necessary optimality conditions are satisfied at any nonzero solution of (2.2) since the gradient of the constraint does not vanish. Hence, if $\mathbf{S}$ is a solution of (2.2), then there exists a $\mu \geq 0$ such that the Fréchet derivative of the Lagrangian vanishes at $\mathbf{S}$. The Lagrangian associated with the optimization problem (2.2) is

(2.5) $$\text{tr } \left((\mathbf{\Lambda}\mathbf{S}^*(\mathbf{\Omega} + \mathbf{S}\mathbf{S}^*)^{-1}\mathbf{S}\mathbf{\Lambda} + \mathbf{\Theta})^{-1} + \mu\mathbf{S}\mathbf{S}^*\right),$$

where the multiplier $\mu \geq 0$ is a real scalar. As shown in the Appendix, when we equate to zero the derivative of the Lagrangian, we obtain (2.3).

We now show that the multiplier μ is strictly positive. Suppose $\mu = 0$. Since $\mathbf{\Omega}$ and $\mathbf{\Theta}$ are positive definite (see section 1), the factors $\mathbf{L}$ and $\mathbf{M}$ in (2.3) are positive definite. Since $\boldsymbol{\lambda} > \mathbf{0}$, $\mathbf{\Lambda}$ is positive definite. If we can show that $(\mathbf{I} - \mathbf{S}^*\mathbf{L}^{-1}\mathbf{S})$ is invertible, then $\mu = 0$ implies that $\mathbf{S} = \mathbf{0}$, which is a contradiction. Thus $\mu > 0$.

To show that $(\mathbf{I} - \mathbf{S}^*\mathbf{L}^{-1}\mathbf{S})$ is invertible, we apply the matrix modification formula [3]

(2.6) $$(\mathbf{I} + \mathbf{Z}\mathbf{Z}^*)^{-1} = \mathbf{I} - \mathbf{Z}(\mathbf{I} + \mathbf{Z}^*\mathbf{Z})^{-1}\mathbf{Z}^*$$

with $\mathbf{Z}^* = \mathbf{\Omega}^{-1/2}\mathbf{S}$ to obtain

$$\begin{aligned} \mathbf{I} - \mathbf{S}^*\mathbf{L}^{-1}\mathbf{S} &= \mathbf{I} - \mathbf{S}^*(\mathbf{\Omega} + \mathbf{S}\mathbf{S}^*)^{-1}\mathbf{S} \\ &= \mathbf{I} - \mathbf{S}^*\mathbf{\Omega}^{-1/2}(\mathbf{I} + \mathbf{\Omega}^{-1/2}\mathbf{S}\mathbf{S}^*\mathbf{\Omega}^{-1/2})^{-1}\mathbf{\Omega}^{-1/2}\mathbf{S} \\ &= \mathbf{I} - \mathbf{Z}(\mathbf{I} + \mathbf{Z}^*\mathbf{Z})^{-1}\mathbf{Z}^* = (\mathbf{I} + \mathbf{Z}\mathbf{Z}^*)^{-1} \\ &= (\mathbf{I} + \mathbf{S}^*\mathbf{\Omega}^{-1}\mathbf{S})^{-1}. \end{aligned}$$

Hence, the matrix $\mathbf{I} - \mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}$ is positive definite and invertible. This completes the proof that $\mu > 0$.

We multiply (2.3) by $\mathbf{S}$ to obtain

$$\mu\mathbf{S}^*\mathbf{S} = (\mathbf{I} - \mathbf{S}^*\mathbf{L}^{-1}\mathbf{S})\mathbf{\Lambda}\mathbf{M}^{-2}\mathbf{\Lambda}\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}. \tag{2.7}$$

Forming the conjugate transpose of (2.7) gives

$$\mu\mathbf{S}^*\mathbf{S} = \mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}\mathbf{\Lambda}\mathbf{M}^{-2}\mathbf{\Lambda}(\mathbf{I} - \mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}). \tag{2.8}$$

Equating the right sides of (2.7) and (2.8) yields

$$(\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S})(\mathbf{\Lambda}\mathbf{M}^{-2}\mathbf{\Lambda}) = (\mathbf{\Lambda}\mathbf{M}^{-2}\mathbf{\Lambda})(\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}). \tag{2.9}$$

Hence, the matrices $\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}$ and $\mathbf{\Lambda}\mathbf{M}^{-2}\mathbf{\Lambda}$ commute. □

We now present cases where (2.2) has a solution with at most one nonzero in each row and column.

LEMMA 2.2. [illegible] $\mathbf{S}$ [illegible] (2.2) [illegible] $\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}$ [illegible] $\mathrm{Prin}_k(\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S})$ [illegible] $k > 0$ [illegible] $\mathbf{\Omega}$ [illegible] $\mathbf{\Lambda}$ [illegible] $\mathrm{Prin}_k(\mathbf{S}) = \mathbf{\Pi}_1\mathbf{\Sigma}\mathbf{\Pi}_2$ [illegible] $\mathbf{\Pi}_1$ [illegible] $\mathbf{\Pi}_2$ [illegible] $\mathbf{\Sigma}$ [illegible].

[illegible]. Since $\mathbf{S}$ is a solution of (2.2), (2.3) holds. We multiply (2.3) by $\mathbf{L}$ to obtain

$$(\mathbf{I} - \mathbf{S}^*\mathbf{L}^{-1}\mathbf{S})\mathbf{\Lambda}\mathbf{M}^{-2}\mathbf{\Lambda}\mathbf{S}^* = \mu\mathbf{S}^*\mathbf{L} = \mu\mathbf{S}^*(\mathbf{\Omega} + \mathbf{S}\mathbf{S}^*).$$

Rearranging this, we have

$$\mathbf{S}^*\mathbf{\Omega} = \mathbf{E}\mathbf{S}^*, \tag{2.10}$$

where

$$\mathbf{E} = \frac{1}{\mu}(\mathbf{I} - \mathbf{S}^*\mathbf{L}^{-1}\mathbf{S})(\mathbf{\Lambda}\mathbf{M}^{-2}\mathbf{\Lambda}) - \mathbf{S}^*\mathbf{S}.$$

Since $\mathbf{\Lambda}$, $\mathbf{\Omega}$, and $\mathbf{\Theta}$ are diagonal and $\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}$ is block diagonal, it follows that $\mathbf{M} = \mathbf{\Lambda}\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}\mathbf{\Lambda} + \mathbf{\Theta}$ is block diagonal and $\mathrm{Prin}_k(\mathbf{M})$ is diagonal. By (2.7), $\mathbf{S}^*\mathbf{S}$ is block diagonal and $\mathrm{Prin}_k(\mathbf{S}^*\mathbf{S})$ is diagonal. Hence, $\mathbf{E}$ is block diagonal and $\mathrm{Prin}_k(\mathbf{E})$ is diagonal. Let e_i denote the ith diagonal element of $\mathbf{E}$. For $1 \le i \le k$ and $1 \le j \le m$, we equate the (i, j) elements in (2.10) to obtain

$$(\mathbf{S}^*)_{ij}\omega_j = e_i(\mathbf{S}^*)_{ij} \quad \text{or} \quad (\mathbf{S}^*)_{ij}(\omega_j - e_i) = 0.$$

If $(\mathbf{S}^*)_{ij} \neq 0$, then $\omega_j = e_i$. By the nondegeneracy assumption, the ω_j, $1 \le j \le m$, are all distinct. Consequently, there is at most one j for which $(\mathbf{S}^*)_{ij} \neq 0$. In other words, each of the first k columns of $\mathbf{S}$ has at most one nonzero. Since $\mathrm{Prin}_k(\mathbf{S}^*\mathbf{S})$ is diagonal, no two of the leading k columns of $\mathbf{S}$ can have their single nonzero in the same row. A suitable permutation of the rows and the first k columns of $\mathbf{S}$ yields a diagonal matrix $\mathbf{\Sigma}$. □

We now apply Lemma 2.2 to the case $\mathbf{\Lambda} = \mathbf{I}$:

LEMMA 2.3. [illegible] $\mathbf{\Lambda} = \mathbf{I}$ [illegible] (2.2) [illegible] $\mathbf{S} = \mathbf{\Pi}_1\mathbf{\Sigma}\mathbf{\Pi}_2$ [illegible] $\mathbf{\Pi}_1$ [illegible] $\mathbf{\Pi}_2$ [illegible] $\mathbf{\Sigma}$ [illegible].

[illegible]. Since any $\mathbf{\Omega}$ and $\mathbf{\Theta}$ can be approximated arbitrarily closely by nondegenerate matrices, there is no loss of generality in assuming that $\mathbf{\Omega}$ and $\mathbf{\Theta}$ are nondegenerate

(see [2]). There exists an optimal solution of (2.2) since the feasible set is compact and the cost function is a continuous function of $\mathbf{S}$.

By Lemma 2.1, the matrices $\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}$ and $\mathbf{\Lambda}\mathbf{M}^{-2}\mathbf{\Lambda}$ commute. Since $\mathbf{\Lambda} = \mathbf{I}$, it follows that $\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}$ and $\mathbf{M}^{-2}$ commute. Since commuting matrices share a common set of eigenvectors [11, p. 249], and since the eigenvectors of $\mathbf{M}^{-2}$ and $\mathbf{M}$ are the same, it follows that $\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}$ and $\mathbf{M}$ commute:

$$(\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S})\mathbf{M} = \mathbf{M}(\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}).$$

This implies that

$$(\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S})(\mathbf{\Theta} + \mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}) = (\mathbf{\Theta} + \mathbf{S}^*\mathbf{L}^{-1}\mathbf{S})(\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}).$$

which reduces to

$$(\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S})\mathbf{\Theta} = \mathbf{\Theta}(\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}).$$

Since $\mathbf{\Theta}$ satisfies the nondegeneracy condition, we conclude that $\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}$ is diagonal. Taking $k = n$ (the number of columns in $\mathbf{S}$) in Lemma 2.2, $\mathbf{S} = \mathrm{Prin}_k(\mathbf{S}) = \mathbf{\Pi}_1\mathbf{\Sigma}\mathbf{\Pi}_2$. □

The case $\mathbf{\Theta} = \mathbf{I}$ and $\mathbf{\Lambda} \neq \mathbf{I}$ is tougher to analyze. In an effort to simplify the structure of a solution to (2.2), we will apply a permutation to our problem. Let $\mathbf{\Pi}$ be a permutation matrix which we will apply to the columns of $\mathbf{S}$. The permuted matrix is $\mathbf{S}_p = \mathbf{S}\mathbf{\Pi}$. Let $\mathbf{\Lambda}_p = \mathbf{\Pi}^*\mathbf{\Lambda}\mathbf{\Pi}$ be the symmetric permutation of the rows and columns of $\mathbf{\Lambda}$. In essence, $\mathbf{\Lambda}_p$ is obtained from $\mathbf{\Lambda}$ by interchanging diagonal elements. Similarly, $\mathbf{\Theta}_p = \mathbf{\Pi}^*\mathbf{\Theta}\mathbf{\Pi}$ denotes the symmetric permutation of $\mathbf{\Theta}$. We replace $\mathbf{S}$, $\mathbf{\Lambda}$, and $\mathbf{\Theta}$ by their representation in terms of the permuted quantities to obtain the following equivalent form of (2.2) (after taking into account the fact that the trace is invariant under a similarity transformation):

$$\min_{\mathbf{S}_p} \quad \mathrm{tr}\ ((\mathbf{S}_p\mathbf{\Lambda}_p)^*(\mathbf{\Omega} + \mathbf{S}_p\mathbf{S}_p^*)^{-1}\mathbf{S}_p\mathbf{\Lambda}_p + \mathbf{\Theta}_p)^{-1} \tag{2.11}$$

$$\text{subject to} \quad \mathrm{tr}\ (\mathbf{S}_p\mathbf{S}_p^*) \leq P, \quad \mathbf{S}_p \in \mathbb{C}^{m\times n}.$$

We begin with the following result:

LEMMA 2.4. $\mathbf{D}$

$$\mathbf{D} = \mathbf{S}^*\mathbf{L}^{-1/2}(\mathbf{I} + \mathbf{W}^*\mathbf{W})^{-2}\mathbf{L}^{-1/2}\mathbf{S}, \tag{2.12}$$

$\mathbf{W} = \mathbf{\Lambda}\mathbf{S}^*\mathbf{L}^{-1/2}$ $\mathbf{L} = \mathbf{\Omega} + \mathbf{S}\mathbf{S}^*$ $d_{ii} = 0$ i $\mathbf{S}$ $\mathbf{\Theta} = \mathbf{I}$ $\mathbf{S}$ (2.2) $\mathbf{\Lambda}$ $\mathbf{D}$ $\mathbf{D}_p = \mathbf{\Pi}^*\mathbf{D}\mathbf{\Pi}$ $\mathbf{D}$ $\mathbf{\Pi}$ $\mathbf{\Lambda}_p^2\mathbf{D}_p$ $\mathbf{S}_p^*\mathbf{L}^{-1}\mathbf{S}_p$ $\mathbf{\Lambda}_p^2\mathbf{D}_p$. By the definition of $\mathbf{D}$, we have

$$d_{ii} = \|(\mathbf{I} + \mathbf{W}^*\mathbf{W})^{-1}\mathbf{L}^{-1/2}\mathbf{s}_i\|^2,$$

where $\mathbf{s}_i$ is the ith column of $\mathbf{S}$. If $d_{ii} = 0$, then $\mathbf{s}_i = \mathbf{0}$.

If $\mathbf{\Theta} = \mathbf{I}$, then $\mathbf{M}$ in (2.4) has the form $\mathbf{I} + \mathbf{W}\mathbf{W}^*$ with $\mathbf{W} = \mathbf{\Lambda}\mathbf{S}^*\mathbf{L}^{-1/2}$. It follows from the matrix modification formula (2.6) that

$$\begin{aligned}\mathbf{M}^{-1}\mathbf{W} &= (\mathbf{I} - \mathbf{W}(\mathbf{I} + \mathbf{W}^*\mathbf{W})^{-1}\mathbf{W}^*)\mathbf{W} \\ &= \mathbf{W} - \mathbf{W}(\mathbf{I} + \mathbf{W}^*\mathbf{W})^{-1}\mathbf{W}^*\mathbf{W} \\ &= \mathbf{W}(\mathbf{I} + \mathbf{W}^*\mathbf{W})^{-1}.\end{aligned}$$

Hence, we have

$$\mathbf{M}^{-2}\mathbf{W} = \mathbf{W}(\mathbf{I} + \mathbf{W}^*\mathbf{W})^{-2},$$

which implies that

$$\begin{aligned} \boldsymbol{\Lambda}\mathbf{M}^{-2}\boldsymbol{\Lambda}\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S} &= \boldsymbol{\Lambda}\mathbf{M}^{-2}\mathbf{W}\mathbf{L}^{-1/2}\mathbf{S} \\ &= \boldsymbol{\Lambda}\mathbf{W}(\mathbf{I} + \mathbf{W}^*\mathbf{W})^{-2}\mathbf{L}^{-1/2}\mathbf{S} \\ &= \boldsymbol{\Lambda}^2\mathbf{S}^*\mathbf{L}^{-1/2}(\mathbf{I} + \mathbf{W}^*\mathbf{W})^{-2}\mathbf{L}^{-1/2}\mathbf{S} = \boldsymbol{\Lambda}^2\mathbf{D}, \end{aligned} \tag{2.13}$$

where $\mathbf{D}$ is defined in (2.12). By (2.13), $\boldsymbol{\Lambda}^2\mathbf{D}$ is the product of Hermitian matrices $\boldsymbol{\Lambda}\mathbf{M}^{-2}\boldsymbol{\Lambda}$ and $\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}$. The matrices $\boldsymbol{\Lambda}\mathbf{M}^{-2}\boldsymbol{\Lambda}$ and $\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}$ commute by Lemma 2.1. Consequently, $\boldsymbol{\Lambda}^2\mathbf{D}$ is Hermitian. Since $\mathbf{D}$ and $\boldsymbol{\Lambda}$ are also Hermitian, we have

$$(\boldsymbol{\Lambda}^2\mathbf{D}) = (\boldsymbol{\Lambda}^2\mathbf{D})^* = \mathbf{D}\boldsymbol{\Lambda}^2.$$

Since the diagonal elements of $\boldsymbol{\Lambda}$ are distinct, $\mathbf{D}$ is diagonal.

By Lemma 2.1, we can commute the factors $\mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}$ and $\boldsymbol{\Lambda}\mathbf{M}^{-2}\boldsymbol{\Lambda}$ in (2.8). Utilizing (2.13) in (2.8) gives

$$\mu\mathbf{S}^*\mathbf{S} = \boldsymbol{\Lambda}^2\mathbf{D}(\mathbf{I} - \mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}). \tag{2.14}$$

Inserting (2.13) in (2.7) gives

$$\mu\mathbf{S}^*\mathbf{S} = (\mathbf{I} - \mathbf{S}^*\mathbf{L}^{-1}\mathbf{S})\boldsymbol{\Lambda}^2\mathbf{D}. \tag{2.15}$$

We equate the right sides of (2.14) and (2.15) to deduce that

$$(\mathbf{I} - \mathbf{S}^*\mathbf{L}^{-1}\mathbf{S})\boldsymbol{\Lambda}^2\mathbf{D} = \boldsymbol{\Lambda}^2\mathbf{D}(\mathbf{I} - \mathbf{S}^*\mathbf{L}^{-1}\mathbf{S}).$$

Hence, the matrix $(\mathbf{I} - \mathbf{S}^*\mathbf{L}^{-1}\mathbf{S})$ and the diagonal matrix $\boldsymbol{\Lambda}^2\mathbf{D}$ commute, and they share a common set of eigenvectors.

Suppose that $\boldsymbol{\Pi}$ is chosen so that the diagonal elements of $\boldsymbol{\Lambda}_p^2\mathbf{D}_p$ are in decreasing order. Hence, zero diagonal elements in $\mathbf{D}_p$ trail at the end of the diagonal, and the corresponding (trailing) columns of $\mathbf{S}_p$ vanish, as shown at the start of the proof. Suppose that $\lambda_i^2 d_{ii} = \lambda_j^2 d_{jj}$ for i and $j \in [p, q]$. The eigenvectors of $\boldsymbol{\Lambda}_p^2\mathbf{D}_p$ correspond to columns p through q of the identity matrix. Since $\boldsymbol{\Lambda}_p^2\mathbf{D}_p$ and $(\mathbf{I} - \mathbf{S}_p^*\mathbf{L}^{-1}\mathbf{S}_p)$ share a common set of eigenvectors, the corresponding eigenvectors of $(\mathbf{I} - \mathbf{S}_p^*\mathbf{L}^{-1}\mathbf{S}_p)$ are linear combinations of columns p through q of the identity matrix. Hence, $\mathbf{S}_p^*\mathbf{L}^{-1}\mathbf{S}_p$ is block diagonal and the size of the blocks is equal to the number of times a positive diagonal element of $\boldsymbol{\Lambda}_p^2\mathbf{D}_p$ repeats. □

Let $\boldsymbol{\Lambda}_k$ and $\boldsymbol{\Omega}_k$, $k = 1, 2, \ldots$, be nondegenerate matrices which approach limits $\boldsymbol{\Lambda}$ and $\boldsymbol{\Omega}$, respectively. Let $\mathbf{S}_k$ be a solution to (2.2) corresponding to $(\boldsymbol{\Lambda}_k, \boldsymbol{\Omega}_k)$. Such a solution exists for each k since the objective function in (2.2) is continuous when $\boldsymbol{\Omega}$ and $\boldsymbol{\Theta}$ are positive definite and the feasible set is a compact set. By suitable pruning of the sequence $(\boldsymbol{\Lambda}_k, \boldsymbol{\Omega}_k)$ if necessary, there is no loss in generality in assuming that the sequence $\mathbf{S}_k$, $k = 1, 2, \ldots$, converges to a limit $\mathbf{S}$, which is a solution of (2.2) (by the continuity of the objective function). We now show, under suitable hypothesis, that the limit $\mathbf{S}$ is a permutation of a diagonal matrix.

LEMMA 2.5. $\boldsymbol{\Theta} = \mathbf{I}$ [illegible] $\mathbf{S}$ [illegible] (2.2) [illegible] $\mathbf{S}_k$, $k = 1, 2, \ldots$, [illegible] $\boldsymbol{\Lambda}_k$ [illegible]

$\boldsymbol{\Omega}_k$, .. , ,-. -. ,-. , , , , , , $\boldsymbol{\Lambda}^2\mathbf{D}$ -. ,-. , .. , $\mathbf{S}$, , , -
$\boldsymbol{\Pi}_1\boldsymbol{\Sigma}\boldsymbol{\Pi}_2$, . $\boldsymbol{\Pi}_1$ - $\boldsymbol{\Pi}_2$, , , , , , , , $\boldsymbol{\Sigma}$- , ,-. ,

In randomly generated test problems, the "distinct diagonal" property of Lemma 2.5 was always satisfied.

, , , . Since the matrices $\boldsymbol{\Lambda}_k$ and $\boldsymbol{\Omega}_k$ are nondegenerate, the associated matrices $\mathbf{D}_k$ (see (2.12)) are diagonal. Since the $\mathbf{D}_k$ converge to $\mathbf{D}$, the limit $\mathbf{D}$ is diagonal. Since the positive diagonal elements of $\boldsymbol{\Lambda}^2\mathbf{D}$ are distinct, the associated diagonal elements of $\boldsymbol{\Lambda}_k^2\mathbf{D}_k$ are distinct for k sufficiently large. Assume that the columns of $\mathbf{S}$ and the rows of $\boldsymbol{\Lambda}$ are permuted so that the diagonal elements of the limit $\boldsymbol{\Lambda}^2\mathbf{D}$ are in decreasing order. Let p be the number of positive diagonal elements of $\mathbf{D}$. By Lemma 2.4, $\mathrm{Prin}_p(\mathbf{S}_k^*\mathbf{L}_k^{-1}\mathbf{S}_k)$ is diagonal. By Lemma 2.2, $\mathrm{Col}_p(\mathbf{S}_k) = \boldsymbol{\Pi}_{1k}\boldsymbol{\Sigma}_k\boldsymbol{\Pi}_{2k}$. Also, by Lemma 2.4, columns $l+1$ through n of $\mathbf{S}$ vanish. Hence, the limit $\mathbf{S}$ can be expressed as a product $\boldsymbol{\Pi}_1\boldsymbol{\Sigma}\boldsymbol{\Pi}_2$. □

Due to the ordering (1.5), one of the permutations in Lemma 2.3 or Lemma 2.5 can be eliminated.

THEOREM 2.6. , ... $\boldsymbol{\Theta} = \mathbf{I}$, $\boldsymbol{\Lambda} = \mathbf{I}$, (2.2) , , , , ,
$\mathbf{S} = \boldsymbol{\Pi}_1\boldsymbol{\Sigma}\boldsymbol{\Pi}_2$, . $\boldsymbol{\Sigma}$- , , , , $\boldsymbol{\Pi}_i$, , , , , (2.2)

, , , , , , , $\boldsymbol{\sigma}$, , , , $\boldsymbol{\Sigma}$. p , , , , , , , ,
p- , , , , , , , $\boldsymbol{\Lambda}$, $\boldsymbol{\Pi}$, , , , , , p , , $\boldsymbol{\Sigma}$
, , , , , , (2.2) , , , $\mathbf{S} = \boldsymbol{\Pi}\boldsymbol{\Sigma}$
, , . The substitution $\mathbf{S} = \boldsymbol{\Pi}_1\boldsymbol{\Sigma}\boldsymbol{\Pi}_2$ in (2.2) yields the following equivalent problem (assuming $l = n$):

$$\min_{\boldsymbol{\Pi}_1,\boldsymbol{\Pi}_2} \ \mathrm{tr}\,\left((\boldsymbol{\Pi}_2\boldsymbol{\Lambda}\boldsymbol{\Pi}_2^*)\boldsymbol{\Sigma}^*(\boldsymbol{\Pi}_1^*\boldsymbol{\Omega}\boldsymbol{\Pi}_1 + \boldsymbol{\Sigma}\boldsymbol{\Sigma}^*)^{-1}\boldsymbol{\Sigma}(\boldsymbol{\Pi}_2\boldsymbol{\Lambda}\boldsymbol{\Pi}_2^*) + \boldsymbol{\Pi}_2\boldsymbol{\Theta}\boldsymbol{\Pi}_2^*\right)^{-1} \quad \text{subject to } \sum_{i=1}^{N}\sigma_i^2 \le P, \tag{2.16}$$

where N is the minimum of m and n. Here the minimization is over diagonal matrices $\boldsymbol{\Sigma}$ with $\boldsymbol{\sigma}$ on the diagonal, and permutation matrices $\boldsymbol{\Pi}_1$ and $\boldsymbol{\Pi}_2$.

A symmetric permutation such as $\boldsymbol{\Pi}_2\boldsymbol{\Lambda}\boldsymbol{\Pi}_2^*$ interchanges diagonal elements. Hence, (2.16) is equivalent to

$$\min_{\pi_1,\pi_2} \ \sum_{i=1}^{N}\frac{\omega_{\pi_1(i)} + \sigma_i^2}{\theta_{\pi_2(i)}\omega_{\pi_1(i)} + (\theta_{\pi_2(i)} + \lambda_{\pi_2(i)}^2)\sigma_i^2} \quad \text{subject to } \sum_{i=1}^{N}\sigma_i^2 \le P, \quad \pi_1 \in \mathcal{P}_m, \quad \pi_2 \in \mathcal{P}_n, \tag{2.17}$$

where $\mathcal{P}_m$ is the set of bijections of $\{1, 2, \ldots, m\}$ onto itself.

Let $\boldsymbol{\sigma}$ denote an optimal solution of (2.17). If $\lambda_{\pi_2(i)} = 0$, then the associated term in the objective function of (2.17) reduces to $1/\theta_{\pi_2(i)}$, independent of σ_i. In this case $\sigma_i = 0$ is optimal (see Theorem 3.1 and (3.2) in the next section). Hence, the number of positive components of $\boldsymbol{\sigma}$ is less than or equal to the rank of $\boldsymbol{\Lambda}$. Define the set

$$\mathcal{S} = \{i : \sigma_i > 0\},$$

and let $p = |\mathcal{S}|$. The function

$$\frac{\omega + x}{\omega\theta + (\theta + \lambda^2)x}, \quad x > 0$$

is monotone increasing in $\omega \geq 0$ and monotone decreasing in $\lambda \geq 0$. Since the objective function is being minimized in (2.17), it follows that $\omega_{\pi_1(i)}$ is one of the p smallest elements of $\boldsymbol{\omega}$. In the same fashion, if $\boldsymbol{\Theta} = \mathbf{I}$ and $i \in \mathcal{S}$, then $\lambda_{\pi_2(i)}$ is one of the p largest elements of $\boldsymbol{\lambda}$.

Finally, let us consider the case $\boldsymbol{\Lambda} = \mathbf{I}$. The cost function in (2.17) is the sum of two expressions:

$$\sum_{i\in\mathcal{S}} \frac{\omega_{\pi_1(i)} + \sigma_i^2}{\theta_{\pi_2(i)}\omega_{\pi_1(i)} + (\theta_{\pi_2(i)} + \lambda^2_{\pi_2(i)})\sigma_i^2} \quad + \quad \sum_{j\in\mathcal{S}^c} \frac{1}{\theta_{\pi_2(j)}}. \tag{2.18}$$

We now show that if $i \in \mathcal{S}$, but $\theta_{\pi_2(i)}$ is not one of the p smallest elements of $\boldsymbol{\theta}$, then the cost function is decreased by exchanging $\pi_2(i)$ with $\pi_2(j)$ where $j \in \mathcal{S}^c$ and $\theta_{\pi_2(j)} < \theta_{\pi_2(i)}$. Let $\beta_1 = \theta_{\pi_2(i)}$ and $\beta_2 = \theta_{\pi_2(j)}$, and define

$$V_1 = \frac{\omega + \sigma^2}{\omega\beta_1 + \sigma^2(\beta_1 + 1)} + \frac{1}{\beta_2} \quad \text{and} \quad V_2 = \frac{\omega + \sigma^2}{\omega\beta_2 + \sigma^2(\beta_2 + 1)} + \frac{1}{\beta_1}.$$

Here V_1 represents the i and j terms in (2.18) after substituting $\lambda_{\pi_2(i)} = 1$, while V_2 reflects the corresponding terms after the exchange of $\pi_2(i)$ with $\pi_2(j)$. Since $\beta_1 > \beta_2$, it can be shown that $V_1 - V_2 \geq 0$ (cross multiply and cancel terms). Hence, by exchanging $\pi_2(j)$ with $\pi_2(i)$, the cost function is decreased. In summary, if either $\boldsymbol{\Theta} = \mathbf{I}$ or $\boldsymbol{\Lambda} = \mathbf{I}$, then for $i \in \mathcal{S}$, $\lambda_{\pi_2}(i)$ is one of the p largest elements in $\boldsymbol{\lambda}$ while $\theta_{\pi_2(i)}$ and $\omega_{\pi_1(i)}$ are among the p smallest elements in $\boldsymbol{\theta}$ and $\boldsymbol{\omega}$, respectively. Due to the ordering (1.5),

$$\{\pi_1(i) : i \in \mathcal{S}\} \subset \{1, 2, \ldots, p\} \quad \text{and} \quad \{\pi_2(i) : i \in \mathcal{S}\} \subset \{1, 2, \ldots, p\}.$$

Let $\pi_3 \in \mathcal{P}_N$ be chosen so that

$$\sigma_{\pi_3(1)} \geq \sigma_{\pi_3(2)} \geq \ldots \geq \sigma_{\pi_3(N)}.$$

Since $\mathcal{S}$ is the set of indices of positive components of $\boldsymbol{\sigma}$, we have

$$\mathcal{S} = \{\pi_3(i) : i = 1, 2, \ldots, p\}.$$

Define $\hat{\pi}_1 = \pi_1(\pi_3)$, $\hat{\pi}_2 = \pi_2(\pi_3)$, and $\hat{\sigma}_i = \sigma_{\pi_3(i)}$. The optimal cost (2.18) can be written

$$\sum_{i=1}^{p} \frac{\omega_{\hat{\pi}_1(i)} + \hat{\sigma}_i^2}{\theta_{\hat{\pi}_2(i)}\omega_{\hat{\pi}_1(i)} + (\theta_{\hat{\pi}_2(i)} + \lambda^2_{\hat{\pi}_2(i)})\hat{\sigma}_i^2} \quad + \quad \sum_{i>p} \frac{1}{\theta_{\hat{\pi}_2(i)}}.$$

Hence, (2.2) has a solution of the form $\widehat{\mathbf{S}} = \widehat{\boldsymbol{\Pi}}_1\widehat{\boldsymbol{\Sigma}}\widehat{\boldsymbol{\Pi}}_2$ where $\widehat{\boldsymbol{\Pi}}_1$ permutes only the first p rows and $\widehat{\boldsymbol{\Pi}}_2$ permutes only the first p columns of $\widehat{\boldsymbol{\Sigma}}$. Let $\overline{\boldsymbol{\Pi}}_1$ be a permutation matrix which is the same as $\widehat{\boldsymbol{\Pi}}_1$ except that it has been expanded (by an identity matrix) or chopped ($\overline{\boldsymbol{\Pi}}_1 = \mathrm{Prin}_n(\widehat{\boldsymbol{\Pi}}_1)$) to match the number of columns of $\mathbf{S}$. Define $\boldsymbol{\Sigma}' = \widehat{\boldsymbol{\Pi}}_1\widehat{\boldsymbol{\Sigma}}\overline{\boldsymbol{\Pi}}_1^*$. $\boldsymbol{\Sigma}'$ is diagonal since it is a symmetric permutation of a diagonal matrix. Consequently, we have

$$\widehat{\mathbf{S}} = \widehat{\boldsymbol{\Pi}}_1\widehat{\boldsymbol{\Sigma}}\widehat{\boldsymbol{\Pi}}_2 = \widehat{\boldsymbol{\Pi}}_1\widehat{\boldsymbol{\Sigma}}\overline{\boldsymbol{\Pi}}_1^*\overline{\boldsymbol{\Pi}}_1\widehat{\boldsymbol{\Pi}}_2 = \boldsymbol{\Sigma}'\boldsymbol{\Pi},$$

where $\boldsymbol{\Pi} = \overline{\boldsymbol{\Pi}}_1\widehat{\boldsymbol{\Pi}}_2$. In a similar manner, we obtain $\mathbf{S} = \boldsymbol{\Pi}\boldsymbol{\Sigma}$ for a different choice of $\boldsymbol{\Pi}$ and $\boldsymbol{\Sigma}$. □

Based on Theorem 2.6, one of the permutation in (2.17) can be deleted when $\mathbf{\Lambda} = \mathbf{I}$ or $\mathbf{\Theta} = \mathbf{I}$. We delete the permutation π_2 to obtain the following problem:

$$\min_{\mathbf{s},\pi} \sum_{i=1}^{M} \frac{\omega_{\pi(i)} + s_i}{\theta_i \omega_{\pi(i)} + (\theta_i + \lambda_i) s_i} \quad \text{subject to} \quad \sum_{i=1}^{M} s_i \le P, \quad \mathbf{s} \ge \mathbf{0}, \quad \pi \in \mathcal{P}_M, \tag{2.19}$$

where $s_i = \sigma_i^2$ and M is the minimum of m and the rank of $\mathbf{\Lambda}$. If $\mathbf{s}$ and π are solutions of (2.19), then $\mathbf{S} = \mathbf{\Pi\Sigma}$ where $\sigma_i^2 = s_i$ is a solution of (2.2). We now combine Theorem 2.6 with the change of variables (2.1).

COROLLARY 2.7. , $\mathbf{H} = \mathbf{I}$, (1.4) , $\mathbf{P} = \mathbf{V}_w \mathbf{\Sigma\Pi V}_t^*$, $\mathbf{\Pi}$, $\mathbf{\Sigma}$, $\mathbf{\Theta} = \mathbf{I}$ (2.2) , 2.5 , (1.4) , $\mathbf{P} = \mathbf{V}_w \mathbf{\Sigma\Pi U}^*$

As in Theorem 2.6, the factor $\mathbf{\Sigma\Pi}$ in Corollary 2.7 can be replaced by $\mathbf{\Pi\Sigma}$.

3. The optimal $\mathbf{\Sigma}$. Assuming the permutation π in (2.19) is given, let us now consider the problem of optimizing over $\boldsymbol{\sigma}$. To simplify the indexing, the permutation is suppressed and we consider the problem:

$$\min \sum_{i=1}^{M} \frac{\omega_i + s_i}{\theta_i \omega_i + (\theta_i + \lambda_i^2) s_i} \quad \text{subject to} \quad \sum_{i=1}^{M} s_i \le P, \quad \mathbf{s} \ge \mathbf{0}. \tag{3.1}$$

The solution of (3.1) can be expressed in terms of a Lagrange multiplier for the constraint (this solution technique is often called "water filling" [1] in the communication literature).

THEOREM 3.1. , (3.1) ,

$$s_i = \frac{1}{\theta_i + \lambda_i^2} \max\left\{ \sqrt{\frac{\omega_i \lambda_i^2}{\mu}} - \theta_i \omega_i, \ 0 \right\}, \tag{3.2}$$

, μ ,

$$\sum_{i=1}^{M} s_i = P. \tag{3.3}$$

. Since the minimization in (3.1) takes place over a closed, bounded set, there exists a solution. Since the function $(\omega_i + x)/(\theta_i \omega_i + (1 + \lambda_i^2)x)$ is a decreasing function of $x \ge 0$, the objective function decreases when s_i increases. Hence, there exists a solution of (3.1) with the inequality constraint active. Due to the strict convexity of the cost function and the convexity of the constraints, (3.1) has a unique solution.

The first-order optimality conditions (KKT conditions) for an optimal solution of (3.1) are the following: There exists a scalar $\mu \ge 0$ and a vector $\boldsymbol{\nu} \in \mathbb{R}^M$ such that

$$\mu - \nu_i - \frac{\omega_i \lambda_i^2}{(\theta_i \omega_i + (\theta_i + \lambda_i^2) s_i)^2} = 0, \quad \nu_i \ge 0, \quad s_i \ge 0, \quad \text{and} \quad \nu_i s_i = 0, \tag{3.4}$$

$1 \le i \le M$. Any solution of (3.4) is the unique optimal solution of (3.1).

A solution to (3.4) is obtained as follows: Define the function

$$s_i(\mu) = \frac{1}{\theta_i + \lambda_i^2}\left(\sqrt{\frac{\omega_i \lambda_i^2}{\mu}} - \theta_i \omega_i\right)^+. \tag{3.5}$$

Here $x^+ = \max\{x, 0\}$. This particular value for s_i is obtained by setting $\nu_i = 0$ in (3.4), solving for s_i, and replacing the solution by 0 when it is negative. Observe that $s_i(\mu)$ is a decreasing function of μ that approaches $+\infty$ as μ approaches 0 and that approaches 0 as μ tends to $+\infty$. Hence, the equation

$$\sum_{i=1}^{M} s_i(\mu) = P \tag{3.6}$$

has a unique positive solution. Observe that $s_i(\mu) = 0$ if and only if $\mu \geq \lambda_i^2/(\theta_i^2 \omega_i)$. Moreover, if $\mu \geq \lambda_i^2/(\omega_i \theta_i^2)$, then

$$\mu - \frac{\omega_i \lambda_i^2}{(\theta_i \omega_i + (\theta_i + \lambda_i^2) s_i(\mu))^2} = \mu - \frac{\lambda_i^2}{\omega_i \theta_i^2} \geq 0.$$

It follows that the KKT conditions are satisfied by the positive solution of (3.6). ∎

4. Optimal permutation for $\mathbf{\Lambda} = \mathbf{I}$. Starting with this section, we will determine optimal permutations π in (2.19). When $\mathbf{\Lambda} = \mathbf{I}$, the optimal permutation is the identity (due to the ordering (1.5)):

THEOREM 4.1. [illegible] $\mathbf{\Lambda} = \mathbf{I}$ [illegible] $\pi(i) = i$ [illegible] (2.19) [illegible]. Recall that the components of $\boldsymbol{\omega}$ and $\boldsymbol{\theta}$ are in increasing order. Let p be the number of positive components of an optimal $\mathbf{s}$ in (2.19). By Theorem 2.6, an optimal permutation π permutes only the first p components of $\boldsymbol{\omega}$; moreover, $s_i > 0$ for $i \leq p$ and $s_i = 0$ for $i > p$.

Suppose that there exists a permutation π which is optimal in (2.19) and with the property that $\omega_{\pi(i)} > \omega_{\pi(j)}$ for some $i < j \leq p$. Since the components of $\boldsymbol{\theta}$ are in increasing order, $\theta_i \leq \theta_j$. We will show that by interchanging components i and j of π, the objective function value does not increase. Consequently, after a finite number of pairwise exchanges, and without increasing the cost, it can be arranged so that $\omega_{\pi(i)}$ is an increasing function of i. Since $1 \leq \pi(i) \leq p$ for $i \leq p$ and since the components of $\boldsymbol{\omega}$ are in increasing order, we conclude that $\pi(i) = i$ for all i is optimal in (2.19).

Let $\mathbf{s}$ denote a solution of (2.19) associated with the permutation π and suppose that $\omega_{\pi(i)} > \omega_{\pi(j)}$ for some $i < j \leq p$. For notational convenience, let us take $i = 1$, $j = 2$, $\pi(1) = 2$, and $\pi(2) = 1$. Define $\omega_1' = \omega_{\pi(1)} = \omega_2$ and $\omega_2' = \omega_{\pi(2)} = \omega_1$. Due to the optimality of $\mathbf{s}$ and π, $t_1 = s_1 > 0$ and $t_2 = s_2 > 0$ is an optimal solution of the following 2-variable problem:

$$\min_{\mathbf{t}} \sum_{i=1}^{2} \frac{\omega_i' + t_i}{\theta_i \omega_i' + (\theta_i + 1) t_i} \tag{4.1}$$

$$\text{subject to} \quad \sum_{i=1}^{2} t_i \leq \bar{P} := s_1 + s_2, \quad \mathbf{t} \geq \mathbf{0}.$$

We will show that the optimal objective function value for the following unpermuted problem is less than or equal to the objective function value for (4.1):

$$\min_{\mathbf{t}} \sum_{i=1}^{2} \frac{\omega_i + t_i}{\theta_i \omega_i + (\theta_i + 1)t_i} \quad \text{subject to} \quad \sum_{i=1}^{2} t_i \le \bar{P}, \quad \mathbf{t} \ge \mathbf{0}. \tag{4.2}$$

By assumption, the solution of (4.1) is strictly positive. We now show that this implies the solution of (4.2) is strictly positive. By Theorem 3.1, the condition $\mathbf{s} > \mathbf{0}$ is equivalent to

$$1/\sqrt{\mu} > \theta_i \sqrt{\omega_i'}. \tag{4.3}$$

The multiplier μ is given by

$$\frac{1}{\sqrt{\mu}} = \frac{\bar{P} + \sum_{j=1}^{2} \frac{\theta_j \omega_j'}{(\theta_j + 1)}}{\sum_{j=1}^{2} \frac{{\omega_j'}^{1/2}}{(\theta_j + 1)}}. \tag{4.4}$$

Combining (4.3) and (4.4) gives

$$\bar{P} > \frac{\theta_1 \sqrt{\omega_1' \omega_2'}}{(1+\theta_2)} - \frac{\theta_2 \omega_1'}{(1+\theta_2)} = \frac{\theta_1 \sqrt{\omega_1 \omega_2}}{(1+\theta_2)} - \frac{\theta_2 \omega_2}{(1+\theta_2)} \text{ and} \tag{4.5}$$

$$\bar{P} > \frac{\theta_2 \sqrt{\omega_1' \omega_2'}}{(1+\theta_1)} - \frac{\theta_1 \omega_2'}{(1+\theta_1)} = \frac{\theta_2 \sqrt{\omega_1 \omega_2}}{(1+\theta_1)} - \frac{\theta_1 \omega_1}{(1+\theta_1)}. \tag{4.6}$$

Above, the first inequality corresponds to the condition $s_1 > 0$ while the second corresponds to $s_2 > 0$. Similarly, the optimal $\mathbf{t}$ in (4.2) is positive if and only if

$$\bar{P} > \frac{\theta_1 \sqrt{\omega_1 \omega_2}}{(1+\theta_2)} - \frac{\theta_2 \omega_1}{(1+\theta_2)} \text{ and} \tag{4.7}$$

$$\bar{P} > \frac{\theta_2 \sqrt{\omega_1 \omega_2}}{(1+\theta_1)} - \frac{\theta_1 \omega_2}{(1+\theta_1)}. \tag{4.8}$$

Since $\omega_1 \le \omega_2$, (4.6) implies that (4.8) holds. Since $\theta_1 \le \theta_2$, we have

$$\frac{1}{1+\theta_1} \ge \frac{1}{1+\theta_2} \quad \text{and} \quad \frac{\theta_1}{1+\theta_1} \le \frac{\theta_2}{1+\theta_2}. \tag{4.9}$$

Combining this with (4.6) gives

$$\begin{aligned} \bar{P} &> \frac{\theta_2 \sqrt{\omega_1 \omega_2}}{(1+\theta_1)} - \frac{\theta_1 \omega_1}{(1+\theta_1)} \ge \frac{\theta_2 \sqrt{\omega_1 \omega_2}}{(1+\theta_2)} - \frac{\theta_2 \omega_1}{(1+\theta_2)} \\ &\ge \frac{\theta_1 \sqrt{\omega_1 \omega_2}}{(1+\theta_2)} - \frac{\theta_2 \omega_1}{(1+\theta_2)}. \end{aligned}$$

Hence, (4.7) is satisfied. Since both (4.7) and (4.8) are satisfied, it follows that the solution to (4.2) is strictly positive.

Using the solution given by Theorem 3.1 and the multiplier (4.4), we obtain the following expression for the optimal objective function value C' for (4.1) (the algebra is omitted):

$$\begin{aligned} C' &= \frac{1}{1+\theta_1} + \frac{1}{1+\theta_2} + \frac{\left(\dfrac{\sqrt{\omega_1'}}{(1+\theta_1)} + \dfrac{\sqrt{\omega_2'}}{(1+\theta_2)}\right)^2}{\bar{P} + \dfrac{\theta_1\omega_1'}{(1+\theta_1)} + \dfrac{\theta_2\omega_2'}{(1+\theta_2)}} \\ &= \frac{1}{1+\theta_1} + \frac{1}{1+\theta_2} + \frac{\left(\dfrac{\sqrt{\omega_2}}{(1+\theta_1)} + \dfrac{\sqrt{\omega_1}}{(1+\theta_2)}\right)^2}{\bar{P} + \dfrac{\theta_1\omega_2}{(1+\theta_1)} + \dfrac{\theta_2\omega_1}{(1+\theta_2)}}. \end{aligned} \tag{4.10}$$

Similarly, the optimal objective function value C for (4.2) is obtained by erasing the primes in (4.10):

$$C = \frac{1}{1+\theta_1} + \frac{1}{1+\theta_2} + \frac{\left(\dfrac{\sqrt{\omega_1}}{(1+\theta_1)} + \dfrac{\sqrt{\omega_2}}{(1+\theta_2)}\right)^2}{\bar{P} + \dfrac{\theta_1\omega_1}{(1+\theta_1)} + \dfrac{\theta_2\omega_2}{(1+\theta_2)}}. \tag{4.11}$$

We will show that $C \le C'$.

Recall the following majorization property [7, p. 141]: If $\mathbf{a}$ and $\mathbf{b} \in \mathbb{R}^n$, then

$$\sum_{i=1}^n a_{[i]} b_{[n-i+1]} \le \sum_{i=1}^n a_i b_i \le \sum_{i=1}^n a_{[i]} b_{[i]},$$

where $a_{[i]}$ denotes the ith largest component of $\mathbf{a}$. We apply the inequality (4.9) and $\omega_1 \le \omega_2$ and the majorization property to the numerators in (4.10) and (4.11) to obtain

$$\left(\frac{\sqrt{\omega_1}}{1+\theta_1} + \frac{\sqrt{\omega_2}}{1+\theta_2}\right)^2 \le \left(\frac{\sqrt{\omega_2}}{1+\theta_1} + \frac{\sqrt{\omega_1}}{1+\theta_2}\right)^2 = \left(\frac{\sqrt{\omega_1'}}{1+\theta_1} + \frac{\sqrt{\omega_2'}}{1+\theta_2}\right)^2.$$

Also, by (4.9) and the majorization property, the denominators in (4.10) and (4.11) satisfy

$$\left(\frac{\theta_1\omega_1}{1+\theta_1} + \frac{\theta_2\omega_2}{1+\theta_2}\right) \ge \left(\frac{\theta_1\omega_2}{1+\theta_1} + \frac{\theta_2\omega_1}{1+\theta_2}\right).$$

Hence, $C \le C'$. This completes the proof. □

5. Optimal permutation for $\boldsymbol{\Theta} = \mathbf{I}$ and large power. When $\boldsymbol{\Theta} = \mathbf{I}$, the optimal permutation depends on P. In this section, we determine the optimal permutation when P is large, while the next section analyzes the case of small P. As shown in Theorem 2.6, the solution to (2.2) can written as either $\boldsymbol{\Pi\Sigma}$ or $\boldsymbol{\Sigma\Pi}$. When

$\boldsymbol{\Theta} = \mathbf{I}$, the analysis is simpler when we take $\mathbf{S} = \boldsymbol{\Sigma}\boldsymbol{\Pi}$, in which case (2.2) reduces to (see (2.17))

$$\min_{\mathbf{s},\pi} \sum_{i=1}^{M} \frac{\omega_i + s_i}{\omega_i + (1+\lambda_{\pi(i)}^2)s_i} \tag{5.1}$$

$$\text{subject to} \quad \sum_{i=1}^{M} s_i \le P, \quad \mathbf{s} \ge \mathbf{0}, \quad \pi \in \mathcal{P}_M,$$

where M is the minimum of m and the rank of $\boldsymbol{\Lambda}$.

THEOREM 5.1. [illegible] π [illegible] (5.1) [illegible]

$$\frac{\lambda_{\pi(1)}}{1+\lambda_{\pi(1)}^2} \ge \frac{\lambda_{\pi(2)}}{1+\lambda_{\pi(2)}^2} \ge \cdots \ge \frac{\lambda_{\pi(M)}}{1+\lambda_{\pi(M)}^2}. \tag{5.2}$$

In the noise term $\boldsymbol{\eta}$ vanishes, the optimal permutation arranged the singular values in increasing order for large P. Since the function $\lambda/(1+\lambda^2)$ is monotone increasing for $\lambda \in [0,1]$ and monotone decreasing for $\lambda > 1$, it follows that when $\boldsymbol{\eta}$ is included in the model and when its covariance is $\mathbf{I}$, the singular values smaller than one are in decreasing order, while the singular values larger than one are in increasing order. Hence, when $\boldsymbol{\Theta} = \mathbf{I}$, the solution of the problem when $\boldsymbol{\eta}$ is included in the model is fundamentally different from the solution when the noise $\boldsymbol{\eta}$ is neglected.

[illegible]. Referring to Theorem 3.1, as P tends to infinity, the optimal multiplier μ tends to zero; consequently, as P tends to infinity, all the components of the optimal $\mathbf{s}$ tend to infinity. We assume that P is large enough that for any permutation of the components of $\boldsymbol{\lambda}$, the $\mathbf{s}$ that satisfies (3.2) and (3.3) is strictly positive.

So far, we have assumed that the components of $\boldsymbol{\lambda}$ are in decreasing order (1.5). In the proof of this theorem, it is more convenient to assume that the components of $\boldsymbol{\lambda}$ are arranged in the order (5.2). In other words,

$$\frac{\lambda_1}{1+\lambda_1^2} \ge \frac{\lambda_2}{1+\lambda_2^2} \ge \cdots \ge \frac{\lambda_M}{1+\lambda_M^2}.$$

Let π by an optimal permutation in (5.1) and define $\lambda_i' = \lambda_{\pi(i)}$. Suppose for some $i < j$, we have $\lambda_i'/(1+\lambda_i'^2) < \lambda_j'/(1+\lambda_j'^2)$. We will show that by interchanging the values of $\pi(i)$ and $\pi(j)$, the objective function cannot increase. Hence, after a finite series of pairwise exchanges, we obtain (5.2) without increasing the objective function.

As in Theorem 4.1, we assume for notational convenience that $i = 1$, $j = 2$, $\pi(1) = 2$, and $\pi(2) = 1$. To summarize, we have

$$\omega_1 \le \omega_2, \quad \lambda_1' = \lambda_2, \quad \lambda_2' = \lambda_1, \quad \text{and} \quad \frac{\lambda_1}{1+\lambda_1^2} > \frac{\lambda_2}{1+\lambda_2^2}. \tag{5.3}$$

If $\mathbf{s}$ is a solution of (5.1), then $t_1 = s_1$ and $t_2 = s_2$ is a solution to

$$\min_{,\pi} \sum_{i=1}^{2} \frac{\omega_i + t_i}{\omega_i + (1+\lambda_i'^2)t_i} \tag{5.4}$$

$$\text{subject to} \quad \sum_{i=1}^{2} t_i \le \bar{P} := s_1 + s_2, \quad \mathbf{t} \ge \mathbf{0}.$$

The unpermuted problem is obtained by erasing the prime:

$$\min_{,\pi} \sum_{i=1}^{2} \frac{\omega_i + t_i}{\omega_i + (1+\lambda_i{}^2)t_i} \quad \text{subject to} \quad \sum_{i=1}^{2} t_i \le \bar{P}, \quad \mathbf{t} \ge \mathbf{0}. \tag{5.5}$$

If $\omega_1 = \omega_2$, then the optimal cost C' for the permuted problem (5.4) equals the optimal cost C for the unpermuted problem since the objective functions are identical. Hence, by interchanging the values of $\pi(1)$ and $\pi(2)$, the objective function value does not change.

Now, let us consider the case where $\omega_1 < \omega_2$. We define

$$N' = \frac{\lambda_1'\sqrt{\omega_1}}{1+\lambda_1'{}^2} + \frac{\lambda_2'\sqrt{\omega_2}}{1+\lambda_2'{}^2} \quad \text{and} \quad D' = \frac{\omega_1}{1+\lambda_1'{}^2} + \frac{\omega_2}{1+\lambda_2'{}^2} = \frac{\omega_1}{1+\lambda_2{}^2} + \frac{\omega_2}{1+\lambda_1{}^2}.$$

Parameters N and D are obtained by erasing the primes in N' and D'. With this notation the multiplier μ given by Theorem 3.1 for the problem (5.4) can be expressed

$$\frac{1}{\sqrt{\mu}} = \frac{\bar{P} + D'}{N'}. \tag{5.6}$$

Moreover, the optimal objective function value C' for (5.4) is

$$C' = \frac{1}{1+\lambda_1'{}^2} + \frac{1}{1+\lambda_2'{}^2} + \frac{N'^2}{\bar{P}+D'} = \frac{1}{1+\lambda_1{}^2} + \frac{1}{1+\lambda_2{}^2} + \frac{N'^2}{\bar{P}+D'}. \tag{5.7}$$

Similarly, the optimal objective function value C for the unpermuted problem is obtained by erasing the primes:

$$C = \frac{1}{1+\lambda_1{}^2} + \frac{1}{1+\lambda_2{}^2} + \frac{N^2}{\bar{P}+D}.$$

The inequality $C < C'$ is equivalent to

$$N^2(\bar{P}+D') < N'^2(\bar{P}+D).$$

Rearranging this, we have

$$\bar{P}(N+N')(N-N') = \bar{P}(N^2 - N'^2) < N'^2 D - N^2 D'.$$

Since $N + N' > 0$, it follows that

$$N - N' \le \frac{N'^2 D - N^2 D'}{\bar{P}(N+N')}. \tag{5.8}$$

By the definitions of N and N', we obtain

$$N - N' = (\sqrt{\omega_1} - \sqrt{\omega_2})\left(\frac{\lambda_1}{1+\lambda_1^2} - \frac{\lambda_2}{1+\lambda_2^2}\right) < 0$$

since $\omega_1 < \omega_2$ and (5.3) holds. Since $N - N' < 0$, it follows that (5.8) holds for P sufficiently large. Equivalently, for P sufficiently large, $C < C'$. This completes the proof. ∎

6. Optimal permutation for $\Theta = \mathbf{I}$ and small power. We now evaluate the optimal solution to (5.1) when P is small.

THEOREM 6.1. [illegible] L [illegible] γ_1 [illegible] λ_1 [illegible] ϵ [illegible]

$$\epsilon = \min\left\{\left|\frac{\sqrt{\omega_k}(\lambda_i\sqrt{\omega_l} - \lambda_j\sqrt{\omega_k})}{(1+\lambda_i^2)\lambda_j}\right| : \ i,j,k,l \in [1,M], \ \ \lambda_i\sqrt{\omega_l} \neq \lambda_j\sqrt{\omega_k}\right\}.$$

[illegible] $P < \epsilon$ [illegible] (5.1)[illegible]

$$s_i = P/L, \quad 1 \le i \le L, \quad s_i = 0, \quad i > L, \quad \pi(i) = i \text{ [illegible] } i. \tag{6.1}$$

[illegible]. Let π and $\mathbf{s}$ be optimal in (5.1) and define $\lambda'_i = \lambda_{\pi(i)}$. We now show that if $s_i > 0$, $s_j > 0$, and $P < \epsilon$, then we have $\lambda'_i\sqrt{\omega_j} = \lambda'_j\sqrt{\omega_i}$. To simplify the notation, we take $i = 1$ and $j = 2$, but in general, i and j are distinct integers between 1 and M. Since $\mathbf{s}$ yields an optimal solution of (5.1), it follows that an optimal solution for the following reduced problem is $t_1 = s_1$ and $t_2 = s_2$:

$$\begin{aligned} &\min_{t_1,t_2} \ \ \frac{\omega_1 + t_1}{\omega_1 + (1+{\lambda'_1}^2)t_1} + \frac{\omega_2 + t_2}{\omega_2 + (1+{\lambda'_2}^2)t_2} \\ &\text{subject to} \ \ t_1 + t_2 = \bar{P} := s_1 + s_2, \quad \mathbf{t} \ge \mathbf{0}. \end{aligned} \tag{6.2}$$

By Theorem 3.1, the t_i can be expressed:

$$t_i = \frac{1}{1+{\lambda'_i}^2}\left(\lambda'_i\sqrt{\frac{\omega_i}{\mu}} - \omega_i\right), \tag{6.3}$$

where μ is obtained from the condition $t_1 + t_2 = \bar{P}$:

$$\mu = \left(\frac{\displaystyle\sum_{i=1}^{2}\frac{\lambda'_i\sqrt{\omega_i}}{1+{\lambda'_i}^2}}{\bar{P} + \displaystyle\sum_{i=1}^{2}\frac{\omega_i}{1+{\lambda'_i}^2}}\right)^2.$$

By (6.3), $t_i > 0$ is equivalent to

$${\lambda'_i}^2 > \omega_i\mu = \omega_i\left(\frac{\displaystyle\sum_{i=1}^{2}\frac{\lambda'_i\sqrt{\omega_i}}{1+{\lambda'_i}^2}}{\bar{P} + \displaystyle\sum_{i=1}^{2}\frac{\omega_i}{1+{\lambda'_i}^2}}\right)^2.$$

We rearrange this to obtain

$$\lambda'_i\left(\bar{P} + \frac{\omega_1}{1+{\lambda'_1}^2} + \frac{\omega_2}{1+{\lambda'_2}^2}\right) > \sqrt{\omega_i}\left(\frac{\lambda'_1\sqrt{\omega_1}}{1+{\lambda'_1}^2} + \frac{\lambda'_2\sqrt{\omega_2}}{1+{\lambda'_2}^2}\right),$$

which reduces to

$$\bar{P}\lambda'_i > \sqrt{\omega_i}\left(\frac{\lambda'_1\sqrt{\omega_1}}{1+{\lambda'_1}^2} + \frac{\lambda'_2\sqrt{\omega_2}}{1+{\lambda'_2}^2}\right) - \lambda'_i\left(\frac{\omega_1}{1+{\lambda'_1}^2} + \frac{\omega_2}{1+{\lambda'_2}^2}\right).$$

Setting $i = 1$ and $i = 2$, respectively, we get

$$\bar{P} > \frac{\sqrt{\omega_2}(\lambda_2'\sqrt{\omega_1} - \lambda_1'\sqrt{\omega_2})}{(1+{\lambda_2'}^2)\lambda_1'}$$

and

$$\bar{P} > \frac{\sqrt{\omega_1}(\lambda_1'\sqrt{\omega_2} - \lambda_2'\sqrt{\omega_1})}{(1+{\lambda_1'}^2)\lambda_2'}.$$

Unless $\lambda_1'\sqrt{\omega_2} = \lambda_2'\sqrt{\omega_1}$, the condition $\epsilon \geq P \geq \bar{P}$ is violated. Hence, $\lambda_1'\sqrt{\omega_2} = \lambda_2'\sqrt{\omega_1}$, and in general, $\lambda_i'\sqrt{\omega_j} = \lambda_j'\sqrt{\omega_i}$ for each i and j with $s_i > 0$ and $s_j > 0$.

By the ordering (1.5), we have $\omega_1 \leq \omega_2$. If $\omega_1 < \omega_2$, then we will show that by exchanging $\pi(1)$ and $\pi(2)$ in (5.1), the value of the objective function is strictly decreased, which violates the optimality of π. In general, whenever $s_i > 0$ and $s_j > 0$, we have $\omega_i = \omega_j$. Since $\lambda_i'\sqrt{\omega_j} = \lambda_j'\sqrt{\omega_i}$ for each i and j for which $s_i > 0$ and $s_j > 0$, it follows that $\lambda_i' = \lambda_j'$. By Theorem 2.6, if $\mathbf{s}$ has p positive components, then π permutes only the p largest components of $\boldsymbol{\lambda}$. Since the components of $\boldsymbol{\lambda}$ and $\boldsymbol{\omega}$ associated with the positive components of $\mathbf{s}$ are all equal, we conclude that the positive components of $\mathbf{s}$ correspond to the minimum of the multiplicities of λ_1 and ω_1, and $\pi(i) = i$ for all i is optimal. Since the L largest components of $\boldsymbol{\lambda}$ and the L smallest components of $\boldsymbol{\omega}$ are all equal, it follows from Theorem 3.1 that the first L components of $\mathbf{s}$ are all equal. Since the s_i sum to P, $s_i = P/L$ for $1 \leq i \leq L$ and $s_i = 0$ for $i > L$, which completes the proof.

Now, let us prove that when $\omega_1 < \omega_2$, the exchange of $\pi(1)$ and $\pi(2)$ yields a strictly smaller value of the objective function, violating the optimality of π (hence, $\omega_1 = \omega_2$). By (5.7) the optimal objective function value C' for (6.2) is

$$C' = \frac{\left(\dfrac{\lambda_1'\sqrt{\omega_1}}{1+{\lambda_1'}^2} + \dfrac{\lambda_2'\sqrt{\omega_2}}{1+{\lambda_2'}^2}\right)^2}{\bar{P} + \dfrac{\omega_1}{1+{\lambda_1'}^2} + \dfrac{\omega_2}{1+{\lambda_2'}^2}} + \frac{1}{1+{\lambda_1'}^2} + \frac{1}{1+{\lambda_2'}^2}. \tag{6.4}$$

Since $\lambda_1'\sqrt{\omega_2} = \lambda_2'\sqrt{\omega_1}$, (6.4) can be written

$$\begin{aligned} C' &= \frac{\omega_1{\lambda_1'}^2\left(\dfrac{1}{1+{\lambda_1'}^2} + \dfrac{{\lambda_2'}^2}{{\lambda_1'}^2(1+{\lambda_2'}^2)}\right)^2}{\bar{P} + \omega_1\left(\dfrac{1}{1+{\lambda_1'}^2} + \dfrac{{\lambda_2'}^2}{{\lambda_1'}^2(1+{\lambda_2'}^2)}\right)} + \frac{1}{1+{\lambda_1'}^2} + \frac{1}{1+{\lambda_2'}^2} \\ &= \frac{\omega_1{\lambda_1'}^2x^2}{\bar{P}+\omega_1 x} + \frac{1}{1+{\lambda_1'}^2} + \frac{1}{1+{\lambda_2'}^2} \\ &= {\lambda_1'}^2x - \frac{\bar{P}{\lambda_1'}^2x}{\bar{P}+\omega_1 x} + \frac{1}{1+{\lambda_1'}^2} + \frac{1}{1+{\lambda_2'}^2} \\ &= {\lambda_1'}^2x - \frac{\bar{P}{\lambda_1'}^2}{\omega_1} + \frac{\bar{P}^2{\lambda_1'}^2}{\omega_1(\bar{P}+\omega_1 x)} + \frac{1}{1+{\lambda_1'}^2} + \frac{1}{1+{\lambda_2'}^2}, \end{aligned}$$

where

$$x = \frac{1}{1+{\lambda_1'}^2} + \frac{{\lambda_2'}^2}{{\lambda_1'}^2(1+{\lambda_2'}^2)}.$$

Exploiting the identity

$$\lambda_1'^{\,2} x + \frac{1}{1+\lambda_1'^{\,2}} + \frac{1}{1+\lambda_2'^{\,2}} = 2,$$

it follows that

$$C' = 2 - \frac{\bar{P}\lambda_1'^{\,2}}{\omega_1} + \frac{\bar{P}^2\lambda_1'^{\,2}}{\omega_1(\bar{P}+\omega_1 x)}.$$

Exchanging the values of $\pi(1)$ and $\pi(2)$ leads to the following permuted version of (6.2):

$$\begin{aligned} &\min_{t_1,t_2} \quad \frac{\omega_1 + t_1}{\omega_1 + (1+\lambda_2'^{\,2})t_1} + \frac{\omega_2 + t_2}{\omega_2 + (1+\lambda_1'^{\,2})t_2} \\ &\text{subject to} \quad t_1 + t_2 = \bar{P}, \quad t_1 \geq 0, \quad t_2 \geq 0. \end{aligned} \tag{6.5}$$

The choice $t_1 = \bar{P}$ and $t_2 = 0$ is feasible in (6.5). Hence, an upper bound C^+ for the optimal objective function value is

$$C^+ = 1 + \frac{\omega_1 + \bar{P}}{(\omega_1 + \bar{P}) + \bar{P}\lambda_2'^{\,2}} = 2 - \frac{\bar{P}\lambda_2'^{\,2}}{\omega_1 + \bar{P}(1+\lambda_2'^{\,2})} = 2 - \frac{\bar{P}\lambda_2'^{\,2}}{\omega_1} + O(\bar{P}^2).$$

Since $\omega_1 < \omega_2$, it follows from the condition $\omega_1\lambda_2'^{\,2} = \omega_2\lambda_1'^{\,2}$ that $\lambda_1'^{\,2} < \lambda_2'^{\,2}$. Comparing C' and C^+, we conclude that for P sufficiently small, $C^+ < C'$, which contradicts the optimality of C'. This completes the proof. □

7. Numerical experiments. Some small test problems were solved to see how P should be chosen in order to observe Theorems 5.1 and 6.1, and to evaluate a conjecture concerning the structure of the optimal permutation in general. In the first experiment, we randomly generate $\omega_i \in [0,1]$ and $\lambda_i \in [0,2]$ in the special case $l = m = n = 10$. The interval $[0,2]$ for $\boldsymbol{\lambda}$ was chosen so that λ_i would be generated on each side of the maximum $x = 1$ for the function $x/(1+x^2)$. These dimensions are small enough that we can enumerate all permutations $\pi \in \mathcal{P}_5$ and select the best. Table 7.1 shows how many times the solution given in Theorems 5.1 or 6.1 is correct for 100 randomly generated problems and for various choices of P.

In another series of experiments, we evaluated the quality of the following M permutations: For each $k = 1, 2, \ldots, M$, let π_k be the permutation defined by

$$\pi_k(i) = i \text{ for } i > k, \quad \pi_k(i) \in [1,k] \text{ for } i \in [1,k], \tag{7.1}$$

TABLE 7.1

and

$$\frac{\lambda_{\pi_k(1)}}{1+\lambda^2_{\pi_k(1)}} \geq \frac{\lambda_{\pi_k(2)}}{1+\lambda^2_{\pi_k(2)}} \geq \ldots \geq \frac{\lambda_{\pi_k(k)}}{1+\lambda^2_{\pi_k(k)}}. \tag{7.2}$$

We optimized (5.1) with the added constraint that π was one of the M permutation π_k, $k = 1, 2, \ldots, M$. In Table 7.2 we consider the same set of test problems used for Table 7.1, and we evaluate the number of times that one of these M permutation yields the exact minimizer. When none of these M permutations yields the exact minimum, we evaluate the relative error in the cost (best approximate cost minus exact cost divided by the exact cost). The average relative error for the best inexact approximation in the set π_k, $1 \leq k \leq M$, is shown in the last column of Table 7.2. Thus, one of the π_k often yields the optimal solution of (5.1). When none of the π_k approximations is optimal, the best approximate cost is nearly optimal.

The motivation for considering the permutations π_k is the following: By Theorem 2.6, there exists an integer $p \geq 1$ (p is the number of positive components of $\boldsymbol{\sigma}$ in an optimal solution) with the property that $\pi(i) = i$ when π is optimal in (5.1) and $i > p$. Hence, we try M different permutations of the form (7.1). When the power P is sufficiently large, we know that the permutation (5.2) is optimal. Thus, we try the same ordering, but applied to the k largest singular values as in (7.2).

8. Conclusions. We analyze the optimization problem (1.4) which arises in linear Bayesian estimation in the presence of noise, and which is relevant to multisensor data fusion problems and wireless communication. Unlike our earlier work [2, 5], we now take into account the noise term $\boldsymbol{\eta}$ in the model (1.1).

By letting the covariance of $\boldsymbol{\eta}$ tends to zero, the results given in the present paper include the results given in [2, 5]. In particular, if we take $\mathbf{N} = \alpha\mathbf{I}$ in (1.3), then a rescaling of $\mathbf{P}$ and $\mathbf{H}$ yields (1.4). In the rescaled problem, the singular values of $\mathbf{H}$ are divided by $\sqrt{\alpha}$. Hence, as α tends to zero, all the singular values in the rescaled problem become larger than 1. Since the function $x/(1+x^2)$ is monotone decreasing for $x > 1$, we deduce that for P sufficiently large, the optimal permutation arranges the singular values in increasing order, the same ordering derived in [2] when the noise $\boldsymbol{\eta}$ was neglected.

For general P, computing the optimal permutation π in (5.1) may not be easy. Nonetheless, we exhibit in section 7 a set of M permutations $\pi_1, \pi_2, \ldots, \pi_M$ which often contains the optimal permutation.

In the case $\mathbf{H} = \mathbf{I}$, the analysis in this paper also yields the results in [5] by taking $\mathbf{N} = \alpha\mathbf{I}$ and letting α tend to zero. It is interesting to note that the analysis in [5] for the case $\boldsymbol{\eta} = \mathbf{0}$ was much more difficult than the analysis of the case $\boldsymbol{\eta} \neq \mathbf{0}$ considered in this paper. Hence, by including the noise term $\boldsymbol{\eta}$ in the model and by letting $\boldsymbol{\eta}$ tend to $\mathbf{0}$, we could recover with less effort the solution given in [5].

9. Appendix. First-order optimality condition. We evaluate the derivative of the Lagrangian (2.5) and set it to zero. Since tr $(\mathbf{A} + \mathbf{A}^*) = 2(\text{Real } [\text{tr } (\mathbf{A})])$ and tr $(\mathbf{AB}) = \text{tr } (\mathbf{BA})$, it follows that the derivative of $\mathbf{SS}^*$ in the direction $\boldsymbol{\delta}\mathbf{S}$ is

$$\text{tr } (\mathbf{S}\boldsymbol{\delta}\mathbf{S}^* + \boldsymbol{\delta}\mathbf{S}\mathbf{S}^*) = 2(\text{Real } [\text{tr } \boldsymbol{\delta}\mathbf{S}\mathbf{S}^*]) = 2(\text{Real } [\text{tr } \mathbf{S}^*\boldsymbol{\delta}\mathbf{S}]). \tag{9.1}$$

For any invertible matrix $\mathbf{M}$, we have

$$\frac{d\mathbf{M}^{-1}}{d\mathbf{T}} = -\mathbf{M}^{-1}\left(\frac{d\mathbf{M}}{d\mathbf{T}}\right)\mathbf{M}^{-1}. \tag{9.2}$$

We equate to zero the derivative of the Lagrangian in the direction $\boldsymbol{\delta}\mathbf{S}$ and utilize (9.1) and (9.2) to obtain

$$\text{Real } \left[\text{tr } \left((\mathbf{I} - \mathbf{S}^*\mathbf{L}^{-1}\mathbf{S})\boldsymbol{\Lambda}\mathbf{M}^{-2}\boldsymbol{\Lambda}\mathbf{S}^*\mathbf{L}^{-1} - \mu\mathbf{S}^*\right)\boldsymbol{\delta}\mathbf{S}\right] = \mathbf{0},$$

where $\mathbf{L}$ and $\mathbf{M}$ are defined in (2.4). Inserting

$$\boldsymbol{\delta}\mathbf{S} = \left((\mathbf{I} - \mathbf{S}^*\mathbf{L}^{-1}\mathbf{S})\boldsymbol{\Lambda}\mathbf{M}^{-2}\boldsymbol{\Lambda}\mathbf{S}^*\mathbf{L}^{-1} - \mu\mathbf{S}^*\right)^*$$

gives

$$(\mathbf{I} - \mathbf{S}^*\mathbf{L}^{-1}\mathbf{S})\boldsymbol{\Lambda}\mathbf{M}^{-2}\boldsymbol{\Lambda}\mathbf{S}^*\mathbf{L}^{-1} = \mu\mathbf{S}^*.$$

Acknowledgments. We thank the reviewers for their comments and suggestions which led to a more precise and complete paper.

THE EFFECT OF AGGRESSIVE EARLY DEFLATION ON THE CONVERGENCE OF THE QR ALGORITHM*

DANIEL KRESSNER†

Abstract. Aggressive early deflation has proven to significantly enhance the convergence of the QR algorithm for computing the eigenvalues of a nonsymmetric matrix. One purpose of this paper is to point out that this deflation strategy is equivalent to extracting converged Ritz vectors from certain Krylov subspaces. As a special case, the single-shift QR algorithm enhanced with aggressive early deflation corresponds to a Krylov subspace method whose starting vector undergoes a Rayleigh-quotient iteration. It is shown how these observations can be used to derive improved convergence bounds for the QR algorithm.

Key words. QR algorithm, deflation, Krylov subspace, convergence

1. Introduction.

Let A be a complex $n \times n$ matrix. The aim of the QR algorithm is to compute a Schur decomposition $S = Q^{\mathsf{H}}AQ$, where $Q \in \mathbb{C}^{n\times n}$ is unitary and $S \in \mathbb{C}^{n\times n}$ is upper triangular. The QR algorithm, as introduced by Francis [13, 14] and Kublanovskaya [20], is an iterative process that generates a sequence of unitarily similar matrices $A_0 \leftarrow A, A_1, A_2, \ldots$. Before each iteration, m so-called shifts $\sigma_1, \ldots, \sigma_m \in \mathbb{C}$ are skillfully chosen, defining the shift polynomial $p_i(\lambda) = (\lambda - \sigma_1)\cdots(\lambda - \sigma_m)$. The QR decomposition of $p_i(A_{i-1})$ determines the unitary similarity transformation that yields the next iterate:

$$\begin{aligned} p_i(A_{i-1}) &= Q_i R_i, \qquad \text{(QR decomposition)}, \\ A_i &\leftarrow Q_i^{\mathsf{H}} A_{i-1} Q_i. \end{aligned} \tag{1}$$

Any practically viable implementation of (1) contains at least two further ingredients: initial reduction to condensed form and deflation.

In the following, we assume that A is already in upper Hessenberg form [15]. It is well known that this condensed form is preserved during the iteration (1) and helps greatly to reduce its computational cost. To be more precise, the implicit Q theorem [15] implies that if the Hessenberg matrix A_{i-1} is unreduced (all subdiagonal entries are different from zero), then (1) is equivalent to reducing $V^{\mathsf{H}}A_{i-1}V$ back to Hessenberg form, where V is a unitary matrix that maps the first column of $p_i(A_{i-1})$ to a scalar multiple of the first unit vector e_1. Such an implicit shifted QR iteration requires only $O(mn^2)$ flops (floating point operations), compared to $O(mn^3)$ flops needed by a literal implementation of (1).

As the QR algorithm proceeds, one or more subdiagonal entries of A_i are expected to approach zero. For example, if $\sigma_1, \ldots, \sigma_m$ are chosen to be the eigenvalues of the trailing $m \times m$ principal submatrix of the current iterate, then—under some mild extra assumptions—the $(n-m+1, n-m)$ subdiagonal entry of A_i converges quadratically

to zero [31]. The classical deflation criterion is to consider a subdiagonal element $a^{(i)}_{l,l+1}$ negligible if it satisfies

$$|a^{(i)}_{l,l+1}| \leq \mathbf{u}\big(|a^{(i)}_{l,l}| + |a^{(i)}_{l+1,l+1}|\big), \tag{2}$$

where $a^{(i)}_{kl}$ denotes the (k,l) entry of A_i and $\mathbf{u}$ the unit roundoff. A negligible subdiagonal entry is set to zero, effectively bringing A_i to block upper triangular form:

$$A_i = \begin{bmatrix} A^{(i)}_{11} & A^{(i)}_{12} \\ 0 & A^{(i)}_{22} \end{bmatrix}, \quad A^{(i)}_{11} \in \mathbb{C}^{l\times l}, \quad A^{(i)}_{22} \in \mathbb{C}^{(n-l)\times(n-l)}.$$

This allows one to apply all subsequent QR iterations to the diagonal blocks $A^{(i)}_{11}$ and $A^{(i)}_{22}$ separately and therefore deflate the problem of computing the Schur decomposition of an $n \times n$ matrix into two smaller problems. The QR algorithm is said to have converged when all deflated diagonal blocks are 1×1.

The state-of-the-art LAPACK implementation of the QR algorithm attains high performance by making use of level 3 BLAS operations [6, 21] and employing additional deflation criteria going far beyond the classical criterion (2). Specifically, the [illegible] strategy developed by Braman, Byers, and Mathias [7] often detects converged eigenvalues much earlier than (2) and therefore significantly decreases the overall number of QR iterations needed until convergence. In this paper, we approach this deflation technique from a rather different direction, based on Krylov subspace relations implicitly maintained during the QR algorithm. It turns out that aggressive early deflation amounts to finding and extracting converged Ritz pairs from a Krylov subspace $\mathcal{K}_w(A^{\mathsf{H}}, u_n)$, where u_n denotes the last column of the accumulated unitary transformation matrix. This not only complements the analyses in [7, 33], partially explaining the remarkable success of aggressive early deflation, but also allows for improved convergence bounds. In particular, we can combine the classical convergence theory of the QR algorithm [31] with the convergence of Krylov subspaces to an invariant subspace [4, 5, 25]. The obtained convergence bounds clearly exhibit the benefits of aggressive early deflation.

The rest of this paper is organized as follows. In section 2, we explore different Krylov subspaces associated with the QR algorithm. The Krylov–Schur algorithm, a reliable means to extract and lock converged Ritz pairs from these Krylov subspaces, is recalled in section 3. Reinterpreting this algorithm in terms of unitary transformations on the QR iterate A_i in section 4 reveals its equivalence to aggressive early deflation. Finally, in section 5 we use this relationship to derive convergence bounds for the QR algorithm with aggressive early deflation. In the following, $\|\cdot\|$ denotes the 2-norm of a vector or matrix while $\|\cdot\|_F$ denotes the Frobenius norm of a matrix.

2. Krylov subspace relations. The QR algorithm can be viewed as a nested subspace iteration [3, 8, 24, 29, 32]. Well suited for theoretical purposes, this approach forms the basis of the elegant convergence theory developed by Watkins and Elsner [31]. Starting with a linear subspace $\mathcal{S}_0 \subseteq \mathbb{C}^n$, it can be shown that the QR iteration (1) effects a subspace iteration of the form

$$\mathcal{S}_i = p_i(A)\mathcal{S}_{i-1}, \qquad i = 1, 2, \ldots. \tag{3}$$

If we let $\hat{p}_i = p_i p_{i-1} \cdots p_1$ denote the product of the shift polynomials, then

$$\mathcal{S}_i = \hat{p}_i(A)\mathcal{S}_0, \qquad i = 1, 2, \ldots. \tag{4}$$

Setting $A_0 \equiv A$, we can define

$$\mathcal{S}_0 = \operatorname{span}\{e_1, e_2, \ldots, e_k\},$$

where k satisfies $1 \leq k \leq n$ and e_j denotes the jth unit vector of appropriate length. It is important to note that (3) and (4) hold for all k [illegible] (giving rise to a [illegible] subspace iteration).

To avoid technical difficulties, we assume for the rest of this section that each $p_i(A)$ is nonsingular (a singular $p_i(A)$ results in sudden convergence), which is equivalent to requiring that none of the zeros of p_i coincides with an eigenvalue of A. Then the concrete relation of (3) to the QR iteration (1) is revealed by

$$\mathcal{S}_i = \operatorname{span}\{\hat{Q}_i e_1, \hat{Q}_i e_2, \ldots, \hat{Q}_i e_k\} \tag{5}$$

for $i \geq 0$ with $\hat{Q}_i = Q_1 \cdots Q_i$. Here, $Q_1, \ldots, Q_i$ are the unitary matrices computed during the QR iteration while $\hat{Q}_0$ is defined to be the identity I_n. A simple way to show (5) is to note that (1) implies a QR decomposition

$$\hat{p}_i(A) = \hat{Q}_i (R_i R_{i-1} \cdots R_1) \tag{6}$$

with nonsingular, upper triangular $R_i R_{i-1} \cdots R_1$.

That the implicit shifted QR algorithm operates on Hessenberg matrices links it intimately to Krylov subspace methods; see, e.g., [30] for a recent discussion. Additionally, assuming that A is in unreduced Hessenberg form, it is well known that

$$\mathcal{S}_i = \mathcal{K}_k(A, u_1) = \operatorname{span}\{u_1, Au_1, \ldots, A^{k-1}u_1\}, \tag{7}$$

where u_1 denotes the first column of $\hat{Q}_i$. In fact, if we let u_j denote the jth column of $\hat{Q}_i$ and partition

$$A_i = \hat{Q}_i^{\mathsf{H}} A \hat{Q}_i = \begin{array}{c} \\ k \\ 1 \\ n-k-1 \end{array} \begin{array}{c} \begin{array}{ccc} k & 1 & n-k-1 \end{array} \\ \begin{bmatrix} H_{11} & H_{12} & H_{13} \\ H_{21} & H_{22} & H_{23} \\ 0 & H_{32} & H_{33} \end{bmatrix} \end{array}, \tag{8}$$

then trivially

$$A[u_1, u_2, \ldots, u_k] = [u_1, u_2, \ldots, u_k] H_{11} + u_{k+1} H_{21}. \tag{9}$$

Under the given assumptions, A_i is in unreduced Hessenberg form and hence the relation (9) happens to be an unreduced Arnoldi decomposition, which implies (7) by [26, Theorem 5.1.1].

Although occasionally mentioned in the literature [10, 29], it is less well known that $\mathcal{S}_i^{\perp}$, the orthogonal complement of $\mathcal{S}_i$, is also a Krylov subspace. To show this, we employ the "flip transpose" of a matrix. Given an $l \times m$ matrix B, let $B^{\mathsf{F}} = F_m B^{\mathsf{H}} F_l$, where F_j denotes the $j \times j$ flip matrix, having ones on the antidiagonal and zeros everywhere else. It can be directly seen that a square matrix B^{F} is in upper Hessenberg (triangular) form if and only if B is in upper Hessenberg (triangular) form. Setting $w = n - k - 1$, the partitioning (8) immediately implies

$$A^{\mathsf{H}}[u_{n-w+1}, \ldots, u_{n-1}, u_n] = [u_{n-w+1}, \ldots, u_{n-1}, u_n] H_{33}^{\mathsf{H}} + u_{n-w} H_{32}^{\mathsf{H}}$$

and, after applying the flip matrix $F \equiv F_w$,

$$A^{\mathsf{H}}[u_n, u_{n-1}, \ldots, u_{n-w+1}] = [u_n, u_{n-1}, \ldots, u_{n-w+1}]H_{33}^{\mathsf{F}} + u_{n-w}H_{32}^{\mathsf{H}}F. \tag{10}$$

Again, (10) is an unreduced Arnoldi decomposition, and therefore

$$\operatorname{span}\{u_n, u_{n-1}, \ldots, u_{n-w+1}\} = \mathcal{K}_w(A^{\mathsf{H}}, u_n)$$

holds for every $w = 1, \ldots, n$. Adjusting w to $w = n - k$, this proves that $\mathcal{S}_i^{\perp}$ indeed coincides with the Krylov subspace $\mathcal{K}_{n-k}(A^{\mathsf{H}}, u_n)$. Since $\hat{p}_i(A)$ is invertible, (6) shows that u_n is parallel to $(\hat{p}_i(A)^{-1})^{\mathsf{H}}e_n =: \hat{p}_i(A)^{-\mathsf{H}}e_n$. Therefore, using the fact that A and $\hat{p}_i(A)^{-1}$ commute,

$$\mathcal{K}_w(A^{\mathsf{H}}, u_n) = \mathcal{K}_w(A^{\mathsf{H}}, \hat{p}_i(A)^{-\mathsf{H}}e_n) = \hat{p}_i(A)^{-\mathsf{H}}\,\mathcal{K}_w(A^{\mathsf{H}}, e_n).$$

3. Extracting Ritz pairs from Krylov subspaces. Given an Arnoldi decomposition of the form (10), a conventional way to extract approximations to eigenvectors from the corresponding Krylov subspace is to compute Ritz pairs and check their residuals. A [illegible] λ from the subspace $\mathcal{K}_w(A^{\mathsf{H}}, u_n)$ is defined as an eigenvalue of the $w \times w$ matrix H_{33}^{F}. The corresponding [illegible] is given by $x = U_w z$, where z is an eigenvector of H_{33}^{F} belonging to λ and $U_w = [u_{n-w+1}, \ldots, u_{n-1}, u_n]$. Taken together, (λ, x) form a so-called [illegible].

With the normalization $\|x\| = \|z\| = 1$, a Ritz pair is usually regarded as converged toward an eigenpair of A^{H} if the norm of the residual $r = A^{\mathsf{H}}x - \lambda x$ is sufficiently small. A practical criterion for deciding upon smallness can be found in the ARPACK manual [23, section 4.6]:

$$\|r\| \leq \max\{\mathbf{u}\|H_{33}^{\mathsf{F}}\|_F, \mathrm{tol} \times |\lambda|\}, \tag{11}$$

where $\mathbf{u}$ denotes the unit roundoff and tol is a tolerance chosen by the user. Note that (10) implies $r = (H_{32}^{\mathsf{H}}Fz)u_{n-w}$ and hence $\|r\| = |H_{32}^{\mathsf{H}}Fz|$. For tol $= 0$, the criterion (11) yields normwise backward stability: (λ, x) is the exact eigenpair of the perturbed matrix $A^{\mathsf{H}} + (\triangle A)^{\mathsf{H}}$, where

$$\triangle A = -xr^{\mathsf{H}} = -(z^{\mathsf{H}}FH_{32})(U_w z)u_{n-w}^{\mathsf{H}} \tag{12}$$

satisfies $\|\triangle A\|_F = \|r\| \leq \mathbf{u}\|H_{33}^{\mathsf{F}}\|_F \leq \mathbf{u}\|A\|_F$.

3.1. Locking converged Ritz values. Stewart's [illegible] [27] provides a numerically reliable means to detect, extract, and lock converged Ritz pairs. For some Ritz value λ, an ordered Schur decomposition [15] of H_{33}^{F} is computed such that λ appears in the top left corner of the triangular factor:

$$V^{\mathsf{H}}H_{33}^{\mathsf{F}}V = \begin{bmatrix} \lambda & T_{12} \\ 0 & T_{22} \end{bmatrix}, \tag{13}$$

where $V \in \mathbb{C}^{w \times w}$ is unitary and $T_{22} \in \mathbb{C}^{(w-1)\times(w-1)}$. A corresponding Ritz vector is given by $x = U_w z$ with $z = Ve_1$. If (11) is satisfied, we partition $U_w V = [x, \widehat{U}_{w-1}]$ and

$$H_{32}^{\mathsf{H}}FV = [\bar{s}_1, s_2^{\mathsf{H}}], \tag{14}$$

where $s_1 = z^{\mathsf{H}} F H_{32}$. Together with (10), this implies

$$A^{\mathsf{H}}[x, \widehat{U}_{w-1}] = [x, \widehat{U}_{w-1}] \begin{bmatrix} \lambda & T_{12} \\ 0 & T_{22} \end{bmatrix} + u_{n-w}[\bar{s}_1, s_2^{\mathsf{H}}]. \tag{15}$$

If (11) is not satisfied, we can test any other Ritz pair by reordering the eigenvalues in the Schur form (13).

Continuing the described process for the Ritz values contained in T_{22} eventually leads to a decomposition of the form

$$A^{\mathsf{H}}[X, \widehat{U}_{w-d}] = [X, \widehat{U}_{w-d}] \begin{bmatrix} \widehat{T}_{11} & \widehat{T}_{12} \\ 0 & \widehat{T}_{22} \end{bmatrix} + u_{n-w}[\hat{s}_1^{\mathsf{H}}, \hat{s}_2^{\mathsf{H}}], \tag{16}$$

where the upper triangular matrix $\widehat{T}_{11}$ contains all d converged Ritz values on its diagonal and

$$\|\hat{s}_1\| \le \sqrt{d} \max\{\mathbf{u}, \mathsf{tol}\} \|H_{33}^{\mathsf{F}}\|_F. \tag{17}$$

The matrices U_w and $[X, \widehat{U}_{w-d}]$ span the same space, i.e., there is a unitary matrix $\widehat{V}$ such that $[X, \widehat{U}_{w-d}] = U_w \widehat{V}$.

3.2. Restoring the Arnoldi decomposition. Note that (16) is not a standard Arnoldi decomposition, which would require $[\hat{s}_1^{\mathsf{H}}, \hat{s}_2^{\mathsf{H}}]$ to be a multiple of e_w^{H}. The vector $\hat{s}_1^{\mathsf{H}}$ is negligible but $\hat{s}_2^{\mathsf{H}}$ is not. Therefore, the last (optional) step of the Krylov–Schur algorithm consists of transforming $\hat{s}_2^{\mathsf{H}}$ back to a multiple of e_{w-d}^{H} while maintaining $\left[\begin{smallmatrix} \widehat{T}_{11} & \widehat{T}_{12} \\ 0 & \widehat{T}_{22} \end{smallmatrix}\right]$ in upper Hessenberg form.

To achieve this goal, first a unitary matrix V_1 is computed such that $V_1^{\mathsf{H}} \hat{s}_2 = \beta e_{w-d}$ with $|\beta| = \|\hat{s}_2\|$. By a row-oriented version of the usual Hessenberg reduction algorithm [26, p. 312], a unitary matrix $V_2 = \tilde{V}_2 \oplus 1$ can be computed such that $\widetilde{T}_{22} = V_2^{\mathsf{H}}(V_1^{\mathsf{H}} \widehat{T}_{22} V_1) V_2$ is again in Hessenberg form. Setting $\widetilde{T}_{12} = \widehat{T}_{12} V_1 V_2$ and $\widetilde{U}_{w-d} = \widehat{U}_{w-d} V_1 V_2$ finally yields

$$A^{\mathsf{H}}[X, \widetilde{U}_{w-d}] = [X, \widetilde{U}_{w-d}] \begin{bmatrix} \widehat{T}_{11} & \widetilde{T}_{12} \\ 0 & \widetilde{T}_{22} \end{bmatrix} + u_{n-w}[\hat{s}_1^{\mathsf{H}}, \bar{\beta} e_{w-d}^{\mathsf{H}}], \tag{18}$$

which becomes an Arnoldi decomposition after setting $\hat{s}_1$ to zero.

4. Aggressive early deflation. In this section, we reinterpret the extraction of Ritz pairs from the Arnoldi decomposition (10) in terms of transformations operating on the $n \times n$ Hessenberg matrix A_i. Let us recall the partitioning (8) with $w = n-k-1$:

$$A_i = \hat{Q}_i^{\mathsf{H}} A \hat{Q}_i = \begin{array}{c} \\ w \\ 1 \\ n-w-1 \end{array} \begin{array}{c} \begin{array}{ccc} n-w-1 & 1 & w \end{array} \\ \begin{bmatrix} H_{11} & H_{12} & H_{13} \\ H_{21} & H_{22} & H_{23} \\ 0 & H_{32} & H_{33} \end{bmatrix} \end{array}.$$

In the context of the QR algorithm, we refer to w as the [illegible] and assume $w \ll n$ to make sure that the cost of the extraction process remains modest in comparison to the cost of a QR iteration.

4.1. Locking converged Ritz values. Note that all variables used in this section refer precisely to the same quantities introduced in section 3. A Ritz value λ has been defined to be an eigenvalue of H_{33}^{F}, and z denotes a corresponding normalized eigenvector. It directly follows that $\bar{\lambda}$ is an eigenvalue of H_{33} having $F_w z$ as a corresponding eigenvector. Setting $V_{\mathsf{F}} = F_w V F_w$, the ordered Schur decomposition (13) implies

$$V_{\mathsf{F}}^{\mathsf{H}} H_{33} V_{\mathsf{F}} = F_w \left(V^{\mathsf{H}} H_{33}^{\mathsf{F}} V\right)^{\mathsf{H}} F_w = F_w \begin{bmatrix} \bar{\lambda} & 0 \\ T_{12}^{\mathsf{H}} & T_{22}^{\mathsf{H}} \end{bmatrix} F_w = \begin{bmatrix} T_{22}^{\mathsf{F}} & F_{w-1} T_{12}^{\mathsf{H}} \\ 0 & \bar{\lambda} \end{bmatrix}, \tag{19}$$

which is an ordered Schur decomposition for H_{33}. Moreover, it follows from (14) that

$$V_{\mathsf{F}}^{\mathsf{H}} H_{32} = F_w V^{\mathsf{H}} (F_w H_{32}) = F_w \begin{bmatrix} s_1 \\ s_2 \end{bmatrix} = \begin{bmatrix} F_{w-1} s_2 \\ s_1 \end{bmatrix}.$$

These two relations yield

$$(I \oplus V_{\mathsf{F}})^{\mathsf{H}} A_i (I \oplus V_{\mathsf{F}}) = \begin{bmatrix} H_{11} & H_{12} & \check{H}_{13} & \check{H}_{14} \\ H_{21} & H_{22} & \check{H}_{23} & \check{H}_{24} \\ 0 & F_{w-1} s_2 & T_{22}^{\mathsf{F}} & T_{12}^{\mathsf{F}} \\ 0 & s_1 & 0 & \bar{\lambda} \end{bmatrix},$$

where we define $\left[\begin{smallmatrix} \check{H}_{13} & \check{H}_{14} \\ \check{H}_{23} & \check{H}_{24} \end{smallmatrix}\right] := \left[\begin{smallmatrix} H_{13} \\ H_{23} \end{smallmatrix}\right] V_{\mathsf{F}}$. Note that the vector $\left[\begin{smallmatrix} F_{w-1} s_2 \\ s_1 \end{smallmatrix}\right]$ is called the [illegible] in [7].

Let us recall that the residual r of the Ritz value λ satisfies $r = (H_{32}^{\mathsf{H}} F z) u_{n-w} = \bar{s}_1 u_{n-w}$, and hence $\|r\| = |s_1|$. Thus if (11) is satisfied for $\mathrm{tol} = 0$, the trailing spike element can be safely set to zero and $\bar{\lambda}$ can be regarded as a computed eigenvalue of A without spoiling the numerical backward stability of the QR algorithm. If $|s_1| > \mathbf{u}\|H_{33}\|_F$, we can test any other eigenvalue of H_{33} by considering a differently ordered Schur decomposition. This is equivalent to the search for converged Ritz values, since the ordered Schur decompositions of H_{33} and H_{33}^{F} are connected to each other in the one-to-one relationship (19).

Extracting and locking further converged Ritz values of H_{33}^{F}, as described in section 3, eventually yields a unitary matrix $\widehat{V}_{\mathsf{F}} \in \mathbb{C}^{w \times w}$ such that

$$\widehat{A}_i = (I \oplus \widehat{V}_{\mathsf{F}})^{\mathsf{H}} A_i (I \oplus \widehat{V}_{\mathsf{F}}) = \begin{bmatrix} H_{11} & H_{12} & \widehat{H}_{13} & \widehat{H}_{14} \\ H_{21} & H_{22} & \widehat{H}_{23} & \widehat{H}_{24} \\ 0 & F_{w-d} \hat{s}_2 & \widehat{T}_{22}^{\mathsf{F}} & \widehat{T}_{12}^{\mathsf{F}} \\ 0 & F_d \hat{s}_1 & 0 & \widehat{T}_{11}^{\mathsf{F}} \end{bmatrix}, \tag{20}$$

where the diagonal of the upper triangular matrix $\widehat{T}_{11}^{\mathsf{F}}$ contains the complex conjugates of all converged Ritz values. The d trailing spike elements in $F_d \hat{s}_1$ are all negligible, since (17) amounts to $\|F_d \hat{s}_1\| \le \sqrt{d}\mathbf{u}\|H_{33}\|_F \le \sqrt{d}\mathbf{u}\|A\|_F$ for $\mathrm{tol} = 0$.

4.2. Restoring the Hessenberg form. To continue the QR algorithm, the matrix $\widehat{A}_i$ in (20) needs to be restored to Hessenberg form. This is exactly what is achieved by the unitary transformations defined in section 3.2. Setting $V_{1,\mathsf{F}} = F_{w-d} V_1 F_{w-d}$ and $V_{2,\mathsf{F}} = F_{w-d} V_2 F_{w-d}$ yields

$$V_{1,\mathsf{F}}^{\mathsf{H}} (F_{w-d} \hat{s}_2) = \beta e_1, \quad V_{2,\mathsf{F}}^{\mathsf{H}} (V_{1,\mathsf{F}}^{\mathsf{H}} \widehat{T}_{22}^{\mathsf{F}} V_{1,\mathsf{F}}) V_{2,\mathsf{F}} = \widetilde{T}_{22}^{\mathsf{F}},$$

where $\widetilde{T}_{22}^{\mathsf{F}}$ is in upper Hessenberg form. Hence,

$$\widetilde{A}_i = (I \oplus V_{1,\mathsf{F}} V_{2,\mathsf{F}} \oplus I_d)^{\mathsf{H}} \widehat{A}_i (I \oplus V_{1,\mathsf{F}} V_{2,\mathsf{F}} \oplus I_d) = \begin{bmatrix} H_{11} & H_{12} & \widetilde{H}_{13} & \widehat{H}_{14} \\ H_{21} & H_{22} & \widetilde{H}_{23} & \widehat{H}_{24} \\ 0 & \beta e_1 & \widetilde{T}_{22}^{\mathsf{F}} & \widetilde{T}_{12}^{\mathsf{F}} \\ 0 & F_d \hat{s}_1 & 0 & \widehat{T}_{11}^{\mathsf{F}} \end{bmatrix}$$

with $\left[\begin{smallmatrix} \widetilde{H}_{13} \\ \widetilde{H}_{23} \end{smallmatrix}\right] = \left[\begin{smallmatrix} \widetilde{H}_{13} \\ \widetilde{H}_{23} \end{smallmatrix}\right] V_{1,\mathsf{F}} V_{2,\mathsf{F}}$. Setting $\hat{s}_1$ to zero returns $\widetilde{A}_i$ to Hessenberg form, and the QR algorithm can be continued on the leading $(n-d) \times (n-d)$ principal submatrix of $\widetilde{A}_i$.

4.3. Comparison to classical deflation. The reader is invited to check that the presented deflation algorithm obtained via the extraction of Ritz pairs from the Krylov subspace $\mathcal{K}_w(A^{\mathsf{H}}, u_n)$ is precisely the same as the aggressive early deflation algorithm originally described in [7]. Let us contemplate what the different deflation criteria for the QR algorithm mean in terms of Krylov subspaces.

The classical deflation criterion (2) tests the smallness of $|a_{l,l+1}^{(i)}|$ for each $l = 1, \ldots, n-1$. From the Arnoldi decomposition (10) it is immediately clear that $|a_{l,l+1}^{(i)}|$ is the minimal norm of a backward error matrix $\triangle A$ such that $\mathcal{K}_{n-l}(A^{\mathsf{H}}, u_n)$ becomes an invariant subspace of $(A + \triangle A)^{\mathsf{H}}$. In other words, classical deflation considers the nested sequence of Krylov subspaces

$$\mathcal{K}_1(A^{\mathsf{H}}, u_n),\ \mathcal{K}_2(A^{\mathsf{H}}, u_n), \ldots, \mathcal{K}_{n-1}(A^{\mathsf{H}}, u_n)$$

and checks whether any of them is a good approximation to an invariant subspace of A^{H} as a whole. If the shifts in the QR algorithm are chosen as the eigenvalues of the $m \times m$ trailing submatrix, a choice sometimes called [illegible], then deflation is most likely to happen for $\mathcal{K}_{n-l}(A^{\mathsf{H}}, u_n)$ with $n - l \leq m$, as the convergence theory [31] states that $\mathcal{K}_m(A^{\mathsf{H}}, u_n)$ converges locally quadratically to an invariant subspace of A^{H}. Roughly speaking (neglecting the effects of ill-conditioning), the approximation quality of $\mathcal{K}_{n-l}(A^{\mathsf{H}}, u_n)$ as a whole is determined by the poorest Ritz vector approximation that can be extracted from $\mathcal{K}_{n-l}(A^{\mathsf{H}}, u_n)$. Hence, slowly converging Ritz vectors hinder the deflation of other, quickly converging Ritz vectors. Aggressive early deflation is fundamentally different and avoids this effect. Only one Krylov subspace $\mathcal{K}_w(A^{\mathsf{H}}, u_n)$ for some fixed value of w is considered. Moreover, not the convergence of $\mathcal{K}_w(A^{\mathsf{H}}, u_n)$ as a whole but the convergence of each individual Ritz vector to an eigenvector of A^{H} is checked. Provided that A has distinct eigenvalues, all Ritz vectors from the Krylov subspace $\mathcal{K}_m(A^{\mathsf{H}}, u_n)$ converge locally quadratically, but some may converge at a significantly faster rate and can be deflated much earlier. This is demonstrated by the following example.

[illegible] 1. We applied the QR algorithm with $m = 4$ Francis shifts to a 250×250 random matrix generated by the following MATLAB commands:

```
randn('state',0);   A = hess(randn(250)+1i*randn(250)).
```

Table 1 compares classical with aggressive early deflation and clearly exhibits the advantages of the latter. For example, consider the Krylov subspace $\mathcal{K}_4(A^{\mathsf{H}}, u_n)$ after $i = 3$ QR iterations. The norms of the residuals for the four corresponding Ritz pairs are 3.8×10^{-2}, 1.3×10^{-3}, 6.0×10^{-4}, and 1.2×10^{-6}. The magnitude of the corresponding subdiagonal element, $|a_{n-4,n-3}^{(3)}| = 4.6 \times 10^{-2}$, is nearly the maximum

TABLE 1
Magnitudes of trailing subdiagonal elements (left set of columns) and minimal residuals for the Ritz pairs extracted from $\mathcal{K}_w(A^{\mathsf{H}}, u_n)$ (right set of columns) after i QR iterations with 4 Francis shifts applied to the matrix from Example 1.

	Classical deflation: $\lvert a_{l+1,l}^{(i)}\rvert$, $l =$				Aggressive early deflation: $\min \lVert r\rVert$, $w =$			
	$n-4$	$n-3$	$n-2$	$n-1$	2	4	6	8
$i=0$	$2.3\times10^{+0}$	$1.7\times10^{+0}$	$1.9\times10^{+0}$	$2.1\times10^{+0}$	$1.3\times10^{+0}$	2.2×10^{-1}	9.1×10^{-2}	7.3×10^{-2}
$i=1$	9.1×10^{-1}	$1.2\times10^{+0}$	$1.8\times10^{+0}$	$2.7\times10^{+0}$	$1.2\times10^{+0}$	6.0×10^{-2}	1.5×10^{-2}	6.4×10^{-3}
$i=2$	4.9×10^{-1}	5.8×10^{-1}	$1.3\times10^{+0}$	6.0×10^{-1}	2.1×10^{-1}	2.0×10^{-3}	8.6×10^{-5}	5.0×10^{-5}
$i=3$	4.6×10^{-2}	9.2×10^{-2}	$1.7\times10^{+0}$	1.8×10^{-2}	8.5×10^{-3}	1.2×10^{-6}	9.6×10^{-9}	7.7×10^{-9}

of these numbers, demonstrating that the convergence of $\mathcal{K}_4(A^{\mathsf{H}}, u_n)$ as a whole is determined by the poorest Ritz pair approximation.

In Table 1, aggressive early deflation already shows dramatic improvements for $w = m$, i.e., when the size of the deflation window coincides with the number of Francis shifts. Choosing $w > m$ enlarges the Krylov subspace and adds a Krylov subspace acceleration to the quadratically converging Ritz vectors. This is explored in more detail in the next section.

2. If each QR iteration is based on a single shift that is defined to be the (n,n) entry of the current iterate, then it is well known that u_n undergoes a Rayleigh-quotient iteration; see, e.g., [26, section 2.1]. To be more specific, let $u_n^{(i-1)}$ denote the last column of the accumulated unitary transformation matrix U_{i-1} satisfying $A_{i-1} = U_{i-1}^{\mathsf{H}} A U_{i-1}$. Then

$$u_n^{(i)} = \frac{\left(A^{\mathsf{H}} - \sigma_1^{(i)}\right)^{-1} u_n^{(i-1)}}{\left\| \left(A^{\mathsf{H}} - \sigma_1^{(i)}\right)^{-1} u_n^{(i-1)} \right\|},$$

provided that $\sigma_1^{(i)} = u_n^{(i-1)\mathsf{H}} A u_n^{(i-1)}$ is not an eigenvalue of A^{H}. Using aggressive early deflation, we deflate converged Ritz pairs from the Krylov subspace $\mathcal{K}_w(A^{\mathsf{H}}, u_n^{(i)})$. This shows that the single-shifted QR iteration equipped with such a deflation strategy is, in fact, a Krylov subspace method where the starting vector undergoes a quadratically convergent iteration.

There are situations for which the classical criterion detects deflations that go undetected if only aggressive early deflation is used. Probably the most practically relevant situation is that linear convergence phenomena occur if the shifts vary slightly in the course of several QR iterations. The typical consequence is that one or more of the leading subdiagonal elements of A_i approach zero. As $w \ll n$, the Krylov subspace $\mathcal{K}_w(A^{\mathsf{H}}, u_n)$ will not benefit from this effect. As a remedy, one could additionally use a variant of aggressive early deflation that considers Ritz pairs from $\mathcal{K}_w(A, u_1)$. However, numerical experiments reported in [18] reveal that these linear convergence phenomena seem to be too rare to justify the extra computational effort.

A quite different situation is pointed out in [7, section 2.5] and it is interesting to see this example in the light of Krylov subspaces. Let

$$A = \begin{bmatrix} 2 & 3 & 4 & 5 & 6 \\ 1 & 2 & 0 & 0 & 1 \\ 0 & 1 & 2 & 0 & 0 \\ 0 & 0 & \varepsilon & 2 & 0 \\ 0 & 0 & 0 & 1 & 2 \end{bmatrix}, \tag{21}$$

where $0 < \varepsilon \ll 1$. The norm of the residual for every Ritz pair from $\mathcal{K}_4(A^H, e_5)$ is approximately given by $\sqrt{\varepsilon}$, even though a perturbation of norm ε [illegible] the deflation window deflates two eigenvalues. Caused by the high nonnormality of $A(2:5, 2:5)$, standard Ritz pair extraction fails to detect the converged left eigenvector contained in $\mathcal{K}_4(A^H, e_5)$. Refined Ritz pairs [16, 17] aim to avoid this effect. For each Ritz value λ, the refined Ritz vector is chosen to minimize the norm of the corresponding residual. Unfortunately, for our example each refined Ritz pair has residual norm of about $\sqrt{\varepsilon/2}$. In [19], a computational procedure based on the distance to uncontrollability was described that optimizes both the refined Ritz vector [illegible] the value. For our example, applying this costly procedure leads to a refined Ritz pair whose residual norm nearly attains ε. So, in principle, refined Ritz pairs can be used to improve aggressive early deflation even further. However, preliminary numerical experiments with several matrices from the matrix market collection [2] indicate that a situation like (21) occurs rarely in practice, at least too seldom to justify the extra computational effort needed for extracting refined Ritz pairs.

5. Convergence bounds. To discuss the impact of aggressive early deflation on the convergence of the QR algorithm, let us return to the notation of section 2. Watkins and Elsner [31, Theorem 6.3] have shown that $\mathcal{S}_i = \mathcal{K}_{n-m}(A, u_1)$ converges locally quadratically to an $(n-m)$-dimensional invariant subspace $\mathcal{X}$ of A, provided that A has distinct eigenvalues and that in each iteration m Francis shifts $\sigma_1, \ldots, \sigma_m$ are chosen. To formalize this statement, let us employ the [illegible] between two subspaces $\mathcal{S}$ and $\mathcal{T}$ (not necessarily of the same dimension) defined as

$$d(\mathcal{S}, \mathcal{T}) := \sup_{\substack{s \in \mathcal{S} \\ \|s\|=1}} \inf_{t \in \mathcal{T}} \|s - t\|.$$

For convenience, we write $d(y, \mathcal{T})$ if $\mathcal{S}$ is spanned by a single vector y. With this notation, the convergence statement reads as follows:

[illegible] $d(\mathcal{S}_i, \mathcal{X}) \to 0$ [illegible] $i \to \infty$ [illegible]

At the time of this writing, the task of finding conditions for global convergence, which seems to hold almost always in practice, remains open and is not the subject of this paper.

Relevant properties of the gap $d(\cdot, \cdot)$ are summarized, e.g., in [4, 31]. We have $d(\mathcal{S}, \mathcal{T}) = 0$ if and only if $\mathcal{S} \subseteq \mathcal{T}$. If $\Pi_{\mathcal{S}}$ and $\Pi_{\mathcal{T}}$ denote orthogonal projections onto $\mathcal{S}$ and $\mathcal{T}$, respectively, then $d(\mathcal{S}, \mathcal{T}) = \|(I - \Pi_{\mathcal{T}})\Pi_{\mathcal{S}}\|$. This readily implies $d(\mathcal{T}^\perp, \mathcal{S}^\perp) = d(\mathcal{S}, \mathcal{T})$. The last property allows us to replace $d(\mathcal{S}_i, \mathcal{X})$ by

$$d(\mathcal{Y}, \mathcal{S}_i^\perp) = d\big(\mathcal{Y}, \mathcal{K}_m(A^H, u_n)\big) = d\big(\mathcal{Y}, \hat{p}_i(A)^{-H}\mathcal{K}(A^H, e_n)\big),$$

with $\mathcal{Y} = \mathcal{X}^\perp$, in the convergence discussion of the QR algorithm. Note that $\mathcal{Y}$ is an invariant subspace of A^H, or, equivalently, a [illegible] invariant subspace of A.

5.1. Convergence of eigenvectors. As discussed in section 4.3, aggressive early deflation has two advantages: (1) approximation by Ritz vectors instead of the whole Krylov subspace, and (2) additional Krylov subspace acceleration. The convergence theory by Watkins and Elsner must be modified in order to accommodate both advantages; the following theorem addresses the first one.

THEOREM 3. [illegible] $A \in \mathbb{C}^{n \times n}$ [illegible]

$$Q^H A Q = \begin{bmatrix} A_{11} & A_{12} \\ 0 & A_{22} \end{bmatrix}, \quad A_{11} \in \mathbb{C}^{(n-m)\times(n-m)}, \quad A_{22} \in \mathbb{C}^{m \times m},$$

[illegible] $Q \in \mathbb{C}^{n\times n}$ [illegible] $\lambda(A_{11}) \cap \lambda(A_{22}) = \emptyset$ [illegible] y [illegible] $\lambda_2 \in \lambda(A_{22})$ [illegible] $\mathcal{Y}$ [illegible] A [illegible] $\lambda(A_{22})$ [illegible] f [illegible] A [illegible]

$$d\big(y, f(A)^{-\mathsf{H}}\mathcal{V}\big) \le \frac{C_T}{1 - C_T\, d(\mathcal{Y},\mathcal{V})}\, \|f(A_{11})^{-1}\|\, |f(\lambda_2)|\, d(y,\mathcal{V}) \tag{22}$$

[illegible] m [illegible] $\mathcal{V}$ [illegible] $C_T\, d(\mathcal{Y},\mathcal{V}) < 1$ [illegible]

$$C_T = \Big(\|P_{A_{11}}\| + \sqrt{1+\|P_{A_{11}}\|^2}\Big)\Big(\|P_{\lambda_2}\| + \sqrt{1+\|P_{\lambda_2}\|^2}\Big).$$

[illegible] $P_{A_{11}} \in \mathbb{C}^{n\times n}$ [illegible] A [illegible] $\lambda(A_{11})$ [illegible] $P_{\lambda_2} \in \mathbb{C}^{m\times m}$ [illegible] A_{22} [illegible] λ_2 [illegible]. In the following, $\kappa(\cdot)$ denotes the 2-norm condition number of a matrix. By [11], there are invertible lower block triangular matrices T_1, T_2 with

$$\kappa(T_1) = \|P_{A_{11}}\| + \sqrt{1+\|P_{A_{11}}\|^2}, \quad \kappa(T_2) = \|P_{\lambda_2}\| + \sqrt{1+\|P_{\lambda_2}\|^2},$$

such that

$$T_1^{-1}\begin{bmatrix} A_{11} & A_{12} \\ 0 & A_{22}\end{bmatrix} T_1 = \begin{bmatrix} A_{11} & 0 \\ 0 & A_{22}\end{bmatrix}, \quad T_2^{-1} A_{22} T_2 = \begin{bmatrix} \widetilde{A}_{22} & 0 \\ 0 & \lambda_2\end{bmatrix}.$$

The matrix $T := QT_1(I \oplus T_2)$ satisfies $\kappa(T) \le \kappa(T_1)\kappa(T_2) = C_T$ and block diagonalizes A:

$$D := T^{-1}AT = A_{11} \oplus \tilde{A}_{22} \oplus \lambda_2. \tag{23}$$

In the following, we first derive a bound for the accordingly transformed subspaces $\widetilde{\mathcal{V}} = T^{\mathsf{H}}\mathcal{V}$ and $f(D)^{-\mathsf{H}}\widetilde{\mathcal{V}}$, which will then be turned into a bound for the original subspaces.

Since $\tilde{y} := T^{\mathsf{H}}y$ is a left eigenvector of the block diagonal matrix $D = T^{-1}AT$ belonging to the simple eigenvalue λ_2, we must have $\tilde{y} = \beta e_n$ for some $\beta \in \mathbb{C}$. To simplify the description, we assume without loss of generality that $\tilde{y} = e_n$. Analogously, we have

$$\widetilde{\mathcal{Y}} := T^{\mathsf{H}}\mathcal{Y} = \operatorname{span}\begin{bmatrix} 0 \\ I_m\end{bmatrix}. \tag{24}$$

By [31, Lemma 4.1], the condition $C_T\, d(\mathcal{Y},\mathcal{V}) < 1$ implies $d(\widetilde{\mathcal{Y}},\widetilde{\mathcal{V}}) < 1$, Hence, no vector in $\widetilde{\mathcal{V}}$ is perpendicular to $\widetilde{\mathcal{Y}}$. Taking (24) into account, this means that no nonzero vector contained in $\widetilde{\mathcal{V}}$ can have m trailing zero entries. Therefore we can choose a basis of the form $V = \left[\begin{smallmatrix} F \\ I_m\end{smallmatrix}\right]$ for $\widetilde{\mathcal{V}}$. The norm of F determines the distance between $\widetilde{\mathcal{V}}$ and $\widetilde{\mathcal{Y}}$. Specifically, we have

$$\|F\| = d(\widetilde{\mathcal{Y}},\widetilde{\mathcal{V}})/\sqrt{1 - d(\widetilde{\mathcal{Y}},\widetilde{\mathcal{V}})^2}; \tag{25}$$

see, e.g., [28].

To obtain a bound on $d\big(e_n, f(D)^{-\mathsf{H}}\widetilde{\mathcal{V}}\big)$, we select the particularly convenient vector

$$v_1 = Ve_m = \begin{bmatrix} Fe_m \\ e_m \end{bmatrix} \in \widetilde{\mathcal{V}}. \tag{26}$$

We have

$$f(D)^{-\mathsf{H}}v_1 = \begin{bmatrix} f(A_{11})^{-\mathsf{H}}Fe_m \\ 1/\overline{f(\lambda_2)}e_m \end{bmatrix},$$

which implies

$$d\big(e_n, f(D)^{-\mathsf{H}}v_1\big) \le \|f(A_{11})^{-\mathsf{H}}Fe_m\||f(\lambda_2)| \le \|f(A_{11})^{-1}\||f(\lambda_2)|\,\|e_n - v_1\|. \tag{27}$$

Note that v_1 is in general not the vector in $\widetilde{\mathcal{V}}$ that is closest to e_n, so we cannot simply replace $\|e_n - v_1\|$ by $d\big(e_n, \widetilde{\mathcal{V}}\big)$ in (27). In fact, the closest vector is the solution of the minimization problem $d(e_n, \widetilde{\mathcal{V}}) = \inf_{v\in\widetilde{\mathcal{V}}} \|e_n - v\|$ and takes the form $v_0 = V(V^{\mathsf{H}}V)^{-1}V^{\mathsf{H}}e_n = V(V^{\mathsf{H}}V)^{-1}e_m$. Lemma 8 from the appendix reveals the relationship

$$\|e_n - v_1\| \le \frac{\sqrt{1+\|F\|^2}}{\sqrt{1+\|F\|^2}-\|F\|}\|e_n - v_0\| = \frac{\|e_n - v_0\|}{1 - d(\widetilde{\mathcal{Y}}, \widetilde{\mathcal{V}})}, \tag{28}$$

where we used (25) for the latter equality.

Combining (27) with (28) shows

$$d\big(e_n, f(D)^{-\mathsf{H}}\widetilde{\mathcal{V}}\big) \le d\big(e_n, f(D)^{-\mathsf{H}}v_1\big) \le \frac{\|f(A_{11})^{-1}\||f(\lambda_2)|}{1 - d(\widetilde{\mathcal{Y}}, \widetilde{\mathcal{V}})} d(\tilde{y}, \widetilde{\mathcal{V}}).$$

Recall that $y = T^{-\mathsf{H}}e_n$, $\mathcal{V} = T^{-\mathsf{H}}\widetilde{\mathcal{V}}$, and $f(A)^{-\mathsf{H}}\mathcal{V} = T^{-\mathsf{H}}f(D)^{-\mathsf{H}}\widetilde{\mathcal{V}}$. Using Lemma 9 from the appendix, we obtain

$$d\big(y, f(A)^{-\mathsf{H}}\mathcal{V}\big) \le C_T \frac{\|f(A_{11})^{-1}\|\,|f(\lambda_2)|}{1 - d(\widetilde{\mathcal{Y}}, \widetilde{\mathcal{V}})} d(y, \mathcal{V}),$$

using $\kappa(T) \le C_T$. The proof is completed after applying the estimate $d(\widetilde{\mathcal{Y}}, \widetilde{\mathcal{V}}) \le C_T\, d(\mathcal{Y}, \mathcal{V})$. □

4. The condition $C_T\, d(\mathcal{Y}, \mathcal{K}_m(A^{\mathsf{H}}, e_n)) < 1$ in Theorem 3 is an artifact of the proof technique and can be removed. Let $\mathcal{U}$ denote the right invariant subspace of A belonging to $\lambda(A_{11})$. Then $\mathcal{U} \cap \mathcal{V} = \{0\}$ is sufficient to guarantee that the condition $d(\widetilde{\mathcal{Y}}, \widetilde{\mathcal{V}}) < 1$ needed in the proof of Theorem 3 is satisfied. Hence, there is a constant C independent of f such that

$$d\big(y, f(A)^{-\mathsf{H}}\mathcal{V}\big) \le C\,\|f(A_{11})^{-1}\|\,|f(\lambda_2)|\,d(y, \mathcal{V}),$$

even under this rather mild assumption. Note that $\mathcal{U} \cap \mathcal{V} = \{0\}$ is always satisfied if A is in unreduced Hessenberg form and $\mathcal{V} = \mathcal{K}_m(A^{\mathsf{H}}, e_n)$ [31].

Theorem 3 is applied to the convergence analysis of the QR algorithm by setting $f = \hat{p}_i$ and $\mathcal{V} = \mathcal{K}_m(A^{\mathsf{H}}, e_n)$. The classical convergence analysis [31, Lemma 4.4] provides bounds of the form

$$d\big(\mathcal{Y}, \hat{p}_i(A)^{-\mathsf{H}}\mathcal{K}_m(A^{\mathsf{H}}, e_n)\big) \le C\,\|\hat{p}_i(A_{11})^{-1}\|\,\|\hat{p}_i(A_{22})\|\,d(\mathcal{Y}, \mathcal{K}_m(A^{\mathsf{H}}, e_n)) \tag{29}$$

for some constant C. [illegible] shifts (i.e., the roots of p_i) need to converge simultaneously to eigenvalues of A_{22} in order to attain superlinear converge. In contrast, the bound (22) predicts superlinear convergence even if only one shift converges to a simple eigenvalue of A_{22}.

Corollary 5. [illegible] 3, [illegible] $p_1, p_2, \ldots$ [illegible] $\hat{p}_i(A)$ [illegible] $\hat{p}_i = p_1 p_2 \cdots p_i$ [illegible] p_j [illegible] λ_2 [illegible] $j \to \infty$ [illegible] $p_j(A_{11})^{-1}$ [illegible] $\rho > 0$ [illegible] C [illegible]

$$d\big(y, \hat{p}_i(A)^{-\mathsf{H}} \mathcal{K}_m(A^{\mathsf{H}}, e_n)\big) \le C\rho^i,$$

[illegible] $\mathcal{U} \cap \mathcal{K}_m(A^{\mathsf{H}}, e_n) = \{0\}$ [illegible] $\mathcal{U}$ [illegible] A [illegible] $\lambda(A_{11})$

[illegible]. Let d be the maximal degree of p_j, and let $C_2 = \max\{1, \widetilde{C}_2 + |\lambda_2|\}$, where $\widetilde{C}_2$ is a uniform upper bound for the magnitude of all roots of p_j for $j = 1, 2, \ldots$. Then $|p_j(\lambda_2)| \le C_2^{d-1} |\lambda_2 - \sigma^{(j)}|$, where $\sigma^{(j)}$ denotes the root that converges to λ_2. Moreover, there is a constant C_1 such that $\|p_j(A_{11})^{-1}\| \le C_1$ for all j. Choosing k sufficiently large guarantees $C_1 C_2^{d-1} |\lambda_2 - \sigma^{(j)}| \le \rho$ for all $j \ge k$. Hence, there is a constant $\widetilde{C}$ such that

$$\|\hat{p}_i(A_{11})^{-1}\| \, |\hat{p}_i(\lambda_2)| \le \big(C_1 C_2^{d-1}\big)^i \prod_{j=1}^{i} |\lambda_2 - \sigma^{(j)}| \le \widetilde{C} \rho^i.$$

Combined with Theorem 3 and Remark 4, this concludes the proof. □

The following theorem incorporates the Krylov subspace acceleration benefited from choosing the deflation window size w larger than m.

Theorem 6. [illegible] 3 [illegible] $C_T \, d(\mathcal{Y}, \mathcal{K}_m(A^{\mathsf{H}}, e_n)) < 1$ [illegible] f [illegible] A

$$d\big(y, f(A)^{-\mathsf{H}} \mathcal{K}_w(A^{\mathsf{H}}, e_n)\big) \le \frac{C_T \|f(A_{11})^{-1}\| \, |f(\lambda_2)| d(y, \mathcal{K}_m(A^{\mathsf{H}}, e_n))}{1 - C_T \, d(\mathcal{Y}, \mathcal{K}_m(A^{\mathsf{H}}, e_n))} \inf_{\phi \in \mathcal{P}_{w-m}} \frac{\|\phi(A_{11})\|}{|\phi(\lambda_2)|}, \tag{30}$$

[illegible] $\mathcal{P}_{w-m}$ [illegible] $w - m$

[illegible]. As in the proof of Theorem 3, we first block diagonalize A and obtain bounds for the accordingly transformed subspaces. Let $T^{-1}AT = D$ with D as in (23) and set $\tilde{y} = T^{\mathsf{H}} y$, $\widetilde{\mathcal{Y}} = T^{\mathsf{H}} \mathcal{Y}$. Without loss of generality, we may again assume $\tilde{y} = e_n$. Moreover, we have

$$T^{\mathsf{H}} f(A)^{-\mathsf{H}} \mathcal{K}_w(A^{\mathsf{H}}, e_n) = \mathcal{K}_w(D^{\mathsf{H}}, t)$$

with $t = f(D)^{-\mathsf{H}} T^{\mathsf{H}} e_n$. It follows that

$$\begin{aligned}
d(e_n, \mathcal{K}_w(D^{\mathsf{H}}, t)) &= \inf_{v \in \mathcal{K}_w(D^{\mathsf{H}}, t)} \|e_n - v\| = \inf_{p \in \mathcal{P}_{w-1}} \|e_n - p(D^{\mathsf{H}}) t\| \\
&= \inf_{\phi \in \mathcal{P}_{w-m}} \inf_{q \in \mathcal{P}_{m-1}} \|e_n - \phi(D^{\mathsf{H}}) q(D^{\mathsf{H}}) t\| \qquad (31) \\
&= \inf_{\phi \in \mathcal{P}_{w-m}} \inf_{q \in \mathcal{P}_{m-1}} \frac{1}{|\phi(\overline{\lambda}_2)|} \|\phi(D^{\mathsf{H}})(e_n - q(D^{\mathsf{H}}) t)\| \\
&= \inf_{\phi \in \mathcal{P}_{w-m}} \inf_{v \in \mathcal{K}_m(D^{\mathsf{H}}, t)} \frac{1}{|\phi(\overline{\lambda}_2)|} \|\phi(D^{\mathsf{H}})(e_n - v)\|. \qquad (32)
\end{aligned}$$

The implicit assumption that no root of ϕ coincides with $\overline{\lambda}_2$ can be justified by the following simple argument. If $\phi(\overline{\lambda}_2)$ is zero, then $\|e_n - \phi(D^{\mathsf{H}})q(D^{\mathsf{H}})t\| \geq 1$. But since the choice $\phi \equiv q \equiv 0$ already gives $\|e_n - \phi(D^{\mathsf{H}})q(D^{\mathsf{H}})t\| = 1$, the infimum in (31) is not increased if $\phi(\overline{\lambda}_2) \neq 0$ is imposed.

The vector $\hat{v} = -\overline{f(\lambda_2)}f(D)^{-\mathsf{H}}v_1$ with v_1 defined as in (26) satisfies $\hat{v} \in \mathcal{K}_m(D^{\mathsf{H}}, t)$ and

$$e_n - \hat{v} = \begin{bmatrix} \overline{f(\lambda_2)}f(A_{11})^{-\mathsf{H}}Fe_m \\ 0 \end{bmatrix}.$$

Choosing $v = \hat{v}$ in (32) and using (28) yields

$$d(e_n, \mathcal{K}_w(D^{\mathsf{H}}, t)) \leq \frac{\|f(A_{11})^{-\mathsf{H}}\||f(\lambda_2)|}{1 - d(\widetilde{\mathcal{Y}}, \mathcal{K}_m(D^{\mathsf{H}}, t))}\, d(e_n, \widetilde{\mathcal{V}}) \inf_{\phi \in \mathcal{P}_{w-m}} \frac{\|\phi(A_{11})\|}{|\phi(\lambda_2)|}.$$

Together with Lemma 9 from the appendix, this completes the proof. ∎

Remark 4 applies analogously to Theorem 6. Comparing (30) with (22), the bound gains the factor $\inf_{\phi \in \mathcal{P}_{w-m}} \|\phi(A_{11})\|/|\phi(\lambda_2)|$. Consider a compact set $\Omega_1 \subset \mathbb{C}$ containing the eigenvalues of A_{11} and define $\kappa(\Omega_1)$ to be the smallest constant for which

$$\|g(A_{11})\| \leq \kappa(\Omega_1) \max_{z \in \Omega_1} |g(z)| \tag{33}$$

holds uniformly for every analytic function g on Ω_1. Then, trivially,

$$\inf_{\phi \in \mathcal{P}_{w-m}} \frac{\|\phi(A_{11})\|}{|\phi(\lambda_2)|} \leq \kappa(\Omega_1) \inf_{\phi \in \mathcal{P}_{w-m}} \frac{\max\{|\phi(z)| : z \in \Omega_1\}}{|\phi(\lambda_2)|}.$$

Such approximation problems play a prominent role in the convergence analysis of Krylov subspace methods for nonnormal matrices. It is clear that $\inf_{\phi \in \mathcal{P}_{w-m}} \max\{|\phi(z)| : z \in \Omega_1\}/|\phi(\lambda_2)|$ cannot be larger than 1 (choose $\phi \equiv 1$) and decays as $w - m$ becomes larger. Estimates for this decay can be found using potential theory (see [4, 12]), but this is beyond the scope of this paper.

In LAPACK 3.1 [1], the default values for the number of shifts and the size of the deflation window for $3000 \leq n < 6000$ are $m = 128$ and $w = 192$, respectively. As explained in more detail in [9], this choice was based on computational experiments with pseudo-random matrices and matrices from [2]. A good choice of these parameters is crucial for the performance of the QR algorithm. For example, choosing a larger w increases the cost of the deflation procedure (which requires $O(w^2 n)$ operations) but also results in earlier deflations and therefore in fewer multishift QR iterations (each requires $O(mn^2)$ operations). While Theorem 6 does not provide any new insight into the choice of m, it does shed some light on a beneficial choice of w. Unfortunately, the exact computation of the quantity $\inf_{\phi \in \mathcal{P}_{w-m}} \frac{\|\phi(A_{11})\|}{|\phi(\lambda_2)|}$ in (30) is infeasible, simply because A_{11} and λ_2 are available only after the Schur form of A has been computed. The results in this paper should thus be understood only as a first step toward developing a strategy that chooses w nearly optimal in each iteration. For this purpose, cheap estimates on the decay of $\inf_{\phi \in \mathcal{P}_{w-m}} \frac{\|\phi(A_{11})\|}{|\phi(\lambda_2)|}$ as w increases need to be developed, possibly using heuristics on the distribution of the eigenvalues of A_{11}.

5.2. Convergence of invariant subspaces. Not only the convergence of individual eigenvectors but also the convergence of the left invariant subspace $\mathcal{Y}$ as a whole is improved using Krylov subspaces of larger dimension. To quantify this effect, we can combine the bound (29) with results by Beattie, Embree, and Rossi [4] on the convergence of invariant subspaces in Krylov subspaces.

THEOREM 7. [illegible] $A \in \mathbb{C}^{n\times n}$ [illegible]

$$Q^{\mathsf{H}} A Q = \begin{bmatrix} A_{11} & A_{12} \\ 0 & A_{22} \end{bmatrix}, \quad A_{11} \in \mathbb{C}^{(n-m)\times(n-m)}, \quad A_{22} \in \mathbb{C}^{m\times m},$$

[illegible] $Q \in \mathbb{C}^{n\times n}$ [illegible] $\lambda(A_{11}) \cap \lambda(A_{22}) = \emptyset$ [illegible] $\mathcal{Y}$ [illegible] [illegible] A [illegible] $\lambda(A_{22})$ [illegible] [illegible] $C_T d\big(\mathcal{Y}, \mathcal{K}_m(A^{\mathsf{H}}, e_n)\big) < 1$ [illegible] $C_T = \|P_{A_{11}}\| + \sqrt{1 + \|P_{A_{11}}\|^2}$ [illegible] $P_{A_{11}}$ [illegible] [illegible] A_{11} [illegible] f [illegible] [illegible] A

(34)
$$d\big(\mathcal{Y}, f(A)^{-\mathsf{H}} \mathcal{K}_w(A^{\mathsf{H}}, e_n)\big) \le C\, \|f(A_{11})^{-1}\| \|f(A_{22})\| \inf_{\phi \in \mathcal{P}_{w-m}} \|\phi(A_{11})\| \|\phi(A_{22})^{-1}\|,$$

[illegible]

$$C = \frac{C_T^2\, d(\mathcal{Y}, \mathcal{K}_m(A^{\mathsf{H}}, e_n))}{\sqrt{1 - C_T^2\, d(\mathcal{Y}, \mathcal{K}_m(A^{\mathsf{H}}, e_n))^2}}.$$

[illegible] There is an invertible lower block triangular matrix T_1 with $\kappa(T_1) = \|P_{A_{11}}\| + \sqrt{1 + \|P_{A_{11}}\|^2}$ such that

$$(QT_1)^{-1} A (QT_1) = \begin{bmatrix} A_{11} & 0 \\ 0 & A_{22} \end{bmatrix} =: D.$$

Let $T = QT$ and $\widetilde{\mathcal{Y}} = T^{\mathsf{H}}\mathcal{Y}$. Then

$$T^{\mathsf{H}} f(A)^{-\mathsf{H}} \mathcal{K}_w(A^{\mathsf{H}}, e_n) = \mathcal{K}_w(D^{\mathsf{H}}, f(D)^{-\mathsf{H}} u)$$

with $u = T^{\mathsf{H}} e_n$. Partition $u = \left[\begin{smallmatrix} u_1 \\ u_2 \end{smallmatrix}\right]$ with $u_2 \in \mathbb{C}^m$. Then Theorem 3.4 in [4] states

$$d\big(\widetilde{\mathcal{Y}}, \mathcal{K}_w(D^{\mathsf{H}}, f(D)^{-\mathsf{H}} u)\big) \le C_1 \inf_{\phi \in \mathcal{P}_{w-m}} \|\phi(A_{11})\| \|\phi(A_{22})^{-1}\|,$$

where

$$C_1 = \max_{\psi \in \mathcal{P}_{m-1}} \frac{\|\psi(A_{11})^{\mathsf{H}} f(A_{11})^{-\mathsf{H}} u_1\|}{\|\psi(A_{22})^{\mathsf{H}} f(A_{22})^{-\mathsf{H}} u_2\|}.$$

Using the fact that $\psi(D)^{\mathsf{H}}$ and $f(D)^{-\mathsf{H}}$ commute, we have

$$\begin{aligned} C_1 &\le \|f(A_{11})^{-1}\| \|f(A_{22})\| \max_{\psi \in \mathcal{P}_{m-1}} \frac{\|\psi(A_{11})^{\mathsf{H}} u_1\|}{\|\psi(A_{22})^{\mathsf{H}} u_2\|} \\ &= \|f(A_{11})^{-1}\| \|f(A_{22})\| \max_{\left[\begin{smallmatrix} v_1 \\ v_2 \end{smallmatrix}\right] \in \mathcal{K}_m(D^{\mathsf{H}}, u)} \frac{\|v_1\|}{\|v_2\|} \\ &\le \|f(A_{11})^{-1}\| \|f(A_{22})\| \frac{d\big(\widetilde{\mathcal{Y}}, \mathcal{K}_m(D^{\mathsf{H}}, u)\big)}{\sqrt{1 - d\big(\widetilde{\mathcal{Y}}, \mathcal{K}_m(D^{\mathsf{H}}, u)\big)^2}}, \end{aligned}$$

where the latter inequality follows as in the proof of Lemma 4.4 in [31]. The proof is concluded by applying Lemma 4.2 in [31] twice, relating the distances between the transformed subspaces to the distances of the original subspaces. ∎

Once again, an analogue of Remark 4 applies, showing that $C_T\, d\big(\mathcal{Y}, \mathcal{K}_m(A^{\mathsf{H}}, e_n)\big) < 1$ can be replaced by the weaker assumption $\mathcal{U} \cap \mathcal{K}_m(A^{\mathsf{H}}, e_n) = \{0\}$. Comparing (34) with the classical bound (29), the extra factor $\inf_{\phi\in\mathcal{P}_{w-m}} \|\phi(A_{11})\|\|\phi(A_{22})^{-1}\|$ is gained. If $\Omega_1, \Omega_2 \subset \mathbb{C}$ are compact sets containing $\lambda(A_{11}), \lambda(A_{22})$, respectively, then

$$\inf_{\phi\in\mathcal{P}_{w-m}} \|\phi(A_{11})\|\|\phi(A_{22})^{-1}\| \leq \kappa(\Omega_1)\kappa(\Omega_2) \min_{\phi\in\mathcal{P}_{w-m}} \frac{\max\{|\phi(z)| : z \in \Omega_1\}}{\min\{|\phi(z)| : z \in \Omega_2\}},$$

where $\kappa(\Omega_1)\kappa(\Omega_2)$ are defined as in (33). Note that the factor $\kappa(\Omega_2)$ can actually be removed (see [5, Theorem 3.3]) at the expense of having a different polynomial approximation problem. In any case, the bound can be expected to decay as $w - m$ increases; see [4, section 4] and [5, section 3] for estimates of this decay. When using Francis shifts, this means that besides the quadratically vanishing $\hat{p}_i(A_{22})$ we have an additional factor that may become very small for larger w, resulting in nearly superquadratic convergence.

Finally, let us remark that there is always a polynomial q, depending on A and f, such that $q(A) = f^{-1}(A)$. This implies an equivalence between the QR algorithm and the Arnoldi method with polynomial restarts, as discussed by Lehoucq [22]. In principle, this connection could be used to apply the bounds in [4, 5] verbatim to the QR algorithm. In contrast, Theorem 7 treats the convergence obtained from the shifts and from the Krylov subspace separately, having the advantage that it allows more insight into the benefits gained from choosing a larger deflation window.

6. Conclusions. This paper contributes to the understanding of why aggressive early deflation works so well in practice. A very intuitive explanation can be drawn from practical experiences with Krylov subspace methods for computing eigenvalues. Extracting Ritz pairs (= aggressive early deflation) is a much more effective strategy for detecting converged eigenvalues than only testing the subdiagonal entries of the Hessenberg factor in an Arnoldi decomposition (= classical deflation). The convergence bounds from section 5 provide a mathematical explanation, stating individual bounds for each converging eigenvalue and showing that the bounds are multiplied by a factor that approaches zero as the deflation window size w increases.

This paper should be seen as a first step toward developing a strategy for choosing w optimally in each QR iteration. In a serial computing environment, the current default value for w implemented in LAPACK already delivers good performance across a wide range of examples, and more sophisticated strategies might not lead to significant speedup. However, in a parallel computing environment, where aggressive early deflation will constitute a bottleneck, we expect the performance to become more sensitive with respect to the choice of w.

Finally, it is tempting to ask whether other Ritz pair extraction techniques, such as refined Ritz vectors, could be used to enhance the convergence of the QR algorithm even further. Although preliminary numerical experiments have indicated no obvious beneficial effect on the average performance of the QR algorithm, the use of these techniques in avoiding exceptional global convergence failures remains to be studied.

Appendix. This section collects two elementary facts needed in the proofs of section 5.

LEMMA 8. . . $V = \left[\begin{smallmatrix} F \\ I_m \end{smallmatrix}\right] \in \mathbb{C}^{n\times m}$ . .

$$\|e_n - Ve_m\| \le \frac{\sqrt{1+\|F\|^2}}{\sqrt{1+\|F\|^2}-\|F\|} \left\|e_n - V(V^{\mathsf{H}}V)^{-1}e_m\right\|.$$

. . . Set $r_0 = e_n - V(V^{\mathsf{H}}V)^{-1}e_m$ and $r_1 = e_n - Ve_m$. Then

$$r_0 = \begin{bmatrix} -F(I+F^{\mathsf{H}}F)^{-1} \\ I-(I+F^{\mathsf{H}}F)^{-1} \end{bmatrix} e_m = \begin{bmatrix} -(I+FF^{\mathsf{H}})^{-1}F \\ (I+F^{\mathsf{H}}F)^{-1}F^{\mathsf{H}}F \end{bmatrix} e_m$$

$$= \begin{bmatrix} (I+FF^{\mathsf{H}})^{-1} & F(I+F^{\mathsf{H}}F)^{-1} \\ -(I+F^{\mathsf{H}}F)^{-1}F^{\mathsf{H}} & (I+F^{\mathsf{H}}F)^{-1} \end{bmatrix} r_1 = (I+E)r_1,$$

where

$$E = \begin{bmatrix} -F(I+F^{\mathsf{H}}F)^{-1}F^{\mathsf{H}} & F(I+F^{\mathsf{H}}F)^{-1} \\ -(I+F^{\mathsf{H}}F)^{-1}F^{\mathsf{H}} & -F^{\mathsf{H}}(I+FF^{\mathsf{H}})^{-1}F \end{bmatrix}.$$

A singular value decomposition of F verifies $\|E\| = \|F\|/\sqrt{1+\|F\|^2}$. Thus $\|E\| < 1$ and $(I+E)$ is invertible. Finally,

$$\|r_1\| \le \|(I+E)^{-1}\|\|r_0\| \le \frac{1}{1-\|E\|}\|r_0\| = \frac{\sqrt{1+\|F\|^2}}{\sqrt{1+\|F\|^2}-\|F\|}\|r_0\|$$

concludes the proof. ∎

LEMMA 9. . $\mathcal{T},\mathcal{U}$ . . . . . P . . . . . .
. . $s \in \mathbb{C}^n$, $d(s,\mathcal{T}) \le \alpha\, d(s,\mathcal{U})$. . . . $d(Ps,P\mathcal{T}) \le \alpha\|P\|\|P^{-1}\|\, d(Ps,P\mathcal{U})$
. . . . Without loss of generality, we may assume $\|s\| = 1$. Then

$$\begin{aligned} d(Ps,P\mathcal{T}) &= \inf_{t\in\mathcal{T}} \frac{\|Ps-Pt\|}{\|Ps\|} \le \frac{\|P\|}{\|Ps\|} \inf_{t\in\mathcal{T}} \|s-t\| \\ &\le \alpha \frac{\|P\|}{\|Ps\|} \inf_{u\in\mathcal{U}} \|s-u\| \le \alpha\,\|P\|\|P^{-1}\| \inf_{u\in\mathcal{U}} \frac{\|Ps-Pu\|}{\|Ps\|} \\ &= \alpha\,\|P\|\|P^{-1}\|\, d(Ps,P\mathcal{U}). \end{aligned}$$ ∎

Acknowledgments. The author is very grateful for illuminating discussions with Ralph Byers, who first pointed out the close relationship between aggressive early deflation and the Krylov–Schur algorithm. He also thanks Mark Embree and the referees for carefully reading the paper and providing helpful suggestions.

A NEW SCALING FOR NEWTON'S ITERATION FOR THE POLAR DECOMPOSITION AND ITS BACKWARD STABILITY*

RALPH BYERS† AND HONGGUO XU‡

Abstract. We propose a scaling scheme for Newton's iteration for calculating the polar decomposition. The scaling factors are generated by a simple scalar iteration in which the initial value depends only on estimates of the extreme singular values of the original matrix, which can, for example, be the Frobenius norms of the matrix and its inverse. In exact arithmetic, for matrices with condition number no greater than 10^{16}, with this scaling scheme no more than 9 iterations are needed for convergence to the unitary polar factor with a convergence tolerance roughly equal to 10^{-16}. It is proved that if matrix inverses computed in finite precision arithmetic satisfy a backward-forward error model, then the numerical method is backward stable. It is also proved that Newton's method with Higham's scaling or with Frobenius norm scaling is backward stable.

Key words. matrix sign function, polar decomposition, singular value decomposition (SVD), Newton's method, numerical stability, scaling

1. Introduction.

Every matrix $A \in \mathbb{C}^{n\times n}$ has a polar decomposition $A = QH$, where $H = H^* \in \mathbb{C}^{n\times n}$ is Hermitian positive semidefinite and $Q \in \mathbb{C}^{n\times n}$ is unitary, i.e., $Q^*Q = I$. The polar decomposition is unique with positive definite symmetric factor H iff A is nonsingular. Its applications include unitary approximation and distance calculations [8, 9, 12]. The polar decomposition generalizes to rectangular matrices; see, for example, [15]. We consider only the square matrix case here, because numerical methods for computing the polar decomposition typically begin by reducing the problem down to the square matrix case using, for example, a QR factorization [5, 8]. (An algorithm that works directly with rectangular matrices appears in [6].)

The polar decomposition may be easily constructed from a singular value decomposition (SVD) of A. However, the SVD is a substantial calculation that displays much more of the structure of A than does the polar decomposition. Constructing the polar decomposition from the SVD destroys this extra information and wastes the arithmetic work used to compute it. It is intuitively more appealing to use the polar decomposition as a preliminary step in the computation of the SVD as in [12].

When A is nonsingular, one way to compute the polar decomposition is through Newton's iteration:

$$Q_{k+1} = \frac{1}{2}\left(\zeta_k Q_k + (\zeta_k Q_k)^{-*}\right), \qquad Q_0 = A, \tag{1.1}$$

where $\zeta_k = \zeta(Q_k) > 0$ is a positive scalar function of Q_k chosen to accelerate convergence [8]. Each iterate Q_k has polar decomposition $Q_k = QH_k$, where Q is

the unitary polar factor of A, $H_0 = H$ is the Hermitian polar factor of A, and $H_{k+1} = (\zeta_k H_k + (\zeta_k H_k)^{-1})/2$, $k \geq 0$. For appropriately chosen acceleration parameters ζ_k, $\lim_{k\to\infty} H_k = I$. Hence, the unitary polar factor is $Q = \lim_{k\to\infty} Q_k$, and the Hermitian polar factor is $H = \lim_{k\to\infty} Q_k^* A$.

Iteration (1.1) was first proposed in [8] and studied further in [5, 6, 14]. It is called "Newton's iteration" because it can be derived from Newton's method applied to the equation $X^*X = I$. It is closely related to Newton's iteration for the matrix sign function [17, 22].

Simplicity is an attractive feature of (1.1). Apart from the computation of ζ_k, each iteration needs only one matrix inversion and one matrix-matrix addition. The simplicity allows implementations of (1.1) to take advantage of the hierarchical memory and parallelism [1, 2, 13]. Many authors have studied choices of the acceleration parameters ζ_k [3, 4, 8, 16, 17, 22]. If $\zeta_k \equiv 1$, then the iterates Q_k converge quadratically to the unitary polar factor Q [8]. Convergence is also quadratic if $\zeta = \zeta(U)$ is a smooth function of $U \in \mathbb{C}^{n\times n}$ and $\zeta(U) = 1$ whenever U is unitary.

The choice

$$\zeta_k^{(2)} = \sqrt{\frac{\|Q_k^{-1}\|_2}{\|Q_k\|_2}}, \tag{1.2}$$

where $\|\cdot\|_2$ is the spectral norm is proposed in [8]. This scale factor is optimal in the sense that, given Q_k, (1.2) minimizes the next error $\|Q_{k+1} - Q\|_2$. With this scale factor, for the matrices Q_k generated by (1.1), the error sequence $\|Q_k - Q\|_2$ converges monotonically to zero. Unfortunately, to determine the scale factor (1.2), one needs to compute two extreme singular values of Q_k at each iteration. In order to preserve the rapid convergence of (1.1) with scaling (1.2), the highly accurate values of these extreme singular values are required to guarantee $\zeta_k^{(2)} \to 1$. This is expensive enough to make scale factor (1.2) unattractive.

To save the cost of computing the extreme singular values, one might approximate (1.2). A commonly used scale factor is the $(1,\infty)$-scaling

$$\zeta_k^{(1,\infty)} = \left(\frac{\|Q_k^{-1}\|_1 \|Q_k^{-1}\|_\infty}{\|Q_k\|_1 \|Q_k\|_\infty}\right)^{\frac{1}{4}}, \tag{1.3}$$

(where $\|\cdot\|_1$ and $\|\cdot\|_\infty$ are the 1-norm and ∞-norm, respectively) which was proposed by Higham in [8]. The factor $\zeta_k^{(1,\infty)}$ is within a constant factor of $\zeta_k^{(2)}$. It adds a negligible amount of arithmetic work compared to the cost of Q_k^{-1}, which is needed at each iteration anyway.

The scale factor

$$\zeta_k^{(F)} = \|Q_k^{-1}\|_F^{1/2} \|Q_k\|_F^{-1/2}, \tag{1.4}$$

(where $\|\cdot\|_F$ is the Frobenius norm) is discussed in [5, 8, 16]. It can also be computed at a negligible cost. It is optimal in the sense that, given Q_k, it minimizes $\|Q_{k+1}\|_F$ and causes the sequence $\|Q_k\|_F$ to converge monotonically [5].

Another relatively inexpensive scale factor is [4]

$$\zeta_k^{(d)} = |\det(Q_k)|^{-1/n}. \tag{1.5}$$

The complex modulus of the determinant is very inexpensively obtained from the same matrix factorization used to calculate Q_k^{-1}. This scaling is optimal in the sense

that, for a given iterate Q_k, it minimizes $D(Q_{k+1}) = \sum_{j=1}^{n} (\ln(\sigma_j^{(k+1)}))^2$, where $\sigma_j^{(k+1)}$ is the jth singular value of Q_{k+1}. The function $D(Q_{k+1})$ is a measure of the departure of Q_{k+1} from the unitary matrices.

This paper considers the [illegible] scaling strategy

$$\zeta_0 = 1/\sqrt{ab}, \quad \zeta_1 = \sqrt{\frac{2\sqrt{ab}}{a+b}}, \quad \zeta_k = 1/\sqrt{\rho(\zeta_{k-1})}, \quad k = 2, 3, \ldots, \tag{1.6}$$

where $\rho(x) = (x + x^{-1})/2$ and a and b are any numbers such that $0 < a \le \|A^{-1}\|_2^{-1} \le \|A\|_2 \le b$. Apart from estimating the extreme singular values of the initial matrix $Q_0 = A$, the scale factor costs only several floating point operations per iteration. Moreover, only the rough estimates of $\|A\|_2$ and $\|A^{-1}\|_2^{-1}$ are needed. One may simply choose $a = \|A^{-1}\|_F^{-1}$ and $b = \|A\|_F$. From Table 2.1 with such choices for any matrices with condition number no greater than 10^{16} and size no greater than 10^{11}, at most nine iterations of (1.1) with scaling (1.6) are necessary to approximate the unitary polar factor Q to within 2-norm distance less than 10^{-16}.

We show below that, in the presence of rounding error, (1.1) with (1.6) is numerically stable assuming that matrix inverses are calculated with small forward-backward error. This is the case, for example, when matrix inverses are computed using the bidiagonal reduction [7, p. 252]. We also prove the numerical stability of Newton's iteration with any of the scalings (1.2)–(1.4).

Commenting on an early draft of this paper, Zięta̧k pointed out that the suboptimal (quasi-optimal) scaling parameters were discovered independently by Kiełbasiński but not published in the open literature. They were presented by Zięta̧k at the 1999 Householder meeting at Whistler and the 1999 ILAS conference at Barcelona. In section 5 of their recent paper [19], Kiełbasiński, Zieliński, and Zięta̧k mention the quasi-optimal scaling parameters. In [18], these authors gave an error analysis of Higham's method [8] with the same mixed backward-forward stability assumption for matrix inversion. They gave numerical experiments in [23].

In the following $A \in \mathbb{C}^{n\times n}$ is always nonsingular. $A = U\Sigma V^*$ is the SVD of A, where U and V are unitary, $\Sigma = \mathrm{diag}(\sigma_1, \cdots, \sigma_n)$ is diagonal, and $\sigma_1 \ge \cdots \ge \sigma_n \ge 0$ are the singular values of A. The set of the singular values is denoted by $\sigma(A)$. The condition number with respect to the spectral norm of A is denoted by $\kappa_2(A) = \sigma_1/\sigma_n$. Following [7, p. 18], a flop is the computational work of a floating point addition, subtraction, multiplication, or division together with the associated subscripting and indexing overhead. It takes two flops to execute the Fortran statement `A(I,J) = A(I,J) + C*A(K,J)`.

2. Scaling and convergence. Let $A \in \mathbb{C}^{n\times n}$ be nonsingular, with the SVD $A = U\Sigma V^*$, with $\Sigma = \mathrm{diag}(\sigma_1, \sigma_2, \ldots, \sigma_n)$. Each Newton iterate Q_k in (1.1) has the SVD $Q_k = U\Sigma_k V^*$, where

$$\Sigma_{k+1} = \left(\zeta_k \Sigma_k + (\zeta_k \Sigma_k)^{-1}\right)/2, \qquad \Sigma_0 = \Sigma. \tag{2.1}$$

In particular, Q_k has singular values $\sigma_1^{(k)}$, $\sigma_2^{(k)}$, $\ldots$ $\sigma_n^{(k)}$ (in no particular order when $k > 0$) that obey

$$\sigma_j^{(0)} = \sigma_j, \quad \sigma_j^{(k+1)} = \frac{1}{2}\left(\zeta_k \sigma_j^{(k)} + \frac{1}{\zeta_k \sigma_j^{(k)}}\right) = \rho(\zeta_k \sigma_j^{(k)}), \quad k = 0, 1, 2, \ldots, \tag{2.2}$$

where $\rho(x) = (x + x^{-1})/2$. For appropriately chosen ζ_k, $\lim_{k\to\infty} \sigma_j^{(k)} = 1$, and $\lim_{k\to\infty} Q_k = UV^* = Q$. Consequently, the convergence properties of (1.1) derive directly from the n scalar sequences $\sigma_j^{(k)}$ determined by (2.2). To attain good convergence behavior in (1.1), the acceleration parameters ζ_k must interact well with $\rho(x) = (x + x^{-1})/2$.

The following two lemmas list some easily verified elementary properties of $\rho(x) = (x + x^{-1})/2$.

LEMMA 2.1. [illegible] $x > 0$ [illegible]

1. $\rho(\frac{1}{x}) = \rho(x)$
2. $1 \le \rho(x) \le \max(x, x^{-1})$ [illegible] $x = 1$
3. $\rho(x)$ [illegible] $x \in (0, 1]$ [illegible] $x \in [1, \infty)$

LEMMA 2.2. [illegible] $0 < a \le b$ [illegible] $\alpha_\zeta = \max\{(\zeta a)^{-1}, \zeta b\}$ [illegible] $\zeta_{opt} = (ab)^{-1/2}$ [illegible]

1. [illegible] $\zeta > 0$, $1 \le \max_{a<x<b} \rho(\zeta x) = \rho(\alpha_\zeta)$ [illegible] $1 = \max_{a<x<b} \rho(\zeta x)$. $\alpha_\zeta = 1$
2. [illegible] $\zeta > 0$, $1 \le \min_{a<x<b} \rho(\zeta x)$ [illegible] $1 = \min_{a<x<b} \rho(\zeta x)$. $\zeta a \le 1 \le \zeta b$
3. $\min_{\zeta>0} \alpha_\zeta = \alpha_{\zeta_{opt}} = \sqrt{b/a}$ [illegible] $\zeta = \zeta_{opt}$ [illegible]
4. $\min_{\zeta>0} \max_{a\le x\le b} \rho(\zeta x) = \min_{\zeta>0} \rho(\alpha_\zeta) = \rho(\alpha_{\zeta_{opt}}) = \rho(\sqrt{b/a})$

In the following, for ease of notation let $\tau(x)$ be the function

$$\tau(x) = \rho(\sqrt{x}) = \frac{1}{2}\left(\sqrt{x} + \frac{1}{\sqrt{x}}\right). \tag{2.3}$$

The k-fold composition of $\tau(x)$ with itself is written $\tau^k(x)$, i.e., $\tau^0(x) = x$, $\tau^1(x) = \tau(x)$, and for $k > 1$, $\tau^{k+1}(x) = \tau(\tau^k(x))$. Similarly $\rho^k(x)$ is the k-fold composition of $\rho(x) = (x + x^{-1})/2$ with itself.

Suppose that $0 < a \le \sigma_n \le \sigma_1 \le b$. Consider the sequence of intervals generated by Newton's iteration: $[a_0, b_0] = [a, b]$, $[a_1, b_1] = \rho(\zeta_0[a_0, b_0])$, $[a_2, b_2] = \rho(\zeta_1[a_1, b_1])$, ... It follows from (2.2) that $\sigma_j^{(k)} \in [a_k, b_k]$, $j = 1, 2, \ldots, n$, $k = 0, 1, \ldots$. Note that $\min_{x>0} \rho(x) = 1$, so for $k \ge 1$, $[a_k, b_k] \subseteq [1, b_k]$ and

$$1 \le \sigma_j^{(k)} \le b_k. \tag{2.4}$$

It is intuitively satisfying to choose the sequence of acceleration parameters ζ_k in (1.1) to minimize the sequence b_k.

From Lemma 2.2, the initial optimal scaling factor is $\zeta_0 = (ab)^{-1/2}$. The initial interval is scaled to be $\zeta_0[a, b] = [\sqrt{a/b}, \sqrt{b/a}]$ which contains 1. The next interval is

$$[a_1, b_1] = \rho(\zeta_0[a, b]) = [1, \rho(\sqrt{b/a})] = [1, \tau(b/a)],$$

where $\tau(x)$ is given by (2.3). The left endpoint is $a_1 = 1$, so the optimal scaling factor for the next iteration is $\zeta_1 = b_1^{-1/2} = 1/\sqrt{\tau(b/a)}$. The next interval is

$$[a_2, b_2] = \rho(\zeta_1[a_1, b_1]) = [1, \rho(\sqrt{\tau(b/a)})] = [1, \tau^2(b/a)].$$

An easy induction shows that the sequence of intervals is $[a_0, b_0] = [a, b]$ and for $k \ge 1$, $[a_k, b_k] = [1, \tau^k(b/a)]$, and the sequence of optimal scaling factors is

$$\zeta_0 = 1/\sqrt{ab}, \quad \zeta_k = 1/\sqrt{\tau^k(b/a)}, \quad k = 1, 2, 3, \ldots, \tag{2.5}$$

which is equivalent to (1.6).

Since $\tau(x) = \rho(\sqrt{x}) \le \rho(x)$ for $x \ge 1$,

$$\tau(b/a) \le \rho(b/a).$$

By induction we have

$$\tau^k(b/a) \le \rho^k(b/a)$$

for all $k \ge 1$. The sequence $b/a, \rho(b/a), \rho^2(b/a), \ldots$, is generated by Newton's iteration $x_{k+1} = \rho(x_k)$, with $x_0 = b/a$. It converges to 1 quadratically. Obviously $\tau^k(b/a) \ge 1$ for $k \ge 0$. So $b/a, \tau(b/a), \tau^2(b/a), \ldots$ also converges to 1 at least quadratically. It is not difficult to show that $1 \le \tau(x) \le x$ for any $x \ge 1$. We have

$$b_k = \tau^k(b/a) = \tau(\tau^{k-1}(b/a)) \le \tau^{k-1}(b/a) = b_{k-1}.$$

Hence, after the first step, the sequence of intervals satisfies

$$[a_1, b_1] \supseteq [a_2, b_2] \supseteq \cdots \supseteq [a_k, b_k] \supseteq \ldots,$$

and it converges to the single point 1 quadratically. (Note $a_k = 1$ for all $k \ge 1$.) The initial interval, $[a_0, b_0] = [a, b]$ is an exception, because, in general, $[a, b] \not\supseteq [1, \tau(b/a)]$.

Based on this fact and (2.4), the convergence properties of (1.1) with (1.6) are clear, and we summarize them in the following theorem.

THEOREM 2.3.

$$0 < a \le \|A^{-1}\|_2^{-1} \le \|A\|_2 \le b \tag{2.6}$$

Q_k (1.1) (1.6)

$$\|Q_k - Q\| \le \tau^k(b/a) - 1 \le \rho^k(b/a) - 1, \quad k = 1, 2, \ldots. \tag{2.7}$$

In fact the convergence properties are highly satisfactory even when b/a is large. Table 2.1 uses Theorem 2.3 to list the number of Newton's iteration (1.1) with scaling (1.6) (and exact arithmetic) required to guarantee selected absolute errors $\delta > \|Q_k - Q\|_2$ and values of b/a. The table demonstrates that Newton's iteration (1.1) with scaling (1.6) typically needs no more than nine iterations to attain typical floating point precision accuracy. The table also demonstrates that convergence is insensitive to the choice of a and b—widely differing values of b/a need similar numbers of iterations to attain similar accuracy. In particular the easy-to-compute choices $a = \|A^{-1}\|_F^{-1}$ and $b = \|A\|_F$ satisfy (2.6) and are unlikely to lead to even one more iteration than the optimum choices of $a = \|A^{-1}\|_2^{-1}$ and $b = \|A\|_2$, particularly for ill-conditioned matrices. For instance, for any $A \in \mathbb{C}^{n\times n}$ with $\kappa_2(A) = 10^{16}$, for $a = \|A^{-1}\|_F^{-1}$ and $b = \|A\|_F$, we have $b/a \le n\kappa(A) = n10^{16}$. Then $b/a \le 10^{27}$ for any $n \le 10^{11}$, and the number of iterations is 9, the same as with the optimum choices.

In Theorem 2.3, smaller values of b/a give smaller values of $\tau^k(b/a)$ and hence better error bounds. Inequality (2.6) implies that $b/a \ge \kappa_2(A) = \|A^{-1}\|_2 \|A\|_2$, and equality can be achieved only with $a = \|A^{-1}\|_2^{-1} = \sigma_n$ and $b = \|A\|_2 = \sigma_1$. With $a = \sigma_n$ and $b = \sigma_1$, the scaling factors (1.6) are

$$\zeta_0 = 1/\sqrt{\sigma_1\sigma_n}, \qquad \zeta_k = 1/\sqrt{\tau^k(\kappa_2(A))}, \quad (k \ge 1), \tag{2.8}$$

and the corresponding intervals are $[\sigma_n, \sigma_1]$, and $[1, \tau^k(\kappa_2(A))]$ for $k \ge 1$. Let Σ_k be the matrices generated by (2.1), with $a = \sigma_n$ and $b = \sigma_1$. It is easy to verify that in

TABLE 2.1
The number of Newton iterations (1.1) *with scaling* (1.6) *(and exact arithmetic) required to guarantee absolute error* $\|Q_k - Q\|_2 < \delta$ *for selected values of* δ *and* b/a *such that* $0 < a \le \|A^{-1}\|_2^{-1} \le \|A\|_2 \le b$. *See Theorem* 2.3.

$\delta \setminus b/a$	10	10^5	10^{10}	10^{15}	10^{20}	10^{25}	10^{27}
10^{-1}	2	4	5	6	6	6	6
10^{-4}	4	5	6	7	7	8	8
10^{-7}	4	6	7	8	8	8	8
10^{-10}	5	7	7	8	8	9	9
10^{-13}	5	7	8	8	9	9	9
10^{-16}	5	7	8	9	9	9	9
10^{-19}	6	7	8	9	9	10	10

this case, the right endpoint of the kth interval is a singular value of Σ_k. This in turn implies that inequality (2.7) is an equality, i.e.,

$$\|Q_k - Q\|_2 = \|\Sigma_k - I\|_2 = \tau^k(\kappa_2(A)) - 1.$$

The number sequence b_k was also derived in [16] in order to show the convergence behavior of Newton's method with the optimal scale factors. It is shown that when $a = \sigma_n$ and $b = \sigma_1$, for Q_k generated with $\zeta_{k-1}^{(2)}$ defined in (1.2), one has $\|Q_k\|_2 \le b_k$ [16, 11]. Due to this fact we call ζ_k defined in (2.5) [illegible] scale factors. Note that b_k is derived based on different interpretations here. It is the right endpoint of the kth interval generated by applying Newton's iteration to the initial interval $[a, b]$. For this interval iteration, ζ_k is the scale factor that minimizes $b_{k+1} - 1$ (i.e., it makes $[a_{k+1}, b_{k+1}]$ as close to 1 as possible).

3. The algorithm. The Newton's method (1.1) with scaling scheme (1.6) is implemented by the following algorithm.

ALGORITHM 3.1 (Newton's method (1.1) with scaling (1.6)).
Input: Nonsingular matrix $A \in \mathbb{C}^{n\times n}$ and a stopping criterion $\delta > 0$.
Output: The polar decomposition $A = QH$.

Step 0: **a.** Set $Q_0 = A$; Compute Q_0^{-*}
b. Choose $a \le \|Q_0^{-1}\|_2^{-1}$ and $b \ge \|Q_0\|_2$; $\zeta_0 = 1/\sqrt{ab}$
c. Set $k = 0$
Step 1: While $\|Q_k - Q_k^{-*}\|_F \ge \delta$
a. $Q_{k+1} = (\zeta_k Q_k + \zeta_k^{-1} Q_k^{-*})/2$
b.
If $k = 0$, $\zeta_1 = \sqrt{\frac{2}{\sqrt{b/a}+\sqrt{a/b}}}$
Else $\zeta_{k+1} = \sqrt{\frac{2}{\zeta_k^{-1}+\zeta_k}}$
End if
c. Compute Q_{k+1}^{-*}
d. $k = k + 1$
End while
Step 2: $Q = (Q_k + Q_k^{-*})/2$; $H = \frac{1}{2}(Q^*A + (Q^*A)^*)$

Here are some remarks.

1. The matrix $A^{-1} = Q_0^{-1}$ needs to be computed in the first iteration anyway. Hence, power iterations on A and A^{-1} may be used evaluate the extreme singular values σ_1 and σ_n^{-1}, respectively, using only $O(n^2)$ extra flops per iteration. These

estimates may then serve as the suboptimal scaling factors b and a^{-1}, respectively. Since highly accurate estimates of σ_1 and σ_n are unnecessary, a few power iterations should suffice. Alternatively, $\|A\|_F$ and $\|A^{-1}\|_F^{-1}$ may be used for b and a.

2. The stopping criterion $\|Q_k - Q_k^{-*}\|_F < \delta$ is essentially equivalent to $\|Q_{k+1} - Q_k\|_F < \delta$, which is used in [11, section 8.9]. This follows from the fact that when $\zeta_k \approx 1$ (which is usually the case for a small δ),

$$Q_{k+1} - Q_k = \frac{1}{2}(\zeta_k^{-1} Q_k^{-*} - (2 - \zeta_k) Q_k) \approx \frac{1}{2}(Q_k^{-*} - Q_k).$$

In practice, in order for the computed Q_k to be within $O(\varepsilon)$ of a unitary matrix, where ε is the machine epsilon, it is sufficient to choose $\delta = O(\sqrt{\varepsilon})$. See (4.16).

3. Commonly the matrix inversion method used in the algorithm is an LU factorization-based method such as the Gaussian elimination with partial pivoting or complete pivoting [8]. Such an inversion method usually works well in practice [18]. In order to guarantee the algorithm to be numerically backward stable, one may use the more expensive bidiagonal reduction-based matrix inversion method provided in Appendix A.1. So the computed matrix inverses satisfy the backward-forward error model. See Assumption 4.1 in section 4 below.

4. Estimating σ_1 and σ_n usually uses $O(n^2)$ flops. Each iteration uses $2n^3$ flops for the matrix inverse by an LU factorization-based method and $O(n^2)$ flops for matrix addition. Computing H uses $2n^3$ flops. If p is the number of iterations for convergence, then the algorithm uses a total of roughly $2(p+1)n^3$ flops [8]. When $p = 9$ it is about $20n^3$ flops, which is less than the QR-like SVD method (which takes $22n^3$ to $26n^3$ flops for the SVD and $4n^3$ for Q and H). If the bidiagonal reduction-based matrix inversion method is used, the total cost will be $2(3p + 1)n^3$ flops.

5. In order to reduce the cost while maintaining numerical stability, one may first use the bidiagonal reduction-based method for a few iterations. When $\kappa_2(Q_k)$ is not too large, say 100, one shifts to an LU factorization-based inversion method for the subsequent iterations. The matrix inverses essentially satisfy the backward-forward error model in the latter case [10, section 14]. Also, it takes only a few iterations for the condition number to drop below 100. In the case when $\kappa_2(A) = 10^{-16}$, with $a = \sigma_n$ and $b = \sigma_1$, then $\|Q_3\|_2 = \tau^3(10^{-16}) \approx 42$. Since this is usually the worst case in practice, the bidiagonal reduction-based method is required in no more than 3 iterations. With this strategy, the maximum cost (with $p = 9$) is $3 \cdot 6n^3 + (9 - 3) \cdot 2n^3 + 2n^3 = 32n^3$ flops.

6. Although the cost for computing the scale factors (1.3)–(1.5) is negligible in Newton's iteration, computing the suboptimal scale factors is essentially costless. Also, the use of suboptimal scaling simplifies the algorithm, since the "shifting scale factor to 1" strategy, which is used for the $(1, \infty)$-scaling ([8]), is not needed. Finally, with suboptimal scaling, in general, the number of iterations is no greater than 9, and it can be obtained by simply computing $\tau^k(b/a) - 1$. It is still not clear how to predict the number of iterations with other scalings, although in practice it is observed that the $(1, \infty)$-scaling and the suboptimal scaling essentially have the same convergence rate.

4. Stability and rounding error analysis. In this section, a first order error analysis establishes that Newton's method (1.1) with scaling (1.6) can be implemented in a backward stable way. The same conclusion is drawn for the scalings (1.2), (1.3), and (1.4). In outline, the approach is to estimate the residual $\|A - \widehat{Q}\widehat{H}\|_2$ for the rounding-error-perturbed unitary factor $\widehat{Q}$ and Hermitian factor $\widehat{H}$ produced by finite

precision arithmetic in the algorithm in section 3. The method here is to first estimate the forward errors $\widehat{Q} - Q$ and $\widehat{H} - H$ and then use them to estimate the residual.

For the error analysis, we employ the standard model of floating point arithmetic with machine epsilon ε [10, section 2.2].

We also need the following assumptions.

ASSUMPTION 4.1. If a nonsingular matrix $A \in \mathbb{C}^{n\times n}$ is inverted using finite precision arithmetic with machine epsilon ε to obtain a "computed inverse" X, then

$$X = (A + E)^{-1} + F,$$

where E, $F \in \mathbb{C}^{n\times n}$ are perturbation matrices satisfying

$$\|E\|_2 \le c_1(n)\varepsilon\|A\|_2, \qquad \|F\|_2 \le c_2(n)\varepsilon\|A^{-1}\|_2,$$

and $c_i(n)$ $(i = 1, 2)$ are some low-degree polynomials of n.

In Newton's method it is typical to use Gaussian elimination with partial or complete pivoting for computing matrix inverses. Although it works well in practice, the computed matrix inverses may not satisfy Assumption 4.1 [10, section 14.1]. We show in Appendix A.1 that Assumption 4.1 is satisfied by a matrix inversion algorithm that uses the bidiagonal reduction method.

ASSUMPTION 4.2.

$$c_3(n)\kappa_2(A)\varepsilon < 1,$$

where $c_3(n)$ is a low-degree polynomial of n.

Note that $1/\kappa_2(A)$ is the measure of the relative distance of a nonsingular A to the nearest singular matrices [7, p. 73], i.e.,

$$\frac{1}{\kappa_2(A)} = \min_{\det(A+E)=0} \frac{\|E\|_2}{\|A\|_2}.$$

If such a condition doesn't hold, then matrices like $A + E$ in Assumption 4.1 can be singular. So this is a condition about the numerical nonsingularity of A. It is essential in the subsequent first order error analysis, although it won't be explicitly stated.

We now begin the error analysis. In practice, rounding errors perturb Newton's method recurrence (1.1). Under Assumptions 4.1, if $\widehat{Q}_k$ is the computed version of Q_k, then

$$\begin{aligned}
\widehat{Q}_{k+1} &= \frac{\zeta_k}{2}\widehat{Q}_k + F_{k,1} + \frac{1}{2\zeta_k}\left((\widehat{Q}_k + F_{k,2})^{-*} + F_{k,3}\right) \\
&= \frac{\zeta_k}{2}(\widehat{Q}_k + F_{k,2}) + \frac{1}{2\zeta_k}(\widehat{Q}_k + F_{k,2})^{-*} + \left(F_{k,1} + \frac{1}{2\zeta_k}F_{k,3} - \frac{\zeta_k}{2}F_{k,2}\right) \\
&=: \frac{\zeta_k}{2}(\widehat{Q}_k + F_{kb}) + \frac{1}{2\zeta_k}(\widehat{Q}_k + F_{kb})^{-*} + F_{kf}, \qquad (4.1)
\end{aligned}$$

where $F_{kb} = F_{k,2}$ and $F_{kf} = (F_{k,1} + \frac{1}{2\zeta_k}F_{k,3} - \frac{\zeta_k}{2}F_{k,2})$. The perturbation matrix $F_{k,1}$ represents rounding errors introduced by floating point matrix addition and scalar multiplication, and the perturbation matrices $F_{k,2}$ and $F_{k,3}$ represent rounding errors

introduced by matrix inversion under Assumption 4.1. The F's obey the bounds

$$\begin{aligned}
\|F_{k,1}\|_2 &\le d_1\varepsilon \max\left(\|\zeta_k\widehat{Q}_k\|_2, \|\zeta_k^{-1}\widehat{Q}_k^{-*}\|_2\right)\\
\|F_{k,2}\|_2 &\le d_2\varepsilon\|\widehat{Q}_k\|_2\\
\|F_{k,3}\|_2 &\le d_3\varepsilon\|\widehat{Q}_k^{-*}\|_2\\
\|F_{kb}\|_2 &\le d_b\varepsilon\|\widehat{Q}_k\|_2\\
\|F_{kf}\|_2 &\le d_f\frac{\varepsilon}{2}\max\left(\|\zeta_k\widehat{Q}_k\|_2, \|\zeta_k^{-1}\widehat{Q}_k^{-*}\|_2\right),
\end{aligned}$$

where ε is the machine epsilon and d_1, $d_2 = d_b$, d_3, and d_f are some modest constants that may depend on n, the details of the arithmetic and the inversion algorithm but depend neither on Q_k nor $\widehat{Q}_k$. Each Q_k is a smooth function of Q_{k-1} and each $F_{k,j} = O(\varepsilon)$, so, by induction,

$$\widehat{Q}_k = Q_k + O(\varepsilon). \tag{4.2}$$

Hence, the bounds above may be loosely expressed in terms of Q_k as

$$\|F_{kb}\|_2 \le d_b\varepsilon\|Q_k\|_2 + O(\varepsilon^2) \tag{4.3}$$

$$\begin{aligned}
\|F_{kf}\|_2 &\le d_f\frac{\varepsilon}{2}\max\left(\|\zeta_k Q_k\|_2, \|\zeta_k^{-1}Q_k^{-*}\|_2\right) + O(\varepsilon^2)\\
&\le d_f\varepsilon\|Q_{k+1}\|_2 + O(\varepsilon^2).
\end{aligned} \tag{4.4}$$

Inequality (4.4) is a consequence of (2.2).

We need the following lemma for continuing our analysis.

LEMMA 4.3. Let $A \in \mathbb{C}^{n\times n}$ [illegible] $A = QH$ [illegible] $Q \in \mathbb{C}^{n\times n}$ [illegible] $H \in \mathbb{C}^{n\times n}$ [illegible] $F \in \mathbb{C}^{n\times n}$ [illegible] $\|F\|_2 = 1$ [illegible] $t \ge 0$ [illegible] t [illegible] $A + tF$ [illegible]

$$A + tF = Q\left((I + tE) + O(t^2)\right)\left(H + tG + O(t^2)\right),$$

[illegible] $G \in \mathbb{C}^{n\times n}$ [illegible]

$$F^*A + A^*F = GH + HG, \tag{4.5}$$

[illegible] $E \in \mathbb{C}^{n\times n}$ [illegible]

$$Q^*F - F^*Q = EH + HE. \tag{4.6}$$

[illegible] E [illegible]

$$E = (Q^*F - G)H^{-1}. \tag{4.7}$$

[illegible]. See proof in Appendix A.2. □

At each of the perturbed Newton iteration (4.1) rounding errors are equivalent to perturbing $\widehat{Q}_k$ to $\widehat{Q}_k + F_{kb}$, taking one Newton step (1.1), then perturbing the result by adding F_{kf}. Let $\widehat{Q}_k = W_k\widehat{H}_k$ and $\widehat{Q}_k + F_{kb} = \widetilde{W}_k\widetilde{H}_k$ be the polar decompositions of $\widehat{Q}_k$ and $\widehat{Q}_k + F_{kb}$, respectively. By Lemma 4.3,

$$\widetilde{W}_k = W_k(I + E_{kb}) + O(\varepsilon^2), \tag{4.8}$$

where E_{kb} satisfies

$$E_{kb}\widehat{H}_k + \widehat{H}_k E_{kb} = W_k^* F_{kb} - F_{kb}^* W_k + O(\varepsilon^2). \tag{4.9}$$

From (4.1),

$$\frac{\zeta_k}{2}(\widehat{Q}_k + F_{kb}) + \frac{1}{2\zeta_k}(\widehat{Q}_k + F_{kb})^{-*} = \widehat{Q}_{k+1} - F_{kf}.$$

Since the unitary factor in the polar decomposition of the left-hand side matrix is $\widetilde{W}_k$, applying Lemma 4.3 to $\widehat{Q}_{k+1}$, we have

$$\widetilde{W}_k = W_{k+1}(I - E_{kf}) + O(\varepsilon^2),$$

or equivalently,

$$W_{k+1} = \widetilde{W}_k(I + E_{kf}) + O(\varepsilon^2), \tag{4.10}$$

where E_{kf} satisfies

$$E_{kf}\widehat{H}_{k+1} + \widehat{H}_{k+1}E_{kf} = W_{k+1}^* F_{kf} - F_{kf}^* W_{k+1} + O(\varepsilon^2). \tag{4.11}$$

Since Q_k has the polar decomposition $Q_k = QH_k$ and $\widehat{Q}_k$ satisfies (4.2), by Lemma 4.3 one also has $\widehat{H}_k = H_k + O(\varepsilon)$, $W_k = Q + O(\varepsilon)$. Based on these first order error results, (4.9) and (4.11) can be expressed as

$$E_{kb}H_k + H_k E_{kb} = Q^* F_{kb} - F_{kb}^* Q + O(\varepsilon^2), \tag{4.12}$$

$$E_{kf}H_{k+1} + H_{k+1}E_{kf} = Q^* F_{kf} - F_{kf}^* Q + O(\varepsilon^2). \tag{4.13}$$

Combining (4.8) and (4.10), one has

$$W_{k+1} = W_k(I + E_{kb} + E_{kf}) + O(\varepsilon^2).$$

It follows by induction (with $W_0 = Q$) that

$$W_j = Q(I + E_j) + O(\varepsilon^2), \quad j > 0,$$

where

$$E_j = \sum_{k=0}^{j-1}(E_{kb} + E_{kf}). \tag{4.14}$$

Suppose that Algorithm 3.1 applied to a nonsingular matrix $A \in \mathbb{C}^{n\times n}$, with polar decomposition $A = QH$ completes after p iterations in Step 1. We obtain $\widehat{Q}_p$ that satisfies $\|\widehat{Q}_p - \widehat{Q}_p^{-*}\|_2 \le \|\widehat{Q}_p - \widehat{Q}_p^{-*}\|_F < \delta$. With the polar decomposition $\widehat{Q}_p = W_p\widehat{H}_p$ and (2.2), we have (see the proof in Appendix A.3)

$$\frac{1}{2}(\widehat{Q}_p + \widehat{Q}_p^{-*}) = W_p + \Delta\widehat{Q}_p, \tag{4.15}$$

where

$$\|\Delta\widehat{Q}_p\|_2 < \delta^2/8.$$

Suppose δ is small. Step 2 of the algorithm produces approximate polar factors

$$\widehat{Q} = \frac{1}{2}(\widehat{Q}_p + \widehat{Q}_p^{-*}) + F, \quad \widehat{H} = \frac{1}{2}\left(\widehat{Q}^* A + A^* \widehat{Q} + K\right),$$

where F accounts for rounding error forming $\widehat{Q}$ from $\widehat{Q}_p$ and K for rounding error forming $\widehat{H}$ from A and $\widehat{Q}$ obeying

$$\|F\| \le d_F \varepsilon, \qquad \|K\| \le d_K \varepsilon \|A\|_2,$$

with modest constants d_F and d_K. So we have

$$\|\widehat{Q} - W_p\|_2 \le d_F \varepsilon + \delta^2/8. \tag{4.16}$$

Since $W_p = Q(I+E)$ with $E := E_p$ defined in (4.14), by (4.15),

$$\widehat{Q} = Q(I+E) + \Delta\widehat{Q}_p + F = Q(I+E+L), \tag{4.17}$$

where $L = Q^*(\Delta\widehat{Q}_p + F)$ satisfies

$$\|L\|_2 \le d_L \max(\varepsilon, \delta^2)$$

for some modest constant d_L, which combines the rounding error F and the effect of stopping criterion. Both d_L and d_K may depend on n and the details of the finite precision arithmetic and computational algorithm, but not on A, $\widehat{Q}$, or $\widehat{H}$. With (4.17) and the fact that E is skew-Hermitian,

$$\begin{aligned}
\widehat{H} &= \frac{1}{2}\left((I+E+L)^* Q^* A + A^* Q (I+E+L) + K\right) \\
&= \frac{1}{2}\left(1 - E + L^*\right) H + H(I+E+L) + K) \\
&= \frac{1}{2}(2H - EH + HE + L^* H + HL + K). \qquad (4.18)
\end{aligned}$$

So by (4.17) and (4.18), to the first order,

$$\begin{aligned}
\widehat{Q}\widehat{H} - A &= \frac{1}{2} Q(I+E+L)(2H - EH + HE + L^*H + HL + K) - A \\
&= \frac{1}{2} Q\left(2H - EH + HE + L^*H + HL + 2EH + 2LH + K\right) - A \\
&\quad + O(\|L\|_2^2) + O(\varepsilon\|L\|_2) + O(\varepsilon^2) \\
&= \frac{1}{2} Q\left(EH + HE + L^*H + HL + 2LH + K\right) + O(\max(\varepsilon^2, \varepsilon\delta^2, \delta^4)).
\end{aligned}$$

From (4.14) this expression can be written

$$\begin{aligned}
\widehat{Q}\widehat{H} - A &= \frac{1}{2} Q \sum_{k=0}^{p-1} (E_{kb} H + H E_{kb} + E_{kf} H + H E_{kf}) \\
&\quad + \frac{1}{2} Q(L^* H + HL + 2LH + K) + O(\max(\varepsilon^2, \varepsilon\delta^2, \delta^4)). \qquad (4.19)
\end{aligned}$$

Note that so far the suboptimal scale factors have not played a role. In order to continue the analysis, we need the following lemma which involves the suboptimal scaling.

LEMMA 4.4. Let $A \in \mathbb{C}^{n\times n}$ have the singular value decomposition $U\Sigma V^*$, $\Sigma = \mathrm{diag}(\sigma_1, \sigma_2, \ldots, \sigma_n)$, $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_n$, and let (2.1) and (1.6) hold. Let $\Sigma_0 = \Sigma$ and $\sigma_j^{(k)}$ be the jth diagonal entry of Σ_k. Let $\sigma_{\max}^{(k)} = \max_{1\leq j\leq n} \sigma_j^{(k)}$. Let a, b satisfy $0 < a \leq \sigma_n$ and $b \geq \sigma_1$. Then for all $k \geq 0$ and $1 \leq i, j \leq n$,

$$\frac{\sigma_{\max}^{(k)}}{\sigma_i^{(k)} + \sigma_j^{(k)}} \leq \frac{b}{\sigma_i + \sigma_j}.$$

Proof. See Appendix A.4. ∎

Recall that E_{kb}, E_{kf} satisfy (4.12) and (4.13), respectively. Let

$$H_k = V\Sigma_k V^*$$

be an eigen-decomposition, where V is unitary and Σ_k is diagonal obeying (2.1). (Recall that throughout the algorithm the singular vectors of the Q_k's are the singular vectors of A. In particular, for all k, the unitary matrix of the right singular vectors of A is also a unitary matrix of the eigenvectors of H_k.) In this notation, (4.12) and (4.13) can be written

$$\widetilde{E}_{kb}\Sigma_k + \Sigma_k\widetilde{E}_{kb} = \widetilde{F}_{kb} - \widetilde{F}_{kb}^* + O(\varepsilon^2),$$
$$\widetilde{E}_{kf}\Sigma_{k+1} + \Sigma_{k+1}\widetilde{E}_{kf} = \widetilde{F}_{kf} - \widetilde{F}_{kf}^* + O(\varepsilon^2),$$

where

$$\widetilde{E}_{kb} = V^*E_{kb}V,\ \widetilde{E}_{kf} = V^*E_{kf}V,\ \widetilde{F}_{kb} = V^*Q^*F_{kb}V,\ \widetilde{F}_{kf} = V^*Q^*F_{kf}V. \tag{4.20}$$

So, the (i,j)th entries of $\widetilde{E}_{kb}$ and $\widetilde{E}_{kf}$ are

$$\widetilde{e}_{ij,kb} = \frac{\widetilde{f}_{ij,kb} - \overline{\widetilde{f}_{ji,kb}}}{\sigma_i^{(k)} + \sigma_j^{(k)}} + O(\varepsilon^2), \qquad \widetilde{e}_{ij,kf} = \frac{\widetilde{f}_{ij,kf} - \overline{\widetilde{f}_{ji,kf}}}{\sigma_i^{(k+1)} + \sigma_j^{(k+1)}} + O(\varepsilon^2). \tag{4.21}$$

Note that $\|\widetilde{E}_{kj}\|_2 = \|E_{kj}\|_2$ and $\|\widetilde{F}_{kj}\|_2 = \|F_{kj}\|_2$ for $j = b, f$, because V and Q are unitary.

Multiplying (4.19) on the left by V^* and on the right by V gives

$$\begin{aligned} V^*(\widehat{Q}\widehat{H} - A)V = {} & \frac{1}{2}V^*QV\sum_{k=0}^{p-1}\left(\widetilde{E}_{kb}\Sigma + \Sigma\widetilde{E}_{kb} + \widetilde{E}_{kf}\Sigma + \Sigma\widetilde{E}_{kf}\right) \\ & + \frac{1}{2}V^*\left(L^*H + HL + 2LH + K\right)V + O(\max(\varepsilon^2, \varepsilon\delta^2, \delta^4)), \end{aligned}$$

where $\widetilde{E}_{kb}$ and $\widetilde{E}_{kf}$ are given by (4.20). From (4.21), the (i,j)th entry of the sum $\sum_{k=0}^{p-1}(\widetilde{E}_{kb}\Sigma + \Sigma\widetilde{E}_{kb} + \widetilde{E}_{kf}\Sigma + \Sigma\widetilde{E}_{kf})$ is

$$\begin{aligned} & \sum_{k=0}^{p-1}(\widetilde{e}_{ij,kb} + \widetilde{e}_{ij,kf})(\sigma_i + \sigma_j) \\ & = \sum_{k=0}^{p-1}\left(\frac{\widetilde{f}_{ij,kb} - \overline{\widetilde{f}_{ji,kb}}}{\sigma_i^{(k)} + \sigma_j^{(k)}} + \frac{\widetilde{f}_{ij,kf} - \overline{\widetilde{f}_{ji,kf}}}{\sigma_i^{(k+1)} + \sigma_j^{(k+1)}}\right)(\sigma_i + \sigma_j) + O(\varepsilon^2) \\ & = \sum_{k=0}^{p-1}\left(\frac{\widetilde{f}_{ij,kb} - \overline{\widetilde{f}_{ji,kb}}}{\sigma_{\max}^{(k)}}\,\frac{(\sigma_i + \sigma_j)\sigma_{\max}^{(k)}}{\sigma_i^{(k)} + \sigma_j^{(k)}} + \frac{\widetilde{f}_{ij,kf} - \overline{\widetilde{f}_{ji,kf}}}{\sigma_{\max}^{(k+1)}}\,\frac{(\sigma_i + \sigma_j)\sigma_{\max}^{(k+1)}}{\sigma_i^{(k+1)} + \sigma_j^{(k+1)}}\right) \\ & \quad + O(\varepsilon^2). \end{aligned}$$

Inequalities (4.3) and (4.4) and Lemma 4.4 imply

$$\begin{aligned}&\left|\sum_{k=0}^{p-1}(\widetilde{e}_{ij,kb}+\widetilde{e}_{ij,kf})(\sigma_i+\sigma_j)\right|\\&\le 2\varepsilon\sum_{k=0}^{p-1}\left(d_b\frac{(\sigma_i+\sigma_j)\sigma_{\max}^{(k)}}{\sigma_i^{(k)}+\sigma_j^{(k)}}+d_f\frac{(\sigma_i+\sigma_j)\sigma_{\max}^{(k+1)}}{\sigma_i^{(k+1)}+\sigma_j^{(k+1)}}\right)+O(\varepsilon^2)\\&\le 2p\varepsilon(d_b+d_f)b+O(\varepsilon^2).\end{aligned}$$

Hence, the residual is bounded as

$$\begin{aligned}\|\widehat{Q}\widehat{H}-A\|_2&\le\|Q\sum_{k=0}^{p-1}\left(E_{kb}H+HE_{kb}+E_{kf}H+HE_{kf}\right)/2\|_2\\&\quad+\|Q(L^*H+HL+2LH+K)/2\|_2+O(\max(\varepsilon^2,\varepsilon\delta^2,\delta^4))\\&\le np\varepsilon(d_b+d_f)b+(2d_L+d_K/2)\max(\varepsilon,\delta^2)\|A\|_2+O(\max(\varepsilon^2,\varepsilon\delta^2,\delta^4)).\end{aligned}$$

In the same way, from (4.18) we can obtain

$$\begin{aligned}\|\widehat{H}-H\|_2&\le\|(-EH+HE)/2\|_2+\|(L^*H+HL+K)/2\|_2+O(\delta^4)\\&\le np\varepsilon(d_b+d_f)b+(d_L+d_K/2)\max(\varepsilon,\delta^2)\|A\|_2+O(\max(\varepsilon^2,\varepsilon\delta^2,\delta^4)).\end{aligned}$$

By applying Lemma 4.4 to (4.21) to estimate $\|E\|_2$, then from (4.17) we can derive

$$\|\widehat{Q}-Q\|_2\le\|QE\|_2+\|QL\|_2\le\theta np\varepsilon(d_b+d_f)b+d_L\max(\varepsilon,\delta^2),$$

where

$$\theta=\begin{cases}\frac{1}{\sigma_n} & A\text{ is complex,}\\ \frac{2}{\sigma_{n-1}+\sigma_n} & A\text{ is real.}\end{cases}\tag{4.22}$$

(The formula in the real case is based on the fact that $\widetilde{e}_{ii,kb}=\widetilde{e}_{ii,kf}=0$ from (4.21).)

We present the above error analysis results as well as (4.16) in the following theorem.

THEOREM 4.5. [illegible] $A\in\mathbb{C}^{n\times n}$ [illegible] 4.2 [illegible] $A=QH$ [illegible] $\widehat{Q}$ [illegible] $\widehat{H}$ [illegible] 3.1 [illegible] p [illegible] 4.1 [illegible]

$$\begin{aligned}\|\widehat{Q}\widehat{H}-A\|_2&\le np\varepsilon(d_b+d_f)b+(2d_L+d_K/2)\max(\varepsilon,\delta^2)\|A\|_2+O(\max(\varepsilon^2,\varepsilon\delta^2,\delta^4))\\\|\widehat{H}-H\|_2&\le np\varepsilon(d_b+d_f)b+(d_L+d_K/2)\max(\varepsilon,\delta^2)\|A\|_2+O(\max(\varepsilon^2,\varepsilon\delta^2,\delta^4))\\\|\widehat{Q}-Q\|_2&\le\theta np\varepsilon(d_b+d_f)b+d_L\max(\varepsilon,\delta^2)\\\|\widehat{Q}-W_p\|_2&\le d_F\varepsilon+\delta^2/8,\end{aligned}$$

[illegible] d_b,d_f,d_L,d_K,d_F [illegible] W_p [illegible] θ [illegible] (4.22)

As noted in Table 2.1, in most practical situations $p\le 9$. Therefore, if b is not too much greater than $\|A\|_2$ and the algorithm uses a stopping criterion δ not too much greater than $\sqrt{\varepsilon}$, then the algorithm is backward stable.

COROLLARY 4.6. , $b = \|A\|_2$, , $\delta = n^{\frac{1}{4}}\sqrt{\varepsilon}$, , ,

$$\|\widehat{Q}\widehat{H} - A\|_2 \le (np(d_b + d_f) + \sqrt{n}(2d_L + d_K/2))\varepsilon\|A\|_2 + O(\varepsilon^2)$$

$$\|\widehat{H} - H\|_2 \le (np(d_b + d_f) + \sqrt{n}(d_L + d_K/2))\varepsilon\|A\|_2 + O(\varepsilon^2)$$

$$\|\widehat{Q} - Q\|_2 \le np(d_b + d_f)\varepsilon(\theta\|A\|_2) + \sqrt{n}d_L\varepsilon$$

$$\|\widehat{Q} - W_p\|_2 \le (d_F + \sqrt{n}/8)\varepsilon.$$

Note that the error bounds for $\|\widehat{H} - H\|_2$ and $\|\widehat{Q} - Q\|_2$ coincide with the perturbation results; see, for example, [8, 21, 20] and [11, section 8.2]. The quantity $\theta\|A\|_2$ serves as the condition number for the perturbation of Q.

, , , 1. The same procedure can be used to give an error analysis for Newton's method with other scalings. Note that the backward stability depends on whether

$$\frac{(\sigma_i + \sigma_j)\sigma_{\max}^{(k)}}{\sigma_i^{(k)} + \sigma_j^{(k)}} = O(\|A\|_2), \tag{4.23}$$

which depends on scaling factors. From Remark 2 in Appendix A.4, (4.23) holds for the optimal scaling (1.2). Lemma A.3 in Appendix A.5 shows that (4.23) also holds for the $(1, \infty)$-scaling (1.3) and the scaling (1.4). Therefore, Newton's method with these three scalings is also backward stable under the same conditions of Theorem 4.5 and an appropriate stopping criterion, when the number of iterations is not too large. (See Remark 3 in Appendix A.5.)

We also observed that the numerical stability doesn't necessarily depend on how fast the method converges. In fact, one can show that when $\|A\|_2 \ge \|A^{-1}\|_2$, Newton's method without scaling ($a = b = 1$) computes a polar decomposition satisfying the same error bounds given in Theorem 4.5.

5. Numerical examples. We did some numerical experiments with Newton's method (1.1) with scaling (1.6) using $a = \|A^{-1}\|_F^{-1}$, $b = \|A\|_F$, and also with the $(1, \infty)$-scaling (1.3). The main purpose is to test the numerical stability results and convergence rate and to compare the suboptimal scaling and $(1, \infty)$-scaling. For this reason we used the bidiagonal reduction matrix inversion method Algorithm BR for computing matrix inverses.

All numerical experiments were done on a Dell personal computer with a Pentium-IV processor, in MATLAB version 7.2 with machine epsilon $\varepsilon \approx 2.22 \times 10^{-16}$.

In the numerical experiments we use stopping criterion $\delta = n^{\frac{1}{4}}\sqrt{\varepsilon}$, where n is the size of matrices. For Newton's method with the $(1, \infty)$-scaling, the scale factor is shifted to 1 when $\|X_{k+1} - X_k\|_F / \|X_{k+1}\|_F < 10^{-2}$. Based on the results in Corollary 4.6, if $\widehat{Q}$ and $\widehat{H}$ are the computed unitary and Hermitian polar factors produced by Algorithm 3.1, then we expect to observe that $\|A - \widehat{Q}\widehat{H}\|_2/\|A\|_2$, $\|H - \widehat{H}\|_2/\|H\|_2$, and $\|Q - \widehat{Q}\|_2/(\theta\|A\|_2)$ are not much larger than ε.

In the tables we will use the following notations:

$$e_Q = \frac{\|Q - \widehat{Q}\|_2}{\theta\|A\|_2}, \quad e_H = \frac{\|H - \widehat{H}\|_2}{\|H\|_2}, \quad res = \frac{\|A - \widehat{Q}\widehat{H}\|_2}{\|A\|_2}, \quad ror = \|\widehat{Q}^*\widehat{Q} - I\|_2,$$

where the "exact" factors Q and H for the matrices in the first example are obtained from the SVD of A using MATLAB's variable precision arithmetic `vpa` with 24 signi-

ficant decimal digits. p is the number of iterations, and n is the dimension of matrices. The symbol "HSF" refers to Newton's method (1.1) with Higham's $(1, \infty)$-scaling. The symbol "SUB" refers to (1.1) with scaling (1.6) using the Frobenius norms for the initial interval, i.e., $a = \|A^{-1}\|_F^{-1}$ and $b = \|A\|_F$.

1. Three groups of twenty real matrices were constructed with dimension 20 by using MATLAB's `gallery('randsvd',20,kappa,5)`, with `kappa` equal to $10^2, 10^8, 10^{15}$, respectively. The singular values of the generated matrices are random values with uniformly distributed logarithm. For each group the ranges of the condition numbers $\kappa_2(A)$ and $\theta\|A\|_2$ are listed below:

`kappa` $= 10^2 : \kappa_2(A) \in [37.7,\ 90.6]$, $\theta\|A\|_2 \in [33.5,\ 83.7]$,
`kappa` $= 10^8 : \kappa_2(A) \in [1.13,\ 6.75] \times 10^7$, $\theta\|A\|_2 \in [0.2,\ 5.44] \times 10^7$,
`kappa` $= 10^{15} : \kappa_2(A) \in [6.35 \times 10^{10},\ 7.53 \times 10^{14}]$, $\theta\|A\|_2 \in [1.78 \times 10^{10},\ 5.22 \times 10^{14}]$.

The test results are summarized in Table 5.1, where, for each group, the minimum and maximum values of the errors, residuals, and numbers of iterations are listed.

2. In this example the test matrices are the Hilbert matrices, which are $n \times n$ matrices with entries $a_{ij} = 1/(i + j - 1)$. The example uses dimensions $n = 6$, $n = 8$, $n = 10$, $n = 12$, and $n = 14$. For every Hilbert matrix, the polar decomposition is $A_n = I_n A_n$.

The condition number $\kappa_2(A_n)$ ranges from 1.5×10^7 to 5.1×10^{17}, and $\theta\|A_n\|_2$ ranges from 2.6×10^5 to 1.0×10^{17}. The test results are reported in Table 5.2.

Newton's method with the suboptimal scaling performed well in both examples calculating the polar factors to nearly full precision. As predicted it takes at most 9 iterations. Newton's method with the $(1, \infty)$-scaling performs equally well.

6. Conclusion. The suboptimal scaling scheme (1.6) is essentially costless and simplifies the algorithm of Newton's iteration (1.1) for computing polar factors. In a typical floating point system, with this scaling scheme, for matrices with $\kappa_2(A) < 10^{16}$, no more than 9 iterations are needed for convergence to the unitary polar factor with a convergence tolerance roughly equal to the machine epsilon. By employing the bidiagonal factorization for matrix inversion, (1.1) with (1.6) forms a provably backward stable algorithm. Newton's method with $(1, \infty)$-scaling and scaling (1.4) is also proved to be backward stable, provided the number of iterations is not too large.

Appendix A.

A.1. Bidiagonal reduction-based matrix inversion algorithm.

ALGORITHM BR.
Input: Nonsingular matrix $A \in \mathbb{C}^{n\times n}$
Output: $G = A^{-1}$

Step 1: Compute $A = UBV^*$, with U, V unitary and B upper bidiagonal.
Step 2: Solve $BY = U^*$ for Y by back substitution.
Step 3: Compute $G = VY$.

In Step 1 one may use the Householder reflectors to perform the reduction. The reduction needs $\frac{8}{3}n^3$ flops and computing U needs $\frac{4}{3}n^3$ flops. The matrix V is stored in factorized form. The cost for solving the matrix equation is $O(n^2)$ flops. With the factorized form of V, it needs $2n^3$ flops to compute G. So the total cost is $6n^3$ flops.

In order to show that a matrix inverse computed by Algorithm BR follows Assumption 4.1, we need the following lemma.

LEMMA A.1. [illegible] $Bx = z$ [illegible] $z \in \mathbb{C}^n$ [illegible] B [illegible]

$$B = \begin{bmatrix} \alpha_1 & \beta_1 & & 0 \\ & & & \\ & & & \beta_{n-1} \\ 0 & & & \alpha_n \end{bmatrix}.$$

[illegible] $\hat{x}$ [illegible] $\hat{x}$ [illegible]

$$\hat{x} = B^{-1}(z + \delta z) + \delta x,$$

[illegible]

$$|\delta z| \le 3n\varepsilon|z| + O(\varepsilon^2), \qquad |\delta x| \le 3n\varepsilon|\hat{x}| + O(\varepsilon^2).$$

[illegible]. The components of the computed vector $\hat{x}$ can be formulated as

$$\hat{x}_n = \frac{z_n}{\alpha_n(1+\epsilon_n)}, \qquad \hat{x}_k = \frac{z_k(1+\delta_k) - \beta_k\hat{x}_{k+1}}{\alpha_k(1+\epsilon_k)}, \quad 1 \le k \le n-1,$$

where $|\epsilon_n|, |\delta_k| < \varepsilon$, $|\epsilon_k| < 3\varepsilon$, $k \le n-1$. So we have

$$\begin{aligned} &\alpha_n\hat{x}_n(1+\epsilon_n) = z_n \\ &\alpha_{n-1}\hat{x}_{n-1}(1+\epsilon_{n-1}) + \beta_{n-1}\hat{x}_n = z_{n-1}(1+\delta_{n-1}) \\ &\qquad\vdots \\ &\alpha_1\hat{x}_1(1+\epsilon_1) + \beta_1\hat{x}_2 = z_1(1+\delta_1). \end{aligned} \tag{A.1}$$

Define $\tilde{x} = [\tilde{x}_1, \ldots, \tilde{x}_n]^T$, $\tilde{z} = [\tilde{z}_1, \ldots, \tilde{z}_n]^T$, with

$$\tilde{x}_n = \hat{x}_n(1+\epsilon_n), \quad \tilde{x}_{n-1} = \hat{x}_{n-1}(1+\epsilon_{n-1})(1+\epsilon_n), \quad \ldots, \quad \tilde{x}_1 = \hat{x}_1 \prod_{k=1}^{n}(1+\epsilon_k),$$

$$\tilde{z}_n = z_n, \quad \tilde{z}_{n-1} = z_{n-1}(1+\delta_{n-1})(1+\epsilon_n), \quad \ldots, \quad \tilde{z}_1 = z_1(1+\delta_1)\prod_{k=2}^{n}(1+\epsilon_k).$$

By multiplying $(1+\epsilon_n)$ to the second equation, $(1+\epsilon_n)(1+\epsilon_{n-1})$ to the third equation, and so on in (A.1), we obtain that $\tilde{x}$ and $\tilde{z}$ satisfy

$$B\tilde{x} = \tilde{z}.$$

Let $\delta z = \tilde{z} - z$, and $\delta x = \hat{x} - \tilde{x}$. Then from $\tilde{x} = B^{-1}\tilde{z}$ we have

$$\hat{x} = B^{-1}(z + \delta z) + \delta x.$$

The error bounds for $|\delta x|$ and $|\delta z|$ follow simply from the definitions. □

THEOREM A.2. [illegible] 4.1 [illegible]. We only consider the first order errors.

Let $\hat{U}\hat{B}\hat{V}^*$ be the computed bidiagonal factorization of A. Then $\hat{U} = U + \Delta U_1$, $\hat{V} = V + \Delta V_1$, where U, V are unitary and $\|\Delta U_1\|_2 \le d_1\varepsilon$, $\|\Delta V_1\|_2 \le d_2\varepsilon$, and

$$U\hat{B}V^* = A + E,$$

where $\|E\|_2 \le d_3\varepsilon\|A\|_2$ for some modest constants d_1, d_2, d_3. Let $\hat{Y}$ be the numerical solution of $\hat{B}Y = \hat{U}^*$ computed by back substitution. By Lemma A.1,

$$\hat{Y} = \hat{B}^{-1}(\hat{U}^* + \Delta U_2) + \Delta Y,$$

where

$$\|\Delta U_2\|_2 \le 3n^{\frac{3}{2}}\varepsilon, \qquad \|\Delta Y\|_2 \le 3n^{\frac{3}{2}}\varepsilon\|\hat{Y}\|_2.$$

Let X be the computed matrix product $\hat{V}\hat{Y}$. We have

$$X = \hat{V}\hat{Y} + \Delta X,$$

where $\|\Delta X\|_2 \le d_4\varepsilon\|\hat{Y}\|_2$ for some modest constant d_4. Now

$$\begin{aligned} X &= \hat{V}\hat{B}^{-1}(\hat{U}^* + \Delta U_2) + \hat{V}\Delta Y + \Delta X = \hat{V}\hat{B}^{-1}\hat{U}^* + \hat{V}\hat{B}^{-1}\Delta U_2 + \hat{V}\Delta Y + \Delta X \\ &=: V\hat{B}^{-1}U^* + F = (A+E)^{-1} + F, \end{aligned}$$

where

$$F = \Delta V_1\hat{B}^{-1}U^* + V\hat{B}^{-1}(\Delta U_1)^* + \hat{V}\hat{B}^{-1}\Delta U_2 + \hat{V}\Delta Y + \Delta X.$$

It is easily verified that $\|F\|_F \le (6n^{\frac{3}{2}} + d_1 + d_2 + d_4)\varepsilon\|A^{-1}\|_2$. □

A.2. Proof of Lemma 4.3. Equations (4.5) and (4.7) are established in the proof of Theorem 2.5 in [8]. Here we slightly modify that proof to establish (4.6).

Let $A(t) = A + tF$ have polar decompositions $Q(t)H(t)$. Note that $H(t) = (A(t)^*A(t))^{1/2}$ (positive definite square root) and $Q(t) = A(t)H(t)^{-1}$ are sums, differences, products, quotients, and compositions with C^∞ functions of the entries of $A(t)$, which is trivially a C^∞ function. Hence, $Q(t)$ and $H(t)$ are also C^∞. (Here we use the fact that A is nonsingular to observe that $H(t) = (A(t)^*A(t))^{1/2}$ avoids the singularity of the square root at zero.) Using $\dot{Q}$ and $\dot{H}$ to denote differentiation by t, Taylor's theorem implies that

$$\begin{aligned} Q(t) &= Q(0) + t\dot{Q}(0) + O(t^2) = Q(I + tQ^*\dot{Q}(0)) + O(t^2) \\ H(t) &= H(0) + t\dot{H}(0) + O(t^2). \end{aligned}$$

The proof of Theorem 2.5 in [8] shows $\dot{H}(0) = G = G^*$, with G given by (4.5) and $Q^*(0)\dot{Q}(0) = E = -E^*$, with E given by (4.7).

Differentiate $A + tF = Q(t)H(t)$ to get $F = \dot{Q}H + Q\dot{H}$. Evaluating at $t = 0$, letting $E = Q^*(0)\dot{Q}(0)$, $G = \dot{H}(0)$ gives $Q^*F = EH + G$. Using the facts that E is skew-Hermitian and G is Hermitian while subtracting this equation to its Hermitian transpose gives (4.6). The Lyapunov operator on the right is nonsingular, because A nonsingular implies that the eigenvalues of the Hermitian polar factor H are real and positive. Hence, the solution E is unique.

A.3. Proof for (4.15). Let $\widehat{Q}_p = U_p\Sigma_pV_p^*$ be the SVD. Recall that the singular values satisfy $\sigma_i^{(p)} \geq 1$. Then $\|\widehat{Q}_p - \widehat{Q}_p^{-*}\|_2 < \delta$ implies that

$$\sigma_i^{(p)} - \frac{1}{\sigma_i^{(p)}} < \delta, \quad i = 1, 2, \ldots, n.$$

Because

$$\sigma_i^{(p)} - \frac{1}{\sigma_i^{(p)}} = \frac{(\sigma_i^{(p)} + 1)(\sigma_i^{(p)} - 1)}{\sigma_i^{(p)}},$$

we have

$$\sigma_i^{(p)} - 1 < \frac{\delta\sigma_i^{(p)}}{\sigma_i^{(p)} + 1}.$$

Then

$$\frac{1}{2}\left(\sigma_i^{(p)} + \frac{1}{\sigma_i^{(p)}}\right) - 1 = \frac{(\sigma_i^{(p)} - 1)^2}{2\sigma_i^{(p)}} < \frac{\sigma_i^{(p)}}{2(\sigma_i^{(p)} + 1)^2}\delta^2.$$

Since the function $x/(x+1)^2$ is decreasing when $x \geq 1$, we have $\sigma_i^{(p)}/(\sigma_i^{(p)}+1)^2 \leq 1/4$. Hence

$$\frac{1}{2}\left(\sigma_i^{(p)} + \frac{1}{\sigma_i^{(p)}}\right) - 1 < \delta^2/8$$

and using $W_p = U_pV_p^*$,

$$\begin{aligned} \|\Delta\widehat{Q}_p\|_2 &= \|(\widehat{Q}_p + \widehat{Q}_p^{-*})/2 - W_p\|_2 = \|U_p((\Sigma_p + \Sigma_p^{-1})/2 - I)V_p^*\|_2 \\ &= \max_i \left(\frac{1}{2}\left(\sigma_i^{(p)} + \frac{1}{\sigma_i^{(p)}}\right) - 1\right) < \delta^2/8. \end{aligned}$$

A.4. Proof of Lemma 4.4. By (2.4), $\sigma_{\max}^{(k)} \le b_k$ for $k \ge 0$.
So we only need to show that

$$\frac{b_k}{\sigma_i^{(k)} + \sigma_j^{(k)}} \le \frac{b}{\sigma_i + \sigma_j}, \quad k \ge 0.$$

An easy calculation shows, for all i and j,

$$\sigma_i^{(k)} + \sigma_j^{(k)} = \frac{\zeta_{k-1}}{2} \left(\sigma_i^{(k-1)} + \sigma_j^{(k-1)}\right) \left(1 + \frac{1}{\zeta_{k-1}^2 \sigma_i^{(k-1)} \sigma_j^{(k-1)}}\right).$$

Recall b_k satisfies

$$b_k = \frac{1}{2}\left(\zeta_{k-1} b_{k-1} + \frac{1}{\zeta_{k-1} b_{k-1}}\right) = \frac{\zeta_{k-1}}{2}\, b_{k-1} \left(1 + \frac{1}{\zeta_{k-1}^2 b_{k-1}^2}\right).$$

Because $\sigma_i^{(k-1)} \sigma_j^{(k-1)} \le b_{k-1}^2$,

$$\begin{aligned} \frac{b_k}{\sigma_i^{(k)} + \sigma_j^{(k)}} &= \frac{\frac{\zeta_{k-1}}{2}\, b_{k-1} \left(1 + \frac{1}{\zeta_{k-1}^2 b_{k-1}^2}\right)}{\frac{\zeta_{k-1}}{2} \left(\sigma_i^{(k-1)} + \sigma_j^{(k-1)}\right) \left(1 + \frac{1}{\zeta_{k-1}^2 \sigma_i^{(k-1)} \sigma_j^{(k-1)}}\right)} \\ &\le \frac{b_{k-1}}{\sigma_i^{(k-1)} + \sigma_j^{(k-1)}}. \end{aligned}$$

An easy induction on k now implies that

$$\frac{b_k}{\sigma_i^{(k)} + \sigma_j^{(k)}} \le \frac{b_0}{\sigma_i^{(0)} + \sigma_j^{(0)}} = \frac{b}{\sigma_i + \sigma_j}, \quad k \ge 0.$$

. . 2.

1. The condition $a \le \|A^{-1}\|_2^{-1}$ is essential for proving Lemma 4.4. Without it one may not have the inequality $\sigma_j^{(k)} \le b_k$, and the result cannot be proved.
2. In the case that the optimal scaling is employed, $b_k = \sigma_{\max}^{(k)}$, and one has the same result.

A.5. Relation (4.23) for the scalings (1.3) and (1.4).

LEMMA A.3. . . . . Q_k . . . . . ,
. . . . . ζ_k . . . . . $\zeta_k^{(1,\infty)}$. (1.3) . $\zeta_k^{(F)}$. (1.4) . . . . . Q_k . . . .

$$\frac{\sigma_{\max}^{(k)}}{\sigma_i^{(k)} + \sigma_j^{(k)}} \le \left(\prod_{\ell=0}^{k-1} \psi_\ell\right) \frac{\|A\|_2}{\sigma_i + \sigma_j} \le n^{\frac{k}{2}} \frac{\|A\|_2}{\sigma_i + \sigma_j}, \quad k \ge 0, \quad 1 \le i, j \le n, \tag{A.2}$$

. . . $\psi_\ell = \max\{1, \frac{1}{\zeta_\ell^2 \sigma_{\max}^{(\ell)} \sigma_{\min}^{(\ell)}}\} \le \sqrt{n}$.
. . . . Let

$$w_k = \frac{1}{\zeta_k^2 \sigma_{\min}^{(k)} \sigma_{\max}^{(k)}}, \quad k \ge 0.$$

If

$$\zeta_k = \zeta_k^{(1,\infty)} = \sqrt[4]{\frac{\|Q_k^{-1}\|_1 \|Q_k^{-1}\|_\infty}{\|Q_k\|_1 \|Q_k\|_\infty}},$$

using the inequalities $\|A\|_2 \le \sqrt{\|A\|_1 \|A\|_\infty} \le \sqrt{n}\|A\|_2$, we have ([11, p. 208])

$$\frac{1}{\sqrt[4]{n}}\,\zeta_k \le \frac{1}{\sqrt{\sigma_{\min}^{(k)} \sigma_{\max}^{(k)}}} \le \sqrt[4]{n}\,\zeta_k. \tag{A.3}$$

If

$$\zeta_k = \zeta_k^{(F)} = \sqrt{\frac{\|Q_k^{-1}\|_F}{\|Q_k\|_F}},$$

using the inequalities $\|A\|_2 \le \|A\|_F \le \sqrt{n}\,\|A\|_2$, we also have (A.3).

So in both cases we have

$$\frac{1}{\sqrt{n}} \le w_k \le \sqrt{n}.$$

Construct an interval $[a_k, b_k]$ according to the rule

$$\begin{array}{lll} a_k = \sigma_{\min}^{(k)} w_k, & b_k = \sigma_{\max}^{(k)}, & w_k \le 1, \\ a_k = \sigma_{\min}^{(k)}, & b_k = \sigma_{\max}^{(k)} w_k, & w_k \ge 1. \end{array}$$

Because $a_k \le \sigma_{\min}^{(k)}$ and $b_k \ge \sigma_{\max}^{(k)}$, we have $\sigma_1^{(k)}, \dots, \sigma_n^{(k)} \in [a_k, b_k]$. Also, in both cases we have $(\zeta_k a_k)^{-1} = \zeta_k b_k$. So $\rho(\zeta_k a_k) = \rho(\zeta_k b_k)$ and

$$\sigma_j^{(k+1)} = \rho(\zeta_k \sigma_j^{(k)}) \in \rho(\zeta_k [a_k, b_k]) = [1, \rho(\zeta_k b_k)], \quad j = 1, 2, \dots, n.$$

Since

$$\rho(\zeta_k b_k) = \frac{1}{2}\left(\zeta_k b_k + \frac{1}{\zeta_k b_k}\right) = \frac{\zeta_k b_k}{2}\left(1 + \frac{1}{(\zeta_k b_k)^2}\right),$$

we have

$$\begin{aligned} \frac{\sigma_{\max}^{(k+1)}}{\sigma_i^{(k+1)} + \sigma_j^{(k+1)}} \le \frac{\rho(\zeta_k b_k)}{\sigma_i^{(k+1)} + \sigma_j^{(k+1)}} &= \frac{\frac{\zeta_k b_k}{2}\left(1 + \frac{1}{(\zeta_k b_k)^2}\right)}{\frac{\zeta_k}{2}(\sigma_i^{(k)} + \sigma_j^{(k)})\left(1 + \frac{1}{\zeta_k^2 \sigma_i^{(k)} \sigma_j^{(k)}}\right)} \\ &= \frac{b_k\left(1 + \frac{1}{(\zeta_k b_k)^2}\right)}{(\sigma_i^{(k)} + \sigma_j^{(k)})\left(1 + \frac{1}{\zeta_k^2 \sigma_i^{(k)} \sigma_j^{(k)}}\right)}. \end{aligned}$$

If $w_k \le 1$, then $b_k = \sigma_{\max}^{(k)}$. Because $\sigma_i^{(k)} \sigma_j^{(k)} \le \left(\sigma_{\max}^{(k)}\right)^2 = b_k^2$, we have

$$\frac{\sigma_{\max}^{(k+1)}}{\sigma_i^{(k+1)} + \sigma_j^{(k+1)}} \le \frac{b_k}{\sigma_i^{(k)} + \sigma_j^{(k)}} = \frac{\sigma_{\max}^{(k)}}{\sigma_i^{(k)} + \sigma_j^{(k)}}.$$

If $w_k \geq 1$, then $b_k = \sigma_{\max}^{(k)} w_k$. Because $\sigma_i^{(k)}\sigma_j^{(k)} \leq \left(\sigma_{\max}^{(k)}\right)^2 \leq b_k^2$, we have

$$\frac{\sigma_{\max}^{(k+1)}}{\sigma_i^{(k+1)} + \sigma_j^{(k+1)}} \leq \frac{b_k}{\sigma_i^{(k)} + \sigma_j^{(k)}} = w_k \frac{\sigma_{\max}^{(k)}}{\sigma_i^{(k)} + \sigma_j^{(k)}}.$$

Hence

$$\frac{\sigma_{\max}^{(k+1)}}{\sigma_i^{(k+1)} + \sigma_j^{(k+1)}} \leq \psi_k \frac{\sigma_{\max}^{(k)}}{\sigma_i^{(k)} + \sigma_j^{(k)}}, \quad \psi_k = \max\{1, w_k\} \leq \sqrt{n}.$$

Then the inequalities in (A.2) can be easily derived. □

. . . 3. Suppose that Newton's method with scaling $\zeta_k^{(1,\infty)}$ or $\zeta_k^{(F)}$ terminates after p iterations. We have the same error bounds as in Theorem 4.5 but with a factor $n^{\frac{p}{2}}$ in the first term of the bounds for $\|\widehat{Q}\widehat{H} - A\|_2$, $\|\widehat{H} - H\|_2$, and $\|\widehat{Q} - Q\|_2$. When n and p are both large, this factor is notably large, and one may not be able to use the bounds to claim backward stability. Unfortunately, we are unable to provide an upper bound for p, although it is observed that p is usually moderate in practice ($p \leq 9$ for the $(1,\infty)$-scaling for all examples in section 5).

However, we argue that the factor $n^{\frac{p}{2}}$ is an overestimate. The point is that, when Q_k is getting close to a unitary matrix, $\zeta_k^{(1,\infty)}$ and $\zeta_k^{(F)}$ are getting close to 1. Then w_k as well as ψ_k will be close to 1. So in practice w_k will be around 1 after a couple of iterations.

Acknowledgments. We thank Nick Higham for detailed suggestions and sending part of his unpublished book [11]. We thank Andrzej Kiełbasiński for pointing out a mistake in an earlier version and the referees for their comments and suggestions.

RELATIVE-ERROR *CUR* MATRIX DECOMPOSITIONS*

PETROS DRINEAS†, MICHAEL W. MAHONEY‡, AND S. MUTHUKRISHNAN§

Abstract. Many data analysis applications deal with large matrices and involve approximating the matrix using a small number of "components." Typically, these components are linear combinations of the rows and columns of the matrix, and are thus difficult to interpret in terms of the original features of the input data. In this paper, we propose and study matrix approximations that are explicitly expressed in terms of a small number of columns and/or rows of the data matrix, and thereby more amenable to interpretation in terms of the original data. Our main algorithmic results are two randomized algorithms which take as input an $m \times n$ matrix A and a rank parameter k. In our first algorithm, C is chosen, and we let $A' = CC^+A$, where C^+ is the Moore–Penrose generalized inverse of C. In our second algorithm C, U, R are chosen, and we let $A' = CUR$. (C and R are matrices that consist of actual columns and rows, respectively, of A, and U is a generalized inverse of their intersection.) For each algorithm, we show that with probability at least $1 - \delta$, $\|A - A'\|_F \leq (1 + \epsilon)\|A - A_k\|_F$, where A_k is the "best" rank-k approximation provided by truncating the SVD of A, and where $\|X\|_F$ is the Frobenius norm of the matrix X. The number of columns of C and rows of R is a low-degree polynomial in k, $1/\epsilon$, and $\log(1/\delta)$. Both the Numerical Linear Algebra community and the Theoretical Computer Science community have studied variants of these matrix decompositions over the last ten years. However, our two algorithms are the first polynomial time algorithms for such low-rank matrix approximations that come with relative-error guarantees; previously, in some cases, it was not even known whether such matrix decompositions exist. Both of our algorithms are simple and they take time of the order needed to approximately compute the top k singular vectors of A. The technical crux of our analysis is a novel, intuitive sampling method we introduce in this paper called "subspace sampling." In subspace sampling, the sampling probabilities depend on the Euclidean norms of the rows of the top singular vectors. This allows us to obtain provable relative-error guarantees by deconvoluting "subspace" information and "size-of-A" information in the input matrix. This technique is likely to be useful for other matrix approximation and data analysis problems.

1. Introduction.

Large $m \times n$ matrices are common in applications since the data often consist of m objects, each of which is described by n features. Examples of object–feature pairs include: documents and words contained in those documents; genomes and environmental conditions under which gene responses are measured; stocks and their associated temporal resolution; hyperspectral images and frequency resolution; and web groups and individual users. In each of these application areas, practitioners spend vast amounts of time analyzing the data in order to understand, interpret, and ultimately use this data for some application-specific task.

Say that A is the $m \times n$ data matrix. In many cases, an important step in data analysis is to construct a compressed representation of A that may be easier to analyze and interpret. The most common such representation is obtained by truncating the SVD at some number $k \ll \min\{m, n\}$ terms, in large part because this provides the "best" rank-k approximation to A when measured with respect to any unitarily invariant matrix norm. Unfortunately, the basis vectors (the so-called eigencolumns and eigenrows) provided by this approximation (and with respect to which every column and row of the original data matrix is expressed) are notoriously difficult to interpret in terms of the underlying data and processes generating that data. For example, the vector $[(1/2)\ \text{age} - (1/\sqrt{2})\ \text{height} + (1/2)\ \text{income}]$, being one of the significant uncorrelated "factors" from a dataset of people's features, is not particularly informative. It would be highly preferable to have a low-rank approximation that is nearly as good as that provided by the SVD but that is expressed in terms of a small number of [illegible] and/or [illegible] of a matrix, rather than linear combinations of those columns and rows.

The main contribution of this paper is to provide such decompositions. In particular, we provide what we call a relative-error [illegible]: given an $m \times n$ matrix A, we decompose it as a product of three matrices, C, U, and R, where C consists of a small number of actual columns of A, R consists of a small number of actual rows of A, and U is a small carefully constructed matrix that guarantees that the product CUR is "close" to A. In fact, CUR will be nearly as good as the best low-rank approximation to A that is traditionally used and that is obtained by truncating the SVD. Hence, the columns of A that are included in C, as well as the rows of A that are included in R, can be used in place of the eigencolumns and eigenrows, with the added benefit of improved interpretability in terms of the original data.

Before describing applications of our main results in the next subsection, we would like to emphasize that two research communities, the Numerical Linear Algebra (NLA) community and the Theoretical Computer Science (TCS) community, have provided significant practical and theoretical motivation for studying variants of these matrix decompositions over the last ten years. In section 3, we provide a detailed treatment of relevant prior work in both the NLA and the TCS literature. The two algorithms presented in this paper are the first polynomial time algorithms for such low-rank matrix approximations that come with relative-error guarantees; previously, in some cases, it was not even known whether such matrix decompositions exist.

1.1. Applications. As an example of this preference for having the data matrix expressed in terms of a small number of actual columns and rows of the original matrix, as opposed to a small number of eigencolumns and eigenrows, consider recent data analysis work in DNA microarray and DNA Single Nucleotide Polymorphism (SNP) analysis [44, 47, 52]. DNA SNP data are often modeled as an $m \times n$ matrix A, where m is the number of individuals in the study, n is the number of SNPs being analyzed, and A_{ij} is an encoding of the jth SNP value for the ith individual. Similarly, for DNA microarray data, m is the number of genes under consideration, n is the number of arrays or environmental conditions, and A_{ij} is the absolute or relative expression level of the ith gene in the jth environmental condition. Biologists typically have an understanding of a single gene that they fail to have about a linear combination of 6000 genes (and also similarly for SNPs, individuals, and arrays); thus, recent work in genetics on DNA microarray and DNA SNP data has focused on heuristics to extract [illegible] genes, environmental conditions, individuals, and SNPs from the eigengenes, eigenconditions, eigenpeople, and eigenSNPs computed from the original

data matrices [44, 47].[1] Our , matrix decomposition is a direct formulation of this problem: determine a small number of actual SNPs that serve as a basis with which to express the remaining SNPs, and a small number of individuals to serve as a basis with which to express the remaining individuals. In fact, motivated in part by this, we have successfully applied a variant of the , matrix decomposition presented in this paper to intra- and interpopulation genotype reconstruction from tagging SNPs in DNA SNP data from a geographically diverse set of populations [52]. In addition, we have applied a different variant of our , matrix decomposition to hyperspectrally resolved medical imaging data [48]. In this application, a column corresponds to an image at a single physical frequency and a row corresponds to a single spectrally resolved pixel, and we have shown that data reconstruction and classification tasks can be performed with little loss in quality even after substantial data compression [48].

A quite different motivation for low-rank matrix approximations expressed in terms of a small number of columns and/or rows of the original matrix is to decompose efficiently large low-rank matrices that possess additional structure such as sparsity or nonnegativity. This often arises in the analysis of, e.g., large term-document matrices [58, 59, 8]. Another motivation comes from statistical learning theory, where the data need not even be elements in a vector space, and thus expressing the Gram matrix in terms of a small number of actual data points is of interest [64, 63, 24, 25]. This procedure has been shown empirically to perform well for approximate Gaussian process classification and regression [64], to approximate the solution of spectral partitioning for image and video segmentation [32], and to extend the eigenfunctions of a data-dependent kernel to new data points [7, 45]. Yet another motivation is provided by integral equation applications [40, 39, 38], where large coefficient matrices arise that have blocks corresponding to regions where the kernel is smooth and that are thus well-approximated by low-rank matrices. In these applications, partial SVD algorithms can be expensive, and a description in terms of actual columns and/or rows is of interest [39, 38]. A final motivation for studying matrix decompositions of this form is to obtain low-rank matrix approximations to extremely large matrices where a computation of the SVD is too expensive [33, 34, 21, 22, 23].

1.2. Our main results. Our main algorithmic results have to do with efficiently computing low-rank matrix approximations that are explicitly expressed in terms of a small number of columns and/or rows of the input matrix. We start with the following definition.

DEFINITION 1. $\ldots$ A $\ldots$ $m \times n$ $\ldots$ $\ldots$ C $\ldots$ $m \times c$ $\ldots$ $\ldots$ c $\ldots$ $\ldots$ A $\ldots$ $m \times n$ $\ldots$ $A' = CX$ $\ldots$ column-based matrix approximation $\ldots$ A $\ldots$ CX matrix decomposition $\ldots$ $c \times n$ $\ldots$ X

Several things should be noted about this definition. First, we will be interested in $c \ll n$ in our applications. For example, depending on the application, c could be constant, independent of n, logarithmic in the size of n, or simply a large constant factor less than n. Second, a CX matrix decomposition expresses each of the columns

[1] For example, in their review article "Vector algebra in the analysis of genome-wide expression data" [44], which appeared in *Genome Biology*, Kuruvilla, Park, and Schreiber describe many uses of the vectors provided by the SVD and PCA in DNA microarray analysis. The three biologists then conclude by stating that: "While very efficient basis vectors, the vectors themselves are completely artificial and do not correspond to actual (DNA expression) profiles. ... Thus, it would be interesting to try to find basis vectors for all experiment vectors, using actual experiment vectors and not artificial bases that offer little insight." That is, they explicitly state that they would like decompositions of the form we provide in this paper!

of A in terms of a linear combination of "dictionary elements" or "basis columns," each of which is an actual column of A. Thus, a CX matrix decomposition provides a low-rank approximation to the original matrix, although one with structural properties that are quite different than those provided by the SVD. Third, given a set of columns C, the approximation $A' = P_C A = CC^+A$ (where $P_C A$ is the projection of A onto the subspace spanned by the columns of C and C^+ is the Moore–Penrose generalized inverse of C, as defined in section 2) clearly satisfies the requirements of Definition 1. Indeed, this is the "best" such approximation to A, in the sense that $\|A - C(C^+A)\|_F = \min_{X \in \mathbb{R}^{c \times n}} \|A - CX\|_F$.

Our first main result is the following.

THEOREM 1. [illegible] $A \in \mathbb{R}^{m \times n}$ [illegible] $k \ll \min\{m, n\}$ [illegible] $c = O(k^2 \log(1/\delta)/\epsilon^2)$ [illegible] A [illegible] C [illegible] $c = O(k \log k \log(1/\delta)/\epsilon^2)$ [illegible] C [illegible] $1 - \delta$

$$\min_{X \in \mathbb{R}^{c \times n}} \|A - CX\|_F = \left\|A - CC^+A\right\|_F \leq (1 + \epsilon) \|A - A_k\|_F . \tag{1}$$

[illegible] C [illegible] A CC^+A [illegible] A [illegible] A_k [illegible] k [illegible] A [illegible] $O(SVD(A, k))$ [illegible] k [illegible] A [37]

Note that we use $c > k$ and have an ϵ error, which allows us to take advantage of linear algebraic structure in order to obtain an efficient algorithm. In general, this would not be the case if, given an $m \times n$ matrix A, we had specified a parameter k and asked for the "best" subset of k columns, where "best" is measured, e.g., by maximizing the Frobenius norm captured by projecting onto those columns or by maximizing the volume of the parallelepiped defined by those columns. Also, it is not clear a priori that C with properties above even exists; see the discussion in sections 3.2 and 3.3. Finally, our result does not include any reference to regularization or conditioning, as is common in certain application domains; a discussion of similar work on related problems in numerical linear algebra may be found in section 3.1.

Our second main result extends the previous result to [illegible] matrix decompositions.

DEFINITION 2. [illegible] A [illegible] $m \times n$ [illegible] C [illegible] $m \times c$ [illegible] c [illegible] A [illegible] R [illegible] $r \times n$ [illegible] r [illegible] A [illegible] $m \times n$ [illegible] $A' = CUR$ [illegible] column-row-based matrix approximation [illegible] A [illegible] CUR matrix decomposition [illegible] [illegible] $c \times r$ [illegible] U

Several things should be noted about this definition. First, a [illegible] matrix decomposition is a CX matrix decomposition, but one with a very special structure; i.e., every column of A can be expressed in terms of the basis provided by C using only the information contained in a small number of rows of A and a low-dimensional encoding matrix. Second, in terms of its singular value structure, U must clearly contain "inverse-of-A" information. For the [illegible] decomposition described in this paper, U will be a generalized inverse of the intersection between C and R. More precisely, if $C = AS_C D_C$ and $R = D_R S_R^T A$, then $U = (D_R S_R^T A S_C D_C)^+$. (See section 2 for a review of linear algebra and notation, such as that for S_C, D_C, S_R, and D_R.) Third, the combined size of C, U, and R is $O(mc + rn + cr)$, which is an improvement over A's size of $O(mn)$ when $c, r \ll n, m$. Finally, note the structural simplicity of a [illegible]

matrix decomposition:

(2) 
Our main result for matrix decomposition is the following.

THEOREM 2. $A \in \mathbb{R}^{m \times n}$ $k \ll \min\{m, n\}$ $c = O(k^2 \log(1/\delta)/\epsilon^2)$ A C $r = O(c^2 \log(1/\delta)/\epsilon^2)$ A R $c = O(k \log k \log(1/\delta)/\epsilon^2)$ A C $r = O(c \log c \log(1/\delta)/\epsilon^2)$ A R $1 - \delta$

$$\|A - CUR\|_F \leq (1 + \epsilon) \|A - A_k\|_F . \tag{3}$$

U C R A_k k A $O(SVD(A, k))$ k A [37]

1.3. Summary of main technical result. The key technical insight that leads to the relative-error guarantees is that the columns are selected by a novel sampling procedure that we call "subspace sampling." Rather than sample columns from A with a probability distribution that depends on the Euclidean norms of the columns of A (which gives provable additive-error bounds [21, 22, 23]), in "subspace sampling" we randomly sample columns of A with a probability distribution that depends on the Euclidean norms of the rows of the top k right singular vectors of A. This allows us to capture entirely a certain subspace of interest. Let $V_{A,k}$ be the $n \times k$ matrix whose columns consist of the top k right singular vectors of A. The "subspace sampling" probabilities $p_i, i \in [n]$ will satisfy

$$p_i \geq \frac{\beta \left| (V_{A,k})_{(i)} \right|_2^2}{k} \qquad \forall i \in [n], \tag{4}$$

for some $\beta \in (0, 1]$, where $(V_{A,k})_{(i)}$ is the ith of $V_{A,k}$. That is, we will sample based on the norms of the rows (not the columns) of the truncated matrix of singular vectors. Note that $\sum_{j=1}^{n} |(V_{A,k})_{(j)}|_2^2 = k$ and that $\sum_{i \in [n]} p_i = 1$. To construct sampling probabilities satisfying Condition (4), it is sufficient to spend $O(SVD(A, k))$ time to compute (exactly or approximately, in which case $\beta = 1$ or $\beta < 1$, respectively) the top k right singular vectors of A. Sampling probabilities of this form will allow us to deconvolute subspace information and "size-of-A" information in the input matrix A, which in turn will allow us to obtain the relative-error guarantees we desire. Note that we have used this method previously [29], but in that case the sampling probabilities contained other terms that complicated their interpretation.

We will use these "subspace sampling" probabilities in our main technical result, which is a random sampling algorithm for approximating the following generalized

version of the standard ℓ_2 regression problem. Our main column/row-based approximation algorithmic results will follow from this result. Given as input a matrix $A \in \mathbb{R}^{m \times n}$ that has rank no more than k and a matrix of target vectors $B \in \mathbb{R}^{m \times p}$ compute

$$\mathcal{Z} = \min_{X \in \mathbb{R}^{n \times p}} \|B - AX\|_F . \tag{5}$$

That is, fit every column of the matrix B to the basis provided by the columns of the rank-k matrix A. Also of interest is the computation of

$$X_{opt} = A^+ B. \tag{6}$$

The main technical result of this paper is a simple sampling algorithm that represents the matrices A and B by a small number of rows so that this generalized ℓ_2 regression problem can be solved to accuracy $1 \pm \epsilon$ for any $\epsilon > 0$.

More precisely, we present and analyze an algorithm (Algorithm 3 of section 6) that constructs and solves an induced subproblem of the generalized ℓ_2 regression problem of (5) and (6). Let $DS^T A$ be the $r \times n$ matrix consisting of the sampled and appropriately rescaled rows of the original matrix A, and let $DS^T B$ be the $r \times p$ matrix consisting of the sampled and appropriately rescaled rows of B. Then consider the problem

$$\tilde{\mathcal{Z}} = \min_{X \in \mathbb{R}^{n \times p}} \left\|DS^T B - DS^T AX\right\|_F . \tag{7}$$

The "smallest" matrix $\tilde{X}_{opt} \in \mathbb{R}^{n \times p}$ among those that achieve the minimum value $\tilde{\mathcal{Z}}$ in this sampled ℓ_2 regression problem is

$$\tilde{X}_{opt} = \left(DS^T A\right)^+ DS^T B. \tag{8}$$

Since we will sample a number of rows $r \ll m$ of the original problem, we will compute (8), and thus (7), exactly. Our main theorem, Theorem 5, states that under appropriate assumptions on the original problem and on the sampling probabilities, the computed quantities $\tilde{\mathcal{Z}}$ and $\tilde{X}_{opt}$ will provide very accurate relative-error approximations to the exact solution $\mathcal{Z}$ and the optimal vector X_{opt}. Rows will be sampled with one of two random sampling procedures. In one case, exactly $r = O(k^2/\epsilon^2)$ rows are chosen, and in the other case, $r = O(k \log k/\epsilon^2)$ rows in expectation are chosen. In either case, the most expensive part of the computation involves the computation of the Euclidean norms of the rows of the right singular vectors of A which are used in the sampling probabilities.

1.4. Outline of the remainder of the paper. In the next two sections, we provide a review of relevant linear algebra, and we discuss related work. Then, in sections 4 and 5, we present in detail our main algorithmic results. In section 4, we describe our main column-based matrix approximation algorithm, and in section 5, we describe our main column-row-based matrix approximation algorithm. Then, in section 6, we present an approximation algorithm for generalized ℓ_2 regression. This is our main technical result, and from it our two main algorithmic results will follow. Finally, in section 7 we present an empirical evaluation of our algorithms, and in section 8 we present a brief conclusion. We devote Appendix A to two prior algorithms for approximate matrix multiplication. These two algorithms select columns and rows in a complementary manner, and they are essential in the proof of our main results.

2. Review of linear algebra. In this section, we provide a review of linear algebra that will be useful throughout the paper; for more details, see [50, 43, 60, 37, 9, 6]. We also review a sampling matrix formalism that will be convenient in our discussion [21].

Let $[n]$ denote the set $\{1, 2, \ldots, n\}$. For any matrix $A \in \mathbb{R}^{m \times n}$, let $A_{(i)}, i \in [m]$ denote the ith row of A as a row vector, and let $A^{(j)}, j \in [n]$ denote the jth column of A as a column vector. In addition, let $\|A\|_F^2 = \sum_{i=1}^{m} \sum_{j=1}^{n} A_{ij}^2$ denote the square of its Frobenius norm, and let $\|A\|_2 = \sup_{x \in \mathbb{R}^n,\ x \neq 0} |Ax|_2 / |x|_2$ denote its spectral norm. These norms satisfy $\|A\|_2 \leq \|A\|_F \leq \sqrt{\min\{m,n\}}\, \|A\|_2$ for any matrix A, and also $\|AB\|_F \leq \|A\|_F \, \|B\|_2$ for any matrices A and B.

If $A \in \mathbb{R}^{m \times n}$, then there exist orthogonal matrices $U = [u^1 u^2 \ldots u^m] \in \mathbb{R}^{m \times m}$ and $V = [v^1 v^2 \ldots v^n] \in \mathbb{R}^{n \times n}$ such that $U^T A V = \Sigma = \mathbf{diag}(\sigma_1, \ldots, \sigma_\xi)$, where $\Sigma \in \mathbb{R}^{m \times n}$, $\xi = \min\{m, n\}$ and $\sigma_1 \geq \sigma_2 \geq \ldots \geq \sigma_\xi \geq 0$. Equivalently, $A = U \Sigma V^T$. The three matrices U, V, and Σ constitute the SVD of A. The σ_i are the singular values of A, the vectors u^i and v^i are the ith left and the ith right singular vectors of A, respectively, and the condition number of A is $\kappa(A) = \sigma_{\max}(A)/\sigma_{\min}(A)$. If $k \leq r = \mathrm{rank}(A)$, then the SVD of A may be written as

(9)
$$A = U_A \Sigma_A V_A^T = \left[\begin{array}{cc} U_k & U_k^\perp \end{array} \right] \left[\begin{array}{cc} \Sigma_k & \mathbf{0} \\ \mathbf{0} & \Sigma_{k,\perp} \end{array} \right] \left[\begin{array}{c} V_k^T \\ V_k^{\perp T} \end{array} \right] = U_k \Sigma_k V_k^T + U_k^\perp \Sigma_{k,\perp} V_k^{\perp T}.$$

Here, Σ_k is the $k \times k$ diagonal matrix containing the top k singular values of A, and $\Sigma_{k,\perp}$ is the $(r-k) \times (r-k)$ diagonal matrix containing the bottom $r-k$ nonzero singular values of A. Also, V_k^T is the $k \times n$ matrix whose rows are the top k right singular vectors of A, $V_k^{\perp T}$ is the $(r-k) \times n$ matrix whose rows are the bottom $r-k$ right singular vectors of A, and U_k and $U_k^\perp$ are defined similarly. If we define $A_k = U_k \Sigma_k V_k^T$, then the distance (as measured by both $\|\cdot\|_2$ and $\|\cdot\|_F$) between A and any rank k approximation to A is minimized by A_k. We will denote by $O(SVD(A,k))$ the time required to compute the best rank-k approximation to the matrix A [37]. Finally, for any orthogonal matrix $U \in \mathbb{R}^{m \times c}$, let $U^\perp \in \mathbb{R}^{m \times (m-c)}$ denote an orthogonal matrix whose columns are an orthonormal basis spanning the subspace of $\mathbb{R}^m$ that is orthogonal to the column space of U.

Given a matrix $A \in \mathbb{R}^{m \times n}$, the unweighted Moore–Penrose generalized inverse of A, denoted by A^+, is the unique $n \times m$ matrix that satisfies the four Moore–Penrose conditions [50, 6]. In terms of the SVD this generalized inverse may be written as $A^+ = V_A \Sigma_A^{-1} U_A^T$ (where the square diagonal $\mathrm{rank}(A) \times \mathrm{rank}(A)$ matrix Σ_A, as in (9), is invertible by construction). If, in addition, $D_1 \in \mathbb{R}^{m \times m}$ and $D_2 \in \mathbb{R}^{n \times n}$ are diagonal matrices with positive entries along the diagonal, then the $\{D_1, D_2\}$-Moore–Penrose generalized inverse of A, denoted by $A^+_{(D_1,D_2)}$, is a generalization of the Moore–Penrose inverse that can be expressed in terms of the unweighted generalized inverse of A as $A^+_{(D_1,D_2)} = D_2^{-1/2} (D_1^{1/2} A D_2^{-1/2})^+ D_1^{1/2}$. Also, in terms of the generalized inverse, the projection onto the column space of any matrix A may be written as $P_A = AA^+$.

Since our main algorithms will involve sampling columns and/or rows from input matrices (using one of two related random sampling procedures described in Appendix A), we conclude this subsection with a brief review of a sampling matrix formalism that was introduced in [21] and with respect to which our sampling matrix operations may be conveniently expressed. First, assume that c' (= c , , ,) columns of A are chosen in c i.i.d. trials by randomly sampling according to

a probability distribution $\{p_i\}_{i=1}^n$ with the EXACTLY(c) algorithm (described in detail in Appendix A), and assume that the i_tth column of A is chosen in the tth (for $t = 1, \ldots, c$) independent random trial. Then, define the sampling matrix $S \in \mathbb{R}^{n \times c}$ to be the zero-one matrix where $S_{i_t t} = 1$ and $S_{ij} = 0$ otherwise, and define the diagonal rescaling matrix $D \in \mathbb{R}^{c \times c}$ to be the diagonal matrix with $D_{tt} = 1/\sqrt{cp_{i_t}}$, where p_{i_t} is the probability of choosing the i_tth column. Alternatively, assume that c' ($\leq c$, with high probability) columns of A are chosen with the EXPECTED(c) algorithm (also described in detail in Appendix A) by including the ith column of A in C with probability $\tilde{p}_i = \min\{1, cp_i\}$. Then, define the sampling matrix $S \in \mathbb{R}^{n \times n}$ to be the zero-one matrix where $S_{ii} = 1$ if the ith column is chosen and $S_{ij} = 0$ otherwise, and define the rescaling matrix $D \in \mathbb{R}^{n \times c'}$ to be the matrix with $D_{ij} = 1/\sqrt{c\tilde{p}_j}$ if $i - 1$ of the previous columns have been chosen and $D_{ij} = 0$ otherwise. Clearly, in both of these cases, $C = ASD$ is an $m \times c'$ matrix consisting of sampled and rescaled copies of the columns of A, and $R = (SD)^T A = DS^T A$ is a $c' \times n$ matrix consisting of sampled and rescaled copies of the rows of A. In certain cases, we will subscript S and D with C or R (e.g., $C = AS_C D_C$ and $R = D_R S_R^T A$) to make explicit that the corresponding sampling and rescaling matrices are operating on the columns or rows, respectively, of A.

3. Relationship with previous related work. In this section, we discuss the relationship between our results and related work in numerical linear algebra and theoretical computer science.

3.1. Related work in numerical linear algebra. Within the numerical linear algebra community, several groups have studied matrix decompositions with similar structural, if not algorithmic, properties to the CX and , matrix decompositions we have defined. Much of this work is related to the QR decomposition, originally used extensively in pivoted form by Golub [36, 11].

Stewart and collaborators were interested in computing sparse low-rank approximations to large sparse term-document matrices [58, 59, 8]. He developed the quasi-Gram–Schmidt method. This method is a variant of the QR decomposition which, when given as input an $m \times n$ matrix A and a rank parameter k, returns an $m \times k$ matrix C consisting of k columns of A whose span approximates the column space of A and also a nonsingular upper-triangular $k \times k$ matrix T_C that orthogonalizes these columns (but it does not explicitly compute the nonsparse orthogonal matrix $Q_C = CT_C^{-1}$). This provides a matrix decomposition of the form $A \approx CX$. By applying this method to A to obtain C and to A^T to obtain an $k \times n$ matrix R consisting of k rows of A, one can show that $A \approx CUR$, where the matrix U is computed to minimize $\|A - CUR\|_F^2$. Although provable approximation guarantees of the form we present were not provided, backward error analysis was performed, and the method was shown to perform well empirically [58, 59, 8].

Goreinov, Tyrtyshnikov, and Zamarashkin [39, 38, 61] were interested in applications such as scattering, in which large coefficient matrices have blocks that can be easily approximated by low-rank matrices. They show that if the matrix A is approximated by a rank-k matrix to within an accuracy ϵ, then , a choice of k columns and k rows, i.e., C and R, and a low-dimensional $k \times k$ matrix U constructed from the elements of C and R, such that $A \approx CUR$ in the sense that $\|A - CUR\|_2 \leq \epsilon f(m, n, k)$, where $f(m, n, k) = 1 + 2\sqrt{km} + 2\sqrt{kn}$. In [39], the choice for these matrices is related to the problem of determining the minimum singular value σ_k of $k \times k$ submatrices of $n \times k$ orthogonal matrices. In addition, in [38]

the choice for C and R is interpreted in terms of the maximum volume concept from interpolation theory, in the sense that columns and rows should be chosen such that their intersection W defines a parallelepiped of maximum volume among all $k \times k$ submatrices of A; in [61] an empirically effective deterministic algorithm is presented which ensures that U is well-conditioned.

Gu and Eisenstat, in their seminal paper [40], describe a strong rank-revealing QR factorization that deterministically selects exactly k columns from an $m \times n$ matrix A. The algorithms of [40] are efficient, in that their running time is $O(mn^2)$ (assuming that $m \geq n$), which is essentially the time required to compute the SVD of A. In addition, Gu and Eisenstat prove that if the $m \times k$ matrix C contains the k selected columns (without any rescaling), then $\sigma_{\min}(C) \geq \sigma_k(A)/f(k,n)$, where $f(k,n) = O(\sqrt{k(n-k)})$. Thus, the columns of C span a parallelepiped whose volume (equivalently, the product of the singular values of C) is "large." Currently, we do not know how to convert this property into a statement similar to that of Theorem 1, although perhaps this can be accomplished by relaxing the number of columns selected by the algorithms of [40] to $O(poly(k, 1/\epsilon))$. For related work prior to Gu and Eisenstat, see Chan and Hansen [12, 13].

Finally, very recently, Martinsson, Rokhlin, and Tygert [49] proposed another related method to efficiently compute an approximation to the best rank-k approximation of an $m \times n$ matrix A. The heart of their algorithm is a random projection method, which projects A to a small number, say ℓ, of random vectors; the entries of these random vectors are i.i.d. Gaussians of zero mean and unit variance. The general form of their bounds is quite complicated, but by setting, e.g., $\ell = k + 20$, they construct a rank-k approximation A' to A such that

$$\|A - A'\|_2 \leq 10\sqrt{(k+20)\,m}\,\|A - A_k\|_2 \tag{10}$$

holds with probability at least $1 - 10^{-17}$. In addition, the authors extend their algorithm to compute the so-called interpolative decomposition of a matrix A. This decomposition is explicitly expressed in terms of a small number of columns of A, and is a more restrictive version of our CX matrix decomposition. More specifically, it additionally requires that every entry of X is bounded in absolute value by a small constant (e.g., two). Thus, their algorithm computes an interpolative approximation $A' = CX$ to A, where C has only $\ell = k + 20$ columns—as opposed to the $O(k \log k)$ columns that are necessary in our work—and satisfies the bound of (10). Notice that their work provides bounds for the spectral norm, whereas our work focuses only on the Frobenius norm. However, their bounds are much weaker than our relative error bounds, since $\sqrt{m(k+20)}\,\|A - A_k\|_2$ might in general be larger even than $\|A\|_F$.

3.2. Related work in theoretical computer science. Within the theory of algorithms community, much research has followed the seminal work of Frieze, Kannan, and Vempala [33, 34]. Their work may be viewed, in our parlance, as sampling columns from a matrix A to form a matrix C such that $\|A - CX\|_F \leq \|A - A_k\|_F + \epsilon\,\|A\|_F$. The matrix C has $poly(k, 1/\epsilon, 1/\delta)$ columns and is constructed after making only two passes over A using $O(m+n)$ work space. Under similar resource constraints, a series of papers have followed [33, 34] in the past seven years [19, 22, 55], improving the dependency of c on $k, 1/\epsilon$, and $1/\delta$, and analyzing the spectral as well as the Frobenius norm, yielding bounds of the form

$$\|A - CX\|_\xi \leq \|A - A_k\|_\xi + \epsilon\,\|A\|_F \tag{11}$$

for $\xi = 2, F$, and thus providing additive-error guarantees for column-based low-rank matrix approximations.

Additive-error approximation algorithms for , matrix decompositions have also been analyzed by Drineas, Kannan, and Mahoney [20, 21, 22, 23, 24, 25]. In particular, in [23], they compute an approximation to an $m \times n$ matrix A by sampling c columns and r rows from A to form $m \times c$ and $r \times n$ matrices C and R, respectively. From C and R, a $c \times r$ matrix U is constructed such that under appropriate assumptions

$$\|A - CUR\|_\xi \leq \|A - A_k\|_\xi + \epsilon \|A\|_F , \tag{12}$$

with high probability, for both the spectral and Frobenius norms, $\xi = 2, F$. In [24, 25], it is further shown that if A is a symmetric positive semidefinite (SPSD) matrix, then one can choose $R = C^T$ and $U = W^+$, where W is the $c \times c$ intersection between C and $R = C^T$, thus obtaining an approximation $A \approx A' = CW^+C^T$. This approximation is SPSD and has provable bounds of the form (12), except that the scale of the additional additive error is somewhat larger [24, 25].

Most relevant for our relative-error CX and , matrix decomposition algorithms is the recent work of Rademacher, Vempala, and Wang [53] and Deshpande, Rademacher, Vempala, and Wang [17]. Using two different methods (in one case iterative sampling in a backwards manner and an induction on k argument [53], and in the other case an argument that relies on estimating the volume of the simplex formed by each of the k-sized subsets of the columns [17]), they reported the of a set of $O(k^2/\epsilon^2)$ columns that provide relative-error CX matrix decomposition. No algorithmic result was presented, except for an exhaustive algorithm that ran in $\Omega(n^k)$ time. Note that their results did not apply to columns and rows . Thus, ours is the first , matrix decomposition algorithm with relative error, and it was previously not even known whether such a relative-error CUR representation existed; i.e., it was not previously known whether columns and rows satisfying the conditions of Theorem 2 existed.

Other related work includes that of Rudelson and Vershynin [54, 62, 56], who provide an algorithm for CX matrix decomposition which has an improved additive error spectral norm bound of the form

$$\|A - CX\|_2 \leq \|A - A_k\|_2 + \epsilon \sqrt{\|A\|_2 \, \|A\|_F} .$$

Their proof uses an elegant result on random vectors in the isotropic position [54], and since we use a variant of their result, it is described in more detail in Appendix A. Achlioptas and McSherry have computed low-rank matrix approximations using sampling techniques that involve zeroing-out and/or quantizing individual elements [2, 1]. The primary focus of their work was in introducing methods to accelerate orthogonal iteration and Lanczos iteration methods, and their analysis relied heavily on ideas from random matrix theory [2, 1]. Agarwal, Har-Peled, and Varadarajan have analyzed so-called "core sets" as a tool for efficiently approximating various extent measures of a point set [3, 4]. The choice of columns and/or rows we present are a "core set" for approximate matrix computations; in fact, our algorithmic solution to Theorem 1 solves an open question in their survey [4]. The choice of columns and rows we present may also be viewed as a set of variables and features chosen from a data matrix [10, 14, 41]. "Feature selection" is a broad area that addresses the choice of columns explicitly for dimension reduction, but the metrics there are typically optimization based [14] or machine-learning based [10]. These formulations tend to have set cover-like solutions

and are incomparable with the linear-algebraic structure such as the low-rank criteria we consider here that is common among data analysts.

3.3. Very recent work on relative-error approximation algorithms. To the best of our knowledge, the first nontrivial [illegible] for relative-error low-rank matrix approximation was provided by a preliminary version of this paper [27, 28]. In particular, an earlier version of Theorem 1 provided the first known relative-error, column-based, low-rank approximation in polynomial time [27, 28]. The major difference between our Theorem 1 and our result in [27, 28] is that the sampling probabilities in [27, 28] are more complicated. (See section 6.2 for details on this.) The algorithm from [27, 28] runs in $O(SVD(A,k))$ time (although it was originally reported to run in only $O(SVD(A))$ time), and it has a sampling complexity of $O(k^2 \log(1/\delta)/\epsilon^2)$ columns.

Subsequent to the completion of the preliminary version of this paper [27, 28], several developments have been made on relative-error low-rank matrix approximation algorithms. First, Har-Peled reported an algorithm that takes as input an $m \times n$ matrix A, and in roughly $O(mnk^2 \log k)$ time returns as output a rank-k matrix A' with a relative-error approximation guarantee [42]. His algorithm uses geometric ideas and involves sampling and merging approximately optimal k-flats; it is not clear if this approximation can be expressed in terms of a small number of columns of A. Then, Deshpande and Vempala [18] reported an algorithm that takes as input an $m \times n$ matrix A that also returns a relative-error approximation guarantee. Their algorithm extends ideas from [53, 17], and it leads to a CX matrix decomposition consisting of $O(k \log k)$ columns of A. The complexity of their algorithm is $O(Mk^2 \log k)$, where M is the number of nonzero elements of A, and their algorithm can be implemented in a data-streaming framework with $O(k \log k)$ passes over the data. In light of these developments, we simplified and generalized our preliminary results [27, 28], and we performed a more refined analysis to improve our sampling complexity to $O(k \log k)$. Most recently, we learned of work by Sarlos [57], who used ideas from the recently developed fast Johnson–Lindenstrauss transform of Ailon and Chazelle [5] to yield further improvements to a CX matrix decomposition.

4. Our main column-based matrix approximation algorithm. In this section, we describe an algorithm and a theorem, from which our first main result, Theorem 1, will follow.

4.1. Description of the algorithm. Algorithm 1 takes as input an $m \times n$ matrix A, a rank parameter k, and an error parameter ϵ. It returns as output an $m \times c$ matrix C consisting of a small number of columns of A. The algorithm is very simple: sample a small number of columns according to a carefully constructed nonuniform probability distribution. Algorithm 1 uses the sampling probabilities

$$p_i = \frac{1}{k} \left| \left(V_{A,k}^T\right)^{(i)} \right|_2^2, \qquad \forall i \in [n], \tag{13}$$

but it will be clear from the analysis of section 6 that any sampling probabilities such that $p_i \geq \beta |(V_{A,k}^T)^{(i)}|_2^2/k$, for some $\beta \in (0,1]$, will also work with a small β-dependent loss in accuracy. Note that Algorithm 1 actually consists of two related algorithms, depending on how exactly the columns are chosen. The EXACTLY(c) algorithm picks exactly c columns of A to be included in C in c i.i.d. trials, where in each trial the ith column of A is picked with probability p_i. The EXPECTED(c) algorithm picks in expectation at most c columns of A to create C, by including the ith column of A

in C with probability $\min\{1, cp_i\}$. See Algorithms 4 and 5 in Appendix A for more details about these two column-sampling procedures.

Data : $A \in \mathbb{R}^{m\times n}$, a rank parameter k, and an error parameter ϵ.
Result : $C \in \mathbb{R}^{m\times c}$

- Compute sampling probabilities p_i for all $i \in [n]$ given by (13);
- (Implicitly) construct a sampling matrix S_C and a diagonal rescaling matrix D_C with the EXACTLY(c) algorithm or with the EXPECTED(c) algorithm;
- Construct and return the matrix $C = AS_CD_C$ consisting of a small number of rescaled columns of A.

Algorithm 1. A randomized algorithm for CX matrix decomposition.

The running time of Algorithm 1 is dominated by the computation of the sampling probabilities (13), for which $O(SVD(A,k))$ time suffices. The top k right singular vectors of A can be efficiently (approximately) computed using standard algorithms [37, 51]. The building block of these algorithms is a series of matrix-vector multiplications, where the input matrix A is iteratively multiplied with a changing set of k orthogonal vectors. In each iteration (which can be implemented by making passes over the input matrix A), the accuracy of the approximation improves. Even though the number of iterations required to bound the error depends on quantities such as the gap between the singular values of A, these algorithms work extremely well in practice. As such, they are often treated as "black boxes" for SVD computation in the TCS literature; see, e.g., [2, 1].

4.2. Statement of the theorem. Theorem 3 is our main quality-of-approximation result for Algorithm 1.

THEOREM 3. Let $A \in \mathbb{R}^{m\times n}$, let k [illegible] $\epsilon \in (0,1]$ [illegible] $c = 3200k^2/\epsilon^2$ [illegible] 1 [illegible] c [illegible] A [illegible] EXACTLY(c) [illegible] 0.7

$$\left\|A - CC^+A\right\|_F \le (1+\epsilon)\left\|A - A_k\right\|_F. \tag{14}$$

[illegible] $c = O(k\log k/\epsilon^2)$ [illegible] 1 [illegible] c [illegible] A [illegible] EXPECTED(c) [illegible] (14) [illegible] 0.7

[illegible]. Since for every set of columns $C = AS_CD_C$, $X_{opt} = C^+A$ is the matrix that minimizes $\|A - CX\|_F$, it follows that

$$\begin{aligned}\left\|A - CC^+A\right\|_F &= \left\|A - (AS_CD_C)(AS_CD_C)^+A\right\|_F \\ &\le \left\|A - (AS_CD_C)(P_{A,k}AS_CD_C)^+P_{A,k}A\right\|_F,\end{aligned} \tag{15}$$

where $P_{A,k} = U_{A,k}U_{A,k}^T$ is a projection onto the top k left singular vectors of A. To bound (15), consider the problem of approximating the solution to $\min_{X\in\mathbb{R}^{m\times m}} \|XA_k - A\|_F$ by randomly sampling columns of A_k and of A. It follows as a corollary of (21) of Theorem 5 of section 6 that

$$\left\|A - (AS_CD_C)(A_kS_CD_C)^+A_k\right\|_F \le (1+\epsilon)\left\|A - AA_k^+A_k\right\|_F = (1+\epsilon)\left\|A - A_k\right\|_F, \tag{16}$$

which, when combined with (15), establishes the theorem. □

For simplicity of presentation, we have presented Algorithm 1 and Theorem 3 such that (14) holds with only constant probability, but this can be boosted to hold with probability at least $1-\delta$ using standard methods. In particular, consider the following: run Algorithm 1 (using either the EXACTLY(c) algorithm or the EXPECTED(c) algorithm, but with the appropriate value of c) independently $\ln(1/\delta)$ times, and return the C such that $\|A - CC^+A\|_F$ is smallest. Then, since in each trial the claim of Theorem 3 fails with probability less than $0.3 < 1/e$, the claim of Theorem 3 will fail for every trial with probability less than $(1/e)^{\ln(1/\delta)} = \delta$. This establishes Theorem 1.

For simplicity of presentation, we have also stated Theorem 3 in such a way that the rank of the approximating matrix $A' = CC^+A$ may be greater than k. This possibility may be undesirable in certain applications, and it can be easily removed. Let $A'' = C(P_{A,k}C)^+P_{A,k}A$. Then, it follows from (16) that A'' is a CX matrix approximation that is within relative error ϵ of the best rank-k approximation to A and that has rank no more than k.

4.3. Discussion of the analysis. Given a matrix A, Theorem 1 asks us to find a set of columns $C = AS_CD_C$ such that CC^+A "captures" almost as much of A as does $A_k = U_{A,k}U_{A,k}^TA$. Given that set (or any other set) of columns C, it is well known that the matrix $X_{opt} = C^+A$ is the "smallest" matrix among those that solve the optimization problem (19). For a given A and C, let us approximate X_{opt} as

$$X_{opt} = C^+A \approx (P_{A,k}C)^+ P_{A,k}A.$$

This approximation is suboptimal with respect to solving the optimization problem (19), i.e.,

$$\left\|A - CC^+A\right\|_F \leq \left\|A - C\left(P_{A,k}C\right)^+ P_{A,k}A\right\|_F,$$

but it can be shown that by choosing C properly, i.e., by choosing S_C and D_C (the column sampling and rescaling matrices) properly, we have that

$$\left\|A - C\left(P_{A,k}C\right)^+ P_{A,k}A\right\|_F \leq (1+\epsilon)\left\|A - A_k\right\|_F.$$

The main technical challenge is to sample in a manner such that the column-sampled version of the matrix consisting of the top k right singular vectors of A is full rank; i.e., $\mathrm{rank}(V_{A,k}^TS_CD_C) = \mathrm{rank}(V_{A,k}^T) = k$. To accomplish this, we sample with respect to probabilities of the form (13). To understand these sampling probabilities, recall that we seek to pick columns that span almost the same subspace as the top k left singular vectors of A (i.e., U_k), and recall that the ith column of A is equal to

$$A^{(i)} = U_k\Sigma_k\left(V_k^T\right)^{(i)} + U_{\rho-k}\Sigma_{\rho-k}\left(V_{\rho-k}^T\right)^{(i)}.$$

Since postmultiplying U_k by Σ_k does not change the span of the columns of U_k, $|(V_k^T)^{(i)}|_2^2$ measures "how much" of the ith column of A lies in the span of $U_{A,k}$, independent of the magnitude of the singular values associated with those directions.

5. Our main column-row-based matrix approximation algorithm. In this section, we describe an algorithm and a theorem that, when combined with the results of section 4, will establish our second main result, Theorem 2.

5.1. Description of the algorithm. Algorithm 2 takes as input an $m \times n$ matrix A, an $m \times c$ matrix C consisting of a small number of columns of A, and an error parameter ϵ. It returns as output an $r \times n$ matrix R consisting of a small number of rows of A and an $r \times c$ matrix W consisting of the corresponding rows of C. The algorithm is very simple: sample a small number of rows according to a carefully constructed nonuniform probability distribution. Algorithm 2 uses the sampling probabilities

$$p_i = \frac{1}{c}\left|\left(U_C^T\right)^{(i)}\right|_2^2, \qquad \forall i \in [m], \tag{17}$$

but it will be clear from the analysis of section 6 that any sampling probabilities $p_i, i \in [m]$, such that $p_i \geq \beta|(U_C^T)^{(i)}|_2^2/c$, for some $\beta \in (0,1]$, will also work with a small β-dependent loss in accuracy. Note that Algorithm 2 actually consists of two related algorithms, depending on how exactly the rows are chosen. The EXACTLY(c) algorithm picks exactly r rows of A to be included in R in r i.i.d. trials, where in each trial the ith row of A is picked with probability p_i. The EXPECTED(c) algorithm picks in expectation at most r rows of A to create R, by including the ith column of A in C with probability $\min\{1, rp_i\}$. See Algorithms 4 and 5 in Appendix A for more details about these two row-sampling procedures.

Data : $A \in \mathbb{R}^{m\times n}$, $C \in \mathbb{R}^{m\times c}$ consisting of c columns of A, a positive integer r, and an error parameter ϵ.

Result : $R \in \mathbb{R}^{r\times n}$ consisting of r rows of A and $W \in \mathbb{R}^{c\times r}$ consisting of the corresponding r rows of C, and $U \in \mathbb{R}^{r\times c}$.

- Compute sampling probabilities p_i for all $i \in [m]$ given by (17);
- (Implicitly) construct a sampling matrix S_R and a diagonal rescaling matrix D_R with the EXACTLY(c) algorithm or with the EXPECTED(c) algorithm;
- Construct and return the matrix $R = D_R S_R^T A$ consisting of a small number of rescaled rows of A;
- Construct and return the matrix $W = D_R S_R^T C$ consisting of the corresponding rescaled rows of C;
- Let $U = W^+$.

Algorithm 2. A randomized algorithm for *CUR* matrix decomposition.

Reading the input matrices to Algorithm 2 takes $O(mn)$ time; computing the full SVD of C requires $O(c^2m)$ time; constructing the matrix R requires $O(rn)$ time; constructing the matrix W requires $O(rc)$ time; and computing U requires $O(c^2r)$ time. Overall, the running time of the algorithm is $O(mn)$ since c, r are constants independent of m, n. This can be improved if the input matrices are sparse, but for simplicity we omit this discussion.

5.2. Statement of the theorem. Theorem 4 is our main quality-of-approximation result for Algorithm 2.

THEOREM 4. Let $A \in \mathbb{R}^{m\times n}$ and $C \in \mathbb{R}^{m\times c}$ [illegible] c [illegible] A [illegible] $\epsilon \in (0,1]$ [illegible] $r = 3200c^2/\epsilon^2$ [illegible] 2 [illegible] r [illegible] A [illegible] C [illegible] EXACTLY(c) [illegible]

0.7

$$\|A - CUR\|_F \leq (1+\epsilon)\left\|A - CC^+A\right\|_F. \tag{18}$$

$r = O(c \log c/\epsilon^2)$ 2 r A C Expected(c) (18)

0.7

Consider the problem of approximating the solution to $\min_{X \in \mathbb{R}^{c \times n}} \|CX - A\|_F$ by randomly sampling rows from C and A. It follows as a corollary of (21) of Theorem 5 of section 6 that

$$\left\|A - C(D_R S_R^T C)^+ D_R S_R^T A\right\|_F \leq (1+\epsilon)\left\|A - CC^+A\right\|_F,$$

where $R = D_R S_R^T A$ and $U = (D_R S_R^T C)^+$, which establishes the theorem. □

For simplicity of presentation, we have presented Algorithm 2 and Theorem 4 such that (18) holds with only constant probability, but this can be boosted to hold with probability at least $1 - \delta$ using standard methods. In addition, this can be combined with Algorithm 1 and Theorem 3 by doing the following: run Algorithm 1 $\ln(2/\delta)$ times, and return the best C; then, with that C run Algorithm 2 $\ln(2/\delta)$ times, and return the best U, R pair. Then

$$\|A - CUR\|_F \leq (1+\epsilon)\left\|A - CC^+A\right\|_F \leq (1+\epsilon)^2 \|A - A_k\|_F \leq (1+\epsilon')\|A - A_k\|_F,$$

where $\epsilon' = 3\epsilon$, and the combined failure probability is no more than $\delta/2 + \delta/2 = \delta$. This establishes Theorem 2.

5.3. Discussion of the analysis. Assume that we are given an $m \times c$ matrix C, consisting of any set of c columns of an $m \times n$ matrix A, and consider the following idea for approximating the matrix A. The columns of C are a set of "basis vectors" that are, in general, neither orthogonal nor normal. To express all the columns of A as linear combinations of the columns of C, we can solve

$$\min_{x_j \in \mathbb{R}^c} \left|A^{(j)} - Cx_j\right|_2,$$

for each column $A^{(j)}, j \in [n]$, in order to find a c-vector of coefficients x_j and get the optimal least-squares fit for $A^{(j)}$. Equivalently, we can solve an optimization problem of the form (19). Note that if m and n are large and $c = O(1)$, then this is an overconstrained least-squares fit problem. It is well known that $X_{opt} = C^+A$ is the "smallest" matrix solving this optimization problem, in which case we are using information from every row of A to compute the optimal coefficient matrix. Let us approximate X_{opt} as

$$X_{opt} = C^+A \approx \left(D_R S_R^T C\right)^+ D_R S_R^T A = \tilde{X}_{opt},$$

and note that $\tilde{X}_{opt} = W^+R$. This matrix $\tilde{X}_{opt}$ is clearly suboptimal with respect to solving the optimization problem (19), i.e.,

$$\left\|A - CC^+A\right\|_F \leq \left\|A - CW^+R\right\|_F,$$

but it can be shown that by choosing S_R and D_R (the row sampling and rescaling matrices) properly we have that

$$\left\|A - CW^+R\right\|_F \leq (1+\epsilon)\left\|A - CC^+A\right\|_F.$$

As in section 4.3, the main technical challenge is to sample in a manner such that the row-sampled version of the matrix consisting of the top c left singular vectors of C is full rank, i.e., $\text{rank}(D_R S_R^T U_{C,c}) = \text{rank}(U_{C,c}) = c$.

6. An approximation algorithm for generalized ℓ_2 regression. The basic linear-algebraic problem of ℓ_2 regression is one of the most fundamental regression problems, and it has found many applications in mathematics and statistical data analysis. Recall the standard ℓ_2 regression (or least-squares fit) problem: given as input a matrix $A \in \mathbb{R}^{m\times n}$ and a target vector $b \in \mathbb{R}^m$, compute $\mathcal{Z} = \min_{x\in\mathbb{R}^n} |b - Ax|_2$. Also of interest is the computation of vectors that achieve the minimum $\mathcal{Z}$. If $m > n$ there are more constraints than variables and the problem is an overconstrained least-squares fit problem; in this case, there does not in general exist a vector x such that $Ax = b$. It is well known that the minimum-length vector among those minimizing $|b - Ax|_2$ is $x_{opt} = A^+b$. We previously presented an elaborate sampling algorithm that represents the matrix A by a matrix by a small number of rows so that this ℓ_2 regression problem can be solved to accuracy $1 \pm \epsilon$ for any $\epsilon > 0$ [29].

This problem is of interest for CX and , matrix decomposition for the following reason. Given a matrix A and a set of its columns C, if we want to get the best fit for every column of A in terms of that basis, we want to solve $CX \approx A$ for the matrix X. More precisely, we would like to solve the optimization problem such as

$$\mathcal{Z} = \min_{X\in\mathbb{R}^{c\times n}} \|A - CX\|_F . \tag{19}$$

It is well known that the matrix $X = C^+A$ is the "smallest" matrix among those that solve this problem. In this case, we are approximating the matrix A as $A' = CC^+A = P_CA$, and by keeping only the columns C we are incurring an error of $\|A - CC^+A\|_F$. Two questions arise:

- First, how do we choose the columns C such that $\|A - CC^+A\|_F$ is within relative error ϵ of $\|A - A_k\|_F$?
- Second, how do we choose the rows R and a matrix U such that $\|A - CUR\|_F$ is within relative error ϵ of $\|A - CC^+A\|_F$?

Motivated by these observations, we will consider the generalized version of the standard ℓ_2 regression problem, as defined in (5) and (6).

In this section, we first present Algorithm 3, which is our main random sampling algorithm for approximating the solution to the generalized ℓ_2 regression problem, and Theorem 5, which provides our main quality-of-approximation bound for Algorithm 3. Then, we discuss the novel nonuniform "subspace sampling" probabilities used by the algorithm. Finally, we present the proof of Theorem 5.

6.1. Description of the algorithm and theorem. Algorithm 3 takes as input an $m \times n$ matrix A with rank no greater than k, an $m \times p$ matrix B, a set of sampling probabilities $\{p_i\}_{i=1}^m$, and a positive integer $r \le m$. It returns as output a number $\tilde{\mathcal{Z}}$ and a $n \times p$ matrix $\tilde{X}_{opt}$. Using the sampling matrix formalism described in section 2, the algorithm (implicitly) forms a sampling matrix S, the transpose of which samples a few rows of A and the corresponding rows of B, and a rescaling matrix D, which is a matrix scaling the sampled rows of A and B. Since r rows of A and the corresponding r rows of B are sampled, the algorithm randomly samples r of the m constraints in the original ℓ_2 regression problem. Thus, the algorithm approximates the solution of the regression problem $AX \approx B$, as formalized in (19) and (5), with the exact solution of the downsampled regression problem $DS^TAX \approx DS^TB$. Note that it is the space of constraints that is sampled and that the dimensions of the unknown matrix X are the same in both problems. Note also that although both m and n are permitted to be large, the problem is effectively overconstrained since $\mathrm{rank}(A) \le k$. As we will see below, $r = O(k \log k)$ or $r = O(k^2)$, depending on exactly how the random sample is constructed. Thus, we will compute the solution to the sampled problem exactly.

Data : $A \in \mathbb{R}^{m \times n}$ that has rank no greater than k, $B \in \mathbb{R}^{m \times p}$, sampling probabilities $\{p_i\}_{i=1}^m$, and $r \leq m$.

Result : $\tilde{X}_{opt} \in \mathbb{R}^{n \times p}$, $\tilde{\mathcal{Z}} \in \mathbb{R}$.

- (Implicitly) construct a sampling matrix S and a diagonal rescaling matrix D with the EXACTLY(c) algorithm or with the EXPECTED(c) algorithm;
- Construct the matrix DS^TA consisting of a small number of rescaled rows of A;
- Construct the matrix DS^TB consisting of a small number of rescaled rows of B;
- $\tilde{X}_{opt} = \left(DS^TA\right)^+ DS^TB$;
- $\tilde{\mathcal{Z}} = \min_{X \in \mathbb{R}^{n \times p}} \left\| DS^TB - DS^TA\tilde{X}_{opt} \right\|_F$.

Algorithm 3. A Monte-Carlo algorithm for approximating ℓ_2 regression.

Theorem 5 is our main quality-of-approximation result for Algorithm 3. Its proof may be found in section 6.3. Recall that for our generalized ℓ_2 regression problem, the matrix A has rank no greater than k.

THEOREM 5. [illegible] $A \in \mathbb{R}^{m \times n}$ [illegible] k, $B \in \mathbb{R}^{m \times p}$, $\epsilon \in (0,1]$, [illegible] $\mathcal{Z} = \min_{X \in \mathbb{R}^{n \times p}} \|B - AX\|_F = \|B - AX_{opt}\|_F$ [illegible] $X_{opt} = A^+B = A_k^+B$ [illegible] 3 [illegible]

$$p_i \geq \beta \frac{\left|(U_{A,k})_{(i)}\right|_2^2}{\sum_{j=1}^n \left|(U_{A,k})_{(j)}\right|_2^2} = \frac{\beta}{k}\left|(U_{A,k})_{(i)}\right|_2^2, \qquad \forall i \in [n], \tag{20}$$

[illegible] $\beta \in (0,1]$ [illegible] $\tilde{\mathcal{Z}}$ [illegible] $n \times p$ [illegible] $\tilde{X}_{opt}$ [illegible] $r = 3200k^2/\beta\epsilon^2$ [illegible] EXACTLY(c) [illegible] 0.7

$$\left\| B - A\tilde{X}_{opt} \right\|_F \leq (1+\epsilon)\,\mathcal{Z}, \tag{21}$$

$$\left\| X_{opt} - \tilde{X}_{opt} \right\|_F \leq \frac{\epsilon}{\sigma_{\min}(A_k)}\mathcal{Z}. \tag{22}$$

[illegible] $\|U_{A,k}U_{A,k}^TB\|_F \geq \gamma \|B\|_F$ [illegible] $\gamma \in (0,1]$ [illegible] 0.7

$$\left\| X_{opt} - \tilde{X}_{opt} \right\|_F \leq \epsilon \left(\kappa(A_k)\sqrt{\gamma^{-2} - 1}\right) \|X_{opt}\|_F. \tag{23}$$

[illegible] $r = O(k \log k/\beta\epsilon^2)$ [illegible] EXPECTED(c) [illegible] 0.7 (21), (22) [illegible] (23) [illegible]

Equation (21) states that if the matrix of minimum-length vectors achieving the minimum in the sampled problem is substituted back into the residual norm for the original problem, then a good approximation to the original ℓ_2 regression problem is obtained. Equation (22) provides a bound for $||X_{opt} - \tilde{X}_{opt}||_F$ in terms of $\sigma_{\min}(A_k)$ and

$\mathcal{Z}$. If most of the "weight" of B lies in the complement of the column space of $A = A_k$ then this will provide a very poor approximation in terms of $\|X_{opt}\|_F$. However, if we also assume that a constant fraction of the "weight" of B lies in the subspace spanned by the columns of A, then we obtain the relative-error approximation of (23). Thus, Theorem 5 returns a good bound for $||X_{opt} - \tilde{X}_{opt}||_F$ if A_k is well-conditioned and if B lies "reasonably well" in the column space of A. Note that if the matrix of target vectors B lies completely within the column space of A, then $\mathcal{Z} = 0$ and $\gamma = 1$. In this case, Theorem 5 shows that Algorithm 3 returns $\tilde{\mathcal{Z}}$ and $\tilde{x}_{opt}$ that are exact solutions of the original ℓ_2 regression problem, independent of $\kappa(A_k)$. Finally, note that in our analysis of CX and [illegible] matrix decompositions we use only the result (21) from Theorem 5, but (22) and (23) are included for completeness.

6.2. Discussion of the method of "Subspace Sampling". An important aspect of Algorithm 3 is the nonuniform sampling probabilities (20) used by the Exactly(c) algorithm and the Expected(c) algorithm in the construction of the induced subproblem. We call sampling probabilities satisfying condition (20) [illegible]" probabilities. Condition (20) states that the sampling probabilities should be close to, or rather not much less than, the lengths, i.e., the Euclidean norms, of the rows of the left singular vectors of the matrix $A = A_k$. (Recall that in this section A is an $m \times n$ matrix with rank no more than k, and thus $U_{A,k}$ is an $m \times k$ matrix. Thus, the Euclidean norm of every [illegible] of $U_{A,k}$ equals 1, but the Euclidean norm of every [illegible] of $U_{A,k}$ is in general not equal and is only bounded above by 1.) Sampling probabilities of the form (20) should be contrasted with sampling probabilities that depend on the Euclidean norms of the columns or rows of A and that have received much attention recently [33, 34, 21, 22, 23, 26]. Since $A = U_A \Sigma_A V_A^T$, sampling probabilities with this latter form depend in a complicated manner on a mixture of subspace information (as found in U_A and V_A) and "size-of-A" information (as found in Σ_A). This convolution of information may account for their ability to capture coarse statistics such as approximating matrix multiplication or computing low-rank matrix approximations to additive error, but it also accounts for their difficulty in dealing with problems such as ℓ_2 regression or computing low-rank matrix approximations to relative error.

Since the solution of the ℓ_2 regression problem involves the computation of a pseudoinverse, the problem is not well-conditioned with respect to a perturbation (such as that introduced by sampling) that entails a change in dimensionality, even if (actually, especially if) that change in dimensionality corresponds to a small singular value. Since sampling probabilities satisfying (20) allow us to disentangle subspace information and "size-of-A" information, we will see that they will allow us to capture (with high probability) the [illegible] subspace of interest by sampling. More precisely, as we will see in Lemma 1, by using sampling probabilities that satisfy condition (20) and by choosing r appropriately, it will follow that

$$\text{rank}(DS^T U_{A,k}) = \text{rank}(U_{A,k}) = k.$$

Thus, the lengths of the Euclidean norms of the rows of $U_{A,k}$ may be interpreted as capturing a notion of information dispersal by the matrix A since they indicate to which part of the m-dimensional vector space the singular value information of A is being dispersed. In this case, condition (20) ensures that the sampling probabilities provide a bias toward the part of the high-dimensional constraint space to which A disperses its singular value information. Then, having constructed the sample, we will go to the low-dimensional, i.e., the r-dimensional rather than the m-dimensional

space, and approximate the ℓ_2 regression problem by doing computations that involve "size-of-A" information on the random sample.

This method of "subspace sampling" was first used in a preliminary version of the ℓ_2 regression results of this section [29]. Note that an immediate generalization of the results of [29] to the generalized ℓ_2 regression problem considered in this section would involve sampling probabilities of the form

(24)
$$p_i = \frac{(1/3)\left|(U_{A,k})_{(i)}\right|_2^2}{\sum_{j=1}^n \left|(U_{A,k})_{(j)}\right|_2^2} + \frac{(1/3)\left|(U_{A,k})_{(i)}\right|_2 \left(U_{A,k}^{\perp} U_{A,k}^{\perp}{}^T B\right)_i}{\sum_{j=1}^n \left|(U_{A,k})_{(j)}\right|_2 \left(U_{A,k}^{\perp} U_{A,k}^{\perp}{}^T B\right)_j} + \frac{(1/3)\left(U_{A,k}^{\perp} U_{A,k}^{\perp}{}^T B\right)_i^2}{\sum_{j=1}^n \left(U_{A,k}^{\perp} U_{A,k}^{\perp}{}^T B\right)_j^2},$$

rather than of the form (20). Since the second and third terms in (24) provide a bias toward the part of the complement of the column space of $A = A_k$ where B has significant weight, we directly obtain variance reduction. Thus, by using probabilities of the form (24) we can sample $O(k^2 \log(1/\delta)/\epsilon^2)$ columns and directly obtain the claims of Theorem 5 with probability at least $1 - \delta$. Although sampling probabilities of the form (20) are substantially simpler, we obtain variance control indirectly. We first establish that each of the claims of Theorem 5 holds with constant probability, and we then can show that each of the claims holds with probability at least $1 - \delta$ by running $O(\log(1/\delta))$ trials and using standard boosting procedures.

6.3. Proof of Theorem 5. In this section we provide a proof of Theorem 5. We will first prove (21), (22), and (23) under the assumption that the rows of A and B are sampled with the EXACTLY(c) algorithm. Then, in section 6.3.5, we will outline modifications to the proof if the rows of A and B are sampled with the EXPECTED(c) algorithm. For simplicity of notation in this section, we will let $\mathcal{S} = DS^T$ denote the $r \times m$ rescaled row-sampling matrix. Let the rank of the $m \times n$ matrix A be $\rho \leq k$, and let its SVD be

$$A = U_A \Sigma_A V_A^T,$$

where $U_A \in \mathbb{R}^{n \times \rho}$, $\Sigma_A \in \mathbb{R}^{\rho \times \rho}$, and $V_A \in \mathbb{R}^{d \times \rho}$. In addition, let the rank of the $r \times \rho$ matrix $\mathcal{S}U_A = DS^T U_A$ be $\tilde{\rho}$, and let its SVD be

$$\mathcal{S}U_A = U_{\mathcal{S}U_A} \Sigma_{\mathcal{S}U_A} V_{\mathcal{S}U_A}^T,$$

where $U_{\mathcal{S}U_A} \in \mathbb{R}^{r \times \tilde{\rho}}$, $\Sigma_{\mathcal{S}U_A} \in \mathbb{R}^{\tilde{\rho} \times \tilde{\rho}}$, and $V_{\mathcal{S}U_A} \in \mathbb{R}^{\rho \times \tilde{\rho}}$. Recall that $\tilde{\rho} \leq \rho \leq k \leq r$.

In order to illustrate the essential difficulty in constructing a sampling algorithm to approximate the solution of the generalized ℓ_2 regression problem, consider inserting $\tilde{X}_{opt} = (\mathcal{S}A_k)^+ \mathcal{S}B$ into $B - A_k X$:

$$\begin{aligned}
B - A_k \tilde{X}_{opt} &= B - A_k \left(\mathcal{S}A_k\right)^+ \mathcal{S}B \\
&= B - U_{A,k}\Sigma_{A,k}V_{A,k}^T \left(\mathcal{S}U_{A,k}\Sigma_{A,k}V_{A,k}^T\right)^+ \mathcal{S}B \\
&= B - U_{A,k}\Sigma_{A,k} \left(\mathcal{S}U_{A,k}\Sigma_{A,k}\right)^+ \mathcal{S}B \\
&= B - U_{A,k}\Sigma_{A,k} \left(U_{\mathcal{S}U_{A,k}}\Sigma_{\mathcal{S}U_{A,k}}V_{\mathcal{S}U_{A,k}}^T\Sigma_{A,k}\right)^+ \mathcal{S}B \\
&= B - U_{A,k}\Sigma_{A,k} \left(\Sigma_{\mathcal{S}U_{A,k}}V_{\mathcal{S}U_{A,k}}^T\Sigma_{A,k}\right)^+ U_{\mathcal{S}U_{A,k}}^T \mathcal{S}B.
\end{aligned}$$

To proceed further, we must deal with the pseudoinverse, which is not well-behaved with respect to perturbations that involve a change in dimensionality. To deal with this, we will focus on probabilities that depend on the subspace that we are down-

sampling, i.e., that depend on $U_{A,k}$, in order to guarantee that we capture the full subspace of interest.

6.3.1. Several lemmas of general interest. In this subsection, we will present three lemmas of general interest. Then, in the next subsections, we will use these lemmas to prove each of the claims of Theorem 5.

Since the $m \times k$ matrix $U_{A,k}$ is a matrix with orthogonal columns, several properties hold for it. For example, $\text{rank}(U_{A,k}) = k$, $U^+ = U^T$, and $A_k^+ = V_{A,k}\Sigma_{A,k}^{-1}U_{A,k}^T$. Although the $r \times k$ matrix $\mathcal{S}U_{A,k}$ does not have orthogonal columns, the following lemma characterizes the manner in which each of these three properties holds, either exactly or approximately. For the first lemma, r depends quadratically on k.

LEMMA 1. [illegible] $\epsilon \in (0,1]$ [illegible] $\Omega = (\mathcal{S}U_{A,k})^+ - (\mathcal{S}U_{A,k})^T$ [illegible] [illegible] (20) [illegible] $r \geq 400k^2/\beta\epsilon^2$ [illegible] [illegible] 0.9

$$\tilde{\rho} = \rho \text{ [illegible] } (\mathcal{S}U_{A,k}) = \text{ [illegible] } (U_{A,k}) = \text{ [illegible] } (A_k), \tag{25}$$

$$\|\Omega\|_2 = \left\|\Sigma_{\mathcal{S}U_{A,k}}^{-1} - \Sigma_{\mathcal{S}U_{A,k}}\right\|_2, \tag{26}$$

$$(\mathcal{S}A_k)^+ = V_{A,k}\Sigma_{A,k}^{-1}\left(\mathcal{S}U_{A,k}\right)^+, \tag{27}$$

$$\left\|\Sigma_{\mathcal{S}U_{A,k}} - \Sigma_{\mathcal{S}U_{A,k}}^{-1}\right\|_2 \leq \epsilon/\sqrt{2}. \tag{28}$$

[illegible]. To prove the first claim, note that for all $i \in [\rho]$

$$\begin{aligned}\left|1 - \sigma_i^2\left(\mathcal{S}U_{A,k}\right)\right| &= \left|\sigma_i\left(U_{A,k}^T U_{A,k}\right) - \sigma_i\left(U_{A,k}^T \mathcal{S}^T \mathcal{S}U_{A,k}\right)\right| \\ &\leq \left\|U_{A,k}^T U_{A,k} - U_{A,k}^T \mathcal{S}^T \mathcal{S}U_{A,k}\right\|_2 \qquad (29) \\ &\leq \left\|U_{A,k}^T U_{A,k} - U_{A,k}^T \mathcal{S}^T \mathcal{S}U_{A,k}\right\|_F. \qquad (30)\end{aligned}$$

Note that (29) follows from Corollary 8.1.6 of [37], and (30) follows since $\|\cdot\|_2 \leq \|\cdot\|_F$. To bound the error of approximating $U_{A,k}^T U_{A,k}$ by $U_{A,k}^T \mathcal{S}^T \mathcal{S}U_{A,k}$, we apply Theorem 6 of Appendix A. Since the sampling probabilities p_i satisfy (20), it follows from Theorem 6 and by applying Markov's inequality that with probability at least 0.9:

$$\begin{aligned}\left\|U_{A,k}^T U_{A,k} - U_{A,k}^T \mathcal{S}^T \mathcal{S}U_{A,k}\right\|_F &\leq 10\,\mathbf{E}\left[\left\|U_{A,k}^T U_{A,k} - U_{A,k}^T \mathcal{S}^T \mathcal{S}U_{A,k}\right\|_F\right] \\ &\leq \frac{10}{\sqrt{\beta r}}\left\|U_{A,k}\right\|_F^2, \qquad (31)\end{aligned}$$

where $\mathbf{E}[\cdot]$ denotes the expectation operator. By combining (30) and (31), recalling that $\|U_{A,k}\|_F^2 = \rho \leq k$, and using the assumed choice of r, it follows that

$$\left|1 - \sigma_i^2\left(\mathcal{S}U_{A,k}\right)\right| \leq \epsilon/2 \leq 1/2$$

since $\epsilon \leq 1$. This implies that all singular values of $\mathcal{S}U_{A,k}$ are strictly positive, and thus that $\text{rank}(\mathcal{S}U_{A,k}) = \text{rank}(U_{A,k}) = \text{rank}(A_k)$, which establishes the first claim.

To prove the second claim, we use the SVD of $\mathcal{S}U_{A,k}$ and note that

$$\begin{aligned}\|\Omega\|_2 &= \left\|\left(\mathcal{S}U_{A,k}\right)^+ - \left(\mathcal{S}U_{A,k}\right)^T\right\|_2 \\ &= \left\|\left(U_{\mathcal{S}U_{A,k}}\Sigma_{\mathcal{S}U_{A,k}}V_{\mathcal{S}U_{A,k}}^T\right)^+ - \left(U_{\mathcal{S}U_{A,k}}\Sigma_{\mathcal{S}U_{A,k}}V_{\mathcal{S}U_{A,k}}^T\right)^T\right\|_2 \\ &= \left\|V_{\mathcal{S}U_{A,k}}\left(\Sigma_{\mathcal{S}U_{A,k}}^{-1} - \Sigma_{\mathcal{S}U_{A,k}}\right)U_{\mathcal{S}U_{A,k}}^T\right\|_2.\end{aligned}$$

The claim follows since $V_{\mathcal{S}U_{A,k}}$ and $U_{\mathcal{S}U_{A,k}}$ are matrices with orthonormal columns.

To prove the third claim, note that

$$\begin{aligned}(\mathcal{S}A_k)^+ &= \left(\mathcal{S}U_{A,k}\Sigma_{A,k}V_{A,k}^T\right)^+ \\ &= \left(U_{\mathcal{S}U_{A,k}}\Sigma_{\mathcal{S}U_{A,k}}V_{\mathcal{S}U_{A,k}}^T\Sigma_{A,k}V_{A,k}^T\right)^+ \\ &= V_{A,k}\left(\Sigma_{\mathcal{S}U_{A,k}}V_{\mathcal{S}U_{A,k}}^T\Sigma_{A,k}\right)^+ U_{\mathcal{S}U_{A,k}}^T. \qquad (32)\end{aligned}$$

To remove the pseudoinverse in the above derivations, notice that since $\rho = \tilde{\rho}$ with probability at least 0.9, all three matrices $\Sigma_{\mathcal{S}U_{A,k}}$, $V_{\mathcal{S}U_{A,k}}$, and $\Sigma_{A,k}$ are full rank square $\rho \times \rho$ matrices, and thus are invertible. In this case,

$$\begin{aligned}\left(\Sigma_{\mathcal{S}U_{A,k}}V_{\mathcal{S}U_{A,k}}^T\Sigma_{A,k}\right)^+ &= \left(\Sigma_{\mathcal{S}U_{A,k}}V_{\mathcal{S}U_{A,k}}^T\Sigma_{A,k}\right)^{-1} \\ &= \Sigma_{A,k}^{-1}V_{\mathcal{S}U_{A,k}}\Sigma_{\mathcal{S}U_{A,k}}^{-1}. \qquad (33)\end{aligned}$$

By combining (32) and (33) we have that

$$\begin{aligned}(\mathcal{S}A_k)^+ &= V_{A,k}\Sigma_{A,k}^{-1}V_{\mathcal{S}U_{A,k}}\Sigma_{\mathcal{S}U_{A,k}}^{-1}U_{\mathcal{S}U_{A,k}}^T \\ &= V_{A,k}\Sigma_{A,k}^{-1}\left(\mathcal{S}U_{A,k}\right)^+,\end{aligned}$$

which establishes the third claim.[2]

Finally, to prove the fourth claim, recall that under the assumptions of the lemma $\rho = \tilde{\rho}$ with probability at least 0.9, and thus $\sigma_i\left(\mathcal{S}U_{A,k}\right) > 0$ for all $i \in [\rho]$. Thus,

$$\begin{aligned}\left\|\Sigma_{\mathcal{S}U_{A,k}}^{-1} - \Sigma_{\mathcal{S}U_{A,k}}\right\|_2 &= \max_{i,j\in[\rho]}\left|\sigma_i\left(\mathcal{S}U_{A,k}\right) - \frac{1}{\sigma_j\left(\mathcal{S}U_{A,k}\right)}\right| \\ &= \max_{i,j\in[\rho]}\frac{\left|\sigma_i\left(\mathcal{S}U_{A,k}\right)\sigma_j\left(\mathcal{S}U_{A,k}\right) - 1\right|}{\left|\sigma_j\left(\mathcal{S}U_{A,k}\right)\right|} \\ &\leq \max_{j\in[\rho]}\frac{\left|\sigma_j^2\left(\mathcal{S}U_{A,k}\right) - 1\right|}{\left|\sigma_j\left(\mathcal{S}U_{A,k}\right)\right|}. \qquad (34)\end{aligned}$$

Using the fact that, by (29), for all $i \in [\rho]$,

$$\left|1 - \sigma_i^2\left(\mathcal{S}U_{A,k}\right)\right| \leq \left\|U_{A,k}^TU_{A,k} - U_{A,k}^T\mathcal{S}^T\mathcal{S}U_{A,k}\right\|_2,$$

it follows that for all $i \in [\rho]$

$$\frac{1}{\sigma_i\left(\mathcal{S}U_{A,k}\right)} \leq \frac{1}{\sqrt{1 - \left\|U_{A,k}^TU_{A,k} - U_{A,k}^T\mathcal{S}^T\mathcal{S}U_{A,k}\right\|_2}}.$$

When these are combined with (34) it follows that

$$\left\|\Sigma_{\mathcal{S}U_{A,k}} - \Sigma_{\mathcal{S}U_{A,k}}^{-1}\right\|_2 \leq \frac{\left\|U_{A,k}^TU_{A,k} - U_{A,k}^T\mathcal{S}^T\mathcal{S}U_{A,k}\right\|_2}{\sqrt{1 - \left\|U_{A,k}^TU_{A,k} - U_{A,k}^T\mathcal{S}^T\mathcal{S}U_{A,k}\right\|_2}}.$$

[2] One might be tempted to suggest that the proof of this third claim should be "simplified" by appealing to the result that the generalized inverse of the product of two matrices equals the product of the generalized inverse of those matrices. This result is, of course, false—see, e.g., section 3.1.1 of [60]—and so we need a more refined analysis such as the one presented here.

Combining this with the Frobenius norm bound of (31), and noticing that our choice for r guarantees that $1 - ||U_{A,k}^T U_{A,k} - U_{A,k}^T \mathcal{S}^T \mathcal{S} U_{A,k}||_2 \geq 1/2$, concludes the proof of the fourth claim.

This concludes the proof of the lemma. □

The next lemma provides an approximate matrix multiplication bound that is useful in the proof of Theorem 5. For this lemma, r depends linearly on k.

LEMMA 2. [illegible] $\epsilon \in (0,1]$ [illegible] (20) [illegible] $r \geq 400k/\beta\epsilon^2$ [illegible] 0.9

$$\left\| U_{A,k}^T \mathcal{S}^T \mathcal{S} U_{A,k}^\perp {U_{A,k}^\perp}^T B \right\|_F \leq \frac{\epsilon}{2} \left\| U_{A,k}^\perp {U_{A,k}^\perp}^T B \right\|_F .$$

[illegible]. First, note that since $U_{A,k}$ is an orthogonal matrix and since $U_{A,k}^T U_{A,k}^\perp = 0$, we have that

$$\begin{aligned} \left\| U_{A,k}^T \mathcal{S}^T \mathcal{S} U_{A,k}^\perp {U_{A,k}^\perp}^T B \right\|_F &= \left\| U_{A,k} U_{A,k}^T \mathcal{S}^T \mathcal{S} U_{A,k}^\perp {U_{A,k}^\perp}^T B \right\|_F \\ &= \left\| U_{A,k} U_{A,k}^T U_{A,k}^\perp {U_{A,k}^\perp}^T B - U_{A,k} U_{A,k}^T \mathcal{S}^T \mathcal{S} U_{A,k}^\perp {U_{A,k}^\perp}^T B \right\|_F . \end{aligned} \tag{35}$$

Since $|(U_{A,k} U_{A,k}^T)_{(i)}|_2 = |(U_{A,k}^T)_{(i)}|_2$, the sampling probabilities (20) satisfy (45), where (45) will appear in Appendix A.2, and thus are appropriate for bounding the right-hand side of (35). Thus, it follows from Markov's inequality and Theorem 6 that with probability at least 0.9:

$$\begin{aligned} \left\| U_{A,k}^T \mathcal{S}^T \mathcal{S} U_{A,k}^\perp {U_{A,k}^\perp}^T B \right\|_F &\leq 10\, \mathbf{E} \left[\left\| U_{A,k}^T \mathcal{S}^T \mathcal{S} U_{A,k}^\perp {U_{A,k}^\perp}^T B \right\|_F \right] \\ &\leq \frac{10}{\sqrt{\beta r}} \left\| U_{A,k} U_{A,k}^T \right\|_F \left\| U_{A,k}^\perp {U_{A,k}^\perp}^T B \right\|_F . \end{aligned}$$

The lemma follows by the choice of r and since $||U_{A,k} U_{A,k}^T||_F = \sqrt{\rho} \leq \sqrt{k}$. □

The final lemma of this subsection relates the norm of the $m \times p$ matrix $U_{A,k}^\perp {U_{A,k}^\perp}^T B$ to the norm of the $r \times p$ matrix $\mathcal{S} U_{A,k}^\perp {U_{A,k}^\perp}^T B$, i.e., the row sampled and rescaled version of the original $m \times p$ matrix. For this lemma, r is independent of k.

LEMMA 3. [illegible] 0.9

$$\left\| \mathcal{S} U_{A,k}^\perp {U_{A,k}^\perp}^T B \right\|_F \leq 10 \left\| U_{A,k}^\perp {U_{A,k}^\perp}^T B \right\|_F .$$

[illegible]. Let $Q = U_{A,k}^\perp {U_{A,k}^\perp}^T B$, and let $j_1, j_2, \ldots, j_r$ be the r rows of Q that were included in $\mathcal{S}Q = DS^T Q$. Clearly,

$$\mathbf{E} \left[\left\| DS^T Q \right\|_F^2 \right] = \mathbf{E} \left[\sum_{t=1}^r \left| Q_{(j_t)} \right|_2^2 \right] = \sum_{t=1}^r \mathbf{E} \left[\left| Q_{(j_t)} \right|_2^2 \right] = \sum_{t=1}^r \sum_{j=1}^n p_j \frac{\left| Q_{(j)} \right|_2^2}{r p_j} = \left\| Q \right\|_F^2 , \tag{36}$$

where the penultimate equality follows by evaluating the expectation. The lemma follows by applying Markov's inequality and taking the square root of both sides of the resulting inequality. □

6.3.2. Proof of (21). In this subsection, we will bound $B - A_k \tilde{X}_{opt}$, thus proving (21). For the moment, let us assume that $r = 400k^2/\beta\epsilon^2$, in which case the assumption on r is satisfied for each of Lemma 1, Lemma 2, and Lemma 3. Thus, the claims of

all three lemmas hold simultaneously with probability at least $1 - 3(0.1) \geq 0.7$, and so let us condition on this event.

First, we have that

$$\begin{aligned} B - A_k\tilde{X}_{opt} &= B - A_k \left(\mathcal{S}A_k\right)^+ \mathcal{S}B \\ &= B - U_{A,k} \left(\mathcal{S}U_{A,k}\right)^+ \mathcal{S}B \qquad (37) \\ &= B - U_{A,k} \left(\mathcal{S}U_{A,k}\right)^+ \mathcal{S}U_{A,k}U_{A,k}^T B - U_{A,k} \left(\mathcal{S}U_{A,k}\right)^+ \mathcal{S}U_{A,k}^\perp {U_{A,k}^\perp}^T B \qquad (38) \\ &= U_{A,k}^\perp {U_{A,k}^\perp}^T B - U_{A,k} \left(\mathcal{S}U_{A,k}\right)^+ \mathcal{S}U_{A,k}^\perp {U_{A,k}^\perp}^T B. \qquad (39) \end{aligned}$$

Equation (37) follows from (27) of Lemma 1, (38) follows by inserting $U_{A,k}U_{A,k}^T + U_{A,k}^\perp {U_{A,k}^\perp}^T = I_n$, and (39) follows since $\left(\mathcal{S}U_{A,k}\right)^+ \mathcal{S}U_{A,k} = I_\rho$ by Lemma 1. We emphasize that $\left(\mathcal{S}U_{A,k}\right)^+ \mathcal{S}U_{A,k} = V_{\mathcal{S}U_{A,k}} V_{\mathcal{S}U_{A,k}}^T = I_\rho$ does not hold for general sampling methods, but it does hold in this case since $\tilde{\rho} = \rho$, which follows from Lemma 1.

By taking the Frobenius norm of both sides of (39), by using the triangle inequality, and recalling that $\Omega = \left(\mathcal{S}U_{A,k}\right)^+ - \left(\mathcal{S}U_{A,k}\right)^T$, we have that

$$\begin{aligned} \left\|B - A_k\tilde{X}_{opt}\right\|_F &\leq \left\|U_{A,k}^\perp {U_{A,k}^\perp}^T B\right\|_F + \left\|U_{A,k} \left(\mathcal{S}U_{A,k}\right)^T \mathcal{S}U_{A,k}^\perp {U_{A,k}^\perp}^T B\right\|_F \\ &\quad + \left\|U_{A,k}\Omega\mathcal{S}U_{A,k}^\perp {U_{A,k}^\perp}^T B\right\|_F \\ &\leq \left\|U_{A,k}^\perp {U_{A,k}^\perp}^T B\right\|_F + \left\|U_{A,k}^T \mathcal{S}^T \mathcal{S}U_{A,k}^\perp {U_{A,k}^\perp}^T B\right\|_F \qquad (40) \\ &\quad + \|\Omega\|_2 \left\|\mathcal{S}U_{A,k}^\perp {U_{A,k}^\perp}^T B\right\|_F, \end{aligned}$$

where (40) follows by submultiplicativity and since $U_{A,k}$ has orthogonal columns. By combining (40) with the bounds provided by Lemma 1 through Lemma 3, it follows that

$$\begin{aligned} \left\|B - A_k\tilde{X}_{opt}\right\|_F &\leq (1 + \epsilon/2 + 10\epsilon/\sqrt{2})\mathcal{Z} \\ &\leq (1 + 8\epsilon)\mathcal{Z}. \end{aligned}$$

Equation (21) follows by setting $\epsilon' = \epsilon/8$ and using the value of r assumed by the theorem.

6.3.3. Proof of (22). In this subsection, we will provide a bound for $||\tilde{X}_{opt} - X_{opt}||_F$ in terms of $\mathcal{Z}$, thus proving (22). For the moment, let us assume that $r = 400k^2/\beta\epsilon^2$, in which case the assumption on r is satisfied for each of Lemma 1, Lemma 2, and Lemma 3. Thus, the claims of all three lemmas hold simultaneously with probability at least $1 - 3(0.1) \geq 0.7$, and so let us condition on this event.

Since $U_{A,k}U_{A,k}^T + U_{A,k}^\perp {U_{A,k}^\perp}^T = I_n$ and $\left(\mathcal{S}U_{A,k}\right)^+ \mathcal{S}U_{A,k} = I_\rho$, we have that

$$\begin{aligned} X_{opt} - \tilde{X}_{opt} &= A_k^+ B - \left(\mathcal{S}A_k\right)^+ \mathcal{S}B \\ &= V_{A,k}\Sigma_{A,k}^{-1}U_{A,k}^T B - V_{A,k}\Sigma_{A,k}^{-1} \left(\mathcal{S}U_{A,k}\right)^+ \mathcal{S}B \\ &= V_{A,k}\Sigma_{A,k}^{-1}U_{A,k}^T B - V_{A,k}\Sigma_{A,k}^{-1} \left(\mathcal{S}U_{A,k}\right)^+ \mathcal{S}U_{A,k}U_{A,k}^T B \\ &\quad - V_{A,k}\Sigma_{A,k}^{-1} \left(\mathcal{S}U_{A,k}\right)^+ \mathcal{S}U_{A,k}^\perp {U_{A,k}^\perp}^T B \\ &= -V_{A,k}\Sigma_{A,k}^{-1} \left(\mathcal{S}U_{A,k}\right)^+ \mathcal{S}U_{A,k}^\perp {U_{A,k}^\perp}^T B. \end{aligned}$$

Thus, it follows that

$$\begin{aligned}
\left\|X_{opt} - \tilde{X}_{opt}\right\|_F &= \left\|V_{A,k}\Sigma_{A,k}^{-1}\left(\mathcal{S}U_{A,k}\right)^{+}\mathcal{S}U_{A,k}^{\perp}{U_{A,k}^{\perp}}^{T}B\right\|_F \\
&= \left\|\Sigma_{A,k}^{-1}\left(\left(\mathcal{S}U_{A,k}\right)^{T} + \Omega\right)\mathcal{S}U_{A,k}^{\perp}{U_{A,k}^{\perp}}^{T}B\right\|_F \\
&\leq \frac{1}{\sigma_{min}(A_k)}\left\|\left(\mathcal{S}U_{A,k}\right)^{T}\mathcal{S}U_{A,k}^{\perp}{U_{A,k}^{\perp}}^{T}B\right\|_F \\
&\quad + \frac{1}{\sigma_{min}(A_k)}\left\|\Omega\mathcal{S}U_{A,k}^{\perp}{U_{A,k}^{\perp}}^{T}B\right\|_F \\
&\leq \frac{1}{\sigma_{min}(A_k)}\left\|U_{A,k}^{T}\mathcal{S}^{T}\mathcal{S}U_{A,k}^{\perp}{U_{A,k}^{\perp}}^{T}B\right\|_F \\
&\quad + \frac{1}{\sigma_{min}(A_k)}\left\|\Omega\right\|_2\left\|\mathcal{S}U_{A,k}^{\perp}{U_{A,k}^{\perp}}^{T}B\right\|_F .
\end{aligned} \tag{41}$$

By combining (41) with Lemmas 1, 2, and 3, it follows that

$$\begin{aligned}
\left\|\tilde{X}_{opt} - X_{opt}\right\|_F &\leq \sigma_{\min}^{-1}(A_k)\left(\epsilon/2 + 10\epsilon/\sqrt{2}\right)\mathcal{Z} \\
&\leq \frac{8\epsilon}{\sigma_{\min}(A_k)}\mathcal{Z}.
\end{aligned}$$

Equation (22) follows by setting $\epsilon' = \epsilon/8$ and using the value of r assumed by the theorem.

6.3.4. Proof of (23). The error bound provided by (22) could be quite weak, since $\min_{X\in\mathbb{R}^{n\times p}}\left\|B - A_kX\right\|_F$ could be quite close or even equal to $\left\|B\right\|_F$, if B has most or all of its "weight" outside of the column space of A_k. Under a slightly stronger assumption, we will provide a bound $||\tilde{X}_{opt} - X_{opt}||_F$ in terms of $\left\|X_{opt}\right\|_F$, thus proving (23).

If we make the additional assumption that a [illegible] of the "weight" of B lies in the subspace spanned by the columns of A_k, then it follows that

$$\begin{aligned}
\mathcal{Z}^2 &= \left(\min_{X\in\mathbb{R}^{n\times p}}\left\|B - A_kX\right\|_F\right)^2 \\
&= \left\|U_{A,k}^{\perp}{U_{A,k}^{\perp}}^{T}B\right\|_F^2 \\
&= \left\|B\right\|_F^2 - \left\|U_{A,k}U_{A,k}^{T}B\right\|_F^2 \\
&\leq \left(\gamma^{-2} - 1\right)\left\|U_{A,k}U_{A,k}^{T}B\right\|_F^2 .
\end{aligned} \tag{42}$$

In order to relate $||U_{A,k}U_{A,k}^{T}B||_F$ and thus $\mathcal{Z}$ to $\left\|X_{opt}\right\|_F$ note that

$$\begin{aligned}
\left\|X_{opt}\right\|_F &= \left\|V_{A,k}\Sigma_{A,k}^{-1}U_{A,k}^{T}B\right\|_F \\
&= \left\|\Sigma_{A,k}^{-1}U_{A,k}^{T}B\right\|_F \\
&\geq \sigma_{\min}(\Sigma_{A,k}^{-1})\left\|U_{A,k}^{T}B\right\|_F \\
&= \frac{\left\|U_{A,k}U_{A,k}^{T}B\right\|_F}{\sigma_{\max}(A_k)}.
\end{aligned} \tag{43}$$

By combining (22) with (42) and (43), we get

$$\begin{aligned}\left\|\tilde{X}_{opt} - X_{opt}\right\|_F &\leq \frac{\epsilon}{\sigma_{\min}(A_k)}\mathcal{Z} \\ &\leq \frac{\epsilon}{\sigma_{\min}(A_k)}\sqrt{\gamma^{-2}-1}\left\|U_{A,k}U_{A,k}^T B\right\|_F \\ &\leq \epsilon\frac{\sigma_{\max}(A_k)}{\sigma_{\min}(A_k)}\sqrt{\gamma^{-2}-1}\left\|X_{opt}\right\|_F,\end{aligned}$$

which establishes (23).

6.3.5. Modifications to the proof with alternate row sampling procedure. If, in Algorithm 3, the rows are sampled with the EXPECTED(c) algorithm, then the proof of the claims of Theorem 5 is analogous to the proof described in the four previous subsections, with the following major exception. The claims of Lemma 1 hold if $r = O(k \log k/\beta\epsilon^2)$ rows are chosen with the EXPECTED(c) algorithm. To see this, recall that to bound the first claim of Lemma 1, we must bound the spectral norm $\|U_{A,k}^T U_{A,k} - U_{A,k}^T \mathcal{S}^T \mathcal{S} U_{A,k}\|_2$ in (29). If the sampling is performed with the EXACTLY(c) algorithm, then this is bounded in (30) by the corresponding Frobenius norm, which is then bounded with Theorem 6. On the other hand, if the sampling is performed with the EXPECTED(c) algorithm, then we can bound (29) directly with the spectral norm bound provided by Theorem 7.

Since the remaining claims of Lemma 1 follow from the first, they are also valid if $r = O(k \log k/\beta\epsilon^2)$ rows are chosen with the EXPECTED(c) algorithm. Lemma 2 still follows if $r = 400k/\beta\epsilon^2$, by using the Frobenius norm bound of Theorem 7, and Lemma 3 also follows immediately. The proofs of (21), (22), and (23) are identical, and thus Theorem 5, under the assumption that the the rows are chosen with the EXPECTED(c) algorithm, follows.

7. Empirical evaluation. Although this is a theoretical paper, it is motivated by applications, and thus one might wonder about the empirical applicability of our methods. For example, if we want to do as well as the best rank $k = 100$ (respectively, $k = 10$) approximation, with relative error bound $\epsilon = 0.1$, then our main theorem samples 3.2 billion (respectively, 32 million) columns of the matrix A using the EXACTLY(c) algorithm. Of course, our main theorem states that it in order to obtain our strong provable worst-case relative-error guarantees it [illegible] to choose that many columns. But, it would be a source of concern if anything like that number of columns is needed in "real" scientific and internet data applications.

In this section, we provide an empirical evaluation of the performance of our two main sampling procedures both for CX and [illegible] decompositions. In particular, we will evaluate how well the proposed column/row selection strategies perform at capturing the Frobenius norm for matrices derived from DNA SNP analysis, recommendation system analysis, and term-document analysis. By applying our algorithms to data sets drawn from these three diverse domains of modern data analysis, we will demonstrate that we can obtain very good Frobenius norm reconstruction by sampling a number of columns and/or rows that equals a small constant, e.g., 2 or 3 or 4 (as opposed to, e.g., a million or a billion), times the rank parameter k.

7.1. Details of our empirical evaluation. The empirical evaluation of our CX and [illegible] matrix decompositions has been performed using the following two types of column/row selection methods:

- "Subspace sampling" (with replacement) using the EXACTLY(c) algorithm; and
- "Subspace sampling" (without replacement) using the EXPECTED(c) algorithm.

In addition, the empirical evaluation has been performed on the following three data sets:

- Matrices derived from the DNA SNP HapMap data [15, 52]—see section 7.2;
- A matrix derived from the Jester recommendation system corpus [35, 48]—see section 7.3; and
- A matrix derived from the Reuters term-document corpus [46, 16]—see section 7.4.

We have chosen these three data sets on which to evaluate the empirical applicability of our algorithms for three reasons: first, these three application domains are representative of a wide range of areas of modern scientific and internet data analysis; second, these matrices are all approximately (to a greater or lesser extent) low-rank, and they are all data for which spectral methods such as low-rank approximations have been successfully applied; and third, we have already (with collaboraters from these application areas) applied our algorithms to these data sets [48, 52, 16]. In these data application papers [48, 52, 16], we have shown that our main CX and CUR decomposition algorithms (either the algorithms for which we have provable performance guarantees and/or greedy variants of these basic algorithms) perform well on tasks such as classification, denoising, reconstruction, prediction, and clustering—tasks that are of more immediate interest to data practitioners than simply capturing the norm of the data matrix.

In this section, however, we we will restrict ourselves to an empirical evaluation of our two main theorems. To do so, we will fix a rank parameter k, and we will present plots of the Frobenius norm error (normalized by $||A - A_k||_F$), as a function of the number of samples chosen. For example, we will consider $\Theta_1 \equiv ||A - CC^+A||_F / ||A - A_k||_F$, where A_k is the best rank-k approximation to the matrix A, as a function of the number c of columns chosen. This ratio corresponds to the quantity that is bounded by $1 + \epsilon$ in Theorem 3. For $c = k$, this quantity will be no less than 1; of course, if we choose $c > k$ columns, then this ratio may be less than 1. Following the remark after Theorem 3, we will also consider $\Theta_2 \equiv ||A - CC^+A_k||_F / ||A - A_k||_F$. This ensures that the approximation has a rank no greater than k (which is of interest in certain applications), and thus the plotted ratio will clearly be no less than 1, for every value of c. We will also consider $\Theta_3 \equiv ||A - CUR||_F / ||A - A_k||_F$, which corresponds to the quantity that is bounded by $1 + \epsilon$ in Theorem 4.

Two technical points should be noted about these plots in the upcoming subsections. First, we ran our CX or CUR decomposition algorithm several—e.g., three or five, depending on the size of the data being plotted—times (corresponding, say, to multiple runs to boost the δ failure probability), and the minimum value over these repetitions was returned; this was repeated several times, and the average of those values is plotted. Second, for the plots of $||A - CUR||_F / ||A - A_k||_F$, the number of rows selected is set to be twice the corresponding number of columns selected; optimizing over this would lead to marginally better performance than that presented.

7.2. DNA SNP HapMap data. Our first dataset comes from the field of human genetics. The HapMap project, a continuation of the Human Genome project, aims to map the loci in the human genome that differ among individuals [15]. The HapMap project focuses on the so-called SNPs, which are a very common type of

variation in the genome (nearly 10^7 such loci have been identified in the human genome). Significant motivation exists in the genetics community for minimizing the number of SNPs that must be assayed, and in [52], we demonstrated how , -type methods may be used to efficiently reconstruct unassayed SNPs from a small number of assayed SNPs.

Both in [52] and here, we consider two regions of the genome known as HOXB and 17q25. Three populations were studied for each region: Yoruban, a sub-Saharan African population; a European population; and a joint Japanese/Chinese population. Each population had 90 individuals, each corresponding to a row of the input matrix. Columns of each matrix correspond to SNPs within the HOXB or 17q25 regions. The genotypic data were encoded appropriately in order to be converted to numeric data in the form of matrices. (Careful preprocessing was done to remove fixed SNPs, as well as SNPs with too many missing entries, etc.) The HapMap project provided data on 370 SNPs in 17q25 and 571 SNP in HOXB [15]. Thus, for example, our matrix for the Yoruban population in HOXB is a 90×571 matrix, whose entries are in the set $\{-1, 0, +1\}$.[3] The other data matrices are of similar (not extremely large) size. See [52] and references therein for details.

Data not presented indicate that for all three populations and for both genomic regions, the data possess a great deal of linear structure. For example, in the 17q25 matrices, one needs 9, 9, and 7 singular vectors to capture 80% of the Frobenius norm for the Yoruban, European, and the Japanese/Chinese populations, respectively; and one needs 18, 16, and 13 singular vectors, respectively, to capture 90%. The matrices for the HOXB region of the genome are even more redundant; one needs only 7, 6, and 4 singular vectors, respectively, to capture 80% of the Frobenius norm.

In Figure 1, data are presented for the Yoruban HOXB data matrix. Each of the six subfigures presents a plot of the Frobenius norm error as a function of the number c of samples chosen. In particular, for two values of the rank parameter, i.e., $k = 5$ and $k = 10$, the ratio $\Theta_i = ||A - A'||_F / ||A - A_k||_F$ is plotted, where $A' = CC^+A$ for $i = 1$; $A' = CC^+A_k$ for $i = 2$; and $A' = CUR$ for $i = 3$. Clearly, in all these cases, only modest oversampling is needed to capture "nearly all" of the dominant part of the spectrum of the data matrix. For example, for $k = 5$: if $c = 5$, then $\Theta_1 = 1.12$; if $c \geq 6$, then $\Theta_1 < 1.1$; and if $c \geq 9$, then $\Theta_1 < 1.0$. Similarly, for $k = 10$: if $c = 10$, then $\Theta_1 = 1.22$; if $c \geq 15$, then $\Theta_1 < 1.1$; and if $c \geq 18$, then $\Theta_1 < 1.0$. Similar results hold if the projection onto the span of the columns is regularized through a rank-k space and also if rows are chosen after the columns. For example, for $k = 10$: if $c \geq 16$, then $\Theta_2 < 1.2$ and if $c \gtrsim 30$, then $\Theta_2 < 1.1$. Similarly, even though the computations for Θ_3 are slightly worse and somewhat noisier due to the second level of sampling (columns and then rows), the results still show that only modest oversampling (of c relative to k) is needed. For example, if $k = 10$, then $\Theta_3 < 1.1$ if $c \geq 20$ or $c \geq 28$, depending on precisely how the columns are chosen. Interestingly, in this last case, not only are the plots noisier, but the EXPECTED(c) algorithm and the EXACTLY(c) algorithm seem to lead to (slightly) different results as a function of c.

Qualitatively similar results are seen for the other populations and the other genomic regions. For example, in Figure 2, data are presented for the European

[3]The encoding should be interpreted as follows: each SNP consists of two alleles (nucleotide bases); these bases are the same for all humans. Say that these bases are A and G. Then a value of +1 corresponds to an individual whose genotype (pair of alleles) is AA, a value of 0 corresponds to an individual whose genotype is AG or GA, and a value of −1 corresponds to an individual whose genotype is GG.

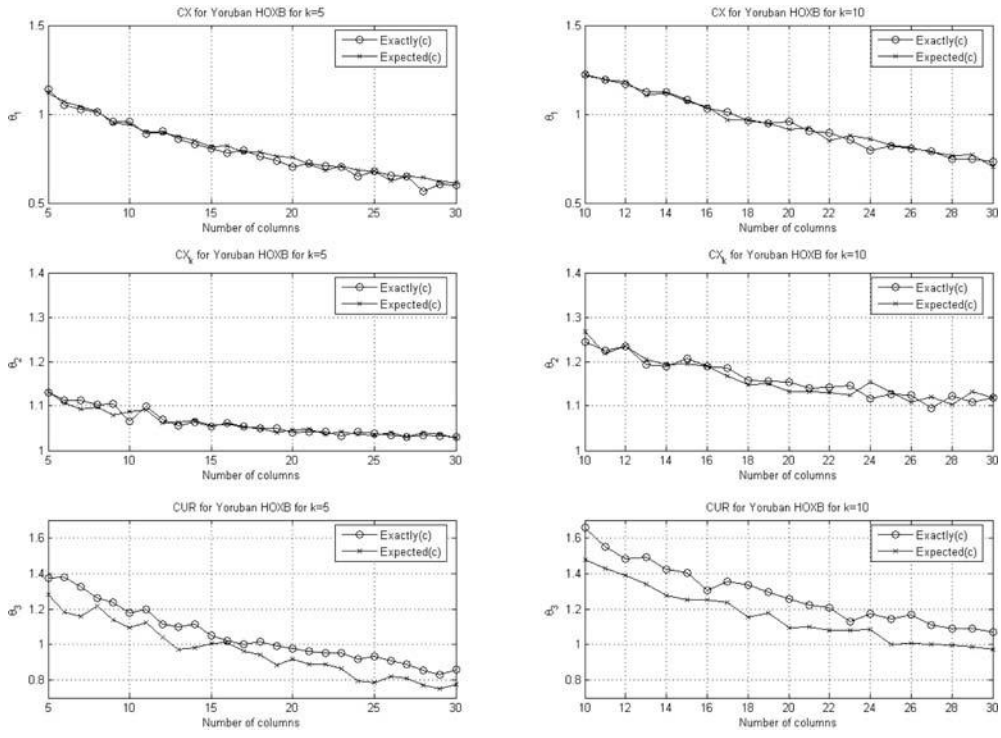

FIG. 1. *Reconstruction error for the Yoruban population in the HOXB region of the genome. Shown are* Θ_1, Θ_2, *and* Θ_3 *(as defined in the text) for two values of the rank parameter* k. *The X-axis corresponds to the number of columns sampled with the* EXACTLY(c) *algorithm or the* EXPECTED(c) *algorithm.*

population for both the HOXB and the 17q25 regions of the genome for the value of the rank parameter $k = 10$. For the HOXB region, $\Theta_1 = 1.36$ if $c = 10$ (this is higher than for the corresponding Yoruban data), $\Theta_1 < 1.0$ if $c \gtrsim 17$ (this is similar to the corresponding Yoruban data), and $\Theta_1 = 0.62$ if $c = 30$ (this is less than the Yoruban data). Similar trends are seen for Θ_2 and Θ_3 and also for the 17q25 region. In all cases, only very modest oversampling is needed for accurate Frobenius norm reconstruction. Data not presented indicate that the data for the joint Japanese/Chinese population is quite similar to or slightly better than those results presented.

7.3. Recommendation system jester data. Our second dataset comes from the field of recommendation system analysis, in which one is typically interested in making purchase recommendations to a user at an electronic commerce web site [35]. Collaborative methods (as opposed to content-based or hybrid) involve recommending to the user items that people with similar tastes or preferences liked in the past. Many collaborative filtering algorithms represent a user as an n dimensional vector, where n is the number of distinct products, and where the components of the vector are a measure of the rating provided by that user for that product. Thus, for a set of m users, the user-product ratings matrix is an $m \times n$ matrix A, where A_{ij} is the rating by user i for product j (or is null if the rating is not provided).

The so-called Jester joke dataset is a commonly used benchmark for recommendation system research and development [35]. In [48], we applied a , decomposition on this data to the problem of reconstructing missing entries and making accurate

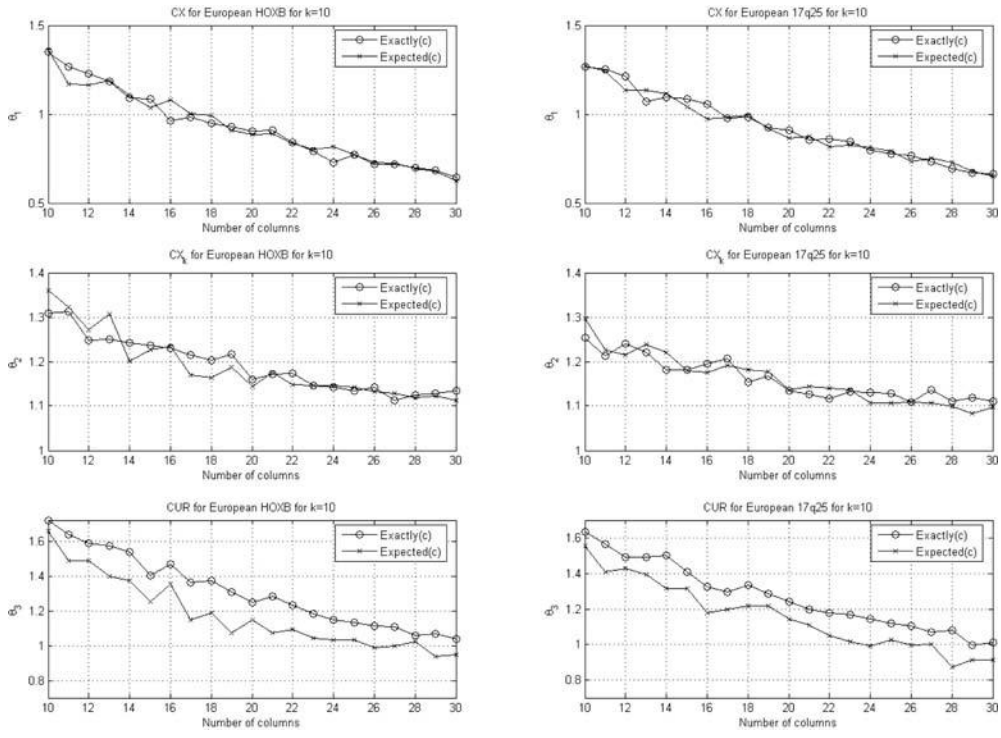

FIG. 2. *Reconstruction error for the European population in both the HOXB and 17q25 regions of the genome. Shown are* Θ_1, Θ_2, *and* Θ_3 *(as defined in the text) for* $k = 10$. *The X-axis corresponds to the number of columns sampled with the* EXACTLY(c) *algorithm or the* EXPECTED(c) *algorithm.*

recommendations. Here, we consider the $m = 14{,}116$ (out of ca. 73,000) users who rated all of the $n = 100$ products (i.e., jokes) in the Jester data. The entries in this $14{,}116 \times 100$ matrix A are real numbers between -10 and $+10$ that represent the user's rating of a product.

Figure 3 presents the empirical results for the Jester recommendation system data. The rank of the $14{,}116 \times 100$ matrix is 100, and although only seven singular vectors are needed to capture 50% of the Frobenius norm, 50 are needed to capture 80%, and 73 are needed to capture 90%. Thus, the spectrum and shape of this matrix (this matrix is very rectangular) are very different from that of the matrices of the previous subsection.

Figure 3 presents reconstruction error results for selecting columns (i.e., products or jokes), for selecting rows (i.e., users), and for selecting both columns and rows simultaneously. For example, when selecting columns from A, if $k = 15$, then $\Theta_1 = 1.14$ if $c = 15$, $\Theta_1 \leq 1$ if $c \gtrsim 29$, and $\Theta_1 = 0.99$ when $c = 30$. Although the matrix is very rectangular, quantitatively very similar results are obtained for the analogue of Θ_1 (called Θ_1^R in the figure) if rows are sampled (or, equivalently if columns are sampled from A^T). Thus, when our main CX decomposition is applied to either A or to A^T, a small number of columns (products) or rows (users), capture most of the Frobenius norm of A that is captured by the best rank k approximation to A. A similar result holds for the simultaneously choosing columns and rows of A (both users and products), and applying our CUR approximation algorithm. As with the data of the previous subsection, the data for Θ_3 are much noisier when both columns

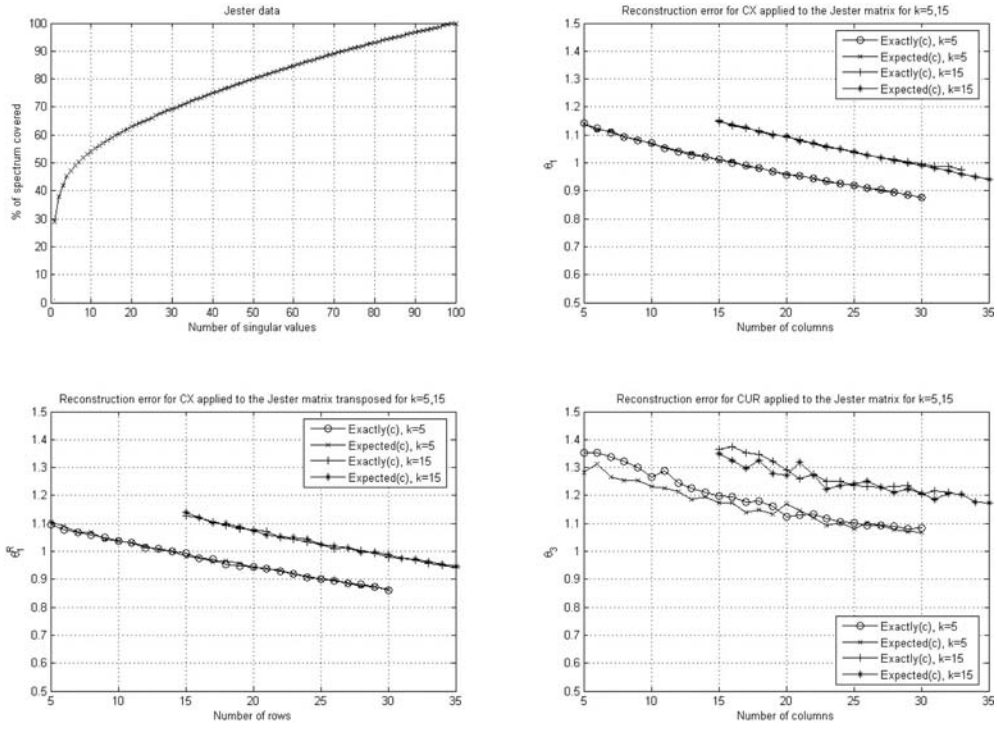

FIG. 3. *Empirical results for the Jester recommendation system data. Shown are: the percentage of the Frobenius norm captured as a function of the number of singular components;* Θ_1 *for sampling columns from* A *for* $k = 5$ *and* $k = 15$*; the analogue of* Θ_1 *for selecting rows from* A *(i.e.,* Θ_1 *for sampling columns from* A^T*); and* Θ_3 *for selecting columns and then rows for* $k = 5$ *and* $k = 15$.

and rows are chosen, but even in this case $\Theta_3 \leq 1.1$ for $k = 5$ if $c \gtrsim 25$ and $\Theta_3 \leq 1.2$ for $k = 15$ if $c \gtrsim 30$. In all these cases, data not presented indicate that qualitatively similar (but shifted) results are obtained for higher values of the rank parameter k.

7.4. Term-document Reuters data. Our third data set comes from the field of text categorization and information retrieval. In these applications, documents are often represented as a so-called "bag of words" and a vector space model is used. In 2000, Reuters Ltd made available a large collection of Reuters News stories for use in research and development of natural language processing, information retrieval, and machine learning systems. This corpus, known as "Reuters Corpus, Volume 1" or RCV1, is significantly larger (it contains over 800,000 news items from 1996-97) than the older, well-known Reuters-21578 collection, which has been heavily used in the text classification community [46]. In [16], we considered the problem of feature selection for improved classification, and we compared a CX-like column selection procedure to several traditional methods. The data come with class labels and possess a hierarchical class structure (which we used in [16]) which we ignored here. Here, we used the ,. -normalized term-document matrix and the training data from the one test-train split provided by Lewis, Yang, Rose, and Li [46]. Thus, the Reuters matrix we considered here is a (very sparse) 47,236 × 23,149 matrix whose elements are real numbers between 0 and 1 that represent a normalized frequency.

Figure 4 presents the empirical results for the Reuters term-document data. Note that this data is not only much larger than the data from the previous two subsec-

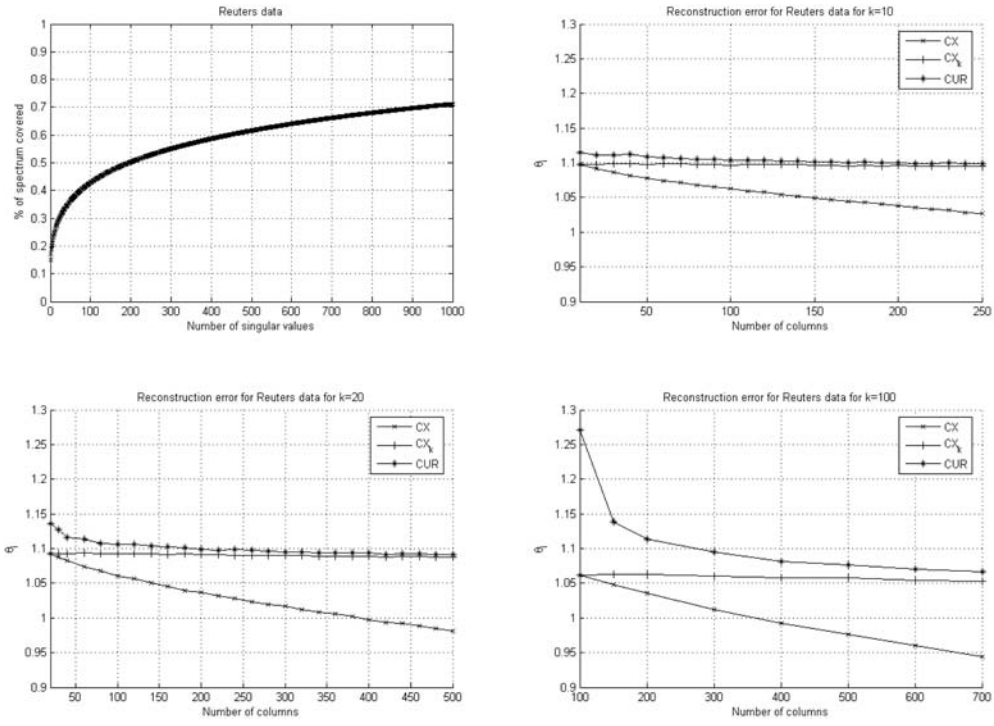

FIG. 4. *Empirical results for the Reuters term-document data. Shown are the percentage of the Frobenius norm captured as a function of the number of singular components;* Θ_1, Θ_2, *and* Θ_3 *as a function of the number of sampled columns and/or rows for three different values of the rank parameter* k.

tions, it is also less well-approximated by a low rank matrix. Less than 50% of the Frobenius norm is captured by the first $k = 100$ singular components, and less than 80% is captured by the first $k = 1500$ singular components. (Nevertheless, spectral methods have frequently been applied to this data.) The matrix is very sparse, and performing computations is expensive in terms of space and time (due to multiple randomized trials and since the dense matrices of singular vectors are large) if the rank parameter k is chosen to be more than a few hundred. Thus, to demonstrate the empirical applicability of our main algorithms, we considered several smaller values of k. Here, we report results for $k = 10$ and $c = 10$ to 250; for $k = 20$ and $c = 20$ to 500; and for $k = 100$ and $c = 100$ to 700. Note that we report results only for columns chosen with the EXPECTED(c) algorithm; initial unreported computations on several smaller systems indicate that very similar results will be obtained with the EXACTLY(c) algorithm.

In all of these cases, and for all values of Θ_1, Θ_2, and Θ_3, only modest oversampling leads to fairly small reconstruction error. The worst data point reported was for $\Theta_3 = 1.272$ for $k = 100$ and $c = 100$, and even in that case $\Theta_3 < 1.1$ for $c \geq 300$. Interestingly, all the curves tend to decrease somewhat more slowly (as a function of oversampling c, relative to k) than the corresponding curves in the previous subsections do. Note that Θ_1 does not decrease below 1.0 for $k = 10$ until after $c = 500$; for $k = 20$, it drops below 1.0 by $c = 400$, and for $k = 100$ (which obviously captures the largest fraction of the Frobenius norm) it drops below 1.0 at $c \approx 350$. Thus, this phenomenon is likely related to the degree to which the chosen value for

the rank parameter k captures a reasonable fraction of the norm of the original matrix. Nevertheless, in all cases, we can achieve $\Theta_i < 1.1$ with only a modest degree of oversampling c relative to k.

8. Conclusion. We have presented and analyzed randomized algorithms for computing low-rank matrix approximations that are explicitly expressed in terms of a small number of columns and/or rows of the input matrix. These algorithm achieve relative-error guarantees, whereas previous algorithms for these problems achieved only additive-error guarantees. These algorithms randomly sample in a novel manner that we call "subspace sampling," and their analysis amounts to approximating a generalized ℓ_2 regression problem by random sampling. As described in section 1.1 and in [52, 48], such low-rank matrix approximations have numerous applications for the improved analysis of data.

We conclude with several open problems:

- To what extent do the results of this paper generalize to other matrix norms?
- What hardness results can be established for the optimal choice of columns and/or rows?
- Does there exist a deterministic approximation algorithm for either of the problems we consider?
- Does there exist an efficient deterministic algorithm to choose columns and/or rows that exactly or approximately optimize the maximum volume of the induced parallelepiped? (As pointed out to us by an anonymous reviewer, [40, 61] provide such procedures; it would be interesting to see if bounds of the form we prove can be established for the algorithms of [40, 61]).
- Can we formulate a simple condition that we can check after we have sampled the columns and/or rows to determine whether we have achieved a $1 + \epsilon$ approximation with that sample?
- Can we obtain similar algorithms and comparable bounds for formulations of these problems that include regularization and/or conditioning?
- What heuristic variants of these algorithms are most appropriate in different application domains?
- Are the algorithms presented in this paper numerically stable?

Appendix A. Approximating matrix multiplication. In this section, we describe two complementary procedures for randomly sampling (and rescaling) columns and/or rows from an input matrix. Then, we describe an algorithm for approximating the product of two matrices by randomly sampling columns and rows from the input matrices using one of the two sampling procedures.

A.1. Sampling columns and rows from matrices. We describe two simple algorithms for randomly sampling a set of columns from an input matrix. Each algorithm takes as input an $m \times n$ matrix A and a probability distribution $\{p_i\}_{i=1}^n$, and each constructs a matrix C consisting of a rescaled copy of a small number of columns from A. Clearly, each algorithm can be modified to sample rows from a matrix. The first algorithm is the EXACTLY(c) algorithm, which is described in Algorithm 4 using the sampling matrix formalism described in section 2. In this algorithm, c columns [illegible] of A are chosen in c i.i.d. trials, where in each trial the ith column of A is picked with probability p_i. Note that because the sampling is performed with replacement, a single column of A may be included in C more than once. The second algorithm is the EXPECTED(c) algorithm, which is described in Algorithm 5, also using the sampling matrix formalism described in section 2. In this algorithm, at most c columns [illegible] of A are chosen by including the

ith column of A in C with probability $\tilde{p}_i = \min\{1, cp_i\}$. Note that the exact value of the number of columns returned is not known before the execution of this second algorithm; we do not perform an analysis of this random variable.

Data : $A \in \mathbb{R}^{m\times n}$, $p_i \geq 0, i \in [n]$ s.t. $\sum_{i\in[n]} p_i = 1$, positive integer $c \leq n$.
Result : Sampling matrix S, rescaling matrix D, and sampled and rescaled columns C.
Initialize S and D to the all zeros matrices.
for $t = 1, \ldots, c$ **do**
  Pick $i_t \in [n]$, where $\mathbf{Pr}(i_t = i) = p_i$;
  $S_{i_t t} = 1$;
  $D_{tt} = 1/\sqrt{cp_{i_t}}$.
end
$C = ASD$.

Algorithm 4. The EXACTLY(c) algorithm to create S, D, and C.

Data : $A \in \mathbb{R}^{m\times n}$, $p_i \geq 0, i \in [n]$ s.t. $\sum_{i\in[n]} p_i = 1$, positive integer $c \leq n$.
Result : Sampling matrix S, rescaling matrix D, and sampled and rescaled columns C.
Initialize S and D to the all zeros matrices.
$t = 1$;
for $j = 1, \ldots, n$ **do**
  Pick j with probability $\min\{1, cp_j\}$;
  if *j is picked* **then**
    $S_{jt} = 1$;
    $D_{tt} = 1/\min\{1, \sqrt{cp_j}\}$;
    $t = t + 1$;
  end
end
$C = ASD$.

Algorithm 5. *The* EXPECTED(c) *algorithm to create S, D, and C.*

A.2. Approximate matrix multiplication algorithms. Algorithm 6 takes as input two matrices A and B, a number $c \leq n$, and a probability distribution $\{p_i\}_{i=1}^n$ over $[n]$. It returns as output two matrices C and R, where the columns of C are a small number of sampled and rescaled columns of A and where the rows of R are a small number of sampled and rescaled rows of B. The sampling and rescaling are performed by calling either the EXACTLY(c) algorithm or the EXPECTED(c) algorithm. When the EXACTLY(c) algorithm is used to choose column-row pairs in Algorithm 6, this is identical to the algorithm of [21]. In particular, note that exactly c column-row pairs are chosen, and a column-row pair could be included in the sample more than once. When the EXPECTED(c) algorithm is used to choose column-row pairs in Algorithm 6, this is a minor variation of the algorithm of [21]. In particular, the

main difference is that at most c column-row pairs are chosen, and no column-row pair is included in the sample more than once.

Data : $A \in \mathbb{R}^{m \times n}$, $B \in \mathbb{R}^{n \times p}$, $\{p_i\}_{i=1}^n$ such that $\sum_{i=1}^n p_i = 1$, $c \leq n$.
Result : $C \in \mathbb{R}^{m \times c}$, $R \in \mathbb{R}^{c \times p}$.

- Form the matrix $C = ASD$ by sampling according to $\{p_i\}_{i=1}^n$ with the EXACTLY(c) algorithm or with the EXPECTED(c) algorithm;
- Form the matrix $R = DS^T B$ from the corresponding rows of B.

Algorithm 6. A fast Monte-Carlo algorithm for approximate matrix multiplication.

The next two theorems are our basic quality-of-approximation results for Algorithm 6. Each states that, under appropriate assumptions, $CR = ASDDS^T B \approx AB$. The most interesting of these assumptions is that the sampling probabilities used to randomly sample the columns of A and the corresponding rows of B are nonuniform and depend on the product of the Euclidean norms of the columns of A and/or the corresponding rows of B. For example, consider sampling probabilities $\{p_i\}_{i=1}^n$ such that

$$p_i \geq \beta \frac{\left|A^{(i)}\right|_2 \left|B_{(i)}\right|_2}{\sum_{j=1}^n \left|A^{(j)}\right|_2 \left|B_{(j)}\right|_2}, \tag{44}$$

for some $\beta \in (0, 1]$. Sampling probabilities of the form (44) use information from the matrices A and B in a very particular manner. If $\beta = 1$, they are optimal for approximating AB by CR in a sense made precise in [21]. Alternatively, sampling probabilities $\{p_i\}_{i=1}^n$ such that

$$p_i \geq \beta \frac{\left|A^{(i)}\right|_2^2}{\|A\|_F^2}, \tag{45}$$

for some $\beta \in (0, 1]$, are also of interest in approximating the product AB by CR if, e.g., only information about A is easily available.

The following theorem is our main quality-of-approximation result for approximating the product of two matrices with Algorithm 6, when column-row pairs are sampled using the EXACTLY(c) algorithm. Its proof (and the statement and proof of similar stronger results) may be found in [21].

THEOREM 6. Suppose $A \in \mathbb{R}^{m \times n}$, $B \in \mathbb{R}^{n \times p}$, $c \leq n$, and C, R are formed by Algorithm 6 using EXACTLY(c) and $\{p_i\}_{i=1}^n$ such that (44) or (45) holds. Then

$$\mathbf{E}\left[\|AB - CR\|_F\right] \leq \frac{1}{\sqrt{\beta c}} \|A\|_F \|B\|_F.$$

The following theorem is our main quality-of-approximation result for approximating the product of two matrices with Algorithm 6, when column-row pairs are sampled using the EXPECTED(c) algorithm. The Frobenius norm bound (46) is new, and the spectral norm bound (47) is due to Rudelson and Vershynin, who proved a similar result in a more general setting [54, 62, 56].

THEOREM 7. [illegible] $A \in \mathbb{R}^{m\times n}$, $B \in \mathbb{R}^{n\times p}$ [illegible] $c \leq n$ [illegible] C [illegible] R [illegible] 6 [illegible] EXPECTED(c) [illegible] $\{p_i\}_{i=1}^n$ [illegible] (44) [illegible] (45) [illegible]

$$\mathbf{E}\left[\,\|AB - CR\|_F\right] \leq \frac{1}{\sqrt{\beta c}}\,\|A\|_F\,\|B\|_F\,. \tag{46}$$

[illegible] $B = A^T$ [illegible]

$$\mathbf{E}\left[\,\left\|AA^T - CC^T\right\|_2\right] \leq O(1)\sqrt{\frac{\log c}{\beta c}}\,\|A\|_F\,\|A\|_2\,. \tag{47}$$

[illegible]. Equation (47) follows from the analysis of Rudelson and Vershynin, who considered spectral norm bounds on approximating the product of two matrices [54, 62, 56]. Note that they considered approximating the product AA^T by sampling with respect to probabilities of the form (45) with $\beta = 1$, but the analysis for general $\beta \in (0, 1]$ is analogous.

Next, we prove that for any set of probabilities $\{p_i\}_{i=1}^n$ the following holds:

$$\mathbf{E}\left[\,\|AB - CR\|_F^2\right] \leq \frac{1}{c}\sum_{j=1}^{n}\frac{\left|A^{(j)}\right|_2^2\left|B_{(j)}\right|_2^2}{p_j}. \tag{48}$$

Equation (46) follows from (48) by using Jensen's inequality and using the form of the sampling probabilities (44) and (45).

To establish (48), recall that the sampling is performed with the EXPECTED(c) algorithm. Let I_j, $j \in [n]$ be the indicator variable that is set to 1 if the jth column of A and the jth row of B are sampled (with probability $\min\{1, cp_j\}$) and is set to 0 otherwise. Recall that if $I_j = 1$, we scale both the jth column of A and the jth row of B by $1/\sqrt{\min\{1, cp_j\}}$. Thus,

$$\begin{aligned}\|AB - CR\|_F^2 &= \left\|AB - ASDDS^TB\right\|_F^2 \\ &= \left\|\sum_{j=1}^{n}\left(1 - \frac{I_j}{\min\{1, cp_j\}}\right)A^{(j)}B_{(j)}\right\|_F^2. \end{aligned}\tag{49}$$

Clearly, if $\min\{1, cp_j\} = 1$, then $I_j = 1$ with probability 1, and $1 - I_j/\min\{1, cp_j\} = 0$. Thus, we can focus on the set of indices $\Lambda = \{j \in [n] : cp_j < 1\} \subseteq [n]$. By taking the expectation of both sides of (49), it follows that

$$\begin{aligned}\mathbf{E}\left[\,\|AB - CR\|_F^2\right] &= \mathbf{E}\left[\left\|\sum_{j\in\Lambda}\left(1 - \frac{I_j}{cp_j}\right)A^{(j)}B_{(j)}\right\|_F^2\right] \\ &= \mathbf{E}\left[\sum_{i_1=1}^{m}\sum_{i_2=1}^{p}\left(\sum_{j\in\Lambda}\left(1 - \frac{I_j}{cp_j}\right)A^{(j)}B_{(j)}\right)_{i_1i_2}^2\right] \\ &= \mathbf{E}\left[\sum_{i_1=1}^{m}\sum_{i_2=1}^{p}\left(\sum_{j\in\Lambda}\left(1 - \frac{I_j}{cp_j}\right)A_{i_1j}B_{ji_2}\right)^2\right]. \end{aligned}$$

By multiplying out the right-hand side, it follows that

(50)
$$\mathbf{E}\left[\,\|AB-CR\|_F^2\right] = \mathbf{E}\left[\sum_{i_1=1}^{m}\sum_{i_2=1}^{p}\sum_{j_1\in\Lambda}\sum_{j_2\in\Lambda}\left(1-\frac{I_{j_1}}{cp_{j_1}}\right)\left(1-\frac{I_{j_2}}{cp_{j_2}}\right)A_{i_1j_1}B_{j_1i_2}A_{i_1j_2}B_{j_2i_2}\right]$$
$$= \sum_{i_1=1}^{m}\sum_{i_2=1}^{p}\sum_{j_1\in\Lambda}\sum_{j_2\in\Lambda}\mathbf{E}\left[\left(1-\frac{I_{j_1}}{cp_{j_1}}\right)\left(1-\frac{I_{j_2}}{cp_{j_2}}\right)\right]A_{i_1j_1}B_{j_1i_2}A_{i_1j_2}B_{j_2i_2}.$$

Notice that for $j\in[\Lambda]$, $\mathbf{E}\left[1-I_j/cp_j\right]=0$ and $\mathbf{E}\left[\left(1-I_j/cp_j\right)^2\right]=(1/cp_j)-1\le 1/cp_j$. Hence,

$$\mathbf{E}\left[\,\|AB-CR\|_F^2\right] = \sum_{i_1=1}^{m}\sum_{i_2=1}^{p}\sum_{j\in\Lambda}\mathbf{E}\left[\left(1-I_j/cp_j\right)^2\right]A_{i_1j}^2B_{ji_2}^2$$
$$\le \sum_{j\in\Lambda}\frac{1}{cp_j}\sum_{i_1=1}^{m}\sum_{i_2=1}^{p}A_{i_1j}^2B_{ji_2}^2 = \frac{1}{c}\sum_{j\in\Lambda}\frac{\left|A^{(j)}\right|_2^2\left|B_{(j)}\right|_2^2}{p_j}.$$

This concludes the proof of (48) and thus of the theorem. □

Acknowledgments. We would like to thank Sariel Har-Peled for writing up his results amidst travel in India [42], Amit Deshpande and Santosh Vempala for graciously providing a copy of [18], and two anonymous reviewers for useful comments.

CHARACTERIZATIONS OF A CLASS OF MATRICES AND PERTURBATION OF THE DRAZIN INVERSE*

N. CASTRO-GONZÁLEZ†, J. ROBLES†, AND J. Y. VÉLEZ-CERRADA†

Abstract. Given a singular square matrix A with index r, $\mathrm{ind}(A) = r$, we establish several characterizations in the Drazin inverse framework of the class of matrices B, which satisfy the conditions $\mathcal{N}(B^s)\cap\mathcal{R}(A^r) = \{0\}$ and $\mathcal{R}(B^s)\cap\mathcal{N}(A^r) = \{0\}$ with $\mathrm{ind}(B) = s$, where $\mathcal{N}(A)$ and $\mathcal{R}(A)$ denote the null space and the range space of a matrix A, respectively. We give explicit representations for B^{D} and BB^{D} and upper bounds for the errors $\|B^{\mathrm{D}} - A^{\mathrm{D}}\|/\|A^{\mathrm{D}}\|$ and $\|BB^{\mathrm{D}} - AA^{\mathrm{D}}\|$. In a numerical example we show that our bounds are better than others given in the literature.

Key words. singular matrix, Drazin inverse, eigenprojectors, perturbation

1. Introduction and preliminaries.

Let $A \in \mathbb{C}^{n\times n}$ be any complex square matrix of order n with $\mathrm{ind}(A) = r$, where $\mathrm{ind}(A)$, the index of A, is the smallest nonnegative integer r such that $\operatorname{rank} A^r = \operatorname{rank} A^{r+1}$. Let $\mathcal{R}(A)$ and $\mathcal{N}(A)$ denote the range space of A and the null space of A, respectively. In our development we consider matrices $B \in \mathbb{C}^{n\times n}$, which satisfy the following condition for some positive integer s:

$$(\mathcal{C}_s) \qquad \mathcal{R}(B^s) \cap \mathcal{N}(A^r) = \{0\} \quad \text{and} \quad \mathcal{N}(B^s) \cap \mathcal{R}(A^r) = \{0\}.$$

A particular case is when the matrix B satisfies

$$\mathcal{R}(B^s) = \mathcal{R}(A^r) \quad \text{and} \quad \mathcal{N}(B^s) = \mathcal{N}(A^r). \tag{1.1}$$

The class of perturbation matrices B related to A by the condition (1.1), which is equivalent to the fact that both matrices have equal eigenprojection at zero, $B^\pi = A^\pi$ with $A^\pi = I - AA^{\mathrm{D}}$, were characterized in [4]. The Drazin inverse of B satisfying (1.1) is given by the formula $B^{\mathrm{D}} = (I + A^{\mathrm{D}}(B - A))^{-1}A^{\mathrm{D}}$. This latter formula was given in [15] for $B = A + E$, where $E = AA^{\mathrm{D}}EAA^{\mathrm{D}}$ and E sufficiently small.

The first and third authors gave in [5] characterizations of the matrices B related to A by the condition that, involving the eigenprojections at zero, $I - (B^\pi - A^\pi)^2$ is nonsingular. Therein, it was proved that $B^{\mathrm{D}} = (I + A^{\mathrm{D}}(B - A) + S)^{-1}A^{\mathrm{D}}(I - S)$ where $S = B^\pi - A^\pi$ and an upper bound for $\|B^{\mathrm{D}} - A^{\mathrm{D}}\|/\|A^{\mathrm{D}}\|$ was given in terms of $\|A^{\mathrm{D}}(B - A)\|$ and $\|B^\pi - A^\pi\|$.

The continuity of the Drazin inverse was studied in [1, 2, 3, 11]. In [2], Campbell and Meyer established that if A_j converges to A, then A_j^{D} converges to A^{D} if and only if $\operatorname{rank} A_j^{r_j} = \operatorname{rank} A^r$ for all sufficiently large j, where $r_j = \mathrm{ind}(A_j)$. Recently, the perturbation of the Drazin inverse was studied by several authors, and upper bounds for the relative error $\|B^{\mathrm{D}} - A^{\mathrm{D}}\|/\|A^{\mathrm{D}}\|$ were given under certain conditions [4, 5, 6, 8, 9, 12, 13, 14, 15, 16].

In this paper, in section 2 we prove that, for a matrix B with $\mathrm{ind}(B) = s$, the fact that B satisfies condition $(\mathcal{C}_s)$ is equivalent to that $I-(B^\pi - A^\pi)^2$ is nonsingular. We establish several new characterizations of the matrices which satisfy condition $(\mathcal{C}_s)$. In terms of matrix rank, this class of matrices is characterized by the condition $\operatorname{rank} A^r = \operatorname{rank} B^s = \operatorname{rank} A^r B^s A^r$ whenever $s = \mathrm{ind}(B)$.

In section 3 we study further characterizations for the class $(\mathcal{C}_1)$, giving a representation of matrices $B \in (\mathcal{C}_1)$ such that $\mathrm{ind}(B) = 1$, with respect to the core-nilpotent block form of the matrix A. We mention that the perturbation of the group inverse is a case of special interest due to its application to stability of Markov chains [3, 10].

In section 4 we extend the characterizations for the group inverse to the general case of perturbations satisfying condition $(\mathcal{C}_s)$. We give an expression for the index 1-nilpotent decomposition of the matrices $B \in (\mathcal{C}_s)$, $\mathrm{ind}(B) = s$, which will be the main tool in the development of perturbation results.

Finally, in section 5 we give an explicit representation of B^{D}, and we derive upper bounds for the errors $\|B^{\mathrm{D}} - A^{\mathrm{D}}\|/\|A^{\mathrm{D}}\|$ and $\|BB^{\mathrm{D}} - AA^{\mathrm{D}}\|$ in terms of norms involving the powers $B^s - A^s$. In a numerical example we compare our bounds with others given recently in [13, 14].

In relation to the study of the continuity of the Drazin inverse, we can say that if A_j converges to A and $\operatorname{rank} A_j^{r_j} = \operatorname{rank} A^r A_j^{r_j} A^r = \operatorname{rank} A^r$ for all sufficiently large j, where $r_j = \mathrm{ind}(A_j)$, then an explicit representation for A_j^{D} and an explicit error bound of $\|A_j^{\mathrm{D}} - A^{\mathrm{D}}\|/\|A^{\mathrm{D}}\|$ are provided.

We recall that the [illegible] $A \in \mathbb{C}^{n\times n}$ is the unique matrix $A^{\mathrm{D}} \in \mathbb{C}^{n\times n}$ satisfying the relations

$$A^{\mathrm{D}} A A^{\mathrm{D}} = A^{\mathrm{D}}, \quad AA^{\mathrm{D}} = A^{\mathrm{D}} A, \quad A^{l+1} A^{\mathrm{D}} = A^l \quad \text{for all } l \geq r,$$

where $r = \mathrm{ind}(A)$. If A is nonsingular, then $\mathrm{ind}(A) = 0$ and the solution to the above equations is $A^{\mathrm{D}} = A^{-1}$. The case when $\mathrm{ind}(A) = 1$, i.e., $\operatorname{rank} A = \operatorname{rank} A^2$, the Drazin inverse is called the [illegible] A and is denoted by $A^\sharp$.

We denote by O a null matrix. Each $A \in \mathbb{C}^{n\times n}$ with $\mathrm{ind}(A) = r$ has a unique [illegible] (see [1, Theorem 11, Chapter 4]),

$$A = C_A + N_A, \quad \mathrm{ind}(C_A) = 1, \quad C_A N_A = N_A C_A = O, \quad N_A^r = O. \tag{1.2}$$

Moreover, we have $A^k = C_A^k + N_A^k$ for all integers $k \geq 1$, and $A^{\mathrm{D}} = C_A^\sharp$.

The following lemma gives a condition for the existence of the group inverse of a partitioned matrix and a formula for its computation (see [3, Theorems 7.7.5 and 7.7.7]).

LEMMA 1.1. [illegible] $M = \left(\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right)$ [illegible] $A \in \mathbb{C}^{d\times d}$ [illegible] $\Psi = I + A^{-1}BCA^{-1}$. [illegible]

(i) $\operatorname{rank} M = \operatorname{rank} A \Longleftrightarrow D = CA^{-1}B$.

[illegible] $k \geq 1$, M^k [illegible]

$$M^k = \begin{bmatrix} I \\ CA^{-1} \end{bmatrix} (A\Psi)^{k-1} A \begin{bmatrix} I & A^{-1}B \end{bmatrix}. \tag{1.3}$$

(ii) [illegible] $\operatorname{rank} M = \operatorname{rank} A$ [illegible] $\mathrm{ind}(M) = 1 \Longleftrightarrow \Psi$ [illegible] M [illegible]

$$M^\sharp = \begin{bmatrix} I \\ CA^{-1} \end{bmatrix} (\Psi A \Psi)^{-1} \begin{bmatrix} I & A^{-1}B \end{bmatrix}. \tag{1.4}$$

Let $A \in \mathbb{C}^{n\times n}$ with $\operatorname{ind}(A) = r$. The [illegible] A [illegible] 0, denoted by A^π, is the uniquely determined [illegible] such that $\mathcal{R}(A^\pi) = \mathcal{N}(A^r)$ and $\mathcal{N}(A^\pi) = \mathcal{R}(A^r)$.

If $\operatorname{ind}(A) = r > 0$, then there exists a nonsingular matrix P such that we can write A in the [illegible]

$$A = P \begin{pmatrix} A_1 & O \\ O & A_2 \end{pmatrix} P^{-1} \quad A_1 \in \mathbb{C}^{d\times d} \text{ nonsingular},\ d = \operatorname{rank} A^r,\ A_2^r = O. \tag{1.5}$$

By [3, Theorem 7.2.1], relative to the form (1.5), the Drazin inverse of A and the eigenprojection of A at zero are given by

$$A^{\mathrm{D}} = P \begin{pmatrix} A_1^{-1} & O \\ O & O \end{pmatrix} P^{-1}, \quad A^\pi = I - AA^{\mathrm{D}} = P \begin{pmatrix} O & O \\ O & I \end{pmatrix} P^{-1}.$$

The case when $\operatorname{ind}(A) = 1$ is equivalent to having $A_2 = O$ in (1.5), and so $A^\pi A = AA^\pi = O$. Moreover, we have $\mathcal{N}(A^\pi) = \mathcal{R}(A)$ and $\mathcal{R}(A^\pi) = \mathcal{N}(A)$.

LEMMA 1.2. [illegible] $A, C \in \mathbb{C}^{n\times n}$ [illegible] $\operatorname{ind}(A) = r$ [illegible] C [illegible]

$$I - A^\pi + CA^\pi C^{-1} A^\pi \text{ [illegible]} \iff I - A^\pi + C^{-1} A^\pi C A^\pi \text{ [illegible]}.$$

[illegible]. Write

$$C = P \begin{pmatrix} C_{11} & C_{12} \\ C_{21} & C_{22} \end{pmatrix} P^{-1} \quad \text{and} \quad C^{-1} = P \begin{pmatrix} X_{11} & X_{12} \\ X_{21} & X_{22} \end{pmatrix} P^{-1},$$

where C_{11}, X_{11}, and A_1 as in (1.5) are the same size. Then

$$I - A^\pi + CA^\pi C^{-1} A^\pi = P \begin{pmatrix} I & C_{12}X_{22} \\ O & C_{22}X_{22} \end{pmatrix} P^{-1},$$

$$I - A^\pi + C^{-1} A^\pi C A^\pi = P \begin{pmatrix} I & X_{12}C_{22} \\ O & X_{22}C_{22} \end{pmatrix} P^{-1}.$$

Hence, since $C_{22}X_{22}$ is nonsingular $\iff$ $X_{22}C_{22}$ is nonsingular, the equivalence given in this lemma follows. ∎

The following lemma is concerned with the rank of a product of matrices (see [17, sec. 2.4]).

LEMMA 1.3. [illegible] $A, B, C \in \mathbb{C}^{n\times n}$ [illegible]

$$\operatorname{rank} AB = \operatorname{rank} B - \dim(\mathcal{R}(B) \cap \mathcal{N}(A)), \tag{1.6}$$

$$\operatorname{rank} ABC \geq \operatorname{rank} AB + \operatorname{rank} BC - \operatorname{rank} B. \tag{1.7}$$

2. Characterizations of matrices satisfying condition ($\mathcal{C}_s$). First, for a matrix B with $\mathrm{ind}(B) = s$ we establish the equivalence among condition ($\mathcal{C}_s$) and conditions involving the matrix rank, and other conditions expressed in terms of the eigenprojections at zero.

THEOREM 2.1. [illegible] $A \in \mathbb{C}^{n\times n}$, $\mathrm{ind}(A) = r$ [illegible] $B \in \mathbb{C}^{n\times n}$ [illegible] $\mathrm{ind}(B) = s$ [illegible]

(a) B [illegible] ($\mathcal{C}_s$)

(b) $\mathrm{rank}\, B^s = \mathrm{rank}\, A^r = \mathrm{rank}\, A^r B^s = \mathrm{rank}\, B^s A^r$

(c) $\mathrm{rank}\, B^s = \mathrm{rank}\, A^r = \mathrm{rank}\, A^r B^s A^r$

(d) $\mathrm{rank}\, B^s = \mathrm{rank}\, A^r$, $I - A^\pi + B^\pi A^\pi$ [illegible]

(e) $I - (B^\pi - A^\pi)^2$ [illegible]

(f) $I - B^\pi - A^\pi$ [illegible]

[illegible] (a) $\Rightarrow$ (b). From the space decomposition $\mathbb{C}^n = \mathcal{R}(A^r) \oplus \mathcal{N}(A^r) = \mathcal{R}(B^s) \oplus \mathcal{N}(B^s)$ and the conditions $\mathcal{N}(B^s) \cap \mathcal{R}(A^r) = \{0\}$ and $\mathcal{R}(B^s) \cap \mathcal{N}(A^r) = \{0\}$, it is clear that $\mathrm{rank}\, B^s = \mathrm{rank}\, A^r$. Moreover, using Lemma 1.3, identity (1.6), we get

$$\mathrm{rank}\, A^r B^s = \mathrm{rank}\, B^s - \dim \mathcal{R}(B^s) \cap \mathcal{N}(A^r)$$

and

$$\mathrm{rank}\, B^s A^r = \mathrm{rank}\, A^r - \dim \mathcal{R}(A^r) \cap \mathcal{N}(B^s).$$

Hence, $\mathrm{rank}\, A^r B^s = \mathrm{rank}\, B^s$ and $\mathrm{rank}\, B^s A^r = \mathrm{rank}\, A^r$. So, (b) is proved.

(b) $\Rightarrow$ (c). Applying Lemma 1.3, formula (1.7), we get

$$\mathrm{rank}\, A^r B^s A^r \geq \mathrm{rank}\, A^r B^s + \mathrm{rank}\, B^s A^r - \mathrm{rank}\, B^s.$$

Hence $\mathrm{rank}\, A^r B^s A^r \geq \mathrm{rank}\, B^s$. We also have $\mathrm{rank}\, A^r B^s A^r \leq \mathrm{rank}\, A^r = \mathrm{rank}\, B^s$, so we conclude that $\mathrm{rank}\, A^r B^s A^r = \mathrm{rank}\, B^s$.

(c) $\Rightarrow$ (d). From condition $\mathrm{rank}\, A^r B^s A^r = \mathrm{rank}\, A^r = \mathrm{rank}\, B^s$, using Lemma 1.3, identity (1.6), we easily derive $\mathcal{R}(A^r) \cap \mathcal{N}(B^s) = \{0\}$ and $\mathcal{N}(A^r) \cap \mathcal{R}(B^s) = \{0\}$. Now, let $(I - A^\pi + B^\pi A^\pi)x = 0$. Then $(I - A^\pi)x = -B^\pi A^\pi x$. From this latter relation it follows that $(I - A^\pi)x \in \mathcal{R}(A^r) \cap \mathcal{N}(B^s)$, and thus $(I - A^\pi)x = 0$. Further, we also have $B^\pi A^\pi x = 0$. Hence $A^\pi x \in \mathcal{R}(B^s) \cap \mathcal{N}(A^r)$ and, consequently, $A^\pi x = 0$. Therefore $x = 0$, and $I - A^\pi + B^\pi A^\pi$ is nonsingular.

(d) $\Rightarrow$ (e). Since $I - (B^\pi - A^\pi)^2 = (I - A^\pi + B^\pi A^\pi)(I - B^\pi + A^\pi B^\pi)$, we have to prove that $I - B^\pi + A^\pi B^\pi$ is nonsingular. We write the core-nilpotent block forms, as in (1.5), $A = P\left(\begin{smallmatrix} A_1 & O \\ O & A_2 \end{smallmatrix}\right)P^{-1}$ and $B = Q\left(\begin{smallmatrix} B_1 & O \\ O & B_2 \end{smallmatrix}\right)Q^{-1}$ with A_1 and B_1 nonsingular matrices. We note that A_1 and B_1 have the same size because $\mathrm{rank}\, B^s = \mathrm{rank}\, A^r$. Moreover, $\left(Q^{-1}B^\pi Q = \left(\begin{smallmatrix} O & O \\ O & I \end{smallmatrix}\right)\right) = P^{-1}A^\pi P$ and, thus, $B^\pi = QP^{-1}A^\pi PQ^{-1}$. Hence $I - A^\pi + B^\pi A^\pi = I - A^\pi + QP^{-1}A^\pi PQ^{-1}A^\pi$. So $I - A^\pi + QP^{-1}A^\pi PQ^{-1}A^\pi$ is nonsingular, and by Lemma 1.2 we conclude that $PQ^{-1}(I - B^\pi + A^\pi B^\pi)QP^{-1} = I - A^\pi + PQ^{-1}A^\pi QP^{-1}A^\pi$ is also nonsingular.

(e) $\Rightarrow$ (f). Let $(I - B^\pi - A^\pi)x = 0$. Then $(I - B^\pi + A^\pi)x = 2A^\pi x$, and hence $(I + B^\pi - A^\pi)(I - B^\pi + A^\pi)x = 2B^\pi A^\pi x = 0$. So, we have $(I - (B^\pi - A^\pi)^2)x = 0$. This implies that $x = 0$, and therefore $I - B^\pi - A^\pi$ is nonsingular.

(f) $\Rightarrow$ (a). This equivalence follows from [7, Theorem 1.2], applying the equivalence of (iii) and (iv) given therein with the projectors $I - A^\pi$ and B^π. □

The next lemma gives properties that are needed in what follows.

LEMMA 2.2. [illegible] $A \in \mathbb{C}^{n\times n}$, $\mathrm{ind}(A) = r$ [illegible] $B \in \mathbb{C}^{n\times n}$ [illegible] $\mathrm{ind}(B) = s$ [illegible] ($\mathcal{C}_s$) [illegible]

(i) $l \geq s$, $I + (A^{\mathrm{D}})^l(B^l - A^l)$

(ii) $I - (I + (A^{\mathrm{D}})^s(B^s - A^s))^{-1}A^\pi - A^\pi(I + (B^s - A^s)(A^{\mathrm{D}})^s)^{-1}$

. (i) Let $l \geq s$ and $(I+(A^{\mathrm{D}})^l(B^l-A^l))x = 0$. Then, $A^\pi x = -(A^{\mathrm{D}})^l B^l x = 0$. Hence, $x \in \mathcal{N}(A^\pi) = \mathcal{R}(A^r)$ and $B^l x \in \mathcal{N}\left((A^{\mathrm{D}})^l\right) = \mathcal{N}(A^r)$. Since $\mathcal{R}(B^l) = \mathcal{R}(B^s)$, then $B^l x \in \mathcal{R}(B^s) \cap \mathcal{N}(A^r)$. So, $B^l x = 0$. Therefore, $x \in \mathcal{N}\left(B^l\right) \cap \mathcal{R}(A^r)$, and thus $x = 0$. So, $I + (A^{\mathrm{D}})^l(B^l - A^l)$ is nonsingular.

(ii) Let $x - (I + (A^{\mathrm{D}})^s(B^s - A^s))^{-1}A^\pi x - A^\pi(I + (B^s - A^s)(A^{\mathrm{D}})^s)^{-1}x = 0$. Then $(I + (A^{\mathrm{D}})^s(B^s - A^s))^{-1}(A^{\mathrm{D}})^s B^s x = A^\pi(I + (B^s - A^s)(A^{\mathrm{D}})^s)^{-1}x$. From this identity and the fact that $(I + (A^{\mathrm{D}})^s(B^s - A^s))^{-1}(A^{\mathrm{D}})^s = (A^{\mathrm{D}})^s(I + (B^s - A^s)(A^{\mathrm{D}})^s)^{-1}$, we conclude that $(I+(A^{\mathrm{D}})^s(B^s-A^s))^{-1}(A^{\mathrm{D}})^s B^s x = 0$ and $A^\pi(I+(B^s-A^s)(A^{\mathrm{D}})^s)^{-1}x = 0$. Therefore, $(A^{\mathrm{D}})^s B^s x = 0$ and so $B^s x \in \mathcal{R}(B^s) \cap \mathcal{N}(A^r)$. Thus, $B^s x = 0$. Moreover, since $(I + (B^s - A^s)(A^{\mathrm{D}})^s)^{-1}x \in \mathcal{R}(A^r)$, $(I + (B^s - A^s)(A^{\mathrm{D}})^s)^{-1}x = A^r y$ for some y. This implies that $x = B^s(A^{\mathrm{D}})^s A^r y$, and so $x \in \mathcal{R}(B^s) \cap \mathcal{N}(B^s)$. Hence, $x = 0$ because $\mathrm{ind}(B) = s$. So, (ii) is proved. ∎

In the following theorem, we will derive a formula for the eigenprojection of B at zero, B^π.

THEOREM 2.3. $A \in \mathbb{C}^{n\times n}$, $\mathrm{ind}(A) = r$, $B \in \mathbb{C}^{n\times n}$ ... $\mathrm{ind}(B) = s$ ... $(\mathcal{C}_s)$ ...

$$B^\pi = -(I + (A^{\mathrm{D}})^s(B^s - A^s))^{-1}A^\pi X^{-1} = -X^{-1}A^\pi(I + (B^s - A^s)(A^{\mathrm{D}})^s)^{-1},$$

...

$$X = I - (I + (A^{\mathrm{D}})^s(B^s - A^s))^{-1}A^\pi - A^\pi(I + (B^s - A^s)(A^{\mathrm{D}})^s)^{-1}.$$

. From Lemma 2.2 we know that $I+(A^{\mathrm{D}})^s(B^s-A^s)$ and X are nonsingular. Using that $A^\pi(I+(A^{\mathrm{D}})^s(B^s-A^s))^{-1} = A^\pi = (I+(B^s-A^s)(A^{\mathrm{D}})^s)^{-1}A^\pi$, it is easily checked that

$$\begin{aligned} &X(I + (A^{\mathrm{D}})^s(B^s - A^s))^{-1}A^\pi \\ &\quad = -A^\pi(I + (B^s - A^s)(A^{\mathrm{D}})^s)^{-1}(I + (A^{\mathrm{D}})^s(B^s - A^s))^{-1}A^\pi \\ &\quad = A^\pi(I + (B^s - A^s)(A^{\mathrm{D}})^s)^{-1}X. \end{aligned} \tag{2.1}$$

Hence

$$(I + (A^{\mathrm{D}})^s(B^s - A^s))^{-1}A^\pi X^{-1} = X^{-1}A^\pi(I + (B^s - A^s)(A^{\mathrm{D}})^s)^{-1}. \tag{2.2}$$

Let $Q = -(I + (A^{\mathrm{D}})^s(B^s - A^s))^{-1}A^\pi X^{-1}$. We observe that

$$\mathcal{R}(Q) = \mathcal{R}((I + (A^{\mathrm{D}})^s(B^s - A^s))^{-1}A^\pi)$$

because X is nonsingular. Let us show that Q is the projector with $\mathcal{N}(Q) = \mathcal{R}(B^s)$ and $\mathcal{R}(Q) = \mathcal{N}(B^s)$. First, using (2.2) and (2.1) we see that

$$Q^2 = X^{-1}A^\pi(I + (B^s - A^s)(A^{\mathrm{D}})^s)^{-1}(I + (A^{\mathrm{D}})^s(B^s - A^s))^{-1}A^\pi X^{-1} = Q.$$

Now, let us assume that $x \in \mathcal{N}(B^s)$. Then $A^\pi x + (A^{\mathrm{D}})^s B^s x = A^\pi x$. From this relation it follows that $x = (A^\pi + (A^{\mathrm{D}})^s B^s)^{-1}A^\pi x$ and, thus, $x \in \mathcal{R}(Q)$. Conversely, assuming $x \in \mathcal{R}(Q)$ we get $(A^\pi + (A^{\mathrm{D}})^s B^s)x = A^\pi y$ for some $y \in \mathbb{C}^n$. Hence $(A^{\mathrm{D}})^s B^s x = A^\pi(y - x)$. Then $(A^{\mathrm{D}})^s B^s x = 0$. Therefore, $B^s x \in \mathcal{R}(B^s) \cap \mathcal{N}(A^r)$. So $B^s x = 0$. Consequently, $\mathcal{R}(Q) = \mathcal{N}(B^s)$.

By (2.2) we have that $\mathcal{N}(Q) = \mathcal{N}\left(X^{-1}A^{\pi}(I + (B^s - A^s)(A^{\mathrm{D}})^s)^{-1}\right)$. Hence it follows that $\mathcal{N}(Q) = \mathcal{N}\left(A^{\pi}(I + (B^s - A^s)(A^{\mathrm{D}})^s)^{-1}\right)$ because X is nonsingular. Let us assume that $x \in \mathcal{N}(Q)$. Then

$$A^{\pi}(A^{\pi} + B^s(A^{\mathrm{D}})^s)^{-1}x = (I - B^s(A^{\mathrm{D}})^s(A^{\pi} + B^s(A^{\mathrm{D}})^s)^{-1})x = 0.$$

Hence, $x = B^s A^{\mathrm{D}}(A^{\pi} + B^s(A^{\mathrm{D}})^s)^{-1}x$, and thus $x \in \mathcal{R}(B^s)$. Since $\mathcal{N}(Q) \subseteq \mathcal{R}(B^s)$, and $\mathbb{C}^n = \mathcal{R}(Q) \oplus \mathcal{N}(Q) = \mathcal{R}(B^s) \oplus \mathcal{N}(B^s)$ because $\mathrm{ind}(B) = s$, we conclude that $\mathcal{N}(Q) = \mathcal{R}(B^s)$. So we have $B^{\pi} = Q$, which is the desired result. □

3. The class $(\mathcal{C}_1)$. We shall first give further characterizations of matrices B satisfying condition $(\mathcal{C}_1)$ and $\mathrm{ind}(B) = 1$. We obtain a representation of B with respect to the core-nilpotent block form of the matrix A.

THEOREM 3.1. [illegible] $A \in \mathbb{C}^{n\times n}$, $\mathrm{ind}(A) = r$ [illegible] $B \in \mathbb{C}^{n\times n}$ [illegible]

(a) B [illegible] $(\mathcal{C}_1)$ [illegible] $\mathrm{ind}(B) = 1$

(b) $B(I + A^{\mathrm{D}}(B - A))^{-1}A^{\pi} = O$, $I + A^{\mathrm{D}}(B - A)$ [illegible] $I + (A^{\mathrm{D}})^2(B^2 - A^2)$ [illegible]

(c) [illegible] A [illegible] (1.5), B [illegible]

$$B = P\begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{21}B_{11}^{-1}B_{12} \end{pmatrix}P^{-1}, \tag{3.1}$$

[illegible] B_{11} [illegible] $I + B_{11}^{-1}B_{12}B_{21}B_{11}^{-1}$ [illegible]

(d) $\mathrm{rank}\, B = \mathrm{rank}\, A^r$, $I + A^{\mathrm{D}}(B - A)$ [illegible] $I + (A^{\mathrm{D}})^2(B^2 - A^2)$ [illegible]

[illegible]. (a) ⇒ (b). Since $\mathrm{ind}(B) = 1$, from Lemma 2.2(i) we get that $I + A^{\mathrm{D}}(B - A)$ and $I + (A^{\mathrm{D}})^2(B^2 - A^2)$ are nonsingular. Finally, using that $BB^{\pi} = O$ and applying Theorem 2.3, we conclude that $B(I + A^{\mathrm{D}}(B - A))^{-1}A^{\pi} = O$.

(b) ⇒ (c). Write

$$B = P\begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{pmatrix}P^{-1}.$$

We compute

$$I + A^{\mathrm{D}}(B - A) = P\begin{pmatrix} A_1^{-1}B_{11} & A_1^{-1}B_{12} \\ O & I \end{pmatrix}P^{-1}.$$

Hence B_{11} is nonsingular because $I + A^{\mathrm{D}}(B - A)$ is nonsingular. We have

$$I + (A^{\mathrm{D}})^2(B^2 - A^2) = P\begin{pmatrix} A_1^{-2}(B_{11}^2 + B_{12}B_{21}) & A_1^{-2}(B_{11}B_{12} + B_{12}B_{22}) \\ O & I \end{pmatrix}P^{-1}.$$

Thus, $B_{11}^2 + B_{12}B_{21}$ is nonsingular because $I + (A^{\mathrm{D}})^2(B^2 - A^2)$ is nonsingular. On the other hand,

$$\begin{aligned} B(I + A^{\mathrm{D}}(B - A))^{-1}A^{\pi} &= P\begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{pmatrix}\begin{pmatrix} B_{11}^{-1}A_1 & -B_{11}^{-1}B_{12} \\ O & I \end{pmatrix}\begin{pmatrix} O & O \\ O & I \end{pmatrix}P^{-1} \\ &= P\begin{pmatrix} O & O \\ O & -B_{21}B_{11}^{-1}B_{12} + B_{22} \end{pmatrix}P^{-1}. \end{aligned}$$

From the assumption $B(I + A^{\mathrm{D}}(B - A))^{-1}A^{\pi} = O$ it follows that $B_{22} = B_{21}B_{11}^{-1}B_{12}$.

(c) $\Leftrightarrow$ (d). From the representation (3.1), applying Lemma 1.1, it follows that $\operatorname{rank} B = \operatorname{rank} B_{11} = \operatorname{rank} A^r$. The rest is easily seen.

Conversely, write

$$B = P \begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{pmatrix} P^{-1}.$$

Since $I + A^{\mathrm{D}}(B - A)$ and $I + (A^{\mathrm{D}})^2(B^2 - A^2)$ are nonsingular, arguing as in the proof of (b) $\Rightarrow$ (c), we get that B_{11} and $I + B_{11}^{-1}B_{12}B_{21}B_{11}^{-1}$ are nonsingular. Finally, from $\operatorname{rank} B = \operatorname{rank} A^r$ we obtain that $\operatorname{rank} B = \operatorname{rank} B_{11}$, and hence by Lemma 1.1(i) we conclude that $B_{22} = B_{21}B_{11}^{-1}B_{12}$.

(c) $\Rightarrow$ (a). Assume that B has the block representation (3.1). By Lemma 1.1(i), (ii), we conclude that $\operatorname{rank} B = \operatorname{rank} B_{11} = \operatorname{rank} A^r$ and $\operatorname{ind}(B) = 1$. On the other hand,

$$\operatorname{rank} A^r B A^r = \operatorname{rank} P \begin{pmatrix} A_1^r B_{11} A_1^r & O \\ O & O \end{pmatrix} P^{-1} = \operatorname{rank} A_1^r B_{11} A_1^r = \operatorname{rank} A^r.$$

Hence, in view of Theorem 2.1 (a)$\Leftrightarrow$(c), we conclude that B satisfy condition $(\mathcal{C}_1)$. ∎

3.2. Conditions (b) and (d) in the above theorem can be replaced by the following symmetrical conditions:

(b′) $A^{\pi}(I + (B - A)A^{\mathrm{D}})^{-1}B = O$, $I + (B - A)A^{\mathrm{D}}$ and $I + (B^2 - A^2)(A^{\mathrm{D}})^2$ are nonsingular.

(d′) $\operatorname{rank} B = \operatorname{rank} A^r$, $I + (B - A)A^{\mathrm{D}}$ and $I + (B^2 - A^2)(A^{\mathrm{D}})^2$ are nonsingular.

Next, we state the following compact representation for B and $B^{\sharp}$.

LEMMA 3.3. [illegible] $A \in \mathbb{C}^{n\times n}$, $\operatorname{ind}(A) = r$ [illegible] $B \in \mathbb{C}^{n\times n}$, $\operatorname{ind}(B) = 1$ [illegible] $(\mathcal{C}_1)$ [illegible]

$$B = P \begin{bmatrix} I \\ S \end{bmatrix} B_1 \begin{bmatrix} I & T \end{bmatrix} P^{-1}, \tag{3.2}$$

[illegible] B_1 [illegible] $I+TS$ [illegible] B [illegible]

$$B^{\sharp} = P \begin{bmatrix} I \\ S \end{bmatrix} [(I + TS)B_1(I + TS)]^{-1} \begin{bmatrix} I & T \end{bmatrix} P^{-1}. \tag{3.3}$$

[illegible]. By Theorem 3.1 (c),

$$B = P \begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{21}B_{11}^{-1}B_{12} \end{pmatrix} P^{-1},$$

where B_{11} and $I + B_{11}^{-1}B_{12}B_{21}B_{11}^{-1}$ are nonsingular. By denoting $B_1 = B_{11}$, $T = B_{11}^{-1}B_{12}$, and $S = B_{21}B_{11}^{-1}$ we get the representation (3.2). Now, applying formula (1.4) given in Lemma 1.1, we obtain the representation for $B^{\sharp}$. ∎

4. The class $(\mathcal{C}_s)$. Next, based on Theorem 3.1, we establish the following new characterizations of B satisfying condition $(\mathcal{C}_s)$.

THEOREM 4.1. [illegible] $A \in \mathbb{C}^{n\times n}$, $\operatorname{ind}(A) = r$ [illegible] $B \in \mathbb{C}^{n\times n}$ [illegible]

(a) B [illegible] $(\mathcal{C}_s)$ [illegible] $\operatorname{ind}(B) = s$

(b) [illegible] s [illegible] $B^s(I+(A^{\mathrm{D}})^s(B^s-A^s))^{-1}A^{\pi}=O$, $I+(A^{\mathrm{D}})^s(B^s-A^s)$ [illegible] $I+(A^{\mathrm{D}})^{s+1}(B^{s+1}-A^{s+1})$ [illegible]

(c) [illegible] 1 [illegible] B [illegible] A, (1.5),

$$B = C_B + N_B = P\begin{bmatrix} I \\ S \end{bmatrix} B_1 \begin{bmatrix} I & T \end{bmatrix} P^{-1} + P\begin{bmatrix} T \\ -I \end{bmatrix} B_2 \begin{bmatrix} S & -I \end{bmatrix} P^{-1}, \tag{4.1}$$

[illegible] B_1 [illegible] $I+TS$ [illegible] $B_2(I+ST)$ [illegible] s

(d) [illegible] s [illegible] $\operatorname{rank} B^s = \operatorname{rank} A^r$, $I+(A^{\mathrm{D}})^s(B^s-A^s)$ [illegible] $I+(A^{\mathrm{D}})^{s+1}(B^{s+1}-A^{s+1})$ [illegible]

. If $\operatorname{ind}(B)=s$ and B satisfies condition $(\mathcal{C}_s)$, then s is the smallest positive integer such that B^s satisfies condition $(\mathcal{C}_1)$ and $\operatorname{ind}(B^s)=1$. Moreover, we observe that for any $k\geq s$, $I+(A^{\mathrm{D}})^k(B^k-A^k)$ is nonsingular if and only if $I+A^{\mathrm{D}}(B^k-A)$ is nonsingular. So, applying Theorem 3.1 with B^s, it follows the equivalence between condition (a) and the following:

(b′) For the smallest positive integer s such that $B^s(I+(A^{\mathrm{D}})^s(B^s-A^s))^{-1}A^{\pi}=O$, $I+(A^{\mathrm{D}})^s(B^s-A^s)$ and $I+(A^{\mathrm{D}})^{2s}(B^{2s}-A^{2s})$ are nonsingular.

We now note that conditions (b′) and (b) are equivalent.

A similar device proves the equivalence between conditions (a) and (d) in this theorem. Applying Theorem 3.1 with B^s we get the equivalence of (a) and the following:

(d′) For the smallest positive integer s such that $\operatorname{rank} B^s = \operatorname{rank} A^r$, we have that $I+(A^{\mathrm{D}})^s(B^s-A^s)$ and $I+(A^{\mathrm{D}})^{2s}(B^{2s}-A^{2s})$ are nonsingular.

Finally, we note that conditions (d′) and (d) are equivalent.

Now, we will prove the equivalence between (a) and (c). Suppose $B=C_B+N_B$ is the index 1-nilpotent decomposition (1.2) of B. We know that if s is the index of B, then $\mathcal{N}(C_B)=\mathcal{N}(B^s)$ and $\mathcal{R}(C_B)=\mathcal{R}(B^s)$. Hence if B satisfies condition $(\mathcal{C}_s)$, then C_B satisfies condition $(\mathcal{C}_1)$ and $\operatorname{ind}(C_B)=1$. By Lemma 3.3 it follows that

$$C_B = P\begin{bmatrix} I \\ S \end{bmatrix} B_1 \begin{bmatrix} I & T \end{bmatrix} P^{-1}, \tag{4.2}$$

where B_1 and $I+TS$ are nonsingular. We observe that $I+ST$ is also nonsingular. Now, write

$$N_B = P\begin{pmatrix} N_{11} & N_{12} \\ N_{21} & N_{22} \end{pmatrix} P^{-1}.$$

Since $C_BN_B=N_BC_B=O$, by direct computations it follows that $N_{11}=TN_{22}S$, $N_{12}=-TN_{22}$, and $N_{21}=-N_{22}S$. So,

$$N_B = P\begin{bmatrix} T \\ -I \end{bmatrix} B_2 \begin{bmatrix} S & -I \end{bmatrix} P^{-1}, \tag{4.3}$$

where we have renamed $B_2=N_{22}$. Thus, for every positive integer k,

$$N_B^k = P\begin{bmatrix} T \\ -I \end{bmatrix} (B_2(I+ST))^{k-1} B_2 \begin{bmatrix} S & -I \end{bmatrix} P^{-1}. \tag{4.4}$$

Condition $N_B^s=O$ implies that $(B_2(I+ST))^s=O$. Therefore, $B_2(I+ST)$ is nilpotent of index s. Hence, from (4.2) and (4.3) we get the representation (4.1).

Conversely, assume that we have the splitting $B = C_B + N_B$, where C_B and N_B have the representation given by (4.1). Clearly $C_B N_B = N_B C_B = O$. Moreover, by Theorem 3.1, equivalence between (a) and (c), it follows that C_B satisfies condition $(\mathcal{C}_1)$ and $\mathrm{ind}(C_B) = 1$. Using (4.4), we see that $N_B^s = O$. So $B = C_B + N_B$ is the core-nilpotent decomposition of B and $\mathrm{ind}(B) = s$. Since $\mathcal{R}(B^s) = \mathcal{R}(C_B)$ and $\mathcal{N}(B^s) = \mathcal{N}(C_B)$, we conclude that $\mathcal{R}(B^s) \cap \mathcal{N}(A^r) = \{0\}$ and $\mathcal{N}(B^s) \cap \mathcal{R}(A^r) = \{0\}$. Thus $B \in (\mathcal{C}_s)$ and $\mathrm{ind}(B) = s$. ∎

Remark 4.2. Conditions (b) and (d) in Theorem 4.1 can be replaced by the corresponding symmetrical conditions, as expressed in Remark 3.2.

Corollary 4.3. Let $A \in \mathbb{C}^{n\times n}$, $\mathrm{ind}(A) = r$, and let $B \in \mathbb{C}^{n\times n}$ be such that $\mathrm{ind}(B) = s$. Then the following are equivalent:

(a) $B \in (\mathcal{C}_s)$.
(b) $I + (A^{\mathrm{D}})^s(B^s - A^s)$ is nonsingular and $B^s(I + (A^{\mathrm{D}})^s(B^s - A^s))^{-1}A^\pi = O$.
(c) $\mathrm{rank}\, B^s = \mathrm{rank}\, A^r$ and $I + (A^{\mathrm{D}})^s(B^s - A^s)$ is nonsingular.

Proof. (a)⇔(b). This equivalence follows from the equivalence (a)⇔(b) established in Theorem 4.1 if we show that, under assumption $\mathrm{ind}(B) = s$, the condition (b) in this theorem implies that $I + (A^{\mathrm{D}})^{s+1}(B^{s+1} - A^{s+1})$ is nonsingular. First, we observe that $\mathcal{N}(B^s) = \mathcal{N}\left(B^{s+1}\right)$ because $\mathrm{ind}(B) = s$. Now, since $A^\pi + (A^{\mathrm{D}})^s B^s$ is nonsingular, then $\mathcal{N}(A^\pi) \cap \mathcal{N}(B^s) = \{0\}$. From $B^s(I + (A^{\mathrm{D}})^s(B^s - A^s))^{-1}A^\pi = O$ it follows that $B^s = B^s(I + (A^{\mathrm{D}})^s(B^s - A^s))^{-1}(A^{\mathrm{D}})^s B^s$. So, we see that $\mathcal{N}\left((A^{\mathrm{D}})^{s+1}B^{s+1}\right) = \mathcal{N}\left((A^{\mathrm{D}})^s B^{s+1}\right) \subseteq \mathcal{N}\left(B^{s+1}\right)$. Thus $A^\pi + (A^{\mathrm{D}})^{s+1}B^{s+1}$ is nonsingular because $\mathcal{N}(A^\pi) \cap \mathcal{N}\left(B^{s+1}\right) = \{0\}$.

(a)⇔(c). This equivalence follows from the equivalence (a)⇔(d) established in Theorem 4.1. The details are omitted. ∎

Next, we give a representation for the powers of B.

Lemma 4.4. Let $A \in \mathbb{C}^{n\times n}$, $\mathrm{ind}(A) = r$, let $B \in \mathbb{C}^{n\times n}$, $\mathrm{ind}(B) = s$, and assume that $B \in (\mathcal{C}_s)$. Then, for $k \geq 1$,

$$B^k = P\left\{\begin{bmatrix} I \\ S \end{bmatrix} (B_1(I+TS))^{k-1}B_1 \begin{bmatrix} I & T \end{bmatrix} + \begin{bmatrix} T \\ -I \end{bmatrix} (B_2(I+ST))^{k-1}B_2 \begin{bmatrix} S & -I \end{bmatrix}\right\} P^{-1},$$

where $B_1 = I + TS$ is nonsingular and $B_2(I+ST)$ is nilpotent of index s.

Proof. The formula for the powers B^k can be derived from the representation (4.1), using the formula (1.3) of Lemma 1.1 and the formula (4.4). ∎

5. Perturbation results. In this section we give an explicit representation of B^{D} and we derive perturbation bounds of the Drazin inverse and the eigenprojection at zero.

Theorem 5.1. Let $A \in \mathbb{C}^{n\times n}$, $\mathrm{ind}(A) = r > 0$, let $B \in \mathbb{C}^{n\times n}$, $\mathrm{ind}(B) = s$, and assume that $B \in (\mathcal{C}_s)$. Let $E_1 = E = B - A$ and $E_s = B^s - A^s$. If $I + A^{\mathrm{D}}E$ is nonsingular, then

(5.1)
$$B^{\mathrm{D}} = \Phi_1^{-1}\Big(A^{\mathrm{D}} + A^{\mathrm{D}}\Psi_{ss}^{-1}\Phi_s^{-1}(A^{\mathrm{D}})^s E_s A^\pi (I - A^\pi E_s (A^{\mathrm{D}})^s \widetilde{\Phi}_s^{-1}) + A^\pi E_s (A^{\mathrm{D}})^s \widetilde{\Phi}_s^{-1}\Psi_{1s}^{-1}$$
$$\times \left(A^{\mathrm{D}} - \Phi_1^{-1}A^{\mathrm{D}}EA^{\mathrm{D}} - \Phi_1^{-1}A^{\mathrm{D}}(\Psi_{ss} - I)\Psi_{ss}^{-1}\right)(I + \Phi_s^{-1}(A^{\mathrm{D}})^s E_s A^\pi)\Big),$$

... $\Phi_i = I + (A^{\mathrm{D}})^i E_i$, $\widetilde{\Phi}_i = I + E_i (A^{\mathrm{D}})^i$, ... $\Psi_{is} = I + \Phi_i^{-1} (A^{\mathrm{D}})^i E_i A^{\pi} E_s (A^{\mathrm{D}})^s \widetilde{\Phi}_s^{-1}$ ... $i = 1$ ... $i = s$ ... $\max\{\|A^{\mathrm{D}}E\|, \|(A^{\mathrm{D}})^s E_s\|, \|E_s (A^{\mathrm{D}})^s\|\} < 1$ ...

(5.2)

$$\begin{aligned}
&\frac{\|B^{\mathrm{D}} - A^{\mathrm{D}}\|}{\|A^{\mathrm{D}}\|} \\
&\quad \le \frac{\|A^{\mathrm{D}}E\|}{1 - \|A^{\mathrm{D}}E\|} + \frac{\|(A^{\mathrm{D}})^s E_s A^{\pi}\| \|\Psi_{ss}^{-1}\|}{(1 - \|A^{\mathrm{D}}E\|)(1 - \|(A^{\mathrm{D}})^s E_s\|)} \left(1 + \frac{\|A^{\pi} E_s (A^{\mathrm{D}})^s\|}{1 - \|E_s (A^{\mathrm{D}})^s\|}\right) \\
&\qquad + \frac{\|A^{\pi} E_s (A^{\mathrm{D}})^s\| \|\Psi_{1s}^{-1}\|}{(1 - \|A^{\mathrm{D}}E\|)(1 - \|E_s (A^{\mathrm{D}})^s\|)} \left(1 + \frac{\|(A^{\mathrm{D}})^s E_s A^{\pi}\|}{1 - \|(A^{\mathrm{D}})^s E_s\|}\right) \\
&\qquad \times \left(1 + \frac{\|A^{\mathrm{D}}E\|}{1 - \|A^{\mathrm{D}}E\|} + \frac{\|(A^{\mathrm{D}})^s E_s A^{\pi}\| \|A^{\pi} E_s (A^{\mathrm{D}})^s\| \|\Psi_{ss}^{-1}\|}{(1 - \|A^{\mathrm{D}}E\|)(1 - \|E_s (A^{\mathrm{D}})^s\|)(1 - \|(A^{\mathrm{D}})^s E_s\|)}\right).
\end{aligned}$$

...

$$\max\{\|A^{\mathrm{D}}E\|, \|(A^{\mathrm{D}})^s E_s\|, \|E_s (A^{\mathrm{D}})^s\|\} < \frac{1}{1 + \sqrt{\|A^{\pi}\|}},$$

... $i = 1$ ... $i = s$

$$\|\Psi_{is}^{-1}\| \le \frac{(1 - \|(A^{\mathrm{D}})^i E_i\|)(1 - \|E_s (A^{\mathrm{D}})^s\|)}{(1 - \|(A^{\mathrm{D}})^i E_i\|)(1 - \|E_s (A^{\mathrm{D}})^s\|) - \|(A^{\mathrm{D}})^i E_i\| \|A^{\pi} E_s (A^{\mathrm{D}})^s\|}. \tag{5.3}$$

... From Theorem 4.1(c), we have that the index 1-nilpotent decomposition of B is given by $B = C_B + N_B$, with $C_B = P \begin{bmatrix} I \\ S \end{bmatrix} B_1 \begin{bmatrix} I & T \end{bmatrix} P^{-1}$ and $N_B = P \begin{bmatrix} T \\ -I \end{bmatrix} B_2 \begin{bmatrix} S & -I \end{bmatrix} P^{-1}$, where B_1 and $I + TS$ are nonsingular and $B_2(I + ST)$ is nilpotent of index s. Hence, applying Lemma 3.3, formulae (3.3), we obtain

$$B^{\mathrm{D}} = C_B^{\sharp} = P \begin{bmatrix} I \\ S \end{bmatrix} [(I + TS) B_1 (I + TS)]^{-1} \begin{bmatrix} I & T \end{bmatrix} P^{-1}. \tag{5.4}$$

Furthermore, we can write $E = B - A$ as

$$E = P \begin{pmatrix} B_1 + TB_2S - A_1 & B_1T - TB_2 \\ SB_1 - B_2S & SB_1T + B_2 - A_2 \end{pmatrix} P^{-1}. \tag{5.5}$$

In view of this latter representation we get

$$I + A^{\mathrm{D}}E = P \begin{pmatrix} A_1^{-1}(B_1 + TB_2S) & A_1^{-1}(B_1T - TB_2) \\ O & I \end{pmatrix} P^{-1}. \tag{5.6}$$

From the assumption that $I + A^{\mathrm{D}}E$ is nonsingular, it follows that $B_1 + TB_2S$ is nonsingular. Using (5.6) and (5.4) we obtain

(5.7)

$$(I + A^{\mathrm{D}}E) B^{\mathrm{D}} = P \begin{pmatrix} A_1^{-1}(I + TS)^{-1} & A_1^{-1}(I + TS)^{-1}T \\ S((I + TS)B_1(I + TS))^{-1} & S((I + TS)B_1(I + TS))^{-1}T \end{pmatrix} P^{-1}.$$

By denoting $\Phi_1 = I + A^{\mathrm{D}}E$, in view of (5.6) we obtain

$$\Phi_1^{-1} = P\begin{pmatrix} (B_1+TB_2S)^{-1}A_1 & -(B_1+TB_2S)^{-1}(B_1T-TB_2) \\ O & I \end{pmatrix} P^{-1}. \tag{5.8}$$

Utilizing the representations of the powers of B given in Lemma 4.4, we write $E_s = B^s - A^s$ as

$$E_s = P\begin{pmatrix} (B_1(I+TS))^{s-1}B_1 - A_1^s & (B_1(I+TS))^{s-1}B_1T \\ S(B_1(I+TS))^{s-1}B_1 & S(B_1(I+TS))^{s-1}B_1T - A_2^s \end{pmatrix} P^{-1}\ .$$

By denoting $\Phi_s = I + (A^{\mathrm{D}})^s E_s$ and $\widetilde{\Phi}_s = I + E_s(A^{\mathrm{D}})^s$ we get

$$\begin{aligned} \Phi_s^{-1} &= P\begin{pmatrix} B_1^{-1}\big((B_1(I+TS))^{(s-1)}\big)^{-1}A_1^s & -T \\ O & I \end{pmatrix} P^{-1}, \\ \widetilde{\Phi}_s^{-1} &= P\begin{pmatrix} A_1^sB_1^{-1}\big((B_1(I+TS))^{(s-1)}\big)^{-1} & O \\ -S & I \end{pmatrix} P^{-1}, \end{aligned} \tag{5.9}$$

and, hence,

$$\Phi_s^{-1}(A^{\mathrm{D}})^s = (A^{\mathrm{D}})^s\widetilde{\Phi}_s^{-1} = P\begin{pmatrix} B_1^{-1}\big((B_1(I+TS))^{(s-1)}\big)^{-1} & O \\ O & O \end{pmatrix} P^{-1}.$$

Furthermore,

$$\Phi_s^{-1}(A^{\mathrm{D}})^s E_s A^{\pi} = P\begin{pmatrix} O & T \\ O & O \end{pmatrix} P^{-1},\ \ A^{\pi}E_s(A^{\mathrm{D}})^s\widetilde{\Phi}_s^{-1} = P\begin{pmatrix} O & O \\ S & O \end{pmatrix} P^{-1}. \tag{5.10}$$

Let $\Psi_{is} = I + \Phi_i^{-1}(A^{\mathrm{D}})^i E_i A^{\pi} E_s (A^{\mathrm{D}})^s \widetilde{\Phi}_s^{-1}$ for $i = 1$ and $i = s$. Using (5.10) we see that

$$\Psi_{ss}^{-1} = P\begin{pmatrix} (I+TS)^{-1} & O \\ O & I \end{pmatrix} P^{-1}, \tag{5.11}$$

and, using (5.5), (5.6), and (5.10) we obtain

$$\begin{aligned} \Psi_{1s} &= P\left[\begin{pmatrix} I & O \\ O & I \end{pmatrix}\right. \\ &\qquad \left. + \begin{pmatrix} I-(B_1+TB_2S)^{-1}A_1 & (B_1+TB_2S)^{-1}(B_1T-TB_2) \\ O & O \end{pmatrix}\begin{pmatrix} O & O \\ S & O \end{pmatrix}\right] P^{-1} \\ &= P\begin{pmatrix} (B_1+TB_2S)^{-1}B_1(I+TS) & O \\ O & I \end{pmatrix} P^{-1}, \end{aligned}$$

and, thus,

$$\Psi_{1s}^{-1} = P\begin{pmatrix} (I+TS)^{-1}B_1^{-1}(B_1+TB_2S) & O \\ O & I \end{pmatrix} P^{-1}. \tag{5.12}$$

Now, let us introduce

$$\begin{aligned}\Sigma_1 &= A^{\mathrm{D}} + A^{\mathrm{D}}\Psi_{ss}^{-1}\Phi_s^{-1}(A^{\mathrm{D}})^s E_s A^{\pi}(I - A^{\pi}E_s(A^{\mathrm{D}})^s\widetilde{\Phi}_s^{-1}),\\ \Omega &= A^{\mathrm{D}} - \Phi_1^{-1}A^{\mathrm{D}}EA^{\mathrm{D}} - \Phi_1^{-1}A^{\mathrm{D}}(\Psi_{ss} - I)\Psi_{ss}^{-1},\\ \Sigma_2 &= A^{\pi}E_s(A^{\mathrm{D}})^s\widetilde{\Phi}_s^{-1}\Psi_{1s}^{-1}\Omega(I + \Phi_s^{-1}(A^{\mathrm{D}})^s E_s A^{\pi}).\end{aligned} \tag{5.13}$$

In order to verify identity (5.1) we will see that the matrix representation of $\Sigma_1 + \Sigma_2$ is equal to the right-hand side of (5.7). We compute

$$\begin{aligned}\Sigma_1 &= P\left[\begin{pmatrix} A_1^{-1} & O\\ O & O\end{pmatrix} + \begin{pmatrix} O & A_1^{-1}(I+TS)^{-1}T\\ O & O\end{pmatrix}\begin{pmatrix} I & O\\ -S & I\end{pmatrix}\right]P^{-1}\\ &= P\begin{pmatrix} A_1^{-1}(I+TS)^{-1} & A_1^{-1}(I+TS)^{-1}T\\ O & O\end{pmatrix}P^{-1}.\end{aligned}$$

On the other hand, utilizing (5.5), (5.8), and (5.11) we see that

$$\Omega = P\begin{pmatrix}(B_1 + TB_2S)^{-1}(I+TS)^{-1} & O\\ O & O\end{pmatrix}P^{-1},$$

and, hence, using (5.12), we get

$$\Psi_{1s}^{-1}\Omega = P\begin{pmatrix}(I+TS)^{-1}B_1^{-1}(I+TS)^{-1} & O\\ O & O\end{pmatrix}P^{-1}.$$

Therefore,

$$\begin{aligned}\Sigma_2 =& P\begin{pmatrix} O & O\\ S & O\end{pmatrix}\begin{pmatrix}(I+TS)^{-1}B_1^{-1}(I+TS)^{-1} & O\\ O & I\end{pmatrix}\begin{pmatrix} I & T\\ O & I\end{pmatrix}P^{-1}\\ =& P\begin{pmatrix} O & O\\ S(I+TS)^{-1}B_1^{-1}(I+TS)^{-1} & S(I+TS)^{-1}B_1^{-1}(I+TS)^{-1}T\end{pmatrix}P^{-1}.\end{aligned}$$

In view of these expressions of Σ_1 and Σ_2 we conclude the proof of the first part. From the identity $B^{\mathrm{D}} - A^{\mathrm{D}} + A^{\mathrm{D}}E(B^{\mathrm{D}} - A^{\mathrm{D}} + A^{\mathrm{D}}) = \Sigma_1 - A^{\mathrm{D}} + \Sigma_2$, taking norms we obtain

$$\|B^{\mathrm{D}} - A^{\mathrm{D}}\| \le \|A^{\mathrm{D}}E\|\|B^{\mathrm{D}} - A^{\mathrm{D}}\| + \|A^{\mathrm{D}}E\|\|A^{\mathrm{D}}\| + \|\Sigma_1 - A^{\mathrm{D}}\| + \|\Sigma_2\|.$$

Since $\max\{\|A^{\mathrm{D}}E\|, \|(A^{\mathrm{D}})^sE_s\|, \|E_s(A^{\mathrm{D}})^s\|\} < 1$, we have

$$\|B^{\mathrm{D}} - A^{\mathrm{D}}\| \le \frac{\|A^{\mathrm{D}}\|\|A^{\mathrm{D}}E\| + \|\Sigma_1 - A^{\mathrm{D}}\| + \|\Sigma_2\|}{1 - \|A^{\mathrm{D}}E\|} \tag{5.14}$$

and

$$\|\Phi_s^{-1}\| \le \frac{1}{1 - \|(A^{\mathrm{D}})^sE_s\|} \quad \text{and} \quad \|\widetilde{\Phi}_s^{-1}\| \le \frac{1}{1 - \|E_s(A^{\mathrm{D}})^s\|}. \tag{5.15}$$

Taking norms in (5.13), and using these upper bounds, we get

$$\|\Sigma_1 - A^{\mathrm{D}}\| \le \frac{\|A^{\mathrm{D}}\|\|(A^{\mathrm{D}})^sE_sA^{\pi}\|\|\Psi_{ss}^{-1}\|}{1 - \|(A^{\mathrm{D}})^sE_s\|}\left(1 + \frac{\|A^{\pi}E_s(A^{\mathrm{D}})^s\|}{1 - \|E_s(A^{\mathrm{D}})^s\|}\right)$$

and

$$\|\Sigma_2\| \leq \frac{\|A^{\mathrm{D}}\|\|A^{\pi}E_s(A^{\mathrm{D}})^s\|\|\Psi_{1s}^{-1}\|}{1-\|E_s(A^{\mathrm{D}})^s\|}\left(1+\frac{\|(A^{\mathrm{D}})^sE_sA^{\pi}\|}{1-\|(A^{\mathrm{D}})^sE_s\|}\right)$$
$$\times\left(1+\frac{\|A^{\mathrm{D}}E\|}{1-\|A^{\mathrm{D}}E\|}+\frac{\|(A^{\mathrm{D}})^sE_sA^{\pi}\|\|A^{\pi}E_s(A^{\mathrm{D}})^s\|\|\Psi_{ss}^{-1}\|}{(1-\|A^{\mathrm{D}}E\|)(1-\|E_s(A^{\mathrm{D}})^s\|)(1-\|(A^{\mathrm{D}})^sE_s\|)}\right).$$

Substituting these upper bounds of $\|\Sigma_1 - A^{\mathrm{D}}\|$ and $\|\Sigma_2\|$ in (5.14) we conclude the proof of (5.2). Finally, if $\max\{\|A^{\mathrm{D}}E\|, \|(A^{\mathrm{D}})^sE_s\|, \|E_s(A^{\mathrm{D}})^s\|\} < \frac{1}{1+\sqrt{\|A^{\pi}\|}}$, then

$$\|\Psi_{is} - I\| \leq \frac{\|(A^{\mathrm{D}})^iE_i\|\|A^{\pi}E_s(A^{\mathrm{D}})^s\|}{(1-\|(A^{\mathrm{D}})^iE_i\|)(1-\|E_s(A^{\mathrm{D}})^s\|)} < 1, \quad i = 1, s.$$

Hence, it follows that

$$\|\Psi_{is}^{-1}\| \leq \frac{(1-\|(A^{\mathrm{D}})^iE_i\|)(1-\|E_s(A^{\mathrm{D}})^s\|)}{(1-\|(A^{\mathrm{D}})^iE_i\|)(1-\|E_s(A^{\mathrm{D}})^s\|)-\|(A^{\mathrm{D}})^iE_i\|\|A^{\pi}E_s(A^{\mathrm{D}})^s\|}, \quad i = 1, s.$$

This completes the proof. □

. . . 5.2. If we denote $\delta_{is} = (1-\|(A^{\mathrm{D}})^iE_i\|)(1-\|E_s(A^{\mathrm{D}})^s\|) - \|(A^{\mathrm{D}})^iE_i\|$ $\|A^{\pi}E_s(A^{\mathrm{D}})^s\|$, then the upper bounds (5.3), for $i = 1$ and $i = s$, can be expressed as

$$\|\Psi_{is}^{-1}\| \leq 1 + \frac{\|(A^{\mathrm{D}})^iE_i\|\|A^{\pi}E_s(A^{\mathrm{D}})^s\|}{\delta_{is}} = 1 + O(\|E\|^2),$$

where in the last identity we have taken into account that $\|E_s\| = O(\|E\|)$ (see [11]).

Substituting this in (5.2) we get that the upper bound of $\|B^{\mathrm{D}} - A^{\mathrm{D}}\|$ up to the first order of $\|E\|$, has the following expression

$$\frac{\|B^{\mathrm{D}}-A^{\mathrm{D}}\|}{\|A^{\mathrm{D}}\|} \leq \frac{\|A^{\mathrm{D}}E\|}{1-\|A^{\mathrm{D}}E\|}+\frac{\|(A^{\mathrm{D}})^sE_sA^{\pi}\|}{(1-\|A^{\mathrm{D}}E\|)(1-\|(A^{\mathrm{D}})^sE_s\|)}$$
$$+\frac{\|A^{\pi}E_s(A^{\mathrm{D}})^s\|}{(1-\|A^{\mathrm{D}}E\|)(1-\|E_s(A^{\mathrm{D}})^s\|)}+O(\|E\|^2). \tag{5.16}$$

In the following corollary we show that the matrices satisfying condition (1.1), or equivalently $B^{\pi} = A^{\pi}$, are a particular case of the matrices satisfying condition $(\mathcal{C}_s)$.

Corollary 5.3. . . $A \in \mathbb{C}^{n\times n}$, $\mathrm{ind}(A) = r > 0$, . . . $B \in \mathbb{C}^{n\times n}$ $\mathrm{ind}(B) = s$ . . . . . $(\mathcal{C}_s)$ . . . $E = B - A$. $A^{\pi}EA^{\mathrm{D}} = A^{\mathrm{D}}EA^{\pi}$ . . . . . $B^{\mathrm{D}} = (I + A^{\mathrm{D}}E)^{-1}A^{\mathrm{D}}$. . . . . $\|A^{\mathrm{D}}E\| < 1$ . . .

$$\frac{\|B^{\mathrm{D}}-A^{\mathrm{D}}\|}{\|A^{\mathrm{D}}\|} \leq \frac{\|A^{\mathrm{D}}E\|}{1-\|A^{\mathrm{D}}E\|}. \tag{5.17}$$

. . . . We have that E has the representation (5.5) given in the proof of Theorem 5.1. From condition $A^{\pi}EA^{\mathrm{D}} = A^{\mathrm{D}}EA^{\pi}$ it follows that

$$B_1T = TB_2 \text{ and } SB_1 = B_2S.$$

Using these relations we get that

$$S(B_1(I+TS))^s = B_2(I+ST)S(B_1(I+TS))^{s-1} = \cdots = (B_2(I+ST))^sS.$$

Applying that $B_2(I+ST)$ is nilpotent of index s and $B_1(I+TS)$ is nonsingular we obtain that $S=O$. Analogously, we can see that $T=O$. Thus, expression (5.6) takes the form

$$I+A^{\mathrm{D}}E=P\begin{pmatrix}A_1^{-1}B_1 & O\\ O & I\end{pmatrix}P^{-1}.$$

Clearly $I+A^{\mathrm{D}}E$ is nonsingular. In view of (5.4) we get

$$B^{\mathrm{D}}=P\begin{pmatrix}B_1^{-1} & O\\ O & O\end{pmatrix}P^{-1}=(I+A^{\mathrm{D}}E)^{-1}A^{\mathrm{D}}.$$

Hence, we get that $B^{\pi}=A^{\pi}$ and the upper bound (5.17). □

THEOREM 5.4. [illegible] $A\in\mathbb{C}^{n\times n}$, $\mathrm{ind}(A)=r>0$, [illegible] $B\in\mathbb{C}^{n\times n}$, $\mathrm{ind}(B)=s$, [illegible] $(\mathcal{C}_s)$ [illegible] $E_s=B^s-A^s$, $\max\{\|(A^{\mathrm{D}})^sE_s\|,\|E_s(A^{\mathrm{D}})^s\|\}<1$, [illegible]

$$\|B^{\pi}-A^{\pi}\|\le\frac{\|(A^{\mathrm{D}})^sE_sA^{\pi}\|}{1-\|(A^{\mathrm{D}})^sE_s\|}+\frac{\|A^{\pi}E_s(A^{\mathrm{D}})^s\|\|\Psi_{ss}^{-1}\|}{(1-\|(A^{\mathrm{D}})^sE_s\|)(1-\|E_s(A^{\mathrm{D}})^s\|)}\left(1+\frac{\|(A^{\mathrm{D}})^sE_sA^{\pi}\|}{1-\|(A^{\mathrm{D}})^sE_s\|}\right),\tag{5.18}$$

[illegible] $\Psi_{ss}=I+(I+(A^{\mathrm{D}})^sE_s)^{-1}(A^{\mathrm{D}})^sE_sA^{\pi}E_s(A^{\mathrm{D}})^s(I+E_s(A^{\mathrm{D}})^s)^{-1}$ [illegible] $\max\{\|(A^{\mathrm{D}})^sE_s\|,\|E_s(A^{\mathrm{D}})^s\|\}<\frac{1}{1+\sqrt{\|A^{\pi}\|}}$ [illegible] $\|\Psi_{ss}^{-1}\|$ [illegible] (5.3).

[illegible]. From Theorem 2.3 we have

$$B^{\pi}+(A^{\mathrm{D}})^sE_sB^{\pi}=-A^{\pi}X^{-1},\tag{5.19}$$

where $X=I-(I+(A^{\mathrm{D}})^sE_s)^{-1}A^{\pi}-A^{\pi}(I+E_s(A^{\mathrm{D}})^s)^{-1}$. Utilizing the expressions of Φ_s^{-1} and $\widetilde{\Phi}_s^{-1}$ given in the proof of Theorem 5.1 by (5.9), we can represent

$$X=P\begin{pmatrix}I & T\\ S & -I\end{pmatrix}P^{-1}\ \text{ and }\ X^{-1}=P\begin{pmatrix}(I+TS)^{-1} & (I+TS)^{-1}T\\ S(I+TS)^{-1} & -I+S(I+TS)^{-1}T\end{pmatrix}P^{-1}.$$

Thus,

$$-A^{\pi}X^{-1}=A^{\pi}+P\begin{pmatrix}O & O\\ -S(I+TS)^{-1} & -S(I+TS)^{-1}T\end{pmatrix}P^{-1}.$$

Hence, in view of the representations (5.10) and (5.11) we may write

$$-A^{\pi}X^{-1}=A^{\pi}-A^{\pi}E_s(A^{\mathrm{D}})^s\widetilde{\Phi}_s^{-1}\Psi_{ss}^{-1}(I+\Phi_s^{-1}(A^{\mathrm{D}})^sE_sA^{\pi}).$$

Substituting the latter identity in (5.19) we obtain

$$B^{\pi}-A^{\pi}=-(A^{\mathrm{D}})^sE_s(B^{\pi}-A^{\pi}+A^{\pi})-A^{\pi}E_s(A^{\mathrm{D}})^s\widetilde{\Phi}_s^{-1}\Psi_{ss}^{-1}(I+\Phi_s^{-1}(A^{\mathrm{D}})^sE_sA^{\pi}).$$

Taking norms

$$\|B^{\pi}-A^{\pi}\|\le\|(A^{\mathrm{D}})^sE_s\|\|B^{\pi}-A^{\pi}\|+\|(A^{\mathrm{D}})^sE_sA^{\pi}\|+\|A^{\pi}E_s(A^{\mathrm{D}})^s\|\|\widetilde{\Phi}_s^{-1}\|\|\Psi_{ss}^{-1}\|(1+\|\Phi_s^{-1}\|\|(A^{\mathrm{D}})^sE_sA^{\pi}\|).$$

TABLE 5.1

TABLE 5.3
Comparison of upper bounds of $\|B^{\mathrm{D}} - A^{\mathrm{D}}\|_F/\|A^{\mathrm{D}}\|_F$.

	Exact value	[14, Thm. 4.1], (4.1)	(5.2)
$B = A + E_1$	1.14×10^{-10}	8.39×10^{-5}	2.42×10^{-9}
$B = A + E_2$	3.47×10^{-11}	8.39×10^{-5}	4.15×10^{-9}

Since $\max\{\|(A^{\mathrm{D}})^s E_s\|, \|E_s(A^{\mathrm{D}})^s\|\} < 1$, regrouping in $\|B^\pi - A^\pi\|$ and substituting $\|\Phi_s^{-1}\|$ and $\|\widetilde{\Phi}_s^{-1}\|$ by the upper bounds (5.15), we get (5.18). □

5.5. If $\max\{\|A^{\mathrm{D}}E\|, \|(A^{\mathrm{D}})^s E_s\|, \|E_s(A^{\mathrm{D}})^s\|\} < \frac{1}{1+\sqrt{\|A^\pi\|}}$, as we have seen in Remark 5.2, the upper bound of $\|B^\pi - A^\pi\|$ up to the first order of $\|E\|$ has the following expression:

$$\|B^\pi - A^\pi\| \leq \frac{\|(A^{\mathrm{D}})^s E_s A^\pi\|}{1 - \|(A^{\mathrm{D}})^s E_s\|} + \frac{\|A^\pi E_s (A^{\mathrm{D}})^s\|}{(1 - \|(A^{\mathrm{D}})^s E_s\|)(1 - \|E_s(A^{\mathrm{D}})^s\|)} + O(\|E\|^2).$$

5.6. In [5, Theorem 3.1 and Remark 3.3], under assumption $\Delta + \|A^{\mathrm{D}}E\| < 1$, where Δ is un upper bound of $\|B^\pi - A^\pi\|$, the following estimation of the Drazin inverse was given:

$$\frac{\|B^{\mathrm{D}} - A^{\mathrm{D}}\|}{\|A^{\mathrm{D}}\|} \leq \frac{\|A^{\mathrm{D}}E\| + 2\Delta}{1 - \|A^{\mathrm{D}}E\| - \Delta}. \tag{5.20}$$

5.7. In Table 5.1 we compare the upper bound for $\|B^\pi - A^\pi\|_2$ derived in Theorem 5.4 with the upper bound given in [13, Theorem 5]. The upper bounds for $\|B^{\mathrm{D}} - A^{\mathrm{D}}\|_2/\|A^{\mathrm{D}}\|_2$ given in Theorem 5.1, Remark 5.2, and Remark 5.6, replacing Δ in (5.20) by the upper bound given in (5.18), are compared in Table 5.2 with the upper bounds given in [13]. Let

$$A = \begin{pmatrix} \frac{1}{100} & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix}, \; E_1 = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & \epsilon & 0 & \epsilon & 0 \\ 0 & 0 & 0 & \epsilon & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix}, \; E_2 = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & \epsilon & \epsilon & 0 \\ 0 & 0 & 0 & \epsilon & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix},$$

where $\epsilon = 10^{-9}$. We have $\mathrm{ind}(A) = \mathrm{ind}(A + E_i) = 2$ and $\mathrm{rank}\, A^2 = \mathrm{rank}(A + E_i)^2 = \mathrm{rank}\, A^2(A + E_i)^2A^2 = 3$, $i = 1, 2$. By Theorem 2.1 we have that $B = A + E_i$ satisfies condition $(\mathcal{C}_2)$.

In Table 5.3 we compare the upper bound (5.2) using the Frobenius norm with the upper bound given in [14], formula (4.1). That formula is based on the separation of matrices $\mathrm{sep}_F(C, N)$, with C and N being the matrices in the following Schur decomposition,

$$Q^H AQ = \begin{bmatrix} C & G \\ O & N \end{bmatrix},$$

where Q is an unitary matrix, C is nonsingular, and N is nilpotent of index $\mathrm{ind}(A)$. In this example $\mathrm{sep}_F(C, N) = 1.42 \times 10^{-4}$.

WEIGHTED POLAR DECOMPOSITION AND WGL PARTIAL ORDERING OF RECTANGULAR COMPLEX MATRICES*

HU YANG† AND HANYU LI‡

Abstract. In this paper, the unique weighted polar decomposition theorem for rectangular complex matrices is first proved based on introducing the weighted partial isometric matrices. Then the simultaneous weighted polar decomposition of two rectangular complex matrices is studied, for which two sufficient conditions and one criterion are proposed. In order to obtain further characteristics of the simultaneous weighted polar decomposition, a new partial ordering called WGL partial ordering is defined on the set of rectangular matrices. Some basic properties of this new partial ordering are derived. In addition, we also provide methods for computing the weighted polar decomposition and discuss error bounds for the approximate generalized positive semidefinite polar factor.

Key words. weighted singular value decomposition, weighted partial isometric matrix, weighted polar decomposition, simultaneous weighted polar decomposition, WGL partial ordering, error bound

1. Introduction.

Let $\mathbb{C}^{m\times n}$ be the set of $m\times n$ complex matrices and $\mathbb{C}_r^{m\times n}$ be the subset of $\mathbb{C}^{m\times n}$ consisting of matrices with rank r. Let $\mathbb{C}_{\geq}^{m}$ be the set of Hermitian positive semidefinite matrices of order m, and $\mathbb{C}_{>}^{m}$ be the subset of $\mathbb{C}_{\geq}^{m}$ consisting of Hermitian positive definite matrices. Let I_r denote the identity matrix of order r. Given $A\in\mathbb{C}^{m\times n}$, the symbols A^*, $r(A)$, $\lambda_1(A)$, $\mathrm{tr}(A)$, $R(A)$, $N(A)$, $\|A\|_F$, $\|A\|_2$, and $\|A\|$ will stand for the conjugate transpose, rank, the largest eigenvalue, trace, range, null space, Frobenius norm, spectral norm, and unitarily invariant norm of A, respectively. Furthermore, without specification, we always assume that $m>n>r$ and the given weight matrices $M\in\mathbb{C}_{>}^{m}, N\in\mathbb{C}_{>}^{n}$.

For an arbitrary matrix $A\in\mathbb{C}^{m\times n}$, there is a unique matrix $X\in\mathbb{C}^{n\times m}$ satisfying the following equations:

$$AXA=A,\quad XAX=X,\quad (MAX)^*=MAX,\quad (NXA)^*=NXA. \tag{1.1}$$

Matrix X is known as the weighted Moore–Penrose inverse of A and denoted by $X=A_{MN}^{+}$. The weighted Moore–Penrose inverse has many applications in weighted linear least squares problems, prediction theory, numerical analysis, and so on (see, e.g., [19, 24]). In particular, when $M=I_m$ and $N=I_n$, the matrix X is reduced to the Moore–Penrose inverse of A and denoted by $X=A^{+}$.

Given the weight matrices M and N, the weighted inner products in $\mathbb{C}^m$ and $\mathbb{C}^n$ may be defined as

$$(x,y)_M=y^*Mx,\ x,y\in\mathbb{C}^m,\ \text{and}\ (x,y)_N=y^*Nx,\ x,y\in\mathbb{C}^n, \tag{1.2}$$

and the weighted vector norms are defined as

$$\|x\|_M=(x^*Mx)^{1/2}=\left\|M^{1/2}x\right\|_2,\qquad x\in\mathbb{C}^m,$$

and

$$\|x\|_N = (x^*Nx)^{1/2} = \left\|N^{1/2}x\right\|_2, \qquad x \in \mathbb{C}^n.$$

Moreover, if $A \in \mathbb{C}^{m\times n}$, then from [19, 24], the matrix $X \in \mathbb{C}^{n\times m}$ satisfying

$$(Ax, y)_M = (x, Xy)_N \quad \text{for all } x \in \mathbb{C}^n,\ y \in \mathbb{C}^m$$

is called the [illegible] (or adjoint) of the matrix A and denoted by $X = A^{\#}$. This together with (1.2) implies

$$A^{\#} = N^{-1}A^*M. \tag{1.3}$$

We now recall two partial orderings and (generalized) polar decomposition of complex matrices as follows.

For $A, B \in \mathbb{C}^{m\times n}$, we say that A is below B with respect to the [illegible] [16] and write $A \overset{\#}{\leq} B$ whenever $A^{\#}A = A^{\#}B$ and $AA^{\#} = BA^{\#}$. For $A, B \in \mathbb{C}^{m\times m}$, we say that A is below B with respect to the [illegible] and write $A \leq_L B$ whenever $(B - A) \in \mathbb{C}^m_{\geq}$.

For $A \in \mathbb{C}^{m\times n}_r$, there are a partial isometric matrix $E \in \mathbb{C}^{m\times n}$ and two Hermitian positive semidefinite matrices $G \in \mathbb{C}^{m\times m}, H \in \mathbb{C}^{n\times n}$ such that

$$A = GE = EH. \tag{1.4}$$

This decomposition is called the [illegible] [2, 22] of A, and E and G, H are called the [illegible] and [illegible] of this decomposition, respectively. Usually, when $r = n$, decomposition (1.4) is called the [illegible] and, in this case, E and H are called the [illegible] and [illegible], respectively.

There have been many published works on both the partial orderings of matrices and the (generalized) polar decomposition (see, e.g., [1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 18, 21, 22, 25]). Among these works, the properties of the (generalized) polar decomposition involved in the partial orderings of matrices were studied by Hauke, Markiewicz, Groß, and Zhuang [6, 8, 18, 25], and numerical methods including direct and iterative methods for computing the (generalized) polar decomposition could be found in [4, 5, 9, 10, 11, 12, 15, 22].

After obtaining an [illegible] solution X of the unitary polar factor E using iterative methods, Sun [21] took $K = \frac{1}{2}(X^*A + A^*X)$ as an approximate solution of the positive definite polar factor H and presented the error estimates for the approximate positive definite polar factor K. Chen and Li [3] extended some results obtained by Sun [21] to the generalized polar decomposition, and derived some error bounds for the approximate positive semidefinite polar factor. In the present paper, we will consider the weighted polar decomposition (WPD), a generalization of the (generalized) polar decomposition.

The rest of this paper is organized as follows. Section 2 provides some preliminaries. Section 3 first proves the unique WPD theorem for rectangular complex matrices after introducing the weighted partial isometric matrices and then defines and studies the simultaneous weighted polar decomposition (SWPD) of two rectangular complex matrices. Two sufficient conditions and a criterion for SWPD are obtained. In section 4, we present a new partial ordering of matrices called WGL partial ordering,

and then we discuss its basic properties. Using this new partial ordering, we study the characteristics of SWPD further. The methods for computing WPD and the error bounds for the approximate generalized positive semidefinite (AGPSD) polar factor are derived in section 5 and section 6, respectively.

2. Preliminaries. First, we introduce some results on the weighted matrix norms. From [24], we know that the [illegible] may be defined as

$$\|A\|_{MN} = \max_{\|x\|_N=1} \|Ax\|_M, \qquad A \in \mathbb{C}^{m\times n},\ x \in \mathbb{C}^n, \tag{2.1}$$

from which it is easy to get the following relation:

$$\|A\|_{MN} = \left\|M^{1/2}AN^{-1/2}\right\|_2. \tag{2.2}$$

We now define two other weighted matrix norms called the [illegible] and the [illegible], respectively, as follows:

$$\|A\|_{F(MN)} = \left\|M^{1/2}AN^{-1/2}\right\|_F, \quad A \in \mathbb{C}^{m\times n}, \tag{2.3}$$

$$\|A\|_{(MN)} = \left\|M^{1/2}AN^{-1/2}\right\|, \qquad A \in \mathbb{C}^{m\times n}. \tag{2.4}$$

It is worth pointing out that the weighted unitary invariant norm defined in (2.4) is essentially equivalent to the (M, N)-invariant norm presented by Rao and Rao [20].

According to the properties of the Frobenius norm and (1.3), we have

$$\|A\|_{F(MN)} = \left(\mathrm{tr}((M^{1/2}AN^{-1/2})^*(M^{1/2}AN^{-1/2}))\right)^{1/2} = (\mathrm{tr}(A^{\#}A))^{1/2}. \tag{2.5}$$

Hence, the weighted Frobenius norm is similar to the Frobenius norm in form.

From Van Loan [23], we know that the (M, N) [illegible] of $A \in \mathbb{C}_r^{m\times n}$ are the elements of the set $\sigma_{MN}(A)$ defined by

$$\sigma_{MN}(A) = \left\{\sigma : \sigma \geq 0, \sigma \text{ is a stationary value of } \frac{\|Ax\|_M}{\|x\|_N}\right\}.$$

By using Lagrange multipliers, for every nonzero element of the set $\sigma_{MN}(A)$, we have

$$\sigma_i = \lambda_i^{1/2}(N^{-1}A^*MA) = \lambda_i^{1/2}(A^{\#}A), \quad i = 1, \ldots, r, \tag{2.6}$$

which together with (2.5) gives

$$\|A\|_{F(MN)}^2 = \sum_{i=1}^{r} \sigma_i^2. \tag{2.7}$$

Van Loan [23] also presented the following (M, N) [illegible] (MN-SVD), which is useful in this paper.

LEMMA 2.1. [illegible] $A \in \mathbb{C}_r^{m\times n}$ [illegible] $U \in \mathbb{C}^{m\times m}$ [illegible] $V \in \mathbb{C}^{n\times n}$ [illegible] $U^*MU = I_m$ [illegible] $V^*N^{-1}V = I_n$ [illegible]

$$A = U\begin{pmatrix} \Sigma & 0 \\ 0 & 0 \end{pmatrix}V^*, \tag{2.8}$$

$\Sigma = \mathrm{diag}(\sigma_1, \ldots, \sigma_r)$, $\sigma_i = \sqrt{\lambda_i}$ $\lambda_1 \geq \cdots \geq \lambda_r > 0$ $A^{\#}A = N^{-1}A^*MA$ $\sigma_1 \geq \cdots \geq \sigma_r > 0$ (M, N) A A

$$A^{+}_{MN} = N^{-1}V \begin{pmatrix} \Sigma^{-1} & 0 \\ 0 & 0 \end{pmatrix} U^*M. \tag{2.9}$$

$U = (U_r, U_{m-r})$ $V = (V_r, V_{n-r})$ $U_r = [u_1, \ldots, u_r] \in \mathbb{C}^{m\times r}$ $V_r = [v_1, \ldots, v_r] \in \mathbb{C}^{n\times r}$

$$A = U_r\Sigma V_r^* \quad A^{+}_{MN} = N^{-1}V_r\Sigma^{-1}U_r^*M. \tag{2.10}$$

$$\|A\|_{MN} = \sigma_1 \quad \left\|A^{+}_{MN}\right\|_{NM} = \frac{1}{\sigma_r}. \tag{2.11}$$

The following four lemmas will be needed in this paper. Lemmas 2.2 and 2.3 can be found in [1] and [13], respectively, and Lemmas 2.4 and 2.5 can be found in [24].

LEMMA 2.2. $A, B \in \mathbb{C}^m_{\geq}$

$$A \leq_L B \quad \lambda_1(B^{+}A) \leq 1 \quad R(A) \subseteq R(B).$$

LEMMA 2.3. $A, B \in \mathbb{C}^{m\times m}$ $P \in \mathbb{C}^{m\times k}$

$A \leq_L B$, $P^*AP \leq_L P^*BP$.

LEMMA 2.4. $A \in \mathbb{C}^{m\times n}_r$ $P \in \mathbb{C}^{k\times m}$ $Q \in \mathbb{C}^{l\times n}$ $P^*P = I_m$ $QQ^* = I_n$

$$(PAQ^*)^{+} = QA^{+}P^*.$$

LEMMA 2.5. $A \in \mathbb{C}^{m\times n}_r$ A^{+}_{MN}

$$A^{+}_{MN} = N^{-1/2}(M^{1/2}AN^{-1/2})^{+}M^{1/2}.$$

3. Weighted partial isometric matrix and WPD. Now we give the definition of the weighted partial isometric matrix.

DEFINITION 3.1. $E \in \mathbb{C}^{m\times n}$

$$\|Ex\|_M = \|x\|_N \quad x \in R(E^{\#}),$$

E (M, N) ( ) $E \in \mathbb{C}^{n\times m}$

$$\|Ex\|_N = \|x\|_M \quad x \in R(E^{\#}),$$

E (N, M) $M = I_m$ $N = I_n$ E ( ) [2, 19, 22])

The following lemma from [19] can be used to determine the orthogonal projector in the weighted inner product.

LEMMA 3.2. [illegible] $\mathbb{C}^m$ [illegible] (1.2) [illegible] $P \in \mathbb{C}^{m\times m}$ [illegible]

(a) $P^2 = P$ [illegible] (b) $(MP)^* = MP$ ($P^{\#} = P$).

From this lemma and the properties of the weighted Moore–Penrose inverse [24], i.e.,

$$R(AA^+_{MN}) = R(A), \quad R(A^+_{MN}A) = N^{-1}R(A^*) = R(A^{\#}), \tag{3.1}$$

we can get that the orthogonal projectors on $R(A)$ and $R(A^{\#})$ in the weighted inner product (1.2) may be given by

$$P_{R(A)} = AA^+_{MN} \text{ and } P_{R(A^{\#})} = A^+_{MN}A. \tag{3.2}$$

Using results from [17], Definition 3.1, and Lemma 3.2, we can draw some equivalent characterizations of the weighted partial isometric matrices.

LEMMA 3.3. [illegible] $E \in \mathbb{C}^{m\times n}$ [illegible]

(a) E [illegible]

(b) $E^{\#}$ [illegible]

(c) $E^+_{MN} = E^{\#}$.

(d) $E^{\#}E$ [illegible] $E^{\#}E = P_{R(E^{\#})}$.

(e) $EE^{\#}$ [illegible] $EE^{\#} = P_{R(E)}$.

(f) $EE^{\#}E = E$.

(g) $E^{\#}EE^{\#} = E^{\#}$.

In order to prove the WPD theorem, we need to introduce the following theorem.

THEOREM 3.4. [illegible] $A \in \mathbb{C}^{m\times n}_r$ [illegible] A U_r [illegible] V_r [illegible] 2.1 [illegible]

(a) $U_r^*MU_r = V_r^*N^{-1}V_r = I_r$ [illegible] $E = U_rV_r^*$ [illegible];

(b) $EE^{\#} = P_{R(A)}$ [illegible] $E^{\#}E = P_{R(A^{\#})}$.

[illegible]. (a) The first part can be obtained from $U^*MU = I_m$, $V^*N^{-1}V = I_n$, and the definitions of U_r and V_r easily.

That $E = U_rV_r^*$ is an MN-WPI matrix can be obtained from Lemma 3.3 and the following result:

$$EE^{\#}E = U_rV_r^*(U_rV_r^*)^{\#}U_rV_r^* = U_rV_r^*N^{-1}(U_rV_r^*)^*MU_rV_r^* = U_rV_r^* = E.$$

(b) From (3.2), Lemma 2.1, and the fact that $E = U_rV_r^*$, we have

$$P_{R(A)} = AA^+_{MN} = U_r\Sigma V_r^*N^{-1}V_r\Sigma^{-1}U_r^*M = UU_r^*M,$$

$$EE^{\#} = U_rV_r^*(U_rV_r^*)^{\#} = U_rV_r^*N^{-1}(U_rV_r^*)^*M = UU_r^*M.$$

Therefore, $EE^{\#} = P_{R(A)}$.

The equality $E^{\#}E = P_{R(A^{\#})}$ can also be proved in a similar way. ∎

THEOREM 3.5. $A \in \mathbb{C}_r^{m\times n}$ A

$$A = GE = EH, \tag{3.3}$$

$E \in \mathbb{C}^{m\times n}$ $MG \in \mathbb{C}_{\geq}^{m}$ $NH \in \mathbb{C}_{\geq}^{n}$ G H $G^{\#} = G$, $H^{\#} = H$. Let the MN-SVD of A be as in (2.8). For any k, where $r \leq k \leq \min\{m, n\}$, similar to U_r and V_r in Lemma 2.1, we define U_k, V_k, and Σ_k as follows:

$$U_k = [u_1, \ldots, u_k] \in \mathbb{C}^{m\times k}, \quad V_k = [v_1, \ldots, v_k] \in \mathbb{C}^{n\times k}, \quad \Sigma_k = \left(\begin{array}{c|c} \Sigma & 0 \\ \hline 0 & 0 \end{array}\right) \in \mathbb{C}^{k\times k}.$$

It is easy to obtain $U_k^* M U_k = V_k^* N^{-1} V_k = I_k$; then (2.8) can be rewritten as

$$\begin{aligned} A &= U_k \Sigma_k V_k^* = U_k \Sigma_k U_k^* M U_k V_k^* = (U_k \Sigma_k U_k^* M)(U_k V_k^*) \\ &= U_k V_k^* N^{-1} V_k \Sigma_k V_k^* = (U_k V_k^*)(N^{-1} V_k \Sigma_k V_k^*), \end{aligned}$$

which together with Theorem 3.4 proves (3.3) with the MN-WPI matrix

$$E = U_k V_k^* \tag{3.4}$$

and the generalized positive semidefinite matrices

$$G = U_k \Sigma_k U_k^* M, \qquad H = N^{-1} V_k \Sigma_k V_k^*. \tag{3.5}$$

In fact,

$$MG = M U_k \Sigma_k U_k^* M \in \mathbb{C}_{\geq}^{m}, \qquad NH = V_k \Sigma_k V_k^* \in \mathbb{C}_{\geq}^{n},$$

which imply $G^{\#} = G$ and $H^{\#} = H$ according to (1.3). ∎

The decomposition (3.3) is called the (WPD) of the rectangular complex matrix A, and E and G, H are called the and the of this decomposition, respectively. From the proof of Theorem 3.5, we find that WPD may not be unique. The uniqueness of WPD can be obtained through the right WPD (3.6) and the left WPD (3.11) as follows.

THEOREM 3.6. $A \in \mathbb{C}_r^{m\times n}$ A

$$A = GE \quad R(A) \subseteq R(E), \tag{3.6}$$

$E \in \mathbb{C}^{m\times n}$ $MG \in \mathbb{C}_{\geq}^{m}$ G $G^{\#} = G$ G E $r(E) = r(A)$ $E = ((AA^{\#})^{1/2})_{MM}^{+} A = A((A^{\#}A)^{1/2})_{NN}^{+}$ $r(G) = r(A)$ G $G = (AA^{\#})^{1/2}$ G E (3.6) $A = (AA^{\#})^{1/2}E$

. From Theorem 3.5, we need only to prove the second part of this theorem.

Since E is an MN-WPI matrix and $R(A) \subseteq R(E)$, from Lemma 3.3, we have

$$A = EE^{\#}A = EE^{\#}GE. \tag{3.7}$$

Then we can get

$$\begin{aligned}(AA^{\#})^{1/2} &= (EE^{\#}GEE^{\#}GEE^{\#})^{1/2} = EE^{\#}GEE^{\#}\\ &\Leftrightarrow\ (AA^{\#})^{1/2}E = AE^{\#}E, \qquad (3.8)\\ (A^{\#}A)^{1/2} &= (E^{\#}GEE^{\#}EE^{\#}GE)^{1/2} = E^{\#}GE\\ &\Leftrightarrow\ E(A^{\#}A)^{1/2} = A. \qquad (3.9)\end{aligned}$$

Let $r(E) = r(A)$. Then $R(A) = R(E)$ and $r(E^{\#}) = r(A^{\#})$. Meanwhile, observing that $R(A^{\#}) \subseteq R(E^{\#})$ from $A = GE$, we have $R(A^{\#}) = R(E^{\#})$. Thus, according to (3.8) and the fact that $R((AA^{\#})^{1/2}) = R(A) = R(E)$, we can get

$$\begin{aligned}&(AA^{\#})^{1/2}E = AE^{\#}E = A\\ &\Leftrightarrow ((AA^{\#})^{1/2})^{+}_{MM}(AA^{\#})^{1/2}E = ((AA^{\#})^{1/2})^{+}_{MM}A\\ &\Leftrightarrow (AA^{\#})^{1/2}((AA^{\#})^{1/2})^{+}_{MM}E = ((AA^{\#})^{1/2})^{+}_{MM}A\\ &\Leftrightarrow E = ((AA^{\#})^{1/2})^{+}_{MM}A.\end{aligned}$$

Similarly, from (3.9) and the fact that $R((A^{\#}A)^{1/2}) = R(A^{\#}) = R(E^{\#})$, we can get

$$E = A((A^{\#}A)^{1/2})^{+}_{NN}.$$

Therefore, E is uniquely determined and

$$E = ((AA^{\#})^{1/2})^{+}_{MM}A = A((A^{\#}A)^{1/2})^{+}_{NN}.$$

Let $r(G) = r(A)$. Then, in view of the fact that $A = GE$, we have $R(G) = R(A)$, which together with $R(A) \subseteq R(E)$ gives

$$R(G) \subseteq R(E). \tag{3.10}$$

Thus, by (3.8) and (3.10), we conclude that

$$(AA^{\#})^{1/2} = AE^{\#} \ \Leftrightarrow\ (AA^{\#})^{1/2} = GEE^{\#} \ \Leftrightarrow\ (AA^{\#})^{1/2} = EE^{\#}G = G.$$

Therefore, G is uniquely determined and $G = (AA^{\#})^{1/2}$. Moreover, given G and E in (3.6), $A = (AA^{\#})^{1/2}E$ can be obtained by (3.7) and (3.8). □

Similar to the right WPD, we can present the left WPD as follows.

THEOREM 3.7. [illegible] $A \in \mathbb{C}_r^{m\times n}$ [illegible] A [illegible]

$$A = EH \text{ [illegible] } R(A^{\#}) \subseteq R(E^{\#}), \tag{3.11}$$

[illegible] $E \in \mathbb{C}^{m\times n}$ [illegible] $NH \in \mathbb{C}^{n}_{\geq}$ [illegible] H [illegible]
[illegible] $H^{\#} = H$
[illegible] H [illegible] E [illegible]

$r(E) = r(A)$ E $E = A((A^{\#}A)^{1/2})^{+}_{NN} = ((AA^{\#})^{1/2})^{+}_{MM}A$

$r(H) = r(A)$ H $H = (A^{\#}A)^{1/2}$

E H (3.11) $A = E(A^{\#}A)^{1/2}$

The following unique WPD theorem follows from Theorems 3.6 and 3.7.

THEOREM 3.8. $A \in \mathbb{C}_r^{m\times n}$ $G = (AA^{\#})^{1/2}$ $H = (A^{\#}A)^{1/2}$

$$A = GE = EH, \tag{3.12}$$

$E = ((AA^{\#})^{1/2})^{+}_{MM}A = A((A^{\#}A)^{1/2})^{+}_{NN}$

Considering the WPDs of two rectangular complex matrices, we introduce the simultaneous weighted polar decomposition (SWPD) as follows.

DEFINITION 3.9. $A, B \in \mathbb{C}^{m\times n}$ $E \in \mathbb{C}^{m\times n}$ $A = G_1E = EH_1$ $B = G_2E = EH_2$ $G_1, G_2 \in \mathbb{C}^{m\times m}$ $H_1, H_2 \in \mathbb{C}^{n\times n}$

From the proof of Theorem 3.5 and the simultaneous (M, N) weighted singular value decomposition (MN-SSVD) [16], we can obtain the following sufficient condition for SWPD.

THEOREM 3.10. $A, B \in \mathbb{C}^{m\times n}$ A, B (M, N) A, B

The following lemma provides a necessary and sufficient condition for MN-SSVD given by Liu [16]. From this lemma, another sufficient condition for SWPD can be presented.

LEMMA 3.11. $A, B \in \mathbb{C}^{m\times n}$ A, B (M, N) $(A^{\#}B)^{\#} = A^{\#}B$, $(AB^{\#})^{\#} = AB^{\#}$ $NA^{\#}B \in \mathbb{C}^n_{\geq}$, $MAB^{\#} \in \mathbb{C}^m_{\geq}$

COROLLARY 3.12. $A, B \in \mathbb{C}^{m\times n}$ $(A^{\#}B)^{\#} = A^{\#}B$, $(AB^{\#})^{\#} = AB^{\#}$ $NA^{\#}B \in \mathbb{C}^n_{\geq}$, $MAB^{\#} \in \mathbb{C}^m_{\geq}$ A, B

In order to derive further criteria for SWPD, next we will show that SWPD can be equivalently defined via left SWPD and right SWPD, respectively.

DEFINITION 3.13. $A, B \in \mathbb{C}^{m\times n}$

(a) A, B $E \in \mathbb{C}^{m\times n}$ $A = EH_1$ $R(A^{\#}) \subseteq R(E^{\#})$ $B = EH_2$ $R(B^{\#}) \subseteq R(E^{\#})$ $H_1, H_2 \in \mathbb{C}^{n\times n}$

(b) A, B $E \in \mathbb{C}^{m\times n}$ $A = G_1E$ $R(A) \subseteq R(E)$ $B = G_2E$ $R(B) \subseteq R(E)$ $G_1, G_2 \in \mathbb{C}^{m\times m}$

LEMMA 3.14. $A, B \in \mathbb{C}^{m\times n}$ A, B

. Let A, B be simultaneously left weighted polar decomposable. From Definition 3.13(a), we have $R(A) \subseteq R(E)$ and $R(B) \subseteq R(E)$. Furthermore, observe that E is an MN-WPI matrix and $R(A^{\#}) \subseteq R(E^{\#})$, $R(B^{\#}) \subseteq R(E^{\#})$. Then we have

$$A = EH_1 \Rightarrow A^{\#} = H_1E^{\#} \Rightarrow E^{\#}EA^{\#} = E^{\#}EH_1E^{\#}$$

$$\Rightarrow A^{\#} = E^{\#}EH_1E^{\#} \Rightarrow A = G_1E,$$

$$B = EH_2 \Rightarrow B^{\#} = H_2E^{\#} \Rightarrow E^{\#}EB^{\#} = E^{\#}EH_2E^{\#}$$

$$\Rightarrow B^{\#} = E^{\#}EH_2E^{\#} \Rightarrow B = G_2E,$$

where $G_1 = EH_1E^{\#}$ and $G_2 = EH_2E^{\#}$ are generalized positive semidefinite matrices. Thus, we get that A, B are simultaneously right weighted polar decomposable. Now the proof can be completed using similar arguments. □

From Theorem 3.6 and Lemma 3.14, we can easily deduce the following theorem.

THEOREM 3.15. [illegible] $A, B \in \mathbb{C}^{m\times n}$ [illegible] A, B [illegible] $E \in \mathbb{C}^{m\times n}$ [illegible]

$$A = (AA^{\#})^{1/2}E, R(A) \subseteq R(E) \text{ and } B = (BB^{\#})^{1/2}E, R(B) \subseteq R(E).$$

Another characterization (Theorem 4.9) for SWPD is associated with a new matrix partial ordering which will be discussed in the following section.

4. WGL partial ordering. Before introducing WGL partial ordering, we first define the following partial ordering of complex matrices which is a generalization of the Löwner partial ordering.

DEFINITION 4.1. [illegible] $A, B \in \mathbb{C}^{m\times m}$ [illegible] A [illegible] B [illegible] $A \leq_{WL} B$ [illegible] $M(B - A) \in \mathbb{C}^m_{\geq}$

The WL partial ordering, important for studying the WGL partial ordering, can be interpreted as the weighted Löwner partial ordering.

A similar definition and some characteristics can be found in [7]. Those characteristics can be used to prove some of our results. However, it will increase the complexity of proof to some extent; therefore, in this paper we use alternative methods to obtain these results.

Now we present the definition of WGL partial ordering formally.

DEFINITION 4.2. [illegible] $A, B \in \mathbb{C}^{m\times n}$ [illegible] A [illegible] B [illegible] WGL [illegible] $A \leq_{WGL} B$ [illegible] $(AA^{\#})^{1/2} \leq_{WL} (BB^{\#})^{1/2}$ [illegible] $AB^{\#} = (AA^{\#})^{1/2}(BB^{\#})^{1/2}$

Next we show that the relation $\leq_{WGL}$ satisfies the three laws of the matrix partial ordering.

(1) $A \leq_{WGL} A$ holds obviously.

(2) If $A \leq_{WGL} B$ and $B \leq_{WGL} C$, to verify $A \leq_{WGL} C$, in view of Definition 4.1, we need only to verify that $AC^{\#} = (AA^{\#})^{1/2}(CC^{\#})^{1/2}$.

From Definition 4.2, Definition 4.1, and Lemma 2.2, we have

$$M(AA^{\#})^{1/2} = M(BB^{\#})^{1/2}K^{\#} \tag{4.1}$$

$$\Leftrightarrow (AA^{\#})^{1/2}M = K(BB^{\#})^{1/2}M \quad \text{for some } K \in \mathbb{C}^{m\times m}.$$

Meanwhile, note that $R(A^{\#}) \subseteq R(B^{\#})$ (see Theorem 4.5 and Lemma 4.3). Hence,

$$A^{\#} = B^{+}_{MN}BA^{\#} \Rightarrow A = AB^{+}_{MN}B. \tag{4.2}$$

Thus, according to (4.1) and (4.2), we conclude that

$$\begin{aligned}
AC^{\#} &= AB^{+}_{MN}BB^{+}_{MN}BC^{\#} = AB^{\#}(B^{+}_{MN})^{\#}B^{+}_{MN}BC^{\#} \\
&= (AA^{\#})^{1/2}(BB^{\#})^{1/2}(B^{+}_{MN})^{\#}B^{+}_{MN}BC^{\#} \\
&= (AA^{\#})^{1/2}MM^{-1}(BB^{\#})^{1/2}(B^{+}_{MN})^{\#}B^{+}_{MN}(BB^{\#})^{1/2}(CC^{\#})^{1/2} \\
&= K(BB^{\#})^{1/2}MM^{-1}(BB^{\#})^{1/2}(B^{+}_{MN})^{\#}B^{+}_{MN}(BB^{\#})^{1/2}(CC^{\#})^{1/2} \\
&= KB(B^{+}_{MN}B)^{\#}B^{+}_{MN}(BB^{\#})^{1/2}(CC^{\#})^{1/2} \\
&= KBB^{+}_{MN}(BB^{\#})^{1/2}(CC^{\#})^{1/2} \\
&= K(BB^{\#})^{1/2}MM^{-1}(CC^{\#})^{1/2} \\
&= (AA^{\#})^{1/2}(CC^{\#})^{1/2}.
\end{aligned}$$

(3) If $A \leq_{WGL} B$, $B \leq_{WGL} A$, then

$$(A-B)(A-B)^{\#} = AA^{\#} - AB^{\#} - BA^{\#} + BB^{\#} = 0,$$

which implies $A = B$.

Therefore, the relation $\leq_{WGL}$ is a partial ordering of matrices. From Definition 4.1, the WGL partial ordering can be viewed as the weighted GL partial ordering [8].

The following lemma is useful for studying the properties of WGL partial ordering later in this paper.

LEMMA 4.3. [illegible] $A, B \in \mathbb{C}^{m\times n}$ [illegible]

[illegible] $AB^{\#} = (AA^{\#})^{1/2}(BB^{\#})^{1/2}$ [illegible] $R(A) \subseteq R(B)$, [illegible] $R(A^{\#}) \subseteq R(B^{\#})$.

[illegible]. Premultiplying the equality $AB^{\#} = (AA^{\#})^{1/2}(BB^{\#})^{1/2}$ by A^{+}_{MN} and postmultiplying it by $(B^{+}_{MN})^{\#}A^{\#}(A^{+}_{MN})^{\#}$ gives

$$A^{+}_{MN}AB^{\#}(B^{+}_{MN})^{\#}A^{\#}(A^{+}_{MN})^{\#} = A^{+}_{MN}(AA^{\#})^{1/2}(BB^{\#})^{1/2}(B^{+}_{MN})^{\#}A^{\#}(A^{+}_{MN})^{\#},$$

which is equivalent to

$$P_{R(A^{\#})}P_{R(B^{\#})}P_{R(A^{\#})} = A^{+}_{MN}(AA^{\#})^{1/2}(BB^{\#})^{1/2}(B^{+}_{MN})^{\#}A^{\#}(A^{+}_{MN})^{\#}, \tag{4.3}$$

while from $R(A) \subseteq R(B)$ and the fact that $AB^{\#} = (AA^{\#})^{1/2}(BB^{\#})^{1/2}$, we have

$$\begin{aligned}
(BB^{\#})^{1/2}(B^{+}_{MN})^{\#}A^{\#} &= (BB^{\#})^{1/2}(AB^{+}_{MN})^{\#} = (BB^{\#})^{1/2}(AB^{+}_{MN}BB^{+}_{MN})^{\#} \\
&= (BB^{\#})^{1/2}(B^{+}_{MN})^{\#}(B^{+}_{MN}B)^{\#}A^{\#} = (BB^{\#})^{1/2}(B^{+}_{MN})^{\#}B^{+}_{MN}BA^{\#} \\
&= (BB^{\#})^{1/2}(B^{+}_{MN})^{\#}B^{+}_{MN}(BB^{\#})^{1/2}(AA^{\#})^{1/2} \\
&= (BB^{\#})^{1/2}(BB^{\#})^{+}_{MN}(BB^{\#})^{1/2}(AA^{\#})^{1/2} \\
&= (AA^{\#})^{1/2},
\end{aligned}$$

which combined with (4.3) leads to

$$\begin{aligned}
P_{R(A^{\#})}P_{R(B^{\#})}P_{R(A^{\#})} &= A^{+}_{MN}(AA^{\#})^{1/2}(AA^{\#})^{1/2}(A^{+}_{MN})^{\#} \\
&= A^{+}_{MN}AA^{\#}(A^{+}_{MN})^{\#} = P_{R(A^{\#})}.
\end{aligned}$$

Therefore,

$$0 = P_{R(A^{\#})}P_{R(B^{\#})}P_{R(A^{\#})} - P_{R(A^{\#})} = P_{R(A^{\#})}(I - P_{R(B^{\#})})P_{R(A^{\#})}$$

$$\Leftrightarrow (I - P_{R(B^{\#})})P_{R(A^{\#})} = 0$$

$$\Leftrightarrow R(P_{R(A^{\#})}) \subseteq N(I - P_{R(B^{\#})}) \Leftrightarrow R(A^{\#}) \subseteq N(I - P_{R(B^{\#})}). \tag{4.4}$$

Observe that the matrix $I - P_{R(B^{\#})}$ is idempotent. Hence, $N(I - P_{R(B^{\#})}) = R(P_{R(B^{\#})}) = R(B^{\#})$, which together with (4.4) gives $R(A^{\#}) \subseteq R(B^{\#})$. □

In the following, we discuss the properties of WGL partial ordering.

THEOREM 4.4. [illegible] $A, B \in \mathbb{C}^{m\times n}$ [illegible]

$$A \leq_{WGL} B \text{ [illegible] } A^{\#} \leq_{WGL} B^{\#}.$$

[illegible]. Let $r(A) = a$ and $r(B) = b$. From Lemma 2.1, we suppose that the MN-SVDs for A and B are $A = U_a\Sigma_a V_a^*$ and $B = U_b\Sigma_b V_b^*$, where $\Sigma_a \in \mathbb{C}_>^a$ and $\Sigma_b \in \mathbb{C}_>^b$ are diagonal matrices, and $U_a \in \mathbb{C}^{m\times a}$, $U_b \in \mathbb{C}^{m\times b}$, $V_a \in \mathbb{C}^{n\times a}$, $V_b \in \mathbb{C}^{n\times b}$ satisfy $U_a^*MU_a = V_a^*N^{-1}V_a = I_a$ and $U_b^*MU_b = V_b^*N^{-1}V_b = I_b$.

From Definition 4.1 and Definition 4.2, we can get $A \leq_{WGL} B$ if and only if

(a) $(AA^{\#})^{1/2} \leq_{WL} (BB^{\#})^{1/2}$

$$\Leftrightarrow M(U_a\Sigma_a V_a^*N^{-1}V_a\Sigma_a U_a^*M)^{1/2} \leq_L M(U_b\Sigma_b V_b^*N^{-1}V_b\Sigma_b U_b^*M)^{1/2}$$

$$\Leftrightarrow M(U_a\Sigma_a U_a^*MU_a\Sigma_a U_a^*M)^{1/2} \leq_L M(U_b\Sigma_b U_b^*MU_b\Sigma_b U_b^*M)^{1/2}$$

$$\Leftrightarrow MU_a\Sigma_a U_a^*M \leq_L MU_b\Sigma_b U_b^*M \Leftrightarrow U_a\Sigma_a U_a^* \leq_L U_b\Sigma_b U_b^*, \tag{4.5}$$

(b) $AB^{\#} = (AA^{\#})^{1/2}(BB^{\#})^{1/2}$

$$\Leftrightarrow U_a\Sigma_a V_a^*N^{-1}V_b\Sigma_b U_b^*M = U_a\Sigma_a U_a^*MU_b\Sigma_b U_b^*M$$

$$\Leftrightarrow V_a^*N^{-1}V_b = U_a^*MU_b, \tag{4.6}$$

and $A^{\#} \leq_{WGL} B^{\#}$ if and only if

(c) $(A^{\#}A)^{1/2} \leq_{WL} (B^{\#}B)^{1/2}$

$$\Leftrightarrow N(N^{-1}V_a\Sigma_a U_a^*MU_a\Sigma_a V_a^*)^{1/2} \leq_L N(N^{-1}V_b\Sigma_b U_b^*MU_b\Sigma_b V_b^*)^{1/2}$$

$$\Leftrightarrow N(N^{-1}V_a\Sigma_a V_a^*N^{-1}V_a\Sigma_a V_a^*)^{1/2} \leq_L N(N^{-1}V_b\Sigma_b V_b^*N^{-1}V_b\Sigma_b V_b^*)^{1/2}$$

$$\Leftrightarrow NN^{-1}V_a\Sigma_a V_a^* \leq_L NN^{-1}V_b\Sigma_b V_b^* \Leftrightarrow V_a\Sigma_a V_a^* \leq_L V_b\Sigma_b V_b^*, \tag{4.7}$$

(d) $A^{\#}B = (A^{\#}A)^{1/2}(B^{\#}B)^{1/2}$

$$\Leftrightarrow N^{-1}V_a\Sigma_a U_a^*MU_b\Sigma_b V_b^* = N^{-1}V_a\Sigma_a V_a^*N^{-1}V_b\Sigma_b V_b^*$$

$$\Leftrightarrow U_a^*MU_b = V_a^*N^{-1}V_b. \tag{4.8}$$

Then, by (4.5), (4.6), (4.7), and (4.8), we have $A \leq_{WGL} B \Leftrightarrow A^{\#} \leq_{WGL} B^{\#}$ if and only if the following relation (4.9) holds under the condition (4.6) (or (4.8)):

$$U_a\Sigma_a U_a^* \leq_L U_b\Sigma_b U_b^* \Leftrightarrow V_a\Sigma_a V_a^* \leq_L V_b\Sigma_b V_b^*. \tag{4.9}$$

According to $A \leq_{WGL} B$, we can get $R(A^{\#}) \subseteq R(B^{\#})$ (see Theorem 4.5 and Lemma 4.3), which combined with the MN-SVDs of A and B gives

$$R(N^{-1}V_a\Sigma_a U_a^* M) \subseteq R(N^{-1}V_b\Sigma_b U_b^* M). \tag{4.10}$$

Note that

$$r(N^{-1}V_i\Sigma_i U_i^* M) = r(N^{-1}V_i), \quad R(N^{-1}V_i\Sigma_i U_i^* M) \subseteq R(N^{-1}V_i), \qquad i = a, b,$$

and hence, $R(N^{-1}V_i D_i U_i^* M) = R(N^{-1}V_i)$, $i = a, b$. Therefore, $R(N^{-1}V_a) \subseteq R(N^{-1}V_b)$. Thus there exists a matrix H such that $N^{-1}V_a = N^{-1}V_b H$. Premultiplying the last equality by $N^{1/2}$, we can get

$$N^{-1/2}V_a = N^{-1/2}V_b H.$$

Consequently,

$$R(N^{-1/2}V_a) \subseteq R(N^{-1/2}V_b). \tag{4.11}$$

Note that $N^{-1/2}V_b(N^{-1/2}V_b)^* N^{-1/2}V_b = N^{-1/2}V_b$. Then $N^{-1/2}V_b$ is a partial isometric matrix [2]. Thus, by (4.11), we have

$$N^{-1/2}V_b(N^{-1/2}V_b)^* N^{-1/2}V_a = N^{-1/2}V_a, \text{ i.e., } V_b V_b^* N^{-1}V_a = V_a. \tag{4.12}$$

According to Lemma 2.3, and considering (4.6) and (4.12), we can conclude that

$$\begin{aligned}
U_a\Sigma_a U_a^* \leq_L U_b\Sigma_b U_b^* &\Rightarrow U_b^* M U_a\Sigma_a U_a^* M U_b \leq_L U_b^* M U_b\Sigma_b U_b^* M U_b \\
&\Rightarrow U_b^* M U_a\Sigma_a U_a^* M U_b \leq_L \Sigma_b \\
&\Rightarrow V_b U_b^* M U_a\Sigma_a U_a^* M U_b V_b^* \leq_L V_b\Sigma_b V_b^* \\
&\Rightarrow V_b V_b^* N^{-1}V_a\Sigma_a V_a^* N^{-1}V_b V_b^* \leq_L V_b\Sigma_b V_b^* \\
&\Rightarrow V_a\Sigma_a V_a^* \leq_L V_b\Sigma_b V_b^*.
\end{aligned}$$

In the similar way, we can get $U_b U_b^* M U_a = U_a$ through $A^{\#} \leq_{WGL} B^{\#}$. Thus from Lemma 2.3 and (4.6), we have

$$\begin{aligned}
V_a\Sigma_a V_a^* \leq_L V_b\Sigma_b V_b^* &\Rightarrow V_b V_b^* N^{-1}V_a\Sigma_a V_a^* N^{-1}V_b V_b^* \leq_L V_b\Sigma_b V_b^* \\
&\Rightarrow V_b U_b^* M U_a\Sigma_a U_a^* M U_b V_b^* \leq_L V_b\Sigma_b V_b^* \\
&\Rightarrow U_b^* M U_a\Sigma_a U_a^* M U_b \leq_L \Sigma_b \\
&\Rightarrow U_b U_b^* M U_a\Sigma_a U_a^* M U_b U_b^* \leq_L U_b\Sigma_b U_b^* \\
&\Rightarrow U_a\Sigma_a U_a^* \leq_L U_b\Sigma_b U_b^*. \qquad \square
\end{aligned}$$

THEOREM 4.5. [illegible] $A, B \in \mathbb{C}^{m\times n}$ [illegible]

$$A \leq_{WGL} B$$

[illegible]

$$\lambda_1(B_{MN}^+ A) \leq 1, \ R(A) \subseteq R(B), \text{ [illegible] } AB^{\#} = (AA^{\#})^{1/2}(BB^{\#})^{1/2}.$$

. According to Lemma 2.2 and the proof of Theorem 4.4 (using the symbols in Theorem 4.4), we can get

$$(AA^{\#})^{1/2} \leq_{WL} (BB^{\#})^{1/2} \Leftrightarrow M^{1/2}U_a\Sigma_a U_a^* M^{1/2} \leq_L M^{1/2}U_b\Sigma_b U_b^* M^{1/2}$$

$$\Leftrightarrow \begin{cases} \lambda_1(((M^{1/2}U_b)\Sigma_b(M^{1/2}U_b)^*)^+ M^{1/2}U_a\Sigma_a U_a^* M^{1/2}) \leq 1, \\ R(M^{1/2}U_a\Sigma_a U_a^* M^{1/2}) \subseteq R(M^{1/2}U_b\Sigma_b U_b^* M^{1/2}). \end{cases} \tag{4.13}$$

Observing (4.6), i.e., $V_a^* N^{-1} V_b = U_a^* M U_b$, and Lemma 2.4, we have

$$\begin{aligned} &\lambda_1(((M^{1/2}U_b)\Sigma_b(M^{1/2}U_b)^*)^+ M^{1/2}U_a\Sigma_a U_a^* M^{1/2}) \\ &= \lambda_1(M^{1/2}U_b\Sigma_b^{-1}U_b^* M U_a\Sigma_a U_a^* M^{1/2}) = \lambda_1(U_a^* M U_b\Sigma_b^{-1}U_b^* M U_a\Sigma_a) \\ &= \lambda_1(V_a^* N^{-1} V_b\Sigma_b^{-1}U_b^* M U_a\Sigma_a) = \lambda_1(N^{-1}V_b\Sigma_b^{-1}U_b^* M U_a\Sigma_a V_a^*) \\ &= \lambda_1(B_{MN}^+ A) \leq 1. \end{aligned} \tag{4.14}$$

Meanwhile, by (4.13), we can also get that there exists a matrix $H \in \mathbb{C}^{m\times m}$ such that

$$M^{1/2}U_a\Sigma_a U_a^* M^{1/2} = M^{1/2}U_b\Sigma_b U_b^* M^{1/2} H.$$

Therefore,

$$U_a\Sigma_a U_a^* M^{1/2} = U_b\Sigma_b U_b^* M^{1/2} H \text{ and } R(U_a\Sigma_a U_a^* M^{1/2}) \subseteq R(U_b\Sigma_b U_b^* M^{1/2}).$$

As a result,

$$R(U_a) \subseteq R(U_b),$$

which together with the MN-SVDs of A and B gives $R(A) \subseteq R(B)$. Then the proof is completed in view of Definition 4.2. □

The weighted star partial ordering of matrices was characterized by Liu using MN-SSVD in [16]. Its characteristics can be useful in comparing the WGL partial ordering with the weighted star partial ordering. The following result is from [16].

LEMMA 4.6. . $A, B \in \mathbb{C}^{m\times n}$. $r(B) = b > r(A) = a \geq 1$. $A \overset{\#}{\leq} B$ . . $U \in \mathbb{C}^{m\times m}$. $V \in \mathbb{C}^{n\times n}$. $U^*MU = I_m$. $V^*N^{-1}V = I_n$.

$$A = U\begin{pmatrix} \Sigma_a & 0 \\ 0 & 0 \end{pmatrix} V^*, \quad B = U\begin{pmatrix} \Sigma_a & 0 & 0 \\ 0 & \Sigma & 0 \\ 0 & 0 & 0 \end{pmatrix} V^*, \tag{4.15}$$

. $\Sigma_a \in \mathbb{C}_>^a$. $\Sigma \in \mathbb{C}_>^{b-a}$

The following theorem is a straightforward consequence of Lemma 4.6, Definition 4.1, and Definition 4.2.

THEOREM 4.7. . $A, B \in \mathbb{C}^{m\times n}$ . .

. $A \overset{\#}{\leq} B$, . . $A \leq_{WGL} B$.

In the next two theorems, we will study WGL partial ordering by WPD and discuss the characteristic for SWPD via WGL partial ordering.

THEOREM 4.8. Let $A, B \in \mathbb{C}^{m\times n}$ be such that $A = G_1E_1, B = G_2E_2$ are the weighted polar decompositions of A and B, respectively, where $G_1 = (AA^{\#})^{1/2}$ and $G_2 = (BB^{\#})^{1/2}$. Then

$$A \leq_{WGL} B \text{ if and only if } G_1 \leq_{WL} G_2 \text{ and } E_1 \overset{\#}{\leq} E_2.$$

Proof. From Definition 4.2, we have

$$A \leq_{WGL} B \Leftrightarrow \begin{cases} (AA^{\#})^{1/2} \leq_{WL} (BB^{\#})^{1/2}, \\ AB^{\#} = (AA^{\#})^{1/2}(BB^{\#})^{1/2} \end{cases} \Leftrightarrow \begin{cases} G_1 \leq_{WL} G_2, \\ AB^{\#} = (AA^{\#})^{1/2}(BB^{\#})^{1/2}. \end{cases}$$

However,

$$AB^{\#} = (AA^{\#})^{1/2}(BB^{\#})^{1/2} \Leftrightarrow G_1E_1E_2^{\#}G_2 = G_1G_2. \tag{4.16}$$

Premultiplying the second equality of (4.16) by $G_{1,MM}^{+}$ and postmultiplying it by $G_{2,MM}^{+}$, and observing the following equalities:

$$\begin{cases} G_1G_{1,MM}^{+} = G_{1,MM}^{+}G_1 = E_1E_1^{\#} = P_{R(A)}, \\ G_2G_{2,MM}^{+} = G_{2,MM}^{+}G_2 = E_2E_2^{\#} = P_{R(B)}, \end{cases} \tag{4.17}$$

we can get

$$G_{1,MM}^{+}G_1E_1E_2^{\#}G_2G_{2,MM}^{+} = G_{1,MM}^{+}G_1G_2G_{2,MM}^{+} \Leftrightarrow E_1E_2^{\#} = E_1E_1^{\#}E_2E_2^{\#}. \tag{4.18}$$

According to the fact that $G_1 \leq_{WL} G_2$ and the proof of Theorem 4.5, we have

$$R(A) \subseteq R(B),$$

which combined with (4.17) and (4.18) gives

$$P_{R(B)}P_{R(A)} = P_{R(A)} \Leftrightarrow E_2E_2^{\#}E_1E_1^{\#} = E_1E_1^{\#} \Leftrightarrow E_2E_1^{\#} = E_1E_1^{\#}. \tag{4.19}$$

Similarly, according to the fact that $G_1 \leq_{WL} G_2$, the proof of Theorem 4.5, the first equality of (4.16), and Lemma 4.3, we can get

$$R(A^{\#}) \subseteq R(B^{\#}).$$

Observing that $E_1^{\#}E_1 = P_{R(A^{\#})}$, $E_2^{\#}E_2 = P_{R(B^{\#})}$, and (4.19), we have

$$P_{R(B^{\#})}P_{R(A\#)} = P_{R(A\#)} \Leftrightarrow E_2^{\#}E_2E_1^{\#}E_1 = E_1^{\#}E_1 \Leftrightarrow E_2^{\#}E_1 = E_1^{\#}E_1.$$

Therefore, $E_1^{\#}E_2 = E_1^{\#}E_1$, which combined with (4.19) leads to $E_1 \overset{\#}{\leq} E_2$.

Conversely, according to $E_1 \overset{\#}{\leq} E_2$, we have $E_2E_1^{\#} = E_1E_1^{\#}$, which together with (4.17) gives $G_1E_1E_2^{\#}G_2 = G_1G_2$. Thus, the proof is completed. ∎

THEOREM 4.9. Let $A, B \in \mathbb{C}^{m\times n}$ be such that $AB^{\#} = (AA^{\#})^{1/2}(BB^{\#})^{1/2}$.

Proof. The necessity of the condition follows from Theorem 3.15. Now we prove the sufficiency.

Since $AB^{\#} = (AA^{\#})^{1/2}(BB^{\#})^{1/2}$, we have

$$BA^{\#} = (AB^{\#})^{\#} = ((AA^{\#})^{1/2}(BB^{\#})^{1/2})^{\#} = (BB^{\#})^{1/2}(AA^{\#})^{1/2}.$$

As a result,

$$((A+B)(A+B)^{\#})^{1/2} = (AA^{\#} + AB^{\#} + BA^{\#} + BB^{\#})^{1/2}$$

$$= (AA^{\#})^{1/2} + (BB^{\#})^{1/2}. \tag{4.20}$$

Then the following relations (4.21) and (4.22) hold:

$$A(A+B)^{\#} = (AA^{\#})^{1/2}((A+B)(A+B)^{\#})^{1/2}, \tag{4.21}$$

$$(BB^{\#})^{1/2} = ((A+B)(A+B)^{\#})^{1/2} - (AA^{\#})^{1/2}, \tag{4.22}$$

where the equality (4.22) implies

$$M(BB^{\#})^{1/2} = M((A+B)(A+B)^{\#})^{1/2} - M(AA^{\#})^{1/2}. \tag{4.23}$$

According to the proof of Theorem 4.4 (using the symbols of Theorem 4.4), we know that $M(BB^{\#})^{1/2} = MU_b\Sigma_b U_b^* M \in \mathbb{C}^m_{\geq}$, which together with (4.23) and Definition 4.1 leads to

$$(AA^{\#})^{1/2} \leq_{WL} ((A+B)(A+B)^{\#})^{1/2}. \tag{4.24}$$

Similarly, we can get that

$$B(A+B)^{\#} = (BB^{\#})^{1/2}((A+B)(A+B)^{\#})^{1/2}, \tag{4.25}$$

$$(BB^{\#})^{1/2} \leq_{WL} ((A+B)(A+B)^{\#})^{1/2}. \tag{4.26}$$

Then, according to (4.21), (4.24), (4.25), (4.26), and Definition 4.2, we conclude that

$$A \leq_{WGL} (A+B) \text{ and } B \leq_{WGL} (A+B),$$

and hence from Theorem 4.8, we have

$$E_1 \overset{\#}{\leq} E \text{ and } E_2 \overset{\#}{\leq} E, \tag{4.27}$$

where

$$E_1 = ((AA^{\#})^{1/2})^{+}_{MM} A = A((A^{\#}A)^{1/2})^{+}_{NN},$$

$$E_2 = ((BB^{\#})^{1/2})^{+}_{MM} B = B((B^{\#}B)^{1/2})^{+}_{NN},$$

$$E = (((A+B)(A+B)^{\#})^{1/2})^{+}_{MM}(A+B)$$

$$= (A+B)(((A+B)^{\#}(A+B))^{1/2})^{+}_{NN}.$$

According to the fact that $A = (AA^{\#})^{1/2}((AA^{\#})^{1/2})^{+}_{MM} A$ and (4.27), we can obtain that

$$AE^{\#} = (AA^{\#})^{1/2}E_1E_1^{\#} = (AA^{\#})^{1/2}((AA^{\#})^{1/2})^{+}_{MM} AA^{\#}((AA^{\#})^{1/2})^{+}_{MM}$$

$$= (AA^{\#})^{1/2}(AA^{\#})^{1/2}((AA^{\#})^{1/2})^{+}_{MM} = (AA^{\#})^{1/2}.$$

Therefore,

$$AE^{\#}E = (AA^{\#})^{1/2}E. \tag{4.28}$$

Meanwhile, according to the fact that

$$A = G_1E_1 \;\Leftrightarrow\; A^{\#} = E_1^{\#}G_1 \;\Rightarrow\; R(A^{\#}) \subseteq R(E_1^{\#})$$

and (4.27), we can get $R(A^{\#}) \subseteq R(E^{\#})$, which combined with (4.28) gives

$$A = (AA^{\#})^{1/2}E. \tag{4.29}$$

Similarly, according to $E_1 = A((A^{\#}A)^{1/2})^{+}_{NN}$, we can derive that

$$EE^{\#}A = E(A^{\#}A)^{1/2} \;\Leftrightarrow\; A = E(A^{\#}A)^{1/2},$$

and according to $E_2 = ((BB^{\#})^{1/2})^{+}_{MM}B = B((B^{\#}B)^{1/2})^{+}_{NN}$, we can derive that

$$BE^{\#} = (BB^{\#})^{1/2} \;\Leftrightarrow\; BE^{\#}E = (BB^{\#})^{1/2}E \;\Leftrightarrow\; B = (BB^{\#})^{1/2}E, \tag{4.30}$$

$$E^{\#}B = (B^{\#}B)^{1/2} \;\Leftrightarrow\; EE^{\#}B = E(B^{\#}B)^{1/2} \;\Leftrightarrow\; B = E(B^{\#}B)^{1/2}. \tag{4.31}$$

Further, since $AE^{\#} = EA^{\#} = (AA^{\#})^{1/2}$, we have $R((AA^{\#})^{1/2}) \subseteq R(E)$. Thus, noting the fact that $R((AA^{\#})^{1/2}) = R(A)$, we can get

$$R(A) \subseteq R(E). \tag{4.32}$$

Similarly, we can get

$$R(B) \subseteq R(E). \tag{4.33}$$

In view of (4.29), (4.30), (4.32), (4.33), and Theorem 3.15, we can see that the sufficiency of the condition holds. □

5. Methods for computing the WPD. From Lemma 2.1 and Theorem 3.8, the generalized positive semidefinite polar factor G can be computed by

$$\begin{aligned} G &= (AA^{\#})^{1/2} = (U_r\Sigma V_r^* N^{-1} V_r \Sigma U_r^* M)^{1/2} \\ &= (U_r\Sigma U_r^* M U_r \Sigma U_r^* M)^{1/2} = U_r\Sigma U_r^* M. \end{aligned} \tag{5.1}$$

Similarly, H can be computed by

$$H = (A^{\#}A)^{1/2} = N^{-1}V_r\Sigma V_r^*. \tag{5.2}$$

Then, we have

$$\begin{aligned} E &= ((AA^{\#})^{1/2})^{+}_{MM}A = A((A^{\#}A)^{1/2})^{+}_{NN} \\ &= (U_r\Sigma U_r^* M)^{+}_{MM}U_r\Sigma V_r^* = U_r\Sigma V_r^*(N^{-1}V_r\Sigma V_r^*)^{+}_{NN} \\ &= U_r\Sigma^{-1}U_r^* M U_r\Sigma V_r^* = U_r\Sigma V_r^* N^{-1}V_r\Sigma^{-1}V_r^* \\ &= U_r V_r^*. \end{aligned} \tag{5.3}$$

Thus, the WPD can be computed by using MN-SVD.

5.1. Method based on MN-SVD. The method for computing WPD based on MN-SVD can be described by the following computational procedure:

1. Compute the MN-SVD (2.8) of $A \in \mathbb{C}_r^{m\times n}$, forming only the first r columns U_r and V_r of U and V, respectively;
2. Form G, H, and E according to (5.1), (5.2), and (5.3), respectively.

The algorithm and programs for (2.8) can be obtained according to the proof of Theorem 5.2.2 in [24] (i.e., Lemma 2.1 in this paper) or Theorem 3 in [23] and the algorithm and programs for singular value decomposition (SVD).

The values of the weighted unitary polar factor E and the generalized positive semidefinite polar factors G, H obtained above are accurate. However, it is unnecessary and expensive to calculate their exact values for most applications [9]. The following subsection will develop an alternative method for computing WPD, which is more effective in practice.

5.2. An iterative method. Consider the following iteration:

$$X_0 = A \in \mathbb{C}_r^{m\times n}, \tag{5.4a}$$

$$X_{k+1} = \frac{1}{2}\left(X_k + (X_{k,MN}^{+})^{\#}\right), \quad k = 0, 1, 2, \ldots . \tag{5.4b}$$

We claim that the sequence X_k converges to the weighted unitary polar factor E of A's WPD. To prove this, we make use of MN-SVD introduced in Lemma 2.1. Define

$$D_k = U^* M X_k N^{-1} V. \tag{5.5}$$

Then, from Lemma 2.1 and (5.4), we obtain

$$D_0 = U^* M X_0 N^{-1} V = U^* M A N^{-1} V = \begin{pmatrix} \Sigma & 0 \\ 0 & 0 \end{pmatrix}, \tag{5.6}$$

$$D_{k+1} = \frac{1}{2}(D_k + U^* M (X_{k,MN}^{+})^{\#} N^{-1} V). \tag{5.7}$$

According to Lemma 2.5, we can get

$$\begin{aligned} U^* M (X_{k,MN}^{+})^{\#} N^{-1} V &= U^* M M^{-1} (X_{k,MN}^{+})^* N N^{-1} V = U^* (X_{k,MN}^{+})^* V \\ &= U^* (N^{-1/2} (M^{1/2} X_k N^{-1/2})^{+} M^{1/2})^* V \\ &= U^* M^{1/2} ((M^{1/2} X_k N^{-1/2})^{+})^* N^{-1/2} V, \end{aligned} \tag{5.8}$$

while

$$\begin{aligned} (M^{-1/2} D_k N^{1/2})_{MN}^{+} &= N^{-1/2} (M^{1/2} M^{-1/2} D_k N^{1/2} N^{-1/2})^{+} M^{1/2} \\ &= N^{-1/2} D_k^{+} M^{1/2}, \end{aligned} \tag{5.9}$$

which implies

$$N^{1/2} (M^{-1/2} D_k N^{1/2})_{MN}^{+} M^{-1/2} = D_k^{+}. \tag{5.10}$$

Meanwhile, according to (5.5), Lemma 2.5, and Lemma 2.4, we have

(5.11)
$$\begin{aligned} N^{1/2}(M^{-1/2}D_kN^{1/2})^+_{MN}M^{-1/2} &= N^{1/2}(M^{-1/2}U^*MX_kN^{-1}VN^{1/2})^+_{MN}M^{-1/2} \\ &= N^{1/2}[N^{-1/2}(M^{1/2}M^{-1/2}U^*MX_kN^{-1}VN^{1/2}N^{-1/2})^+M^{1/2}]M^{-1/2} \\ &= (U^*M^{1/2}M^{1/2}X_kN^{-1/2}N^{-1/2}V)^+ \\ &= (N^{-1/2}V)^*(M^{1/2}X_kN^{-1/2})^+(U^*M^{1/2})^* \\ &= V^*N^{-1/2}(M^{1/2}X_kN^{-1/2})^+M^{1/2}U, \end{aligned}$$

which together with (5.10) and (5.8) gives

$$U^*M(X^+_{k,MN})^{\#}N^{-1}V = (D^+_k)^*. \tag{5.12}$$

Then, (5.7) can be rewritten as

$$D_{k+1} = \frac{1}{2}(D_k + (D^+_k)^*). \tag{5.13}$$

Using the method from [4, 9], we can conclude that

$$D_k \to \begin{pmatrix} I_r & 0 \\ 0 & 0 \end{pmatrix}, \quad k \to \infty. \tag{5.14}$$

Furthermore, by (5.5), we can obtain

$$UD_kV^* = UU^*MX_kN^{-1}VV^* = UU^{-1}X_k(V^*)^{-1}V^* = X_k. \tag{5.15}$$

Therefore,

$$X_k \to U\begin{pmatrix} I_r & 0 \\ 0 & 0 \end{pmatrix}V^* = U_rV_r^* = E, \quad k \to \infty. \tag{5.16}$$

Then the sequence X_k converges to the weighted unitary polar factor E.

In addition, similarly as in the discussions in [9], we can get

$$D_{k+1} - \begin{pmatrix} I_r & 0 \\ 0 & 0 \end{pmatrix} = \frac{1}{2}\left(D_k - \begin{pmatrix} I_r & 0 \\ 0 & 0 \end{pmatrix}\right)D^+_k\left(D_k - \begin{pmatrix} I_r & 0 \\ 0 & 0 \end{pmatrix}\right). \tag{5.17}$$

Premultiplying and postmultiplying the equation (5.17) by U and V^*, respectively, and considering (5.15), we have

$$X_{k+1} - E = \frac{1}{2}U\left(D_k - \begin{pmatrix} I_r & 0 \\ 0 & 0 \end{pmatrix}\right)D^+_k\left(D_k - \begin{pmatrix} I_r & 0 \\ 0 & 0 \end{pmatrix}\right)V^*, \tag{5.18}$$

which combined with (2.2) leads to

$$\|X_{k+1}-E\|_{MN} = \left\|\frac{1}{2}U\left(D_k-\begin{pmatrix} I_r & 0\\ 0 & 0\end{pmatrix}\right)D_k^+\left(D_k-\begin{pmatrix} I_r & 0\\ 0 & 0\end{pmatrix}\right)V^*\right\|_{MN} \tag{5.19}$$

$$= \frac{1}{2}\left\|M^{1/2}U\left(D_k-\begin{pmatrix} I_r & 0\\ 0 & 0\end{pmatrix}\right)D_k^+\left(D_k-\begin{pmatrix} I_r & 0\\ 0 & 0\end{pmatrix}\right)V^*N^{-1/2}\right\|_2$$

$$= \frac{1}{2}\left\|\left(D_k-\begin{pmatrix} I_r & 0\\ 0 & 0\end{pmatrix}\right)D_k^+\left(D_k-\begin{pmatrix} I_r & 0\\ 0 & 0\end{pmatrix}\right)\right\|_2$$

$$= \frac{1}{2}\max_{1\le i\le r}\left(\frac{(\sigma_i(X_k)-1)^2}{\sigma_i(X_k)}\right).$$

Similarly,

$$\|X_{k+1}-E\|_{F(MN)} = \frac{1}{2}\left\|\left(D_k-\begin{pmatrix} I_r & 0\\ 0 & 0\end{pmatrix}\right)D_k^+\left(D_k-\begin{pmatrix} I_r & 0\\ 0 & 0\end{pmatrix}\right)\right\|_F \tag{5.20}$$

$$= \frac{1}{2}\left(\sum_{i=1}^{r}\left(\frac{(\sigma_i(X_k)-1)^2}{\sigma_i(X_k)}\right)^2\right)^{1/2},$$

where $\sigma_i(X_k)$ is the nonzero (M,N) weighted singular value of X_k. Thus, we have the following theorem.

THEOREM 5.1. [illegible] $A\in\mathbb{C}_r^{m\times n}$ [illegible] (5.4). [illegible] X_k [illegible] E [illegible] A' [illegible] (5.19) [illegible] (5.20) [illegible].

5.3. Accelerating convergence. Similar to the explanations in [4, 9], the quadratic convergence of iteration (5.4) ensures rapid convergence in the final stages of the iteration. Initially, however, the speed of convergence can be inordinately slow; hence it is necessary to scale the matrix A before the iteration.

5.3.1. The theoretical result. Higham [9] provides a quite good method to scale the matrix A for computing the polar decomposition; the method can be applied to the iteration (5.4).

Consider the scaling $X_k\to\gamma_k X_k, \gamma_k>0$. From (5.4), we have

$$X_0 = A\in\mathbb{C}_r^{m\times n}, \tag{5.21a}$$

$$X_{k+1} = \frac{1}{2}\left(\gamma_k X_k+\frac{1}{\gamma_k}(X_{k,MN}^+)^{\#}\right),\quad k=0,1,2,\ldots. \tag{5.21b}$$

In this case, the equalities (5.19) and (5.20) are changed to

$$\|X_{k+1}-E\|_{MN} = \frac{1}{2}\max_{1\le i\le r}\left(\frac{(\gamma_k\sigma_i(X_k)-1)^2}{\gamma_k\sigma_i(X_k)}\right), \tag{5.22}$$

$$\|X_{k+1}-E\|_{F(MN)} = \frac{1}{2}\left(\sum_{i=1}^{r}\left(\frac{(\gamma_k\sigma_i(X_k)-1)^2}{\gamma_k\sigma_i(X_k)}\right)^2\right)^{1/2}. \tag{5.23}$$

Applying the method introduced in [22], we can show that the optimal parameter is

$$\gamma_{opt}^{(k)} = (\sigma_1(X_k)\sigma_r(X_k))^{-1/2}. \tag{5.24}$$

However, it is not feasible to compute $\gamma_{opt}^{(k)}$ exactly at each stage, since this would require computation of the extremal (M, N) weighted singular values of X_k, but a good approximation to $\gamma_{opt}^{(k)}$ can be computed at negligible cost.

5.3.2. The practical algorithm. Define

$$\alpha_k = \sqrt{\left\|M^{1/2}X_kN^{-1/2}\right\|_1 \left\|M^{1/2}X_kN^{-1/2}\right\|_\infty},$$

$$\beta_k = \sqrt{\left\|N^{1/2}X_{k,MN}^{+}M^{-1/2}\right\|_1 \left\|N^{1/2}X_{k,MN}^{+}M^{-1/2}\right\|_\infty},$$

where $\|X\|_1$ and $\|X\|_\infty$ denote the 1-norm and ∞-norm (see, e.g., [2]) of the matrix X, respectively. According to the introductions in [4, 9], the optimal parameter $\gamma_{opt}^{(k)}$ can be replaced by $\gamma_{pra}^{(k)} = \sqrt{\beta_k/\alpha_k}$. (A detailed proof can be found in [9].) As a result, we have the following practical algorithm.

Given weight matrices M and N;
$X_0 = A \in \mathbb{C}_r^{m\times n}$,
$Y_k = X_{k,MN}^{+}, \quad k = 0, 1, 2, \ldots$.
if $\|X_k - E\|_{MN} \le \varepsilon$ (a very small positive number),
$\gamma_k = 1$,
else
$\alpha_k = \sqrt{\left\|M^{1/2}X_kN^{-1/2}\right\|_1 \left\|M^{1/2}X_kN^{-1/2}\right\|_\infty}$,
$\beta_k = \sqrt{\left\|N^{1/2}Y_kM^{-1/2}\right\|_1 \left\|N^{1/2}Y_kM^{-1/2}\right\|_\infty}$,
$\gamma_k = \sqrt{\frac{\beta_k}{\alpha_k}}$,
$X_{k+1} = \frac{1}{2}\left(\gamma_k X_k + \frac{1}{\gamma_k}Y_k^{\#}\right)$.
Until converged.

Thus, we have $E \approx X = X_{k+1}$. In order to compute the approximate solution of the generalized positive semidefinite polar factor H (G can be discussed similarly; hereafter we study only H) and ensure that it would satisfy $H^{\#} = H$, we take the following matrix K as an AGPSD polar factor of H:

$$K = \frac{1}{2}(X^{\#}A + A^{\#}X). \tag{5.25}$$

In section 6, we will discuss the error bounds for the AGPSD polar factor K.

5.4. Numerical experiment. Next we use a testing matrix from [4] to test the iterative methods given above. The matrix is

$$A = \begin{pmatrix} B + C & 0 \\ 0 & 0 \end{pmatrix} \in \mathbb{C}_{35}^{38\times 36},$$

where

$$B = \mathrm{diag}(1, 2^4, 3^4, \cdots, 35^4) \times 10,$$

$$C = \begin{pmatrix} sum(\quad(1,10)) & \cdots & \quad(\quad(1,10)) \\ \vdots & \ddots & \vdots \\ \quad(\quad(1,10)) & \cdots & \quad(\quad(1,10)) \end{pmatrix} \times 10^6 \in \mathbb{C}^{35\times 35},$$

and the stopping criterion is

$$\|X_{k+1} - E\|_{MN} \leq 2 \times 10^{-8}, \tag{5.26}$$

in which the weighted unitary polar factor E is computed by MN-SVD.

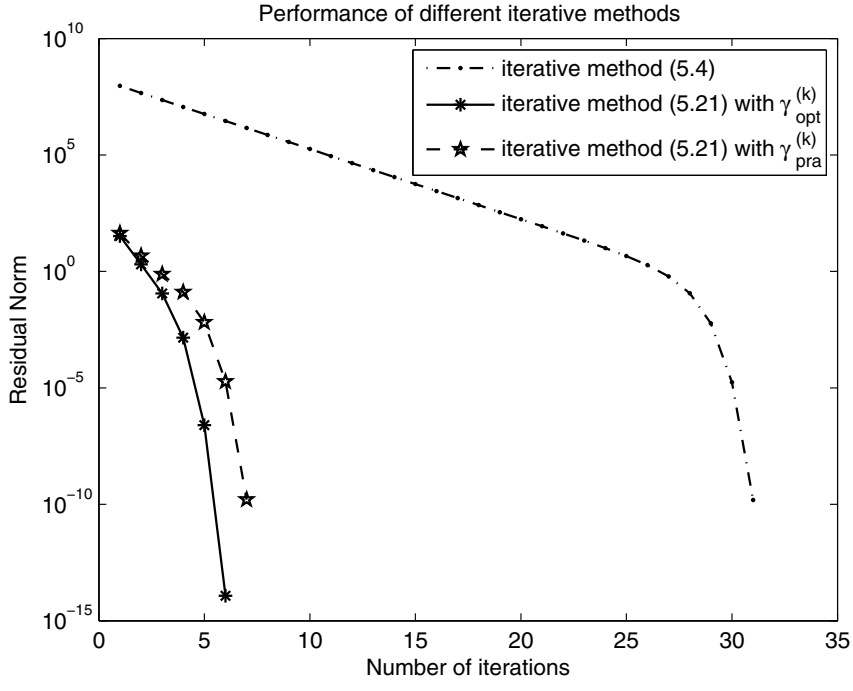

FIG. 5.1. *Performance of different iterative methods.*

Moreover, in order to obtain the reasonable weight matrices, a method to derive the Hermitian positive definite matrix is introduced as follows.

1. Generate an $m \times m$ random array with normal distribution: $M_1 = \quad(m, m)$;
2. Compute the covariance matrix of the random array: $M_2 = cov(M_1)$;
3. Form the $m \times m$ Hermitian positive definite matrix: $M = M_2 + eye(m) * m$; where the commands can be found in detail in any book on MATLAB.

Figure 5.1 describes the comparisons among the above iterative methods. According to the stopping criteria (5.26), the iterative method (5.4) needs to iterate 31 times, while the iterative method (5.21) with $\gamma_{opt}^{(k)}$ needs 6 times and the iterative method (5.21) with $\gamma_{pra}^{(k)}$ needs 7 times.

6. Error bounds for AGPSD polar factor. In this section, we will present the error bounds for the AGPSD polar factor K defined in (5.25) in weighted unitary invariant norm and weighted Frobenius norm, respectively.

THEOREM 6.1. Let $A \in \mathbb{C}_r^{m\times n}$ [illegible] 3.8. [illegible] $X \in \mathbb{C}^{m\times n}$ [illegible] E [illegible] K [illegible] (5.25), [illegible]

$$\|H-K\|_{(NN)} \le \|A\|_{MN}\,\|X-E\|_{(MN)}. \tag{6.1}$$

[illegible]. By (5.2), (5.3), and (2.10), we can obtain

$$2H = E^{\#}A + A^{\#}E,$$

which combined with (5.25) implies

$$\begin{aligned} H-K &= \frac{1}{2}(2H - X^{\#}A - A^{\#}X) = \frac{1}{2}(E^{\#}A + A^{\#}E - X^{\#}A - A^{\#}X) \\ &= \frac{1}{2}\left((E^{\#}-X^{\#})A + A^{\#}(E-X)\right), \end{aligned} \tag{6.2}$$

which together with (2.4) and (2.2) gives

$$\begin{aligned} \|H-K\|_{(NN)} &= \frac{1}{2}\left\|(E^{\#}-X^{\#})A + A^{\#}(E-X)\right\|_{(NN)} \\ &= \frac{1}{2}\left\|N^{1/2}\left((E^{\#}-X^{\#})A + A^{\#}(E-X)\right)N^{-1/2}\right\| \\ &\le \frac{1}{2}\left(\left\|N^{1/2}(E^{\#}-X^{\#})AN^{-1/2}\right\| + \left\|N^{1/2}A^{\#}(E-X)N^{-1/2}\right\|\right) \\ &= \frac{1}{2}\left\|N^{-1/2}(E-X)^{*}M^{1/2}M^{1/2}AN^{-1/2}\right\| \\ &\quad + \frac{1}{2}\left\|N^{-1/2}A^{*}M^{1/2}M^{1/2}(E-X)N^{-1/2}\right\| \\ &\le \frac{1}{2}\left\|N^{-1/2}(E-X)^{*}M^{1/2}\right\|\left\|M^{1/2}AN^{-1/2}\right\|_2 \\ &\quad + \frac{1}{2}\left\|N^{-1/2}A^{*}M^{1/2}\right\|_2\left\|M^{1/2}(E-X)N^{-1/2}\right\| \\ &= \|A\|_{MN}\,\|E-X\|_{(MN)} = \|A\|_{MN}\,\|E-X\|_{(MN)}. \end{aligned} \tag{6.3}$$

□

THEOREM 6.2. Let $A \in \mathbb{C}_r^{m\times n}$ [illegible] 3.8. [illegible] $X \in \mathbb{C}^{m\times n}$ [illegible] E [illegible] $R(X^{\#}) = R(A^{\#})$ [illegible] K [illegible] (5.25), [illegible]

$$\begin{aligned} \|H-K\|_{F(NN)} &\le \frac{1}{2}\|A\|_{MN}\left\|(E-X)^{\#}(E-X)\right\|_{F(NN)} \\ &\quad + \frac{1}{2}\left(\|A\|_{MN} - \frac{1}{\left\|A_{MN}^{+}\right\|_{NM}}\right)\sqrt{\|X^{\#}(E-X)\|_{F(NN)}^2 - \frac{1}{r}\left|\mathrm{tr}[X^{\#}(E-X)]\right|^2}. \end{aligned} \tag{6.4}$$

. From Theorem 3.8 and (5.2), we can obtain

$$R(A^{\#}) = R(E^{\#}) = R(H) = R(N^{-1}V_r).$$

Then

$$R(X^{\#}) = R(A^{\#}) = R(E^{\#}) = R(H) = R(N^{-1}V_r),$$

which combined with Lemma 3.3 and (5.3) leads to

$$X^{\#}X = E^{\#}E = N^{-1}V_rV_r^*. \tag{6.5}$$

According to (6.2) and (3.12), and observing the fact that $H^{\#} = H$, we have

$$\begin{aligned} H - K &= \frac{1}{2}(E^{\#}A + A^{\#}E - X^{\#}A - A^{\#}X) \\ &= \frac{1}{2}(E^{\#}EH + HE^{\#}E - X^{\#}EH - HE^{\#}X) \\ &= \frac{1}{2}H(E^{\#}E - E^{\#}X - X^{\#}E + X^{\#}X) \\ &\quad + \frac{1}{2}(HX^{\#}E - HX^{\#}X + E^{\#}EH - X^{\#}EH) \\ &= \frac{1}{2}\left(H(E-X)^{\#}(E-X) + HX^{\#}(E-X) + (E^{\#} - X^{\#})EH\right), \end{aligned} \tag{6.6}$$

whereas if $(E^{\#} - X^{\#})E = E^{\#}E - X^{\#}E = X^{\#}X - X^{\#}E = X^{\#}(X - E)$, then

$$\begin{aligned} &\|H - K\|_{F(NN)} \\ &= \frac{1}{2}\left\|H(E-X)^{\#}(E-X) + HX^{\#}(E-X) - X^{\#}(E-X)H\right\|_{F(NN)} \\ &\le \frac{1}{2}\left\|N^{1/2}H(E-X)^{\#}(E-X)N^{-1/2}\right\|_F \\ &\quad + \frac{1}{2}\left\|N^{1/2}(HX^{\#}(E-X) - X^{\#}(E-X)H)N^{-1/2}\right\|_F \\ &\le \frac{1}{2}\|H\|_{NN}\left\|(E-X)^{\#}(E-X)\right\|_{F(NN)} \\ &\quad + \frac{1}{2}\left\|N^{1/2}(HX^{\#}(E-X) - X^{\#}(E-X)H)N^{-1/2}\right\|_F. \end{aligned} \tag{6.7}$$

However, considering (5.2) and the fact that $V^*N^{-1}V = (N^{-1/2}V)^*N^{-1/2}V = I_n$, we have

$$\begin{aligned} &\left\|N^{1/2}(HX^{\#}(E-X) - X^{\#}(E-X)H)N^{-1/2}\right\|_F \\ &= \left\|N^{1/2}(N^{-1}V_r\Sigma V_r^*X^{\#}(E-X) - X^{\#}(E-X)N^{-1}V_r\Sigma V_r^*)N^{-1/2}\right\|_F \\ &= \left\|N^{-1/2}V_r\Sigma V_r^*X^{\#}(E-X)N^{-1/2} - N^{1/2}X^{\#}(E-X)N^{-1}V_r\Sigma V_r^*N^{-1/2}\right\|_F \\ &= \left\|V^*N^{-1}V_r\Sigma V_r^*X^{\#}(E-X)N^{-1}V - V^*X^{\#}(E-X)N^{-1}V_r\Sigma V_r^*N^{-1}V\right\|_F, \end{aligned}$$

which together with $V_r^* N^{-1} V_r = I_r$, $V_{n-r}^* N^{-1} V_r = V_r^* N^{-1} V_{n-r} = 0$, (5.3), and (6.5) gives

$$\begin{aligned}(6.8)\quad &\left\| N^{1/2}(HX^{\#}(E-X) - X^{\#}(E-X)H)N^{-1/2} \right\|_F \\ &\qquad = \left\| \Sigma V_r^* X^{\#}(E-X)N^{-1}V_r - V_r^* X^{\#}(E-X)N^{-1}V_r \Sigma \right\|_F .\end{aligned}$$

Let $C = V_r^* X^{\#}(E-X)N^{-1}V_r = (c_{ij})$. Then (6.8) can be rewritten as

$$\begin{aligned}(6.9)\quad &\left\| N^{1/2}(HX^{\#}(E-X) - X^{\#}(E-X)H)N^{-1/2} \right\|_F^2 = \|\Sigma C - C\Sigma\|_F^2 \\ &\qquad = \sum_{i,j=1}^{r} ((\sigma_i - \sigma_j)|c_{ij}|)^2 \le (\sigma_1 - \sigma_r)^2 \left(\|C\|_F^2 - \sum_{i=1}^{r} (|c_{ii}|)^2 \right).\end{aligned}$$

Since $\operatorname{tr}(AB) = \operatorname{tr}(BA)$ and $N^{-1}V_r V_r^* X^{\#} = X^{\#}, N^{-1}V_r V_r^* E^{\#} = E^{\#}$, we have

$$\begin{aligned}(6.10)\quad &\sum_{i=1}^{r} (|c_{ii}|)^2 \ge \frac{1}{r} \left| \sum_{i=1}^{r} c_{ii} \right|^2 = \frac{1}{r} |\operatorname{tr}(C)|^2 = \frac{1}{r} \left| \operatorname{tr}(V_r^* X^{\#}(E-X)N^{-1}V_r) \right|^2 \\ &\qquad = \frac{1}{r} \left| \operatorname{tr}(N^{-1}V_r V_r^* X^{\#}(E-X)) \right|^2 = \frac{1}{r} \left| \operatorname{tr}(X^{\#}(E-X)) \right|^2\end{aligned}$$

and

$$\begin{aligned}(6.11)\quad \|C\|_F^2 &= \operatorname{tr}(C^*C) = \operatorname{tr}\left((V_r^* X^{\#}(E-X)N^{-1}V_r)^* V_r^* X^{\#}(E-X)N^{-1}V_r \right) \\ &= \operatorname{tr}\left(V_r^* N^{-1}(E-X)^*(X^{\#})^* V_r V_r^* X^{\#}(E-X)N^{-1}V_r \right) \\ &= \operatorname{tr}\left(N^{-1}V_r V_r^* N^{-1}(E-X)^* M X N^{-1} V_r V_r^* X^{\#}(E-X) \right) \\ &= \operatorname{tr}\left(N^{-1}V_r V_r^* (E-X)^{\#} X X^{\#}(E-X) \right) \\ &= \operatorname{tr}\left((E-X)^{\#} X X^{\#}(E-X) \right).\end{aligned}$$

Then, observing (2.5) and (6.11), we have

$$(6.12)\qquad \|C\|_F^2 = \left\| X^{\#}(E-X) \right\|_{F(NN)}^2 .$$

Therefore, together with (6.12), (6.10), (6.9), and (6.7), we can conclude that

$$\begin{aligned}(6.13)\quad \|H-K\|_{F(NN)} &\le \frac{1}{2} \|H\|_{NN} \left\| (E-X)^{\#}(E-X) \right\|_{F(NN)} \\ &\quad + \frac{1}{2}(\sigma_1 - \sigma_r) \sqrt{ \|X^{\#}(E-X)\|_{F(NN)}^2 - \frac{1}{r} |\operatorname{tr}(X^{\#}(E-X))|^2 }.\end{aligned}$$

The desired result follows from $\|A\|_{MN} = \|H\|_{NN} = \sigma_1$ and $\left\| A_{MN}^{+} \right\|_{MN} = \frac{1}{\sigma_r}$. ∎

If $R = A - XK$ is defined as the residual of A about X, then we have the following theorem.

THEOREM 6.3. [illegible] 6.2 [illegible]

$$(6.14)\qquad \|H-K\|_{F(NN)} \le \sqrt{ \|A\|_{MN}^2 \|X^{\#}(X-E)\|_{F(NN)}^2 - \|X^{\#}R\|_{F(NN)}^2 }.$$

. According to (5.25) and the fact that $X^{\#}XH = HX^{\#}X = H$, we have

$$H - K = \frac{1}{2}(X^{\#}XH + HX^{\#}X - X^{\#}EH - HE^{\#}X) \tag{6.15}$$
$$= \frac{1}{2}\left(H(X-E)^{\#}X + X^{\#}(X-E)H\right).$$

Meanwhile, from $R = A - XK$, we can get

$$X^{\#}R = X^{\#}EH - \frac{1}{2}X^{\#}X(X^{\#}EH + HE^{\#}X) \tag{6.16}$$
$$= \frac{1}{2}(2X^{\#}EH - X^{\#}XX^{\#}EH - X^{\#}XHE^{\#}X)$$
$$= \frac{1}{2}(X^{\#}EH - HE^{\#}X) = \frac{1}{2}(X^{\#}EH - H + H - HE^{\#}X)$$
$$= \frac{1}{2}(X^{\#}EH - X^{\#}XH + HX^{\#}X - HE^{\#}X)$$
$$= \frac{1}{2}\left(H(X^{\#} - E^{\#})X - X^{\#}(X-E)H\right).$$

In addition, we have the following fact:

$$\|Z\|^2_{F(NN)} = \left\|N^{1/2}ZN^{-1/2}\right\|_F^2 = \left\|\frac{1}{2}(N^{1/2}ZN^{-1/2} + N^{-1/2}Z^*N^{1/2})\right\|_F^2$$
$$+ \left\|\frac{1}{2}(N^{1/2}ZN^{-1/2} - N^{-1/2}Z^*N^{1/2})\right\|_F^2.$$

Setting $Z = X^{\#}(X-E)H$ and considering (6.15), (6.16), we have

$$\|H-K\|^2_{F(NN)} = \left\|\frac{1}{2}(Z^{\#} + Z)\right\|^2_{F(NN)} = \left\|\frac{1}{2}(N^{1/2}(Z^{\#} + Z)N^{-1/2})\right\|_F^2 \tag{6.17}$$
$$= \left\|\frac{1}{2}(N^{-1/2}Z^*N^{1/2} + N^{1/2}ZN^{-1/2})\right\|_F^2$$
$$= \|Z\|^2_{F(NN)} - \left\|\frac{1}{2}(N^{-1/2}Z^*N^{1/2} - N^{1/2}ZN^{-1/2})\right\|_F^2$$
$$= \|Z\|^2_{F(NN)} - \left\|X^{\#}R\right\|^2_{F(NN)},$$

i.e.,

$$\|H-K\|^2_{F(NN)} = \left\|X^{\#}(X-E)H\right\|^2_{F(NN)} - \left\|X^{\#}R\right\|^2_{F(NN)} \tag{6.18}$$
$$\leq \|H\|^2_{NN}\left\|X^{\#}(X-E)\right\|^2_{F(NN)} - \left\|X^{\#}R\right\|^2_{F(NN)}.$$

Then, the proof is completed by noting that $\|A\|_{MN} = \|H\|_{NN} = \sigma_1$. ∎

7. Conclusions. In this paper, we prove the unique WPD theorem and derive some necessary and sufficient conditions for SWPD. A new partial ordering of matrices called WGL partial ordering is also defined and studied. Using the new partial ordering, we present a characteristic of SWPD. In addition, the methods for computing WPD and the error bounds for the AGPSD polar factor are also discussed. However, this paper is not involved with various applications of WPD. As we all know, the (generalized) polar decomposition has a wide range of applications. Therefore, it is of interest to probe the applications of WPD with the development of research on the weighted generalized inverses of matrices, weighted least squares problems, weighted optimization problem, and so on. This will be our future work.

Acknowledgments. The authors would like to thank the editor, Professor R.-C. Li, and two anonymous referees for their valuable comments and helpful suggestions, which improved the presentation. The second author also wishes to thank Professor J. Hauke for sending him reference [7].

CONVERGENCE OF STATIONARY ITERATIVE METHODS FOR HERMITIAN SEMIDEFINITE LINEAR SYSTEMS AND APPLICATIONS TO SCHWARZ METHODS*

ANDREAS FROMMER†, REINHARD NABBEN‡, AND DANIEL B. SZYLD§

Abstract. A simple proof is presented of a quite general theorem on the convergence of stationary iterations for solving singular linear systems whose coefficient matrix is Hermitian and positive semidefinite. In this manner, elegant proofs are obtained of some known convergence results, including the necessity of the P-regular splitting result due to Keller, as well as recent results involving generalized inverses. Other generalizations are also presented. These results are then used to analyze the convergence of several versions of algebraic additive and multiplicative Schwarz methods for Hermitian positive semidefinite systems.

Key words. linear systems, Hermitian semidefinite systems, singular systems, stationary iterative methods, seminorm, convergence analysis, algebraic Schwarz methods

1. Introduction.

We consider the linear system

$$Ax = b, \tag{1.1}$$

where the coefficient matrix $A \in \mathbb{C}^{n\times n}$ is assumed to be singular and Hermitian positive semidefinite. Denoting by $\mathrm{Null}(A)$ the nullspace of A and by $\mathrm{Range}(A)$ its range, we assume that $b \in \mathrm{Range}(A)$. This implies that the solution set of (1.1) is nonempty and it is given as an affine space $x^* + \mathrm{Null}(A)$ for some $x^* \in \mathbb{C}^n$ solution of (1.1).

If A is large and sparse, iterative methods for solving (1.1) are the standard approach. In this paper, we focus on stationary iterative methods, including, for example, certain algebraic multigrid methods and additive and multiplicative Schwarz methods. Sometimes, these iterations are accelerated by using them as preconditioners to Krylov subspace methods like conjugate gradients. While we do not consider the latter aspect in any detail in this work, let us just mention that one usually assumes convergence of the preconditioner as a prerequisite in this context, so our work is relevant in this case as well.

We consider the very general situation in which we are given an iteration matrix H for (1.1) of the form

$$H = I - \widetilde{M}A, \tag{1.2}$$

where $\widetilde{M} \in \mathbb{C}^{n\times n}$ is a matrix which might be singular but is injective on Range(A), i.e.,

$$\text{Null}(\widetilde{M}A) = \text{Null}(A). \tag{1.3}$$

The matrices H and $\widetilde{M}$ induce the iteration

$$x^{k+1} = Hx^k + \widetilde{M}b. \tag{1.4}$$

Since any solution x^* of (1.1) satisfies $\widetilde{M}Ax^* = \widetilde{M}b$, we see that each such x^* is a fixed point of the iteration (1.4). Conversely, if x^* is a fixed point of (1.4), then $0 = -\widetilde{M}Ax^* + \widetilde{M}b$, and since $\widetilde{M}$ is injective on Range(A) we get $Ax^* = b$. We conclude that under the conditions (1.2) and (1.3), x^* is a solution of (1.1) if and only if x^* is a fixed point of (1.4).

The rest of this paper is devoted to the analysis of situations where we can guarantee that the iteration (1.4) converges to a fixed point. Due to the singularity of A, such a limiting fixed point usually depends on the starting vector x^0. Actually, condition (1.3) implies that convergence of the iteration (1.4) is equivalent to H being semiconvergent according to the following definition;[1] see, e.g., [3], [7], [18].

DEFINITION 1.1. [illegible] $H \in \mathbb{C}^{n\times n}$ [illegible] $\rho(H) = 1$, $\lambda = 1$ [illegible] 1 [illegible] $\lambda = 1$ [illegible] H [illegible]

It follows, then, that one goal is to find simple conditions for which we can show that H of the form (1.2) is such that (1.3) holds and it is semiconvergent.

Our general form of the iteration operator from (1.2) applies in particular to iterations induced by splittings of the form $A = M - N$, M nonsingular, in which $\widetilde{M}$ is taken to be M^{-1}. Then condition (1.3) is automatically satisfied. There are iterations which can be interpreted as being of the form (1.2) with $\widetilde{M} = M^\dagger$, the Moore–Penrose pseudoinverse of some singular matrix M; see [7], [12], [13], where such iterations are studied. This situation occurs in particular in the analysis of Schwarz iterations where the artificial boundary conditions between subdomains are of Neumann type; see, e.g., [17], [19].

The rest of the paper is organized as follows. In section 2 we derive a fundamental convergence result based on an estimate in the energy seminorm. In section 3 the fundamental result is used in two directions: We obtain simple and elegant proofs for some known convergence results, and we develop new convergence results which improve over some that have been published previously. We then consider algebraic additive and multiplicative Schwarz methods. The paper finishes with a conclusion in section 4. We mention that applications of the fundamental result to algebraic multigrid methods are presented in the forthcoming paper [8].

2. A fundamental result. In the analysis to follow, we use the bilinear form $\langle\cdot,\cdot\rangle_A$ defined for a Hermitian matrix $A \in \mathbb{C}^{n\times n}$ as

$$\langle\cdot,\cdot\rangle_A : \mathbb{C}^n \times \mathbb{C}^n \to \mathbb{C},\ \ (x,y) \mapsto \langle x,y\rangle_A = \langle Ax,y\rangle\ (= \langle x,Ay\rangle).$$

Here, $\langle x,y\rangle$ denotes the standard Euclidean inner product. Since in our context A is only positive semidefinite, the bilinear form is only semidefinite as well. We collect some trivial properties of $\langle\cdot,\cdot\rangle_A$ in the following lemma.

LEMMA 2.1. [illegible] A [illegible]

[1] We note that in some papers such a matrix is simply called *convergent*.

(i) [illegible] $x \in \mathbb{C}^n$ [illegible] $\langle x, x\rangle_A \geq 0$
(ii) $\langle x, x\rangle_A = 0$ [illegible] $x \in \mathrm{Null}(A)$
(iii) [illegible] $x \in \mathrm{Null}(A)$ [illegible] $y \in \mathrm{Null}(A)$ [illegible] $\langle x, y\rangle_A = 0$

In what follows, $\|x\|_A$ denotes the seminorm $\langle x, x\rangle_A^{1/2}$.

We now turn to formulate a fundamental theorem on the convergence of the iteration (1.4). We include a simple proof before discussing how it is related to similar results in recent publications.

THEOREM 2.2. [illegible] $H = I - \widetilde{M}A \in \mathbb{C}^{n\times n}$ [illegible] (1.4) [illegible]

$$x \notin \mathrm{Null}(A) \Longrightarrow \|Hx\|_A < \|x\|_A. \tag{2.1}$$

[illegible]
(i) $\mathrm{Null}(\widetilde{M}A) = \mathrm{Null}(A)$ [illegible] $\widetilde{M}$ [illegible] $\mathrm{Range}(A)$
(ii) H [illegible]

[illegible] $b \in \mathrm{Range}(A)$ [illegible] (1.4) [illegible] (1.1) [illegible] x^0 [illegible]. First observe that $\mathrm{Null}(\widetilde{M}A) = \mathrm{Null}(I - H)$. For $y \notin \mathrm{Null}(A)$ the hypothesis (2.1) gives $Hy \neq y$, i.e., $y \notin \mathrm{Null}(I - H)$. On the other hand $y \in \mathrm{Null}(A)$ implies $y \in \mathrm{Null}(I - H)$, by the definition of H. This shows $\mathrm{Null}(\widetilde{M}A) = \mathrm{Null}(I - H) = \mathrm{Null}(A)$, i.e., (i) holds.

To prove (ii), let x be an eigenvector for an eigenvalue λ of H. If $x \notin \mathrm{Null}(A)$, we have $\|x\|_A > 0$, and from (2.1) we get $|\lambda| \cdot \|x\|_A < \|x\|_A$ which implies $|\lambda| < 1$. If $x \in \mathrm{Null}(A)$, we know that $Hx = x$, i.e., $\lambda = 1$. So $\rho(H) = 1$, and $\lambda = 1$ is the only eigenvalue of modulus 1. It remains to show that $\lambda = 1$ is semisimple.

Assume that, on the contrary, $\lambda = 1$ is not a semisimple eigenvalue of H. Then there exists a level-2 generalized eigenvector for the eigenvalue $\lambda = 1$, i.e., a vector $v \neq 0$ satisfying

$$Hv = v + u, \text{ where } Hu = u, u \neq 0.$$

Since v is not an eigenvector of H we have $v \notin \mathrm{Null}(A)$. We also have $u \in \mathrm{Null}(A)$, since u is an eigenvector of H for the eigenvalue $\lambda = 1$ and $\widetilde{M}$ is injective on $\mathrm{Range}(A)$. Thus, using parts (ii) and (iii) of Lemma 2.1, we get

$$\langle Hv, Hv\rangle_A = \langle v, v\rangle_A + \langle v, u\rangle_A + \langle u, v\rangle_A + \langle u, u\rangle_A = \langle v, v\rangle_A,$$

which contradicts (2.1). Therefore, there is no level-2 generalized eigenvector for the eigenvalue $\lambda = 1$; i.e., $\lambda = 1$ is semisimple. □

[illegible] 2.3. Since $Hx = x$ for $x \in \mathrm{Null}(A)$, the operator H canonically induces a linear operator $\mathcal{H}$ on the quotient space $\mathcal{Q} = \mathbb{C}^n/\mathrm{Null}(A)$ on which $\|\cdot\|_A$ canonically induces a true norm $\|x + \mathrm{Null}(A)\|_A := \|x\|_A$. Therefore, the implication (2.1) is actually equivalent to

$$\|Hx\|_A \leq \|\mathcal{H}\|_A \cdot \|x\|_A \text{ with } \|\mathcal{H}\|_A < 1. \tag{2.2}$$

We will write $\|H\|_A$ for $\|\mathcal{H}\|_A$ in what follows and, for simplicity, we will always formulate our convergence results to come by stating that $\|H\|_A < 1$, having in mind that this means that $\widetilde{M}$ is injective on $\mathrm{Range}(A)$ and that the iteration (1.4) converges to a solution of (1.1) whenever $b \in \mathrm{Range}(A)$.

Theorem 2.2 complements several recently published results. In [12], it was observed that $\|H\|_A < 1$ is sufficient for $\lim_{k\to\infty}(Ax^k - b) = 0$ for the iterates of (1.4) in the case that $\widetilde{M} = M^\dagger$, the Moore–Penrose inverse of a matrix M satisfying Range$(A) \subseteq$ Range(M) and $b \in$ Range(A). This kind of convergence is called [illegible], and an iterative scheme (1.4) satisfying $\|H\|_A < 1$ is called [illegible] (or [illegible]) in [12]. It was then shown in [7] that quotient convergence is actually equivalent to "usual" convergence, i.e., $\lim_{k\to\infty} x^k = x^*$ with $Ax^* = b$. This is precisely the assertion of Theorem 2.2 except that we do not require $\widetilde{M}$ to be a Moore–Penrose pseudoinverse. The references [7], [12] use such pseudoinverses since they view the iteration (1.4) as arising from a splitting $A = M - N$ of A. Since every matrix $\widetilde{M}$ is the Moore–Penrose inverse of its own Moore–Penrose inverse, i.e., $\widetilde{M} = (\widetilde{M}^\dagger)^\dagger$, we see that there is nothing special in requiring $\widetilde{M}$ to be a Moore–Penrose pseudoinverse.

The crucial condition is (2.1) (or, equivalently, (2.2)), implying (1.3) and the semiconvergence of H, which is equivalent to convergence and quotient convergence [7]. The beauty of Theorem 2.2 is that, on one hand, only the condition (2.1) is required for convergence and, on the other, its proof is simple.

3. Applications of the fundamental result. As first applications of Theorem 2.2 we give simple proofs of the necessity of a well-known result of Keller [11] (see also [7]) and a generalization which contains as a special case a recent result from [13].

THEOREM 3.1. [illegible] $A \in \mathbb{C}^{n\times n}$ [illegible] M [illegible] $H = I - M^{-1}A$ [illegible] $M + M^H - A$ [illegible] Range$(M^{-1}A)$ [illegible] $\|H\|_A < 1$

Here, M^H denotes the conjugate transpose of the matrix M.

[illegible]. Using the identity

$$H^H A H = A - AM^{-H}(M + M^H - A)M^{-1}A,$$

we see that

$$\langle Hx, Hx\rangle_A = x^H H^H A H x = \langle x, x\rangle_A - \langle M^{-1}Ax, (M + M^H - A)M^{-1}Ax\rangle. \tag{3.1}$$

For $x \notin$ Null(A) the vector $M^{-1}Ax$ is nonzero, so that due to the positive definiteness of $M + M^H - A$ on Range$(M^{-1}A)$ we obtain

$$x \notin \text{Null}(A) \Longrightarrow \langle Hx, Hx\rangle_A < \langle x, x\rangle_A,$$

and $\|H\|_A < 1$ follows by Remark 2.3.

On the other hand, if $\|H\|_A < 1$, then $\langle Hx, Hx\rangle_A < \langle x, x\rangle_A$ for all $x \notin$ Null(A), so that (3.1) gives

$$\langle M^{-1}Ax, (M + M^H - A)M^{-1}Ax\rangle = \langle x, x\rangle_A - \langle Hx, Hx\rangle_A > 0.$$

Since every nonzero $y \in$ Range$(M^{-1}A)$ can be expressed as $y = M^{-1}Ax$ with $x \notin$ Null(A), this shows that $M + M^H - A$ is positive definite on Range$(M^{-1}A)$. □

Recall that by Theorem 2.2 and Remark 2.3, $\|H\|_A < 1$ implies that the iteration (1.4) converges towards a solution of (1.1) for every starting vector. It is in these terms that the above theorem was originally formulated in [11].

One application of Theorem 3.1 is for the relaxed Gauss–Seidel iteration. With $A = D - L - L^H$ denoting the canonical decomposition of A into its diagonal part

D, its lower triangular part $-L$ and its upper triangular part $-L^H$, one then has $M = \frac{1}{\omega}D - L$. This matrix M is nonsingular if no diagonal element of A is zero, and $M + M^H - A = \frac{2-\omega}{\omega}D$ is positive definite on the whole space for $\omega \in (0, 2)$.

We now turn to the announced generalization, where M is allowed to be singular.

THEOREM 3.2. [illegible] $A \in \mathbb{C}^{n\times n}$ [illegible] $M, \widetilde{M} \in \mathbb{C}^{n\times n}$ [illegible]

$$M\widetilde{M}A = A \tag{3.2}$$

[illegible] $H = I - \widetilde{M}A$ [illegible] $\|H\|_A < 1$, [illegible] $M + M^H - A$, [illegible] Range$(\widetilde{M}A)$

[illegible]. We first observe that since $M\widetilde{M}A = A$ we have $\mathrm{Null}(\widetilde{M}A) = \mathrm{Null}(A)$, i.e., $\widetilde{M}$ is injective on Range(A). We also have $A(\widetilde{M})^H M^H = A$ and thus

$$\begin{aligned} H^H A H &= A - A\widetilde{M}A - A(\widetilde{M})^H A + A(\widetilde{M})^H A\widetilde{M}A \\ &= A - A(\widetilde{M})^H \cdot \big(M + M^H - A\big) \cdot \widetilde{M}A. \end{aligned} \tag{3.3}$$

So, if $M+M^H-A$ is positive definite on Range$(\widetilde{M}A)$, we see that for $x \notin \mathrm{Null}(\widetilde{M}A) = \mathrm{Null}(A)$ one has

$$\|Hx\|_A < \|x\|_A$$

so that $\|H\|_A < 1$ follows again from Remark 2.3.

The converse follows in the same manner as in the proof of Theorem 3.1, so we do not reproduce it here. □

This result allows us to use for $\widetilde{M}$ various generalized inverses of M. In the case that $\widetilde{M}$ is the Moore–Penrose inverse $M^\dagger$ of M, a sufficient condition for $M\widetilde{M}A = A$ is to require Range$(A) \subseteq$ Range(M). With this more restrictive condition, Theorem 3.2 was essentially proved in [12, Theorem 4.4]; see also [7]. The paper [13] uses the same condition Range$(A) \subseteq$ Range(M) but allows $\widetilde{M}$ to just be an inner inverse of M, i.e., an operator satisfying $M\widetilde{M}M = M$. The convergence results there, however, come in a quite different flavor. Instead of assuming the positive definiteness of $M + M^H - A$ on Range$(\widetilde{M}A)$, they require a further, more indirectly defined matrix to be an inner inverse.

We note that Cao [7] presents the following example indicating that condition (3.2) is essential for the necessity part of Theorem 3.2.

[illegible] 3.3. Let

$$A = \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}, \quad M = \frac{1}{2}\begin{bmatrix} 0 & -1 \\ 0 & 1 \end{bmatrix}, \quad \widetilde{M} = M^\dagger = \begin{bmatrix} 0 & 0 \\ -1 & 1 \end{bmatrix},$$

for which it holds that $\widetilde{M}A = A$, and thus $M\widetilde{M}A = MA = M \neq A$. On the other hand, we have that

$$H = I - \widetilde{M}A = I - A = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix},$$

so that $\|H\|_A = 0 < 1$, but it holds that $(\widetilde{M}A)^H(M^H + M - A)(\widetilde{M}A) = 0$, and thus $M^H + M - A$ is not positive definite on Range$(\widetilde{M}A)$.

Theorem 2.2 can be used to derive further conditions implying the convergence of iteration (1.4). The following result has the same spirit as Theorem 3.1, but note that the hypothesis (3.2) is not needed here. This result is used later in the paper.

THEOREM 3.4. [illegible] $A \in \mathbb{C}^{n\times n}$ [illegible] $H = I - \widetilde{M}A$ [illegible]

(3.4) $\widetilde{M} + \widetilde{M}^H - \widetilde{M}^H A\widetilde{M}$ [illegible] Range(A)

[illegible] $\|H\|_A < 1$ [illegible]. We have

$$H^H AH = A - A(\widetilde{M} + \widetilde{M}^H - \widetilde{M}^H A\widetilde{M})A. \tag{3.5}$$

So if $\widetilde{M} + \widetilde{M}^H - \widetilde{M}^H A\widetilde{M}$ is positive definite on Range(A), we immediately get that for $x \notin \text{Null}(A)$ we have $\|Hx\|_A < \|x\|_A$, i.e., $\|H\|_A < 1$. On the other hand, if $\|H\|_A < 1$ and $x \notin \text{Null}(A)$, then $\|Hx\|_A^2 < \|x\|_A^2$. From (3.5) we see that this means $\langle Ax, (\widetilde{M} + \widetilde{M}^H - \widetilde{M}^H A\widetilde{M})Ax\rangle > 0$, i.e., $(\widetilde{M} + \widetilde{M}^H - \widetilde{M}^H A\widetilde{M})$ is positive definite on Range(A). ∎

We note that for the matrices of Example 3.3 we have that

$$\widetilde{M} + \widetilde{M}^H - \widetilde{M}^H A\widetilde{M} = \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix},$$

which is the identity on Range(A), and thus positive definite on Range(A).

3.1. Application to additive Schwarz. We start this section with a general result where the generic operator $\widetilde{M}$ is decomposed into p operators and involves a positive damping factor θ; i.e., we have $\widetilde{M} = \theta \sum_{i=1}^{p} \widetilde{M}_i$ and

$$H = I - \widetilde{M}A = I - \theta \sum_{i=1}^{p} \widetilde{M}_i A. \tag{3.6}$$

As we shall see, this general formulation applies in particular to several variants of additive Schwarz iterations.

One of the hypotheses we use is that there exists a number $\gamma > 0$ such that

$$\Re\langle x, \widetilde{M}_i Ax\rangle_A \geq \gamma \cdot \langle \widetilde{M}_i Ax, \widetilde{M}_i Ax\rangle_A \text{ for all } x \in \mathbb{C}^n \text{ and for } i = 1, \ldots, p. \tag{3.7}$$

Here, $\Re z$ denotes the real part of a complex number z. It is easy to see that (3.7) is equivalent to the hypothesis (cf. (3.4))

$$\widetilde{M}_i + \widetilde{M}_i^H - 2\gamma \widetilde{M}_i^H A\widetilde{M}_i \text{ is positive semidefinite on Range}(A). \tag{3.8}$$

In the following theorems we give convergence results requiring upper bounds for the damping factor θ in (3.6). These upper bounds are given in terms of p (usually representing the number of subdomains). Nevertheless, in the same way as is done in the convergence analysis for classical additive Schwarz methods for Hermitian positive definite matrices, where q "colors" are used, the bounds can be enlarged to be in terms of q; see Remark 3.14.

THEOREM 3.5. [illegible] $A \in \mathbb{C}^{n\times n}$ [illegible] $\widetilde{M}_i \in \mathbb{C}^{n\times n}$, $i = 1, \ldots, p$ [illegible]

(i) [illegible] $\gamma > 0$ [illegible] (3.7) [illegible]

(ii) $\cap_{i=1}^{p}\mathrm{Null}(A\widetilde{M}_iA) = \mathrm{Null}(A)$

$\bar{\theta} \geq \frac{2\gamma}{p}$ $0 < \theta < \bar{\theta}$ H (3.6) $\|H\|_A < 1$ $\widetilde{M}$ (3.4)

(3.9) $|\langle \widetilde{M}_iAx, \widetilde{M}_jAx\rangle_A| \leq c_{ij} \cdot \|\widetilde{M}_iAx\|_A \cdot \|\widetilde{M}_jAx\|_A$ $x \in \mathbb{C}^n$, $i,j = 1,\ldots,p$,

$0 \leq c_{ij} = c_{ji} \leq 1$ $c_{ii} = 1$ $\bar{\theta}$ $\bar{\theta} \geq (2\gamma)/\lambda_{max}(C)$ $\lambda_{max}(C)$ $C = (c_{ij})$. For all $x \in \mathbb{C}^n$ we have

$$\langle Hx, Hx\rangle_A = \langle x,x\rangle_A - 2\theta\sum_{i=1}^{p}\Re\langle x, \widetilde{M}_iAx\rangle_A + \theta^2\sum_{i,j=1}^{p}\langle \widetilde{M}_iAx, \widetilde{M}_jAx\rangle_A. \tag{3.10}$$

For ease of notation we put

$$m_i = \|\widetilde{M}_iAx\|_A, \qquad i = 1,\ldots,p, \tag{3.11}$$

and observe that using hypothesis (i) it holds that

$$\gamma \cdot m_i^2 = \gamma \cdot \langle \widetilde{M}_iAx, \widetilde{M}_iAx\rangle_A \leq \Re\langle x, \widetilde{M}_iAx\rangle_A. \tag{3.12}$$

Also, using the Cauchy–Schwarz inequality, one has $\langle \widetilde{M}_iAx, \widetilde{M}_jAx\rangle_A \leq m_im_j$. Let now $m = (m_1,\ldots,m_p)^T$ and $E \in \mathbb{C}^{p\times p}$ be the matrix of all ones. Then from (3.10) we obtain

$$\begin{aligned}\langle Hx, Hx\rangle_A &\leq \langle x,x\rangle_A - 2\theta\gamma\sum_{i=1}^{p}m_i^2 + \theta^2\sum_{i,j=1}^{p}m_im_j \\ &= \langle x,x\rangle_A - \theta\cdot\langle m, (2\gamma I - \theta E)m\rangle. \end{aligned}\tag{3.13}$$

For $\theta < (2\gamma)/p$ the matrix $2\gamma I - \theta E$ is strictly diagonally dominant and thus Hermitian and positive definite. Therefore, once we have shown that $m \neq 0$ for $x \notin \mathrm{Null}(A)$ we will have proven the first part of the theorem, since then, by (3.13), we have $\langle Hx, Hx\rangle_A < \langle x,x\rangle_A$, i.e., $\|H\|_A < 1$. But if $m_i = 0$ for $i = 1,\ldots,p$, we have $\widetilde{M}_iAx \in \mathrm{Null}(A)$ and thus $x \in \mathrm{Null}(A\widetilde{M}_iA)$ for $i = 1,\ldots,p$. By (ii) this gives $x \in \mathrm{Null}(A)$.

The fact that $\widetilde{M}$ fulfills (3.4) follows directly from Theorem 3.4.

If the strengthened Cauchy–Schwarz inequalities (3.9) hold, we can replace (3.13) with the stronger

$$\langle Hx, Hx\rangle_A \leq \langle x,x\rangle_A - \theta\cdot\langle m, (2\gamma I - \theta C)m\rangle.$$

Since $2\gamma I - \theta C$ is Hermitian and positive definite for $\theta < (2\gamma)/\lambda_{\max}(C)$, the same arguments as before prove the last part of the theorem. ∎

THEOREM 3.6. $A \in \mathbb{C}^{n\times n}$ (i) (ii) 3.5 3.5 $q < p$ $i \in \{1,\ldots,p\}$ Range$(\widetilde{M}_i)$ Range$(\widetilde{M}_j), j = 1,\ldots,p$ $j \neq i$ $q-1$ $\bar{\theta}$ $\bar{\theta} \geq (2\gamma)/q$. By the hypothesis, we have strengthened Cauchy–Schwarz inequalities (3.9), where for each i at most q of the c_{ij} are nonzero, and the nonzero ones can be

chosen to be equal to 1. Therefore, all row sums of C are bounded by q, and thus by Gershgorin's theorem (see, e.g., [20]), we have $\lambda_{\max}(C) \le q$. ∎

In the results presented so far, the operators $\widetilde{M}_i$ were allowed to be of quite general nature; in particular, they may be non-Hermitian. In many situations, however, the operators $\widetilde{M}_i$ are Hermitian and positive semidefinite on Range(A). In this case, $x \in \text{Null}(A\widetilde{M}_i A)$ implies $0 = \langle x, (A\widetilde{M}_i A)x\rangle = \langle Ax, \widetilde{M}_i Ax\rangle$ and thus $Ax \in \text{Null}(\widetilde{M}_i)$, i.e., $x \in \text{Null}(\widetilde{M}_i A)$. In this situation we consequently have $\cap_{i=1}^p \text{Null}(A\widetilde{M}_i A) = \cap_{i=1}^p \text{Null}(\widetilde{M}_i A)$, which directly gives the following corollary to Theorem 3.5.

THEOREM 3.7. [illegible] $A \in \mathbb{C}^{n\times n}$ [illegible] $\widetilde{M}_i \in \mathbb{C}^{n\times n}$, $i = 1, \dots, p$, [illegible]

(i) $\widetilde{M}_i$ [illegible] $i = 1, \dots, p$

(ii) [illegible] $\gamma > 0$ [illegible] (3.7) [illegible]

(iii) $\cap_{i=1}^p \text{Null}(\widetilde{M}_i A) = \text{Null}(A)$

[illegible] 3.5 [illegible]

To study additive Schwarz methods, we need some further notation. We consider a decomposition of $\mathbb{C}^n$ into p subspaces of dimensions n_i, $i = 1, \dots, p$, represented by $\mathbb{C}^{n_i}$. By R_i we denote the projections ("restrictions") onto these subspaces, represented as matrices $R_i \in \mathbb{C}^{n_i \times n}$ having full rank n_i. We define the Galerkin operators

$$A_i = R_i A R_i^H \in \mathbb{C}^{n_i \times n_i}, \qquad i = 1, \dots, p.$$

The following result on the range of the Galerkin operator will be useful later.

LEMMA 3.8. [illegible] A [illegible]

$$\text{Range}(A_i) = \text{Range}(R_i A).$$

[illegible]. Since A_i is Hermitian, the assertion is equivalent to $\text{Null}(A_i) = \text{Null}(AR_i^H)$. Clearly, $\text{Null}(A_i) \supseteq \text{Null}(AR_i^H)$. On the other hand, if $x \in \text{Null}(A_i)$, it satisfies $0 = \langle A_i x, x\rangle = \langle AR_i^H x, R_i^H x\rangle$, which implies $R_i^H x \in \text{Null}(A)$, i.e., $x \in \text{Null}(AR_i^H)$, showing that we also have $\text{Null}(A_i) \subseteq \text{Null}(AR_i^H)$. ∎

For the moment, let us assume that, although A is only Hermitian positive semidefinite, all Galerkin operators are nonsingular (and thus positive definite); i.e., we assume that $\text{Range}(R_i^H) \cap \text{Null}(A) = \{0\}$ for all i; see, e.g., [4], [6], [15], [16], for examples when this situation occurs. The additive (damped) Schwarz iteration for solving $Ax = b$ is then given as (1.4) with

$$\widetilde{M} = \theta \sum_{i=1}^{p} R_i^H A_i^{-1} R_i \text{ and } H = I - \widetilde{M}A. \tag{3.14}$$

We refer the reader, e.g., to [17], [19], and references therein for details on Schwarz methods, and to [2], [9] for algebraic formulations.

THEOREM 3.9. [illegible] $A \in \mathbb{C}^{n\times n}$ [illegible] R_i [illegible]

$$\cap_{i=1}^p \text{Null}(R_i) = \{0\}, \tag{3.15}$$

[illegible] $A_i = R_i A R_i^H$ [illegible] $i = 1, \dots, p$ [illegible] $0 < \theta < \frac{2}{p}$ [illegible] H [illegible] (3.14) [illegible] $\|H\|_A < 1$ [illegible] $\widetilde{M}$ [illegible] (3.4)

[illegible]. We show that $\widetilde{M}_i = R_i^H A_i^{-1} R_i$ satisfies hypotheses (i)–(iii) of Theorem 3.7 with $\gamma = 1$. Obviously, $\widetilde{M}_i$ is Hermitian. For (ii) we have

$$\widetilde{M}_i A \widetilde{M}_i A = R_i^H A_i^{-1} R_i A R_i^H A_i^{-1} R_i A = R_i^H A_i^{-1} A_i A_i^{-1} R_i A = R_i^H A_i^{-1} R_i A = \widetilde{M}_i A,$$

which shows that the $\widetilde{M}_i A$ are projections, i.e., (ii) holds with $\gamma = 1$. For (iii) let $x \in \cap_{i=1}^{p} \mathrm{Null}(\widetilde{M}_i A)$; then

$$0 = \langle R_i^H A_i^{-1} R_i A x, x \rangle_A = \langle A_i^{-1} R_i A x, R_i A x \rangle,$$

which, since A_i is Hermitian positive definite, implies $R_i A x = 0$, $i = 1, \ldots, p$, i.e.,

$$A x \in \cap_{i=1}^{p} \mathrm{Null}(R_i) = \{0\}.$$

Thus, $x \in \mathrm{Null}(A)$. So we have $\cap_{i=1}^{p} \mathrm{Null}(\widetilde{M}_i A) \subseteq \mathrm{Null}(A)$, and since the opposite inclusion is trivial we have (iii). ∎

3.10. The restriction operators R_i in our formulation of Schwarz methods are very general. In the special case when they are Boolean gather operators (i.e., their rows being rows of the identity), using Theorem 3.9 we recover the convergence part of [16, Theorem 4.2].

Let us also note that for the "prolongation" operators $P_i = R_i^H$, we have $\mathrm{Range}(P_i) = \mathrm{Null}(R_i)^{\perp}$. Thus, condition (3.15) can equivalently be stated as

$$\sum_{i=1}^{p} \mathrm{Range}(P_i) = \mathbb{C}^n,$$

as is done, e.g., in [10].

Theorem 3.9 can be extended to the case where the Galerkin matrices A_i are singular, if we replace their inverses by the Moore-Penrose pseudoinverses $A_i^{\dagger}$.

THEOREM 3.11. [illegible] $A \in \mathbb{C}^{n \times n}$ [illegible] $0 < \theta < \frac{2}{p}$ [illegible]

$$H = I - \widetilde{M} A, \quad \widetilde{M} = \theta \sum_{i=1}^{p} R_i^H A_i^{\dagger} R_i, \quad A_i = R_i A R_i^H. \tag{3.16}$$

[illegible] R_i [illegible]

$$\cap_{i=1}^{p} \mathrm{Null}(R_i^H A_i^{\dagger} R_i A) = \mathrm{Null}(A).$$

[illegible] H [illegible] (3.16) [illegible] $\|H\|_A < 1$ [illegible] $\widetilde{M}$ [illegible] (3.4) [illegible]. All we need to do is show that with $\widetilde{M}_i = R_i^H A_i^{\dagger} R_i$, $i = 1, \ldots, p$, the hypotheses (i) and (ii) of Theorem 3.7 (with $\gamma = 1$) are satisfied, (iii) being assumed. Since A_i is Hermitian positive semidefinite, so is $A_i^{\dagger}$, and therefore also is $\widetilde{M}_i$. For (ii), we have

$$R_i^H A_i^{\dagger} R_i A R_i^H A_i^{\dagger} R_i A = R_i^H A_i^{\dagger} A_i A_i^{\dagger} R_i A = R_i^H A_i^{\dagger} R_i A \tag{3.17}$$

showing that the matrices $R_i^H A_i^{\dagger} R_i A$ are again projections, i.e., (ii) holds with equality. ∎

We next consider a situation usually referred to as inexact solution of the local problems; see, e.g., [1], [5], [17], [19]. This is the situation, e.g., when the solution of the local problem

$$A_i y_i = z_i \tag{3.18}$$

is not obtained exactly. Thus one replaces $A_i^{-1} z_i$ or $A_i^{\dagger} z_i$ with a vector other than a solution of (3.18), and this is represented by $\tilde{A}_i z_i$. In this case we have $\widetilde{M}_i = R_i^H \tilde{A}_i R_i$;

and using Lemma 3.8 it is easy to see that the hypothesis (3.8), or equivalently (3.7), can be rewritten as

$$\tilde{A}_i + \tilde{A}_i^H - 2\gamma \tilde{A}_i^H A_i \tilde{A}_i \text{ is positive semidefinite on Range}(A_i). \tag{3.19}$$

Observe that here $\tilde{A}_i$ is not assumed to be symmetric, and thus neither is $\widetilde{M}_i$.

We are ready now to establish the convergence of (damped) additive Schwarz iterations with inexact local solvers, which follows directly from Theorem 3.5.

THEOREM 3.12. [illegible] $A \in \mathbb{C}^{n\times n}$ [illegible] $A_i = R_i A R_i^H$, $i = 1, \ldots, p$ [illegible] $\tilde{A}_i$ [illegible] γ [illegible] (3.19) [illegible] $0 < \theta < (2\gamma)/p$ [illegible]

$$H = I - \widetilde{M}A, \text{ [illegible] } \widetilde{M} = \theta \sum_{i=1}^{p} \widetilde{M}_i = \theta \sum_{i=1}^{p} R_i^H \tilde{A}_i R_i.$$

[illegible] R_i [illegible]

$$\cap_{i=1}^{p} \text{Null}(A R_i^H \tilde{A}_i R_i A) = \text{Null}(A).$$

[illegible] H [illegible] $\|H\|_A < 1$ [illegible] $\widetilde{M}$ [illegible] (3.4)

Note that condition (3.19) is fulfilled with $\gamma = \frac{1}{2}$ if $\tilde{A}_i + \tilde{A}_i^H - \tilde{A}_i^H A_i \tilde{A}_i$ is positive definite on Range(A_i), which is precisely (3.4) from Theorem 3.4. So in this special case, by Theorem 3.4, we have $\|I - \tilde{A}_i A_i\|_{A_i} < 1$, or that an iteration for the solution of the local problem (3.18) with iteration matrix $I - \tilde{A}_i A_i$ is convergent. One particular general example of this situation is when one uses a splitting of $A_i = B_i - C_i$, and the solution of the system (3.18) is approximated by κ classical stationary iterations associated with this splitting. Thus, for this example

$$\tilde{A}_i = \sum_{j=0}^{\kappa-1} (B_i^{-1} C_i)^j B_i^{-1}. \tag{3.20}$$

Of course one can have different values of κ for different local problems. As a particular case, consider the canonical decompositions $A_i = D_i - L_i - L_i^H$ and put $B_i = \frac{1}{\omega} D_i - L_i$, i.e., relaxed Gauss–Seidel. If one sets $\tilde{A}_i = B_i^{-1}$ the local solutions are approximated by one step of the relaxed Gauss–Seidel, i.e., $\kappa = 1$. Assuming that no diagonal element of A_i is zero and that $\omega \in (0, 2)$, a simple calculation shows that (3.19) is fulfilled with $\gamma = \frac{1}{2}$. Since we then have that the relaxed Gauss–Seidel iteration is convergent, using Theorem 3.4, we see that the $\tilde{A}_i$ of (3.20) also fulfills (3.19) with $\gamma = \frac{1}{2}$ for all integer values of κ.

[illegible] 3.13. We note that a special case of Theorem 3.12 when R_i are Boolean gather operators and $\tilde{A}_i$ are symmetric and nonsingular is [16, Theorem 6.1], where the hypothesis used there is equivalent to

$$\langle z, \tilde{A}_i z \rangle \le \langle z, A_i^{-1} z \rangle \quad \text{for all } z \in \mathbb{C}^{n_i} \text{ and for } i = 1, \ldots, p,$$

which implies (3.19) with $\gamma \le 1$. Indeed, in this case, we have that the difference $\tilde{A}_i^{-1} - A_i$ is positive semidefinite, and we write

$$2\tilde{A}_i - 2\gamma \tilde{A}_i^H A_i \tilde{A}_i = 2\tilde{A}_i \left(\tilde{A}_i^{-1} - \gamma A_i \right) \tilde{A}_i.$$

3.14. If in Theorems 3.7, 3.9, 3.11, and 3.12, we add the hypothesis that there exists a natural number $q < p$ such that for each $i \in \{1, \ldots, p\}$ the space $\text{Range}(R_i^H)$ is orthogonal to all spaces $\text{Range}(R_j^H)$, $j = 1, \ldots, p$, $j \neq i$, except for at most $q - 1$ such indices, then, using Theorem 3.6, the results hold for $\theta < 2/q$ (or $\theta < (2\gamma)/q$ in Theorem 3.12); cf. [10, Chapter 11.2.4], where this is done for classical additive Schwarz for A Hermitian positive definite. See also [2], [9], and [16] for other such situations.

We note that Hermitian positive semidefinite matrices $\widetilde{M}_i$ different from those considered in Theorems 3.9, 3.11, and 3.12 also do appear in other Schwarz contexts, and our general Theorem 3.5 would apply to such cases as well. For example, in [14] matrices of the form $\widetilde{M}_i = R_i^H(A_i + G_i)R_i$ are used, where G_i derives from the Robin boundary conditions.

3.2. Multiplicative Schwarz. Instead of an additive we now consider a multiplicative combination of p operators $\widetilde{M}_i$ resulting in

$$H = (I - \widetilde{M}_p A)(I - \widetilde{M}_{p-1}A) \cdots (I - \widetilde{M}_1 A) = \prod_{i=p}^{1} (I - \widetilde{M}_i A). \tag{3.21}$$

Of course, the iteration operator H can be written in the form $H = I - \widetilde{M}A$, but an explicit formula for $\widetilde{M}$ is not needed in our convergence analysis. As in the additive case, the general formulation (3.21) applies, for particular choices of the matrices $\widetilde{M}_i$, to several variants of multiplicative Schwarz methods, including, for example, those corresponding to Robin boundary conditions [14].

As we did in the additive case, we first state a general theorem which we then apply to the multiplicative Schwarz setting.

THEOREM 3.15. [illegible] $A \in \mathbb{C}^{n\times n}$ [illegible] $\widetilde{M}_i \in \mathbb{C}^{n\times n}$, $i = 1, \ldots, p$, [illegible]

(i) A [illegible] $\widetilde{M}_i A$, $i = 1, \ldots, p$, [illegible] $\text{Null}(A\widetilde{M}_i A) = \text{Null}(\widetilde{M}_i A)$, $i = 1, \ldots, p$

(ii) [illegible] $\gamma > \frac{1}{2}$ [illegible] (3.7) [illegible]

(iii) $\cap_{i=1}^{p} \text{Null}(\widetilde{M}_i A) = \text{Null}(A)$

[illegible] H [illegible] (3.21) [illegible] H [illegible] $\|H\|_A < 1$ [illegible] $H = I - \widetilde{M}A$ [illegible] $\widetilde{M}$ [illegible] (3.4)

[illegible]. We first note that by (ii) we have, for $x \in \mathbb{C}^n$ and $i = 1, \ldots, p$,

$$\begin{aligned} \langle (I - \widetilde{M}_i A)x, (I - \widetilde{M}_i A)x\rangle_A &= \langle x, x\rangle_A - 2\Re\langle x, \widetilde{M}_i Ax\rangle_A + \langle \widetilde{M}_i Ax, \widetilde{M}_i Ax\rangle_A \\ &\leq \langle x, x\rangle_A - (2\gamma - 1)\langle \widetilde{M}_i Ax, \widetilde{M}_i Ax\rangle_A. \end{aligned} \tag{3.22}$$

Now let $x^{(1)} = z$ and $x^{(i+1)} = (I - \widetilde{M}_i A)x^{(i)}$, $i = 1, \ldots, p$, so that $x^{(p+1)} = Hx^{(1)} = Hz$. Using (3.22) repeatedly we obtain

$$\langle Hz, Hz\rangle_A - \langle z, z\rangle_A \leq -(2\gamma - 1)\sum_{i=1}^{p} \langle \widetilde{M}_i Ax^{(i)}, \widetilde{M}_i Ax^{(i)}\rangle_A. \tag{3.23}$$

The right-hand side of (3.23) is nonpositive. It remains to show that it is zero only when $z \in \text{Null}(A)$. Now the right-hand side of (3.23) is zero if and only if $\langle \widetilde{M}_i Ax^{(i)}, \widetilde{M}_i Ax^{(i)}\rangle_A = 0$ for $i = 1, \ldots, p$. This is equivalent to $\widetilde{M}_i Ax^{(i)} \in \text{Null}(A)$, i.e., $x^{(i)} \in \text{Null}(A\widetilde{M}_i A)$, which by assumption (i) implies $x^{(i)} \in \text{Null}(\widetilde{M}_i A)$ for

$i = 1, \ldots, p$. But then $x^{(i+1)} = (I - \widetilde{M}_i A)x^{(i)} = x^{(i)}$ for $i = 1, \ldots, p$, resulting in $x^{(i)} = z$ for $i = 1, \ldots, p$, and $z \in \mathrm{Null}(\widetilde{M}_i A)$ for $i = 1, \ldots, p$. By assumption (iii) this means $z \in \mathrm{Null}(A)$. So we have shown $\|H\|_A < 1$. The fact that $\widetilde{M}$ fulfills condition (3.4) follows directly from Theorem 3.4. ∎

We now use Theorem 3.15 for the analysis of multiplicative Schwarz methods. We use the notation introduced in section 3.1. As in the additive case, we first consider the case where the Galerkin operators $A_i = R_i A R_i^H$ are nonsingular, i.e., we have

$$\widetilde{M}_i = R_i^H A_i^{-1} R_i, \qquad i = 1, \ldots, p. \tag{3.24}$$

THEOREM 3.16. [illegible] $A \in \mathbb{C}^{n \times n}$ [illegible] R_i [illegible]

$$\cap_{i=1}^{p} \mathrm{Null}(R_i) = \{0\},$$

[illegible] $A_i = R_i A R_i^H$ [illegible] $i = 1, \ldots, p$ [illegible] H [illegible] (3.21) [illegible] $\widetilde{M}_i$ [illegible] (3.24) [illegible] $\|H\|_A < 1$ [illegible] $H = I - \widetilde{M}A$ [illegible] $\widetilde{M}$ [illegible] (3.4)

[illegible]. We need to show that the hypotheses (i)–(iii) of Theorem 3.15 are fulfilled with $\gamma = 1$. For (ii) and (iii), this was already done in the proof of Theorem 3.9. To show that (i) holds, we first note that, trivially, $\mathrm{Null}(A\widetilde{M}_i A) \supseteq \mathrm{Null}(\widetilde{M}_i A)$. On the other hand, $x \in \mathrm{Null}(A\widetilde{M}_i A)$ implies $0 = \langle x, A\widetilde{M}_i Ax \rangle = \langle Ax, \widetilde{M}_i Ax \rangle$, which, since $\widetilde{M}_i$ is Hermitian positive semidefinite, yields $Ax \in \mathrm{Null}(\widetilde{M}_i)$, i.e., $x \in \mathrm{Null}(\widetilde{M}_i A)$. ∎

The next theorem considers the case where the Galerkin operators can be singular.

THEOREM 3.17. [illegible] $A \in \mathbb{C}^{n \times n}$ [illegible] $A_i = R_i A R_i^H$ [illegible] $\widetilde{M}_i = R_i^H A_i^{\dagger} R_i$ [illegible] $i = 1, \ldots, p$ [illegible] H [illegible] (3.21) [illegible] R_i [illegible]

$$\cap_{i=1}^{p} \mathrm{Null}(R_i^H A_i^{\dagger} R_i A) = \mathrm{Null}(A).$$

[illegible] H [illegible] $\|H\|_A < 1$ [illegible] $H = I - \widetilde{M}A$ [illegible] $\widetilde{M}$ [illegible] (3.4)

[illegible]. The proof follows again by showing that assumptions (i) to (iii) of Theorem 3.15 are fulfilled with $\gamma = 1$. But (iii) is assumed and (i) follows in exactly the same manner as in the proof of Theorem 3.16, whereas (ii) holds with $\gamma = 1$ since the $\widetilde{M}_i A$ are projections as shown in (3.17). ∎

We end this section considering multiplicative Schwarz iterations with inexact solutions of the local problems (3.18), i.e., when $\widetilde{M}_i = R_i^H \tilde{A}_i R_i$.

THEOREM 3.18. [illegible] $A \in \mathbb{C}^{n \times n}$ [illegible] $A_i = R_i A R_i^H$, $i = 1, \ldots, p$ [illegible] $\widetilde{M}_i = R_i^H \tilde{A}_i R_i$ [illegible] $\tilde{A}_i$ [illegible]

(a) $\tilde{A}_i$ [illegible]

(b) $\tilde{A}_i + \tilde{A}_i^H$ [illegible] $\mathrm{Range}(A_i)$

[illegible] $\gamma > \frac{1}{2}$ [illegible] (3.19) [illegible] R_i [illegible]

$$\cap_{i=1}^{p} \mathrm{Null}(R_i^H \tilde{A}_i R_i A) = \mathrm{Null}(A).$$

[illegible] H [illegible] (3.21) [illegible] $\|H\|_A < 1$ [illegible] $H = I - \widetilde{M}A$ [illegible] $\widetilde{M}$ [illegible] (3.4)

. We have to prove that assumptions (i) and (ii) of Theorem 3.15 hold, (iii) being part of the assumptions. Recall that (i) from Theorem 3.15 says that $\mathrm{Null}(A\widetilde{M}_i A) = \mathrm{Null}(\widetilde{M}_i A)$, where only the inclusion $\mathrm{Null}(A\widetilde{M}_i A) \subseteq \mathrm{Null}(\widetilde{M}_i A)$ is nontrivial. In the case that $\tilde{A}_i$ is Hermitian positive definite, $\widetilde{M}_i$ is Hermitian positive definite, too, and (i) of Theorem 3.15 follows as in the proof of Theorem 3.16. In the case that $\tilde{A}_i + \tilde{A}_i^H$ is positive definite on $\mathrm{Range}(A_i)$, assume that $A\widetilde{M}_i Ax = 0$. Then

$$\begin{aligned} 0 = \langle x, AR_i^H \tilde{A}_i R_i Ax\rangle &= \langle R_i Ax, \tilde{A}_i R_i Ax\rangle, \\ 0 = \langle AR_i^H \tilde{A}_i R_i Ax, x\rangle &= \langle R_i Ax, \tilde{A}_i^H R_i Ax\rangle, \end{aligned}$$

and thus $0 = \langle R_i Ax, (\tilde{A}_i + \tilde{A}_i^H) R_i Ax\rangle$. By Lemma 3.8, we have $R_i Ax \in \mathrm{Range}(A_i)$, and since $\tilde{A}_i + \tilde{A}_i^H$ is positive definite on that space we get $R_i Ax = 0$. This yields $R_i^H \tilde{A}_i R_i Ax = 0$, i.e., $x \in \mathrm{Null}(\widetilde{M}_i A)$, so that we have again shown that (i) of Theorem 3.15 holds.

Finally, since (3.19) is equivalent to (3.7), we also have (ii). ∎

We observe again that assuming $\|I - \tilde{A}_i A_i\|_{A_i} < 1$ is sufficient for (3.19) to hold. Indeed, by Theorem 3.4, this assumption is equivalent to that $\tilde{A}_i + \tilde{A}_i^H - \tilde{A}_i^H A_i \tilde{A}_i$ is positive definite on $\mathrm{Range}(A_i)$, which implies that $\tilde{A}_i + \tilde{A}_i^H$ is positive definite on $\mathrm{Range}(A_i)$ and that $\tilde{A}_i + \tilde{A}_i^H - 2\gamma \tilde{A}_i^H A_i \tilde{A}_i$ is still positive semidefinite on $\mathrm{Range}(A_i)$ for $\gamma > \frac{1}{2}$ sufficiently close to $\frac{1}{2}$. Hence, we have the following corollary.

COROLLARY 3.19. . $A \in \mathbb{C}^{n\times n}$, . $A_i = R_i A R_i^H$, $i = 1, \ldots, p$. $\widetilde{M}_i = R_i^H \tilde{A}_i R_i$ . . $\tilde{A}_i$.

$$\|I - \tilde{A}_i A_i\|_{A_i} < 1. \tag{3.25}$$

. R_i .

$$\cap_{i=1}^{p} \mathrm{Null}(R_i^H \tilde{A}_i R_i A) = \mathrm{Null}(A).$$

. H . (3.21) . $\|H\|_A < 1$ . . $H = I - \widetilde{M}A$. $\widetilde{M}$. (3.4)

Again, one can use relaxed Gauss–Seidel, i.e., $\tilde{A}_i = B_i = \frac{1}{\omega} D_i - L_i$, where $A_i = D_i - L_i - L_i^H$. We have $\tilde{A}_i + \tilde{A}_i^H = \frac{2-\omega}{\omega} D + A$, which is positive definite for $\omega \in (0, 2)$ if A_i has no zero diagonal elements. Thus, assumption (ii) of Theorem 3.18 and assumption (3.25) of Corollary 3.19 are fulfilled in this case, as well as for $\tilde{A}_i$ as in (3.20).

We note also that for $\tilde{A}_i$ nonsingular, [16, Theorem 6.4] follows from Theorem 3.18, since in [16] it is assumed that $\tilde{A}_i^{-1} + \tilde{A}_i^{-H} - A_i$ is positive definite. This assumption can be written $\tilde{A}_i^{-H}(\tilde{A}_i^H + \tilde{A}_i - \tilde{A}_i^H A_i \tilde{A}_i)\tilde{A}_i^{-1}$ being positive definite, so that (3.19) holds for some $\gamma > 1/2$.

4. Conclusions. We presented a very general convergence result for stationary iterative methods for linear systems whose coefficient matrix A is Hermitian and positive semidefinite. It is shown that if for $x \notin \mathrm{Null}(A)$, $\langle x, Hx\rangle_A < \langle x, x\rangle_A$, with $H = I - \widetilde{M}A$, then $\widetilde{M}$ is injective on $\mathrm{Range}(A)$, and H is semiconvergent. This result allowed us to give simple proofs of well-known results as well as to generalize them in several directions. We further used these new results to give convergence proofs of several variants of additive and multiplicative Schwarz iterations. These variants include those with local problems with Neumann or Robin boundary conditions as well as the inexact solution of the local problems.

Acknowledgments. We thank Zhi-Hao Cao and Yimin Wei for making available to us advanced copies of their papers [7], [13]. We also thank them, Sébastien Loisel, and two anonymous referees for their comments on an earlier version of the paper.

SPECIAL ISSUE ON TENSOR DECOMPOSITIONS AND APPLICATIONS

This issue of [illegible] was motivated by the Workshop on Tensor Decompositions and Applications, held in Luminy, France from August 29 to September 2, 2005. The issue was announced through both the SIMAX and the workshop web sites.

Though decompositions of higher-order tensors have been around for many years, the door is now opening on greater mathematical understanding and new applications. Tensor decompositions have been applied by researchers in psychometrics and chemometrics since the seventies. More recently, tensors have found their way to signal processing via the use of high-order statistics, joint matrix techniques, and applications in telecommunications. Other applications include complexity theory, (blind) system identification, biomedical engineering, numerical analysis, and data mining, among others.

This volume contains 15 papers that together form a nice cross-section of current research on tensor decompositions. The papers present new algorithms, basic algebraic results including the introduction of new decompositions, and applications in signal processing, scientific computing, and large-scale problems.

Many thanks are due to all the authors for their valuable contributions. We would also like to thank Henk van der Vorst, Mitch Chernoff, and the SIAM staff for their support.

Since the initial submission of the papers, two of the authors have passed away. Richard Harshman and Gene Golub were both authorities in their field.

TUCKER DIMENSIONALITY REDUCTION OF THREE-DIMENSIONAL ARRAYS IN LINEAR TIME*

I. V. OSELEDETS†, D. V. SAVOSTIANOV†, AND E. E. TYRTYSHNIKOV†

Abstract. We consider Tucker-like approximations with an $r \times r \times r$ core tensor for three-dimensional $n \times n \times n$ arrays in the case of $r \ll n$ and possibly very large n (up to 10^4–10^6). As the approximation contains only $\mathcal{O}(rn + r^3)$ parameters, it is natural to ask if it can be computed using only a small amount of entries of the given array. A similar question for matrices (two-dimensional tensors) was asked and positively answered in [S. A. Goreinov, E. E. Tyrtyshnikov, and N. L. Zamarashkin, *A theory of pseudo-skeleton approximations*, Linear Algebra Appl., 261 (1997), pp. 1–21]. In the present paper we extend the positive answer to the case of three-dimensional tensors. More specifically, it is shown that if the tensor admits a good Tucker approximation for some (small) rank r, then this approximation can be computed using only $\mathcal{O}(nr)$ entries with $\mathcal{O}(nr^3)$ complexity.

Key words. multidimensional arrays, Tucker decomposition, tensor approximations, low-rank approximations, skeleton decompositions, dimensionality reduction, data compression, large-scale matrices, data-sparse methods

1. Introduction.

Multidimensional arrays of data appear in many different applications. One can mention signal processing, statistics [3, 1, 4], chemometrics [5], face recognition [7], and solving multidimensional integral and differential equations [6] (a very comprehensive list of references on the subject can be found on the Three-Mode Company's Web site, [2]). These arrays often cannot be handled by standard methods because of their huge sizes: we cannot solve linear systems or calculate required decompositions due to speed or memory restrictions. The obvious solution is to perform a sort of [illegible] : an initial "large" array is transformed to a smaller array for which we can use standard methods. However, such a reduction by conventional approaches may be computationally still too expensive. In this paper we suggest a way to make it not only feasible but even quite fast. We will focus only on three-dimensional arrays mostly to simplify the presentation and note that our results can be generalized to more dimensions.

The most useful method to reduce dimension is based on the celebrated [illegible] [22] and solves the following problem: [illegible] ([illegible]) $\mathcal{A} = [a_{ijk}]$, $i = 1, \ldots, n_1$, $j = 1, \ldots, n_2$, $k = 1, \ldots, n_3$, [illegible]

[illegible]

$$a_{ijk} = \sum_{i'=1}^{r_1} \sum_{j'=1}^{r_2} \sum_{k'=1}^{r_3} g_{i'j'k'} u_{ii'} v_{jj'} w_{kk'} + e_{ijk} \tag{1.1}$$

[illegible] e_{ijk} [illegible] r_1, r_2, r_3. The matrices $U = [u_{ii'}]$,

$V = [v_{jj'}]$, $W = [w_{kk'}]$ will be referred to as , and the $r_1 \times r_2 \times r_3$ tensor $\mathcal{G} = [g_{i'j'k'}]$ as the .

A well-known method for the computation of the Tucker decomposition is based on the SVD algorithm. Consider three rectangular "unfolding" matrices of appropriate sizes $A^{(1)}, A^{(2)}, A^{(3)}$, which contain n-mode vectors (columns, rows, and fibers, respectively) of the tensor $\mathcal{A}$. The left ("short") singular vectors of the SVDs of these matrices

$$A^{(1)} = U\Sigma_1\Phi_1^\top, \qquad A^{(2)} = V\Sigma_2\Phi_2^\top, \qquad A^{(3)} = W\Sigma_3\Phi_3^\top \tag{1.2}$$

give the factors U, V, W of the Tucker decomposition, possibly after an appropriate truncation, and the core is computed as

$$g_{i'j'k'} = \sum_{i=1}^{n}\sum_{j=1}^{n}\sum_{k=1}^{n} a_{ijk}u_{ii'}v_{jj'}w_{kk'}. \tag{1.3}$$

The tensor dimension can be large (for example, $n = 10^4 - 10^6$ for some tensors coming from three-dimensional integral equations). The array itself cannot even be stored in the operative memory as $\mathcal{O}(n^3)$ memory cells are needed. The computation of the SVDs in (1.2) by standard methods costs $\mathcal{O}(n^4)$ operations and is prohibitive for $n \geq 1000$.

However, we are chiefly interested in the case $r \ll n$, and the Tucker decomposition contains only $\mathcal{O}(rn + r^3)$ parameters. If a good approximation exists, we can ask if it can be computed using only a small amount of entries of the tensor $\mathcal{A}$. A similar question for matrices (two-dimensional tensors) was asked and positively answered in [14]. In the present paper we extend the positive answer to the case of three-dimensional tensors. More specifically, it will be shown that if the tensor admits a good Tucker approximation for some (small) rank r, then this approximation can be computed using only $\mathcal{O}(nr)$ entries with $\mathcal{O}(nr^3)$ complexity.

Prior to investigation of special low-parametric (data-sparse) representations obtained only from the knowledge of a small portion of the data entries, we use a general assumption that low-parametric approximations exist. In other words, we consider the cases with sufficiently small approximate tensor rank estimates. Several estimates for many interesting for practial purposes cases are developed in [15, 18, 19]. We can mention also some practical algorithms using interpolation and other function approximation techniques or additional structural properties rather than the given arrays of data [15, 21]. [20] is closest to the paradigm of a completely data-based method (using no knowledge beyond the data themselves); however, [20] contains no proof for the existence of a sufficiently good low-rank representation and does not suggest a general adaptive procedure for selecting "most meaningful" entries. Recently, much attention has been paid to the approximation of a given matrix by a low-rank matrix using randomized algorithms, for example, see [23]. To our best knowledge, these algorithms are fast only asymptotically with very large constants in the estimates and cannot be applied in practice. Moreover, the authors do not report any numerical results in their articles, so we cannot compare their methods with our method. In this paper we present the existence results and the adaptive three-dimensional cross algorithms.

2. Notations and definitions. Let us recall some basic facts about tensors [10, 11].

DEFINITION 2.1. $n_1 \times n_2 \times n_3$ $\mathcal{A}$ $A^{(1)}$ $n_1 \times n_2 n_3$, $A^{(2)}$ $n_2 \times n_1 n_3$, $A^{(3)}$ $n_3 \times n_1 n_2$

$$A^{(1)} = [a^1_{i(jk)}] = [a_{ijk}], \quad A^{(2)} = [a^2_{j(ki)}] = [a_{ijk}], \quad A^{(3)} = [a^3_{k(ij)}] = [a_{ijk}]. \tag{2.1}$$

$1, 2, 3$ ( ) ”

DEFINITION 2.2. $n_1 \times n_2 \times n_3$ $\mathcal{A} = [a_{ijk}]$

$$||\mathcal{A}|| = ||\mathcal{A}||_F = \left(\sum_{i=1}^{n_1} \sum_{j=1}^{n_2} \sum_{k=1}^{n_3} a^2_{ijk} \right)^{1/2}.$$

$$||\mathcal{A}||_C = \max_{i,j,k} |a_{ijk}|$$

Chebyshev norm $\mathcal{A}$.

DEFINITION 2.3 (outer product). $\mathcal{A}$ $a_{i_1,i_2,\ldots,i_p}$ $\mathcal{B}$ $b_{j_1,j_2,\ldots,j_q}$, $\mathcal{C} = \mathcal{A} \otimes B$ (+)

$$c_{i_1,i_2,\ldots,i_p,j_1,j_2,\ldots,j_q} = a_{i_1,i_2,\ldots,i_p} b_{j_1,j_2,\ldots,j_q}.$$

Tensors can be multiplied by matrices along a specified index (mode) direction.

DEFINITION 2.4 (mode convolution or n-mode product). $\mathcal{A} = [a_{ijk}]$ $n_1 \times n_2 \times n_3$ U $m_1 \times n_1$ $\mathcal{B} = [b_{ijk}]$ $m_1 \times n_2 \times n_3$

$$\mathcal{B} = \mathcal{A} \times_i U, \qquad b_{ijk} = \sum_{i'=1}^{n_1} u_{ii'} a_{i'jk}.$$

The operations $\mathcal{A} \times_j U$, $\mathcal{A} \times_k U$ are defined analogously, provided that U and $\mathcal{A}$ have appropriate sizes. In this notation, the Tucker decomposition (1.1) can be written as

$$\mathcal{A} = \mathcal{G} \times_i U \times_j V \times_k W.$$

We will say that a tensor has a (r_1, r_2, r_3) ( ) if (1.1) holds [10, 11].

The important objects are of the three-dimensional arrays.

DEFINITION 2.5. $\mathcal{A} = [a_{ijk}]$ $n_1 \times n_2 \times n_3$ k [1] $n_1 \times n_2$ A_k

$$(A_k)_{ij} = a_{ijk}.$$

The “short” vectors along the modes i, j, and k will be referred to as and , respectively.

[1] The slices by other two indices can also be defined, but it may lead to ambiguity. Since in this paper only kth slices are used, we omit these definitions here.

3. Existence theory. Suppose an $n_1 \times n_2 \times n_3$ tensor $\mathcal{A} = [a_{ijk}]$ is given and there exists a rank-(r_1, r_2, r_3) Tucker approximation to $\mathcal{A}$ with the accuracy ε:

$$\mathcal{A} = \mathcal{G} \times_i U \times_j V \times_k W + \mathcal{E}, \quad ||\mathcal{E}|| = \varepsilon. \tag{3.1}$$

If we are aware that such an approximation exists, then a generally different approximation of the same type with the accuracy bound $c\varepsilon$ (where $c > 1$ is a [illegible]) can be constructed from the knowledge of roughly the same amount of entries as those explicitly involved in (3.1). We want to prove this together with a bound on the deterioration coefficient c depending only upon dimensions and ranks but not on the entries of the array.

THEOREM 3.1. [illegible] (3.1) [illegible] $U, V,$ [illegible] W [illegible] $\mathcal{G}$. [illegible] $U', V',$ [illegible] W' [illegible] $n_1 \times r_1$, $n_2 \times r_2$, [illegible] $n_3 \times r_3$ [illegible] r_1 [illegible] r_2 [illegible] r_3 [illegible] $\mathcal{A}$, [illegible] $\mathcal{G}'$ [illegible]

$$\mathcal{A} = \mathcal{G}' \times_i U' \times_j V' \times_k W' + \mathcal{E}',$$

[illegible]

$$||\mathcal{E}'||_C \le (r_1 r_2 r_3 + 2r_1 r_2 + 2r_1 + 1)\varepsilon.$$

[illegible] Consider an unfolding matrix $A^{(1)}$ of the array $\mathcal{A}$. Since $\mathcal{A}$ has a rank-(r_1, r_2, r_3) approximation with accuracy ε, it is easy to see from (3.1) that $A^{(1)}$ has a rank-r_1 approximation with the same accuracy. A low-rank matrix can be approximated by its [illegible]

$$A^{(1)} = C\hat{C}^{-1}B^\top + \mathcal{E}_1,$$

where C is a $n_1 \times r_1$ matrix containing some r_1 columns of $A^{(1)}$, B is a $n_2 n_3 \times r_1$ matrix containing some r_1 rows of $A^{(1)}$, and $\hat{C}$ is a submatrix on the intersection of these rows and columns. In [13] it was proved that if $\hat{C}$ is a [illegible] (that is, the $r_1 \times r_1$ submatrix which has the largest absolute value of the determinant) in $\mathcal{A}^{(1)}$, then ε_1 is bounded as follows:

$$||\mathcal{E}_1||_C \le (r_1 + 1)\varepsilon,$$

where $||\cdot||_C$ denotes the largest magnitude element of a matrix (array). Also, if $\hat{C}$ is a maximal volume submatrix, it is easy to prove (cf. [13]) that the elements of $C\hat{C}^{-1}$ are not greater than 1 in modulus. Consequently,

$$\left| a_{ijk} - \sum_{s=1}^{r_1} \gamma_{is} z_{jks} \right| \le (r_1 + 1)\varepsilon,$$

where

$$|\gamma_{is}| \le 1, \qquad 1 \le i \le n_1,$$

and z_{jks} are in a one-to-one correspondence with the entries of $B^\top$ (for a fixed s these elements present a slice by the index i of the array $\mathcal{A}$). Also note that

$$\gamma_{is} = \sum_{l=1}^{r_1} u_{il}\phi_{ls},$$

where the matrix $[u_{il}]$ consists of some columns of $\mathcal{A}$.

Now let us look more closely at the matrix $B^\top$. In a reshaped form, it becomes the tensor with the elements z_{jks}. As previously, unfold this tensor along the index j. The ε-rank[2] of the unfolding matrix does not exceed r_2.

Again using the result of [13], we obtain the following inequalities:

$$\left| z_{jks} - \sum_{t=1}^{r_2} \sum_{\tau=1}^{r_2} \psi_{t\tau} v_{jt} w_{ks\tau} \right| \le (r_2 + 1)\varepsilon,$$

where the arrays $[v_{jt}]$ and $[w_{ks\tau}]$ consist of some rows and fibers of $\mathcal{A}$.

Unfolding the array $[w_{ks\tau}]$ by the index k, we observe that the ε-rank of the unfolding matrix cannot be larger than k_3. Hence, this matrix admits the skeleton approximation with the error bound

$$\left| w_{ks\tau} - \sum_{\alpha=1}^{k_3} \sum_{\beta=1}^{k_3} x_{k\alpha} \zeta_{\alpha\beta} y_{\alpha s\tau} \right| \le (r_3 + 1)\varepsilon.$$

Finally,

$$\begin{aligned}
\left| a_{ijk} - \sum_{l=1}^{r_1} \sum_{s=1}^{r_1} \sum_{t=1}^{r_2} \sum_{\tau=1}^{r_2} \sum_{\alpha=1}^{r_3} \sum_{\beta=1}^{r_3} (\phi_{ls} \psi_{t\tau} \zeta_{\alpha\beta} y_{\alpha t\tau}) u_{il} v_{jt} x_{k\alpha} \right| &\le \left| a_{ijk} - \sum_{s=1}^{r_1} \gamma_{is} z_{jks} \right| \\
+ \sum_{s=1}^{r_1} \left| z_{jks} - \sum_{t=1}^{r_2} \sum_{\tau=1}^{r_2} \psi_{t\tau} v_{jt} w_{ks\tau} \right| &+ \sum_{s=1}^{r_1} \sum_{\tau=1}^{r_2} \left| w_{ks\tau} - \sum_{\alpha=1}^{k_3} \sum_{\beta=1}^{k_3} x_{k\alpha} \zeta_{\alpha\beta} y_{\alpha s\tau} \right| \\
&\le (r_1 + 1)\varepsilon + r_1(r_2 + 1)\varepsilon + r_1 r_2 (r_3 + 1)\varepsilon,
\end{aligned}$$

which completes the proof. □

If $r_1 = r_2 = r_3 = r$, then the error bound becomes $(r+1)(r^2+r+1)\varepsilon \le (r+1)^3\varepsilon$. In the general case, we are not completely satisfied with the error bound of this theorem because it is not a symmetric function of r_1, r_2, r_3. Of course, the answer can be formally symmetrized, using different permutations of modes (for example, $n_3 \times n_2 \times n_1$) and taking the minimum of all these error bounds, but the obtained result seems to be rather artificial. So here we note that a "truly symmetric" version of this theorem is likely to need a different technique.

COROLLARY 3.2. [illegible]

$$||\mathcal{E}'||_F \le (r_1 r_2 r_3 + 2r_1 r_2 + 2r_1 + 1)\sqrt{n_1 n_2 n_3}\varepsilon.$$

4. The cross approximation method. For presentation purposes from now on we will assume that $n_1 = n_2 = n_3 = n$ and $r_1 = r_2 = r_3 = r$.

4.1. The two-dimensional-cross method. In the works [13, 14, 17] the problem of finding a rank-r approximation to a given matrix was connected with finding in matrix A a [illegible] (that is, determinant in modulus) among all $r \times r$ submatrices. The latter problem is hard to solve. However, we may be satisfied with a "sufficiently good" submatrix and some heuristic algorithms. Since these algorithms are to fetch a cross of some columns and rows, we call them [illegible]

[2]The matrix A is said to have ε-rank r if there exists a rank-r matrix B such that $\|A - B\| \le \varepsilon$.

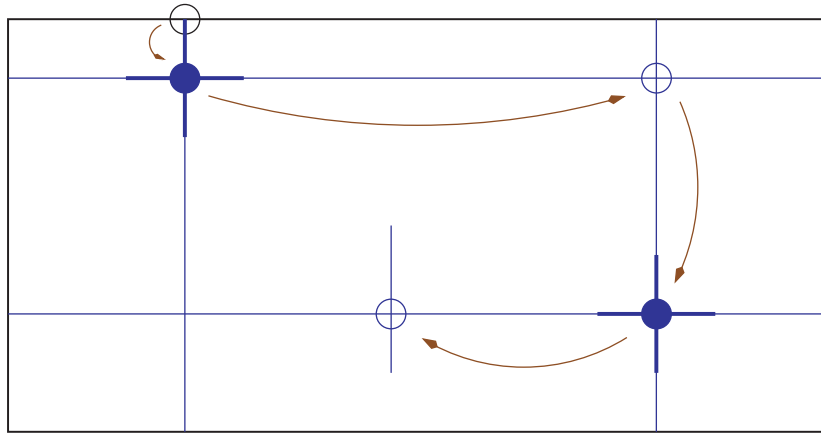

FIG. 1. *How a cross method works. Filled dots: elements used for the calculation of cross*(i_p, j_p). *Empty dots: row–pivot, step* (2).

. Probably the most simple and effective cross algorithm is the Gauss elimination method using some pivoting technique over dynamically selected sets of the entries of the "active matrix" (for a general description, see [9]). We will use here the column and row pivoting considered in [8]. This method is simple but may breakdown (quit when a good approximation is not obtained) if applied as it is. A cheap practical remedy proposed in [16] is a restarted version of this cross method. For the readers convenience, we give here a brief description of the algorithm.

ALGORITHM 1 (CROSS2D). Given a matrix A of approximate rank r, approximate it by a matrix $\tilde{A}_r$, which is a sum of r rank-1 matrices $u_p v_p^\top$ (so-called skeletons). The principle scheme is given in Figure 1.

(0) Numbering the steps by p, set $p = 1$. Choose some column in A, and assign its index to j_p.
(1) Calculate column j_p of the matrix A, and subtract from all elements the corresponding elements of already calculated skeletons. In the resulting vector find the largest magnitude element. Suppose it is located in the row i_p.
(2) Calculate the row i_p of the residue and the next pivot which is its largest magnitude element with a restriction that the element from the j_pth column cannot be chosen again (see Figure 1). Suppose this pivot is located in the j_{p+1}th column.
(3) Calculate the new cross centered at (i_p, j_p).
(4) If a stopping criterion is not satisfied, set $p := p + 1$, and go to step (1).

The approximation $\tilde{A}_p = \sum_{\alpha=1}^{p} u_\alpha v_\alpha^\top$ is considered good if

$$\|A - \tilde{A}_p\| \le \varepsilon \|A\|_F \approx \varepsilon \|\tilde{A}_p\|_F.$$

However, the exact computation of the error requires all matrix elements and n^2 operations, which is unacceptable. At the same time, the norm $\|\tilde{A}_p\|_F$ can be computed via the formula

$$\|\tilde{A}_p\|_F^2 = \sum_{i=1}^{m}\sum_{j=1}^{n}\left(\sum_{\alpha=1}^{r} u_{i\alpha} v_{j\alpha}\right)^2 = \sum_{\alpha=1}^{r}\sum_{\alpha'=1}^{r}(u_\alpha, u_{\alpha'})(v_\alpha, v_{\alpha'})$$

using $\mathcal{O}(p^2 n)$ operations. And as a practical estimator of the error (stopping criterion),

we use the norm of a newly computed rank-1 correction. Specifically, we stop if

$$(n-p)\|u_p\|_2\|v_p\|_2 \le \varepsilon\|\tilde{A}_r\|_F.$$

The number $n-p$ is a heuristic constant. Note that after p steps of the cross algorithm exactly p rows and columns of the residue are zeroed, so if we assume that the error is "equally distributed" among the remaining $n-p$ rows, then we immediately arrive at the presented stopping criteria.

Such version of the cross method requires $2rn$ evaluations of matrix elements and $\mathcal{O}(r^2n)$ additional operations (the reason for counting the number of element computations is that the calculation of one element may be a very time-consuming operation). Even if the stopping criteria is satisfied, in some cases the obtained approximation is not good enough (but this does not happen very often). To make the method more robust, the [illegible] step is performed: we create a sample from the elements of the residue matrix $A - \tilde{A}_r$. If the error estimated from that sample is large, we proceed with step (3) using the largest magnitude element in the sample as a pivot.

4.2. Towards the three-dimensional-cross method. Consider the unfoldings of the array $\mathcal{A}$ (rectangular matrices of sizes $n \times n^2$ defined by (2.1)), and apply to them the cross approximation algorithm. If the array $\mathcal{A}$ possesses a good Tucker rank-(r, r, r) approximation, then there exist rank-r approximations for the unfoldings $A^{(1)}$, $A^{(2)}$, and $A^{(3)}$ which are also good:

$$\tilde{A}^{(1)}_r = U\Psi^\top, \qquad \tilde{A}^{(2)}_r = V\Phi^\top, \qquad \tilde{A}^{(3)}_r = W\Upsilon^\top,$$

where U, V, W are $n \times r$ matrices with [illegible] and matrices Ψ, Φ, Υ are $n^2 \times r$. The Tucker core is calculated by the convolution of the form (1.3) with a_{ijk} being replaced with their approximate values. For example, using the decomposition by the first direction, $\tilde{A}^{(1)}_r = U\Psi^\top$, we have

$$a_{ijk} \approx \tilde{a}_{ijk} = \sum_{\alpha=1}^{r} u_{i\alpha}\psi_{jk\alpha},$$

where the rows of the matrix $\Psi = [\psi_{(jk)\alpha}]$ are numbered by a pair of indices (jk). Substituting this into (1.3), we obtain

$$\begin{aligned} g_{i'j'k'} &= \sum_{i=1}^{n}\sum_{j=1}^{n}\sum_{k=1}^{n}\left(\sum_{\alpha=1}^{r} u_{i\alpha}\psi_{jk\alpha}\right)u_{ii'}v_{jj'}w_{kk'} \\ &= \sum_{\alpha=1}^{r}(u_\alpha, u_{i'})\left(\sum_{j=1}^{n}\sum_{k=1}^{n} v_{jj'}w_{kk'}\psi_{jk\alpha}\right) \\ &= \sum_{j=1}^{n}\sum_{k=1}^{n} v_{jj'}w_{kk'}\psi_{jki'}. \end{aligned} \tag{4.1}$$

This computation needs $\mathcal{O}(n^2r)$ evaluations of the elements of $\mathcal{A}$ plus $\mathcal{O}(n^2r^2)$ operations.

Of course, $\mathcal{O}(n^2)$ is much smaller than the total number of elements in the array $\mathcal{A}$, but it is still too large when n is about 10^3.

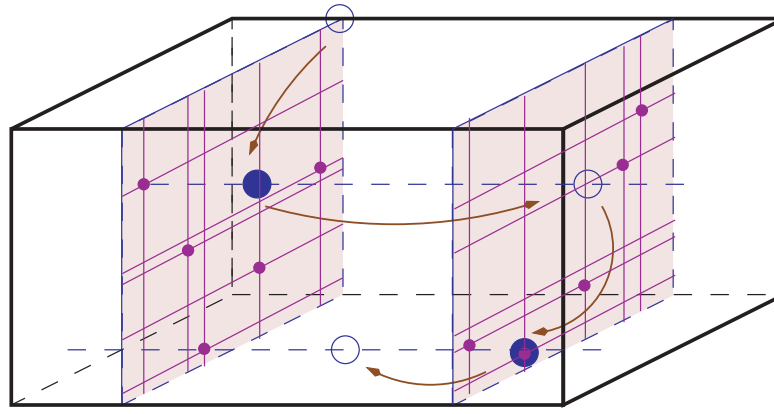

FIG. 2. *The work of the three-dimensional-cross method. The big filled and empty dots correspond to elements for the "outer" cross algorithm, and small dots show elements used for the "inner" cross algorithm, approximating a particular two-dimensional slice*

4.3. How to achieve linear complexity. We want to achieve linear complexity in n. To this end, we have to get rid of the computation of all elements in the slices of $\mathcal{A}$ used in the unfoldings (2.1) (then we avoid n^2-long vectors). We suggest to approximate the slices by the same cross algorithm developed for matrices. Since $\mathcal{A}$ has a good Tucker approximation with the accuracy ε, each slice $A_k = [(a_k)_{ij}]$ can be accurately approximated by a rank-r matrix. In what follows, we will never store a slice as a full $n \times n$ matrix and will never refer to all its elements. Instead, we deal only with some low-rank approximations for the slices.

ALGORITHM 2. Given an $n \times n \times n$ array $\mathcal{A}$, take one of the indices i, j, k as the "leading index," let it be k. Then consider the corresponding unfolding matrix of size $n \times n^2$, and approximate it applying the cross method. The columns of the unfolding matrix are calculated as usual, but each of the long rows is considered as a matrix of size $n \times n$ to be approximated by the same cross method. Therefore, at each step of the "outer" cross method we add one skeleton of form $A \otimes w$ with the long vector A represented by the sum of r skeletons in the "inner" cross method; therefore, we add a tensor of form $\sum_{q=1}^{r} u_q \otimes v_q \otimes w$. After r steps the approximant has the form

$$\tilde{A} = \sum_{p=1}^{r} \left(\sum_{q=1}^{r} u_q^{\{p\}} \otimes v_q^{\{p\}} \right) \otimes w^{\{p\}},$$

where $u_q^{\{p\}}$ and $v_q^{\{p\}}$, $q = 1, \ldots, r$, are vectors comprising the skeleton approximation to the long vector at the step with number p. Note that unlike vectors u and v, vectors w are numbered only by p, because k is the leading index. The principle scheme is given in Figure 2.

The expected number of arithmetic operations is [illegible] in sizes of the array: the complexity is $\mathcal{O}(nr^d)$ operations for some small $d > 0$.

(0) Numbering the steps by p, set p to 1. Choose a slice $A_k = [(a_k)_{ij}]$ in $\mathcal{A}$, for example, and assume its index to k_1. Set $\tilde{\mathcal{A}} = 0$.

(1a) Find an approximation A_{k_p} to the k_pth slice of the residue $\mathcal{R} = \mathcal{A} - \tilde{\mathcal{A}}_p$ by the cross method:

$$A_{k_p} = \sum_{q=1}^{r} u_q v_q^{\top}.$$

(1b) Find the largest magnitude element in the matrix A_{k_p}; let it be located at (i_p, j_p).

(2) Compute the vector w corresponding to the fiber of $\mathcal{R}$ with index (i_p, j_p),

$$w_k = \mathcal{R}_{i_p, j_p, k},$$

perform the scaling

$$w := w / w_{k_p},$$

and find in w the largest magnitude element from those whose index is not equal to k_p.[3] Suppose it is located at the k_{p+1}th position of w.

(3) Compute a new approximation:

$$\tilde{\mathcal{A}} := \tilde{\mathcal{A}} + A_{k_p} \otimes w = \tilde{\mathcal{A}} + \left(\sum_{q=1}^{r} u_q v_q^\top \right) \otimes w = \tilde{\mathcal{A}} + \sum_{q=1}^{r} u_q \otimes v_q \otimes w.$$

(4) If the stopping criterion is not satisfied, set $p := p + 1$, and go to step (1).

In the end, the array $\mathcal{A}$ is approximated by $\tilde{\mathcal{A}} = [\tilde{a}_{ijk}]$ having a Tucker-like decomposition (also viewed as a trilinear, PARAFAC, or CANDECOMP decomposition [1, 5]) of the form (in elementwise notation)

$$\tilde{a}_{ijk} = \sum_{p=1}^{r} \left(\sum_{q=1}^{r} u_{iq}^{\{p\}} v_{jq}^{\{p\}} \right) w_k^{\{p\}} = \sum_{\alpha=1}^{r^2} u_{i\alpha} v_{j\alpha} w_{k\alpha}, \tag{4.2}$$

where in the second sum for simplicity all terms are numbered by a single index α instead of a complicated sum on the left.

During the implementation of this method, we encounter several problems that should be solved with a linear complexity in n:

- determine the largest magnitude element in a low-rank matrix, step (1)b;
- estimate the quantities in the relationships

$$\|\mathcal{A} - \tilde{\mathcal{A}}\|_F \le \varepsilon \|\mathcal{A}\|_F \approx \varepsilon \|\tilde{\mathcal{A}}\|_F$$

so as to have a sound stopping criterion, step (4).

The first problem is not trivial, and we do not know if there is an exact and fast way to find a maximal element in a low-rank matrix. However, we are able to design a heuristic algorithm, based on the submatrix of maximal volume. It manifests a very good practical performance (see Appendix A).

The stopping criterion in the Cross3D method is identical to the two-dimensional case, by the comparison of the approximant norm and the norm of a newly computed cross-correction. The norm $\|\tilde{\mathcal{A}}\|_F$ is computed by the formulas

$$\begin{aligned} \|\tilde{\mathcal{A}}\|_F^2 &= \sum_{i=1}^{n} \sum_{j=1}^{n} \sum_{k=1}^{n} \left(\sum_{\alpha=1}^{r^2} u_{i\alpha} v_{j\alpha} w_{k\alpha} \right)^2 \\ &= \sum_{\alpha=1}^{r^2} \sum_{\alpha'=1}^{r^2} (u_\alpha, u_{\alpha'})(v_\alpha, v_{\alpha'})(w_\alpha, w_{\alpha'}). \end{aligned}$$

[3] It is worthy to note that we cannot also use elements with indices $k_1, \ldots, k_{p-1}$, but it can be verified that they are all zeroes, so they cannot have maximal modulus.

The cost of Algorithm 2 is $\mathcal{O}(nr^2)$ evaluations of the elements of $\mathcal{A}$ plus $\mathcal{O}(nr^4)$ arithmetic operations (at each outer step of the method we compute a new slice from which we should subtract the elements of the previously computed approximation, and that results in a relatively big constant r^4 at the size n). This is already a linear complexity. However, we are going to present a "clever" implementation with a significantly better performance.

4.4. The three-dimensional-cross algorithm. We can improve the efficiency of Algorithm 2 by using a more compact way to store and handle the slices A_{k_p} so that the required number of vectors to represent them is reduced from $\mathcal{O}(r^2)$ to $\mathcal{O}(r)$.

At each step we approximate the computed slices A_{k_p} in the format

$$A_{k_p} = UB_pV^\top, \tag{4.3}$$

where $n \times r$ matrices U, V are orthogonal and the core matrices B_p are $r \times r$. It is worth noting that (4.3) is also known as a Tucker2 decomposition, where only 2 of 3 modes are compressed. The storage for p slices is now $2nr + pr^2$ which is asymptotically equal to $\mathcal{O}(nr)$. The existence of matrices U, V, follows from the existence of a "good" Tucker approximation. In fact, we can try U and V as the Tucker factors. The computation of this simultaneous matrix decomposition is equivalent to the computation of the Tucker decomposition of a $n \times n \times p$ array:

$$\mathcal{A}' = [A_{k_1} \dots A_{k_p}].$$

Indeed, if

$$a_{ijk_p} = \sum_{i'=1}^{r} \sum_{j'=1}^{r} \sum_{p'=1}^{r} g_{i'j'p'} u_{ii'} v_{jj'} w_{pp'},$$

then, setting

$$\sum_{p'=1}^{r} g_{i'j'p'} w_{pp'} = b_{i'j'p} = (b_p)_{i'j'},$$

we immediately arrive at (4.3).

Another important modification concerns the computation of the slices. Suppose the p steps are done and we are going to compute the $p+1$th slice $A_{k_{p+1}}$. Instead of using the "full" cross method for this slice, we first find an approximation of the form

$$A_{k_{p+1}} \approx U\Phi V^\top,$$

where U, V come from (4.3) and a matrix Φ is $r \times r$. Such an approximation can be obtained quite cheaply by the following scheme:

- Find $r \times r$ [illegible] in U and V. Suppose they have indices $i_1, \dots, i_r$ and $j_1, \dots, j_r$. Denote these submatrices by $\hat{U}$ and $\hat{V}$.
- Compute the $r \times r$ submatrix S in $A_{k_{p+1}}$ lying on the intersection of rows with indices $i_1, \dots, i_r$ and columns with indices $j_1, \dots j_r$.
- Compute

$$\Phi = \hat{U}^{-1} S \hat{V}^{-1}. \tag{4.4}$$

We can prove that this approximation approach is robust (see Appendix B). After Φ is computed, we check the approximation error by taking some random samples of a true matrix A_{k_p}. If the approximation is not good enough, then we perform some steps of the cross approximation algorithm, starting from a good approximation. However, as a rule, only a few steps (or even none) of the cross algorithm are required.

ALGORITHM 3 (CROSS3D). Suppose an $n \times n \times n$ three-way array $\mathcal{A}$ is given.

(0) Perform one step of Algorithm 2 (with $p = 1$). Upon completion, $p = 2$, and $\mathcal{A}$ is represented as

$$\tilde{A} = \left(\sum_{q=1}^{r} u_q^{\{1\}} (v_q^{\{1\}})^\top \right) \otimes w^{\{1\}} = \sum_{q=1}^{r} u_q^{\{1\}} \otimes v_q^{\{1\}} \otimes w^{\{1\}}.$$

Form matrices $U_1 = [u_q^{\{1\}}]$, $V_1 = [v_q^{\{1\}}]$, and compute orthonormal bases U, V of these subspaces using two QR-decompositions:

$$U_1 = UR_u, \qquad V_1 = VR_v.$$

Then $\mathcal{A}$ is represented as

$$\tilde{A} = (UR_uR_v^\top V^\top) \otimes w^{\{1\}} = (UB_1V^\top) \otimes (w^{\{1\}}/\|w^{\{1\}}\|_2),$$

$$B_1 = R_uR_v^\top \|w^{\{1\}}\|_2.$$

Set $w^{\{1\}} := w^{\{1\}}/\|w^{\{1\}}\|$. (Note that in this algorithm we will keep bases U, V, and W orthonormal.) In the vector $w^{\{1\}}$ compute the largest magnitude element; suppose it has index k_2.

(1.1) Compute Φ from (4.4). If necessary, perform some additional steps of the cross method to obtain an approximation to the slice A_{k_p}:

$$A_{k_p} \approx \tilde{A}_{k_p} = U\Phi V^\top + \sum_{q=1}^{r_p} u_q^{\{p\}} (v_q^{\{p\}})^\top.$$

(Note that r_p is supposed to be small even compared to r.)

(1.2) Add new vectors $U_p = [u_q^{\{p\}}]$, $V_p = [v_q^{\{p\}}]$, $q = 1, \ldots, r$, to bases U, V, and orthogonalize the extended matrices $[UU_p]$, $[VV_p]$:

$$[UU_p] = [U\hat{U}_p] \begin{bmatrix} I & M_u \\ 0 & R_u \end{bmatrix}, \quad [VV_p] = [V\hat{V}_p] \begin{bmatrix} I & M_v \\ 0 & R_v \end{bmatrix},$$

$$U^\top \hat{U}_p = 0, \qquad V^\top \hat{V}_p = 0, \qquad \hat{U}_p^\top \hat{U}_p = I, \qquad \hat{V}_p^\top \hat{V}_p = I.$$

(1.3) Compute new $(r + r_p) \times (r + r_p)$ core B_p:

$$B_p = \begin{bmatrix} M_u \\ R_u \end{bmatrix} \begin{bmatrix} M_v^\top R_v^\top \end{bmatrix}.$$

Other slices in a new basis have the form

$$A_{k_q} = [U\hat{U}_p] \begin{bmatrix} B_q & 0 \\ 0 & 0 \end{bmatrix} [V\hat{V}_p]^\top, \qquad q = 1, \ldots, p-1.$$

Therefore, approximation $\tilde{\mathcal{A}}_{p-1}$ is represented as

$$\tilde{\mathcal{A}}_{p-1} = \sum_{q=1}^{p-1} \left(U' B'_q V'^{\top}\right) \otimes w_q,$$

$$U' = [U\hat{U}_p], \qquad V' = [V\hat{V}_p], \qquad B'_q = \begin{bmatrix} B_q & 0 \\ 0 & 0 \end{bmatrix}, \qquad q = 1, \ldots, p-1.$$

Set also $B'_p = B_p$.

(1.4) In the new slice A_{k_p} the largest magnitude element is found. Suppose it is located in (i_p, j_p).

(2.1) The fiber $w^{\{p\}}$ of the residue $\mathcal{A} - \tilde{\mathcal{A}}_{p-1}$ corresponding to (i_p, j_p) is computed.

(2.2) Vector $w^{\{p\}}$ is orthogonalized to vectors $W = [w^{\{1\}}, \ldots, w^{\{p-1\}}]$:

$$w^{\{p\}} = \sum_{q=1}^{p-1} c_q w^{\{q\}} + \hat{w}^{\{p\}}, \qquad (\omega^{\{q\}})^{\top} \hat{w}^{\{p\}} = 0, \qquad q = 1, \ldots, p-1.$$

Cores of old slices B'_q, $q = 1, \ldots, p-1$, are modified:

$$B''_q = B'_q + c_q B'_p, \qquad q = 1, \ldots, p-1.$$

Vector $\hat{w}^{\{p\}}$ is normalized:

$$w^{\{p\}} := \hat{w}^{\{p\}} / \|\hat{w}^{\{p\}}\|_2, \qquad B''_p = \|\hat{w}^{\{p\}}\|_2 B'_p.$$

(3) The approximation $\tilde{\mathcal{A}}_p$ is represented as

$$\tilde{\mathcal{A}}_p = \sum_{q=1}^{p} \left(U' B''_q V'^{\top}\right) \otimes w^{\{q\}}. \tag{4.5}$$

To reduce the sizes of the $(r + r_p) \times (r + r_p)$ matrices B''_q, we apply the Tucker reduction method.

(3.1) Create a three-way array $\mathcal{B}'' = [B''_1 \ldots B''_p]$ of size $(r + r_p) \times (r + r_p) \times p$, and compute its Tucker decomposition.

$$b''_{ijk} = \sum_{i'=1}^{r} \sum_{j'=1}^{r} \sum_{k'=1}^{r} g^{\clubsuit}_{i'j'k'} u^{\clubsuit}_{ii'} v^{\clubsuit}_{jj'} w^{\clubsuit}_{kk'}.$$

If we introduce matrices $B_{\clubsuit k}$ with elements

$$(B_{\clubsuit k})_{i'j'} = \sum_{k'=1}^{r} g^{\clubsuit}_{i'j'k'} w^{\clubsuit}_{kk'},$$

then we have

$$B''_k = U_{\clubsuit} B_{\clubsuit k} V_{\clubsuit}^{\top}, \qquad k = 1, \ldots, p, \tag{4.6}$$

where matrices $U_{\clubsuit}$ and $V_{\clubsuit}$ are $(r + r_1) \times r$ and cores $B_{\clubsuit k}$ are $r \times r$.

(3.2) Substituting (4.6) into (4.5), we obtain that

$$\tilde{\mathcal{A}}_p = \sum_{k=1}^{p} \Big((U' U_{\clubsuit}) B_{\clubsuit_k} (V' V_{\clubsuit})^\top \Big) \otimes w^{\{k\}} = \sum_{k=1}^{p} \big(U B_k V^\top \big) \otimes w^{\{k\}}, \tag{4.7}$$

where $U = U' U_{\clubsuit}$, $V = V' V_{\clubsuit}$ are orthogonal and cores $B_k = B_{\clubsuit_k}$ are $r \times r$. The format (4.3) is restored.

(4) Check stopping criteria; if it is not satisfied, go to (1.1).

At each step of the outer cross method we obtain a new Tucker approximant with the core of the dimension $(r + r_p) \times (r + r_p) \times r$; the purpose of steps (3.1)–(3.2) is to compress this tensor back.

The Algorithm 3 is the final version of Cross3D. The numerical complexity of the method is $\mathcal{O}(nr)$ evaluations of the array elements and $\mathcal{O}(nr^3)$ additional operations.

5. Numerical experiments. We illustrate the performance of our algorithm on some model tensors which allow good low-rank approximation.

Specifically, we consider the following two types of arrays:

$$\mathcal{A} = [a_{ijk}], \qquad a_{ijk} = \frac{1}{i + j + k}, \qquad 1 \le i, j, k \le n,$$

$$\mathcal{B} = [b_{ijk}], \qquad b_{ijk} = \frac{1}{\sqrt{i^2 + j^2 + k^2}}, \qquad 1 \le i, j, k \le n.$$

The rank estimates obtained in [15, 18, 19] have the form

$$r \le C(\log n \log^2 \varepsilon),$$

where ε is an error of the approximation, so the rank grows only logarithmically with n and ε.

These two examples arise from the numerical solution of integral equations. For example, the array $\mathcal{B}$ is obtained from the integral equation with kernel $\frac{1}{||x-y||}$ acting on a unit cube and being disretized by the Nyström method on a uniform grid.

Table 1 shows the ranks, accuracies, and size of the computed Tucker approximation for the array $\mathcal{A}$; Table 2 shows the same for $\mathcal{B}$. The accuracy of the approximation was computed by sampling the elements of the array, since it is not possible to check all the elements for large n. The size of the sample was determined by the following rule: if the sample size was doubled, the estimated error should change by no more than 10%. As it can be seen, the approximation method is robust and leads to astonishing memory savings: the arrays that would need in the full format an enormous storage of 2 petabytes ($2 \cdot 2^{50}$ PB) are compressed to the sizes of 100 MB.

Moreover, our algorithm works with arrays on this huge scale on a personal workstation. The timings made on a personal computer (`Pentium-4` with 3.4 Ghz clock) are shown in Figure 3. This figure confirms that the approximation time is almost linear in n. More precisely, we demonstrate the $\mathcal{O}(nr^3)$ complexity of the Cross3D algorithm with rank estimated as $r \sim \log n$ for fixed ε. Therefore, the complexity of the algorithm is estimated as

$$t \le cn \log^3 n.$$

In Figure 3 real timings, measured for different ε, are shown together with "theoretical" bounds $cn \log^3 n$, plotted for two different values of c. The somewhat irregular

behavior on the timing plots is caused by the effects of caching (for small n) and by some rank overestimation by the stopping criteria for large n.

Two dense tensors considered come from a simple disretization of integral equations. Despite their "regularity" they are quite representative: in more complex cases our method behaves similarly. In other areas where tensor decomposition is used, the researchers often obtain more irregular and possibly sparse tensors. We want to note that sparseness is [illegible] for Cross3D because in that case the residue can be measured [illegible] and the pivots during the cross approximation stage can be also found exactly, leading to a [illegible] method. The applications of the three-dimensional-cross approach to more complex tensors will be reported elsewhere.

Appendix A. How to find the maximal element in a slice. One of the important ingredients of the three-dimensional-cross method is the determination of the maximal element in a given low-rank matrix in linear time.

Suppose we have computed a skeleton approximation to a low-rank matrix

$$A = UV^{\top},$$

where U, V are $n \times r$, and we want to find the largest magnitude element in it. This

problem can be solved by comparing all the elements of the matrix, but it costs $\mathcal{O}(n^2)$ operations. The proposed algorithm is based on the following hypothesis.

Consider $r \times r$ submatrices in a rank-r matrix A. Let B be a submatrix of maximal volume among all such submatrices. Then

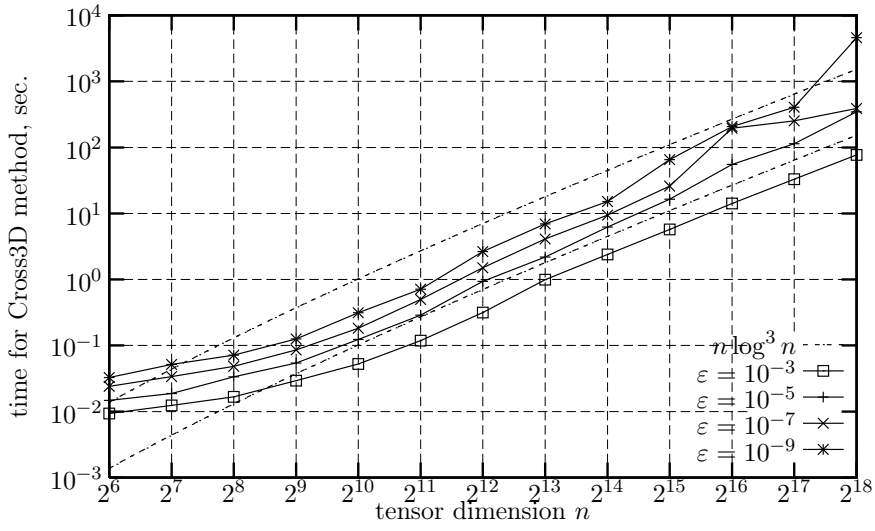
$$||B||_C \ge \frac{||A||_C}{r}.$$

So the maximal element in the submatrix of maximal volume cannot be very much different from the maximal element in the whole matrix A.

How does one determine a submatrix of maximal volume? This submatrix of A lies on the intersection of rows $i_1, \ldots, i_r$, coinciding with rows which contain the submatrix of maximal volume in U, and columns $j_1, \ldots, j_r$, which contain the submatrix of maximal volume in $V^\top$. To find the submatrix of maximal volume in a $n \times r$ matrix, we will use the algorithm, proposed in [12]. For the readers convenience we describe it below.

ALGORITHM 4. Suppose U is a $n \times r$ matrix and its $r \times r$ submatrix with maximal volume is needed.

$$\mathcal{A} = [a_{ijk}], \qquad a_{ijk} = \frac{1}{i+j+k}, \qquad 1 \le i,j,k \le n$$



$$\mathcal{B} = [b_{ijk}], \qquad b_{ijk} = \frac{1}{\sqrt{i^2+j^2+k^2}}, \qquad 1 \le i,j,k \le n$$

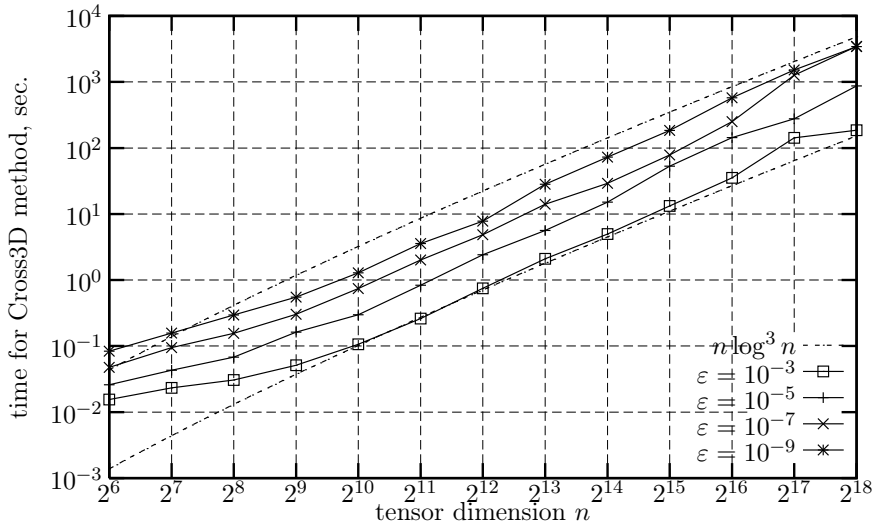


FIG. 3. *Approximation time, sec.*

(0) Let A_γ be a leading submatrix. In the beginning set A_γ to any nonsingular submatrix of A, and permute the rows so that A_γ is located in the first r rows.

(1) Compute

$$AA_\gamma^{-1} = \begin{bmatrix} I_{r\times r} \\ Z \end{bmatrix} = B.$$

(2) Find the largest magnitude element $|z_{ij}|$ in Z.
(3) **If** $\gamma = |z_{ij}| > 1$, **then**
Permute in B rows $r+i$ and j. The upper submatrix in B after the permutation has the form

$$\begin{pmatrix} 1 & & & & & \\ & \ddots & & & & \\ * & * & \gamma & * & * & \\ & & & \ddots & & \\ & & & & 1 & \end{pmatrix},$$

and its determinant is equal to $\gamma \geq 1+\varepsilon$, that is, it increased. Denote by A_γ the new submatrix in the first r rows of A, and return to step (1).
Otherwise terminate the algorithm.

In practice, to avoid a huge number of transpositions a more "soft" stopping criteria is used in step (3). The algorithm stops if $|z_{ij}| \leq 1+\nu$, where ν is a some small parameter.

Appendix B. The $U\Phi V^\top$ decomposition. In this appendix we will prove that the usage of (4.4) for the construction of the low-rank approximation to a slice is "legal."

THEOREM B.1. [illegible] A [illegible] $n_1 \times n_2$ [illegible] U, V [illegible] $n_1 \times r_1$ [illegible] $n_2 \times r_2$ [illegible] Φ [illegible]

$$A = U\Phi V^\top + E, \quad ||E||_F \leq \varepsilon.$$

[illegible] Φ' [illegible] (4.4) [illegible]

$$||A - U\Phi' V^\top||_F \leq (\sqrt{n_1 r_1 n_2 r_2} + 1)\varepsilon.$$

[illegible]. If $\hat{U}$ and $\hat{V}$ are submatrices of maximal volume in U and V, respectively, and $\hat{A}$ is a submatrix in A lying on the intersection of the selected rows from U and columns from $V^\top$, then

$$\hat{A} = \hat{U}\Phi\hat{V}^\top + \hat{E},$$

where $\hat{E}$ is a submatrix of E occupying the same positions in E as $\hat{A}$ in A.

$$||\Phi - \Phi'|| \leq ||\hat{U}^{-1}||\ ||\hat{E}||\ ||\hat{V}^{-1}||.$$

The norms $\hat{U}^{-1}, \hat{V}^{-1}$ can be estimated as follows. We know that the elements of

$$U\hat{U}^{-1}$$

are not greater than 1 in modulus (because $\hat{U}$ is a submatrix of maximal volume). Therefore,

$$||\hat{U}^{-1}||_F \leq \sqrt{n_1 r_1}.$$

Using this estimate we immediately complete the proof as follows:

$$\|A - U\Phi' V^\top\|_F \leq \|U\Phi V^\top - U\Phi' V^\top\|_F + \|E\|_F = \|\Phi - \Phi'\| + \varepsilon \leq \sqrt{n_1 r_1}\sqrt{n_2 r_2}\varepsilon + \varepsilon. \qquad \square$$

Acknowledgment. We are very grateful to both of the referees of our paper. The remark of one of the referees helped us to discover a nasty bug in the program code.

TENSOR-CUR DECOMPOSITIONS FOR TENSOR-BASED DATA*

MICHAEL W. MAHONEY†, MAURO MAGGIONI‡, AND PETROS DRINEAS§

Abstract. Motivated by numerous applications in which the data may be modeled by a variable subscripted by three or more indices, we develop a tensor-based extension of the matrix CUR decomposition. The tensor-CUR decomposition is most relevant as a data analysis tool when the data consist of one mode that is qualitatively different from the others. In this case, the tensor-CUR decomposition approximately expresses the original data tensor in terms of a basis consisting of underlying subtensors that are actual data elements and thus that have a natural interpretation in terms of the processes generating the data. Assume the data may be modeled as a $(2+1)$-tensor, i.e., an $m \times n \times p$ tensor $\mathcal{A}$ in which the first two modes are similar and the third is qualitatively different. We refer to each of the p different $m \times n$ matrices as "slabs" and each of the mn different p-vectors as "fibers." In this case, the tensor-CUR algorithm computes an approximation to the data tensor $\mathcal{A}$ that is of the form $\mathcal{CUR}$, where $\mathcal{C}$ is an $m \times n \times c$ tensor consisting of a small number c of the slabs, $\mathcal{R}$ is an $r \times p$ matrix consisting of a small number r of the fibers, and $\mathcal{U}$ is an appropriately defined and easily computed $c \times r$ encoding matrix. Both $\mathcal{C}$ and $\mathcal{R}$ may be chosen by randomly sampling either slabs or fibers according to a judiciously chosen and data-dependent probability distribution, and both c and r depend on a rank parameter k, an error parameter ϵ, and a failure probability δ. Under appropriate assumptions, provable bounds on the Frobenius norm of the error tensor $\mathcal{A} - \mathcal{CUR}$ are obtained. In order to demonstrate the general applicability of this tensor decomposition, we apply it to problems in two diverse domains of data analysis: hyperspectral medical image analysis and consumer recommendation system analysis. In the hyperspectral data application, the tensor-CUR decomposition is used to *compress* the data, and we show that classification quality is not substantially reduced even after substantial data compression. In the recommendation system application, the tensor-CUR decomposition is used to *reconstruct* missing entries in a user-product-product preference tensor, and we show that high quality recommendations can be made on the basis of a small number of basis users and a small number of product-product comparisons from a new user.

Key words. CUR decomposition, tensor decomposition, hyperspectral imagery, recommendation system

1. Introduction.

Novel algorithmic methods to structure large data sets are of continuing interest. A particular challenge is presented by tensor-based data, i.e., data which are modeled by a variable subscripted by three or more indices [44, 31, 46, 61, 11]. Numerous examples suggest themselves, but to guide the discussion consider the following three. First, in internet data applications, if one is studying the properties of a large time-evolving graph, the data may consist of a graph or its adjacency matrix sampled at a large number of sequential time steps, in which case $\mathcal{A}_{ijk}$ may represent the weight of the edge between nodes i and j at time step k. Second, in biomedical

data applications, if one is studying cancer diagnosis, the data may consist of a large number of hyperspectrally resolved biopsy images, in which case $\mathcal{A}_{ijk}$ may represent the absorbed or transmitted light intensity of a biopsy sample at pixel ij at frequency k. Third, in consumer data applications, if one is studying recommendation systems, the data may consist of product-product preference data for a large number of users, in which case $\mathcal{A}_{ijk}$ may be ± 1, depending on whether product i or j is preferred by user k. Tensor-based data are particularly challenging due to their size and since many data analysis tools based on graph theory and linear algebra do not easily generalize.

When compared with algorithmic results for data modeled by either matrices or graphs, algorithmic results for data modeled by multimode tensors are modest. For example, even computing the rank of a general tensor $\mathcal{A}$ (defined as the minimum number of rank-one tensors into which $\mathcal{A}$ can be decomposed) is an NP-hard problem [32]. On the other hand, the model proposed by Tucker [61], as well as the related "canonical decomposition" [11] or "parallel factors" models [31], have a long history in applied data analysis [39, 40, 41, 44]. They provide exact or approximate decompositions for higher-order tensors. Recent research has focused on the relationship between these data tensor models and efforts to extend linear algebraic notions such as the SVD to multimode data tensors [44, 45, 46, 48].

A seemingly unrelated line of work has focused on matrix CUR decompositions [19, 22, 23]. As discussed in more detail in section 2.2, a matrix CUR decomposition provides a low-rank approximation of the form $A \approx \tilde{A} = CUR$, where C is a matrix consisting of a small number of columns of A, R is a matrix consisting of a small number of rows of A, and U is an appropriately defined low-dimensional encoding matrix [19]. Thus, a matrix CUR decomposition provides a dimensionally reduced low-rank approximation to the original data matrix A that is expressed in terms of a small number of actual columns and a small number of actual rows of the original data matrix, rather than, e.g., orthogonal linear combinations of those columns and rows.

In this paper, we extend a recently developed and provably accurate matrix CUR decomposition to tensor-based data sets in which there is a "distinguished" mode, and we apply it to problems in two of the three data set domains mentioned previously. When applied to hyperspectral image data, we use tensor-CUR to perform compression in order to run a classification on a more concise input, and when applied to recommendation system data, we use tensor-CUR to perform reconstruction in the absence of the full input.

By a "distinguished" mode, we mean a mode that is qualitatively different from the other modes in an application-dependent manner. The most appropriate data structure for a data set consisting of, e.g., a time-evolving internet graph or a set of hyperspectrally resolved biopsy images or user-product-product preference data for consumers depends on the application and is a matter of debate. Nevertheless, we will view such a data set as a tensor, albeit one in which one of the modes is "distinguished." For example, in these three applications, the distinguished mode would be the mode describing, respectively, the temporal evolution of the graph, the frequency or spectral variation in the images, and the users. The tensor-CUR decomposition computes an approximation to the original data tensor that is expressed as a linear combination of subtensors of the original data tensor. As we shall see, since these subtensors are actual data elements, rather than, e.g., more complex functions of data elements, in many cases they lend themselves more readily to application-specific interpretation.

2. Review of relevant linear and multilinear algebra. In this section, we provide a brief review of relevant multilinear algebra as well as recent work on matrix CUR decompositions.

2.1. Tensor-based extension of the SVD. We shall use calligraphic letters to denote higher-order or multimode tensors with $d > 2$ modes. For example, let $\mathcal{A} \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_d}$ be a d-mode tensor of size $n_1 \times n_2 \times \cdots \times n_d$ and let $N_\alpha = \prod_{i \neq \alpha} n_i$. Consider the following definitions:

- Given a tensor $\mathcal{A}$ and a particular mode $\alpha \in \{1, \ldots, d\}$, define the matrix $A_{[\alpha]} \in \mathbb{R}^{n_\alpha \times N_\alpha}$, where the columns of the matrix consist of varying the αth coordinate of $\mathcal{A}$ while leaving the rest fixed. We refer to the (usually implicit) construction of $A_{[\alpha]}$ as *matricizing* [36] or *unfolding* [44] $\mathcal{A}$ along mode α and define the *α-rank* of the tensor $\mathcal{A}$ to be the rank of the matrix $A_{[\alpha]}$.
- Given an $n_1 \times n_2 \times \cdots \times n_d$ d-mode tensor $\mathcal{A}$, a particular mode α, and any $n_\alpha \times c_\alpha$ matrix B, define the *α-mode tensor-matrix product* to be the d-mode tensor of size $n_1 \times \cdots \times n_{\alpha-1} \times c_\alpha \times n_{\alpha+1} \times \cdots \times n_d$ whose $i_1 \cdots i_d$ element is

$$(\mathcal{A} \otimes_\alpha B)_{i_1 \cdots i_d} = \sum_{i=1}^{n_\alpha} \mathcal{A}_{i_1 \cdots i_{\alpha-1} i i_{\alpha+1} \cdots i_d} B_{i i_\alpha}. \tag{1}$$

  Note that the α-mode tensor-matrix product satisfies $(\mathcal{A} \otimes_\alpha B) \otimes_{\alpha'} C = (\mathcal{A} \otimes_{\alpha'} C) \otimes_\alpha B = \mathcal{A} \otimes_\alpha B \otimes_{\alpha'} C$, assuming that the various individual products are defined.
- Given a tensor $\mathcal{A}$, let us denote the SVD of $A_{[\alpha]}$ by

$$A_{[\alpha]} = U_{[\alpha]} \Sigma_{[\alpha]} V_{[\alpha]}^T, \tag{2}$$

  where, e.g., $U_{[\alpha]}$ is an $n_\alpha \times \operatorname{rank}(A_{[\alpha]})$ matrix and $U_{[\alpha],k_\alpha}$ is an $n_\alpha \times k_\alpha$ matrix consisting of the left singular vectors corresponding to the top k_α singular values of $A_{[\alpha]}$.
- Given a d-mode tensor $\mathcal{A}$, define the (square of its) *Frobenius norm* to be

$$\|\mathcal{A}\|_F^2 = \sum_{i_1=1}^{n_1} \cdots \sum_{i_d=1}^{n_d} \mathcal{A}_{i_1 \cdots i_d}^2. \tag{3}$$

- Given a tensor $\mathcal{A}$ and a particular mode α, let us refer to *slabs* as each of the n_α $d-1$-mode tensors of size $n_1 \times \cdots \times n_{\alpha-1} \times n_{\alpha+1} \times \cdots \times n_d$ constructed by fixing the αth coordinate to some particular value $i_\alpha \in \{1, \ldots, n_\alpha\}$. Similarly, let us refer to as *fibers* each of the N_α vectors (mode-one tensors) of size n_α constructed by fixing each of the other coordinates to a particular value.

Remark. See [44, 45, 36] and the references therein for a more detailed description of these tensor-related definitions. In particular, note that, although they will not be of interest to our main result, the *higher-order SVD* of $\mathcal{A}$ has been defined as the decomposition of $\mathcal{A}$ of the form $\mathcal{A} = \mathcal{S} \times_1 U_{[1]} \times_2 \cdots \times_d U_{[d]}$, where the $\operatorname{rank}(A_{[1]}) \times \cdots \times \operatorname{rank}(A_{[d]})$ tensor $\mathcal{S}$ is the so-called core tensor, and the *best rank-$(k_1, k_2, \ldots, k_d)$ approximation* to the tensor $\mathcal{A}$ has been defined as $\tilde{\mathcal{A}} = \mathcal{S} \times_1 U_{[1],k_1} \times_2 \cdots \times_d U_{[d],k_d}$. See [23] for a randomized algorithm that computes an approximation to this quantity. The algorithm of [23] is similar to the algorithms presented in this paper, except that it "unfolds" the tensor along every mode and computes an approximation to the top singular vectors of the unfolded matrix by random sampling.

Remark. Tensors are a natural generalization of matrices (see, e.g., [30] for more details) and have been studied in several fields. For example, tensors have been studied in mathematics and computer science for their algebraic properties, their ability to efficiently represent multidimensional functions, and the relationship between their properties and problems in complexity theory [30, 27, 32, 50, 8]. In addition, tensors provide a natural way to represent many large and complex data sets [44, 43, 31, 36, 46, 61, 11, 65].

Remark. The dimensionality of the linear space generated by the α-slabs is the α-rank of $\mathcal{A}$. It is worth emphasizing that computing the rank of a general tensor $\mathcal{A}$ (defined as the minimum number of rank-one tensors into which $\mathcal{A}$ can be decomposed) is an NP-hard problem, that only weak bounds are known relating the α-rank and the tensor rank, and that there do not exist definitions of tensor rank and associated tensor SVD such that the optimality properties of the matrix rank and matrix SVD are preserved [40, 33, 41, 32, 45, 38, 48, 67].

2.2. Matrix CUR decomposition. Recent work in theoretical computer science, numerical linear algebra, and statistical learning theory [19, 23, 59, 60, 7, 29, 28, 66, 22] has focused on low-rank matrix decompositions with structural properties that satisfy the following definition.

DEFINITION 1. *Let A be an $m \times n$ matrix. In addition, let C be an $m \times c$ matrix whose columns consist of a small number c of columns of the matrix A, let R be an $r \times n$ matrix whose rows consist of a small number r of rows of the original matrix A, and let U be a $c \times r$ matrix. Then $\tilde{A}$ is a* column-row-based low-rank approximation*, or a* CUR approximation*, to A if it may be explicitly written as*

$$\tilde{A} = CUR. \tag{4}$$

Several things should be noted about this definition. First, for data applications, we prefer not to provide too precise a characterization of what we mean by a "small" number of columns and/or rows, but one should think of $r, c \ll m, n$. For example, they could be constant, independent of m and n, logarithmic in the size of m and n, or simply a large constant factor less than m, n. Second, since the approximation is expressed in terms of a small number of columns and rows of the original data matrix, it will provide a low-rank approximation to the original matrix, although one with structural properties that are quite different from those provided by truncating the SVD. Third, a CUR approximation approximately expresses all of the columns of A in terms of a linear combination of a small number of "basis columns," and it does this similarly for the rows.

Finally, and most relevant for the present paper, note that a matrix CUR decomposition has structural properties that are auspicious for its use as a tool in the analysis of large data sets. For example, if the data matrix A is large and sparse but well-approximated by a low-rank matrix, then C and R (consisting of actual columns and rows) are sparse, whereas the matrices consisting of the top left and right singular vectors will not, in general, be sparse. In addition, in many applications, interpretability is important; practitioners often have an intuition about the actual columns and rows that they fail to have about linear combinations of (up to) all the columns or rows.

The following algorithmic result regarding a matrix CUR approximation was recently proven [19].

THEOREM 1. *There exists a randomized algorithm (see the* LINEARTIMECUR *algorithm of* [19]*) that takes as input an $m \times n$ matrix A and a fixed rank parameter*

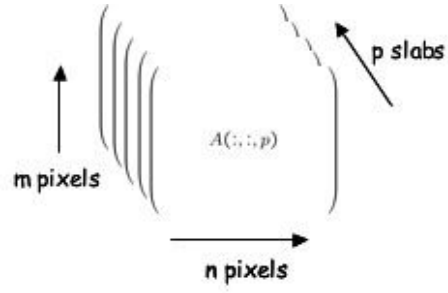

FIG. 1. *Pictorial representation of a* $(2+1)$*-data tensor.*

k and that returns as output an $m \times c$ matrix C consisting of c columns of A, an $r \times n$ matrix R consisting of r rows of A, and a $c \times r$ matrix U. The columns/rows are randomly sampled in c/r independent trials according to a judiciously chosen probability distribution depending on the Euclidean norm of the corresponding column/row. If $c = O(k \log(1/\delta)/\epsilon^4)$ and $r = O(k/\delta^2\epsilon^2)$, then

$$\|A - CUR\|_F \leq \|A - A_k\|_F + \epsilon \|A\|_F \tag{5}$$

holds with probability at least $1 - \delta$. The algorithm requires $O(m+n)$ additional time and scratch space after reading the matrix A twice from external storage.

Our two tensor-CUR algorithms are tensor-based extensions of this matrix algorithm. For more details about these results, see [17, 18, 19, 22].

3. A tensor-based extension of the matrix CUR decomposition.

3.1. A tensor-CUR decomposition for (2 + 1)-data tensors. In this subsection, for simplicity of exposition and in light of the two applications we will consider, we restrict ourselves to tensors that are subscripted by three indices, i.e., so-called 3-mode tensors.

Consider an $n_1 \times n_2 \times n_3$ tensor $\mathcal{A}$, defined as the collection of elements

$$\{\mathcal{A}_{ijk} | i = 1, \ldots, n_1; j = 1, \ldots, n_2; k = 1, \ldots, n_3\}.$$

The elements may be thought of as a data cube, i.e, a three-dimensional block such that index i runs along the vertical axis, index j runs along the horizontal axis, and index k runs along the "depth" axis. Since by assumption there is a "distinguished" mode, we are considering the special case of a $(2+1)$-*tensor*, i.e., an $n_1 \times n_2 \times n_3$ tensor in which two modes (without loss of generality, we will assume they are the first two) are similar in some application-dependent manner and the third is qualitatively different. See Figure 1 for a pictorial description of a $(2+1)$-data tensor. In this case, we refer to each of the n_3 different $n_1 \times n_2$ matrices as "slabs" and each of the $n_1 n_2$ different n_3-vectors as "fibers."

With this in mind, consider the $(2+1)$-TENSOR-CUR algorithm, described in Figure 2. This algorithm takes as input an $n_1 \times n_2 \times n_3$ tensor $\mathcal{A}$, a probability distribution $\{p_i\}_{i=1}^{n_3}$ over the slabs, a probability distribution $\{q_i\}_{i=1}^{n_1 n_2}$ over the fibers, a number c of slabs to choose, and a number r of fibers to choose. (Without loss of generality, we have assumed that the preferred mode $\alpha \in \{1, 2, 3\}$ is the third mode.) The tensor $\mathcal{A}$ is decomposed along this mode in a manner analogous to the original CUR matrix decomposition [19]. More precisely, this algorithm computes the

Input: An $n_1 \times n_2 \times n_3$ tensor $\mathcal{A}$, a probability distribution $\{p_i\}_{i=1}^{n_3}$, a probability distribution $\{q_i\}_{i=1}^{n_1 n_2}$, and positive integers c and r.
Output: An $n_1 \times n_2 \times c$ tensor $\mathcal{C}$, a $c \times r$ matrix $\mathcal{U}$, and an $r \times n_3$ matrix $\mathcal{R}$.

1. Select c slabs of $\mathcal{A}$ in c independent and identically distributed (i.i.d.) trials according to $\{p_i\}_{i=1}^{n_3}$.
   (a) Let $\mathcal{C}$ be the $n_1 \times n_2 \times c$ tensor consisting of the chosen slabs.
   (b) Let D_C be the $c \times c$ diagonal scaling matrix with $(D_C)_{tt} = \frac{1}{\sqrt{c p_{i_t}}}$ if the i_tth slab is chosen in the tth independent trial.
2. Select r fibers of $\mathcal{A}$ in r i.i.d. trials according to $\{q_i\}_{i=1}^{n_1 n_2}$.
   (a) Let $\mathcal{R}$ be the $r \times n_3$ matrix consisting of the chosen fibers.
   (b) Let D_R be the $r \times r$ diagonal scaling matrix with $(D_R)_{tt} = \frac{1}{\sqrt{r q_{j_t}}}$ if the j_tth slab is chosen in the tth independent trial.
3. Let the $r \times c$ matrix W be the matricized intersection between $\mathcal{C}$ and $\mathcal{R}$.
4. Define the $c \times r$ matrix $\mathcal{U} = D_C \left(D_R W D_C\right)^+ D_R$.

FIG. 2. *The* $(2+1)$-TENSOR-CUR *algorithm.*

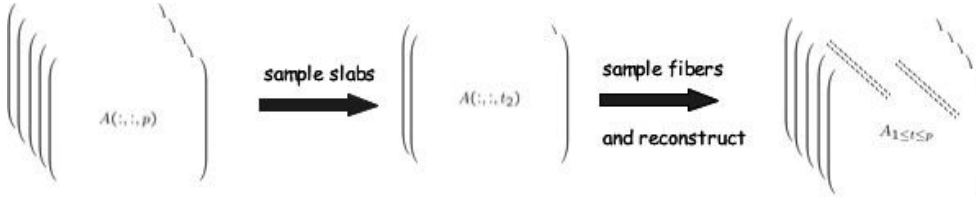

FIG. 3. *Pictorial representation of the action of the tensor-CUR decomposition.*

approximation by performing the following: first, choose c slabs (2-mode subtensors, i.e., matrices) in independent random trials and choose r fibers (1-mode subtensors, i.e., vectors) in independent random trials according to the input probability distributions; second, define the $n_1 \times n_2 \times c$ tensor $\mathcal{C}$ to consist of the c chosen slabs and also define the $r \times n_3$ matrix $\mathcal{R}$ to consist of the chosen fibers; third, let $\mathcal{U}$ be an appropriately defined and easily computed (given $\mathcal{C}$ and $\mathcal{R}$) $c \times r$ matrix.

Clearly, $\tilde{\mathcal{A}} = \mathcal{C} \otimes_3 \mathcal{U}\mathcal{R}$, where $\otimes_3$ is a tensor-matrix multiplication, is an $n_1 \times n_2 \times n_3$ tensor. Thus, by using the $(2+1)$-TENSOR-CUR algorithm, we make the following approximation:

$$\mathcal{A} \approx \tilde{\mathcal{A}} = \mathcal{C} \otimes_3 \mathcal{U}\mathcal{R}. \tag{6}$$

Thus, in particular, if $i \in 1, \ldots, n_3$ is one of the slabs that is not randomly selected, then by using the $(2+1)$-TENSOR-CUR algorithm, we make the following approximation:

$$\mathcal{A}(:,:,i) \approx \sum_{\xi \in C} \mathcal{A}(:,:,\xi) X(\xi, i), \tag{7}$$

where $\mathcal{A}(:,:,i)$ is the $n_1 \times n_2$ matrix formed from $\mathcal{A}$ by fixing the value of the third mode to be i, C is a set indicating which c indices were randomly chosen, and $X(:,i)$ is a vector consisting of the ith column of the matrix $\mathcal{U}\mathcal{R}$.

See Figure 3 for a pictorial description of the action of the algorithm and this approximation. In particular, note that a small number of slabs are sampled, and every other slab is approximately reconstructed using the information in those slabs as

a basis along with the information in a small number of fibers (depicted as the dashed lines). The extent to which (6) or (7) is a good approximation has to do with the selection of slabs and fibers. In sections 4 and 5, we show that (6) holds empirically for our two applications if the slabs and fibers are chosen uniformly and/or nonuniformly with probabilities that depend on the Frobenius norms of slabs and Euclidean norms of fibers, respectively. See the proof of Theorem 2 in section 3.2 and also [17, 18, 19] for a discussion of the algorithmic justification for this sampling.

We emphasize that, as with the matrix CUR decomposition, when this tensor-CUR decomposition is applied to data, there is a natural interpretation in terms of underlying data elements. For our imaging application, a "slab" corresponds to an image at a given frequency step and a "fiber" corresponds to a time- or frequency-resolved pixel. Similarly, for our recommendation system application, a "slab" corresponds to a product-product preference matrix for a single user and a "fiber" corresponds to preference information from every user about a single product-product pair.

3.2. A general tensor-CUR decomposition for very large data tensors. In this subsection, to provide a theoretical justification for the tensor-CUR decomposition of section 3.1, we present our main algorithmic result. Our main algorithmic result is a generalization of the $(2+1)$-Tensor-CUR algorithm and an associated provable quality-of-approximation bound for the Frobenius norm of the error tensor $\mathcal{A} - \mathcal{C} \otimes_3 \mathcal{U}\mathcal{R}$.

The Tensor-CUR algorithm, described in Figure 4, takes as input a d-mode tensor $\mathcal{A} \in \mathbb{R}^{n_1 \times \cdots \times n_d}$, a "distinguished" mode $\alpha \in \{1, \ldots, d\}$, a rank parameter k_α, an error parameter $\epsilon > 0$, and a failure probability $\delta \in (0, 1)$. The algorithm returns as output three carefully constructed subtensors that, when multiplied together, are an approximation $\tilde{\mathcal{A}}$ to $\mathcal{A}$. Both the number of slabs c_α and the number of fibers r_α that are randomly sampled depend on the rank parameter k_α, an error parameter ϵ, and a failure probability δ. The subtensors $\mathcal{C}$ and $\mathcal{R}$ are chosen by sampling according to a carefully constructed nonuniform probability distribution. In order to obtain the provable quality-of-approximation bounds of Theorem 2, the probability distribution depends on the Frobenius norms of the slabs and the Euclidean norms of the fibers, respectively. Intuitively, this biases the random sampling toward the subtensors that are of most interest; see [17, 18, 19] for details.

In more detail, the approximation $\tilde{\mathcal{A}}$ is computed by performing the following: first, form (implicitly) each of the n_α subtensors (slabs of mode $d-1$) defined by fixing $i \in \{1, \ldots, n_\alpha\}$, and also form (implicitly) each of the $N_\alpha = \prod_{i \neq \alpha} n_i$ subtensors (fibers of mode 1, i.e., vectors) defined by fixing a value for each of the modes $i \neq \alpha$; second, construct nonuniform probability distributions with which to sample the slabs and the fibers; third, choose c_α of the $d-1$-mode slabs in independent random trials, and also choose r_α of the 1-mode fibers in independent random trials; fourth, define the tensor $\mathcal{C} \in \mathbb{R}^{n_1 \times \cdots \times n_{\alpha-1} \times c_\alpha \times n_{\alpha+1} \times \cdots \times n_d}$ to consist of the c_α chosen $d-1$-mode slabs, and also define the tensor $\mathcal{R} \in \mathbb{R}^{r_\alpha \times n_\alpha}$ to consist of the r_α chosen 1-mode fibers; and finally, let $\mathcal{U} \in \mathbb{R}^{c_\alpha \times r_\alpha}$ be an appropriately defined and easily computed (given $\mathcal{C}$ and $\mathcal{R}$) tensor of mode 2 (i.e., matrix). Then we may define

$$\tilde{\mathcal{A}} = \mathcal{C} \otimes_\alpha \mathcal{U}\mathcal{R}, \tag{8}$$

where $\mathcal{C} \otimes_\alpha \mathcal{U}\mathcal{R}$ is the α-mode tensor-matrix product between $\mathcal{C}$ and $\mathcal{U}\mathcal{R}$, to be an $n_1 \times \cdots \times n_{\alpha-1} \times n_\alpha \times n_{\alpha+1} \times \cdots \times n_d$ tensor that is an approximation to the original tensor $\mathcal{A}$. (The awkward form of $\mathcal{U}$ is currently necessary for our provable results. Nevertheless, $\mathcal{U}$ is a subspace perturbation of the Moore–Penrose generalized inverse

Input: An $n_1 \times n_2 \times \cdots \times n_d$ tensor $\mathcal{A}$, a mode $\alpha \in \{1, \ldots, d\}$, a rank parameter k_α, an error parameter $\epsilon > 0$, and a failure probability $\delta \in (0, 1)$.
Output: An $n_1 \times \cdots \times n_{\alpha-1} \times c_\alpha \times n_{\alpha+1} \times \cdots \times n_d$ tensor $\mathcal{C}$, a $c_\alpha \times r_\alpha$ matrix $\mathcal{U}$, and an $r_\alpha \times n_\alpha$ matrix $\mathcal{R}$.

1. Let $c_\alpha = 4k_\alpha\big(1 + \sqrt{8\log(2/\delta)}\big)^2/\epsilon^4$, $r_\alpha = 4k_\alpha/\delta^2\epsilon^2$, and $N_\alpha = \prod_{i \neq \alpha} n_i$.
2. Define $\{p_i\}_{i=1}^{n_\alpha}$ to be $p_i = \frac{\left|(A_\alpha)^{(i)}\right|^2}{\|\mathcal{A}\|_F^2}$.
3. Define $\{q_j\}_{j=1}^{N_\alpha}$ to be $q_j = \frac{\left|(A_\alpha)_{(j)}\right|^2}{\|\mathcal{A}\|_F^2}$.
4. Select c_α slabs of $\mathcal{A}$ in c_α i.i.d. trials according to the probability distribution $\{p_i\}_{i=1}^{n_\alpha}$.
   (a) Let $\mathcal{C}$ be the $n_1 \times \cdots \times n_{\alpha-1} \times c_\alpha \times n_{\alpha+1} \times \cdots \times n_d$ tensor consisting of the chosen slabs.
   (b) Let D_C be the $c_\alpha \times c_\alpha$ diagonal scaling matrix with $(D_C)_{tt} = \frac{1}{\sqrt{c p_{i_t}}}$ if the i_tth slab is chosen in the tth independent trial.
5. Select r_α fibers of $\mathcal{A}$ in r_α i.i.d. trials according to the probability distribution $\{q_i\}_{i=1}^{N_\alpha}$.
   (a) Let $\mathcal{R}$ be the $r_\alpha \times n_\alpha$ matrix consisting of the chosen fibers (from all the slabs).
   (b) Let Ψ be the $r_\alpha \times c_\alpha$ matrix consisting of the chosen fibers (from the chosen slabs).
   (c) Let D_R be the $r_\alpha \times r_\alpha$ diagonal scaling matrix with $(D_R)_{tt} = \frac{1}{\sqrt{r q_{j_t}}}$ if the j_tth slab is chosen in the tth independent trial.
6. Let Φ be the best rank-k approximation to the Moore–Penrose generalized inverse of $(\mathcal{C} \otimes_\alpha D_C)_{[\alpha]}^T (\mathcal{C} \otimes_\alpha D_C)_{[\alpha]}$.
7. Define the $c_\alpha \times r_\alpha$ matrix $\mathcal{U} = \Phi\,(D_R\Psi)^T$.

FIG. 4. *The* TENSOR-CUR *algorithm.*

of the matricized intersection between $\mathcal{C}$ and $\mathcal{R}$. Thus, for the $(2+1)$-TENSOR-CUR algorithm and for the applications described in sections 4 and 5, we have taken it to be exactly this quantity.)

Our main quality-of-approximation bound for the TENSOR-CUR algorithm is given by the following theorem, in which we bound the Frobenius norm of the error tensor $\tilde{\mathcal{E}} = \mathcal{A} - \tilde{\mathcal{A}}$.

THEOREM 2. *Let $\mathcal{A}$ be an $n_1 \times n_2 \times \cdots \times n_d$ tensor, and let $\alpha \in \{1, \ldots, d\}$ be a particular mode, k_α be a rank parameter, $\epsilon > 0$ be an error parameter, and $\delta \in (0, 1)$ be a failure probability. Construct a tensor-CUR approximate decomposition to $\mathcal{A}$ with the output of the* TENSOR-CUR *algorithm. Then, with probability at least $1 - \delta$,*

$$\|\mathcal{A} - \mathcal{C} \otimes_\alpha \mathcal{U}\mathcal{R}\|_F \leq \left\|A_{[\alpha]} - \left(A_{[\alpha]}\right)_{k_\alpha}\right\|_F + \epsilon \|\mathcal{A}\|_F . \tag{9}$$

Proof. Since "unfolding" $\mathcal{A}$ along any mode does not change the value of its Frobenius norm (as it is simply a reordering of indices in a summation), it follows that

$$\|\mathcal{A} - \mathcal{C} \otimes_\alpha \mathcal{U}\mathcal{R}\|_F = \left\|A_{[\alpha]} - (\mathcal{C} \otimes_\alpha \mathcal{U}\mathcal{R})_{[\alpha]}\right\|_F . \tag{10}$$

Note that the Frobenius norm on the left-hand side of (10) is a tensor norm and that the Frobenius norm on the right-hand side of (10) is a matrix norm. Due to the form

of the sampling probabilities used in the TENSOR-CUR algorithm, it is this latter quantity that Theorem 5 of [19] bounds. By applying this result [19], the theorem follows. □

3.3. Remarks on tensor-CUR decompositions and data applications.

Remark. In (9), the $\left\|A_{[\alpha]} - (A_{[\alpha]})_{k_\alpha}\right\|_F$ term is a measure of the extent to which the "unfolded" matrix $A_{[\alpha]}$ is not well-approximated by a rank-k_α matrix, and the $\epsilon \|\mathcal{A}\|_F$ term is a measure of the loss in approximation quality due to the choice of slabs and fibers (rather than, e.g., the top k_α eigenslabs and eigenfibers along the α mode). This latter measure is of the form of an arbitrary (but fixed) precision, scaled by a measure of the size of the tensor $\mathcal{A}$.

Remark. The values for c_α and r_α in general differ, as they do with matrix CUR decompositions. Although this is an artifact of the proof techniques [19], this allows for greater flexibility in data applications. For example, if the noise properties of the slabs and fibers differ, then one may wish to oversample the slabs or fibers in different ways.

Remark. The choice for slabs and fibers in the TENSOR-CUR algorithm takes advantage only of linear and not multilinear structure in the data tensors. Equivalently, the algorithm reduces to the corresponding matrix algorithm. It is an open problem whether one can choose slabs and/or fibers to preserve some nontrivial multilinear tensor structure in the original tensor $\mathcal{A}$.

Remark. A crucial decision in applying these techniques to data will be the proper choice (if any) of the preferred mode α. This depends on the application area from which the data are drawn. The theorems will be true but uninteresting if this choice is not made carefully.

Remark. Assume, for simplicity, that the tensor $\mathcal{A}$ is stored externally, and assume that $k_i = O(1)$ and that $n_i = n$ for every $i = 1, \ldots, d$. Then the matrices $C_{[i]}$ each occupy only $O(n)$ additional scratch space. In general, $O(n^{d-1})$ additional scratch space will be needed to compute the probabilities of the form used by the TENSOR-CUR algorithm, and this will be comparable to the overall memory requirements if d is large. On the other hand, if the uniform probabilities are approximately optimal for each of the d nodes, then only $O(n)$ additional scratch space and computation time are needed, resulting in a substantial scratch memory and time savings. See [17] for additional discussion of resource issues within the framework of the pass-efficient model of data streaming computation.

Remark. Although sampling with respect to the proper probability distribution is critical for our provable results, one might expect that in many cases the slabs and/or fibers will all be approximately the same length due to the manner in which the data are generated, in which case uniform sampling may be successfully employed. This was seen to be the case for an application of the CUR algorithm of [19] to kernel-based learning [21, 22, 66].

Remark. Alternatively, one might expect that in many cases the data are generated in such a way that information about the Frobenius norm of each of the slabs and/or fibers is easily computed at the data generation step. For example, in the case of a $(2+1)$-imaging application, the Frobenius norm of a slab corresponds to the total absorption at one time step or frequency value. In this case, these approximations to the probabilities could be used in the TENSOR-CUR algorithm.

Remark. Although $c_\alpha = 4k_\alpha\left(1+\sqrt{8\log(2/\delta)}\right)^2/\epsilon^4$ slabs and $r_\alpha = 4k_\alpha/\delta^2\epsilon^2$ fibers suffice to prove the claims of Theorem 2, they can be rather large for even moderate values of k_α, δ, and ϵ. In the applications we consider, choosing many fewer slabs and

fibers suffices, e.g., on the order of tens or hundreds; see sections 4 and 5 for more detail.

4. Application to hyperspectral image data. In hyperspectral imagery, an object or scene is imaged at a large number of contiguous wavelengths [51]. Although hyperspectral imagery originated in astronomy and geosensing, it has been employed more recently in numerous other application areas, including agriculture, manufacturing, forensics, and medicine. In many of these applications, target resolution is limited by available spatial resolution. By considering the spectral variation of light intensity, one obtains rich information about the object or scene being imaged that complements traditional spatial information. One also obtains very large data sets that may be represented as a tensor and that contain much redundancy. For example, if a single scene is imaged at 128 frequency bands, where at each frequency a 495×656 image is generated, then the data cube generated for this single object consists of 40 million values and may be represented by a $495 \times 656 \times 128$ tensor $\mathcal{A}$, where $\mathcal{A}_{ijk}$ represents the absorbed or transmitted light intensity at pixel ij at physical frequency k.

In this section, we describe an application of the tensor-CUR decomposition to a problem in hyperspectral medical image analysis. In particular, the tensor-CUR decomposition is used to *compress* the data, and we show that tissue segmentation and nuclei classification quality are not substantially reduced even after substantial data compression. In more detail, in section 4.1, we describe the data and its generation. Then, in section 4.2, we describe the reconstruction of the full data from a small sample of slabs and fibers. In section 4.3, we describe the classification task of tissue segmentation, i.e., classifying the pixels in a single image into different tissue types, as a function of how heavily we downsample on the slabs and fibers. This task is of intermediate interest, since nuclei are the most discriminative structures in the final classification task of interest. Finally, in section 4.4, we describe the classification of data cubes into, e.g., normal and malignant, as a function of downsampling on the slabs and fibers.

4.1. Description of data and data generation. The application of hyperspectral imaging to medicine, and pathology in particular, while not new, is becoming more widespread and powerful. A variety of proprietary spectral splitting devices, including prisms and mirrors [64], interferometers [25, 55], variable interference filter-based monochromometers [53], and tuned liquid crystals [47], mounted on microscopes in combination with CCD cameras and computers, have been used to discriminate among cell types, tissue patterns, and endogenous and exogenous pigments [47]. Although the increasing power of these methods holds the promise for developing automatic diagnostics, the increased volume and formal dimensionality of the data make the development of more efficient algorithms necessary in order to extract statistically useful and reliable information about the data.

The prototype-tuned light source used to generate the data we studied (Plain Sight Systems, Inc.; see [16] for details) can generate a large number of combinations of light frequencies, ranging from about 440 nm to about 700 nm, with a wavelength resolution of up to approximately 6 nm. The light modulated by the prototype is shone via a fiber optic cable directed in a Nikon Biophot microscope and transilluminates hematoxylin and eosin (H & E) stained microarray tissue sections of normal, benign (adenoma), and malignant carcinoma colon biopsies. Hyperspectral photomicrographs, collected in random order at 400X magnification, are obtained with a CCD camera (Sensovation) from 59 different patient biopsies (20 normal, 19 benign ade-

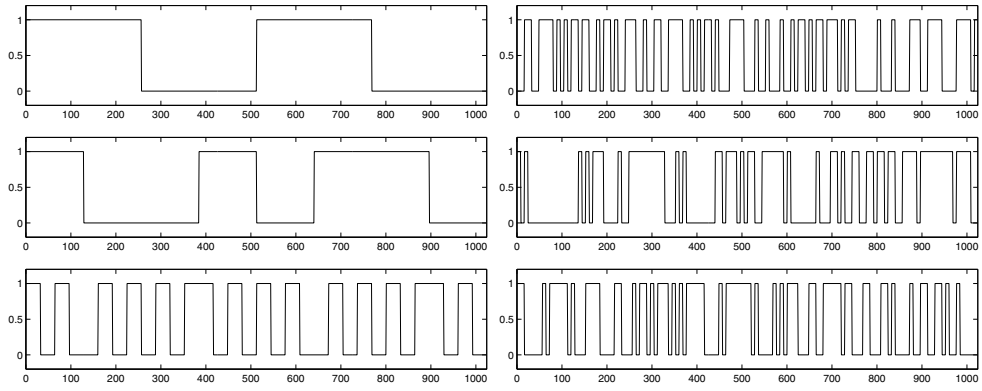

FIG. 5. *Examples of Hadamard patterns (left) and randomized Hadamard patterns (right). The latter are used at the data generation step to improve the signal-to-noise ratio; see the text for details.*

noma, and 20 malignant carcinoma), mounted as a microarray on a single glass slide [14, 2, 3, 5]. From these, 59 hyperspectral grayscale images at 400X magnification are derived. The biopsies are collected randomly on the slide across and within the different groups of biopsies in order to avoid any biases due to instrumentation, e.g., due to temperature or time of collection. This data was collected by G. L. Davis, M.D., as discussed in [51].

Each measurement yields a data cube, which is a set $\{I_i\}_{i=1\ldots128}$ of 128 images, each of which is 495 by 656 pixels in size. (That is, there is one data cube for each of the 59 biopsies.) The intensity of the pixel $I_i(x,y)$ is (ideally) the transmitted light at location (x,y) when the ith light pattern ψ_i shone through the sample. The data is collected by using randomized Hadamard patterns in order to maximize the signal-to-noise ratio. The noise in the measurement of the hyperspectral image can be modeled as independent of the intensity of light shown through the sample. The signal-to-noise ratio of the measurement of each I_i, for a fixed integration time for the measurement of I_i, is maximized when the amount of modulated light shone through the sample is maximized. The instrument allows us to shine patterns $\{\psi_i\}_{i=1,\ldots,S} = \{\psi_i(\nu) = \sum_{j=1}^{N} \epsilon_{ij}\delta_j(\nu)\}$, where $(\epsilon)_{ij}$ is an S by N matrix with entries in $\{0,1\}$, and $(\delta)_j$, an S-dimensional vector, represents (ideally) a Dirac δ-function at physical frequency $\nu_j \sim (700-440)j/N+440$. In our experiment, we set $N = 256$ (the instrument would allow up to $N = 1024$) and $S = 128$. Ideally, $I_i(x,y)$, $i = 1,\ldots,S$, is the value of the inner product (in the frequency variable ν)

$$I_i(x,y) = \langle f(x,y,\nu), \psi_i(\nu)\rangle_\nu = \sum_j f(x,y,\nu_j)\psi_i(\nu_j)\,,$$

where $f(x,y,\nu)$ is the transmittance of the sample at location (x,y) and frequency ν. The choice of the patterns ψ_i is crucial in determining the signal-to-noise ratio of the measurements for a fixed integration time and total intensity of the light source: we use the idea of *multiplexing* and shine a sequence of *randomized Hadamard patterns* $\{\psi_i^H\}_{i=1,\ldots,N}$, obtained from standard Hadamard patterns by randomly shuffling the frequency axis. See Figure 5 for examples of Hadamard and randomized Hadamard patterns.

Thus, each data cube consists of 128 images, each 495 by 656 pixels in size (for a

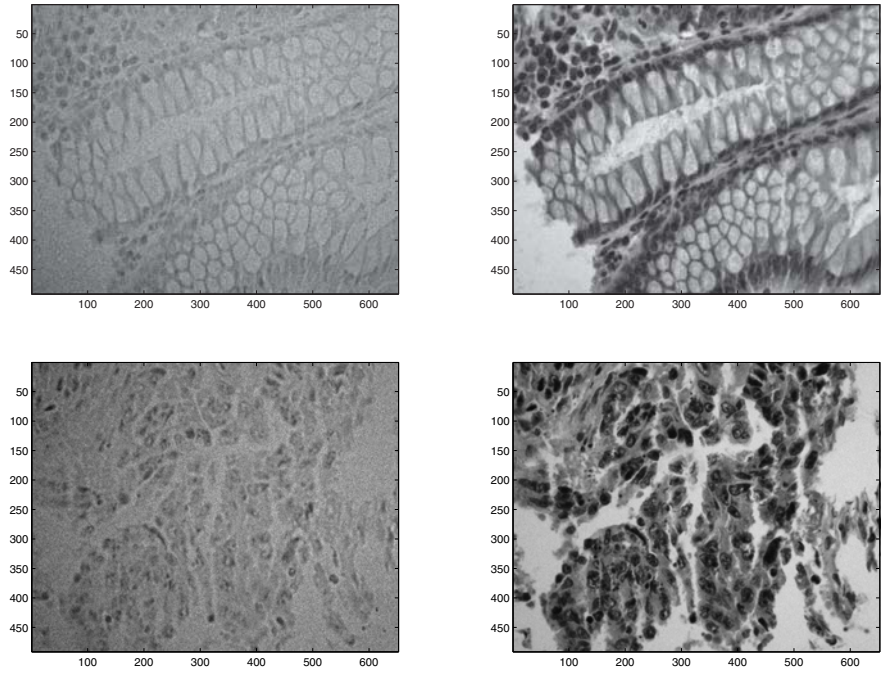

FIG. 6. *Two different spectral slices, i.e., two different images each at a single frequency, from a hyperspectral data cube derived from a normal sample (top) and from a hyperspectral data cube derived from a very malignant sample (bottom).*

total of about 40 million pixels), measuring the modulated light transmitted through the sample. We view this as a $495 \times 656 \times 128$ 3-mode tensor $\mathcal{A}$, where the entry $\mathcal{A}_{ijk}$ is proportional to the light with spectral modulation k transmitted at location (i, j). Each biopsy contains either normal, benign (adenoma), or malignant (cancerous) tissue and is labeled by G. L. Davis, M.D., pathologist. Various algorithms have previously been shown to find and classify automatically normal, abnormal, and malignant small portions of each biopsy [14, 15, 51] using the complete data cube. As we describe in more detail in the next three subsections, we couple the tensor-CUR decomposition described in section 3.1 with ideas from [14, 15, 51] in order to speed up computations, denoise, compress, and preprocess the data, and we show that this causes only a small loss of performance of these algorithms.

In order to gain a feel for the data, consider Figures 6 and 7. Figure 6 illustrates two of the 128 images, i.e., two hyperspectral images at two distinct frequencies, in a normal sample and in a very malignant sample. Similarly, Figure 7 illustrates a typical frequency-resolved pixel in both a normal and a malignant nucleus as well as a single spectrum in the malignant sample and the spectrum averaged over every one of the ca. 324,000 frequency-resolved pixels in the malignant data cube. Note that both successive images and pixels from different spatial regions are strongly correlated with one another.

In this imaging application, the tensor $\mathcal{C}$ in the tensor-CUR decomposition consists of a small number of dictionary or basis images (which are actual and not eigenimages) with respect to which the remaining images are expressed. Similarly, the

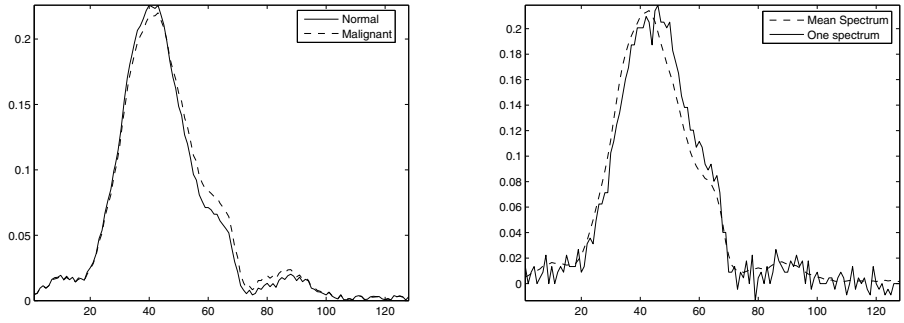

FIG. 7. *Left: Average normalized nuclei spectrum from a normal and a malignant sample. Right: Average normalized spectrum and a single typical spectrum in one hyperspectral data cube. The vertical axis represents normalized energy per frequency in the spectra, and the horizontal axis is the slab index.*

matrix $\mathcal{R}$ consists of the spectral variation of a small number of dictionary or basis pixels with respect to which spectral variation of the remaining pixels is expressed. In the next three subsections, we will see that the tensor-CUR decomposition can be applied to this hyperspectral image data in order to compress the data and to perform two classification tasks of interest on the data. That is, the tensor-CUR algorithm will downsample slabs $\mathcal{A}(:,:,\nu_i)$ by sampling a set of images at certain randomly chosen wavelengths $\{\nu_i\}_{i=1}^{128}$ and fibers $\mathcal{A}(x_i, y_i, :)$ by sampling spectra at certain randomly chosen locations $\{(x_i, y_i)\}$. Slabs will be chosen randomly with a probability proportional to the average normalized spectrum of Figure 7, i.e., with probability proportional to $||\mathcal{A}(:,:,\nu)||_F$, and fibers will be chosen uniformly at random. The data-dependent motivation for this is that the intensity of transmitted light captures a meaningful notion of information as a function of varying frequency but not as a function of varying spatial coordinates due to the particular staining technology.

4.2. Reconstruction of hyperspectral data. For each slab we did not randomly sample, we use the tensor-CUR decomposition to reconstruct that slab in the basis provided by the sampled slabs, and we do so using only a small number of pixels in that slab. In Figure 8, we present a representative example of the reconstruction of two spectral slices from a normal biopsy and two spectral slices from a malignant biopsy. The redundancy in the data is evident by the quality of the reconstruction under very heavy downsampling. For example, it suffices to judiciously choose as few as 8 or even 2 of the original 128 slabs, and to reconstruct the remaining slabs, it suffices to choose ca. 1000 (or fewer) of the original ca. 324,000 fibers.

In Figure 9, we present the approximation error as a function of downsampling to different numbers of slabs and then to different numbers of fibers. As expected, as the number of sampled slabs and fibers increases, the approximation error decreases. The approximation error is very small in the middle range of the frequencies, where the energy per frequency is larger, and hence the sampling probability is larger. Thus, due to the form of the slab sampling probabilities, slabs between ca. 30 and ca. 60 tend to be reproduced much better than those toward the tails of the spectrum. Slabs below ca. 20 and above ca. 70 tend to have a lower signal-to-noise ratio and are less important for the problem of approximate data reconstruction (but not necessarily for other problems). Sampling more than 1200 fibers does not lead to significant

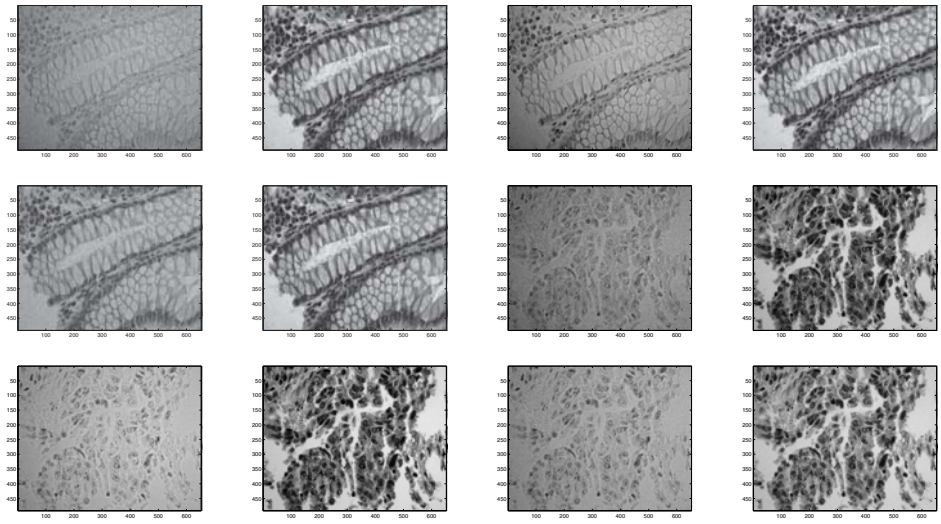

FIG. 8. *Typical reconstruction of the hyperspectral data cubes as a function of sampling. Shown in this figure are two different spectral slabs from a normal biopsy and two from a malignant biopsy, each reconstructed under three different compression ratios. In particular, the three figures in the first column are from slab number* 30 *(out of* 128*) from a normal sample; the second column is from slab number* 60 *from the same normal sample; and the third and fourth columns are slabs number* 30 *and* 60*, respectively, from another biopsy that is malignant. Presented are the original data (in the top row), the data when it is compressed with* 8 *slabs and* 1200 *fibers (in the middle row), and even more compressed data with only* 2 *slabs and* 1200 *fibers (in the bottom row).*

improvements (unless several tens of thousands fibers are sampled).

At this point, we observe that the spectra reconstructed after compression are far less noisy than the original spectra. More precisely, a close examination of images such as those presented in Figure 8 reveals a subtle interplay between sampling-induced error and denoising due to the low dimensionality of the sample. This has a denoising and a regularization effect on the spectra, and we can interpret the low-dimensional projection achieved by compression as a denoising mechanism, tuned to each data cube. Note that by giving our tensor-CUR algorithm the flexibility to sample different numbers of slabs and fibers, we can, e.g., sample slabs to a level appropriate for structure identification and sample more fibers for denoising purposes.

4.3. Tissue-type segmentation. In medical applications, one is interested in the classification of an entire data cube, i.e., a medical sample, as normal or malignant. Biological reasons suggest that nuclei are the most discriminative structures for this task. Thus, as an intermediate step, one is interested in classifying the pixels in a single data cube into different tissue types, e.g., nuclei, cytoplasm, or lamina propria, based on the spectral response ("fiber") associated with each pixel. For each of the 59 images, we use the algorithm described in [14, 15, 51] for segmenting the pixels in the image into three sets of regions corresponding to different tissue types. This algorithm is based on the local discriminant basis (LDB) algorithm [13, 56, 57] to find features that best discriminate among the different classes and a nearest neighbor classifier in a discriminant projection found by LDB. Note that for the normal versus malignant classification task of the next subsection (in which we classify entire data cubes), we have access to a label (assumed correct) provided by a pathologist [51],

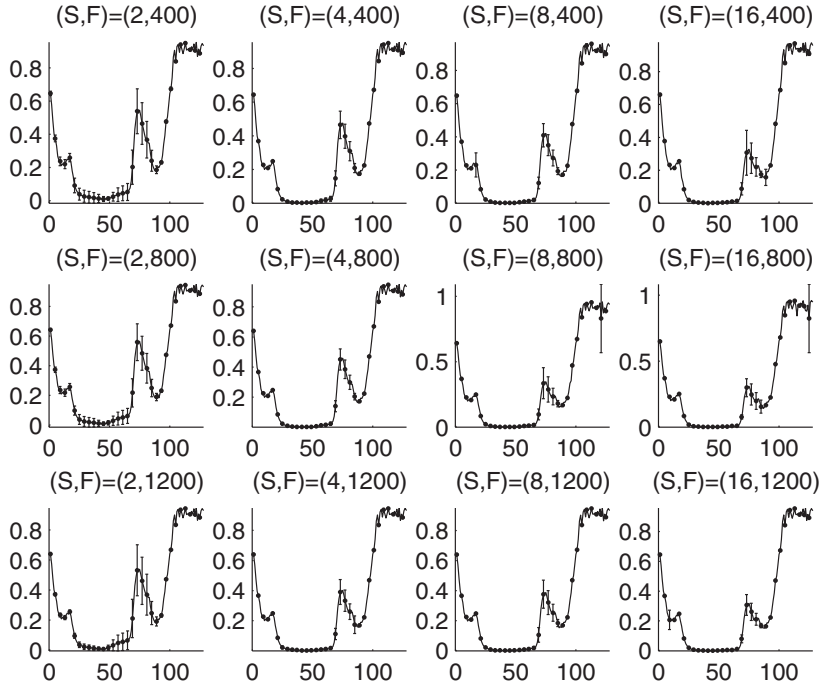

FIG. 9. *Reconstruction error. The caption indicates how many slabs (S) and fibers (F) were sampled. The vertical axis is the relative reconstruction error (for the Frobenius norm). The horizontal axis is the slab index. Average and standard deviation are over* 4 *slab draws and* 3 *fiber draws.*

while no such ground truth is available for this tissue classification in this section (in which we classify pixels in each image).

In Figure 10, we present typical results for running this tissue classification algorithm on two data cubes (one normal and one malignant) with increasing compression ratios. We see that the tissue classification is affected in two different ways. When we sample 16 slabs, the tissue classification, at least qualitatively speaking, improves by becoming less noisy and by generating fewer misclassification errors. See, e.g., the isolated red pixels, which correspond to nuclei, in the images in the leftmost column of Figure 10. As the compression ratio increases further, we observe a slight decreased performance in the tissue classification algorithm. As with the reconstruction problem, in both cases there is little quality loss until the number of fiber samples is less than ca. 1000. In addition, as before, a careful analysis reveals a complex interplay between sampling-induced information loss and sampling-induced denoising. Unfortunately, it is not possible for us to quantify these results, since this would require an individual to mark, by hand and with high precision, the correct tissue segmentation.

4.4. Classification of nuclei and data cubes. If the nuclei identified by the tissue classification described in section 4.3 are then used to classify data cubes, the results can be compared with the true value (assigned by the pathologist). For each nucleus, we consider the mean spectrum, and we use partial least squares (PLS) to build a linear classifier to classify this spectrum. We consider the following two

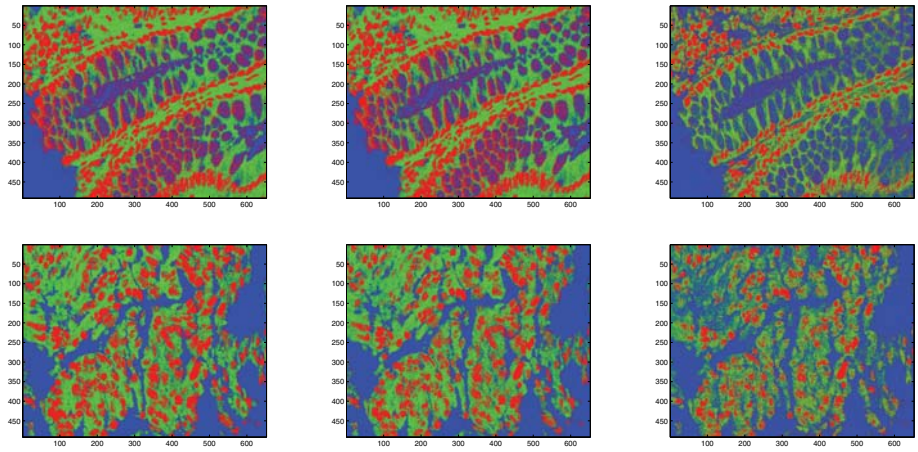

FIG. 10. *Segmentation into three tissue types in a normal biopsy (top row) and a malignant biopsy (bottom row): red for nuclei (the only class that we are interested in for the next classification task), green for cytoplasm, and blue for lamina propria and other regions. classification tasks: classify as normal or malignant; and classify as normal, abnormal, or malignant. In addition, we use two cross-validation procedures, described below, for each classification task. See [14, 15, 51] for more details on these procedures.

We define the patches we want to classify as follows. A patch is a subset of a data cube of the form $Q^l_{x_0,y_0} \times S$, where $Q^l_{x_0,y_0}$ is a square of side l pixels long, centered at (x_0, y_0), and S denotes the complete spectral range. A patch is *admissible* if it contains at least $\frac{8}{10}l^2$ nuclei pixels. From now on, we will consider each patch simply as a collection of the nuclei spectra it contains and hence as a cloud in $\mathbb{R}^{128}$. For the results reported here, we have chosen and fixed $l = 64$, which provides a size that roughly corresponds to the size of a single nucleus. The set of $l \times l$ patches we consider consists of 3298 patches chosen by the algorithm by randomly picking a square in the slide and checking if it is admissible. About 60 patches per slide are collected. We denote by $\{N_{i,k}\}_{k \in K_i}$ the set of nuclei spectra in the ith patch P_i.

For each admissible patch P_i collected, we compute the mean of the nuclei spectra $\{N_{i,k}\}_k$, and we normalize it to unit energy. We denote this set of normalized average nuclei spectra by $\mathcal{N}$. (Therefore, $|\mathcal{N}| = 3298$, as above.) The label (e.g., normal or abnormal) attached to the patch is transferred to the corresponding mean nucleus spectrum. We used PLS, keeping $k = 15$ top vectors, and we ran 50 rounds of 25-fold cross-validation to avoid overfitting. We run this cross-validation in two different ways:

- (Weak CV) Extract a random training subset of size $\frac{3}{4}|\mathcal{N}|$ and predict on the remaining subset of size $\frac{1}{4}|\mathcal{N}|$.
- (Strong CV) Extract a random subset of biopsies, of size $\frac{3}{4}$#biopsies, train the algorithm on the corresponding normalized average nuclei in $\mathcal{N}$ extracted from those biopsies, and test the algorithm on the remaining subset of $\mathcal{N}$, corresponding to averaged normalized nuclei extracted from the remaining biopsies.

Thus, in each case, the training and testing sets are subsets of biopsies. Note that the

first cross-validation is weaker. Since we expect correlations between (nuclei) spectra in the same data cube, and since in (weak CV) the training set contains, with high probability, nuclei spectra from all the biopsies, training and testing sets cannot be assumed to be completely independent. Most of this lack of independence, we think, is due to normalization issues, sample preparation, lighting, and other data collection conditions, which exhibit variations across biopsies. Since we can consider different biopsies as being independent samples as they were collected in random order and independently of the type (e.g., normal, abnormal, or malignant), the second cross-validation is stronger.

We are interested in measuring any change of performance of the classification algorithm as a function of the compression ratio. The confusion matrices of the classifiers obtained are summarized in Tables 1, 2, 3, and 4 for classifiers of patches of size $l = 64$. These confusion matrices are averages over the performance on the testing set in several cross-validation runs. For the full data, the two-class discrimination between normal and carcinoma nuclei correctly identifies 79% of normal and 74% of malignant nuclei. The three-class discrimination among normal, abnormal (adenoma), and carcinoma nuclei is much more challenging (independently of compression), with identification rates of 33%, 73%, and 40% for normal, abnormal, and carcinoma samples, respectively. We study how this performance changes under compression of the data cubes. As can be seen, in general, high quality results are obtained using samples of 16 and 8 slabs, but quality degrades if only 2 slabs are used. Also, note that the algorithm performs more poorly (about 25% error in the discrimination of the 3 classes of biopsies) on completely new biopsies. This is related to normalization of the data, due both to the process of staining and to the instrument calibration and data collection. Current research is addressing these issues.

In Tables 1 and 2, we classify normal and malignant, and then we run the same classifier on data cubes compressed at different compression ratios; we also show the difference between weak and strong cross-validation. Observe that the performance of the algorithm is very good across compression ratios, except for a significant decrease of performance for a very high compression ratio (sampling of only 2 slabs!). We interpret this as a balancing effect between the possible loss of information due to compression and the denoising and regularization effect due to the dimensionality reduction.

In Tables 3 and 4, we classify normal, abnormal, and malignant, and again we

run the same classifier on data cubes compressed at different compression ratios; we also show the difference between weak and strong cross-validation. Here we observe a interesting phenomenon: under (weak CV), the algorithm performs much more poorly on the original data than on the compressed data. Hence the compression has a regularization effect that greatly helps the learning phase. This advantage is partly lost when we consider the (strong CV). Of course, the three-class problem is expected to be much harder than the two-class problem, not only because, from a machine-learning perspective, multiclass problems are harder but also because the abnormal samples are often quite similar to normal samples, and even in the field of pathology, the differences are qualitative and often not large.

5. Application to recommendation system analysis. In recommendation system analysis, one is typically interested in making purchase recommendations to a user at an electronic commerce web site. Collaborative methods (as opposed to content-based or hybrid) involve recommending to the user items that people with similar tastes or preferences liked in the past. Probably the most well-known example of a collaborative filtering system is that of Amazon.com, which is based on rules of the form "users who are interested in item X are also likely to be interested in item Y" [49]. Many collaborative filtering algorithms represent a user as an n-dimensional vector, where n is the number of distinct products, and where the components of the vector are a measure of the rating provided by that user for that product. Thus, for a set of m users, the user-product ratings matrix is an $m \times n$ matrix A, where A_{ij} is the rating by user i for product j (or is null if the rating is not provided). A recommendation algorithm generates recommendations for a new user based on a few users who are

most similar to the user after querying the new user about his (or her) rating on a small number of products. For more details, see [54, 10, 1].

A matrix CUR decomposition has been used to obtain competitive recommendation performance by judiciously sampling $O(m+n)$ entries of the user-product ratings matrix and reconstructing missing entries [20]. In more detail, assuming access to a matrix C consisting of the ratings of every user for a small number of products and a matrix R consisting of the ratings of a small number of users for every product, then, under assumptions, CUR is a provably good approximation to the user-product matrix A [20]. Prior theoretical work on recommendation systems includes Kumar et al. [42], who offer competitive algorithms even with only two samples/customer, assuming a strong clustering of the products; Azar et al. [4], who use spectral methods to recreate very accurately the user-product ratings matrix A, assuming a certain gap requirement and a sample of $\Omega(mn)$ entries of A; Kleinberg and Sandler [37], who develop recommendation algorithms with provable performance guarantees in a probabilistic mixture mode; and (most relevant for our work) Drineas, Kerenidis, and Raghavan [20], who obtain competitive performance by sampling $O(m + n)$ entries of the user-product ratings matrix and reconstructing missing entries with a matrix CUR decomposition. Other applications of linear algebra have used the SVD for dimensionality reduction [9, 58, 26].

Although the ratings in the user-product matrix A are often interpreted in terms of the utility of product j for user i, utility in neoclassical economics is an ordinal and not a cardinal concept. This is because utility functions are constructs that encode preference information and because the same preferences are described when the utility function is subject to a wide class of monotonic transformations. This observation motivates the definition of an $m \times n \times n$ user-product-product $(2 + 1)$-tensor $\mathcal{A}$, where $\mathcal{A}_{ijk}$ is $+1$ or -1 depending on whether product j or product k is preferred by user i. Similar preference-based models have appeared [12, 24, 35, 34] and have been motivated by such observations as that two users with very similar preferences for items may have very different rating schemes. When faced with a new user, this preference model depends on obtaining pairwise preference information such as that the user bought product `A` when he could have bought product `B` or that the user clicked on link `A` when he could have clicked on link `B`.

5.1. Description of data and the model. Under this preference model for recommendation system analysis, the tensor $\mathcal{C}$ consists of a small number of dictionary or basis elements from a small number of users, where each element corresponds to the full $n \times n$ pairwise preference matrix for a single user. Similarly, the matrix $\mathcal{R}$ consists of a dictionary or basis set of preference information from every user about a small number of product-product pairs.

In the next subsection, we will see that the tensor-CUR decomposition can be applied to recommendation system data under this model to reconstruct missing entries in the user-product-product preference tensor in order to make high-quality recommendations. Since most recommendation system databases do not provide data in this preference-based format, the data set we will consider will be derived from the ratings in the well-studied Jester data [26]. As an initial application, we consider the $m = 14{,}116$ (out of ca. 73,421) users who rated all of the $n = 100$ products (i.e., jokes). From this $m \times n$ user-product ratings matrix, we define an $m \times n \times n$ user-product-product preference tensor by performing the following for each user: convert the n-dimensional rating vector into an $n \times n$ preference matrix in which the ij entry is $+1$ or -1 depending on whether or not the user prefers product i to product j.

(Although this results in ordered and fully consistent preferences, this is not required by our decomposition.) In this application, in the absence of a better model, both slabs and fibers will be chosen uniformly at random.

5.2. Recommendation quality results. We now describe our results for the tensor-CUR decomposition when applied to the Jester dataset in the context of recommendation systems. Let c be an integer between 1 and 14,116 (recall that this is the total number of users that fully rated all 100 jokes in the Jester data), and assume that we sample uniformly at random c of the 14,116 users. For each sampled user, we assume that the corresponding 100×100 slab of the $100 \times 100 \times 14{,}116$ tensor representing the Jester dataset (see the previous section for details) is fully known or, in other words, that we know all pairwise product-product (i.e., joke-joke) comparisons for the c sampled users.

Consider the $14{,}116 - c$ slabs (i.e., users) that we did not sample. For each such *target* slab (i.e., *target* user), we use the tensor-CUR decomposition to reconstruct it as a linear combination of the c sampled slabs. Thus, it suffices to compute c coefficients such that a linear combination of the basis slabs using these coefficients achieves a satisfactory reconstruction of the target slab. However, in order to do such a reconstruction, we need some information from the target slab. This information consists of a small number of product-product preference queries sampled uniformly at random from the target slab. These elements of the target slab will allow us to approximately infer the coefficients to be used in expressing the target slab as a linear combination of the c basis slabs. Once the target slab (i.e., preference matrix) is reconstructed, we can use this reconstruction to make recommendations by picking the N products with the largest row sums. In our model, where the (i, j)th entry of the preference matrix is set to 1 if product i is preferred over product j and to -1 otherwise, such rows correspond to the most desirable products for this user.

To formally evaluate the quality of our recommender system, we use the well-known top-N procedure and compute the precision, recall, and the $F1$ statistic [58]. More specifically, let $\mathcal{T}_N$ be the actual set of the top N products for a certain user, and let $\mathcal{S}_K$ be a set of K products that are *suggested* to this user by a recommender system. Clearly, K can be equal to or larger than N, whereas values of K that are smaller than N are typically not interesting. For some combinations of N and K, we shall measure the following four quantities.

Successful recommendations. The number of elements in the intersection of $\mathcal{T}_N$ and $\mathcal{S}_K$ or, in other words, the number of products that are in the top-N preferred products for a particular user *and* were recommended by an algorithm that made K suggestions.

Recall. The number of successful recommendations divided by the number of suggestions (K) made by the algorithm. This quantity normalizes the number of successful recommendations to take into account the fact that increasing the number of suggestions increases the number of top-N products recommended by the algorithm.

Precision. The number of successful recommendations divided by N. Remember that N essentially determines the number of products that a user is interested in, and hence this quantity normalizes the number of successful recommendations to take into account the fact that increasing N increases the number of top-N products recommended by the algorithm.

F1 statistic. The formal definition is

$$\text{F1 statistic} = \frac{2 \cdot \text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}},$$

and it is commonly used to reconcile the mutually conflicting nature of the precision and recall statistics. (Notice, for example, that increasing N tends to increase recall but decreases precision [58].)

Prior to presenting the results of our experimental evaluation, we briefly discuss our choices for the four parameters involved in our experiments. First, recall that c denotes the number of basis users that reveal all their pairwise product preferences to the algorithm; we let c be all powers of 2 between 2 and 1024. This choice provides a clear picture of the behavior of tensor-CUR for very small (e.g., $c \leq 32$), medium-sized (e.g., $64 \leq c \leq 256$), and large (e.g., $c = 512, 1024$) basis sets. Second, N is set to be either 5 or 10, implying the algorithm is successful if it recommends one of the top 5 or top 10 products for a certain user. Third, K is set to be equal to N or $2N$, and hence the algorithm is allowed to suggest either 5 or 10 products for the top-5 case and either 10 or 20 products for the top-10 case. Fourth, the number of fibers that the tensor-CUR algorithm samples or, in other words, the number of product-product pairwise comparisons of a target user that are revealed to the algorithm is again set to all powers of 2 between 2 and 1024; the rationale is the same as above. In the first experiment, we will set the number of fibers to $100^2 = 10{,}000$ (all available fibers), in order to illustrate the limiting behavior of tensor-CUR. We emphasize that both the sampling of slabs and the sampling of fibers are done uniformly at random without replacement, and hence sampling 10,000 fibers is equivalent to picking all the fibers.

In our first experiment, we seek to determine an upper bound on the quality of recommendations based on using a small number of basis slabs and all fibers for the remaining users. Clearly, this experiment seeks only to characterize the limiting behavior of tensor-CUR, since having all fibers trivially allows perfect recommendations. Figures 11 and 12 illustrate that almost all users can be very accurately expressed as a linear combination of a small number of basis users, chosen uniformly at random without replacement. In later experiments, given this observation, we will attempt to approximate the coefficients of this linear combination using a small number of fibers.

Figure 11 shows the results for $N = 5$. Notice that using 512 or 1024 slabs and only 5 suggestions results in 4 or more successful recommendations; if the algorithm is allowed to make 10 suggestions, 64 or more slabs are enough to make roughly four successful recommendations. (As a trivial but weak lower bound on quality, by making five suggestions uniformly at random, we expect that we will make ca. .5 predictions correctly, since we are making 5 predictions and there are 100 products.) Notice that the $F1$ statistic shows a change of phase as the number of slabs increases above 256: making more than 5 suggestions is not necessary anymore, since the number of basis slabs suffices to accurately capture the high-ranking products. Given less than 256 basis slabs (e.g., 128 slabs), our results suggest that making 10 suggestions is qualitatively better. The same conclusions essentially apply to Figure 12 as well, which shows the results for $N = 10$. However, we should emphasize that the effect of making 20 versus 10 suggestions, as measured by the $F1$ statistic, is much less obvious in this case. Notice that making 20 suggestions does not result in a significant advantage even for a small number of basis slabs and is clearly worse as the number of basis slabs increases above 128.

In our second experiment, we show that by using a basis of preference information from (say) 128 users and performing a small number of product-product preference queries on a new user, we can make a large number of high-quality recommendations both for the top-5 and top-10 cases; see Figures 13 and 14, respectively. Since we are sampling a small number of fibers in this case, we are performing an approximate least-squares fit using just the information about a new user contained in a small number

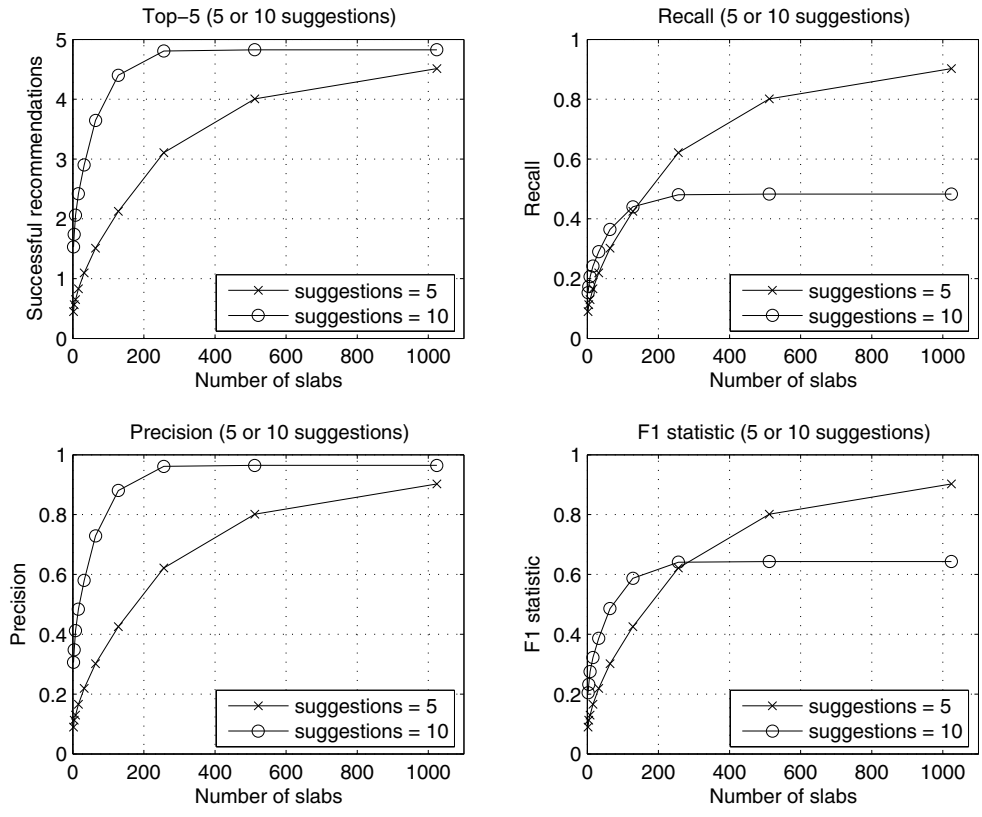

FIG. 11. *Effect of user basis size on top-5 recommendation quality using complete pairwise product-product preference information. The basis users are sampled uniformly at random without replacement.*

of fibers. If the algorithm is allowed to make 10 suggestions, the statistics for top-5 recommendations remain competitive with the upper bounds suggested in Figure 11. However, if the algorithm is allowed only 5 suggestions, the results are markedly worse, especially given a small number of pairwise product-product comparisons. Naturally, the $F1$ statistic illustrates that suggesting 10 products is now always preferable to suggesting 5 products. This observation changes when we evaluate the algorithm on top-10 recommendations, where the $F1$ statistic shows that suggesting 10 or 20 products is essentially the same, and thus suggesting 10 products is the right course of action. Notice that even though the performance of the algorithm is worse than the optimal one of Figure 12, it is clearly well above the random level. We would also like to note the nonmonotonicity near ca. 64 queries; this seems to be a fitting issue. Figures 15 and 16 show the results for top-10 recommendations when the number of basis users is set to 64 and 256, respectively. The results are qualitatively similar, but it is worth noticing that the algorithm making 10 suggestions outperforms the algorithm making 20 suggestions given 256 basis slabs and more than 256 fibers. The results for top-5 recommendations using 64 and 256 basis users are omitted, since they are qualitatively the same as in Figure 11.

In our third and final experiment, we present the distribution of correct top-10 predictions for the 14,116 users by using 64 or 128 basis users and a variable number

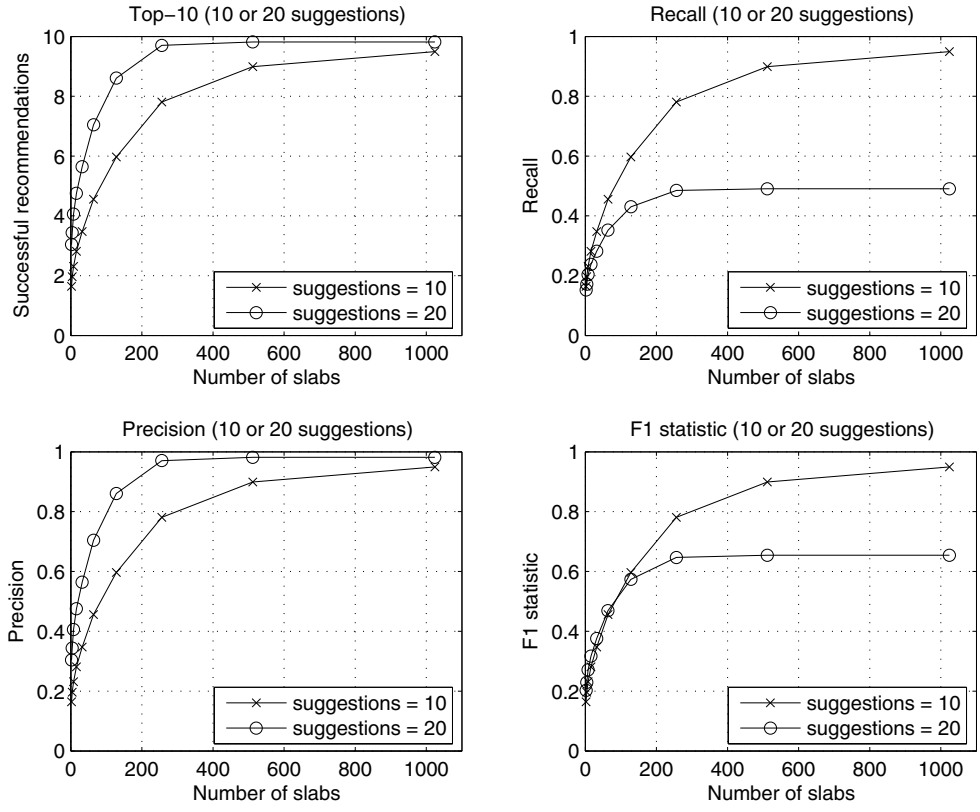

FIG. 12. *Effect of user basis size on top-*10 *recommendation quality using complete pairwise product-product preference information. The basis users are sampled uniformly at random without replacement.*

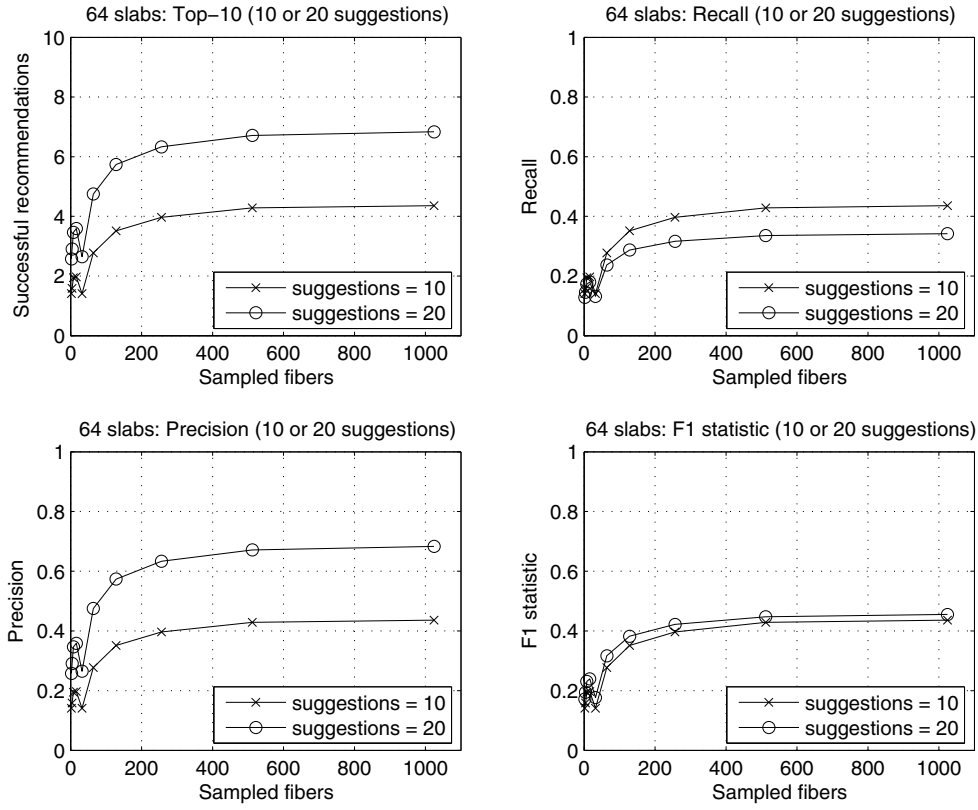

FIG. 15. *Effect of number of sampled fibers (pairwise product-product comparisons) on the top-10 recommendation quality given 64 basis users, sampled uniformly at random without replacement. The fibers are also sampled uniformly at random without replacement.*

of pairwise product-product comparisons; see Figure 17. Clearly, as the number of basis slabs or sampled fibers increases, the curves are shifted to the right, illustrating that a larger number of users receives more accurate recommendations. In this case, we plot results for the algorithm making 10 suggestions. Similar results are seen in all other cases.

In evaluating performance, we distinguish between prediction and reconstruction. In the former, we want to know how much user i will like product j (in a ratings model) or whether user i will prefer product j or product k (in a preference model). In the latter, which is of interest to us, we want to give a list of, e.g., the top-10 products for user i. We use tensor reconstruction as an intermediate step to making high-quality recommendations.

6. Conclusion. We have developed a tensor-based extension of the matrix CUR decomposition. This tensor-CUR decomposition is of most interest when the data may be modeled by a variable subscripted by three or more indices and when one of those indices/modes is qualitatively different from the others. In this case, the tensor-CUR decomposition approximately expresses the original data tensor in terms of a basis consisting of underlying subtensors that are actual data elements and thus that have natural interpretation in terms of the processes generating the data. In addition, we have applied the tensor-CUR decomposition to problems in two diverse domains of

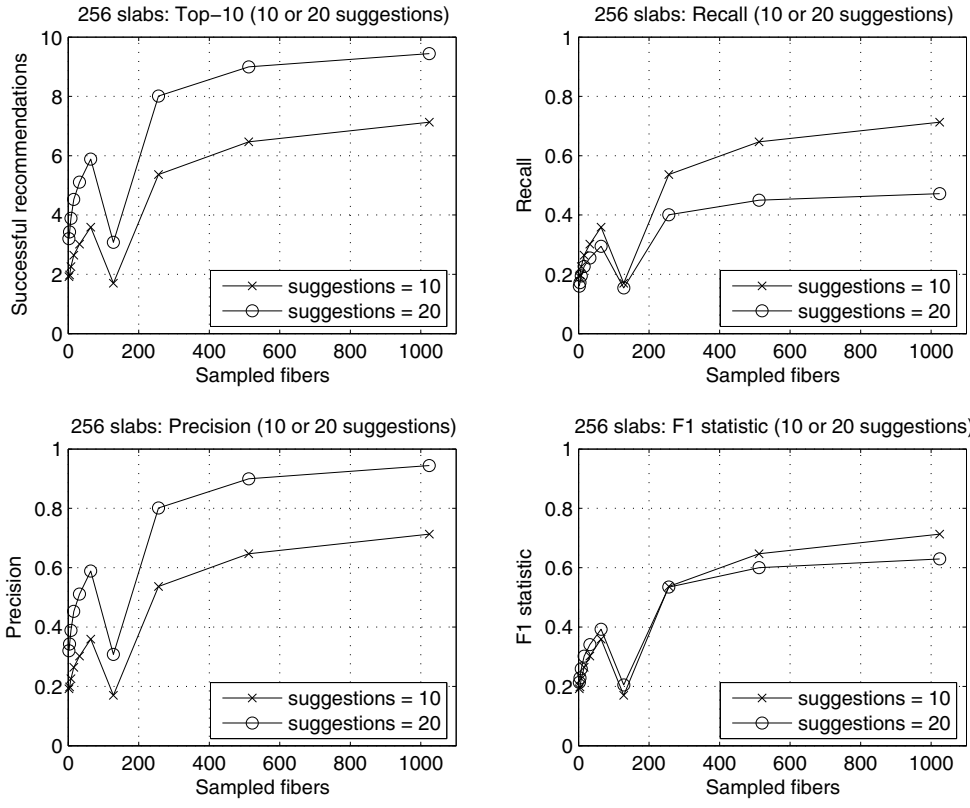

FIG. 16. *Effect of number of sampled fibers (pairwise product-product comparisons) on the top-10 recommendation quality given 256 basis users, sampled uniformly at random without replacement. The fibers are also sampled uniformly at random without replacement.*

data analysis: hyperspectral medical image analysis and consumer recommendation system analysis.

Similarities and differences between the methods discussed in this paper and the image analysis techniques known as "eigenfaces" and "tensor-faces" should be mentioned. The method of eigenfaces computes the eigenvectors of the covariance matrix of a large number of images of faces [62]. Eigenanalysis (and, more generally, SVD analysis) successively computes axes of maximum variation in the data, conditioned on being orthogonal to previously computed axes. Since this orthogonality is not present in natural images of faces, its imposition results in the characteristic "ringing" oscillations generated by eigenanalysis of facial images that in turn leads to difficulty interpreting the eigenfaces after the first few. The methods of the present paper are applicable to a set of time-resolved or frequency-resolved images of a single object. One could apply SVD-type analysis for data compression, i.e., to reduce the dimensionality along the slabs and/or the fibers. On the other hand, it will likely be difficult to interpret the principal components. Our tensor-CUR algorithms provide approximate low-rank tensor decompositions in terms of actual data elements. If orthogonality is not present in the data, e.g., if there are different fibers and/or pixels, then the tensor-CUR decompositions will be in terms of nonorthogonal data elements. Partly in response to ringing artifacts of eigenface analysis, a tensor-based

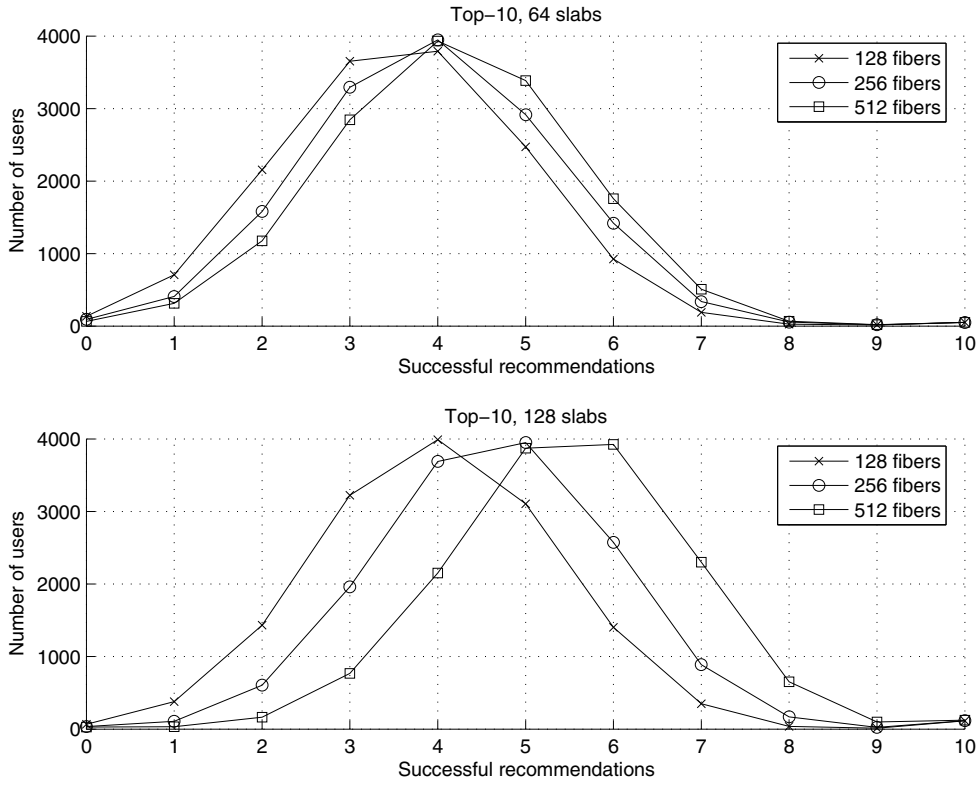

FIG. 17. *Distribution of number of users getting a given number of successful top-*10 *recommendations for a basis consisting of* 64 *or* 128 *users for different numbers of sampled fibers. Both the basis slabs and the fibers are sampled uniformly at random without replacement.*

analysis of facial images has been introduced [65]. This analysis involves applying a tensor-based generalization of the SVD to a user-defined set of features derived from a set of images of faces. A randomized variant of this generalization has been presented and analyzed in [23]. This randomized tensor-SVD algorithm bears some similarity to the randomized tensor-CUR algorithms described in this paper. It differs, however, in that there is no preferred mode; instead, the tensor is "unfolded" along every mode, and a projection along each mode is constructed by sampling columns along that mode.

We conclude with several related extensions of the present work. First, it would be worth examining how these methods can be coupled with more traditional methods of image analysis and recommendation system analysis. This could be performed either by choosing slabs and fibers and then analyzing each slab or fiber with more traditional methods, or by using structural insights from more traditional methods to construct the sample of slabs and fibers, or by compressing each individual slab with more traditional methods. Second, it would be worth determining whether the sample of slabs and/or fibers could be chosen to preserve some interesting multilinear structure in the data tensors that is damaged by the sampling techniques we have used. Third, it would be worth determining the extent to which it would be possible to combine fibers from several data cubes into a "dictionary" that could be used, along with a few slabs in a new data cube, to describe the entire new data cube. Fourth, it

would be worth understanding in greater detail the relationship between the methods we have presented for analyzing tensor data and the well-studied model proposed by Tucker, the "canonical decomposition" model, the "parallel factors" model, and the higher-order SVD model; due to lack of space, a comparison with these models has been omitted. Finally, cross-approximation techniques are powerful and well-developed adaptive methods for low-rank approximation of matrices [6, 63]; it is worth understanding in greater detail the relationship between these methods and matrix CUR decompositions.

Acknowledgment. We thank the authors of [51], in particular Gustave L. Davis of Yale University, for making available the hyperspectral data.

LOW-RANK APPROXIMATION OF GENERIC $p \times q \times 2$ ARRAYS AND DIVERGING COMPONENTS IN THE CANDECOMP/PARAFAC MODEL*

ALWIN STEGEMAN†

Abstract. We consider the low-rank approximation over the real field of generic $p \times q \times 2$ arrays. For all possible combinations of p, q, and R, we present conjectures on the existence of a best rank-R approximation. Our conjectures are motivated by a detailed analysis of the boundary of the set of arrays with at most rank R. We link these results to the Candecomp/Parafac (CP) model for three-way component analysis. Essentially, CP tries to find a best rank-R approximation to a given three-way array. In the case of $p \times q \times 2$ arrays, we show (under some regularity condition) that if a best rank-R approximation does not exist, then any sequence of CP updates will exhibit diverging CP components, which implies that several components are highly correlated in all three modes and their component weights become arbitrarily large. This extends Stegeman [*Psychometrika*, 71 (2006), pp. 483–501], who considers $p \times p \times 2$ arrays of rank $p+1$ or higher. We illustrate our results by means of simulations.

Key words. low-rank tensor approximations, border rank, arrays, Candecomp, Parafac, three-way arrays, degenerate Parafac solutions

1. Introduction.

We consider the problem of finding a best low-rank approximation to a three-way array $\underline{\mathbf{X}} \in \mathbb{R}^{p \times q \times 2}$. In this introductory section, we discuss the general problem of finding a best low-rank approximation to a k-way array and its applications in algebraic complexity theory (the multiplicative complexity of the computation of bilinear forms) and psychometrics (the Candecomp/Parafac (CP) model for three-way component analysis). Also, the consequences of an array not having a best low-rank approximation are discussed for these fields of research. Finally, we consider some results of the theory of matrix pencils with implications on the rank of $p \times q \times 2$ arrays, and show how our analysis fits into this literature.

1.1. Low-rank approximation of arrays.

Let the rank over a field $\mathcal{F}$ of a k-way array $\underline{\mathbf{X}} \in \mathcal{F}^{d_1 \times \cdots \times d_k}$ be defined in the usual way, i.e., as the smallest number of rank-1 arrays in $\mathcal{F}^{d_1 \times \cdots \times d_k}$ whose sum equals $\underline{\mathbf{X}}$; see Hitchcock [15, 16]. A k-way array has rank 1 over $\mathcal{F}$ if it is the outer product of k vectors in $\mathcal{F}^{d_1}, \ldots, \mathcal{F}^{d_k}$. The problem of finding a best rank-R approximation of $\underline{\mathbf{X}} \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ boils down to minimizing

$$\left\| \underline{\mathbf{X}} - \sum_{r=1}^{R} \mathbf{a}_r^{(1)} \circ \cdots \circ \mathbf{a}_r^{(k)} \right\| \tag{1.1}$$

over the vectors $\mathbf{a}_r^{(j)} \in \mathcal{F}^{d_j}$, $j = 1, \ldots, k$, $r = 1, \ldots, R$, where $\circ$ denotes the outer product and $\|\cdot\|$ denotes some norm on $\mathcal{F}^{d_1 \times \cdots \times d_k}$. Unless stated otherwise, we will

assume that $\mathcal{F} = \mathbb{R}$ and $\|\cdot\|$ is the Frobenius norm. We denote the rank of an array $\underline{\mathbf{X}}$ as $\text{rank}_\circ(\underline{\mathbf{X}})$.

For $k = 2$, all best rank-R approximations can be obtained from the singular value decomposition of the matrix to be approximated; see Eckart and Young [11]. However, for $k \geq 3$ a best rank-R approximation does not always exist. Examples of arrays that can be approximated arbitrarily well by arrays of lower rank are known from the algebraic complexity literature; see Bini et al. [1], Bini, Lotti, and Romani [2], and Bini [3], as well as from the psychometric and chemometric literature; see ten Berge, Kiers, and De Leeuw [37] and Paatero [30]. Stegeman [34] has shown, under some regularity condition, that generic $p \times p \times 2$ arrays of rank $p+1$ (a set of positive volume in $\mathbb{R}^{p\times p\times 2}$) do not have a best rank-p approximation. De Silva and Lim [10] show that a best rank-1 approximation always exists, while for any $k \geq 3$, any $d_1, \ldots, d_k \geq 2$, and any $R \in \{2, \ldots, \min(d_1, \ldots, d_k)\}$, a rank-$(R+1)$ array exists which has no best rank-R approximation. Also, [10] show that all $2 \times 2 \times 2$ arrays of rank 3 (a set of positive volume in $\mathbb{R}^{2\times 2\times 2}$) have no best rank-2 approximation, and that, for any $d_1, d_2, d_3 \geq 2$, the set of arrays in $\mathbb{R}^{d_1\times d_2\times d_3}$ which have no best rank-2 approximation has positive volume.

1.2. Algebraic complexity theory and array rank. An important problem in algebraic complexity theory is the multiplicative complexity of the computation of a set of bilinear forms $\mathbf{u}^T\mathbf{X}_k\mathbf{v}$, $k = 1, \ldots K$, where $\mathbf{u}$ and $\mathbf{v}$ are indeterminates and the $\mathbf{X}_k$ have elements in a field $\mathcal{F}$. Strassen [36] showed that the K bilinear forms $\mathbf{u}^T\mathbf{X}_k\mathbf{v}$ can be computed with R nonscalar multiplications (i.e., multiplications of two elements not in $\mathcal{F}$), where R is the rank over $\mathcal{F}$ of the array $\underline{\mathbf{X}}$ with slices $\mathbf{X}_k$. Indeed, if $\underline{\mathbf{X}} = \sum_{r=1}^{R} \mathbf{a}_r \circ \mathbf{b}_r \circ \mathbf{c}_r$, for vectors $\mathbf{a}_r$, $\mathbf{b}_r$, and $\mathbf{c}_r$ with elements in $\mathcal{F}$, then we have

$$\mathbf{u}^T\mathbf{X}_k\mathbf{v} = \sum_{r=1}^{R} (\mathbf{u}^T\mathbf{a}_r)\,(\mathbf{b}_r^T\mathbf{v})\,c_{kr}\,, \tag{1.2}$$

and the K bilinear forms $\mathbf{u}^T\mathbf{X}_k\mathbf{v}$ can be computed using R nonscalar multiplications. See also Brockett and Dobkin [6].

Suppose $\mathcal{F} = \mathbb{R}$ and $\underline{\mathbf{X}}$ can be approximated arbitrarily well by rank-$(R-1)$ arrays. In that case, we could replace $\underline{\mathbf{X}}$ in (1.2) by a rank-$(R-1)$ array close to it and use only $R-1$ nonscalar multiplications in the computation of the bilinear form. Since the rank-$(R-1)$ array can be chosen arbitrarily close to $\underline{\mathbf{X}}$, the error in the computation of the bilinear form can be made arbitrarily small. This idea was pointed out by Bini et al. [1], Bini, Lotti, and Romani [2], and Bini [3, 4] and has been used in the design of algorithms for matrix multiplication; see Bürgisser, Clausen, and Shokrollahi [7, Chapter 15] and the references therein. Hence, the nonexistence of a best rank-$(R-1)$ approximation of $\underline{\mathbf{X}}$ yields a faster and arbitrarily accurate computation of the bilinear forms.

To express the optimal computational gain that can be achieved by approximating $\underline{\mathbf{X}}$ with arrays of lower rank, Bini, Lotti, and Romani [2] have introduced the notion of *border rank*. The border rank of an array $\underline{\mathbf{X}}$, which we denote by $\text{rank}_B(\underline{\mathbf{X}})$, is defined as

$$\text{rank}_B(\underline{\mathbf{X}}) = \min\{R : \ \underline{\mathbf{X}} \text{ can be approximated arbitrarily well by arrays of rank } R\}\,. \tag{1.3}$$

From this definition it follows that $\text{rank}_B(\underline{\mathbf{X}}) \leq \text{rank}_\circ(\underline{\mathbf{X}})$. Results on the border rank of various arrays have been obtained by Bini [4, 5] and Landsberg [25]. For later

use we state the following result. Let $\text{rank}_i(\underline{\mathbf{X}})$ denote the rank of the set of mode i fibers of $\underline{\mathbf{X}}$, where a mode i fiber is a vector obtained by varying the mode i index and keeping all other indices fixed. This notion of rank is due to Hitchcock [15, 16] and the set of $\text{rank}_i(\underline{\mathbf{X}})$ for all i is called the *multilinear rank* of $\underline{\mathbf{X}}$ in De Silva and Lim [10]

PROPOSITION 1.1. *For a k-way array $\underline{\mathbf{X}} \in \mathbb{R}^{d_1 \times \cdots \times d_k}$, there holds*

$$\max_i \text{rank}_i(\underline{\mathbf{X}}) \leq \text{rank}_B(\underline{\mathbf{X}}) \leq \text{rank}_\circ(\underline{\mathbf{X}}) \,. \tag{1.4}$$

Proof. The second inequality follows from (1.3). A proof of the inequality $\text{rank}_i(\underline{\mathbf{X}}) \leq \text{rank}_\circ(\underline{\mathbf{X}})$ is given by De Silva and Lim [10]. We state it here for completeness. Let $R = \text{rank}_\circ(\underline{\mathbf{X}})$ and $\underline{\mathbf{X}} = \sum_{r=1}^{R} \mathbf{a}_r^{(1)} \circ \cdots \circ \mathbf{a}_r^{(k)}$. Then all mode i fibers lie in the span of $\mathbf{a}_1^{(i)}, \ldots, \mathbf{a}_R^{(i)}$. This implies $\text{rank}_i(\underline{\mathbf{X}}) \leq R$.

We show the first inequality by contradiction. Suppose $t = \text{rank}_B(\underline{\mathbf{X}}) < \text{rank}_i(\underline{\mathbf{X}})$. Then there exists a sequence of rank-t arrays $\underline{\mathbf{Y}}^{(n)}$ converging to $\underline{\mathbf{X}}$. But then also the matrices $\mathbf{Y}_i^{(n)}$, containing as columns the mode i fibers of $\underline{\mathbf{Y}}^{(n)}$, must converge to the matrix $\mathbf{X}_i$ containing the mode i fibers of $\underline{\mathbf{X}}$. This is a contradiction, since $\text{rank}(\mathbf{Y}_i^{(n)}) \leq t < \text{rank}(\mathbf{X}_i)$ for all n, and a matrix cannot be approximated arbitrarily well by matrices of lower rank. Note that the upper semicontinuity of the multilinear rank is used here; see De Silva and Lim [10]. ∎

1.3. The CP model and diverging components. Carroll and Chang [9] and Harshman [13] have independently proposed the same method for component analysis of three-way data arrays and named it Candecomp and Parafac, respectively. We denote the CP model as

$$\underline{\mathbf{X}} = \sum_{r=1}^{R} \omega_r \, (\mathbf{a}_r \circ \mathbf{b}_r \circ \mathbf{c}_r) + \underline{\mathbf{E}} \,, \tag{1.5}$$

where $\underline{\mathbf{X}}$ is a $d_1 \times d_2 \times d_3$ data array, ω_r is the weight of component r, and $\|\mathbf{a}_r\| = \|\mathbf{b}_r\| = \|\mathbf{c}_r\| = 1$ for $r = 1, \ldots, R$. The Frobenius norm of $\underline{\mathbf{E}}$ is minimized to find the R components $\mathbf{a}_r \circ \mathbf{b}_r \circ \mathbf{c}_r$ and the weights ω_r. For an overview and comparison of CP algorithms, see Hopke et al. [17] and Tomasi and Bro [41]. From (1.5) it is clear that the CP model tries to find a best rank-R approximation to the three-way array $\underline{\mathbf{X}}$.

The CP model (1.5) can be seen as a three-way extension of the principal component analysis model for matrices. For example, if the vectors $\mathbf{a}_r$ are interpreted as the components in mode 1, then $\mathbf{b}_r$ and $\mathbf{c}_r$ are the loadings on these components for modes 2 and 3, respectively. The real-valued CP model, i.e., where $\underline{\mathbf{X}}$ and the model parameters are real-valued, is used in a majority of applications in psychometrics and chemometrics; see Kroonenberg [21] and Smilde, Bro, and Geladi [33]. Complex-valued applications of CP occur in, e.g., signal processing and telecommunications research; see Sidiropoulos [32]. In this paper, we consider only the real-valued CP model.

A matrix notation of the CP model (1.5) is as follows. Let $\mathbf{X}_k$ $(d_1 \times d_2)$ and $\mathbf{E}_k$ $(d_1 \times d_2)$ denote the kth slices of $\underline{\mathbf{X}}$ and $\underline{\mathbf{E}}$, respectively. Then (1.5) can be written as

$$\mathbf{X}_k = \mathbf{A} \, \mathbf{C}_k \, \mathbf{\Omega} \, \mathbf{B}^T + \mathbf{E}_k \,, \qquad k = 1, \ldots K \,, \tag{1.6}$$

where $\mathbf{A}$ $(d_1 \times R)$ and $\mathbf{B}$ $(d_2 \times R)$ have the vectors $\mathbf{a}_r$ and $\mathbf{b}_r$ as columns, respectively, $\mathbf{\Omega}$ $(R \times R)$ is the diagonal matrix with the weights ω_r on its diagonal, and $\mathbf{C}_k$ $(R \times R)$

is the diagonal matrix with the kth elements of the vectors $\mathbf{c}_r$ on its diagonal. The model part of the CP model is characterized by $(\mathbf{A}, \mathbf{B}, \mathbf{C}, \mathbf{\Omega})$, where $\mathbf{C}$ $(d_3 \times R)$ has the vectors $\mathbf{c}_r$ as columns. We refer to $\mathbf{A}, \mathbf{B}, \mathbf{C}$ as the component matrices and to $\mathbf{\Omega}$ as the weights matrix.

The most attractive feature of CP is its uniqueness property. Kruskal [22] has shown that, for fixed residuals $\underline{\mathbf{E}}$, the vectors $\mathbf{a}_r$, $\mathbf{b}_r$, and $\mathbf{c}_r$ and the weights ω_r are unique up to sign changes and a reordering of the summands in (1.5) if

$$k_{\mathbf{A}} + k_{\mathbf{B}} + k_{\mathbf{C}} \geq 2\,R + 2\,, \tag{1.7}$$

where $k_{\mathbf{A}}$, $k_{\mathbf{B}}$, $k_{\mathbf{C}}$ denote the k-ranks of the component matrices. The k-rank of a matrix is the largest number x such that every subset of x columns of the matrix is linearly independent. Hence, contrary to the matrix principal components model, the CP components are rotationally unique if (1.7) holds.

However, the practical use of CP has been hampered by the occurrence of diverging CP components. In the majority of such cases, exactly two components displayed the following pattern. Let the model parameters of the nth update of a CP algorithm be denoted by a superscript (n). In the case of two diverging CP components, say s and t, the weights $\omega_s^{(n)}$ and $\omega_t^{(n)}$ become arbitrarily large in magnitude while the vectors $\mathbf{a}_s^{(n)}$, $\mathbf{b}_s^{(n)}$, and $\mathbf{c}_s^{(n)}$ become nearly identical (up to sign changes) to $\mathbf{a}_t^{(n)}$, $\mathbf{b}_t^{(n)}$, and $\mathbf{c}_t^{(n)}$ such that

$$\sum_{r=s,t} \omega_r^{(n)} \, (\mathbf{a}_r^{(n)} \circ \mathbf{b}_r^{(n)} \circ \mathbf{c}_r^{(n)})$$

remains "small." Hence, the contributions of components s and t diverge in nearly opposite directions, but their sum still contributes to a better fit of the CP model. The CP algorithm becomes very slow when this occurs; see Mitchell and Burdick [28]. When the CP algorithm is terminated, the CP components obtained are said to form a *degenerate CP solution*. Since this use of the term *degenerate* is different from its general meaning in mathematics, we will speak of *diverging CP components* instead. This also reflects the fact that this phenomenon occurs when running a CP algorithm, while a degenerate CP solution suggests a property of one CP solution only.

The first case of two diverging CP components was reported in Harshman and Lundy [14]. Contrived examples are given by ten Berge, Kiers, and De Leeuw [37] and Paatero [30]. The latter has also constructed sequences of CP updates with three and four diverging components.

Kruskal, Harshman, and Lundy [24] have argued that diverging CP components occur due to the fact that the array $\underline{\mathbf{X}}$ has no best rank-R approximation. They reason that every sequence of CP updates of which the objective value is approaching the infimum of the CP objective function must fail to converge and displays a pattern of diverging CP components. Stegeman [34] confirms this statement (under some regularity condition) for generic $p \times p \times 2$ arrays of rank $p+1$ with $R = p$. Stegeman [35] confirms the statement of [24] for generic $3 \times 3 \times p$ arrays with symmetric slices of rank $p+1$ with $R = p$, $p = 4, 5$, for generic $3 \times 3 \times 5$ arrays of rank 6 with $R = 5$, and for generic $8 \times 4 \times 3$ arrays of rank 9 with $R = 8$.

For given $d_1, d_2, d_3 \geq 2$, let

$$\mathcal{S}_R = \{\underline{\mathbf{Y}} \in \mathbb{R}^{d_1 \times d_2 \times d_3} : \operatorname{rank}_\circ(\underline{\mathbf{Y}}) \leq R\}\,, \tag{1.8}$$

and let $\overline{\mathcal{S}}_R$ denote its closure. We assume that $\operatorname{rank}_\circ(\underline{\mathbf{X}}) > R$. Hence, if $\underline{\mathbf{X}}$ has a best rank-R approximation, it will be a boundary point of $\mathcal{S}_R$. So far, all but one

mathematically analyzed case of diverging CP components (i.e., ten Berge, Kiers, and De Leeuw [37], Paatero [30], Stegeman [34, 35], and the results in the present paper) are due to the fact that the sequence $\underline{\mathbf{Y}}^{(n)} \in \mathcal{S}_R$ of CP updates converges to a boundary point $\widetilde{\underline{\mathbf{X}}}$ of $\mathcal{S}_R$ with $\text{rank}_\circ(\widetilde{\underline{\mathbf{X}}}) > R$, i.e., $\widetilde{\underline{\mathbf{X}}} \in \overline{\mathcal{S}}_R \backslash \mathcal{S}_R$, where $\widetilde{\underline{\mathbf{X}}}$ is a best approximation of $\underline{\mathbf{X}}$ from $\overline{\mathcal{S}}_R$. In these cases, the phenomenon of diverging CP components can be formalized as follows. There exist disjoint index sets $I_1, \ldots, I_m \subset \{1, \ldots, R\}$ such that as $\underline{\mathbf{Y}}^{(n)} \to \widetilde{\underline{\mathbf{X}}}$,

$$|\omega_r^{(n)}| \to \infty \qquad \text{for all } r \in I_j\,, \quad j = 1, \ldots, m\,, \tag{1.9}$$

$$\text{while} \quad \left\| \sum_{r \in I_j} \omega_r^{(n)} \, (\mathbf{a}_r^{(n)} \circ \mathbf{b}_r^{(n)} \circ \mathbf{c}_r^{(n)}) \right\| \qquad \text{is bounded}\,, \quad j = 1, \ldots, m\,. \tag{1.10}$$

For two diverging CP components, we have $m = 1$ and $\text{card}(I_1) = 2$. For three diverging CP components, we have $m = 1$ and $\text{card}(I_1) = 3$. For two groups of diverging CP components we have $m = 2$, et cetera. For the case of generic $p \times q \times 2$ arrays it will be shown in section 3 how the rank of $\widetilde{\underline{\mathbf{X}}}$ is related to the number of groups m and the number of diverging CP components in each group.

Note that we do not consider cases where $\text{rank}_\circ(\underline{\mathbf{X}}) = R$ and its CP decomposition resembles a case of diverging CP components, examples of which can be found in Mitchell and Burdick [28] and Paatero [30].

If $\underline{\mathbf{X}}$ does not have a best rank-R approximation, this implies that all best approximations $\widetilde{\underline{\mathbf{X}}}$ of $\underline{\mathbf{X}}$ from $\overline{\mathcal{S}}_R$ have at least rank $R+1$. In the cases analyzed so far, any sequence $\underline{\mathbf{Y}}^{(n)}$ of CP updates converging to $\widetilde{\underline{\mathbf{X}}}$ has been shown (under some regularity conditions) to exhibit diverging CP components in this situation. Hence, modified CP algorithms designed to avoid diverging CP components (e.g., Rayens and Mitchell [31] and Cao et al. [8]) are no remedy here.

As mentioned above, there is one known case where $\underline{\mathbf{X}}$ has a best rank-R approximation, but diverging CP components may still occur. This is the case of $3 \times 3 \times 5$ arrays of rank 6 and $R = 5$. Here, a best rank-5 approximation $\widetilde{\underline{\mathbf{X}}}$ of $\underline{\mathbf{X}}$ may exist while sequences $\underline{\mathbf{Y}}^{(n)}$ of CP updates converging to $\widetilde{\underline{\mathbf{X}}}$ sometimes show diverging CP components and sometimes do not; see Stegeman [35]. This is due to the partial uniqueness of the CP decomposition of $\underline{\mathbf{Y}}^{(n)}$; see ten Berge [40].

Diverging CP components are a problem in the analysis of three-way arrays, since the obtained CP solution is hardly interpretable. Diverging CP components can be avoided by imposing orthogonality constraints on the components matrices (see Harshman and Lundy [14]) but this will come with some loss of fit. Lim [27] shows that for nonnegative $\underline{\mathbf{X}}$ and nonnegative component matrices there always exists an optimal CP solution and diverging CP components do not occur.

1.4. Matrix pencils and the rank of $p \times q \times 2$ arrays. A matrix pencil $\mathbf{X}_1 + \lambda \mathbf{X}_2$ consists of two matrices $\mathbf{X}_1$ and $\mathbf{X}_2$ with elements in a field $\mathcal{F}$ and a scalar λ. A matrix pencil is called *regular* if both $\mathbf{X}_1$ and $\mathbf{X}_2$ are square matrices and there exists an λ such that $\det(\mathbf{X}_1 + \lambda \mathbf{X}_2) \neq 0$. In all other cases, the pencil is called *singular*. For regular matrix pencils, equivalence results and a canonical form were established by Weierstrass [42]. The corresponding theory for singular pencils was developed by Kronecker [20]. For an overview of matrix pencil theory we refer the reader to Gantmacher [12, Chapter XII].

Ja' Ja' [19] has extended Kronecker's [20] equivalence results for $p \times q$ matrix pencils to $p \times q \times 2$ arrays. The same author [18] obtained results on the multiplicative complexity of computing two bilinear forms by considering the Kronecker canonical form of the associated matrix pencil and gave a complete characterization of the rank of the associated $p \times q \times 2$ array. In particular, Ja' Ja' [18] showed that for $p \geq q$,

$$\underline{\mathbf{X}} \in \mathbb{R}^{p \times q \times 2} \quad \Longrightarrow \quad \operatorname{rank}_\circ(\underline{\mathbf{X}}) \leq q + \min(q, \operatorname{floor}(p/2)) \,, \tag{1.11}$$

where the rank is over the real field and $\operatorname{floor}(x)$ denotes the largest integer smaller than or equal to x; see also Kruskal [23]. The upper bound (1.11) is sharp, i.e., there exist $p \times q \times 2$ arrays with rank equal to the upper bound. For later use, we state the following result, also due to Ja' Ja' [18].

PROPOSITION 1.2. *Let $\underline{\mathbf{X}} \in \mathbb{R}^{p \times p \times 2}$ with $p \times p$ slices $\mathbf{X}_i$, $i = 1, 2$. Suppose $det(\mathbf{X}_1) \neq 0$ and $\mathbf{X}_2\mathbf{X}_1^{-1}$ has p real eigenvalues. Let the Jordan normal form (see Gantmacher* [12, Chapter VI]) *of $\mathbf{X}_2\mathbf{X}_1^{-1}$ be given by* $\operatorname{diag}(J_{n_1}(\lambda_1), \ldots, J_{n_r}(\lambda_r))$, *where $J_{n_j}(\lambda_j)$ denotes an $n_j \times n_j$ Jordan block with diagonal elements equal to λ_j. Then*

$$\operatorname{rank}_\circ(\underline{\mathbf{X}}) = p + k \,, \tag{1.12}$$

where the rank is over the real field and k is the number of Jordan blocks $J_{n_j}(\lambda_j)$ with $n_j > 1$.

For a $p \times p$ matrix $\mathbf{Z}$ with eigenvalues $\lambda_1, \ldots, \lambda_r$, we define the *algebraic multiplicity* of λ_j as the multiplicity of λ_j as root of the characteristic polynomial $\det(\mathbf{Z} - \lambda \mathbf{I}_p)$, and the *geometric multiplicity* of λ_j as the maximum number of linearly independent eigenvectors of $\mathbf{Z}$ associated with λ_j (i.e., the dimensionality of the eigenspace of λ_j). Recall that for $\mathbf{Z} = \operatorname{diag}(J_{n_1}(\lambda_1), \ldots, J_{n_r}(\lambda_r))$, the eigenvalues are $\lambda_1, \ldots, \lambda_r$ (not necessarily distinct), and each Jordan block $J_{n_j}(\lambda_j)$ adds n_j to the algebraic multiplicity of λ_j and 1 to the geometric multiplicity of λ_j. This establishes a relation between the eigenvalues of $\mathbf{X}_2\mathbf{X}_1^{-1}$ and the rank of the array $\underline{\mathbf{X}}$ in Proposition 1.2. In particular, if $\mathbf{X}_2\mathbf{X}_1^{-1}$ has p real eigenvalues and is diagonalizable, then $\operatorname{rank}_\circ(\underline{\mathbf{X}}) = p$ (see also Ten Berge [38]). Ja' Ja' [18] also showed that if $\mathbf{X}_2\mathbf{X}_1^{-1}$ has at least one pair of complex eigenvalues, then $\operatorname{rank}_\circ(\underline{\mathbf{X}}) \geq p + 1$ (see also [38]).

For generic $p \times q \times 2$ arrays, Ten Berge and Kiers [39] showed that, for $p > q$, the rank of $\underline{\mathbf{X}}$ is equal to $\min(p, 2q)$ almost everywhere, i.e., $\operatorname{rank}(\underline{\mathbf{X}}) \neq \min(p, 2q)$ on a set of zero volume in $\mathbb{R}^{p \times q \times 2}$. We call this rank value the *typical rank*. The same authors show that for $p = q$, the typical rank of $\underline{\mathbf{X}}$ is two-valued, namely $\{p,\ p+1\}$, where the sets of both rank values have positive volume. Notice that for $p \times q \times 2$ arrays the set $\mathcal{S}_R$ of arrays with rank less than or equal to R has dimensionality $2pq$ if R is larger than or equal to the typical rank. If R is smaller than the typical rank, then $\mathcal{S}_R$ has dimensionality lower than $2pq$. Analogously, if R is larger than the typical rank, then the set $\mathcal{S}_R^c = \mathbb{R}^{p \times q \times 2} \backslash \mathcal{S}_R$ has dimensionality lower than $2pq$.

Notice that if $p \geq 2q$, then both the typical rank and the maximum rank (1.11) are equal to $2q$. If $2q > p > q$, then the typical rank equals p, while the maximum rank equals

$$q + \operatorname{floor}(p/2) \geq ((p+1)/2) + \operatorname{floor}(p/2) \geq p \,. \tag{1.13}$$

Bini [4] has studied the border rank of so-called *nondegenerate* $p \times q \times 2$ arrays, where a 3-way array $\underline{\mathbf{X}} \in \mathbb{R}^{d_1 \times d_2 \times d_3}$ is called nondegenerate if $\operatorname{rank}_i(\underline{\mathbf{X}}) = d_i$ for $i = 1, 2, 3$. The use of the term *nondegenerate* here is a bit strange, since generic $p \times q \times 2$ arrays

are nondegenerate only if $p \leq 2q$ and $q \leq 2p$. The following result is based on the results of Ja' Ja' [18] and is due to Bini [4].

PROPOSITION 1.3. *Let* $\underline{\mathbf{X}} \in \mathbb{R}^{p\times q\times 2}$ *such that* $rank_1(\underline{\mathbf{X}}) = p$, $rank_2(\underline{\mathbf{X}}) = q$, *and* $rank_3(\underline{\mathbf{X}}) = 2$. *Let* $\mathbf{X}_1$ *and* $\mathbf{X}_2$ *be the* $p \times q$ *slices of* $\underline{\mathbf{X}}$.

(i) *Let* $p = q$ *and* $det(\mathbf{X}_1) \neq 0$. *Then* $rank_B(\underline{\mathbf{X}}) = p$ *if and only if* $\mathbf{X}_2\mathbf{X}_1^{-1}$ *has* p *real eigenvalues. If* $\mathbf{X}_2\mathbf{X}_1^{-1}$ *has at least one pair of complex eigenvalues, then* $rank_B(\underline{\mathbf{X}}) = p + 1$.

(ii) *Let* $p = q$ *and* $det(\mathbf{X}_1) = 0$. *Then* $rank_B(\underline{\mathbf{X}}) = p$ *if* $det(\mathbf{X}_1 + \lambda\mathbf{X}_2)$ *has* p *real roots* λ. *If* $det(\mathbf{X}_1 + \lambda\mathbf{X}_2)$ *has at least one pair of complex roots, then* $rank_B(\underline{\mathbf{X}}) \in \{p, p + 1\}$.

(iii) *If* $p > q$, *then* $rank_B(\underline{\mathbf{X}}) = p$ *if* $det(\mathbf{Y}_1 + \lambda\mathbf{Y}_2)$ *has only real roots* λ, *where* $\mathbf{Y}_1 + \lambda\mathbf{Y}_2$ *is the regular pencil kernel in the Kronecker canonical form of* $\mathbf{X}_1 + \lambda\mathbf{X}_2$. *If* $det(\mathbf{Y}_1 + \lambda\mathbf{Y}_2)$ *has at least one pair of complex roots, then* $rank_B(\underline{\mathbf{X}}) \in \{p, p + 1\}$.

Next, we discuss the link between the results in the present paper and the existing results mentioned above. In this paper, we consider the low-rank approximation of generic real-valued $p \times q \times 2$ arrays, where we assume $p \geq q$ without loss of generality. Such an array has typical rank $\min(p, 2q)$ and we show whether or not it has a best rank-R approximation, with $R < \min(p, 2q)$. If such a generic array is nondegenerate in the sense of Bini [4], then it has typical rank $\min(p, 2q) = p$ and $\text{rank}_\circ(\underline{\mathbf{X}}) \geq p$; see (1.4). If $\text{rank}_\circ(\underline{\mathbf{X}}) = p$, then it follows from (1.4) that also $\text{rank}_B(\underline{\mathbf{X}}) = p$. The case $\text{rank}_B(\underline{\mathbf{X}}) = p+1$ is possible only for arrays $\underline{\mathbf{X}}$ with rank larger than the typical rank p, and such arrays are not generic. Hence, our results are not covered by Proposition 1.3.

To obtain our results, we study the boundary of $\mathcal{S}_R$, the set of $p \times q \times 2$ arrays with rank at most R, and distinguish boundary arrays lying in $\mathcal{S}_R$ from those with rank larger than R. Clearly, a boundary array $\underline{\widetilde{\mathbf{X}}}$ of $\mathcal{S}_R$ has border rank at most R and is not a nondegenerate array in the sense of Bini [4] since $\text{rank}_1(\underline{\widetilde{\mathbf{X}}}) \leq R < p$; see (1.4). However, we transform the set $\mathcal{S}_R$ to a subset of the smaller space of $R \times R \times 2$ arrays if $R \leq q$, or $R \times q \times 2$ arrays if $R > q$, and Propositions 1.2 and 1.3 apply to individual boundary arrays in this smaller space. But to answer the question whether a generic $p \times q \times 2$ array has a best rank-R approximation almost everywhere, or on a set of positive volume, or on a set of zero volume, we need dimensionality arguments to establish which rank values have positive volume on the boundary of $\mathcal{S}_R$. Moreover, we do not use the Kronecker canonical form in (iii) of Proposition 1.3 to obtain our results.

This paper is organized as follows. We present our results on the existence of a best rank-R approximation to generic $p \times q \times 2$ arrays in section 2. In section 3 we show (under some regularity condition) that if there is no best rank-R approximation, then, in the CP model, any sequence $\underline{\mathbf{Y}}^{(n)} \in \mathcal{S}_R$ converging to an optimal boundary point $\underline{\widetilde{\mathbf{X}}}$ of $\mathcal{S}_R$ (with $\text{rank}_\circ(\underline{\widetilde{\mathbf{X}}}) > R$) will exhibit diverging CP components as defined by (1.9) and (1.10). Moreover, we show that there is a direct relation between the rank of $\underline{\widetilde{\mathbf{X}}}$ and the number of groups of diverging CP components. This extends Stegeman [34] who considered rank-p approximations to generic $p \times p \times 2$ arrays of rank $p + 1$. In section 4 we illustrate our results by means of calculating rank-R approximations to random $p \times q \times 2$ arrays for a variety of values for p, q, and R. Finally, section 5 contains a discussion on the presented results.

2. Low-rank approximation of generic $p \times q \times 2$ arrays. For generic $\underline{\mathbf{X}} \in \mathbb{R}^{p\times q\times 2}$, we consider the problem

$$\begin{aligned} &\text{Minimize} \|\underline{\mathbf{X}} - \underline{\mathbf{Y}}\| \\ &\text{subject to } \underline{\mathbf{Y}} \in \mathcal{S}_R\,, \end{aligned} \tag{2.1}$$

where $\mathcal{S}_R$ is the set of real-valued $p \times q \times 2$ arrays of rank at most R (see (1.8)) and the rank is taken over the real field. We also consider the related problem

$$\begin{aligned} &\text{Minimize} \|\underline{\mathbf{X}} - \underline{\mathbf{Y}}\| \\ &\text{subject to } \underline{\mathbf{Y}} \in \overline{\mathcal{S}}_R\,, \end{aligned} \tag{2.2}$$

where $\overline{\mathcal{S}}_R$ is the closure of $\mathcal{S}_R$, i.e., the union of $\mathcal{S}_R$ and all its boundary points. Suppose $\text{rank}_\circ(\underline{\mathbf{X}}) > R$. There holds that any optimal solution of problem (2.2) is a boundary point of $\mathcal{S}_R$. Indeed, from any interior point $\underline{\mathbf{Y}}$ of $\mathcal{S}_R$ a line to $\underline{\mathbf{X}}$ can be drawn which intersects with the boundary of $\mathcal{S}_R$. Suppose the intersection occurs at boundary point $\widetilde{\underline{\mathbf{X}}}$. Then $\widetilde{\underline{\mathbf{X}}}$ has a lower objective value (i.e., is closer to $\underline{\mathbf{X}}$) than the interior point $\underline{\mathbf{Y}}$. Hence, problem (2.1) has an optimal solution, or, equivalently, $\underline{\mathbf{X}}$ has a best rank-R approximation, if there exists a boundary point $\widetilde{\underline{\mathbf{X}}} \in \mathcal{S}_R$ which is an optimal solution of problem (2.2). Clearly, this always holds if $\mathcal{S}_R$ is a closed set. However, De Silva and Lim [10] have shown that $\mathcal{S}_R$ is closed only for $R = 1$. Hence, an investigation of the boundary points of $\mathcal{S}_R$ is necessary to ascertain whether a best rank-R approximation exists almost everywhere, or on a set of positive volume, or on a set of zero volume.

We consider all possible combinations of p, q, and R, where, without loss of generality, we assume that $p \geq q$. As mentioned in section 1, we transform the set $\mathcal{S}_R$ to a subset of the smaller space of $R \times R \times 2$ arrays if $R \leq q$ or $R \times q \times 2$ arrays if $R > q$ and use the results of Stegeman [34] and Proposition 1.2 to characterize the boundary points of $\mathcal{S}_R$; in particular, whether they are in $\mathcal{S}_R$ or in $\mathcal{S}_R^c$.

Unfortunately, our results are not complete. That is, they rely on conjectures relating the dimensionality of parts of the boundary of $\mathcal{S}_R$ to the existence of optimal solutions of problem (2.1). Table 2.1 gives a summary of our results. Below, we consider all cases in Table 2.1 and state explicitly whether we use a conjecture. Except for cases 1, 4, and 6, the statements on the existence of a best rank-R approximation are (partly) based on conjectures.

Cases 1, 4, and 6. In these cases, R is larger than or equal to the typical rank of $\underline{\mathbf{X}}$, i.e., $\underline{\mathbf{X}}$ itself lies in $\mathcal{S}_R$ almost everywhere. Hence, the best rank-R approximation of $\underline{\mathbf{X}}$ is $\underline{\mathbf{X}}$ itself.

Cases 2, 3, 5, 7, 8, and 9. For these cases, there holds $\underline{\mathbf{X}} \notin \mathcal{S}_R$ almost everywhere. As discussed above, we need to characterize the boundary of $\mathcal{S}_R$. We define the following subsets of $\mathbb{R}^{p \times q \times 2}$. Let

$$\mathcal{W}_R = \{\underline{\mathbf{Y}} \in \mathbb{R}^{p \times q \times 2} : \text{rank}[\mathbf{Y}_1 | \mathbf{Y}_2] \leq R\} = \{\underline{\mathbf{Y}} \in \mathbb{R}^{p \times q \times 2} : \text{rank}_1(\underline{\mathbf{Y}}) \leq R\}\,, \tag{2.3}$$

where $\mathbf{Y}_1$ and $\mathbf{Y}_2$ denote the $p \times q$ slices of $\underline{\mathbf{Y}}$, and let

$$\mathcal{V}_{R+1} = \{\underline{\mathbf{Y}} \in \mathcal{W}_R : \text{rank}_\circ(\underline{\mathbf{Y}}) \geq R + 1\} = \mathcal{W}_R \cap \mathcal{S}_R^c\,. \tag{2.4}$$

We need the following lemma.

LEMMA 2.1. *We have the following results.*

(i) *The set $\mathcal{W}_R$ is closed and the boundary of $\mathcal{W}_R$ is the set $\mathcal{W}_R$ itself.*

TABLE 2.1
Results (cases 1, 4, and 6) and conjectures (cases 2, 3, 5, 7, 8, and 9) on the existence of a best rank-R approximation to generic $p \times q \times 2$ arrays. Here, $p \geq q \geq 2$ and $R \geq 2$.

Case	$\underline{\mathbf{X}} \in \mathbb{R}^{p \times q \times 2}$	$\text{rank}_\circ(\underline{\mathbf{X}})$	R	Best rank-R approx. exists?
1	$p = q$	$p+1$	$R \geq p+1$	almost everywhere
2	$p = q$	$p+1$	$R = p$	zero volume
3	$p = q$	$p+1$	$R < p$	positive volume
4	$p = q$	p	$R \geq p$	almost everywhere
5	$p = q$	p	$R < p$	positive volume
6	$p > q$	$\min(p, 2q)$	$R \geq \min(p, 2q)$	almost everywhere
7	$p > q$	$\min(p, 2q)$	$\min(p, 2q) > R > q$	almost everywhere
8	$p > q$	$\min(p, 2q)$	$R = q$	positive volume
9	$p > q$	$\min(p, 2q)$	$R < q$	positive volume

(ii) *There holds*

$$\mathcal{W}_R = \mathcal{S}_R \cup \mathcal{V}_{R+1} \qquad \text{and} \qquad \mathcal{S}_R \cap \mathcal{V}_{R+1} = \emptyset\,. \tag{2.5}$$

(iii) *In case 2, there holds $\mathcal{W}_R = \mathbb{R}^{p \times q \times 2}$.*

Proof. Statement (i) follows from the fact that any matrix of rank at most R can be approximated arbitrarily well by rank-$(R+1)$ matrices.

Next, we prove (ii). From (1.4) it follows that $\mathcal{S}_R \subseteq \mathcal{W}_R$. Since $\mathcal{V}_{R+1} = \mathcal{W}_R \cap \mathcal{S}_R^c$, we have $\mathcal{S}_R \cap \mathcal{V}_{R+1} = \emptyset$ by definition. Hence, $\mathcal{W}_R = (\mathcal{W}_R \cap \mathcal{S}_R) \cup (\mathcal{W}_R \cap \mathcal{S}_R^c) = \mathcal{S}_R \cup \mathcal{V}_{R+1}$.

In case 2, we have $R = p = q$, which implies that $[\mathbf{Y}_1 | \, \mathbf{Y}_2]$ is a matrix of order $p \times 2p$. Obviously, this matrix always has rank less than or equal to p. Hence, $\mathcal{W}_R = \mathbb{R}^{p \times q \times 2}$ in case 2. This proves (iii). ∎

Next, we consider the boundary points of $\mathcal{S}_R$. The complement of $\mathcal{S}_R$ is equal to

$$\mathcal{S}_R^c = \mathcal{W}_R^c \cup \mathcal{V}_{R+1} \qquad \text{with} \qquad \mathcal{W}_R^c \cap \mathcal{V}_{R+1} = \emptyset\,. \tag{2.6}$$

Hence, the boundary of $\mathcal{S}_R$ consists of the boundary between $\mathcal{S}_R$ and $\mathcal{V}_{R+1}$ and the boundary between $\mathcal{S}_R$ and $\mathcal{W}_R^c$. Note that these two boundaries may have a nonempty intersection. We denote the boundary of $\mathcal{S}_R$ as $\partial\mathcal{S}_R$ and partition it into the following two sets. Let

$$\mathcal{U}_R^{(1)} = \partial\mathcal{S}_R \cap \partial\mathcal{V}_{R+1} \qquad \text{and} \qquad \mathcal{U}_R^{(2)} = \partial\mathcal{S}_R \cap (\partial\mathcal{V}_{R+1})^c\,. \tag{2.7}$$

Hence, $\mathcal{U}_R^{(1)}$ consists of all points on the boundary between $\mathcal{S}_R$ and $\mathcal{V}_{R+1}$, i.e., all points which can be approximated arbitrarily well from both $\mathcal{S}_R$ and $\mathcal{V}_{R+1}$.

From Lemma 2.1 it follows that

$$\partial\mathcal{S}_R \subseteq \mathcal{W}_R = \mathcal{S}_R \cup \mathcal{V}_{R+1}\,. \tag{2.8}$$

The following lemma states that $\mathcal{U}_R^{(2)}$ is either the empty set or is a subset of $\mathcal{S}_R$.

LEMMA 2.2. *We have the following results.*

(i) *In case 2, there holds $\mathcal{U}_R^{(2)} = \emptyset$.*

(ii) *In cases* 3, 5, 7, 8, *and* 9, *there holds* $\mathcal{U}_R^{(2)} \subseteq \mathcal{S}_R$.

Proof. From (2.8) it follows that $\mathcal{U}_R^{(1)} \subseteq \mathcal{W}_R$ and $\mathcal{U}_R^{(2)} \subseteq \mathcal{W}_R$. In case 2, we have $\mathcal{W}_R = \mathbb{R}^{p\times q\times 2}$ (see Lemma 2.1) and, hence, $\mathcal{V}_{R+1} = \mathcal{S}_R^c$. This implies that $\mathcal{U}_R^{(1)}$ consists of all points which can be approximated arbitrarily well from $\mathcal{S}_R$ and $\mathcal{S}_R^c$. Since these are all boundary points of $\mathcal{S}_R$, it follows that $\mathcal{U}_R^{(2)} = \emptyset$. This proves (i).

Next, consider cases 3, 5, 7, 8, and 9. Here, $\mathcal{W}_R^c \neq \emptyset$. Suppose $\underline{\mathbf{Y}} \in \mathcal{V}_{R+1}$ and $\underline{\mathbf{Y}} \in \partial\mathcal{S}_R$. Since $\mathcal{S}_R \cap \mathcal{V}_{R+1} = \emptyset$, it follows that $\underline{\mathbf{Y}} \in \partial\mathcal{V}_{R+1}$ and, hence, $\underline{\mathbf{Y}} \in \mathcal{U}_R^{(1)}$. This implies $\mathcal{V}_{R+1} \cap \mathcal{U}_R^{(2)} = \emptyset$. Moreover, from $\mathcal{U}_R^{(2)} \subseteq \mathcal{W}_R = \mathcal{S}_R \cup \mathcal{V}_{R+1}$, we obtain $\mathcal{U}_R^{(2)} \subseteq \mathcal{S}_R$. This proves (ii). ∎

In the remaining part of this section, we consider the part $\mathcal{U}_R^{(1)}$ of the boundary of $\mathcal{S}_R$. For each of the cases 2, 3, 5, 7, 8 and 9 in Table 2.1, we argue that the nonexistence of a best rank-R approximation is due to the fact that $\mathcal{U}_R^{(1)} \not\subseteq \mathcal{S}_R$.

Case 2. We have $p = q = R$, $\mathcal{W}_R = \mathbb{R}^{p\times q\times 2} = \mathcal{S}_R \cup \mathcal{V}_{R+1}$, $\mathcal{V}_{R+1} = \mathcal{S}_R^c$, $\mathcal{U}_R^{(2)} = \emptyset$, and $\underline{\mathbf{X}} \in \mathcal{S}_R^c$. The typical rank of $p \times p \times 2$ arrays is equal to $\{p,\, p+1\}$, where the sets of both rank values have positive volume. This implies that the sets $\mathcal{S}_R$ and $\mathcal{V}_{R+1}$ have equal dimensionality $2p^2$. We partition $\partial\mathcal{S}_R = \mathcal{U}_R^{(1)}$ into the following three sets. Let

$$\mathcal{U}_R^{(11)} = \{\underline{\mathbf{Y}} \in \mathcal{U}_R^{(1)} \text{ with } \mathbf{Y}_1 \text{ nonsingular and } \mathbf{Y}_2\mathbf{Y}_1^{-1} \text{ diagonalizable}\}\,, \tag{2.9}$$

$$\mathcal{U}_R^{(12)} = \{\underline{\mathbf{Y}} \in \mathcal{U}_R^{(1)} \text{ with } \mathbf{Y}_1 \text{ nonsingular and } \mathbf{Y}_2\mathbf{Y}_1^{-1} \text{ not diagonalizable}\}\,, \tag{2.10}$$

$$\mathcal{U}_R^{(13)} = \{\underline{\mathbf{Y}} \in \mathcal{U}_R^{(1)} \text{ with } \mathbf{Y}_1 \text{ singular}\}\,. \tag{2.11}$$

In Stegeman [34], it is shown that $\underline{\mathbf{Y}} \in \mathcal{U}_R^{(11)} \cup \mathcal{U}_R^{(12)}$ if and only if $\mathbf{Y}_2\mathbf{Y}_1^{-1}$ has p real eigenvalues which are not all distinct. Although its proof is entirely different, this result is closely related to Propositions 1.2 and 1.3(i). From Proposition 1.2 it follows that $\mathcal{U}_R^{(11)} \subset \mathcal{S}_R$ and $\mathcal{U}_R^{(12)} \subset \mathcal{S}_R^c$. Stegeman [34] also shows that the dimensionality of $\mathcal{U}_R^{(11)}$ is lower that the dimensionality of $\mathcal{U}_R^{(12)}$.

Any array in $\mathcal{U}_R^{(13)}$ can be approximated arbitrarily well by arrays in $\mathcal{U}_R^{(11)} \cup \mathcal{U}_R^{(12)}$. The reverse, however, is not true. This implies that $\mathcal{U}_R^{(13)}$ has lower dimensionality than $\mathcal{U}_R^{(11)} \cup \mathcal{U}_R^{(12)}$. Combined with the reasoning above, this implies that the subset of the boundary of $\mathcal{S}_R$ with the highest dimensionality is $\mathcal{U}_R^{(12)}$. Since these boundary points have rank larger than R, we conjecture that for a generic $\underline{\mathbf{X}} \in \mathbb{R}^{p\times p\times 2}$ array an optimal solution $\underline{\widetilde{\mathbf{X}}}$ of problem (2.2) has rank larger than R almost everywhere. Hence, we conjecture that problem (2.1) does not have an optimal solution almost everywhere, and $\underline{\mathbf{X}}$ does not have a best rank-R approximation almost everywhere.

Case 7. We have $p > q$ and $\min(p, 2q) > R > q$. From the definition of $\mathcal{W}_R$ in (2.3) it follows that $\underline{\mathbf{Y}} \in \mathcal{W}_R$ if and only if there exists a nonsingular matrix $\mathbf{S}$ such that

$$\mathbf{S}\,\mathbf{Y}_1 = \begin{bmatrix} \mathbf{H}_1 \\ \mathbf{O} \end{bmatrix} \qquad \text{and} \qquad \mathbf{S}\,\mathbf{Y}_2 = \begin{bmatrix} \mathbf{H}_2 \\ \mathbf{O} \end{bmatrix}, \tag{2.12}$$

where $\mathbf{H}_1$ and $\mathbf{H}_2$ are $R \times q$ matrices and $\mathbf{O}$ is the $(p-R) \times q$ all-zero matrix. By $\underline{\mathbf{H}}$ we denote the $R \times q \times 2$ array with slices $\mathbf{H}_1$ and $\mathbf{H}_2$. The transformation $\mathbf{S}$ in (2.12)

is rank preserving, i.e., $\text{rank}_\circ(\underline{\mathbf{Y}}) = \text{rank}_\circ(\underline{\mathbf{H}})$. Hence, it follows from (2.4) and (2.5) that

$$\mathcal{S}_R = \{\underline{\mathbf{Y}} \in \mathcal{W}_R : \ \text{rank}_\circ(\underline{\mathbf{H}}) \leq R \ \text{ for } \underline{\mathbf{H}} \text{ in (2.12)}\} \tag{2.13}$$

and

$$\mathcal{V}_{R+1} = \{\underline{\mathbf{Y}} \in \mathcal{W}_R : \ \text{rank}_\circ(\underline{\mathbf{H}}) \geq R+1 \ \text{ for } \underline{\mathbf{H}} \text{ in (2.12)}\}\,. \tag{2.14}$$

It is important to note that the set of arrays $\underline{\mathbf{H}}$ which can be obtained in (2.12) has full dimensionality $2qR$. The typical rank of $R \times q \times 2$ arrays (with $2q > R > q$) equals R. When the maximal rank of $R \times q \times 2$ arrays equals their typical rank, we have $\mathcal{V}_{R+1} = \emptyset$, and $\mathcal{S}_R = \mathcal{W}_R$ is a closed set. This is the case when $R = 4$ and $q = 3$, e.g., see (1.11). Since $\mathcal{S}_R$ is closed, a best rank-R approximation to $\underline{\mathbf{X}}$ exists almost everywhere.

Next, suppose the maximal rank of $R \times q \times 2$ arrays is larger than their typical rank R, i.e., $\mathcal{V}_{R+1} \neq \emptyset$. This is the case when $R = 5$ and $q = 3$, e.g., see (1.11). For the arrays in $\mathcal{V}_{R+1}$, the array $\underline{\mathbf{H}}$ has a *nontypical* rank value, i.e., larger than or equal to $R+1$. This implies that $\mathcal{V}_{R+1}$ has lower dimensionality than the set $\mathcal{S}_R$. From (2.4) and (2.5) it then follows that any $\underline{\mathbf{Y}} \in \mathcal{V}_{R+1}$ can be approximated arbitrarily closely by arrays in $\mathcal{S}_R$ and it holds that $\mathcal{U}_R^{(1)} = \mathcal{V}_{R+1}$; see (2.7). Moreover, any array in $\mathcal{S}_R$ can be approximated arbitrarily well from $\mathcal{W}_R^{\text{c}}$ and, hence, $\mathcal{U}_R^{(2)} = \mathcal{S}_R$. This implies that

$$\partial\mathcal{S}_R = \mathcal{V}_{R+1} \cup \mathcal{S}_R = \mathcal{W}_R = \overline{\mathcal{S}}_R\,. \tag{2.15}$$

Since $\mathcal{V}_{R+1}$ has lower dimensionality than $\mathcal{S}_R$, we conjecture that an optimal solution $\widetilde{\underline{\mathbf{X}}}$ of problem (2.2) lies in $\mathcal{S}_R$ almost everywhere. Hence, we conjecture that $\underline{\mathbf{X}}$ has a best rank-R approximation almost everywhere.

Case 8. We have $p > q$ and $R = q$. As in case 7, there holds $\underline{\mathbf{Y}} \in \mathcal{W}_R$ if and only if a nonsingular $\mathbf{S}$ exists such that (2.12) holds. The sets $\mathcal{S}_R$ and $\mathcal{V}_{R+1}$ are defined by (2.13) and (2.14), respectively. The array $\underline{\mathbf{H}}$ in (2.12) has order $R \times R \times 2$ and the typical rank of $R \times R \times 2$ arrays is equal to $\{R,\, R+1\}$, where the sets of both rank values have positive volume. As in case 2, this implies that the sets $\mathcal{S}_R$ and $\mathcal{V}_{R+1}$ have equal dimensionality.

Let $\underline{\mathbf{X}}^*$ be an optimal solution of the following problem:

$$\begin{aligned} &\text{Minimize} \|\underline{\mathbf{X}} - \underline{\mathbf{Y}}\| \\ &\text{subject to } \underline{\mathbf{Y}} \in \mathcal{W}_R\,. \end{aligned} \tag{2.16}$$

Based on Lemma 2.1, we conjecture that, for generic $\underline{\mathbf{X}}$, the set where $\underline{\mathbf{X}}^* \in \mathcal{S}_R$ and the set where $\underline{\mathbf{X}}^* \in \mathcal{V}_{R+1}$ both have positive volume. If $\underline{\mathbf{X}}^* \in \mathcal{S}_R$, then $\underline{\mathbf{X}}^*$ is an optimal solution of the problem (2.1) and, hence, $\underline{\mathbf{X}}$ has a best rank-R approximation. If all optimal solutions of problem (2.16) lie in $\mathcal{V}_{R+1}$, then $\underline{\mathbf{X}}$ may not have a best rank-R approximation. This will be explained below.

The boundary of $\mathcal{S}_R$ is partitioned into $\mathcal{U}_R^{(1)}$ and $\mathcal{U}_R^{(2)}$, where $\mathcal{U}_R^{(2)} \subseteq \mathcal{S}_R$; see (2.7) and Lemma 2.2. Analogous to case 2, we partition $\mathcal{U}_R^{(1)}$ into the following sets:

$$\mathcal{U}_R^{(11)} = \{\underline{\mathbf{Y}} \in \mathcal{U}_R^{(1)} \text{ with } \mathbf{H}_1 \text{ in (2.12) nonsingular and } \mathbf{H}_2\mathbf{H}_1^{-1} \text{ diagonalizable}\}\,, \tag{2.17}$$

$$\mathcal{U}_R^{(12)} = \{\underline{\mathbf{Y}} \in \mathcal{U}_R^{(1)} \text{ with } \mathbf{H}_1 \text{ in (2.12) nonsingular and } \mathbf{H}_2\mathbf{H}_1^{-1} \text{ not diagonalizable}\}, \tag{2.18}$$

$$\mathcal{U}_R^{(13)} = \{\underline{\mathbf{Y}} \in \mathcal{U}_R^{(1)} \text{ with } \mathbf{H}_1 \text{ in (2.12) singular}\}. \tag{2.19}$$

Note that since $\operatorname{rank}(\mathbf{H}_1) = \operatorname{rank}(\mathbf{S}\,\mathbf{Y}_1) = \operatorname{rank}(\mathbf{Y}_1)$ and $\operatorname{rank}_\circ(\underline{\mathbf{Y}}) = \operatorname{rank}_\circ(\mathbf{H})$, combined with Proposition 1.2, it follows that the sets in (**??**)–(2.19) do not depend on the choice of $\mathbf{S}$ in (2.12). Analogous to case 2, there holds $\underline{\mathbf{Y}} \in \mathcal{U}_R^{(11)} \cup \mathcal{U}_R^{(12)}$ if and only if $\mathbf{H}_2\mathbf{H}_1^{-1}$ has R real eigenvalues which are not all distinct. Also, we have $\mathcal{U}_R^{(11)} \subset \mathcal{S}_R$ and $\mathcal{U}_R^{(12)} \subset \mathcal{S}_R^c$. Moreover, the sets $\mathcal{U}_R^{(11)}$ and $\mathcal{U}_R^{(13)}$ have lower dimensionality than $\mathcal{U}_R^{(12)}$. Hence, if all optimal solutions of problem (2.2) lie in $\mathcal{U}_R^{(1)}$, then they have rank larger than R almost everywhere on $\mathcal{U}_R^{(1)}$, and $\underline{\mathbf{X}}$ does not have a best rank-R approximation.

Above, we conjectured that, for generic $\underline{\mathbf{X}}$, an optimal solution $\underline{\mathbf{X}}^*$ of problem (2.16) lies in $\mathcal{S}_R$ on a set of positive volume. Hence, we conjecture that $\underline{\mathbf{X}}$ has a best rank-R approximation on a set of positive volume. Next, we argue that the set on which $\underline{\mathbf{X}}$ has no best rank-R approximation also has positive volume. This can be seen as follows. Let $\mathbf{Y} \in \mathcal{V}_{R+1}$ be an interior point of $\mathcal{V}_{R+1}$ on $\mathcal{W}_R$, i.e., for a small $\epsilon > 0$ we have $\mathcal{B}_\epsilon(\underline{\mathbf{Y}}) = \{\underline{\mathbf{Z}} \in \mathcal{W}_R : \|\underline{\mathbf{Z}} - \underline{\mathbf{Y}}\| < \epsilon\} \subset \mathcal{V}_{R+1}$. This is the case if $\mathbf{H}_2(\mathbf{H}_1)^{-1}$ has R distinct eigenvalues which are not all real, where $\mathbf{H}_i$ are as in (2.12); see Stegeman [34]. For any interior point $\underline{\mathbf{Y}}$ of $\mathcal{V}_{R+1}$, we can find a set $\mathcal{D} \subset \mathcal{W}_R^c$ close to $\mathcal{B}_\epsilon(\underline{\mathbf{Y}})$ such that $\mathcal{D}$ has positive volume and for any $\underline{\mathbf{X}} \in \mathcal{D}$ problem (2.16) will have all optimal solutions in $\mathcal{B}_\epsilon(\underline{\mathbf{Y}})$. Moreover, for $\underline{\mathbf{Y}}$ close enough to some point on $\mathcal{U}_R^{(12)}$, i.e., the boundary between $\mathcal{S}_R$ and $\mathcal{V}_{R+1}$, we conjecture that all optimal solutions of problem (2.2) will lie on the boundary $\mathcal{U}_R^{(12)}$ and have rank larger than R. Hence, we conjecture that no $\underline{\mathbf{X}} \in \mathcal{D}$ has a best rank-R approximation, where $\mathcal{D}$ has positive volume. Therefore, we conjecture that the set on which $\underline{\mathbf{X}}$ has no best rank-R approximation has positive volume.

Cases 3, 5, and 9. We have $p \geq q$ and $R < q$. Instead of $\mathcal{W}_R$, we define

$$\widetilde{\mathcal{W}}_R = \left\{\underline{\mathbf{Y}} \in \mathbb{R}^{p\times q\times 2} : \operatorname{rank}[\mathbf{Y}_1|\,\mathbf{Y}_2] \leq R \text{ and } \operatorname{rank}\begin{bmatrix}\mathbf{Y}_1\\ \mathbf{Y}_2\end{bmatrix} \leq R\right\}$$

$$= \{\underline{\mathbf{Y}} \in \mathbb{R}^{p\times q\times 2} : \operatorname{rank}_1(\underline{\mathbf{Y}}) \leq R \text{ and } \operatorname{rank}_2(\underline{\mathbf{Y}}) \leq R\}. \tag{2.20}$$

Analogous to Lemma 2.1, the set $\widetilde{\mathcal{W}}_R$ is closed. It can be seen that $\underline{\mathbf{Y}} \in \widetilde{\mathcal{W}}_R$ if and only if there exist nonsingular $\mathbf{S}$ and $\mathbf{T}$ such that

$$\mathbf{S}\,\mathbf{Y}_1\,\mathbf{T} = \begin{bmatrix}\mathbf{G}_1 & \mathbf{O}\\ \mathbf{O} & \mathbf{O}\end{bmatrix} \quad \text{and} \quad \mathbf{S}\,\mathbf{Y}_2\,\mathbf{T} = \begin{bmatrix}\mathbf{G}_2 & \mathbf{O}\\ \mathbf{O} & \mathbf{O}\end{bmatrix}, \tag{2.21}$$

where $\mathbf{G}_1$ and $\mathbf{G}_2$ are $R \times R$ matrices. We denote the $R \times R \times 2$ array with slices $\mathbf{G}_1$ and $\mathbf{G}_2$ by $\underline{\mathbf{G}}$. Note that the set of arrays $\underline{\mathbf{G}}$ which can be obtained by (2.21) has full dimensionality $2R^2$. Since the transformations $\mathbf{S}$ and $\mathbf{T}$ are rank preserving, we have, analogous to (2.13), that

$$\mathcal{S}_R = \{\underline{\mathbf{Y}} \in \widetilde{\mathcal{W}}_R : \operatorname{rank}_\circ(\underline{\mathbf{G}}) \leq R \text{ for } \underline{\mathbf{G}} \text{ in (2.21)}\}. \tag{2.22}$$

We define

$$\widetilde{\mathcal{V}}_{R+1} = \{\underline{\mathbf{Y}} \in \widetilde{\mathcal{W}}_R : \ \text{rank}_\circ(\underline{\mathbf{G}}) \geq R+1 \ \text{ for } \underline{\mathbf{G}} \text{ in (2.21)}\}\,. \tag{2.23}$$

Analogous to Lemma 2.1, there holds

$$\widetilde{\mathcal{W}}_R = \mathcal{S}_R \cup \widetilde{\mathcal{V}}_{R+1} \qquad \text{and} \qquad \mathcal{S}_R \cap \widetilde{\mathcal{V}}_{R+1} = \emptyset\,. \tag{2.24}$$

The typical rank of $R \times R \times 2$ arrays is equal to $\{R,\, R+1\}$, where both sets of rank values have positive volume. As in case 2, this implies that the sets $\mathcal{S}_R$ and $\widetilde{\mathcal{V}}_{R+1}$ have equal dimensionality. We are in the same situation as in case 8, with $\widetilde{\mathcal{W}}_R$ playing the role of $\mathcal{W}_R$, $\widetilde{\mathcal{V}}_{R+1}$ playing the role of $\mathcal{V}_{R+1}$, and $\underline{\mathbf{G}}$ playing the role of $\underline{\mathbf{H}}$. The remaining part of the explanation for cases 3, 5, and 9 is completely analogous to case 8 and is therefore omitted.

3. Diverging CP components for $p \times q \times 2$ arrays. In the previous section, we showed that if $\underline{\mathbf{X}}$ does not have a best rank-R approximation, this is due to the fact that the optimal solutions of problem (2.2) do not lie in $\mathcal{S}_R$, i.e., they have rank of at least $R+1$. From now on we assume there is one optimal solution $\widetilde{\underline{\mathbf{X}}}$ of problem (2.2). The general case is completely analogous. As a regularity condition, we assume that $\widetilde{\underline{\mathbf{X}}} \in \partial\mathcal{S}_R \cap \mathcal{S}_R^c$ lies in a subset $\mathcal{Q}_{R+1} \subset \partial\mathcal{S}_R \cap \mathcal{S}_R^c$ such that the dimensionality of $(\partial\mathcal{S}_R \cap \mathcal{S}_R^c) \backslash \mathcal{Q}_{R+1}$ is lower than the dimensionality of $\mathcal{Q}_{R+1}$ itself. In each of cases 2, 3, 5, 8, and 9 of Table 2.1, the set $\mathcal{Q}_{R+1}$ will be specified, and we show that if a sequence of CP updates $\underline{\mathbf{Y}}^{(n)}$ converges to $\widetilde{\underline{\mathbf{X}}}$, then $\underline{\mathbf{Y}}^{(n)}$ will exhibit diverging CP components as defined by (1.9) and (1.10). This implies that in these cases of Table 2.1, we conjecture that diverging CP components occur almost everywhere (case 2) or on a set of positive volume (cases 3, 5, 8, and 9). In Table 3.1 these conjectures are stated explicitly.

TABLE 3.1
Conjectures on the occurrence of diverging CP components when calculating a best rank-R approximation to generic $p \times q \times 2$ arrays. Here, $p \geq q \geq 2$ and $R \geq 2$.

Case	$\underline{\mathbf{X}} \in \mathbb{R}^{p\times q\times 2}$	$\text{rank}_\circ(\underline{\mathbf{X}})$	R	Diverging CP components?
2	$p = q$	$p+1$	$R = p$	almost everywhere
3	$p = q$	$p+1$	$R < p$	positive volume
5	$p = q$	p	$R < p$	positive volume
7	$p > q$	$\min(p, 2q)$	$\min(p, 2q) > R > q$	zero volume
8	$p > q$	$\min(p, 2q)$	$R = q$	positive volume
9	$p > q$	$\min(p, 2q)$	$R < q$	positive volume

Case 2. We have $p = q = R$ and $\text{rank}_\circ(\underline{\mathbf{X}}) = p+1$. We assume that $\widetilde{\underline{\mathbf{X}}}$ lies in $\mathcal{U}_R^{(12)}$, which is the set $\mathcal{Q}_{R+1}$ in this case. The set $\mathcal{U}_R^{(12)}$ is defined by (2.10). This implies that $\widetilde{\mathbf{X}}_2\widetilde{\mathbf{X}}_1^{-1}$ has p real eigenvalues and is not diagonalizable; see Stegeman [34]. From Proposition 1.2 it follows that $\text{rank}_\circ(\widetilde{\underline{\mathbf{X}}}) = p+k$, where k is the number of eigenvalues of $\widetilde{\mathbf{X}}_2\widetilde{\mathbf{X}}_1^{-1}$ with algebraic multiplicity larger than the geometric multiplicity. Suppose the sequence of CP updates $\underline{\mathbf{Y}}^{(n)}$ converges to $\widetilde{\underline{\mathbf{X}}}$. Since $\underline{\mathbf{Y}}^{(n)} \in \mathcal{S}_R$ and a singular $\mathbf{Y}_1^{(n)}$ does not occur in practice, it follows from Proposition 1.2 that

$\mathbf{Y}_2^{(n)}(\mathbf{Y}_1^{(n)})^{-1}$ has p real eigenvalues and is diagonalizable. Let $\mathbf{Y}_2^{(n)}(\mathbf{Y}_1^{(n)})^{-1}$ have the eigendecomposition

$$\mathbf{Y}_2^{(n)}(\mathbf{Y}_1^{(n)})^{-1} = \mathbf{K}^{(n)}\mathbf{\Lambda}^{(n)}(\mathbf{K}^{(n)})^{-1}\,, \tag{3.1}$$

where $\mathbf{K}^{(n)}$ has columns of length 1. A rank-p decomposition (1.6) of $\underline{\mathbf{Y}}^{(n)}$ is given by

$$\mathbf{A}^{(n)} = \mathbf{K}^{(n)}\,, \qquad (\mathbf{B}^{(n)})^T = \mathbf{\Omega}_b^{(n)}\,(\mathbf{K}^{(n)})^{-1}\mathbf{Y}_1^{(n)}\,, \tag{3.2}$$

$$\mathbf{C}^{(n)} = \begin{bmatrix} 1 & \cdots & 1 \\ \lambda_1^{(n)} & \cdots & \lambda_p^{(n)} \end{bmatrix} \mathbf{\Omega}_c^{(n)}\,, \qquad \mathbf{\Omega}^{(n)} = (\mathbf{\Omega}_b^{(n)}\,\mathbf{\Omega}_c^{(n)})^{-1}\,, \tag{3.3}$$

where $\mathbf{\Omega}_b^{(n)}$ and $\mathbf{\Omega}_c^{(n)}$ are the $p \times p$ diagonal matrices such that the columns of $\mathbf{B}^{(n)}$ and $\mathbf{C}^{(n)}$, respectively, have length 1. Hence, $\mathbf{C}_1^{(n)} = \mathbf{\Omega}_c^{(n)}$ and $\mathbf{C}_2^{(n)} = \mathbf{\Lambda}^{(n)}\mathbf{\Omega}_c^{(n)}$ in (1.6). It is clear that $k_{\mathbf{A}^{(n)}} = p$, $k_{\mathbf{B}^{(n)}} = p$, and $k_{\mathbf{C}^{(n)}} = 2$ if the eigenvalues in $\mathbf{\Lambda}^{(n)}$ are distinct. In this case, Kruskal's condition (1.7) holds and the rank-p decomposition (3.2)–(3.3) of $\underline{\mathbf{Y}}^{(n)}$ is unique. Since identical eigenvalues in $\mathbf{\Lambda}^{(n)}$ do not occur in practice, we assume they are all distinct (see Stegeman [34] for identical eigenvalues).

By continuity, the matrix $\mathbf{Y}_2^{(n)}(\mathbf{Y}_1^{(n)})^{-1}$ will converge to $\widetilde{\mathbf{X}}_2\widetilde{\mathbf{X}}_1^{-1}$. Since the latter matrix does not have p linearly independent eigenvectors and the rank-p decomposition (3.2)–(3.3) is unique, it follows that $\mathbf{A}^{(n)}$ in (3.2) converges to the singular matrix of eigenvectors of $\widetilde{\mathbf{X}}_2\widetilde{\mathbf{X}}_1^{-1}$. Let $I_1, \ldots, I_m \subset \{1, \ldots, R\}$ be the disjoint index sets of linearly dependent columns of the latter matrix such that each I_j contains the linearly dependent eigenvectors associated with a different eigenvalue of $\widetilde{\mathbf{X}}_2\widetilde{\mathbf{X}}_1^{-1}$ which has algebraic multiplicity larger than the geometric multiplicity. Then the columns $I_1, \ldots, I_m$ of the matrix $(\mathbf{K}^{(n)})^{-1}$ will become arbitrarily large as $\underline{\mathbf{Y}}^{(n)} \to \widetilde{\underline{\mathbf{X}}}$. The columns I_j of $\mathbf{C}^{(n)}$ will become identical, since these correspond to identical eigenvalues of $\widetilde{\mathbf{X}}_2\widetilde{\mathbf{X}}_1^{-1}$, $j = 1, \ldots, m$. It follows that in (3.2)–(3.3), we have $|\omega_r^{(n)}| \to \infty$ for all $r \in I_j$, $j = 1, \ldots, m$. Hence, (1.9) holds.

Next, we show that (1.10) also holds. For $j \in \{1, \ldots, m\}$, we consider the contribution of components I_j to the rank-p decomposition (3.2)–(3.3) for slices $\mathbf{Y}_1^{(n)}$ and $\mathbf{Y}_2^{(n)}$ separately. For $\mathbf{Y}_1^{(n)}$, the contribution of I_j equals

$$\mathbf{P}_j^{(n)} = \mathbf{K}_j^{(n)}\,(\mathbf{K}^{(n)})_j^{-1}\mathbf{Y}_1^{(n)}\,, \tag{3.4}$$

where $\mathbf{K}_j^{(n)}$ denotes columns I_j of $\mathbf{K}^{(n)}$ and $(\mathbf{K}^{(n)})_j^{-1}$ denotes rows I_j of $(\mathbf{K}^{(n)})^{-1}$. The limit point of $\mathbf{K}^{(n)}$ has columns I_j linearly dependent, while they are linearly independent of all its other columns. Hence, for n large enough, $\mathbf{K}^{(n)}$ will have columns I_j close to linear dependence but linearly independent of all its other columns. This, together with $\|\mathbf{Y}_1^{(n)}\|$ being bounded, yields that $\|\mathbf{P}_j^{(n)}\|$ in (3.4) is bounded.

For $\mathbf{Y}_2^{(n)}$, the contribution of I_j equals

$$\mathbf{Q}_j^{(n)} = \mathbf{K}_j^{(n)}\,\mathbf{\Lambda}_j^{(n)}\,(\mathbf{K}^{(n)})_j^{-1}\mathbf{Y}_1^{(n)}\,, \tag{3.5}$$

where $\mathbf{\Lambda}_j^{(n)}$ denotes the submatrix of $\mathbf{\Lambda}^{(n)}$ containing rows I_j and columns I_j. The diagonal matrix $\mathbf{\Lambda}_j^{(n)}$ converges to $\lambda\,\mathbf{I}_z$, where λ is the eigenvalue of $\widetilde{\mathbf{X}}_2\widetilde{\mathbf{X}}_1^{-1}$ associated

with eigenvectors I_j and $z = \text{card}(I_j)$. The matrix $\mathbf{K}_j^{(n)}$ contains the z eigenvectors associated with the eigenvalues of $\mathbf{Y}_2^{(n)}(\mathbf{Y}_1^{(n)})^{-1}$ on the diagonal of $\mathbf{\Lambda}_j^{(n)}$. As $\underline{\mathbf{Y}}^{(n)} \to \widetilde{\underline{\mathbf{X}}}$, the eigenvectors $\mathbf{K}_j^{(n)}$ converge to linear dependence but they remain linearly independent of all other eigenvectors. This, together with $\|\mathbf{Y}_1^{(n)}\|$ being bounded, yields that $\|\mathbf{Q}_j^{(n)}\|$ in (3.5) is bounded. Since

$$\left\| \sum_{r \in I_j} \omega_r^{(n)} \left(\mathbf{a}_r^{(n)} \circ \mathbf{b}_r^{(n)} \circ \mathbf{c}_r^{(n)} \right) \right\| = \sqrt{\|\mathbf{P}_j^{(n)}\|^2 + \|\mathbf{Q}_j^{(n)}\|^2}\,, \tag{3.6}$$

it follows that the left-hand side of (3.6) is bounded. Hence, (1.10) holds and the sequence of rank-p decompositions of $\underline{\mathbf{Y}}^{(n)}$ will exhibit diverging CP components as $\underline{\mathbf{Y}}^{(n)} \to \widetilde{\underline{\mathbf{X}}}$. Moreover, the groups $I_1, \ldots, I_m$ of diverging CP components and the number of components in each group are related to the eigenvalues and eigenvectors of $\widetilde{\mathbf{X}}_2\widetilde{\mathbf{X}}_1^{-1}$ as we have seen above.

Case 8. We have $p > q$ and $R = q$. We assume that the optimal solution $\widetilde{\underline{\mathbf{X}}}$ of problem (2.2) lies in $\mathcal{U}_R^{(12)}$, which is the set $\mathcal{Q}_{R+1}$ in this case. The set $\mathcal{U}_R^{(12)}$ is defined by (2.18). This implies that for any nonsingular $\mathbf{S}$ such that

$$\mathbf{S}\,\widetilde{\mathbf{X}}_1 = \begin{bmatrix} \mathbf{H}_1 \\ \mathbf{O} \end{bmatrix} \qquad \text{and} \qquad \mathbf{S}\,\widetilde{\mathbf{X}}_2 = \begin{bmatrix} \mathbf{H}_2 \\ \mathbf{O} \end{bmatrix}, \tag{3.7}$$

the $R \times R$ matrix $\mathbf{H}_2\mathbf{H}_1^{-1}$ has R real eigenvalues (which are not all distinct) and is not diagonalizable. By Proposition 1.2, $\text{rank}_\circ(\widetilde{\underline{\mathbf{X}}}) = \text{rank}_\circ(\underline{\mathbf{H}}) \geq R + 1$. Let $\underline{\mathbf{Y}}^{(n)}$ be a sequence of CP updates converging to $\widetilde{\underline{\mathbf{X}}}$. For a fixed $\mathbf{S}$ in (3.7), let $\mathbf{S}^{(n)}$ be such that it is nonsingular for all n, $\mathbf{S}^{(n)} \to \mathbf{S}$ and

$$\mathbf{S}^{(n)}\,\mathbf{Y}_1^{(n)} = \begin{bmatrix} \mathbf{H}_1^{(n)} \\ \mathbf{O} \end{bmatrix} \qquad \text{and} \qquad \mathbf{S}^{(n)}\,\mathbf{Y}_2^{(n)} = \begin{bmatrix} \mathbf{H}_2^{(n)} \\ \mathbf{O} \end{bmatrix}. \tag{3.8}$$

Then $\text{rank}_\circ(\underline{\mathbf{H}}^{(n)}) \leq R$ and $\underline{\mathbf{H}}^{(n)} \to \underline{\mathbf{H}}$ as $\underline{\mathbf{Y}}^{(n)} \to \widetilde{\underline{\mathbf{X}}}$. Since $\underline{\mathbf{H}}^{(n)}$, $\underline{\mathbf{H}} \in \mathbb{R}^{R \times R \times 2}$, it follows from case 2 above that the sequence $\underline{\mathbf{H}}^{(n)}$ will exhibit diverging CP components as it converges to $\underline{\mathbf{H}}$. Denote the unique rank-R decomposition of $\underline{\mathbf{H}}^{(n)}$ by $(\mathbf{A}^{(n)}, \mathbf{B}^{(n)}, \mathbf{C}^{(n)}, \mathbf{\Omega}^{(n)})$. Then the rank-$R$ decomposition of $\underline{\mathbf{Y}}^{(n)}$ is

$$\left((\mathbf{S}^{(n)})^{-1} \begin{bmatrix} \mathbf{A}^{(n)} \\ \mathbf{O} \end{bmatrix}, \mathbf{B}^{(n)}, \mathbf{C}^{(n)}, \mathbf{\Omega}^{(n)} \right). \tag{3.9}$$

The k-rank of $\mathbf{A}^{(n)}$ equals the k-rank of the first component matrix in (3.9). Hence, by virtue of Kruskal's condition (1.7) also the rank-R decomposition (3.9) is unique. Moreover, the decomposition will exhibit the same pattern of diverging CP components as $(\mathbf{A}^{(n)}, \mathbf{B}^{(n)}, \mathbf{C}^{(n)}, \mathbf{\Omega}^{(n)})$ when $\underline{\mathbf{Y}}^{(n)} \to \widetilde{\underline{\mathbf{X}}}$. Note that $\text{rank}_\circ(\underline{\mathbf{H}}) = \text{rank}_\circ(\widetilde{\underline{\mathbf{X}}})$ and Proposition 1.2 imply that the number of groups of diverging CP components does not depend on $\mathbf{S}$.

Cases 3, 5, and 9. We have $p \geq q$ and $R < q$. We assume that the optimal solution $\widetilde{\underline{\mathbf{X}}}$ of problem (2.2) satisfies

$$\mathbf{S}\,\widetilde{\mathbf{X}}_1\,\mathbf{T} = \begin{bmatrix} \mathbf{G}_1 & \mathbf{O} \\ \mathbf{O} & \mathbf{O} \end{bmatrix} \qquad \text{and} \qquad \mathbf{S}\,\widetilde{\mathbf{X}}_2\,\mathbf{T} = \begin{bmatrix} \mathbf{G}_2 & \mathbf{O} \\ \mathbf{O} & \mathbf{O} \end{bmatrix}, \tag{3.10}$$

where $\mathbf{S}$ and $\mathbf{T}$ are nonsingular and the $R \times R$ matrix $\mathbf{G}_2\mathbf{G}_1^{-1}$ has R real eigenvalues (which are not all distinct) and is not diagonalizable. By Proposition 1.2, $\text{rank}_\circ(\underline{\widetilde{\mathbf{X}}}) = \text{rank}_\circ(\underline{\mathbf{G}}) \geq R+1$. Let $\underline{\mathbf{Y}}^{(n)}$ be a sequence of CP updates converging to $\underline{\widetilde{\mathbf{X}}}$. For fixed $\mathbf{S}$ and $\mathbf{T}$ in (3.10), let $\mathbf{S}^{(n)}$ and $\mathbf{T}^{(n)}$ be such that they are nonsingular for all n, $\mathbf{S}^{(n)} \to \mathbf{S}$, $\mathbf{T}^{(n)} \to \mathbf{T}$, and

$$\text{(3.11)} \quad \mathbf{S}^{(n)}\,\mathbf{Y}_1^{(n)}\,\mathbf{T}^{(n)} = \begin{bmatrix} \mathbf{G}_1^{(n)} & \mathbf{O} \\ \mathbf{O} & \mathbf{O} \end{bmatrix} \qquad \text{and} \qquad \mathbf{S}^{(n)}\,\mathbf{Y}_2^{(n)}\,\mathbf{T}^{(n)} = \begin{bmatrix} \mathbf{G}_2^{(n)} & \mathbf{O} \\ \mathbf{O} & \mathbf{O} \end{bmatrix}.$$

Then $\text{rank}_\circ(\underline{\mathbf{G}}^{(n)}) \leq R$ and $\underline{\mathbf{G}}^{(n)} \to \underline{\mathbf{G}}$ as $\underline{\mathbf{Y}}^{(n)} \to \underline{\widetilde{\mathbf{X}}}$. Since $\underline{\mathbf{G}}^{(n)}$, $\underline{\mathbf{G}} \in \mathbb{R}^{R\times R\times 2}$, it follows from case 2 that the sequence $\underline{\mathbf{G}}^{(n)}$ will exhibit diverging CP components as it converges to $\underline{\mathbf{G}}$. Denote the unique rank-R decomposition of $\underline{\mathbf{G}}^{(n)}$ by $(\mathbf{A}^{(n)}, \mathbf{B}^{(n)}, \mathbf{C}^{(n)}, \mathbf{\Omega}^{(n)})$. Then the rank-$R$ decomposition of $\underline{\mathbf{Y}}^{(n)}$ is

$$\text{(3.12)} \qquad \left((\mathbf{S}^{(n)})^{-1} \begin{bmatrix} \mathbf{A}^{(n)} \\ \mathbf{O} \end{bmatrix}, (\mathbf{T}^{(n)})^{-T} \begin{bmatrix} \mathbf{B}^{(n)} \\ \mathbf{O} \end{bmatrix}, \mathbf{C}^{(n)}, \mathbf{\Omega}^{(n)} \right).$$

The k-ranks of $\mathbf{A}^{(n)}$ and $\mathbf{B}^{(n)}$ equal the k-ranks of the first two component matrices in (3.12). Hence, by virtue of Kruskal's condition (1.7) the rank-R decomposition (3.12) is also unique. Moreover, the decomposition will exhibit the same pattern of diverging CP components as $(\mathbf{A}^{(n)}, \mathbf{B}^{(n)}, \mathbf{C}^{(n)}, \mathbf{\Omega}^{(n)})$ when $\underline{\mathbf{Y}}^{(n)} \to \underline{\widetilde{\mathbf{X}}}$. Note that $\text{rank}_\circ(\underline{\mathbf{G}}) = \text{rank}_\circ(\underline{\widetilde{\mathbf{X}}})$ and Proposition 1.2 imply that the number of groups of diverging CP components does not depend on $\mathbf{S}$ and $\mathbf{T}$.

4. Simulation results. Here, we illustrate the cases in Table 3.1 by trying to calculate (using a CP algorithm) a best rank-R approximation of random $p \times q \times 2$ arrays, the elements of which are sampled independently from the uniform distribution on $[-1, 1]$. We consider cases 3, 5, 8, and 9, in which we conjecture diverging CP components to occur on a set of positive volume, and case 7, in which we conjecture diverging CP components to occur on a set of zero volume. Simulation results in Stegeman [34] show that for case 2 diverging CP components always occur, which is in agreement with our conjecture in this case. Although different sampling distributions will give different results on the percentages of cases of diverging CP components, we feel that the outcomes presented below are useful to show that diverging CP components are a serious problem indeed. As a CP algorithm, we use the multilinear engine by Paatero [29].

The simulation results in Stegeman [34] have indicated that, for random $p \times p \times 2$ arrays $\underline{\mathbf{X}}$, problem (2.2) has a unique optimal solution $\underline{\widetilde{\mathbf{X}}}$. If $\underline{\widetilde{\mathbf{X}}} \in \mathcal{S}_R$, then problem (2.1) has a unique optimal solution and diverging CP components do not occur. If $\underline{\widetilde{\mathbf{X}}} \notin \mathcal{S}_R$, then it is approximated arbitrarily close by arrays in $\mathcal{S}_R$. Notice that if the component matrices $\mathbf{A}$, $\mathbf{B}$, and $\mathbf{C}$ have full k-rank (which they usually have), then Kruskal's condition (1.7) holds in cases 3, 5, 7, 8, and 9. Hence, if $\underline{\widetilde{\mathbf{X}}} \notin \mathcal{S}_R$, then the arrays in $\mathcal{S}_R$ close to $\underline{\widetilde{\mathbf{X}}}$ have a unique CP decomposition exhibiting diverging CP components.

The reasoning above implies that it suffices to use only one run of the CP algorithm for each array $\underline{\mathbf{X}}$ (with random starting values for the component matrices). For cases 3 and 5, we consider 100 random $4 \times 4 \times 2$ arrays $\underline{\mathbf{X}}$ and $R = 3$. The rank of $\underline{\mathbf{X}}$ depends on whether $\mathbf{X}_2\mathbf{X}_1^{-1}$ has 4 real eigenvalues (rank 4) or some complex eigenvalues (rank 5). In cases 8 and 9, we consider 100 random $5 \times 3 \times 2$ arrays and 50 random $5 \times 4 \times 2$ arrays, respectively, both with $R = 3$. For case 7, we consider

100 random $6 \times 3 \times 2$ arrays and $R = 5$. Table 4.1 gives the relative frequency of the occurrence of diverging CP components we encountered in these cases. As can be seen, diverging CP components occur quite often in cases 3, 5, 8, and 9, and they do not occur at all in case 7. Hence, the results in Table 4.1 are in agreement with our conjectures in Tabel 3.1 regarding the occurrence of diverging CP components.

TABLE 4.1
Results of calculating rank-R approximations to random $p \times q \times 2$ arrays in cases 3, 5, 7, 8, *and* 9 *of Table* 3.1.

Case	$\underline{\mathbf{X}}$: $p \times q \times 2$	rank($\underline{\mathbf{X}}$)	R	Diverging CP components
3	$4 \times 4 \times 2$	5	3	44 out of 70 (63%)
5	$4 \times 4 \times 2$	4	3	6 out of 30 (20%)
7	$6 \times 3 \times 2$	6	5	0 out of 100
8	$5 \times 3 \times 2$	5	3	51 out of 100 (51%)
9	$5 \times 4 \times 2$	5	3	24 out of 50 (48%)

5. Discussion. We have considered low-rank approximations to generic $p \times q \times 2$ arrays. For all combinations of p, q, and R, we presented conjectures on whether a best rank-R approximation exists almost everywhere, on a set of positive volume or on a set of zero volume. In the cases where no best rank-R approximation exists, this is due to the fact that the optimal boundary points of $\mathcal{S}_R$ (i.e., the optimal solutions of problem (2.2)) do not lie in $\mathcal{S}_R$ itself. We showed (under some regularity condition) that if a sequence of CP updates converges to such an optimal boundary point, it necessarily exhibits diverging CP components.

This explanation of diverging CP components confirms the statement of Kruskal, Harshman, and Lundy [24] that these occur due to the fact that the CP objective function does not attain its infimum, and that any sequence of CP updates of which the objective value is approaching the infimum must fail to converge and exhibits diverging CP components. Also, the concept of a sequence of CP updates converging to a boundary point $\widetilde{\underline{\mathbf{X}}} \notin \mathcal{S}_R$ can be found in Kruskal, Harshman, and Lundy [24] for the case $p = q = R = 2$. Whether diverging CP components always occur if there is no best rank-R approximation is still an open problem.

As in Stegeman [34], the occurrence of diverging CP components in the cases in Table 3.1 and their explanations are still valid when the Frobenius norm in the CP objective function is replaced by any other norm (e.g., weighted least squares or Gaussian maximum likelihood). This is because all norms on the finite-dimensional vector space are equivalent and induce the same (i.e., the Euclidian) topology.

Note that, as in Stegeman [34], the occurrence of diverging CP components in Table 3.1 does not depend on the algorithm used to minimize the CP objective function. Hence, modified CP algorithms designed to avoid diverging CP components are of no use here.

The diverging CP components in case 2 of Table 3.1 occur due to the two-valued typical rank of real-valued $p \times p \times 2$ arrays and the uniqueness of their rank-p decomposition; see the discussion in Stegeman [34]. Our results on diverging CP components for $p \times q \times 2$ arrays are based upon this. The typical rank of $p \times p \times 2$ arrays over the complex field is p. Therefore, the cases of diverging CP components described in this paper do not occur in the complex-valued CP model. However, also for the complex

field, a best low-rank approximation does not always exist. See the example in De Silva and Lim [10, Proposition 4.6], which carries over to the complex field.

In cases 3, 5, 8, and 9 of Table 3.1, diverging CP components occur due to the fact that we may transform the CP problem for $p \times q \times 2$ arrays to the lower-dimensional CP problem for $R \times R \times 2$ arrays, for which case 2 applies. This shows that a two-valued typical rank of the target array $\underline{\mathbf{X}}$ is not necessary for diverging CP components to occur. However, the two-valued typical rank for $R \times R \times 2$ arrays is still necessary for diverging CP components to occur.

Zijlstra and Kiers [43] observed that cases of two diverging CP components occur not only in CP but also in other variants of factor analysis. They show that two-way and three-way factor analysis models which yield diverging components necessarily have rotationally unique components. For the cases we have examined, diverging CP components always occur together with uniqueness of the CP solution. This raises the question whether (partial) uniqueness of the CP solution is necessary for diverging components to occur. Stegeman [35] has shown that this is not the case. Indeed, in the cases of $3 \times 3 \times 5$ arrays with symmetric slices and $8 \times 4 \times 3$ arrays, diverging CP components occur on a set of positive volume while the CP decompositions of the CP updates are not unique.

Acknowledgments. The author would like to thank the anonymous reviewers for valuable suggestions to improve the paper and for bringing to the author's attention the algebraic complexity literature dealing with array rank and border rank.

FAST MULTILINEAR SINGULAR VALUE DECOMPOSITION FOR STRUCTURED TENSORS*

ROLAND BADEAU† AND RÉMY BOYER‡

Abstract. The higher-order singular value decomposition (HOSVD) is a generalization of the singular value decomposition (SVD) to higher-order tensors (i.e., arrays with more than two indices) and plays an important role in various domains. Unfortunately, this decomposition is computationally demanding. Indeed, the HOSVD of a third-order tensor involves the computation of the SVD of three matrices, which are referred to as "modes" or "matrix unfoldings." In this paper, we present fast algorithms for computing the full and the rank-truncated HOSVD of third-order structured (symmetric, Toeplitz, and Hankel) tensors. These algorithms are derived by considering two specific ways to unfold a structured tensor, leading to structured matrix unfoldings whose SVD can be efficiently computed.

Key words. multilinear SVD, fast algorithms, structured and unstructured tensors

1. Introduction.

The subject of multilinear decomposition is now mature [5, 19]. There are essentially two families. The first one is known under the name of CANDECOMP/PARAFAC (CANonical DECOMPosition or PARAllel FACtors model) and was independently proposed in [4, 8]. This decomposition is very useful in several applications and is linked to the tensor rank [9]. The second one is related to the multidimensional rank [6] and is known under the name of Tucker decomposition [21]. This decomposition is a more general form which is often used. Orthogonality constraints are not required in the general Tucker decomposition but if needed, one can refer to the higher-order singular value decomposition (HOSVD) [6] or multilinear SVD.

The HOSVD is a generalization of the SVD to higher-order tensors (i.e., arrays with more than two indices). This decomposition plays an important role in various domains, such as harmonic retrieval [17], image processing [10], telecommunications, biomedical applications (magnetic resonance imaging and electrocardiography), web search [20], computer facial recognition [23], handwriting analysis [18], and statistical methods involving independent component analysis (ICA) [6].

In [14], it was shown that the HOSVD of a third-order tensor involves the computation of the SVD of three matrices called modes, leading to a high computational cost. A first approach for reducing the complexity of tensor-based methods consists of a dimensionality reduction: only the principal components of the HOSVD are calculated, leading to the *rank-truncated* HOSVD. In this paper, we present a standard and fast algorithm for calculating the full and rank-truncated HOSVD, which computes only the left factors of the three SVD's. Next, we focus on structured tensors, such as

symmetric and Toeplitz tensors, which naturally arise in signal processing methods involving higher-order statistics [11, Chapter 9], and Hankel tensors [17], introduced in the context of the harmonic retrieval problem [15], which is at the heart of many signal processing applications. To the best of our knowledge, there are no specific HOSVD algorithms proposed in the literature for exploiting tensors structures. In this paper, however, we show that such tensors can be efficiently decomposed. We first observe that standard unfoldings [14, 12] do not present a particularly noticeable structure even in the case of structured tensors. Consequently, we introduce two different ways to unfold a structured tensor which clarify the link between structured modes and structured tensors. By doing this, we can exploit fast product techniques [7]. A second point of this work concerns Hankel and symmetric tensors. The modes of these structured tensors are column-redundant so it is possible to reduce the computational cost of the HOSVD algorithm by taking the redundant structure of each mode into account. Finally, our fastest implementation of the rank-truncated HOSVD (dedicated to Hankel tensors) has a quasilinear complexity with respect to the tensor dimension.

Note that, for applications involving very large tensor dimensions, an even lower complexity may be required. In this case, one may be interested in rank-revealing tensor decompositions which can be computed faster than the rank-truncated HOSVD. Such an approach is developed in [16], based on cross approximation techniques which are derived from LU factorizations [22, 2]. An algorithm is proposed which provides a Tucker-like low rank approximation of unstructured cube tensors, the complexity of which is linear with respect to the tensor dimension in many cases [16]. This linear complexity is nevertheless obtained via an approximated rank reduction, in comparison with an exact Tucker decomposition such as the HOSVD.

2. Preliminaries in multilinear algebra. We present some basic definitions in the context of third-order tensor algebra. These definitions can be extended to order greater than three, and we refer the interested reader to [5, 6] for instance.

Tucker's product. The Tucker's product, also called the s-mode product, of a third-order complex-valued tensor $\mathcal{A} \in \mathbb{C}^{I_1 \times I_2 \times I_3}$ by a matrix $B \in \mathbb{C}^{J_s \times I_s}$ for $s \in [1:3]$ is defined according to the following:

$$[\mathcal{A} \times_1 B]_{j_1 i_2 i_3} = \sum_{i_1=0}^{I_1-1} [\mathcal{A}]_{i_1 i_2 i_3} [B]_{j_1 i_1}, \tag{2.1}$$

$$[\mathcal{A} \times_2 B]_{i_1 j_2 i_3} = \sum_{i_2=0}^{I_2-1} [\mathcal{A}]_{i_1 i_2 i_3} [B]_{j_2 i_2}, \tag{2.2}$$

$$[\mathcal{A} \times_3 B]_{i_1 i_2 j_3} = \sum_{i_3=0}^{I_3-1} [\mathcal{A}]_{i_1 i_2 i_3} [B]_{j_3 i_3}, \tag{2.3}$$

where we denoted the entries of $\mathcal{A}$ by $[\mathcal{A}]_{i_1 i_2 i_3}$ with $i_s \in \{0 \dots I_s - 1\}$. We have the following properties:

$$\mathcal{A} \times_s B \times_{s'} C = (\mathcal{A} \times_s B) \times_{s'} C = (\mathcal{A} \times_{s'} C) \times_s B, \tag{2.4}$$

$$(\mathcal{A} \times_s B) \times_s C = \mathcal{A} \times_s (BC). \tag{2.5}$$

Mode of a tensor. There are several ways to represent an $I_1 \times I_2 \times I_3$ third-order complex-valued tensor $\mathcal{A}$ as a collection of matrices.

DEFINITION 2.1. *The modes (also called "matrix unfoldings") A_1, A_2, A_3 are usually defined as follows:*

$$[A_1]_{i_1, i_2 I_3 + i_3} = [\mathcal{A}]_{i_1 i_2 i_3}, \tag{2.6}$$

$$[A_2]_{i_2, i_3 I_1 + i_1} = [\mathcal{A}]_{i_1 i_2 i_3}, \tag{2.7}$$

$$[A_3]_{i_3, i_1 I_2 + i_2} = [\mathcal{A}]_{i_1 i_2 i_3}. \tag{2.8}$$

These matrices are of dimension $(I_1 \times I_2 I_3)$, $(I_2 \times I_3 I_1)$, $(I_3 \times I_1 I_2)$, respectively.

The dimensions of the vector spaces generated by the columns of the modes of $\mathcal{A}$ are called column rank (or 1-mode rank) R_1, row rank (or 2-mode rank) R_2, and 3-mode rank R_3, respectively.

2.1. Multilinear SVD (HOSVD).

THEOREM 2.2 (third-order SVD [6, 21]). *Every $I_1 \times I_2 \times I_3$ tensor $\mathcal{A}$ can be written as the product*

$$\mathcal{A} = \mathcal{S} \times_1 U^{(1)} \times_2 U^{(2)} \times_3 U^{(3)}, \tag{2.9}$$

where $\times_s$ represents the Tucker s-mode product [6]*, $U^{(s)}$ is a unitary $I_s \times I_s$ matrix, and $\mathcal{S}$ is an all-orthogonal and ordered $I_1 \times I_2 \times I_3$ tensor. All-orthogonality means that the matrices $S_{i_s=\alpha}$, obtained by fixing the sth index to α, are mutually orthogonal with respect to (w.r.t.) the standard inner product. Ordering means that $\|S_{i_s=0}\| \geqslant \|S_{i_s=1}\| \geqslant \cdots \geqslant \|S_{i_s=I_s-1}\|$ for all possible values of s. The Frobenius-norms $\|S_{i_s=i}\|$, symbolized by $\sigma_i^{(s)}$, are the s-mode singular values of $\mathcal{A}$ and the columns of $U^{(s)}$ are the s-mode singular factors.*

This decomposition is a generalization of the SVD because the diagonality of the matrix containing the singular values (in the matrix case) is a special case of all-orthogonality. Also, the HOSVD of a second-order tensor (matrix) yields the matrix SVD, up to trivial indeterminacies. The matrix of s-mode singular factors, $U^{(s)}$, can be found as the matrix of left singular vectors of the mode A_s, defined in (2.6)–(2.8). The s-mode singular values correspond to the singular values of this matrix unfolding. Note that the s-mode singular factors of a tensor, corresponding to the nonzero s-mode singular values, form an orthonormal basis for its s-mode vector subspace, as in the matrix case.

The core tensor $\mathcal{S}$ can then be computed (if needed) by bringing the matrices of s-mode singular factors to the left side of (2.9):

$$\mathcal{S} = \mathcal{A} \times_1 {U^{(1)}}^H \times_2 {U^{(2)}}^H \times_3 {U^{(3)}}^H, \tag{2.10}$$

where $(.)^H$ denotes the conjugate transpose.

Mode decompositions. Expression (2.9) can be written in terms of modes as follows:

$$A_1 = U^{(1)} S_1 \left(U^{(3)} \otimes U^{(2)}\right)^H,$$

$$A_2 = U^{(2)} S_2 \left(U^{(3)} \otimes U^{(1)}\right)^H,$$

$$A_3 = U^{(3)} S_3 \left(U^{(1)} \otimes U^{(2)}\right)^H,$$

where $\otimes$ denotes the Kronecker product, and S_1, S_2, and S_3 denote, respectively, the first, second, and third modes of the core tensor $\mathcal{S}$.

2.2. HOSVD algorithm for unstructured tensors. In this section we present an efficient implementation of the HOSVD in the general framework of unstructured tensors, from which our fast algorithms for structured tensors will be derived in section 4. Let $I = \frac{1}{3}(I_1 + I_2 + I_3)$. The computational costs of the various algorithms presented below are related to the flop (*floating point operation*) count. For example, a dot product of I-dimensional vectors involves $2I$ flops (I multiplications plus I additions).

The calculation of the HOSVD of tensor $\mathcal{A}$ requires the computation, for all $s \in [1:3]$, of the left factor $U^{(s)}$ in the full SVD of matrix A_s, as defined previously. Note that, in many applications we are interested in computing the HOSVD truncated at ranks (M_1, M_2, M_3), which means that we compute only the M_s first columns of the matrix $U^{(s)}$ (M_s is often supposed to be much lower than I_s). We will suppose throughout this paper that this possibly truncated SVD is computed by means of the orthogonal iteration method, although other algorithms such as the Golub–Reinsch SVD and R-SVD [7, pp. 253–254] could also be applied. When computing only the $n \times r$ left factor U in the rank r-truncated SVD of an $n \times m$ matrix A with $n < m$, the orthogonal iteration method consists of recursively computing the $n \times r$ matrix $B_i = A(A^H U_{i-1})$, involving $2r$ matrix/vector products, and the QR factorization $B_i = U_i R_i$ of this $n \times r$ matrix [7, pp. 410–411]. Thus the computational cost of one iteration is $2r\, c(n,m) + 2r^2 n$ flops, where $c(n,m) = 2nm$ is the cost of 1 matrix/vector product, and $2r^2 n$ is the cost of 1 QR factorization [7, pp. 231–232]. Besides, the s-mode A_s has $n = I_s$ rows and $m = \prod_{s' \neq s} I_{s'}$ columns. Assuming that $\prod_{s' \neq s} I_{s'}$ is much greater than I_s, the dominant cost of one iteration for computing $U^{(s)}$ is $4M_s I_1 I_2 I_3$ flops. Finally, the Tucker product (2.10) can be computed by folding, for instance, its first mode given by

$$S_1 = {U^{(1)}}^H A_1 \left(U^{(3)} \otimes U^{(2)} \right). \tag{2.11}$$

A fast implementation of (2.11) was proposed in [1], whose complexity is $6M_s I_1 I_2 I_3$ flops, where $M = \frac{1}{3}(M_1 + M_2 + M_3)$. Note that the computation of the Tucker product is generally not needed in applications, which is why it will be omitted in the following developments.

The computational cost of the full and rank-truncated HOSVD is summarized in Table 2.1 (the full HOSVD is the same as the rank-truncated HOSVD with $M_s = I_s$ for all $s = 1, 2, 3$). In this table and afterward, the global cost is provided as a maximum w.r.t. I_1, I_2, I_3, under the constraint $I_1 + I_2 + I_3 = 3I$. In particular, the maximal complexity per iteration is obtained for cube tensors ($I_1 = I_2 = I_3 = I$) and equals $12MI^3$.

TABLE 2.1
HOSVD Algorithm for unstructured tensors.

(the cost corresponds to a single iteration of the orthogonal iteration method)

Operation	Cost per iteration
SVD of A_1	$4M_1 I_1 I_2 I_3$
SVD of A_2	$4M_2 I_1 I_2 I_3$
SVD of A_3	$4M_3 I_1 I_2 I_3$
Global cost	$12MI^3$

3. Structured tensors and reordered tensor modes. In this section, we present three tensor structures which are usual in many applications. Next, we intro-

duce new reordered tensor modes which clarify the link between structured tensors and structured modes.

3.1. Structured tensors.

DEFINITION 3.1 (Toeplitz tensors). *A* Toeplitz *tensor is a structured tensor which satisfies the following property: for all* $i_1 \in \{0 \dots I_1 - 1\}$, $i_2 \in \{0 \dots I_2 - 1\}$, $i_3 \in \{0 \dots I_3 - 1\}$ *for all* $k \in \{0 \dots \min(I_1 - i_1, I_2 - i_2, I_3 - i_3) - 1\}$,

$$[\mathcal{A}]_{i_1+k,i_2+k,i_3+k} = [\mathcal{A}]_{i_1 i_2 i_3}.$$

Below, any permutation of 3 elements will be denoted $\pi = (\pi_1, \pi_2, \pi_3)$, where $\pi_1, \pi_2, \pi_3 \in \{1, 2, 3\}$, according to the following definition:

$$\pi : \quad (i_1, i_2, i_3) \quad \mapsto \quad (i_{\pi_1}, i_{\pi_2}, i_{\pi_3}).$$

DEFINITION 3.2 (symmetric tensors). *A cube* $(I \times I \times I)$ *tensor* $\mathcal{A}$*, which is unchanged by any permutation* π*, is called a* symmetric *tensor:*

$$\forall i_1, i_2, i_3 \in \{0, \dots, I-1\}, \ [\mathcal{A}]_{\pi(i_1,i_2,i_3)} = [\mathcal{A}]_{i_1 i_2 i_3}.$$

Example 1 (fast higher-order PCA for real moment and cumulant). The HOSVD can be viewed (cf. [13]) as a higher-order principal component analysis (PCA). This technique is often used as a data dimensional reduction for moment and cumulant tensors [6]. Third-order moment and cumulant tensors are defined according to

$$[\mathcal{M}]_{t_1 t_2 t_3} = E\{x(t_1)x(t_2)x(t_3)\}, \tag{3.1}$$

$$\begin{aligned} [\mathcal{C}]_{t_1 t_2 t_3} = \ & E\{x(t_1)x(t_2)x(t_3)\} + 2E\{x(t_1)\}E\{x(t_2)\}E\{x(t_3)\} \\ - \ & E\{x(t_1)\}E\{x(t_2)x(t_3)\} - E\{x(t_2)\}E\{x(t_1)x(t_3)\} \\ - \ & E\{x(t_3)\}E\{x(t_1)x(t_2)\}, \end{aligned} \tag{3.2}$$

where $t_1, t_2, t_3 \in \{0, \dots, I-1\}$, and $x(t)$ is a real random process.

Moment and cumulant tensors, defined in (3.1) and (3.2), are symmetric tensors according to Definition 3.2. The proof is straightforward and can be generalized to larger orders [5]. Moreover, if $x(t)$ is a third-order stationary process, the moment and cumulant tensors defined in (3.1) and (3.2) are third-order Toeplitz tensors according to Definition 3.2. Indeed, if $x(t)$ is a stationary process, its probability distribution is invariant to temporal translations. This property implies $[\mathcal{C}]_{t+i_1,t+i_2,t+i_3} = [\mathcal{C}]_{i_1 i_2 i_3}$.

DEFINITION 3.3 (Hankel tensors). *A Hankel tensor is a structured tensor whose coefficients* $[\mathcal{A}]_{i_1 i_2 i_3}$ *depend only on* $i_1 + i_2 + i_3$.

Note that a cube Hankel tensor is symmetric. Hankel tensors were introduced in [17] in the context of the harmonic retrieval problem [15]. This problem is at the heart of many signal processing applications.

Example 2 (definition and properties of the harmonic model). We consider the complex harmonic model defined according to

$$x_n = \sum_{m=1}^{M} \alpha_m z_m^n, \quad \text{for} \quad n \in [0 : N-1], \tag{3.3}$$

where N is the analysis duration and M is the known number of components, $z_m = e^{\delta_m + i\phi_m}$ is called the mth pole of x_n where $i = \sqrt{-1}$, ϕ_m is called the mth angular-frequency belonging to $(-\pi, \pi]$, and δ_m is the mth damping factor. In what follows,

we assume that all the poles are distinct. In addition, $\alpha_m = a_m e^{i\phi_m}$ is the nonzero mth complex amplitude, i.e., $a_m \neq 0 \, for \, all \, m$. Besides, we define the Vandermonde matrices $Z^{(I_1)}$, $Z^{(I_2)}$, and $Z^{(I_3)}$ associated to model (3.3), according to $[Z^{(I_s)}]_{n,m} = z_m^n$, and we assume that $M \leq \min(I_1, I_2, I_3)$. Then the Hankel tensor $[\mathcal{A}]_{i_1 i_2 i_3} = x_{(i_1+i_2+i_3)}$ associated to model (3.3) is diagonalizable according to

$$\mathcal{A} = \mathcal{D} \times_1 Z^{(I_1)} \times_2 Z^{(I_2)} \times_3 Z^{(I_3)},$$

where $\times_i$ denotes the ith Tucker's product and

$$[\mathcal{D}]_{jk\ell} = \begin{cases} \alpha_j & \text{if } j = k = \ell, \\ 0 & \text{otherwise} \end{cases}$$

is a hyper-cubic $M \times M \times M$ super-diagonal core tensor. As a consequence, the Hankel tensor $\mathcal{A}$ is a rank-(M, M, M) tensor. Following standard subspace-based parametric estimation methods, the harmonic model can then be estimated by computing the rank M-truncated HOSVD of tensor $\mathcal{A}$ [17].

3.2. Modes of structured tensors. As mentioned in the introduction, standard unfoldings of structured tensors [14, 12] do not present a particularly noticeable structure. Consequently, we introduce in this section two different ways to unfold a structured tensor which clarify the link between structured modes and structured tensors.

Example 3. Consider the $4 \times 4 \times 4$ symmetric and Toeplitz tensor $[\mathcal{A}]_{ijk} = 3 * \max(i, j, k) - \text{sum}(i, j, k)$. The classical 1-mode is formed of four symmetric submatrices:

$$A_1 = \left[\begin{bmatrix} 0 & 2 & 4 & 6 \\ 2 & 1 & 3 & 5 \\ 4 & 3 & 2 & 4 \\ 6 & 5 & 4 & 3 \end{bmatrix} \begin{bmatrix} 2 & 1 & 3 & 5 \\ 1 & 0 & 2 & 4 \\ 3 & 2 & 1 & 3 \\ 5 & 4 & 3 & 2 \end{bmatrix} \begin{bmatrix} 4 & 3 & 2 & 4 \\ 3 & 2 & 1 & 3 \\ 2 & 1 & 0 & 2 \\ 4 & 3 & 2 & 1 \end{bmatrix} \begin{bmatrix} 6 & 5 & 4 & 3 \\ 5 & 4 & 3 & 2 \\ 4 & 3 & 2 & 1 \\ 3 & 2 & 1 & 0 \end{bmatrix} \right].$$

However, by permuting its columns, we define another mode A_1' (referred to below as the *type*-1 *reordered tensor mode*), which is formed of four Toeplitz matrices T_0, T_1, T_2, and T_3 (referred to below as the *type*-1 *oblique submatrices*):

$$A_1' = \left[\underbrace{\begin{bmatrix} 6 \\ 5 \\ 4 \\ 3 \end{bmatrix}}_{T_3} \underbrace{\begin{bmatrix} 4 & 5 \\ 3 & 4 \\ 2 & 3 \\ 4 & 2 \end{bmatrix}}_{T_2} \underbrace{\begin{bmatrix} 2 & 3 & 4 \\ 1 & 2 & 3 \\ 3 & 1 & 2 \\ 5 & 3 & 1 \end{bmatrix}}_{T_1} \underbrace{\begin{bmatrix} 0 & 1 & 2 & 3 \\ 2 & 0 & 1 & 2 \\ 4 & 2 & 0 & 1 \\ 6 & 4 & 2 & 0 \end{bmatrix}}_{T_0} \underbrace{\begin{bmatrix} 2 & 3 & 4 \\ 1 & 2 & 3 \\ 3 & 1 & 2 \\ 5 & 3 & 1 \end{bmatrix}}_{T_1} \underbrace{\begin{bmatrix} 4 & 5 \\ 3 & 4 \\ 2 & 3 \\ 4 & 2 \end{bmatrix}}_{T_2} \underbrace{\begin{bmatrix} 6 \\ 5 \\ 4 \\ 3 \end{bmatrix}}_{T_3} \right].$$

It can be noted that this reordered mode satisfies an axial blockwise symmetry with respect to its central oblique submatrix T_0. Obviously, the left singular factor $U^{(1)}$ in the SVD of A_1 is the same as the left singular factor in the SVD of A_1', since both matrices have the same columns. However, we will show that the SVD of A_1' can be computed efficiently, by exploiting the Toeplitz structure of the oblique submatrices T_k.

Example 4. Consider the $4 \times 4 \times 4$ Hankel tensor $[\mathcal{A}]_{ijk} = i + j + k$. The standard 1-mode is formed of four Hankel submatrices:

$$A_1 = \left[\begin{bmatrix} 0 & 1 & 2 & 3 \\ 1 & 2 & 3 & 4 \\ 2 & 3 & 4 & 5 \\ 3 & 4 & 5 & 6 \end{bmatrix} \begin{bmatrix} 1 & 2 & 3 & 4 \\ 2 & 3 & 4 & 5 \\ 3 & 4 & 5 & 6 \\ 4 & 5 & 6 & 7 \end{bmatrix} \begin{bmatrix} 2 & 3 & 4 & 5 \\ 3 & 4 & 5 & 6 \\ 4 & 5 & 6 & 7 \\ 5 & 6 & 7 & 8 \end{bmatrix} \begin{bmatrix} 3 & 4 & 5 & 6 \\ 4 & 5 & 6 & 7 \\ 5 & 6 & 7 & 8 \\ 6 & 7 & 8 & 9 \end{bmatrix} \right].$$

However, by permuting its columns, we define another mode A_1'' (referred to below as the *type-2 reordered tensor mode*), which is formed of 7 rank-1 matrices $R_0,\dots,R_6$ (referred to below as the *type-2 oblique submatrices*):

$$A_1'' = \left[\underbrace{\begin{bmatrix}0\\1\\2\\3\end{bmatrix}}_{R_0} \underbrace{\begin{bmatrix}1&1\\2&2\\3&3\\4&4\end{bmatrix}}_{R_1} \underbrace{\begin{bmatrix}2&2&2\\3&3&3\\4&4&4\\5&5&5\end{bmatrix}}_{R_2} \underbrace{\begin{bmatrix}3&3&3&3\\4&4&4&4\\5&5&5&5\\6&6&6&6\end{bmatrix}}_{R_3} \underbrace{\begin{bmatrix}4&4&4\\5&5&5\\6&6&6\\7&7&7\end{bmatrix}}_{R_4} \underbrace{\begin{bmatrix}5&5\\6&6\\7&7\\8&8\end{bmatrix}}_{R_5} \underbrace{\begin{bmatrix}6\\7\\8\\9\end{bmatrix}}_{R_6} \right].$$

Again, the left singular factor in the SVD of A_1 is the same as the left singular factor in the SVD of A_1'', since both matrices have the same columns. However, we will show that the SVD of A_1'' can be computed efficiently by exploiting the rank-1 structure of the oblique submatrices R_k and the Hankel structure of the matrix obtained by removing the repeated columns in A_1''.

In the following section, the type-1 and type-2 oblique submatrices will be defined in the general case by "slicing" a third-order tensor according to two different oblique directions, as shown in Figure 3.1.

3.2.1. Oblique submatrices of a tensor.

DEFINITION 3.4 (type-1 and type-2 oblique submatrices of a tensor). *For any permutation π, the oblique submatrices of a tensor $\mathcal{A}$ are defined as follows:*

- *For all $k \in \{0,\dots,I_{\pi_3}-1\}$, let $J^{(1)}_{(\pi_2,\pi_3)}(k) = \min(I_{\pi_2}, I_{\pi_3}-k)$. The coefficients of the kth type-1 oblique $I_{\pi_1} \times J^{(1)}_{(\pi_2,\pi_3)}(k)$ submatrix of $\mathcal{A}$ are*

$$[T_k^{(\pi)}]_{ij} = [\mathcal{A}]_{\pi^{-1}(i,j,k+j)}, \tag{3.4}$$

  where $0 \le i \le I_{\pi_1}-1$ and $0 \le j \le J^{(1)}_{(\pi_2,\pi_3)}(k)-1$.
- *For all $k \in \{0,\dots,I_{\pi_2}+I_{\pi_3}-2\}$, let*

$$J^{(2)}_{(\pi_2,\pi_3)}(k) = \min(I_{\pi_2}, I_{\pi_3}, 1+k, I_{\pi_2}+I_{\pi_3}-1-k). \tag{3.5}$$

  The coefficients of the $I_{\pi_1} \times J^{(2)}_{(\pi_2,\pi_3)}(k)$ type-2 oblique submatrix of $\mathcal{A}$ are

$$[R_k^{(\pi)}]_{ij} = [\mathcal{A}]_{\pi^{-1}(i,\ \max(k-I_{\pi_3}+1,0)+j,\ \min(k,I_{\pi_3}-1)-j)}, \tag{3.6}$$

  where $0 \le i \le I_{\pi_1}-1$ and $0 \le j \le J^{(2)}_{(\pi_2,\pi_3)}(k)-1$.

PROPOSITION 3.5.

1. *If $\mathcal{A}$ is an $(I \times I \times I)$ symmetric tensor, then for all $k \in \{0,\dots,I-1\}$, all type-1 oblique submatrices $T_k^{(\pi)}$ are equal (*i.e.*, for all k, $T_k^{(\pi)} = T_k$ does not depend on π).*
2. *If $\mathcal{A}$ is a Toeplitz tensor, then for all permutation π and index $k \in \{0,\dots,I_{\pi_3}-1\}$, the type-1 oblique submatrix $T_k^{(\pi)}$ is Toeplitz.*
3. *If $\mathcal{A}$ is a Hankel tensor, all columns of the type-2 oblique submatrix $R_k^{(\pi)}$ are equal.*

Proof.

1. If the tensor $\mathcal{A}$ is symmetric, then (3.4) yields $[T_k^{(\pi)}]_{ij} = [\mathcal{A}]_{i,j,k+j}$, which does not depend on π.

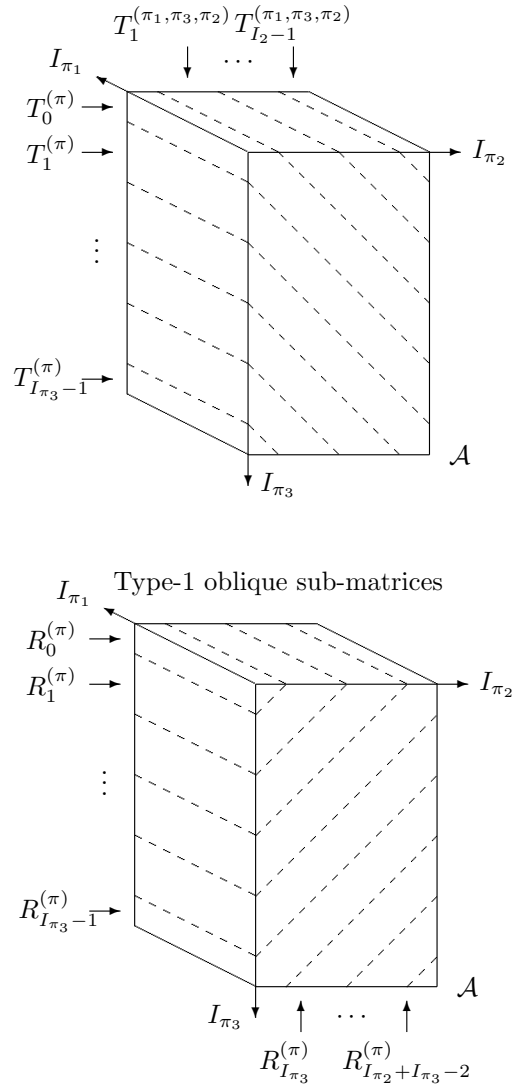

FIG. 3.1. *Type-*1 *and type-*2 *oblique submatrices of a tensor.*

2. Applying (3.4) to $i+1$ and $j+1$ (for all $0 \le i < I_{\pi_1} - 1$ and $0 \le j < J^{(1)}_{(\pi_2,\pi_3)}(k) - 1$) yields $[T_k^{(\pi)}]_{i+1,j+1} = [\mathcal{A}]_{\pi^{-1}(i+1,j+1,k+j+1)}$. However, since the tensor $\mathcal{A}$ is Toeplitz, $[\mathcal{A}]_{\pi^{-1}(i+1,j+1,k+j+1)} = [\mathcal{A}]_{\pi^{-1}(i,j,k+j)} = [T_k^{(\pi)}]_{ij}$. Therefore $[T_k^{(\pi)}]_{i+1,j+1} = [T_k^{(\pi)}]_{ij}$, which means that the matrix T_k is Toeplitz.
3. If $[\mathcal{A}]_{i_1 i_2 i_3}$ is of the form $[\mathcal{A}]_{i_1 i_2 i_3} = x_{(i_1+i_2+i_3)}$, then (3.6) shows that for all permutation π and index $k \in \{0, \dots, I_{\pi_2} + I_{\pi_3} - 2\}$, $[R_k^{(\pi)}]_{ij} = x_{(i+k)}$ does not depend on j. □

3.2.2. Reordered tensor modes. In the definition below we introduce the type-1 and type-2 reordered tensor modes, formed by concatenating the type-1 and

type-2 oblique submatrices.

DEFINITION 3.6. *The type-*1 reordered tensor modes *are defined by concatenating the type-*1 *oblique submatrices:*

- A'_1 *is the* $I_1 \times (I_2 I_3)$ *matrix* $[T^{(1,3,2)}_{I_2-1}, \dots, T^{(1,3,2)}_0 = T^{(1,2,3)}_0, \dots, T^{(1,2,3)}_{I_3-1}]$,
- A'_2 *is the* $I_2 \times (I_3 I_1)$ *matrix* $[T^{(2,1,3)}_{I_3-1}, \dots, T^{(2,1,3)}_0 = T^{(2,3,1)}_0, \dots, T^{(2,3,1)}_{I_1-1}]$,
- A'_3 *is the* $I_3 \times (I_1 I_2)$ *matrix* $[T^{(3,2,1)}_{I_1-1}, \dots, T^{(3,2,1)}_0 = T^{(3,1,2)}_0, \dots, T^{(3,1,2)}_{I_2-1}]$.

*In the same way, the type-*2 reordered tensor modes *are defined by concatenating the type-*2 *oblique submatrices:*

- A''_1 *is the* $I_1 \times (I_2 I_3)$ *matrix* $[R^{(1,2,3)}_0, \dots, R^{(1,2,3)}_{I_2+I_3-2}]$,
- A''_2 *is the* $I_2 \times (I_3 I_1)$ *matrix* $[R^{(2,3,1)}_0, \dots, R^{(2,3,1)}_{I_3+I_1-2}]$,
- A''_3 *is the* $I_3 \times (I_1 I_2)$ *matrix* $[R^{(3,1,2)}_0, \dots, R^{(3,1,2)}_{I_1+I_2-2}]$.

PROPOSITION 3.7.

1. *For all* $s = 1, 2, 3$*, the mode* A_s *and the reordered modes* A'_s*,* A''_s *admit the same singular values and left singular vectors.*
2. *If* $\mathcal{A}$ *is a symmetric tensor, then* $A'_1 = A'_2 = A'_3$*, and this unique mode admits an axial blockwise symmetry w.r.t. its central oblique submatrix.*

Proof.

1. For all $s = 1, 2, 3$, the columns of the reordered modes A'_s and A''_s form a permutation of the columns of the mode A_s defined in section 2.
2. This is a corollary of point 2 in Proposition 3.5. ∎

4. Fast algorithms for computing the HOSVD of structured tensors. In this section, the reordered tensor modes introduced previously are used to efficiently compute the HOSVD of structured tensors. The first improvement consists of exploiting the column-redundancy of symmetric and Hankel tensors. To further reduce the computational cost, we then exploit the fast matrix-vector product techniques specific to Toeplitz and Hankel matrices.

4.1. Algorithms exploiting column-redundancy. Here we suppose that the s-mode of tensor $\mathcal{A}$ is redundant, e.g., some columns of the s-mode are equal (this is the case of symmetric and Hankel tensors, for example). We aim at exploiting this redundancy in order to efficiently implement the HOSVD of $\mathcal{A}$. Toward this end, we define the $I_s \times J_s$ matrix H_s as the matrix obtained by removing the repeated columns in the s-mode ($J_s \leq \prod_{s' \neq s} I_{s'}$), and we denote $d^{(s)}_k$ the number of occurrences of the kth column of H_s in the s-mode. Then we consider the $I_s \times I_s$ correlation matrix of the s-mode: $C^{(s)} = A_s {A_s}^H$. It is clear that this matrix can be factorized as

$$C^{(s)} = H_s D_s^2 H_s^H,$$

where

$$D_s = \operatorname{diag}\left(\sqrt{d^{(s)}_0} \dots \sqrt{d^{(s)}_{J_s-1}}\right)$$

(if the s-mode is not redundant, then we define H_s as the s-mode itself and D_s is defined as the $J_s \times J_s$ identity matrix). As a consequence, the M_s highest singular values and left singular vectors of the s-mode of dimensions $I_s \times \prod_{s' \neq s} I_{s'}$ are the same as those of the smaller $I_s \times J_s$ matrix $H_s D_s$.

Algorithms for symmetric tensors. In the case of $(I \times I \times I)$ symmetric tensors, we proved in point 2 of Proposition 3.7 that $A'_1 = A'_2 = A'_3$, and that this unique mode admits an axial blockwise symmetry. Therefore we can define the following:

- the nonredundant matrix $H_s = [T_0^{(1,2,3)}, \ldots, T_{I-1}^{(1,2,3)}]$, for all $s \in \{1,2,3\}$, of dimension $I \times J$ with $J = I(I+1)/2$;
- the weighting factors $d_k^{(s)} = \begin{cases} 1 & \text{if } 0 \le k < I, \\ 2 & \text{if } I \le k < J. \end{cases}$

In this way, the cost of the (rank-truncated) HOSVD is reduced to that of the (rank-truncated) SVD of $H_s D_s$, which is $2MI^3$ flops per iteration. In particular, it can be noted that the compression and weighting of the modes lead to a complexity six times as low as that of the algorithm in Table 2.1.

Algorithms for Hankel tensors. In the case of $(I_1 \times I_2 \times I_3)$ Hankel tensors, $[\mathcal{A}]_{i_1 i_2 i_3}$ is of the form $[\mathcal{A}]_{i_1 i_2 i_3} = x_{(i_1+i_2+i_3)}$, and we proved in point 3 of Proposition 3.5 that for all permutation π and index $k \in \{0, \ldots, I_{\pi_2} + I_{\pi_3} - 2\}$, $[R_k^{(\pi)}]_{ij} = x_{(i+k)}$. In particular, all columns of the type-2 oblique submatrix $R_k^{(\pi)}$ are equal. Therefore, for each s-mode we can define the following:

- the nonredundant Hankel matrix $H_s(i,k) = x_{(i+k)}$ of dimension $I_s \times J_s$ with $J_s = (\sum_{s' \neq s} I_{s'}) - 1$;
- the weighting factors $d_k^{(s)} = J^{(2)}_{\{\pi_{s'}\}_{s' \neq s}}(k) = \min(\{I_{s'}\}_{s' \neq s}, 1+k, J_s - k)$ (here $d_k^{(s)}$ is the number of columns of the kth oblique submatrix of the s-mode, defined in (3.5)). It can be noted that the weighting function $1 + k \mapsto d_k^{(s)}$ (plotted in Figure 4.1) is piecewise linear:

(4.1)
$$d_k^{(s)} = \begin{cases} 1+k & \text{if } 1 \le 1+k < \min(\{I_{s'}\}_{s' \neq s}), \\ \min(\{I_{s'}\}_{s' \neq s}) & \text{if } \min(\{I_{s'}\}_{s' \neq s}) \le 1+k \le \max(\{I_{s'}\}_{s' \neq s}), \\ J_s - k & \text{if } \max(\{I_{s'}\}_{s' \neq s}) < 1+k \le J_s, \\ 0 & \text{elsewhere.} \end{cases}$$

Operation	Cost per iteration
SVD of A'_1	$2M_1(90I^2\log_2(I) + M_1I_1)$
SVD of A'_2	$2M_2(90I^2\log_2(I) + M_2I_2)$
SVD of A'_3	$2M_3(90I^2\log_2(I) + M_3I_3)$
Global cost	$6M\ 90I^2\log_2(I)$

of the modes allow a reduction of the complexity of one order of magnitude w.r.t. the algorithm in Table 2.1. If, additionally, the Hankel tensor is cube ($I_1 = I_2 = I_3 = I$), then it is symmetric and the three modes are equal. In this case, the global complexity is reduced $8MI^2$ flops.

4.2. Algorithms exploiting the Toeplitz or Hankel structure. In the above developments, we assumed that the rank-r rank-truncated SVD of an $n \times m$ matrix with $n < m$ was computed by means of the orthogonal iteration method [7, pp. 410–411], which consists of recursively performing $2r$ matrix/vector products and 1 QR factorization of an $n \times r$ matrix (a full SVD corresponds to the case $r = n$). We mentioned that the computational cost of one iteration is $2r\,c(n,m) + 2r^2n$ flops, where $c(n,m)$ is the cost of 1 matrix/vector product, and $2r^2n$ is the cost of 1 QR factorization [7, pp. 231–232].

In the following, we will focus on the HOSVD of Toeplitz or Hankel tensors, which can be computed efficiently using fast matrix/vector products. Indeed, the computational cost of a product between a $p \times q$ Toeplitz or Hankel matrix and a vector can be reduced from $2pq$ flops to $15(p+q)\log_2(p+q)$ flops by means of fast Fourier transforms (FFTs) [7, pp. 188-191,201–202].

Algorithms for Toeplitz tensors. In the case of Toeplitz tensors, we mentioned in point 2 of Proposition 3.5 that for all permutation π and index $k \in \{0, \dots, I_{\pi_3} - 1\}$, the type-1 oblique submatrix $T_k^{(\pi)}$ is Toeplitz. Therefore the oblique modes A'_s are formed of Toeplitz blocks. As a consequence, the computational cost of the multiplication of A'_s by a vector of appropriate dimension can be reduced from $2I^3$ flops to $90I^2\log_2(I)$ flops.[1] By introducing those fast products into the orthogonal iteration method, the cost of the (rank-truncated) SVD of A'_s is reduced to $2M_s(90I^2\log_2(I) + M_sI_s)$ per iteration.

The fast algorithm for computing the full or rank-truncated HOSVD of a Toeplitz tensor is summarized in Table 4.2. If, additionally, the tensor $\mathcal{A}$ is symmetric, then the three modes are equal. Moreover, as shown in section 4.1, the SVD of A'_s can be replaced by that of H_sD_s, where the $I \times \frac{I(I+1)}{2}$ matrix H_s is also block-Toeplitz. Therefore the cost of the SVD of H_sD_s is half that of the SVD of A'_s. As a consequence, the compression and weighting of the modes lead to a complexity six times as low as that of the fast HOSVD algorithm in Table 4.2.

[1] Under the constraint $I_1+I_2+I_3 = 3I$, the maximum cost is obtained for cube tensors ($I_1 = I_2 = I_3 = I$). Besides, left or right multiplying an $I \times k$ oblique submatrix $T_{I-k}^{(\pi)}$ by a vector of appropriate dimension normally involves $2Ik$ flops. This complexity is reduced to $15(I+k)\log_2(I+k)$ flops by means of FFT's. Therefore, left or right multiplying the block-Toeplitz matrix A'_s by a vector of appropriate dimension normally involves $2\sum_{k=0}^{I-1} 2Ik \sim 2I^3$ flops, or $2\sum_{k=0}^{I-1} 15(I+k)\log_2(I+k) \sim 90I^2\log_2(I)$ by means of FFT's.

Algorithms for Hankel tensors. In the case of Hankel tensors, we noted in section 4.1 that the HOSVD could be obtained by computing the SVD of the matrices $H_s D_s$, where each compressed mode H_s is a Hankel matrix ($H_s(i,k) = x_{(i+k)}$). Therefore, we can again use fast matrix-vector products to further reduce the complexity. More precisely, the computational cost of the multiplication of the $I_s \times ((\sum_{s' \neq s} I_{s'}) - 1)$ Hankel matrix H_s by a vector of appropriate dimension can be reduced from $4I^2$ flops to $45I \log_2(I)$ flops, by means of FFT's. By introducing those fast products into the orthogonal iteration method, the cost of the SVD of $H_s D_s$ is reduced to $2M_s(45I \log_2(I) + M_s I_s)$ per iteration.

The ultrafast algorithm for computing the full or rank-truncated HOSVD of a Hankel tensor is summarized in Table 4.3. Its global cost is provided as a maximum over M_1, M_2, M_3, under the constraint $M_1 + M_2 + M_3 = 3M$. It can be noted that the cost due to the fast matrix/vector products and the cost due to the QR factorizations can be of the same order of magnitude if $M = O(\log_2(I))$.

TABLE 4.3
Ultrafast HOSVD algorithm for Hankel tensors.

(the cost corresponds to a single iteration of the orthogonal iteration method)

Operation	Cost per iteration
SVD of $H_1 D_1$	$2M_1(45I \log_2(I) + M_1 I_1)$
SVD of $H_2 D_2$	$2M_2(45I \log_2(I) + M_2 I_2)$
SVD of $H_3 D_3$	$2M_3(45I \log_2(I) + M_3 I_3)$
Global cost	$6M(45I \log_2(I) + MI)$

If, additionally, the Hankel tensor is cube ($I_1 = I_2 = I_3 = I$), then it is symmetric, and the three modes are equal. In this case, the global complexity is three times as low as that of the ultrafast HOSVD algorithm in Table 4.3.

TABLE 4.4
Complexities of the HOSVD algorithms.

(the cost corresponds to a single iteration of the orthogonal iteration method)

Structure	Global cost per iteration
Unstructured	$12MI^3$
Symmetric	$2MI^3$
Toeplitz (fast)	$540MI^2 \log_2(I)$
Symmetric Toeplitz (fast)	$90MI^2 \log_2(I)$
Hankel (fast)	$24MI^2$
Cube Hankel (fast)	$8MI^2$
Hankel (ultrafast)	$270MI \log_2(I) + 6M^2 I$
Cube Hankel (ultrafast)	$90MI \log_2(I) + 2M^2 I$

4.3. Comparison of the complexities. The overall costs of the various HOSVD algorithms presented above are summarized in Table 4.4 (sorted in decreasing order of complexity). Note that only the complexity upper bounds are given in this table, and that the calculation of the tensor $\mathcal{S}$ is not included. Besides, it can be noted that the FFT-based HOSVD algorithms are not always the fastest, because of the high constants in Table 4.4. The best choice for computing the HOSVD actually depends on I and possibly on M (the dominant cost of all algorithms is linear w.r.t. M, except that of the ultrafast algorithms for Hankel tensors). Figure 4.2 represents the different complexities for $M = 10$. From this figure we can draw general remarks, which actually stand for any value of parameter M:

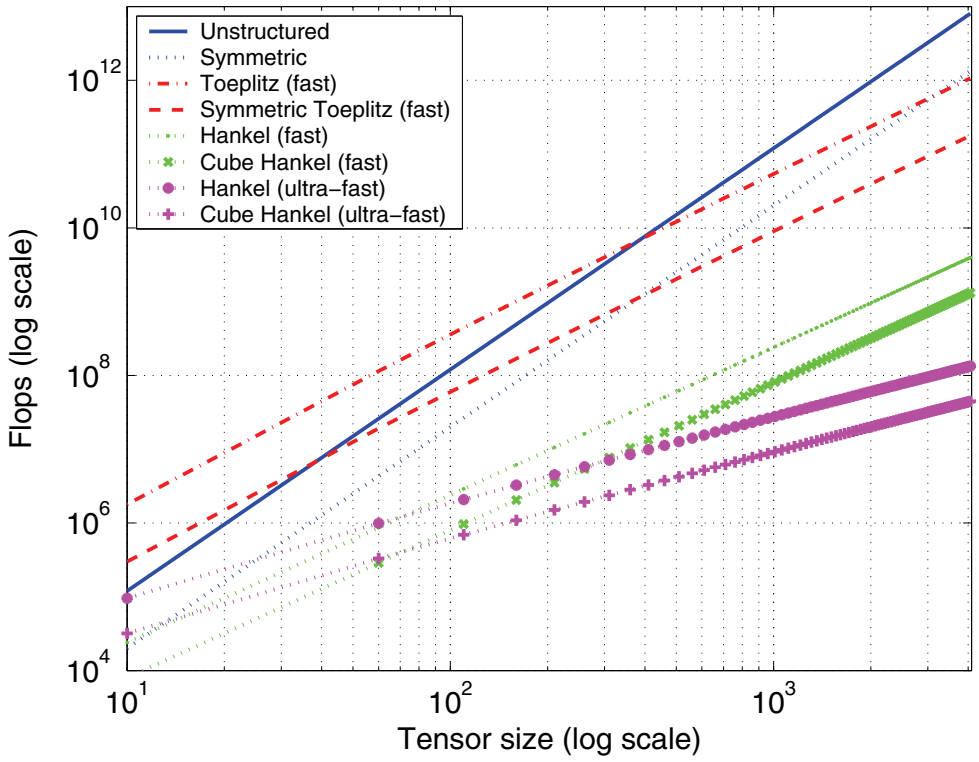

FIG. 4.2. *Flops count versus size I for $M = 10$.*

- the best algorithm for computing the HOSVD of Toeplitz (resp., symmetric Toeplitz) tensors is that dedicated to such tensors if $I \gtrsim 400$, or that dedicated to unstructured (resp., symmetric) tensors otherwise;
- the best algorithms for computing the HOSVD of symmetric, Hankel, and cube Hankel tensors are always those dedicated to such tensors.

In other respects, the comparison between the fast and ultrafast computations of the HOSVD for Hankel and cube Hankel tensors are sensitive to parameter M, as can be noted in Table 4.4. Our simulations showed the following:

- for small values of M ($M \ll I$), the ultrafast algorithm is faster if $I \gtrsim 70$;
- for moderate values of M ($M \simeq I/2$), the ultrafast algorithm is faster if $I \gtrsim 80$;
- for large values of M ($M \simeq I$), the ultrafast algorithm is faster if $I \gtrsim 100$.

5. Conclusions. In this paper, we proposed decreasing the computational cost of the full or rank-truncated HOSVD, which is basically $O(MI^3)$, by exploiting the structure of symmetric, Toeplitz, and Hankel tensors. For symmetric and Hankel tensors, our solution is based on the fact that the HOSVD can be reduced to the SVD of three nonredundant (no columns are repeated) matrices whose columns are multiplied by a given weighting function. In the case of Toeplitz and Hankel tensors, we propose a new way to perform the tensor unfolding which allows fast matrix/vector products. Finally, our fastest implementation of the HOSVD has a complexity of $O(MI\log_2(I))$ in the case of Hankel tensors.

DECOMPOSITIONS OF A HIGHER-ORDER TENSOR IN BLOCK TERMS—PART I: LEMMAS FOR PARTITIONED MATRICES*

LIEVEN DE LATHAUWER†

Abstract. In this paper we study a generalization of Kruskal's permutation lemma to partitioned matrices. We define the k'-rank of partitioned matrices as a generalization of the k-rank of matrices. We derive a lower-bound on the k'-rank of Khatri–Rao products of partitioned matrices. We prove that Khatri–Rao products of partitioned matrices are generically full column rank.

Key words. multilinear algebra, higher-order tensor, Tucker decomposition, canonical decomposition, parallel factors model

AMS subject classifications. 15A18, 15A69

DOI. 10.1137/060661685

1. Introduction.

1.1. Organization of the paper. In a companion paper we introduce decompositions of a higher-order tensor in several types of block terms [3]. For the analysis of these decompositions, we need a number of tools. Some of these are introduced in the present paper. In section 2 we derive a generalization of Kruskal's permutation lemma [6], which we call the equivalence lemma for partitioned matrices. Section 2 also introduces the k'-rank of partitioned matrices as a generalization of the k-rank of matrices [6]. In section 3 we present some results on the rank and k'-rank of Khatri–Rao products of partitioned matrices (see (1.1)).

1.2. Notation. We use $\mathbb{K}$ to denote $\mathbb{R}$ or $\mathbb{C}$ when the difference is not important. In this paper scalars are denoted by lowercase letters (a, b, ...), vectors are written in boldface lowercase ($\mathbf{a}$, $\mathbf{b}$, ...), and matrices correspond to boldface capitals ($\mathbf{A}$, $\mathbf{B}$, ...). This notation is consistently used for lower-order parts of a given structure. For instance, the entry with row index i and column index j in a matrix $\mathbf{A}$, i.e., $(\mathbf{A})_{ij}$, is symbolized by a_{ij} (also $(\mathbf{a})_i = a_i$). If no confusion is possible, the ith column vector of a matrix $\mathbf{A}$ is denoted as $\mathbf{a}_i$, i.e., $\mathbf{A} = [\mathbf{a}_1\ \mathbf{a}_2\ \ldots]$. Sometimes we use the MATLAB colon notation to indicate submatrices of a given matrix or subtensors of a given tensor. Italic capitals are also used to denote index upper bounds (e.g., $i = 1, 2, \ldots, I$). The symbol $\otimes$ denotes the Kronecker product,

$$\mathbf{A} \otimes \mathbf{B} = \begin{pmatrix} a_{11}\mathbf{B} & a_{12}\mathbf{B} & \ldots \\ a_{21}\mathbf{B} & a_{22}\mathbf{B} & \ldots \\ \vdots & \vdots & \end{pmatrix}.$$

Sabbelaan 53, 8500 Kortrijk, Belgium (Lieven.DeLathauwer@kuleuven-kortrijk.be), and Department of Electrical Engineering (ESAT), Katholieke Universiteit Leuven, Kasteelpark Arenberg 10, B-3001 Leuven, Belgium (Lieven.DeLathauwer@esat.kuleuven.be, http://homes.esat.kuleuven.be/~delathau/home.html).

Let $\mathbf{A} = [\mathbf{A}_1 \ \dots \ \mathbf{A}_R]$ and $\mathbf{B} = [\mathbf{B}_1 \ \dots \ \mathbf{B}_R]$ be two partitioned matrices. Then the Khatri–Rao product is defined as the partitionwise Kronecker product and represented by $\odot$ [7]:

$$\mathbf{A} \odot \mathbf{B} = (\mathbf{A}_1 \otimes \mathbf{B}_1 \dots \mathbf{A}_R \otimes \mathbf{B}_R)\,. \tag{1.1}$$

In recent years, the term "Khatri–Rao product" and the symbol $\odot$ have been used mainly in cases where $\mathbf{A}$ and $\mathbf{B}$ are partitioned into vectors. For clarity, we denote this particular, columnwise Khatri–Rao product by $\odot_c$:

$$\mathbf{A} \odot_c \mathbf{B} = (\mathbf{a}_1 \otimes \mathbf{b}_1 \dots \mathbf{a}_R \otimes \mathbf{b}_R)\,.$$

The column space of a matrix and its orthogonal complement will be denoted by $\mathrm{span}(\mathbf{A})$ and $\mathrm{null}(\mathbf{A})$. The rank of a matrix $\mathbf{A}$ will be denoted by $\mathrm{rank}(\mathbf{A})$ or $r_{\mathbf{A}}$. The superscripts $\cdot^T$, $\cdot^H$, and $\cdot^\dagger$ denote the transpose, complex conjugated transpose, and Moore–Penrose pseudoinverse, respectively. The $(N \times N)$ identity matrix is represented by $\mathbf{I}_{N\times N}$. The $(I \times J)$ zero matrix is denoted by $\mathbf{0}_{I\times J}$.

2. The equivalence lemma for partitioned matrices. Let $\omega(\mathbf{x})$ denote the number of nonzero entries of a vector $\mathbf{x}$. The following lemma was originally proposed by Kruskal in [6]. It is known as the *permutation lemma*. It plays a crucial role in the analysis of the uniqueness of the canonical/parallel factor (CANDECOMP/PARAFAC) decomposition [1, 5]. The proof was reformulated in terms of accessible basic linear algebra in [9]. An alternative proof was given in [4]. The link between the two proofs is also discussed in [9].

LEMMA 2.1 (permutation lemma). *Consider two matrices $\bar{\mathbf{A}}, \mathbf{A} \in \mathbb{K}^{I\times R}$ that have no zero columns. If for every vector $\mathbf{x}$ such that $\omega(\mathbf{x}^T\bar{\mathbf{A}}) \leqslant R - r_{\bar{\mathbf{A}}} + 1$, we have $\omega(\mathbf{x}^T\mathbf{A}) \leqslant \omega(\mathbf{x}^T\bar{\mathbf{A}})$, then there exists a unique permutation matrix $\mathbf{\Pi}$ and a unique nonsingular diagonal matrix $\mathbf{\Lambda}$ such that $\bar{\mathbf{A}} = \mathbf{A}\cdot\mathbf{\Pi}\cdot\mathbf{\Lambda}$.*

Below, we present a generalization of the permutation lemma for matrices that are partitioned as in $\mathbf{A} = [\mathbf{A}_1 \dots \mathbf{A}_R]$. This generalization is essential in the study of the uniqueness of the decompositions introduced in [3].

Let us first introduce some additional prerequisites. Let $\omega'(\mathbf{x})$ denote the number of parts of a partitioned vector $\mathbf{x}$ that are not all-zero. We call the partitioning of a partitioned matrix $\mathbf{A}$ uniform when all submatrices are of the same size. We also have the following definition.

DEFINITION 2.2. *The* Kruskal rank *or* k-rank *of a matrix $\mathbf{A}$, denoted by* $\mathrm{rank}_k(\mathbf{A})$ *or $k_{\mathbf{A}}$, is the maximal number r such that any set of r columns of $\mathbf{A}$ is linearly independent* [6].

We call a property generic when it holds with probability one when the parameters of the problem are drawn from continuous probability density functions. Let $\mathbf{A} \in \mathbb{K}^{I\times R}$. Generically, we have $k_{\mathbf{A}} = \min(I, R)$. K-ranks appear in the formulation of the famous Kruskal condition for CANDECOMP/PARAFAC uniqueness (see [3, Theorem 1.14]).

We now generalize the k-rank concept to partitioned matrices.

DEFINITION 2.3. *The* k'-rank *of a (not necessarily uniformly) partitioned matrix $\mathbf{A}$, denoted by* $\mathrm{rank}_{k'}(\mathbf{A})$ *or $k'_{\mathbf{A}}$, is the maximal number r such that any set of r submatrices of $\mathbf{A}$ yields a set of linearly independent columns.*

Let $\mathbf{A} \in \mathbb{K}^{I\times LR}$ be uniformly partitioned in R matrices $\mathbf{A}_r \in \mathbb{K}^{I\times L}$. Generically, we have $k'_{\mathbf{A}} = \min(\lfloor \frac{I}{L} \rfloor, R)$. K'-ranks will appear in the formulation of generalizations of Kruskal's condition to block term decompositions [3].

The generalization of the permutation lemma to partitioned matrices is now as follows.

LEMMA 2.4 (equivalence lemma for partitioned matrices). *Consider* $\bar{\mathbf{A}}, \mathbf{A} \in \mathbb{K}^{I \times \sum_{r=1}^{R} L_r}$*, partitioned in the same but not necessarily uniform way into* R *submatrices that are full column rank. Suppose that for every* $\mu \leqslant R - k'_{\bar{\mathbf{A}}} + 1$ *there holds that for a generic*[1] *vector* $\mathbf{x}$ *such that* $\omega'(\mathbf{x}^H \bar{\mathbf{A}}) \leqslant \mu$*, we have* $\omega'(\mathbf{x}^H \mathbf{A}) \leqslant \omega'(\mathbf{x}^H \bar{\mathbf{A}})$*. Then there exists a unique block-permutation matrix* $\mathbf{\Pi}$ *and a unique nonsingular block-diagonal matrix* $\mathbf{\Lambda}$*, such that* $\bar{\mathbf{A}} = \mathbf{A} \cdot \mathbf{\Pi} \cdot \mathbf{\Lambda}$*, where the block-transformation is compatible with the block-structure of* $\mathbf{A}$ *and* $\bar{\mathbf{A}}$*.*

The permutation lemma is not only about permutations. Rather it gives a condition under which two matrices are *equivalent* up to columnwise permutation *and scaling*. The lemma thus makes sure that two matrices belong to the same quotient class of the equivalence relation defined by $\mathbf{A} \sim \mathbf{B} \Leftrightarrow \mathbf{A} = \mathbf{B} \cdot \mathbf{\Pi} \cdot \mathbf{\Lambda}$, in which $\mathbf{\Pi}$ is an arbitrary permutation matrix and $\mathbf{\Lambda}$ an arbitrary nonsingular diagonal matrix, respectively. We find it therefore appropriate to call Lemma 2.4 the *equivalence* lemma for partitioned matrices.

We note that the rank $r_{\bar{\mathbf{A}}}$ in the permutation lemma has been replaced by the k'-rank $k'_{\bar{\mathbf{A}}}$ in Lemma 2.4, because the permutation lemma admits a simpler proof when we can assume that $r_{\bar{\mathbf{A}}} = k_{\bar{\mathbf{A}}}$. It is this simpler proof, given in [4], that will be generalized in this paper. We stay quite close to the text of [4]. We recommend studying the proof in [4] before reading the remainder of this section.

We work as follows. First we have a closer look at the meaning of the condition in the equivalence lemma for partitioned matrices (Lemma 2.5). Then we prove that $\mathbf{A}$ and $\bar{\mathbf{A}}$ are equivalent when the condition in the equivalence lemma for partitioned matrices holds for all $\mu \leqslant R$ (Lemma 2.6). Finally we show that it is sufficient to claim that the condition holds for $\mu \leqslant R - k'_{\bar{\mathbf{A}}} + 1$ (Lemma 2.7).

LEMMA 2.5. *Consider* $\bar{\mathbf{A}}, \mathbf{A} \in \mathbb{K}^{I \times L}$*, partitioned in the same but not necessarily uniform way into* R *submatrices that are full column rank. The following two statements are equivalent:*

(i) *For every* $\mu \leqslant R - k'_{\bar{\mathbf{A}}} + 1$ *there holds that for a generic vector* $\mathbf{x}$ *such that* $\omega'(\mathbf{x}^H \bar{\mathbf{A}}) \leqslant \mu$*, we have* $\omega'(\mathbf{x}^H \mathbf{A}) \leqslant \omega'(\mathbf{x}^H \bar{\mathbf{A}})$*.*

(ii) *If a vector is orthogonal to* $c \geqslant k'_{\bar{\mathbf{A}}} - 1$ *submatrices of* $\bar{\mathbf{A}}$*, then it must generically be orthogonal to at least* c *submatrices of* $\mathbf{A}$*.*

These, in turn, imply the following:

(iii) *For every set of* $c \geqslant k'_{\bar{\mathbf{A}}} - 1$ *submatrices of* $\bar{\mathbf{A}}$*, there exists a set of at least* c *submatrices of* $\mathbf{A}$ *such that span(matrix formed by these* $c \geqslant k'_{\bar{\mathbf{A}}} - 1$ *submatrices of* $\bar{\mathbf{A}}$*)* $\supseteq$ *span(matrix formed by the* c *or more submatrices of* $\mathbf{A}$*).*

Proof. The equivalence of (i) and (ii) follows directly from the definition of $\omega'(\mathbf{x})$.

[1] We mean the following. Consider, for instance, a partitioned matrix $\bar{\mathbf{A}} = [\mathbf{a}_1\ \mathbf{a}_2 | \mathbf{a}_3\ \mathbf{a}_4] \in \mathbb{K}^{4 \times 4}$ that is full column rank. The set $\mathsf{S} = \{\mathbf{x} | \omega'(\mathbf{x}^H \bar{\mathbf{A}}) \leqslant 1\}$ is the union of two subspaces, S_1 and S_2, consisting of the set of vectors orthogonal to $\{\mathbf{a}_1, \mathbf{a}_2\}$ and $\{\mathbf{a}_3, \mathbf{a}_4\}$, respectively. When we say that for a generic vector $\mathbf{x}$ such that $\omega'(\mathbf{x}^H \bar{\mathbf{A}}) \leqslant 1$, we have $\omega'(\mathbf{x}^H \mathbf{A}) \leqslant \omega'(\mathbf{x}^H \bar{\mathbf{A}})$, we mean that $\omega'(\mathbf{x}^H \mathbf{A}) \leqslant \omega'(\mathbf{x}^H \bar{\mathbf{A}})$ holds with probability one for a vector $\mathbf{x}$ drawn from a continuous probability density function over S_1 and that $\omega'(\mathbf{x}^H \mathbf{A}) \leqslant \omega'(\mathbf{x}^T \bar{\mathbf{A}})$ also holds with probability one for a vector $\mathbf{x}$ drawn from a continuous probability density function over S_2. In general, the set $\mathsf{S} = \{\mathbf{x} | \omega'(\mathbf{x}^H \bar{\mathbf{A}}) \leqslant \mu\}$ consists of a finite union of subspaces, where we count only the subspaces that are not contained in another subspace. For each of these subspaces, the property should hold with probability one for a vector $\mathbf{x}$ drawn from a continuous probability density function over that subspace.

We now prove in two ways that (ii) implies (iii). The first proof is a generalization of [4, Remark 1]. This proof is by contradiction. Suppose that there is a set of $c_0 \geqslant k'_{\bar{\mathbf{A}}} - 1$ submatrices of $\bar{\mathbf{A}}$, say, $\bar{\mathbf{A}}_1, \ldots, \bar{\mathbf{A}}_{c_0}$, and that there are only $c_0 - k$ submatrices of $\mathbf{A}$, say, $\mathbf{A}_1, \ldots, \mathbf{A}_{c_0-k}$, such that

$$\operatorname{span}([\bar{\mathbf{A}}_1 \ \ldots \ \bar{\mathbf{A}}_{c_0}]) \supseteq \operatorname{span}([\mathbf{A}_1 \ \ldots \ \mathbf{A}_{c_0-k}]),$$

where $1 \leqslant k \leqslant c_0$. The column space of none of the remaining submatrices of $\mathbf{A}$, i.e., $\mathbf{A}_{c_0-k+1}, \ldots, \mathbf{A}_R$, is contained in $\operatorname{span}([\bar{\mathbf{A}}_1 \ \ldots \ \bar{\mathbf{A}}_{c_0}])$; otherwise, k can be reduced. This implies that for every $i = c_0 - k + 1, \ldots, R$, there exists a certain nonzero vector $\mathbf{x}_i \in \operatorname{null}([\bar{\mathbf{A}}_1 \ \ldots \ \bar{\mathbf{A}}_{c_0}])$ such that

$$\mathbf{x}_i^H \mathbf{A}_i \neq [0 \ \ldots \ 0]. \tag{2.1}$$

We can assume that $\operatorname{null}([\bar{\mathbf{A}}_1 \ \ldots \ \bar{\mathbf{A}}_{c_0}])$ is a subspace of dimension $m \geqslant 1$. The case $m = 0$ corresponds to $\operatorname{span}([\bar{\mathbf{A}}_1 \ \ldots \ \bar{\mathbf{A}}_{c_0}]) = \mathbb{K}^I$. In this case, the span of all submatrices of $\mathbf{A}$ is contained in $\operatorname{span}([\bar{\mathbf{A}}_1 \ \ldots \ \bar{\mathbf{A}}_{c_0}])$.

Due to the existence of $\mathbf{x}_i$ in (2.1), we have for $i = c_0 - k + 1, \ldots, R$ that $\operatorname{null}([\bar{\mathbf{A}}_1 \ \ldots \ \bar{\mathbf{A}}_{c_0}\mathbf{A}_i])$ is a proper subspace of $\operatorname{null}([\bar{\mathbf{A}}_1 \ \ldots \ \bar{\mathbf{A}}_{c_0}])$ with dimension at most $m-1$. Since the union of a countable number of at most $(m-1)$-dimensional subspaces of $\mathbb{K}^I$ cannot cover an m-dimensional subspace of $\mathbb{K}^I$, there holds for a generic vector $\mathbf{x}_0 \in \operatorname{null}([\bar{\mathbf{A}}_1 \ \ldots \ \bar{\mathbf{A}}_{c_0}])$ that

$$\mathbf{x}_0^H \mathbf{A}_i \neq [0 \ \ldots \ 0], \quad i = c_0 - k + 1, \ldots, R.$$

We have a contradiction with (ii).

The second proof is direct.[2] If a vector is orthogonal to c submatrices of $\bar{\mathbf{A}}$, then it is in the left null space of c submatrices of $\bar{\mathbf{A}}$. Denote the matrix formed by these c submatrices by $\bar{\mathbf{A}}_c$. By assumption, we have that the vector is generically also in the left null space of $\bar{c} \geqslant c$ submatrices of $\mathbf{A}$. Denote the matrix formed by these $\bar{c}$ submatrices by $\mathbf{A}_{\bar{c}}$. Since

$$\operatorname{null}(\bar{\mathbf{A}}_c) \subseteq \operatorname{null}(\mathbf{A}_{\bar{c}})$$

we have

$$\operatorname{span}(\bar{\mathbf{A}}_c) \supseteq \operatorname{span}(\mathbf{A}_{\bar{c}}).$$

This completes the proof. ∎

We now demonstrate the equivalence of matrices under a condition that seems stronger than the one in the equivalence lemma for partitioned matrices.

LEMMA 2.6. *Consider $\bar{\mathbf{A}}, \mathbf{A} \in \mathbb{K}^{I \times L}$, partitioned in the same but not necessarily uniform way into R submatrices that are full column rank. The following two statements are equivalent:*

(i) *There exists a unique block-permutation matrix $\mathbf{\Pi}$ and a unique nonsingular block-diagonal matrix $\mathbf{\Lambda}$, such that $\bar{\mathbf{A}} = \mathbf{A} \cdot \mathbf{\Pi} \cdot \mathbf{\Lambda}$, where the block-transformation is compatible with the block-structure of $\mathbf{A}$ and $\bar{\mathbf{A}}$.*

(ii) *For every $\mu \leqslant R$ there holds that, for a generic vector $\mathbf{x}$ such that $\omega'(\mathbf{x}^H \bar{\mathbf{A}}) \leqslant \mu$, we have $\omega'(\mathbf{x}^H \mathbf{A}) \leqslant \omega'(\mathbf{x}^H \bar{\mathbf{A}})$.*

[2] This proof was suggested by an anonymous reviewer.

Proof. The implication of (ii) from (i) is trivial. The implication of (i) from (ii) is proved by induction on the number of submatrices R.

For $R = 1$, the condition in the lemma means that $\omega'(\mathbf{x}^H\mathbf{A}) = 0$ for a generic vector $\mathbf{x}$ satisfying $\omega'(\mathbf{x}^H\bar{\mathbf{A}}) = 0$. This implies that $\text{null}(\bar{\mathbf{A}}) \subseteq \text{null}(\mathbf{A})$. Since $\text{null}(\mathbf{A})$ and $\text{null}(\bar{\mathbf{A}})$ are the orthogonal complements of $\text{span}(\mathbf{A})$ and $\text{span}(\bar{\mathbf{A}})$, respectively, we have $\text{span}(\mathbf{A}) \subseteq \text{span}(\bar{\mathbf{A}})$. Since both $\mathbf{A}$ and $\bar{\mathbf{A}}$ are full column rank, the dimensions of $\text{span}(\mathbf{A})$ and $\text{span}(\bar{\mathbf{A}})$ are equal. Hence, we have $\text{span}(\mathbf{A}) = \text{span}(\bar{\mathbf{A}})$ and $\mathbf{A} = \bar{\mathbf{A}} \cdot \mathbf{\Lambda}$, where $\mathbf{\Lambda}$ is $(L \times L)$ nonsingular.

Now assume that the lemma holds for all $R \leqslant K$. We show that it then also holds for $R = K + 1$. The proof is by contradiction. We assume that in the induction step matrices $\mathbf{A}_1$ and $\bar{\mathbf{A}}_1$ are appended to $[\mathbf{A}_2 \ \ldots \ \mathbf{A}_{K+1}]$ and $[\bar{\mathbf{A}}_2 \ \ldots \ \bar{\mathbf{A}}_{K+1}]$, respectively. Both $\mathbf{A}_1$ and $\bar{\mathbf{A}}_1$ have L_1 columns. Without loss of generality, we assume that none of the other submatrices $\mathbf{A}_2, \ldots, \mathbf{A}_{K+1}, \bar{\mathbf{A}}_2, \ldots, \bar{\mathbf{A}}_{K+1}$ has less than L_1 columns.

Assume that $\text{span}(\bar{\mathbf{A}}_1)$ does not coincide with $\text{span}(\mathbf{A}_j)$ for any $j = 1, \ldots, R = K+1$. This means that for all j, $\text{span}([\bar{\mathbf{A}}_1 \ \mathbf{A}_j]) \supset \text{span}(\bar{\mathbf{A}}_1)$. Equivalently, $\text{null}(\bar{\mathbf{A}}_1) \supset \text{null}([\bar{\mathbf{A}}_1 \ \mathbf{A}_j])$. Denote $\dim(\text{null}(\bar{\mathbf{A}}_1)) = I - \alpha$ and $\dim(\text{null}([\bar{\mathbf{A}}_1 \ \mathbf{A}_j])) = I - \alpha - \beta_j$, with $\beta_j \geqslant 1$, $j = 1, \ldots, R$. Since the union of a countable number of subspaces of dimension $I - \alpha - \beta_j$ cannot cover a subspace of dimension $I - \alpha$, $\bigcup_{j=1}^{R} \text{null}([\bar{\mathbf{A}}_1 \ \mathbf{A}_j])$ does not cover $\text{null}(\bar{\mathbf{A}}_1)$. This implies that for a generic vector $\mathbf{x}_0$ in $\text{null}(\bar{\mathbf{A}}_1)$ we have

$$\omega'(\mathbf{x}_0^H\bar{\mathbf{A}}_1) = 0, \quad \omega'(\mathbf{x}_0^H\mathbf{A}_j) = 1, \quad j = 1, \ldots, R.$$

This means that for a generic vector $\mathbf{x}_0$ in $\text{null}(\bar{\mathbf{A}}_1)$ we have

$$\omega'(\mathbf{x}_0^H\bar{\mathbf{A}}) \leqslant R - 1 \leqslant R = \omega'(\mathbf{x}_0^H\mathbf{A}).$$

We have a contradiction with the condition in the lemma. Therefore, there exists a submatrix of $\mathbf{A}$, say, $\mathbf{A}_{j_0}$, such that $\bar{\mathbf{A}}_1 = \mathbf{A}_{j_0} \cdot \mathbf{L}$, in which $\mathbf{L}$ is square nonsingular.

We now construct a submatrix $\bar{\mathbf{A}}_0$ of $\bar{\mathbf{A}}$ by removing $\bar{\mathbf{A}}_1$ and a submatrix $\mathbf{A}_0$ of $\mathbf{A}$ by removing $\mathbf{A}_{j_0}$. Since for every vector $\mathbf{x}$, $\omega'(\mathbf{x}^H\bar{\mathbf{A}}_1) = \omega'(\mathbf{x}^H\mathbf{A}_{j_0})$ and, on the other hand, $\omega'(\mathbf{x}^H\mathbf{A}) \leqslant \omega'(\mathbf{x}^H\bar{\mathbf{A}})$ generically, we also have $\omega'(\mathbf{x}^H\mathbf{A}_0) \leqslant \omega'(\mathbf{x}^H\bar{\mathbf{A}}_0)$ generically. That is, $\mathbf{A}_0$ and $\bar{\mathbf{A}}_0$ satisfy the condition in the lemma, but they consist of only K submatrices. From the induction step we then have that $\bar{\mathbf{A}} = \mathbf{A} \cdot \mathbf{\Pi} \cdot \mathbf{\Lambda}$. This completes the proof. ∎

As mentioned above, the condition in Lemma 2.6 can be relaxed to the one in the equivalence lemma for partitioned matrices.

LEMMA 2.7. *Consider $\bar{\mathbf{A}}, \mathbf{A} \in \mathbb{K}^{I \times L}$, partitioned in the same but not necessarily uniform way into R submatrices that are full column rank. The following two statements are equivalent*:

(i) *For every $\mu \leqslant R$ there holds that for a generic vector $\mathbf{x}$ such that $\omega'(\mathbf{x}^H\bar{\mathbf{A}}) \leqslant \mu$, we have $\omega'(\mathbf{x}^H\mathbf{A}) \leqslant \omega'(\mathbf{x}^H\bar{\mathbf{A}})$.*

(ii) *For every $\mu \leqslant R - k'_{\bar{\mathbf{A}}} + 1$ there holds that for a generic vector $\mathbf{x}$ such that $\omega'(\mathbf{x}^H\bar{\mathbf{A}}) \leqslant \mu$, we have $\omega'(\mathbf{x}^H\mathbf{A}) \leqslant \omega'(\mathbf{x}^H\bar{\mathbf{A}})$.*

Proof. The implication of (ii) from (i) is trivial. The implication of (i) from (ii) is proved by contradiction.

Suppose there exists a nonzero vector $\mathbf{x}_0$ such that $\omega'(\mathbf{x}_0^H\mathbf{A}) > \omega'(\mathbf{x}_0^H\bar{\mathbf{A}})$ while $\omega'(\mathbf{x}_0^H\bar{\mathbf{A}}) > R - k'_{\bar{\mathbf{A}}} + 1$. Suppose that $\omega'(\mathbf{x}_0^H\bar{\mathbf{A}})$ is the smallest number bigger than $R - k'_{\bar{\mathbf{A}}} + 1$ for which (ii) does not hold, i.e., suppose that for every $\mu < \omega'(\mathbf{x}_0^H\bar{\mathbf{A}})$ there holds that for a generic vector $\mathbf{x}$ such that $\omega'(\mathbf{x}^H\bar{\mathbf{A}}) \leqslant \mu$, we have $\omega'(\mathbf{x}^H\mathbf{A}) \leqslant \omega'(\mathbf{x}^H\bar{\mathbf{A}})$. We can write

$$\omega'(\mathbf{x}_0^H\bar{\mathbf{A}}) = R - k'_{\bar{\mathbf{A}}} + \alpha \tag{2.2}$$

with $2 \leqslant \alpha < k'_{\bar{\mathbf{A}}}$ and

$$\omega'(\mathbf{x}_0^H \mathbf{A}) = R - k'_{\bar{\mathbf{A}}} + \alpha + \beta \tag{2.3}$$

with $1 \leqslant \beta < k'_{\bar{\mathbf{A}}} - \alpha$. Associated with $\mathbf{x}_0$, we have $k'_{\bar{\mathbf{A}}} - \alpha$ submatrices of $\bar{\mathbf{A}}$, say, $\bar{\mathbf{A}}_1, \ldots, \bar{\mathbf{A}}_{k'_{\bar{\mathbf{A}}}-\alpha}$, and $k'_{\bar{\mathbf{A}}} - \alpha - \beta$ submatrices of $\mathbf{A}$, say, $\mathbf{A}_1, \ldots, \mathbf{A}_{k'_{\bar{\mathbf{A}}}-\alpha-\beta}$, such that

$$\mathbf{x}_0 \in \operatorname{null}([\bar{\mathbf{A}}_1 \ \ldots \ \bar{\mathbf{A}}_{k'_{\bar{\mathbf{A}}}-\alpha}]) \cap \operatorname{null}([\mathbf{A}_1 \ \ldots \ \mathbf{A}_{k'_{\bar{\mathbf{A}}}-\alpha-\beta}]).$$

$\mathbf{A}_1, \ldots, \mathbf{A}_{k'_{\bar{\mathbf{A}}}-\alpha-\beta}$ are the only submatrices of $\mathbf{A}$ of which the column space can possibly be contained in $\operatorname{span}([\bar{\mathbf{A}}_1 \ \ldots \ \bar{\mathbf{A}}_{k'_{\bar{\mathbf{A}}}-\alpha}])$. Otherwise, if there is one more submatrix, say, $\mathbf{A}_R$, of which the column space is contained in $\operatorname{span}([\bar{\mathbf{A}}_1 \ \ldots \ \bar{\mathbf{A}}_{k'_{\bar{\mathbf{A}}}-\alpha}])$, then $\mathbf{x}_0^H \mathbf{A}_R = \mathbf{0}$ such that $\omega'(\mathbf{x}_0^H \mathbf{A}) = R - k'_{\bar{\mathbf{A}}} + \alpha + \beta - 1$, which contradicts (2.3).

Recall that by definition of $\omega'(\mathbf{x}_0^H \bar{\mathbf{A}})$ for every $\mu \leqslant R - k'_{\bar{\mathbf{A}}} + \alpha - 1 < \omega'(\mathbf{x}_0^H \bar{\mathbf{A}})$ there holds that for generic $\mathbf{x}$ such that $\omega'(\mathbf{x}^H \bar{\mathbf{A}}) \leqslant \mu$, we have $\omega'(\mathbf{x}^H \mathbf{A}) \leqslant \omega'(\mathbf{x}^H \bar{\mathbf{A}})$. Similar to Lemma 2.5, we can show that this implies that for every set of $c \geqslant k'_{\bar{\mathbf{A}}} - \alpha + 1$ submatrices of $\bar{\mathbf{A}}$, there exists a set of at least c submatrices of $\mathbf{A}$ such that span(matrix formed by these $c \geqslant k'_{\bar{\mathbf{A}}} - \alpha + 1$ submatrices of $\bar{\mathbf{A}}$) $\supseteq$ span(matrix formed by the c or more submatrices of $\mathbf{A}$).

Now we consider the matrices $[\bar{\mathbf{A}}_1 \ \ldots \ \bar{\mathbf{A}}_{k'_{\bar{\mathbf{A}}}-\alpha}]$ and $[\bar{\mathbf{A}}_1 \ \ldots \ \bar{\mathbf{A}}_{k'_{\bar{\mathbf{A}}}-\alpha} \ \bar{\mathbf{A}}_i]$, $i = k'_{\bar{\mathbf{A}}} - \alpha + 1, \ldots, R$. For each of these matrices we consider the submatrices of $\mathbf{A}$ of which the column space is contained in the column space of the given matrix.

First, recall that $\mathbf{A}_1, \ldots, \mathbf{A}_{k'_{\bar{\mathbf{A}}}-\alpha-\beta}$ are the only submatrices of $\mathbf{A}$ of which the column space is contained in $\operatorname{span}([\bar{\mathbf{A}}_1 \ \ldots \ \bar{\mathbf{A}}_{k'_{\bar{\mathbf{A}}}-\alpha}])$. Next, since $[\bar{\mathbf{A}}_1 \ \ldots \ \bar{\mathbf{A}}_{k'_{\bar{\mathbf{A}}}-\alpha} \ \bar{\mathbf{A}}_i]$ consists of $k'_{\bar{\mathbf{A}}} - \alpha + 1$ submatrices of $\bar{\mathbf{A}}$, there exist at least $k'_{\bar{\mathbf{A}}} - \alpha + 1$ submatrices $\mathbf{A}_{i_1}, \ldots, \mathbf{A}_{i_{k'_{\bar{\mathbf{A}}}-\alpha+1}}$ such that $\operatorname{span}([\bar{\mathbf{A}}_1 \ \ldots \ \bar{\mathbf{A}}_{k'_{\bar{\mathbf{A}}}-\alpha} \ \bar{\mathbf{A}}_i]) \supseteq \operatorname{span}([\mathbf{A}_{i_1} \ \ldots \ \mathbf{A}_{i_{k'_{\bar{\mathbf{A}}}-\alpha+1}}])$. Combining these results, we conclude that at least $\beta+1 = (k'_{\bar{\mathbf{A}}}-\alpha+1)-(k'_{\bar{\mathbf{A}}}-\alpha-\beta)$ submatrices of $[\mathbf{A}_{i_1} \ \ldots \ \mathbf{A}_{i_{k'_{\bar{\mathbf{A}}}-\alpha+1}}]$, other than $\mathbf{A}_1, \ldots, \mathbf{A}_{k'_{\bar{\mathbf{A}}}-\alpha-\beta}$, have a column space that is in the span of $[\bar{\mathbf{A}}_1 \ \ldots \ \bar{\mathbf{A}}_{k'_{\bar{\mathbf{A}}}-\alpha} \ \bar{\mathbf{A}}_i]$. Denote by ϕ_i the set of those $\beta+1$ or more submatrices of $[\mathbf{A}_{i_1} \ \ldots \ \mathbf{A}_{i_{k'_{\bar{\mathbf{A}}}-\alpha+1}}]$.

We prove that every two ϕ_i and ϕ_j are disjoint for $i \neq j$. Assume that a certain submatrix, say, $\mathbf{A}_j^i$, belongs to both ϕ_i and ϕ_j; then there exist matrices $\mathbf{X}$ and $\mathbf{Y}$ such that

$$\mathbf{A}_j^i = [\bar{\mathbf{A}}_1 \ \ldots \ \bar{\mathbf{A}}_{k'_{\bar{\mathbf{A}}}-\alpha} \bar{\mathbf{A}}_i] \cdot \mathbf{X} = [\bar{\mathbf{A}}_1 \ \ldots \ \bar{\mathbf{A}}_{k'_{\bar{\mathbf{A}}}-\alpha} \bar{\mathbf{A}}_j] \cdot \mathbf{Y}.$$

This, in turn, implies that there exists a matrix $\mathbf{Z}$ such that

$$[\bar{\mathbf{A}}_1 \ \ldots \ \bar{\mathbf{A}}_{k'_{\bar{\mathbf{A}}}-\alpha} \ \bar{\mathbf{A}}_i \ \bar{\mathbf{A}}_j] \cdot \mathbf{Z} = \mathbf{0}.$$

This is in contradiction with the definition of $k'_{\bar{\mathbf{A}}}$ and the fact that $\alpha \geqslant 2$.

Let us now count the number of submatrices of $\mathbf{A}$ in the above disjoint sets. In $\{\mathbf{A}_1, \ldots, \mathbf{A}_{k'_{\bar{\mathbf{A}}}-\alpha-\beta}\}$, there are $k'_{\bar{\mathbf{A}}} - \alpha - \beta$ submatrices. In each set ϕ_i there are at least $\beta + 1$ submatrices, and we have $R - k'_{\bar{\mathbf{A}}} + \alpha$ such ϕ_i. Therefore, the total number of submatrices of $\mathbf{A}$ from all disjoint sets is at least

$$k'_{\bar{\mathbf{A}}} - \alpha - \beta + (\beta + 1)(R - k'_{\bar{\mathbf{A}}} + \alpha) = \beta(R - k'_{\bar{\mathbf{A}}}) + R + (\alpha - 1)\beta,$$

which is strictly greater than R for $\alpha \geqslant 2$ and $\beta \geqslant 1$. Obviously, $\mathbf{A}$ has only R submatrices, so we have a contradiction. ∎

3. Rank and k'-rank of Khatri–Rao products of partitioned matrices. In our analysis of the uniqueness of block decompositions [3], we make use of additional lemmas, besides the equivalence lemma for partitioned matrices, that establish certain Khatri–Rao products of partitioned matrices are full column rank. These are derived in the present section.

We start from a lemma that gives a lower-bound on the k-rank of a columnwise Khatri–Rao product. This lemma is proved in [8]. A shorter proof is given in [9, 10]. We give yet another proof, which is easier to generalize to Khatri–Rao products of arbitrarily partitioned matrices.

LEMMA 3.1. *Consider matrices* $\mathbf{A} \in \mathbb{K}^{I \times R}$ *and* $\mathbf{B} \in \mathbb{K}^{J \times R}$.

(i) *If* $k_{\mathbf{A}} = 0$ *or* $k_{\mathbf{B}} = 0$, *then* $k_{\mathbf{A} \odot_c \mathbf{B}} = 0$.

(ii) *If* $k_{\mathbf{A}} \geqslant 1$ *and* $k_{\mathbf{B}} \geqslant 1$, *then* $k_{\mathbf{A} \odot_c \mathbf{B}} \geqslant \min(k_{\mathbf{A}} + k_{\mathbf{B}} - 1, R)$.

Proof. First, we prove (i). If $k_{\mathbf{A}} = 0$, then $\mathbf{A}$ has an all-zero column. Consequently, $\mathbf{A} \odot_c \mathbf{B}$ also has an all-zero column and $k_{\mathbf{A} \odot_c \mathbf{B}} = 0$. The same holds if $k_{\mathbf{B}} = 0$. This completes the proof of (i).

Next, we prove (ii). Suppose $k_{\mathbf{A}} \geqslant 1$ and $k_{\mathbf{B}} \geqslant 1$. Let $m = \min(k_{\mathbf{A}} + k_{\mathbf{B}} - 1, R)$. We have to prove that any set of m columns of $\mathbf{A} \odot_c \mathbf{B}$ is linearly independent. Without loss of generality we prove that this is the case for the first m columns of $\mathbf{A} \odot_c \mathbf{B}$. (Another set of m columns can first be permuted to the first positions. This does not change the k-rank. We can then continue as below.) Let $\mathbf{A}_f = [\mathbf{a}_1 \dots \mathbf{a}_m]$, $\mathbf{B}_f = [\mathbf{b}_1 \dots \mathbf{b}_m]$, $\mathbf{A}_g = [\mathbf{a}_1 \dots \mathbf{a}_{k_{\mathbf{A}}}]$, $\mathbf{B}_g = [\mathbf{b}_{m-k_{\mathbf{B}}+1} \dots \mathbf{b}_m]$. Suppose $\mathbf{U} = (\mathbf{S}\mathbf{A}_f) \odot_c (\mathbf{T}\mathbf{B}_f) = (\mathbf{S} \otimes \mathbf{T})(\mathbf{A}_f \odot_c \mathbf{B}_f)$, where $\mathbf{S} \otimes \mathbf{T}$ is nonsingular if both $\mathbf{S}$ and $\mathbf{T}$ are nonsingular. Premultiplying a matrix by a nonsingular matrix does not change its rank nor its k-rank. Hence the rank of $\mathbf{U}$ is equal to the rank of $\mathbf{A}_f \odot_c \mathbf{B}_f$ if $\mathbf{S}$ and $\mathbf{T}$ are nonsingular. The same holds for the k-rank. We choose $\mathbf{S}$ and $\mathbf{T}$ in the following way:

$$\mathbf{S} = \begin{pmatrix} \mathbf{A}_g^{\dagger} \\ \mathbf{A}_g^{\dagger,\perp} \end{pmatrix} \quad \mathbf{T} = \begin{pmatrix} \mathbf{B}_g^{\dagger} \\ \mathbf{B}_g^{\dagger,\perp} \end{pmatrix} \tag{3.1}$$

in which $\mathbf{A}_g^{\dagger,\perp}$ is an (arbitrary) $((I - k_{\mathbf{A}}) \times I)$ matrix such that $\operatorname{span}[(\mathbf{A}_g^{\dagger,\perp})^T] = \operatorname{null}(\mathbf{A}_g)$, and in which $\mathbf{B}_g^{\dagger,\perp}$ is an (arbitrary) $((J - k_{\mathbf{B}}) \times J)$ matrix such that $\operatorname{span}[(\mathbf{B}_g^{\dagger,\perp})^T] = \operatorname{null}(\mathbf{B}_g)$. If we choose $\mathbf{S}$ and $\mathbf{T}$ this way, $\mathbf{U}$ has a very special structure.

Let us first illustrate this with an example. Assume a matrix $\mathbf{A} \in \mathbb{K}^{2 \times 4}$ with $k_{\mathbf{A}} = 2$ and a matrix $\mathbf{B} \in \mathbb{K}^{3 \times 4}$ with $k_{\mathbf{B}} = 3$. Then we have $\mathbf{A}_f = \mathbf{A}$, $\mathbf{B}_f = \mathbf{B}$, $k_{\mathbf{A}_f} = k_{\mathbf{A}}$ and $k_{\mathbf{B}_f} = k_{\mathbf{B}}$. We now have

$$\tilde{\mathbf{A}} = \mathbf{S} \cdot \mathbf{A}_f = \begin{pmatrix} 1 & 0 & \tilde{a}_{13} & \tilde{a}_{14} \\ 0 & 1 & \tilde{a}_{23} & \tilde{a}_{24} \end{pmatrix},$$

$$\tilde{\mathbf{B}} = \mathbf{T} \cdot \mathbf{B}_f = \begin{pmatrix} \tilde{b}_{11} & 1 & 0 & 0 \\ \tilde{b}_{21} & 0 & 1 & 0 \\ \tilde{b}_{31} & 0 & 0 & 1 \end{pmatrix},$$

$$\mathbf{U} = \tilde{\mathbf{A}} \odot_c \tilde{\mathbf{B}} = \begin{pmatrix} \tilde{b}_{11} & 0 & 0 & 0 \\ \tilde{b}_{21} & 0 & \tilde{a}_{13} & 0 \\ \tilde{b}_{31} & 0 & 0 & \tilde{a}_{14} \\ 0 & 1 & 0 & 0 \\ 0 & 0 & \tilde{a}_{23} & 0 \\ 0 & 0 & 0 & \tilde{a}_{24} \end{pmatrix}.$$

Note that neither $\tilde{a}_{23}$ nor $\tilde{a}_{24}$ can be equal to zero, otherwise $k_{\tilde{\mathbf{A}}} < 2 = k_{\mathbf{A}_f}$ while $\mathbf{S}$ is nonsingular. On the other hand, $[\tilde{b}_{11}\ \tilde{b}_{21}\ \tilde{b}_{31}]$ cannot be equal to $[0\ 0\ 0]$, otherwise $k_{\tilde{\mathbf{B}}} = 0 < 3 = k_{\mathbf{B}_f}$ while $\mathbf{T}$ is nonsingular. We conclude that $\mathbf{U}$ is full column rank. Since $\mathbf{S}$ and $\mathbf{T}$ are nonsingular, $\mathbf{A}_f \odot_c \mathbf{B}_f$ is also full column rank.

In general, we have

$$\tilde{\mathbf{A}} = \mathbf{S} \cdot \mathbf{A}_f = \begin{pmatrix} \overbrace{\mathbf{I}_{k_\mathbf{A} \times k_\mathbf{A}}}^{k_\mathbf{A}} & \overbrace{\tilde{\mathbf{A}}(1 : k_\mathbf{A}, k_\mathbf{A} + 1 : m)}^{m - k_\mathbf{A}} \\ \mathbf{0}_{(I - k_\mathbf{A}) \times k_\mathbf{A}} & \tilde{\mathbf{A}}(1 + k_\mathbf{A} : I, k_\mathbf{A} + 1 : m) \end{pmatrix},$$

$$\tilde{\mathbf{B}} = \mathbf{T} \cdot \mathbf{B}_f = \begin{pmatrix} \underbrace{\tilde{\mathbf{B}}(1 : k_\mathbf{B}, 1 : m - k_\mathbf{B})}_{m - k_\mathbf{B}} & \underbrace{\mathbf{I}_{k_\mathbf{B} \times k_\mathbf{B}}}_{k_\mathbf{B}} \\ \tilde{\mathbf{B}}(k_\mathbf{B} + 1 : J, 1 : m - k_\mathbf{B}) & \mathbf{0}_{(J - k_\mathbf{B}) \times k_\mathbf{B}} \end{pmatrix}.$$

Key to understanding the structure of $\mathbf{U} = \tilde{\mathbf{A}} \odot_c \tilde{\mathbf{B}}$ is the specific form of the first $k_\mathbf{A}$ columns of $\tilde{\mathbf{A}}$ and the last $k_\mathbf{B}$ columns of $\tilde{\mathbf{B}}$, together with the fact that by definition of m, $m - k_\mathbf{B} < k_\mathbf{A}$ and $m - k_\mathbf{A} < k_\mathbf{B}$. This structure neatly generalizes the structure in the example above. The first $m - k_\mathbf{B}$ columns of $\mathbf{U}$ form a block-diagonal matrix, containing the first $m - k_\mathbf{B}$ columns of $\tilde{\mathbf{B}}$ in the diagonal blocks and zeros below. Each of the next $R - 2m + k_\mathbf{A} + k_\mathbf{B}$ columns of $\mathbf{U}$ is all-zero, except for a single 1 that is also the only nonzero entry of its row. The last $m - k_\mathbf{A}$ columns of $\mathbf{U}$ contain the corresponding entries of $\tilde{\mathbf{A}}(k_\mathbf{A} : I, k_\mathbf{A} + 1 : m)$ in rows where they form the only nonzero entries. The columns of $\tilde{\mathbf{A}}(k_\mathbf{A} : I, k_\mathbf{A} + 1 : m)$ cannot be all-zero. Suppose by contradiction that the nth column of $\tilde{\mathbf{A}}(k_\mathbf{A} : I, k_\mathbf{A} + 1 : m)$ is all-zero. Then the first $k_\mathbf{A} - 1$ columns of $\tilde{\mathbf{A}}$, together with its $(k_\mathbf{A} + n)$th column, form a linearly dependent set. Hence, $k_{\tilde{\mathbf{A}}} < k_\mathbf{A} \leqslant k_{\mathbf{A}_f}$ while $\mathbf{S}$ is nonsingular. We have a contradiction. On the other hand, none of the first $m - k_\mathbf{B}$ columns of $\tilde{\mathbf{B}}$ can be all-zero either, otherwise $k_{\tilde{\mathbf{B}}} = 0 < k_\mathbf{B} \leqslant k_{\mathbf{B}_f}$ while $\mathbf{T}$ is nonsingular. We conclude that $\mathbf{U}$ is full column rank. Hence, $\mathbf{A}_f \odot_c \mathbf{B}_f$ is also full column rank. This completes the proof. ∎

Lemma 3.1 can be generalized to Khatri–Rao products of arbitrarily partitioned matrices as follows.

LEMMA 3.2. *Consider partitioned matrices* $\mathbf{A} = [\mathbf{A}_1\ \ldots\ \mathbf{A}_R]$ *with* $\mathbf{A}_r \in \mathbb{K}^{I \times L_r}$, $1 \leqslant r \leqslant R$, *and* $\mathbf{B} = [\mathbf{B}_1\ \ldots\ \mathbf{B}_R]$ *with* $\mathbf{B}_r \in \mathbb{K}^{J \times M_r}$, $1 \leqslant r \leqslant R$.

(i) *If* $k'_\mathbf{A} = 0$ *or* $k'_\mathbf{B} = 0$, *then* $k'_{\mathbf{A} \odot \mathbf{B}} = 0$.

(ii) *If* $k'_\mathbf{A} \geqslant 1$ *and* $k'_\mathbf{B} \geqslant 1$, *then* $k'_{\mathbf{A} \odot \mathbf{B}} \geqslant \min(k'_\mathbf{A} + k'_\mathbf{B} - 1, R)$.

Proof. We work in analogy with the proof of Lemma 3.1.

First, we prove (i). If $k'_\mathbf{A} = 0$, then $\mathbf{A}$ has a rank-deficient submatrix. Consequently, $\mathbf{A} \odot \mathbf{B}$ also has a rank-deficient submatrix and $k'_{\mathbf{A} \odot \mathbf{B}} = 0$. The same holds if $k'_\mathbf{B} = 0$. This completes the proof of (i).

Next, we prove (ii). Suppose $k'_\mathbf{A} \geqslant 1$ and $k'_\mathbf{B} \geqslant 1$. Let $m = \min(k'_\mathbf{A} + k'_\mathbf{B} - 1, R)$. We have to prove that any set of m submatrices of $\mathbf{A} \odot \mathbf{B}$ yields a linearly independent set of columns. Without loss of generality we prove that this is the case for the first m submatrices of $\mathbf{A} \odot \mathbf{B}$. Let $\mathbf{A}_f = [\mathbf{A}_1 \ldots \mathbf{A}_m]$, $\mathbf{B}_f = [\mathbf{B}_1 \ldots \mathbf{B}_m]$, $\mathbf{A}_g = [\mathbf{A}_1 \ldots \mathbf{A}_{k'_\mathbf{A}}]$, $\mathbf{B}_g = [\mathbf{B}_{m - k'_\mathbf{B} + 1} \ldots \mathbf{B}_m]$. Suppose $\mathbf{U} = (\mathbf{S}\mathbf{A}_f) \odot (\mathbf{T}\mathbf{B}_f) = (\mathbf{S} \otimes \mathbf{T})(\mathbf{A}_f \odot \mathbf{B}_f)$. Hence the rank of $\mathbf{U}$ is equal to the rank of $\mathbf{A}_f \odot \mathbf{B}_f$ if $\mathbf{S}$ and $\mathbf{T}$ are nonsingular. The same holds for the k'-rank. We choose $\mathbf{S}$ and $\mathbf{T}$ as in (3.1). Let $\tilde{\mathbf{A}} = \mathbf{S} \cdot \mathbf{A}_f$ and $\tilde{\mathbf{B}} = \mathbf{T} \cdot \mathbf{B}_f$. The structure of $\mathbf{U}$ allows for a similar reasoning as in Lemma 3.1.

Let us first illustrate this with an example. Assume a matrix $\mathbf{A} \in \mathbb{K}^{4\times 6}$, consisting of 3 (4×2) submatrices, with $k'_{\mathbf{A}} = 2$, and a matrix $\mathbf{B} \in \mathbb{K}^{4\times 6}$, also consisting of three (4×2) submatrices, with $k'_{\mathbf{B}} = 2$. Then we have $\mathbf{A}_f = \mathbf{A}$, $\mathbf{B}_f = \mathbf{B}$, $k'_{\mathbf{A}_f} = k'_{\mathbf{A}}$, and $k'_{\mathbf{B}_f} = k'_{\mathbf{B}}$. We now have

$$\tilde{\mathbf{A}} = \mathbf{S} \cdot \mathbf{A}_f = \left(\begin{array}{cc|cc|cc} 1 & & & & \tilde{a}_{15} & \tilde{a}_{16} \\ & 1 & & & \tilde{a}_{25} & \tilde{a}_{26} \\ \hline & & 1 & & \tilde{a}_{35} & \tilde{a}_{36} \\ & & & 1 & \tilde{a}_{45} & \tilde{a}_{46} \end{array}\right),$$

$$\tilde{\mathbf{B}} = \mathbf{T} \cdot \mathbf{B}_f = \left(\begin{array}{cc|cc|cc} \tilde{b}_{11} & \tilde{b}_{12} & 1 & & & \\ \tilde{b}_{21} & \tilde{b}_{21} & & 1 & & \\ \tilde{b}_{31} & \tilde{b}_{31} & & & 1 & \\ \tilde{b}_{41} & \tilde{b}_{41} & & & & 1 \end{array}\right),$$

$$\mathbf{U} = \tilde{\mathbf{A}} \odot \tilde{\mathbf{B}} = \left(\begin{array}{cc|cc|cc|cccc} \tilde{b}_{11} & \tilde{b}_{12} & & & & & \tilde{a}_{15} & & \tilde{a}_{16} & \\ \tilde{b}_{21} & \tilde{b}_{22} & & & & & & \tilde{a}_{15} & & \tilde{a}_{16} \\ \tilde{b}_{31} & \tilde{b}_{32} & & & & & \tilde{a}_{25} & & \tilde{a}_{26} & \\ \tilde{b}_{41} & \tilde{b}_{42} & & & & & & \tilde{a}_{25} & & \tilde{a}_{26} \\ \hline & & \tilde{b}_{11} & \tilde{b}_{12} & & & \tilde{a}_{35} & & \tilde{a}_{36} & \\ & & \tilde{b}_{21} & \tilde{b}_{22} & & & & \tilde{a}_{35} & & \tilde{a}_{36} \\ & & \tilde{b}_{31} & \tilde{b}_{32} & & & \tilde{a}_{45} & & \tilde{a}_{46} & \\ & & \tilde{b}_{41} & \tilde{b}_{42} & & & & \tilde{a}_{45} & & \tilde{a}_{46} \\ \hline & & & & 1 & & & & & \\ & & & & & 1 & & & & \\ & & & & & & 1 & & & \\ & & & & & & & 1 & & \\ & & & & & & & & & \\ & & & & & & & & & \\ & & & & & & & & & \\ & & & & & & & & & \end{array}\right).$$

Note that $\tilde{\mathbf{A}}(3:4, 5:6)$ cannot be rank-deficient, otherwise $k'_{\tilde{\mathbf{A}}} < 2 = k'_{\mathbf{A}_f}$ while $\mathbf{S}$ is nonsingular. On the other hand, $\tilde{\mathbf{B}}(:, 1:2)$ cannot be rank-deficient, otherwise $k'_{\tilde{\mathbf{B}}} = 0 < 2 = k'_{\mathbf{B}_f}$ while $\mathbf{T}$ is nonsingular. We conclude that $\mathbf{U}$ is full column rank.

In general, the structure of $\mathbf{U}$ is as follows. Its leftmost $m - k'_{\mathbf{B}}$ submatrices form a block-diagonal matrix. The matrices in the diagonal blocks can be rank-deficient only if the corresponding submatrix of $\tilde{\mathbf{B}}$ is rank-deficient. This would imply that $k'_{\tilde{\mathbf{B}}} = 0 < k'_{\mathbf{B}_f}$ while $\mathbf{T}$ is nonsingular. Each column of the next $R - 2m + k'_{\mathbf{A}} + k'_{\mathbf{B}}$ submatrices of $\mathbf{U}$ is all-zero except for a single 1 that is also the only nonzero entry of its row. Consider the partitioning $\tilde{\mathbf{A}}(\sum_{r=1}^{k'_{\mathbf{A}}-1} L_r + 1 : I, \sum_{r=1}^{k'_{\mathbf{A}}} L_r + 1 : \sum_{r=1}^{m} L_r) = [\bar{\mathbf{A}}_{k'_{\mathbf{A}}+1} \dots \bar{\mathbf{A}}_m]$. The matrices $\bar{\mathbf{A}}_{k'_{\mathbf{A}}+1}, \dots, \bar{\mathbf{A}}_m$ can be rank-deficient only if $k'_{\tilde{\mathbf{A}}} < k'_{\mathbf{A}_f}$ while $\mathbf{S}$ is nonsingular. These matrices yield additional independent columns in $\mathbf{U}$. We conclude that $\mathbf{U}$ is full column rank. Hence, $\mathbf{A}_f \odot \mathbf{B}_f$ is full column rank. This completes the proof. □

Lemma 3.2 is a first tool that will be used in [3] to make sure that certain Khatri–Rao products of partitioned matrices are full column rank. Next, we generalize Lemma 2.2 in [2], saying that a columnwise Khatri–Rao product is generically full column rank, to Khatri–Rao products of arbitrarily partitioned matrices.

LEMMA 3.3. *Consider partitioned matrices* $\mathbf{A} = [\mathbf{A}_1 \ \ldots \ \mathbf{A}_R]$ *with* $\mathbf{A}_r \in \mathbb{K}^{I \times L_r}$, $1 \leqslant r \leqslant R$, *and* $\mathbf{B} = [\mathbf{B}_1 \ \ldots \ \mathbf{B}_R]$ *with* $\mathbf{B}_r \in \mathbb{K}^{J \times M_r}$, $1 \leqslant r \leqslant R$. *Generically we have that* $\operatorname{rank}(\mathbf{A} \odot \mathbf{B}) = \min(IJ, \sum_{r=1}^{R} L_r M_r)$.

Proof. We prove the theorem by induction on R.

For $R = 1$, $\mathbf{A}_1$ and $\mathbf{B}_1$ are generically nonsingular. Hence, $\mathbf{A} \odot \mathbf{B} = \mathbf{A}_1 \otimes \mathbf{B}_1$ is generically nonsingular.

Now assume that the lemma holds for $R = 1, 2, \ldots, \tilde{R} - 1$. Then we prove that it also holds for $R = \tilde{R}$. Assume that $IJ \geqslant \sum_{r=1}^{\tilde{R}} L_r M_r$. A similar reasoning applies when $IJ > \sum_{r=1}^{\tilde{R}-1} L_r M_r$ but $IJ < \sum_{r=1}^{\tilde{R}} L_r M_r$. Let the columns of $\mathbf{A}_{\tilde{R}}^{\perp}$ form a basis for $\operatorname{null}(\mathbf{A}_{\tilde{R}})$ and let the columns of $\mathbf{B}_{\tilde{R}}^{\perp}$ form a basis for $\operatorname{null}(\mathbf{B}_{\tilde{R}})$. Define $\tilde{\mathbf{A}} = [\mathbf{A}_{\tilde{R}} \ \mathbf{A}_{\tilde{R}}^{\perp}]$ and $\tilde{\mathbf{B}} = [\mathbf{B}_{\tilde{R}} \ \mathbf{B}_{\tilde{R}}^{\perp}]$. Generically, $\mathbf{A}_{\tilde{R}}$ and $\mathbf{B}_{\tilde{R}}$ are full column rank. Hence, $\tilde{\mathbf{A}}$, $\tilde{\mathbf{B}}$, and $\tilde{\mathbf{A}} \otimes \tilde{\mathbf{B}}$ are also generically full column rank. Now replace the columns of $\mathbf{A}_{\tilde{R}} \otimes \mathbf{B}_{\tilde{R}}$ in $\tilde{\mathbf{A}} \otimes \tilde{\mathbf{B}}$ by random vectors $\mathbf{v}_j \in \mathbb{K}^{IJ}$, $j = 1, \ldots, L_{\tilde{R}} M_{\tilde{R}}$. Call the resulting matrix $\mathbf{C}$ and define $\mathbf{V} = [\mathbf{v}_1 \ \ldots \ \mathbf{v}_{L_{\tilde{R}} M_{\tilde{R}}}]$. For $\mathbf{C}$ to be rank deficient, a nontrivial linear combination of the columns of $[\mathbf{A}_{\tilde{R}}^{\perp} \otimes \mathbf{B}_{\tilde{R}} \ \ \mathbf{A}_{\tilde{R}} \otimes \mathbf{B}_{\tilde{R}}^{\perp} \ \ \mathbf{A}_{\tilde{R}}^{\perp} \otimes \mathbf{B}_{\tilde{R}}^{\perp}]$ must be in $\operatorname{span}(\mathbf{V})$. This is a probability-zero event. Turned the other way around, if $\mathbf{v}_j \in \mathbb{K}^{IJ}$, $j = 1, \ldots, L_{\tilde{R}} M_{\tilde{R}}$ are a given linearly independent set of vectors and if we randomly choose $\mathbf{A}_{\tilde{R}} \in \mathbb{K}^{I \times L_{\tilde{R}}}$ and $\mathbf{B}_{\tilde{R}} \in \mathbb{K}^{J \times M_{\tilde{R}}}$, then the associated matrix $\mathbf{C}$ is full rank with probability one. Now let the vectors $\mathbf{v}_j$ be orthogonal to $\operatorname{span}(\mathbf{A}_1 \otimes \mathbf{B}_1 \ \ldots \ \mathbf{A}_{\tilde{R}-1} \otimes \mathbf{B}_{\tilde{R}-1})$. Since the intersection of $\operatorname{span}(\mathbf{V})$ and the orthogonal complement of $\mathbf{A}_{\tilde{R}} \otimes \mathbf{B}_{\tilde{R}}$ is generically zero, $\mathbf{V}^T(\mathbf{A}_{\tilde{R}} \otimes \mathbf{B}_{\tilde{R}})$ is generically full rank. In other words, $\mathbf{A}_{\tilde{R}} \otimes \mathbf{B}_{\tilde{R}}$ adds $L_{\tilde{R}} M_{\tilde{R}}$ independent directions to $[\mathbf{A}_1 \otimes \mathbf{B}_1 \ \ldots \ \mathbf{A}_{\tilde{R}-1} \otimes \mathbf{B}_{\tilde{R}-1}]$. Hence, $[\mathbf{A}_1 \otimes \mathbf{B}_1 \ \ldots \ \mathbf{A}_{\tilde{R}} \otimes \mathbf{B}_{\tilde{R}}]$ is generically full column rank. ∎

DECOMPOSITIONS OF A HIGHER-ORDER TENSOR IN BLOCK TERMS—PART II: DEFINITIONS AND UNIQUENESS*

LIEVEN DE LATHAUWER†

Abstract. In this paper we introduce a new class of tensor decompositions. Intuitively, we decompose a given tensor block into blocks of smaller size, where the size is characterized by a set of mode-n ranks. We study different types of such decompositions. For each type we derive conditions under which essential uniqueness is guaranteed. The parallel factor decomposition and Tucker's decomposition can be considered as special cases in the new framework. The paper sheds new light on fundamental aspects of tensor algebra.

Key words. multilinear algebra, higher-order tensor, Tucker decomposition, canonical decomposition, parallel factors model

DOI. 10.1137/070690729

1. Introduction.

The two main tensor generalizations of the matrix singular value decomposition (SVD) are, on one hand, the Tucker decomposition/higher-order singular value decomposition (HOSVD) [59, 60, 12, 13, 15] and, on the other hand, the canonical/parallel factor (CANDECOMP/PARAFAC) decomposition [7, 26]. These are connected with two different tensor generalizations of the concept of matrix rank. The Tucker decomposition/HOSVD is linked with the set of mode-n ranks, which generalize column rank, row rank, etc. CANDECOMP/PARAFAC has to do with rank in the meaning of the minimal number of rank-1 terms that are needed in an expansion of the matrix/tensor. In this paper we introduce a new class of tensor SVDs, which we call block term decompositions. These lead to a framework that unifies the Tucker decomposition/HOSVD and CANDECOMP/PARAFAC. Block term decompositions also provide a unifying view on tensor rank.

We study different types of block term decompositions. For each type, we derive sufficient conditions for essential uniqueness, i.e., uniqueness up to trivial indeterminacies. We derive two types of uniqueness conditions. The first type follows from a reasoning that involves invariant subspaces associated with the tensor. This type of conditions generalizes the result on CANDECOMP/PARAFAC uniqueness that is presented in [6, 40, 47, 48]. The second type generalizes Kruskal's condition for CANDECOMP/PARAFAC uniqueness, discussed in [38, 49, 54].

In the following subsection we explain our notation and introduce some basic definitions. In subsection 1.2 we recall the Tucker decomposition/HOSVD and also the CANDECOMP/PARAFAC decomposition and summarize some of their properties.

In section 2 we define block term decompositions. We subsequently introduce decomposition in rank-$(L, L, 1)$ terms (subsection 2.1), decomposition in rank-(L, M, N) terms (subsection 2.2), and type-2 decomposition in rank-$(L, M, \cdot)$ terms (subsection 2.3). The uniqueness of these decompositions is studied in sections 4, 5, and 6, respectively. In the analysis we use some tools that have been introduced in [19]. These will briefly be recalled in section 3.

Several proofs of lemmas and theorems establishing Kruskal-type conditions for essential uniqueness of the new decompositions generalize results for PARAFAC presented in [54]. We stay quite close to the text of [54]. We recommend studying the proofs in [54] before reading this paper.

1.1. Notation and basic definitions.

1.1.1. Notation. We use $\mathbb{K}$ to denote $\mathbb{R}$ or $\mathbb{C}$ when the difference is not important. In this paper scalars are denoted by lowercase letters (a, b, ...), vectors are written in boldface lowercase ($\mathbf{a}$, $\mathbf{b}$, ...), matrices correspond to boldface capitals ($\mathbf{A}$, $\mathbf{B}$, ...), and tensors are written as calligraphic letters ($\mathcal{A}$, $\mathcal{B}$, ...). This notation is consistently used for lower-order parts of a given structure. For instance, the entry with row index i and column index j in a matrix $\mathbf{A}$, i.e., $(\mathbf{A})_{ij}$, is symbolized by a_{ij} (also $(\mathbf{a})_i = a_i$ and $(\mathcal{A})_{ijk} = a_{ijk}$). If no confusion is possible, the ith column vector of a matrix $\mathbf{A}$ is denoted as $\mathbf{a}_i$, i.e., $\mathbf{A} = [\mathbf{a}_1\ \mathbf{a}_2\ \ldots]$. Sometimes we will use the MATLAB colon notation to indicate submatrices of a given matrix or subtensors of a given tensor. Italic capitals are also used to denote index upper bounds (e.g., $i = 1, 2, \ldots, I$). The symbol $\otimes$ denotes the Kronecker product,

$$\mathbf{A} \otimes \mathbf{B} = \begin{pmatrix} a_{11}\mathbf{B} & a_{12}\mathbf{B} & \ldots \\ a_{21}\mathbf{B} & a_{22}\mathbf{B} & \ldots \\ \vdots & \vdots & \end{pmatrix}.$$

Let $\mathbf{A} = [\mathbf{A}_1\ \ldots\ \mathbf{A}_R]$ and $\mathbf{B} = [\mathbf{B}_1\ \ldots\ \mathbf{B}_R]$ be two partitioned matrices. Then the Khatri–Rao product is defined as the partitionwise Kronecker product and represented by $\odot$ [46]:

$$\mathbf{A} \odot \mathbf{B} = (\mathbf{A}_1 \otimes \mathbf{B}_1 \ldots \mathbf{A}_R \otimes \mathbf{B}_R). \tag{1.1}$$

In recent years, the term "Khatri–Rao product" and the symbol $\odot$ have been used mainly in the case where $\mathbf{A}$ and $\mathbf{B}$ are partitioned into vectors. For clarity, we denote this particular, columnwise, Khatri–Rao product by $\odot_c$:

$$\mathbf{A} \odot_c \mathbf{B} = (\mathbf{a}_1 \otimes \mathbf{b}_1 \ldots \mathbf{a}_R \otimes \mathbf{b}_R).$$

The column space of a matrix and its orthogonal complement will be denoted by $\mathrm{span}(\mathbf{A})$ and $\mathrm{null}(\mathbf{A})$. The rank of a matrix $\mathbf{A}$ will be denoted by $\mathrm{rank}(\mathbf{A})$ or $r_{\mathbf{A}}$. The superscripts $\cdot^T$, $\cdot^H$, and $\cdot^\dagger$ denote the transpose, complex conjugated transpose, and Moore–Penrose pseudoinverse, respectively. The operator $\mathrm{diag}(\cdot)$ stacks its scalar arguments in a square diagonal matrix. Analogously, $\mathrm{blockdiag}(\cdot)$ stacks its vector or matrix arguments in a block-diagonal matrix. For vectorization of a matrix $\mathbf{A} = [\mathbf{a}_1\ \mathbf{a}_2\ \ldots]$ we stick to the following convention: $\mathrm{vec}(\mathbf{A}) = [\mathbf{a}_1^T\ \mathbf{a}_2^T\ \ldots]^T$. The symbol δ_{ij} stands for the Kronecker delta, i.e., $\delta_{ij} = 1$ if $i = j$ and 0 otherwise. The $(N \times N)$ identity matrix is represented by $\mathbf{I}_{N\times N}$. The $(I \times J)$ zero matrix is denoted by $\mathbf{0}_{I\times J}$. $\mathbf{1}_N$ is a column vector of all ones of length N. The zero tensor is denoted by $\mathcal{O}$.

1.1.2. Basic definitions.

DEFINITION 1.1. *Consider* $\mathcal{T} \in \mathbb{K}^{I_1 \times I_2 \times I_3}$ *and* $\mathbf{A} \in \mathbb{K}^{J_1 \times I_1}$, $\mathbf{B} \in \mathbb{K}^{J_2 \times I_2}$, $\mathbf{C} \in \mathbb{K}^{J_3 \times I_3}$. *Then the* Tucker mode-1 product $\mathcal{T} \bullet_1 \mathbf{A}$, mode-2 product $\mathcal{T} \bullet_2 \mathbf{B}$, and mode-3 product $\mathcal{T} \bullet_3 \mathbf{C}$ *are defined by*

$$(\mathcal{T} \bullet_1 \mathbf{A})_{j_1 i_2 i_3} = \sum_{i_1=1}^{I_1} t_{i_1 i_2 i_3} a_{j_1 i_1} \qquad \forall j_1, i_2, i_3,$$

$$(\mathcal{T} \bullet_2 \mathbf{B})_{i_1 j_2 i_3} = \sum_{i_2=1}^{I_2} t_{i_1 i_2 i_3} b_{j_2 i_2} \qquad \forall i_1, j_2, i_3,$$

$$(\mathcal{T} \bullet_3 \mathbf{C})_{i_1 i_2 j_3} = \sum_{i_3=1}^{I_3} t_{i_1 i_2 i_3} c_{j_3 i_3} \qquad \forall i_1, i_2, j_3,$$

respectively [11].

In this paper we denote the Tucker mode-n product in the same way as in [10]; in the literature the symbol $\times_n$ is sometimes used [12, 13, 15].

DEFINITION 1.2. *The* Frobenius norm *of a tensor* $\mathcal{T} \in \mathbb{K}^{I \times J \times K}$ *is defined as*

$$\|\mathcal{T}\| = \left(\sum_{i=1}^{I} \sum_{j=1}^{J} \sum_{k=1}^{K} |t_{ijk}|^2 \right)^{\frac{1}{2}}.$$

DEFINITION 1.3. *The outer product* $\mathcal{A} \circ \mathcal{B}$ *of a tensor* $\mathcal{A} \in \mathbb{K}^{I_1 \times I_2 \times \cdots \times I_P}$ *and a tensor* $\mathcal{B} \in \mathbb{K}^{J_1 \times J_2 \times \cdots \times J_Q}$ *is the tensor defined by*

$$(\mathcal{A} \circ \mathcal{B})_{i_1 i_2 \ldots i_P j_1 j_2 \ldots j_Q} = a_{i_1 i_2 \ldots i_P} b_{j_1 j_2 \ldots j_Q}$$

for all values of the indices.

For instance, the outer product $\mathcal{T}$ of three vectors $\mathbf{a}$, $\mathbf{b}$, and $\mathbf{c}$ is defined by $t_{ijk} = a_i b_j c_k$ for all values of the indices.

DEFINITION 1.4. *A* mode-n vector *of a tensor* $\mathcal{T} \in \mathbb{K}^{I_1 \times I_2 \times I_3}$ *is an* I_n*-dimensional vector obtained from* $\mathcal{T}$ *by varying the index* i_n *and keeping the other indices fixed* [34].

Mode-n vectors generalize column and row vectors.

DEFINITION 1.5. *The* mode-n rank *of a tensor* $\mathcal{T}$ *is the dimension of the subspace spanned by its mode-*n *vectors.*

The mode-n rank of a higher-order tensor is the obvious generalization of the column (row) rank of a matrix.

DEFINITION 1.6. *A third-order tensor is* rank-(L, M, N) *if its mode-*1 *rank, mode-*2 *rank, and mode-*3 *rank are equal to* L, M, *and* N, *respectively.*

A rank-$(1, 1, 1)$ tensor is briefly called rank-1. This definition is equivalent to the following.

DEFINITION 1.7. *A third-order tensor* $\mathcal{T}$ *has* rank 1 *if it equals the outer product of* 3 *vectors.*

The rank (as opposed to mode-n rank) is now defined as follows.

DEFINITION 1.8. *The* rank *of a tensor* $\mathcal{T}$ *is the minimal number of rank-*1 *tensors that yield* $\mathcal{T}$ *in a linear combination* [38].

The following definition has proved useful in the analysis of PARAFAC uniqueness [38, 49, 51, 54].

DEFINITION 1.9. *The* Kruskal rank *or* k-rank *of a matrix* $\mathbf{A}$*, denoted by* $\text{rank}_k(\mathbf{A})$ *or* $k_{\mathbf{A}}$*, is the maximal number* r *such that any set of* r *columns of* $\mathbf{A}$ *is linearly independent* [38].

We call a property generic when it holds with probability one when the parameters of the problem are drawn from continuous probability density functions. Let $\mathbf{A} \in \mathbb{K}^{I\times R}$. Generically, we have $k_{\mathbf{A}} = \min(I, R)$.

It will sometimes be useful to express tensor properties in terms of matrices and vectors. We therefore define standard matrix representations of a third-order tensor.

DEFINITION 1.10. *The standard* $(JK \times I)$ *matrix representation* $(\mathcal{T})_{JK\times I} = \mathbf{T}_{JK\times I}$*,* $(KI \times J)$ *representation* $(\mathcal{T})_{KI\times J} = \mathbf{T}_{KI\times J}$*, and* $(IJ \times K)$ *representation* $(\mathcal{T})_{IJ\times K} = \mathbf{T}_{IJ\times K}$ *of a tensor* $\mathcal{T} \in \mathbb{K}^{I\times J\times K}$ *are defined by*

$$\begin{aligned}(\mathbf{T}_{JK\times I})_{(j-1)K+k,i} &= (\mathcal{T})_{ijk},\\ (\mathbf{T}_{KI\times J})_{(k-1)I+i,j} &= (\mathcal{T})_{ijk},\\ (\mathbf{T}_{IJ\times K})_{(i-1)J+j,k} &= (\mathcal{T})_{ijk}\end{aligned}$$

for all values of the indices [34].

Note that in these definitions indices to the right vary more rapidly than indices to the left. Further, the ith $(J \times K)$ matrix slice of $\mathcal{T} \in \mathbb{K}^{I\times J\times K}$ will be denoted as $\mathbf{T}_{J\times K,i}$. Similarly, the jth $(K \times I)$ slice and the kth $(I \times J)$ slice will be denoted by $\mathbf{T}_{K\times I,j}$ and $\mathbf{T}_{I\times J,k}$, respectively.

1.2. HOSVD and PARAFAC. We have now enough material to introduce the Tucker/HOSVD [12, 13, 15, 59, 60] and CANDECOMP/PARAFAC [7, 26] decompositions.

DEFINITION 1.11. *A* Tucker decomposition *of a tensor* $\mathcal{T} \in \mathbb{K}^{I\times J\times K}$ *is a decomposition of* $\mathcal{T}$ *of the form*

$$\mathcal{T} = \mathcal{D} \bullet_1 \mathbf{A} \bullet_2 \mathbf{B} \bullet_3 \mathbf{C}. \tag{1.2}$$

An HOSVD is a Tucker decomposition, normalized in a particular way. The normalization was suggested in the computational strategy in [59, 60].

DEFINITION 1.12. *An* HOSVD *of a tensor* $\mathcal{T} \in \mathbb{K}^{I\times J\times K}$ *is a decomposition of* $\mathcal{T}$ *of the form*

$$\mathcal{T} = \mathcal{D} \bullet_1 \mathbf{A} \bullet_2 \mathbf{B} \bullet_3 \mathbf{C}, \tag{1.3}$$

in which

- *the matrices* $\mathbf{A} \in \mathbb{K}^{I\times L}$*,* $\mathbf{B} \in \mathbb{K}^{J\times M}$*, and* $\mathbf{C} \in \mathbb{K}^{K\times N}$ *are columnwise orthonormal,*
- *the core tensor* $\mathcal{D} \in \mathbb{K}^{L\times M\times N}$ *is*
  - *all-orthogonal,*

$$\begin{aligned}\langle \mathbf{D}_{M\times N,l_1}, \mathbf{D}_{M\times N,l_2}\rangle = \text{trace}(\mathbf{D}_{M\times N,l_1} \cdot \mathbf{D}^H_{M\times N,l_2}) = \sigma^{(1)^2}_{l_1}\delta_{l_1,l_2},\\ 1 \leqslant l_1, l_2 \leqslant L,\\ \langle \mathbf{D}_{N\times L,m_1}, \mathbf{D}_{N\times L,m_2}\rangle = \text{trace}(\mathbf{D}_{N\times L,m_1} \cdot \mathbf{D}^H_{N\times L,m_2}) = \sigma^{(2)^2}_{m_1}\delta_{m_1,m_2},\\ 1 \leqslant m_1, m_2 \leqslant M,\\ \langle \mathbf{D}_{I\times J,n_1}, \mathbf{D}_{I\times J,n_2}\rangle = \text{trace}(\mathbf{D}_{L\times M,n_1} \cdot \mathbf{D}^H_{L\times M,n_2}) = \sigma^{(3)^2}_{n_1}\delta_{n_1,n_2},\\ 1 \leqslant n_1, n_2 \leqslant N,\end{aligned}$$

– *ordered*,

$$\sigma_1^{(1)^2} \geqslant \sigma_2^{(1)^2} \geqslant \ldots \geqslant \sigma_L^{(1)^2} \geqslant 0,$$
$$\sigma_1^{(2)^2} \geqslant \sigma_2^{(2)^2} \geqslant \ldots \geqslant \sigma_M^{(2)^2} \geqslant 0,$$
$$\sigma_1^{(3)^2} \geqslant \sigma_2^{(3)^2} \geqslant \ldots \geqslant \sigma_N^{(3)^2} \geqslant 0.$$

The decomposition is visualized in Figure 1.1.

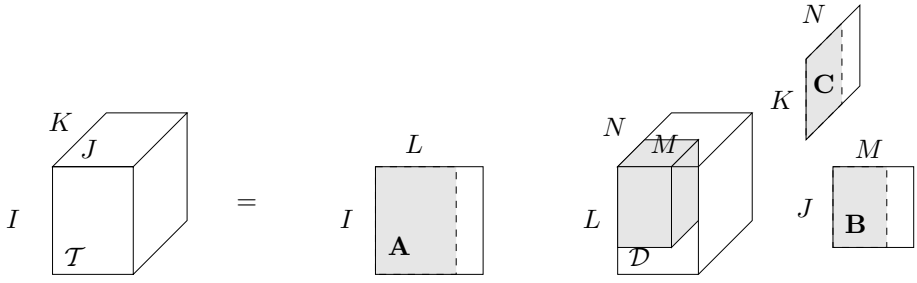

FIG. 1.1. *Visualization of the HOSVD/Tucker decomposition.*

Equation (1.3) can be written in terms of the standard $(JK \times I)$, $(KI \times J)$, and $(IJ \times K)$ matrix representations of $\mathcal{T}$ as follows:

$$\mathbf{T}_{JK\times I} = (\mathbf{B} \otimes \mathbf{C}) \cdot \mathbf{D}_{MN\times L} \cdot \mathbf{A}^T, \tag{1.4}$$

$$\mathbf{T}_{KI\times J} = (\mathbf{C} \otimes \mathbf{A}) \cdot \mathbf{D}_{NL\times M} \cdot \mathbf{B}^T, \tag{1.5}$$

$$\mathbf{T}_{IJ\times K} = (\mathbf{A} \otimes \mathbf{B}) \cdot \mathbf{D}_{LM\times N} \cdot \mathbf{C}^T. \tag{1.6}$$

The HOSVD exists for any $\mathcal{T} \in \mathbb{K}^{I\times J\times K}$. The values L, M, and N correspond to the rank of $\mathbf{T}_{JK\times I}$, $\mathbf{T}_{KI\times J}$, and $\mathbf{T}_{IJ\times K}$, i.e., they are equal to the mode-1, mode-2 and mode-3 rank of $\mathcal{T}$, respectively. In [12] it has been demonstrated that the SVD of matrices and the HOSVD of higher-order tensors have some analogous properties.

Define $\tilde{\mathcal{D}} = \mathcal{D} \bullet_3 \mathbf{C}$. Then

$$\mathcal{T} = \tilde{\mathcal{D}} \bullet_1 \mathbf{A} \bullet_2 \mathbf{B} \tag{1.7}$$

is a (normalized) *Tucker*-2 *decomposition* of $\mathcal{T}$. This decomposition is visualized in Figure 1.2.

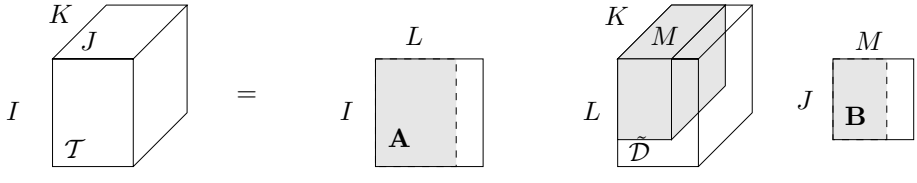

FIG. 1.2. *Visualization of the (normalized) Tucker*-2 *decomposition.*

Besides the HOSVD, there exist other ways to generalize the SVD of matrices. The most well known is CANDECOMP/PARAFAC [7, 26].

DEFINITION 1.13. *A* canonical or parallel factor decomposition (CANDECOMP/PARAFAC) *of a tensor* $\mathcal{T} \in \mathbb{K}^{I\times J\times K}$ *is a decomposition of* $\mathcal{T}$ *as a linear combination*

*of rank-*1 *terms*:

$$\mathcal{T} = \sum_{r=1}^{R} \mathbf{a}_r \circ \mathbf{b}_r \circ \mathbf{c}_r. \tag{1.8}$$

The decomposition is visualized in Figure 1.3.

In terms of the standard matrix representations of $\mathcal{T}$, decomposition (1.8) can be written as

$$\mathbf{T}_{JK\times I} = (\mathbf{B} \odot_c \mathbf{C}) \cdot \mathbf{A}^T, \tag{1.9}$$

$$\mathbf{T}_{KI\times J} = (\mathbf{C} \odot_c \mathbf{A}) \cdot \mathbf{B}^T, \tag{1.10}$$

$$\mathbf{T}_{IJ\times K} = (\mathbf{A} \odot_c \mathbf{B}) \cdot \mathbf{C}^T. \tag{1.11}$$

In terms of the $(J \times K)$, $(K \times I)$, and $(I \times J)$ matrix slices of $\mathcal{T}$, we have

$$\mathbf{T}_{J\times K,i} = \mathbf{B} \cdot \mathrm{diag}(a_{i1}, \ldots, a_{iR}) \cdot \mathbf{C}^T, \quad i = 1, \ldots, I. \tag{1.12}$$

$$\mathbf{T}_{K\times I,j} = \mathbf{C} \cdot \mathrm{diag}(b_{j1}, \ldots, b_{jR}) \cdot \mathbf{A}^T, \quad j = 1, \ldots, J. \tag{1.13}$$

$$\mathbf{T}_{I\times J,k} = \mathbf{A} \cdot \mathrm{diag}(c_{k1}, \ldots, c_{kR}) \cdot \mathbf{B}^T, \quad k = 1, \ldots, K. \tag{1.14}$$

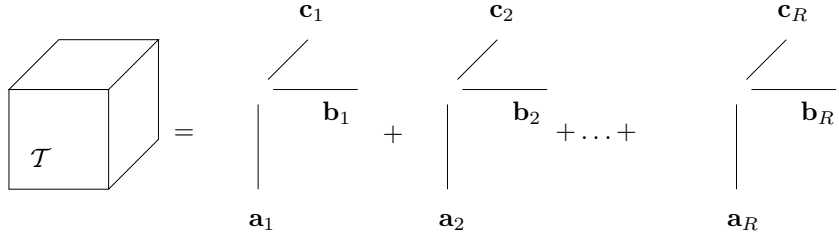

FIG. 1.3. *Visualization of the CANDECOMP/PARAFAC decomposition.*

The fully symmetric variant of PARAFAC, in which $\mathbf{a}_r = \mathbf{b}_r = \mathbf{c}_r$, $r = 1, \ldots, R$, was studied in the nineteenth century in the context of invariant theory [9]. The unsymmetric decomposition was introduced by F. L. Hitchcock in 1927 [27, 28]. Around 1970, the unsymmetric decomposition was independently reintroduced in psychometrics [7] and phonetics [26]. Later, the decomposition was applied in chemometrics and the food industry [1, 5, 53]. In these various disciplines PARAFAC is used for the purpose of multiway factor analysis. The term "canonical decomposition" is standard in psychometrics, while in chemometrics the decomposition is called a parallel factors model. PARAFAC has found important applications in signal processing and data analysis [37]. In wireless telecommunications, it provides powerful means for the exploitation of different types of diversity [49, 50, 18]. It also describes the basic structure of higher-order cumulants of multivariate data on which all algebraic methods for independent component analysis (ICA) are based [8, 14, 29]. Moreover, the decomposition is finding its way to scientific computing, where it leads to a way around the curse of dimensionality [2, 3, 24, 25, 33].

To a large extent, the practical importance of PARAFAC stems from its uniqueness properties. It is clear that one can arbitrarily permute the different rank-1 terms. Also, the factors of a same rank-1 term may be arbitrarily scaled, as long as their product remains the same. We call a PARAFAC decomposition essentially unique when it is subject only to these trivial indeterminacies. The following theorem establishes a condition under which essential uniqueness is guaranteed.

THEOREM 1.14. *The PARAFAC decomposition* (1.8) *is essentially unique if*

$$k_{\mathbf{A}} + k_{\mathbf{B}} + k_{\mathbf{C}} \geqslant 2R + 2. \tag{1.15}$$

This theorem was first proved for real tensors in [38]. A concise proof that also applies to complex tensors was given in [49]; in this proof, the permutation lemma of [38] was used. The result was generalized to tensors of arbitrary order in [51]. An alternative proof of the permutation lemma was given in [31]. The overall proof was reformulated in terms of accessible basic linear algebra in [54]. In [17] we derived a more relaxed uniqueness condition that applies when $\mathcal{T}$ is tall in one mode (meaning that, for instance, $K \geqslant R$).

2. Block term decompositions.

2.1. Decomposition in rank-$(L, L, 1)$ terms.

DEFINITION 2.1. *A* decomposition of a tensor $\mathcal{T} \in \mathbb{K}^{I \times J \times K}$ in a sum of rank-$(L, L, 1)$ terms *is a decomposition of* $\mathcal{T}$ *of the form*

$$\mathcal{T} = \sum_{r=1}^{R} \mathbf{E}_r \circ \mathbf{c}_r, \tag{2.1}$$

in which the $(I \times J)$ *matrices* $\mathbf{E}_r$ *are rank-*L.

We also consider the decomposition of a tensor in a sum of matrix-vector outer products, in which the different matrices do not necessarily all have the same rank.

DEFINITION 2.2. *A* decomposition of a tensor $\mathcal{T} \in \mathbb{K}^{I \times J \times K}$ in a sum of rank-$(L_r, L_r, 1)$ terms, $1 \leqslant r \leqslant R$, *is a decomposition of* $\mathcal{T}$ *of the form*

$$\mathcal{T} = \sum_{r=1}^{R} \mathbf{E}_r \circ \mathbf{c}_r, \tag{2.2}$$

in which the $(I \times J)$ *matrix* $\mathbf{E}_r$ *is rank-*L_r, $1 \leqslant r \leqslant R$.

If we factorize $\mathbf{E}_r$ as $\mathbf{A}_r \cdot \mathbf{B}_r^T$, in which the matrix $\mathbf{A}_r \in \mathbb{K}^{I \times L_r}$ and the matrix $\mathbf{B}_r \in \mathbb{K}^{J \times L_r}$ are rank-L_r, $r = 1, \ldots, R$, then we can write (2.2) as

$$\mathcal{T} = \sum_{r=1}^{R} (\mathbf{A}_r \cdot \mathbf{B}_r^T) \circ \mathbf{c}_r. \tag{2.3}$$

Define $\mathbf{A} = [\mathbf{A}_1 \ldots \mathbf{A}_R]$, $\mathbf{B} = [\mathbf{B}_1 \ldots \mathbf{B}_R]$, $\mathbf{C} = [\mathbf{c}_1 \ldots \mathbf{c}_R]$. In terms of the standard matrix representations of $\mathcal{T}$, (2.3) can be written as

$$\mathbf{T}_{IJ \times K} = [(\mathbf{A}_1 \odot_c \mathbf{B}_1)\mathbf{1}_{L_1} \ \ldots \ (\mathbf{A}_R \odot_c \mathbf{B}_R)\mathbf{1}_{L_R}] \cdot \mathbf{C}^T, \tag{2.4}$$

$$\mathbf{T}_{JK \times I} = (\mathbf{B} \odot \mathbf{C}) \cdot \mathbf{A}^T, \tag{2.5}$$

$$\mathbf{T}_{KI \times J} = (\mathbf{C} \odot \mathbf{A}) \cdot \mathbf{B}^T. \tag{2.6}$$

In terms of the matrix slices of $\mathcal{T}$, (2.3) can be written as

$$\mathbf{T}_{J \times K, i} = \mathbf{B} \cdot \mathrm{blockdiag}([(\mathbf{A}_1)_{i1} \ \ldots \ (\mathbf{A}_1)_{iL_1}]^T, \ldots, [(\mathbf{A}_R)_{i1} \ \ldots \ (\mathbf{A}_R)_{iL_R}]^T) \cdot \mathbf{C}^T, \quad i = 1, \ldots, I, \tag{2.7}$$

$$\mathbf{T}_{K \times I, j} = \mathbf{C} \cdot \mathrm{blockdiag}([(\mathbf{B}_1)_{j1} \ \ldots \ (\mathbf{B}_1)_{jL_1}], \ldots, [(\mathbf{B}_R)_{j1} \ \ldots \ (\mathbf{B}_R)_{jL_R}]) \cdot \mathbf{A}^T, \quad j = 1, \ldots, J, \tag{2.8}$$

$$\mathbf{T}_{I \times J, k} = \mathbf{A} \cdot \mathrm{blockdiag}(c_{k1}\mathbf{I}_{L_1 \times L_1}, \ldots, c_{kR}\mathbf{I}_{L_R \times L_R}) \cdot \mathbf{B}^T, \quad k = 1, \ldots, K. \tag{2.9}$$

It is clear that in (2.3) one can arbitrarily permute the different rank-$(L_r, L_r, 1)$ terms. Also, one can postmultiply $\mathbf{A}_r$ by any nonsingular $(L_r \times L_r)$ matrix $\mathbf{F}_r \in \mathbb{K}^{L_r \times L_r}$, provided $\mathbf{B}_r$ is premultiplied by the inverse of $\mathbf{F}_r$. Moreover, the factors of a same rank-$(L_r, L_r, 1)$ term may be arbitrarily scaled, as long as their product remains the same. We call the decomposition essentially unique when it is subject only to these trivial indeterminacies. Two representations $(\mathbf{A}, \mathbf{B}, \mathbf{C})$ and $(\bar{\mathbf{A}}, \bar{\mathbf{B}}, \bar{\mathbf{C}})$ that are the same up to trivial indeterminacies are called essentially equal. We (partially) normalize the representation of (2.2) as follows. Scale/counterscale the vectors $\mathbf{c}_r$ and the matrices $\mathbf{E}_r$ such that $\mathbf{c}_r$ are unit-norm. Further, let $\mathbf{E}_r = \mathbf{A}_r \cdot \mathbf{D}_r \cdot \mathbf{B}_r^T$ denote the SVD of $\mathbf{E}_r$. The diagonal matrix $\mathbf{D}_r$ can be interpreted as an $(L_r \times L_r \times 1)$ tensor. Then (2.2) is equivalent to

$$\mathcal{T} = \sum_{r=1}^{R} \mathbf{D}_r \bullet_1 \mathbf{A}_r \bullet_2 \mathbf{B}_r \bullet_3 \mathbf{c}_r. \tag{2.10}$$

Note that in this equation each term is represented in HOSVD form. The decomposition is visualized in Figure 2.1.

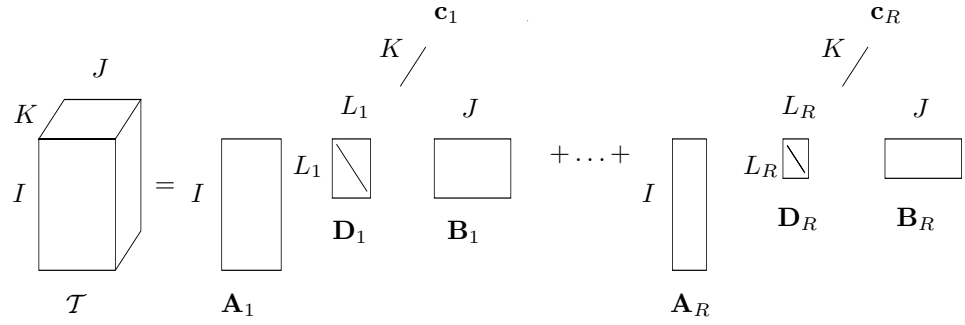

FIG. 2.1. *Visualization of the decomposition of a tensor in a sum of rank-$(L_r, L_r, 1)$ terms, $1 \leqslant r \leqslant R$.*

2.2. Decomposition in rank-(L, M, N) terms.

DEFINITION 2.3. *A* decomposition of a tensor $\mathcal{T} \in \mathbb{K}^{I \times J \times K}$ in a sum of rank-(L, M, N) terms *is a decomposition of $\mathcal{T}$ of the form*

$$\mathcal{T} = \sum_{r=1}^{R} \mathcal{D}_r \bullet_1 \mathbf{A}_r \bullet_2 \mathbf{B}_r \bullet_3 \mathbf{C}_r, \tag{2.11}$$

in which $\mathcal{D}_r \in \mathbb{K}^{L \times M \times N}$ are full rank-(L, M, N) and in which $\mathbf{A}_r \in \mathbb{K}^{I \times L}$ (with $I \geqslant L$), $\mathbf{B}_r \in \mathbb{K}^{J \times M}$ (with $J \geqslant M$), and $\mathbf{C}_r \in \mathbb{K}^{K \times N}$ (with $K \geqslant N$) are full column rank, $1 \leqslant r \leqslant R$.

Remark 1. One could also consider a decomposition in rank-(L_r, M_r, N_r) terms, where the different terms possibly have different mode-n ranks. In this paper we focus on the decomposition in rank-(L, M, N) terms.

Define partitioned matrices $\mathbf{A} = [\mathbf{A}_1 \ldots \mathbf{A}_R]$, $\mathbf{B} = [\mathbf{B}_1 \ldots \mathbf{B}_R]$, and $\mathbf{C} = [\mathbf{C}_1 \ldots \mathbf{C}_R]$. In terms of the standard matrix representations of $\mathcal{T}$, (2.11) can be written as

$$\mathbf{T}_{JK \times I} = (\mathbf{B} \odot \mathbf{C}) \cdot \text{blockdiag}((\mathcal{D}_1)_{MN \times L}, \ldots, (\mathcal{D}_R)_{MN \times L}) \cdot \mathbf{A}^T, \tag{2.12}$$

$$\mathbf{T}_{KI \times J} = (\mathbf{C} \odot \mathbf{A}) \cdot \text{blockdiag}((\mathcal{D}_1)_{NL \times M}, \ldots, (\mathcal{D}_R)_{NL \times M}) \cdot \mathbf{B}^T, \tag{2.13}$$

$$\mathbf{T}_{IJ \times K} = (\mathbf{A} \odot \mathbf{B}) \cdot \text{blockdiag}((\mathcal{D}_1)_{LM \times N}, \ldots, (\mathcal{D}_R)_{LM \times N}) \cdot \mathbf{C}^T. \tag{2.14}$$

It is clear that in (2.11) one can arbitrarily permute the different terms. Also, one can postmultiply $\mathbf{A}_r$ by a nonsingular matrix $\mathbf{F}_r \in \mathbb{K}^{L\times L}$, $\mathbf{B}_r$ by a nonsingular matrix $\mathbf{G}_r \in \mathbb{K}^{M\times M}$, and $\mathbf{C}_r$ by a nonsingular matrix $\mathbf{H}_r \in \mathbb{K}^{N\times N}$, provided $\mathcal{D}_r$ is replaced by $\mathcal{D}_r \bullet_1 \mathbf{F}_r^{-1} \bullet_2 \mathbf{G}_r^{-1} \bullet_3 \mathbf{H}_r^{-1}$. We call the decomposition essentially unique when it is subject only to these trivial indeterminacies. We can (partially) normalize (2.11) by representing each term by its HOSVD. The decomposition is visualized in Figure 2.2.

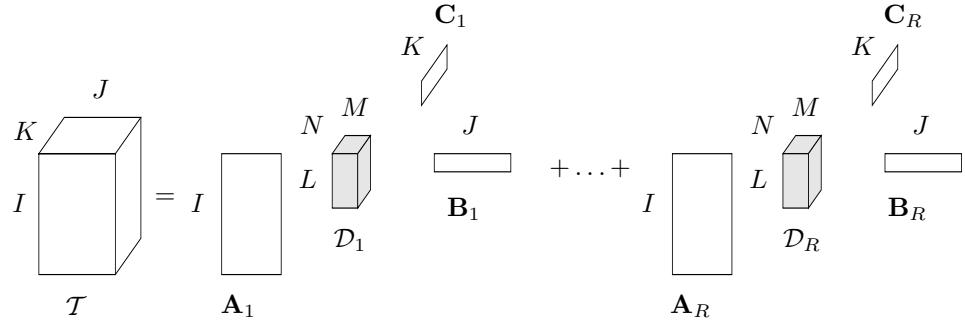

FIG. 2.2. *Visualization of the decomposition of a tensor in a sum of rank-(L, M, N) terms.*

Define $\mathcal{D} = \text{blockdiag}(\mathcal{D}_1, \ldots, \mathcal{D}_R)$. Equation (2.11) can now also be seen as the multiplication of a block-diagonal core tensor $\mathcal{D}$ by means of factor matrices $\mathbf{A}$, $\mathbf{B}$, and $\mathbf{C}$:

$$\mathcal{T} = \mathcal{D} \bullet_1 \mathbf{A} \bullet_2 \mathbf{B} \bullet_3 \mathbf{C}. \tag{2.15}$$

This alternative interpretation of the decomposition is visualized in Figure 2.3. Two representations $(\mathbf{A}, \mathbf{B}, \mathbf{C}, \mathcal{D})$ and $(\bar{\mathbf{A}}, \bar{\mathbf{B}}, \bar{\mathbf{C}}, \bar{\mathcal{D}})$ that are the same up to trivial indeterminacies are called essentially equal.

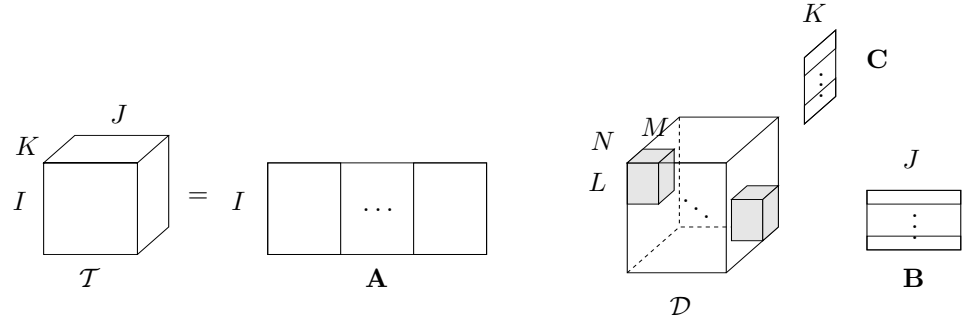

FIG. 2.3. *Interpretation of decomposition* (2.11) *in terms of the multiplication of a block-diagonal core tensor $\mathcal{D}$ by transformation matrices* **A**, **B**, *and* **C**.

2.3. Type-2 decomposition in rank-$(L, M, \cdot)$ terms.

DEFINITION 2.4. *A* type-2 decomposition of a tensor $\mathcal{T} \in \mathbb{K}^{I\times J\times K}$ in a sum of rank-$(L, M, \cdot)$ terms *is a decomposition of $\mathcal{T}$ of the form*

$$\mathcal{T} = \sum_{r=1}^{R} \mathcal{C}_r \bullet_1 \mathbf{A}_r \bullet_2 \mathbf{B}_r, \tag{2.16}$$

in which $\mathcal{C}_r \in \mathbb{K}^{L\times M\times K}$ *(with mode-*1 *rank equal to* L *and mode-*2 *rank equal to* M*) and in which* $\mathbf{A}_r \in \mathbb{K}^{I\times L}$ *(with* $I \geqslant L$*) and* $\mathbf{B}_r \in \mathbb{K}^{J\times M}$ *(with* $J \geqslant M$*) are full column rank,* $1 \leqslant r \leqslant R$*.*

Remark 2. The label "type 2" is reminiscent of the term "Tucker-2 decomposition."

Remark 3. One could also consider a type-2 decomposition in rank-$(L_r, M_r, \cdot)$ terms, where the different terms possibly have different mode-1 and/or mode-2 rank. In this paper we focus on the decomposition in rank-$(L, M, \cdot)$ terms.

Define partitioned matrices $\mathbf{A} = [\mathbf{A}_1 \dots \mathbf{A}_R]$ and $\mathbf{B} = [\mathbf{B}_1 \dots \mathbf{B}_R]$. In terms of the standard matrix representations of $\mathcal{T}$, (2.16) can be written as

$$\mathbf{T}_{IJ\times K} = (\mathbf{A} \odot \mathbf{B}) \cdot \begin{pmatrix} (\mathcal{C}_1)_{(LM\times K)} \\ \vdots \\ (\mathcal{C}_R)_{(LM\times K)} \end{pmatrix}, \tag{2.17}$$

$$\mathbf{T}_{JK\times I} = [(\mathcal{C}_1 \bullet_2 \mathbf{B}_1)_{JK\times L} \ \dots \ (\mathcal{C}_R \bullet_2 \mathbf{B}_R)_{JK\times L}] \cdot \mathbf{A}^T, \tag{2.18}$$

$$\mathbf{T}_{KI\times J} = [(\mathcal{C}_1 \bullet_1 \mathbf{A}_1)_{KI\times M} \ \dots \ (\mathcal{C}_R \bullet_1 \mathbf{A}_R)_{KI\times M}] \cdot \mathbf{B}^T. \tag{2.19}$$

Define $\mathcal{C} \in \mathbb{K}^{LR\times MR\times K}$ as an all-zero tensor, except for the entries given by

$$(\mathcal{C})_{(r-1)L+l,(r-1)M+m,k} = (\mathcal{C}_r)_{lmk} \quad \forall l, m, k, r.$$

Then (2.16) can also be written as

$$\mathcal{T} = \mathcal{C} \bullet_1 \mathbf{A} \bullet_2 \mathbf{B}.$$

It is clear that in (2.16) one can arbitrarily permute the different terms. Also, one can postmultiply $\mathbf{A}_r$ by a nonsingular matrix $\mathbf{F}_r \in \mathbb{K}^{L\times L}$ and postmultiply $\mathbf{B}_r$ by a nonsingular matrix $\mathbf{G}_r \in \mathbb{K}^{M\times M}$, provided $\mathcal{C}_r$ is replaced by $\mathcal{C}_r \bullet_1 (\mathbf{F}_r)^{-1} \bullet_2 (\mathbf{G}_r)^{-1}$. We call the decomposition essentially unique when it is subject only to these trivial indeterminacies. Two representations $(\mathbf{A}, \mathbf{B}, \mathcal{C})$ and $(\bar{\mathbf{A}}, \bar{\mathbf{B}}, \bar{\mathcal{C}})$ that are the same up to trivial indeterminacies are called essentially equal. We can (partially) normalize (2.16) by representing each term by its normalized Tucker-2 decomposition. The decomposition is visualized in Figure 2.4.

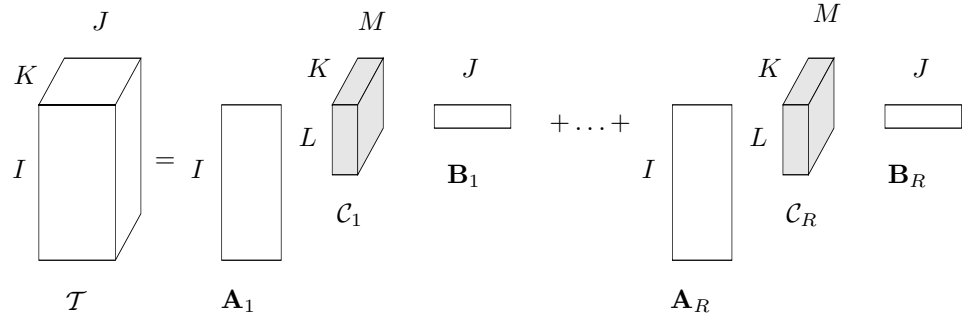

FIG. 2.4. *Visualization of the type-*2 *decomposition of a tensor in a sum of rank-*$(L, M, \cdot)$ *terms.*

3. Basic lemmas. In this section we list a number of lemmas that we will use in the analysis of the uniqueness of the block term decompositions.

Let $\omega(\mathbf{x})$ denote the number of nonzero entries of a vector $\mathbf{x}$. The following lemma was originally proposed by Kruskal in [38]. It is known as the *permutation lemma.*

It plays a crucial role in the proof of (1.15). The proof was reformulated in terms of accessible basic linear algebra in [54]. An alternative proof was given in [31]. The link between the two proofs is also discussed in [54].

LEMMA 3.1 (permutation lemma). *Consider two matrices* $\bar{\mathbf{A}}$, $\mathbf{A} \in \mathbb{K}^{I \times R}$, *that have no zero columns. If for every vector* $\mathbf{x}$ *such that* $\omega(\mathbf{x}^T\bar{\mathbf{A}}) \leqslant R - r_{\bar{\mathbf{A}}} + 1$, *we have* $\omega(\mathbf{x}^T\mathbf{A}) \leqslant \omega(\mathbf{x}^T\bar{\mathbf{A}})$, *then there exists a unique permutation matrix* $\mathbf{\Pi}$ *and a unique nonsingular diagonal matrix* $\mathbf{\Lambda}$ *such that* $\bar{\mathbf{A}} = \mathbf{A} \cdot \mathbf{\Pi} \cdot \mathbf{\Lambda}$.

In [19] we have introduced a generalization of the permutation lemma to partitioned matrices. Let us first introduce some additional prerequisites. Let $\omega'(\mathbf{x})$ denote the number of parts of a partitioned vector $\mathbf{x}$ that are not all-zero. We call the partitioning of a partitioned matrix $\mathbf{A}$ uniform when all submatrices are of the same size. Finally, we generalize the k-rank concept to partitioned matrices [19].

DEFINITION 3.2. *The* k'-rank *of a (not necessarily uniformly) partitioned matrix* $\mathbf{A}$, *denoted by* $\text{rank}_{k'}(\mathbf{A})$ *or* $k'_{\mathbf{A}}$, *is the maximal number* r *such that any set of* r *submatrices of* $\mathbf{A}$ *yields a set of linearly independent columns.*

Let $\mathbf{A} \in \mathbb{K}^{I \times LR}$ be uniformly partitioned in R matrices $\mathbf{A}_r \in \mathbb{K}^{I \times L}$. Generically, we have $k'_{\mathbf{A}} = \min(\lfloor \frac{I}{L} \rfloor, R)$.

We are now in a position to formulate the lemma that generalizes the permutation lemma.

LEMMA 3.3 (equivalence lemma for partitioned matrices). *Consider* $\bar{\mathbf{A}}$, $\mathbf{A} \in \mathbb{K}^{I \times \sum_{r=1}^{R} L_r}$, *partitioned in the same but not necessarily uniform way into* R *submatrices that are full column rank. Suppose that for every* $\mu \leqslant R - k'_{\bar{\mathbf{A}}} + 1$ *there holds that for a generic*[1] *vector* $\mathbf{x}$ *such that* $\omega'(\mathbf{x}^T\bar{\mathbf{A}}) \leqslant \mu$, *we have* $\omega'(\mathbf{x}^T\mathbf{A}) \leqslant \omega'(\mathbf{x}^T\bar{\mathbf{A}})$. *Then there exists a unique block-permutation matrix* $\mathbf{\Pi}$ *and a unique nonsingular block-diagonal matrix* $\mathbf{\Lambda}$, *such that* $\bar{\mathbf{A}} = \mathbf{A} \cdot \mathbf{\Pi} \cdot \mathbf{\Lambda}$, *where the block-transformation is compatible with the block-structure of* $\mathbf{A}$ *and* $\bar{\mathbf{A}}$.

(Compared to the presentation in [19] we have dropped the irrelevant complex conjugation of $\mathbf{x}$.)

We note that the rank $r_{\bar{\mathbf{A}}}$ in the permutation lemma has been replaced by the k'-rank $k'_{\bar{\mathbf{A}}}$ in Lemma 3.3. The reason is that the permutation lemma admits a simpler proof when we can assume that $r_{\bar{\mathbf{A}}} = k_{\bar{\mathbf{A}}}$. It is this simpler proof, given in [31], that is generalized in [19].

The following lemma gives a lower-bound on the k'-rank of a Khatri–Rao product of partitioned matrices [19].

LEMMA 3.4. *Consider partitioned matrices* $\mathbf{A} = [\mathbf{A}_1 \ \ldots \ \mathbf{A}_R]$ *with* $\mathbf{A}_r \in \mathbb{K}^{I \times L_r}$, $1 \leqslant r \leqslant R$, *and* $\mathbf{B} = [\mathbf{B}_1 \ \ldots \ \mathbf{B}_R]$ *with* $\mathbf{B}_r \in \mathbb{K}^{J \times M_r}$, $1 \leqslant r \leqslant R$.

(i) *If* $k'_{\mathbf{A}} = 0$ *or* $k'_{\mathbf{B}} = 0$, *then* $k'_{\mathbf{A} \odot \mathbf{B}} = 0$.

(ii) *If* $k'_{\mathbf{A}} \geqslant 1$ *and* $k'_{\mathbf{B}} \geqslant 1$, *then* $k'_{\mathbf{A} \odot \mathbf{B}} \geqslant \min(k'_{\mathbf{A}} + k'_{\mathbf{B}} - 1, R)$.

Finally, we have a lemma that says that a Khatri–Rao product of partitioned matrices is generically full column rank [19].

[1] We mean the following. Consider, for instance, a partitioned matrix $\bar{\mathbf{A}} = [\mathbf{a}_1 \ \mathbf{a}_2 | \mathbf{a}_3 \ \mathbf{a}_4] \in \mathbb{K}^{4 \times 4}$ that is full column rank. The set $\mathsf{S} = \{\mathbf{x} | \omega'(\mathbf{x}^T\bar{\mathbf{A}}) \leqslant 1\}$ is the union of two subspaces, S_1 and S_2, consisting of the set of vectors orthogonal to $\{\mathbf{a}_1, \mathbf{a}_2\}$ and $\{\mathbf{a}_3, \mathbf{a}_4\}$, respectively. When we say that for a generic vector $\mathbf{x}$ such that $\omega'(\mathbf{x}^T\bar{\mathbf{A}}) \leqslant 1$, we have $\omega'(\mathbf{x}^T\mathbf{A}) \leqslant \omega'(\mathbf{x}^T\bar{\mathbf{A}})$, we mean that $\omega'(\mathbf{x}^T\mathbf{A}) \leqslant \omega'(\mathbf{x}^T\bar{\mathbf{A}})$ holds with probability one for a vector $\mathbf{x}$ drawn from a continuous probability density function over S_1 and that $\omega'(\mathbf{x}^T\mathbf{A}) \leqslant \omega'(\mathbf{x}^T\bar{\mathbf{A}})$ also holds with probability one for a vector $\mathbf{x}$ drawn from a continuous probability density function over S_2. In general, the set $\mathsf{S} = \{\mathbf{x} | \omega'(\mathbf{x}^T\bar{\mathbf{A}}) \leqslant \mu\}$ consists of a finite union of subspaces, where we count only the subspaces that are not contained in an other subspace. For each of these subspaces, the property should hold with probability one for a vector $\mathbf{x}$ drawn from a continuous probability density function over that subspace.

LEMMA 3.5. *Consider partitioned matrices* $\mathbf{A} = [\mathbf{A}_1 \ \ldots \ \mathbf{A}_R]$ *with* $\mathbf{A}_r \in \mathbb{K}^{I \times L_r}$, $1 \leqslant r \leqslant R$, *and* $\mathbf{B} = [\mathbf{B}_1 \ \ldots \ \mathbf{B}_R]$ *with* $\mathbf{B}_r \in \mathbb{K}^{J \times M_r}$, $1 \leqslant r \leqslant R$. *Generically we have that* $\operatorname{rank}(\mathbf{A} \odot \mathbf{B}) = \min(IJ, \sum_{r=1}^{R} L_r M_r)$.

4. The decomposition in rank-$(L_r, L_r, 1)$ terms. In this section we derive several conditions under which essential uniqueness of the decomposition in rank-$(L, L, 1)$ or rank-$(L_r, L_r, 1)$ terms is guaranteed. We use the notation introduced in section 2.1.

For decompositions in generic rank-$(L, L, 1)$ terms, the results of this section can be summarized as follows. We have essential uniqueness if

(i) Theorem 4.1:

$$\min(I, J) \geqslant LR \quad \text{and} \quad \mathbf{C} \text{ does not have proportional columns;} \tag{4.1}$$

(ii) Theorem 4.4:

$$K \geqslant R \quad \text{and} \quad \min\left(\left\lfloor \frac{I}{L} \right\rfloor, R\right) + \min\left(\left\lfloor \frac{J}{L} \right\rfloor, R\right) \geqslant R + 2; \tag{4.2}$$

(iii) Theorem 4.5:

$$I \geqslant LR \quad \text{and} \quad \min\left(\left\lfloor \frac{J}{L} \right\rfloor, R\right) + \min(K, R) \geqslant R + 2 \tag{4.3}$$

or

$$J \geqslant LR \quad \text{and} \quad \min\left(\left\lfloor \frac{I}{L} \right\rfloor, R\right) + \min(K, R) \geqslant R + 2; \tag{4.4}$$

(iv) Theorem 4.7:

$$\left\lfloor \frac{IJ}{L^2} \right\rfloor \geqslant R \quad \text{and} \quad \min\left(\left\lfloor \frac{I}{L} \right\rfloor, R\right) + \min\left(\left\lfloor \frac{J}{L} \right\rfloor, R\right) + \min(K, R) \geqslant 2R + 2. \tag{4.5}$$

First we mention a result of which the first version appeared, in a slightly different form, in [52]. The proof describes a procedure by which, under the given conditions, the components of the decomposition may be computed. This procedure is a generalization of the computation of PARAFAC from the generalized eigenvectors of the pencil $(\mathbf{T}_{I \times J,1}^T, \mathbf{T}_{I \times J,2}^T)$, as explained in [20, section 1.4].

THEOREM 4.1. *Let* $(\mathbf{A}, \mathbf{B}, \mathbf{C})$ *represent a decomposition of* $\mathcal{T}$ *in rank-*$(L_r, L_r, 1)$ *terms,* $1 \leqslant r \leqslant R$. *Suppose that* $\mathbf{A}$ *and* $\mathbf{B}$ *are full column rank and that* $\mathbf{C}$ *does not have proportional columns. Then* $(\mathbf{A}, \mathbf{B}, \mathbf{C})$ *is essentially unique.*

Proof. Assume that $c_{21}, \ldots, c_{2R}$ are different from zero and that c_{11}/c_{21}, $\ldots$, c_{1R}/c_{2R} are mutually different. (If this is not the case, consider linear combinations of matrix slices in the reasoning below.) From (2.9) we have

$$\mathbf{T}_{I \times J,1} = \mathbf{A} \cdot \operatorname{blockdiag}(c_{11}\mathbf{I}_{L_1 \times L_1}, \ldots, c_{1R}\mathbf{I}_{L_R \times L_R}) \cdot \mathbf{B}^T, \tag{4.6}$$

$$\mathbf{T}_{I \times J,2} = \mathbf{A} \cdot \operatorname{blockdiag}(c_{21}\mathbf{I}_{L_1 \times L_1}, \ldots, c_{2R}\mathbf{I}_{L_R \times L_R}) \cdot \mathbf{B}^T. \tag{4.7}$$

This means that the columns of $(\mathbf{A}^T)^\dagger$ are generalized eigenvectors of the pencil $(\mathbf{T}_{I \times J,1}^T, \mathbf{T}_{I \times J,2}^T)$ [4, 22]. The columns of the rth submatrix of $\mathbf{A}$ are associated with the same generalized eigenvalue c_{1r}/c_{2r} and can therefore not be separated, $1 \leqslant r \leqslant R$. This is consistent with the indeterminacies of the decomposition. On the other

hand, the different submatrices of $\mathbf{A}$ can be separated, as they correspond to different generalized eigenvalues. After computation of a possible matrix $\mathbf{A}$, the corresponding matrix $\mathbf{B}$ can be computed, up to scaling of its submatrices, from (4.7):

$$(\mathbf{A}^{\dagger} \cdot \mathbf{T}_{I\times J,2})^T = \mathbf{B} \cdot \text{blockdiag}(c_{21}\mathbf{I}_{L_1\times L_1}, \ldots, c_{2R}\mathbf{I}_{L_R\times L_R}).$$

Matrix $\mathbf{C}$ finally follows from (2.4):

$$\mathbf{C} = \left\{[(\mathbf{A}_1 \odot_c \mathbf{B}_1)\mathbf{1}_{L_1} \ \ldots \ (\mathbf{A}_R \odot_c \mathbf{B}_R)\mathbf{1}_{L_R}]^{\dagger} \cdot \mathbf{T}_{IJ\times K}\right\}^T. \qquad \square$$

Next, we derive generalizations of Kruskal's condition (1.15) under which essential uniqueness of $\mathbf{A}$, or $\mathbf{B}$, or $\mathbf{C}$ is guaranteed. Lemma 4.2 concerns essential uniqueness of $\mathbf{C}$. In its proof, we assume that the partitioning of $\mathbf{A}$ and $\mathbf{B}$ is uniform. Hence, the lemma applies only to the decomposition in rank-$(L, L, 1)$ terms. Lemma 4.3 concerns essential uniqueness of $\mathbf{A}$ and/or $\mathbf{B}$. This lemma applies more generally to the decomposition in rank-$(L_r, L_r, 1)$ terms. Later in this section, essential uniqueness of the decomposition of $\mathcal{T}$ will be inferred from essential uniqueness of one or more of the matrices $\mathbf{A}$, $\mathbf{B}$, $\mathbf{C}$.

LEMMA 4.2. *Let* $(\mathbf{A}, \mathbf{B}, \mathbf{C})$ *represent a decomposition of* $\mathcal{T}$ *in* R *rank-*$(L, L, 1)$ *terms. Suppose the condition*

$$k'_{\mathbf{A}} + k'_{\mathbf{B}} + k_{\mathbf{C}} \geqslant 2R + 2 \tag{4.8}$$

holds and that we have an alternative decomposition of $\mathcal{T}$*, represented by* $(\bar{\mathbf{A}}, \bar{\mathbf{B}}, \bar{\mathbf{C}})$*. Then there holds* $\bar{\mathbf{C}} = \mathbf{C} \cdot \mathbf{\Pi}_c \cdot \mathbf{\Lambda}_c$*, in which* $\mathbf{\Pi}_c$ *is a permutation matrix and* $\mathbf{\Lambda}_c$ *a nonsingular diagonal matrix.*

Proof. We work in analogy with [54]. Equality of $\mathbf{C}$ and $\bar{\mathbf{C}}$, up to column permutation and scaling, follows from the permutation lemma if we can prove that for any $\mathbf{x}$ such that $\omega(\mathbf{x}^T\bar{\mathbf{C}}) \leqslant R - r_{\bar{\mathbf{C}}} + 1$, there holds $\omega(\mathbf{x}^T\mathbf{C}) \leqslant \omega(\mathbf{x}^T\bar{\mathbf{C}})$. This proof is structured as follows. First, we derive an upper-bound on $\omega(\mathbf{x}^T\bar{\mathbf{C}})$. Then we derive a lower-bound on $\omega(\mathbf{x}^T\bar{\mathbf{C}})$. Combination of the two bounds yields the desired result.

(i) *Derivation of an upper-bound on* $\omega(\mathbf{x}^T\bar{\mathbf{C}})$. From (2.9) we have that $\text{vec}(\mathbf{T}^T_{I\times J,k}) = [(\mathbf{A}_1 \odot_c \mathbf{B}_1)\mathbf{1}_L \ \ldots \ (\mathbf{A}_R \odot_c \mathbf{B}_R)\mathbf{1}_L] \cdot [c_{k1} \ldots c_{kR}]^T$. Consider the linear combination of $(I \times J)$ slices $\sum_{k=1}^K x_k \mathbf{T}_{I\times J,k}$. Since $(\mathbf{A}, \mathbf{B}, \mathbf{C})$ and $(\bar{\mathbf{A}}, \bar{\mathbf{B}}, \bar{\mathbf{C}})$ both represent a decomposition of $\mathcal{T}$, we have

$$\begin{aligned}&[(\mathbf{A}_1 \odot_c \mathbf{B}_1)\mathbf{1}_L \ \ldots \ (\mathbf{A}_R \odot_c \mathbf{B}_R)\mathbf{1}_L] \cdot \mathbf{C}^T\mathbf{x} \\ &\quad = [(\bar{\mathbf{A}}_1 \odot_c \bar{\mathbf{B}}_1)\mathbf{1}_L \ \ldots \ (\bar{\mathbf{A}}_R \odot_c \bar{\mathbf{B}}_R)\mathbf{1}_L] \cdot \bar{\mathbf{C}}^T\mathbf{x}.\end{aligned}$$

By Lemma 3.4, the matrix $\mathbf{A} \odot \mathbf{B}$ has full column rank. The matrix $[(\mathbf{A}_1 \odot_c \mathbf{B}_1)\mathbf{1}_L \ \ldots \ (\mathbf{A}_R \odot_c \mathbf{B}_R)\mathbf{1}_L]$ is equal to $(\mathbf{A} \odot \mathbf{B}) \cdot [\text{vec}(\mathbf{I}_{L\times L})^T \ \ldots \ \text{vec}(\mathbf{I}_{L\times L})^T]^T$ and thus also has full column rank. This implies that if $\omega(\mathbf{x}^T\bar{\mathbf{C}}) = 0$, then also $\omega(\mathbf{x}^T\mathbf{C}) = 0$. Hence, $\text{null}(\bar{\mathbf{C}}) \subseteq \text{null}(\mathbf{C})$. Basic matrix algebra yields $\text{span}(\mathbf{C}) \subseteq \text{span}(\bar{\mathbf{C}})$ and $r_{\mathbf{C}} \leqslant r_{\bar{\mathbf{C}}}$. This implies that if $\omega(\mathbf{x}^T\bar{\mathbf{C}}) \leqslant R - r_{\bar{\mathbf{C}}} + 1$, then

$$\omega(\mathbf{x}^T\bar{\mathbf{C}}) \leqslant R - r_{\bar{\mathbf{C}}} + 1 \leqslant R - r_{\mathbf{C}} + 1 \leqslant R - k_{\mathbf{C}} + 1 \leqslant k'_{\mathbf{A}} + k'_{\mathbf{B}} - (R + 1), \tag{4.9}$$

where the last inequality corresponds to condition (4.8).

(ii) *Derivation of a lower-bound on* $\omega(\mathbf{x}^T\bar{\mathbf{C}})$. By (2.9), the linear combination of $(I \times J)$ slices $\sum_{k=1}^K x_k \mathbf{T}_{I\times J,k}$ is given by

$$\begin{aligned}&\mathbf{A} \cdot \text{blockdiag}(\mathbf{x}^T\mathbf{c}_1\mathbf{I}_{L\times L}, \ldots, \mathbf{x}^T\mathbf{c}_R\mathbf{I}_{L\times L}) \cdot \mathbf{B}^T \\ &\quad = \bar{\mathbf{A}} \cdot \text{blockdiag}(\mathbf{x}^T\bar{\mathbf{c}}_1\mathbf{I}_{L\times L}, \ldots, \mathbf{x}^T\bar{\mathbf{c}}_R\mathbf{I}_{L\times L}) \cdot \bar{\mathbf{B}}^T.\end{aligned}$$

We have

$$\begin{aligned} L\omega(\mathbf{x}^T\bar{\mathbf{C}}) &= r_{\text{blockdiag}(\mathbf{x}^T\bar{\mathbf{c}}_1\mathbf{I}_{L\times L},\ldots,\mathbf{x}^T\bar{\mathbf{c}}_R\mathbf{I}_{L\times L})} \\ &\geqslant r_{\bar{\mathbf{A}}\cdot\text{blockdiag}(\mathbf{x}^T\bar{\mathbf{c}}_1\mathbf{I}_{L\times L},\ldots,\mathbf{x}^T\bar{\mathbf{c}}_R\mathbf{I}_{L\times L})\cdot\bar{\mathbf{B}}^T} \\ &= r_{\mathbf{A}\cdot\text{blockdiag}(\mathbf{x}^T\mathbf{c}_1\mathbf{I}_{L\times L},\ldots,\mathbf{x}^T\mathbf{c}_R\mathbf{I}_{L\times L})\cdot\mathbf{B}^T}. \end{aligned} \tag{4.10}$$

Let $\gamma = \omega(\mathbf{x}^T\mathbf{C})$ and let $\tilde{\mathbf{A}}$ and $\tilde{\mathbf{B}}$ consist of the submatrices of $\mathbf{A}$ and $\mathbf{B}$, respectively, corresponding to the nonzero elements of $\mathbf{x}^T\mathbf{C}$. Then $\tilde{\mathbf{A}}$ and $\tilde{\mathbf{B}}$ both have γL columns. Let $\mathbf{u}$ be the $(\gamma \times 1)$ vector containing the nonzero elements of $\mathbf{x}^T\mathbf{C}$ such that

$$\mathbf{A}\cdot\text{blockdiag}(\mathbf{x}^T\mathbf{c}_1\mathbf{I}_{L\times L},\ldots,\mathbf{x}^T\mathbf{c}_R\mathbf{I}_{L\times L})\cdot\mathbf{B}^T = \tilde{\mathbf{A}}\cdot\text{blockdiag}(u_1\mathbf{I}_{L\times L},\ldots,u_\gamma\mathbf{I}_{L\times L})\cdot\tilde{\mathbf{B}}^T.$$

Sylvester's inequality now yields

$$\begin{aligned} r_{\mathbf{A}\cdot\text{blockdiag}(\mathbf{x}^T\mathbf{c}_1\mathbf{I}_{L\times L},\ldots,\mathbf{x}^T\mathbf{c}_R\mathbf{I}_{L\times L})\cdot\mathbf{B}^T} &= r_{\tilde{\mathbf{A}}\cdot\text{blockdiag}(u_1\mathbf{I}_{L\times L},\ldots,u_\gamma\mathbf{I}_{L\times L})\cdot\tilde{\mathbf{B}}^T} \\ &\geqslant r_{\tilde{\mathbf{A}}} + r_{\text{blockdiag}(u_1\mathbf{I}_{L\times L},\ldots,u_\gamma\mathbf{I}_{L\times L})\cdot\tilde{\mathbf{B}}^T} - \gamma L \\ &= r_{\tilde{\mathbf{A}}} + r_{\tilde{\mathbf{B}}} - \gamma L, \end{aligned} \tag{4.11}$$

where the last equality is due to the fact that $\mathbf{u}$ has no zero elements. From the definition of k′-rank, we have

$$r_{\tilde{\mathbf{A}}} \geqslant L\min(\gamma, k'_{\mathbf{A}}), \quad r_{\tilde{\mathbf{B}}} \geqslant L\min(\gamma, k'_{\mathbf{B}}). \tag{4.12}$$

Combination of (4.10)–(4.12) yields the following lower-bound on $\omega(\mathbf{x}^T\bar{\mathbf{C}})$:

$$\omega(\mathbf{x}^T\bar{\mathbf{C}}) \geqslant \min(\gamma, k'_{\mathbf{A}}) + \min(\gamma, k'_{\mathbf{B}}) - \gamma. \tag{4.13}$$

(iii) *Combination of the two bounds.* Combination of (4.9) and (4.13) yields

$$\min(\gamma, k'_{\mathbf{A}}) + \min(\gamma, k'_{\mathbf{B}}) - \gamma \leqslant \omega(\mathbf{x}^T\bar{\mathbf{C}}) \leqslant k'_{\mathbf{A}} + k'_{\mathbf{B}} - (R+1). \tag{4.14}$$

To be able to apply the permutation lemma, we need to show that $\gamma = \omega(\mathbf{x}^T\mathbf{C}) \leqslant \omega(\mathbf{x}^T\bar{\mathbf{C}})$. By (4.14), it suffices to show that $\gamma < \min(k'_{\mathbf{A}}, k'_{\mathbf{B}})$. We prove this by contradiction. Suppose $\gamma > \max(k'_{\mathbf{A}}, k'_{\mathbf{B}})$. Then (4.14) yields $\gamma \geqslant R+1$, which is impossible. Suppose next that $k'_{\mathbf{A}} \leqslant \gamma \leqslant k'_{\mathbf{B}}$. Then (4.14) yields $k'_{\mathbf{B}} \geqslant R+1$, which is also impossible. Since $\mathbf{A}$ and $\mathbf{B}$ can be exchanged in the latter case, we have that $\gamma < \min(k'_{\mathbf{A}}, k'_{\mathbf{B}})$. Equation (4.14) now implies that $\omega(\mathbf{x}^T\mathbf{C}) \leqslant \omega(\mathbf{x}^T\bar{\mathbf{C}})$. By the permutation lemma, there exist a unique permutation matrix $\mathbf{\Pi}_c$ and a nonsingular diagonal matrix $\mathbf{\Lambda}_c$ such that $\bar{\mathbf{C}} = \mathbf{C}\cdot\mathbf{\Pi}_c\cdot\mathbf{\Lambda}_c$. □

In the following lemma, we prove essential uniqueness of $\mathbf{A}$ and $\mathbf{B}$ when we restrict our attention to alternative $\bar{\mathbf{A}}$ and $\bar{\mathbf{B}}$ that are, in some sense, "nonsingular." What we mean is that there are no linear dependencies between columns that are not imposed by the dimensionality constraints.

LEMMA 4.3. *Let* $(\mathbf{A}, \mathbf{B}, \mathbf{C})$ *represent a decomposition of* $\mathcal{T}$ *in rank-*$(L_r, L_r, 1)$ *terms,* $1 \leqslant r \leqslant R$. *Suppose the condition*

$$k'_{\mathbf{A}} + k'_{\mathbf{B}} + k_{\mathbf{C}} \geqslant 2R + 2 \tag{4.15}$$

holds and that we have an alternative decomposition of $\mathcal{T}$, *represented by* $(\bar{\mathbf{A}}, \bar{\mathbf{B}}, \bar{\mathbf{C}})$, *with* $k'_{\bar{\mathbf{A}}}$ *and* $k'_{\bar{\mathbf{B}}}$ *maximal under the given dimensionality constraints. Then there holds* $\bar{\mathbf{A}} = \mathbf{A}\cdot\mathbf{\Pi}_a\cdot\mathbf{\Lambda}_a$, *in which* $\mathbf{\Pi}_a$ *is a block permutation matrix and* $\mathbf{\Lambda}_a$ *a square*

nonsingular block-diagonal matrix, compatible with the block structure of $\mathbf{A}$*. There also holds* $\bar{\mathbf{B}} = \mathbf{B} \cdot \mathbf{\Pi}_b \cdot \mathbf{\Lambda}_b$*, in which* $\mathbf{\Pi}_b$ *is a block permutation matrix and* $\mathbf{\Lambda}_b$ *a square nonsingular block-diagonal matrix, compatible with the block structure of* $\mathbf{B}$*.*

Proof. It suffices to prove the lemma for $\mathbf{A}$. The result for $\mathbf{B}$ can be obtained by switching modes. We work in analogy with the proof of Lemma 4.2. Essential uniqueness of $\mathbf{A}$ now follows from the equivalence lemma for partitioned matrices.

(i) *Derivation of an upper-bound on* $\omega'(\mathbf{x}^T\bar{\mathbf{A}})$*.* The constraint on $k'_{\bar{\mathbf{A}}}$ implies that $k'_{\bar{\mathbf{A}}} \geqslant k'_{\mathbf{A}}$. Hence, if $\omega'(\mathbf{x}^T\bar{\mathbf{A}}) \leqslant R - k'_{\bar{\mathbf{A}}} + 1$, then

$$\omega'(\mathbf{x}^T\bar{\mathbf{A}}) \leqslant R - k'_{\bar{\mathbf{A}}} + 1 \leqslant R - k'_{\mathbf{A}} + 1 \leqslant k'_{\mathbf{B}} + k_{\mathbf{C}} - (R+1), \tag{4.16}$$

where the last inequality corresponds to condition (4.15).

(ii) *Derivation of a lower-bound on* $\omega'(\mathbf{x}^T\bar{\mathbf{A}})$*.* By (2.7), the linear combination of $(J \times K)$ slices $\sum_{i=1}^{I} x_i \mathbf{T}_{J\times K,i}$ is given by

$$\mathbf{B} \cdot \text{blockdiag}(\mathbf{A}_1^T\mathbf{x}, \ldots, \mathbf{A}_R^T\mathbf{x}) \cdot \mathbf{C}^T = \bar{\mathbf{B}} \cdot \text{blockdiag}(\bar{\mathbf{A}}_1^T\mathbf{x}, \ldots, \bar{\mathbf{A}}_R^T\mathbf{x}) \cdot \bar{\mathbf{C}}^T.$$

We have

$$\begin{aligned} \omega'(\mathbf{x}^T\bar{\mathbf{A}}) &= r_{\text{blockdiag}(\bar{\mathbf{A}}_1^T\mathbf{x},\ldots,\bar{\mathbf{A}}_R^T\mathbf{x})} \\ &\geqslant r_{\bar{\mathbf{B}}\cdot\text{blockdiag}(\bar{\mathbf{A}}_1^T\mathbf{x},\ldots,\bar{\mathbf{A}}_R^T\mathbf{x})\cdot\bar{\mathbf{C}}^T} \\ &= r_{\mathbf{B}\cdot\text{blockdiag}(\mathbf{A}_1^T\mathbf{x},\ldots,\mathbf{A}_R^T\mathbf{x})\cdot\mathbf{C}^T}. \end{aligned} \tag{4.17}$$

Let $\gamma = \omega'(\mathbf{x}^T\mathbf{A})$ and let $\tilde{\mathbf{B}}$ and $\tilde{\mathbf{C}}$ consist of the submatrices of $\mathbf{B}\cdot\text{blockdiag}(\mathbf{A}_1^T\mathbf{x}, \ldots, \mathbf{A}_R^T\mathbf{x})$ and $\mathbf{C}$, respectively, corresponding to the parts of $\mathbf{x}^T\mathbf{A}$ that are not all-zero. Then $\tilde{\mathbf{B}}$ and $\tilde{\mathbf{C}}$ both have γ columns. Sylvester's inequality now yields

$$r_{\mathbf{B}\cdot\text{blockdiag}(\mathbf{A}_1^T\mathbf{x},\ldots,\mathbf{A}_R^T\mathbf{x})\cdot\mathbf{C}^T} \geqslant r_{\tilde{\mathbf{B}}} + r_{\tilde{\mathbf{C}}} - \gamma. \tag{4.18}$$

The matrix $\tilde{\mathbf{B}}$ consists of γ nonzero vectors, sampled in the column spaces of the submatrices of $\mathbf{B}$ that correspond to the parts of $\mathbf{x}^T\mathbf{A}$ that are not all-zero. From the definition of k′-rank, we have

$$r_{\tilde{\mathbf{B}}} \geqslant \min(\gamma, k'_{\mathbf{B}}). \tag{4.19}$$

On the other hand, from the definition of k-rank, we have

$$r_{\tilde{\mathbf{C}}} \geqslant \min(\gamma, k_{\mathbf{C}}). \tag{4.20}$$

Combination of (4.17)–(4.20) yields the following lower-bound on $\omega'(\mathbf{x}^T\bar{\mathbf{A}})$:

$$\omega'(\mathbf{x}^T\bar{\mathbf{A}}) \geqslant \min(\gamma, k'_{\mathbf{B}}) + \min(\gamma, k_{\mathbf{C}}) - \gamma. \tag{4.21}$$

(iii) *Combination of the two bounds.* This is analogous to Lemma 4.2. □

We now use Lemmas 4.2 and 4.3, which concern the essential uniqueness of the individual matrices $\mathbf{A}$, $\mathbf{B}$, and $\mathbf{C}$, to establish essential uniqueness of the overall decomposition of $\mathcal{T}$. Theorem 4.4 states that if $\mathbf{C}$ is full column rank and tall (meaning that $R \leqslant K$), then its essential uniqueness implies essential uniqueness of the overall tensor decomposition. Theorem 4.5 is the equivalent for $\mathbf{A}$ (or $\mathbf{B}$). However, none of

the factor matrices needs to be tall for the decomposition to be unique. A more general case is dealt with in Theorem 4.7. Its proof makes use of Lemma 4.6, guaranteeing that under a generalized Kruskal condition, $\mathbf{A}$ and $\mathbf{B}$ not only are individually essentially unique but, moreover, are subject to the same permutation of their submatrices.

We first consider essential uniqueness of a tall full column rank matrix $\mathbf{C}$.

THEOREM 4.4. *Let* $(\mathbf{A}, \mathbf{B}, \mathbf{C})$ *represent a decomposition of* $\mathcal{T}$ *in* R *rank-*$(L, L, 1)$ *terms. Suppose that we have an alternative decomposition of* $\mathcal{T}$*, represented by* $(\bar{\mathbf{A}}, \bar{\mathbf{B}}, \bar{\mathbf{C}})$*. If*

$$k_{\mathbf{C}} = R \quad \textit{and} \quad k'_{\mathbf{A}} + k'_{\mathbf{B}} \geqslant R + 2, \tag{4.22}$$

then $(\mathbf{A}, \mathbf{B}, \mathbf{C})$ *and* $(\bar{\mathbf{A}}, \bar{\mathbf{B}}, \bar{\mathbf{C}})$ *are essentially equal.*

Proof. From (2.4) we have

$$\begin{aligned} \mathbf{T}_{IJ\times K} &= [(\mathbf{A}_1 \odot_c \mathbf{B}_1)\mathbf{1}_L \ \ldots \ (\mathbf{A}_R \odot_c \mathbf{B}_R)\mathbf{1}_L] \cdot \mathbf{C}^T \\ &= [(\bar{\mathbf{A}}_1 \odot_c \bar{\mathbf{B}}_1)\mathbf{1}_L \ \ldots \ (\bar{\mathbf{A}}_R \odot_c \bar{\mathbf{B}}_R)\mathbf{1}_L] \cdot \bar{\mathbf{C}}^T. \end{aligned} \tag{4.23}$$

From Lemma 4.2 we have

$$\bar{\mathbf{C}} = \mathbf{C} \cdot \mathbf{\Pi}_c \cdot \mathbf{\Lambda}_c. \tag{4.24}$$

Since $k_{\mathbf{C}} = R$, $\mathbf{C}$ is full column rank. Substitution of (4.24) in (4.23) now yields

$$\begin{aligned} &[(\mathbf{A}_1 \odot_c \mathbf{B}_1)\mathbf{1}_L \ \ldots \ (\mathbf{A}_R \odot_c \mathbf{B}_R)\mathbf{1}_L] \\ &\quad = [(\bar{\mathbf{A}}_1 \odot_c \bar{\mathbf{B}}_1)\mathbf{1}_L \ \ldots \ (\bar{\mathbf{A}}_R \odot_c \bar{\mathbf{B}}_R)\mathbf{1}_L] \cdot \mathbf{\Lambda}_c^T \cdot \mathbf{\Pi}_c^T. \end{aligned} \tag{4.25}$$

Taking into account that $(\bar{\mathbf{A}}_r \odot_c \bar{\mathbf{B}}_r)\mathbf{1}_L$ is a vector representation of the matrix $\bar{\mathbf{A}}_r \cdot \bar{\mathbf{B}}_r^T$, $1 \leqslant r \leqslant R$, this implies that the matrices $\bar{\mathbf{A}}_r \cdot \bar{\mathbf{B}}_r^T$ are ordered in the same way as the vectors $\bar{\mathbf{c}}_r$. Furthermore, if $\bar{\mathbf{c}}_i = \lambda \mathbf{c}_j$, then $(\bar{\mathbf{A}}_i \odot_c \bar{\mathbf{B}}_i)\mathbf{1}_L = \lambda^{-1}(\mathbf{A}_j \odot_c \mathbf{B}_j)\mathbf{1}_L$, or, equivalently, $\bar{\mathbf{A}}_i \cdot \bar{\mathbf{B}}_i^T = \lambda^{-1}\mathbf{A}_j \cdot \mathbf{B}_j^T$. ∎

We now consider essential uniqueness of a tall full column rank matrix $\mathbf{A}$ or $\mathbf{B}$.

THEOREM 4.5. *Let* $(\mathbf{A}, \mathbf{B}, \mathbf{C})$ *represent a decomposition of* $\mathcal{T}$ *in rank-*$(L_r, L_r, 1)$ *terms,* $1 \leqslant r \leqslant R$*. Suppose that we have an alternative decomposition of* $\mathcal{T}$*, represented by* $(\bar{\mathbf{A}}, \bar{\mathbf{B}}, \bar{\mathbf{C}})$*, with* $k'_{\bar{\mathbf{A}}}$ *and* $k'_{\bar{\mathbf{B}}}$ *maximal under the given dimensionality constraints. If*

$$k'_{\mathbf{A}} = R \quad \textit{and} \quad k'_{\mathbf{B}} + k_{\mathbf{C}} \geqslant R + 2 \tag{4.26}$$

or

$$k'_{\mathbf{B}} = R \quad \textit{and} \quad k'_{\mathbf{A}} + k_{\mathbf{C}} \geqslant R + 2, \tag{4.27}$$

then $(\mathbf{A}, \mathbf{B}, \mathbf{C})$ *and* $(\bar{\mathbf{A}}, \bar{\mathbf{B}}, \bar{\mathbf{C}})$ *are essentially equal.*

Proof. It suffices to prove the theorem for condition (4.26). The result for (4.27) is obtained by switching modes.

From (2.5) we have

$$\mathbf{T}_{JK\times I} = (\mathbf{B} \odot \mathbf{C}) \cdot \mathbf{A}^T = (\bar{\mathbf{B}} \odot \bar{\mathbf{C}}) \cdot \bar{\mathbf{A}}^T. \tag{4.28}$$

From Lemma 4.3 we have

$$\bar{\mathbf{A}} = \mathbf{A} \cdot \mathbf{\Pi}_a \cdot \mathbf{\Lambda}_a. \tag{4.29}$$

Since $k'_{\mathbf{A}} = R$, $\mathbf{A}$ is full column rank. Substitution of (4.29) in (4.28) now yields

$$\mathbf{B} \odot \mathbf{C} = (\bar{\mathbf{B}} \odot \bar{\mathbf{C}}) \cdot \mathbf{\Lambda}_a^T \cdot \mathbf{\Pi}_a^T. \tag{4.30}$$

This implies that the matrices $\bar{\mathbf{B}}_r \otimes \bar{\mathbf{c}}_r$ are ordered in the same way as the matrices $\bar{\mathbf{A}}_r$. Furthermore, if $\bar{\mathbf{A}}_i = \mathbf{A}_j \cdot \mathbf{L}$, with $\mathbf{L}$ nonsingular, then $\bar{\mathbf{B}}_i \otimes \bar{\mathbf{c}}_i = (\mathbf{B}_j \otimes \mathbf{c}_j) \cdot \mathbf{L}^{-T}$, or, equivalently, $\bar{\mathbf{B}}_i \circ \bar{\mathbf{c}}_i = (\mathbf{B}_j \cdot \mathbf{L}^{-T}) \circ \mathbf{c}_j$. □

We now prove that under a generalized Kruskal condition, the submatrices of $\bar{\mathbf{A}}$ and $\bar{\mathbf{B}}$ in an alternative decomposition of $\mathcal{T}$ are ordered in the same way.

LEMMA 4.6. *Let $(\mathbf{A}, \mathbf{B}, \mathbf{C})$ represent a decomposition of $\mathcal{T}$ into rank-$(L_r, L_r, 1)$ terms, $1 \leqslant r \leqslant R$. Suppose that we have an alternative decomposition of $\mathcal{T}$, represented by $(\bar{\mathbf{A}}, \bar{\mathbf{B}}, \bar{\mathbf{C}})$, with $k'_{\bar{\mathbf{A}}}$ and $k'_{\bar{\mathbf{B}}}$ maximal under the given dimensionality constraints. If the condition*

$$k'_{\mathbf{A}} + k'_{\mathbf{B}} + k_{\mathbf{C}} \geqslant 2R + 2 \tag{4.31}$$

holds, then $\bar{\mathbf{A}} = \mathbf{A} \cdot \mathbf{\Pi} \cdot \mathbf{\Lambda}_a$ and $\bar{\mathbf{B}} = \mathbf{B} \cdot \mathbf{\Pi} \cdot \mathbf{\Lambda}_b$, in which $\mathbf{\Pi}$ is a block permutation matrix and $\mathbf{\Lambda}_a$ and $\mathbf{\Lambda}_b$ nonsingular block-diagonal matrices, compatible with the block structure of $\mathbf{A}$ and $\mathbf{B}$.

Proof. From Lemma 4.3 we know that $\bar{\mathbf{A}} = \mathbf{A} \cdot \mathbf{\Pi}_a \cdot \mathbf{\Lambda}_a$ and $\bar{\mathbf{B}} = \mathbf{B} \cdot \mathbf{\Pi}_b \cdot \mathbf{\Lambda}_b$. We show that $\mathbf{\Pi}_a = \mathbf{\Pi}_b$ if (4.31) holds. We work in analogy with [38, pp. 129–132] and [54].

From (2.9) we have

$$\begin{aligned}\mathbf{T}_{I \times J, k} &= \mathbf{A} \cdot \operatorname{blockdiag}(c_{k1}\mathbf{I}_{L_1 \times L_1}, \ldots, c_{kR}\mathbf{I}_{L_R \times L_R}) \cdot \mathbf{B}^T \\ &= \bar{\mathbf{A}} \cdot \operatorname{blockdiag}(\bar{c}_{k1}\mathbf{I}_{L_1 \times L_1}, \ldots, \bar{c}_{kR}\mathbf{I}_{L_R \times L_R}) \cdot \bar{\mathbf{B}}^T.\end{aligned}$$

For vectors $\mathbf{v}$ and $\mathbf{w}$ we have

$$\begin{aligned}&(\mathbf{v}^T\mathbf{A}) \cdot \operatorname{blockdiag}(c_{k1}\mathbf{I}_{L_1 \times L_1}, \ldots, c_{kR}\mathbf{I}_{L_R \times L_R}) \cdot (\mathbf{w}^T\mathbf{B})^T \\ &\quad = (\mathbf{v}^T\bar{\mathbf{A}}) \cdot \operatorname{blockdiag}(\bar{c}_{k1}\mathbf{I}_{L_1 \times L_1}, \ldots, \bar{c}_{kR}\mathbf{I}_{L_R \times L_R}) \cdot (\mathbf{w}^T\bar{\mathbf{B}})^T \\ &\quad = (\mathbf{v}^T\mathbf{A}\mathbf{\Pi}_a) \cdot \mathbf{\Lambda}_a \cdot \operatorname{blockdiag}(\bar{c}_{k1}\mathbf{I}_{L_1 \times L_1}, \ldots, \bar{c}_{kR}\mathbf{I}_{L_R \times L_R}) \cdot \mathbf{\Lambda}_b^T \cdot (\mathbf{w}^T\mathbf{B}\mathbf{\Pi}_b)^T.\end{aligned} \tag{4.32}$$

We stack (4.32), for $k = 1, \ldots, K$, in

$$\begin{aligned}&\mathbf{C} \cdot \operatorname{blockdiag}(\mathbf{v}^T\mathbf{A}) \cdot \operatorname{blockdiag}(\mathbf{B}^T\mathbf{w}) \cdot \begin{pmatrix} 1 \\ \vdots \\ 1 \end{pmatrix} \\ &= \bar{\mathbf{C}} \cdot \operatorname{blockdiag}(\mathbf{v}^T\mathbf{A}\mathbf{\Pi}_a) \cdot \mathbf{\Lambda}_a \cdot \mathbf{\Lambda}_b^T \cdot \operatorname{blockdiag}(\mathbf{\Pi}_b^T\mathbf{B}^T\mathbf{w}) \cdot \begin{pmatrix} 1 \\ \vdots \\ 1 \end{pmatrix}.\end{aligned} \tag{4.33}$$

We define

$$\mathbf{p} = \operatorname{blockdiag}(\mathbf{v}^T\mathbf{A}) \cdot \operatorname{blockdiag}(\mathbf{B}^T\mathbf{w}) \cdot \begin{pmatrix} 1 \\ \vdots \\ 1 \end{pmatrix} = \begin{pmatrix} \mathbf{v}^T\mathbf{A}_1 \cdot \mathbf{B}_1^T\mathbf{w} \\ \vdots \\ \mathbf{v}^T\mathbf{A}_R \cdot \mathbf{B}_R^T\mathbf{w} \end{pmatrix}.$$

Let the index function $g(x)$ be given by $\mathbf{A}\mathbf{\Pi}_a = \begin{pmatrix}\mathbf{A}_{g(1)} & \mathbf{A}_{g(2)} & \dots & \mathbf{A}_{g(R)}\end{pmatrix}$. Let a second index function $h(x)$ be given by $\mathbf{B}\mathbf{\Pi}_b = \begin{pmatrix}\mathbf{B}_{h(1)} & \mathbf{B}_{h(2)} & \dots & \mathbf{B}_{h(R)}\end{pmatrix}$. We define

$$\mathbf{q} = \text{blockdiag}(\mathbf{v}^T\mathbf{A}\mathbf{\Pi}_a)\cdot\mathbf{\Lambda}_a\cdot\mathbf{\Lambda}_b^T\cdot\text{blockdiag}(\mathbf{\Pi}_b^T\mathbf{B}^T\mathbf{w})\cdot\begin{pmatrix}1\\ \vdots\\ 1\end{pmatrix}$$
$$= \begin{pmatrix}\mathbf{v}^T\mathbf{A}_{g(1)}\cdot\mathbf{\Lambda}_{a,1}\cdot\mathbf{\Lambda}_{b,1}^T\cdot\mathbf{B}_{h(1)}^T\mathbf{w}\\ \vdots\\ \mathbf{v}^T\mathbf{A}_{g(R)}\cdot\mathbf{\Lambda}_{a,R}\cdot\mathbf{\Lambda}_{b,R}^T\cdot\mathbf{B}_{h(R)}^T\mathbf{w}\end{pmatrix},$$

where $\mathbf{\Lambda}_{a,r}$ and $\mathbf{\Lambda}_{b,r}$ denote the rth block of $\mathbf{\Lambda}_a$ and $\mathbf{\Lambda}_b$, respectively.

Equation (4.33) can now be written as $\mathbf{C}\cdot\mathbf{p} = \bar{\mathbf{C}}\cdot\mathbf{q}$. Below we show by contradiction that $\mathbf{\Pi}_a = \mathbf{\Pi}_b$ if (4.31) holds. If $\mathbf{\Pi}_a \neq \mathbf{\Pi}_b$, then we will be able to find vectors $\mathbf{v}$ and $\mathbf{w}$ such that $\mathbf{q} = \mathbf{0}$ and $\mathbf{p} \neq \mathbf{0}$ has less than $k_{\mathbf{C}}$ nonzero elements. This implies that a set of less than $k_{\mathbf{C}}$ columns of $\mathbf{C}$ is linearly dependent, which contradicts the definition of $k_{\mathbf{C}}$.

Suppose that $\mathbf{\Pi}_a \neq \mathbf{\Pi}_b$. Then there exists an r such that $\mathbf{A}_r$ is the sth submatrix of $\mathbf{A}\mathbf{\Pi}_a$, $\mathbf{B}_r$ is the tth submatrix of $\mathbf{B}\mathbf{\Pi}_b$, and $s \neq t$. Formally, there exists an r such that $r = g(s) = h(t)$ and $s \neq t$. We now create two index sets $\mathsf{S}, \mathsf{T} \subset \{1,\dots,R\}$ as follows:

- Put $g(t)$ in S and $h(s)$ in T.
- For $x \in \{1,\dots,R\}\setminus\{s,t\}$, add $g(x)$ to S if $\text{card}(\mathsf{S}) < k'_{\mathbf{A}} - 1$. Otherwise, add $h(x)$ to T.

The sets S and T have the following properties. Since $k'_{\mathbf{A}} - 1 \leqslant R-1$, S contains exactly $k'_{\mathbf{A}} - 1$ elements. The set T contains $R - \text{card}(\mathsf{S}) = R - k'_{\mathbf{A}} + 1$ elements. Because of (4.31) and $k_{\mathbf{C}} \leqslant R$, this is less than or equal to $k'_{\mathbf{B}} - 1$ elements. In the xth element of $\mathbf{q}$ we have either $g(x) \in \mathsf{S}$ or $h(x) \in \mathsf{T}$, $x = 1,\dots,R$. The index $r = g(s) = h(t)$ is neither an element of S nor an element of T. Denote $\{i_1, i_2, \dots, i_{k'_{\mathbf{A}}-1}\} = \mathsf{S}$ and $\{j_1, j_2, \dots, j_{R-k'_{\mathbf{A}}+1}\} = \mathsf{T}$.

We choose vectors $\mathbf{v}$ and $\mathbf{w}$ such that $\mathbf{v}^T\mathbf{A}_i = \mathbf{0}$ if $i \in \mathsf{S}$, $\mathbf{w}^T\mathbf{B}_j = \mathbf{0}$ if $j \in \mathsf{T}$ and $\mathbf{v}^T\mathbf{A}_r\mathbf{B}_r^T\mathbf{w} \neq 0$. This is possible for the following reasons. By the definition of $k'_{\mathbf{A}}$, $[\mathbf{A}_{i_1} \ \dots \ \mathbf{A}_{i_{k'_{\mathbf{A}}-1}} \ \mathbf{A}_r]$ is full column rank. We have to choose $\mathbf{v}$ in $\text{null}([\mathbf{A}_{i_1} \ \dots \ \mathbf{A}_{i_{k'_{\mathbf{A}}-1}}])$. The projection of this subspace on $\text{span}(\mathbf{A}_r)$ is of dimension L_r. By varying $\mathbf{v}$ in $\text{null}([\mathbf{A}_{i_1} \ \dots \ \mathbf{A}_{i_{k'_{\mathbf{A}}-1}}])$, $\mathbf{v}^T\mathbf{A}_r$ can be made equal to any vector in $\mathbb{K}^{1\times L_r}$. For instance, we can choose $\mathbf{v}$ such that $\mathbf{v}^T\mathbf{A}_r = (1\ 0\ \dots\ 0)$. Similarly, we can choose a vector $\mathbf{w}$ in $\text{null}([\mathbf{B}_{j_1} \ \dots \ \mathbf{B}_{j_{R-k'_{\mathbf{A}}+1}}])$ satisfying $\mathbf{w}^T\mathbf{B}_r = (1\ 0\ \dots\ 0)$.

For the vectors $\mathbf{v}$ and $\mathbf{w}$ above, we have $\mathbf{q} = \mathbf{0}$. On the other hand, the rth element of $\mathbf{p}$ is nonzero. Define $\mathsf{S}^c = \{1,\dots,R\}\setminus\mathsf{S}$ and $\mathsf{T}^c = \{1,\dots,R\}\setminus\mathsf{T}$. The number of nonzero entries of $\mathbf{p}$ is bounded from above by

$$\text{card}(\mathsf{S}^c \cap \mathsf{T}^c) \leqslant \text{card}(\mathsf{S}^c) \leqslant R - k'_{\mathbf{A}} + 1 \leqslant k_{\mathbf{C}} - 1,$$

where the last inequality is due to (4.31) and $k'_{\mathbf{B}} \leqslant R$. Hence, $\mathbf{C}\cdot\mathbf{p} = \mathbf{0}$ implies that a set of less than $k_{\mathbf{C}}$ columns of $\mathbf{C}$ is linearly dependent, which contradicts the definition of $k_{\mathbf{C}}$. This completes the proof. □

THEOREM 4.7. *Let $(\mathbf{A},\mathbf{B},\mathbf{C})$ represent a decomposition of $\mathcal{T}$ in generic rank-$(L_r,L_r,1)$ terms, $1 \leqslant r \leqslant R$. Suppose that we have an alternative decomposition of $\mathcal{T}$, represented by $(\bar{\mathbf{A}},\bar{\mathbf{B}},\bar{\mathbf{C}})$, with $k'_{\bar{\mathbf{A}}}$ and $k'_{\bar{\mathbf{B}}}$ maximal under the given dimensionality*

constraints. If the conditions

$$IJ \geqslant \sum_{r=1}^{R} L_r^2, \tag{4.34}$$

$$k'_{\mathbf{A}} + k'_{\mathbf{B}} + k_{\mathbf{C}} \geqslant 2R + 2 \tag{4.35}$$

hold, then $(\mathbf{A}, \mathbf{B}, \mathbf{C})$ *and* $(\bar{\mathbf{A}}, \bar{\mathbf{B}}, \bar{\mathbf{C}})$ *are essentially equal.*

Proof. From Lemma 4.6 we have that $\bar{\mathbf{A}} = \mathbf{A} \cdot \mathbf{\Pi} \cdot \mathbf{\Lambda}_a$ and $\bar{\mathbf{B}} = \mathbf{B} \cdot \mathbf{\Pi} \cdot \mathbf{\Lambda}_b$. Put the submatrices of $\bar{\mathbf{A}}$ and $\bar{\mathbf{B}}$ in the same order as the submatrices of $\mathbf{A}$ and $\mathbf{B}$. After reordering, we have $\bar{\mathbf{A}} = \mathbf{A} \cdot \mathbf{\Lambda}_a$, with $\mathbf{\Lambda}_a = \text{blockdiag}(\mathbf{\Lambda}_{a,1}, \ldots, \mathbf{\Lambda}_{a,R})$, and $\bar{\mathbf{B}} = \mathbf{B} \cdot \mathbf{\Lambda}_b$, with $\mathbf{\Lambda}_b = \text{blockdiag}(\mathbf{\Lambda}_{b,1}, \ldots, \mathbf{\Lambda}_{b,R})$. From (2.4) we have that

$$\begin{aligned}
\mathbf{T}_{IJ\times K} &= (\mathbf{A} \odot_c \mathbf{B}) \cdot \text{blockdiag}(\mathbf{1}_{L_1}, \ldots, \mathbf{1}_{L_R}) \cdot \mathbf{C}^T \\
&= (\mathbf{A} \odot \mathbf{B}) \cdot \text{blockdiag}(\text{vec}(\mathbf{I}_{L_1 \times L_1}), \ldots, \text{vec}(\mathbf{I}_{L_R \times L_R})) \cdot \mathbf{C}^T \\
&= (\bar{\mathbf{A}} \odot \bar{\mathbf{B}}) \cdot \text{blockdiag}(\text{vec}(\mathbf{I}_{L_1 \times L_1}), \ldots, \text{vec}(\mathbf{I}_{L_R \times L_R})) \cdot \bar{\mathbf{C}}^T \\
&= (\mathbf{A} \odot \mathbf{B}) \cdot \text{blockdiag}(\text{vec}(\mathbf{\Lambda}_{a,1} \cdot \mathbf{\Lambda}_{b,1}^T), \ldots, \text{vec}(\mathbf{\Lambda}_{a,R} \cdot \mathbf{\Lambda}_{b,R}^T)) \cdot \bar{\mathbf{C}}^T. \qquad (4.36)
\end{aligned}$$

From [19, Lemma 3.3] we have that, under condition (4.34), $\mathbf{A} \odot \mathbf{B}$ is generically full column rank. Equation (4.36) then implies that there exist nonzero scalars α_r such that $\mathbf{\Lambda}_{a,r} \cdot \mathbf{\Lambda}_{b,r}^T = \alpha_r \mathbf{I}_{L_r \times L_r}$ (i.e., $\mathbf{\Lambda}_{a,r} = \alpha_r \mathbf{\Lambda}_{b,r}^{-T}$) and $\mathbf{c}_r = \alpha_r \bar{\mathbf{c}}_r$, $1 \leqslant r \leqslant R$. In other words, $(\mathbf{A}, \mathbf{B}, \mathbf{C})$ and $(\bar{\mathbf{A}}, \bar{\mathbf{B}}, \bar{\mathbf{C}})$ are equal up to trivial indeterminacies. ∎

5. The decomposition in rank-(L, M, N) terms. In this section we study the uniqueness of the decomposition in rank-(L, M, N) terms. We use the notation introduced in section 2.2. Section 5.1 concerns uniqueness of the general decomposition. In section 5.2 we have a closer look at the special case of rank-$(2, 2, 2)$ terms.

5.1. General results. In this section we follow the same structure as in section 4:

Theorem 5.1	corresponds to	Theorem 4.1
Lemma 5.2		Lemma 4.3
Theorem 5.3		Theorem 4.5
Lemma 5.4		Lemma 4.6
Theorem 5.5		Theorem 4.7.

For decompositions in generic rank-(L, M, N) terms, the results of this section can be summarized as follows. We have essential uniqueness if

(i) Theorem 5.1:

$$\begin{aligned}
&L = M \quad \text{and} \quad I \geqslant LR \quad \text{and} \quad J \geqslant MR \quad \text{and} \quad N \geqslant 3 \\
&\qquad \text{and} \quad \mathbf{C}_r \text{ is full column rank, } 1 \leqslant r \leqslant R; \qquad (5.1)
\end{aligned}$$

(ii) Theorem 5.3:

(5.2)

$$I \geqslant LR \quad \text{and} \quad N > L + M - 2 \quad \text{and} \quad \min\left(\left\lfloor \frac{J}{M} \right\rfloor, R\right) + \min\left(\left\lfloor \frac{K}{N} \right\rfloor, R\right) \geqslant R + 2;$$

or

$$J \geqslant MR \quad \text{and} \quad N > L + M - 2 \quad \text{and} \quad \min\left(\left\lfloor \frac{I}{L} \right\rfloor, R\right) + \min\left(\left\lfloor \frac{K}{N} \right\rfloor, R\right) \geqslant R + 2.$$

(5.3)

(iii) Theorem 5.5:

$$N > L + M - 2 \quad \text{and} \quad \min\left(\left\lfloor \frac{I}{L} \right\rfloor, R\right) + \min\left(\left\lfloor \frac{J}{M} \right\rfloor, R\right) + \min\left(\left\lfloor \frac{K}{N} \right\rfloor, R\right) \geqslant 2R + 2. \tag{5.4}$$

First we have a uniqueness result that stems from the fact that the column spaces of $\mathbf{A}_r$, $1 \leqslant r \leqslant R$, are invariant subspaces of quotients of tensor slices.

THEOREM 5.1. *Let* $(\mathbf{A}, \mathbf{B}, \mathbf{C}, \mathcal{D})$ *represent a decomposition of* $\mathcal{T} \in \mathbb{K}^{I \times J \times K}$ *in* R *rank-*(L, L, N) *terms. Suppose that* $\operatorname{rank}(\mathbf{A}) = LR$, $\operatorname{rank}(\mathbf{B}) = LR$, $\operatorname{rank}_{k'}(\mathbf{C}) \geqslant 1$, $N \geqslant 3$, *and that* $\mathcal{D}$ *is generic. Then* $(\mathbf{A}, \mathbf{B}, \mathbf{C}, \mathcal{D})$ *is essentially unique.*

Proof. From Theorem 6.1 below we have that under the conditions specified in Theorem 5.1, a decomposition in terms of the form $\mathcal{D}_r \bullet_1 \mathbf{A}_r \bullet_2 \mathbf{B}_r$ is essentially unique. Consequently, a decomposition in terms of the form $\mathcal{D}_r \bullet_1 \mathbf{A}_r \bullet_2 \mathbf{B}_r \bullet_3 \mathbf{C}$ is essentially unique if $\mathbf{C}$ is full column rank. A fortiori, reasoning as in the proof of Theorem 6.1, a decomposition in terms of the form $\mathcal{D}_r \bullet_1 \mathbf{A}_r \bullet_2 \mathbf{B}_r \bullet_3 \mathbf{C}_r$, in which the matrices $\mathbf{C}_r$ are possibly different, is essentially unique if these matrices $\mathbf{C}_r$ are full column rank. □

Remark 4. The generalization to the decomposition in rank-(L_r, L_r, N_r) terms, $1 \leqslant r \leqslant R$, is trivial.

Remark 5. In the nongeneric case, lack of uniqueness can be due to the fact that tensors $\mathcal{D}_r$ can be further block-diagonalized by means of basis transformations in their mode-1, mode-2, and mode-3 vector space. We give an example.

Example 1. Assume a tensor $\mathcal{T} \in \mathbb{K}^{12 \times 12 \times 12}$ that can be decomposed in three rank-$(4, 4, 4)$ terms as follows:

$$\mathcal{T} = \sum_{r=1}^{3} \mathcal{D}_r \bullet_1 \mathbf{A}_r \bullet_2 \mathbf{B}_r \bullet_3 \mathbf{C}_r$$

with $\mathcal{D}_r \in \mathbb{K}^{4 \times 4 \times 4}$, $\mathbf{A}_r, \mathbf{B}_r, \mathbf{C}_r \in \mathbb{K}^{12 \times 4}$, $1 \leqslant r \leqslant 3$. Now assume that $\mathcal{D}_1$, $\mathcal{D}_2$, and $\mathcal{D}_3$ can be further decomposed as follows:

$$\begin{aligned}
\mathcal{D}_1 &= \mathbf{u}_1 \circ \mathbf{v}_1 \circ \mathbf{w}_1 + \mathbf{u}_2 \circ \mathbf{v}_2 \circ \mathbf{w}_2 + \mathcal{H}_1 \bullet_1 \mathbf{E}_1 \bullet_2 \mathbf{F}_1 \bullet_3 \mathbf{G}_1, \\
\mathcal{D}_2 &= \mathbf{u}_3 \circ \mathbf{v}_3 \circ \mathbf{w}_3 + \mathcal{H}_2 \bullet_1 \mathbf{E}_2 \bullet_2 \mathbf{F}_2 \bullet_3 \mathbf{G}_2, \\
\mathcal{D}_3 &= \mathbf{u}_4 \circ \mathbf{v}_4 \circ \mathbf{w}_4 + \mathcal{H}_3 \bullet_1 \mathbf{E}_3 \bullet_2 \mathbf{F}_3 \bullet_3 \mathbf{G}_3,
\end{aligned}$$

where $\mathbf{u}_s, \mathbf{v}_s, \mathbf{w}_s \in \mathbb{K}^4$, $1 \leqslant s \leqslant 4$, $\mathbf{E}_1, \mathbf{F}_1, \mathbf{G}_1 \in \mathbb{K}^{4 \times 2}$, $\mathbf{E}_2, \mathbf{E}_3, \mathbf{F}_2, \mathbf{F}_3, \mathbf{G}_2, \mathbf{G}_3 \in \mathbb{K}^{4 \times 3}$, $\mathcal{H}_1 \in \mathbb{K}^{2 \times 2 \times 2}$, $\mathcal{H}_2, \mathcal{H}_3 \in \mathbb{K}^{3 \times 3 \times 3}$. Then we have the following alternative decomposition in three rank-$(4, 4, 4)$ terms:

$$\begin{aligned}
\mathcal{T} = {} & [(\mathbf{A}_2\mathbf{u}_3) \circ (\mathbf{B}_2\mathbf{v}_3) \circ (\mathbf{C}_2\mathbf{w}_3) + (\mathbf{A}_3\mathbf{u}_4) \circ (\mathbf{B}_3\mathbf{v}_4) \circ (\mathbf{C}_3\mathbf{w}_4) \\
& + \mathcal{H}_1 \bullet_1 (\mathbf{A}_1\mathbf{E}_1) \bullet_2 (\mathbf{B}_1\mathbf{F}_1) \bullet_3 (\mathbf{C}_1\mathbf{G}_1)] \\
& + [(\mathbf{A}_1\mathbf{u}_1) \circ (\mathbf{B}_1\mathbf{v}_1) \circ (\mathbf{C}_1\mathbf{w}_1) + \mathcal{H}_2 \bullet_1 (\mathbf{A}_2\mathbf{E}_2) \bullet_2 (\mathbf{B}_2\mathbf{F}_2) \bullet_3 (\mathbf{C}_2\mathbf{G}_2)] \\
& + [(\mathbf{A}_1\mathbf{u}_2) \circ (\mathbf{B}_1\mathbf{v}_2) \circ (\mathbf{C}_1\mathbf{w}_2) + \mathcal{H}_3 \bullet_1 (\mathbf{A}_3\mathbf{E}_3) \bullet_2 (\mathbf{B}_3\mathbf{F}_3) \bullet_3 (\mathbf{C}_3\mathbf{G}_3)].
\end{aligned}$$

We now prove essential uniqueness of $\mathbf{A}$ and $\mathbf{B}$ under a constraint on the block dimensions and a Kruskal-type condition.

LEMMA 5.2. *Let* $(\mathbf{A}, \mathbf{B}, \mathbf{C}, \mathcal{D})$ *represent a decomposition of* $\mathcal{T}$ *in* R *rank-*(L, M, N) *terms. Suppose that the conditions*

$$N > L + M - 2, \tag{5.5}$$

$$k'_{\mathbf{A}} + k'_{\mathbf{B}} + k'_{\mathbf{C}} \geqslant 2R + 2 \tag{5.6}$$

hold and that we have an alternative decomposition of $\mathcal{T}$*, represented by* $(\bar{\mathbf{A}}, \bar{\mathbf{B}}, \bar{\mathbf{C}}, \bar{\mathcal{D}})$*, with* $k'_{\bar{\mathbf{A}}}$ *and* $k'_{\bar{\mathbf{B}}}$ *maximal under the given dimensionality constraints. For generic* $\mathcal{D}$ *there holds that* $\bar{\mathbf{A}} = \mathbf{A} \cdot \mathbf{\Pi}_a \cdot \mathbf{\Lambda}_a$*, in which* $\mathbf{\Pi}_a$ *is a block permutation matrix and* $\mathbf{\Lambda}_a$ *a square nonsingular block-diagonal matrix, compatible with the structure of* $\mathbf{A}$*. There also holds* $\bar{\mathbf{B}} = \mathbf{B} \cdot \mathbf{\Pi}_b \cdot \mathbf{\Lambda}_b$*, in which* $\mathbf{\Pi}_b$ *is a block permutation matrix and* $\mathbf{\Lambda}_b$ *a square nonsingular block-diagonal matrix, compatible with the structure of* $\mathbf{B}$*.*

Proof. It suffices to prove the lemma for $\mathbf{A}$. The result for $\mathbf{B}$ can be obtained by switching modes. We work in analogy with [54] and the proof of Lemma 4.2 and 4.3. We use the equivalence lemma for partitioned matrices to prove essential uniqueness of $\mathbf{A}$.

(i) *Derivation of an upper-bound on* $\omega'(\mathbf{x}^T \bar{\mathbf{A}})$. The constraint on $k'_{\bar{\mathbf{A}}}$ implies that $k'_{\bar{\mathbf{A}}} \geqslant k'_{\mathbf{A}}$. Hence, if $\omega'(\mathbf{x}^T \bar{\mathbf{A}}) \leqslant R - k'_{\bar{\mathbf{A}}} + 1$, then

$$\omega'(\mathbf{x}^T \bar{\mathbf{A}}) \leqslant R - k'_{\bar{\mathbf{A}}} + 1 \leqslant R - k'_{\mathbf{A}} + 1 \leqslant k'_{\mathbf{B}} + k_{\mathbf{C}} - (R + 1), \tag{5.7}$$

where the last inequality corresponds to condition (5.6).

(ii) *Derivation of a lower-bound on* $\omega'(\mathbf{x}^T \bar{\mathbf{A}})$. Consider $\mathcal{D}_r \bullet_1 (\mathbf{x}^T \mathbf{A}_r)$ and $\bar{\mathcal{D}}_r \bullet_1 (\mathbf{x}^T \bar{\mathbf{A}}_r)$, $1 \leqslant r \leqslant R$, as $(M \times N)$ matrices. Then the linear combination of slices $\sum_{i=1}^{I} x_i \mathbf{T}_{J \times K, i}$ is given by

$$\begin{aligned} &\mathbf{B} \cdot \text{blockdiag}[\mathcal{D}_1 \bullet_1 (\mathbf{x}^T \mathbf{A}_1), \ldots, \mathcal{D}_R \bullet_1 (\mathbf{x}^T \mathbf{A}_R)] \cdot \mathbf{C}^T \\ &\quad = \bar{\mathbf{B}} \cdot \text{blockdiag}[\bar{\mathcal{D}}_1 \bullet_1 (\mathbf{x}^T \bar{\mathbf{A}}_1), \ldots, \bar{\mathcal{D}}_R \bullet_1 (\mathbf{x}^T \bar{\mathbf{A}}_R)] \cdot \bar{\mathbf{C}}^T. \end{aligned}$$

Taking into account that $N > M$, we have

$$\begin{aligned} M\omega'(\mathbf{x}^T \bar{\mathbf{A}}) &\geqslant r_{\text{blockdiag}[\bar{\mathcal{D}}_1 \bullet_1 (\mathbf{x}^T \bar{\mathbf{A}}_1), \ldots, \bar{\mathcal{D}}_R \bullet_1 (\mathbf{x}^T \bar{\mathbf{A}}_R)]} \\ &\geqslant r_{\bar{\mathbf{B}} \cdot \text{blockdiag}[\bar{\mathcal{D}}_1 \bullet_1 (\mathbf{x}^T \bar{\mathbf{A}}_1), \ldots, \bar{\mathcal{D}}_R \bullet_1 (\mathbf{x}^T \bar{\mathbf{A}}_R)] \cdot \bar{\mathbf{C}}^T} \\ &= r_{\mathbf{B} \cdot \text{blockdiag}[\mathcal{D}_1 \bullet_1 (\mathbf{x}^T \mathbf{A}_1), \ldots, \mathcal{D}_R \bullet_1 (\mathbf{x}^T \mathbf{A}_R)] \cdot \mathbf{C}^T}. \end{aligned} \tag{5.8}$$

Since the tensors $\mathcal{D}_r$ are generic, and because of condition (5.5), all the $(M \times N)$ matrices $\mathcal{D}_r \bullet_1 (\mathbf{x}^T \mathbf{A}_r)$ are rank-M. (Rank deficiency would imply that $N - M + 1$ determinants are zero, while $\mathbf{x}$ provides only $L - 1$ independent parameters and an irrelevant scaling factor.) Define $(K \times M)$ matrices $\underline{\mathbf{C}}_r = \mathbf{C}_r \cdot [\mathcal{D}_r \bullet_1 (\mathbf{x}^T \mathbf{A}_r)]^T$, $1 \leqslant r \leqslant R$. Let $\gamma = \omega'(\mathbf{x}^T \mathbf{A})$ and $\underline{\mathbf{C}} = (\underline{\mathbf{C}}_1 \ \ldots \ \underline{\mathbf{C}}_R)$. Let $\tilde{\mathbf{B}}$ and $\tilde{\underline{\mathbf{C}}}$ consist of the submatrices of $\mathbf{B}$ and $\underline{\mathbf{C}}$, respectively, corresponding to the parts of $\mathbf{x}^T \mathbf{A}$ that are not all-zero. From (5.8) we have

$$M\omega'(\mathbf{x}^T \bar{\mathbf{A}}) \geqslant r_{\tilde{\mathbf{B}} \cdot \tilde{\underline{\mathbf{C}}}^T}. \tag{5.9}$$

Both $\tilde{\mathbf{B}}$ and $\tilde{\underline{\mathbf{C}}}$ have γM columns. Sylvester's inequality now yields

$$r_{\tilde{\mathbf{B}} \cdot \tilde{\underline{\mathbf{C}}}^T} \geqslant r_{\tilde{\mathbf{B}}} + r_{\tilde{\underline{\mathbf{C}}}} - \gamma M. \tag{5.10}$$

From the definition of k′-rank, we have

$$r_{\tilde{\mathbf{B}}} \geqslant M \min(\gamma, k'_{\mathbf{B}}). \tag{5.11}$$

On the other hand, $\underline{\tilde{\mathbf{C}}}$ consists of γ $(K \times M)$ submatrices, of which the columns are sampled in the column space of the corresponding submatrix of $\mathbf{C}$. From the definition of k′-rank, we must have

$$r_{\underline{\tilde{\mathbf{C}}}} \geqslant M \min(\gamma, k'_{\mathbf{C}}). \tag{5.12}$$

Combination of (5.9)–(5.12) yields the following lower-bound on $\omega'(\mathbf{x}^T \bar{\mathbf{A}})$:

$$\omega'(\mathbf{x}^T \bar{\mathbf{A}}) \geqslant \min(\gamma, k'_{\mathbf{B}}) + \min(\gamma, k'_{\mathbf{C}}) - \gamma. \tag{5.13}$$

(iii) *Combination of the two bounds.* This is analogous to Lemma 4.2. □

If matrix $\mathbf{A}$ or $\mathbf{B}$ is tall and full column rank, then its essential uniqueness implies essential uniqueness of the overall tensor decomposition.

THEOREM 5.3. *Let* $(\mathbf{A}, \mathbf{B}, \mathbf{C}, \mathcal{D})$ *represent a decomposition of* $\mathcal{T}$ *in* R *rank-*(L, M, N) *terms, with* $N > L + M - 2$. *Suppose that we have an alternative decomposition of* $\mathcal{T}$, *represented by* $(\bar{\mathbf{A}}, \bar{\mathbf{B}}, \bar{\mathbf{C}}, \bar{\mathcal{D}})$, *with* $k'_{\bar{\mathbf{A}}}$ *and* $k'_{\bar{\mathbf{B}}}$ *maximal under the given dimensionality constraints. For generic* $\mathcal{D}$ *there holds that if*

$$k'_{\mathbf{A}} = R \quad \textit{and} \quad k'_{\mathbf{B}} + k'_{\mathbf{C}} \geqslant R + 2 \tag{5.14}$$

or

$$k'_{\mathbf{B}} = R \quad \textit{and} \quad k'_{\mathbf{A}} + k'_{\mathbf{C}} \geqslant R + 2, \tag{5.15}$$

then $(\mathbf{A}, \mathbf{B}, \mathbf{C}, \mathcal{D})$ *and* $(\bar{\mathbf{A}}, \bar{\mathbf{B}}, \bar{\mathbf{C}}, \bar{\mathcal{D}})$ *are essentially equal.*

Proof. It suffices to prove the theorem for $\mathbf{A}$. The result for $\mathbf{B}$ is obtained by switching modes. From (2.12) we have

$$\begin{aligned} \mathbf{T}_{JK \times I} &= (\mathbf{B} \odot \mathbf{C}) \cdot \text{blockdiag}((\mathcal{D}_1)_{MN \times L}, \ldots, (\mathcal{D}_R)_{MN \times L}) \cdot \mathbf{A}^T \\ &= (\bar{\mathbf{B}} \odot \bar{\mathbf{C}}) \cdot \text{blockdiag}((\bar{\mathcal{D}}_1)_{MN \times L}, \ldots, (\bar{\mathcal{D}}_R)_{MN \times L}) \cdot \bar{\mathbf{A}}^T. \end{aligned} \tag{5.16}$$

From Lemma 5.2 we have

$$\bar{\mathbf{A}} = \mathbf{A} \cdot \mathbf{\Pi}_a \cdot \mathbf{\Lambda}_a. \tag{5.17}$$

Since $k'_{\mathbf{A}} = R$, $\mathbf{A}$ is full column rank. Substitution of (5.17) in (5.16) now yields

$$\begin{aligned} &(\mathbf{B} \odot \mathbf{C}) \cdot \text{blockdiag}((\mathcal{D}_1)_{MN \times L}, \ldots, (\mathcal{D}_R)_{MN \times L}) \\ &\quad = (\bar{\mathbf{B}} \odot \bar{\mathbf{C}}) \cdot \text{blockdiag}((\bar{\mathcal{D}}_1)_{MN \times L}, \ldots, (\bar{\mathcal{D}}_R)_{MN \times L}) \cdot \mathbf{\Lambda}_a^T \cdot \mathbf{\Pi}_a^T. \end{aligned} \tag{5.18}$$

This implies that the matrices $(\bar{\mathbf{B}}_r \otimes \bar{\mathbf{C}}_r) \cdot (\bar{\mathcal{D}}_r)_{MN \times L}$ are permuted in the same way with respect to $(\mathbf{B}_r \otimes \mathbf{C}_r) \cdot (\mathcal{D}_r)_{MN \times L}$ as the matrices $\bar{\mathbf{A}}_r$ with respect to $\mathbf{A}_r$. Furthermore, if $\bar{\mathbf{A}}_i = \mathbf{A}_j \cdot \mathbf{F}$, then $(\bar{\mathbf{B}}_i \otimes \bar{\mathbf{C}}_i) \cdot (\bar{\mathcal{D}}_i)_{MN \times L} \cdot \mathbf{F}^T = (\mathbf{B}_j \otimes \mathbf{C}_j) \cdot (\mathcal{D}_j)_{MN \times L}$. Equivalently, we have $\bar{\mathcal{D}}_i \bullet_2 \bar{\mathbf{B}}_i \bullet_3 \bar{\mathbf{C}}_i = \mathcal{D}_j \bullet_1 \mathbf{F}^{-1} \bullet_2 \mathbf{B}_j \bullet_3 \mathbf{C}_j$. □

We now prove that under conditions (5.5) and (5.6), the submatrices of $\bar{\mathbf{A}}$ and $\bar{\mathbf{B}}$ in an alternative decomposition of $\mathcal{T}$ are ordered in the same way.

LEMMA 5.4. *Let* $(\mathbf{A}, \mathbf{B}, \mathbf{C}, \mathcal{D})$ *represent a decomposition of* $\mathcal{T}$ *in* R *rank-*(L, M, N) *terms. Suppose that we have an alternative decomposition of* $\mathcal{T}$, *represented by* $(\bar{\mathbf{A}}, \bar{\mathbf{B}}, \bar{\mathbf{C}}, \bar{\mathcal{D}})$, *with* $k'_{\bar{\mathbf{A}}}$ *and* $k'_{\bar{\mathbf{B}}}$ *maximal under the given dimensionality constraints. For generic* $\mathcal{D}$ *there holds that if conditions* (5.5) *and* (5.6) *hold, then* $\bar{\mathbf{A}} = \mathbf{A} \cdot \mathbf{\Pi} \cdot \mathbf{\Lambda}_a$ *and* $\bar{\mathbf{B}} = \mathbf{B} \cdot \mathbf{\Pi} \cdot \mathbf{\Lambda}_b$, *in which* $\mathbf{\Pi}$ *is a block permutation matrix and* $\mathbf{\Lambda}_a$ *and* $\mathbf{\Lambda}_b$ *square nonsingular block-diagonal matrices, compatible with the block structure of* $\mathbf{A}$ *and* $\mathbf{B}$.

Proof. From Lemma 5.2 we know that $\bar{\mathbf{A}} = \mathbf{A} \cdot \mathbf{\Pi}_a \cdot \mathbf{\Lambda}_a$ and $\bar{\mathbf{B}} = \mathbf{B} \cdot \mathbf{\Pi}_b \cdot \mathbf{\Lambda}_b$. We show that $\mathbf{\Pi}_a = \mathbf{\Pi}_b$ if (5.5) and (5.6) hold. We work in analogy with [38, pp. 129–132], [54], and the proof of Lemma 4.6.

Since both $(\mathbf{A}, \mathbf{B}, \mathbf{C}, \mathcal{D})$ and $(\bar{\mathbf{A}}, \bar{\mathbf{B}}, \bar{\mathbf{C}}, \bar{\mathcal{D}})$ represent a decomposition of $\mathcal{T}$, we have for vectors $\mathbf{v}$ and $\mathbf{w}$,

$$\begin{aligned} \mathcal{T} \bullet_1 \mathbf{v}^T \bullet_2 \mathbf{w}^T &= \sum_{r=1}^{R} \mathcal{D}_r \bullet_1 (\mathbf{v}^T \mathbf{A}_r) \bullet_2 (\mathbf{w}^T \mathbf{B}_r) \bullet_3 \mathbf{C}_r \\ &= \sum_{r=1}^{R} \bar{\mathcal{D}}_r \bullet_1 (\mathbf{v}^T \bar{\mathbf{A}}_r) \bullet_2 (\mathbf{w}^T \bar{\mathbf{B}}_r) \bullet_3 \bar{\mathbf{C}}_r. \end{aligned} \tag{5.19}$$

Let the index functions $g(x)$ and $h(x)$ be given by $\mathbf{A\Pi}_a = \begin{pmatrix} \mathbf{A}_{g(1)} & \mathbf{A}_{g(2)} & \dots & \mathbf{A}_{g(R)} \end{pmatrix}$ and $\mathbf{B\Pi}_b = \begin{pmatrix} \mathbf{B}_{h(1)} & \mathbf{B}_{h(2)} & \dots & \mathbf{B}_{h(R)} \end{pmatrix}$, respectively. Then (5.19) can be written as

$$\mathbf{C} \cdot \mathbf{p} = \bar{\mathbf{C}} \cdot \mathbf{q}, \tag{5.20}$$

in which $\mathbf{p}$ and $\mathbf{q}$ are defined by

$$\mathbf{p} = \begin{pmatrix} (\mathcal{D}_1)_{N \times LM} \cdot [(\mathbf{A}_1^T \mathbf{v}) \otimes (\mathbf{B}_1^T \mathbf{w})] \\ \vdots \\ (\mathcal{D}_R)_{N \times LM} \cdot [(\mathbf{A}_R^T \mathbf{v}) \otimes (\mathbf{B}_R^T \mathbf{w})] \end{pmatrix},$$

$$\mathbf{q} = \begin{pmatrix} (\bar{\mathcal{D}}_1)_{N \times LM} \cdot [(\mathbf{\Lambda}_{a,1}^T \bar{\mathbf{A}}_{g(1)}^T \mathbf{v}) \otimes (\mathbf{\Lambda}_{b,1}^T \bar{\mathbf{B}}_{h(1)}^T \mathbf{w})] \\ \vdots \\ (\bar{\mathcal{D}}_R)_{N \times LM} \cdot [(\mathbf{\Lambda}_{a,R}^T \bar{\mathbf{A}}_{g(R)}^T \mathbf{v}) \otimes (\mathbf{\Lambda}_{b,R}^T \bar{\mathbf{B}}_{h(R)}^T \mathbf{w})] \end{pmatrix},$$

where $\mathbf{\Lambda}_{a,r}$ and $\mathbf{\Lambda}_{b,r}$ denote the rth block of $\mathbf{\Lambda}_a$ and $\mathbf{\Lambda}_b$, respectively.

We will now show by contradiction that $\mathbf{\Pi}_a = \mathbf{\Pi}_b$. If $\mathbf{\Pi}_a \neq \mathbf{\Pi}_b$, then we will be able to find vectors $\mathbf{v}$ and $\mathbf{w}$ such that $\mathbf{q} = \mathbf{0}$ and $\mathbf{p} \neq \mathbf{0}$ has less than $k'_{\mathbf{C}}$ nonzero $(N \times 1)$ subvectors. This implies that a set of less than $k'_{\mathbf{C}}$ vectors, each sampled in the column space of a different submatrix of $\mathbf{C}$, is linearly dependent, which contradicts the definition of $k'_{\mathbf{C}}$.

Suppose that $\mathbf{\Pi}_a \neq \mathbf{\Pi}_b$. Then there exists an r such that $\mathbf{A}_r$ is the sth submatrix of $\mathbf{A\Pi}_a$, $\mathbf{B}_r$ is the tth submatrix of $\mathbf{B\Pi}_b$, and $s \neq t$. Formally, there exists an r such that $r = g(s) = h(t)$ and $s \neq t$. We now create two index sets $\mathsf{S}, \mathsf{T} \subset \{1, \dots, R\}$ in the same way as in the proof of Lemma 4.6.

Since $k'_{\mathbf{A}} - 1 \leqslant R - 1$, S contains exactly $k'_{\mathbf{A}} - 1$ elements. The set T contains $R - \text{card}(\mathsf{S}) = R - k'_{\mathbf{A}} + 1$ elements. Because of (5.6) and $k'_{\mathbf{C}} \leqslant R$, this is less than or equal to $k'_{\mathbf{B}} - 1$ elements. In the xth element of $\mathbf{q}$ we have either $g(x) \in \mathsf{S}$ or $h(x) \in \mathsf{T}$, $x = 1, \dots, R$. The index $r = g(s) = h(t)$ is neither an element of S nor an element of T. Denote $\{i_1, i_2, \dots, i_{k'_{\mathbf{A}}-1}\} = \mathsf{S}$ and $\{j_1, j_2, \dots, j_{R-k'_{\mathbf{A}}+1}\} = \mathsf{T}$.

We choose a vector $\mathbf{v}$ such that $\mathbf{v}^T \mathbf{A}_i = \mathbf{0}$ if $i \in \mathsf{S}$, and $\mathbf{v}^T \mathbf{A}_r \neq 0$. This is always possible. The vector $\mathbf{v}$ has to be chosen in $\text{null}([\mathbf{A}_{i_1} \ \dots \ \mathbf{A}_{i_{k'_{\mathbf{A}}-1}}])$, which is an $(I - (k'_{\mathbf{A}} - 1)L)$-dimensional space. If a column of $\mathbf{A}_r$ is orthogonal to all possible vectors $\mathbf{v}$, then it lies in $\text{span}([\mathbf{A}_{i_1} \ \dots \ \mathbf{A}_{i_{k'_{\mathbf{A}}-1}}])$. Then we would have a contradiction with the definition of $k'_{\mathbf{A}}$. Similarly, we can choose a vector $\mathbf{w}$ such that $\mathbf{w}^T \mathbf{B}_j = \mathbf{0}$ if $j \in \mathsf{T}$, and $\mathbf{w}^T \mathbf{B}_r \neq 0$.

Because of condition (5.5), the genericity of $\mathcal{D}_r$, and the fact that $\mathbf{v}^T \mathbf{A}_r \neq 0$, the $(N \times M)$ matrix $\mathcal{D}_r \bullet_1 (\mathbf{v}^T \mathbf{A}_r)$ is rank-M. Rank deficiency would imply that $N - M + 1$

determinants are zero, while $\mathbf{v}^T\mathbf{A}_r$ provides only $L-1$ parameters and an irrelevant scaling factor. Since $\mathcal{D}_r \bullet_1 (\mathbf{v}^T\mathbf{A}_r)$ is full column rank, and since $\mathbf{w}^T\mathbf{B}_r \neq 0$, we have $\mathcal{D}_r \bullet_1 (\mathbf{v}^T\mathbf{A}_r) \bullet_2 (\mathbf{w}^T\mathbf{B}_r) \neq \mathbf{0}$. Equivalently, $(\mathcal{D}_r)_{N\times LM} \cdot [(\mathbf{A}_r^T\mathbf{v}) \otimes (\mathbf{B}_r^T\mathbf{w})] \neq \mathbf{0}$.

Define $\mathsf{S}^c = \{1,\ldots,R\} \setminus \mathsf{S}$ and $\mathsf{T}^c = \{1,\ldots,R\} \setminus \mathsf{T}$. The number of nonzero subvectors of $\mathbf{p}$ is bounded from above by

$$\mathrm{card}(\mathsf{S}^c \cap \mathsf{T}^c) \leqslant \mathrm{card}(\mathsf{S}^c) \leqslant R - k'_{\mathbf{A}} + 1 \leqslant k'_{\mathbf{C}} - 1,$$

where the last inequality is due to (5.6) and $k'_{\mathbf{B}} \leqslant R$. Hence, $\mathbf{C}\cdot\mathbf{p} = \mathbf{0}$ implies that a set of less than $k'_{\mathbf{C}}$ columns, each sampled in the column space of a different submatrix of $\mathbf{C}$, is linearly dependent, which contradicts the definition of $k'_{\mathbf{C}}$. This completes the proof. ∎

THEOREM 5.5. *Let $(\mathbf{A},\mathbf{B},\mathbf{C},\mathcal{D})$ represent a decomposition of $\mathcal{T}$ in R rank-(L,M,N) terms. Suppose that we have an alternative decomposition of $\mathcal{T}$, represented by $(\bar{\mathbf{A}},\bar{\mathbf{B}},\bar{\mathbf{C}},\bar{\mathcal{D}})$, with $k'_{\bar{\mathbf{A}}}$ and $k'_{\bar{\mathbf{B}}}$ maximal under the given dimensionality constraints. For generic $\mathcal{D}$ there holds that, if conditions* (5.5) *and* (5.6) *hold, then $(\mathbf{A},\mathbf{B},\mathbf{C},\mathcal{D})$ and $(\bar{\mathbf{A}},\bar{\mathbf{B}},\bar{\mathbf{C}},\bar{\mathcal{D}})$ are essentially equal.*

Proof. From Lemma 5.4 we have that $\bar{\mathbf{A}} = \mathbf{A}\cdot\mathbf{\Pi}\cdot\mathbf{\Lambda}_a$ and $\bar{\mathbf{B}} = \mathbf{B}\cdot\mathbf{\Pi}\cdot\mathbf{\Lambda}_b$. Put the submatrices of $\bar{\mathbf{A}}$ and $\bar{\mathbf{B}}$ in the same order as the submatrices of $\mathbf{A}$ and $\mathbf{B}$. After reordering, we have $\bar{\mathbf{A}} = \mathbf{A}\cdot\mathbf{\Lambda}_a$, with $\mathbf{\Lambda}_a = \mathrm{blockdiag}(\mathbf{\Lambda}_{a,1},\ldots,\mathbf{\Lambda}_{a,R})$, and $\bar{\mathbf{B}} = \mathbf{B}\cdot\mathbf{\Lambda}_b$, with $\mathbf{\Lambda}_b = \mathrm{blockdiag}(\mathbf{\Lambda}_{b,1},\ldots,\mathbf{\Lambda}_{b,R})$. From (2.14) we have that

$$\begin{aligned}\mathbf{T}_{IJ\times K} &= (\mathbf{A}\odot\mathbf{B})\cdot\mathrm{blockdiag}((\mathcal{D}_1)_{LM\times N},\ldots,(\mathcal{D}_R)_{LM\times N})\cdot\mathbf{C}^T\\ &= (\bar{\mathbf{A}}\odot\bar{\mathbf{B}})\cdot\mathrm{blockdiag}((\bar{\mathcal{D}}_1)_{LM\times N},\ldots,(\bar{\mathcal{D}}_R)_{LM\times N})\cdot\bar{\mathbf{C}}^T\\ &= (\mathbf{A}\odot\mathbf{B})\cdot\mathrm{blockdiag}((\mathbf{\Lambda}_{a,1}\otimes\mathbf{\Lambda}_{b,1})\cdot(\bar{\mathcal{D}}_1)_{LM\times N},\ldots,\\ &\qquad (\mathbf{\Lambda}_{a,R}\otimes\mathbf{\Lambda}_{b,R})\cdot(\bar{\mathcal{D}}_R)_{LM\times N})\cdot\bar{\mathbf{C}}^T. \qquad (5.21)\end{aligned}$$

From Lemma 3.4 we have that $k'_{\mathbf{A}\odot\mathbf{B}} \geqslant \min(k'_{\mathbf{A}} + k'_{\mathbf{B}} - 1, R)$. From (5.6) we have that $k'_{\mathbf{A}} + k'_{\mathbf{B}} - 1 \geqslant 2R + 1 - k'_{\mathbf{C}} \geqslant R+1$. Hence, $k'_{\mathbf{A}\odot\mathbf{B}} = R$, which implies that $\mathbf{A}\odot\mathbf{B}$ is full column rank. Multiplying (5.21) from the left by $(\mathbf{A}\odot\mathbf{B})^\dagger$, we obtain that

$$(\mathbf{\Lambda}_{a,r}\otimes\mathbf{\Lambda}_{b,r})\cdot(\bar{\mathcal{D}}_r)_{LM\times N}\cdot\bar{\mathbf{C}}_r^T = (\mathcal{D}_r)_{LM\times N}\cdot\mathbf{C}_r^T, \quad 1\leqslant r\leqslant R.$$

This can be rewritten as

$$\bar{\mathcal{D}}_r \bullet_1 \mathbf{\Lambda}_{a,r} \bullet_2 \mathbf{\Lambda}_{b,r} \bullet_3 \bar{\mathbf{C}}_r = \mathcal{D}_r \bullet_3 \mathbf{C}_r, \quad 1\leqslant r\leqslant R.$$

This means that $(\mathbf{A},\mathbf{B},\mathbf{C},\mathcal{D})$ and $(\bar{\mathbf{A}},\bar{\mathbf{B}},\bar{\mathbf{C}},\bar{\mathcal{D}})$ are equal up to trivial indeterminacies. ∎

5.2. Rank-(2, 2, 2) blocks. In the Kruskal-type results of the previous section, we have only considered rank-(L,M,N) terms for which $N > L+M-2$. Rank-$(2,2,3)$ terms, for instance, satisfy this condition. However, it would also be interesting to know whether the decomposition of a tensor in rank-$(2,2,2)$ terms is essentially unique. This special case is studied in this section.

A first result is that in $\mathbb{C}$ the decomposition of a tensor $\mathcal{T}$ in $R\geqslant 2$ rank-$(2,2,2)$ terms is not essentially unique. This is easy to understand. Assume, for instance, that $\mathcal{T}$ is the sum of two rank-$(2,2,2)$ terms $\mathcal{T}_1$ and $\mathcal{T}_2$. It is well known that in $\mathbb{C}$ the rank of rank-$(2,2,2)$ tensor is always equal to 2 [55]. Hence we have for some vectors $\mathbf{a}_r$,

$\mathbf{b}_r$, $\mathbf{c}_r$, $1 \leqslant r \leqslant 4$,

$$\begin{aligned}\mathcal{T} &= \mathcal{T}_1 + \mathcal{T}_2 \\ &= (\mathbf{a}_1 \circ \mathbf{b}_1 \circ \mathbf{c}_1 + \mathbf{a}_2 \circ \mathbf{b}_2 \circ \mathbf{c}_2) + (\mathbf{a}_3 \circ \mathbf{b}_3 \circ \mathbf{c}_3 + \mathbf{a}_4 \circ \mathbf{b}_4 \circ \mathbf{c}_4) \\ &= (\mathbf{a}_1 \circ \mathbf{b}_1 \circ \mathbf{c}_1 + \mathbf{a}_3 \circ \mathbf{b}_3 \circ \mathbf{c}_3) + (\mathbf{a}_2 \circ \mathbf{b}_2 \circ \mathbf{c}_2 + \mathbf{a}_4 \circ \mathbf{b}_4 \circ \mathbf{c}_4) \\ &= \tilde{\mathcal{T}}_1 + \tilde{\mathcal{T}}_2.\end{aligned}$$

Since $\tilde{\mathcal{T}}_1$ and $\tilde{\mathcal{T}}_2$ yield an other decomposition, the decomposition of $\mathcal{T}$ in 2 rank-$(2,2,2)$ terms is not essentially unique.

Theorem 5.5 does not hold in the case of rank-$(2,2,2)$ terms because Lemma 5.2 does not hold. The problem is that in (5.8) the (2×2) matrices $\mathcal{D}_r \times_1 (\mathbf{x}^T \mathbf{A}_r)$ are not necessarily rank-2. Indeed, let λ be a generalized eigenvalue of the pencil formed by the (2×2) matrices $(\mathcal{D}_r)_{1,:,:}$ and $(\mathcal{D}_r)_{2,:,:}$. Then $\mathcal{D}_r \bullet_1 (\mathbf{x}^T \mathbf{A}_r)$ is rank-1 if $\mathbf{x}^T \mathbf{A}_r$ is proportional to $(1, -\lambda)$. As a result, (5.12) does not hold.

On the other hand, if we work in $\mathbb{R}$, the situation is somewhat different. In $\mathbb{R}$, rank-$(2,2,2)$ terms can be either rank-2 or rank-3 [30, 39, 55]. If $\mathcal{D}_r$ is rank-2 in $\mathbb{R}$, then the pencil $((\mathcal{D}_r)_{1,:,:}, (\mathcal{D}_r)_{2,:,:})$ has two real generalized eigenvalues. Conversely, if the generalized eigenvalues of $((\mathcal{D}_r)_{1,:,:}, (\mathcal{D}_r)_{2,:,:})$ are complex, then $\mathcal{D}_r$ is rank-3. (The tensor $\mathcal{D}_r$ can also be rank-3 when an eigenvalue has algebraic multiplicity two but geometric multiplicity one. This case occurs with probability zero when the entries of $\mathcal{D}_r$ are drawn from continuous probability density functions and will not further be considered in this section.) We now have the following variant of Theorem 5.5.

THEOREM 5.6. *Let* $(\mathbf{A}, \mathbf{B}, \mathbf{C}, \mathcal{D})$ *represent a real decomposition of* $\mathcal{T} \in \mathbb{R}^{I \times J \times K}$ *in* R *rank-*$(2,2,2)$ *terms. Suppose that the condition*

$$k'_{\mathbf{A}} + k'_{\mathbf{B}} + k'_{\mathbf{C}} \geqslant 2R + 2$$

holds and that the generalized eigenvalues of $((\mathcal{D}_r)_{1,:,:}, (\mathcal{D}_r)_{2,:,:})$ *are complex,* $1 \leqslant r \leqslant R$. *Then* $(\mathbf{A}, \mathbf{B}, \mathbf{C}, \mathcal{D})$ *is essentially unique.*

Proof. Under the condition on the generalized eigenvalues of $((\mathcal{D}_r)_{1,:,:}, (\mathcal{D}_r)_{2,:,:})$, the matrices $\mathcal{D}_r \bullet_1 (\mathbf{x}^T \mathbf{A}_r)$ in (5.8) are necessarily rank-2, and the reasoning in the proof of Lemma 5.2 remains valid.

On the other hand, assuming that $\bar{\mathbf{A}} = \mathbf{A} \cdot \mathbf{\Pi}_a \cdot \mathbf{\Lambda}_a$ and $\bar{\mathbf{B}} = \mathbf{B} \cdot \mathbf{\Pi}_b \cdot \mathbf{\Lambda}_b$, only a technical modification of the proof of Lemma 5.4 is required to make sure that $\mathbf{\Pi}_a = \mathbf{\Pi}_b$ does hold. We only have to verify whether vectors $\mathbf{v}$ and $\mathbf{w}$ can be found such that $\mathbf{v}^T \mathbf{A}_i = \mathbf{0}$ if $i \in \mathsf{S}$, $\mathbf{w}^T \mathbf{B}_j = \mathbf{0}$ if $j \in \mathsf{T}$, and $(\mathcal{D}_r)_{N \times LM} \cdot [(\mathbf{A}_r^T \mathbf{v}) \otimes (\mathbf{B}_r^T \mathbf{w})] \neq \mathbf{0}$. Reasoning as in the proof of Lemma 5.4, we see that the constraint $\mathbf{v}^T \mathbf{A}_i = \mathbf{0}$, $i \in \mathsf{S}$, still leaves enough freedom for $\mathbf{v}^T \mathbf{A}_r$ to be any vector in $\mathbb{R}^2$. Equivalently, the constraint $\mathbf{w}^T \mathbf{B}_j = \mathbf{0}$, $j \in \mathsf{T}$, leaves enough freedom for $\mathbf{w}^T \mathbf{B}_r$ to be any vector in $\mathbb{R}^2$. We conclude that it is always possible to find the required vectors $\mathbf{v}$ and $\mathbf{w}$ if $\mathcal{D}_r \neq \mathcal{O}$.

Essential uniqueness of the overall tensor decomposition now follows from $\bar{\mathbf{A}} = \mathbf{A} \cdot \mathbf{\Pi} \cdot \mathbf{\Lambda}_a$ and $\bar{\mathbf{B}} = \mathbf{B} \cdot \mathbf{\Pi} \cdot \mathbf{\Lambda}_b$ in the same way as in the proof of Theorem 5.5. ∎

From Theorem 5.6 follows that a generic decomposition in real rank-3 rank-$(2,2,2)$ terms is essentially unique provided,

$$\min\left(\left\lfloor \frac{I}{2} \right\rfloor, R\right) + \min\left(\left\lfloor \frac{J}{2} \right\rfloor, R\right) + \min\left(\left\lfloor \frac{K}{2} \right\rfloor, R\right) \geqslant 2R + 2.$$

Finally, we have the following variant of Theorem 5.1.

THEOREM 5.7. *Let* $(\mathbf{A},\mathbf{B},\mathbf{C},\mathcal{D})$ *represent a real decomposition of* $\mathcal{T}\in\mathbb{R}^{I\times J\times K}$ *in* R *rank-*(L,M,N) *terms, with* $L=M=N=2$. *Suppose that* $\operatorname{rank}(\mathbf{A})=2R$, $\operatorname{rank}(\mathbf{B})=2R$, $\operatorname{rank}_{k'}(\mathbf{C})\geqslant 1$ *and that all generalized eigenvalues of the pencil* $((\mathcal{D}_r)_{L\times M,1},(\mathcal{D}_r)_{L\times M,2})$ *are complex,* $1\leqslant r\leqslant R$. *Then* $(\mathbf{A},\mathbf{B},\mathbf{C},\mathcal{D})$ *is essentially unique.*

Proof. Consider two vectors $\mathbf{x},\mathbf{y}\in\mathbb{R}^K$ for which $\mathbf{x}^T\mathbf{C}_r$ is not proportional to $\mathbf{y}^T\mathbf{C}_r$, $1\leqslant r\leqslant R$. Since all matrices $\mathbf{C}_r$ are full column rank, this is the case for generic vectors $\mathbf{x},\mathbf{y}$. Define $\mathbf{T}_1=\sum_{k=1}^K x_k\mathbf{T}_{I\times J,k}$ and $\mathbf{T}_2=\sum_{k=1}^K y_k\mathbf{T}_{I\times J,k}$. We have

$$\begin{aligned}\mathbf{T}_2\cdot\mathbf{T}_1^\dagger=\mathbf{A}\cdot\operatorname{blockdiag}\{&([\mathcal{D}_1\bullet_3(\mathbf{y}^T\mathbf{C}_1)]\cdot[\mathcal{D}_1\bullet_3(\mathbf{x}^T\mathbf{C}_1)]^\dagger,\ldots,\\&[\mathcal{D}_R\bullet_3(\mathbf{y}^T\mathbf{C}_R)]\cdot[\mathcal{D}_R\bullet_3(\mathbf{x}^T\mathbf{C}_R)]^\dagger)\}\cdot\mathbf{A}^\dagger.\end{aligned}$$

From this equation it is clear that the column space of any $\mathbf{A}_r$ is an invariant subspace of $\mathbf{T}_2\cdot\mathbf{T}_1^\dagger$.

Define $\mathbf{C}_r^T\mathbf{x}=\tilde{\mathbf{x}}_r$ and $\mathbf{C}_r^T\mathbf{y}=\tilde{\mathbf{y}}_r$. We have

$$\begin{aligned}\mathcal{D}_r\bullet_3(\mathbf{x}^T\mathbf{C}_r)&=(\tilde{\mathbf{x}}_r)_1(\mathcal{D}_r)_{L\times M,1}+(\tilde{\mathbf{x}}_r)_2(\mathcal{D}_r)_{L\times M,2},\\\mathcal{D}_r\bullet_3(\mathbf{y}^T\mathbf{C}_r)&=(\tilde{\mathbf{y}}_r)_1(\mathcal{D}_r)_{L\times M,1}+(\tilde{\mathbf{y}}_r)_2(\mathcal{D}_r)_{L\times M,2}.\end{aligned}$$

If there exist real values α and β, with $\alpha^2+\beta^2=1$, such that $\alpha\,\mathcal{D}_r\bullet_3(\mathbf{x}^T\mathbf{C}_r)+\beta\,\mathcal{D}_r\bullet_3(\mathbf{y}^T\mathbf{C}_r)$ is rank-1, then there also exist real values γ en μ, with $\gamma^2+\mu^2=1$, such that $\gamma\,(\mathcal{D}_r)_{L\times M,1}+\mu\,(\mathcal{D}_r)_{L\times M,2}$ is rank-1. The condition on the generalized eigenvalues of the pencils $((\mathcal{D}_r)_{L\times M,1},(\mathcal{D}_r)_{L\times M,2})$ implies thus that the blocks $[\mathcal{D}_r\bullet_3(\mathbf{y}^T\mathbf{C}_r)]\cdot[\mathcal{D}_r\bullet_3(\mathbf{x}^T\mathbf{C}_r)]^\dagger$ cannot be diagonalized by means of a real similarity transformation. We conclude that the only two-dimensional invariant subspaces of $\mathbf{T}_2\cdot\mathbf{T}_1^\dagger$ are the column spaces of the matrices $\mathbf{A}_r$. In other words, $\mathbf{A}$ is essentially unique.

Essential uniqueness of the overall decomposition now follows from (2.12). Assume that we have an alternative decomposition of $\mathcal{T}$, represented by $(\bar{\mathbf{A}},\bar{\mathbf{B}},\bar{\mathbf{C}},\bar{\mathcal{D}})$. We have $\bar{\mathbf{A}}=\mathbf{A}\cdot\mathbf{\Pi}_a\cdot\mathbf{\Lambda}_a$, in which $\mathbf{\Pi}_a$ is a block-permutation matrix and $\mathbf{\Lambda}_a=\operatorname{blockdiag}(\mathbf{\Lambda}_{a,1},\ldots,\mathbf{\Lambda}_{a,R})$ a square nonsingular block-diagonal matrix, compatible with the block structure of $\mathbf{A}$. From (2.12) we have

$$\begin{aligned}\mathbf{T}_{JK\times I}&=(\mathbf{B}\odot\mathbf{C})\cdot\operatorname{blockdiag}((\mathcal{D}_1)_{MN\times L},\ldots,(\mathcal{D}_R)_{MN\times L})\cdot\mathbf{A}^T\\&=(\bar{\mathbf{B}}\odot\bar{\mathbf{C}})\cdot\operatorname{blockdiag}((\bar{\mathcal{D}}_1)_{MN\times L},\ldots,(\bar{\mathcal{D}}_R)_{MN\times L})\cdot\mathbf{\Pi}_a^T\cdot\mathbf{\Lambda}_a^T\cdot\mathbf{A}^T.\end{aligned}$$

Right multiplication by $(\mathbf{A}^T)^\dagger$ yields

$$\begin{aligned}&(\mathbf{B}\odot\mathbf{C})\cdot\operatorname{blockdiag}((\mathcal{D}_1)_{MN\times L},\ldots,(\mathcal{D}_R)_{MN\times L})\\&=(\bar{\mathbf{B}}\odot\bar{\mathbf{C}})\cdot\operatorname{blockdiag}((\bar{\mathcal{D}}_1)_{MN\times L},\ldots,(\bar{\mathcal{D}}_R)_{MN\times L})\cdot\mathbf{\Pi}_a^T\cdot\mathbf{\Lambda}_a^T.\end{aligned}\tag{5.22}$$

Assume that the rth submatrix of $\mathbf{A}$ corresponds to the s-th submatrix of $\bar{\mathbf{A}}$. Then we have from (5.22) that

$$(\mathbf{B}_r\odot\mathbf{C}_r)\cdot(\mathcal{D}_r)_{MN\times L}=(\bar{\mathbf{B}}_s\odot\bar{\mathbf{C}}_s)\cdot(\bar{\mathcal{D}}_s)_{MN\times L}\cdot\mathbf{\Lambda}_{a,s}^T$$

in which $\mathbf{\Lambda}_{a,s}$ is the sth block of $\mathbf{\Lambda}_a$. Equivalently,

$$\mathcal{D}_r\bullet_2\mathbf{B}_r\bullet_3\mathbf{C}_r=\bar{\mathcal{D}}_s\bullet_1\mathbf{\Lambda}_{a,s}\bullet_2\bar{\mathbf{B}}_s\bullet_3\bar{\mathbf{C}}_s.$$

This completes the proof. ∎

6. Type-2 decomposition in rank-$(L, M, \cdot)$ terms. In this section we derive several conditions under which the type-2 decomposition in rank-$(L, M, \cdot)$ terms is unique. We use the notation introduced in section 2.3.

First we have a uniqueness result that stems from the fact that the column spaces of $\mathbf{A}_r$, $1 \leqslant r \leqslant R$, are invariant subspaces of quotients of tensor slices. This result is the counterpart of Theorem 4.1 in section 4 and Theorem 5.1 in section 5.1.

THEOREM 6.1. *Let* $(\mathbf{A}, \mathbf{B}, \mathcal{C})$ *represent a type-*2 *decomposition of* $\mathcal{T} \in \mathbb{K}^{I \times J \times K}$ *in* R *rank-*$(L, L, \cdot)$ *terms. Suppose that* $\operatorname{rank}(\mathbf{A}) = LR$, $\operatorname{rank}(\mathbf{B}) = LR$, $K \geqslant 3$, *and that* $\mathcal{C}$ *is generic. Then* $(\mathbf{A}, \mathbf{B}, \mathcal{C})$ *is essentially unique.*

Proof. We have

$$\mathbf{T}_{I\times J,2} \cdot \mathbf{T}^{\dagger}_{I\times J,1} = \mathbf{A} \cdot \operatorname{blockdiag}((\mathcal{C}_1)_{L\times M,2} \cdot (\mathcal{C}_1)^{\dagger}_{L\times M,1}, \ldots, (\mathcal{C}_R)_{L\times M,2} \cdot (\mathcal{C}_R)^{\dagger}_{L\times M,1}) \cdot \mathbf{A}^{\dagger},$$

where $M = L$. From this equation it is clear that the column space of any $\mathbf{A}_r$ is an invariant subspace of $\mathbf{T}_{I\times J,2} \cdot \mathbf{T}^{\dagger}_{I\times J,1}$. However, any set of eigenvectors forms an invariant subspace. To determine which eigenvectors belong together, we use the third slice $\mathbf{T}_{I\times J,3}$. We have

(6.1)
$$\mathbf{T}_{I\times J,3} \cdot \mathbf{T}^{\dagger}_{I\times J,1} = \mathbf{A} \cdot \operatorname{blockdiag}((\mathcal{C}_1)_{L\times M,3} \cdot (\mathcal{C}_1)^{\dagger}_{L\times M,1}, \ldots, (\mathcal{C}_R)_{L\times M,3} \cdot (\mathcal{C}_R)^{\dagger}_{L\times M,1}) \cdot \mathbf{A}^{\dagger}.$$

It is clear that the column space of any $\mathbf{A}_r$ is also an invariant subspace of $\mathbf{T}_{I\times J,3} \cdot \mathbf{T}^{\dagger}_{I\times J,1}$. On the other hand, because of the genericity of $\mathcal{C}$, we can interpret $(\mathcal{C}_r)_{L\times M,3} \cdot (\mathcal{C}_r)^{\dagger}_{L\times M,1}$ as $(\mathcal{C}_r)_{L\times M,2} \cdot (\mathcal{C}_r)^{\dagger}_{L\times M,1} + \mathbf{E}_r$, in which $\mathbf{E}_r \in \mathbb{K}^{L\times L}$ is a generic perturbation, $1 \leqslant r \leqslant R$. Perturbation analysis now states that the individual eigenvectors of $\mathbf{T}_{I\times J,3} \cdot \mathbf{T}^{\dagger}_{I\times J,1}$ do not correspond to those of $\mathbf{T}_{I\times J,2} \cdot \mathbf{T}^{\dagger}_{I\times J,1}$ [23, 32]. We conclude that $\mathbf{A}$ is essentially unique.

Essential uniqueness of the overall decomposition follows directly from the essential uniqueness of $\mathbf{A}$. Assume that we have an alternative decomposition of $\mathcal{T}$, represented by $(\bar{\mathbf{A}}, \bar{\mathbf{B}}, \bar{\mathcal{C}})$. We have $\bar{\mathbf{A}} = \mathbf{A} \cdot \mathbf{\Pi}_a \cdot \mathbf{\Lambda}_a$, in which $\mathbf{\Pi}_a$ is a block-permutation matrix and $\mathbf{\Lambda}_a$ a square nonsingular block-diagonal matrix, compatible with the block structure of $\mathbf{A}$. From (2.18) we have

$$\begin{aligned}\mathbf{T}_{JK\times I} &= [(\mathcal{C}_1 \bullet_2 \mathbf{B}_1)_{JK\times L} \ \ldots \ (\mathcal{C}_R \bullet_2 \mathbf{B}_R)_{JK\times L}] \cdot \mathbf{A}^T \\ &= \left[(\bar{\mathcal{C}}_1 \bullet_2 \bar{\mathbf{B}}_1)_{JK\times L} \ \ldots \ (\bar{\mathcal{C}}_R \bullet_2 \bar{\mathbf{B}}_R)_{JK\times L}\right] \cdot \bar{\mathbf{A}}^T.\end{aligned}$$

Hence,

$$\begin{aligned}&[(\mathcal{C}_1 \bullet_2 \mathbf{B}_1)_{JK\times L} \ \ldots \ (\mathcal{C}_R \bullet_2 \mathbf{B}_R)_{JK\times L}] \\ &\quad = \left[(\bar{\mathcal{C}}_1 \bullet_2 \bar{\mathbf{B}}_1)_{JK\times L} \ \ldots \ (\bar{\mathcal{C}}_R \bullet_2 \bar{\mathbf{B}}_R)_{JK\times L}\right] \cdot \mathbf{\Lambda}_a^T \cdot \mathbf{\Pi}_a^T.\end{aligned}$$

This implies that the matrices $(\mathcal{C}_r \bullet_2 \mathbf{B}_r)_{JK\times L}$ are ordered in the same way as the matrices $\mathbf{A}_r$. Furthermore, if $\bar{\mathbf{A}}_i = \mathbf{A}_j \cdot \mathbf{F}$, then $(\bar{\mathcal{C}}_i \bullet_2 \bar{\mathbf{B}}_i)_{JK\times L} \cdot \mathbf{F}^T = (\mathcal{C}_j \bullet_2 \mathbf{B}_j)_{JK\times L}$. Equivalently, we have $\bar{\mathcal{C}}_i \bullet_2 \bar{\mathbf{B}}_i = \mathcal{C}_j \bullet_1 \mathbf{F}^{-1} \bullet_2 \mathbf{B}_j$. This means that $(\mathbf{A}, \mathbf{B}, \mathcal{C})$ and $(\bar{\mathbf{A}}, \bar{\mathbf{B}}, \bar{\mathcal{C}})$ are essentially equal. ∎

Remark 6. The generalization to the decomposition in rank-$(L_r, L_r, \cdot)$ terms, $1 \leqslant r \leqslant R$, is trivial.

Remark 7. In the nongeneric case, lack of uniqueness can be due to the fact that tensors $\mathcal{C}_r$ can be subdivided in smaller blocks by means of basis transformations in their mode-1 and mode-2 vector space. We give an example.

Example 2. Consider a tensor $\mathcal{T} \in \mathbb{K}^{10\times 10\times 5}$ that can be decomposed in two rank-$(5,5,\cdot)$ terms as follows:

$$\mathcal{T} = \sum_{r=1}^{2} \mathcal{C}_r \bullet_1 \mathbf{A}_r \bullet_2 \mathbf{B}_r$$

with $\mathcal{C}_r \in \mathbb{K}^{5\times 5\times 5}$, $\mathbf{A}_r \in \mathbb{K}^{10\times 5}$, and $\mathbf{B}_r \in \mathbb{K}^{10\times 5}$, $1 \leqslant r \leqslant 2$. Now assume that $\mathcal{C}_1$ and $\mathcal{C}_2$ can be further decomposed as follows:

$$\begin{aligned}\mathcal{C}_1 &= \mathcal{G}_{11} \bullet_1 \mathbf{E}_{11} \bullet_2 \mathbf{F}_{11} + \mathcal{G}_{12} \bullet_1 \mathbf{E}_{12} \bullet_2 \mathbf{F}_{12},\\ \mathcal{C}_2 &= \mathcal{G}_{21} \bullet_1 \mathbf{E}_{21} \bullet_2 \mathbf{F}_{21} + \mathcal{G}_{22} \bullet_1 \mathbf{E}_{22} \bullet_2 \mathbf{F}_{22},\end{aligned}$$

where $\mathcal{G}_{11}, \mathcal{G}_{21} \in \mathbb{K}^{2\times 2\times 5}$, $\mathcal{G}_{12}, \mathcal{G}_{22} \in \mathbb{K}^{3\times 3\times 5}$, $\mathbf{E}_{11}, \mathbf{E}_{21}, \mathbf{F}_{11}, \mathbf{F}_{21} \in \mathbb{K}^{5\times 2}$, $\mathbf{E}_{12}, \mathbf{E}_{22}$, $\mathbf{F}_{12}, \mathbf{F}_{22} \in \mathbb{K}^{5\times 3}$. Define

$$\begin{aligned}\tilde{\mathbf{A}}_1 &= [\mathbf{A}_1 \cdot \mathbf{E}_{11} \ \mathbf{A}_2 \cdot \mathbf{E}_{22}], \qquad \tilde{\mathbf{A}}_2 = [\mathbf{A}_2 \cdot \mathbf{E}_{21} \ \mathbf{A}_1 \cdot \mathbf{E}_{12}],\\ \tilde{\mathbf{B}}_1 &= [\mathbf{B}_1 \cdot \mathbf{F}_{11} \ \mathbf{B}_2 \cdot \mathbf{F}_{22}], \qquad \tilde{\mathbf{B}}_2 = [\mathbf{B}_2 \cdot \mathbf{F}_{21} \ \mathbf{B}_1 \cdot \mathbf{F}_{12}],\end{aligned}$$

$$\begin{aligned}&(\tilde{\mathcal{C}}_1)_{1:2,1:2,:} = \mathcal{G}_{11}, \quad (\tilde{\mathcal{C}}_1)_{3:5,3:5,:} = \mathcal{G}_{22}, \quad (\tilde{\mathcal{C}}_1)_{1:2,3:5,:} = \mathcal{O}, \quad (\tilde{\mathcal{C}}_1)_{3:5,1:2,:} = \mathcal{O},\\ &(\tilde{\mathcal{C}}_2)_{1:2,1:2,:} = \mathcal{G}_{21}, \quad (\tilde{\mathcal{C}}_2)_{3:5,3:5,:} = \mathcal{G}_{12}, \quad (\tilde{\mathcal{C}}_2)_{1:2,3:5,:} = \mathcal{O}, \quad (\tilde{\mathcal{C}}_2)_{3:5,1:2,:} = \mathcal{O}.\end{aligned}$$

Then an alternative decomposition of $\mathcal{T}$ in rank-$(5,5,\cdot)$ terms is given by

$$\mathcal{T} = \sum_{r=1}^{2} \tilde{\mathcal{C}}_r \bullet_1 \tilde{\mathbf{A}}_r \bullet_2 \tilde{\mathbf{B}}_r. \tag{6.2}$$

For the case in which $\mathcal{C}_r \in \mathbb{R}^{2\times 2\times 2}$, $1 \leqslant r \leqslant R$, we have the following theorem.

THEOREM 6.2. *Let* $(\mathbf{A}, \mathbf{B}, \mathcal{C})$ *represent a real type-2 decomposition of* $\mathcal{T} \in \mathbb{R}^{I\times J\times 2}$ *in* R *rank-*$(L, M, 2)$ *terms with* $L = M = 2$. *Suppose that* $\operatorname{rank}(\mathbf{A}) = 2R$, $\operatorname{rank}(\mathbf{B}) = 2R$ *and that all generalized eigenvalues of the pencil* $((\mathcal{C}_r)_{L\times M,1}, (\mathcal{C}_r)_{L\times M,2})$ *are complex,* $1 \leqslant r \leqslant R$. *Then* $(\mathbf{A}, \mathbf{B}, \mathcal{C})$ *is essentially unique.*

Proof. This theorem is a special case of Theorem 5.7. The tensors $\mathcal{D}_r$ in Theorem 5.7 correspond to $\mathcal{C}_r$, and the matrices $\mathbf{C}_r$ in Theorem 5.7 are equal to $\mathbf{I}_{2\times 2}$. ∎

In some cases, uniqueness of the decomposition can be demonstrated by direct application of the equivalence lemma for partitioned matrices. This is illustrated in the following example.

Example 3. We show that the decomposition of a tensor $\mathcal{T} \in \mathbb{K}^{5\times 6\times 6}$ in $R = 3$ generic rank-$(2,2,\cdot)$ terms is essentially unique. Denote $I = 5$, $J = K = 6$, and $L = M = 2$. Let the decomposition be represented by $(\mathbf{A}, \mathbf{B}, \mathcal{C})$ and let us assume the existence of an alternative decomposition, represented by $(\bar{\mathbf{A}}, \bar{\mathbf{B}}, \bar{\mathcal{C}})$, which is "nonsingular" in the sense that the columns of $\bar{\mathbf{A}}$ are as linearly independent as possible.

To show that $(\mathbf{A}, \mathbf{B}, \mathcal{C})$ and $(\bar{\mathbf{A}}, \bar{\mathbf{B}}, \bar{\mathcal{C}})$ are essentially equal, we first use the equivalence lemma for partitioned matrices to show that $\bar{\mathbf{A}} = \mathbf{A} \cdot \mathbf{\Pi}_a \cdot \mathbf{\Lambda}_a$, in which $\mathbf{\Pi}_a$ is a block permutation matrix and $\mathbf{\Lambda}_a$ a square nonsingular block-diagonal matrix, both consisting of (2×2) blocks. We show that for every $\mu \leqslant R - k'_{\bar{\mathbf{A}}} + 1 = 2$ there holds that for a generic vector $\mathbf{x} \in \mathbb{K}^5$ such that $\omega'(\mathbf{x}^T\bar{\mathbf{A}}) \leqslant \mu$, we have $\omega'(\mathbf{x}^T\mathbf{A}) \leqslant \omega'(\mathbf{x}^T\bar{\mathbf{A}})$. We will subsequently examine the different cases corresponding to $\mu = 0, 1, 2$.

We first derive an inequality that will prove useful. Denote by $(\mathbf{C}_r \bullet_1 (\mathbf{x}^T\mathbf{A}_r))_{M\times K}$ the $(M \times K)$ matrix formed by the single slice of $\mathbf{C}_r \bullet_1 (\mathbf{x}^T\mathbf{A}_r)$, and denote by

$(\bar{\mathbf{C}}_r \bullet_1 (\mathbf{x}^T \bar{\mathbf{A}}_r))_{M\times K}$ the $(M \times K)$ matrix formed by the single slice of $\bar{\mathbf{C}}_r \bullet_1 (\mathbf{x}^T \bar{\mathbf{A}}_r)$, $1 \leqslant r \leqslant R$. Then the $(J \times K)$ matrix formed by the single slice of $\mathcal{T} \bullet_1 \mathbf{x}^T$ is given by

$$\bar{\mathbf{B}} \cdot \begin{pmatrix} (\bar{\mathbf{C}}_1 \bullet_1 (\mathbf{x}^T \bar{\mathbf{A}}_1))_{M\times K} \\ \vdots \\ (\bar{\mathbf{C}}_R \bullet_1 (\mathbf{x}^T \bar{\mathbf{A}}_R))_{M\times K} \end{pmatrix} = \mathbf{B} \cdot \begin{pmatrix} (\mathbf{C}_1 \bullet_1 (\mathbf{x}^T \mathbf{A}_1))_{M\times K} \\ \vdots \\ (\mathbf{C}_R \bullet_1 (\mathbf{x}^T \mathbf{A}_R))_{M\times K} \end{pmatrix}.$$

For the rank of this matrix, we have

$$\begin{aligned} M\omega'(\mathbf{x}^T \bar{\mathbf{A}}) &\geqslant \operatorname{rank} \left[\bar{\mathbf{B}} \cdot \begin{pmatrix} (\bar{\mathbf{C}}_1 \bullet_1 (\mathbf{x}^T \bar{\mathbf{A}}_1))_{M\times K} \\ \vdots \\ (\bar{\mathbf{C}}_R \bullet_1 (\mathbf{x}^T \bar{\mathbf{A}}_R))_{M\times K} \end{pmatrix} \right] \\ &= \operatorname{rank} \left[\mathbf{B} \cdot \begin{pmatrix} (\mathbf{C}_1 \bullet_1 (\mathbf{x}^T \mathbf{A}_1))_{M\times K} \\ \vdots \\ (\mathbf{C}_R \bullet_1 (\mathbf{x}^T \mathbf{A}_R))_{M\times K} \end{pmatrix} \right]. \end{aligned}$$

Let $\tilde{\mathbf{B}}$ and $\tilde{\mathbf{D}}(\mathbf{x})^T$ consist of the submatrices of $\mathbf{B}$ and

$$\begin{pmatrix} (\mathbf{C}_1 \bullet_1 (\mathbf{x}^T \mathbf{A}_1))_{M\times K} \\ \vdots \\ (\mathbf{C}_R \bullet_1 (\mathbf{x}^T \mathbf{A}_R))_{M\times K} \end{pmatrix},$$

respectively, corresponding to the nonzero subvectors of $\mathbf{x}^T \mathbf{A}$. Then we have

$$M\omega'(\mathbf{x}^T \bar{\mathbf{A}}) \geqslant r_{\tilde{\mathbf{B}} \cdot \tilde{\mathbf{D}}(\mathbf{x})^T}.$$

Since $\mathbf{B}$ is generic, we have

$$M\omega'(\mathbf{x}^T \bar{\mathbf{A}}) \geqslant r_{\tilde{\mathbf{D}}(\mathbf{x})^T}. \tag{6.3}$$

First, note that due to the "nonsingularity" of $\bar{\mathbf{A}}$, there does not exist a vector $\mathbf{x}$ such that $\omega'(\mathbf{x}^T \bar{\mathbf{A}}) = 0$. This means that the case $\mu = 0$ does not present a difficulty.

Next, we consider the case $\mu = 1$. Since $\omega'(\mathbf{x}^T \bar{\mathbf{A}}) \leqslant \mu$, we have that $M\omega'(\mathbf{x}^T \bar{\mathbf{A}})$ in (6.3) is less than or equal to 2. Since $\mathbf{x}$ is orthogonal to two submatrices of $\bar{\mathbf{A}}$, the set V of vectors $\mathbf{x}$ satisfying $\omega'(\mathbf{x}^T \bar{\mathbf{A}}) \leqslant \mu$ is the union of three one-dimensional subspaces in $\mathbb{K}^5$. We prove by contradiction that for a generic $\mathbf{x} \in \mathsf{V}$, we have $\omega'(\mathbf{x}^T \mathbf{A}) \leqslant 1$. Assume first that $\omega'(\mathbf{x}^T \mathbf{A}) = 2$. Then $\tilde{\mathbf{D}}(\mathbf{x})$ in (6.3) is a (6×4) matrix. For this (6×4) matrix to be rank-2, eight independent conditions on $\mathbf{x}$ have to be satisfied. (This value is the total number of entries (i.e., 24) minus the number of independent parameters in a (6×4) rank-2 matrix (i.e., 16). The latter value can easily be determined as the number of independent parameters in, for instance, an SVD.) These conditions can impossibly be satisfied in a subset of V that is not of measure zero. We conclude that for a generic $\mathbf{x} \in \mathsf{V}$, $\omega'(\mathbf{x}^T \mathbf{A}) \neq 2$. Next assume that $\omega'(\mathbf{x}^T \mathbf{A}) = 3$. Then $\tilde{\mathbf{D}}(\mathbf{x})$ in (6.3) is a (6×6) matrix. For this matrix to be rank-2, $36 - 20 = 10$ independent conditions on $\mathbf{x}$ have to be satisfied. We conclude that for a generic $\mathbf{x}$, $\omega'(\mathbf{x}^T \mathbf{A}) \neq 3$. This completes the case $\mu = 1$.

Finally, we consider the case $\mu = 2$. We now have that $M\omega'(\mathbf{x}^T \bar{\mathbf{A}})$ in (6.3) is less than or equal to 4. Since $\mathbf{x}$ is orthogonal to one submatrix of $\bar{\mathbf{A}}$, the set V of vectors $\mathbf{x}$

satisfying $\omega'(\mathbf{x}^T\bar{\mathbf{A}}) \leqslant \mu$ is the union of three three-dimensional subspaces in $\mathbb{K}^5$. We prove by contradiction that for a generic $\mathbf{x} \in \mathsf{V}$, we have $\omega'(\mathbf{x}^T\mathbf{A}) \leqslant 2$. Assume that $\omega'(\mathbf{x}^T\mathbf{A}) = 3$. Then $\tilde{\mathbf{D}}(\mathbf{x})$ in (6.3) is a (6×6) matrix. For this matrix to be rank-4, $36 - 32 = 4$ independent conditions on $\mathbf{x}$ have to be satisfied. These conditions can impossibly be satisfied in a subset of V that is not of measure zero. This completes the case $\mu = 2$.

We conclude that the condition of the equivalence lemma for partitioned matrices is satisfied. Hence, $\bar{\mathbf{A}} = \mathbf{A} \cdot \mathbf{\Pi}_a \cdot \mathbf{\Lambda}_a$. Essential uniqueness of the decomposition follows directly from the essential uniqueness of $\mathbf{A}$; cf. the proof of Theorem 6.1.

7. Discussion and future research. In this paper we introduced the concept of block term decompositions. A block term decomposition of a tensor $\mathcal{T} \in \mathbb{K}^{I\times J\times K}$ decomposes the given $(I \times J \times K)$-dimensional block in a number of blocks of smaller size. The size of a block is characterized by its mode-n rank triplet. (We mean the following. Consider a rank-(L, M, N) tensor $\mathcal{T} \in \mathbb{K}^{I\times J\times K}$. The observed dimensions of $\mathcal{T}$ are I, J, K. However, its inner dimensions, its inherent size, are given by L, M, N.) The number of blocks that are needed in a decomposition depends on the size of the blocks. On the other hand, the number of blocks that is allowed determines which size they should minimally be.

The concept of block term decompositions unifies HOSVD/Tucker's decomposition and CANDECOMP/PARAFAC. HOSVD is a meaningful representation of a rank-(L, M, N) tensor as a single block of size (L, M, N). PARAFAC decomposes a rank-R tensor in R scalar blocks.

In the case of matrices, column rank and row rank are equal; moreover, they are equal to the minimal number of rank-1 terms in which the matrix can be decomposed. This is a consequence of the fact that matrices can be diagonalized by means of basis transformations in their column and row space. On the other hand, tensors cannot in general be diagonalized by means of basis transformations in their mode-1, mode-2, and mode-3 vector space. This has led to the distinction between mode-n rank triplet and rank. Like HOSVD and PARAFAC, these are the two extrema in a spectrum. It is interesting to note that "the" rank of a higher-order tensor is actually a combination of the two aspects: one should specify the number of blocks *and* their size. This is not clear at the matrix level because of the lack of uniqueness of decompositions in nonscalar blocks.

Matrices can actually be diagonalized by means of orthogonal (unitary) basis transformations in their column and row space. On the other hand, by imposing orthogonality constraints on PARAFAC one obtains different (approximate) decompositions, with different properties [8, 35, 36, 42]. Generalizations to block decompositions can easily be formulated. For instance, the generalization of [8, 42] to decompositions in rank-(L, M, N) terms is simply obtained by claiming that $\mathbf{A}_r^H \cdot \mathbf{A}_s = \mathbf{0}_{L\times L}$, $\mathbf{B}_r^H \cdot \mathbf{B}_s = \mathbf{0}_{M\times M}$, and $\mathbf{C}_r^H \cdot \mathbf{C}_s = \mathbf{0}_{N\times N}$, $1 \leqslant r \neq s \leqslant R$.

Interestingly enough, the generalization of different aspects of the matrix SVD most often leads to different tensor decompositions. Although the definition of block term decompositions is very general, tensor SVDs that do not belong to this class do exist. For instance, a variational definition of singular values and singular vectors was generalized in [41]. Although Tucker's decomposition and the best rank-(L, M, N) approximation can be obtained by means of a variational approach [13, 15, 61], the general theory does not fit in the framework of block decompositions.

Block term decompositions have an interesting interpretation in terms of the decomposition of homogeneous polynomials or multilinear forms. The PARAFAC de-

composition of a fully symmetric tensor (i.e., a tensor that is invariant under arbitrary index permutations) can be interpreted in terms of the decomposition of the associated homogeneous polynomial (quantic) in a sum of powers of linear forms [9]. For block term decompositions we now have the following. Given the quantic, linear forms are defined and clustered in subsets. Only within the same subset, products are admissible. The block term decomposition then decomposes the quantic in a sum of admissible products.

For instance, let $\mathcal{P} \in \mathbb{K}^{I\times I\times I}$ be fully symmetric. Let $\mathbf{x} \in \mathbb{K}^I$ be a vector of unknowns. Associate the quantic $p(\mathbf{x}) = \mathcal{P} \bullet_1 \mathbf{x}^T \bullet_2 \mathbf{x}^T \bullet_3 \mathbf{x}^T$ to $\mathcal{P}$. Let a PARAFAC decomposition of $\mathcal{P}$ be given by

$$\mathcal{P} = \sum_{r=1}^{R} d_r \, \mathbf{a}_r \circ \mathbf{a}_r \circ \mathbf{a}_r.$$

Define $y_r = \mathbf{x}^T\mathbf{a}_r$, $1 \leqslant r \leqslant R$. Then the quantic can be written as

$$p(\mathbf{y}) = \sum_{r=1}^{R} d_r \, y_r^3.$$

On the other hand, let a decomposition of $\mathcal{P}$ in rank-(L_r, L_r, L_r) terms be given by

$$\mathcal{P} = \sum_{r=1}^{R} \mathcal{D}_r \bullet_1 \mathbf{A}_r \bullet_2 \mathbf{A}_r \bullet_3 \mathbf{A}_r,$$

in which $\mathcal{D}_r \in \mathbb{K}^{L_r\times L_r\times L_r}$ and $\mathbf{A}_r \in \mathbb{K}^{I\times L_r}$, $1 \leqslant r \leqslant R$. Define $y_{lr} = \mathbf{x}^T(\mathbf{A}_r)_{:,l}$, $1 \leqslant l \leqslant L_r$, $1 \leqslant r \leqslant R$. Then the quantic can be written as

$$p(\mathbf{y}) = \sum_{r=1}^{R} \sum_{l_1,l_2,l_3=1}^{L_r} (\mathcal{D}_r)_{l_1l_2l_3} \, y_{l_1r} y_{l_2r} y_{l_3r}.$$

In this paper we have presented EVD-based and Kruskal-type conditions guaranteeing essential uniqueness of the decompositions. Important work that remains to be done is the relaxation of the dimensionality constraints on the blocks in the Kruskal-type conditions. Some results based on simultaneous matrix diagonalization are presented in [44]. Also, we have restricted our attention to alternative decompositions that are "nonsingular." We should now check whether, for generic block terms, alternative decompositions in singular terms can exist.

It would be interesting to investigate, given the tensor dimensions I, J, and K, for which block sizes and number of blocks one obtains a generic (in the sense of existing with probability one) or a typical (in the sense of existing with probability different from zero) decomposition. In the context of PARAFAC, generic and typical rank have been studied in [55, 56, 57, 58].

In this paper we limited ourselves to the study of some algebraic aspects of block term decompositions. The computation of the decompositions, by means of alternating least squares algorithms, is addressed in [20]. Some applications are studied in [21, 43, 45].

Acknowledgments. The author wishes to thank A. Stegeman (Heijmans Institute, The Netherlands) and N. Sidiropoulos (Technical University of Crete, Greece)

for sharing the manuscript of [54] before its publication. The author also wishes to thank A. Stegeman for proofreading an early version of the manuscript. A large part of this research was carried out when L. De Lathauwer was with the French Centre National de la Recherche Scientifique (C.N.R.S.).

DECOMPOSITIONS OF A HIGHER-ORDER TENSOR IN BLOCK TERMS—PART III: ALTERNATING LEAST SQUARES ALGORITHMS*

LIEVEN DE LATHAUWER† AND DIMITRI NION‡

Abstract. In this paper we derive alternating least squares algorithms for the computation of the block term decompositions introduced in Part II. We show that degeneracy can also occur for block term decompositions.

Key words. multilinear algebra, higher-order tensor, Tucker decomposition, canonical decomposition, parallel factors model

AMS subject classifications. 15A18, 15A69

1. Introduction.

1.1. Organization of the paper. In the companion paper [11] we introduce decompositions of a higher-order tensor in several types of block terms. In the present paper we propose alternating least squares (ALS) algorithms for the computation of these different decompositions.

In the following subsections we first explain our notation and introduce some basic definitions. In section 1.4 we briefly recall the Tucker decomposition/higher-order singular value decomposition (HOSVD) [40, 41, 6, 7, 8] and also the Canonical/Parallel Factor (CANDECOMP/PARAFAC) decomposition [3, 15] and explain how they can be computed.

In section 2 we present an ALS algorithm for the computation of the decomposition in rank-$(L_r, L_r, 1)$ terms. In section 3 we discuss the decomposition in rank-(L, M, N) terms. Section 4 deals with the type-2 decomposition in rank-$(L, M, \cdot)$ terms. Section 5 is a note on degeneracy.

1.2. Notation. We use $\mathbb{K}$ to denote $\mathbb{R}$ or $\mathbb{C}$ when the difference is not important. In this paper scalars are denoted by lowercase letters (a, b, ...), vectors are written in boldface lowercase ($\mathbf{a}$, $\mathbf{b}$, ...), matrices correspond to boldface capitals ($\mathbf{A}$, $\mathbf{B}$, ...), and tensors are written as calligraphic letters ($\mathcal{A}$, $\mathcal{B}$, ...). This notation is consistently used for lower-order parts of a given structure. For instance, the entry with row index i and column index j in a matrix $\mathbf{A}$, i.e., $(\mathbf{A})_{ij}$, is symbolized by a_{ij} (also $(\mathbf{a})_i = a_i$ and $(\mathcal{A})_{ijk} = a_{ijk}$). If no confusion is possible, the ith column vector of a matrix $\mathbf{A}$

Sabbelaan 53, 8500 Kortrijk, Belgium (Lieven.DeLathauwer@kuleuven-kortrijk.be), and Department of Electrical Engineering (ESAT), Katholieke Universiteit Leuven, Kasteelpark Arenberg 10, B-3001 Leuven, Belgium (Lieven.DeLathauwer@esat.kuleuven.be, http://homes.esat.kuleuven.be/~delathau/home.html).

‡Department of Electronic and Computer Engineering, Technical University of Crete, Kounoupidiana Campus, Chania, Crete, 731 00, Greece (nion@telecom.tuc.gr).

is denoted as $\mathbf{a}_i$, i.e., $\mathbf{A} = [\mathbf{a}_1\ \mathbf{a}_2\ \ldots]$. Sometimes we will use the MATLAB colon notation to indicate submatrices of a given matrix or subtensors of a given tensor. Italic capitals are also used to denote index upper bounds (e.g., $i = 1, 2, \ldots, I$). The symbol $\otimes$ denotes the Kronecker product,

$$\mathbf{A} \otimes \mathbf{B} = \begin{pmatrix} a_{11}\mathbf{B} & a_{12}\mathbf{B} & \ldots \\ a_{21}\mathbf{B} & a_{22}\mathbf{B} & \ldots \\ \vdots & \vdots & \end{pmatrix}.$$

Let $\mathbf{A} = [\mathbf{A}_1\ \ldots\ \mathbf{A}_R]$ and $\mathbf{B} = [\mathbf{B}_1\ \ldots\ \mathbf{B}_R]$ be two partitioned matrices. Then the Khatri–Rao product is defined as the partitionwise Kronecker product and represented by $\odot$ [34]:

$$\mathbf{A} \odot \mathbf{B} = (\mathbf{A}_1 \otimes \mathbf{B}_1 \ldots \mathbf{A}_R \otimes \mathbf{B}_R). \tag{1.1}$$

In recent years, the term "Khatri–Rao product" and the symbol $\odot$ have mainly been used in the case where $\mathbf{A}$ and $\mathbf{B}$ are partitioned into vectors. For clarity, we denote this particular, columnwise, Khatri–Rao product by $\odot_c$:

$$\mathbf{A} \odot_c \mathbf{B} = (\mathbf{a}_1 \otimes \mathbf{b}_1 \ldots \mathbf{a}_R \otimes \mathbf{b}_R).$$

The superscripts $\cdot^T$, $\cdot^H$, and $\cdot^\dagger$ denote the transpose, complex conjugated transpose, and Moore–Penrose pseudoinverse, respectively. The operator diag$(\cdot)$ stacks its scalar arguments in a square diagonal matrix. Analogously, blockdiag$(\cdot)$ stacks its vector or matrix arguments in a block-diagonal matrix. The $(N \times N)$ identity matrix is represented by $\mathbf{I}_{N\times N}$. $\mathbf{1}_N$ is a column vector of all ones of length N. The zero tensor is denoted by $\mathcal{O}$.

1.3. Basic definitions.

DEFINITION 1.1. *Consider* $\mathcal{T} \in \mathbb{K}^{I_1\times I_2\times I_3}$ *and* $\mathbf{A} \in \mathbb{K}^{J_1\times I_1}$, $\mathbf{B} \in \mathbb{K}^{J_2\times I_2}$, $\mathbf{C} \in \mathbb{K}^{J_3\times I_3}$. *Then the* Tucker mode-1 product $\mathcal{T} \bullet_1 \mathbf{A}$, mode-2 product $\mathcal{T} \bullet_2 \mathbf{B}$, and mode-3 product $\mathcal{T} \bullet_3 \mathbf{C}$ *are defined by*

$$(\mathcal{T} \bullet_1 \mathbf{A})_{j_1 i_2 i_3} = \sum_{i_1=1}^{I_1} t_{i_1 i_2 i_3} a_{j_1 i_1} \qquad \forall j_1, i_2, i_3,$$

$$(\mathcal{T} \bullet_2 \mathbf{B})_{i_1 j_2 i_3} = \sum_{i_2=1}^{I_2} t_{i_1 i_2 i_3} b_{j_2 i_2} \qquad \forall i_1, j_2, i_3,$$

$$(\mathcal{T} \bullet_3 \mathbf{C})_{i_1 i_2 j_3} = \sum_{i_3=1}^{I_3} t_{i_1 i_2 i_3} c_{j_3 i_3} \qquad \forall i_1, i_2, j_3,$$

respectively [5].

In this paper we denote the Tucker mode-n product in the same way as in [4]; in the literature the symbol $\times_n$ is sometimes used [6, 7, 8].

DEFINITION 1.2. *The* Frobenius norm *of a tensor* $\mathcal{T} \in \mathbb{K}^{I\times J\times K}$ *is defined as*

$$\|\mathcal{T}\| = \left(\sum_{i=1}^{I} \sum_{j=1}^{J} \sum_{k=1}^{K} |t_{ijk}|^2 \right)^{\frac{1}{2}}.$$

DEFINITION 1.3. *The outer product* $\mathcal{A} \circ \mathcal{B}$ *of a tensor* $\mathcal{A} \in \mathbb{K}^{I_1 \times I_2 \times \ldots \times I_P}$ *and a tensor* $\mathcal{B} \in \mathbb{K}^{J_1 \times J_2 \times \ldots \times J_Q}$ *is the tensor defined by*

$$(\mathcal{A} \circ \mathcal{B})_{i_1 i_2 \ldots i_P j_1 j_2 \ldots j_Q} = a_{i_1 i_2 \ldots i_P} b_{j_1 j_2 \ldots j_Q}$$

for all values of the indices.

For instance, the outer product $\mathcal{T}$ of three vectors $\mathbf{a}$, $\mathbf{b}$, and $\mathbf{c}$ is defined by $t_{ijk} = a_i b_j c_k$ for all values of the indices.

DEFINITION 1.4. *A* mode-n vector *of a tensor* $\mathcal{T} \in \mathbb{K}^{I_1 \times I_2 \times I_3}$ *is an* I_n*-dimensional vector obtained from* $\mathcal{T}$ *by varying the index* i_n *and keeping the other indices fixed* [19].

Mode-n vectors generalize column and row vectors.

DEFINITION 1.5. *The* mode-n rank *of a tensor* $\mathcal{A}$ *is the dimension of the subspace spanned by its mode-*n *vectors.*

The mode-n rank of a higher-order tensor is the obvious generalization of the column (row) rank of a matrix.

DEFINITION 1.6. *A third-order tensor is* rank-(L, M, N) *if its mode-*1 *rank, mode-*2 *rank, and mode-*3 *rank are equal to* L, M, *and* N, *respectively.*

A rank-$(1, 1, 1)$ tensor is briefly called rank-1. The rank of a tensor is now defined as follows.

DEFINITION 1.7. *The* rank *of a tensor* $\mathcal{T}$ *is the minimal number of rank-*1 *tensors that yield* $\mathcal{T}$ *in a linear combination* [24].

It will be useful to write tensor expressions in terms of matrices or vectors. We therefore define standard matrix and vector representations of a third-order tensor.

DEFINITION 1.8. *The standard* $(JK \times I)$ *matrix representation* $(\mathcal{T})_{JK \times I} = \mathbf{T}_{JK \times I}$, $(KI \times J)$ *representation* $(\mathcal{T})_{KI \times J} = \mathbf{T}_{KI \times J}$, *and* $(IJ \times K)$ *representation* $(\mathcal{T})_{IJ \times K} = \mathbf{T}_{IJ \times K}$ *of a tensor* $\mathcal{T} \in \mathbb{K}^{I \times J \times K}$ *are defined by*

$$\begin{aligned}(\mathbf{T}_{JK \times I})_{(j-1)K+k,i} &= (\mathcal{T})_{ijk},\\ (\mathbf{T}_{KI \times J})_{(k-1)I+i,j} &= (\mathcal{T})_{ijk},\\ (\mathbf{T}_{IJ \times K})_{(i-1)J+j,k} &= (\mathcal{T})_{ijk}\end{aligned}$$

for all values of the indices [19]. *The standard* $(IJK \times 1)$ *vector representation* $(\mathcal{T})_{IJK} = \mathbf{t}_{IJK}$ *of* $\mathcal{T}$ *is defined by*

$$(\mathbf{t}_{IJK})_{(i-1)JK+(j-1)K+k} = (\mathcal{T})_{ijk}$$

for all values of the indices.

Note that in these definitions indices to the right vary more rapidly than indices to the left. Further, the kth $(I \times J)$ matrix slice of $\mathcal{T} \in \mathbb{K}^{I \times J \times K}$ will be denoted as $\mathbf{T}_{I \times J,k}$.

1.4. HOSVD and PARAFAC. We have now enough material to introduce the HOSVD [6, 7, 8] and PARAFAC [15] decompositions.

DEFINITION 1.9. *A* HOSVD *of a tensor* $\mathcal{T} \in \mathbb{K}^{I \times J \times K}$ *is a decomposition of* $\mathcal{T}$ *of the form*

$$\mathcal{T} = \mathcal{D} \bullet_1 \mathbf{A} \bullet_2 \mathbf{B} \bullet_3 \mathbf{C} \tag{1.2}$$

in which

- *the matrices* $\mathbf{A} \in \mathbb{K}^{I \times L}$, $\mathbf{B} \in \mathbb{K}^{J \times M}$ *and* $\mathbf{C} \in \mathbb{K}^{K \times N}$ *are columnwise orthonormal,*

- *the core tensor* $\mathcal{D} \in \mathbb{K}^{L \times M \times N}$ *is*
  - *all-orthogonal*,

$$\begin{aligned}
\langle \mathbf{D}_{M\times N,l_1}, \mathbf{D}_{M\times N,l_2} \rangle &= \operatorname{trace}(\mathbf{D}_{M\times N,l_1} \cdot \mathbf{D}_{M\times N,l_2}^H) = {\sigma_{l_1}^{(1)}}^2 \delta_{l_1,l_2}, \\
&\qquad 1 \leqslant l_1, l_2 \leqslant L, \\
\langle \mathbf{D}_{N\times L,m_1}, \mathbf{D}_{N\times L,m_2} \rangle &= \operatorname{trace}(\mathbf{D}_{N\times L,m_1} \cdot \mathbf{D}_{N\times L,m_2}^H) = {\sigma_{m_1}^{(2)}}^2 \delta_{m_1,m_2}, \\
&\qquad 1 \leqslant m_1, m_2 \leqslant M, \\
\langle \mathbf{D}_{I\times J,n_1}, \mathbf{D}_{I\times J,n_2} \rangle &= \operatorname{trace}(\mathbf{D}_{L\times M,n_1} \cdot \mathbf{D}_{L\times M,n_2}^H) = {\sigma_{n_1}^{(3)}}^2 \delta_{n_1,n_2}, \\
&\qquad 1 \leqslant n_1, n_2 \leqslant N;
\end{aligned}$$

  - *ordered*,

$$\begin{aligned}
{\sigma_1^{(1)}}^2 &\geqslant {\sigma_2^{(1)}}^2 \geqslant \ldots \geqslant {\sigma_L^{(1)}}^2 \geqslant 0, \\
{\sigma_1^{(2)}}^2 &\geqslant {\sigma_2^{(2)}}^2 \geqslant \ldots \geqslant {\sigma_M^{(2)}}^2 \geqslant 0, \\
{\sigma_1^{(3)}}^2 &\geqslant {\sigma_2^{(3)}}^2 \geqslant \ldots \geqslant {\sigma_N^{(3)}}^2 \geqslant 0.
\end{aligned}$$

Equation (1.2) can be written in terms of the standard $(JK \times I)$, $(KI \times J)$, and $(IJ \times K)$ matrix representations of $\mathcal{T}$ as follows:

$$\mathbf{T}_{JK\times I} = (\mathbf{B} \otimes \mathbf{C}) \cdot \mathbf{D}_{MN\times L} \cdot \mathbf{A}^T, \tag{1.3}$$

$$\mathbf{T}_{KI\times J} = (\mathbf{C} \otimes \mathbf{A}) \cdot \mathbf{D}_{NL\times M} \cdot \mathbf{B}^T, \tag{1.4}$$

$$\mathbf{T}_{IJ\times K} = (\mathbf{A} \otimes \mathbf{B}) \cdot \mathbf{D}_{LM\times N} \cdot \mathbf{C}^T. \tag{1.5}$$

This decomposition is a specific instance of the Tucker decomposition, introduced in [40, 41]; columnwise orthonormality of $\mathbf{A}$, $\mathbf{B}$, $\mathbf{C}$ and all-orthogonality and ordering of $\mathcal{D}$ were suggested in the computational strategy in [40, 41]. The decomposition exists for any $\mathcal{T} \in \mathbb{K}^{I\times J\times K}$. The matrices $\mathbf{A}$, $\mathbf{B}$, and $\mathbf{C}$ can be computed as the matrices of right singular vectors associated with the nonzero singular values of $\mathbf{T}_{JK\times I}$, $\mathbf{T}_{KI\times J}$, and $\mathbf{T}_{IJ\times K}$, respectively. The core tensor is then given by $\mathcal{D} = \mathcal{T} \bullet_1 \mathbf{A}^H \bullet_2 \mathbf{B}^H \bullet_3 \mathbf{C}^H$. The values L, M, and N correspond to the rank of $\mathbf{T}_{JK\times I}$, $\mathbf{T}_{KI\times J}$, and $\mathbf{T}_{IJ\times K}$, i.e., they are equal to the mode-1, mode-2, and mode-3 rank of $\mathcal{T}$, respectively. Given the way (1.2) can be computed, it comes as no surprise that the SVD of matrices and the HOSVD of higher-order tensors have some analogous properties [6].

Define $\tilde{\mathcal{D}} = \mathcal{D} \bullet_3 \mathbf{C}$. Then

$$\mathcal{T} = \tilde{\mathcal{D}} \bullet_1 \mathbf{A} \bullet_2 \mathbf{B} \tag{1.6}$$

is a (normalized) *Tucker-2 decomposition* of $\mathcal{T}$.

We are often interested in the best *approximation* of a given tensor $\mathcal{T}$ by a tensor of which the mode-1 rank, mode-2 rank, and mode-3 rank are upper-bounded by L, M, and N, respectively. Formally, we want to find $(\mathbf{A}, \mathbf{B}, \mathbf{C}, \mathcal{D})$ such that $\hat{\mathcal{T}} = \mathcal{D} \bullet_1 \mathbf{A} \bullet_2 \mathbf{B} \bullet_3 \mathbf{C}$ minimizes the least-squares cost function $f(\hat{\mathcal{T}}) = \|\mathcal{T} - \hat{\mathcal{T}}\|^2$. One difference between matrices and tensors is that this optimal approximation cannot in general be obtained by simple truncation of the HOSVD. The algorithms discussed in [7, 8, 14, 17, 20, 21, 22, 23, 44] aim at finding the optimal approximation. These algorithms can be initialized with the approximation obtained by truncation.

Besides the HOSVD, there exist other ways to generalize the SVD of matrices. The most well known is CANDECOMP/PARAFAC [3, 15].

DEFINITION 1.10. *A* canonical or parallel factor decomposition (CANDECOMP/PARAFAC) *of a tensor* $\mathcal{T} \in \mathbb{K}^{I\times J\times K}$ *is a decomposition of* $\mathcal{T}$ *as a linear combination of rank-*1 *terms*:

$$\mathcal{T} = \sum_{r=1}^{R} \mathbf{a}_r \circ \mathbf{b}_r \circ \mathbf{c}_r. \tag{1.7}$$

In terms of the standard matrix representations of $\mathcal{T}$, decomposition (1.7) can be written as

$$\mathbf{T}_{JK\times I} = (\mathbf{B} \odot_c \mathbf{C}) \cdot \mathbf{A}^T, \tag{1.8}$$

$$\mathbf{T}_{KI\times J} = (\mathbf{C} \odot_c \mathbf{A}) \cdot \mathbf{B}^T, \tag{1.9}$$

$$\mathbf{T}_{IJ\times K} = (\mathbf{A} \odot_c \mathbf{B}) \cdot \mathbf{C}^T. \tag{1.10}$$

In terms of the $(IJK\times 1)$ vector representation of $\mathcal{T}$, the decomposition can be written as

$$\mathbf{T}_{IJK} = (\mathbf{A} \odot_c \mathbf{B} \odot_c \mathbf{C}) \cdot \begin{pmatrix} 1 \\ \vdots \\ 1 \end{pmatrix}. \tag{1.11}$$

PARAFAC components are usually estimated by minimization of the quadratic cost function

$$f(\mathbf{A}, \mathbf{B}, \mathbf{C}) = \|\mathcal{T} - \sum_{r=1}^{R} \mathbf{a}_r \circ \mathbf{b}_r \circ \mathbf{c}_r\|^2. \tag{1.12}$$

This is most often done by means of an ALS algorithm, in which the vectors are updated mode per mode [3, 37]. Since PARAFAC is trilinear in its arguments, updating $\mathbf{A}$, given $\mathbf{B}$ and $\mathbf{C}$, is just a linear least squares problem. The same holds for updating $\mathbf{B}$, given $\mathbf{A}$ and $\mathbf{C}$, and updating $\mathbf{C}$, given $\mathbf{A}$ and $\mathbf{B}$. The algorithm is outlined in Table 1.1. The normalization of $\mathbf{B}$ and $\mathbf{C}$, in steps 2 and 3, respectively, is meant to avoid over- and underflow. Scaling factors are absorbed in the matrix $\mathbf{A}$. Note that the matrices $\mathbf{B} \odot_c \mathbf{C}$, $\mathbf{C} \odot_c \mathbf{A}$, and $\mathbf{A} \odot_c \mathbf{B}$ have to have at least as many rows as columns and that they have to be full column rank.

ALS iterations are sometimes slow. In addition, it is sometimes observed that the algorithm moves through a "swamp": the algorithm seems to converge, but then the convergence speed drastically decreases and remains small for several iteration steps, after which it may suddenly increase again. Recently, it has been understood that the multilinearity of PARAFAC allows for the determination of the optimal step size, which improves convergence [33].

In many applications one can assume that $\mathbf{A}$ and $\mathbf{B}$ are full column rank (this implies that $R \leqslant \min(I, J)$) and that $\mathbf{C}$ does not contain collinear vectors. Assume for convenience that the values $c_{21}, \ldots, c_{2R}$ are nonzero, such that $\mathbf{T}_{I\times J,2}$ is rank-R, and that the values $c_{11}/c_{21}, \ldots, c_{1R}/c_{2R}$ are mutually different. (If this is not the case, then we can consider linear combinations of slices such that the following reasoning applies.) Then $\mathbf{A}$ follows from the eigenvalue decomposition (EVD) $\mathbf{T}_{I\times J,1} \cdot \mathbf{T}^{\dagger}_{I\times J,2} = \mathbf{A} \cdot \mathrm{diag}(c_{11}/c_{21}, \ldots, c_{1R}/c_{2R}) \cdot \mathbf{A}^{\dagger}$. In other words, the columns of $(\mathbf{A}^T)^{\dagger}$ are generalized eigenvectors of the pencil $(\mathbf{T}^T_{I\times J,1}, \mathbf{T}^T_{I\times J,2})$; see [1, 13] and references therein. After having found $\mathbf{A}$, matrix $\mathbf{B}$ may, up to a scaling of its columns, be

TABLE 1.1
ALS algorithm for CANDECOMP/PARAFAC.

- Initialize $\mathbf{B}$, $\mathbf{C}$
- Iterate until convergence:
  1. Update $\mathbf{A}$:
  $$\mathbf{A} \leftarrow \left[(\mathbf{B} \odot_c \mathbf{C})^\dagger \cdot \mathbf{T}_{JK\times I}\right]^T$$
  2. Update $\mathbf{B}$:
  $$\tilde{\mathbf{B}} = \left[(\mathbf{C} \odot_c \mathbf{A})^\dagger \cdot \mathbf{T}_{KI\times J}\right]^T$$
  For $r = 1, \ldots, R$: $\mathbf{b}_r \leftarrow \tilde{\mathbf{b}}_r / \|\tilde{\mathbf{b}}_r\|$
  3. Update $\mathbf{C}$:
  $$\tilde{\mathbf{C}} = \left[(\mathbf{A} \odot_c \mathbf{B})^\dagger \cdot \mathbf{T}_{IJ\times K}\right]^T$$
  For $r = 1, \ldots, R$: $\mathbf{c}_r \leftarrow \tilde{\mathbf{c}}_r / \|\tilde{\mathbf{c}}_r\|$

obtained from $(\mathbf{A}^\dagger \cdot \mathbf{T}_{I\times J,2})^T = \mathbf{B} \cdot \mathrm{diag}(c_{21}, \ldots, c_{2R})$. Matrix $\mathbf{C}$ may then be computed as $\left[(\mathbf{A} \odot_c \mathbf{B})^\dagger \cdot \mathbf{T}_{IJ\times K}\right]^T$. The EVD solution may subsequently be used to initialize the ALS algorithm. This approach has been proposed in [2, 26, 35, 36].

From a numerical point of view, it is preferable to take all the matrix slices of $\mathcal{T}$ into account, instead of only two of them. We therefore proposed to compute the solution by means of simultaneous matrix diagonalization in [9]. It was shown in [10] that the solution can still be obtained by means of a simultaneous matrix diagonalization when $\mathcal{T}$ is tall in its third mode (meaning that $R \leqslant K$) and $R(R-1) \leqslant I(I-1)J(J-1)/2$.

In [32] a Gauss–Newton method is described, in which all the factors are updated simultaneously; in addition, the inherent indeterminacy of the decomposition has been fixed by adding a quadratic regularization constraint on the component entries. Instead of the least squares error (1.12), one can also minimize the least absolute error. To this end, an alternating linear programming algorithm as well as a weighted median filtering iteration are derived in [42].

2. Decomposition in rank-$(L_r, L_r, 1)$ terms.

2.1. Definition.

DEFINITION 2.1. *A* decomposition of a tensor $\mathcal{T} \in \mathbb{K}^{I\times J\times K}$ in a sum of rank-$(L_r, L_r, 1)$ terms, $1 \leqslant r \leqslant R$, *is a decomposition of* $\mathcal{T}$ *of the form*

$$\mathcal{T} = \sum_{r=1}^{R} (\mathbf{A}_r \cdot \mathbf{B}_r^T) \circ \mathbf{c}_r, \tag{2.1}$$

in which the matrix $\mathbf{A}_r \in \mathbb{K}^{I\times L_r}$ *and the matrix* $\mathbf{B}_r \in \mathbb{K}^{J\times L_r}$ *are rank-*L_r, $1 \leqslant r \leqslant R$.

Define $\mathbf{A} = [\mathbf{A}_1 \ldots \mathbf{A}_R]$, $\mathbf{B} = [\mathbf{B}_1 \ldots \mathbf{B}_R]$, $\mathbf{C} = [\mathbf{c}_1 \ldots \mathbf{c}_R]$. In terms of the standard matrix representations of $\mathcal{T}$, (2.1) can be written as

$$\mathbf{T}_{IJ\times K} = [(\mathbf{A}_1 \odot_c \mathbf{B}_1)\mathbf{1}_{L_1} \ \ldots \ (\mathbf{A}_R \odot_c \mathbf{B}_R)\mathbf{1}_{L_R}] \cdot \mathbf{C}^T, \tag{2.2}$$

$$\mathbf{T}_{JK\times I} = (\mathbf{B} \odot \mathbf{C}) \cdot \mathbf{A}^T, \tag{2.3}$$

$$\mathbf{T}_{KI\times J} = (\mathbf{C} \odot \mathbf{A}) \cdot \mathbf{B}^T. \tag{2.4}$$

TABLE 2.1
ALS algorithm for decomposition in rank-$(L_r, L_r, 1)$ terms.

- Initialize $\mathbf{B}$, $\mathbf{C}$
- Iterate until convergence:
  1. Update $\mathbf{A}$:
$$\mathbf{A} \leftarrow \left[(\mathbf{B} \odot \mathbf{C})^\dagger \cdot \mathbf{T}_{JK \times I}\right]^T$$
  2. Update $\mathbf{B}$:
$$\tilde{\mathbf{B}} = \left[(\mathbf{C} \odot \mathbf{A})^\dagger \cdot \mathbf{T}_{KI \times J}\right]^T$$
  For $r = 1, \ldots, R$: QR-factorization: $\tilde{\mathbf{B}}_r = \mathbf{QR}$, $\mathbf{B}_r \leftarrow \mathbf{Q}$
  3. Update $\mathbf{C}$:
$$\tilde{\mathbf{C}} = \left\{[(\mathbf{A}_1 \odot_c \mathbf{B}_1)\mathbf{1}_{L_1} \ \ldots \ (\mathbf{A}_R \odot_c \mathbf{B}_R)\mathbf{1}_{L_R}]^\dagger \cdot \mathbf{T}_{IJ \times K}\right\}^T$$
  For $r = 1, \ldots, R$: $\mathbf{c}_r \leftarrow \tilde{\mathbf{c}}_r / \|\tilde{\mathbf{c}}_r\|$

2.2. Algorithm. Like PARAFAC, the decomposition in rank-$(L_r, L_r, 1)$ terms is trilinear in the component matrices $\mathbf{A}$, $\mathbf{B}$, and $\mathbf{C}$. This means that updating $\mathbf{A}$, given $\mathbf{B}$ and $\mathbf{C}$, is just a linear least squares problem. The same holds for updating $\mathbf{B}$, given $\mathbf{A}$ and $\mathbf{C}$, and updating $\mathbf{C}$, given $\mathbf{A}$ and $\mathbf{B}$. The update rules follow directly from (2.2)–(2.4). The algorithm is outlined in Table 2.1. The normalization in steps 2 and 3 are meant to avoid under- and overflow. Moreover, the normalization in step 2 prevents the submatrices of $\mathbf{B}$ from becoming ill-conditioned. Analogous to the situation for PARAFAC, the matrices $\mathbf{B} \odot_c \mathbf{C}$, $\mathbf{C} \odot_c \mathbf{A}$, and $[(\mathbf{A}_1 \odot_c \mathbf{B}_1)\mathbf{1}_{L_1} \ \ldots \ (\mathbf{A}_R \odot_c \mathbf{B}_R)\mathbf{1}_{L_R}]$ have to have at least as many rows as columns and have to be full column rank.

If $\mathbf{A}$ and $\mathbf{B}$ are full column rank and $\mathbf{C}$ does not have collinear vectors, then this algorithm may be initialized by means of a (generalized) EVD, as explained in the proof of [11, Theorem 4.1].

2.3. Numerical experiments. We generate tensors $\tilde{\mathcal{T}} \in \mathbb{C}^{5 \times 6 \times 5}$ in the following way:

$$\tilde{\mathcal{T}} = \frac{\mathcal{T}}{\|\mathcal{T}\|} + \sigma_N \frac{\mathcal{N}}{\|\mathcal{N}\|}, \tag{2.5}$$

in which $\mathcal{T}$ can be decomposed as in (2.1). We consider $R = 3$ rank-$(2, 2, 1)$ terms, i.e., $\mathbf{A}_r \in \mathbb{C}^{5 \times 2}$, $\mathbf{B}_r \in \mathbb{C}^{6 \times 2}$, $\mathbf{C}_r \in \mathbb{C}^{6 \times 1}$, $1 \leqslant r \leqslant 3$. The decomposition of $\mathcal{T}$ is essentially unique by [11, Theorem 4.4]. The second term in (2.5) is a noise term. The entries of $\mathbf{A}$, $\mathbf{B}$, $\mathbf{C}$ and $\mathcal{N}$ are drawn from a zero-mean unit-variance Gaussian distribution. The parameter σ_N controls the noise level.

A Monte Carlo experiment consisting of 200 runs was carried out. The algorithm was initialized with three random starting values.

The accuracy is measured in terms of the relative error $e = \|\mathbf{C} - \hat{\mathbf{C}}\|/\|\mathbf{C}\|$, in which $\hat{\mathbf{C}}$ is the estimate of $\mathbf{C}$, optimally ordered and scaled. The median results are plotted in Figure 2.1. We plot the median instead of the mean because, in some of the

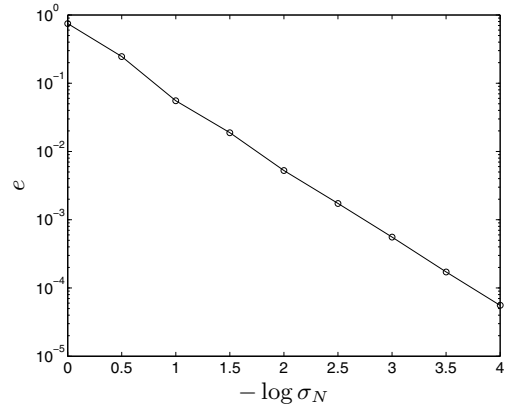

FIG. 2.1. *Median relative error obtained in the first experiment in section* 2.3.

runs, the convergence became too slow for the algorithm to find a sufficiently accurate estimate in a reasonable time.

In a second experiment, we generate tensors $\tilde{\mathcal{T}} \in \mathbb{C}^{10\times 10\times 10}$ as in (2.5). We consider $R = 5$ rank-$(2,2,1)$ terms, i.e., $\mathbf{A}_r \in \mathbb{C}^{10\times 2}$, $\mathbf{B}_r \in \mathbb{C}^{10\times 2}$, $\mathbf{C}_r \in \mathbb{C}^{10\times 1}$, $1 \leqslant r \leqslant 5$. The five rank-$(2,2,1)$ terms are scaled such that their Frobenius norm equals 1, 3.25, 5.5, 7.75, and 10, respectively. The fact that there is a difference of 20 dB between the strongest and the weakest term makes this problem quite hard. The decomposition of $\mathcal{T}$ is essentially unique by [11, Theorem 4.1]. In Figure 2.2 we show the median accuracy obtained when the algorithm in Table 2.1 is initialized (i) by means of a (generalized) EVD, as explained in the proof of [11, Theorem 4.1], and (ii) by means of a random starting value. It is clear that the global optimum is not found when the algorithm is initialized randomly. However, the initialization by means of a (generalized) EVD does lead to the global solution when the signal-to-noise ratio (SNR) is sufficiently high. As a matter of fact, the (generalized) EVD yields the exact solution when the data are noise-free.

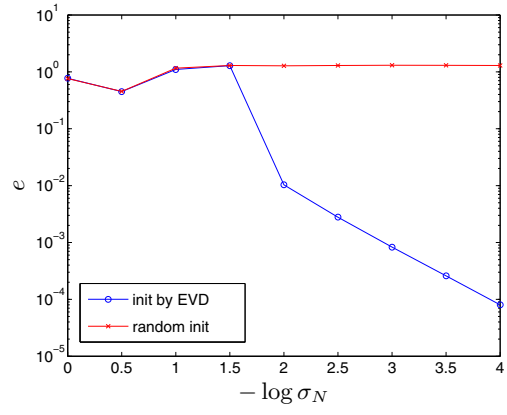

FIG. 2.2. *Median relative error obtained in the second experiment in section* 2.3.

3. Decomposition in rank-(L, M, N) terms.

3.1. Definition.

DEFINITION 3.1. *A* decomposition of a tensor $\mathcal{T} \in \mathbb{K}^{I\times J\times K}$ in a sum of rank-(L, M, N) terms *is a decomposition of* $\mathcal{T}$ *of the form*

$$\mathcal{T} = \sum_{r=1}^{R} \mathcal{D}_r \bullet_1 \mathbf{A}_r \bullet_2 \mathbf{B}_r \bullet_3 \mathbf{C}_r, \tag{3.1}$$

in which $\mathcal{D}_r \in \mathbb{K}^{L\times M\times N}$ *are full rank-*(L, M, N) *and in which* $\mathbf{A}_r \in \mathbb{K}^{I\times L}$ *(with* $I \geqslant L$*),* $\mathbf{B}_r \in \mathbb{K}^{J\times M}$ *(with* $J \geqslant M$*), and* $\mathbf{C}_r \in \mathbb{K}^{K\times N}$ *(with* $K \geqslant N$*) are full column rank,* $1 \leqslant r \leqslant R$*.*

Define partitioned matrices $\mathbf{A} = [\mathbf{A}_1 \dots \mathbf{A}_R]$, $\mathbf{B} = [\mathbf{B}_1 \dots \mathbf{B}_R]$, and $\mathbf{C} = [\mathbf{C}_1 \dots \mathbf{C}_R]$. In terms of the standard matrix representations of $\mathcal{T}$, (3.1) can be written as

$$\mathbf{T}_{JK\times I} = (\mathbf{B} \odot \mathbf{C}) \cdot \text{blockdiag}((\mathcal{D}_1)_{MN\times L}, \dots, (\mathcal{D}_R)_{MN\times L}) \cdot \mathbf{A}^T, \tag{3.2}$$

$$\mathbf{T}_{KI\times J} = (\mathbf{C} \odot \mathbf{A}) \cdot \text{blockdiag}((\mathcal{D}_1)_{NL\times M}, \dots, (\mathcal{D}_R)_{NL\times M}) \cdot \mathbf{B}^T, \tag{3.3}$$

$$\mathbf{T}_{IJ\times K} = (\mathbf{A} \odot \mathbf{B}) \cdot \text{blockdiag}((\mathcal{D}_1)_{LM\times N}, \dots, (\mathcal{D}_R)_{LM\times N}) \cdot \mathbf{C}^T. \tag{3.4}$$

In terms of the $(IJK\times 1)$ vector representation of $\mathcal{T}$, the decomposition can be written as

$$\mathbf{t}_{IJK} = (\mathbf{A} \odot \mathbf{B} \odot \mathbf{C}) \cdot \begin{pmatrix} (\mathcal{D}_1)_{LMN} \\ \vdots \\ (\mathcal{D}_R)_{LMN} \end{pmatrix}. \tag{3.5}$$

3.2. Algorithm. The decomposition in rank-(L, M, N) terms is quadrilinear in its factors $\mathbf{A}$, $\mathbf{B}$, $\mathbf{C}$, and $\mathcal{D}$. Hence, the conditional update of $\mathbf{A}$, given $\mathbf{B}$, $\mathbf{C}$, and $\mathcal{D}$, is a linear least squares problem. The same holds for conditional updates of $\mathbf{B}$, $\mathbf{C}$, and $\mathcal{D}$. The update rules follow directly from (3.2)–(3.5). The algorithm is outlined in Table 3.1. This algorithm is a generalization of the algorithm in [43] for the computation of the best rank-(L, M, N) approximation of a given tensor. The matrices $(\mathbf{B} \odot \mathbf{C}) \cdot \text{blockdiag}((\mathcal{D}_1)_{MN\times L}, \dots, (\mathcal{D}_R)_{MN\times L})$, $(\mathbf{C} \odot \mathbf{A}) \cdot \text{blockdiag}((\mathcal{D}_1)_{NL\times M}, \dots, (\mathcal{D}_R)_{NL\times M})$, and $(\mathbf{A} \odot \mathbf{B}) \cdot \text{blockdiag}((\mathcal{D}_1)_{LM\times N}, \dots, (\mathcal{D}_R)_{LM\times N})$ have to have at least as many rows as columns and have to be full column rank.

The order of the updates in Table 3.1 is not mandatory. We have observed in numerical experiments that it is often advantageous to alternate between a few updates of $\mathbf{A}$ and $\mathcal{D}$, then alternate between a few updates of $\mathbf{B}$ and $\mathcal{D}$, and so on.

3.3. Numerical experiments. We generate tensors $\tilde{\mathcal{T}} \in \mathbb{C}^{5\times 5\times 7}$ as in (2.5). The tensors $\mathcal{T}$ can now be decomposed as in (3.1). We consider $R = 2$ terms characterized by $\mathbf{A}_r \in \mathbb{C}^{5\times 2}$, $\mathbf{B}_r \in \mathbb{C}^{5\times 2}$, $\mathbf{C}_r \in \mathbb{C}^{7\times 3}$, and $\mathcal{D}_r \in \mathbb{C}^{2\times 2\times 3}$, $1 \leqslant r \leqslant 2$. The entries of $\mathbf{A}_r$, $\mathbf{B}_r$, $\mathbf{C}_r$, $\mathcal{D}_r$, and $\mathcal{N}$ are drawn from a zero-mean unit-variance Gaussian distribution. The decomposition of $\mathcal{T}$ is essentially unique by [11, Theorem 5.1].

A Monte Carlo experiment consisting of 200 runs was carried out. The algorithm was initialized with three random starting values.

The accuracy is measured in terms of the relative error $e = \|\mathbf{C}-\hat{\mathbf{C}}\|/\|\mathbf{C}\|$, in which $\hat{\mathbf{C}}$ is the estimate of $\mathbf{C}$, of which the submatrices are optimally ordered and multiplied from the right by a (3×3) matrix. The median results are plotted in Figure 3.1.

Next, we check what happens if the algorithm in Table 3.1 is used for the computation of the decomposition in rank-$(L, L, 1)$ terms. In this case, the tensors $\mathcal{D}_r$ are of

TABLE 3.1
ALS algorithm for decomposition in rank-(L, M, N) terms.

- Initialize $\mathbf{B}$, $\mathbf{C}$, $\mathcal{D}$
- Iterate until convergence:
  1. Update $\mathbf{A}$:

$$\tilde{\mathbf{A}} = \left[\text{blockdiag}((\mathcal{D}_1)^{\dagger}_{MN\times L}, \ldots, (\mathcal{D}_R)^{\dagger}_{MN\times L}) \cdot (\mathbf{B} \odot \mathbf{C})^{\dagger} \cdot \mathbf{T}_{JK\times I}\right]^T$$

  For $r = 1, \ldots, R$: QR-factorization: $\tilde{\mathbf{A}}_r = \mathbf{QR}$, $\mathbf{A}_r \leftarrow \mathbf{Q}$
  2. Update $\mathbf{B}$:

$$\tilde{\mathbf{B}} = \left[\text{blockdiag}((\mathcal{D}_1)^{\dagger}_{NL\times M}, \ldots, (\mathcal{D}_R)^{\dagger}_{NL\times M}) \cdot (\mathbf{C} \odot \mathbf{A})^{\dagger} \cdot \mathbf{T}_{KI\times J}\right]^T$$

  For $r = 1, \ldots, R$: QR-factorization: $\tilde{\mathbf{B}}_r = \mathbf{QR}$, $\mathbf{B}_r \leftarrow \mathbf{Q}$
  3. Update $\mathbf{C}$:

$$\tilde{\mathbf{C}} = \left[\text{blockdiag}((\mathcal{D}_1)^{\dagger}_{LM\times N}, \ldots, (\mathcal{D}_R)^{\dagger}_{LM\times N}) \cdot (\mathbf{A} \odot \mathbf{B})^{\dagger} \cdot \mathbf{T}_{IJ\times K}\right]^T$$

  For $r = 1, \ldots, R$: QR-factorization: $\tilde{\mathbf{C}}_r = \mathbf{QR}$, $\mathbf{C}_r \leftarrow \mathbf{Q}$
  4. Update $\mathcal{D}$:

$$\begin{pmatrix} (\mathcal{D}_1)_{LMN} \\ \vdots \\ (\mathcal{D}_R)_{LMN} \end{pmatrix} \leftarrow (\mathbf{A} \odot \mathbf{B} \odot \mathbf{C})^{\dagger} \cdot \mathbf{t}_{IJK}$$

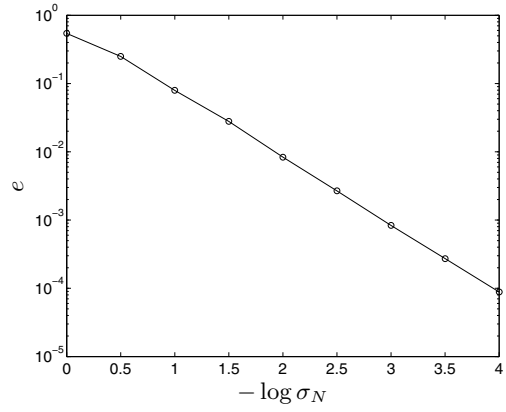

FIG. 3.1. *Median relative error obtained in the first experiment in section* 3.3.

dimension $(L \times L \times 1)$. The data are generated as in the first experiment in section 2.3. We compare three algorithms: (i) the algorithm of Table 2.1, which we denote as Alg $(L, L, 1)$, (ii) the algorithm of Table 3.1, which we denote as Alg (L, M, N), and (iii) a variant of the algorithm of Table 3.1 in which one alternates between a few updates of $\mathbf{A}$ and $\mathbf{D}$, then alternates between a few updates of $\mathbf{B}$ and $\mathbf{D}$, and so on, as explained at the end of section 3.2. The latter algorithm is denoted as Alg $(L, M, N)^*$. The inner iteration is terminated if the Frobenius norm of the difference between two consecutive approximations of $\mathcal{T}$ drops below $1e-6$, with a maximum of 10 inner iterations. We observed that most of the time not more than two or three inner iterations were carried out. We computed the results for one and two random initializations, respectively.

The median results for accuracy and computation time are plotted in Figures 3.2 and 3.3, respectively. From Figure 3.2 it is clear that Alg (L, M, N) does not find the global optimum if it is initialized only once. One should perform inner iterations, or initialize several times. However, both remedies increase the computational cost, as is clear from Figure 3.3. Given that Alg (L, M, N) is by itself more expensive than Alg $(L, L, 1)$, we conclude that it is advantageous to compute the decomposition in rank-$(L, L, 1)$ terms by means of Alg $(L, L, 1)$.

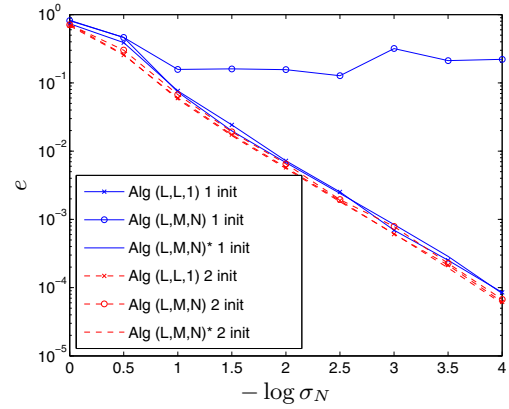

FIG. 3.2. *Median relative error obtained in the second experiment in section* 3.3.

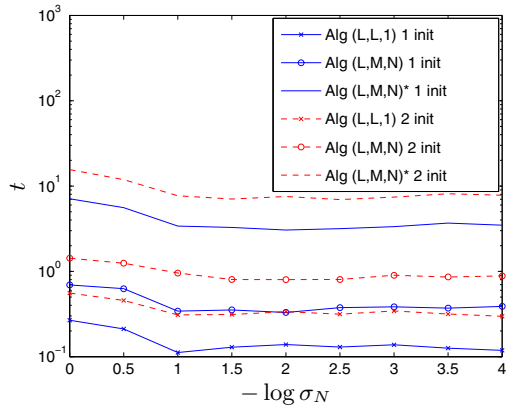

FIG. 3.3. *Median computation time in the second experiment in section* 3.3.

4. Type-2 decomposition in rank-$(L, M, \cdot)$ terms.

4.1. Definition.

DEFINITION 4.1. *A* type-2 decomposition of a tensor $\mathcal{T} \in \mathbb{K}^{I \times J \times K}$ in a sum of rank-$(L, M, \cdot)$ terms *is a decomposition of* $\mathcal{T}$ *of the form*

$$\mathcal{T} = \sum_{r=1}^{R} \mathcal{C}_r \bullet_1 \mathbf{A}_r \bullet_2 \mathbf{B}_r, \tag{4.1}$$

in which $\mathcal{C}_r \in \mathbb{K}^{L \times M \times K}$ *(with mode-1 rank equal to* L *and mode-2 rank equal to* M*), and in which* $\mathbf{A}_r \in \mathbb{K}^{I \times L}$ *(with* $I \geqslant L$*) and* $\mathbf{B}_r \in \mathbb{K}^{J \times M}$ *(with* $J \geqslant M$*) are full column rank,* $1 \leqslant r \leqslant R$.

TABLE 4.1
ALS algorithm for type-2 decomposition in rank-$(L, M, \cdot)$ terms.

- Initialize $\mathbf{B}, \mathcal{C}_1, \ldots, \mathcal{C}_R$
- Iterate until convergence:
  1. Update $\mathbf{A}$:

$$\tilde{\mathbf{A}} = \left\{ [(\mathcal{C}_1 \bullet_2 \mathbf{B}_1)_{JK\times L} \ \ldots \ (\mathcal{C}_R \bullet_2 \mathbf{B}_R)_{JK\times L}]^\dagger \cdot \mathbf{T}_{JK\times I} \right\}^T$$

  2. Update $\mathbf{B}$:

$$\tilde{\mathbf{B}} = \left\{ [(\mathcal{C}_1 \bullet_1 \mathbf{A}_1)_{KI\times M} \ \ldots \ (\mathcal{C}_R \bullet_1 \mathbf{A}_R)_{KI\times M})]^\dagger \cdot \mathbf{T}_{KI\times J} \right\}^T$$

  For $r = 1, \ldots, R$: QR-factorization: $\tilde{\mathbf{B}}_r = \mathbf{QR}$, $\mathbf{B}_r \leftarrow \mathbf{Q}$
  3. Update $\mathcal{C}_1, \ldots, \mathcal{C}_R$:

$$\begin{pmatrix} (\mathcal{C}_1)_{(LM\times K)} \\ \vdots \\ (\mathcal{C}_R)_{(LM\times K)} \end{pmatrix} \leftarrow (\mathbf{A} \odot \mathbf{B})^\dagger \cdot \mathbf{T}_{IJ\times K}$$

Define partitioned matrices $\mathbf{A} = [\mathbf{A}_1 \ldots \mathbf{A}_R]$ and $\mathbf{B} = [\mathbf{B}_1 \ldots \mathbf{B}_R]$. In terms of the standard matrix representations of $\mathcal{T}$, (4.1) can be written as

$$\mathbf{T}_{IJ\times K} = (\mathbf{A} \odot \mathbf{B}) \cdot \begin{pmatrix} (\mathcal{C}_1)_{(LM\times K)} \\ \vdots \\ (\mathcal{C}_R)_{(LM\times K)} \end{pmatrix}, \tag{4.2}$$

$$\mathbf{T}_{JK\times I} = [(\mathcal{C}_1 \bullet_2 \mathbf{B}_1)_{JK\times L} \ \ldots \ (\mathcal{C}_R \bullet_2 \mathbf{B}_R)_{JK\times L}] \cdot \mathbf{A}^T, \tag{4.3}$$

$$\mathbf{T}_{KI\times J} = [(\mathcal{C}_1 \bullet_1 \mathbf{A}_1)_{KI\times M} \ \ldots \ (\mathcal{C}_R \bullet_1 \mathbf{A}_R)_{KI\times M}] \cdot \mathbf{B}^T. \tag{4.4}$$

4.2. Algorithm. Since the type-2 decomposition in rank-$(L, M, \cdot)$ terms is trilinear in $\mathbf{A}$, $\mathbf{B}$, and $\mathcal{C}$, an ALS algorithm consists of successive linear least squares problems. The update rules for $\mathbf{A}$, $\mathbf{B}$, and $\mathcal{C}$ follow directly from (4.3), (4.4), and (4.2), respectively. The algorithm is outlined in Table 4.1. The matrices $\mathbf{A} \odot \mathbf{B}$, $[(\mathcal{C}_1 \bullet_2 \mathbf{B}_1)_{JK\times L} \ \ldots \ (\mathcal{C}_R \bullet_2 \mathbf{B}_R)_{JK\times L}]$, and $[(\mathcal{C}_1 \bullet_1 \mathbf{A}_1)_{KI\times M} \ \ldots \ (\mathcal{C}_R \bullet_1 \mathbf{A}_R)_{KI\times M}]$ have to have at least as many rows as columns and have to be full column rank.

4.3. Numerical experiment. We generate tensors $\tilde{\mathcal{T}} \in \mathbb{C}^{5\times 6\times 6}$ as in (2.5). The tensors $\mathcal{T}$ can now be decomposed as in (4.1). We consider $R = 3$ terms characterized by $\mathbf{A}_r \in \mathbb{C}^{5\times 2}$, $\mathbf{B}_r \in \mathbb{C}^{6\times 2}$, and $\mathcal{C}_r \in \mathbb{C}^{2\times 2\times 6}$, $1 \leqslant r \leqslant 3$. The entries of $\mathbf{A}_r$, $\mathbf{B}_r$, $\mathbf{C}_r$, and $\mathcal{N}$ are drawn from a zero-mean unit-variance Gaussian distribution. The decomposition of $\mathcal{T}$ is essentially unique by [11, Example 3].

A Monte Carlo experiment consisting of 200 runs was carried out. The algorithm was initialized with three random starting values.

The accuracy is measured in terms of the relative error $e = \|\mathbf{B} - \hat{\mathbf{B}}\|/\|\mathbf{B}\|$, in which $\hat{\mathbf{B}}$ is the estimate of $\mathbf{B}$, of which the submatrices are optimally ordered and multiplied from the right by a (2×2) matrix. The median results are plotted in Figure 4.1.

5. Degeneracy. In the real field, PARAFAC algorithms sometimes show the following behavior. The norm of individual terms in (1.12) goes to infinity, but these terms almost completely cancel each other, such that the overall error continues to

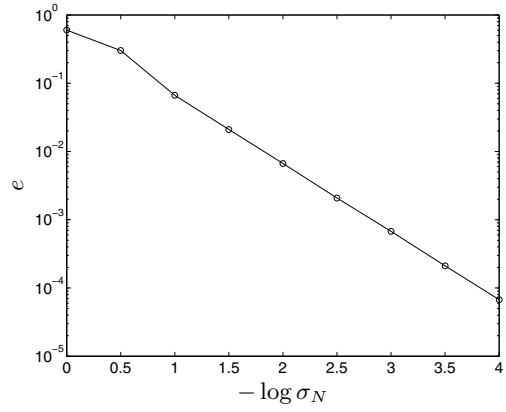

FIG. 4.1. *Median relative error obtained in the experiment in section* 4.3.

decrease. This phenomenon is known as "degeneracy" [16, 25, 27]. It is caused by the fact that for $\tilde{R} \geqslant 2$, the set

$$\mathsf{U}_{\tilde{R}} = \{\mathcal{T} \in \mathbb{R}^{I \times J \times K} | \text{rank}(\mathcal{T}) \leqslant \tilde{R}\}$$

is not closed [12, 25, 38]. The set of tensors that are the sum of at most $\tilde{R} \geqslant 2$ rank-(L, M, N) terms,

$$\mathsf{V}_{\tilde{R}} = \{\mathcal{T} \in \mathbb{R}^{I \times J \times K} | \mathcal{T} \text{ decomposable as in (3.1), with } R \leqslant \tilde{R} \text{ and } \tilde{R} \geqslant 2\},$$

is not closed either. We give an explicit example that is a straightforward generalization of the example given for PARAFAC in [12]. Analogous results hold for the other types of block term decompositions.

Let $\mathbf{I}_1 \in \mathbb{R}^{4 \times 2}$ and $\mathbf{I}_2 \in \mathbb{R}^{4 \times 2}$ consist of the first (resp., last) two columns of $\mathbf{I}_{4 \times 4}$. Consider the tensor $\mathcal{E} \in \mathbb{R}^{2 \times 2 \times 2}$ defined by

$$\begin{aligned} &e_{111} = e_{221} = e_{122} = 1, \\ &e_{121} = e_{211} = e_{112} = e_{212} = e_{222} = 0. \end{aligned}$$

This tensor is rank-3 in $\mathbb{R}$; see [5, pp. 21–22] and [18, section 3]. Now define $\mathcal{T} \in \mathbb{R}^{4 \times 4 \times 4}$ as follows:

$$\begin{aligned} \mathcal{T}(1:2, 1:2, 1:2) &= \mathcal{T}(3:4, 3:4, 1:2) = \mathcal{T}(1:2, 3:4, 3:4) = \mathcal{E}, \\ \mathcal{T}(3:4, 1:2, 1:2) &= \mathcal{T}(3:4, 1:2, 3:4) = \mathcal{T}(1:2, 3:4, 1:2) \\ &= \mathcal{T}(1:2, 1:2, 3:4) = \mathcal{T}(3:4, 3:4, 3:4) = \mathcal{O}_{2 \times 2 \times 2}. \end{aligned}$$

This tensor can be decomposed in three rank-$(2, 2, 2)$ terms:

$$\mathcal{T} = \mathcal{E} \bullet_1 \mathbf{I}_1 \bullet_2 \mathbf{I}_1 \bullet_3 \mathbf{I}_1 + \mathcal{E} \bullet_1 \mathbf{I}_1 \bullet_2 \mathbf{I}_2 \bullet_3 \mathbf{I}_2 + \mathcal{E} \bullet_1 \mathbf{I}_2 \bullet_2 \mathbf{I}_2 \bullet_3 \mathbf{I}_1. \tag{5.1}$$

However, it cannot be decomposed in two rank-$(2, 2, 2)$ terms. We prove this by contradiction. Assume that a decomposition in two rank-$(2, 2, 2)$ terms does exist:

$$\mathcal{T} = \mathcal{D}_1 \bullet_1 \mathbf{A}_1 \bullet_2 \mathbf{B}_1 \bullet_3 \mathbf{C}_1 + \mathcal{D}_2 \bullet_1 \mathbf{A}_2 \bullet_2 \mathbf{B}_2 \bullet_3 \mathbf{C}_2. \tag{5.2}$$

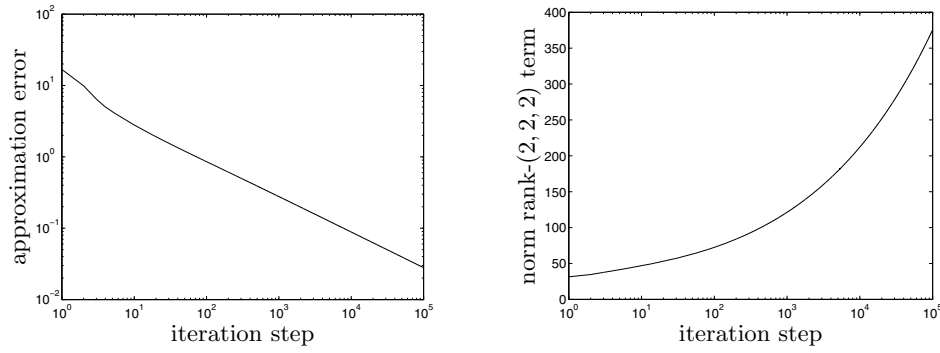

FIG. 5.1. *Visualization of the degeneracy in Example* 1. *Left*: *evolution of the approximation error. Right*: *evolution of the norm of the rank-*$(2,2,2)$ *terms.*

We can normalize this decomposition such that the first row of $\mathbf{C} = [\mathbf{C}_1\ \mathbf{C}_2]$ is equal to (1 0 1 0), and $\mathcal{D}_1 \bullet_3 (1\ 0) = \mathcal{D}_2 \bullet_3 (1\ 0) = \mathbf{I}_{2\times 2}$. Define $\mathbf{A} = [\mathbf{A}_1\ \mathbf{A}_2]$ and $\mathbf{B} = [\mathbf{B}_1\ \mathbf{B}_2]$. We have $\mathbf{T}_{I\times J,1} = \mathbf{I}_{4\times 4} = \mathbf{A}\cdot\mathbf{B}^T$. Hence, $\mathbf{A}$ and $\mathbf{B}$ are nonsingular. Define $\mathbf{X} = [\mathbf{x}_1\ \ldots\ \mathbf{x}_4] = \mathbf{A}^{-1}$ and $\mathbf{Y} = [\mathbf{y}_1\ \ldots\ \mathbf{y}_4] = \mathbf{B}^{-1}$. From (5.2) we have that all the $(I\times J)$ slices of $\tilde{\mathcal{T}} = \mathcal{T} \bullet_1 \mathbf{X} \bullet_2 \mathbf{Y}$ are block-diagonal, consisting of two (2×2) blocks. From the definition of $\mathcal{T}$, we have that $\tilde{\mathbf{T}}_{I\times J,4} = \mathbf{x}_1\cdot\mathbf{y}_4^T$. From the block-diagonality of this rank-1 matrix follows that, without loss of generality, we can assume that the third and fourth entries of $\mathbf{x}_1$ and $\mathbf{y}_4$ are zero. Further, we have that $\tilde{\mathbf{T}}_{I\times J,3} = \mathbf{x}_1\cdot\mathbf{y}_3^T + \mathbf{x}_2\cdot\mathbf{y}_4^T$. From the block-diagonality of this rank-2 matrix and the structure of $\mathbf{x}_1$ and $\mathbf{y}_4$ follows that the third and fourth entries of $\mathbf{x}_2$ and $\mathbf{y}_3$ are zero. Finally, we have that $\tilde{\mathbf{T}}_{I\times J,2} = \mathbf{x}_1\cdot\mathbf{y}_2^T + \mathbf{x}_3\cdot\mathbf{y}_4^T$. From the block-diagonality of this rank-2 matrix and the structure of $\mathbf{x}_1$ and $\mathbf{y}_4$ follows that the third and fourth entries of $\mathbf{x}_3$ and $\mathbf{y}_2$ are zero. We have a contradiction with the fact that $\mathbf{X}$ and $\mathbf{Y}$ are full rank. We conclude that $\mathcal{T}$ cannot be decomposed in a sum of two rank-$(2,2,2)$ terms.

On the other hand, there does not exist an approximation $\hat{\mathcal{T}}$, consisting of a sum of two rank-$(2,2,2)$ terms, that is optimal in the sense of minimizing the error $\|\mathcal{T} - \hat{\mathcal{T}}\|$. Define $\hat{\mathcal{T}}_n$ as follows, for increasing integer values of n:

$$\hat{\mathcal{T}}_n = \mathcal{E} \bullet_1 \mathbf{I}_1 \bullet_2 (\mathbf{I}_1 - n\mathbf{I}_2) \bullet_3 \mathbf{I}_1 + \mathcal{E} \bullet_1 \left(\mathbf{I}_1 + \frac{1}{n}\mathbf{I}_2\right) \bullet_2 (n\mathbf{I}_2) \bullet_3 \left(\mathbf{I}_1 + \frac{1}{n}\mathbf{I}_2\right). \tag{5.3}$$

We have

$$\hat{\mathcal{T}}_n = \mathcal{T} + \frac{1}{n}\,\mathcal{E} \bullet_1 \mathbf{I}_2 \bullet_2 \mathbf{I}_2 \bullet_3 \mathbf{I}_2.$$

Clearly, $\|\mathcal{T} - \hat{\mathcal{T}}_n\|$ goes to zero as n goes to infinity. However, at the same time the norms of the individual terms in (5.3) go to infinity. This shows that degeneracy also exists for block term decompositions.

Example 1. Figure 5.1 shows a typical degeneracy. We constructed a tensor $\mathcal{T}$ as in (5.1) with $\mathcal{E}$, however, defined by

$$e_{111} = -14 \quad e_{121} = -4 \quad e_{211} = 6 \quad e_{221} = 7,$$
$$e_{112} = 8 \quad e_{122} = 13 \quad e_{212} = 7 \quad e_{222} = 7.$$

The eigenvalues of $\mathbf{E}_{I\times J,1}\cdot\mathbf{E}_{I\times J,2}^{-1}$ are complex, so $\mathcal{E}$ is rank-3 in $\mathbb{R}$. The algorithm in Table 3.1 was used to approximate $\mathcal{T}$ by a sum of two rank-$(2,2,2)$ terms. The

left plot shows a monotonous decrease of the approximation error. The right plot shows the evolution of the norm of the rank-$(2, 2, 2)$ terms (the curves for both terms coincide).

6. Conclusion. We have derived ALS algorithms for the different block term decompositions that were introduced in [11]. ALS is actually a very simple approach. For PARAFAC, combining ALS with (exact) line search improves the performance [33]. An other technique that has proved useful for PARAFAC is the Levenberg–Marquardt type optimization [39]. When the tensor is tall in one mode, PARAFAC may often be computed by means of a simultaneous matrix decomposition [10]. Since the submission of this manuscript, we have been studying generalizations of such methods to block term decompositions [28, 29, 30, 31].

Acknowledgment. The authors wish to thank A. Stegeman (Heijmans Institute, The Netherlands) for proofreading an early version of the manuscript. A large part of this research was carried out when L. De Lathauwer and D. Nion were with the ETIS lab of the French Centre National de la Recherche Scientifique (C.N.R.S.).

TENSOR RANK AND THE ILL-POSEDNESS OF THE BEST LOW-RANK APPROXIMATION PROBLEM*

VIN DE SILVA† AND LEK-HENG LIM‡

Abstract. There has been continued interest in seeking a theorem describing optimal low-rank approximations to tensors of order 3 or higher that parallels the Eckart–Young theorem for matrices. In this paper, we argue that the naive approach to this problem is doomed to failure because, unlike matrices, tensors of order 3 or higher can fail to have best rank-r approximations. The phenomenon is much more widespread than one might suspect: examples of this failure can be constructed over a wide range of dimensions, orders, and ranks, regardless of the choice of norm (or even Brègman divergence). Moreover, we show that in many instances these counterexamples have positive volume: they cannot be regarded as isolated phenomena. In one extreme case, we exhibit a tensor space in which *no* rank-3 tensor has an optimal rank-2 approximation. The notable exceptions to this misbehavior are rank-1 tensors and order-2 tensors (i.e., matrices). In a more positive spirit, we propose a natural way of overcoming the ill-posedness of the low-rank approximation problem, by using *weak solutions* when true solutions do not exist. For this to work, it is necessary to characterize the set of weak solutions, and we do this in the case of rank 2, order 3 (in arbitrary dimensions). In our work we emphasize the importance of closely studying concrete low-dimensional examples as a first step toward more general results. To this end, we present a detailed analysis of equivalence classes of $2 \times 2 \times 2$ tensors, and we develop methods for extending results upward to higher orders and dimensions. Finally, we link our work to existing studies of tensors from an algebraic geometric point of view. The rank of a tensor can in theory be given a semialgebraic description; in other words, it can be determined by a system of polynomial inequalities. We study some of these polynomials in cases of interest to us; in particular, we make extensive use of the *hyperdeterminant* Δ on $\mathbb{R}^{2\times2\times2}$.

1. Introduction.

Given an order-k tensor $A \in \mathbb{R}^{d_1\times\cdots\times d_k}$, one is often required to find a *best rank-r approximation* to A—in other words, determine vectors $\mathbf{x}_i \in \mathbb{R}^{d_1}, \mathbf{y}_i \in \mathbb{R}^{d_2}, \ldots, \mathbf{z}_i \in \mathbb{R}^{d_k}$, $i = 1, \ldots, r$, which minimize

$$\|A - \mathbf{x}_1 \otimes \mathbf{y}_1 \otimes \cdots \otimes \mathbf{z}_1 - \cdots - \mathbf{x}_r \otimes \mathbf{y}_r \otimes \cdots \otimes \mathbf{z}_r\|;$$

or, in short,

$$(\text{APPROX}(A, r)) \qquad \operatorname{argmin}_{\operatorname{rank}_\otimes(B)\le r} \|A - B\|.$$

Here $\|\cdot\|$ denotes some choice of norm on $\mathbb{R}^{d_1\times\cdots\times d_k}$. When $k = 2$, the problem is completely resolved for unitarily invariant norms on $\mathbb{R}^{m\times n}$ with the *Eckart–Young*

theorem [28], which states that if

$$A = U\Sigma V = \sum\nolimits_{i=1}^{\operatorname{rank}(A)} \sigma_i \mathbf{u}_i \otimes \mathbf{v}_i, \quad \sigma_i \geq \sigma_{i+1},$$

is the singular value decomposition of $A \in \mathbb{R}^{m\times n}$, then a best rank-$r$ approximation is given by the first r terms in the above sum [33]. The best rank-r approximation problem for higher order tensors is a problem of central importance in the statistical analysis of multiway data [11, 16, 20, 21, 45, 50, 38, 56, 66, 67, 75, 76].

It is therefore not surprising that there has been continued interest in finding a satisfactory "singular value decomposition" and an "Eckart–Young theorem"-like result for tensors of higher order. The view expressed in the conclusion of [46] is representative of such efforts, and we reproduce it here:

> *An Eckart–Young type of best rank-r approximation theorem for tensors continues to elude our investigations but can perhaps eventually be attained by using a different norm or yet other definitions of orthogonality and rank.*

It will perhaps come as a surprise to the reader that the problem of finding an "Eckart–Young-type theorem" is ill-founded because of a more fundamental difficulty: the best rank-r approximation problem $\textsc{approx}(A, r)$ has no solution in general! This paper seeks to provide an answer to this and several related questions.

1.1. Summary. Since this is a long paper, we present an "executive summary" of selected results in this section and the next. We begin with the five main objectives of this article:

1. $\textsc{approx}(A, r)$ *is ill-posed for many* r. We will show that, regardless of the choice of norm, the problem of determining a best rank-r approximation for an order-k tensor in $\mathbb{R}^{d_1\times\cdots\times d_k}$ has no solution in general for $r = 2, \ldots, \min\{d_1, \ldots, d_k\}$ and $k \geq 3$. In other words, the best low-rank approximation problem for tensors is ill-posed for all orders (higher than 2), all norms, and many ranks.
2. $\textsc{approx}(A, r)$ *is ill-posed for many* A. We will show that the set of tensors that fail to have a best low-rank approximation has positive volume. In other words, such failures are not rare; if one randomly picks a tensor A in a suitable tensor space, then there is a nonzero probability that A will fail to have a best rank-r approximation for some $r < \operatorname{rank}_{\otimes}(A)$.
3. *Weak solutions to* $\textsc{approx}(A, r)$. We will propose a natural way to overcome the ill-posedness of the best rank-r approximation problem with the introduction of "weak solutions," which we explicitly characterize in the case $r = 2$, $k = 3$.
4. *Semialgebraic description of tensor rank.* From the Tarski–Seidenberg theorem in model theory [72, 65] we will deduce the following: for any $d_1, \ldots, d_k$, there exists a finite number of polynomial functions, $\Delta_1, \ldots, \Delta_m$, defined on $\mathbb{R}^{d_1\times\cdots\times d_k}$ such that the rank of any $A \in \mathbb{R}^{d_1\times\cdots\times d_k}$ is completely determined by the signs of $\Delta_1(A), \ldots, \Delta_m(A)$. We work this out in the special case $\mathbb{R}^{2\times2\times2}$.
5. *Reduction.* We will give techniques for reducing certain questions about tensors (orbits, invariants, limits) from high-dimensional tensor spaces to lower-dimensional tensor spaces. For instance, if two tensors in $\mathbb{R}^{c_1\times\cdots\times c_k}$ lie in distinct $\mathrm{GL}_{c_1,\ldots,c_k}(\mathbb{R})$-orbits, then they lie in distinct $\mathrm{GL}_{d_1,\ldots,d_k}(\mathbb{R})$-orbits in $\mathbb{R}^{d_1\times\cdots\times d_k}$ for any $d_i \geq c_i$.

The first objective is formally stated and proved in Theorem 4.10. The two notable exceptions where APPROX(A, r) has a solution are the cases $r = 1$ (approximation by rank-1 tensors) and $k = 2$ (A is a matrix). The standard way to prove these assertions is to use brute force: show that the sets where the approximators are to be found may be defined by polynomial equations. We will provide alternative elementary proofs of these results in Propositions 4.2 and 4.3 (see also Proposition 4.4).

The second objective is proved in Theorem 8.4, which holds true on $\mathbb{R}^{d_1 \times d_2 \times d_3}$ for arbitrary $d_1, d_2, d_3 \geq 2$. Stronger results can hold in specific cases: in Theorem 8.1, we will give an instance where *every* rank-r tensor fails to have a best rank-$(r-1)$ approximator.

The third objective is primarily possible because of the following theorem, which asserts that the boundary of the set of rank-2 tensors can be explicitly parameterized. The proof, and a discussion of weak solutions, is given in section 5.

THEOREM 1.1. *Let $d_1, d_2, d_3 \geq 2$. Let $A_n \in \mathbb{R}^{d_1 \times d_2 \times d_3}$ be a sequence of tensors with $\operatorname{rank}_\otimes(A_n) \leq 2$ and*

$$\lim_{n \to \infty} A_n = A,$$

where the limit is taken in any norm topology. If the limiting tensor A has rank higher than 2, then $\operatorname{rank}_\otimes(A)$ must be exactly 3, and there exist pairs of linearly independent vectors $\mathbf{x}_1, \mathbf{y}_1 \in \mathbb{R}^{d_1}$, $\mathbf{x}_2, \mathbf{y}_2 \in \mathbb{R}^{d_2}$, $\mathbf{x}_3, \mathbf{y}_3 \in \mathbb{R}^{d_3}$ such that

$$A = \mathbf{x}_1 \otimes \mathbf{x}_2 \otimes \mathbf{y}_3 + \mathbf{x}_1 \otimes \mathbf{y}_2 \otimes \mathbf{x}_3 + \mathbf{y}_1 \otimes \mathbf{x}_2 \otimes \mathbf{x}_3. \tag{1.1}$$

Furthermore, the above result is not vacuous since

$$A_n = n\left(\mathbf{x}_1 + \frac{1}{n}\mathbf{y}_1\right) \otimes \left(\mathbf{x}_2 + \frac{1}{n}\mathbf{y}_2\right) \otimes \left(\mathbf{x}_3 + \frac{1}{n}\mathbf{y}_3\right) - n\mathbf{x}_1 \otimes \mathbf{x}_2 \otimes \mathbf{x}_3$$

is an example of a sequence that converges to A.

A few conclusions can immediately be drawn from Theorem 1.1: (i) the boundary points of all order-3 rank-2 tensors can be completely parameterized by (1.1); (ii) a sequence of order-3 rank-2 tensors cannot "jump rank" by more than 1; (iii) A in (1.1), in particular, is an example of a tensor that has no best rank-2 approximation.

The formal statements and proofs of the fourth objective appear in section 6. The fifth objective is exemplified by our approach throughout the paper; some specific technical tools are discussed in sections 5.1 and 7.5.

On top of these five objectives, we pick up the following smaller results along the way. Some of these results address frequently asked questions in tensor approximation. They are discussed in sections 4.3–4.7, respectively.

6. *Divergence of coefficients.* Whenever a low-rank sequence of tensors converges to a higher-rank tensor, some of the terms in the sequence must blow up. In examples of minimal rank, all the terms blow up.
7. *Maximum rank.* For $k \geq 3$, the maximum rank of an order-k tensor in $\mathbb{R}^{d_1 \times \cdots \times d_k}$ (where $d_i \geq 2$) always exceeds $\min(d_1, \ldots, d_k)$. In contrast, for matrices $\min(d_1, d_2)$ does bound the rank.
8. *Tensor rank can leap large gaps.* Conclusion (ii) above does not generalize to rank $r > 2$. We will show that a sequence of fixed rank tensors can converge to a limiting tensor of arbitrarily higher rank.
9. *Brègman divergences do not help.* If we replace the norm by any continuous measure of "nearness" (including nonmetric measures like Brègman divergences), it does not change the ill-foundedness of APPROX(A, r).

10. *Leibniz tensors.* We will construct a rich family of sequences of tensors with degenerate limits, labeled by partial derivative operators. The special case $L_3(1)$ is in fact the principal example (1.1) in this paper.

1.2. Relation to prior work. The existence of tensors that can fail to have a best rank-r approximation has been known to algebraic geometers as early as the 19th century, albeit in a different language—the locus of rth secant planes to a Segre variety may not define a (closed) algebraic variety. It is also known to computational complexity theorists as the phenomenon underlying the concept of *border rank* [5, 6, 12, 48, 54] and is related to (but different from) what chemometricians and psychometricians call "CANDECOMP/PARAFAC degeneracy" [49, 51, 63, 68, 69]. We do not claim to be the first to have found such an example—that honor belongs to Bini, Capovani, Lotti, and Romani, who gave an explicit example of a sequence of rank-5 tensors converging to a rank-6 tensor in 1979 [7]. The novelty of Theorem 1.1 is not in demonstrating that a tensor may be approximated arbitrarily well by tensors of strictly lower rank but in *characterizing all such tensors* in the order-3 rank-2 case.

Having said this, we would like to point out that the ill-posedness of the best rank-r approximation problem for high-order tensors is not at all well known, as is evident from the paragraph quoted earlier as well as other discussions in recent publications [44, 45, 46, 47, 80]. One likely reason is that in algebraic geometry, computational complexity, chemometrics, and psychometrics, the problem is neither stated in the form nor viewed in the light of obtaining a best low-rank approximation with respect to a choice of norm (we give several equivalent formulations of $\text{APPROX}(A, r)$ in Proposition 4.1). As such, one goal of this paper will be to debunk, once and for all, the question of finding best low-rank approximations for tensors of order 3 or higher. As we stated earlier (as our first and second objectives), our contribution will be to show that such failures (i) can and will occur for tensors of *any* order higher than 2, (ii) will occur for tensors of many different ranks, (iii) will occur regardless of the choice of norm, and (iv) will occur with nonzero probability. Formally, we have the following two theorems (which will appear as Theorems 4.10 and 8.4 subsequently).

THEOREM 1.2. *Let $k \geq 3$ and $d_1, \dots, d_k \geq 2$. For any s such that $2 \leq s \leq \min\{d_1, \dots, d_k\}$, there exists $A \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ with $\operatorname{rank}_{\otimes}(A) = s$ such that A has no best rank-r approximation for some $r < s$. The result is independent of the choice of norms.*

THEOREM 1.3. *If $d_1, d_2, d_3 \geq 2$, then the set*

$$\{A \in \mathbb{R}^{d_1 \times d_2 \times d_3} \mid A \text{ does not have a best rank-2 approximation}\}$$

has positive volume; indeed, it contains a nonempty open set.

A few features distinguish our work in this paper from existing studies in algebraic geometry [13, 14, 54, 55, 79] and algebraic computational complexity [2, 3, 5, 6, 7, 8, 12, 70]: (i) we are interested in tensors over $\mathbb{R}$ as opposed to tensors over $\mathbb{C}$ (it is well known that the rank of a tensor is dependent on the underlying field; cf. (7.5) and [4]); (ii) our interest is not limited to order-3 tensors (as is often the case in algebraic computational complexity)—we would like to prove results that hold for tensors of any order $k \geq 3$; (iii) since we are interested in questions pertaining to approximations in the norm, the Euclidean (norm-induced) topology will be more relevant than the

Zariski topology[1] on the tensor product spaces—note in particular that the claim that a set is not closed in the Euclidean topology is a stronger statement than the corresponding claim in Zariski topology.

Our work in this paper in general, and in section 4.2 in particular, is related to studies of "CANDECOMP/PARAFAC degeneracy" or "diverging CANDECOMP/PARAFAC components" in psychometrics and chemometrics [49, 51, 63, 68, 69]. Diverging coefficients are a necessary consequence of the ill-posedness of APPROX(A, r) (see Propositions 4.8 and 4.9). In fact, examples of "k-factor divergence" abound for arbitrary k—see sections 4.4 and 4.7 for various constructions.

Section 5.4 discusses how the nonexistence of a best rank-r approximation poses serious difficulties for multilinear statistical models based on such approximations. In particular, we will see (i) why it is meaningless to ask for a "good" rank-r approximation when a best rank-r approximation does not exist; (ii) why even a small perturbation to a rank-r tensor can result in a tensor that has no best rank-r approximation; and (iii) why the computational feasibility of finding a "good" rank-r approximation is questionable.

1.3. Outline of the paper. Section 2 introduces the basic algebra of tensors and k-way arrays. Section 3 defines tensor rank and gives some of its known (and unknown) algebraic properties. Section 4 studies the topological properties of tensor rank and the phenomenon of rank-jumping. Section 5 characterizes the problematic tensors in $\mathbb{R}^{2\times2\times2}$ and discusses the implications for approximation problems. Section 6 gives a short exposition of the semialgebraic point of view. Section 7 classifies tensors in $\mathbb{R}^{2\times2\times2}$ by orbit type. The orbit structure of tensor spaces is studied from several different aspects. Section 8 is devoted to the result that failure of APPROX$(A, 2)$ occurs on a set of positive volume.

2. Tensors. Even though tensors are well-studied objects in the standard graduate mathematics curriculum [1, 27, 41, 52, 64] and more specifically in multilinear algebra [9, 34, 59, 60, 62, 78], a "tensor" continues to be viewed as a mysterious object by outsiders. We feel that we should say a few words to demystify the term.

In mathematics, the question "What is a vector?" has the simple answer "A vector is an element of a vector space"—in other words, a vector is characterized by the axioms that define the algebraic operations on a vector space. In physics, however, the question "What is a vector?" often means "What kinds of physical quantities can be represented by vectors?" The criterion has to do with the change of basis theorem: an n-dimensional vector is an "object" that is represented by n real numbers once a basis is chosen *only* if those real numbers transform themselves as expected when one changes the basis. For exactly the same reason, the meaning of a tensor is obscured by its more restrictive use in physics. In physics (and also engineering), a tensor is an "object" represented by a k-way array of real numbers that transforms according to certain rules (cf. (2.2)) under a change of basis. In mathematics, these "transformation rules" are simply consequences of the multilinearity of the tensor product and the change of basis theorem for vectors. Today, books written primarily for a physics audience [32, 61] have increasingly adopted the mathematical definition, but a handful of recently published books continue to propagate the obsolete (and vague) definition. To add to the confusion, "tensor" is frequently used to refer to a

[1] Note that the Zariski topology on $\mathbb{k}^n$ is defined for any field $\mathbb{k}$ (not just algebraically closed ones). It is the weakest topology such that all polynomial functions are continuous. In particularly, the closed sets are precisely the zero sets of collections of polynomials.

tensor field (e.g., metric tensor, stress tensor, Riemann curvature tensor).

For our purposes, an order-k *tensor* $\mathbf{A}$ is simply an element of a *tensor product* of k real vector spaces, $V_1 \otimes V_2 \otimes \cdots \otimes V_k$, as defined in any standard algebra textbook [1, 9, 27, 34, 41, 52, 59, 60, 62, 64, 78]. Up to a choice of bases on $V_1, \dots, V_k$, such an element may be *coordinatized*, i.e., represented as a k-way array A of real numbers—much as an element of an n-dimensional vector space may be, up to a choice of basis, represented by an n-tuple of numbers in $\mathbb{R}^n$. We will let $\mathbb{R}^{d_1 \times \cdots \times d_k}$ denote the vector space of k-way array of real numbers $A = [\![a_{j_1 \cdots j_k}]\!]_{j_1=1,\dots,j_k=1}^{d_1,\dots,d_k}$ with addition and scalar multiplication defined coordinatewise:

$$[\![a_{j_1 \cdots j_k}]\!] + [\![b_{j_1 \cdots j_k}]\!] := [\![a_{j_1 \cdots j_k} + b_{j_1 \cdots j_k}]\!] \quad \text{and} \quad \lambda [\![a_{j_1 \cdots j_k}]\!] := [\![\lambda a_{j_1 \cdots j_k}]\!]. \tag{2.1}$$

A k-way array of numbers (or k-array) is also sometimes referred to as a k-dimensional *hypermatrix* [30].

It may be helpful to think of a k-array as a *data structure*, convenient for representing or storing the coefficients of a tensor with respect to a set of bases. The tensor itself carries with it an *algebraic structure*, by virtue of being an element of a tensor product of vector spaces. Once bases have been chosen for these vector spaces, we may view the order-k tensor as a k-way array equipped with the algebraic operations defined in (2.1) and (2.3). Despite this correspondence, it is not wise to regard "tensor" as being synonymous with "array."

Notation. We will denote elements of abstract tensor spaces in boldface uppercase letters, whereas k-arrays will be denoted in italic uppercase letters. Thus $\mathbf{A}$ is an abstract tensor, which may be represented by an array of numbers A with respect to a basis. We will use double brackets to enclose the entries of a k-array—$A = [\![a_{j_1 \cdots j_k}]\!]_{j_1=1,\dots,j_k=1}^{d_1,\dots,d_k}$—and when there is no risk of confusion, we will leave out the range of the indices and simply write $A = [\![a_{j_1 \cdots j_k}]\!]$.

2.1. Multilinear matrix multiplication. Matrices can act on other matrices through two independent multiplication operations: left-multiplication and right-multiplication. Matrices act on order-3 tensors via *three* different multiplication operations. These can be combined into a single formula. If $A = [\![a_{ijk}]\!] \in \mathbb{R}^{d_1 \times d_2 \times d_3}$ and $L = [\lambda_{pi}] \in \mathbb{R}^{c_1 \times d_1}$, $M = [\mu_{qj}] \in \mathbb{R}^{c_2 \times d_2}$, $N = [\nu_{rk}] \in \mathbb{R}^{c_3 \times d_3}$, then the array A may be transformed into an array $A' = [\![a'_{pqr}]\!] \in \mathbb{R}^{c_1 \times c_2 \times c_3}$ by the equation

$$a'_{pqr} = \sum\nolimits_{i,j,k=1}^{d_1,d_2,d_3} \lambda_{pi} \mu_{qj} \nu_{rk} a_{ijk}. \tag{2.2}$$

We call this operation the *multilinear multiplication* of A by matrices L, M, N, which we write succinctly as

$$A' = (L, M, N) \cdot A.$$

Informally, we are multiplying the 3-way array A on its three "sides" by the matrices L, M, N, respectively.

Remark. This notation is standard in mathematics—the elements of a product $G_1 \times G_2 \times G_3$ are generally grouped in the form (L, M, N), and when a set with some algebraic structure G acts on another set X, the result of $g \in G$ acting on $x \in X$ is almost universally written $g \cdot x$ [1, 9, 27, 41, 52, 64]. Here we are just looking at the case when $G = \mathbb{R}^{c_1 \times d_1} \times \mathbb{R}^{c_2 \times d_2} \times \mathbb{R}^{c_3 \times d_3}$ and $X = \mathbb{R}^{d_1 \times d_2 \times d_3}$. This is consistent with notation adopted in earlier work [42], but more recent publications such as [20, 21] have used $A \times_1 L^\top \times_2 M^\top \times_3 N^\top$ in place of $(L, M, N) \cdot A$.

Multilinear matrix multiplication extends in a straightforward way to arrays of arbitrary order: if $A = [\![a_{i_1\cdots i_k}]\!] \in \mathbb{R}^{d_1\times\cdots\times d_k}$ and $L_1 = [\lambda_{ij}^{(1)}] \in \mathbb{R}^{c_1\times d_1}, \dots, L_k = [\lambda_{ij}^{(k)}] \in \mathbb{R}^{c_k\times d_k}$, then $A' = (L_1, \dots, L_k) \cdot A$ is the array $A' = [\![a'_{i_1\cdots i_k}]\!] \in \mathbb{R}^{c_1\times\cdots\times c_k}$ given by

$$a'_{i_1\cdots i_k} = \sum\nolimits_{i_1,\dots,i_k=1}^{d_1,\dots,d_k} \lambda_{i_1 j_1} \cdots \lambda_{i_k j_k} a_{j_1\cdots j_k}. \tag{2.3}$$

We will now see how a 3-way array representing a tensor in $V_1 \otimes V_2 \otimes V_3$ transforms under changes of bases of the vector spaces V_i. Suppose the 3-way array $A = [\![a_{ijk}]\!] \in \mathbb{R}^{d_1\times d_2\times d_3}$ represents an order-3 tensor $\mathbf{A} \in V_1 \otimes V_2 \otimes V_3$ with respect to bases $\mathcal{B}_1 = \{\mathbf{e}_i \mid i = 1, \dots, d_1\}$, $\mathcal{B}_2 = \{\mathbf{f}_j \mid j = 1, \dots, d_2\}$, $\mathcal{B}_3 = \{\mathbf{g}_k \mid k = 1, \dots, d_3\}$ on V_1, V_2, V_3, i.e.,

$$\mathbf{A} = \sum\nolimits_{i,j,k=1}^{d_1,d_2,d_3} a_{ijk} \mathbf{e}_i \otimes \mathbf{f}_j \otimes \mathbf{g}_k. \tag{2.4}$$

Suppose we choose different bases $\mathcal{B}'_1 = \{\mathbf{e}'_i \mid i = 1, \dots, d_1\}$, $\mathcal{B}'_2 = \{\mathbf{f}'_j \mid j = 1, \dots, d_2\}$, $\mathcal{B}'_3 = \{\mathbf{g}'_k \mid k = 1, \dots, d_3\}$ on V_1, V_2, V_3, where

$$\mathbf{e}_i = \sum\nolimits_{p=1}^{d_1} \lambda_{ip} \mathbf{e}'_p, \quad \mathbf{f}_j = \sum\nolimits_{q=1}^{d_2} \mu_{jq} \mathbf{f}'_q, \quad \mathbf{g}_k = \sum\nolimits_{r=1}^{d_3} \nu_{kr} \mathbf{g}'_r, \tag{2.5}$$

and $L = [\lambda_{pi}] \in \mathbb{R}^{d_1\times d_1}$, $M = [\mu_{qj}] \in \mathbb{R}^{d_2\times d_2}$, $N = [\nu_{rk}] \in \mathbb{R}^{d_3\times d_3}$ are the respective change-of-basis matrices. Substituting the expressions for (2.5) into (2.4), we get

$$\mathbf{A} = \sum\nolimits_{p,q,r=1}^{d_1,d_2,d_3} a'_{pqr} \mathbf{e}'_p \otimes \mathbf{f}'_q \otimes \mathbf{g}'_r,$$

where

$$a'_{pqr} = \sum\nolimits_{i,j,k=1}^{d_1,d_2,d_3} \lambda_{pi} \mu_{qj} \nu_{rk} a_{ijk} \tag{2.6}$$

or, more simply, $A' = (L, M, N) \cdot A$. Here the 3-way array $A' = [\![a'_{pqr}]\!] \in \mathbb{R}^{d_1\times d_2\times d_3}$ represents $\mathbf{A}$ with respect to the new choice of bases $\mathcal{B}'_1, \mathcal{B}'_2, \mathcal{B}'_3$.

All of this extends immediately to order-k tensors and k-way arrays. Henceforth, when a choice of basis is implicit, we will not distinguish between an order-k tensor and the k-way array that represents it.

The change-of-basis matrices L, M, N in the discussion above are of course invertible; in other words they belong to their respective *general linear* groups. We write $\mathrm{GL}_d(\mathbb{R})$ for the group of nonsingular matrices in $\mathbb{R}^{d\times d}$. Thus $L \in \mathrm{GL}_{d_1}(\mathbb{R})$, $M \in \mathrm{GL}_{d_2}(\mathbb{R})$, and $N \in \mathrm{GL}_{d_3}(\mathbb{R})$. In addition to general linear transformations, it is natural to consider orthogonal transformations. We write $\mathrm{O}_d(\mathbb{R})$ for the subgroup of $\mathrm{GL}_d(\mathbb{R})$ of transformations which preserve the Euclidean inner product. The following shorthand is helpful:

$$\mathrm{GL}_{d_1,\dots,d_k}(\mathbb{R}) := \mathrm{GL}_{d_1}(\mathbb{R}) \times \cdots \times \mathrm{GL}_{d_k}(\mathbb{R}),$$
$$\mathrm{O}_{d_1,\dots,d_k}(\mathbb{R}) := \mathrm{O}_{d_1}(\mathbb{R}) \times \cdots \times \mathrm{O}_{d_k}(\mathbb{R}).$$

Then $\mathrm{O}_{d_1,\dots,d_k}(\mathbb{R}) \le \mathrm{GL}_{d_1,\dots,d_k}(\mathbb{R})$, and both groups act on $\mathbb{R}^{d_1\times\cdots\times d_k}$ via multilinear multiplication.

DEFINITION 2.1. *Two tensors $A, A' \in \mathbb{R}^{d_1\times\cdots\times d_k}$ are said to be* GL*-equivalent (or simply "equivalent") if there exists $(L_1, \dots, L_k) \in \mathrm{GL}_{d_1,\dots,d_k}(\mathbb{R})$ such that $A' =$*

$(L_1, \dots, L_k) \cdot A$. *More strongly, we say that* A, A' *are* O*-equivalent if such a transformation* L *can be found in* $\mathrm{O}_{d_1,\dots,d_k}(\mathbb{R})$.

For example, if $V_1, \dots, V_k$ are vector spaces and $\dim(V_i) = d_i$, then $A, A' \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ represent the same tensor in $V_1 \otimes \cdots \otimes V_k$ with respect to two different bases if and only if A, A' are GL-equivalent.

We finish with some trivial properties of multilinear matrix multiplication: for $A, B \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ and $\alpha, \beta \in \mathbb{R}$,

$$(L_1, \dots, L_k) \cdot (\alpha A + \beta B) = \alpha (L_1, \dots, L_k) \cdot A + \beta (L_1, \dots, L_k) \cdot B \tag{2.7}$$

and for $L_i \in \mathbb{R}^{c_i \times d_i}$, $M_i \in \mathbb{R}^{b_i \times c_i}$, $i = 1, \dots, k$,

$$(M_1, \dots, M_k) \cdot [(L_1, \dots, L_k) \cdot A] = (M_1 L_1, \dots, M_k L_k) \cdot A. \tag{2.8}$$

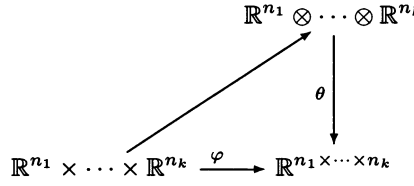
Last, the name *multilinear* matrix multiplication is justified since for any $M_i, N_i \in \mathbb{R}^{c_i \times d_i}$, $\alpha, \beta \in \mathbb{R}$,

$$\begin{aligned}(L_1, \dots, \alpha M_i + \beta N_i, \dots, L_k) \cdot A = \alpha (L_1, \dots, M_i, \dots, L_k) \cdot A \\ + \beta (L_1, \dots, N_i, \dots, L_k) \cdot A.\end{aligned} \tag{2.9}$$

2.2. Outer-product rank and outer-product decomposition of a tensor. Let $\mathbb{R}^{d_1} \otimes \cdots \otimes \mathbb{R}^{d_k}$ be the tensor product of the vector spaces $\mathbb{R}^{d_1}, \dots, \mathbb{R}^{d_k}$. Note that the *Segre map*

$$\mathbb{R}^{d_1} \times \cdots \times \mathbb{R}^{d_k} \to \mathbb{R}^{d_1 \times \cdots \times d_k}, \qquad (\mathbf{x}_1, \dots, \mathbf{x}_k) \mapsto [\![x^{(1)}_{j_1} \cdots x^{(k)}_{j_k}]\!]^{d_1,\dots,d_k}_{j_1,\dots,j_k=1} \tag{2.10}$$

is multilinear and so by the universal property of the tensor product [1, 9, 27, 34, 41, 52, 59, 60, 62, 64, 78], we have a unique linear map φ such that the following diagram commutes:



Clearly,

$$\varphi(\mathbf{x}_1 \otimes \cdots \otimes \mathbf{x}_k) = [\![x^{(1)}_{j_1} \cdots x^{(k)}_{j_k}]\!]^{d_1,\dots,d_k}_{j_1,\dots,j_k=1} \tag{2.11}$$

and φ is a vector space isomorphism since $\dim(\mathbb{R}^{d_1 \times \cdots \times d_k}) = \dim(\mathbb{R}^{d_1} \otimes \cdots \otimes \mathbb{R}^{d_k}) = d_1 \cdots d_k$. Henceforth we will not distinguish between these two spaces. The elements of $\mathbb{R}^{d_1} \otimes \cdots \otimes \mathbb{R}^{d_k} \cong \mathbb{R}^{d_1 \times \cdots \times d_k}$ will be called a tensor and we will also drop φ in (2.11) and write

$$\mathbf{x}_1 \otimes \cdots \otimes \mathbf{x}_k = [\![x^{(1)}_{j_1} \cdots x^{(k)}_{j_k}]\!]^{d_1,\dots,d_k}_{j_1,\dots,j_k=1}. \tag{2.12}$$

Note that the symbol $\otimes$ in (2.11) denotes the formal tensor product and by dropping φ, we are using the same symbol $\otimes$ to define the *outer product* of the vectors $\mathbf{x}_1, \dots, \mathbf{x}_k$ via the formula (2.12). Hence, a tensor can be represented either as a k-dimensional array or as a sum of formal tensor products of k vectors, where the equivalence between

these two objects is established by taking the formal tensor product of k vectors as defining a k-way array via (2.12).

It is clear that the map in (2.10) is not surjective—the image consists precisely of the *decomposable tensors*: a tensor $A \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ is said to be *decomposable* if it can be written in the form

$$A = \mathbf{x}_1 \otimes \cdots \otimes \mathbf{x}_k$$

with $\mathbf{x}_i \in \mathbb{R}^{d_i}$ for $i = 1, \ldots, k$. It is easy to see that multilinear matrix multiplication of decomposable tensors obeys the formula

$$(L_1, \ldots, L_k) \cdot (\mathbf{x}_1 \otimes \cdots \otimes \mathbf{x}_k) = L_1\mathbf{x}_1 \otimes \cdots \otimes L_k\mathbf{x}_k. \tag{2.13}$$

Remark. The outer product can be viewed as a special case of multilinear matrix multiplication. For example, a linear combination of outer products of vectors may be expressed in terms of multilinear matrix multiplication:

$$\sum\nolimits_{i=1}^{r} \lambda_i \mathbf{x}_i \otimes \mathbf{y}_i \otimes \mathbf{z}_i = (X, Y, Z) \cdot \Lambda$$

with matrices $X = [\mathbf{x}_1, \ldots, \mathbf{x}_r] \in \mathbb{R}^{l \times r}$, $Y = [\mathbf{y}_1, \ldots, \mathbf{y}_r] \in \mathbb{R}^{m \times r}$, $Z = [\mathbf{z}_1, \ldots, \mathbf{z}_r] \in \mathbb{R}^{n \times r}$ and a "diagonal tensor" $\Lambda = \operatorname{diag}[\lambda_1, \ldots, \lambda_r] \in \mathbb{R}^{r \times r \times r}$.

We now come to the main concept of interest in this paper.

DEFINITION 2.2. *A tensor has* outer-product rank r *if it can be written as a sum of* r *decomposable tensors, but no fewer. We will write* $\operatorname{rank}_{\otimes}(A)$ *for the outer-product rank of* A. *So*

$$\operatorname{rank}_{\otimes}(A) := \min \left\{ r \mid A = \sum\nolimits_{i=1}^{r} \mathbf{u}_i \otimes \mathbf{v}_i \otimes \cdots \otimes \mathbf{z}_i \right\}.$$

Note that a nonzero decomposable tensor has outer-product rank 1.

Despite several claims of originality as well as many misplaced attributions to these claims, the concepts of tensor rank and the decomposition of a tensor into a sum of outer products of vectors was the product of much earlier work by Frank L. Hitchcock in 1927 [39, 40]. We call this the outer-product rank mainly to distinguish it from the *multilinear rank* to be defined in section 2.5 (also due to Hitchcock), but we will use the term *rank* or *tensor rank* most of the time when there is no danger of confusion.

LEMMA 2.3 (invariance of tensor rank). (1) *If* $A \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ *and* $(L_1, \ldots, L_k) \in \mathbb{R}^{c_1 \times d_1} \times \cdots \times \mathbb{R}^{c_k \times d_k}$, *then*

$$\operatorname{rank}_{\otimes}((L_1, \ldots, L_k) \cdot A) \leq \operatorname{rank}_{\otimes}(A). \tag{2.14}$$

(2) *If* $A \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ *and* $(L_1, \ldots, L_k) \in \mathrm{GL}_{d_1,\ldots,d_k}(\mathbb{R}) := \mathrm{GL}_{d_1}(\mathbb{R}) \times \cdots \times \mathrm{GL}_{d_k}(\mathbb{R})$, *then*

$$\operatorname{rank}_{\otimes}((L_1, \ldots, L_k) \cdot A) = \operatorname{rank}_{\otimes}(A). \tag{2.15}$$

Proof. Inequality (2.14) follows from (2.13) and (2.7). Indeed, if $A = \sum_{j=1}^{r} \mathbf{x}_1^j \otimes \cdots \otimes \mathbf{x}_k^j$, then $(L_1, \ldots, L_k) \cdot A = \sum_{j=1}^{r} L_1\mathbf{x}_1^j \otimes \cdots \otimes L_k\mathbf{x}_k^j$. Furthermore, if the L_i are invertible, then by (2.8) we get

$$A = (L_1^{-1}, \ldots, L_k^{-1}) \cdot [(L_1, \ldots, L_k) \cdot A],$$

and so $\operatorname{rank}_{\otimes}(A) \leq \operatorname{rank}_{\otimes}((L_1, \ldots, L_k) \cdot A)$, and hence (2.15). ∎

2.3. The outer product and direct sum operations on tensors. The outer product of vectors defined earlier is a special case of the *outer product* of two tensors. Let $A \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ be a tensor of order k and $B \in \mathbb{R}^{c_1 \times \cdots \times c_\ell}$ be a tensor of order ℓ; then the outer product of A and B is the tensor $C := A \otimes B \in \mathbb{R}^{d_1 \times \cdots \times d_k \times c_1 \times \cdots \times c_l}$ of order $k + \ell$ defined by

$$c_{i_1 \cdots i_k j_1 \cdots j_l} = a_{i_1 \cdots i_k} b_{j_1 \cdots j_l}.$$

The *direct sum* of two order-k tensors $A \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ and $B \in \mathbb{R}^{c_1 \times \cdots \times c_k}$ is the order-k tensor $C := A \oplus B \in \mathbb{R}^{(c_1+d_1) \times \cdots \times (c_k+d_k)}$ defined by

$$c_{i_1,\ldots,i_k} = \begin{cases} a_{i_1,\ldots,i_k} & \text{if } 1 \le i_\alpha \le d_\alpha,\ \alpha = 1,\ldots,k; \\ b_{i_1-d_1,\ldots,i_k-d_k} & \text{if } d_\alpha + 1 \le i_\alpha \le c_\alpha + d_\alpha,\ \alpha = 1,\ldots,k; \\ 0 & \text{otherwise.} \end{cases}$$

For matrices, the direct sum of $A \in \mathbb{R}^{m_1 \times n_1}$ and $B \in \mathbb{R}^{m_2 \times n_2}$ is simply the block-diagonal matrix

$$A \oplus B = \begin{bmatrix} A & 0 \\ 0 & B \end{bmatrix} \in \mathbb{R}^{(m_1+m_2) \times (n_1+n_2)}.$$

The direct sum of two order-3 tensors $A \in \mathbb{R}^{l_1 \times m_1 \times n_1}$ and $B \in \mathbb{R}^{l_2 \times m_2 \times n_2}$ is a "block tensor" with A in the $(1,1,1)$-block and B in the $(2,2,2)$-block

$$A \oplus B = \left[\begin{array}{cc|cc} A & 0 & 0 & 0 \\ 0 & 0 & 0 & B \end{array}\right] \in \mathbb{R}^{(l_1+l_2) \times (m_1+m_2) \times (n_1+n_2)}.$$

In abstract terms, if U_i, V_i, W_i are vector spaces such that $W_i = U_i \oplus V_i$ for $i = 1,\ldots,k$, then tensors $A \in U_1 \otimes \cdots \otimes U_k$ and $B \in V_1 \otimes \cdots \otimes V_k$ have direct sum $A \oplus B \in W_1 \otimes \cdots \otimes W_k$.

2.4. Tensor subspaces. Whenever $c \le d$ there is a canonical embedding $\mathbb{R}^c \subseteq \mathbb{R}^d$ given by identifying the c coordinates of $\mathbb{R}^c$ with the first c coordinates of $\mathbb{R}^d$.

Let $c_i \le d_i$ for $i = 1,\ldots,k$. Then there is a canonical embedding $\mathbb{R}^{c_1 \times \cdots \times c_k} \subset \mathbb{R}^{d_1 \times \cdots \times d_k}$, defined as the tensor product of the embeddings $\mathbb{R}^{c_i} \subseteq \mathbb{R}^{d_i}$. We say that $\mathbb{R}^{c_1 \times \cdots \times c_k}$ is a *tensor subspace* of $\mathbb{R}^{d_1 \times \cdots \times d_k}$. More generally, if U_i, V_i are vector spaces with $U_i \subset V_i$ for $i = 1,\ldots,k$, then there is an inclusion $U_1 \otimes \cdots \otimes U_k \subset V_1 \otimes \cdots \otimes V_k$ defined as the tensor product of the inclusions $U_i \subset V_i$. Again we say that $U_1 \otimes \cdots \otimes U_k$ is a tensor subspace of $V_1 \otimes \cdots \otimes V_k$.

If $B \in \mathbb{R}^{c_1 \times \cdots \times c_k}$ then its image under the canonical embedding into $\mathbb{R}^{d_1 \times \ldots d_k}$ can be written in the form $B \oplus 0$, where $0 \in \mathbb{R}^{(d_1-c_1) \times \cdots \times (d_k-c_k)}$ is the zero tensor. A tensor $A \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ is said to be GL-*equivalent* (or simply "equivalent") to B if there exists $(L_1,\ldots,L_k) \in \mathrm{GL}_{d_1,\ldots,d_k}(\mathbb{R})$ such that $B \oplus 0 = (L_1,\ldots,L_k) \cdot A$. More strongly, we say that A is O-*equivalent* ("orthogonally equivalent") to B if such a transformation can be found in $\mathrm{O}_{d_1,\ldots,d_k}(\mathbb{R})$.

We note that A is GL-equivalent to B if and only if there exist full-rank matrices $M_i \in \mathbb{R}^{d_i \times c_i}$ such that $A = (M_1,\ldots,M_k) \cdot B$. In one direction, M_i can be obtained as the first c_i columns of L_i^{-1}. In the other direction, L_i^{-1} can be obtained from M_i by adjoining extra columns. There is a similar statement for O-equivalence. Instead of full rank, the condition is that the matrices M_i have orthogonal columns.

An important simplifying principle in tensor algebra is that questions about a tensor—such as "What is its rank?"—can sometimes, as we shall see, be reduced to analogous questions about an equivalent tensor in a lower-dimensional tensor subspace.

2.5. Multilinear rank and multilinear decomposition of a tensor. Although we focus on outer product rank in this paper, there is a simpler notion of multilinear rank which directly generalizes the column and row ranks of a matrix to higher order tensors.

For convenience, we will consider order-3 tensors only. Let $A = [\![a_{ijk}]\!] \in \mathbb{R}^{d_1 \times d_2 \times d_3}$. For fixed values of $j \in \{1, \dots, d_2\}$ and $k \in \{1, \dots, d_3\}$, consider the vector $A_{\bullet jk} := [a_{ijk}]_{i=1}^{d_1} \in \mathbb{R}^{d_1}$. Likewise consider (column) vectors $A_{i\bullet k} := [a_{ijk}]_{j=1}^{d_2} \in \mathbb{R}^{d_2}$ for fixed values of i, k, and consider (row) vectors $A_{ij\bullet} := [a_{ijk}]_{k=1}^{d_3} \in \mathbb{R}^{d_3}$ for fixed values of i, j. In analogy with row rank and column rank, define

$$\begin{aligned} r_1(A) &:= \dim(\operatorname{span}_{\mathbb{R}}\{A_{\bullet jk} \mid 1 \le j \le d_2, 1 \le k \le d_3\}), \\ r_2(A) &:= \dim(\operatorname{span}_{\mathbb{R}}\{A_{i\bullet k} \mid 1 \le i \le d_1, 1 \le k \le d_3\}), \\ r_3(A) &:= \dim(\operatorname{span}_{\mathbb{R}}\{A_{ij\bullet} \mid 1 \le i \le d_1, 1 \le j \le d_2\}). \end{aligned}$$

For another interpretation, note that $\mathbb{R}^{d_1 \times d_2 \times d_3}$ can be viewed as $\mathbb{R}^{d_1 \times d_2 d_3}$ by ignoring the multiplicative structure between the second and third factors. Then $r_1(A)$ is simply the rank of A regarded as $d_1 \times d_2 d_3$ matrix. There are similar definitions for $r_2(A)$ and $r_3(A)$.

The *multilinear rank* of A, denoted[2] $\operatorname{rank}_{\boxplus}(A)$, is the 3-tuple $(r_1(A), r_2(A), r_3(A))$. Again, this concept is not new but was first explored by Hitchcock in the same papers where he introduced tensor rank [39, 40]. Hitchcock introduces a very general *multiplex rank*, which includes tensor rank and the separate terms of our multilinear rank as special cases. A point to note is that $r_1(A)$, $r_2(A)$, $r_3(A)$, and $\operatorname{rank}_{\otimes}(A)$ are in general all different—a departure from the case of matrices, where the row rank, column rank, and outer product rank are always equal. Observe that we will always have

$$r_i(A) \le \min\{\operatorname{rank}_{\otimes}(A), d_i\}. \tag{2.16}$$

Let us verify this for r_1: if $A = \mathbf{x}_1 \otimes \mathbf{y}_1 \otimes \mathbf{z}_1 + \cdots + \mathbf{x}_r \otimes \mathbf{y}_r \otimes \mathbf{z}_r$, then each vector $A_{\bullet jk}$ belongs to $\operatorname{span}(\mathbf{x}_1, \dots, \mathbf{x}_r)$. This implies that $r_1 \le \operatorname{rank}_{\otimes}(A)$, and $r_1 \le d_1$ is immediate from the definitions. A simple but useful consequence of (2.16) is that

$$\operatorname{rank}_{\otimes}(A) \ge \|\operatorname{rank}_{\boxplus}(A)\|_\infty = \max\{r_i(A) \mid i = 1, \dots, k\}. \tag{2.17}$$

If $A \in \mathbb{R}^{d_1 \times d_2 \times d_3}$ and $\operatorname{rank}_{\boxplus}(A) = (r_1, r_2, r_3)$, then there exist subspaces $U_i \subset \mathbb{R}^{d_i}$ with $\dim(U_i) = r_i$, such that $A \in U_1 \otimes U_2 \otimes U_3$. We call these the *supporting subspaces* of A. The supporting subspaces are minimal in the sense that if $A \in V_1 \otimes V_2 \otimes V_3$, then $U_i \subset V_i$ for $i = 1, 2, 3$. This observation leads to an alternate definition:

$$r_i(A) = \min\{\dim(U_i) \mid U_1 \subset \mathbb{R}^{d_1}, U_2 \subset \mathbb{R}^{d_2}, U_3 \subset \mathbb{R}^{d_3}, A \in U_1 \otimes U_2 \otimes U_3\}.$$

An immediate consequence of this characterization is that $\operatorname{rank}_{\boxplus}(A)$ is invariant under the action of $\mathrm{GL}_{d_1,d_2,d_3}(\mathbb{R})$: if $A' = (L, M, N) \cdot A$, where $(L, M, N) \in \mathrm{GL}_{d_1,d_2,d_3}(\mathbb{R})$, then $\operatorname{rank}_{\boxplus}(A) = \operatorname{rank}_{\boxplus}((L, M, N) \cdot A)$. Indeed, if U_1, U_2, U_3 are the supporting subspaces of A, then $L(U_1)$, $M(U_2)$, $N(U_3)$ are the supporting subspaces of $(L, M, N) \cdot A$.

More generally, we have multilinear rank equivalents of (2.14) and (2.15): if $A \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ and $(L_1, \dots, L_k) \in \mathbb{R}^{c_1 \times d_1} \times \cdots \times \mathbb{R}^{c_k \times d_k}$, then

$$\operatorname{rank}_{\boxplus}((L_1, \dots, L_k) \cdot A) \le \operatorname{rank}_{\boxplus}(A), \tag{2.18}$$

[2]The symbol $\boxplus$ is meant to evoke an impression of the rows and columns in a matrix.

and if $A \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ and $(L_1, \ldots, L_k) \in \mathrm{GL}_{d_1,\ldots,d_k}(\mathbb{R})$, then

$$\mathrm{rank}_{\boxplus}((L_1, \ldots, L_k) \cdot A) = \mathrm{rank}_{\boxplus}(A). \tag{2.19}$$

Suppose $\mathrm{rank}_{\boxplus}(A) = (r_1, r_2, r_3)$. By applying transformations $L_i \in \mathrm{GL}_{d_i}(\mathbb{R})$ which carry U_i to $\mathbb{R}^{r_i}$, it follows that A is equivalent to some $B \in \mathbb{R}^{r_1 \times r_2 \times r_3}$. Alternatively there exist $B \in \mathbb{R}^{r_1 \times r_2 \times r_3}$ and full-rank matrices $L \in \mathbb{R}^{d_1 \times r_1}$, $M \in \mathbb{R}^{d_2 \times r_2}$, $N \in \mathbb{R}^{d_3 \times r_3}$, such that

$$A = (L, M, N) \cdot B.$$

The matrices L, M, N may be chosen to have orthonormal columns or to be unit lower-triangular—a fact easily deduced from applying the QR-decomposition or the LU-decomposition to the full-rank matrices L, M, N and using (2.8).

To a large extent, the study of tensors $A \in \mathbb{R}^{d_1 \times d_2 \times d_3}$ with $\mathrm{rank}_{\boxplus}(A) \leq (r_1, r_2, r_3)$ reduces to the study of tensors in $\mathbb{R}^{r_1 \times r_2 \times r_3}$. This is a useful reduction, but (unlike the matrix case) it does not even come close to giving us a full classification of tensor types.

2.6. Multilinear orthogonal projection. If U is a subspace of an inner-product space V (for instance, $V = \mathbb{R}^n$ with the usual dot product), then there is an orthogonal projection from V onto U, which we denote π_U. We regard this as a map $V \to V$. As such, it is self-adjoint (i.e., has a symmetric matrix with respect to any orthonormal basis) and satisfies $\pi_U^2 = \pi_U$, $\mathrm{im}(\pi_U) = U$, $\ker(\pi_U) = U^\perp$. We note Pythagoras's theorem for any $\mathbf{v} \in V$:

$$\|\mathbf{v}\|^2 = \|\pi_U \mathbf{v}\|^2 + \|(1 - \pi_U)\mathbf{v}\|^2.$$

We now consider orthogonal projections for tensor spaces. If U_1, U_2, U_3 are subspaces of V_1, V_2, V_3, respectively, then $U_1 \otimes U_2 \otimes U_3$ is a tensor subspace of $V_1 \otimes V_2 \otimes V_3$, and the multilinear map $\Pi = (\pi_{U_1}, \pi_{U_2}, \pi_{U_3})$ is a projection onto that subspace. In fact, Π is orthogonal with respect to the Frobenius norm. The easiest way to see this is to identify $U_i \subset V_i$ with $\mathbb{R}^{c_i} \subset \mathbb{R}^{d_i}$ by taking suitable orthonormal bases; then Π acts by zeroing out all the entries of a $d_1 \times d_2 \times d_3$ array outside the initial $c_1 \times c_2 \times c_3$ block. In particular we have Pythagoras's theorem for any $A \in V_1 \otimes V_2 \otimes V_3$:

$$\|A\|_F^2 = \|\Pi A\|_F^2 + \|(1 - \Pi)A\|_F^2. \tag{2.20}$$

Being a multilinear map, Π is nonincreasing for $\mathrm{rank}_{\otimes}, \mathrm{rank}_{\boxplus}$, as in (2.14), (2.18).

There is a useful orthogonal projection Π_A associated with any tensor $A \in \mathbb{R}^{d_1 \times d_2 \times d_3}$. Let U_1, U_2, U_3 be the supporting subspaces of A so that $A \in U_1 \otimes U_2 \otimes U_3$, and $\dim(U_i) = r_i(A)$ for $i = 1, 2, 3$. Define

$$\Pi_A = (\pi_1(A), \pi_2(A), \pi_3(A)) = (\pi_{U_1}, \pi_{U_2}, \pi_{U_3}).$$

PROPOSITION 2.4. $\Pi_A(A) = A$.

Proof. A belongs to $U_1 \otimes U_2 \otimes U_3$, which is fixed by Π_A. ∎

PROPOSITION 2.5. *The function $A \mapsto \Pi_A$ is continuous over subsets of $\mathbb{R}^{d_1 \times d_2 \times d_3}$ on which $\mathrm{rank}_{\boxplus}(A)$ is constant.*

Proof. We show, for example, that $\pi_1 = \pi_1(A)$ depends continuously on A. For any $A \in \mathbb{R}^{d_1 \times d_2 \times d_3}$, select $r = r_1(A)$ index pairs (j, k) such that the vectors $A_{\bullet jk}$ are linearly independent. For any B near A, assemble the marked vectors as a matrix

$X = X(B) \in \mathbb{R}^{d_i \times r}$. Then $\pi_1 = X(X^\top X)^{-1}X^\top =: P(B)$ by a well-known formula in linear algebra. The function $P(B)$ is defined and continuous as long as the r selected vectors remain independent, which is true on a neighborhood of A. Finally, the orthogonal projection defined by $P(B)$ maps onto the span of the r selected vectors. Thus, if $r_1(B) = r$, then $P(B) = \pi_1(B)$. ∎

It is clear that the results of this section apply to tensor spaces of all orders.

3. The algebra of tensor rank. We will state and prove a few basic results about the outer-product rank.

PROPOSITION 3.1. *Let $A \in \mathbb{R}^{c_1 \times \cdots \times c_k} \subset \mathbb{R}^{d_1 \times \cdots \times d_k}$. The rank of A regarded as a tensor in $\mathbb{R}^{c_1 \times \cdots \times c_k}$ is the same as the rank of A regarded as a tensor in $\mathbb{R}^{d_1 \times \cdots \times d_k}$.*

Proof. For each i the identity on $\mathbb{R}^{c_i}$ factors as a pair of maps $\mathbb{R}^{c_i} \overset{\iota_i}{\hookrightarrow} \mathbb{R}^{d_i} \overset{\pi_i}{\twoheadrightarrow} \mathbb{R}^{c_i}$, where ι_i is the canonical inclusion and π is the projection map given by deleting the last $d_i - c_i$ coordinates. Applying (2.14) twice, we have

$$\begin{aligned}\operatorname{rank}_\otimes(A) \geq \operatorname{rank}_\otimes((\iota_1, \dots, \iota_k) \cdot A) &\geq \operatorname{rank}_\otimes((\pi_1, \dots, \pi_k) \cdot (\iota_1, \dots, \iota_k) \cdot A) \\ &= \operatorname{rank}_\otimes((\pi_1\iota_1, \dots, \pi_k\iota_k) \cdot A) \\ &= \operatorname{rank}_\otimes(A),\end{aligned}$$

so $A \in \mathbb{R}^{c_1 \times \cdots \times c_k}$ and its image $(\iota_1, \dots, \iota_k) \cdot A \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ must have equal tensor ranks. ∎

COROLLARY 3.2. *Suppose $A \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ and $\operatorname{rank}_\boxplus(A) \leq (c_1, \dots, c_k)$. Then $\operatorname{rank}_\otimes(A) = \operatorname{rank}_\otimes(B)$ for an equivalent tensor $B \in \mathbb{R}^{c_1 \times \cdots \times c_k}$.*

The next corollary asserts that tensor rank is consistent under a different scenario: when order-k tensors are regarded as order-l tensors for $l > k$ by taking the tensor product with a nonzero monomial term.

COROLLARY 3.3. *Let $A \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ be an order-k tensor and $\mathbf{u}_{k+1} \in \mathbb{R}^{d_{k+1}}, \dots, \mathbf{u}_{k+\ell} \in \mathbb{R}^{d_{k+\ell}}$ be nonzero vectors. Then*

$$\operatorname{rank}_\otimes(A) = \operatorname{rank}_\otimes(A \otimes \mathbf{u}_{k+1} \otimes \cdots \otimes \mathbf{u}_{k+\ell}).$$

Proof. Let $c_{k+1} = \cdots = c_{k+l} = 1$ and apply Proposition 3.1 to $A \in \mathbb{R}^{d_1 \times \cdots \times d_k} = \mathbb{R}^{d_1 \times \cdots \times d_k \times c_{k+1} \times \cdots \times c_{k+\ell}} \hookrightarrow \mathbb{R}^{d_1 \times \cdots \times d_k \times d_{k+1} \times \cdots \times d_{k+\ell}}$. Note that the image of the inclusion is $A \otimes \mathbf{e}_1^{(k+1)} \otimes \cdots \otimes \mathbf{e}_1^{(k+\ell)}$, where $\mathbf{e}_1^{(i)} = (1, 0, \dots, 0)^\top \in \mathbb{R}^{d_i}$. So we have

$$\operatorname{rank}_\otimes(A \otimes \mathbf{e}_1^{(k+1)} \otimes \cdots \otimes \mathbf{e}_1^{(k+\ell)}) = \operatorname{rank}_\otimes(A).$$

The general case for arbitrary nonzero $\mathbf{u}_i \in \mathbb{R}^{d_i}$ follows from applying to $A \otimes \mathbf{e}_1^{(k+1)} \otimes \cdots \otimes \mathbf{e}_1^{(k+\ell)}$ a multilinear multiplication $(I_{d_1}, \dots, I_{d_k}, L_1, \dots, L_\ell) \in \mathrm{GL}_{d_1,\dots,d_{k+\ell}}(\mathbb{R})$, where I_d is the $d \times d$ identity matrix and L_i is a nonsingular matrix with $L_i\mathbf{e}_i = \mathbf{u}_i$. It then follows from Lemma 2.3 that

$$\begin{aligned}&\operatorname{rank}_\otimes(A \otimes \mathbf{u}_{k+1} \otimes \cdots \otimes \mathbf{u}_{k+\ell}) \\ &\qquad = \operatorname{rank}_\otimes[(I_{d_1}, \dots, I_{d_k}, L_1, \dots, L_\ell) \cdot (A \otimes \mathbf{e}_1^{(k+1)} \otimes \cdots \otimes \mathbf{e}_1^{(k+\ell)})] \\ &\qquad = \operatorname{rank}_\otimes(A \otimes \mathbf{e}_1^{(k+1)} \otimes \cdots \otimes \mathbf{e}_1^{(k+\ell)}).\end{aligned}$$ ∎

Let $E = \mathbf{u}_{k+1} \otimes \mathbf{u}_{k+2} \otimes \cdots \otimes \mathbf{u}_{k+\ell} \in \mathbb{R}^{d_{k+1} \times \cdots \times d_{k+\ell}}$. So $\operatorname{rank}_\otimes(E) = 1$ and Corollary 3.3 says that $\operatorname{rank}_\otimes(A \otimes E) = \operatorname{rank}_\otimes(A) \operatorname{rank}_\otimes(E)$. Note that this last relation does not generalize. If $\operatorname{rank}_\otimes(A) > 1$ and $\operatorname{rank}_\otimes(B) > 1$, then it is true that

$$\operatorname{rank}_\otimes(A \otimes B) \leq \operatorname{rank}_\otimes(A) \operatorname{rank}_\otimes(B),$$

since one can multiply decompositions of A, B term by term to obtain a decomposition of $A \otimes B$, but it can happen (cf. [12]) that

$$\operatorname{rank}_{\otimes}(A \otimes B) < \operatorname{rank}_{\otimes}(A) \operatorname{rank}_{\otimes}(B).$$

The corresponding statement for direct sum is still an open problem for tensors of order 3 or higher. It has been conjectured by Strassen [70] that

$$\operatorname{rank}_{\otimes}(A \oplus B) \stackrel{?}{=} \operatorname{rank}_{\otimes}(A) + \operatorname{rank}_{\otimes}(B) \tag{3.1}$$

for all order-k tensors A and B. However JáJá and Takche [43] have shown that for the special case when A and B are of order 3 and at least one of them is a matrix pencil (i.e., a tensor of size $p \times q \times 2$, $p \times 2 \times q$, or $2 \times p \times q$ that may be regarded as a pair of $p \times q$ matrices), then the direct sum conjecture holds.

THEOREM 3.4 (JáJá–Takche [43]). *Let $A \in \mathbb{R}^{c_1 \times c_2 \times c_3}$ and $B \in \mathbb{R}^{d_1 \times d_2 \times d_3}$. If $2 \in \{c_1, c_2, c_3, d_1, d_2, d_3\}$, then*

$$\operatorname{rank}_{\otimes}(A \oplus B) = \operatorname{rank}_{\otimes}(A) + \operatorname{rank}_{\otimes}(B).$$

It is not hard to define tensors of arbitrarily high rank so long as we have sufficiently many linearly independent vectors in every factor.

LEMMA 3.5. *For $\ell = 1, \dots, k$, let $\mathbf{x}_1^{(\ell)}, \dots, \mathbf{x}_r^{(\ell)} \in \mathbb{R}^{d_i}$ be linearly independent. Then the tensor defined by*

$$A := \sum_{j=1}^{r} \mathbf{x}_j^{(1)} \otimes \mathbf{x}_j^{(2)} \otimes \cdots \otimes \mathbf{x}_j^{(k)} \in \mathbb{R}^{d_1 \times d_2 \times \cdots \times d_k}$$

has $\operatorname{rank}_{\otimes}(A) = r$.

Proof. Note that $\operatorname{rank}_{\boxplus}(A) = (r, r, \dots, r)$. By (2.17), we get

$$\operatorname{rank}_{\otimes}(A) \geq \max\{r_i(A) \mid i = 1, \dots, k\} = r.$$

On the other hand, it is clear that $\operatorname{rank}_{\otimes}(A) \leq r$. ∎

Thus, in $\mathbb{R}^{d_1 \times \cdots \times d_k}$, it is easy to write down tensors of any rank r in the range $0 \leq r \leq \min\{d_1, \dots, d_k\}$. For matrices, this exhausts all possibilities; the rank of $A \in \mathbb{R}^{d_1 \times d_2}$ is at most $\min\{d_1, d_2\}$. In contrast, for $k \geq 3$, there will always be tensors in $\mathbb{R}^{d_1 \times d_k}$ that have rank exceeding $\min\{d_1, \dots, d_k\}$. We will see this in Theorem 4.10.

4. The topology of tensor rank. Let $A = [\![a_{i_1 \cdots i_k}]\!] \in \mathbb{R}^{d_1 \times \cdots \times d_k}$. The *Frobenius norm* of A and its associated inner product are defined by

$$\|A\|_F^2 := \sum\nolimits_{i_1, \dots, i_k = 1}^{d_1, \dots, d_k} |a_{i_1 \cdots i_k}|^2, \quad \langle A, B \rangle_F := \sum\nolimits_{i_1, \dots, i_k = 1}^{d_1, \dots, d_k} a_{i_1 \cdots i_k} b_{i_1 \cdots i_k}.$$

Note that for a decomposable tensor, the Frobenius norm satisfies

$$\|\mathbf{u} \otimes \mathbf{v} \otimes \cdots \otimes \mathbf{z}\|_F = \|\mathbf{u}\|_2 \|\mathbf{v}\|_2 \cdots \|\mathbf{z}\|_2, \tag{4.1}$$

where $\|\cdot\|_2$ denotes the l^2-norm of a vector, and more generally

$$\|A \otimes B\|_F = \|A\|_F \|B\|_F \tag{4.2}$$

for arbitrary tensors A, B. Another important property which follows from (2.13) and (4.1) is orthogonal invariance:

$$\|(L_1, \dots, L_k) \cdot A\|_F = \|A\|_F \tag{4.3}$$

whenever $(L_1, \dots, L_k) \in \mathrm{O}_{d_1,\dots,d_k}(\mathbb{R})$. There are of course many other natural choices of norms on tensor product spaces [25, 36]. The important thing to note is that $\mathbb{R}^{d_1 \times \cdots \times d_k}$ being finite dimensional, all these norms will induce the same topology.

We define the following (topological) subspaces of $\mathbb{R}^{d_1 \times \cdots \times d_k}$:

$$\begin{aligned} \mathcal{S}_r(d_1, \dots, d_k) &= \left\{ A \in \mathbb{R}^{d_1 \times \cdots \times d_k} \mid \operatorname{rank}_\otimes(A) \le r \right\}, \\ \overline{\mathcal{S}}_r(d_1, \dots, d_k) &= \text{closure of } \mathcal{S}_r(d_1, \dots, d_k) \subset \mathbb{R}^{d_1 \times \cdots \times d_k}. \end{aligned}$$

Clearly the only reason to define $\overline{\mathcal{S}}_r$ is the sad fact that $\mathcal{S}_r$ is not necessarily (or even usually) closed—the theme of this paper. See section 4.2.

We occasionally refer to elements of $\mathcal{S}_r$ as "rank-r tensors." This is slightly inaccurate, since lower-rank tensors are included, but convenient. However, the direct assertions "A has rank r" and "$\operatorname{rank}(A) = r$" are always meant in the precise sense. The same remarks apply to "border rank," which is defined in section 5.5. We refer to elements of $\overline{\mathcal{S}}_r$ as "border-rank-r tensors" and describe them as being "rank-r-approximable."

Theorem 5.1 asserts that $\overline{\mathcal{S}}_2(d_1, d_2, d_3) \subset \mathcal{S}_3(d_1, d_2, d_3)$ for all d_1, d_2, d_3, and that the exceptional tensors $\overline{\mathcal{S}_2}(d_1, d_2, d_3) \setminus \mathcal{S}_2(d_1, d_2, d_3)$ are all of a particular form.

4.1. Upper semicontinuity. Discrete-valued rank functions on spaces of matrices or tensors cannot usefully be continuous, because they would then be constant and would not have any classifying power. As a sort of compromise, matrix rank is well known to be an upper semicontinuous function; if $\operatorname{rank}(A) = r$, then $\operatorname{rank}(B) \ge r$ for all matrices B in a neighborhood of A. This is not true for the outer-product rank of tensors (as we will see in section 4.2). There are several equivalent ways of formulating this assertion.

PROPOSITION 4.1. *Let $r \ge 2$ and $k \ge 3$. Given the norm-topology on $\mathbb{R}^{d_1 \times \cdots \times d_k}$, the following statements are equivalent:*

(a) *The set $\mathcal{S}_r(d_1, \dots, d_k) := \{A \in \mathbb{R}^{d_1 \times \cdots \times d_k} \mid \operatorname{rank}_\otimes(A) \le r\}$ is not closed.*

(b) *There exists a sequence $A_n \in \mathbb{R}^{d_1 \times \cdots \times d_k}$, $\operatorname{rank}_\otimes(A_n) \le r$, $n \in \mathbb{N}$, converging to $B \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ with $\operatorname{rank}_\otimes(B) > r$.*

(c) *There exists $B \in \mathbb{R}^{d_1 \times \cdots \times d_k}$, $\operatorname{rank}_\otimes(B) > r$, that may be approximated arbitrarily closely by tensors of strictly lower rank, i.e.,*

$$\inf\{\|B - A\| \mid \operatorname{rank}_\otimes(A) \le r\} = 0.$$

(d) *There exists $C \in \mathbb{R}^{d_1 \times \cdots \times d_k}$, $\operatorname{rank}_\otimes(C) > r$, that does not have a best rank-r approximation; i.e.,*

$$\inf\{\|C - A\| \mid \operatorname{rank}_\otimes(A) \le r\}$$

is not attained (by any A with $\operatorname{rank}_\otimes(A) \le r$).

Proof. It is obvious that (a) $\Rightarrow$ (b) $\Rightarrow$ (c) $\Rightarrow$ (d). To complete the chain, we just need to show that (d) $\Rightarrow$ (a). Suppose $\mathcal{S} := \mathcal{S}_r(d_1, \dots, d_k)$ is closed. Since the closed ball of radius $\|C\|$ centered at C, $\{A \in \mathbb{R}^{d_1 \times \cdots \times d_k} \mid \|C - A\| \le \|C\|\}$, intersects

$\mathcal{S}$ nontrivially (e.g., 0 is in both sets), their intersection $\mathcal{T} = \{A \in \mathbb{R}^{d_1 \times \cdots \times d_k} \mid \operatorname{rank}_\otimes(A) \leq r, \|C - A\| \leq \|C\|\}$ is a nonempty compact set. Now observe that

$$\delta := \inf\{\|C - A\| \mid A \in \mathcal{S}\} = \inf\{\|C - A\| \mid A \in \mathcal{T}\}$$

since any $A' \in \mathcal{S} \backslash \mathcal{T}$ must have $\|C - A'\| > \|C\|$ while we know that $\delta \leq \|C\|$. By the compactness of $\mathcal{T}$, there exists $A_* \in \mathcal{T}$ such that $\|C - A_*\| = \delta$. So the required infimum is attained by $A_* \in \mathcal{T} \subset \mathcal{S}$. ∎

We caution the reader that there exist tensors of rank $> r$ that do not have a best rank-r approximation but *cannot* be approximated arbitrarily closely by rank-r tensors, i.e., $\inf\{\|C - A\| \mid \operatorname{rank}_\otimes(A) \leq r\} > 0$. In other words, statement (d) applies to a strictly larger class of tensors than statement (c) (cf. section 8). The tensors in statement (d) are sometimes called "degenerate" in the psychometrics and chemometrics literature (e.g., [49, 51, 63, 68, 69]), but we prefer to avoid this term since it is inconsistent (and often at odds) with common usage in Mathematics. For example, in Table 7.1, the tensors in the orbit classes of D_2, D_2', D_2'' are all degenerate, but statement (d) does not apply to them; on the other hand, the tensors in the orbit class of G_3 are nondegenerate, but Theorem 8.1 tells us that they are all of the form in statement (d).

We begin by getting three well-behaved cases out of the way. The proofs shed light on what can go wrong in all the other cases.

PROPOSITION 4.2. *For all $d_1, \ldots, d_k$, we have $\overline{\mathcal{S}}_1(d_1, \ldots, d_k) = \mathcal{S}_1(d_1, \ldots, d_k)$.*

Proof. Suppose $A_n \to A$, where $\operatorname{rank}_\otimes(A_n) \leq 1$. We can write

$$A_n = \lambda_n \mathbf{u}_{1,n} \otimes \mathbf{u}_{2,n} \otimes \cdots \otimes \mathbf{u}_{k,n},$$

where $\lambda_n = \|A_n\|$ and the vectors $\mathbf{u}_{i,n} \in \mathbb{R}^{d_i}$ have unit norm. Certainly $\lambda_n = \|A_n\| \to \|A\| =: \lambda$. Moreover, since the unit sphere in $\mathbb{R}^{d_i}$ is compact, each sequence $\mathbf{u}_{i,n}$ has a convergent subsequence, with limit $\mathbf{u}_i$, say. It follows that there is a subsequence of A_n which converges to $\lambda \mathbf{u}_1 \otimes \cdots \otimes \mathbf{u}_k$. This must equal A, and it has rank at most 1. ∎

PROPOSITION 4.3. *For all r and d_1, d_2, we have $\overline{\mathcal{S}}_r(d_1, d_2) = \mathcal{S}_r(d_1, d_2)$. In other words, matrix rank is upper-semicontinuous.*

Proof. Suppose $A_n \to A$, where $\operatorname{rank}(A_n) \leq r$, so we can write

$$A_n = \lambda_{1,n} \mathbf{u}_{1,n} \otimes \mathbf{v}_{1,n} + \cdots + \lambda_{r,n} \mathbf{u}_{r,n} \otimes \mathbf{v}_{r,n}.$$

Convergence of the sequence A_n does not imply convergence of the individual terms $\lambda_{i,n}$, $\mathbf{u}_{i,n}$, $\mathbf{v}_{i,n}$, even in a subsequence. However, if we take the singular value decomposition, then the $\mathbf{u}_{i,n}$ and $\mathbf{v}_{i,n}$ are unit vectors and the $\lambda_{i,n}$ satisfy

$$\lambda_{1,n}^2 + \cdots + \lambda_{r,n}^2 = \|A_n\|.$$

Since $\|A_n\| \to \|A\|$ this implies that the $\lambda_{i,n}$ are uniformly bounded. Thus we can find a subsequence with convergence $\lambda_{i,n} \to \lambda_i$, $\mathbf{u}_{i,n} \to \mathbf{u}_i$, $\mathbf{v}_{i,n} \to \mathbf{v}_i$ for all i. Then

$$A = \lambda_1 \mathbf{u}_1 \otimes \mathbf{v}_1 + \cdots + \lambda_r \mathbf{u}_r \otimes \mathbf{v}_r,$$

which has rank at most r. ∎

PROPOSITION 4.4. *The multilinear rank function $\operatorname{rank}_\boxplus(A) = (r_1(A), \ldots, r_k(A))$ is upper-semicontinuous.*

Proof. Each r_i is the rank of a matrix obtained by rearranging the entries of A, and is therefore upper-semicontinuous in A by Proposition 4.3. ∎

COROLLARY 4.5. *Every tensor has a best rank-1 approximation. Every matrix has a best rank-r approximation. Every order-k tensor has a best approximation with* $\operatorname{rank}_{\boxplus} \leq (r_1, \dots, r_k)$ *for any specified* $(r_1, \dots, r_k)$.

Proof. These statements follow from Propositions 4.2, 4.3, and 4.4, together with the implication (d)⇒(a) from Proposition 4.1. ∎

4.2. Tensor rank is not upper-semicontinuous. Here is the simplest example of the failure of outer-product rank to be upper-semicontinuous. This is the first example of a more general construction which we discuss in section 4.7. A formula similar to (4.4) appeared as Exercise 62 in section 4.6.4 of Knuth's *The Art of Computer Programming* [48] (the original source is [8]). Other examples have appeared in [7] (the earliest known to us) and [63], as well as in unpublished work of Kruskal.

PROPOSITION 4.6. *Let* $\mathbf{x}_1, \mathbf{y}_1 \in \mathbb{R}^{d_1}$, $\mathbf{x}_2, \mathbf{y}_2 \in \mathbb{R}^{d_2}$, *and* $\mathbf{x}_3, \mathbf{y}_3 \in \mathbb{R}^{d_3}$ *be vectors such that each pair* $\mathbf{x}_i, \mathbf{y}_i$ *is linearly independent. Then the tensor*

$$A := \mathbf{x}_1 \otimes \mathbf{x}_2 \otimes \mathbf{y}_3 + \mathbf{x}_1 \otimes \mathbf{y}_2 \otimes \mathbf{x}_3 + \mathbf{y}_1 \otimes \mathbf{x}_2 \otimes \mathbf{x}_3 \in \mathbb{R}^{d_1 \times d_2 \times d_3} \tag{4.4}$$

has rank 3 *but can be approximated arbitrarily closely by tensors of rank* 2. *In particular, A does not have a best rank-*2 *approximation.*

Proof. For each $n \in \mathbb{N}$, define

$$A_n := n\left(\mathbf{x}_1 + \frac{1}{n}\mathbf{y}_1\right) \otimes \left(\mathbf{x}_2 + \frac{1}{n}\mathbf{y}_2\right) \otimes \left(\mathbf{x}_3 + \frac{1}{n}\mathbf{y}_3\right) - n\mathbf{x}_1 \otimes \mathbf{x}_2 \otimes \mathbf{x}_3. \tag{4.5}$$

Clearly, $\operatorname{rank}_{\otimes}(A_n) \leq 2$, and since, as $n \to \infty$,

$$\|A_n - A\|_F \leq \frac{1}{n}\|\mathbf{y}_1 \otimes \mathbf{y}_2 \otimes \mathbf{x}_3 + \mathbf{y}_1 \otimes \mathbf{x}_2 \otimes \mathbf{y}_3 + \mathbf{x}_1 \otimes \mathbf{y}_2 \otimes \mathbf{y}_3\|_F + \frac{1}{n^2}\|\mathbf{y}_1 \otimes \mathbf{y}_2 \otimes \mathbf{y}_3\|_F \to 0,$$

we see that A is approximated arbitrary closely by tensors A_n.

It remains to establish that $\operatorname{rank}_{\otimes}(A) = 3$. From the three-term format of A, we deduce only that $\operatorname{rank}_{\otimes}(A) \leq 3$. A clean proof that $\operatorname{rank}_{\otimes}(A) > 2$ is included in the proof of Theorem 7.1, but this depends on the properties of the polynomial Δ defined in section 5.3. A more direct argument is given in the next lemma. ∎

LEMMA 4.7. *Let* $\mathbf{x}_1, \mathbf{y}_1 \in \mathbb{R}^{d_1}$, $\mathbf{x}_2, \mathbf{y}_2 \in \mathbb{R}^{d_2}$, $\mathbf{x}_3, \mathbf{y}_3 \in \mathbb{R}^{d_3}$, *and*

$$A = \mathbf{x}_1 \otimes \mathbf{x}_2 \otimes \mathbf{y}_3 + \mathbf{x}_1 \otimes \mathbf{y}_2 \otimes \mathbf{x}_3 + \mathbf{y}_1 \otimes \mathbf{x}_2 \otimes \mathbf{x}_3.$$

Then $\operatorname{rank}_{\otimes}(A) = 3$ *if and only if* $\mathbf{x}_i, \mathbf{y}_i$ *are linearly independent for* $i = 1, 2, 3$.

Proof. Only two distinct vectors are involved in each factor of the tensor product, so $\operatorname{rank}_{\boxplus}(A) \leq (2, 2, 2)$ and we can work in $\mathbb{R}^{2\times 2\times 2}$ (Corollary 3.2). More strongly, if any of the pairs $\{\mathbf{x}_i, \mathbf{y}_i\}$ is linearly dependent, then A is GL-equivalent to a tensor in $\mathbb{R}^{1\times 2\times 2}$, $\mathbb{R}^{2\times 1\times 2}$, or $\mathbb{R}^{2\times 2\times 1}$. These spaces are isomorphic to $\mathbb{R}^{2\times 2}$, so the maximum possible rank of A is 2.

Conversely, suppose each pair $\{\mathbf{x}_i, \mathbf{y}_i\}$ is linearly independent. We may as well assume that

$$A = \left[\begin{array}{cc|cc} 0 & 1 & 1 & 0 \\ 1 & 0 & 0 & 0 \end{array}\right] \tag{4.6}$$

since we can transform A to that form using a multilinear transformation (L_1, L_2, L_3), where $L_i(\mathbf{x}_i) = \mathbf{e}_1$ and $L_i(\mathbf{y}_i) = \mathbf{e}_2$ for $i = 1, 2, 3$.

Suppose, for a contradiction, that $\operatorname{rank}_\otimes(A) \leq 2$; then we can write

$$A = \mathbf{u}_1 \otimes \mathbf{u}_2 \otimes \mathbf{u}_3 + \mathbf{v}_1 \otimes \mathbf{v}_2 \otimes \mathbf{v}_3 \tag{4.7}$$

for some $\mathbf{u}_i, \mathbf{v}_i \in \mathbb{R}^{d_i}$.

Claim 1. The vectors $\mathbf{u}_1, \mathbf{v}_1$ are independent. If they are not, then let $\varphi : \mathbb{R}^2 \to \mathbb{R}$ be a nonzero linear map such that $\varphi(\mathbf{u}_1) = \varphi(\mathbf{v}_1) = 0$. Using the expressions in (4.7) and (4.6), we find that

$$\mathbf{0} = (\varphi, I, I) \cdot A = \begin{bmatrix} \varphi(\mathbf{e}_2) & \varphi(\mathbf{e}_1) \\ \varphi(\mathbf{e}_1) & 0 \end{bmatrix}$$

in $\mathbb{R}^{1\times 2\times 2} \cong \mathbb{R}^{2\times 2}$, which is a contradiction because $\varphi(\mathbf{e}_1)$ and $\varphi(\mathbf{e}_2)$ cannot both be zero.

Claim 2. The vectors $\mathbf{u}_1, \mathbf{e}_1$ are dependent. Indeed, let $\varphi_u : \mathbb{R}^2 \to \mathbb{R}$ be a linear map whose kernel is spanned by $\mathbf{u}_1$. Then

$$\varphi_u(\mathbf{v}_1)(\mathbf{v}_2 \otimes \mathbf{v}_3) = (\varphi_u, I, I) \cdot A = \begin{bmatrix} \varphi_u(\mathbf{e}_2) & \varphi_u(\mathbf{e}_1) \\ \varphi_u(\mathbf{e}_1) & 0 \end{bmatrix}$$

in $\mathbb{R}^{1\times 2\times 2} \cong \mathbb{R}^{2\times 2}$. The left-hand side (LHS) has rank at most 1, which implies on the right-hand side (RHS) that $\varphi_u(\mathbf{e}_1) = 0$, and hence $\mathbf{e}_1 \in \operatorname{span}\{\mathbf{u}_1\}$.

Claim 3. The vectors $\mathbf{v}_1, \mathbf{e}_1$ are dependent. Indeed, let $\varphi_v : \mathbb{R}^2 \to \mathbb{R}$ be a linear map whose kernel is spanned by $\mathbf{v}_1$. Then

$$\varphi_v(\mathbf{u}_1)(\mathbf{u}_2 \otimes \mathbf{u}_3) = (\varphi_v, I, I) \cdot A = \begin{bmatrix} \varphi_v(\mathbf{e}_2) & \varphi_v(\mathbf{e}_1) \\ \varphi_v(\mathbf{e}_1) & 0 \end{bmatrix}$$

in $\mathbb{R}^{1\times 2\times 2} \cong \mathbb{R}^{2\times 2}$. The LHS has rank at most 1, which implies on the RHS that $\varphi_v(\mathbf{e}_1) = 0$, and hence $\mathbf{e}_1 \in \operatorname{span}\{\mathbf{v}_1\}$.

Taken together, the three claims are inconsistent. This is the desired contradiction. Thus $\operatorname{rank}_\otimes(A) > 2$, and therefore $\operatorname{rank}_\otimes(A) = 3$. ∎

Remark. Note that if we take $d_1 = d_2 = d_3 = 2$, then (4.4) is an example of a tensor whose outer-product rank exceeds $\min\{d_1, d_2, d_3\}$.

4.3. Diverging coefficients. What goes wrong in the example of Proposition 4.6? Why do the rank-2 decompositions of the A_n fail to converge to a rank-2 decomposition of A? We can attempt to mimic the proofs of Propositions 4.2 and 4.3 by seeking convergent subsequences for the rank-2 decompositions of the A_n. We fail because we cannot simultaneously keep all the variables bounded. For example, in the decomposition

$$A_n = n\left(\mathbf{x}_1 + \frac{1}{n}\mathbf{y}_1\right) \otimes \left(\mathbf{x}_2 + \frac{1}{n}\mathbf{y}_2\right) \otimes \left(\mathbf{x}_3 + \frac{1}{n}\mathbf{y}_3\right) - n\mathbf{x}_1 \otimes \mathbf{x}_2 \otimes \mathbf{x}_3$$

the vector terms converge but the coefficients $\lambda_1 = \lambda_2 = n$ tend to infinity. In spite of this, the sequence A_n itself remains bounded.

In fact, rank-jumping always occurs like this (see also [49]).

PROPOSITION 4.8. *Suppose* $A_n \to A$, *where* $\operatorname{rank}_\otimes(A) \geq r+1$ *and* $\operatorname{rank}_\otimes(A_n) \leq r$ *for all* n. *If we write*

$$A_n = \lambda_{1,n}\mathbf{u}_{1,n} \otimes \mathbf{v}_{1,n} \otimes \mathbf{w}_{1,n} + \cdots + \lambda_{r,n}\mathbf{u}_{r,n} \otimes \mathbf{v}_{r,n} \otimes \mathbf{w}_{r,n},$$

where the vectors $\mathbf{u}_{i,n}$, $\mathbf{v}_{i,n}$, $\mathbf{w}_{i,n}$ *are unit vectors, then* $\max_i\{|\lambda_{i,n}|\} \to \infty$ *as* $n \to \infty$. *Moreover, at least two of the coefficient sequences* $\{\lambda_{i,n} \mid n = 1, 2, \dots\}$ *are unbounded.*

Proof. If the sequence $\max_i\{|\lambda_{i,n}|\}$ does not diverge to ∞, then it has a bounded subsequence. In this subsequence, the coefficients and vectors are all bounded, so we can pass to a further subsequence in which each of the coefficient sequences and vector sequences is convergent:

$$\lambda_{i,n} \to \lambda_i, \quad \mathbf{u}_{i,n} \to \mathbf{u}_i, \quad \mathbf{v}_{i,n} \to \mathbf{v}_i, \quad \mathbf{w}_{i,n} \to \mathbf{w}_i.$$

It follows that $A = \lambda_1\mathbf{u}_1 \otimes \mathbf{v}_1 \otimes \mathbf{w}_1 + \cdots + \lambda_r\mathbf{u}_r \otimes \mathbf{v}_r \otimes \mathbf{w}_r$, so it has rank at most r, which is a contradiction.

Thus $\max_i\{|\lambda_{i,n}|\}$ diverges to ∞. It follows that at least one of the coefficient sequences has a divergent subsequence. If there were only one such coefficient sequence, all the others being bounded, then (on the subsequence) A_n would be dominated by this term and consequently $\|A_n\|$ would be unbounded. Since $A_n \to A$, this cannot happen. Thus there are at least two unbounded coefficient sequences. ∎

For a *minimal* rank-jumping example, *all* the coefficients must diverge to ∞.

PROPOSITION 4.9. *Suppose* $A_n \to A$, *where* $\operatorname{rank}_\otimes(A) = r+s$ *and* $\operatorname{rank}_\otimes(A_n) \le r$ *for all* n. *If we write*

$$A_n = \lambda_{1,n}\mathbf{u}_{1,n} \otimes \mathbf{v}_{1,n} \otimes \mathbf{w}_{1,n} + \cdots + \lambda_{r,n}\mathbf{u}_{r,n} \otimes \mathbf{v}_{r,n} \otimes \mathbf{w}_{r,n},$$

where the vectors $\mathbf{u}_{i,n}$, $\mathbf{v}_{i,n}$, $\mathbf{w}_{i,n}$ *are unit vectors, then there are two possibilities: either* (i) *all of the sequences* $|\lambda_{i,n}|$ *diverge to* ∞ *as* $n \to \infty$ *or* (ii) *in the same tensor space there exists* $B_n \to B$, *where* $\operatorname{rank}_\otimes(B) \ge r' + s$ *and* $\operatorname{rank}_\otimes(B_n) \le r'$ *for all* n, *for some* $r' < r$.

Proof. Suppose one of the coefficient sequences, say, $|\lambda_{i,n}|$, fails to diverge as $n \to \infty$; so it has a bounded subsequence. In a further subsequence, the ith term $R_n = \lambda_{i,n}\mathbf{u}_{i,n} \otimes \mathbf{v}_{i,n} \otimes \mathbf{w}_{i,n}$ converges to a tensor R of rank (at most) 1. Writing $B_n = A_n - R_n$, we find that $B_n \to B = A - R$ on this subsequence, with $\operatorname{rank}_\otimes(B_n) \le r-1$. Moreover, $r+s \le \operatorname{rank}_\otimes(A) \le \operatorname{rank}_\otimes(B) + \operatorname{rank}_\otimes(R)$, so $\operatorname{rank}_\otimes(B) \ge (r-1)+s$. ∎

Remark. Clearly the arguments in Propositions 4.8 and 4.9 apply to tensors of all orders, not just order 3. We also note that the vectors ($\mathbf{u}_{i,n}$, etc.) need not be unit vectors; they just have to be uniformly bounded.

One interpretation of Proposition 4.8 is that if one attempts to minimize

$$\|A - \lambda_1\mathbf{u}_1 \otimes \mathbf{v}_1 \otimes \mathbf{w}_1 - \cdots - \lambda_r\mathbf{u}_r \otimes \mathbf{v}_r \otimes \mathbf{w}_r\|$$

for a tensor A which does not have a best rank-r approximation, then (at least some of) the coefficients λ_i become unbounded. This phenomenon of diverging summands has been observed in practical applications of multilinear models in psychometrics and chemometrics and is commonly referred to in those circles as "CANDECOMP/PARAFAC degeneracy" or "diverging CANDECOMP/PARAFAC components" [49, 51, 63, 68, 69]. More precisely, these are called "k-factor degeneracies" when there are k diverging summands whose sum stays bounded. 2- and 3-factor degeneracies were exhibited in [63] and 4- and 5-factor degeneracies were exhibited in [68]. There are uninteresting (see section 4.4) and interesting (see section 4.7) ways of generating k-factor degeneracies for arbitrarily large k.

4.4. Higher orders, higher ranks, arbitrary norms. We will now show that the rank-jumping phenomenon—that is, the failure of $\mathcal{S}_r(d_1, \dots, d_k)$ to be closed—is independent of the choice of norms and can be extended to arbitrary order. The norm

independence is a trivial consequence of a basic fact in functional analysis: all norms on finite dimensional vector spaces are equivalent; in particular, any norm will induce the same unique topology on a finite dimensional vector space.

THEOREM 4.10. *For $k \geq 3$ and $d_1, \dots, d_k \geq 2$, the problem of determining a best rank-r approximation for an order-k tensor in $\mathbb{R}^{d_1 \times \cdots \times d_k}$ has no solution in general for any $r = 2, \dots, \min\{d_1, \dots, d_k\}$. In particular, there exists $A \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ with*

$$\operatorname{rank}_{\otimes}(A) = r + 1$$

that has no best rank-r approximation. The result is independent of the choice of norms.

Proof. We begin by assuming $k = 3$.

Higher rank. Let $2 \leq r \leq \min\{d_1, d_2, d_3\}$. By Lemma 3.5, we can construct a tensor $B \in \mathbb{R}^{(d_1-2)\times(d_2-2)\times(d_3-2)}$ with rank $r-2$. By Proposition 4.6, we can construct a convergent sequence of tensors $C_n \to C$ in $\mathbb{R}^{2\times 2\times 2}$ with $\operatorname{rank}_{\otimes}(C_n) \leq 2$ and $\operatorname{rank}_{\otimes}(C) = 3$. Let $A_n = B \oplus C_n \in \mathbb{R}^{d_1 \times d_2 \times d_3}$. Then $A_n \to A := B \oplus C$ and $\operatorname{rank}_{\otimes}(A_n) \leq \operatorname{rank}_{\otimes}(B) + \operatorname{rank}_{\otimes}(C_n) \leq r$. The result of JáJá–Takche (Theorem 3.4) implies that $\operatorname{rank}_{\otimes}(A) = \operatorname{rank}_{\otimes}(B) + \operatorname{rank}_{\otimes}(C) = r + 1$.

Arbitrary order. Let $\mathbf{u}_4 \in \mathbb{R}^{d_4}, \dots, \mathbf{u}_k \in \mathbb{R}^{d_k}$ be unit vectors and set

$$\tilde{A}_n := A_n \otimes \mathbf{u}_4 \otimes \cdots \otimes \mathbf{u}_k, \qquad \tilde{A} := A \otimes \mathbf{u}_4 \otimes \cdots \otimes \mathbf{u}_k.$$

By (4.2),

$$\|\tilde{A}_n - \tilde{A}\|_F = \|A_n - A\| = \|B \oplus C_n - B \oplus C\| = \|C_n - C\| \to 0 \text{ as } n \to \infty.$$

Moreover, Corollary 3.3 ensures that $\operatorname{rank}_{\otimes}(\tilde{A}) = r + 1$ and $\operatorname{rank}_{\otimes}(\tilde{A}_n) \leq r$.

Norm independence. Whether the sequence $\tilde{A}_n$ converges to $\tilde{A}$ is entirely dependent on the norm-induced topology on $\mathbb{R}^{d_1 \times \cdots \times d_k}$. Since it has a unique topology induced by any of its equivalent norms as a finite dimensional vector space, the convergence is independent of the choice of norms. ∎

We note that the proof above exhibits an order-k tensor, namely, $\tilde{A}$, that has rank strictly larger than $\min\{d_1, \dots, d_k\}$.

4.5. Tensor rank can leap an arbitrarily large gap. How can we construct a sequence of tensors of rank r that converge to a tensor of rank $r+2$? An easy trick is to take the direct sum of two sequences of rank-2 tensors of the form shown in (4.5). The resulting sequence converges to a limiting tensor that is the direct sum of two rank-3 tensors, each of the form shown in (4.4). To show that the limiting tensor has rank 6 (and does not have some miraculous lower-rank decomposition), we once again turn to the theorem of JáJá–Takche, which contains just enough of the direct sum conjecture (3.1) for our purposes.

PROPOSITION 4.11. *Given any $s \in \mathbb{N}$ and $r \geq 2s$, there exists a sequence of order-3 tensors B_n such that $\operatorname{rank}_{\otimes}(B_n) \leq r$ and $\lim_{n\to\infty} B_n = B$ with $\operatorname{rank}_{\otimes}(B) = r + s$.*

Proof. Let $d = r - 2s$. By Lemma 3.5, there exists a rank-d tensor $C \in \mathbb{R}^{d\times d\times d}$. Let $A_n \to A$ be a convergent sequence in $\mathbb{R}^{2\times 2\times 2}$ with $\operatorname{rank}_{\otimes}(A) \leq 2$ and $\operatorname{rank}_{\otimes}(A) = 3$. Define

$$B_n = C \oplus A_n \oplus \cdots \oplus A_n, \quad B = C \oplus A \oplus \cdots \oplus A,$$

where there are s terms A_n and A. Then $B_n \to B$, and $\operatorname{rank}_{\otimes}(B_n) \leq r - 2s + 2s = r$. By applying the JáJá–Takche theorem sequentially s times, once for each summand A, we deduce that $\operatorname{rank}_{\otimes}(B) = r - 2s + 3s = r + s$. ∎

As usual the construction can be extended to order-k tensors by taking an outer product with a suitable number of nonzero vectors in the new factors.

COROLLARY 4.12. *Given any $s \geq 1$, $r \geq 2$, and $k \geq 3$, with $r \geq 2s$, there exists $A \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ such that $\operatorname{rank}_{\otimes}(A) = r + s$ and A has no best rank-r approximation.*

Proof. This follows from Proposition 4.11 and the previous remark. ∎

4.6. Brègman divergences and other continuous measures of proximity. In data analytic applications, one frequently encounters low-rank approximations with respect to "distances" that are more general than norms. Such a "distance" may not even be a metric, an example being the Brègman divergence [10, 26] (sometimes also known as the Brègman distance). The definition here is based on the definition given in [26]. Recall first that if $S \subset \mathbb{R}^n$, the *relative interior* of S is simply the interior of S considered as a subset of its affine hull and is denoted by $\operatorname{ri}(S)$.

DEFINITION 4.13. *Let $S \subseteq \mathbb{R}^{d_1 \times \cdots \times d_k}$ be a convex set. Let $\varphi : S \to \mathbb{R}$ be a lower-semicontinuous, convex function that is continuously differentiable and strictly convex in $\operatorname{ri}(S)$. Let φ have the property that for any sequence $\{C_n\} \subset \operatorname{ri}(S)$ that converges to $C \in S \setminus \operatorname{ri}(S)$, we have*

$$\lim_{n\to\infty} \|\nabla\varphi(C_n)\| = +\infty.$$

The Brègman divergence $D_\varphi : S \times \operatorname{ri}(S) \to \mathbb{R}$ *is defined by*

$$D_\varphi(A, B) = \varphi(A) - \varphi(B) - \langle \nabla\varphi(B), A - B\rangle.$$

It is natural to ask if the analogous problem APPROX(A, r) for Brègman divergence will always have a solution. Note that a Brègman divergence, unlike a metric, is not necessarily symmetric in its two arguments, and thus there are *two* possible problems:

$$\operatorname{argmin}_{\operatorname{rank}_{\otimes}(B)\leq r} D_\varphi(A, B) \qquad \text{and} \qquad \operatorname{argmin}_{\operatorname{rank}_{\otimes}(B)\leq r} D_\varphi(B, A).$$

As the following proposition shows, the answer is no in both cases.

PROPOSITION 4.14. *Let D_φ be a Brègman divergence. Let A and A_n be defined as in* (4.4) *and* (4.5)*, respectively. Then*

$$\lim_{n\to\infty} D_\varphi(A, A_n) = 0 = \lim_{n\to\infty} D_\varphi(A_n, A).$$

Proof. The Brègman divergence is jointly continuous in both arguments with respect to the norm topology, and $A_n \to A$ in the norm, so $D_\varphi(A, A_n) \to D_\varphi(A, A) = 0$ and $D_\varphi(A_n, A) \to D_\varphi(A, A) = 0$. ∎

Proposition 4.14 extends trivially to any other measure of nearness that is continuous with respect to the norm topology in at least one argument.

4.7. Difference quotients. We thank Landsberg [53] for the insight that the expression in (4.4) is best regarded as a derivative. Indeed, if

$$f(t) = (\mathbf{x} + t\mathbf{y})^{\otimes 3} = (\mathbf{x} + t\mathbf{y}) \otimes (\mathbf{x} + t\mathbf{y}) \otimes (\mathbf{x} + t\mathbf{y}),$$

then

$$\left.\frac{df}{dt}\right|_{t=0} = \mathbf{y} \otimes \mathbf{x} \otimes \mathbf{x} + \mathbf{x} \otimes \mathbf{y} \otimes \mathbf{x} + \mathbf{x} \otimes \mathbf{x} \otimes \mathbf{y}$$

by the Leibniz rule. On the other hand,

$$\left.\frac{df}{dt}\right|_{t=0} = \lim_{t\to 0}\left[\frac{(\mathbf{x}+t\mathbf{y})\otimes(\mathbf{x}+t\mathbf{y})\otimes(\mathbf{x}+t\mathbf{y}) - \mathbf{x}\otimes\mathbf{x}\otimes\mathbf{x}}{t}\right],$$

and the difference quotient on the RHS has rank 2. The expression in (4.5) can be obtained from this by taking $t = 1/N$.

We can extend Landsberg's idea to more general partial differential operators. It will be helpful to use the degree-k Veronese map [37], which is $V_k(\mathbf{x}) = \mathbf{x}^{\otimes k} = \mathbf{x}\otimes\cdots\otimes\mathbf{x}$ (a k-fold product). Then, for example, the six-term symmetric tensor

$$\mathbf{x}\otimes\mathbf{y}\otimes\mathbf{z} + \mathbf{x}\otimes\mathbf{z}\otimes\mathbf{y} + \mathbf{y}\otimes\mathbf{z}\otimes\mathbf{x} + \mathbf{y}\otimes\mathbf{x}\otimes\mathbf{z} + \mathbf{z}\otimes\mathbf{x}\otimes\mathbf{y} + \mathbf{x}\otimes\mathbf{y}\otimes\mathbf{x}$$

can be written as a partial derivative

$$\left.\frac{\partial^2}{\partial s\,\partial t}\right|_{s=t=0} (\mathbf{x}+s\mathbf{y}+t\mathbf{z})^{\otimes 3},$$

which is a limit of a four-term difference quotient:

$$\lim_{s,t\to 0}\left[\frac{V_3(\mathbf{x}+s\mathbf{y}+t\mathbf{z}) - V_3(\mathbf{x}+s\mathbf{y}) - V_3(\mathbf{x}+t\mathbf{z}) + V_3(\mathbf{x})}{st}\right].$$

This example lies naturally in $\mathbb{R}^{3\times 3\times 3}$, taking $\mathbf{x},\mathbf{y},\mathbf{z}$ to be linearly independent. Another example, in $\mathbb{R}^{2\times 2\times 2\times 2}$, is the six-term symmetric order-4 tensor

$$\begin{aligned}\mathbf{x}\otimes\mathbf{x}\otimes\mathbf{y}\otimes\mathbf{y} + \mathbf{x}\otimes\mathbf{y}\otimes\mathbf{x}\otimes\mathbf{y} + \mathbf{x}\otimes\mathbf{y}\otimes\mathbf{y}\otimes\mathbf{x}\\ + \mathbf{y}\otimes\mathbf{x}\otimes\mathbf{x}\otimes\mathbf{y} + \mathbf{y}\otimes\mathbf{x}\otimes\mathbf{y}\otimes\mathbf{x} + \mathbf{y}\otimes\mathbf{y}\otimes\mathbf{x}\otimes\mathbf{x}.\end{aligned}$$

This can be written as the second-order derivative

$$\left.\frac{\partial^2}{\partial t^2}\right|_{t=0} \frac{(\mathbf{x}+t\mathbf{y})^{\otimes 4}}{2!},$$

which is a limit of a three-term difference quotient:

$$\lim_{t\to 0}\left[\frac{V_4(\mathbf{x}+2t\mathbf{y}) - 2V_4(\mathbf{x}+t\mathbf{y}) + V_4(\mathbf{x})}{2!\,t^2}\right].$$

We call these examples *symmetric Leibniz tensors* for the differential operators $\partial^2/\partial s\,\partial t$ and $\partial^2/\partial t^2$, of orders 3 and 4, respectively. More generally, given positive integers k and $a_1,\dots,a_j$ with $a_1+\cdots+a_j = a \le k$, the symmetric tensor

$$L_k(a_1,\dots,a_j) := \sum_{\text{Sym}} \mathbf{x}^{\otimes(k-a)}\otimes\mathbf{y}_1^{\otimes a_1}\otimes\cdots\otimes\mathbf{y}_j^{\otimes a_j}$$

can be written as a partial derivative,

$$\left.\frac{\partial^a}{\partial {t_1}^{a_1}\dots\partial {t_j}^{a_j}}\right|_{t_1=\dots=t_j=0} \frac{V_k(\mathbf{x}+t_1\mathbf{y}_1+\cdots+t_j\mathbf{y}_j)}{(a_1!)\cdots(a_j!)},$$

which is a limit of a difference quotient with $(a_1+1)\cdots(a_j+1)$ terms. On the other hand, the number of terms in the limit $L_k(a_1,\dots,a_j)$ is given by a multinomial coefficient, and that is usually much bigger.

This construction gives us a ready supply of candidates for rank-jumping. However, we do not know—even for the two explicit six-term examples above — whether the limiting tensors actually have the ranks suggested by their formulas. We can show that $\operatorname{rank}_\otimes(L_k(1)) = k$ for all k and over any field, generalizing Lemma 4.7. Beyond that it is not clear to us what is likely to be true. The optimistic conjecture is

$$\operatorname{rank}_\otimes(L_k(a_1,\dots,a_j)) \stackrel{?}{=} \binom{k}{k-a,a_1,\dots,a_j} = \frac{k!}{(k-a)!\,a_i!\cdots a_j!}. \tag{4.8}$$

Comon et al. [18] show that the *symmetric* rank of $L_k(1)$ over the complex numbers is k, so that is another possible context in which (4.8) may be true.

5. Characterizing the limit points of order-3 rank-2 tensors. If an order-3 tensor can be expressed as a limit of a sequence of rank-2 tensors but itself has rank greater than 2, then we show in this section that it takes a particular form. This kind of result may make it possible to overcome the ill-posedness of $\text{APPROX}(A, r)$ by defining weak solutions.

THEOREM 5.1. *Let $d_1, d_2, d_3 \geq 2$. Let $A_n \in \mathbb{R}^{d_1\times d_2\times d_3}$ be a sequence of tensors with $\operatorname{rank}_\otimes(A_n) \leq 2$ and*

$$\lim_{n\to\infty} A_n = A,$$

where the limit is taken in any norm topology. If the limiting tensor A has rank higher than 2, then $\operatorname{rank}_\otimes(A)$ must be exactly 3, and there exist pairs of linearly independent vectors $\mathbf{x}_1, \mathbf{y}_1 \in \mathbb{R}^{d_1}$, $\mathbf{x}_2, \mathbf{y}_2 \in \mathbb{R}^{d_2}$, $\mathbf{x}_3, \mathbf{y}_3 \in \mathbb{R}^{d_3}$ such that

$$A = \mathbf{x}_1\otimes\mathbf{x}_2\otimes\mathbf{y}_3 + \mathbf{x}_1\otimes\mathbf{y}_2\otimes\mathbf{x}_3 + \mathbf{y}_1\otimes\mathbf{x}_2\otimes\mathbf{x}_3. \tag{5.1}$$

The proof of this theorem will occupy the next few subsections.

5.1. Reduction. Our first step is to show that we can limit our attention to the particular tensor space $\mathbb{R}^{2\times2\times2}$. Here the orthogonal group action is important. Recall that the actions of $\mathrm{O}_{d_1,\dots,d_k}(\mathbb{R})$ and $\mathrm{GL}_{d_1,\dots,d_k}(\mathbb{R})$ on $\mathbb{R}^{d_1\times\cdots\times d_k}$ are continuous and carry decomposable tensors to decomposable tensors. It follows that the subspaces $\mathcal{S}_r$ and $\overline{\mathcal{S}}_r$ are preserved. The next theorem provides a general mechanism for passing to a tensor subspace.

THEOREM 5.2. *Let $r_i = \min(r, d_i)$ for all i. The restricted maps*

$$\mathrm{O}_{d_1,\dots,d_k}(\mathbb{R}) \times \mathcal{S}_r(r_1,\dots,r_k) \to \mathcal{S}_r(d_1,\dots,d_k),$$
$$\mathrm{O}_{d_1,\dots,d_k}(\mathbb{R}) \times \overline{\mathcal{S}}_r(r_1,\dots,r_k) \to \overline{\mathcal{S}}_r(d_1,\dots,d_k)$$

given by $((L_1,\dots,L_k), A) \mapsto (L_1,\dots,L_k)\cdot A$ are both surjective.

In other words, every rank-r tensor in $\mathbb{R}^{d_1\times\cdots\times d_k}$ is equivalent by an orthogonal transformation to a rank-r tensor in the smaller space $\mathbb{R}^{r_1\times\cdots\times r_k}$. Similarly every rank-$r$-approximable tensor in $\mathbb{R}^{d_1\times\cdots\times d_k}$ is equivalent to a rank-r-approximable tensor in $\mathbb{R}^{r_1\times\cdots\times r_k}$.

Proof. If $A \in \mathcal{S}_r(d_1,\dots,d_k)$ is any rank-r tensor then we can write $A = \sum_{j=1}^r \mathbf{x}_1^j \otimes \cdots \otimes \mathbf{x}_k^j$ for vectors $\mathbf{x}_i^j \in \mathbb{R}^{d_i}$. For each i, the vectors $\mathbf{x}_i^1,\dots,\mathbf{x}_i^r$ span a subspace $V_i \subset \mathbb{R}^{d_i}$ of rank at most r_i. Choose $L_i \in \mathrm{O}_{d_i}(\mathbb{R})$ so that $L_i(\mathbb{R}^{d_i}) \supseteq V_i$. Let $B = (L_1^{-1},\dots,L_k^{-1})\cdot A$. Then $A = (L_1,\dots,L_k)\cdot B$ and $B \in \mathcal{S}_r(d_1,\dots,d_k)$. This argument shows that the first of the maps is surjective.

Now let $A \in \overline{\mathcal{S}}_r(d_1, \dots, d_k)$ be any rank-r-approximable tensor. Let $(A^{(n)})_{n=1}^{\infty}$ be any sequence of rank-r tensors converging to A. For each n, by the preceding result, we can find $B^{(n)} \in \overline{\mathcal{S}}_r(d_1, \dots, d_k)$ and $(L_1^{(n)}, \dots, L_k^{(n)}) \in \mathrm{O}_{d_1,\dots,d_k}(\mathbb{R})$ with $(L_1^{(n)}, \dots, L_k^{(n)}) \cdot B^{(n)} = A^{(n)}$. Since $\mathrm{O}_{d_1,\dots,d_k}(\mathbb{R})$ is compact, there is a convergent subsequence $(L_1^{(n_j)}, \dots, L_k^{(n_j)}) \to (L_1, \dots, L_k)$. Let $B = (L_1, \dots, L_k)^{-1} \cdot A$. Then $A = (L_1, \dots, L_k) \cdot B$; and $B^{(n_j)} = (L_1^{(n_j)}, \dots, L_k^{(n_j)})^{-1} \cdot A^{(n_j)} \to (L_1, \dots, L_k)^{-1} \cdot A = B$, so $B \in \overline{\mathcal{S}}_r(d_1, \dots, d_k)$. Thus the second map is also surjective. ∎

COROLLARY 5.3. *If Theorem* 5.1 *is true for the tensor space* $\mathbb{R}^{2\times 2\times 2}$ *then it is true in general.*

Proof. The general case is $V_1 \otimes V_2 \otimes V_3 \cong \mathbb{R}^{d_1 \times d_2 \times d_3}$. Suppose $A \in \overline{\mathcal{S}}_2(d_1, d_2, d_3)$ and $\operatorname{rank}_{\otimes}(A) \geq 3$. By Theorem 5.2, there exists $(L_1, L_2, L_3) \in \mathrm{O}_{d_1,d_2,d_3}(\mathbb{R})$ and $B \in \overline{\mathcal{S}}_2(2, 2, 2)$ with $(L_1, L_2, L_3) \cdot B = A$. Moreover, $\operatorname{rank}_{\otimes}(B) = \operatorname{rank}_{\otimes}(A) \geq 3$ in $\mathbb{R}^{l\times m\times n}$ and hence $\operatorname{rank}_{\otimes}(B) \geq 3$ in $\mathbb{R}^{2\times 2\times 2}$ by Proposition 3.1. Since the theorem is assumed true for $\mathbb{R}^{2\times 2\times 2}$ and B satisfies the hypotheses, it can be written in the specified form in terms of vectors $\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3$ and $\mathbf{y}_1, \mathbf{y}_2, \mathbf{y}_3$. It follows that A takes the same form with respect to the vectors $L_1\mathbf{x}_1, L_2\mathbf{x}_2, L_3\mathbf{x}_3$ and $L_1\mathbf{y}_1, L_2\mathbf{y}_2, L_3\mathbf{y}_3$. ∎

5.2. Tensors of rank 1 and 2. We establish two simple facts for later use.

PROPOSITION 5.4. *If* $A \in \mathbb{R}^{d_1\times\cdots\times d_k}$ *has rank* 1, *then we can write* $A = (L_1, \dots, L_k) \cdot B$, *where* $(L_1, \dots, L_k) \in \mathrm{GL}_{d_1,\dots,d_k}(\mathbb{R})$ *and* $B = \mathbf{e}_1 \otimes \cdots \otimes \mathbf{e}_k$.

Proof. Write $A = \mathbf{x}_1 \otimes \cdots \otimes \mathbf{x}_k$ and choose the L_i so that $L_i(\mathbf{e}_i) = \mathbf{x}_i$. ∎

PROPOSITION 5.5. *Assume* $d_i \geq 2$ *for all* i. *If* $A \in \mathbb{R}^{d_1\times\cdots\times d_k}$ *has rank* 2, *then we can write* $A = (L_1, \dots, L_k) \cdot B$, *where* $(L_1, \dots, L_k) \in \mathrm{GL}_{d_1,\dots,d_k}(\mathbb{R})$ *and* $B \in \mathbb{R}^{2\times\cdots\times 2}$ *is of the form* $B = \mathbf{e}_1 \otimes \cdots \otimes \mathbf{e}_1 + \mathbf{f}_1 \otimes \cdots \otimes \mathbf{f}_k$. *Here* $\mathbf{e}_1$ *denotes the standard basis vector* $(1, 0)^\top$; *each* $\mathbf{f}_i$ *is equal either to* $\mathbf{e}_1$ *or to* $\mathbf{e}_2 = (0, 1)^\top$; *and at least two of the* $\mathbf{f}_i$ *are equal to* $\mathbf{e}_2$.

Proof. We can write $A = \mathbf{x}_1 \otimes \cdots \otimes \mathbf{x}_k + \mathbf{y}_1 \otimes \cdots \otimes \mathbf{y}_k$. Since $\operatorname{rank}_{\otimes}(A) = 2$ all of the $\mathbf{x}_i$ and $\mathbf{y}_i$ must be nonzero. We claim that $\mathbf{y}_i, \mathbf{x}_i$ must be linearly independent for at least two different indices i. Otherwise, suppose $\mathbf{y}_i = \lambda_i\mathbf{x}_i$ for $k - 1$ different indices, say, $i = 1, \dots, k - 1$. It would follow that

$$A = \mathbf{x}_1 \otimes \cdots \otimes \mathbf{x}_{k-1} \otimes \ (\mathbf{x}_k + (\lambda_1 \cdots \lambda_{k-1})\mathbf{y}_k),$$

contradicting $\operatorname{rank}_{\otimes}(A) = 2$.

For each i choose $L_i : \mathbb{R}^2 \to \mathbb{R}^{d_i}$ such that $L_i\mathbf{e}_1 = \mathbf{x}_i$ and such that $L_i\mathbf{e}_2 = \mathbf{y}_i$ if $\mathbf{y}_i$ is linearly independent of $\mathbf{x}_i$; otherwise $L_i\mathbf{e}_2$ may be arbitrary. It is easy to check that $(L_1, \dots, L_k)^{-1} \cdot A = \mathbf{e}_1 \otimes \cdots \otimes \mathbf{e}_1 + \lambda\mathbf{f}_1 \otimes \cdots \otimes \mathbf{f}_k$, where the $\mathbf{f}_i$ are as specified in the theorem, and λ is the product of the λ_i over those indices where $\mathbf{y}_i = \lambda_i\mathbf{x}_i$. This is almost in the correct form. To get rid of the λ, replace $L_i\mathbf{e}_2 = \mathbf{y}_i$ with $L_i\mathbf{e}_2 = \lambda\mathbf{y}_i$ at one of the indices i for which $\mathbf{x}_i, \mathbf{y}_i$ are linearly independent. This completes the construction. ∎

5.3. The discriminant polynomial Δ. The structure of tensors in $\mathbb{R}^{2\times 2\times 2}$ is largely governed by a quartic polynomial Δ which we define and discuss here. This same polynomial was discovered by Cayley in 1845 [15]. More generally, Δ is the $2 \times 2 \times 2$ special case of an object called the *hyperdeterminant* revived in its modern form by Gelfand, Kapranov, and Zelevinsky [30, 31]. We give an elementary treatment of the properties we need.

As in our discussion in section 2.1, we identify a tensor $\mathbf{A} \in \mathbb{R}^2 \otimes \mathbb{R}^2 \otimes \mathbb{R}^2$ with the array $A \in \mathbb{R}^{2\times 2\times 2}$ of its eight coefficients with respect to the standard basis

$\{\mathbf{e}_i \otimes \mathbf{e}_j \otimes \mathbf{e}_k : i, j, k = 1, 2\}$. Pictorially, we can represent it as a pair of side-by-side 2×2 slabs:

$$\mathbf{A} = \sum_{i=1}^{2}\sum_{j=1}^{2}\sum_{k=1}^{2} a_{ijk}\mathbf{e}_i \otimes \mathbf{e}_j \otimes \mathbf{e}_k = \left[\begin{array}{cc|cc} a_{111} & a_{112} & a_{211} & a_{212} \\ a_{121} & a_{122} & a_{221} & a_{222} \end{array}\right] = A.$$

The general strategy is to find ways of simplifying the representation of A by applying transformations in $\mathrm{GL}_{2,2,2}(\mathbb{R}) = \mathrm{GL}_2(\mathbb{R}) \times \mathrm{GL}_2(\mathbb{R}) \times \mathrm{GL}_2(\mathbb{R})$. This group is generated by the following operations: decomposable row operations applied to both slabs simultaneously; decomposable column operations applied to both slabs simultaneously; decomposable slab operations (for example, adding a multiple of one slab to the other).

Slab operations on a tensor $A = [A_1 \,|\, A_2]$ generate new 2×2 slabs of the form $S = \lambda_1 A_1 + \lambda_2 A_2$. One can check that

$$\det(S) = \lambda_1^2 \det(A_1) + \lambda_1\lambda_2 \frac{\det(A_1 + A_2) - \det(A_1 - A_2)}{2} + \lambda_2^2 \det(A_2). \tag{5.2}$$

We define Δ to be the discriminant of this quadratic polynomial:

$$\Delta([A_1 \,|\, A_2]) = \left[\frac{\det(A_1 + A_2) - \det(A_1 - A_2)}{2}\right]^2 - 4\det(A_1)\det(A_2). \tag{5.3}$$

Explicitly, if $A = [\![a_{ijk}]\!]_{i,j,k=1,2} \in \mathbb{R}^{2\times2\times2}$, then

$$\begin{aligned}\Delta(A) = {} & (a_{111}^2a_{222}^2 + a_{112}^2a_{221}^2 + a_{121}^2a_{212}^2 + a_{122}^2a_{211}^2) \\ & - 2(a_{111}a_{112}a_{221}a_{222} + a_{111}a_{121}a_{212}a_{222} + a_{111}a_{122}a_{211}a_{222} \\ & + a_{112}a_{121}a_{212}a_{221} + a_{112}a_{122}a_{221}a_{211} + a_{121}a_{122}a_{212}a_{211}) \\ & + 4(a_{111}a_{122}a_{212}a_{221} + a_{112}a_{121}a_{211}a_{222}).\end{aligned}$$

PROPOSITION 5.6. *Let $A \in \mathbb{R}^{2\times2\times2}$, let A' be obtained from A by permuting the three factors in the tensor product, and let $(L_1, L_2, L_3) \in \mathrm{GL}_{2,2,2}(\mathbb{R})$. Then $\Delta(A') = \Delta(A)$ and $\Delta((L_1, L_2, L_3) \cdot A) = \det(L_1)^2 \det(L_2)^2 \det(L_3)^2 \Delta(A)$.*

Proof. To show that Δ is invariant under all permutations of the factors of $\mathbb{R}^{2\times2\times2}$, it is enough to check invariance in the cases of two distinct transpositions. It is clear from (5.3) that Δ is invariant under the transposition of the second and third factors, since this amounts to replacing A_1, A_2 with their transposes $A_1^\top, A_2^\top$. To show that Δ is invariant under transposition of the first and third factors, write $A = [\mathbf{u}_{11}, \mathbf{u}_{12} \,|\, \mathbf{u}_{21}, \mathbf{u}_{22}]$, where the $\mathbf{u}_{ij}$ are column vectors. One can verify that

$$\begin{aligned}\Delta(A) = {} & \det[\mathbf{u}_{11}, \mathbf{u}_{22}]^2 + \det[\mathbf{u}_{21}, \mathbf{u}_{12}]^2 \\ & - 2\det[\mathbf{u}_{11}, \mathbf{u}_{12}]\det[\mathbf{u}_{21}, \mathbf{u}_{22}] - 2\det[\mathbf{u}_{11}, \mathbf{u}_{21}]\det[\mathbf{u}_{12}, \mathbf{u}_{22}],\end{aligned}$$

which has the desired symmetry.

In view of the permutation invariance of Δ, it is enough to verify the second claim in the case $(L_1, L_2, L_3) = (I, L_2, I)$. Then $(L_1, L_2, L_3) \cdot A = [L_2A_1 \,|\, L_2A_2]$ and an extra factor $\det(L_2)^2$ appears in all terms of (5.3), exactly as required. ∎

COROLLARY 5.7. *The sign of Δ is invariant under the action of $\mathrm{GL}_{2,2,2}(\mathbb{R})$.*

COROLLARY 5.8. *The value of Δ is invariant under the action of $\mathrm{O}_{2,2,2}(\mathbb{R})$.*

Using the properties of Δ, we can easily prove, in a slightly different way, a result due originally to Kruskal (unpublished work) and ten Berge [73].

PROPOSITION 5.9. *If* $\Delta(A) > 0$ *then* $\operatorname{rank}_\otimes(A) \leq 2$.

PROPOSITION 5.10. *If* $\operatorname{rank}_\otimes(A) \leq 2$ *then* $\Delta(A) \geq 0$.

Proof of Proposition 5.9. If the discriminant $\Delta(A)$ is positive then the homogeneous quadratic equation (5.2) has two linearly independent root pairs $(\lambda_{11}, \lambda_{12})$ and $(\lambda_{21}, \lambda_{22})$. It follows that we can use slab operations to transform $[A_1 \mid A_2] \to [B_1 \mid B_2]$, where $B_i = \lambda_{i1}A_1 + \lambda_{i2}A_2$. By construction $\det(B_i) = 0$, so we can write $B_i = \mathbf{f}_i \otimes \mathbf{g}_i$ for some $\mathbf{f}_i, \mathbf{g}_i \in \mathbb{R}^2$ (possibly zero). It follows that $[B_1 \mid B_2] = \mathbf{e}_1 \otimes \mathbf{f}_1 \otimes \mathbf{g}_1 + \mathbf{e}_2 \otimes \mathbf{f}_2 \otimes \mathbf{g}_2$; so $\operatorname{rank}_\otimes(A) = \operatorname{rank}_\otimes([B_1 \mid B_2]) \leq 2$. ∎

Proof of Proposition 5.10. It is easy to check that $\Delta(A) = 0$ if $\operatorname{rank}_\otimes(A) \leq 1$, since we can write $A = (L_1, L_2, L_3) \cdot (\mathbf{e}_1 \otimes \mathbf{e}_1 \otimes \mathbf{e}_1)$ or else $A = 0$.

It remains to be shown that $\Delta(A)$ is not negative when $\operatorname{rank}_\otimes(A) = 2$. Proposition 5.5 implies that A can be transformed by an element of $\mathrm{GL}_{2,2,2}(\mathbb{R})$ (and a permutation of factors, if necessary) into one of the following tensors:

$$I_1 = \left[\begin{array}{cc|cc} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{array}\right] \quad \text{or} \quad I_2 = \left[\begin{array}{cc|cc} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{array}\right].$$

Since $\Delta(I_1) = 1$ and $\Delta(I_2) = 0$, it follows that $\Delta(A) \geq 0$. ∎

Kruskal and also ten Berge deserve complete credit for discovering the above result. In fact, the hyperdeterminant for $2 \times 2 \times 2$ tensor Δ is known by the name *Kruskal polynomial* in the psychometrics community [73]. Our goal is not so much to provide alternative proofs for Propositions 5.9 and 5.10 but to include them so that our proof of Theorem 5.1 can be self-contained. We are now ready to give that proof, thereby characterizing all limit points of order-3 rank-2 tensors.

Proof of Theorem 5.1. Note that the theorem is stated for order-3 tensors of any size $d_1 \times d_2 \times d_3$. We begin with the case $A \in \mathbb{R}^{2\times 2\times 2}$. Suppose $A \in \overline{\mathcal{S}}_2(2,2,2) \setminus \mathcal{S}_2(2,2,2)$. Then we claim that $\Delta(A) = 0$. Indeed, since $A \notin \mathcal{S}_2$, Proposition 5.9 implies that $\Delta(A) \leq 0$. On the other hand, since $A \in \overline{\mathcal{S}}_2$, it follows from Proposition 5.10 and the continuity of Δ that $\Delta(A) \geq 0$.

Since $\Delta(A) = 0$, the homogeneous quadratic equation (5.2) has a nontrivial root pair (λ_1, λ_2). It follows that A can be transformed by slab operations into the form $[A_i \mid S]$, where $S = \lambda_1 A_1 + \lambda_2 A_2$ and $i = 1$ or 2. By construction $\det(S) = 0$, but $S \neq 0$ for otherwise $\operatorname{rank}_\otimes(A) = \operatorname{rank}(A_i) \leq 2$. Hence $\operatorname{rank}(S) = 1$ and by a further transformation we can reduce A to the form

$$B = \left[\begin{array}{cc|cc} p & q & 1 & 0 \\ r & s & 0 & 0 \end{array}\right].$$

In fact we may assume $p = 0$ (the operation "subtract p times the second slab from the first slab" will achieve this), and moreover $s^2 = \Delta(B) = 0$. Both q and r must be nonzero; otherwise $\operatorname{rank}_\otimes(A) = \operatorname{rank}_\otimes(B) \leq 2$. If we rescale the bottom rows by $1/r$ and the right-hand columns by $1/q$ we are finally reduced to

$$B' = \left[\begin{array}{cc|cc} 0 & 1 & 1 & 0 \\ 1 & 0 & 0 & 0 \end{array}\right] = \mathbf{e}_2 \otimes \mathbf{e}_1 \otimes \mathbf{e}_1 + \mathbf{e}_1 \otimes \mathbf{e}_2 \otimes \mathbf{e}_1 + \mathbf{e}_1 \otimes \mathbf{e}_1 \otimes \mathbf{e}_2.$$

By reversing all the row, column, and slab operations we can obtain a transformation $(L_1, L_2, L_3) \in \mathrm{GL}_{2,2,2}(\mathbb{R})$ such that $A = (L_1, L_2, L_3) \cdot B'$. Then A can be written in the required form, with $\mathbf{x}_i = L_i\mathbf{e}_1$, $\mathbf{y}_i = L_i\mathbf{e}_2$ for $i = 1, 2, 3$.

This completes the proof of Theorem 5.1 in the case of the tensor space $\mathbb{R}^{2\times 2\times 2}$. By Corollary 5.3 this implies the theorem in general. ∎

5.4. Ill-posedness and ill-conditioning of the best rank-r approximation problem. Recall that a problem is called *well-posed* if a solution exists, is unique, and is stable (i.e., depends continuously on the input data). If one or more of these three criteria are not satisfied, the problem[3] is called *ill-posed*.

From sections 4 and 8, we see that tensors will often fail to have a best rank-r approximation. In all applications that rely on $\text{APPROX}(A, r)$ or a variant of it as the underlying mathematical model, we should fully expect the ill-posedness of $\text{APPROX}(A, r)$ to pose a serious difficulty. Even if it is known a priori that a tensor A has a best rank-r approximation, we should remember that in applications, the data array $\hat{A}$ available at our disposal is almost always one that is corrupted by noise, i.e., $\hat{A} = A + E$, where E denotes the collective contributions of various errors, limitations in measurements, background noise, rounding off, etc. Clearly there is no guarantee that $\hat{A}$ will also have a best rank-r approximation.

In many situations, one needs only a "good" rank-r approximation rather than the best rank-r approximation. It is tempting to argue, then, that the nonexistence of the best solution does not matter—it is enough to seek an "approximate solution." We discourage this point of view for two main reasons. First, there is a serious conceptual difficulty: if there is no solution, then what is the "approximate solution" an approximation of? Second, even if one disregards this and ploughs ahead to compute an "approximate solution," we argue below that this task is ill-conditioned and the computation is unstable.

For notational simplicity and since there is no loss of generality (cf. Theorem 4.10 and Corollary 4.12), we will use the problem of finding a best rank-2 approximation to a rank-3 tensor to make our point. Let $A \in \mathbb{R}^{d_1 \times d_2 \times d_3}$ be an instance where

$$\operatorname{argmin}_{\mathbf{x}_i, \mathbf{y}_i \in \mathbb{R}^{d_i}} \|A - \mathbf{x}_1 \otimes \mathbf{x}_2 \otimes \mathbf{x}_3 - \mathbf{y}_1 \otimes \mathbf{y}_2 \otimes \mathbf{y}_3\| \tag{5.4}$$

does not have a solution (such examples abound; cf. section 8). If we disregard the fact that a solution does not exist and plug the problem into a computer program,[4] we will still get some sort of "approximate solution" because of the finite-precision error inherent in the computer. What really happens here [77] is that we are effectively solving a problem perturbed by some small $\varepsilon > 0$; the "approximate solution" $\mathbf{x}_i^*(\varepsilon), \mathbf{y}_i^*(\varepsilon) \in \mathbb{R}^{d_i}$ $(i = 1, 2, 3)$ is really a solution to the perturbed problem

$$\begin{aligned} &\|A - \mathbf{x}_1^*(\varepsilon) \otimes \mathbf{x}_2^*(\varepsilon) \otimes \mathbf{x}_3^*(\varepsilon) - \mathbf{y}_1^*(\varepsilon) \otimes \mathbf{y}_2^*(\varepsilon) \otimes \mathbf{y}_3^*(\varepsilon)\| \\ &\qquad = \varepsilon + \inf_{\mathbf{x}_i, \mathbf{y}_i \in \mathbb{R}^{d_i}} \|A - \mathbf{x}_1 \otimes \mathbf{x}_2 \otimes \mathbf{x}_3 - \mathbf{y}_1 \otimes \mathbf{y}_2 \otimes \mathbf{y}_3\|. \end{aligned} \tag{5.5}$$

Since we are attempting to find a solution of (5.4) that does not exist, in exact arithmetic the algorithm will never terminate, but in reality the computer is limited by its finite precision, and so the algorithm terminates at an "approximate solution," which may be viewed as a solution to a perturbed problem (5.5). This process of forcing a solution to an ill-posed problem is almost always guaranteed to be ill-conditioned because of the infamous rule of thumb in numerical analysis [22, 23, 24]:

A well-posed problem near an ill-posed one is ill-conditioned.

[3] Normally, existence is taken for granted, and an ill-posed problem often means one whose solution lacks either uniqueness or stability. In this paper, the ill-posedness is of a more serious kind—the existence of a solution is itself in question.

[4] While there is no known globally convergent algorithm for $\text{APPROX}(A, r)$, we will ignore this difficulty for a moment and assume that the ubiquitous alternating least squares algorithm would yield the required solution.

The root of the ill-conditioning lies in the fact that we are solving the (well-posed but ill-conditioned) problem (5.5) that is a slight perturbation of the ill-posed problem (5.4). The ill-conditioning manifests itself as the phenomenon described in Proposition 4.8, namely,

$$\|\mathbf{x}_1^*(\varepsilon) \otimes \mathbf{x}_2^*(\varepsilon) \otimes \mathbf{x}_3^*(\varepsilon)\| \to \infty \qquad \text{and} \qquad \|\mathbf{y}_1^*(\varepsilon) \otimes \mathbf{y}_2^*(\varepsilon) \otimes \mathbf{y}_3^*(\varepsilon)\| \to \infty$$

as $\varepsilon \to 0$. The ill-conditioning described here was originally observed in numerical experiments by psychometricians and chemometricians, who named the phenomenon "diverging CANDECOMP/PARAFAC components" or "CANDECOMP/PARAFAC degeneracy" [49, 51, 63, 68, 69].

To fix the ill-conditioning, we should first fix the ill-posedness, i.e., find a well-posed problem. This leads us to the subject of the next section.

5.5. Weak solutions. In the study of PDEs [29], there often arise systems of PDEs that have no solutions in the traditional sense. A standard way around this is to define a so-called *weak solution*, which may not be a continuous function or even a function (which is a tad odd since one would expect a *solution* to a PDE to be at least differentiable). Without going into the details, we will just say that weak solution turns out to be an extremely useful concept and is indispensable in modern studies of PDEs. Under the proper context, a weak solution to an ill-posed PDE may be viewed as the limit of *strong* or *classical solutions* to a sequence of well-posed PDEs that are slightly perturbed versions of the ill-posed one in question. Motivated by the PDE analogies, we will define weak solutions to APPROX(A, r).

We let $\mathcal{S}_r(d_1, \dots, d_k) := \{A \in \mathbb{R}^{d_1 \times \cdots \times d_k} \mid \operatorname{rank}_\otimes(A) \le r\}$ and let $\overline{\mathcal{S}}_r(d_1, \dots, d_k)$ denote its closure in the (unique) norm-topology.

DEFINITION 5.11. *An order-k tensor $A \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ has* border rank r *if*

$$A \in \overline{\mathcal{S}}_r(d_1, \dots, d_k) \qquad \textit{and} \qquad A \notin \overline{\mathcal{S}}_{r-1}(d_1, \dots, d_k).$$

This is denoted by $\underline{\operatorname{rank}}_\otimes(A)$. *Note that*

$$\overline{\mathcal{S}}_r(d_1, \dots, d_k) = \{A \in \mathbb{R}^{d_1 \times \cdots \times d_k} \mid \underline{\operatorname{rank}}_\otimes(S) \le r\}.$$

Remark. Clearly $\underline{\operatorname{rank}}_\otimes(A) \le \operatorname{rank}_\otimes(A)$ for any tensor A. Since $\overline{\mathcal{S}}_0 = \mathcal{S}_0$ (trivially) and $\overline{\mathcal{S}}_1 = \mathcal{S}_1$ (by Proposition 4.2), it follows that $\underline{\operatorname{rank}}_\otimes(A) = \operatorname{rank}_\otimes(A)$ whenever $\operatorname{rank}_\otimes(A) \le 2$. Moreover, $\underline{\operatorname{rank}}_\otimes(A) \ge 2$ if $\operatorname{rank}_\otimes(A) \ge 2$.

Our definition differs slightly from the usual definition of border rank in the algebraic computational complexity literature [5, 6, 12, 48, 54], which uses the Zariski topology (and is normally defined for tensors over $\mathbb{C}$).

Let $A \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ with $d_i \ge 2$ and $k \ge 3$. Then the way to ensure that APPROX(A, r), the optimal rank-r approximation problem

$$\operatorname{argmin}_{\operatorname{rank}_\otimes(B) \le r} \|A - B\|, \tag{5.6}$$

always has a meaningful solution for any $A \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ is to instead consider the optimal border-rank-r approximation problem

$$\operatorname{argmin}_{\underline{\operatorname{rank}}_\otimes(B) \le r} \|A - B\|. \tag{5.7}$$

It is an obvious move to propose to fix the ill-posedness of APPROX(A, r) by taking the closure. However, without a characterization of the limit points such a proposal

will at best be academic—it is not enough to simply say that weak solutions are limits of rank-2 tensors without giving an explicit expression (or a number of expressions) for them that may be plugged into the objective function to be minimized.

Theorem 5.1 solves this problem in the order-3 rank-2 case—it gives a complete description of these limit points with an explicit formula and, in turn, a constructive solution to the border-rank approximation problem. In case this is not obvious, we will spell out the implication of Theorem 5.1.

COROLLARY 5.12. *Let* $d_1, d_2, d_3 \geq 2$. *Let* $A \in \mathbb{R}^{d_1 \times d_2 \times d_3}$ *with* $\operatorname{rank}_{\otimes}(A) = 3$. A *is the limit of a sequence* $A_n \in \mathbb{R}^{d_1 \times d_2 \times d_3}$ *with* $\operatorname{rank}_{\otimes}(A_n) \leq 2$ *if and only if*

$$A = \mathbf{y}_1 \otimes \mathbf{x}_2 \otimes \mathbf{x}_3 + \mathbf{x}_1 \otimes \mathbf{y}_2 \otimes \mathbf{x}_3 + \mathbf{x}_1 \otimes \mathbf{x}_2 \otimes \mathbf{y}_3$$

for some $\mathbf{x}_i, \mathbf{y}_i$ *linearly independent vectors in* $\mathbb{R}^{d_i}$, $i = 1, 2, 3$.

This implies that every tensor in $\overline{\mathcal{S}}_2(d_1, \dots, d_k)$ can be written in one of two forms:

$$\mathbf{y}_1 \otimes \mathbf{x}_2 \otimes \mathbf{x}_3 + \mathbf{x}_1 \otimes \mathbf{y}_2 \otimes \mathbf{x}_3 + \mathbf{x}_1 \otimes \mathbf{x}_2 \otimes \mathbf{y}_3 \tag{5.8}$$

or

$$\mathbf{x}_1 \otimes \mathbf{x}_2 \otimes \mathbf{x}_3 + \mathbf{y}_1 \otimes \mathbf{y}_2 \otimes \mathbf{y}_3. \tag{5.9}$$

These expressions may then be used to define the relevant objective function(s) in the minimization of (5.7). As in the case of PDEs, every classical (strong) solution is also a weak solution to APPROX(A, r).

PROPOSITION 5.13. *If* B *is a solution to* (5.6) *then* B *is a solution to* (5.7).

Proof. If $\|A - B\| \leq \|A - B'\|$ for all $B' \in \mathcal{S}_r$, then $\|A - B\| \leq \|A - B'\|$ for all $B' \in \overline{\mathcal{S}}_r$ by continuity. ∎

6. Semialgebraic description of tensor rank. One may wonder whether the result in Propositions 5.9 and 5.10 extends to more general *hyperdeterminants*. We know from [30, 31] that a hyperdeterminant may be uniquely defined (up to a constant scaling) in $\mathbb{R}^{d_1 \times \cdots \times d_k}$ whenever $d_1, \dots, d_k$ satisfy

$$d_i - 1 \leq \sum_{j \neq i} (d_j - 1) \qquad \text{for } i = 1, \dots, k. \tag{6.1}$$

(Note that for matrices, (6.1) translates to $d_1 = d_2$, which may be viewed as one reason why the determinant is defined only for square matrices.) Let $\operatorname{Det}_{d_1,\dots,d_k} : \mathbb{R}^{d_1 \times \cdots \times d_k} \to \mathbb{R}$ be the polynomial function defined by the hyperdeterminant whenever (6.1) is satisfied. Propositions 5.9 and 5.10 tell us that the rank of a tensor is 2 on the set $\{A \mid \operatorname{Det}_{2,2,2}(A) > 0\}$ and 3 on the set $\{A \mid \operatorname{Det}_{2,2,2}(A) < 0\}$. One may start by asking whether the tensor rank in $\mathbb{R}^{d_1 \times \cdots \times d_k}$ is constant-valued on the sets

$$\{A \mid \operatorname{Det}_{d_1,\dots,d_k}(A) < 0\} \qquad \text{and} \qquad \{A \mid \operatorname{Det}_{d_1,\dots,d_k}(A) > 0\}.$$

The answer, as Sturmfels has kindly communicated to us [71], is *no* with explicit counterexamples in cases $2 \times 2 \times 2 \times 2$ and $3 \times 3 \times 3$. We will not reproduce Sturmfels's examples here (one reason is that $\operatorname{Det}_{2,2,2,2}$ already contains close to 3 million monomial terms [35]) but instead refer our readers to his forthcoming paper.

We will prove that although there is no single polynomial Δ that will separate $\mathbb{R}^{d_1 \times \cdots \times d_k}$ into regions of constant rank as in the case of $\mathbb{R}^{2 \times 2 \times 2}$, there is always a finite number of polynomials $\Delta_1, \dots, \Delta_m$ that will achieve this.

Before we state and prove the result, we will introduce a few notions and notations. We will write $\mathbb{R}[X_1, \dots, X_m]$ for the ring of polynomials in m variables $X_1, \dots, X_m$ with real coefficients. Subsequently, we will be considering polynomial functions on tensor spaces and will index our variables in a consistent way (for example, when discussing polynomial functions on $\mathbb{R}^{l\times m\times n}$, the polynomial ring in question will be denoted $\mathbb{R}[X_{111}, X_{112}, \dots X_{lmn}]$). Given $A = [\![a_{ijk}]\!] \in \mathbb{R}^{l\times m\times n}$ and $p(X_{111}, X_{112}, \dots X_{lmn}) \in \mathbb{R}[X_{111}, X_{112}, \dots X_{lmn}]$, $p(A)$ will mean the obvious thing, namely, $p(A) = p(a_{111}, a_{112}, \dots, a_{lmn}) \in \mathbb{R}$.

A *polynomial map* is a function $F : \mathbb{R}^n \to \mathbb{R}^m$, defined for each $\mathbf{a} = [a_1, \dots, a_n]^\top \in \mathbb{R}^n$ by $F(\mathbf{a}) = [f_1(\mathbf{a}), \dots, f_m(\mathbf{a})]^\top$, where $f_i \in \mathbb{R}[X_1, \dots, X_n]$ for all $i = 1, \dots, m$.

A *semialgebraic set* in $\mathbb{R}^n$ is a union of finitely many sets of the form[5]

$$\{\mathbf{a} \in \mathbb{R}^n \mid p(\mathbf{a}) = 0,\ q_1(\mathbf{a}) > 0,\ \dots,\ q_\ell(\mathbf{a}) > 0\},$$

where $\ell \in \mathbb{N}$ and $p, q_1, \dots, q_\ell \in \mathbb{R}[X_1, \dots, X_n]$. Note that we do not exclude the possibility of p or any of the q_i being constant (degree-0) polynomials. For example, if p is the zero polynomial, then the first relation $0 = 0$ is trivially satisfied and the semialgebraic set will be an open set in $\mathbb{R}^n$.

It is easy to see that the class of all semialgebraic sets in $\mathbb{R}^n$ is closed under finite unions, finite intersections, and taking the complement. Moreover, if $\mathcal{S} \subseteq \mathbb{R}^{n+1}$ is a semialgebraic set and $\pi : \mathbb{R}^{n+1} \to \mathbb{R}^n$ is the projection onto the first n coordinates, then $\pi(\mathcal{S})$ is also a semialgebraic set; this seemingly innocuous statement is in fact the Tarski–Seidenberg theorem [65, 72], possibly the most celebrated result about semialgebraic sets. We will restate it in a (somewhat less common) form that better suits our purpose.

THEOREM 6.1 (Tarski–Seidenberg). *If $\mathcal{S} \subseteq \mathbb{R}^n$ is a semialgebraic set and $F : \mathbb{R}^n \to \mathbb{R}^m$ is a polynomial map, then the image $F(\mathcal{S}) \subseteq \mathbb{R}^m$ is also a semialgebraic set.*

These and other results about semialgebraic sets may be found in [19, Chapter 2], which, in addition, is a very readable introduction to semialgebraic geometry.

THEOREM 6.2. *The set $\mathcal{R}_r(d_1, \dots, d_k) := \{A \in \mathbb{R}^{d_1\times\cdots\times d_k} \mid \operatorname{rank}_\otimes(A) = r\}$ is a semialgebraic set.*

Proof. Let $\psi_r : (\mathbb{R}^{d_1} \times \mathbb{R}^{d_1} \times \cdots \times \mathbb{R}^{d_k})^r \to \mathbb{R}^{d_1\times d_2\times\cdots\times d_k}$ be defined by

$$\psi_r(\mathbf{u}_1, \mathbf{v}_1, \dots, \mathbf{z}_1; \dots; \mathbf{u}_r, \mathbf{v}_r, \dots, \mathbf{z}_r) = \mathbf{u}_1 \otimes \mathbf{v}_1 \otimes \cdots \otimes \mathbf{z}_1 + \cdots + \mathbf{u}_r \otimes \mathbf{v}_r \otimes \cdots \otimes \mathbf{z}_r.$$

It is clear that the image of ψ_r is exactly $\mathcal{S}_r(d_1, \dots, d_k) = \{A \mid \operatorname{rank}_\otimes(A) \le r\}$. It is also clear that ψ_r is a polynomial map.

It follows from Theorem 6.1 that $\mathcal{S}_r(d_1, \dots, d_k)$ is semialgebraic. This holds for arbitrary r. So $\mathcal{R}_r(d_1, \dots, d_k) = \mathcal{S}_r(d_1, \dots, d_k) \setminus \mathcal{S}_{r-1}(d_1, \dots, d_k)$ is also semialgebraic. ∎

COROLLARY 6.3. *There exist $\Delta_0, \dots, \Delta_m \in \mathbb{R}[X_{1\cdots 1}, \dots, X_{d_1\cdots d_k}]$ from which the rank of a tensor $A \in \mathbb{R}^{d_1\times\cdots\times d_k}$ can be determined purely from the signs (i.e., + or − or 0) of $\Delta_0(A), \dots, \Delta_m(A)$.*

In the next section, we will see examples of such polynomials for the tensor space $\mathbb{R}^{2\times 2\times 2}$. We will stop short of giving an explicit semialgebraic characterization of rank, but it should be clear to the reader how to get one.

[5] Only one p is necessary, because multiple equality constraints $p_1(\mathbf{a}) = 0, \dots, p_k(\mathbf{a}) = 0$ can always be amalgamated into a single equation $p(\mathbf{a}) = 0$ by setting $p = p_1^2 + \cdots + p_k^2$.

7. Orbits of real $2 \times 2 \times 2$ tensors. In this section, we study the equivalence of tensors in $\mathbb{R}^{2\times2\times2}$ under multilinear matrix multiplication. We will use the results and techniques of this section later on in section 8 where we determine *which* tensors in $\mathbb{R}^{2\times2\times2}$ have an optimal rank-2 approximation.

Recall that A and $B \in \mathbb{R}^{2\times2\times2}$ are said to be ($\mathrm{GL}_{2,2,2}(\mathbb{R})$-)equivalent if and only if there exists a transformation $(L, M, N) \in \mathrm{GL}_{2,2,2}(\mathbb{R})$ such that $A = (L, M, N) \cdot B$. The question is whether there is a finite list of "canonical tensors" so that every $A \in \mathbb{R}^{2\times2\times2}$ is equivalent to one of them. For matrices $A \in \mathbb{R}^{m\times n}$, $\operatorname{rank}(A) = r$ if and only if there exist $M \in \mathrm{GL}_m(\mathbb{R}), N \in \mathrm{GL}_n(\mathbb{R})$ such that

$$(M, N) \cdot A = MAN^{\top} = \begin{bmatrix} I_r & 0 \\ 0 & 0 \end{bmatrix}.$$

So every matrix of rank r is equivalent to one that takes the canonical form $\left[\begin{smallmatrix} I_r & 0 \\ 0 & 0 \end{smallmatrix}\right]$. Note that this is the same as saying that the matrix A can be transformed into $\left[\begin{smallmatrix} I_r & 0 \\ 0 & 0 \end{smallmatrix}\right]$ using elementary row and column operations—adding a scalar multiple of a row/column to another, scaling a row/column by a nonzero scalar, interchanging two rows/columns—since every $(L_1, L_2) \in \mathrm{GL}_{m,n}(\mathbb{R})$ is a sequence of such operations.

We will see that there is indeed a finite number of canonical forms for tensors in $\mathbb{R}^{2\times2\times2}$, although the classification is somewhat more intricate than the case of matrices; two tensors in $\mathbb{R}^{2\times2\times2}$ can have the same rank but be inequivalent (i.e., reduce to different canonical forms).

In fancier language, what we are doing is classifying the *orbits* of the *group action* $\mathrm{GL}_{2,2,2}(\mathbb{R})$ on $\mathbb{R}^{2\times2\times2}$. We are doing for $\mathbb{R}^{2\times2\times2}$ what Gelfand, Kapranov, and Zelevinsky did for $\mathbb{C}^{2\times2\times2}$ in the last sections of [30, 31]. Not surprisingly, the results that we obtained are similar but not identical; there are *eight* distinct orbits for the action of $\mathrm{GL}_{2,2,2}(\mathbb{R})$ on $\mathbb{R}^{2\times2\times2}$ as opposed to *seven* distinct orbits for the action of $\mathrm{GL}_{2,2,2}(\mathbb{C})$ on $\mathbb{C}^{2\times2\times2}$—a further reminder of the dependence of such results on the choice of field.

THEOREM 7.1. *Every tensor in $\mathbb{R}^{2\times2\times2}$ is equivalent via a transformation in $\mathrm{GL}_{2,2,2}(\mathbb{R})$ to precisely one of the canonical forms indicated in Table* 7.1*, with its invariants taking the values shown.*

Proof. Write $A = [A_1 \mid A_2]$, $A_i \in \mathbb{R}^{2\times2}$ for $[\![a_{ijk}]\!] \in \mathbb{R}^{2\times2\times2}$. If $\operatorname{rank}(A_1) = 0$, then

$$A = \left[\begin{array}{cc|cc} 0 & 0 & \times & \times \\ 0 & 0 & \times & \times \end{array}\right].$$

Using matrix operations, A must then be equivalent to one of the forms (depending on $\operatorname{rank}(A_2)$)

$$\left[\begin{array}{cc|cc} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{array}\right], \qquad \left[\begin{array}{cc|cc} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \end{array}\right], \qquad \left[\begin{array}{cc|cc} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{array}\right],$$

which correspond to D_0, D_1, and D_2, respectively (after reordering the slabs).

If $\operatorname{rank}(A_1) = 1$, then we may assume that

$$A = \left[\begin{array}{cc|cc} 1 & 0 & a & b \\ 0 & 0 & c & d \end{array}\right].$$

TABLE 7.1
GL-*orbits of* $\mathbb{R}^{2\times2\times2}$. *The letters* D, G *stand for "degenerate" and "generic," respectively.*

tensor	sign(Δ)	rank	$\text{rank}_\otimes$	$\underline{\text{rank}}_\otimes$
$D_0 = \left[\begin{array}{cc\|cc} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{array}\right]$	0	$(0,0,0)$	0	0
$D_1 = \left[\begin{array}{cc\|cc} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{array}\right]$	0	$(1,1,1)$	1	1
$D_2 = \left[\begin{array}{cc\|cc} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{array}\right]$	0	$(1,2,2)$	2	2
$D_2' = \left[\begin{array}{cc\|cc} 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{array}\right]$	0	$(2,1,2)$	2	2
$D_2'' = \left[\begin{array}{cc\|cc} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{array}\right]$	0	$(2,2,1)$	2	2
$G_2 = \left[\begin{array}{cc\|cc} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{array}\right]$	+	$(2,2,2)$	2	2
$D_3 = \left[\begin{array}{cc\|cc} 1 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{array}\right]$	0	$(2,2,2)$	3	2
$G_3 = \left[\begin{array}{cc\|cc} 1 & 0 & 0 & -1 \\ 0 & 1 & 1 & 0 \end{array}\right]$	−	$(2,2,2)$	3	3

If $d \neq 0$ then we may transform this to G_2 as follows:

$$\left[\begin{array}{cc\|cc} 1 & 0 & a & b \\ 0 & 0 & c & d \end{array}\right] \rightsquigarrow \left[\begin{array}{cc\|cc} 1 & 0 & \times & 0 \\ 0 & 0 & 0 & d \end{array}\right] \rightsquigarrow \left[\begin{array}{cc\|cc} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{array}\right].$$

If $d = 0$, then

$$\left[\begin{array}{cc\|cc} 1 & 0 & a & b \\ 0 & 0 & c & 0 \end{array}\right] \rightsquigarrow \left[\begin{array}{cc\|cc} 1 & 0 & 0 & b \\ 0 & 0 & c & 0 \end{array}\right].$$

In this situation we can normalize b, c separately, reducing these matrices to one of the following four cases (according to whether b, c are zero):

$$\left[\begin{array}{cc\|cc} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{array}\right], \quad \left[\begin{array}{cc\|cc} 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{array}\right], \quad \left[\begin{array}{cc\|cc} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{array}\right], \quad \left[\begin{array}{cc\|cc} 1 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{array}\right],$$

which are D_1, D_2', D_2'', and D_3, respectively.

Finally, if $\text{rank}(A_1) = 2$, then we may assume that

$$A = [A_1 \mid A_2] = \left[\begin{array}{cc\|cc} 1 & 0 & \times & \times \\ 0 & 1 & \times & \times \end{array}\right].$$

By applying a transformation of the form (I, L, L^{-1}), we can keep A_1 fixed while conjugating A_2 into (real) Jordan canonical form. There are four cases.

If A_2 has repeated real eigenvalues and is diagonalizable, then we get D_2:

$$\left[\begin{array}{cc|cc} 1 & 0 & \lambda & 0 \\ 0 & 1 & 0 & \lambda \end{array}\right] \rightsquigarrow \left[\begin{array}{cc|cc} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{array}\right].$$

If A_2 has repeated real eigenvalues and is not diagonalizable, then we have

$$\left[\begin{array}{cc|cc} 1 & 0 & \lambda & 1 \\ 0 & 1 & 0 & \lambda \end{array}\right] \rightsquigarrow \left[\begin{array}{cc|cc} 1 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 \end{array}\right],$$

which is equivalent (after swapping columns and swapping slabs) to D_3.

If A_2 has distinct real eigenvalues, then A reduces to G_2:

$$\left[\begin{array}{cc|cc} 1 & 0 & \lambda & 0 \\ 0 & 1 & 0 & \mu \end{array}\right] \rightsquigarrow \left[\begin{array}{cc|cc} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & \mu-\lambda \end{array}\right] \rightsquigarrow \left[\begin{array}{cc|cc} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{array}\right].$$

If A_2 has complex eigenvalues, then we can reduce A to G_3:

$$\left[\begin{array}{cc|cc} 1 & 0 & a & -b \\ 0 & 1 & b & a \end{array}\right] \rightsquigarrow \left[\begin{array}{cc|cc} 1 & 0 & 0 & -b \\ 0 & 1 & b & 0 \end{array}\right] \rightsquigarrow \left[\begin{array}{cc|cc} 1 & 0 & 0 & -1 \\ 0 & 1 & 1 & 0 \end{array}\right].$$

Thus, every $2 \times 2 \times 2$ tensor can be transformed into one of the canonical forms listed in the statement of the theorem. Moreover, the invariants $\operatorname{sign}(\Delta)$ and $\operatorname{rank}_{\boxplus}$ are easily computed for the canonical forms and suffice to distinguish them. It follows that the listed forms are pairwise inequivalent.

We confirm the given values of $\operatorname{rank}_{\otimes}$. It is clear that $\operatorname{rank}_{\otimes}(D_0) = 0$ and $\operatorname{rank}_{\otimes}(D_1) = 1$. By Proposition 5.4, any tensor of rank 1 must be equivalent to D_1. Thus D_2, D_2', D_2'', and G_2 are all of rank 2. By Proposition 5.5, every tensor of rank 2 must be equivalent to one of these. In particular, D_3 and G_3 must have rank at least 3. Evidently $\operatorname{rank}_{\otimes}(D_3) = 3$ from its definition; and the same is true for G_3 by virtue of the less obvious relation

$$G_3 = (\mathbf{e}_1 + \mathbf{e}_2) \otimes \mathbf{e}_2 \otimes \mathbf{e}_2 + (\mathbf{e}_1 - \mathbf{e}_2) \otimes \mathbf{e}_1 \otimes \mathbf{e}_1 + \mathbf{e}_2 \otimes (\mathbf{e}_1 + \mathbf{e}_2) \otimes (\mathbf{e}_1 - \mathbf{e}_2).$$

Finally, we confirm the tabulated values of $\underline{\operatorname{rank}}_{\otimes}$. By virtue of the remark after Definition 5.11, it is enough to verify that $\underline{\operatorname{rank}}_{\otimes}(D_3) \leq 2$ and that $\underline{\operatorname{rank}}_{\otimes}(G_3) = 3$. The first of these assertions follows from Proposition 4.6. The set of tensors of type G_3 is an open set, which implies the second assertion. □

Remark. We note that D_3 is equivalent to any of the tensors obtained from it by permutations of the three factors. Indeed, all of these tensors have $\operatorname{rank}_{\boxplus} = (2, 2, 2)$ and $\Delta = 0$. Similar remarks apply to G_2, G_3.

Remark. The classification of $\mathrm{GL}_{2,2,2}(\mathbb{C})$-orbits in $\mathbb{C}^{2\times2\times2}$ differs only in the treatment of G_3, since there is no longer any distinction between real and complex eigenvalues.

We caution the reader that the *finite* classification in Theorem 7.1 is, in general, not possible for tensors of arbitrary size and order simply because the dimension or "degrees of freedom" of $\mathbb{R}^{d_1\times\cdots\times d_k}$ exceeds that of $\mathrm{GL}_{d_1,\ldots,d_k}(\mathbb{R})$ as soon as $d_1 \cdots d_k > d_1^2 + \cdots + d_k^2$ (which is almost always the case). Any attempt at an explicit classification must necessarily include continuous parameters. For the case of $\mathbb{R}^{2\times2\times2}$ this argument is not in conflict with our finite classification, since $2 \cdot 2 \cdot 2 < 2^2 + 2^2 + 2^2$.

7.1. Generic rank. We called the tensors in the orbit classes of G_2 and G_3 *generic* in the sense that the property of being in either one of these classes is an open condition. One should note that there is often no one single *generic outer-product rank* for tensors over $\mathbb{R}$ [50, 74]. (For tensors over $\mathbb{C}$ such a generic rank always exists [18].) The "generic outer-product rank" for tensors over $\mathbb{R}$ should be regarded as set-valued:

$$\text{generic-rank}_{\otimes}(\mathbb{R}^{d_1\times\cdots\times d_k}) = \{r \in \mathbb{N} \mid \mathcal{S}_r(d_1,\dots,d_k) \text{ has nonempty interior}\}.$$

So the generic outer-product rank in $\mathbb{R}^{2\times2\times2}$ is $\{2,3\}$. Another term, preferred by some and coined originally by ten Berge, is *typical rank* [74].

Given $d_1,\dots d_k$, the determination of the generic outer-product rank is an open problem in general and a nontrivial problem even in simple cases; see [13, 14] for results over $\mathbb{C}$ and [73, 74] for results over $\mathbb{R}$. Fortunately, the difficulty does not extend to multilinear rank; a single unique *generic multilinear rank* always exists and depends only on $d_1,\dots d_k$ (and not on the base field; cf. Proposition 7.4).

PROPOSITION 7.2. *Let* $A \in \mathbb{R}^{d_1\times\cdots\times d_k}$. *If* $\operatorname{rank}_{\boxplus}(A) = (r_1(A),\dots,r_k(A))$, *then*

$$r_i(A) = \min\left(d_i, \prod_{j\neq i} d_j\right), \quad i = 1,\dots,k,$$

generically.

Proof. Let $\mu_i : \mathbb{R}^{d_1\times\cdots\times d_k} \to \mathbb{R}^{d_i\times\prod_{j\neq i} d_j}$ be the forgetful map that "flattens" or "unfolds" a tensor into a matrix in the ith mode. It is easy to see that

$$r_i(A) = \operatorname{rank}(\mu_i(A)), \tag{7.1}$$

where "rank" here denotes matrix rank. The results then follow from the fact that the generic rank of a matrix in $\mathbb{R}^{d_i\times\prod_{j\neq i} d_j}$ is $\min(d_i, \prod_{j\neq i} d_j)$. ∎

For example, for order-3 tensors,

$$\text{generic-rank}_{\boxplus}(\mathbb{R}^{l\times m\times n}) = (\min(l, mn), \min(m, ln), \min(n, lm)).$$

7.2. Semialgebraic description of orbit classes. For a general tensor $A \in \mathbb{R}^{2\times2\times2}$, its orbit class is readily determined by computing the invariants $\operatorname{sign}(\Delta(A))$ and $\operatorname{rank}_{\boxplus}(A)$ and comparing with the canonical forms. The ranks $r_i(A)$ which constitute $\operatorname{rank}_{\boxplus}(A)$ can be evaluated algebraically as follows. If $A \neq 0$, then each $r_i(A)$ is either 1 or 2. For example, note that $r_1(A) < 2$ if and only if the vectors $A_{\bullet11}$, $A_{\bullet12}$, $A_{\bullet21}$, $A_{\bullet22}$ are linearly dependent, which happens if and only if all the 2-by-2 minors of the matrix

$$\begin{bmatrix} a_{111} & a_{112} & a_{121} & a_{122} \\ a_{211} & a_{212} & a_{221} & a_{222} \end{bmatrix}$$

are zero. Explicitly, the following six equations must be satisfied:

$$\begin{aligned} &a_{111}a_{212} = a_{211}a_{112}, \quad a_{111}a_{221} = a_{211}a_{121}, \quad a_{111}a_{222} = a_{211}a_{122}, \\ &a_{112}a_{221} = a_{212}a_{121}, \quad a_{112}a_{222} = a_{212}a_{122}, \quad a_{121}a_{222} = a_{221}a_{122}. \end{aligned} \tag{7.2}$$

Similarly, $r_2(A) < 2$ if and only if

$$\begin{aligned} &a_{111}a_{122} = a_{121}a_{112}, \quad a_{111}a_{221} = a_{121}a_{211}, \quad a_{111}a_{222} = a_{121}a_{212}, \\ &a_{112}a_{122} = a_{122}a_{211}, \quad a_{112}a_{222} = a_{122}a_{212}, \quad a_{211}a_{222} = a_{221}a_{212}; \end{aligned} \tag{7.3}$$

and $r_3(A) < 2$ if and only if

$$\begin{aligned} &a_{111}a_{122} = a_{112}a_{121}, \quad a_{111}a_{212} = a_{112}a_{211}, \quad a_{111}a_{222} = a_{112}a_{221}, \\ &a_{121}a_{212} = a_{122}a_{211}, \quad a_{121}a_{222} = a_{122}a_{221}, \quad a_{211}a_{222} = a_{212}a_{221}. \end{aligned} \tag{7.4}$$

The equations (7.2)–(7.4) lead to twelve distinct polynomials (beginning with $\Delta_1 = a_{111}a_{212} - a_{211}a_{112}$) which, together with $\Delta_0 := \Delta$, make up the collection $\Delta_0, \dots, \Delta_{12}$ of polynomials used in the semialgebraic description of the orbit structure of $\mathbb{R}^{2\times2\times2}$, as in Corollary 6.3. Indeed, we note that in Table 7.1 the information in the fourth and fifth columns ($\operatorname{rank}_\otimes(A)$, $\underline{\operatorname{rank}}_\otimes(A)$) is determined by the information in the second and third columns ($\operatorname{sign}(\Delta)$, $\operatorname{rank}_\boxplus(A)$).

7.3. Generic rank on $\Delta = 0$. The notion of generic rank also makes sense on subvarieties of $\mathbb{R}^{2\times2\times2}$—for instance, on the $\Delta = 0$ hypersurface.

PROPOSITION 7.3. *The tensors on the hypersurface* $\mathcal{D}_3 = \{A \in \mathbb{R}^{2\times2\times2} \mid \Delta(A) = 0\}$ *are all of the form*

$$\mathbf{x}_1 \otimes \mathbf{x}_2 \otimes \mathbf{y}_3 + \mathbf{x}_1 \otimes \mathbf{y}_2 \otimes \mathbf{x}_3 + \mathbf{y}_1 \otimes \mathbf{x}_2 \otimes \mathbf{x}_3,$$

and they have rank 3 *generically.*

Proof. From the canonical forms in Table 7.1, we see that if $\Delta(A) = 0$, then

$$A = \mathbf{x}_1 \otimes \mathbf{x}_2 \otimes \mathbf{y}_3 + \mathbf{x}_1 \otimes \mathbf{y}_2 \otimes \mathbf{x}_3 + \mathbf{y}_1 \otimes \mathbf{x}_2 \otimes \mathbf{x}_3$$

for some $\mathbf{x}_i, \mathbf{y}_i \in \mathbb{R}^2$, not necessarily linearly independent. It remains to be shown that $\operatorname{rank}_\otimes(A) = 3$ generically.

From Theorem 7.1 and the subsequent discussion, if $\Delta(A) = 0$, then $\operatorname{rank}_\otimes(A) \le 2$ if and only if at least one of the equation sets (7.2), (7.3), (7.4) is satisfied. Hence $\mathcal{D}_2 := \{A \mid \Delta(A) = 0, \operatorname{rank}_\otimes(A) \le 2\}$ is an algebraic subset of $\mathcal{D}_3$.

On the other hand, $\mathcal{D}_3 \setminus \mathcal{D}_2$ is dense in $\mathcal{D}_3$ with respect to the Euclidean, and hence the Zariski, topology. Indeed, each of the tensors D_0, D_1, D_2, D_2', D_2'' can be approximated by tensors of type D_3; for instance,

$$\left[\begin{array}{cc|cc} 1 & 0 & 0 & \epsilon \\ 0 & 1 & 0 & 0 \end{array}\right] \to \left[\begin{array}{cc|cc} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{array}\right] = D_2 \quad \text{as } \epsilon \to 0.$$

Multiplying by an arbitrary $(L, M, N) \in \mathrm{GL}_{2,2,2}(\mathbb{R})$, it follows that any tensor in $\mathcal{D}_2$ can be approximated by tensors of type D_3.

It follows that the rank-3 tensors $\mathcal{D}_3 \setminus \mathcal{D}_2$ in $\mathcal{D}_3$ constitute a generic subset of $\mathcal{D}_3$ in the Zariski sense (and hence in all the other usual senses). ∎

Remark. In fact, it can be shown that $\mathcal{D}_3$ is an irreducible variety. If we accept that, then the fact that $\mathcal{D}_2$ is a proper subvariety of $\mathcal{D}_3$ immediately implies that the rank-3 tensors form a generic subset of $\mathcal{D}_3$. The denseness argument becomes unnecessary.

7.4. Base field dependence. It is interesting to observe that the $\mathrm{GL}_{2,2,2}(\mathbb{R})$-orbit classes of G_2 and G_3 merge into a single orbit class over $\mathbb{C}$ (under the action of $\mathrm{GL}_{2,2,2}(\mathbb{C})$). Explicitly, if we write $\mathbf{z}_k = \mathbf{x}_k + i\mathbf{y}_k$ and $\bar{\mathbf{z}}_k = \mathbf{x}_k - i\mathbf{y}_k$, then

$$\begin{aligned} &\mathbf{x}_1 \otimes \mathbf{x}_2 \otimes \mathbf{x}_3 + \mathbf{x}_1 \otimes \mathbf{y}_2 \otimes \mathbf{y}_3 - \mathbf{y}_1 \otimes \mathbf{x}_2 \otimes \mathbf{y}_3 + \mathbf{y}_1 \otimes \mathbf{y}_2 \otimes \mathbf{x}_3 \\ &\qquad = \frac{1}{2}(\bar{\mathbf{z}}_1 \otimes \mathbf{z}_2 \otimes \bar{\mathbf{z}}_3 + \mathbf{z}_1 \otimes \bar{\mathbf{z}}_2 \otimes \mathbf{z}_3). \end{aligned} \tag{7.5}$$

The LHS is in the $\mathrm{GL}_{2,2,2}(\mathbb{R})$-orbit class of G_3 and has outer-product rank 3 over $\mathbb{R}$. The RHS is in the $\mathrm{GL}_{2,2,2}(\mathbb{C})$-orbit class of G_2 and has outer-product rank 2 over $\mathbb{C}$. To see why this is unexpected, recall that an $m \times n$ matrix with real entries has the same rank whether we regard it as an element of $\mathbb{R}^{m\times n}$ or of $\mathbb{C}^{m\times n}$. Note, however, that G_2 and G_3 have the same multilinear rank; this is not coincidental but is a manifestation of the following result.

PROPOSITION 7.4. *The multilinear rank of a tensor is independent of the choice of base field. If $\mathbb{K}$ is an extension field of $\Bbbk$, the value* $\operatorname{rank}_{\boxplus}(A)$ *is the same whether A is regarded as an element of $\Bbbk^{d_1\times\cdots\times d_k}$ or of $\mathbb{K}^{d_1\times\cdots\times d_k}$.*

Proof. This follows immediately from (7.1) and the base field independence of matrix rank. □

In 1969, Bergman [4] considered linear subspaces of matrix spaces, and showed that the minimum rank on a subspace can become strictly smaller upon taking a field extension. He gave a class of examples, the simplest instance being the 2-dimensional subspace

$$s\begin{bmatrix}1 & 0\\ 0 & 1\end{bmatrix} + t\begin{bmatrix}0 & 1\\ -1 & 0\end{bmatrix}$$

of $\mathbb{R}^{2\times 2}$. Every (nonzero) matrix in this subspace has rank 2, but the complexified subspace contains a matrix of rank 1. Intriguingly, this example is precisely the subspace spanned by the slabs of G_3. We suspect a deeper connection.

7.5. Injectivity of orbits. The tensor rank has the property of being invariant under the general multilinear group (cf. (2.15)). Indeed, much of its relevance comes from this fact. Moreover, from Proposition 3.1 we know that tensor rank is preserved when a tensor space is included in a larger tensor space. Similar assertions are true for the multilinear rank (cf. (2.19)).

The situation is more complicated for the function Δ defined on $\mathbb{R}^{2\times2\times2}$. The sign of Δ is $\mathrm{GL}_{2,2,2}(\mathbb{R})$-invariant, and Δ itself is invariant under $\mathrm{O}_{2,2,2}(\mathbb{R})$. For general $d_1, d_2, d_3 \geq 2$, we do not have an obvious candidate function Δ defined on $\mathbb{R}^{d_1\times d_2\times d_3}$. However, there is a natural definition of Δ restricted to the subset of tensors A for which $\operatorname{rank}_{\boxplus}(A) \leq (2,2,2)$. Such a tensor can be expressed as

$$A = (L, M, N)\cdot(B \oplus 0),$$

where $B \in \mathbb{R}^{2\times2\times2}$, $0 \in \mathbb{R}^{(d_1-2)\times(d_2-2)\times(d_3-2)}$, and $(L, M, N) \in \mathrm{O}_{d_1,d_2,d_3}(\mathbb{R})$. We provisionally define $\Delta(A) = \Delta(B)$, subject to a check that this is independent of the choices involved. Given an alternative expression $A = (L', M', N')\cdot(B' \oplus 0)$, it follows that $B \oplus 0$ and $B' \oplus 0$ are in the same $\mathrm{O}_{d_1,d_2,d_3}(\mathbb{R})$-orbit. Indeed,

$$B \oplus 0 = (L^{-1}L', M^{-1}M', N^{-1}N')\cdot(B' \oplus 0).$$

If we can show, more strongly, that B, B' belong to the same $\mathrm{O}_{2,2,2}(\mathbb{R})$-orbit, then the desired equality $\Delta(B) = \Delta(B')$ follows from the orthogonal invariance of Δ.

The missing step is supplied by the next theorem, which we state in a basis-free form for abstract vector spaces. If V is a vector space, we write $\mathrm{GL}(V)$ for the group of invertible linear maps from $V \to V$. If, in addition, V is an inner-product space, we write $\mathrm{O}(V)$ for the group of norm-preserving linear maps $V \to V$. In particular, $\mathrm{GL}(\mathbb{R}^d) \cong \mathrm{GL}_d(\mathbb{R})$ and $\mathrm{O}(\mathbb{R}^d) \cong \mathrm{O}_d(\mathbb{R})$.

THEOREM 7.5 (injectivity of orbits). *Let $\Bbbk = \mathbb{R}$ or $\mathbb{C}$ and $V_1, \ldots, V_k$ be $\Bbbk$-vector spaces. Let $U_1 \leq V_1, \ldots, U_k \leq V_k$.* (1) *Suppose $B, B' \in U_1 \otimes \cdots \otimes U_k$ are in*

distinct $\mathrm{GL}(U_1) \times \cdots \times \mathrm{GL}(U_k)$*-orbits of* $U_1 \otimes \cdots \otimes U_k$*; then* B *and* B' *are in distinct* $\mathrm{GL}(V_1) \times \cdots \times \mathrm{GL}(V_k)$*-orbits of* $V_1 \otimes \cdots \otimes V_k$*.* (2) *Suppose* $B, B' \in U_1 \otimes \cdots \otimes U_k$ *are in distinct* $\mathrm{O}(U_1) \times \cdots \times \mathrm{O}(U_k)$*-orbits of* $U_1 \otimes \cdots \otimes U_k$*; then* B *and* B' *are in distinct* $\mathrm{O}(V_1) \times \cdots \times \mathrm{O}(V_k)$*-orbits of* $V_1 \otimes \cdots \otimes V_k$*.*

LEMMA 7.6. *Let* $W \leq U \leq V$ *be vector spaces and* $L \in \mathrm{GL}(V)$*. Suppose* $L(W) \leq U$*. Then there exists* $\tilde{L} \in \mathrm{GL}(U)$ *such that* $L|_W = \tilde{L}|_W$*. Moreover, if* $L \in \mathrm{O}(V)$*, then we can take* $\tilde{L} \in \mathrm{O}(U)$*.*

Proof. Extend $L|_W$ to U by mapping the orthogonal complement of W in U by a norm-preserving map to the orthogonal complement of $L(W)$ in U. The resulting linear map $\tilde{L}$ has the desired properties and is orthogonal if L is orthogonal. ∎

Proof of Theorem 7.5. We prove the contrapositive form of the theorem. Suppose $B' = (L_1, \ldots, L_k) \cdot B$, where $L_i \in \mathrm{GL}(V_i)$. Let $W_i \leq U_i$ be minimal subspaces such that B is in the image of $W_1 \otimes \cdots \otimes W_k \hookrightarrow U_1 \otimes \cdots \otimes U_k$. It follows that $L_i(W_i) \leq U_i$, for otherwise we could replace W_i by $L_i^{-1}(L_i(W_i) \cap U_i)$. We can now use Lemma 7.6 to find $\tilde{L}_i \in \mathrm{GL}(U_i)$ which agree with L_i on W_i. By construction, $(\tilde{L}_1, \ldots, \tilde{L}_k) \cdot B = (L_1, \ldots, L_k) \cdot B = B'$. In the orthogonal case, where $L_i \in \mathrm{O}(V_i)$, we may choose $\tilde{L}_i \in \mathrm{O}(U_i)$. ∎

COROLLARY 7.7. *Let* φ *be a* $\mathrm{GL}_{d_1,\ldots,d_k}(\mathbb{R})$*-invariant (respectively,* $\mathrm{O}_{d_1,\ldots,d_k}(\mathbb{R})$*-invariant) function on* $\mathbb{R}^{d_1 \times \cdots \times d_k}$*. Then* φ *naturally extends to a* $\mathrm{GL}_{d_1,\ldots,d_k}(\mathbb{R})$*-invariant (respectively,* $\mathrm{O}_{d_1,\ldots,d_k}(\mathbb{R})$*-invariant) function on the subset*

$$\{A \in \mathbb{R}^{(d_1+e_1)\times\cdots\times(d_k+e_k)} \mid r_i(A) \leq d_i \text{ for } i = 1, \ldots, k\}$$

of $\mathbb{R}^{(d_1+e_1)\times\cdots\times(d_k+e_k)}$*.*

Proof. As with Δ above, write $A = (L_1, \ldots, L_k) \cdot B$ for $B \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ and define $\varphi(A) = \varphi(B)$. By Theorem 7.5 this is independent of the choices involved. ∎

The problem of classification is closely related to finding invariant functions. We end this section with a strengthening of Theorem 7.1.

COROLLARY 7.8. *The eight orbits in Theorem* 7.1 *remain distinct under the embedding* $\mathbb{R}^{2\times2\times2} \hookrightarrow \mathbb{R}^{d_1\times d_2\times d_3}$ *for any* $d_1, d_2, d_3 \geq 2$*. Thus, Theorem* 7.1 *immediately gives a classification of tensors* $A \in \mathbb{R}^{d_1\times d_2\times d_3}$ *with* $\operatorname{rank}_{\boxplus}(A) \leq (2, 2, 2)$*, into eight classes under* $\mathrm{GL}_{d_1,d_2,d_3}(\mathbb{R})$*-equivalence.*

The corollary allows us to extend the notion of tensor type to $\mathbb{R}^{d_1\times d_2\times d_3}$. For instance, we will say that $A \in \mathbb{R}^{d_1\times d_2\times d_3}$ has type G_3 if and only if A is GL-equivalent to $G_3 \in \mathbb{R}^{2\times2\times2} \subset \mathbb{R}^{d_1\times d_2\times d_3}$.

Note that order-k tensors can be embedded in order-$(k+1)$ tensors by taking the tensor product with a 1-dimensional factor. Distinct orbits remain distinct, so the results of this subsection extend to inclusions into tensor spaces of higher order.

8. Volume of tensors with no optimal low-rank approximation. At this point, it is clear that there exist tensors that can fail to have optimal low-rank approximations. However, it is our experience that practitioners have sometimes expressed optimism that such failures might be rare abnormalities that are not encountered in practice. In truth, such optimism is misplaced: the set of tensors with no optimal low-rank approximation has positive volume. In other words, a randomly chosen tensor will have a nonzero chance of failing to have a optimal low-rank approximation.

We begin this section with a particularly striking instance of this.

THEOREM 8.1. *No tensor of rank* 3 *in* $\mathbb{R}^{2\times2\times2}$ *has an optimal rank-*2 *approximation (with respect to the Frobenius norm). In particular,* $\textsc{approx}(A, 2)$ *has no solution for tensors of type* G_3*, which comprise a set that is open and therefore of positive volume.*

LEMMA 8.2. *Let* $A \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ *with* $\operatorname{rank}_\otimes(A) \geq r$. *Suppose* $B \in \mathcal{S}_r(d_1, \ldots, d_k)$ *is an optimal rank-r approximation for A. Then* $\operatorname{rank}_\otimes(B) = r$.

Proof. Suppose $\operatorname{rank}_\otimes(B) \leq r-1$. Then $B \neq A$, and so $B - A$ has at least one nonzero entry in its array representation. Let $E \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ be the rank-1 tensor which agrees with $B - A$ at that entry and is zero everywhere else. Then $\operatorname{rank}_\otimes(B + E) \leq r$ but $\|A - (B + E)\|_F < \|A - B\|_F$, so B is not optimal. ∎

Proof of Theorem 8.1. Let $A \in \mathbb{R}^{2\times 2\times 2}$ have rank 3, and suppose that B is an optimal rank-2 approximation to A. Propositions 5.9 and 5.10, together with the continuity of Δ, imply that $\Delta(B) = 0$. Lemma 8.2 implies that $\operatorname{rank}_\otimes(B) = 2$. By Theorem 7.1, it follows that B is of type D_2, D_2', or D_2''.

We may assume without loss of generality that B is of type D_2. The next step is to put B into a helpful form by making an orthogonal change of coordinates. This gives an equivalent approximation problem, thanks to the O-invariance of the Frobenius norm. From Table 7.1, we know that $\operatorname{rank}_\boxplus(B) = (1, 2, 2)$. Such a B is orthogonally equivalent to a tensor of the following form:

$$\left[\begin{array}{cc|cc} \lambda & 0 & 0 & 0 \\ 0 & \mu & 0 & 0 \end{array}\right]. \tag{8.1}$$

Indeed, a rotation in the first tensor factor brings B entirely into the first slab, and further rotations in the second and third factors put the resulting matrix into diagonal form, with singular values $\lambda, \mu \neq 0$.

Henceforth we assume that B is equal to the tensor in (8.1). We will consider perturbations of the form $B + \epsilon H$, which will be chosen so that $\Delta(B + \epsilon H) = 0$ for all $\epsilon \in \mathbb{R}$. Then $B + \epsilon H \in \overline{\mathcal{S}}_2(2, 2, 2)$, and we must have

$$\|A - B\|_F \leq \|A - (B + \epsilon H)\|_F$$

for all ϵ. In fact

$$\|A - (B + \epsilon H)\|_F^2 - \|A - B\|_F^2 = -2\epsilon\langle A - B, H\rangle_F + \epsilon^2\|H\|_F^2,$$

so if this is to be nonnegative for all small values of ϵ, it is necessary that

$$\langle A - B, H\rangle_F = 0. \tag{8.2}$$

Tensors H which satisfy the condition $\Delta(B + \epsilon H) \equiv 0$ include the following:

$$\left[\begin{array}{cc|cc} \times & \times & 0 & 0 \\ \times & \times & 0 & 0 \end{array}\right], \quad \left[\begin{array}{cc|cc} 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{array}\right], \quad \left[\begin{array}{cc|cc} 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{array}\right], \quad \left[\begin{array}{cc|cc} 0 & 0 & \lambda & 0 \\ 0 & 0 & 0 & \mu \end{array}\right]$$

since the resulting tensors have types D_2, D_3, D_3, and D_2, respectively.

Each of these gives a constraint on $A - B$, by virtue of (8.2). Putting the constraints together, we find that

$$A - B = \left[\begin{array}{cc|cc} 0 & 0 & a\mu & 0 \\ 0 & 0 & 0 & -a\lambda \end{array}\right] \qquad \text{or} \qquad A = \left[\begin{array}{cc|cc} \lambda & 0 & a\mu & 0 \\ 0 & \mu & 0 & -a\lambda \end{array}\right]$$

for some $a \in \mathbb{R}$. Thus $A = (\lambda\mathbf{e}_1 + a\mu\mathbf{e}_2) \otimes \mathbf{e}_1 \otimes \mathbf{e}_1 + (\mu\mathbf{e}_1 - a\lambda\mathbf{e}_2) \otimes \mathbf{e}_2 \otimes \mathbf{e}_2$ has rank 2, which is a contradiction. ∎

COROLLARY 8.3. *Let* $d_1, d_2, d_3 \geq 2$. *If* $A \in \mathbb{R}^{d_1 \times d_2 \times d_3}$ *is of type* G_3, *then A does not have an optimal rank-2 approximation.*

Proof. We use the projection Π_A defined in subsection 2.6. For any $B \in \mathbb{R}^{d_1 \times d_2 \times d_3}$, Pythagoras's theorem (2.20) gives

$$\begin{aligned}\|B - A\|_F^2 &= \|\Pi_A(B - A)\|_F^2 + \|(1 - \Pi_A)(B - A)\|_F^2 \\ &= \|\Pi_A(B) - A\|_F^2 + \|B - \Pi_A(B)\|_F^2.\end{aligned}$$

If B is an optimal rank-2 approximation, then it follows that $B = \Pi_A(B)$; for otherwise $\Pi_A(B)$ would be a better approximation. Thus $B \in U_1 \otimes U_2 \otimes U_3$, where U_1, U_2, U_3 are the supporting subspaces of A. These are 2-dimensional, since $\operatorname{rank}_{\boxplus}(A) = (2, 2, 2)$, so $U_1 \otimes U_2 \otimes U_3 \cong \mathbb{R}^{2\times 2\times 2}$. The optimality of B now contradicts Theorem 8.1. ∎

Our final result is that the set of tensors A for which $\textsc{approx}(A, 2)$ has no solution is a set of positive volume for all tensor spaces of order 3 except those isomorphic to a matrix space—in other words, Theorem 1.3. Note that the G_3-tensors comprise a set of zero volume in all cases except $\mathbb{R}^{2\times 2\times 2}$. Here is the precise statement.

THEOREM 8.4. *Let $d_1, d_2, d_3 \geq 2$. The set of tensors $A \in \mathbb{R}^{d_1 \times d_2 \times d_3}$ for which* $\textsc{approx}(A, 2)$ *does not have a solution (in the Frobenius norm) contains an open neighborhood of the set of tensors of type G_3. In particular, this set is nonempty and has positive volume.*

For $A \in \mathbb{R}^{d_1 \times d_2 \times d_3}$, let $\mathcal{B}(A)$ denote the set of optimal border-rank-2 approximations for A. Since $\overline{\mathcal{S}}_2(d_1, d_2, d_3)$ is nonempty and closed, it follows that $\mathcal{B}(A)$ is nonempty and compact.

We can restate the theorem as follows. Let A_0 be an arbitrary G_3-tensor. We must show that if A is close to A_0, and $B \in \mathcal{B}(A)$, then $\operatorname{rank}_{\otimes}(B) > 2$, i.e., B is a D_3-tensor. Our proof strategy is contained in the steps of the following lemma.

LEMMA 8.5. *Let $A_0 \in \mathbb{R}^{d_1 \times d_2 \times d_3}$ be a fixed tensor of type G_3. Then there exist positive numbers $\rho = \rho(A_0)$, $\delta = \delta(A_0)$ such that the following statements are true for all $A \in \mathbb{R}^{d_1 \times d_2 \times d_3}$.*

1. *If A is a G_3-tensor and $B \in \mathcal{B}(A)$, then B is a D_3-tensor and $\Pi_B = \Pi_A$.*
2. *If $\|A - A_0\|_F < \rho$ and $\operatorname{rank}_{\boxplus}(A) \leq (2, 2, 2)$, then A is a G_3-tensor.*
3. *If $\|A - A_0\|_F < \delta$ and $B \in \mathcal{B}(A)$, define $A' = \Pi_B(A)$. Then $\|A' - A_0\|_F < \rho$ and $B \in \mathcal{B}(A')$.*

Proof of Theorem 8.4*, assuming Lemma* 8.5. Fix $A_0 \in \mathbb{R}^{d_1 \times d_2 \times d_3}$ and suppose $\|A - A_0\|_F < \delta$. It is not generally true that $\operatorname{rank}_{\boxplus}(A) \leq (2, 2, 2)$, so we cannot apply (2) directly to A. Let $B \in \mathcal{B}(A)$. Then $A' = \Pi_B(A)$ is close to A_0, by (3). Since $\operatorname{rank}_{\boxplus}(B) \leq (2, 2, 2)$ and Π_B is the projection onto the subspace spanned by B, it follows that $\operatorname{rank}_{\boxplus}(A') \leq (2, 2, 2)$. Now (2) implies that A' is a G_3-tensor. Since $B \in \mathcal{B}(A')$, by (3), it follows from (1) that B is a D_3-tensor. ∎

Proof of Lemma 8.5 (1). This is essentially Corollary 8.3: B cannot have rank 2 or less, but it has border-rank 2, so B must be a D_3-tensor. Since $B = \Pi_A(B)$ it follows that the supporting subspaces of B are contained in the supporting subspaces of A. However, $\operatorname{rank}_{\boxplus}(B) = (2, 2, 2) = \operatorname{rank}_{\boxplus}(A)$, so the two tensors must have the same supporting subspaces, and so $\Pi_B = \Pi_A$. ∎

Proof of Lemma 8.5 (2). Let $\overline{\mathcal{S}}_2^+(d_1, d_2, d_3)$ denote the set of nonG_3 tensors in $\mathbb{R}^{d_1 \times d_2 \times d_3}$ with $\operatorname{rank}_{\boxplus} \leq (2, 2, 2)$. Since $A_0 \notin \overline{\mathcal{S}}_2^+(d_1, d_2, d_3)$, it is enough to show that $\overline{\mathcal{S}}_2^+(d_1, d_2, d_3)$ is closed, for then it would be disjoint from the ρ-ball about A_0 for some $\rho > 0$. Note that

$$\overline{\mathcal{S}}_2^+(d_1, d_2, d_3) = \mathrm{O}_{d_1,d_2,d_3}(\mathbb{R}) \cdot \overline{\mathcal{S}}_2^+(2, 2, 2).$$

Now $\overline{\mathcal{S}}_2^+(2, 2, 2) = \{A \in \mathbb{R}^{2\times 2\times 2} \mid \Delta(A) \geq 0\}$ is a closed subset of $\mathbb{R}^{2\times 2\times 2}$, and the

action of the compact group $\mathrm{O}_{d_1,d_2,d_3}(\mathbb{R})$ is proper. It follows that $\overline{\mathcal{S}}_2^+(d_1,d_2,d_3)$ is closed, as required. ∎

Proof of Lemma 8.5 (3). We begin with the easier part of the statement, which is that $B \in \mathcal{B}(A')$. To prove this, we will show that $\|A'-B\|_F \le \|A'-B'\|_F$ whenever $B' \in \mathcal{B}(A')$, establishing the optimality of B as an approximation to A'. Accordingly, let $B' \in \mathcal{B}(A')$. Since $\Pi_B(A') = A'$, it follows from (2.20) with Π_B that

$$\|A'-B'\|_F^2 = \|A'-\Pi_B(B')\|_F^2 + \|B'-\Pi_B(B')\|_F^2,$$

so, since B' is optimal, we must have $\Pi_B(B') = B'$. We can now apply (2.20) with Π_B to both sides of the inequality $\|A-B\|_F^2 \le \|A-B'\|_F^2$ to get

$$\|A'-B\|_F^2 + \|A-A'\|_F^2 \le \|A'-B'\|_F^2 + \|A-A'\|_F^2,$$

and hence $\|A'-B\|_F \le \|A'-B'\|_F$, as claimed.

We now turn to the proof that $\Pi_B(A)$ is close to A_0 if A is close to A_0. This is required to be uniform in A and B. In other words, there exists $\delta = \delta(A_0) > 0$ such that for all A and all $B \in \mathcal{B}(A)$ if $\|A-A_0\|_F < \delta$, then $\|\Pi_B(A) - A_0\| < \rho$. Here $\rho = \rho(A_0)$ is fixed from part (2) of this lemma.

We need control over the location of B. Let $\mathcal{B}_\epsilon(A_0)$ denote the ϵ-neighborhood of $\mathcal{B}(A_0)$ in $\overline{\mathcal{S}}_2(d_1,d_2,d_3)$.

Proposition 8.6. *Given $\epsilon > 0$, there exists $\delta > 0$ such that if $\|A-A_0\|_F < \delta$ then $\mathcal{B}(A) \subset \mathcal{B}_\epsilon(A_0)$.*

Proof. The set $\overline{\mathcal{S}}_2(d_1,d_2,d_3) \setminus \mathcal{B}_\epsilon(A_0)$ is closed, and so it attains its minimum distance from A_0. This must exceed the absolute minimum $\|A_0-B_0\|_F$ for $B_0 \in \mathcal{B}(A_0)$ by a positive quantity 2δ, say. If $\|A-A_0\|_F < \delta$ and $B' \in \overline{\mathcal{S}}_2(d_1,d_2,d_3) \setminus \mathcal{B}_\epsilon(A_0)$ then

$$\begin{aligned}
\|A-B'\|_F &\ge \|B'-A_0\|_F - \|A-A_0\|_F \\
&> \|A_0-B_0\|_F + 2\delta - \delta \\
&= \|A_0-B_0\|_F + \delta \\
&> \|A_0-B_0\|_F + \|A-A_0\|_F \\
&\ge \|A-B_0\|_F
\end{aligned}$$

using the triangle inequality in the first and last lines. Thus $B' \notin \mathcal{B}(A)$. ∎

We claim that if ϵ is small enough, then $\mathrm{rank}_{\boxplus}(B) = (2,2,2)$ for all $B \in \mathcal{B}_\epsilon(A_0)$. Indeed, this is already true on $\mathcal{B}(A_0)$, by part (1). Since $\mathrm{rank}_{\boxplus}$ is upper-semicontinuous and does not exceed $(2,2,2)$ on $\overline{\mathcal{S}}_2(d_1,d_2,d_3)$, it must be constant on a neighborhood of $\mathcal{B}(A_0)$ in $\overline{\mathcal{S}}_2(d_1,d_2,d_3)$. Since $\mathcal{B}(A_0)$ is compact, the neighborhood can be taken to be an ϵ-neighborhood.

Part (1) implies that $\Pi_{B_0} = \Pi_{A_0}$ for all $B_0 \in \mathcal{B}(A_0)$. If ϵ is small enough that $\mathrm{rank}_{\boxplus}(B) = (2,2,2)$ on $\mathcal{B}_\epsilon(A_0)$, then Π_B depends continuously on $B \in \mathcal{B}_\epsilon(A_0)$, by Proposition 2.5. Since $\mathcal{B}(A_0)$ is compact, we can choose ϵ small enough so that the operator norm of $\Pi_B - \Pi_{A_0}$ is as small as we like, uniformly over $\mathcal{B}_\epsilon(A_0)$.

We are now ready to confine $\Pi_B(A)$ to the ρ-neighborhood of A_0. Suppose, initially, that $\|A-A_0\|_F \le \rho/2$ and $B \in \mathcal{B}_\epsilon(A_0)$. Then

$$\begin{aligned}
\|\Pi_B(A) - A_0\|_F &\le \|(\Pi_B - \Pi_{A_0})\cdot A\|_F + \|\Pi_{A_0}\cdot A - A_0\|_F \\
&\le \|\Pi_B - \Pi_{A_0}\|\|A\|_F + \|\Pi_{A_0}\cdot(A-A_0)\|_F \\
&\le \|\Pi_B - \Pi_{A_0}\|(\|A_0\|_F + \rho/2) + \|A-A_0\|_F \\
&\le \|\Pi_B - \Pi_{A_0}\|(\|A_0\|_F + \rho/2) + \rho/2.
\end{aligned}$$

Now choose $\epsilon > 0$ so that the operator norm $\|\Pi_B - \Pi_{A_0}\|$ is kept small enough to guarantee that the RHS is less than ρ. For this ϵ, choose δ as given by Proposition 8.6. Ensure also that $\delta < \rho/2$.

Then, if $\|A - A_0\|_F < \delta$ and $B \in \mathcal{B}(A)$, we have $B \in \mathcal{B}_\epsilon(A_0)$. By the preceding calculation, $\|A' - A_0\|_F < \rho$. This completes the proof. □

9. Closing remarks. We refer interested readers to [17, 18, 57, 58] for a discussion of similar issues for symmetric tensors and nonnegative tensors. In particular, the reader will find in [18] an example of a symmetric tensor of symmetric rank r (r may be chosen to be arbitrarily large) that does not have a best symmetric-rank-2 approximation. In [57, 58], we show that such failures do not occur in the context of nonnegative tensors; a nonnegative tensor of nonnegative-rank r will always have a best nonnegative-rank-s approximation for any $s \leq r$.

In this paper we have focused our attention on the real case; the complex case has been studied in great detail in algebraic computational complexity theory and algebraic geometry. For the interested reader, we note that the rank-jumping phenomenon still occurs: Proposition 4.6 and its proof carry straight through to the complex case. On the other hand, there is no distinction between G_3- and G_2-tensors over the complex numbers; if $\Delta(A) \neq 0$, then A has rank 2. The results of section 8 have no direct analogue.

The major open question in tensor approximation is how to overcome the ill-posedness of APPROX(A, r). In general this will conceivably require an equivalent of Theorem 5.1 that characterizes the limit points of rank-r order-k tensors. It is our hope that some of the tools developed in our study, such as Theorems 5.2 and 7.5 (both of which apply to general r and k), may be used in future studies. The type of characterization in Corollary 5.12, for $r = 2$ and $k = 3$, is an example of what one might hope to achieve.

Acknowledgments. We thank the anonymous reviewers for some exceptionally helpful comments. We also gratefully acknowledge Joseph Landsberg and Bernd Sturmfels for enlightening pointers that helped improved sections 4.7 and 6. Lek-Heng Lim thanks Gene Golub for his encouragement and helpful discussions. Both authors thank Gunnar Carlsson and the Department of Mathematics, Stanford University, where some of this work was done.

ENHANCED LINE SEARCH: A NOVEL METHOD TO ACCELERATE PARAFAC*

MYRIAM RAJIH†, PIERRE COMON†, AND RICHARD A. HARSHMAN‡

Abstract. Several modifications have been proposed to speed up the alternating least squares (ALS) method of fitting the PARAFAC model. The most widely used is line search, which extrapolates from linear trends in the parameter changes over prior iterations to estimate the parameter values that would be obtained after many additional ALS iterations. We propose some extensions of this approach that incorporate a more sophisticated extrapolation, using information on nonlinear trends in the parameters and changing all the parameter sets simultaneously. The new method, called "enhanced line search (ELS)," can be implemented at different levels of complexity, depending on how many different extrapolation parameters (for different modes) are jointly optimized during each iteration. We report some tests of the simplest parameter version, using simulated data. The performance of this lowest-level of ELS depends on the nature of the convergence difficulty. It significantly outperforms standard LS when there is a "convergence bottleneck," a situation where some modes have almost collinear factors but others do not, but is somewhat less effective in classic "swamp" situations where factors are highly collinear in all modes. This is illustrated by examples. To demonstrate how ELS can be adapted to different N-way decompositions, we also apply it to a four-way array to perform a blind identification of an under-determined mixture (UDM). Since analysis of this dataset happens to involve a serious convergence "bottleneck" (collinear factors in two of the four modes), it provides another example of a situation in which ELS dramatically outperforms standard line search.

Key words. PARAFAC, alternating least squares (ALS), line search, enhanced line search (ELS), acceleration, swamps, bottlenecks, collinear factors, degeneracy

DOI. 10.1137/06065577

1. Introduction.

PARAFAC can be seen as a generalization of two-way factor analysis to multiway data. It was first introduced by Harshman in 1970 [9] based on the principle of parallel proportional profiles (PP) proposed by Cattell in 1944 [4]. The PP principle states that if two (or more) different two-way models are described by the same set of loading vectors but their relative proportions or weights change from one model to the other, then those loading vectors lead to a new model which is unambiguous with respect to (w.r.t.) rotation [4, 5, 2]. In other words, suppose that the matrix $\mathbf{X}_1$ can be modeled:

$$\mathbf{X}_1 = \mathbf{a}_1\mathbf{b}_1^T c_{11} + \mathbf{a}_2\mathbf{b}_2^T c_{12} + \cdots + \mathbf{a}_F\mathbf{b}_F^T c_{1F} + \mathbf{E}_1,$$

where $\mathbf{a}_f$ and $\mathbf{b}_f$ $(1 \le f \le F)$ are the columns of matrices $\mathbf{A}$ and $\mathbf{B}$, respectively, and $\mathbf{E}_1$ is a matrix of random disturbances (and/or other unmodeled variation). And suppose that another matrix $\mathbf{X}_2$ can be modeled using the same set of loading vectors only in different proportions (i.e., $\frac{c_{11}}{c_{21}} \neq \frac{c_{12}}{c_{22}} \neq \cdots \frac{c_{1F}}{c_{2F}}$):

$$\mathbf{X}_2 = \mathbf{a}_1\mathbf{b}_1^T c_{21} + \mathbf{a}_2\mathbf{b}_2^T c_{22} + \cdots + \mathbf{a}_F\mathbf{b}_F^T c_{2F} + \mathbf{E}_2.$$

Then, we can build a combined model:

$$\mathbf{X}_k = \mathbf{A}\mathbf{C}_k\mathbf{B}^T + \mathbf{E}_k, k = 1, 2, \tag{1}$$

where $\mathbf{C}_k$ is a diagonal matrix with the elements of vector $\mathbf{c}_k$ in its diagonal, where $\mathbf{c}_k$ denotes the kth row of the slice weighting or "occasion weights" matrix $\mathbf{C}$ [13]. The trilinear decomposition used in the model is also known as CANDECOMP for CANonical DECOMPosition; it was introduced by Caroll and Chang in 1970 [3] to provide a basis for fitting INDSCAL, an important generalization of multidimensional scaling that provides unique dimensions and allows the estimation of dimension weights for individual subjects. Alternatively, the model can be written in scalar form as

$$X_{ijk} = \sum_f A_{if}B_{jf}C_{kf} + E_{ijk}.$$

Matrices $\mathbf{A}$, $\mathbf{B}$, and $\mathbf{C}$ are called loading matrices.

The three-way PARAFAC model, along with its extension to higher orders [9, 3], has most often been applied in psychometrics and chemometrics [26, 27], and in the signal processing area [18, 6, 7]. While the two-way factor model suffers a rotational indeterminacy that yields an infinite set of solutions, the PARAFAC model enjoys a uniqueness property under conditions that often can be met in real data situations. Uniqueness properties have been studied by multiple authors, with some of the most important general results found in [10] and its recent generalization [15], the Kruskal theorems in, e.g., [16], and the extensions in [26], and elsewhere. Progress in this area is ongoing—for example, in the case of "tall" arrays, a significantly more relaxed condition has been derived in [19]. A relatively complete list of relevant articles up to 2006-07 can be found in [15].

A variety of algorithms have been used to fit the PARAFAC model (for a detailed summary and discussion; see, e.g., [28]. The most widely used is the alternating least squares (ALS) algorithm. The convergence of ALS was found to be very slow in some cases, typically when two factors are almost collinear. Line search [2, 24] is one of the most important solutions proposed to cope with the problem of slow convergence. We focus in this paper on the line search solution and present a generalization of this method for speeding up ALS; we discuss its simplest version and demonstrate that it can exhibit very good performance in some circumstances, yet perform less successfully in others—opening interesting directions for further exploration. We call this method enhanced line search (ELS).

A regularized (ridge) regression was proposed by Rayens and Mitchell in [23] to speed up the ALS algorithm in case of ill-posed problems. While the estimates produced by ridge regression are biased, they suggested ways of dealing with this, including a switch back to regular ALS estimation at the end of the fitting procedure, when the approximate solution has been reached. They designed their method to avoid difficulties which they called convergence "swamps," characterized by high factor collinearity in all three modes. We will see that ELS (at least the simple version tested here) is most successful with a different kind of convergence difficulty.

In [22], Paatero proposed the multilinear engine (ME) program to accelerate the fit of the PARAFAC model. ME changes all of the sets of parameters at once, whereas ELS is based on ALS, and updates alternatively each of the loading factors.

In [8], Franc proposed an acceleration to the convergence of PARAFAC based on a gradient method. In fact, the loading matrices $\mathbf{A}$, $\mathbf{B}$, and $\mathbf{C}$ are updated using the gradient descent.

A closed-form solution to fit the PARAFAC model was proposed by Sanchez and Kowalski in [25]. It reduces the problem to a rectangular eigenvalue-eigenvector equation, but it needs at least two of the loading matrices to be linearly independent.

Another closed-form solution for three-way arrays, and based on a single matrix eigenvalue decomposition (EVD) was presented in [21] by Leurgans, Ross, and Abel. It also requires that two of the loading matrices are linearly independent and that every pair of columns of the last loading matrix is linearly independent. Previous approaches are made more robust in [20] by taking all matrix slices into account, which leads to a simultaneous matrix decomposition. All of these methods require that the array rank (as defined in [17], for instance), F, is less than or equal to two of the array dimensions. In [19] De Lathauwer generalizes the approach presented in [20] to the case where F is less than or equal to one of the array's dimensions, and subject to a condition involving the product of the remaining array dimensions. One advantage of ELS is that it can be applied even if the previous conditions are not met.

2. Model and notation. We consider the three-way PARAFAC model of expression (1). This model can be written in a compact form using the Khatri–Rao product $\odot$ (columnwise Kronecker product) as, possibly up to an error term,

$$\mathbf{X}^{(I\times JK)} \approx \mathbf{A}(\mathbf{C}\odot\mathbf{B})^T,$$

where matrices $\mathbf{A}$, $\mathbf{B}$, and $\mathbf{C}$ are matrices of size $I\times F$, $J\times F$, and $K\times F$, and $\mathbf{X}^{(I\times JK)}$ is the matrix of size $I\times JK$ obtained by unfolding the array $\mathbf{X}$ of size $I\times J\times K$ in the first mode. There exist several algorithms that fit the PARAFAC model. We focus on the most widely used among all: the ALS algorithm. ALS consists of estimating one of the three matrices at each step by minimizing in the least squares sense the error

$$\Upsilon = \| \mathbf{X}^{(I\times JK)} - \mathbf{A}(\mathbf{C}\odot\mathbf{B})^T \|_F^2,$$

where $\| \bullet \|_F$ denotes the Frobenius norm. With matrices $\mathbf{B}$ and $\mathbf{C}$ fixed to initial values, the estimate of $\mathbf{A}$ in the least square sense is given by

$$\widehat{\mathbf{A}} = \mathbf{X}^{(I\times JK)}(\mathbf{Z}_a^+)^T, \tag{2}$$

where $\mathbf{Z}_a = \mathbf{C}\odot\mathbf{B}$ and $(^+)$ is the Moore–Penrose pseudoinverse. We estimate matrices $\mathbf{B}$ and $\mathbf{C}$ in an equivalent way, with $\mathbf{Z}_b = \mathbf{A}\odot\mathbf{C}$ and $\mathbf{Z}_c = \mathbf{B}\odot\mathbf{A}$, and repeat the same steps until a convergence criterion is reached—typically when the error Υ exhibits, between two iterations, a change smaller than a predefined threshold, which varies depending on the data. For simple data it can be set to 10^{-6}, for example, but it should be smaller for difficult data, 10^{-10}, for example. Note that, in order to avoid a threshold that is scale dependent, a relative error can be used instead, or array $\mathbf{X}$ can be prenormalized by its Frobenius norm.

We summarize the steps of the ALS algorithm in Figure 1.

It sometimes happens that the convergence needs a very large number of iterations. Choosing good starting values will, in some cases, help to reach the global minimum very quickly. Sometimes, however, it is impossible to reach a global minimum quickly by ALS from any starting point because the solution is embedded in a deep swamp, or is in fact unreachable at the solution rank, and can only be approached through an infinite series of diverging better fitting sets of loadings, as described by Kruskal.

3. Line search. Bro (in [2, p. 95–96]) and Harshman (in [9, p. 32–33]) have pointed out the important fact that, when the convergence is slow, there exist cycles of convergence defined by a unique direction. Within a given cycle, the loading factors evolve in the same direction to the final solution of that cycle. The following cycles exhibit the same scenario. The convergence within the cycle can take several iterations. To limit the number of iterations of a given cycle, Harshman and Bro propose

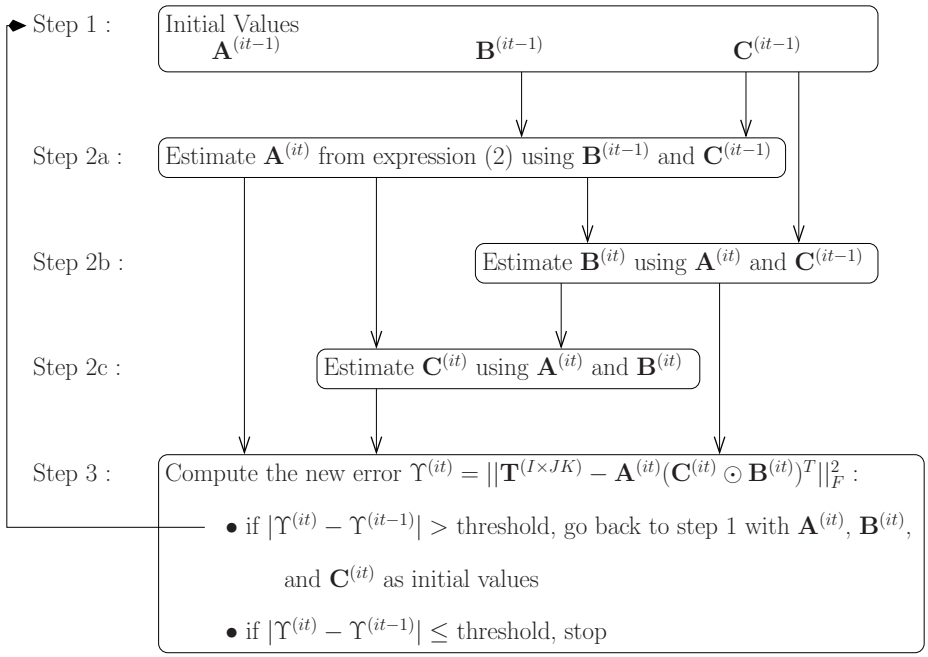

FIG. 1. *Steps of the ALS algorithm.*

to extrapolate, or more precisely, they propose to predict the value of the loading factors a certain number of iterations ahead by computing a sort of linear regression:

$$\mathbf{A}^{(new)} = \mathbf{A}^{(it-2)} + R_{LS}(\mathbf{A}^{(it-1)} - \mathbf{A}^{(it-2)}) \tag{3}$$

$\mathbf{A}^{(it-1)}$ is the estimate of matrix $\mathbf{A}$ obtained in the ALS iteration $(it-1)$, and $\mathbf{A}^{(new)}$ is the matrix that will be used in the itth iteration instead of $\mathbf{A}^{(it-1)}$. $(\mathbf{A}^{(it-1)} - \mathbf{A}^{(it-2)})$ defines the direction of the cycle. Matrices $\mathbf{B}^{(new)}$ and $\mathbf{C}^{(new)}$ are obtained in an equivalent way using the same relaxation factor R_{LS}. Of course, extrapolation should be very simple and does not make sense if it requires more time than the corresponding iterations. The simplest case is, of course, when R_{LS} is given a fixed value (between 1.2 and 1.3) [9], or is set to $it^{1/3}$ [2].

At every iteration it, the "new" loading factors are used to compute the error

$$\Upsilon^{(new)} = \| \mathbf{X}^{(I\times JK)} - \mathbf{A}^{(new)}(\mathbf{C}^{(new)} \odot \mathbf{B}^{(new)})^T \|_F^2 . \tag{4}$$

If $\Upsilon^{(new)} \geq \Upsilon^{(it-1)}$, then this means that we went too far in the extrapolation because R_{LS} is too large; R_{LS} is decreased, and we take the loading factors of iteration $(it-1)$ instead of the "new" ones. However, if $\Upsilon^{(new)} < \Upsilon^{(it-1)}$ then acceleration is accomplished and we gain some iterations.

The steps of the ALS algorithm with line search, as proposed by Andersson and Bro in [1], are summarized in Figure 2. The dashed area corresponds to the line search part.

Line search is executed after a few iterations of the ALS algorithm in order to wait for the system to stabilize. In [1] "few" is set to 6 but it could be higher depending on the data. The relaxation factor R_{LS} is defined for iteration (it) by : $R_{LS} = it^{1/n}$, with n fixed to 3 at the beginning of the simulation. When the acceleration fails several times (5 times in [1]), R_{LS} is decreased to $it^{1/(n+1)}$ and $\mathbf{A}^{(it-1)}$, $\mathbf{B}^{(it-1)}$, and $\mathbf{C}^{(it-1)}$

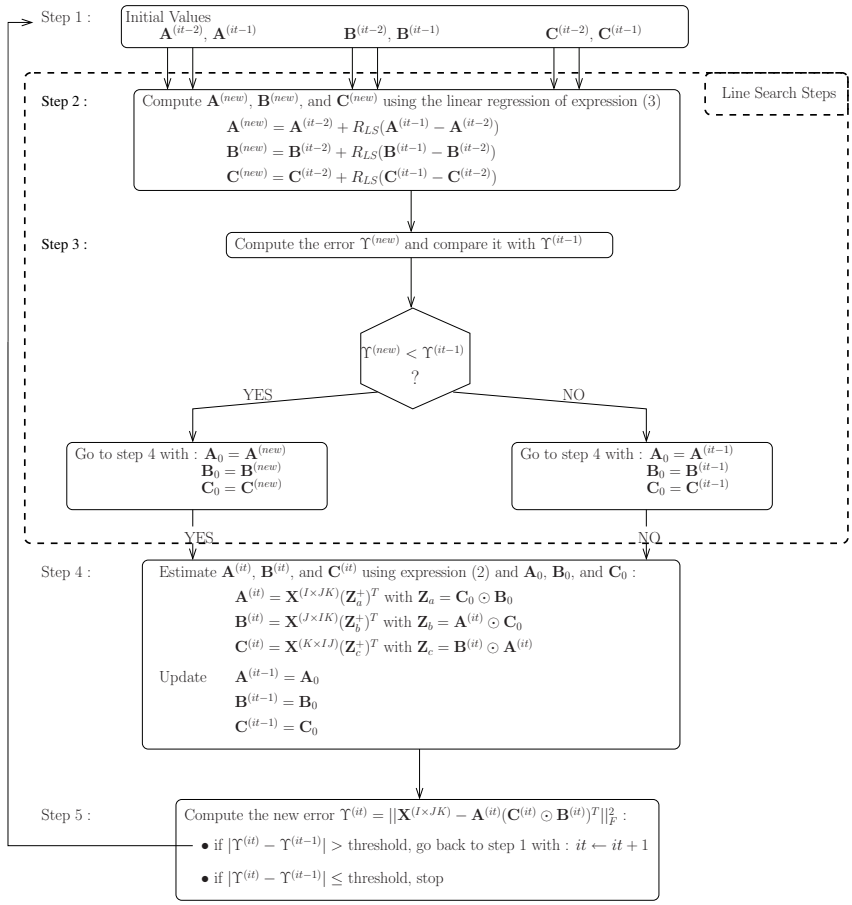

FIG. 2. *Steps of the ALS algorithm with LS.*

are used to update the loading factors of the current iteration (it) as described by the graph in Figure 2 at the end of the third step. However, when $\Upsilon^{(new)} < \Upsilon^{(it-1)}$, matrices $\mathbf{A}_0$, $\mathbf{B}_0$, and $\mathbf{C}_0$ are set to $\mathbf{A}^{(new)}$, $\mathbf{B}^{(new)}$, and $\mathbf{C}^{(new)}$, respectively. After estimating the loading factors at step 4, we update the loading matrices of iteration $(it-1)$ to $\mathbf{A}_0$, $\mathbf{B}_0$, and $\mathbf{C}_0$, and use them with those of iteration (it) for the next iteration (unless the algorithm has converged).

The fact that R_{LS} has a small value would suggest that the acceleration is not very efficient. This is not true since the effect of R_{LS} is compounded from one iteration to the next, leading eventually to a noticeable reduction of the number of iterations, as shown in Figure 10.

This linear extrapolation was applied to our synthetic data in section 5.6, as a basis for comparison with our ELS method. We will see that it can produce a clear improvement, for example reducing iterations in one example from about 10,000 to 5,000. However, since the number required is still high, it is still of interest to look for a novel method to reduce the number of iterations even further.

4. Enhanced line search (ELS). The idea of the enhanced line search (ELS) consists of seeking the optimal relaxation factor R_{LS} that leads to the final solution of a given cycle in only one step. For iteration (it), define $\mathbf{G}_a^{(it)} = \mathbf{A}^{(it-1)} - \mathbf{A}^{(it-2)}$ as the

direction of the cycle for loading matrix $\mathbf{A}$. $\mathbf{G}_b^{(it)}$ and $\mathbf{G}_c^{(it)}$ are defined equivalently. Instead of fixing a single value R_{LS} for the three modes as in expression (3), we may look for the optimal triplet (R_a, R_b, R_c) that minimizes

$$\begin{aligned}\Upsilon_{ELS} =& \| \mathbf{X}^{(I\times JK)} - (\mathbf{A}^{(it-2)} + R_a\mathbf{G}_a^{(it)}) \\ & \left((\mathbf{C}^{(it-2)} + R_c\mathbf{G}_c^{(it)}) \odot (\mathbf{B}^{(it-2)} + R_b\mathbf{G}_b^{(it)})\right)^T \|_F^2 \,. \end{aligned} \tag{5}$$

ELS is performed at the beginning of the ALS algorithm as shown in Figure 3, where step $1'$ corresponds to the ELS part. Relaxation factors applied to the loadings are no longer fixed as for the line search method in Figure 2, but they are computed at step $1'$ of Figure 3 as the optimal values that provide the smallest error Υ_{ELS}. At step 3, after estimating the loading matrices of iteration (it), we update those of iteration $(it-1)$ to $\mathbf{A}^{(new)}$, $\mathbf{B}^{(new)}$, and $\mathbf{C}^{(new)}$. Loading matrices of both iterations $(it-1)$ and (it) will then be used in the next iteration if the algorithm does not reach convergence.

The optimal solution is obtained when we jointly minimize Υ_{ELS} w.r.t. the three different factors R_a, R_b, and R_c. In this case the problem consists of solving a system of three polynomials in three unknowns, which leads to a high numerical complexity. Solutions with a smaller complexity are obtained by taking only two unknowns, or the same factor for all the modes $R = R_a = R_b = R_c$. Some of the possible optimizations are listed below:

- (R_a, R_b, R_c) which gives the optimal solution and involves a polynomial in three unknowns of degree 6.
- (R, R, R_c) where we use the same factor for $\mathbf{A}$ and $\mathbf{B}$ and we minimize Υ_{ELS} w.r.t. two variables R and R_c. This involves a polynomial in two unknowns of degree 6.
- (R, R, R) where we use the same factor for all matrices and involves a polynomial in a single unknown of degree 6.
- $R(R_b, R_c)$ where we use the relaxation factor of line search $R = it^{1/3}$ for matrix $\mathbf{A}$, and minimize (5) w.r.t. R_b and R_c. This involves a polynomial in two unknowns of degree 4.
- $R(R, R)$ which is the same as $R(R_b, R_c)$ with $R_b = R_c$, and involves a polynomial in a single unknown of degree 4.
- $R, R(R)$ where we optimize only w.r.t. to R_c.

In this article, the exploration of alternative ELS models is initiated by implementing (R, R, R), which is the simplest one that is "fully ELS." In this case, the error Υ_{ELS} is a polynomial of degree 6 in R (we omit the iteration index (it) to simplify the notation):

$$\begin{aligned}\Upsilon_{ELS}(R) &= \sum_{ijk}\left(X_{ijk} - \sum_{f=1}^{F}(A_{if} + RG_{a,if})(B_{jf} + RG_{b,jf})(C_{kf} + RG_{c,kf})\right)^2 \\ &= \sum_{d=0}^{6} p_d R^d, \end{aligned} \tag{6}$$

where p_d, $d = 0, \ldots, 6$ are functions of observed values stored array $\mathbf{X}$ and coefficients

of loading matrices of iterations $(it-1)$ and $(it-2)$; the expression of p_d are given in section A.2. To find the optimal R it suffices to determine the roots of polynomial $\Upsilon'_{ELS}(R)$, which provides five possible values of R. We feed those values into expression (6) and keep the one that gives the smallest error Υ_{ELS}.

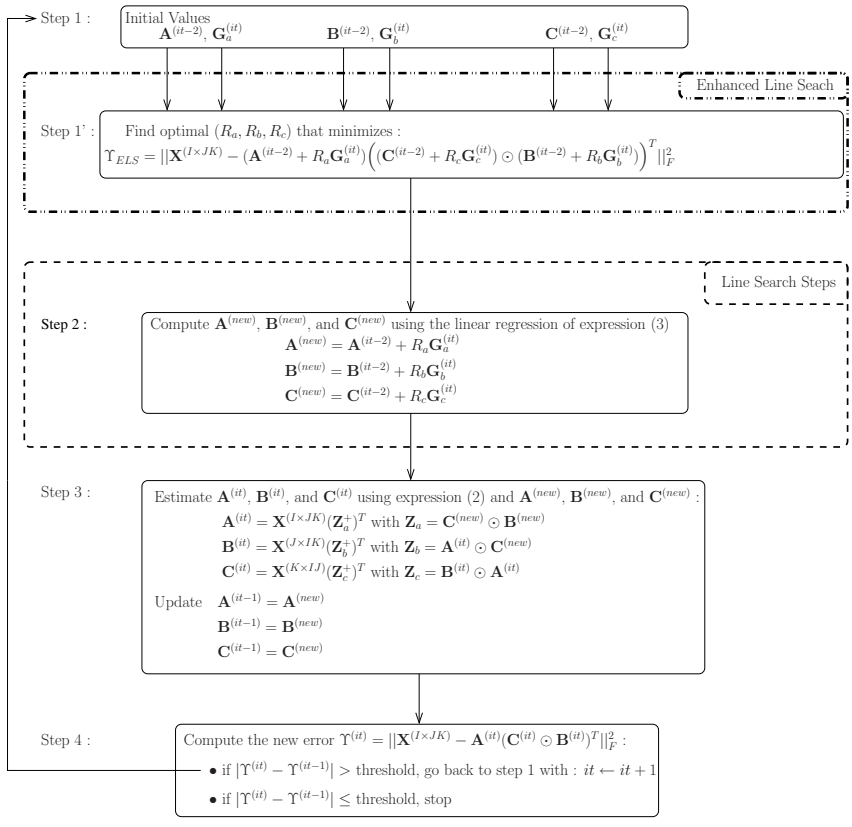

FIG. 3. *Steps of the ALS algorithm with ELS.*

To obtain some insight into whether the extrapolation is likely to be advantageous in the short-range sense (cf. question (i) posed at the end of this section), we can estimate the relative computation required by a single ELS iteration compared to LS. To do this, we compute the complexity of ALS and compare it with the complexity of optimization (R, R, R), for example. At each ALS iteration the following steps are performed:

1. Compute the optimal relaxation factor R by minimizing expression (5). To do so, take the derivative of (5) w.r.t. R, and root the obtained polynomial of degree 5 in one unknown.

2. Compute the new loading factors as in (3) and compute the corresponding error Υ_{new} given by expression (4).

3. Use $\mathbf{A}^{(new)}$, $\mathbf{B}^{(new)}$, and $\mathbf{C}^{(new)}$ as starting values for the PARAFAC iteration instead of $\mathbf{A}^{(it-1)}$, $\mathbf{B}^{(it-1)}$, and $\mathbf{C}^{(it-1)}$, and estimate the first loading factor $\widehat{\mathbf{A}}$ as shown in (2).

4. Perform step 3. To estimate each of the remaining loading factors $\widehat{\mathbf{B}}$ and $\widehat{\mathbf{C}}$, by using matrices $\widehat{\mathbf{A}}$ and $\mathbf{C}^{(new)}$ to estimate $\widehat{\mathbf{B}}$, and matrices $\widehat{\mathbf{A}}$ and $\widehat{\mathbf{B}}$ to estimate $\widehat{\mathbf{C}}$.

According to the details given in section A.1, one (ALS+ELS) iteration corresponds to about $(F + 7F^2)(IJ + JK + IK) + 3IJKF + 11F^3 + 2F^2(I + J + K) + (8F + 10)IJK$ multiplications. For instance, this equals 2601 multiplications, when $I = 2$, $J = 3$, $K = 3$, and $F = 3$. Without ELS, ALS requires $(F + 7F^2)(IJ + JK + IK) + 3IJKF + 11F^3 + 2F^2(I + J + K)$, which means 1989 multiplications in the same conditions. On the other hand, ELS makes the number of iterations decrease from 7100 to 250 iterations, hence allowing a decrease of the overall complexity from 14121900 to 650250 multiplications.

It is worth noting that $\Upsilon^{(new)}$ is always smaller than $\Upsilon^{(it-1)}$ when we use optimal values for R_a, R_b, and R_c as is the case for the first three optimizations. However, when we use a fixed relaxation factor as in LS, $\Upsilon^{(new)}$ can exceed $\Upsilon^{(it-1)}$, which means that the acceleration may fail.

This can explain the fact that, in theory, a single iteration of ELS should always improve fit as much as and almost always more than LS at any given point in the solution space. The questions then become: (i) Does the fit improvement turn out to be more beneficial than the cost of added computation is detrimental? (ii) Does the method find a significantly better path to the solution? Question (ii) is particularly important in cases where progress becomes very slow because of local characteristics of the hypersurface along which the fitting procedure is moving. Question (ii) is much subtler than (i). For example, one can easily imagine that a good long-range method might trade off some locally slower steps for a much better path a bit further along (a shortcut just over the horizon). This sort of question can only be answered well through application of a method to simulated and/or real data.

5. Computer results. To compare the performance of ELS to LS, a standard PARAFAC program was minimally modified to change the line search to ELS and to record time and fit information on each iteration. The test datasets were three-way and four-way synthetic data arrays, constructed according to the PARAFAC model to have specific kinds of factor structure and levels of random error. Then, in each test, the two algorithms were given identical problems; that is, they were given the same synthetic datasets, with the same analysis options, and started from the same random starting positions. This allowed us to compare the progress of the two methods step-by-step as they proceeded from a given starting point toward the best least-squares solution.

To obtain a general picture of the relative performance of ELS and LS, we considered a wide range of datasets[1]. A fully systematic exploration has not yet been completed, and even the partial results obtained so far require much more space than is available for this article, so we present here summary conclusions for each of our main test conditions, and give a few illustrative examples.

In most experimental conditions (i.e., most of the data structure types tested), the iteration count for ELS was substantially lower than that for LS, and in no condition was it (reliably) higher. This is consistent with the theoretical expectations described earlier. On the other hand, ELS *execution times* were longer than LS by

[1]We took as our "standard" the PARAFAC function contained in Andersson and Bro's [1] N-way Toolbox for MATLAB (which may be found at http://www.models.kvl.dk/source/nwaytoolbox/index.asp). The same MATLAB code was used except that the ELS extrapolation code replaced the LS extrapolation code in the function. In both versions of the PARAFAC function, a few lines were inserted that obtained time information on each iteration and saved it along with the current value of fit computed by the program at that iteration. Release 7 of MATLAB was used in all experiments.

more than we expected—generally the ratio of ELS to LS execution time per iteration was always the same for any given problem, but was larger than we would predict from our approximate estimates of complexity computation; despite streamlining and vectorization of the code, the ELS to LS ratio was still somewhat larger than our complexity estimates by roughly a factor of three. This might be due to inefficiencies in our ELS algorithm, or perhaps some particularly efficient features in the LS code, or as yet unanticipated considerations. Since reduction in the execution time is the goal of the proposed method, we feel that it is important to communicate both the time and iteration reductions we have observed, even though we are not yet sure of how to interpret the time information (or even whether or not it is somehow artifactual). We will describe a theoretical adjustment that brings times in line with computational complexity, and this provides one way of dealing with the current uncertainty in our timing results.

Complexity differences. In applications where the rank F is small in the sense of inequality (7) given in the appendix, the (R, R, R) version of ELS will significantly increase the complexity per iteration, and hence the CPU time required per iteration over that of LS. Whether or not ELS is attractive thus depends in part on the problem size and dimensionality.

Datasets sizes and numbers of factors to be extracted from them vary from one discipline to the next. In chemometrics and signal processing, typical problems might involve data arrays of the order of $60 \times 60 \times 20$ and perhaps three or four factors to be extracted. In such cases, the computational complexity of ELS is approximately three times that of LS, at least as estimated by the formulae in the appendix. For these problems, use of ELS would be attractive only for classes of problems in which it is clearly superior to LS in ability to traverse the curvature of the solution space. To provide a benefit beyond the use of LS, the ELS method needs to reduce the number of iterations required by LS.

It turns out that a single "bottleneck"—one of the most common and simple kinds of convergence slowdown—appears to have the required properties. We have also found other classes, such as triple bottleneck, where ELS will actually increase substantially the time needed to find the solution.

The data variation that turned out to have the most important impact on the relative performance of the two methods was the factor correlation structure both within and across modes. When no modes had collinear factors and all factors were of roughly equal size, there was no convergence difficulty for either method. For example, midsized datasets (e.g., $45 \times 40 \times 35$) often satisfied the convergence criterion—usually a change in root mean square error (RMS) of 10^{-8} between successive iterations—in 15–75 iterations. ELS usually took fewer iterations to converge, but the iterations were slower. In other words, with our MATLAB implementation, ELS often took on the order of 15%-25% *more time* than LS to reach the convergence criterion, even if figures given by computational complexity calculations are more optimistic.

5.1. Dealing with bottlenecks. We have considered several different situations where convergence of ALS PARAFAC algorithms become slow, but have focused mainly on the one that is the simplest and (outside of the social sciences) the most common: simple factor collinearity. This has several different versions; some or all factors can be collinear in one or several factor loading matrices that define the variation structure of an array. We only briefly look at the other important case—the more complicated kind of convergence difficulties caused by "degenerate PARAFAC solutions."

When one of the factor matrices in the optimal solution has two or more collinear columns, resolving them can seriously slow down the overall progress of ALS estimation of the factors, even though the solution may eventually be well defined. Harshman terms this situation a "bottleneck" [12]. When such collinearity is present in two or

three modes of the array (i.e., two or three of the "latent" factor loading matrices), then one has a structure with a "double" or "triple" bottleneck. We created synthetic data involving single, double, and triple bottleneck structure to test the performance of ELS vs. LS in these conditions. The (R, R, R) version of ELS that we used for these tests behaved quite differently in single vs. multiple bottleneck situations—at least for three-way arrays.

5.2. Single bottleneck situations: When factors in one mode are collinear. In our tests, ELS always outperformed LS when only one mode had factor loading vectors that were almost collinear, providing the analysis reached a global optimum in which all factors were approximately recovered. The time and iteration values observed in one such run are shown in Figure 4.

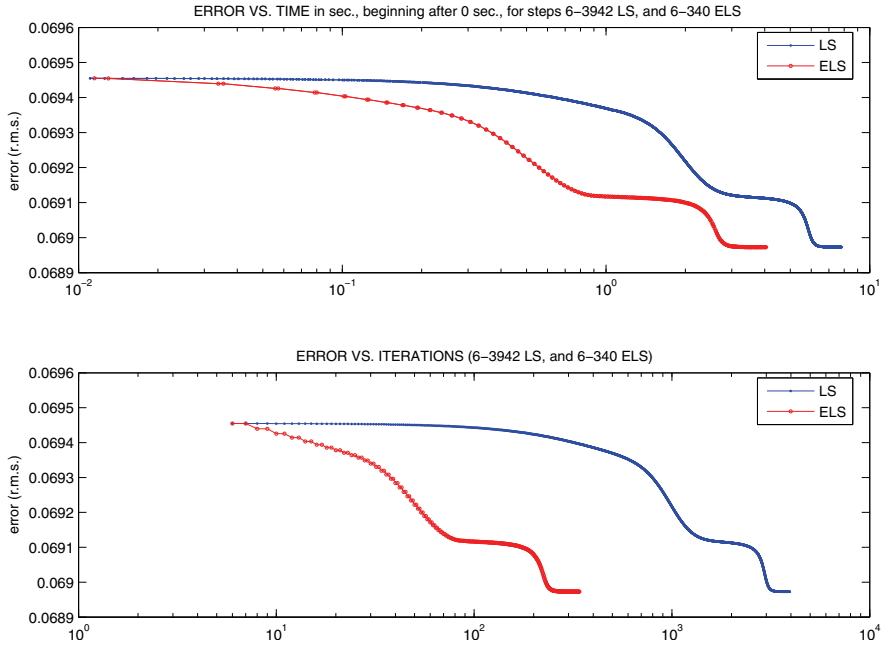

FIG. 4. *Performance of ALS with both LS or* (R, R, R)*-ELS accelerations, on a* $12 \times 11 \times 10$ *array of rank* 5*, in the presence of a single bottleneck (*3 *factors out of* 5 *are almost collinear in one of the* 3 *modes).*

The example shown is for an array with 5 factors and the lowest level of random noise used in the tests (0.1%). Three of the factors were almost collinear (separated by 10 degrees in the Mode C factor space) while the other two were roughly orthogonal to the other factors. The shape of the curves is quite similar. This suggests that the two algorithms are following "similar" or somewhat parallel paths through the solution space, and are encountering a similar sequence of more and less difficult regions in the solution space, but they are progressing at different rates because ELS tends to make bigger improvements in fit. As shown here, ELS often reduced the total number of iterations by approximately an order of magnitude, but because its iterations took somewhat longer (at least with our MATLAB implementation), the time reduction was between half and two-thirds of the size of the reduction in iterations. The fit and time curves in Figure 4 are based on a relatively small dataset ($12 \times 11 \times 10$ with five factors). In that case, index (7) is 1.37, which shows that an ELS iteration is more complex than LS.

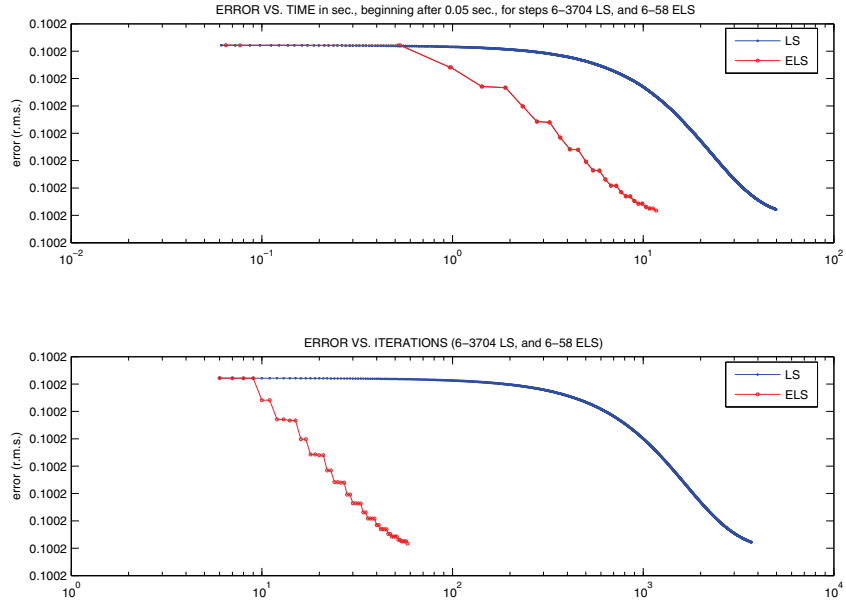

FIG. 5. *Performance of ALS with both LS or* (R, R, R)*-ELS accelerations, on a* $80 \times 60 \times 20$ *array of rank* 5*, in the presence of a single bottleneck.*

With the larger dataset considered next, index (7) is even smaller, and the relative computational complexity of ELS is at least three times that of LS per iteration. Our MATLAB implementation takes closer to 9 times as much time, for reasons that we are not yet able to fully explain. ELS is, however, still attractive in this low-rank large-dimension case, despite the relatively high complexity per iteration.

Note the clear two-step pattern in Figure 5, both in the fit drop and in the associated time needed at each successive iteration (i.e., two-iteration values are close to one another, and then there is a larger interval, and two are close to one another again). The pattern is present in both curves, but is much more obvious in the ELS curve because of the rapid drop in fit at every other step. This "paired-step" pattern is due to the way LS is currently implemented in the PARAFAC function for the N-way toolbox. The program collects two sets of loadings, from two successive iterations, and then extrapolates based on those two, and collects two more, etc. Thus the extrapolation occurs on every other iteration. Because ELS was incorporated into the exact same loops that governed LS, it too is applied on every other iteration.

Our tests indicate that LS is considerably more effective when the extrapolation is performed on every iteration, as in the original extrapolation used in Harshman 1970 [9]. However, we concentrate in this article on a direct comparison of paired-step LS with paired-step ELS (we have also begun some comparisons between the two methods when both are performed at every iteration, and our preliminary results suggest that in this case the performance difference between them is smaller).

For this dataset, as with all other "single bottleneck" cases we have tested, paired-step ELS clearly outperforms paired-step LS—so long as they find the global optimum. However, when the path taken by an analysis traps it in a local optimum, or when some of the highly collinear factors are too poorly resolved due to error in the data, the behavior of LS and/or ELS changes and the time advantage offered by ELS is reduced or eliminated. ELS continues to require fewer iterations, but the difference between the counts becomes small enough that ELS does not reduce the overall time

(at least with our MATLAB implementation).

5.3. Multiple bottlenecks and degenerate solutions. Multiple bottlenecks and degenerate solutions appear when experimental requirements or practical limitations in data collection make collinearity of some factors unavoidable; this most commonly applies to only one mode of the data array. The previous results are for single-mode bottlenecks which leads us to the tentative conclusion that for such cases ELS would seem an attractive estimation method. There are situations, though, in which some subset of the factors will be collinear in two modes, or even in all three modes of a three-way array. Our experiments therefore simulated these (less common) kinds of data as well. We found that the advantage of ELS does not generally extend to these situations. The curvature of the path to the optimum gets more complicated and apparently makes ELS "shortcut" methods less successful. This is another demonstration of the subtlety of the considerations involved in nonlinear extrapolation of PARAFAC solutions.

Neither double- nor triple-bottleneck situations benefited much from the simplest (R, R, R) version ELS. In general, the *time* required by our MATLAB implementation to reach the converged solution was increased. However, our test cases often were hard to fit, so we had to take care to distinguish global optimum cases from local optimum ones. To obtain global optima with adequate frequency in the double-bottleneck case, the angle between factors had to be increased to moderate values (25 degrees in the case of Figure 6), making the collinearity in individual factor spaces less extreme but the combined effects of the collinearity in the two or three modes was still fairly severe. Unfortunately, even in clear cases of having reached the global optimum, where recovery of all factors was close to perfect (when the noise level was set at 0.001), the ELS method usually took longer (in CPU time) to converge than simple LS. Figure 6 shows the results of one such triple-bottleneck case.

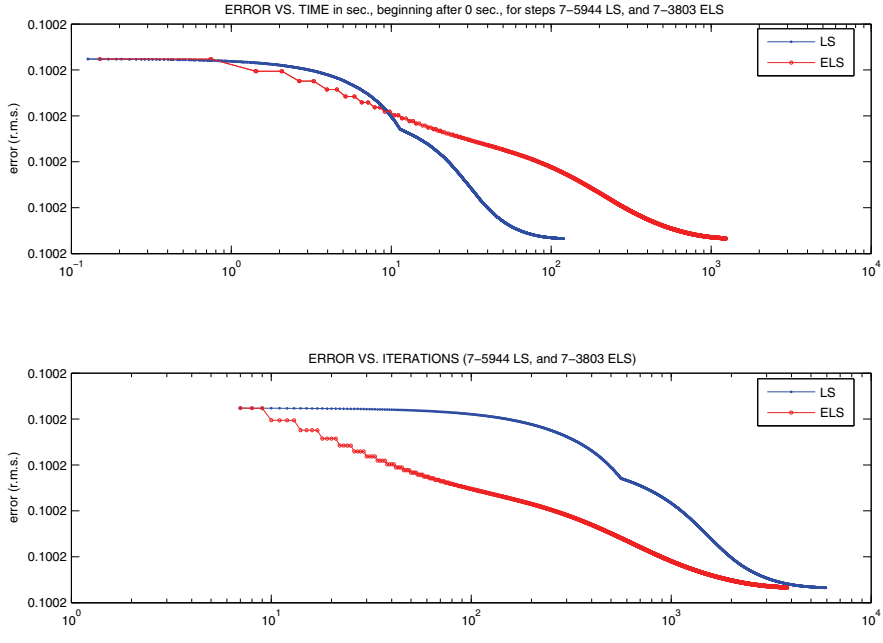

FIG. 6. *Performance of ALS with both LS or* (R, R, R)*-ELS accelerations, on a* $80 \times 60 \times 20$ *array of rank* 4*, in the presence of a triple bottleneck.*

5.4. Degenerate and quasi-degenerate solutions. There is another important situation in which serious convergence difficulties arise. This happens when the factors are not particularly collinear on average, but the angle between them varies greatly across levels of the array (i.e., differs across values of the third array index). This kind of variation in factor structure is not consistent with the PARAFAC model. However, PARAFAC can fit part of the "axis wobble" or "Tucker Variation" [14] by reweighting axes after the space has been sheared [11]. Thus, when too much axis "wobble" is present, the **A**, **B**, and **C** factor spaces become inversely sheared to better fit it, creating a "degenerate solution," which involves strong collinearities and seriously impedes convergence. Degenerate solutions are usually dealt with by imposing constraints. However, speedup methods like ELS could be useful if they accelerated progress through "swamps" or deep into a swamp to find a final solution. In our initial tests of the (R, R, R) method, ELS has not been helpful in dealing with swamps, but it is not unreasonable to conjecture that versions more sophisticated than (R, R, R), as suggested in section 4, might do better in these situations.

5.5. A four-way example with two collinear and two noncollinear modes. From the experiments reported so far, it is unclear whether the relative lack of ELS success when applied to factor structures with double and triple bottlenecks is because of too many bottlenecks or too little "wiggle room." That is, we cannot distinguish the cases that have multiple modes with bottlenecks from those that do not have multiple modes without bottlenecks. In the present section, we report some earlier studies on the impact of ELS on ALS in four-way arrays. In these arrays, two modes have almost collinear factors and two do not. If multiple bottlenecks is what creates the convergence problem, then ELS should also encounter difficulties in these datasets. If lack of "wiggle room" is what creates the convergence problem, then ELS should be better at dealing with double bottlenecks.

The experiments we are about to describe are simpler in two important ways: (a) the tests did not measure or record *execution time* information; (b) the datasets were constructed as error-free arrays, that is, without adding any random noise. The first limitation makes the interpretation difficult, but the dramatic reduction in iteration counts does appear impressive when compared to the relatively modest differences in iterations in, for example, Figure 6. The second limitation can be minimized by qualifying our interpretation. The difference is nontrivial because when collinearities are combined with error, it can complicate the algorithm's task of resolving the highly similar factor profiles. However, the results are still informative if considered as demonstrating certain theoretical/mathematical properties of four-way (R, R, R)-ELS. They might also be interpreted as simulations of real world cases where the error is sufficiently small to make the behavior of the algorithms roughly equivalent to those found in these error-free cases.

We consider the four-way PARAFAC model:

$$X_{ijkl} = \sum_{f=1}^{F} A_{if} B_{jf} C_{kf} D_{lf},$$

where

$$\mathbf{A} = \begin{pmatrix} 1 & \cos(\theta) & 0 & \sin(\theta) \\ 0 & \sin(\theta) & 1 & \cos(\theta) \end{pmatrix},$$

$$\mathbf{B} = \begin{pmatrix} 3 & \cos(\theta) & 0 & \sin(\theta) \\ 0 & \sin(\theta) & 1 & \cos(\theta) \\ 0 & \sin(\theta) & 0 & \sin(\theta) \end{pmatrix},$$

and $\mathbf{C}$ and $\mathbf{D}$ are randomly generated matrices of size 3×4. The collinearity is controlled through variable θ. We take $\theta = \pi/60$ in Figures 7 and 8. The first and second columns of each of the matrices $\mathbf{A}$ and $\mathbf{B}$ are almost collinear as θ is very close to zero ($\theta \simeq 0.052$). The same thing holds for the third and fourth columns of $\mathbf{A}$ and $\mathbf{B}$.

This example demonstrates one of the cases where results of [25] and [21] cannot be applied, since there are more columns than rows in the loading matrices and so they do not have full column rank.

We notice from Figure 7 that ELS reduces the number of iterations needed to meet the criterion for approximate convergence from more than 10000 to about 2000! We report in Figure 8 the median of the loss function for one dataset, over 100 independent trials (with 100 different random initial values). We notice that even though ALS + LS reaches the error 10^{-4} very quickly, it is then trapped for many iterations ("trapped in the bottleneck"). In contrast, ALS + ELS escapes comparatively quickly from the bottleneck (after 1000 iterations) and converges to smaller values of the error 10^{-12}, while ALS and ALS+LS remain in the plateaux 10^{-4} and 10^{-5}, respectively.

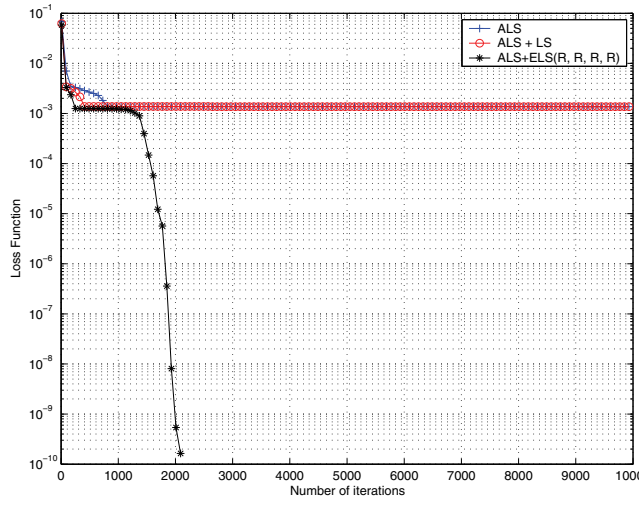

FIG. 7. *Loss function* Υ *as a function of the number of iterations for ALS with LS, and ELS with optimization* (R, R, R, R) *for* $\theta = \pi/60$.

Figure 9 appears to confirm this hypothesis by showing more frequent changes in parameter sets. It gives the variation of the coefficients of matrix $\hat{\mathbf{A}}$ as a function of the number of iterations. During progress through a bottleneck, the variation of $\hat{\mathbf{A}}$ coefficients is very small and this increases when we get out of the bottleneck. The same thing is evident in matrices $\hat{\mathbf{B}}$ and $\hat{\mathbf{C}}$.

5.6. ELS applied to blind channel identification of an UDM. This second four-way example demonstrates an application of ELS to blind identification of an under-determined mixture (UDM). Specifically, we use ELS to accelerate ALESCAF, the algorithm proposed in [7] for blind channel identification based on the characteristic function in an UDM.

Using the notation defined in [7], ALESCAF leads to a four-way PARAFAC model:

$$\mathbf{T}^{(P \times KP^2)} = \mathbf{A}(\mathbf{D} \odot \mathbf{A} \odot \mathbf{A})^T.$$

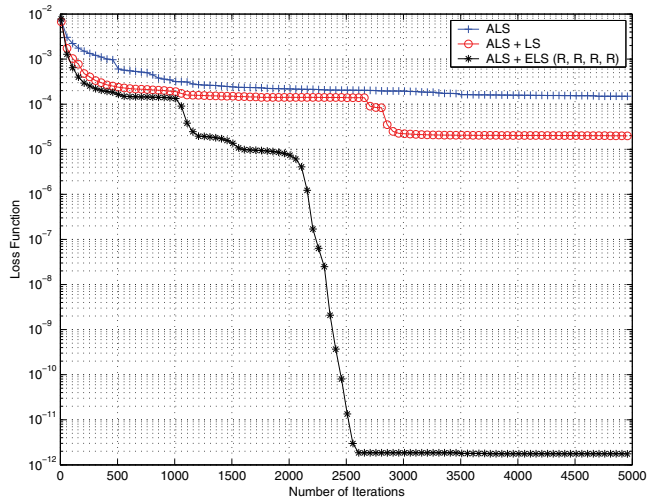

FIG. 8. *Loss function* Υ *as a function of the number of iterations for ALS with LS, and ELS with optimization* (R, R, R, R) *for* $\theta = \pi/60$*, median value over* 100 *independent trials.*

The array $\mathbf{T}$ contains the third derivatives of the joint characteristic function of the observations computed at K points of the grid Ω. Matrix $\mathbf{D}$ is obtained from the independence property of the sources and its entries are defined as

$$D_{kn} = \psi_n^{(3)} \left(\sum_q A_{qn} u_q[k] \right),$$

where $1 \leq k \leq K$ and $1 \leq n \leq N$. $\mathbf{A}$ is the channel matrix of size 2×3 to be identified.

As in our earlier tests, we use the MATLAB ALS implementation of PARAFAC made available by Andersson and Bro (http://www.models.kvl.dk) and described in [1]. Also as before, we create our ELS version by replacing their LS procedure by our ELS procedure, this time the (R, R, R, R) version. The three sources are BPSK, and we generate an "infinite block" of data by taking all of the 2^3 possible combinations of $\{-1, 1\}$, and we take 10000 as the maximum number of iterations. As in the previous four-way example, noise is not taken into account.

In Figure 10 we report the gap between estimated and actual mixing matrix using ELS and compare it with ALS with LS and nonaccelerated ALS. Figure 11 gives the error as a function of the number of iterations. The figure shows that ELS is very useful for reducing the number of iterations needed in three-bottleneck versions of four-way arrays. The number of iterations decreases from 5000 when using ALS with LS, to 500 when using optimization (R, R, R, R) of ELS. On the one hand, these results seem to be too dramatic to be "canceled out" by increases in iteration time, but on the other hand, the LS and ELS parameter changes (Figure 11) make us somewhat more cautious, since these seem more similar.

Overall, these four-way results encourage us to hope that when there is at least one mode that is free of collinearities, this type of ELS might be generally helpful.

A few cautionary points should be noted: When making comparisons of the methods, it might be wise to underemphasize the dramatic ELS drops of the error (or objective function) when the value falls below something like 10^{-3} or 10^{-4}, since these would be impossible with most real data containing measurement error or other disturbances of the data values. It is also not known how the behavior in the graphs

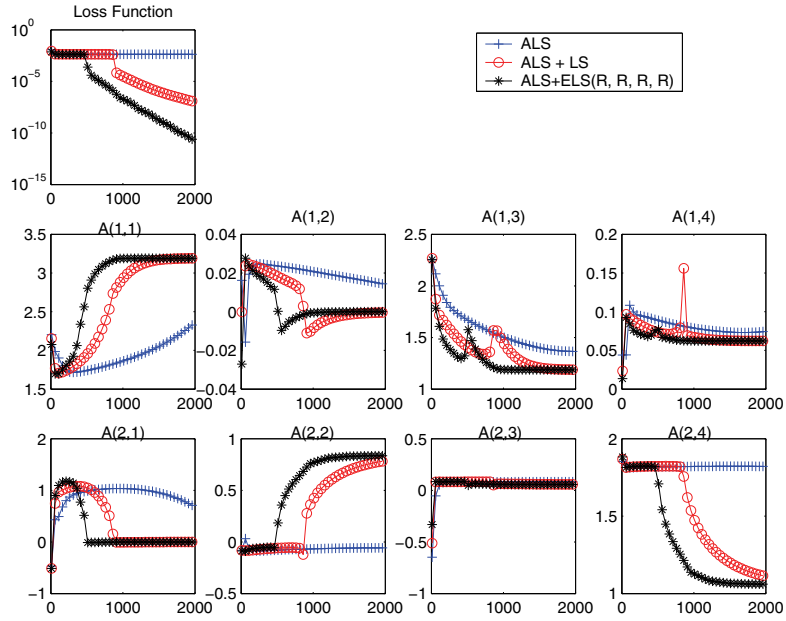

FIG. 9. $\hat{\mathbf{A}}$ *coefficients as a function of the number of iterations.*

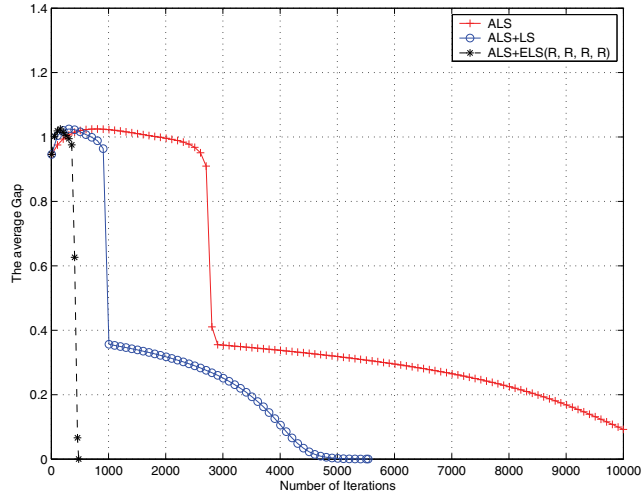

FIG. 10. *Gap between estimated and original channel matrix as a function of the number of iterations using ALS, ALS with LS, and ALS with ELS.*

associated with our four-way examples might be modified even at higher levels by the presence of random error; the three-way experiments suggest that some differences can be expected.

6. Concluding remarks. ELS is a novel technique aiming at accelerating convergence of the ALS algorithm when used to fit the PARAFAC model. Our simulations indicated that ELS could be a very attractive way to deal with "single bottleneck" situations—three-way arrays that have factor collinearities in one of the modes. As

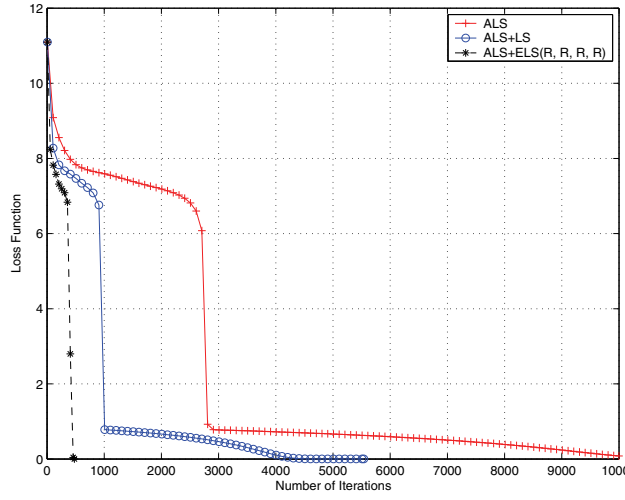

FIG. 11. *Loss function* Υ *as a function of the number of iterations using ALS, ALS with LS, and ALS with ELS.*

shown in Figures 4 and 5, ELS often decreased the number of iterations by an order of magnitude and the time to convergence by at least half to two-thirds of an order of magnitude (except when trapped in a local optimum). This was more than enough to counterbalance the longer iteration times due to the higher computational complexity.

On the other hand, in double- and triple-bottleneck three-way factor structures (i.e., where at most only one mode is free of collinearities), the (R, R, R) version of ELS that was tested here did not offer an advantage, but instead appeared to lengthen the overall time to convergence. However, we remain open to the possibility that our MATLAB time information is somehow unrepresentative or at least does not reflect what might be possible.

Two applications involving four-way arrays (with high rank) lacked information on execution time but some comparison based on computational complexity ratios could be a basis for tentative predictions. The encouraging reductions in iterations seen here open up the possibility that even when an array has three modes with collinearities, this is not necessarily a problem for ELS—if there is also one mode without factor collinearities. This possibility should be explored further.

This article presents some initial exploration of a nonlinear approach to ALS extrapolation, but the investigation is obviously a work in progress. Our theoretical understanding of multistep properties of ELS is still quite incomplete. We have identified some classes of problems where it works better than LS and others in which it may not. The dramatic improvements that can be obtained by ELS in "single bottleneck" situations is well demonstrated. And even if the (R, R, R) implementation of ELS reaches its limits and does not perform significantly better than LS in the absence of two noncollinear modes, or in the presence of convergence swamps arising from "degenerate PARAFAC solutions," there may be other implementations of ELS, such as that called $R(R, R)$ in section 4, which could be more successful in these circumstances. These issues remain to be studied.

Appendix A.

A.1. ELS steps and complexity. During one iteration of the ALS algorithm, the following operations are performed (we list the operations for the estimation of

$\widehat{\mathbf{A}}$, but similar operations are required for the two other loading factors):

1. Compute the Khatri–Rao product to obtain matrix $\mathbf{Z}^a$. This costs FJK multiplications.

2. Compute $\mathbf{Z}_a^+$ by reduced SVD of $\mathbf{Z}_a$, which requires $7JKF^2 + \frac{11}{3}F^3$ multiplications.

3. Estimate the factor loading $\widehat{\mathbf{A}}$ as shown in expression (2), which requires $IJKF + IF^2 + IF$ multiplications (if we assume $F \leq JK$).

As a consequence, the whole ALS iteration for the 3 modes requires an order of $(F + 7F^2)(IJ + JK + IK) + 3IJKF + 11F^3 + 2F^2(I + J + K)$multiplications.

Now let us evaluate the additional computational complexity involved by ELS. In order to do this, note that the ELS criterion can be rewritten as

$$\Upsilon_{ELS} = \sum_{ijk} \left[Y_{ijk} + R\, D_{ijk} - R^2\, E_{ijk} + R^3\, F_{ijk} \right]^2 .$$

The explicit calculation of arrays $\mathbf{Y}$, $\mathbf{D}$, $\mathbf{E}$, and $\mathbf{F}$ requires an order of $8IJKF$ multiplications. Next, the calculation of the coefficients of the degree-6 polynomial in R requires $10IJK$ multiplications. The computation of stationary points and the selection of the absolute minimum yield a negligible complexity since of order $O(5^3)$. As a conclusion, the additional complexity generated by ELS is thus of order $(8F+10)IJK$ multiplications when we choose the optimization with respect to a single factor R, that is, (R, R, R) for a three-way PARAFAC model. This is not negligible and can be considered to be small only for large enough F and small enough dimensions. More precisely, if

$$F\left(\frac{1}{I} + \frac{1}{J} + \frac{1}{K}\right) \gg 1, \tag{7}$$

then the additional complexity required by ELS may be considered to be negligible over that of LS. For instance, this is the case of generic arrays of size $(I, J, K) = (10, 10, 10)$, which have a rank $F = 36$.

More generally, it is interesting to evaluate the computational complexity for N-way arrays of size $I_1 \times I_2 \times \ldots \times I_N$, when all of the dimensions are of the same order $O(I)$. For ALS we get $\frac{11}{3}NF^3 + 2F^2NI + NI^NF + 7F^2NI^{N-1} + FNI^{N-1}$. On the other hand, it can be shown that ELS requires $[2^N F + O(N^2)]I^N + O((2N-1)^3)$ additional multiplications.

A.2. Expression of p_d. We define $q_{f,d}$ for $d = 0, \ldots, 6$ as

$$\begin{aligned}
q_{f,0} &= A_{if}B_{jf}C_{kf}, \\
q_{f,1} &= A_{if}B_{jf}G_{c,kf} + A_{if}G_{b,jf}C_{kf} + G_{a,if}B_{jf}C_{kf}, \\
q_{f,2} &= A_{if}G_{b,jf}G_{c,kf} + G_{a,if}B_{jf}G_{c,kf} + G_{a,if}G_{b,jf}C_{kf}, \\
q_{f,3} &= G_{a,if}G_{b,jf}G_{c,kf}.
\end{aligned}$$

$q_{f,d}$ depends on i, j, k but we omit the indices for simplicity. Then polynomial coefficients p_d are given by

$$\begin{aligned}
p_0 &= \textstyle\sum_{ijk} \big(X_{ijk} - \sum_f q_{f,0}\big)^2,\\
p_1 &= -2\textstyle\sum_{ijk} \big(X_{ijk} - \sum_f q_{f,0}\big)\big(\sum_f q_{f,1}\big),\\
p_2 &= \textstyle\sum_{ijk} \big(\sum_f q_{f,1}\big)^2 - 2\big(X_{ijk} - \sum_f q_{f,0}\big)\big(\sum_f q_{f,2}\big),\\
p_3 &= 2\textstyle\sum_{ijk} \big(\sum_f q_{f,1}\big)\big(\sum_f q_{f,2}\big) - \big(X_{ijk} - \sum_f q_{f,0}\big)\big(\sum_f q_{f,3}\big),\\
p_4 &= \textstyle\sum_{ijk} \big(\sum_f q_{f,2}\big)^2 + 2\big(\sum_f q_{f,1}\big)\big(\sum_f q_{f,3}\big),\\
p_5 &= 2\textstyle\sum_{ijk} \big(\sum_f q_{f,2}\big)\big(\sum_f q_{f,3}\big),\\
p_6 &= \textstyle\sum_{ijk} \big(\sum_f q_{f,3}\big)^2.
\end{aligned}$$

SENSITIVITY ANALYSIS FOR THE PROBLEM OF MATRIX JOINT DIAGONALIZATION*

BIJAN AFSARI†

Abstract. We investigate the sensitivity of the problem of nonorthogonal (matrix) joint diagonalization (NOJD). First, we consider the uniqueness conditions for the problem of exact joint diagonalization (EJD), which is closely related to the issue of uniqueness in tensor decompositions. As a byproduct, we derive the well-known identifiability conditions for independent component analysis (ICA) based on an EJD formulation of ICA. We next introduce some known cost functions for NOJD and derive flows based on these cost functions for NOJD. Then we define and investigate the noise sensitivity of the stationary points of these flows. We show that the condition number of the joint diagonalizer and uniqueness of the joint diagonalizer as measured by modulus of uniqueness (as defined in this paper) affect the sensitivity. We also investigate the effect of the number of matrices on the sensitivity. Our numerical experiments confirm the theoretical results.[1]

Key words. joint diagonalization, independent component analysis (ICA), simultaneous diagonalization, sensitivity analysis, perturbation analysis, CANDECOMP/PARAFAC, tensor decompositions

1. Introduction and a case study.

Many interesting recent problems and paradigms in blind signal processing can be formulated as the problem of matrix joint diagonalization (JD). This problem in its simplest form can be phrased as follows: given a set of N symmetric matrices $\{C_i\}_{i=1}^N$ of dimension $n \times n$, find a nonsingular matrix B such that all BC_iB^T's are "as diagonal as possible," where B^T denotes the transpose of matrix B. Note that here diagonalization is meant in the sense of congruence. The matrix joint diagonalization problem is also referred to as simultaneous matrix diagonalization. In practice, i.e., when C_i's are constructed from empirical data, we do not expect a B to exist such that all BC_iB^T's are diagonal. Therefore, maybe a more exact name for this problem can be approximate joint diagonalization. Nevertheless, we choose to call this problem as joint diagonalization, where approximation is implicitly assumed, and we refer to the problem when exact joint diagonalization is possible as exact joint diagonalization (EJD).

Historically, the problem of matrix joint diagonalization in the signal processing community was first considered in the restricted form of orthogonal joint diagonalization (OJD) in [9], where an efficient algorithm for it was proposed. In the OJD problem the joint diagonalizer is assumed to be orthogonal. This situation can happen, for example, when one tries to blindly separate non-Gaussian sources that are spatially whitened [9]. The orthogonality assumption on B is not justified in many occasions, and one expects that by allowing more freedom in the search space "more

[1]While this paper was under review a few of its results were presented in ICASSP07 conference in Honolulu, HI [4].

diagonalization" would be possible. We refer to the problem of joint diagonalization, when B is only assumed to be nonsingular, as the problem of nonorthogonal joint diagonalization (NOJD). The focus of this paper is the NOJD problem.

Nonorthogonal joint diagonalization arises in a variety of problems. As a case study, we will see how the problem of independent component analysis (ICA) can be considered as an NOJD problem. In the problem of blind separation of nonstationary mixtures [21], one can perform NOJD on a set of correlation matrices to find the unmixing matrix. Blind separation of instantaneous mixtures using only second order statistics also results in NOJD of a set of covariance matrices [7]. Moreover, the NOJD problem is closely related to the problem of tensor decomposition and CANDECOMP/PARAFAC modeling [14, 11]. Since applications or algorithms are not the focus of this work, we will not cite numerous applications where the NOJD problem is useful. Instead, we consider the ICA problem, as a case study, to give the reader a feeling of the recurring situation, where the NOJD problem shows itself in numerous applications.

1.1. A case study: Independent component analysis (ICA). ICA [10] is one of the major paradigms in which joint diagonalization and tensorial methods have proven useful. We refer the reader to [13] for further discussion on this issue. The basic model in ICA is

$$\vec{\mathbf{x}}_{n\times 1} = A_{n\times n}\vec{\mathbf{s}}_{n\times 1}, \tag{1}$$

where $\vec{\mathbf{s}}_{n\times 1}$ is a random vector of dimension n with independent components of zero mean, and A is an $n \times n$ nonsingular matrix. We can think of $\vec{\mathbf{s}}_{n\times 1}$ to represent a source with independent components whose signals are mixed by the mixing matrix A and $\vec{\mathbf{x}}_{n\times 1}$ to represent the observed mixture. The problem is to find the matrix A or its inverse, assuming that only realizations or the moments of the random mixture $\vec{\mathbf{x}}_{n\times 1}$ are available . Obviously, we can only hope to find A up to column permutation and column scaling. The key assumption of independence of the elements of $\vec{\mathbf{s}}$ imposes some specific structure on certain matrices that can be formed from the cumulants of the observation $\vec{\mathbf{x}}$. The main theme here is that independence implies diagonality. We investigate this further. First, note that $R_{\mathbf{xx}}$, the covariance matrix of $\vec{\mathbf{x}}$, satisfies

$$R_{\mathbf{xx}} = A\Lambda_{\mathbf{ss}}A^T, \tag{2}$$

where $\Lambda_{\mathbf{ss}}$ is the (diagonal) covariance matrix of $\vec{\mathbf{s}}$. We can trace this structure in higher cumulants of $\vec{\mathbf{x}}$ as well. The kth order cumulant of a random vector $\vec{\mathbf{z}}_{n\times 1}$ is a tensor $\mathcal{C}^k_{\mathbf{z}}$ of order k and dimension $n \times \cdots \times n$. The cumulants are closely related to the moments, and they give information about the shape of the probability density function of $\vec{\mathbf{z}}_{n\times 1}$. In fact, the second order cumulant tensor is the covariance matrix. Each element of $\mathcal{C}^k_{\mathbf{z}}$ can be indexed by k indices $i_1, \ldots, i_k$, where $1 \le i_1, \ldots, i_k \le n$. If we fix all but two indices and vary the remaining two indices we obtain a matrix slice of the tensor. The notation $\mathcal{C}^k_{\mathbf{z}}(i_1, i_2, \ldots, i_{k-2}, :, :)$ represents such a matrix that is found by fixing all but the last two indices. An important fact is that, if $\vec{\mathbf{z}}_{n\times 1}$ is of independent components, then its cumulant tensors of any order are diagonal. Since $\vec{\mathbf{s}}_{n\times 1}$ is of independent components, its cumulant tensors are diagonal, i.e., only the elements $\mathcal{C}^k_{\mathbf{s}}(i, \ldots, i)$ can be nonzero. Based on the multilinear property of cumulants we can show that for $k \ge 3$:

$$\mathcal{C}^k_{\mathbf{x}}(i_1, i_2, \ldots, i_{k-2}, :, :) = A\Lambda_{i_1 i_2 \ldots i_{k-2}}A^T, \tag{3}$$

where $\Lambda_{i_1 i_2 \dots i_{k-2}}$ is a diagonal matrix that depends on elements of A and $\mathcal{C}_{\mathbf{s}}^k(i,\dots,i)$'s, the auto-cumulants of $\vec{\mathbf{s}}$, as

$$[\Lambda_{i_1 i_2 \dots i_{k-2}}]_{ii} = a_{i_1 i} a_{i_2 i} \dots a_{i_{k-2} i} \mathcal{C}_{\mathbf{s}}^k(i,\dots,i), \quad 1 \le i \le n. \tag{4}$$

Note that (2) is also of this form except that the diagonal matrix $\Lambda_{\mathbf{ss}}$ does not depend on A. There is a profound difference between cumulant matrix slices of order higher than two and the covariance matrix of $\vec{\mathbf{x}}_{n\times 1}$, in that the latter is always positive definite whereas the former need not be of any definite sign, and their signs depend both on the signs of the $\mathcal{C}_{\mathbf{s}}^k(i,\dots,i)$'s as well as the elements of A. From (2) and (3) one can see how NOJD and ICA are related: in order to find A^{-1}, search for a nonsingular matrix B that jointly diagonalizes all the cumulant matrix slices, including the covariance matrix. In section 2.2 we show that under certain conditions, which are basically the uniqueness conditions for the EJD problem, A can be found (up to the inherent indeterminacies) from the NOJD of the cumulant slices. The interesting point here is that restoration of diagonality can be equivalent to restoration of independence, and in this process we do not need to know much about the source $\vec{\mathbf{s}}_{n\times 1}$ or its statistical distribution.

1.2. Scope and organization of the paper. In [29, 3, 6, 28, 25, 1, 20] and many other works, different algorithms have been proposed to find the nonorthogonal joint diagonalizer of a given set of matrices. Although one might think of other ideas, the NOJD problem has been considered as a minimization problem whose solution gives the joint diagonalizer. There are not so many cost functions known that can be used for this purpose. Given a set of matrices

$$C_i \approx A \Lambda_i A^T, \quad 1 \le i \le N, \tag{5}$$

where Λ_i's are diagonal, the hope of NOJD is that if a B if found such that all BC_iB^T's are "as diagonal as possible," then B is close to A^{-1} up to permutation and diagonal scaling. Therefore, the accuracy or usefulness of a NOJD algorithm depends on the actual algorithm and on the cost function used, in the sense that how its minimizers differ from A^{-1} when we have (5) instead of an equality. The focus of this work is on what factors affect the sensitivity of the NOJD cost functions. Using a perturbation analysis for the stationary points of certain minimization flows, we will show that this sensitivity is closely related to the uniqueness properties of the corresponding exact joint diagonalization problem. Also, not unexpectedly, we show that if norm of A^{-1} is large, then again the NOJD will be sensitive. Note that this can happen if the norm of A is small or if A is ill-conditioned. One of our main motivations in considering the sensitivity issue is to investigate the effect of the number of matrices included in the NOJD process. Inclusion of more matrices cannot only help to reduce the harm of noise by an averaging effect but also by reducing the sensitivity through improvement of measures of uniqueness defined in section 2.

The organization of this paper is as follows: in section 2 we investigate the uniqueness conditions for the problem of exact joint diagonalization. We also use this result to derive the well-known identifiability conditions for the ICA problem [10]. In section 3 we introduce some of the known cost functions for NOJD and derive the corresponding flows whose stationary points characterize the joint diagonalizers. In section 4 we perform a perturbation analysis on the stationary points of the introduced flows in order to find the sensitivity properties. We also elaborate on the effect of the number of matrices in the NOJD process. Numerical simulations in section 5 confirm the derived results.

1.3. Notations. Throughout the paper all variables are real valued unless otherwise stated. Boldface small letters denote random variables. A and B both are $n \times n$ nonsingular matrices unless otherwise stated. If X is a matrix, then x_{ij} or X_{ij} or $[X]_{ij}$ denotes its entry at position (i, j). $\|X\|_F$ and $\|X\|_2$ denote the Frobenius norm and the 2-norm of the matrix X, respectively. X^T denotes the transpose of X, and X^{-T} denotes the transpose of the inverse of X. $\mathrm{tr}(X)$ is the trace of the square matrix X. $\mathrm{cond}(A)$ is the 2-norm based condition number of the matrix A. For a square matrix, $\mathrm{diag}(X)$ is the diagonal part of X, i.e., a diagonal matrix whose diagonal is equal to the diagonal of X. I or $I_{n\times n}$ denotes the $n \times n$ identity matrix. Unless otherwise stated, letters D and Π denote a nonsingular diagonal matrix and a permutation matrix, respectively. For a vector x, $\mathrm{diag}(x)$ is a diagonal matrix with diagonal x. Λ_i is a diagonal matrix and we denote the kth diagonal element of Λ_i by λ_{ik}. $\|x\|$ is the 2-norm of the vector x. We also define $X^\circ = X - \mathrm{diag}(X)$. $\mathrm{GL}(n)$ and $\mathrm{SO}(n)$ denote the Lie groups of nonsingular $n \times n$ matrices and orthogonal $n \times n$ matrices with $+1$ determinant, respectively. T_pM denotes the tangent space of the manifold M at point p on the manifold. Notation $X \leftarrow Y$ means that "the new value of X is Y."

2. Uniqueness conditions for exact joint diagonalization (EJD). Consider matrices

$$C_i = A\Lambda_i A^T, \quad 1 \le i \le N, \tag{6}$$

where Λ_i's are diagonal matrices, i.e., $\Lambda_i = \mathrm{diag}([\lambda_{i1}, \ldots, \lambda_{in}])$. One interesting problem is that given only $\{C_i\}_{i=1}^N$, find A. We call this problem the exact joint diagonalization (EJD) problem. Note that with only the information that Λ_i's are diagonal, A can be determined only up to permutation and diagonal scaling, i.e., if A is a solution then $AD\Pi$ is also a solution, for any D and Π. We say that the EJD has a unique[2] solution if the permutation and diagonal scaling are the only ambiguities in finding A. If the EJD has a unique solution, then finding A is equivalent to finding a $B \in \mathrm{GL}(n)$ such that all BC_iB^T's are diagonal, hence the name "joint diagonalization."

The issue of uniqueness in the EJD problem can be considered as a special case of uniqueness in the CANDECOMP/PARAFAC model, which has been addressed in [16]. In order to quantify the uniqueness property, which as will be seen in section 4 is closely related to the sensitivity issue of the NOJD problem, we rephrase the necessary and sufficient conditions for uniqueness differently from the related literature.

DEFINITION 1. *For the set of diagonal matrices $\{\Lambda_i\}_{i=1}^N$, let*

$$\rho_{kl} = \frac{\displaystyle\sum_{i=1}^{N} \lambda_{ik}\lambda_{il}}{\left(\displaystyle\sum_{i=1}^{N} \lambda_{il}^2\right)^{\frac{1}{2}} \left(\displaystyle\sum_{i=1}^{N} \lambda_{ik}^2\right)^{\frac{1}{2}}}, \quad 1 \le k \ne l \le N, \tag{7}$$

with the convention that $\rho_{kl} = 1$ if $\lambda_{ik} = 0$ for some k and all i. Let ρ be equal to one of the ρ_{kl}'s that have the maximum absolute value among all. The modulus of uniqueness for this set is defined as $|\rho|$.

Note that $|\rho| \le 1$ and $|\rho| = 1$ if and only if at least two columns of the matrix $[\Lambda]_{ij} = \lambda_{ij}$ are collinear, i.e., if there is a real number K and integers p and q such that

[2] In some works this is referred to as "essential uniqueness."

$\lambda_{ip} = K\lambda_{iq}$, for $1 \leq i \leq N$. $|\rho|$ measures the maximum degree of collinearity between any two columns of the matrix $[\Lambda]_{ij} = \lambda_{ij}$. This measure to quantify collinearity may seem to be chosen arbitrarily, but as will be seen later it shows itself naturally in the analysis of certain cost functions for NOJD. Another measure, which also naturally appears in the analysis of the log-likelihood based cost (see section 3.2.3) function is given in the following definition.

DEFINITION 2. *For the set of positive definite diagonal matrices $\{\Lambda_i\}_{i=1}^N$, let*

$$\mu_{kl} = \frac{1}{N^2}\left(\sum_{i=1}^{N}\frac{\lambda_{ik}}{\lambda_{il}}\right)\left(\sum_{i=1}^{N}\frac{\lambda_{il}}{\lambda_{ik}}\right), \quad 1 \leq k \neq l \leq N. \tag{8}$$

Let μ be the minimum value of μ_{kl}'s. The modulus of uniqueness of second type for this set is defined as μ.

Note that $\mu \geq 1$ with equality if and only if $|\rho| = 1$. μ also measures the maximum collinearity between the columns of Λ, with the assumption that Λ_i's are positive definite.

If $N = 1$, then $|\rho| = 1$ and the diagonalizer is not unique. For $N > 1$, the modulus of uniqueness also captures the uniqueness property in an exact sense.

THEOREM 1. *Let C_i's satisfy* (6). *The necessary and sufficient condition to have unique nonorthogonal joint diagonalizer is that $|\rho| < 1$.*

Proof. First we consider the case $n = 2$. If $|\rho| = 1$, then either (a) there is a real number K such that $\lambda_{i2} = K\lambda_{i1}$ for all $1 \leq i \leq N$, or (b) $\lambda_{i1} = 0$ for all $1 \leq i \leq N$ and $\lambda_{i2} \neq 0$ for some i, or (c) $\lambda_{i1} = \lambda_{i2} = 0$ for all i, which is a trivial situation. In case of (a) we have:

$$C_i = \lambda_{i1} A \underbrace{\begin{bmatrix} 1 & 0 \\ 0 & \sqrt{|K|} \end{bmatrix}}_{D_K} \begin{bmatrix} 1 & 0 \\ 0 & \rho \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & \sqrt{|K|} \end{bmatrix} A^T. \tag{9}$$

We have denoted the diagonal matrix that includes $\sqrt{|K|}$ as D_K. Let us first assume that $K \neq 0$. Now, if $\rho = +1$, then let $B = Q_{+1}D_K^{-1}A^{-1}$, where

$$Q_{+1} = \begin{bmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{bmatrix}. \tag{10}$$

This B diagonalizes every C_i for all θ. If $\rho = -1$, then let $B = Q_{-1}D_K^{-1}A^{-1}$, where

$$Q_{-1} = \begin{bmatrix} \cosh\theta & \sinh\theta \\ \sinh\theta & \cosh\theta \end{bmatrix}. \tag{11}$$

This B diagonalizes every C_i for all θ. If $K = 0$ (and hence $\rho = 1$), then let $B = Q_1A^{-1}$, where

$$Q_1 = \begin{bmatrix} 1 & \theta \\ 0 & 1 \end{bmatrix}. \tag{12}$$

This B diagonalizes every C_i for all θ. Also, in case of (b), $B = Q_1^TA^{-1}$ diagonalizes every C_i for all θ. Therefore, for $|\rho| = 1$ the nonorthogonal joint diagonalizer is not unique. For $n > 2$, $|\rho| = 1$ means that the situation described for $n = 2$ happens between two diagonal elements, in the same positions within Λ_i's; and we can apply

the previous argument to those elements. Hence, for $n > 2$ also $|\rho| = 1$ implies nonuniqueness of the joint diagonalizer. To see the necessary part, first note that existence of more than one exact joint diagonalizer means that there exists a C which differs from a permuted diagonal matrix such that the matrices $D_i = C\Lambda_i C^T$ are diagonal. For the moment, assume that one of the Λ_i's, say Λ_1, is nonsingular. Then $D_i D_1^{-1} = C\Lambda_i\Lambda_1^{-1}C^{-1}$ for $1 < i \leq N$. These are the eigendecompositions of diagonal matrices $\Lambda_i\Lambda_1^{-1}$'s, for $1 < i \leq N$. Nonuniqueness of C happens only when there are two integers $1 \leq k \neq l \leq n$, such that $\frac{\lambda_{ik}}{\lambda_{1k}} = \frac{\lambda_{il}}{\lambda_{1l}}$, $1 < i \leq N$. This means that $|\rho| = 1$. If C is not unique and all Λ_i's are singular, then two cases can happen. In the first case, all Λ_i's have one zero diagonal element at a common position, i.e., there exists an integer $1 \leq k \leq n$ such that for all $1 \leq i \leq N$ we have $\lambda_{ik} = 0$, which implies that $\rho = 1$. If the first case is not true, then there exists a linear combination of Λ_i's like Λ_0, which is nonsingular, and $D_0 = C\Lambda_0 C^T$ is diagonal; then we are back to the nonsingular case. This completes the proof. □

This result and more general ones have been referred to in [23] using the concept of Kruskal's rank.

2.1. On the minimum number of matrices needed for EJD. Let A be an orthogonal matrix. Then the equations in (6) are the eigendecompositions of C_i's. If C_1 or, equivalently, Λ_1 has distinct eigenvalues, then A can be found from eigendecomposition of C_1, uniquely up to permutations. If Λ_1 has only two equal diagonal elements at positions k and l, and if we can find another Λ_i with distinct values at those positions, then A can again be found uniquely from eigendecompositions of C_1 and C_i. Therefore, if for each pair of k and l we can find an i for which $\lambda_{il} \neq \lambda_{ik}$, then A can be determined uniquely. As a result, in the generic case orthogonal joint diagonalization is in fact a one-matrix problem and the inclusion of more matrices can be justified by the presence of noise. The uniqueness properties of OJD as well as its sensitivity analysis have been addressed in [8].

There is a huge difference between the uniqueness properties of the orthogonal and nonorthogonal joint diagonalization problems. From the proof of Theorem 1 it should be evident that $N = 1$ matrix is not enough to find a unique nonorthogonal (joint) diagonalizer. NOJD allows more degrees of freedom in finding the diagonalizer. Let us count the degrees of freedom in both sides of the equations in (6). Recall that a symmetric $n \times n$ matrix has $\frac{n(n+1)}{2}$ degrees of freedom, and A has $n^2 - n$ degrees of freedom (as far as the NOJD problem is concerned). Hence, the left-hand side of (6) has total $N\frac{n(n+1)}{2}$ degrees of freedom, and its right-hand side has $n^2 - n + Nn$ degrees of freedom. Equating the degrees of freedom from both sides and solving for N gives $N = 2$. Therefore, the minimum number of matrices to give enough equations to find a unique nonorthogonal joint diagonalizer is $N = 2$; and hence, the NOJD problem, in the generic case, is a two-matrix problem. For two arbitrary and generic matrices $\{C_1, C_2\}$, whether the equations in (6) yield a real valued solution for $\{A, \Lambda_1, \Lambda_2\}$ depends on the matrices.[3] It is well known that if one of the two matrices is positive definite, then they admit a (real) exact jointly diagonalizer [15, pp. 461–462]. As we will show in section 4.4.1, for only two matrices, if their dimension is moderately large ($n > 20$, for example), then the modulus of uniqueness is close to unity. This in turn, as will be shown in section 4, means that the NOJD of the two matrices is an

[3]Assuming C_1 is invertible (which is true for a generic matrix), in order for (6) to hold, we should have that $C_2 C_1^{-1} = A\Lambda_2\Lambda_1^{-1}A^{-1}$, which is an eigendecomposition. Again in a generic case, this would give a unique and (in general) complex valued $\{A, \Lambda_1, \Lambda_2\}$.

ill-conditioned problem; and hence, it is better to include more matrices in the NOJD process.

2.2. Identifiability of the ICA problem. Now we would like to apply the previous theorem to the case of the ICA problem. It is obvious that if we can find two cumulant matrix slices of $\vec{\mathbf{x}}_{n\times 1}$ for which $|\rho|$ is not unity, then the matrix A in (1) can be found uniquely. From (3) and (4), one can show that for the set $\{\mathcal{C}^k_{\mathbf{x}}(i_1, i_2, \dots, i_{k-2}, :, :)\}_{1\le i_1,\dots,i_{k-2}\le n}$ with $k > 2$ we have $|\rho| \neq 1$, if and only if none of $\mathcal{C}^k_{\mathbf{s}}(i, \dots, i)$'s are zero. To see this, first note that if $\mathcal{C}^k_{\mathbf{s}}(i, \dots, i) = 0$ for some i, then $|\rho| = 1$. Now assume that none of $\mathcal{C}^k_{\mathbf{s}}(i, \dots, i)$'s are zero, and $|\rho| = 1$. Since $|\rho| = 1$, there are two columns of A like j and l and a real number K such that

$$a_{i_1 j} a_{i_2 j} \dots a_{i_{k-2} j} \mathcal{C}^k_{\mathbf{s}}(j, \dots, j) = K a_{i_1 l} a_{i_2 l} \dots a_{i_{k-2} l} \mathcal{C}^k_{\mathbf{s}}(l, \dots, l) \tag{13}$$

for all $1 \le i_1, ..., i_{k-2} \le n$. Because none of the $\mathcal{C}^k_{\mathbf{s}}(i, ..., i)$'s are zero, and since there is at least one nonzero element like a_{pj} in the j^{th} column of A, by setting $i_2 = \dots = i_{k-2} = p$ we have that there is another real number K' such that

$$a_{i_1 j} = K' a_{i_1 l} \tag{14}$$

for all $1 \le i_1 \le n$. This contradicts the invertibility of A. Hence, with an invertible A, $|\rho|$ cannot be unity unless at least one of $\mathcal{C}^k_{\mathbf{s}}(i, \dots, i)$'s is zero.

Now assume that the covariance matrix of $\vec{\mathbf{s}}_{n\times 1}$ is nonsingular, i.e., there is no source component with zero variance. Then by inclusion of the covariance matrix of $\vec{\mathbf{x}}_{n\times 1}$ in the above set we can weaken the uniqueness condition, i.e., for $\{R_{\mathbf{xx}}, \mathcal{C}^k_{\mathbf{x}}(i_1, i_2, \dots, i_{k-2}, :, :)\}_{1\le i_1,\dots,i_{k-2}\le n}$ with $k > 2$, we have $|\rho| \neq 1$ if and only if at most one of $\mathcal{C}^k_{\mathbf{s}}(i, \dots, i)$'s is zero. Therefore, if we start with the covariance matrix of $\vec{\mathbf{x}}_{n\times 1}$ and then include its third order cumulant slices, and if at most one of the skewness' $\mathcal{C}^3_{\mathbf{s}}(i, \dots, i)$ is zero, then A can be determined uniquely. If at least two $\mathcal{C}^3_{\mathbf{s}}(i, \dots, i)$'s are zero, then we can go to the cumulants of higher orders and check the same condition. Note that this process fails if and only if there are at least two source elements s_p and s_q for which $\mathcal{C}^k_{\mathbf{s}}(p, \dots, p) = \mathcal{C}^k_{\mathbf{s}}(q, \dots, q) = 0$ for all $k \ge 3$. It is well known that such random variables have Gaussian distribution. As a result, exact nonorthogonal joint diagonalization of the set of all cumulant matrix slices of $\vec{\mathbf{x}}_{n\times 1}$ gives A uniquely, unless $\vec{\mathbf{s}}_{n\times 1}$ has at least two Gaussian components. To summarize we state this theorem (cf. Corollary 13 in [10]).

THEOREM 2 (identifiability of ICA:EJD formulation). *Consider the model* (1). *About* $\vec{\mathbf{s}}_{n\times 1}$*, assume that its covariance matrix is nonsingular, its* k*th order cumulants (for some* $k > 2$*) exist, and at most one of them is zero. Then exact joint diagonalization of the set* $\{R_{\mathbf{xx}}, \mathcal{C}^k_{\mathbf{x}}(i_1, i_2, \dots, i_{k-2}, :, :)\}_{1\le i_1,\dots,i_{k-2}\le n}$ *results in finding* A *up to column permutation and scaling. For a source vector with finite cumulants of all orders, this process fails to identify* A *if only if the source vector has more than one Gaussian component.*

This result suggests that EJD can be used as a basis to define a contrast function [10] for ICA. Note that this identifiability condition is derived solely based on the algebraic structure of the ICA model and that we have not used the Skitovich–Darmois theorem [10, 18]. OJD or NOJD of cumulant matrix slices of order three, four, or even higher have been suggested in many works, e.g., [9, 28, 29, 19, 13, 2]. The OJD scenario arises when one assumes that the mixture is already uncorrelated or whitened.

3. Cost functions for joint diagonalization. The joint diagonalization problem has been posed, in the literature, mostly as an optimization problem [9, 28, 25, 20]. We mention that in [28, 25] the joint diagonalization problem has been addressed with a different formulation than ours. As mentioned before, generically, in the OJD problem one matrix ($N = 1$), and in the NOJD problem two matrices ($N = 2$) are enough to find a unique joint diagonalizer. However, it is believed that inclusion of more matrices is useful in making the solution less vulnerable to noise. Therefore, the proposed cost functions for joint diagonalization are designed to mitigate the effect of noise via averaging.

3.1. A cost function for orthogonal joint diagonalization. The OJD problem was introduced earlier than the NOJD problem. In [9] a natural cost function together with an efficient algorithm for OJD was introduced. The cost function $J_1 : \mathrm{SO}(n) \to \mathbb{R}$ for OJD, introduced in [9], is

$$J_1(\Theta) = \sum_{i=1}^{n} \left\| \Theta C_i \Theta^T - \mathrm{diag}(\Theta C_i \Theta^T) \right\|_F^2, \tag{15}$$

where $\{C_i\}_{i=1}^N$ is the set of symmetric matrices to be diagonalized. If Θ minimizes J_1, then we call Θ an orthogonal joint diagonalizer of $\{C_i\}_{i=1}^N$. Note that, since $\mathrm{SO}(n)$ is a compact manifold, a priori we know that a minimizer exists for J_1. Whether, generically, this cost function has only global minimum on $\mathrm{SO}(n)$, and whether the minimizers are unique up to permutation are not known.

3.2. Cost functions for nonorthogonal joint diagonalization. Introducing a cost function for NOJD has been a challenge. First, note that a simple extension of J_1 from $\mathrm{SO}(n)$ to $\mathrm{GL}(n)$ is not effective. We remind that the NOJD problem in the exact case is a scale-invariant problem, i.e., if $B \in \mathrm{GL}(n)$ is an exact joint diagonalizer for a set of matrices, then DB also should be a joint diagonalizer for any nonsingular diagonal D. We expect or require this to be true for the case of NOJD as well, i.e., if B is a nonorthogonal joint diagonalizer for a set of matrices, we expect DB also to be a nonorthogonal joint diagonalizer for that set. However, in general $J_1(DB) \neq J_1(B)$. In fact, we can reduce $J_1(B)$ just by reducing the norm of B, and $J_1(B)$ has a global infimum at $B = 0$.

3.2.1. A nonholonomic flow for NOJD based on J_1. For the derivations in this subsection we refer the reader to [2]. We also refer the reader to [17] for more comprehensive treatment of gradient flows for optimization on manifolds. On the Lie group of nonsingular matrices, we can define a right-invariant Riemannian metric[4] that matches the group structure as

$$\begin{aligned} \langle ., . \rangle_B &: T_B GL(n) \times T_B GL(n) \to \mathbb{R} \\ \langle \xi_1, \xi_2 \rangle_B &= \mathrm{tr}((\xi_1 B^{-1})^T \xi_2 B^{-1}), \end{aligned} \tag{16}$$

where $T_B\mathrm{GL}(n)$ is the tangent space to $\mathrm{GL}(n)$ at B. In general, a tangent vector ξ at a point B on $\mathrm{GL}(n)$ (and any Lie group) can be written as $\xi = \zeta B$ where ζ belongs to

[4]The significance of the right-invariant metric is that it matches the invariance property of the NOJD problem, which as mentioned is that the joint diagonalizer does not change by left multiplication by nonsingular diagonal matrices. A discretization of a right-invariant flow such as $\frac{dB}{ds} = \Omega B$ has the form $B_{k+1} = (I + \Omega_k) B_k$.

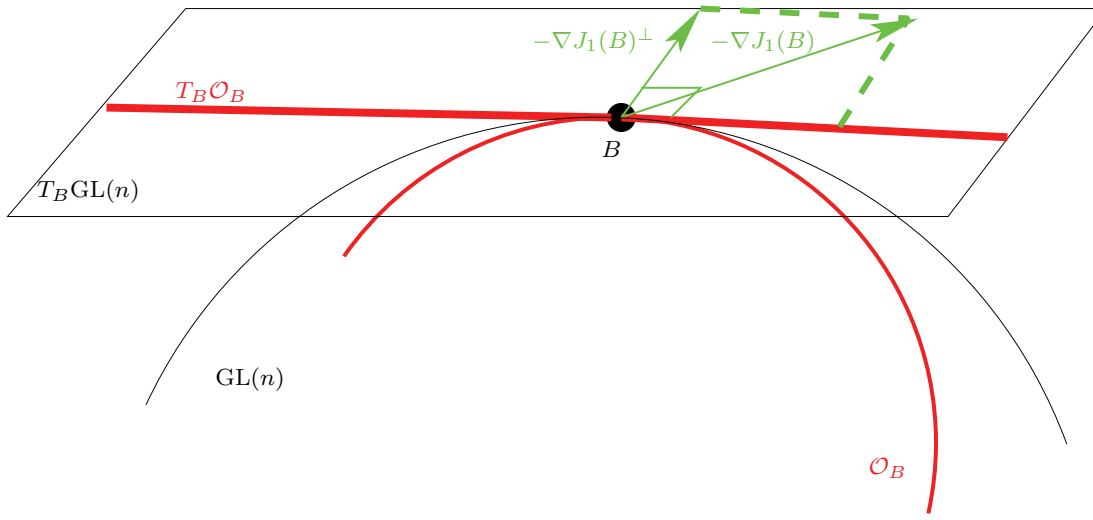

FIG. 1. *The group of nonsingular diagonal matrices acts on the manifold $GL(n)$ at B via left multiplication. $\mathcal{O}_B$ is the orbit of this action. The linearization of this orbit (i.e., the tangent space to it) at B is $T_B\mathcal{O}_B \subset T_B GL(n)$. This figure shows how $-\nabla J_1(B)$ should be projected onto the orthogonal complement of $T_B\mathcal{O}_B$ in order to have a flow for NOJD based on J_1 which is not a scale-invariant cost function for NOJD.*

the tangent space at the identity. Also, the tangent spaces at B and the identity are isometric in the previous metric. Let $s \mapsto \tilde{B}(s)$ be any smooth curve with $\tilde{B}(0) = B$. With respect to the Riemannian metric in (16), the gradient of $J_1 : \mathrm{GL}(n) \to \mathbb{R}$ is defined as a vector field ∇J_1 that satisfies

$$\dot{J}_1 = \langle \nabla J_1, \dot{B} \rangle_B, \tag{17}$$

where $\dot{J}_1 = \frac{dJ_1(\tilde{B}(s))}{ds}\big|_{s=0}$ and $\dot{B} = \frac{d\tilde{B}(s)}{ds}\big|_{s=0}$. From this, it is easy to verify that up to a scalar factor

$$\nabla J_1(B) = \Omega_1 B, \tag{18}$$

where

$$\Omega_1 = \sum_{i=1}^{N} (BC_iB^T)^{\circ} BC_iB^T. \tag{19}$$

We can show that the stationary points of J_1, i.e., values of B for which $\nabla J_1(B) = 0$ and hence $\Omega_1 = 0$, satisfy $BC_iB^T = \mathrm{diag}(BC_iB^T)$. Therefore, if C_i's do not have an exact joint diagonalizer, then J_1 will have no stationary points on $\mathrm{GL}(n)$. A gradient flow for minimization of J_1 has the form $\frac{dB}{ds} = -\nabla J_1(B) = -\Omega_1 B$. As we mentioned before, the problem with minimizing J_1 as a cost function for NOJD is that it can be reduced by diagonal matrices. At each point $B \in \mathrm{GL}(n)$, we can project the gradient of J_1 (or more accurately the negative of the gradient) to directions that do not correspond to diagonal scaling. The group of nonsingular diagonal matrices of dimension n can act on the group $\mathrm{GL}(n)$ via left multiplication. At B the orbit of this action is simply $\mathcal{O}_B = \{DB | D = \text{nonsigngular and diagonal}\}$ and it is in fact a

submanifold which we would like our NOJD flow to avoid. The linearization or the tangent space to the orbit at B is $T_B\mathcal{O}_B = \{DB|D = \text{diagonal}\}$, which is a linear subspace of $T_B\mathrm{GL}(n)$. The orthogonal complement of $T_B\mathcal{O}_B$ in the tangent space $T_B\mathrm{GL}(n)$, with respect to the defined Riemannian metric, is $(T_B\mathcal{O}_B)^\perp = \{\Xi B|\Xi \in \mathbb{R}^{n\times n},\ \mathrm{diag}(\Xi) = 0\}$. Therefore, the projection of ∇J_1 onto $(T_B\mathcal{O}_B)^\perp$ is $\nabla J_1^\perp = \Omega_1^\circ B$. Figure 1 shows the process of constraining the negative of the gradient to directions along $(T_B\mathcal{O}_B)^\perp$, at each point B. The corresponding nonholonomic[5] flow for NOJD is

$$\frac{dB}{ds} = -\nabla J_1^\perp = -\Omega_1^\circ B. \tag{20}$$

The stationary points or equilibria of this flow are defined by $\Omega_1^\circ = 0$, or

$$\sum_{i=1}^{N} \left((BC_iB^T)^\circ BC_iB^T\right)^\circ = 0. \tag{21}$$

Hence, if a nonorthogonal joint diagonalizer of $\{C_i\}_{i=1}^N$ based on the above nonholonomic flow exists, then it should satisfy (21). In [3, 29] and many other works, minimization schemes for J_1 are proposed, which try to find the stationary points in (21).

3.2.2. A Frobenius norm scale-invariant cost function. Note that $J_1 : \mathrm{SO}(n) \to \mathbb{R}$ in (15) can also be written as

$$J_1(\Theta) = \sum_{i=1}^{n} \left\|C_i - \Theta^{-1}\mathrm{diag}(\Theta C_i\Theta^T)\Theta^{-T}\right\|_F^2. \tag{22}$$

Let $J_2 : \mathrm{GL(n)} \to \mathbb{R}$ be the extension of this form of J_1 to $\mathrm{GL}(n)$ defined by

$$J_2(B) = \sum_{i=1}^{n} \left\|C_i - B^{-1}\mathrm{diag}(BC_iB^T)B^{-T}\right\|_F^2. \tag{23}$$

Then it is easy to check that $J_2(\Pi DB) = J_2(B)$ for any nonsingular diagonal D and permutation Π. Therefore, J_2 is a scale and permutation invariant cost function for NOJD. Note that J_1 and J_2 are scaled versions of each other in the sense that

$$\frac{J_1(B)}{n^2\|B\|_2^4} \le J_2(B) \le n^2\|B^{-1}\|_2^4 J_1(B). \tag{24}$$

Also, note that we can reduce J_2 without changing the norm of B. This means that reducing J_2, if the norm of B is not changed, can result in reduction of the upper bound of J_1. This cost function has been introduced in [5, 3].

3.2.3. Log-likelihood function for NOJD. In [20], another cost function for NOJD of a set of positive definite matrices $\{C_i\}_{i=1}^N$ has been introduced. This cost function has the form

$$J_3(B) = \sum_{i=1}^{N} \log\left(\frac{\det \mathrm{diag}(BC_iB^T)}{\det BC_iB^T}\right). \tag{25}$$

[5] A nonholonomic flow is a flow whose velocity vector field is constrained by nonintegrable constraints.

A matrix $B \in \mathrm{GL}(n)$ that minimizes J_3 is the joint diagonalizer of $\{C_i\}_{i=1}^N$. It can be shown that $J_3(B) \geq 0$, and the equality holds if and only if all BC_iB^T's are diagonal. It is easy to check that J_3 is scale and permutation invariant, i.e., $J_3(\Pi DB) = J_3(B)$, for any Π and D. The specific form of this cost function is imposed by the log-likelihood function of correlation matrices of Gaussian nonstationary sources [20]. Let us consider the same right-invariant Riemannian metric as in section 3.2.1. Using the well-known identity $\frac{\partial}{\partial B} \log\det B = (B^T)^{-1}$ we can show (see (17) also) that

$$\dot{J}_3 = 2\sum_{i=1}^{N} \mathrm{tr}\Big((\dot{B}B^{-1})^T \big((\mathrm{diag}(BC_iB^T))^{-1} BC_iB^T - I \big) \Big). \tag{26}$$

As a result, with respect to the above Riemannian metric, the gradient vector field of J_3 up to a scalar factor is

$$\nabla J_3(B) = \frac{1}{N}\sum_{i=1}^{N} \big(\mathrm{diag}((BC_iB^T))^{-1} BC_iB^T - I \big) B := \Omega_3 B. \tag{27}$$

It is interesting to note that $\mathrm{diag}(\Omega_3) = 0$ (cf. (19) and (20)). A gradient flow for NOJD based on minimization of J_3 is $\frac{dB}{ds} = -\Omega_3 B$. The stationary points for this flow are characterized by $\Omega_3 = 0$; and if B is a joint diagonalizer, then it should satisfy

$$\frac{1}{N}\sum_{i=1}^{N} BC_iB^T \big(\mathrm{diag}(BC_iB^T) \big)^{-1} = I. \tag{28}$$

4. Sensitivity analysis. An interesting question to ask is: "which set of matrices are hard to be jointly diagonalized?" In other words, which factors affect the condition or sensitivity of the joint diagonalization problem? Consider the matrices $C_i = A\Lambda_i A^T,\ 1 \leq i \leq N$, where Λ_i's are diagonal. Obviously, $\{C_i\}_{i=1}^N$ have a joint diagonalizer $B = A^{-1}$. Note that, here equality is understood up to permutation and diagonal scaling. Now, we add noise to the matrices as

$$C_i = A\Lambda_i A^T + tN_i, \quad t \in [-\delta, \delta], \delta > 0, \tag{29}$$

where $\{N_i\}_{i=1}^N$ are symmetric error or noise matrices, and t shows the noise gain or contribution. The joint diagonalizer of this noisy set will deviate from A^{-1} as t deviates from zero. If the sensitivity is high, then the deviation from A^{-1} will be large. In this case, we say that the NOJD problem is very sensitive or ill-conditioned. Note that the true goal of NOJD is to find A and not just diagonalizing the matrices $\{C_i\}_{i=1}^N$. It is in this context that the sensitivity of the problem is defined. If the modulus of uniqueness for $\{\Lambda_i\}_{i=1}^N$ is unity, then $\{C_i\}_{i=1}^N$ has already infinite sensitivity; since the joint diagonalizer can change even in absence of noise. Hence, one should expect the sensitivity for joint diagonalization to be closely related to the issue of uniqueness. To quantify this relation, we will perform a perturbation analysis of the stationary points of the NOJD cost functions or flows defined in section 3. The results for different cost functions are very much similar.

4.1. Sensitivity analysis for NOJD based on J_1. The J_1-based nonorthogonal joint diagonalizer of $\{C_i\}_{i=1}^N$, B is defined by (21). As t deviates from zero in (29), $B(t)$, the joint diagonalizer, varies smoothly. For small enough δ, from the implicit function theorem and basic properties of Lie groups, we have

$$B(t) = (I + t\Delta)A^{-1} + o(t), \quad t \in [-\delta, \delta], \tag{30}$$

where $\Delta \in \mathbb{R}^{n\times n}$ with $\mathrm{diag}(\Delta) = 0$ and $\frac{\|o(t)\|}{t} \to 0$ as $t \to 0$. The restriction $\mathrm{diag}(\Delta) = 0$ matches the structure of the nonholonomic flow for NOJD derived in section 3.2.1. Note that the norm of Δ measures the sensitivity of the NOJD problem to noise. Our goal is to calculate Δ. Using $B(0) = A^{-1}$ and $\frac{dB}{dt}(0) = \Delta A^{-1}$, and after plugging (29) into (21), and then differentiating with respect to t, we can easily verify that

$$\sum_{i=1}^{N} \big(\Delta\Lambda_i + \Lambda_i\Delta^T\big)\Lambda_i = -\sum_{i=1}^{N} \big(A^{-1}N_i(A^{-1})^T\big)^{\circ}\Lambda_i. \tag{31}$$

The right-hand side of the above equation manifests the possible noise amplification that can happen due to large $\|A^{-1}\|$, i.e., when A is small in norm or more importantly when A is ill-conditioned. Equation (31) is a linear equation in terms of Δ. Let us define

$$\mathcal{T} = \sum_{i=1}^{N} (A^{-1}N_i(A^{-1})^T)^{\circ}\Lambda_i. \tag{32}$$

Now, it is easy to check that the two entries Δ_{kl} and Δ_{lk} decouple from the rest of the entries of Δ and we have

$$\begin{bmatrix} \sum_{i=1}^{N}\lambda_{il}^2 & \sum_{i=1}^{N}\lambda_{ik}\lambda_{il} \\ \sum_{i=1}^{N}\lambda_{ik}\lambda_{il} & \sum_{i=1}^{N}\lambda_{ik}^2 \end{bmatrix} \begin{bmatrix} \Delta_{kl} \\ \Delta_{lk} \end{bmatrix} = -\begin{bmatrix} \mathcal{T}_{kl} \\ \mathcal{T}_{lk} \end{bmatrix},\ 1 \le k < l \le n. \tag{33}$$

Recall the definition of ρ_{kl} (Definition 1). Also, let

$$\gamma_{kl} = \left(\sum_{i=1}^{N}\lambda_{ik}^2\right)^{\frac{1}{2}}\left(\sum_{i=1}^{N}\lambda_{il}^2\right)^{\frac{1}{2}},\quad \eta_{kl} = \frac{\left(\sum_{i=1}^{N}\lambda_{ik}^2\right)^{\frac{1}{2}}}{\left(\sum_{i=1}^{N}\lambda_{il}^2\right)^{\frac{1}{2}}}. \tag{34}$$

We denote the coefficients matrix in (33) by M_{kl},

$$M_{kl} = \gamma_{kl}\begin{bmatrix} \eta_{kl}^{-1} & \rho_{kl} \\ \rho_{kl} & \eta_{kl} \end{bmatrix},\qquad 1 \le k < l \le n. \tag{35}$$

Then (33) is equivalent to

$$\begin{bmatrix} \Delta_{kl} \\ \Delta_{lk} \end{bmatrix} = -M_{kl}^{-1}\begin{bmatrix} \mathcal{T}_{kl} \\ \mathcal{T}_{lk} \end{bmatrix} = \frac{-1}{\gamma_{kl}(1-\rho_{kl}^2)}\begin{bmatrix} \eta_{kl} & -\rho_{kl} \\ -\rho_{kl} & \eta_{kl}^{-1} \end{bmatrix}\begin{bmatrix} \mathcal{T}_{kl} \\ \mathcal{T}_{lk} \end{bmatrix},\ \ 1 \le k < l \le n. \tag{36}$$

Note that the eigenvalues of M_{kl}^{-1} are

$$\lambda_{max}, \lambda_{min} = \frac{\eta_{kl} + \eta_{kl}^{-1} \pm \sqrt{(\eta_{kl} + \eta_{kl}^{-1})^2 - 4(1-\rho_{kl}^2)}}{2\gamma_{kl}(1-\rho_{kl}^2)}. \tag{37}$$

Also, it is easy to check that

$$\frac{\eta_{kl}+\eta_{kl}^{-1}-1}{\gamma_{kl}(1-\rho_{kl}^2)} \leq \lambda_{max} < \frac{\eta_{kl}+\eta_{kl}^{-1}}{\gamma_{kl}(1-\rho_{kl}^2)}, \tag{38}$$

and

$$\frac{1}{\gamma_{kl}(\eta_{kl}+\eta_{kl}^{-1})} \leq \lambda_{min} \leq \frac{1}{\gamma_{kl}}. \tag{39}$$

Therefore, we can also establish the bounds

$$\frac{1}{\gamma_{kl}(\eta_{kl}+\eta_{kl}^{-1})} \left\| \begin{bmatrix} \Delta_{kl} \\ \Delta_{lk} \end{bmatrix} \right\| \leq \left\| \begin{bmatrix} \Delta_{kl} \\ \Delta_{lk} \end{bmatrix} \right\| < \frac{\eta_{kl}+\eta_{kl}^{-1}}{\gamma_{kl}(1-\rho_{kl}^2)} \left\| \begin{bmatrix} \mathcal{T}_{kl} \\ \mathcal{T}_{lk} \end{bmatrix} \right\|. \tag{40}$$

Because γ_{kl} is not scale-invariant, $\gamma_{kl} \approx 0$ by itself does not imply a high sensitivity. The definitions of the parameters reveal that γ_{kl} plays more of a scaling role, whereas ρ_{kl} plays a structural role. Hence, as far as sensitivity to noise is concerned, the interesting situation (approximate singularity) happens when $|\rho_{kl}| \approx 1$. Note that as $|\rho_{kl}| \to 1$, λ_{max} and λ_{min} approach their upper and lower bounds, respectively. Moreover, in that case λ_{max} grows unboundedly and λ_{min} remains bounded. Since $\mathcal{T}$ depends on random noise, there always will be a component of $\left[\begin{smallmatrix} \mathcal{T}_{kl} \\ \mathcal{T}_{lk} \end{smallmatrix}\right]$ along the direction of the eigenvector of M_{kl}^{-1} corresponding to λ_{max}. Therefore, when $|\rho_{kl}|$ approaches unity, $\| \left[\begin{smallmatrix} \Delta_{kl} \\ \Delta_{lk} \end{smallmatrix}\right] \|$ tends towards the upper bound in (40). Hence, the upper bound is the more interesting one and it is not a loose bound in the sense that it can be achieved very closely when $|\rho_{kl}| \approx 1$.[6] One can easily check that

$$\|\Delta\|_F < \frac{\alpha}{(1-\rho^2)}\|\mathcal{T}\|_F \leq \frac{n\alpha\|A^{-1}\|_2^2}{(1-\rho^2)} \sum_{i=1}^{N} \|N_i\|_2 \|\Lambda_i\|_2, \tag{41}$$

where $\alpha = \max_{k\neq l} \frac{\eta_{kl}+\frac{1}{\eta_{kl}}}{\gamma_{kl}}$, and $|\rho|$ is the modulus of uniqueness for the set $\{\Lambda_i\}_{i=1}^N$ as defined before. Since an approximate nonuniqueness of the joint diagonalizer can happen when only one of $|\rho_{kl}|$'s is close to unity, the above bound might seem exaggerative. Again one can imagine a worse case scenario in which all $|\rho_{kl}|$'s are close to unity, and the bound would not be very loose. In summary, we have the following theorem.

THEOREM 3. *Let $C_i = A\Lambda_i A^T + tN_i, 1 \leq i \leq N$ ($t \in [-\delta, \delta]$). Let us define $B(t)$ the nonorthogonal joint diagonalizer for $\{C_i\}_{i=1}^N$ as the minimizer of J_1 under the nonholonomic flow with equilibria defined in* (21). *Then for small enough δ, the joint diagonalizer can be written as: $B(t) = (I+t\Delta)A^{-1}+o(t)$, where Δ (with $diag(\Delta) = 0$) satisfies* (36) *as well as* (41).

The bound in (41) confirms the intuition that if the joint diagonalizer is close to nonuniqueness, as measured by the modulus of uniqueness, or if it is ill-conditioned, then the sensitivity of the NOJD problem will be high. Note that our derivations suggest that there is another scenario that can result in high sensitivity, which is when A and Λ_i (i.e., γ_{kl}'s) are small in norm. Of course, this is not an interesting scenario. We could have avoided this by imposing a constraint on the norm of the noise in (29). For example, we could assume that $\|N_i\|_2 \leq \|A\|_2^2\|\Lambda_i\|_2$. This choice

[6] It is common in matrix perturbation theory to have bounds that only handle the worse cases well. For a discussion on this issue, see [22, p. 124].

makes the bound (41) such that it is unchanged if A or Λ_i's all are scaled by a scalar. Hence, one might be tempted to define $\frac{\mathrm{cond}(A)^2}{1-\rho^2}$ as the condition number for the NOJD problem based on J_1.

4.2. Sensitivity analysis for NOJD based on J_2. We can follow the same path as in the previous subsection and perform a perturbation analysis for the stationary points of J_2 in presence of noise. In [5], it is shown that the stationary points of J_2 satisfy

$$\begin{cases} \sum_{i=1}^{N} \big(\Psi_i \mathrm{diag}\big(BC_iB^T\big) - \mathrm{diag}\big(\Psi_i\big)BC_iB^T\big) = 0, \\ \Psi_i = (BB^T)^{-1}\big(BC_iB^T - \mathrm{diag}(BC_iB^T)\big)(BB^T)^{-1}, \end{cases} \tag{42}$$

$B(t)$, the minimizer of J_2 with C_i's defined in (29), can be written as (30). Our goal is to find Δ, when $B(t)$ satisfies (42). Similar to the previous subsection, we can show that Δ satisfies

$$\sum_{i=1}^{N} \big(A^TA(\Delta\Lambda_i + \Lambda_i\Delta^T)A^TA\Lambda_i\big)^\circ = -\sum_{i=1}^{N} \big(A^TA\big(A^{-1}N_i(A^{-1})^T\big)^\circ A^TA\Lambda_i\big)^\circ. \tag{43}$$

Presence of the terms A^TA in (43) makes the decoupling that we saw in (31) not possible here. Note that in (31) the effect of A and Λ_i are separated very much, but in (43) this is not the case. This is because J_2 is not congruence preserving, i.e., it is not expressed in terms of only the BC_iB^T's. Note that if A is close to a diagonal multiple of an orthogonal matrix, i.e., if $A \approx QD$, where D is a nonsingular diagonal matrix and Q is orthogonal, then $A^TA \approx D^TD$; and as a result, we have that (43) reduces to

$$\sum_{i=1}^{N} \big(\Delta\Lambda_i + \Lambda_i\Delta^T\big)\Lambda_i \approx -\sum_{i=1}^{N} \big(A^{-1}N_i(A^{-1})^T\big)^\circ\Lambda_i, \tag{44}$$

which is the approximated version of (31). This case is of practical interest. Many algorithms for NOJD try to iteratively reduce the data matrices C_i's, by congruence transforms, to diagonal matrices, i.e., $C_i \leftarrow B_kC_iB_k^T$, where B_k is the local joint diagonalizer found at step k. After a number of iterations, and when the matrices under transformation become close to diagonal, we have $C_i = BA\Lambda_i(BA)^T + tBN_iB^T$, where B is the product of the local joint diagonalizers. In this case, the new A ($A \leftarrow BA$) is close to diagonal, so is A^TA. Also, in another case if one of the C_i's, say C_1, is positive definite, then we can apply the transformation $C_i \leftarrow C_1^{-\frac{1}{2}}C_i(C_1^{-\frac{1}{2}})^T = C_1^{-\frac{1}{2}}A\Lambda_i(C_1^{-\frac{1}{2}}A)^T + tC_1^{-\frac{1}{2}}N_i(C_1^{-\frac{1}{2}})^T$, where $C_1^{\frac{1}{2}}$ is a square root of C_1, i.e., $C_1^{\frac{1}{2}}(C_1^{\frac{1}{2}})^T = C_1$. Again, we can show that if the noise is not too strong, for the new A ($A \leftarrow C_1^{-1/2}A$), we have $A \approx QD$, for some orthogonal Q and nonsingular diagonal D. This case can, for example, correspond to the so-called prewhitening step in the ICA problem, where C_1 is a covariance matrix. We can maintain that the sensitivity properties of NOJD based on J_2 are very similar to those of NOJD based on J_1.

4.3. Sensitivity analysis for NOJD based on J_3. A stationary point $B(t)$ of J_3, when C_i's are of the form (29) and Λ_i's are positive definite, satisfies (28). Similar to previous derivations, by differentiating (28) with respect to t and considering (29)

and (30), we have that Δ, with $\mathrm{diag}(\Delta)=0$, satisfies

$$\sum_{i=1}^{N}\Delta+\Lambda_i\Delta^T\Lambda_i^{-1}=-\sum_{i=1}^{N}\left(A^{-1}N_i(A^{-1})^T\right)^{\circ}\Lambda_i^{-1}. \tag{45}$$

We have used the fact $\frac{d}{dt}X^{-1}=-X^{-1}(\frac{d}{dt}X)X^{-1}$, where X is a nonsingular differentiable matrix function of t. Let us define

$$\tau_{kl}=\frac{1}{N}\sum_{i=1}^{N}\frac{\lambda_{ik}}{\lambda_{il}},\quad \mu_{kl}=\tau_{kl}\tau_{lk}=\frac{1}{N^2}\left(\sum_{i=1}^{N}\frac{\lambda_{ik}}{\lambda_{il}}\right)\left(\sum_{i=1}^{N}\frac{\lambda_{il}}{\lambda_{ik}}\right). \tag{46}$$

Also let:

$$\mathcal{S}=\textstyle\sum_{i=1}^{N}\left(A^{-1}N_i(A^{-1})^T\right)^{\circ}\Lambda_i^{-1},\quad H_{kl}=N\begin{bmatrix}1 & \tau_{kl}\\ \tau_{lk} & 1\end{bmatrix}. \tag{47}$$

Here $\mathcal{S}$ is very similar to $\mathcal{T}$ and represents possible noise amplification due to small norm or ill-conditioning of A. The structure of $\mathcal{S}$ also shows that if Λ_i's are close to singularity, then noise amplification can happen. Note that the cost function J_3 requires Λ_i's to be positive definite, and as this condition is close to violation (by one of Λ_i's being almost singular), then J_3 becomes very sensitive to noise. Equation (45) decouples as

$$H_{kl}\begin{bmatrix}\Delta_{kl}\\ \Delta_{lk}\end{bmatrix}=-\begin{bmatrix}\mathcal{S}_{kl}\\ \mathcal{S}_{lk}\end{bmatrix},\ 1\le k<l\le n, \tag{48}$$

or, equivalently,

$$\begin{bmatrix}\Delta_{kl}\\ \Delta_{lk}\end{bmatrix}=\frac{1}{N(\mu_{kl}-1)}\begin{bmatrix}1 & -\tau_{kl}\\ -\tau_{lk} & 1\end{bmatrix}\begin{bmatrix}\mathcal{S}_{kl}\\ \mathcal{S}_{lk}\end{bmatrix},\ 1\le k<l\le n. \tag{49}$$

It is easy to see that $\|H_{kl}^{-1}\|_F^2=\frac{2+\tau_{kl}^2+\tau_{lk}^2}{(N(\mu_{kl}-1))^2}$, and hence σ_{max}, the larger singular value of H_{kl}^{-1}, satisfies

$$\frac{1}{\sqrt{2}}\frac{\sqrt{\tau_{kl}^2+\tau_{lk}^2+2}}{N(\mu_{kl}-1)}\le\sigma_{max}<\frac{\sqrt{\tau_{kl}^2+\tau_{lk}^2+2}}{N(\mu_{kl}-1)}. \tag{50}$$

From (49) and the previous bound we have

$$\left\|\begin{bmatrix}\Delta_{kl}\\ \Delta_{lk}\end{bmatrix}\right\|\le\sigma_{max}\left\|\begin{bmatrix}\mathcal{S}_{kl}\\ \mathcal{S}_{lk}\end{bmatrix}\right\|<\frac{\sqrt{\tau_{kl}^2+\tau_{lk}^2+2}}{N(\mu_{kl}-1)}\left\|\begin{bmatrix}\mathcal{S}_{kl}\\ \mathcal{S}_{lk}\end{bmatrix}\right\|. \tag{51}$$

It is also easy to establish the following bound:

$$\|\Delta\|_F<\frac{\beta}{N(\mu-1)}\|\mathcal{S}\|_F\le\frac{n\beta\|A^{-1}\|_2^2}{N(\mu-1)}\sum_{i=1}^{N}\|N_i\|_2\|\Lambda_i^{-1}\|_2, \tag{52}$$

where $\beta=\max_{k\neq l}\sqrt{\tau_{kl}^2+\tau_{lk}^2+2}$ and $\mu=\min_{k\neq l}\mu_{kl}$. In summary we have the following theorem.

THEOREM 4. *Let $C_i=A\Lambda_iA^T+tN_i, 1\le i\le N$ ($t\in[-\delta,\delta]$) with Λ_i's positive definite. Let us define $B(t)$, the nonorthogonal joint diagonalizer for $\{C_i\}_{i=1}^N$, as the*

minimizer of J_3. Then for small enough δ the joint diagonalizer can be written as $B(t) = (I + t\Delta)A^{-1} + o(t)$, where Δ (with diag$(\Delta) = 0$) satisfies (48) *as well as* (52).

Note that here, similar to the case of NOJD based on J_1, the modulus of uniqueness (μ) and the condition number of A affect the sensitivity. If one of the Λ_i's is close to singularity, i.e., if $\|\Lambda_i^{-1}\|$ is large, then the NOJD problem can be ill-conditioned. Therefore, almost similar to section 4.1, we might impose the constraint $\|N_i\|_2 \leq \|A\|_2^2 \|\Lambda_i^{-1}\|_2^{-1}$ and define the condition number for the NOJD problem based on J_3 as $\frac{\text{cond}(A)^2}{\mu - 1}$. The imposed condition simply means that if $\|\Lambda_i^{-1}\|_2$ is large, then $\|N_i\|_2$ must be small or $\|A\|_2$ should be large.

4.4. Effect of the number of matrices. One of our motivations in performing sensitivity analysis for the problem of NOJD has been to consider the effect of the number of matrices on the accuracy of the solution. $N = 2$ matrices are enough to find a unique nonorthogonal joint diagonalizer if $|\rho| < 1$. However, to combat noise, we may want to include more matrices. Inclusion of more matrices can have two effects: first on how $\mathcal{T}$ in (41) or $\mathcal{S}$ in (52) changes, second on how ρ, γ and α in (41), or on how μ and α in (52) may change. The first effect is related to noise cancellation through averaging; and the second one is related to improvement of uniqueness measures. Both, of course, depend on how N_i's and Λ_i's are statistically distributed. Let us consider a J_1-based-NOJD problem. Assume that the elements of N_i's are i.i.d. with zero mean, and that the elements of Λ_i's are i.i.d. with mean m and variance σ^2. Also, assume that the matrices are independent from each other. Then, by the strong law of large numbers, we have that $\|\frac{\mathcal{T}}{N}\| \to 0$, $\rho \to \frac{m^2}{\sigma^2 + m^2}$, and $N\alpha \to \frac{2}{\sigma^2 + m^2} < \infty$ as $N \to \infty$ with probability one. Hence, $\|\Delta\|_F \to 0$ as $N \to \infty$ with probability one. Note that this might not happen if N_i's and Λ_i's are of nonzero mean. For small values of N such as $N = 2, 3$, or 4, and, especially when n is large, $|\rho|$ can be very close to unity (for $N = 1$, $|\rho| = 1$). Moreover, the cancellation or averaging effect that we expect to happen in $\mathcal{T}$ for large values of N is not likely to happen for small N. Hence, for small N the NOJD problem can be very sensitive.

4.4.1. More on the number of matrices and modulus of uniqueness. Our claim that for small N the modulus of uniqueness $|\rho|$ can be close to unity deserves more elaboration. From Definition 1, we can interpret ρ_{kl} as the cosine of the angle between two N dimensional vectors $(\lambda_{1k}, \ldots, \lambda_{Nk})^T$ and $(\lambda_{1l}, \ldots, \lambda_{Nl})^T$. Without loss of generality, we can assume that the vectors are of unit length, i.e., they represent points on the unit sphere in $\mathbb{R}^N$. Now $|\rho|$ is the maximum of the absolute value of the cosine of the angles between n points on the unit sphere in $\mathbb{R}^N$. Since $|\rho|$ is independent of the direction of the vectors, we can assume that all the points lie on the same hemisphere on the unit sphere in $\mathbb{R}^N$. The fact that $|\rho|$ can be large when n is much larger than N is related to the fact that among n points on the unit hemisphere in $\mathbb{R}^N$ at least two of them cannot be very far apart from each other. In other words, there are at least two of the points which are closer to each other than a deterministic distance, which depends on n and N. As n increases and the points become denser this deterministic distance decreases and $|\rho|$ approaches unity. Note that $|\rho|$ can become large if there is a large obtuse angle (an angle with negative cosine) between two of the points as well. However, we can only argue that as the number of points increases, they should become denser at some region, and hence, the upper bound on the minimum angular distance between them should decrease. We cannot account for a lower bound on the maximum obtuse angles between the points

unless we know a specific distribution for the points.[7]

Unfortunately, finding the mentioned deterministic bound is difficult for arbitrary N. However, for $N = 2$ it is surprisingly easy to find. Assume that we have $n \geq 3$ points on the unit semicircle. Then we can divide the circumference of the semicircle into $n-1$ arcs each of length $\frac{\pi}{n-1}$. Then by putting n points on the unit semicircle at least two of them will lie on the same arc. Hence, for $N = 2$ we should have $|\rho| \geq \cos\frac{\pi}{n-1}$, for $n \geq 3$. This implies that for two 20×20 matrices, $|\rho| > 0.98$. Of course, for typical matrices this can be worse, since the bound we found is a lower bound. Again, note that this bound is solely based on an upper bound on the minimum of angular distances between the points. In fact, the configuration that achieves the bound $\frac{\pi}{n-1}$ has two antipodal points for which $\rho = -1$. Therefore, the bound is conservative. With more information about the points, we can find better lower bounds. For example, if the matrices are positive definite (i.e., $\lambda_{ik} > 0$ and hence $\rho > 0$), then we can consider points on a quarter of a circle and hence have a lower bound of $\cos\frac{\pi}{2(n-1)}$ on ρ. As a result, for two positive definite matrices of dimension only $n = 10$ we have that $\rho > 0.98$. Maybe the most interesting finding of this paper is that the NOJD of two matrices, if their dimension is fairly large, is ill-conditioned. This is true despite the fact that, as explained before, we might be able to find an exact nonorthogonal joint diagonalizer for the two matrices. Therefore, in general it is better to use more matrices not only to combat noise but also to improve the sensitivity.

The problem of finding an upper bound for the minimum distance between n points on the unit sphere in $\mathbb{R}^N$ is an old problem in the set of problems known as sphere packing problems. Tight bounds for these problems are in general very difficult to find. This specific problem is known as Tammes' problem or "dictators on a planet problem" [12]. One well-known result about it is a bound for $N = 3$. According to this result [24], for $n \geq 3$ points on the unit sphere in $\mathbb{R}^3$, there are at least two points whose spherical (angular) distance is smaller than $d_n = \cos^{-1}\frac{\cot^2\omega_n - 1}{2}$, where $\omega_n = \frac{n}{n-2}\frac{\pi}{6}$. Unfortunately, the proof for this result does not allow an extension to a parallel result for points on the hemisphere. However, we might argue, via homogeneity, that an approximate bound for n points on the hemisphere can be obtained by setting $2n$ points on the sphere and using d_{2n}. Hence, we have $\frac{\cot^2\omega_{2n}-1}{2}$ as an approximate lower bound for $|\rho|$ with $N = 3$. If we ignore the effect of the edge of the hemisphere, this scaling argument sounds quite plausible. Note that the scaling argument becomes more plausible for dense points. We expect the lower bound on $|\rho|$ to be smaller for $N = 3$ than that for $N = 2$, with equal n; and this is exactly what we observe. In Figure 2 we have plotted four curves. The lower two curves show the deterministic lower bounds on $|\rho|$ for $N = 2$ and $N = 3$ in terms of n. As can be seen, the bound for $N = 2$ is higher than the one for $N = 3$. The upper two curves show the average $|\rho|$ in terms of n, this time, for the uniform distribution of points on the circle and sphere. By uniform distribution on the sphere we mean that if $0 \leq \phi < 2\pi$ and $0 \leq \theta \leq \pi$ are the spherical coordinates of a point on the sphere, then these two random variables are uniformly distributed on their domains. Therefore, we generate n points (on the

[7] A more natural framework is to equip the unit sphere with a quotient topology and to identify its antipodal points, which results in the real projective plane in $\mathbb{R}^N$. This way we automatically take into account both the small acute and the large obtuse angles. While this paper was at the final stages of publication, the author realized that a more general version of the problem described previously, rather recently, has been addressed in the literature under the name of "Grassmannian packing problem." Nevertheless, the simplistic analysis presented here seems to be adequate for our main purposes.

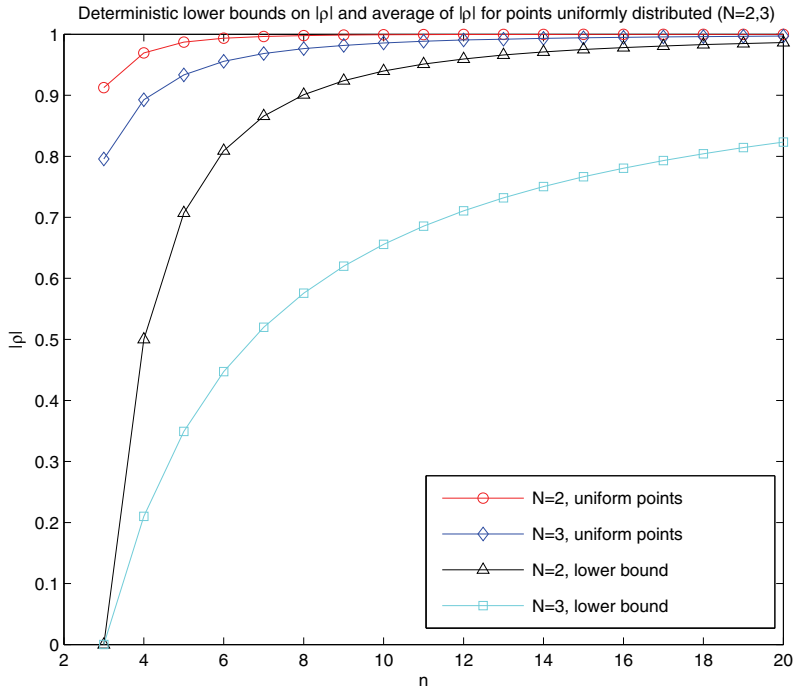

FIG. 2. *This graph shows two forms of variation of* $|\rho|$ *in terms of* n *for* $N = 2$ *and* $N = 3$. *The higher two curves show the average* $|\rho|$ *for points that are uniformly distributed on the circle and sphere. Here uniform means that the angular coordinates of the points in the spherical coordinate are uniformly distributed over the appropriate ranges. The lower two curves are the deterministic lower bounds described in the text. The deterministic bound for* $N = 2$ *is higher than the one for* $N = 3$, *as expected.*

circle or the sphere), find the $|\rho|$ for them, repeat this experiment $10,000$ times, and find the average $|\rho|$. As can be seen, these values of $|\rho|$ are much higher than the bounds.

How about for other values of N? Let us pretend that we could extend the simple argument for the circle to higher dimensions. This helps us unveil the main dynamics between n and N in affecting $|\rho|$. Denote the surface area of the unit sphere in $\mathbb{R}^N$ by S_N. Assume we could divide the surface of the hemisphere into $n-1$ congruent hyper-spherical regular polygons. This, of course, is a very difficult assumption to make. Let the angular diameter of each polygon be θ. If n is large, then we can approximate the area of the polygon by $V_{N-1}(\frac{\theta}{2})^{N-1}$, where V_{N-1} is the volume of the unit hyper-sphere in $\mathbb{R}^{N-1}$. Hence, we have $(n-1) \times V_{N-1}(\frac{\theta}{2})^{N-1} \approx \frac{S_N}{2}$, or $\theta \approx 2(\frac{1}{n-1})^{\frac{1}{N-1}}(\frac{S_N}{2V_{N-1}})^{\frac{1}{N-1}}$. One can see (for example, from the explicit formula for the surface and volume of the hyper-sphere in [27] and the formula related to the Gamma function in [26]) that $(\frac{S_N}{2V_{N-1}})^{\frac{1}{N-1}}$ is of order $O(1)$ for large N; and in fact, it converges to 1. Here $O(.)$ is the big O notation. Now, $\theta \approx 2(\frac{1}{n})^{\frac{1}{N}}$ for large n and

N, which in turn implies

$$|\rho| \geq \cos(\theta) \approx 1 - 2\left(\frac{1}{n}\right)^{\frac{2}{N}}. \tag{53}$$

This is in agreement, at least in its form, with a much more rigorous bound given in [12, Equation (66), p. 28]. To be accurate, the result in [12] states that if n is the maximum number of spherical caps of angular diameter $0 < \theta < 63^\circ$ that can be placed on the surface of the unit sphere in $\mathbb{R}^N$ without overlapping, then for large N

$$\cos\theta \gtrsim 1 - \left(\frac{1}{4}\right)^{0.099}\left(\frac{1}{n}\right)^{\frac{2}{N}} \approx 1 - 0.87\left(\frac{1}{n}\right)^{\frac{2}{N}}. \tag{54}$$

We can replace n with $2n$ to have a similar (approximate) result for the hyper-hemisphere, which essentially does not change the asymptotic bound. Either bounds suggests that in order to control $|\rho|$, as n increases, it suffices to have $N = O(\log n)$, which is encouraging! As a result, we do not need to have too many matrices in order to avoid the ill-conditioning that happens due to a small number of matrices being used. Note that if there is a structural cause of ill-conditioning within Λ_i's, then this recipe is irrelevant. Also, note that in (54) for fixed n as N increases $|\rho|$ does not decrease indefinitely; and there is an asymptotic nonzero lower bound of 0.13. Unfortunately, our approximate bound in (53) does not give an interesting answer in this case. The mentioned behavior is observed in our simulations. Figure 3 shows the experimental and fitted behavior of ρ in terms of N for $n = 20$. The experimental ρ comes from generating λ_{ik}'s independently from uniform distribution on $[0, 1]$. Each value of ρ is an average over 1000 runs. The graph also shows the curve $\tilde{\rho} = 1 - 0.20(\frac{1}{n})^{\frac{5.59}{N}}$ (with $n = 20$), which is fitted to the experimental data. These two curves obviously demonstrate the predicted dynamics between n and N in determining ρ. The mentioned asymptotic lower bound for ρ as $N \to \infty$ in this case is 0.8. The interesting point is that, for small N improvement of ρ is dramatic as N increases, whereas for larger N and better ρ increasing N does not improve the sensitivity significantly. Recall that the important quantity in the sensitivity is $\frac{1}{1-\rho^2}$ which drops rapidly at the first few N's. In fact for the experimental data it drops from 10^4 at $N = 2$ to 8.6 at $N = 10$. In this case the NOJD of only ten 20×20 matrices is well-conditioned or safe. Of course, use of more matrices improves the answer via averaging out the noise.

The preceding discussion concerned the behavior of $|\rho|$ in terms of N and n. Unfortunately, a similar framework and analysis for μ does not seem obvious. Nevertheless, simulations show that, expectedly, whenever $\rho \approx 1$, μ is also close to unity. Therefore, our conclusion that "for small N and large n, the NOJD problem is ill-conditioned" stays valid when J_3 is used, as well.

5. Numerical experiments. In this section we perform some experiments to examine the derived results. The first example is just a toy example and the second one is more realistic in the context of blind source separation (BSS).

5.1. Example 1. We investigate the effect of ρ, N, and the condition number of A, $\mathrm{cond}(A)$, on the sensitivity of NOJD for matrices generated as in (29). We generate $\{\Lambda_i\}_{i=1}^N$ with elements that are i.i.d. exponential random variables with mean 1. We choose $n = 10$. We also generate $A_{n\times n}$ randomly. Note that with probability one the joint diagonalizer for $\{C_i\}_{i=1}^N$ is unique. The noise matrices are with standard normal elements.

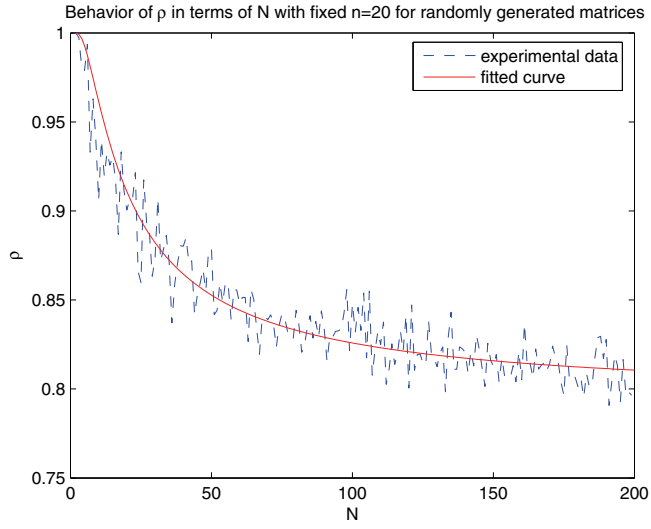

FIG. 3. *A typical behavior of* $|\rho|$ *in terms of* N *for fixed* n. *Here* $n = 20$ *and the* λ_{ik}*'s are generated from a uniform distribution on* $[0, 1]$. *The dashed curve shows the experimental* ρ. *Each point is an average over* 1000 *runs. The solid curve shows the curve* $\tilde{\rho} = 1 - 0.20(\frac{1}{n})^{\frac{5.59}{N}}$ *(with* $n = 20$*), which is fitted to the data.*

We consider the quality of joint diagonalization in terms of noise level t, ρ, and the condition number of A. We only consider J_1 and J_2 based methods. We use the QRJ2D algorithm,[8] introduced in [3], to find B and measure the error by

$$\text{Index}(P) = \sum_{i=1}^{n}\left(\sum_{j=1}^{n}\frac{|p_{ij}|}{\max_k |p_{ik}|} - 1\right) + \sum_{j=1}^{n}\left(\sum_{i=1}^{n}\frac{|p_{ij}|}{\max_k |p_{kj}|} - 1\right) \tag{55}$$

with $P = BA$. $\text{Index}(BA) \geq 0$ and the equality happens only when $BA = \Pi D$ (and hence $B = \Pi D A^{-1}$) for some Π and D. The smaller the index is, the better joint diagonalization is, in the sense that B is closer to A^{-1}. We try different values of N (and hence ρ). We also investigate the effect of cond(A), by keeping the Λ_i's the same, and increasing cond(A) while $\|A\|_F$ is constant. Table 5.1 gives the results. The left subtable shows the index for different values of N (hence ρ) for two different noise levels $t = 0$ and $t = 0.01$. By increasing the number of matrices and hence improving the modulus of uniqueness, the sensitivity improves. Note that for $N = 2$, sensitivity is so high that the QRJ2D algorithm does not give a good answer even at zero noise. The right subtable also shows the sensitivity degradation that happens because of increasing cond(A). In this experiment $\|A\|_F = 1$, $N = 100$, $t = 0$, and 0.0001. Sensitivity increases as conditioning of A degrades. Although the actual error values depend on the specific algorithm used, the trend of the error values as the parameters change gives an insight as to what factors affect the sensitivity.

5.2. Example 2: Separation of nonstationary sources. Now we consider a more realistic situation, which is the separation of nonstationary sources using NOJD

[8]The MATLAB code for this algorithm is available online at http://www.isr.umd.edu/Labs/ISL/ICA2006/.

TABLE 5.1

Left: Sensitivity of Index(BA) with respect to noise level t as N, and, hence ρ changes in Example 1. cond(A) = 25.11. Right: Sensitivity of Index(BA) with respect to noise level t as cond(A) increases and $\|A\|_F = 1$ ($\rho = .68$).

Index(BA)	$t = 0$	$t = 0.01$
$N = 2, \rho = 0.9999$	3.9	17.0
$N = 4, \rho = 0.9959$	0.00	3.46
$N = 10, \rho = 0.9662$	0.00	1.46
$N = 100, \rho = 0.6903$	0.00	0.29
$N = 200, \rho = 0.60$	0.00	0.19

Index(BA) ($N = 100, \rho = .68$)	t=0	t=0.0001
cond(A) = 1	0.00	0.01
cond(A) = 2	0.00	0.01
cond(A) = 10	0.00	0.12
cond(A) = 50	0.00	3.02
cond(A) = 100	0.00	28.51

of correlation matrices. This example also allows us to compare NOJD based on J_1 and J_3. The idea of using nonstationarity to separate sources has been described in [21]. Consider model (1) where the source vector is a Gaussian vector of independent components. Also, assume that the sources are nonstationary with varying variances. $R_{\mathbf{xx}}(t_i)$ the correlation matrix of the mixture at time t_i is

$$R_{\mathbf{xx}}(t_i) = A\Lambda_s(t_i)A^T, \tag{56}$$

where $\Lambda_s(t_i)$ is the (diagonal) correlation matrix of the source at time t_i. Suppose that we gather the correlation matrices at times $t_1, ..., t_N$, and form the set $\{R(t_i)\}_{i=1}^N$. If $\Lambda_s(t_i)$ changes enough such that the modulus of uniqueness for this set is smaller than one, then NOJD of this set yields an estimation for A^{-1}; and hence, it can result in the separation of the mixture.

We have $n = 10$ sources. First we generate a random matrix $A_{n\times n}$. The condition number for this matrix is 75.11. Then we generate the sources as follows. We assume that the sources are stationary on short periods of $T = 100$ samples, and that they change their variances randomly at the end of each period. We consider $N = 20$ periods. During the ith stationary period, the jth source has Gaussian distribution with zero mean and a random variance λ_{ij}. We draw each random standard deviation $\sqrt{\lambda_{ij}}$ from a uniform distribution on $[0, 1]$. Also, during the stationary periods each source generates independent samples. The sources are mixed through A. In each stationary period, we use the observed 100 samples of the mixture to estimate the correlation matrix for the mixture in that period. After the first stationary period, at the end of each stationary period, we perform an NOJD of the estimated correlation matrices gathered up to that time, in order to estimate A^{-1}. Also, as time passes, we compute ρ and μ for the set of true correlation matrices based on λ_{ij}'s. We use three different methods for NOJD of the estimated correlation matrices: (i) Pham's algorithm [20] which uses J_3 and requires positive definite matrices, (ii) QRJ2D algorithm, which is based on J_2, and (iii) FFDIAG [29] which is based on J_1. As we mentioned before, J_1 and J_2 based NOJD have similar sensitivity properties. We use QRJ2D and FFDIAG, since we want to have more evidence for comparing J_1-based-NOJD and J_3-based-NOJD. The output of each of these algorithms is an unmixing matrix B. In order to measure the performance we use two measures. One is Index(BA), which we introduced before. The other one is the mean-squared interference to signal ratio (ISR), which measures how much other sources are present at each restored source. Note that from (30) for the recovered source vector $\vec{\mathbf{y}}$ we have

$$\vec{\mathbf{y}} = B(t) \qquad \vec{\mathbf{x}} = B(t) \qquad \vec{\mathbf{s}} \approx \vec{\mathbf{s}} + t\Delta\vec{\mathbf{s}}. \tag{57}$$

Here again, we have ignored the possible scaling and permutation ambiguity in the

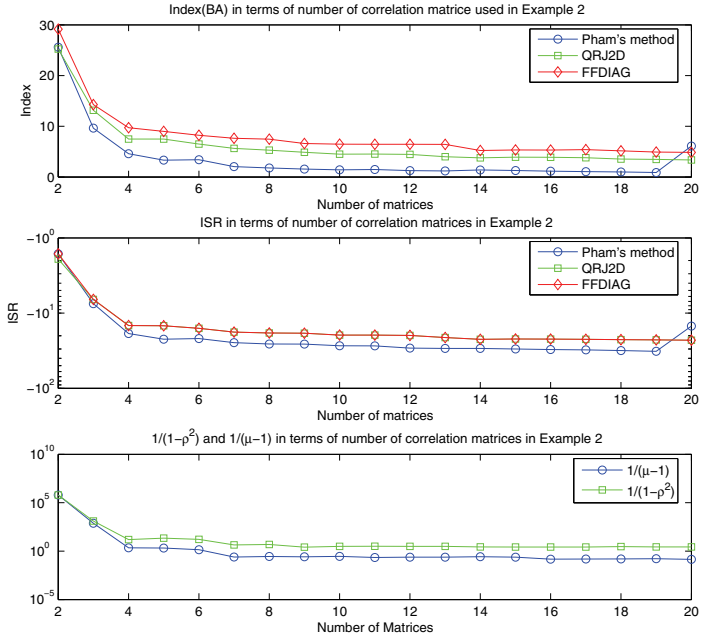

FIG. 4. *This figure shows the performance of source separation for nonstationary sources based on NOJD of correlation matrices at different times. As time passes, more correlation matrices are used. Three different methods for NOJD are employed: Pham'a algorithm, which is based on J_3, QRJ2D algorithm, which uses J_2, and FFDIAG, which uses J_1. Top: Index(BA) in terms of the number of correlation matrices used. Middle: ISR in terms of the number of correlation matrices used. Bottom: $\frac{1}{1-\rho^2}$ and $\frac{1}{\mu-1}$ in terms of the number of correlation matrices used. The jump seen at $i = 20$ in the graphs for J_3-based-NOJD is because in the last period some of the sources become extremely weak and the correlation matrix for that period becomes almost singular.*

restored vector. In practice, of course, we compute Δ from $P = BA$, after reordering and normalizing the rows of P. As the above equation suggests, $\|\Delta\|_F$ also measures the mean-squared ISR,[9] i.e., how much interference from other sources is present in each recovered source. We use

$$\text{ISR} = 10 \log \frac{\|\Delta\|_F^2}{n} \tag{58}$$

as a measure of the interference. Note that in this example we have no noise and the source of error is the estimation error due to a finite number of data samples. Another point that we want to examine is the sensitivity of NOJD based on J_3, in the case when one of the matrices becomes almost singular. For that purpose, in the last ($i = 20$) interval we set the standard deviation of six of the sources to 10^{-10}.

Figure 4 shows the results of the experiment. The top graph shows the Index(BA) in terms of i (which is the number of correlation matrices used) for different methods. The middle graph gives the ISR in terms of i. Note that the ISR measures for QRJ2D and FFDIAG are very close; however, the index measure for these two methods differ. The bottom graph shows $\frac{1}{1-\rho^2}$ and $\frac{1}{\mu-1}$ in terms of i for the correlation matrices

[9]The author is thankful to one of the anonymous reviewers for a reminder of this observation.

involved. As explained before, these two numbers, in fact, can be considered as condition numbers for NOJD based on J_1 and J_3, respectively (we have omitted the effect of A, i.e., $\mathrm{cond}(A)^2$, which is common in both condition numbers; see the last paragraphs of sections 4.1 and 4.3). For $i = 2, 3$ the numbers are very high for both of the cases. One can see that after the first few i, the condition numbers do not improve much. Note that the condition number for the J_1-based-NOJD is higher than that of the J_3-based-NOJD; and at the same time the J_3-based-NOJD yields better separation except for $i = 2$ and $i = 20$. From our theoretical results this is certainly what we expect. However, we cannot relate these two facts immediately, since the actual numbers depend on many factors. Note that NOJD for $i = 2, 3$ is not so effective, since the ISR measure is really poor (around or above -7dB). As a comparison, the best ISR that Pham's method achieves is -32dB, and the best one that QRJ2D or FFDIAG achieve is about -23dB. The jumps at $i = 20$ in $\mathrm{Index}(BA)$ and in ISR for Pham's method are due to the fact that the last correlation matrix is almost nonsingular. As we can see, the NOJD based on J_1 gives better separation in this case. Recall that J_1 does not require nonsingular matrices, and the condition number we assigned for J_3-based-NOJD was based on the assumption that $\|\Lambda_i^{-1}\|_2$'s are not too large. At $i = 20$ this condition is violated and that is why despite the fact that $\frac{1}{\mu-1} < \frac{1}{1-\rho^2}$, the J_1-based-NOJD performs better. For the curious reader, we mention that despite some evidence in this example, for a given $\{\Lambda_i\}_{i=1}^N$ the conjecture that $\frac{1}{\mu_{kl}-1} \leq \frac{1}{1-\rho_{kl}^2}$ or $\frac{1}{\mu-1} \leq \frac{1}{1-\rho^2}$ is not true. However, note that for $\frac{1}{\mu-1} \leq \frac{1}{1-\rho^2}$ to hold it is sufficient to have $\mu \geq 2$, which can be achieved since the range for μ is the long half-line $[1, +\infty)$. This may explain why in most simulations and in this example $\frac{1}{\mu-1} < \frac{1}{1-\rho^2}$.

6. Conclusions. We introduced the NOJD problem and the related EJD problem. We derived the uniqueness conditions for the EJD problem. We gave a joint diagonalization based formulation of ICA. Factors that affect the sensitivity of the NOJD problem were investigated. Modulus of uniqueness captures the uniqueness of the exact joint diagonalization problem and it affects the sensitivity of the NOJD problem that arises from adding noise to clean matrices. Also we showed that if the sought joint diagonalizer is ill-conditioned, then sensitivity will be high. We tried to quantitatively show how dimension of the matrices and the number of matrices can affect the modulus of uniqueness. In particular, we showed that the NOJD problem can be very ill-conditioned if the number of matrices is small and they are fairly large. Sensitivity of the NOJD problem depends on the cost function used; and in one example we gave a comparison of the behaviors of two different cost functions for NOJD.

Acknowledgments. The framework outlined in section 3.2.1 to derive the non-holonomic flow for NOJD has been conveyed to the author by Prof. P. S. Krishnaprasad. The author also would like to thank him for his support of this work. The author feels indebted to the anonymous reviewers who have read this paper and whose insightful suggestions have helped in improving the work. Also, the author cordially thanks Dr. Mehdi Kalantari for his comments and suggestions to improve this paper.

LOWER-RANK TENSOR APPROXIMATION AND MULTIWAY FILTERING*

DAMIEN MUTI†, SALAH BOURENNANE†, AND JULIEN MAROT†

Abstract. This paper presents some recent filtering methods based on the lower-rank tensor approximation approach for denoising tensor signals. In this approach, multicomponent data are represented by tensors, that is, multiway arrays, and the presented tensor filtering methods rely on multilinear algebra. First, the classical channel-by-channel SVD-based filtering method is overviewed. Then, an extension of the classical matrix filtering method is presented. It is based on the lower rank-$(K_1, \ldots, K_N)$ truncation of the higher order SVD which performs a multimode principal component analysis (PCA) and is implicitly developed for an additive white Gaussian noise. Two tensor filtering methods recently developed by the authors are also overviewed. The first method consists of an improvement of the multimode PCA-based tensor filtering in the case of an additive correlated Gaussian noise. This improvement is specially done thanks to the fourth order cumulant slice matrix. The second method consists of an extension of Wiener filtering for data tensors. The performances and comparative results between all these tensor filtering methods are presented for the cases of noise reduction in color images, multispectral images, and multicomponent seismic data.

Key words. multilinear algebra, tensor decomposition, multiway arrays, lower-rank approximation, filtering

1. Introduction.

Tensor data modeling and tensor analysis have been improved and used in several application fields, such as quantum physics, economy, chemometrics, psychology, and data analysis. Nevertheless, only recent studies focus their interest on tensor methods in signal processing applications. Tensor formulation in signal processing has received great attention since the recent development of multicomponent sensors, especially in imagery (color or multispectral images, video, etc.) and seismic fields (antenna of sensors recording waves with polarization properties). Indeed, the digital data obtained from these sensors are fundamentally higher order tensor objects, that is, multiway arrays whose elements are accessed via more than two indexes. Each index is associated with a dimension of the tensor generally called "nth-mode" [13, 14, 28, 29].

In recent decades, the classical algebraic processing methods have been specifically developed for vector and matrix representations. They are usually based on the covariance matrix, the cross-spectral matrix, or, more recently, the higher order statistics. Their overall aim is classically to determine a subspace associated with the signal or the parameters to estimate. They mainly rely on three algebraic tools.

(1) The singular value decomposition (SVD) [18], which is used in principal component analysis (PCA);

(2) Penrose–Moore matrix inversion [18]; and

(3) The matrix lower rank approximation, which, according to the Eckart–Young theorem [15], can be achieved thanks to a simple SVD truncation.

These methods have proved to be very efficient in several applications.

When dealing with multicomponent data represented as tensors, the classical processing techniques consist in rearranging or splitting the data set into matrices or vectors in order for the previously quoted classical algebraic processing methods to be applicable. The original data structure is then built anew, after processing.

In order to keep the data tensor as a whole entity, new signal processing methods have been proposed [35, 36, 37]. Hence, instead of adapting the data tensor to the classical matrix-based algebraic techniques (by rearrangement or splitting), these new methods propose to adapt their processing to the tensor structure of the multicomponent data. This new approach implicitly implies the use of multilinear algebra and mathematical tools that extend the SVD to tensors.

Two main tensor decomposition methods that generalize the matrix SVD have been initially developed to achieve a multimode PCA and recently used in tensor signal processing. They rely on two models, the TUCKER3 model and the PARAFAC model.

The TUCKER3 model [29, 48] was adopted in higher order SVD (HOSVD) [2, 13] and in lower rank-$(K_1, \ldots, K_N)$ tensor approximation [11, 14, 47]. We denote by HOSVD-$(K_1, \ldots, K_N)$ the truncation of HOSVD, performed with ranks $(K_1, \ldots, K_N)$, in modes $1, \ldots, N$, respectively. This model recently has been used as multimode PCA, in seismics for wave separation based on a subspace method, in image processing for face recognition and expression analysis [49, 52], and in noise filtering of color images [36].

The PARAFAC model and the CANDECOMP model were developed in [20] and [10], respectively. In [30] the link was set between CANDECOMP and PARAFAC models. The CANDECOMP/PARAFAC model, referred to as the CP model [25], has recently been applied to the food industry [9], array processing [45], and telecommunications [46].

These two decomposition methods differ in the tensor rank definition on which they are based. The HOSVD-$(K_1, \ldots, K_N)$ and the rank-$(K_1, \ldots, K_N)$ approximation rely on the nth-mode rank definition, that is, the rank of the tensor nth-mode flattening matrix [13, 14]. The rank-$(K_1, \ldots, K_N)$ approximation [14] relies on an optimization algorithm which is initialized by the HOSVD-$(K_1, \ldots, K_N)$ [13]. The rank-$(K_1, \ldots, K_N)$ approximation improves the approximation obtained with the HOSVD-$(K_1, \ldots, K_N)$. It relies on the determination of the signal subspace in every nth-mode of the data tensor and copes with additive white Gaussian noise. The rank-$(K_1, \ldots, K_N)$ approximation provides the best approximation in the sense of least Frobenius norm of the difference between estimated and expected tensors. Nevertheless it assumes a noncorrelated Gaussian noise. To face the case of correlated Gaussian noise, a variant of rank-$(K_1, \ldots, K_N)$ approximation, based on fourth order cumulants, was proposed [39]. Indeed, as it is proved in [33], the fourth order cumulants of a Gaussian variable are null.

A tensor framework was employed by [12] to express the solution to the linear independent component analysis (ICA) problem which employs fourth order cumulants. The multilinear ICA (N-mode ICA) model [50, 51], which was developed for face recognition, encodes the fourth order cumulants for each of the nth-mode flattening matrices of the tensor.

The CP model relies on a canonical decomposition of a tensor into a summation of rank-one tensors and on the extension of the classical matrix rank. Details on the tensor ranks and orthogonal tensor decomposition can be found in [22, 27].

When the TUCKER3 model and the PARAFAC model are associated with an ALS loop, they are known respectively as the TUCKALS3 algorithm [29, 28] and

the PARAFAC ALS algorithm [30, 20]. Many recent studies have been conducted to improve the convergence of these algorithms [14, 26, 56, 44].

The goal of this paper is to present an overview of the principal results concerning this new approach of data tensor filtering. More details on the algorithms presented in this survey can be found in [35, 36, 38, 39]. These algorithms are analogous to multilinear ICA but were developed independently for image filtering. The presented algorithms are based on a signal subspace approach, so they are efficient when the noise components are uncorrelated, when the signal and the additive noise are uncorrelated, and when some rows or columns of the image are redundant. In this case it is possible to distinguish between a signal subspace and a noise subspace, as for the traditional SVD-based filtering and Wiener filtering algorithms. Wiener filtering requires prior knowledge on the expected noisefree signal or image. However, multiway filtering methods provide the following advantage over traditional filtering methods: by apprehending a multiway data set as a whole entity, they take into account the dependence between modes thanks to ALS algorithms. The goal of the paper is also to present some simulations and comparative results concerning color images and multicomponent seismic signal filtering.

The paper is organized as follows. Section 2 presents the tensor data and a short overview of its main properties. Section 3 introduces the tensor formulation of the classical noise-removal problem as well as some new tensor filtering notations. First, we explain how the channel-by-channel SVD-based method processes successively each component of the data tensor. Second, we consider two methods that take into account the relationships between each component of the considered tensor. These two methods are based on the nth-mode signal subspace. The first method for signal tensor estimation is based on multimode PCA achieved by rank-$(K_1, \ldots, K_N)$ approximation. The second method is a new tensor version of Wiener filtering. Section 4 presents some comparative results where the overviewed multiway filtering methods are applied to noise reduction in color images, denoising of multispectral images, and denoising of multicomponent seismic waves. Section 5 concludes the paper.

The following notation is used in the rest of the paper. Scalars are denoted by italic lowercase roman (a); vectors by boldface lowercase roman ($\mathbf{a}$); matrices by boldface uppercase roman ($\mathbf{A}$); and tensors by uppercase calligraphic ($\mathcal{A}$). We distinguish a random vector, like $\mathbf{a}$, from one of its realizations by using a supplementary index, like $\mathbf{a}_i$.

2. Tensor representation and properties. We define a tensor of order N as a multidimensional array whose entries are accessed via N indexes. A tensor is denoted by $\mathcal{A} \in \mathbb{R}^{I_1 \times \cdots \times I_N}$, where each element is denoted by $a_{i_1 \cdots i_N}$, and $\mathbb{R}$ is the real manifold. Each dimension of a tensor is called nth-mode, where n refers to the n^{th} index. Figure 2.1 shows how a color image can be represented by a third order tensor $\mathcal{A} \in \mathbb{R}^{I_1 \times I_2 \times I_3}$, where I_1 is the number of rows, I_2 is the number of columns, and I_3 is the number of color channels. In the case of a color image, we have $I_3 = 3$. Let us define $E^{(n)}$ as the nth-mode vector space of dimension I_n, associated with the nth-mode of tensor $\mathcal{A}$. By definition, $E^{(n)}$ is generated by the column vectors of the nth-mode flattening matrix. The nth-mode flattening matrix $\mathbf{A}_n$ of tensor $\mathcal{A} \in \mathbb{R}^{I_1 \times \cdots \times I_N}$ is defined as a matrix from $\mathbb{R}^{I_n \times M_n}$, where

$$M_n = I_{n+1} I_{n+2} \cdots I_N I_1 I_2 \cdots I_{n-1}. \tag{2.1}$$

For example, when we consider a third order tensor, the definition of the matrix flattening involves the dimensions $I_1,\ I_2,\ I_3$ in a backward cyclic way [5, 13, 25].

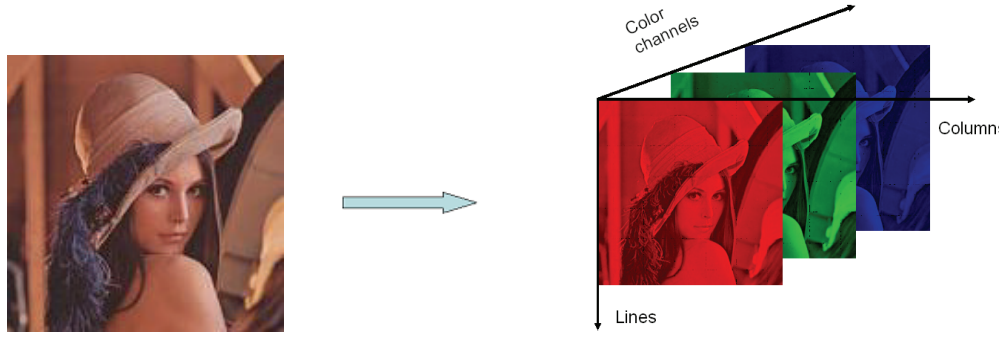

FIG. 2.1. *Lena standard color image and its tensor representation.*

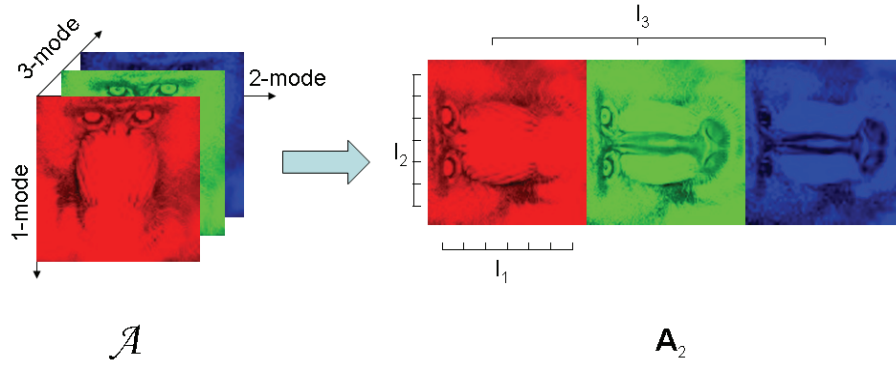

FIG. 2.2. *2nd-mode flattening of tensor* $\mathcal{A}$*:* $\mathbf{A}_2$.

When dealing with a 1st-mode flattening of dimensionality $I_1 \times (I_2 I_3)$, we formally assume that the index i_2 varies more slowly than i_3. For all $n = 1$ to 3, $\mathbf{A}_n$ columns are the I_n-dimensional vectors obtained from $\mathcal{A}$ by varying the index i_n from 1 to I_n and keeping the other indexes fixed. These vectors are called the nth-mode vectors of tensor $\mathcal{A}$. An illustration of the 2nd-mode flattening of a color image is presented in Figure 2.2.

In the following, we use the operator $\times_n$ as the nth-mode product, which generalizes the matrix product to tensors. Given $\mathcal{A} \in \mathbb{R}^{I_1 \times \cdots \times I_N}$ and a matrix $\mathbf{U} \in \mathbb{R}^{J_n \times I_n}$, the nth-mode product between tensor $\mathcal{A}$ and matrix $\mathbf{U}$ leads to the tensor $\mathcal{B} = \mathcal{A} \times_n \mathbf{U}$, which is a tensor of $\mathbb{R}^{I_1 \times \cdots I_{n-1} \times J_n \times I_{n+1} \times \cdots \times I_N}$, whose entries are given by

$$b_{i_1 \cdots i_{n-1} j_n i_{n+1} \cdots i_N} = \sum_{i_n=1}^{I_n} a_{i_1 \cdots i_{n-1} i_n i_{n+1} \cdots i_N} u_{j_n i_n}. \tag{2.2}$$

The next section presents the recent filtering methods for tensor data.

3. Tensor filtering problem formulation. The tensor data extend the classical vector data. The measurement of a multidimensional and multiway signal $\mathcal{X}$ by multicomponent sensors with additive noise $\mathcal{N}$ results in a data tensor $\mathcal{R}$ such that

$$\mathcal{R} = \mathcal{X} + \mathcal{N}. \tag{3.1}$$

$\mathcal{R}$, $\mathcal{X}$, and $\mathcal{N}$ are tensors of order N from $\mathbb{R}^{I_1 \times \cdots \times I_N}$. Tensors $\mathcal{N}$ and $\mathcal{X}$ represent noise and signal parts of the data, respectively. The goal of this study is to estimate the expected signal $\mathcal{X}$ thanks to a multidimensional filtering of the data [35, 36, 38, 39]:

$$\widehat{\mathcal{X}} = \mathcal{R} \times_1 \mathbf{H}^{(1)} \times_2 \mathbf{H}^{(2)} \times_3 \cdots \times_N \mathbf{H}^{(N)}, \tag{3.2}$$

From a signal processing point of view, the nth-mode product is a nth-mode filtering of data tensor $\mathcal{R}$ by nth-mode filter $\mathbf{H}^{(n)}$. Consequently, for all $n = 1$ to N, $\mathbf{H}^{(n)}$ is the nth-mode filter applied to the nth-mode of the data tensor $\mathcal{R}$.

In this paper we assume that the noise $\mathcal{N}$ is independent from the signal $\mathcal{X}$ and that the nth-mode rank K_n is smaller than the nth-mode dimension I_n ($K_n < I_n$, for all $n = 1$ to N). Then it is possible to extend the classical subspace approach to tensors by assuming that, whatever the nth-mode, the vector space $E^{(n)}$ is the direct sum of two orthogonal subspaces, namely, $E_1^{(n)}$ and $E_2^{(n)}$, which are defined as follows:

- $E_1^{(n)}$ is the subspace of dimension K_n, spanned by the K_n singular vectors associated with the K_n largest singular values of matrix $\mathbf{X}_n$; $E_1^{(n)}$ is called the signal subspace [1, 33, 55, 54].
- $E_2^{(n)}$ is the subspace of dimension $I_n - K_n$, spanned by the $I_n - K_n$ singular vectors associated with the $I_n - K_n$ smallest singular values of matrix $\mathbf{X}_n$; $E_2^{(n)}$ is called the noise subspace [1, 33, 55, 54].

The dimensions $K_1, K_2, \ldots, K_N$ can be estimated by means of the well-known Akaike information criterion (AIC) or Minimum description length (MDL) criteria [53], which are entropy-based information criteria. Hence, one way to estimate signal tensor $\mathcal{X}$ from noisy data tensor $\mathcal{R}$ is to estimate $E_1^{(n)}$ in every nth-mode of $\mathcal{R}$. The following section presents three tensor filtering methods based on nth-mode signal subspaces. The first method is an extension of classical matrix filtering algorithms. It consists of a channel-by-channel SVD-based filtering.

The second filtering method is based on multimode PCA achieved by rank-$(K_1, \ldots, K_N)$ approximation. Two algorithms are presented for this case. The first algorithm is implicitly developed for an additive *white* and Gaussian noise assumption, whereas the second algorithm represents an improvement of the first one in the case of a *correlated* Gaussian noise. This improvement is achieved thanks to higher order statistics.

The third method, the multiway Wiener filtering (Wmm-$(K_1, \ldots, K_N)$), is an algorithm that extends the classical two-dimensional Wiener filtering to tensor data.

3.1. Channel-by-channel SVD-based filtering. The classical algebraical methods operate on two-dimensional data matrices and are based on the SVD [1, 3, 4] and on the Eckart–Young theorem concerning the best lower rank approximation of a matrix [15] in the least-squares sense.

In the first method, a preprocessing is applied to the multidimensional and multiway data. It consists in splitting data tensor $\mathcal{R}$, representing the noisy multicomponent image into two-dimensional "slice matrices" of data, each representing a specific channel. According to the classical signal subspace methods [8], the left and right signal subspaces, corresponding to, respectively, the column and the row vectors of each slice matrix, are simultaneously determined by processing the SVD of the matrix associated with the data of the slice matrix. Let us consider the slice matrix $\mathcal{R}(:, :, i_3, \ldots, i_j, \ldots, i_N)$ of data tensor $\mathcal{R}$. Projectors $\mathbf{P}$ on the left signal subspace and $\mathbf{Q}$ on the right signal subspace are built from, respectively, the left and the right singular vectors associated with the K largest singular values of $\mathcal{R}(:, :, i_3, \ldots, i_j, \ldots, i_N)$.

The parameter K simultaneously defines the dimensions of the left and right signal subspaces. Applying the projectors $\mathbf{P}$ and $\mathbf{Q}$ on the slice $\mathcal{R}(:,:,i_3,\ldots,i_j,\ldots,i_N)$ amounts to computing its best lower rank-K matrix approximation [15] in the least-squares sense.

The filtering of each slice matrix of data tensor $\mathcal{R}$ separately is called in the following "channel-by-channel" SVD-based filtering of $\mathcal{R}$. It consists of a first way to estimate the signal tensor $\mathcal{X}$ and can be summarized by the following steps:

1. input: data tensor $\mathcal{R}$, left and right signal subspace dimension K.
   for $i_N = 1$ to I_N:
   for $i_{N-1} = 1$ to I_{N-1}:
   $\vdots$
   for $i_4 = 1$ to I_4:
   for $i_3 = 1$ to I_3:

   (a) calculate matrix $\mathcal{R}(:,:,i_3,\ldots,i_j,\ldots,i_N)$ SVD:

   $$\mathcal{R}(:,:,i_3,\ldots,i_j,\ldots,i_N) = \mathbf{U}\cdot\mathbf{\Sigma}\cdot\mathbf{V}^T,$$

   where $\mathbf{\Sigma}$ is the core matrix regrouping the singular values of the matrix $\mathcal{R}(:,:,i_3,\ldots,i_j,\ldots,i_N)$, and $\mathbf{U} = [\mathbf{u}_1\ldots\mathbf{u}_{I_1}]$ and $\mathbf{V} = [\mathbf{v}_1\ldots\mathbf{v}_{I_2}]$ are the matrices containing the left and right singular vectors defined respectively by $\mathbf{u}_{i_1}$ and $\mathbf{v}_{i_2}$.
   (b) construct matrices $\mathbf{U}_K = [\mathbf{u}_1\ldots\mathbf{u}_K]$ and $\mathbf{V}_K = [\mathbf{v}_1\ldots\mathbf{v}_K]$ containing the K largest left and right eigenvectors of $\mathcal{R}(:,:,i_3,\ldots,i_j,\ldots,i_N)$;
   (c) compute the projector $\mathbf{P} = \mathbf{U}_K\mathbf{U}_K^T$ on the column signal subspace, and projector $\mathbf{Q} = \mathbf{V}_K\mathbf{V}_K^T$ on the row signal subspace.
   (d) compute the two-dimensional slice matrices of the estimated expected signal $\widehat{\mathcal{X}}$:

   $$\widehat{\mathcal{X}}(:,:,i_3,\ldots,i_j,\ldots,i_N) = \mathbf{P}\mathcal{R}(:,:,i_3,\ldots,i_j,\ldots,i_N)\mathbf{Q}$$

2. output: estimated expected signal: $\widehat{\mathcal{X}}$.

Channel-by-channel SVD-based filtering is based on a common efficient method but exhibits a major drawback: it does not take into account the relationships between the components of the processed tensor. Moreover, channel-by-channel SVD-based filtering is appropriate only on some conditions. For example, applying SVD-based filtering to an image is generally appropriate when the rows or columns of an image are redundant, that is, linearly dependent. In this case, the rank K of the image is equal to the number of linearly independent rows or columns. It is only in this case that it would be safe to throw out eigenvectors from $K+1$ on. It is only in this special case that the noise subspace is orthogonal to the signal subspace. Otherwise, the noise simply increases the variance of the signal subspace and underestimating the signal subspace dimension would result in throwing out both signal and noise information. Thus, one would lose spatial resolution.

The next subsection presents a multiway filtering method that processes jointly, and not successively, each component of the data tensor.

3.2. Tensor filtering based on multimode PCA.

3.2.1. White decorrelated Gaussian noise and second-order-statistics-based method. Assuming that the dimension K_n of the signal subspace is known

for all $n = 1$ to N, one way to estimate the expected signal tensor $\mathcal{X}$ from the noisy data tensor $\mathcal{R} = \mathcal{X} + \mathcal{N}$ is to orthogonally project, for every nth-mode, the vectors of tensor $\mathcal{R}$ on the nth-mode signal subspace $E_1^{(n)}$ for all $n = 1$ to N. This statement is equivalent to replacing in (3.2) the filters $\mathbf{H}^{(n)}$ by the projectors $\mathbf{P}^{(n)}$ on the nth-mode signal subspace:

$$\widehat{\mathcal{X}} = \mathcal{R} \times_1 \mathbf{P}^{(1)} \times_2 \cdots \times_N \mathbf{P}^{(N)}. \tag{3.3}$$

In this last formulation, projectors $\mathbf{P}^{(n)}$ are estimated thanks to a multimode PCA applied to data tensor $\mathcal{R}$. This multimode PCA-based filtering generalizes the classical matrix filtering methods [16, 17, 21, 23, 24, 32] and implicitly supposes that the additive noise is *white* and *Gaussian*.

In the vector or matrix formulation, the definition of the projector on the signal subspace is based on the eigenvectors associated with the largest eigenvalues of the covariance matrix of the set of observation vectors. Hence, the determination of the signal subspace amounts to determine the best approximation (in the least-squares sense) of the observation matrix or the covariance matrix.

As an extension to the vector and matrix cases, in the tensor formulation, the projectors on the nth-mode vector spaces are determined by computing the rank-$(K_1, \ldots, K_N)$ approximation of $\mathcal{R}$ in the least-squares sense. From a mathematical point of view, the rank-$(K_1, \ldots, K_N)$ approximation of $\mathcal{R}$ is represented by tensor $\mathcal{R}^{K_1,\ldots,K_N}$ which minimizes the quadratic tensor Frobenius norm $\|\mathcal{R} - \mathcal{B}\|^2$ subject to the condition that $\mathcal{B} \in \mathbb{R}^{I_1 \times \ldots \times I_N}$ is a rank-$(K_1, \ldots, K_N)$ tensor. The description of the TUCKALS3 algorithm used in rank-$(K_1, \ldots, K_N)$ approximation is provided in the following.

Rank-$(K_1, \ldots, K_N)$ approximation - TUCKALS3 algorithm.

1. **Input:** data tensor $\mathcal{R}$, and dimensions $K_1, \ldots, K_N$ of all nth-mode signal subspaces.
2. **Initialization** $k = 0$: For $n = 1$ to N, calculate the projectors $\mathbf{P}_0^{(n)}$ given by HOSVD-$(K_1, \ldots, K_N)$:
   (a) nth-mode flatten $\mathcal{R}$ into matrix $\mathbf{R}_n$;
   (b) Compute the SVD of $\mathbf{R}_n$;
   (c) Compute matrix $\mathbf{U}_0^{(n)}$ formed by the K_n eigenvectors associated with the K_n largest singular values of $\mathbf{R}_n$. $\mathbf{U}_0^{(n)}$ is the initial matrix of the nth-mode signal subspace orthogonal basis vectors;
   (d) Form the initial orthogonal projector $\mathbf{P}_0^{(n)} = \mathbf{U}_0^{(n)}\mathbf{U}_0^{(n)^T}$ on the nth-mode signal subspace;
   (e) Compute the HOSVD-$(K_1, \ldots, K_N)$ of tensor $\mathcal{R}$ given by $\mathcal{B}_0 = \mathcal{R} \times_1 \mathbf{P}_0^{(1)} \times_2 \cdots \times_N \mathbf{P}_0^{(N)}$;
3. **ALS loop:**
   Repeat until convergence, that is, for example, while $\|\mathcal{B}_{k+1} - \mathcal{B}_k\|^2 > \epsilon$, $\epsilon > 0$ being a prior fixed threshold,
   (a) For $n = 1$ to N:
      i. Form $\mathcal{B}^{(n),k}$: $\mathcal{B}^{(n),k} = \mathcal{R} \times_1 \mathbf{P}_{k+1}^{(1)} \times_2 \cdots \times_{n-1} \mathbf{P}_{k+1}^{(n-1)} \times_{n+1} \mathbf{P}_k^{(n+1)} \times_{n+2} \cdots \times_N \mathbf{P}_k^{(N)}$;
      ii. nth-mode flatten tensor $\mathcal{B}^{(n),k}$ into matrix $\mathbf{B}_n^{(n),k}$;
      iii. Compute matrix $\mathbf{C}^{(n),k} = \mathbf{B}_n^{(n),k}\mathbf{R}_n^T$;
      iv. Compute matrix $\mathbf{U}_{k+1}^{(n)}$ composed of the K_n eigenvectors associated

with the K_n largest eigenvalues of $\mathbf{C}^{(n),k}$. $\mathbf{U}_k^{(n)}$ is the matrix of the nth-mode signal subspace orthogonal basis vectors at the k^{th} iteration;

v. Compute $\mathbf{P}_{k+1}^{(n)} = \mathbf{U}_{k+1}^{(n)} \mathbf{U}_{k+1}^{(n)^T}$;

(b) Compute $\mathcal{B}_{k+1} = \mathcal{R} \times_1 \mathbf{P}_{k+1}^{(1)} \times_2 \cdots \times_N \mathbf{P}_{k+1}^{(N)}$;

(c) Increment k.

4. **Output:** the estimated signal tensor is obtained through $\widehat{\mathcal{X}} = \mathcal{R} \times_1 \mathbf{P}_{k_{stop}}^{(1)} \times_2 \cdots \times_N \mathbf{P}_{k_{stop}}^{(N)}$. $\widehat{\mathcal{X}}$ is the rank-$(K_1, \ldots, K_N)$ approximation of $\mathcal{R}$, where k_{stop} is the index of the last iteration after the convergence of TUCKALS3 algorithm.

In this algorithm, the second order statistics come from the SVD of matrix $\mathbf{R}_n$ at step 2(b), which is equivalent, up to $\frac{1}{M_n}$ multiplicative factor, to the estimation of tensor $\mathcal{R}$ nth-mode vectors [39]. The definition of M_n is given in (2.1). In the same way, at step 3(a)iii, matrix $\mathbf{C}^{(n),k}$ is, up to $\frac{1}{M_n}$ multiplicative factor, the estimation of the covariance matrix between tensor $\mathcal{R}$ and tensor $\mathcal{B}^{(n),k}$ nth-mode vectors. According to step 3(a)ii, $\mathcal{B}^{(n),k}$ represents data tensor $\mathcal{R}$ filtered in every mth-mode but the nth-mode, by projection-filters $\mathbf{P}_l^{(m)}$, with $m \neq n$, $l = k$ if $m > n$ and $l = k + 1$ if $m < n$. TUCKALS3 algorithm has recently been used to process a multimode PCA in order to perform white noise removal in color images [36].

A good approximation of the rank-$(K_1, \ldots, K_N)$ approximation can simply be achieved by computing the HOSVD-$(K_1, \ldots, K_N)$ of tensor $\mathcal{R}$ [14, 34]. Indeed, the HOSVD-$(K_1, \ldots, K_N)$ of $\mathcal{R}$ consists of the initialization step of TUCKALS3 algorithm and hence can be considered as a suboptimal solution for the rank-$(K_1, \ldots, K_N)$ approximation of tensor $\mathcal{R}$ [14]. This HOSVD-based technique has recently been used in [39] for denoising and source separation of multicomponent seismic waves.

3.2.2. Correlated Gaussian noise and higher-order-statistics-based method. In practice, the condition of noise whiteness is not always fulfilled. Hence, in the case of an additive *correlated* Gaussian noise, the TUCKALS3 algorithm is theoretically incapable of providing a good estimation of the nth-mode signal subspaces since it is based on second order moments. A classical means to remove the Gaussian (noise) components is to use the higher order statistics, and especially the higher order cumulants. The tensor framework has been used to compute the fourth order cumulants as a means of solving the ICA problem [12]. Vasilescu and Terzopoulos introduced a multilinear ICA (N-mode ICA) for face recognition, which encodes the higher order statistics associated with each mode of the tensor [50, 51]. The related methods are based on the well-known cumulant property stating that the higher order cumulants of a Gaussian variable are null [31, 33].

As a consequence, in the case of an additive *correlated* Gaussian noise, a recent study [39] has proposed to improve the multimode PCA-based filtering by incorporating into the TUCKALS3 algorithm the fourth order cumulants instead of the second order moments.

From a practical point of view, second order matrices $\mathbf{C}^{(n),0}$ and $\mathbf{C}^{(n),k}$ at steps 2(b) and 3(a)iii of the TUCKALS3 algorithm are replaced with the corresponding fourth order cumulants. In the following, we present only the details of the procedure for matrix $\mathbf{C}^{(n),k}$. Obtaining the details concerning $\mathbf{C}^{(n),0}$ is straightforward.

We assume that $\{\mathbf{r}_p^{(n)}, p = 1, \ldots, M_n\}$ and $\{\mathbf{b}_p^{(n),k}, p = 1, \ldots, M_n\}$ are the M_n realizations of two random vectors $\mathbf{r}^{(n)}$ and $\mathbf{b}^{(n),k}$. In practice, we take as the realizations of these two random vectors the nth-mode vectors of data tensors $\mathcal{R}$ and $\mathcal{B}^{(n),k}$.

Matrix $\mathbf{C}^{(n),k}$ reads

$$\mathbf{C}^{(n),k} = \sum_{p=1}^{M_n} \mathbf{b}_p^{(n),k} \mathbf{r}_p^{(n)^T}. \tag{3.4}$$

The fourth order cumulants associated with vectors $\mathbf{r}^{(n)}$ and $\mathbf{b}^{(n),k}$ are denoted by

$$\mathcal{C}^{(n),k} = \mathrm{Cum}(\mathbf{b}^{(n),k}, \mathbf{b}^{(n),k^T}, \mathbf{r}^{(n)}, \mathbf{r}^{(n)^T}), \tag{3.5}$$

where $\mathrm{Cum}(\cdot)$ denotes the cumulant operator. $\mathcal{C}^{(n),k}$ is a fourth order super-symmetric tensor from $\mathbb{R}^{I_n \times I_n \times I_n \times I_n}$, whose generic term for indexes (i_1, i_2, j_1, j_2), for centered variables, is given by [19, 31]

$$\begin{aligned}(\mathcal{C}^{(n),k})_{i_1,i_2,j_1,j_2} &= \mathrm{E}[b_{i_1}^{(n),k} b_{i_2}^{(n),k} r_{j_1}^{(n)} r_{j_2}^{(n)}] \\ &\quad - \mathrm{E}[b_{i_1}^{(n),k} r_{j_1}^{(n)}]\mathrm{E}[b_{i_2}^{(n),k} r_{j_2}^{(n)}], -\mathrm{E}[b_{i_1}^{(n),k} r_{j_2}^{(n)}]\mathrm{E}[b_{i_2}^{(n),k} r_{j_1}^{(n)}]\end{aligned} \tag{3.6}$$

where $b_i^{(n),k}$ and $r_j^{(n)}$ are the ith and jth components of random vectors $\mathbf{b}^{(n),k}$ and $\mathbf{r}^{(n)}$, and $\mathrm{E}[\cdot]$ is the expectation operator. The practical estimation of $(\mathcal{C}^{(n),k})_{i_1,i_2,j_1,j_2}$ is given by

$$\begin{aligned}(\mathcal{C}^{(n),k})_{i_1,i_2,j_1,j_2} &= \frac{1}{M_n}\left(\sum_{p=1}^{M_n}\left(b_{i_1p}^{(n),k} b_{i_2p}^{(n),k} r_{j_1p}^{(n)} r_{j_2p}^{(n)}\right)\right) \\ &\quad - \frac{1}{{M_n}^2}\left(\sum_{p=1}^{M_n}\left(b_{i_1p}^{(n),k} r_{j_1p}^{(n)}\right)\right)\left(\sum_{p=1}^{M_n}\left(b_{i_2p}^{(n),k} r_{j_2p}^{(n)}\right)\right) \\ &\quad - \frac{1}{{M_n}^2}\left(\sum_{p=1}^{M_n}\left(b_{i_1p}^{(n),k} r_{j_2p}^{(n)}\right)\right)\left(\sum_{p=1}^{M_n}\left(b_{i_2p}^{(n),k} r_{j_1p}^{(n)}\right)\right).\end{aligned} \tag{3.7}$$

Here, $b_{ip}^{(n),k}$ and $r_{ip}^{(n)}$ are the elements at position (i, j) of tensors $\mathcal{B}^{(n),k}$ and $\mathcal{R}$ nth-mode flattening matrices $\mathbf{B}_n^{(n),k}$ and $\mathbf{R}_n$.

In the classical TUCKALS3 algorithm, the K_n nth-mode signal subspace basis vectors, given by matrix $\mathbf{U}^{(n),k}$, are estimated by computing, at step 3a, the eigenvectors associated with the K_n largest eigenvalues of matrix $\mathbf{C}^{(n),k}$. This amounts to computing the best lower rank-K_n approximation of $\mathbf{C}^{(n),k}$. In [41] fourth order cumulants are used instead of the covariance matrix because of their ability to remove Gaussian noise. Indeed, the fourth order cumulants of Gaussian variables are null. Therefore, when dealing with an additive *correlated* Gaussian noise, we also use fourth order cumulants [39].

The main drawback of fourth order cumulants is the high computational load to build every fourth order cumulant tensor associated with the nth-mode of the data tensor. This computational load depends on the size of the data tensor $\mathcal{R}$, that is, the values of I_n, for all $n = 1$ to N. One way to reduce the computational load has been proposed in [39] and consists in using the fourth order cumulant slice matrix. The cumulant slice matrix has initially been introduced in array processing for source localization or directions-of-arrival (DOA) estimation [7, 55, 54]. In [19, 55, 54], it is proved that the signal subspace spanned by the eigenvectors associated with the largest eigenvalues of a cumulant slice matrix is the same as signal subspace obtained from the whole cumulant tensor defined in (3.5) [55, 54]. Therefore, we use only the

eigenvectors of one cumulant slice matrix in our algorithm (see step 2(a)iii because the other cumulant slice matrices provide redundant information. The use of the fourth order cumulant slice matrix provides a much faster algorithm [54]. In our application, the fourth order cumulant slice matrix $\mathbf{C}_q^{(n),k}$ can be defined, from (3.6), by fixing the q^{th} component of vector $\mathbf{b}^{(n),k}$ as follows:

$$\left(\mathbf{C}_q^{(n),k}\right)_{ij} = \mathrm{E}\left[(b_q^{(n),k})^2 r_i^{(n)} r_j^{(n)}\right] - 2\mathrm{E}\left[b_q^{(n),k} r_i^{(n)}\right]\mathrm{E}\left[b_q^{(n),k} r_j^{(n)}\right]. \tag{3.8}$$

The practical estimation of $(\mathbf{C}_q^{(n),k})_{ij}$ can be given by

$$\left(\mathbf{C}_q^{(n),k}\right)_{ij} = \frac{1}{M_n}\left(\sum_{p=1}^{M_n}\left(b_{qp}^{(n),k}\right)^2 r_{ip}^{(n)} r_{jp}^{(n)}\right) - \frac{2}{M_n^2}\left(\sum_{p=1}^{M_n} b_{qp}^{(n),k} r_{ip}^{(n)}\right)\left(\sum_{p=1}^{M_n} b_{qp}^{(n),k} r_{jp}^{(n)}\right), \tag{3.9}$$

where $b_{ij}^{(n),k}$ and $r_{ij}^{(n)}$ are, respectively, the elements at position (i,j) in the nth-mode flattening matrices $\mathbf{B}_n^{(n),k}$ and $\mathbf{R}_n$ of tensors $\mathcal{B}^{(n),k}$ and $\mathcal{R}$.

As a consequence, in the case of an additive *correlated* Gaussian noise, the K_n nth-mode signal subspace basis vectors can now be estimated by computing matrix $\mathbf{C}_q^{(n),k}$ lower rank-K_n approximation. Then, the fourth order cumulant slice matrix-based multimode PCA-based filtering can be summarized as follows:

1. **Initialization** $k = 0$:
   For all $n = 1$ to N, $\mathbf{P}_0^{(n)} = \mathbf{U}_0^{(n)}\mathbf{U}_0^{(n)^T}$. $\mathbf{U}_0^{(n)}$ is the matrix of the K_n eigenvectors associated with the K_n largest eigenvalues of fourth order cumulant slice matrix $\mathbf{C}_q^{(n),0}$ of tensor $\mathcal{R}$ nth-mode vectors.
2. **ALS loop:**
   The steps (b) and (c) of the ALS loop are the same as in the algorithm "**rank-$(K_1,\ldots,K_N)$ approximation - TUCKALS3 algorithm**" described previously, and step (a) is replaced by
   (a) For $n = 1$ to N:
      i. $\mathcal{B}^{(n),k} = \mathcal{R}\times_1\mathbf{P}_{k+1}^{(1)}\times_2\cdots\times_{n-1}\mathbf{P}_{k+1}^{(n-1)}\times_{n+1}\mathbf{P}_k^{(n+1)}\times_{n+2}\cdots\times_N\mathbf{P}_k^{(N)}$;
      ii. Compute cumulant slice matrix $\mathbf{C}_q^{(n),k}$ associated with the fourth order cumulants of tensors $\mathcal{R}$ and $\mathcal{B}^{(n),k}$ nth-mode vectors. Every element of $\mathbf{C}_q^{(n),k}$ is given in (3.9);
      iii. Process matrix $\mathbf{C}_q^{(n),k}$ eigenvalue decomposition (EVD) and put the K_n eigenvectors associated with the K_n largest eigenvalues into $\mathbf{U}_{k+1}^{(n)}$;
      iv. Compute projector $\mathbf{P}_{k+1}^{(n)} = \mathbf{U}_{k+1}^{(n)}\mathbf{U}_{k+1}^{(n)^T}$;
3. **Output:** $\widehat{\mathcal{X}} = \mathcal{R}\times_1\mathbf{P}_{k_{stop}}^{(1)}\times_2\cdots\times_N\mathbf{P}_{k_{stop}}^{(N)}$, with k_{stop} being the index of the last iteration after convergence of the algorithm.

It was experimentally shown in [39] that when the parameter q involved in $\mathbf{C}_q^{(n),k}$ is chosen properly, multimode PCA filtering based on fourth order cumulants (denoted by rank$-\mathcal{C}(K_1,\ldots,K_N)$) and on fourth order cumulant slice matrix (denoted by rank$-\mathbf{C}_1(K_1,\ldots,K_N)$) give sensibly the same performances in regard to noise reduction in color images and multicomponent seismic waves.

3.3. Multiway Wiener filtering. Let $\mathbf{R}_n$, $\mathbf{X}_n$, and $\mathbf{N}_n$ be the nth-mode flattening matrices of tensors $\mathcal{R}$, $\mathcal{X}$, and $\mathcal{N}$, respectively.

In the previous subsection, the estimation of signal tensor $\mathcal{X}$ has been performed by projecting noisy data tensor $\mathcal{R}$ on each nth-mode signal subspace. The nth-mode

projectors have been estimated thanks to the use of multimode PCA achieved by rank-$(K_1, \ldots, K_N)$ approximation. Despite the good results given by this method, it is possible to improve the tensor filtering quality by determining nth-mode filters $\mathbf{H}^{(n)}$, $n = 1$ to N, in (3.2), which optimize an estimation criterion. The most classical method is to minimize the mean squared error between the expected signal tensor $\mathcal{X}$ and the estimated signal tensor $\widehat{\mathcal{X}}$ given in (3.2):

$$\mathrm{e}(\mathbf{H}^{(1)}, \ldots, \mathbf{H}^{(N)}) = \mathrm{E}[\|\mathcal{X} - \mathcal{R} \times_1 \mathbf{H}^{(1)} \times_2 \cdots \times_N \mathbf{H}^{(N)}\|^2]. \tag{3.10}$$

Due to the criterion which is minimized, filters $\mathbf{H}^{(n)}$, $n = 1$ to N, can be called "nth-mode Wiener filters" [38].

According to the calculations presented in Appendix A, especially from (A.1) to (A.15), the minimization of (3.10) with respect to filter $\mathbf{H}^{(n)}$, for fixed $\mathbf{H}^{(m)}$, $m \neq n$, leads to the following expression of nth-mode Wiener filter:

$$\mathbf{H}^{(n)} = \gamma_{\mathbf{XR}}^{(n)} {\mathbf{\Gamma}_{\mathbf{RR}}^{(n)}}^{-1}, \tag{3.11}$$

where

$$\gamma_{\mathbf{XR}}^{(n)} = \mathrm{E}\left[\mathbf{X}_n \mathbf{T}^{(n)} \mathbf{R}_n^T\right] \tag{3.12}$$

is the $\mathbf{T}^{(n)}$-weighted covariance matrix between the random column vectors of signal $\mathbf{X}_n$ and data $\mathbf{R}_n$, with

$$\mathbf{T}^{(n)} = \mathbf{H}^{(1)} \otimes \cdots \otimes \mathbf{H}^{(n-1)} \otimes \mathbf{H}^{(n+1)} \otimes \cdots \otimes \mathbf{H}^{(N)}, \tag{3.13}$$

where $\otimes$ stands for Kronecker product, and

$$\mathbf{\Gamma}_{\mathbf{RR}}^{(n)} = \mathrm{E}\left[\mathbf{R}_n \mathbf{Q}^{(n)} \mathbf{R}_n^T\right] \tag{3.14}$$

is the $\mathbf{Q}^{(n)}$-weighted covariance matrix of the data $\mathbf{R}_n$, with

$$\mathbf{Q}^{(n)} = {\mathbf{T}^{(n)}}^T \mathbf{T}^{(n)}. \tag{3.15}$$

In order to obtain $\mathbf{H}^{(n)}$ through (3.11), we suppose that the filters $\{\mathbf{H}^{(m)}, m = 1 \text{ to } N, m \neq n\}$ are known. Data tensor $\mathcal{R}$ is available, but signal tensor $\mathcal{X}$ is unknown. So, only the term $\mathbf{\Gamma}_{\mathbf{RR}}^{(n)}$ can be derived, and not the term $\gamma_{\mathbf{XR}}^{(n)}$. Hence, some more assumptions on $\mathcal{X}$ have to be made in order to overcome the indetermination over $\gamma_{\mathbf{XR}}^{(n)}$ [35, 38]. In the one-dimensional case, a classical assumption is to consider that a signal vector is a weighted combination of the signal subspace basis vectors. In extension to the tensor case, [35, 38] have proposed considering that the nth-mode flattening matrix $\mathbf{X}_n$ can be expressed as a weighted combination of K_n vectors from the nth-mode signal subspace $E_1^{(n)}$:

$$\mathbf{X}_n = \mathbf{V}_s^{(n)} \mathbf{O}^{(n)} \tag{3.16}$$

with $\mathbf{X}_n \in \mathbb{R}^{I_n \times M_n}$, and $\mathbf{V}_s^{(n)} \in \mathbb{R}^{I_n \times K_n}$ being the matrix containing the K_n orthonormal basis vectors of nth-mode signal subspace $E_1^{(n)}$. Matrix $\mathbf{O}^{(n)} \in \mathbb{R}^{K_n \times M_n}$ is a weight matrix and contains the whole information on expected signal tensor $\mathcal{X}$. This model implies that signal nth-mode flattening matrix $\mathbf{X}_n$ is orthogonal to nth-mode

noise flattening matrix $\mathbf{N}_n$, since signal subspace $E_1^{(n)}$ and noise subspace $E_2^{(n)}$ are supposed mutually orthogonal.

Supposing that noise $\mathcal{N}$ in (3.1) is white, Gaussian, and independent from signal $\mathcal{X}$, and introducing the signal model (3.16) in (3.11) leads to a computable expression of nth-mode Wiener filter $\mathbf{H}^{(n)}$ (see Appendix B),

$$\mathbf{H}^{(n)} = \mathbf{V}_s^{(n)} \gamma_{\mathbf{OO}}^{(n)} \mathbf{\Lambda}_{\mathbf{\Gamma s}}^{(n)^{-1}} \mathbf{V}_s^{(n)^T}, \tag{3.17}$$

where $\gamma_{\mathbf{OO}}^{(n)} \mathbf{\Lambda}_{\mathbf{\Gamma s}}^{(n)^{-1}}$ is a diagonal weight matrix given by

$$\gamma_{\mathbf{OO}}^{(n)} \mathbf{\Lambda}_{\mathbf{\Gamma s}}^{(n)^{-1}} = \operatorname{diag}\left[\frac{\beta_1}{\lambda_1^{\Gamma}}, \cdots, \frac{\beta_{K_n}}{\lambda_{K_n}^{\Gamma}}\right], \tag{3.18}$$

where $\lambda_1^{\Gamma}, \ldots, \lambda_{K_n}^{\Gamma}$ are the K_n largest eigenvalues of $\mathbf{Q}^{(n)}$-weighted covariance matrix $\mathbf{\Gamma}_{\mathbf{RR}}^{(n)}$ (see (3.14)). Parameters $\beta_1, \ldots, \beta_{K_n}$ depend on $\lambda_1^{\gamma}, \ldots, \lambda_{K_n}^{\gamma}$, which are the K_n largest eigenvalues of $\mathbf{T}^{(n)}$-weighted covariance matrix $\gamma_{\mathbf{RR}}^{(n)} = \mathrm{E}[\mathbf{R}_n \mathbf{T}^{(n)} \mathbf{R}_n^T]$, according to the following relation:

$$\beta_{k_n} = \lambda_{k_n}^{\gamma} - \sigma_{\Gamma}^{(n)^2} \ \forall\ k_n = 1, \ldots, K_n. \tag{3.19}$$

Superscript γ refers to the $\mathbf{T}^{(n)}$-weighted covariance and subscript $\mathbf{\Gamma}$ to the $\mathbf{Q}^{(n)}$-weighted covariance. $\sigma_{\Gamma}^{(n)^2}$ is the degenerated eigenvalue of noise $\mathbf{T}^{(n)}$-weighted covariance matrix $\gamma_{\mathbf{NN}}^{(n)} = \mathrm{E}\left[\mathbf{N}_n \mathbf{T}^{(n)} \mathbf{N}_n^T\right]$. Thanks to the additive noise and the signal independence assumptions, the $I_n - K_n$ smallest eigenvalues of $\gamma_{\mathbf{RR}}^{(n)}$ are equal to $\sigma_{\Gamma}^{(n)^2}$ and thus can be estimated by the following relation:

$$\widehat{\sigma}_{\Gamma}^{(n)^2} = \frac{1}{I_n - K_n} \sum_{k_n = K_n + 1}^{I_n} \lambda_{k_n}^{\gamma}. \tag{3.20}$$

In order to determine the nth-mode Wiener filters $\mathbf{H}^{(n)}$ that minimize the mean squared error (3.10), the alternating least squares (ALS) algorithm has been proposed in [35, 38]. It can be summarized in the following steps:

1. **Initialization** $k = 0$**:** $\mathcal{R}^0 = \mathcal{R} \Leftrightarrow \mathbf{H}_0^{(n)} = \mathbf{I}_{In}$, Identity matrix, $\forall\ n = 1 \ldots N$.
2. **ALS loop:**
   Repeat until convergence, that is, $\left\|\mathcal{R}^{k+1} - \mathcal{R}^k\right\|^2 < \epsilon$, with $\epsilon > 0$ prior fixed threshold,
   (a) for $n = 1$ to N:
      i. Form $\mathcal{R}^{(n),k}$: $\mathcal{R}^{(n),k} = \mathcal{R} \times_1 \mathbf{H}_{k+1}^{(1)} \times_2 \cdots \times_{n-1} \mathbf{H}_{k+1}^{(n-1)} \times_{n+1} \mathbf{H}_k^{(n+1)} \times_{n+2} \ldots \times_N \mathbf{H}_k^{(N)}$;
      ii. Determine $\mathbf{H}_{k+1}^{(n)} = \arg\min_{\mathbf{Z}^{(n)}} \left\|\mathcal{X} - \mathcal{R}^{(n),k} \times_n \mathbf{Z}^{(n)}\right\|^2$
      subject to $\mathbf{Z}^{(n)} \in \mathbb{R}^{I_n \times I_n}$ thanks to the following procedure:
         A. nth-mode flatten $\mathcal{R}^{(n),k}$ into $\mathbf{R}_n^{(n),k} = \mathbf{R}_n(\mathbf{H}_{k+1}^{(1)} \otimes \cdots \otimes \mathbf{H}_{k+1}^{(n-1)} \otimes \mathbf{H}_k^{(n+1)} \otimes \cdots \otimes \mathbf{H}_k^{(N)})^T$, and $\mathcal{R}$ into $\mathbf{R}_n$;
         B. Compute $\gamma_{\mathbf{RR}}^{(n)} = \mathrm{E}[\mathbf{R}_n \mathbf{R}_n^{(n),k^T}]$,
         C. Determine $\lambda_1^{\gamma}, \ldots, \lambda_{K_n}^{\gamma}$, the K_n largest eigenvalues of $\gamma_{\mathbf{RR}}^{(n)}$;

D. For $k_n = 1$ to I_n, estimate $\sigma_\Gamma^{(n)^2}$ thanks to (3.20) and for $k_n = 1$ to K_n, estimate β_{k_n} thanks to (3.19);
E. Compute $\mathbf{\Gamma}_{\mathbf{RR}}^{(n)} = \mathrm{E}[\mathbf{R}_n^{(n),k}\mathbf{R}_n^{(n),k^T}]$;
F. Determine $\lambda_1^\Gamma, \ldots, \lambda_{K_n}^\Gamma$, the K_n largest eigenvalues of $\mathbf{\Gamma}_{\mathbf{RR}}^{(n)}$;
G. Determine $\mathbf{V}_s^{(n)}$, the matrix of the K_n eigenvectors associated with the K_n largest eigenvalues of $\mathbf{\Gamma}_{\mathbf{RR}}^{(n)}$;
H. Compute the weight matrix $\gamma_{\mathbf{OO}}^{(n)}\mathbf{\Lambda}_{\mathbf{\Gamma s}}^{(n)^{-1}}$ given in (3.18);
I. Compute $\mathbf{H}_{k+1}^{(n)}$, the nth-mode Wiener filter at the $(k+1)^{\text{th}}$ iteration, using (3.17);

(b) Form $\mathcal{R}^{k+1} = \mathcal{R} \times_1 \mathbf{H}_{k+1}^{(1)} \times_2 \cdots \times_N \mathbf{H}_{k+1}^{(N)}$;
(c) Increment k;

3. **output:** $\widehat{\mathcal{X}} = \mathcal{R} \times_1 \mathbf{H}_{k_{stop}}^{(1)} \times_2 \cdots \times_N \mathbf{H}_{k_{stop}}^{(N)}$, with k_{stop} being the last iteration after convergence of the algorithm.

In subsection 3.2, we presented the adaptation of multimode PCA to the case of a noncorrelated Gaussian noise, by using higher order statistics. In the same way, it is possible to use higher order statistics for multiway Wiener filtering. For this, one should replace step 2(a)iiB by step 2(a)ii of the ALS loop in subsection 3.2, and replace step 2(a)iiE by the computation of the cumulant slice $\mathbf{C}_q^{(n),k}$ associated with the fourth order cumulants of matrix $\mathbf{R}_n^{(n),k}$ and matrix $(\mathbf{R}_n^{(n),k})^T$. Elements of $\mathbf{C}_q^{(n),k}$ are given in (3.9).

4. Simulation results. In the following simulations, the channel-by-channel SVD-based filtering defined in subsection 3.1 and the rank-$(K_1, \ldots, K_N)$ approximation-based multiway and multidimensional filtering are applied to the denoising of color images and multispectral images and to the denoising of seismic signals. Color images, multispectral images, and seismic signals can be represented by a third order tensor from $\mathbb{R}^{I_1 \times I_2 \times I_3}$, where I_1, I_2, and I_3 take different values. In all these applications, the efficiency of denoising is tested in the presence of an additive Gaussian noise, either correlated or not.

A multidimensional and multiway white Gaussian noise $\mathcal{N}$ which is added to signal tensor $\mathcal{X}$ can be expressed as

$$\mathcal{N} = \alpha \cdot \mathcal{G}, \tag{4.1}$$

where every element of $\mathcal{G} \in \mathbb{R}^{I_1 \times I_2 \times I_3}$ is an independent realization of a normalized centered Gaussian law and where α is a coefficient that permits to set the signal-to-noise ratio (SNR) in noisy data tensor $\mathcal{R}$.

When we process images impaired by correlated Gaussian noise, the noise which is added is a third order tensor defined by

$$\mathcal{N}^c = \mathcal{N} \times_1 \mathbf{W}^{(1)} \times_2 \mathbf{W}^{(2)} \times_3 \mathbf{W}^{(3)}, \tag{4.2}$$

where every element of $\mathcal{N}$ represents an independent realization of a white Gaussian noise and $\mathbf{W}^{(n)}$ is a weight matrix in the nth-mode, $n = 1, 2, 3$.

In order to evaluate the performances of the overviewed tensor signal processing methods, a particular performance criterion is employed as proposed in [38, 39].

4.1. Performance criterion. Following the representation of (3.1), the multiway noisy data tensor is expressed as $\mathcal{R} = \mathcal{X} + \mathcal{N}$, where $\mathcal{X}$ is the expected signal

tensor and $\mathcal{N}$ is the additive noise tensor. Let us define the SNR, in dB, in the noisy data tensor by

$$\text{SNR} = 10 \log \left(\frac{\|\mathcal{X}\|^2}{\|\mathcal{N}\|^2} \right). \tag{4.3}$$

In order to a posteriori verify the quality of the estimated signal tensor, we use the normalized quadratic error criterion (NQE) defined as follows:

$$\text{NQE}(\widehat{\mathcal{X}}) = \frac{\|\widehat{\mathcal{X}} - \mathcal{X}\|^2}{\|\mathcal{X}\|^2}. \tag{4.4}$$

The NQE criterion permits a quantitative comparison of the channel-by-channel SVD-based filtering and the rank-(K_1, K_2, K_3) approximation multiway and multidimensional filtering. Considering this criterion, we expect the rank-(K_1, K_2, K_3) approximation to give better results than the channel-by-channel SVD-based filtering method.

4.2. Denoising of color images. Denoising of color images has been studied in several works [6, 40, 43]. Some solutions have been brought from the field of wavelet processing, exhibiting good results in terms of output SNR. These studies concern only bidimensional data, whereas the methods that we compare are adapted to the processing of third order tensors as a whole, and in particular to three-channel images. We focus on subspace-based methods. We first consider the channel-by-channel SVD-based filtering, the rank-(K_1, K_2, K_3) approximation and multiway Wiener filtering (Wmm-(K_1, K_2, K_3)), applied to images impaired by an additive white Gaussian noise.

Then we present the results obtained with rank-(K_1, K_2, K_3) based on second order and higher order statistics, applied to images impaired by an additive correlated Gaussian noise. We compare the performances of the methods applied in this subsection in terms of denoising efficiency and computational load.

4.2.1. Denoising of a color image impaired by additive Gaussian noise. Let us consider the "sailboat" standard color image of Figure 4.1(a) represented as a third order tensor $\mathcal{X} \in \mathbb{R}^{256 \times 256 \times 3}$. The ranks of the signal subspace for each mode are 30 for the 1st-mode, 30 for the 2nd-mode, and 2 for the 3rd-mode. This is fixed thanks to the following process. For Figure 4.1(a), we took the standard nonnoisy sailboat image and artificially reduced the ranks of the nonnoisy image, that is, we set the parameters (K_1, K_2, K_3) to $(30, 30, 2)$, thanks to the truncation of HOSVD. This ensures that, for each mode, the rank of the signal subspace is lower than the corresponding dimension. This also permits us to evaluate the performances of the filtering methods applied, independently from the accuracy of the estimation of the values of the ranks by MDL or AIC criterion.

Figure 4.1(b) shows the noisy image resulting from the impairment of Figure 4.1(a) and represented as $\mathcal{R} = \mathcal{X} + \mathcal{N}$. Third-order noise tensor $\mathcal{N}$ is defined by relation (4.1) by choosing α such that, considering previous definition of (4.3), the SNR in the noisy image of Figure 4.1(b) is 8.1 dB. In these simulations, the value of the parameter K of channel-by-channel SVD-based filtering, the values of the dimensions of the row and column signal subspace are supposed to be known and fixed to 30. In the same way, parameters (K_1, K_2, K_3) of rank-(K_1, K_2, K_3) approximation are fixed to $(30, 30, 2)$.

The channel-by-channel SVD-based filtering of noisy image $\mathcal{R}$ (see Figure 4.1(b)) yields the image of Figure 4.1(c), and rank-$(30, 30, 2)$ approximation of noisy data ten-

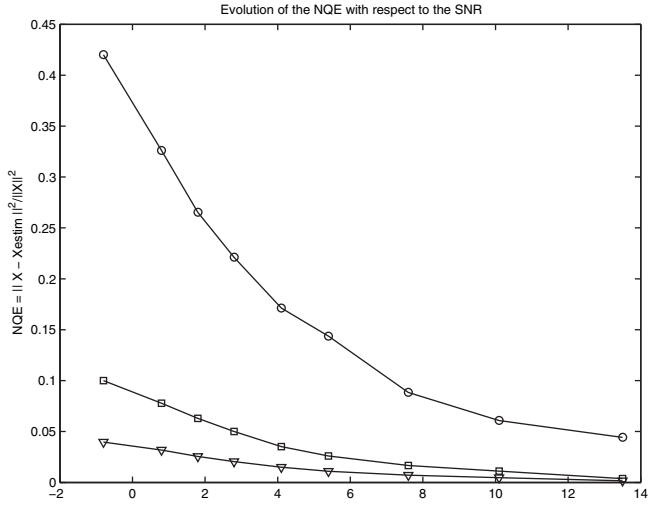

FIG. 4.2. *NQE evolution with respect to SNR* (dB): *channel-by-channel SVD-based filtering of parameter* 30 *(-○-), rank-(*$30, 30, 2$*) approximation (-□-), Wmm-(*$30, 30, 2$*) filtering (-▽-).*

sor $\mathcal{R}$ yields the image of Figure 4.1(d). The NQE, defined in (4.4), permits a qualitative comparison between channel-by-channel SVD-based filtering and rank-$(30, 30, 2)$ approximation. Figure 4.2, which presents the evolution of the NQE with respect to SNR varying from 3 dB to 18 dB, shows the NQE obtained with Wmm-$(30, 30, 2)$ is lower than the NQE obtained with the filtering with rank-$(30, 30, 2)$ approximation.

For this simulation, the rank-(K_1, K_2, K_3) approximation gives better results than channel-by-channel SVD-based filtering according to the NQE criterion. From the resulting image, presented on Figure 4.1(d), we note that dimension reduction leads to a loss of spatial resolution. However, the choice of a set of values K_1, K_2, K_3 which are small enough is the condition for an efficient noise reduction effect.

Therefore, a trade-off should be considered between noise reduction and detail preservation. This trade-off was discussed in [42]. We were interested in using the minimum description length (MDL) criterion [53], applied to the left singular values of the flattening matrices computed over the successive nth-modes. As a rule of thumb, the MDL criterion overestimates the value of parameters K_1, K_2, and K_3. This results in the preservation of the details in the processed image, at the expense of an efficient denoising.

Concerning the qualitative results obtained with this color image, we note that the intraclass variance of the pixel values of each component (or color mode) of the resulting image is lower for the image obtained with Wmm-$(30, 30, 2)$ than for those images obtained with other methods applied in this subsection. This allows, for example, appling after denoising a high level classification method with a higher efficiency than when classification is applied after channel-by-channel SVD-based filtering or HOSVD-$(30, 30, 2)$.

For the $256 \times 256 \times 3$ sailboat image of Figure 4.1, the computational times needed when Matlab programs are used on a 3 Ghz Pentium 4 processor running Windows are as follows. HOSVD-$(30, 30, 2)$ lasts 1.61 seconds, the channel-by-channel SVD-based filtering lasts 1.94 seconds, the rank-$(30, 30, 2)$ approximation run with 25 iterations lasts 54.1 seconds, and Wmm-$(30, 30, 2)$ run with 25 iterations lasts 40.0 seconds.

The results presented in Figure 4.1 show that Wmm-(K_1, K_2, K_3) allows one to obtain better results in terms of NQE with a computational load which is lower than that of the rank-(K_1, K_2, K_3) approximation. In the next two examples we study the influence of the values of the nth-mode ranks. In the example of Figure 4.3 we set, in the same way as in the previous example, the ranks of the truncated image to $(30, 30, 3)$ (see Figure 4.3(a)). Note that $K_3 = I_3 = 3$. Thus the assumption $K_3 < I_3$ is not fulfilled. We aim at studying the behavior of the proposed tensor filtering algorithms when the color mode rank is equal to the color mode dimension ($K_3 = I_3$). The truncated image is impaired by a noncorrelated Gaussian noise such that SNR = 8.1 dB (see Figure 4.3(b)). The results obtained show that channel-by-channel Wiener-based filtering of parameter $K = 30$ (see Figure 4.3(c)) is outperformed by rank-$(30, 30, 3)$ approximation (see Figure 4.3(d)) and Wmm-$(30, 30, 3)$ (see Figure 4.3(e)). Indeed, the proposed tensor filtering algorithms rely on an ALS loop which permits us to take into account the relationships between the filters of each mode when multiway filters are used. In particular, concerning multiway Wiener filtering, it can be adapted to the case where it is applied with $K_3 = I_3$. For this, the weight matrix $\gamma^{(3)}_{\mathbf{OO}} \mathbf{\Lambda}^{(3)^{-1}}_{\mathbf{\Gamma s}}$ of step 2aiiH of the multiway Wiener filtering algorithm presented in subsection 3.3 is set to identity. That is, $\mathbf{H}^{(3)}$ is replaced by $\mathbf{P}^{(3)}$. We adapted the algorithm in order to take into account the channel mode information for the computation of the two spatial filters thanks to the ALS loop.

This proves the interest of multiway filtering even in the case where the rank of the signal subspace along the third mode is equal to the number of channels.

In the example of Figure 4.4 we study the case where the ranks of the signal subspaces are underestimated for the spatial modes. Let us consider the "Mondriaan" standard color image of Figure 4.4 represented as a third order tensor $\mathcal{X} \in \mathbb{R}^{256 \times 256 \times 3}$. We set the ranks of the truncated image to $(150, 150, 3)$. The ranks along the spa-

FIG. 4.4. (a) *Nonnoisy image.* (b) *Image to be processed, impaired by an additive white Gaussian noise, with SNR*$= 8.0$ *dB.* (c) *Channel-by-channel SVD-based filtering of parameter* $K = 19$. (d) *rank-(*$19, 19, 3$*) approximation.* (e) *Wmm-(*$19, 19, 3$*) filtering.*

tial modes will be fixed intentionally to a value which is smaller than 150 when the reviewed methods are applied. Figure 4.4(a) gives the nonnoisy image, Figure 4.4(b) shows the noisy image resulting from the impairment, with SNR= 8.0 dB, of the image of Figure 4.4(a). Figure 4.4(c) gives the result obtained with channel-by-channel SVD-based filtering of parameter $K = 19$. Figure 4.4(d) gives the result obtained with rank-$(19, 19, 3)$ approximation, and Figure 4.4(e) gives the result obtained with Wmm-$(19, 19, 3)$ filtering. Note that choosing (K_1, K_2, K_3)=$(19, 19, 3)$ results in throwing out both signal and noise information along the spatial modes, as the ranks of the noisy image are $(150, 150, 3)$. Underestimating the ranks along the spatial modes induces some blurry effect in the result images: part of the spatial resolution is lost. The presented subspace-based algorithms perform well if there is a high level of redundancy in the column or row space or if the image exhibits many soft or blurry edges, and the nth-mode ranks are not underestimated.

4.2.2. HOSVD-(K_1, K_2, K_3), rank-(K_1, K_2, K_3) approximation based on second order and higher order statistics, applied to an image impaired by an additive correlated Gaussian noise. The purpose here is to compare methods based on second order statistics with methods based on higher order statistics when an image is impaired by a correlated Gaussian noise. Figure 4.5 shows the results obtained with the HOSVD-(K_1, K_2, K_3), and the rank-(K_1, K_2, K_3) approximation based on second order and higher order statistics, used for the denoising of an image impaired by an additive correlated Gaussian noise. We consider the nonnoisy image of Figure 4.5(a) whose ranks are fixed to $(30, 30, 2)$: we artificially reduced the ranks of the nonnoisy image, that is, we set the parameters (K_1, K_2, K_3) to (30,30,2), thanks to the truncation of HOSVD. This image is impaired by a correlated Gaussian noise (see (4.2)). Figure 4.5(b) shows the noisy image. The result of HOSVD-(K_1, K_2, K_3) is given in Figure 4.5(c), and the result of rank-(K_1, K_2, K_3) approximation based on second order statistics is given in Figure 4.5(d), the result of

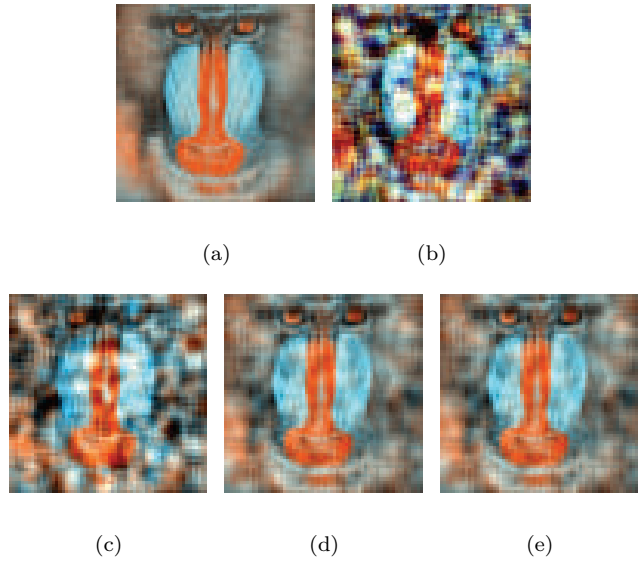

FIG. 4.5. (a) *Initial nonnoisy image.* (b) *Initial image with an additive correlated Gaussian noise, SNR = 2.48 dB.* (c) *HOSVD-(30, 30, 2) .* (d) *rank-$\mathcal{C}$(30, 30, 2) approximation.* (e) *rank-$\mathbf{C}_1$(30, 30, 2) approximation.*

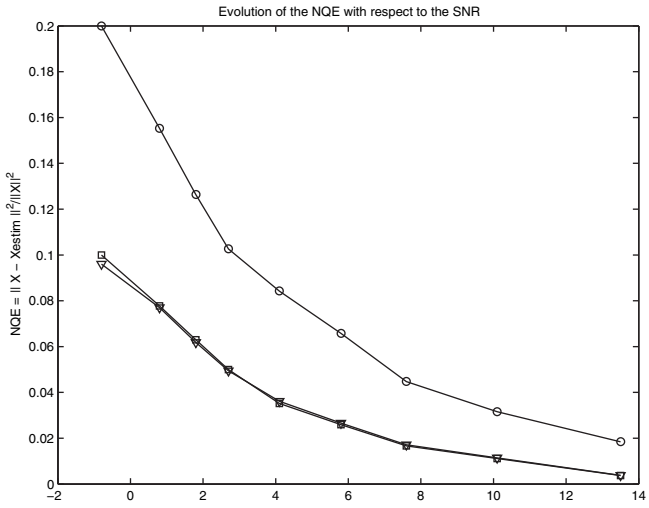

FIG. 4.6. *Evolution of the NQE with respect to the SNR(dB) for each tensor filtering method:* ○*: HOSVD-*$(30, 30, 2)$*;* ▽*: rank-*$\mathcal{C}(30, 30, 2)$*;* □*: rank-*$\mathbf{C}_1(30, 30, 2)$*.*

rank$-\mathcal{C}(K_1, K_2, K_3)$ approximation based on higher order statistics is given in Figure 4.5(e). The evolution of the NQE with respect to the SNR for HOSVD-$(30, 30, 2)$, rank-$\mathcal{C}(30, 30, 2)$ approximation based on fourth order cumulants, rank-$\mathbf{C}_1(30, 30, 2)$ approximation based on one slice of the fourth order cumulants is represented in Figure 4.6.

The main conclusion from Figure 4.5 is that the methods based on fourth order cumulants give similar visual results and better results than HOSVD-$(30, 30, 2)$. Whatever the SNR, the methods based on fourth order cumulants give a lower NQE value than the methods based on second order statistics. The method based on fourth order cumulant slice matrix gives sensibly the same NQE values as the method based on fourth order cumulants.

For the $256 \times 256 \times 3$ baboon image of Figure 4.5, the computational times needed in the same conditions of processor and software as in previous subsection are the following: HOSVD-$(30, 30, 2)$ lasts 1.61 seconds, rank-$\mathcal{C}(30, 30, 2)$ based filtering lasts 2h. 11 min. 40 seconds, rank-$\mathbf{C}_1(30, 30, 2)$ lasts 3 min. 50 seconds.

4.3. Denoising of multispectral images. The results obtained from the processing of a multispectral image composed of 72 rows, 160 columns and 100 spectral channels representing a truck are considered. This set of spectral images can be represented as a tensor $\mathcal{X} \in \mathbb{R}^{72 \times 160 \times 100}$. Images shown on Figures 4.7(a) to 4.7(e) represent channels 30 to 34 of the multispectral image. To evaluate the performances of the reviewed methods, some signal-independent white Gaussian noise $\mathcal{N}$ is added to $\mathcal{X}$ and results in noisy tensor $\mathcal{R} = \mathcal{X} + \mathcal{N}$. Channels 30 to 34 of noisy multispectral image represented as $\mathcal{R}$ are shown in Figures 4.7(f) to 4.7(j), and correspond to a noise impairment level SNR $= -1$ dB. Figures 4.7(k) to 4.7(o) represent channels 30 to 34 of the multispectral image obtained by applying channel-by-channel-based SVD-filtering to noisy image $\mathcal{R}$. Finally, Figures 4.7(p) to 4.7(t) represent channels 30 to 34 of the multispectral image obtained after applying rank-(30,30,30) approximation to noisy image $\mathcal{R}$. This last simulation clearly shows that the rank-(30,30,30) approximation-based filtering gives better results than channel-by-channel SVD-based

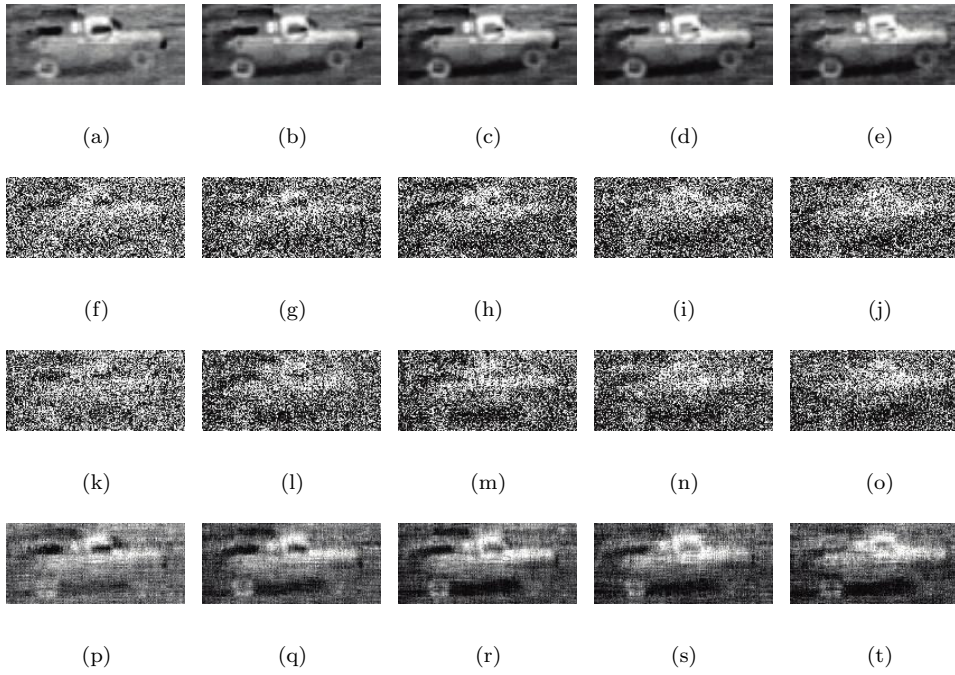

FIG. 4.7. *Channels* 30 *to* 34 *of the processed multispectral images are presented:* (a)–(e) *Nonnoisy multispectral image.* (f)–(j) *Impaired multispectral image.* (k)–(o) *Results obtained with channel-by-channel SVD filtering.* (p)–(t) *Results obtained with rank-*$(30, 30, 30)$ *approximation.*

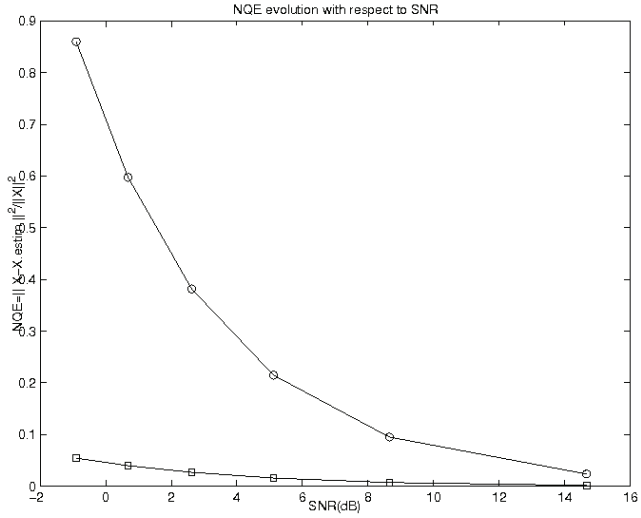

FIG. 4.8. *NQE evolution with respect to SNR (from* -1 *to* 15 *dB): channel-by-channel SVD-based filtering of parameter* 30 *(-∘-), and rank-(*$30, 30, 30$*) approximation (-□-).*

filtering in regard to denoising. Moreover, the evolution of the NQE with respect to the SNR varying from -1 dB to 15 dB, represented in Figure 4.8, shows that the NQE obtained with Wmm-(K_1, K_2, K_3) is lower than the NQE obtained with a previously existing method.

For this simulation the estimation quality, respect to the NQE criterion, is better for rank-(K_1, K_2, K_3) approximation, compared to channel-by-channel SVD-based filtering. Superiority of rank-(K_1, K_2, K_3) approximation compared to channel-by-channel SVD-based filtering is confirmed.

According to the simulations performed on a color image and on a multispectral image, it is possible to conclude that the more channels the image is composed of, the better the denoising. This can be explained by a better estimation of projectors on 1st-mode and 2nd-mode signal subspaces in the case of the multispectral image. Indeed, the number of spectral channels in a multispectral image is much larger than in a color image. Equivalently, I_3 is much larger than 3, so M_1 and M_2 are much larger than for a color image, and the estimation of matrices $\mathbf{C}^{(1),k}$ and $\mathbf{C}^{(2),k}$ presented in (3.4) are computed with more realization vectors.

4.4. Statistical performances. The goal of the following simulation is to test the robustness to noise of channel-by-channel SVD-based filtering of parameter K and of rank-(K_1, K_2, K_3) approximation, with respect to the NQE criterion. We process the Sailboat standard color image, impaired by an additive Gaussian noise, with SNR values varying from -0.7 dB to 15 dB; 100 trials are performed. For each trial one realization of additive Gaussian noise is simulated and added to the nonnoisy image. The mean and standard deviation are computed over the NQE values obtained each time the channel-by-channel SVD-based filtering and the rank-(K_1, K_2, K_3) approximation are run. The evolution of the mean NQE

$$m_{\mathrm{NQE}} = \frac{1}{100} \sum_{i=1}^{100} \mathrm{NQE}_i, \tag{4.5}$$

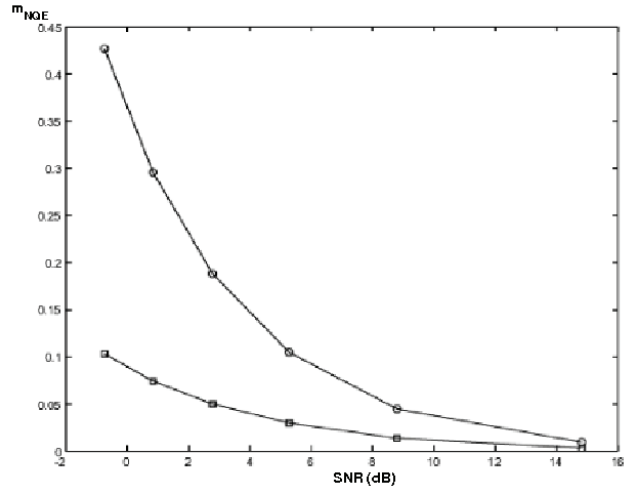
where index i refers to the ith noise realization, is represented in Figure 4.9(a) with respect to SNR. The evolution of the standard deviation of the NQE,

$$\mathrm{std}_{\mathrm{NQE}} = \sqrt{\frac{1}{100} \sum_{i=1}^{100} (\mathrm{NQE}_i - m_{\mathrm{NQE}})^2}, \tag{4.6}$$

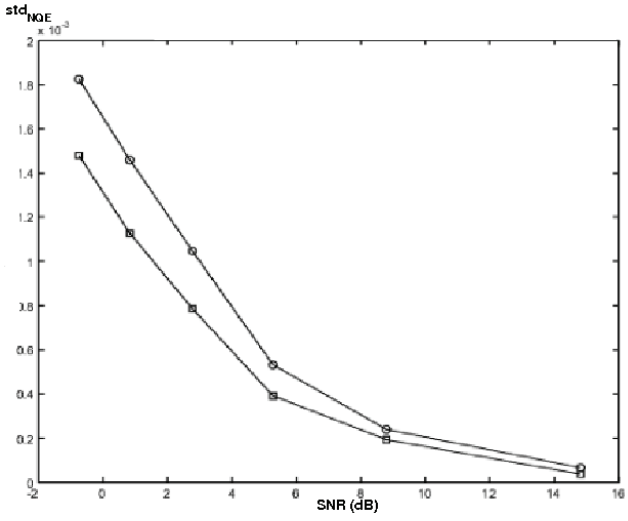
is represented in Figure 4.9(b), with respect to the SNR. Figure 4.9 shows that the mean and standard deviation values of the NQE obtained with rank-(K_1, K_2, K_3) approximation and computed over 100 noise realizations are both lower than the mean and the standard deviation values obtained with channel-by-channel SVD-based filtering. Thus, for these simulations, the rank-(K_1, K_2, K_3) approximation gives better results than channel-by-channel SVD-based filtering in regard to the robustness of tensor estimation and considering the NQE criterion.

4.5. Filtering of a multicomponent seismic type signal.

4.5.1. Filtering of a multicomponent seismic type signal impaired by an additive white Gaussian noise. In this simulation, a multicomponent seismic wave is received on a linear antenna composed of 10 sensors. The direction of propagation of the wave is assumed to be contained in a plane which is orthogonal to the antenna. The three components of the wave, represented as signal tensor $\mathcal{X}$, are called Component 1, Component 2, and Component 3 and are represented in Figures 4.10(a)–(c). In each seismic slice, the x-axis corresponds to the time sampling (200 or 100 time samples) and the y-axis corresponds to the spatial sensors (10 sensors). Each consecutive component presents a $\frac{\pi}{2}$ radian phase shift. The three components of noisy data tensor



(a)



(b)

FIG. 4.9. *(∘): results obtained with channel-by-channel SVD-based filtering of parameter* 30*; (□): results obtained with rank-(*30, 30, 2*) approximation.* (a) *Evolution of the mean NQE with respect to SNR (dB).* (b) *Evolution of the standard deviation of NQE with respect to SNR (dB).*

$\mathcal{R}$ are represented in Figures 4.10(d)–(f), where the additive noise is considered as white and Gaussian and for which the SNR = −10 dB. The classical Wiener filtering of parameter K (Wcc-K) of each component, with a signal subspace dimension fixed to $K = 8$, permits us to obtain the results presented in Figures 4.10(g)–(i). The multimode PCA-based filtering achieved by applying HOSVD-(8,8,3) to noisy data tensor permits to obtain the results presented in Figures 4.10(j)–(l). Finally, the results obtained with multiway Wiener filtering applied to the noisy data tensor are presented in Figures 4.10(m)–(o). The evolution of the NQE with respect to the SNR

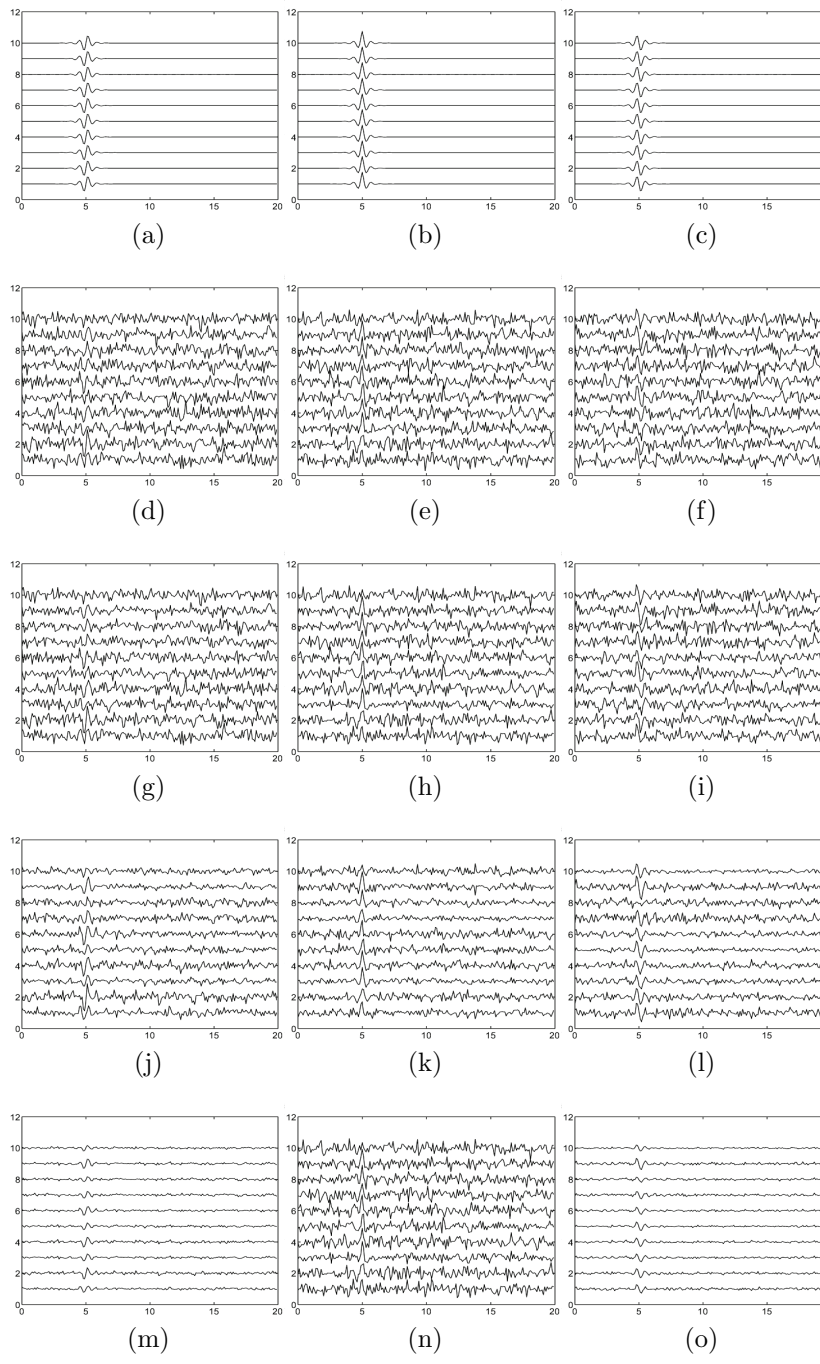


FIG. 4.10. *Nonnoisy, impaired, and processed seismic wave: the three polarization components.* (a)–(c) *Components* $1, 2,$ *and* 3 *of the nonnoisy seismic wave.* (d)–(f) *Components* $1, 2,$ *and* 3 *of the seismic wave, impaired by an additive white Gaussian noise (SNR* $= -10$ *dB).* (g)–(i) *Wiener filtering applied component by component (Wcc-K), with rank* $K = 8$. (a) (b) (c)

FIG. 4.12. *Multicomponent seismic signal.* (a)–(c) *Components* 1 *to* 34 *of the nonnoisy seismic wave.*

(dB) is given in Figure 4.11. As well as in the case of color image filtering, in this simulation, the best quality, in terms of noise reduction, is given by multiway Wiener filtering since, for all considered SNR values, the NQE values given by this method are lower than the values given by both HOSVD-$(8, 8, 3)$ and Wcc-8.

4.5.2. Filtering of a multicomponent seismic type signal impaired by an additive correlated Gaussian noise. In this simulation, we consider a multicomponent seismic wave, impaired by a correlated Gaussian noise. The purpose here is to compare the perfomances of multiway filtering algorithms based on either second order moments or fourth order cumulants. Figures 4.12 and 4.13 show the efficiency, in terms of noise reduction, of rank-$\mathcal{C}(K_1, K_2, K_3)$ based filtering and rank-$\mathbf{C_1}(K_1, K_2, K_3)$ based filtering compared to rank-(K_1, K_2, K_3) approximation based on second order statistics, when seismic signals impaired by a correlated Gaussian noise are considered.

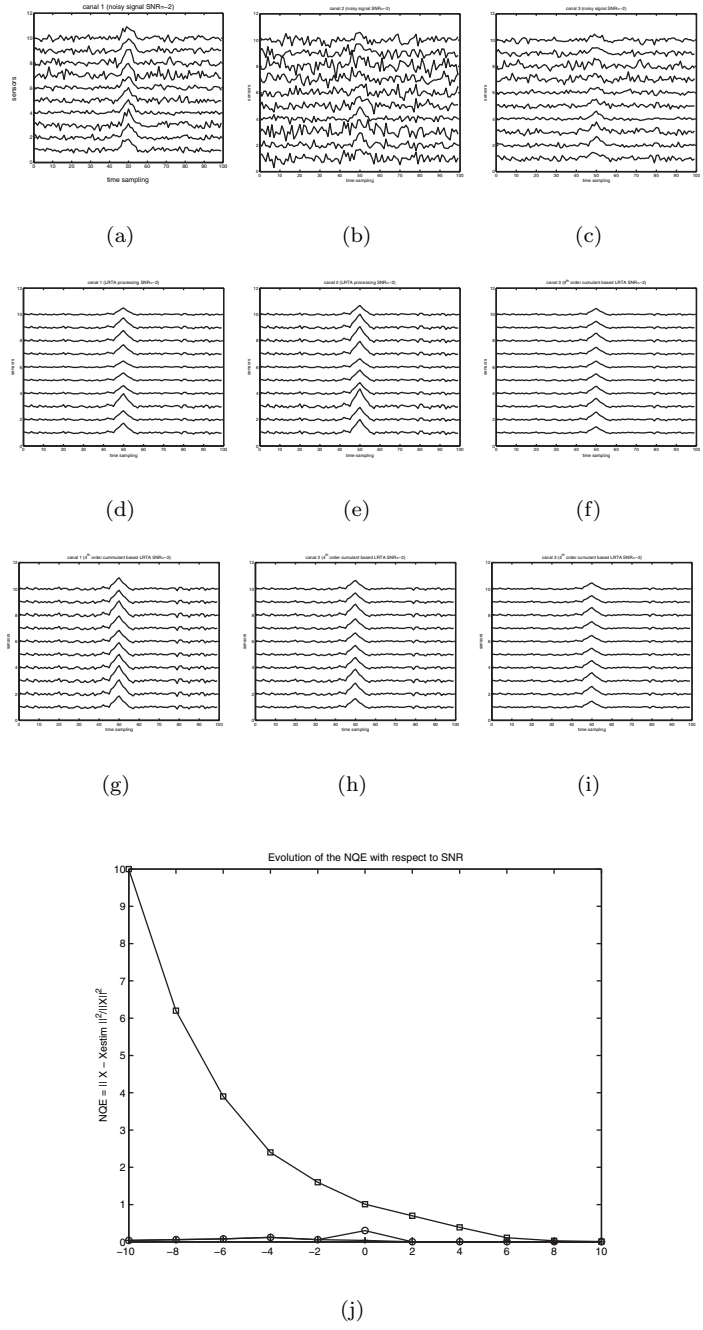

FIG. 4.13. *Denoising of a multicomponent seismic wave impaired by an additive correlated Gaussian noise (SNR= −2 dB), using multiway filtering based on fourth order cumulants: comparison of rank–$\mathcal{C}(8,8,3)$, and rank–$\mathbf{C}_1(8,8,3)$.* (a)–(c) *Noised signal; components* 1 *to* 3 *impaired by a correlated Gaussian noise (SNR= −2 dB).* (d)–(f) *rank-$\mathcal{C}(8,8,3)$ based filtering.* (g)–(i) *rank-$\mathbf{C}_1(8,8,3)$ based filtering.* (j) *Evolution of NQE with respect to SNR (dB) for rank-$(8,8,3)$ approximation (□), rank-$\mathbf{C}_1(8,8,3)$ using fourth order cumulant slice matrix (∘), and rank-$\mathcal{C}(8,8,3)$ using fourth order cumulants (+).*

5. Conclusion. In this paper, an overview on new mathematical methods dedicated to multicomponent data is presented. Multicomponent data are represented as tensors, that is, multiway arrays, and the tensor filtering methods that are presented rely on multilinear algebra. First we present how to perform channel-by-channel SVD-based filtering. Then we review three methods that take into account the relationships between each component of a processed tensor. The first method consists of an extension of the classical SVD-based filtering method. In the case of an additive white Gaussian noise, the signal tensor is estimated thanks to a multimode PCA achieved by applying a lower rank-$(K_1, \ldots, K_N)$ approximation to the noisy data tensor, or a lower rank-$(K_1, \ldots, K_N)$ truncation of its HOSVD. This method is implicitly based on second order statistics and relies on the orthogonality between nth-mode noise and signal subspaces. The second presented method consists of an improvement of the multimode PCA-based tensor filtering in the case of an additive correlated Gaussian noise. In this case, the covariance matrix involved in TUCKALS3 algorithm is replaced with the fourth order cumulant matrix of the related vectors. We reviewed a low computational load procedure involving the fourth order cumulant slice matrix instead of fourth order cumulants. This improved multimode PCA provides good performances compared to the multimode PCA method based on second order statistics, as was shown in the case of noise reduction in color images and multicomponent seismic waves.

Finally, the third reviewed method is a multiway version of the classical Wiener filtering. In extension to the one-dimensional case, the nth-mode Wiener filters are estimated by minimizing the mean squared error between the expected signal tensor and the estimated signal tensor obtained by applying the nth-mode Wiener filters to the noisy data tensor thanks to the nth-mode product operator. An alternating least squares algorithm has been presented to determine the optimal nth-mode Wiener filters. The performances of this multiway Wiener filtering and comparative results with multimode PCA have been presented in the case of additive white noise reduction in a color image and in a multicomponent seismic wave.

Appendix A. nth-mode Wiener filter analytical expression. The following computations are related to section 3.3. They rely on the definitions and properties of tensors and multilinear algebra that can be found in [11, 13, 14].

The mean squared error involved in multiway Wiener filtering is given by relation

$$\begin{aligned} \mathrm{e}(\mathbf{H}^{(1)}, \ldots, \mathbf{H}^{(N)}) = {} & \mathrm{E}\left[\|\mathcal{X}\|^2\right] - 2\mathrm{E}\left[\left\langle \mathcal{X}, \mathcal{R} \times_1 \mathbf{H}^{(1)} \times_2 \cdots \times_N \mathbf{H}^{(N)} \right\rangle\right] \\ & + \mathrm{E}\left[\left\| \mathcal{R} \times_1 \mathbf{H}^{(1)} \times_2 \cdots \times_N \mathbf{H}^{(N)} \right\|^2\right]. \end{aligned} \tag{A.1}$$

The Frobenius norm of a tensor is also equal to the norm of any of its nth-mode flattening matrices. In order to determine the expression of filter $\mathbf{H}^{(n)}$ associated with fixed filters $\mathbf{H}^{(m)}$, for all $m \neq n$, the nth-mode flattening of (A.1) is processed.

Let us define matrix $\mathbf{F}^{(n)}_{\mathbf{XR}}$ as

$$\mathbf{F}^{(n)}_{\mathbf{XR}} = \mathbf{X}_n \mathbf{T}^{(n)} \mathbf{R}_n^T \tag{A.2}$$

with

$$\mathbf{T}^{(n)} = \mathbf{H}^{(1)} \otimes \cdots \otimes \mathbf{H}^{(n-1)} \otimes \mathbf{H}^{(n+1)} \otimes \cdots \otimes \mathbf{H}^{(N)}. \tag{A.3}$$

Hence, for all $n = 1$ to N,

$$\left\langle \mathcal{X}, \mathcal{R} \times_1 \mathbf{H}^{(1)} \times_2 \cdots \times_N \mathbf{H}^{(N)} \right\rangle = \mathrm{tr}\left(\mathbf{F}^{(n)}_{\mathbf{XR}} {\mathbf{H}^{(n)}}^T \right). \tag{A.4}$$

Let us define matrix $\mathbf{G}_{\mathbf{RR}}^{(n)}$ as

$$\mathbf{G}_{\mathbf{RR}}^{(n)} = \mathbf{R}_n \mathbf{Q}^{(n)} {\mathbf{R}_n}^T \tag{A.5}$$

with

$$\mathbf{Q}^{(n)} = \mathbf{T}^{(n)T} \mathbf{T}^{(n)}$$

$$\mathbf{Q}^{(n)} = {\mathbf{H}^{(1)}}^T \mathbf{H}^{(1)} \otimes \cdots \otimes {\mathbf{H}^{(n-1)}}^T \mathbf{H}^{(n-1)} \otimes {\mathbf{H}^{(n+1)}}^T \mathbf{H}^{(n+1)} \otimes \cdots \otimes {\mathbf{H}^{(N)}}^T \mathbf{H}^{(N)}. \tag{A.6}$$

Hence for all $n = 1$ to N,

$$\left\| \mathcal{R} \times_1 \mathbf{H}^{(1)} \times_2 \cdots \times_N \mathbf{H}^{(N)} \right\|^2 = \mathrm{tr}\left(\mathbf{H}^{(n)} \mathbf{G}_{\mathbf{RR}}^{(n)} {\mathbf{H}^{(n)}}^T \right). \tag{A.7}$$

Minimization of mean squared error $\mathbf{e(H^{(1)}, \ldots, H^{(N)})}$. The expression of the nth-mode flattened mean squared error $\mathrm{e}(\mathbf{H}^{(1)}, \ldots, \mathbf{H}^{(N)})$ is the following:

$$\begin{aligned} \mathrm{e}(\mathbf{H}^{(1)}, \ldots, \mathbf{H}^{(N)}) = \mathrm{E}\left[\|\mathbf{X}_n\|^2 \right] - 2\mathrm{E}\left[\mathrm{tr}\left(\mathbf{F}_{\mathbf{XR}}^{(n)} {\mathbf{H}^{(n)}}^T \right) \right] \\ + \mathrm{E}\left[\mathrm{tr}\left(\mathbf{H}^{(n)} \mathbf{G}_{\mathbf{RR}}^{(n)} {\mathbf{H}^{(n)}}^T \right) \right]. \end{aligned} \tag{A.8}$$

Assuming that m-mode filters $\mathbf{H}^{(m)}$ are fixed for all $m \neq n$, mean squared error $\mathrm{e}(\mathbf{H}^{(1)}, \ldots, \mathbf{H}^{(N)})$ is minimal when its gradient with respect to nth-mode filter $\mathbf{H}^{(n)}$ is null,

$$\mathbf{grad}(\mathrm{e}) = \left[\frac{\partial \mathrm{e}}{\partial \mathbf{H}^{(1)}}, \ldots, \frac{\partial \mathrm{e}}{\partial \mathbf{H}^{(N)}} \right]^T, \tag{A.9}$$

that is, when $\frac{\partial \mathrm{e}}{\partial \mathbf{H}^{(n)}}$ are conjointly null for all $n = 1$ to N. Let us study $\frac{\partial \mathrm{e}}{\partial \mathbf{H}^{(n)}}$ for a given nth-mode. The nth-mode filters $\mathbf{H}^{(m)}$ are supposed to be fixed for all $m \in \{1, \ldots, N\} - \{n\}$. Then $\frac{\partial \mathrm{e}}{\partial \mathbf{H}^{(n)}} = 0$ implies that

$$\mathrm{E}\left[\frac{\partial}{\partial \mathbf{H}^{(n)}} \mathrm{tr}\left(\mathbf{H}^{(n)} \mathbf{G}_{\mathbf{RR}}^{(n)} {\mathbf{H}^{(n)}}^T \right) \right] = 2\mathrm{E}\left[\frac{\partial}{\partial \mathbf{H}^{(n)}} \mathrm{tr}\left(\mathbf{F}_{\mathbf{XR}}^{(n)} {\mathbf{H}^{(n)}}^T \right) \right], \tag{A.10}$$

We compute then the derivatives on both sides in (A.10), taking into account the fact that $\mathbf{G}_{\mathbf{RR}}^{(n)}$ and $\mathbf{F}_{\mathbf{XR}}^{(n)}$ are independent from $\mathbf{H}^{(n)}$:

$$\frac{\partial}{\partial \mathbf{H}^{(n)}} \mathrm{tr}\left(\mathbf{F}_{\mathbf{XR}}^{(n)} {\mathbf{H}^{(n)}}^T \right) = \mathbf{F}_{\mathbf{XR}}^{(n)}, \tag{A.11}$$

$$\frac{\partial}{\partial \mathbf{H}^{(n)}} \mathrm{tr}\left(\mathbf{H}^{(n)} \mathbf{G}_{\mathbf{RR}}^{(n)} {\mathbf{H}^{(n)}}^T \right) = 2\mathbf{H}^{(n)} \mathbf{G}_{\mathbf{RR}}^{(n)}. \tag{A.12}$$

Expression of $\mathbf{H}^{(\ )}$, nth-mode Wiener filter. Replacing (A.11) and (A.12) into expression (A.10) leads to the expression of $\mathbf{H}^{(n)}$ nth-mode Wiener filter associated with fixed $\mathbf{H}^{(m)}$ m-mode filters, $m \neq n$:

$$\mathbf{H}^{(n)} = \gamma_{\mathbf{XR}}^{(n)} {\mathbf{\Gamma}_{\mathbf{RR}}^{(n)}}^{-1}, \tag{A.13}$$

where

$$\gamma_{\mathbf{XR}}^{(n)} = \mathrm{E}\left[\mathbf{F}_{\mathbf{XR}}^{(n)} \right] \tag{A.14}$$

is the $\mathbf{T}^{(n)}$-weighted covariance matrix between the signal $\mathbf{X}_n$ and the data $\mathbf{R}_n$ and

$$\mathbf{\Gamma}^{(n)}_{\mathbf{RR}} = \mathrm{E}\left[\mathbf{G}^{(n)}_{\mathbf{RR}}\right] \tag{A.15}$$

is the $\mathbf{Q}^{(n)}$-weighted correlation matrix of the data.

Appendix B. Assumptions and related expression of the *n*th-mode Wiener filter. The following computations are related to section 3.3. Let us consider matrices $\mathbf{T}^{(n)}$ and $\mathbf{Q}^{(n)}$ defined in (A.3) and (A.6). Their generic (i,j)-terms are denoted respectively by $T^{(n)}_{ij}$ and by $Q^{(n)}_{ij}$.

Weight matrix term independence. The terms of weight matrix $\mathbf{O}^{(n)} \in \mathbb{R}^{K_n \times M_n}$ are supposed mutually independent,

$$\mathrm{E}\left[o_{kl}o_{mn}\right] = \alpha_{kl}\delta_{km}\delta_{ln}, \tag{B.1}$$

whatever k and $m \in \{1,\ldots,K_n\}$, l and $n \in \{1,\ldots,M_n\}$ and where α_{kl} is not null.

White and Gaussian noise condition. White and Gaussian noise condition applied to the nth-mode flattening $\mathbf{N}_n$ can be expressed by

$$\mathrm{E}\left[n_{kl}n_{pq}\right] = \sigma_n^2\delta_{kp}\delta_{lq}, \tag{B.2}$$

where $(k,p) \in \{1,\ldots,K_n\}^2$, $(l,q) \in \{1,\ldots,M_n\}^2$ and σ_n^2 is the nth-mode noise power.

Noise and signal independence. The condition on noise and signal independence can be expressed by

$$\mathrm{E}\left[x_{kl}n_{pq}\right] = 0 \tag{B.3}$$

for all $(k,p) \in \{1,\ldots,K_n\}^2$ and $(l,q) \in \{1,\ldots,M_n\}^2$. Hence, $\mathbf{T}^{(n)}$ and $\mathbf{Q}^{(n)}$-weighted $(\mathbf{X},\mathbf{N})$-covariance matrices are null:

$$\begin{aligned} \gamma^{(n)}_{\mathbf{XN}} &= \gamma^{(n)}_{\mathbf{NX}} = \mathbf{0}, \\ \mathbf{\Gamma}^{(n)}_{\mathbf{XN}} &= \mathbf{\Gamma}^{(n)}_{\mathbf{NX}} = \mathbf{0}. \end{aligned} \tag{B.4}$$

Indeed, their (i,j)-term is

$$\begin{aligned} \left(\gamma^{(n)}_{\mathbf{XN}}\right)_{ij} &= \sum_{k=1}^{M_n}\sum_{l=1}^{M_n} T^{(n)}_{kl}\mathrm{E}\left[x_{ik}n_{jl}\right], \\ \left(\mathbf{\Gamma}^{(n)}_{\mathbf{XN}}\right)_{ij} &= \sum_{k=1}^{M_n}\sum_{l=1}^{M_n} Q^{(n)}_{kl}\mathrm{E}\left[x_{ik}n_{jl}\right]. \end{aligned} \tag{B.5}$$

Expressions of weighted covariance matrices.

Covariance matrix $\gamma^{(\ )}_{\mathbf{RR}}$. As $\mathbf{R}_n = \mathbf{X}_n + \mathbf{N}_n$, the expression of $\gamma^{(n)}_{\mathbf{RR}}$ reads

$$\gamma^{(n)}_{\mathbf{RR}} = \gamma^{(n)}_{\mathbf{XX}} + \gamma^{(n)}_{\mathbf{XN}} + \gamma^{(n)}_{\mathbf{NX}} + \gamma^{(n)}_{\mathbf{NN}}. \tag{B.6}$$

So according to (B.4), $\gamma^{(n)}_{\mathbf{RR}}$ weighted covariance matrix can be expressed by

$$\gamma^{(n)}_{\mathbf{RR}} = \gamma^{(n)}_{\mathbf{XX}} + \gamma^{(n)}_{\mathbf{NN}}. \tag{B.7}$$

Moreover,

$$\gamma^{(n)}_{\mathbf{XR}} = \gamma^{(n)}_{\mathbf{XX}} + \gamma^{(n)}_{\mathbf{XN}} = \gamma^{(n)}_{\mathbf{XX}}. \tag{B.8}$$

Covariance matrix $\mathbf{\Gamma}^{(\,)}_{\mathbf{RR}}$. Relations (B.6), (B.7), and (B.8) hold as well for $\mathbf{\Gamma}^{(n)}_{\mathbf{RR}}$:

$$\mathbf{\Gamma}^{(n)}_{\mathbf{RR}} = \mathbf{\Gamma}^{(n)}_{\mathbf{XX}} + \mathbf{\Gamma}^{(n)}_{\mathbf{XN}} + \mathbf{\Gamma}^{(n)}_{\mathbf{NX}} + \mathbf{\Gamma}^{(n)}_{\mathbf{NN}}$$

and

$$\mathbf{\Gamma}^{(n)}_{\mathbf{RR}} = \mathbf{\Gamma}^{(n)}_{\mathbf{XX}} + \mathbf{\Gamma}^{(n)}_{\mathbf{NN}}. \tag{B.9}$$

Moreover,

$$\mathbf{\Gamma}^{(n)}_{\mathbf{XR}} = \mathbf{\Gamma}^{(n)}_{\mathbf{XX}} + \mathbf{\Gamma}^{(n)}_{\mathbf{XN}} = \mathbf{\Gamma}^{(n)}_{\mathbf{XX}}. \tag{B.10}$$

Expressions of $\mathbf{\Gamma}^{(\,)}_{\mathbf{NN}}$ and $\boldsymbol{\gamma}^{(\,)}_{\mathbf{NN}}$. According to (B.2), the (i,j)-term of $\mathbf{\Gamma}^{(n)}_{\mathbf{NN}}$ is the following:

$$\left(\mathbf{\Gamma}^{(n)}_{\mathbf{NN}}\right)_{ij} = \sum_{k=1}^{M_n}\sum_{l=1}^{M_n} Q^{(n)}_{kl}\mathrm{E}[n_{ik}n_{jl}] = {\sigma^{(n)}_{\Gamma}}^2 \delta ij \tag{B.11}$$

with

$${\sigma^{(n)}_{\Gamma}}^2 = \mathrm{tr}(\mathbf{Q}^{(n)})\sigma_n^2. \tag{B.12}$$

Hence

$$\mathbf{\Gamma}^{(n)}_{\mathbf{NN}} = {\sigma^{(n)}_{\Gamma}}^2 \mathbf{I}_{I_n}. \tag{B.13}$$

The (i,j)-term of $\gamma^{(n)}_{\mathbf{NN}}$ can also be expressed by

$$\left(\gamma^{(n)}_{\mathbf{NN}}\right)_{ij} = \sum_{k=1}^{M_n}\sum_{l=1}^{M_n} T^{(n)}_{kl}\mathrm{E}[n_{ik}n_{jl}] = {\sigma^{(n)}_{\gamma}}^2 \delta ij$$

with

$${\sigma^{(n)}_{\gamma}}^2 = \mathrm{tr}(\mathbf{T}^{(n)})\sigma_n^2.$$

Hence

$$\gamma^{(n)}_{\mathbf{NN}} = {\sigma^{(n)}_{\gamma}}^2 \mathbf{I}_{I_n}. \tag{B.14}$$

Expressions of $\mathbf{\Gamma}^{(\,)}_{\mathbf{XX}}$ and $\boldsymbol{\gamma}^{(\,)}_{\mathbf{XX}}$. Considering the signal model (3.16),

$$\gamma^{(n)}_{\mathbf{XX}} = \mathbf{V}^{(n)}_s \gamma^{(n)}_{\mathbf{OO}} {\mathbf{V}^{(n)}_s}^T, \tag{B.15}$$

where

$$\gamma^{(n)}_{\mathbf{OO}} = \mathrm{E}\left[\mathbf{O}^{(n)}\mathbf{T}^{(n)}{\mathbf{O}^{(n)}}^T\right]. \tag{B.16}$$

According to (B.1), the generic term of $\gamma^{(n)}_{\mathbf{OO}}$ is

$$\left(\gamma^{(n)}_{\mathbf{OO}}\right)_{ij} = \sum_{k=1}^{M_n}\sum_{l=1}^{M_n} T^{(n)}_{kl}\mathrm{E}\left[n_{ik}n_{jl}\right] = \beta_i\delta_{ij}, \tag{B.17}$$

where, for all $i = 1$ to K_n,

$$\beta_i = \sum_{k=1}^{M_n} T_{kk}^{(n)} \alpha_{ik}, \tag{B.18}$$

and where α_{ik} is defined in (B.1). So, $\gamma_{\mathbf{OO}}^{(n)}$ is a diagonal matrix:

$$\gamma_{\mathbf{OO}}^{(n)} = \begin{bmatrix} \beta_1 & & 0 \\ & \ddots & \\ 0 & & \beta_{K_n} \end{bmatrix}. \tag{B.19}$$

The matrix $\mathbf{\Gamma}_{\mathbf{XX}}^{(n)}$ is also expressed as

$$\mathbf{\Gamma}_{\mathbf{XX}}^{(n)} = \mathbf{V}_s^{(n)} \mathbf{\Gamma}_{\mathbf{OO}}^{(n)} \mathbf{V}_s^{(n)^T}, \tag{B.20}$$

where $\mathbf{\Gamma}_{\mathbf{OO}}^{(n)}$ is the diagonal matrix

$$\mathbf{\Gamma}_{\mathbf{OO}}^{(n)} = \begin{bmatrix} \epsilon_1 & & 0 \\ & \ddots & \\ 0 & & \epsilon_{K_n} \end{bmatrix}, \tag{B.21}$$

and

$$\epsilon_i = \sum_{k=1}^{M_n} Q_{kk}^{(n)} \alpha_{ik}, \tag{B.22}$$

where α_{ik} is defined in (B.1).

Final expression of $\mathbf{H}^{(\ )}$, nth-mode Wiener filter. According to (B.8) and (B.15),

$$\gamma_{\mathbf{XR}}^{(n)} = \mathbf{V}_s^{(n)} \gamma_{\mathbf{OO}}^{(n)} \mathbf{V}_s^{(n)^T}. \tag{B.23}$$

According to (B.9), (B.13), and (B.20),

$$\mathbf{\Gamma}_{\mathbf{RR}}^{(n)} = \mathbf{V}_s^{(n)} \mathbf{\Gamma}_{\mathbf{OO}}^{(n)} \mathbf{V}_s^{(n)^T} + {\sigma_\Gamma^{(n)}}^2 \mathbf{I}_{I_n},$$

which can be expressed as

$$\mathbf{\Gamma}_{\mathbf{RR}}^{(n)} = \begin{bmatrix} \mathbf{V}_s^{(n)} \mathbf{V}_b^{(n)} \end{bmatrix} \begin{bmatrix} \mathbf{\Gamma}_{\mathbf{OO}}^{(n)} + {\sigma_\Gamma^{(n)}}^2 \mathbf{I}_{K_n} & 0 \\ 0 & {\sigma_\Gamma^{(n)}}^2 \mathbf{I}_{I_n - K_n} \end{bmatrix} \begin{bmatrix} \mathbf{V}_s^{(n)^T} \\ \mathbf{V}_b^{(n)^T} \end{bmatrix} \tag{B.24}$$

with $\mathbf{V}_b^{(n)} \in \mathrm{St}(I_n, I_n - K_n)$ the columnwise orthogonal matrix containing the noise subspace basis vectors. The assumption of noise and signal independence implies that the noise and signal subspaces are orthogonal:

$$\mathbf{V}_s^{(n)^T} \mathbf{V}_b^{(n)} = \mathbf{0}. \tag{B.25}$$

Let us call

$$\mathbf{\Lambda}_s^{(n)} = \mathbf{\Gamma}_{\mathbf{OO}}^{(n)} + {\sigma_\Gamma^{(n)}}^2 \mathbf{I}_{K_n} \tag{B.26}$$

and

$$\mathbf{\Lambda}_b^{(n)} = {\sigma_{\mathbf{\Gamma}}^{(n)}}^2 \mathbf{I}_{I_n - K_n}. \tag{B.27}$$

Inserting the last expressions of $\gamma_{\mathbf{XR}}^{(n)}$ and $\mathbf{\Gamma}_{\mathbf{RR}}^{(n)}$ (see (B.23) and (B.24)) into Wiener nth-mode filter expression (A.13) leads to

$$\mathbf{H}^{(n)} = \mathbf{V}_s^{(n)} \gamma_{\mathbf{OO}}^{(n)} \mathbf{V}_s^{(n)^T} \left[\mathbf{V}_s^{(n)} \, \mathbf{V}_b^{(n)} \right] \begin{bmatrix} {\Lambda_s^{(n)}}^{-1} & 0 \\ 0 & {\Lambda_b^{(n)}}^{-1} \end{bmatrix} \begin{bmatrix} \mathbf{V}_s^{(n)^T} \\ \mathbf{V}_b^{(n)^T} \end{bmatrix}, \tag{B.28}$$

which can be expressed as

$$\mathbf{H}^{(n)} = \left[(\mathbf{V}_s^{(n)} \gamma_{\mathbf{OO}}^{(n)} \mathbf{V}_s^{(n)^T} \mathbf{V}_s^{(n)}) \; (\mathbf{V}_s^{(n)} \gamma_{\mathbf{OO}}^{(n)} \mathbf{V}_s^{(n)^T} \mathbf{V}_b^{(n)}) \right] \begin{bmatrix} {\mathbf{\Lambda}_s^{(n)}}^{-1} \mathbf{V}_s^{(n)^T} & 0 \\ 0 & {\mathbf{\Lambda}_b^{(n)}}^{-1} \mathbf{V}_b^{(n)^T} \end{bmatrix} \tag{B.29}$$

Considering noise and signal orthogonality condition (B.25) and the fact that $\mathbf{V}_n^{(n)} \mathbf{V}_n^{(n)^T} = \mathbf{I}_{K_n}$, the final Wiener nth-mode filter expression becomes

$$\mathbf{H}^{(n)} = \mathbf{V}_s^{(n)} \gamma_{\mathbf{OO}}^{(n)} {\mathbf{\Lambda}_{\mathbf{\Gamma s}}^{(n)}}^{-1} \mathbf{V}_s^{(n)^T}. \tag{B.30}$$

NEWTON METHOD FOR JOINT APPROXIMATE DIAGONALIZATION OF POSITIVE DEFINITE HERMITIAN MATRICES*

MARCEL JOHO†

Abstract. In this paper we present a Newton method to jointly approximately diagonalize a set of positive definite Hermitian matrices. To this end, we derive the local gradient and Hessian of the underlying cost function in closed form. The algorithm is derived for the complex case and can also update a nonsquare diagonalization matrix. We analyze the cost function at the critical points and show its relation to a different cost function that is commonly studied.

Key words. joint approximate diagonalization, independent component analysis, Newton method, gradient and Hessian of a complex matrix-valued cost function

1. Problem formulation and cost function.

The mathematical problem of jointly approximately diagonalizing a set of P covariance matrices, $\{\mathbf{R}_p\}_{p=1}^{P}$, is of interest in statistical methods such as common principal component analysis [7]. Recently the joint diagonalization problem has received more attention also in the community of independent component analysis and blind signal separation, as some problems that occur in those fields can be formulated as a joint diagonalization optimization problem. As an example, we can describe one class of blind signal separation problems as follows:

Let $\mathbf{s}(t)$ be an M-dimensional vector containing the time series of M mutually independent *source signals* that are mixed by a *mixing matrix* $\mathbf{A}^{N\times M}$, such that $\mathbf{x}(t) = \mathbf{A}\,\mathbf{s}(t)$ is an N-dimensional vector containing the time series of N *sensor signals*. In the blind signal separation problem the assumption is made that $\mathbf{s}(t)$ and $\mathbf{A}$ are unknown; only the signals at the sensors, $\mathbf{x}(t)$, are known. Furthermore, the assumption is made that the source signals are nonstationary and mutually independent. Hence, $\mathbf{R}_{\mathbf{ss}}(t) \triangleq E\{\mathbf{s}(t)\mathbf{s}^H(t)\}$ depends on t and has a diagonal structure. If we further assume that the source signals are nonstationary, then $\mathbf{R}_{\mathbf{ss}}(t)$ is time-varying but always has a diagonal structure. The correlation matrix of the sensor signals $\mathbf{R}_{\mathbf{xx}}(t) \triangleq E\{\mathbf{x}(t)\mathbf{x}^H(t)\} = \mathbf{A}\,E\{\mathbf{s}(t)\mathbf{s}^H(t)\}\mathbf{A}^H = \mathbf{A}\,\mathbf{R}_{\mathbf{ss}}(t)\mathbf{A}^H$ becomes also time-varying but has no diagonal structure in general. In order to recover the unknown source signals, we aim at finding a *separation matrix* $\mathbf{W}$ such that $\mathbf{u}(t) = \mathbf{W}\mathbf{x}(t)$ becomes an estimate of the original source signals $\mathbf{s}(t)$, aside from a possible scaling and permutation of the elements in $\mathbf{u}(t)$. In order for $\mathbf{u}(t)$ to become an estimate of $\mathbf{s}(t)$, the correlation matrix

$$\mathbf{R}_{\mathbf{uu}}(t) \triangleq E\{\mathbf{u}(t)\mathbf{u}^H(t)\} = \mathbf{W}\,\mathbf{R}_{\mathbf{xx}}(t)\mathbf{W}^H \tag{1}$$

has to be diagonal for all t. Assuming that $\mathbf{W}$ is time-invariant, $\mathbf{W}$ has to be of the following structure:

$$\mathbf{W} = \mathbf{D}\mathbf{P}\mathbf{A}^{-1} \tag{2}$$

or, if $\mathbf{A}^{N\times M}$ is a tall matrix ($N > M$),

$$\mathbf{W} = \mathbf{DPA}^{\#}, \tag{3}$$

where $\mathbf{D}$ is an arbitrary diagonal matrix, $\mathbf{P}$ is an arbitrary permutation matrix, and $\mathbf{A}^{\#}$ denotes the pseudoinverse of $\mathbf{A}$. If we take P snapshots of $\mathbf{R_{xx}}(t)$, $\mathbf{R}_p \triangleq \mathbf{R_{xx}}(t_p)$, where t_p is the time instance of the pth snapshot, then we can formulate the task of finding a proper $\mathbf{W}$ as the following *joint diagonalization problem*:

Given a set of P positive definite Hermitian matrices $\mathbf{R}_p$, find a single matrix $\mathbf{W}$ that approximately joint diagonalizes the whole set $\{\mathbf{R}_p\}$ such that $\mathbf{W}\mathbf{R}_p\mathbf{W}^H$ is diagonal for all p.

Perfect diagonalization is typically not possible for a set of random positive definite Hermitian matrices $\{\mathbf{R}_p\}$, unless $\{\mathbf{R}_p\}$ is a set of commuting matrices [9]. However, the set $\{\mathbf{W}\,\mathbf{R}_p\mathbf{W}^H\}$ can still be approximately jointly diagonalized subject to a given cost function $\mathcal{J}(\mathbf{W};\{\mathbf{R}_p\}_{p=1}^P)$ that measures the degree of joint diagonalization.

Several cost functions for the joint diagonalization problem have been published in the last decade. In [5] Cardoso and Souloumiac have proposed a joint diagonalization cost function and have given a very effective Jacobi-type algorithm that minimizes their cost function under the constraint that the diagonalization matrix $\mathbf{W}$ is unitary. The core idea of their algorithm has been used in JADE [4] and SOBI [1], both very popular blind signal separation algorithms.

In [17] Yeredor published an algorithm, AC-DC, that uses a different cost function and is based on a subspace-fitting formulation. One advantage is that no orthogonality constraints are imposed on the diagonalization matrix $\mathbf{W}$. However, $\mathbf{W}$ needs to be square and real. In [19] Yeredor, Ziehe, and Müller also derived an algorithm based on the *natural gradient* that works even with nonpositive definite matrices $\mathbf{R}_p$; however, $\mathbf{W}$ needs to be real and square. Yeredor has also described in [18] how to compute a good initial value $\mathbf{W}_0$ for any iterative algorithm.

Another joint diagonalization algorithm, FFDIAG, that seems to have a very fast convergence rate, was presented by Ziehe, Laskov, and Müller in [20]. FFDIAG also requires that $\mathbf{R}_p$ and $\mathbf{W}$ be real square matrices. An extension of FFDIAG where $\mathbf{W}$ can be nonsquare or complex has not been published so far.

Recently, Vollgraf and Obermayer [16] published an algorithm for the real case, QDIAG, that also works for a nonsquare $\mathbf{W}$. Their algorithm sequentially solves a quadratic subproblem, which avoids the appearance of any higher-order terms in their cost function. QDIAG seems to have a similar convergence performance as FFDIAG and is very appealing from a computational point of view for joint-diagonalizing large sets of matrices.

In [14], Pham presented an efficient joint diagonalization algorithm that imposes no optimization constraints on $\mathbf{W}$, except that $\mathbf{W}$ must be square ($N = M$). This algorithm is also a Jacobi-type algorithm. In contrast to most other joint diagonalization algorithms, which minimize a constraint optimization problem, Pham's algorithm is formulated to minimize an unconstrained optimization problem. The underlying cost function of this algorithm is based on some preliminary work by Flury [7] and Flury and Gautschi [8], namely,

$$\mathcal{J}(\mathbf{W}) \triangleq \sum_{p=1}^{P} \beta_p \left[\log\left(\det\left(\operatorname{diag}\left(\mathbf{W}\,\mathbf{R}_p\,\mathbf{W}^H\right)\right)\right) - \log\left(\det\left(\mathbf{W}\,\mathbf{R}_p\,\mathbf{W}^H\right)\right)\right], \tag{4}$$

where the matrices $\mathbf{R}_p \in \mathbb{C}^{N\times N}$ are Hermitian and need to be positive definite. The weights β_p are positive scalars. Consequently, the matrix products $\mathbf{W}\,\mathbf{R}_p\,\mathbf{W}^H \in$

$\mathbb{C}^{M\times M}$ are also Hermitian and positive definite, assuming $\mathbf{W}$ has full rank. The cost function (4) is motivated by the Hadamard inequality

$$\det(\,\mathbf{Q}\,) \leq \det(\,\mathrm{diag}(\,\mathbf{Q}\,)\,) \tag{5}$$

with equality if and only if $\mathbf{Q}$ is diagonal [9].

In the following, we will also use the cost function (4) as the basis of a Newton-type algorithm that we will derive. There are a few fundamental differences between the derived Newton algorithm and Pham's Jacobi-type algorithm. In Pham's algorithm, every iteration consists of a pairwise update of two rows at a time. One *sweep* of the algorithm consists of iterating once through all possible combinations of pairing two rows. Pham has shown that near a minimum, an iteration of his algorithm behaves similarly to a *quasi-Newton–Raphson* iteration.

In contrast to Pham's algorithm, we will use a pure Newton algorithm that updates *all coefficients* in $\mathbf{W}$ in every iteration. The main difficulty in deriving a pure Newton algorithm, as opposed to a *quasi*-Newton algorithm, is that the Hessian needs to be known in closed form in every iteration. One major difference to Pham's algorithm will be that we drop the constraint that $\mathbf{W}$ needs to be square, and we allow $\mathbf{W} \in \mathbb{C}^{M\times N}$ to be rectangular with $M \leq N$. Translated to the blind signal separation problem, our algorithm is also capable of working in cases where more sensor signals than source signals are present. This is particularly useful when the number of source signals is not known beforehand.

In the following sections, we will derive the gradient and Hessian of the cost function (4) in close form. To this end, we will use the matrix-form representation of the second-order Taylor series expansion as described by Manton in [13]. This form allows us to represent the gradient and the Hessian in a very compact form with the help of Kronecker products. As we will see, just as products of matrices reveal more structure than nested sums, the use of Kronecker products reveals the structure of the Hessian on an even higher level than by using matrices inside nested sums. Thorough treatments of Kronecker products and their properties are given in [3, 12].

1.1. Notation. The notation used throughout this paper is the following: Vectors are written in lowercase, matrices in uppercase. Matrix and vector transpose, complex conjugation, and Hermitian transpose are denoted by $(.)^T$, $(.)^*$, and $(.)^H$, respectively. The $M \times M$ identity matrix is denoted by $\mathbf{I}_{M\times M}$. The Frobenius norm and the trace of a matrix are denoted by $\|\,.\,\|_F$ and $\mathrm{tr}\,(.)$, respectively. The spectral radius of a matrix $\mathbf{Q}$ is the nonnegative real number $\rho(\mathbf{Q}) = \max\{|\lambda_{\max}(\mathbf{Q})|\}$; see [9]. Matrix dimensions are given in superscript, e.g., $\mathbf{W}^{M\times N}$. The operator $\mathrm{vec}(\,\mathbf{W}\,)$ forms a column vector by stacking the columns of $\mathbf{W}$, and $\mathbf{W}^{M\times N} = \mathrm{mat}_{M\times N}(\mathbf{w})$ is the inverse operation of $\mathbf{w} = \mathrm{vec}(\,\mathbf{W}^{M\times N}\,)$. The Kronecker product [3] is denoted by $\otimes$. The $MN \times MN$-dimensional permutation matrix $\mathbf{P}_{M\times N}$, where the subscript $M \times N$ is the argument of $\mathbf{P}_{M\times N}$, is uniquely defined with

$$\mathrm{vec}(\,\mathbf{W}^T\,) \equiv \mathbf{P}_{M\times N}\,\mathrm{vec}(\,\mathbf{W}^{M\times N}\,) \tag{6}$$

as $\mathrm{vec}(\,\mathbf{W}\,)$ and $\mathrm{vec}(\,\mathbf{W}^T\,)$ contain the same elements, just arranged in a different order. With $\bar{\mathbf{Q}} = \mathrm{diag}(\,\mathbf{q}\,)$ we get a square diagonal matrix that contains the elements of the vector $\mathbf{q}$ in its diagonal. The matrix $\bar{\mathbf{Q}} = \mathrm{diag}(\,\mathbf{Q}\,)$ is a diagonal matrix where its diagonal elements are the same as the diagonal elements of $\mathbf{Q}$, and

$$\mathrm{off}(\,\mathbf{Q}\,) \triangleq \mathbf{Q} - \mathrm{diag}(\,\mathbf{Q}\,) \tag{7}$$

keeps all off-diagonal elements of $\mathbf{Q}$ and sets all diagonal elements of $\mathbf{Q}$ to zero. Furthermore, we define the two $M^2 \times M^2$ diagonal projection matrices

$$\mathbf{P}_{\text{diag}} \triangleq \text{diag}(\,\text{vec}(\,\mathbf{I}_{M\times M}\,)\,), \tag{8}$$

$$\mathbf{P}_{\text{off}} \triangleq \mathbf{I}_{M^2\times M^2} - \mathbf{P}_{\text{diag}}, \tag{9}$$

which appear in the following two relations:

$$\text{vec}(\,\text{diag}(\,\mathbf{Z}\,)\,) = \mathbf{P}_{\text{diag}}\,\text{vec}(\,\mathbf{Z}\,), \tag{10}$$

$$\text{vec}(\,\text{off}(\,\mathbf{Z}\,)\,) = \mathbf{P}_{\text{off}}\,\text{vec}(\,\mathbf{Z}\,). \tag{11}$$

2. Second-order Taylor series of the cost function $\mathcal{J}(\mathbf{W})$.

2.1. Matrix form of second-order Taylor approximation. In the following we will derive the gradient and Hessian of the cost function (4) with respect to the free parameters, i.e., the elements of $\mathbf{W}$. First we need to define how the gradient and Hessian are represented. Since the free parameters in the cost function (4) are arranged in the matrix $\mathbf{W}$, we decide to use the matrix form of the second-order Taylor series as given by Manton in [13]:

Let $\mathcal{J} : \mathbb{C}^{M\times N} \to \mathbb{R}$ be a cost function. Then we can describe the Taylor series expansion of $\mathcal{J}$ at $\mathbf{W}$ as

$$\begin{aligned}\mathcal{J}(\mathbf{W}+\delta\mathbf{Z}) = \mathcal{J}(\mathbf{W}) &+ \delta\,\mathfrak{Re}\{\text{tr}\,(\mathbf{Z}^H\mathbf{D}_{\mathbf{W}})\}\\ &+ \frac{\delta^2}{2}\,\text{vec}(\,\mathbf{Z}\,)^H\mathbf{H}_{\mathbf{W}}\,\text{vec}(\,\mathbf{Z}\,)\\ &+ \frac{\delta^2}{2}\mathfrak{Re}\{\text{vec}(\,\mathbf{Z}\,)^T\mathbf{C}_{\mathbf{W}}\,\text{vec}(\,\mathbf{Z}\,)\} + O(\delta^3),\end{aligned} \tag{12}$$

where $\mathbf{W}, \mathbf{Z} \in \mathbb{C}^{M\times N}$, $\mathbf{D}_{\mathbf{W}} \in \mathbb{C}^{M\times N}$ is the gradient of $\mathcal{J}$ evaluated at $\mathbf{W}$, and $\mathbf{H}_{\mathbf{W}}, \mathbf{C}_{\mathbf{W}} \in \mathbb{C}^{MN\times MN}$ are the Hessian of $\mathcal{J}$ evaluated at $\mathbf{W}$. The scalar δ is a small real number. Uniqueness can be achieved by requiring $\mathbf{H}_{\mathbf{W}}^H = \mathbf{H}_{\mathbf{W}}$ and $\mathbf{C}_{\mathbf{W}}^T = \mathbf{C}_{\mathbf{W}}$.

In contrast to the commonly known vector form of the Taylor series expansion

$$\mathcal{J}(\mathbf{w}+\delta\mathbf{z}) = \mathcal{J}(\mathbf{w}) + \delta\,\mathbf{z}^T\mathbf{d} + \frac{\delta^2}{2}\mathbf{z}^T\mathbf{H}\,\mathbf{z} + O(\delta^3), \tag{13}$$

where the coefficients of $\mathbf{W}$ are rearranged in the real vector

$$\mathbf{w} \triangleq \begin{pmatrix}\mathbf{w}^{\text{re}}\\ \mathbf{w}^{\text{im}}\end{pmatrix} \triangleq \begin{pmatrix}\mathfrak{Re}\{\text{vec}(\mathbf{W})\}\\ \mathfrak{Im}\{\text{vec}(\mathbf{W})\}\end{pmatrix}, \tag{14}$$

the matrix form often reveals the structure of the gradient and the Hessian in a much more transparent form via matrix and Kronecker products. The gradients and the Hessians of the two Taylor expansion forms (12) and (13) can be transformed into each other, as described in [10].

2.2. Derivation of the gradient and Hessian. In order to simplify the derivation of the gradient and Hessian of $\mathcal{J}\,(.)$, we rewrite the cost function (4) as

$$\mathcal{J}\,(\mathbf{W}\,;\{\beta_p\},\{\mathbf{R}_p\}) \triangleq \sum_{p=1}^{P}\beta_p\,\widetilde{\mathcal{J}}\,(\mathbf{W};\mathbf{R}_p) \tag{15}$$

with

$$\widetilde{\mathcal{J}}\left(\mathbf{W};\mathbf{R}_p\right) \triangleq \mathcal{J}^{(1)}\left(\mathbf{W};\mathbf{R}_p\right) - \mathcal{J}^{(2)}\left(\mathbf{W};\mathbf{R}_p\right), \tag{16}$$

$$\mathcal{J}^{(1)}\left(\mathbf{W};\mathbf{R}\right) \triangleq \log\left(\det\left(\operatorname{diag}\left(\mathbf{W}\,\mathbf{R}\,\mathbf{W}^H\right)\right)\right), \tag{17}$$

$$\mathcal{J}^{(2)}\left(\mathbf{W};\mathbf{R}\right) \triangleq \log\left(\det\left(\mathbf{W}\,\mathbf{R}\,\mathbf{W}^H\right)\right). \tag{18}$$

2.3. Gradient and Hessian of $\mathcal{J}^{(1)}(.)$. In order to derive the gradient and Hessian of $\mathcal{J}^{(1)}$, defined in (17), we do the following expansion:

$$\mathcal{J}^{(1)}\left(\mathbf{W}+\delta\,\mathbf{Z}\right) \triangleq \log\left(\det\left(\operatorname{diag}\left(\left(\mathbf{W}+\delta\,\mathbf{Z}\right)\mathbf{R}\left(\mathbf{W}+\delta\,\mathbf{Z}\right)^H\right)\right)\right) \tag{19}$$

$$= \log\left(\det\left(\operatorname{diag}\left(\left(\mathbf{W}\,\mathbf{R}\,\mathbf{W}^H + \delta\left(\mathbf{W}\,\mathbf{R}\,\mathbf{Z}^H + \mathbf{Z}\,\mathbf{R}\,\mathbf{W}^H\right) + \delta^2\mathbf{Z}\,\mathbf{R}\,\mathbf{Z}^H\right)\right)\right)\right). \tag{20}$$

By substituting

$$\bar{\mathbf{Q}} \triangleq \operatorname{diag}\left(\mathbf{W}\,\mathbf{R}\,\mathbf{W}^H\right) \tag{21}$$

we can formulate (20) as

$$\begin{aligned}\mathcal{J}^{(1)}\left(\mathbf{W}+\delta\,\mathbf{Z}\right) &= \log\Big(\det\Big(\bar{\mathbf{Q}}\left(\mathbf{I}+\delta\,\bar{\mathbf{Q}}^{-1}\operatorname{diag}\left(\mathbf{W}\,\mathbf{R}\,\mathbf{Z}^H+\mathbf{Z}\,\mathbf{R}\,\mathbf{W}^H\right)\right.\\ &\qquad \left.+\,\delta^2\,\bar{\mathbf{Q}}^{-1}\operatorname{diag}\left(\mathbf{Z}\,\mathbf{R}\,\mathbf{Z}^H\right)\right)\Big)\Big) \qquad (22)\\ &= \mathcal{J}^{(1)}\left(\mathbf{W}\right) + \log\Big(\det\Big(\mathbf{I}+\delta\,\bar{\mathbf{Q}}^{-1}\operatorname{diag}\left(\mathbf{W}\,\mathbf{R}\,\mathbf{Z}^H+\mathbf{Z}\,\mathbf{R}\,\mathbf{W}^H\right)\\ &\qquad +\,\delta^2\,\bar{\mathbf{Q}}^{-1}\operatorname{diag}\left(\mathbf{Z}\,\mathbf{R}\,\mathbf{Z}^H\right)\Big)\Big) \qquad (23)\\ &= \mathcal{J}^{(1)}\left(\mathbf{W}\right) + \log\left(\det\left(\mathbf{I}+\delta\,\mathbf{A}+\delta^2\mathbf{B}\right)\right) \qquad (24)\end{aligned}$$

with

$$\mathbf{A} \triangleq \bar{\mathbf{Q}}^{-1}\operatorname{diag}\left(\mathbf{W}\,\mathbf{R}\,\mathbf{Z}^H+\mathbf{Z}\,\mathbf{R}\,\mathbf{W}^H\right), \tag{25}$$

$$\mathbf{B} \triangleq \bar{\mathbf{Q}}^{-1}\operatorname{diag}\left(\mathbf{Z}\,\mathbf{R}\,\mathbf{Z}^H\right). \tag{26}$$

Here we made use of $\det\mathbf{X}\mathbf{Y} = \det\mathbf{X}\det\mathbf{Y}$, which is valid for square matrices $\mathbf{X},\mathbf{Y}$. Before we continue to simplify (24), we introduce the following proposition.

PROPOSITION 2.1. *Let* $\mathbf{A},\mathbf{B}\in\mathbb{C}^{N\times N}$. *Then, for* $\delta\to 0$,

$$\log\left(\det\left(\mathbf{I}+\delta\,\mathbf{A}+\delta^2\mathbf{B}\right)\right) = \delta\operatorname{tr}\mathbf{A} + \delta^2\operatorname{tr}\mathbf{B} - \frac{1}{2}\delta^2\operatorname{tr}\mathbf{A}^2 + O(\delta^3). \tag{27}$$

Proof. Let $\mathbf{S}\in\mathbb{C}^{N\times N}$ with *spectral radius* $\rho(\mathbf{S})<1$. We know that for any nonsingular $\mathbf{G}\in\mathbb{C}^{N\times N}$ we have $\log\left(\det\left(\mathbf{G}\right)\right) = \operatorname{tr}\left(\log\left(\mathbf{G}\right)\right)$. We also know that $\log\left(\mathbf{I}+\mathbf{G}\right) = \sum_k \frac{(-1)^{k+1}}{k}\mathbf{G}^k$ for any $\mathbf{G}\in\mathbb{C}^{N\times N}$ with $\rho(\mathbf{G})<1$. Note that the assumption $\rho(\mathbf{S})<1$ implies that $\mathbf{I}+\mathbf{S}$ is nonsingular. Hence, combining the above results we have

$$\log(\det(\mathbf{I}+\mathbf{S})) = \sum_k \frac{(-1)^{k+1}}{k}\mathbf{S}^k. \tag{28}$$

Now, if we insert $\mathbf{S} = \delta\,\mathbf{A}+\delta^2\,\mathbf{B}$ into (28) and let $\delta\to 0$, we obtain (27). ∎

Note that the logarithm for complex arguments is not uniquely defined. However, we will only apply (28) for Hermitian matrices $\mathbf{S}$ with $\rho(\mathbf{S})<1$. Consequently all eigenvalues of $\mathbf{I}+\mathbf{S}$, and also $\det(\mathbf{I}+\mathbf{S})$, will be real and positive.

If we apply (27) in (24), we obtain

$$\mathcal{J}^{(1)}\left(\mathbf{W}+\delta\,\mathbf{Z}\right)=\mathcal{J}^{(1)}\left(\mathbf{W}\right)+\delta\,\mathrm{tr}\,\mathbf{A}+\delta^2\,\mathrm{tr}\,\mathbf{B}-\frac{1}{2}\delta^2\,\mathrm{tr}\,\mathbf{A}^2+O(\delta^3), \tag{29}$$

where $\mathbf{A}$ and $\mathbf{B}$ are defined in (25) and (26), respectively. We now analyze each of the three δ terms in (29) separately. We start with

$$\mathrm{tr}\,\mathbf{A}=\mathrm{tr}\left(\bar{\mathbf{Q}}^{-1}\,\mathbf{W}\,\mathbf{R}\,\mathbf{Z}^H+\bar{\mathbf{Q}}^{-1}\,\mathbf{Z}\,\mathbf{R}\,\mathbf{W}^H\right) \tag{30}$$

$$=\mathrm{tr}\left(\mathbf{Z}^H\,\bar{\mathbf{Q}}^{-1}\,\mathbf{W}\,\mathbf{R}+\mathbf{R}\,\mathbf{W}^H\,\bar{\mathbf{Q}}^{-1}\,\mathbf{Z}\right) \tag{31}$$

$$=2\,\mathfrak{Re}\big\{\,\mathrm{tr}\left(\mathbf{Z}^H\,\bar{\mathbf{Q}}^{-1}\,\mathbf{W}\,\mathbf{R}\right)\big\}. \tag{32}$$

Here we made use of $\mathrm{tr}\left(\mathrm{diag}(\mathbf{X})\,\mathrm{diag}(\mathbf{Y})\right)=\mathrm{tr}\left(\mathbf{X}\,\mathrm{diag}(\mathbf{Y})\right)=\mathrm{tr}\left(\mathrm{diag}(\mathbf{X})\,\mathbf{Y}\right)$. The third term in (29), where $\mathbf{A}$ is defined in (25), can be modified as

$$\begin{aligned}\mathrm{tr}\,\mathbf{A}^2&=\mathrm{tr}\left(\bar{\mathbf{Q}}^{-1}\left(\mathbf{W}\,\mathbf{R}\,\mathbf{Z}^H+\mathbf{Z}\,\mathbf{R}\,\mathbf{W}^H\right)\bar{\mathbf{Q}}^{-1}\,\mathrm{diag}\left(\mathbf{W}\,\mathbf{R}\,\mathbf{Z}^H+\mathbf{Z}\,\mathbf{R}\,\mathbf{W}^H\right)\right) &(33)\\
&=\mathrm{tr}\left(\bar{\mathbf{Q}}^{-1}\mathbf{W}\,\mathbf{R}\,\mathbf{Z}^H\bar{\mathbf{Q}}^{-1}\,\mathrm{diag}\left(\mathbf{W}\,\mathbf{R}\,\mathbf{Z}^H\right)\right)\\
&\quad+\mathrm{tr}\left(\bar{\mathbf{Q}}^{-1}\mathbf{W}\,\mathbf{R}\,\mathbf{Z}^H\bar{\mathbf{Q}}^{-1}\,\mathrm{diag}\left(\mathbf{Z}\,\mathbf{R}\,\mathbf{W}^H\right)\right)\\
&\quad+\mathrm{tr}\left(\bar{\mathbf{Q}}^{-1}\mathbf{Z}\,\mathbf{R}\,\mathbf{W}^H\bar{\mathbf{Q}}^{-1}\,\mathrm{diag}\left(\mathbf{W}\,\mathbf{R}\,\mathbf{Z}^H\right)\right)\\
&\quad+\mathrm{tr}\left(\bar{\mathbf{Q}}^{-1}\mathbf{Z}\,\mathbf{R}\,\mathbf{W}^H\bar{\mathbf{Q}}^{-1}\,\mathrm{diag}\left(\mathbf{Z}\,\mathbf{R}\,\mathbf{W}^H\right)\right) &(34)\\
&=2\,\mathrm{tr}\left(\mathbf{Z}^H\,\bar{\mathbf{Q}}^{-1}\,\mathrm{diag}\left(\mathbf{Z}\,\mathbf{R}\,\mathbf{W}^H\right)\bar{\mathbf{Q}}^{-1}\mathbf{W}\,\mathbf{R}\right)\\
&\quad+\mathrm{tr}\left(\mathbf{Z}\,\mathbf{R}\,\mathbf{W}^H\,\bar{\mathbf{Q}}^{-1}\,\mathrm{diag}\left(\mathbf{Z}\,\mathbf{R}\,\mathbf{W}^H\right)\bar{\mathbf{Q}}^{-1}\right)\\
&\quad+\mathrm{tr}\left(\mathbf{Z}^H\,\bar{\mathbf{Q}}^{-1}\,\mathrm{diag}\left(\mathbf{W}\,\mathbf{R}\,\mathbf{Z}^H\right)\bar{\mathbf{Q}}^{-1}\mathbf{W}\,\mathbf{R}\right), &(35)\end{aligned}$$

where we used $\mathrm{tr}\left(\mathbf{X}\,\mathbf{Y}\right)=\mathrm{tr}\left(\mathbf{Y}\,\mathbf{X}\right)$ and some elementary properties of $\mathrm{tr}\left(.\right)$ with diagonal matrices. With the help of (94) and (95) we obtain

$$\begin{aligned}\mathrm{tr}\,\mathbf{A}^2&=2\,\mathrm{vec}(\mathbf{Z})^H\left[\left(\bar{\mathbf{Q}}^{-1}\,\mathbf{W}\,\mathbf{R}\right)^T\otimes\bar{\mathbf{Q}}^{-1}\right]\mathrm{vec}\big(\,\mathrm{diag}\left(\mathbf{Z}\,\mathbf{R}\,\mathbf{W}^H\right)\big)\\
&\quad+\mathrm{vec}(\mathbf{Z})^T\,\mathbf{P}_{M\times N}^T\left[\bar{\mathbf{Q}}^{-T}\otimes\mathbf{R}\,\mathbf{W}^H\,\bar{\mathbf{Q}}^{-1}\right]\mathrm{vec}\big(\,\mathrm{diag}\left(\mathbf{Z}\,\mathbf{R}\,\mathbf{W}^H\right)\big)\\
&\quad+\mathrm{vec}(\mathbf{Z})^H\left[\left(\bar{\mathbf{Q}}^{-1}\,\mathbf{W}\,\mathbf{R}\right)^T\otimes\bar{\mathbf{Q}}^{-1}\right]\mathrm{vec}\big(\,\mathrm{diag}\left(\mathbf{W}\,\mathbf{R}\,\mathbf{Z}^H\right)\big). &(36)\end{aligned}$$

Next we make use of (10). With further help of (93) and (84) we get

$$\begin{aligned}\mathrm{tr}\,\mathbf{A}^2&=2\,\mathrm{vec}(\mathbf{Z})^H\left[\left(\bar{\mathbf{Q}}^{-1}\,\mathbf{W}\,\mathbf{R}\right)^T\otimes\bar{\mathbf{Q}}^{-1}\right]\mathbf{P}_{\mathrm{diag}}\left[\left(\mathbf{R}\,\mathbf{W}^H\right)^T\otimes\mathbf{I}_M\right]\mathrm{vec}(\mathbf{Z})\\
&\quad+\mathrm{vec}(\mathbf{Z})^T\,\mathbf{P}_{M\times N}^T\left[\bar{\mathbf{Q}}^{-T}\otimes\mathbf{R}\,\mathbf{W}^H\,\bar{\mathbf{Q}}^{-1}\right]\mathbf{P}_{\mathrm{diag}}\left[\left(\mathbf{R}\,\mathbf{W}^H\right)^T\otimes\mathbf{I}_M\right]\mathrm{vec}(\mathbf{Z})\\
&\quad+\mathrm{vec}(\mathbf{Z})^H\left[\left(\bar{\mathbf{Q}}^{-1}\,\mathbf{W}\,\mathbf{R}\right)^T\otimes\bar{\mathbf{Q}}^{-1}\right]\mathbf{P}_{\mathrm{diag}}\left[\mathbf{I}_M\otimes\mathbf{W}\,\mathbf{R}\right]\mathbf{P}_{M\times N}\,\mathrm{vec}(\mathbf{Z})^*. &(37)\end{aligned}$$

In this case $\mathbf{P}_{\mathrm{diag}}$ is an $M^2\times M^2$-dimensional matrix. By making use of (92) we obtain

$$\begin{aligned}\mathrm{tr}\,\mathbf{A}^2&=2\,\mathrm{vec}(\mathbf{Z})^H\left[\mathbf{R}^T\,\mathbf{W}^T\,\bar{\mathbf{Q}}^{-T}\otimes\bar{\mathbf{Q}}^{-1}\right]\mathbf{P}_{\mathrm{diag}}\left[\mathbf{W}^*\,\mathbf{R}^T\otimes\mathbf{I}_M\right]\mathrm{vec}(\mathbf{Z})\\
&\quad+\mathrm{vec}(\mathbf{Z})^T\left[\mathbf{R}\,\mathbf{W}^H\,\bar{\mathbf{Q}}^{-1}\otimes\bar{\mathbf{Q}}^{-T}\right]\mathbf{P}_{M\times M}\,\mathbf{P}_{\mathrm{diag}}\left[\mathbf{W}^*\mathbf{R}^T\otimes\mathbf{I}_M\right]\mathrm{vec}(\mathbf{Z})\\
&\quad+\mathrm{vec}(\mathbf{Z})^H\left[\mathbf{R}^T\,\mathbf{W}^T\bar{\mathbf{Q}}^{-T}\otimes\bar{\mathbf{Q}}^{-1}\right]\mathbf{P}_{\mathrm{diag}}\,\mathbf{P}_{M\times M}\left[\mathbf{W}\,\mathbf{R}\otimes\mathbf{I}_M\right]\mathrm{vec}(\mathbf{Z})^*. &(38)\end{aligned}$$

Since $\mathbf{P}_{N\times M} = \mathbf{P}_{M\times N}^{-1} = \mathbf{P}_{M\times N}^{T}$ and $\mathbf{P}_{M\times M}\,\mathbf{P}_{\text{diag}} = \mathbf{P}_{\text{diag}}\,\mathbf{P}_{M\times M}$, we get

$$\begin{aligned}
\operatorname{tr}\mathbf{A}^2 &= 2\,\operatorname{vec}(\mathbf{Z})^H \left[\mathbf{R}^T\,\mathbf{W}^T\,\bar{\mathbf{Q}}^{-T}\otimes\bar{\mathbf{Q}}^{-1}\right]\mathbf{P}_{\text{diag}}\left[\mathbf{W}^*\,\mathbf{R}^T\otimes\mathbf{I}_M\right]\operatorname{vec}(\mathbf{Z}) \\
&\quad + \operatorname{vec}(\mathbf{Z})^T\left[\mathbf{R}\,\mathbf{W}^H\,\bar{\mathbf{Q}}^{-1}\otimes\bar{\mathbf{Q}}^{-T}\right]\mathbf{P}_{\text{diag}}\,\mathbf{P}_{M\times M}\left[\mathbf{W}^*\mathbf{R}^T\otimes\mathbf{I}_M\right]\operatorname{vec}(\mathbf{Z}) \\
&\quad + \operatorname{vec}(\mathbf{Z})^H\left[\mathbf{R}^T\,\mathbf{W}^T\bar{\mathbf{Q}}^{-T}\otimes\bar{\mathbf{Q}}^{-1}\right]\mathbf{P}_{\text{diag}}\,\mathbf{P}_{M\times M}\left[\mathbf{W}\,\mathbf{R}\otimes\mathbf{I}_M\right]\operatorname{vec}(\mathbf{Z})^* \qquad (39)\\
&= 2\,\operatorname{vec}(\mathbf{Z})^H\left[\mathbf{R}^T\,\mathbf{W}^T\,\bar{\mathbf{Q}}^{-T}\otimes\bar{\mathbf{Q}}^{-1}\right]\mathbf{P}_{\text{diag}}\left[\mathbf{W}^*\,\mathbf{R}^T\otimes\mathbf{I}_M\right]\operatorname{vec}(\mathbf{Z}) \\
&\quad + 2\,\mathfrak{Re}\big\{\operatorname{vec}(\mathbf{Z})^T\left[\mathbf{R}\,\mathbf{W}^H\,\bar{\mathbf{Q}}^{-1}\otimes\bar{\mathbf{Q}}^{-T}\right]\mathbf{P}_{\text{diag}}\,\mathbf{P}_{M\times M}\left[\mathbf{W}^*\mathbf{R}^T\otimes\mathbf{I}_M\right]\operatorname{vec}(\mathbf{Z})\big\}. \qquad (40)
\end{aligned}$$

In the last step we used the fact that $\mathbf{R}^* = \mathbf{R}^T$ and $\bar{\mathbf{Q}}^* = \bar{\mathbf{Q}}^T$, as $\mathbf{R}$ and $\bar{\mathbf{Q}}$ are both Hermitian. Finally, the second term in (29) can be modified with (95) as

$$\begin{aligned}
\operatorname{tr}\mathbf{B} &= \operatorname{tr}\left(\bar{\mathbf{Q}}^{-1}\,\operatorname{diag}\big(\mathbf{Z}\,\mathbf{R}\,\mathbf{Z}^H\big)\right) = \operatorname{tr}\left(\bar{\mathbf{Q}}^{-1}\,\mathbf{Z}\,\mathbf{R}\,\mathbf{Z}^H\right) \qquad (41)\\
&= \operatorname{tr}\left(\mathbf{Z}^H\bar{\mathbf{Q}}^{-1}\,\mathbf{Z}\,\mathbf{R}\right) \qquad (42)\\
&= \operatorname{vec}(\mathbf{Z})^H\left[\mathbf{R}^T\otimes\bar{\mathbf{Q}}^{-1}\right]\operatorname{vec}(\mathbf{Z}). \qquad (43)
\end{aligned}$$

Inserting (32), (40), and (43) into (29) yields

$$\begin{aligned}
&\mathcal{J}^{(1)}(\mathbf{W}+\delta\,\mathbf{Z}) \\
&\quad = \mathcal{J}^{(1)}(\mathbf{W}) + 2\,\delta\,\mathfrak{Re}\big\{\operatorname{tr}\left(\mathbf{Z}^H\,\bar{\mathbf{Q}}^{-1}\,\mathbf{W}\,\mathbf{R}\right)\big\} + \delta^2\operatorname{vec}(\mathbf{Z})^H\cdot \\
&\qquad \cdot\Big(\left[\mathbf{R}^T\otimes\bar{\mathbf{Q}}^{-1}\right] - \left[\mathbf{R}^T\,\mathbf{W}^T\,\bar{\mathbf{Q}}^{-T}\otimes\bar{\mathbf{Q}}^{-1}\right]\mathbf{P}_{\text{diag}}\left[\mathbf{W}^*\,\mathbf{R}^T\otimes\mathbf{I}_M\right]\Big)\operatorname{vec}(\mathbf{Z}) \\
&\qquad - \delta^2\,\mathfrak{Re}\big\{\operatorname{vec}(\mathbf{Z})^T\left[\mathbf{R}\,\mathbf{W}^H\,\bar{\mathbf{Q}}^{-1}\otimes\bar{\mathbf{Q}}^{-T}\right]\mathbf{P}_{\text{diag}}\,\mathbf{P}_{M\times M}\left[\mathbf{W}^*\mathbf{R}^T\otimes\mathbf{I}_M\right]\operatorname{vec}(\mathbf{Z})\big\} \\
&\quad + O(\delta^3). \qquad (44)
\end{aligned}$$

By coefficient comparison between (44) and the matrix form of the second-order Taylor series (12), and using $\mathbf{R}^T = \mathbf{R}^*$ and (91), we finally obtain

$$\mathbf{D}_{\mathbf{W}}^{(1)} = 2\,\bar{\mathbf{Q}}^{-1}\,\mathbf{W}\,\mathbf{R}, \qquad (45)$$

$$\mathbf{H}_{\mathbf{W}}^{(1)} = 2\left[\mathbf{R}^T\otimes\bar{\mathbf{Q}}^{-1}\right] - 2\left[\mathbf{R}^T\,\mathbf{W}^T\otimes\mathbf{I}_M\right]\left[\bar{\mathbf{Q}}^{-T}\otimes\bar{\mathbf{Q}}^{-1}\right]\mathbf{P}_{\text{diag}}\left[\mathbf{W}^*\,\mathbf{R}^*\otimes\mathbf{I}_M\right], \qquad (46)$$

$$\mathbf{C}_{\mathbf{W}}^{(1)} = -2\left[\mathbf{R}\,\mathbf{W}^H\otimes\mathbf{I}_M\right]\left[\bar{\mathbf{Q}}^{-1}\otimes\bar{\mathbf{Q}}^{-T}\right]\mathbf{P}_{\text{diag}}\,\mathbf{P}_{M\times M}\left[\mathbf{W}^*\mathbf{R}^*\otimes\mathbf{I}_M\right], \qquad (47)$$

where $\bar{\mathbf{Q}}$ is defined in (21).

2.4. Gradient and Hessian of $\mathcal{J}^{(2)}(.)$. Deriving the gradient and Hessian of $\mathcal{J}^{(2)}(\mathbf{W}) \triangleq \log\left(\det\left(\mathbf{W}\,\mathbf{R}\,\mathbf{W}^H\right)\right)$, as defined in (18), can be done in a similar way to how it was done for $\mathcal{J}^{(1)}$ in the previous section. To this end, we expand $\mathcal{J}^{(2)}$ as

$$\begin{aligned}
&\mathcal{J}^{(2)}(\mathbf{W}+\delta\,\mathbf{Z}) = \log\left(\det\left((\mathbf{W}+\delta\,\mathbf{Z})\,\mathbf{R}\,(\mathbf{W}+\delta\,\mathbf{Z})^H\right)\right) \qquad (48)\\
&\qquad = \log\left(\det\left(\mathbf{W}\,\mathbf{R}\,\mathbf{W}^H + \delta\left(\mathbf{W}\,\mathbf{R}\,\mathbf{Z}^H + \mathbf{Z}\,\mathbf{R}\,\mathbf{W}^H\right) + \delta^2\mathbf{Z}\,\mathbf{R}\,\mathbf{Z}^H\right)\right). \qquad (49)
\end{aligned}$$

By substituting

$$\mathbf{Q} \triangleq \mathbf{W}\,\mathbf{R}\,\mathbf{W}^H \qquad (50)$$

we can rewrite (49) as

$$\begin{aligned}
&\mathcal{J}^{(2)}(\mathbf{W}+\delta\,\mathbf{Z}) \\
&\quad = \log\left(\det\left(\mathbf{Q}\,\left(\mathbf{I} + \delta\,\mathbf{Q}^{-1}\left(\mathbf{W}\,\mathbf{R}\,\mathbf{Z}^H + \mathbf{Z}\,\mathbf{R}\,\mathbf{W}^H\right) + \delta^2\,\mathbf{Q}^{-1}\mathbf{Z}\,\mathbf{R}\,\mathbf{Z}^H\right)\right)\right) \qquad (51)\\
&\quad = \mathcal{J}^{(2)}(\mathbf{W}) + \log\left(\det\left(\mathbf{I} + \delta\,\mathbf{Q}^{-1}\left(\mathbf{W}\,\mathbf{R}\,\mathbf{Z}^H + \mathbf{Z}\,\mathbf{R}\,\mathbf{W}^H\right) + \delta^2\,\mathbf{Q}^{-1}\mathbf{Z}\,\mathbf{R}\,\mathbf{Z}^H\right)\right). \qquad (52)
\end{aligned}$$

By inspection, we see that (52) has the same structure as (23) and therefore can also be written in the form

$$\mathcal{J}^{(2)}\left(\mathbf{W}+\delta\,\mathbf{Z}\right)=\mathcal{J}^{(2)}\left(\mathbf{W}\right)+\log\left(\det\left(\mathbf{I}+\delta\,\mathbf{A}+\delta^2\mathbf{B}\right)\right), \tag{53}$$

this time with

$$\mathbf{A}\triangleq\mathbf{Q}^{-1}\left(\mathbf{W}\,\mathbf{R}\,\mathbf{Z}^H+\mathbf{Z}\,\mathbf{R}\,\mathbf{W}^H\right), \tag{54}$$

$$\mathbf{B}\triangleq\mathbf{Q}^{-1}\mathbf{Z}\,\mathbf{R}\,\mathbf{Z}^H. \tag{55}$$

One difference, though, is that the matrices $\mathbf{Q}$, $\mathbf{A}$, and $\mathbf{B}$ are this time no longer diagonal, in general. However, since in the previous calculations we only made the assumption that these matrices needed to be Hermitian and not diagonal, we can use (27) again and carry out the further steps in exactly the same manner as it was done for $\mathcal{J}^{(1)}$. By going through the same derivation steps, we finally obtain

$$\mathbf{D}_{\mathbf{W}}^{(2)}=2\,\mathbf{Q}^{-1}\,\mathbf{W}\,\mathbf{R}, \tag{56}$$

$$\mathbf{H}_{\mathbf{W}}^{(2)}=2\left[\,\mathbf{R}^T\otimes\mathbf{Q}^{-1}\right]-2\left[\,\mathbf{R}^T\,\mathbf{W}^T\otimes\mathbf{I}_M\,\right]\left[\,\mathbf{Q}^{-T}\otimes\mathbf{Q}^{-1}\right]\left[\,\mathbf{W}^*\,\mathbf{R}^*\otimes\mathbf{I}_M\right], \tag{57}$$

$$\mathbf{C}_{\mathbf{W}}^{(2)}=-2\left[\,\mathbf{R}\,\mathbf{W}^H\otimes\mathbf{I}_M\right]\left[\,\mathbf{Q}^{-1}\otimes\mathbf{Q}^{-T}\right]\mathbf{P}_{M\times M}\left[\,\mathbf{W}^*\mathbf{R}^*\otimes\mathbf{I}_M\right]. \tag{58}$$

By comparing (56)–(58) with (45)–(47), respectively, basically $\bar{\mathbf{Q}}$ is replaced by its nondiagonal version $\mathbf{Q}$, and $\mathbf{P}_{\text{diag}}$ is replaced by $\mathbf{I}_M$.

2.5. Gradient and Hessian of $\mathcal{J}\,(.)$. Because of the definitions (16), (17), and (18) we can write the gradient and the Hessian of $\widetilde{\mathcal{J}}(.)$ as

$$\widetilde{\mathbf{D}}_{\mathbf{W}}\left(\mathbf{W};\mathbf{R}_p\right)=\mathbf{D}_{\mathbf{W}}^{(1)}\left(\mathbf{W};\mathbf{R}_p\right)-\mathbf{D}_{\mathbf{W}}^{(2)}\left(\mathbf{W};\mathbf{R}_p\right), \tag{59}$$

$$\widetilde{\mathbf{H}}_{\mathbf{W}}\left(\mathbf{W};\mathbf{R}_p\right)=\mathbf{H}_{\mathbf{W}}^{(1)}\left(\mathbf{W};\mathbf{R}_p\right)-\mathbf{H}_{\mathbf{W}}^{(2)}\left(\mathbf{W};\mathbf{R}_p\right), \tag{60}$$

$$\widetilde{\mathbf{C}}_{\mathbf{W}}\left(\mathbf{W};\mathbf{R}_p\right)=\mathbf{C}_{\mathbf{W}}^{(1)}\left(\mathbf{W};\mathbf{R}_p\right)-\mathbf{C}_{\mathbf{W}}^{(2)}\left(\mathbf{W};\mathbf{R}_p\right), \tag{61}$$

where $\mathbf{D}_{\mathbf{W}}^{(1)}$, $\mathbf{H}_{\mathbf{W}}^{(1)}$, and $\mathbf{C}_{\mathbf{W}}^{(1)}$ are defined in (45), (46), and (47), respectively, and $\mathbf{D}_{\mathbf{W}}^{(2)}$, $\mathbf{H}_{\mathbf{W}}^{(2)}$, and $\mathbf{C}_{\mathbf{W}}^{(2)}$ are defined in (56), (57), and (58), respectively. By inserting these terms into (59), (60), and (61), after some rearranging we finally obtain, for all p,

$$\widetilde{\mathbf{D}}_{\mathbf{W}}\left(\mathbf{W};\mathbf{R}\right)=2\left(\,\bar{\mathbf{Q}}^{-1}-\mathbf{Q}^{-1}\,\right)\mathbf{W}\,\mathbf{R}, \tag{62}$$

$$\begin{aligned}\widetilde{\mathbf{H}}_{\mathbf{W}}\left(\mathbf{W};\mathbf{R}\right)=\;&2\left[\,\mathbf{R}^T\otimes\left(\,\bar{\mathbf{Q}}^{-1}-\mathbf{Q}^{-1}\,\right)\right]\\&+2\left[\,\mathbf{R}^T\,\mathbf{W}^T\otimes\mathbf{I}_M\,\right]\Big(\left[\,\mathbf{Q}^{-T}\otimes\mathbf{Q}^{-1}\,\right]-\left[\,\bar{\mathbf{Q}}^{-T}\otimes\bar{\mathbf{Q}}^{-1}\,\right]\mathbf{P}_{\text{diag}}\Big)\\&\cdot\left[\,\mathbf{W}^*\,\mathbf{R}^*\otimes\mathbf{I}_M\right],\end{aligned} \tag{63}$$

$$\widetilde{\mathbf{C}}_{\mathbf{W}}\left(\mathbf{W};\mathbf{R}\right)=2\left[\,\mathbf{R}\,\mathbf{W}^H\otimes\mathbf{I}_M\,\right]\Big(\left[\,\mathbf{Q}^{-1}\otimes\mathbf{Q}^{-T}\,\right]-\left[\,\bar{\mathbf{Q}}^{-1}\otimes\bar{\mathbf{Q}}^{-T}\,\right]\mathbf{P}_{\text{diag}}\Big)\cdot\mathbf{P}_{M\times M}\left[\,\mathbf{W}^*\mathbf{R}^*\otimes\mathbf{I}_M\right]. \tag{64}$$

Finally, because of (15), we can write the gradient and the Hessian of the cost function $\mathcal{J}$ as

$$\mathbf{D}_{\mathbf{W}}=\sum_{p=1}^{P}\beta_p\,\widetilde{\mathbf{D}}_{\mathbf{W}}\left(\mathbf{W};\mathbf{R}_p\right), \tag{65}$$

$$\mathbf{H}_{\mathbf{W}} = \sum_{p=1}^{P} \beta_p \, \widetilde{\mathbf{H}}_{\mathbf{W}} \left(\mathbf{W}; \mathbf{R}_p \right), \tag{66}$$

$$\mathbf{C}_{\mathbf{W}} = \sum_{p=1}^{P} \beta_p \, \widetilde{\mathbf{C}}_{\mathbf{W}} \left(\mathbf{W}; \mathbf{R}_p \right). \tag{67}$$

Equations (62) to (67) are the gradient and the Hessian of the cost function (4).

2.6. Comparison between gradient and Hessian of $\mathcal{J}$ and $\mathcal{J}_{\text{off}}$. A well-known cost function used for the joint diagonalization problem is [5]

$$\mathcal{J}_{\text{off}} \left(\mathbf{W} \, ; \{\beta_p\}, \{\mathbf{R}_p\} \right) \triangleq \sum_{p=1}^{P} \beta_p \left\| \, \text{off}(\, \mathbf{W} \, \mathbf{R}_p \, \mathbf{W}^H \,) \, \right\|_F^2 \tag{68}$$

subject to a constraint that prevents $\mathbf{W}$ from becoming zero. We now like to make a comparison between the gradient and Hessian of $\mathcal{J}$ and $\mathcal{J}_{\text{off}}$. The gradient and Hessian of the term $\hat{\mathcal{J}} \triangleq \|\text{off}(\, \mathbf{W} \, \mathbf{R}_p \, \mathbf{W}^H \,)\|_F^2$, which appears in (68), are [10]

$$\widehat{\mathbf{D}}_{\mathbf{W}} \left(\mathbf{W}; \mathbf{R} \right) = 4 \, \text{off}(\, \mathbf{Q} \,) \, \mathbf{W} \, \mathbf{R}, \tag{69}$$

$$\widehat{\mathbf{H}}_{\mathbf{W}} \left(\mathbf{W}; \mathbf{R} \right) = 4 \left[\, \mathbf{R}^T \otimes \text{off}(\, \mathbf{Q} \,) \, \right] + 4 \left[\, \mathbf{R}^T \, \mathbf{W}^T \otimes \mathbf{I}_M \, \right] \mathbf{P}_{\text{off}} \left[\, \mathbf{W}^* \, \mathbf{R}^* \otimes \mathbf{I}_M \right], \tag{70}$$

$$\widehat{\mathbf{C}}_{\mathbf{W}} \left(\mathbf{W}; \mathbf{R} \right) = 4 \left[\, \mathbf{R} \, \mathbf{W}^H \otimes \mathbf{I}_M \, \right] \mathbf{P}_{\text{off}} \, \mathbf{P}_{M \times M} \left[\, \mathbf{W}^* \mathbf{R}^* \otimes \mathbf{I}_M \right]. \tag{71}$$

We wish to bring the gradient and Hessian of $\mathcal{J}$ into a similar form. To this end, we reformulate the term $\bar{\mathbf{Q}}^{-1} - \mathbf{Q}^{-1}$ as

$$\bar{\mathbf{Q}}^{-1} - \mathbf{Q}^{-1} = \bar{\mathbf{Q}}^{-1} \, (\, \mathbf{Q} - \bar{\mathbf{Q}} \,) \mathbf{Q}^{-1} = \bar{\mathbf{Q}}^{-1} \, \text{off}(\, \mathbf{Q} \,) \, \mathbf{Q}^{-1}, \tag{72}$$

where off(.) is defined in (7) and $\bar{\mathbf{Q}} \triangleq \text{diag}(\, \mathbf{Q} \,)$; see (21) and (50). Furthermore, since $\mathbf{P}_{\text{diag}} + \mathbf{P}_{\text{off}} = \mathbf{I}$ we have

$$\begin{aligned} &\left[\, \mathbf{Q}^{-T} \otimes \mathbf{Q}^{-1} \, \right] - \left[\, \bar{\mathbf{Q}}^{-T} \otimes \bar{\mathbf{Q}}^{-1} \, \right] \mathbf{P}_{\text{diag}} \\ &\qquad = \left(\left[\, \mathbf{Q}^{-T} \otimes \mathbf{Q}^{-1} \, \right] - \left[\, \bar{\mathbf{Q}}^{-T} \otimes \bar{\mathbf{Q}}^{-1} \, \right] \right) \mathbf{P}_{\text{diag}} + \left[\, \mathbf{Q}^{-T} \otimes \mathbf{Q}^{-1} \, \right] \mathbf{P}_{\text{off}}. \end{aligned} \tag{73}$$

By inserting (72) into (62) and (63), and (73) into (63) and (64) we can write the gradient and Hessian of $\mathcal{J}$ as

$$\widetilde{\mathbf{D}}_{\mathbf{W}} \left(\mathbf{W}; \mathbf{R} \right) = 2 \, \bar{\mathbf{Q}}^{-1} \, \text{off}(\, \mathbf{Q} \,) \, \mathbf{Q}^{-1} \, \mathbf{W} \, \mathbf{R}, \tag{74}$$

$$\begin{aligned} \widetilde{\mathbf{H}}_{\mathbf{W}} \left(\mathbf{W}; \mathbf{R} \right) &= 2 \left[\, \mathbf{R}^T \otimes \bar{\mathbf{Q}}^{-1} \, \text{off}(\, \mathbf{Q} \,) \, \mathbf{Q}^{-1} \, \right] \\ &\quad + 2 \left[\, \mathbf{R}^T \, \mathbf{W}^T \otimes \mathbf{I}_M \, \right] \left(\left[\, \mathbf{Q}^{-T} \otimes \mathbf{Q}^{-1} \, \right] - \left[\, \bar{\mathbf{Q}}^{-T} \otimes \bar{\mathbf{Q}}^{-1} \, \right] \right) \mathbf{P}_{\text{diag}} \left[\, \mathbf{W}^* \, \mathbf{R}^* \otimes \mathbf{I}_M \right] \\ &\quad + 2 \left[\, \mathbf{R}^T \, \mathbf{W}^T \otimes \mathbf{I}_M \, \right] \left[\, \mathbf{Q}^{-T} \otimes \mathbf{Q}^{-1} \, \right] \mathbf{P}_{\text{off}} \left[\, \mathbf{W}^* \, \mathbf{R}^* \otimes \mathbf{I}_M \right], \end{aligned} \tag{75}$$

$$\begin{aligned} &\widetilde{\mathbf{C}}_{\mathbf{W}} \left(\mathbf{W}; \mathbf{R} \right) \\ &\quad = 2 \left[\, \mathbf{R} \, \mathbf{W}^H \otimes \mathbf{I}_M \, \right] \left(\left[\, \mathbf{Q}^{-1} \otimes \mathbf{Q}^{-T} \, \right] - \left[\, \bar{\mathbf{Q}}^{-1} \otimes \bar{\mathbf{Q}}^{-T} \, \right] \right) \mathbf{P}_{\text{diag}} \, \mathbf{P}_{M \times M} \left[\, \mathbf{W}^* \, \mathbf{R}^* \otimes \mathbf{I}_M \right] \\ &\quad + 2 \left[\, \mathbf{R} \, \mathbf{W}^H \otimes \mathbf{I}_M \, \right] \left[\, \mathbf{Q}^{-1} \otimes \mathbf{Q}^{-T} \, \right] \mathbf{P}_{\text{off}} \, \mathbf{P}_{M \times M} \left[\, \mathbf{W}^* \, \mathbf{R}^* \otimes \mathbf{I}_M \right]. \end{aligned} \tag{76}$$

This form allows us to see clear similarities between the gradient and Hessian terms of the two cost functions $\mathcal{J}_{\text{off}}$ and $\mathcal{J}$ when comparing (69)–(71) with (74)–(76), respectively: In the gradient and the first term of the Hessian, off($\mathbf{Q}$) is replaced by

$\bar{\mathbf{Q}}^{-1}\,\mathrm{off}(\,\mathbf{Q}\,)\,\mathbf{Q}^{-1}$. Note that $\mathbf{Q}$ and $\bar{\mathbf{Q}}$ are both positive definite matrices. The last terms of the Hessian terms also show a very similar structure. The only difference is the additional term $\mathbf{Q}^{-T} \otimes \mathbf{Q}^{-1}$ in the Hessian of $\mathcal{J}$, which is also positive definite. The second term of $\widetilde{\mathbf{H}}_{\mathbf{W}}$ and the first term of $\widetilde{\mathbf{C}}_{\mathbf{W}}$ have no corresponding terms in $\widehat{\mathbf{H}}_{\mathbf{W}}$ and $\widehat{\mathbf{C}}_{\mathbf{W}}$.

2.7. Discussion of critical points. The critical points are defined where the gradient of $\mathcal{J}$ becomes zero. From (74) we see that $\widetilde{\mathbf{D}}_{\mathbf{W}}$ becomes zero if $\mathrm{off}(\,\mathbf{Q}\,) \equiv \mathbf{0}$ and consequently $\mathbf{Q} \equiv \bar{\mathbf{Q}}$. Since we can reformulate, similar to (72),

(77)
$$\left[\,\mathbf{Q}^{-T} \otimes \mathbf{Q}^{-1}\,\right] - \left[\,\bar{\mathbf{Q}}^{-T} \otimes \bar{\mathbf{Q}}^{-1}\,\right] = -\left[\,\mathbf{Q}^{-T} \otimes \mathbf{Q}^{-1}\,\right] \mathrm{off}(\;\mathbf{Q}^{T} \otimes \mathbf{Q}\;)\left[\,\bar{\mathbf{Q}}^{-T} \otimes \bar{\mathbf{Q}}^{-1}\,\right]$$

and the Kronecker product of two diagonal matrices is a diagonal matrix, the term $\mathrm{off}(\,\bar{\mathbf{Q}}^{T} \otimes \bar{\mathbf{Q}}\,)$ becomes zero. Hence, the Hessian terms of $\mathcal{J}$ at the critical points are

$$\widetilde{\mathbf{H}}_{\mathbf{W}}\,(\mathbf{W};\mathbf{R}) = 2\left[\,\mathbf{R}^{T}\,\mathbf{W}^{T} \otimes \mathbf{I}_{M}\,\right]\left[\,\bar{\mathbf{Q}}^{-T} \otimes \bar{\mathbf{Q}}^{-1}\,\right]\mathbf{P}_{\mathrm{off}}\left[\,\mathbf{W}^{*}\,\mathbf{R}^{*} \otimes \mathbf{I}_{M}\right], \tag{78}$$

$$\widetilde{\mathbf{C}}_{\mathbf{W}}\,(\mathbf{W};\mathbf{R}) = 2\left[\,\mathbf{R}\,\mathbf{W}^{H} \otimes \mathbf{I}_{M}\,\right]\left[\,\bar{\mathbf{Q}}^{-1} \otimes \bar{\mathbf{Q}}^{-T}\,\right]\mathbf{P}_{\mathrm{off}}\,\mathbf{P}_{M\times M}\left[\,\mathbf{W}^{*}\,\mathbf{R}^{*} \otimes \mathbf{I}_{M}\right]. \tag{79}$$

When comparing (78) and (79) with (70) and (71), respectively, we make the interesting discovery that, besides the diagonal matrix $\bar{\mathbf{Q}}^{-T} \otimes \bar{\mathbf{Q}}^{-1}$ and a scaling factor, the Hessian of $\mathcal{J}$ and $\mathcal{J}_{\mathrm{off}}$ at the critical points have an identical structure.

3. The Newton algorithm. Once we have derived the gradient and Hessian of our cost function, we can now formulate the Newton algorithm. The Newton update at iteration k can be written as

$$\mathbf{W}_{k+1} = \mathbf{W}_{k} + \mu_{k}\mathbf{S}_{k}, \tag{80}$$

where $\mathbf{S}_k$ is the *search direction* and μ_k is the *step size* of the kth update. The individual steps of the Newton algorithm are given in Figure 1. Since our cost function is nonquadratic, we use a modified Newton step that incorporates an Armijo line search. In the vicinity of the minimum the update will approach the pure Newton step.

The described Newton algorithm is built upon a vector-form Newton algorithm, where the complex coefficients of $\mathbf{W}_k$ are arranged in a length $2MN$ real vector $\mathbf{w}_k$ as defined in (14). Hence, the vector $\mathbf{d}_k$ and the matrix $\mathbf{H}_k$ are the gradient and Hessian of the vector form of the Taylor series expansion of $\mathcal{J}(\mathbf{w}_k)$; see (13).

Since our cost function is not quadratic, the Hessian $\mathbf{H}_k$ can have negative eigenvalues. By choosing σ_k such that $\mathbf{H}_k + \sigma_k\mathbf{I}$ becomes positive definite, the inverse $[\,\mathbf{H}_k + \sigma_k\mathbf{I}]^{-1}$ will be positive definite as well. This will ensure that $\mathbf{s}_k$ and $\mathbf{S}_k$ will point to a descent direction, just like the negative gradient $-\mathbf{d}_k$ does. Hence, σ_k must be chosen larger than $-\lambda_{min}(\mathbf{H}_k)$ if $\mathbf{H}_k$ has nonpositive eigenvalues, where λ_{min} is the smallest eigenvalue of $\mathbf{H}_k$. In the vicinity of a local minimum, σ_k will become zero and the update will approach the pure Newton update for $\mu_k = 1$. On the other hand, if σ_k is chosen very large, the search direction $\mathbf{s}_k$ will become close to the direction of the negative gradient. For efficiency reasons, $\mathbf{H}_k$ is often regularized via a modified Cholesky factorization method [2, sec. 1.4]. Therefore the described modified Newton algorithm should be understood more as a prototype algorithm. The step size μ_k is obtained from a line-search step, e.g., an *Armijo line-search method* [2, 6, 11, 15], which guarantees that $\mathcal{J}(\mathbf{W}_{k+1}) \leq \mathcal{J}(\mathbf{W}_k)$ and μ_k is chosen *not too small*. The reason to include a variable step size μ_k into the Newton update is motivated by the

Modified Newton algorithm

Initialization ($k = 0$): $\mathbf{W}_0 \in \mathbb{C}^{M\times N}$.

For $k = 1, 2, \ldots$ until convergence,

1. Compute gradient $\mathbf{D}_{\mathbf{W}k}$ with (65) and (62).
2. Compute Hessian $\{\mathbf{H}_{\mathbf{W}k}, \mathbf{C}_{\mathbf{W}k}\}$ with (66), (63), (67), and (64).
3. Compute the real vector
$$\mathbf{d}_k \triangleq \begin{pmatrix} \mathbf{d}^{\mathrm{re}} \\ \mathbf{d}^{\mathrm{im}} \end{pmatrix} := \begin{pmatrix} \mathfrak{Re}\{\mathrm{vec}(\mathbf{D}_{\mathbf{W}})\} \\ \mathfrak{Im}\{\mathrm{vec}(\mathbf{D}_{\mathbf{W}})\} \end{pmatrix}.$$
4. Compute the real matrix
$$\mathbf{H}_k := \begin{bmatrix} \mathfrak{Re}\{\mathbf{H}_{\mathbf{W}} + \mathbf{C}_{\mathbf{W}}\} & -\mathfrak{Im}\{\mathbf{H}_{\mathbf{W}} + \mathbf{C}_{\mathbf{W}}\} \\ \mathfrak{Im}\{\mathbf{H}_{\mathbf{W}} - \mathbf{C}_{\mathbf{W}}\} & \mathfrak{Re}\{\mathbf{H}_{\mathbf{W}} - \mathbf{C}_{\mathbf{W}}\} \end{bmatrix}.$$
5. Compute the real vector
$$\mathbf{s}_k := -\left[\mathbf{H}_k + \sigma_k \mathbf{I}\right]^{-1} \mathbf{d}_k,$$
where $\sigma_k \geq 0$ is chosen such that $\mathbf{H}_k + \sigma_k \mathbf{I}$ becomes positive definite.
6. Compute the complex matrix $\mathbf{S}_k := \mathrm{mat}_{M\times N}(\mathbf{s}_k^{\mathrm{re}} + j\mathbf{s}_k^{\mathrm{im}})$ which corresponds to the inverse operation of
$$\mathbf{s}_k \triangleq \begin{pmatrix} \mathbf{s}^{\mathrm{re}} \\ \mathbf{s}^{\mathrm{im}} \end{pmatrix} = \begin{pmatrix} \mathfrak{Re}\{\mathrm{vec}(\mathbf{S}_k)\} \\ \mathfrak{Im}\{\mathrm{vec}(\mathbf{S}_k)\} \end{pmatrix}.$$
7. Perform update $\mathbf{W}_{k+1} := \mathbf{W}_k + \mu_k \mathbf{S}_k$, where the step size μ_k is found via a line-search algorithm, e.g., an Armijo line search (see Appendix B).

FIG. 1. *Modified Newton algorithm.*

fact that in our case $\mathcal{J}$ is a nonquadratic cost function. In this case the Newton step, $\mu_k = 1$, often overshoots the local minimum, even if the Hessian $\mathbf{H}_k$ is positive definite. Close to a minimum, where the cost function can be approximated by a quadratic curvature, the Armijo line-search method will often set μ_k automatically to one.

4. Simulation example. We give now a simulation example where the performance between the Newton algorithm and a steepest-descent algorithm are compared. This simulation is set up such that a perfect joint diagonalization is possible. The chosen parameters are $M = 3$ and $N = 5$. For each simulation trial we generate a random complex matrix $\mathbf{A} \in \mathbb{C}^{5\times 3}$, such that $\mathbf{A}^H\mathbf{A} = \mathbf{I}_3$. Then we generate for each trial a set of $P = 15$ correlation matrices $\{\mathbf{R}_p\}_{p=1}^{15} = \{\mathbf{A}\,\mathbf{\Lambda}_p\,\mathbf{A}^H\}_{p=1}^{15}$ where each $\mathbf{\Lambda}_p \in \mathbb{R}^{3\times 3}$ is a diagonal matrix whose elements are randomly chosen from a uniform distribution between 0.1 and 1. Hence, each $\mathbf{\Lambda}_p$ is positive definite, and each $\mathbf{R}_p$ is positive semidefinite and has rank 3. Figure 2 compares the performance between the Newton algorithm, using Armijo line searches, and a gradient-type update. The top curve shows the performance of the cost function $\mathcal{J}$, defined in (4); the bottom curve

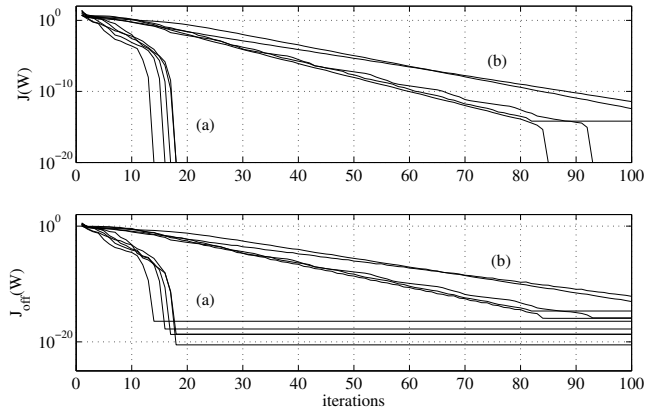

FIG. 2. *Learning curves of* $\mathcal{J}(\mathbf{W}_k)$ *(top) and* $\mathcal{J}_{\text{off}}(\mathbf{W}_k)$ *(bottom) for five independent simulations using* (a) *the modified Newton method and* (b) *the steepest-descent algorithm.*

shows how the cost function $\mathcal{J}_{\text{off}}$, given in (68), behaves. For this simulation we premultiply $\mathbf{W}_k$ after every iteration with a diagonal matrix, such that the rows of $\mathbf{W}_k$ have unit norm, i.e., $\text{diag}(\mathbf{W}_k\,\mathbf{W}_k^H) = \mathbf{I}_3$. This normalization step does not affect the value of the cost function $\mathcal{J}$, as $\mathcal{J}$ is scale-invariant to such an operation; however, it is important for a meaningful interpretation of $\mathcal{J}_{\text{off}}$. Without this normalization a small value of $\mathcal{J}_{\text{off}}$ could also be caused by $\|\,\mathbf{W}_k\,\|_F \ll 1$, which would result in a misleading performance interpretation. From the simulation curves it is clearly seen that once the Newton algorithm approaches the vicinity of a minimum, it reveals a *superlinear convergence* and attains the minimum within a few steps.

5. Conclusion. The problem of joint approximate diagonalization of a set of positive definite matrices has become of great interest in blind signal separation applications. Most algorithms known for the joint diagonalization task impose some constraints on the diagonalization matrix $\mathbf{W}$, namely, that $\mathbf{W}$ needs to be (i) real, (ii) unitary, or (iii) square. We have derived a Newton algorithm for this problem which has none of these restrictions. We allow the diagonalization matrix $\mathbf{W}$ to be complex, nonunitary, and even rectangular.

The most general case where the diagonalization matrix $\mathbf{W}$ can be rectangular, instead of being square, is of particular interest in blind signal separation. This scenario occurs when access to more sensor signals than source signals is available. In this case the correlation matrices $\mathbf{R}_p$ are no longer positive definite; they only will be positive semidefinite. Algorithms that use the same cost function as given in (4), but constrain $\mathbf{W}$ to being square, require that $\mathbf{R}_p$ be positive definite; otherwise $\det\left(\mathbf{W}\,\mathbf{R}_p\,\mathbf{W}^H\right)$ becomes zero. Since our algorithm can also update a rectangular $M \times N$ matrix $\mathbf{W}$, where $M \leq N$, we impose a much weaker constraint, namely, that the product $\mathbf{W}\,\mathbf{R}_p\,\mathbf{W}^H$ needs to be positive definite and not $\mathbf{R}_p$. For a given set of $\{\mathbf{R}_p\}$ we can simply achieve this by reducing M, the number of rows of $\mathbf{W}$, until $\{\mathbf{W}\,\mathbf{R}_p\,\mathbf{W}^H\}$ has full rank for all p.

A major contribution of this paper is the derivation of the Hessian in closed form for every $\mathbf{W}$ and not only at the critical points. It turned out that the matrix form of the Taylor series expansion (12), as given by Manton in [13], has provided the foundation of this derivation. This form preserves the matrix structure of the underlying problem which allows a compact-form representation of the gradient and

Hessian through matrix and Kronecker products. Finally, we have shown that there exists a close similarity between the gradient and Hessian of two commonly used cost functions for the joint diagonalization problem.

Appendix A. Useful relations for deriving the gradient and Hessian of a matrix-valued cost function. The following equalities were very useful for the derivation of the gradient and Hessian. Some basic relations are

$$\| \mathbf{A} \|_F^2 = \mathrm{tr}\,(\mathbf{A}\mathbf{A}^H)\,, \tag{81}$$

$$\mathrm{tr}\,(\mathbf{A}\mathbf{B}) = \mathrm{tr}\,(\mathbf{B}\mathbf{A})\,, \tag{82}$$

$$\mathrm{tr}\left(\mathbf{A}^H\right) = \mathrm{tr}\,(\mathbf{A}^*) = (\mathrm{tr}\,(\mathbf{A}))^*\,. \tag{83}$$

Furthermore, we have some useful equalities with the vec(.) operation and Kronecker product [3] with $\mathbf{Z} \in \mathbb{C}^{M\times N}$:

$$\mathrm{vec}(\,\mathbf{Z}^T\,) = \mathbf{P}_{M\times N}\,\mathrm{vec}(\,\mathbf{Z}\,), \tag{84}$$

$$\mathrm{tr}(\mathbf{Z}^H\mathbf{A}) = \mathrm{vec}(\,\mathbf{Z}\,)^H\,\mathrm{vec}(\,\mathbf{A}\,), \tag{85}$$

$$\begin{aligned}\mathrm{tr}\,(\mathbf{Z}\mathbf{A}) &= \mathrm{vec}(\,\mathbf{Z}^T\,)^T\,\mathrm{vec}(\,\mathbf{A}\,) \\ &= \mathrm{vec}(\,\mathbf{Z}\,)^T\,\mathbf{P}_{M\times N}^T\,\mathrm{vec}(\,\mathbf{A}\,),\end{aligned} \tag{86, 87}$$

$$(\mathbf{A}\otimes\mathbf{B})^T = \mathbf{A}^T\otimes\mathbf{B}^T, \tag{88}$$

$$(\mathbf{A}\otimes\mathbf{B})^H = \mathbf{A}^H\otimes\mathbf{B}^H, \tag{89}$$

$$(\mathbf{A}\otimes\mathbf{B})^{-1} = \mathbf{A}^{-1}\otimes\mathbf{B}^{-1}, \tag{90}$$

$$(\,\mathbf{A}\,\mathbf{B}\otimes\mathbf{C}\,\mathbf{D}\,) = (\,\mathbf{A}\otimes\mathbf{C}\,)(\,\mathbf{B}\otimes\mathbf{D}\,), \tag{91}$$

$$\mathbf{A}^{P\times Q}\otimes\mathbf{B}^{R\times S} = \mathbf{P}_{P\times R}\,(\,\mathbf{B}\otimes\mathbf{A}\,)\,\mathbf{P}_{S\times Q}, \tag{92}$$

$$\mathrm{vec}(\,\mathbf{A}\,\mathbf{Z}\,\mathbf{B}\,) = (\,\mathbf{B}^T\otimes\mathbf{A}\,)\,\mathrm{vec}(\,\mathbf{Z}\,), \tag{93}$$

where the permutation matrix $\mathbf{P}_{M\times N}$ is uniquely defined with (84). Sometimes $\mathbf{P}_{M\times N}$ is called the *commutation matrix* [12]. Since $\mathbf{P}_{M\times N}$ is a permutation matrix, $\mathbf{P}_{M\times N} = \mathbf{P}_{N\times M}^T = \mathbf{P}_{N\times M}^{-1}$. For the special case where $M = N$, the commutation matrix is *involutory*, $\mathbf{P}_{M\times M}^2 = \mathbf{I}$, as $\mathbf{P}_{M\times M}^T = \mathbf{P}_{M\times M}$ is symmetric. See [3, 12] for a thorough list of properties of Kronecker products.

The following relations, where $\mathbf{Z}_1, \mathbf{Z}_2 \in \mathbb{C}^{M\times N}$ and the argument of tr (.) is a square matrix, have been proven to be very useful in the derivation of the Hessian:

$$\mathrm{tr}\,(\mathbf{Z}_1\,\mathbf{A}\,\mathbf{Z}_2\,\mathbf{B}) = \mathrm{vec}(\,\mathbf{Z}_1\,)^T\,\mathbf{P}_{M\times N}^T\,(\,\mathbf{B}^T\otimes\mathbf{A}\,)\,\mathrm{vec}(\,\mathbf{Z}_2\,), \tag{94}$$

$$\mathrm{tr}\left(\mathbf{Z}_1^H\mathbf{A}\,\mathbf{Z}_2\,\mathbf{B}\right) = \mathrm{vec}(\,\mathbf{Z}_1\,)^H\,(\,\mathbf{B}^T\otimes\mathbf{A}\,)\,\mathrm{vec}(\,\mathbf{Z}_2\,), \tag{95}$$

$$\mathrm{tr}\left(\mathbf{Z}_1^H\mathbf{A}\,\mathbf{Z}_2^H\,\mathbf{B}\right) = \mathrm{vec}(\,\mathbf{Z}_1\,)^H\,(\,\mathbf{B}^T\otimes\mathbf{A}\,)\,\mathbf{P}_{M\times N}\,\mathrm{vec}(\,\mathbf{Z}_2\,)^*. \tag{96}$$

Equation (95) can be derived with (85) and (93). Equations (94) and (96) can be derived with (85), (93), (87), and (83).

Appendix B. Armijo rule for matrix form. The Armijo rule for choosing a step size μ_k at the kth iteration is defined as $\mu_k = \mu_0\,\gamma^m$, where m is the first nonnegative integer that fulfills

$$\mathcal{J}(\mathbf{W}_k) - \mathcal{J}(\mathbf{W}_k + \mu_0\,\gamma^m\,\mathbf{S}_k) \geq -\eta\,\mu_0\,\gamma^m\,\mathfrak{Re}\{\langle\mathbf{S}_k, \mathbf{D}_{\mathbf{W}k}\rangle\}. \tag{97}$$

The search direction and the gradient of $\mathcal{J}$ at $\mathbf{W}_k$ are denoted as $\mathbf{S}_k$ and $\mathbf{D}_{\mathbf{W}k}$, respectively, and $\langle\mathbf{S}_k, \mathbf{D}_{\mathbf{W}k}\rangle \triangleq \mathrm{tr}\left(\mathbf{S}_k^H\mathbf{D}_{\mathbf{W}k}\right)$ defines an inner product between $\mathbf{S}_k$ and $\mathbf{D}_{\mathbf{W}k}$.

Acknowledgments. The author would like to thank Pascal Vontobel for helpful discussions and the anonymous reviewers for insightful comments and suggestions. They all helped to improve this paper.

A JACOBI-TYPE METHOD FOR COMPUTING ORTHOGONAL TENSOR DECOMPOSITIONS*

CARLA D. MORAVITZ MARTIN† AND CHARLES F. VAN LOAN‡

Abstract. Suppose $\mathcal{A} = (a_{ijk}) \in \mathbb{R}^{n\times n\times n}$ is a three-way array or third-order tensor. Many of the powerful tools of linear algebra such as the singular value decomposition (SVD) do not, unfortunately, extend in a straightforward way to tensors of order three or higher. In the two-dimensional case, the SVD is particularly illuminating, since it reduces a matrix to diagonal form. Although it is not possible in general to diagonalize a tensor (i.e., $a_{ijk} = 0$ unless $i = j = k$), our goal is to "condense" a tensor in fewer nonzero entries using orthogonal transformations. We propose an algorithm for tensors of the form $\mathcal{A} \in \mathbb{R}^{n\times n\times n}$ that is an extension of the Jacobi SVD algorithm for matrices. The resulting tensor decomposition reduces $\mathcal{A}$ to a form such that the quantity $\sum_{i=1}^{n} a_{iii}^2$ or $\sum_{i=1}^{n} a_{iii}$ is maximized.

1. Introduction.

The SVD of a matrix gives us important information about a matrix such as its rank, an orthonormal basis for the column or row space, and reduction to diagonal form. In applications, especially those involving multiway data analysis, information about the rank and reduction of tensors to have fewer nonzero entries are useful concepts to try to extend to higher dimensions.

Suppose $\mathcal{A} = (a_{ijk}) \in \mathbb{R}^{n\times n\times n}$ is a three-way array or third-order tensor. This paper is about computing a tensor decomposition of $\mathcal{A}$ such that $\mathcal{A}$ is written as a linear combination of rank-1 tensors of the form

$$w \otimes v \otimes u, \tag{1.1}$$

where $u, v, w \in \mathbb{R}^n$ and "$\otimes$" denotes the Kronecker product. The rank-1 tensor in (1.1) can also be denoted using the tensor outer product notation. In particular, (1.1) is equivalent to a vectorization of $u \circ v \circ w$.

The contribution of this paper is a higher-order generalization of the Jacobi SVD algorithm for matrices [14, p. 457] that works by solving small subproblems where $n = 2$. In the higher-order generalization, we find a tensor decomposition of the form

$$a = \sum_{i=1}^{n}\sum_{j=1}^{n}\sum_{k=1}^{n} \sigma_{ijk}(w_k \otimes v_j \otimes u_i), \tag{1.2}$$

where u_i, v_j, and w_k are the ith, jth, and kth columns of orthogonal matrices $U, V, W \in \mathbb{R}^{n\times n}$, respectively, and σ_{ijk} is the (i, j, k)th element of a tensor $\Sigma \in$

$\mathbb{R}^{n\times n\times n}$. The orthogonal matrices U, V, W are chosen to maximize either the sums of squares of the diagonals ($\sum_{i=1}^{n} \sigma_{iii}^2$) or the "trace" ($\sum_{i=1}^{n} \sigma_{iii}$).

Several Jacobi-like procedures have been implemented in the area of tensor decompositions already. In the case of symmetric tensors, there exist Jacobi algorithms to compute tensor decompositions of real or complex tensors [6, 7, 8, 12]. In particular, [12] shows that the solution to the Jacobi subproblem for symmetric tensors has an SVD solution of a particular symmetric matrix. We use a similar method when we show how to maximize the trace of a tensor. A Jacobi-type algorithm in [24] is used to simultaneously diagonalize positive definite Hermitian matrices using nonorthogonal transformations. This is relevant to tensors since [13] shows that a nonorthogonal tensor decomposition can be rewritten in terms of a simultaneous diagonalization problem for matrices. Furthermore, [13] proposes a Jacobi approach to simultaneous diagonalization (see also [4]) and shows that maximizing the sums of squares of the diagonals of a $2 \times 2 \times 2$ tensor using orthogonal transformations is equivalent to finding the roots of a polynomial of degree eight [13].

Tensor decompositions are used in many applications to help explain interactions among multiway data. These applications include chemometrics [3, 27], psychometrics [22], computer image and human motion recognition [29, 30], signal processing [25, 26], and many other areas using multiway data analyses [9]. Sometimes the tensor decompositions have a minimal number of terms in the linear combination, therefore "condensing" $\mathcal{A}$ into fewer nonzero entries so that interactions can be better explained.

A large amount of work has already been devoted to creating algorithms to compute orthogonal tensor decompositions. The most widely used algorithm is TUCKER3 originally proposed by Tucker [28]. Many improvements have been made to the algorithm since its original introduction, and the current version has been implemented in a MATLAB toolbox [1, 2]. A greedy algorithm to compute an orthogonal tensor decomposition has been proposed by [21], and [10] uses TUCKER3 to describe a higher-order generalization of the SVD for tensors. Several methods have also been developed to compute a "compressed" third-order orthogonal tensor decomposition, i.e., maximum variance of squares [16], maximum sums of squares of the diagonals of each face of a tensor [22], and maximum sums of squares of the diagonals of a third-order tensor [18].

A special case of TUCKER3 is the CANDECOMP-PARAFAC algorithm simultaneously proposed by [5] and [15]. Algorithms have also been developed to compute the nearest rank-1 tensor to a given tensor $\mathcal{A}$ (see [11, 20, 21, 32]). Furthermore, since the CANDECOMP-PARAFAC representation is equivalent to simultaneously diagonalizing a set of matrices, there are a number of recent algorithms related to simultaneous diagonalization (see [13] and the references therein).

Our presentation is organized as follows. First, we describe some matrix tools necessary to describe tensors and tensor decompositions in section 2. In section 3 we describe different ways to represent tensors. In sections 4 and 5 we describe the higher-order generalization of the Jacobi SVD algorithm—first for tensors $\mathcal{A} \in \mathbb{R}^{2\times 2\times 2}$ and then for general tensors $\mathcal{A} \in \mathbb{R}^{n\times n\times n}$. We examine the algorithm cost in section 6, and describe a block version and an $\ell \times m \times n$ version in sections 7 and 8, respectively. Extending the algorithm to order-p tensors is discussed briefly in section 9. Finally, in section 10 we examine the performance of the algorithm.

2. Some properties of the Kronecker product. We review a few essential facts about the Kronecker product which are found in [31]. Computations that involve the Kronecker product require an understanding of the `vec` and `reshape` operators.

If $B \in \mathbb{R}^{m\times n}$, then $\texttt{vec}(B) \in \mathbb{R}^{mn}$ is the vector formed by "stacking" the columns of B.

The vec operator can be used to convert between matrix-vector and matrix-matrix products. For example, let $F \in \mathbb{R}^{m\times m}, G \in \mathbb{R}^{n\times n}, X \in \mathbb{R}^{n\times m}$. Then

$$Y = GXF^T \qquad \Longleftrightarrow \qquad \texttt{vec}(Y) = (F \otimes G)\texttt{vec}(X). \tag{2.1}$$

Another important property of vec involves outer products. For $x \in \mathbb{R}^m, y \in \mathbb{R}^n$, $\texttt{vec}(xy^T) = y \otimes x$.

The vec operator can be used in combination with the outer product to write certain matrix factorizations as vectors. For example, if $A \in \mathbb{R}^{m\times n}$ and $A = UBV^T$, where $U \in \mathbb{R}^{m\times m}$ and $V \in \mathbb{R}^{n\times n}$, then

$$A = \sum_{i=1}^{m}\sum_{j=1}^{n} b_{ij}u_iv_j^T \qquad \Longleftrightarrow \qquad \texttt{vec}(A) = \sum_{i=1}^{m}\sum_{j=1}^{n} b_{ij}(v_j \otimes u_i), \tag{2.2}$$

where u_i, v_j are the ith and jth columns of U and V, respectively.

We can also write $\texttt{vec}(A)$ as a matrix-vector product. If $a = \texttt{vec}(A)$ and $b = \texttt{vec}(B)$, then by (2.1)

$$a = (V \otimes U) \cdot b. \tag{2.3}$$

The reshape operator is a more general way of rearranging the entries in a matrix (it is also a MATLAB function). If $b \in \mathbb{R}^{mn}$, then $\texttt{reshape}(b, m, n)$ creates an $m \times n$ matrix from b. This operator is useful when converting between $B \otimes C$ and $C \otimes B$. If the vec *permutation matrix* $\Pi_{n,mn} \in \mathbb{R}^{mn\times mn}$ is defined by

$$\Pi_{n,mn} = \begin{bmatrix} I_{mn}(1:m:mn,:) \\ I_{mn}(2:m:mn,:) \\ \vdots \\ I_{mn}(m:m:mn,:) \end{bmatrix},$$

then it can be shown that (see [31])

$$\Pi_{n,mn}^T(B \otimes C)\Pi_{n,mn} = C \otimes B.$$

3. Tensor decompositions. We use the accepted notation where a third-order tensor is indexed by three indices and can be represented as a "cube" of data [19]. While the cube orientation is not unique, here we say that the kth index indicates the face of the cube. See Figure 1 for an illustration when $n = 2$.

An $n \times n \times n$ tensor $\mathcal{A}$ is also a three-way array where the kth face is represented using MATLAB notation as $A(:,:,k)$. The entries $\texttt{vec}(\mathcal{A})$ can also be rearranged to correspond to viewing the cube in different ways (see Figure 2 for an illustration when $n = 2$). Viewing the tensor cube in different orientations corresponds to a rearrangement of the elements of $\mathcal{A}$. This can be better described by a permutation of the elements of $\texttt{vec}(\mathcal{A})$ by a reshape operation. For example, if $\mathcal{A} \in \mathbb{R}^{n\times n\times n}$ and $a = \texttt{vec}(\mathcal{A})$, then the different cuts can be represented in vector form as

$$\begin{aligned} a_1 &= \texttt{vec}(\texttt{reshape}(\Pi_{n,n^3}^T \cdot a, n, n^2)) && \text{(top-bottom)}, \\ a_2 &= \texttt{vec}(\texttt{reshape}(\Pi_{n^2,n^3}^T \cdot a, n, n^2)) && \text{(left-right)}, \\ a_3 &= \texttt{vec}(\texttt{reshape}(a, n, n^2)) && \text{(front-back)}, \end{aligned} \tag{3.1}$$

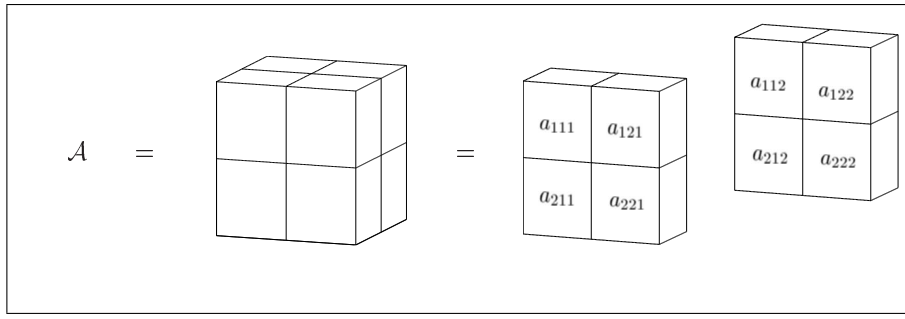

FIG. 1. *Illustration of a third-order tensor as a cube of data when* $n = 2$.

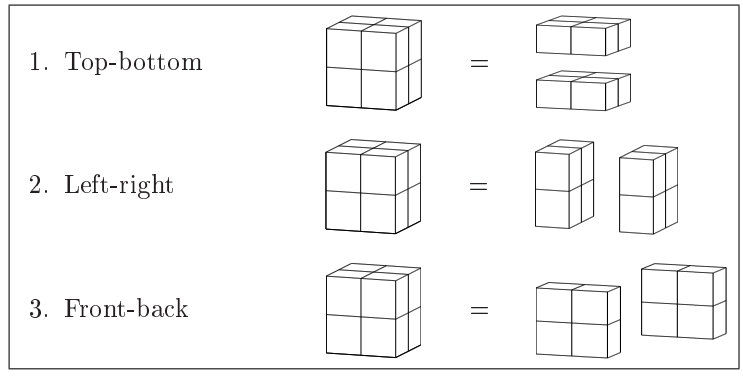

FIG. 2. *Three ways to cut a cube of data for a third-order tensor.*

where $a_3 = \texttt{vec}(\mathcal{A})$. Viewing the different faces of the cube side by side as matrices also corresponds to *unfolding matrices* [10] or *matricizations* [19].

The vec operator is used in the same way on tensors as on matrices. If $\mathcal{A} \in \mathbb{R}^{n\times n\times n}$, then $\texttt{vec}(\mathcal{A}) \in \mathbb{R}^{n^3}$ is the vector formed by stacking the column vectors $\texttt{vec}(A(:,:,i))$ for $i = 1,\ldots,n$.

Hence, given $\mathcal{A} \in \mathbb{R}^{n\times n\times n}$, the basic goal of this work is to find orthogonal matrices $U, V, W \in \mathbb{R}^{n\times n}$ such that

$$a \equiv \texttt{vec}(\mathcal{A}) = \sum_{i=1}^{n}\sum_{j=1}^{n}\sum_{k=1}^{n} \sigma_{ijk}(w_k \otimes v_j \otimes u_i), \tag{3.2}$$

and either of the two quantities $\sum_{i=1}^{n} \sigma_{iii}^2$ or $\sum_{i=1}^{n} \sigma_{iii}$ are maximized. In (3.2), u_i, v_j, and w_k are the ith, jth, and kth columns of U, V, and W, respectively.

By (2.2) and (2.3), (3.2) can also be written as the matrix-vector product

$$a = (W \otimes V \otimes U) \cdot \sigma, \tag{3.3}$$

where $\sigma = \texttt{vec}(\Sigma)$ and $\Sigma = (\sigma_{ijk}) \in \mathbb{R}^{n\times n\times n}$. The representation in (3.3) will be used to describe our algorithm in the sections that follow.

One may ask whether it would be better to choose U, V, and W in (3.2) such that the tensor $\Sigma = (\sigma_{ijk})$ is "diagonal" (i.e., $\sigma_{ijk} = 0$ unless $i = j = k$). In this scenario, (3.2) reduces exactly to the matrix SVD in two dimensions. However, diagonality from orthogonal transformations is possible only for tensors of order three or higher

in special cases. In general it is not possible to find orthogonal matrices U, V, W such that the tensor Σ is diagonal [10].

4. `Jacobi-Compress` algorithm for $n \times n \times n$ tensors. We now describe `Jacobi-Compress`, the higher-order generalization of the Jacobi SVD algorithm in [14, p. 457]. The overall idea is to compute tensor decompositions of the form (3.2) of $2 \times 2 \times 2$ subtensors. Here, we explain the general procedure when $\mathcal{A} \in \mathbb{R}^{n \times n \times n}$. The next section details how to solve the $2 \times 2 \times 2$ subproblem.

In the spirit of the Jacobi SVD algorithm, the first step is to choose a (p, q) pair and form the corresponding $2 \times 2 \times 2$ subtensor $\tilde{A}$ given by

$$\tilde{A}(:,:,1) = \begin{bmatrix} a_{ppp} & a_{pqp} \\ a_{qpp} & a_{qqp} \end{bmatrix}, \qquad \tilde{A}(:,:,2) = \begin{bmatrix} a_{ppq} & a_{pqq} \\ a_{qpq} & a_{qqq} \end{bmatrix}.$$

Using the representation in (3.3), suppose we have orthogonal matrices $\tilde{U}, \tilde{V}, \tilde{W} \in \mathbb{R}^{2\times 2}$ such that

$$\begin{bmatrix} \sigma_{ppp} \\ \sigma_{qpp} \\ \sigma_{pqp} \\ \sigma_{qqp} \\ \sigma_{ppq} \\ \sigma_{qpq} \\ \sigma_{pqq} \\ \sigma_{qqq} \end{bmatrix} = (\tilde{W}^T \otimes \tilde{V}^T \otimes \tilde{U}^T) \begin{bmatrix} a_{ppp} \\ a_{qpp} \\ a_{pqp} \\ a_{qqp} \\ a_{ppq} \\ a_{qpq} \\ a_{pqq} \\ a_{qqq} \end{bmatrix}, \tag{4.1}$$

and either $(\sigma_{ppp}^2 + \sigma_{qqq}^2)$ or $(\sigma_{ppp} + \sigma_{qqq})$ is maximized. To update $a = \texttt{vec}(\mathcal{A}) \in \mathbb{R}^{n^3}$, set U to be the $n \times n$ identity matrix, except that $I(p:q, p:q) = \tilde{U}$ and analogously for V and W. Then perform the update

$$\sigma \leftarrow (W^T \otimes V^T \otimes U^T) \cdot a, \tag{4.2}$$

where $a = [\texttt{vec}(\tilde{A}(:,:,1)); \texttt{vec}(\tilde{A}(:,:,2))]$. In practice, significant savings are achieved by observing that the only elements of a that change are those with a p or q in the index; i.e., the pth and qth front-back faces, the pth and qth side faces, and the pth and qth top-bottom faces. This avoids the actual computation of the above Kronecker product.

Rather than just repeating *sweeps* through all the possible (p, q) pairs as in the Jacobi SVD algorithm, we alternate the view or orientation of the cube (Figure 2) at each sweep. Therefore, one *iteration* of `Jacobi-Compress` includes three sweeps: one sweep for each orientation. Changing the orientation simply involves a `reshape` operation defined in (3.1). `Jacobi-Compress` is complete when an iteration does not significantly change (within some specified tolerance) the sums of squares of the diagonals or the trace of the tensor.

5. The $2 \times 2 \times 2$ subproblem. Suppose $\mathcal{A} \in \mathbb{R}^{2\times 2\times 2}$ and $a = \texttt{vec}(\mathcal{A})$. We now show how to solve (4.1). That is, the goal is to find 2×2 orthogonal matrices $\tilde{U}$, $\tilde{V}$, and $\tilde{W}$ such that

$$\sigma = (\tilde{W}^T \otimes \tilde{V}^T \otimes \tilde{U}^T)a$$

has maximum $(\sigma_{111}^2 + \sigma_{222}^2)$ or $(\sigma_{111} + \sigma_{222})$.

The idea behind solving the subproblem is an iterative approach that differs based on whether we are maximizing the trace or sums of squares. However, both approaches involve taking an SVD of a specific 2×2 matrix.

5.1. Maximizing the trace. Maximizing the trace involves holding one variable constant while varying the others. For example, suppose we have performed the following three steps:

$$\begin{aligned} \sigma_1 &\leftarrow (I \otimes \tilde{V}_1^T \otimes \tilde{U}_1^T)a, \\ \sigma_2 &\leftarrow (\tilde{W}_1^T \otimes I \otimes \tilde{U}_2^T)\sigma_1, \\ \sigma_3 &\leftarrow (\tilde{W}_2^T \otimes \tilde{V}_2^T \otimes I)\sigma_2. \end{aligned} \tag{5.1}$$

Then a tensor decomposition of a has been computed since

$$\begin{aligned} \sigma_3 &= (\tilde{W}_2^T \otimes \tilde{V}_2^T \otimes I)(\tilde{W}_1^T \otimes I \otimes \tilde{U}_2^T)(I \otimes \tilde{V}_1^T \otimes \tilde{U}_1^T)a \\ &= (\tilde{W}_2^T\tilde{W}_1^T \otimes \tilde{V}_2^T\tilde{V}_1^T \otimes \tilde{U}_2^T\tilde{U}_1^T)a \\ &= (\tilde{W}^T \otimes \tilde{V}^T \otimes \tilde{U}^T)a, \end{aligned}$$

where $\tilde{U} = \tilde{U}_1\tilde{U}_2$, $\tilde{V} = \tilde{V}_1\tilde{V}_2$, and $\tilde{W} = \tilde{W}_1\tilde{W}_2$.

The steps in (5.1) illustrate the central idea behind our algorithm. After each step, the trace of σ is maximized. The updates (5.1) are all algorithmically equivalent since

$$\Pi_{4,8}^T(\tilde{W}^T \otimes I \otimes \tilde{U}^T)\Pi_{4,8} = (I \otimes \tilde{U}^T \otimes \tilde{W}^T),$$

$$\Pi_{2,8}^T(\tilde{W}^T \otimes \tilde{V}^T \otimes I)\Pi_{2,8} = (I \otimes \tilde{W}^T \otimes \tilde{V}^T).$$

Therefore it suffices to describe how to find $\tilde{U}, \tilde{V}$ such that

$$\sigma = (I \otimes \tilde{V}^T \otimes \tilde{U}^T)a. \tag{5.2}$$

A remark about (5.2) is necessary. Equation (5.2) can be rewritten in terms of matrices as

$$\begin{aligned} \begin{bmatrix} \sigma_{111} & \sigma_{121} \\ \sigma_{211} & \sigma_{221} \end{bmatrix} &= \tilde{U}^T \begin{bmatrix} a_{111} & a_{121} \\ a_{211} & a_{221} \end{bmatrix} \tilde{V}, \\ \begin{bmatrix} \sigma_{112} & \sigma_{122} \\ \sigma_{212} & \sigma_{222} \end{bmatrix} &= \tilde{U}^T \begin{bmatrix} a_{112} & a_{122} \\ a_{212} & a_{222} \end{bmatrix} \tilde{V}. \end{aligned} \tag{5.3}$$

However, we emphasize that solving (5.3) is not a joint SVD problem. The joint SVD problem [17, 23] uses a least squares approach to find matrices $\tilde{U}, \tilde{V}$ that diagonalize the left two matrices above. A Jacobi-like algorithm was proposed in [23] that reduces the problem to finding joint SVDs of 2×2 matrices by maximizing the sums of squares of the diagonals. In [23] it is shown that the joint SVD problem with 2×2 matrices has an explicit solution, namely, that maximizing the sums of squares is equivalent to maximizing the trace. In our case, we are maximizing the sums of squares or trace of the *tensor* diagonals. The two problems are not equivalent in our case.

The solution depends on whether $\tilde{U}$ and $\tilde{V}$ are both rotation or reflection matrices or whether one is a rotation matrix and one is a reflection matrix.

First, suppose $\tilde{U}_1$ and $\tilde{V}_1$ are the rotation matrices

$$\tilde{U}_1 = \begin{bmatrix} c_1 & s_1 \\ -s_1 & c_1 \end{bmatrix}, \qquad \tilde{V}_1 = \begin{bmatrix} c_2 & s_2 \\ -s_2 & c_2 \end{bmatrix}. \tag{5.4}$$

Then

$$\begin{aligned}\operatorname{tr}(\sigma) &= c_1c_2(a_{111}+a_{222}) + s_1c_2(-a_{211}+a_{122}) \\ &\quad + c_1s_2(-a_{121}+a_{212}) + s_1s_2(a_{221}+a_{112}).\end{aligned} \tag{5.5}$$

If

$$B_1 = \begin{bmatrix} a_{111}+a_{222} & a_{121}-a_{212} \\ a_{211}-a_{122} & a_{221}+a_{112} \end{bmatrix}, \tag{5.6}$$

then the $(1,1)$-entry of $\tilde{U}_1^T B_1 \tilde{V}_1$ is exactly (5.5). Therefore, maximizing (5.5) is equivalent to finding the SVD of B_1, since the largest singular value is the largest $(1,1)$-entry possible. The same result can be derived if $\tilde{U}_1$ and $\tilde{V}_1$ are both reflection matrices. In this scenario, we must ensure that the SVD consists of either both rotation matrices or both reflection matrices. Using an SVD solution to the trace problem is similar to a method used in [23] to compute the joint SVD.

Now, suppose that $\tilde{U}_2$ is a rotation matrix and $\tilde{V}_2$ is a reflection matrix:

$$\tilde{U}_2 = \begin{bmatrix} c_1 & s_1 \\ -s_1 & c_1 \end{bmatrix}, \qquad \tilde{V}_2 = \begin{bmatrix} c_2 & s_2 \\ s_2 & -c_2 \end{bmatrix}. \tag{5.7}$$

Then

$$\begin{aligned}\operatorname{tr}(\sigma) &= c_1c_2(a_{111}-a_{222}) + s_1c_2(a_{211}+a_{122}) \\ &\quad + c_1s_2(-a_{121}-a_{212}) + s_1s_2(a_{112}-a_{221}).\end{aligned} \tag{5.8}$$

If

$$B_2 = \begin{bmatrix} a_{111}-a_{222} & a_{121}+a_{212} \\ a_{211}+a_{122} & a_{221}-a_{112} \end{bmatrix}, \tag{5.9}$$

then the $(1,1)$-entry of $\tilde{U}_2^T B_2^T \tilde{V}_2$ is exactly (5.8), and therefore maximizing (5.8) is equivalent to taking the SVD of B_2. The same result holds if $\tilde{U}_2$ is a reflection matrix and $\tilde{V}_2$ is a rotation matrix.

Comparing the (1,1)-entries of B_1 and B_2 determines how $\tilde{U}$ and $\tilde{V}$ are chosen. For example, if

$$a_{111}+a_{222} > a_{111}-a_{222},$$

then we use B_1 and the SVD should involve either both rotation matrices or both reflection matrices. On the other hand, if

$$a_{111}+a_{222} < a_{111}-a_{222},$$

then we compute the SVD of B_2 and the result should involve one rotation matrix and one reflection matrix.

5.2. Maximizing the sums of squares. Setting up the problem to maximizing the sums of squares in a similar way to section 5.1 involves solving a nonlinear optimization problem that does not have a straightforward explicit solution. Here, we instead hold two variables constant and vary the third, which results in an explicit solution involving the SVD. The basic problem requires solving

$$\begin{aligned}\sigma_1 &\leftarrow (I \otimes I \otimes \tilde{U}^T)a, \\ \sigma_2 &\leftarrow (I \otimes \tilde{V}^T \otimes I)\sigma_1, \\ \sigma_3 &\leftarrow (\tilde{W}^T \otimes I \otimes I)\sigma_2.\end{aligned} \tag{5.10}$$

Similar to section 5.1, each of the steps above are equivalent since they involve permuting the tensor elements at each step. We therefore describe how to find $\tilde{U}$ such that

$$\sigma = (I \otimes I \otimes \tilde{U})\, a = \begin{bmatrix} \tilde{U} & & & \\ & \tilde{U} & & \\ & & \tilde{U} & \\ & & & \tilde{U} \end{bmatrix} \begin{bmatrix} a_{111} \\ a_{211} \\ a_{121} \\ a_{221} \\ a_{112} \\ a_{212} \\ a_{122} \\ a_{222} \end{bmatrix}. \tag{5.11}$$

From (5.11), it suffices to find orthogonal $\tilde{U}$ that maximizes the sums of squares of the diagonals of the matrix $\tilde{U}A$, where

$$A = \begin{bmatrix} a_{111} & a_{122} \\ a_{211} & a_{222} \end{bmatrix}. \tag{5.12}$$

Suppose the SVD of A is given by

$$A = U \begin{bmatrix} \sigma_1 & 0 \\ 0 & \sigma_2 \end{bmatrix} \begin{bmatrix} c & s \\ -s & c \end{bmatrix},$$

where (c, s) is a cosine/sine pair. Indeed, if we have a 2×2 orthogonal matrix Z such that the sums of squares of the diagonals of

$$Z \begin{bmatrix} \sigma_1 & 0 \\ 0 & \sigma_2 \end{bmatrix} \begin{bmatrix} c & s \\ -s & c \end{bmatrix} \tag{5.13}$$

are maximized, then we set $\tilde{U} = ZU^T$. We now explain how to obtain Z.

Without loss of generality, assume that Z is the rotation matrix

$$Z = \begin{bmatrix} \tilde{c} & \tilde{s} \\ -\tilde{s} & \tilde{c} \end{bmatrix}.$$

From (5.13) we are trying to find the pair $(\tilde{c}, \tilde{s})$ that maximizes

$$(\sigma_1 \tilde{c} c - \sigma_2 \tilde{s} s)^2 + (-\sigma_1 \tilde{s} s + \sigma_2 \tilde{c} c)^2. \tag{5.14}$$

After some simplification, (5.14) is equivalent to

$$(\sigma_1^2 + \sigma_2^2) - \left\| M \begin{bmatrix} \tilde{c} \\ \tilde{s} \end{bmatrix} \right\|_2^2, \tag{5.15}$$

where

$$M = \begin{bmatrix} \sigma_2 s & \sigma_1 c \\ \sigma_1 s & \sigma_2 c \end{bmatrix}. \tag{5.16}$$

Since

$$\sigma_1^2 + \sigma_2^2 = \|M\|_F^2 = \sigma_{max}(M)^2 + \sigma_{min}(M)^2, \tag{5.17}$$

where $\sigma_{max}(M)$ and $\sigma_{min}(M)$ are the largest and smallest singular values of M, respectively, we choose $[\tilde{c}, \tilde{s}]^T$ to be the right singular vector of M associated to the smallest singular value. This also means that the maximum sums of squares of the diagonals of A are equal to $\sigma_{max}(M)^2$. The same result is obtained if Z is chosen to be a reflection matrix.

$[\tilde{U}, \tilde{V}, \tilde{W}, \sigma] = \textbf{Solve2-by-2-by-2}(\mathcal{A})$

FIG. 4. *Jacobi-Compress for $n \times n \times n$ tensors.*

pairs. Solving the $2\times2\times2$ subproblem is constant work in both the case of maximizing the sums of squares and the trace. It is important to note that the update (4.2) can be computed in linear time by only updating those elements that are affected. Therefore, one iteration of `Jacobi-Compress` is $\mathcal{O}(n^3)$.

7. Block version. `Jacobi-Compress` can be converted to a block algorithm by representing an $n\times n\times n$ tensor as an $N\times N\times N$ block tensor with block size $r\times r\times r$, where $n = Nr$. For example, a $6\times6\times6$ tensor $\mathcal{A}$ can be regarded as a $3\times3\times3$ block

tensor with $2 \times 2 \times 2$ entries. The block version chooses a (p, q) pair, a $2r \times 2r \times 2r$ tensor, to be solved by `Jacobi-Compress`. Therefore, the only difference between the block version and standard `Jacobi-Compress` is the order in which the subproblems are solved.

8. Extension to $\ell \times m \times n$ tensors. Thus far, we have considered only three-way tensors for which each dimension is equal. Many applications involve data with unequal dimensions. By padding the data with zeros, `Jacobi-Compress` can be used for $\ell \times m \times n$ tensors.

Specifically, if $\tilde{p} = \max(\ell, m, n)$, then we pad the tensor with zeros that results in a $\tilde{p} \times \tilde{p} \times \tilde{p}$ tensor. Similar to the Jacobi SVD algorithm, unwanted fill does not occur. Note that computational shortcuts are taken so as to not actually store and perform calculations with zeros. In particular, if, say, $\ell >> m, n$, then many of the subproblems will contain all zeros. Therefore a sweep may contain considerably fewer subproblems than $\tilde{p}(\tilde{p} - 1)/2$.

9. Extension to order-p tensors. `Jacobi-Compress` can be extended to p-way tensors, but the results are not very practicable as p gets large. Maximizing the sums of squares of the diagonals is a direct extension of the $p = 3$ case in section 5.2; i.e., it involves taking SVDs of p 2×2 matrices. Unfortunately, extending the trace solution of section 5.1 does not involve an explicit solution to the subproblem but instead requires the help of a nonlinear solver to solve the optimization problem. More work is needed in this area.

10. Algorithm performance. In this section we describe the performance and numerical convergence typically seen in practice. In randomly generated examples, `Jacobi-Compress` typically converges in three iterations or less, i.e., the sums of squares of the diagonals or trace do not improve (up to a specified tolerance) after three iterations of the algorithm. We also note that in cases where a tensor is orthogonally diagonalizable, our algorithm finds that optimal form. The next example shows the compression of the algorithm.

Example 10.1. Let $\mathcal{A} \in \mathbb{R}^{3\times3\times3}$ be given by (in order of first face, second face, third face)

$$\mathcal{A} = \left[\begin{array}{ccc|ccc|ccc} 8 & 8 & 3 & 10 & 8 & 10 & 9 & 3 & 4 \\ 10 & 5 & 7 & 8 & 3 & 7 & 7 & 7 & 6 \\ 10 & 5 & 4 & 5 & 5 & 3 & 2 & 7 & 5 \end{array}\right].$$

Then `Jacobi-Compress` produces

$$\Sigma = \left[\begin{array}{ccc|ccc|ccc} \mathbf{.15} & -1.1 & 1.4 & 2.7 & .01 & -1.8 & -1.8 & -1.5 & .05 \\ 3.2 & .01 & .63 & 0 & \mathbf{33.4} & .03 & -.66 & .16 & -1.6 \\ -2.2 & 4.8 & .04 & -.17 & .30 & -.83 & -.03 & -.17 & \mathbf{-6.2} \end{array}\right].$$

One way to measure the compression of the algorithm is to look at the the "percent of norm" of the elements in the diagonals. For example, for an $n \times n \times n$ tensor, we can compute

$$\gamma = \frac{\sum_{i=1}^{n} \sigma_{iii}^2}{\sum_{i,j,k=1}^{n} \sigma_{ijk}^2},$$

which measures "how much" of the norm is contained in the diagonals of the tensor. The closer γ is to one, the better the compression. If the tensor is diagonalizable with

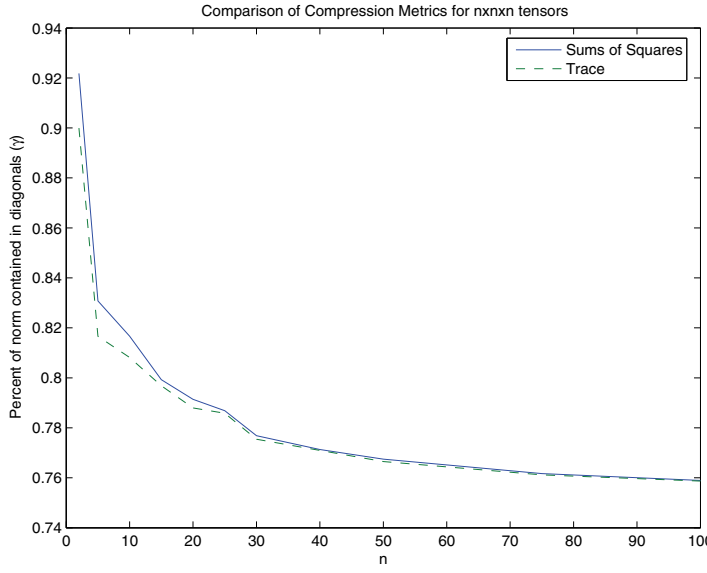

FIG. 5. *Percent of total norm obtained in the diagonal entries for randomly generated starting vectors using different metrics for compression for $n \times n \times n$ tensors.*

orthogonal transformations, γ should be equal to one. Figure 5 shows the average value of γ for different n after running `Jacobi-Compress` for $p = 3$ and the direct extension when $p = 4$. For comparison, γ tends to zero as n increases for random vectors. The clear trend from Figure 5 is that compression decreases as n increases. The inverse relationship between the amount of compression and n is expected since we have relatively fewer elements with which to explain n^3 or n^4 entries of the tensor. More importantly, however, is that the compression is quite high and tends to be around 75 percent compared to before running `Jacobi-Compress`, which is the result we focus attention to in Figure 5.

11. Conclusion. In this paper an algorithm based on the Jacobi SVD algorithm for matrices is given to compute an orthogonal tensor decomposition. The resulting tensor decomposition maximizes the sums of the squares of the "diagonals" or the trace of the tensor. The idea of the algorithm is to compute tensor decompositions of $2 \times 2 \times 2$ subtensors using an alternating least squares approach. In each case, the subproblem has an explicit solution involving the SVD. The general p-way case is still being explored.

TENSOR-PRODUCT APPROXIMATION TO MULTIDIMENSIONAL INTEGRAL OPERATORS AND GREEN'S FUNCTIONS*

WOLFGANG HACKBUSCH† AND BORIS N. KHOROMSKIJ†

Abstract. The Kronecker tensor-product approximation combined with the $\mathcal{H}$-matrix techniques provides an efficient tool to represent integral operators as well as a discrete elliptic operator inverse $A^{-1} \in \mathbb{R}^{N\times N}$ in $\mathbb{R}^d$ (the discrete Green's function) with a high spatial dimension d. In the present paper we give a survey on modern methods of the structured tensor-product approximation to multidimensional integral operators and Green's functions and present some new results on the existence of low tensor-rank decompositions to a class of function-related operators. The memory space of the considered data-sparse representations is estimated by $\mathcal{O}(dn\log^q n)$ with q independent of d, retaining the approximation accuracy of order $O(n^{-\delta})$, where $n = N^{1/d}$ is the dimension of the discrete problem in *one* space direction. In particular, we apply the results to the Newton, Yukawa, and Helmholtz kernels $\frac{1}{|x-y|}$, $\frac{e^{-\lambda|x-y|}}{|x-y|}$, and $\frac{\cos(\lambda|x-y|)}{|x-y|}$, respectively, with $x, y \in \mathbb{R}^d$.

1. Introduction.

In a wide range of applications one deals with quantities described by higher-order tensors, which are the higher-order analogues of vectors and matrices. Examples are multidimensional integral equations, elliptic, parabolic, and hyperbolic boundary value problems posed in $\mathbb{R}^d$, $d \geq 2$, Lyapunov and Riccati matrix equations, computation of spectral projection operators associated with the density matrix ansatz for solving the Hartree–Fock equation, as well as collision integrals of the deterministic Boltzmann equation. A naive numerical implementation of the corresponding multilinear algebra in the dimension $N = n^d$ with large d suffers from the so-called curse of dimensionality because of the exponential scaling in d. This phenomenon can be relaxed by invoking various data-sparse tensor-product formats to represent the fully populated higher-order tensors.

As a result of developments over more than three decades, we now have several well-established concepts of structured representation to higher-order tensors, which are based either on the so-called Tucker model [27] or on the CANDECOMP/PARAFAC (CP) decomposition [3, 21] (see section 2.1 for definitions). There are numerous successful applications of the Tucker and CP models in higher-order statistics, independent component analysis, chemometrics, telecommunications, signal processing, data mining, mathematical biology, complexity theory, and many other fields.

In the present paper we give a survey on modern methods of the structured tensor-product approximation to multidimensional integral operators and Green's functions and present some new results on the existence of low tensor-rank decompositions to a class of function-related operators. In particular, we focus on the construction of exponentially convergent in the tensor-rank decompositions. The asymptotic complexity of considered data-sparse representations is estimated by $\mathcal{O}(dn\log^q n)$ with q

independent of d, where $n = N^{1/d}$ is the dimension of the discrete problem in *one* space direction. In particular, we apply the results to the Newton, the Yukawa, and the Helmholtz potentials $\frac{1}{|x-y|}$, $\frac{e^{-\lambda|x-y|}}{|x-y|}$, and $\frac{\cos(\lambda|x-y|)}{|x-y|}$, respectively, with $x, y \in \mathbb{R}^d$.

The class of *hierarchical ($\mathcal{H}$) matrices* allows an approximate matrix arithmetic with almost linear complexity [14, 15, 16, 12]. An $\mathcal{H}$-matrix approximation of the class of operator-valued functions of elliptic operators was developed in [8, 9, 10, 13]. For multidimensional problems, even approximations with linear complexity $\mathcal{O}(n^d)$ are not satisfactory. To avoid an exponential scaling in d, one can try to represent the corresponding data (matrices and vectors) in a *tensor-product form* (cf. [1, 19, 28]) to reach the complexity $\mathcal{O}(dn\log^q n)$ with $q \geq 1$ independent of d (see section 2.2). For this purpose the $\mathcal{H}$-matrix approach can be combined with the tensor-product approximations.

The *hierarchical Kronecker tensor-product* (HKT) representation of an integral operator $\mathbb{G} : L^2(\Omega) \to L^2(\Omega)$,

$$(\mathbb{G}u)(x) := \int_\Omega g(x,y)u(y)\mathrm{d}y, \quad x, y \in \Omega := [0,1]^d \in \mathbb{R}^d,$$

is based on a separable approximation to the explicitly given kernel function $g(x,y)$ accomplished with an $\mathcal{H}$-matrix representation of the canonical factors (cf. [19, 17, 18]).

In [11, 18], the $\mathcal{H}$-matrix techniques combined with the Kronecker tensor-product approximation (cf. [19, 28]) were applied to represent the inverse of a discrete elliptic operator $\mathbb{L}^{-1} : H^{-1}(\Omega) \to H_0^1(\Omega)$ in a hypercube $\Omega := (0,1)^d \in \mathbb{R}^d$,

$$\mathbb{L} = -\sum_{j=1}^d \frac{\partial}{\partial x_j} a_j(x_j) \frac{\partial}{\partial x_j} + \sum_{j=1}^d \left[b_j(x_j)\frac{\partial}{\partial x_j} + c_j(x_j) \right], \quad x = (x_1, \ldots, x_d) \in \Omega.$$

The approach is based on the efficient quadrature approximation to a certain integral representation of $\mathbb{L}^{-1}$ (see section 4).

The rest of the paper is organized as follows. Section 2 presents a sketch on multilinear algebra including the description of the canonical and Tucker models. In section 3 we consider approximation of function-related tensors. Section 4 discusses the tensor-product decomposition of multidimensional integral operators. In section 5 we consider data-sparse structured approximation of negative powers of elliptic operators. The appendix collects auxiliary results about the Sinc-approximation method.

2. Structured tensor-product decompositions.

2.1. Canonical and Tucker models. A dth order tensor $\mathcal{A} = [a_{i_1 \ldots i_d}] \in \mathbb{C}^{\mathcal{I}}$ is given, defined on the product index set $\mathcal{I} = I_1 \times \cdots \times I_d$. The canonical CP model is defined by

$$\mathcal{A}_{(r)} = \sum_{k=1}^r b_k \times_1 V_k^{(1)} \times_2 \cdots \times_d V_k^{(d)} \equiv \sum_{k=1}^r b_k \bigotimes_{\ell=1}^d V_k^{(\ell)} \approx \mathcal{A}, \quad b_k \in \mathbb{C}, \tag{2.1}$$

where the Kronecker factors $V_k^{(\ell)} \in \mathbb{C}^{I_\ell}$ are unit-norm vectors. Here and in the following we use the notation $\times_\ell$ to represent the canonical tensor

$$\mathcal{U} \equiv \{u_{\mathbf{i}}\}_{\mathbf{i}\in\mathcal{I}} = b \times_1 U^{(1)} \times_2 \cdots \times_d U^{(d)} \in \mathbb{C}^{\mathcal{I}},$$

defined by $u_{i_1\dots i_d} = b \cdot u^{(1)}_{i_1} \cdots u^{(d)}_{i_d}$ with $U^{(\ell)} \equiv \{u^{(\ell)}_{i_\ell}\}_{i_\ell \in I_\ell} \in \mathbb{C}^{I_\ell}$. We make use of the multi-index notation $\mathbf{i} := (i_1, \dots, i_d) \in \mathcal{I}$.

The minimal number r in the representation (2.1) is called the Kronecker rank of a given tensor $\mathcal{A}_{(r)}$. We denote by $\boldsymbol{\mathcal{C}}_r$ the set of componentwise normalized tensors parametrized by (2.1) and by $\boldsymbol{\mathcal{C}}_{r,\perp} \subset \boldsymbol{\mathcal{C}}_r$ the corresponding subset of orthogonally decomposable tensors (i.e., the columns of matrices $\mathbf{V}^{(\ell)} = [V^{(\ell)}_1 V^{(\ell)}_2 \dots V^{(\ell)}_r]$ ($\ell = 1, \dots, d$) are orthogonal).

The Tucker model deals with the approximation

$$\mathcal{A}_{(\mathbf{r})} = \sum_{k_1=1}^{r_1} \dots \sum_{k_d=1}^{r_d} b_{k_1\dots k_d} \times_1 V^{(1)}_{k_1} \times_2 \cdots \times_d V^{(d)}_{k_d} \equiv \sum_{\mathbf{k}=1}^{\mathbf{r}} b_{\mathbf{k}} \bigotimes_{\ell=1}^{d} V^{(\ell)}_{k_\ell} \approx \mathcal{A}, \tag{2.2}$$

where the Kronecker factors $V^{(\ell)}_{k_\ell} \in \mathbb{C}^{I_\ell}$ ($k_\ell = 1, \dots, r_\ell$, $\ell = 1, \dots, d$) are complex vectors of the respective size $n_\ell = |I_\ell|$, $\mathbf{r} = (r_1, \dots, r_d)$ (the Tucker rank) and $b_{k_1\dots k_d} \in \mathbb{C}$.

Without loss of generality, we assume that the vectors $\{V^{(\ell)}_{k_\ell}\}$ are orthonormal, i.e.,

$$\left\langle V^{(\ell)}_{k_\ell}, V^{(\ell)}_{m_\ell} \right\rangle = \delta_{k_\ell, m_\ell}, \quad k_\ell, m_\ell = 1, \dots, r_\ell;\ \ell = 1, \dots, d,$$

where δ_{k_ℓ, m_ℓ} is Kronecker's delta. In the following, we denote by $\boldsymbol{\mathcal{T}}_{\mathbf{r}}$ the set of tensors parametrized by (2.2) (i.e., $\mathbf{V}^{(\ell)} = [V^{(\ell)}_1 V^{(\ell)}_2 \dots V^{(\ell)}_{r_\ell}]$ is an orthogonal matrix for $\ell = 1, \dots, d$). We use the short notation

$$\mathcal{A}_{(\mathbf{r})} = \mathcal{B} \times_1 \mathbf{V}^{(1)} \times_2 \mathbf{V}^{(2)} \cdots \times_d \mathbf{V}^{(d)}, \tag{2.3}$$

with tensors $\mathbf{V}^{(\ell)} \in \mathbb{R}^{I_\ell \times r_\ell}$ and $\mathcal{B} = \{b_{\mathbf{k}}\} \in \mathbb{R}^{r_1 \times \dots \times r_d}$, where the latter is called the core tensor. Notice that the representation of elements $\mathcal{A} \in \boldsymbol{\mathcal{T}}_{\mathbf{r}}$ is still not unique due to the rotational uncertainty in the core tensor $\mathcal{B}$.

The decomposition (2.1) can be viewed as a special case of the Tucker model (2.2), where $r = r_1 = \cdots = r_d$ and $b_{k_1\dots k_d} = 0$ unless $k_1 = k_2 = \cdots = k_d$, i.e., only the superdiagonal of $\mathcal{B} = \{b_{\mathbf{k}}\}$ is nonzero. If we let $r = r_\ell$, $n = n_\ell$ ($\ell = 1, \dots, d$), then both the CP and Tucker models require only *drn* numbers to represent the canonical components plus r (resp., r^d) memory units for the core tensor.

The main computational problem is the approximation of a given higher-order tensor $\mathcal{A}_0$ in a certain set of low-rank structured tensors $\boldsymbol{\mathcal{S}}$. In particular, $\boldsymbol{\mathcal{S}}$ may be one of the classes $\boldsymbol{\mathcal{T}}_{\mathbf{r}}$, $\boldsymbol{\mathcal{C}}_r$, or $\boldsymbol{\mathcal{C}}_{r,\perp}$ mentioned above. There are *algebraic*, *analytically based*, and *combined strategies* for computing a Kronecker tensor-product decomposition of a higher-order tensor.

Algebraic methods are the most general ones. The common approach is to derive the components of $\mathcal{A}_{(\mathbf{r})}$ (resp., $\mathcal{A}_{(r)}$) by straightforward minimization of the quadratic *cost functional* $f(\mathcal{A}) := \|\mathcal{A} - \mathcal{A}_0\|^2$,

$$\mathcal{A}_{(\mathbf{r})} = \operatorname{argmin} \|\mathcal{A} - \mathcal{A}_0\|^2, \tag{2.4}$$

over all rank-$\mathbf{r}$ (resp., rank-r) tensors $\mathcal{A} \in \boldsymbol{\mathcal{S}}$. Here and in the following we make use of the Frobenius (energy) norm $\|\mathcal{A}\| := \sqrt{\langle \mathcal{A}, \mathcal{A} \rangle}$ induced by the inner product $\langle \mathcal{A}, \mathcal{B} \rangle := \sum_{(i_1,\dots,i_d) \in \mathcal{I}} a_{i_1\dots i_d} b_{i_1\dots i_d}$ (the maximum-norm is defined by $\|\mathcal{A}\|_\infty := \max_{\mathbf{i} \in \mathcal{I}} |a_{\mathbf{i}}|$). The difficulties in the rigorous analysis and efficient implementation

of the minimization process are due to (a) multiple local minima of the cost functional, (b) degeneracy of a minimizing sequence (in the case of the CP model), and (c) high-dimensional nonlinear optimization.

Analytically based representation methods are efficient for a special class of *function-related* operators/tensors. *Combined* methods are designed to take advantage of both algebraic and analytic approaches and, at the same time, to relax their limitations (cf. [24]).

In the case of the canonical decomposition one can find local minima of (2.4) via Newton-type algorithms applied to the Lagrange equation corresponding to the unconstrained minimization problem: Find $\mathcal{A} \in \boldsymbol{\mathcal{C}}_r$ and the Lagrange multipliers $\lambda^{(k,\ell)} \in \mathbb{R}$ such that

$$\langle \mathcal{A} - \mathcal{A}_0, \mathcal{A} - \mathcal{A}_0 \rangle + \sum_{k=1}^{r} \sum_{\ell=1}^{d} \lambda^{(k,\ell)} \left(\|V_k^{(\ell)}\|^2 - 1 \right) \to \min. \tag{2.5}$$

The complexity of one Newton step may be estimated at least by $O(dr^2 n + r^d)$.

As a second common approach, one can resort to an alternating least-squares (ALS) algorithm which is as follows: let $B = \operatorname{diag}\{b_1, \dots, b_d\}$ in (2.1) and assume that all matrices $\mathbf{V}^{(\ell)}$, $\ell \neq m$, are fixed. Then (2.4) is a quadratic expression in the components of the matrix $\mathbf{V}^{(m)} \cdot B$; hence we obtain a classical least-squares problem. To drive the solution toward local minima, an ALS iteration repeats this procedure for each component $m = 1, \dots, d$ until convergence (or termination). The components of $B = \operatorname{diag}\{b_1, \dots, b_d\}$ are obtained by normalization of the columns $V_k^{(m)}$ $(k = 1, \dots, r)$. An alternative method to compute the canonical decomposition was introduced in [5].

In general, the convergence analysis of both Newton's and ALS schemes is still an open question. In some cases, the lack of robust convergence of such nonlinear iterations is due to the already mentioned effect of degeneracy of a minimizing sequence (if $d > 2$, the corresponding set $\boldsymbol{\mathcal{C}}_r$ of structured tensors is no longer closed).

Notice that in the case of orthogonally decomposable tensors in $\boldsymbol{\mathcal{C}}_{r,\perp}$ the incremental rank-1 approximation algorithm correctly computes its CP representation (cf. [25, 30]).

We refer to [4] concerning orthogonal rank-$(r_1, \dots, r_d)$ Tucker decomposition. *Analytically based and combined* methods will be the focus of the present paper.

2.2. Canonical HKT matrix decomposition. We consider the representation problem for a class of real-valued square matrices related to discrete multidimensional operators posed in $\mathbb{R}^d$, such that $A \in \mathbb{R}^{N \times N}$, $N = n^d$. In general, such matrices can be interpreted as high-order fully populated tensors, which makes the standard matrix arithmetic almost nonfeasible. To overcome this difficulty, one needs numerically tractable data-sparse representations of high-dimensional tensors.

The HKT format as proposed in [19, 17] reads

$$A = \sum_{k=1}^{r} b_k V_k^{(1)} \otimes \cdots \otimes V_k^{(d)}, \quad b_k \in \mathbb{R}, \tag{2.6}$$

where the Kronecker factors $V_k^{(\ell)} \in \mathbb{R}^{n \times n}$ are $\mathcal{H}$-matrices (see [12, 13, 14, 15, 16] for the definition, approximation properties, and applications of $\mathcal{H}$-matrices). We recall that the Kronecker product of matrices $A \otimes B$ is defined as a block matrix $[a_{ij}B]$, provided that $A = [a_{ij}]$. The operation "$\otimes$" can be applied to arbitrary rectangular

matrices (in particular, to row or column vectors) and in the multifactor version as in (2.6).

We write $A \in \mathrm{HKT}_{(r,s)}$ if A is of the form (2.6) and if the matrices $V_k^{(\ell)}$ have a hierarchical block partitioning (independent of k) with blocks of rank at most s. The minimal number of Kronecker-product terms r involved is referred to as the *Kronecker rank*.

Approximations of function-related matrices by matrices of the form (2.6) were first studied in [19, 28]. The main result of these papers are estimates of the form $r = O(\log^2 \varepsilon)$ and $r = O(|\log \varepsilon| \log n)$, where ε is the prescribed approximation accuracy. However, if there is no structure in the Kronecker factors, then the storage is $O(drn^2)$, while the matrix-times-matrix complexity is $O(dr^2n^3)$, which may be far from being satisfactory. A possible remedy is the hierarchical ($\mathcal{H}$-matrix) approximation to the Kronecker factors (HKT approximations) with the advantage of rigorously proved existence theorems [19] with estimates of the form $r = O(\log^2 \varepsilon)$, $s = O(\log \varepsilon^{-1})$ (under certain assumptions on the origin of the matrices).

If $A \in \mathrm{HKT}_{(r,s)}$, then only the $V_k^{(\ell)}$ needs to be stored. Since, by definition, they have the $\mathcal{H}$-format, we arrive at the following complexity bounds (the linear complexity would be $O(n^d)$):

- the storage for A is $O(drsn \log n)$, indicating the *sublinear complexity*;
- multiplication of A by a rank-r_1 vector $x = \sum_{k=1}^{r_1} b_k x_k^{(1)} \otimes \cdots \otimes x_k^{(d)}$ requires $O(drr_1 sn \log n)$ operations;
- the complexity of the matrix-matrix multiplication is $O(dr^2 s^2 n \log^q n)$.

In this paper we discuss existence results for the low Kronecker rank approximation to a class of discrete integral operators.

2.3. General rank-$(r_1, \ldots, r_d)$ matrix decomposition. Let $A \in \mathbb{R}^{\mathcal{I} \times \mathcal{I}}$ be a real-valued matrix defined on the index set $\mathcal{I} := I_1 \times \cdots \times I_d$ with $I_\ell = \{1, \ldots, n_\ell\}$. A matrix A can be multiplied by a vector $X \in \mathbb{R}^{\mathcal{I}}$, so that $AX \in \mathbb{R}^{\mathcal{I}}$. The generalization to the case $A \in \mathbb{R}^{\mathcal{I} \times \mathcal{J}}$, $X \in \mathbb{R}^{\mathcal{J}}$, is straightforward.

A matrix A (resp., a vector X) can also be regarded as a dth order tensor $\mathcal{A} \in \mathbb{R}^{I_1^2 \times \cdots \times I_d^2}$ (resp., $X \in \mathbb{R}^{I_1 \times \cdots \times I_d}$).

DEFINITION 2.1. *We introduce the following rank-$(r_1, \ldots, r_d)$ tensor-product matrix format:*

$$\mathcal{A} = \sum_{k_1=1}^{r_1} \cdots \sum_{k_d=1}^{r_d} b_{k_1 \ldots k_d} V_{k_1}^{(1)} \otimes \cdots \otimes V_{k_d}^{(d)} \in \mathbb{R}^{I_1^2 \times \cdots \times I_d^2}, \tag{2.7}$$

where the Kronecker factors $V_{k_\ell}^{(\ell)} \in \mathbb{R}^{I_\ell \times I_\ell}$, $k_\ell = 1, \ldots, r_\ell$, $\ell = 1, \ldots, d$, are matrices of a certain structure (say, $\mathcal{H}$-matrix, wavelet based format, Toeplitz/circulant, low-rank, etc.). Here $\mathbf{r} = (r_1, \ldots, r_d)$ is again called the Kronecker rank.

The matrix representation by the format (2.7) is a model reduction, which is a generalization of the low-rank approximation of matrices, corresponding to the case $d = 2$.

Remark 2.2. The matrix representation (2.7) is reminiscent of the Tucker decomposition of multidimensional tensors (cf. (2.2)), while (2.6) comply with the CP model (cf. (2.1)). With the help of the so-called n-mode tensor-matrix product (cf. [4]), we introduce the short notation

$$\mathcal{A} = \mathcal{B} \times_1 \mathbf{V}^{(1)} \times_2 \mathbf{V}^{(2)} \cdots \times_d \mathbf{V}^{(d)} \equiv \mathcal{B} \times_{\mathbf{r}} \{\mathbf{V}\}, \tag{2.8}$$

with tensors $\mathbf{V}^{(\ell)} \in \mathbb{R}^{I_\ell \times I_\ell \times r_\ell}$ and $\mathcal{B} = \{b_{\mathbf{k}}\} \in \mathbb{R}^{r_1 \times \cdots \times r_d}$, where the latter is the core tensor. We denote matrices by uppercase letters, e.g., A, and tensors by calligraphic letters, e.g., $\mathcal{B}$. In addition, we set $\mathbf{A} = [A_1 A_2 \dots]$, where A_i is the ith column matrix/vector of $\mathbf{A}$, e.g., $\mathbf{V}^{(\ell)} = [V_1^{(\ell)} V_2^{(\ell)} \dots V_{r_\ell}^{(\ell)}]$.

Similarly to the class of tensors $\boldsymbol{\mathcal{T}}_{\mathbf{r}}$ in the Tucker model, i.e., if the components $V_{k_\ell}^{(\ell)} \in \mathbb{R}^{I_\ell}$ in (2.2) are mutually orthogonal vectors of an arbitrary structure, we introduce the notation $A \in \boldsymbol{\mathcal{T}}_{\mathcal{H},\mathbf{r}}$ for the tensor-product matrix format (2.8) with the canonical components having hierarchical structure.

Clearly, we have

$$\boldsymbol{\mathcal{C}}_r = \boldsymbol{\mathcal{T}}_{\mathbf{r}} \quad \text{if } r = 1; \quad \boldsymbol{\mathcal{C}}_r^{\perp} \subset \boldsymbol{\mathcal{T}}_{\mathbf{r}} \quad \text{if } \mathbf{r} = (r, \dots, r).$$

In general, the CP decomposition (2.1) cannot be retrieved by rotation and "diagonal truncation" of the Tucker model. However, it is possible for orthogonally decomposable tensors in $\boldsymbol{\mathcal{C}}_r^{\perp}$.

We simplify the complexity analysis and set $r_\ell = r$, $n_\ell = n$ $(\ell = 1, \dots, d)$; the general case can be treated completely similarly. A dth order tensor is called supersymmetric if it is invariant under arbitrary permutations of indices in $\{1, \dots, d\}$.

LEMMA 2.3 (see [24]). *The storage cost for $A \in \boldsymbol{\mathcal{T}}_{\mathcal{H},\mathbf{r}}$ is estimated by $O(drsn \log n) + r^d$, while for the supersymmetric tensor we arrive at the memory consumption $O(rsn \log n) + \frac{r^d}{d}$.*

Multiplication by a rank-r_0 vector requires $O(drr_0sn \log n)$ operations. Let $A_1, A_2 \in \boldsymbol{\mathcal{T}}_{\mathcal{H},\mathbf{r}}$. Then both $A_1 A_2$ and the Hadamard matrix product $A_1 \odot A_2$ can be computed and stored in $O(dr^2 s^2 n \log n) + r^{2d}$ operations.

Proof. The storage requirement for A is trivial. Let $\mathcal{X} = \times_1 x_1 \times_2 \cdots \times_d x_d$ with $x_\ell \in \mathbb{R}^{I_\ell}$. Then

$$\mathcal{A}\mathcal{X} \equiv \mathcal{B} \times_1 \mathbf{V}^{(1)} \times_2 \mathbf{V}^{(2)} \cdots \times_d \mathbf{V}^{(d)} \mathcal{X} = \mathcal{B} \times_1 \mathbf{V}^{(1)} x_1 \times_2 \mathbf{V}^{(2)} x_2 \cdots \times_d \mathbf{V}^{(d)} x_d$$

implies the second assertion. Now we set

$$\mathcal{A}_1 = \mathcal{B} \times_1 \mathbf{V}^{(1)} \times_2 \mathbf{V}^{(2)} \cdots \times_d \mathbf{V}^{(d)}, \quad \mathcal{A}_2 = \mathcal{C} \times_1 \mathbf{U}^{(1)} \times_2 \mathbf{U}^{(2)} \cdots \times_d \mathbf{U}^{(d)}$$

to obtain the representation

$$\mathcal{A}_1 \mathcal{A}_2 = \left(\sum_{\mathbf{k}=1}^{\mathbf{r}} b_{\mathbf{k}} \bigotimes_{\ell=1}^{d} V_{k_\ell}^{(\ell)} \right) \left(\sum_{\mathbf{m}=1}^{\mathbf{r}} c_{\mathbf{m}} \bigotimes_{\ell=1}^{d} U_{m_\ell}^{(\ell)} \right) = \sum_{\mathbf{k}=1}^{\mathbf{r}} \sum_{\mathbf{m}=1}^{\mathbf{r}} b_{\mathbf{k}} c_{\mathbf{m}} \bigotimes_{\ell=1}^{d} V_{k_\ell}^{(\ell)} U_{m_\ell}^{(\ell)},$$

which includes dr^2 canonical components, and where the core tensor $\{b_{\mathbf{k}} c_{\mathbf{m}}\}$ has $(r^2)^d = r^{2d}$ entries. Analogously, for the Hadamard product we have

$$\mathcal{A}_1 \odot \mathcal{A}_2 = \left(\sum_{\mathbf{k}=1}^{\mathbf{r}} b_{\mathbf{k}} \bigotimes_{\ell=1}^{d} V_{k_\ell}^{(\ell)} \right) \odot \left(\sum_{\mathbf{m}=1}^{\mathbf{r}} c_{\mathbf{m}} \bigotimes_{\ell=1}^{d} U_{m_\ell}^{(\ell)} \right) = \sum_{\mathbf{k}=1}^{\mathbf{r}} \sum_{\mathbf{m}=1}^{\mathbf{r}} b_{\mathbf{k}} c_{\mathbf{m}} \bigotimes_{\ell=1}^{d} V_{k_\ell}^{(\ell)} \odot U_{m_\ell}^{(\ell)}$$

and take into account that the Hadamard product of two $\mathcal{H}$-matrices has linear-logarithmic cost (cf. [22]). This completes our proof. ∎

In the case of the CP decomposition (2.6) we introduce the notation $A \in \boldsymbol{\mathcal{C}}_{\mathcal{I}\times\mathcal{I},r}$ or more specifically $A \in \boldsymbol{\mathcal{C}}_{\mathcal{H},r}$ if the canonical components are matrices of the general or $\mathcal{H}$-matrix structure, respectively (in particular, we can now identify $HKT_{(r,s)} \equiv \boldsymbol{\mathcal{C}}_{\mathcal{H},r}$).

3. Approximation of function generated tensors. In this section we discuss the low Kronecker rank approximation of a special class of higher-order tensors related to certain "discretizations" of multivariate functions, which will be called function-generated tensors (FGTs). They directly arise from

(a) Nyström/collocation/Galerkin discretizations of integral operators;

(b) the approximation to some analytic matrix-valued functions.

3.1. Basic definitions. In the following we define FGTs corresponding to the Nyström/collocation and Galerkin discretizations.

In the case of an interpolation method, we let $\mathcal{I}_\ell = I_{\ell,1} \times \cdots \times I_{\ell,p}$ be the product index set, where we use multi-indices $\mathbf{i}_\ell = (i_{\ell,1}, \ldots, i_{\ell,p}) \in \mathcal{I}_\ell$ $(\ell = 1, \ldots, d)$ with the components $i_{\ell,m} \in \{1, \ldots, n\}$ $(m = 1, \ldots, p)$. Furthermore, let ω_ℓ be a uniform rectangular grid on $\Pi := [a_0, b_0]^p$, $a_0, b_0 > 0$, indexed by $\mathcal{I}_\ell$, and let $\{\zeta^{(1)}_{\mathbf{i}_1}, \ldots, \zeta^{(d)}_{\mathbf{i}_d}\}$ with $\mathbf{i}_\ell \in \mathcal{I}_\ell$ $(\ell = 1, \ldots, d)$ be a set of collocation points living on the tensor-product lattice $\omega_{\mathbf{d}} := \omega_1 \times \cdots \times \omega_d$ in a hypercube $\Omega := \Pi^d \subset \mathbb{R}^{\mathbf{d}}$ with $\mathbf{d} = dp$ so that $(\mathbf{i}_1, \ldots, \mathbf{i}_d) \in \mathcal{I}^{(\mathbf{d})} := \mathcal{I}_1 \times \cdots \times \mathcal{I}_d$. We also define $|\mathbf{i}_\ell| = \max_{m \le p} |i_{\ell,m}|$ and similarly for $|\mathbf{i}|$, $\mathbf{i} = (i_1, \ldots, i_d)$. In our applications we have $d \ge 2$ with some fixed $p = 1, 2, 3$.

DEFINITION 3.1 (collocation case, FGT(C)). *Given a multivariate function $g : \Omega \to \mathbb{R}$, we introduce the collocation-type FGT of order d by*

$$\mathcal{A} \equiv \mathcal{A}(g) := [a_{\mathbf{i}_1 \ldots \mathbf{i}_d}] \in \mathbb{R}^{\mathcal{I}_1 \times \cdots \times \mathcal{I}_d} \quad \textit{with} \quad a_{\mathbf{i}_1 \ldots \mathbf{i}_d} := g(\zeta^{(1)}_{\mathbf{i}_1}, \ldots, \zeta^{(d)}_{\mathbf{i}_d}). \tag{3.1}$$

In the case of Galerkin schemes we make use of tensor-product test functions

$$\phi^{\mathbf{i}}(x_1, \ldots, x_d) = \prod_{\ell=1}^{d} \phi^{i_\ell}_\ell(x_\ell), \quad \mathbf{i} = (i_1, \ldots, i_d) \in \mathbb{R}^{\mathcal{I}_1 \times \cdots \times \mathcal{I}_d},\ i_\ell \in I_n := \{1, \ldots, n\}, \tag{3.2}$$

and $\psi^{\mathbf{j}}$ with $\mathbf{j} = (j_1, \ldots, j_d) \in \mathbb{R}^{\mathcal{J}_1 \times \cdots \times \mathcal{J}_d}$, $j_\ell \in I_n$, of similar product form.

DEFINITION 3.2 (Galerkin case, FGT(G)). *Given a multivariate function $g : \Omega \times \Omega \to \mathbb{R}$ with $\Omega \subset \mathbb{R}^d$, and a tensor-product basis set* (3.2)*, we let $p = 2$, $\zeta^{(\ell)} = (x_\ell, y_\ell)$, $\mathbf{m}_\ell = (i_\ell, j_\ell) \in \mathcal{M}_\ell := I_{\ell,1} \times I_{\ell,2}$ and introduce the Galerkin-type dth order FGT by $\mathcal{A} \equiv \mathcal{A}(g) := [a_{\mathbf{m}_1 \ldots \mathbf{m}_d}] \in \mathbb{R}^{\mathcal{M}_1 \times \ldots \times \mathcal{M}_d}$ with*

$$a_{\mathbf{m}_1 \ldots \mathbf{m}_d} := \int_{\Omega \times \Omega} g(\zeta^{(1)}, \ldots, \zeta^{(d)}) \phi^{\mathbf{i}}(x_1, \ldots, x_d) \psi^{\mathbf{j}}(y_1, \ldots, y_d) dx dy. \tag{3.3}$$

In the numerical calculations involving integral operators (e.g., arising from the Hartree–Fock or Boltzmann equations), n may vary from several hundreds to several thousands, and therefore, for $d \ge 3$, a naive "entrywise" representation to the tensor $\mathcal{A}$ in (3.1) amounts to substantial computer resources (at least of the order $O(n^{dp})$).

3.2. Kronecker rank in CP decomposition. We recall that CP-type decompositions like (2.1) (or (2.6) in the matrix case) can be derived by using a corresponding separable expansion of the generating function g (see [17, 19] for more details). Assume that we are given a set of functions $\{\Phi^{(\ell)}_k : \mathbb{R}^p \to \mathbb{R}\}$ $(\ell = 1, \ldots, d)$ with the following property.

PROPOSITION 3.3. *Suppose that a multivariate function $g : \Omega \to \mathbb{R}$ can be approximated by a separable expansion*

$$g_r(\boldsymbol{\zeta}) := \sum_{k=1}^{r} \mu_k \Phi^{(1)}_k(\zeta^{(1)}) \cdots \Phi^{(d)}_k(\zeta^{(d)}) \approx g(\boldsymbol{\zeta}), \quad \zeta^{(\ell)} \in \mathbb{R}^p, \quad \ell = 1, \ldots, d, \tag{3.4}$$

where $\mu_k \in \mathbb{R}$ *and* $\Phi_k^{(\ell)} : \Pi \to \mathbb{R}$. *Then the FGT(C) defined by the CP decomposition* (2.1) *via* $\mathcal{A}_{(r)} := \mathcal{A}(g_r)$ *as in Definition* 3.1 *with*

$$V_k^{(\ell)} = \{\Phi_k^{(\ell)}(\zeta_{\mathbf{i}_\ell}^{(\ell)})\}_{\mathbf{i}_\ell \in \mathcal{I}_\ell} \in \mathbb{R}^{\mathcal{I}_\ell}, \quad b_k = \mu_k, \tag{3.5}$$

and the FGT(G), corresponding to the choice

$$V_k^{(\ell)} = \int \Phi_k^{(\ell)}(\zeta_{\mathbf{i}_\ell}^{(\ell)})\phi_\ell^{i_\ell}(x_\ell)\psi_\ell^{j_\ell}(y_\ell)dx_\ell dy_\ell \in \mathbb{R}^{\mathcal{I}_\ell \times \mathcal{J}_\ell}, \quad \ell = 1, \dots, d, \quad k = 1, \dots, r, \tag{3.6}$$

both provide the error estimate $\|\mathcal{A}(g) - \mathcal{A}_{(r)}(g_r)\|_\infty \le C\|g - g_r\|_{L^\infty(\Omega)}$, *where* $C = 1$ *in the FGT(C) case.*

Proof. The analysis for FGT(C) is presented in [17]. In the Galerkin case we readily obtain

$$\begin{aligned} |a_{\mathbf{m}_1 \dots \mathbf{m}_d} - a^{(r)}_{\mathbf{m}_1 \dots \mathbf{m}_d}| &= \left| \int_{\Omega \times \Omega} (g(x,y) - g_r(x,y))\phi^{\mathbf{i}}(x)\psi^{\mathbf{j}}(y)dxdy \right| \\ &\le \|g - g_r\|_{L^\infty(\Omega)} \int_{\Omega \times \Omega} \left|\phi^{\mathbf{i}}(x)\psi^{\mathbf{j}}(y)\right| dxdy; \end{aligned}$$

then the result follows. □

In computationally efficient algorithms the separation rank r is supposed to be as small as possible, while the set of functions $\{\Phi_k^{(\ell)} : \mathbb{R}^p \to \mathbb{R}\}$ can be fixed a priori or chosen adaptively to the problem.

Though in general the construction of a decomposition (3.4) with small separation rank r is a complicated numerical task, in many interesting applications efficient approximation methods are available. In particular, for a class of multivariate functions (say, certain shift-invariant *Green's kernels* in $\mathbb{R}^d$) it is possible to obtain a dimensionally independent Kronecker rank estimate $r = O(\log n |\log \varepsilon|)$ based on *sinc*-quadrature methods or an approximation by exponential sums (cf. case study examples in [2, 17, 23]).

In the rest of this section we discuss the constructive CP decomposition of FGTs applied to a *general class of generating functions* characterized in terms of their Laplace transform. The construction is based on *sinc-approximation methods*.

We consider a class of multivariate functions $g : \mathbb{R}^d \to \mathbb{R}$ parametrized by $g(\boldsymbol{\zeta}) = G(\rho)$ with $\rho = \rho_1(\zeta_1) + \dots + \rho_d(\zeta_d) > 0$, $\rho_\ell : \mathbb{R}^p \to \mathbb{R}_+$ (with small $p \in \mathbb{N}_{\ge 1}$), where a univariate function $G : \mathbb{R}_+ \to \mathbb{R}$ can be represented via the Laplace transform

$$G(\rho) = \int_{\mathbb{R}_+} \mathcal{G}(\tau)e^{-\rho\tau}d\tau.$$

Now the FGT(G) approximation corresponds to $p = 2$, $\zeta_\ell = (x_\ell, y_\ell)$. Without loss of generality, we suppose that $\phi_\ell^{i_\ell}(\cdot) = \phi(\cdot + (i_\ell - 1)h)$ $(\ell = 1, \dots, d)$ with a single scaling function ϕ, where $h > 0$ is the mesh parameter, and the same for $\psi_\ell^{j_\ell}(\cdot)$. We also simplify and set $\rho_\ell = \rho_0(x_\ell, y_\ell)$ $(\ell = 1, \dots, d)$ and, moreover, $\rho_0 : [a,b]^2 \to [a_1, b_1] \subset \mathbb{R}_{>0}$, while $\rho \in [a_d, b_d] \subset \mathbb{R}_{>0}$. The more general multilevel setting (say, corresponding to a wavelet basis) can be analyzed completely similarly. For each $i, j \in I_n$, we introduce the parameter-dependent function

$$\Psi_{i,j}(\tau) := \int_{\mathbb{R}^2} e^{-\tau\rho_0(x,y)}\phi(x + (i-1)h)\psi(y + (j-1)h)dxdy, \quad \tau \ge 0,$$

as well as an auxiliary function $f_I(\tau) := \mathcal{G}(\tau)e^{-\rho\tau}$.

THEOREM 3.4 (FGT(C) approximation). *Assume that*

(a) $\mathcal{G}(\tau)$ *has an analytic extension* $\mathcal{G}(w)$, $w \in \Omega_{\mathcal{G}}$, *into a certain domain* $\Omega_{\mathcal{G}} \subset \mathbb{C}$ *which can be mapped conformally onto the strip* D_δ *(see the appendix), such that* $w = \phi(z)$, $z \in D_\delta$, *and* $\phi^{-1} : \Omega_{\mathcal{G}} \to D_\delta$;

(b) *for each* $\rho \in [a_d, b_d]$ *with* $a_d > 0$, *the function* $f(z) := \phi'(z) f_I(\phi(z))$ *belongs to the Hardy space* $H^1(D_\delta)$ *with* $N(f, D_\delta) < \infty$ *uniformly in* ρ;

(c) $f(t)$, $t \in \mathbb{R}$, *has* (c1) *exponential or* (c2) *hyperexponential decay as* $t \to \pm\infty$.

Then, for each $M \in \mathbb{N}_+$, *the FGT(C),* $\mathcal{A}(g)$, *defined on* $[a, b]^d$ *allows an exponentially convergent supersymmetric CP decomposition* $\mathcal{A}_{(r)} \in \boldsymbol{\mathcal{C}}_r$ *with* $V_k^{(\ell)}$ *as in* (3.5), *where* $\Phi_k^{(\ell)}(\zeta^{(\ell)}) = e^{-a_k \zeta^{(\ell)}}$ $(\ell = 1, \ldots, d)$, *and where* μ_k, a_k *are given by applying the sinc-quadrature* (6.2) *with* $f(t) = \phi'(t) f_I(\phi(t))$, *such that we have*

$$\|\mathcal{A}(g) - \mathcal{A}_{(r)}\|_\infty \le Ce^{-\alpha M^\nu} \quad \text{with } r = 2M + 1, \tag{3.7}$$

where $\nu = \frac{1}{2}$, $\alpha = \sqrt{2\pi\delta b}$ *in the case* (c1) *and with* $\nu = 1$, $\alpha = \frac{2\pi\delta b}{\log(2\pi a M/b)}$ *in the case* (c2).

(FGT(G) approximation) *Assume that* (a) *holds and for each* $\rho \in [a_d, b_d]$ *and* $(\mathbf{i}, \mathbf{j}) \in \mathcal{I} \times \mathcal{J}$:

(b′) *The transformed integrand* $f(z) := \phi'(z)\mathcal{G}(\phi(z)) \prod_{\ell=1}^d \Psi_{i_\ell j_\ell}(\phi(z))$ *belongs to the Hardy space* $H^1(D_\delta)$ *with* $N(f, D_\delta) < \infty$ *uniformly in* ρ; *item* (c) *holds.*

Then, for each $M \in \mathbb{N}$, *the FGT(G),* $\mathcal{A}(g)$, *defined on* $[a, b]^d$ *allows a supersymmetric CP decomposition* $\mathcal{A}_{(r)} \in \boldsymbol{\mathcal{C}}_r$ *with* $V_k^{(\ell)}$ *as in* (3.6) *that yields the error estimate* (3.7).

Proof. In the FGT(C) case, we directly apply the sinc-quadrature theory to the transformed integrand $f(z)$ to obtain $T_M(f, \mathfrak{h}) := \mathfrak{h} \sum_{k=-M}^M f(k\mathfrak{h}) \approx G(\rho)$ (cf. the appendix) with

$$|G(\rho) - T_M(\rho)| \le Ce^{-\alpha M^\nu}, \quad \rho \in [a_d, b_d],$$

and with the respective α, ν. Combining this estimate with Proposition 3.3 and taking into account the separability property of the exponential proves the first assertion.

To prove the FGT(G) case, we notice that by definition

$$a_{\mathbf{ij}} = \int_{\mathbb{R}_+} \mathcal{G}(\tau) \prod_{\ell=1}^d \Psi_{i_\ell j_\ell}(\tau) d\tau \quad \text{for } (\mathbf{i}, \mathbf{j}) \in \mathcal{I} \times \mathcal{J}.$$

We again apply the sinc-quadrature to the transformed integrand $f(z)$ and obtain the exponential convergence as in the case of FGT(C) approximation. Notice that our quadrature does not depend on the index $(\mathbf{i}, \mathbf{j})$, which completes the proof. □

Theorem 3.4 proves the existence of a CP decomposition to the FGT $\mathcal{A}(g)$ with the Kronecker rank $r = O(|\log \varepsilon| \log n)$ (in the case (c2)) or $r = O(\log^2 \varepsilon)$ (in the case (c1)).

3.3. Rank estimates for rank-$(r_1, \ldots, r_d)$ Tucker model. For the class of applications based on separation via tensor-product interpolation, the CP model typically leads to the Kronecker rank estimate $r_{CP} = r^d$ with $r = O(\log n |\log \varepsilon|)$, where the dimensional parameter d gets into the exponent. In such cases one can apply the rank-$(r_1, \ldots, r_d)$ Tucker decomposition instead of the rank-r_{CP} canonical model.

The next lemma shows that the error of the Tucker decomposition is directly related to the error of the separable approximation of the generating function.

LEMMA 3.5 (see [24]). *Let $g : \Omega \to \mathbb{R}$ be approximated by a separable expansion*
(3.8)
$$g_{\mathbf{r}}(\boldsymbol{\zeta}) := \sum_{k_1=1}^{r_1} \cdots \sum_{k_d=1}^{r_d} b_{k_1\dots k_d} \Phi^{(1)}_{k_1}(\zeta^{(1)}) \cdots \Phi^{(d)}_{k_d}(\zeta^{(d)}) \approx g, \quad \zeta^{(\ell)} \in \mathbb{R}^p, \quad 1 \le \ell \le d,$$

where $b_{k_1\dots k_d} \in \mathbb{R}$. Then both the FGT(C) of the form $\mathcal{A}_{(\mathbf{r})} := \mathcal{A}(g_{\mathbf{r}}) \in \boldsymbol{\mathcal{T}}_{\mathbf{r}}$ generated by $g_{\mathbf{r}}$ with

$$V^{(\ell)}_{k_\ell} = \{\Phi^{(\ell)}_{k_\ell}(\zeta^{(\ell)}_{\mathbf{i}_\ell})\}_{\mathbf{i}_\ell \in \mathcal{I}_\ell} \in \mathbb{R}^{\mathcal{I}_\ell} \tag{3.9}$$

and the FGT(G), corresponding to the choice
(3.10)
$$V^{(\ell)}_{k_\ell} = \int \Phi^{(\ell)}_{k_\ell}(\zeta^{(\ell)}_{\mathbf{i}_\ell}) \phi^{i_\ell}_\ell(x_\ell) \psi^{j_\ell}_\ell(y_\ell) dx_\ell dy_\ell \in \mathbb{R}^{\mathcal{I}_\ell \times \mathcal{J}_\ell}, \quad \ell = 1, \dots, d, \quad k_\ell = 1, \dots, r_\ell,$$

provide the error estimate $\|\mathcal{A}(g) - \mathcal{A}_{(\mathbf{r})}(g_{\mathbf{r}})\|_\infty \le C\|g - g_{\mathbf{r}}\|_{L^\infty(\Omega)}$, where $C = 1$ in the FGT(C) case.

Proof. In the FGT(C) case, by the construction of $\mathcal{A}_{(\mathbf{r})}$ we have

$$\|\mathcal{A} - \mathcal{A}_{(\mathbf{r})}\|_\infty = \max_{(\mathbf{i}_1,\dots,\mathbf{i}_d) \in \mathcal{I}^{\mathbf{d}}} \left\{ \left| g(\zeta^{(1)}_{\mathbf{i}_1}, \dots, \zeta^{(d)}_{\mathbf{i}_d}) - \sum_{k_1=1}^{r_1} \cdots \right. \right.$$
$$\left. \left. \sum_{k_d=1}^{r_d} b_{k_1\dots k_d} \Phi^{(1)}_{k_1}(\zeta^{(1)}_{\mathbf{i}_1}) \cdots \Phi^{(d)}_{k_d}(\zeta^{(d)}_{\mathbf{i}_d}) \right| \right\},$$

which proves the first assertion. The Galerkin-type approximation can be analyzed as in Proposition 3.3. ∎

For a class of analytic functions with point singularities the expansion (3.8) can be derived via tensor-product *Sinc*-interpolation, which is motivated by various favorable features of the Sinc-basis in $L^2(\mathbb{R})$ (cf. [22]).

COROLLARY 3.6. *Assume that $g(\zeta)$ satisfies the requirements for the tensor-product sinc-interpolation (cf. the appendix). Then the FGT(C), $\mathcal{A}(g)$, allows an exponentially convergent rank-$(r,\dots,r)$ decomposition $\mathcal{A}_{(\mathbf{r})} \in \boldsymbol{\mathcal{T}}_{\mathbf{r}}$ with $V^{(\ell)}_{k_\ell}$ as in* (3.9)*, where $\Phi^{(\ell)}_{k_\ell}(\zeta^{(\ell)}) = \operatorname{sinc}(-a_{k_\ell}\zeta^{(\ell)})$ $(\ell = 1,\dots,d)$, and where $b_{\mathbf{k}}$ are represented via the sinc-interpolation* (6.3) *applied to the function g, such that*

$$\|\mathcal{A}(g) - \mathcal{A}_{(\mathbf{r})}\|_\infty \le C(1 + \log M)^d e^{-\alpha M^\nu} \quad \text{with } r = 2M + 1, \tag{3.11}$$

with $\nu = \frac{1}{2}$, $\alpha = \sqrt{2\pi\delta b}$ in the case (c1) *and with $\nu = 1$, $\alpha = \frac{2\pi\delta b}{\log(2\pi a M/b)}$ in the case* (c2) *as in Theorem* 3.4*. A similar result holds in the FGT(G) case.*

Proof. We apply Lemma 3.5, yielding an exponential error bound for the tensor-product sinc-interpolation (cf. the appendix), which proves the first assertion. The FGT(G) case can be analyzed similarly. ∎

The error estimate (3.11) yields $\max_\ell r_\ell = O(|\log\varepsilon|\delta^{-1})$. In some cases we get the estimate $\delta^{-1} = O(\log n)$ (cf. [17]).

4. Structured approximation of integral operators.

4.1. Canonical-HKT decomposition in $\mathbb{R}^d$. The principal ingredient in the HKT representation of integral operators in many spatial dimensions is a separable approximation of the multivariate function representing the kernel of the operator. Given the integral operator $\mathbb{G} : L^2(\Omega) \to L^2(\Omega)$ in $\Omega := [0,1]^d \subset \mathbb{R}^d$, $d \geq 2$,

$$(\mathbb{G}u)(x) := \int_\Omega g(x,y)u(y)\mathrm{d}y, \quad x, y \in \Omega,$$

with some shift-invariant kernel function $g(x,y) = g(|x-y|)$, which, therefore, can be represented in the form

$$g(x,y) = G(\zeta_1, \ldots, \zeta_d) \equiv g\left(\sqrt{\zeta_1^2 + \cdots + \zeta_d^2}\right),$$

where $\zeta_\ell = |x_\ell - y_\ell| \in [0,1]$, $\ell = 1, \ldots, d$.

In the case of a continuous kernel function one can apply the so-called Nyström approximation with respect to the tensor-product grid $\omega_h \times \omega_h \in \Pi^d \times \Pi^d$,

$$(\mathbb{G}u) \approx \sum_{y_{\mathbf{j}} \in \omega_h} g(x_{\mathbf{i}}, y_{\mathbf{j}})u(y_{\mathbf{j}}), \quad x_{\mathbf{i}} \in \omega_h.$$

Hence the previous analysis for the FGT(C) approximation directly applies to the arising stiffness matrix $A = \{g(x_{\mathbf{i}}, y_{\mathbf{j}})\}$.

In the presence of diagonal singularities, a separable approximation may be easier for the following modified kernels. With some fixed $0 \leq \alpha_0 < 1$, we introduce the auxiliary function

$$F(\zeta_1, \ldots, \zeta_d) := (\zeta_1 \cdots \zeta_{d-1})^{\alpha_0} G(\zeta_1, \ldots, \zeta_d). \tag{4.1}$$

In this section we suppose that the multivariate function $F : \mathbb{R}^d \to \mathbb{R}$ can be approximated by a separable expansion

$$F_r(\zeta_1, \ldots, \zeta_d) := \sum_{k=1}^{r} \Phi_k^{(1)}(\zeta_1) \cdots \Phi_k^{(d)}(\zeta_d) \approx F, \tag{4.2}$$

where the set of functions $\{\Phi_k^{(\ell)} : \ell = 1, \ldots, d,\ k = 1, \ldots, r\}$ with $\Phi_k^{(\ell)} : [0,1] \to \mathbb{R}$ may be fixed or can be chosen adaptively. Various methods for constructing approximations which are exponentially convergent in r are discussed in [17].

We consider a Galerkin scheme with tensor-product test functions

$$\phi^{\mathbf{i}}(x_1, \ldots, x_d) = \phi_1^{i_1}(x_1) \cdot \ldots \cdot \phi_d^{i_d}(x_d),$$
$$\mathbf{i} = (i_1, \ldots, i_d),\ i_\ell \in I_n := \{1, \ldots, n\},\ \ell = 1, \ldots, d.$$

Now we approximate the Galerkin stiffness matrix

$$A = \{(\mathbb{G}\phi^{\mathbf{i}}, \phi^{\mathbf{j}})_{L^2}\}_{\mathbf{i},\mathbf{j} \in I_n^d} \in \mathbb{R}^{N \times N}, \quad N = n^d,$$

by a matrix $A_{(r)}$ of the form (2.6), where the $V_k^{(\ell)}$ are $n \times n$ matrices given by

$$V_k^{(\ell)} = \left\{ \int_0^1 |x_\ell - y_\ell|^{-\alpha_\ell} \Phi_k^\ell(|x_\ell - y_\ell|) \phi_\ell^{i_\ell}(x_\ell) \phi_\ell^{j_\ell}(y_\ell) \mathrm{d}x_\ell \mathrm{d}y_\ell \right\}_{i_\ell, j_\ell = 1}^{n}, \quad \ell = 1, \ldots, d, \tag{4.3}$$

with $\alpha_\ell = \alpha_0$, $\ell = 1, \dots, d-1$, and $\alpha_d = 0$ (see (4.1)).

In the following we apply the approximation properties of asymptotically smooth functions. We recall that a function $g(x,y)$, $x, y \in \mathbb{R}^d$, is called asymptotically smooth if there exists $\gamma \geq 1$, and $p \in \mathbb{R}$ such that for all $x, y \in \mathbb{R}^d$, $x \neq y$, and all multi-indices α, β such that $|\alpha| + |\beta| > 0$ with $|\alpha| = \alpha_1 + \cdots + \alpha_d$, there holds

$$|\partial_x^\alpha \partial_y^\beta g(x,y)| \leq C\alpha!\beta!\gamma^{|\alpha|+|\beta|}|x-y|^{-p-|\alpha|-|\beta|}.$$

The next lemma shows that the error $\|A - A_{(r)}\|_\infty$ is directly related to the error $\|F - F_r\|_\infty$ of the separable approximation (4.2) of F (see the discussion in [19]). It also specifies sufficient conditions for $\mathcal{H}$-matrix approximability to the Kronecker factors $V_k^{(\ell)}$.

LEMMA 4.1 (see [18]). *Let* (4.2) *be valid; then for any* $\mathbf{i}, \mathbf{j} \in I_n^d$, *we have the estimate*

$$|a_{\mathbf{i},\mathbf{j}} - a^r_{\mathbf{i},\mathbf{j}}| \leq \|F - F_r\|_\infty \prod_{\ell=1}^d \left\| |x_\ell - y_\ell|^{-\alpha_\ell} \phi_\ell^{i_\ell}(x_\ell)\phi_\ell^{j_\ell}(y_\ell) \right\|_{L^1([0,1]\times[0,1])}$$

for the components of $A - A_{(r)}$. *We assume that the function*

$$g_{\ell,k}(u,v) := |u-v|^{-\alpha_\ell}\Phi_k^{(\ell)}(|u-v|), \quad (u,v) \in [0,1]^2,$$

is asymptotically smooth for $\ell = 1, \dots, d$, $k = 1, \dots, r$. *Then, for low-order piecewise polynomial basis functions,* $V_k^{(\ell)}$ *can be approximated by a rank-m* $\mathcal{H}$*-matrix* $\widetilde{V}_k^{(\ell)}$ *with an error*

$$\|V_k^{(\ell)} - \widetilde{V}_k^{(\ell)}\| \leq C\eta^m \quad \text{for some} \quad \eta < 1.$$

Proof. By construction we obtain

$$\begin{aligned}
|a_{\mathbf{i},\mathbf{j}} - a^r_{\mathbf{i},\mathbf{j}}| &= \left| \int_{\Omega\times\Omega} (F - F_r) \left(\prod_{\ell=1}^d |x_\ell - y_\ell|^{-\alpha_\ell} \right) \phi^{\mathbf{i}}(x)\phi^{\mathbf{j}}(y)\mathrm{d}x\mathrm{d}y \right| \\
&\leq \|F - F_r\|_\infty \left\| \left(\prod_{\ell=1}^d |x_\ell - y_\ell|^{-\alpha_\ell} \right) \phi^{\mathbf{i}}(x)\phi^{\mathbf{j}}(y) \right\|_{L^1(\Omega\times\Omega)} \\
&= \|F - F_r\|_\infty \prod_{\ell=1}^d \left\| |x_\ell - y_\ell|^{-\alpha_\ell} \phi_\ell^{i_\ell}(x_\ell)\phi_\ell^{j_\ell}(y_\ell) \right\|_{L^1([0,1]\times[0,1])},
\end{aligned}$$

where the last equation follows by inserting the tensor-product basis and by separating the $2d$-dimensional integral.

To prove the second statement, we note that $V_k^{(\ell)}$ given by (4.3) appears to be the exact Galerkin stiffness matrix for an integral operator with the kernel function $g_{\ell,k}(u,v)$ defined on $[0,1]\times[0,1]$. Since $g_{\ell,k}(u,v)$ is supposed to be asymptotically smooth, the result follows by the conventional theory of the $\mathcal{H}$-matrix approximation (cf. [12, 14, 15, 16]). ∎

Note that due to Lemma 4.1, $\|A - A_{(r)}\|$ can be easily estimated in, say, the Frobenius, l_2, or l_∞ matrix norms. In particular, we have

$$\|A - A_{(r)}\|_\infty \leq n^d \|F - F_r\|_\infty \prod_{\ell=1}^d \left\| |x_\ell - y_\ell|^{-\alpha_\ell} \phi_\ell^{i_\ell}(x_\ell)\phi_\ell^{j_\ell}(y_\ell) \right\|_{L^1([0,1]\times[0,1])}.$$

Several methods of separable approximations to multivariate functions are presented in [17]. In the general case, the approximability property (4.2) can be validated by using the tensor-product Sinc-interpolation. In this case the function $\Phi_k^{(\ell)}(|u-v|)$ can be proved to be asymptotically smooth. For the class of kernel functions approximated by the quadrature method or by exponential sums, the factor $\Phi_k^{(\ell)}(|u-v|)$ even appears to be globally smooth (indeed, it is the entire function).

LEMMA 4.2 (see [18]). *For both, the tensor-product Sinc-interpolation and quadrature approximation methods, the function $g_{\ell,k}(u,v)$ from Lemma 4.1 is asymptotically smooth.*

Proof. In the first case we have

$$g_{\ell,k}(u,v) = |u-v|^{-\alpha_\ell} S(k,\mathfrak{h})(\phi^{-1}(|u-v|)), \qquad u,v \in [0,1],$$

where $S(k,\mathfrak{h})$ refers for the kth Sinc-function with step-size $\mathfrak{h}$, and (cf. [17, section 2])

$$\phi^{-1}(x) = \operatorname{arsinh}\left(\operatorname{arcosh}\left(\frac{1}{x}\right)\right).$$

Since the Sinc-function $S(k,\mathfrak{h})(x)$, $x \in \mathbb{R}$, is holomorphic in x, and since the factor $|u-v|^{-\alpha_\ell}$ is asymptotically smooth, we conclude that $g_{\ell,k}(u,v)$ is also asymptotically smooth. In the case of a quadrature method, we obtain the entire function

$$\Phi_k^{(\ell)}(|u-v|) = \exp(-t_k|u-v|^2), \quad t_k > 0.$$

Then the previous argument completes the proof. □

Applying Lemmas 4.1 and 4.2 proves the existence of a low Kronecker rank HKT approximation to the class of multidimensional integral operators. In general, given a tolerance $\varepsilon > 0$, we have the bound

$$r = \mathcal{O}\left(\left[\log\left(h^{-1}\right)\log\left(\varepsilon^{-1}\right)\log\left(\log\varepsilon^{-1}\right)\right]^{d-1}\right),$$

where h is the mesh parameter of the finite element discretization. However, for the class of translation-invariant kernels (see [17] and the examples below), we obtain a dimensionally independent bound

$$r = \mathcal{O}\left(\log\left(h^{-1}\right)\log\left(\varepsilon^{-1}\right)\log\left(\log\varepsilon^{-1}\right)\right).$$

4.2. Tucker-HKT approximation. Following Definition 3.2, we introduce the dth order FGT(G) that represents the integral operator $\mathbb{G}$,

$$\mathcal{A} \equiv \mathcal{A}(g) := [a_{\mathbf{m}_1\dots\mathbf{m}_d}] \in \mathbb{R}^{\mathcal{M}_1\times\cdots\times\mathcal{M}_d}$$

with

$$a_{\mathbf{m}_1\dots\mathbf{m}_d} := \int_{\Omega\times\Omega} g(\zeta^{(1)},\dots,\zeta^{(d)})\phi^{\mathbf{i}}(x)\phi^{\mathbf{j}}(y)dxdy, \tag{4.4}$$

where

$$\zeta^{(\ell)} = (x_\ell, y_\ell),\ \mathbf{m}_\ell = (i_\ell, j_\ell) \in \mathcal{M}_\ell \equiv I_\ell \times I_\ell,\ \ell = 1,\dots,d.$$

Assume that the kernel function $g(x,y) \equiv g(\zeta^{(1)},\dots,\zeta^{(d)})$ allows a separable approximation (3.8) via the Sinc-interpolation that converges exponentially in $r = \max_\ell r_\ell$

(see Corollary 3.6). Then the associated rank-$(r_1,\dots,r_d)$ Tucker decomposition in $\boldsymbol{\mathcal{T}}_{\mathbf{r}}$ (cf. Definition 2.1),

$$\mathcal{A}_{(\mathbf{r})} = \sum_{k_1=1}^{r_1} \dots \sum_{k_d=1}^{r_d} b_{k_1\dots k_d} V_{k_1}^{(1)} \otimes \dots \otimes V_{k_d}^{(d)} \in \mathbb{R}^{\mathcal{M}_1\times\dots\times\mathcal{M}_d}, \tag{4.5}$$

is specified by the Kronecker factors $V_{k_\ell}^{(\ell)} \in \mathbb{R}^{\mathcal{M}_\ell}$, explicitly defined by

$$V_{k_\ell}^{(\ell)} = \int \Phi_{k_\ell}^{(\ell)}(\zeta_{\mathbf{i}_\ell}^{(\ell)})\phi_\ell^{i_\ell}(x_\ell)\phi_\ell^{j_\ell}(y_\ell)dx_\ell dy_\ell \in \mathbb{R}^{\mathcal{M}_\ell}, \quad \ell = 1,\dots,d, \quad k_\ell = 1,\dots,r_\ell. \tag{4.6}$$

Let $\mathbf{r} = (r,\dots,r)$. Corollary 3.6 now yields the error estimate

$$\|\mathcal{A}(g) - \mathcal{A}_{(\mathbf{r})}\|_\infty \le Ce^{-\alpha M^\nu} \quad \text{with } r = 2M+1, \tag{4.7}$$

and with constants α, ν from (3.11).

As was already mentioned, (4.7) yields $\max_\ell r_\ell = O(|\log\varepsilon|\delta^{-1})$. In turn, for a class of shift-invariant kernels we get the estimate $\delta^{-1} = O(\log n)$. The numerical complexity of the Tucker decomposition (4.5) is estimated by $drn^2 + r^d$. Applying Lemma 4.2 we conclude that the functions $\Phi_{k_\ell}^{(\ell)}$ are asymptotically smooth; hence the canonical components $V_{k_\ell}^{(\ell)}$ can be approximated by a rank-m $\mathcal{H}$-matrix $\widetilde{V}_{k_\ell}^{(\ell)}$ with an error

$$\|V_{k_\ell}^{(\ell)} - \widetilde{V}_{k_\ell}^{(\ell)}\| \le C\eta^m \quad \text{for some} \quad \eta < 1.$$

The storage cost for the corresponding Tucker-HKT approximation in $\boldsymbol{\mathcal{T}}_{\mathcal{H},\mathbf{r}}$ has the complexity $drnm\log^q n + r^d$, while the complexity of further matrix operations is estimated in Lemma 2.3. Notice that the Tucker-HKT approximation can be applied to more general kernel functions compared with the canonical-HKT representation (the latter is restricted to the class of translation-invariant kernels).

4.3. Examples: Newton, Yukawa, and Helmholtz potentials. Let $x, y \in \mathbb{R}^d$, $p = 2$, and define $\rho = |x-y|^2 = \zeta_1^2 + \dots + \zeta_d^2$ with $\zeta_\ell = x_\ell - y_\ell : \mathbb{R}^2 \to \mathbb{R}$, $\boldsymbol{\zeta} \in \mathbb{R}^d$. The family of functions

$$g(x,y) \equiv g(\boldsymbol{\zeta}) := 1/\rho^\lambda \quad \text{with } \lambda \in \mathbb{R}_{>0}$$

arises in potential theory, in quantum chemistry, and in computational gas dynamics (cf. [23]). The choice $\lambda = 1/2$ corresponds to the classical Newton potential, while $\lambda = -1/2$ refers to the distance function.

Low separation rank decomposition to the multivariate functions $1/\rho$, $1/\sqrt{\rho}$ and to the related Galerkin approximations were discussed in [2, 17, 18, 19, 24], while the kernel function ρ^μ, $\mu \in \mathbb{R}$, was considered in [23].

Let us take a closer look at the FGT(G) for the Newton potential $1/\sqrt{\rho}$ in the hypercube $[-R,R]^d \in \mathbb{R}^d$. As a basic example, we consider piecewise linear finite elements defined by scaling functions $\phi(x) = \psi(x)$ associated with a tensor-product grid with step-size $h > 0$.

LEMMA 4.3 (see [24]). *The FGT(G) for the Newton potential $1/\sqrt{\rho}$ in the hypercube $[-R,R]^d \subset \mathbb{R}^d$ allows a CP approximation with exponential convergence rate (independent of d) as in* (3.11) *with $\nu = 1/2$.*

Proof. We apply the FGT(G)-version of Theorem 3.4. In our case we have $\rho_0(x,y) = (x-y)^2$ $(x,y \in \mathbb{R})$; hence, making use of the Gaussian transform

$$\frac{1}{\sqrt{\rho}} = \frac{2}{\sqrt{\pi}} \int_{\mathbb{R}_+} e^{-\rho\tau^2} d\tau,$$

we obtain $\Psi_{i,j}(\tau) = \Psi_{|i-j|}(\tau) := \int_{\mathbb{R}^2} e^{-\tau^2(x-y)^2} \phi(x)\psi(y+|i-j|h)dxdy$, $\tau \geq 0$. Following [26], we choose the analyticity domain as a sector $\Omega_{\mathcal{G}} := \{w \in \mathbb{C} : |\arg(w)| < \delta\}$ with apex angle $0 < 2\delta < \pi/2$ (here $\mathcal{G} = 1$), and then apply the conformal map $\varphi^{-1} : \Omega_{\mathcal{G}} \to D_\delta$ with $w = \varphi(z) = e^z$, $\varphi^{-1}(w) = \log(w)$ (cf. Theorem 3.4(a)).

To check condition (b′) of Theorem 3.4, first we notice that the transformed integrand

$$f(z) := \exp(z) \prod_{\ell=1}^{d} \Psi_{i_\ell j_\ell}(\phi(z))$$

belongs to the Hardy space $H^1(D_\delta)$. Let $H = (H_1, \ldots, H_d) \in \mathbb{R}^d$ with $H_\ell = |i_\ell - j_\ell|h \leq R$ and let

$$(f * g)(u) = \int_{\mathbb{R}} f(x)g(u-x)dx$$

be the convolution product in $\mathbb{R}^d$, provided that $q(x) = |f| * |g|$ is locally integrable. Now, using the shift property of convolution, $f(\cdot + C) * g(\cdot) = f * g(\cdot + C)$ and applying the Fubini theorem in the form

$$(f * g, \mu)_{L^2} = \int_{\mathbb{R}^d \times \mathbb{R}^d} f(x)g(y)\mu(x+y)dxdy, \quad \mu \in \mathcal{D}(\mathbb{R}^d),$$

we obtain (see [24] for more details)

$$\int_{\mathbb{R}^d \times \mathbb{R}^d} e^{-w^2|x-y|^2} \phi(x)\psi(y-H)dxdy = \int_{\mathbb{R}^d} e^{-w^2|v-H|^2} (\phi * \psi)(v)dv,$$

taking into account that the functions ϕ and ψ have compact support $[-h,h]^d$.

Notice that $\operatorname{supp}(\phi * \psi) = [-2h, 2h]^d$. Now we estimate the constant $N(f, D_\delta)$ by

$$\begin{aligned}
N(f, D_\delta) &= \int_{\partial\Omega_{\mathcal{G}}} |f(w)|\,|dw| \\
&= \int_{\partial\Omega_{\mathcal{G}}} \int_{\mathbb{R}^d \times \mathbb{R}^d} \left| e^{-w^2|x-y|^2} \phi(x)\psi(y-H)dxdy \right| |dw| \\
&= 2 \int_{\mathbb{R}_+} \int_{\mathbb{R}^d} \left| e^{-\zeta^2 \exp(2i\delta)|u-H|^2} (\phi * \psi)(u)du \right| d\zeta \\
&\leq 2 \int_{\mathbb{R}^d} \int_{\mathbb{R}_+} \left| e^{-\zeta^2 \exp(2i\delta)|u-H|^2} \right| d\zeta\, |\phi * \psi|(u)du \\
&= 2 \int_{\mathbb{R}^d} \int_{\mathbb{R}_+} e^{-\zeta^2 cos(2\delta)|u-H|^2} d\zeta\, |\phi * \psi|(u)du \\
&\leq \frac{Cmeas(\operatorname{supp}(\phi * \psi))}{diam(\operatorname{supp}(\phi * \psi))\sqrt{cos(2\delta)}}.
\end{aligned}$$

Finally, we check that condition (c1) is also valid, which completes the proof. ∎

A similar result holds for the Yukawa potential (cf. [24]). Moreover, the above arguments can be also applied to the analysis for the Helmholtz potential in the domain $[-R,R]^d$ for a fixed and not too large R.

4.4. Numerical tests. Numerical tests for the analytic CP approximation to the FGT(C) representation of the Newton and some other potentials are given in [17]. In the following, we present the convergence history for the algebraically optimal rank-(r,r,r) Tucker decomposition to the FGT(C) representations of the target integral operators. We make use of the cell-centred collocation on the $30 \times 30 \times 30$ tensor-product grid on $[0,R]^d$, where $R = 10$ for the first two kernel-functions and with $R = 2\pi$ for the Helmholtz kernel.

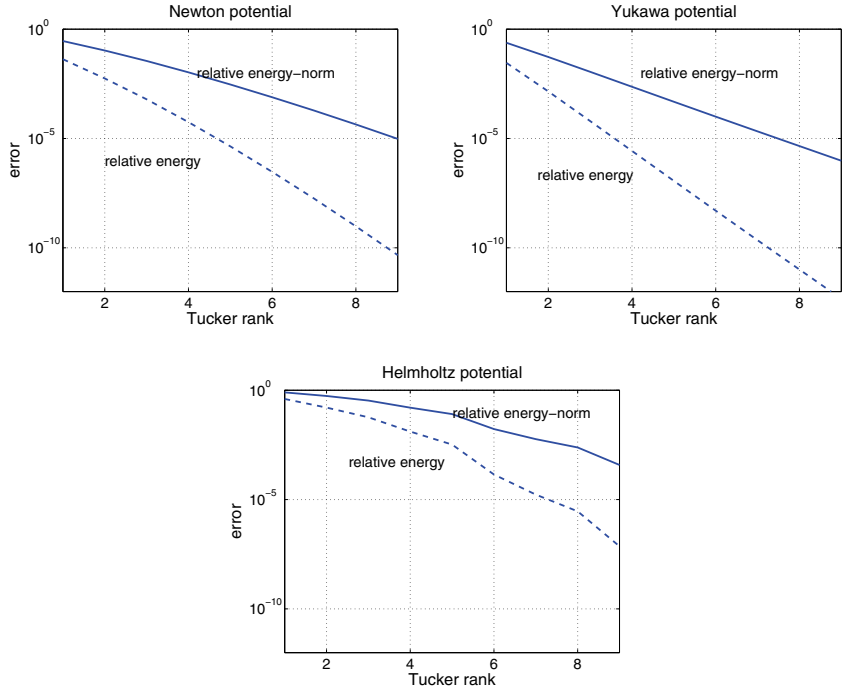

FIG. 4.1. *Rank-$(r,\dots,r)$ Tucker approximation to the Newton (top left), the Yukawa (top right), and the Helmholtz (bottom) potentials for $r = 1,\dots,9$, and with $d = 3$.*

We compute the best rank-(r,r,r) Tucker approximation by the ALS algorithm (implemented in MATLAB) applied to the Lagrange equation for the minimization problem (2.4) with $\mathcal{A} \in \boldsymbol{\mathcal{T}}_{\mathbf{r}}$ (cf. [4]). Figure 4.1 indicates the exponential convergence of the best rank-(r,r,r) approximation in r with $r \in [1,9]$ for each of the three potentials considered.

5. Elliptic operator inverse.

5.1. General framework. We consider the elliptic operator $\mathbb{L} : H_0^1(\Omega) \to H^{-1}(\Omega)$ given in the form

$$\mathbb{L} = -\sum_{j=1}^{d} \frac{\partial}{\partial x_j} a_j(x_j) \frac{\partial}{\partial x_j} + \sum_{j=1}^{d} \left[b_j(x_j) \frac{\partial}{\partial x_j} + c_j(x_j) \right], \quad x = (x_1,\dots,x_d) \in \Omega.$$

To derive the tensor-product representation, we employ a finite difference discretization A of $\mathbb{L}$ (e.g., a three-point stencil in each variable) using a uniform tensor-product grid in $\mathbb{R}^d$ with n grid points in each spatial direction. The discretization

matrix has the form $A = \sum_{j=1}^{d} A_j$ with $A, A_j \in \mathbb{R}^{N\times N}$, $N = n^d$, where the matrices A_j are mutually commutable.

Let A be positive definite. The negative fractional power $A^{-\sigma}$ can be represented by

$$A^{-\sigma} = \frac{1}{\Gamma(\sigma)} \int_0^\infty t^{\sigma-1} \mathrm{e}^{-tA} \mathrm{d}t \qquad (\sigma > 0) \tag{5.1}$$

(cf. [11]), provided that the integral exists.

We apply an exponentially convergent quadrature rule (cf. [11, 23]) to represent the integral (5.1) by a sum involving only factorized expressions,

$$A^{-\sigma} \approx \sum_{k=-M}^{M} c_k t_k^{\sigma-1} \prod_{j=1}^{d} \exp(-t_k A_j) \quad (t_k, c_k \in \mathbb{R} \text{ quadrature points and weights}),$$

which leads to the desired HKT representation (2.6). The complexity of the HKT approximation can be estimated by $\mathcal{O}(dn \log^q n)$, where q is some fixed constant independent of d.

Note that with the choice $\mathcal{A} = -\Delta$, the representation (2.6) is of particular interest in the cases $\sigma = 1/2$ (preconditioner of the Laplace–Beltrami operator $(-\Delta)^{1/2}$, and for hypersingular integral operators, e.g., in BEM applications), $\sigma = 1$ (inverse Laplacian), and $\sigma = 2$ (preconditioner for the biharmonic operator).

5.2. Laplace operator inverse. The finite difference "d-dimensional Laplacian" on the uniform $n\times\cdots\times n$ tensor-product grid (subject to homogeneous Dirichlet boundary conditions) takes the form

$$A := V^1 \otimes I \otimes \cdots \times I + I \otimes V^2 \otimes \cdots \otimes I + \cdots + I \otimes I \otimes \cdots \otimes V^d \in \mathbb{R}^{n^d \times n^d}$$

with $V^j, I \in \mathbb{R}^{n\times n}$, where I is the identity matrix and $V^j = \mathrm{tridiag}\{-1, 2, -1\}$, $j = 1, \ldots, d$. We construct the CP approximation in the form

$$A_{(r)} = \sum_{k=-M}^{M} c_k \bigotimes_{\ell=1}^{d} \exp(-t_k V^j) \approx A^{-1} \quad (t_k, c_k \in \mathbb{R}),$$

providing exponential convergence in $r = 2M + 1$. The choice of coefficients t_k, c_k corresponds to the sinc-quadrature rule applied to the integral representation

$$\frac{1}{\rho} = \int_{\mathbb{R}_+} e^{-\rho\tau} d\tau \equiv \int_{\mathbb{R}} e^t e^{-\rho e^t} dt.$$

Figure 5.1 indicates the exponential convergence of the CP approximation $A_{(r)}$ in r in the case of two different quadratures. We calculate (in MATLAB) the Laplace operator inverse on the domain $(0, 1)^d$ with $n = 128$ grid points in each spatial direction. We recall that the memory requirements for our algorithm are estimated by $O(drn)$ (compare with the linear complexity $N = n^d$).

Direct application of Theorem 6.1 in the case of exponential decay (6.4) with $b = 1$ leads to the choice

$$t_k = e^{k\mathfrak{h}}, \quad c_k = \mathfrak{h} t_k, \quad \mathfrak{h} = \pi/\sqrt{M},$$

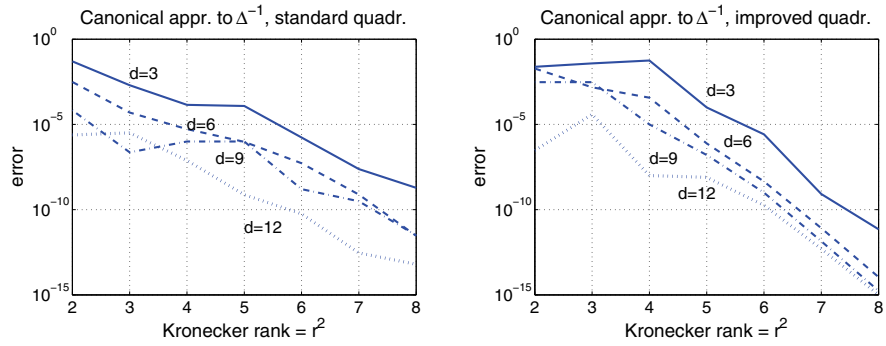

FIG. 5.1. *Rank-r CP approximation to the Laplace operator inverse with* $d = 3, 6, 9, 12$.

providing the convergence rate

$$\left\|A^{-1} - A_{(r)}\right\| \le Ce^{-\pi\sqrt{M}}.$$

This case corresponds to the left part in Figure 5.1. Using a special substitution of variables (see [17] for more details) we obtain an integral with hyperexponential decay as in (6.5),

$$\frac{1}{\rho} = \int_{\mathbb{R}} f_2(w)\mathrm{d}w \quad \text{with } f_2(w) = \frac{\cosh(w)}{1+\mathrm{e}^{-\sinh(w)}}\mathrm{e}^{-\rho\log(1+\mathrm{e}^{\sinh(w)})}. \tag{5.2}$$

Substitution of $\mathfrak{h} = C_0 \log M/M$ into (6.2) leads to the approximation error estimate

$$\left\|A^{-1} - A_{(r)}\right\| \le Ce^{-sM/\log(M)}.$$

This case corresponds to the right-hand part in Figure 5.1.

6. Appendix: Sinc-approximation. Following the standard tools in the sinc methods (cf. [26]), we introduce the Hardy space $H^1(D_\delta)$ as the set of all complex-valued functions f, which are analytic in the strip

$$D_\delta := \{z \in \mathbb{C} : |\Im\mathfrak{m}\, z| < \delta\},$$

such that

$$N(f, D_\delta) := \int_{\partial D_\delta} |f(z)|\,|\mathrm{d}z| = \int_{\mathbb{R}} \left(|f(x+i\delta)| + |f(x-i\delta)|\right)\mathrm{d}x < \infty.$$

Let

$$S(k,\mathfrak{h})(x) = \frac{\sin\left[\pi(x-k\mathfrak{h})/\mathfrak{h}\right]}{\pi(x-k\mathfrak{h})/\mathfrak{h}} \equiv \mathrm{sinc}\left(\frac{x}{\mathfrak{h}} - k\right) \qquad (k \in \mathbb{Z},\ \mathfrak{h} > 0,\ x \in \mathbb{R})$$

be the kth Sinc-function with step-size $\mathfrak{h}$, evaluated at x, where the Sinc-function is defined by

$$\mathrm{sinc}(z) = \frac{\sin(\pi z)}{\pi z}, \quad z \in \mathbb{C}. \tag{6.1}$$

Given $f \in H^1(D_\delta)$, $\mathfrak{h} > 0$, and $M \in \mathbb{N}_0$, the corresponding sinc-quadrature read as

$$T_M(f,\mathfrak{h}) := \mathfrak{h} \sum_{k=-M}^{M} f(k\mathfrak{h}) \approx \int_{\mathbb{R}} f(\xi)\mathrm{d}\xi. \tag{6.2}$$

The classical Sinc interpolant (cardinal series representation) reads as

$$C_M(f,\mathfrak{h}) = \sum_{\nu=-M}^{M} S(\nu,\mathfrak{h}) f(\nu\mathfrak{h}) \approx f. \tag{6.3}$$

THEOREM 6.1. *Let $f \in H^1(D_\delta)$, $\mathfrak{h} > 0$, and $M \in \mathbb{N}_0$ be given. If*

$$|f(\xi)| \le C\exp(-b|\xi|) \qquad \text{for all } \xi \in \mathbb{R} \text{ with } b, C > 0, \tag{6.4}$$

then the quadrature error satisfies

$$\left| \int_{\mathbb{R}} f(\xi)\mathrm{d}\xi - T_M(f,\mathfrak{h}) \right| \le C e^{-\sqrt{2\pi\delta b M}} \quad \text{with } \mathfrak{h} = \sqrt{2\pi\delta/bM},$$

and with a positive constant C depending only on f, δ, b (cf. [26]). *If f possesses the hyperexponential decay*

$$|f(\xi)| \le C\exp(-b\mathrm{e}^{a|\xi|}) \qquad \text{for all } \xi \in \mathbb{R} \quad \text{with } a, b, C > 0, \tag{6.5}$$

then the choice $\mathfrak{h} = \log(\frac{2\pi a M}{b})/(aM)$ leads to (cf. [10])

$$\left| \int_{\mathbb{R}} f(\xi)\mathrm{d}\xi - T_M(f,\mathfrak{h}) \right| \le C\, N(f, D_\delta)\, \mathrm{e}^{-2\pi\delta a M/\log(2\pi a M/b)}.$$

If (6.4) *holds, then the interpolation error satisfies* (cf. [26])

$$\|f - C_M(f,\mathfrak{h})\|_\infty \le C M^{1/2} e^{-\sqrt{\pi\delta b M}} \quad \text{with } \mathfrak{h} = \sqrt{\pi\delta/bM}.$$

Assuming the hyperexponential decay of f, we obtain (cf. [10])

$$\|f - C_M(f,\mathfrak{h})\|_\infty \le C\,\frac{N(f,D_\delta)}{2\pi\delta}\mathrm{e}^{-\pi\delta a M/\log(\pi a M/b)} \quad \text{with } \mathfrak{h} = \log\left(\frac{\pi a M}{b}\right)/(aM).$$

Note that $2M+1$ is the number of quadrature/interpolation points. If f is an even function, the number of quadrature/interpolation points reduces to $M+1$.

The Sinc-interpolation method can be extended to the multidimensional case. Let $g_\ell(\cdot) : I_\ell \to \mathbb{R}$ be a univariate parameter-dependent function, which is the restriction of a multivariate function g onto I_ℓ with fixed remaining variables. Suppose that $g_\ell(\cdot)$ satisfies all the regularity and decay conditions above, uniformly in $\ell = 1, \dots, d$. It is shown in [17] that the *tensor-product Sinc-interpolation* $\mathbf{C}_M$ with respect to d variables,

$$\mathbf{C}_M g := C_M^{(1)} \dots C_M^{(d)} g,$$

provides the exponential error estimate

$$|g(\zeta) - \mathbf{C}_M(g,\mathfrak{h})(\zeta)| \le \frac{C\Lambda_M^d}{2\pi\delta} \max_{\ell=1,\dots,d} N(g_\ell(\cdot), D_\delta)\, \mathrm{e}^{\frac{-\pi\delta M}{\log M}}$$

with the Lebesgue constant $\Lambda_M = O(\log M)$, and where $C_M^{(\ell)} g = C_M^{(\ell)}(g,\mathfrak{h})$ denotes the univariate Sinc-interpolation from (6.3) applied to the variable $\zeta_\ell \in I_\ell$.

SYMMETRIC TENSORS AND SYMMETRIC TENSOR RANK*

PIERRE COMON†, GENE GOLUB‡, LEK-HENG LIM‡, AND BERNARD MOURRAIN§

Abstract. A symmetric tensor is a higher order generalization of a symmetric matrix. In this paper, we study various properties of symmetric tensors in relation to a decomposition into a symmetric sum of outer product of vectors. A rank-1 order-k tensor is the outer product of k nonzero vectors. Any symmetric tensor can be decomposed into a linear combination of rank-1 tensors, each of which is symmetric or not. The *rank* of a symmetric tensor is the minimal number of rank-1 tensors that is necessary to reconstruct it. The *symmetric rank* is obtained when the constituting rank-1 tensors are imposed to be themselves symmetric. It is shown that rank and symmetric rank are equal in a number of cases and that they always exist in an algebraically closed field. We will discuss the notion of the generic symmetric rank, which, due to the work of Alexander and Hirschowitz [*J. Algebraic Geom.*, 4 (1995), pp. 201–222], is now known for any values of dimension and order. We will also show that the set of symmetric tensors of symmetric rank at most r is not closed unless $r = 1$.

1. Introduction.

We will be interested in the decomposition of a symmetric tensor into a minimal linear combination of symmetric outer products of vectors (i.e., of the form $\mathbf{v} \otimes \mathbf{v} \otimes \cdots \otimes \mathbf{v}$). We will see that a decomposition of the form

$$A = \sum_{i=1}^{r} \lambda_i \mathbf{v}_i \otimes \mathbf{v}_i \otimes \cdots \otimes \mathbf{v}_i \tag{1.1}$$

always exists for any symmetric tensor A (over any field). One may regard this as a generalization of the eigenvalue decomposition for symmetric matrices to higher order symmetric tensors. In particular, this will allow us to define a notion of *symmetric tensor rank* (as the minimal r over all such decompositions) that reduces to the matrix rank for order-2 symmetric tensors.

We will call (1.1) the *symmetric outer product decomposition* of the symmetric tensor A and we will establish its existence in Proposition 4.2. This is often abbreviated as CANDECOMP in signal processing. The decomposition of a tensor into an (asymmetric) outer product of vectors and the corresponding notion of tensor rank was first introduced and studied by Frank L. Hitchcock in 1927 [29, 30]. This same decomposition was rediscovered in the 1970s by psychometricians in their attempts to define

data analytic models that generalize factor analysis to multiway data [60]. The name CANDECOMP, for canonical decompositions, was used by Carroll and Chang [11] and the name PARAFAC, for parallel factor analysis, was used by Harshman [28] for their respective models.

The symmetric outer product decomposition is particularly important in the process of *blind identification of underdetermined mixtures* (UDM), i.e., linear mixtures with more inputs than observable outputs. See [14, 17, 20, 50, 51] and references therein for a list of other application areas, including speech, mobile communications, machine learning, factor analysis of k-way arrays, biomedical engineering, psychometrics, and chemometrics.

Despite a growing interest in the symmetric decomposition of symmetric tensors, this topic has not been adequately addressed in the general literature, and even less so in the engineering literature. For several years, the alternating least squares algorithm has been used to fit data arrays to a multilinear model [36, 51]. Yet the minimization of this matching error is an ill-posed problem in general, since the set of symmetric tensors of symmetric rank not more than r is not closed, unless $r = 1$ (see sections 6 and 8)—a fact that parallels the ill-posedness discussed in [21]. The focus of this paper is mainly on symmetric tensors. The asymmetric case will be addressed in a companion paper, and will use similar tools borrowed from algebraic geometry.

Symmetric tensors form a singularly important class of tensors. Examples where these arise are higher order derivatives of smooth functions [40] and moments and cumulants of random vectors [44]. The decomposition of such symmetric tensors into simpler ones, as in the symmetric outer product decomposition, plays an important role in *independent component analysis* [14] and constitutes a problem of interest in its own right. On the other hand, the asymmetric version of the outer product decomposition defined in (4.1) is central to *multiway factor analysis* [51].

In sections 2 and 3, we discuss some classical results in multilinear algebra [5, 26, 39, 42, 45, 64] and algebraic geometry [27, 65]. While these background materials are well known to many pure mathematicians, we found that practitioners and applied mathematicians (in signal processing, neuroimaging, numerical analysis, optimization, etc.)—for whom this paper is intended—are often unaware of these classical results. For instance, some do not realize that the classical definition of a symmetric tensor given in Definition 3.2 is equivalent to the requirement that the coordinate array representing the tensor be invariant under all permutations of indices, as in Definition 3.1. Many authors have persistently mislabeled the latter a "*supersymmetric* tensor" (cf. [10, 34, 46]). In fact, we have found that even the classical definition of a symmetric tensor is not as well known as it should be. We see this as an indication of the need to inform our target readership. It is our hope that the background materials presented in sections 2 and 3 will serve such a purpose.

Our contributions begin in section 4, where the notions of maximal and generic rank are analyzed. The concepts of *symmetry* and *genericity* are recalled in sections 3 and 4, respectively. The distinction between symmetric rank and rank is made in section 4, and it is shown in section 5 that they must be equal in specific cases. It is also pointed out in section 6 that the generic rank always exists in an algebraically closed field and that it is not maximal except in the binary case. More precisely, the sequence of sets of symmetric tensors of symmetric rank r increases with r (in the sense of inclusion) up to the generic symmetric rank and *decreases* thereafter. In addition, the set of symmetric tensors of symmetric rank at most r and order $d > 2$ is closed only for $r = 1$ and $r = R_S$, the maximal symmetric rank. Values of the generic symmetric rank and the uniqueness of the symmetric outer product decomposition

are addressed in section 7. In section 8, we give several examples of sequences of symmetric tensors converging to limits having strictly higher symmetric ranks. We also give an explicit example of a symmetric tensor whose values of symmetric rank over $\mathbb{R}$ and over $\mathbb{C}$ are different.

In this paper, we restrict our attention mostly to decompositions over the complex field. A corresponding study over the real field will require techniques rather different from those introduced here, as we will elaborate in section 8.2.

2. Arrays and tensors. A *k-way array* of complex numbers will be written in the form $A = [\![a_{j_1\cdots j_k}]\!]_{j_1,\ldots,j_k=1}^{n_1,\ldots,n_k}$, where $a_{j_1\cdots j_k} \in \mathbb{C}$ is the $(j_1,\ldots,j_k)$-entry of the array. This is sometimes also called a k-dimensional *hypermatrix*. We denote the set of all such arrays by $\mathbb{C}^{n_1\times\cdots\times n_k}$, which is evidently a complex vector space of dimension $n_1\cdots n_k$ with respect to entrywise addition and scalar multiplication. When there is no confusion, we will leave out the range of the indices and simply write $A = [\![a_{j_1\cdots j_k}]\!] \in \mathbb{C}^{n_1\times\cdots\times n_k}$.

Unless noted otherwise, arrays with at least two indices will be denoted in uppercase; vectors are one-way arrays and will be denoted in bold lowercase. For our purpose, only a few notations related to arrays [14, 20] are necessary.

The *outer product* (or *Segre outer product*) of k vectors $\mathbf{u} \in \mathbb{C}^{n_1}, \mathbf{v} \in \mathbb{C}^{n_2}, \ldots, \mathbf{z} \in \mathbb{C}^{n_k}$ is defined as

$$\mathbf{u}\otimes\mathbf{v}\otimes\cdots\otimes\mathbf{z} := [\![u_{j_1}v_{j_2}\cdots z_{j_k}]\!]_{j_1,j_2,\ldots,j_k=1}^{n_1,n_2,\ldots,n_k}.$$

More generally, the outer product of two arrays A and B, respectively, of orders k and ℓ is an array of order $k+\ell$, $C = A\otimes B$ with entries

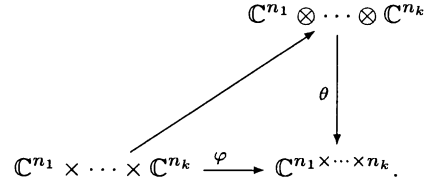
$$c_{i_1\cdots i_k j_1\cdots j_\ell} := a_{i_1\cdots i_k} b_{j_1\cdots j_\ell}.$$

For example, the outer product of two vectors, $\mathbf{u}\otimes\mathbf{v}$, is a matrix. The outer product of three vectors, or of a matrix with a vector, is a 3-way array.

How is an array related to a tensor? Recall that a tensor is simply an element in the tensor product of vector spaces [5, 26, 39, 42, 45, 64]. One may easily check that the so-called Segre map

$$\begin{aligned}\varphi : \mathbb{C}^{n_1}\times\cdots\times\mathbb{C}^{n_k} &\to \mathbb{C}^{n_1\times\cdots\times n_k},\\ (\mathbf{u},\ldots,\mathbf{z}) &\mapsto \mathbf{u}\otimes\cdots\otimes\mathbf{z}\end{aligned}$$

is multilinear. By the universal property of the tensor product [5, 26, 39, 42, 45, 64], there exists a linear map θ



Since $\dim(\mathbb{C}^{n_1}\otimes\cdots\otimes\mathbb{C}^{n_k}) = \dim(\mathbb{C}^{n_1\times\cdots\times n_k})$, θ is an isomorphism of the vector spaces $\mathbb{C}^{n_1}\otimes\cdots\otimes\mathbb{C}^{n_k}$ and $\mathbb{C}^{n_1\times\cdots\times n_k}$. Consider the canonical basis of $\mathbb{C}^{n_1}\otimes\cdots\otimes\mathbb{C}^{n_k}$,

$$\{\mathbf{e}_{j_1}^{(1)}\otimes\cdots\otimes\mathbf{e}_{j_k}^{(k)} \mid 1\le j_1\le n_1,\ldots,1\le j_k\le n_k\},$$

where $\{\mathbf{e}_1^{(\ell)}, \dots, \mathbf{e}_{n_\ell}^{(\ell)}\}$ denotes the canonical basis in $\mathbb{C}^{n_\ell}$, $\ell = 1, \dots, k$. Then θ may be described by

$$\theta\Big(\sum\nolimits_{j_1,\dots,j_k=1}^{n_1,\dots,n_k} a_{j_1,\dots,j_k} \mathbf{e}_{j_1}^{(1)} \otimes \cdots \otimes \mathbf{e}_{j_k}^{(k)}\Big) = [\![a_{j_1\cdots j_k}]\!]_{j_1,\dots,j_k=1}^{n_1,\dots,n_k}.$$

So an order-k tensor in $\mathbb{C}^{n_1} \otimes \cdots \otimes \mathbb{C}^{n_k}$ and a k-way array in $\mathbb{C}^{n_1 \times \cdots \times n_k}$ that represents the tensor with respect to a basis may be regarded as synonymous (up to, of course, the choice of basis). We will illustrate how the k-array representation of an order-k tensor is affected by a change-of-basis. Let $A = [\![a_{ijk}]\!] \in \mathbb{C}^{n_1 \times n_2 \times n_3}$ and let L, M, and N be three matrices of size $r_1 \times n_1$, $r_2 \times n_2$, and $r_3 \times n_3$, respectively. Then the tensor A may be transformed by the multilinear map (L, M, N) into a tensor $A' = [\![a'_{pqr}]\!] \in \mathbb{C}^{r_1 \times r_2 \times r_3}$ defined by

$$a'_{pqr} = \sum\nolimits_{i,j,k} l_{pi} m_{qj} n_{rk} a_{ijk}. \tag{2.1}$$

When $r_i = n_i$ and L, M, N are nonsingular matrices, the above multilinear map may be thought of as a change-of-bases (refer to [21] for further discussions). We will call this map a *multilinear transform* of A.

In addition to the outer product, we also have an *inner product* or *contraction product* of two arrays. The mode-p inner product between two arrays A, B having the same pth dimension is denoted $A \bullet_p B$ and is obtained by summing over the pth index. More precisely, if A and B are of orders k and ℓ, respectively, this yields for $p = 1$ the array $C = A \bullet_1 B$ of order $k + \ell - 2$:

$$c_{i_2 \cdots i_k j_2 \cdots j_\ell} = \sum\nolimits_{\alpha} a_{\alpha i_2 \cdots i_k} b_{\alpha j_2 \cdots j_\ell}.$$

Note that some authors [20, 24, 60] denoted this contraction product as $A \times_p B$ or $\langle A, B \rangle_p$. By convention, when the contraction is between a tensor and a matrix, it is convenient to assume that the summation is always done on the second matrix index. For instance, the multilinear transform in (2.1) may be expressed as $A' = A \bullet_1 L \bullet_2 M \bullet_3 N$. An alternative notation for (2.1) from the theory of group actions is $A' = (L, M, N) \cdot A$, which may be viewed as multiplying A on "three sides" by the matrices L, M, and N [21, 32].

3. Symmetric arrays and symmetric tensors. We shall say that a k-way array is *cubical* if all its k dimensions are identical, i.e., $n_1 = \cdots = n_k = n$. A cubical array will be called *symmetric* if its entries do not change under any permutation of its k indices. Formally, if $\mathfrak{S}_k$ denotes the symmetric group of permutations on $\{1, \dots, k\}$, then we have the following definition.

DEFINITION 3.1. *A k-way array $[\![a_{j_1 \cdots j_k}]\!] \in \mathbb{C}^{n \times \cdots \times n}$ is called* symmetric *if*

$$a_{i_{\sigma(1)} \cdots i_{\sigma(k)}} = a_{i_1 \cdots i_k}, \qquad i_1, \dots, i_k \in \{1, \dots, n\},$$

for all permutations $\sigma \in \mathfrak{S}_k$.

For example, a 3-way array $[\![a_{ijk}]\!] \in \mathbb{C}^{n \times n \times n}$ is symmetric if

$$a_{ijk} = a_{ikj} = a_{jik} = a_{jki} = a_{kij} = a_{kji}$$

for all $i, j, k \in \{1, \dots, n\}$.

Such arrays have been improperly labeled "supersymmetric" tensors (cf. [10, 34, 46] among others); this terminology should be avoided since it refers to an entirely

different class of tensors [7]. The word "supersymmetric" has *always* been used in both mathematics and physics [25, 61, 63] to describe objects with a $\mathbb{Z}_2$-grading, and so using it in the sense of [10, 34, 46] is both inconsistent and confusing. (The correct usage will be one in the sense of [7].) In fact, we will show in Proposition 3.7 that there is no difference between Definition 3.1 and the usual definition of a symmetric tensor in mathematics [5, 26, 39, 42, 45, 64]. In other words, the prefix "super" in "supersymmetric tensor," when used in the sense of [10, 34, 46], is superfluous.

We will write $\mathsf{T}^k(\mathbb{C}^n) := \mathbb{C}^n \otimes \cdots \otimes \mathbb{C}^n$ (k copies), the set of all order-k dimension-n cubical tensors. We define a group action $\mathfrak{S}_k$ on $\mathsf{T}^k(\mathbb{C}^n)$ as follows. For any $\sigma \in \mathfrak{S}_k$ and $\mathbf{x}_{i_1} \otimes \cdots \otimes \mathbf{x}_{i_k} \in \mathsf{T}^k(\mathbb{C}^n)$, we let

$$\sigma(\mathbf{x}_{i_1} \otimes \cdots \otimes \mathbf{x}_{i_k}) := \mathbf{x}_{i_{\sigma(1)}} \otimes \cdots \otimes \mathbf{x}_{i_{\sigma(k)}}$$

and extend this linearly to all of $\mathsf{T}^k(\mathbb{C}^n)$. Thus each $\sigma \in \mathfrak{S}_k$ defines a linear operator $\sigma : \mathsf{T}^k(\mathbb{C}^n) \to \mathsf{T}^k(\mathbb{C}^n)$. The standard definition of a symmetric tensor in mathematics [5, 26, 39, 42, 45, 64] looks somewhat different from Definition 3.1 and is given as follows.

DEFINITION 3.2. *An order-k tensor $A \in \mathsf{T}^k(\mathbb{C}^n)$ is* symmetric *if*

$$\sigma(A) = A \tag{3.1}$$

for all permutations $\sigma \in \mathfrak{S}_k$. The set of symmetric tensors in $\mathsf{T}^k(\mathbb{C}^n)$ will be denoted by $\mathsf{S}^k(\mathbb{C}^n)$.

Let $S : \mathsf{T}^k(\mathbb{C}^n) \to \mathsf{T}^k(\mathbb{C}^n)$ be the linear operator defined by

$$S := \frac{1}{k!} \sum\nolimits_{\sigma \in \mathfrak{S}_k} \sigma.$$

Note that given any $\sigma \in \mathfrak{S}_k$,

$$\sigma \circ S = S \circ \sigma = S.$$

Here $\circ$ denotes the composition of the linear operators σ and S.

PROPOSITION 3.3. *An order-k tensor $A \in \mathsf{T}^k(\mathbb{C}^n)$ is symmetric if and only if*

$$S(A) := \frac{1}{k!} \sum\nolimits_{\sigma \in \mathfrak{S}_k} \sigma(A) = A.$$

Proof. Clearly, if A is symmetric, then

$$S(A) = \frac{1}{k!} \sum\nolimits_{\sigma \in \mathfrak{S}_k} \sigma(A) = \frac{1}{k!} \sum\nolimits_{\sigma \in \mathfrak{S}_k} A = A.$$

Conversely, if $S(A) = A$, then

$$\sigma(A) = \sigma(S(A)) = \sigma \circ S(A) = S(A) = A$$

for all $\sigma \in \mathfrak{S}_k$; and so A is symmetric. ∎

In other words, a symmetric tensor is an eigenvector of the linear operator S with eigenvalue 1. $\mathsf{S}^k(\mathbb{C}^n)$ is the 1-eigenspace of $S : \mathsf{T}^k(\mathbb{C}^n) \to \mathsf{T}^k(\mathbb{C}^n)$. Proposition 3.3 implies that $\mathsf{S}^k(\mathbb{C}^n) = S(\mathsf{T}^k(\mathbb{C}^n))$ and it is also easy to see that S is a projection of $\mathsf{T}^k(\mathbb{C}^n)$ onto the subspace $\mathsf{S}^k(\mathbb{C}^n)$, i.e., $S^2 = S$.

3.1. Equivalence with homogeneous polynomials. We adopt the following standard shorthand. For any $\mathbf{e}_{i_1}, \dots, \mathbf{e}_{i_k} \in \mathbb{C}^n$ with $i_1, \dots, i_k \in \{1, \dots, n\}$, we write

$$\mathbf{e}_{i_1} \cdots \mathbf{e}_{i_k} := S(\mathbf{e}_{i_1} \otimes \cdots \otimes \mathbf{e}_{i_k}) = \frac{1}{k!} \sum\nolimits_{\sigma \in \mathfrak{S}_k} \mathbf{e}_{i_{\sigma(1)}} \otimes \cdots \otimes \mathbf{e}_{i_{\sigma(k)}}. \tag{3.2}$$

Then since $S\sigma = S$, the term $\mathbf{e}_{i_1} \cdots \mathbf{e}_{i_k}$ depends only on the number of times each $\mathbf{e}_i$ enters this product and we may write

$$\mathbf{e}_{i_1} \cdots \mathbf{e}_{i_k} = \mathbf{e}_1^{p_1} \cdots \mathbf{e}_n^{p_n}, \tag{3.3}$$

where p_i is the multiplicity (which may be 0) of occurrence of $\mathbf{e}_i$ in $\mathbf{e}_{i_1} \cdots \mathbf{e}_{i_k}$. Note that $p_1, \dots, p_n$ are nonnegative integers satisfying $p_1 + \cdots + p_n = k$.

PROPOSITION 3.4. *Let $\{\mathbf{e}_1, \dots, \mathbf{e}_n\}$ be a basis of $\mathbb{C}^n$. Then*

$$\{S(\mathbf{e}_{i_1} \otimes \cdots \otimes \mathbf{e}_{i_k}) \mid 1 \le i_1 \le \cdots \le i_k \le n\}$$

or, explicitly,

$$\Big\{ \frac{1}{k!} \sum\nolimits_{\sigma \in \mathfrak{S}_k} \mathbf{e}_{i_{\sigma(1)}} \otimes \cdots \otimes \mathbf{e}_{i_{\sigma(k)}} \;\Big|\; 1 \le i_1 \le \cdots \le i_k \le n \Big\}$$

is a basis of $\mathsf{S}^k(\mathbb{C}^n)$. Furthermore,

$$\dim_{\mathbb{C}} \mathsf{S}^k(\mathbb{C}^n) = \binom{n+k-1}{k}.$$

Proof. Since $\mathcal{B} = \{\mathbf{e}_{i_1} \otimes \cdots \otimes \mathbf{e}_{i_k} \mid 1 \le i_1 \le n, \dots, 1 \le i_k \le n\}$ is a basis for $\mathsf{T}^k(\mathbb{C}^n)$ and since S maps $\mathsf{T}^k(\mathbb{C}^n)$ onto $\mathsf{S}^k(\mathbb{C}^n)$, the set

$$S(\mathcal{B}) = \{\mathbf{e}_{i_1} \cdots \mathbf{e}_{i_k} \mid 1 \le i_1 \le \cdots \le i_k \le n\} = \{\mathbf{e}_1^{p_1} \cdots \mathbf{e}_n^{p_n} \mid p_1 + \cdots + p_n = k\}$$

spans $\mathsf{S}^k(\mathbb{C}^n)$. Vectors in $S(\mathcal{B})$ are linearly independent: if $(p_1, \dots, p_n) \neq (q_1, \dots, q_n)$, then the tensors $\mathbf{e}_1^{p_1} \cdots \mathbf{e}_n^{p_n}$ and $\mathbf{e}_1^{q_1} \cdots \mathbf{e}_n^{q_n}$ are, respectively, linear combinations of two nonintersecting subsets of basis elements of $\mathsf{T}^k(\mathbb{C}^n)$. The cardinality of $S(\mathcal{B})$ is precisely the number of partitions of k into a sum of n nonnegative integers, i.e., $\binom{n+k-1}{k}$. ∎

If we regard $\mathbf{e}_j$ in (3.3) as variables (i.e., indeterminates), then every symmetric tensor of order k and dimension n may be uniquely associated with a *homogeneous polynomial* of degree k in n variables. Recall that these are just polynomials in n variables whose constituting monomials all have the same total degree k. Homogeneous polynomials are also called *quantics* and those of degrees 1, 2, and 3 are often called *linear forms*, *quadratic forms*, and *cubic forms* (or just *cubics*), respectively. From now on, we will use more standard notation for the variables—x_j instead of $\mathbf{e}_j$. So the monomial on the right-hand side of (3.3) now becomes $x_1^{p_1} \cdots x_n^{p_n}$. To further simplify this notation, we will adopt the following standard *multi-index notation*:

$$\mathbf{x}^{\boldsymbol{p}} := \prod\nolimits_{k=1}^{n} x_k^{p_k} \quad \text{and} \quad |\boldsymbol{p}| := \sum\nolimits_{k=1}^{n} p_k,$$

where $\boldsymbol{p}$ denotes a k-vector of nonnegative integers. We will also write $\mathbb{C}[x_1, \dots, x_n]_k$ for the set of homogeneous polynomials of degree k in n variables (again a standard notation). Then any symmetric tensor $[\![a_{j_1 \cdots j_k}]\!] = [\![a_{\boldsymbol{j}}]\!] \in \mathsf{S}^k(\mathbb{C}^n)$ can be associated with a unique homogeneous polynomial $F \in \mathbb{C}[x_1, \dots, x_n]_k$ via the expression

$$F(\mathbf{x}) = \sum\nolimits_{\boldsymbol{j}} a_{\boldsymbol{j}} \mathbf{x}^{\boldsymbol{p}(\boldsymbol{j})}, \tag{3.4}$$

where for every $\boldsymbol{j} = (j_1, \ldots, j_k)$, one associates bijectively the nonnegative integer vector $\boldsymbol{p}(\boldsymbol{j}) = (p_1(\boldsymbol{j}), \ldots, p_n(\boldsymbol{j}))$ with $p_j(\boldsymbol{j})$ counting the number of times index j appears in $\boldsymbol{j}$ [16, 14]. We have in particular $|\boldsymbol{p}(\boldsymbol{j})| = k$. The converse is true as well, and the correspondence between symmetric tensors and homogeneous polynomials is obviously bijective. Thus

$$\mathsf{S}^k(\mathbb{C}^n) \cong \mathbb{C}[x_1, \ldots, x_n]_k. \tag{3.5}$$

This justifies the use of the Zariski topology, where the elementary closed subsets are the common zeros of a finite number of homogeneous polynomials [49]. Note that for asymmetric tensors, the same association is not possible (although they can still be associated with polynomials via another bijection). As will be subsequently seen, this identification of symmetric tensors with homogeneous polynomials will allow us to prove some interesting facts about symmetric tensor rank.

We will now proceed to define a useful "inner product" on $\mathbb{C}[x_1, \ldots, x_n]_k$. For any $F, G \in \mathbb{C}[x_1, \ldots, x_n]_k$ written as

$$F(\mathbf{x}) = \sum\nolimits_{|\boldsymbol{p}|=k} \binom{k}{p_1, \ldots, p_n} a_{\boldsymbol{p}} \mathbf{x}^{\boldsymbol{p}}, \qquad G(\mathbf{x}) = \sum\nolimits_{|\boldsymbol{p}|=k} \binom{k}{p_1, \ldots, p_n} b_{\boldsymbol{p}} \mathbf{x}^{\boldsymbol{p}},$$

we let

$$\langle F, G \rangle := \sum\nolimits_{|\boldsymbol{p}|=k} \binom{k}{p_1, \ldots, p_n} a_{\boldsymbol{p}} b_{\boldsymbol{p}} = \sum\nolimits_{p_1+\cdots+p_n=k} \frac{k!}{p_1! \cdots p_n!} a_{p_1 \cdots p_n} b_{p_1 \cdots p_n}.$$

Note that $\langle \cdot, \cdot \rangle$ cannot be an inner product in the usual sense since $\langle F, F \rangle$ is in general complex valued (recall that for an inner product, we will need $\langle F, F \rangle \geq 0$ for all F). However, we will show that it is a nondegenerate symmetric bilinear form.

LEMMA 3.5. *The bilinear form $\langle \cdot, \cdot \rangle : \mathbb{C}[x_1, \ldots, x_n]_k \times \mathbb{C}[x_1, \ldots, x_n]_k \to \mathbb{C}$ defined above is symmetric and nondegenerate. In other words, $\langle F, G \rangle = \langle G, F \rangle$ for every $F, G \in \mathbb{C}[x_1, \ldots, x_n]_k$, and if $\langle F, G \rangle = 0$ for all $G \in \mathbb{C}[x_1, \ldots, x_n]_k$, then $F \equiv 0$.*

Proof. The bilinearity and symmetry is immediate from definition. Suppose $\langle F, G \rangle = 0$ for all $G \in \mathbb{C}[x_1, \ldots, x_n]_k$. Choose G to be the monomials

$$G_{\boldsymbol{p}}(\mathbf{x}) = \binom{k}{p_1, \ldots, p_n} \mathbf{x}^{\boldsymbol{p}},$$

where $|\boldsymbol{p}| = k$, and we see immediately that

$$a_{\boldsymbol{p}} = \langle F, G_{\boldsymbol{p}} \rangle = 0.$$

Thus $F \equiv 0$. ∎

In the special case where G is the kth power of a linear form, we have the following lemma. The main interest in introducing this inner product lies precisely in establishing this lemma.

LEMMA 3.6. *Let $G = (\beta_1 x_1 + \cdots + \beta_n x_n)^k$. Then for any $F \in \mathbb{C}[x_1, \ldots, x_n]_k$, we have*

$$\langle F, G \rangle = F(\beta_1, \ldots, \beta_n),$$

i.e., F evaluated at $(\beta_1, \ldots, \beta_n) \in \mathbb{C}^n$.

Proof. Let $b_{\boldsymbol{p}} = \beta_1^{p_1} \cdots \beta_n^{p_n}$ for all $\boldsymbol{p} = (p_1, \dots, p_n)$ such that $|\boldsymbol{p}| = k$. The multinomial expansion then yields

$$(\beta_1 x_1 + \cdots + \beta_n x_n)^k = \sum\nolimits_{|\boldsymbol{p}|=k} \binom{k}{p_1, \dots, p_n} b_{\boldsymbol{p}} \mathbf{x}^{\boldsymbol{p}}.$$

For any $F(\mathbf{x}) = \sum_{|\boldsymbol{p}|=k} \binom{k}{p_1,\dots,p_n} a_{\boldsymbol{p}} \mathbf{x}^{\boldsymbol{p}}$,

$$F(\beta_1, \dots, \beta_n) = \sum\nolimits_{|\boldsymbol{p}|=k} \binom{k}{p_1, \dots, p_n} a_{\boldsymbol{p}} b_{\boldsymbol{p}} = \langle F, G \rangle$$

as required. ∎

3.2. Equivalence with usual definition. As mentioned earlier, we will show that a tensor is symmetric in the sense of Definition 3.2 if and only if its corresponding array is symmetric in the sense of Definition 3.1.

PROPOSITION 3.7. *Let $A \in \mathsf{T}^k(\mathbb{C}^n)$ and $[\![a_{j_1 \cdots j_k}]\!] \in \mathbb{C}^{n \times \cdots \times n}$ be its corresponding k-array. Then*

$$\sigma(A) = A$$

for all permutations $\sigma \in \mathfrak{S}_k$ if and only if

$$a_{i_{\sigma(1)} \cdots i_{\sigma(k)}} = a_{i_1 \cdots i_k}, \qquad i_1, \dots, i_k \in \{1, \dots, n\},$$

for all permutations $\sigma \in \mathfrak{S}_k$.

Proof. Suppose $[\![a_{i_1 \cdots i_k}]\!] \in \mathbb{C}^{n \times \cdots \times n}$ is symmetric in the sense of Definition 3.1. Then the corresponding tensor

$$A = \sum\nolimits_{i_1, \dots, i_k = 1}^{n} a_{i_1 \cdots i_k} \mathbf{e}_{i_1} \otimes \cdots \otimes \mathbf{e}_{i_k},$$

where $\{\mathbf{e}_1, \dots, \mathbf{e}_n\}$ denotes the canonical basis in $\mathbb{C}^n$, satisfies the following:

$$\begin{aligned}
S(A) &= \sum\nolimits_{i_1, \dots, i_k = 1}^{n} a_{i_1 \cdots i_k} S(\mathbf{e}_{i_1} \otimes \cdots \otimes \mathbf{e}_{i_k}) && (S \text{ linear}) \\
&= \frac{1}{k!} \sum\nolimits_{i_1, \dots, i_k = 1}^{n} a_{i_1 \cdots i_k} \Big[\sum\nolimits_{\sigma \in \mathfrak{S}_k} \mathbf{e}_{i_{\sigma(1)}} \otimes \cdots \otimes \mathbf{e}_{i_{\sigma(k)}} \Big] \\
&= \frac{1}{k!} \sum\nolimits_{i_1, \dots, i_k = 1}^{n} \Big[\sum\nolimits_{\sigma \in \mathfrak{S}_k} a_{i_{\sigma(1)} \cdots i_{\sigma(k)}} \Big] \mathbf{e}_{i_1} \otimes \cdots \otimes \mathbf{e}_{i_k} \\
&= \frac{1}{k!} \sum\nolimits_{i_1, \dots, i_k = 1}^{n} k! a_{i_1 \cdots i_k} \mathbf{e}_{i_1} \otimes \cdots \otimes \mathbf{e}_{i_k} && ([\![a_{i_1 \cdots i_k}]\!] \text{ symmetric}) \\
&= A.
\end{aligned}$$

Hence A is a symmetric tensor in the sense of Definition 3.2.

Conversely, let $A \in \mathsf{T}^k(\mathbb{C}^n)$ be symmetric in the sense of Definition 3.2 and

$$A = \sum\nolimits_{i_1, \dots, i_k = 1}^{n} a_{i_1 \cdots i_k} \mathbf{e}_{i_1} \otimes \cdots \otimes \mathbf{e}_{i_k}$$

be the expression of A with respect to $\{\mathbf{e}_{i_1} \otimes \cdots \otimes \mathbf{e}_{i_k} \mid 1 \le i_1, \dots i_k \le n\}$, the canonical basis of $\mathsf{T}^k(\mathbb{C}^n)$. Then

$$S(A) = A$$

implies

$$\sum\nolimits_{i_1,\ldots,i_k=1}^{n}\left[\frac{1}{k!}\sum\nolimits_{\sigma\in\mathfrak{S}_k} a_{i_{\sigma(1)}\cdots i_{\sigma(k)}}\right]\mathbf{e}_{i_1}\otimes\cdots\otimes\mathbf{e}_{i_k}=\sum\nolimits_{i_1,\ldots,i_k=1}^{n} a_{i_1\cdots i_k}\mathbf{e}_{i_1}\otimes\cdots\otimes\mathbf{e}_{i_k}.$$

Since $\{\mathbf{e}_{i_1}\otimes\cdots\otimes\mathbf{e}_{i_k} \mid 1\le i_1,\ldots i_k\le n\}$ is a linearly independent set, we must have

$$\frac{1}{k!}\sum\nolimits_{\sigma\in\mathfrak{S}_k} a_{i_{\sigma(1)}\cdots i_{\sigma(k)}}=a_{i_1\cdots i_k}\qquad\text{for all } i_1,\ldots,i_k\in\{1,\ldots,n\}. \tag{3.6}$$

For any given $\tau\in\mathfrak{S}_k$, we have

$$\begin{aligned}
a_{i_{\tau(1)}\cdots i_{\tau(k)}} &= \frac{1}{k!}\sum\nolimits_{\sigma\in\mathfrak{S}_k} a_{i_{\sigma(\tau(1))}\cdots i_{\sigma(\tau(k))}} && \text{(by (3.6))}\\
&= \frac{1}{k!}\sum\nolimits_{\sigma\in\tau\mathfrak{S}_k} a_{i_{\sigma(1)}\cdots i_{\sigma(k)}} &&\\
&= \frac{1}{k!}\sum\nolimits_{\sigma\in\mathfrak{S}_k} a_{i_{\sigma(1)}\cdots i_{\sigma(k)}} && (\tau\mathfrak{S}_k=\mathfrak{S}_k \text{ as } \mathfrak{S}_k \text{ is a group})\\
&= a_{i_1\cdots i_k} && \text{(by (3.6)).}
\end{aligned}$$

Since this holds for arbitrary $\tau\in\mathfrak{S}_k$, the array $[\![a_{i_1\cdots i_k}]\!]$ is symmetric in the sense of Definition 3.1. ∎

4. Notions of rank for symmetric tensors. We will discuss two notions of rank for symmetric tensors—the outer product rank (defined for all tensors) and the symmetric outer product rank (defined only for symmetric tensors). We will show that under certain conditions, they are one and the same. However, it is not known if they are equal on all symmetric tensors in general.

4.1. Outer product decomposition and rank. Any tensor can always be decomposed (possibly nonuniquely) as

$$A=\sum\nolimits_{i=1}^{r}\mathbf{u}_i\otimes\mathbf{v}_i\otimes\cdots\otimes\mathbf{w}_i. \tag{4.1}$$

The *tensor rank*, $\operatorname{rank}(A)$, is defined as the smallest integer r such that this decomposition holds exactly [29, 30]. Among other properties, note that this outer product decomposition remains valid in a ring and that an outer product decomposition of a multilinear transform of A equals the multilinear transform of an outer product decomposition of A. In other words, if (4.1) is an outer product decomposition of A, then

$$A\bullet_1 L\bullet_2 M\bullet_3\cdots\bullet_k N=\sum\nolimits_{i=1}^{r} L\mathbf{u}_i\otimes M\mathbf{v}_i\otimes\cdots\otimes N\mathbf{w}_i$$

is an outer product decomposition of $A\bullet_1 L\bullet_2 M\bullet_3\cdots\bullet_k N$, which may also be written as $(L,M,\ldots,N)\cdot A$. The outer product decomposition has often been regarded synonymously as the data analytic models CANDECOMP [11] and PARAFAC [28], where the decomposition is used to analyze multiway psychometric data.

DEFINITION 4.1. *The rank of* $A=[\![a_{j_1\cdots j_k}]\!]\in\mathbb{C}^{d_1\times\cdots\times d_k}$ *is defined as*

$$\operatorname{rank}(A):=\min\{r \mid A=\textstyle\sum_{i=1}^{r}\mathbf{u}_i\otimes\mathbf{v}_i\otimes\cdots\otimes\mathbf{w}_i\}.$$

If $A=[\![a_{j_1\cdots j_k}]\!]\in\mathsf{S}^k(\mathbb{C}^n)$*, then we may also define the notion of symmetric rank via*

$$\operatorname{rank}_{\mathsf{S}}(A):=\min\{s \mid A=\textstyle\sum_{i=1}^{s}\mathbf{y}_i\otimes\cdots\otimes\mathbf{y}_i\}.$$

Note that over $\mathbb{C}$, the coefficients λ_i appearing in decomposition (1.1) may be set to 1; this is legitimate since any complex number admits a kth root in $\mathbb{C}$. Henceforth, we will adopt the following notation:

$$\mathbf{y}^{\otimes k} := \overbrace{\mathbf{y} \otimes \cdots \otimes \mathbf{y}}^{k \text{ copies}}. \tag{4.2}$$

If in (4.1) we have $\mathbf{u}_i = \mathbf{v}_i = \cdots = \mathbf{w}_i$ for every i, then we may call it a *symmetric outer product decomposition*, yielding a *symmetric rank*, $\operatorname{rank}_{\mathsf{S}}(A)$. Constraints other than full symmetry may be relevant in some application areas, such as partial symmetry as in INDSCAL [11, 58], or positivity/nonnegativity [41, 51, 55].

The definition of symmetric rank is not vacuous because of the following result.

LEMMA 4.2. *Let $A \in \mathsf{S}^k(\mathbb{C}^n)$. Then there exist $\mathbf{y}_1, \ldots, \mathbf{y}_s \in \mathbb{C}^n$ such that*

$$A = \sum\nolimits_{i=1}^{s} \mathbf{y}_i^{\otimes k}.$$

Proof. What we have to prove is that the vector space generated by the kth powers of linear forms $L(\mathbf{x})^k$ (for all $L \in \mathbb{C}^n$) is not included in a hyperplane of $\mathsf{S}^k(\mathbb{C}^n)$. This is indeed true, because otherwise there would exist a nonzero element of $\mathsf{S}^k(\mathbb{C}^n)$ which is orthogonal, under the bilinear form $\langle \cdot, \cdot \rangle$, to all $L(\mathbf{x})^k$ for $L \in \mathbb{C}^n$. Equivalently, by Lemma 3.6, there exists a nonzero polynomial $q(\mathbf{x})$ of degree k such that $q(L) = 0$ for all $L \in \mathbb{C}^n$. But this is impossible, since a nonzero polynomial does not vanish identically on $\mathbb{C}^n$. ∎

Lemma 4.2 may be viewed as a particular case of a basic result in algebraic geometry, stating that the linear space generated by points of an algebraic variety that is not included in a hyperplane, i.e., a subspace of codimension 1, is the whole space [27, 18, 49]. For completeness, a proof of our special case is given above. Note that it follows from the proof that

$$\operatorname{rank}_{\mathsf{S}}(A) \leq \binom{n+k-1}{k}$$

for all $A \in \mathsf{S}^k(\mathbb{C}^n)$.

On the other hand, given a symmetric tensor A, one can compute its outer product decomposition either in $\mathsf{S}^k(\mathbb{C}^n)$ or in $\mathsf{T}^k(\mathbb{C}^n)$. Since the outer product decomposition in $\mathsf{S}^k(\mathbb{C}^n)$ is constrained, it follows that for all $A \in \mathsf{S}^k(\mathbb{C}^n)$,

$$\operatorname{rank}(A) \leq \operatorname{rank}_{\mathsf{S}}(A). \tag{4.3}$$

We will show that equality holds generically when $\operatorname{rank}_{\mathsf{S}}(A) \leq n$ and when k is sufficiently large with respect to n and always holds when $\operatorname{rank}_{\mathsf{S}}(A) = 1, 2$. While we do not know if the equality holds in general, we suspect that this is the case as we are unaware of any counterexample.

4.2. Secant varieties of the Veronese variety. Let us recall here the correspondence between symmetric outer product decompositions and secant varieties of the Veronese variety. By the bijective correspondence between symmetric tensors and homogeneous polynomials established in (3.5), we may discuss this in the context of homogeneous polynomials. The set of homogeneous polynomials that may be written as a kth power of a linear form, $\beta(x)^k = (\beta_1 x_1 + \cdots + \beta_n x_n)^k$ for $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_n) \in \mathbb{C}^n$, is a closed algebraic set. We may consider this construction as a map from $\mathbb{C}^n$ to the

space of symmetric tensors given by

$$\begin{aligned}\nu_{n,k} : \mathbb{C}^n &\to \mathbb{C}[x_1, \ldots, x_n]_k \cong \mathsf{S}^k(\mathbb{C}^n),\\ \boldsymbol{\beta} &\mapsto \beta(x)^k.\end{aligned}$$

The image $\nu_{n,k}(\mathbb{C}^n)$ is called the *Veronese variety* and is denoted $\mathcal{V}_{n,k}$ [27, 65]. Following this point of view, a symmetric tensor is of symmetric rank 1 if it corresponds to a point on the Veronese variety. A symmetric tensor is of symmetric rank r if it is a linear combination of r symmetric tensors of symmetric rank 1 but not a linear combination of $r-1$ or fewer such tensors. In other words, a symmetric tensor is of symmetric rank not more than r if it is in the linear space spanned by r points of the Veronese variety. The closure of the union of all linear spaces spanned by r points of the Veronese variety $\mathcal{V}_{n,k}$ is called[1] the $(r-1)$*th-secant variety* of $\mathcal{V}_{n,k}$. See [27, 65] for examples and general properties of these algebraic sets. In the asymmetric case, a corresponding notion is obtained by considering the *Segre variety*, i.e., the image of the Segre map defined in section 2.

4.3. Why rank can exceed dimension. We are now in a position to state and prove the following proposition, which is related to a classical result in algebraic geometry stating that r points in $\mathbb{C}^n$ form the solution set of polynomial equations of degree $\leq r$ [27, p. 6]. This implies that we can find a polynomial of degree $\leq r-1$ that vanishes at $r-1$ of the points L_i but not at the last one, and hence the independence of polynomials $L_1^{r-1}, \ldots, L_r^{r-1}$ follows. Since this proposition is important to our discussion in section 5 (via its corollary), we give a direct and simple proof.

PROPOSITION 4.3. *Let $L_1, \ldots, L_r \in \mathbb{C}[x_1, \ldots, x_n]_1$, i.e., linear forms in n variables. If for all $i \neq j$, L_i is not a scalar multiple of L_j, then for any $k \geq r-1$, the polynomials $L_1^k, \ldots, L_r^k$ are linearly independent in $\mathbb{C}[x_1, \ldots, x_n]$.*

Proof. Let $k \geq r-1$. Suppose that for some $\lambda_1, \ldots, \lambda_r$, $\sum_{i=1}^r \lambda_i L_i^k = 0$. Hence, by the duality property of Lemma 3.6,

$$\sum\nolimits_{i=1}^r \lambda_i \langle F, L_i^k \rangle = \sum\nolimits_{i=1}^r \lambda_i F(L_i) = 0$$

for all $F \in \mathbb{C}[x_1, \ldots, x_n]_k$. Let us prove that we can find a homogeneous polynomial F of degree k that vanishes at $L_1, \ldots, L_{r-1}$ and not at L_r.

Consider a homogeneous polynomial F of degree $k \geq r-1$ that is a multiple of the product of $r-1$ linear forms H_i vanishing at L_i but not at L_r. We have $F(L_r) \neq 0$ but $F(L_j) = 0$, $1 \leq j \leq r-1$. As a consequence, we must have $\lambda_r = 0$. By a similar argument, we may show that $\lambda_i = 0$ for all $i = 1, \ldots, r$. It follows that the polynomials $L_1^k, \ldots, L_r^k$ are linearly independent. ∎

Notice that the bound $r-1$ on the degree can be reduced by d if a d-dimensional linear space containing any $d+1$ of these points does not contain one of the other points [27, p. 6]. In this case, we can replace the product of $d+1$ linear forms H_i vanishing at $d+1$ points by just 1 linear form vanishing at these $d+1$ points.

COROLLARY 4.4. *Let $\mathbf{v}_1, \ldots, \mathbf{v}_r \in \mathbb{C}^n$ be r pairwise linearly independent vectors. For any integer $k \geq r-1$, the rank-1 symmetric tensors*

$$\mathbf{v}_1^{\otimes k}, \ldots, \mathbf{v}_r^{\otimes k} \in \mathsf{S}^k(\mathbb{C}^n)$$

are linearly independent.

[1] This seemingly odd choice, i.e., $r-1$ instead of r, is standard [27, 65] because one wants to be consistent with the usual meaning of a secant, i.e., 1-secant, as a line intersecting *two* points in the variety.

This corollary extends results of [19, Lemma 2.2] and [33, Appendix]. Note that vectors $\mathbf{v}_1, \ldots, \mathbf{v}_r$ need not be linearly independent.

Example 4.5. Vectors $\mathbf{v}_1 = (1, 0)$, $\mathbf{v}_2 = (0, 1)$, and $\mathbf{v}_3 = (1, 1)$ are pairwise noncollinear but linearly dependent. According to Corollary 4.4, the symmetric tensors $\mathbf{v}_1^{\otimes k}, \mathbf{v}_2^{\otimes k}, \mathbf{v}_3^{\otimes k}$ are linearly independent for any $k \geq 2$. Evidently, we see that this holds true for $k = 2$ since the matrix below has rank 3:

$$\begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 1 & 1 & 1 \end{bmatrix}.$$

4.4. Genericity. Roughly speaking, a property is referred to as *typical* if it holds true on a non-zero-volume set and *generic* if is true almost everywhere. Proper definitions will follow later in section 6. It is important to distinguish between typical and generic properties; for instance, as will be subsequently seen, there can be several *typical ranks* but by definition only a single *generic rank*. We will see that there can be only one typical rank over $\mathbb{C}$, and it is thus generic.

Through the bijection (3.4), the symmetric outer product decomposition (4.1) of symmetric tensors can be carried over to quantics, as pointed out in [16]. The bijection allows one to talk indifferently about the symmetric outer product decomposition of order-k symmetric tensors and the decomposition of degree-k quantics into a sum of linear forms raised to the kth power.

For a long time, it was believed that there was no explicit expression for the generic rank. As Reznick pointed out in [48], Clebsh proved that even when the numbers of free parameters are the same on both sides of the symmetric outer product decomposition, the generic rank may not be equal to $\frac{1}{n}\binom{n+k-1}{k}$. For example, in the case $(k, n) = (4, 3)$, there are $\binom{6}{4} = 15$ degrees of freedom but the generic symmetric rank $R_{\mathsf{S}}(4, 3) = 6 \neq 5 = \frac{1}{3}\binom{6}{4}$. In fact, this holds true over both $\mathbb{R}$ [48] and $\mathbb{C}$ [22]. In section 7, we will see that the generic rank in $\mathsf{S}^k(\mathbb{C}^n)$ is now known for any order and dimension due to the ground breaking work of Alexander and Hirschowitz.

The special case of cubics ($k = 3$) is much better known—a complete classification has been known since 1964, although a constructive algorithm to compute the symmetric outer product decomposition was proposed only recently [35]. The simplest case of binary quantics ($n = 2$) has also been known for more than two decades [62, 16, 38]—a result that is used in real-world engineering problems [15].

5. Rank and symmetric rank. Let $\overline{R}_{\mathsf{S}}(k, n)$ be the generic symmetric rank and $R_{\mathsf{S}}(k, n)$ be the maximally attainable symmetric rank in the space of symmetric tensors $\mathsf{S}^k(\mathbb{C}^n)$. Similarly, let $\overline{R}(k, n)$ be the generic rank and $R(k, n)$ be the maximally attainable rank in the space of order-k dimension-n cubical tensors $\mathsf{T}^k(\mathbb{C}^n)$. Since $\mathsf{S}^k(\mathbb{C}^n)$ is a subspace of $\mathsf{T}^k(\mathbb{C}^n)$, generic and maximal ranks (when they exist) are related for every fixed order k and dimension n as follows:

$$\overline{R}(k, n) \geq \overline{R}_{\mathsf{S}}(k, n) \quad \text{and} \quad R(k, n) \geq R_{\mathsf{S}}(k, n). \tag{5.1}$$

It may seem odd that the inequalities in (5.1) and (4.3) are reversed, but there is no contradiction since the spaces are not the same.

It is then legitimate to ask whether the symmetric rank and the rank are always equal. We show that this holds generically when $\operatorname{rank}_{\mathsf{S}}(A) \leq n$ (Proposition 5.3) or when the order k is sufficiently large relative to the dimension n (Proposition 5.4).

This always holds (not just generically) when $\operatorname{rank}_{\mathsf{S}}(A) = 1, 2$ (Proposition 5.5). We will need some preliminary results in proving these assertions.

LEMMA 5.1. *Let $\mathbf{y}_1, \dots, \mathbf{y}_s \in \mathbb{C}^n$ be linearly independent. Then the symmetric tensor defined by*

$$A := \sum\nolimits_{i=1}^{s} \mathbf{y}_i^{\otimes k}$$

has $\operatorname{rank}_{\mathsf{S}}(A) = s$.

Proof. Suppose $\operatorname{rank}_{\mathsf{S}}(A) = r$. Then there exist $\mathbf{z}_1, \dots, \mathbf{z}_r \in \mathbb{C}^n$ such that

$$\sum\nolimits_{i=1}^{s} \mathbf{y}_i^{\otimes k} = A = \sum\nolimits_{j=1}^{r} \mathbf{z}_j^{\otimes k}. \tag{5.2}$$

By the linear independence of $\mathbf{y}_1, \dots, \mathbf{y}_s$, there exist covectors $\varphi_1, \dots, \varphi_s \in (\mathbb{C}^n)^*$ that are dual to $\mathbf{y}_1, \dots, \mathbf{y}_s$, i.e.,

$$\varphi_i(\mathbf{y}_j) = \begin{cases} 1 & \text{if } i = j, \\ 0 & \text{if } i \neq j. \end{cases}$$

Contracting both sides of (5.2) in the first $k-1$ modes with $\varphi_i^{\otimes(k-1)} \in \mathsf{S}^{k-1}((\mathbb{C}^n)^*)$, we get

$$\mathbf{y}_i = \sum\nolimits_{j=1}^{r} \alpha_j \mathbf{z}_j,$$

where $\alpha_j = \varphi_i(\mathbf{z}_j)^{k-1}$. In other words, $\mathbf{y}_i \in \operatorname{span}\{\mathbf{z}_1, \dots, \mathbf{z}_r\}$. Since this holds for each $i = 1, \dots, s$, it implies that the s linearly independent vectors $\mathbf{y}_1, \dots, \mathbf{y}_s$ are contained in $\operatorname{span}\{\mathbf{z}_1, \dots, \mathbf{z}_r\}$. Hence we must have $r \geq s$. On the other hand, it is clear that $r \leq s$. Thus we must have equality. ∎

LEMMA 5.2. *Let $s \leq n$. Let $A \in \mathsf{S}^k(\mathbb{C}^n)$ with* $\operatorname{rank}_{\mathsf{S}}(A) = s$ *and*

$$A = \sum\nolimits_{i=1}^{s} \mathbf{y}_i^{\otimes k}$$

be a symmetric outer product decomposition of A. Then vectors of the set $\{\mathbf{y}_1, \dots, \mathbf{y}_s\}$ are generically linearly independent.

Proof. We will write

$$\mathcal{Y}_s := \{A \in \mathsf{S}^k(\mathbb{C}^n) \mid \operatorname{rank}_{\mathsf{S}}(A) \leq s\} \quad \text{and} \quad \mathcal{Z}_s := \{A \in \mathsf{S}^k(\mathbb{C}^n) \mid \operatorname{rank}_{\mathsf{S}}(A) = s\}.$$
